FOREWORD

E. R. BRAITHWAITE

This publication contains lectures and posters presented at the Climax Fifth International Conference on the Chemistry and Uses of Molybdenum held at the University of Newcastle, 1–5 July 1985. Two hundred and sixty participants from 26 countries attended the meeting and have provided an update on current research into molybdenum chemistry and the important uses of molybdenum compounds.

The conference was sponsored by Climax Molybdenum Co. Ltd, an affiliate of AMAX, and the Dalton Division of The Royal Society of Chemistry.

The interdisciplinary nature of previous conferences was preserved, though one was aware of the increased interest in the application of solid-state chemistry to heterogeneous catalysis.

I would like to thank the Chairmen of the sessions and all who helped with the conference, including the Managing Committee consisting of Professor A. G. Sykes, Professor C. D. Garner, Dr M. L. H. Green, FRS, and Dr P. C. H. Mitchell, without whose help the conference would not have been possible. Especially I would like to thank Professor Sykes, who was responsible for all the domestic arrangements and the academic programme. A very special thank you is also due to Mrs Rhoda Stafford for her invaluable secretarial help and constant good humour which helped to preserve our equanimity.

This special journal issue has been edited jointly by Professor Sykes and Dr Mitchell, an onerous task for which I am duly grateful.

HIGHLIGHTS OF RECENT RESEARCH ON COMPOUNDS WITH Mo–Mo BONDS

F. ALBERT COTTON

Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A&M University, College Station, TX 77843, U.S.A.

(*Received* 26 *June* 1985)

Abstract—Research during the period 1981 to the present in two areas of molybdenum chemistry is surveyed. The first area is that of equilateral triangular cluster compounds. Some very new work, such as that on the $Mo_3S_4^{4+}$ aquo ion, will also be mentioned. The second area is that of Mo–Mo triple and quadruple bonds. Several ways in which quadruply bonded Mo_2 compounds have been used to investigate the properties of strong metal–metal bonds in general will be emphasized.

The chemistry of molybdenum is so extensive and diverse as to discourage any effort by one person to survey it broadly. It is to be hoped that the combined efforts of those participating in this conference will add up to such a broad review. For my own part, I have elected to focus on two areas in which my research group has been especially active in the past few years. While our own work will feature prominently in this paper, I shall endeavor to cite some important contributions from other laboratories. My topics will be: (1) triangular trinuclear molybdenum compounds with Mo–Mo bonds, and (2) binuclear molybdenum complexes with strong Mo–Mo bonds. Even after so limiting my purview, I can still offer no warrant of completeness.

TRIANGULAR TRINUCLEAR COMPOUNDS WITH Mo–Mo BONDS

Back in 1980 we knew that two general types of trimolybdenum cluster compounds existed, those shown as (a) and (b) in Fig. 1. Rather little was known about either type. With regard to type (a), there was, in fact, only one publication in which, as we now know, there was an error.[1] This error is of little importance when measured against the major contribution which that publication made, namely, showing what happens to most of the molybdenum when $Mo(CO)_6$ is refluxed with a mixture of CH_3CO_2H and $(CH_3CO)_2O$. In that reaction, as first reported by Bannister and Wilkinson[2] years before, dimolybdenum tetraacetate appears as a beautiful yellow crystalline product. The yield of this product based on molybdenum is at best around 20% (although it can be made much higher by using other solvents such as diglyme) but strangely, for about 15 years, no one found out what became of the rest of the molybdenum. It is interesting to note that the analogous reaction of $W(CO)_6$ with CH_3CO_2H–$(CH_3CO)_2O$ produces *no* $W_2(O_2CCH_3)_4$, and nobody had correctly identified the products that were formed. It was into this state of virtually total ignorance that the 1976 paper by Bino *et al.*[3] shone a prescient beam of light. The ability of these workers to make a major advance was due to the fact that they used a technique no one had used before in addressing this problem, namely, ion exchange chromatography. Attempts to obtain characterizable substances by other, conventional techniques (e.g. crystallization and extraction) had always failed. Ion exchange chromatography has

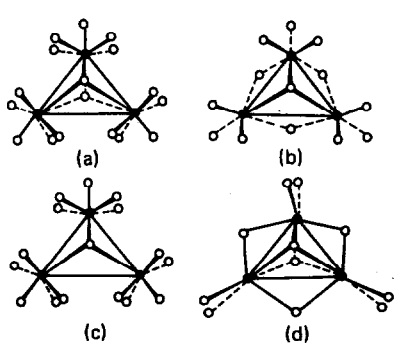

Fig. 1. Schematic drawings of four types of equilateral trinuclear metal cluster compounds.

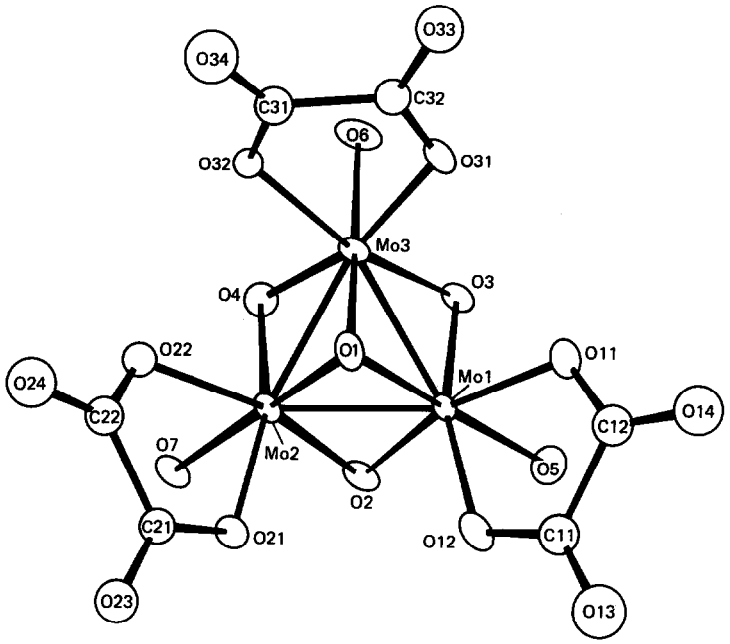

Fig. 2. Structure of $[Mo_3O_4(C_2O_4)_3(H_2O)_3]^{2-}$.

been the key to success in this type of chemistry ever since.

With regard to species of type (b) a bit more was known in 1980. Bino *et al.*[3] showed in 1978 that from solutions of the aquo molybdenum(IV) ion (about the nature of which great controversy still raged) one could isolate the oxalato anion

$$[Mo_3O_4(C_2O_4)_3(H_2O)_3]^{2-},$$

whose structure is shown in Fig. 2. This work established for the first time that this type of cluster can occur as a discrete entity in solution and crystals (it was previously known only in the solid state as a part of a continuous, fused array). Equally important, it provided a wholly new idea of what the aquo molybdenum(IV) ion might be: neither a monomer nor a dimer, but a trimer, with a central $Mo_3O_4^{4+}$ core surrounded by nine water molecules. This notion was soon strongly supported by our isolation[4] of an EDTA complex in which the central $Mo_3O_4^{4+}$ core was present.

An attempt in 1979 to check this by EXAFS study of the solution was inconclusive,[5] although this sort of study was later carried out much more thoroughly and did afford conformation.[6]

Also prior to 1981 was a preliminary report of an isotopic exchange study by Murmann and Shelton[7] (the full report of which appeared only recently[8]) which provided another completely independent line of very convincing evidence that the aquo molybdenum(IV) ion is trinuclear. Indeed, from Murmann's detailed report[8] we now know that the exchange rates for the four types of oxygen atoms in the $[Mo_3O_4(H_2O)_9]^{4+}$ ion vary from >3 years (27°C) for the three μ_2-O atoms to *ca* 5 days (27°C) for the μ_3-O atom, to *ca* 1 h (27°C) for the three H_2Os *trans* to μ_3-O, and to 20 months (0°C) for the other six outer H_2O molecules.

Several other points ought to be mentioned to round out the pre-1981 picture. There is no doubt that a *very* long time ago[9] Spittle and Wardlaw (1929) had isolated molybdenum(IV) complexes containing the $Mo_3O_4^{4+}$ core, which they formulated as "$R_2[Mo_3O_4(C_2O_4)_3 \cdot 5H_2O]$, where R = K, NH_4 or C_5H_6N". These workers even surmised that the complex anion was triangular, but without X-ray crystallography they could go no further. I became cognizent of their paper only a few years ago, and I don't think that anyone else working in this field in the late 1970s was aware of it.

In 1979, Bino *et al.*[10] showed that the structure of type (b) is a theme that can accommodate many variations by preparing and characterizing the $[Mo_3OCl_3(O_2CCH_3)_3(H_2O)_3]^{2+}$ ion, which differs from derivatives of the $Mo_3O_4^{4+}$ species in two ways: the three μ-O atoms are replaced by μ-Cl atoms and there are eight rather than six electrons in the Mo_3 core.

It is also noteworthy that the reaction of $W(CO)_6$ with CH_3CO_2H–$(CH_3CO)_2O$ was shown[11,12] to generate exclusively $W_3(\mu_3\text{-}O)_2(O_2CCH_3)_6L_3$ species; the tungsten chemistry is thus very similar to the molybdenum chemistry except that no

$W_2(O_2CCH_3)_4$ can be made under these acid conditions.

Finally, there was some important work done in the later 1970s, mainly by Achim Müller and his school,[12] that led to the characterization of the $[Mo_3(\mu_3\text{-}S)(S_2)_6]^{2-}$ ion. While this ion has certain obvious superficial differences from the complexes of the $Mo_3O_4^{4+}$ ion, it is, as we shall later see clearly, closely allied.

Let us now turn to a selective review of some of the progress that has been made since 1980. Much of this progress has been with the bicapped structures of type (a). As clearly noted, prior to the period under review, 1981 to the present, there was only one short publication[1] dealing with them as well as one fairly extensive paper[11] on the bioxocapped tritungsten compounds.

During 1981, the fundamental point was established[13–15] that, by appropriate control of the reaction conditions, the reaction of a CH_3CO_2H–$(CH_3CO)_2O$ mixture with molybdenum hexacarbonyl could give rise to three types of compounds, all having a structure of the bicapped type, namely (a) in Fig. 1. The ones with two capping oxygen atoms were not surprising, especially in view of the ease with which the tungsten analogs can be made under similar conditions.[11] Subsequently, there have been a number of studies of these bioxocapped molybdenum compounds[16–20] in which many of their properties have been established and methods for their preparation have been diversified. One of their most remarkable properties is the stability of the entire $Mo_3O_2(O_2CR)_6L_3$ unit, which we attribute, at least in part, to the fact that each metal atom is forming nine bonds and thus utilizing fully its valence shell orbitals. A striking example of this stability is provided by the

$$[Mo_3O_2(O_2CPh)_6(H_2O)_3]^{2+} \text{ ion,}^{19}$$

which can be fully nitrated in all phenyl groups under the usual aromatic nitration conditions (1 : 1 mixture of conc. H_2SO_4 and conc. HNO_3 at 45°C) without observable decomposition.

Perhaps the biggest surprise in this chemistry has been that there are $Mo_3(\mu_3\text{-}X)_2(O_2CR)_6L_3$ species in which one or both capping groups, μ_3-X, are alkylidyne groups.[13–15,21,22] The

$$[Mo_3(CCH_3)_2(O_2CCH_3)_6(H_2O)_3]^{2+}$$

ion, shown in Fig. 3, is of special interest since it is the species originally[1] thought to be

$$[Mo_3(OCH_2CH_3)_2(O_2CCH_3)_6(H_2O)_3]^{2+}.$$

Figure 4 shows the mixed-cap species,

$$[Mo_3O(CCH_3)(O_2CCH_3)_6(H_2O)_3]^{+}.$$

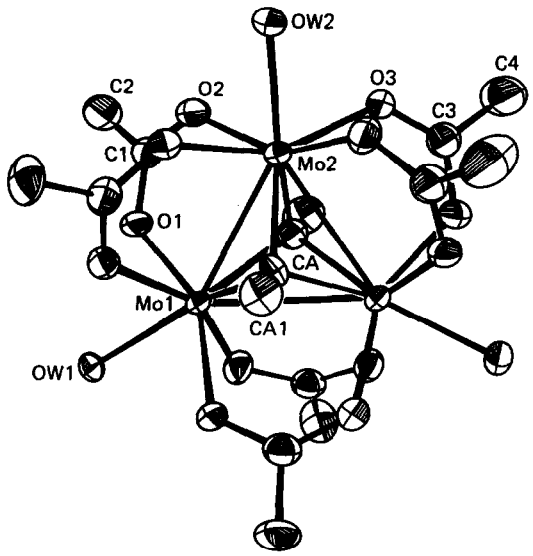

Fig. 3. Structure of $[Mo_3(CCH_3)_2(O_2CCH_3)_6(H_2O)_3]^{2+}$ ion.

Considering that these compounds are all very stable toward oxygen, aqueous acids, and even toward permanganate (which does, however, oxidize the core, see below), it is quite amazing that they contain metal–carbon bonds. Presumably, the stability of these Mo–C bonds towards oxidative and hydrolytic attack is kinetic in nature. It may be noted that, while no bi-alkylidyne capped tritungsten species have yet been observed, the

$$[W_3(\mu_3\text{-}O)(\mu_3\text{-}CCH_3)(O_2CCH_3)_6(H_2O)_3]^{+}$$

ion[23] has been made.

The electronic structures of both the type (a) and type (b) triangular species have been analyzed by molecular-orbital methods and a basic understanding of the metal–metal bonding has been achieved.[24] The bi-capped clusters can accommodate a maximum of six cluster electrons, whereby three M–M single bonds are formed. In several compounds there are only five or four such electrons and the M–M bond orders are then only $\frac{5}{6}$ and $\frac{2}{3}$, respectively. Reasonable increases in the bond lengths (*ca* 0.06 Å) accompany each decrease of $\frac{1}{6}$ in the bond order. The type (b) clusters can accommodate six M–M bonding electrons but also one or two more that can enter an orbital that has little if any M–M antibonding character. The

$$[Mo_3(\mu_3\text{-}O)(\mu_2\text{-}Cl)_3(O_2CCH_3)_3(H_2O)_3]^{2+}$$

ion mentioned earlier[10] is an example (the first) of an eight-electron cluster of this type. Very recently, we have provided another example of such an eight-electron species,[25] which is perhaps even more interesting because it is also the first example of a

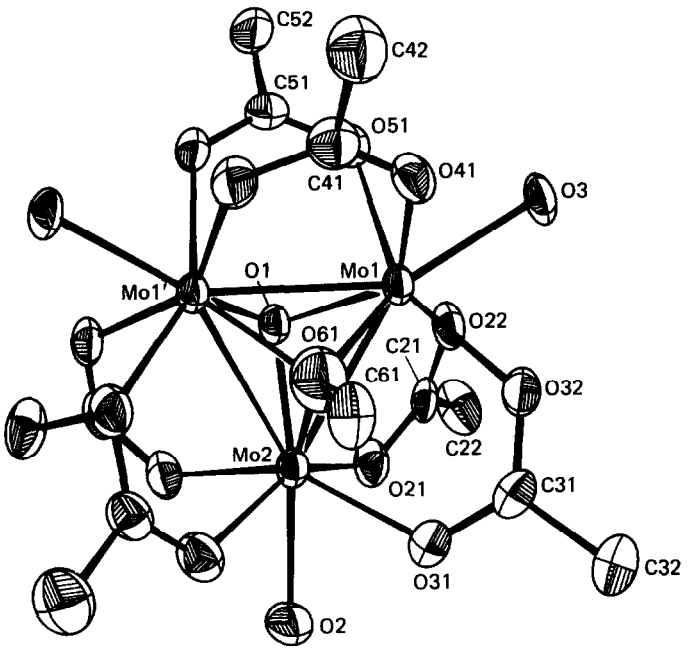

Fig. 4. Structure of $[Mo_3O(CCH_3)(O_2CCH_3)_6(H_2O)_3]^+$ ion.

type (b) structure in which the capping group is an alkylidyne. The species in question is

$$[Mo_3(\mu_3\text{-}CCH_3)(\mu_2\text{-}Br)_3(O_2CCH_3)_3(H_2O)_3]^+.$$

It is also pertinent to note here that niobium analogs of the bioxo-capped trimolybdenum compounds have recently been made.[26] These are of the type $[Nb_3O_2(O_2CR)_6(THF)_3]^+$ and they have four cluster electrons. They therefore have triplet ground states ($a_1^2e^2$) with bond orders of $\frac{2}{3}$ and Nb—Nb distances of *ca* 2.84 Å.

In the case of tungsten, one compound with the hemicapped structure [type (c) in Fig. 1] has been prepared and characterized.[27] We are still trying to learn how to obtain the molybdenum analog of this $[W_3(\mu_3\text{-}O)(O_2CCH_3)_6(H_2O)_3]^{2+}$ ion. At the time of writing, we believe that we may have done so, but disclosure of our results would be premature.

It is noteworthy that the

$$[M_3O_2(O_2CR)_6(H_2O)_3]^{2+}$$

ions are distinctly acidic; protons from the outer water molecules may be ionized leaving species with a mixture of H_2O and OH ligands in these positions. As Bino and Gibson[28] have shown, these mixed species associate with each other through

$$M—O(H)\cdots H\cdots O(H)—M$$

bridges, which are, in effect hydrated hydroxide ions, $HOHOH^-$.

Still a fourth type of equilateral triangular molybdenum cluster has been reported by Chisholm *et al.*[29] This is represented schematically by (d) in Fig. 1, and real examples are

$$[Mo_3(\mu_3\text{-}O)(\mu_3\text{-}OR)(\mu\text{-}OR)_3(OR)_6],$$

where $R = (CH_3)_2CH$ or $(CH_3)_3CCH_2$. The electronic and spectroscopic properties of such compounds have been elucidated by physical and theoretical studies.[30]

To conclude this section I wish to return to the species of type (b) in Fig. 1, of which the aquo ion, $Mo_3O_4^{4+}(aq)$, and its complexes are probably the most important examples so far. I have already mentioned several early publications in which these complexes were isolated in crystalline form, thus providing clear indications that the core of the aquo molybdenum(IV) ion is the $Mo_3O_4^{4+}$ unit. There have been several other reports of such isolated and crystallographically characterized complexes[31–34] as well as further studies of the aquo ion in solution.[32,35,36] For obvious reasons, a chemist might naturally wonder about the possibility of replacing one, three or all four of the oxygen atoms in the $Mo_3O_4^{4+}$ ion by sulfur atoms. In fact, a number of workers in addition to me and my coworkers[37,38] have been attracted by this possibility, and some interesting progress has been made.[39–43]

Müller and Reinsch[39] were by far the first (1980) to isolate a derivative of $Mo_3S_4^{4+}$, which they did by treating the $[Mo_3S(S_2)_6]^{2-}$ ion with excess aqueous KCN. The cyanide ions convert S_2^{2-} ions to $S^{2-} + SCN^-$ and then also occupy positions in the coordination sphere, thus giving the

$[Mo_3S_4(CN)_9]^{5-}$ ion. The same species has also been described (1983) by another group,[40] and has been further studied by Wieghardt *et al.*[41] In this case, three outer coordination positions on each Mo atom of $Mo_3S_4^{4+}$ are occupied, as would be expected by analogy to the stereochemistry around the $Mo_3O_4^{4+}$ ion.

In another synthetic procedure[42] that begins with the $[Mo_3S(S_2)_6]^{2-}$ ion, an excess of $Na_2(SCH_2CH_2S)$ and $(NEt_4)Br$ were used and the product was $(NEt_4)_2[Mo_3S_4(SCH_2CH_2S)_3]$. It was found that treatment of this with elemental sulfur converts it to $[Mo_3S(S_2)_3(SCH_2CH_2S)_3]^{2-}$, from which the $[Mo_3S_4(SCH_2CH_2S)_3]^{2-}$ ion can again be obtained by treatment with more $Na_2(SCH_2CH_2S)$, PPh_3 or CN^- in acetonitrile. Clearly, we are again dealing with reactions in which sulfur atoms are extracted from S_2^{2-} ions to give S^{2-} ions plus appropriate other products such as $[S_2CH_2CH_2S]^{2-}$, Ph_3PS or SCN^-. It is noteworthy that in the $[Mo_3S_4(SCH_2CH_2S)_3]^{2-}$ ion there are only two outer ligand positions occupied on each metal atom rather than three.

Japanese workers have reported the only example of a mixed sulfur–oxygen species, $Ba[Mo_3(\mu_3\text{-}S)O_3(HNTA)_3]$, were H_3NTA = nitrilotriacetic acid.[43] They prepared this in about 20% yield by heating the μ-S–μ-O binuclear complex $Mg[Mo_2O_3S(EDTA)]$ with aqueous K_2CO_3 followed by neutralization, cation exchange chromatography and addition of H_3NTA and $BaCl_2$.

Our own work in this area also began with $(NH_4)_2[Mo_3S(S_2)_6]$, which we call Müller's compound. We first found[37] that it is not necessary to add any reagent to serve as a sulfur atom acceptor. Simply by treatment of Müller's compound with a large excess of either oxalic acid or H_3NTA under reflux, the color changes from red to green and it is possible to isolate products containing the

$$[Mo_3S_4(HNTA)_3]^{2-}$$

and

$$[Mo_3S_4(C_2O_4)_3(H_2O)_3]^{2-}$$

ions. We believe that the expulsion of S and S_2^{2-} simply leads to formation of species such as S_3^{2-}.

In order to simplify and diversify this chemistry efficiently, we have sought to obtain aqueous solutions of the $Mo_3S_4^{4+}$(aq) ion, and we have been successful.[38] One way to do it is to hydrolyze the $[Mo_3S_4(HNTA)_3]^{2-}$ complex in 2 M HCl for 8 h, from which a clear green solution is obtained. From this the $Mo_3S_4^{4+}$ ion can be caught on a cation exchange column and solutions prepared by elution with various acids such as 2 M $HClO_4$. These solutions are stable in air for at least 2 weeks and allow the preparation of a variety of complexes, including those previously known.

Of far more interest, however, is a new and much superior way to obtain solutions of the $Mo_3S_4^{4+}$(aq) ion. To do this, $Mo(CO)_6$ is refluxed in $(CH_3CO)_2O$ containing dry Na_2S, under nitrogen, and the cooled reaction mixture hydrolyzed with water. This solution deposits a green band at the top of a Dowex 50W × 2 cation exchange column. The $Mo_3S_4^{4+}$(aq) ion can be eluted with 1 M $HClO_4$. A second green species, which elutes only with much more concentrated acid, is still under investigation.* We have also obtained solutions of the $W_3S_4^{4+}$(aq) ion by a similar procedure. Figure 5 shows the structure of the oxalato complex,

$$[Mo_3S_4(C_2O_4)_3(H_2O)_3]^{2-},$$

* This is now known to be the $Mo_4S_4^{5+}$ ion.

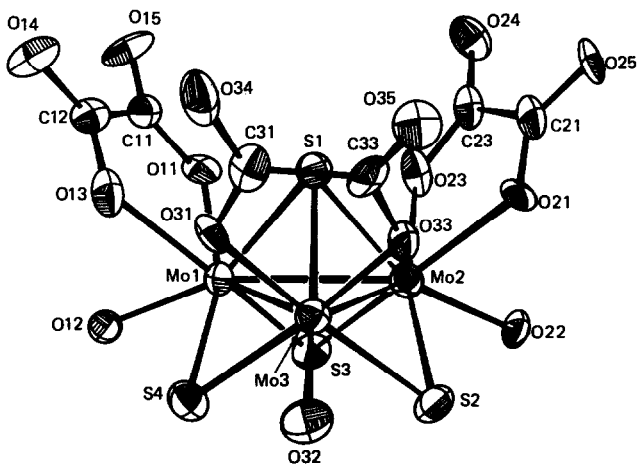

Fig. 5. $[Mo_3S_4(C_2O_4)_3(H_2O)_3]^{2-}$ ion as prepared by addition of oxalate ions to a solution of the $Mo_3S_4^{4+}$(aq) ion.

obtained from an aqueous solution of the $Mo_3S_4^{4+}$(aq) ion.

QUADRUPLE BONDS IN DIMOLYBDENUM COMPOUNDS

The level of activity in research on multiple bonds between metal atoms continues to be very high. The 1982 book *Multiple Bonds between Metal Atoms*, by Walton and me,[44] covered the literature to about the end of 1980, with most citations being to a period of *ca* 16 years immediately preceding 1980. In the years 1981–1984 there have been roughly half as many publications as in all of the previous years. Of that number (*ca* 450 publications) about 40% have dealt with dimolybdenum compounds. Clearly, the Mo–Mo triple and quadruple bonds have been the chief testing grounds for ideas and experiments on M–M multiple bonds. This is because molybdenum is relatively inexpensive and readily forms a great variety of compounds, many of which are fairly easy to handle.

It is symptomatic of how much work has been done on the chemistry of compounds with Mo–Mo quadruple bonds that during the four year period 1981–1984 67 new molecular structures have been determined by X-ray crystallography, and one by gas-phase electron diffraction. These are listed in Table 1 in the same way as earlier structures were listed in Table 3.1.1 of Ref. 44. The number of structures in the earlier table, which covers all those done prior to 1981, is only 71. The compounds listed in Table 1 are a rather diverse lot: although they are not necessarily a random sampling of all the compounds that have been studied in the four year period, they are probably indicative of the directions research on Mo–Mo quadruple bonds has been taking.

[a] See Table 3.1.1 of Ref. 44 for a list of earlier structures and definitions.
[b] The list of references to this table is given in the Appendix.
[c] Not reported.
[d] Not relevant.

The two alkoxide compounds, $Mo_2(OPr^i)_4py_4$ and $Mo_2(OCH_2CMe_3)_4(PMe_3)_4$, contain the longest Mo–Mo quadruple bonds yet reported, 2.195(1) and 2.209(1) Å, respectively. These are about as long as most Mo–Mo triple bonds and thus clearly illustrate the fact that bond order and bond length are not as simply related in the realm of metal–metal bonds as in the traditional chemistry of the light elements.

Another record established by one of the structures listed is that of the shortest bond length for the $Mo_2Cl_8^{4-}$ ion, viz. 2.129 Å in the piperidinium salt $(pipH)_4[Mo_2Cl_8]\cdot 4H_2O$.

Because of the time limitation on this lecture, I shall restrict myself to just three lines of work that have been carried out on Mo–Mo quadruple bonds: All three concern the response of a quadruple bond when the molecule containing it is caused to twist away from its preferred conformation, namely, that in which it is eclipsed. The three important responses are: (1) a lengthening of the bond, (2) a change in the energy of the $\delta \rightarrow \delta^*$ transition, and (3) the development of optical activity.

Bond lengthening

The notion that a quadruple bond should weaken and therefore lengthen as the molecular conformation changes from eclipsed to staggered is well known. Qualitatively, this is due to the dependence of the δ-component of the bond on the degree of staggering. Quantitatively, the strength of the δ-bond should vary with cos 2χ, where χ is the angle of internal rotation, taken as zero in the eclipsed conformation.[45] The way in which χ is caused to change from zero in a generally homologous series of compounds is to employ compounds of the type

$$Mo_2X_4[R_2P(CH_2)_{1,2}PR_2]_2,$$

in which the diphosphine ligands bridge the metal atoms. A representative compound is shown in Fig. 6. Both the angle of twist and the Mo–Mo distance are ascertained by X-ray crystallography. If it is then assumed that the bond length will be linearly proportional to the strength of the δ-bond, and further that no other factors (e.g. electronic or steric properties of the R groups) are important, one might expect an inverse linear relationship between the Mo–Mo bond lengths and cos 2χ.

First with three compounds,[46] and later with 10,[47] the approximate validity of such a relationship was demonstrated. However, because of concern about some unexpected scatter, we have recently been led to take into account the possible effect of a systematic difference between alkyl and aryl groups in the diphosphine. A way to make an empirical correction for this (employing dirhenium compounds in which there are no delta bonds) has been found, and in this way the correlation shown in Fig. 7 has been obtained.[48] This seems to be about as far as this general concept can be developed, and it gives the result that complete loss of the δ-bond from a Mo–Mo quadruple bond causes an increase of $\sim$0.10 Å in the bond length.

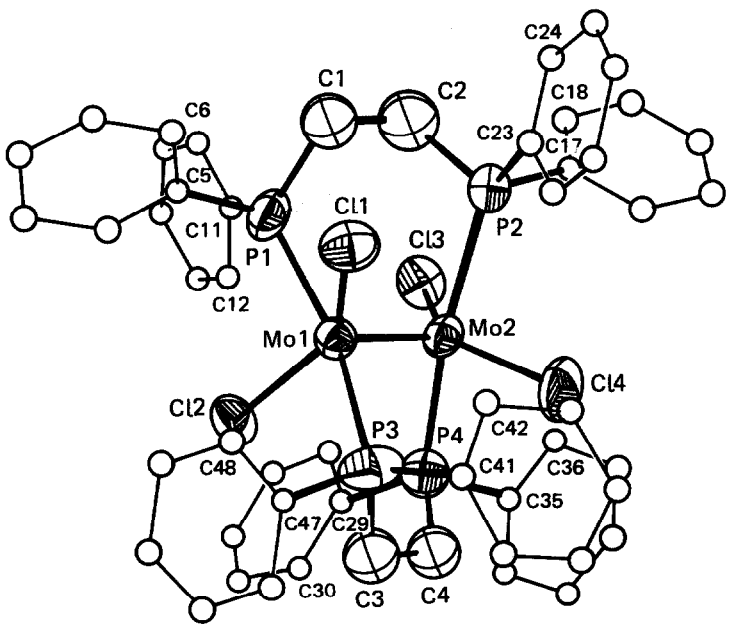

Fig. 6. $Mo_2Cl_4(Ph_2PCH_2CH_2PPh_2)_2$ molecule.

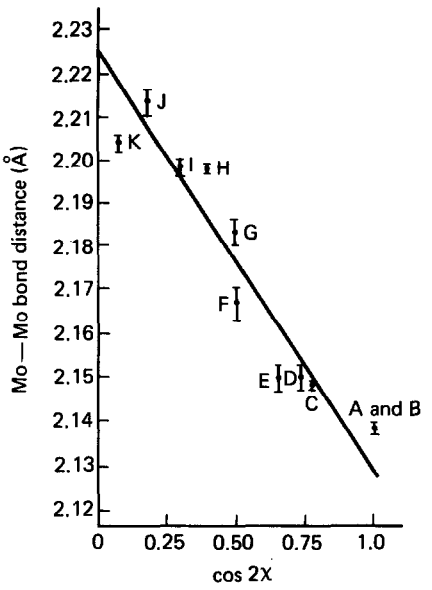

Fig. 7. Plot of Mo–Mo bond length vs cos 2χ for 11 compounds of the type $Mo_2X_4[R_2P(CH_2)_{1,2}PR_2]_2$, where an empirical correction has been applied to combine data for R = alkyl and aryl.

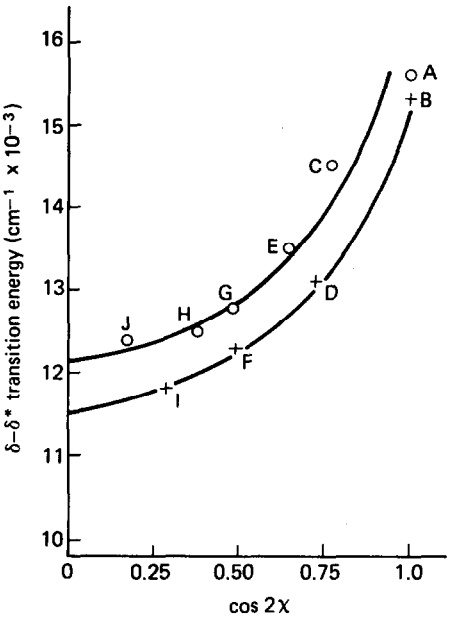

Fig. 8. $\delta \rightarrow \delta^*$ transition energies vs cos 2χ for 10 compounds of the type $Mo_2X_4[R_2P(CH_2)_{1,2}PR_2]_2$. The upper curve is for compounds with X = Cl and the lower one for X = Br.

The $\delta \rightarrow \delta^*$ transition energy

As the strength of the δ-interaction is decreased by twisting a quadruple bond, the energy of the electronic absorption band assignable to the $A_{1g}(\delta^2) \rightarrow A_{2u}(\delta\delta^*)$ transition (normally called, simply, the $\delta \rightarrow \delta^*$ transition) should become lower. The same set of compounds used to study the relationship between metal–metal bond length and cos 2χ can be used to establish the dependence of the energy of the $\delta \rightarrow \delta^*$ transition on cos 2χ. The relationship found[49] is shown in Fig. 8. The fact that the transition energy tends not to zero but to an extrapolated limit in the neighborhood of 12,000 cm^{-1} confirms that, for this weakly bonded δ-manifold, the correlation energy makes a large contribution to the energies of the states. It suggests that this energy contributes around 12,000 cm^{-1} to the transition energy, which is in reasonable agreement with theoretical estimates of about 10,000 cm^{-1}.

Optical activity

A twisted molecule such as that shown in Fig. 6 is, of course, chiral. However, the enantiomers interconvert rather rapidly in solution, and in order to observe the optical consequences of this chirality (e.g. CD or ORD spectra) it is necessary to employ a ligand, such as *S,S*-$Ph_2PCH(CH_3)CH(CH_3)PPh_2$, that locks the molecule into one enantiomer, as shown in Fig. 9. When this is done, a beautiful CD spectrum (Fig. 10), can then be observed.

The one feature of this CD spectrum that will be discussed here is the negative feature at *ca* 730 nm.

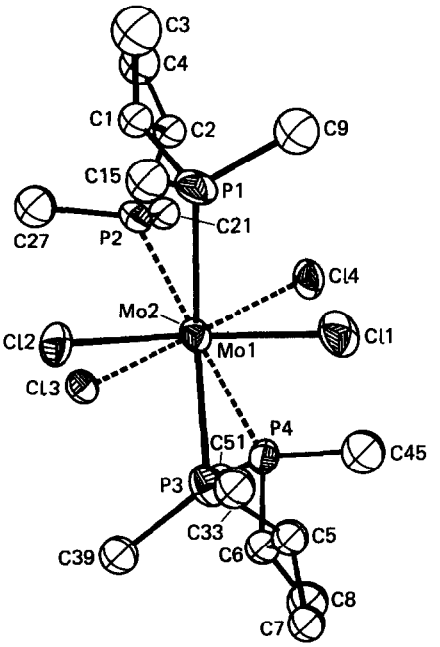

Fig. 9. View down the Mo–Mo axis of the $Mo_2Cl_4[S,S\text{-}Ph_2PCH(CH_3)CH(CH_3)PPh_2]_2$ molecule, showing its absolute conformation, which is Γ (a counterclockwise helix).

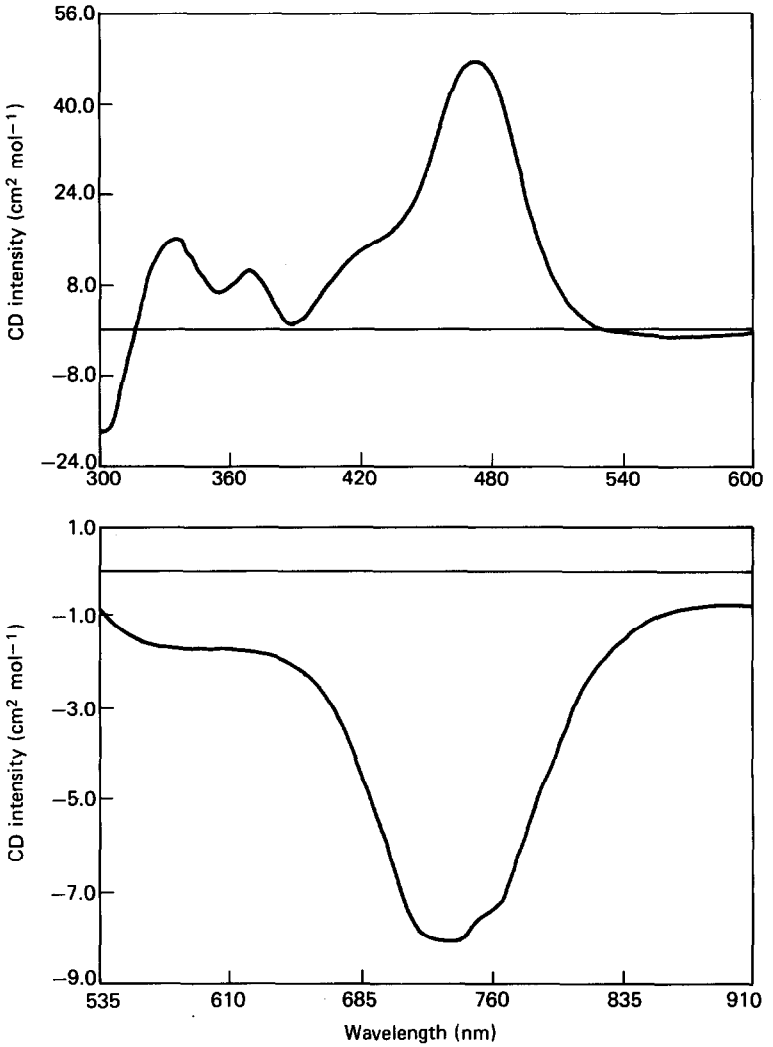

Fig. 10. Circular dichroism spectrum of $Mo_2Cl_4[S,S\text{-}Ph_2PCH(CH_3)CH(CH_3)PPh_2]_2$.

This corresponds to the $\delta \rightarrow \delta^*$ transition. By an unequivocal, qualitative argument it can be shown[50] that for the direction and magnitude of the angle of twist (Fig. 9) a negative CD must be expected for the $\delta \rightarrow \delta^*$ transition. We thus have a powerful piece of evidence that the generally accepted picture of the quadruple bond in Mo_2^{4+} systems is correct.

Acknowledgements—I wish to acknowledge the tremendous contributions made by a number of coworkers to the work done in my laboratory. Their names will be found in the references, but I must make special mention of Professor Zvi Dori, of The Technion, Haifa, Israel, who could not attend this meeting. Zvi Dori has been not only a fountain of good ideas, a masterful laboratory chemist and the man who put me in touch with all of my other Israeli coworkers, but a friend of rare qualities. The National Science Foundation has been the principal supporter of our work, but assistance from the US–Israel Science Foundation, The Robert A. Welch Foundation and the Texas A&M University is also gratefully acknowledged.

REACTIVITY OF QUADRUPLY BONDED DIMOLYBDENUM(II) COMPLEXES WITH ALKYL ISOCYANIDES: Mo–Mo BOND CLEAVAGE OR RETENTION?

W. S. HARWOOD, JU-SHENG QI and R. A. WALTON*

Department of Chemistry, Purdue University, West Lafayette, IN 47907, U.S.A.

(*Received* 14 *June* 1985)

Abstract—The quadruply-bonded dimolybdenum(II) complexes $Mo_2(\mu\text{-dppm})_2X_4$ (X = Br or I) can be prepared in high yield from $Mo_2(\mu\text{-dppm})_2Cl_4$ (dppm = $Ph_2PCH_2PPh_2$) via simple halide-exchange reactions (using NaX in acetone). The complexes $Mo_2(\mu\text{-dppm})_2X_4$ (X = Cl, Br or I) react with one equivalent of RNC (R = *i*-Pr or *t*-Bu) in the presence of $TlPF_6$ (in THF) or KPF_6 (in acetone) to give $[Mo_2X_3(dppm)_2(CNR)]PF_6$, the first examples of multiply bonded Mo_2^{4+} complexes that contain coordinated π-acceptor RNC ligands. The reactions of $Mo_2(\mu\text{-dppm})_2X_4$ with an excess of RNC lead to seven-coordinate mononuclear cations $[MoX(dppm)(CNR)_4]^+$, which are in turn converted into $[Mo(CNR)_5(dppm)]^{2+}$ and thence $[Mo(CNR)_7]^{2+}$. The significance of these results, insofar as they relate to the cleavage of mixed halide–phosphine complexes of dimolybdenum(II) by isocyanides and the substitution chemistry of $[Mo(CNR)_7](PF_6)_2$ by phosphine ligands, are discussed. Comparisons are made with related chemistry of dinuclear and mononuclear molybdenum(II) complexes that contain bidentate nitrogen donors such as 2,2′-bipyridine, 1,10-phenanthroline and 1,4-disubstituted diaza-1,3-butadienes. The reactions between *cis*-$Mo_2(mhp)_2Cl_2(PMePh_2)_2$ (mhp is the anion of 2-hydroxy-6-methylpyridine) and *t*-BuNC (in the presence of KPF_6) result in the formation of mixtures of $Mo_2(mhp)_4$ and $[Mo(CN\text{-}t\text{-}Bu)_5(PMePh_2)_2](PF_6)_2$

The cleavage of multiply bonded dimetal units in M_2L_8 systems (especially when M = Mo, W, Re or Ru; L represents a conventional σ-donor ligand) by π-acceptor ligands such as CO and RNC (R = alkyl or aryl) has provided a convenient and important synthetic route to a variety of mononuclear complexes.[1,2] Little is known, however, about the mechanisms of these cleavage reactions although recent studies on dirhenium(II) complexes that contain stable intramolecular phosphine-ligand bridges, e.g. $Re_2Cl_4(dppm)_2$ (dppm = $Ph_2PCH_2PPh_2$), have, for the first time, allowed for the stabilization of multiply bonded species that contain CO and/or RNC ligands, e.g. $Re_2Cl_4(dppm)_2(CO)_n$ ($n = 1$ or 2).[3] These compounds can be viewed as intermediates in the cleavage process.

In the present report we address the situation as it pertains to the quadruply bonded $(Mo{\equiv}Mo)^{4+}$ core. The results of previous studies, which have led to the formation of mononuclear molybdenum isocyanide complexes, are briefly reviewed and new data are described which provide evidence for the formation of the multiply bonded dimolybdenum(II) complexes $[Mo_2X_3(dppm)_2(CNR)]PF_6$ (X = Cl, Br or I; R = *i*-Pr or *t*-Bu).

EXPERIMENTAL

Starting materials

The following compounds were prepared by standard literature procedures: *iso*-propyl isocyanide (*i*-PrNC),[4] *tert*-butyl isocyanide (*t*-BuNC),[4] $Mo_2(\mu\text{-dppm})_2X_4$ (X = Cl or Br)[5,6]† and

* Author to whom correspondence should be addressed.

† This procedure involves the reaction between $(NH_4)_4Mo_2Br_8$ and dppm in refluxing methanol. Full details are provided elsewhere[7] and are available upon request from Dr T. J. Smith.

$Mo_2Cl_4(PMePh_2)_4$.[8] Samples of thallium(I) hexafluorophosphate ($TlPF_6$) and dppm, which were obtained from Strem Chemical Co., and 2-hydroxy-6-methylpyridine (Hmhp), obtained from Aldrich Chemical Co., were used without further purification.

Reaction procedures

All reactions were carried out under a dry nitrogen atmosphere, and all reaction solvents were dried and deoxygenated prior to use by purging with N_2 gas for 15 min. In those cases where compounds were prepared by very similar procedures, details of representative recipes only are given. In those instances where microanalytical data are not given, identification of products is based upon their spectroscopic and electrochemical properties which showed the samples to be pure.

A. *Preparation of* $Mo_2(\mu\text{-dppm})_2X_4$. (i) $Mo_2(\mu\text{-dppm})_2I_4 \cdot 1.5C_3H_6O$. A 50-$cm^3$ round-bottom flask was charged with a mixture comprising $Mo_2(\mu\text{-dppm})_2Cl_4$ (0.505 g, 0.46 mmol), NaI (1.04 g, 6.93 mmol) and 20 cm^3 of acetone. The reaction mixture was refluxed for 12 h, cooled and then filtered in air. The green precipitate was washed with water, ethanol and pentane, and then vacuum dried: yield 0.55 g (77%). Calc. for $C_{54.5}H_{53}I_4Mo_2O_{1.5}P_4$: C, 42.1; H, 3.4; I, 32.6%. Found: C, 42.1; H, 3.6; I, 32.2%. The presence of lattice acetone was confirmed by IR spectroscopy [Nujol mull, ν(CO) at 1705s cm^{-1}] and ^1H NMR spectroscopy (CD_2Cl_2 solvent, δ +2.12 ppm for CH_3 of acetone: integration showed dppm: acetone $\simeq$ 4:3).

(ii) $Mo_2(\mu\text{-dppm})_2Br_4 \cdot 2C_3H_6O$. A procedure similar to A(i) was used but with NaBr in place of NaI: yield 81%. It was obtained as its bis-acetone solvate as shown by IR spectroscopy [Nujol mull, ν(CO) at 1705s cm^{-1}] and ^1H NMR spectroscopy (CD_2Cl_2 solvent, δ +2.14 ppm for CH_3 of acetone: integration showed dppm: acetone = 1:1).

B. *Reactions of* $Mo_2(\mu\text{-dppm})_2X_4$ *with alkyl isocyanides.*

(i) $[Mo_2Cl_3(dppm)_2(CNCMe_3)]PF_6 \cdot CH_2Cl_2$.

A 100-cm^3 three-neck round-bottom flask was charged with $Mo_2(\mu\text{-dppm})_2Cl_4$ (0.40 g, 0.36 mmol) and $TlPF_6$ (0.156 g, 0.45 mmol). A quantity of THF (50 ml) was syringed into the flask, followed by 46 μl (0.44 mmol) of *t*-BuNC, and the resulting green suspension was stirred at room temperature for 7 h. The precipitate was collected by filtration and washed with THF (3 × 5 ml) and then with pentane (5 ml). The product was extracted into dry, freshly distilled CH_2Cl_2 and the extract filtered from the insoluble residue and then evaporated to dryness. The green solid was washed with 10 cm^3 of a CH_2Cl_2–pentane mixture (1:3) and vacuum dried: yield 0.25 g (50%). Calc. for $C_{56}H_{55}Cl_5F_6Mo_2NP_5$: C, 48.7; H, 4.0; Cl, 12.8%. Found: C, 49.0; H, 4.1; Cl, 12.2%. The presence of lattice CH_2Cl_2 was confirmed by ^1H NMR spectroscopy ($CDCl_3$ solvent, δ +5.28 ppm). This complex could be obtained as an acetone solvate [ν(CO) at 1709s cm^{-1}] when acetone was used as the reaction solvent.

(ii) $[Mo_2Cl_3(dppm)_2(CNCHMe_2)]PF_6$. This complex was prepared from the reaction between $Mo_2(\mu\text{-dppm})_2Cl_4$ (0.24 g, 0.22 mmol), *i*-PrNC (21 μl, 0.23 mmol) and KPF_6 (0.39 g, 2.12 mmol) in 10 cm^3 of refluxing acetone for 6–8 h. The reaction mixture was then cooled to room temperature, filtered, and the solid washed with acetone and then very sparingly with CH_2Cl_2. The solid product was dissolved in the minimum volume of dry, freshly distilled CH_2Cl_2 (100–120 ml), filtered, and the filtrate evaporated under a blanket of nitrogen. The solid residue was washed with pentane and cold CH_2Cl_2 (3 × 5 ml), and then vacuum dried: yield 0.17 g (63%). Calc. for $C_{54}H_{51}Cl_3F_6Mo_2NP_5$: C, 50.6; H, 4.0; Cl, 8.3%. Found: C, 49.5; H, 4.2; Cl, 8.1%. The microanalytical data are consistent with the presence of a trace of lattice CH_2Cl_2.

(iii) $[Mo_2Br_3(dppm)_2(CNCMe_3)]PF_6$. This complex was prepared from $Mo_2(\mu\text{-dppm})_2Br_4$, $TlPF_6$ and *t*-BuNC using a procedure similar to that described in B(i): yield 50%. Calc. for $C_{55}H_{53}Br_3F_6Mo_2NP_5$: C, 46.2; H, 3.7; Br, 16.8%. Found: C, 46.1; H, 3.6; Br, 17.8%. The somewhat high halogen microanalysis probably reflects the presence of a trace of lattice CH_2Cl_2. Unfortunately, the poor solubility properties of this complex (in solvents other than CH_2Cl_2) precluded the measurement of a ^1H NMR spectrum that would confirm the presence of CH_2Cl_2. This complex could be obtained as an acetone solvate [ν(CO) at 1705s cm^{-1}] when acetone was used as the reaction solvent.

(iv) $[Mo_2Br_3(dppm)_2(CNCHMe_2)]PF_6$. This was prepared as described in B(iii): yield 44%. Calc. for $C_{54}H_{51}Br_3F_6Mo_2NP_5$: C, 45.8; H, 3.6%. Found: C, 44.8; H, 3.6%.

(v) $[Mo_2I_3(dppm)_2(CNCMe_3)]PF_6 \cdot C_3H_6O$. A mixture comprising $Mo_2(\mu\text{-dppm})_2I_4 \cdot 1.5C_3H_6O$ (0.39 g, 0.25 mmol) and KPF_6 (0.51 g, 2.77 mmol) was brought to reflux in acetone (15 ml). A small quantity of *t*-BuNC (28 μl, 0.27 mmol) was added and reflux continued for 4 h. The reaction mixture was cooled, stirring continued overnight, and the insoluble green product filtered off, washed with water, ethanol, THF and pentane, and finally vacuum dried: yield 0.33 g (81%). Calc. for $C_{58}H_{59}F_6I_3Mo_2NOP_5$:

C, 42.8; H, 3.7; I, 23.4%. Found: C, 42.8; H, 4.2; I, 23.4%. IR spectroscopy confirmed the presence of lattice acetone [Nujol mull, ν(CO) at 1707s cm^{-1}].

(vi) $[Mo_2I_3(dppm)_2(CNCHMe_2)]PF_6$. This complex was prepared from $Mo_2(\mu\text{-dppm})_2I_4$, $TlPF_6$ and *i*-PrNC using THF as solvent [see B(i)]: yield 41%. Calc. for $C_{54}H_{51}F_6I_3Mo_2NP_5$: C, 41.7; H, 3.3%. Found: C, 41.5; H, 3.4%.

(vii) $[MoCl(dppm)(CNCMe_3)_4]PF_6 \cdot 0.25CH_2Cl_2$. The complex $Mo_2(\mu\text{-dppm})_2Cl_4$ (0.70 g, 0.64 mmol) was treated with an excess of *t*-BuNC (0.40 cm^3, 3.79 mmol) and this mixture refluxed in 40 cm^3 of CH_2Cl_2 for 6 h. The reaction solution was then evaporated to dryness, 0.3 g of KPF_6 added, and the residue dissolved in a small volume of methanol. This was stirred for 15 min, 100 cm^3 of diethyl ether was added, and the KPF_6 that precipitated was filtered off. The filtrate was evaporated to dryness and the residue dissolved in a minimum volume of CH_2Cl_2. Diethyl ether was carefully layered over this solution which was allowed to slowly evaporate under a stream of nitrogen to give small orange-yellow crystals: yield 0.55 g (43%). Calc. for $C_{45.25}H_{58.5}Cl_{1.5}F_6MoN_4P_3$: C, 53.6; H, 5.8; Cl, 5.2%. Found: C, 53.7; H, 5.9; Cl, 5.1%. The micro-analytical data and ^1H NMR spectroscopy (acetone-d_6 solvent, δ +5.34 ppm) indicated the presence of a small amount of lattice CH_2Cl_2.

(viii) $[MoBr(dppm)(CNCMe_3)_4]PF_6$. This complex was prepared from $Mo_2(\mu\text{-dppm})_2Br_4$ as described in B(vii): yield 49%. Calc. for $C_{45}H_{58}BrF_6MoN_4P_3$: C, 52.1; H, 5.6; Br, 7.7%. Found: C, 52.0; H, 5.7; Br, 7.7%.

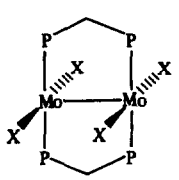
(ix) $[MoI(dppm)(CNCMe_3)_4]PF_6$. A procedure similar to B(vii) was used with $Mo_2(\mu\text{-dppm})_2I_4$ in place of $Mo_2(\mu\text{-dppm})_2Cl_4$: yield 50%. This complex was identified on the basis of its spectroscopic properties which were very similar to those of its chloride and bromide analogues.

C. *Preparation of* $Mo_2(\mu\text{-mhp})_2Cl_2(PMePh_2)_2$. The reaction between $Mo_2Cl_4(PMePh_2)_4$ (1.21 g, 1.07 mmol) and 2-hydroxy-6-methylpyridine (0.23 g, 2.15 mmol) was carried out in 20 cm^3 of refluxing toluene for 16 h. The red mixture was concentrated to half volume under a stream of dry nitrogen gas, filtered, and the insoluble red product washed with methanol (5 cm^3) and vacuum dried: yield 0.77 g (82%), Calc. for $C_{38}H_{38}Cl_2Mo_2N_2O_2P_2$: C, 51.9; H, 4.4%. Found: C, 51.2; H, 4.1%.

D. *Reactions of* $Mo_2(\mu\text{-mhp})_2Cl_2(PMePh_2)_2$ *with* *t*-BuNC. The reactions between $Mo_2(\mu\text{-mhp})_2Cl_2(PMePh_2)_2$ and *t*-BuNC (2–12 equivalents) were carried out in hot methanol. After a reaction time of *ca* 18 h, the reaction mixture was cooled and then filtered. The precipitate (if present) was identified as $Mo_2(mhp)_4$ on the basis of its electrochemical and spectroscopic properties.[9] The orange colored reaction filtrate was treated with an excess of KPF_6, stirred for 1 h, evaporated to dryness, and the residue extracted into CH_2Cl_2. The extract was filtered and added dropwise with stirring to either diethyl ether or diethyl ether–petroleum ether mixtures. The orange solid was shown to be $[Mo(CNCMe_3)_5(PMePh_2)_2](PF_6)_2$: it possessed an identical cyclic voltammogram, and IR and ^{31}P NMR spectral properties to those exhibited by an authentic sample of this complex.[10] Further details concerning these reactions are given in Results and Discussion.

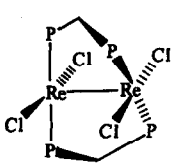
Physical measurements

IR spectra were recorded on KBr plates in the region 4800–400 cm^{-1} and on polyethylene plates in the region 500–50 cm^{-1} using IBM Instruments IR/32 and IR/98 FTIR spectrometers, respectively. Electronic absorption spectra were recorded as CH_2Cl_2 solutions on an IBM 9420 (350–900 nm) UV–visible spectrophotometer. Conductivity measurements were performed on 1×10^{-3} M acetonitrile solutions using an Industrial Instruments Inc. Model RC-16B2 conductivity bridge. Electrochemical measurements were made in CH_2Cl_2 containing 0.1 M tetra-*n*-butyl ammonium hexafluorophosphate (TBAH) as supporting electrolyte. $E_{1/2}$ values were determined as $(E_{p,a} + E_{p,c})/2$ and referenced to the silver–silver chloride (Ag–AgCl) electrode at room temperature and are uncorrected for junction potentials. Voltammetric experiments were performed using a Bioanalytical Systems Inc. Model CV-1A instrument in conjunction with a Hewlett–Packard model 7035 x–y recorder. ^1H NMR and ^{31}P–$\{^1H\}$ NMR spectra were recorded on a Varian XL-200 spectrometer operated at 200.0 and 80.98 MHz, respectively. ^{31}P resonances were referenced to an external standard of aqueous 85% H_3PO_4 and ^1H NMR spectra were referenced to the residual protons of the solvent [$CDCl_3$, $\delta = +7.24$ ppm; CD_2Cl_2, $\delta = +5.32$ ppm; $(CD_3)_2CO$, $\delta = +2.04$ ppm]. Microanalyses were performed by Dr H. D. Lee of the Purdue University micro-analytical laboratory.



RESULTS AND DISCUSSION

Dinuclear and mononuclear molybdenum(II) complexes containing isocyanide and phosphine ligands



The ease with which multiply bonded dimolybdenum species are cleaved by π-acceptor ligands is

exemplified by the conversion of the quadruply bonded complexes $Mo_2Cl_4(dppm)_2$, $Mo_2Cl_4(dppe)_2$ and $Mo_2Cl_4(PR_3)_4$ (dppe = $Ph_2PCH_2CH_2PPh_2$, and PR_3 = PEt_3, P-*n*-Pr_3 or $PEtPh_2$) by isocyanide ligands RNC (R = Me, *t*-Bu or C_6H_{11}) to the mononuclear species $[Mo(CNR)_5(dppm)]^{2+}$, $[Mo(CNR)_5(dppe)]^{2+}$, $[Mo(CNR)_5(PR_3)_2]^{2+}$ or $[Mo(CNR)_6(PR_3)]^{2+}$ when a large excess of isocyanide is used.[10] In some instances, the seven-coordinate homoleptic species $[Mo(CNR)_7]^{2+}$ can be generated in these reactions, and it is the primary product when $Mo_2(O_2CCH_3)_4$ and $K_4Mo_2Cl_8$ are reacted with an excess of RNC in hot methanol.[11] Upon reaction of $[Mo(CNR)_7]^{2+}$ with an excess of dppm, dppe or PR_3, the preceding mixed phosphine–isocyanide complexes can be produced in high yield.[10] In contrast to these non-redox cleavage reactions, aryl isocyanide ligands (ArNC) react with $Mo_2(O_2CCH_3)_4$ to give the homoleptic Mo(0) complexes $Mo(CNAr)_6$.[12,13]

While $Mo_2(\mu\text{-dppm})_2X_4$ are very easily converted into $[Mo(CNR)_5(dppm)]^{2+}$,[10] the related dirhenium(II) complex, $Re_2(\mu\text{-dppm})_2Cl_4$, forms stable dinuclear complexes with isocyanide ligands and also with CO.[3] The complexes $Mo_2(\mu\text{-dppm})_2X_4$ (X = Cl or Br) and $Re_2(\mu\text{-dppm})_2Cl_4$ have similar molecular structures (**I** and **II**, respectively) in which the dppm ligands form

I

(P ⌒ P = dppm)

II

intramolecular bridges. However, they differ in that the dimolybdenum complex, which possess a Mo–Mo quadruple bond ($\sigma^2\pi^4\delta^2$ configuration), has an eclipsed rotational geometry[14,15] while the triply bonded dirhenium complex ($\sigma^2\pi^4\delta^2\delta^{*2}$ configuration) is staggered.[16]

The preceding structural difference not withstanding, we wondered whether intermediates in this cleavage process might not be isolated in the case of $Mo_2(\mu\text{-dppm})_2X_4$ (X = halide) with a judicious choice of mild reaction conditions. This possibility first led us to develope a procedure for the preparation of the iodo derivative $Mo_2(\mu\text{-dppm})_2I_4$ via a halide exchange reaction [eqn (1)]:

$$Mo_2(\mu\text{-dppm})_2Cl_4 + 4NaI \xrightarrow{\text{acetone}} Mo_2(\mu\text{-dppm})_2I_4 + 4NaCl. \quad (1)$$

This procedure works equally well for the preparation of $Mo_2(\mu\text{-dppm})_2Br_4$ (using NaBr), and provides a fourth method for preparing the latter complex: others are: (i) the reaction of $Mo_2Br_4(PEt_3)_4$ with dppm in methanol;[5] (ii) the reaction of $(NH_4)_4Mo_2Br_8$ with dppm in methanol;[6] and (iii) the reaction between $Mo_2(O_2CCH_3)_4$, Me_3SiBr and dppm in THF.[15] The procedure we used affords the iodo the bromo derivatives as their acetone solvates. The propensity of $Mo_2(\mu\text{-dppm})_2X_4$ to form solvates has been well documented previously.[14,15]

A comparison of the far-IR spectra of $Mo_2(\mu\text{-dppm})_2X_4$ (recorded as Nujol mulls) shows the expected shift in the ν(Mo—X) modes [338s (X = Cl), 259m (X = Br), and 214m-w (X = I) cm^{-1}].* The ratios ν(Mo—Br)/ν(Mo—Cl) = 0.77 and ν(Mo—I)/ν(Mo—Cl) = 0.63 are in good agreement with those reported for other terminal metal–halogen stretching modes.[17] In the case of their electronic absorption spectra (Table 1), these complexes display a smooth trend in the position of the $\delta \rightarrow \delta^*$ transition (λ_{max} = 634, 650 and 684 nm for X = Cl, Br and I, respectively). The intense absorptions at 360 and 429 nm in the case of the bromo and iodo derivatives are tentatively assigned to allowed halogen (π) → Mo transitions. The ^1H NMR spectra show the expected pentet for the methylene protons of the dppm ligands (Table 1), while the $^{31}P\text{–}\{^1H\}$ NMR spectra are characterized by singlets for the chemically and magnetically equivalent phosphorus atoms.

The electrochemical properties of these complexes were studied using the cyclic voltammetric technique. The measured half-wave or peak potentials vs Ag–AgCl for 0.1 M TBAH–CH_2Cl_2 solutions of $Mo_2(\mu\text{-dppm})_2X_4$ are listed in Table 1 (see also Fig. 1). Each complex exhibits a process at *ca* +0.7 V. In the case of X = Cl or Br this process is reversible and corresponds to a one-electron oxidation (as determined by coulometry). The couple is characterized by $i_{p,a}/i_{p,c} = 1$ and a constant $i_p/v^{1/2}$ ratio for sweep rates between 50 and 400 mV s^{-1}. The potential separation between the anodic and cathodic peaks, ΔE_p, was between 100 and 120 mV for a sweep rate of 200 mV s^{-1} and increased slightly with increase in sweep rate. These properties are (with our cell configuration) consistent with a reversible electron-transfer process or one that approaches reversibility.[18] This behavior resembles closely that of other dimolybdenum(II) complexes

*Similar data for the chloride and bromide were reported earlier in Ref. 5 (viz. 340s and 260w cm^{-1}, respectively).

Table 1. Spectroscopic and electrochemical properties of $Mo_2(\mu\text{-dppm})_2X_4$ (X = Cl, Br or I)

Complex	Electronic absorption spectra[a] (nm)	NMR (δ)		Voltammetric half-wave potentials[d]		
		^1H[b]	$^{31}P-\{^1H\}$[c]	$E_{p,a}$	$E_{1/2}$(ox)	$E_{p,c}$
$Mo_2(\mu\text{-dppm})_2Cl_4$	634 (2100), 462 (600), ~ 360sh	4.35p (J_{P-H} = 5.0 Hz)	+16.14s		+0.66 (100)	~ −1.50
$Mo_2(\mu\text{-dppm})_2Br_4$	650 (2600), 480 (1000), 360	4.44p (J_{P-H} = 4.4 Hz)	+14.85s		+0.71 (120)	−1.28
$Mo_2(\mu\text{-dppm})_2I_4$	684 (3000), 499 (720), 480sh 429 (3800), 400sh	4.54p (J_{P-H} = 4.6 Hz)	+12.43s	+1.21	+0.77[e]	−1.03

[a] Recorded in CH_2Cl_2 solutions in the region 900–350 nm: ε_{max} values are given in parentheses.
[b] Recorded in CD_2Cl_2: each resonance is a pentet.
[c] Recorded in CH_2Cl_2. Positive values are downfield of 85% H_3PO_4.
[d] In V (Ag–AgCl). Recorded on solutions in 0.1 M TBAH–CH_2Cl_2 using a Pt-bead electrode. Data obtained at v = 200 mV s^{-1}. $E_{p,a}-E_{p,c}$ values are given in parentheses.
[e] Irreversible process: $E_{p,a}$ value given.

that contain halide and phosphine ligands, all of which show a reversible oxidation in the vicinity of +0.5 V.[18] In the case of the iodide complex $Mo_2(\mu\text{-dppm})_2I_4$, a second well-defined oxidation process is seen in the single-scan cyclic voltammogram at $E_{p,a}$ = +1.21 V.

While $Mo_2(\mu\text{-dppm})_2X_4$ reacts with an excess of RNC (R = Me, *t*-Bu or C_6H_{11}) to give $[Mo(CNR)_5(dppm)]^{2+}$ and, in some instances, $[Mo(CNR)_7]^{2+}$,[10] we find that the use of a much smaller amount of RNC (five–six equivalents) gives the mononuclear complexes [MoX(CN-*t*-Bu)$_4$(dppm)]PF_6 (X = Cl, Br or I) as the major products. With this "deficiency" of *t*-BuNC, the yields of [MoX(CN-*t*-Bu)$_4$(dppm)]PF_6 do not (as expected) exceed *ca* 50%. An increase in the amount of RNC (up to eight equivalents) leads to the formation of appreciable quantities of [Mo(CN-*t*-Bu)$_5$(dppm)]$(PF_6)_2$. Indeed, the reaction of [MoCl(CN-*t*-Bu)$_4$(dppm)]PF_6 with one–three equivalents of *t*-BuNC (in the presence of KPF_6) in refluxing methanol gives [Mo(CN-*t*-Bu)$_5$(dppm)]$(PF_6)_2$ in high yield (up to *ca* 80%), a result which implies that [MoX(CN-*t*-Bu)$_4$(dppm)]PF_6 is a precursor to [Mo(CN-*t*-Bu)$_5$(dppm)]$(PF_6)_2$, and that this is in turn converted into [Mo(CN-*t*-Bu)$_7$]$(PF_6)_2$ in the presence of a sufficient excess of *t*-BuNC.

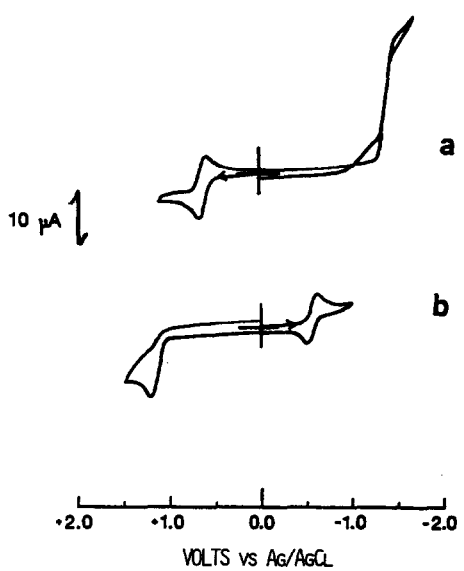


Fig. 1. Cyclic voltammograms (scan rate 200 mV s^{-1} at a Pt-bead electrode) in 0.1 M TBAH–CH_2Cl_2 of: (a) $Mo_2(\mu\text{-dppm})_2Cl_4$, and (b) $[Mo_2Cl_3(dppm)_2(CN\text{-}t\text{-}Bu)]PF_6$.

The pertinent spectroscopic properties of these monohalide complexes are summarized in Table 2. The simplicity of the $^{31}P-\{^1H\}$ and ^1H NMR spectra signify that these complexes are stereochemically non-rigid in solution at ambient temperatures. These complexes dissolve in acetonitrile to give solutions (*ca* 10^{-3} M) that have conductivities ($\Lambda_M \simeq 130\,\Omega^{-1}$ cm^2 mol^{-1}) which are in the range expected for 1:1 electrolytes (120–160 Ω^{-1} cm^2 mol^{-1}).[19] The electrochemical properties of [MoX(CN-*t*-Bu)$_4$(dppm)]PF_6 (Table 2) are characterized by a reversible one-electron (by coulometry) oxidation at $E_{1/2} \simeq$ +0.5 V (Ag–AgCl). The comparable redox process in the cyclic voltammograms of $[Mo(CNR)_5(dppm)](PF_6)_2$ (R = Me or C_6H_{11}) is at *ca* +1.0 V (SCE).[10] This shift (of *ca* 0.5 V) to more negative potentials upon replacing a RNC ligand by a halide, is similar to that found between the corresponding redox processes (one-electron oxida-

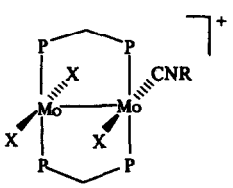
[b] Recorded in acetone-d_6.
[c] Recorded in acetone. Positive values are downfield of 85% H_3PO_4.
[d] In V (Ag–AgCl). Recorded on solutions in 0.1 M TBAH–CH_2Cl_2 using a Pt-bead electrode. Data obtained at ν = 200 mV s^{-1}. $E_{p,a}-E_{p,c}$ values are given in parentheses.
[e] Singlet due to Me_3CNC ligands.
[f] Triplet due to —CH_2— of the dppm ligand (J_{P-H} ~ 10 Hz).
[g] This resonance is at δ +5.05 ppm in CH_2Cl_2 solution.

tion) of $[Re(CNAr)_6]^+$ and $Re(CNAr)_5X$,[20,21] and betwween those of $[Mo(CNR)_7]^{2+}$ and $[Mo(CNR)_6Cl]^+$.[22]



Although we found no evidence for multiply bonded dimolybdenum intermediates in the reactions between $Mo_2(\mu\text{-dppm})_2X_4$ and RNC when these reactions were carried out in CH_2Cl_2, we were eventually able to modify the reaction procedure to give such species. The reaction of $Mo_2(\mu\text{-dppm})_2X_4$ with one equivalent of RNC (R = *i*-Pr or *t*-Bu) in THF in the presence of $TlPF_6$, or in acetone with excess KPF_6 present, gives the monoisocyanide complexes $[Mo_2X_3(dppm)_2(CNR)]PF_6$. These complexes behave as 1 : 1 electrolytes in acetonitrile ($\Lambda_M \simeq 130\ \Omega^{-1}\ cm^2\ mol^{-1}$ for $C_m \simeq 10^{-3}$ M) and display a single sharp ν(CN) band in their IR spectra at 2170(±5) cm^{-1}. Unfortunately, these complexes have low solubility in polar solvents, and in halogenated hydrocarbons, in which they are most soluble, the solutions decompose on standing. However, freshly prepared solutions in CH_2Cl_2 have the spectroscopic and electrochemical properties given in Table 3. Each complex displays an intense transition (tentatively assigned as $\delta \rightarrow \delta^*$) in the

region 715–790 nm, the energy of which decreases in the order Cl ≳ Br > I. The electrochemical properties of $[Mo_2X_3(dppm)_2(CNR)]PF_6$ are quite different from those of the parent complexes $Mo_2(\mu\text{-dppm})_2X_4$ (compare Tables 1 and 3 and Fig. 1). Once again, the replacement of an isocyanide ligand by halide makes the complex much easier to oxidize and, consequently, harder to reduce. In all instances the monoisocyanide complexes are characterized by an irreversible oxidation at $E_{p,a} \simeq +1.2$ V and a reversible process at $E_{1/2} \simeq -0.5$ V (Ag–AgCl) that corresponds to a one-electron reduction (Table 3 and Fig. 1). The poor solubility properties of these complexes precluded us from obtaining high-quality NMR spectra. The ^1H NMR spectra (recorded in CD_2Cl_2) show an AB pattern, with superimposed P–H coupling, for the $-CH_2-$ protons of the bridging dppm ligands. This inequivalence of the protons of the bridgehead methylene groups (H_α and H_β) implies the presence of an asymmetric structure. This conclusion is supported by the $^{31}P-\{^1H\}$ NMR spectrum of $[Mo_2Cl_3(dppm)_2(CN\text{-}t\text{-}Bu)]PF_6$ which exhibits an AA'BB' pattern ($\delta_A = +20.82$, $\delta_B = +11.51$) of a type that is commonly encountered in asymmetric multiply bonded dimetal species that contain two bridging dppm ligands.[23] While we have been unable as yet to obtain single crystals of any of the derivatives $[Mo_2X_3(dppm)_2(CNR)]PF_6$ that are suitable for a single-crystal X-ray structure analysis, the available evidence supports their possessing structure **III**, although we have not been able to

III

establish the rotational geometry (eclipsed or staggered).

On the basis of the aforementioned results we can represent the sequence of reactions that lead to the conversion of $Mo_2(\mu\text{-dppm})_2X_4$ to $[Mo(CNR)_7]^{2+}$ in terms of the following steps [(1)–(5)]:

$$Mo_2(\mu\text{-dppm})_2X_4$$

$$\xrightarrow[(1)]{RNC} [Mo_2X_3(dppm)_2(CNR)]^+$$

$$\xrightarrow[(2)]{RNC} \{[Mo_2X_3(dppm)_2(CNR)_n]^+\}$$

$$\xrightarrow[(3)]{RNC} [MoX(CNR)_4(dppm)]^+$$

$$\xrightarrow[(4)]{RNC} [Mo(CNR)_5(dppm)]^{2+}$$

$$\xrightarrow[(5)]{RNC} [Mo(CNR)_7]^{2+}.$$

The details of step (2), in which other isocyanide containing multiply bonded dimolybdenum(II) species are presumably formed, have not yet been delineated, although we do have evidence that the reaction of $[Mo_2Cl_3(dppm)_2(CN\text{-}t\text{-}Bu)]PF_6$ with one equivalent of *t*-BuNC in THF gives the analogous *bis*-isocyanide complex, albeit somewhat impure.* This complex is analogous to the dirhenium(II) complexes of stoichiometry $[Re_2Cl_3(dppm)_2(CNR)_2]PF_6$.[23]

We have also studied the reactivity of other dimolybdenum(II) species towards RNC ligands. Of special note are the species *cis*-$Mo_2(mhp)_2Cl_2(PR_3)_2$, whose preparation and spectroscopic and electrochemical properties [along with those of $Mo_2(mhp)Cl_3(PR_3)_3$ and $Mo_2(mhp)_3Cl(PR_3)$] will be the subject of a future detailed report.[24] The structure of this group of molecules has been established by a single-crystal X-ray analysis of *cis*-$Mo_2(mhp)_2Cl_2(PEt_3)_2$.[25] A study of the reactions of its $PMePh_2$ analogue towards various amounts of *t*-BuNC did not afford us any isocyanide-containing dimolybdenum species. No products were isolated from the reaction of *cis*-$Mo_2(mhp)_2Cl_2(PMePh_2)_2$ with one equivalent of *t*-BuNC in the presence of $T1PF_6$ or KPF_6. Reactions using 2–12 equivalents of *t*-BuNC in acetone gave $Mo_2(mhp)_4$ and $[Mo(CN\text{-}t\text{-}Bu)_5(PMePh_2)_2](PF_6)_2$ as the only identifiable products. It seems likely that cleavage of the dimolybdenum complex occurs with concomitant loss of mhp ligand which in turn attacks unreacted (or partially reacted) starting material to give $Mo_2(mhp)_4$. The $PMePh_2$ so released then reacts with mononuclear cleavage products to give stable $[Mo(CN\text{-}t\text{-}Bu)_5(PMePh_2)_2](PF_6)_2$. Whereas very little $Mo_2(mhp)_4$ is produced with a $Mo_2(mhp)_2Cl_2(PMePh_2)_2$: *t*-BuNC stoichiometric ratio of 1:2 or 1:4, the yields of $Mo_2(mhp)_4$ and $[Mo(CN\text{-}t\text{-}Bu)_5(PMePh_2)_2](PF_6)_2$ are 17 and 26%, respectively, with a 1:6 ratio. Thereafter, the yield of

* Preliminary spectroscopic and electrochemical characterizations of this green 1:2 complex are as follows: IR (Nujol) ν(CN) 2182sh and 2164s cm^{-1}; ^1H NMR (CD_2Cl_2) δ +1.52 (s, Me_3CNC, 18H), δ +4.55 (p, $-CH_2-$ of dppm, 4H, $J_{P-H} = 4.8$ Hz); CV (in 0.1 M TBAH–CH_2Cl_2): $E_{p,a} = +1.22$ V, $E_{1/2}$(red) = −0.32 V, and $E_{1/2}$(red) = −1.28 V (Ag–AgCl).

the former decreases while the latter increases (e.g. a 1:12 ratio gives 7 and 51% of isolated products, respectively).

Mixed isocyanide–nitrogen donor complexes of molybdenum(II)

The detailed study of the reactions between $Mo_2(\mu\text{-dppm})_2X_4$ and RNC has provided insights into the reaction pathway involved in the cleavage of the Mo≡Mo bond by the π-acceptor ligands. In the case of the corresponding reaction chemistry involving dimolybdenum compounds that contain heterocyclic amine ligands, we have found that both similarities and some striking differences exist. Thus $Mo_2Cl_4(bpy)_2$ and $Mo_2Cl_4(py)_4$ (bpy = 2,2′-bipyridine and py = pyridine) are converted into mononuclear $[MoCl(CN\text{-}t\text{-}Bu)_4(bpy)]PF_6$ and $[Mo(CN\text{-}t\text{-}Bu)_6(py)](PF_6)_2$, respectively.[26] On the other hand, the reactions of mononuclear $[Mo(CNR)_7](PF_6)_2$ with the bidentate nitrogen donors (abbreviated N–N) bpy, 4,4′-dimethyl-2,2′-bipyridine (Me_2bpy) and 1,10-phenanthroline (phen) show an interesting dependence upon the nature of the RNC ligand. In the case of $[Mo(CNR)_7](PF_6)_2$, where R = Me, Me_2CH or C_6H_{11}, dark red-purple complexes of the type $[Mo(CNR)_5(N\text{–}N)](PF_6)_2$ are formed in high yield when the reactions are carried out in refluxing 1-propanol.[26] However, $[Mo(CN\text{-}t\text{-}Bu)_7](PF_6)_2$ reacts with bpy, Me_2bpy and phen under these same conditions to produce the cyano-bridged complexes $\{[Mo(CN\text{-}t\text{-}Bu)_4(N\text{–}N)]_2(\mu\text{-}CN)\}(PF_6)_3$, through dealkylation of a *t*-BuNC ligand.[26] The crystal structure of $\{[Mo(CN\text{-}t\text{-}Bu)_4(bpy)]_2(\mu\text{-}CN)\}(PF_6)_3$ has been determined and shows the presence of seven-coordinate molybdenum atoms and an essentially linear Mo—N≡C—Mo bridge. However, the mononuclear complex $[Mo(CN\text{-}t\text{-}Bu)_5(bpy)](PF_6)_2$ can be prepared from $\{[Mo(CN\text{-}t\text{-}Bu)_4(bpy)]_2(\mu\text{-}CN)\}(PF_6)_3$, as shown in eqn (2):

$$\{[Mo(CN\text{-}t\text{-}Bu)_4(bpy)]_2(\mu\text{-}CN)\}(PF_6)_3$$

$$\xrightarrow[\text{heat}]{t\text{-BuCl, MeOH}} [Mo(CN\text{-}t\text{-}Bu)_4(bpy)Cl]PF_6$$

$$\xrightarrow[\text{heat}]{t\text{-BuNC, KPF}_6\text{, MeOH}} [Mo(CN\text{-}t\text{-}Bu)_5(bpy)](PF_6)_2$$

$$\xrightarrow[\text{reflux, 1}\tfrac{1}{2}\text{ h}]{\text{1-propanol}} \{[Mo(CN\text{-}t\text{-}Bu)_4(bpy)]_2(\mu\text{-}CN)\}(PF_6)_3 \qquad (2)$$

and it can in turn be converted back to the cyano-bridged species thermally.[26]

An alternative procedure for synthesizing the mononuclear molybdenum complexes $[Mo(CNR)_5(N\text{–}N)](PF_6)_2$ {which is, incidentally, also applicable to the tungsten(II) analogues $[W(CNR)_5(N\text{–}N)](PF_6)_2$} involves the $PhICl_2$ oxidation of $Mo(CO)_4(N\text{–}N)$ in the presence of a stoichiometric quantity of RNC [eqn (3)].[27]

$$Mo(CO)_4(N\text{–}N) \xrightarrow[\text{(2) RNC (six equivalents), KPF}_6]{\text{(1) PhICl}_2\text{, MeOH, RT}} [Mo(CNR)_5(N\text{–}N)](PF_6)_2. \qquad (3)$$

These one-pot syntheses, using readily available starting materials, offer advantages over the somewhat more elaborate procedure used previously to prepare the EtNC complex $[Mo(CNEt)_5(bpy)](BF_4)_2$.[28]

A variation of the reaction depicted in eqn (3) has been used to prepare the mononuclear complexes

$$[Mo(CNR)_5(R'\text{-DAB})](PF_6)_2$$

$$(R'\text{-DAB} = R'\text{—N=CH—CH=N—}R')$$

which cannot be generated by the direct reaction of $[Mo(CNR)_7](PF_6)_2$ with the bidentate 1,4-di-substituted diaza-1,3-butadiene ligands R′-DAB (R′ = *i*-Pr, *t*-Bu or C_6H_{11}).[26] We have found that the reactions of the molybdenum(II) species

$$Mo(CO)_3(R'\text{-DAB})(SnCl_3)Cl$$

[which are themselves prepared by treating $Mo(CO)_4(R'\text{-DAB})$ with $SnCl_4$ in CH_2Cl_2] with RNC (R = *i*-Pr, *t*-Bu or C_6H_{11}) in the presence of KPF_6 lead to the formation of

$$[MoCl(CNR)_4(R'\text{-DAB})]PF_6$$

or

$$[Mo(CNR)_5(R'\text{-DAB})](PF_6)_2$$

(R′ = *i*-Pr or Cy) depending upon the reaction stoichiometry and reaction conditions.[29] The monocationic chloro species are converted into

$$[Mo(CNR)_5(R'\text{-DAB})](PF_6)_2$$

upon heating with the stoichiometric amount of RNC. Under similar reaction conditions $Mo(CO)_3(t\text{-Bu-DAB})(SnCl_3)Cl$ (i.e. R′ = *t*-Bu) reacts with RNC with the reductive-elimination of the elements of $SnCl_4$ and the formation of octahedral $Mo(CO)_3(CNR)(t\text{-Bu-DAB})$.[29] The latter compounds represent a class of mixed carbonyl–isocyanide complexes of molybdenum(0) for which other preparative procedures have recently been devised, and for which an interesting and quite extensive redox chemistry has been uncovered.[30]

INTERCONVERTING MULTIPLE BONDS BETWEEN MOLYBDENUM AND TUNGSTEN ATOMS: OXIDATIVE-ADDITIONS AND REDUCTIVE-ELIMINATIONS FROM DINUCLEAR CENTERS

MALCOLM H. CHISHOLM

Department of Chemistry, Indiana University, Bloomington, IN 47405, U.S.A.

(*Received* 18 *June* 1985)

Abstract—Analogies between the chemistry of mononuclear group 8, 9 and 10 transition elements and the chemistry of dinuclear molybdenum and tungsten compounds are noted. Just as the d^8- and d^6-configurations determine preferred coordination numbers, geometries, substitution patterns and the propensity for oxidative-addition or reductive-elimination, so does the M–M bonding configuration influence the coordination chemistry and reactivity of dinuclear compounds. The presence of two metal atoms united by a multiple bond provides an electron source or sink for multi-electron redox reactions and a template for substrate assembly and coupling. The presence of two metal centers poses fascinating mechanistic questions concerning cooperative interactions between the metal atoms and the detailed reaction profile for even simple addition–elimination sequences. These general principles are illustrated in studies of the formation of M–M quadruple bonds by reductive-elimination from $(M{\equiv}M)^{6+}$ centers and oxidative-additions leading to $(M{=}M)^{8+}$ and $(M{-}M)^{10+}$ centers.

Several years ago I began to speculate about the reactivity of compounds containing M–M multiple bonds[1] and started a systematic search for reactions leading to stepwise changes in bond order akin to those well known in organic chemistry. In particular, redox reactions involving dinuclear compounds should find many parallels with mononuclear chemistry. Oxidative-additions and reductive-eliminations interconverting d^8 and d^6 transition-metal-containing complexes are well-documented and provide fundamental steps in numerous homogeneous catalytic or stoichiometric reactions.[2,3] Although the intimate mechanism of a given reaction may vary from metal to metal and substrate to substrate, the general concept of reactivity based on d^n-configuration, coordination geometry and ligand substitution lability are relatively well-advanced for mononuclear metal centers.[4,5] Surely we can extend these principles to dinuclear compounds where the M–M bonding electronic configuration takes the place of the ligand field stabilized d^n set of electrons? Walton, Cotton and coworkers[6,7] were the first to show that simple electrochemical oxidations and reductions could interconvert M–M bonds of order 4, 3.5 and 3 by feeding electrons in and out of δ- and δ^*-orbitals. Our work has focused attention on chemical reactions wherein the ligands are intimately involved in the redox process.

FORMING QUADRUPLE BONDS, $\sigma^2\pi^4\delta^2$, BY REDUCTIVE-ELIMINATIONS FROM COMPOUNDS CONTAINING TRIPLE BONDS, $\sigma^2\pi^4$

Our initial strategy was to devise routes to thermodynamically stable quadruply bonded compounds by elimination of kinetically labile organic molecules (fragments). Suitable precursor compounds were the 1,2-diorgano-dimetal-tetraamides which can readily be prepared according to the reaction sequence outlined in eqn (1):

$$M_2(NMe_2)_6 + 2Me_3SiCl \rightarrow 1,2\text{-}M_2Cl_2(NMe_2)_4 + 2Me_3SiNMe_2, \quad (1i)$$

$$1,2\text{-}M_2Cl_2(NMe_2)_4 + 2LiR \rightarrow 1,2\text{-}M_2R_2(NMe_2)_4 + 2LiCl. \quad (1ii)$$

Largely through the work of Chetcuti and Haitko, a wide variety of R groups have been attached to the dinuclear metal center including Me, Et, Pr (*n* and *i*), Bu (*n*, *i*, *s* and *t*), Ph, *o*- and *p*-tolyl, CH_2Ph, CH_2CMe_3 and CH_2SiMe_3.[8,9] More recently the dimetallacycles, where $R = (CH_2)_4$, have been prepared.[10]

A common structural feature of these compounds is a central ethane-like $M_2N_4C_2$ core with M≡M distances in the range 2.2 (M = Mo)–2.3 Å (M = W). In the solid state either *anti* or *gauche* rotamers may be found and in solution there is generally a mixture of the two with the equilibrium being in favor of the *gauche*. These compounds are thermally stable at room temperature and may be sublimed *in vacuo* at *ca* 80–120°C, 10^{-4} torr, with little decomposition. The reluctance of these compounds to undergo facile β-hydrogen elimination can be understood in terms of the existence of: (i) the M≡M bond, and (ii) the strong Me_2N–M π-bonding. Quite simply metal *d*-orbitals are not available for M–H–C interactions. On thermodynamic grounds we also would not expect the formation of an M–M quadruply bonded compound to be favored by either C–C or C–N coupling reactions. The inorganic residue formed by such an elimination, $Mo_2(NMe_2)_4$ or $Mo_2R(NMe_2)_3$, has no known analogue and might be expected to be a relatively high energy species.

Since CO_2 is known to react with M–NMe_2 bonds to generate, by a formal insertion process,[11] carbamate ligands,[12] O_2CNMe_2, a reaction between $M_2R_2(NMe_2)_4$ compounds and CO_2 was expected to yield a route to $M_2(O_2CNMe_2)_4$ compounds, analogues of the well-known carboxylates of formula $Mo_2(O_2CR)_4$ (M≡M),[6] providing that the organo ligands, R, yielded a kinetically labile elimination pathway.

This expectation was realized in the chemistry of 1,2-$Mo_2R_2(NMe_2)_4$ compounds where R = an alkyl containing a β-hydrogen atom. These react with CO_2 according to the reaction shown in eqn (2):[13]

$$Mo_2R_2(NMe_2)_4 + CO_2 \rightarrow Mo_2(O_2CNMe_2)_4 + \text{alkene} + \text{alkane}. \quad (2)$$

Similarly reactions involving 1,3-diaryltriazines led to elimination from the dimolybdenum center and formation of quadruply bonded compounds of formula $Mo_2(ArN_3Ar)_4$ [eqn (3)]:[13]

$$1,2\text{-}Mo_2R_2(NMe_2)_4 + 4ArNNNHAr \rightarrow Mo_2(ArN_3Ar)_4 + 4HNMe_2 + \text{alkene} + \text{alkane}. \quad (3)$$

Rather interestingly, reactions employing $W_2R_2(NMe_2)_4$ compounds (R = an alkyl ligand containing β-hydrogen atoms) do not react similarly to their molybdenum analogues in eqns (2) and (3), though a general procedure for the formation of quadruple bonds has been devised. This involves the addition of carboxylic anhydrides to $M_2R_2(NMe_2)_4$ compounds [eqn (4)]:[14,15]

$$1,2\text{-}M_2R_2(NMe_2)_4 + 4R'COOCOR' \rightarrow M_2(O_2CR')_4 + 4R'CONMe_2 + \text{alkene} + \text{alkane}. \quad (4)$$

The reaction shown in eqn (4) has proven general for R' = Me, Et, Bu^t and Ph.

From labelling studies involving the alkyl ligands in the $M_2R_2(NMe_2)_4$ compounds, we have found that the β-hydrogen atom of one alkyl ligand is transferred to the α-carbon atom of the other in the elimination process, e.g. as shown in eqn (5):

$$CD_3CH_2M{\equiv}MCH_2CD_3 \rightarrow M{\equiv}M + CD_3CH_2D + CD_2{=}CH_2. \quad (5)$$

In reactions involving the metallacyclic compound $Mo_2(CH_2)_2(NMe_2)_4$, the formation of the Mo–Mo quadruple bond is accompanied by the liberation of 2 equivalents of ethylene.[15]

Reactions employing $M_2R_2(NMe_2)_4$ compounds where R = an alkyl ligand lacking β-hydrogen atoms, e.g. Me, CH_2Ph or CH_2CMe_3, cannot undergo this type of reductive-elimination (alkyl group disproportionation) and compounds of the type $M_2R_2(O_2CX)_4$, where X = NMe_2[16] or R',[17,18] have been isolated. Reductive-elimination is still possible and may occur by a radical pathway which may be promoted either thermally or photochemically.[17–19] The ease of reductive-elimination follows the order Mo > W and $PhCH_2$ > Bu^tCH_2. An extension of this type of reductive-elimination involves reactions of

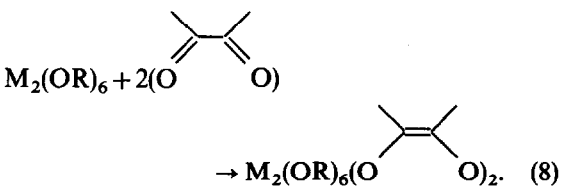
$$(L_nM')(Me_2N)_2M{\equiv}M(NMe_2)_2(M'L_n),$$

where L_nM' = $CpFe(CO)_2$ or $(Me_3Sn)_3Sn$ [eqn (6)]:[20,21]

$$(L_nM')(Me_2N)_2Mo{\equiv}Mo(NMe_2)_2(M'L_n) + CO_2 \rightarrow Mo_2(O_2CNMe_2)_4 + 2L_nM''. \quad (6)$$

The fate of the L_nM'' radicals, as with R$^{\cdot}$, depends upon its relative reactivity. For $CpFe(CO)_2^{\cdot}$ coupling to the dimer is favored as for $PhCH_2^{\cdot}$ in aromatic solvents. For $(Me_3Sn)_3Sn^{\cdot}$ a decomposition to Me_4Sn and Sn(metal) occurs while for R = *t*-$BuCH_2^{\cdot}$, hydrogen–deuterium atom abstraction from the solvent is favored.[15,18]

OXIDATIVE-ADDITIONS TO $(M{\equiv}M)^{6+}$ CENTERS LEADING TO $(M{=}M)^{8+}$ AND $(M{-}M)^{10+}$



Our initial approach was to start with a $(M{\equiv}M)^{6+}$ compound and convert this to a known

compound containing either an $(M{=}M)^{8+}$ or an $(M{-}M)^{10+}$ center. The dinuclear alkoxide $Mo_2(OPr^i)_6$[22] was converted to $Mo_2(OPr^i)_8$[23] by reaction with Pr^iOOPr^i [eqn (7)]:[24]

$$Mo_2(OPr^i)_6 + Pr^iOOPr^i \rightarrow Mo_2(OPr^i)_8. \quad (7)$$

Steric considerations are apparently important in reactions of type(7) since attempted reactions employing Bu^tO ligands and/or Bu^tOOBu^t failed to react.

Additions of the halogens, X_2, to solutions of $Mo_2(OPr^i)_6$ proceed directly to $Mo_2X_4(OPr^i)_6$ (M—M) compounds (X = Cl, Br and I)[24] and only in the case of I_2 is there any evidence for the formation of an intermediate. Similarly reactions involving a variety of substituted (H, alkyl and Cl) ortho-quinones with $M_2(OR)_6$ compounds yield 2:1 adducts,[25,26] as do α-diketones.[27] These reactions can be summarized by eqn (8) in which each ligand is reduced by two electrons upon complexation to the dimetal center:

$$M_2(OR)_6 + 2(O\!=\!\!-\!\!-\!\!=O) \rightarrow M_2(OR)_6(O\!=\!\!-\!\!-\!\!=O)_2. \quad (8)$$

In the reaction between $Mo_2(OPr^i)_6$ and 1,4-diisopropyl-1,4-diaza-1,3-butadiene a 1:1 adduct is formed, $Mo_2(OPr^i)_6(Pr^iNCH{=}CHNPr^i)$ (M=M).[28] Formally this may be viewed as a Diels–Alder type of addition to the Mo≡Mo bond, though the structure in the solid state reveals that the bis-amide ligand is chelated to one metal atom.

The $M_2(OR)_6$ compounds also react with π-acceptor ligands such as CO and acetylenes to form 1:1 adducts which may be viewed in terms of redox reactions between the π-acceptor ligand and the M≡M bond as the donor.[29] From studies of these reactions it is clear that the reducing power of the M≡M bond follows the order W > Mo. Within this context the remarkable metathesis reactions involving $W_2(OBu^t)_6$ and alkynes[30,31] or nitriles,[30] [eqns (9) and (10)] may be viewed as oxidative-cleavages which are favorable for W but not Mo:*

$$W_2(OBu^t)_6 + RC{\equiv}CR \rightarrow 2(Bu^tO)_3W{\equiv}CR, \quad (9)$$

$$W_2(OBu^t)_6 + RC{\equiv}N \rightarrow (Bu^tO)_3W{\equiv}CR + (Bu^tO)_3W{\equiv}N. \quad (10)$$

These redox reactions [(7)–(10)] are synergistic. The ligand is reduced by the metal and the metal receives electrons from the ligand in forming new metal–ligand bonds.

The reactions between $W_2(NMe_2)_6$ and alcohols have proved to yield a variety of products depending upon the reaction conditions and the alcohol. For the not so sterically demanding alcohols oxidative-addition is commonly observed. For example, the reaction involving Pr^iOH yields $W_4(H)_2(OPr^i)_{14}$ which may be viewed as a dimer of dinuclear compounds, $[W_2(H)(OPr^i)_7]_2$.[33] The reaction sequence leading to this product has proved to be quite fascinating. Formally the reaction represents the simple addition of Pr^iOH across the W≡W bond. Mechanistically the path is much more complex since a direct alcoholysis involving $W_2(OBu^t)_6$ and Pr^iOH yields only $[W(OPr^i)_3]_4$.[34] Moreover, $W_2(OPr^i)_6(HNMe_2)_2$, which is the major product formed in the reaction between $W_2(NMe_2)_6$ and Pr^iOH (excess) in hexane or toluene at short reaction times, fails to react further with Pr^iOH. However, the addition of base ($HNMe_2$, NEt_3, NMe_3 or proton sponge) to a hydrocarbon solution of $W_2(OPr^i)_6(HNMe_2)_2$ in the presence of Pr^iOH does yield $W_4(H)_2(OPr^i)_{14}$. Also reactions involving either $W_2(OBu^t)_6$ or $W_2(OPr^i)_6(HNMe_2)_2$ in hexane–Pr^iOH solvent with $NaOPr^i$ yield $NaW_2(H)(OPr^i)_8$ which can be isolated in crystalline form as a diglyme adduct.[34] A subsequent reaction with a mild proton source in hexane–Pr^iOH yields essentially quantitative formation of $W_4(H)_2(OPr^i)_{14}$, while treatment of the latter compound with $NaOPr^i$ regenerates the mixed metal hydrido alkoxide.[34] This overall sequence is summarized by the reactions shown in eqns (11)–(13):

$$W_2(OBu^t)_6 + NaOPr^i \xrightarrow[\text{hexane–}Pr^iOH]{25^\circ C} NaW_2(H)(OPr^i)_8, \quad (11)$$

$$NaW_2(H)(OPr^i)_8 + Me_2NH_2^+I^- \xrightarrow[\text{hexane–}Pr^iOH]{25^\circ C} \tfrac{1}{2}W_4(H)_2(OPr^i)_{14} + NaI + Me_2NH, \quad (12)$$

$$W_4(H)_2(OPr^i)_{14} + 2NaOPr^i \rightarrow 2NaW_2(H)(OPr^i)_8. \quad (13)$$

From these studies it seems likely that the role of the base in the oxidative-addition of Pr^iOH to the W_2^{6+} center involves the initial conversion of an unbridged to a bridged d^3–d^3 dimer, perhaps in a manner akin to that seen by Rothwell and coworkers[35] in the reaction between *p*-cresol and $Mo_2(NMe_2)_6$ which yields the salt $Me_2NH_2^+Mo_2(OAr)_7(HNMe_2)_2^-$.

* Cleavage of the Mo≡Mo bond in the reaction between $Mo_2(OBu^t)_6$ and PhC≡CH (*ca* 15-fold excess) has been noted but it is clear from this and other studies that the Mo≡Mo bond is less reducing. See Refs 29 and 32.

COUPLED ADDITION–ELIMINATION SEQUENCES

Essential to many catalytic or stoichiometric reactions involving mononuclear metal centers is the coupling of addition–elimination sequences and such reaction sequences hold great promise for dinuclear compounds with M–M bonds. A very facile example is seen in the alcoholyses of 1,2-$Mo_2R_2(NMe_2)_4$ compounds where the alkyl group R contains β-hydrogen atoms. These reactions yield $Mo_2R''(OR')_5$ compounds according to eqn (14) (R = Et, Pr or Bu):[36]

$$1,2\text{-}Mo_2R_2(NMe_2)_4 + R'OH \rightarrow Mo_2R''(OR')_5 + 4HNMe_2 + RH. \quad (14)$$

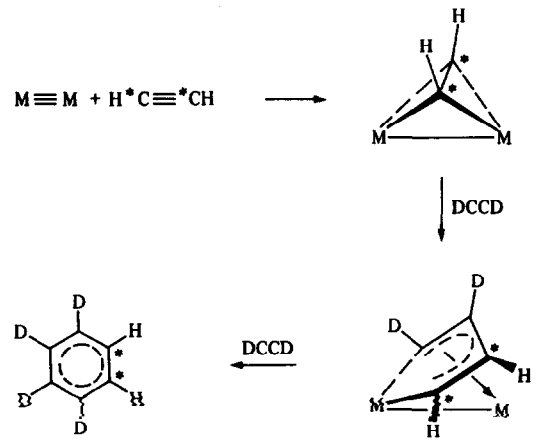
Reaction (14) contrasts with reactions involving β-hydrogen-lacking alkyl ligands, R, which give 1,2-$Mo_2R_2(OR')_4$ compounds according to eqn (15) (R = Me, R' = Bu^t; R = CH_2CMe_3 or CH_2Ph; R' = Pr^i, Bu^t or Et):[36]

$$1,2\text{-}Mo_2R_2(NMe_2)_4 + R'OH \rightarrow 1,2\text{-}Mo_2R_2(OR')_4 + 4HNMe_2. \quad (15)$$

Studies of reaction (14) employing labelled alkyl ligands show that elimination of alkane involves a β-hydrogen atom transfer akin to that shown in eqn (5) and furthermore that the alkyl group results from the hydroxyl proton of the alcohol and the liberated alkene [eqn (5)].[36] The sequence thus involves: (i) reductive-elimination from the $(Mo{\equiv}Mo)^{6+}$ center generating a reactive $(Mo{\equiv}Mo)^{4+}$ species, and (ii) oxidative-addition of R'OH followed by insertion of alkene to a metal hydride. Evidence in support of this pathway includes the isolation of a quadruply bonded compound, $Mo_2(OPr^i)_4(HOPr^i)_4$,[37] in reaction (16):

$$1,2\text{-}Mo_2(Bu^i)_2(NMe_2)_4 + Pr^iOH \rightarrow Mo_2(OPr^i)_4(HOPr^i)_4 + 4HNMe_2 + Bu^iH + Me_2C{=}CH_2, \quad (16)$$

and its conversion to the ethyl compound in reaction (17):[37]



$$Mo_2(OPr^i)_4(HOPr^i)_4 + C_2H_4 \rightarrow Mo_2Et(OPr^i)_5 + 3Pr^iOH. \quad (17)$$

The regeneration of the alkyl ligand in eqn (14) occurs such that the most sterically hindered ligand is kinetically favored, e.g. if R = Pr^n then R'' = Pr^i, and if R = Bu^i than R'' = Bu^t. A subsequent isomerization of R'' to the least sterically encumbered alkyl ligand (e.g. Pr^i to Pr^n) is promoted by Lewis bases such as pyridine or PMe_3.[36,38]

Another sequence in which addition–elimination reactions involve use of the M—M bond as a reservoir of electrons is the catalytic cyclization of alkynes (C_2H_2 and C_2Me_2) by $Mo_2(OR)_6$ compounds.[39] The initial step in the reaction involves the formation of 1:1 alkyne adducts. The alkyne is bonded in the perpendicular mode with C—C = *ca* 1.40 Å and Mo—Mo = *ca* 2.60 Å for the central $Mo_2(\mu\text{-}C_2)$ moiety. These distances may be viewed as somewhere between M–M and C–C double- and single-bond distances. The next step in the reaction involves the coupling of two alkyne units at the dimetal center to give a $Mo_2(\mu\text{-}C_4R_4)$ moiety which may be viewed as one metallacyclopentadiene unit π-bonded to the other metal atom. A further reaction with acetylene promotes benzene elimination and the cycle is repeated. This sequence involves only the linking of C_2 units; this has been determined from labelling studies* (see Scheme 1). Rather interestingly, $W_2(OR)_6$ compounds are not catalysts for cyclotrimerization of alkynes because the hydrocarbon fragments attached to the dimetal center are not readily released.[41] This provides yet another example of the ease of reductive-elimination, Mo > W, which is the converse of the order of oxidative-addition at the dinuclear centers. Though tungsten is not catalytic in cyclotrimerization of alkynes, stable compounds of formula

$$W_2(OPr^i)_6(\mu\text{-}C_4R_4)(\eta^2\text{-}C_2R_2),$$

where R = H or Me, have been isolated.[40] These provide models for reactive intermediates in the $Mo_2(OR)_6$-catalyzed sequence. The W—W distances are *ca* 2.8 Å, representing weak single bonds.

Scheme 1. Cyclotrimerization of ethyne molecules at the dinuclear center. The specific combination of labels shown here involved $Mo_2(OCH_2Bu^t)_6(py)_2$ in [$^2H_8$]toluene at room temperature.

* The labelling experiments shown in the scheme were performed by Dr David Hoffman.

CONCLUDING REMARKS

Oxidative-additions and reductive-eliminations at dimolybdenum and ditungsten centers can lead to stepwise changes in M–M bond order. There are notable parallels in these reactions at dinuclear metal centers with those well documented for the group 8, 9 and 10 transition elements. We have not yet noted the facile oxidative-addition of molecular hydrogen or alkyl halides,[41] reactions which are common to the later mononuclear transition-metal complexes. This may merely reflect unsuitable orbital energetics in our compounds and this may be markedly influenced by the ligand set attached to the dinuclear center. However, working with alkoxide ligands we have found a number of reactions which have no parallel in mononuclear chemistry. The redox power of the M–M multiple bond and the template action of the metal atoms may be extended when two dinuclear compounds act in consort. One spectacular example of this is seen in the reaction between $W_2(OPr^i)_6(py)_2$ and acetone [eqn (18)]:[42]

$$2W_2(OPr^i)_6(py)_2 + 2Me_2C{=}O \rightarrow W_4O_2(OPr^i)_{12} + Me_2C{=}CMe_2 + 4py. \quad (18)$$

This provides us with a molecular model for the McMurray reagent[43] which is now believed to involve finely divided Ti metal.[45,46]

The detailed reaction pathways of these transformations at dinuclear metal centers remain to be elucidated and should provide a fertile area for future work.

(*Received* 14 *June* 1985)

Abstract—Reaction of $Mo_2(O_2CMe)_4$ with $[Me_3O][BF_4]$ in MeCN solution at room temperature produces red crystals of $[Mo_2(O_2CMe)_2(NCMe)_6][BF_4]_2$, which have been characterized by X-ray crystallography and NMR spectroscopy. The central $[Mo_2(O_2CMe)_2]^{2+}$ core, with a quadruple Mo–Mo bond of length 2.136(1) Å, has two acetate bridges in *cis* positions. Octahedral coordination of each Mo atom is completed by two equatorial and one axial MeCN ligand, with the axial Mo—N much longer than the equatorial Mo—N. The MeCN ligands are labile in MeCN solution, giving complete scrambling on the NMR time-scale.

Reactions of dimolybdenum tetracarboxylates with a strong acid (CF_3SO_3H or $HBF_4 \cdot Et_2O$) in acetonitrile solution have recently been shown to produce derivatives of the $[Mo_2(O_2CR)_2]^{2+}$ core; products were formulated as, *inter alia*,

$$[Mo_2(O_2CMe)_2(NCMe)_4][CF_3SO_2]_2$$

and

$$[Mo_2(O_2CMe)_2(NCMe)_5][BF_3OH]_2$$

on the basis of elemental analysis and spectroscopic investigations.[1] We have found that treatment of $Mo_2(O_2CMe)_4$ with $[Me_3O][BF_4]$ in MeCN at room temperature gives red crystals of $[Mo_2(O_2CMe)_2(NCMe)_6][BF_4]_2$, which have been characterized by X-ray crystallography and NMR spectroscopy.

EXPERIMENTAL

Preparation

Manipulations were performed under an atmosphere of dinitrogen, with freshly dried and distilled solvents. $Mo_2(O_2CMe)_4$ (1.12 g, 2.62 mmol) was added to a stirred solution of $[Me_3O][BF_4]$ (1.55 g, 10 mmol) in MeCN (50 cm^3), and the mixture stirred at room temperature for 30 min, to produce a red solution. Concentration of the solution by evaporation, followed by slow cooling, gave red crystals of the product, which was recrystallized from MeCN. Yield *ca* 1.5 g (84%). Found: C, 26.3; H, 3.3; N, 10.9; Mo, 25.7%. Calc: C, 26.3; H, 3.3; N, 11.5; Mo, 26.3%.

Spectroscopy

^1H NMR: Perkin–Elmer R34 (220 MHz) and Varian SC300 (300 MHz) FT spectrometers. ^{13}C NMR: Bruker WP-80 FT spectrometer at 20.1 MHz. CD_3CN solutions, TMS standard.

Crystallography

$M_r = 729.9$, $P2_1/m$, $a = 7.160(1)$ Å, $b = 10.642(1)$ Å, $c = 19.402(2)$ Å, $\beta = 99.47(1)°$, $V = 1458.2$ Å^3, $Z = 2$, $D_x = 1.662$ g cm^{-3}, $F(000) = 720$, λ(Mo-K_α) = 0.71069 Å, $\mu = 0.92$ mm^{-1}. Of 3753 reflections measured with a Stoe–Siemens AED diffractometer[2] ($2\theta_{max} = 55°$), 3524 were unique, and 2774 with $F > 4\sigma(F)$ were used for structure solution by Patterson and difference syntheses.[3] Blocked-

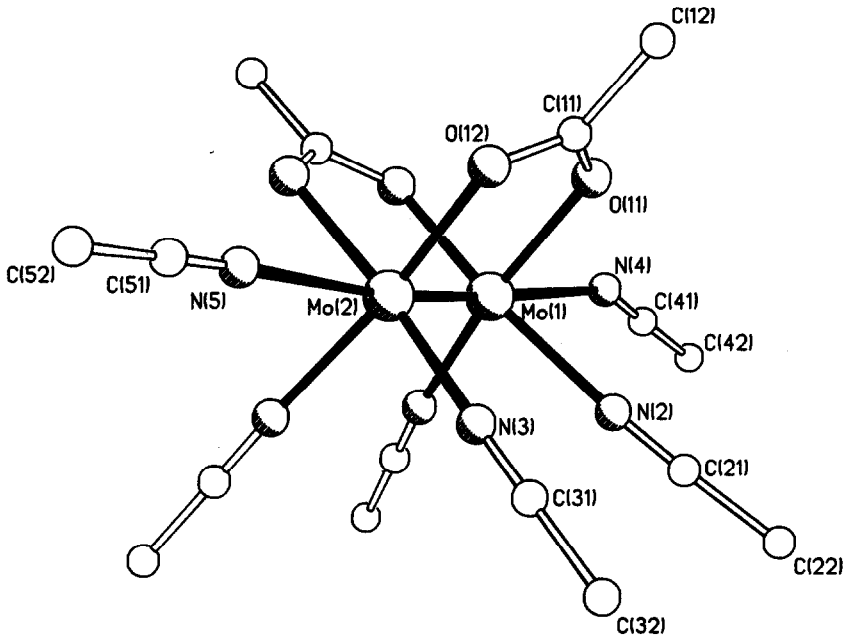

Fig. 1. Structure of the cation, showing the numbering scheme.

cascade least-squares refinement on F with $w^{-1} = \sigma^2(F) + 0.00068F^2$, anisotropic thermal parameters, no hydrogen atoms, and a disordered anion, gave $R = 0.053$ and $R_w = 0.055$.

RESULTS AND DISCUSSION

In the crystal structure, the cation and both anions lie on mirror planes. One anion is disordered; both show high thermal motion. The mirror plane in the cation passes through both Mo atoms and between the acetate bridges (Fig. 1). These two bridges occupy *cis* positions, and an essentially octahedral coordination of each Mo atom is completed by two equatorial and one axial MeCN ligands (Table 1).

The length of the Mo–Mo quadruple bond [2.136(1) Å] is typical of Mo_2^{4+} complexes with two carboxylate bridges, and is intermediate in length

Table 1. Coordination geometry[a]

Bond length (Å)			
Mo(1)—Mo(2)	2.136(1)	Mo(1)—O(11)	2.075(4)

[a] The suffix a on an atom number indicates an atom generated by reflection in the mirror plane.

between those in $[Mo_2(O_2CR)_4 \cdot 2L]$ and $[Mo_2X_4(NCMe)_4]$ complexes with four and no carboxylate bridges, respectively.[4–6] The axial Mo—N bonds are considerably longer than the equatorial bonds, by about 0.6 Å.

In the ^1H NMR spectrum (CD_3CN solution) one signal is observed for the acetate and one for the acetonitrile ligands. Thus, on the NMR time-scale, all the acetonitrile ligands are equivalent. The signal due to the acetonitrile ligand protons is at the same chemical shift as for free MeCN, indicating labile ligands. This is supported by the ^{13}C NMR spectrum (CD_3CN solution), which shows two signals for the acetate carbon atoms, and only two peaks for acetonitrile. This behaviour contrasts sharply with that of the corresponding Rh(II) complex, $[Rh_2(O_2CMe)_2(NCMe)_6]^{2+}$, in which axial and equatorial ligands can be distinguished by NMR.[7]

A pink solution of the Mo complex in methanol slowly turns yellow, more quickly on direct exposure to the atmosphere. An aqueous solution is yellow, but addition of acetonitrile turns it pink. The reversibility of this ligand exchange is gradually lost on prolonged exposure to water or moist air. The displacement of the labile MeCN ligands provides a route to other complexes of the $[Mo_2(O_2CMe)_2]^{2+}$ core.

ISOMERIZATION REACTIONS OF BRIDGED AND CHELATED DIMOLYBDENUM COMPLEXES

SHEENA CHRISTIE, IAIN F. FRASER, ANDREW McVITIE and ROBERT D. PEACOCK†

Department of Chemistry, The University, Glasgow G12 8QQ, U.K.

(*Received* 14 *June* 1985)

Abstract—The isomerization reactions of complexes of general formula $Mo_2Cl_4(P\frown P)_2$, where $P\frown P$ is a diphosphine, are considered. Such complexes can exist as chelated or bridged isomers. When the diphosphine has a C_2 backbone the chelated isomer spontaneously isomerizes to the bridged complex. With diphosphines with a C_3 backbone, however, it is possible to stabilize the chelated isomer in certain solvents and, indeed, for bridged → chelated isomerization to occur.

Dimolybdenum complexes of general formula $Mo_2X_4(P\frown P)_2$, where $P\frown P$ is a diphosphine ligand,‡ can exist in two isomeric forms (Fig. 1). In the α or chelated isomer the bidentate ligands chelate both molybdenum atoms, the chelate rings are *trans* to each other and the ligators are eclipsed. In the structurally characterized complexes with ethane backbone ligands the rings are in the "envelope" conformation with the carbon backbone lying above the Mo—Mo bond and in close proximity to the halide atoms.[1] In the β or bridged isomers the ligands bridge between two molybdenum atoms and, when the ligand has two or more carbon atoms in the backbone, the two sets of ligators are twisted with respect to each other. This twist angle is, for example, 60° in $Mo_2Cl_4(dppe)_2$[2] and 23° in $Mo_2Cl_4(S,S\text{-dppb})_2$.[3]

We have recently shown[4] for a number of complexes with C_2 backbone ligands that the α-isomer spontaneously isomerizes to the corresponding β-isomer with first-order kinetics and a rate constant in the range 10^{-3}–10^{-6} s^{-1} (Table 1). We concluded that the rate-determining step was most likely to involve a rotation about the Mo—Mo bond since only this geometric change would lead to the observed changes in the energy and intensity of the $\delta \rightarrow \delta^*$ transition. It is unfortunately difficult to ascribe much meaning to the Arrhenius factors which are, in some cases, the major cause of isomerization rate differences between complexes. However, if we compare the rates for the isomerization of α-$Mo_2Cl_4(dppe)_2$ and α-$Mo_2Cl_4(R\text{-dppp})_2$ where the Arrhenius factors are essentially identical, we can see that the faster isomerization of the latter complex is largely accounted for by the smaller activation energy. The fact that α-$Mo_2Cl_4(S,S\text{-dppb})_2$ cannot (easily?) be prepared may be simply a consequence of an even lower activation energy (E_a) in this case (an

[a] k, rate constant; $t_{1/2}$, half-life; E_a, activation energy.

E_a of 93 kJ mol^{-1} and log A of 16 would give a half-life of less than a second). We have now prepared β-$Mo_2Cl_4(R\text{-phenphos})_2$ but find that the α-isomer either cannot be prepared or has a very short half-life. The absorption and circular dichroism (CD) of the bridged isomer are extremely similar to those of β-$Mo_2Cl_4(R\text{-dppp})_2$, which suggests that the twist angles of the complexes and so, probably, the conformations of the ligands are nearly identical. The much faster isomerization rate of α-$Mo_2Cl_4(R\text{-phenphos})_2$ is probably due, therefore, to the very unfavourable interaction of the phenyl group on the backbone with the halide atoms on the adjacent molybdenum.

We have recently begun to study the chemistry of dimolybdenum complexes with diphosphine ligands which have three carbon atoms in the backbone and we present some preliminary results. Figure 2 shows the change in absorption spectrum as α-$Mo_2Cl_4(dppp)_2$ isomerizes to the β-form. The reaction is first order in the α-isomer and the rate constant and E_a are in the same range as the other complexes we have studied (Table 1). The $\delta \rightarrow \delta^*$ transition of the bridged isomer comes at a much higher energy than those of any of the bridged complexes with dppe-type ligands and indeed is close to that of the α-isomer. This suggests that the ligators in β-$Mo_2Cl_4(dppp)_2$ are nearly eclipsed, a structure most likely achieved by a twist angle of close to 90°.

Perhaps the most interesting chemistry which we have discovered among complexes with propane backbone diphosphine ligands is the isomerization behaviour of $Mo_2Cl_4(S\text{-chairphos})_2$. Here we find that whether the α- or the β-isomer is thermodyn-

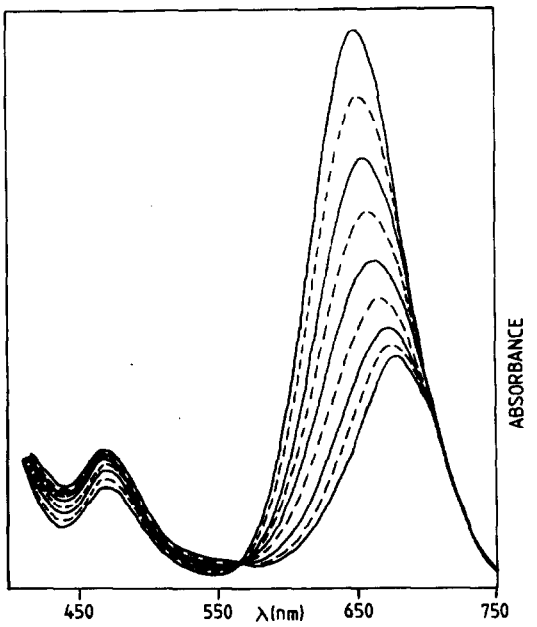

Fig. 2. Change in the electronic spectrum with time as α-$Mo_2Cl_4(dppp)_2$ isomerizes to β-$Mo_2Cl_4(dppp)_2$ in dry dichloromethane solution.

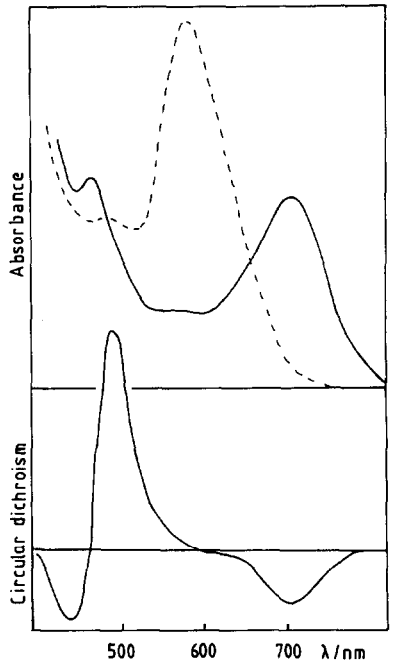

Fig. 3. Absorption spectrum of α- (dashed line, acetonitrile solution), and absorption and CD spectra of β- (full line, benzene solution) $Mo_2Cl_4(S\text{-chairphos})_2$.

amically more stable depends upon the solvent. Preparation of the complex from $K_4Mo_2Cl_8$ and the ligand in methanol gives the α-isomer. This is stable in methanol, ethanol, acetonitrile and methylene chloride which is in direct contrast to the behaviour of all of the other chelated isomers we have studied. On dissolving the solid in benzene or toluene at room temperature, however, the β-isomer is immediately formed. The absorption spectrum of the α-isomer and the absorption and CD spectra of the β-isomer are shown in Fig. 3. This $\alpha \rightleftarrows \beta$ interconversion is reversible in both directions, although a little decomposition usually occurs even when solvents are dried and degassed on a vacuum line. The isomerization rate is comparable with the rate of solution at room temperature, but we know that the reaction is a true solution isomerization because the rate is sufficiently slow at the freezing point of acetonitrile for the colour change to be followed as the solution warms up. Inspection of the crystal structure of α-$Re_2Cl_4(dppp)_2$ shows that the interactions of the carbon backbone with the opposite chlorine atoms are less severe than in the chelated complexes with dppe-type ligands. Also, in this complex, the phenyl groups are quite close together in parallel pairs, suggesting strong hydrophobic interactions and reminiscent of "charge-transfer" complexes. It may be that these phenyl interactions produce an extra stability which can only be overcome by an aromatic solvent. Work on this system, and on complexes with *S,S*-skewphos, is continuing.

CIRCULAR DICHROISM OF CONFIGURATIONALLY CHIRAL DIMOLYBDENUM COMPLEXES

IAIN F. FRASER, ANDREW McVITIE and ROBERT D. PEACOCK*

Department of Chemistry, The University, Glasgow G12 8QQ, U.K.

(*Received* 14 *June* 1985)

Abstract—We present an account of the preparation, structure and circular dichroism spectra of configurationally chiral quadruply bonded dimolybdenum complexes. A simple metal-localized model for the optical activity is described which provides a correlation between the stereochemistry of the complexes and the signs of both the $\delta \rightarrow \delta^*$ and $\delta \rightarrow x^2 - y^2$ transitions.

Chiral complexes may be divided into two general types: those in which the chromophore is dissymmetric (configurational chirality) and those in which the chromophore is symmetric, the overall molecular chirality arising from chiral substituents or ligands attached to the chromophore (conformational or vicinal chirality). Examples of a symmetric chromophore in a chiral environment include the carbonyl group in optically active ketones or the NiN_4 chromophore in square planar $[Ni(R\text{-pn})_2]^{2+}$;† examples of intrinsically dissymmetric chromophores include twisted chiral olefins or tris-chelate complexes such as Λ-$[Co(en)_3]^{3+}$, where the two triangles of ligating nitrogen atoms are twisted with respect to each other about the C_3-axis.

Most quadruply bonded dimolybdenum complexes contain eclipsed Mo_2L_8 or $Mo_2L_4L'_4$ chromophores and so are not configurationally chiral even if the co-ordinated ligands are themselves chiral. Complexes containing chiral monodentate phosphines, for example, come into this category. The simplest method of producing a twisted chromophore of D_4- or D_2-symmetry is to involve ligands having two or more carbon atoms separating the ligators, for example dppe. Such ligands can co-ordinate to the Mo_2 unit in two ways (Fig. 1) giving chelated (α) isomers of C_{2h} chromophoric symmetry and bridged (β) isomers of D_2-symmetry. The bridged isomer is in many cases the one which is thermodynamically more stable.[1]

In this paper we discuss a range of complexes of general formula $Mo_2X_4(P\frown P)_2$ [X = Cl or Br, P⌒P is a chiral bis(diphenyl)diphosphine ligand] or $[Mo_2(N\frown N)_4]^{4+}$ (where N⌒N is a chiral diamine). We present an account of the circular dichroism (CD) spectra of these complexes and show how the CD spectra may be used, in favourable cases, to make structural assignments.

CD of quadruply bonded dimolybdenum complexes

It is generally accepted[2] that the lowest energy absorption band in the electronic spectrum of quadruply bonded dimolybdenum complexes is due to the $\delta \rightarrow \delta^*$ ($b_{2g} \rightarrow b_{2u}$ in D_{4h}-symmetry) transition. This generally occurs between 12,000 and 17,000 cm^{-1} for the $Mo_2X_4P_4$ (X = Cl or Br) chromophore and around 20,000 cm^{-1} for the Mo_2N_8 chromophore. An experimental correlation between the energy of the $\delta \rightarrow \delta^*$ transition and the twist angle (χ) between the two MoX_2P_2 units has been published[3] for the phosphine complexes. The $\delta \rightarrow \delta^*$ transition is electric dipole allowed in a direction parallel to the Mo—Mo bond. This is shown in Fig. 2 which also serves to illustrate the method of orbital phase multiplication[4] which enables one to obtain the transient charge distribution accompanying the electronic excitation. This pictorial method is particularly useful for illustrating the transient charge distribution for the $\delta \rightarrow \delta^*$ transition when the chromophore is twisted. Figure 3 shows the product of the δ- and δ^*-orbital phases looking along the Mo—Mo bond for a twisted chromophore with the Λ absolute configuration in which the twist is between 0 and 45° [Fig. 3(a)] and between 45 and 90° [Fig. 3(b)]. The direction of charge movement accompanying the excitation is obtained, as in Fig. 2, by following the positive to negative phases *through the shortest distance*. Thus, in Fig. 3(a) the electron can be considered to take a left-handed helical path along and around the Mo—Mo bond, and in Fig. 3(b) a right-handed helical path. The former gives rise to a negative CD or Cotton effect and the latter to a positive CD or Cotton effect.[5] At a twist of 45° the simple metal-localized model described above predicts zero intensity for both the absorption and CD of the $\delta \rightarrow \delta^*$ transition. The signs of the Cotton effects are reversed for the Δ absolute configuration. The net result is the sign rule shown in Fig. 4 in which the sign of the CD associated with the $\delta \rightarrow \delta^*$ transition is given by the signs within the segments containing the rear set of ligators.

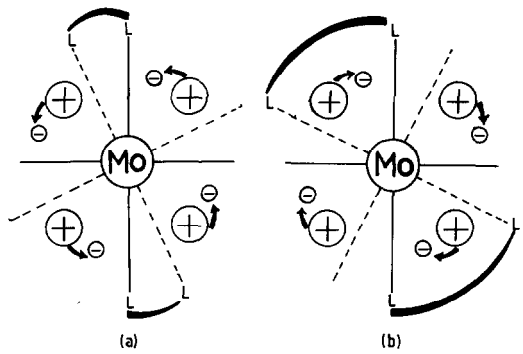

Fig. 3. The transient charge distribution for the $\delta \rightarrow \delta^*$ transition of the twisted $Mo_2L_4L'_4$ chromophore. (a) On rotating the rear set of ligators through an angle of less than 45° in the counterclockwise direction the transient charge distribution is that of a left-handed helix. (b) On rotating counterclockwise through an angle of greater than 45° the transition gives rise to a right-handed helical charge displacement.

The helical charge displacement can be decomposed into the product of a translation along (electric dipole transition) and a rotation about (magnetic dipole transition) the Mo—Mo bond. Both of these may be quantified within the metal-localized model as follows. The electric dipole transition moment, $\hat{\mu}$, has its maximum values at 0 and 90° and is zero for a twist of 45°:

$$\hat{\mu}(\chi) = \hat{\mu}_{max} \cos 2\chi.$$

The magnetic dipole transition moment, $\hat{m}$, on the

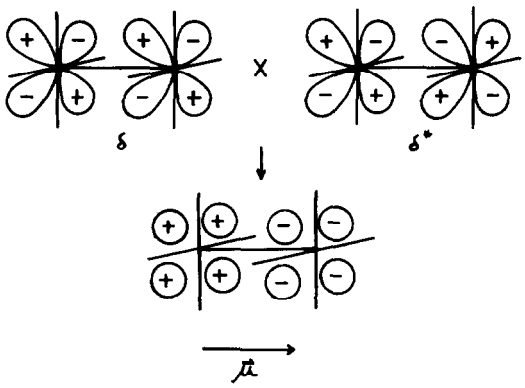

Fig. 2. The transient charge distribution for the $\delta \rightarrow \delta^*$ transition of an eclipsed chromophore obtained by multiplying the phases of the δ- and δ^*-orbitals.

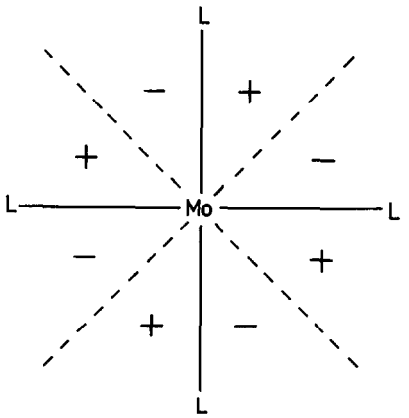

Fig. 4. Sign rule for the CD of the $\delta \rightarrow \delta^*$ transition. The sign of the CD is that of the sectors containing the rear set of ligating atoms.

other hand, is at a maximum for a twist of 45° and is zero for the eclipsed configurations:

$$\hat{m}(\chi) = \hat{m}_{max} \sin 2\chi.$$

Thus, the dipole strength (D), which is proportional to $|\hat{\mu}|^2$ and the rotational strength (R), which is proportional to $\hat{\mu} \times \hat{m}$, may be written as:

$$D(\chi) = D_{max} \cos^2 2\chi,$$

$$R(\chi) = R_{max} \cos 2\chi \sin 2\chi.$$

Finally the dissymmetry factor, $g\,(= \Delta\varepsilon/\varepsilon)$, which is a measure of the ratio of the magnetic to the electric dipole strength of the transition may be written as:

$$g(\chi) = g_{max} \tan 2\chi.$$

These relationships are summarized in Fig. 5 for the Δ absolute configuration.

Calculations[6] on the $[Mo_2Cl_8]^{4-}$ ion assign the next highest absorption after the $\delta \rightarrow \delta^*$ transition to a pair of magnetic dipole transitions, $\delta \rightarrow x^2-y^2$ ($b_{2g} \rightarrow b_{1g}$), which involves a rotation of charge about the Mo—Mo bond and $\pi \rightarrow \delta^*$ ($e_u \rightarrow b_{1u}$) which involves rotation of charge about the metal–ligand axes. The absorption which occurs at around 21,000 cm^{-1} in the phosphine complexes and around 27,000 cm^{-1} in the diamine complexes must be characterized as magnetic dipole in the parent chromophoric symmetry because of the magnitude of its dissymmetry factor. We have attempted to assign the transition causing this absorption by measuring the m.c.d. spectrum of $[Mo_2(en)_4]^{4+}$. Irrespective of whether the ligands are chelating or bridging in this complex the symmetry cannot be lower than D_4 and so the double degeneracy of the ^1E excited state of the $\pi \rightarrow \delta^*$ transition should be preserved. Were the absorption due to this transition we would expect to see an A term in the m.c.d. spectrum whereas only very weak B terms were observed. We therefore assign the 27,000-cm^{-1} absorption in the diamine complexes to $\delta \rightarrow x^2-y^2$. The strong similarity between the absorption and CD spectra of the diamine and phosphine complexes makes this assignment likely in the latter species also. A recent calculation[7] on the twisted diphosphine complexes has confirmed the assignment and has also assigned the higher energy transitions observed in their spectra.

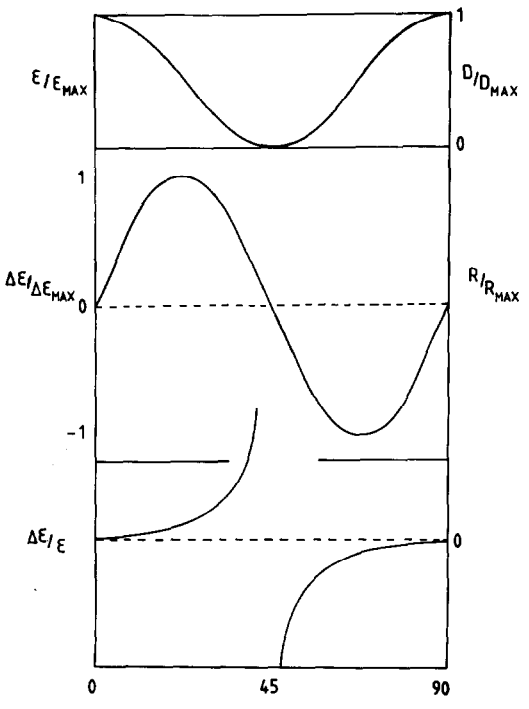

Fig. 5. The variation of dipole strength (D) (and ε), rotational strength (R) (and $\Delta\varepsilon$) and the dissymmetry factor ($\Delta\varepsilon/\varepsilon$) with twist angle χ (for the $\delta \rightarrow \delta^*$ transition of a complex with the Δ absolute configuration).

Having assigned the $\delta \rightarrow x^2-y^2$ transition we may construct a sign rule for its CD in the same way as was done for the $\delta \rightarrow \delta^*$ transition. The product of the phases of the δ-orbital and the x^2-y^2 orbital leads to a rotation of charge about the Mo—Mo bond (Fig. 6). Displacement of the rear set of ligators (Λ absolute configuration) of between 0 and 45° introduces a linear displacement of charge along the Mo—Mo bond and inspection of Fig. 7(a) shows that the net helical displacement is in the clockwise direction, thus giving a positive CD. At an angle of 45° the transition becomes magnetic dipole forbidden and in the twist range 45–90° the helical displacement is counterclockwise [Fig. 7(b)]. The sign rule for the $\delta \rightarrow x^2-y^2$ transition has therefore

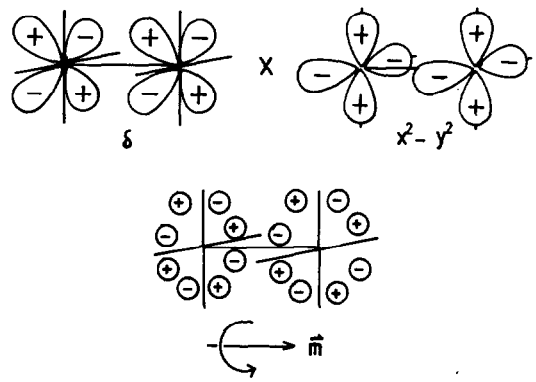

Fig. 6. The transient charge distribution for the $\delta \rightarrow x^2-y^2$ transition of an eclipsed chromophore obtained by multiplying the phases of the δ and x^2-y^2 orbitals.

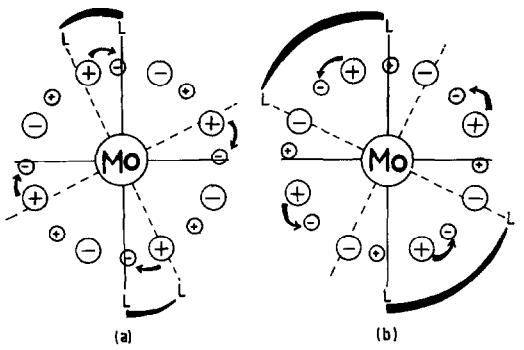

Fig. 7. The transient charge distribution for the $\delta \rightarrow x^2-y^2$ transition of the twisted $Mo_2L_4L'_4$ chromophore. (a) On rotating the rear set of ligators through an angle of less than 45° in the counterclockwise direction the transient charge distribution is that of a right-handed helix. (b) On rotating counterclockwise through an angle of greater than 45° the transition gives rise to a left-handed helical charge displacement.

the same nodal planes but opposite signs to that obtained for the $\delta \rightarrow \delta^*$ transition.

In summary, our metal-localized picture predicts that the $\delta \rightarrow \delta^*$ transition and the $\delta \rightarrow x^2-y^2$ transition should show a CD of opposite sign and that this CD should have, for the $\delta \rightarrow \delta^*$ transition, a negative R for a counterclockwise twist of between 0 and 45° and a positive R for a twist of between 45 and 90° in the same direction. Since the $\delta \rightarrow x^2-y^2$ transition is magnetic and the $\delta \rightarrow \delta^*$ transition is electric dipole allowed in the untwisted chromophore we expect the g value of the former to be considerably larger than that of the latter.

COMPLEXES WITH CHIRAL DIPHOSPHINE LIGANDS

There are two ways of obtaining one enantiomer of a chiral complex: one is to resolve the racemate [of, for example, $Mo_2Cl_4(dppe)_2$], the other to perform an asymmetric synthesis. Resolution of neutral species is especially difficult and requires special methods, e.g. HPLC on chiral columns, chiral clatheration or (if one is lucky) spontaneous enantiomorphic crystallization. We chose, therefore, to synthesize complexes using resolved chiral phosphines in the hope that they would force the complex to take up only one absolute configuration. Scale models suggest that a substituent with R-configuration on the ethane backbone of a diphosphine ligand, for example, would force the molecule to adopt the Λ absolute configuration if the substituent is to be in the equatorial plane of the $Mo_2P_2C_2$ ring.

The absorption and CD spectra of $Mo_2Cl_4(R\text{-dppp})_2$ and $Mo_2Cl_4(S,S\text{-dppb})_2$ are shown in Fig. 8. Apart from slight energy and intensity differences due to the complexes having slightly different torsion angles, the CD spectra have a mirror-image relationship to each other. The g values for both transitions are large, being at the upper end of the range observed for electric- and magnetic-dipole transitions, respectively, of configurationally chiral metal complexes, and we concluded that an essentially complete asymmetric synthesis had been achieved.

Given the conformational requirement that the S,S-dppb ligands should force a Λ and the R-dppp ligands a Δ configuration on the complexes, we concluded that the twist between the two sets of ligators is in the range 0–45°. When these spectra were first obtained the only crystal structures available of quadruply bonded bridged complexes were of $W_2Cl_4(dppe)_2$ and $Mo_2Br_4(arphos)_2$, where the twist angles were greater than 45° [59° for $W_2Cl_4(dppe)_2$[8] and 61° for $Mo_2Br_4(arphos)_2$[9]]. This cast some doubt upon our analysis and we felt that the crystal structure of one of our chiral complexes was necessary. Fortunately $Mo_2Cl_4(S,S\text{-dppb})_2$ forms suitable quality single crystals from a number of solvents and we were able to have the structure of

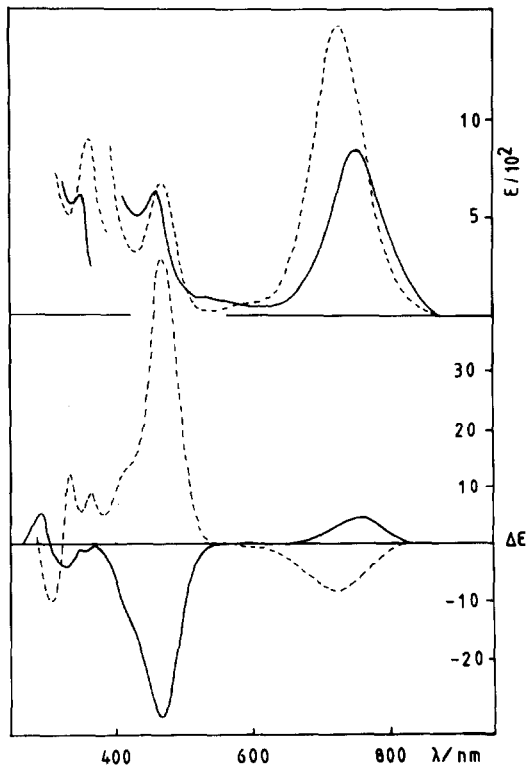

Fig. 8. Absorption and CD spectra of $Mo_2Cl_4(R\text{-dppp})_2$ (full line) and $Mo_2Cl_4(S,S\text{-dppb})_2$, all in dichloromethane solution.

the acetonitrile solvate determined by Manojlovic-Muir and Muir. The structure of the THF solvate was solved independently by Agaskar and Cotton and the results of the two determinations are in complete agreement.[10,11] Mo_2Cl_4(*S,S*-dppb)$_2$ does indeed have the Λ absolute configuration with an average twist angle of 23° in the counterclockwise direction. This confirms our analysis of the CD spectra and our sign rule. The evidence of two independent crystal structures giving the Λ configuration together with the large g values (which are identical in solution and the solid state) leads us to believe that, for the six-membered complexes at least, the syntheses are entirely stereospecific and this in turn gives us confidence in our application of conformational analysis to the six-membered $Mo_2P_2C_2$ rings.

Table 1 contains a summary of the energies and g values for the $\delta \rightarrow \delta^*$ and $\delta \rightarrow x^2-y^2$ transitions of the various chiral complexes that we have synthesized.[10,12–14] The complexes of *R*-phenphos were prepared in the hope that their isomerization kinetics could be compared with those of the *R*-dppp complexes:[1] unfortunately we have been able to synthesize only β-isomers of the former. A comparison of the CD spectrum of Mo_2Cl_4(*R*-phenphos)$_2$ with that of Mo_2Cl_4(*R*-dppp)$_2$ shows that the effect on the conformation of the $Mo_2P_2C_2$ ring of replacing methyl by the phenyl group is negligible. The crystal structure of β-Mo_2Cl_4(dppe)$_2$ has now been determined[15] and shows the complex to have a twist angle of 60°. Successive substitution of the ethane backbone causes the angle to "tighten" from 60° when the ligand is dppe, through ~27° for *R*-dppp and *R*-phenphos (interpolated using Campbell *et al*'s plot[3]) to 23° for *S,S*-dppb. The bromide complexes have very similar spectra to their chloride analogues, with slightly smaller g values which may be due to more metal–ligand mixing in the former species. The crystal structure of Mo_2Br_4(*S,S*-dppb)$_2$ has been determined.[7,11] The complex has the expected Λ configuration with a twist angle of 21°. We have prepared β-Mo_2I_4(dppe)$_2$ but have had no success in obtaining analogous complexes with the chiral diphosphine ligands.

We have recently turned our attention to chiral diphosphine ligands with three carbon atoms in their backbones, *S*-chairphos and *S,S*-skewphos, and present some preliminary results. The first point to be made is that complexes with these ligands are much less stable than those with the ethane backbone diphosphines. Both α- and β-Mo_2Cl_4(*S*-chairphos)$_2$ and β-Mo_2Cl_4(*S,S*-skewphos)$_2$ have been synthesized by refluxing the appropriate ligand with $K_4Mo_2Cl_8$ in methanol. The solids so obtained give satisfactory analyses but redissolving the solids always causes some decomposition even when the solvents are thoroughly dried and degassed on a vacuum line. The spectra of α- and β-Mo_2Cl_4(*S*-chairphos)$_2$ are shown in Fig. 9. The α-isomer has a CD which is too weak to be measured on our apparatus ($g < 5 \times 10^{-5}$). The g value of the bridged isomer [and that of β-Mo_2Cl_4(*S,S*-skewphos)$_2$] is somewhat lower than that found for the ethane backbone diphosphine complexes. This may reflect the smaller twist angle in the seven-membered ring complexes but may also indicate an incomplete asymmetric synthesis. The $\delta \rightarrow \delta^*$ transition energies are somewhat higher than those of the six-membered ring complexes. Interpolating the energies into Campbell *et al*'s curve[3] leads to twist angles of 18 or 72° for β-Mo_2Cl_4(*S*-chairphos)$_2$ and 22 or 68° for β-Mo_2Cl_4(*S,S*-skewphos)$_2$. The smaller twist angle does not seem to be acceptable since it is extremely

unlikely that the seven-membered $Mo_2P_2C_3$ rings could have smaller torsion angles than the six-membered $Mo_2P_2C_2$ ones. We therefore suggest that the complexes have the larger twist angle in each case. This, together with the sign of the CD spectra, leads to a Δ absolute configuration for both complexes. This is also the structure which conformational analysis of the seven-membered heterocyclic rings suggests is most favourable.

COMPLEXES OF CHIRAL DIAMINE LIGANDS

Some years ago Bowen and Taube reported[16] the preparation of $[Mo_2(en)_4]^{4+}$. Until our present work[14] this was the sole example of a dimolybdenum complex with aliphatic amine ligands and it is interesting to contrast the paucity of such complexes with their dominant rôle in mononuclear co-ordination chemistry. The structure of $[Mo_2(en)_4]^{4+}$ has not been determined. We, and doubtless others, have attempted to obtain single crystals but without success.

It was a logical extension of our work with chiral diphosphine complexes to prepare analogues of $[Mo_2(en)_4]^{4+}$ with the chiral diamines *R*-pn and *S,S*-bn. Both the complexes $[Mo_2(R\text{-pn})_4]^{4+}$ and $[Mo_2(S,S\text{-bn})_4]^{4+}$ are prepared in an analogous way to the ethylenediamine complex although the *S,S*-bn complex is difficult to purify. The absorption and CD spectrum of $[Mo_2(R\text{-pn})_4]^{4+}$ is shown in Fig. 10. Apart from a blue shift in the energy and a reduction in intensity the spectra clearly show a strong similarity to those of the diphosphine complexes shown in Fig. 8. The complex with *S,S*-bn has an essentially identical absorption spectrum and an enantiomeric CD to that with *R*-pn.

The g values for both the $\delta \rightarrow \delta^*$ and the $\delta \rightarrow x^2 - y^2$ transition are larger than in the phosphine complexes. Indeed that for the $\delta \rightarrow x^2 - y^2$ transition of $[Mo_2(R\text{-pn})_4]^{4+}$ (17×10^{-2}) is among the largest ever recorded for a solution CD and is comparable to even the largest single-crystal g values. This, and the fact that the eclipsed chelated isomers of Mo_2Cl_4(*R*-dppp)$_2$ and Mo_2Cl_4(*S*-chairphos)$_2$ have g values of less than 5×10^{-5}, provides conclusive evidence that the Mo_2N_8 chromophore is configurationally chiral. Since all chelated dimolybdenum complexes so far characterized have eclipsed chromophores, we conclude that the two chiral diamine complexes and, by extension, $[Mo_2(en)_4]^{4+}$ have bridging diamine ligands.

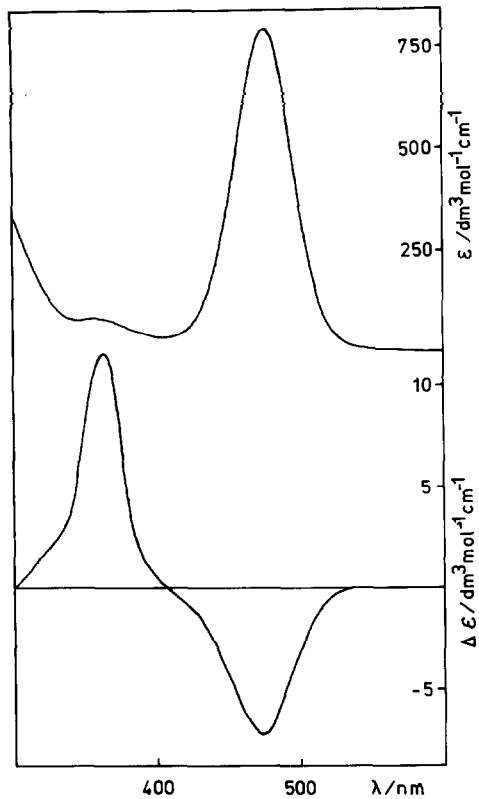

Fig. 10. Absorption and CD spectra of $[Mo_2(R\text{-pn})_4]^{4+}$ as the chloride salt in 10^{-2} mol l^{-1} HCl.

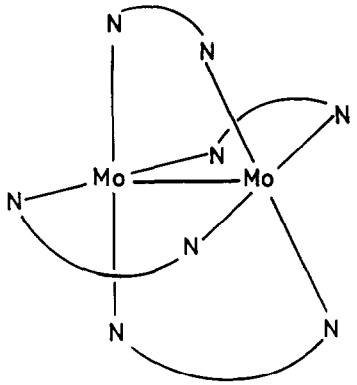

Fig. 11. Schematic diagram of the suggested structure of $[Mo_2(en)_4]^{4+}$.

The conformational preference of *R*-pn is the same as that of *R*-dppp and yet $[Mo_2(R\text{-pn})_4]^{4+}$ has a CD of opposite sign to that of $Mo_2Cl_4(R\text{-dppp})_2$. This implies that the diamine complex has a twist angle of between 45 and 90° in contrast to the diphosphine complexes. This is illustrated schematically in Fig. 11.

ELECTROGENERATED CHEMILUMINESCENCE OF $Mo_6Cl_{14}^{2-}$: FREE-ENERGY EFFECTS ON CHEMILUMINESCENCE REACTIVITY

R. D. MUSSELL and D. G. NOCERA†

Department of Chemistry, Michigan State University, East Lansing, MI 48824, U.S.A.

(*Received* 15 *June* 1985)

Abstract—Electrogenerated $Mo_6Cl_{14}^{-}$ and $Mo_6Cl_{14}^{3-}$ react with electroactive donors (D^-s) (nitroaromatic radical anions) and acceptors (A^+s) (aromatic amine radical cations), respectively, to produce the luminescent excited state of $Mo_6Cl_{14}^{2-}$. The dependence of the electrogenerated chemiluminescence (ecl) reactivity on the free-energy driving force of the $Mo_6Cl_{14}^{3-}$–A^+ and $Mo_6Cl_{14}^{-}$–D^- annihilation reactions has systematically been probed by varying the $A^{+/0}$ and $D^{0/-}$ reduction potentials. The $Mo_6Cl_{14}^{3-}$–A^+ reaction exhibits an ecl threshold free energy 0.18 V more positive than that of the $Mo_6Cl_{14}^{-}$–D^- reaction, suggesting that electron transfer between $Mo_6Cl_{14}^{-}$ and D^- to produce electronically excited cluster confronts a larger reorganizational barrier than the $Mo_6Cl_{14}^{3-}$–A^+ system.

The lower-halide clusters of molybdenum and tungsten [$M_6X_{14}^{2-}$: M = Mo(II) or W(II); X = Cl, Br or I] constitute an exciting new class of inorganic reagents for redox-induced chemiluminescent reactions. For the molybdenum chloride cluster, reaction of electrogenerated intermediates, $Mo_6Cl_{14}^{-}$ and $Mo_6Cl_{14}^{3-}$, yields a red luminescence attributable to an electronically excited ion ($Mo_6Cl_{14}^{2-}$*: $\tau_o = 180$ μs, $\phi_e = 0.20$, $\lambda_{em,max} = 805$ nm in CH_3CN at 25°C).[1] Observation of electrogenerated chemiluminescence (ecl) from $M_6X_{14}^{2-}$ ions is of interest because ecl chemistry of inorganic complexes is limited to only a few transition-metal systems: Ru(II)- and Os(II)–polypyridyl chelates,[2] Pd(II) and Pt(II) metalloporphyrins,[3] Re(I)–phenanthroline complexes,[4] and Pt(II) pyrophosphite dimer.[5] Potentially high electrical efficiencies, coupled with visible and near-IR chemiluminescence, have suggested the application of inorganic ecl systems to the design of light-emitting devices.[6] In addition, ecl reactions can provide insight into fundamental processes of electron-transfer reactions in highly exothermic regimes.[7]

Our studies are centered on elucidating the factors fundamental to the ecl reactivity of the $M_6X_{14}^{2-}$ ions. We report here investigations on the energy dynamics of the $Mo_6Cl_{14}^{2-}$ ecl process. The approach we have taken is centered on the oxidation–reduction reactions of $Mo_6Cl_{14}^{-}$ and $Mo_6Cl_{14}^{3-}$ with electroactive donor (D^-) and acceptor (A^+), respectively:

$$Mo_6Cl_{14}^{-} + D^- \rightarrow Mo_6Cl_{14}^{2-} + D \quad (1a)$$

$$Mo_6Cl_{14}^{-} + D^- \rightarrow Mo_6Cl_{14}^{2-}{}^* + D \quad (1b)$$

$$Mo_6Cl_{14}^{3-} + A^+ \rightarrow Mo_6Cl_{14}^{2-} + A \quad (2a)$$

$$Mo_6Cl_{14}^{3-} + A^+ \rightarrow Mo_6Cl_{14}^{2-}{}^* + A \quad (2b)$$

By tuning the free-energy driving force of reactions (1) and (2) with the respective $D^{0/-}$ and $A^{+/0}$ reduction potentials, the energy dependence of $Mo_6Cl_{14}^{2-}$ ecl can conveniently be monitored. The magnitude of the $Mo_6Cl_{14}^{-/2-}$ and $Mo_6Cl_{14}^{2-/3-}$ reduction couples in conjunction with the low energy of the $Mo_6Cl_{14}^{2-}$ emissive excited state has allowed us to systematically probe the ecl chemistry of $Mo_6Cl_{14}^{2-}$ over a wide potential-energy range.

EXPERIMENTAL

CH_2Cl_2, obtained from Burdick and Jackson Laboratories, was degassed by seven freeze–pump–thaw (fpt) cycles and then vacuum distilled onto activated 4-Å molecular sieves. The sieves were contained in a 1-liter flask equipped with a high-vacuum Teflon valve. Solutions for electrochemical, spectroscopic and quenching experiments were prepared on a high-vacuum manifold and were

† Author to whom correspondence should be addressed.

degassed by an additional three fpt cycles prior to measurements.

Tetrabutylammonium perchlorate (TBAP: Southwestern Analytical Chemicals) was recrystallized from a pentane–ethyl acetate solution and dried *in vacuo* for 12 h at 60°C. Preceding all electrochemical and quenching experiments, the TBAP salt was heated for an additional 4 h at 100°C. Molybdenum dichloride was purchased from Cerac Inc. and converted to the acid salt by established procedures.[8] Addition of tetrabutylammonium chloride to 6 M HCl solutions of the hydronium salt afforded $(NBu_4)_2Mo_6Cl_{14}$. The yellow powder was taken up in CH_2Cl_2 and the solution was dried over $MgSO_4$, filtered, and evaporated in air to yield large yellow-orange crystals. Nitroaromatics and aromatic amines were purchased from Aldrich except 10-methylphenothiazine (Pfaltz and Bauer), 4,4′-dimethoxydiphenylamine (Alfa Products) and tris-(*p*-tolyl)amine, which was synthesized using a published procedure.[9] Solids were purified by multiple sublimations and liquids by fractional distillation.

Electrochemical measurements were obtained with a Princeton Applied Research (PAR) 173 potentiostat/galvanostat driven by a PAR 175 universal programmer and a PAR 179 digital coulometer. Experiments were performed in CH_2Cl_2 ($\mu = 0.1$ M TBAP) using a three-electrode system: Pt wire or button working, Pt mesh auxiliary and Ag wire reference electrodes. A conventional H-cell design was used for determination of D and A redox couples. Potentials were referenced to a ferrocene internal standard and related to the SCE reference scale with a value of 0.31 V vs SCE for the ferricinium–ferrocene couple.[10] Ecl experiments utilized a high-vacuum electrochemical cell which permitted all sample manipulations and solvent transfers to be performed in the absence of oxygen and moisture. A triple-step square wave potential program was employed to generate ecl transients. Chemiluminescence was sought by interfacing the high-vacuum cell to the detection side of a red-sensitive emission spectrometer built at MSU.

Stern–Volmer quenching experiments were performed on CH_2Cl_2 solutions ($[(NBu_4)_2Mo_6Cl_{14}] = 3$ mM, $\mu = 0.1$ M TBAP) contained in high-vacuum cells, consisting of a 10-ml round bottom connected to a 1-cm quartz cuvette sidearm. Quencher concentrations spanned a 10^{-3}–10^{-2} M range; quencher additions were made under high-vacuum conditions. Luminescence intensities were measured on the MSU-constructed emission spectrometer. Quenching rate constants were determined from plots of I_o/I vs $[Q]$ using τ_o ($Mo_6Cl_{14}^{2-}$*) = 160 μs in CH_2Cl_2 at 25°C.

RESULTS AND DISCUSSION

Ds and As suitable for reactions (1) and (2) should fulfill several criteria for their successful application as probes of $Mo_6Cl_{14}^{2-}$ ecl: (i) the lowest-energy excited states of Ds and As should be energetically inaccessible, thereby ensuring that the electrochemical excitation energy is channelled via the cluster's excited state; (ii) Ds and As should be inefficient quenchers of $Mo_6Cl_{14}^{2-}$ luminescence since ensuing electron- or energy-transfer reactions between $Mo_6Cl_{14}^{2-}$* and the D or A will modulate ecl intensity; and (iii) Ds and As must exhibit reversible electrochemistry. Finally, structurally and electronically related Ds and As will facilitate the comparison of the ecl chemistry between the series.

Table 1 collects the spectroscopic, electrochemical and quenching data for electroactive Ds and As employed in our ecl studies. Cyclic voltammograms show reversible oxidation and reduction waves for Ds and As, respectively, in CH_2Cl_2 solutions; $E_{1/2}$ values are listed in Table 1 as reduction potentials vs the SCE reference. From these data, and $Mo_6Cl_{14}^{2-}$ redox couples, reaction free energies for electron-transfer reactions (1a) and (2a) may be calculated. Comparison of these energies ($\Delta G_r^{o'}$ in Table 1) with the lowest-energy D and A excited states indicates that production of electronically excited Ds and As is an unimportant electron-transfer reaction pathway. Additionally, the quenching rate constants shown in Table 1 are well below the diffusion-controlled limit and indicate that the Ds and As are inefficient quenchers of $Mo_6Cl_{14}^{2-}$ luminescence.

Ecl experiments were performed on CH_2Cl_2 solutions containing equimolar concentrations of $Mo_6Cl_{14}^{2-}$ and electroactive species. Reactions (1) and (2) were established upon pulsing a Pt working electrode with potentials appropriate to ensure production of electrogenerated species in the mass-controlled region. D and A systems exhibiting ecl are indicated in Table 2. For systems yielding chemiluminescence, the ecl spectrum is identical to the emission spectrum of $Mo_6Cl_{14}^{2-}$ in CH_2Cl_2. As originally inferred from spectroscopic data, the absence of D and A emission for all systems listed in Table 1 confirms that the population of D or A electronic excited states is not an energetically favorable process. That luminescence is observed only when the potentials applied to the Pt working electrode are stepped into the oxidation–reduction waves of the electroactive species establishes that ecl results from annihilation of the electrogenerated products.

Inspection of the calculated free energies for reactions (1b) and (2b), listed in Table 2, clearly reveals an energy dependence for the ecl chemistry of

the $Mo_6Cl_{14}^{2-}$ ion. While both reactions yield the same excited state species, annihilation between $Mo_6Cl_{14}^{-}$ and D^- to produce chemiluminescence requires a driving force 0.18 V in excess of the chemiluminescence threshold free energy of the $Mo_6Cl_{14}^{3-}$–A^+ system.

The difference in D and A ecl threshold free energies can be appreciated from a simple electron-transfer analysis of the $Mo_6Cl_{14}^{-}$–D^- and $Mo_6Cl_{14}^{3-}$–A^+ annihilation reactions. Figure 1 illustrates chemiluminescence in terms of a potential-energy surface for reactants, one for products in their ground states, and a potential surface in which one or more products are electronically excited. High exergonicities of chemiluminescence reactions can cause the reactant well to become imbedded in the ground-state well.[11] In this case, electron transfer to excited-state species will be more favorable than direct reaction to the ground state. From Marcus theory,[11(b),12] the rate for electron transfer to

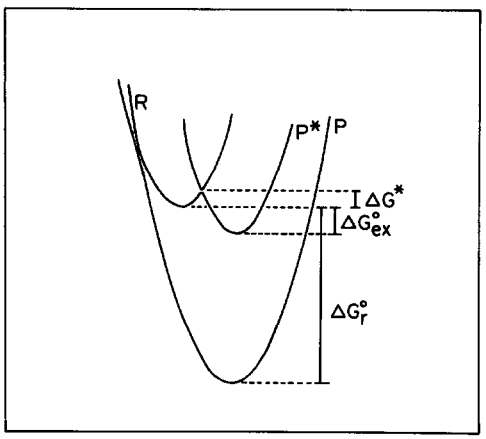

Fig. 1. Profile of potential-energy surfaces for reactants (R), products in their ground states (P), and products which are electronically excited (P*). ΔG_{ex}^{o} and ΔG_r^{o} are reaction free energies for electron transfer to produce excited- and ground-state products, respectively, and ΔG^* is the activation energy for the excited-state reaction.

[a] $\Delta G^o_{ex} = \Delta G^{o'}_r - \Delta G^o_{ES}$, where ΔG^o_{ES} is the free-energy content of electronically excited $Mo_6Cl^{2-}_{14}$ over the ground state. ΔG^o_{ES} may be determined from the energy of the 0,0 transition (1.9 eV) with corrections for entropic contributions ($T\Delta S$ = 0.1 V; C. P. Bock, J. A. Connor, A. R. Gutierrez, T. J. Meyer, D. G. Whitten, B. P. Sullivan and J. K. Nagle, *J. Am. Chem. Soc.* 1979, **101**, 4815).

excited-state products is given by:

$$k_{et} = \kappa(k_B T/h)\exp(-\Delta G^*/RT), \quad (3)$$

$$\Delta G^* = w_r + \frac{(\lambda + \Delta G^{o'}_r)^2}{4\lambda}, \quad (4)$$

$$\Delta G^o_r = \Delta G^{o'}_r + w_p - w_r. \quad (5)$$

In the above expressions, ΔG^* is the free energy required to reach the activated complex, κ is the probability for electron transfer within the activated complex, w_r is the work required to bring reactants together, w_p is the corresponding product work term, λ is the reorganizational energy for electron transfer, and $\Delta G^{o'}_r$ is the standard free-energy change of the reaction. The vertical displacement of the potential-energy surfaces for products relative to the reactant well is defined by ΔG^o_r. For the $Mo_6Cl^{3-}_{14}$–A^+ system, $w_p = 0$, giving an effective ecl threshold free energy, $\Delta G^o_{ecl}(Mo_6Cl^{3-}_{14}\text{–}A^+) = -0.21\text{ V} - w_r$. Because w_r is a negative quantity, $\Delta G^o_{ecl}(Mo_6Cl^{3-}_{14}\text{–}A^+)$ is > -0.21 V. Likewise, $w_p = 0$ for the electron-transfer reaction between $Mo_6Cl^{-}_{14}$ and D^-; however, w_r is >0 and, therefore, $\Delta G^o_{ecl}(Mo_6Cl^{-}_{14}\text{–}D^-)$ is < -0.39 V. Thus, the 0.18 V difference between the ecl threshold free energies of the D and A series represents a lower limit. According to eqn (3), the more exothermic ecl threshold free energy for the D series suggests that the reaction of $Mo_6Cl^{-}_{14}$ and D^- to produce electronically excited $Mo_6Cl^{2-}_{14}$ confronts a larger activation barrier and, therefore, a greater reorganizational energy than the chemiluminescent reaction between $Mo_6Cl^{3-}_{14}$ and A^+. Studies currently underway in our laboratories are directed toward defining the nature of the reorganizational barriers confronting $Mo_6Cl^{2-}_{14}$ ecl pathways and toward assessing the importance of nonadiabatic electron transfer on the overall ecl efficiency of the $Mo_6Cl^{2-}_{14}$ system.

SOME STRUCTURE–BONDING CORRELATIONS IN REDUCED TERNARY MOLYBDENUM OXIDES WITH INFINITE CHAINS OF EDGE-SHARED OCTAHEDRAL CLUSTER UNITS

R. E. McCARLEY

Ames Laboratory, U.S.D.O.E., and Department of Chemistry, Iowa State University, Ames, IA 50011, U.S.A.

(*Received* 18 *June* 1985)

Abstract—The work reported here is concerned with the structure–bonding relationships among compounds belonging to the structure types $NaMo_4O_6$, $Sc_{0.75}Zn_{1.25}Mo_4O_7$, $Mn_{1.5}Mo_8O_{11}$, $Ca_{5.45}Mo_{18}O_{32}$ and $LiMo_8O_{10}$. Each of these structures is dominated by Mo–Mo bonding in infinite chains composed of edge-shared octahedral cluster repeat units. It is shown that the application of both Mo–O and Mo–Mo bond distance–bond order equations can provide useful information about the bonding in these chains. In both simple and complex structures reasonable estimates have been obtained for valence of Mo atoms, net charges on cluster anion repeat units, and numbers of electrons actually involved in the Mo–Mo bonding.

During the past few years the synthesis, structure and properties of many different metal–metal-bonded oxide compounds having molybdenum in oxidation states lower than 4+ have been studied in this laboratory.[1–6] Because of the complexity of the structures involved even the matter of counting electrons available for construction of the various metal–metal-bonded units may be obscure. Beyond the matter of simply counting the number of electrons which are formally available for participation in metal–metal bonding there is the further problem of assessing the relative number of electrons which really contribute to the bonding (reside in bonding states), as opposed to the number which may reside in nonbonding or antibonding states.

This paper is concerned with the application of bond distance–bond order relations to these ternary molybdenum oxide compounds to derive both Mo–O and Mo–Mo bond orders, and subsequently the use of these bond orders to estimate oxidation states of the Mo atoms, formal anion charges, and number of electrons available for Mo–Mo bonding. In the materials to be discussed here this approach has been so successful that even the relative numbers of electrons in bonding and antibonding states may be estimated. A description of the structure types containing infinite chains of edge-shared octahedral cluster units will be given first, and then the application of the bond distance–bond order relations will be discussed.

OXIDE COMPOUNDS HAVING INFINITE CHAINS OF CONDENSED OCTAHEDRAL CLUSTER UNITS

Up to the present time five different crystallographic structure types have been identified as belonging to this class of compounds. Some crystallographic information, and members of each type for which accurate structural data are available, are listed in Table 1. Type 1, $M_xMo_4O_6$, is characterized by $[Mo_4O_6]$ infinite octahedral cluster chains extended along the tetragonal *c*-axis.[1] These chains are then coupled through Mo–O–Mo interchain linkage to weave a square pattern and forming tunnels parallel to *c* in which the ternary metal ions are located. A view of this structure as projected down the *c*-axis is provided in Fig. 1 and a view of one cluster chain perpendicular to the direction of chain growth is given in Fig. 2. Unshared Mo atoms [Mo(a)] occupy apex positions in the cluster repeat units, while Mo atoms [Mo(w)] on the shared edges occupy waist positions along the chain.

Table 1. Molybdenum oxide compounds having edge-shared octahedral cluster chains

Structure type	Crystal class	Lattice constants	Space group	Isomorphous members	Reference
1 $NaMo_4O_6$	Tetragonal	$a = 9.570(3)$ Å $c = 2.8634(8)$ Å	*P4/mbm*	$InMo_4O_6$ $Sn_{0.9}Mo_4O_6$, $Pb_{0.8}Mo_4O_6$	1 7
2 $Zn_{1.25}Sc_{0.75}Mo_4O_7$	Orthorhombic	$a = 6.085(1)$ Å $b = 17.002(4)$ Å $c = 5.764(1)$ Å	*Imam*	$M_xM'_{2-x}Mo_4O_7$ [$MM' = Ti_{0.5}Zn_{1.5}$, $Sc_{0.5}Fe_{1.5}$, $Fe(Fe_{0.89}Mo_{0.11})$, $Zn(Zn_{0.4}Al_{0.5}Mo_{0.1})$, $(Al_{0.4}Fe_{1.5}Mo_{0.1})$	4, 5 8 8 8
3 $Mn_{1.5}Mo_8O_{11}$	Monoclinic	$a = 9.859(3)$ Å $b = 16.921(4)$ Å $c = 2.846(1)$ Å $\beta = 94.94(4)°$	$P2_1/a$	None	9
4 $Ca_{5.45}Mo_{18}O_{32}$	Monoclinic	$a = 24.234(7)$ Å $b = 2.8503(7)$ Å $c = 9.875(7)$ Å $\beta = 109.82(4)°$	$C2/m$	None	6
5 $ZnMo_8O_{10}$	Tetragonal	$a = 5.8961(4)$ Å $c = 24.840(3)$ Å	$I4_1md$	$LiMo_8O_{10}$	8

Both intra- and intercluster sharing of atoms is represented in the connectivity formula

$$Na^+[(Mo_2Mo_{4/2}O_{8/2}O_{2/2})O_{2/2}]^-.$$

All Mo atoms are found with coordination number 11 [Mo(a), 5O + 6Mo; Mo(w), 4O + 7Mo), and within each Mo_4O_6 repeat unit there is a total of 13 Mo–Mo bonds, with distances in $NaMo_4O_6$ ranging from 2.75 to 2.86 Å. Based on M–O bond distances for the ternary metal ions located in the tunnel sites it appears that these have the respective valences: Na and In,[6] +1; Pb and Sn,[7] +2. The coordination number and geometries are: Na, 8, compressed cube; In and Pb, 4, square pyramidal; Sn, 4, square planar.

Compounds of type **2**, with $Sc_{0.75}Zn_{1.25}Mo_4O_7$ as prototype,[4,5] are orthorhombic with the infinite cluster chains extending along the *c*-axis. The repeat unit along the chains is doubled compared to that in

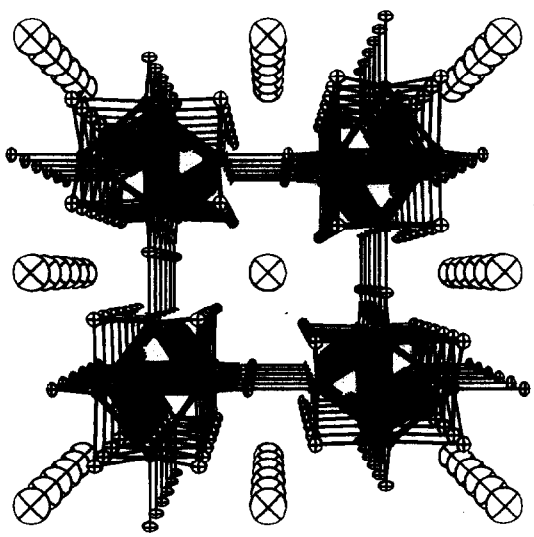

Fig. 1. The structure of $NaMo_4O_6$ as viewed down the tetragonal *c*-axis. Mo–Mo bonds in the octahedral cluster units are shown by heavy filled lines. Mo–O bonds are shown by light unfilled lines. Unconnected ellipsoids represent the Na atoms.

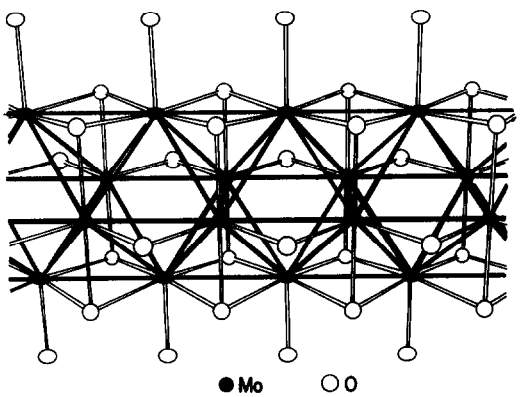

Fig. 2. The structure of a segment of one chain from $NaMo_4O_6$ as viewed perpendicular to the chain axis. The O atoms connected to the apex Mo atoms above and below the chain also form the Mo–O–Mo links to neighboring chains.

compounds of type **1**. A consequence of this doubling is that the octahedral cluster units may be tilted slightly about the edge-shared Mo–Mo bonds. This tilting of units results in alternately long and short Mo(a)–Mo(a) bonds along the chain, i.e. pairwise joining of the apex atoms. The three-dimensional structure can be viewed as formed from the stacking of layers perpendicular to the *b*-axis, with the infinite chains of one layer shifted by $\frac{1}{2}a$ with respect to the layers above and below. Within a given layer the infinite chains are linked together through unique O atoms having square planar geometry and forming bonds to two Mo(w) atoms of each adjacent chain. The ternary metal ions are located in both tetrahedral (M^t) and octahedral (M^o) coordination sites formed by the stacking of the layers. The number of M^t and M^o sites is each equal to one per formula unit $M^tM^oMo_4O_7$. Stability of this structure apparently demands that the average valences of M^t and M^o be in the range 2.3–2.5. This requires either mixed valency for one ternary element, or two elements, M(2+) and M′(3+). Examples are $Fe_{1.89}Mo_{4.11}O_7$ and $Fe_{1.5}Sc_{0.5}Mo_4O_7$, where the occupation of tetrahedral and octahedral sites is, respectively,

$$Fe^t_1(Fe^o_{0.89}Mo^o_{0.11})Mo_4O_7$$

and

$$Fe^t_1(Fe^o_{0.5}Sc^o_{0.5})Mo_4O_7.^8$$

With the exception of $Fe_{1.5}Sc_{0.5}Mo_4O_7$ all members of this family appear to have about 10 atom % of Mo in the octahedral sites, a phenomenon which is not understood at the present time. Because of the presence of this Mo in an undetermined oxidation state in the octahedral sites, and the evident mixed valency of other atoms (e.g. Fe and Ti) in the ternary metal ion sites, the anion charge and metal-centered electrons (MCE) available for Mo–Mo bonding in the infinite chains is difficult to assess from the formula alone. However it is obvious that in compounds of type **2** the MCE per cluster unit is higher than that in the compounds of type **1**, *ca* 14.5–14.75 in the former and 13.0–14.0 in the latter.

Compounds of type **3** are represented by the formula $M_xMo_8O_{11}$ of which $Mn_{1.5}Mo_8O_{11}$ is the sole member known to date.[9] In this monoclinic structure the infinite chains, composed of $Mo_4O_{5.5}$ repeat units, run parallel to the *c*-axis. This structure as viewed along the *c*-axis is shown in Fig. 3. The odd stoichiometry is introduced by the unique coupling of adjacent chains in the lattice as represented by the connective formula for the $Mo_4O_{5.5}$ repeat unit,

$$[(Mo_2Mo_{4/2}O_{6/2}O_{2/3}O_{2/2})O_{1/2}O_{1/3}].$$

Of special note are the unusual geometries around two sets of the O atoms involved in the intercluster Mo–O–Mo linkages. One set of O atoms has distorted square planar bonding, and another set, observed also in structure types **2** and **5**, exhibits a bond configuration about oxygen like that about sulfur in SF_4. The unique coupling of the chains in this compound provides channels with coordination spaces surrounded by six O atoms in a distorted trigonal prismatic geometry. Upon occupation of these spaces the Mn atoms seek sites of lower coordination number which is achieved by moving out of the center of the prismatic site. Two sites are thus occupied with about equal population, one having coordination number 4, and the other 5. Because of their close proximity within the same cavity these two sites cannot be simultaneously

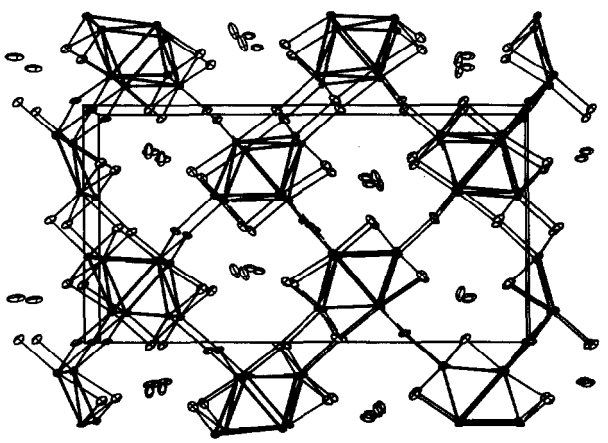

Fig. 3. A projection of the structure of $Mn_{1.5}Mo_8O_{11}$ as viewed down the monoclinic *c*-axis. The infinite cluster chains are paralled to the direction of view, and the unit cell is outlined. Mo atoms, filled ellipsoids; O atoms, connected, open ellipsoids; Mn atoms, open, unconnected ellipsoids.

occupied. It is probable that these sites are occupied in an ordered fashion because oscillation photographs show superstructure reflections indicating the true unit cell is some (as yet undetermined) multiple of the subcell in the *c* direction. Magnetic susceptibility results show that the Mn is present as high-spin Mn^{2+}, as should be expected in such a highly reduced compound.

Structure type **4** is represented by the compound $Ca_{5.45}Mo_{18}O_{32}$,[6] for which a projection of the unit cell along the *b*-axis is given in Fig. 4. This compound is unique among those discussed here in having three kinds of infinite chains, each of which runs parallel to the *b*-axis with repeat distance of 2.8503(7) Å. The three kinds of chains are indicated by the formula

$$Ca_{5.45}(MoO_3)_2(Mo_2O_{3.5})_4(Mo_4O_6)_2,$$

with repeat units (MoO_3) consisting of single Mo atom chains like those found parallel to the *c*-axis in the rutile structure, repeat units $(Mo_2O_{3.5})$ composed of *trans* edge-shared rhomboidal clusters like those found in $NaMo_2O_4$,[6] and repeat units Mo_4O_6 like those in $NaMo_4O_6$ (**1**).[1] Within this complex framework the Ca atoms are located in tunnels formed along the *b* direction, in eight-coordinate sites having six O atoms in roughly trigonal prismatic array and two additional bonds to O atoms located outside the square faces of the prism. Each site is only partially occupied such that on the average 5.45 atoms reside in the eight sites available in the unit cell. No evidence of superstructure reflections has been found in single-crystal oscillation photographs of this compound; thus the Ca sites appear to be randomly occuped. As noted in the following section an assessment of anion charges from bond length–bond strength calculations provided the formula

$$Ca_{5.45}(MoO_3^{2.2-})_2(Mo_2O_{3.5}^{0.24-})_4(Mo_4O_6^{2.6-})_2.$$

In the subsequent section only the $Mo_4O_6^{2.6-}$ cluster chains will be of interest for further discussion.

Only two compounds, $LiMo_8O_{10}$ and $ZnMo_8O_{10}$, having structure type **5** have been discovered so far.[8] The outstanding feature of this structure type is that the infinite octahedral cluster chains run in two orthogonal directions, parallel to the *a* and *b* tetragonal axes. A schematic representation of this structure is shown in Fig. 5. The structure may be regarded as a cross-wise stacking of layers perpendicular to the *c*-axis, each layer composed of infinite chains oriented with their axes orthogonal to those of the chains in adjacent layers. The mode of interchain coupling through Mo–O–Mo linkages is shown in Fig. 5. Within the layers the bridging O atoms again have square planar bond configuration, and the O atoms which provide the links between chains in two different layers again show "sawhorse" geometry (as in SF_4). The small cavities resulting from the cross-wise layer stacking provide coordination sites of tetrahedral (actually C_{2v}) symmetry which appear to be fully occupied by Li^+ or Zn^{2+} cations. Another interesting feature of this structure is that it may be conceptually obtained from the $M^IM^oMo_4O_7$ structure by substituting an octahedral cluster chain for the M^o atoms, which themselves form a chain (nonbonded) parallel to the *a*-axis of structure type **2**. This may be represented more clearly by rewriting the formula of **2** as $M^I(M^oO_2)(Mo_4O_5)$ and then replacing the M^oO_2 unit with a second Mo_4O_5 unit,

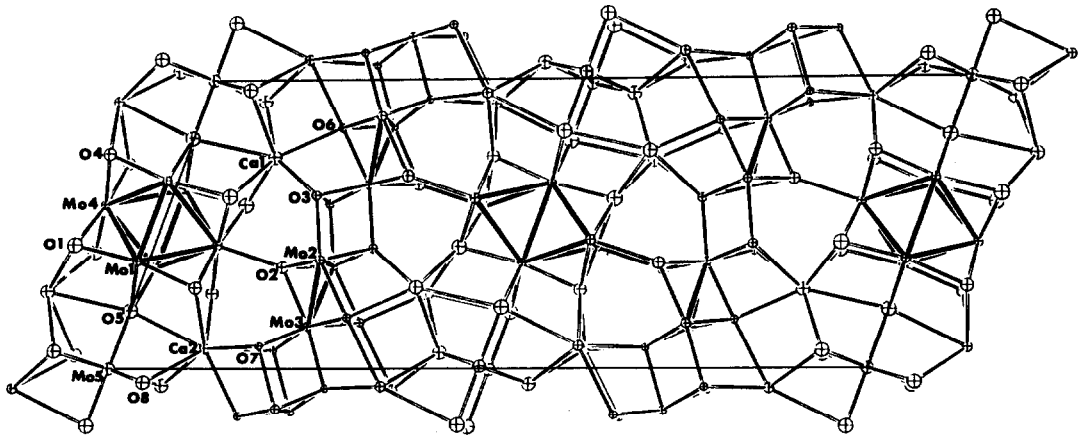

Fig. 4. The contents of one unit cell of $Ca_{5.45}Mo_{18}O_{32}$ as viewed down the monoclinic *b*-axis parallel to the direction of chain growth. Mo1 and Mo4 belong to edge-shared octahedral cluster chains, Mo2 and Mo3 belong to edge-shared rhomboidal cluster chains, and Mo5 belongs to single-atom chains like those in rutile.

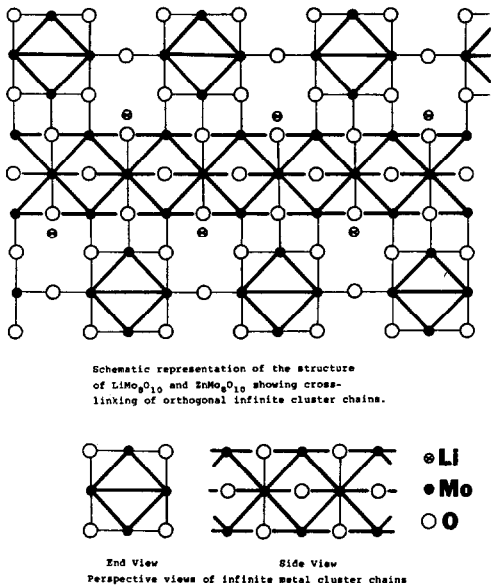

Fig. 5. Schematic representation of the structure of $LiMo_8O_{10}$ or $ZnMo_8O_{10}$ as viewed down the *a* tetragonal axis.

$M^I(Mo_4O_5)(Mo_4O_5)$. Finally, it should be noted that $ZnMo_8O_{10}$ is the most reduced molybdenum oxide compound currently known, and indeed it attains the highest MCE per cluster unit, 15, of any compound containing the condensed octahedral cluster units.

APPLICATION OF BOND LENGTH–BOND ORDER RELATIONS

The relation between bond distance and bond order for metal–metal bonds in metallic elements and their compounds has been given by Pauling[10] as:

$$d(n) = d(1) - 0.6 \log n, \qquad (1)$$

where $d(n)$ and $d(1)$ are the bond distances for bonds of order n and 1, respectively, and n is the bond order. Recently Corbett[11] has shown, for reduced halides and chalcides of the early transition metals, that Pauling bond order (PBO) sums for metal–metal-bonded compounds correlate well with the number of electrons available. The number of electrons available are those remaining on the metal atom after subtraction of those transferred to or shared with the nonmetal atoms, which thereby achieve a closed-shell configuration. Generally the correlation works very well in compounds where the nonmetal/metal ratio is less than 2 and the coordination number of the metal atom (with respect to nonmetal atoms) is less than 6. In this context "very well" means that the PBO sum divided by the number of MCE (PBO/e) falls in the range 0.8–1.0. Exceptions to this occur when "matrix effects"[11] become important, as for example when nonmetal–nonmetal spacings dictate weakened metal–metal bonds, or when the metal–metal bonding must take place through shared edges or faces of polyhedra formed by the nonmetal coordination sphere around the metal atom.

In the compounds discussed here we find that the PBO/e values, calculated from the observed Mo–Mo distances, without exception fall in the range 0.9–1.0 *when the counting of MCE is unambiguous.* This result is not really surprising in view of a number of factors which are particularly favorable in these structures. (1) The O/Mo ratios are < 2.0 and coordination numbers of the metal atoms towards oxygen are < 6. (2) Because of the small radius of the oxide ion [$r(O^{2-}) = 1.38$ Å][12] O–O nonbonded contacts are sufficiently short that Mo–Mo bonds formed at the same distance are still reasonably strong. (This is important for bonding along infinite chains where M–M bond distances parallel to the chain direction are dictated by and must be the same as the nonbonded O–O distance.) (3) The structures feature high total coordination numbers, M–M + M–O, about the metal atoms. Thus the bonding environment is similar to that found in the metal itself, from which the parameters of the PBO equation were established.[12] It is well known that the PBO equation works best for cases where the individual M–M bond orders are $\leqslant 1$.

Our encounter with the compound $Ca_{5.45}Mo_{18}O_{32}$[6] stimulated a further consideration of the bond length–bond order relations. In this compound the structure is built up from *three* types of metal–metal-bonded chains, as reflected in the formula $Ca_{5.45}(MoO_3^{m-})_2(Mo_2O_{3.5}^{n-})_4(Mo_4O_6^{p-})_2$. Assuming that each Ca transfers two electrons to the molybdenum oxide framework we see that

$$2m + 4n + 2p = 2(5.45) = 10.9.$$

Thus the important question concerns the evaluation of the individual anion charges m, n and p and simultaneously the correct MCE to be assigned to each kind of metal cluster repeat unit in the infinite chains. Fortunately a method to evaluate this electron distribution is provided by the M–O bond length–bond strength relations,[13] which permits evaluation of the net oxidation state of the individual metal atoms in the structure. The latter corresponds to the number of MCE given to M–O bonding, and hence the anion charge (assuming all oxygen atoms are always O^{2-}) and the MCE available for M–M bonding may be computed.

For most metal atoms reasonably reliable

empirical relations have been established for assessment of M–O bond strengths (synonymous with bond order) in oxide compounds. For this purpose equations of the general type

$$s(\text{M–O}) = [d(\text{M–O})/d_1(\text{M–O})]^{-n}$$

have been used,[13] where s = bond strength in valence units (v.u.), d(M–O) = observed M–O bond distance (Å), d_1(M–O) = M–O single bond distance (Å), and n is an exponential parameter having a value characteristic of each metal atom. The best values of the parameters d_1(M–O) and n have been derived for most metallic elements from fitting data for many oxide structures where accurate bond distances are known and the oxidation state of the M atom is unambiguous. The parameters in this equation perhaps have been established with greater confidence for molybdenum than for any other element. In particular, Bart and Ragaini[14] have arrived at "best" parameters by examining data for a wide variety of oxygen-ligated molybdenum compounds with molybdenum in oxidation states from 2+ to 6+. They find d_1(Mo–O) = 1.882 and n = 6.0 provide the best results for calculating the valence of molybdenum in the broad range of compounds from binary oxides (Mo_xO_y) to complexes like $Mo_2(O_2CMe)_4$. In this paper all calculations of individual Mo–O bond orders are thus made with the equation:

$$s(\text{Mo–O}) = [d(\text{Mo–O})/1.882]^{-6.0}. \quad (2)$$

Since s(Mo–O) is given in v.u. the sum of all Mo–O bond orders about a given Mo atom gives the valence of that atom [eqn (3)]:

$$\sum s(\text{Mo–O}) = v(\text{valence}) \quad (3)$$

and the anion charge on a unit $Mo_xO_y^{q-}$ in the lattice is given by:

$$q^- = xv - 2y. \quad (4)$$

In cases where several crystallographically distinct metal atoms exist in the structure, e.g. as in $NaMo_4O_6$ with Mo(1) and Mo(2), the sum over all metal atoms must be taken [eqn (5)]:

$$q^- = \sum_i x_i v_i - 2y, \quad (5)$$

where x_i represents the number of equivalent atoms Mo(i) having valence v_i in the formula unit.

These calculations are given in detail for $NaMo_4O_6$ in Table 2. In the infinite chain structure of this compound there are two distinct kinds of Mo atoms in the Mo_4O_6 repeat units, viz. the Mo(a) and Mo(w), each occurring twice in the formula unit, $NaMo(a)_2Mo(w)_2O_6$. We expect that the Na atoms transfer their valence electrons to the oxide framework, hence the formulation $Na^+Mo_4O_6^-$ and q^- (expected) = −1.00. From the values of s(Mo–O) given in Table 2 we obtain

$$q^-(\text{calc.}) = [2(3.13)+2(2.46)]-6(2) = -0.82 \pm 0.20.$$

The error of ±0.2 in this calculated value for q^- is the *maximum* error produced by an error of one standard deviation in all of the Mo–O bond distances used to compute the Mo–O bond strengths. Within this error limit the agreement between the expected and calculated anion charge is satisfactory. Thus in a case where we can be confident of the correct anion charge the procedure based on Mo–O bond strengths does indeed provide a reliable result.

Application of this procedure to the compound $Ca_{5.45}Mo_{18}O_{32}$ should then provide estimates of the anion charges for the three types of anion chains found in the structure. The pertinent Mo–O bond distances and bond strengths are given in Table 3. From these results, values of the individual anion charges have been calculated as shown in Table 3. The sum over all anion units gives the total anion charge

$$q^- = 2(-2.2)+4(-0.24)+2(-2.6) = -10.6.$$

Within the expected error the latter is in good agreement with the total cation charge arising from Ca^{2+}, $q^+ = 2(5.45) = 10.9$. Furthermore, the MCE derived from these individual anion charges for each kind of repeat unit are in agreement with those found in related compounds having only one of the corresponding structural repeat units. For example, the $Mo_2O_{3.5}^{0.24-}$ repeat units compose infinite chains of edge-fused rhomboidal clusters like those found in $NaMo_2O_4$.[6] The MCE/repeat unit is 5.24 in the former and 5.0 in the latter. A comparison of the $Mo_4O_6^{2.6-}$ repeat units with those in many other compounds having the same edge-fused octahedral cluster chains is given in the following section.

ELECTRON-COUNTING SCHEMES

We wish to relate here how further use of the bond length–bond order (bond strength) empirical relations can be applied to derive useful estimates of the numbers of electrons involved in M–O and M–M bonding, and even to estimate whether any electrons enter antibonding states with respect to the M–M interactions. Although extended Hückel band structure calculations[15] have been made for structure types **1** and **2** these do not have sufficient accuracy to provide a complete understanding of the three-dimensional band structure in these complex materials. The placement of bands near the Fermi

[c] Number in parentheses indicates maximum error produced by change in bond distance of one standard deviation.

level is especially important in accurately predicting the electron occupation number and bonding or antibonding character of the occupied states. These calculations however do provide valuable insights about the nature of the orbital overlaps, which M–M interactions are most important, and how the interactions are changed or adapt upon change of structure type.

A very important point which must be established first is in regard to the degree of participation of the metal valence electrons in M–M interactions. For example, in the compound $NaMo_4O_6$ we can deduce readily from the average oxidation state of the Mo atoms of 2.75 that 3.25 e/Mo are left for potential involvement in Mo–Mo bonding. However, in the absence of persuasive evidence to the contrary we cannot state with confidence that all of these electrons will indeed enter into M–M bonding. Localization of electrons in essentially nonbonding orbitals is of course always possible in suitable structure types and becomes increasingly favored for elements occurring later in the transition series.

If the bond length–bond order expressions work correctly, for a given metal atom the number of electrons devoted to M–O bonding is given by eqn (6):

$$n_e(\text{M–O}) = v = \sum S(\text{M–O}) \tag{6}$$

and the number of electrons devoted to M–M bonding is given by eqn (7):

$$n_e(\text{M–M}) = \sum n(\text{M–M}). \tag{7}$$

Thus, if all electrons in the valence shell of the metal atom are involved in bonding the sum of n_e(M–O) and n_e(M–M) should equal the periodic group number. For Mo we have the condition:

$$N_e = n_e(\text{Mo–O}) + n_e(\text{Mo–Mo}) = 6. \tag{8}$$

Calculations for all compounds where accurate structural refinements have been performed are

[g] Numbers in parentheses are estimated maximum error in least significant digit.

listed in Table 4.* The results for N_e given in column 1 confirm that essentially in all cases the valence electrons of Mo are completely utilized in bonding according to this criterion.

From this point we can proceed in three ways to obtain the MCE/repeat unit for metal–metal bonding. First, from a summation of all Mo–Mo bond orders around each Mo atom in the repeat unit we get directly the total MCE/unit. We will designate this estimate MCE ($\sum n$). Second, we may obtain the valence of each Mo atom in the repeat unit via summation of Mo–O bond orders. The MCE/Mo is then obtained from the relation MCE = $6-v$, and the total MCE/repeat unit is MCE($\sum s$) = $\sum_i$ MCE$_i$(Mo$_i$). Third, if the average valence of the Mo can be reliably determined from the formula, as in cases where the valence of all other elements can be assigned with confidence, the MCE/repeat unit can be determined from MCE(Formula) = $x(6-\bar{v})$, where x is the number of Mo atoms and $\bar{v}$ is the average valence. This method of course is not subject to uncertainties introduced by errors in the bond distances, but does rest on the assumption that all valence electrons are involved in the bonding, i.e. there are no localized nonbonding electrons.

Estimates of the MCE/repeat unit by each of these methods is given in Table 4 for all compounds containing the condensed octahedral cluster repeat units. It is notable that the three methods are in essential agreement for the simplest of these compounds, $NaMo_4O_6$. This may be interpreted as an indication that $NaMo_4O_6$ is perfectly bonded with all valence electrons of the Mo atoms in either Mo–Mo or Mo–O bonding states. Accordingly we conclude that nonbonding and antibonding states are essentially unoccupied. Extended Hückel calculations[15] corroborate this result and place the Mo–O valence band well below the bands derived from Mo–Mo interactions. The density of states at the Fermi level also is predicted to be quite low, and this is consistent with resistivity measurements, which indicate that $NaMo_4O_6$ passes through a metal–semiconductor transition at low temperatures. This implies that antibonding states are separated from the filled bonding states by a small energy gap at low temperature. In this structure type

* All Mo–Mo bond orders have been calculated using the single-bond distance d_1(Mo–Mo) = 2.614 Å. This value is slightly different from the value of 2.592 Å given by Pauling's[10] single-bond radius, R_1(Mo) (1.296 Å). The value of d_1 = 2.614 Å was calculated from the nearest neighbor [d(n.n)] and next nearest neighbor [d(n.n.n.)] distances in bcc Mo–metal by solving the three equations based on the PBO equations for the two distances and the condition that $8n$(n.n.) + $6n$(n.n.n.) = 6, where n(n.n.) and n(n.n.n.) are the bond orders for nearest neighbor and next nearest neighbor Mo–Mo bonds, respectively.

apparently 13 e/repeat unit are required for complete occupation of the bonding states.

If the above conclusions are correct one may ask, what are the consequences of adding additional electrons to this structure? The answer is not easily obtained because synthesis of compounds having M^{2+} in the ternary cation sites leads to: (a) incomplete occupation of the metal ion sites with consequent superstructure effects, and/or (b) involvement of the ternary metal *s* and *p* valence orbitals in the valence and conduction bands. Both of these effects are important with the compounds $Sn_{0.9}Mo_4O_6$ and $Pb_{0.8}Mo_4O_6$, while only the latter is involved in the case of $InMo_4O_6$. In contrast to $NaMo_4O_6$ both $Sn_{0.9}Mo_4O_6$ and $InMo_4O_6$[7] are metallic conductors, with a normal temperature dependence of their resistivity down to 2 K. Thus the structure of the conduction band is different for the latter pair, even though $InMo_4O_6$ appears to be isoelectronic with $NaMo_4O_6$. As shown by the data in Table 4 the difference in MCE($\sum s$) and MCE($\sum n$) for $InMo_4O_6$ is quite significant. Because MCE($\sum n$) is low the Mo–Mo bonding is evidently weaker than in $NaMo_4O_6$. Weaker Mo–Mo bonding could result either from a lower population of electrons in the bonding states, inferring that In transfers fewer electrons to the Mo_4O_6 units, or from the population of antibonding levels, inferring that In transfers more electrons and adopts an average valence >1.0. The result MCE($\sum s$) = 13.1(2) seemingly negates both of these possibilities. A third possibility is that mixing of the In *s*-orbitals (which have lower energy) with the Mo4*d* orbitals in the conduction band results in lifting some of the *d*-states to antibonding character. Since the *s*-orbitals of In^+ remain occupied this would result in the occupation of some antibonding *d*-states and a consequent lowering of the Mo–Mo bond orders.

The results given in Table 4 reveal an obvious trend that, with the exception of the numbers for $NaMo_4O_6$, all MCE($\sum n$) are significantly lower than MCE($\sum s$) or MCE(Formula), with differences, Δ, [MCE(Formula) − MCE($\sum n$)], of 0.6–1.1 e/repeat unit. A plausible explanation for this behavior concerns the limiting MCE based on occupation of only bonding states in the undistorted chains (as in $NaMo_4O_6$) and the interplay between occupation of antibonding states and stabilizing distortions of the cluster units with increasing MCE. Distortions of the cluster units can result in the creation of additional bonding states via band splitting and lowering resulting from reduced symmetry. This effect has been treated and discussed by Hughbanks and Hoffmann[15] for compounds of type **2**. However, their study did not permit a reliable estimate of the total occupied states at the Fermi energy because of the complicated band structure. Consequently, a reliable estimate of the MCE/repeat unit was not derived from their calculations. It can be stated with confidence however that the doubling of the cluster repeat unit and the pairwise Mo(a)–Mo(a) interactions resulting from the tilting of adjacent octahedral units does indeed create additional bonding states. Thus it can be asserted that the observed distortion is electronically driven and the net Mo–Mo bonding within the chains is thereby enhanced for MCE > 13.

Notably, the widest range of Mo–Mo bond distances is found within the cluster units of $LiMo_8O_{10}$ and $ZnMo_8O_{10}$, having MCE of 14.5 and 15.0, respectively. In these compounds the true repeat unit is again doubled and even more drastic pairwise coupling of adjacent atoms is observed, except that these occur in a less understandable fashion than in compounds of type **2**. Some shortened Mo–Mo distances in $ZnMo_8O_{10}$ are 2.581(2), 2.680(2) and 2.694(2) Å, and some lengthened distances are 3.246(2), 3.202(2) and 2.952(2) Å, all relative to the averaged Mo–Mo bond distance of 2.809 Å. The latter average bond distance differs little from the corresponding average distance of 2.803 Å in $NaMo_4O_6$, whereas the values of MCE($\sum n$) are 14.1 and 12.7 for $ZnMo_8O_{10}$ and $NaMo_4O_6$, respectively. This large difference in MCE($\sum n$) illustrates dramatically the effect that distortions can have on the net metal–metal bond orders within cluster units. For example, the PBO equation gives a lower $\sum n$ for two bonds of equal length than that for the same bonds, one lengthened and the other shortened by the same increment. This simply reflects the well-known fact that bond energies and bond orders increase exponentially with decreasing bond distance. In this connection we note that important distortions occur in the cluster units of all structure types having MCE $\geqslant 14$. The particular form of the cluster distortion is governed by symmetry constraints of the lattice and metal positions, which in turn are determined by the ternary metal ions through their direction of the structure type adopted.

ESTIMATION OF MCE IN ANTIBONDING STATES

The basis for this approach is suggested by the results given in Table 4 and discussed in the previous section. Namely, since $\sum s + \sum n$ approach 6.0 in all cases there is valid reason to believe that all Mo valence electrons are involved in bonding interactions. Why then do the values MCE($\sum n$) consistently fall below those of either MCE($\sum s$) or MCE(Formula)? If the latter arises because some

electrons enter antibonding states which then weaken the Mo–Mo bonding, the number of such electrons may then be estimated from the results of the bond order summations. In order to derive an expression for this purpose we need to make the assumption that the number of electrons in nonbonding states is negligibly small compared to those in bonding or antibonding states. If we take MCE(Formula), given below as MCE(F), as the true measure of the total number of cluster electrons, and define n_b and n_a as the number of bonding and antibonding electrons, respectively, we get eqns (9) and (10):

$$\mathrm{MCE}(F) = n_b + n_a, \tag{9}$$

$$\sum n = (n_b - n_a)/2, \tag{10}$$

where $\sum n^*$ is the PBO sum over all M–M bonds in the repeat unit. These equations yield the solutions:

$$n_b = \mathrm{MCE}(F)/2 + \sum n, \tag{11}$$

$$n_a = \mathrm{MCE}(F) - n_b. \tag{12}$$

Noting that $2\sum n = \mathrm{MCE}(\sum n)$ and defining the quantity Δ as

$$\mathrm{MCE}(F) - 2\sum n = \mathrm{MCE}(F) - \mathrm{MCE}(\sum n)$$

we get the final equations:

$$n_a = \Delta/2, \tag{13}$$

$$n_b = \mathrm{MCE}(F) - \Delta/2. \tag{14}$$

The results Δ, n_b and n_a for all of the compounds are listed in Table 4. With the exception of $NaMo_4O_6$ the values of Δ are rather significant for all compounds, but still the number of antibonding electrons is small for all structures. Within the limits of error $NaMo_4O_6$ has no electrons in antibonding states. Again, the small range of 0.3–0.6 antibonding electrons for the range of MCE from 13 to 15 e/cluster unit illustrates the effectiveness of internal distortions and adaptation of Mo–Mo bonding in avoiding the population of antibonding states. It will be interesting to see if MCE = 15 represents an upper limit for structures derived from the edge-shared octahedral cluster chains, or if new compounds having higher MCE may be prepared. Based on the correlations presented here it appears that the cluster units in the edge-shared octahedral cluster chains are likely to suffer such severe distortions for MCE > 15 that alternate modes of cluster condensation will be favored for higher e/M ratios than those observed in these structures.

* Note here that $\sum n$ represents the sum over *individual Mo–Mo bonds*, rather than over the individual Mo atoms, of the cluster repeat unit. By taking the sum over atoms each bond is counted twice, thus $\sum n(\text{bonds}) = \sum n(\text{atoms})/2$.

HYDROGEN INSERTION COMPOUNDS OF THE MOLYBDIC ACIDS

S. CROUCH-BAKER and P. G. DICKENS*

Inorganic Chemistry Laboratory, South Parks Road, Oxford OX1 3QR, U.K.

(*Received* 26 *June* 1985)

Abstract—This paper describes the structural and thermodynamic characterization of hydrogen insertion compounds of the molybdic acids, $H_xMoO_3 \cdot nH_2O$, comparing, where possible, the properties of this system with those of the hydrogen insertion compounds of MoO_3 itself.

The three compounds $MoO_3 \cdot 2H_2O$, yellow (or β-) $MoO_3 \cdot H_2O$ and white (or α-) $MoO_3 \cdot H_2O$, known as the molybdic acids, constitute the three stoichiometric, well-characterized hydrates of MoO_3. The dihydrate consists of infinite layers of vertex-sharing MoO_6 octahedra;[1,2] one terminal oxygen in each octahedron forms a short Mo—O bond while the opposite oxygen is replaced by a coordinated water molecule. There are also discrete water molecules between the layers.[3] The yellow monohydrate is formed by the topotactic loss of the interlayer water molecules on dehydration of the dihydrate while retaining the $MoO_5(OH_2)$ layer structure.[4] In the white monohydrate there are isolated double chains of edge-sharing octahedra with each molybdenum atom bearing a coordinated water molecule.[5]

Hydrogen insertion into MoO_3[6] produces four phases of H_xMoO_3 in the range $0 < x \leqslant 2$. This paper describes the characterization of corresponding insertion compounds of the molybdic acids.

REDUCED MOLYBDIC ACIDS

Recently, the preparation of hydrogen insertion compounds of $MoO_3 \cdot 2H_2O$ and yellow $MoO_3 \cdot H_2O$ by catalytic hydrogenation has been described by the authors[7,8] leading to materials of composition $H_{1.0}MoO_3 \cdot 2H_2O$ and $H_{1.0}MoO_3 \cdot H_2O$. Further, it has been noted that the white monohydrate shows no reaction under similar conditions.[7]

Initial characterization by the authors[8] showed these hydrogen insertion compounds to be metallic with insignificant long-range proton mobility. Further structural and thermodynamic characterization has been carried out using the following techniques.

IR spectroscopy

The IR spectrum of $H_{1.0}MoO_3 \cdot H_2O$ is shown in Fig. 1 compared with that of yellow $MoO_3 \cdot H_2O$. A new absorption band is found in the spectrum of the reduced material at 1200 cm^{-1}. This is assigned to the bend of an Mo—O—H group.[9,10] A similar assignment has been made in the case of $H_{0.36}MoO_3$ on the basis of inelastic neutron-scattering data.[11] An identical band appears in the IR spectrum of the reduced dihydrate and is assigned similarly.

Single-crystal X-ray diffraction

A single crystal of $H_xMoO_3 \cdot 2H_2O$ was prepared by exposing a single crystal of $MoO_3 \cdot 2H_2O$ to gaseous hydrogen at room temperature in the presence of a platinized silica catalyst. Analysis of single-crystal diffraction data collected at room temperature showed there is no major structural rearrangement of the dihydrate on hydrogen insertion. Significant changes were revealed, however, in the immediate coordination environment of each molybdenum atom, in particular in the arrangement of bridging oxygen atoms. In $MoO_3 \cdot 2H_2O$ itself the four bridging oxygen atoms around each molybdenum atom are arranged in two sets of two (at ~1.75–1.80 and ~2.05–2.18 Å from the molybdenum), whereas in the reduced material

* Author to whom correspondence should be addressed.

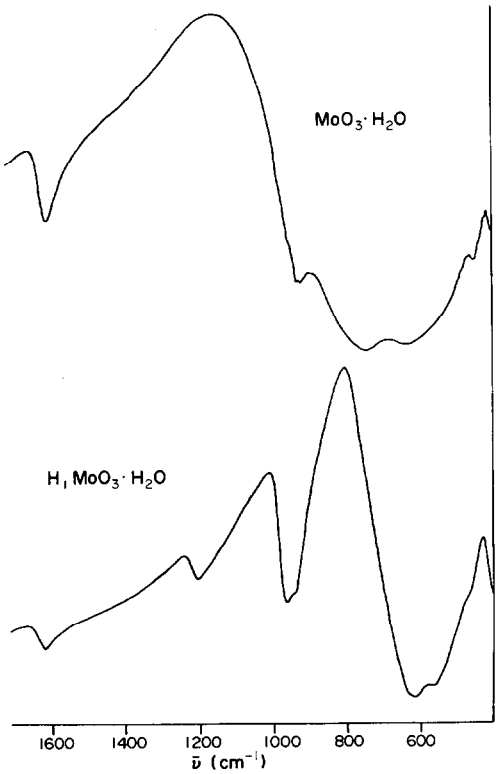

Fig. 1. IR spectra.

this distinction is removed and the oxygen atoms lie at intermediate distances from the molybdenum (at ~1.85–2.05 Å).

The reduction of MoO_3 to give $H_{0.36}MoO_3$ has been studied by powder neutron diffraction.[11] It was found that the inserted hydrogen atoms are attached to the oxygen atoms which bridge two molybdenum atoms in MoO_3 as OH groups. It was also shown that, on hydrogen insertion, the distances from the molybdenum atom to the bridging oxygen atoms, which are very different in MoO_3 itself, become equal. Hence it is proposed that the inserted hydrogen atoms in $H_xMoO_3 \cdot 2H_2O$ are attached, as part of OH groups, to the bridging oxygen atoms in the molybdic acid structure. The resulting hydrogen-bonding arrangement is shown in Fig. 2. Along each O---O line (approximately 3 Å long) there will be two possible hydrogen atom positions, only one of which may be occupied. This gives a maximum hydrogen content of $x = 1.0$, as is observed experimentally. Such an arrangement of hydrogen atoms is compatible with the extremely low rate of proton diffusion observed in the reduced molybdic acids.[8] The rigidity of the molybdic acid layer dictates that the only motion available to a proton is hopping between the two available sites along its own O---O lines. In the case of $H_{1.68}MoO_3$, a good proton conductor, diffusion probably takes place between the MoO_3 layers. The hydrogen atoms are attached to the terminal oxygen atom in MoO_3 as either OH_2 or OH groups; protons may be transferred from one site to another via a Grotthus type mechanism involving reorientation of the coordinated OH_2 groups.

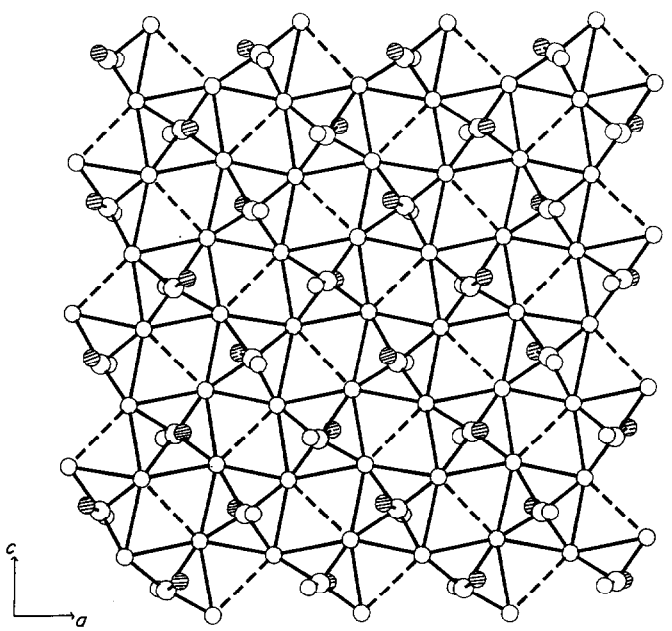

Fig. 2. Arrangement of hydrogen-bonds in $H_xMoO_3 \cdot 2H_2O$. For convenience the interlayer water molecules are not shown. Coordinated OH_2 groups are represented by shaded circles. A broken line between oxygen atoms indicates the unit O—H---O.

Solution calorimetry

The enthalpy change of the reaction

$$\frac{1}{2}H_2(g)+\frac{1}{x}MoO_3\cdot H_2O(s)=\frac{1}{x}H_xMoO_3\cdot H_2O(s)$$

at $x = 1.04$ has been determined[12] as $\Delta H = -43.9$ kJ mol^{-1}. This gives the mean O—H bond energy associated with the guest hydrogen atoms (ignoring the effects of any hydrogen-bonding) as approximately 470 kJ mol^{-1}, a value very similar to those quoted for OH groups in other solids, e.g. 486 kJ mol^{-1} in $H_{0.34}MoO_3$ and 470 kJ mol^{-1} in $H_{1.68}MoO_3$.[13]

Thermogravimetric analysis

The thermogravimetric decomposition curve for $H_{1.0}MoO_3\cdot 2H_2O$ is shown in Fig. 3 compared with that of the unreduced dihydrate. The decomposition curve of the latter shows two sharp weight losses corresponding to the two steps:[4]

$$MoO_3\cdot 2H_2O \overset{323\ K}{=\!=} MoO_3\cdot H_2O \overset{383\ K}{=\!=} MoO_3.$$

In the case of the decomposition of the reduced dihydrate (in an inert atmosphere), two similar dehydration steps are observed, analogous to those in the parent, leading to the formation of a material of composition $H_{1.0}MoO_3$. At approximately 473 K this material undergoes another dehydration step, distinctly less sharp than the previous two, removing constitutional oxygen and hydrogen to leave a material of composition $MoO_{2.5}$, the composition of which was confirmed thermogravimetrically by oxidation to MoO_3. The material $MoO_{2.5}$ was deep purple in colour and largely amorphous to X-rays. However, a powder X-ray pattern did contain the two strongest peaks due to MoO_2. Similar results were found for the reduced monohydrate without, of course, the initial dehydration at 323 K.

The thermal decomposition *in vacuo* of $H_{0.36}MoO_3$ has also been investigated.[14,15] The conclusions obtained are the same as those reached here, i.e. that thermal decomposition proceeds via dehydration giving materials of composition $MoO_{3-x/2}$.

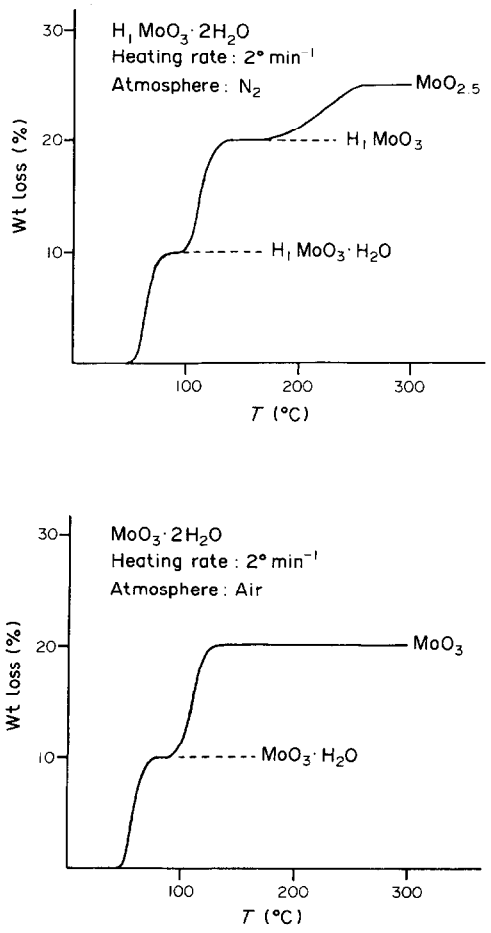

Fig. 3. Thermogravimetric decomposition curves.

CONCLUSION

Based on the results quoted here, and those stated previously,[7,8] it is concluded that hydrogen insertion into $MoO_3\cdot 2H_2O$ and yellow $MoO_3\cdot H_2O$ proceeds to give hydrogen insertion compounds closely analogous to $H_{0.36}MoO_3$, with the inserted hydrogen bound to bridging oxygen atoms as OH groups.

STRUCTURAL AND COMPOSITIONAL CHANGES IN A HYDROGEN MOLYBDENUM BRONZE, $H_{0.83}MoO_3$, BY VACUUM HEATING

NORIYUKI SOTANI

College of Liberal Arts, Kobe University, Tsurukabuto, Nada, Kobe 657, Japan

(*Received* 18 *June* 1985)

Abstract—$H_{0.83}MoO_3$ was a mixture of blue orthorhombic and blue monoclinic phases and decomposed, accompanied by structural and compositional changes, as follows:

$$H_{0.83}MoO_3 \xrightarrow{\sim 232°C} H_{0.58}MoO_{2.88} \xrightarrow{\sim 290°C} H_{0.21}MoO_{2.69} \xrightarrow{\sim 375°C} H_{0.02}MoO_{2.60} \xrightarrow{\sim 378°C} MoO_{2.59}.$$

It was reported by Birtill and Dickens[1] that a hydrogen molybdenum bronze, H_xMoO_3 ($0 < x \leqslant 2$) has four phases. Among them, many studies on a blue orthorhombic phase ($0.23 < x < 0.40$) by means of X-ray diffraction analysis,[2] neutron diffraction analysis,[3] IR spectroscopy[4] and NMR spectroscopy[5] have been reported. The others studied[6–8] the thermal stability of the orthorhombic bronze, $H_{0.30}MoO_3$, when it was treated *in vacuo* and in various gases by isothermal heat treatment and by heat treatment with increasing temperature, and its structural and compositional change was also studied. Since a bronze with higher hydrogen contents was obtained, the author tried to characterize this bronze as in the case of $H_{0.30}MoO_3$.

EXPERIMENTAL

The sample was prepared by the Glemser's method.[9,10] The composition was $H_{0.83}MoO_3$ by chemical analysis[11] and thermogravimetry.[7] $H_{0.83}MoO_3$ was composed of a mixture of blue orthorhombic and blue monoclinic ($0.85 < x < 1.04$) phases. A conventional high-vacuum system equipped with a Cahn electromicrobalance was used for measurements of weight changes. Samples after heat treatment *in vacuo* were studied by X-ray diffraction analysis and IR spectroscopy.

RESULTS AND DISCUSSION

Samples were heated isothermally at various temperatures (101–444°C) after pretreatment for 1 h in a vacuum of 10^{-4} torr. When the sample was treated at 373°C the fraction reacted, α, reached 1 within 20 min. On the other hand, when it was heated at 332°C for more than 3 h, α increased gradually, but did not reach 1.

Figure 1 shows X-ray patterns of samples heated isothermally at various temperatures. The X-ray result gave four kinds of patterns. Pattern (A) is due

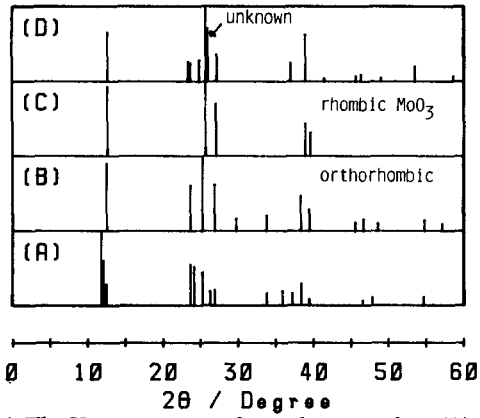

Fig. 1. The X-ray patterns of samples treated at: (A) room temperature–202°C, (B) 250°C, (C) 299–332°C, and (D) above 373°C.

to an original sample and samples heated below 202°C, and shows a mixture of orthorhombic and monoclinic phases. Pattern (B) is due to the sample heated at 250°C and shows only the orthorhombic phase. Patterns (C) and (D) of samples treated above 299°C show the rhombic MoO_3 phase, but, in addition to this phase, samples treated above 373°C gave an unknown phase.

The original sample and samples heated below 202°C show bands at 1004, 986, 942, 641 and 559 cm^{-1}, and the sample heated at 250°C shows bands at 1004, 975, 830, 631 and 559 cm^{-1}. Samples treated above 299°C show bands at 969, 830 and 559 cm^{-1}. According to the literature, bands due to the orthorhombic bronze[6,12] appeared at 1004 (835), 626 and 569 cm^{-1}, and those due to the rhombic MoO_3[13–15] at 998, 878, 820 and 557 cm^{-1}. As described above, bands for the original sample agree with those for the orthorhombic phase except for the band at 942 cm^{-1}. This suggests that the band at 942 cm^{-1} should be a characteristic band for the blue monoclinic bronze. On the other hand, bands of the samples treated above 299°C are for the rhombic MoO_3 but there is a small difference. As mentioned above, X-ray and thermogravimetric data proved that samples treated above 299°C were composed of a nonstoichiometric compound with a rhombic MoO_3 phase. It is, therefore, assumed that small shifts in frequencies resulted from this nonstoichiometry.

The gas eliminated from the sample was confirmed to be only H_2O and no other gas was detected. As in the case of $H_{0.30}MoO_3$,[8] this means that hydrogen atoms reacted with lattice oxygen and H_2O was produced.

Figure 2 shows plots of α against temperature. Curve I is the change in α at the isothermal-heating temperature and curve II that in α obtained from the weight loss by increasing temperature with a heating rate of 1.6°C min^{-1}. There is little difference in α over a temperature range of 100–300°C between samples obtained by isothermal treatment and by treatment by increasing temperature. In this range curve II could be expected to approach curve I if samples were heated at a heating rate slower than 1.6°C min^{-1}. Curve II shows discontinuity at points A, B and C. The change in α from C to D was small but steep. Considering X-ray and thermogravimetric results, α and the corresponded temperature were estimated as follows: (A) $\alpha = 0.30$ (232°C), (B) $\alpha = 0.75$ (290°C), (C) $\alpha = 0.98$ (375°C), and (D) $\alpha = 1.00$ (378°C). Consequently, the hydrogen content could be calculated from these values, and the composition of the stable phase at each point was also determined. Therefore, it is concluded that the decomposition of $H_{0.83}MoO_3$ proceeds by four steps as follows:

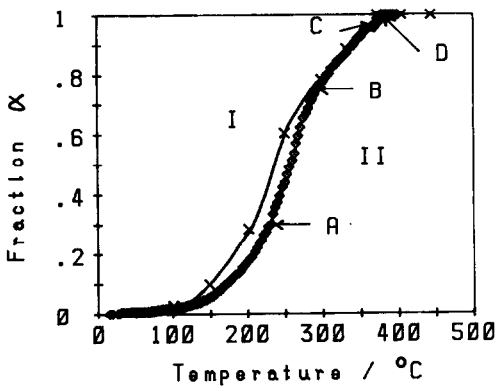

Fig. 2. Plot of α against temperature. Curve I = isothermal heat treatment, and curve II = heat treatment by increasing temperature.

$$H_{0.83}MoO_3 \xrightarrow{\sim 232°C} H_{0.58}MoO_{2.88},^{*} \quad (1)$$

$$H_{0.58}MoO_{2.88} \xrightarrow{\sim 290°C} H_{0.21}MoO_{2.69},^{\dagger} \quad (2)$$

$$H_{0.21}MoO_{2.69} \xrightarrow{\sim 375°C} H_{0.02}MoO_{2.60},^{\ddagger} \quad (3)$$

$$H_{0.02}MoO_{2.60} \xrightarrow{\sim 378°C} MoO_{2.59}.^{\S} \quad (4)$$

Processes (1) and (2) are the decomposition from the mixture of orthorhombic and monoclinic phases to the orthorhombic phase. This means that decomposition from the monoclinic to the orthorhombic phase occurs and hydrogen reacts easily with lattice oxygen. As reported previously,[8] the blue orthombic bronze decomposed through the isomorphous compound with a rhombic MoO_3 phase to the nonstoichiometric compound with a rhombic MoO_3 phase. In the present work, processes (3) and (4) correspond to these processes and complete removal of hydrogens, which should be distributed sparsely, takes place without any structural change.

TEMPERATURE-PROGRAMMED DECOMPOSITION STUDIES OF A HYDROGEN MOLYBDENUM BRONZE, $H_{0.83}MoO_3$

NORIYUKI SOTANI* and MASATOMO HASEGAWA

College of Liberal Arts, Kobe University, Tsurukabuto, Nada, Kobe 657, Japan

(*Received* 18 *June* 1985)

Abstract—A temperature-programmed decomposition (TPD) study of a hydrogen molybdenum bronze, $H_{0.83}MoO_3$, is reported. TPD spectra obtained from changes in pressure showed four bands (PI, PII, PIII and PIV); activation energies, E_a, determined from the shifts in maximum peak temperatures were 23.8 (PI), 106.7 (PII), 118.6 (PIII) and 164.3 (PIV) kJ mol^{-1}. E_as obtained from thermogravimetric data varied from 52.7 to 153.2 kJ mol^{-1} as the fraction reacted increased. E_as obtained from both methods were in good agreement.

It is reported in this issue[1] that the thermal decomposition of a hydrogen molybdenum bronze, $H_{0.83}MoO_3$, took place by four steps as follows:

$$H_{0.83}MoO_3 \xrightarrow{\sim 232°C} H_{0.58}MoO_{2.88}$$
$$\xrightarrow{\sim 290°C} H_{0.21}MoO_{2.69}$$
$$\xrightarrow{\sim 375°C} H_{0.02}MoO_{2.60}$$
$$\xrightarrow{\sim 378°C} MoO_{2.59}.$$

$H_{0.83}MoO_3$ is a mixture of orthorhombic and monoclinic phases and it decomposes to $MoO_{2.59}$, a nonstoichiometric compound with a rhombic MoO_3 phase through the orthorhombic phase. During the decomposition, hydrogens in the bronze reacted with lattice oxygen and H_2O was, therefore, produced. In the present work, the bronze was studied by a temperature-programmed decomposition (TPD) technique and the authors tried to compare the results obtained for changes in pressure and weight.

EXPERIMENTAL

A hydrogen molybdenum bronze, $H_{0.83}MoO_3$, was prepared by Glemser's method,[2] and was a mixture of blue orthorhombic and blue monoclinic phases.[1]

A high-vacuum line was used for the experiment.[3] Samples were studied by the TPD technique. The TPD spectrum was obtained from the change in pressure by using a Pirani gauge and thermogravimetric data were obtained by using a Cahn electromicrobalance. The rate of heating was controlled by a temperature-programmed controller.

RESULTS AND DISCUSSION

The bronze $H_{0.83}MoO_3$ was degassed at room temperautre in a vacuum of 10^{-4} torr for 1 h and then heated at various heating rates (βs) (1.6–6.9°C min^{-1}). The change in pressure was recorded with a Pirani gauge. Figure 1 shows TPD spectra at β 1.6, 3.4, 4.5 and 6.9°C min^{-1}. A small band appeared below 150°C, but above 150°C the TPD spectrum showed two distinct peaks at around 300 and 400°C, and two shoulders at around 200 and 350°C. This suggests that the spectrum may be composed of four bands and the line shape of each band may be symmetrical. Therefore, the spectra above 150°C could be analysed by using a computer.[3] One of the results is shown in Fig. 2. This shows that the spectrum above 150°C consists of four bands (PI, PII, PIII and PIV). The peak temperatures are denoted as T_m(I), T_m(II), T_m(III) and T_m(IV) in order from the lowest temperature. All spectra in Fig. 1 were analyzed by the same technique. Shifts in each peak temperature to a higher temperature were observed when β was increased. The T_m(I) appeared over a temperature range of 198–281°C and the

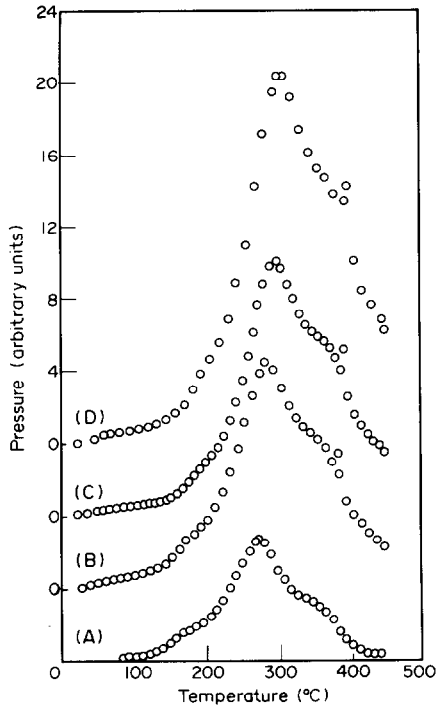

Fig. 1. TPD spectra of the samples heated at various heating rates: (A) 1.6, (B) 3.4, (C) 4.5, and (D) 6.9°C min^{-1}.

T_m(II) at 270–299°C. The T_m(III) and T_m(IV) appeared at 331–362 and 369–400°C, respectively.

The activation energy, E_a, can be estimated from the shift in the peak temperatures.[4] The plot of $-\ln(\beta T_m^{-2})$ vs $1/T_m$ is a straight line and the slope corresponds to E_a/R, where R is constant. From the slope, E_a was determined to be 23.8 (PI), 106.7 (PII), 118.6 (PIII) and 164.3 (PIV) kJ mol^{-1}, respectively.

The rising-temperature technique has been widely used in kinetic investigation of thermal decomposition and other reactions of solids.[4–7] Applying this technique, Ozawa[7] proposed a simple and useful method to analyze thermogravimetric data and determine the E_a of the decomposition of calcium oxalate and the degradation of Nylon 6. According to his technique, E_a can be easily determined as follows: initially the fraction reacted, α, is plotted against the reciprocal absolute temperature ($1/T$), and the value of $1/T$ corresponding to the $1-\alpha$ of each β curve can be estimated. Secondly, E_a can be determined from the plot of log β vs $1/T$ obtained from the above plot. If the decomposition proceeds in one step, E_a estimated from plots of log β vs $1/T$ should be equal at every α.

Figure 3 shows plots of E_a at every 0.05 of $1-\alpha$. Vertical arrows indicate the $1-\alpha$ which corresponds to stable phases in the decomposition process as described previously.[1] E_a varies greatly, from 52.7 to 153.2 kJ mol^{-1}, with the increase in α. Analysing in detail, E_a increases gradually at first, is constant over the range of $\alpha = 0.45$–0.85, and finally increases steeply. Also in Fig. 3 the ranges of $1-\alpha$ corresponding to the peaks of the TPD spectra are indicated by horizontal bidirectional arrows. As mentioned previously, T_m(I) appeared over a very wide range and over that range E_a also varied widely as shown in Fig. 3. Considering these results, it is reasonable that disagreement exists on the E_a obtained from the change in pressure and weight loss. On the other hand, E_as of PII, PIII and PIV are a

little larger than that in Fig. 3, but they agree well with each other.

THE ADSORPTION OF HEPTAMOLYBDATE IONS ON OXIDIC SURFACES

J. A. R. VAN VEEN* and P. A. J. M. HENDRIKS

Koninklijke/Shell-Laboratorium, Amsterdam (Shell Research B.V.), P.O. Box 3003, 1003 AA Amsterdam, The Netherlands

(*Received* 19 *June* 1985)

Abstract—The adsorption of ammonium heptamolybdate (AHM) on γ-Al_2O_3 is governed by the basic surface hydroxyl groups. Having determined the number of these groups on the γ-Al_2O_3 used, we can give a quantitative description of the adsorption isotherm. When too highly concentrated AHM solutions are used, a (surface) precipitate is formed as well. On TiO_2, only the formation of a surface precipitate is observed, even at low [AHM]; this effect is probably due to the acidic surface OH groups. On SiO_2, not much adsorption takes place, but AHM reacts with the oxide to form a molybdosilicate solution species.

The qualitative features of the interaction of aqueous ammonium heptamolybdate (AHM) solutions with γ-Al_2O_3 are well known:[1] important are those OH groups on the γ-Al_2O_3 surface which can be released into solution as OH^- ions, and the reaction between these OH^- ions and heptamolybdate to form MoO_4^{2-}. Adsorption occurs through electrostatic attraction between the positively charged Al_2O_3 surface and the molybdate ions in solution:

$$Al_s—OH \rightleftarrows Al_s^+ + OH^-, \quad (1)$$

$$Mo_7O_{24}^{6-} + 8OH^- \rightleftarrows 7MoO_4^{2-} + 4H_2O, \quad (2)$$

$$2Al_s^+ + MoO_4^{2-} \rightleftarrows (Al_s)_2MoO_4, \quad (3)$$

$$6Al_s^+ + Mo_7O_{24}^{6-} \rightleftarrows (Al_s)_6Mo_7O_{24}, \quad (4)$$

where the subscript s denotes surface species. As to the shape of the AHM–γ-Al_2O_3 adsorption isotherm and the limiting adsorption level, no unanimity exists, no less than five different isotherms having been reported.[1–5] Interestingly, the maximum Mo uptake is found to increase with increasing ratio of the weight of γ-Al_2O_3 to the volume of the AHM solution used in the adsorption experiments. Also, some isotherms show only one plateau region, while others show two. We have attempted to resolve this problem, and in this poster we will: (i) describe what we think is the true adsorption isotherm, (ii) offer an explanation of its form and the limiting adsorption capacity observed, (iii) indicate under which conditions deviations from this isotherm may occur, and (iv) describe some results concerning the adsorption of AHM on TiO_2 and SiO_2, and compare them with those obtained for γ-Al_2O_3.

EXPERIMENTAL

Adsorption isotherms were determined as follows. The oxide was contacted with aqueous AHM solutions in various ratios (standard 2g/100 cm^3) and the mixture shaken occasionally. After the desired adsorption time, 1–14 days, the Mo uptake was determined by measuring the Mo concentration left in solution (atomic absorption spectrometry) and/or the Mo content of the solid (X-ray fluorescence). To gauge the stability of AHM solutions, blank experiments were performed. The number of basic hydroxyl groups on γ-Al_2O_3 was determined through adsorption of $MoO_2(acac)_2$, a complex extremely sensitive to OH^-, from a methanolic solution.[6] IR spectra of γ-Al_2O_3 before and after AHM adsorption were recorded on a Digilab FT instrument. Raman spectra were determined with a Spex Ramalog spectrometer and TPR profiles were measured on a laboratory-built instrument.

The oxides used were: γ-Al_2O_3, AC 300 (Shell) (250 $m^2\ g^{-1}$); TiO_2, P25 (ex Degussa) (50 $m^2\ g^{-1}$); and SiO_2 spheres (Shell) (285 $m^2\ g^{-1}$).

* Author to whom correspondence should be addressed.

RESULTS AND DISCUSSION

The AHM–γ-Al_2O_3 adsorption isotherm, obtained under conditions such that no precipitates develop in solution on a time scale comparable to that of the adsorption experiment and that a true equilibrium has been reached (cf. below), is shown in Fig. 1. To see whether the shape and the limiting Mo uptake are explicable in terms of eqns (1)–(4), we need an independent measurement of the number of surface OH groups that can react according to eqn (1). For our γ-Al_2O_3 sample, $MoO_2(acac)_2$ adsorption leads to a value of 0.80 mmol g^{-1}. That in fact only the basic OH groups are involved in the adsorption of $MoO_2(acac)_2$ as well as of AHM follows from the observation that, as expected,[7] in both cases only the high-frequency band in the OH stretch region of the IR spectrum of γ-Al_2O_3 had disappeared. The quantitative description of the isotherm is now easy.

At low [AHM], i.e. when the [AHM]/basic OH molar ratio in the system is smaller than 8, there are sufficient hydroxyl ions to depolymerize all heptamolybdate (HM) ions [eqn (2)], and the adsorption reaction proceeds, in the first instance, according to eqns (1)–(3):

$$8Al_s\text{—}OH + Mo_7O_{24}^{6-} \rightarrow 4(Al_s)_2MoO_4 + 3MoO_4^{2-}. \quad (5)$$

However, there are still some basic OH groups left, and if the pH of the solution is lower than the isoelectric point (IEP) of the solid, these will start dissociating, which will in turn lead to adsorption of some of the MoO_4^{2-} ions still left in solution. That is, more Mo will be adsorbed than follows from eqn (5) and the deviation will be larger the lower the Mo loading (IEP of our γ-Al_2O_3 sample is about 8.2, it decreases with increasing Mo loading; the pH of an AHM solution is around 5). When the [AHM] and the amount of OH groups just balance, eqn (5) predicts an adsorption of 0.038 g Mo $(g\ Al_2O_3)^{-1}$ at $c' = 0.86 \times 10^{-3}$ M AHM. The actual isotherm and that predicted by eqn (5) do indeed meet at this point (Fig. 1). Thus, the first part of the adsorption isotherm can be accounted for in terms of eqns (1), (3) and (5).

At higher [AHM], there are not sufficient OH^- ions to depolymerize all the HM ions, and so, after all basic OH groups have reacted, we are left with a mixture of MoO_4^{2-} and $Mo_7O_{24}^{6-}$ ions, the latter increasingly predominating as [AHM] increases. Adsorption now occurs according to eqns (3) and (4). In the limit [AHM] $\rightarrow \infty$, eqn (4) predicts an adsorption of 0.090 g Mo $(g\ Al_2O_3)^{-1}$, and so, after the first plateau, the isotherm will rise again and strive towards this limiting value, as observed (Fig. 1).

Under which conditions can isotherms be obtained that deviate from the one just discussed? Isotherms without the first plateau are obtained when the adsorption time is too short. This is due to the fact that splitting off OH^- ions to increase the pH towards the IEP value is a very slow process, as is also observed in the absence of AHM (it takes about a week to reach equilibrium). This state of affairs is reflected in the pH of the AHM solution after the adsorption experiment: while adsorption occurs according to eqn (5) the pH does not rise above 6; only after all the AHM has reacted and the second process comes into play [eqns (1) and (3)] does the pH slowly rise to reach, at lower [AHM], 7.8 at equilibrium.

Sometimes[2,3] rather high ratios of the weight of Al_2O_3 to the volume of AHM solution are used in the determination of the adsorption isotherm. Under these conditions, much higher loadings of Mo can be achieved, as we have verified. However, rather concentrated AHM solutions have to be applied here, and these tend to be unstable, developing a precipitate {presumably[8] $[(NH_4)_6Mo_8O_{27}]_n$} in a matter of hours at the highest concentration (2.2 M in Mo). In other words, the high Mo loadings are not so much due to adsorption as to precipitation (see below). We have found that where the adsorption time is much shorter than the time needed for a precipitate to develop in solution, no precipitated phase is present on the Al_2O_3 surface.

We propose, then, the existence of three surface

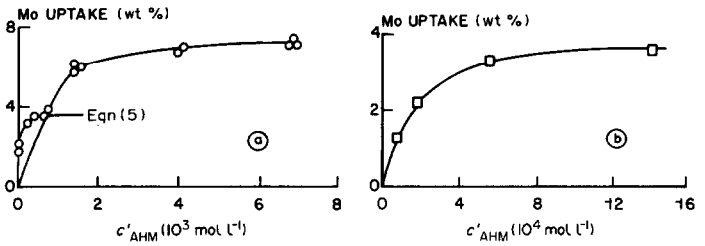

Fig. 1. Adsorption isotherms of AHM on γ-Al_2O_3 (a) and TiO_2 (b).

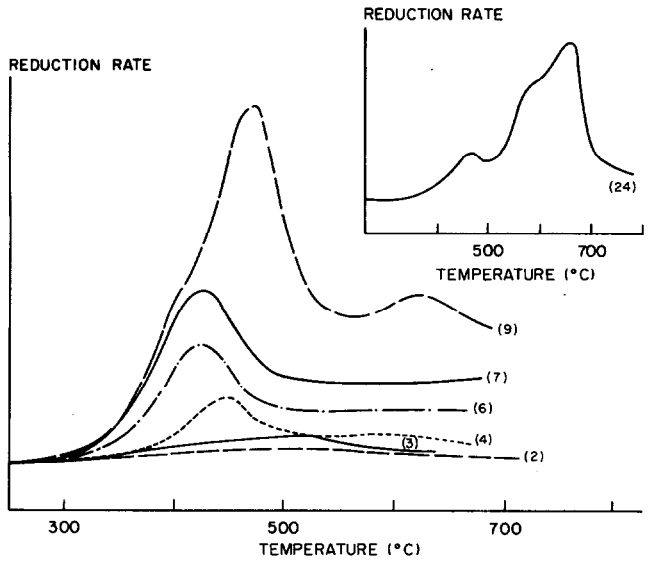

Fig. 2. TPR profiles of AHM–γ-Al_2O_3 catalysts (numbers in parentheses give the wt % Mo in the samples).

species: (i) adsorbed monomolybdate, (ii) adsorbed HM, and (iii) a precipitate. It turns out that these three species can be distinguished by TPR and Raman spectroscopy. Typical TPR profiles are shown in Fig. 2. A sample is first calcined at 600°C in 5% O_2 in He, and after cooling down a TPR is run using 5% H_2 in N_2 (heating rate 5°C min^{-1}; gas flow 6 cm^3 min^{-1}). It is apparent that at low loadings a Mo species is present which is difficult to reduce (T_{max} about 530°C, amount of H_2 consumed per Mo in the temperature interval 200–665°C, H_2/Mo, about 0.2), and that between 4 and 7% wt Mo, a more easily reducible species becomes dominant (T_{max} about 425°C, H_2/Mo increases to 0.37), corresponding to (the calcination products of) adsorbed monomolybdate and HM, respectively. At still higher loadings (9 and 24 wt % in Fig. 2) a third feature develops, which is due to the (surface) precipitate, and is characterized by a relatively high T_{max} and high H_2/Mo (around 1.0).

Raman spectroscopy of the dried samples also shows the existence of three different species: at low Mo loadings we observe a small, broad band at about 965 cm^{-1}, above 4% Mo a second broad band appears centred at about 995 cm^{-1}, while the precipitates are characterized by two sharp bands at 995 and 955 cm^{-1}, and a broad feature at 635 cm^{-1}. In sum, the TPR and Raman data are fully consistent with the adsorption scheme proposed here. Thus, the true AHM–γ-Al_2O_3 adsorption isotherm is the one shown in Fig. 1; it can be explained in terms of eqns (1)–(5), and deviations can occur, at low loadings, when the adsorption time is too short, and at high loadings when the AHM solutions used are not stable enough.

TiO_2

Since TiO_2 also contains basic surface OH groups—in the case of our sample 0.14 mmol g^{-1} (determined by F^- exchange[9])—an adsorption behaviour similar to that of γ-Al_2O_3 might have been expected. However, much more Mo is adsorbed than can be accounted for in terms of the basic OH groups [max. 1.6 wt % Mo (Fig. 1b)]. Since TiO_2 contains quite a few fairly acidic surface OH groups as well (in the present case, 0.33 mmol g^{-1}, determined by NaOH adsorption[9]), and since insoluble species tend to form in AHM solution when it is acidified,[8] we suggest that TiO_2 does not really adsorb a Mo species, but that it catalyses the formation of a surface precipitate. TPR results, in showing a highly reducible species (H_2/Mo about 0.8), and the Raman spectrum of the 3.7% Mo–TiO_2 sample, being similar to that of the precipitate referred to above (although shifted to higher wavenumbers, the doublet now appearing at 1057 and 1044 cm^{-1}), do not disagree with this suggestion.

SiO_2

Silica does not posses basic surface hydroxyl groups and so eqns (1)–(4) will not be appropriate. On the other hand, although many acidic silanol groups are present, a surface precipitate does not form either. Instead, $Mo_7O_{24}^{6-}$ ions react with SiO_2

to form $[SiMo_{12}O_{40}]^{4-}$ ions, which are subsequently released into solution [little Mo is left on the SiO_2 surface (less than 1 wt %)]. The occurrence of this reaction has been suggested before.[10]

Acknowledgements—We would like to thank Mr E. J. G. M. Romers for the TPR experiments, Dr C. A. Emeis for the IR measurements, and Dr C. A. Emeis and Mr H. de Wit for the Raman work.

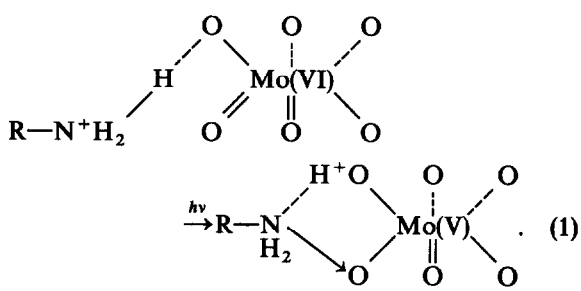
MULTI-ELECTRON REDUCTION SITES OF POLYMOLYBDATES AS PHOTOREDOX CATALYSTS

TOSHIHIRO YAMASE

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227, Japan

(*Received* 14 *June* 1985)

Abstract—During our studies on the photochemistry of polyoxometalates we have found that the polyoxometalates are potential photosensitizers and electron relay species in redox cycles for chemical conversion of light energy. This paper describes the characterization of multi-electron reduction sites in $[Mo_8O_{26}(MoO_4)_2]^{8-}$ and $[Mo_7O_{24}]^{6-}$, based on the analysis of ESR spectra for UV-irradiated $[NH_3Me]_8[Mo_8O_{26}(MoO_4)_2]\cdot 2H_2O$ and $[NH_3Pr^i]_6[Mo_7O_{24}]\cdot 3H_2O$ single crystals. The ESR spectra show the formation of two distinct localized $Mo(V)O_5(OH)$ sites in the lattice. The analysis of the ESR parameters g, $^{95,97}Mo$ hyperfine structure, and ^1H superhyperfine structure indicates the direct participation of H1*s* in the half-occupied molecular orbital. From the direction of the maximum principal value of the ^1H superhyperfine tensor, which lies close to the Mo(V) . . . $H^+(O)$ direction, two paramagnetic sites in the anion can be determined. The results show that the multi-electron photoreduction consists of separate and independent one-electron reductions at four and two octahedral sites in $[Mo_8O_{26}(MoO_4)_2]^{8-}$ and $[Mo_7O_{24}]^{6-}$, respectively. On the other hand, a single crystal of $[NH_2Pr^i_2]_4[H_{1.5}W_{10}O_{32}]\cdot 8H_2O$, which was a photochemically 1.5-electron reduced species, exhibits extensive delocalization of the paramagnetic electron (around $g = 1.84$) interacting with eight equivalent hydrogen-bonding protons.



During our studies of the photoredox reactions of polyoxometalates with water,[1] carboxylic acids,[2] alcohols,[3] alkynes[4] and alkenes,[5] photoreactive centers of the alkylammonium polymolybdates

$$[NH_3Pr^i]_6[Mo_8O_{26}(OH)_2]\cdot 2H_2O$$

and

$$[NH_3Pr]_6[Mo_7O_{24}]\cdot 3H_2O$$

have been investigated by single-crystal ESR.[6,7] The reduction of Mo(VI) to Mo(V) proceeds via photoexcitation of the oxygen-to-molybdenum charge-transfer band in a terminal Mo=O bond with an accompanying transfer of a hydrogen-bonding proton from alkylammonium nitrogen to a bridging oxygen atom, followed by an interaction of the nonbonding electrons of the amino nitrogen with the terminal oxo-group leading to a charge-transfer complex (**I**) as shown in reaction (1):

(1)

I

Single-crystal ESR spectra of the UV-irradiated alkylammonium polyoxomolybdates at room temperature shows the formation of a localized Mo(V) site. Based on the analysis of ESR parameters, the paramagnetic site in the anion has been determined in correlation with the X-ray crystal structure data.

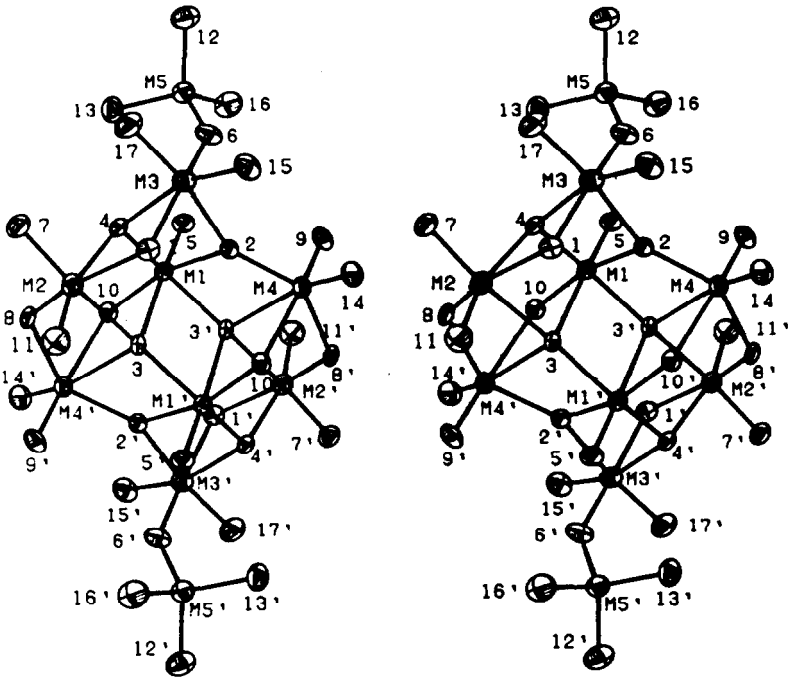


Fig. 1. Stereoscopic drawing of $[Mo_{10}O_{34}]^{8-}$. M represents an Mo atom.

The Mo(V) site in the $[Mo_8O_{26}(OH)_2]^{6-}$ lattice has been observed at the octahedral site where the molybdenum atom originally co-ordinates a hydroxide group.[6] The Mo(V) formation in the $[Mo_7O_{24}]^{6-}$ lattice occurs at the end of three octahedra in a line in the central horizontal level of the $[Mo_7O_{24}]^{6-}$ polyhedral configuration.[7] Studies of the paramagnetic sites in the polyoxoanions have been extended to the decamolybdate $[Mo_{10}O_{34}]^{8-}$ and decatungstate $[W_{10}O_{32}]^{4-}$. The structural configuration of the

$$[Mo_{10}O_{34}]^{8-} \equiv [Mo_8O_{26}(MoO_4)_2]^{8-}$$

lattice,[8] having an arrangement of eight edge-shared distorted MoO_6 octahedra linked by a pair of distorted MoO_4 tetrahedra as shown in Fig. 1, is the same as that of dihydrogen octamolybdate $[Mo_8O_{26}(OH)_2]^{6-}$ as found by us.[9] Although structurally very similar, $[Mo_8O_{26}(MoO_4)_2]^{8-}$ in this work is a linkage isomer of the decamolybdate reported by Fuchs *et al.*[10] These two decamolybdates can be distinguished by a different linkage of the MoO_4 groups.

EXPERIMENTAL

Octakis (methylammonium) decamolybdate (VI) dihydrate, $[NH_3Me]_8[Mo_{10}O_{34}]\cdot 2H_2O$, was obtained by the method previously described.[11]* Single crystals were grown by slow evaporation from aqueous solutions at room temperature. Well-developed colorless crystals of approximate dimensions $3 \times 2 \times 1$ mm were obtained. The crystal is monoclinic with $a = 12.596$ Å, $b = 17.175$ Å, $c = 10.653$ Å, $\beta = 91.40°$, $Z = 2$, $R = 0.041$ and space group $P2_1/n$. The two molecules in the unit cell, being related by a center of inversion, are magnetically equivalent. A crystal was irradiated at room temperature with UV light of $\lambda \geqslant 313$ nm from a 500-W super-high-pressure mercury lamp in conjunction with filters. After about 30 min of irradiation, the crystal, which is reddish brown, was mounted on a quartz rod for the ESR study.

Blue single crystals of

$$[NH_2Pr^i_2]_4[H_{1.5}W_{10}O_{32}]\cdot 8H_2O$$

were prepared by irradiating the deaerated aqueous solution of $[NH_2Pr^i_2]_4[W_{10}O_{32}]$ at pH 2 with

* MAM, IPAM, PAM and 6IAP8M2 in Ref. 11 must be rewritten as

$[NH_3Me]_8[Mo_{10}O_{34}]\cdot 2H_2O$,

$[NH_3Pr^i]_6[Mo_7O_{24}]\cdot 3H_2O$,

$[NH_3Pr]_6[Mo_7O_{24}]\cdot 3H_2O$

and

$[NH_3Pr^i]_6[Mo_8O_{26}(OH)_2]\cdot 2H_2O$,

respectively.

UV light. The crystal is monoclinic with $a = 11.48$ Å, $b = 12.22$ Å, $c = 10.79$ Å, $\beta = 100.3°$, $Z = 2$, $R = 0.12$ and space group $P2_1/n$. Analysis of W(V) in the crystal was carried out at room temperature by titration of $KMnO_4$ for the aqueous solution of the blue crystal under an atmosphere of nitrogen, which resulted in the disappearance of the blue color due to W(V). Blue crystals consisted of one- and two-electron reduction species in *ca* 1:1 molar ratio, since the absorption spectrum of the deaerated aqueous solution of the blue crystal exhibited absorption maxima at 780 and 630 nm due to one- and two-electron reduced species, respectively.[3]

ESR experiments were performed on a Varian E-12 spectrometer with *X*-band (100-kHz field modulation). DPPH was used as a field marker. Spectra were recorded at intervals of 10°, as the magnet was rotated about each of the orthogonal *X*-, *Y*- and *Z*-axes to which our results were referred. After completion of ESR measurements the orientation of the body-fixed orthogonal *X*-, *Y*- and *Z*-axes with respect to the crystallographic axes was determined by both oscillation and Weissenberg photographs.

RESULTS AND DISCUSSION

Multi-electron reduction sites in $[Mo_8O_{26}(MoO_4)_2]^{8-}$ *and* $[Mo_7O_{24}]^{6-}$

The spectrum obtained with the UV-irradiated

$$[NH_3Me]_8[Mo_{10}O_{34}]\cdot 2H_2O$$

single crystal reveals the presence of two paramagnetic Mo(V)(OH) sites, A and B, as shown in Fig. 2. The spectrum of each Mo(V) center consists of two sets of lines, a doublet and a sextet of doublet. The first set of lines is attributed to the interaction (*ca* 10 G) of the unpaired electron with a ^1H which has a nuclear spin (I) of $\frac{1}{2}$. The nature of this more intense set of lines corresponds to the zero nuclear spin ^{96}Mo atom. The second set of lines, of less intensity, characterizes the hyperfine spectrum of ^{95}Mo and ^{97}Mo further split by the same superhyperfine interaction of the first set of lines. The relative intensity of the two sets of lines agrees well with the molybdenum isotopic composition. The spectrum has been interpreted using the spin Hamiltonian [eqn (2)] with $S = \frac{1}{2}$, $I_{Mo} = \frac{5}{2}$ and $I_H = \frac{1}{2}$:

$$\mathcal{H} = \beta g \cdot H \cdot S + A_{Mo} \cdot I_{Mo} \cdot S + A_H \cdot I_H \cdot S. \quad (2)$$

ESR parameters g, A_{Mo} and A_H tensors have been obtained using successively a least-squares fitting subroutine and performing a direct diagonalization of the Hamiltonian. We have previously described this procedure elsewhere.[6,7] The results are given in Table 1. Two sets of tensor, g, A_{Mo} and A_H, can be referred to two magnetically inequivalent paramagnetic sites A and B in the unit cell, where two molecules are magnetically equivalent related to a center of inversion.[8] It is interesting that the parameters found in the present work are quite compatible with those for the octahedral Mo(V) site in $[Mo_8O_{26}(OH)_2]^{6-}$ or $[Mo_7O_{24}]^{6-}$.[6,7] This indicates that the sign choice for the tensor components of sites A and B is the same as that for the Mo(V) site in $[Mo_7O_{24}]^{6-}$, which gives the total spin density closest to unity. It is this which we report in Table 1. The non-coincidence of principal axes of the g- and A-tensors originates in the extensive d-orbital mixing allowed by the low-symmetry ligand field in the site, indicating the displacement of the directions of the principal g values from the Mo—O axes.

The principal values of $^{95,97}Mo$ hyperfine tensors in units of 10^{-4} cm^{-1} are 23.7, 40.2 and 73.5 for site A (28.0, 41.8 and 76.8 for site B). To an approximation,

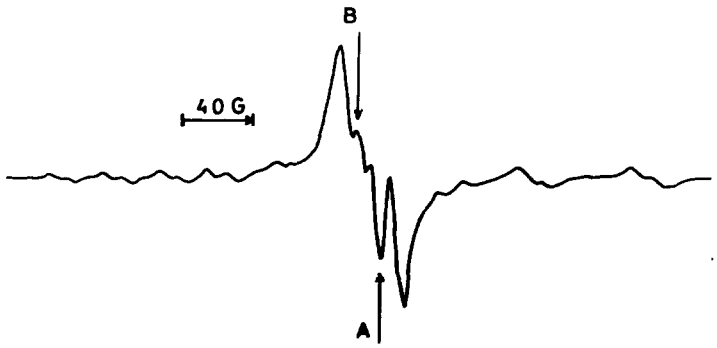

Fig. 2. Example of ESR spectrum obtained with an UV-irradiated crystal of $[NH_3Me]_8[Mo_{10}O_{34}]\cdot 2H_2O$ at room temperature. H_0 is in the ZX plane at an angle of 20° to the X-axis. A and B correspond to the two paramagnetic sites.

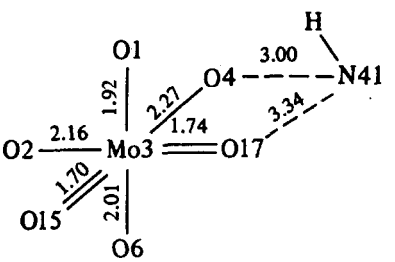
[a] $g_0 = (g_1+g_2+g_3)/3$.
[b] Units in 10^{-4} cm^{-1}, $A_{Mo0} = (A_{Mo1}+A_{Mo2}+A_{Mo3})/3$.
[c] The signals due to ^{95,97}Mo hyperfine structure were too weak to analyse at all orientations.
[d] Units in 10^{-4} cm^{-1}, $A_{H0} = (A_{H1}+A_{H2}+A_{H3})/3$.
[e] In Ref. 6 a choice of signs for ^{1}H tensors was not decided.

therefore, the hyperfine tensors are axial with $A_{Mo\parallel} = 73.5 \times 10^{-4}$ cm^{-1} (76.8×10^{-4} cm^{-1} for site B) and $A_{Mo\perp} = 31.9 \times 10^{-4}$ cm^{-1} (34.9×10^{-4} cm^{-1}). Defining an anisotropic hyperfine parameter for *d*-orbitals as $\frac{2}{7}(A_{Mo\parallel} - A_{Mo\perp})$ and dividing its value, 48.3×10^{-4} cm^{-1} (49.0×10^{-4} cm^{-1}), by $P = g\beta\gamma_{Mo}\langle r^{-3}\rangle_{4d}$ for ^{95,97}Mo (150.7 MHz[12] = 50.3×10^{-4} cm^{-1}) gives an estimate of 0.96 (0.97 for site B) for the spin population in Mo4*d* orbitals, when $A_{Mo\parallel}$ and $A_{Mo\perp}$ have the same sign. If $A_{Mo\parallel}$ and $A_{Mo\perp}$ are assumed to have opposite signs one obtains an estimated Mo4*d* contribution of 2.55. This constitutes an unacceptably large total spin density and strongly implies that $A_{Mo\parallel}$ and $A_{Mo\perp}$ have the same sign. The ^{95,97}Mo isotropic hyperfine interaction is equal to 45.8×10^{-4} cm^{-1} for site A (48.9×10^{-4} cm^{-1} for site B). The isotropic hyperfine interaction for unit spin density in the Mo5*s* orbital, which is obtained by computing $A = (8\pi g\beta\gamma/3)\psi^2(0)$, is 66.2×10^{-3} cm^{-1};[7,12] hence an Mo5*s* contribution of 0.07 for each of two sites is indicated. Since the physically most reasonable sign choice for ^{1}H superhyperfine tensor components is the positive sign, as discussed in a previous paper,[7] an H1*s* contribution of 0.02 may be derived from dividing $A_{H0} = 9.86 \times 10^{-4}$ cm^{-1} (9.63×10^{-4} cm^{-1} for site B) by the isotropic hyperfine interaction 474 $\times 10^{-4}$ cm^{-1}[13] for unit spin density in the 1*s* orbital of the H atom. The total spin density for site A is therefore $0.96 + 0.07 + 0.02 = 1.05$ (1.06 for site B), a reasonably satisfactory result.

The positive sign of the ^{1}H superhyperfine tensors indicates that H1*s* participates directly in the half occupied molecular orbital and that the highest of the principal values $A_{H3} = 12.4 \times 10^{-4}$ cm^{-1} for site A (12.3×10^{-4} cm^{-1} for site B) is approximately parallel to the Mo(V) . . . H$^+$(O) direction.[7] The proton at the photoreduced MoO_6 site in the UV-irradiated specimen of

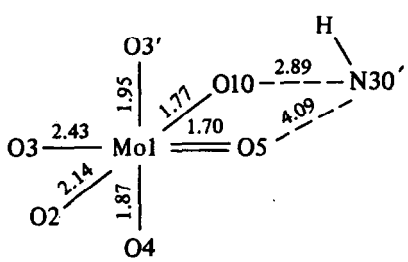
$$[NH_3Pr^i]_6[Mo_8O_{26}(OH)_2]\cdot 2H_2O$$

and



$$[NH_3Pr]_6[Mo_7O_{24}]\cdot 3H_2O$$

was derived from the transfer of the alkylammonium hydrogen-bonding proton to the bridging oxygen atom, which resulted from the photoexcitation of the l.m.c.t. band of the terminal Mo=O bond [eqn (1)].[6,7] The hydrogen-bonding proton at the Mo(V) site of the photoreduced $[Mo_{10}O_{34}]^{8-}$ would be situated around the N . . . O line in range of one-fourth to three-fourths of the N . . . O distance (2.77–3.20 Å)[8] from the oxygen atom, in conjunction with the fact that methylammonium N$^+$—H and hydroxide O—H distances are 0.68–0.83[8] and 0.82 Å, respectively. Since there was no significant change in both IR spectra and X-ray diffraction powder patterns between non-irradiated and irradiated samples, it is assumed that the structure of the parent oxidized form is retained upon irradiation, as proposed in the solid-state photochemistry of



$$[NH_3Pr]_6[Mo_7O_{24}]\cdot 3H_2O.^7$$

Thus, the present ESR results are in agreement with the site symmetry determined for $[Mo_{10}O_{34}]^{8-}$. This enables us to determine the paramagnetic sites in the anion.

The molecule viewed in projection along the *Z*-axis is represented together with the principal A_{H3} directions in Fig. 3, where dotted lines indicate the N . . . O distance of 2.77–3.20 Å, with the involvement of a hydrogen-bonding proton. The Mo sites, in which the Mo . . . H$^+$(O) direction seems to accord well with the direction of the A_{H3} for each of molecular views projected along the *X*-, *Y*- and *Z*-axes, are determined. Thus, we can assign the paramagnetic site A to Mo3 . . . H$^+$ (O4 . . . N41) and site B to Mo1 . . . H$^+$ (O10 . . . N30′). Any other Mo sites are extremely improbable. As shown in (3) the Mo3 atom is surrounded by a distorted octahedral set of six O atoms, two of which belong to the terminal doubly bonded *cis*-dioxo group and four are bridging. This arrangement resembles the photoreducible MoO_6 sites in two anions, $[Mo_7O_{24}]^{6-}$ and $[Mo_8O_{26}(OH)_2]^{6-}$. On the other hand, Mo1 is surrounded by one terminal doubly bonded oxygen (O5) and five bridging oxygen atoms, as shown in (4).

(3)

(4)

ESR signals (Fig. 2) showed both ^{95,97}Mo hyperfine and ^{1}H superhyperfine structures without any exchange broadening, which were characteristic of the unpaired electron localized on one Mo site only. Therefore, the signals indicate the small extent

of antiferromagnetic coupling of the two electrons at the adjacent edge-shared octahedral sites of Mo(V)1 and Mo(V)3 (Fig. 1). This may be attributed to the significant departure of both Mo1—O2—Mo3 (103.3°) and Mo1—O4—Mo3 (108.7°) angles[8] from linearity. The conclusion that both Mo1 and Mo3 sites are photoreducible gives also paramagnetic sites at both Mo1′ and Mo3′, since the arrangement of polyhedra can be related to the inversion center in the anion (Fig. 1). This implies the occurrence of four separate and independent one-electron photoreductions at Mo1, Mo1′, Mo3 and Mo3′ in $[Mo_{10}O_{34}]^{8-}$. The nonlinear arrangement of Mo1—O3—Mo1′ (104.3°)[8] seems to be a factor for the localization of the unpaired electron at each Mo(V) site of Mo1 and Mo1′, showing that there are two distinct sites for four-electron reduction of the anion.

In the light of the ESR signals from the Mo(V)1 and Mo(V)3 sites in $[Mo_{10}O_{34}]^{8-}$, one may state the alternative possibility that the ESR signals belong to the one-electron reduction at either the Mo1 or the Mo3 site in the anion. In this case, the two kinds of species of Mo(V)1 and Mo(V)3 must be randomly distributed over the whole lattice, since there was no significant difference in the signal intensities between the two sites. It must be recalled that the rate of the UV-induced coloration due to Mo(V) formation for the $[Mo_{10}O_{34}]^{8-}$ lattice was a few times higher than that of $[Mo_8O_{26}(OH)_2]^{6-}$ or $[Mo_7O_{24}]^{6-}$.[11] In conjunction with the similarity of the absorption spectra ($\lambda_{max} = 480 \sim 510$ nm) among these UV-irradiated polyoxomolybdates solids,[11] a high efficiency of the rate of photocoloration of the

$$[NH_3Me]_8[Mo_{10}O_{32}]\cdot 2H_2O$$

solid strongly supports four separate and independent one-electron reductions of $[Mo_{10}O_{34}]^{8-}$. Failure to observe the tetrahedral Mo(V)5 site can be explained by the electrostatic repulsion between the proton and the hole photogenerated at the terminal O12, O13 and O16 atoms (Fig. 3), which gives little possibility of a proton transfer at the Mo5 site resulting in thermal deactivation to the original Mo=O state without any formation of the charge-transfer complex (I).

Two distinct paramagnetic centers have also been observed for the UV-irradiated

$$[NH_3Pr^i]_6[Mo_7O_{24}]\cdot 3H_2O$$

single crystal.[1] Unfortunately, the final R value of 0.060 for the crystal structure data made interatomic distances and angles of the hydrogen bonds uncertain,[14] and resulted in the difficulty in assigning the photoreducible Mo site. On the other hand, the Mo(V) formation in the

$$[NH_3Pr]_6[Mo_7O_{24}]\cdot 3H_2O$$

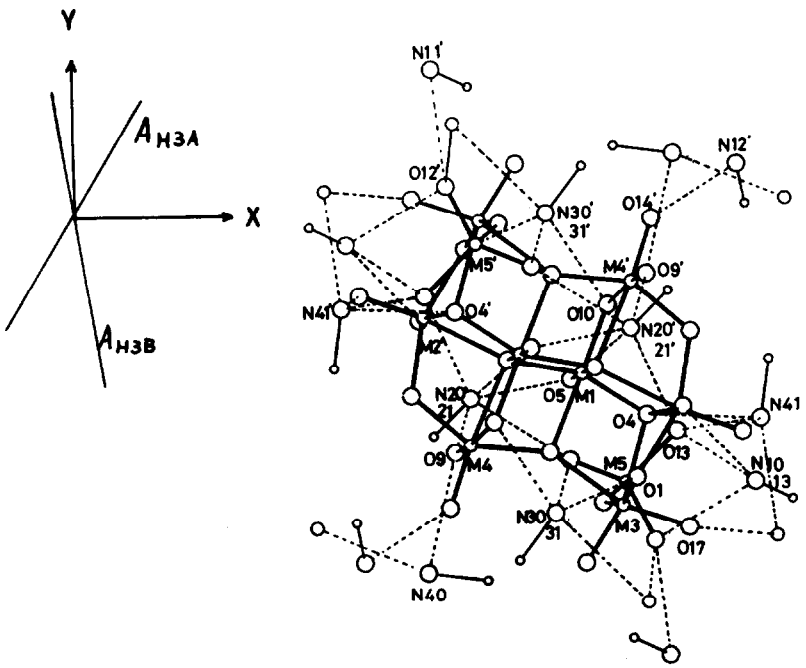


Fig. 3. Drawing of the molecular structure, viewed in projection along the Z-axis. A_{H3A} and A_{H3B} denote the principal A_{H3} directions of sites A and B, respectively, in the XY plane.

crystal occurred at an end of three octahedra in a line in the central horizontal level of the $[Mo_7O_{24}]^{6-}$ configuration.[7] Therefore, it is suggested that the two paramagnetic Mo(V) sites in the $[NH_3Pr^i]_6[Mo_7O_{24}]\cdot 3H_2O$ (space group $P2/n$, $Z = 4$)[14] belong to two ends (two-electron reduction) of three octahedra in the central level of $[Mo_7O_{24}]^{6-}$ or one at alternate ends (one-electron reduction), which must be randomly distributed over the lattice. Figure 4 shows photoreducible octahedra sites for multi-electron reduction sites in $[Mo_8O_{26}(MoO_4)_2]^{8-}$ and $[Mo_7O_{24}]^{6-}$.

Photoreduction of $[W_{10}O_{32}]^{4-}$

The structure of $[W_{10}O_{32}]^{4-}$ is shown in Fig. 5.[15] The photolysis of $[NH_2Pr^i_2]_4[W_{10}O_{32}]$ in aqueous solution led to the formation of one- and two-electron reduced decatungstate anions, which were coupled with the oxidation of water (to $^{\cdot}OH$) and $[NH_2Pr^i_2]^+$ (to acetone).[1,3] The photolyte exhibited an ESR signal at 77 K due to W(V), which consisted of a singlet isotropic line ($g = 1.84$, $\Delta H_{ms} = 20$ G) without a hyperfine structure. During the photolysis process leading to the formation of the two-electron reduced species, the signal intensity decreased steadily without a change in the g value, suggesting that the two-electron reduction species is diamagnetic.[3] There was no significant difference in W—O distances and W—O—W angles between the oxidized and photoreduced decatungstates crystals. A typical ESR spectrum of the

$$[NH_2Pr^i_2]_4[H_{1.5}W_{10}O_{32}]\cdot 8H_2O$$

crystal, recorded at 77 K, is shown in Fig. 6. The increasing number of lines around $g = 1.84$ is attributed to interaction of the unpaired electron with the protons. The superhyperfine structure can be fairly well accounted for if we assume eight

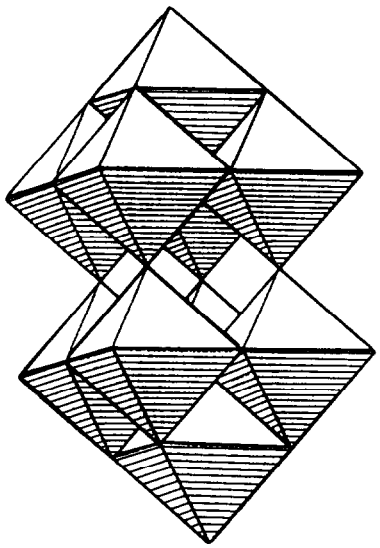

Fig. 5. Structure of $[W_{10}O_{32}]^{4-}$.

equivalent protons. Obviously these eight equivalent protons, giving nine lines with intensities in ratio 1:8:28:56:70:56:28:8:1, must be hydrogen-bonding protons at WO_6 sites in the anions. It is unlikely that the side signal corresponds to ^{183}W ($I = \frac{1}{2}$) hyperfine line, since the natural abundance (14.28%) of ^{183}W is low. Both g and superhyperfine tensors exhibited little anisotropy. The results indicate a complete delocalization of the unpaired electron over 10 tungsten atoms. Therefore, it is concluded that the protonation induced by the photoreduction of $[W_{10}O_{32}]^{4-}$ is not constrained at a peculiar octahedron site but delocalized over 10 WO_6 sites, different from the photoreductions of the above isopolymolybdates. The difference in the localization of the unpaired electron between the molybdate and tungsten isopolyanions is probably due to the larger extension of the W5*d* orbitals.

SUPERCONDUCTING CHEVREL PHASES: PROSPECTS AND PERSPECTIVES

R. CHEVREL,* M. HIRRIEN and M. SERGENT

Université de Rennes-Beaulieu, Laboratoire de Chimie Minérale B, UA CNRS No. 254, Avenue du Géneral Leclerc, 35042 Rennes, France

(*Received* 4 *July* 1985)

Abstract—Research on superconducting Chevrel phases and other properties is reviewed: the impact of this large family of compounds on solid-state cluster chemistry, their novel pseudo-molecular structures with a new manner of coupling the clusters producing some outstanding physical properties: ternary superconductors, high T_c and H_{c_2} superconductors, interplay between superconductivity and long-range magnetic order, magnetic-field induced superconductivity and potential developement of superconducting wires are described; the electron donor–acceptor role of the Mo_6 cluster and cation donor–acceptor role of the channels of the structure of the quasi rigid Mo_6X_8 building blocks provide potential for cationic electrodes for secondary batteries.

STRUCTURAL OVERVIEW: CHEVREL PHASES AND SOLID-STATE CLUSTER CHEMISTRY

"*First comes synthesis*"

For over a decade, the outstanding superconducting properties of the ternary Mo chalcogenides, so-called Chevrel phases,[1] have stimulated a great amount of interest in the scientific community. These materials can be described by the formula $M_xMo_6X_8$, where M = Pb, Sn, Ln (lanthanon), K, Ca, Cu, Li . . . , $\simeq$40 different elements, and X is usually S, Se or Te (and occasionally Br or I). They are prepared at high temperatures (1000–1100°C) as black polycrystalline powders or single crystals.

Some of the highlights of this research will be described in this paper.

Certain ternary Mo chalcogenides have relatively high superconducting temperatures, as high as 15 K for $PbMo_6S_8$,[2] with an extremely high upper critical field approaching 60 T or more,[3] others with lanthanides[4] provide a unique opportunity to study the competition between superconductivity and long-range magnetic order.[5] Another property is the high reversible mobility of the counterions M^{n+}, e.g. lithium, copper and nickel ions, in these compounds allowing us to envisage cationic electrodes in secondary batteries.[6,7]

A great surprise was the discovery of the superconductivity of these sulfur- or selenium-based materials because superconductivity was until then exclusive to metals, alloys or intermetallic compounds [Pb, (Nb, Ti), Nb_3Sn]. The interest of these phases is that they are new ternary mineral-based cluster superconductors. So, the "ternary-superconductors" era began.[8] It was a breakthrough in superconductivity and the starting point for an intensive research on new ternary-cluster-based materials (borides, stannides, germanides, silicides and other chalcogenides).[5] Actually, it seems that the clustering of the transition-metal atoms has been found to be a feature common to ternary high-T_c superconductors.

Why do these materials which are bad conductors become very good superconductors? The answer is in the structural feature of the material: it contains Mo_6 octahedral clusters, "little bits of metal".

After the report of the discovery of Chevrel phases (over 100 Mo chalcogenides), parallel and subsequent synthetic efforts have led to the identification of many metal-rich halides, oxides and other ligands that possess a related, though unique, structural chemistry of considerable novelty. These are new and unusual compounds that lie at the interface between metal and molecular compounds.

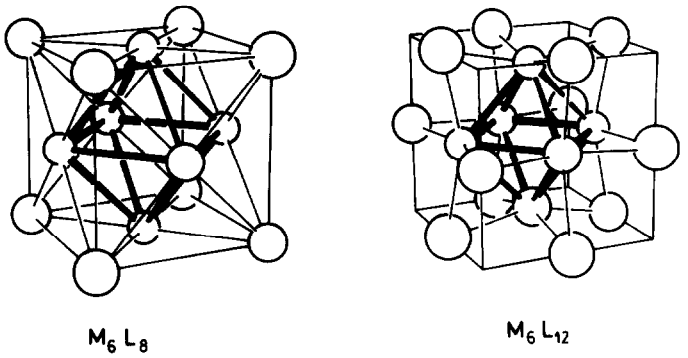

Fig. 1. Environment of the octahedral M_6 clusters (outlined in bold) in the M_6L_8 and M_6L_{12} units.

The novelty of most of these materials is due to the presence of one of the two fundamental cubic structural units, M_6L_8 and M_6L_{12}, which form the framework of their structure. The cubic block units containing octahedral clusters of the M_6L_8 type consist of eight non-metal atoms which lie above the triangular faces of the metal octahedron (μ_3-ligand), while, in the M_6L_{12} type, 12 non-metal atoms bridge the edges of the metal octahedron (μ_2-ligand) (Fig. 1).

A classification of most of these materials can be based on, first, progressive condensation of ligands (terminal *a*, bridging *a–a*, inner *i* and mixed *i–a*) and, second, condensation of clusters (apex, edge and face-sharing).

A basic structural principle apparently always applies to the bonding between isolated Mo_6 clusters throughout the solid. The empty region that otherwise lies outward (apical or exo position) from the metal vertex in each cluster is invariably occupied by a fifth non-metal neighbor. This leads to an $(M_6X_8)X_6$ pseudo-group. For instance, the additional six chlorine atoms that serve only to complete the clusters in $PbMo_6Cl_{14}$ are terminal $Pb(Mo_6Cl_8^i)Cl_6^a$. The discrete molecules $(Mo_6Cl_8)Cl_6^{2-}$ are linked together via the Pb^{2+} ions. On contrary, the exo atoms can serve to bridge the clusters between them in a three-dimensional solid as in Nb_6I_{11} or $Mo_6Cl_{10}S$: $(M_6X_8^i)X_{6/2}^{a-a}$, or both at once as in $MoCl_2$: $(Mo_6Cl_8^i)Cl_{4/2}^{a-a}Cl_2^a$. There are no direct metal–metal intercluster interactions. In other cases, some inner (*i*) atoms must also function as exo (*a*) atoms to vertices in other clusters. This occurs with Zr_6I_{12} where the connectivity is $(Zr_6I_6^iI_{6/2}^{i-a})I_{6/2}^{a-i}$.[9] A higher condensation is the cluster condensation, for instance the M_6X_{12} unit found in niobium monoxide, where the Nb atoms of the Nb_6 cluster are all connected in three dimensions, forms a framework of three-dimensional vertex-linked M_6 octahedra giving metallic properties.

Another type of condensation of M_6X_{12} units via edge-sharing Mo_6 clusters is described by McCarley[10] in $NaMo_4O_6$ compound. The $M_xMo_6X_8$ phases are the last step between the condensed-cluster phases and discrete clusters. They contain Mo_6X_8 building blocks but lack additional anions for the exo sites; they fill exo positions with six out of eight inner chalcogens from six other clusters: $(Mo_6X_{6/2}^{i-a}X_2^i)X_{6/2}^{a-i}$ (Fig. 2). The structure appears to be the face-capped equivalent of the edge-bridged Zr_6I_{12}.

Owing to the strength of these (MoX^{a-i}) intercluster bridges, the metal–metal intercluster interactions become important and are essential for understanding the striking physical properties of these materials. The Mo—Mo intercluster distance can vary between 3.1 and 3.6 Å; it depends on the nature of the chalcogen and the M-intercalated counterion. The average Mo—Mo intracluster distance is about 2.7 Å.[11]

In conclusion, it is a new manner of coupling Mo_6 clusters and Mo_6X_8 units. This intercluster metal–metal bonding persists, though often at longer distances in two dimensions for $Re_6Se_8Cl_2$,[12] where

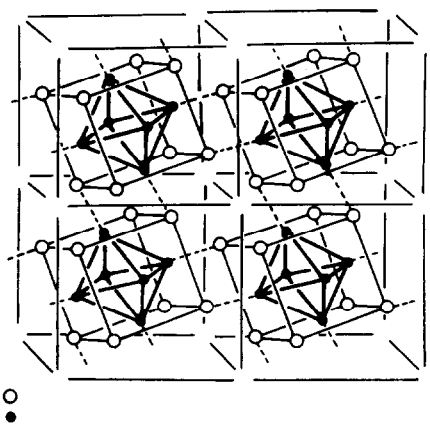

Fig. 2. A new way of stacking M_6L_8 cluster units: view of the rhombohedral structure of Mo_6X_8 binary compounds (X = S or Se).

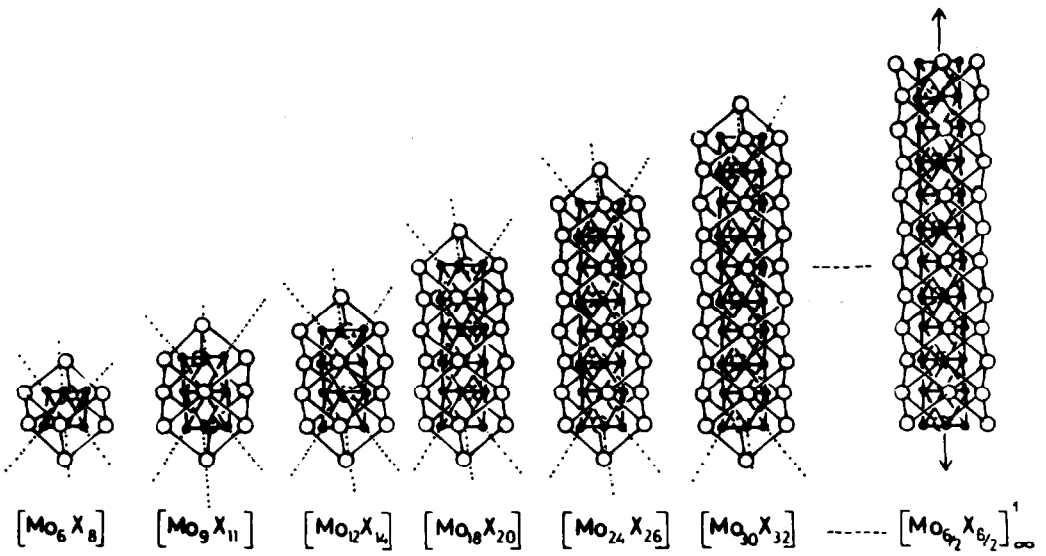

Fig. 3. Face-sharing Mo_6 cluster condensation.

the two additional chlorines cap two apices, and, in one dimension, in some of the derivatives, such as $Mo_6Br_6S_3$[13] and $Mo_6I_8Se_2$.[14]

FACE-SHARING OCTAHEDRAL CLUSTERS

It is natural that a non-metal : metal ratio below 8 : 6 leads to cluster condensation if the above concepts regarding face capping and exo bonding are maintained. Fortunately, the bonding is favorable and large extended clusters are formed by the face sharing of six–eight groups, namely the Mo_9X_{11}, $Mo_{12}X_{14}$, $Mo_{18}X_{20}$, $Mo_{24}X_{26}$ and $Mo_{30}X_{32}$ clusters shown in Fig. 3 along with the Mo_6X_8 cluster. The Mo_9X_{11} and $Mo_{12}X_{14}$ units were first discovered crystallizing with Mo_6X_8 clusters, but have recently been found alone. If we omit the Mo_9X_{11} unit, these new condensed clusters crystallize alone in a new large series, $M_{2n-2}Mo_{6n}X_{6n+2}$.[15]

The central units of these condensed clusters are planar Mo_3X_3 groups, while exo-bridging groups are far away at the ends of the extended clusters where pairs of intercluster Mo—X bonds again generate intercluster Mo—Mo bonds. The limit for this type of condensation is found in the $M_2Mo_6X_6$ phases. Here, the infinite chains $^1_\infty|Mo_3X_3^{-1}|$ have the same structure[16] as the central part of the discrete condensed clusters but without any interchain bonding (except that provided by the M^+ cations). The chains separated by the ternary element have a large intercluster Mo—Mo distance (6.4 Å) compared to 3.4 Å commonly observed for the Chevrel phases.

An interesting product would be the oxidized and cation-free material with presumably weak interchain interaction, Van der Waals' bonds only, in two dimensions. Actually, the metastable $(Mo_3Se_3)^1_\infty$ compound has been synthesized by deintercalation of the M^+ cation by an HCl flow at about 400°C.[17] So the fact of very weak interaction between the linear, one-dimensional chains allows us to think of separating the different molecular fibers in solution (Fig. 4). Tarascon and Di Salvo[18] have succeeded in obtaining the first example of monodispersed $(Mo_3X_3)^1_\infty$ clusters. The pseudo-one-dimensional compounds ($M_2Mo_6X_6$; X = Se or Te, M = Li or Na) can be dissolved in highly polar solvents such as DMSO and NMF. These solutions contain individual $(Mo_3X_3)^1_\infty$ chains; they are the first examples of purely inorganic transition-metal polymer solutions.

ELECTRONIC STRUCTURE AND PROPERTIES

It is generally agreed that the origin of superconductivity in Chevrel phases is the Mo4*d* electrons which are strongly localized at the Mo_6 octahedra because the Mo—Mo intercluster distance (3.3 Å) is about 10–20% larger than the Mo—Mo intracluster distance (2.7 Å). This gives rise to very narrow bands and high, needle-shaped peaks in the density of states $N(E_F)$. This picture is supported by several band structure calculations[19] which also show the common feature of a gap in $N(E)$ corresponding to 24 electrons per Mo_6 cluster or two electrons per Mo—Mo bond (as for $MoCl_2$).

Another idea concerning cluster atoms is the

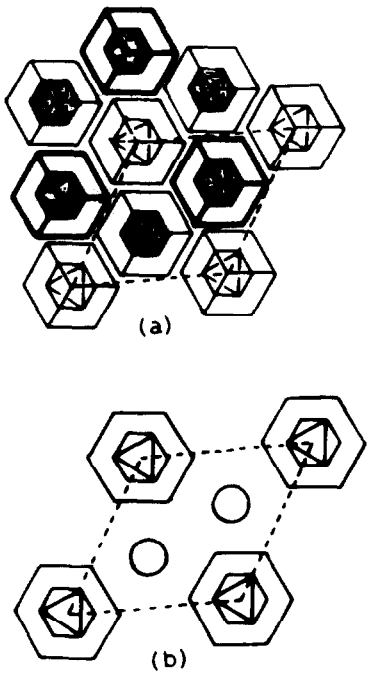

Fig. 4. Schematic projection onto the (001) basal hexagonal plane. (a) $M_xMo_6X_8$ and $M_{2n-2}Mo_{6n}X_{6n+2}$. For clarity, the M ions have been omitted. (b) $M_2Mo_6X_6$. Open circles are the M ions.

addition of interstitial atoms (or molecular units). Actually, the intercalation of e^- donors (metal M between the clusters) adds electrons to the clusters and leads to their stabilization. In Chevrel phases, the Mo_6S_8 binary phase cannot be prepared by high-temperature synthesis like the $M_xMo_6X_8$ phases but only by deintercalation of $M_xMo_6S_8$ (M = Fe, Co, Ni, Cu . . .) in dilute HCl.[20] Mo_6S_8 is a metastable compound containing only 20 electrons per Mo_6 cluster; it is the most electron-poor compound with electron-deficient Mo—Mo bond. So, the addition of metal atoms like copper atoms in the three-dimensional channels between the Mo_6S_8 units adds electrons to the cluster and stabilizes the cluster unit. The Mo—Mo intracluster bond becomes shorter (mainly d_1 Mo—Mo intracluster distance parallel to the three-fold axis of the hexagonal cell) and the octahedron becomes regular for 24 e^- per cluster. The Mo_6 cluster most oxidized is the largest cluster (20 e^-) and becomes smaller (24 e^-) when it is reduced.

The Mo_6 cluster plays the electron donor–acceptor role. That explains why a large variety of ions can be intercalated into the channels (Na^+, Pb^{2+}, Ln^{3+}, U^{4+} or Cu_x^+, $1 < x < 4$).

Curiously, it looks like the iron–sulfur cluster of the ferredoxin in the chloroplasts of the green plants which plays the e^- acceptor or donor role related to the symmetry and bonds of the cluster.[21]

Furthermore, M_6 metal cluster complex ions in homogeneous solutions are well known to be able to undergo redox reactions (one–four electrons) owing to the fact that the M_6 clusters are stable in electron-deficient states (delocalized e^--deficient bonding). It was shown some time ago[6] that the Mo cluster chalcogenides Mo_6X_8 (X = S or Se) with a framework lattice have a similar electronic flexibility and are able to undergo reversible topotactic electron–ion transfer reactions. These solid-state reactions are able to proceed:

$$xA^+ + xe^- + Mo_6X_8 \leftrightarrows A_x^+Mo_6X_8^{x-},$$

since the lattice provides, in addition to suitable electronic properties, an intersecting network of empty channels that can be occupied by ions of appropriate size and charge. Recently, a rechargeable non aqueous lithium–Mo_6S_8 battery has been investigated.[7]

The extreme flexibility of the structure allows us to synthesize, at high temperatures, the pseudo-binaries $Mo_6S_6Br_2$ and $Mo_6S_6I_2$, stabilized with 22 e^- per Mo_6 cluster. These compounds are very high T_c superconductors (T_c = 13.8 and 14 K, respectively) like the best $SnMo_6S_8$ and $PbMo_6S_8$ superconducting Chevrel phases (22 e^- per cluster).[22] The gradual filling of the conduction bands gives a gap for 24 e^- per Mo_6 cluster. So, the semiconducting pseudo-binary $(Mo_2Re_4)S_8$ with 24 e^- per cluster has been synthesized.[23]

Another interesting property is the ability to obtain at low temperatures new metastable ternary compounds by intercalation.[17] For instance, a $TlMo_6Se_8$ metastable compound is found superconducting at 12.2 K.[24] Likewise, activity and selectivity of Chevrel phase catalysts were further investigated.[25]

COEXISTENCE OR INTERPLAY BETWEEN MAGNETISM AND SUPERCONDUCTIVITY

Usually, small quantities of magnetic impurities in a metal will destroy its superconducting properties completely. Likewise, the addition of 3*d* elements (Fe, Mn . . .) ($\simeq$0.5 atom %) to $SnMo_6S_8$ or $PbMo_6S_8$ destroys superconductivity completely because the magnetic ions are distributed at random throughout the channels.

The fact that the Mo4*d* electrons are responsible for the superconductivity of these materials led us to think that a magnetic M element added to the channels of the structure, with a weak exchange interaction between e^- conduction and magnetic

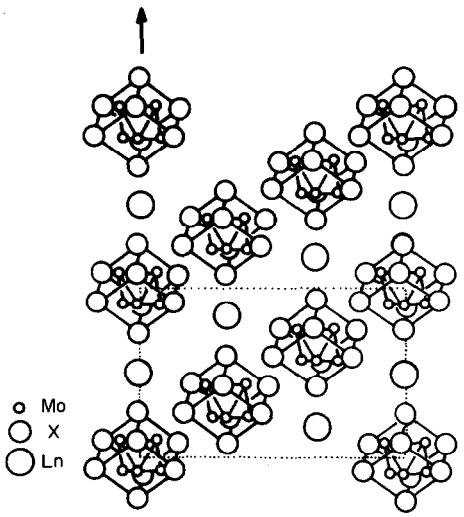

Fig. 5. Projection onto the $(11\bar{2}0)$ hexagonal plane of the $LnMo_6X_8$ chalcogenides. The Ln ions are about 6.5 Å apart. Ln is a lanthanide.

moment, i.e. a large M—Mo distance, would not affect the superconductivity too much; for instance large cations in origin site like Ln ions.

The Ln ions in the ternary $LnMo_6X_8$ compounds form a regular (nearly cubic) array and are screened from the Mo atoms (Ln—Mo > 4.10 Å) (Fig. 5).

Most of the $LnMo_6X_8$ chalcogenides become superconducting (except Ce and Eu) well above their magnetic ordering temperatures (very weak *d–f* exchange). In fact, it is a completely new situation: it was the first time that a system containing a regular lattice of magnetic ions was found to be superconducting. The question then arises: what does the superconducting state become when the magnetic order appears? Most $LnMo_6X_8$ compounds are found to order antiferromagnetically (Dy, Pr, Gd, Tb...) and it is now well established that superconductivity coexists with long-range antiferromagnetism.*

The $HoMo_6S_8$ compound becomes superconducting at 1.2 K, but becomes normal again below 0.65 K; this state is called reentrant superconductivity. At this temperature, the superconducting state is practically destroyed by the onset of the ferromagnetic order. Recently, a "domain walls" superconductivity has been discovered in the ferromagnetic state.[26]

Likewise, in a narrow temperature range near the ferromagnetic transition temperature, a sinusoidally magnetic state with a wavelength of about 250 Å coexists with a superconducting state.

As a result of the discovery of these compounds, research activity is very intense in cluster chemistry to solve the problem of the coexistence of superconductivity and magnetism, research on new materials and the manufacture of large single crystals.

MAGNETIC FIELD INDUCED SUPERCONDUCTIVITY

It is well known that a magnetic field tends to destroy superconductivity [curve $H(T)$]. So, a completely new situation occurs in a series $Sn_{1-x}Eu_xMo_6(S,Se)_8$. For $x \simeq 0.8$ and $T < 1$ K, superconductivity is destroyed at low magnetic field (0.6–1.0 T) and, in a striking manner, appears again around 8 T and finally disappears only above 20 T[27] (Fig. 6). Here, superconductivity appears with a magnetic field.

This phenomenon is explained by the exchange field compensation effect proposed by Jaccarino and Peter. The exchange field created by the 4*f* electrons of europium is opposite to the applied field. The conduction *d*-electrons "see" only the difference between the applied field and the internal exchange field. Previously, this two-domain superconductivity had never been seen in spite of a negative exchange interaction observed in many compounds

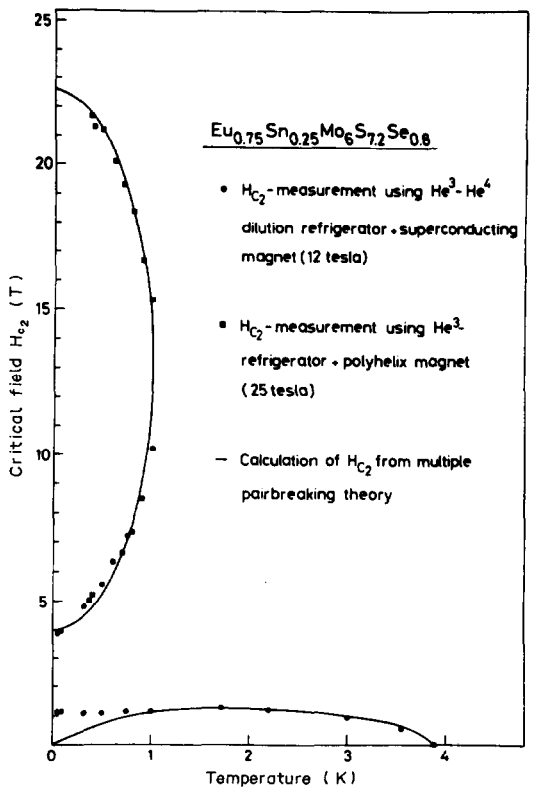

Fig. 6. First example of magnetic field induced superconductivity (from Ref. 28).

* This aspect is reviewed in Ref. 5.

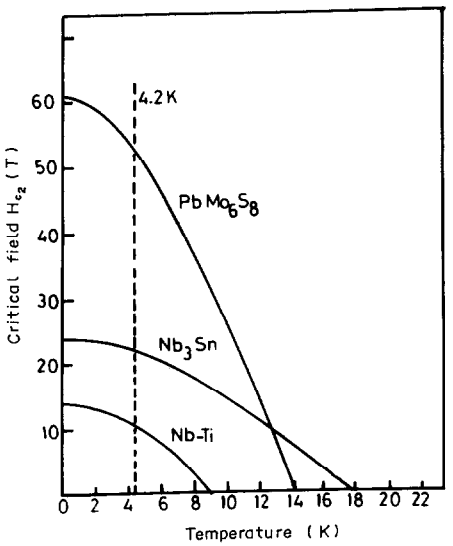

Fig. 7. Upper critical field H_{c_2} vs temperature. NbTi is a technical superconductor.

because of the coherence length, ξ, was too large ($H_{c_2} = \phi_o/2\pi\xi^2$) or the observed critical field was too low.

POTENTIAL FOR TECHNICAL APPLICATIONS

The compounds $PbMo_6S_8$, $PbGd_xMo_6S_8$, $SnMo_6S_8$ and $SnAl_xMo_6S_8$ were found to be the best superconductors in the Chevrel phases. The compounds were synthesized from mixed elemental powders by reaction in evacuated quartz ampoules heated to various temperatures for 24 h and then slowly cooled. $PbGd_xMo_6S_8$ gave the maximum T_c of 14.4 K, dH_{c_2}/dT of 6 T K^{-1}, H_{c_2} (4.2 K) higher than 51 T and estimated $H_{c_2}(0)$ of 60 T. This is of course the highest critical field of any bulk superconductor. It exceeds the highest value reported for the best binary compound, Nb_3Ge, by more than 20 T in spite of the fact that lead molysulfide has a much lower T_c.

The technical superconducting material NbTi has a T_c of 9 K and a H_{c_2} (4.2 K) of 10 T (Fig. 7). So, the ternary molybdenum sulfide $PbMo_6S_8$ is a very interesting candidate for future applications because of its high critical field, connected with a pseudo-molecular structure. But, this compound, like an A15 compound (for instance Nb_3Sn), is a brittle material,

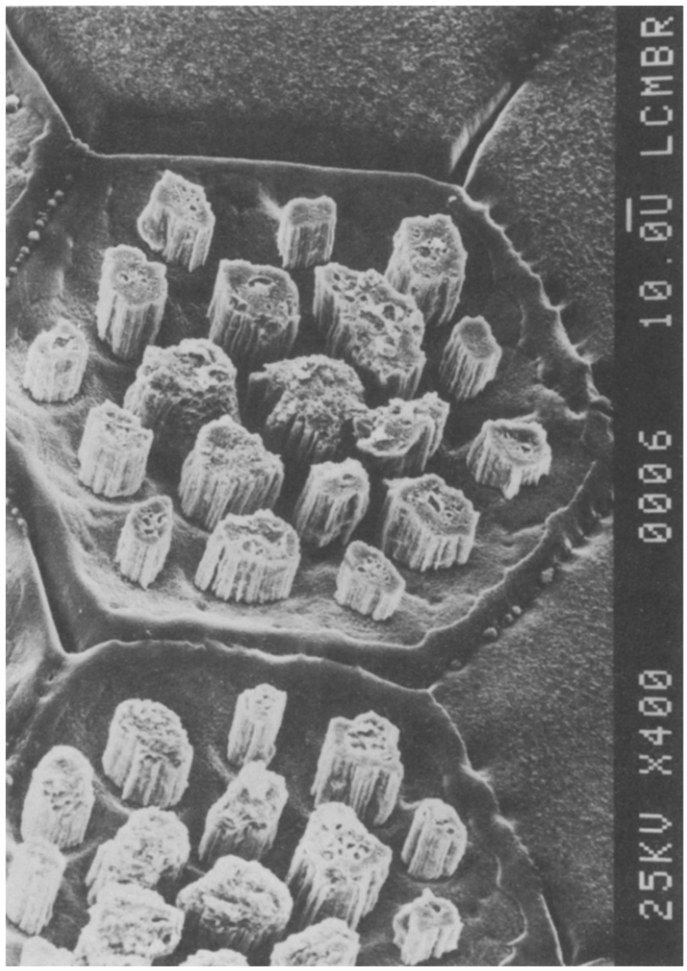

Plate 1. Details of the strands of Chevrel phase in a copper matrix (285 filaments in a 1-mm diameter wire).

whereas NbTi is a ductible alloy. Thus, this material cannot be manufactured easily into wires or ribbons.

The first results ($2–5 \times 10^7$ A m^{-2} at 4.2 K) were relatively low[28] but further results on bulk samples allow us to hope for the improvement of critical current densities: 3×10^8 A m^{-2} in a 10-T field[29] and 10^8 A m^{-2} at 14 T.[30] Investigations on thin films [31] and new progress in the processing of wires have revealed substantially higher critical current densities, J_c. Special technology has to be used to make wires. Two problems arise, the manufacture of wires and the current-carrying capacity. $PbMo_6S_8$ monofilamentary wires were fabricated by a powder process using Ta and Mo as sheath material.[32,33] The value of J_c is about 2×10^8 A m^{-2} at 6 T and more recently 10^8 A m^{-2} at 10 T.

The first attempt at multifilamentary feasibility has been performed by cold hydrostatic extrusion of powder-metallurgy-processed superconducting Chevrel phases. Hydrostatically extruded multifilamentary composites of $PbMo_6S_8$ powder in a copper billet were drawn into fine wires without intermediate annealing. The powder was isostatically compacted in the form of a cylinder. A less than 1-mm wire with 285 filaments of $PbMo_6S_8$ has been made.

The average filament is about 10–30 μm in diameter (Plate 1). The first superconducting characteristics of such monofilamentary wires exhibit T_c of 14 K, dH_{c_2}/dT of about 4 T K^{-1} and critical current densities at 4.2 K of about 10^8 A m^{-2} at 5 T.[34]

These results show promise for large-scale fabrication of powder-metallurgy processed superconductors.

It is clear that Chevrel phase material is capable of further improvement. The increase of one order of magnitude of critical current densities would make this new superconducting material competitive with respect to other technical superconductors (NbTi and Nb_3Sn). The range of fields where these materials will become interesting is between 15 and 40 T for the production of ultra-high static magnetic fields. Another problem will arise concerning degradation of the superconducting properties of the wires under mechanical strains due to magnetic forces.

Much remains to be done on basic and applied research on Chevrel phases.

(*Received* 18 *June* 1985)

Abstract—Nuclear quadrupole interactions as measured by time differential perturbed angular correlation on ^{99}Tc have been used to characterize molybdenum sulfides and an Al_2O_3-supported Mo catalyst. The technique proved successful for the detection of anion vacancies and hydrogen uptake in highly disperse unsupported MoS_2. The results obtained for the supported catalyst suggest the presence of non-stoichiometric MoS_2-like species with a high density of anion vacancies and presumably containing appreciable amounts of hydrogen.

The investigation of the ^{99}Tc (daughter of ^{99}Mo, $T_{1/2} = 66$ h) nuclear quadrupole interaction (NQI) on Mo sites in molybdates proved very useful for the differentiation between isolated and condensed Mo polyhedra in crystalline solids,[1] frozen molybdate solutions[2] and surface adsorbates.[3] The principle is as follows: isolated polyhedra are essentially undistorted and lead to a vanishing NQI at the Mo site: on the contrary, the condensation of polyhedra leads to a considerable distortion and hence to a well-defined non-zero NQI. Both the strength and symmetry of the electric field gradient (EFG) tensor are used as fingerprints to characterize a specific compound. In this contribution we report on the application of γ–γ-correlation spectroscopy of ^{99}Mo labels [TDPAC (time-differential perturbed angular correlation)] to protonated "MoS_2" species. "MoS_2" species appear to be very important in Mo-based supported catalysts.[4,5] The mode of hydrogen activation under catalytic conditions is not clear at present, although hydrogen uptake in MoS_2 has been clearly established.[6–8] On the basis of neutron-scattering data, the formation of SH groups during H_2 uptake has been suggested.[6,7] The proton uptake is expected to modify both the strength and symmetry of the EFG, even in cases where structural changes are minute. Therefore we performed TDPAC experiments to distinguish between ordinary MoS_2 and protonated forms.

EXPERIMENTAL

Spectrometer

The TDPAC spectrometer was a conventional fast–slow four-detector set-up with NaI(Tl) scintillation crystals mounted on RCA 8850 photomultipliers. The experimental time resolution (τ_{res}) was typically 2.2 ns. The four detectors are mounted in a plane at 90° intervals. Since each detector served as a start-and-a-stop detector eight out of 12 possible coincidences (four × 180°, four × 90°) were stored simultaneously.

TDPAC and nuclear quadrupole interaction

The coincidence count rate between two successively emitted γ-quanta in a nuclear γ–γ-cascade can be written as:[9]

$$W(t, \theta) = e^{-t/\tau_N}[1 + A_{22} G_{22}(t)(P_2 \cos \theta)], \quad (1)$$

‡ Author to whom correspondence should be addressed.

where τ_N = the nuclear lifetime of the intermediate nuclear state of the cascade, A_{22} = anisotropy of the cascade (depends on nuclear properties only), $P_2 \cos\theta$ = Legendre polynomial, θ = angle between emission direction of the first and second γ-quantum, and $G_{22}(t)$ = perturbation function (contains all information on the NQI).

In the present experiment, we use the 740–181 keV cascade in ^{99}Tc which is fed via β-decay from ^{99}Mo ($T_{1/2}$ = 66 h). For this cascade we have τ_N = 5.05 ns, $A_{22} \cong +0.1$ and spin $I = \frac{5}{2}$ for the intermediate (181-keV) state. The NQI leads to a splitting of the $\frac{5}{2}$ state into three substates with quantum numbers (m) of $\pm\frac{5}{2}$, $\pm\frac{3}{2}$ and $\pm\frac{1}{2}$. For an axial EFG tensor, the energy differences $E_{\pm 3/2} - E_{\pm 1/2}$, $E_{\pm 5/2} - E_{\pm 3/2}$ and $E_{\pm 5/2} - E_{\pm 1/2}$ are $\hbar\omega$, $2\hbar\omega$ and $3\hbar\omega$, respectively, where $\omega = 3\pi\nu_Q/10$ with the quadrupole frequency:

$$\nu_Q = e^2qQ/h. \tag{2}$$

eQ denotes the nuclear quadrupole moment, eq is the largest component of the EFG tensor (V_{zz}), and h is Planck's constant. For this case the perturbation function reads for a polycrystalline (random powder) sample:

$$G_{22}(t) = 0.2 + 0.371 \cos\omega t + 0.286 \cos 2\omega t + 0.143 \cos 3\omega t. \tag{3}$$

If the EFG tensor deviates from axial symmetry, both the frequency (ω), its harmonics, and the coefficients in front of the cosine terms depend on the asymmetry parameter (η):

$$\eta = \left(\frac{V_{xx} - V_{yy}}{V_{zz}}\right), \tag{4}$$

with V_{ii} being the EFG tensor components in the principal-coordinate system. The expression of eqn (1) with eqn (3) has to be convoluted with the experimental time resolution. The difficulty for practical applications with this γ–γ-cascade lies in the fact, that τ_N is rather short, not much larger than our experimental time resolution. Furthermore, eQ is presumably small and hence typically one precession period (T) ($= 2\pi/\omega$) or less can only be observed.

Sample preparation

In all cases ^{99}Mo ($T_{1/2}$ = 66 h) was obtained by irradiating Mo-containing samples with natural isotopic abundance in a thermal neutron flux of 10^{13} n cm^{-2} s for a few hours. In some cases radiation damage occurs and has to be considered. In the following we list the important aspects of all samples used.

MoO_3. This was used in neutron-irradiated form: irradiation causes oxygen vacancies (colour centers);[10] the disappearance of these colour centers with time was monitored.

MoS_2. This was prepared by iodine vapour transport from the elements; used in neutron-irradiated form since no radiation damage was detected; in one case it was subsequently treated in an H_2 atmosphere.

$Li_{1.1}(NH)_3)_{0.6}MoS_2$: This was prepared by reaction of neutron-irradiated MoS_2 in excess Li dispersed in liquid NH_3 at -60°C for $\frac{1}{2}$ h.[11]

$(NH_4)_2MoS_4$. This was prepared by passing gaseous H_2S through an ammoniacal ammonium paramolybdate (APM) solution,[12] neutron irradiated, dissolved in water and subsequently precipitated with butanol–acetone to eliminate radiation damage.

Amorphous MoS_3 (a-MoS_3). This was prepared from neutron-irradiated $(NH_4)_2MoS_4$ by thermal decomposition at 473 K.[13]

"H_xMoS_2". This was prepared from radioactive a-MoS_3 by H_2 treatment at 673 K for 48 h.[13]

"MoS_2" (*highly disperse*). This was prepared as "H_xMoS_2" but stored in air for at least half a year, and therefore assumed to be substantially oxidized: it was neutron irradiated, and reduced and sulfided in H_2–H_2S (9 : 1) at 623 K for 18 h; subsequently it was annealed at Ar at 623 K for 40 h, and subsequently treated with H_2 at 623 K for 120 h.

Mo12Al. Al_2O_3 (BET surface area 148 m^2 g^{-1}), obtained from CONDEA PURAL SB by calcination in air at 1023 K for 16 h without further preactivation before use, was impregnated with neutron-irradiated APM solution (12% MoO_3 equivalent) by a pore-filling method, dried, calcined at 773 K for 2 h in air, sulfided in H_2–H_2S (9 : 1) at 623 K for 18 h, and subsequently treated with H_2 at 623 K for 18 h.

RESULTS AND DISCUSSION

In the following we use ω, η and the possible population in multicomponent spectra to characterize and identify Mo species.

Colour centers in MoO_3

The NQI at ^{99}Tc on Mo sites in MoO_3 has been studied previously[1] and will not be discussed here. Of interest in the present paper is the NQI associated with the colour centers which are due to oxygen vacancies.[10] These lead to a rather high ω of the order of 1.0–1.2 GRad s^{-1} as compared to the undistorted Mo environment with ω = 210 MRad s^{-1} and η = 1.0. In Fig. 1 we show the time evolution of this high-frequency component. ω first shifts from almost 1.2 to 1.0 GRad s^{-1} and finally disappears. This is

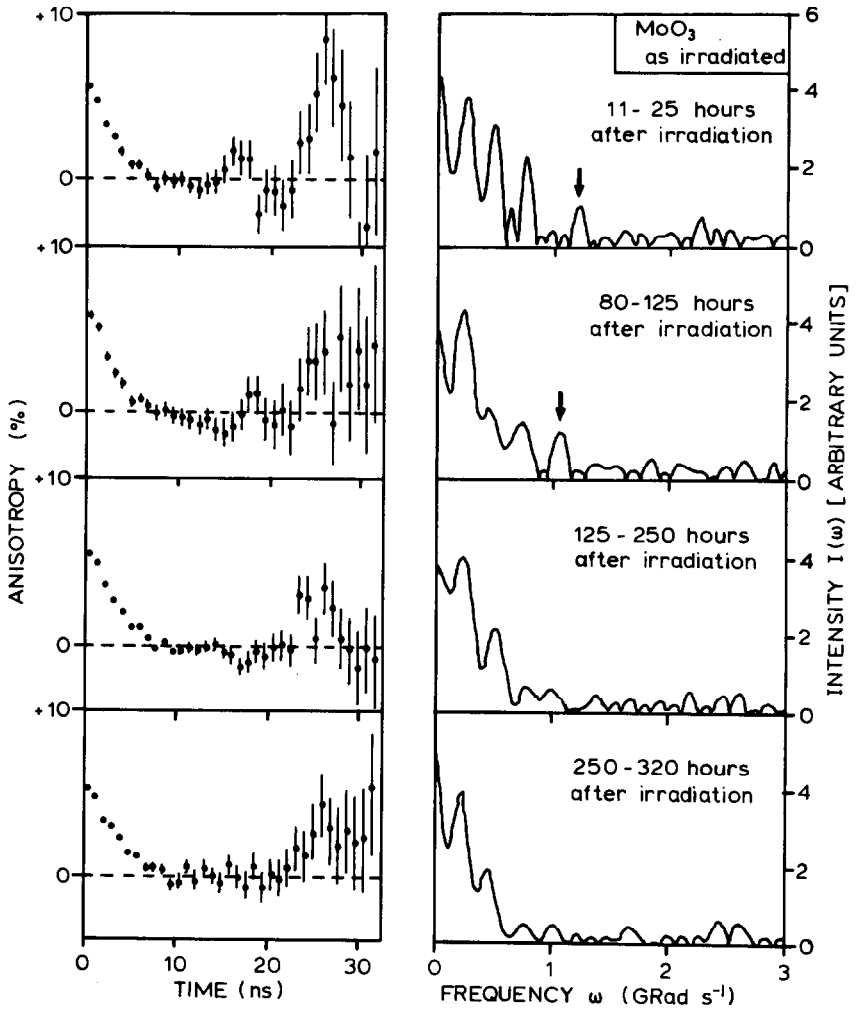

Fig. 1. TDPAC spectra (left) and their Fourier transforms (right) for neutron-irradiated MoO_3 at 300 K. The high-frequency components around $\omega = 1.0 \ldots 1.2$ GRad s^{-1}, marked by arrows, are attributed to colour centers (oxygen vacancies) and disappear gradually with time due to oxygen vacancy recombination.

interpreted to be the consequence of oxygen vacancy recombination. We report such high-frequency components in catalytically relevant materials below.

Bulk MoS_2

Since MoS_2-like species are generally assumed for the surface species of Al_2O_3-supported sulfided Mo-based catalysts[4,5] a study of bulk MoS_2 seemed appropriate. Both a polycrystalline powder and a single crystal in several orientations were studied and yielded practically identical results: $\omega = 112$ MRad s^{-1} and $\eta = 0.0$. A typical TDPAC spectrum for a single crystal averaged over three different orientations is shown in Fig. 2 (top). Axial symmetry is required because MoS_2 has a three-fold rotation axis around Mo sites. Powder samples at various temperatures from 77 up to 673 K showed that the temperature variation of the EFG is negligible. Furthermore, radiation damage appeared to be unimportant, since annealing at 673 K yielded no change. Interestingly enough, treatment in H_2 for at least 48 h did not show any change in ω and η. Hence, there was no indication of hydrogen uptake in bulk MoS_2. The results of least-squares fits like eqn (3) to the data points are summarized in Table 1.

"H_xMoS_2"

A TDPAC spectrum for the starting material $(NH_4)_2MoS_4$ is shown in Fig. 3. Apart from the small fraction of a high-frequency component with $\omega =$ 341 MRad s^{-1} (with $\eta = 0.0$ assumed), the main

[a] If no error limits are quoted the corresponding quantity was not treated as an adjustable parameter. Unless stated otherwise we assumed $\eta = 0$ and a negligible spread in ω.

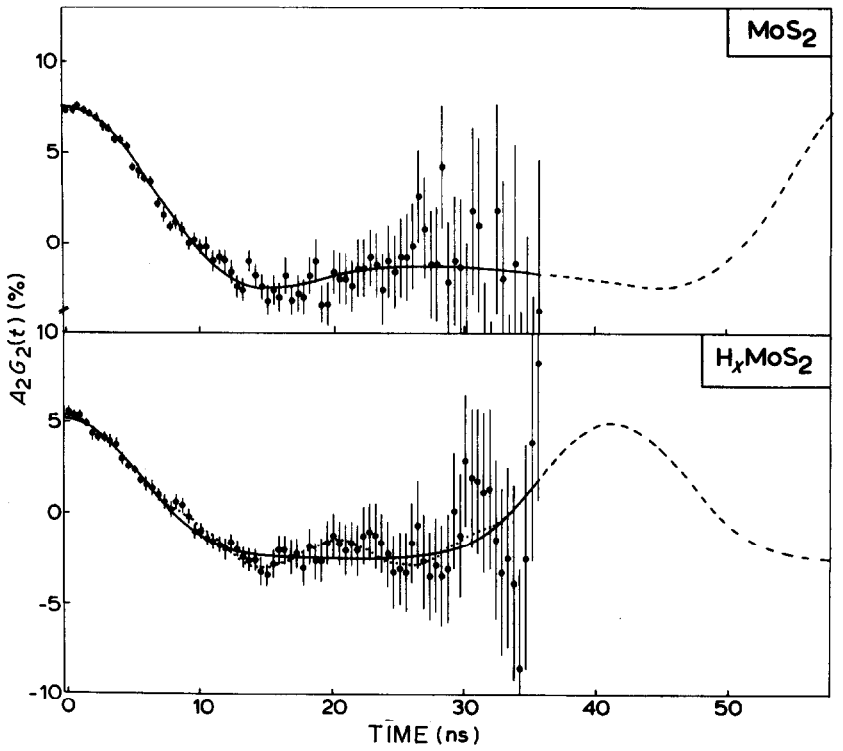

Fig. 2. TDPAC spectrum for a MoS_2 single crystal (averaged over three different orientations) at 300 K (top) compared to "H_xMoS_2" obtained by treating amorphous MoS_3 in H_2 at 673 K for 40 h (bottom). The dotted line in the lower picture represents an improved fit allowing for a second, high-frequency site.

interaction can be described as a distribution with a width (Γ) (35 MRad s^{-1}) centered around a mean value of $\omega = 0$ MRad s^{-1}. This is in good agreement with earlier observations for compounds with isolated Mo–O tetrahedra.[1,2] Apparently, the MoS_4 tetrahedron is only weakly deformed. The small component with $\omega = 341$ MRad s^{-1} is ascribed to Mo sites with a defective environment which could be a consequence of the precipitation procedure. The spectrum, taken *in situ* for a-MoS_3, obtained by thermal decomposition of $(NH_4)_2MoS_4$, is shown in Fig. 4. One clearly observes a main-frequency component of $\omega = 93$ MRad s^{-1} and $\eta = 0.0$, and

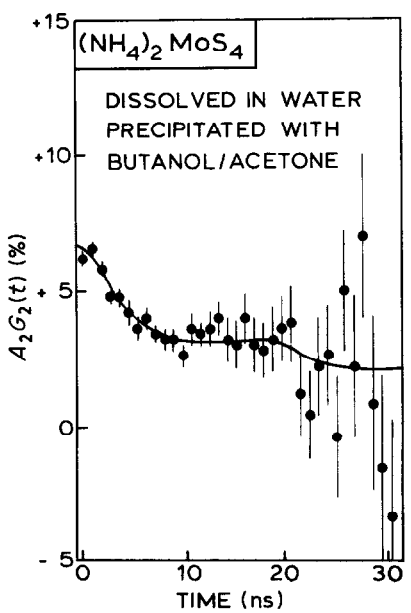

Fig. 3. TDPAC spectrum for $(NH_4)_2MoS_4$ at 300 K.

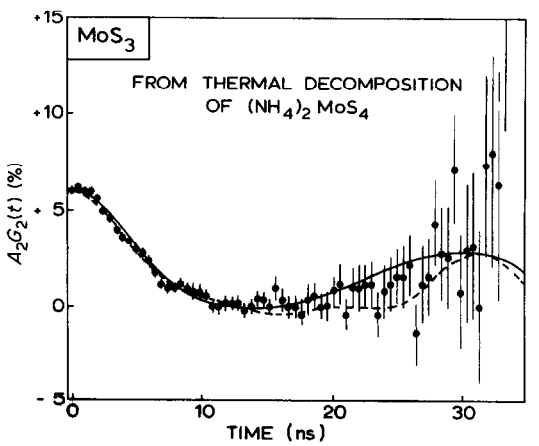

Fig. 4. TDPAC spectrum for a-MoS_3 at 300 K. Solid line: single site with a broad frequency distribution; dashed line: two equally populated sites with sharp frequencies.

another high-frequency component with $\omega = 194$ MRad s^{-1} ($\eta = 0$ assumed) with about equal populations. It appears that in a-MoS_3 two inequivalent Mo sites occur. The recently proposed structure models[14] would be consistent with two inequivalent Mo sites. The TDPAC spectrum for hydrogen treated a-MoS_3 is shown in Fig. 2 (bottom). A comparison with the spectrum for bulk MoS_2 [Fig. 2 (top)] shows that a different compound, denoted "H_xMoS_2", has been formed rather than MoS_2. The results of least-squares fits for all three compounds discussed above are listed in Table 1. In order to characterize this "H_xMoS_2" compound further, we studied the effect of charge transfer on the NQI in the intercalation compound $Li_{1.1}(NH_3)_{0.6}MoS_2$. This compound seemed most appropriate because the Li uptake and consequently the charge transfer is extremely large. The cointercalation of NH_3 ensures a high intercalate mobility and the solvent NH_3 is thought to prevent the reduction to Mo metal. The measurements were performed at 195 K to minimize amide formation. Unfortunately we did not observe a single-frequency component as expected for this compound. Rather we observed a smaller fraction (20%) with $\omega = 485$ MRad s^{-1} ($\eta = 0.0$ is assumed), a larger fraction (65%) with $\omega = 119$ MRad s^{-1} and $\eta = 0.0$, and the remainder with $\omega = 0$ MRad s^{-1}. If we identify the high-frequency signal with the maximum possible uptake of Li, i.e. a charge transfer of 1.1 e^-/MoS_2, we can quote a frequency increase with charge transfer of 340 MRad s^{-1} per e^-. This compares qualitatively with our previous observations in MoO_3 and $Na_{1/2}(H_2O)_xMoO_3$.[1] The larger part of the signal may be identified with either unreacted MoS_2, with a subsequent decomposition product, or both. The least-squares fit parameters for $Li_{1.1}(NH_3)_{0.6}MoS_2$ are also listed in Table 1. Since the protons in H_xMoS_2 are known to reside in the van der Waals' gap and to form S—H bonds[6] we can derive a value of $x = 0.12(2)$ for the hydrogen uptake in our "H_xMoS_2". Of course, this number has to be used with precautions because the comparison with just a single intercalation compound could be dangerous. However, previous experience with the rather extensively studied intercalation compounds of 2H-TaS_2[15] showed that a rather universal correlation between the NQI at Ta sites and the charge transfer exists, and we suggest that this holds true for MoS_2, too. The above estimate is in agreement with the values derived from ^1H NMR[16] and volumetric measurements.[6–8,17] Since bulk MoS_2 does not take up hydrogen we consider the reduction process from a-MoS_3 to "H_xMoS_2" and its high degree of dispersion essential for the H_2 dissociation and uptake in the form of protons.

Highly disperse "MoS_2"

The behaviour of highly disperse "MoS_2" which was partially oxidized was found to be quite different compared to "H_xMoS_2" freshly prepared by reduction in H_2 of a-MoS_3. This material was studied after various treatments: (a) as irradiated, (b) during H_2 treatment, (c) after reduction and sulfidation in H_2–H_2S, (d) during Ar treatment following (c), and (e) during H_2 exposure following (d). All procedures were performed *in situ*. The results for these samples from least-squares fits are summarized in Table 1.

First, we note that the frequency for the compound measured as irradiated, $\omega = 134$ MRad s^{-1}, disagrees with that for bulk MoS_2. We tend to attribute this to the partial oxidation rather than to the disperse nature because the NQI is a very short-range interaction and the ratio of surface/volume is still large for our material with a surface area of approximately 50 m^2 g^{-1}. Second, the interaction frequency decreases considerably to $\omega = 75$ MRad s^{-1} ($\eta = 0.0$ is assumed) upon H_2 treatment. Simultaneously, a second rather high frequency component with $\omega = 1.2$ GRad s^{-1} ($\eta = 0.0$ is assumed) shows up. The low-frequency component cannot be assigned at present. The high-frequency component is considered to be due to the formation of a substantial fraction of anion vacancies ($\sim$2–3%, if each vacancy is assumed to be signalized by three Mo neighbours), in analogy to the O vacancies in the MoO_3. With regard to the presumably very small quadrupole moment of the 5/2 state in ^{99}Tc these high frequencies imply very high EFGs which can hardly be produced in the presently studied compounds without defects in the first coordination shell.

When the starting "MoS_2" was reduced and sulfided initially we observe $\omega = 115$ MRad s^{-1} and $\eta = 0.0$, quite comparable with the results for bulk MoS_2. There are no vacancy type frequency components. It is, however, dangerous to conclude that O has been substituted quantitatively by S and that no proton uptake has occurred. This is borne out by subsequent treatments. First, treating such a sample in Ar at 623 K leads to dramatic changes: within the first 24 h ω increased to 204 MRad s^{-1} and a vacancy type frequency at $\omega \sim 950$ MRad s^{-1} with a fraction of 31% shows up (see Table 1). During prolonged Ar treatment ω decreases to 153 MRad s^{-1} and the high-frequency component gradually disappears. It is difficult to understand that the Ar treatment causes such drastic changes unless the preceeding reduction and sulfidation was incomplete and hydrogen uptake had occurred. In this case a partial release of H_2 could lead to H_2S and H_2O

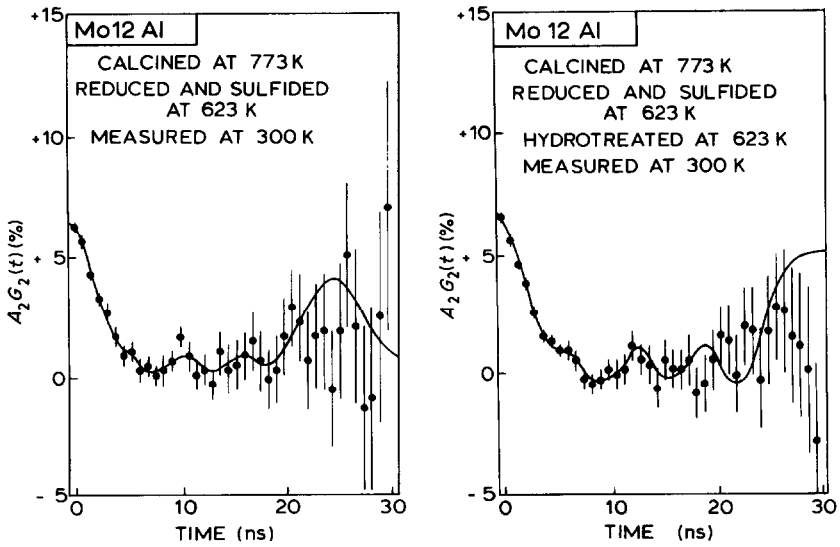

Fig. 5. TDPAC spectra for a reduced–sulfided Mo12Al catalyst (left) and after subsequent H_2 treatment (right).

formation and hence create anion vacancies. A further hint of an incomplete reduction and sulfidation follows from the fact that a subsequent H_2 treatment of the Ar-treated sample yields $\omega = 62$ MRad s^{-1}, in very close agreement with the results for the starting material which was H_2 treated only. During the first 24 h vacancy type high-frequency components reappear, which later vanish. Whereas the appearance of defect sites is very likely related to sulfur loss, their disappearance with time can tentatively be connected with lattice relaxation or self-intercalation. It is, however, not understood why these self-intercalates do not show up in the spectra as a new distinct-frequency component.

Mo12Al *catalysts*

We are now in a position to attack the final goal: the characterization of the surface species on sulfided Mo-based supported catalysts. Typical TDPAC spectra taken for a reduced and sulfided Mo12Al catalyst and after a subsequent H_2 treatment are shown in Fig. 5. The results derived from least-squares fits are listed in Table 1. We note that in both spectra the main component has $\omega \sim 220$–260 MRad s^{-1}; a further characteristic high-frequency component of $\omega = 1.2$ GRad s^{-1} (before H_2 treatment) and $\omega = 1.0$ GRad s^{-1} (after H_2 treatment) shows up. Both observations resemble those made for highly disperse, partially oxidized, reduced and sulfided and Ar-treated "MoS_2", especially for the spectra taken during the first 24 h. The high-frequency components around $\omega = 1.0$–1.2 GRad s^{-1} show that a large fraction ($\sim 10\%$) of anion vacancies is produced during reduction and sulfidation.

CONCLUSIONS

It has been shown that hydrogen uptake in MoS_2 and anion vacancy formation can be monitored via the ^{99}Tc NQI by TDPAC. The results obtained for unsupported "MoS_2" can be used as reference data for the interpretation of the results obtained for sulfided Mo12Al catalysts. Bulk MoS_2 or "$H_{0.12}MoS_2$" cannot be detected on Mo12Al after the sulfidation conditions applied in this study. The comparison with unsupported highly disperse "MoS_2" suggests that, during reduction and sulfidation of the oxidic precursor, a non-stoichiometric MoS_2-like species with a high concentration of anion vacancies ($\sim 10\%$) is formed which presumably has taken up a fair amount of hydrogen. Our data do not allow us to draw a conclusion concerning the completeness of the sulfidation. Experiments addressing the question whether there is a correlation between the catalytic activity of Mo-based supported catalysts and the anion vacancy concentration are presently under way.

Acknowledgements—We are grateful to Prof. W. K. Hall for valuable discussion during the course of this work and for providing the highly disperse MoS_2 powder. We thank Prof. A. Wold for an MoS_2 single crystal. The irradiation of the samples was kindly performed at the Forschungsreaktor Garching. This work was supported by the Deutsche Forschungsgemeinschaft and the Deutsche Gesellschaft für Mineralölwissenschaft und Kohlechemie e.V.

EFFECT OF PHOSPHORUS ON THE OXIDATION SELECTIVITY OF MoO_3-BASED CATALYSTS

M. AI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227, Japan

(*Received* 7 *June* 1985)

Abstract—Vapor-phase air oxidation of propylene, 1-butene, propionic acid and isobutyric acid was performed with a variety of MoO_3-based mixed oxides and heteropoly compounds. The results indicate that the selectivity is not fully explained by the difference in the reactivities between the reactant and the product because the oxidation reaction is accompanied by C—C bond fission. A remarkable increase in the selectivity was observed by the addition of phosphorus. It is proposed that phosphorus plays a role in eliminating the basic sites which promote the C—C bond fission.

MoO_3 and V_2O_5 are fundamental components of selective oxidation catalysts because both oxides possess acidic and, at the same time, redox[1] properties. The oxidation activity of metal-oxide catalysts has been studied mainly in connection with their redox function. However, such data are not sufficient to explain the catalytic activity and selectivity in the case of mild oxidation, though the possession of a redox function is undoubtedly one of the necessary conditions for an oxidation catalyst.

Recently, it has been proposed that, in the case of mild oxidation, the catalytic activity is governed by the activation of the reactant molecule, which is attributed to an acid–base-type interaction between the catalyst surface and the reactant to be oxidized, rather than by the activation of oxygen, and that the selectivity is brought about by the difference in the mode or degree of reactant activation.[2]

The presence of a large difference in reactivities between the reactant and the product is surely a necessary condition to achieve a high selectivity, but it is not always a sufficient condition. For example, oxidation catalysts effective for production of acidic products are, without exception, strongly acidic oxides, e.g. MoO_3- or V_2O_5-based oxides. However, it is still difficult to explain the selectivities only by the possession of a sufficiently acidic property in the case of certain partial oxidations, such as formation of maleic anhydride from butene or butane, of acrylic acid from propylene, and of methacrylic acid from methacrolein or isobutyric acid.

In this connection, it is also proposed that the oxidation reaction is sometimes accompanied by a side pathway consisting of C—C bond fission, which is considered to be promoted by the action of acidic sites, much as the oxidation reations.[3]

EXPERIMENTAL

In view of this, and to extract some new rules effective for a better understanding of the selectivity of MoO_3-based catalysts for an acid formation reaction, the following four reactions were studied as models of competitive reactions between oxidation and C—C bond fission:

$$CH_3CH_2COOH \begin{cases} \nearrow CH_2{=}CHCOOH \\ \searrow CH_3CHO \text{ or } CH_3COOH + CO_x \end{cases} \quad (1)$$

$$CH_3CH(CH_3)COOH \begin{cases} \nearrow CH_2{=}C(CH_3)COOH \\ \searrow CH_3COCH_3 \text{ or } CH_2{=}CHCH_3 + CO_x \end{cases} \quad (2)$$

$$CH_2{=}CHCH_3 \begin{cases} \nearrow CH_2{=}CHCOOH \\ \searrow CH_3COOH + CO_x \rightarrow CO_x \end{cases} \quad (3)$$

$$CH_2{=}CHCH_2CH_3 \begin{cases} \nearrow \text{maleic anhydride} \\ \searrow 2CH_3COOH \end{cases} \quad (4)$$

RESULTS AND DISCUSSION

The selectivities of each reaction at a fixed conversion are listed in Table 1.

The results may be summarized as follows:

(i) The reactants in the four reactions are much more reactive than the corresponding acidic products,[3] indicating that the selectivities cannot be explained by differences in reactivities between the reactant and the product.

(ii) The addition of V_2O_5 or amphoteric oxides such as TiO_2, SnO_2, Fe_2O_3, and Co_3O_4 enhances the oxidation activity, but it cannot suppress the C—C bond fission.

(iii) A remarkable increase in the selectivities for partial oxidation is brought about by the addition of phosphorus.

As for the role of phosphorus, it may be possible to connect the high selectivity with some structural aspects commonly observed in phosphorus-containing catalysts, but we would like to ascribe the high selectivity to some chemical property of phosphorus. As chemical factors, (i) an acidic property, and (ii) a basic property are presented as possibilities.

The addition of phosphorus to MoO_3 or V_2O_5 causes a marked increase in the acidic property,[4] but the addition of V_2O_5 to MoO_3 and that of amphoteric oxides to MoO_3 or V_2O_5 also causes a marked increase in the acidic property.[2] On the other hand, it is unlikely that the acidic sites promote the oxidation reaction in preference to the C—C bond fission. Therefore, the selectivity may not be related to the acidic property.

Accordingly, the view that the addition of phosphorus plays a role in eliminating the basic sites seems to be probable. This leads us to assume that the C—C bond fission is promoted by a cooperative action of the acid and base. Indeed, it has already been pointed out that the C—C bond fission in the oxidation of butene is ascribed to the action of basic sites at the step

$$CH_3CH(OH)CH_2CH_3 \rightarrow CH_3COCH_2CH_3,$$

and that methylethylketone is susceptible to decomposition.[5] The situation may be the same in the case of the oxidation of propylene; the

$$CH_3CH(OH)CH_3 \rightarrow CH_3COCH_3$$

step is promoted by the action of a base, and acetone is decomposed to acetic acid and CO_x.[6] However, it is still unsolved whether the C—C bond fission of the carboxylic acids proceeds in the same manner. Further studies are needed.

It should be noted that, if the basic property is eliminated completely by the addition of acidic compounds such as phosphorus, the catalyst surely loses its oxidation activity, because the oxidizing sites are closely related to the basic sites.[2,7] It may be most important for the selective-oxidation catalysts that the basic sites are suppressed just sufficiently not to eliminate completely the oxidizing function. We consider at present that phosphorus is best for this

SURFACE STRUCTURE AND REACTIVITY OF MoO_3

JERZY HABER and EWA SERWICKA*

Institute of Catalysis and Surface Chemistry, Polish Academy of Sciences,
30-239 Krakow, ul. Niezapominajek 1, Poland

(*Received* 18 *June* 1985)

Abstract—Interaction of propene and diallyloxalate vapour with MoO_3 specimens of different crystallite habits was studied by ESR. The reducibility of a sample whose surface was predominantly the (010) crystal plane increased greatly when the diallyloxalate was used. The results indicate that the selective insertion of lattice oxygen into the hydrocarbon molecule occurs at the (010) basal plane, whereas the side crystal faces are responsible for the activation of a propene molecule.

It is now well-established that in molybdate catalysts it is the molybdenum–oxygen sublattice that is responsible for the insertion of oxygen into the organic molecule in the selective oxidation of hydrocarbons. When an organic molecule is activated by some other route, pure MoO_3 performs the insertion of oxygen very efficiently.[1] In an extensive catalytic study Brückman *et al.*[2] reported that the yield of acrolein from allylic compounds was linearly dependent on the surface area of the (010) face, showing that only this plane was responsible for insertion of oxygen into the activated hydrocarbon molecule. On the other hand, the product distribution in propene oxidation could be explained by assuming that its activation took place at the side (100) and (101) faces, and total oxidation occurred at all faces of the MoO_3 catalyst.

In order to elucidate this point further, the ESR study reported here on the interaction of MoO_3 specimens of different crystallite habits with propene and diallyloxalate was undertaken.

EXPERIMENTAL

Two polycrystalline MoO_3 materials of different crystal habits were used:

(a) Climax Molybdenum Co. product with plate-like crystallites exposing predominantly the (010) face, BET surface area 0.6 $m^2 g^{-1}$, denoted MoO_3(p).

(b) Climax Molybdenum Co. product with needle-like crystallites and no preference for any particular crystal face, BET surface area 2.7 $m^2 g^{-1}$, denoted MoO_3(n).

Both materials were subjected to standard oxidizing pretreatment in air at 620 K for 24 h in order to remove possible organic impurities, and to assure sample stoichiometry. Subsequently approximately 0.05 g of the MoO_3 samples were placed in quartz ESR tubes, connected to the vacuum line, outgassed at room temperature for 0.5 h *in vacuo* at 10^{-3} Pa and subjected to reduction with propene or diallyloxalate in the temperature range 400–570 K for different periods. After each stage of reduction the ESR spectrum was recorded. Propene and diallyloxalate used were purified by repeated freeze–thaw pump cycles.

ESR spectra were recorded at 77 and 293 K by using an ESR X-band spectrometer type SE/X produced by the Technical University, Wroclaw, equipped with a magnetometer. Spin densities were estimated by use of a $VOSO_4$ standard. A DPPH sample ($g = 2.0036$) was used for determination of g values.

RESULTS AND DISCUSSION

After the standard pretreatment in air, both the MoO_3(p) and MoO_3(n) were white and, according to ESR analysis, contained negligible amounts of Mo^{5+} ions (0.0002%).

Upon heating in an atmosphere of C_3H_6 at 1.3×10^4 Pa the specimens of different crystal habit showed different behaviour. The MoO_3(n) sample

* Author to whom correspondence should be addressed.

changed colour to white-greyish at 400 K, and simultaneously a strong signal appeared in the ESR spectrum (Fig. 1). The main ESR absorption was characterized by $g_x = 1.943$, $g_y = 1.954$, and $g_z = 1.878$, and a well-resolved hyperfine pattern due to the 25% abundant ^{95}Mo and ^{97}Mo isotopes ($A_x = 3.2$ mT, $A_y = 3.0$ mT, and $A_z = 7.0$ mT). A similar spectrum was reported by us for the first time for polycrystalline MoO_3 reduced with atomic hydrogen at room temperature.[3] There the experimental conditions ensured samples with fully occupied anionic sites resulting in an octahedral environment of Mo^{5+}. Hence the above signal can be ascribed to an hexacoordinated Mo^{5+} ion forming a molybdenyl bond with one of the surrounding oxygens.

The signal intensity normalized to surface area increased with time and temperature of the reducing treatment (Table 1). Simultaneously disappearance of the hyperfine pattern and loss of resolution of the perpendicular g factor components due to dipolar broadening effects were observed.

The MoO_3(p) sample treated with propene under similar conditions showed slightly poorer reducibility when compared to MoO_3(n) (Table 1). As in the former case the ESR spectrum consisted of a well-resolved signal characteristic of the hexacoordinated Mo^{5+} ion.

In both samples the appearance of a singlet line at $g = 2.003$ was observed, in addition to the Mo^{5+} signal. Similar signals have been observed previously for various oxides subjected to the reducing

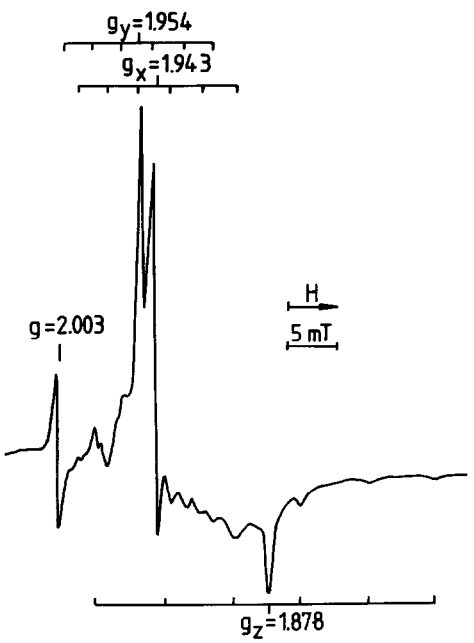

Fig. 1. ESR spectrum of MoO_3(n) reduced with propene at 400 K. Spectrum recorded at 77 K.

Table 1. Mo^{5+} concentration in the MoO_3(n) and MoO_3(p) samples after reduction with C_3H_6, determined from the ESR spectra

treatment.[4–8] There is no unequivocal interpretation of this absorption; F centres, carbon impurities or organic radicals could be responsible. The exact nature of this signal is currently being studied and the results will be published in a separate paper.

It is known that the activation of a propene molecule over molybdena catalysts consists of a hydrogen atom abstraction to form the allyl radical, which in turn undergoes further transformation by incorporation of the lattice oxygen. The results of reduction experiments with propene are consistent with the assumption, based on the catalytic tests, that the side crystal planes perpendicular to the (010) face are responsible for the propene activation. Obviously, the catalyst reduction occurs on account of both the activation and the oxidation processes. This explains the enhanced reducibility of the MoO_3(n) specimen, where the (100) and (101) planes are present in high abundance.

Further evidence for the mechanism of lattice oxygen insertion into the hydrocarbon molecule was found in experiments in which MoO_3(n) and MoO_3(p) were subjected to reduction by diallyloxalate vapour. This substance decomposes readily to yield free allyl radicals which are the intermediate species necessary for the selective pathway of propene oxidation.

The experiments showed that both samples were readily reduced by diallyloxalate vapour at 400 K (Table 2). The ESR spectra revealed the formation of Mo^{5+} species similar to those observed in the case of propene reduction. From Table 2 it can be seen that the rate of the reduction is much higher for the MoO_3(p) sample than for the MoO_3(n) catalyst. It is evident that here the experimental conditions, i.e. the supply of allyl species, enhances the formation of Mo^{5+} ions in the MoO_3(p) sample. Obviously, when the selective oxidation pathway is favoured, it is the abundance of the (010) plane which controls the catalyst reducibility. This indicates that the insertion

Table 2. Mo^{5+} concentration in the MoO_3(n) and MoO_3(p) samples after reduction with diallyloxalate vapour, determined from the ESR spectra

	10	0.8	3.7
	30	1.3	6.7

of the lattice oxygen into the hydrocarbon molecule takes place at the (010) basal plane of MoO_3.

The ESR parameters of the Mo^{5+} spectra produced in the course of reduction with propene and diallyloxalate vapour show that the molybdenyl bond is preserved. This indicates that the reduction occurs at the expense of bridging oxygen atoms, possibly those most nucleophilic in "*trans*" position to the molybdenyl bond. Strong evidence supporting this model is provided by our study of the vacuum-reduced MoO_3.[9] Analysis of the values of the g tensor revealed the appearance of two different Mo^{5+} centres: one formed at an early stage of reduction and assigned to square pyramidal surrounding with the $\sigma\pi$-double bonded oxygen, and the second appearing in the later stages of the reduction and due to Mo^{5+} in octahedra along the shear planes. Similar behaviour was observed for the hydrogen-reduced MoO_3 samples.[10] Comparison with the situation at the surface of MoO_3 crystallites leads to the conclusion that it is the surface oxygen ion bridging two adjacent octahedra in the double string of edge-linked Mo–O octahedra which is removed on reduction of MoO_3. When the concentration of vacancies increases, a crystallographic shear takes place and Mo^{5+} cations assume an octahedral coordination along the shear planes.

We could not detect the pentacoordinated Mo^{5+} species in the samples reduced with propene and diallyloxalate. The ESR spectra showed only the presence of octahedrally coordinated Mo^{5+} ions. This might be due either to the immediate rearrangement of the surface polyhedra, resulting in the elimination of the oxygen vacancies, or to the completion of the coordination sphere of the $(MoO_5)^{5-}$ cluster by the product of propene or allyl oxidation, to form hexacoordinated Mo^{5+} species.

ACIDIC PROPERTIES OF MOLYBDATE-BASED CATALYSTS FOR PROPYLENE OXIDATION

I. MATSUURA,* S. MIZUNO and H. HASHIBA

Faculty of Science, Toyama University, Toyama 930, Japan

(*Received* 15 *June* 1985)

Abstract—Propylene oxidation on Bi- and Fe-doped molybdate ($MMoO_4$)-based catalysts proceeds to acrylic acid via acrolein utilizing their bifunctional properties. The first step of acrolein formation occurs on the surface of Bi molybdate; acrolein is subsequently oxidized to acrylic acid on the acid sites. The acidic site is related to the coordinatively unsaturated Mo ion in the surface Mo oxide coordinated with $MMoO_4$.

Many of catalysts for selective oxidation of hydrocarbons to unsaturated aldehydes, acids or acidic anhydrides are constructed with molybdate-based complex solid oxides that are either converted into a solid solution or remain polyphase. The industrial development of oxidation catalysts started with the report of Hearne and Adams[1] in 1948 that acrolein could be produced from propylene by the use of a mixed Cu–Mo oxide as oxidant. Around 1960 Veach *et al.*[2] reported the use of Bi molybdate with a composition $Bi_9PMo_{12}O_{52}$ for propylene oxidation to acrolein and for the conversion of propylene, ammonia and oxygen to acrylonitrile. This latter process was commercialized by SOHIO. Today this catalyst has been replaced by the so-called "multicomponent molybdate catalysts" that are composed of a variety of elements such as Ni, Co, Fe, Mg, P and K but always contain Bi and Mo. The principal advantages of the multicomponent molybdate catalysts are a low content of expensive Bi, somewhat higher conversions and specially a high yield of acrolein at low reaction temperature.

One of us[3] reported X-ray photoelectron spectroscopy (XPS) measurements on the multicomponent molybdate catalysts, and proposed a skin model consisting of a core of a molybdate matrix material, $MMoO_4$ (where M is a divalent cation, commonly Co, Ni, Mg or Mn) covered by successive layers of Fe(III) and Bi molybdates. Later this model was improved by more accurate measurements.[4] The surface was supposed to be Bi molybdate enclosed in Mo oxide. SOHIO[5] reported that $MMoO_4$ impregnated with a small amount of Fe and Bi gave high activity and selectivity for propylene ammoxidation to acrylonitrile. The composition is $(M_{11}Mo_{12}O_x)Fe_{0.3}Bi_{0.1}$, where M is Co, Ni, Mg, Mn, Fe and/or a mixture of them.

On the other hand, Pb and Ca molybdate having the Scheelite structure are active for propylene oxidation to acrolein via simultaneous incorporation of Bi ions and cation vacancies.[6] The limiting composition of this catalyst system is $Bi_2Mo_3O_{12}$. The $MMoO_4$-related α-$CoMoO_4$, α-$MnMoO_4$ and Scheelite structures with incorporation of Bi ions make a catalyst for selective oxidation of hydrocarbons.

In the presence of water, propylene or acrolein is oxidized to acrylic acid over Co, Va and Tl molybdate[7–9] and heteropoly compounds of Mo.[10] The so-called "multicomponent molybdate catalysts" have an activity in the oxidation of propylene to acrolein but also to acrylic acid as a subsequent product in the chain of the oxidation reaction. An important feature of these catalysts is that they might have acidic sites. These acidic sites may consist of surface hydroxyl groups and they can promote the formation of propene-diol as a reaction intermediate in the formation of acrylic acid.[11]

The present work is an attempt to study the structure and acidity of $MMoO_4$ system catalysts with the addition of Bi in selective oxidation of propylene to acrolein and acrylic acid, and to discuss

* Author to whom correspondence should be addressed.

the results in terms of current hypotheses on the mechanism of propylene oxidation.

EXPERIMENTAL

The catalysts used in this work are listed in Table 1. To prepare $CoMo_4$, powdered H_2MoO_4 was added to a stirred hot solution of $Co(NO_3)_2 \cdot 6H_2O$; the atomic ratio Co:Mo was 10:12. Dilute ammonia was then added until the pH was 5. The mixture was dried and freed of NH_4NO_3 by spraying on a hot plate at 350°C. The collected powder was further calcinated at 520°C for 2 h. Other samples were prepared by the same procedure. A sample was impregnated with Fe and Bi by slowly adding a solution of Fe and Bi in nitric acid and drying and calcining at 520°C for 2 h. Most samples were impregnated with 3% Fe and 1% Bi. Bi_2MoO_6 was prepared as follows. Solid basic Bi nitrate, $BiO(NO_3)$, and molybdic acid, H_2MoO_4, were powdered, slurried in water, and boiled with stirring 16 h. Then, the solid material was filtered and dried. The initial Bi:Mo ratio was 2:1.02 for the synthesis of active γ-Bi_2MoO_6.

The catalytic activity of the various samples for the oxidation of propylene to acrolein and acrylic acid was measured using a flow system at atmospheric pressure at 340°C. In each experiment samples (0.2–4 g) were used, the gas flows were 10 $cm^3\ min^{-1}$ of propylene and 100 $cm^3\ min^{-1}$ of air containing 10% water vapor. Dehydration of iso-propyl alcohol was also measured on 1 g of catalyst at 180°C.

^{18}O-exchange experiments between $H_2{}^{18}O$ and acrolein and acrylic acid were carried out by a pulse method at 340°C; a quadrupole mass spectrometer, ULVAC-190, was connected directly to the outlet of the pulse reactor containing 1 g of catalyst.

Table 1. Rate of propylene oxidation and iso-propyl alcohol dehydration[a]

X-ray diffraction measurements were performed on a Shimazu XD7A spectrometer with Cu-K_α radiation and Ni filter.

XPS measurements were performed using an AEI ES200 spectrometer with Mg-K_α radiation. The power supply was run at 12 kV and 15 mA, the spectra being collected with a PPDS computer and stored in a 32 K disc. The powder sample was pressed on a sample holder covered with indium.

The IR spectra of samples were recorded with a JASCO IRA-2 spectrometer in the range 1250–400 cm^{-1} using the conventional KBr disk techniques. The Raman spectra of powders from 1200 to 0 cm^{-1} were measured on a rotating disk at liquid-nitrogen temperature.

RESULTS

Figure 1 shows the results of propylene oxidation on the $CoMoO_4$-based catalysts and Bi_2MoO_6. The $CoMoO_4$-based catalyst shows a high activity for propylene oxidation and subsequent acrolein oxidation to acrylic acid [Fig. 1(a)]. However, after

the addition of KOH to the $CoMoO_4$-based catalyst, propylene oxidation stayed at the same level of activity but acrylic acid formation was suppressed [Fig. 1(b)]. Bi_2MoO_6 was not so active and we found a low conversion to acrylic acid from propylene [Fig. 1(c)]. The results suggest the oxidation of propylene to acrylic acid through acrolein with the successive first-order reaction. Table 1 shows the rate of overall propylene oxidation and acrylic acid formation. The rate of iso-propyl alcohol dehydration as an indicator of the catalyst acidity is also shown in Table 1.

$NiMoO_4$, $CoMoO_4$ and $FeMoO_4$ have two different phases. One is a high-temperature modification of the α-$MnMoO_4$ type and the other is a low-temperature modification of α-$CoMoO_4$-type. The X-ray diffraction lines of $MMoO_4$-based catalysts having α-$CoMoO_4$-type structure are listed in Table 2. Our samples of $NiMoO_4$ and $CoMoO_4$ show the α-$CoMoO_4$ structure as described by Smith and Ibers.[12,13] The mixed Ni–Co and Co–Fe molybdates show that these X-ray diffraction lines shift from one molybdate to the other systematically. This observation indicates that the mixed molybdates form a solid solution. The unit cell dimensions of the samples of α-$CoMoO_4$ structure are shown in Table 3.

Table 3. Lattice constants of α-$CoMoO_4$-structure molybdates

	a (Å)	*b* (Å)	*c* (Å)	*β* (°)
$NiMoO_4$	9.592	8.765	7.665	114.25
$Ni_{0.5}Co_{0.5}MoO_4$	9.652	8.765	7.665	114.25
$CoMoO_4$	9.712	8.865	7.666	114.15
$Co_{0.7}Fe_{0.3}MoO_4$	9.749	8.903	7.664	114.03
$FeMoO_4$	9.805	8.950	7.660	114.05

The IR and Raman frequencies of the samples examined are listed in Table 4 for the α-$CoMoO_4$ and α-$MnMoO_4$-structure molybdates. These two structures have the same space group ($C2/m$) and similar cell dimensions. The basic difference between the two structures is the coordination of Mo by oxygen which is octahedral in α-$CoMoO_4$ and tetrahedral in α-$MnMoO_4$. In the structures there are two crystallographically independent Mo atoms which are displaced from the center of their octahedra with Mo—O distances ranging from 1.73 to 2.31 Å and from 1.72 to 2.33 in α-$CoMoO_4$, and from their tetrahedra with Mo—O distances ranging from 1.731 to 1.795 and from 1.724 to 1.851 Å in α-$MnMoO_4$. We assume that for both symmetries the base structural unit is the system of tetrahedra in the C_2- and C_s-lattices and the space group has C^3_{2h}-symmetry. In Table 4 we give a description of normal modes for MoO_4 in lattice modes C_2 and C_s for our samples.

XPS was performed on our catalysts. The method gives information about the outermost 15–40 Å of the particles. Quantitative analysis of metal ions from XPS was calculated the method proposed by Carter *et al.*[14] who applied the photoelectron cross-sections of Scofield.[15] The results are shown in Table 5. Comparison with the bulk compositions shows the surfaces to be covered by MoO_3 with Bi ions appearing in the surface MoO_3 layer. On the contrary, the $PbMoO_4$-based catalyst has a surface composition nearly equal to that of the bulk composition.

acrolein and acrylic acid are given in Table 6. For the ^{18}O-exchange between $H_2{}^{18}O$ and acrolein during the oxidation reaction it was found that the ^{18}O content of unreacted acrolein and the reaction products was very high over the $CoMoO_4$-based catalyst but not over the $PbMoO_4$-based catalyst or Bi_2MoO_6.

DISCUSSION

Our XPS experiments on $MMoO_4$-based catalysts show that the surface is mainly covered by MoO_3 and Bi ions dispersed in the MoO_3 surface layer over the core of $MMoO_4$. The solid-state reaction between MoO_3 and Bi_2O_3 forms Bi molybdate. It confirms the model of Bi molybdate enclosed in the MoO_3 surface layer on a core of $MMoO_4$. It is known that the Bi molybdates are good catalyst for propylene oxidation to acrolein. On the $MMoO_4$-based catalysts propylene oxidation to acrolein proceeds on the surface Bi molybdate enclosed in the MoO_3 surface layer. However, acrylic acid formation occurs only on the $MMoO_4$-based catalysts and not on Bi molybdates. Our experimental result shows propylene oxidized successively to acrylic acid through acrolein on the $MMoO_4$-based catalysts. Moro-oka *et al.*[16] studied propylene oxidation on mixed Co and Mo oxides. They found that when the atomic ratio of Co/Mo was higher than 1 the main oxidation product was acetone; when the ratio was near 1, acrylic acid was observed in the oxidation products. It is known that V and Tl molybdate and also heteropoly compounds of Mo are good catalysts for acrylic acid formation by acrolein oxidation. The acidic property of these catalysts is an important factor for the reaction. The $MMoO_4$-based catalysts have acidic sites because they have a catalytic activity for iso-propyl alcohol dehydration. When the $CoMoO_4$-based catalyst was treated with KOH, the catalyst lost its activity for iso-propyl alcohol dehydration and acrylic acid formation from propylene oxidation was also suppressed. There is no doubt that the acidic sites on $MMoO_4$-based catalysts are necessary for acrylic acid formation from propylene oxidation. Figure 2 shows the rate of iso-propyl alcohol dehydration as an indication of acidity against the rate of acrylic acid formation on the $MMoO_4$-based catalysts. Increasing the rate of iso-propyl alcohol dehydration leads to an increase in the rate of acrylic acid formation.

There are three different structures for $MMoO_4$ compounds, viz. α-$CoMoO_4$, α-$MnMoO_4$ and the Scheelite structure which depends on the M^{2+} cation size in the molybdate. The first two structures have the same space group ($C2/m$) and similar cell

dimensions. The basic difference between the two structures is the coordination of Mo by oxygen which is octahedral in α-$CoMoO_4$ and essentially tetrahedral in α-$MnMoO_4$. The M^{2+} cations coordinate six oxygens in both structures. The high-temperature form is always found to have the α-$MnMoO_4$ structure, while the low-temperature form is found to have the α-$CoMoO_4$ structure. Under our experimental conditions for propylene oxidation, these catalysts have the α-$CoMoO_4$ structure. Figure 3(a) shows the basic structure of α-$CoMoO_4$ in which infinite chains formed by Mo and Co edge-sharing octahedra parallel to the *c*-axis are surrounded by other chains. The distances between cations in α-$CoMoO_4$ are close to those found in the complex Mo oxides Mo_8O_{23} and Mo_9O_{26} or $(Mo_7O_{24})^{6-}$ and $(Mo_8O_{24})^{4-}$ ions.[17,18] Figure 3(b) shows MoO_3 have a layer structure in which some oxygen atoms are three-coordinate whilst others are two-coordinate or terminal. The Raman spectra of MoO_3 shows frequencies at 999s, 821vs and 668w cm^{-1}. If the surface of the $MMoO_4$-based catalyst is covered by MoO_3, the Raman bands should be observed. We observed the typical band at 999 cm^{-1} of MoO_3 in the $MnMoO_4$-based catalyst but no MoO_3 bands in the $CoMoO_4$-based catalyst. We suggest that the surface MoO_3 on the α-$CoMoO_4$-based catalyst is strongly coordinated with octahedral Mo ions in α-$CoMoO_4$ as shown in Fig. 3(c).

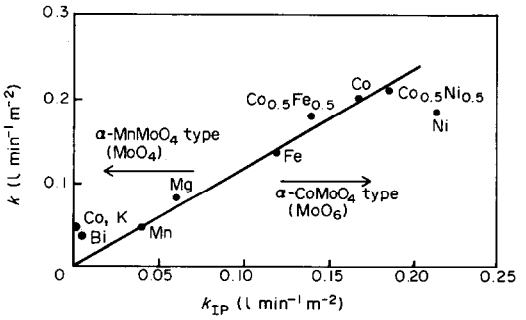

Fig. 2. Correlation of the rate of iso-propyl alcohol dehydration (k_{IP}) with the rate of acrylic acid formation (k) on $MMoO_4$-based catalysts.

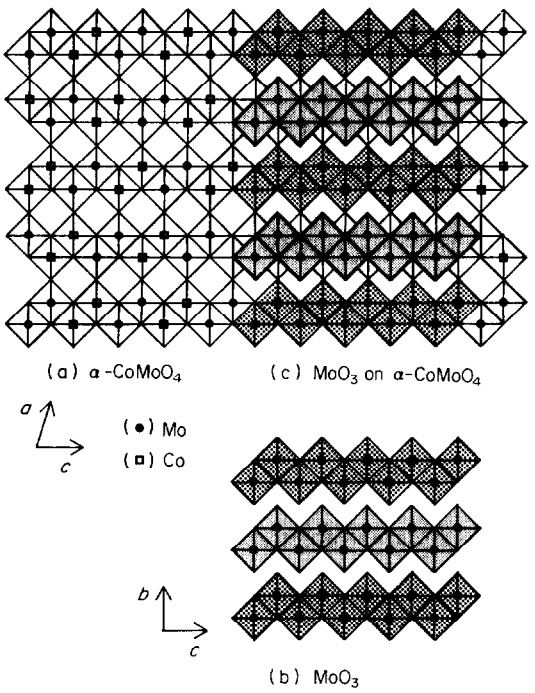
The acidic sites of the $MMoO_4$-based catalysts may be their coordinatively unsaturated surface Mo ions connected with the surface MoO_3 layer. Figure 4 shows the relation between the rate of iso-propyl alcohol dehydration and the square of the frequency



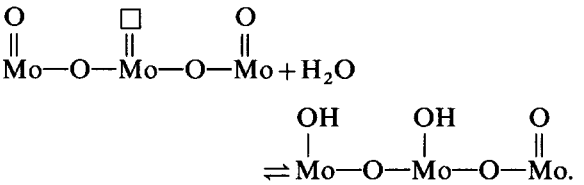


Fig. 3. Postulated surface state of an α-$CoMoO_4$-based catalyst.

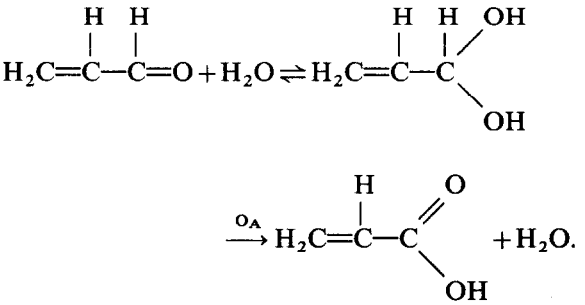

for Mo—O stretching in the C_2-mode in $MMoO_4$. The coordinatively unsaturated surface Mo ions of the α-$CoMoO_4$ structure have more acidic properties than the Mo ions of the α-$MnMoO_4$ structure. Scheelite molybdate and Bi_2MoO_6 have no acidic sites.

In the ^{18}O-exchange between $H_2{}^{18}O$ and acrolein during the oxidation reaction it was found that the ^{18}O content of unreacted acrolein and the reaction products was very high on $CoMoO_4$-based catalysts but not on $PbMoO_4$-based catalysts and Bi_2MoO_6 as shown in Table 6. A similar result for the exchange reaction between $H_2{}^{18}O$ and acrylic acid was found. These results indicate that the acid sites are important for the oxidation of acrolein to acrylic acid. Acrylic acid formation from acrolein oxidation on $MMoO_4$-based catalysts proceeds by oxidative dehydrogenation with H_2O.

The coordinatively unsaturated surface Mo ions forms hydroxyl groups by H_2O adsorption:

Then acrolein forms propenediol as a reaction intermediate. Thereafter oxidative dehydrogenation proceeds:

We propose that the $MMoO_4$-based catalysts have bifunctional catalytic properties, one yielding acrolein from propylene oxidation on the surface Bi molybdate and another oxidizing acrolein to acrylic acid on the acidic sites of coordinatively unsaturated surface Mo ions. The reaction model is shown in Fig. 5.

A small amount of acrylic acid forms during propylene oxidation on Bi_2MoO_6 and the $PbMoO_4$-based catalyst even though they have no acidic sites. The mechanism of acrylic acid formation should be different from the propenediol intermediate mechanism because no ^{18}O-exchange between H_2O and acrolein was observed on these catalysts. One of us has studied the adsorption of acrolein on Bi_2MoO_6.[19] The adsorption of acrolein was explained by assuming that the hydrogen from the COH group is dissociated and donated to a surface O atom while the residual carbonyl group occupies a surface anion vacancy with its oxygen atom, thereby becoming bonded to a neighboring

surface oxygen:

The hydrogen donated to a surface O atom transfers to the adsorbed carbonyl. After desorption acrylic acid is formed and the adsorption site is reduced.

MECHANISM OF OXIDATIVE DEHYDROGENATION OF 1-BUTENE OVER BISMUTH MOLYBDATE

M. F. PORTELA,* M. M. OLIVEIRA and M. J. PIRES

Centro de Processos Químicos (INIC), Technical University of Lisbon, Instituto Superior Técnico, Aven. Rovisco Pais, 1096 Lisboa Codex, Portugal

(*Received* 20 *June* 1985)

Abstract—The oxygen reaction rate and the amount of retained oxygen, when mixtures of 1-butene and oxygen are pulsed over the low-temperature Bi_2O_3, MoO_3 (γ) pure phase, were recorded as a function of the pulse number. Results provided direct evidence that the sites at which oxygen enters the catalyst and the sites at which oxygen is used for oxidation reactions are separate and also of an inhibiting competitive adsorption of 1-butene over the reduced sites.

In previous studies of the oxidative dehydrogenation of 1-butene:

$$C_4H_8 + \tfrac{1}{2}O_2 \rightarrow C_4H_6 + H_2O$$

over bismuth molybdates, carried out by the continuous-flow method and using the initial-rate approach, it was observed that, keeping the oxygen partial pressure constant, the rate of butadiene formation, after a pseudo-linear initial increase with the butene partial pressure, attains a maximum and decreases afterwards with increasing olefin pressure.[1–3] This decrease for the higher butene pressures was interpreted as being due to an inhibiting competitive adsorption of the olefin over the reduced sites. On the other hand, it was reported that reoxidation of the catalyst occurs at surface sites which are separate from the olefin activation sites.[4] However no direct evidence of such phenomena have been provided. Such evidence clearly emerges from the results reported in this paper.

EXPERIMENTAL

The unsupported low-temperature Bi_2O_3, MoO_3 (γ) pure phase was prepared by a reproducible coprecipitation technique.[5] X-ray diffraction and IR and Raman spectroscopies did not show traces of impurities. Analysis by XPS confirmed the right Bi/Mo atomic ratio. The BET surface area was 1.0 $m^2\ g^{-1}$.

For the catalytic tests, the classical pulse method was used with a Pyrex reactor. The operating pressure was 4 bar (absolute). The catalyst was diluted with quartz of the same grain size (0.50–0.63 mm) whose inertness had been checked. Pulses of 2 standard cm^3 were used.

The experiments were performed at 280 and 350°C, with reaction mixtures of constant butene partial pressure (42 kPa) and variable oxygen pressure (2–72 kPa) with nitrogen. They were carried out so as to obtain differential conversions, adjusting the catalyst charge in order to eliminate the influence of the reaction products. The degradation to CO_2, although detectable, was negligible.

The reactants and reaction products were analyzed by a 3920 Perkin–Elmer gas chromatograph with a hot wire detector and 2,4-dimethylsulpholane (for CO_2 and hydrocarbons) and 13X molecular sieve (for O_2 and N_2) columns.

Other details of the experimental techniques are given elsewhere.[1]

RESULTS AND DISCUSSION

Figure 1 shows that the oxygen reaction rates decrease with the pulse number and tend to level off. At 280°C the curves are practically independent of the oxygen content in the reaction mixture, indicating a zero order in oxygen. However, at 350°C the reaction rates are practically equal after the first pulse and when activity levels off are lower the lower the oxygen pressure, showing a pressure dependence with respect to oxygen. It is obvious that in both

* Author to whom correspondence should be addressed.

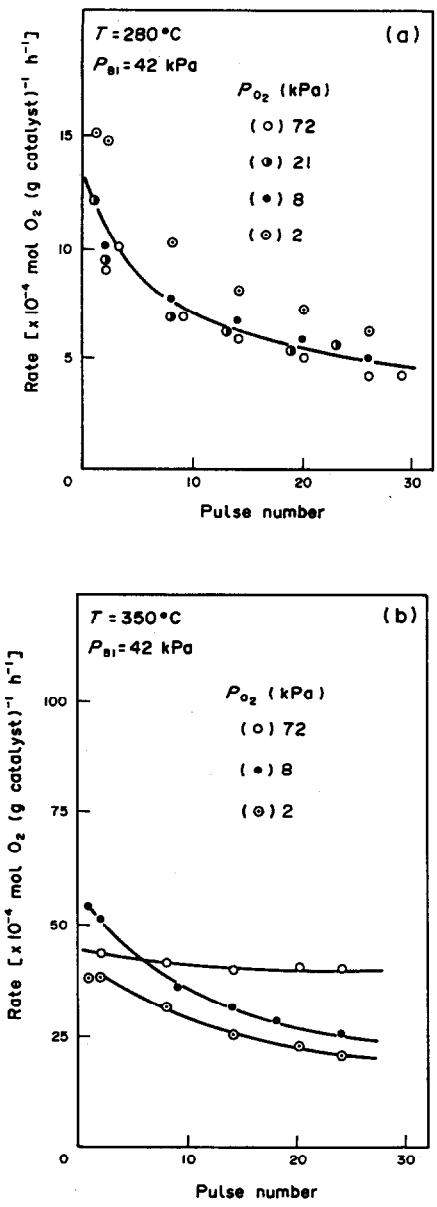

Fig. 1. Oxygen reaction rate vs pulse number at: (a) 280, and (b) 350°C. The oxygen reaction rate is half the butadiene formation rate.

cases activity tends to level off when the catalyst reduction rate is equal to its reoxidation rate. The data in Fig. 1 for lower oxygen partial pressures correspond to a butene partial pressure higher than the one which gives a rise to the previously mentioned maximum in the butadiene formation rate in continuous-flow experiments.[2,3]

To understand better the above results, we investigated the change with pulse number of the amount of oxygen retained by the catalyst after each pulse, and the balance of oxygen retained less oxygen consumed in the olefin oxidative dehydrogenation. The results are given in Table 1.

Table 1. Oxygen retained and oxygen balance as a function of pulse number[a]

Oxygen pressure (kPa)	Pulse number	Oxygen retained ($\times 10^{-6}$ mol O_2 g^{-1})	Oxygen balance ($\times 10^{-6}$ mol O_2 g^{-1})
	Temperature = 280°C

	24	5.0	1.98
	25	4.6	1.39

[a] Butene partial pressure = 42 kPa.

We see that at the lowest oxygen pressure the catalyst is progressively reduced with successive pulses, but the amount of retained oxygen decreases with the pulse number, and a stage is reached in which the oxygen of the reaction mixture is not able to reoxidize the reduced catalyst. Increasing the oxygen pressure, we observe a negative balance of oxygen with the first pulses, indicating reduction of the catalyst, but a positive balance is recorded later, although data in Fig. 1 show that catalyst reduction occurs.

We conclude that the sites of catalyst reduction and reoxidation are different, and that reoxidation is progressively inhibited by the butene remaining adsorbed over the reduced sites of the catalyst after each pulse.

INFLUENCE OF Mo–SiO_2 CATALYST PREPARATION ON MOLYBDENUM COORDINATION AND CATALYTIC PROPERTIES

M. CHE,* C. LOUIS*† and J. M. TATIBOUËT‡

*Laboratoire de Réactivité de Surface et Structure, UA CNRS 1106, Université P. et M. Curie, 4 Place Jussieu, 75230 Paris Cedex 05, France; and ‡Laboratoire de Catalyse Organique, LA CNRS 231, Université Lyon I, 43 Bd du 11 novembre 1918, 69622 Villeurbanne Cedex, France

(*Received* 18 *June* 1985)

Abstract—Mo–SiO_2 catalysts were prepared by grafting, i.e. by reacting $MoCl_5$ with the hydroxyl groups of silica. The analysis of the Mo coordination sphere during grafting by reflectance spectroscopy and EPR indicates that grafting occurs probably through the following mechanism: $MoCl_5 + SiOH \rightarrow SiOMoCl_4 + HCl$. Grafted Mo–$SiO_2$ catalysts differ from Mo–SiO_2 catalysts prepared by impregnation by the presence of a tetracoordinated Mo^{5+} species (identified by EPR after thermal activation), a better molybdenum dispersion and stronger Mo–silica interactions. The methanol oxidation reaction was found to be sensitive to molybdenum dispersion and this might be an appropriate way to evaluate the dispersion of supported oxides.

The slower progress towards understanding catalysis on supported oxides compared to catalysis on supported metals arises from the difficulty of preparing well-dispersed oxides and from the lack of a reliable method of measuring the dispersion, similar to that of hydrogen chemisorption for supported metals. The aim of this work is to investigate the influence of molybdenum dispersion of various Mo–SiO_2 catalysts on both the coordination sphere of molybdenum ions and their catalytic properties.

EXPERIMENTAL

Two preparation methods were used:

(1) classical impregnation of silica with an aqueous solution of ammonium heptamolybdate; and

(2) grafting of $MoCl_5$ onto dehydrated silica via its silanol groups in strict absence of air and water. The grafting is performed either with $MoCl_5$ dissolved in cyclohexane[1,2] or with $MoCl_5$ vapour at 200°C.[2] The advantage of using $MoCl_5$ vapour is that the grafting can be monitored by EPR and UV spectroscopies.[2]

RESULTS AND DISCUSSION

Dehydrated silica at 400°C exhibits a charge-transfer band at about 260 nm in the UV region and two vibration bands at 1365 and 2190 nm in the near IR, assigned to SiOH groups[3] (Fig. 1).

When silica is heated in the presence of $MoCl_5$ at 200°C, a decrease in intensity of the near-IR bands is observed, indicating that $MoCl_5$ reacted with the silanol groups. Simultaneously, bands appear in the UV–visible region and an EPR signal is observed (Fig. 2). The EPR parameters ($g_\perp = 1.952$ and $g_\parallel = 1.968$, $A_\perp = 37$ G and $A_\parallel = 70$ G) and the presence of a hyperfine structure in the signal obtained after grafting, due to interaction with the nuclear spins ($I = 5/2$) of the ^{95}Mo and ^{97}Mo isotopes (natural abundance 25%), show that this signal arises from Mo^{5+} ions. The EPR signal possesses axial symmetry whereas that of $MoCl_5$ in cyclohexane is isotropic at 77 K.[2] The change of symmetry indicates that the Mo^{5+} coordination sphere is affected on grafting and confirms the

† Author to whom correspondence should be addressed.

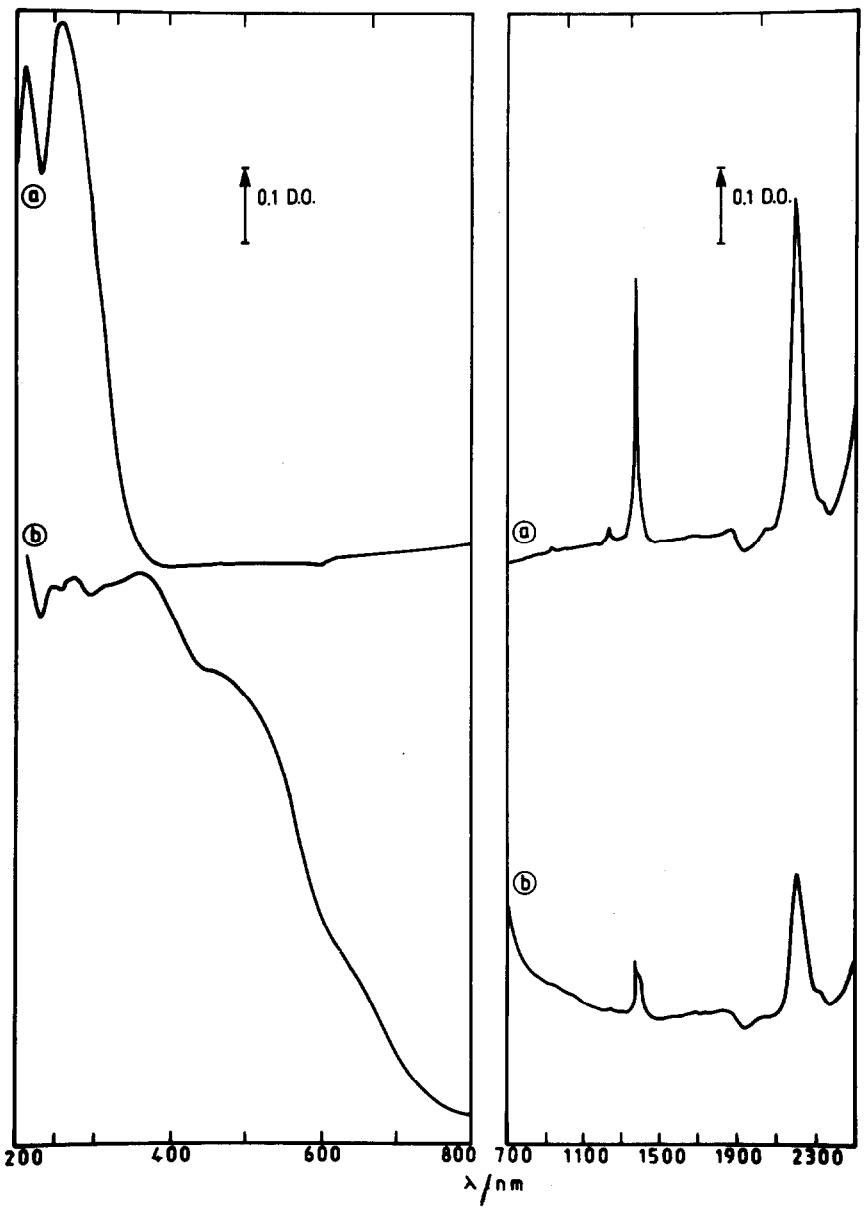

Fig. 1. UV–visible–near-IR reflectance spectra: (a) dehydrated silica at 400°C, and (b) silica after grafting with $MoCl_5$ vapour at 200°C.

formation of bonds with silica. Finally, the parameters of the EPR signal and of the UV spectrum of Mo after grafting have been compared, respectively, with those of $MoCl_5$,[2,4] $[MoOCl_4]^-$[5] and $[MoOCl_5]^{2-}$[6,7] and found to be very similar to those of the $[MoOCl_4]^-$ ion.

The previous results can be interpreted in terms of the following grafting reaction:

$$MoCl_5 + SiOH \rightarrow SiOMoCl_4 + HCl.$$

It is also observed that a part of $MoCl_5$ does not react and is only adsorbed on the silica support in a dimer state, Mo_2Cl_{10}, which does not exhibit an EPR signal, due to electron pairing. This adsorbed molybdenum is evidenced as follows. When exposed to air, the catalyst, which was red-brown, instantaneously turns blue because of hydrolysis and partial oxidation of Mo_2Cl_{10} to molybdenum blues[8,9] (mixed Mo^{5+}–Mo^{6+} hydroxides). Its UV–visible spectrum is then similar to that of molybdenum blues,[10] i.e. an intervalence band around 900–1000 nm is observed, which arises from electron hopping between Mo^{5+} and Mo^{6+} ions. The molybdenum blues can be eliminated by washing with water or ammonia solutions and the sample turns greyish brown which is the colour

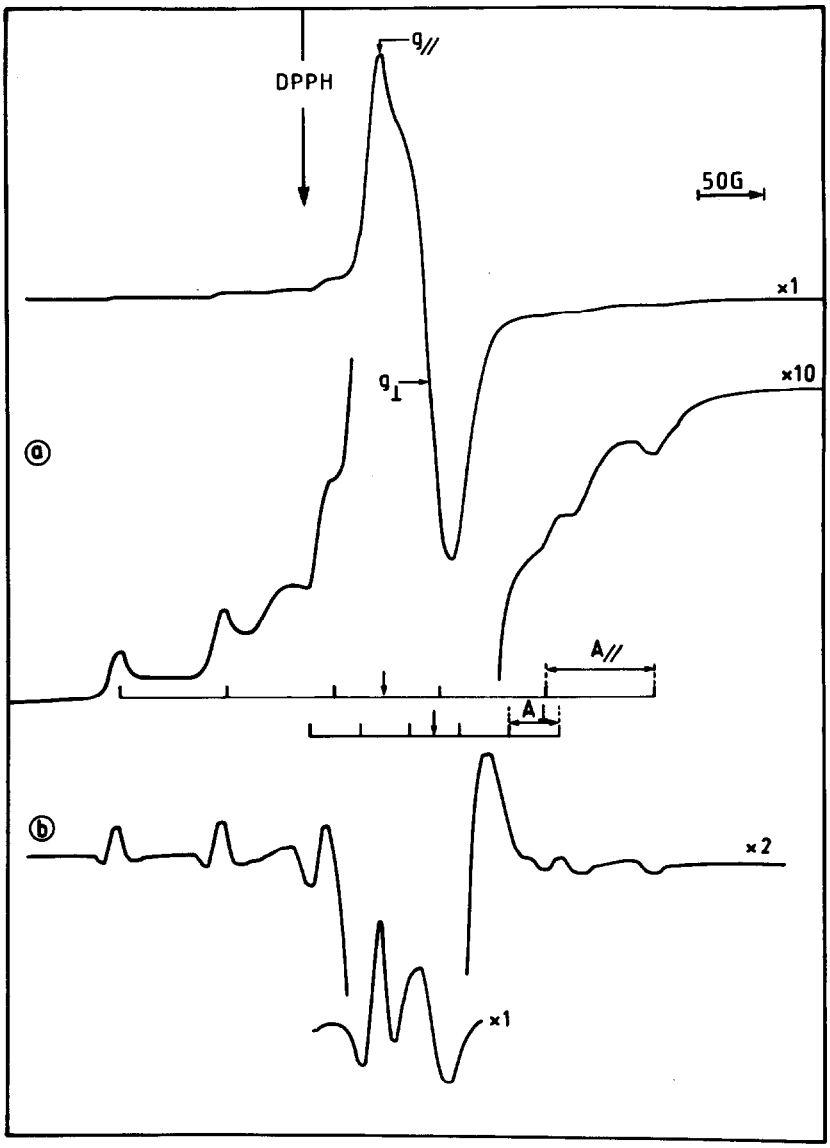

Fig. 2. EPR spectra recorded at 77 K of Mo–SiO_2 catalysts obtained after grafting with $MoCl_5$ vapour at 200°C: (a) first derivative, and (b) third derivative.

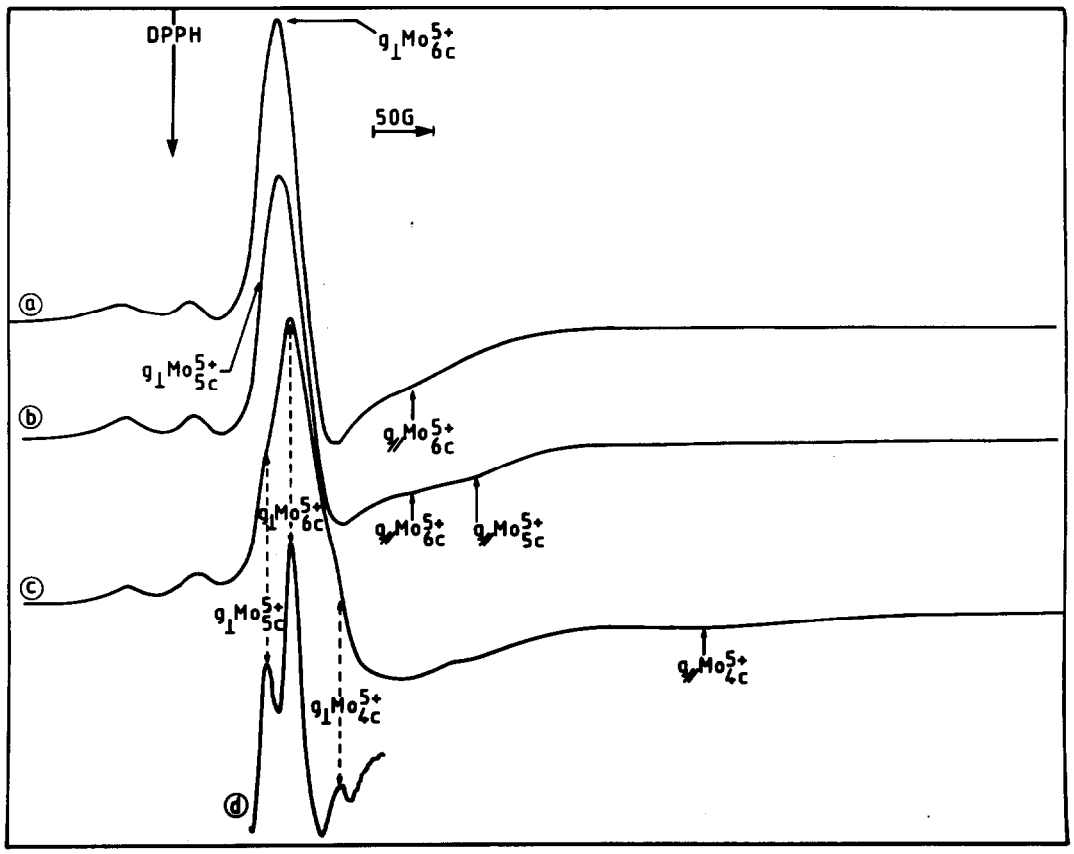
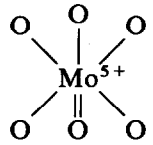
characteristic of grafted molybdenum remaining on silica. The intervalence band is no longer present whereas a *d–d* band of Mo^{5+} around 450 nm and a charge-transfer band of Mo^{6+} around 280 nm are observed. These facts suggest that the Mo^{5+} and Mo^{6+} ions are isolated from each other. In the following, the term "grafted" refers to samples which have been washed in order to eliminate the adsorbed molybdenum.

When, after grafting, the sample is directly evacuated at increasing temperatures, without any intermediate contact with air or water, the following changes are observed: at around 200°C, the relative values of the g components are reversed with $g_\perp$ becoming larger than $g_\parallel$ (Fig. 3). At 300°C, a second Mo^{5+} signal with $g_\perp > g_\parallel$ appears and, at 500°C, three different signals corresponding to three types of Mo^{5+} ions in axial symmetry are clearly visible ($g_\perp = 1.944$ and $g_\parallel = 1.892$, $g_\perp = 1.957$ and $g_\parallel = 1.866$, and $g_\perp = 1.926$ and $g_\parallel = 1.755$, referred to as Mo^{5+}_{6c}, Mo^{5+}_{5c} and Mo^{5+}_{4c}, respectively). During evacuation of the sample at increasing temperatures, the spin concentration measurements indicate that the number of Mo^{5+} ions remains constant, suggesting that the spectral changes arise only from modification within the Mo^{5+} coordination sphere.

The spectrum observed after evacuation at 500°C is also detected for the grafted catalyst after washing and thermal activation (oxidation, reduction under H_2 at 500°C and evacuation at the same





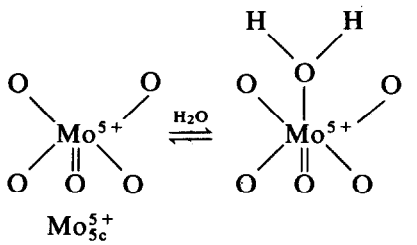


Fig. 3. EPR spectra recorded at 77 K of the Mo–SiO_2 catalysts prepared by grafting with $MoCl_5$ vapour at 200°C, followed by evacuation: (a) at 200°C for 30 min, (b) at 300°C for 30 min, and (c) at 500°C for 30 min; and (d) third-derivative spectrum of (c).

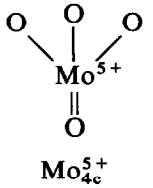
temperature). It should be noted that impregnated Mo–SiO_2 catalysts possess only two Mo^{5+} species (Mo^{5+}_{5c} and Mo^{5+}_{6c}) and exhibit a spectrum analogous to that obtained after grafting and evacuation at 300°C. One of these common species (Mo^{5+}_{6c}) possesses EPR parameters very close to those of $[Mo_6O_{19}]^{3-}$.[11] This polyanion is composed of six molybdenum ions (one Mo^{5+} and five Mo^{6+}) in octahedral symmetry. Each molybdenum ion is surrounded itself by an octahedron of O^{2-} ions and possesses one molybdenum–oxygen bond of molybdenyl type.[11] It is deduced that Mo^{5+}_{6c} is hexacoordinated with one molybdenyl bond:

Mo^{5+}_{6c}

The coordination of the two other species (Mo^{5+}_{4c} and Mo^{5+}_{5c}) has been determined using probe molecules. On impregnated catalysts, adsorption of water transforms the Mo^{5+}_{5c} EPR signal into Mo^{5+}_{6c}, due to the introduction of one water molecule into the coordination sphere, according to the following reaction:[11]



Mo^{5+}_{5c}

Adsorption of water at room temperature and increasing pressures is found to transform the third species (Mo^{5+}_{4c}) observed on grafted Mo–SiO_2 into Mo^{5+}_{5c} and then into Mo^{5+}_{6c}.[2] It suggests that Mo^{5+}_{4c} is less coordinated than Mo^{5+}_{5c}, i.e. with more than one vacancy in its coordination sphere. During adsorption, the spin concentration is found to remain constant, showing that water acts only as a ligand and not as a redox agent. This is reasonable owing to the temperatures (25°C) and the pressures (1–18 torr) involved. Since the species obtained after water adsorption have a molybdenyl character, it

can be deduced that the starting Mo_{4c}^{5+} species also possesses a molybdenyl character.

In order to determine the number of vacancies within its coordination sphere, adsorptions of CO and ^{13}CO have been performed onto the Mo_{4c}^{5+} species. The analysis of the new signal obtained ($g_1 = 1.965$, $g_2 = 1.969$, g_3 not resolved), and of the superhyperfine structure due to interaction between the unpaired electron of Mo^{5+} and the nuclear spin ($I = \frac{1}{2}$) of ^{13}C (one set of three lines for each g value of the new signal, with relative intensity 1:2:1 and a coupling constant $A = 7.5$ G), reveals that two CO molecules can enter into the Mo_{4c}^{5+} coordination sphere. Hence, Mo_{4c}^{5+} possesses two vacancies in its coordination sphere and the following model for this species can be proposed:

Mo_{4c}^{5+}

The changes described above, when a catalyst after grafting is evacuated at increasing temperatures, may be interpreted on the basis of the previous results. At 200°C, the change of the g components from $g_{\parallel} > g_{\perp}$ to $g_{\perp} > g_{\parallel}$ involves the replacement of chlorine by oxygen ligands in the Mo^{5+} coordination sphere, leading to the Mo_{6c}^{5+} signal. At 300°C, a part of the Mo_{6c}^{5+} species is transformed into Mo_{5c}^{5+} owing to the formation of one vacancy within the coordination sphere. Above 500°C, a second vacancy is created, leading to the Mo_{4c}^{5+} signal. Hence, increasing the temperature causes the formation of vacancies within the Mo^{5+} coordination sphere. The Mo_{4c}^{5+} signal seems to be characteristic of grafted samples.

The grafted and impregnated Mo–SiO_2 samples differ from each other in several other ways. It was also found[1] that grafted molybdenum interacts more strongly with silica than impregnated molybdenum: whereas impregnated molybdenum is easily dissolved in water, grafted molybdenum remains fixed on silica. More drastic tests in hot HF–H_2SO_4 solutions show that, for the grafted sample, molybdenum and silica dissolve very little while they completely dissolve in the case of impregnated catalysts. On the other hand, grafted molybdenum is found to be less reducible than impregnated molybdenum. Thermogravimetric and micromanometric measurements have allowed us to derive the mean oxidation state of molybdenum at the end of a reduction step performed under hydrogen at 600°C: it is 4 for grafted samples instead of 2–3 for impregnated ones. The increased resistance to reduction of grafted molybdenum may be interpreted in terms of a stronger interaction with silica which would limit reduction or/and a better dispersion of molybdenum. The molybdenum behaves more as bulk molybdenum oxide on impregnated catalysts than on grafted ones and can thus be viewed as aggregates of molybdenum oxide on the former catalysts.

The electron-transfer reaction $Mo^{5+} + O_2 \rightarrow Mo^{6+}–O_2^-$ was used to measure the Mo^{5+} dispersion by EPR spectroscopy.[1,2] In conditions precluding bulk oxidation (77 K, 10^{-1} torr), O_2 is adsorbed on catalysts previously thermally reduced by H_2. The Mo^{5+} signal decreases as the O_2^- signal appears. The Mo^{5+} dispersion can be calculated from the ratio of the integrated intensities of the Mo^{5+} EPR signal:

$$\frac{I_i(Mo^{5+}) - I_f(Mo^{5+})}{I_i(Mo^{5+})},$$

where $I_i(Mo^{5+})$ is determined before O_2 adsorption and $I_f(Mo^{5+})$ after. For example, for Mo–SiO_2 samples containing 1% of Mo by weight, the calculated Mo^{5+} dispersion is found to be 80% for the grafted sample against 30% for the impregnated one.

The reaction of methanol partial oxidation is known to be structure-sensitive.[12] Whereas, on polycrystalline MoO_3 oxide, it essentially produces formaldehyde, on orientated crystallites the selectivity to formaldehyde, methylal or dimethylether depends on the exposed face. The same reaction performed over an Mo–SiO_2-supported catalyst leads essentially to formaldehyde and methylformate. On grafted catalysts, methylformate is the principal product, whereas on impregnated ones it is formaldehyde. For example, for 1% molybdenum loading, the selectivity towards methylformate is equal to 90% for grafted catalysts and only 20% for the impregnated ones. For smaller molybdenum loadings, as the Mo^{5+} dispersion increases, the selectivity to methylformate also increases. For molybdenum loadings between 1 and 0.07%, the Mo^{5+} dispersion of grafted catalysts varies from 80 to 100% and their selectivity (at 230°C) from 90 to 95%, whereas for impregnated samples the Mo^{5+} dispersion varies from 30 to 100% and the selectivity from 20 to 91%. These results indicate that a correlation exists between the molybdenum dispersion and the selectivity in methanol oxidation, and that this reaction is not only structure-sensitive but also dispersion-sensitive.

The mechanism for the formation of methylformate may be summarized as follows. Formaldehyde is produced on molybdenum of Mo–SiO_2 catalysts in the same way as for polycrystalline

bulk MoO_3. However, instead of desorbing, formaldehyde migrates onto silica and reacts with methoxy group arising from dehydration between methanol and silanol surface group. A hemiacetal intermediate can be formed to lead to methylformate. The same type of mechanism has been recently proposed by Cant *et al.*[13] using various deuterated compounds on copper-based catalysts.

CONCLUSION

The absence of any intervalence Mo^{5+}–Mo^{6+} band, the high dispersion of Mo^{5+} ions, and the significant selectivity in methylformate, lead us to conclude that the grafting method using $MoCl_5$, is suitable for preparing highly dispersed molybdenum. The methanol oxidation appears to be a good reaction to compare the dispersion of supported molybdenum catalysts prepared differently. The grafted catalysts differ from the impregnated ones by the presence of the Mo^{5+}_{4c} tetracoordinated species detected by EPR, a stronger Mo–silica interaction and a better molybdenum dispersion connected with the significant selectivity to methylformate in methanol oxidation.

OXY-METHOXY COMPOUNDS OF MOLYBDENUM(VI) AND THEIR RELATIONSHIP TO THE SELECTIVE OXIDATION OF METHANOL OVER MOLYBDATE CATALYSTS

E. M. McCARRON III* and A. W. SLEIGHT

Central Research and Development Department, E.I. du Pont de Nemours and Co., Experimental Station, Wilmington, DE 19898, U.S.A.

(*Received* 18 *June* 1985)

Abstract—The selective oxidation of methanol to formaldehyde over molybdate catalysts has been modeled synthetically by the formation of oxy-methoxy compounds of molybdenum(VI). The formation, decomposition and reoxidation of the compound $Mo_2O_5(OCH_3)_2$ are found to correspond remarkably well with the three elementary steps of the catalytic cycle. Thermal decomposition experiments performed on the compounds

$$Mo_2O_5(OCH_3)_2,\ Mo_2O_5(OCD_3)_2,\ Mo_2O_5(OCH_3)_2 \cdot 2CH_3OH$$

and $Na_4[Mo_8O_{24}(OCH_3)_4] \cdot 8CH_3OH$ imply that C—H bond breaking is rate-limiting in accord with the kinetically determined catalytic result. The nature of the catalytic site, inhibition of the reaction by water, and poisoning of the catalyst by pyridine are also adequately modeled. The structure of $Na_4[Mo_8O_{24}(OCH_3)_4] \cdot 8CH_3OH$ is seen as a model for coordination geometry of the molybdenum–methoxy interaction at the catalyst surface.

In our laboratory much effort has been directed at understanding the mechanism of the selective oxidation of methanol to formaldehyde over molybdate catalysts.[1] While much of the work has involved reactor studies, surface science, and numerous physical techniques, a small but no less important effort has been aimed at synthesizing model compounds, i.e. compounds which mimic the chemistry of the catalytic process. In this paper we present the results of our model-compound studies and discuss how these compounds either helped to provide us with new insight or served to reinforce our earlier conclusions regarding methanol oxidation. The compounds to be discussed are

$$Mo_2O_5(OCH_3)_2,\ Mo_2O_5(OCD_3)_2,$$
$$Mo_2O_5(OCH_3)_2 \cdot 2CH_3OH,$$
$$Na_4[Mo_8O_{24}(OCH_3)_4] \cdot 8CH_3OH$$

and

$$(C_5H_5NH)_4[Mo_8O_{26}(C_5H_5N)_2] \cdot 2(CH_3)_2SO.$$

METHANOL OXIDATION

What follows is a brief, general overview of the selective oxidation of methanol to formaldehyde over molybdate catalysts. For a detailed account of how these conclusions were reached see the review of Cheng *et al.*[1]

Methanol reacts with molybdate surfaces at room temperature forming methoxy groups and liberating water. As the temperature is raised the methoxy groups begin to decompose forming formaldehyde and more water. These products rapidly desorb from the surface leaving the molybdate phase reduced. Rapid reoxidation of the catalyst takes place to complete the catalytic cycle. The rate-limiting step in this process is the abstraction of a methoxy hydrogen. The reaction is highly selective towards formaldehyde, with water found to be an inhibitor.

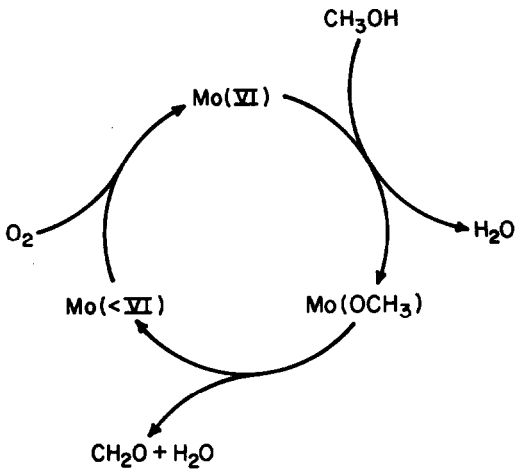

Fig. 1. Schematic diagram for the selective oxidation of methanol to formaldehyde over molybdate catalysts.

The active sites are determined to be coordinatively unsaturated molybdenum atoms.

The rest of this paper will deal with how the study of model compounds has either influenced or confirmed many of these above conclusions.

REACTIONS

A schematic diagram of the conversion of methanol to formaldehyde at a molybdate site is given in Fig. 1. The mechanism is seen to involve three elementary steps.[2] Parallels between each of the individual steps and the chemistry of the model compound, $Mo_2O_5(OCH_3)_2$, are given below.

Step 1

The uptake of methanol by MoO_3 at room temperature has been quantified by adsorption studies[2] and the formation of methoxy groups on the surface confirmed by IR measurements.[3] Less than monolayer coverage implies that MoO_3 is not very reactive towards methanol at low temperatures. This lack of reactivity can be attributed to the layer structure of MoO_3,[4] the surface of which consists predominantly of coordinatively saturated molybdenum atoms.

Fortunately, $MoO_3 \cdot 2H_2O$[5] is more reactive than MoO_3 at low temperatures. This enhanced reactivity is a result of the lability of the water molecule bound directly to molybdenum.[6]* A comparison of the layer structures of MoO_3 and $MoO_3 \cdot 2H_2O$ is given in Fig. 2.

In the case of $MoO_3 \cdot 2H_2O$, water loss makes coordinatively unsaturated molybdenum sites available for reaction:

$$MoO_{1/1}O_{4/2}H_2O_{1/1} \cdot H_2O \rightarrow MoO_{1/1}O_{4/2}\square_{1/1} + 2H_2O. \quad (1)$$

As a result, $MoO_3 \cdot 2H_2O$ reacts in absolute methanol as follows:[7]

$$2MoO_3 \cdot 2H_2O + 2CH_3OH \xrightarrow{60°C} Mo_2O_5(OCH_3)_2 + 5H_2O, \quad (2)$$

$$2MoO_3 \cdot 2H_2O + 4CH_3OH \xrightarrow{0°C} Mo_2O_5(OCH_3)_2 \cdot 2CH_3OH + 5H_2O. \quad (3)$$

Both reaction products are white microcrystalline powders with plate-like habits. The dimethanolate [eqn (3)] loses methanol at roughly 100°C

* The bond strength, s, of the Mo—OH_2 bond is 0.31, as calculated from the expression $s = (d/1.882)^{-6.0.24}$

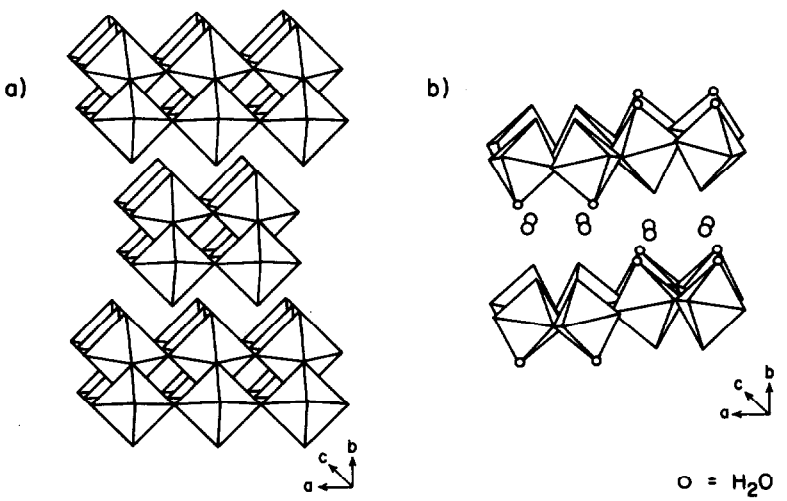

Fig. 2. The layer structures of: (a) MoO_3, and (b) $MoO_3 \cdot 2H_2O$.

converting to the simple dimethoxide [eqn (2)]. Hydrolysis of the dimethoxide gives the hemihydrate:[8]

$$Mo_2O_5(OCH_3)_2 + 2H_2O \rightarrow 2MoO_3 \cdot \tfrac{1}{2}H_2O + 2CH_3OH. \quad (4)$$

Hydrolysis may account for the inhibiting effect which water displays in the catalytic reaction.[9]

As yet the actual structure of $Mo_2O_5(OCH_3)_2$ is unknown, but a structure can be proposed consistent with the following observations: (1) $Mo_2O_5(OCH_3)_2$ exhibits a single-line solid-state ^{13}C NMR spectrum (Fig. 3), implying that all carbon environments are equivalent; and (2) $Mo_2O_5(OCH_3)_2$ adopts a plate-like crystal habit, suggesting that the structure is layered. The proposed structure, shown in Fig. 4, is based on stacked double layers (ReO_3-type) of $MoO_{5/2}(OCH_3)_{1/1}$ corner-sharing octahedra.

A comparison of the IR spectra of methoxy groups bound to the surface of MoO_3 and $Mo_2O_5(OCH_3)_2$ is shown in Fig. 5. The similarity of the IR data led us to conclude that the chemistry taking place in both cases is essentially equivalent. This apparent chemical equivalence, when coupled with the seeming necessity that coordinatively unsaturated molybdenum atoms be present for reaction to occur [from eqn (1)], led us to speculate that the *010* surface of MoO_3 would be inactive with respect to methanol chemisorption. In fact, it has been shown that, in the case of oriented single crystals, methanol adsorbs intact on the *010* surface but does not dissociatively chemisorb.[10] Therefore, methanol oxidation must take place on non-*010* surfaces ($\sim 10\%$ of the total surface area of a typical MoO_3 sample). Subsequent temperature-programmed desorption experiments have shown that only 12% of the surface molybdenum sites are catalytically active, further supporting this hypothesis.[11]

Step 2

The rate-limiting step in methanol oxidation, as determined by kinetic studies,[12] is the transfer of a

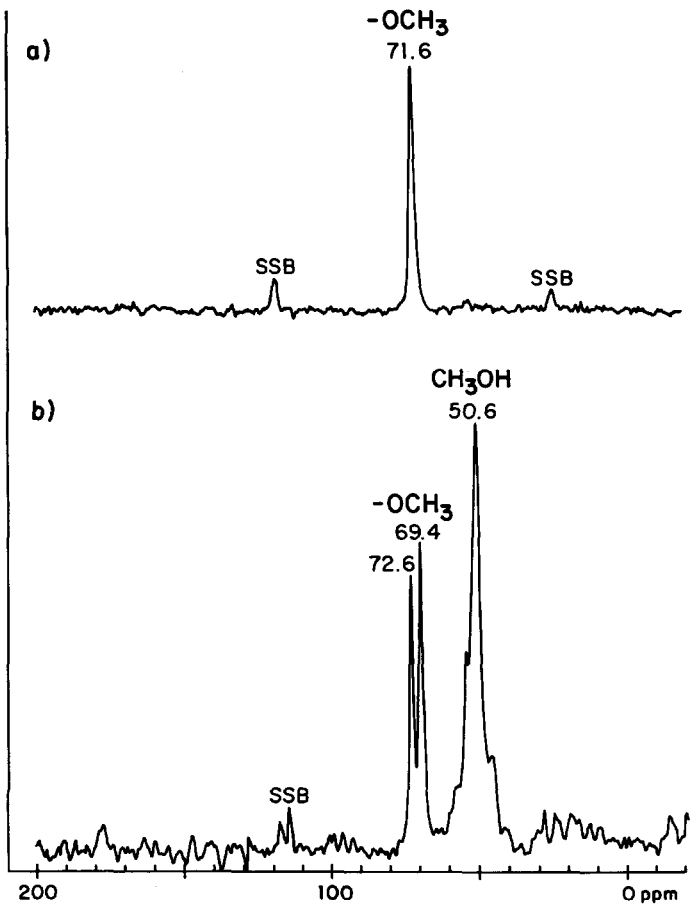

Fig. 3. Solid-state ^{13}C NMR spectra (^{13}C CP-MAS, 75 MHz) for: (a) $Mo_2O_5(OCH_3)_2$, and (b) $Na_4[Mo_8O_{24}(OCH_3)_4] \cdot 8CH_3OH$.

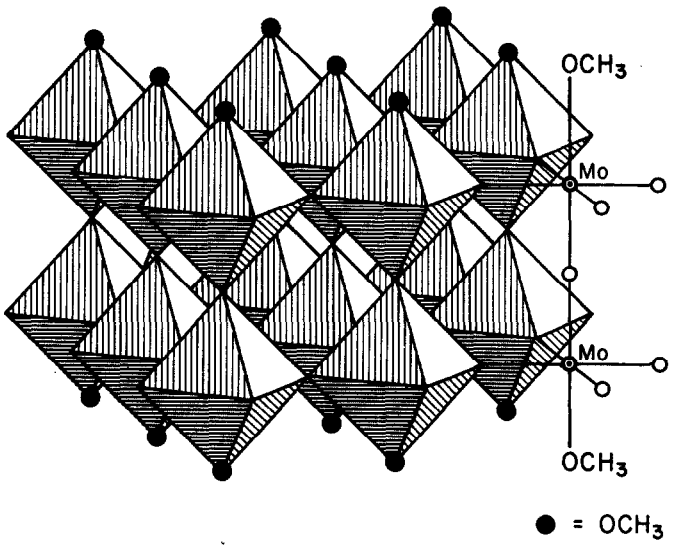

Fig. 4. Proposed structure for $Mo_2O_5(OCH_3)_2$.

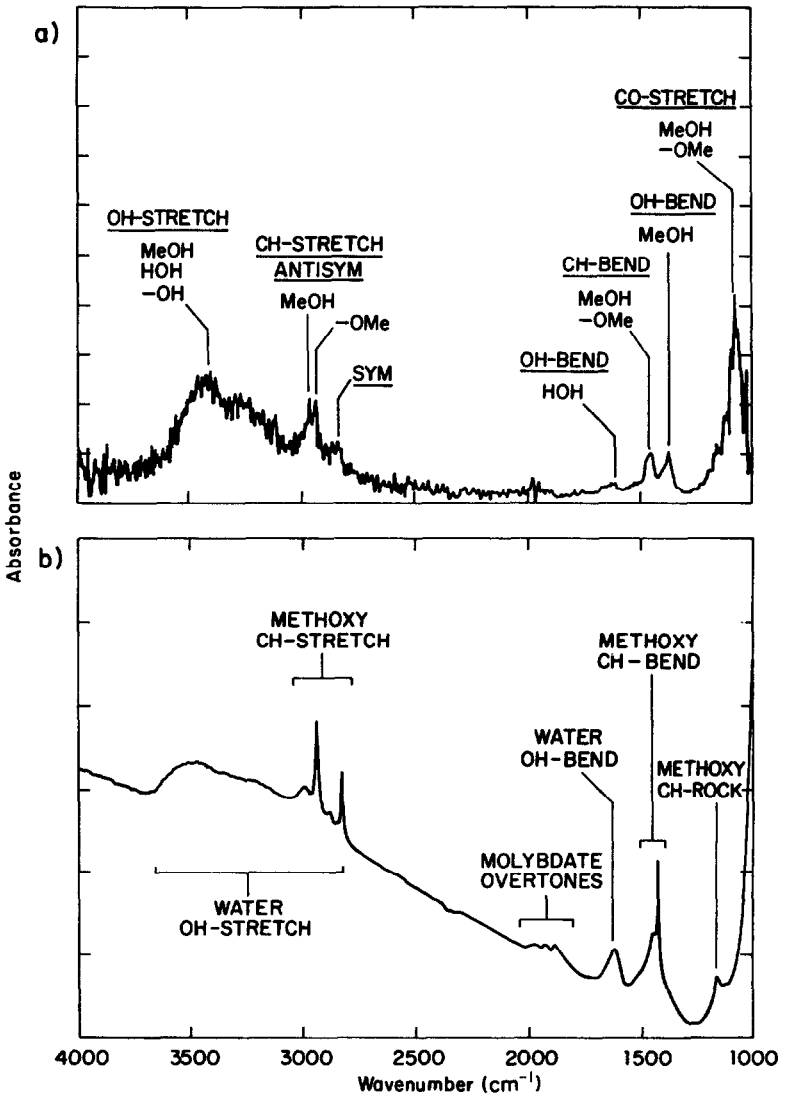

Fig. 5. A comparison of the FTIR spectra (MoO_3–CH_3OH—reflectance IR; $Mo_2O_5(OCH_3)_2$—transmission IR) of: (a) MoO_3–CH_3OH surface species, and (b) $Mo_2O_5(OCH_3)_2$.

hydrogen from a methoxy group to a surface oxygen. Coupled to the hydrogen transfer is the rapid loss of formaldehyde and water, with concomitant reduction of the molybdate catalyst.

$Mo_2O_5(OCH_3)_2$ is also observed to undergo redox chemistry. When exposed to sunlight, white $Mo_2O_5(OCH_3)_2$ photodecomposes leaving a blue-colored, amorphous residue. Subsequent photolysis experiments, monitored by mass spectroscopy, revealed that, in the initial stages of decomposition, roughly equal amounts of formaldehyde and methanol were produced:

$$Mo_2O_5(OCH_3)_2 \rightarrow [Mo_2O_5] + CH_2O + CH_3OH. \quad (5)$$

This result is consistant with either photon-assisted C—H bond breaking[13] or photo-generation of methoxy radicals.[14] However, an observed increase in the formaldehyde:methanol ratio with time suggests that C—H bond activation is indeed responsible—as photodecomposition decreases the number of methoxy groups available for reaction with photo-liberated hydrogen:

$$—OCH_3 \rightarrow CH_2O + —H, \quad (6)$$

the probability of forming methanol:

$$—H + —OCH_3 \xrightarrow{-2\bar{e}} CH_3OH \quad (7)$$

must also decrease.

This leads to a build-up of hydrogen in the reduced molybdate residue. In the limit that no methanol is formed, the reaction becomes:

$$Mo_2O_5(OCH_3)_2 \rightarrow [H_2Mo_2O_5] + 2CH_2O. \quad (8)$$

The extent of reduction, x [a measure of the relative rates of eqns (5) and (8)], of the molybdate phase has never been quantitatively determined, but could be measured in principle by monitoring either the quantities of the gases evolved or by counting the residual protons [combining eqns (5) and (8)]:

$$Mo_2O_5(OCH_3)_2 \rightarrow [H_{2x}Mo_2O_5] + (1+x)CH_2O + (1-x)CH_3OH, \quad (9)$$

where x will have a value between 0 and 1.

Step 3

The reoxidation of the reduced molybdate catalyst phase is fast under catalytic condition owing to the high surface oxygen mobility and high electronic conductivity of the reduced phase at temperatures above 200°C. At room temperature, as in the case of photochemically decomposed $Mo_2O_5(OCH_3)_2$, reoxidation of the residue is found to be slow. However, thermogravimetric analysis has shown that reoxidation of the photochemically reduced residue is complete at 350°C, the normal operating temperature of the catalytic reaction:[15]

$$[H_{2x}Mo_2O_5] + \left(\frac{1+x}{2}\right)O_2 \rightarrow 2MoO_3 + xH_2O. \quad (10)$$

THERMAL-DECOMPOSITION EXPERIMENTS

$Mo_2O_5(OCH_3)_2$

The nature of the photolysis experiments is such that complete decomposition of $Mo_2O_5(OCH_3)_2$ is never certain. Therefore, the thermal decomposition of $Mo_2O_5(OCH)_3)_2$ was investigated as a means of determining the full extent of the redox chemistry.

Thermogravimetric curves for $Mo_2O_5(OCH_3)_2$ both *in vacuo* and in oxygen are shown in Fig. 6. The general observations to note are the following: (1) $Mo_2O_5(OCH_3)_2$ decomposes sharply at ~225°C; (2) *in vacuo*, a second sharp decomposition takes place at ~325°C; and (3) in oxygen, decomposition and reoxidation of the molybdenum oxide residue appear to occur simultaneously. Additionally, it was noted that the degree of reduction of the residue (maximum weight loss *in vacuo*) was dependent upon the heating rate, with faster rates leading to deeper reduction. A series of experiments was performed in an attempt to sort out the effect of thermal treatment upon $Mo_2O_5(OCH_3)_2$ decomposition.

A typical decomposition experiment involved the rapid heating of $Mo_2O_5(OCH_3)_2$ *in vacuo* to a given temperature and holding it there until gas evolution ceased. Evolved gases were monitored by mass spectroscopy and the decomposition residues characterized by powder X-ray diffraction. Experiments run in a flowing helium atmosphere allowed for the quantitative analysis of the evolved gases by gas chromatography. After annealing at 500°C *in vacuo* to remove water, the relative degree of reduction of molybdenum oxide residue was measured thermogravimetrically by uptake of oxygen [see eqns (11) and (13) below].

All thermal-decomposition experiments resulted in the production of the following gaseous products: formaldehyde, water, methanol and dimethyl ether. Changes in the product distribution, reflected by changes in the O/Mo ratio of the residues, were monitored over the temperature range 200–400°C, at roughly 50°C intervals. Table 1 lists the results.

A gross change in the nature of the product distribution is seen to occur at ~325°C, the

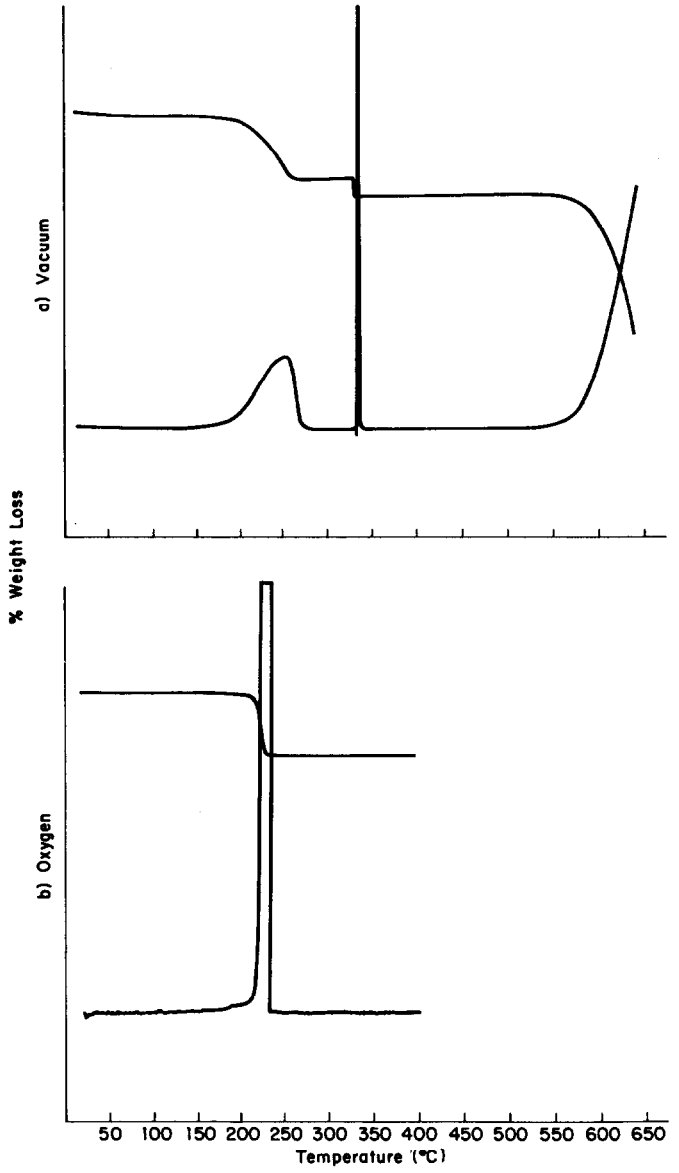

Fig. 6. TGA data (Du Pont 951-990 instrument at a heating rate of 5°C min^{-1}) for $Mo_2O_5(OCH_3)_2$: (a) *in vacuo*, and (b) in oxygen.

temperature of the sharp decomposition in the vacuum TGA data (Fig. 6). Below 325°C the distribution of the products was such that, as the reaction temperature at which the $Mo_2O_5(OCH_3)_2$ sample was decomposed was increased, the amounts of formaldehyde and water produced increased at the expense of methanol and dimethyl ether. At all temperatures above 325°C, the product distribution remained constant. Closer examination of this 325°C event revealed that it coincided with an abrupt water loss and a change in the molybdate residue from an amorphous to a crystalline state. The crystalline material was determined to be a mixture of MoO_2 and Mo_4O_{11}. Following from eqn (9):

$$3[H_{2x}Mo_2O_5] \xrightarrow{325°C} (2+4x)MoO_2 + (1-x)Mo_4O_{11} + 3xH_2O. \quad (11)$$

Apparently, above 325°C, water formation [following from eqn (6)]:

$$2(\text{—H}) + O^{2-} \xrightarrow{-4\bar{e}} H_2O \quad (12)$$

is facile and controls the product distribution by competing successfully with methanol formation [eqn (7)].

Table 1. Temperature dependence of the thermal decomposition of $Mo_2O_5(OCH_3)_2$

Decomposition temperature (°C)	$MoO_2 : Mo_4O_{11}$ ratio[a]	O/Mo[b]	Product formation trend			
			CH_2O	H_2O	CH_3OH	$(CH_3)_2O$
150	Trace MoO_2	2.75	↓	↓	↑	↑
200	~1:2	2.68				
250	~1:1	2.60				
300	~3:2	2.54				
350[c]	~2:1	2.50				
400[c]	~2:1	2.50				

[a] Determined by a comparison of the relative X-ray powder diffraction peak intensities of the individual molybdenum oxide phases of the residue [see eqn (9)] with those observed for simple physical mixtures of the phases.

[b] O/Mo for the molybdenum oxide residues was determined thermogravimetrically by weight gain in oxygen, in accordance with eqn (13). Deeper reduction corresponds to lower O/Mo values.

[c] Above ~325°C, O/Mo is observed to be constant.

Oxygen uptake measurements on samples decomposed at temperatures above 325°C indicate that $x = 0$ [O/Mo = 2.5 (Table 1)] for eqn (13):

$$(2+4x)MoO_2 + (1-x)Mo_4O_{11} + \tfrac{3}{2}(1+x)O_2 \xrightarrow{500°C} 6MoO_3. \quad (13)$$

This implies that $x = 0$ for eqn (11) also, which is at odds with the observed water loss. In fact, for decompositions run at lower temperatures, x appeared to be negative {O/Mo > 2.5 [$x = 5 - 2$(O/Mo)] (see Table 1)}. These apparent contradictions can be attributed to the production of dimethyl ether:

$$Mo_2O_5(OCH_3)_2 \rightarrow 2MoO_3 + (CH_3)_2O. \quad (14)$$

The production of dimethyl ether does not involve the reduction of Mo(VI). This leads to an anomalously low x value as measured by oxygen uptake. Therefore, the true measure of the extent of the reduction of $Mo_2O_5(OCH_3)_2$ would involve quantifying the water formed [eqn (11)].

Regarding dimethyl ether formation, it should be noted that the steady-state catalytic reaction of methanol on MoO_3 can produce significant quantities of dimethyl ether under low-conversion conditions where the surface concentration of methoxy groups is expected to be greatest.[9] This is in qualitative agreement with the $Mo_2O_5(OCH_3)_2$ results embodied in eqn (14).

Table 1 indicates that dimethyl ether formation is favored at lower reaction temperatures. This result can be understood as being a result of the fact that C—H bond breaking is rate-limiting. Thus, at lower temperatures, where the energy for C—H bond breaking is less, the rate of methoxy decomposition is slow. This allows for intact methoxy groups to react with liberated methanol [eqns (6) and (7)] to produce hydroxyl groups and form dimethyl ether:

$$—OCH_3 + CH_3OH \rightarrow —OH + (CH_3)_2O. \quad (15)$$

As the reaction temperature is increased, the rate of methoxy decomposition increases and, as a result, the number of methoxy groups available for reaction with methanol must decrease, suppressing the formation of $(CH_3)_2O$. Furthermore, the increased rate of methoxy decomposition [eqn (6)] makes available more hydroxyl groups:

$$—H + O^{2-} \xrightarrow{-2\bar{e}} —OH \quad (16)$$

for recombination with any liberated methanol:

$$—OH + CH_3OH \rightarrow —OCH_3 + H_2O, \quad (17)$$

which, in turn, leads to further reduction:

$$2(—OCH_3) \xrightarrow{-(2+2x)\bar{e}} 2x(—H) + (1+x)CH_2O + (1-x)CH_3OH. \quad (18)$$

The net result is that increasing the reaction temperature leads to increased formaldehyde formation and, consequently, deeper reduction of the molybdenum oxide residue. Further evidence for this line of thinking will be presented in the next two sections and the section on $[Mo_8O_{24}(OCH_3)_4]^{4-}$.

For the most part the thermal-decomposition results are similar to those observed for photodecomposition. The major difference lies in the formation of dimethyl ether. That dimethyl ether formation is absent during the room-temperature photodecomposition experiments implies that the reaction mechanism which leads to dimethyl ether

has a thermal-activation threshold somewhat above ambient conditions.

$Mo_2O_5(OCH_3)_2 \cdot 2CH_3OH$

With respect to thermal decomposition, the additional two methanol molecules of the dimethanolate, $Mo_2O_5(OCH_3)_2 \cdot 2CH_3OH$, should promote the formation of dimethyl ether as indicated by eqn (15). This has been observed experimentally; for a given reaction temperature, the degree of reduction of the residue is found to be less for

$$Mo_2O_5(OCH_3)_2 \cdot 2CH_3OH$$

than for $Mo_2O_5(OCH_3)_2$ (see Table 2).

Deuteration

$MoO_3 \cdot 2H_2O$ was reacted with CD_3OH to produce $Mo_2O_5(OCD_3)_2$. In a gross demonstration of the kinetic isotope effect, it was observed that, for a given reaction temperature, the degree of reduction of the residue of $Mo_2O_5(OCD_3)_2$ was less than that of the undeuterated material (see Table 2). Again the suppression of C—H bond breaking, this time by the kinetic isotope effect, slows the rate of methoxy decomposition and enhances the probability that liberated methanol will combine with intact methoxy groups to produce dimethyl ether [eqn (15)].

Additionally, it was noted that the photodecomposition of the deuterated material was not as rapid as that of $Mo_2O_5(OCH_3)_2$ under similar conditions.

ISOPOLYMOLYBDATES

Unfortunately, the state of surface science at present does not allow for a direct, detailed examination of the surface molybdenum–methoxy coordination geometry. Therefore, the only hope of inferring the structure of the surface species lies in making analogies with model compounds.

Although the correspondence between the chemistry of $Mo_2O_5(OCH_3)_2$ and the surface chemistry of MoO_3 is clearly evident from the above discussions, the lack of structural details for $Mo_2O_5(OCH_3)_2$ was particularly distressing, since, given the chemical similarity, a structural similarity was most probable.

$[Mo_8O_{24}(OCH_3)_4]^{4-}$

Fortunately, on the basis of the work of Klemperer and co-workers[16–18] and the work of Knoth and Harlow,[19] it appeared that chemistry similar to that described for the $Mo_2O_5(OCH_3)_2$ system could be performed on isopolymolybdate anions.

The compound

$$Na_4[Mo_8O_{24}(OCH_3)_4] \cdot 8CH_3OH,^{20}$$

can be produced by any of the following reactions:

$$2Na_2MoO_4 + 6MoO_3 + 12CH_3OH \xrightarrow[CH_3OH]{abs.} Na_4[Mo_8O_{24}(OCH_3)_4 + 8CH_3OH + 2H_2O, \quad (19)$$

$$4NaOCH_3 + 8MoO_3 + 8CH_3OH \xrightarrow[CH_3OH]{abs.} Na_4[Mo_8O_{24}(OCH_3)_4] + 8CH_3OH, \quad (20)$$

$$8MoO_3 \cdot 2H_2O + 12CH_3OH + 4Na^+ \xrightarrow[CH_3OH]{abs.} Na_4[Mo_8O_{24}(OCH_3)_4] + 8CH_3OH + 18H_2O + 4H^+. \quad (21)$$

Table 2. Comparison of the degree of reduction (as measured by the O/Mo of the molybdenum oxide residues)[a] of the compounds $Mo_2O_5(OCH_3)_2$, $Mo_2O_5(OCD_3)_2$ and $Mo_2O_5(OCH_3)_2 \cdot 2CH_3OH$ as a function of temperature

Decomposition temperature (°C)	O/Mo[b]		
	$Mo_2O_5(OCH_3)_2$	$Mo_2O_5(OCD_3)_2$	$Mo_2O_5(OCH_3)_2 \cdot 2CH_3OH$
150	2.75	2.88	2.94
250	2.60	2.73	2.80
350	2.50	2.61	2.71

[a] The degree of reduction is inversely proportional to O/Mo, with deeper reduction corresponding to lower O/Mo values.

[b] O/Mo determined thermogravimetrically by weight gain in oxygen, in accordance with eqn (13).

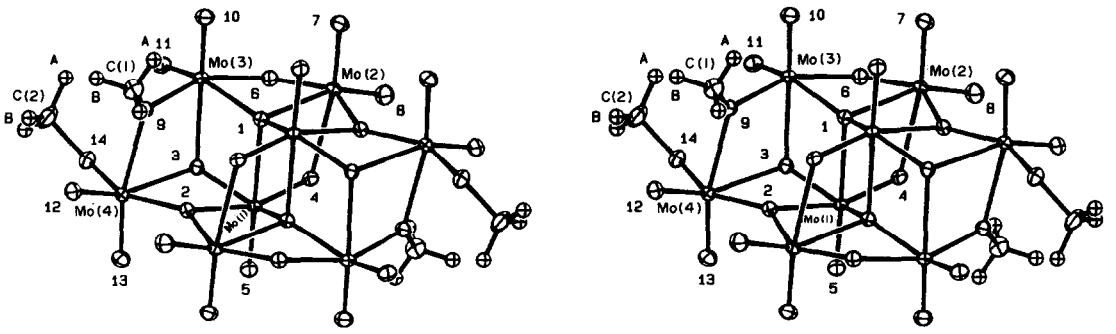

Fig. 7. Stereoscopic view of the $[Mo_8O_{24}(OCH_3)_4]^{4-}$ anion.

$Na_4[Mo_8O_{24}(OCH_3)_4]\cdot 8CH_3OH$ is soluble in methanol and is readily recrystallized from it. Absolute methanol also acts as a drying agent preventing hydrolysis:[21]

$$Na_4[Mo_8O_{24}(OCH_3)_4]\cdot 8CH_3OH + 4H_2O \rightarrow Na_4[Mo_8O_{26}]\cdot 2H_2O\cdot 8CH_3OH + 4CH_3OH. \quad (22)$$

The structure of the $[Mo_8O_{24}(OCH_3)_4]^{4-}$ anion is shown in Fig. 7. Both terminal and bridging methoxy groups are present and resonances for each have been identified in the solid-state ^{13}C NMR spectrum (Fig. 3). Presumably both types of methoxy group may be present on the surface of the MoO_3 catalyst, but so far attempts to probe the surface species by NMR techniques have been unsuccessful.

The structural details of the molybdenum–methoxy interactions are presented in Table 3. The Mo—O bond lengths and calculated bond strengths along with the Mo—O—C bond angles clearly indicate that the Mo—OCH_3 bond is of order 1, and not a molybdenyl type of interaction, Mo=OCH_3, for which a shorter Mo—O bond length and a more nearly linear Mo—O—C bond angle would be expected.

Photolysis of $Na_4[Mo_8O_{24}(OCH_3)_4]\cdot 8CH_3OH$ generates formaldehyde. There is one short intermolecular C—H—O contact for each of the two types of methoxy groups. Additionally, there is one short intramolecular C—H—O contact involving the terminal methoxy group. Table 4 lists the short C—H—O contacts which presumably are the sites of hydrogen transfer. A theoretical model for this photon-assisted C—H bond activation has recently been proposed by Anderson and Ray.[13]

In contrast, the thermal decomposition of $Na_4[Mo_8O_{24}(OCH_3)_4]\cdot 8CH_3OH$ generates primarily dimethyl ether. This is seen as a natural extension of eqn (15), since there are two coordinated methanol molecules for each methoxy group in the structure. Consequently, as more of the coordinated methanol is removed by gentle heating in a vacuum, more formaldehyde is detected as a decomposition product.

$[Mo_8O_{26}(C_5H_5N)_2]^{4-}$

The determination of the number of catalytically active sites on the surface of molybdates typically involves selective poisoning. A base which binds

Atoms[a]	O—H (Å)	C—H—O (°)	H—O—Mo (°)
C(1)—H(1)A—O(10)	2.49	116	90
C(2)—H(2)A—O(11)	2.48	120	109
C(2)—H(2)A—O(8″)	2.47	123	126

[a] Atom labels refer to Fig. 7.

more strongly to the molybdate surface than methanol is reacted with the molybdate in gradually increasing amounts. The base acts so as to block sites and inhibit methanol chemisorption. Just at the point where base addition effectively inhibits methanol chemisorption, the number of base molecules are counted and taken as a measure of the number of catalytically active sites. Pyridine is the base of choice for this selective poisoning. Accordingly, $MoO_3\cdot C_5H_5N$[22] does not react with methanol, whereas $MoO_3\cdot 2H_2O$ does.

The structure of $MoO_3\cdot C_5H_5N$ had not been solved completely and therefore the nature of the molybdenum(VI)–pyridine interaction was not known in detail. However, $MoO_3\cdot 2H_2O$ is observed to react with pyridine as follows:[23]

$$8MoO_3\cdot 2H_2O + 6C_5H_5N \xrightarrow{45°C} (C_5H_5NH)_4[Mo_8O_{26}(C_5H_5N)_2] + 14H_2O. \quad (23)$$

The product was recrystallized from dimethyl sulfoxide to give

$$(C_5H_5NH)_4[Mo_8O_{26}(C_5H_5N)_2]\cdot 2(CH_3)_2SO.$$

The structure of the anion is shown in Fig. 8. The strength of the Mo–N interaction is compared with other molybdenum–base interactions in Table 5.

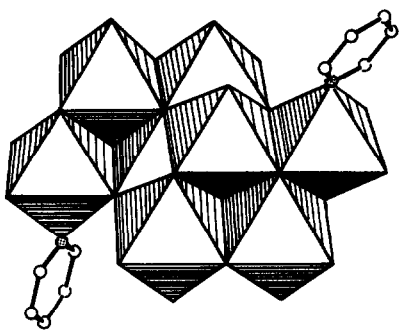

Fig. 8. The structure of the $[Mo_8O_{26}(C_5H_5N)_2]^{4-}$ anion.

Table 5. Comparison of molybdenum–base (Mo–X) interactions in various molybdenum(VI) oxide structures

X	d (Å)	s[a]	Dissociation temperature (°C)	Reference
H_2O	2.293	0.31	~120	6
C_5H_5N	2.279	0.32	~150	23
$(CH_3)_2SO$	2.245	0.35	~180	25

[a] Bond strengths calculated as in Ref. 24.

Once formed, the molybdenum–pyridine interaction cannot be displaced by the weaker base methanol even though the chemisorption of methanol would result in the formation of the stronger molybdenum–methanol interaction (Table 3).

CONCLUSIONS

The chemistry of the selective oxidation of methanol to formaldehyde over molybdate catalysts has been shown to be adequately modeled by both molybdenum oxy-methoxides and methoxy-containing isopolymolybdates. Formaldehyde formation, kinetics (rate-limiting C—H bond breaking and water inhibition), and the nature of the catalytically active sites are accounted for by analogy with the model compounds. Additionally, structural studies of the isopolymolybdates have provided coordination geometries which could not be determined by surface science.

(*Received* 15 *June* 1985)

Abstract—Catalysts from the series $K_xH_{3-x}PMo_{12}O_{40}$ have been characterized by X-ray diffraction, solid-state NMR, TGA–DTA and ESR, and the selectivity of this and similar systems in acrolein oxidation is discussed in the light of their multiphase nature.

Catalysts based on 12-molybdophosphoric acid have been shown to be highly selective in the oxidation of unsaturated aldehydes, such as acrolein and methacrolein, to the corresponding acids.[1,2] Several authors have investigated the effect of partial or total proton substitution by different cations on the catalytic performance, and the formation of the corresponding acid salts of the form

$$(M^+)_x(H_3O^+)_{3-x}PMo_{12}O_{40}$$

is usually assumed.[3–7]

In this note we report results indicating that in the case of the $K_xH_{3-x}PMo_{12}O_{40}$ series ($0 < x < 3$) the working catalysts are complex, multiphase systems; consequently simple correlations lose their significance.

EXPERIMENTAL

Materials

The catalysts were prepared by previously described procedures.[5,8] $H_3PMo_{12}O_{40} \cdot 28H_2O$ (ex BDH Ltd, "AnalaR" grade) was dissolved in water and the required quantities of K_2CO_3 (ex BDH Ltd, "AnalaR" grade) were added to the solution. The final product was obtained by evaporation to dryness under reduced pressure at 353 K. Fresh catalysts were calcined in air at 673 K.

Thermogravimetric analysis was carried out in static air in a Stanton–Redcroft STA-780 thermal analyser. Samples of around 150 mg (TGA only) or 15 mg (simultaneous TGA–DTA) were heated at 10 K min^{-1} up to 873 K.

Powder X-ray diffraction data were obtained with a Phillips PW-1720 diffractometer and a Guiner–Haag focusing camera.

A JEOL FX-200 spectrometer operating at 80.9 MHz was used to acquire ^{31}P solid-state NMR spectra. Magic angle sample spinning in Delrin rotors at 4 kHz was employed, and all spectra were referenced externally to 85% orthophosphoric acid.

ESR spectra were recorded at room temperature and at 77 K with a Varian E-112 century-line spectrometer equipped with a fieldial, operating in the *X*-band. DPPH ($g = 2.0036$) was used as a standard for the determination of *g*-factors.

Catalyst testing was carried out in a continuous flow microreactor at 623 K in an atmosphere of 4.5% acrolein and 10.5% oxygen in nitrogen. Organic products were detected with a flame ionization detector, and carbon oxides with a katharometer. Catalyst charges were between 0.3 and 1.0 g, and selectivity–conversion curves were obtained by varying the overall flow rate over the catalyst between 60 and 7.5 ml min^{-1}.

RESULTS AND DISCUSSION

The presence of more than one phase in the freshly prepared catalysts was initially detected by X-ray diffraction. A pattern characteristic of the cubic lattice of $K_3PMo_{12}O_{40}$ was detected in all potassium-containing samples. Extra peaks belonging to some of the hydrates of $H_3PMo_{12}O_{40}$ could be detected for compositions with $x < 2$.

Further evidence was supplied by the ^{31}P solid-state NMR spectra of the fresh catalysts shown in Fig. 1. The resonance at $\sigma = 4.3$ ppm is characteristic of $K_3PMo_{12}O_{40}$,[9] and the resonance at $\sigma = 3.9$ ppm is found in spectra of the free acids $H_3PMo_{12}O_{40} \cdot nH_2O$ with $n = 30$ and 9, but not with $n = 0$. This latter resonance also agrees well with the solution resonance of the $[PMo_{12}O_{40}]^{3-}$ anion ($\delta = -3.9$ ppm).[10]

The thermogravimetric results provide evidence that there is no solid solution range as x approaches 3. The only feature in the TGA curve for fresh $K_3PMo_{12}O_{40}$ [Fig. 2(a)] is the loss of physisorbed water below 500 K: otherwise it is thermally stable up to 873 K. On the other hand, the $H_3PMo_{12}O_{40}$ sample [Fig. 2(b)] loses its water of crystallization by 450 K, and the weight loss observed in the range 500–700 K corresponds exactly to the weight loss expected on complete decomposition of the acid (1.5 water molecules per Keggin anion). TGA profiles for the catalysts with intermediate values of x up to 2.75 were obtained, and all samples behaved as mixtures of the end members of the series, $H_3PMo_{12}O_{40}$ and $K_3PMo_{12}O_{40}$. The curve for $K_{2.5}H_{0.5}PMo_{12}O_{40}$ is presented as an example in Fig. 2(c). In particular, the weight loss between 500 and 750 K was consistent

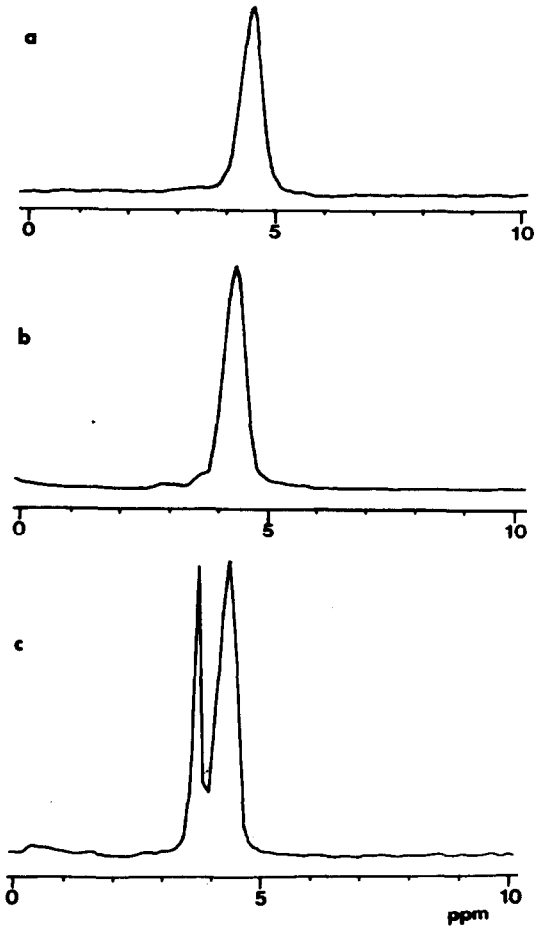

Fig. 1. Solid-state ^{31}P NMR spectra of: (a) $K_3PMo_{12}O_{40}$, (b) $K_2H_1PMo_{12}O_{40}$, and (c) $K_1H_2PMo_{12}O_{40}$.

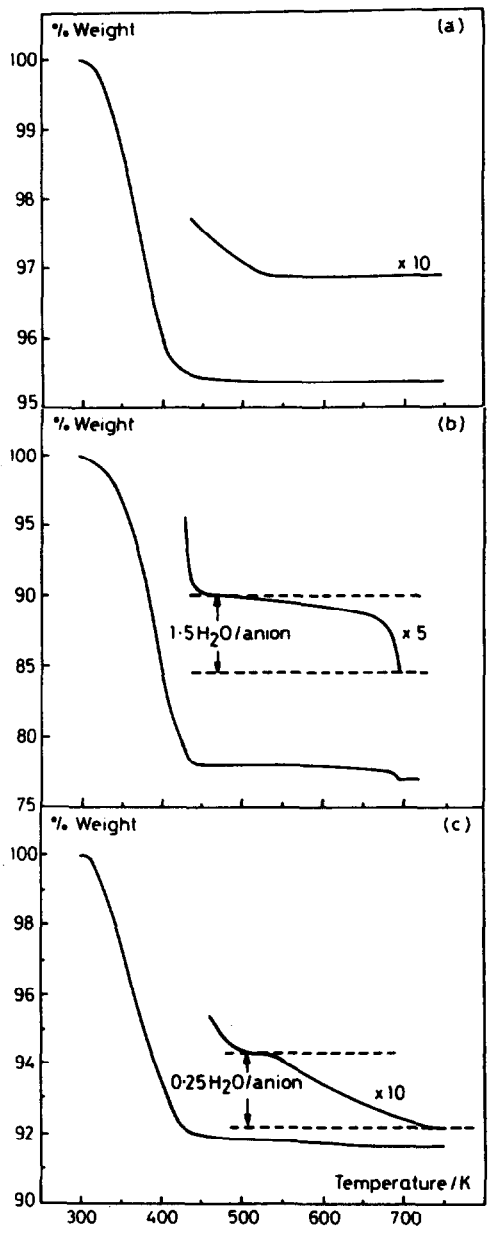

Fig. 2. TGA traces for: (a) $K_3PMo_{12}O_{40}$, (b) $H_3PMo_{12}O_{40} \cdot 28H_2O$, and (c) $K_{2.5}H_{0.5}PMo_{12}O_{40}$.

with the formulation $(x/3)K_3PMo_{12}O_{40}+(3-x)/3H_3PMo_{12}O_{40}$, but not with the solid solution stoichiometry

$$(M^+)_x(H_3O^+)_{3-x}PMo_{12}O_{40}^{3-}.$$

In addition, the features observed in the DTA curve for $H_3PMo_{12}O_{40}$ are reproduced at the same temperatures in all samples with $x < 3$.

Decomposition of $H_3PMo_{12}O_{40}$ begins by 500 K; although it only becomes rapid above 675 K, the thermal instability of this component in all of the catalysts means that the calcined catalysts must have an even more complex phase composition.

X-ray diffraction of the calcined $H_3PMo_{12}O_{40}$ catalyst showed the presence of MoO_3, indicating that at least part of the acid component undergoes complete decomposition on calcination. ESR investigation of the calcined samples showed that the MoO_3 formed is slightly oxygen-deficient, since the Mo(V) signal characteristic of the $[(MoO)O_4]^{5-}$ could be identified (Fig. 3).[11] This signal could be

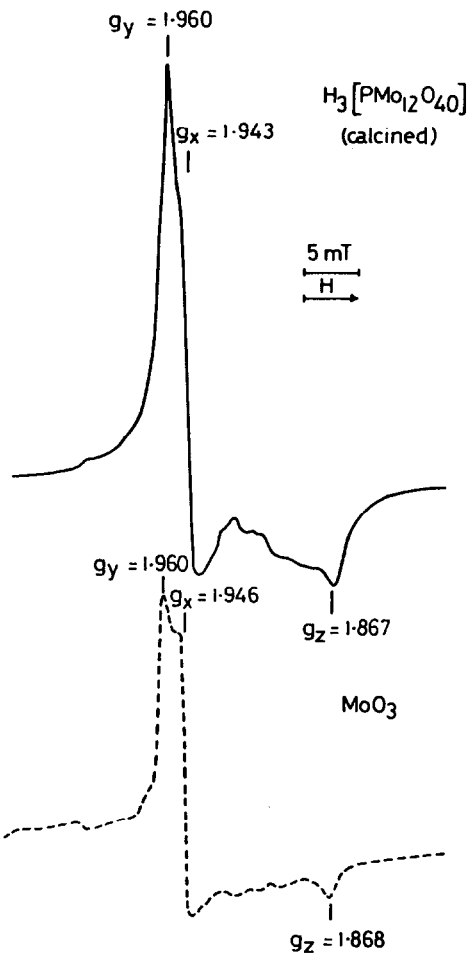

Fig. 3. ESR spectra of calcined $H_3PMo_{12}O_{40}$ and $[(MoO)O_4]^{5-}$ in MoO_3.

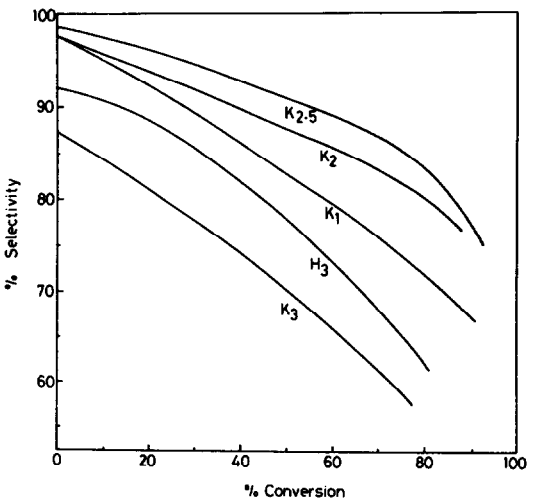

Fig. 4. Selectivity–conversion curves for catalysts from the series $K_xH_{3-x}PMo_{12}O_{40}$ in acrolein oxidation.

detected, in decreasing intensity, across the entire composition range up to (but not including) $x = 3$. Since MoO_3 is known to have a significant catalytic activity in many oxidation reactions, any discussion of catalytic results must take into account its presence as part of the multiphase working catalyst.

Figure 4 shows selectivity–conversion profiles for the oxidation of acrolein over the whole series of calcined catalysts. It can be seen that the maximum efficiency is achieved for $K_{2.5}H_{0.5}PMo_{12}O_{40}$. The catalytic performance of MoO_3 supported on Al_2O_3 was checked for comparison; MoO_3 was found to be active but non-selective in acrolein oxidation. In view of this we associate the steady fall in selectivity for $x < 2.5$ with the increasing amount of MoO_3 and possibly other decomposition products of $H_3PMo_{12}O_{40}$ in the calcined catalysts. The poorer selectivity of $K_3PMo_{12}O_{40}$ is thought to be due to the lack of sufficient Bronsted acidity necessary for desorption of the reaction product.

In conclusion, it is clear that the $K_xH_{3-x}PMo_{12}O_{40}$ system is a complex multiphase mixture, and this must be appreciated in interpreting the catalytic data. Other 12-molybdophosphate systems prepared in a similar manner, such as $Cs_xH_{3-x}PMo_{12}O_{40}$ and $(NH_4)_xH_{3-x}PMo_{12}O_{40}$, are most probably multiphase mixtures as well, contrary to the accepted view representing them as acid salts. Their catalytic properties, which correspond closely to those reported here for the potassium-based series,[12,13] must be reinterpreted in the light of this finding.

DEFECT STRUCTURE AND CATALYTIC PROPERTIES OF MOLYBDENUM SULFIDE

HENRY WISE

Materials Research Laboratory, SRI International, Menlo Park, CA 94025, U.S.A.; and Department of Materials Science and Engineering, Stanford University, Stanford, CA 94305, U.S.A.

(*Received in revised form* 26 *June* 1985)

The physical properties of layered transition-metal chalcogenides have been studied in considerable detail. The work has led to a basic understanding of the relationships between their structural, optical, magnetic, superconductive and electrical properties.[1–3] Among these compounds the group VI dichalcogenides MoS_2 and WS_2 are of special interest because of their wide range of catalytic properties, extending from hydrodesulfurization (HDS) and hydrodenitrogenation to hydrogenation, isomerization and methanation.

Thus it is timely to inquire into the relationships which may exist between the electronic properties of these materials and their catalytic behavior.

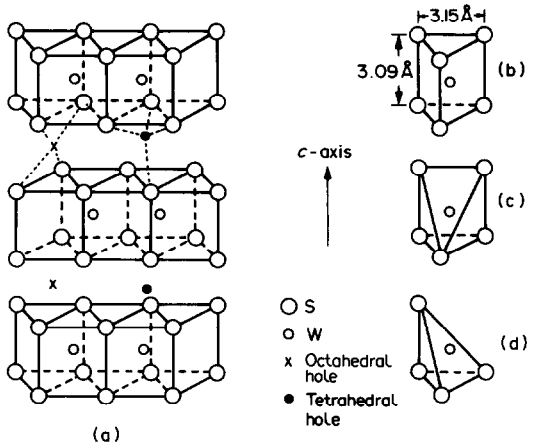

Fig. 1. Crystal structure of MoS_2.

PHYSICAL PROPERTIES

Crystal structure

Molybdenum sulfide, as well as tungsten sulfide, exhibits a hexagonal or rhombohedral crystal structure, in which one cation layer is sandwiched between two anion layers. Bonding of each metal atom to six sulfur atoms is covalent with trigonal prismatic coordination. Each of the three-layer slabs is stacked in the z-direction and held together by weak van der Waals' (vdW) forces (Fig. 1). As a result cleavage between the slabs is readily achieved. Two-dimensional projections of the hexagonal and rhombohedral polymorphs of MoS_2, designated by 2H-MoS_2 and 3R-MoS_2, are indicated in Fig. 2. (The prefixes indicate the number of metal atoms in each unit cell.) Empty octahedral and tetrahedral sites are found in the vdW gap, which can be filled by intercalation with foreign metal atoms.[4] This process is to be distinguished from substitutional or interstitial doping.

Band structure and electronic properties

Based on electrical and optical measurements, band diagrams[5] have been constructed for the dichalcogenides (Fig. 3). For the group VI sulfides with d^2-configuration on the metal atom, as for MoS_2, the overlap of the d_{z^2}-orbitals results in the formation of a full d_{z^2} band. As a result MoS_2 is a semiconductor. For the group V compounds with d^1-configuration, such as NbS_2, the d_{z^2} band is half filled. As a result metallic properties are exhibited by this material. For the group IV compounds with d^0-configuration, such as ZrS_2, the d_{z^2} band is empty and insulator properties are observed. In MoS_2 the conduction band (Fig. 4), made up of the Mo4d orbitals ($4d_{xy}$ and $4d_{x^2-y^2}$), is about 3 eV wide. The

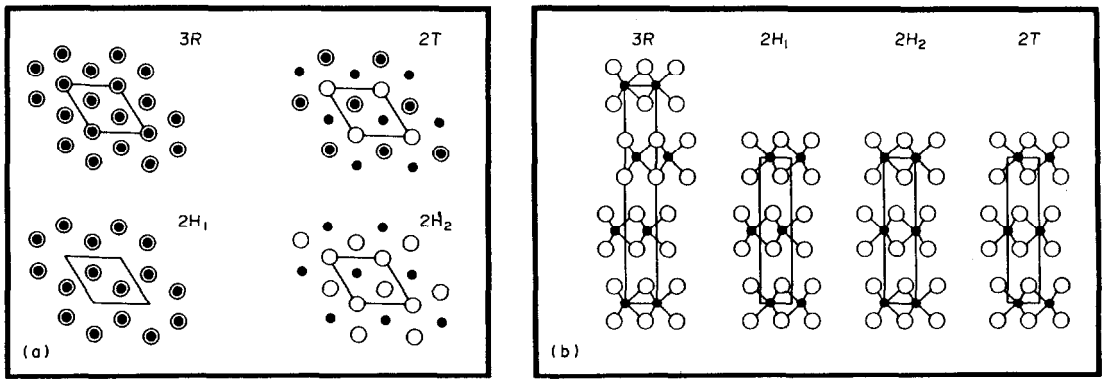

Fig. 2. MoS_2 crystal polytypes (from *Bull. CDB* 1973, **17**, 5, Climax Molybdenum Co.). (a) Along *c*-axis, and (b) along a_2-axis. (●) Mo, and (○) S: Mo and S atoms located one above the other.

non-bonding $4d_{z^2}$ orbitals are 1.75–2 eV below the conduction band. Overlapping with the $Mo4d_{z^2}$ band is the S3*p* valence band, approximately 5 eV wide. The narrow $Mo4d_{z^2}$ band near the valence band allows *d–d* transitions. Both *p*- and *n*-type conductivity are exhibited by molybdenum sulfide as a result of: (1) doping with foreign cations[6] with valence states different from that of Mo^{4+}, or (2) by adjusting the ratio S^{2-}/Mo^{4+} in the material. For $Mo_{1\pm x}S_2$ the stability range appears to be quite large.

For a single crystal of molybdenum sulfide the defects associated with a range of sulfur activities were evaluated from equilibrium conductivity studies in the presence of H_2S–H_2 gas mixtures of different composition. The catalyst, in the form of a small single crystal ($1 \times 1 \times 0.1$ cm), was cut from a larger crystal of naturally occurring molybdenite* [hexagonal crystal structure (C7)]. It was mounted in a quartz reactor provided with Pt feedthroughs for electrical conductivity measurements by the four-probe technique. The electrical conductors were made of Pt wire (0.075 cm in thickness) and attached to the four corners of the crystals. Good electrical contact was achieved by drilling a small hole in each corner of the crystal and tightly looping the Pt wire through the opening and around the crystal. The resistivity of the original crystal was measured and found to be comparable to that reported for molybdenum sulfide.[7]

The layer structure of MoS_2 favors rapid transport of ionic species within the lattice at elevated temperatures. Also measurements of the Hall coefficient, after establishment of equilibrium at the gas–solid interface, permit identification of the type of lattice defects.

*This material was kindly provided by Climax Molybdenum Co. of Michigan.

For *n*-type molybdenum sulfide,* the starting material in our studies, the interaction with a sulfur-containing atmosphere may be formulated as:

$$S_2(g) + 4e + 2V_a \rightleftarrows 2S^{2-}, \quad (1)$$

where e represents an electron and V_a an unoccupied anion vacancy, with an effective charge of +2 relative to the normal lattice since it can trap one or two electrons. Reaction (1) in the forward direction describes the addition of sulfur to the lattice with depletion of electrons and anion vacancies.

For low vacancy concentrations, the law of mass action yields at equilibrium:

$$K = 1/p_{S_2}[n_e]^4[V_a]^2, \quad (2)$$

where $[n_e]$ denotes the electron density and $[V_a]$ the anion vacancy density. Since the electrons and vacancies contribute to conduction, the electrical conductivity is given by:

$$\sigma \propto (Kp_{S_2})^{-1/6}, \quad (3)$$

i.e. the conductivity is inversely proportional to the sulfur pressure raised to the $\frac{1}{6}$th power. By analogous reasoning the prevalence of singly charged lattice defects (V_a^-) would yield a conductivity dependence on sulfur pressure of:

$$\sigma \propto (K'p_{S_2})^{-1/4} \quad (4)$$

and for doubly charged imperfections (V_a^{2-}):

$$\sigma \propto (K''p_{S_2})^{-1/2}. \quad (5)$$

Thus, measurement of the electrical conductivity as a function of sulfur pressure allows identification of the type of anion vacancy constituting the lattice defect in the catalyst.

For sulfur pressures of less than 10^{-8} atm, a decline in electrical conductivity was observed with increasing sulfur pressure (Fig. 5). The conductivity data exhibit a sulfur pressure exponent of about $-\frac{1}{8}$, somewhat less than the value derived from the equilibrium given by eqn (2). This discrepancy may be associated with inadequate quenching of the equilibrium composition and/or the presence of impurities in the crystal.

At a partial pressure of S_2 near 10^{-8} atm the conductivity passes through a minimum and the semiconductor becomes intrinsic, with equal concentration of electron and hole carriers. Because of variations in mobility of the carriers this condition does not coincide with the ideal stoichiometry of MoS_2 (i.e. $S^{2-}/Mo^{4+} = 2$). At higher sulfur activities

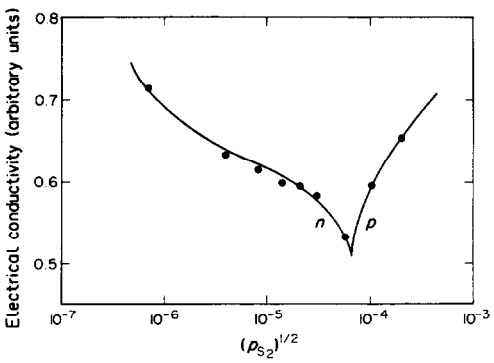

Fig. 5. Electrical conductivity of molybdenum sulfide equilibrated with sulfur at 893 K and quenched to 300 K.

an increase in conductivity is observed with a transition from *n*- to *p*-type behavior. In this region the predominant process of sulfur addition to the crystal proceeds by way of

$$S_2(g) \rightleftarrows 2S^{2-} + 4p + V_c,$$

where V_c represents a cation vacancy and p an electron hole.

Over the range of sulfur activities used in the conductivity measurements, the carrier density is estimated to vary from 10^{16} to 10^{18} cm^{-3} based on available mobility data.[7]

An alternative method for changing the electronic carrier density and carrier type in molybdenum sulfide is the introduction of foreign cations with different valence states from that of Mo^{4+}. In this case the use of Co^{2+} is of special interest because of its prevalent use as a promoter in various catalysts based on molybdenum sulfide. Based on the principle of "controlled conductivity", the incorporation of a foreign divalent cation will result in the formation of Mo^{4+} cation vacancies and hole conduction.

The introduction of Co^{2+} into MoS_2 was achieved by exposure of the crystal to an aqueous 0.1 M solution of $Co(NO_3)_2$, followed by evaporation of the solvent, sintering and exposure to H_2S. As detailed in Table 1, the doping process was monitored by electrical conductivity and Hall coefficient measurements. Both an increase in conductivity and change in carrier type from *n*- to *p*-type were observed (Table 1). Based on the conductivity data, the doping level was estimated to be of the order of 10–100 ppm.

CHARGE TRANSFER DURING SURFACE CATALYSIS

A series of HDS experiments were performed in which pulses of gaseous butyl mercaptan were

*As determined in separate Hall coefficient measurements.

Table 1. Electronic properties of doped MoS_2 crystal with Co^{2+}

Treatment	Electrical conductivity[a] (mho cm^{-1})	Electronic carrier type
Before doping	0.17	*n*
After doping[b]	0.47	*p*

[a] Measured at 300 K.

[b] Heated in He at 900 K for 18 h, in H_2 at 800 K for 12 h, and in H_2S–H_2 (1000 ppm) at 880 K for 4 h.

injected into the carrier stream of H_2 which passed over the single crystal of molybdenum sulfide at a flow rate of 2 cm^3 s^{-1}, at 760 torr. After leaving the reactor the gas mixture entered the gas chromatograph for quantiative determination of the products (butene, butane, H_2S and butyl mercaptan). Provisions were made for pretreatment of the crystal with H_2 or H_2S–H_2 at elevated temperatures (850–900 K). In addition the conductivity of the crystal was monitored during passage of the butyl mercaptan pulse. The electrical responses observed were found to be strongly dependent on the type and concentration of defects in the crystal. For *n*-type material containing more than 10^{18} electrons cm^{-3}, the charge exchange at the gas–crystal interface was of the type shown in Fig. 6. The transient electrical response during the pulsed HDS reaction was accompanied by a rapid decline in conductivity followed by a recovery to less than the initial value. Subsequent pulses, as shown for pulse numbers 3 and 15, continued to show the same pattern of conductivity response. The time between pulses was varied from 5 to 10 min during which the catalyst crystal was exposed to the flowing H_2 carrier gas. With each pulse of butyl mercaptan the electron density of the crystal was reduced. Most likely this

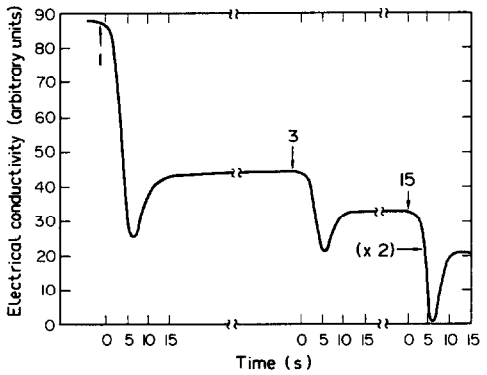

Fig. 6. Conductivity change of molybdenum sulfide crystal at 530 K during passage of reactant pulse.

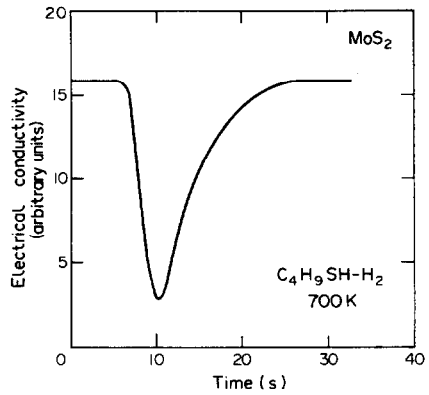

Fig. 7. Electrical response of MoS_2 crystal to passage of reactant pulse.

effect was accompanied by the incorporation of sulfur from the reactant pulse into the anion vacancies of the crystal. In accordance with eqn (1) the process results in a decrease in conductivity. On the other hand, for a catalyst with significantly lower anion vacancies, brought about by pretreatment in 4000 ppm H_2S (in H_2), the electrical response was entirely different (Fig. 7). Exposure to a pulse of butyl mercaptan caused a transient conductivity change with complete recovery to its initial value. The electron injection rate during the pulse was estimated to be about 10^{15}–10^{16} electrons cm^{-3} s^{-1}.

As shown by the results presented in Fig. 8, both the conversion of butyl mercaptan and the distribution of products were a function of the defect structure. At high concentrations of anion vacancies (high conductivity) the conversion of reactant was

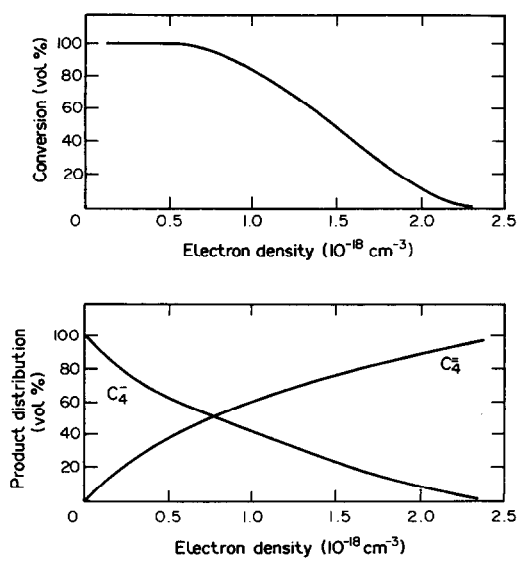

Fig. 8. HDS activity and product distribution at 700 K (C_4H_9SH).

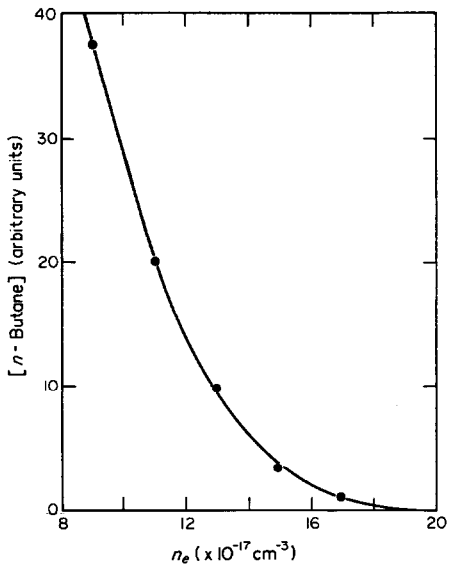

Fig. 9. Catalytic activity of molybdenum sulfide for 1-butene hydrogenation at 623 K.

relatively low and the major C_4 product was butene. However with decreasing anion vacancies, the conversion grew and butane predominated. In separate experiments of 1-butene hydrogenation the electron density was observed to control the conversion of the olefin to the alkane (Fig. 9). The results suggest that, during HDS of butyl mercaptan, the initial step involves the formation of butene which can be hydrogenated subsequently to butane if the catalyst exhibits *p*-type conductivity.

The results clearly demonstrate the close relationship between defect structure, catalytic activity and product specificity. This effect is further exemplified by the HDS properties of the cobalt-doped molybdenum sulfide crystal. In continuous flow experiments the steady-state conversion of butyl mercaptan was examined at 700 K at a feed mixture ratio of $H_2/C_4H_9SH = 1$ and compared to that of undoped molybdenum sulfide (Table 2) the data show the superior properties of the *p*-type crystal for HDS as compared to that of the *n*-type crystal. Of special interest is the formation of butane as a product in the case of electron holes as majority carriers.

This aspect is related to the high rate of hydrogen adsorption exhibited by the *p*-type catalyst and its high equilibrium coverage with chemisorbed hydrogen. For a highly dispersed molybdenum sulfide sample made from ammonium thiomolybdate[8] and pretreated at 800 K in H_2S–H_2 gas mixtures, the amount of H_2 adsorbed at different sulfur activities is shown in Fig. 10. It attains a value corresponding to a stoichiometry of $H_{0.039}MoS_2$. This value corresponds very closely to the saturation coverage of $H_{0.04}WS_2$ recently reported[9] from inelastic neutron-scattering experiments. For molybdenum sulfide the stoichiometry $H_{0.067}MoS_2$ was measured by the same authors.[10] The chemisorbed hydrogen is bonded to sulfur atoms. As a matter of fact the acidic nature of the SH group formed can be titrated with ammonia.[11]

In the presence of electron hole as majority carriers the adsorption of hydrogen may be facilitated by a process, such as:

$$\tfrac{1}{2}H_2(g) + p \rightleftarrows H^+(a).$$

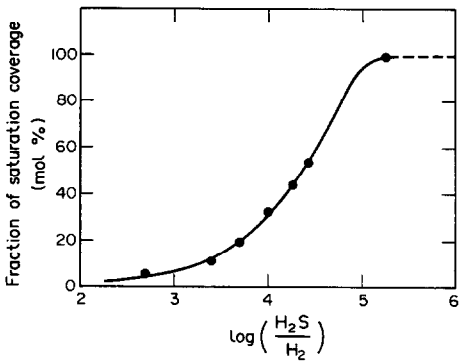

Fig. 10. Fractional surface coverage with H_2 of catalyst A at 475 K [saturation coverage = 123×10^{-6} mol (g catalyst)$^{-1}$ at $H_2S/H_2 > 10^5$ ppm].

Table 2. HDS activity and product distribution at 700 K

Catalyst	Electronic carrier type	Density ($\times 10^{-17}$ cm^{-3})	Conversions (vol %)	C_4H_{10} specificity (vol %)
MoS_2	*n*	17	8	30
	n	10	70	50
$MoS_2(Co^{2+})$	*p*	2.5	87	100
	p	1.9	68	100

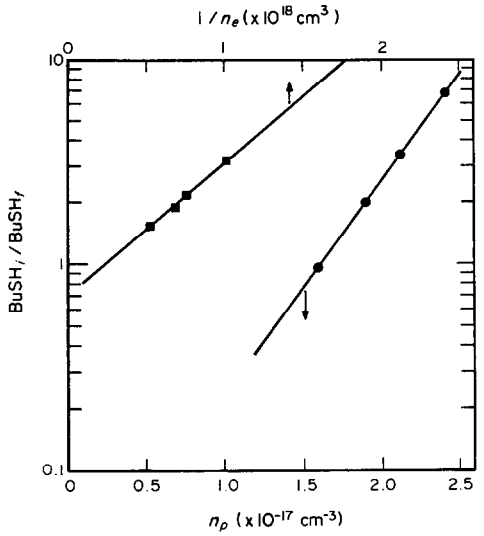

Fig. 11. HDS activity as a function of electronic carrier density: (●) *p*-type, (■) *n*-type.

Thus *p*-type conductivity induced by pretreatment at high H_2S levels or by doping with Co^{2+} provide a suitable path for chemisorption of hydrogen. Its presence explains the versatility of the molybdenum sulfide catalyst for such a range of catalytic processes extending from olefin hydrogenation to HDS, each of which requires hydrogen addition as a step in the reaction sequence.

For HDS of butyl mercaptan (BuSH) in the presence of a large excess of H_2 (H_2 : RSH > 40 : 1) the rate equation for this process may be expressed as a product of a first-order dependency on mercaptan concentration and the electron hole carrier density:

$$-d(\text{BuSH})/dt = k_p n_p(\text{BuSH}). \quad (6)$$

At constant space velocity, i.e. contact time with the single-crystal catalyst, one obtains on integration of eqn (3):

$$\ln [(\text{BuSH})_i/(\text{BuSH})_f] = k'_p n_p, \quad (7)$$

where the subscripts *i* and *f* represent the initial and final concentrations of reactant and *k'* the product of the rate constant and contact time (*kt*). Indeed the dependency of HDS on hole density, as given by eqn (7) is exhibited by the data presented in Fig. 11. On the other hand, for *n*-type molybdenum sulfide, with electrons as majority carriers, the HDS rate exhibits an inverse dependency on n_e:

$$-d(\text{BuSH})/dt = k'_e(\text{BuSH})/n_e. \quad (8)$$

as shown in Fig. 11.

Under equilibrium conditions

$$K_i = n_e n_p = N_c V_v \exp(-E_i/kT),$$

where K_i is the equilibrium constant, n_e and n_p the electron and hole densities, N_c the number of available states in the conduction band, N_v that in the valence band, and E_i is the band-gap energy ($E_c - E_v$). In view of the fact that $n_p = K_i/n_e$, it is apparent that the functional relationship between n_e and n_p exhibited by the data in Fig. 11 is to be expected on the basis of solid-state theory.

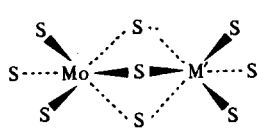
THE RELATION BETWEEN ELECTRONIC TRENDS AND THE PROMOTER EFFECT ON CATALYTIC ACTIVITY OF HYDRODESULFURIZATION CATALYSTS

SUZANNE HARRIS

Exxon Research and Engineering Co., Route 22 East, Clinton Township, Annandale, NJ 08801, U.S.A.

(*Received* 1 *July* 1985)



Abstract—The origin of the promoting effect of certain first-row transition metals on the hydrodesulfurization (HDS) activity of MoS_2 is not well understood. We have carried out a systematic theoretical study of the electronic structure of simple clusters which model these catalyst systems and have used the results of these calculations to establish an electronic basis for the trends in promotion effects observed in the MoS_2 systems. Both Co and Ni, which serve as promoters, have the ability to donate electrons to Mo, while Cu, which serves as a poison, withdraws electrons from Mo. The other first-row transition metals, which have little effect on the HDS activity of MoS_2, do not have the ability to donate to or accept electrons from Mo. Thus promotion is associated with an increase in electron density on Mo while poisoning is associated with a decrease in electron density. These results are consistent with previous results for binary catalysts which related particular electronic factors to the HDS activity of the sulfide.

Recently, we described a relation between trends in the calculated electronic structure of the transition-metal sulfides (TMS) and trends in the measured hydrodesulfurization (HDS) activity of these materials.[1] The experimental trends in the activities of the unsupported TMS had been previously measured using the HDS of dibenzothiophene as a model reaction,[2] and a theoretical basis for understanding these experimental trends had been initiated by studying the electronic structure of the first- and second-row TMS.[3] Calculations were carried out for a group of octahedral MS_6^{n-} clusters, where the transition metal M was varied systematically across both the first and second transition series, and based on these calculations it was shown[1] that a relation exists betwen the calculated electronic structure of the sulfides and their activity as HDS catalysts. Several electronic factors were identified which appear to be related to catalytic activity, and these factors were incorporated into a calculated activity parameter which correlates with the observed catalytic activity of the sulfides. We have now extended this combined theoretical and experimental approach to study the promoted or "synergic" MoS_2 catalyst systems, and in this paper we show that there is an electronic basis for the promotion effect observed in MoS_2-based catalysts.

Although it is well known that the addition of a second transition metal such as Co or Ni to a binary sulfide such as MoS_2 or WS_2 brings about an increase in HDS activity, the basis for this promotion effect is certainly not well understood. Work from numerous laboratories[4–6] has established, however, that the promoter atoms are associated with the edge planes of the layered compounds MoS_2 and WS_2, in close proximity to the Mo or W atoms. Several studies[7,8] also suggest that the effect of this edge promoter is electronic rather than structural (i.e. the promoter influences the quality of the active site rather than altering the number of active sites). In order to further explore the idea that the basis for promotion is electronic in nature, a systematic study of the promoting effect of the first-row transition metals V–Zn on the HDS activity of MoS_2 was carried out in our laboratory.[9] In this study the activities of unsupported MS_x–MoS_2 (M = V, Cr, Mn, Fe, Co, Ni, Cu or Zn) catalysts in the HDS of

DBT were measured. It was found that: (1) V, Cr, Mn, Fe and Zn have little or no effect on the HDS activity of MoS_2; (2) Co and Ni, in agreement with previous literature, act as strong promoters; and (3) Cu acts as a poison, serving to decrease the activity of MoS_2. In order to understand these effects we have carried out a systematic theoretical study of the electronic structure of simple clusters which model these promoted catalyst systems. As mentioned above, the importance of the edge planes and the proximity of the promoter and Mo atoms in MoS_2-based catalyst systems has been previously established, and we have chosen the model clusters so that their structure is consistent with this established information.

Calculations were carried out for a group of clusters $MoM'S_9^{n-}$, where the first-row transition metal M′ was varied systematically across the series from V to Zn. Each cluster carries a negative charge $(n-)$ because enough electrons were included in each cluster so that each sulfur is formally S^{2-}, the molybdenum is formally Mo^{4+}, and the first-row metal M′ has the formal oxidation state appropriate for the corresponding metal sulfide stable under reactor conditions. The geometry of the cluster can be seen in Fig. 1. Both metals are octahedrally coordinated by six sulfurs, three of which are shared between the two metals. Thus the model cluster is composed of two face-sharing octahedra. Within each cluster, all of the metal–sulfur bond distances were taken to be equal. These distances were determined for each cluster by averaging 2.42 Å, the Mo—S distance in MoS_2, and the M′—S distance in the corresponding first-row transition-metal sulfide. The choice of octahedral coordination around Mo allowed us to compare the Mo–S bonding and Mo electronic configuration in these model clusters with that in the simple binary clusters used previously. If the first-row transition metal M′ occupies sites around the edges of MoS_2, an examination of a model of MoS_2 suggests that M′ might occupy either octahedral or tetrahedral sites and share sulfurs with an adjacent Mo. Once again, we chose to use octahedral coordination for M′ because it allows us to make comparisons readily with our earlier

M′ = V,Cr,Mn,Fe,Co,Ni,Cu or Zn

Fig. 1. Geometry of a model cluster $MoM'S_9^{n-}$ used for the molecular-orbital calculations.

calculations. We verified with selected calculations using tetrahedrally coordinated M′ that a change in geometry would not change the major conclusions of our calculations using octahedrally coordinated M′. As in our previous work[1,3] all the calculations on these clusters were carried out using the SCF-$X\alpha$ scattered wave method with tangent spheres.[10] The atomic sphere radii were chosen according to Norman's criteria.[11] The atomic exchange parameter α values for the regions within the metal and sulfur spheres are those of Schwarz.[12] A weighted average of these atomic α values was used for the intersphere and outersphere region.

In our previous reports we described in detail the electronic structure and bonding in the model octahedral first- and second-row transition-metal–sulfur clusters. Figure 2(a) shows a schematic diagram of the valance energy levels calculated for those clusters. Each group of levels, except for those corresponding to the metal *d*-orbitals, is represented by a block which is labelled according to the atomic orbital making the major contribution to these levels. There is of course some mixing between the metal and sulfur orbitals, but this mixing is not important for this discussion. Lying at the lowest energy is a group of levels arising from the sulfur 3*s* orbitals. The next group of levels arises primarily from combinations of sulfur 3*p* orbitals. At the top of this group of sulfur levels is the $1t_{1g}$ level, a nonbonding combination of sulfur 3*p* orbitals. Finally, at the highest energy (in most of the clusters) are the $2t_{2g}$ and $3e_g$ levels. These levels correspond primarily to the metal 3*d* or 4*d* orbitals. We found that a major effect of varying the transition metal in these octahedral clusters is a shift in the energy of the metal *d*-orbitals relative to the energy of the sulfur 3*p* orbitals. As measured by the difference in energy between the $2t_{2g}$ and $1t_{1g}$ orbitals, it was found that from Ti to Ni in the first transition series the energy of the 3*d* orbitals shifts downward in energy (i.e. closer in energy to the sulfur 3*p* orbitals) by about 1.5 eV. This shift is expected when moving from left to right in the transition series and is confirmed by available photoelectron spectra of the TMS.[3]

For the face-sharing octahedral clusters considered here, we can also draw a schematic energy level diagram showing the main features and patterns of the energy levels resulting from the calculations. It should be noted that the point group symmetry of the face-shared cluster is C_{3v} (as compared to O_h in the octahedral clusters). Since in the C_{3v} point group there are no triply degenerate representations, the set of 3*d* or 4*d* orbitals which in O_h-symmetry transform as the t_{2g} representation are no longer degenerate in these clusters. The remnants of the octahedral splitting between the t_{2g}- and e_g-

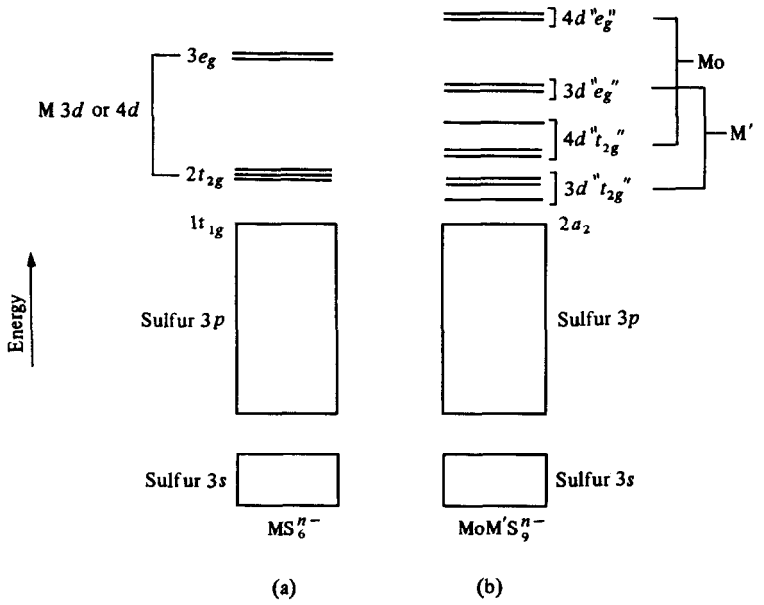


Fig. 2. Schematic valence energy level diagrams for: (a) an octahedral MS_6^{n-} cluster, and (b) an $MoM'S_9^{n-}$ cluster made up of two face-sharing octahedra. The ordering of 3*d* and 4*d* levels is for M′ = Co or Ni.

orbitals are still apparent in these lower-symmetry clusters, however, so that we continue to label "t_{2g}" and "e_g" sets of metal *d*-orbitals. A schematic level diagram for a $MoM'S_9^{n-}$ cluster is shown in Fig. 2(b). Once again, the sulfur 3*s* levels lie below the broader group of levels resulting from the sulfur 3*p* levels. The top of the sulfur 3*p* group of levels is once again delineated by a nonbonding combination of sulfur 3*p* orbitals, in this case the $2a_2$ level as shown in the diagram. The really notable feature of this level diagram is the presence, above the sulfur 3*p* levels, of levels resulting from both the Mo 4*d* and M′ 3*d* metals. Each set of five *d*-orbitals forms "t_{2g}" and "e_g" sets of levels, so on the diagram we see a "t_{2g}" and "e_g" set of levels for both the metal 3*d* and 4*d* orbitals. The schematic diagram in Fig. 2(b) would correspond to the case where the M′ levels lie low enough in energy that the M′ 3*d* "t_{2g}" and "e_g" sets of levels each lie below the corresponding Mo 4*d* sets of orbitals but not so low in energy that the entire 3*d* manifold of levels lies below the 4*d* levels. This relative energy separation applies to most of the clusters considered here. The relative energies of these levels and the numbers of electrons and their distributions within these levels both depend on M′. We will see below that it is these quantities which are related to the ability of the 3*d* metal M′ to serve as a promoter.

As we noted earlier, the metal 3*d* orbitals become more stable upon proceeding from the left to the right side of the transition series, i.e. dropping in energy relative to the sulfur 3*p* orbitals. This means that in these clusters, which contain both a 3*d* metal and Mo, the metal 3*d* orbitals also drop in energy relative to the Mo 4*d* orbitals. Proceeding across the 3*d* series from V to Zn this drop in energy is quite large. For V, Cr and Mn the 3*d* and Mo 4*d* "t_{2g}" sets of levels are very close in energy. Moving to the right, however, the 3*d* levels shift lower in energy so that the 3*d* and 4*d* sets of levels lie in the order illustrated in Fig. 2(b). Finally, for Cu and Zn the shift in energy becomes large enough that the entire set of 3*d* levels lies below the Mo 4*d* levels. At the same time that the 3*d* levels decrease in energy, the number of 3*d* electrons occupying the orbitals increases. For all the clusters, Mo contributes two "*d*"-electrons while the number of "*d*"-electrons contributed by the first-row metal depends on the metal. Thus the total number of "*d*"-electrons in the clusters varies from four in the V–Mo cluster all the way up to 12 in the Zn–Mo cluster. The distribution of electrons among the metal orbtitals depends on the relative energies of the orbitals, and an examination of the metal orbital occupations reveals an important difference between the clusters containing 3*d* metals which are known to promote or poison the activity of MoS_2 and the clusters containing those 3*d* metals which have no effect on the activity.

In the clusters containing Co or Ni, the two metals which can act as promoters, we find that Co and Ni donate electrons to Mo so that Mo is formally reduced relative to the Mo present in MoS_2. This occurs because Co and Ni provide seven and eight "*d*"-electrons, respectively, to the cluster. In a pure Co–S or Ni–S cluster, the 3*d* "e_g" orbitals would be occupied. In these clusters containing Mo, however, the lower energy Mo "t_{2g}" orbitals are available so

that a net transfer of charge from Co or Ni to Mo occurs. This is a result of the Mo "t_{2g}" orbitals lying energetically between the 3*d* "t_{2g}" and "e_g" orbitals and Co and Ni having a high eneough *d*-electron count that the 3*d* "e_g" orbitals would normally be partially occupied. The electron transfer of this type only occurs because both of these effects are present. In both the Co–Mo and Ni–Mo clusters, the Mo is thus formally reduced relative to the Mo present in MoS_2. In the cluster containing Cu, a metal which poisons the activity of MoS_2, we find that Mo is formally oxidized relative to the Mo in MoS_2. This occurs because, while all five of the Cu 3*d* orbitals now lie well below the Mo 4*d* levels, Cu contributes only nine "*d*"-electrons to the cluster. As a result there is a net transfer of electrons from Mo to Cu. This is not entirely surprising because it is known that in CuS[13] (which contains nominally Cu^{2+} and S^{2-}) the Cu 4*d* levels lie low enough in energy that some of the Cus are reduced to Cu^{+}, while some sulfurs are oxidized to S_2^{2-}. In our Cu–Mo cluster the Mo electrons are even more available than the sulfur 3*p* electrons and thus the Mo is oxidized relative to the Mo in MoS_2. In all the other clusters (those containing V, Cr, Mn, Fe and Zn) there is no such clear transfer of electrons between the Mo and the 3*d* metal, and the electronic state of Mo is similar to the Mo in MoS_2. For these metals the relative energies of the 3*d* and Mo 4*d* orbitals and/or the number of 3*d* electrons are not appropriate for electron transfer.

In summary, when the first-row transition metal M′ is varied in these Mo–M′ clusters, the changes in electronic structure depend on changes in both the relative energies of the Mo 4*d* and M′ 3*d* orbitals and the number of "*d*"-electrons which M′ contributes to the cluster. As the 3*d* levels drop in energy across the first transition series, the number of 3*d* electrons occupying these levels increases. It is only when M′ is Co, Ni or Cu, however, that these effects combine in such a way that the electronic state of Mo is formally affected. Since it is these three first-row metals which have a measurable effect on the HDS activity of MoS_2, we associate their ability to reduce or oxidize Mo with their promoting or poisoning effect.

Not only do these results identify an electronic origin for the promotion effect, but they are also consistent with our earlier theory relating catalytic activity to several electronic factors for the binary sulfides. One of those factors is the ability of the transition metal to bond covalently, in both a sigma and pi fashion, to the 3*p* orbitals of sulfur. This factor serves to differentiate the 3*d* from the 4*d* transition metals, since the 3*d* metals covalently bond much less effectively to sulfur than do the 4*d* metals. We defined a quantity, called *B*, which measures the covalent contribution to the metal–sulfur bond strength and found that a large value of *B*, and thus a strong covalent contribution to the metal–sulfur bonding, correlates with high activity. Another important factor is *n*, the number of "*d*"-electrons in the highest occupied orbital. We saw that a large value of *n* also correlates with high activity. Thus the most active catalysts have large values of *n* and/or *B*. We combined these quantities to form an activity parameter "A_2", where:

$$A_2 = nB.$$

This parameter provided us with a simple quantiative relationship between the calculated electronic structure and the HDS catalytic activity of the TMS. A metal sulfide with a large value of A_2 will have a high HDS activity.

Our model cluster calculations indicate that in the promoted Co–Mo and Ni–Mo systems one of these electronic factors for Mo, *n*, the number of electrons in the HOMO, is increased by the presence of the promoter. Since these extra electrons occupy an antibonding orbital, the Mo—S bonds are somewhat weakened. Thus the factor *B* which enters the activity parameter and measures the relative Mo—S covalent bond strength decreases in the presence of the promoter. On the other hand, the presence of a poison such as Cu has just the opposite effect. To a first approximation, for all the other systems considered here the two electronic factors *n* and *B* for Mo are unaffected by the presence of the 3*d* transition metal. We can calculate an activity parameter for the Mo portion of the model clusters treated here. This activity parameter, along with the experimental HDS activities of the real catalyst systems, is plotted in Fig. 3, and from this figure we see that the trends in activity are reproduced by the

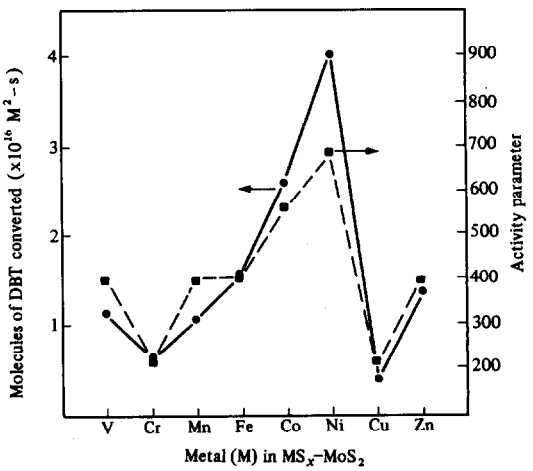

Fig. 3. Calculated activity parameter for each mixed-metal sulfide system (right-hand scale). Shown for comparison, using the left-hand scale, are the measured HDS activities.[9]

trends in the value of the activity parameters. The qualitative correlations obtained here thus indicate that the electronic factors identified earlier in our study of the binary sulfides are influenced by the presence of a promoter. It should be noted that the variations in the activity parameter are dominated by changes in n rather than B, and it appears that the dominant electronic factor related to promotion of MoS_2 is the increase in the number of "d"-electrons on Mo. This result is consistent with the physical picture and model for thiophene binding which we described earlier for the binary sulfide systems. We suggested that these active catalysts can bind to the ring sulfur atom in thiophene and donate electron density into an empty thiophene pi* orbital. It is reasonable, then, that in the promoted MoS_2 catalysts an increase in the number of electrons occupying the Mo 4d orbitals will result in an increase in catalytic activity, since an increase in d-electron density on Mo would strengthen the interaction between Mo and the ring sulfur atom in thiophene.

In conclusion, by combining measured trends in the HDS activity of promoted MoS_2 catalysts with calculated trends in the electronic structure of cluster models of these catalyst systems, we have established that there is an electronic basis for the promotion effects observed in MoS_2-based HDS catalysts. The calculated electronic structure of the cluster models of the promoted catalyst systems indicates that Co and Ni have the ability to formally reduce Mo in these systems, while Cu has the ability to formally oxidize Mo. None of the other 3d metals have this ability. The number of 3d electrons which Co, Ni or Cu contribute to the cluster and the energies of their 3d orbitals relative to the Mo 4d orbitals make these metals unique when combined with Mo. These results are consistent with our earlier identification of electronic factors which are related to the HDS activity of binary sulfide catalysts and with our model for thiophene binding to the catalyst.

(*Received* 14 *June* 1985)

Abstract—The catalytic performances (activity, selectivity, deactivation by phase transformation . . .) of hydrotreating catalysts composed of supported Mo associated with a promoter (Co or Ni) and working in a sulphided state are greatly dependent on the sequences and conditions of the preparation process. A large number of works dealing with the description of one or several steps in the catalyst elaboration have been already published, specially in the previous Molybdenum Conference in which review articles can be found. However, in these works, all the preparations sequences are not always considered and some experimental conditions are far from those used in *industrial catalyst preparation* in the oxide or commercial form. In this paper we report new results about the architecture of oxide precursors of series of Mo-based catalysts prepared according to industrial conditions. These results will be compared and discussed with other descriptions already published. Starting with the support and commercial products chosen because they are very soluble in water, easily decomposed and less expensive [ammonium heptamolybdate (AHM), and cobalt or nickel nitrate], six steps, viz. molybdate impregnation, intermediate drying and calcination, impregnation of the promoter solution, drying and final calcination, are necessary to obtain the final or commercial catalyst. Moreover after the intermediate or final calcination, the samples prepared can be modified by aging during storage in the laboratory atmosphere. The nature and quantity of the supported species, their structure and size, the chemical state of the elements, their dispersion on the support, the interaction between the molybdate entities, with the support or with the promoter, are among the main aspects, considered in this investigation for which we used techniques dealing with surface characterization X-ray photoelectron spectroscopy (XPS) and ion-scattering spectroscopy (ISS)] and a vibrational technique such as laser Raman spectroscopy (LRS). During the first impregnation step, an electrostatic interaction between the ionized surface species of the support and the molybdate ions in solution occurs. The subsequent drying and calcination steps induce formation of strong chemical bonds between the supported molybdate species and the carrier. After this step, the species are well dispersed on the support as proved by XPS and ISS. The second impregnation transforms the molecular aggregates previously created by (partial) hydrolysis and therefore gives back the initial species. The added promoter is then interacting with the polymolybdate or the support. Calcination can provoke a partial incorporation of the promoter into the support but bilayers in which the promoter is between the molybdate phase and the support are not detected. Aging of the catalyst after the calcination step is a hydration process. Reverse dehydration can be achieved by a new calcination step.

A large number of studies of the preparation, surface characterization, activation (sulphidation) and catalytic performance with model molecules and real feeds of MoO_3–γ-Al_2O_3 catalysts, with which a promoter (CoO or NiO) can be associated, have been published in recent years. Those catalysts are generally used in hydrotreatment, namely hydrodesulfurization (HDS), hydrodenitrogenation

§ Author to whom correspondence should be addressed.

(HDN), hydrodemetallation (HDM) and hydrodeoxygenation (HDO), of petroleum fractions, heavy residues or coal liquids. They represent a large proportion of catalysts used in modern petrochemistry and, according to Jacobsen,[1] the hydroprocessing catalyst market is about 25,000–30,000 tons year^{-1} at a value of the order of 250 million \$ year^{-1}.

Even though commercial catalysts exist and work well, there is a challenge to improve them by considering in particular the relations which should exist between the genesis stage leading to the commercial precursor oxides and the working state in which the active components are sulphided. As a matter of fact, in the previous Molybdenum Conferences several papers concerned with this objective can be found. In particular in the review of Delmon,[2] a description of the species present in the oxide form of CoO–MoO_3–γ-Al_2O_3 catalysts and their localization is given and it is shown how the oxide precursor determines the nature and dispersion of the species in the active form. Hall[3] related the preparation and properties of molybdena–alumina catalysts obtained by using an equilibrium adsorption method from a polymolybdate solution. These catalysts can be described as small islands containing seven or more Mo atoms and perhaps two layers thick. However, in both cases, all the preparation sequences were not always considered and, in Hall's work,[3] the impregnation method is quite different from that generally used in industrial catalyst preparations.

Therefore, in this paper we report results about the genesis and architecture of oxide precursors of Mo-based catalysts prepared in six elementary steps, viz. (i) molybdate impregnation, (ii) drying, (iii) intermediate calcination, (iv) promoter impregnation, (v) drying, and (vi) final calcination. For each step, we took care to simulate conditions as close as possible to industrial operations. The six-step procedure is in some cases applied on the large scale. We will show also that aging of the catalysts, after calcination, in the laboratory atmosphere can modify the structure of the supported phase. In this investigation, we will not consider the problem of support choice as we always used well-defined γ-Al_2O_3 extrudates nor the activation or sulphidation step which generally takes place before the catalytic run and transforms the catalyst into supported sulphides.

EXPERIMENTAL

Sample preparation

The support, as extrudates 1.2 mm in diameter, is γ-Al_2O_3 of high purity which has a surface area of 246 $m^2\,g^{-1}$ and a total pore volume (v_p) of 0.50 $cm^3\,g^{-1}$. In industrial preparations, the chosen impregnating compounds must be very soluble in water, easily decomposed and less expensive. Therefore, we used ammonium heptamolybdate (AHM), $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$, from Merck and cobalt or nickel nitrate hexahydrate from Prolabo.

The alumina extrudates were impregnated by the pore-filling (or incipient wetness impregnation) method. Solutions containing the exact amount of Mo (or Co or Ni) to yield catalysts of desired composition were prepared. The alumina extrudates were gently agitated in a rotating drum, and the freshly prepared solution was slowly added in order to ensure a good distribution and elimination of wetting heat. The volume of the solution corresponded exactly to the v_p of the carrier. The wet samples were left at room temperature in closed flasks (maturation) for a few hours to obtain equilibrium in the pores and then dried at 110°C overnight. Note that the wet samples examined by laser Raman (LR) spectroscopy (LRS) after impregnation had been left at room temperature for a longer time as the preparation was performed in the IFP laboratories and the characterization at Lille University. Then the samples were calcined in air at various temperatures (up to 900°C for 2 h) for the intermediate calcination or at 500°C for 2 h for the final calcination. After each preparation step a small sample was left out for characterization. The MoO_3 loading of the samples [x (in % by weight of MoO_3)] varies between 2 and 24%.

Characterization

The samples were characterized by LRS and XPS for which the procedures have been given.[4] ISS measurements were also performed on the same spectrometer as used for XPS using He^+ ions as projectiles. The experimental conditions have been fully described previously.[5]

RESULTS AND DISCUSSION

MoO_3–γ-Al_2O_3 *preparation and characterization*

Impregnation. When impregnating molybdate solutions on γ-Al_2O_3, both pH and Mo concentration can modify the nature of the adsorbed species. γ-Al_2O_3, among other mineral oxides in suspension in aqueous solution, tends to be electrically charged[6] and the isoelectric point (IEP) is about pH 8. Therefore, in acidic medium (pH < 8), the γ-Al_2O_3 particles, positively charged, are surrounded by anions, whereas, at pH > 8, the inverse situation

occurs, according to eqns (1) and (2):

$$Al—OH + H^+,A^- \rightleftarrows Al—OH_2^+,A^-, \quad pH < IEP, \quad (1)$$

$$Al—OH + B^+,A^- \rightleftarrows Al—O,B^+ + H_2O, \quad pH > IEP, \quad (2)$$

$$IEP(\gamma\text{-}Al_2O_3): pH \simeq 8.$$

As molybdates in solution are always negatively charged (except at very low pH), the impregnation step should preferably occur at pH < IEP (Al_2O_3). This was experimentally shown by an equilibrium adsorption process with solutions at various pH: for pH $\gtrsim$ 8, the amount of Mo adsorbed is very small.[7] This result can be extended to other anionic species.[8]

In the pore-filling method, as adsorption of Mo is forced (it can be, in fact, Mo deposition rather adsorption) during water elimination (drying and calcination stages) it is not necessary, *a priori*, to adjust the pH of the solution to obtain MoO_3–γ-Al_2O_3 catalysts. However, the real nature of the molybdate ions starting from the heptamolybdate (HM) in solution is a function of the Mo concentration and pH according to eqn (3):

$$Mo_7O_{24}^{6-} + 4H_2O \underset{K}{\rightleftarrows} 7MoO_4^{2-} + 8H^+. \quad (3)$$

(In this investigation we will not consider $Mo_8O_{26}^{4-}$, which is only detected at low pH.)

The equilibrium constant K ($[HM]/[M][H^+]^8$) was reported to be $10^{57.7}$ in 3 M $NaClO_4$ at 25°C.[9] The AHM concentration, C_{AHM}, of the impregnating solution depends on the desired MoO_3 loading, x, of the final catalyst [eqn (4)]:

$$C_{AHM} = \frac{x}{100-x} \times \frac{1}{v_p} \times 0.992 \text{ mol } l^{-1}. \quad (4)$$

The ratio [M]/[HM] in solution changes when x increases (Fig. 1) (M represents the monomer species MoO_4^{2-} and HM $Mo_7O_{24}^{6-}$).

From Tsigdinos *et al.*,[9] the pH of the AHM solution varies from 5.1 to ~5.5 when C_{AHM} increases so that in the impregnating solution [M]/[HM] is between $\sim 9.10^{-2}$ ($x = 2$, pH → 5.1) and $\sim 1.8\ 10^{-2}$ ($x = 24$, pH → 5.5) and, as a consequence, HM is the major species when using solutions with their "natural" pH.

Due to the amphoteric character of γ-Al_2O_3, the dispersion can be changed when the impregnating solution fills the pores of the support. LRS is a suitable technique to follow the evolution of the species in contact with γ-Al_2O_3 as M and HM have quite different Raman spectra.[4,10,11] M, a perfect tetrahedral species (T_d) in solution, has the major Raman band at 898 cm^{-1}, whereas the main band of HM is at 941 cm^{-1}. In the low-wavenumber region,

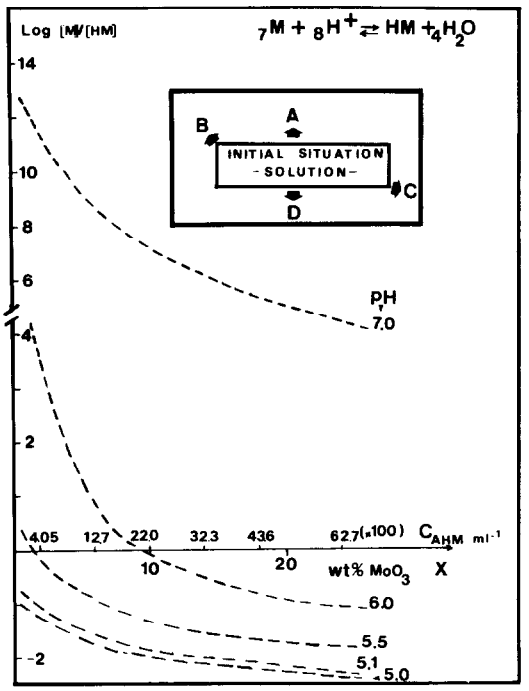

Fig. 1. Variation of $\log_{10}$ [M]/[HM] as a function of the HM concentration, C_{AHM}, of the impregnating solution which determines the final Mo loading x (% MoO_3 by weight). log $K = 10^{57.7}$ is taken from Ref. 9. In the insert at the corner are schematically shown the trends which could occur, if, starting from a given situation in solution: (A) interaction with γ-Al_2O_3 is effective, pH increases; (B) there is a concentration gradient from outside to inside the pores and an interaction with γ-Al_2O_3 as in A; (C) water is eliminated during drying and calcination at moderate temperature (no interaction with γ-Al_2O_3); and (D) NH_4^+ is decomposed into NH_3 and H^+ ads during calcination.

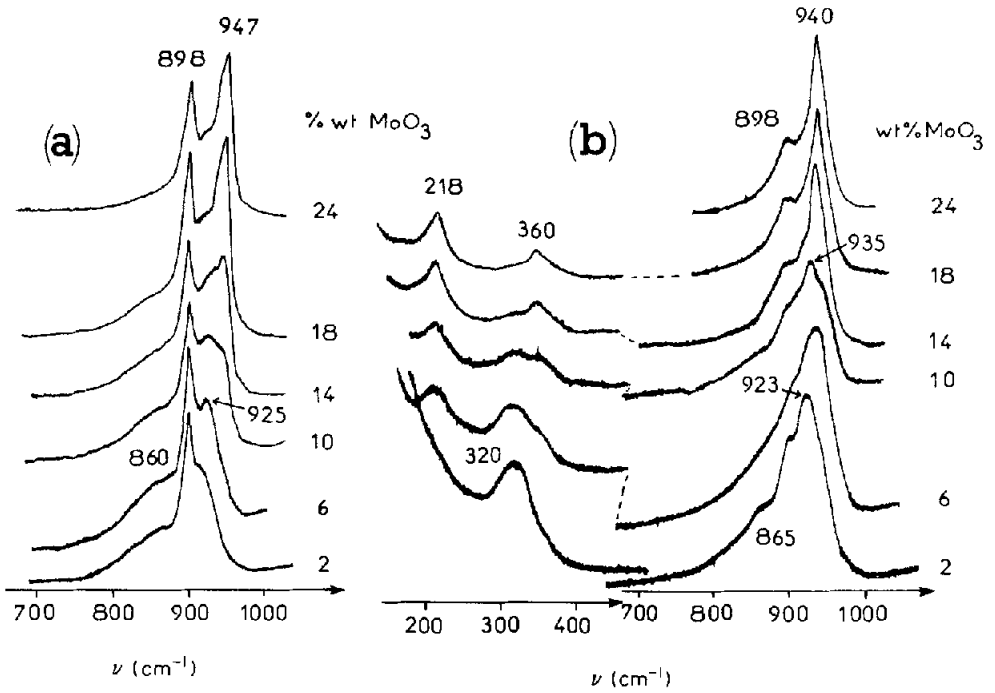
there is also some difference: 316 cm^{-1} for M, 357 and 217 cm^{-1} for HM. In Fig. 2(a), the Raman spectra in the 700–1000-cm^{-1} region obtained on the impregnated samples maintained at room temperature are reported. Four bands at 860 (a broad shoulder), 898, 925 and 947 cm^{-1} are clearly detected. For low Mo loading samples ($x = 2.6$), the M characteristic band (898 cm^{-1}) only is present with two shoulders at 860 and 925 cm^{-1}. As the loading increases, the 947-cm^{-1} line assigned to HM appears and becomes the major band at $x = 18$ and 24 whereas the 860-cm^{-1} shoulder seems to decrease and even disappears for $x = 24$. Due to the overlap or broadening of the 898- and 947-cm^{-1} lines, the presence of the 925-cm^{-1} band is not obvious for high-x samples. Although the HM anion is the major species in solution, its presence is not detected in impregnated samples corresponding to low Mo loading. Therefore, as already reported,[12] γ-Al_2O_3 causes a pH increase which, by consuming H_3O^+, transforms HM into M (see Fig. 1, arrows A and B if



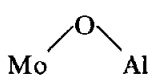


Fig. 2. Raman spectra of: (a) "wet" samples, and (b) samples after drying (110°C overnight).

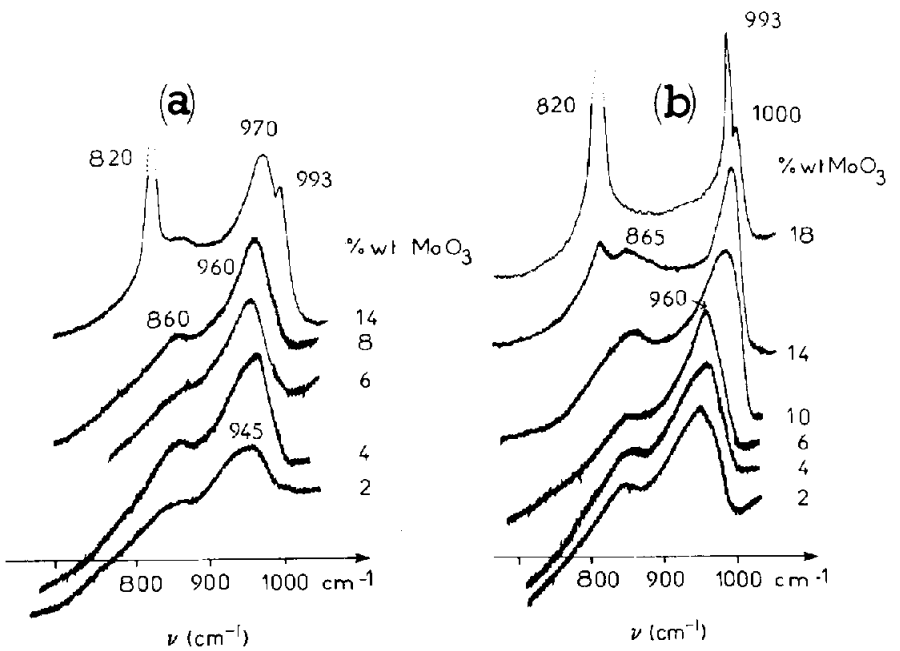
there is also a concentration gradient into the pores of Al_2O_3). As C_{AHM} increases for higher-x samples, one can see from Fig. 1 that a small local pH increase is not enough to produce high amounts of M and in this case HM remains the predominant species. Although the LRS information is not quantitative because: (i) the scattering Raman cross-sections of these species can be different in solution and in contact with or adsorbed on a solid, and (ii) the spectra result both from the solution remaining in the pores and from adsorbed species, it appears that, for concentrated solutions, the pH shift due to γ-Al_2O_3 is not sufficient to completely transform HM into M.

We propose that the 925- and 860-cm^{-1} bands, which are not present in solutions (only for M is a very weak and broad band detected[11] at 846 cm^{-1}) can be assigned to vibrational modes of, respectively, Mo=O(t) (symmetric stretching) and Mo—O—Al bridges of adsorbed species M whose tetrahedral symmetry is distorted by interaction with the support. This first point is in agreement with Iannibello *et al.*,[13] who suggested that the shift to higher wavenumber of MoO_4^{2-} in tetrahedral coordination reflects the distortion from T_d symmetry and increases the Mo(VI)=O double bond character. Note that HM does not seem to be strongly shifted (941–947 cm^{-1}) when in contact or adsorbed on γ-Al_2O_3 at high x. For this larger-size anion, γ-Al_2O_3 has probably no distortion effect so that the Mo=O(t) stretching vibration is not really affected. The

bond with the support, vibrations of which should be detected in the 900-cm^{-1} region,[14] is not seen because of the presence of the remaining line of M.

All this information on wet samples can be compared with results already published. Those of Jeziorowski and Knözinger[11] at pH = 6 using a pore-filling method are in complete agreement with ours as they found lines at 918 and 894 cm^{-1} on a 3% MoO_3 sample and at 938 and 921 cm^{-1} on an 8% MoO_3 sample. In addition, a broad tail is observed at wavenumbers below 900 cm^{-1}. Their conclusion was that HM is degraded by interaction with Al_2O_3 and M is the initial adsorbed species. However even with 8% MoO_3 some HM remains (938-cm^{-1} line). No higher Mo loading samples were investigated. Comparison with Hall's work,[3,10] who reached different conclusions, is more difficult as: (i) the impregnation method is different, and (ii) the pH of the solution chosen (and imposed) are lower (1.0 or 3.9) or higher (8.6).

Drying. In Fig. 2(b) we report the Raman spectra of the dried samples. For low x values, the 920-cm^{-1} line is prominent whereas the 898-cm^{-1} line has completely disappeared. All the M ions are in



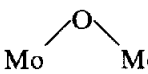


Fig. 3. Raman spectra of samples calcined in air (500°C for 2 h) by using: (a) a low laser power (~40 mW), and (b) a high laser power (~300 mW).

chemical interaction with Al_2O_3 according to eqn (5):

$$MoO_4^{2-} + Al{-}OH_2^+ \rightarrow Al{-}O{-}MoO_3^- + H_2O. \quad (5)$$

$$898\ cm^{-1} \qquad \sim 860 \quad 920\ cm^{-1}$$

We will see later that the species on the right-hand side of eqn (5) is hydrated (if samples are not sufficiently calcined) and should be written as Al—O—MoO_3...H. To confirm that the 920-cm^{-1} vibration is not a result of the polymerization of M, note the absence in the low-wavenumber region of the (360- and 220-cm^{-1} bands characteristic of polymolybdate species

For high x values, water elimination by a concentration effect should locally slightly decrease the pH inside the pores (arrow C in Fig. 1) which is not favorable for producing M. However, when interaction with Al_2O_3 occurs, the trend is along arrow A so that drying of a high-x sample might result in combination of arrows C and A. However, as the H^+ exchange of Al_2O_3 appears limited, the trend is not sufficient to see the complete transformation of HM into M during drying. Note also that during drying (and more probably during calcination), NH_4^+ in solution can be decomposed which leaves H^+ adsorbed on Al_2O_3 (arrow D in Fig. 1). All these arguments favor the conclusion that the ~940-cm^{-1} line is characteristic of HM (hydrated form, as we will see later) bound to Al_2O_3 probably through a few Mo—O—Al bonds which are not perturbing the whole anion (no or small shift with HM in solution). However, perturbed M anions (898 cm^{-1}, not or weakly adsorbed) are not detected: water elimination seems incomplete in the pores.

Calcination: standard conditions. In Fig. 3 we report the Raman spectra of samples after standard calcination (500°C for 2 h in air) recorded: (i) at low laser power which does not modify the nature of the supported species, and (ii) at high laser power which can be considered as an additional calcination.[14]

On the 14 and 18% MoO_3 samples, the bands at 993 and 820 cm^{-1} are assigned to bulk MoO_3 which means that all the HM anions are not really bound to γ-Al_2O_3 even in the drying step. These free HM species decompose to MoO_3.

So except for these two bands, the Raman features in the 800–1000-cm^{-1} region appear very similar. In particular the Mo=O(t) stretching vibration is always at 940–1000 cm^{-1}, as already reported,[4,15–19] and depends on both the Mo content (higher degree of aggregation of Mo species) and the extent of hydration of the supported molybdate. So in order to choose among the following hypotheses: (i) the initial adsorbed species are maintained "intact", (ii) the initial adsorbed species are transformed by surface polymerization, and (iii) the initial adsorbed

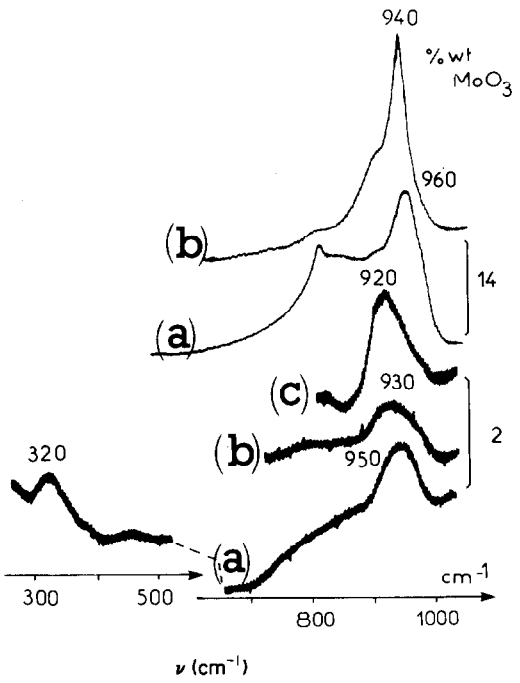

Fig. 4. Raman spectra of MoO_3–γ-Al_2O_3 samples with two Mo loadings ($x = 2$ and 14): (a) just calcined, and (b) and (c) after more or less prolonged aging (laboratory atmosphere).

species are transformed by surface depolymerization which will correspond to a sample of a given Mo loading, both the Raman spectra of the samples in the (freshly) calcined state [Fig. 3(a) and (b)] and after aging (which produces surface hydration) (Fig. 4) will be considered.

The molybdate species, which gives a band at 920 cm^{-1} after adsorption is rather isolated on the support (6% MoO_3 corresponds to ~ 1 Mo nm^{-2}) and polymerization is highly improbable during calcination. This treatment only reinforces the bonds with γ-Al_2O_3 (shift to 945 cm^{-1}, a value which has already been reported[11–13]), according to eqn (6):

$$\text{Al—O—MoO}_3\ldots\text{H} + \text{Al—OH} \underset{\text{aging}}{\overset{\text{calcination}}{\rightleftharpoons}} (\text{Al—O})_2\text{MoO(OH)}_2 \rightleftarrows \cdots \quad (6)$$

This 945-cm^{-1} line can be shifted to higher-wavenumber values if more severe treatments are performed[14] (i.e. *in vacuo* at 700°C) to provoke complete dehydration. However these reactions are reversible if the samples are aging in (wet) air as seen in Fig. 4. Obtaining lines at 930–920 cm^{-1} after aging is significantly in favor of the presence of monomer species in the calcined state for low-x samples.

For the HM species, it is much more difficult to determine the transformation upon calcination. For x from 6 to 24 wt% MoO_3, the adsorbed HM species can be considered isolated: one Mo occupies ~ 1–~ 0.20 nm^2, but HM (seven Mo atoms) adsorbed as a whole according to the Hall's hypothesis[3] occupies ~ 7–~ 1.40 nm^2. Then, if the adsorbed HM is not mobile within the standard calcination conditions, polymerization is highly improbable. The shifts observed in Fig. 3(b) are then more suggestive of a different dehydration level with an increasing number of links with Al_2O_3 than of HM aggregation. By aging (Fig. 4), a shift from 960 to 940 cm^{-1} is observed which once again confirms our hypothesis that HM is maintained "intact" during calcination.

Calcination: effect of temperature. The effect of the calcination temperature has been investigated on the $x = 14MoO_3$–γ-Al_2O_3 sample whose color changes: white from 25 to 100°C, yellow to 200°C, heterogeneous white and dark blue at 350°C, pale green from 450 to 700°C and white-blue at 900°C. In that case, sintering due to γ-Al_2O_3 transformation is observed. The LR spectra and X-ray photoelectron spectroscopy (XPS)–ion-scattering spectroscopy (ISS) intensity ratios are reported in Figs 5 and 6. In the Raman spectrum of the sample calcined at 900°C, the characteristic bands of $Al_2(MoO_4)_3$ are observed,[14,20,21] which are absent at lower temperatures. Note also that the 820- and 995-cm^{-1} bands of MoO_3, present at 500°C, disappeared at higher temperatures and probably by sublimation of MoO_3, unless, as in the case of WO_3–γ-Al_2O_3 samples,[22] bulk MoO_3 reacts with Al_2O_3 to give $Al_2(MoO_4)_3$.

The XPS Mo/Al (Mo3*d* and Al2*p* peaks) ratio is indicative of a small change of dispersion between 100 and 350°C as already pointed out by Houalla *et al.*,[23] whereas the O/Al ratio (O1*s*–Al2*p* peaks) considerably decreases at 900°C, which is again indicative of γ-Al_2O_3 transformation. The ISS results give similar conclusions but sensitivity is much better when the ion incident energy used is the lowest (500 eV). By LRS one can see that: (i) the dispersion effect observed by XPS–ISS corresponds to transformation of the adsorbed species "wet state" to molybdate species really bound to Al_2O_3, and (ii) the 950–980-cm^{-1} line observed at low laser power is shifted to ~ 1000 cm^{-1} when high laser power is used (*in situ* dehydration). The 860-cm^{-1} line, still present in the wet state, increases up to 350°C and then appears slightly constant with respect to the major line. As a consequence, the interaction between species in solution with Al_2O_3 occurs mainly between 25 and 350°C, this last temperature corresponding to salt decomposition. Therefore, from this study it appears that the lower limit for calcination is 350°C and $Al_2(MoO_4)_3$ should not be formed during standard calcination (500°C for 2 h).

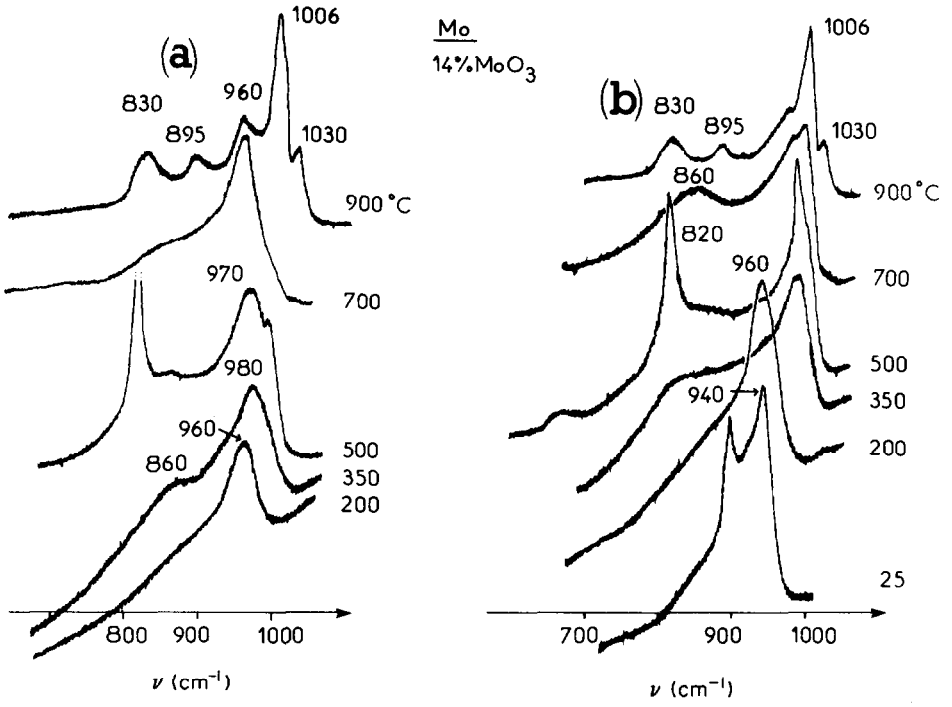

Fig. 5. Raman spectra of a 14 wt % MoO_3 sample calcined at different temperatures (2 h): (a) low laser power (~40 mW), and (b) high laser power (~300 mW).

14% MoO_3–3% promoter oxide–γ-Al_2O_3: characterization

Special attention is given to this system with a promoter/(Mo + promoter) atomic ratio close to 0.3 (promoter is Co or Ni) as this composition is generally found to provide the best synergy for optimum catalytic performance.[2,24] Hence, the majority of commercial catalysts have relative compositions similar to that considered here.

Aging of the calcined MoO_3–γ-Al_2O_3, in which the main supported species are HM in interaction with γ-Al_2O_3, provokes (partial) hydrolysis of the Al—O—Mo bonds; then during the promoter solution impregnation, an interaction of the Co^{2+} or Ni^{2+} cations may occur with HM weakly bound to

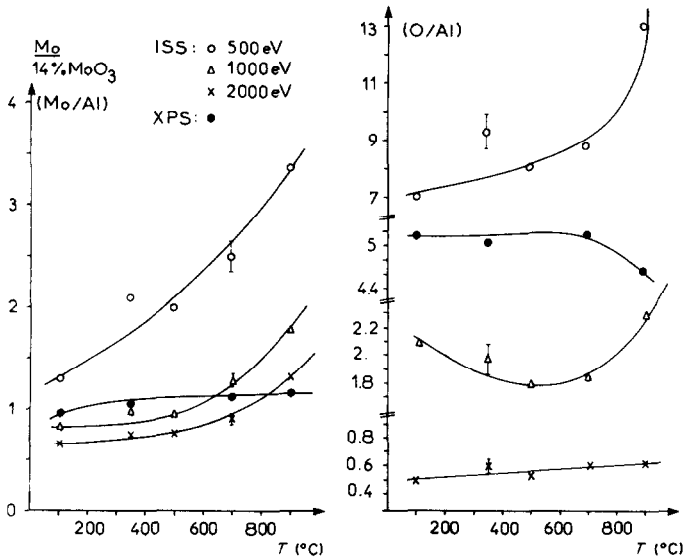

Fig. 6. XPS and ISS intensity ratios as a function of the calcination temperature of the 14 wt % MoO_3 sample.

alumina. However Co^{2+} or Ni^{2+} cations may also interact with the free surface of Al_2O_3. On drying, no discernible reaction occurred between Ni^{2+} or Co^{2+} with HM as evidenced by Raman spectra in Fig. 7. The 950-cm^{-1} line still characterizes the HM species which is weakly bound to Al_2O_3 because the 860-cm^{-1} broad band is almost absent. The 1050-cm^{-1} line is assigned to NO_3^- which is not decomposed at this stage. On *in situ* calcination, the Raman features change: the 1050-cm^{-1} line disappeared and the 1000-cm^{-1} band, characteristic of the dehydrated supported molybdate,[14] is prominent. On the low-wavenumber tail, maxima at 860 and ~930 cm^{-1} can be distinguished. The presence of the latter band can be due to incomplete dehydration which is not really controlled in these experiments. At this step, the main point, perhaps, emerging from this analysis is the absence of a detectable effect of the promoter on the 1000-cm^{-1} Mo=O(t) stretching vibration.

During the sequences of drying and calcination, after the promoter impregnation, the Mo and promoter dispersion changes have been followed by ISS and XPS and, for Mo compared with the results obtained before impregnation (Fig. 8). As already discussed in the preceding paragraph, calcination of the impregnated Mo–Al_2O_3 sample slightly improves Mo dispersion by eliminating residual water

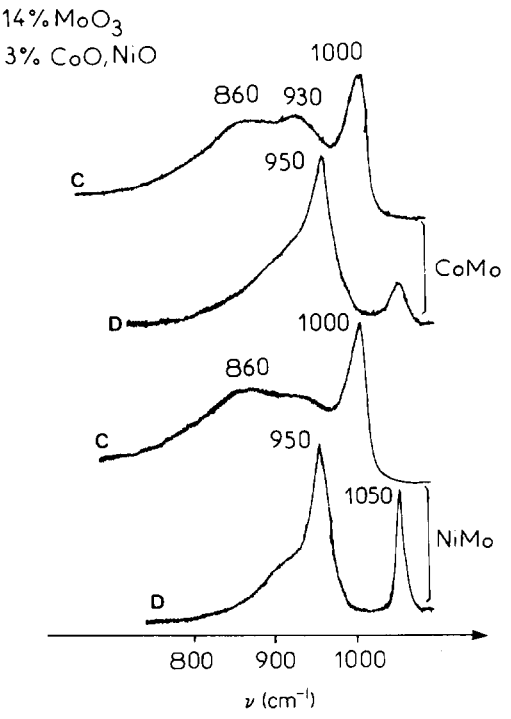

Fig. 7. Raman spectra of dry (D) and calcined (C) (by laser beam) MoO_3–promoter oxide–γ-Al_2O_3 samples. The MoO_3–γ-Al_2O_3 precursor was prepared by AHM impregnation at pH = 2[4] which leads to only HM species in solution.

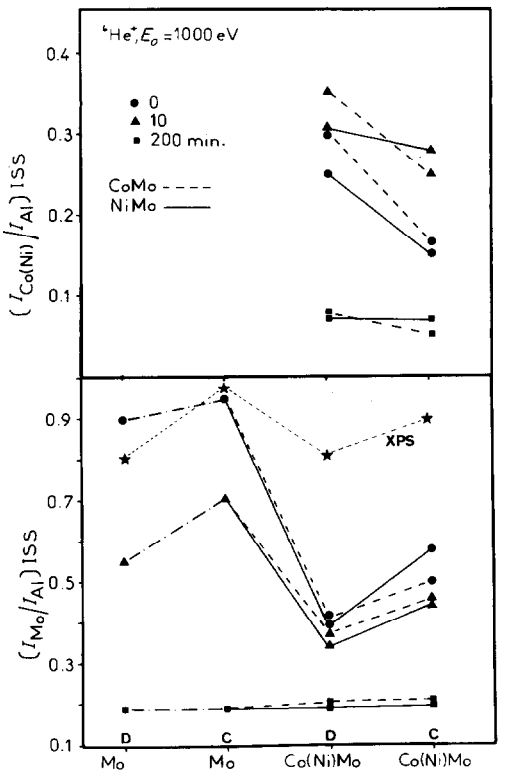

Fig. 8. Variation of the Mo/Al and Co(Ni)/Al intensity ratios as a function of the step of preparation. The XPS results, presented in the bottom part, have been previously reported[4] and concern a MoO_3–γ-Al_2O_3 sample prepared at pH = 2. All the drying and calcination parameters are the same.

and NH_4^+. The reverse trend is observed when the promoter solution is added. The relative Mo/Al ratio decrease is much more pronounced for ISS than for XPS, which means that, on the atomic scale, in addition to remaining water and other species, the promoter ions Co^{2+} and Ni^{2+} partly block the supported molybdate. After the final calcination, a small increase in the Mo signal relative to Al is detected but the initial value is not restored. As H_2O and NO_3^- are eliminated (see the Raman results) only the promoter ions can have a shadowing effect on the Mo phase which is therefore (partly) covered by Co or Ni. On the other hand, the relative promoter intensity slightly decreases. This can be interpreted by diffusion of the promoter ions into Al_2O_3 (this diffusion appears to be more easy with Co than with Ni). This was already evidenced by Jeziorowski *et al.*[25] using ISS and this effect is much more important when the calcination temperature increases.

MoO_3–*promoter oxide*–γ-Al_2O_3 *of other compositions: characterization*

To achieve this investigation, MoO_3–CoO (or NiO)–γ-Al_2O_3 samples of various compositions

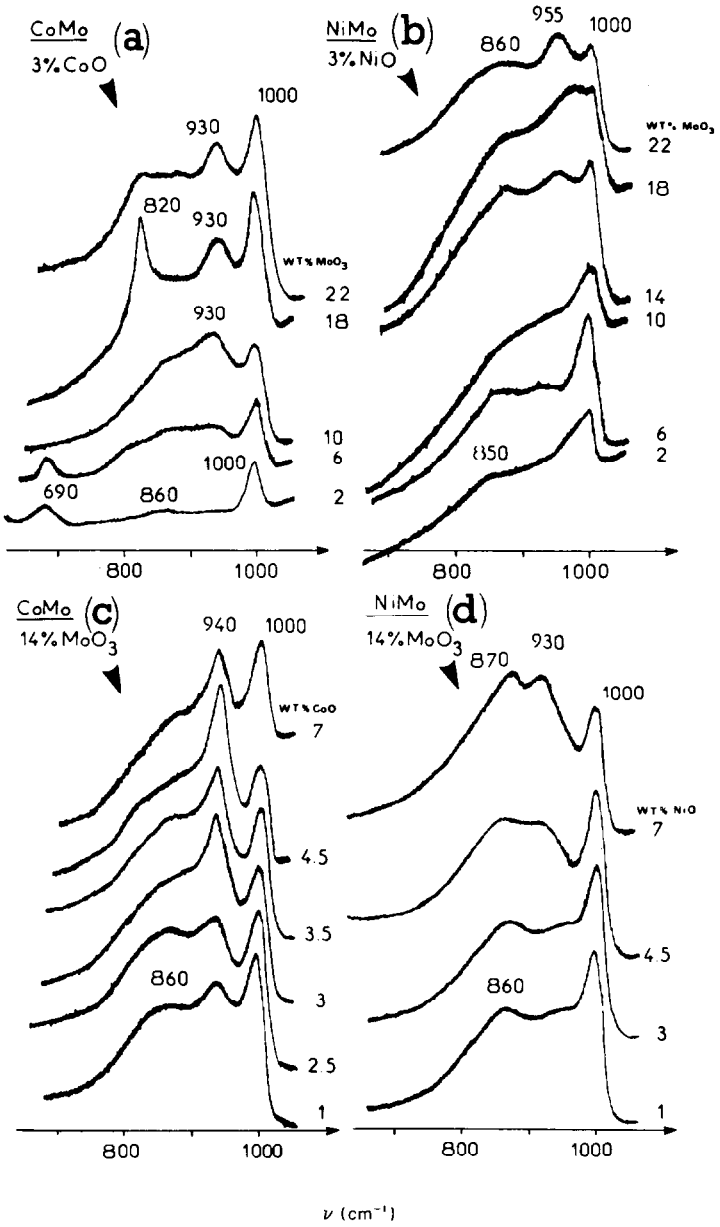

Fig. 9. Raman spectra (high laser power ≃ 300 mW) of Co–Mo and Ni–Mo samples calcined in air (500°C, 2 h): (a) constant Co content (3% CoO), (b) constant Ni content (3% NiO), and (c) and (d) constant Mo content (14% MoO_3).

have been characterized by LRS after a final calcination at 500°C for 2 h. In Fig. 9 are reported the main Raman features in the ~700–1000-cm^{-1} region obtained by using a high laser power (~300 mW). However, dehydration of the supported molybdate is not proven to be complete in all the examined samples as local temperature at the sample, light focusing etc . . . are not always reproducible. Nevertheless, the effect of promoter is clearly detected. The 1000-cm^{-1} line is easily obtained on the low MoO_3 loading samples when the promoter, Co or Ni, is present [Fig. 9(a) and (b)], whereas, in the same recording conditions, this line is not visible on the sample without promoter [Fig. 3(b)]. A more severe treatment (i.e. *in vacuo* at 700°C,[14]) is necessary to obtain this line. It therefore appears that dehydration is favored by the presence of a promoter whose location might be close to the adsorbed molybdate. On the Co–Mo samples at low Mo loading [Fig. 9(a)], the 690-cm^{-1} line is assigned to the presence of $CoAl_2O_4$ and/or Co_3O_4.[26] For such low Mo loadings, the uncovered surface of Al_2O_3 is quite large so that Co (or Ni) may easily interact with the support. By subsequent heating,

some of the promoter then diffuses into the Al_2O_3 as already shown by XPS–ISS.

As the Mo loading increases, the broad feature between 800 and 1000 cm^{-1} increases [Fig. 9(a) and (b)] and the bands at 930–950 cm^{-1}, characteristic of hydrated supported molybdate still remain, which means that the presence of the promoter influences the extent of hydration or makes the dehydration reaction incomplete. Analysis of a series of samples with constant MoO_3 loading (14 wt %) and increasing amount of promoter complements this observation. As the promoter loading increases, the relative intensity of the 940-cm^{-1} line increases [Fig. 9(c) and (d)]. Even for 1% CoO, this 940-cm^{-1} line remains. Comparison of Fig. 9(c) and (d) shows that presence of Ni favors the 860-cm^{-1} band relative to the 930–940- and 1000-cm^{-1} lines. No definitive explanation can be given at the moment to take into account this difference; it may be suggested that the Ni–molybdate interaction is stronger than the Co–molybdate one. Within this hypothesis, formation of a surface like Ni–heteropolymolybdate bound to the alumina surface, as already postulated by Knözinger,[27] is possible.

CONCLUSIONS

Starting with a well-defined γ-Al_2O_3 support, the whole sequence of the preparation of MoO_3–CoO or NiO–γ-Al_2O_3 hydrotreating catalysts have been studied and the following conclusions can be drawn.

(i) Although the main species in the impregnating solution with natural pH are HM anions, in the low Mo loading samples the major species are M.

(ii) By adsorption on γ-Al_2O_3, M species are distorted.

(iii) For higher Mo loading samples, HM species are also adsorbed. Bonds with the support do not appreciably modify the Mo=O(t) stretching vibration of HM.

(iv) Standard calcination (500°C, for 2 h) reinforces the links between M and/or HM with the support. Polymerization of HM on the γ-Al_2O_3 surface to form a supported polymolybdate phase of higher Mo number seems improbable unless, during calcination, adsorbed HM is mobile.

(v) Calcination at higher temperature forms $Al_2(MoO_4)_3$. Thus, to obtain optimum Mo dispersion, calcination between ~350 and ~500°C is preferred.

(vi) Aging of the catalyst is shown by hydration of the supported molybdate. This reaction modifies the bonds of the supported species with Al_2O_3 by hydrolysis. Calcination and aging are therefore two antagonistic reactions; only NH_3 desorption during calcination is an irreversible step.

(vii) The promoter added to the MoO_3–γ-Al_2O_3 samples may be close to or on the supported molybdate and on the free surface of Al_2O_3.

(viii) By calcination, some of the promoter diffuses into the support. The rest, in a strong interaction with the supported molybdate, modifies its hydration dehydration properties.

(ix) The exact location of the promoter in contact with the supported molybdate phase is not defined for the moment but it can be assumed that this promoter–molybdate entity is the precursor of the small MoS_2 patches "decorated" at the edge sites by Co or Ni.[28]

A COMPARISON OF THE SURFACE CHEMISTRY AND CATALYTIC PROPERTIES OF REDUCED VS SULFIDED MOLYBDENA–ALUMINA CATALYSTS

WILLIAM S. MILLMAN, KOH-ICHI SEGAWA,* DALE SMRZ and W. KEITH HALL†

Department of Chemistry, Laboratory of Surface Studies, University of Wisconsin—Milwaukee, Milwaukee, WI 53201, U.S.A.; and * Department of Chemistry, Sophia University, 7-1 Kioicho Chiyoda-ku, Tokyo 102, Japan

(*Received* 15 *June* 1985)

Abstract—Molybdena–alumina catalysts have been studied by both chemisorption and spectroscopic methods to relate their surface properties to catalytic function. IR studies of the OH region and CO_2 chemisorption have been used to determine the variation in the exposed alumina surface area as a function of Mo loading, and of the extent of reduction. NO chemisortion has been used as a selective probe of the molybdena portion of the surface. The data show that H_2 reduction decreases the coverage with molybdena and suggests that this phase undergoes a surface rearrangement with concomitant agglomeration. These processes are accentuated by sulfiding. The effects of loading on the ease of reduction and sulfiding were characterized and found to be different. The NO data show little change in the nature of the sites upon sulfiding. Catalytic reactions of ethene, propene and 1,3-butadiene with H_2 or D_2 were studied. Although changes in rate occurred on reduction or sulfiding, tracer experiments revealed that these changes did not alter the reaction mechanisms. The changes in the activity of the catalysts could be entirely attributed to changes in the active-site concentration rather than to the nature of the catalytic sites.

Molybdena–alumina catalysts are used industrially in both the reduced (oxidic) and sulfided forms. Because they are good hydrogenation catalysts which are relatively tolerant to sulfur and nitrogen compounds, they have attracted increasing interest in recent years. Both their surface chemistry and their catalytic properties are here compared for the two kinds of catalysts (oxide vs sulfide anions).

At a previous Molybdenum Chemistry Conference, Hall[1] reviewed progress in understanding the surface chemistry of the oxidic forms. During preparation molybdena becomes bound to the alumina surface as polymeric clusters as $H_6Mo_7O_{24}$ undergoes condensation with (replaces) alumina surface OH groups. On reduction with H_2, the Al—O—Mo bonds are attacked, regenerating (partially) the surface OH groups. More and more surface OH reappear as the catalysts are reduced more and more extensively. On reduction with CO, CO_2 is produced,[2] and such preparations have been reported[3] to have catalytic properties similar to the H_2-reduced forms.

The EXAFS studies of Clausen *et al.*[4] have indicated that the small cluster size (seven or eight Mo/cluster) is maintained on mild reduction although sintering and recrystallization into larger units (bound, oxygen-deficient MoO_2 crystallites) may occur under more severe conditions. A similar chemistry is now known for the sulfided catalysts. During sulfiding, recrystallization into sulfur-deficient surface-bound MoS_2 occurs.[5–7]

In the present paper important aspects of the surface chemistry and catalytic properties of reduced catalysts are compared with those of the sulfided ones. Attention is focused on the hydrogenation of simple olefins and diolefins, and on the development and assay of the catalytic centers. The chemistry over both catalysts is believed to center around alkyl,

† Author to whom correspondence should be addressed. Present address: P.O. Box 102, Chemistry Building, University of Pittsburgh, PA 15260, U.S.A.

alkylidene and allylic intermediates, with the ability of the latter to convert into metallocyclobutanes. Thus, it is noteworthy that olefin metathesis is not observed over the sulfided catalysts, but is facile over the oxidic one.[8]

EXPERIMENTAL

Catalysts

These were prepared either by the incipient wetness technique or by the equilibrium adsorption method. The source of Mo was ammonium heptamolybdate. Two nearly identical aluminas were used in this study. The first was Ketjen CK-300 and the second was JRC-ALO-4. Both had surface areas of about 185 $m^2\ g^{-1}$ with pore volumes of about 0.50 ml g^{-1}. The impurity levels were very low, particularly for transition metals, and the IR spectra showed nearly identical OH regions. All catalysts were dried at 110°C before calcining in air to 500°C.

Pretreatment of the catalysts involved, first, evacuation or flushing with purified He for 2 h at 500°C, or at the final reduction temperature, whichever has higher. Following this procedure they were treated with dry O_2 overnight at a reduction temperature of 500°C as described above. The He was purified by passing through a charcoal trap thermostatted at −195°C. The O_2 was passed through a column of anhydrous magnesium perchlorate to remove water.

Activation of the catalysts in H_2 *(reduction)*

This was carried out either in a recirculation system (500 torr initial pressure) with an in-line trap thermostatted at −195°C to remove water or in flowing H_2 (at 60 $cm^3\ min^{-1}$) for 1 h. Typically the reduction temperature was 500°C. Other temperatures, when used, are noted in the text. Following reduction, the catalyst was either evacuated or flushed with He at the same temperature before cooling *in vacuo* or in He flow.

Alternatively, the catalysts were sulfided. The oxidized catalysts were purged with purified He flowing at 75 $cm^3\ min^{-1}$ for 20 min at 500°C. The temperature was then lowered to 350°C where the He was replaced for 4 h with a preblended 10:1 H_2–H_2S mixture flowing at 80 $cm^3\ min^{-1}$. The gas stream was then switched back to He and the catalyst flushed for 20 min before raising the temperature to 500°C where the He was flow maintained for an additional hour to equilibrate the surface to the same OH content used for the reduced catalysts and in other studies[2] where actual H_2 contents were determined by isotope dilution methods.

Temperature-programmed reduction (TPR)

TPR experiments were carried out with a linear temperature programmer linked to a gold reflective furnace (Trans Temp Co, Type C). With this furnace, a uniform temperature was maintained to within 1″ from each end. The typical procedure was to treat the catalyst with pure dry O_2 overnight at 600°C before flushing with pure He for an additional hour during which it was cooled to ambient temperature. The He was then replaced with 5% H_2 in N_2 flowing at 75 $cm^3\ min^{-1}$. This gas was passed through a glass wool trap thermostatted with an *n*-hexane slush bath (~ −95°C) prior to entry into the thermal conductivity detector. After a stable baseline was obtained, the temperature program was started at 2.5° min. Upon reaching 600°C, the temperature was held constant until the baseline was again reached. Then the reductive gas was replaced with He. The sample was cooled to ambient conditions and the reactor sealed so it could be transferred to an all-glass recirculation system for quantitative reoxidation with O_2 to independently measure the extent of reduction achieved in the TPR experiment.

IR experiments

These were carried out using a Nicolet MX-1 Fourier Transform spectrometer using the absorbance mode. The resolution was controlled at 2 cm^{-1} by the spectrometer software. The cell design used has been reported previously.[9]

Reaction studies

These were carried out in an all-glass recirculation system as before.[3] The propene hydrogenations were carried out using 22 cm^3 (NTP) of propene and 110 cm^3 (NTP) of H_2. The total system volume was about 500. The products were separated on a $4' \times \frac{1}{4}''$ GLC column filled with 80–100-mesh Durapak at 0°C. For ethene hydrogenation a 1:1 mixture of ethene and D_2 [130 cm^3 (NTP)] was employed. The same column could be used for the separation of the products from these experiments by lowering the column temperature to −20°C. D_2 distributions in the several products were analyzed by mass spectrometry. The 1,3-butadiene experiments were carried out in a similar way using 100 torr of 1,3-butadiene [60 cm^3 (NTP)] and 200 torr of D_2. These products were separated on two columns in series. The first $15' \times \frac{1}{4}''$ column contained 40% dimethylsulfolane on Anakrom C22A held at 25°C; the second was a $10' \times \frac{1}{4}''$ column containing 30% propylene carbonate on Chromosorb P thermostatted at 20°C. The He flow rate used was 85 $cm^3\ min^{-1}$. The latter

column was needed only to obtain a quantitative separation of *cis*-2-butene from *trans*-2-butene. Isotopic analyses were made using a Hitachi Model RMU-6 magnetic sector mass spectrometer. The D distributions and the average D content were derived. The ionization voltage used was between 9.8 and 12 eV depending on the appearance potential of the individual molecule. The location of the deuterium within the molecules was determined using a Bruker WM-250 Fourier transform NMR equipped with an Aspect 2000 data system and a multinuclear probe. The deuterium was located by examining the ^2H NMR spectrum which was broad band decoupled from the ^1H nuclei. Typical pulse delay times of 25 ms were required, as determined experimentally from the perhydro standard, to obtain correct integrations. The amount of D in each position was then determined by normalizing the NMR integrated area to the average D content from the mass spectral data. This was then distributed about the molecular positions according to the integration for each unique resonance.

RESULTS AND DISCUSSION

IR and chemisorption studies

These were carried out to look for differences and/or similarities in the surface chemistry of reduced vs sulfided molybdena–alumina catalysts. In Fig. 1A, the OH spectra from the oxidized, reduced and sulfided forms of a catalyst loaded with $\sim 5 \times 10^{20}$ Mo g^{-1} are compared with that for the parent alumina. The corresponding spectra for the OD region, shown in Fig. 1B, were obtained from

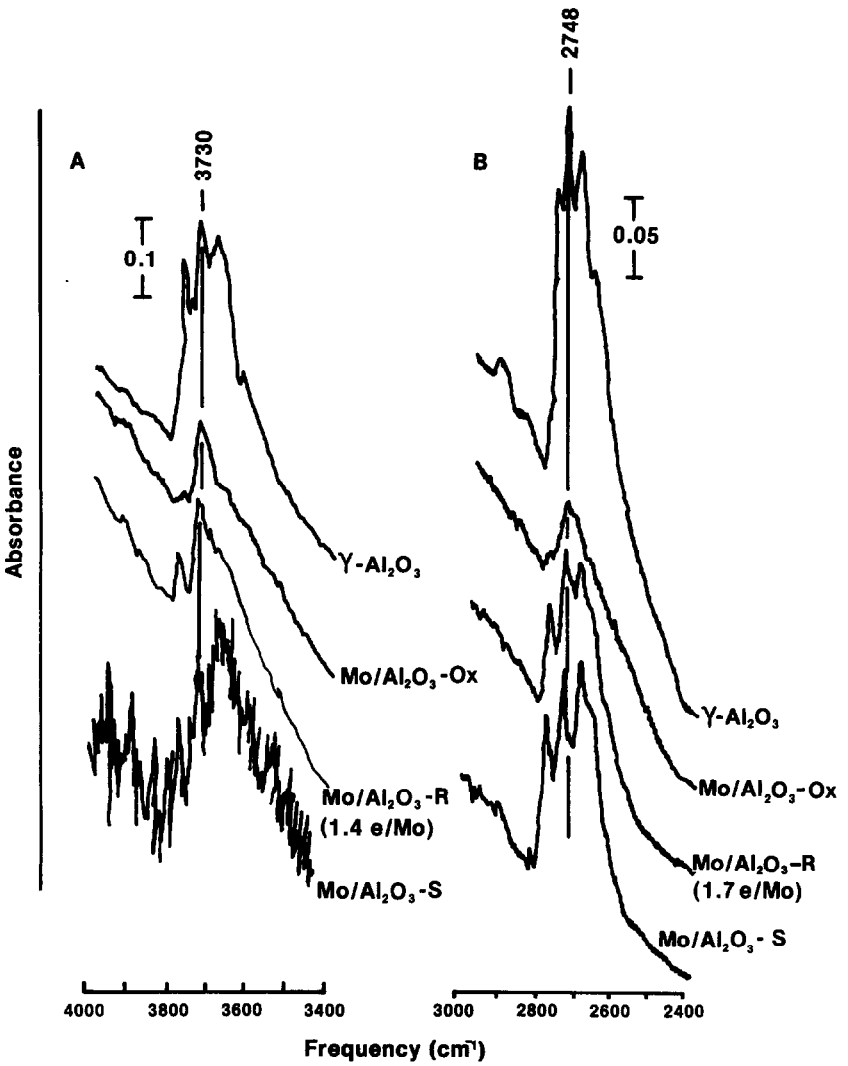

Fig. 1. IR spectra of: (A) the OH, and (B) the OD stretching regions from the parent alumina, and the catalyst in its oxidized, reduced and sulfided forms. In all cases the catalysts were evacuated at 500°C as the final step in preparation. The activation procedures are given in the text.

samples prepared as those in Fig. 1A following exhaustive exchange with D_2O or D_2. As reported earlier,[5] the OH spectrum from the sulfided preparation was very noisy; it was much cleaner in the OD region. Otherwise the two sets of spectra were in good general agreement. The alumina OH bands appeared in all of the spectra, but they were very weak in the oxidized form of the catalyst because of the well-known[1,2,10] bonding of molybdena to alumina by replacement of the surface OH groups. The regeneration of these bands as the catalyst was reduced[1,2,10] or sulfided[5] has also been reported previously. On sulfiding, the integrated intensity in the OH region appeared to be somewhat higher than with the reduced catalyst, but this was difficult to assess because of the noise. The OD spectra were taken to check this point. The increase, if real, was not large enough to be significant. Differences in relative intensity, particularly for the high-frequency band near 3785 cm^{-1}, may be noted, but like the low-frequency shoulder apparent in the spectrum from the deuterated sulfided preparation cannot be presently interpreted.

It is by now well established that NO and O_2 are absorbed selectively by the molybdena portion of the surface, apparently on the catalytically active CUS (coordinatively unsaturated sites). Moreover, evidence has been presented[9] suggesting that CO_2 is adsorbed selectively by the exposed alumina portions of the surface. As shown in Fig. 2, the two

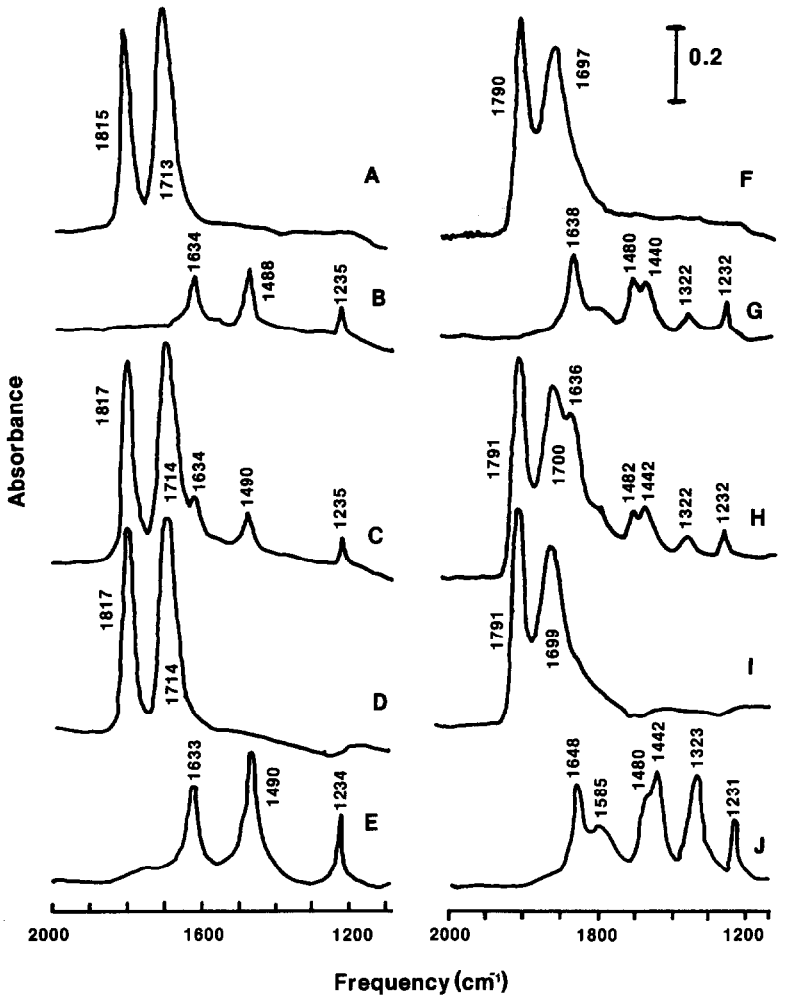

Fig. 2. IR spectra showing the independent chemisorption of CO_2 and NO on reduced (e/Mo = 1.8) molybdena–alumina catalyst (5×10^{20} g^{-1}): (A) NO on reduced catalyst, (B) CO_2 on reduced catalyst, (C) NO adsorbed on top of CO_2 on preparation shown in spectrum B, (D) spectrum C minus spectrum B (by computer subtraction), and (E) CO_2 adsorbed on parent alumina pretreated as was the reduced catalyst. IR spectra for comparable sulfided preparations are shown side by side: (F) NO on same catalyst sulfided, (G) CO_2 on sulfided catalyst, (H) NO adsorbed on top of CO_2 on preparation in spectrum G, (I) spectrum H minus spectrum G (by computer subtraction), and (J) CO_2 on parent alumina after same sulfiding pretreatment used with the molybdena–alumina catalyst.

adsorbed molecules do not interfere with each other as judged by the ability of either to be adsorbed after the other without altering the intensity of the IR bands, e.g. compare Fig. 2A and D; the latter spectrum was obtained by computer subtraction of spectrum B from C, i.e. by subtraction of the CO_2 bands from the spectrum having both NO and CO_2 bands. Note that spectrum D is in all respects identical with Fig. 2A which was obtained from the freshly reduced preparation. The reverse experiment,[9] where NO was adsorbed first and CO_2 was adsorbed second, produced the same CO_2 spectrum as if CO_2 was adsorbed alone, after the NO spectrum was subtracted. Results from sulfided catalysts (Fig. 2F–J) may be compared with those from reduced catalysts (Fig. 2A–E). The same pattern of behavior was obtained for both kinds of preparations, the sole difference being in the CO_2 spectrum from the sulfided preparations. On treatment with H_2S–H_2, alumina undergoes a change leading to extra bands at 1323, 1442 and 1585 cm^{-1} not present in the unsulfided material (Fig. 2E and J). When this has been taken into account, the NO spectrum (Fig. 2I) obtained by subtraction is in all respects identical to the one obtained from the clean catalyst (Fig. 2F). The spectra for NO adsorbed on the reduced and sulfided catalysts may be compared side by side in Fig. 2A and F; the similarity is striking. Dinitrosyl species are formed on both surfaces, although the frequencies for the sulfided catalyst were lower by from 15 to 25 cm^{-1}. Thus, except for an unidentified change in the alumina portion of the surface, the surface chemistry of reduced vs sulfided catalysts appears remarkably similar. Delgado *et al.*[11] have found, however, significant changes in the spectra from CO adsorbed at subzero temperatures on similar preparations, which they attributed to lower-valence states in the sulfided preparation.

The chemisorption of CO_2 may be used to assay the extent of exposed alumina surface. The irreversible chemisorption for a series of catalysts of increasing loading (made by the equilibrium adsorption method[1] using JRC-ALO-4 alumina) was determined. These data, together with the surface areas of the catalysts, are plotted in Fig. 3. The data show the chemisorption falling, as the uncovered alumina surface decreases with increasing loading, to zero at about 12% MoO_3 where monolayer coverage is expected. The corresponding decrease in intensities in the OH region with increasing loading has been noted previously.[1,2,10,12]

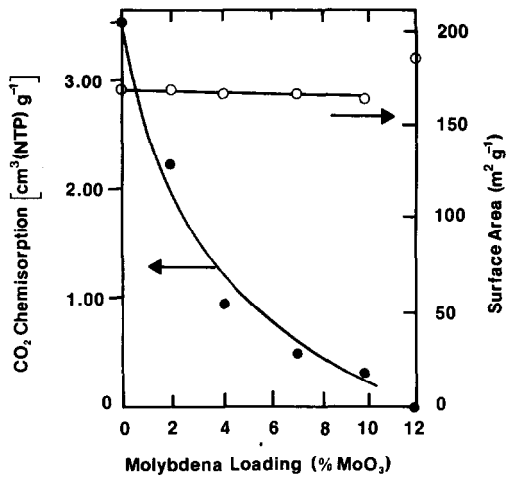

Fig. 3. CO_2 chemisorption as a function of loading for a series of calcined molybdena–alumina catalysts after evacuation at 500°C. Adsorption was carried out for 30 min (to saturation) at room temperature and the preparations were then evacuated for 30 min. The irreversible chemisorption is plotted. Surface areas per gram of the alumina support are also shown.

Extent of reduction

The changes in the extent of alumina surface as the catalyst is reduced can similarly be deduced.[9] Figure 4A demonstrates that the extent of free alumina surface increases about linearly with increasing extent of reduction, e/Mo (defined as the average number of electrons the Mo^{6+} ions have been reduced). For reference, the parent alumina chemisorbed about 3.5 cm^3 (NTP) g^{-1} (Fig. 3): thus, the maximum chemisorption for the catalyst loaded to 5×10^{20} Mo g^{-1} (8% Mo or 2.5×10^{14} cm^{-2}) when fully reduced was about 50% of that for the parent alumina, a value which is in good agreement with the fractional increase in surface OH concentration[9] or as estimated from Fig. 4B. These data suggest a doubling of cluster thickness. They are plotted in another way in Fig. 5 where the fraction of the total surface which is uncovered alumina is plotted as a function of the extent of reduction. The 12% MoO_3–Al_2O_3 catalyst was selected for this demonstration since in its oxidized state it was the one which had just about a completely covered the free alumina surface (see Fig. 3). They show that the free alumina surface starts to appear at about e/Mo = 0.5. This intercept is reminiscent of similar ones for O_2, NO and H_2 chemisorption[13,14] and the data are in general agreement with our earlier ^1H NMR work.[15] These results illustrate the hazards of taking correlations to imply relationships. As demonstrated by Fig. 2, these molecules do not chemisorb on alumina, but on CUS of molybdena which are formed concomitantly. The solid square of Fig. 5 is datum from the same catalyst after sulfiding. It demonstrates the continuity of system. As shown previously,[5] the sulfided catalyst is

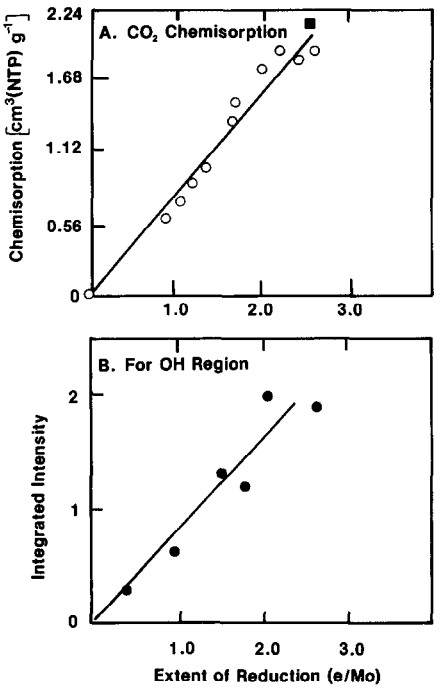

Fig. 4. Estimation of free alumina surface for the 12% MoO_3–Al_2O_3 catalyst. (A) Variation in CO_2 chemisorption as a function of the extent of reduction; the open circles are from the reduced oxidic form, and the solid square from the sulfided form of the catalyst; (B) variation of the integrated intensity of the OH groups as a function of the extent of reduction. Data are the increases in integrated intensity over that of the oxidized catalyst.

generally more deeply reduced (to e/Mo ~ 2.5), is a bit better crystallized, and therefore has a slightly higher fraction of exposed alumina surface than the reduced form. Noteworthy is the fact that a substantial fraction of the molybdenum ions have valence states *lower* than Mo^{4+}.

Another interesting feature of these systems is shown in Fig. 6. These data confirm the well-known fact that molybdena–alumina catalysts become easier to reduce with H_2 as the loading increases, or conversely. They also show that the reverse is true when the reducing agent is H_2–H_2S. Two sets of experiments are shown for H_2 reduction which, although they varied in several details, showed the same trend in e/Mo with increasing loading. The solid circles are data taken from Ref. 1 for a series of catalysts made by the equilibrium adsorption method[16] using Ketjen CK-300 alumina. The reductions were carried out by TPR, with a gradient of 5° min^{-1} up to 600°C, where a flow of 17% H_2 of 60 cm^3 min^{-1} was continued for an additional 2 h. The open circles are new data obtained from a similar set of preparations made using the Japanese JRC-ALO-4 alumina (177 m^2 g^{-1}). The temperature gradient in these experiments was 2.5° min^{-1} and the reducing gas was 5% H_2 in N_2; the program was stopped at 600°C where the catalysts were purged with He. They were then cooled to room temperature and the sealed tubes were removed to a volumetric apparatus and the e/Mo values measured[17] volumetrically from the O_2 consumed for complete reoxidation. The older data were values calculated from the consumption of H_2 during reduction corrected for the H_R (a high-temperature form of adsorbed H_2[1,17]) determined separately. Although the two sets of results are not in quantitative agreement, the trends are the same and the differences may be attributed to the different catalyst preparation and other experimental variables (time at high temperatures etc.) as well as the uncertainties in the evaluation of H_R.[1] The really significant difference is the reverse trend found on sulfiding. These data (squares) were obtained from sulfided preparations made from the same set of catalysts[1] shown as solid circles by reoxidation.[5] The salient feature is that the low-loading catalysts,

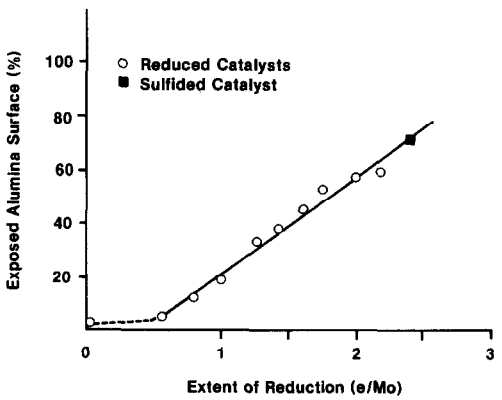

Fig. 5. Percentage of free alumina surface as a function of the extent of reduction of the standard 8% Mo catalyst. Data were calculated from the CO_2 chemisorptions on a per unit weight of alumina (metal free) basis.

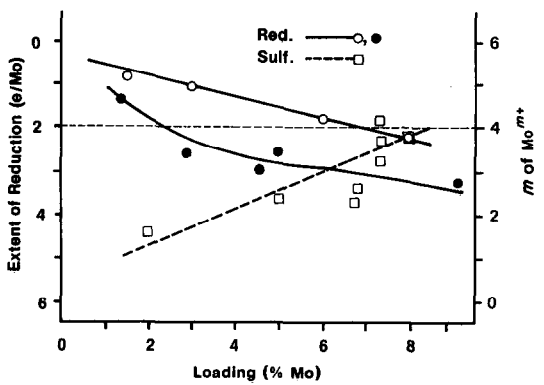

Fig. 6. Variation in the average valence state of Mo^{m+} in reduced and sulfided catalysts as a function of Mo loading; see text for details. Note that $m = 6 - e/Mo$.

which contained predominantly tetrahedral monomeric surface-bound molybdena, stubbornly resist attack by H_2, whereas these same species appear to be easily destroyed in the presence of H_2S. Note also that valence states below Mo^{4+} are common in these preparations, i.e. all the points which fall below the dashed line of Fig. 6 have average values, e/Mo $\geqslant 2$, i.e. higher than that required for stoichiometric MoS_2 or MoO_2. That metallic molybdenum is not a likely source for these low values is shown by the work of Burwell and Brenner[18] who reported that Mo(0), freed by decomposition of $Mo(CO)_6$ on alumina surfaces, becomes spontaneously oxidized by reaction with surface OH groups, freeing H_2. Recently, we have presented evidence that the active centers (CUS) may be Mo^{2+}.[5,19,20]

Relationships with catalysis

This is the ultimate goal of much research in the area of surface chemistry. We have fixed our attention on hydrogenation of olefins and butadiene in an effort to link the foregoing surface chemistry to catalytic function. Data obtained for the reactions of ethane with D_2 are listed in Table 1. Only a little exchange into the unreacted ethene was observed at low conversions over the reduced catalyst and the principal product was ethane-d_2. With increasing conversion the extent of exchange into the olefin (with the resulting production of ethane-d_1 and ethane-d_3) was more extensive than reported earlier.[21] The reasons for this are not known, but may reflect differences in the extent of reduction or other experimental variables. Nevertheless, these effects are secondary and provide some perspective in looking at the existing literature. In agreement with the data of Tanaka and Okuhara,[22] exchange was more important with the sulfided catalysts than with the reduced ones, and this was reflected in a further spreading of the distribution in the ethanes. Ethane-d_2 remained the most important product, but the d_1 and d_3 paraffins increased substantially. Thus, a continuous gradation of behavior exists with ZnO[23] and chromia[24] catalysts at one extreme yielding only ethane-d_2 and ethene-d_0 (no alkyl reversal), to sulfided molybdena–alumina and MoS_2, where substantial back-exchange was observed into the reactant olefin. The reduced preparations appeared to be intermediate cases with the importance of aklyl reversal depending on the extent of reduction, temperature, type of reactor used etc. As shown earlier,[21] HD formed by exchange of D_2 with the reactant olefin rapidly reacted with ethene forming ethane-d_1; similarly, ethane-d_3 was formed efficiently by reaction of ethene-d_1, already held on the catalyst surface with D_2.

The D distributions in the products of deuteration of olefins over oxides and sulfides differ dramatically from those obtained over metals.[25] This difference may be attributed to the ease with which the olefin interacts reversibly with the catalytic sites relative to hydrogenation. Thus, for metals the chemistry is commonly written:

$$D_2(g) + C_2H_4(g) \underset{k_d}{\overset{k_a}{\rightleftharpoons}} \underset{*}{CH_2}\text{—}\underset{*}{CH_2} + \underset{*}{2D}$$

$$\underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} DCH_2\text{—}\underset{*}{CH_2} + \underset{*}{D} \xrightarrow{k_2} C_2H_{6-x}D_x,$$

where * is taken to mean a surface metal atom. In these cases, $k_{-1} \gg k_2$, leading to both exchanged ethene and a broad binomial deuterium distribution in the ethanes. With ZnO and chromia $k_2 \gg k_{-1}$ and so only ethane-d_2 is produced. The reversibility is somewhat higher over reduced (even more so over sulfided) molybdena–alumina and the distribution in the ethanes starts to broaden, but to nowhere near the extent found for metals. In all these cases, alkyl reversal (the half-hydrogenated state) is either slow or zero. Even at high conversions, the deuteration appears to be limited to ethane-d_4. It was for this reason that we previously suggested[21] that exchange might occur by a reversible interconversion of the alkyl into ethylidene carbene.

Table 1. Deuterium distributions from the reaction of ethene with deuterium over molybdena–alumina catalysts

Catalyst preparation	Conversion (%)	Ethene					Ethane						
		d_0	d_1	d_2	d_3	d_4	d_0	d_1	d_2	d_3	d_4	d_5	d_6
Reduced	9	95	4	1	—	—	—	11	89	—	—	—	—
	28	91	7	2	—	—	—	16	79	5	—	—	—
	35	86	11	3	—	—	—	18	76	6	—	—	—
Sulfided	25	87	12	2	—	—	—	30	61	8	1	—	—
	45	81	16	2	—	—	—	36	53	10	1	—	—
	66	67	29	5	—	—	—	38	50	11	1	—	—

The reaction of propene with D_2 was studied earlier.[3] These results fit neatly into the picture. The propene-d_0 concentration decreased about linearly with per cent conversion while the propene-d_1 and propene-d_2 increased from zero. Propene-d_3 also formed, but appeared as a product of secondary reaction. These results should be compared with those of Table 1. As with ethene the exchange into the paraffin appeared to be limited to propane-d_4.

The hydrogenation rate for propene was slower, other things being equal, than for ethene. This may be attributed to additional chemistry which becomes possible with propene due to its allylic hydrogen. Thus, sites which chemisorb H_2 with which olefins react to form bound alkyls, may be occupied by the allylic species characterized for ZnO,[26] or metallocyclobutane complexes. In the present work, 1-butene was found to react quite similarly.

Rates of hydrogenation of propene are presented in Fig. 7. The open circles are data for reduced catalysts reported earlier;[3] the open squares are new data for the same catalyst repeated in the present work for comparison with sulfided catalysts (open and filled triangles). The extents of reduction for the latter were determined by reoxidation.[5] These data fit nicely onto the upper end of the curve for the reduced catalysts, demonstrating that no basic differences exist except for higher rates because of the lower average valence states of the sulfided catalysts.

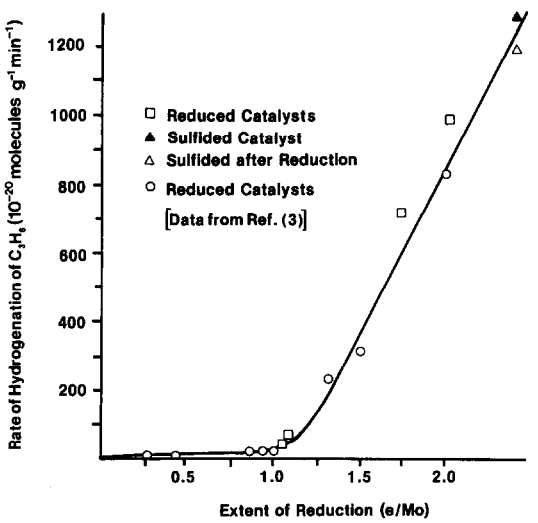

Fig. 7. Rates of propene hydrogenation as a function of the extent of reduction for H_2 and H_2–H_2S reduced catalysts. Rates reported were measured at −27°C in a recirculation BET system. The data are based on GLC analyses of the products. Data points for e/Mo $\leqslant$ 1.0 were taken using 1 g of catalyst and those for e/Mo $\geqslant$ 1.0 using 0.1 g to avoid pump limitation.

This observation is in agreement with the recent observations of Burwell *et al.*[27]

Because of the additional complications introduced with propylene due to its allylic hydrogen, some studies of the reactions of butadiene with deuterium were made to complete the picture. This conjugated diolefin reacted more slowly than propene, and was slower over sulfided catalysts than over reduced ones. Although a detailed study of the kinetics was not made, the rate was strongly inhibited by increase in diolefin pressure, more strongly so with the sulfided catalysts, and $k_H/k_D \simeq 1.4$ for hydrogenation vs deuteration, respectively. These facts suggested that the diolefin interacted strongly with the hydrogenation sites and that the hydrogenation rate was limited by the adsorption of H_2 (D_2).

The dominant primary product of hydrogenation was 1-butene, although smaller amounts of 2-butene were also formed. Exchange of butadiene with D_2 was competitive with deuteration. The distribution of D in the separated reaction products was determined in the usual way[3] by mass spectrometry, i.e. the mole fractions, N_i, of the particular hydrocarbon containing i deuterium atoms were determined. The distribution of D in each molecule was then derived from ^2H resonance spectra of each product molecule. Some results of this work are shown in Fig. 8. Butadiene exchanged at all positions, but was faster at the terminal vinyl positions than at the internal ones. Presumably, the former resulted from formation of the secondary, and the latter from the primary alkylidene. The addition of a second D would lead to 1-butene in each case, while exchange would result from reversal to the diolefin. The relatively small extents of exchange at ~20% conversion suggests that this reversal is slow with butadiene, as with monoolefins. The 1-butene formed reflects this underlying exchange and in addition clearly shows the saturation of one double bond producing (approximately) 1-butene-3,4-d_2.

The average compositions of the 1-butene product and the remaining butadiene for the reduced and sulfided catalyst at a similar conversion level may be compared in Fig. 8A and B, respectively. The close correspondence of the data demonstrates clearly that the catalytic sites on the two forms of the catalyst are virtually the same.

Sufficient data now exist to define the primary reaction centers as low-valent Mo^{n+} ions with multiple coordinative unsaturation. H_2 is dissociated at such sites and this chemisorption may be competitive with hydrocarbons. The hydrogen, so dissociated may spill over into the bulk-forming bronzes of composition such as $H_{0.1}MoS_2$,[28]

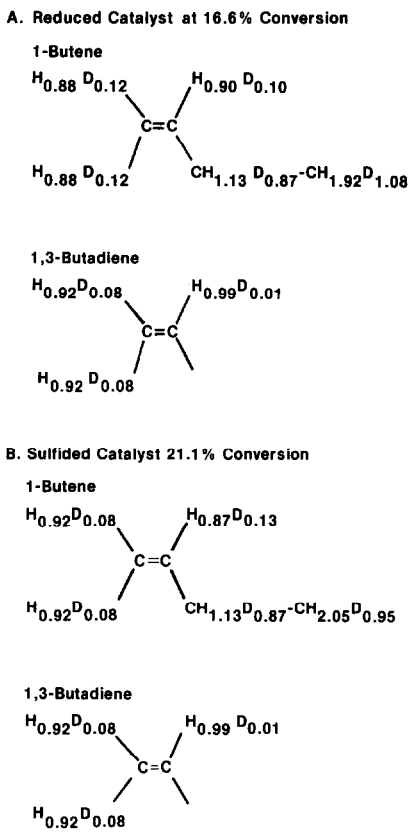

Fig. 8. Quantities of deuterium incorporated into 1-butene and 1,3-butadiene over: (A) reduced catalysts, and (B) sulfided ones. These evaluations were obtained by combining mass spectrometric and ^2H NMR results (see text).

inducing as yet unrecognized catalytic effects. Conceivably, this ability to travel may make possible the catalysis of certain reactions on the basal planes as well as the CUS. The structure of MoS_2, and the present knowledge that the active component of sulfided molybdena catalysts has a similar structure, strongly suggests that these CUS must be at the edges and corners of the chalcogenite wafers. Moreover, whatever the exact nature of these centers, they must be closely similar for both reduced and sulfided catalysts. It seems unlikely, therefore, that these active centers could be Mo^{4+} for reduced catalysts and Mo^{2+} for sulfided ones as suggested recently by Delgado *et al.*[11]

CHARACTERIZATION OF SUPPORTED MoO_3 BY TEMPERATURE-PROGRAMMED REDUCTION

JOAQUÍN BRITO and JORGE LAINE*

Laboratorio de Catálisis Heterogénea, Centro de Química, I.V.I.C., Apartado 1827, Caracas 1010-A, Venezuela

(*Received* 17 *June* 1985)

Abstract—Temperature-programmed reduction (TPR) was employed for the characterization of molybdena catalysts. The effect of several variables on reduction of the supported catalysts was determined. The TPR spectra changed significantly with both the amount of MoO_3, from 5 to 80 wt %, and the type of support, several silica–alumina carriers, of compositions ranging from pure SiO_2 to pure Al_2O_3. The peak assigned to buildup of multilayers of molybdena on the γ-Al_2O_3 supports was affected by the calcination temperature and by the amount of promoter (0–5 wt % NiO). Nickel-promoted catalysts activated hydrogen easier than both cobalt-promoted and unpromoted catalysts.

The activation of molybdena-based hydrotreating catalysts is brought about by reductive processes, which occur mainly during pretreatments or during the first stages of the catalytic reaction, the role of hydrogen being still imperfectly understood.

Classical work on reduction of catalysts has been carried out by using conventional, static or dynamic adsorption and reaction studies (mainly by means of gravimetric or volumetric techniques), or by characterizing the catalysts during or after the reductive treatment. Currently, there have been an increasing number of papers aiming at similar goals by means of transient temperature-programmed reduction (TPR) techniques,[1] whose various advantages (high sensitivity to hydrogen, readiness and low cost) compensate the complexity of the interpretation of the TPR spectra.

Most of the early reports (up to about 1977) concerning reduction of molybdena catalysts and of their assumed components, have been reviewed by Massoth.[2] More recent work, introducing the use of TPR to the characterization of hydrotreatment catalysts, includes that of Thomas *et al.*,[3] Nag *et al.*[4] and Yao.[5]

In this paper, the effects of several variables such as type of support, calcination temperature, and amount of Mo and promoters upon the reduction characteristics of supported MoO_3 are investigated using TPR.

EXPERIMENTAL

Catalysts

Three series of catalysts were prepared by the method of incipient wetness ("dry") impregnation, followed by drying (at 120°C), and firing at various temperatures. In one series (MoAlSi), commercial silica (Merck) was first impregnated with $Al(NO_3)_3$ solutions, dried and calcined at 550°C, in order to obtain six carriers (0, 5, 15, 25, 75 and 100 wt % Al_2O_3, the remainder SiO_2), which were impregnated with ammonium heptamolybdate (AHM) solutions, dried and calcined again at 550°C, resulting in solids with 5, 10, 30 and 80 wt % MoO_3.

In another series of catalysts (NiMoAl), commercial γ-Al_2O_3 (Filtrol) was impregnated with an AHM solution, dried and calcined at 400°C (12 wt % MoO_3). Afterwards, it was impregnated with $Ni(NO_3)_2$ solutions, in order to obtain catalysts with 0, 1, 3 and 5 wt % NiO. Portions of these solids were calcined at 400, 500, 600, 660 and 800°C.

The third series (CoNiMoAl) was prepared by impregnating another commercial γ-Al_2O_3 (Akzo Ketjen) with an AHM solution, and then with $Ni(NO_3)_2$ and $Co(NO_3)_2$ solutions, to give a composition of 10.4 wt % MoO_3 and 3.5 wt % (CoO + NiO), the atomic ratio r [Co/(Co + Ni)] varying between 0 and 1. The samples were divided in two parts and calcined at 500 and 600°C. Further details of the preparation of these catalysts have been given elsewhere.[6]

TPR apparatus

It consisted of a quartz tube with an intern frit which supported the samples. Heating was effected by means of a tubular furnace and a temperature programmer. Gas purity was assured by using molecular sieves, deoxo and liquid nitrogen traps for collecting traces of water and other impurities. The flow of gases was controlled with electronic mass flowmeters. A thermal conductivity detector allowed monitoring of the changes in the composition of the reductive gas.

Experimental conditions

Reducing gas: 15 vol% H_2 in N_2, flowing at 40 cm^3 min^{-1}. The samples were not pretreated, and were heated at 20°C min^{-1} from 190 to 910°C. The typical sample weight was 100 mg, except for the highest MoO_3 content catalysts (80 wt %), where it was 50 mg. The attenuation of the detector was varied in order to obtain spectra of similar size.

The samples were introduced to the quartz reactor, positioned in the furnace and, after stabilization of the baseline (usually several minutes), the run was started. A liquid nitrogen trap after the reactor removed the H_2O produced during the reduction. Thus, the TCD signal was proportional to the H_2 concentration. The TPR traces, which were perfectly reproducible, consisted of various peaks; we define a quantity T_m for each peak as the temperature of the maximum rate of H_2 consumption.

RESULTS AND DISCUSSION

MoAlSi *series*

Figure 1 shows the spectra of the MoO_3–SiO_2–Al_2O_3 catalysts. From 5 to 30 wt% MoO_3 the shape of the TPR spectra is strongly dependent on the type of carrier. The 100:0 and 75:25 supports give solids with the characteristic, two-peaks pattern which has been observed previously for MoO_3–Al_2O_3.[3,5] The first peak (lower T_m) has been attributed to Mo multilayers,[3(a)] which appears to be reasonable as the size of this peak increases with increasing Mo content. In particular, for the 5 wt% MoO_3 catalysts the ratio of the second to the first peak is high, which suggests a good dispersion, though not as a monolayer. The dispersion becomes poorer as the Mo content becomes higher. The silica (0:100)-supported catalysts also show two peaks, but closer than the alumina-rich solids. In this case it is the first peak which has been assigned to a single Mo monolayer,[3(b)] and our results agree, as the size of the second peak increases with higher Mo content. The peaks of MoO_3 supported on SiO_2 are sharper than on Al_2O_3, suggesting either a better crystallinity or more homogeneity of the reducible phases. The fact that the peak for the monolayer of MoO_3 supported on Al_2O_3 appears at a much higher T_m agrees with the stronger interaction of MoO_3 with this support compared to silica.

The lower T_m of the peak assigned to MoO_3 multilayers relative to the monolayer signal in Al_2O_3-rich catalysts could be explained as a stabilization effect of the neighbouring Mo cations upon the one which undergoes reduction. Several Mo atoms bridged by O anions should share better the excess negative charge than single molybdate groups directly mounted on the support, as Al is less capable of changing its oxidation state than Mo. In the case of the silica support, apparently there is no formation of multilayers but nucleation leading to MoO_3 microcrystallites, because the second peak of MoO_3–SiO_2 has a T_m similar to bulk MoO_3 (not shown).

Mo supported on the intermediate, silica-rich carriers gave ill-defined traces, with single but broad and highly complex bands, which seem to be composed of the superposition of various peaks. This may be related to the high heterogeneity of MoO_3–SiO_2–Al_2O_3. Indeed, by means of ammonia adsorption measurements we have shown[7] that this kind of catalyst is both more acidic and more heterogeneous (from the point of view of acid-site distribution) than either MoO_3–SiO_2 or MoO_3–Al_2O_3.

The catalysts with the highest MoO_3 content have spectra whose shapes are quite similar, except for

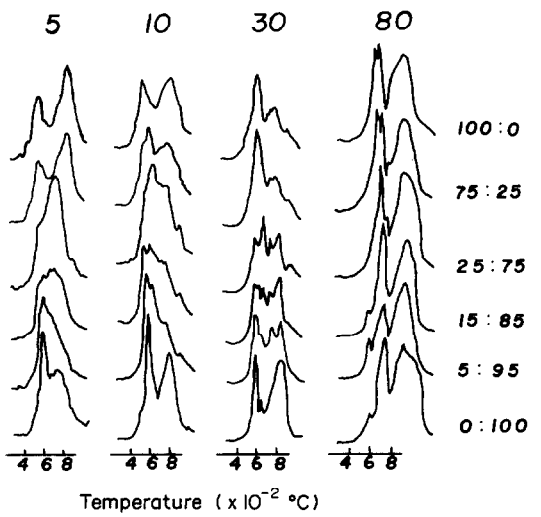

Fig. 1. TPR spectra of MoAlSi catalysts. Each row corresponds to a type of support, indicated on the right as wt % Al_2O_3: wt % SiO_2. The MoO_3 content varies from column to column, and is indicated over each as wt %.

some fine details, regardless of the carrier composition. However, this similarity is only apparent, as the T_m value of the lower-temperature peaks varies smoothly in a wide range from the 0 : 100 carrier (single peak, $T_m = 760°C$) to the 100:0 support (two close peaks, $T_m = 680$ and 710°C). This reveals that even at high Mo concentration the interaction with the support (or, in this case, modifier) may bring about significant differences between the catalysts' reducibilities.

NiMoAl *series*

The most conspicuous change in the TPR spectra of MoO_3–Al_2O_3 catalysts brought about by the incorporation of Ni (Fig. 2) is the appearance of a broad band, with a T_m intermediate between the two peaks of the unpromoted catalyst. This extra signal, however, is only well defined in the patterns of catalysts with high Ni contents and lower firing temperatures. It is evident that the position of this band changes with increasing calcination temperature, being superimposed on the second Mo peak at >600°C, as reflected in the higher size of this peak with increasing Ni concentration. Conversely, contrary to a previous suggestion,[4] the size of the first peak does not change with Ni content, showing that this promoter does not affect the dispersion of MoO_3 in the oxidic precursors.

TPR spectra of bulk NiO (single sharp peak at about 300°C) and of Ni–Al_2O_3 (broad band appearing at >700°C, see also below), allow us to suggest that the extra peak is probably due to a spinel-like surface phase, and that the movement to higher T_m is due to increasing interaction of Ni with the support.

Although the size of the first peak does not change with Ni content, the T_m decreases with increasing concentration of the promoter (Fig. 3). This suggests that, while Ni does not change the nature of MoO_3 multilayers, it favours their reduction. It may also be appreciated in Fig. 3 that, at the lower calcination temperatures, the 3 wt % NiO catalyst is similar to the 5 wt % NiO-promoted catalyst, but, as the firing temperature increases, it becomes similar to the 1 wt % NiO one. As Ni cations tend to enter the alumina lattice with increasing calcination temperature, it may be inferred that the effect of Ni on the reducibility of the MoO_3 multilayers is related to its presence on the catalyst surface, and could be attributed to a spill-over of hydrogen from Ni-reduced centers to the molybdena surface.

CoNiMoAl *series*

In Fig. 4a, we show the TPR spectra of these solids. Once again, Ni lowers the T_m of the first peaks with respect to the unpromoted catalysts (from 480 to 430°C when calcined at 500°C, and from 480 to 455°C at a firing temperature of 600°C). Incorporation of Co in the MoO_3–Al_2O_3 system causes an increase in the size of both peaks, though a slight one in the first peak. No extra bands, as in the case of Ni, are observed, even at the lowest calcination temperature. This was unexpected, as the TPR trace of a Co–Al_2O_3 catalyst of similar Co content has a peak with lower T_m than Ni–Al_2O_3. The possible explanation is that Co interacts more with Mo than Ni does or that the presence of Mo promotes the interaction between Co and the support. The T_m of both Co–Mo–Al_2O_3 peaks are similar to those

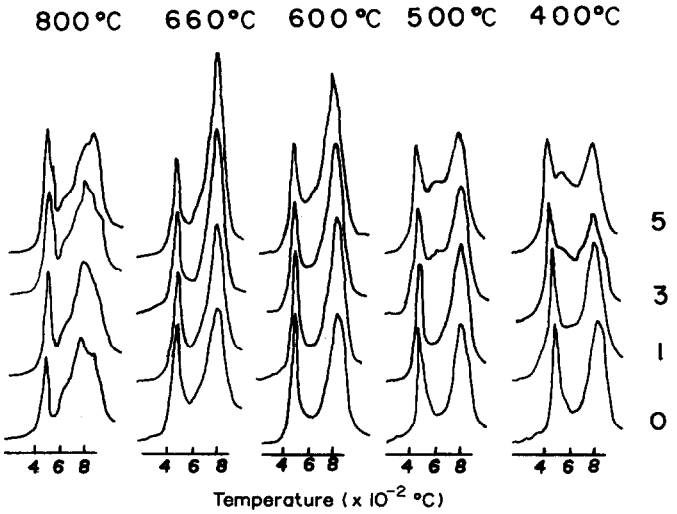

Fig. 2. TPR spectra of the NiMoAl catalysts. The calcination temperature is given over the corresponding column. Each row corresponds to a Ni content, displayed on the right as wt % NiO.

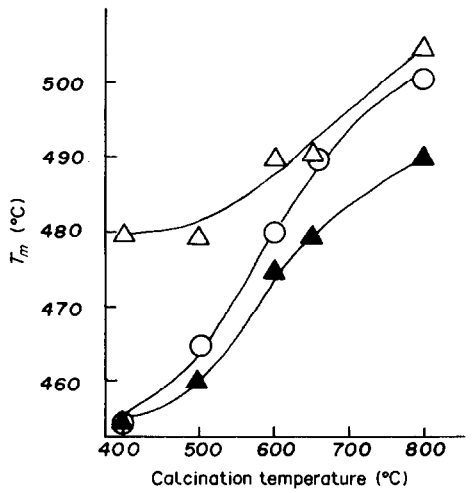

Fig. 3. Dependence of the T_m value for the first TPR peak of the NiMoAl catalysts on their calcination temperature. (△) 1 wt % NiO, (○) 3 wt % NiO, and (▲) 5 wt % NiO.

for Mo–Al_2O_3, showing that Co does not favour hydrogen activation as Ni does.

As commented above, the patterns of Co–Al_2O_3 show peaks with lower T_m than those of Ni–Al_2O_3. Also, these peaks are sharper. Both these facts may suggest that, in the Co catalyst, there are bulk-like cobalt oxide phases, contrary to the case of Ni–Al_2O_3 (as discussed above). This possibility is being examined at present by obtaining TPR spectra of bulk compounds: $CoAl_2O_4$, $NiAl_2O_4$, CoO and Co_3O_4.

The trimetallic catalysts show a gradual change of the T_m of the first peak, from 430 (only Ni) to 480°C (only Co), whereas the second peak vary more abruptly: its T_m is 800°C between $r = 0$ and $r = 0.6$, and then it changes to 825–830°C. It has been reported[6] that this trimetallic system has an optimum composition for the best hydrodesulfurization activity, but no features of the TPR spectra have been found that correlate with that activity behaviour.

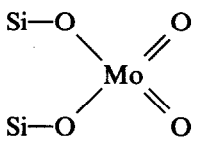
STRUCTURE OF Mo CATALYSTS SUPPORTED ON SILICA: IR AND GRAVIMETRIC RESULTS

M. CORNAC, A. JANIN and J. C. LAVALLEY*

UA 414, Laboratoire de Spectrochimie, I.S.M.Ra, Université de Caen, 14032 Caen Cedex, France



(*Received* 18 *June* 1985)

Abstract—Isotopic exchange with $H_2{}^{18}O$ followed by IR spectroscopy, and H_2S chemisorption followed by gravimetry, show that the species formed on MoO_3–SiO_2 at low loading is:

(X = Si or Mo). O atoms of the Mo=O bond and the Mo—O—X bridge are exchangeable by ^{18}O or S atoms.

The MoO_3–SiO_2 system is of interest for catalyzing oxidation[1] or ammoxidation reactions. FTIR spectroscopy has enabled us to determine the stepwise appearance on MoO_3–SiO_2 samples of at least three species,[2] depending on the Mo loading. The species formed at low loading (species **I**) has been assigned[3] a tetrahedral structure by comparison with work on MoO_3–Al_2O_3:[4]

This species is the active one in the selective oxidation of methanol to acetaldehyde.[5]

To clarify the nature of this surface phase, we have studied the isotopic exchange $^{16}O \rightarrow {}^{18}O$ by IR spectroscopy.

Also, as our system is close to precursors of HDS catalysts, which are used in sulfided form, we have followed the action of H_2S by IR spectroscopy and gravimetry. The results enable us to specify the nature of species **I** and to propose a model of interaction between the Mo phase and the surface.

EXPERIMENTAL

The preparation of catalysts, sulfidation method and IR measurements have been described elsewhere.[2] The isotopic exchange was performed by repeated cycles of hydration by $H_2{}^{18}O$ at 150°C and dehydration at 400°C. The labelled water was 98% enriched, from CEA-ORIS. Weight changes have been followed with a McBain microbalance,[6] for the following sulfidation method: $H_2S + H_2$ introduction at room temperature, equilibration, and evacuation at temperatures increasing from 20 to 300°C.

RESULTS

In a previous study,[2] we showed the presence of three species on MoO_3–SiO_2 catalysts, depending on the Mo loading:

(i) species **I**, appearing at low loading, characterized by IR bands at 990 and 920 cm^{-1};

(ii) species **II**, for medium-loading samples, IR band at 970 cm^{-1}, probably a polymer phase [Fig. 1(a)];

* Author to whom correspondence should be addressed.

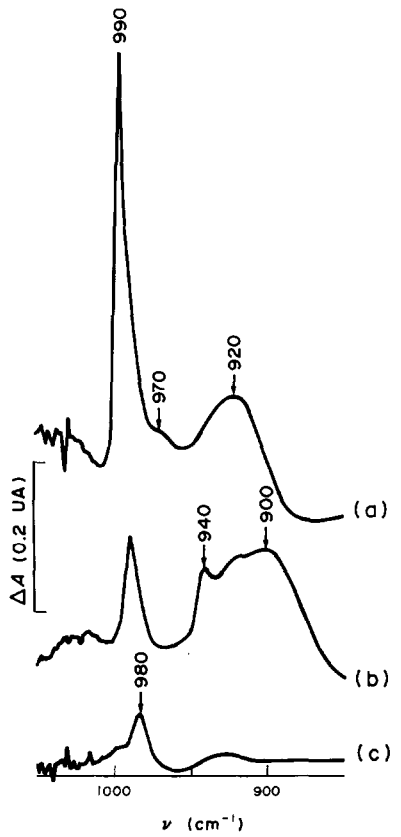


Fig. 1. IR spectra of oxymolybdenum species (obtained by subtraction of the spectrum of the same amount of pure silica): (a) Mo-8–SiO_2, O_2 calcined at 400°C; (b) after isotopic exchange with $H_2{}^{18}O$ at 150°C and dehydration at 400°C; and (c) effect of the addition of 5-torr H_2O on (a).

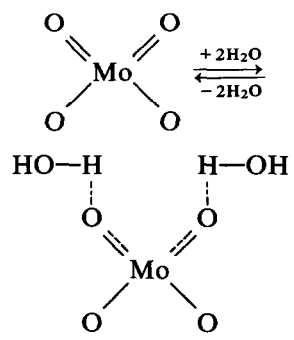
(iii) species **III**, at high loading, IR bands at 875, 820 and 670 cm^{-1}, a pseudo-MoO_3 phase.

Progressive addition of water at room temperature to the different calcined samples decreases the intensity of the 990- and 920-cm^{-1} bands while the 990-cm^{-1} band continuously shifts to 980 cm^{-1} [Fig. 1(c)]. Complete disappearance of the bands is obtained by heating at 400°C for 20 min (P_{H_2O} = 10 torr). Heating *in vacuo* at 400°C regenerates the initial bands. The 970-cm^{-1} band, characteristic of species **II** in Mo-8 and Mo-14 samples, disappears completely with the addition of even a small amount of water at room temperature.

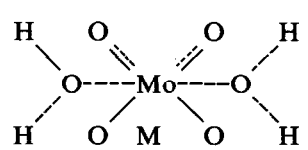
On all the catalysts, water addition creates a broad band at 3550 cm^{-1}, which shifts to 3450 cm^{-1} on further water addition. Corresponding to this band is another band at 1615 cm^{-1}, characteristic of the water bending vibration. We assign these bands to molecular water adsorption.

We observe the same phenomena using $H_2{}^{18}O$. However after the final dehydration at 400°C, we observe that each of the two bands of species **I** (990 and 920 cm^{-1}) has decreased in intensity and is accompanied by a second band at lower wavenumber (940 and 900 cm^{-1}, respectively) [Fig. 1(b)]. We deduce that an isotopic exchange $^{16}O(Mo) \rightarrow {}^{18}O(Mo)$ has occurred. The 970-cm^{-1} band is also decreased in intensity but, because of its low intensity, we are not able to observe the shifted band.



An experiment was also carried out using H_2S. We have reported before[2] the effects of $H_2 + H_2S$ addition on the IR spectra of MoO_3–SiO_2 samples. The same results are observed using H_2S alone: the intensity of the 990- and 920-cm^{-1} bands, and eventually of the 970-cm^{-1} band, decreases even at room temperature, and a broad band at 3550 cm^{-1} and a sharp band at 1615 cm^{-1} appear, showing the formation of water. By gravimetric measurements we found that the calcined Mo-2 sample, which contains 136 μmol g^{-1} of Mo as species **I**, chemisorbs irreversibly 280 μmol g^{-1} of H_2S at room temperature, i.e. $2H_2S$ per 1 Mo. Evacuation from 20 to 300°C removed the water formed, approximately 270 μmol g^{-1} in agreement with the equation

$$2H_2S + 2O(Mo) \rightarrow 2H_2O + 2S(Mo).$$

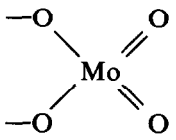


The ultimate weight increase corresponds to the replacement of 2O per Mo atom by 2S.

DISCUSSION

Raman studies have shown that the vibrational spectra of the Mo or W surface species in MoO_3– or WO_3–Al_2O_3 catalysts are influenced by the water content of the samples.[7,8] In particular, Stencel *et al.*[7] have reported that the Mo=O band at 1000 cm^{-1} was progressively shifted to 950 cm^{-1} by water exposure; repeated H_2O exposure and O_2 calcination cycles showed that this shift was reversible. It has been explained by the following equilibria:

or



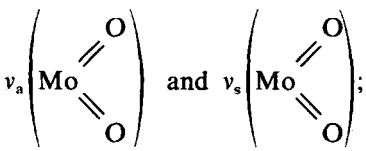
The present study shows that the IR bands characteristic of species **I** and **II** disappear with water addition. By isotopic $^{16}O \rightarrow {}^{18}O$ exchange, the shift, $\Delta\nu$, is 50 cm^{-1} for the 990-cm^{-1} band, and only 20 cm^{-1} for the 920-cm^{-1} band (species **I**).

At first approximation a band characteristic of an Mo—O simple oscillator is expected to lead to an isotopic ratio of:

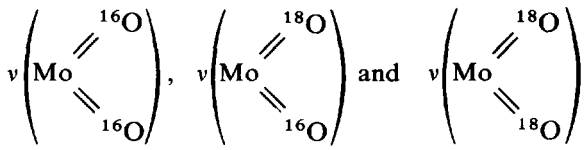
$$\frac{\nu(\text{Mo}-{}^{16}\text{O})}{\nu(\text{Mo}-{}^{18}\text{O})} = \left(\frac{\frac{1}{96}+\frac{1}{18}}{\frac{1}{96}+\frac{1}{16}}\right)^{1/2} = 0.951.$$

The observed isotopic shift on the high-frequency band of species **I** (50 cm^{-1}) is almost exactly equal to the theoretical shift (49 cm^{-1}). Therefore, the 990-cm^{-1} band is assigned to a terminal Mo=O bond.

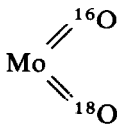
In a



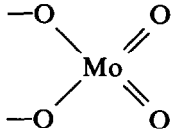
species with C_{2v}-symmetry the two Mo=O vibrations should be coupled



(unless the M=O angle is 90°),



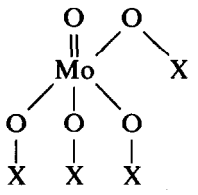
giving antisymmetric (a) and symmetric (s) modes



each mode would be affected by the $^{16}O \rightarrow {}^{18}O$ exchange, and would lead to three bands, i.e.

When the isotopic exchange is incomplete, the

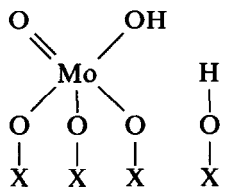
band is expected to be predominant. In the present study, we were unable to detect any intermediate band between 990 and 945 and 920 and 900 cm^{-1}, respectively. So we discard a species of the



type.

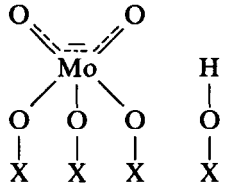
Our results are more in favour of a species with a single Mo=O bond.

The frequency shift of the low-wavenumber band (920 cm^{-1}) of species **I** is smaller ($\Delta\nu$ = 20 cm^{-1}). Therefore this band does not correspond to a terminal Mo=O bond. In the previous paper,[2] we assigned it to the vibration of a Si—O—Mo group in agreement with Ref. 9. It has a particular character as we find that the oxygen is exchangeable by $H_2{}^{18}O$ at room temperature.



We deduce that the 2O per Mo that are exchangeable by S through H_2S adsorption at room temperature are the oxygen of the terminal Mo=O bond and the oxygen in the particular X—O—Mo bridge.

Our results agree with the conclusions of a Raman study of Kasztelan on MoO_3–Al_2O_3.[10] Structure **A**



A

(X = Al or Mo) was proposed for calcined MoO_3–Al_2O_3; the particular Mo—O—X bridge is sensitive to H_2O addition. This species would be formed by dehydration of **B**:

B

H^+

C

Addition of H_2O to **A** (with X = Si or Mo in our case) leads to species **B** in equilibrium with **C**. The reversibility of the process explains why after dehydration the O atoms of the Mo=O bond and the X—O—Mo bridge are exchanged. These two particular O atoms are certainly those replaced by S atoms in the H_2S reaction. Experiments are in

progress to determine the nature and structure of the sulfided species formed.

STABILITY AND CATALYTIC PROPERTIES OF Mo-CONTAINING Y-TYPE ZEOLITE CATALYSTS CALCINED BY AN ISOBARIC THERMAL DECOMPOSITION PROCEDURE

ANTONIO LÓPEZ AGUDO,* RUBY CID,† FRESIA ORELLANA† and JOSÉ LUIS G. FIERRO

Instituto de Catálisis y Petroleoquímica, C.S.I.C., Madrid, Spain; and † Facultad de Ciencias, Universidad de Concepción, Concepción, Chile

(*Received* 15 *June* 1985)

Abstract—A study has been made of the effect of calcination temperature, under isobaric thermal conditions, on the structural stability and catalytic activity for thiophene conversion of Mo-impregnated NaY and NH_4NaY zeolite catalysts. The IR spectra, X-ray diffraction, BET surface area and sorption capacity results indicated that catalyst crystallinity was largely preserved after treatment at 110°C, and decreased substantially after calcination at over 350°C. All Mo-containing zeolite catalysts remained stable in air.

Interest in the preparation of stable Mo-containing zeolite catalysts has increased in recent years.[1–6] However, there is not general agreement about the stability of the zeolite, even using the same forms of zeolites and similar methods to incorporate Mo,[4,5] as well as the effect of the activation conditions on its stability.

The present work was undertaken to study the effect of calcination temperature under isobaric conditions on the stability of the Na- and NH_4-forms of zeolite Y impregnated with ammonium heptamolybdate (AHM). Several physico-chemical techniques, viz. IR spectroscopy, X-ray diffraction (XRD), BET surface area (S_{BET}) and sorption capacity, including catalytic-activity measurements, have been used to characterize these catalysts.

EXPERIMENTAL

The NaY parent zeolite was LZ-Y52 from Union Carbide. The 0.68-NH_4NaY zeolite (denoted as HNaY) was prepared by repeated ion exchange of the NaY with 0.5 M ammonium acetate solution at 20°C for 4 h. Both NaY and HNaY zeolites were impregnated with aqueous solutions of AHM of the appropriate concentration to obtain a nominal loading of 10 wt % MoO_3. The slurry was stirred for about 2 h and then the excess of water was evaporated under vacuum in a rotary evaporator. The resulting precursor was calcined gradually from room temperature to 520°C at a constant decomposition rate using an isobaric (8×10^{-2} torr) thermal procedure (ITD). Portions of the sample were withdrawn at 110, 350, 440 and 520°C; they are denoted as Mo–NaY(x) or Mo–HNaY(x), where x is the calcination temperature. Additionally, two samples, Mo–NaY(520)F and Mo–HNaY(520)F, were prepared by fast calcination at 520°C in air, in a current furnace, of aliquots of the hydrate Mo-impregnated NaY and HNaY zeolites, respectively. IR spectra were recorded in a Perkin–Elmer 580 B spectrophotometer by the KBr technique (1/100). Sorption capacities of catalysts thoroughly outgassed at 350°C were measured using a Setaram microbalance. XRD patterns were obtained on a Philips PW-1010 diffractometer using Cu-K_α radiation. S_{BET}s were measured at −195°C with N_2. Catalytic activity for thiophene conversion was measured at 340°C and atmospheric pressure in a flow microreactor, using 0.3 g catalyst and 30 cm^3 min^{-1} of H_2 saturated with 10 mol % thiophene–methylcyclohexane mixture at 0°C. Catalysts were pre-sulfided "*in situ*" at 320°C in 10% H_2S–H_2 mixture at 18 cm^3 min^{-1} for 5 h. Reaction products were analyzed by gas chromatography.

* Author to whom correspondence should be addressed.

RESULTS

Figure 1 shows that the intensities of the framework vibration bands of the Mo-impregnated zeolites calcined at 110 and 350°C decreased only slightly in comparison with those of the NaY and HNaY zeolites. Calcination at higher temperature resulted in a gradual decrease in band intensity and some band broadening, which was relatively more pronounced for the Mo–HNaY series. Comparison between catalysts calcined at 520°C in air (spectra f and f') and by using the ITD procedure (spectra e and e') showed that the former exhibited less intense bands than the latter. A shoulder (or small band) gradually appeared in the region 900–920 cm^{-1} with increasing calcination temperature, which was clearly present in the catalysts calcined at 520°C, as observed previously.[2,4–6]

The position of the bands in general did not change with calcination, except for the catalysts Mo–NaY(520) and Mo–HNaY(520) (spectra e and e', respectively) in which various bands (~1000, 800 and 585 cm^{-1}) were slightly shifted to higher frequencies. These shifts, accompanied by a marked decrease in band intensities, are indicative of a loss of crystallinity rather than dealumination.

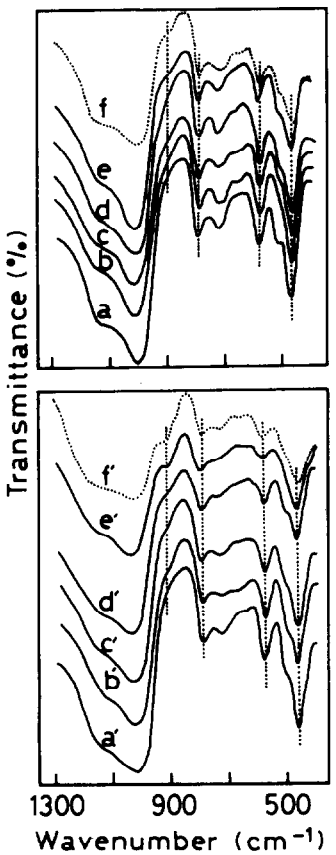

Fig. 1. IR spectra in the mid-frequency region of: (a) NaY, (b) Mo–NaY(110), (c) Mo–NaY(350), (d) Mo–NaY(440), and (e) Mo–NaY(520)F. Primes denote the same treatments on the Mo–HNaY series.

The relative adsorption capacities (from isotherms not shown here) of both adsorbates for the Mo-impregnated zeolites when compared with those for the NaY and HNaY decreased gradually with increasing calcination temperature (Fig. 2). The relative change was significantly larger in the Mo–HNaY than in the Mo–NaY series.

The XRD patterns (not shown here) of all the Mo-impregnated zeolite catalysts were similar to that for the NaY parent zeolite, except for the peak intensities, which decreased slightly after impregnation with AHM and more markedly with increasing calcination temperature. Relative crystallinities compared to the NaY or NaHY zeolites decreased (Fig. 2) generally with increasing calcination temperature. It is interesting to note that the relative crystallinities for the samples calcined in air by a conventional procedure (series F) were much lower than the corresponding catalysts calcined by the ITD procedure.

In Fig. 2 it can be seen that the relative change in S_{BET} of all Mo-impregnated zeolite catalysts (identically outgassed) with respect to the parent NaY or HNaY zeolites decreased also with calcination temperature, in parallel with crystallinity as determined by XRD.

The variations with reaction time of the thiophene conversion at 340°C on catalysts calcined at 350, 440 and 520°C are shown in Fig. 3. A rapid catalyst decay, more marked for the Mo–HNaY series, was initially observed. The reaction products on all the catalysts consisted mainly of butenes and traces of *n*-butane; propylene was also produced in appreciable amounts (~7% conversion of thiophene) on the Mo–HNaY series, and generally as traces on the Mo–NaY series. Complementary activity measurements on NaY and HNaY revealed that the former initially was slightly active to convert thiophene, while the latter initially showed an overall activity comparable to that of the Mo–HNaY catalysts, but on both NaY and HNaY catalysts activity decreased dramatically throughout the experiment, in such a way that after 100 min the catalysts were nearly inactive.

DISCUSSION

When NaY and HNaY were impregnated with AHM and then calcined by the ITD procedure at 110°C their crystallinity was largely maintained (> 90%) according to the IR spectra, and slightly decreased (80–90%) according to the XRD or the S_{BET} results. The lower values of crystallinity for

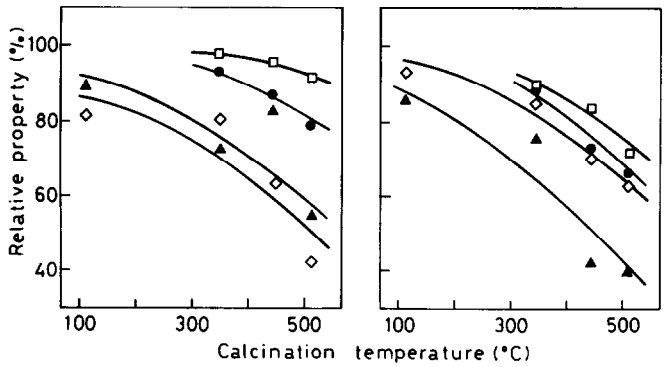

Fig. 2. Relative variation of XRD crystallinity (▲), S_{BET} (◇) and H_2O (□) and *n*-hexane (●) sorption capacity as a function of calcination temperature of Mo-impregnated zeolites. Values for NaY and HNaY taken as references (100%).

XRD and S_{BET} were probably due to the dilution effect caused by the incorporation of molybdate and some blocking of the zeolite cavities by molybdate, respectively. By calcining at 350°C an additional slight loss in both crystallinity (XRD) and S_{BET} occurred. However, the sorption capacities of such calcined catalysts and their structure-sensitive band intensities varied insignificantly, particularly for the Mo–NaY(350) catalyst. It is then interpreted that at 350°C the samples still retain a high degree of crystallinity, but the zeolite lattice may present some partial breakdown and/or distortion caused by some interaction of the molybdate anions with the oxygen of the zeolite lattice. This interaction may occur when dehydration takes place. A further increase in the calcination temperature up to 440 and 520°C led to substantial loss of crystallinity and sorption capacity of both zeolites (more pronounced in the HNaY series) which is related to complete dehydration and partial dehydroxylation of the zeolites, and the following bonding of Mo to the zeolite framework. This was supported by the appearance of a band at about 900 cm^{-1} clearly present in the Mo–HNaY(520) catalyst, which is usually attributed to an Mo—O or Mo=O vibration.[1,2,4–6] It seens that the presence of hydroxyl groups, as in the HNaY zeolite, favoured the bonding of molybdate anions to the zeolite framework and then caused the loss of crystallinity.

The decrease in activity (steady-state values) of the Mo–NaY catalysts series with increasing calcination temperature (Fig. 3) is in agreement with the loss of crystallinity and surface area of the zeolite, as a result probably of the decreasing dispersion of the accessible Mo-active phase on the zeolite support. Since Mo migration from the external surface of the zeolite to inside the cavities has been observed by XPS analysis,[7] the possibility that differences in accesibility of Mo to the reactant could also contribute to the decrease in activity must not be excluded. In the case of the Mo–HNaY catalysts, we cannot separate rigorously the contribution of the Mo-active phase from that of the HNaY zeolite support, which showed increasing thiophene conversion with increasing preactivation temperature of the HNaY zeolite.

Finally, on comparing the catalyst calcined under the ITD procedure and in air at 520°C, it is evident, as shown by IR and XRD, that the former maintained a higher level of crystallinity than the latter. Thus, the ITD is a useful method to prepare stable calcined Mo-containing zeolites with crystallinity > 50%.

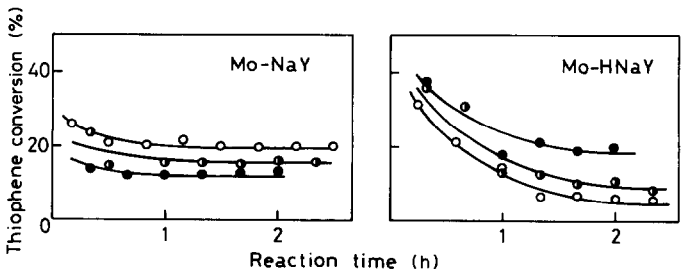

Fig. 3. Thiophene conversion at 340°C vs reaction time on Mo-impregnated zeolites calcined at: (○) 350, (◑) 440, and (●) 520°C.

(*Received* 15 *June* 1985)

Abstract—ESR studies on ZrO_2-supported Mo oxide catalysts indicate the presence of two types of paramagnetic Mo^{5+} species on the support surface. The oxygen uptake capacities (at −78°C), as well as the hydrodesulfurization and hydrogenation activities of the catalysts are found to correlate with the Mo loadings on the support. The results are explained with the help of a "patch" model of the Mo oxide phase.

Supported Mo-containing catalysts are used in many important reactions including hydroprocessing, coal liquefaction, hydrogenation (HYD), polymerization and metathesis of olefins. Numerous studies have been devoted towards understanding of the surface structure of the supported Mo oxide phase and its consequence upon the resulting activity and selectivity for certain reactions.[1,2] Pursuant to our earlier ESR[3] and oxygen chemisorption[4] studies on V_2O_5–Al_2O_3 catalysts an investigation has been made with the Mo–ZrO_2 system by these techniques in order to gain some information on the surface structure of the Mo oxide phase and its relevance to probe reactions like hydrodesulfurization (HDS) of thiophene and HYD of cyclohexene.

EXPERIMENTAL

Catalyst preparation

The ZrO_2 support was prepared by precipitating Zr hydroxide from $ZrOCl_2 \cdot 8H_2O$ by dilute ammonia solution. The precipitate was freed from chloride ions, dried at 120°C for 24 h and finally calcined at 540°C for 4 h in air. The supported Mo oxide catalysts were prepared by an incipient wetting technique: a calculated amount of ammonium heptamolybdate (spectroscopic grade, Baker) corresponding to the desired Mo loading on the support was dissolved in that volume of water which corresponded exactly to the total pore volume of the quantity of support used for impregnation. The support was then uniformly wetted by the solution, stirred well for 30 min and allowed to stand for 1 h. The impregnated sample thus obtained was dried at 120°C for 16 h and then calcined in air for 12 h at 540°C.

Chemisorption measurements

A conventional static high-vacuum (up to 10^{-6} torr) system, with the facility for reducing the catalysts *in situ* by flowing hydrogen, was used for oxygen chemisorption, which was performed at −78°C, following the procedure of Parekh and Weller.[5] The same system was used to measure the BET surface areas of the catalysts by N_2 (0.162 nm^2) adsorption at −196°C. The details of the experimental set-up and chemisorption procedure have been given elsewhere.[4]

* Authors to whom correspondence should be addressed.

Activity measurements

Thiophene HDS and cyclohexene HYD were chosen as the model reactions for testing the activities of the catalysts which were sulfided at 400°C for 2 h in a flow of a purified hydrogen and CS_2 mixture before the reactions. For this purpose, a fixed-bed differential flow microreactor operating under normal atmospheric pressure and interfaced with a gas chromatograph by a six-way sampling valve for product analysis was used. The conversions were kept within 10%. The experimental procedure and method of activity calculation have been described elsewhere.[6]

ESR and XRD measurements

The ESR spectra of the catalysts were recorded *in vacuo* (10^{-6} torr) and at 25°C on a JEOL FE 3X X-band spectrometer with 100-KHz modulation. The details of sample preparation and the experimental procedure have been elaborated in a previous paper.[3] The X-ray diffractograms were recorded on a Philips PW 1051 diffractometer by using Ni-filtered Cu-K_α radiation.

RESULTS AND DISCUSSION

Representative ESR spectra of the unreduced [(a) and (b)] and the reduced [(c)] catalysts are shown in Fig. 1. A comparison of these spectra with those of Mo–SiO_2 catalysts[7,8] shows that for the 1% Mo–ZrO_2 catalyst the ESR spectrum due to Mo^{5+} represents a "solution-like" behaviour due to incomplete removal of water ($g_{iso} = 1.975$). For the catalysts with Mo contents higher than 1%, an axially symmetric spectrum appears at the centre of the pattern [Fig. 1(b)] with $g_{\|} = 1.910$ and $g_{\perp} = 1.932$ ($g_{\|} < g_{\perp}$). The intensity of the anisotropic spectrum increased with increasing Mo loading. Upon reduction, the "solution-like" behaviour almost disappears, while an anisotropic spectrum appeared with maximum intensity for the sample

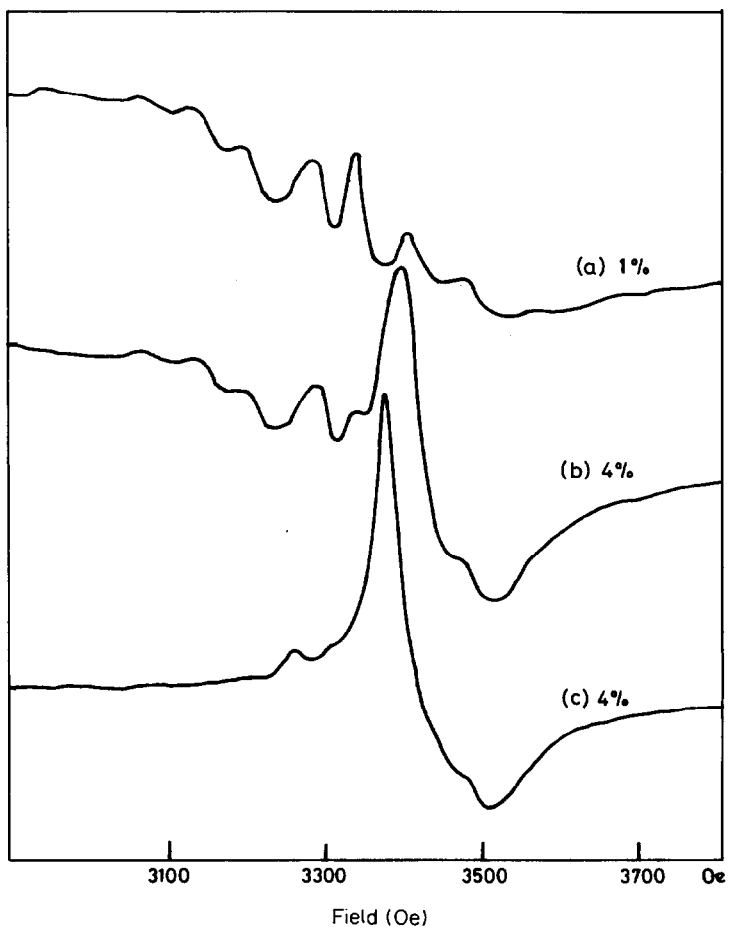

Fig. 1. ESR spectra of unreduced [(a) and (b)] and reduced [(c)] Mo–ZrO_2 catalysts recorded at 27°C and 10^{-6} torr.

with 1% Mo loading (not shown in Fig. 1). The intensity of this spectrum, unlike in the case of the unreduced catalysts, decreased rapidly with increasing Mo loading and became asymptotic just above 4% Mo loading.

The oxygen uptake capacities, HDS and HYD activities of the reduced catalysts are given as a function of Mo loading on ZrO_2 in Fig. 2. The oxygen chemisorption (at −78°C) behaviour of the Mo–ZrO_2 catalysts shows a similarity with that of the well-studied Mo–Al_2O_3 catalysts.[9] As observed from Fig. 2, the oxygen uptake increases as a function of Mo loading up to about 3.5% and then levels off. This saturation level indicates the completion of a monolayer coverage of the "active" ZrO_2 surface by Mo oxide. The monolayer corresponds to about 10 μmol Mo m^{-2} of the support surface. This value is about twice as high as the corresponding value for Mo–Al_2O_3 catalysts. The maximum oxygen uptake by the Mo–ZrO_2 catalysts is found to be about 3 μmol m^{-2} compared to about 0.3 μmol m^{-2} for Mo–Al_2O_3 catalysts. These results therefore, indicate that the Mo oxide is dispersed better on ZrO_2 than on Al_2O_3. This conclusion is made from the higher surface coverage and higher oxygen uptake capacity at the monolayer level of the Mo–ZrO_2 catalysts.

The HDS and HYD activities of the catalysts [curves (b) and (c) of Fig. 2] show a sharp rise as a function of Mo loading upto the monolayer level. Beyond this level, the activities show a very slow rise as a function of Mo loading. A closer look at Fig. 2 also reveals a good correlation of both HDS and HYD activities with the oxygen uptake capacities of the catalysts. These results indicate, therefore, that: (1) the HDS and HYD active sites, i.e. the coordinatively unsaturated sites (CUS), are titrable by oxygen chemisorbed at low temperatures; and (2) beyond the monolayer coverage, further addition of the active component, i.e. Mo oxide, does not contribute to the generation of active CUS upon which oxygen chemisorption, HDS and HYD reactions can take place.

Based on the "patch" model of Hall,[2] the nature of the oxygen chemisorption sites on Mo–Al_2O_3 catalysts has recently been discussed by Nag.[9] It has been envisaged that at lower Mo loadings small patches of Mo oxide, two layers thick and with Mo in an octahedral coordination, are formed on the support surface. Upon reduction, CUS are generated by the removal of oxygen from the edge and corner sites of the patches. These are the sites upon which oxygen chemisorption, HDS and HYD reactions

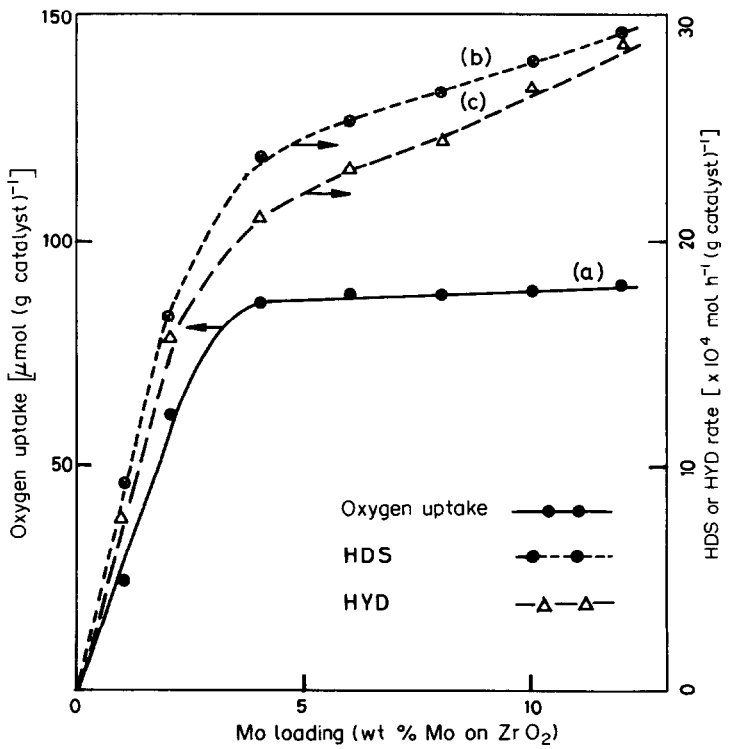

Fig. 2. Oxygen uptake at −78°C (a), hydrodesulfurization (HDS) of thiophene at 420°C (b) and hydrogenation (HYD) of cyclohexene at 400°C (c). Activities as a function of Mo loading. All the data are corrected for the contributions by the support.

take place. It has also been proposed that as the Mo loading increases the number of these patches increases with attendant increase in the number of CUS up to the monolayer level. Beyond the monolayer level the patches grow three-dimensionally, thus decreasing the dispersion of Mo oxide. It is proposed that a similar mechanism operates in the Mo–ZrO_2 system, and the present results can be explained with the help of the above concepts. Thus the initial increase and subsequent levelling off in the oxygen uptake capacity of the catalysts as a function of Mo loading are due to generation of new CUS up to the monolayer level and a subsequent decrease in the edge and corner CUS beyond the monolayer level due to crystal growth. Since the HYD and HDS activities are correlated with the CUS, their initial increase and subsequent levelling off tendencies can be understood by the same mechanism. It is worth mentioning here that, indeed, XRD lines of reduced Mo oxide were detectable only with samples containing Mo oxide at greater than the monolayer level.

Several conclusions can be derived from this present work: (1) as in the case of the Mo–Al_2O_3 system, the CUS of highly dispersed Mo oxide on ZrO_2 responsible for HDS and HYD reactions can be titrated by low-temperature oxygen chemisorption; (2) low-temperature oxygen chemisorption data can precisely determine the Mo level where the formation of a monolayer reaches completion; and (3) Mo oxide is dispersed better on the ZrO_2 support than on the Al_2O_3 support.

EFFECT OF THE ACTIVATION CONDITIONS ON THE STRUCTURE AND CATALYTIC ACTIVITY OF A Co–Mo–γ-Al_2O_3 HYDRODESULFURIZATION CATALYST

Groupe de Physico-Chimie Minérale et de Catalyse, Université Catholique de Louvain, Place Croix du Sud, 1, B-1348 Louvain-la-Neuve, Belgium

(*Received* 13 *June* 1985)

Abstract—A Co–Mo–γ-Al_2O_3 hydrodesulfurization catalyst was activated under an H_2S–H_2 mixture at temperatures ranging from 673 to 1073 K using two different procedures. The samples were characterized by ion-scattering spectrometry (ISS), dynamic O_2 chemisorption (DOC) and dynamic NO chemisorption (DNOC). Comparison of ISS and DOC indicates that the decrease in activity with increasing activation temperature could be due to the sintering of MoS_2 but also to an incomplete sulfuration of molybdenum due to the formation of difficultly sulfidable MoO_2. Comparison of DOC and DNOC suggests that the amount of sulfided cobalt increases with increasing activation temperature up to 923 K. This phenomenon was confirmed by diffuse-reflectance spectroscopy, which revealed a drastic decrease in tetrahedral Co^{2+} species (cobalt pseudo aluminate) with increasing activation temperature.

This poster reports some new results of a research program aimed at a systematic investigation of the influence of the conditions of pretreatment and activation on the structure and catalytic activity of a Co–Mo–γ-Al_2O_3 hydrodesulfurization (HDS) catalyst.

We have previously studied how activity and selectivity are affected by the nature of the sulfiding molecules.[1] We have also reported preliminary results about the dependence of the activity on the activation temperature under an H_2S–H_2 mixture.[2] Optimum HDS activity was observed after activation in the range 673–803 K. Characterization of the activated samples by high-resolution electron microscopy (HREM), X-ray photoelectron spectroscopy (XPS), ion-scattering spectroscopy (ISS) and dynamic O_2 chemisorption (DOC) indicated that optimum activity corresponded to an optimum dispersion of MoS_2-like crystallites. The activity decrease at high sulfidation temperature accompanies a sintering of these crystallites.

The results presented in this poster complement this latter investigation in three directions: (i) it is shown that the activity of the samples sulfided at high temperature may be improved by some modification of the activation procedure, (ii) comparison of O_2 and NO chemisorption highlights the higher sensitivity of the latter molecules toward the active sites and suggests an increasing sulfidation of cobalt with increasing activation temperature, and (iii) characterization by diffuse reflectance spectroscopy and XPS of catalysts reoxidized in air at 673 K after activation gives evidence that part of the cobalt initially entrapped in the alumina lattice as cobalt aluminate migrates back toward the surface during activation at high temperature.

The Co–Mo–γ-Al_2O_3 catalyst used in this study is the commercial precursor (namely before reduction sulfidation) HR 306 from Procatalyse (3% CoO, 14% MoO_3, 195 $m^2\ g^{-1}$). In the previous study,[2] the activation procedure consisted in heating 2 g of this precursor in Ar up to the sulfidation temperature (673, 803, 923 or 1073 K) and then sulfiding them at this temperature for 4 h in a flow of an H_2S–H_2 (15% H_2S) mixture at atmospheric pressure. In the present work, an alternative activation procedure was used for sulfidation temperatures higher than 673 K: the sample was heated in Ar up to 673 K, it was then exposed to the H_2S–H_2 mixture, heating was continued at the same rate up to the final sulfidation temperature (803, 923 or 1073 K), and the activation was completed for 4 h at this temperature with the

Table 1. Variation in the MoO_3 content and the BET surface area (S_{BET}) as a function of sulfidation temperature

Pretreatment temperature (K)	% MoO_3	S_{BET} ($m^2\ g^{-1}$)
673	13.5	198
803	—	195
923	13.3	170
1073	13.1	130

same H_2S–H_2 mixture. These activation procedures will be called, in the following, the first and the second procedure, respectively.

Table 1 presents the molybdenum content (measured as equivalent MoO_3 by atomic absorption spectrometry) and the BET surface area (S_{BET}) of the catalysts activated following the second procedure. These results do not differ significantly for the two procedures. The molybdenum content did not change during the heating but sintering of alumina occurred during activation at 923 and 1073 K.

After introduction in the high-pressure catalytic reactor, the samples were resulfided for 2 h at 673 K in 4% H_2S in H_2 at 2 MPa. Their activities for the HDS of thiophene and hydrogenation (HYD) of cyclohexene were measured at 510 K under a total pressure of 3 MPa using the same conditions as described previously,[2] in the test reaction using, as a feed, a mixture of 0.5% thiophene, 30% cyclohexene and 69.5% cyclohexane.

Figure 1 shows the variations in HDS and HYD conversion as a function of the activation temperature for both pretreatments: heating under Ar (full circles) and under an H_2S–H_2 mixture (open circles). It is shown that the second activation procedure gives a higher activity after activation at high temperature. The optimum temperature range extends in this case from 673 up to 923 K.

The experimental conditions for ISS measurements have been described previously.[2] All samples have been protected from oxidation by keeping them under a meniscus of iso-octane which evaporated during pumping of the spectrometer chamber. The ISS peak intensity ratio $(I_{Mo}/I_{Al})_{ISS}$ is, to a first approximation, proportional to the ratio of the surface area of the phases containing molybdenum and aluminium. As the S_{BET} is essentially equal to the surface area of alumina alone, the product $(I_{Mo}/I_{Al})_{ISS} \cdot S_{BET}$ should be approximately proportional to the dispersion of the molybdenum species.

Figure 2(a) presents the variation of this expression for catalysts pretreated following the

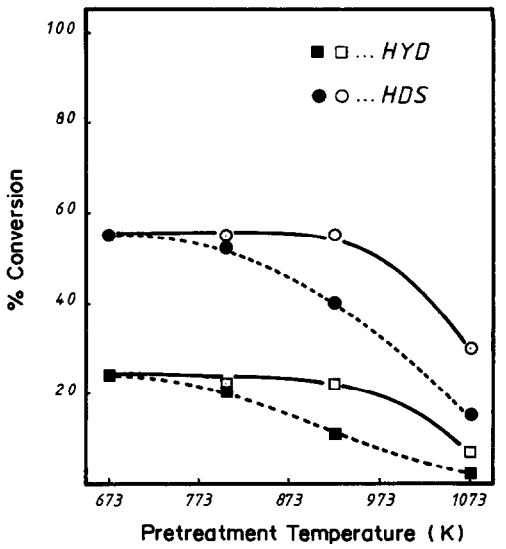

Fig. 1. Variation in HDS and HYD conversions as a function of activation conditions. (■) and (●) heating in Ar ("first procedure"), and (□) and (○) heating under a H_2S–H_2 mixture ("second procedure").

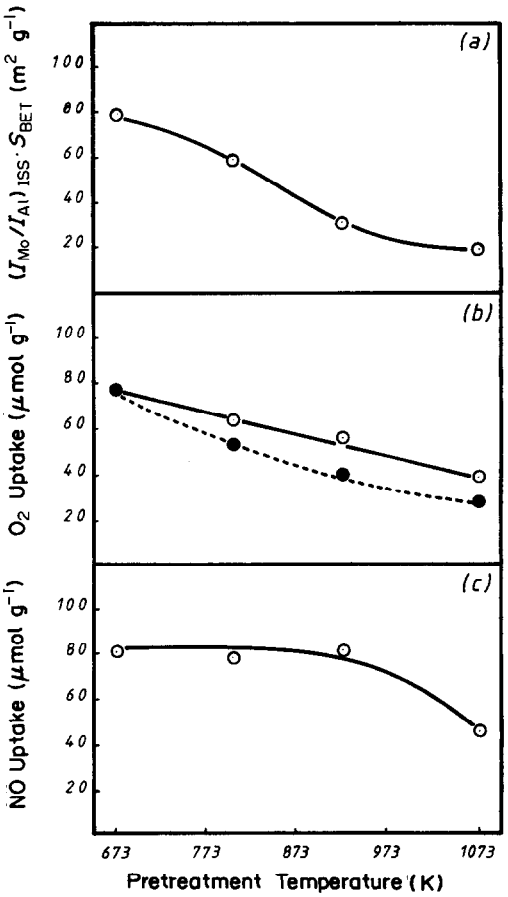

Fig. 2. Variation as a function of activation conditions of: (a) $(I_{Mo}/I_{Al})_{ISS} \cdot S_{BET}$, (b) oxygen uptake, and (c) NO uptake. (●) Heating in Ar ("first procedure"), and (○) heating under a H_2S–H_2 mixture ("second procedure").

second procedure as a function of the sulfiding temperature. The values do not differ significantly for the two procedures. A decrease in molybdenum dispersion is observed with increasing sulfiding temperature.

DOC and dynamic NO chemisorption (DNOC) at room temperature were measured using a pulse technique.[3] The samples activated by both procedures were resulfided in a U-pyrex tube reactor in a flow of H_2S–H_2 (15% H_2S) at 673 K, atmospheric pressure, for 2 h and flushed in Ar for 0.5 h at this temperature. The catalysts were then maintained in a flow of He at 293 K and 2-ml pulses of 5% O_2 or NO in He were injected until equilibrium was reached. Results are expressed as μmols of gas adsorbed per gram of catalyst.

Figure 2(b) shows the O_2 chemisorption results for catalysts activated following both procedures: heating in Ar (full circles) and heating in an H_2S–H_2 mixture (open circles). In both procedures, the O_2 uptake decreases continuously with increasing sulfidation temperature. However, the O_2 uptake decreases more for catalysts pretreated following the first procedure.

Figure 2(c) shows the NO chemisorption results for the samples sulfided using the second procedure. It shows that the NO uptake remains constant for the catalysts sulfided up to 923 K and decreases strongly for the sample activated at 1073 K. This variation is conspicuously similar to the variation of the catalytic activity (Fig. 1). For samples sulfided using the first procedure, NO uptake measurements have not been made.

From an investigation involving HREM, DOC and ISS, it was previously concluded that the loss of activity observed when increasing the activation temperature (using the first procedure) should be mainly ascribed to the sintering of the active phase. It is thus tempting to explain the dependence of activity on the activation procedure (Fig. 1) by involving a different degree of sintering. Indeed, one might speculate that sintering is greater when the catalyst is suddenly exposed to the H_2S–H_2 mixture after having been heated under Ar than when it is exposed to the H_2S–H_2 mixture from 673 K. This explanation is only partly supported by experiment: the lower O_2 uptake after the first procedure suggests a lower dispersion of the active phase [Fig. 1(b)]; however, ISS was unable to detect a significant difference in the dispersion of molybdenum after the two procedures. This disagreement points toward more subtle differences between the samples. An explanation based on the present knowledge on the chemistry of reduction–sulfidation of Mo–Co catalysts[4,5] is the following; when exposing the sample suddenly to the H_2S–H_2 mixture at high temperature (first procedure), the rate of reduction (by H_2) could be too high in comparison with the rate of sulfidation, so that MoO_2 could be formed. As MoO_2 cannot be easily sulfided, incomplete sulfurization of molybdenum would result.[4] Such a phenomenon might explain the differences between the ISS and the DOC results.

In Fig. 2, the different variations in ISS, DOC and DNOC results as a function of activation temperature indicate strikingly that each technique is sensitive to a different type of "surface species". Only DNOC appears to be sensitive to the type of species which is responsible for the HDS activity. It has been reported in the literature that NO adsorbs on both cobalt and molybdenum in the sulfided state, whereas the O_2 uptake is not modified when the ratio Co/Mo or Ni/Mo in the catalyst is below 0.5.[6–8] The fact that the NO uptake remains constant up to 923 K, whereas O_2 uptake decreases monotonously with increasing temperature may thus suggest that, up to 923 K, the decrease in the dispersion of MoS_2 is compensated for by an increase in the amount of sulfided cobalt. The strong decrease in the NO uptake at 1073 K would be due to the sintering of both cobalt sulfide and molybdenum sulfide.

The increase in the amount of sulfided cobalt suggested by DNOC could simply originate from the increasing sulfidation of cobalt entrapped in the alumina lattice in the form of cobalt aluminate. In order to check this hypothesis, the catalysts activated by the second procedure were reoxidized by calcination in a flow of air at 673 K for 15 h. The mere

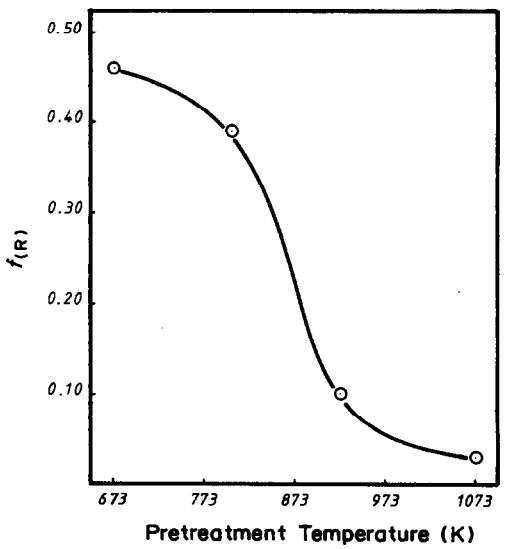

Fig. 3. Dependence of the Kubelka–Munk function [$f_{(R)}$] for the cobalt species as a function of sulfidation temperature.

change of colour (blue to green) with increasing sulfidation temperature suggested a diminution in the amount of cobalt aluminate after activation at higher temperatures. The samples were analyzed by diffuse-reflectance spectroscopy (DRS). Figure 3 shows the dependence of the Kubelka–Munk function for the cobalt species in tetrahedral coordination [$Co^{2+}_{(tet)}$] as a function of sulfidation temperature. The strong decrease in these $Co^{2+}_{(tet)}$ species indicates the migration of an increasing amount of these species toward the surface where they can become sulfided. Hence, this observation supports the conclusion drawn from the DNOC results. A more in-depth investigation of this phenomenon by Mössbauer emission spectroscopy, DRS, XPS and IR spectroscopy will be published elsewhere.[9]

X-RAY ABSORPTION SPECTROSCOPY STUDIES OF CALCINED $Mo-Al_2O_3$ AND $Co-Mo-Al_2O_3$ HYDRODESULFURIZATION CATALYSTS

BJERNE S. CLAUSEN,*† BRUNO LENGELER‡ and HENRIK TOPSØE*

(*Received* 1 *July* 1985)

Abstract—X-ray absorption spectroscopy has been used to obtain information on the Co and Mo structures present in calcined $Co-Mo-Al_2O_3$ and $Mo-Al_2O_3$ catalysts. The results indicate that the elements are present in disordered structures. From a detailed analysis of the X-ray absorption fine structure (EXAFS), information on the oxygen coordination around Co and Mo is obtained. An apparent decrease in the oxygen coordination number around Mo with increasing Mo loading is explained by a change in the Debye–Waller factor, presumably due to a decrease in the support interactions. The presence of Co in the catalysts is found to have very little effect on the local structure around the Mo atoms. The Co EXAFS results indicate that Co is predominantly octahedrally coordinated.

X-ray absorption spectroscopy, and, in particular, extended X-ray absorption fine structure (EXAFS), has become an important and widely used probe of short-range order in many different catalyst systems (see, for example, Refs 1 and 2). Previous EXAFS studies combined with studies using a variety of other techniques have given detailed insight into the structure and catalytic properties of the sulfided state of Co–Mo hydrodesulfurization (HDS) catalysts (see, for example, Ref. 3). As a result the structure of the sulfided catalysts is now quite well understood. However, the structure of the Co and Mo phases in the calcined precursor state is still open to discussion in the literature. There is some evidence that the Mo atoms are present in both tetrahedrally and octahedrally coordinated environments[4–6] with the latter species being favored at high Mo loadings. Although EXAFS should be an ideal tool for such studies, the previous EXAFS results have been interpreted in quite different ways.[7–10]

Regarding the state of Co in the calcined catalyst, it has been generally accepted that Co may be present in tetrahedral coordination in the alumina lattice. Recent studies show, however, that octahedrally coordinated Co may also be present.[11–13] Furthermore, this Co species was found to be precursor for the active Co–Mo–S phase.[11,14]

† Author to whom correspondence should be addressed.

In order to obtain more information on the local structure (e.g. bond lengths and coordination numbers) around the Co and Mo atoms we have studied the EXAFS of both the Co and Mo absorption *K*-edges.

EXPERIMENTAL

The preparation of the HDS catalysts has been reported previously.[15] Calcination of the catalysts was carried out at 775 K for 2 h. The various model compounds

$$[MoO_3,\ MoO_2,\ Al_2(MoO_4)_3,$$
$$CoMoO_4,\ K_2MoO_4,\ Na_2MoO_4 \cdot 2H_2O,$$
$$Ba_2CaMoO_6,\ Co_3O_4,\ CoO \text{ and } CoAl_2O_4]$$

were either obtained commercially or synthesized in the laboratory. The phase purity of all the samples was checked by X-ray diffraction.

The X-ray absorption spectra were recorded by placing appropriate mixtures of the catalysts and boron nitride in thin aluminum frames equipped with Kapton windows. The absorber thickness, x, of all the samples was chosen such that $\mu x \sim 1$ (μ is the linear absorption coefficient), on the high-energy side of the absorption edge, and great care was taken in

order to make samples of homogeneous thickness. The experiments were performed at DESY in Hamburg using the synchrotron radiation from the DORIS storage ring and the experimental RÖMO set-up. The X-rays were monochromatized by two single crystals [Si(111) for the Co *K*-edge and Si(311) for the Mo *K*-edge], and the incident and transmitted intensity were recorded by use of two ionization chambers [filled with N_2 (Co *K*-edge) or Ar (Mo *K*-edge)]. The calibration of the energy scale is essential for the determination of the small changes in the core level threshold occurring when the chemical state of the absorbing atom changes. Therefore, a third ionization chamber was placed after a thin foil of the absorbing atoms in the metallic state in order to have an "internal energy calibration". The EXAFS oscillations were analyzed according to the procedure described in detail in Refs 16 and 17. This procedure involves a background subtraction by means of cubic spline functions, multiplication of the EXAFS by a factor k^2, and normalization by the jump height at the *K*-edge. All the data reported in this paper were obtained at liquid-nitrogen temperature.

RESULTS AND DISCUSSION

The Fourier transform of the Mo EXAFS for both $Mo–Al_2O_3$ and $Co–Mo–Al_2O_3$ catalysts in the calcined (oxidic) state shows only a single strong backscatter peak due to oxygen atoms present in the nearest neighbor shell (Fig. 1). The apparent absence of more distinct peaks suggests that a well-defined Mo-containing compound is not present in any appreciable amounts. Rather the structures are amorphous, disordered, or consist of extremely small entities. From a fit of the contribution to the EXAFS due to the first shell (using the phase and

Table 1. Bond lengths, R, and coordination numbers, N, obtained by fitting the Fourier-filtered Mo EXAFS of calcined catalysts

Catalyst	R (Å)	N
4% $Mo–Al_2O_3$	1.76	3.3
8.6% $Mo–Al_2O_3$	1.73	2.8
11.5% $Mo–Al_2O_3$	1.73	2.4
1.4% Co–8.6% $Mo–Al_2O_3$	1.74	3.0

amplitude functions of K_2MoO_4), the Mo—O bond lengths and coordination numbers listed in Table 1 were estimated for the calcined catalysts. The presence of Co was not observed to influence these parameters significantly, whereas the Mo loading is seen to have a small effect on the coordination number, the apparent value of which seems to decrease slightly with increasing Mo loading (Table 1).

Recent results by Chiu *et al.*[9] show the same trend and they interpreted their results in terms of an increased distortion of MoO_6 octahedra with increasing Mo loading. It should be stressed that, for disordered systems, the true coordination number is not trivial to obtain. Contrary to well-ordered compounds, where this parameter may be determined to an accuracy of about 10%, the uncertainty may be much larger in distorted systems due to the presence of non-Gaussian thermal as well as static disorder. Furthermore, since the Debye–Waller factor and the coordination number enter as a product in the expression used to fit the EXAFS, a change in the apparent coordination number may also be due to a change in the Debye–Waller factor. The apparent decrease in the observed coordination number with increasing Mo loading may therefore originate from the presence of larger entities of Mo species which have less interaction (and thus a smaller Debye–Waller factor) with the alumina support. This interpretation is in accordance with the observations[4–6] that by increasing the Mo loading the coordination changes from tetrahedral to octahedral, since the tetrahedrally coordinated Mo is generally believed to be bonded to the alumina surface via two oxygen atoms, whereas the octahedrally coordinated Mo atoms are assumed to be predominantly bridged to each other. The latter type of Mo species will presumably have less support interaction than the former.

The shape of the absorption edge itself also gives information on the local structure around the Mo atoms, although an unambiguous distinction between tetrahedral and octahedral coordination is not possible. The edge spectra of all the calcined catalysts show a weak peak or "shoulder" on the low-energy side of the edge. This peak is assigned to a $1s \rightarrow 4d$ transition which is allowed for Mo in a tetrahedral field but is also observed in compounds with Mo in a distorted octahedron of oxygen atoms.[9,18] Thus we can rule out the presence of Mo in a strictly octahedral field in these catalysts. It has recently been proposed that the relative intensity of another transition ($1s \rightarrow 5p$) can be used as a measure of the degree of distortion.[9]

The Fourier transform of the Co EXAFS for the calcined $Co–Mo–Al_2O_3$ catalyst shows only one strong peak. The absence of well-defined peaks outside the first coordination shell of oxygen atoms suggests that cobalt in the present calcined catalysts is not located in well-ordered surroundings like, for example, those found in Co_3O_4, CoO, $CoAl_2O_4$ or $CoMoO_4$. Rather, the results suggest that the Co atoms are present in a disordered phase. These results are in agreement with Mössbauer emission spectroscopy results.[11] From an analysis of the present EXAFS data, a Co—O bond length of about 1.99 Å and a coordination number of about 6 are found. In Ref. 10 a bond length identical to the above was reported, but a coordination number of 4 was given. The coordination number found presently is consistent with recent Mössbauer emission, magnetic and IR results,[11–13] which show that in the present catalysts (which have been calcined at rather low temperatures), the majority of Co atoms are present in octahedral surroundings probably in the surface layers of the alumina. The observed bond length of 1.99 Å is also in accordance with an octahedral location in the alumina [radius of holes in alumina: $(Me—O)_{oct} \sim 1.98$ Å and $(Me—O)_{tet} \sim 1.71$ Å].

INORGANIC-CHEMISTRY APPROACH TO THE PREPARATION OF SULFIDED "MIXED-PHASE" HYDROTREATING CATALYSTS USING THIOMETALATES AS PRECURSORS

W. ELTZNER, M. BREYSSE,* M. LACROIX and M. VRINAT

Institut de Recherches sur la Catalyse, Laboratoire Propre du CNRS, Conventionné à l'Université Claude Bernard, Lyon I, 2 Avenue Albert Einstein, 69626 Villeurbanne Cedex, France

(*Received* 17 *June* 1985)

Abstract—The application of bisthiometalato complexes of the type $[M'(MS_4)_2]^{n-}$ ($n = 2$ or 3, M' = Co or Ni, and M = Mo or W) as precursors for the preparation of hydrotreating catalysts was investigated. The thermal decomposition of the tetraethylammonium salts of these complexes in an H_2–H_2S atmosphere at 400°C leads to the formation of catalytically active materials which were characterized by physico-chemical methods and their catalytic activities in biphenyl hydrogenation. As the molecular structures of the starting complexes are known, the resulting catalysts can be discussed as "modified precursors". Structural models of these catalysts have been developed on the basis of this assumption and the present results.

In recent years discussion of the structure of the active centers in unsupported promoted group VI sulfides has gained special interest. This problem is still a matter of controversy in the literature and has led to the development of different models.[1–3] The CoMo-based catalysts have received the largest attention because of their widespread industrial application as HDS catalysts. The extensive work of Topsøe's group on this system has shown that a mixed "CoMoS phase" is present in unsupported and supported catalysts.[4,5]

The appearance of a "mixed phase" is discussed for catalysts prepared also by the "comaceration" method (CM),[6] as for those prepared by "homogeneous sulfide precipitation" (HSP).[4] Interesting results concerning the structure of the "mixed phase" have been found by the use of Mössbauer emission spectroscopy and EXAFS on unsupported samples,[7] suggesting that the CoMoS phase could be regarded as an MoS_2 structure with Co atoms located at the edge positions. Nevertheless the discussion about the composition and constitution of CoMoS, CoWS, NiMoS and NiWS "mixed phases" has not yet led to a complete description. A reason for this may be the insufficiently well characterized precursor states of these catalysts. As in both preparation methods (CM and HSP) a great part of aqueous solution chemistry is involved, it is surprising that little is known concerning the chemistry of aqueous M', M and S^{2-} mixtures. With the CM method the formation of a large variety of species is limited by the "insolubility" of Co_3O_4 in this medium, whereas, in the case of the HSP method, depending on the pH of the metal salt solution, the formation of several different species (e.g. heteropolyanions, thioanions and metal sulfur clusters) besides M' or M sulfides come into consideration.

Our new approach to this problem consists in using well-defined tetraethylammonium salts of $[M'(MS_4)_2]^{n-}$ ($n = 2$ or 3) complexes as precursors which can be easily synthesized in each combination of M' = Co or Ni with M = Mo or W. The tetraethylammonium cation was choosen as its facile decomposition into volatile products on heating could be assumed.[8]

All these complexes isolated from aqueous or organic solutions can be obtained pure and in high yields (70–95%).

As already mentioned, almost all of these complexes are structurally characterized by single-crystal X-ray analysis.[9,10] Two representative examples of the structure are given in Fig. 1.

Interestingly the Co—S distance in

* Author to whom correspondence should be addressed.

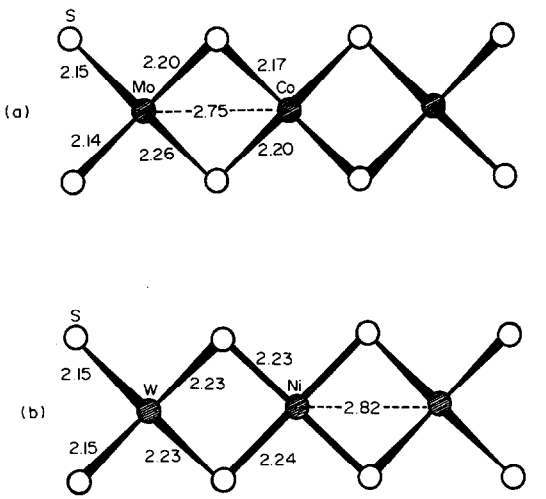

Fig. 1. Schematic representation of the structures of: (a) $[Co(MoS_4)_2]^{3-}$,[9] and (b) $[Ni(WS_4)_2]^{2-}$.[10]

$[Co(MoS_4)_2]^{3-}$ (~2.2 Å) is of the same order as the one found by EXAFS spectroscopy (Co-K_α edge) in CoMoS catalysts (~2.3 Å), and also the coordination number around Co in the first shell (4.6)[7] is almost equal to the molecular model. These structural similarities and the recent patent claims[11] gave rise to the investigation of bisthiometalato complexes as catalyst precursors. In order to obtain comparable catalysts, the tetraethylammonium salts were decomposed thermally in a flow of H_2–H_2S (15%) at 400°C. The decomposition was controlled by DTA–TG and the solid products were characterized by XRD, XPS, VIS spectroscopy and catalytic tests of biphenyl hydrogenation.

EXPERIMENTAL

Preparation of the complexes

According to the general equation:

$$2(Et_4N)^+ + M'^{2+} + 2MS_4^{2-} \rightarrow (Et_4N)_2[M'(MS_4)_2] \quad (1)$$

bisthiometalato complexes with M' = Ni and M = Mo or W can be isolated from aqueous solutions.[10] $(Et_4N)_3[Co(MoS_4)_2]$ (**1**) was prepared in an organic solvent (CH_3CN) using thiophenol as reducing agent.[12] The syntheses of $(Et_4N)_2[Co(WS_4)_2]$ (**2**), $(Et_4N)_2[Ni(MoS_4)_2]$ (**3**) and $(Et_4N)_2[Ni(WS_4)_2]$ (**4**) were carried out in deoxygenated water under an argon atmosphere. All chemicals used were of p.a. quality. Organic solvents used were of reagent grade, dried using standard procedures. $(NH_4)_2MoS_4$ and $(NH_4)_2WS_4$ were prepared by literature methods.[13,14] As an example, the preparation of **3** is given:

Preparation of **3**. To an aqueous solution (150 cm^3) of $Ni(NO_3)_2 \cdot 6H_2O$ (2.91 g, 10 mmol) and Et_4NBr (4.20 g, 20 mmol) an aqueous solution (150 cm^3) of $(NH_4)_2MoS_4$ (5.20 g, 20 mmol) was added dropwise under stirring. The dark-brown precipitate was washed with water, ethanol and ether, and dried *in vacuo* over P_4O_{10}.

2 and **4** were synthesized similarly.

Pretreatment of the precursor

The complexes obtained by the described procedures were decomposed under a reducing atmosphere [H_2–H_2S(15%)] during 4 h at 400°C. After cooling to room temperature under the same atmosphere, the catalysts were purged with N_2 and stored in sealed bottles under argon. This procedure was chosen in order to treat the complexes in the same manner as the HSP precursor.

Physico-chemical and catalytic measurements

Thermogravimetric experiments were performed using a Sartorius 4102 Microbalance and the DTA measurements were obtained against γ-Al_2O_3 as reference.

Electronic spectra of solutions and the solids (using an integrating sphere) were recorded with a Varian Carry 219 spectrometer.

XPS measurements were carried out with a Hewlett–Packard spectrometer using monochromatic Al-K_α radiation. Charge compensation on the complex precursor was effected by an electron floodgun and the values were calibrated to C1*s* = 284.5 eV as internal standard.

XRD experiments on powdered samples were performed using Co-K_α radiation (λ = 1.54178 Å).

The catalytic activities were determined during the hydrogenation of biphenyl (BP). This reaction test was carried out in the vapour phase using a dynamic high-pressure microreactor working at 22.5 $\times 10^5$ Pa. The partial pressure of BP was 8×10^2 Pa. A small amount of H_2S ($P_{H_2S} = 4.5 \times 10^2$ Pa) was added to the gas flow in order to maintain the sulfidation degree of the catalyst. The specific rate A_s is calculated using the following equation:

$$A_s = Q \cdot \frac{\tau}{m} \text{ (mol s}^{-1}\text{ g}^{-1}\text{)}, \quad (2)$$

with Q = BP flow (mol s^{-1}), τ = conversion, and m = weight of catalyst (g).

The intrinsic rate, A_i, is defined by A_s/S, in which S is the surface area of the sample. In a typical run the

specific rate was determined at 257°C in the pseudo-stationary state.

In order to estimate the stability of the catalyst, a catalytic run was performed at 400°C. After 16 h on stream, the reaction temperature was decreased to 257°C and the percentage of activity loss observed was calculated by eqn (3):

$$\Delta r = \frac{A_b - A_a}{A_b} \quad \text{(at 257°C)}, \qquad (3)$$

with A_b = BP hydrogenation rate at 257°C before the test at 400°C, and A_a = BP hydrogenation rate at 257°C after the test at 400°C.

RESULTS AND DISCUSSION

Thermal analysis

The thermal decomposition of the $(Et_4N)_n[M'(MS_4)_2]$ ($n = 2$ or 3) salts were studied in the range of 25–600°C under an inert gas atmosphere. The results given in Table 1 show that decomposition steps occur between 200 and 300°C in connection with endothermic reactions.

In the cases of **2–4** the total weight losses obtained at 400°C correspond to the loss of 2 mol triethylamine and 1 mol diethylsulfide (**2** and **3**) or diethyldisulfide (**4**) which could also be identified chemically. The same decomposition products were also obtained by the thermal decomposition of simple tetraethylammonium tetrathiomolybdates.[8] Therefore the general equation for the thermal decomposition of **2–4** can be given as follows:

$$(Et_4N)_2[M'(MS_4)_2] \xrightarrow{\Delta T} 2Et_3N + Et_2S \text{ (or } Et_2S_2) + M'M_2S_{6-7}. \qquad (4)$$

From chemical analysis and the TG experiments we deduce the following reaction scheme for the decomposition of **1** in an N_2 atmosphere:

$$(Et_4N)_3[Co(MoS_4)_2] \xrightarrow{\Delta T} 3Et_3N + Et_2S + \tfrac{1}{2}Et_2S_2 + CoMo_2S_6. \qquad (5)$$

The same experiments were also performed under an H_2–H_2S (15%) atmosphere. As in these cases the weight losses at 400°C are slightly higher, the loss of 1 mol H_2S in addition to the above-mentioned products had to be assumed. These treatments led to solids with the analytical composition $M'M_2S_{5-6}$.

The results show that these compounds decompose at moderate temperatures under the formation of volatile products which mainly originate from the quaternary alkylammonium cation.

Catalytic activities

Table 2 presents the activities of the different catalysts prepared either by decomposition of the complexes or by using the HSP method. Both kind of catalysts present the same deactivation curve but their extent is much lower than the one previously reported for unpromoted catalysts prepared by the decomposition of ammonium thiometalates.[15] As for these unpromoted samples, a large part of the deactivation has been attributed to catalyst sintering. Surface areas have been measured after the catalytic run.

From the results reported in Table 2 the following conclusions can be drawn:

(a) independently of the preparation method, the

[c] See Ref. 15.

hydrogenation activities follow the order NiWS > NiMoS ≫ CoMoS;

(b) the presence of Ni greatly promotes the hydrogenation function, whatever the preparation method;

(c) the decomposed bisthiometalato complexes lead to catalysts having an activity 2–3 times higher than the corresponding HSP samples; and

(d) for a given MM′ system, the same activity loss is observed after a catalytic test at 400°C.

The former observation refers to the stability of the active species under hydrogen atmosphere. Breysse *et al.*[16] have shown on HSP samples that, for example, the active "CoMoS phase" segregates into Co_9S_8 and MoS_2 under the applied conditions of high temperature, pressure and a reducing atmosphere. This phase segregation decreases drastically the amount of active sites and consequently the catalytic activity.

Recently we have also evidenced the same trend for a series of NiWS catalysts[17] in which the nickel concentration, defined by the atomic ratio Ni/(Ni + W), varied from 0.1 to 0.8.

This phase segregation is not surprising, as, according to Topsøe's model, the promoter atoms (Co or Ni) are located at the edge planes of lamellar MoS_2 or WS_2. The similar kinetic results obtained on samples with different precursors (HSP and complexes) suggest that the same kinds of active centers are responsible for the catalytic activity. The higher efficiency observed with the ex complex samples favors a higher amount of Co or Ni involved in the "mixed phase", meaning most probably that the promoter atoms are not only located at the edge positions of MoS_2 but are also distributed throughout the "entire" structure of the group VI sulfide.

X-ray analysis

The samples obtained after thermal decomposition of the complexes in an H_2–H_2S (15%) atmosphere and after the catalytic test were investigated by X-ray powder diffraction. Generally, the curves of the decomposed complexes resemble the results obtained on thermally decomposed diammonium tetrathiomolybdate[18] and -tungstate.[19]

Two examples of X-ray intensity curves of the CoMoS and NiWS catalysts before and after a catalytic run are presented in Fig. 2.

For the decomposed complexes (upper curves) the scattering curves of both samples show the same features as almost completely X-ray amorphous group VI disulfides. Only very broad maxima at about 14, 33 and 58° (2θ) are observed, which correspond well with those obtained on a-MoS_2 and a-WS_2. In the case of crystalline group VI disulfides these maxima can be attributed to the (002), (100, 101) and (110) Bragg reflections, respectively. Several attempts have been made to get more structural information on CoMoS[7] and also NiWS[20] "mixed phases" by the use of EXAFS spectroscopy and RDF calculations. The EXAFS investigations of Topsøe *et al.*[3] showed that the presence of the promoter atom Co in the CoMoS "mixed phase" was indicated by a peak at $r \sim 2.3$ Å, which was assigned to a Co—S distance, but also that, in spite of the presence of Co, the MoS_2 structure dominates.

Contrary to this, a comparison with the X-ray

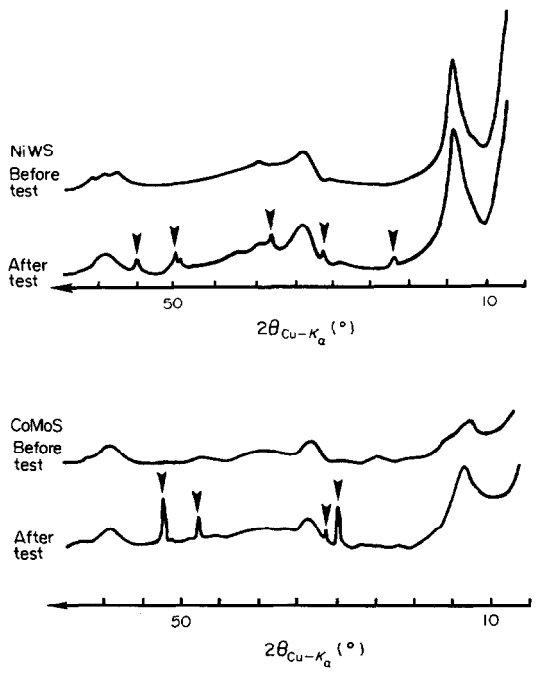

Fig. 2. X-ray intensity curves of NiWS and CoMoS ex complex samples before and after catalytic test (the arrows indicate the reflexions of Ni_3S_2 and Co_9S_8).

patterns of the corresponding binary sulfides showed that "badly crystalline" molybdenum disulfide and tungsten disulfide and crystalline Co_9S_8 or Ni_3S_2 were present in the samples after a catalytic test. Co_9S_8 and Ni_3S_2 are the thermodynamically most stable sulfides of these metals under these conditions[21,22] ($T = 400°C$, $P_{H_2} = 23 \times 10^5$ Pa). This behavior was in accordance with the observed activity loss and showed that severe structural changes occur, i.e. a partial destruction of the active phase.

Electron spectroscopy

Diffuse-reflectance spectra. Complexes of the type $[M'(MS_4)_2]^{n-}$ possess unique electronic properties characterized by a strong $M' \rightarrow MS_4$ electron delocalization.[10] The deeply coloured tetrathiometalates show electron absorption bands in the visible region where the lowest-energy bands were assigned to a $T_1 \rightarrow 2E$, i.e. $L \rightarrow M$, charge-transfer transition. It could be shown that, on co-ordination to a heterometal center, mainly the lowest-energy band, ν_1, of the free tetrathiometalato ligand was affected. For example a splitting into two bands at higher and lower energies compared to ν_1 could be obtained in the spectra of $[M'(MS_4)_2]^{n-}$ complexes which was proposed to be due to the non-equivalence of the sulfur atoms in the complexes.[23] The diffuse-reflectance spectra recorded from the complex precursor and the catalysts before test of the CoMoS and NiWS samples (Fig. 3) showed also the predicted splitting of the ν_1 charge-transfer band.

Surprisingly the catalysts before testing present a similar splitting (more pronounced in the spectrum of the NiWS sample) which cannot be easily explained but may also be due to the different $S(3p) \rightarrow M(nd)$ transitions.

XPS measurements. In order to get more insight into the electronic properties, especially of the NiWS system, the XPS of the starting complex and the catalysts before and after testing were taken. These results were compared with those obtained for a

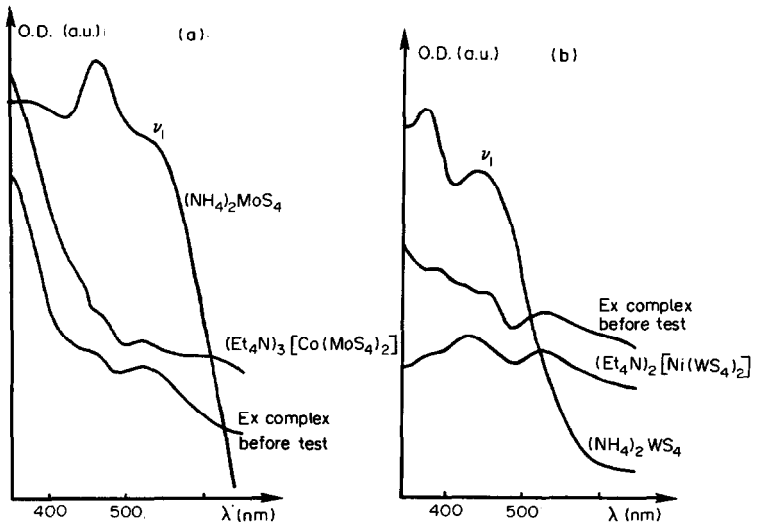

Fig. 3. Diffuse-reflectance spectra of: (a) CoMoS samples, and (b) NiWS samples in comparison with the corresponding tetrathiometalates (MgO reference).

Table 3. XPS data

Compound	Binding energy (eV)[a]

[a] Relative to C1s = 285.0 eV of the Et_4N^+ cation.
[b] Broad; no resolution of $S2p_{1/2}$ and $S2p_{3/2}$ levels.

NiWS sample prepared by the HSP method, WS_2 and NiS (Table 3).

Concerning the S2p binding energies (BEs) no large deviations from the mean value of $S2p_{3/2} \simeq$ 161.9 eV were measured for the different samples except for the complex precursor **4** ($S2p_{3/2}$ = 161.5 eV). The value of $S2p_{3/2} \simeq$ 161.9 eV is characteristic for S^{2-} ligands with a high co-ordination number whereas in **4** two different types of S^{2-} ligands (μ_2-S^{2-} and $S^{2-}_{term.}$) exist. (A dependence of the BE of S^{2-} ligands on the co-ordination number was shown recently in a series of molybdenum–sulfur complexes.[24]) This situation may be responsible for the fact that only a broad band at 161.5 eV without the typical resolution into the $S2p_{1/2}$ and $S2p_{3/2}$ levels could be measured.

Again the BE measured for the $W4f_{7/2}$ levels (~32.4 eV) of all compounds except for **4** [formally W(VI)], are representative for a W(IV) oxidation state. Similar results and also a higher value for **4** $W4f_{7/2}$ BE = 32.9 eV) were published recently.[25]

Interestingly the trend observed for S2p and W4f electron BEs is not as straight concerning the $Ni2p_{3/2}$ core levels (Table 2 and Fig. 4).

NiS serves as a reference for a compound with only Ni(II) in a sulfur environment ($Ni2p_{3/2}$ BE = 853.3 eV). As **4** ($Ni2p_{3/2}$ BE = 853.9 eV) reflects a situation of $M' \rightarrow MS_4$ electron delocalisation this fact seems to be also valid for the catalyst before testing ($Ni2p_{3/2}$ BE = 854.1 eV). Even in the case of the catalyst after testing, where the presence of Ni_3S_2 was detected by X-ray methods, the unexpectedly high value of $Ni2p_{3/2}$ (854.7 eV) and the large half-width of the peak probably indicate the existence of Ni in several oxidation states. Contrary to this the catalyst before test shows a half-width of the band which is comparable to that found in NiS.

The valence band spectra given in Fig. 5 will be discussed only qualitatively as no exact estimation of

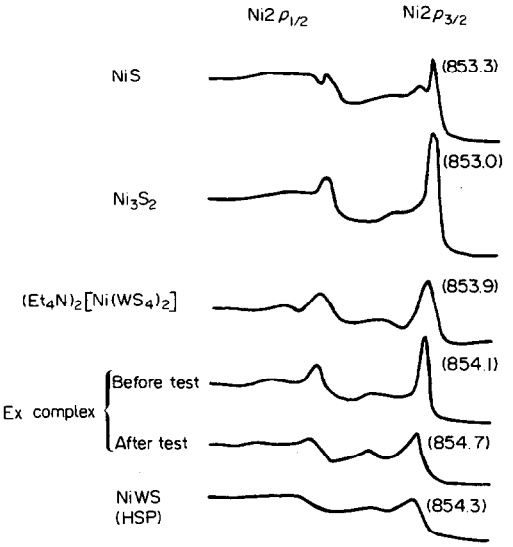

Fig. 4. XPS of different NiWS catalysts and Ni sulfides in the region of Ni2p electron energy levels. Binding energies are given in parentheses.

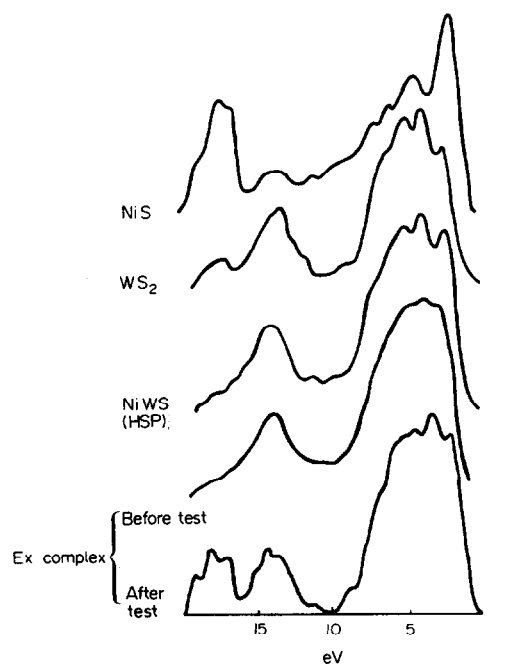
the Fermi level was performed. In the case of NiS and WS_2 we found, according to the literature,[26,27] a pronounced separation of the highest Mnd band from the bands arising from Mnd–S3p MOs and S3p levels, which again are separated from the S3s bands. The catalyst before test presents an almost unique valence band spectrum. No distinct separations of the bands are observed, but only an envelope type curve between 0 and 10 eV. This high density of states



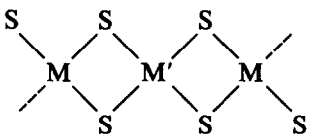


Fig. 5. XP valence band spectra.

may be discussed as a consequence of the mixing of Ni3*d* energy levels into the W4*d*–S3*p* band. The valence band spectrum of the sample after testing is almost identical to that of NiWS (HSP). Interestingly both samples possess the same catalytic activity.

Generally the features of the valence band spectra of transition-metal sulfides can be approximately represented by the use of simple MO considerations on the basis of an $[MS_6]^{n-}$ model in which the metal is octahedrally co-ordinated by six sulfur atoms.[28] In the spectra of simple 3*d* transition-metal sulfides the tendency of a decreasing gap (going from left to right in the 3*d* period) between the bands corresponding to the HOMO (mainly M*nd*-localized) and the sulfur π-band (nonbonding Sπ-orbitals) occurs, whereas the gap between the bands arising from nonbonding Sπ-orbitals and mixing of M*nd*–Sπ orbitals is always very narrow. If one treats the mixed-sulfide systems (CoMoS, NiWS etc.) as if the MOs of an $[MS_6]^{n-}$ (M = Mo or W) complex are perturbed by M'3*d* (M' = Co or Ni) levels, one can easily imagine that a higher density of states and a mixing of M'3*d* orbitals into M4*d*–S3*p* orbitals may occur. The envelop type curve in the region between 0 and 10 eV of the NiWS (ex complex) system seems to indicate this possibility. One short comment will be given on the presence of peaks with varying intensity in the region of 17–18 eV in NiS, WS_2 and the catalyst after testing. A plausible explanation may be the presence of S_2^{2-} groups.[29] As the penetration of the radiation used several Ångströms, S_2^{2-} groups may be present at the surface of the solids.

Structural models

Regarding the results obtained on the catalysts with complex precursor, a structural model of the "mixed-phase" M'MS, containing "paradigmatic"

units, already present in the precursor state, was developed.

For two models the X-ray intensity curves were calculated[30] using Debye's equation. The calculation of the X-ray curve of a given model is in principle the reverse procedure as the calculation of the radial distribution function from an experimental curve.

Our calculations were performed on the NiWS system as this catalyst showed the highest catalytic activity and the atomic co-ordinates of the complex $[Ni(WS_4)_2]^{2-}$ were available.[31] The results obtained on this system may be also valid for the NiMoS and CoMoS catalysts.

Model a consists of 10 units as drawn above, arranged in a chain-like manner. In order to have a "realistic" co-ordination number on tungsten the model was modified in the way that between each W–W pair an S_2^{2-} group was introduced. The following distances were taken from the single-crystal X-ray structure of **4**: d(M—M') = 2.82, d(M—M) = 2.96, d(M—S) and d(M'—S) = 2.24,[10] and $d(S—S)_{S_2^{2-}}$ = 2.00 Å.

The second model (b) consists of two parallel chains (d_{ch-ch} = 6.5 Å) of model a, where the chains are shifted against each other by about 4.3 Å. This type of arrangement represents a part of a WS_2 layer structure, in which certain positions of W atoms are substituted by Ni. The calculated X-ray intensity curves of the models a and b together with the experimental curves of the NiWS catalyst before testing and amorphous WS_2 are given in Fig. 6.

The difference between the single-chain model (a) (curve a) and model b (curve b) is demonstrated by an enhancement of the maximum at $2\theta \sim 14°$. The fact that curve b shows a better correlation with the experimental curve c, and the similarity of curves c and d suggests that some type of substituted WS_2 layer structure is present in the catalyst.

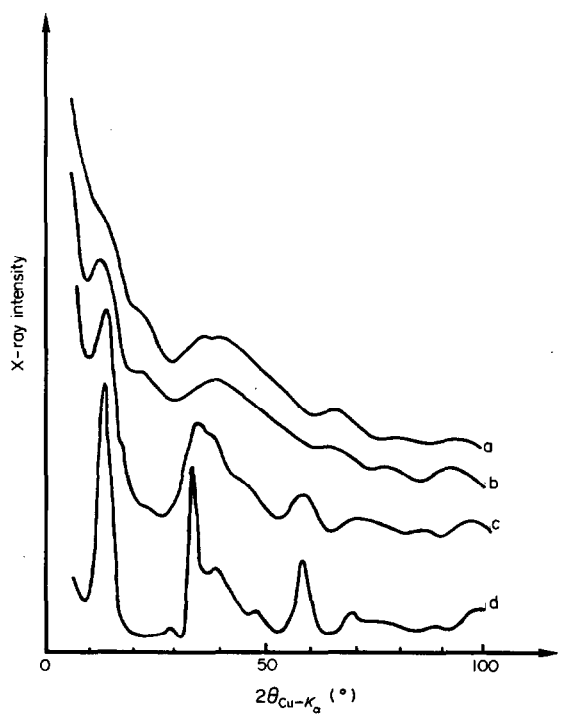

Fig. 6. X-ray intensity curves of: (a) model a (see text), (b) model b (see text), (c) NiWS ex complex before test, and (d) amorphous WS_2.

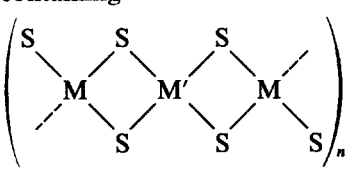
CONCLUSIONS

From the physico-chemical and catalytic results the following conclusions can be drawn:

(a) Concerning the different precursor preparation methods (CM, HSP or complexes) of unsupported, promoted hydrotreating catalysts, undoubtedly the bisthiometalato complexes are the best defined ones. They can be isolated as the *only* species from simple procedures.



(b) The catalysts obtained after thermal decomposition of the complexes in an H_2–H_2S atmosphere show a catalytic activity in the hydrogeneration of BP, which is 2–3 times higher than those prepared by the HSP method.

(c) As the deactivation behavior of these catalysts is similar to those prepared by conventional methods, the same nature for the catalytic active sites is suggested.

(d) The XRD results show the amorphous character of the active catalysts. Under the conditions of a catalytic test, "crystallization" occurs, and simultaneously the activity decreases.

(e) The electronic properties of the catalysts resemble those of the complex precursor, i.e. of electron-delocalized systems $M' \rightarrow MS_n$, which was evidenced by the unique features of the VIS, XPS and valence band spectra.

(f) The fact that not only the final states (after a catalytic test) but also the precursor states are structurally characterized enables us to propose a model of the intermediate states (catalysts before testing). This model is related to the structure of the precursor containing

units supposed to be characteristic of the bulk catalyst.

Abstract—Unsupported NiMo sulfide catalysts are prepared by an original coprecipitation technique performed at low temperature. Studies by several surface investigation techniques (X-ray diffraction, electron microscopy, O_2-chemisorption, and X-ray photoelectron and ion-scattering spectroscopy) provide a good qualitative picture of these catalysts. The existence of an Ni–Mo–S mixed phase is observed over the whole range of composition. This MoS_2-like structure is supported on Ni_xS_y if $Ni/(Ni+Mo) > 0.25$, resulting in an enhancement of catalytic activities (on hydrogenolysis and hydrogenation). These results are discussed with respect to the geometrical model of hydrotreating catalysts. This work points out the extreme importance of the degree of exposure of active edges of the Ni–Mo–S phase on the overall activity.

Even if unsupported catalysts have much less industrial application than supported catalysts, studies on these materials are of great interest because the active-phase characterization is not modified by the presence of the support.

Different authors have prepared mixed-sulfide catalysts by several methods: sulfidation of coprecipitated oxides,[1,2] the comaceration method described by Hagenbach *et al.*,[3,4] or homogeneous sulfide precipitation (HSP) described by Candia *et al.*[5]

With these various preparation techniques, the authors obtained different results, but, generally, complete structural descriptions of their samples are not available, and unitary interpretation of their activity results is not possible. In order to study the state of Ni in unsupported catalysts, we have developed a new method of preparation,[6–8] which is to some extent similar to the HSP method. This paper deals with catalytic results obtained on that new generation of unsupported catalysts, related to their structure; new aspects of the phase relationships in the metastable low-temperature ternary Ni–Mo–S system are demonstrated.

EXPERIMENTAL

Catalysts of various atomic ratios {r [Ni/(Ni + Mo)] = 0–1} obtained directly in sulfided forms, at low temperature, were subjected to a multi-technique analysis approach:

(a) catalytic-activity determinations for the

following reactions: (i) atmospheric-pressure hydrogenolysis of dibenzothiophene (DBT) at 513 K,[6] (ii) high-pressure hydrogenolysis of DBT at 24×10^5 Pa and 530 K,[6] and (iii) high-pressure hydrogenation of toluene at 60×10^5 Pa and 623 K.

(b) textural measurements (porosity and BET).

(c) physical investigations using various surface techniques: high-resolution electron microscopy (HREM) (JEOL 120X), analytical electron microscopy (AEM) (VG HB5), X-ray diffraction (XRD), X-ray photoelectron spectroscopy (ESCA) (AEI ES 200B spectrometer), ion-scattering spectroscopy (ISS) (LEYBOLD LH-S10), and O_2-chemisorption.

CATALYTIC RESULTS

Specific activity patterns of our mixed NiMo sulfides are shown in Fig. 1 for atmospheric-pressure HDS of DBT, high-pressure HDS or DBT and toluene hydrogenation. Reference activities of an industrial NiMo catalyst are reported for each reaction.

A maximum activity is obtained for $r = 0.7$. This ratio is unusual for such catalysts. On the three reaction diagrams, Mo efficiency increases with the increase in Ni content. However, the variation is not linear and we can consider two catalytic regions: the Mo-rich region, $r < 0.3$, for which all activities are low, and the Ni-rich region for which activities are high.

The comparison with the commercial NiMo–Al_2O_3 catalyst (Fig. 1) shows two different activity behaviours for unsupported catalysts, one for hydrogenolysis reactions, and one for the hydrogenation reaction.

Although our unsupported NiMo catalysts have a low activity in DBT hydrogenolysis our Ni-rich catalysts are more active in toluene hydrogenation than the industrial NiMo–Al_2O_3 catalyst [Fig. 1(c)]. The activities in toluene hydrogenation of the industrial catalyst and our NiMo catalyst of the

Conversion vs mole fraction Ni for: (a) dibenzothiophene HDS at 1 atm, 513 K; (b) dibenzothiophene HDS at 24×10^5 Pa, 530 K; and (c) toluene hydrogenation at 60×10^5 Pa, 623 K. Symbols: (■) our unsupported catalysts, and (▲) γ-alumina-supported industrial NiMo–Al_2O_3 catalyst.

same composition are similar. This suggests that the active sites are the same in the two types of catalyst.

STRUCTURAL RESULTS

Textural results

The distinction between two regions observed for catalytic activities is also observed if we consider porosities of the catalysts. In the Mo-rich region, catalysts are microporous with small crystallites (average diameter 5 nm); with increase of total Ni content, macroporosity appears, suggesting the presence of large crystallites (average diameter 100–200 nm) in the catalysts, together with smaller ones.

The BET specific surface is greater for Mo-rich catalysts than for Ni-rich catalysts. The average value, 50 $m^2\ g^{-1}$, is important for such catalysts.

XRD

Figure 2 shows XRD patterns of catalysts before catalytic experiments. No nickel sulfides are present in the Mo-rich region, where a MoS_2-like phase only is apparent, whereas nickel sulfides are present in the Ni-rich region, in various crystalline forms, such as NiS or NiS_2.

Ni_3S_2 is the thermodynamically stable nickel sulfide under our catalytic working conditions. We verified that Ni_3S_2 was present in the mixed catalysts after testing.[6,8] However, after catalytic runs the catalysts were not a simple mixture of MoS_2 and Ni_3S_2. Post-run sulfur analysis[6] showed a gap between observed sulfur content and theoretical content for mixtures of MoS_2 and Ni_3S_2. In the Mo-rich region S/(Ni + Mo) was constant at about 1.8–1.9; in the Ni-rich region the linear variation of S/(Ni + Mo) was consistent with the presence of a mixture of the Ni–Mo–S phase and Ni_3S_2.[6,8]

ESCA

ESCA is a well-known surface investigation technique, and is of great interest in approaching the surface composition of the catalysts specially in the Mo-rich region.

Figure 3 is a plot of the composition "seen" by ESCA expressed as the ratio of the intensity of the Ni2$p_{3/2}$ peak to the sum of the intensities of the Mo3d and Ni2$p_{3/2}$ peak vs bulk composition of our materials. These results show the same difference between two composition regions. For Mo-rich catalysts, the overall composition is the same as the ESCA composition; the surface composition is the same as the bulk. However, at higher Ni content, a Mo enrichment of the crystallite surfaces is clear.

ISS

The enrichment of the surface with Mo is confirmed by ISS experiments.

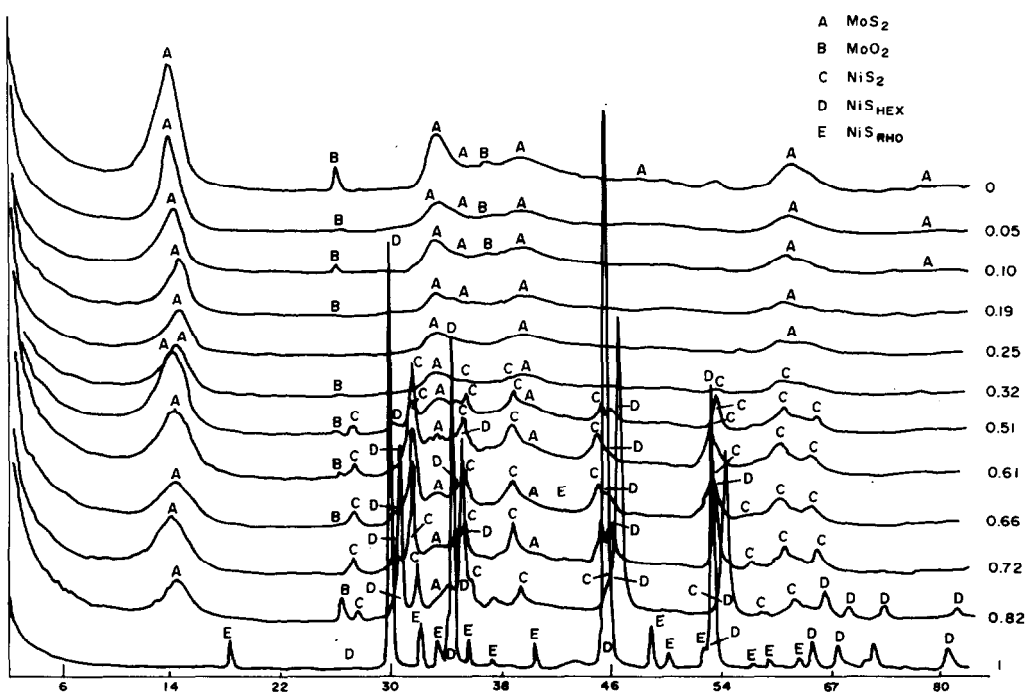

Fig. 2. XRD patterns before testing.

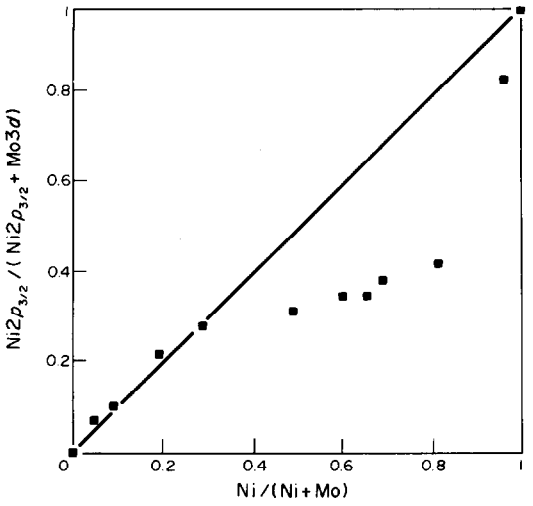

Fig. 3. ESCA results.

ESCA and ISS do not provide in this case an unambiguous location of Ni in the catalysts; but they do show a certain disposition of phases. The only way to have more Mo located at the surface of a catalyst than in the bulk is to support the Mo-containing phase on Ni sulfides since solid solutions of Mo in Ni sulfides are not known. The other important point is that Mo is always associated with Ni in ISS experiments. We know, however, that pure Mo sulfide is not present in the catalysts; but association of Ni with the MoS_2 structure is possible, giving a mixed Ni–Mo–S phase with a similar structure.

Electron microscopy

In order to visualize the catalysts, high-resolution transmission electron microscopy was performed. We produce two typical pictures to illustrate our results. In the Mo-rich region, only one phase is observed, with the typical "fingerprint" structure attributed to MoS_2.[1,2] For an Ni content with $r > 0.25$, large crystallites of different Ni sulfides appear and coating of the MoS_2-like structure is evident.

AEM analysis did not enable us to find any Ni-free zones in the MoS_2-like structure.

Figure 4(1) is a high-resolution photograph of $r = 0.2$ catalyst. We see that incorporation of nickel in an MoS_2 catalyst does not change drastically the well-known structure of MoS_2. In Fig. 4(2), representing $r = 0.6$ catalyst, coating of the mixed Ni–Mo–S phase on an NiS_2 large crystallite is very well displayed.

It is worth emphasizing what appears as an essential difference between Ni–Mo–S phase morphology in our "supported" unsupported catalysts and in an industrial alumina-based catalyst. In the former, five or six Ni–Mo–S slabs are stacked along the (002) axis for $r < 0.25$, against four or five for $r > 0.25$, as shown by the (002) XRD peak analysis and HREM micrographs, whereas in the latter single slabs only (and very rarely two or three stacked slabs) are visible by HREM, according to our results[9,10] and many others reported elsewhere.[11]

O_2-chemisorption

Dynamic O_2-chemisorption experiments performed for the catalysts at 333 K show a poor uptake ($0.05–0.5 \times 10^{-4}$ O_2-mol g^{-1}) compared to the industrial catalyst (1.8×10^{-4} O_2-mol g^{-1}), except at high Ni content, where some oxidation begins to occur with the Ni sulfides. These results tend to prove that the active phase is less dispersed in unsupported mixed sulfides than in the commercial catalyst, a result in agreement with the description obtained by all other investigation techniques.

DISCUSSION

The results show that our Ni–Mo–S system is quite unusual compared to all unsupported NiMo catalysts described in the literature.

First, activities in both hydrogenation and hydrogenolysis reactions are a maximum at $r = 0.7$. Pratt *et al.*[2] obtained comparable results for atmospheric thiophene hydrogenolysis on unsupported NiMo catalysts.

Second, the system shows two regions with different characteristics; for r between 0 and 0.25, activities are not very high. Catalysts are composed of monophasic small crystallites. This unique phase is an MoS_2-like structure phase containing Ni. The incorporation of Ni in the structure goes along with some changes in the structure, as apparent diminution of the c parameter corresponding to the (002) broad peak in the MoS_2 XRD diagram. In the first composition region the parameter decreases. When Ni sulfides appear, for $r > 0.25$, the parameter begins to increase up to its original value (Fig. 5).

We cannot relate these variations to a precise change in the structure of the MoS_2-like phase. The effect can be due simply to the changes in the crystallinity of the mixed Ni–Mo–S phase. Electron microscopy studies seem to prove that the mixed phase is better organized with the incorporation of Ni; better crystallinity, larger crystallites. . . .

The novelty of our catalysts is the structure found at high Ni content. Catalysts are made of a mixed Ni–Mo–S phase coated onto Ni sulfides crystallites. All

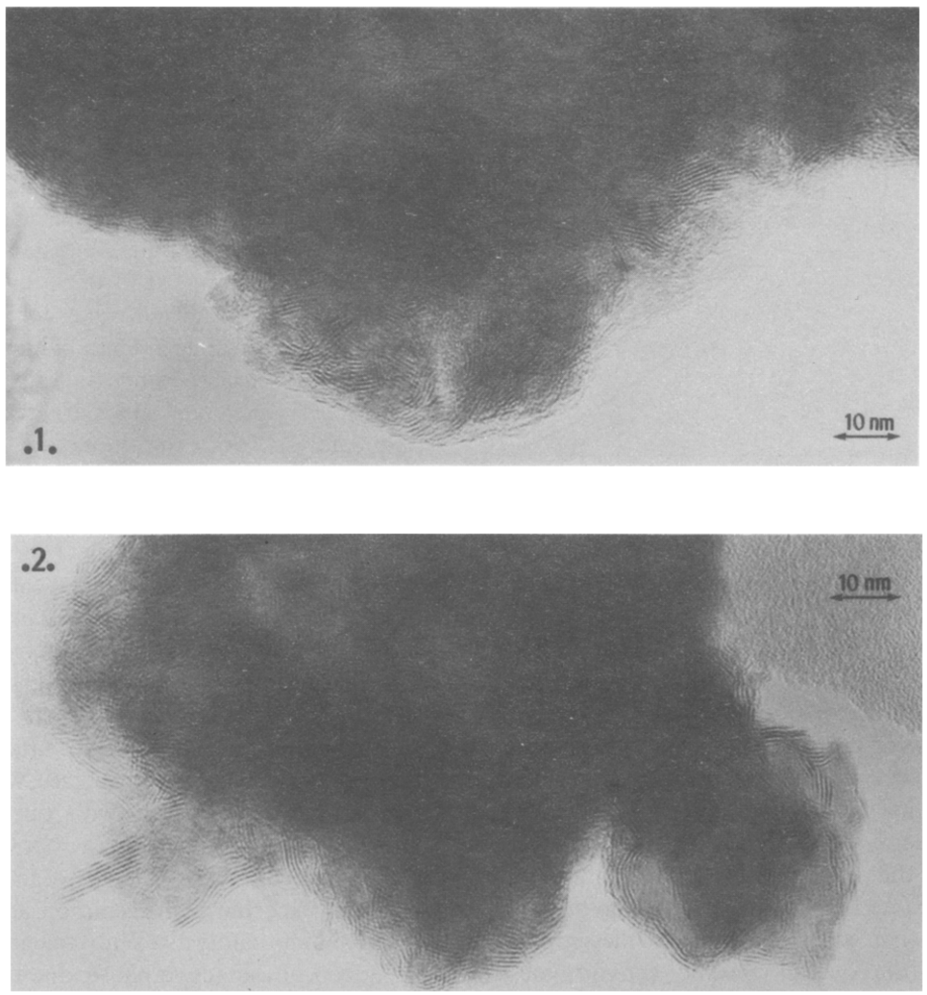

Fig. 4. CTEM images of the catalysts. The pictures show the MoS_2-like structure of the Ni–Mo–S phase (1) and its coating on NiS_2 (2) at high Ni content. (1) Ni/(Ni + Mo) = 0.2; (2) Ni/(Ni + Mo) = 0.60.

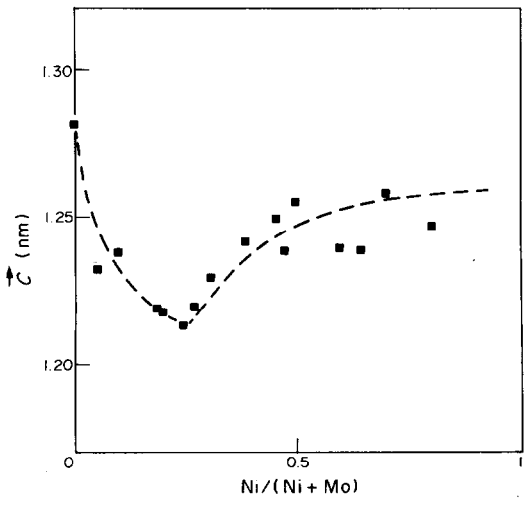

Fig. 5. Evolution of MoS_2 (002) parameter.

experimental results (stoichiometry and ESCA results) suggest that Ni sulfides, specially Ni_3S_2, which is thermodynamically stable under catalytic conditions, are really the support of the mixed phase, which is the active phase in all reactions (an Ni-only catalyst is poorly active for all reactions).

For $r = 0$–0.25, all the nickel is incorporated in the MoS_2 structure. After this value the mixed phase does not incorporate more Ni and its composition seems to be constant. This fact was verified[6] using selective extractions of the mixed phase in the Ni-rich catalysts.

For $r > 0.25$, the excess of Ni segregates into large Ni sulfide crystallites. The role of these large crystallites is to support the mixed phase, and the major consequence is to enhance the catalytic activities.

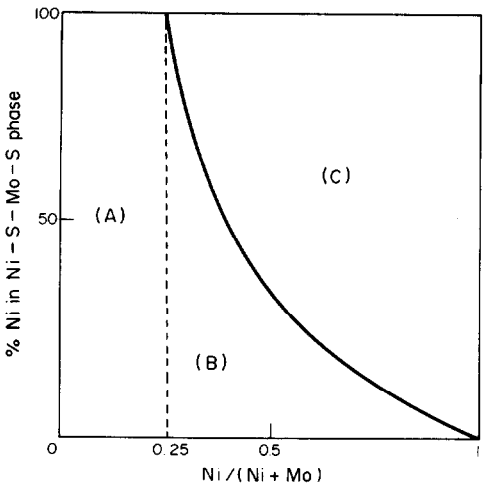

Fig. 6. Pseudo-phase diagram: (a) solid solution of NiSMoS phase in MoS_2, (B) NisSMoS phase supported on Ni_xS_y, and (C) Ni_xS_y.

These considerations enable us to build a "pseudo-phase diagram" for our Ni–Mo–S system. In the region between pure MoS_2 and $r = 0.25$ catalyst, all the Ni is incorporated in the MoS_2 structure. For $r > 0.25$, the Ni_3S_2 phase appears, and the mixed phase does not accept more Ni in its structure. The amount of the active phase then decreases with the Ni content (see Fig. 6).

The fact that, when the amount of the active phase decreases, the overall specific activity goes on increasing proves that the number of active sites is closely connected with the dispersion of the mixed phase.

It is of a great interest to connect these results with the geometrical model for hydrotreating catalysts proposed by Kasztelan.[12] In this theory, the activity of catalysts can be related to crystallite geometry by postulating that active sites are the Mo edge atoms in MoS_2 crystallites. From this point of view, an optimum size of crystallite is obvious for a given number of Mo atoms, in order to get the maximum specific activity. The role of the promoter, assumed to decorate MoS_2 crystallites (that is to say, Ni atoms placed in the Mo plane at the edge), is in this model to enhance the catalytic activity of each active site. We can understand, that for a given number of Mo atoms, and a given form for MoS_2 crystallites, a number of active sites (edge Mo atoms) and an optimum Ni : Mo ratio exist for which the catalytic activity is a maximum. All results for this theory are consistent with independent experimental results, activities, O_2-chemisorption, sulfur content measurements etc.

For instance, with a rhombohedral form for MoS_2 crystallites, an optimum r of 0.33 is found.

It is possible to apply the geometrical model of a hydrotreating catalyst to our system, even if the model refers to supported catalysts. In a sense Ni_3S_2 is a support for the Ni–Mo–S active phase in our "unsupported" catalysts. We can say that there is no contradiction between our results and the geometrical model. In fact, Paulus' results show that the mixed phase exhibits a quasi constant r for high Ni content, in the range 0.20–0.25, a value in good agreement with predicted values for rhombohedral slab sizes in the range 5–8 nm (which are observed values in HREM experiments) [Fig. 4(2)].

Another interesting fact is the agreement between our catalysts and the industrial reference for hydrogenation activity. In Fig. 1(c), the specific activity for the commercial catalyst lies on the curve obtained for unsupported mixed NiMo sulfide catalysts.

We think that the differences between the two kinds of material essentially consist in the dispersion of the active phase, and that the active phase is the same for all catalysts (and is a mixed Ni–Mo–S phase with the MoS_2 structure).

On the commercial catalyst surface, the active phase is known to be well-dispersed, which is not the case to the same extent with our unsupported materials. The consequence is a poor O_2 uptake and a poor specific hydrogenolysis activity, but an equivalent specific hydrogenation activity, for the mixed-sulfide catalysts. With the increase in the dispersion of the active phase, due to a less active phase for more Ni sulfides as a support in the catalyst (see Fig. 6), all specific activities increase, but electron microscopy shows that the dispersion remains poor, compared to commercial catalysts, even when activities are maximum. For these reasons, we think that hydrogenolysis sites and hydrogenation sites are different.

All sites are sensitive to the active-phase dispersion, but in different ways. We may assume that a good hydrogenolysis activity needs a significant dispersion of the Ni–Mo–S structure and a good aromatic hydrogenation needs stacked active-phase slabs. If both reactions take place on the edge sites of decorated MoS_2 slabs, (according to Kasztelan's model), the effect of stacking seems to be predominant particularly for aromatic hydrogenation, even if supports' influences, on industrial or in our "unsupported" catalysts, are not very well defined.

In conclusion, it is possible to say that we elucidated the structure of this system involving Ni, Mo and sulfur in a very fine mixture. The preparation method leads to catalysts with significant hydrogenation activities (the efficiency of Mo is better in most of our materials than in a commercial catalyst).

The structure resolved by our investigation techniques is new, and promises developments for this class of materials.

Abstract—Unsupported CoMo, NiMo and FeMo catalysts have been prepared by the homogeneous sulfide precipitation method and the coprecipitation method. The presence of a group VIII metal (Me) causes a decrease in the reactivity with O_2 and an increase in the reducibility in H_2. These effects are correlated with the increase in the catalytic activity. The stability of cobalt and iron sulfide species in CoMo and FeMo catalysts was studied by Mössbauer spectroscopy. A significant amount of Me–Mo–S structure remains stable after strong reducing treatment. Catalysts contain also sulfur-rich group VIII metal sulfide species which appear stabilized by MoS_2. The role of these species in promoting HDS activity is evaluated.

The optimum activity of hydrodesulfurization (HDS) catalysts based on Mo is usually achieved with the addition of a proportion of group VIII metal (Me) (Co, Ni or Fe) corresponding to an atomic ratio (r) [Me/(Me + Mo)] of $\simeq 0.3$. The central question remains the chemical nature of this group VIII metal under catalytic conditions.[1] The compounds Co_9S_8, Ni_3S_2 and FeS should be the only stable phases from the thermodynamic point of view. However, analysis of CoMo and FeMo catalysts by Mössbauer spectroscopy shows the presence of cobalt and iron species other than these stable phases.[2,3] Much interest has been concentrated recently in the so-called Me–Mo–S structure proposed by Topsøe and coworkers.[4,5] This structure would consist of the coverage of the edges of MoS_2 crystal flakes by some mixed MeMo sulfide species.

In order to learn more about the nature and stability of group VIII metal species in HDS catalysts, we have prepared unsupported MeMo catalysts by methods reported to maximize the formation of Me–Mo–S structures. We have studied the reactivity of these catalysts with H_2 and O_2 by temperature-programmed methods. Mössbauer spectroscopy was used to characterize the group VIII metal species in CoMo and FeMo catalysts and to investigate their stability under various reducing treatments. We evaluate the correlations between these results and the activity of the samples in the HDS of thiophene.

EXPERIMENTAL

Sample preparation

Unsupported CoMo and NiMo catalyst precursors with $r = 0.3$ were prepared by the so-called homogeneous sulfide precipitation (HSP) method.[6] Briefly, this method consists in adding a solution of Co or Ni nitrate and ammonium heptamolybdate (AHM) slowly to a solution of $(NH_4)_2S$. The atomic ratio S/(Me+4Mo) in the final mixture was larger than 1.5 (i.e. more than 1.5 times the ratio needed for the complete sulfuration of Me and Mo into MeS and MoS_4^{2-}). The solid precursor is obtained by allowing the mixture to evaporate to dryness.

For the Mössbauer emission spectroscopy (MES) measurements, a ^{57}Co-labelled precursor with $r = 0.3$ was prepared under identical conditions, using about 1 mCi of ^{57}Co per 0.5 g of sample.

A FeMo precursor with $r = 0.3$ was prepared by the HSP method, using $FeCl_2 \cdot 4H_2O$ instead of nitrate.

A FeMo precursor with $r = 0.15$ was prepared by the so-called coprecipitation (CP) method,[7] which consists in adding slowly a solution of $Fe(NO_3)_3 \cdot 9H_2O$ to a solution of ammonium thiomolybdate. In this case, the atomic ratio S/(Fe+4Mo) was 1.03. This mixed slurry was evaporated to dryness.

A precursor containing only molybdenum was prepared following the HSP method by adding a solution of AHM to a solution of $(NH_4)_2S$. More details about the preparation of samples are in Refs 7 and 8.

The precursors are named by the metal(s) present, followed by the method of preparation and the composition ratio r (e.g. Mo–HSP–0.0, CoMo–HSP–0.3 and FeMo–CP–0.15).

Reduction–sulfidation treatments

The precursors were converted into active catalysts by a standard activation by reduction–sulfidation. This activation consists in heating the samples for 4 h at 653 K in a flow of 15% H_2S–H_2 and cooling them thereafter to room temperature under argon. Catalysts obtained after this standard activation will be designated by adding the letter S to the name of the precursor.

Some of these catalysts were thereafter submitted to various reducing treatments designed to test their stability. These treatments are listed in Table 1 in order of increasing reducing strength. Except for treatment C, all treatments consist of a reduction in pure H_2 followed by resulfuration in H_2S–H_2 mixture.

Table 1. Reducing treatments

Name	Gas	P (MPa)	T (K)	Time (h)
A	H_2	0.1	573	6
	15% H_2S–H_2	0.1	573	1
B	H_2	0.1	723	6
	15% H_2S–H_2	0.1	723	2
C	0.1% H_2S–H_2	3.0	723	6
D	H_2	3.0	723	6
	5% H_2S–H_2	3.0	723	2
E	H_2	3.0	723	6
	0.1% H_2S–H_2	3.0	723	2

Catalytic-activity measurements

The activity in the HDS of thiophene and hydrogenation of cyclohexene was measured at 573 K on 0.5 g of catalyst under 3 MPa, using a feed containing 69.5 wt % cyclohexane, 30.0 wt % cyclohexene and 0.5 wt % thiophene. The mass flow rate of the liquid feed was 48 g h^{-1}. As exposure to air could not be avoided during the transfer of the sample in the reactor, the catalysts were exposed *in situ* to 4% H_2S–H_2 at 573 K under 3 MPa for 1 h prior to the catalytic reaction. The intrinsic HDS activities at steady state (i.e. after 8 h of reaction) are expressed as the amount of thiophene converted per second and per unit surface area of the catalyst.

Temperature-programmed oxidation (TPO)

The reactivity of the catalysts under air was studied by differential thermal analysis. Three hundred milligrams of precursor were first sulfided by heating at a constant rate of 11 K min^{-1} from 373 to 703–723 K under 15% H_2S–H_2 mixture at atmospheric pressure. The sample was then kept at 673 K for 2 h under the same atmosphere and allowed to cool down to room temperature under argon. (One may consider that this pretreatment is nearly equivalent to the standard activation treatment S.) This sample was then heated under air at a rate of 11 K min^{-1}. The thermal effects during the oxidation in air were monitored by measuring the temperature difference between the sample and a 300-mg SiO_2 reference. More details about the TPO measurements may be found in Ref. 8.

Temperature-programmed reduction (TPR)

The experiment was carried out at atmospheric pressure in a flow reactor.[9,10] Two hundred

milligrams of catalyst were first resulfided *in situ* under 15% H_2S–H_2, at 673 K, for 2 h. After purging with argon and cooling to room temperature, the sample was heated to 773 K at a rate of 0.17 K s^{-1} in a flow of 0.5 cm^3 s^{-1} of pure H_2. The H_2S evolving from the reactor was measured by a thermal conductivity detector.

Mössbauer spectroscopy

The Mössbauer spectra were recorded at 298 K using a constant-acceleration spectrometer. MES of CoMo samples enriched in ^{57}Co was performed by use of a moving single line absorber of $K_4Fe(CN)_6 \cdot 3H_2O$ enriched with ^{57}Fe. For Mössbauer absorption spectrometry (MAS) of the FeMo samples, use was made of a moving ^{57}Co source in a Rh matrix. All isomer shifts were referred to pure α-iron. The experimental spectra were fitted by a sum of Lorentzian lines using an iterative non-linear least-squares program. The relative amounts of the components were computed from the peak areas assuming that all species have an identical f factor. The estimated error is ±5%. More details about the Mössbauer measurements may be found in Refs 9, 11 and 12.

RESULTS

Figure 1 presents, as an illustration, the DTA curves recorded during the TPO of samples Mo–HSP–0.0–S and NiMo–HSP–0.3–S. The major feature common to all samples is the broad exothermic effect starting at a temperature (T_0) between 600 and 700 K. The reactivity of the samples in air is less, the higher the T_0 of the start of the exothermic effect.

Figure 2 (right-hand side) presents the values of T_0 for four samples of MeMo–HSP–0.3–S as a function of the intrinsic HDS activity of the samples. As a rule, T_0 increases with increasing amount of group VIII metal and this effect is the strongest for Ni and the weakest for Fe. The HDS activity increases with increasing T_0.

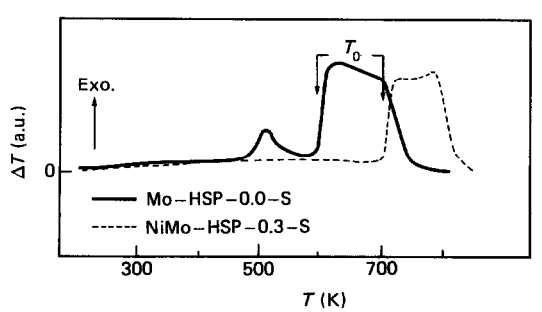

Fig. 1. TPO curves for samples Mo–HSP–0.0–S and NiMo–HSP–0.3–S.

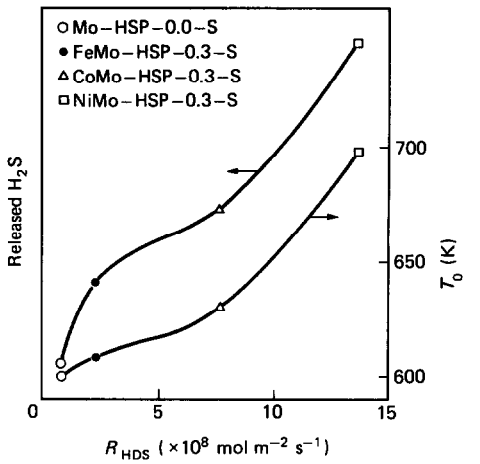

Fig. 2. Correlation between the intrinsic HDS activity and (right-hand side) the temperature T_0 of the onset of oxidation in TPO, or (left-hand side) the amount of H_2S released during TPR.

Figure 2 (left-hand side) also presents the total amount of H_2S released during TPR (up to 773 K) of the same samples of MeMo–HSP–0.3–S. The increase in HDS activity correlates well with the increase in the amount of released H_2S.

Owing to the low crystallinity of the samples, Mössbauer spectroscopy is usually the only method of studying the nature and stability of group VIII metal species in the catalysts. The decomposition of the MES spectra of the CoMo samples (enriched with ^{57}Co) enabled us to distinguish three types of cobalt species in three different environments: Co_9S_8, CoS_{1+x} and the Co–Mo–S structure described by Topsøe *et al.*[2] (More details about the decomposition of the MES spectra may be found in Ref. 11.) We made use of MES to investigate the stability of these three cobalt species in a catalyst, CoMo–HSP–0.3–S, exposed to treatments A and B (described in Table 1). The results are given in Table 1 together with the HDS activity of three samples. It is noteworthy that the HDS activity increases when the amount of cobalt in Co–Mo–S decreases.

Three types of Fe species were distinguished in the MAS spectra of FeMo catalysts: FeS, FeS_2 and Fe–Mo–S. (More details about the decomposition of the MAS spectra may be found in Ref. 12.) Table 2 gives the variation of the amount of these three Fe species in a catalyst, FeMo–CP–0.15–S, subjected to treatments B, C, D and E. The amount of Fe in Fe–Mo–S remains unaffected by the treatments. Except for the untreated sample, the HDS activity appears to decrease with decreasing amount of FeS_2 (or with increasing amount of FeS).

DISCUSSION

The results summarized in Fig. 2 indicate a direct correlation between catalytic activity and reducibility of the catalyst by H_2, and an inverse correlation between activity and reactivity with O_2. The correlation between catalytic activity and reducibility is not too surprising. Indeed, it is widely believed that active sites in HDS are located at sulfur vacancies at the surface of the catalyst. The role of group VIII metal in promoting the release of sulfur may be due either to a weaker bonding of sulfur at the surface or to the "activation" of H_2 by some sort of spill-over effect according to the remote-control hypothesis.[13] Correlation between HDS activity and reducibility was previously reported by Hoodless *et al.*[14]

The broad exothermic effect at high temperature in the TPO curves (Fig. 1) corresponds to the oxidation of MoS_2 with formation of MoO_2 and SO_2.[15] The presence of a group VIII metal brings about a lower reactivity of MoS_2 with O_2 so that a higher temperature is needed for the onset of the reaction. As the edges of MoS_2 crystals are much more reactive than the basal planes, it is generally assumed that oxidation proceeds from the edges.[16] (It is known that oxygen adsorbs preferentially on the edges.[17]) It may thus be concluded that group VIII metal modifies the nature of the edges. Such a modification could involve the formation of the Me–Mo–S structure proposed by Topsøe and coworkers.[4,5] It has been proposed that the bond strength of sulfur exposed on the edges is weaker in the Me–Mo–S structure than in MoS_2.[4,18] This would justify the higher release of H_2S in TPR. One may speculate that the adsorption of oxygen on such a structure creates a "passivating" layer which hinders the further oxidation of the crystal.

In the case of CoMo catalysts, it was shown that the temperature of the onset of oxidation of the catalyst was similar to the temperature of the onset of oxidation of pure cobalt sulfide.[8] Instead of postulating the presence of a Me–Mo–S structure, the change of reactivity with oxygen could thus be also explained by the presence of a layer of group VIII metal sulfide covering the edge of MoS_2 and protecting it from oxidation.

The MES and MAS results presented in Tables 2 and 3 reveal the presence of two different cobalt or iron sulfide phases beside the Me–Mo–S structure. Thermodynamically, Co_9S_8 and FeS should be the only stable phases under the conditions of the catalytic reaction.[19] It could thus be expected that the Me–Mo–S structures and the sulfur-rich CoS_{1+x} and FeS_2 phases would decompose after prolonged exposure to the reducing conditions prevalent during the reaction.

In the catalyst CoMo–HSP–0.3–S (Table 2), it is found that the amount of cobalt in Co–Mo–S decreases after increasingly severe reducing treatment. However, a significant amount of Co–Mo–S remains even after 6 h of exposure to pure H_2 at 723 K. The sulfur-rich CoS_{1+x} phase also remains abundant and even increases after exposure to H_2 at 723 K. (This may be caused by the resulfidation in 15% H_2S–H_2 at 723 K.) The thermodynamically unstable phase CoS_{1+x} appears to be stabilized by the presence of MoS_2. This stabilizing effect is supported by the appearance of peaks attributed to the phase β'-$CoS_{1.097}$ in X-ray diffractograms of unsupported CoMo catalysts.[9]

In the catalyst FeMo–CP–0.15–S, the amount of iron in Fe–Mo–S seems unaffected by the reducing treatments. The amount of sulfur-rich sulfide FeS_2 decreases progressively when increasing the strength of the reducing treatment (or when decreasing the proportion of H_2S in the H_2S–H_2 mixture). Nevertheless, this amount remains surprisingly

[a] Determined by MES.

large. This suggests again some sort of stabilizing effect caused by the presence of MoS_2.

It may be suggested that the presence of these sulfur-rich group VIII metal sulfide phases can be related to the increased release of H_2S in TPR and, possibly, to the decreased reactivity of MoS_2 with O_2.

Mössbauer spectroscopy characterizes the nature of the species in the whole bulk of the samples whereas catalytic activity is a property of the accessible surface only. Unsupported catalysts studied in this work have a BET surface area of *ca* 10 m^2 g^{-1}.[9,10] Hence, direct comparison of MES or MAS results and catalytic activity data is dubious. In addition, the reducing treatments bring about some sintering of phases and changes of the distribution of the species between surface and bulk.[9] We notice that Tables 2 and 3 reveal no direct correlation between the amount of Me–Mo–S and the HDS activity of the samples. If one excepts the case of the untreated samples (first line), comparison of the second and fourth columns in Tables 2 and 3 seems to suggest a possible correlation between the catalytic activity and the amount of sulfur-rich group VIII metal sulfide. It is worth mentioning in this context that Vissers[20] has recently concluded that the active sites for HDS in carbon-supported CoMo catalysts are located exclusively on the cobalt atoms.

CONCLUSIONS

The following conclusions may be drawn about unsupported MeMo catalysts.

(1) The higher the HDS activity, the higher the removal of sulfur by H_2 and the lower the reactivity with O_2.

(2) The influences of group VIII metal on the reactivity with O_2 may be due to the coverage of the edges of MoS_2 by the Me–Mo–S structure or by a group VIII metal sulfide.

(3) The Me–Mo–S structure remains present in the catalysts even after drastic reducing treatments.

(4) Sulfur-rich metal sulfide species (CoS_{1+x} and FeS_2) are stabilized by the presence of MoS_2.

(5) It is possible that these sulfur-rich species play an important role in promoting the activity.

INVESTIGATION OF UNSUPPORTED Co–Mo CATALYSTS IN THEIR OXIDIC STATE AND DURING SULFIDATION BY THIOPHENE

T. I. KORÁNYI, T. SZILÁGYI, I. MANNINGER and Z. PAÁL*

Institute of Isotopes, Hungarian Academy of Sciences, H-1525 Budapest, P.O. Box 77, Hungary

(*Received* 15 *June* 1985)

Abstract—Unsupported Co–Mo oxides of various compositions were investigated by IR, XRD and XPS techniques. They contain $CoMoO_4$ plus the corresponding oxide with slight Mo enrichment on the surface. After reduction with H_2, the changes in their catalytic activity in thiophene HDS were monitored with the reactant itself as the sulfiding agent. Relatively high activities with good C_4-selectivities were observed when the degree of sulfidation of the catalysts was relatively low. Partially sulfided surface species possess the highest activity, especially in hydrogenation.

The structure of Co–Mo–Al_2O_3 catalysts has been studied recently by a large number of surface physico-chemical methods.[1] Their unsupported analogues have also been studied frequently[2] because of the absence of any support effects which—however important in preserving a high activity—may conceal the inherent catalytic properties of Mo and Co species. The present study deals with the structure and surface composition of unsupported Co–Mo catalysts in their oxide forms and also with the changes in yields and product composition in thiophene hydrodesulfurization during a period of sulfidation with the reactant itself. The latter approach permitted us to determine an "activity pattern" characterizing the development of catalytically active sites *by the reaction itself*, although we are not able to identify them with any species seen by surface methods. Few publications relate to the initial period of sulfidation.[3]

CATALYST CHARACTERIZATION

Aqueous solutions of $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$ and $Co(NO_3)_2 \cdot 6H_2O$ were dried in air and calcined for 4 h at 723 K in atomic ratios $\{r\ [Co/(Co+Mo)]\}$ of 0, 0.17, 0.38, 0.50, 0.75 and 1. The calcined, oxidic form of the catalysts contains a-$CoMoO_4$ ($r = 0.5$) mixed with MoO_3 ($r < 0.5$) or with Co_3O_4 ($r > 0.5$) according to XRD, XPS and IR measurements. The interplanar spacings and relative intensities measured by XRD are in accordance with the literature data of the Powder Diffraction File of ICPDS of these compounds. The IR data[4–6] (Fig. 1) clearly show the gradual transition from the bands of MoO_3 through the bands of a-$CoMoO_4$ to the bands of Co_3O_4. The XPS binding energies are in relatively good agreement with literature data,[7,8] taking into account our different reference line (C1*s* = 285.0 eV). The "surface" r atomic ratios seen by XPS were calculated by the method of Grimblot *et al.*[9] A slight surface enrichment in Mo is seen from Table 1 which is in agreement with the results of Okamoto *et al.*[10] Specific surface areas of the calcined (oxidic) catalysts, and those of samples prereduced for 2 h at 673 K in 40 ml min^{-1} H_2, were measured by the BET method with N_2. Prereduction increased greatly the specific surface areas of the catalysts with $r = 0.38$–0.75 (from about 20 to about 100 $m^2\ g^{-1}$).

THIOPHENE CONVERSIONS

The "activity profiles" were determined by injecting 0.5 μl thiophene pulses on to the prereduced catalysts (20 mg weighed in the calcined state, reaction temperature 673 K, H_2 stream: 40 ml min^{-1}). The products were analyzed by gas

chromatography.[11] Two 0.5-μl dimethylsulfoxide (DMSO) pulses were introduced between each two thiophene pulses, in order to accelerate sulfur uptake. DMSO is claimed to decompose on the catalyst giving H_2S.[12]

Thiophene conversions during subsequent pulses show a maximum in the second thiophene pulse with Mo-rich catalysts ($r = 0$ and 0.17) and decrease monotonically with other samples (Fig. 2). The C_4-selectivity in the first pulse decreases gradually with increasing Co content (Table 2). Except for pure Co, it has reached already, however, a rather high value by the second pulse which increases further only slowly. We took the ratio of *n*-butane to the sum of butanes as characteristic of the hydrogenation selectivity (Fig. 3). This has a maximum value for all catalysts (except for $r = 1$). The indication of a maximum between the two pulses is justified by analogous experiments carried out without DMSO pulses where the sulfur uptake should have been slower (Fig. 3, insert). Figures 2 and 3 show also

Table 1. "Surface" compositions of the calcined (oxidic) catalysts as seen by XPS

comparative literature data.[3,11] Here the amount of sulfur introduced was related to a 20 mg Co plus Mo oxide content of the catalyst. The distribution of the fragments shows an excess of CH_4 in the first pulse, and C_3 excess (propane plus propene) in the second and third pulses. The amount of C_2 fragments was always lower than expected on the basis of random rupture of the C_4 hydrocarbon chain.

The activity profiles point to a profound change in the catalytic activity of our unsupported samples during their contact with the first sulphur-containing reactants after reduction. There is disagreement in the literature as far as the chemical state of Mo is concerned after reduction: Mo^{4+} and Mo^{2+} have been proposed.[13,14] They must be surrounded by O-anions which, during sulfidation, are exchanged for S-anions. Our measurements show that maximum activity is reached when this exchange is far from complete. For example, the sulfur atoms from thiophene transformed in the first

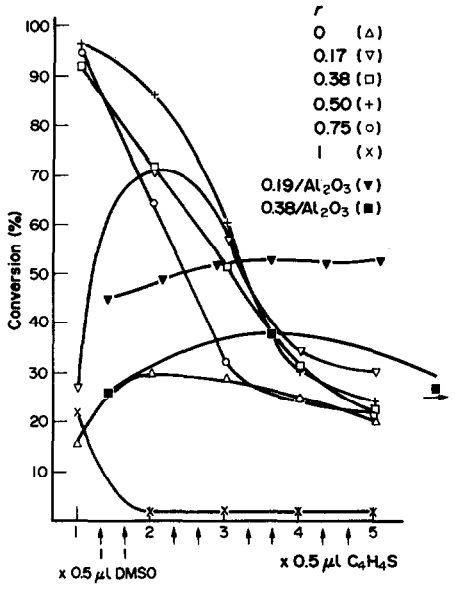

Fig. 2. Thiophene conversions during subsequent pulses on catalysts with different *r* atomic ratios. The amount of sulfur introduced onto supported catalysts was recalculated to 20 mg oxide content: (▼) Ref. 3, and (■) Ref. 11.

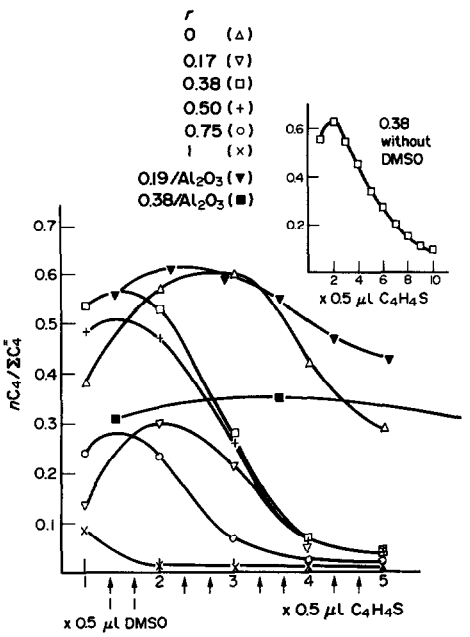

Fig. 3. Butane–butenes ($nC_4/\sum C_4^=$) ratios during subsequent pulses (see also caption to Fig. 2).

pulse would be sufficient to sulfide about 1% of the catalysts and the maximum upper limit of sulfidation at maximum activity—pulse 2—would be 5–10%, even if all the DMSO were used for catalyst sulfidation. This may mean that the most active surface species may be Mo oxysulfides. Delgado *et al.*[15] argue that a further reduction of Mo takes place under sulfidation (perhaps that of Mo^{4+} to Mo^{2+}) and this process can also contribute to the formation of catalytically active sites. Oxidic catalysts produce mainly fragments (pulse 1); upon partial sulfidation (pulses 2 and 3), hydrogenation activity is maximum, whereas HDS activity decreases monotonically during these, as well as subsequent pulses. Accumulation of carbonaceous residues may also occur (cf. the methane deficit in pulses 2 and 3) and this may be the reason why the surface S : Mo ratio was always lower when sulfidation was carried out with thiophene instead of H_2S.[10] Comparison with supported catalysts[11] indicates that the "Mo-type" activity profile having a maximum at low sulfidation levels is characteristic for samples with r between 0 and 0.38. This confirms the strong interaction between the Co–Mo species and the support up to a higher Mo content and also shows that $CoMoO_4$ species—present here in ample amounts—may not be precursors of catalytically active species on an Al_2O_3 support. Supported catalysts show a similar behaviour in hydrogenation selectivities but a much more stable HDS activity.

(*Received* 21 *June* 1985)

Abstract—Unsupported MoS_2 samples with surface areas ranging from 1 to 83 $m^2\ g^{-1}$ were prepared by treatment of different precursors in a H_2–H_2S atmosphere at 673 K. Their catalytic properties were determined for several hydrotreating reactions. Dibenzothiophene hydrodesulfurization, and biphenyl and cyclohexene hydrogenations were found to be "texture-insensitive", while pyridine hydrogenation and piperidine hydrodenitrogenation appeared to be "texture-sensitive". It is proposed that the catalytic sites responsible for the reactions involving nitrogen-containing molecules are different from those where other reactions take place. These sites probably contain more atoms and are more dependent on the environment. The peculiar nature of the sites of nitrogen-containing molecule reactions is supported by comparison of the catalytic properties of these MoS_2 samples with those of a cobalt-promoted molybdenum sulfide catalyst.

Recent work has shown the presence of several different functions on hydrotreatment MoS_2-based catalysts, i.e. hydrodesulfurization (HDS), hydrogenation (HN), hydrodenitrogenation (HDN), cracking (CK) etc . . . , and it has been assumed that these reactions utilize distinct sites. This hypothesis rests upon the different responses to preparation and pretreatment methods and to reaction conditions. For example, the presence of H_2S in the reactant flow has a higher negative influence in HDS than in HN, whereas H_2S improves the HDN function.[1]

The question of the nature of these sites is still under discussion. It is generally agreed that HDS reactions take place on sulfur vacancies, but their location is not firmly established, since some authors consider different activities for edge or basal sites in the MoS_2 structure.[2,3] In a recent paper, some of us have shown that the rates for HDS of dibenzothiophene and HN of biphenyl (BP) were proportional to the surface areas of unsupported MoS_2 and WS_2 catalysts. They have proposed that these reactions are "texture-insensitive"; this notion has been preferred to the "structure sensitivity" one because significant modification of H_2S pressure may alter the S/metal ratio which can modify the rate constants.[4]

Moreover, literature data show that it is not certain that HN of aromatics or olefinics implies the same type of sites and their location seems to be different from that of the HDS sites.[5] As a matter of fact, many of the HN studies have been deduced from selectivity measurements during HDS reactions.

Concerning HDN sites, only a few papers deal with their nature. Satterfield and Yang[6] suggest that C—N bond hydrogenolysis occurs on Brönsted acidic sites resulting from the dissociative adsorption of H_2S on anionic vacancies of the sulfide. Laine[7] proposes that the first step of the C—N bond cleavage is the formation of a metalloazocyclic intermediate or an iminium complex on a metallic site of the active phase. However, no information is given about the location and complexity of these sites in the solid structure.

By analogy with the notion of reaction sensitivity

on metal catalysts, it seemed useful to investigate simple-model reactions with model catalysts in order to describe the variations of reaction rates with surface areas. Indeed, the existence of a simple proportionality between these parameters ("structure or texture sensitivity") would imply simple and (or) numerous catalytic sites, whereas the contrary would suggest the participation of sites with complex geometry and (or) limited number.

In the present work, a series of unsupported MoS_2 samples of varying surface areas were studied for several hydrotreating catalytic model reactions, viz. HDS of dibenzothiophene (DBT), HN of BP, cyclohexene and pyridine, and HDN of piperidine. For comparison, an unsupported molybdenum sulfide promoted by cobalt was also studied for the same reactions.

EXPERIMENTAL

Catalysts preparation

For the preparation of pure molybdenum catalysts, several precursors were used: (i) ammonium tetrathiomolybdate (ATTM), (ii) ammonium oxothiomolybdate (AOTM), (iii) commercial molybdenum trioxide (MoO_3), (iv) commercial metallic molybdenum (Mo), and (v) commercial molybdenum disulfide (MoS_2).

ATTM and AOTM were prepared by reacting MoO_3 with an aqueous solution of $(NH_4)_2S$ at 343 K. By crystallization at room temperature, the resulting solution led to ATTM; by evaporation to dryness at 343 K in the presence of traces of air, it led to AOTM.

For the preparation of the cobalt–molybdenum sample, the precursor was obtained by the homogeneous sulfide precipitation (HSP) method described by Candia *et al.*[8] The atomic ratio Co/(Co + Mo) was taken as equal to 0.3, which corresponds to the maximum of the synergetic effect in HDS.

The different precursors were heated in a flow of H_2–15% H_2S up to 673 K and kept at this temperature for 4 h. Changes in heating rates allowed us to obtain samples with different surface areas from ATTM and AOTM. After cooling down to room temperature under the sulfiding atmosphere, the samples were flushed with nitrogen and stored under argon in sealed bottles.

Catalytic-activity determination.

The catalytic activities were determined in dynamic microreactors, working in the gaseous phase, at low conversion and under atmospheric or medium high pressure. Rates were measured in the pseudo steady state. The reaction conditions are summarized in Table 1.

Surface-area measurement

The specific surface areas of the different catalysts were determined before and after reaction, since previous results had shown that a drastic decrease occurs during catalytic tests.[4] Measurements were performed gravimetrically (with a Sartorius 4102 microbalance) by the BET method, using argon as absorbent at 77 K. At this temperature, the area of an atom of argon, in the adsorbed state, was taken as equal to 13.4 Å^2. Samples were first treated *in vacuo* (1.3×10^{-3} Pa) at 673 K until a steady weight was obtained.[9]

RESULTS AND DISCUSSION

The initial and final (FSA) surface areas of the catalysts in $m^2\,g^{-1}$, the apparent activation energies in kcal mol^{-1}, and the specific (SR) and intrinsic (SR/FSA) reactions rates, respectively, in 10^{-8} mol $s^{-1}\,g^{-1}$ and 10^{-8} mol $s^{-1}\,m^{-1}$, determined at 530 K for the HDS of DBT and the HN of BP, at 523 K for the HN of cyclohexene and pyridine, and at 548 K for the HDN of piperidine, are given in Tables 2–6.

For HDS of DBT and HN of BP and cyclohexene, the intrinsic reaction rates are constant whatever the

nature of the precursor and the range of surface area values. These results are consistent with those of Furimsky and Amberg[10] concerning the HDS of thiophene, and of Thakur *et al.*[11] concerning this latter reaction and the HN of cyclohexene. They do not follow the results of Tauster *et al.*,[3] in which a direct proportionality between surface area and rate constant for HDS of DBT was not found. This discrepancy may arise either from our experimental conditions (low reaction temperatures and low order with respect to hydrocarbons) or from sample purity. One can conclude that these reactions are "texture-insensitive" and that the corresponding catalytic sites are rather simple.

For HN of pyridine and HDN of piperidine, the intrinsic rates are not constant and it was not possible to find a relationship with the nature of the precursor.

A particular behaviour of nitrogen-containing molecules also appears for the CoMo(HSP) catalyst. The activity of this latter sample was found to be 4–7 times higher than that of MoS_2 in HN of BP and HDS of DBT, respectively.[12] In the present work, the promoting effect of cobalt was nil for the reactions with pyridine and piperidine. In that case, however, cobalt has a clear effect on the textural stability of the catalyst. Therefore, we can conclude that the behaviour of reactions involving nitrogen-containing molecules is different from that of other model reactions studied. It must be emphasized that the reactions with nitrogen heterocompounds are performed under rather different experimental conditions. Actually, a high partial pressure of H_2S is necessary to get a measurable HDN rate. On the other hand, during these reactions, heavy by-products are formed and they may remain adsorbed on the surface after the outgassing treatment performed prior to the surface-area determination. Consequently, the values of the FSA have to be considered with caution.

Nevertheless, we believe that these observations are not sufficient to explain the different comportment of nitrogen-containing molecule reactions and, even if the variations in intrinsic rates are lower than one order of magnitude, we proposed that HN of pyridine and HDN of piperidine are "texture-sensitive". They would, therefore, take place on sites which are made up of a large number of atoms and are dependent on their environment.

EFFECT OF CATALYST COMPOSITION ON THE HYDROGENOLYSIS OF ANISOLE

M. K. HUUSKA*

Department of Chemistry, Helsinki University of Technology, SF-02150 Espoo 15, Finland

(*Received* 14 *June* 1985)

Abstract—The hydrogenolysis of anisole was studied in a fixed-bed reactor at 300°C and 5 MPa hydrogen pressure on pure carriers and different catalysts containing Mo or Ni. Catalysts based on an acidic carrier gave mainly phenol and methyl-substituted phenols. On catalysts without an acidic support very little methyl substitution occurred and the main products were phenol and cyclic hydrocarbons. Reaction mechanisms and the structure of possible active sites are briefly discussed.

Mo catalysts have been employed in the petroleum industry for hydrodesulfurization (HDS) and hydrotreating processes for a long time.[1,2] More recently, these catalysts have found extensive use in hydrorefining and hydrodeoxygenation (HDO) of shale oils, coal-derived liquids, and other synthetic crudes.[3,4]

The surface of the working molybdena–alumina catalysts can be envisioned to consist of the molybdena portion and the uncovered alumina portion. These parts of the surface can be studied separately by different methods. Gil Llambías *et al.*[5] applied electrophoretic migration and Mo extraction measurements for determination of the apparent surface coverages of differently prepared and treated molybdena–alumina catalysts. They came to the conclusion that the Mo is present on the alumina surface not exclusively as a monolayer but also forming patches in multilayers, even at low loadings. The usual Mo loadings of the industrial HDS catalysts (10–12 wt % of MoO_3) were found to cover up to 60% of the alumina surface. Chemisorption measurements have been widely applied to study the surface portions and active sites of Mo–alumina catalysts. For instance, Segawa and Hall[6] have reported that on a reduced Mo–alumina catalyst, CO_2 adsorbs selectively on the uncovered alumina portion of the surface, whereas NO adsorbs selectively on the molybdena portion, on coordinatively unsaturated sites. On the contrary, NH_3 and pyridine have been found to chemisorb *unselectively* on both the alumina and the molybdena portions of the surface.[7] It is evident that active sites acidic in nature exist on both portions of the catalyst surface.[8] However, the acid strength and character of these sites obviously are quite different due to the chemically different environments that they are located in.

In previous work we studied the hydrogenolytic reactions of anisole and some other oxygen-containing aromatics on a hydrocracking catalyst ($NiMo–SiO_2–Al_2O_3$) and an HDS catalyst ($CoMo–\gamma\text{-}Al_2O_3$).[9,10] It was concluded that the hydrogenolysis of anisole may take place via different reaction routes depending on the nature of the catalytically active sites involved in the reactions. Thus, reaction (1) in Fig. 1 occurs predominantly on acidic sites of the carriers, whereas reactions (2) and (3) are catalyzed by sites which possess some hydrogenation–dehydrogenation activity, i.e. active sites on the metals or metal sulfides.

In the present work simple catalytic materials, including pure carriers and unsupported metal sulfides, were used to study the hydrogenolysis of anisole in order to confirm the reaction pathways proposed in Fig. 1 and to further elucidate the reaction mechanisms.

EXPERIMENTAL

All chemicals were pure or analytical-grade reagents. Hydrogen was laboratory grade and was used without further purification.

* Present address: Chemical Laboratory, Technical Research Centre of Finland, Biologinkuja 7, SF-02150 Espoo 15, Finland.

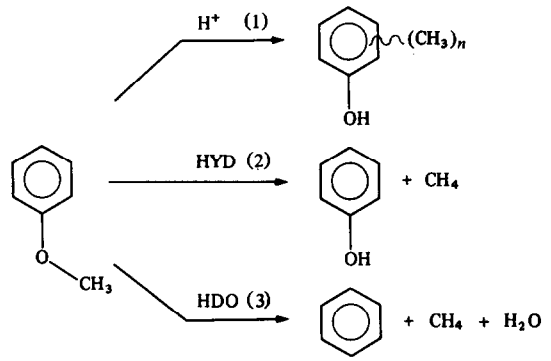

Fig. 1. Reaction pathways in the hydrogenolysis of anisole.[9,10]

The composition and major properties of the catalysts studied are listed in Table 1. Most of the catalysts were commercial samples. Catalyst C, unsupported MoS_2, was prepared by pressing small tablets from a pure MoS_2 powder, followed by crushing and sieving. Catalyst G was prepared by impregnating γ-Al_2O_3 tablets with a dilute nickel acetate solution, drying and calcining at 500°C. Catalysts D–G were sulfided *in situ* at 275°C and 5 MPa hydrogen pressure with a feed containing 0.5 vol % CS_2 in benzene for 4–5 h (LHSV = 2.0 h^{-1}). Catalyst E was studied also in the unsulfided (oxidic) form.

The fixed-bed tubular reactor and its use have been described previously.[9] The catalyst load was usually 5 cm^3 but in the case of the unsupported MoS_2 catalyst 8 cm^3 was used. The feedstock was neat anisole containing 0.05 vol % CS_2 in order to maintain the catalyst in the sulfided state. With catalysts A, B and E in unsulfided form no CS_2 was added to the feed.

Product analysis was carried out with gas chromatography, mainly as described earlier.[9] Some analyses were also done with a HP 5880 A equipment applying silica capillary columns. Water content of the feedstock and the reaction products was analyzed by Karl Fischer titration using an electrometric end-point recognition. Anisole feed was found to contain less than 0.1 wt % water. The reaction products contained up to 6 wt % water depending on the extent of the HDO reaction.

RESULTS AND DISCUSSION

In order to obtain comparable results most of the runs reported in this paper were carried out under fixed reaction conditions: temperature 300°C, pressure 5 MPa of hydrogen, H_2/anisole molar ratio $\simeq$ 100, and LHSV = 2.0 h^{-1}. For catalyst C a lower space velocity of 1.0 h^{-1} was applied due to the low surface area of this catalyst. Normally, over 90% of the reaction product could be accounted for. The selectivities, calculated on the basis of anisole reacted, were normalized to 100% of the conversion. The results are shown in Table 2. On some catalysts a steep decrease in activity was observed at the beginning of a run. To level off this initial high activity and to stabilize the reaction products runs were continued for a few hours before representative samples were taken.

Carrier materials

On the pure carrier materials studied, γ-Al_2O_3 and SiO_2–Al_2O_3, the main reaction products were phenol and methyl-substituted phenols. On SiO_2–Al_2O_3 appreciable amounts of methyl anisoles, *o*-methyl anisole dominating, were also formed. The loss of methyl groups as methane was minor as was the formation of hydrocarbons.

The conversion of anisole dropped quickly. For both carrier materials studied it was approximately halved during the first 4 h on stream.

It can be concluded that in the hydrogenolysis of anisole the acidic carriers exhibit only isomerization and methyl group transferring activity but no

hydrogenation or HDO activity. The reactions of the methyl groups proceed most probably through a carbonium ion mechanism.[10] The rapid deactivation of the carriers is obviously due to carbon deposition on the catalyst surface as the coke-forming precursors cannot be hydrogenated to desorbable products.

Unsupported MoS_2

The conversion of anisole was on this catalyst surprisingly high in spite of the very low surface area. The product distribution was simple: mainly phenol and benzene. Only minor amounts of methyl-substituted products were formed. The catalyst was stable and no deactivation could be noted in 5 h. Very similar results have also been obtained on an unsupported WS_2 catalyst (surface area 2.6 m^2 g^{-1}).[11]

It is obvious that on unsupported sulfide catalysts of this kind hydrogenolysis activity is the dominating catalytic function and acidity, if present in any appreciable amount, does not take part in the reactions. It may be envisioned that the radicals, formed through homolytic splitting on the catalyst surface, are immediately hydrogenated by adsorbed hydrogen atoms to products readily desorbable.[10] This scheme explains the high activity of these low-area catalysts: as the adsorbed species stay only for a very short moment on the surface high turnover numbers of individual sites can be reached.

$Ni–SiO_2$

Silica is usually regarded as a rather inactive carrier material for catalysts[12–14] and the results obtained in the present study support this view. The conversion of anisole was very low and the product distribution nearly the same as on the unsupported MoS_2 catalyst. The finding that despite a very large surface area (see Table 1) the activity of the $Ni–SiO_2$ catalyst is low may be due to a very poor dispersion of the metal or to a low activity of the sulfided Ni for this type of reaction. The latter explanation is more probable because the Ni load was quite high (11%).

$Mo–\gamma\text{-}Al_2O_3$

This catalyst gave high conversion of anisole both in the sulfided and unsulfided forms. The sulfided form was found to be more stable but in product distribution no clear differences were noted. It is known that hydrodenitrogenation reactions, in contrast to HDS reactions, take place on the oxidic as well as on the sulfidic forms of the CoMo–alumina catalysts.[15] It has been even reported that in the HDO of 1-naphthol the oxidic forms are, especially initially, more active than the sulfidic forms.[16] Thus the results obtained in the present work are in accordance with previous knowledge.

In addition to the main reaction products, phenol and *o*-cresol, 2,6-dimethylphenol was also formed in appreciable amounts. The share of methylated anisoles was very small, especially compared to that obtained on pure carriers. Nearly similar reaction products have been obtained also on oxidic $Cr–\gamma\text{-}Al_2O_3$ catalysts.[17]

The HDO activity of the $Mo–\gamma\text{-}Al_2O_3$ catalyst was much lower than found previously for sulfided $NiMo–SiO_2–Al_2O_3$ and $CoMo–\gamma\text{-}Al_2O_3$ catalysts.[10] Ni and Co evidently are effective promoters

for the Mo catalysts not only in HDS reactions but also in HDO reactions.

Ni–γ-Al_2O_3

The two Ni–alumina catalysts studied, F and G, contained very different loadings of Ni, viz. 11 and 0.5%. Catalyst G, with the low loading of Ni, surprisingly gave a higher conversion of anisole than any of the other catalysts studied in this work. The reaction product consisted exclusively of phenol and methyl-substituted phenols. This high activity can be explained as follows: the γ-Al_2O_3 carrier is a very active catalyst in isomerization and disproportionation of methylated phenols *initially*, but due to a high rate of coke formation the activity decreases steeply as was noted for catalysts A and B. A small amount of Ni inhibits this deactivation by hydrogenating the coke-forming precursors on the catalyst surface. Some kind of spillover mechanism can be envisioned to transfer hydrogen atoms from the metal to alumina. It is also possible that during the impregnation stage of the catalyst preparation Ni adsorbs mainly on the most active sites which otherwise would form the coke-forming centers.

On catalyst F the main reaction products were phenol and benzene as on catalysts C and D. Thus it may be concluded that a high metal load is essential for HDO of anisole. Catalysts D and F contained equal amounts of Ni (11%) but on different supports. The higher activity of the alumina support is clearly noted. However, the Ni–SiO_2 catalyst is more active in HDO of anisole. It is evident that strong metal–support interactions may play important roles in the catalytic reactions of anisole but these questions are outside the scope of this paper.

Concluding remarks

The results obtained on different catalysts indicate that the reactions proposed in Fig. 1 are characteristic of the catalytic hydrogenolysis of anisole. Whether the HDO reaction takes place directly from anisole or via phenol as an intermediate is not clear. However, if the dissociative adsorption of anisole as a phenoxide ion or a phenoxy radical is accepted,[10] the direct splitting of a methoxy group can be ruled out.

Abstract—The poisoning of a Co–Mo–alumina hydrodesulphurization (HDS) catalyst by metal-free, vanadium and nickel etio- and tetraphenyl porphyrins and the binding and reactivity of the porphyrins on oxide and sulfide surfaces is described. The surface interactions of porphyrins were studied by adsorption from solution, and UV–visible diffuse-reflectance and ESR spectroscopy. Metalloporphyrins undergo demetallation at acidic sites. The porphyrin ring is oxidized at a *meso*-carbon by oxomolybdenum(VI) species and adsorbed oxygen to a cation radical and an oxophlorin. During HDS porphyrin bound to the catalyst is hydrogenated at the *meso*-carbon to phlorin. Interaction of the porphyrins with surfaces is similar to that of polynuclear aromatic hydrocarbons. The relevance of these results to catalyst deactivation and catalytic demetallation is discussed.

Hydroprocessing catalysts are poisoned by metalloporphyrins in petroleum crudes. In this paper we report a study of the interaction of vanadium and nickel etioporphyrin (ETP) (**1a**) and tetraphenylporphyrin (TPP) (**1b**) and the metal-free porphyrins with molybdenum-based catalysts. Our object was to discover specific interactions between the porphyrins and the molybdenum species in the catalysts.

EXPERIMENTAL

The catalytic hydrodesulphurization (HDS) of thiophene (i.e. reaction with hydrogen with elimination of H_2S) was studied at 250–350°C and 1 atm in a conventional flow microreactor.[1] The catalyst was a commercial Co–Mo–Al_2O_3 catalyst (Co 3.2 and Mo 7.7 wt %, surface area 268 $m^2\ g^{-1}$). The catalyst was presulphided in H_2S/H_2. Thiophene was injected into the inlet dihydrogen. In the poisoning experiments, solutions of porphyrins in dichloromethane were injected in successive por-

tions onto the catalyst bed. Surface concentrations of the porphyrins were *ca* 10^{-5} mol (g catalyst)$^{-1}$, equivalent to *ca* 0.2 wt % V or Ni.

UV–visible diffuse-reflectance spectra (DRS)[2] and ESR spectra[3] of the supported porphyrins were recorded.

The amount of porphyrin adsorbed by the catalysts was determined from the decrease of light absorbance of porphyrin solutions in dichloromethane contacted with the catalysts.

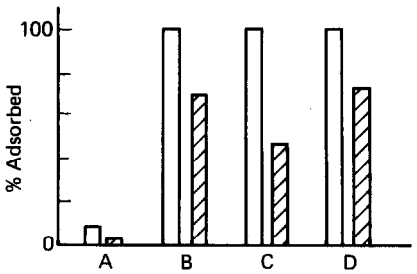

Fig. 2. Adsorption of H_2ETP (open) and VOETP (hatched bars) (10^{-3} mol l^{-1} in CH_2Cl_2) by γ-alumina (A), MoO_3–Al_2O_3 (B), CoO–MoO_3–Al_2O_3 (C) and MoS_2 (D).

RESULTS AND DISCUSSION

Catalyst deactivation

Thiophene conversions at 300°C are plotted against the amount of porphyrin added to the catalyst in Fig. 1. Poisoning of the catalysts is shown by the decrease of thiophene conversion. We observe:

(a) The metal-free porphyrins are initially more severe poisons than the metalloporphyrins. Evidently the whole metalloporphyrin molecule, not just the metal, poisons the catalyst.

(b) The first additions of VOETP increase the catalytic activity. With NiETP the activity is, at first greater, than with the metal-free H_2ETP. Therefore, either the metalloporphyrins are themselves active in HDS or, more likely, they are part demetallated and the metal ions released promote the HDS reaction until the poisoning effect of increasing amounts of porphyrin becomes dominant.

The poisoning and promoter effects imply that the porphyrins bind and decompose at molybdenum sites.

Adsorption of porphyrins by the catalysts

The catalysts, and also γ-alumina and MoS_2 were suspended in solutions of the porphyrins in dichloromethane (10^{-3} mol l^{-1}) and the amount of porphyrin adsorbed was determined from the decrease of light absorbance of the solutions. In Fig. 2 we show the relative amounts of H_2ETP and VOETP adsorbed. We observe:

(a) A strong interaction with the molybdenum-containing catalysts, especially MoS_2. (Note that the surface area of MoS_2 was <10 m^2 g^{-1}.)

(b) The amount of metal-free porphyrin, H_2ETP, adsorbed is greater than that of VOETP; the adsorption of VOETP is greater on MoO_3–Al_2O_3, which is more acidic, than on Al_2O_3. These two observations suggest that acidic sites, Lewis sites or surface protons, may be involved in the adsorption process.

In an earlier paper[3] we suggested, from an analysis of the ESR parameters of adsorbed VO porphyrins, that metalloporphyrins lie flat on the support and bind to the surface via a charge-transfer interaction from the π-system of the porphyrin ring to surface acceptor sites. The fraction of the surface covered when a porphyrin monolayer is established is $<5\%$ of the available surface. Evidently there are preferred binding sites, possibly flat slabs with acidic molybdenum species.

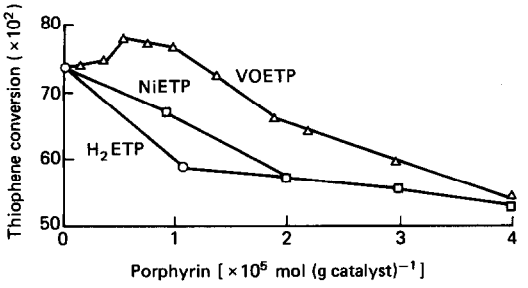

Fig. 1. Poisoning of a Co–Mo–Al_2O_3 catalyst by metal-free (H_2ETP), nickel (NiETP) and vanadyl (VOETP) ETP. Thiophene conversion (300°C, 1 atm) vs porphyrin concentration on the catalyst.

Demetallization

DRS of the porphyrins on the catalysts and acidic supports are shown in Fig. 3. For the more acidic supports, HF–SiO_2 and NiO–MoO_3–Al_2O_3, we see absorption peaks of protonated porphyrins. These peaks are not observed on the less acidic alumina. Demetallization of VOTPP on HF–SiO_2 and NiO–MoO_3–Al_2O_3 is evident from the appearance of a new peak in the spectrum at 650–660 nm assigned to the protonated porphyrin released by demetallization. There is no such peak on alumina. Thus interaction with surface protons causes demetallization of VOTPP. There appears to be no, or much less, decomposition of VOETP. Instead with VOETP a new peak appears near 650 nm; this is discussed later.

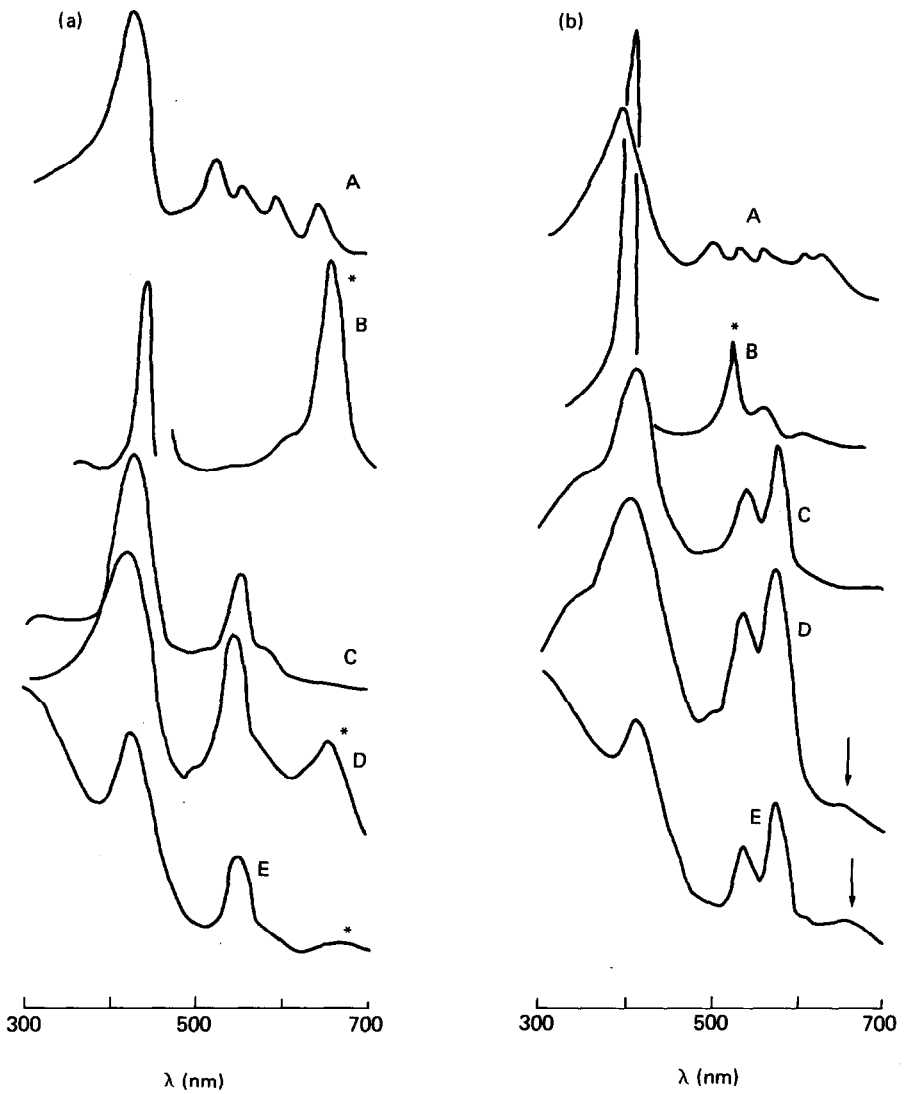

Fig. 3. UV–visible DRS of surface-bound porphyrins [*ca* 5×10^{-6} mol (g catalyst)$^{-1}$]. (a) Tetraphenylporphyrin (TPP): H_2TPP on Al_2O_3 (A) and HF–SiO_2 (B); VOTPP on Al_2O_3 (C), HF–SiO_2 (D) and NiO–MoO_3–Al_2O_3 (E). (b) ETP: H_2ETP on Al_2O_3 (A) and HF–SiO_2 (B); VOETP on Al_2O_3 (C), HF–SiO_2 (D) and NiO–MoO_3–Al_2O_3 (E). Light absorbance increases vertically. Peaks marked (*) characteristic of protonated porphyrin; vertical arrow, oxophlorin.

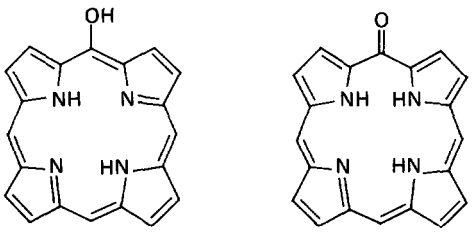

Oxidation of surface-bound porphyrin by oxomolybdenum (VI)

Porphyrins supported on MoO_3–Al_2O_3 and Co–Mo–Al_2O_3 were heated under nitrogen at 300°C. Typical ESR spectra are shown in Fig. 4. In the spectrum of H_2ETP on MoO_3–Al_2O_3 we see lines assigned to oxomolybdenum(V) ($g = 1.928$), oxomolybdenum(V) porphyrin ($g = 1.968$), and a porphyrin radical ($g = 2.003$).[4] Evidently the porphyrin has been oxidized to a cation radical by oxomolybdenum(VI) which has been reduced. The spectrum of VOETP similarly shows the lines of oxomolybdenum(VI) and the porphyrin radical, although not MoOETP. Similar results were obtained with NiETP.

The porphyrin radical was also observed for porphyrins on silica–alumina (but not alumina). Here the porphyrins are apparently behaving in the same way as adsorbed polyaromatic hydrocarbons, the oxidation being effected by adsorbed oxygen and surface protons.[5]

The effect on the UV–visible spectrum of heating the surface-bound metalloporphyrins was to collapse the peaks in the visible region. This change is consistent with formation of a porphyrin cation radical.[6]

We can now explain the new peak at *ca* 650 nm in

2a 2b

the DRS spectrum of VOETP on acidic supports (see Fig. 3). This peak is characteristic of an oxophlorin, i.e. a compound with O or OH at a bridging (*meso*) carbon (**2**).[7] We conclude, then, that surface-bound porphyrins oxidize to a cation radical and an oxophlorin. These reactions are well known in the solution chemistry of porphyrins but have not, as far as we know, been reported previously for surface-bound porphyrins.

Hydrogenation of surface-bound porphyrin

The ESR spectra of VOETP on a sulfided Co–Mo–Al_2O_3 catalyst which had been used for thiophene HDS are shown in Fig. 5. The significant feature is new lines (starred), in addition to those of VOETP, in the spectrum of the catalyst before it had been exposed to air. After exposure to air these new lines disappear and the spectrum is that of VOETP. Evidently the compound responsible for the new lines oxidizes in air. This behaviour is typical of a phlorin, i.e. a compound in which a *meso*-carbon has been hydrogenated (**3**).[8] We suggest, therefore, that during the HDS reaction the bound porphyrin is hydrogenated at a *meso*-carbon. The hydrogenation is presumably catalysed by MoS_2.

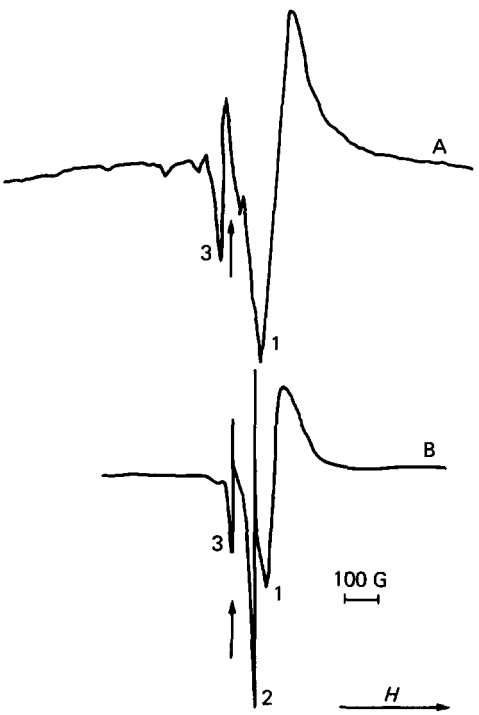

Fig. 4. ESR derivative spectra after heating (300°C, 1 h, under N_2): VOETP on CoO–MoO_3–Al_2O_3 (A) and H_2ETP on MoO_3–Al_2O_3 (B). Line assignments: (1) oxoMo(V) ($g = 1.928$), (2) oxoMo(V) porphyrin ($g = 1.968$), and (3) porphyrin radical ($g = 2.003$). Vertical arrow = DPPH calibrant.

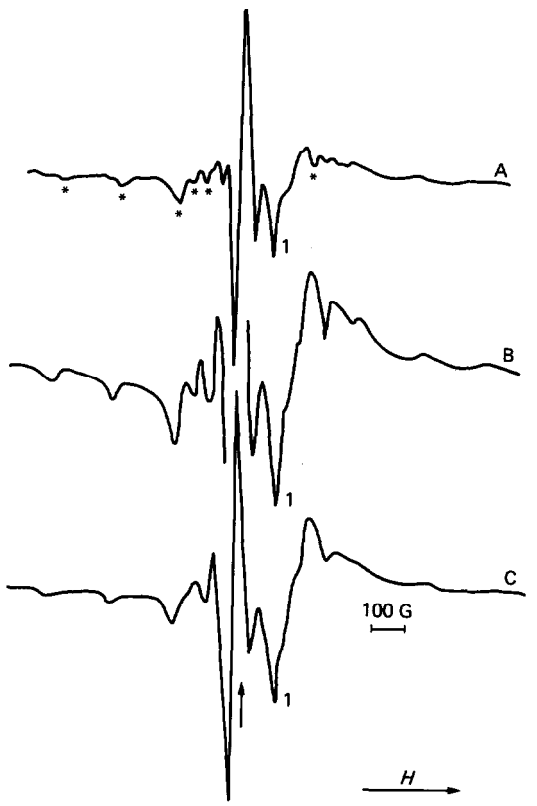

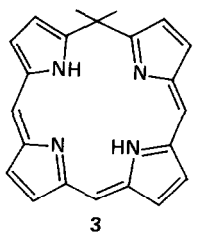

Fig. 5. ESR derivative spectra of VOETP (*ca* 0.2 wt %) on sulfided Co–Mo–Al_2O_3 catalyst after thiophene HDS: sample kept in nitrogen (A), exposed to air (B), and extracted with CH_2Cl_2 (C). Lines marked (*) are additional to those of VOETP and assigned to a VO phlorin; line 1 = oxoMo(V); vertical arrow = DPPH calibrant.

3

CONCLUSIONS

We identify three types of surface reaction of porphyrins with molybdenum-containing catalysts:

(a) demetallization by reaction with protons, (b) oxidation of the porphyrin ring by oxo-molybdenum(VI) at a *meso*-carbon giving a porphyrin radical and an oxophlorin, and (c) hydrogenation of the porphyrin also at a *meso*-carbon giving a phlorin. Further work is in progress to confirm these suggestions through synthesis of metallo-oxophlorins and phlorins and a study of their characteristic properties.

The significance of these observations for catalyst deactivation and demetallization is as follows. The initial poisoning by metalloporphyrins is due to the whole molecule, not just the metal; the porphyrins behave like nitrogen bases. Demetallization of the metalloporphyrins is accomplished by reaction with surface protons of acidic catalysts. Both oxidation and hydrogenation of the porphyrins are likely to increase their binding to acidic sites since oxophlorins and phlorins are more basic than porphyrins.[9] Also, for the oxophlorins, oxo or hydroxo groups in the porphyrin ring provide a further point of attachment to a surface. Increased binding may, of course, be desirable if the object is to prevent the porphyrin from passing through the HDS catalyst. On the other hand increased binding is likely to mean more poisoning. The practical conclusion would seem to be that porphyrin removal, and the accompanying chemistry, is best done before the hydroprocessing stage on, for example, an MoO_3–Al_2O_3 catalyst in a guard reactor.

SUPPORT EFFECTS ON HYDROCRACKING AND HYDROGENATION ACTIVITIES OF MOLYBDENUM CATALYSTS USED FOR UPGRADING COAL-DERIVED LIQUIDS

A. NISHIJIMA,* H. SHIMADA, T. SATO, Y. YOSHIMURA and J. HIRAISHI

National Chemical Laboratory for Industry, 1-1, Higashi, Yatabe, Ibaraki 305, Japan

(*Received* 13 *June* 1985)

Abstract—Studies of the effect of supports on the molybdenum catalysts used for upgrading coal-derived liquids showed that hydrocracking and hydrogenation activities are greatly dependent upon their supports. The relation between catalytic selectivities and properties of the molybdenum catalysts were investigated by using an X-ray photoelectron spectrometer and a Raman spectrometer. A TiO_2 support gave the highest hydrocracking activity among simple oxides examined, while a Al_2O_3 support showed the highest hydrogenation activity. Both hydrocracking and hydrogenation activities of the molybdenum catalysts increased when some double oxides such as TiO_2–Al_2O_3 or TiO_2–ZrO_2 were used as catalyst supports.

Molybdenum catalysts have been much used in the petroleum industry for hydrotreating and hydrodesulfurization. Recently, these catalysts have been employed in coal liquefaction and upgrading of coal-derived liquids. However, improvement of the selectivity of the molybdenum catalysts for hydrocracking (HC) and hydrogenation (HY) activities is required for upgrading the coal-derived liquids and producing effective recycle solvents. In this work, the support effect on the selectivity of the molybdenum catalysts was investigated to find the most suitable supports by which higher HC and HY activities of the catalysts could be obtained. The catalysts were characterized using an X-ray photoelectron spectrometer (XPS) and a Raman spectrometer. The reactions of separate model tests, as well as the upgrading of coal-derived liquids, were performed to clarify catalytic functionalities of the catalysts. A high hydrogen pressure was used for the test reactions; experiments in previous studies of the support effects have been undertaken under atmospheric pressure.[1,2]

EXPERIMENTAL

TiO_2 and ZrO_2 supports were prepared by precipitation from aqueous solutions of $Ti(SO_4)_2$ and $ZrOCl_2$, respectively. Some double oxides such as TiO_2–Al_2O_3 or TiO_2–ZrO_2 were also prepared by similar methods. Commercially available supports, such as Al_2O_3 and SiO_2, were used as catalyst supports. A series of Mo and Ni–Mo supported catalysts were prepared by an impregnation method. The supports prepared were impregnated in a solution of ammonium paramolybdate or solutions of ammonium paramolybdate and nickel nitrate.[3] Catalysts were then dried at 110°C for 10 h, and finally calcined at 500°C for 4 h. The catalysts were presulfided in a stream of 10 vol % of H_2S (balance H_2) at 400°C for 2 h before reaction.

The reactions of upgrading of coal-derived liquids and the separate model tests were carried out using batch type reactors (50 cm^3). Ten cubic centimetres of coal-derived liquid and 0.5 g of catalyst were charged into the reactor. After being pressurized with H_2 to 9.8 MPa, the microreactor was injected into an oven heated at 430°C. The temperature of the reactor was kept at 400°C during the 2-h reaction. An initial H_2 pressure of 6.9 MPa was used for HC of diphenylmethane and HY of 1-methylnaphthalene. Reaction products were analyzed by a gas chromatograph and a mass spectrometer. The surface area and the pore volume of each catalyst were measured by a nitrogen adsorption technique and a BET method. Temperature-programmed desorption (TPD) of NH_3 was employed to measure

* Author to whom correspondence should be addressed.

acidic properties of the catalysts. The characterization of the molybdenum catalysts, such as the electronic state or the structure of the molybdenum species, was carried out using XPS, a Raman spectrometer and an X-ray diffractometer.

RESULT AND DISCUSSION

Simple-oxide support

Table 1 shows the catalytic functionalities of the molybdenum catalyst obtained on each support. Among simple oxides examined, the effectiveness order of the support for HC and HY is as follows:

$$\text{HC: } TiO_2 \gg SiO_2 > ZrO_2 > Al_2O_3 \gg MgO,$$

$$\text{HY: } Al_2O_3 > TiO_2 \gg MgO > ZrO_2 > SiO_2.$$

The TiO_2 support gave the highest HC activity, while the MgO support gave no activity for HC. In the case of HY activity, the Al_2O_3 support showed the highest HY activity. The TiO_2 support also gave a higher HY activity compared to other supports. The HY activity increased with the increase in the surface area of the catalyst, when the chemical composition of the support used was the same. The HY activity also increased with the increase in the amount of MoO_3 supported on the carrier. However, after a certain amount of MoO_3, the HY activity remained constant. These results seem to indicate that a highly dispersed state of molybdenum species is required for the HY activity of the catalysts.

Characterization of the catalysts

Figure 1 shows Raman spectra of the molybdenum catalysts observed on various supports. In the Raman spectra, the bands between 900 and 1000 cm^{-1}, which were assigned to a Mo—O stretching vibration mode of the molybdenum species on the catalysts, shifted on changing the chemical composition of the support. The sharp bands at 998 and 820 cm^{-1} indicate the presence of crystalline MoO_3. Strong peaks of crystalline MoO_3 were observed on the SiO_2 support, though no peak was detected by the X-ray diffractometer. The poor dispersion of the molybdenum species on SiO_2 might result in a lower HY activity on SiO_2. The broad and intense band at 950 cm^{-1} shifted to 970 cm^{-1} when the support was changed from Al_2O_3 to TiO_2. This result shows the presence of a more highly aggregated molybdenum species on the TiO_2 support.[4] The spectrum of MoO_3–MgO may suggest the formation of a tetrahedral structure of MoO_4^{2-} on MgO.[5] Figure 2 shows Raman spectra of MoO_3–TiO_2 catalysts prepared as a function of Mo loading. At 2 wt % of MoO_3 loading a broad band at 945 cm^{-1} was observed. As the MoO_3 loading increased from 2 to 10 wt %, the band shifted to higher wavenumbers, reaching 970 cm^{-1}. This result shows a lower dispersion of the molybdenum species at a higher loading of MoO_3. After the monolayer coverage was exceeded (calculated to be about 8 wt %), sharp bands at 820 and 998 cm^{-1} ap-

peared, indicating the formation of crystalline MoO_3 on the TiO_2 support.

The relevant active sites of the molybdenum catalysts for HC have been considered to be acidic. However, no correlation was obtained under a high pressure of H_2 between HC activities and acidic properties of the catalysts measured by TPD of NH_3. The amount of acid sites on the TiO_2 support was much less than that on Al_2O_3, suggesting that all the acid sites cannot be active for HC. The XPS analyses showed that the binding energy of the Mo3*d* line shifted from 232.6 (MoO_3–Al_2O_3) to 231.8 (MoO_3–TiO_2), while that of the pure MoO_3 appeared at 232.4 eV (Fig. 3). The molybdenum ion on the MgO support was less electronegative (233.0 eV) than that on the Al_2O_3 support. Thus, the interaction between the support and the molybdenum affects the electronic state of the molybdenum ion. An electronegative state of the molybdenum ion will be necessary for the HC activity of the catalyst.

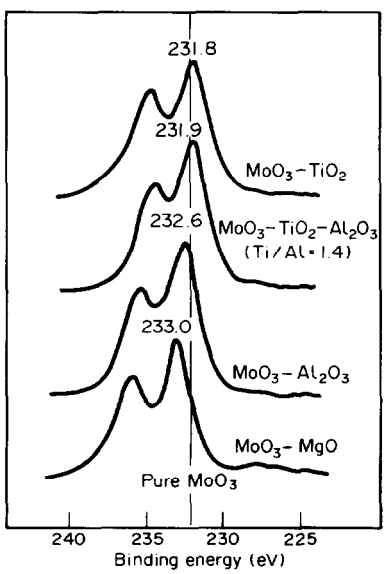

Fig. 3. Mo3*d* photoelectron spectra for molybdenum catalysts.

Double-oxide support

The TiO_2 support gave the highest activity for HC. On the other hand Al_2O_3 showed the highest HY activity. Accordingly, double oxides consisting of TiO_2 and Al_2O_3 were prepared by changing the atomic ratio of Ti/Al. Properties of the TiO_2–Al_2O_3 supports prepared are summarized in Table 2. Figure 4 shows the HC activities of the molybdenum catalysts when TiO_2–Al_2O_3 supports were used instead of simple-oxide supports. Much higher HC activities were obtained on TiO_2–Al_2O_3 supports, indicating a cooperative or a synergistic effect of both component supports. No peak was observed from three kinds of TiO_2–Al_2O_3 supports by the X-ray diffractometer. As shown in Fig. 3, the XPS analyses showed that the electronic state of the molybdenum ions on TiO_2–Al_2O_3 supports was almost the same as that on the TiO_2 support, showing that the molybdenum ions exist in a suitable electronic state for HC. On the other hand, in the case of HY activity, no cooperative effect was obtained on TiO_2–Al_2O_3 supports (Fig. 5).

Similar trends were observed on TiO_2–ZrO_2 supports. Figure 6 shows the effect of the supports on the HY activities of the catalysts. TiO_2–ZrO_2 supports also gave higher HC activities than the simple oxides (TiO_2 and ZrO_2). However, little cooperative effect was observed on TiO_2–MgO supports in the HC of diphenylmethane, though the

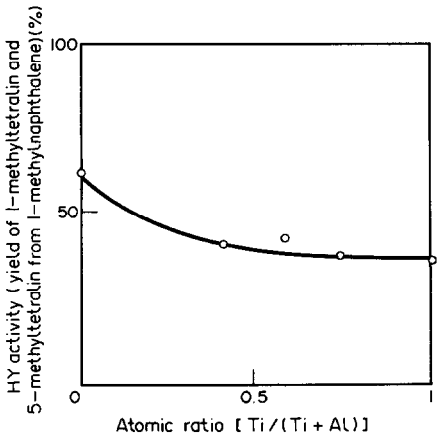

Fig. 5. Effect of support on HY activities of molybdenum catalysts.

HC activities on TiO_2–Fe_2O_3 supports increased to some extent (Fig. 7). These results clearly show that proper combinations of simple oxides, such as the combination of TiO_2 with Al_2O_3, are necessary to design suitable supports for the molybdenum catalysts.

Upgrading of coal-derived liquids

Based on the results obtained from the test reactions on various supports and the characterization of the molybdenum catalysts, some of the molybdenum catalysts were examined for upgrading coal-derived liquids. Middle and heavy distillates obtained from Wandoan coal were used as starting materials. After upgrading the coal-derived liquids, elemental anlyses, such as for nitrogen or sul-

[f] The heavy distillate contains 0.67 wt % of nitrogen.
[g] 10 wt % of MoO_3 was supported. Each catalyst was used as a powder.
[h] 2 wt % of NiO and 7 wt % of MoO_3 were supported. Extrudate catalysts were used.

fur, were performed to determine the hydrodenitrogenation and hydrodesulfurization activities of the catalysts. Ratios of tetralin/naphthalene and octahydrophenanthrene/phenanthrene measured by the gas chromatograph were used as the index of HY activity. The catalytic activities and selectivities of the catalysts used for the upgrading of the coal-derived liquids are summarized in Table 3. For the upgrading of the middle distillate, TiO_2 and Al_2O_3 supports showed higher hydrodenitrogenation (HDN) activities among the simple oxides. When Ni–Mo-supported catalysts were used, the HDN activities of the catalysts increased to a great extent. A $TiO_2-Al_2O_3$ support (Ti/Al = 2.5) gave a much higher HDN activity than the Al_2O_3 support. The effectiveness order of HY activities agreed with that measured in the HY of 1-methylnaphthalene. These results for the upgrading of the middle distillate are compatible with the results obtained from the catalytic functionalities of the catalysts. Similar trends were observed in the upgrading of the heavy distillate, though the HDN and HY activities of the catalysts for the heavy distillate were much lower than those for the middle distillate. Higher amounts of carbonaceous deposits were observed on the catalysts used for upgrading the heavy distillate, indicating deactivation of the catalysts in the early stage of the run.[6] In the upgrading of the heavy distillate, catalyst shapes will also affect the HDN activities of the catalysts because of the pore diffusional limitation. In fact, the powder catalyst ($MoO_3-Al_2O_3$) showed a higher HDN activity than the extrudate catalyst ($NiO-MoO_3-Al_2O_3$), though the pore structure of Al_2O_3 used was the same. The $TiO_2-Al_2O_3$ supports also showed much higher activities for HDN and HY than the Al_2O_3 support in the upgrading of the heavy distillate.

The HDN catalyst requires both HC and HY activities. As shown in Figs 4 and 5, $TiO_2-Al_2O_3$ supports showed higher activities for HC and HY. Moreover, the $TiO_2-Al_2O_3$ support showed excellent activities for HDN and HY of the coal-derived liquids (Table 3). Accordingly, $TiO_2-Al_2O_3$ supports seem to be suitable supports for the molybdenum catalysts used for hydrotreating coal-derived liquids.

(*Received* 26 *June* 1985)

Abstract—Molybdenum provides one of the most versatile sets of materials for synthesis gas catalysis. In its reduced states (Mo^0–Mo^{4+}), molybdenum can act as a "metal" system yielding mainly hydrocarbon products. In its oxidized state, as the trioxide or as a metal molybdate, molybdenum may serve as an alcohol synthesis catalyst or as an alcohol to hydrocarbon conversion system. The oxides can also be used as a support for more typical syngas catalysts. Molydenum hexacarbonyl undergoes chemistry which can be related to these reactions. These relationships offer a frontier between molybdenum homogeneous and heterogeneous catalysis. Literature and mechanistic studies indicate that the formate and formyl intermediates represent the link between homogeneous catalysis by molybdenum carbonyl and oxide catalysis of reactions of carbon monoxide. The formate approach centers on the fact that virtually all catalysts that have a water-gas shift activity will promote, or are themselves, methanol catalysts. It is more than coincidental that these two embodied reactions have been shown to involve a similar type of intermediate, metal formates. This moiety, found in base-promoted molybdenum carbonyl and molybdenum trioxide catalyzed water-gas shift reactions, symbolizes the link between these chemistries and the potential route to developing new methanol catalyst systems. The use of carbon monoxide and water, or low-H_2 : CO ratio syngas, for the direct production of methanol and/or hydrocarbons with heterogeneous molybdenum systems can be explained. The formyl approach is based on a stoichiometric reaction of some main-group hydrides with molybdenum carbonyl to yield methanol. This chemistry is related to metal oxide catalyzed methanol synthesis from high-ratio ($2:1 \leqslant H_2$: CO) syngas. The molybdenum carbonyl or oxide is used to coordinate or fix the carbon monoxide while another metal system functions by activating the hydrogen. This can be pictured as the reduction of a carbonyl group by a complex metal hydride. Initial demonstration of the conceptual basis of each of these approaches has been accomplished at Brookhaven National Laboratory. Concepts for the extension of homogeneous catalysis into these regions of overlap with some examples will be presented.

The chemical versatility of molybdenum can provide a fertile link between homogeneous and heterogeneous catalysis.[1] Connections and similarities in surface molybdenum oxide chemistry and homogeneously catalyzed reactions of molybdenum hexacarbonyl are found for example in olefin metathesis,[2] desulfurization,[3] aqueous coal liquefaction[4] and expoxidation reactions.[5] This paper will emphasize relationships in the synthesis gas reactions of molybdenum oxide and molybdenum hexacarbonyl. Since comparisons of catalytic behavior utilizing the same metal give more insight than comparisons involving different metals, the common features and the similitudes of active species and

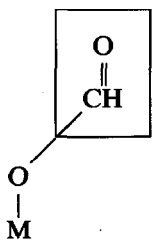
elementary steps in these reactions provided a guide for the design of new catalysts for the methanol synthesis.



Typically the scientist extracts interpretations of heterogeneous catalytic effects by examining the mechanism of homogeneous catalytic reactions. In this work homogeneous catalytic features were adapted to information concerning the mechanism of the reaction extracted from a variety of catalytic studies of heterogeneous molybdenum and related oxides. These include the water-gas shift reaction, methanol synthesis and the formic acid and methanol decomposition reactions.

BACKGROUND

There are two proposed mechanisms for the heterogeneous methanol synthesis reactions (Fig. 1).[6]

The key intermediates are the initially formed hydrogenated carbon monoxide species; the formyl group (1) in mechanism A and the formate (2) in mechanism B. These species represent the connection between homogeneous catalysis by molybdenum hexacarbonyl and oxide catalysis of reactions of synthesis gas.

Mechanisms A and B are interrelated. If one considers the surface in mechanism A (Fig. 1) to be a metal oxide, the formyl would be coordinated to an oxygen resulting in a metal formate species. In other words, the surface in mechanism B is the metal of the catalytic oxide. The carbon monoxide of mechanism A was activated by oxide coordination as in the carbon monoxide oxidation[7] reaction. Hydrogen is initially activated in a similar manner in mechanism B:

Metal oxides tend to yield methanol rather than hydrocarbons because this formate–oxyformyl "serves" the activated carbon monoxide to a hydrogenation site. The coordination of the carbon monoxide to the oxide inhibits dissociation and therefore hydrocarbon formation.[8]

Other work on the decomposition of metal formates demonstrates this proposition. This decomposition is thought to need vacant sites and is enhanced by the presence of foreign metal ions.[9] A bicoordinated structure is visualized from the "served" carbon monoxide which reacts by one of three pathways (Fig. 2).

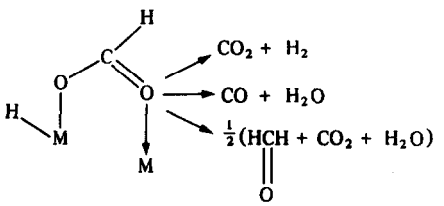


Fig. 2. Formate decomposition.[9]

Most interest in the literature has been focused

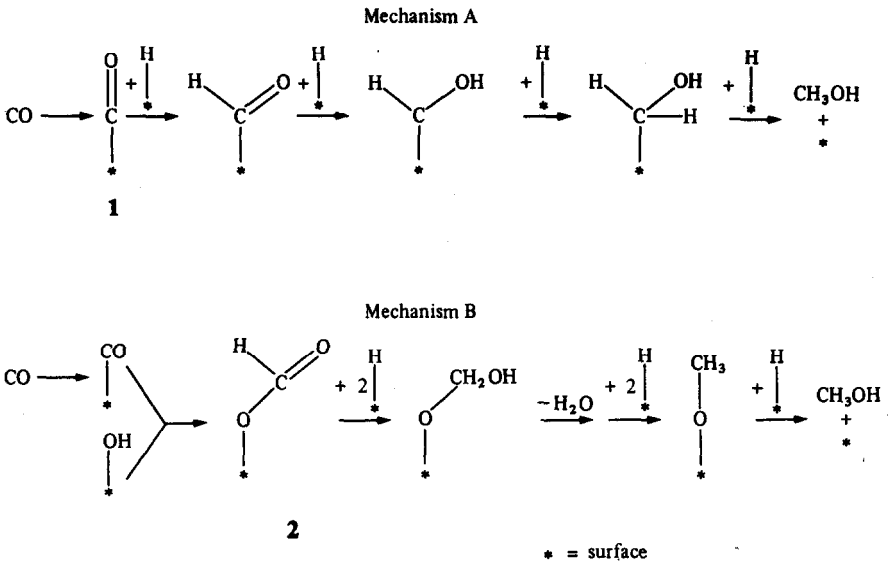

Fig. 1. Current methanol mechanisms.[6]

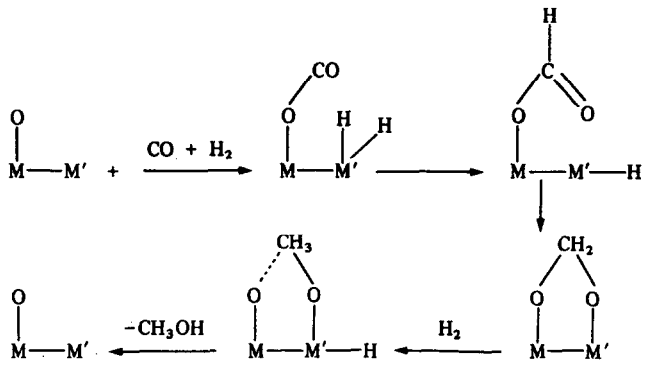

Fig. 3. Proposed methanol mechanism.

upon the dehydrogenation and dehydration reactions, but the minor reaction, which leads to the formation of formaldehyde, became the center of our attention. Although little data on this byproduct are available, and little is known about the mechanism involved, appreciable amounts (~10%) of formaldehyde are formed in formic acid decompositions catalyzed by thoria, molybdena and zinc oxide.[10] In fact, the high yield of formaldehyde (~25%) from the decomposition of zinc formate was the likely cornerstone of the earliest methanol synthesis.[11] If the site receiving the formate has the ability to hydrogenate the formaldehyde intermediate, methanol is generated.

The formaldehyde–formate relationship leads to an encompassing mechanism for the formation of methanol from synthesis gas which integrates identified reaction intermediates (Fig. 3).

With this mechanism as a guide to methanol synthesis, the chemistry of molybdenum offers an interesting model for study.

HETEROGENEOUS MOLYBDENUM AND METHANOL CATALYSIS

The chemical features of molybdenum are relevant to its role in the methanol mechanism described above: (1) In heterogeneous systems, substrates tend to react with oxide ions of the molybdenum oxide lattice. For example oxidation of carbon monoxide proceeds via nucleophilic attack on the lattice oxygen (Fig. 4).

This coordination of carbon monoxide occurs on a strong electron donor (Lewis base) molybdenum oxide surface.[12] (2) Molybdates also form the basis of a family of sulfur-tolerant water-gas shift catalysts. Formate is the intermediate in this chemistry.[13] (3) Formic acid decomposition over molybdenum oxides yields small, but measurable, amounts of formaldehyde.[10] (4) As these points suggest, the synthesis of methanol over complex molybdenum oxides is possible (a sluggish reaction under traditional commercial conditions.[14] Recently an alkali-promoted (which would increase formate) molybdenum on silica was shown to afford a more active system.[15] (5) Finally, most catalysts for the methanol synthesis are oxides developed by studying the methanol decomposition reaction and, although a poor synthesis catalyst, we also felt that the high selectivity molybdenum oxide exhibited for the oxidative dehydrogenation of methanol to formaldehyde could provide a similar model. Mechanistic considerations of this reverse reaction indicate initial dissociation to a surface methoxy species (**a**) followed by rate-determining breakage of the C—H bond of methoxy (**b**). Further reaction yields the formate species (**c**) and eventual decomposition to hydrogen and carbon monoxide (Fig. 5).

Since similar syngas species are found in $Mo(CO)_6$ chemistry, could these intermediates be directed to produce methanol?

Taken together these observations confirmed our mechanistic evaluation of methanol synthesis but, if one also considers homogeneous molybdenum hexacarbonyl chemistry, some interesting approaches to new catalyst design are possible.

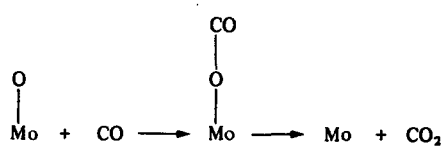

Fig. 4. Carbon monoxide oxidation

MOLYBDENUM HEXACARBONYL AND METHANOL CATALYSIS

To envision the catalytic system based on molybdenum hexacarbonyl for the reduction of carbon monoxide, the $Mo(CO)_6$ was substituted in function for the metal oxide surface (Fig. 6).

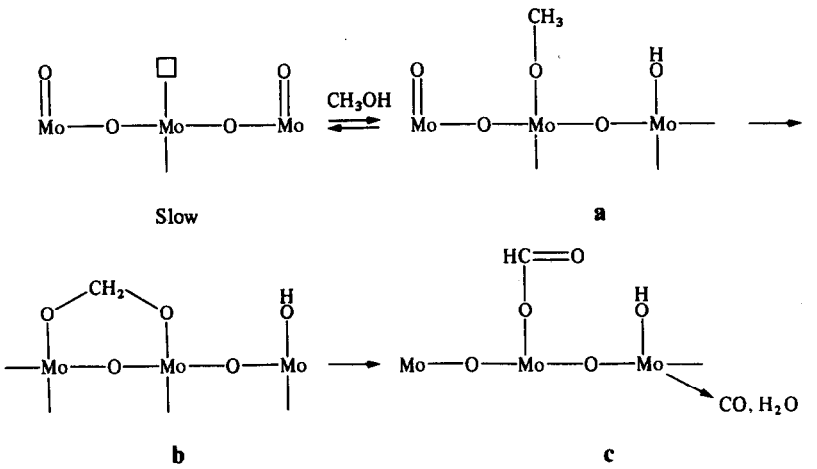

Fig. 5. Methanol dehydrogenation mechanism.[16]

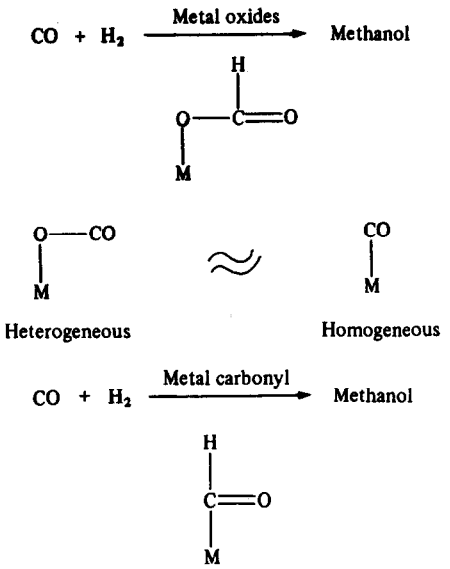

Fig. 6. Homogeneous methanol analogy.

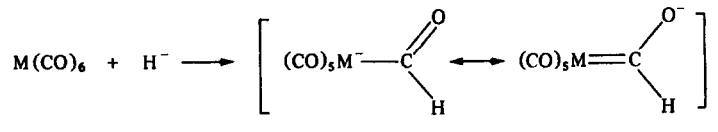
As in the heterogeneous system, to achieve the synthesis of the formyl intermediate a separate metal center would be needed for hydrogenation, e.g. the hydrogen attack must be external from the metal center coordinating the carbon monoxide. Work on stoichiometric reactions of carbon monoxide and metal hydrides provided the clue to this design.



When molybdenum hexacarbonyl was treated with lithium borohydride in wet tetrahydrofuran under carbon monoxide pressure at 70°C, methanol is produced in high yields. A blank reaction showed that the metal carbonyl was catalytic:[18]

$$CO + NaBH_4 \xrightarrow{Mo(CO)_6} CH_3OH.$$

The product arises from a nucleophilic attack by the hydride at the carbonyl carbon and results in the formation of a formyl–metal carbonyl anion (**d**) (Fig. 7). These anions have been isolated in similar reactions.[19]

This result showed that hydride attack upon molybdenum hexacarbonyl may be related to the methanol synthesis. To turn this stoichiometric reaction into a catalytic reaction a replacement for the hydride would be needed. Screening was started using complex transition-metal reducing agents, metal systems formed from salts with complex hydrides. These hydrogenate in a hydride-like manner.

The reducing agent nickel boride, formed from nickel acetate and sodium borohydride,[20] was selected. Indeed a cooperative effect of the heterogeneous nickle boride and molybdenum hexacarbonyl yielded methanol from carbon monoxide and hydrogen in tetrahydrofuran. This

d

Fig. 7. Hydride metal carbonyl reaction.

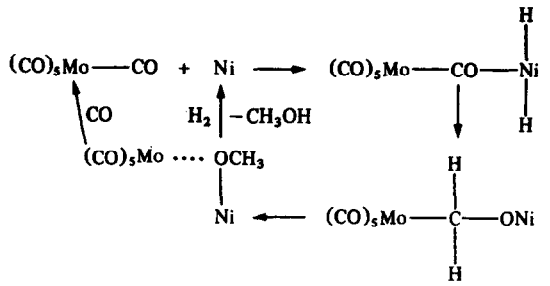


Fig. 8. Proposed reaction sequence.

system, although only very modest in activity, functions similarly to that described for the alkali hydrides but is catalytic in the hydrogenation function. Exploratory work directed toward improved design and formulation has begun.

Other, more active, heterogeneous nickel catalysts have also been developed. These catalytic systems are effective at temperatures below 150°C and have batch-measured volumetric activities equal to or greater than conventional methanol catalysts.[21]

It should be noted that the synergistic relationship of the heterogeneous nickel and homogeneous carbonyl offers a new approach to molecular catalyst design and reaction tailoring which to our knowledge has not been described in the literature. The possibility of reaction control and product selectivity is unique.

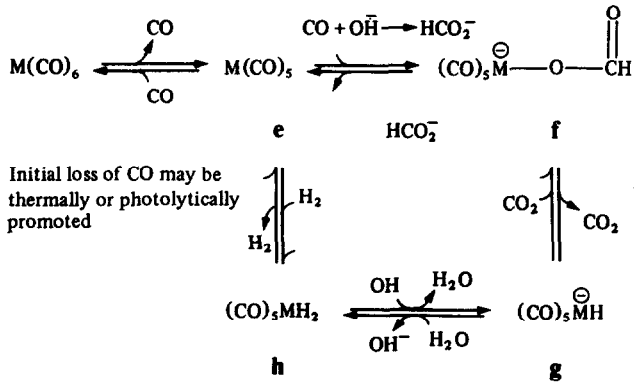
The molybdenum carbonyl in this system demonstrates a new mode of reaction in homogeneous catalysis. Normally a homogeneous catalyst must loose a ligand to be effective; an open site must be generated to coordinate the reactant molecule. The molybdenum carbonyl in the described methanol system already carried the activated reactant in a saturated (more stable) state. Upon hydrogenation, the reaction of the carbonyl ligand generates an open site on the catalyst, promoting further reaction. This may account for the activity of the catalyst system since the driving force to form the product is the reforming of the stable carbonyl. This also allows the catalyst to be effective at moderate or industrial pressures.

Another unique and important aspect is that the homogeneous catalyst, the molybdenum carbonyl, "carries" the preactivated carbon monoxide molecule to the heterogeneous nickel surface in a mode that is similar to the metal formate in traditional systems (Fig. 8). Since the reaction temperature is below the dissociation temperature of the metal carbonyl, it is likely that the carbon monoxide molecule is brought to the surface still coordinated and is placed, or "served", in the proper configuration for reaction. This would account for the lower reaction temperature since a lower activation energy is needed to reduce the carbon monoxide. In this configuration the molecule seems to be predisposed to form methanol rather than any other product. Typically, heterogeneous nickel catalysts give methane as the major product in synthesis gas reactions. The preactivated carbon monoxide also negates some of the poisoning effect that carbon monoxide has on hydrogenation catalysts. Since the heterogeneous catalyst is mainly a reducing agent, a great variety of systems are available for study.

The base-promoted molybdenum hexacarbonyl catalyzed water-gas shift reaction gave us an alternative approach to methanol catalysis.[22] The homogeneous mechanism is shown in Fig. 9.

An essential feature of this reaction is the intermediacy of the formate complex, **f**, formed from the reaction of a coordinately unsaturated metal carbonyl complex, **e**, with the formate ion, which in turn is formed by the facile reaction of carbon monoxide with the hydroxide ion.

From earlier discussions regarding heterogeneous catalysts, it is evident that this homogeneous formate complex might be reduced to methanol by the



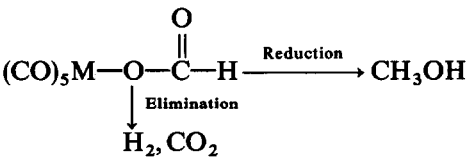


Fig. 9. Homogeneous water-gas shift mechanism.[22]

hydride complexes, **g** and **h**, in this reaction. These intermediates are generated by the base-promoted reaction of carbon monoxide and water so that methanol would be synthesized by the reaction:

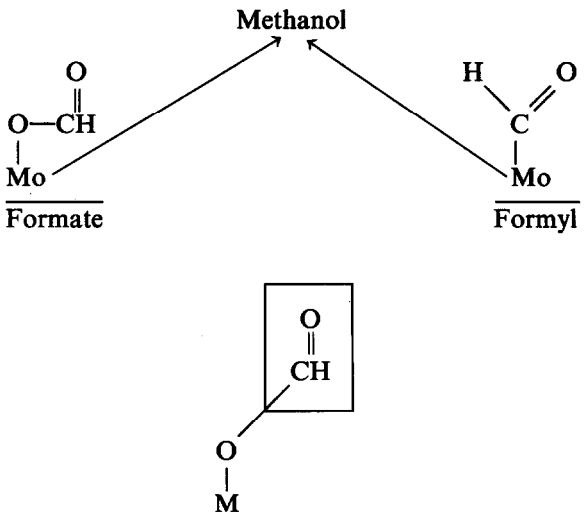
$$3CO + 2H_2O \rightarrow CH_3OH + 2CO_2.$$

In fact, molybdenum carbonyl does catalyze the formation of methanol from carbon monoxide and water at temperature below 150°C, making it one of the few effective homogeneous catalysts for methanol synthesis.

In attempting to improve the yields of methanol, several factors warrant particular attention. In this system the water-gas shift reaction competes with methanol formation, with the formate complex being the branch point:

Ideally, it would be desirable to minimize the tendency for carbon dioxide elimination or to enhance the rate of reduction of the formate complex. The molybdenum hydride complexes, **g** and **h** in Fig. 9, are notably poor reducing agents. On the other hand, particular metal carbonyls, notably osmium, form little hydrogen but are highly effective reduction catalysts under conditions comparable to those used. Preliminary experiments indicate that addition of very small quantities of osmium carbonyl afford substantial improvements in the yield of methanol with molybdenum carbonyl as catalyst.

Although this work emphasizes carbon monoxide plus water routes to methanol, the addition of hydrogen to these reactions also proves encouraging:



$$2CO + H_2O + H_2 \rightarrow CH_3OH + CO_2.$$

Improved yields of methanol can be achieved by the hydrogenation of formate complex with traditional reducing catalysts (Fig. 10). The experimental embodiment of these reactions was unusual in that, while the metal carbonyl formate complex was in a homogeneous phase, the hydrogenation catalyst was usually a heterogeneous solid.

The mechanism followed (Fig. 10) is similar to that proposed for commercialy heterogeneous catalysts (Fig. 3) in that the formate group delivers carbon monoxide to the hydrogenating center.

CONCLUSION

Connections between molybdenum hexacarbonyl and molybdenum oxide catalyzed synthesis gas reactions offer an interesting insight into the workings of methanol catalysts. Two interrelated routes are available:

and three stoichiometries (Fig. 11).

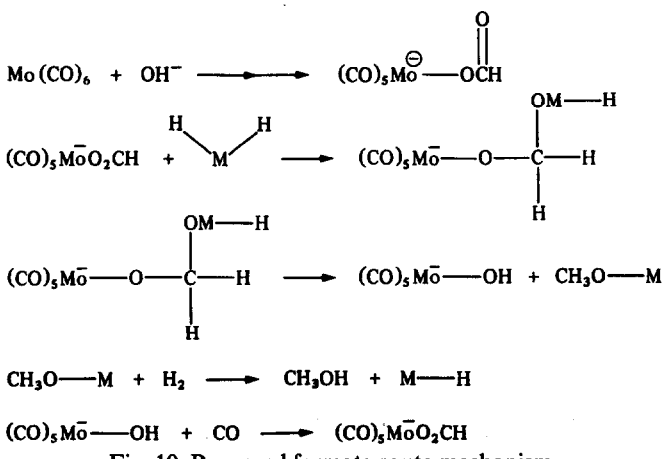


Fig. 10. Proposed formate route mechanism.

Formyl		Formate
$CO + 2H_2$	$2CO + H_2 + H_2O$	$3CO + 2H_2O$
$NiB_2 + Mo(CO)_6$	$Pd-Al_2O_3 + Mo(CO)_6$-base	$Mo(CO)_6$-base

EFFECTS OF Mo PRECURSORS ON THE ACTIVITY OF ALKALI-PROMOTED Mo CATALYSTS FOR ALCOHOL SYNTHESIS FROM CO–H_2

TAKASHI TATSUMI,* ATSUSHI MURAMATSU, TETSUYA FUKUNAGA and HIRO-O TOMINAGA

Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Tokyo 113, Japan

(*Received* 18 *June* 1985)

Abstract—Three Mo precursors, $(NH_4)_6Mo_7O_{24}$, $H_3PMo_{12}O_{40}$ and $MoO_2(acac)_2$ (acacH is acetylacetone), have been used to prepare SiO_2-supported Mo catalysts. SiO_2 was pretreated with either KCl or K_2CO_3. The effects of these Mo precursors on the activity and product selectivity of the Mo catalysts in CO hydrogenation were examined at 16 kg cm^{-2} and 573 K. Selectivity for alcohols vs hydrocarbons was greatly influenced by the precursors and K salts. Catalysts prepared from $(NH_4)_6Mo_7O_{24}$ and supported on KCl-treated SiO_2 had the highest activity and selectivity for alcohols. Catalysts prepared from $MoO_2(acac)_2$ produced mainly hydrocarbons. The observed changes in activity and selectivity with preparation method seem to be governed by the oxidation state of Mo.

The selective production of C_{2+} alcohols remains one of the main goals of syntheses from carbon oxides and hydrogen. The C_2–C_4 alcohols can be easily converted to the corresponding C_2–C_4 olefins to replace the manufacture of these important monomers from petroleum. Furthermore, the mixed alcohols can be used as additives in gasoline to enhance the octane number.[1] Since the use of methanol raises the problem of its solubility in the hydrocarbons, higher alcohols are better additives. While methanol synthesis from CO and H_2 is a mature process, direct synthesis of C_{2+} alcohols is only in the research and development stage. Recently, the Institut Français de Petrole patented a Co–Cu–K catalyst for synthesis of C_1–C_5 alcohols.[2] In the course of our study of the catalysis of supported Mo, we found that SiO_2-supported Mo catalysts, promoted by alkali-metal halides, give C_1–C_5 alcohols with good selectivity.[3] Here we report the effects of molybdenum precursors on the performance of the Mo catalysts.

EXPERIMENTAL

Catalysts (10 wt % Mo) were prepared by impregnating SiO_2 (Fuji Davison ID) with an aqueous solution of $(NH_4)_6Mo_7O_{24}$ or $H_3PMo_{12}O_{40}$ or an acetone solution of $MoO_2(acac)_2$ (acacH = acetylacetone). In most cases 1.67 wt % K^+ (K/Mo molar ratio = 0.4) was added to the silica by impregnation with KCl or K_2CO_3, followed by air calcination at 673 K for 1 h and then impregnation with the molybdenum salts. Catalysts were treated in flowing He at 673 K for 1 h and then reduced in flowing H_2 at 773 K for 12 h. The synthesis reaction was carried out in a stainless steel tubular reactor holding 1.0 g catalyst in a flow system. Reaction products were analyzed by GC using several columns. Details of the reaction and analysis will be published separately.

Catalytic surface areas of reduced, supported Mo catalysts were measured by O_2 adsorption at 195 K.[4,5] Prior to each adsorption measurement 0.4–0.5 g of catalyst was weighed into a Pyrex chemisorption cell. The material was next reduced as previously described and evacuated to 1×10^{-5} torr at 723 K for 2 h and then cooled to 195 K. The adsorption isotherm was measured at 195 K over a pressure range of 50–200 torr. The sample was then evacuated to 1×10^{-5} torr at 195 K and a second isotherm was determined. The difference between the two isotherms after extrapolation to zero pressure was assumed to be the amount which chemisorbed on the surface.

* Author to whom correspondence should be addressed.

The apparent oxidation number of the Mo on various catalysts was assayed by oxygen titration.[6] The reduced catalyst was flushed with He at 723 K and cooled to room temperature. Pulses of O_2 (<0.2 O/Mo) were injected into the He and consumption of O_2 was calculated from the amount which passed the catalyst. The catalyst was then heated stepwise up to 773 K while further pulses of O_2 were passed. The original oxidation number of the Mo could then be calculated from the total amount of O_2 consumed, assuming that Mo(VI) was the final product. X-ray powder diffraction measurements were performed using a Rigaku Denki diffractometer RU-200A with Cu-K_α radiation.

RESULTS AND DISCUSSION

The conversion and product distribution of the various Mo catalysts changed significantly with time on stream. Steady-state activities were reached within 24–100 h on stream, depending on the catalyst, and are summarized in Table 1. As is expected from the CO shift activity of the Mo catalysts, almost all of the oxygen in products leaves the reactor as CO_2 rather than as H_2O.[7–9] For this reason the product distribution is given on a CO_2-free basis.

The CO conversion over the Mo catalysts supported on KCl-treated SiO_2 depended on the Mo precursor in the following order: $H_3PMo_{12}O_{40}$ < $(NH_4)_6Mo_7O_{24}$ < $MoO_2(acac)_2$. However, the sample prepared from $MoO_2(acac)_2$ gave hydrocarbons as the major products. The selectivity for C_1–C_5 alcohols increased in the order

$$MoO_2(acac)_2 < H_3PMo_{12}O_{40} < (NH_4)_6Mo_7O_{24}.$$

Thus the catalyst derived from $(NH_4)_6Mo_7O_{24}$ was the most active in alcohol production. Incidentally, without KCl addition, Mo–SiO_2 gave hardly any alcohols.[3]

When K_2CO_3 was used in place of KCl, the selectivity for alcohols was slightly suppressed for both $(NH_4)_6Mo_7O_{24}$- and $H_3PMo_{12}O_{24}$-derived catalysts; the choice of precursor resulted in no significant difference in the product selectivity. In view of the higher CO conversion, however, $(NH_4)_6Mo_7O_{24}$ was a better precursor than $H_3PMo_{12}O_{40}$. It should be noted that C_{2+} alcohol/methanol ratios were higher for K_2CO_3-treated catalysts than for KCl-treated catalysts. The Mo catalyst derived from $(NH_4)_6Mo_7O_{24}$ and supported on KCl-treated SiO_2 proved to be the best one for alcohol synthesis. The product distribution was greatly dependent on the content of Mo and K and the reaction condition; the best catalyst gave C_1–C_6 alcohols with 80% selectivity by weight of the total product, exclusive of CO_2, and the space–time yield (STY) of the alcohols exceeded 400 g (kg catalyst)$^{-1}$ h^{-1}.[10]

Values of O_2 adsorption uptake following reduction, apparent oxidation number of the Mo and STY of alcohols and hydrocarbons are shown in Table 2 for Mo catalysts supported on KCl-treated SiO_2. There is no apparent correlation between initial CO hydrogenation activity and the quantity of oxygen adsorbed for fresh catalysts. The initial specific activity (CO turnover frequency) was estimated on the basis of site densities measured by O_2 adsorption assuming O/Mo = 1 and then listed in Table 2. The high initial specific activity of the catalyst derived from $MoO_2(acac)_2$ seems to be related to the low apparent oxidation number. The exact oxidation state of the surface Mo is uncertain. There is evidence from previous studies that the activity of reduced Mo for CO hydrogenation producing hydrocarbons increases with decreasing

oxidation state.[8] The lower initial specific activities of the samples prepared from $(NH_4)_6Mo_7O_{24}$ and $H_3PMo_{12}O_{40}$ are consistent with the higher oxidation number. There is no significant difference for the initial alcohol productivity of the three catalysts and no correlation of alcohol yield with oxygen uptake or average oxidation number was observed.

During reaction at 573 K for 50–100 h, the mass-based alcohol production activity of the $(NH_4)_6Mo_7O_{24}$-derived catalyst increased by a factor of 4, while the activities of the other catalysts increased by only 40–50%. The hydrocarbon production over the $(NH_4)_6Mo_7O_{24}$-derived catalyst increased, while the production over the other catalysts decreased slightly. The increase in alcohol yield for the $(NH_4)_6Mo_7O_{24}$-derived catalyst might be explained by formation of active sites induced by reduction with CO or CO–H_2.[10] These sites cannot be brought out by H_2 reduction and should be specific for alcohol synthesis. On the other hand, extensive reduction of Mo with H_2 occurred in the case of the $MoO_2(acac)_2$-derived catalyst, yielding active sites for hydrocarbon formation. Interaction of P and Mo seemingly caused a smaller increase in alcohol formation over the $H_3PMo_{12}O_{24}$-derived catalyst.

X-ray patterns for reduced Mo–SiO_2 contained lines characteristic of MoO_2 and Mo metal. In addition, the presence of KCl was evident for the catalyst derived from $MoO_2(acac)_2$. On the contrary, there was no XRD evidence of KCl for the catalysts prepared from $(NH_4)_6Mo_6O_{24}$ and $H_3PMo_{12}O_{40}$. These findings suggest that the Mo on the $MoO_2(acac)_2$-derived sample is hardly influenced by KCl, leading to a hydrocarbon-forming catalyst. The extensive reduction of molybdenum in this case could be a result of weak $MoO_2(acac)_2$–support interaction. It has been found that $H_3PMo_{12}O_{40}$ is more reducible than $(NH_4)_6Mo_7O_{24}$,[11] but the apparent oxidation number for the $H_3PMo_{12}O_{40}$-derived catalyst was found to be about the same as for the $(NH_4)_6Mo_7O_{24}$-derived catalyst. This behaviour may be explained by formation of K salts of $H_3PMo_{12}O_{40}$, which are much less reducible than $H_3PMo_{12}O_{40}$[12] on the catalyst surface. It is noteworthy that, without K salt addition, supported $H_3PMo_{12}O_{40}$ was a highly active catalyst for hydrocarbon formation.[10]

CATION–ANION EFFECTS IN HETEROPOLY COMPOUNDS WITH KEGGIN STRUCTURES

J. B. MOFFAT

Department of Chemistry and Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1

(*Received* 10 *June* 1985)

Abstract—In heteropoly compounds with anions of Keggin structure, the elemental composition of the anion has been shown, through temperature-programmed desorption, photoacoustic FTIR spectroscopy, and extended Hückel calculations, to influence the protonic mobility, the lability of the anionic outer oxygen atoms, and the surface and catalytic properties of these heteropoly solids. The nature and size of the cation, in addition to altering the catalytic activity and selectivity, has been demonstrated to have a significant effect on the pore structures of the heteropoly compounds, with some salts displaying microporosity, tentatively attributed to the shifting of anionic outer oxygen atoms to form channels from interstitial void spaces.

Heterogeneous catalysts have widespread application in industrial chemical processes as a means of directing reactions to the desired products at appreciable rates. Heteropoly compounds offer appealing characteristics as heterogeneous catalysts as a consequence of both their chemical and physical properties.[1–17] These compounds are complex ionic solids with large cage-like anions, the latter containing a minimum of three elements. The heteropoly compounds of interest in the present work have anions with a central atom such as phosphorus, silicon and arsenic, surrounded by four oxygen atoms arranged tetrahedrally. Twelve octahedra with oxygen atoms at their vertices and a peripheral metal atom at each of their centres envelope the central tetrahedron and share oxygen atoms with the latter and with each other (Fig. 1). A number of excellent reviews on heteropoly compounds may be consulted for additional details.[18–23]

Structures

What may well be the most definitive structural information on any heteropoly compound has been provided by Brown *et al.*[24] for 12-tungstophosphoric acid (HPW). Through X-ray and neutron diffraction techniques these workers have shown that the proton is surrounded by and coplanar with four water molecules, each with the oxygen atom pointing toward the proton (Fig. 2). A two-fold thermal disorder exists between the proton and four water molecules, so that the proton is hydrogen-bonded to only two water molecules at a given time. In turn the water molecules are hydrogen-bonded to the terminal oxygen atoms of the heteropoly anion (Fig. 3).

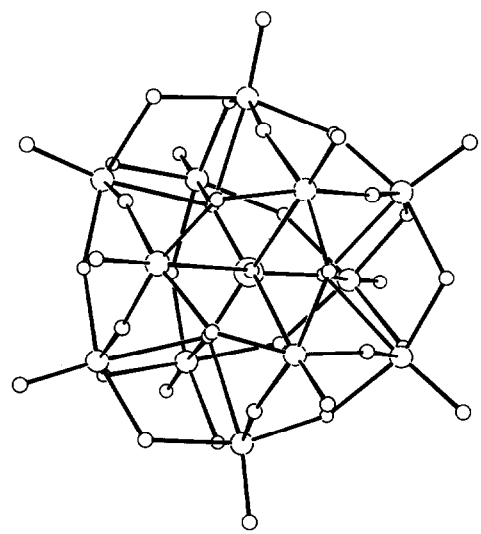

Fig. 1. Anion of 12-molybdosilicic acid ($SiMo_{12}O_{40}^{4-}$).

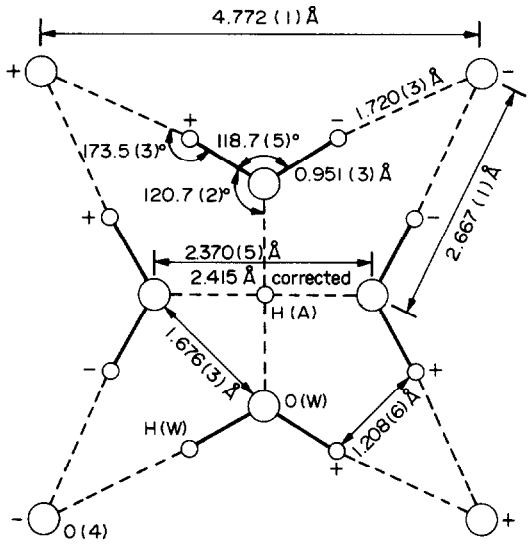

Fig. 2. Structural arrangement of the proton, four water molecules and oxygen atoms of the anions.[24]

Catalytic properties

In earlier work from this laboratory it has been shown that 12-tungstophosphoric acid catalyzes the conversion of methanol to hydrocarbons, although the selectivity is dependent upon both the pretreatment environment and temperature as well as the reaction conditions.[1] Substitution of silicon for phosphorus as the central metal atom in HPW produces a catalyst, 12-tungstosilicic acid (HSiW), which is only slightly reduced in selectivity for methanol conversion. However, 12-molybdophosphoric acid (HPMo), in which tungsten is replaced by molybdenum as the peripheral metal element, converts methanol to oxidation products such as carbon monoxide. Evidently the peripheral metal element is of particular importance in the methanol conversion process.

Loss of water

Temperature-programmed desorption (TPD)[8,11,12,15,16] and photoacoustic FTIR spectroscopy[7,10,11,13–15] have shown that water is eliminated from the aforementioned heteropoly acids at two different temperatures, one at approximately 200°C, the other in the range of 450–500°C, the former due to the desorption of hydrogen-bonded water, the latter apparently resulting from water formed by the acidic protons and anionic oxygen (Fig. 4). Photoacoustic FTIR spectroscopy[7,10] has been employed to identify two bands characteristic of the Keggin structure for the anion, one at 1080 cm^{-1} attributed to the triply degenerate asymmetric stretch of the central XO_4 tetrahedron, and a second at 980 cm^{-1}

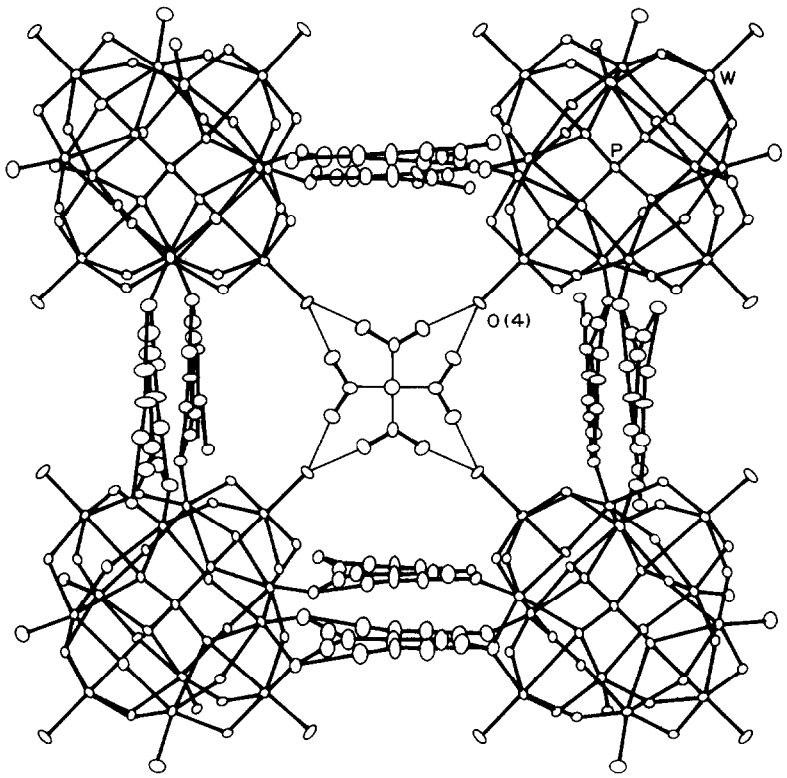

Fig. 3. Structural arrangement of anions, protons and water molecules in HPW.[24]

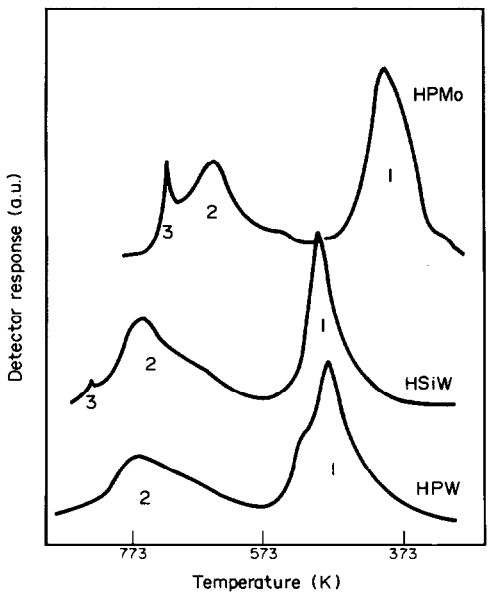

Fig. 4. TPD profiles for HPW, HSiW and HPMo after pretreatment at 298 K for 16 h.

resulting from the stretching vibration of the M—O bond where M is the peripheral metal atom and O is the terminal oxygen atom (Fig. 5). These two bands remain essentially intact after the loss of water at the higher temperature in the TPD studies. Temperature-programmed reduction (TPR) and temperature-programmed exchange (TPE) studies,[16] the former with protium, the latter with deuterium, have provided ancillary information on the subject.

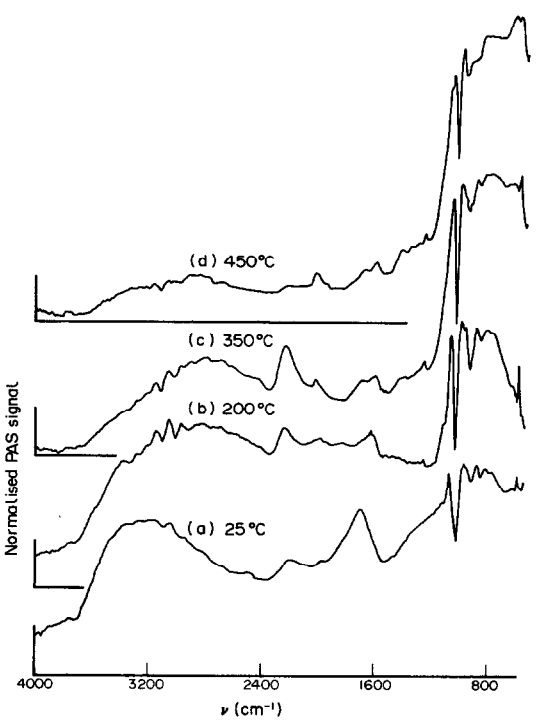

Fig. 5. Photoacoustic FTIR spectra of HPW after heating at various temperatures *in vacuo*.

It is of interest to note that the high-temperature peak in the TPD spectra (Fig. 4) emerges at a lower temperature with HPMo than with either HPW or HSiW, suggesting that the oxygen atoms in the molybdenum-containing anion are more labile than those in the corresponding tungsten species. Such a conclusion presumably implies that the Mo—O_t bond, where O_t refers to a terminal oxygen atom of the heteropoly anion, is weaker than the W—O_t bond, regardless of the nature of the central atom in the anion. Semi-empirical calculations with the extended Hückel technique,[6,11,12,13,15] on a fragment (Fig. 6) consisting of the central tetrahedron and three octahedra of the anion, designed to simulate results expected for the complete anion, show that the magnitude of the charge on the terminal oxygen atoms of the heteropoly anions with a Keggin structure is larger with HPMo than with either HPW or HSiW (Fig. 7). Consequently the protons in the former solid are less mobile and hence less acidic than those in the latter two materials, a conclusion which is consistent with the observations of the catalytic selectivities in the conversion of methanol. In addition, the calculations demonstrate that the M—O_t bond in HPMo is weaker than that in either HPW or HSiW, consistent with the aforementioned conclusions from TPD, TPR and TPE experiments, as well as reaction studies with methanol.

Cation effects

Turning now to cation effects, it has been shown[3] that, although the activity of a variety of metallic salts of HPW in the conversion of methanol is uniformly high, the selectivity to hydrocarbons is markedly dependent on the cation, being lowest for sodium and higher for aluminum. The selectivity to C_4 hydrocarbons, for example, was shown to be inversely proportional to the magnitude of the charge on the terminal oxygen atoms of the anion, a correlation again consistent with the results of TPD, TPR and TPE experiments as well as extended Hückel calculations.

Unexpectedly, however, the ammonium salt of HPW produced the highest yield of all the salts and the parent acid in the methanol conversion process, but particularly surprisingly produced primarily saturated paraffins, unlike the olefinic species found with the aforementioned catalysts[4] (Fig. 8). Most recently it has been shown that, in contrast, the tetramethylammonium salt of HPW is less effective

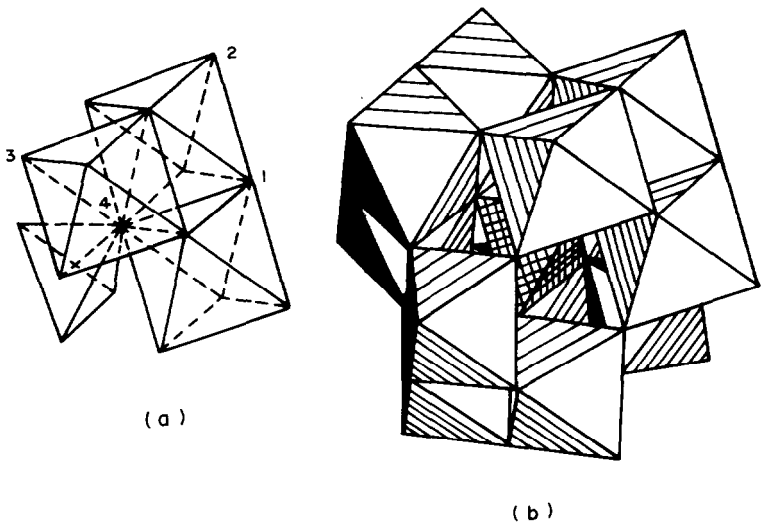

Fig. 6. (a) Fragment $[XM_3O_{16}]^{n-}$ of heteropoly anion; (b) heteropoly anion showing fragment as part of the complete structure.

than the ammonium salt of HPW and even than the parent acid itself.[17]

The present work examines the effect of changes both in the cations and the anions on the pore structures, and in particular the microporosity of heteropoly compounds. The present work is restricted to a series of monovalent cations and the anions of HPW, HPMo and HSiW.

EXPERIMENTAL

The parent acids HPW and HPMo were obtained as Analar grade from BDH and were further purified by recrystallization, where appropriate. The heteropoly acid HSiW was purchased from Baker and was used without further purification. The monovalent heteropoly salts were prepared by

precipitation or crystallization from aqueous solutions.[3]

Adsorption–desorption isotherms were obtained with nitrogen at 77.4 K in a standard glass volumetric system. Samples were evaluated at 10^{-5} torr and 473 K for 2 h prior to adsorption measurements.

Analyses of pore size distributions were obtained for mesopores and micropores with the Roberts[25] and MP[26] methods, respectively. The *t*-plot required with the latter method was generated by employing the C_{BET} matching technique of Lecloux and Pirard.[27]

X-ray powder diffraction patterns were obtained with a Phillips model PW-1011/60 diffractometer with the incident Cu-K_α radiation filtered through nickel.

RESULTS

Surface areas

The BET surface areas for the monovalent salts of HPW, HPMo and HSiW are listed in Table 1 and shown plotted as a function of cation diameter in Fig. 9. For salts such as those of sodium where the cation is relatively small, the surface area is itself small. However, as the size of the cation increases, the surface areas increase markedly, remain high but fall precipitously when the methyl ammonium salts are reached. The adsorption isotherms of all salts with high surface areas show sharp increases in the amount adsorbed at low relative pressures, characteristic of the presence of micropores, and in some cases adsorption–desorption hysteresis is also observed at higher relative pressures. High values (>300) of the *C* parameter in the BET equation, also indicative of the presence of micropores, are found for the large area salts (Table 2). In addition, the salts displaying characteristics expected of microporous substances have reduced ranges of linearity in BET plots (Table 3).

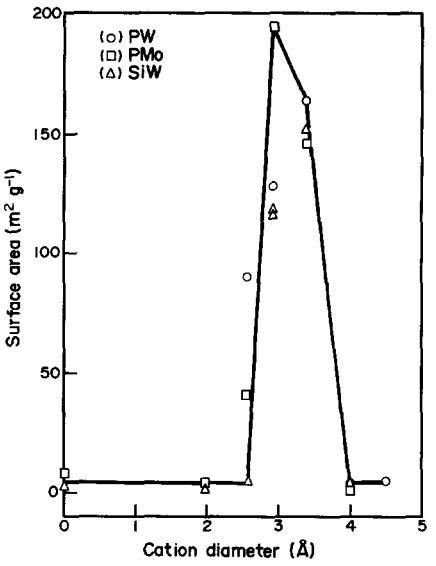

Fig. 9. Surface areas (BET) for monovalent salts of HPW, HPMo and HSiW, as a function of cation diameter.

Microporosity

The C_{BET}-dependent standard isotherms of Lecloux and Pirard[27] were employed, along with the experimental nitrogen adsorption–desorption isotherms to generate *t*-plots for the large-area heteropoly salts. In all such cases these plots could be extrapolated through the origin and displayed negative deviations from linearity, the latter being

further evidence for the presence of a microporous structure. Micropore volumes were estimated by extrapolation of the portion of the t-plot for relative pressures greater than 0.4 to the $t = 0$ axis and converting to a liquid volume. Typical micropore volume distributions as calculated by the MP method[26] are shown in Figs 10–12 for the ammonium salts of HPW, HPMo and HSiW. With all of these solids a maximum in the distribution is found in the region of 8–10 Å, while a second maximum occurs with the ammonium salt in the range of 13–14 Å. The onset of mesoporosity is also evident in the micropore distribution for the latter salt. Satisfactory internal self-consistency is evident from the agreement between the BET surface areas and those from t-plots for the microporous solids (Table 4).

The experimentally measured nitrogen adsorption isotherms were fitted to the n-layer BET equation:[28]

$$n = \frac{Cv_m x[1-(n+1)x^n+nx^{n+1}]}{(1-x)[1+(c-1)x-Cx^{n+1}]},$$

where n represents the maximum attainable number of adsorbate layers, by first employing the infinite-layer BET to generate a v_m and C value for each isotherm, followed by trial and error selection of best-fit n values. The optimum n values were found to be small ($\leqslant 5$) for all heteropoly compounds displaying microporosity. The mean micropore radius is found to be a reasonably good linear function of the n value, providing further supporting evidence for the validity of the micropore analysis (Fig. 13).

DISCUSSION

With the three anions PW, PMo and SiW studied in the present work there is a marked similarity between the results obtained for the micropore structures. This is evident in the dependence of surface areas and micropore volumes on cation and cation diameter (Table 1 and Figs 14–16) as well as from the micropore distributions. Although any dependence of micropore structure on the composition of the anion appears to be minimal, one observation should be noted. While KPW and KPMo possess appreciable micropore structure, the corresponding potassium salt of HSiW has little or no microporosity. Additional structural information will be required before a satisfactory explanation of this difference can be offered.

It is of some interest to investigate the relationship between the microporous structures found in the heteropoly salts and relevant structural factors. Both the reproducibility of the results and the internal self-consistency of the data provide assurance that the

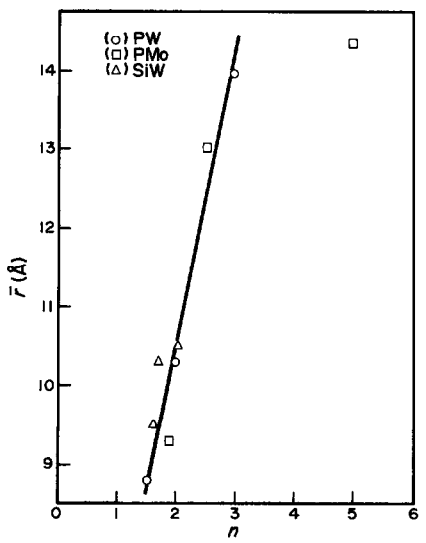

Fig. 13. Mean micropore radius as a function of the n value calculated from the n-layer BET equation for the microporous salts.

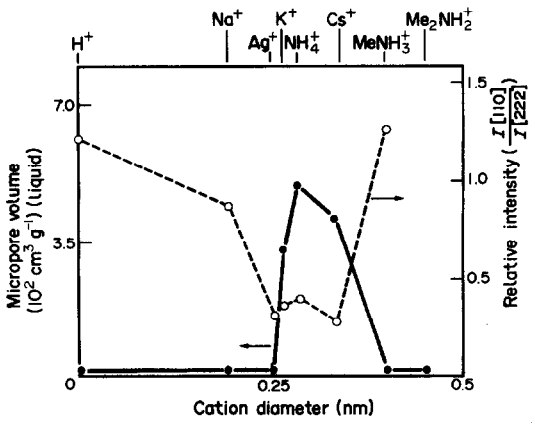

Fig. 14. Micropore volume and XRD [110]/[222] intensity ratio for various monovalent salts of HPW.

observation of microporosity is neither fortuitous nor a function of the preparative methods. In addition, no relationship to the crystal structure is evident. However, data obtained from X-ray diffraction (XRD) analysis has provided an interesting correlation. The intensity of the [110] reflection relative to that of the [222] plane, the latter of which is usually the most intense reflection, shows an approximately inverse relationship to the micropore volume (Figs 14–16). For salts with little or no microporosity the intensity ratio is relatively high, for each of the three anions, while with the microporous salts this ratio has decreased to significantly smaller values, often as much as a factor of three smaller.

An ion-packing model, assuming a cubic structure, demonstrates the presence of interstitial voids apparently separated from one another by the terminal oxygen atoms of the anions and capable of alignment with each other in directions parallel with or normal to the [110] plane of the crystal. Since the

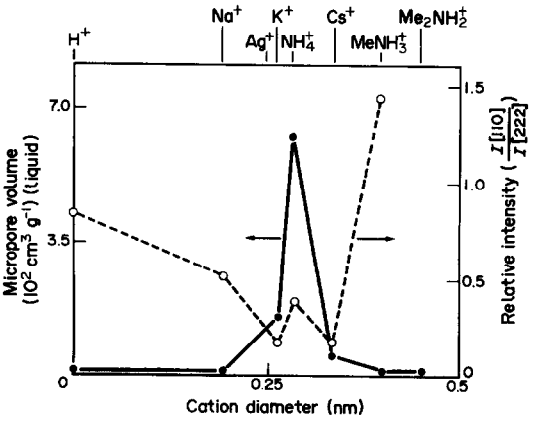

Fig. 15. Micropore volume and XRD [110]/[222] intensity ratio for various monovalent salts of HPMo.

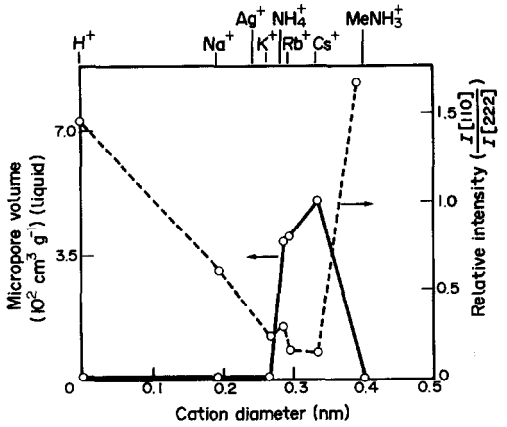

Fig. 16. Micropore volume and XRD [110]/[222] intensity ratio for various monovalent salts of HSiW.

cubic lattice parameter of the heteropoly salts increases with increasing cation size, the separation of the anions which accompanies this increase would be expected to result in widening of the interstitial voids, changes in the anionic bonding pattern, and reorientation of the anions within the secondary structure. This may alter the position of the anionic oxygen atoms so that the XRD intensity of the [110] plane is decreased, the interstitial voids are no longer separated, and channels running both parallel with and normal to this plane are formed. These channels would be observed in the present experiments provided that their diameters are sufficiently large to permit nitrogen molecules to enter. That the pores widen as the cation increases in size is evident from Fig. 13. While the absence of measurable microporosity may be due to the lack of pores of size sufficient to permit entry of nitrogen molecules, it is more probable that the terminal oxygen atoms occupy positions separating interstitial voids from one another.

There are, of course, a number of additional factors which may influence the observation of microporosity. The nature of the cation as well as its shape and size may be important. The absence of microporosity in the methylammonium salts may originate from the nonspherical shape of this cation, the substituent group penetrating into the interstitial void spaces to block the entrance of nitrogen into the [110] plane.

The present work has shown that, in addition to the effects of anion composition on the catalytic activity and selectivity of heteropoly compounds, the cations influence not only such properties but also the morphological structure of the salts in which they are found.

EPOXIDATION OF ETHYLENE CATALYSED BY MOLYBDENUM COMPLEXES

Z. DAWOODI and R. L. KELLY*

Research and Development Department, BP Chemicals Ltd, Salt End, Hull HU12 8DS, U.K.

(*Received* 24 *June* 1985)

Abstract—A series of MoO_2L_2 (L = N⌒O) complexes has been examined which exhibit activity as catalysts for the epoxidation of ethylene by *t*-butyl hydroperoxide. Improvements in selectivity and reproducibility for these catalysts have been shown to result from the addition of cyclohexene oxide to the reaction mixture. A mechanism which invokes dissociation of an N⌒O ligand is suggested.

Olefin epoxides are intermediates for a wide variety of commercial products based on epoxide polymers and co-polymers. Currently the most important is ethylene oxide with annual production of the order of 4–5 million tonnes. It is produced worldwide by the direct oxidation of ethylene over a heterogeneous silver catalyst. Considerable effort has been directed over a long period towards improving this process which has been optimized at yields between 72 and 78% based on ethylene consumed. The balance of the ethylene is lost as carbon dioxide and water. Increasing costs of the ethylene feedstock dictate improvements in process efficiency and the work reported here has been directed towards developing a homogeneous catalyst for this purpose.

The route investigated proceeds *via* the reaction between ethylene and *t*-butyl hydroperoxide (TBHP), which results in the formation of ethylene oxide and co-product *t*-butanol. This co-product can contribute to the process economics through its market potential as an octane improver in low-lead gasoline. TBHP is accessible by direct aerial oxidation of isobutane via known technology, and an attractive feature of this route is the ready availability of this raw material from gas-condensate fields, including the North Sea.

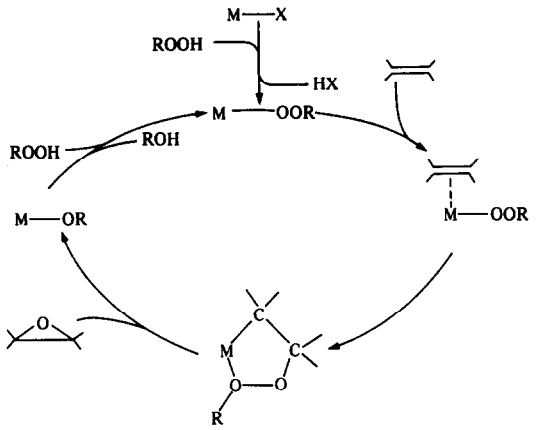
Homogeneous metal complex catalysts for the epoxidation of olefins other than ethylene are well-known[1] and indeed a major commercial process for the manufacture of propylene oxide employing a homogeneous molybdenum catalyst is operated by the Halcon Corp. and their licencees.[2] However, in the case of ethylene, most systems give a low selectivity to ethylene oxide based on TBHP, with reaction (1) predominating:

$$t\text{-BuOOH} \rightarrow t\text{-BuOH} + \tfrac{1}{2}O_2. \qquad (1)$$

This is consistent with the observation that in general, electron-rich olefins are the more reactive for this particular route.[3]

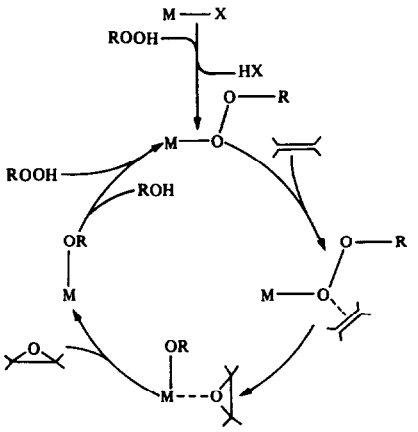
REACTION MECHANISM

A number of mechanisms have been proposed for transition-metal-catalysed hydroperoxide epoxidation of olefins. These may be separated into two main types, both invoking the initial formation of a catalyst–hydroperoxide complex.



Olefin insertion mechanism

This proceeds via prior co-ordination of the olefin to the metal hydroperoxide, followed by insertion to form a cyclic intermediate and thence elimination of the epoxide as shown in Scheme 1.[4]



Metal-activated hydroperoxide mechanism

In mechanisms of this type the role of the metal catalyst is that of a Lewis acid which serves to activate by electronic induction the oxygen atoms of the hydroperoxide ligand towards electrophilic attack on olefin substrates.[5] One example is illustrated in Scheme 2.

Scheme 1.

Scheme 2.

RESULTS AND DISCUSSION

Sheldon and Kochi[6] have stated that a good catalyst for the hydroperoxide epoxidation of olefins should be both a strong Lewis acid and a poor oxidizing agent. The former characteristic should produce an active catalyst as rationalized above, whilst the latter would be expected to inhibit loss of selectivity resulting from breakdown of the hydroperoxide substrate. Previous work has shown that molybdenum complexes offer the best combination of rate and selectivity.[7] However, because most of this work was carried out on olefins other than ethylene, a preliminary screening of a range of metal complexes was carried out. The results are shown in Table 1 and offer little reason for deviating from molybdenum. Potential catalysts for ethylene epoxidation were selected from complexes possessing robust, non-oxidizable ligands which would be expected to confer stability towards the powerful oxidizing properties of TBHP (Table 2).

The suggested chemistry involved in generating this intermediate is shown in Scheme 3. Addition of the epoxide across a Mo=O bond can generate a relatively unstable 7-coordinate intermediate **A**. On reaction with TBHP this can then eliminate N⌒OH to give the proposed active catalyst for the Sharpless mechanism,[5] **B**. Elimination of the epoxide followed by uptake of ethylene could then give **C** which can be considered as the Mimoun mechanism active catalyst.[4]

Testing was carried out in batch reactions between TBHP and ethylene in toluene solvent typically at 90°C at pressures of 60–90 bar, in a stirred autoclave. Although a number of these catalysts work well for propylene, in general selectivities to ethylene oxide were low. High TBHP conversions were obtained but the product predominating was *t*-butanol.

Significant increases in ethylene oxide yield with respect to TBHP were however obtained when molybdenum dioxo complexes possessing N⌒O donor ligands were employed (Table 3).

The highest ethylene oxide selectivity was obtained with MoO_2(8-hydroxyquinoline)$_2$ which

exhibits TBHP conversion of 42% with 69% selectivity to ethylene oxide. In an effort to improve the yields a small quantity of epoxide, usually cyclohexene oxide for convenience, was added to the reaction mixture at the start of an experiment. This resulted in most cases in increased yields of ethylene oxide. A comparison of some of the most active catalysts with and without the inclusion of starting epoxide is shown in Table 4. Although the yields of ethylene oxide obtained for MoO_2(8-hydroxy-

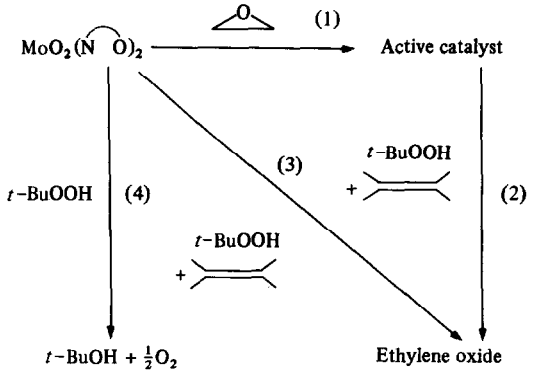
quinoline)$_2$ did not improve, problems with reproducibility which had been a feature of this work were largely alleviated.



The role of the added epoxide, we believe, is to facilitate rapid formation of the active catalyst for carrying out the epoxidation step. In Scheme 4 if steps (1) and (2) take place faster or in preference to steps (3) and (4), and step (4) is faster than step (3), then on adding cyclohexene oxide the active catalyst is rapidly formed. This can then turn over TBHP and ethylene to autocatalytically generate further active catalyst. If, however, epoxide is not present at the start then decomposition of TBHP results giving the alcohol and oxygen.

Support for this mechanism may be drawn from a series of experiments using dioxomolybdenum bis-salicylimino complexes as epoxidation catalysts (Table 5). The salicylimino ligands were prepared via condensation of salicylaldehyde with the appropriate amine, and the basicity of the imine ligand in each case may be directly linked to the basicity constants (K_b) of the amine precursor. For the series *n*-propylamine to cyclohexylamine all with similar K_b values, it is apparent that the catalysts give higher TBHP conversions according to increasing bulk of the amine precursor of the salicylimino ligand. This is consistent with a mechanism in which formation of the active catalyst occurs via dissociation of a salicylimino ligand. The lower ethylene oxide yields obtained are presumably a result of the tendency

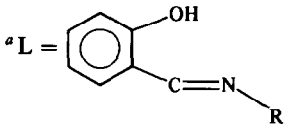
for elimination of both the weakly bound ligands. This would generate the bis (diolato) analogue of **B** in Scheme 3, which decomposes TBHP unproductively.

EXPERIMENTAL

t-BHP was supplied by Laporte Industries as an anhydrous solution in toluene. Ethylene used contained maximum levels of water and oxygen of 1 ppm. Toluene was distilled from sodium–benzophenone and stored over molecular sieves.

Catalysts used were either obtained commercially or prepared according to the following procedures.

MoO_2L_2 *complexes*



Typically, two molar equivalents of the appropriate ligand (L) were added to a solution of either $MoO_2(acac)_2$ or $MoO_2(OCH_2CH_2OH)_2$ in ethanol or methanol under a nitrogen atmosphere. The mixture was refluxed for 3–6 h and then allowed to reach room temperature. The solution was then filtered and concentrated under reduced pressure to precipitate the crystalline product. The product was then recrystallized from methanol or methanol solution.

$MoO_2(OCH_2CH_2OH)_2$

A slurry of $MoO_2(acac)_2$ (50 g) in ethylene glycol (100 ml) was heated to 80°C under a nitrogen atmosphere for 1 h. Isopropanol (250 ml) was then added and the mixture allowed to reach room temperature. It was then poured into diethyl ether (1 l). The white solid thus formed was filtered off, washed with diethyl ether and then dried *in vacuo*. Yield 30.8 g (80%).

Table 5. MoO_2L_2[a] complexes tested for epoxidation[ab]

n-Propylamine	3.8×10^{-4}	55	34
t-Butylamine	4.1×10^{-4}	75	34
Cyclohexylamine	4×10^{-4}	88	28

[a] L = 

Salicylimino

[b] All reactions carried out at 90°C and 80-bar ethylene pressure for 2 h.

[c] As for Table 3.

Epoxidation reactions

Batch reactions between ethylene and TBHP were carried out in Roth magnetically stirred Monel autoclaves at pressures up to 100 bar as follows.

Typically, a 100-ml autoclave was charged with a solution of TBHP in toluene (20 cm^3 of 3.45 M soln, 0.069 mol) and the catalyst (0.12 mmol). The autoclave was sealed and purged twice by pressurizing to 50 bar with ethylene, followed by venting. It was then charged with 90-bar ethylene pressure and heated at 90°C for 1 h. After this time it was allowed to reach room temperature, cooled further in dry ice–acetone and vented. The products were discharged into a cooled vessel and analysed by GC.

MOLYBDENUM BIS(DIPHENYLPHOSPHINE)ETHANE COMPLEXES: STRUCTURE AND REACTIVITY IN CATALYTIC EPOXIDATION OF OLEFINS WITH ORGANIC HYDROPEROXIDES

A. HERBOWSKI

Institute of Chemistry, Silesian University, Katowice, Poland

and

J. M. SOBCZAK and J. J. ZIÓŁKOWSKI*

Institute of Chemistry, University of Wrocław, 50-383 Wrocław, Poland

(*Received* 11 *June* 1985)

Abstract—Catalytic activity of molybdenum complexes in different oxidation states with bis(diphenylphosphine)ethane and the related phosphonium cation was examined in olefin epoxidation with organic hydroperoxides.

Mo compounds are well-known, effective catalysts for epoxidation of olefins with organic hydroperoxides.[1] However, only a few literature data on the catalytic activity of Mo phosphine complexes in olefin epoxidation reactions are available, although the transition-metal phosphine complexes are widely applied in numerous catalytic reactions.[2] The possibility of the simple synthesis of Mo complexes in different oxidation states (from +2 to +5) with the same ligand bis(diphenylphosphine)ethane (dppe)[3] gave the chance for studies on correlation between the structure and catalytic reactivity of these compounds in catalytic epoxidation reactions of olefins by the organic hydroperoxides.

The subjects of our studies were: the Mo(V) compounds $(dppeH_2)[MoOCl_5]$,[4] $MoOCl_3(dppe)$ (brown[4] and red[5] isomers) and

$$Mo_2O_{2.5}Cl_5(dppe)_2;^{4}$$

the Mo(IV) compound

$$[MoOCl(dppe)_2]Cl;^{6}$$

the Mo(III) compounds

$$(dppeH_2)_{1.5}[MoCl_8H],^{6}$$

$$(dppeH_2)_{1.5}[MoCl_6]\cdot 6H_2O,^{7}$$

$$(dppeH_2)_2[Mo_2(OH)_2Cl_8]^{3}$$

and

$$Mo_2Cl_6(dppe)_2;^{6}$$

and the Mo(II) compounds $MoCl_2(dppe)_2$ and α-$Mo_2Cl_4(dppe)_2$.[8]

EXPERIMENTAL

The catalytic activities of these complexes were examined in the decomposition reaction of cumene hydroperoxide (ROOH) and in cyclohexene epoxidation. Catalytic decomposition of ROOH was examined in the system: $[ROOH]_o = 0.1–0.35$ M, $[cat.] = 1\times10^{-4}–1\times10^{-3}$ M, temperature = 35–70°C, solvent = PhCl, atmosphere = Ar.

RESULTS AND DISCUSSION

ROOH decomposition is catalyzed by: $(dppeH_2)[MoOCl_5]$ (24.3), $MoOCl_3(dppe)$ [brown (46.4) and red (39.3) isomers], $(dppeH_2)_{1.5}$

* Author to whom correspondence should be addressed.

$[MoCl_8H]$ (35.0) and $(dppeH_2)_2[Mo_2(OH)_2Cl_8]$ (57.2); activation energies in kcal mol^{-1} in the temperature range 35–70°C are given in parentheses. Acetone and phenol are the main cumene hydroperoxide decomposition products in chlorobenzene. Characteristic features of all decomposition reactions are induction time, appearance of a yellow colour during the process, which quickly turned to brown-red, and precipitation of the brown precipitate from post-reaction mixtures. The shape of the kinetic curves, indicating inhibition of the reaction (Fig. 1), points to catalyst deactivation (it was confirmed experimentally by introduction of an additional amount of ROOH to the reaction system). The brown precipitate was carefully examined and the results revealed the complete destruction of the initial Mo catalyst.[9]

Analysis of the catalytic activities of the Mo complexes under study revealed that the induction time and ROOH decomposition rate are functions of the stability of the initial compounds used as catalysts. In the case of the air- and moisture-sensitive compounds, such as

$$(dppeH_2)[Mo_2(OH)_2Cl_8]$$

and

$$(dppeH_2)_{1.5}[Mo_2Cl_8H],$$

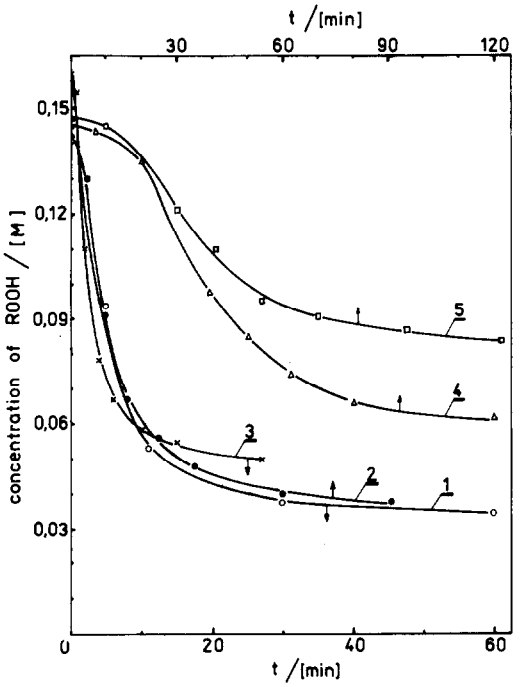

Fig. 1. Cumene hydroperoxide (ROOH) decomposition catalyzed by the Mo complexes $(dppeH_2)_2[Mo_2(OH)_2Cl_8]$ (1), $(dppeH_2)[MoOCl_5]$ (2), $(dppeH_2)_{1.5}[Mo_2Cl_8H]$ (3) and $MoOCl_3(dppe)$ [red (4) and brown (5) isomers]. $[Mo]_o = 1 \times 10^{-4}$ M, PhCl, 50°C, Ar.

the induction times were short and the ROOH decomposition rates were high. For the relatively stable complexes such as $MoOCl_3(dppe)$ isomers, the induction time is much longer (for the brown isomer about 15 min) and the reaction rate is lower. The other complexes, stable in air, are inactive as ROOH catalysts.

All Mo (II, III, IV and V) complexes under study are catalytically active in olefin epoxidation with the organic hydroperoxides. As a model reaction we have chosen cyclohexene epoxidation by ROOH examined in the system: $[cyclohexene]_o = 0.7–2.0$ M, $[ROOH]_o = 0.1–1.0$ M, $[cat.] = 1 \times 10^{-4}–1 \times 10^{-3}$ M, solvent = PhCl, temperature = 50–70°C, neutral atmosphere (Ar). All catalytic reactions have no induction time. Kinetic studies of epoxidation were limited to the initial reaction stage. The reaction orders determined vs olefin ROOH and catalyst are about one. Activation energies determined for that stage can be used as a factor determining the reactivity of the initial form of the molybdenum complex (Table 1).

Generally speaking, for the reactive complexes activation energy values are lower, e.g. for $(dppeH_2)_2[Mo_2(OH)_2Cl_8]$ (17.5). As a rule, for these compounds higher reaction rates were observed. Selectivity of epoxidation with time was examined to conclude that independently of the starting structure of the Mo compound used, selectivity approached a certain limiting value (~82%). This suggests that the Mo complexes used in epoxidation undergo "*in situ*" transformation to one type of compound. Such a statement was confirmed by isolation from the post-reaction mixtures of the compound formulated as $MoO_2(C_6H_{11}O_2)(dppeO_2)$ (analogous to the compound described earlier[9]). This compound exhibits great catalytic activity in epoxidation but does not catalyze ROOH decomposition. Simultaneously the

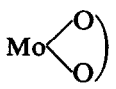

Table 1. Activation energies

Catalyst	E_a (kcal mol^{-1})
$(dppeH_2)[MoOCl_5]$	26.0
$MoOCl_3(dppe)$ red isomer	32.0
$MoOCl_3(dppe)$ brown isomer	43.9
$Mo_2O_{2.5}Cl_5(dppe)_2$	57.7
$[MoOCl(dppe)_2]Cl$	112.3
$(dppeH_2)_{1.5}[Mo_2Cl_8H]$	38.2
$Mo_2Cl_6(dppe)_2$	43.6
$(dppeH_2)_{1.5}[MoCl_6]\cdot 6H_2O$	47.6
$(dppeH_2)_2[Mo_2(OH_2)_2Cl_8]$	17.5

side-product of cyclohexene epoxidation was isolated, i.e. cyclohexanediol-1,2.

The ^1H NMR spectrum (in $CDCl_3$) of this compound (δ3.38; s, 2H from OH; δ3.50 for *trans* isomer) and its melting point 97.7–98.5°C, point to the *cis* isomer.

Formation of *cis*-cyclohexanediol-1,2 suggests its formation within the coordination sphere of the Mo catalyst. Epoxide interaction with the Mo=O group, leading to the formation of

seems to be most likely, whereas liberation of diol from the coordination sphere is realized in the subsequent reaction with ROOH.

SELECTIVE ETHYLENE OXIDE HYDROLYSIS CATALYSED BY OXO-MOLYBDENUM SPECIES*

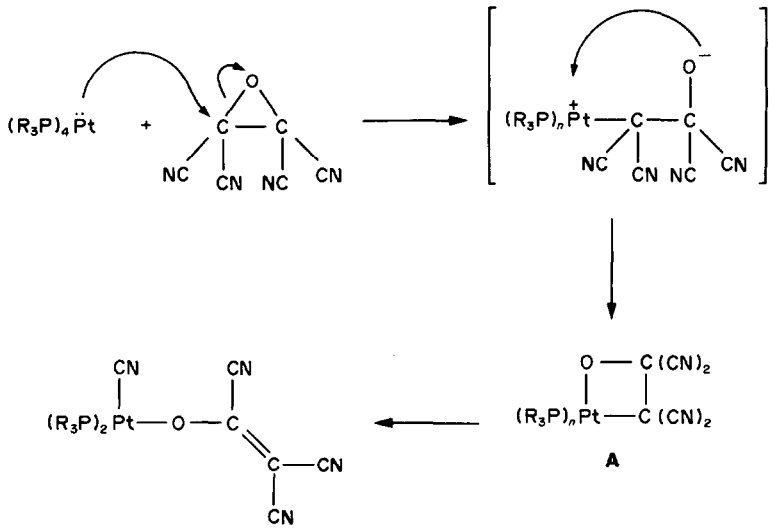
JOHN R. BRIGGS,† ARNOLD M. HARRISON and JOHN H. ROBSON

Long Range Catalyst Group, Union Carbide Corp., P.O. Box 8361,
South Charleston, WV 25303, U.S.A.

(*Received* 28 *June* 1985)

Abstract—Ortho-molybdate and ortho-tungstate (MO_4^{2-}, M = Mo or W) are selective catalysts for the hydrolysis of ethylene oxide. Model compounds synthesized from epoxides and organic soluble molybdate and tungstate salts of the bis(triphenylphosphine)iminium cation suggest that intermediates in this reaction are anionic molybdenum(VI) or tungsten(VI) alkoxide complexes of type $[MO_2(OCH_2CH_2O)_2]^{2-}$, containing chelating vicinal dialkoxide ligands derived from the epoxide residue. Hydrolysis of an ethylene oxide derived complex has been shown to yield exclusively monoethylene glycol as the organic product, with the regeneration of the metallate dianion (MO_4^{2-}).

Ethylene oxide is a valuable and versatile chemical intermediate. Its synthesis forms the basis of the ethylene-based route to monoethylene glycol, a product which consumes a large portion of the industrial production of this material. We have been interested in the interaction of epoxides with transition-metal complexes, and particularly in the possibility of catalytically transforming epoxides into desirable derivatives. Here we report our investigations into the use of high-valent group 6 oxy-metal anions as catalysts for the selective hydrolysis of epoxides to monoglycols.



Transition metals are known to catalyze a large number of transformations of epoxides including hydrogenation, hydroformylation, carbonylation and deoxygenation.[1] Some mechanistic information has been inferred from reactions of "model" transition-metal complexes and epoxides, but in general, considering the industrial importance of epoxides as chemical intermediates, their transition-metal-mediated chemistry appears to have been somewhat neglected. The catalytic synthesis of epoxides, on the other hand, has received much study.[2]

A particularly fruitful area involving epoxide transformations has involved the use of low-valent and electron-rich noble-metal complexes and electron-deficient epoxides (for example, often bearing electron-withdrawing cyano groups).[3] A frequently observed feature in these studies is that the low-valent complex oxidatively adds to the C—O bond of the epoxide, resulting in the generation of an oxametallacyclobutane moiety. In many cases, subsequent transformations can lead to the isolation of rearranged products. For example, upon treatment with tetracyanoethylene oxide (Scheme 1), platinum(0) phosphine complexes, $[Pt(PR_3)_n]$, yield bisphosphine oxaplatinacyclobutane complexes, $[(R_3P)_2\overline{PtOC(CN)_2C}(CN)_2]$ (A in Scheme 1). When $R_3P = PPh_2Me$, or with the analogous and kinetically more labile palladium complexes, rearrangement leads to the isolation of tricyanoethanolato complexes. Although ring opening of epoxides usually occurs by C—O bond cleavage, oxidative addition of this type of low-valent complex into the C—C bond of an epoxide has also been reported,[4] but this report is probably erroneous.[3(a)]

The proposed mechanism for the formation of these metallacyclic complexes (Scheme 1) involves initial S_{N^2} type fission of the C—O bond of the epoxide upon nucleophilic attack by the lone pair of electrons on the metal complex. The resulting zwitterionic species, $\overset{+}{Pt}—C—C—\bar{O}$, is not observed, but rapidly recyclizes to yield the observed product. Support for this mechanism is claimed[3(c),5]

Scheme 1. Ring-opening of epoxides by low-valent noble-metal phosphine complexes.

in the observation that tricyanoethylene oxide, $(NC)_2\dot{C}—\dot{C}H(CN)\dot{O}$, yields a metallacycle of type $\dot{P}t—\dot{C}(CN)_2\dot{C}H(CN)\dot{O}$, where the hydrogen is located β to the metal, indicative of platinum attacking the more electropositive carbon (bearing two cyano groups). This observation alone, however, does not rule out prior coordination of epoxide through oxygen before ring opening. Much of the above chemistry has been reviewed.[6]

Nucleophilic ring opening of epoxides by anionic transition-metal complexes, e.g. $[CpFe(CO)_2]^-$ (Cp = cyclopentadienyl), has also been proposed.[7] In this case, deoxygenation occurs, ultimately yielding iron(II) olefin complexes. Lack of vacant coordination sites on iron presumably precludes recyclization in this case.

Although most reports detailing this chemistry appear to favor the first step in ring opening as nucleophilic attack of metal complex on epoxide, initial coordination by epoxide through oxygen is a possible first step. However, to our knowledge only a single example of an isolated complex containing an intact epoxide ligand exists, viz. $[CpMo(CO)_3(\dot{O}CH_2\dot{C}H_2)]^+$.[8]

RESULTS AND DISCUSSION

Catalysis

The uncatalysed hydrolysis of ethylene oxide yields a mixture of ethylene glycols (mono-, di-, tri- and higher), the proportions of which depend principally upon the hydrolysis ratio (the weight ratio of water to ethylene oxide used during the hydrolysis reaction). The higher glycols are formed by reaction of product glycols with unreacted epoxide, and consequently a higher hydrolysis ratio enhances the formation of lower molecular weight glycols.

We have found that water-soluble salts of both molybdate and tungstate are effective homogeneous catalysts for the selective hydrolysis of ethylene oxide to monoethylene glycol. Typical plots of monoethylene glycol selectivity against hydrolysis ratio at several sodium molybdate catalyst concentrations are shown in Fig. 1. As can be seen, selectivity is a

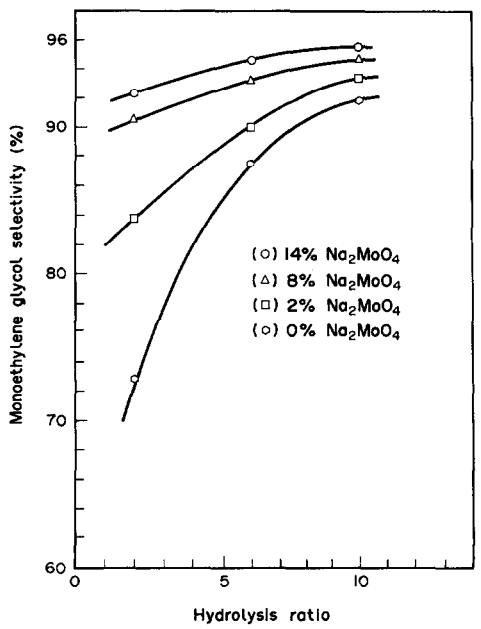

Fig. 1. Monoethylene glycol selectivity as a function of hydrolysis ratio: effect of catalyst concentration.

strong function of hydrolysis ratio and catalyst concentration. Since we are working in aqueous solution, these selectivity curves are a composite of the uncatalyzed and catalyzed routes. Consequently the effect of increasing catalyst concentration is most dramatically seen at low hydrolysis ratio, since, under these conditions, less of the monoglycol selectivity is generated by the uncatalyzed route.

Synthesis of model compounds

Bis(triphenylphosphine)iminium cation, $[(Ph_3P)_2N]^+$ (PPN), metallates. Our main goal in this work was to detail the reaction sequence by attempting to isolate and identify intermediates in the catalytic reaction. Our approach was based upon the use of salts of the metallates (molybdate and tungstate) which were soluble in organic solvents. We thought it unlikely that we would be able to isolate intermediates in the catalytic cycle by working in aqueous solution, since we anticipated that such species would be hydrolytically unstable. Thus, initially, we undertook the synthesis of metallate salts which we hoped would possess the desired solubility characteristics. The metallate salts of PPN proved to be suitable for our studies. Their solubility in dichloromethane of >0.3 mol l^{-1} was sufficient to enable us to obtain good-quality NMR spectra (including ^{95}Mo and ^{183}W), and additionally the proton resonances of the cation proved to be well removed from those of the epoxide residues which we were to study.

The synthesis of these salts is straightforward. They can be prepared most readily by precipitation from stirred hot (60°C) aqueous solutions of sodium metallate and PPN chloride. It is important to maintain the temperature around 60°C, otherwise the desired products are contaminated by precipitated PPN chloride. A second treatment with hot aqueous sodium metallate, although not absolutely necessary when good temperature control is achieved, generally ensures that a substantially chloride-free product is obtained. Additionally, these materials can be synthesized by treating a freshly prepared suspension of silver metallate ($AgNO_3 + Na_2MO_4$) in dichloromethane with PPN chloride. Anion exchange results in the formation of soluble PPN metallate and insoluble silver chloride. Again, a second treatment of the PPN metallate with fresh silver metallate ensures removal of any excess chloride ion. Materials prepared by both routes are identical by IR spectroscopy.

These materials have been characterized by IR and metal NMR spectroscopies. The IR spectra of both the molybdate and tungstate salts contain a band at 830 cm^{-1} arising from the anion, in addition to all the bands present in the spectrum of PPN chloride. This should be compared with bands at 830 cm^{-1} for molybdate and 830 and 850 cm^{-1} for tungstate as hydrated sodium salts (all spectra measured as KBr wafers).

In anhydrous dichloromethane solution, both compounds show a single resonance in their respective metal NMR spectra close to that of our reference samples of aqueous sodium metallate, and we therefore formulate them as tetrahedral MO_4^{2-} species. The sharpness of the molybdenum signal, in particular, suggests that the species is highly symmetric.

In some early experiments, we treated dichloromethane solutions of PPN molybdate in a NMR tube with some of the materials to be found under ethylene oxide hydrolysis reaction conditions, i.e. water, ethylene oxide and ethylene glycol. Addition of small (1–2 mol equivalents) amounts of water results in the broadening of the molybdenum resonance at probe temperature ($\simeq 23$°C), and, upon cooling to -30°C, a second resonance appears several ppm to low field of the original PPN_2MoO_4 resonance. This second, minor resonance can be increased by further addition of water, or by cooling, and can be decreased by warming. Recooling of a warmed solution regenerates the second resonance. These observations can be interpreted in terms of molybdate ligation by water via an equilibrium:

$$MoO_4^{2-} + xH_2O \rightleftharpoons [MoO_4(H_2O)_x]^{2-} \qquad (x = 1 \text{ or } 2).$$

Oxygen atom exchange between ^{17}O-labelled water and molybdate has been previously observed,[9] although species of the type postulated above were not directly identified.

In a similar fashion, we have found that a new, minor resonance to low field of that assigned to MoO_4^{2-} is generated upon addition of 1 mol of ethylene glycol to PPN_2MoO_4 in dichloromethane solution at ambient temperature. We assign this peak to an octahedral $[MoO_4(HOCH_2CH_2OH)]^{2-}$ species containing a chelating glycol ligand. Neither the monomethyl-ether of ethylene glycol, $MeOCH_2CH_2OH$, nor methanol give any indication from the ^{95}Mo spectra of being able to ligate molybdate under these conditions. Presumably the bidentate nature of ethylene glycol makes it the most potent ligand of the three alcohols studied. By these criteria, ethylene oxide shows no indication of being able to ligate molybdate in experiments performed at 23 and -30°C. Analogous experiments have not yet been performed with the corresponding tungstate salts due to the extended length of time required to achieve a good signal : noise ratio in ^{183}W spectra.

Epoxide adducts. We have prepared adducts of

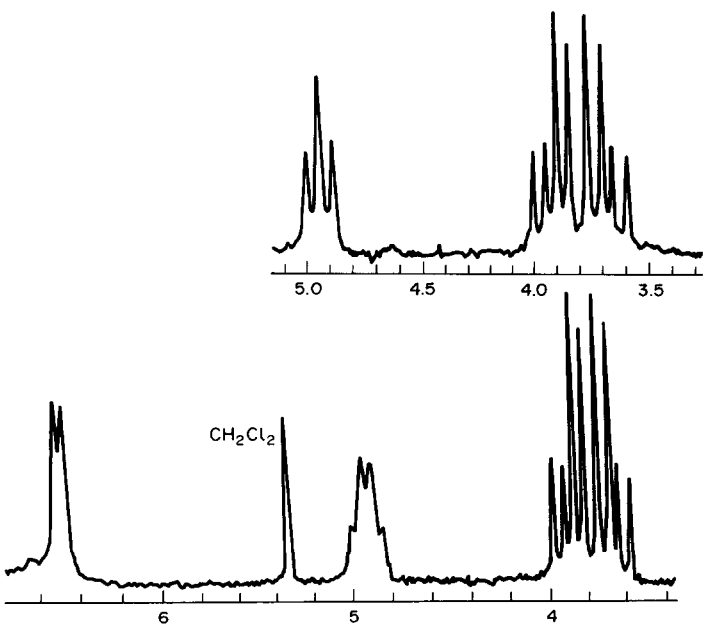
ethylene and styrene oxides with both molybdate and tungstate, but those of styrene oxide have proven most amenable to spectral analysis, and we have done most work with these species. Most of the discussion of spectral properties will be concerned with these adducts, although when relevant we will also discuss ethylene oxide adducts.

Treatment of dichloromethane solutions of the PPN_2MO_4 (M = W or Mo) with an excess of styrene oxide at *ca* 100°C for molybdate, 140°C for tungstate, for *ca* 3 h in a sealed vessel (see Experimental) results in the formation of species of stoichiometry $[MO_4(epoxide)_2]^{2-}$. Removal of volatiles *in vacuo* and repeated washing with ether gives the impure materials (sometimes contaminated with unreacted PPN_2MO_4) as white powders. We have not been able to obtain analytically pure materials from these preparations, but rather our structural assignments are based on the spectroscopic properties of these products.

The proton NMR spectra of the products are essentially identical for molybdate and tungstate, with only minor variations in chemical shifts and coupling constants. A spectrum of the methine–methylene region of the styrene oxide molybdate adduct is shown in Fig. 2, and data are shown in Table 1. The spectra are characterized by an ABX spin system for the methylene–methine protons, and a complex aromatic resonance for cation and styrene phenyl protons. Integration of methylene and methine signals against a combined cation and styrene oxide derived phenyl signals gives a ratio of epoxide to cation of 1 : 1, i.e. two epoxides per metal atom. This ratio is variable from preparation to preparation, but never exceeds two epoxides per metal (integration of resonances of such disparate intensities is somewhat difficult).

The ethylene oxide adducts contain a single resonance in their ^1H NMR spectra in addition to a complex aromatic resonance. Again the tungstate and molybdate adducts are essentially identical. The singlet resonance in the spectra which we assign to the equivalent methylenes occurs very close to those of free glycol, but can be distinguished by spiking a sample of molybdate adduct with free glycol. In this case, two separate signals are observed. Thus, in these complexes, all epoxide-derived protons are equivalent, and for this reason we formulate them and the related styrene oxide derived adduct as *trans*-$[MoO_2(OCH_2CH_2O)_2]^{2-}$ species.

The IR spectrum of the styrene oxide–molybdate adduct, measured as a KBr wafer, shows bands due to PPN. The presence of an epoxide residue is most clearly demonstrated by the presence of weak ν(C—H) bands below 3000 cm^{-1}. The band at 830 cm^{-1} observed in the spectrum of PPN_2MoO_4 had disappeared, and a new band at 870–880 cm^{-1}, presumably due to an Mo—O vibration, has appeared. Definite structural assignment from IR spectra is prevented by the presence of other bands in the metal–oxygen region, and, because some bands may be obscured, we are unable to obtain any conclusive evidence regarding the molybdenum coordination sphere by this technique.



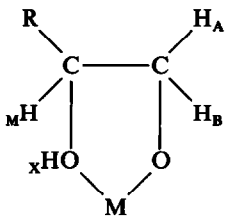


Fig. 2. ^1H NMR spectra (aliphatic region) of $[MoO_2(OCH_2CH(Ph)OH)_2]$ (lower) and $[MoO_2(OCH_2CH(Ph)O)_2]$ (upper).

Sheldon[10] has reported that complexes of the type *trans*-$[MoO_2(OCH_2CH_2OH)_2]$ have been isolated from reaction mixtures containing molybdenum formulated to perform catalytic epoxidation of olefins. Such species are isolated no matter what the source of molybdenum, and probably arise as a secondary product from reaction of epoxide with molybdenum complexes present in solution. These products are closely related to those which we have isolated, but few spectroscopic details are provided for the complexes with which we are able to compare our results. We believe that similar complexes are formed upon treatment of our anionic epoxide adducts with acids (see later).

Hydrolysis of epoxide adducts

Treatment of an isolated sample of $PPN_2[MoO_2(OCH_2CH_2O)_2]$ in dichloromethane solution with water (4 equivalents), followed by extraction of the organic layer with additional water, and gas chromatographic analysis of the aqueous layer, showed the formation of only monoethylene glycol. No higher glycols were produced. IR analysis of material obtained from the organic layer shows that it contains PPN_2MoO_4. Some information relevant to this hydrolysis can be gained from proton NMR spectra of the styrene oxide adducts.

In some preparations of the styrene epoxide adducts, the low-field triplet, assigned to the methine proton, appears as a broad featureless resonance, while in one preparation it appeared as a quartet (NMR data in Table 1) shown in Fig. 2. In this latter case, an additional resonance appears as a doublet at *ca* δ 6.5 also. This proton is clearly coupled to the methine proton, and to no other (see Fig. 2).

We suggest that this extra resonance and coupling arise from the presence of a scavenged proton which resides upon the oxygen closed to the methine proton. No protonation of the second oxygen is apparent. This proton is probably derived from acidity present in the methylene chloride during the preparation. Intermediate cases where the methine resonance appears broad, probably indicate partial protonation, or a fluxional process. It should be noted that in all these cases, the AB portion of the spectrum remains stoically unchanged. These products are analogous to those reported by Sheldon.

The addition of either solid sodium hydroxide or *p*-toluene sulfonic acid to a CD_2Cl_2 solution of the molybdate–styrene oxide adduct exhibiting a broad methine resonance sharpens up the signal to a sharp triplet. In the former case we believe that the oxygen is deprotonated, while, in the latter, the presence of excess protons moves us into a fast exchange regime.

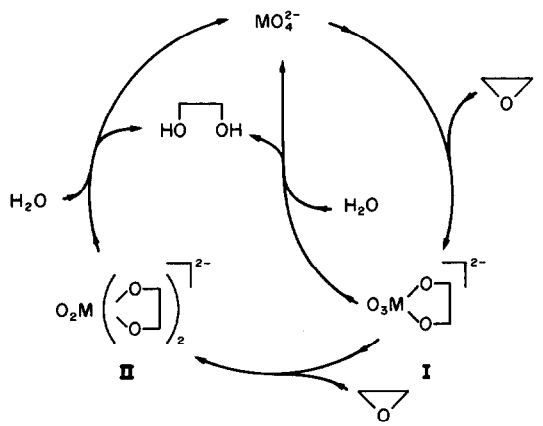
The addition of water alone, or acid alone does not result in cleavage of styrene glycol from this adduct, as measured by proton NMR, but rather both of these are required to give rapid cleavage of glycol. This is also accompanied by the precipitation of green crystals of a molybdenum-containing material

which we suggest is a condensed polymolybdate. A similar colored material is produced upon addition of acid to solutions of PPN_2MoO_4.

Thus it would seem that protonation of the adducts is the first step in the hydrolysis to give glycol and regenerated metallate.

EXPERIMENTAL

All manipulations were performed under an argon atmosphere using standard techniques unless otherwise stated. Solvents were distilled from appropriate drying agents before use; other reagents were used as received. Ethylene glycol analyses were performed by gas chromatography using a Chromasorb 101 column using 2-ethyl-1,3-hexanediol as internal standard.



IR spectra were measured on a Perkin–Elmer 683 spectrometer, FT NMR spectra on either a Nicolet NT 200 widebore for ^{95}Mo and ^{183}W or a Varian XL-100-15 with Nicolet data system for ^{1}H.

The preparation of the PPN salts of molybdate and tungstate are essentially the same. That for molybdate, $[(Ph_3P)_2N]_2[MoO_4]$, is given as an example.

Sodium molybdate dihydrate (6.32 g, 26.12 mmol) was dissolved in distilled water (100 cm^3) and heated to 55°C—at this temperature the solution was homogeneous. To this solution was added a solution of $[(Ph_3P)_2N]Cl$ (30.00 g, 52.25 mmol) in distilled water (600 cm^3), also at 55°C. The resulting cloudy solution was stirred at 55°C for 75 min before being allowed to cool to 45°C. At this temperature a precipitate, often very oily, was produced. This generally solidified on stirring at this temperature for a few minutes, and then the product was isolated by filtration. This material was washed with 3 × 100 cm^3 of distilled water at 50°C to remove unchanged $[(Ph_3P)_2N]Cl$. The product contained large quantities of water, which was removed by drying firstly in air, then *in vacuo* over P_2O_5. Yield is typically 60–70%.

The preparation of the epoxide adducts is exemplified by that of the styrene oxide–molybdate adduct, $[PPN]_2[MoO_2(OCH_2CH(Ph)O)_2]$.

PPN_2MoO_4 (10.57 g, 8.55 mmol) was dissolved in dichloromethane (55 cm^3) and this solution dried over activated 4-Å molecular sieves for 3 h. This solution was transferred to a 300-cm^3 Parr stainless steel autoclave. To this, styrene oxide (11.5 g, 96.6 mmol) was added. The mixture was heated to 100°C for 3 h. After cooling, this solution was stripped of volatiles and washed with a total of 400 cm^3 of diethyl ether. The product, in almost quantitative yield, is a white powder.

Scheme 2. Proposed reaction sequence for metallate-catalysed epoxide hydrolysis.

CONCLUSIONS

Aqueous soluble salts of molybdate and tungstate are effective catalysts for selective hydrolysis of ethylene oxide to monoethylene glycol. From studies with model compounds we proposed the catalytic cycle of Scheme 2 as an outline of the reaction mechanism.

We envision the first step as nucleophilic ring opening of epoxide by molybdate followed by recyclization to give species **I**. Further reaction with epoxide giving species **II** may not occur in aqueous solution, since **I** probably is hydrolyzed rapidly. In non-aqueous solution, we isolate species of type **II**. These are hydrolyzed after protonation to complete the catalytic cycle.

Further work to elucidate the mechanism in more detail is being undertaken.

CATALYSIS BY TETRABROMOOXOMOLYBDATE(V) COMPLEX: OXIDATION OF OLEFINS AND ALCOHOLS WITH *t*-BUTYL HYDROPEROXIDE

YASUHIKO KURUSU* and YOSHIRO MASUYAMA

Department of Chemistry, Faculty of Science and Technology, Sophia University, 7-1 Kioicho, Chiyoda-ku, Tokyo 102, Japan

(*Received* 14 *June* 1985)

Abstract—Molybdenum is a good catalyst for epoxidation of olefins with *t*-butyl hydroperoxide (*t*-BuOOH). However, use of this system for oxidation of alcohols has seldom been reported. Therefore, the catalytic activity of substituted ammonium tetrabromooxomolybdate(V) for *t*-BuOOH oxidation was investigated. The type of substituted ammonium ion used as a counter cation became a dominant factor. The ion with no hydrogen on the nitrogen showed only oxidation of alcohol, but ions with hydrogen on the nitrogen exhibited epoxidation activity. The investigation of oxidation of alcohols and olefins with *t*-BuOOH in the presence of the molybdenum complexes with substituted ammonium ion as a counter cation is described and discussed.

From the point of view of economics, selectivity and safety, *t*-butyl hydroperoxide (*t*-BuOOH) is one of the best sources of oxygen atoms for a variety of organic oxygenations.[1] *t*-BuOOH shows heterolysis of the O—O bond by nucleophilic attack,[2] and we are interested in metal-catalyzed reactions for the activation of *t*-BuOOH. It is well known that molybdenum, vanadium and tungsten are effective as metal catalysts for this reaction. During our investigations of molybdenum catalysts[3] we found that the tetrabromooxomolybdate(V) complex showed a characteristic reactivity. Substituted ammonium as a counter cation (A) of the tetrabromooxomolybdate(V) complex controls catalytic activity for oxidation of alcohols and epoxidation of olefins with *t*-BuOOH.[4,5] The chemoselective oxidation is a very interesting theme in synthetic organic chemistry.

In this paper, we report our results on chemoselective reactions for olefin epoxidation and alcohol oxidation with *t*-BuOOH in the presence of various substituted ammonium tetrabromooxomolybdate(V) complexes.

RESULTS AND DISCUSSION

Catalytic activity of substituted ammonium tetrabromoxomolybdate(V) complexes

During investigations of the epoxidation of olefins with *t*-BuOOH in the presence of various molybdenum compounds,[6] we found that the reactivity of the complex was dependent on A. In order to clarify this dependency, we prepared tetrabromooxomolybdate(V) complexes with A = benzyltrimethylammonium (**1**), *N*-methylpyridinium (**2**), trimethylenebispyridinium (**3**), pyridinium (**4**), quinolinium (**5**), 1.3-propanediammonium (**6**) and 1,6-hexanediammonium (**7**). The results are shown in Table 1; **1** shows the highest activity in the decomposition of *t*-BuOOH. When the cation A of tetrabromooxomolybdate(V) has no hydrogen on the nitrogen atom (**1–3**) the decomposition of *t*-BuOOH and oxidation of alcohols to carbonyl compounds took place smoothly, but the epoxidation of olefins with *t*-BuOOH did not proceed. On the other hand, decomposition is rarely found in **6** and **7**, but epoxidation occurs in good yield. When an equimolar mixture of cyclohexene and 2-octanol was epoxidized with *t*-BuOOH in the presence of **6**, the

[a] Conditions—decomposition: 0.05 mol *t*-BuOOH, 50 cm^3 benzene, 0.2 mmol molybdenum catalyst, 60°C, 1 h; epoxidation: 0.05 mol cyclohexene, 0.05 mol *t*-BuOOH, 50 cm^3 benzene, 0.2 mmol molybdenum catalyst, 60°C, 1 h; oxidation: 3 mmol 2-octanol, 5 mmol *t*-BuOOH, 3 cm^3 benzene, 0.15 mmol molybdenum catalyst, 60°C, 24 h.

olefin was epoxidized but the alcohol was not oxidized, as shown in eqn (1).

Oxidation of primary and secondary alcohols

The oxidation of various alcohols is shown in Table 2. An equimolar mixture of 1- and 2-octanol under the same conditions leads to complete conversion of the secondary alcohol (80% yield of 2-octanone) and to recovery of the primary alcohol (~100%). This selectivity for a secondary over a primary alcohol is also easily demonstrated in the intermolecular case [eqn (2)].

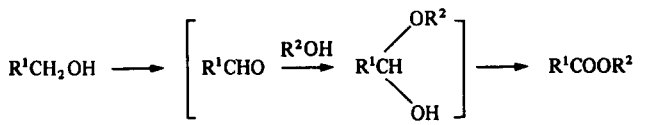
Conditions: 1 mmol 1 - octanol, 1 mmol 2 - octanol, 1 mmol *t* - BuOOH, 0.2 mmol **1**, 2 cm³ benzene.

temperature causes 1-octanol to oxidize to octyl octanoate via hemiacetal intermediate. The oxidation of 1-octanol in methanol provides methyl octanoate [eqn (3)]. Aldehyde as an intermediate was not observed in this reaction and no by-products were detected. So aldehyde was spontaneously reacted with alcohol to form hemiacetal, which then oxidized to ester, as shown in eqn (4). In the reaction of diol, cyclic ester was obtained in good yield [eqn (5)].



On the other hand, in the case of the diol containing secondary and primary hydroxyl groups, the secondary hydroxyl group was selectively oxidized by this system. A hydroxy ketone was obtained as shown in eqn (6). These reactions are thought to proceed through the abstraction of a hydride ion.

Oxidation of borneol and isoborneol was carried out to investigate the effect of the stereochemical hindrance in the case of hydroxyl group. Our results

obtained with the molybdenum complex–*t*-BuOOH system are shown in Table 3. Isoborneol is more readily oxidized to the ketone. The reactivity of borneol and isoborneol is the same as that reported by Iwamura and Hirao,[7] who used 2,3-dichloro-5,6-dicyano-1,4-benzoquinone as oxidant. Thus, a reasonable explanation for reactivity in this case can be the strain relief of the sterically hindered hydroxyl group.

The oxidation of 2-octanol in the presence of **1**, which is mixed with an equivalent amount of acid or base, was investigated; the results are shown in Table 4. Acid has no effect, but capric acid was effective in some degree. The effect comes from its hydrophobic character rather than from its acidity. As bases, sodium methoxide and sodium acetate were used but there was no effect.

On the other hand, this reaction was influenced considerably by solvent. These results are shown in Table 5. Polar solvents were effective for the reaction. This showed that the reaction proceeds through an ionic process. This reaction was not affected by a radical scavenger such as 2,6-di-*t*-butyl-4-methylphenol. These results suggest the reaction process shown in eqn (7).

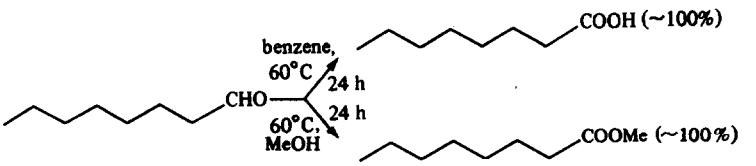
120	67.0	72.2	60.1	59.4



[a] 1 mmol 2-octanol, 2 mmol *t*-BuOOH, 0.1 mmol **1**, 3 cm^3 benzene, 50°C, 0.1 mmol additive.
[b] Yield was calculated by GC.

Oxidation of aldehydes

As mentioned above, aldehydes were not obtained but ester was formed so we think that the oxidation of alchol to aldehyde is the rate-determining step and that the reaction of aldehyde with alcohol proceeds spontaneously. Thus the oxidation of aldehydes was investigated as shown in eqn (8).

(7)

(8)

Conditions: 3 mmol aldehyde, 5 mmol *t*-BuOOH, 0.2 mmol **1**, 5 cm^3 solvent.

120	67.0	91.6	100

[a] 1 mmol 2-octanol, 2 mmol *t*-BuOOH, 0.1 mmol **1**, 3 cm^3 solvent, 50°C.

[b] Yield was calculated by GC.

In benzene the corresponding carboxylic acid was obtained but in methanol a methylester was formed quantitatively. The oxidation of an olefinic aldehyde was more difficult than that of other aldehydes. The results are shown in eqn (9):

(9)

Conditions: 2 mmol aldehyde, 4 mmol *t* - BuOOH, 0.2 mmol **1**, 3 cm^3 solvent.

This low reactivity was caused by the hindrance of oxidation with *t*-BuOOH owing to complex formation between the olefin and the molybdenum complex.

Selective oxidation of alcohol containing carbon–carbon double bond

Olefinic alcohols could be oxidized selectively with *t*-BuOOH in the presence of **3**. The results are shown in Table 6. The hydroxyl group of allylic alcohol was easily oxidized and no epoxidation of olefin was observed. As the hydroxyl group at the allyl position was activated, oxidation occurred easily. However, alcohols with a carbon–carbon double bond at the γ-position were not easily oxidized, because the molybdenum complex and the olefin got close and interacted, and also because of the difficulty of activation at the α-position. In the presence of cyclohexene, oxidation of 2-octanol was disturbed. Lee and Noureldin[8] reported the same reactivity in the presence of $Cu(MnO_4)_2 \cdot 8H_2O$. They proposed π-complex formation between manganese and olefin. Complex formation was also recognized in our case.

Molybdenum complexes are not widely used in the oxidation of alcohols with *t*-BuOOH. Nevertheless, we could find that the molybdenum complex $R_4N^+O^-MoBr_4$ showed a high activity for oxidation with hydroperoxide. In this case, R_4N^+ as the counter cation of the complex exerted an influence upon the chemoselectivity of *t*-BuOOH. When all the R are alkyl groups, alcohol oxidation occurred quantitatively, but when one R is hydrogen, alcohol oxidation and olefin epoxidation were observed at the same time. Thus, chemoselective oxidation of a hydroxyl group in the presence of olefin or a carbon–carbon double bond in the same molecule was observed in the reaction with *t*-BuOOH when we used **1**–**3**.

EXPERIMENTAL

Materials

4 and **5** were prepared according to the procedure of Allen and Neumann.[9] Similar procedures were used for the preparation of other ammonium tetrabromooxomolybdate(V) complexes. The complexes were characterised by elemental analysis (Mo by EDTA and Br by the Volhard method), and spectral measurements. **1**, Found: C, 20.6; H, 2.9; N, 2.43; Mo, 15.8; Br, 54.6%. Calc. for $C_{10}H_{16}Br_4MoNO$: C, 20.6; H, 2.8; N, 2.4; Mo, 16.5; Br, 54.9%. **2**. Found: C, 13.6; H, 1.5; N, 2.9; Mo, 18.2%. t-BuOOH supplied by Nippon Oils & Fats Co. was used after purification by vacuum distillation.

General procedure for decomposition

In a test tube with a screw cap, benzene (50 cm^3) and *t*-BuOOH (0.05 mol) were mixed with a catalytic amount of molybdenum complex (0.2 m-equiv). Then the tube contents were stirred at 60°C for 60 min in an aluminum block thermostat. The products were analyzed by GC: the column packing material was DOP/chromosorb PNAW, carrier gas was hydrogen.

General procedure for epoxidation of olefin

Cyclohexene (0.05 mol) was dissolved in benzene (50 cm^3) and the mixture was stirred at 60°C. Then

Table 6. Oxidation of olefinic alcohols[a]

Entry	Alcohol	Time (h)	Product	Yield[b] (%)
1		72		37[c]
2		20		60
3		48		48(82)[d]
4		48		57
5		72		65
6		24		11(97)[d]
7		24		18(95)[d]

[a] Conditions: 3 mmol alcohol, 3–4 mmol *t*-BuOOH, 0.2 mmol **1**, 3 cm^3 benzene.

[b] Yield was calculated by GC. All yields are for isolated pure products. Yields in parentheses are based on consumed starting material. No by-product was detected under these conditions.

[c] Room temperature.

[d] 1 mmol alcohol, 2 mmol *t*-BuOOH, 0.2 mmol **1**, 3 cm^3 benzene.

molybdenum catalyst (0.2 m-equiv) and *t*-BuOOH (0.05 mol) were added to the solution. The stirring was continued at 60°C for 60 min. Cyclohexene oxide was separated by GC (DOP/chromosorb PNAW, carrier gas nitrogen or helium) and identified by NMR and IR.

General procedure for oxidation of alcohol

A solution of molybdenum complex (0.15 m-equiv) *t*-BuOOH (5 mol) and the alcohol (3 mmol) in benzene (3 cm^3) was stirred at 60°C. The solution was evaporated. After ether extraction and evaporation, the product was purified by distillation or chromatography and identified by NMR and IR.

NEW MONO-DINITROGEN COMPLEXES OF MOLYBDENUM*

T. ADRIAN GEORGE† and ROBERT C. TISDALE
University of Nebraska—Lincoln, Lincoln, NE 68588, U.S.A.

(*Received* 14 *June* 1985)

Abstract—The synthesis is reported of a mono-dinitrogen complex of molybdenum, $Mo(N_2)(triphos)(PMe_2Ph)_2$, where triphos = $PhP(CH_2CH_2PPh_2)_2$, that yields significant yields of ammonia and hydrazine when treated with HCl or HBr in organic solvents. Generally, increasing the temperature increases the combined yield of ammonia and hydrazine.

The bis-dinitrogen complexes of molybdenum (and tungsten) stand out among all the known dinitrogen complexes of transition metals because of the reactivity of coordinated dinitrogen, as exemplified by: (i) alkylation,[2,3(a)] and (ii) protonation.[1,3] This is in dramatic contrast to the general lack of reaction displayed by coordinated dinitrogen in the many mono-dinitrogen complexes of molybdenum.‡ We wish to report one example of an extensive new series of mono-dinitrogen complexes[5] of molybdenum that react with strong acid to form ammonia or ammonia and hydrazine. These complexes contain five group 15 atoms bound to molybdenum. Only one such complex, $Mo(N_2)(PMe_3)_5$, has been reported previously.[6]

EXPERIMENTAL

General procedures

All preparations and reactions were carried out in a dinitrogen atmosphere or *in vacuo*. Compounds were handled using standard inert atmosphere techniques. Elemental analyses were performed by Galbraith Laboratories Inc., Knoxville, TN.

Procedures for acid reactions and analyses of ammonia and hydrazine have been detailed previously.[1]

Reagents and materials. All solvents were reagent grade and dried rigorously by heating at reflux over an appropriate drying agent followed by distillation in a dinitrogen atmosphere and saturated with dinitrogen immediately before use by bubbling the gas through the solvent for up to 3 h. Chemicals were purchased from commercial sources and used without purification. $MoCl_3(triphos)$ (1) was prepared according to a published procedure.[1]

Spectral studies. IR spectra (4000–200 cm^{-1}) were recorded on a Perkin–Elmer 283 or 1430 spectrophotometer as KBr pellets. $^{31}P-\{^1H\}$ NMR spectra were obtained with a Varian XL-200 spectrometer operating at 80.984 MHz. Chemical shifts (ppm) are referenced to 85% H_3PO_4. Triphos-phosphorus atom assignments are: central—PhP_a; terminal—Ph_2P_b and Ph_2P_c.

Preparation of $Mo(N_2)(triphos)(PMe_2Ph)_2$. In a dry box ($N_2$ atmosphere) a 500 cm^3 Fischer–Porter pressure bottle was charged with a magnetic stir-bar, 3.0 g (4.07 mmol) $MoCl_3(triphos)$ and THF (100 cm^3). To this stirred bright yellow suspension was added PMe_2Ph (1.2 cm, 8.43 mmol) by syringe followed by 1% sodium amalgam (0.6 g Na, 26 mmol). Immediately the reaction vessel was sealed (enclosing *ca* 4.2 equiv. of N_2) and transferred to an ice bath before being pressurized to *ca* 75 lb in^{-2} with argon. The reaction was stirred for *ca* 15 h (with reaction reaching room temperature after a few hours). The reaction vessel was transferred to a N_2-filled glove-bag and depressurized. The dark red solution was decanted from the amalgam and filtered through *ca* 1″ celite in a medium-porosity frit. The

* Reactions of coordinated dinitrogen—XIX. For Part XVIII see Ref. 1.

‡ A notable exception would be the reaction of $(MeC_6H_5)Mo(PPh_3)_2N_2$ with $[(C_5H_5)Fe(dmpe)(Me_2CO)]BF_4$ to form the {Mo–N_2–Fe} complex.[4]

resultant filtrate was bubbled vigorously with N_2 until the volume of the solvent was reduced to *ca* 35 cm^3 before *ca* 150 cm^3 MeOH was added, while stirring, in 10-cm^3 aliquots to induce precipitation of a bright orange solid. The solid was collected by filtration and washed with MeOH (two 20-cm^3 aliquots) before being dried *in vacuo* (which causes the solid to acquire a dark brown color). Refilling the drying tube with N_2 restores the characteristic bright orange color. The yield of $Mo(N_2)$(triphos)$(PMe_2Ph)_2$ was 3.0 g (78%). Calc. for $C_{50}H_{55}MoN_2P_5$: C, 64.24; H, 5.93; N, 3.00; P, 16.56%. Found: C, 63.56; H, 5.93; N, 2.87; P, 16.28%. ^{31}P NMR (C_6D_6): 85.91 (dd, $^2J_{P_aP_e} = 101.5$, $^2J_{P_aP_d} = 11.5$, $^2J_{P_aP_b} = {}^2J_{P_aP_c} = 0.0$ Hz, P_a), 66.41 (ddd, $^2J_{P_bP_d} = 93.0$, $^2J_{P_bP_c} \approx 4$, $^2J_{P_bP_e} \approx 18$ Hz, P_b), 58.96 (complex t, $^2J_{P_cP_d} \approx {}^2J_{P_cP_e} \approx 18$ Hz, P_c), 1.41 (ddt, P_d), −3.57 (ddt, P_e). IR (KBr): ν(NN) 1978 cm^{-1}.

Preparation of fac-Mo(CO)(triphos)$(PMe_2Ph)_2$. Orange **2A** (0.15 g) was placed in a round-bottom flask (50 cm^3) and subjected to a high vacuum (*ca* 48 h) in room light. The color gradually darkened to give a very dark brown colored solid by which time the pressure was 5×10^{-6} torr or less. Refilling the flask with CO (1 atm) resulted in a rapid (*ca* 20 min) restoration of a bright orange solid. IR (KBr): ν(CO) 1768 cm^{-1}. ^{31}P NMR (C_6D_6): 84.89 (ddd, $^2J_{P_aP_d} = 84.9$, $^2J_{P_aP_e} = 9.8$, $^2J_{P_aP_b} = 4.9$ Hz, P_a), 73.93 (split dt, $^2J_{P_bP_e} = 74.3$, $^2J_{P_bP_c} = 16.2$, $^2J_{P_bP_d} = 3.1$ Hz, P_b), 40.76 (multiplet, P_c), 0.61 (split dq, $^2J_{P_dP_e} = 19.7$ Hz, P_d), −2.28 (split dt, P_e).

Preparation of $Mo(^{15}N_2)$(triphos)$(PMe_2Ph)_2$. This complex was made in an analogous manner to the above carbonyl complex. IR (KBr): ν(NN) 1918 cm^{-1}.

RESULTS AND DISCUSSION

Reduction of $MoCl_3$(triphos) in a large excess of dinitrogen (*ca* 13 equiv.) in the presence of 1 equiv. of monodentate phosphine affords a high yield of the corresponding bis-dinitrogen complex [eqn (1)]:[1,7]

$$MoCl_3(\text{triphos}) + PR_3 \xrightarrow[\text{THF}]{\text{Na–Hg, } N_2} Mo(N_2)_2(\text{triphos})(PR_3), \quad (1)$$

where $PR_3 = PPh_3$ or PPh_2Me. However, when $PR_3 = PMe_2Ph$ an oil rather than a solid was obtained.[8] Similar reactions carried out with only a small excess of dinitrogen (*ca* 4 equiv.) and 2 equiv. of PMe_2Ph or 1 equiv. of a bidentate ligand produced an extensive novel series of mono-dinitrogen complexes [eqn (2)]:[5]

$$MoCl_3(\text{triphos}) + L_2 \text{ (or 2L)} \xrightarrow[\text{THF}]{\text{Na–Hg, } N_2} Mo(N_2)(\text{triphos})(L_2), \quad (2)$$

where L = PMe_2Ph (**2A**), $L_2 = Me_2PCH_2PMe_2$ (**2B**), $L_2 = 1,2\text{-}(Me_2As)_2C_6H_4$ (**2C**), $L_2 = Ph_2PCH_2PPh_2$ (**2D**), $L_2 = Ph_2PCH_2CH_2PPh_2$ (**2E**), or $L_2 = 1,1'\text{-}[Ph_2PC_5H_4]_2Fe$ (**2F**).

Complex **2A**, obtained in 78% yield, gave a first-order spectrum in which four of the phosphorus atoms displayed large *trans* coupling constants, including the PMe_2Ph ligands. Previous work[9] with six-coordinate molybdenum(0) complexes containing the triphos ligand have shown that when triphos adopts a meridional configuration, $J_{P_aP_b} = 0$ Hz, whereas when triphos is facial $J_{P_aP_b} > 0$ Hz. The data clearly show that triphos is facial in **2A** and N_2 is *trans* to a terminal triphos-phosphorus atom, P_c. This is in contrast to the bis-dinitrogen complexes in which triphos is meridional.

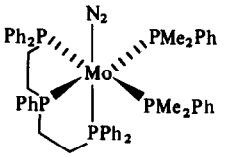

Table 1. Yields of ammonia and hydrazine from $Mo(N_2)$(triphos)$(PMe_2Ph)_2$ and acid

Acid (mol)	Solvent	Time (h)	Temperature (°C)	N_2[ab]	NH_3[a]	N_2H_4[a]
HCl (40)	CH_2Cl_2	64	18	0.28	0.32	0.17
HBr (40)	CH_2Cl_2	36	18	0.35	0.51	0.30
HCl (36)	Toluene	15	61	0.54	0.51	0.29
HBr (40)	Toluene	39	70	0.56	0.36	0.48
HCl (10)	THF	38	55	—[c]	0.10	0.12
HCl (80)	THF	38	55	0.68	0.84	0.41
HBr (20)	THF	96	25	0.82	0.08	0

[a] Mol (mol of **2A**)$^{-1}$.

[b] Also H_2.

[c] Significant H_2 evolution; total gas = 1.30 mol (mol of **2A**)$^{-1}$.

In vacuo, dinitrogen is slowly lost from solid **2A** to produce a dark brown solid. The process appears to be reversible since exposure of this solid to dinitrogen at room temperature spontaneously regenerates orange **2A**. With $^{15}N_2$ and CO, **2A**-($^{15}N_2$) and Mo(CO)(triphos)(PMe_2Ph)$_2$ are produced, respectively. Reaction of **2A** with CO in solution results in the loss of N_2 and PMe_2Ph.

Complex **2A** reacts with anhydrous HCl and HBr in organic solvents to produce ammonia and hydrazine (see Table 1). Generally, increasing the temperature increases the combined yield of ammonia and hydrazine, as well as producing dihydrogen. As far as we know **2A** is the first mono-dinitrogen complex of any metal that affords significant amounts of ammonia and hydrazine.

and

F. TAKUSAGAWA

Department of Chemistry, University of Kansas, Lawrence, KS 66045, U.S.A.

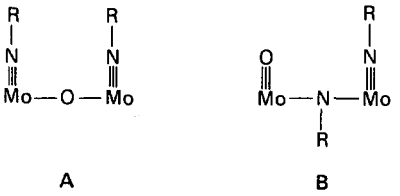
(*Received* 12 *June* 1985)

Abstract—Two series of *p*-tolylimido (Ntol) complexes of Mo(VI), Mo(V) and Mo(IV) are described. One series, containing diethyldithiocarbamate ligands, is formed via oxygen atom abstraction from Mo(VI)O(Ntol)$(S_2CNEt_2)_2$ using tertiary phosphines which affords the oxo-bridged Mo(V) dimer $[Mo(Ntol)(S_2CNEt_2)_2]_2O$ and the Mo(IV) species $Mo(Ntol)(S_2CNEt_2)_2$. In solution, the Mo(V) dimer participates in a disproportionation equilibrium affording the Mo(VI) and Mo(IV) complexes. $Mo(Ntol)(S_2CNEt_2)_2$ reacts with O_2 to regenerate $MoO(Ntol)(S_2CNEt_2)_2$, thus completing a catalytic phosphine oxidation cycle. $Mo(Ntol)(S_2CNEt_2)_2$ also reacts with Me_2SO to yield the Mo(VI) complex and Me_2S, and with dimethylacetylenedicarboxylate to yield the alkyne complex, $Mo(Ntol)(DMAC)(S_2CNEt_2)_2$. The second series of *p*-tolylimido complexes contains chloride and phosphine co-ligands and derives from the Mo(VI) species $Mo(Ntol)Cl_4(THF)$. In the presence of tertiary phosphines, this complex undergoes reduction to afford monomeric Mo(V) complexes of the form $Mo(Ntol)Cl_3L_2$ ($L = Ph_3P$, $EtPh_2P$ and Me_3P; $L_2 = Ph_2PC_2H_4PPh_2$). The bis(monodentate phosphine) complexes possess the *trans, mer*-geometry while the diphos complex is assigned the *cis, mer*-configuration. Reduction of $Mo(Ntol)Cl_3(Me_3P)_2$ by Na–Hg in the presence of Me_3P affords the Mo(IV) complex *cis, mer*-$Mo(Ntol)Cl_2(Me_3P)_3$ whose molecular structure is described.

In recent years, an increasing research effort has been focused on transition-metal complexes bearing organoimido ligands (NR), and it is now clear that such species are of importance and utility in a diverse array of processes ranging from synthetic procedures (e.g. the amination,[1] aziridination[2] and metathesis[3] of olefins) to biological functions (e.g. metabolism of certain hydrazines[4]). Molybdenum organoimido complexes are of additional interest in that they may serve as models of the {Mo(NH)} species that are likely intermediates in nitrogen fixation[5] and in the ammoxidation of propylene.[6]

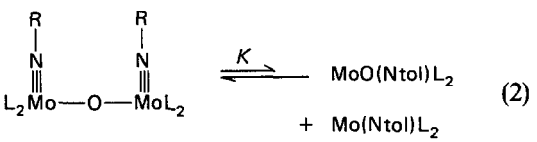
Most of the organoimido molybdenum complexes prepared to date are Mo(VI) species.[7] Herein we describe two series of *p*-tolylimido complexes of Mo(VI), M(V) and Mo(IV). One series, containing diethyldithiocarbamate ligands, displays prominent oxygen atom transfer reactivity; the second series, containing chloride and phosphine ligands, is characterized by facile oxidation and reduction reactions.

* Author to whom correspondence should be addressed.



RESULTS AND DISCUSSION

Dithiocarbamate complexes

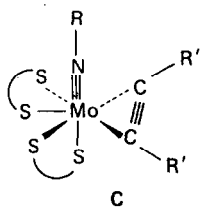


The reaction of the *p*-tolylimido Mo(VI) species $MoO(Ntol)L_2$ ($L = S_2CNEt_2$) with 0.5 equivalents of Ph_3P or $EtPh_2P$ in CH_2Cl_2 produces the corresponding phosphine oxide and a dinuclear Mo(V) complex $Mo_2O(Ntol)_2L_4$ [eqn (1)]:[8]

$$MoO(Ntol)L_2 + 0.5R_3P \rightarrow Mo_2O(Ntol)_2L_4 + 0.5R_3PO. \quad (1)$$

Two core structures, **A** and **B**, are conceivable for the Mo(V) dimer; the oxo-bridged structure **A** is

indicated by IR data [absence of ν(Mo=O)] and ^{17}O NMR studies [$\delta(^{17}O) = 1002$ ppm]. The electronic spectrum of $(Mo(Ntol)L_2)_2O$ in toluene displays an intense absorption at 533 nm, a region characteristic of mono-oxo-bridged Mo(V) dimers.[9] However, this band does not obey Beer's law, a result which by analogy to the behavior of the corresponding $Mo_2O_3L_4$ system,[10] suggests the occurrence of the disproportionation equilibrium shown in eqn (2):



(2)

In support of this proposition, we find that toluene solutions of $[Mo(Ntol)L_2]_2O$ react with $EtPh_2P$ to produce $EtPh_2PO$ and the reactive 16-electron Mo(IV) species $Mo(Ntol)L_2$ [eqn (3)]:

$$[Mo(Ntol)L_2]_2O + EtPh_2P \rightarrow 2Mo(Ntol)L_2 + EtPh_2PO. \quad (3)$$

Although we have not isolated a pure sample of $Mo(Ntol)L_2$, we have been able to probe its reactivity in solution. Thus, when the reaction of eqn (3) is conducted in the presence of an excess of the activated alkyne dimethylacetylenedicarboxylate (DMAC), the bright yellow alkyne complex $Mo(Ntol)(DMAC)L_2$ is formed. Solution ^1H NMR results and an X-ray diffraction study[11] confirm the expected pentagonal bipyramidal geometry for this species (**C**).

Solutions of $Mo(Ntol)L_2$ react rapidly with O_2 (1 atm) at ambient temperature to regenerate $MoO(Ntol)L_2$ [eqn (4)]:

$$Mo(Ntol)L_2 + \tfrac{1}{2}O_2 \rightarrow MoO(Ntol)L_2. \quad (4)$$

Thus, taken collectively, eqns (1), (3) and (4) constitute a catalytic phosphine oxidation cycle. We have observed the oxidation of *ca* 50 equiv. of PPh_3 using this system without any diminution of catalytic activity. $Mo(Ntol)L_2$ solutions also react with dimethylsulfoxide to afford $MoO(Ntol)L_2$ and dimethyl sulfide [eqn (5)]:

$$Mo(Ntol)L_2 + Me_2SO \rightarrow MoO(Ntol)L_2 + Me_2S. \quad (5)$$

Chloride and phosphine species

The reaction of *p*-tolylazide with $MoCl_4(THF)_2$ (THF = tetrahydrofuran) in 1,2-dichloroethane provides the *p*-tolylimido Mo(VI) species $Mo(Ntol)Cl_4(THF)$ in excellent yield [eqn (6)]:[12]

$$MoCl_4(THF)_2 + p\text{-}tolN_3 \rightarrow Mo(Ntol)Cl_4(THF) + N_2. \quad (6)$$

The molecular structure of this 16-electron species features a short Mo—N bond [1.717(3) Å] and a near-linear Mo—N—C bond angle [174.5(3)°], consonant with the presence of a triply-bonded, four-electron donor tolylimido ligand. The Mo—O bond length of 2.234(3) Å for the THF molecule suggests that the tolylimido ligand exerts a *trans*-influence of *ca* 0.2 Å in this complex.

The reaction of $Mo(Ntol)Cl_4(THF)$ with various tertiary phosphines (L) in 1,2-dichloroethene solution induces reduction of the metal and affords *p*-tolylimido Mo(V) complexes of the form $Mo(Ntol)Cl_3L_2$ [eqn (7)]:[13]

$$Mo(Ntol)Cl_4(THF) + 2L \rightarrow Mo(Ntol)Cl_3L_2, \quad (7)$$

where $L = Ph_3P$, $EtPh_2P$ or Me_3P; and $L_2 = Ph_2PC_2H_4PPh_2$. These 17-electron monomeric d^1 complexes are air-stable in the solid state and display magnetic moments near the spin-only value of 1.73 μ_B. The molecular structure of $Mo(Ntol)Cl_3(EtPh_2P)_2$ displays a pseudo-octahedral coordination about the Mo atom, with a

meridional arrangement of the chlorine atoms and a *trans*-disposition of the phosphine ligands. Thus, the overall geometry is similar to that previously found for the analogous Re and W complexes,

$$Re(NMe)Cl_3(EtPh_2P)_2$$[14]

and

$$W(NPh)Cl_3(Ph_3P)_2.$$[15]

Solutions of the $Mo(Ntol)Cl_3L_2$ complexes give rise to sharp ESR spectra at room temperature. The spectra of the Ph_3P, $EtPh_2P$ and Me_3P complexes are very similar and reveal superhyperfine coupling to two equivalent ^{31}P nuclei, consistent with their expected *trans, mer*-geometry. The ESR spectrum of the chelating diphos complex, however, shows strong coupling to only one ^{31}P nucleus: since the unpaired electron is expected to reside in the formally non-bonding Mo d_{xy}-orbital, the *cis, mer*-geometry is indicated for this species.

The phosphine ligands in $Mo(Ntol)Cl_3(EtPh_2P)_2$ can be substituted by the corresponding phosphine oxide [eqn (8)]:

$$Mo(Ntol)Cl_3(EtPh_2P)_2 + 2EtPh_2PO \rightarrow Mo(Ntol)Cl_3(OPEtPh_2)_2. \quad (8)$$

ESR evidence suggests that the *trans, mer*-geometry is maintained for the bis(phosphine oxide) complex. When a toluene solution containing either

$$Mo(Ntol)Cl_3(EtPh_2P)_2$$

or

$$Mo(Ntol)Cl_3(OPEtPh_2)_2$$

is exposed to moist air, crystals of the Mo(VI) complex

$$[MoO_2Cl_2(OPEtPh_2)\cdot\tfrac{1}{2}\text{toluene}]$$

are deposited and the mother liquor is found to contain *p*-toluidine and $EtPh_2PO$. When the preceeding experiment is conducted under an atmosphere of dry O_2, an extremely hydrolytically sensitive intermediate species containing a terminal oxo ligand and a tolylimido group can be identified by IR spectra. We believe this species to be $MoO(Ntol)Cl_2(OPEtPh_2)_2$ by analogy to the known complex $MoO(NH)Cl_2(OPEtPh_2)_2$,[16] which also contains a readily hydrolyzed imido ligand.

Sodium amalgam reduction of

$$Mo(Ntol)Cl_3(Me_3P)_2$$

in toluene in the presence of PMe_3 proceeds cleanly to give a dark green, diamagnetic Mo(IV) species, $Mo(Ntol)Cl_2(Me_3P)_3$ [eqn (9)]:

$$Mo(Ntol)Cl_3(Me_3P)_2 + Me_3P + Na\text{–}Hg \rightarrow Mo(Ntol)Cl_2(Me_3P)_3. \quad (9)$$

A meridional arrangement of the Me_3P ligands is indicated by NMR spectroscopy. In the ^1H spectrum, the methyl protons of the Me_3P groups appear as a triplet (δ 1.42, J_{HP} = 3.6 Hz, 18 H) and a doublet (δ 1.28, J_{HP} = 7.8 Hz, 9 H), while the $^{31}P\text{–}\{^1H\}$ spectrum consists of a triplet at δ 5.38 (J_{pp} = 18.1 Hz; area 1) and a doublet at δ −7.32 [J_{pp} = 18.1 Hz (area 2)].

The molecular structure of $Mo(Ntol)Cl_2(Me_3P)_3$ has been determined. A drawing of the molecule is shown in Fig. 1 and selected bond lengths and angles are given in Table 1. The pseudo-octahedral structure features the expected meridional configuration of the Me_3P ligands with the chlorine atoms occupying mutually *cis*-positions. Perhaps the most salient aspect of the structure is the absence of a *trans*-influence exerted by the tolylimido ligand: the *trans* Mo—Cl(3) bond distance of 2.497(1) Å is in fact *ca* 0.03 Å *shorter* than the *cis* Mo—Cl(2) distance [2.525(1) Å]. This small lengthening of Mo—Cl(2) can be ascribed to the *trans*-influence of the Me_3P ligand which is also evidenced by the Mo—P bond lengths: the pair of mutually *trans* phosphines display identical Mo—P distances of 2.509(1) Å while the Mo—P(4) bond length is *ca* 0.04 Å shorter at 2.471(1) Å.

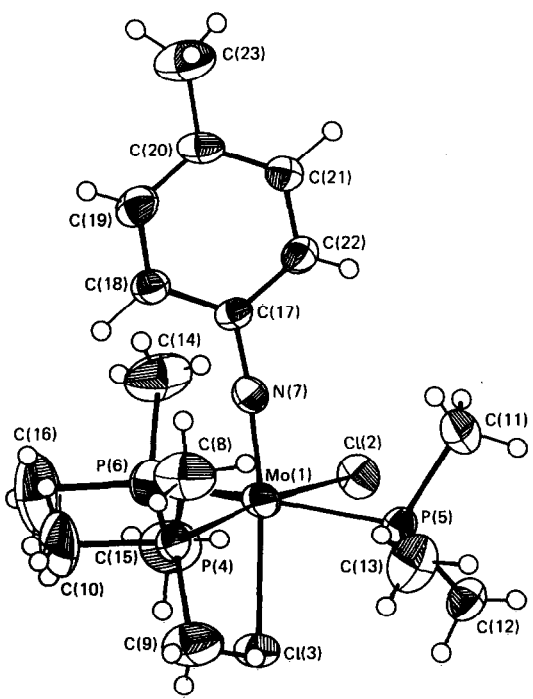


Fig. 1. An ORTEP drawing of $Mo(Ntol)Cl_2(Me_3P)_3$. Thermal ellipsoids are drawn at the 50% probability level.

Table 1. Selected bond distances (Å) and angles (°) in $Mo(Ntol)Cl_2(Me_3P)_3$

EXPERIMENTAL

Crystal data for $Mo(Ntol)Cl_2(Me_3P)_3$

$C_{16}H_{34}NCl_2P_3Mo$, $M = 500.22$, monoclinic, $P2_1/n$, $a = 11.214(2)$ Å, $b = 22.371(3)$ Å, $c = 9.525(2)$ Å, $\beta = 94.62(1)°$, $U = 2381.8(5)$ Å^3, $Z = 4$, $D_c = 1.395$, $\mu = 9.63$ cm^{-1}.

Data collection

Syntex $P2_1$ diffractometer, graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å), θ–2θ technique, scan range 1.0° below $K_{\alpha1}$ and 1.1° above $K_{\alpha2}$, scan speed 1.5–20.0° min^{-1}, $4.0 \leqslant 2\theta \leqslant 45.0°$, 3616 reflections measured, 3134 unique [data with $I_o < 0.2\sigma(I_o)$ reset to $I_o = 0.2\sigma(I_o)$], empirical absorption correction applied.

Structure solution and refinement

Heavy-atom, two block matrix least squares. Non-hydrogen atoms assigned anisotropic thermal parameters, hydrogen atoms isotropic. Anomalous dispersion corrections for Mo, Cl and P. Final agreement factors: $R = 0.032$, and $R_w = 0.036$. Other details as described in Ref. 11.

SYNTHESIS AND CHEMICAL CHARACTERIZATION OF DIAZENIDO DERIVATIVES OF OXOMOLYBDATE CLUSTERS: THE STRUCTURES OF THE TETRANUCLEAR COMPLEXES $[Mo_4O_8(OR)_2(NNC_6H_5)_4]^{2-}$ (R = CH_3 OR C_2H_5)

T.-C. HSIEH and J. A. ZUBIETA*

Department of Chemistry, State University of New York at Albany,
Albany, NY 12222, U.S.A.

(*Received* 18 *June* 1985)

Abstract—α-$[Mo_8O_{26}]^{4-}$ reacts with phenylhydrazine in alcohols to yield tetranuclear clusters of the type $[Mo_4O_8(OR)_2(NNC_6H_5)_4]^{2-}$, with R = CH_3, C_2H_5 or $CH(CH_3)_2$, depending on the solvent alcohol employed. The crystallizations from alcohol–ether mixtures afford single crystals of the various derivatives. $(HNEt_3)_2[Mo_4O_8(OCH_3)_2(NNC_6H_5)_4]$ (**1**) crystallizes in the triclinic space group $P\bar{1}$, a = 12.326(3) Å, b = 12.799(3) Å, c = 16.190(3) Å, α = 83.56(1)°, β = 83.94(1)°, γ = 83.67(1)°, V = 2521(1) Å^3, Z = 2. Refinement based on 4243 reflections converged at a residual of 0.050. One form of

$$(NBu^n_4)_2[Mo_4O_8(OCH_3)_2(NNC_6H_5)_4]$$

(**1a**) crystallizes in the monoclinic space group $P2_1/c$, a = 19.735(4) Å, b = 16.222(3) Å, c = 23.802(4) Å, β = 111.92(1)°, V = 7069(2) Å^3, Z = 4. Refinement was based on 3390 reflections and converged at a residual of 0.050. One form of

$$(NBu^n_4)_2[Mo_4O_8(OC_2H_5)_2(NNC_6H_5)_4]$$

(**2**) is isomorphous with **1a**, crystallizing in the monoclinic space group $P2_1/c$, a = 19.840(3) Å, b = 16.445(3) Å, c = 24.074(4) Å, β = 112.39(1)°, V = 7264(1) Å^3, Z = 4; refinement converged at a value of 0.060 for the conventional R factor. A second modification of $(NBu^n_4)_2[Mo_4O_8(OC_2H_5)_2(NNC_6H_5)_4]$ crystallizes in the tetragonal space group $I4_1/a$, a = 35.236(6) Å, b = 35.236(6) Å, c = 12.137(4) Å, V = 15066.0(13) Å^3, Z = 8. Refinement based on 1734 reflections converged at a residual of 0.082. The structures consist of discrete tetranuclear units, presenting *cis*-bisdiazenido moieties, $[Mo(NNC_6H_5)_2]^{2+}$, bridged by two alkoxy groups and two tetra-oxomolybdate, $[MoO_4]^{2-}$, fragments.

The polyoxoanions of molybdenum are of fundamental chemical interest as catalysts,[1] as selective labelling and imaging agents for biological systems, as spectroanalytical reagents, and most recently as photosensitizers[2] and as catalysts in the photooxidation of organic compounds.[3] The perceived analogies of the polyoxoanions to metal oxide surfaces and their real and potential catalytic applications[4–6] provide the current focus of attention. The derivative chemistry of heteropolyanions has involved replacement of peripheral metal–oxygen groups by other metal–ligand units,[7] attachment of low-valent transition-metal organometallic fragments to the heteropoly framework,[8] the incorporation of organic groups into the heteropolybackbone,[9] and electrophilic *O*-alkylation of bridging oxygen atoms of the heteropoly anion.[10] Isopolymolybdate chemistry has also been expanded to include coordination chemistry of small organic molecules, as illustrated by the characterization of a formylated derivative, $[(HCO)_2Mo_8O_{28}]^{6-}$,[11] of a methoxy derivative, $[Mo_8O_{24}(OCH_3)_4]^{4-}$,[12] of a species incorporating

* Author to whom correspondence should be addressed.

a methylene group, $[CH_2Mo_4O_{15}H]^{3-}$,[13] and of an octamolybdate containing coordinated pyridine $[(C_5H_5N)_2Mo_8O_{26}]^{4-}$.[14] In each of the examples of derivatized isopolymolybdates cited above, each molybdenum atom is octahedrally coordinated either exclusively to oxygen donors or to five oxygen donors and a single nitrogen donor ligand.

Since the ability of polymolybdates to coordinate nitrogen donors has been established, we sought to extend this chemistry to the organodiazenido group, NNR, a ligand known to form robust complexes with molybdenum by the displacement of *cis*-dioxo groups to give the *cis*-$[Mo(NNR)_2]^{2+}$ structural unit.[15] We report herein the synthesis and structural characterization of a series of tetranuclear dianions, $[Mo_4O_8(OR)_2(NNC_6H_5)_4]^{2-}$ (R = CH_3, C_2H_5 or $CH(CH_3)_2$).*

EXPERIMENTAL

Preparations

All compounds were prepared from commercially available materials. All solvents were degassed, and subsequent reactions were carried out in an atmosphere of purified nitrogen. Microanalyses were performed by MicAnal Laboratories, Tucson, AZ.

Preparation of

$(HNEt_3)_2[Mo_4O_8(OCH_3)_2(NNC_6H_5)_4]$ (**1**).

A mixture of phenylhydrazine (4.32 g) and triethylamine (8.08 g) in methanol (50 cm^3) was added to a refluxing solution of

$[MoO_2(C_4H_9O_2)_2]\cdot 2C_4H_{10}O_2$

(2.43 g)[17] in methanol (200 cm^3). A deep purple color developed immediately. After refluxing for 0.5 h, the solution was allowed to cool to room temperature, whereupon diethylether was carefully layered over the solution. After standing for 1 week at room temperature, lustrous purple-black crystals and a red powder were observed. The crystalline material analysed for

$(HNEt_3)[Mo_2O_4(OCH_3)(NNC_6H_5)_2]$

and conductivity measurements in acetonitrile indicated a 2:1 electrolyte, suggesting the tetranuclear formulation

$(HNEt_3)_2[Mo_4O_8(OCH_3)_2(NNC_6H_5)_4]$.

The crystalline material proved to be neither air- nor moisture-sensitive, requiring no special precautions. Yield 20–25%.

Analysis of the red powder is consistent with the formulation

$[Mo(NNC_6H_5)_2(C_4H_9O_2)_2]\cdot H_2NNHC_6H_5$.

Attempts to confirm the structural identity of this species proved unsuccessful. Yield 30–35%.

Preparation of

$(NBu^n_4)_2[Mo_4O_8(OCH_3)_2(NNC_6H_5)_4]$ (**1a**).

A mixture of phenylhydrazine (12.96 g) and triethylamine (24.24 g) in methanol (150 cm^3) was added to a refluxing solution of

α-$(NBu^n_4)_4[Mo_8O_{26}]$

(3.17 g) in methanol (200 cm^3). The characteristic deep purple color developed after 0.5 h of refluxing. After cooling to room temperature, diethylether was layered carefully over the solution; this mixture was allowed to stand at room temperature for several weeks, whereupon lustrous purple cyrstals were observed growing at the solvent interface. Yield 30–40%.

$(NBu^n_4)_2[Mo_4O_8(OC_2H_5)_2(NNC_6H_5)_4]$ (**2**) and

$(NBu^n_4)_2[Mo_4O_8(OPr^i)_2(NNC_6H_5)_4]$ (**3**)

were synthesized in an anologous manner using the appropriate alcohol as solvent. In the case of the ethoxy derivative, three crystal forms were isolated. The purple-black irregular crystals proved to be

$(NBu^n_4)_2[Mo_4O_8(OC_2H_5)_2(NNC_6H_5)_4]$,

while the lustrous red crystals of hexagonal habit have been identified as

$(NBu^n_4)_4[Mo_8O_{20}(NNC_6H_5)_6]$.[22]

Storage at 4°C for 1 week of the filtrate from which these species were isolated yields crystals of tetragonal habit,

$(NBu^n_4)_2[Mo_4O_8(OC_2H_5)_2(NNC_6H_5)_4]$ (**2a**).

Analytical data are presented in Table 1.

Spectroscopic measurements

Electronic spectra of chloroform solutions were obtained on a Cary 14 spectrophotometer at concentrations of 10^{-3}–10^{-5} M using 1-cm matched quartz cells. IR spectra were taken on a Beckman IR-12 instrument in the range 4000–200 cm^{-1} using KBr pellets. The spectra were calibrated against polystyrene. Table 1 summarizes the relevant spectroscopic data.

*A preliminary report of the structure of $[Mo_4O_8(OCH_3)_2(NNC_6H_5)]^{2-}$ has appeared.[16]

X-ray crystallography

The crystal data and experimental details of the structure determinations are given in Table 2. A full description of the experimental details and the methods of structure solution may be found in Ref. 18.

RESULTS AND DISCUSSION

Preparations

In methanolic solution, polyisomolybdate anions react to give a variety of oxy-methoxy species of hexavalent molybdenum, of which

$$[Mo_8O_{24}(OCH_3)_4]^{4-}$$ [12]

and

$$Mo_2O_5(OCH_3)_2 \cdot 2CH_3OH$$ [19]

constitute the major products. The initial step of the synthesis of the diazenido derivatives would appear to be the formation of some equilibrium mixture of these oxy-methoxy species, which subsequently react with phenylhydrazine, with concomitant cluster dissociation and reaggregation [eqns (1) and (2)]:

$$[Mo_8O_{26}]^{4-} + 4CH_3OH \rightarrow [Mo_8O_{24}(OCH_3)_4]^{4-} + 2H_2O, \quad (1)$$

$$[Mo_8O_{24}(OCH_3)_4]^{4-} + 8H_2NNHC_6H_5 \rightarrow 2[Mo_4O_8(OCH_3)_2(NNHC_6H_5)_4]^{2-} + 8H_2O. \quad (2)$$

The reaction with phenylhydrazine may be viewed formally as a simple condensation reaction to yield:

$$-Mo{=}O + H_2NNHR \rightarrow -Mo{=}N{=}N(H)R + H_2O. \quad (3)$$

the Mo=N=NHR unit [eqn (3)], but evidently some internal redox step, perhaps involving Mo—OH, is necessary to remove the remaining hydrogen atom. The deep purple color developed in the methanol solution of the complex is characteristic of the *cis*-bisdiazenido molybdenum unit,[20] a robust chemical core which persists in the reaction chemistry of these species.

The successful syntheses of the analogous ethoxy and isopropoxy derivatives confirms the scope of the general synthetic procedure and the stability of the tetranuclear unit, $[Mo_4O_8(OR)_2(NNC_6H_5)_4]^{2-}$. Attempts to synthesize analogous species from phenol yielded intensely colored oils from which no solid materials were recoverable, although solution IR spectra exhibited bands characteristic of the tetranuclear core.

The reaction of the molybdenum(VI)–diolato complex,

$$[MoO_2(C_4H_9O_2)_2] \cdot 2C_4H_{10}O_2,$$

with phenylhydrazine provides an alternative route to

$$[Mo_4O_8(OR)_2(NNC_6H_5)_4]^{2-}$$

species. The initial step appears to be formation of

$$[Mo(NNC_6H_5)_2(C_4H_9O_2)_2]$$

by the condensation pathway, followed by hydrolysis, proton transfer and rearrangement over the reaction and the recrystallization period. In a purely formal sense, the reaction may be represented by eqns (4) and (5):

$$[MoO_2(C_4H_9O_2)_2] + 2H_2NNHC_6H_5 \rightarrow [Mo(NNC_6H_5)_2(C_4H_9O_2)_2] + 2H_2O, \quad (4)$$

$$2[Mo(NNC_6H_5)_2(C_4H_9O_2)_2] + 2[MoO_2(C_4H_9O_2)_2] + 2CH_3OH + 4H_2O \xrightarrow{NEt_3} [Mo_4O_8(OCH_3)_2(NNC_6H_5)_4]^{2-} + 2(HNEt_3)^+ + 8C_4H_{10}O_2. \quad (5)$$

Under these conditions, two major reaction products are isolated, lustrous purple crystalline **1a** and a dark-red powder analyzing for

$$[Mo(NNH_6H_5)_2(C_4H_9O_6)_2] \cdot H_2NNHC_6H_5.$$

Although this latter complex gives satisfactory analytical results and exhibits IR spectral characteristics consistent with the presence of the *cis*-bisdiazenido unit and with the absence of Mo–oxo groups, molecular-weight data are ambiguous, suggesting some degree of aggregation. Since all attempts to crystallize this species proved futile, its structural identity remains in doubt.

IR and electronic spectroscopy

The IR spectra of the tetranuclear complexes exhibit two bands in the 1560–1640-cm^{-1} region characteristic of the symmetric and antisymmetric

[d] *International Tables for X-ray Crystallography*, Vol. 3. Kynoch Press, Birmingham, U.K. (1962).

[e] $R = [\sum |F_o|-|F_c|/\sum |F_o|]$. $R_w = [\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2}$. $w = 1/\delta^2(F_o)+g^*(F_o)^2$. $g = 0.001$.

[f] $[\sum w(|F_o|-|F_c|)^2/(NO-NV)]^{1/2}$, where NO is the number of observations and NV is the number of variables.

stretching modes of the *cis*-bisdiazenido grouping. In addition, all derivatives display a pattern of five bands in the 720–930-cm^{-1} range attributable to Mo–O modes. Finally, sharp C—H stretch features in the 2950-cm^{-1} region and alkyl CO stretch features at *ca* 1160 cm^{-1} confirm the presence of the coordinated alkoxy groups.

The electronic spectra of the complexes are characterized by intense absorptions in the visible region, at *ca* 510 and 410 nm, and by three absorption bands in the UV range, at *ca* 300 and 270 nm. The electronic spectrum of

$$[Mo_2(SC_6H_5)_5(NNC_6H_5)_4]^-,^{21}$$

an example of a species possessing the *cis*-bisdiazenido-molybdenum core, exhibits intense bands at 515 and 270 nm. Strong absorption bands in the 510–520- and 270-nm regions may be characteristic of the *cis*-bisdiazenido-molybdenum unit. Unambiguous and complete assignment of the spectra of the tetranuclear complexes must await more detailed spectroscopic analysis of additional examples of this structural type.

Solid-state structures

Atomic positional parameters with standard deviations are available as supplementary material from Dr Mitchell. Relevant bond distances and angles are presented in Table 3. Figures 1(a) and (b) show the structures of

$$[Mo_4O_8(OCH_3)_2(NNC_6H_5)_4]^{2-}$$

and

$$[Mo_4O_8(OC_2H_5)_2(NNC_6H_5)_4]^{2-},$$

respectively, and indicate the atom-labelling scheme.

The structure of **1a** consists of two crystallographically independent $(Bu_4N)^+$ cations and a discrete tetranuclear anion

$$[Mo_4O_8(OCH_3)_2(NNC_6H_5)_4]^{2-}.$$

The overall geometry may be viewed as two

$$[Mo(NNC_6H_5)_2]^{2+}$$

units bridged by two methoxy groups and two $[MoO_4]^{2-}$ units, functioning as bidentate bridging ligands. The

$$[Mo_2(OCH_3)_2(NNR)_4]$$

fragment is nearly planar with maximum deviations of *ca* 0.05 Å from the least-squares plane through all atoms. The Mo_4O_4 heterocycle forms a puckered ring, elongated along the Mo2–Mo4 axis, which presents a Mo2—Mo4 distance of 6.08 Å, relative to 3.455 Å for Mo1—Mo3. The

Mo1–Mo3–O1–O2–O3–O4

unit is nearly planar, with Mo4 and Mo2 disposed slightly above and below the plane, respectively. The bridging $[MoO_4]^{2-}$ units display tetrahedral geometry about the Mo atoms with valence angles approaching the ideal tetrahedral limit and average Mo—terminal oxo and Mo—bridging oxo distances of 1.71(1) and 1.80(1) Å, respectively. The diazenido-coordinated Mo atoms enjoy distorted octahedral geometry through ligation to the oxygen atoms of the bridging methoxy groups, to the bridging oxo groups of the $[MoO_4]^{2-}$ units, and to the terminal nitrogens of the diazenido ligands, with average bond distances of 2.14(1), 2.06(1) and 1.81(1) Å, respectively.

Whereas derivatized isopolymolybdate structures previously described exhibit molybdenum atoms that are exclusively pseudooctahedrally coordinated Mo(VI) units, the present structures are characterized by tetrahedral $[MoO_4]^{2-}$ units sharing vertices with each of the Mo1 and Mo3 octahedra, which in turn share an edge defined by the O11–O12 vector.

The linearity of the Mo–N–N linkages, together with the short average Mo—N distance of 1.81(1) Å and the short average N—N distance of 1.25(2) Å, is indicative of extensive delocalization throughout the Mo–N–N unit and significant multiple bond character to the Mo—N and N—N bonds. These metrical parameters are consistent with the description of the phenyldiazo linkage as the three-electron donating N_2R^+ structure.[29] Electron counting is also consistent with this assignment and with the absence of a metal–metal bond, a feature consistent with the observed Mo1—Mo3 distance.

The *cis*-bisdiazenido-molybdenum unit appears to be a persistent theme of the structural chemistry of molybdenum.[20–22] Since the structural parameters associated with the bridging $[MoO_4]^{2-}$ groups are similar to those observed for $Na_2MoO_4 \cdot 2H_2O$,[23] the formal oxidation state of these Mo centers may be assigned as Mo(VI). Thus, the Mo centers of the $[Mo(NNC_6H_5)_2]^{2+}$ units may be described as Mo(0), an assignment also consistent with the presence of the phenyldiazo group, N_2R^+.

Structural parameters for **1** are nearly identical to those discussed for **1a**, as illustrated in Table 4. The ethoxy-bridged derivative exhibits two crystal modifications: **2** which is isomorphous with **1a** and presents analogous structural features, and the tetragonal form **2a**. The structure of **2a** consists of centrosymmetrically generated tetranuclear units

$$[Mo_4O_8(OC_2H_5)_2(NNC_6H_5)_4]^{2-}$$

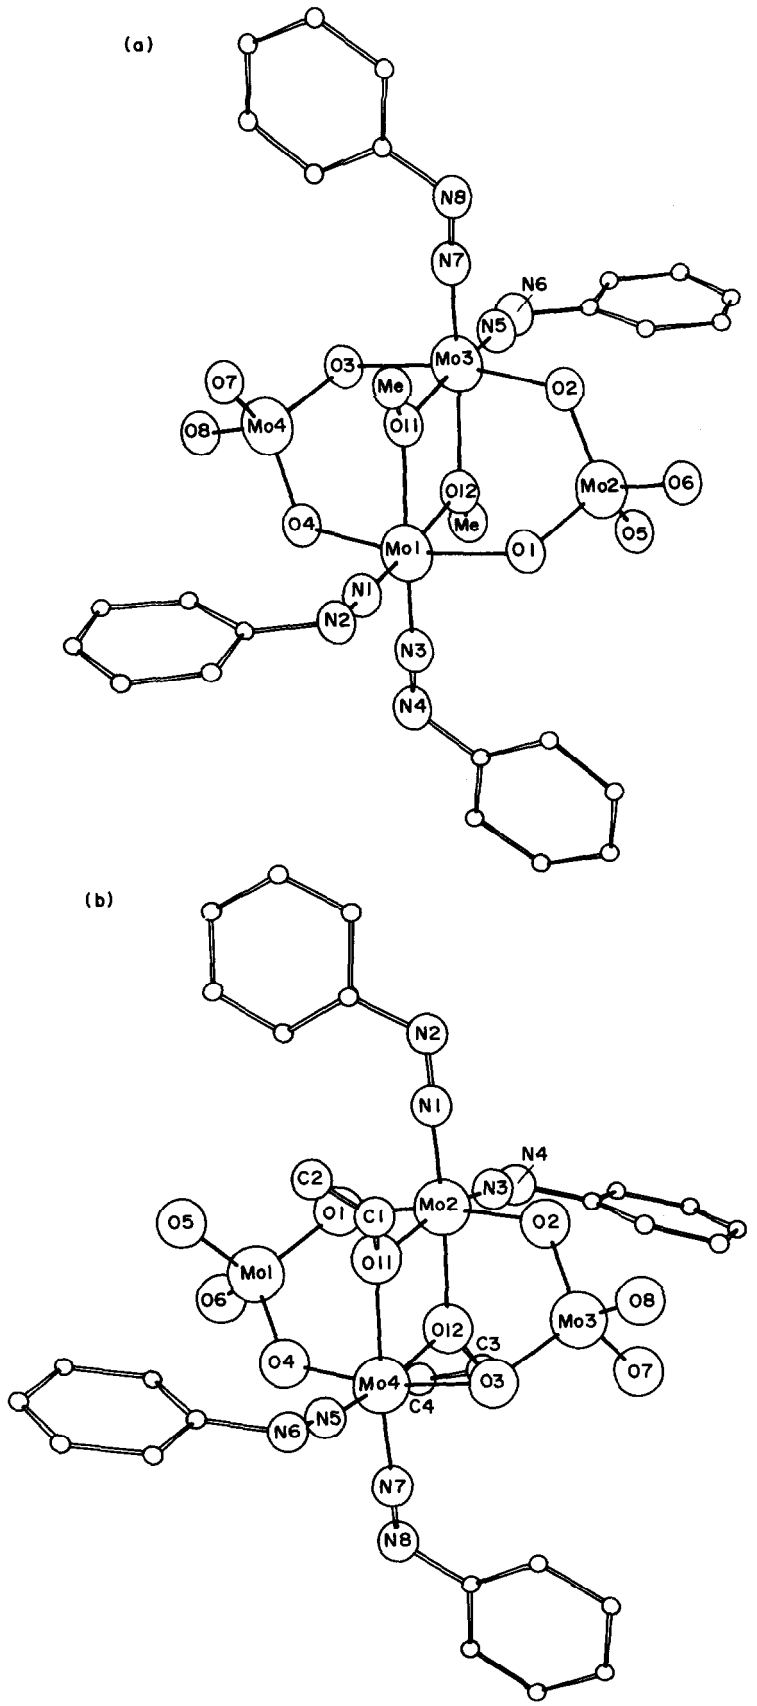

Fig. 1 (a) ORTEP representation of the structure of the tetranuclear dianion $[Mo_4O_8(OCH_3)_2(NNC_6H_5)_4]^{2-}$. (b) Structure of the tetranuclear dianion $[Mo_4O_8(OC_2H_5)_2(NNC_6H_5)_4]^{2-}$.

[a] Atom designators in parentheses refer to the symmetry-generated atoms in structures **1** and **2a**. The structure of **1** consists of two tetranuclear units, each generated from crystallographically independent binuclear units, $[Mo_2O_4(OCH_3)(NNC_6H_5)_2]$, and a center of symmetry located at the mid-point of the Mo1–Mo1a vector. The structure of **2a** consists of a single crystallographically independent $[Mo_2O_4(OC_2H_5)(NNC_6H_5)_2]$ unit.

with an overall geometry similar to that observed for **1**, **1a** and **2**. The interesting structural features are the Mo—N and N—N bond distances which average 1.73 and 1.31 Å, respectively. Although the relatively poor resolution achieved for this structure precludes an unambiguous conclusion, these distances suggest a degree of valence isomerism for the diazenido-molybdenum unit in these structures. The molybdenum–diazenido interaction may be represented by the limiting formalisms **I** and **II**, for which expected bond distances may be estimated.[24]

We see that the bond distances in **1**, **1a** and **2** closely approximate those expected for **I**, while those in **2a** suggest a significant contribution from **II**, representing about a 40:60 mixture of **I** and **II**.

Synthetic investigations

The structural studies reveal that the $[Mo(NNC_6H_5)_2]^{2+}$ core is persistent and displays significant delocalized multiple bond character; in contrast, the bridging $[MoO_4]^{2-}$ units and the alkoxy ligands exhibit relatively long bond distances. Since the relative strengths of the various molybdenum–ligand interactions is reflected in the bond lengths, the bond strengths, s, may be derived from the expression:[25]

$$s = (d/1.882)^{-6.0},$$

where d is the bond length. For diazenido-coordinated molybdenum atom–ligand interactions, average bond strengths of 1.26, 0.58 and 0.46 are calculated for Mo—N, Mo—O(oxo) and Mo—O(alkoxy), respectively. This observation suggests that, whereas the *cis*-bisdiazenido-molybdenum(0) core may be chemically robust, the alkoxy and oxo groups are relatively weakly bonded and may be readily displaced upon reaction with appropriate ligands.

Indeed, the complex anions are reactive toward both oxidation–reduction reactions and substitution reactions at the oxo and alkoxy centers, providing useful synthetic precursors for a variety of complexes incorporating the $[Mo(NNC_6H_5)_2]^{2+}$ core. Thus, reaction with arenethiolate ligands yields binuclear species, $[Mo_2(NNC_6H_5)_4(SAr)_5]^-$:[21]

$$[Mo_4O_8(OR)_2(NNC_6H_5)_4]^{2-} + 15HSAr + NEt_3 \rightarrow (HNEt_3)[Mo_2(NNC_6H_5)_4(SAr)_5] + 2[MoO(SAr)_4]^- + ArSSAr + 6H_2O + 2ROH. \quad (6)$$

The thiolate acts both as ligand and as reducing agent for the Mo(VI) centers. Addition of excess phenylhydrazine to this reaction mixture does not substantially improve the yield of

$$[Mo_2(NNC_6H_5)_4(SAr)_5]^-.$$

The nature of the thiolate ligand does influence the reaction chemistry. Thus, reaction of

$$[Mo_4O_8(OR)_2(NNC_6H_5)_4]^{2-}$$

clusters with ethanedithiol again results in dimer formation, but with displacement of diazenido units and protonation of ligated diazenido groups to yield

the unusual species

$$[Mo_2(SCH_2CH_2S)_3(SCH_2CH_2SH)(NNC_6H_5)(NNHC_6H_5)]^{2-}.$$[26]

Displacement of a diazenido group also occurs upon reaction with sterically-hindered thiolates such as 2,4,6-triisopropylthiophenol (TIPT), where the monomeric species

$$[Mo(NNC_6H_5)(CH_3CN)(TIPT)_3]$$

is isolated.[27] In this and other reactions involving TIPT, steric constraints appear to dominate the course of the reaction.

Reaction with dialcohols in chlorinated solvents invariably results in C—C bond cleavage and the formation of alkoxy-bridged dimers. Thus, reaction of

$$[Mo_4O_8(OR)_2(NNC_6H_5)_4]^{2-}$$

with butane-2,3-diol in CH_2Cl_2 yields

$$[Mo_2Cl_2(OC_2H_5)_2(HOC_2H_5)_2(NNC_6H_5)_4],$$

the chloro ligand presumably extracted from the chlorinated solvent.[28] In this case, the *cis*-bisdiazenido-molybdenum core is retained and appears structurally identical to that reported for **1a**.

Reactions with dithiocarbamates, $^-S_2CNR_2$, and dithiophosphates, $^-S_2P(OR)_2$, yield mononuclear species of the type $[Mo(NNC_6H_5)_2(SS)_2]$, where (SS) is the bidentate 1,1-dithioacid ligand. Likewise, with tetradentate ligands such as

$$HSCH_2CH_2X(CH_2)_nXCH_2CH_2SH, (HSXXSH),$$

[X = S or NR], species of the type

$$[Mo(NNC_6H_5)_2(SXXS)]$$

have been isolated. Both series of complexes display the $[Mo(NNC_6H_5)_2]^{2+}$ core.

The tetranuclear clusters appear to provide useful synthetic precursors. The *cis*-bisdiazenido-molybdenum unit is persistent throughout much of this chemistry, suggesting that it provides a chemically robust core, somewhat reminiscent of the *cis*-$[MoO_2]^{2+}$ unit now well-documented in the structural chemistry of Mo(VI).

MOLYBDENUM PHTHALOCYANINE

STEPHEN J. EDMONDSON and PHILIP C. H. MITCHELL*

Department of Chemistry, The University, Whiteknights, Reading RG6 2AD, U.K.

(*Received* 11 *June* 1985)

Abstract—Reaction of ammonium heptamolybdate with fused phthalodinitrile (1,2-dicyanobenzene) gave blue oxomolybdenum(IV) phthalocyanine, $MoO(C_{32}H_{16}N_8)$ (MoOPc). Reactions involved in the preparation are discussed. MoOPc sublimes at 400°C *in vacuo* giving a violet second crystalline form. The IR spectrum showed a characteristic Mo=O vibration at 974 cm^{-1}. The electronic spectrum of MoOPc in 1,2,4-trichlorobenzene showed a characteristic metallophthalocyanine peak at 703 nm and a weaker peak at 643 nm. In pyridine new peaks appeared and the spectrum changed with time. Methods of synthesis and applications of molybdenum phthalocyanines are reviewed.

Phthalocyanines of most of the metallic elements are well-known and well-characterized with, until recently, the notable exception of a molybdenum phthalocyanine, although molybdenum porphyrins are well-known. Molybdenum phthalocyanines have been mentioned in the literature, especially patents, but the nature of the substances is obscure. Compounds claimed include MoPc,[1] MoOPc,[2] MoO_2Pc[3] and $MoClPc_2$.[4] In 1966 Hill and Norgett[2] reported the preparation of oxomolybdenum(IV) phthalocyanine, MoOPc (Pc^{2-} is the phthalocyaninato anion, $C_{32}H_{16}N_8^{2-}$), in very low yield. While our work was in progress Borschel and Strahle[5] reported the preparation of MoOPc, from $Mo(CO)_6$ and phthalodinitrile in a sealed tube, and its crystal structure. The structure of MoOPc is similar to the structure of VOPc. The molybdenum coordination is square pyramidal. The molybdenum atom is located 69 pm above the plane of the four nitrogens of the phthalocyanine and forms a short bond of 166.8 pm to oxygen.

The molybdenum phthalocyanines are potentially interesting and useful. Patents claim applications of molybdenum phthalocyanines as pigments and corrosion inhibitors, as catalysts for the epoxidation of olefins and the electroreduction of oxygen,[6] and as sulphur-resistant catalysts for the hydrogenation of quinoline and coal-derived liquids.[7] The dimeric $MoPc_2Cl$ is said to have "semiconductor properties".[4]

* Author to whom correspondence should be addressed.

The object of our work was to devise syntheses of molybdenum phthalocyanines as a preliminary to studying their properties and applications. Our initial experience was that attempts to repeat preparations described in the literature produced substances of doubtful composition and purity in low yields. Clearly there is a preparative problem. This paper describes a convenient, high-yield synthesis and characterization of MoOPc.

EXPERIMENTAL

Preparation of MoOPc, $MoO(C_{32}H_{16}N_8)$

Ammonium heptamolybdate,

$$(NH_4)_6Mo_7O_{24}\cdot 4H_2O,$$

and phthalodinitrile (PDN), $C_6H_4(CN)_2$, in the ratio 1Mo : 4PDN were ground together and heated in a closed vacuum system at 270°C for 0.75 h. The blue solid formed was washed with potassium hydroxide solution and water to remove any unreacted molybdate or MoO_3 and phthalimide, and then with ethanol and acetone until the washings were colourless. Alternatively, purification could be carried out by Soxhlet extraction with butanone for 6 h.

The reaction can also be carried out in air. When a tube containing phthalodinitrile and ammonium heptamolybdate was heated the PDN melted at

140°C, the liquid turned brown at 200°C, and at 240°C reaction started with vigorous gas evolution.

As much as 50 g of MoOpc in yields > 70% based on molybdenum have been prepared by this method.

Analysis

Routine CHN microanalysis of the sublimed substance corresponded closely to MoOPc. Found: C, 61.5; H, 2.8; N, 18.0%. Calc. for $C_{32}H_{16}MoN_8O$: C, 61.5; H, 2.6; N, 18.0%.

Physical measurements

UV–visible spectra of solutions of the compounds were recorded on a Pye Unicam SP1800 spectrophotometer. IR spectra of compounds in Nujol mulls and KBr discs were recorded on a Perkin–Elmer 983 IR spectrophotometer. X-ray diffraction patterns of powders were recorded on a Phillips PW1710/00 instrument.

RESULTS AND DISCUSSION

Preparative chemistry and reactions

The reaction between ammonium heptamolybdate and fused phthalodinitrile produced MoOPc in high yield. The IR spectrum and X-ray diffraction pattern of the blue product showed the absence of MoO_3, MoO_2, metal-free phthalocyanine and unreacted phthalodinitrile. Some phthalimide was formed by hydrolysis of the phthalodinitrile.

Reduction of molybdenum(VI) is accomplished by ammonia (from ammonium heptamolbydate). When sodium molybdate was used in place of ammonium heptamolybdate there was no reaction.

Properties of MoOPc

Our sample of MoOPc sublimed at 400°C and 10^{-3} torr with some decomposition. The sublimate was violet and appeared to be the same crystalline form as reported by Borschel and Strahle.[5] Grinding

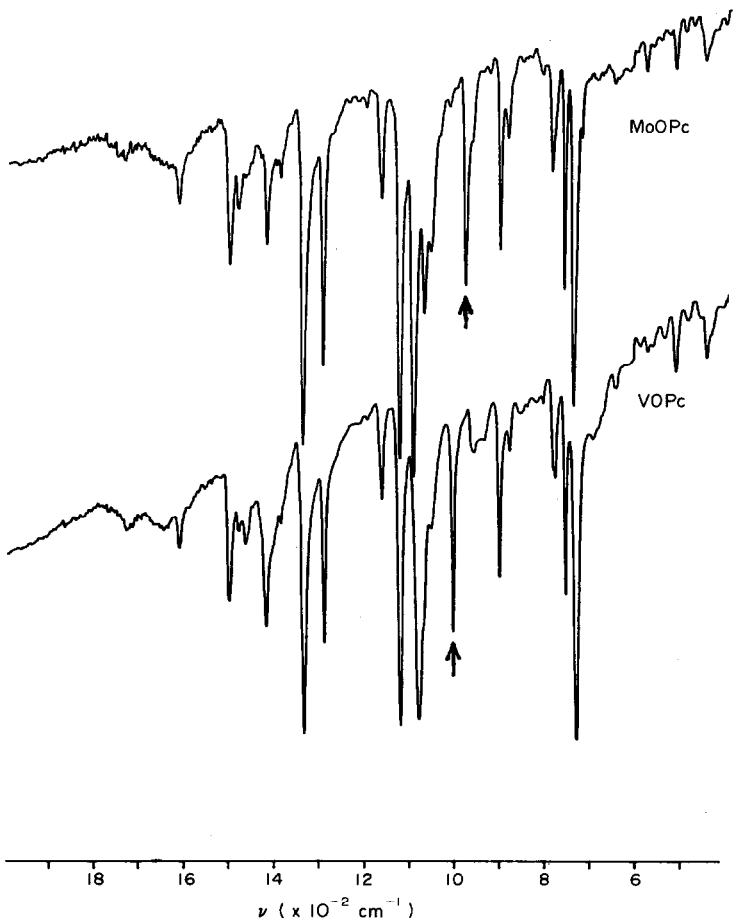

Fig. 1. IR spectra of MoOPc and VOPc in KBr discs. The arrows show the metal–oxygen vibrations.

of the violet form caused a reversion to the blue form. The blue residue remaining from the sublimation was shown to contain the blue form of MoOPc and some MoO_2 by X-ray diffraction.

MoOPc is slightly soluble in chlorobenzenes and chloronaphthalenes and acetone and butanone and rather more soluble in pyridine. It dissolved in concentrated sulphuric acid; reprecipitation at 0°C by addition of water gave a green compound which is still being investigated.

X-ray diffraction powder pattern

The strong diffraction lines were at the following values of $2\theta°$ (relative intensities are in parentheses): 3.1 (2.4), 3.5 (1.4), 3.6 (1.3), 4.0 (2.15), 5.3 (1.0) and 7.0 (1.5). Lines due to metal-free phthalocyanine, phthalodinitrile and MoO_2 were absent from the purified MoOPc. The powder pattern is a useful criterion of purity.

The X-ray diffraction pattern which we calculated from the X-ray crystallographic data of Borschell and Strahle[5] was different from ours; strong lines at our 2θ were not present. This, together with the different colours of the compounds (ours is bluc and theirs violet) suggests that there are two crystal forms of MoOPc, our preparation giving a different crystal form. The existence of different crystal forms is not uncommon with metallophthalocyanines.

IR spectra

The IR spectra of MoOPc and VOPc, which has the same structure, are shown in Fig. 1. The two spectra are similar both in the number and positions of the bands except that the wavenumber of the metal–oxygen vibration is lower for MoOPc (974 cm^{-1}) than for VOPc (1002 cm^{-1}). We estimate the effect of the different atomic masses of molybdenum and vanadium from the simple expression for the vibration frequency (v) [$(k/m)^{0.5}$, where k is the force constant and m is the reduced mass]. The calculated value for MoOPc is 1001 cm^{-1}, nearly 30 cm^{-1} higher than the experimental value. The observed Mo=O vibration frequency is therefore lower than can be accounted for by the mass different; evidently, in the phthalocyanine complexes, the Mo=O force constant is less and the Mo=O bond weaker than the V=O bond.

UV–visible spectrum

The spectrum of MoOPc in 1,2,4-trichlorobenzene shows a characteristic metallophthalocyanine peak at 703 nm and a weaker peak at 643 nm. The corresponding peaks of VOPc are at 700 and 630 nm and of metal-free phthalocyanine at 697 and 659 nm.

The spectrum of MoOPc in pyridine changed with time. The bands shifted to 710 and 652 nm and a new band at 676 nm appeared and grew in intensity with time.

(*Received* 17 *June* 1985)

Abstract—The reaction of *cis*-$[MoO_2(C_5H_{10}NO)_2]$ ($C_5H_{10}NOH$ = 1-piperidinol) with benzene 1,2-diol (catechol) in $CHCl_3$ leads to the formation of $[MoO(C_5H_{10}NO)_2(C_6H_4O_2)]$, which has been characterized by X-ray crystallography, NMR spectroscopy and cyclic voltammetry.

We have been interested in developing the chemistry of complexes of the type *cis*-$[MoO_2(R^1R^2NO)_2]$ (R^1R^2NO = *N*,*N*-dialkylhydroxylamido(1−)-*O*,*N*) because they are the only six-coordinate Mo(VI) complexes found to date in which an oxo group can be replaced by a sulphido group.[1–3] The $\{MoOS\}^{2+}$ centre produced by this reaction is thought to be relevant to the nature of the coordination environment about Mo in xanthine oxidase and related enzymes.[4] We report herein that an oxo group in these complexes can also be replaced by a catecholate moiety to give complexes of the type $MoO(R^1R^2NO)_2$(catecholate). The salient properties of the prototypical member of this series, $[MoO(C_5H_{10}NO)_2(C_6H_4O_2)]$ ($C_5H_{10}NOH$ = 1-piperidinol), are described.

EXPERIMENTAL

To a solution of *cis*-$[MoO_2(C_5H_{10}NO)_2]$[1] in $CHCl_3$ was added an equimolar amount of solid catechol. After stirring for *ca* 1 h, the purple solution was evaporated to dryness under reduced pressure, giving analytically pure $[MoO(C_5H_{10}NO)_2(C_6H_4O_2)]$ as a deep purple powder.

RESULTS

NMR spectroscopy

The 75 MHz ^{13}C NMR spectrum of the complex dissolved in $CDCl_3$ showed 11 signals: five in the 1-piperidinolate region, and six in the catecholate region. The former implies a symmetry element in the molecule which relates the 1-piperidinolate rings. This cannot be a C_2-axis, because of the six catecholate signals observed, and must, therefore, be a mirror plane. If this plane relates one half of each piperidinolate ring to the other half of the *same* ring, then, given the expected[1,2] mode of coordination of the 1-piperidinolate ligand, this would require all the ligand donor atoms to be coplanar with Mo—a highly unusual and sterically unfavourable arrangement. Thus, we are driven to the conclusion that the molecule possesses C_s point symmetry, with the catecholate ligand lying in the mirror plane.

The detailed assignments of the 300-MHz ^1H and 75-MHz ^{13}C NMR spectra were not trivial: although the ^1H resonances of the aromatic protons are readily interpreted, assignment of the corresponding ^{13}C resonances are equivocal. Conversely, the ^{13}C resonances of the 1-piperidinolate groups are easily elucidated but the methylene proton resonances are very complicated. Therefore, a two-dimensional ^1H–^{13}C chemical-shift correlation (Fig. 1) was used to complete the assignment of

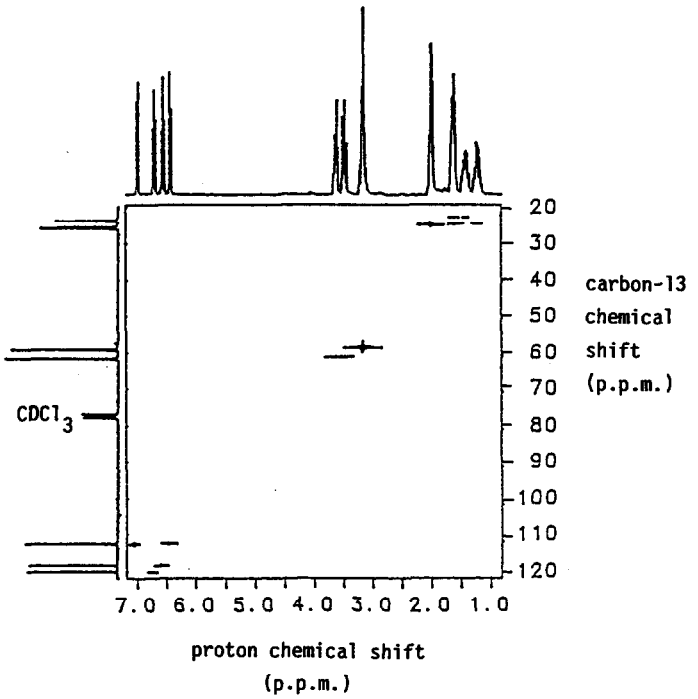

Fig. 1. Two-dimensional proton–carbon chemical-shift correlation for $[MoO(C_5H_{10}NO)_2(C_6H_4O_2)]$ in $CDCl_3$. The corresponding one-dimensional proton and carbon spectra (300- and 75-MHz, respectively) are plotted along the axes.

each spectrum. This two-dimensional technique generates spectra as a function of both the proton and carbon chemical shifts: one peak appears for each distinct CH group. This improves the effective resolution of the spectrum, since it is very rare for both the ^1H and ^{13}C resonances of two CH groups to be accidentally coincident.

X-ray crystallography

A single crystal of $[MoO(C_5H_{10}NO)_2(C_6H_4O_2)]$ was selected from a batch grown by diffusing *n*-heptane into a solution of the complex in $CHBr_3$, and examined by X-ray diffraction techniques.* $[MoO(C_5H_{10}NO)_2(C_6H_4O_2)]$ crystallizes in the tetragonal space group $P\bar{4}2_1/c$ with $a = 14.080(4)$ Å, $c = 18.099(8)$ Å and $Z = 8$. The molecular unit (see Fig. 2) involves the distorted pentagonal bipyramidal arrangement of ligand donor atoms typical of seven-coordinate Mo(VI), with the catecholate ligand spanning an equatorial and an axial site, thus confirming the deductions from NMR spectroscopy. A notable aspect of the molecular structure is that there is no appreciable static trans effect due to Mo—O_t; the lengths of the Mo—O bonds involving the catecholate ligand are 2.016(5) Å (*cis*) and 2.012(5) Å (*trans*). Other important molecular dimensions are: Mo—O1 = 1.688(6) Å, C31—O31 = 1.352(9) Å, C36—O32 = 1.375(9) Å, O1—Mo—O31

$[MoO(C_5H_{10}NO)_2$(catecholate)]	−1.7
$[MoO(C_5H_{10}NO)_2$(4-nitrocatecholate)]	−1.4

[a] Versus the ferricenium–ferrocene couple.

= 163.9(3)°, and O1—Mo—O32 = 87.4(3)°. The Mo atom is displaced 0.14 Å out of the best plane through the equatorial ligand donor atoms towards O1.

Cyclic voltammetry

Cyclic voltammetry at a Pt wire in MeCN indicates that the complex undergoes an irreversible one-electron reduction, deviating towards a two-electron stoichiometry at slow scan rates. This observation is confirmed by controlled-potential electrolysis at a Hg surface, when 2 mol of electrons are consumed per mol of complex. Analogous complexes with 4-*t*-butylcatechol and 3,5-di-*t*-butylcatechol also undergo a reversible one-electron oxidation. The peak potentials for oxidation and reduction vary in the expected manner with substitution of the catecholate ring; in comparison with the electrochemical properties of the parent complex, *cis*-$[MoO_2(C_5H_{10}NO)_2]$,[3] the catecholate ligand imparts a greater facility to reduction of the complex (see Table 1).

COORDINATION CHEMISTRY OF Mo– AND W–S COMPOUNDS AND SOME ASPECTS OF HYDRODESULFURIZATION CATALYSIS

A. MÜLLER

Faculty of Chemistry, University, 4800 Bielefeld, F.R.G.

(*Received* 4 *July* 1985)

Abstract—The coordination chemistry of Mo– and W–S compounds has been reviewed with emphasis on new results of our laboratory (including a systematic treatment of the compound types with different functional groups and the different reaction types). Molecular models for crystalline MoS_2 and the nitrosylated CoMoS phase as well as for the promoting effect of the Co atoms on hydrodesulfurization catalysis have been discussed.

During the last few years a tremendous amount of material has been collected about Mo– and W–S complexes and clusters. There is no other transition metal for which so many pure and discrete heterometal–S species (with only S_x^{2-} ligands; $x = 1, 2, \ldots$) are known (even more than for Cu). The relevance to the bioinorganic chemistry[1–6] of Mo and also to heterogeneous catalysis [especially hydrodesulfurization (HDS)][7–9] has been stressed several times in the literature. In this article we will develop a systematic treatment of the coordination chemistry of Mo– and W–S compounds with emphasis on new results of our institute (for a recent review of the corresponding solid-state chemistry see Ref. 10). Mo compounds and especially those with only "S ligands" are considered preferable. Representative examples for different types of species regarding molecular and electronic structure are given in Tables 1 and 2.

SURVEY OF COMPOUND TYPES

Simple di-($\{Mo_2S_2\}^{n+}$), *tri-*($\{Mo_3S_4\}^{n+}$) *and tetra-*($\{Mo_4S_4\}^{n+}$) *nuclear* Mo–S *clusters*

Species with different electron populations and with the same central units as the ferredoxins, that means with $\{Mo_2S_2\}^{n+}$, $\{Mo_3S_4\}^{n+}$ and $\{Mo_4S_4\}^{n+}$ {see Fig. 1 for the structure of $[Mo_4S_4(CN)_{12}]^{8-}$}, can be prepared (see Table 1). Cyano derivatives which can be reversibly reduced and oxidized might have been of importance for the evolution of Mo enzymes[12,38] (compound types and references in Table 1).

Species with functional groups of high reactivity

Species with $\{M{=}S_t\}^{n+}$ *groups.* The reactivity of a terminal Mo=S group, for instance, is very high compared to that of a bridging Mo—S—Mo one. Quite a number of species with $\{M{=}S_t\}^{n+}$ units, which are only stable in the higher oxidation states of M, are known (compound types and references in Table 1). Species with the binuclear (central) $\{M_2S_2(X_t)_2\}^{2+}$ (X = O or S) unit have a high formation tendency. For some of those see Fig. 2 and later.

Metal–sulfur aggregates with no metal–metal interactions and μ_n-S^{2-} *ligands.* Metal–sulfur aggregates with no metal–metal interaction exist preferably with strong π-acceptor ligands like NO. $[Mo_4(NO)_4(S_2)_5S_3]^{4-}$, built up by four Mo atoms, contains (besides S_2^{2-} ligands, see next section) two μ_3-S^{2-} and one μ_4-S^{2-} ligand. An interesting species with a bridging Mo=S=Mo group is $[(CN)_6MoSMo(CN)_6]^{6-}$, which was obtained by us by the reaction of molybdate with H_2S in the presence of CN^- (compound types and references in Table 1).

Mono- and polynuclear species with S_x^{2-} *ligands* ($x > 1$). W and (especially) Mo have a very high tendency to form polysulfido compounds with S_2^{2-} and S_4^{2-} ligands. It is worthwhile distinguishing between species with terminal S_x^{2-} ligands [$\{M(S_2)\}^{n+}$ ($n = 4, 3$ or 2) and $\{M(S_4)\}^{n+}$ ($n = 3$ or 2) groups] and those with bridging ones [i.e. with

[a] Number of coordinating S-atoms per thiometalate ligand.
[b] Number of M′—S bonds formed per $MS_nO_{4-n}^{2-}$ (n = 2, 3, or 4) ligand.
[c] Abbreviations: sp, square pyramidal; tp, trigonal planar; t, tetrahedral; o, octahedral; sqp, square planar; mc, missing corner(s).
[d] M′ = M.
[e] M–O distance.
[f] Not given because of disorder.
[g] With different electron populations; strongly delocalized MOs (in trianions).

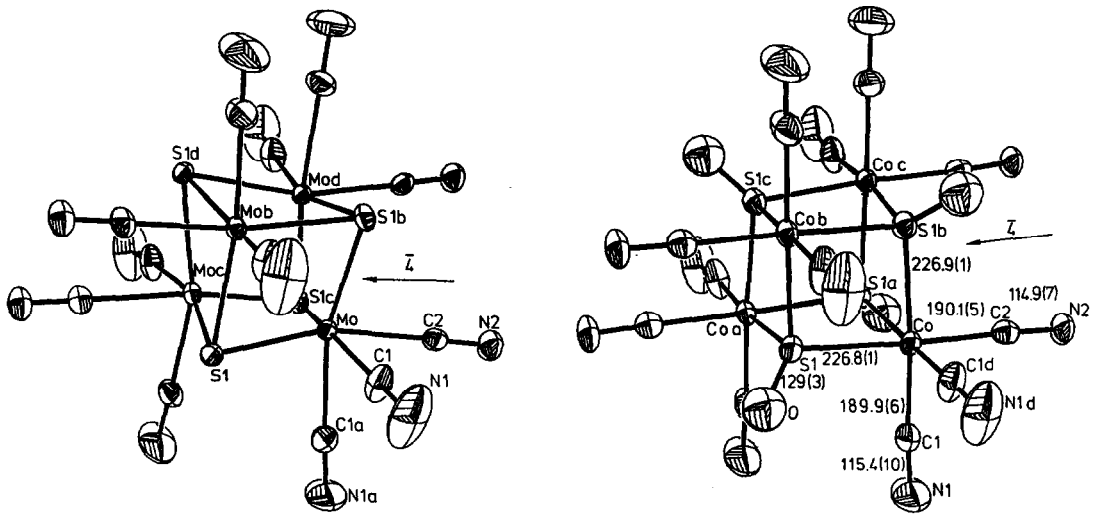

Fig. 1. Structures of $[Mo_4S_4(CN)_{12}]^{8-}$ and $[Co_4S_3(SO)(CN)_{12}]^{8-}$ (see last section) (bond lengths in pm) in crystals of $K_8[Mo_4S_4(CN)_{12}]\cdot 4H_2O$ and $K_8[Co_4S_3(SO)(CN)_{12}]\cdot 4H_2O$.[16,91]

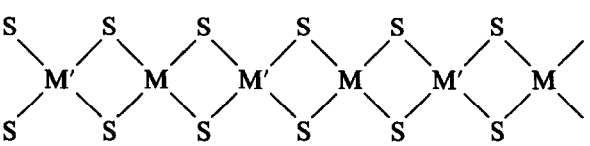
$M(S_x)M$ moieties]. In $[Mo_2(S_2)_6]^{2-}$ and $[Mo_3S(S_2)_6]^{2-}$ (Fig. 3) both types occur. A large variety of different coordination types, especially of S_2^{2-}, exists.[39,40] In the two tetranuclear complexes $[Mo_4(NO)_4(S_2)_5S_3]^{4-}$ and $[Mo_4(NO)_4(S_2)_6O]^{2-}$, which have nearly the same stoichiometry, for instance, four different types of coordinated S_2^{2-} ligands occur (in the nomenclature of Ref. 39 structural types Ia, Ib, IIb and III). In $[Mo_2(NO)_2(S_2)_3(S_5)(OH)]^{3-}$ the doubly bridging S_5^{2-} ligand occurs (compound types and references in Table 1).

Species with SH^- *ligands.* Compounds containing SH^- ligands are interesting with respect to the possible activation of H_2 at the S sites of HDS catalysts. Very few species are known as yet, like

$$[WS_3(SH)]^-, \quad [W(CN)_7(SH)]^{4-}$$

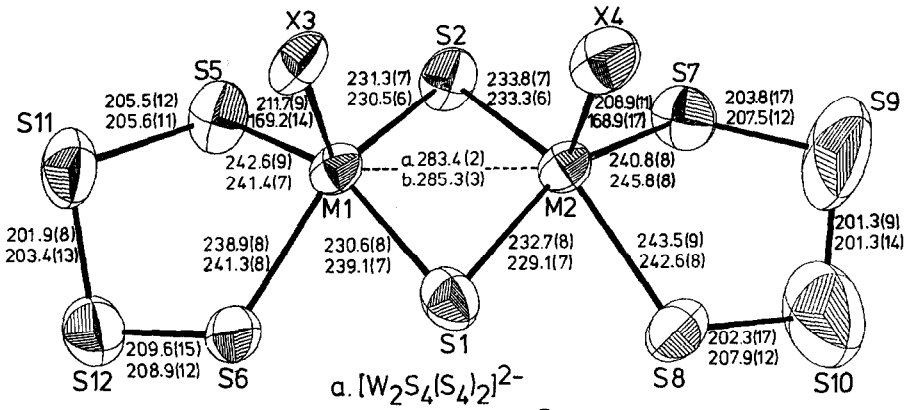
and



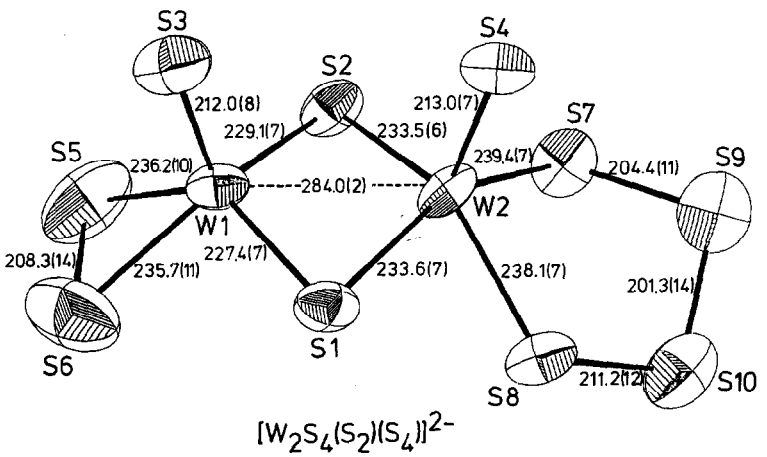
$$[Mo_2S_2(SH)_2(Me_n\text{-cp})_2]^{36,37}$$

(see Table 1 and references, and Fig. 4).

Heterometallic aggregates with thiometalato ligands



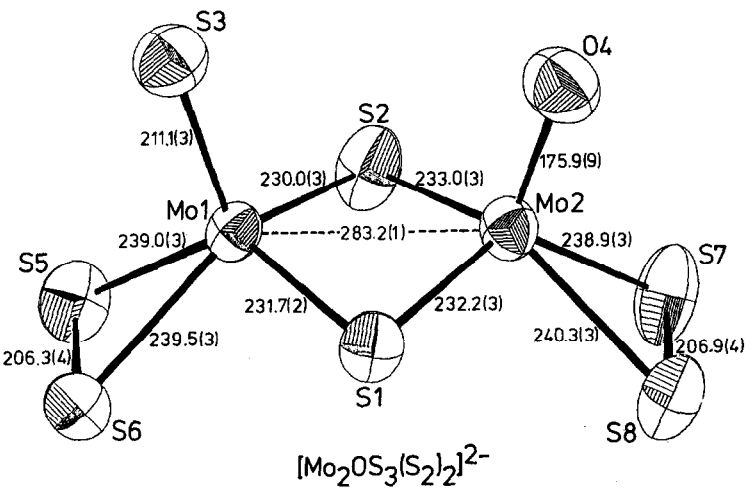
Since the isolation of $[Ni(WS_4)_2]^{2-}$, the first discrete thiometalato complex, in 1971 by us, anions of the type $MO_{4-n}S_n^{2-}$ have gained growing attention in complex chemistry. At present, more than a hundred complexes are known with the following elements: Fe, Co, Ni, Cu, Zn, Mo, Ru, Pd, Ag, Cd, Sn, W, Pt, Au, Hg and Pb. The interest in this class of compounds is mainly due to three reasons: (1) the thiometalates show a versatile coordination behaviour, (2) many of the multi-metal systems possess unique electronic properties (existence of species with different electron populations), and (3) some of the species are of bioinorganic or catalytical interest (for instance the thermal-decomposition products of salts of $[Ni(WS_4)_2]^{2-}$ and $[Co(MoS_4)_2]^{3-}$ act as excellent hydrogenation and HDS catalysts).

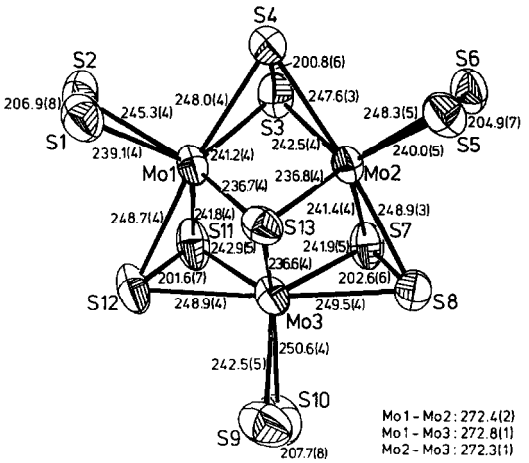


If complexes with univalent (like $[M'(MS_4)_2]^{3-}$, M' = Cu or Ag; for structures see Fig. 5) or formally univalent (like $[Fe(WS_4)_2]^{3-}$) M' cations exist, compounds with a catena structure of the anions like $(PPh_4)Fe(WS_4)$ and $PPh_4Ag(WS_4)$ can be obtained, too. (All corresponding compounds are isostructural.) Though no single-crystal structure determination could be done for the microcrystalline material of the polymeric compounds, vibrational spectroscopy (mainly resonance-Raman), powder diffraction studies and Mössbauer spectroscopy (for the Fe species) suggest strongly the presence of chains ($M'S_4$ and MS_4 tetrahedra sharing edges) in the compounds $(PPh_4)M'(MS_4)$:[60,61]

where M' = Fe, Cu or Ag; M = Mo or W.

The Fe^{n+}–WS_4^{2-} system is, in particular, very interesting. While $[Fe(WS_4)_2]^{2-}$, $[Fe(WS_4)_2]^{3-}$ and $[Fe(H_2O)_2(WS_4)_2]^{2-}$ can be precipitated directly from an aqueous solution,[45]





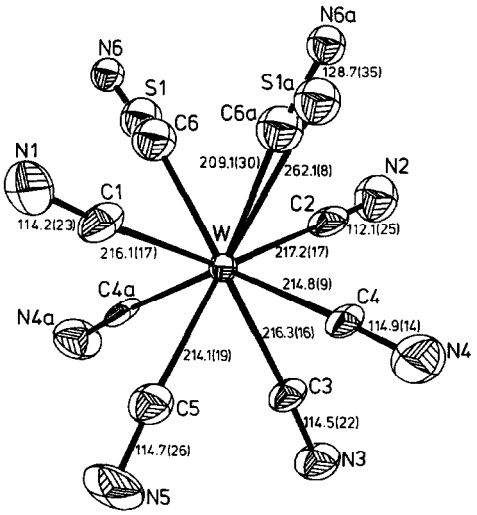


Fig. 2. Structures of $[W_2S_4(S_4)_2]^{2-}$ (with bond lengths (pm) also for $[Mo_2O_2S_2(S_4)_2]^{2-}$), $[W_2S_4(S_2)(S_4)]^{2-}$ and $[Mo_2OS_3(S_2)_2]^{2-}$ in crystals of $(PPh_4)_2[W_2S_4(S_4)_2] \cdot 0.5DMF$, $(PPh_4)_2[Mo_2O_2S_2(S_4)_2]$, $(PPh_4)_2[W_2S_4(S_2)(S_4)] \cdot 0.5DMF$ and $(PPh_4)(NEt_4)[Mo_2OS_3(S_2)_2] \cdot MeCN$.[21]

$[Mo_3S(S_2)_6]^{2-}$ ($AsPh_4^+$-salt)

Fig. 3. Structure of $[Mo_3S(S_2)_6]^{2-}$ in crystals of the new $(AsPh_4)_2[Mo_3S(S_2)_6]\cdot 2MeCN$ [$P\bar{1}$, $a = 1107.5(3)$ pm, $b = 1231.9(3)$ pm, $c = 2443.7(6)$ pm, $\alpha = 94.37(2)°$, $\beta = 103.67(2)°$, $\gamma = 110.49(2)°$, bond lengths in pm].[96]

$[W(CN)_7(SH)]^{4-}$

Fig. 4. Structure of $[W(CN)_7(SH)]^{4-}$ in crystals of $K_4[W(CN)_7(SH)]\cdot 2H_2O$ [*Pnma*, $a = 1657.6(6)$ pm, $b = 1157.8(3)$ pm, $c = 873.2(3)$ pm; bond lengths in pm]. Refinement in space group $Pna2_1$ showed the S atom occupying one position only. However, since, due to correlation effects, the structure could not be refined properly in $Pna2_1$, *Pnma* was chosen even though in this space group a mirror plane through W, Cl, N1, C2, N2, C3, N3, C5 and N5 causes a "disorder" of the SH^- and a CN^- ligand (S1 and C6, N6).[35]

$[Fe_3S_2(WS_4)_3]^{4-}$ [54] and the linear tetranuclear $[Fe_2S_2(WS_4)_2]^{4-}$ [45] (with fully reduced $\{Fe_2S_2\}^o$ core!) can be obtained from organic solvents.

The Fe^{n+}–MoS_4^{2-} solvent system is not as versatile due to the high formation tendency of the reduced $[Fe(MoS_4)_2]^{3-}$ [55] species. (It is formed simply in aqueous solution from Fe(II) and MoS_4^{2-} [60]). The discrete dianion could not be isolated until now, only a polymeric substance with the rough composition $(PPh_4)_2Fe(MoS_4)_2$ showing a powder diffraction pattern characteristic for an X-ray amorphous substance.[62]* All known pure metal–sulfur di- and trianions, which exist with different electron populations, are presented in Table 2.

Several mixed-ligand complexes are known (Table 2). Those with NO ligands with formally very low oxidation states of the central atoms are of interest for the characterization of the HDS catalyst {see Figs 6 and 7 for the structures of $[(NO)_2Co(WS_4)_2]^-$, $[(NO)_2Co(MoO_2S_2)_2]^-$ and $[(NO)Fe(WS_4)_2]^{2-}$, Table 2 and the previous section}.

A detailed report on many Cu complexes has been written by Garner *et al.*[5]

Species with oxidized S_x^{2-} *and organo substituted* S *ligands*

$[Mo_2S_4(S_2)(S_3O)]^{2-}$ and $[Mo_2O_2S_2(S_2)(S_3O_2)]^{2-}$ are examples of complexes in which S_x^{2-} ligands are oxidized (see Fig. 8).[64,65] Three complexes with organo substituted ligands, which have been obtained from pure chalcogeno species should be considered here: $[Mo_2O_2S_2(DMAD)_2]^{2-}$ with an Mo(V)—C bond (obtained from $[Mo_2O_2S_2(S_2)_2]^{2-}$ [66]), $[Mo_2S_4(dtc)_2]$ (from $[Mo_2(S_2)_6]^{2-}$ [67]) and $[Mo_3S_4(SCH_2CH_2S)_3]^{2-}$ (from $[Mo_3S(S_2)_6]^{2-}$).[68]

SYNTHESIS AND REACTIVITY

A tremendous variety of simple species containing only S (and O) and M exist: e.g. MO_3S^{2-}, $MO_2S_2^{2-}$, MOS_3^{2-}, MS_4^{2-}, $[MoS(S_4)_2]^{2-}$, $[MoO(S_4)_2]^{2-}$, $[Mo_2(S_2)_6]^{2-}$, $[Mo_2S_4(S_2)_2]^{2-}$, $[M_2S_4(S_4)_2]^{2-}$, $[M_2S_4(S_2)(S_4)]^{2-}$, $[Mo_2OS_3(S_2)_2]^{2-}$,

$[Mo_2O_2S_2(S_2)(S_x)]^{2-}$ ($x = 2$ or 4),

$[Mo_2O_2S_2(S_2)(S_3O_2)]^{2-}$, $[Mo_2S_4(S_2)(S_3O)]^{2-}$ and $[MX(MS_4)_2]^{2-}$ (X = O or S, M = Mo or W)† (see Tables 1 and 2 as well as different figures).

* Besides Ref. 83 this is the first note on the bioinorganic relevance of the Fe^{n+}–MoS_4^{2-} system.

† In addition, some higher aggregated species like $[Mo_3S(S_2)_6]^{2-}$, $[Mo_2O_2S_2(S_2)(MoS_4)]^{2-}$, $[WS(WS_4)(WS_3(S_2))]^{2-}$ and $[W_2S_4(WS_4)_2]^{2-}$.[64,65,75,100]

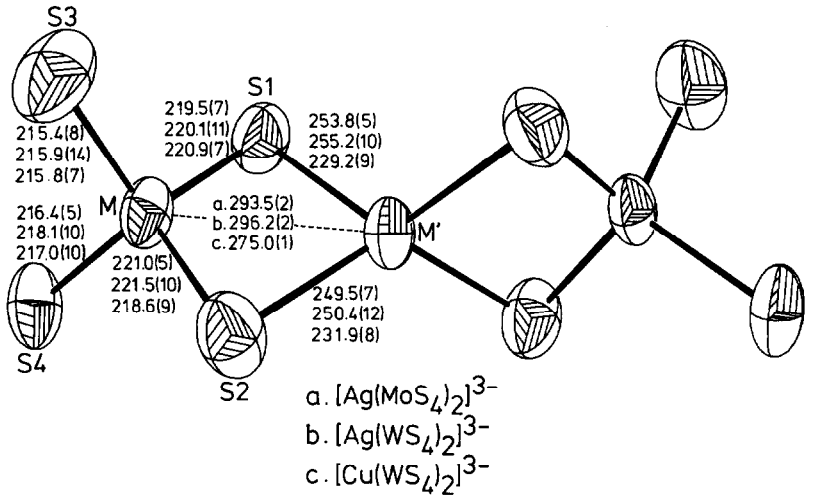

Fig. 5. Structure of $[Ag(MoS_4)_2]^{3-}$ with bond lengths (pm) together with data for $[Ag(WS_4)_2]^{3-}$ and $[Cu(WS_4)_2]^{3-}$ in crystals of $(Ph_3PNPPh_3)_2(NEt_4)[M'(MS_4)_2] \cdot n$MeCN (M = Mo or W, M' = Ag or Cu, $n = 1$ for M' = Ag, $n = 2$ for M' = Cu). All salts crystallize in the space group $P2_12_12$; cell constants for the Ag–Mo compound: $a = 1254.6(5)$ pm, $b = 3431.1(13)$ pm, $c = 1079.0(4)$ pm.[96]

Synthesis of species with S_x^{2-} ligands (x = 1 or 2)

Because of the high affinity, especially of Mo, for S (see the next section), compounds with Mo—S bonds are easily formed. Reagents for the preparation may be S_8, S^{2-}, SH^-, H_2S, S_x^{2-} and organic polysulfides like BzSSSBz. There is a special tendency to form $Mo(S_x)$ ($x = 2$ or 4) units. Even in nearly boiling water containing S_x^{2-} a species is formed which contains only S and no O: $(NH_4)_2[Mo_3S(S_2)_6] \cdot nH_2O$ ($n = 0$–2; the unit cell dimensions vary with the H_2O content[90]).

An example of the variety of Mo–S species in a solution containing Mo^{n+} and S_x^{2-} ions: the Mo^{n+}–S_x^{2-}–H_2O system with special reference to $(NH_4)_2[Mo_3S(S_2)_6] \cdot nH_2O$ (n = 0–2)[30,69,70]

The formation of $[Mo_3S(S_2)_6]^{2-}$ proceeds easily on heating a solution of MoO_4^{2-} [reduction to Mo(IV)] and ammonium polysulfide* ($[Mo_2(S_2)_6]^{2-}$ is formed from the filtrate at room temperature). At a reaction temperature of about 45°C after 16 h mainly the formation of MoS_4^{2-} is observed (the oxothiomolybdates $MoO_nS_{4-n}^{2-}$ are formed correspondingly much faster). At reaction temperatures >95°C after 16 h *only* $(NH_4)_2[Mo_3S(S_2)_6] \cdot nH_2O$ is obtained (if the reaction time is reduced considerably, the yield is also reduced) and from the filtrate $[Mo_2(S_2)_6]^{2-}$ (as NH_4^+ salt) at room temperature. We have also studied the influence of the amount of elemental S used for the preparation of the polysulfide solution. The yield of $[Mo_3S(S_2)_6]^{2-}$

* For its preparation see Ref. 70.

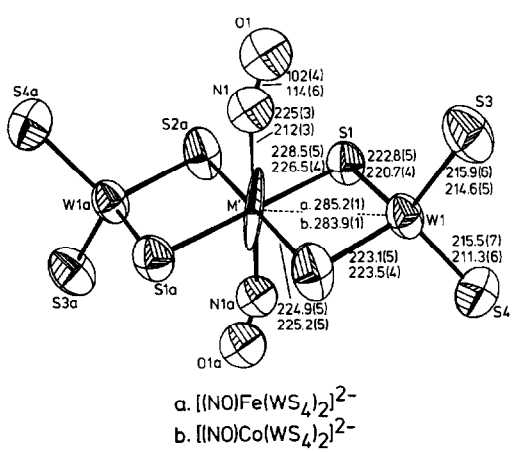

Fig. 6. Structure of disordered $[(NO)Fe(WS_4)_2]^{2-}$ with bond lengths (pm) together with data for $[(NO)Co(WS_4)_2]^{2-}$ in crystals of their PPh_4^+ salts.[43]

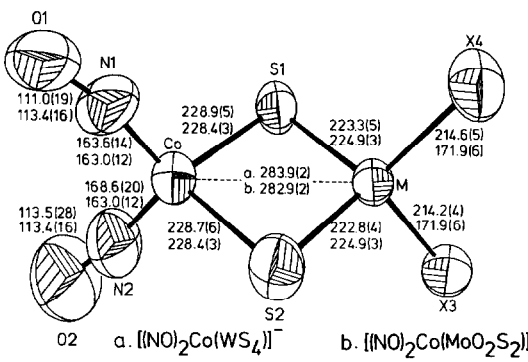

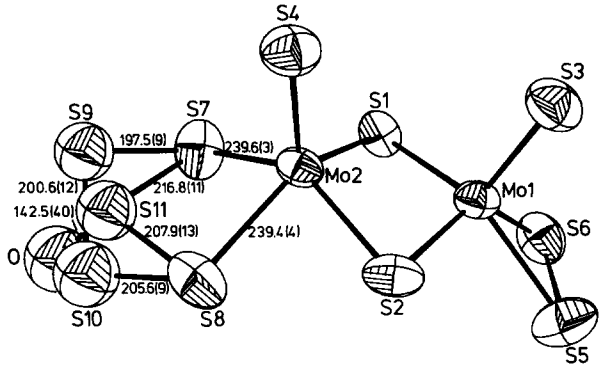

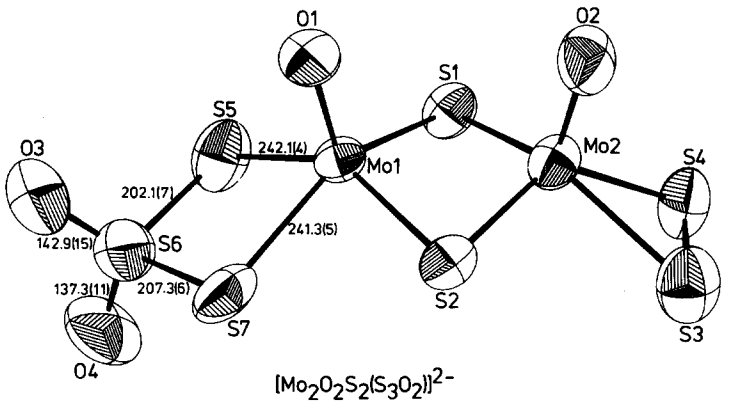

Fig. 7. Structure of $[(NO)_2Co(WS_4)]^-$ with bond lengths (pm) together with data for $[(NO)_2Co(MoO_2S_2)]^-$ in crystals of their PPh_4^+ and NEt_4^+ salts, respectively.[43]

$[Mo_2S_4(S_2)(S_4)]^{2-}_{0.6}$ $[Mo_2S_4(S_2)(S_3O)]^{2-}_{0.4}$

$[Mo_2O_2S_2(S_3O_2)]^{2-}$

Fig. 8. Structures of $[Mo_2S_4(S_2)(S_4)]^{2-}$ (in pure form[97]), $[Mo_2S_4(S_2)(S_3O)]^{2-}$ and $[Mo_2O_2S_2(S_3O_2)]^{2-}$ in crystals of $(PPh_4)_2[Mo_2S_4(S_2)(S_4)]_{0.6}[Mo_2S_4(S_2)(S_3O)]_{0.4}$ [$P\bar{1}$, $a = 1043.0(2)$ pm, $b = 1166.3(2)$ pm, $c = 2212.2(4)$ pm, $\alpha = 76.27(12)°$, $\beta = 85.84(2)°$, $\gamma = 78.23(2)°$] and $(PPh_4)_2[Mo_2O_2S_2(S_3O_2)]$ with bond lengths (pm) of the ligands attached to the $\{Mo_2X_2S_2(S_2)\}$ (X = O or S) fragment.[64,65]

increases strongly with an increasing S content. If S_x^{2-} solutions containing a high amount of S are heated for a long time the yield of $(NH_4)_2[Mo_3S(S_2)_6]\cdot nH_2O$ is nearly quantitative.[30,69]

The cluster anion $[Mo_3S(S_2)_6]^{2-}$ can also be obtained with an organic cation upon heating the reaction mixture of $(NH_4)_2[Mo_3S(S_2)_6]\cdot nH_2O$ and $(AsPh_4)Cl$ in acetonitrile (see structure in Fig. 3).

The high formation tendency of

$$[Mo_3(IV)S(S_2)_6]^{2-}$$

at higher temperatures in solution corresponds to that of $Mo(IV)S_2$ in the solid state (see last section on catalysis).

Reaction types

Electron-transfer processes (mainly intramolecular ones) keep the chemistry in check. Reactions are known where only "S ligands" (type II), only metal centers (type I) or both (types III and IVa–d) show redox processes. No redox process necessarily occurs when the M–S moiety acts as a nucleophile (type V) (see Table 3 for details, examples and references as well as the previous section for a discussion of type II').

Reversible redox processes of type I (leading to "stable" species) preferably occur in cases where clusters have π-acceptor ligands like CN^- and mainly cp^- (contrary to comparable clusters of the 3*d* metals like $[Fe_4S_4X_4]^{n-}$ existing with ligands X = Hal or SR, and also with different electron populations).

If a neutral S atom transfer occurs from an M—S_t bond (abstracted by a nucleophile) the M center is reduced and consequently M—M bonds can be formed[18] (III). However, if the S atom transfer occurs at an $M(S_2)M$ unit there is no change in the oxidation state of M (type II). Processes like III and IV where the oxidation state of M and the "S ligands" change simultaneously (type III with reduction of both) are very important, especially for the relevant chemistry of Mo.

Table 3. Different reaction types of Mo and W complexes with S_x^{2-} ligands ($x = 1, 2, \ldots$)[a]

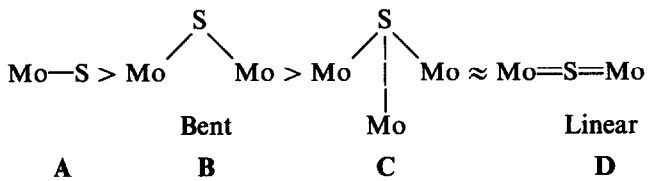
[a] Abbreviations: N, nucleophile; EA, electron acceptor; E, electrophile; ED, electron donor; $[M]^{ox/red}$, metal center(s); [S], S_x^{2-} ligand(s); $[S]^{red}$, S^{2-} ligand(s); $[S]^{ox}$, S_x^{2-} ligand(s) ($x > 1$).

[b] $[S]^{red/ox}$ stands for at least one oxidized or reduced ligand.

[c] First step with abstraction of neutral S according to type II.

[d] Oxidized ligand S_2^{2-} very probably in the intermediate product.



[e] Reductive elimination.

[f] [S] is not defined because of the not exactly defined states of the "S ligands" in a-MoS_3 and the {MoS} cluster; similar to II'.

Quite a number of the intramolecular redox reactions are known. If there is no electron balance for the intramolecular redox process, an electron acceptor (EA) or electron donor (ED) has to be added (IVb). The pathways for reactions IVa (with addition of an electrophile, which may act as an EA, too) and IVc (without addition of a reagent and where the educt or an intermediate may act as an EA) are not completely understood.

If the electron density on S atoms of M—S_t bonds is high, type V reactions can occur. [In this case, interesting oxidations of S_x^{2-} ligands by O_2 are also possible, leading to novel ligands like $S_3O_2^{2-}$ or S_3O^{2-} (see Fig. 8) (type IVa).[64,65]]

An especially remarkable reaction is that of type IVd. For example, $Cs_2[Mo_2(S_2)_6]\cdot nH_2O$ can be used as an S_2 generator at rather low temperatures (reductive-elimination process).[40,89]

CHARACTERIZATION BY PHYSICAL METHODS AND MO CALCULATIONS: ELECTRONIC STRUCTURE AND CHEMICAL BONDING

Several, mostly simple species, have been characterized in detail by physical methods and MO calculations. Typical examples, especially of Mo compounds, are presented in Table 4.

An important feature of Mo—S bonds, in general, is the occurrence of π-bonding over a wide range of bond lengths (*ca* 2.1–2.4 Å) if S3*p* lone-pairs are available. This is strongly supported by the fact that the overlap integral S (Mo4*d*, S3*p*) varies to a relatively small extent with the internuclear distance (compared, for example, to M—O bonds). Besides, the Mo4*d* and S3*p* VOIPs are nearly equal. Thus, very different electron density distributions within the Mo—S bonds are possible (depending on geometry, electron population and additional ligands).

The series

Mo—S > Mo Mo > Mo Mo ≈ Mo=S=Mo

A B C D

is characterized by a decrease in the negative charge on S (large charge separation, for example, in MoS_4^{2-} and almost equal net charges of Mo and S in $[Mo_2S(CN)_{12}]^{6-}$). The facility of charge displacement is important for the properties of Mo–S systems in Mo–S catalysts and enzymes.

Charge-transfer bands of the type S → Mo are observed in compounds with structure types **A** and **B** but not type **C**, whereas the opposite transition (Mo → S) is found for type **D**.

It is interesting that there is no such clear correlation between the oxidation state of Mo and the preferred μ_n-S coordination type found for clusters with weak covalent metal–sulfur bonds (for example $\{Fe_xS_y\}^{n+}$ type clusters). A simplified explanation for this is the following: in Mo–S species, upon reduction, the additional charge "goes into the bonds". Therefore, there is a considerable change in the Mo—Mo and Mo—S bond lengths accompanying the reduction, for example from $[Mo_2S_2(CN)_8]^{4-}$ to $[Mo_2S_2(CN)_8]^{6-}$. In the Fe–S

Table 4. Characterization by physical methods (with major references only)

	Physical method (spectra), procedure	Results	Interpretation, conclusion[a]	Reference
MoS_4^{2-}	(1) IR, normal-coordinate analysis (NCA)	$^{92/100}$Mo isotope frequencies, force constants	Strong π-bonding, high electron density on S, strong σ-acceptor ligand, LUMO 2e with strong contribution from S and Mo AOs	3, 76–80
	(2) Resonance-Raman	Anharmonicity constants, excitation profile		
	(3) Electronic absorption spectrum	Assignment of the S → Mo charge-transfer bands, oscillator strength	$\nu_1 \hat{=} t_1 \rightarrow 2e$, $\nu_2 \hat{=} 3t_2 \rightarrow 2e$, $\nu_3 \hat{=} t_1 \rightarrow 4t_2$[b]	
	(4) mcd	Description of the electronic structure		
	(5) MO calculations			
	(6) Valence band XPS			
$MoOS_3^{2-}$	(1) Resonance-Raman	Progression of only ν_s(MoS) bands (λ_e = 488 nm), assignment of the $a_2 \rightarrow e$ [π(S) → d(Mo)] transition	Weak mixing between MOs with Mo–O and Mo–S character, S → O substitution increases Mo—S bond strength	3, 79, 81, 82
	(2) Valence band XPS	Distinction between MOs with predominantly Mo—S and Mo—O bond character		
	(3) MO calculations			
$[Ni(MoS_4)_2]^{2-}$	(1) IR	$^{64/68}$Ni and $^{92/100}$Mo isotope frequencies, force constants	Partial interligand S—S bond (reduction of Ni center)	83, 84
	(2) MO calculations			
$[Cl_2Fe(MoS_4)]^{2-}$	(1) ^{57}Fe Mössbauer	Very low IS value for Fe(II) (0.48 at RT, α-Fe)	Strong σ-acceptor property of MoS_4^{2-} ligand	84, 85, 99
	(2) MO calculations			
	(3) Magnetic measurement	5.00 μ_B (RT)	Consistent with high-spin Fe(II)–Mo(VI) description	
$(PPh_4)Fe(MoS_4)$	(1) ^{57}Fe Mössbauer	Very low IS value for Fe(II)	Very strong electron delocalization (highly delocalized MOs in the chain)	60, 61, 84
	(2) Resonance-Raman (λ_e = 647.1 nm)	ν_s(WS) + ν_s(FeS) combination band enhanced		

$[Co(WS_4)_2]^{2-/3-}$	(1) Magnetic measurement	Low μ_{eff} values for a $^4A_2$ ground state ($[2^-]$), 4.0 μ_B (RT)	Strong electron delocalization Co → WS_4, upon reduction additional charge mainly on terminal W—S bonds	84, 86
	(2) Cyclic voltammetry	$[2^-] \rightleftharpoons [3^-]$		
	(3) MO calculations			
	(4) Electronic absorption spectrum	"Nonclassical" VIS–NIR bands of high intensity		
$[(CuCl)_3(MoOS_3)]^{2-}$	(1) X-ray	Very short Cu–Mo distances	(Closed shell!) Cu(I) → $MoOS_3^{2-}$ electron delocalization	48, 87
	(2) Resonance-Raman (λ_e = 488 nm)	Enhancement of ν_s(Cu—S) [and not (!) ν_s(Mo—S)] band		
$[Fe_2S_2(WS_4)_2]^{4-}$	(1) Resonance-Raman (λ_e = 488 nm)	Enhanced intensity of $\nu_s(FeS_2Fe)$ + ν_s[Fe—S(W)] band, IS = 0.33 mm s^{-1}	Very strong $\{Fe_2S_2\}^0$ → WS_4^{2-} electron delocalization	61, 84, 87
	(2) Mössbauer			
$[Fe_3S_2(WS_4)_3]^{4-}$	(1) Magnetic measurement	$J = -268$ cm^{-1}	Very strong $\{Fe_3S_2\}^{2+}$ → WS_4^{2-} electron delocalization, strong antiferromagnetic coupling, small repulsive interaction between Fe(II) centers	61, 84, 87
	(2) Mössbauer	IS = 0.30 mm s^{-1} (RT, α-Fe)		
	(3) MO calculations			
$[WS(WS_4)]^{2-}$	(1) Magnetic measurement	Diamagnetic electronic ground state	Mixed-valence species with (approximate) W(IV) and W(VI)	84
	(2) MO calculations			
$[Mo_2S_2(CN)_8]^{4/6-}$	(1) IR, R, NCA		Strong Mo—Mo bonds, strong variation in the electron density distribution in the Mo—S bonds in different species	12
$[Mo_3S_4(CN)_9]^{5-}$	(2) Cyclic voltammetry	Reversible redox processes		
$[Mo_4S_4(CN)_{12}]^{8-}$	(3) ν(CN) IR-band intensities	Strongly dependent on species		
	(4) Resonance-Raman	Identification of bands in the VIS range		
	(5) Electronic absorption spectra			
	(6) MO calculations	Cluster bonding MOs 70–80% Mo4*d*–S3*p* contributions		
	(7) XPS	Distinction between μ_2-S^{2-} and μ_3-S^{2-}		
	(8) Magnetic measurement	All diamagnetic		
$[Mo_2S(CN)_{12}]^{6-}$	(1) Resonance-Raman (λ_e = 647.1)	Enhancement of bands due to *all* ν_s stretchings	Strongly delocalized MOs over the whole system	12
	(2) MO calculations			
$[Mo_2(S_2)(SO_2)(CN)_8]^{4-/5-}$	(1) ESR	g = 2.012, $A(^{95}Mo)$ = 19.2 G ($[5-]$)	The unpaired electron spin of the less stable $[5-]$ ion is strongly delocalized, (approximate) SO_2^{2-} ligand	32
	(2) XPS			
	(3) IR	Low ν(SO) frequencies		
	(4) Magnetic measurement	$S = \frac{1}{2}$($[5-]$)

	Physical method (spectra), procedure	Results	Interpretation, conclusion	Reference
$[Mo_2O_2S_2(S_2)_2]^{2-}$	(1) Electronic absorption spectra	Identification of a $\pi^*(S_2^{2-}) \rightarrow d(Mo)$ transition		40, 88, 89
	(2) Vibrational spectra ($^{92/100}Mo$), NCA	$\nu(MoS_2Mo)$ ring vibrations at 467 (IR) and 428 (R)		
	(3) MO calculations	HOMO: $\pi^*(S_2^{2-})$		
$[Mo_2O_2S_2(S_2)(S_3O_2)]^{2-}$	XPS	Identification of the "S^{6+}" of the dithiosulfate ligand		65

[a] In general obtained from all results!

[b] Improved assignment mainly according to the study of the halfwidth of the charge-transfer bands in species with negligible $M'(d^{10})$–MoS_4^{2-} π-interaction.[2,79]

clusters, the additional charge is mostly stored on the S atoms (which can accommodate charge more easily in the case of "positivation of the sulfurs" as a consequence of their higher coordination numbers in higher aggregated species).

The fact that the Mo4*d* and S3*p* VOIPs are nearly equal has other important consequences: the easy formation of S_x^{2-} ligands attached to Mo (mainly in valence states IV and V) and the tendency of Mo–S compounds towards intramolecular redox reactions in general.

A remarkable aspect of Mo–S and W–S chemistry is the electron-withdrawing power of the MoS_4^{2-} and WS_4^{2-} ligands, with the consequence that species exist with different electron populations like $[Fe(WS_4)_2]^{2-/3-}$ (even the "fully reduced" $\{Fe_2S_2\}^0$ core can be stabilized by WS_4^{2-} ligands in $[Fe_2S_2(WS_4)_2]^{4-}$).[45]

SOME ASPECTS WITH RELEVANCE TO HDS CATALYSIS

HDS involves the conversion of S from crude oil fractions or coal-derived liquids in the presence of H_2 into H_2S. Some aspects of the structure and catalytic activity of MoS_2 and the CoMoS phase[7,8] (present on the industrial catalyst) as well as their model systems should be presented here.

It turns out, from many independent experiments, that MoS_2 is the most stable binary Mo–S compound in the solid state while the $[Mo_3S(S_2)_6]^{2-}$ ion seems to be the corresponding most stable discrete species [both contain Mo(IV)!]. Structurally, both are closely related and can be prepared from each other (cf. Fig. 9). Removing the apical S atom from $[Mo_3S(S_2)_6]^{2-}$, the S_2^{2-} groups can be ordered symmetrically around the Mo_3 triangle (see below). By some variation of the bond distances [*d*(Mo—Mo) from 2.72 to 3.15 Å and *d*(S—S) from 2.0 to 3.6 Å] we have already a complete section from the MoS_2 lattice. On the other hand $[Mo_3S(S_2)_6]^{2-}$ may also be regarded as a model for the surface of MoS_2 crystallites (basal plane with μ_3-S atoms and edges with S_2^{2-} groups).

We have studied earlier the thermal decomposition of $(NH_4)_2[Mo_3S(S_2)_6] \cdot nH_2O$ to MoS_2 by DTA–TG measurements accompanied by a control of the gas phase with a mass spectrometer, by IR spectra and by XRD measurements of intermediate products.[90] Some additional experiments have been carried out and, using Debye's scattering equation, we have also calculated the X-ray scattered intensity for different (short-range order) models.[98] The main features* are shown in

* Formal treatment.

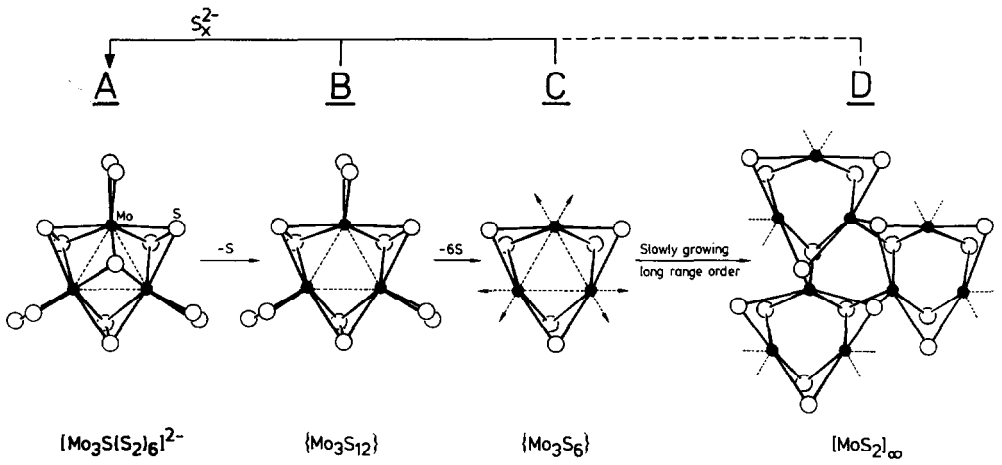

Fig. 9. Schematical representation of the thermal decomposition reaction $(NH_4)_2[Mo_3S(S_2)_6] \rightarrow MoS_2$ (for further details of the overall reaction, see Ref. 98).

Fig. 9. After the loss of the water of crystallization up to 150°C (if $n > 0$) the first reaction of the anion **A** itself is to release the apical S atom (at *ca* 260°C in the form of H_2S, together with some loss of ammonia). The bridging S_2^{2-} groups, which were centered below the Mo_3 plane in structure **A**, can now bind symmetrically (with a mirror plane through the three metal atoms). The metal–metal distance should not change greatly and stays at about 2.7 Å.

Proceeding to higher temperatures, from about 310°C the sample loses continuously up to 6 mol of neutral S, which can formally be released from the terminal S_2^{2-} groups of structure **B**. This reductive-elimination step leaves two electrons per Mo center which can be used to reduce the bridging S_2^{2-} groups to two bridging S^{2-} ligands (the S–S distance changes from 2.0 to 3.6 Å). The resulting unit, **C**, still with short Mo–Mo distances, will not be stable and adds bridging S^{2-} ligands from neighboring triangles to the coordinatively unsaturated Mo sites. As a result, at about 430°C, structure **D** is obtained. Each Mo now has more than two metal neighbors and the Mo–Mo distance should increase to its final value, i.e. 3.15 Å, with six Mo neighbors in the MoS_2 structure.

Since the average number of S atoms in the first coordination shell of Mo does not vary significantly, the major changes in the X-ray scattered intensity of the intermediate products will be mainly due to a variation in the Mo–Mo distances. There should be two diffuse maxima in the scattering curve between 20 and 100° (at $2\theta \approx 42$ and 86° with Cu-K_α radiation for structure **A**, shifting to $2\theta_{max} \approx 36$ and 65° for structure **D**). Although, particularly at lower angles, the experimental-scattering curves are screened by crystalline residues of $(NH_4)_2[Mo_3S(S_2)_6]$ or the beginning of crystallization of MoS_2, respectively, the experimental data show the behavior expected from the computations. The material with the greatest conversion ($T = 450$°C) shows two maxima in the range 60–90°, indicating the presence of both Mo_3 triangles with short and long metal–metal distances, paralleled by a pronounced crystallization in the *ab* plane {increase in the [100] reflection of MoS_2 and a less pronounced growing of the crystallites parallel to the *c*-axis of MoS_2 ([002] reflection)}.

Our investigations regarding the catalytic activity of thermally decomposed $(NH_4)_2[Mo_3S(S_2)_6] \cdot nH_2O$ (and also of the thiometalato complexes of Ni and Co) are promising as expected.[94]

A problem which could not be explained until now is the reason for the promoting effect of Co. We could isolate the "pseudo-isostructural" metal–sulfur cluster anions $[Mo_4S_4(CN)_{12}]^{8-}$ and $[Co_4S_4O(CN)_{12}]^{8-}$[91] (the valence states of the metal atoms in the clusters being comparable to those in the CoMoS phase). An SCCC-MO calculation shows that the electron density at the S atoms in the Co cluster is much higher than in the Mo one. Consequently, it can be understood that the Co cluster species is oxidized in the presence of air (μ_3-$S^{2-} \rightarrow \mu_3$-SO^{2-}) but not $[Mo_4S_4(CN)_{12}]^{8-}$. One influence of Co in the catalyst should definitely be the increase in the electron density at the S atoms, which could improve the activation of H_2 for instance.

IR studies of NO absorption of Al_2O_3-supported and unsupported Co–Mo HDS catalysts have shown that the CoMoS phase consists of Co atoms at the edges of MoS_2. (A high coverage of the MoS_2 edges and a high MoS_2 edge dispersion achieves a large promotion.) The IR spectrum of "NO absorbed" on a sulfided Co–Mo–Al_2O_3 catalyst shows three bands, which can be assigned to Co [ν(NO) 1850 and 1785 cm^{-1}] and Mo [ν(NO) 1785 and 1690 cm^{-1}] sites.[92] As ν(NO) frequencies are

very sensitive to the electronic state of the coordination centers it is worthwhile investigating the corresponding ν(NO) values of model substances[43] like $[(NO)_2Co(MoS_4)]^-$ [ν(NO) 1852 and 1770 cm^{-1}] and $[(NO)_2Co(MoO_2S_2)]^-$ [ν(NO) 1859 and 1781 cm^{-1}] (both with a $\{Co(NO)_2\}^{10}$ configuration which has a very high formation tendency) and $[(NO)_2Mo(NCS)_4]^{2-}$ with an $\{Mo(NO)_2\}^6$ configuration [ν(NO) 1782 and 1661 cm^{-1}].[93] The excellent agreement between the ν(NO) frequencies proves that the electronic environment of the Co and Mo centers in the model systems and the nitrosylated catalyst are comparable. Mononitrosyl complexes of Mo and Co have significant lower ν(NO) frequencies. The $(NO)_2CoS_2Mo$ moiety of the above-mentioned complex should therefore be abundant on the nitrosylated catalyst, too.[94]

(*Received* 5 *August* 1985)

Abstract—This paper reviews recent work from our laboratory on redox chemistry of Mo–S systems. Mo and S are each capable of existing in multiple oxidation states. When found together in the same compound, these elements elicit numerous redox possibilities. The classical situation involving simple changes in the oxidation state of Mo is well known. Recent work has also documented the ability of coordinated S ligands (e.g. S^{2-}, S_2^{2-} and S_4^{2-}) to undergo redox while Mo remains in a given state of oxidation. In this paper cases are presented wherein both the Mo and S oxidation states change. For example, the reaction of the red MoS_4^{2-} ion with organic disulfides gives the purple $Mo_2S_8^{2-}$ ion in high yield. The oxidizing disulfide added to the hexavalent MoS_4^{2-} ion leads quantiatively to the reduced pentavalent dinuclear $Mo_2S_8^{2-}$ ion. Mechanistically, this reaction proceeds in two stages involving a green intermediate of yet unknown structure. The net reaction embodies an induced internal electron transfer from S to Mo in the same sense that Taube *et al.* elucidated in the chemistry of cobalt. Application of the concept of induced internal electron transfer allows access to new low-valent Mo–S systems by adding oxidants to Mo(VI)–S species. For example, the reactions of MoS_4^{2-} with thiuram disulfides give compounds of the form $MoS_2(S_2CNR_2)_3$ (R = Et or *i*-Bu). These are mononuclear EPR-active Mo(V) complexes containing eight-coordinate Mo. As expected, W shows distinctly less reactivity than Mo in S → M redox processes. The ability of S^{2-} ligands to act as donors and Mo and W atoms to act as acceptors of electron density has also been exploited in the synthesis of new heteronuclear "thiocubane" clusters.

Mo and S, in their respective groups VI of the periodic table, are each renowned for their ability to form numerous compounds in relatively large numbers of oxidation states.[1] For Mo, states −II to VI have been reported, and for S the same range is spanned, as exemplified by the inorganic limits, S^{2-} and SO_4^{2-}. Whenever Mo *or* S is present in a compound, redox reactions often play a central role in the chemistry of that compound.

Redox chemistry also plays a potential role in the action of Mo enzymes[2] and Mo-based heterogeneous catalytic systems.[3] In such systems, Mo can span oxidation states IV–VI with the possible presence of trivalent Mo as well. In many of these systems seemingly simple Mo-based redox reactions may be crucial to catalysis and have been proposed as key steps in reaction pathways. However, the assumption of a purely metal-based redox process must always be questioned when the ligand involved is S-containing and thereby has capacity for redox of its own or in conjunction with Mo-based redox.

Although examples are known in which one cannot meaningfully disect the metal or ligand contribution to a given redox process, such ambiguous cases will not be encountered in the present paper. Rather, here we consider cases in which, on chemical or physical grounds, the bulk redox change can be regarded as a discrete combination of metal and ligand-based redox processes. For Mo, these discrete changes interconvert specific *d*-electron configurations which embody characteristic Mo–Mo bonding, structural,

* Author to whom correspondence should be addressed.

spectroscopic and magnetic behavior. For example, Mo(VI), $4d^0$, compounds display no tendency to form Mo–Mo bonds and have no "*d–d*" bands. In contrast, Mo(V), $4d^1$, compounds have a tendency to form dinuclear compounds with a single metal–metal bond or, if mononuclear, show a single unpaired *d*-electron with characteristic EPR signal.

Changes in S oxidation state likewise correlate with distinct structural differences. For example, S^{2-}, the most reduced form of S, tends to multiply bond to Mo, either by forming double or triple bonds to a single Mo atom or by bridging two or three Mo atoms.[4] There is no S—S bonding in this most highly reduced form of the S ligand. However, upon oxidation to S_2^{2-} there is clearly an S–S bond at ~2.05 Å, characteristic of S(−I) containing compounds[5] (analogous to the O–O single bond in the peroxide ion, O_2^{2-}). Even if we restrict our consideration to ligands containing only S, we find an extensive series that includes S_8,[6] S_6^{2-},[7] S_5^{2-},[8] S_4^{2-},[7] S_3^{2-}[9,10] and S_2^{2-}.[11] In this series, the oxidation state of S ranges from 0 to −II. For example, formally, the non-ligating S atoms in a chelating or bridging S_n^{2-} ligand are S(0), while each of the terminal S atoms are S(−I). Clearly, rudimentary inspection of the structural and spectroscopic properties of Mo–S complexes is sufficient to assign oxidation states and corresponding electron configurations. For the purpose of systematizing the chemistry of these and related compounds, it is crucial to make such assignments.

In this paper we review recent work on the redox chemistry of Mo–S systems. We use formal oxidation states to keep track of redox changes and we show that internal electron transfer between S and Mo occurs commonly and can explain seemingly paradoxical redox events.

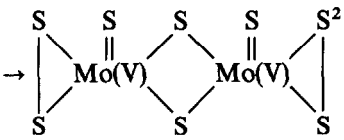
LIGAND-BASED REDOX

The availability of Mo–S complexes with S_2^{2-} ligands, namely the Mo(V) complex $Mo_2(S_2)_6^{2-}$[12] and the Mo(IV) complex $Mo_3S(S_2)_6^{2-}$,[13] led us to attempt reactions, wherein the disulfido ligands constitute the sites of reactivity. Although the reactions are quite general,[14,15] in the examples below we use only ethane-1,2-dithiolate as our reductant and ligand. The dinuclear complex reacts according to Ref. 14:

$$Mo_2(S_2)_6^{2-} + \text{excess } \begin{matrix} CH_2S^- \\ | \\ CH_2S^- \end{matrix} \rightarrow Mo_2S_4(SCH_2CH_2S)_2^{2-}.$$

The $Mo_2(S_2)_6^{2-}$ starting material[12] is a Mo(V) dinuclear species, as is the $Mo_2S_4(SCH_2CH_2S)_2^{2-}$ product. Although no Mo redox is involved, the reaction nevertheless involves a 12-electron reduction in which the six disulfido ligands are reduced to four sulfido ligands and eight free S^{2-} ions (or HS^- or H_2S, depending on the acidity). Similarly, $Mo_3S(S_2)_6^{2-}$ reacts according to Ref. 15:

$$Mo_3S(S_2)_6^{2-} + \text{excess } \begin{matrix} CH_2S^- \\ | \\ CH_2S^- \end{matrix} \rightarrow Mo_3S_4(SCH_2CH_2S)_3^{2-}.$$



Here the $Mo_3S(S_2)_6^{2-}$[13] starting material is a Mo(IV) trinuclear complex, as is the $Mo_3S_4(SCH_2CH_2S)_3^{2-}$ product. Again, the 12-electron redox reaction involves only the S ligands. Clearly, extensive redox activity is inherent in *S*-donor ligands bound to Mo.

INTERNAL REDOX PROCESSES

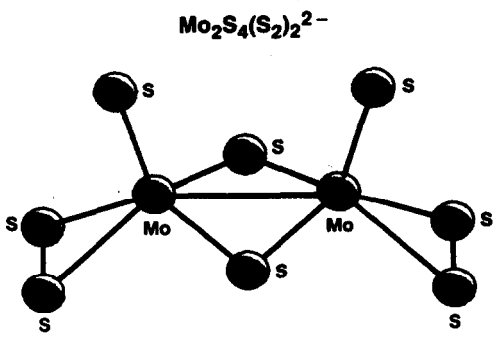
The ligand redox activity augments the well-known metal-based redox reactivity, which is characteristic of Mo complexes. In certain cases, both metal and ligand redox can occur during a given reaction. The result is often a seemingly paradoxical redox change. For example, the addition of the oxidant S_8 to the Mo(VI) complex MoS_4^{2-} leads[16,17] to the Mo(IV) complex MoS_9^{2-}, i.e. addition of *oxidant* leads to the *reduction* of the metal center.

A very clear example of this process occurs in the reaction:[18]

$$2Mo(VI)S_4^{2-} + RSSR \rightarrow$$

$$+ 2RS^-.$$

The structure of the $Mo_2S_8^{2-}$ product is shown in Fig. 1. The presence of four sulfido and two disulfido ligands leave no doubt as to the appropriateness of the Mo(V) formulation of the dianionic product. Here, addition of the organic disulfide oxidant,



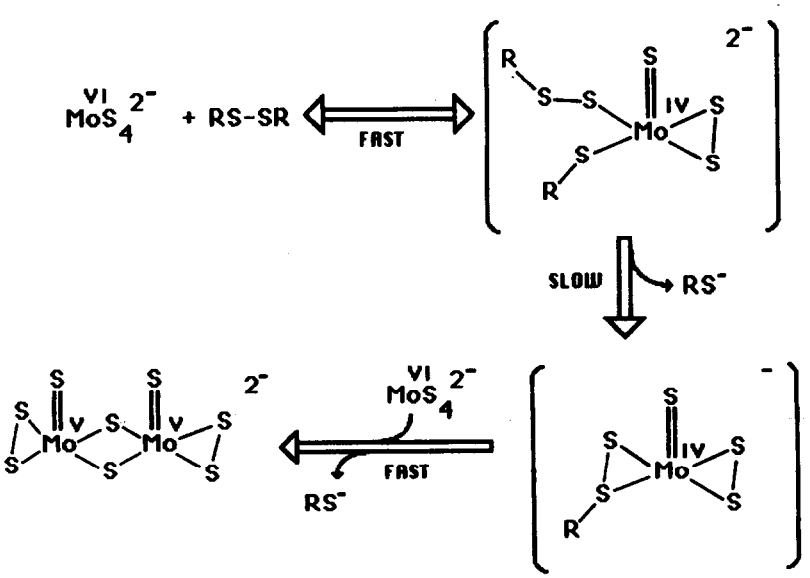


Fig. 1. Structure of $Mo_2S_8^{2-}$.[18]

RSSR, leads to the oxidation of two MoS_4^{2-} ions by two electrons (i.e. $2MoS_4^{2-} \rightarrow Mo_2S_8^{2-} + 2e^-$). Moreover, since $Mo_2S_8^{2-}$ contains Mo in the V oxidation state the external *oxidant* has led to internal *reduction* of the metal center. However, the source of electrons (reductant) is clearly those bound sulfido ligands that are oxidized to disulfido ligands during the reaction. Indeed, the ligands undergo a four-electron oxidation ($4S^{2-} \rightarrow 2S_2^{2-} + 4e^-$). Two of the electrons are transferred to the RSSR oxidant ($RSSR + 2e^- \rightarrow 2RS^-$) while the remaining two go, one each, to the two Mo(VI) ions generating the two Mo(V) ions. The reaction thus involves an internal electron transfer from S → Mo that is induced by the external oxidant RSSR.

Such *induced internal electron transfers* are known in the chemistry of other systems. For example, Taube[19] has shown that the oxalato Co(III) complex $Co(NH_3)_5(C_2O_4)^+$ reacts with one equivalent of the one-electron oxidant Ce^{4+} to generate Ce^{3+} and Co^{2+}. Each metal ion can be reduced by one electron as the coordinated oxalate is oxidized by two electrons to CO_2 ($C_2O_4^{2-} \rightarrow 2CO_2 + 2e^-$). In this case, the external oxidant, Ce^{4+}, induces ligand → Co(III) internal electron transfer. The analogy with MoS_4^{2-} oxidation by RSSR is clear, and the Mo–S reaction is therefore also described as an induced internal electron transfer process.

We have investigated the mechanism of formation of $Mo_2S_8^{2-}$ from $2MoS_4^{2-}$.[20] Reaction of the red MoS_4^{2-} ion with RSSR establishes an equilibrium with the formation of a green intermediate. The rate of formation of this intermediate is first order in both RSSR and MoS_4^{2-} and depends upon the nature of R. Electron-withdrawing R groups cause the intermediate to be formed more rapidly and shift the equilibrium toward more complete reaction. The green intermediate ($\lambda_{max} = 620$) decays by pseudo first-order kinetics to give the purple $Mo_2S_8^{2-}$ product. A sequence of events consistent with the data is shown in Scheme 1. The implied mononuclear, even-electron nature of the intermediate, although not unequivocally established, is consistent with all experimental data obtained to date. The occurrence of a mononuclear intermediate suggests that a mononuclear complex could be trapped if appropriate measures were taken. For example, if the organic disulfide were part of a chelating ligand, the resultant thiolate, i.e. the reduced form of the disulfide oxidant, might remain bound to and stabilize the mononuclear Mo center. Such a strategy has indeed been effective in yielding mononuclear reduced Mo centers.

Reaction of MoS_4^{2-} with tetraethylthiuram disulfide, $(C_2H_5)_2NC(S)S\text{-}SC(S)N(C_2H_5)_2$,[21] leads to the isolation of a mononuclear Mo(V) complex, $MoS_2[S_2CN(C_2H_5)_2]_3$. The structure of this complex and its EPR spectrum are shown in Fig. 2 and Fig. 3, respectively. The EPR spectrum, with its characteristic Mo(V) parameters, illustrates dramatically the $4d^1$ configuration of the Mo(V) complex. This configuration is, of course, unequivocally inferred from the valency of the ligands, i.e. three dtc^- ligands and one S_2^{2-} ligand in this neutral complex. Clearly, in this case the Mo center has been reduced by internal electron transfer from the bound sulfide ligands, while the latter are concomitantly oxidized to bound S_2^{2-} (and to free oxidized S-

Scheme 1.

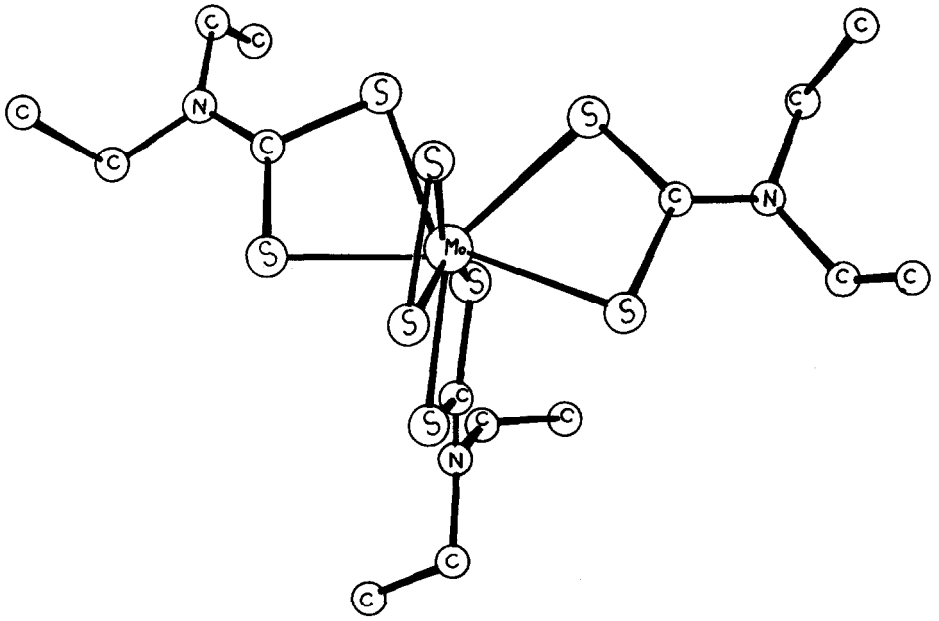

Fig. 2. Structure of $Mo(S_2)[(C_2H_5)_2dtc]_3$.[21]

containing species). Remarkably, it has thus proven possible to produce *new reduced Mo–S complexes* by adding *oxidants* to MoS_4^{2-} which contains Mo in its highest oxidation state (VI). This is a synthetically useful procedure leading to high yields of the new products.

Although this paper concentrates on the chemistry of Mo–S systems, we briefly discuss some W–S chemistry for the purpose of comparison. WS_4^{2-} reacts with S_8 upon heating[22] to produce the $(S_4)W(S)S_2WS(S_4)^{2-}$ ion containing a W(V), $W_2S_4^{2+}$-core and peripheral bidentate tetrasulfide S_4^{2-} ligands. At room temperature, unlike MoS_4^{2-}, which reacts with S_8 to give MoS_9^{2-},[16,17] WS_4^{2-} does not react with S_8. The W(IV) oxidation state required to form WS_9^{2-} may not be attainable. The greater difficulty in reducing W(VI), cf. Mo(VI), is also clearly manifested in the reaction of WS_4^{2-} with the tetraalkylthiuram disulfide. Here, in sharp contrast with the MoS_4^{2-} case (*vide supra*), WS_4^{2-} reacts with $R_2NC(S)S\text{-}SC(S)NR_2$ to yield $WS(S_2)(R_2dtc)_2$, a W(VI) complex, whose structure is shown in Fig. 4.[21] Clearly, while MoS_4^{2-} reacts by internal $S \rightarrow Mo$ redox, WS_4^{2-} reacts via a purely ligand-based redox process in which no $S \rightarrow W$ electron transfer occurs. The reactivity comparison of WS_4^{2-} and MoS_4^{2-} emphasizes the known trend that Mo compounds are more easily reduced than their W analogs.

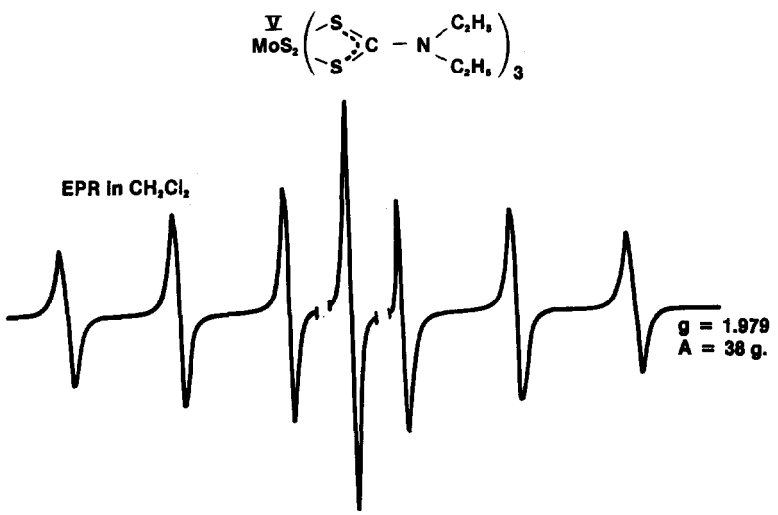

Fig. 3. EPR spectrum of $Mo(S_2)[(C_2H_5)_2dtc]_3$.

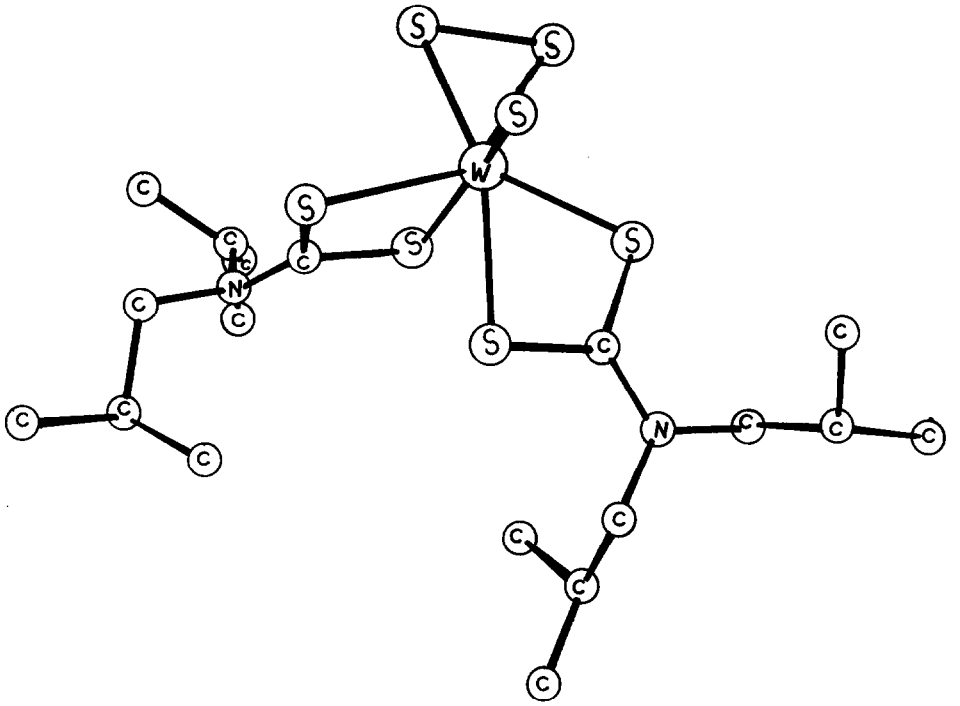

Fig. 4. Structure of $WS(S_2)[(C_4H_9)_2dtc]_2$.[21]

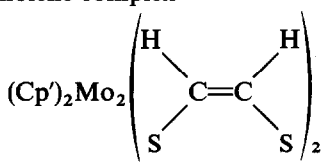
In Mo chemistry it is possible to change the redox tendency of a given complex by changing ligands. In particular, substitution of oxo for sulfido ligands makes it more difficult to reduce the resultant complex. For example, $Mo_2O_2S_2(R_2dtc)_2$ is more difficult to reduce than $Mo_2S_4(R_2dtc)_2$.[23] We therefore tried the reaction of $MoO_2S_2^{2-}$ with the thiuram disulfide to see whether it would undergo S → Mo internal electron transfer, as does MoS_4^{2-}, or purely ligand redox, as does WS_4^{2-}. The product of the reaction of $MoO_2S_2^{2-}$ and thiuram disulfide is the known complex $MoO(S_2)(R_2dtc)_2$,[24] the oxo analog of the W reaction product. Therefore, substitution of oxo for sulfido changes the reaction pathway of the Mo complex from one involving S → M internal electron transfer to one involving simple ligand redox. In a sense substitution of oxo for sulfido causes Mo to behave more like W.

The varied redox reactivity of Mo–S systems is indicative of facile electron transfer between Mo and S components of a given complex. This in turn implies that frontier orbitals which are predominantly "Mo" and "S" in character may lie very close in energy. Therefore, an external agent, e.g. an oxidant, can sufficiently perturb the energy levels to precipitate the internal redox process. Indeed, in other systems, thermal or photochemical activation may also provoke internal redox. For example, the conversion of $(NH_4)_2MoS_4$ to MoS_3[25] upon heating involves metal reduction and ligand oxidation, i.e. the formulation of the amorphous trisulfide as $Mo_2(S_2)(S)_4$, invokes Mo in the V oxidation state. Moreover, the photochemical conversion of $(Cp')_2Mo_2S_4$ to $(Cp')_2Mo_2S_2(S_2)$,[26] involves an Mo(V) sulfido complex converting to an Mo(IV) disulfido complex upon excitation with visible light. Clearly, S → Mo redox can be facilitated by various *physical* or *chemical* stimuli.



So far we have only considered cases in which internal *S* → *Mo* electron transfer occurs. However, *Mo* → *S* electron transfer is also possible. MoS_9^{2-} contains Mo in the IV oxidation state and tetrasulfide ligands. Addition of ethane-1,2-dithiol to MoS_9^{2-} leads quantitatively to the formation of MoS_4^{2-} containing hexavalent Mo.[18] Since no oxidant was added, the oxidation of Mo(IV) here was undoubtedly internal with S_4^{2-} ligands serving as oxidants for both the Mo by internal redox and the dithiolate ligand by external redox. Clearly, in lower-valent Mo complexes containing oxidized S ligands, Mo → S internal electron transfer processes may also be common.

BONDING, ORGANIC REACTIVITY AND SYNTHONS

The closeness of the energy levels available to Mo(IV), Mo(V) and Mo(VI) and S ligands also manifests itself in highly delocalized bonding in

binary Mo–S systems. For example, recent first-principles molecular orbital calculations on $Mo_3S_9^{2-}$[27] and $Mo_2S_8^{2-}$[28] reveal, respectively, a highly delocalized HOMO and very closely lying S- and Mo-based levels. This delocalized nature and closeness of the HOMOs and LUMOs also influences the reactivity of the complexes in question. We will use the reactivity of acetylenes to illustrate this influence.

Classically, coordination compounds are considered to react most readily at sites of real or potential coordinative unsaturation on their *metal* centers. For example, $MoO(R_2dtc)_2$ reacts with substituted acetylenes ($R'C{\equiv}CR'$, R' = H, C_6H_5 or CO_2CH_3) to produce adducts such as $MoO(R'C{\equiv}CR')(R_2dtc)_2$ where the acetylene is π-bound directly to the metal in the classical manner.[29] In contrast, Rakowski DuBois *et al.*[30] have shown that $(Cp')_2Mo_2S_4$ reacts with acetylene to yield the bridged dithiolene complex

in which the acetylene has reacted solely with the four S^{2-} ligands of the complex. Moreover, we have reported[31] that $Mo_2O_2S_2(S_2)_2^{2-}$ reacts with

$$R'C{\equiv}CR' \ (R' = CO_2CH_3)$$

to yield

$$\{Mo_2O_2S_2[SSC(CO_2CH_3)]_2\}^{2-},$$

a complex containing a vinyl disulfide ligand formed by insertion of the activated acetylene into one Mo—S bond of an MoS_2 linkage. Clearly, in specific circumstances, either metal-based, ligand-based or delocalized reactivity can occur.

Finally, the ability of bound sulfide to donate and high-valent Mo to accept electron density causes high-valent binary Mo–S complexes to act as potent ligands to transition-metal ions in low oxidation states. For example, $Fe(MoS_4)_2^{3-}$,[32] and $Co(MoS_4)_2^{3-}$[33] contain tetrahedral, high-spin Fe(I) and Co(I) ions, respectively, bound to bidentate MoS_4^{2-} ligands. These complexes are stabilized by metal–metal back donation from Fe or Co to Mo. Likewise, $Mo_3S_9^{2-}$, i.e. $MoS(MoS_4)_2^{2-}$, contains an MoS^{2+} thiomolybdenyl core also stabilized by back donation to the chelating bidentate tetrathiomolybdate ligands.[34] Clearly, MoS_4^{2-} is a versatile ligand that serves as a building block for the formation of polynuclear transition-metal sulfide clusters. Similarly, complexes containing the $Mo_2S_4^{2+}$ core can serve as building blocks to tetranuclear clusters. For example, terminal sulfide serves as the donor and Mo as an electron acceptor in the reaction of $Mo_2S_4(R_2dtc)_2$ with $Co_2(CO)_8$ to form a compound containing the thiocubane, $Mo_2Co_2S_4^{2+}$, core structure.[35] Similar reactions[36] indicate the potential utility of a "synthon", i.e. building-block, approach to the planned synthesis of heteronuclear clusters.

CONCLUSIONS

Mo–S complexes display great versatility in redox, bonding and reactivity. This versatility is at least in part due to the closeness of S and Mo energy levels, which leads in turn to facile redox and chemical reactivity. It is perhaps, in part, this type of reactivity that is responsible for the common presence of Mo–S systems in enzymic and industrial catalytic systems.

(*Received* 15 *July* 1985)

Abstract—The synthesis of the new dithiolene complexes, $[\{(MeOOC)_2C_2S_2\}_2Mo(\mu_2\text{-}S)]_2^-$ and $[OMo(S_2C_2(COOMe)_2)_2]^{2-}$, is reported. These complexes are obtained by the reaction of dicarbomethoxyacetylene (DMA) with either $[(S_4)Mo(S)(\mu_2\text{-}S)_2Mo(S)(S_4)]^{2-}$ or $[(CS_4)Mo(S)(\mu_2\text{-}S)_2Mo(S)(CS_4)]^{2-}$ and $[OMo(S_4)_2]^{2-}$, respectively. The reaction of $[(S_4)Mo(O)(\mu_2\text{-}S)_2Mo(O)(S_2)]^{2-}$ with DMA results in the new dithiolene complex $[\{(MeOOC)_2C_2S_2\}Mo(O)(\mu_2\text{-}S)]_2^-$, which is the isomeric form of the vinyl disulfide complex obtained in the reaction of the $[(S_2)Mo(O)(\mu_2\text{-}S)_2Mo(O)(S_2)]^{2-}$ complex with DMA. The difference in reactivity between the two complexes that contain the same $[Mo_2O_2S_2]^{2+}$ core is attributed to the intrinsically different reactivity characteristics of the S_4^{2-} and S_2^{2-} ligands. As a result of Mo–S d_π–p_π bonding an alternation in the S—S bond lengths is observed in virtually all of the structurally characterized Mo–S_4 units. The consequent weakening of the S—S bonds adjacent to the Mo—S bonds allows for the ready dissociation of S_2^0 from the Mo-coordinated S_4^{2-} ligands. This weakening also accounts for the facile formation of dithiolenes in cycloaddition reactions of alkynes with the Mo–S_4 units. By comparison, the S—S bond in side-on Mo-coordinated S_2^{2-} ligands is strengthened as a result of depopulation of the ligand π^*-orbitals. Reactions of the latter with alkynes do not proceed by cycloaddition. Instead, insertion into the Mo—S bond has been reported for at least one such reaction. The importance of activated polysulfide ligands in the hydrodesulfurization reaction is discussed.

The extensive chemistry of molecular binary molybdenum sulfide compounds presents a unique opportunity for the study of units which may be structurally and electronically similar to the Mo–S active sites in the catalysts employed in the hydrodesulfurization (HDS) reaction.

The wide variety of binary molybdenum sulfides that have emerged in recent years derives primarily from the reactivity of the MoS_4^{2-} dianion toward sulfur reagents. The complex equilibria and interconversions between Mo thioanions that prevail in MoS_4^{2-}–$(NH_4)_2S_x$ or MoS_4^{2-}–S_8 solutions, in aqueous or non-aqueous media, have been described.[1] Depending on the conditions employed and the nature of the counterions salts of thioanions, such as $[Mo_2(S_2)_6]^{2-}$,[2] $(MoS_9)^{2-}$,[1] $[Mo_2(S)_4(S_2)(S_4)]^{2-}$,[1,3] $[Mo_2(S)_4(S_4)_2]^{2-}$,[1] $[(MoS_4)_2MoS]^{2-}$,[4] $(Mo_3S_{13})^{2-}$[5] and $(Mo_2S_8)^{2-}$,[6] can be isolated from these solutions in crystalline form and their structures have been determined (Fig. 1).

The reaction chemistry of the Mo thioanions with electrophilic reagents is extensive. With electrophiles such as CS_2 and dicarboalcoxyacetylenes the $(MoS_9)^{2-}$ and $[Mo_2(S)_4(S_4)_2]^{2-}$ anions react to form the $[(CS_4)_2MoS]^{2-}$,[7] $[Mo_2(S)_4(CS_4)_2]^{2-}$[7] and $\{Mo[S_2C_2(COOR)_2]_3\}^{2-}$[8] complexes. The CS_4^{2-} and dithiolene ligands in these compounds possibly are generated by cycloaddition reactions to the coordinated S_x^{2-} ligands. The $[Mo_2S_6O_2]^{2-}$ anion displays unique reactivity in its reaction with dicarbomethoxyacetylene and forms the very interesting $\{Mo_2O_2S_2[SSC_2(COOMe)_2]_2\}^{2-}$ complex.[9] In the latter, insertion of the alkyne into the

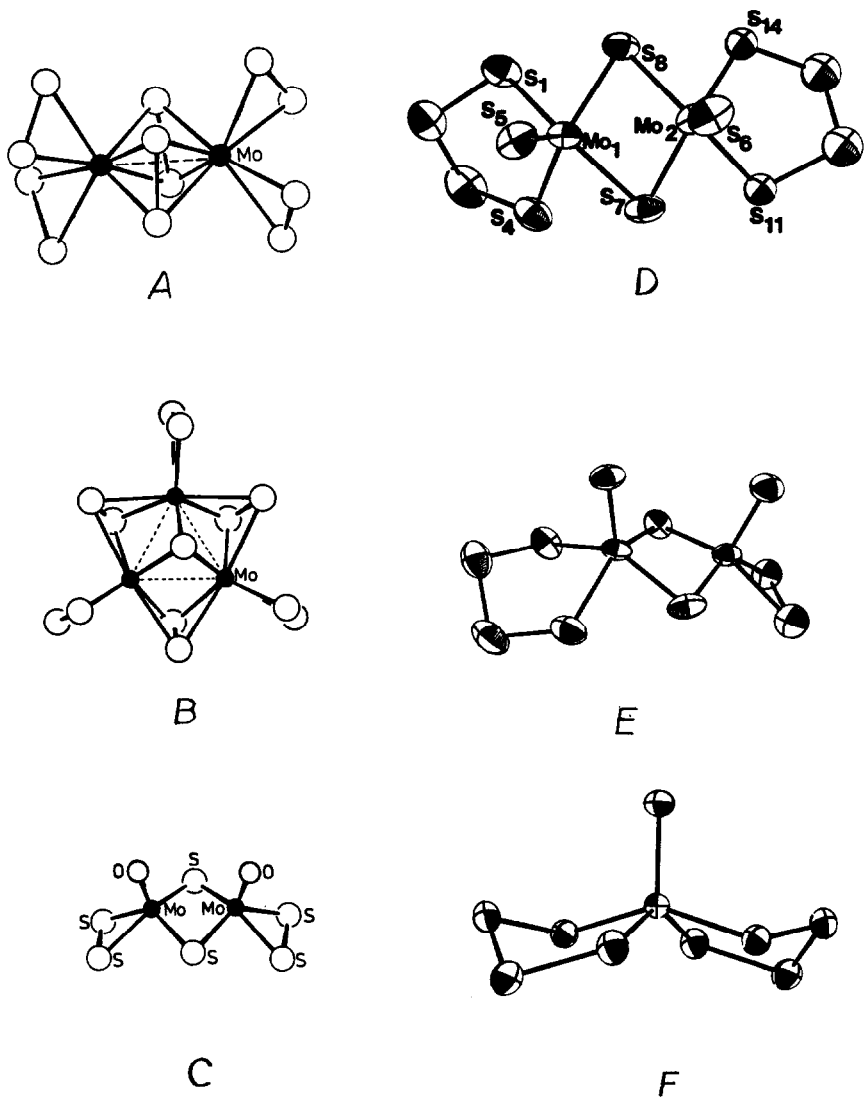

Fig. 1. Structures of: (A) $[Mo_2(S_2)_6]^{2-}$,[2] (B) $(Mo_3S_{13})^{2-}$,[5] (C) $(Mo_2S_8)^{2-}$,[6] (D) $[Mo_2(S)_4(S_4)_2]^{2-}$,[1] (E) $[Mo_2(S)_4(S_2)(S_4)]^{2-}$,[1,3] and (F) $[MoS_9]^{2-}$ and $[MoS_8O]^{2-}$.[1]

Mo—S bond results in the formation of a vinyl disulfide chelate ligand which is S,C bound to the Mo(V) ion.

The reactivity of the Mo thioanions often can be attributed to facile intramolecular charge-transfer or redox processes that activate the Mo–S_x units prior to their reactions with electrophiles.[6] This reactivity depends on the nature of the S_x^{2-} ligand coordinated to the Mo atom and appears to be different for the S_4^{2-} ligands by comparison with the S_2^{2-} ligands. This difference in reactivity reflects the structural and electronic differences between the "side-on" bonded S_2^{2-} ligand and the chelating S_4^{2-} ligands.

The S—S bond in the "side-on" coordinated S_2^{2-} ligand in the Mo–S_2 units is longer than the S—S bond in S_2^0 but shorter than the S–S single bond in S_2^{2-}. By contrast a pronounced lengthening of the S—S bonds adjacent to the Mo atom in the Mo–CS_4 and Mo–S_4 units is readily apparent in virtually all of the structurally characterized complexes that contain these units. This structural effect has been attributed previously to significant S–Mo p_π–d_π bonding[1] and results in an alternation of the S—S bonds lengths within the Mo-coordinated S_4^{2-} ligand.

Recently we have been exploring the comparative reaction chemistry of the Mo–S_2 and Mo–S_4 units. In this paper we present evidence for the difference in the reactivity characteristics of the Mo–S_4 and Mo–S_2 units.

EXPERIMENTAL

Synthesis

The chemicals in this research were used as purchased. Acetonitrile (CH_3CN), dichloromethane (CH_2Cl_2) and diethyl ether were distilled over calcium hydride. Dimethyl acetylene dicarboxylate (DMA) was distilled under reduced pressure at $\sim 50°C$. All syntheses were carried out under a dinitrogen atmosphere.

Physical methods

Visible and UV spectra were obtained on Cary Model 118 and 219 spectrophotometers. A Debye–Scherrer camera with nickel-filtered copper radiation was utilized to obtain X-ray powder diffraction patterns.

Electrochemical measurements were performed with a PAR Model 173 potentiostat/galvanostat and a PAR Model 175 universal programmer. The electrochemical cell used had platinum working and auxiliary electrodes. As the reference electrode a saturated calomel electrode was used. All solvents used in the electrochemical measurements were properly dried and distilled, and tetra-*n*-butylammonium perchlorate was used as the supporting electrolyte. Normal concentrations used were ~ 0.001 M in the electroanalyte and 0.1 M in the supporting electrolyte. Purified dinitrogen was used to purge the solutions prior to the electrochemical measurements.

Preparation of compounds

Bis(tetraphenylphosphonium)bis(μ - thio)(bis - [bis(1,2 - dimethylcarboxylate)dithioethylene) molybdate(V)] $(Ph_4P)_2[Mo_2S_2(S_2C_2(COOMe)_2)_4]$. *Method A.* To a solution of $(Ph_4P)_2Mo_2S_{10}/S_{12} \cdot \frac{1}{2}DMF$[1] (0.52 g, 0.42 mmol) in 300 cm^3 of CH_3CN was added with stirring 0.21 cm^3 (1.67 mmol) of freshly distilled DMA. The ensuing brown solution was refluxed for *ca* 30 min. The color of the solution changed to violet and then to a final green color. Upon cooling to ambient temperature and removing the solvent *in vacuo*, a green residue was obtained. The residue was washed with a 30-cm^3 portion of CH_2Cl_2 and the remaining solid was dissolved in the minimum amount of a DMF–CH_2Cl_2 (6 : 1) mixture. The slow diffusion of diethyl ether resulted in the formation of green crystals. The yield after drying was 0.22 g (26%).

Method B. To a solution of 0.26 g (0.21 mmol) of $(Ph_4P)_2Mo_2S_4(CS_4)_2 \cdot \frac{1}{2}DMF$[7] in the minimum amount of CH_3CN was added 0.10 cm^3 (0.80 mmol) of freshly distilled DMA. After refluxing for *ca* 30 min. the dark solution was allowed to cool to ambient temperature and the solvent was removed under vacuum. A workup procedure similar to the one described in Method A above yielded 0.10 g of product (26% yield). The X-ray powder pattern, electrochemistry and electronic spectrum of this material was identical to the product obtained by Method A. The X-ray powder pattern of the crystalline product is identical to the pattern calculated on the basis of the single-crystal X-ray diffraction data.*

Electronic spectrum

680 nm ($\varepsilon = 10{,}600$); 582 nm ($\varepsilon = 14{,}600$); 430 nm (sh) and 380 nm ($\varepsilon = 20{,}000$).

IR spectrum (selected characteristic vibrations)

ν(C=O): 1705(s), 1675(s) and 1650 cm^{-1}; 1220 cm^{-1} (v.s. broad absorption).

Electrochemical data

The cyclic voltammogram (in CH_3CN) of this material shows a quasireversible reduction at -0.67 V and an irreversible oxidation at $+0.85$ V (vs SCE).

Bis(tetraethylammonium)bis(1,2 - dimethyl - carboxylate)dithioethylene oxomolybdate(IV) $(Et_4N)_2MoO(S_2C_2COOMe)_2)_2$. To a solution of 2.0 g (3.18 mmol) of recrystallized $(Et_4N)_2MoO(S_4)_2$ in *ca* 350 cm^3 of CH_3CN was added 0.9 cm^3 (7.32 mmol) of DMA. The reaction mixture was stirred for 10 min and an orange red solution was obtained. The solution was concentrated to 30 cm^3, by evaporation of the solvent *in vacuo*, and then filtered. To the filtrate was added 100 cm^3 of tetrahydrofuran (THF). Upon standing, a solid deposited, was isolated and washed with three 30-cm^3 portions of THF. The crude product was recrystallized from a concentrated CH_3CN solution upon addition of THF and standing at ambient temperature for *ca* 10 h. Brown red needles formed and were isolated. The yield after drying was 1.20 g (48.1%). The powder pattern of this compound was identical to the pattern calculated on the basis of single-crystal X-ray diffraction data.[10]

* A detailed description of the structures of

$$\{Mo_2S_2[S_2C_2(COOMe)_2]_4\}^{2-}$$

and

$$[OMo(S_2C_2COOMe)_2]^{2-}$$

will be published elsewhere.

RESULTS AND DISCUSSION

Synthetic studies

Our studies of the reactions of the $(MoS_9)^{2-}$, $(Mo_2S_{10})^{2-}$ and $(Mo_2S_{12})^{2-}$ complexes thus far have shown that these anions readily react with CS_2. The crystalline $[(CS_4)_2MoS]^{2-}$, (*cis* or *trans*) and $[(CS_4)_2Mo_2S_4]^{2-}$ anions contain the S–S chelating perthiocarbonate ligand[7] (Fig. 2). The reaction of $(MoS_9)^{2-}$ with 2-butynedimethanoate (DMA) also proceeds smoothly and the $\{Mo[S_2C_2(COOCH_3)_2]_3\}^{2-}$ anion contains the bidentate $[S_2C_2(COOCH_3)]^{2-}$ ligands and a nearly trigonal prismatic MoS_6 core[8] (Fig. 3B). Under the assumption that the $\{Mo[S_2C_2(COOCH_3)_2]_3\}^{2-}$ complex was a final product of a series of intermediate Mo–sulfido-dithiolene complexes we proceeded with a detailed study of the reactions of the Mo thioanions with DMA. The $[(CS_4)_2Mo_2S_4]^{2-}$ and $[(S_4)_2Mo_2S_4]^{2-}$ anions react with DMA in a 1 : 4 molar ratio to afford in modest yields the $\{Mo_2S_2[S_2C_2(COOMe)_2]_4\}^{2-}$ anion[10] (**1**) (Fig. 3A). The synthesis of **1** can also be accomplished by the reaction of $(MoS_9)^{2-}$ with DMA under *aerobic* conditions. The same reaction under a N_2 atmosphere affords the $\{Mo[S_2C_2(COOCH_3)_2]_3\}^{2-}$ complex. A clue regarding the possible reaction pathway toward the synthesis of **1** from $(MoS_9)^{2-}$ is provided by the corresponding reaction of $[MoS_8O]^{2-}$ with DMA. In the latter reaction, the $\{OMo[S_2C_2(COOMe)_2]\}^{2-}$ complex is obtained[10] (Fig. 3C) and contains five-coordinate Mo(IV). By analogy, it is reasonable to assume that the MoS_5^{2-} anion reacts with DMA initially to form the $\{SMo[S_2C_2(COOMe)_2\}^{2-}$ complex. Oxidation

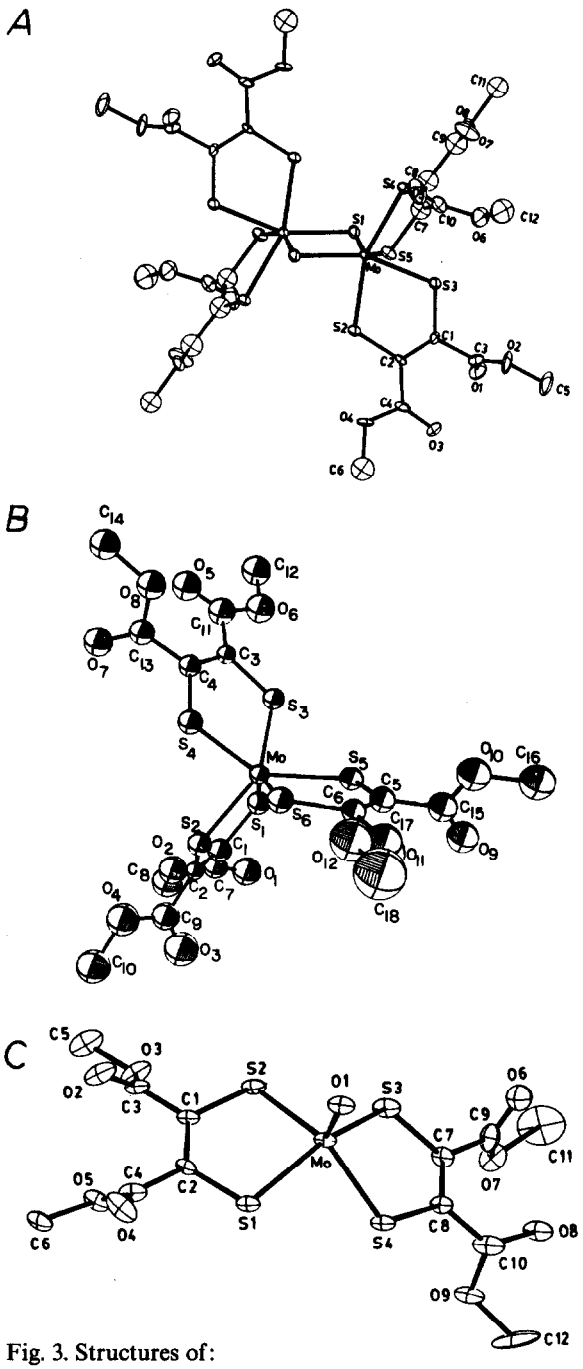

Fig. 3. Structures of:

(A) $\{Mo_2S_2[S_2C_2COOMe)_2]_4\}^{2-}$,[10]

(B) $\{Mo[S_2C_2(COOMe)_2]_3\}^{2-}$,[8]

and

(C) $\{OMo[S_2C_2(COOMe)_2]\}^{2-}$.[10]

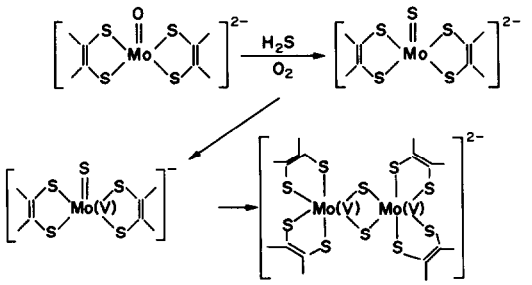

Fig. 4. Reaction of $\{OMo[S_2C_2(COOMe)_2]\}^{2-}$ with H_2S.

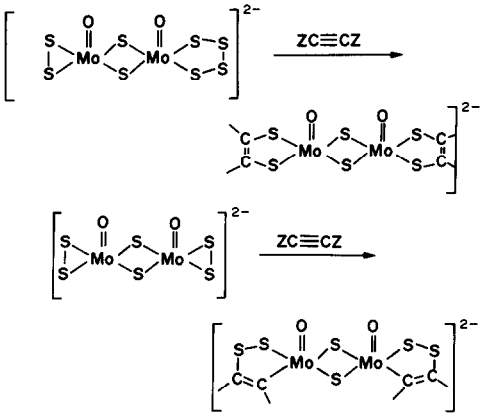
of this complex to the monoanion followed by dimerization will result in the formation of **1**. This assumption is supported by the reaction of $\{OMo[S_2C_2(COOMe)_2]\}^{2-}$ with H_2S. The only product that can be isolated from this reaction (Fig. 4) is **I**.

The formation of the $[S_2C_2(COOMe)_2]^{2-}$ ligand in the reactions of Mo-coordinated S_4^{2-} ligands with DMA contrasts with the reaction of the coordinated S_2^{2-} ligand in the $[Mo_2S_6O_2]^{2-}$ anion (Fig. 1C). The latter inserts DMA into the Mo—S bond with formation of a product that contains the S–C-coordinated vinyl disulfide ligand[9] (Fig. 5).

The $[(S_4)MoO(\mu\text{-}S)_2Mo(O)(S_2)]^{2-}$ complex reacts with DMA at ambient temperature to give the same vinyl disulfide complex (Fig. 5). The same reaction under reflux conditions affords the $[(L)Mo(O)(\mu\text{-}S)_2Mo(O)(L)]^{2-}$ dithiolene isomer,[11(a)] $\{L = [S_2C_2(COOR)_2]^{2-}\}$. Apparently, the $[Mo_2S_6O_2]^{2-}$ anion (Fig. 1C), obtained by dissociation of S_2^0 from the $[(S_4)Mo(O)(\mu\text{-}S)_2Mo(O)(S_2)]^{2-}$ complex, reacts rapidly with DMA



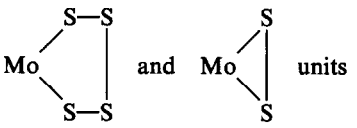


Fig. 5. Reactions of dicarbomethoxyacetylene with the

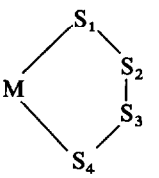

units

to form the vinyl disulfide complex. The latter, as verified by NMR spectral changes, rearranges thermally to the dithiolene dimer (Fig. 5). A similar thermal rearrangement was observed[11(b)] previously in the formation of the $(Cp)_2Ti[S_2C_2(COOR)_2]$ dithiolene complex from the corresponding vinyl disulfide isomer.

[a] Distances in Å.

[b] Contains two symmetry-independent CS_4^{2-} ligands.

S_2^{2-} ligands[12] shows that the effect of coordination is quite different for the two ligands. Thus, the S—S bond length in the "side-on" bound S_2^{2-} ligands ranges[12] from 2.03 to 2.074(5) Å and is slightly longer than the S—S bond in elemental S_8. By contrast, an alternation in the S—S bond lengths is apparent in the bidentate S_4^{2-} ligand in complexes that contain the Mo–S_4 unit. The significant elongation of the S—S bonds directly adjacent to the Mo atom correlates directly with a shortening of the corresponding Mo—S bonds and suggests that bonding electrons from the S—S bond are transferred to Mo–S bonding orbitals. The facile transfer of this type most likely arises as a result of the effective energy matching of the appropriate atomic wavefunctions.*

The ease by which the coordinated S_4^{2-} ligands dissociate S_2^0 following interactions with electrophilic molecules such as CS_2 or DMA very likely is due to the proximal S—S bond activation by the Mo atom. It should be emphasized that the S_4^{2-} ligand in the tetrahedral $[Zn(S_4)_2]^{2-}$ complex anion,[14] which contain the d^{10} Zn(II) ion, does not show an alternation of the S—S bond lengths (Table 1).

A lengthening of the S—S bond adjacent to the Mo atom also is apparent in the structures of both the *cis*- and *trans*-$[(Cs_4)_2MoS]^{2-}$ complex anions (Fig. 2) and in the $[(CS_4)Mo(S)(\mu\text{-}S)_2Mo(S)(CS_4)]^{2-}$ complex (Table 2). As observed with the S_4^{2-} ligands, the Mo—S bond directly adjacent to the lengthened S—S bond of the CS_4^{2-} ligand always is significantly shorter than the Mo—S bond with the thiolate sulfur of the ligand. Such differences in M–S bonding, or lengthening of the S—S bond are not apparent in the structure of the $[N_1(CS_4)_2]^{2-}$ complex[14] (Table 2).

With the Mo-"side-on"-bound S_2^{2-} ligand, and in the absence of other activating interactions, the transfer of electron density to the Mo—S bonds would originate from the antibonding π^*-orbital and should result in a strengthening of the S—S bond. A bond order >1 for the "side-on"-coordinated S_2^{2-} ligand is evident in the S—S stretching vibrations (500–600 cm^{-1}) and the S—S bond lengths (2.00–2.10 Å) in these species. The corresponding values for the uncoordinated S_2, S_2^- and S_2^{2-} fragments are: S_2^0, 725 cm^{-1}, 1.89 Å; S_2^-, 589 cm^{-1}, 2.00 Å; S_2^{2-}, 446 cm^{-1}, 2.13 Å. A net depopulation of the S_2^{2-} π^*-orbital in the Mo–S_2 complexes and the π^* nature of the LUMO result in a situation where a cycloaddition of an acetylene or olefin to the Mo-"side-on"-bound S_2^{2-} would be a symmetry-forbidden process, it is not surprising therefore that such cycloaddition reactions with "*pure*" Mo–S_2 units are virtually unknown. In the only well-documented reaction of DMA with such a unit [in the $(Mo_2S_6O_2)^{2-}$ complex], the alkyne has inserted into the Mo—S bond.[9]

The reactions of the Mo-coordinated S_4^{2-} ligands with DMA and the subsequent formation of the dithiolene ligand, are analogous to other reactions of M–S_x units with DMA. Such reactions as the addition of DMA to the Fe–S_5 unit in $(Fe_2S_{12})^{2-}$,[20,21] the addition of DMA to the Ti–S_5 unit in $(Cp)_2TiS_5$ and the V–S_5 unit in $(Cp)_2VS_5$,[22] give rise to dithiolene complexes that contain $M[S_2C_2(COOMe)_2]$ units. An important mechanistic step in these reactions very likely involves the cycloaddition of the electrophilic alkyne to the coordinated S_x^{2-} chelate (Fig. 6). Interactions of the type depicted in Fig. 6 have a precedence in dithiolene chemistry. The addition of alkenes

*For the neutral free atoms, a compilation of Roothaan–Hartree–Fock atomic wavefunctions show the sulfur 3*p* orbitals with an energy of −0.43694 a.u. and the molybdenum $4d(s^1d^5)$ with an energy of −0.34811 a.u. The localization of partial positive charge on the Mo and partial negative charge on the S is expected to bring these energies even closer together.[13]

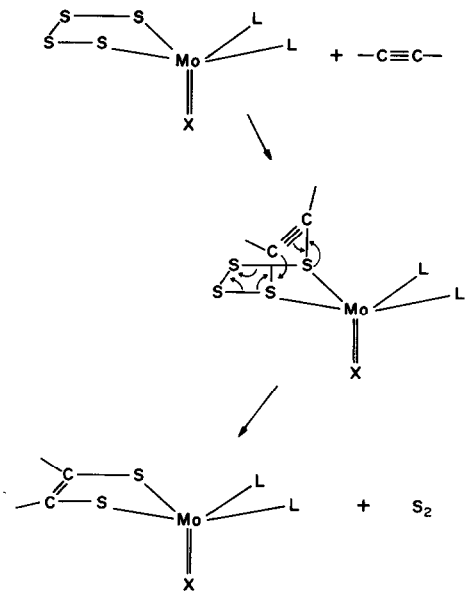

Fig. 6. Cycloaddition of alkynes to the Mo–S_4 unit.

across the coordinated *S*-donor atoms in the $Ni[S_2C_2(Ph)_2]_2$ complexes has been reported by Schrauzer and Mayweg[23] and the norbornadiene adduct of $Ni[S_2C_2(CF_3)_2]_2$ has been obtained and structurally characterized.[24]

The activation, and change in reactivity patterns of the Mo-bound S_2^{2-} ligand, following the addition of elemental sulfur and formation of the Mo–S_4 units, may be of relevance to the HDS reaction. The HDS reaction is important in the catalytic hydrogenolysis of organosulfur compounds, and the heterogeneous catalysts employed in this reaction contain "sulfided" molybdenum and cobalt salts supported on β-alumina.[25] Proposed mechanisms for the HDS reaction[25–27] invariably involve the metals (Mo and Co) directly in the activation of H_2 and the C—S bond cleavage reactions. The suggestion has been advanced[28] that S_2^{2-} pairs, present in the catalyst, may be directly linked with thiophene HDS activity. This suggestion is supported by the pioneering work of Rakowski Dubois, who has demonstrated that appropriately activated S_2^{2-} units in the $(CpMoS_2)_2$ complex are capable of activating H_2[29] and catalyze the reduction of elemental sulfur and the hydrogenation of alkynes.[30] With appropriately activated Mo–S_2 units, in fact, one can envision all of the HDS important reaction steps occurring directly on the S_2 unit (Fig. 7).

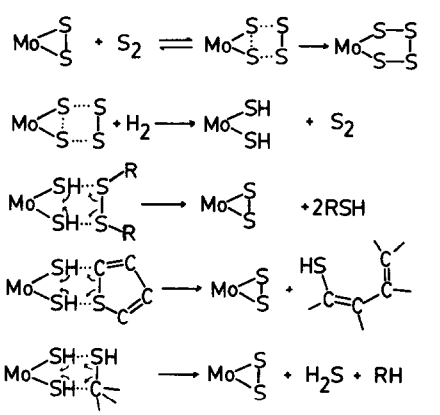

Fig. 7. Possible reactions of the activated S_2^{2-} ligand relevant to the HDS process.

PREPARATION OF TRINUCLEAR MOLYBDENUM(IV) ION, $Mo_3S_4^{4+}$, AND X-RAY STRUCTURE OF $Ca[Mo_3S_4\{HN(CH_2CO_2)_2\}_3]\cdot 11.5H_2O$

TAKASHI SHIBAHARA* and HISAO KUROYA

Department of Chemistry, Okayama University of Science, 1-1 Ridai-cho, Okayama 700, Japan

(*Received* 13 *June* 1985)

Abstract—The equilateral trinuclear Mo(IV) ion of incomplete cubane-type structure, $Mo_3S_4^{4+}$, was prepared by the reduction of $[Mo_2O_2S_2(cys)_2]^{2-}$ with $NaBH_4$ followed by air oxidation and Sephadex G-10 separation. The resultant green solution was analyzed to give S/Mo = 1.33. The spectrum $\{\lambda_{max}[\varepsilon(M^{-1}cm^{-1})]: 367(5190), 500sh(290)$ and $602(351)$ in 2 M HPTS$\}$ remains unchanged in the air. The existence of the Mo_3S_4 core has been confirmed by X-ray structure analysis of $Ca[Mo_3S_4(ida)_3]\cdot 11.5H_2O$ (H_2ida = iminodiacetic acid) which was prepared from the $Mo_3S_4^{4+}$ ion and H_2ida. Crystal data: orthorhombic, $a = 13.815(3)$ Å, $b = 26.189(9)$ Å, $c = 9.447(3)$ Å, $V = 3417.9(17)$ Å^3, $Z = 4$, $D_c = 2.053$ g cm^{-3}, space group $P2_12_12_1$. R value is 0.048 for 3705 reflections $[F_o \geqslant 3\sigma(F_o)]$. The anion $[Mo_3S_4(ida)_3]^{2-}$ has an approximate symmetry of C_{3v} and contains an incomplete cubane-type Mo_3S_4 core. Selected mean bond distances are as follows: Mo—Mo, 2.754 Å, Mo—μ_3-S, 2.349 Å; Mo—μ_2-S, 2.295 Å; Mo—O, 2.167 Å, Mo—N, 2.227 Å. The existence of an $[Mo(IV)]_2Mo(III)$ oxidation state has been indicated for the first time from the cyclic voltammogram and polarogram of the anion.

The presence of equilateral trinuclear Mo(IV) ions of incomplete cubane-type structure, $Mo_3O_4^{4+}$,[1] and sulfur-capped $Mo_3O_3S^{4+}$,[2] has been reported, the latter showing a greater stability toward air oxidation. Several reports on the X-ray structure of the Mo_3O_4 core[3] and a report on that of the Mo_3O_3S core[2] have appeared. We will describe here the preparation and characterization of an incomplete cubane-type Mo(IV) ion, $Mo_3S_4^{4+}$, and the X-ray structure analysis of $Ca[Mo_3S_4(ida)_3]\cdot 11.5H_2O$ (H_2ida = iminodiacetic acid) having the Mo_3S_4 core. Accounts of the electrochemistry and a new oxidation state, $[Mo(IV)]_2Mo(III)$, will be given and the effects of introducing sulfur(s) into the Mo_3O_4 core will be discussed.

EXPERIMENTAL

Preparation of $Mo_3S_4^{4+}$ *ion*

Two grams (3.1 mmol) of the di-μ-sulfidomolybdenum(V) dimer, $Na_2[Mo_2O_2S_2(cys)_2]\cdot 4H_2O$[4] dissolved in diluted HCl (0.03 M, 200 cm^3) was transferred into a round-bottom flask containing $NaBH_4$ (1 g, 20 mmol). Concentrated HCl (30 cm^3) was added slowly with stirring to the mixture, which was then kept overnight in a refrigerator. Up to now all operations were performed under an N_2 atmosphere. Air oxidation of the resultant brown solution in a hot bath gave dark green solution, which gave four greenish bands through Sephadex G-10 separation. The species in the last band was purified by the use of ion exchange technique: that is, after dilution with three parts of water, the solution was absorbed on a Dowex 50W-X2 cation

exchanger, and this was washed with 1 M HCl, and the green eluant was obtained by the use of 2 M HCl. The solution was analysed to give S/Mo = 1.33 ±0.02 (three determinations).[5] The yield was ca 15%, based on the starting binuclear complex. The HPTS solution of the ion was obtained by absorption of the ion on the cation exchanger from the HCl solution followed by the elution of it with 2 M HPTS.

Preparation of $Ca[Mo_3S_4(ida)_3]\cdot 11.5H_2O$

H_2ida ($H_2ida/Mo \simeq 10$) dissolved in a minimum amount of concentrated KOH (*ca* 10 M) was added to the $Mo_3S_4^{4+}$ solution in 2 M HCl. Concentrated KOH at first, and then diluted KOH, was added very slowly (in *ca* 4 days) to raise the pH of the solution to *ca* 10. After being diluted, the resultant solution was absorbed on a Dowex 1-X2 anion exchanger, which was washed with 0.05 M $CaCl_2$. Elution with 0.3 M $CaCl_2$ gave two major bands. The solution obtained from the first band was passed through a Sephadex G-10 column for desaltation, after the volume of the solution had been decreased to *ca* one third by the use of a rotary evaporator. The resultant solution was diluted *ca* 10 times, and again absorbed on a Dowex 1-X2 anion exchanger. Green crystals were deposited from the solution obtained by the use of 1 M $CaCl_2$ as an eluent.

Spectrophotometry and electrochemistry

Spectra were recorded with a Hitachi 330 spectrophotometer. Absorption coefficients (ε) recorded are per trimer. Cyclic voltammetry was conducted with a Yanaco Polarographic Analyzer P1100 using a glassy carbon working electrode, a Pt counter electrode, and a saturated calomel electrode (SCE). The polarogram was obtained with the same instrument.

Crystallographic study of $Ca[Mo_3S_4(ida)_3]\cdot 11.5H_2O$

Crystal data: Formula weight = 1056.60, orthorhombic, $a = 13.815(3)$ Å, $b = 26.189(9)$ Å, $c = 9.447(3)$ Å, $V = 3417.9(17)$ Å^3, $Z = 4$, $D_c = 2.053$ g cm^{-3}, space group $P2_12_12_1$, $\lambda(\text{Mo-}K_\alpha) = 0.71073$ Å, $\mu(\text{Mo-}K_\alpha) = 15.27$ cm^{-1}.

Data collection. The crystal employed for data collection was approximately $0.2 \times 0.3 \times 0.4$ mm in dimension with well-defined faces. Intensity data ($2\theta \leqslant 55°$) were collected on a RIGAKU AFC-6A four-circle diffractometer. During data collection, three standard reflections monitored after every 150 reflections did not show any appreciable decay. A total of 4437 reflections were collected, of which 3705 with $F_o \geqslant 3\sigma(F_o)$ were used for the structure analysis. Intensities were corrected for polarization and Lorentz factors, but not for absorption.

Structure solution and refinement. The coordinates of three Mos were determined by means of MALTAN and the remaining non-hydrogen atoms were located from successive difference Fourier maps. The block-diagonal least-squares refinement with anisotropic temperature factors for all non-hydrogen atoms gave $R = 0.048$ and $R'[(\Sigma\omega\Delta F^2/\Sigma\omega F_o^2)^{1/2}] = 0.045$. The function minimized was $\Sigma\omega(F_o - |F_c|)^2$, where $\omega = 1/\sigma^2(F_o)$ was used. No attempt was made to locate hydrogen atoms. A final different Fourier map revealed no peak greater than 1.3 e Å^{-3} in the vicinity of Mo atoms. The computer programs involved have been described before.[6] Atomic coordinates, anisotropic thermal parameters, bond distances, bond angles and a list of F_o and F_c values have been deposited with the Editor as supplementary material.

RESULTS AND DISCUSSION

Preparation of $Mo_3S_4^{4+}$ *and* $[Mo_3S_4(ida)_3]^{2-}$

Four greenish species were prepared by the reduction of the Mo(V) dimer $[Mo_2O_2S_2(cys)_2]^{2-}$ with $NaBH_4$, and the $Mo_3S_4^{4+}$ ion is the fourth species from the Sephadex G-10 column.* The charge of the ion is estimated to be 4+ on the basis of its behavior, similar to those of $Mo_3O_4^{4+}$ and $Mo_3O_3S^{4+}$ ions on the ion exchanger. $Mo_3S_4^{4+}$ ion in 2 M HCl or HPTS is stable toward air oxidation.

The anion exchanger separation of the reaction mixture of $Mo_3S_4^{4+}$ and H_2ida gives two green bands. The green air-stable complex $[Mo_3S_4(ida)_3]^{2-}$ has been obtained as a calcium salt from the first band. The electronic spectrum of the crystals obtained from the second band in a similar manner shows the same peak positions as those of the crystals obtained from the first band, although the peak positions of the solution from the second band are slightly different from those of the solution from the first band. The unit cell dimensions of the crystal from the second band are found to be the same as those of the crystals from the first band.

Electronic spectra

The electronic spectrum of the $Mo_3S_4^{4+}$ ion in 2 M HPTS {$\lambda_{max}[\varepsilon\ (M^{-1}\ cm^{-1})]$: 367(5190), 500sh(290) and 602(351)} is shown in Fig. 1 together with those of the $Mo_3O_4^{4+}$ and $Mo_3O_3S^{4+}$ ions. The spectrum of $[Mo_3S_4(ida)_3]^{2-}$ in water [$\lambda_{max}(\varepsilon)$: 246(21,700),

* Three other species have been characterized and will be reported elsewhere.

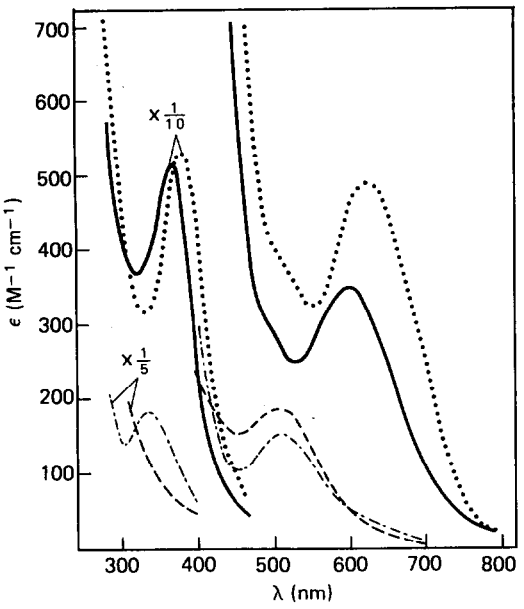

Fig. 1. Electronic spectra of trinuclear Mo(IV) ions in 2 M HPTS except for (d): (a) $Mo_3S_4^{4+}$ (——), (b) $Mo_3O_3S^{4+}$(— - — - —), (c) $Mo_3O_4^{4+}$ (— —), and (d) $[Mo_3S_4(ida)_3]^{2-}$ in water (- - - -).

380(5330), 520sh(374) and 622(494)] is also included in Fig. 1. No peaks appear for the $Mo_3S_4^{4+}$ and $[Mo_3S_4(ida)_3]^{2-}$ ions in the near-IR region. The positions of maximal absorption are shifted toward a longer wavelength upon substitution of sulfur(s) for oxygen(s) in the Mo_3O_4 core: it seems that the influence of μ_2-S on the red shift is larger than that of μ_3-S.

X-ray crystal structure of $Ca[Mo_3S_4(ida)_3]\cdot 11.5H_2O$

A perspective view of the complex anion is given in Fig. 2. The anion has an approximate symmetry of C_{3v} and contains an incomplete cubane-type Mo_3S_4 core. This supports the existence of an $Mo_3S_4^{4+}$ ion (probably $[Mo_3S_4(H_2O)_9]^{4+}$) in solution. Every nitrogen in the ida^{2-} ligands occupies a position *trans* to μ_3-S and every Mo has an octahedral coordination distorted by three S atoms from the core and two O and one N atom from the ida^{2-} ligand. Selected bond distances and angles are listed in Table 1. A comparison of some bond distances is made among clusters with Mo_3S_4, Mo_3O_3S and Mo_3O_4 cores (Table 2). The Mo—Mo distance of $[Mo_3S_4(ida)_3]^{2-}$ is slightly shorter than that of other complexes with an Mo_3S_4 core and is evidently longer than that of complexes with an Mo_3O_3S or Mo_3O_4 core. Mo—μ_2-S and Mo—μ_3-S distances are similar to each other, except for $[Mo_3S_4(h\text{-}C_5H_5)_3]^+$. The calcium ion is surrounded by six water molecules: Ca—O distances range from 2.364(10) to 2.428(15) Å, with a mean value of 2.40(2) Å.

Electrochemistry

The $Mo_3S_4^{4+}$ ion reacts easily with mercury, showing a color change, and, therefore, a definite cyclic voltammogram of this ion at a hanging mercury electrode was not obtained, although sharp reduction and oxidation peaks were seen ($E_{p,c}$ −0.185 and $E_{p,a}$ −0.105 V (SCE)). On the other

[a] Mean values.

hand, no peak appeared in the region of 0 to ~ −0.5 V (SCE) at a glassy carbon electrode.

The cyclic voltammogram of $[Mo_3S_4(ida)_3]^{2-}$ (Fig. 3) shows two reversible one-electron waves and an ill-defined one. This clearly indicates the existence of $[Mo(IV)]_2Mo(III)$ and $Mo(IV)[Mo(III)]_2$ oxidation states. The polarogram (Fig. 4) for this compound also supports the existence of both oxidation states. No such an oxidation state of trinuclear molybdenum cluster as

$$[Mo(IV)]_2Mo(III)$$

has been found in the reduction process of $Mo_3O_4^{4+}$ or

$$[Mo_3O_4(C_2O_4)_3(H_2O)_3]^{2-}.^{\text{I(b)-(d)}}$$

The introduction of sulfur into the Mo_3O_4 core can be one of the causes* of the appearance of the $[Mo(IV)]_2Mo(III)$ oxidation state and the presence of aqua ligand(s) may prevent $Mo_3O_4^{4+}$ or

$$[Mo_3O_4(C_2O_4)_3(H_2O)_3]^{2-}$$

from exhibiting the $[Mo(IV)]_2Mo(III)$ oxidation state. Further studies on the electrochemistry of the

* $[Mo_3O_3S(ida)_3]^{2-}$ also shows the $[Mo(IV)]_2Mo(III)$ oxidation state (unpublished data).

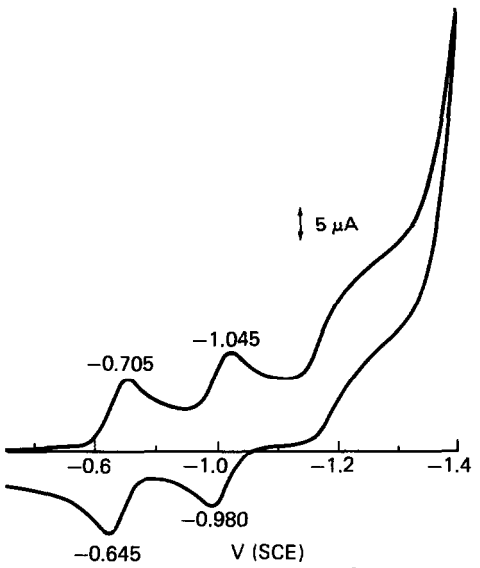

Fig. 3. Cyclic voltammogram of $[Mo_3S_4(ida)_3]^{2-}$ (0.96 mM) in 0.1 M KCl at a glassy carbon electrode: scan rate 100 mV s^{-1}, reference electrode is an SCE; temperature 25°C.

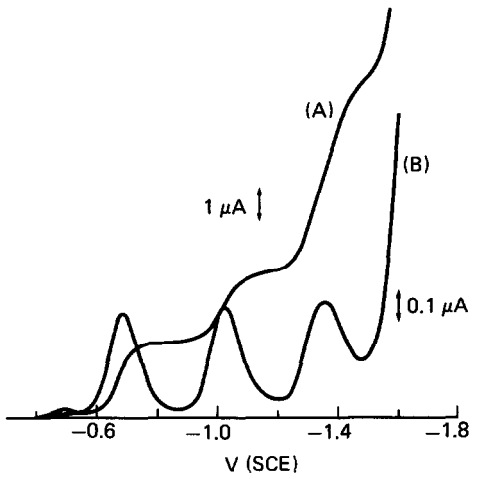

Fig. 4. Polarogram (a) and difference polarogram (b) of $[Mo_3S_4(ida)_3]^{2-}$ (0.96 mM) in 0.1 M KCl.

compounds with an Mo_3S_4 core, as well as those with an Mo_3O_4 core, are to be expected.

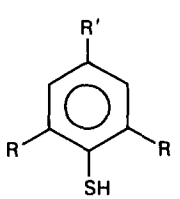
(*Received* 28 *June* 1985)

Abstract—$[MoBr_2(CO)_4]$ reacts with 2,4,6-$Pr^i_3C_6H_2S^-$ ($TIPT^-$) to give trigonal bipyramidal $[Mo(CO)_2(TIPT)_3]^-$ (**I**). The tungsten and rhenium analogues are isostructural. Complex **I** reacts with neutral donors to give $[Mo(TIPT)_3(CO)L]^-$ (L = MeCN, Bu^tCN, MeNC, Bu^tNC or PMe_2Ph) and with $[PhN_2][BF_4]$ to give $[Mo(N_2Ph)(TIPT)_3(MeCN)]$ (**II**). Complex **II** is also trigonal bipyramidal with axial N_2Ph and MeCN ligands. $[MoCl_3(MeCN)_3]$ reacts with TIPT in MeCN to give "$[Mo(MeCN)(TIPT)_4]$". By contrast, $MoCl_4$ in dimethoxyethane with TIPT gives $[Mo_2(TIPT)_6]$ together with $[MoO(TIPT)_4]^-$. An X-ray crystal structure of $[Mo_2(TIPT)_6]$ revealed an Mo–Mo triple bond analogous to $[Mo_2(OR)_6]$ species. The phenylated thiol, 2,6-$Ph_2C_6H_3S^-$ (DPT^-), reacts with $[MoBr_2(CO)_4]$ in dimethoxyethane to give $[Mo(CO)(DPT)_2]$. One of the *o*-phenyl groups is η^6-bonded to give a distorted piano-stool structure. The η^6-phenyl group is readily displaced by a range of neutral donor ligands to give access to a new series of Mo(II) thiolato-derivatives.



There is now strong evidence from EXAFS studies that the metal ions in nitrogenase are ligated primarily by sulphur. However, there are comparatively few reported examples of molybdenum–sulphur complexes containing small molecules such as CO, H_2 and NO, and none with dinitrogen. In this paper we describe our attempts to prepare reactive monomeric molybdenum complexes using bulky 2,6-disubstituted aryl thiols of the types shown in Fig. 1.

The Mo(IV) complex $[MoCl_4(thf)_2]$ (thf = tetrahydrofuran) reacts with

$$2,4,6\text{-}Pr^i_3C_6H_2S^- \ (TIPT^-)$$

in thf in the presence of CO to give $[Mo(TIPT)_3(CO)_2]^-$ (**I**), isolated as a tetraphenylphosphonium salt. Complex **I** can also be prepared more conveniently by reaction of $[MoCl_2(CO)_4]$ with three equivalents of TIPTH in methanol in the presence of triethylamine. The bright pink complex **I** is diamagnetic and shows ν(CO) at 1860 cm^{-1} in the IR spectrum. An X-ray crystal structure revealed a trigonal bipyramidal structure with axial CO ligands.[1] Reaction with neutral two-electron donor ligands gave purple $[Mo(TIPT)_3(CO)L]$ (L = MeCN, Bu^tCN, MeNC, Bu^tNC or PMe_2Ph).

However, reaction with $[PhN_2][BF_4]$ in aceto-

R' = R = Me or Pr^i
R' = H, R = Ph

† Author to whom correspondence should be addressed.

nitrile occurred rapidly and smoothly to give green $[Mo(N_2Ph)(TIPT)_3(MeCN)]$ (**II**). An X-ray crystal structure of complex **II** again revealed a trigonal bipyramidal structure (Fig. 2) with apical N_2Ph and MeCN groups. The N_2Ph ligand has a linear Mo—N—N— system and the bond lengths are also consistent with the diazenido-ligand functioning as a three-electron donor, giving the metal an overall 14-electron configuration. The complex is isostructural with the closely related nitrosyl derivative $[Mo(TIPT)_3(NO)(NH_3)]$ which contains a nearly linear Mo—N—O moiety. ^{15}N NMR spectra of ^{15}N-labelled complex **II** revealed two resonances for the β-nitrogen consistent with two isomers depending on the concentration of the aryl groups of the thiolate ligands relative to the diazenido-ligand. The shift in the β-nitrogen resonance on addition of acid is consistent with the formation of the hydrazido(2−)-complex $[Mo(NNHPh)(TIPT)_3(MeCN)]^+$.

The reaction of the Mo(IV) precursors with $TIPT^-$ leads to reduction of the molybdenum. By contrast, reaction of $[MoCl_3(MeCN)_3]$ with TIPTH in dry acetonitrile under reflux in the presence of triethylamine gives brown crystalline air-sensitive $[Mo(TIPT)_4(MeCN)]$ (**III**) with nett oxidation of the metal. Suitable crystals for an X-ray structure have not yet been obtained and the formulation is based on elemental analysis, ^1H NMR and molecular-weight determinations. Complex **III** is related to $[Mo(SBu^t)_4]$[2] but is stabilized with respect to C—S bond cleavage which dominates the chemistry of the *t*-butylthiolato-complex.[2] The MeCN is readily displaced by other two-electron donor ligands, providing ready access to a range of Mo(IV) thiolato-derivatives.

The products obtained from the reaction of molybdenum halido-precursors with the sterically demanding thiolates are also highly dependent on the solvent used in the reaction. Thus reaction of $MoCl_4$ with NaTIPT in 1,2-dimethoxyethane gave $[MoO(TIPT)_4]^-$ (**IV**), isolated as a tetraphenylphosphonium salt from methanol (40% yield) and a red crystalline, hexane-soluble complex of empirical formula $Mo(TIPT)_3$ (**V**).

The formation of the Mo(V) oxo-complex (**IV**) demonstrates the high oxygen affinity of these molybdenum thiolato-systems and it is found as a

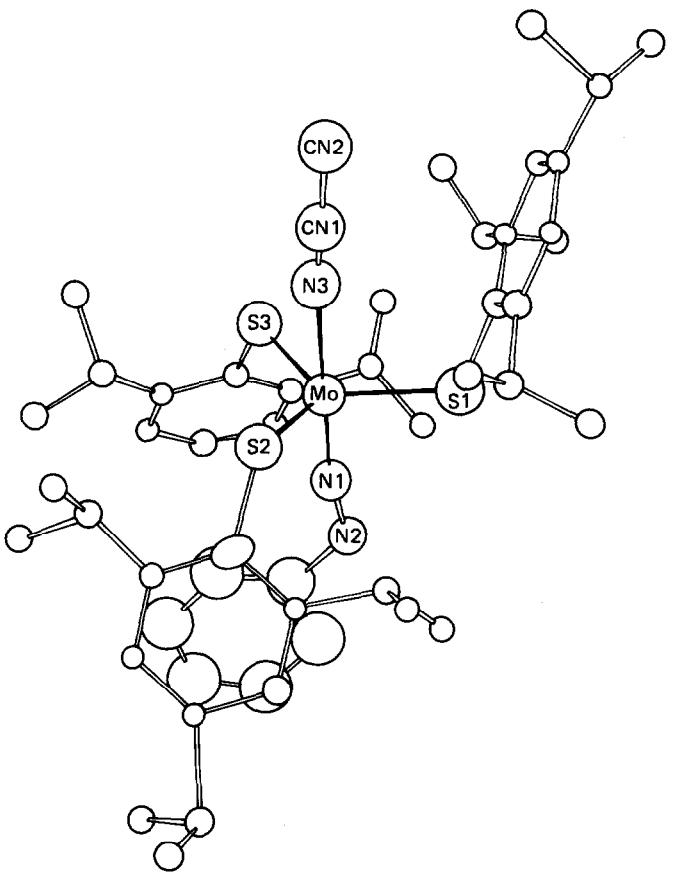

Fig. 2. Structure of $[Mo(NNPh)(TIPT)_3(MeCN)]$.

contaminant in many reactions. The source of the oxygen is not certain but equivalent yields are also produced when the reactions are done in a glove-box at oxygen concentrations of less than 1 ppm O_2. Traces of water in the solvent or the solvent itself may be responsible. The ready formation of the oxo-species is also illustrated by reaction of $[MoCl_4(PPh_3)_2]$ with NaTIPT in toluene under N_2 when the only isolable characterizable product was yellow-orange crystalline $[Mo_2O_4(TIPT)_2(PPh_3)_2]$ (**VI**) shown by an X-ray crystal structure to have both terminal and bridging oxo groups.

The Mo(V) oxo-complexes (**IV**) are deep blue paramagnetic d^1-systems with EPR spectra extremely similar to the known thiophenolato-complex $[MoO(SPh)_4]^-$,[3,4] suggesting an analogous square pyramidal structure with an apical oxo-group. They can be synthesized more systematically by reaction of $[Bu^n_4N][MoOCl_4]$ with NaTIPT in thf in near quantitative yield. The purple tungsten analogue is prepared analogously from $WOCl_4$. Cyclic voltammetric measurements show that, whereas the thiophenolate complex is irreversibly oxidized and quasi-reversibly reduced, complex **IV** is reversibly oxidized and totally irreversibly reduced. This is consistent with facile expulsion of bulky thiolate anion on reduction and stabilization of the Mo(VI) oxo-species formed on oxidation.

The second reaction product (**V**) mentioned above of empirical formula $Mo(TIPT)_3$ was shown to be dimeric by cryoscopic measurements in benzene. An X-ray crystal structure (Fig. 3) revealed a dimeric structure with an Mo–Mo triple bond. The complex has a closely related structure to the complex $[Mo_2(2,4,6\text{-}Me_3C_6H_2S)_6]$ reported earlier by Chisholm *et al.*[5] However, the synthesis we report here is more convenient, proceeding in one step from readily available $MoCl_4$ and avoiding the more difficult preparation of $[Mo_2(NMe_2)_6]$ and several succeeding complex substitution steps. The bulk of the thiolate ligands drastically reduces the reactivity of the complex and there is no sign of the reactions with small molecules such as acetylenes and other multiply bonded species reported for analogous alkoxides such as $[Mo_2(OPr^i)_6]$.

If the sterically hindered thiolates bear phenyl groups in the *ortho*-positions then completely different co-ordination behaviour is observed. Thus the sodium salt of 2,6-diphenylthiophenol (NaDPT) reacts with $[MoBr_2(CO)_4]$ in 1,2-dimethoxyethane

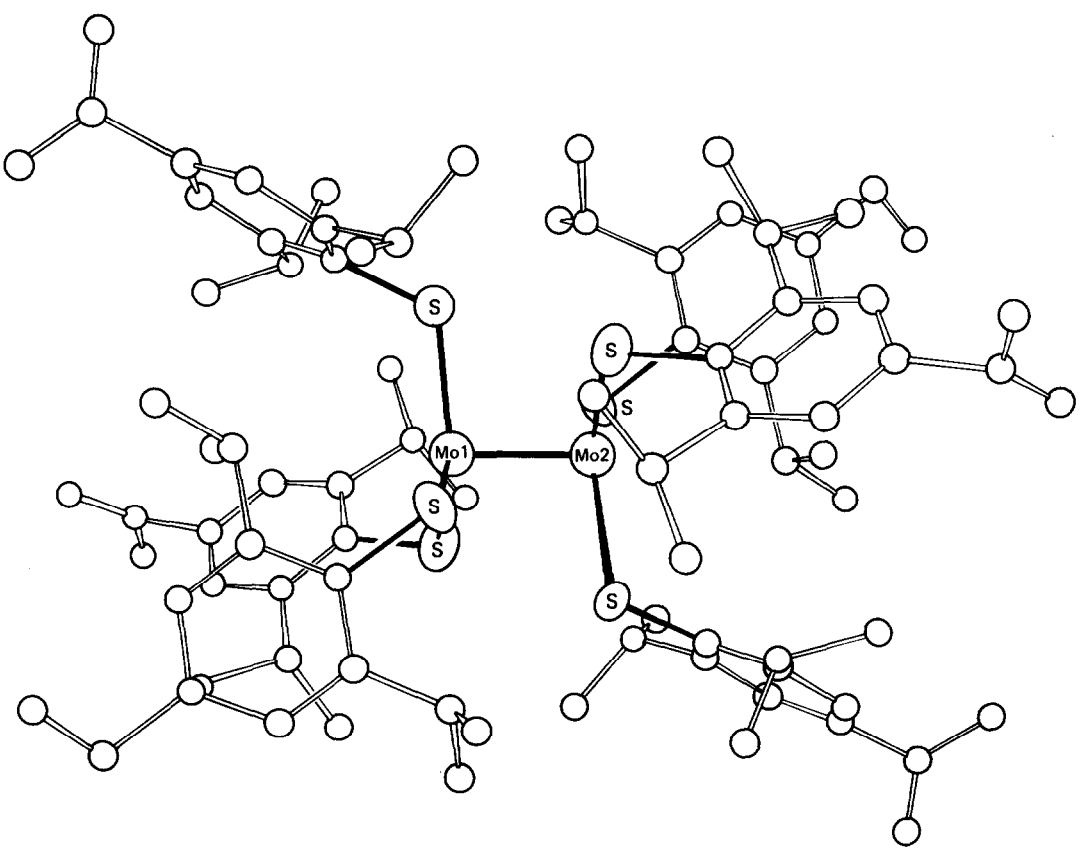

Fig. 3. Structure of $[Mo_2(TIPT)_6]$.

at room temperature to give a green air-stable solid of empirical formula $[Mo(DPT)_2(CO)]$ (**VII**).[6] This complex shows ν(CO) in the IR spectrum at 1915 cm^{-1} and the ^1H NMR spectrum reveals a pattern of resonances in the 5–7-ppm region characteristic of an η^6-bonded phenyl group. This was confirmed by an X-ray crystal structure of complex **VII** shown in Fig. 4 in partial form. The overall structure is best described as a distorted piano-stool with one of the *o*-phenyl substituents of the thiol η^6-bonded to the molybdenum.

The η^6-bonded group is labile and is readily displaced by CO to give a purple polycarbonyl complex. This has not been isolated as it readily loses CO during work up to reform the π-arene complex. Reaction of the arene complex (**VII**) with bipyridyl gives a purple-pink crystalline complex in less than 50% yield which shows two IR bands at 1855 and 1950 cm^{-1} assignable to ν(CO). Elemental analysis and ^1H NMR are consistent with the empirical formulation $[Mo(DPT)_2(bipy)(CO)_2]$ (**VIII**) (bipy = bipyridyl). An X-ray crystal structure of complex **VIII** revealed a pseudo-octahedral *dicarbonyl* complex with *cis* carbonyl groups. The mechanism of formation of the dicarbonyl product from a monocarbonyl precursor is obscure but a bridged carbonyl intermediate could possibly be involved. The remaining molybdenum complex has not yet been identified, but contains no co-ordinated CO groups, as evidenced by IR.

In contrast, the reaction of complex **VII** with $Ph_2PCH_2CH_2PPh_2$ (dppe) gives the pink five-co-ordinate *monocarbonyl* complex $[Mo(DPT)_2(CO)(dppe)]$ (**IX**). Complex **IX** exists in solution as two isomers which are distinguishable by ^{31}P NMR and solution IR spectroscopy.

EXPERIMENTAL

All reactions were carried out under dinitrogen using dry solvents and conventional Schlenk apparatus or in a Faircrest glove-box and recirculator. IR spectra were determined on Pye Unicam SP2000 and Perkin–Elmer 1330 spectrophotometers, and ^1H and ^{31}P NMR spectra on JEOL FX 90Q and Bruker 80 multinuclear instruments. Microanalyses were made by Mrs A. Olney at the University of Sussex. The following materials were synthesized by literature methods: $[MoBr_2(CO)_2]$,[7] $MoCl_4$,[8] $[MoCl_3(MeCN)_3]$[9] and $[Mo(CO)_2(TIPT)_3]^-$ and $WOCl_4$.[10] The thiols TIPTH and DPTH were prepared by slight modifications of reported methods.

Hexakis(2,4,6 - triisopropylbenzenethiolato)dimolybdenum(III), $[Mo_2(TIPT)_6]$

HTIPT (2.1 cm^3, 9.8 mmol) was added to an excess of sodium pieces in 1,2-dimethoxyethane (20 cm^3) and heated under reflux for 2 h. This solution of NaTIPT was added to $MoCl_4$ (0.38 g, 2.0 mmol) in 1,2-dimethoxyethane (15 cm^3), and the solution stirred for 16 h. It was then filtered through Celite, the solvent removed and the residue titrated with hexane (15 cm^3) to give a dark coloured solid. This was washed with dry methanol until the washings were free of blue $[MoO(TIPT)_4]^-$. The pinkish-brown solid was recrystallized as red prisms by diffusion of acetonitrile into a dichloromethane solution which yielded crystals suitable for the X-ray crystal structure. Found: C, 67.2; H, 8.9%. $Mo_2S_6C_{90}H_{138}$ requires: C, 67.4; H, 6.8%.

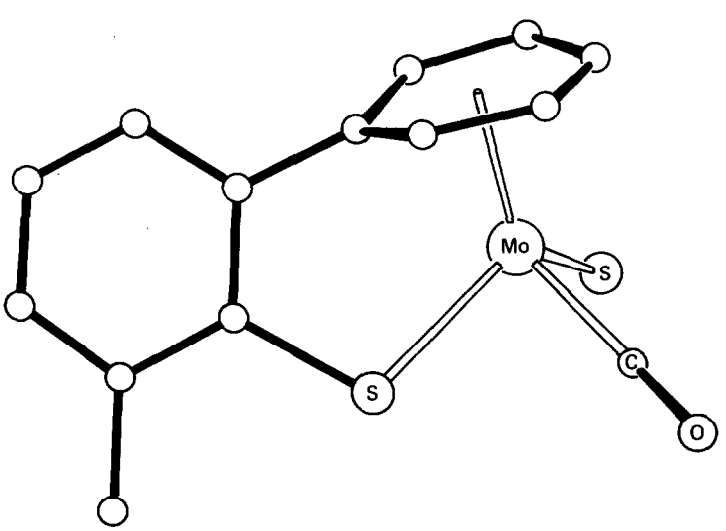

Fig. 4. Partial structure of $[Mo(DPT)_2(CO)]$.

Tetraphenylphosphonium oxotetrakis(2,4,6 - triiso - propylbenzenethiolato)molybdenum(V), $[Ph_4P][MoO(TIPT)_4]$

$[Bu^n_4N][MoOCl_4]$ (1.04 g, 2.1 mmol) was dissolved in acetonitrile (30 cm^3), and HTIPT (2.20 cm^3, 10 mmol) and triethylamine (1.16 cm^3, 8.4 mmol) added. The resulting dark blue solution was evaporated to dryness and the residue extracted with methanol. Addition of $[Ph_4P]Br$ gave the complex (2.8 g). Found: C, 72.1; H, 7.7%. $MoOS_4PC_{84}H_{112}$ requires: C, 72.5; H, 7.7%.

The tungsten analogue $[WO(TIPT)_4]^-$ was prepared similarly using $WOCl_4$.

Acetonitrile(phenyldiazemdo)tris(2,4,6 - triisopropyl - benzenethiolato)molybdenum(II), $[Mo(NNPh)(TIPT)_3(N_2Ph)]$

$[PhN_2][BF_4]$ (0.063 g, 0.33 mmol) in acetonitrile (10 cm^3) was added dropwise to a solution of $[Ph_4P][Mo(TIPT)_3(CO)_2]$ in acetonitrile (25 cm^3). Rapid evolution of CO occurred with formation of a green crystalline precipitate (the complex). Found: C, 66.8; H, 8.0; N, 3.8%. $MoN_3S_3C_{53}H_{77}$ requires: C, 67.2; H, 8.1; N, 4.4%.

[η^6 - 2 - *Phenyl* - 6 - *phenylbenzenethiolato*)(2,6 - *diphenylbenzenethiolato)carbonylmolybdenum(II)*, $[Mo(\eta^6 - Ph)PhC_6H_3S - 2,6)(SC_6H_3Ph_2 - 2,6)(CO)]$

Sodium DPT (2.0 g, 7.1 mmol) dissolved in 1,2-dimethoxyethane (20 cm^3) was added dropwise to a solution of $[MoBr_2(CO)_4]$ (1 g, 3.6 mmol) in 1,2-dimethoxyethane (30 cm^3) and stirred for 12 h. The green-yellow solution was filtered through Celite and the filtrate evaporated to dryness. The resulting green-yellow oil was titrated with warm hexane for 5 min to yield the complex as a green powder. Yield 1.6 g (73.3%). Found: C, 69.0; H, 5.2%. $MoOS_2C_{37}H_{36}$ requires: C, 68.7; H, 4.0%.

Bis(2,6 - diphenylbenzenethiolato)bipyridylbiscarbonylmolybdenum(II), $[Mo(DPT)_2(bipy)(CO)_2]$

Excess bipyridyl (0.1 g) was added to a solution of the π-arenethiolato complex in 1,2-dimethoxyethane giving an immediate dark purple solution. After 3 h the solution was evaporated to dryness and the residue chromatographed on neutral alumina using dichloromethane as solvent. The deep purple band was eluted and collected, evaporated and the residue titrated with diethyl ether to yield the complex as a purple-red powder.

MONONUCLEAR THIOLATE COMPLEXES OF Mo(II) AND Mo(III): X-RAY CRYSTAL STRUCTURE OF *TRANS*-$[Mo(SBu^n)_2(Ph_2PCH_2CH_2PPh_2)_2]$

DAVID C. POVEY

Department of Chemistry, University of Surrey, Guildford GU2 5XH, U.K.

and

RAYMOND L. RICHARDS* and CAROLINE SHORTMAN

AFRC Unit of Nitrogen Fixation, University of Sussex, Brighton BN1 9RQ, U.K.

(*Received* 18 *June* 1985)

Abstract—The complexes *trans*-$[Mo(SR)_2(diphos)_2]$ (A) [R = alkyl, C_6F_5 or C_6H_4X-4, where X = H, F, Cl, CH_3, NH_2 or OCH_3; diphos = $Ph_2PCH_2CH_2PPh_2$ (dppe) or $(C_6H_4CH_3$-$3)_2PCH_2CH_2P(C_6H_4CH_3$-$3)_2$ (dmtpe)] have been prepared by treatment of *trans*-$[Mo(N_2)_2(diphos)_2]$ with RSH. *trans*-$[Mo(SBu^n)_2(dppe)_2]$ crystallizes in the monoclinic space group $C2/c$ with $a = 25.605(5)$ Å, $b = 12.055(2)$ Å, $c = 19.637(4)$ Å, $\beta = 107.08(2)°$ and final $R = 0.041$. The molecule is centrosymmetric with Mo—S = 2.363(1) Å and $Mo—P_{average} = 2.511(1)$ Å. Compounds (A) are diamagnetic and the ^{31}P NMR chemical shifts and $E^{ox}_{1/2}$ values of (A, R = C_6H_4X-4) show a linear dependence upon the Hammett σ function for X. Chemical oxidation ($FeCl_3$ or $CuCl_2$) followed by anion exchange gives the complexes $[Mo(SR)_2(dppe)_2][BPh_4]$, whose ESR spectra show a rhombic signal in frozen solution having hyperfine splitting which is solvent-dependent.

Of relevance to the study of molybdenum enzymes and of nitrogenase in particular is information upon the nature of molybdenum–thiolate bonding, especially in the lower oxidation states of this metal.[1] Whilst pursuing our interest in the reactions of dinitrogen complexes of molybdenum,[2] we obtained a number of thiolate complexes of Mo(II), *trans*-$[Mo(SR)_2(dppe)_2]$, by treatment of *trans*-$[Mo(N_2)_2(dppe)_2]$ with RSH.[3] These compounds have the *trans*-arrangement of groups and thus the tendency of the thiolate ligands to undergo *cis*-elimination, dealkylation or form bridges, which creates difficulties in attempted preparations of mononuclear complexes,[4] are avoided.

The mononuclear series (A) allows us to examine the behaviour of thiolate ligands at a single metal centre by spectroscopic and electrochemical means. In this paper we describe the preparation of an extension of the original series of complexes to include (A, R = C_6H_4X-4), which allows an examination of the electronic effects of the thiolate within the complexes. One-electron oxidation of compound (A) is not only a means of probing such electronic effects, but it has also led to the preparation of a series of Mo(III) complexes, $[Mo(SR)_2(dppe)_2]Y$ (B) (Y = $FeCl_4$ or BPh_4), which show interesting ESR properties.

PREPARATION OF COMPLEXES AND STRUCTURE OF *TRANS*-$[Mo(SBu^n)_2(dppe)_2]$

Complexes (A) were prepared by treating *trans*-$[Mo(N_2)_2(diphos)_2]$ in thf solution with an excess of RSH as described earlier[3] [eqn (1)]:

$$trans\text{-}[Mo(N_2)_2(diphos)_2] + 2RSH \rightleftharpoons trans\text{-}[Mo(SR)_2(diphos)_2] + 2N_2 + H_2 \quad (1)$$

Analytical and other data for these diamagnetic compounds are shown in Table 1. The reaction

proceeds via green intermediates which have been isolated for certain bulky R groups[5] and shown to be the hydrides $[MoH(SR)(dppe)_2]$.

Attempts to carry out the same reaction for *trans*-$[W(N_2)_2(dppe)_2]$ gave only mixtures of products which contained thiolate but could not be purified.

Compound (A, R = Bu^n) forms yellow crystals (thf–Et_2O) in space group $C2/c$ with four molecules in the unit cell. Disordered water molecules are also found which must have arisen adventitiously during the recrystallization process. The molybdenum is surrounded by six ligating atoms in an essentially octahedral array with the equatorial plane defined by the four phosphorus atoms of the chelating diphosphine and the thiolate ligands in the *trans*, *anti*-configuration (Fig. 1). The methylene bridges of the two diphosphine ligands have an eclipsed configuration. Relevant bond distances and angles are in Table 2. The P—phenyl distances range from 1.840(5) to 1.854(4) Å, which is within the usual range[6] of 1.838 ± 0.026 Å for the P—C (sp^3) distance: all the phenyl rings are planar within experimental error.

The butyl groups of the thiolate lie between two $P(C_6H_5)_2$ moieties of the dppe chelate ligands. On the electron-density maps, the rather diffuse electron-density contours in the region of the

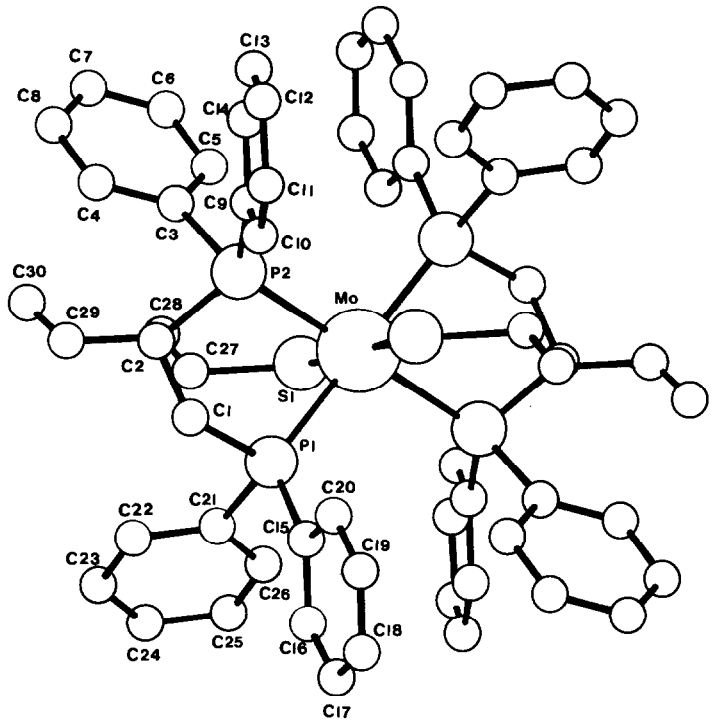

Fig. 1. Molecular structure of *trans*-[Mo(SBu^n)$_2$(dppe)$_2$].

terminal carbon atoms, C(29) and C(30), of the SBu^n moiety suggest some thermal disorder. This is borne out by the high thermal parameters of these two atoms. This might imply a low thermal barrier to isomerization of this group from the observed *anti*-conformation to the *syn*-arrangement. The poor solubility of these compounds has prevented an examination of isomerisation by variable-temperature ^{1}H NMR studies, but a very low barrier to isomerization has been established by NMR for the compound *cis*-[Mo(SBu^t)$_2$(CNBu^t)$_4$].[7]

The structure of (**A**, R = Bu^n) appears to be dominated by the steric constraints imposed by the dppe ligands. As in other [ML$_2$(dppe)$_2$] compounds,[8(a),(b)] a *trans*-octahedral geometry ensures a minimum in steric repulsions, although electronic factors can override this, e.g. in *cis*-[Mo(CO)$_2$(dppe)$_2$].[8(b)]

The phenyl groups in each P(C$_6$H$_5$)$_2$ moiety are nearly mutually perpendicular, and thus direct protons towards the electron-rich centre of a neighbouring phenyl ring, a situation similar to that found in free dppe[9] and in others of its complexes such as *trans*-[MoCl$_2$(dppe)$_2$].[8(a)] The average Mo—P distance, 2.511(1) Å, is in the range normally found for dppe compounds with the P—Mo—P angle, 78.63(4)°, being at the lower end of the expected range.

Since compounds (**A**) are formally 16-electron species it is interesting to consider whether the sulphur atoms are able to release π-electron density to the metal, which might be reflected in the Mo—S distance. It is, however, difficult to decide whether or not the Mo—S distances in *trans*-[Mo(SBu^n)$_2$(dppe)$_2$] are especially short because of the lack of suitable complexes with which to compare them. Table 3 lists mononuclear thiolate compounds of Mo(II) which have been structurally characterized and includes both Mo—S distances and the Mo—S—C angles, which might also be diagnostic of Mo—S π-interaction. These data, although not all pertaining to the same geometry, do not suggest that the Mo—S distance in (**A**, R = Bu^n) is particularly short.

The Mo—S—C angle is at the high end of the observed range, which would be consistent with some interaction of the "lone pair" electrons on sulphur with the metal centre. We note that a π-interaction of chloride lone pair electrons has been suggested to occur in *trans*-[MoCl$_2$(dppe)$_2$] on the basis of the Mo—Cl distance, which is thought to be short by comparison with Mo—Cl distances in a range of other complexes.[8(a)] If this conclusion is correct, one would expect a similar interaction in complexes (**A**). The diamagnetism of the complexes is not unexpected, since their analogue [Mo(SBu^t)$_2$(CNBu^t)$_4$] and other thiolate complexes of Mo(II) are diamagnetic.[10]

SPECTROSCOPIC AND ELECTROCHEMICAL PROPERTIES

The ^{31}P chemical shifts, UV–visible spectroscopic and electrochemical data for compounds (**A**, diphos = dppe) are shown in Table 4. Singlet ^{31}P resonances are expected for these diamagnetic *trans*-complexes and they fall in the range −87.54 to −92.02 ppm [relative to P(OMe)$_3$], to high field of the parent *trans*-[Mo(N$_2$)$_2$(dppe)$_2$], which resonates at −75.3 ppm.

For the series (**A**, R = C$_6$H$_4$X-4), the ^{31}P shift

varies with X and a plot of shift against the Hammett σ_p function for X is linear ($r = 0.98$), whereas there is no linear correlation with σ_p^+. This correlation indicates that the ^{31}P shift is influenced by a through inductive effect rather than one involving conjugation of the arene substituent.

The electronic spectra of compounds (**A**) are very similar with dominant, high-intensity charge-transfer bands below 400 nm and an intense peak at 400–580 nm for all complexes (Table 4). Accurate extinction coefficients could not be obtained due to the low solubilities of the complexes, but they are of the order 2×10^4 dm^3 mol^{-1} cm^{-1}, indicative of charge-transfer transitions. These are possibly thiolate-to-metal ($n \rightarrow \pi^*$) in origin due to the electron deficiency of the 16-electron metal centre as discussed earlier. For (**A**, R = C_6H_4X-4) ν_{max} moves to longer wavelengths as X is more electron-donating. A similar trend has been reported for $[MoO(SR)_4]^-$ (R = C_6H_5, $C_6H_4CH_3$-4 or C_6Cl_5) and was considered to involve an S-ligand-to-metal charge transfer.[11]

For (**A**, R = alkyl) ν_{max} is essentially invariant and is at shorter wavelengths than for (**A**, R = aryl) as might be expected since there are no conjugative effects for R = alkyl.

Electrochemical data for (**A**, R = aryl) are shown in Table 4. All complexes show a primary oxidation in the range −0.24 to +0.3 V, which meets the criteria for a diffusion-controlled, reversible, one-electron oxidation.[12] The values of $E_{1/2}^{ox}$ can be considered to be a relative measure of the HOMO in these complexes[13] and, as expected, the more electron-donating thiolate groups form the most easily oxidized complexes. A plot of $E_{1/2}^{ox}$ against Hammett σ_p is linear ($r = 0.99$) with Hammett σ_p^+ giving a poor correlation ($r = 0.95$). Thus the same type of apparently solely inductive correlation is seen for both $E_{1/2}^{ox}$ and ^{31}P shift measurements. This observation does not necessarily exclude an Mo—S π-interaction, however, since the basis of ^{31}P shift correlations in co-ordination complexes is not established and the HOMO, which relates to the value of $E_{1/2}^{ox}$, may be essentially non-bonding and therefore only be affected by the overall charge on the metal and not directly sense a conjugative effect. With regard to the last point, it has been concluded that in the series $[Cr(CO)_5L]$ (L = PR_3, RNC, halide etc.) the ligands influence the energy of the HOMO (and hence $E_{1/2}^{ox}$) mainly by an inductive process, with L not conjugated to the HOMO, although ligands such as RNC are good π-acceptors.[14]

For (**A**, C_6H_4X-4; X = H, CH_3, NH_2. OCH_3, F or Cl) a secondary oxidation is observed in the region +0.34 to +0.84 V, but it is not so reversible as the primary oxidation at slow scan rates. The ease of the second oxidation depends upon the electron release exerted by the thiolate ligands, since, for (**A**, R = C_6F_5), where the thiolate substituent is strongly electron-withdrawing, the second oxidation is not observed within the range afforded by the thf solvent. For comparison, *trans*-$[MoCl_2(dppe)_2]$ oxidizes at −0.05 V (vs SCE in thf–0.2 M $[NBu_4][BF_4]$) which is identical to the value for *trans*-$[Mo(SPh)_2(dppe)_2]$. However, a second oxidative wave is not observed for the chloride species, which suggests that either the thiolate ligands induce stabilization through electron release or possibly the second oxidation is ligand-based. A third oxidation peak is seen for (**A**, R = $C_6H_4NH_2$-4) at +0.74 V. The oxidized species so produced may be stabilized by the electron release of the thiolate or possibly the oxidation is ligand-based, involving the NH_2 group.

It has been shown that the analogue of compounds (**A**), *cis*-$[Mo(SBu^t)_2(CNBu^t)_4]$,[10] undergoes reversible oxidation at +0.4 V in dimethylformamide. Thus this compound is more difficult to oxidize than compounds (**A**), a reflection of the electron-withdrawing properties of the $CNBu^t$ ligands as compared to dppe and possibly the *cis*-geometry.

All complexes of the above series show reduction waves which are partially reversible at a scan rate of 200 mV s^{-1} [except for (**A**, R = $C_6H_4NH_2$-4)], but which tend to irreversibility at slow scan rates ($\sim$10 mV s^{-1}). It has been shown elsewhere[14] that the product of the electron-transfer process is unstable and undergoes loss of SR^-. The species $[MoSR(dppe)_2]$ thus generated react with available substrates.[15]

PREPARATION AND ESR SPECTRA OF *TRANS*-$[Mo(SR)_2(dppe)_2]Y$ (B, Y = $FeCl_4$ OR BPh_4)

Following the observation by electrochemistry of the formation of a stable product by one-electron oxidation of (**A**), it has proved possible to isolate the cationic Mo(III) complexes *trans*-$[Mo(SR)_2(dppe)_2]Y$ (**B**, Y = $FeCl_4$ or BPh_4) by reaction steps (2):

$$\textit{trans}\text{-}[Mo(SR)_2(dppe)_2] + FeCl_3(\text{excess}) \xrightarrow[20°C]{MeOH} [Mo(SR)_2(dppe)_2][FeCl_4]$$

$$\xrightarrow[Na[BPh_4]]{MeOH} [Mo(SR)_2(dppe)_2][BPh_4] \qquad (2)$$

Analytical data and other data for these complexes are shown in Table 1. Compounds (**B**) are sufficiently soluble in acetonitrile for conductivity measurements, which establishes them as 1 : 1 electrolytes in this solvent (Table 1).

Cyclic voltammetry of compounds (**B**) in thf (Pt electrode–0.2 M $[NBu_4][BF_4]$) showed a reversible one-electron reduction, shown by addition of (**A**) to unambiguously correspond to the (**A**)–(**B**) couple. Thus the product of chemical oxidation is the oxidised species observed by voltammetry. The reversibility of the system showed that no gross structural changes had occurred on bulk chemical oxidation, i.e. the *trans*-octahedral geometry is retained on oxidation.

The ESR spectra of compounds (**B**) in frozen solution (approximately 4×10^{-4} M) established that they are low-spin Mo(III) ($S = \frac{1}{2}$) species, of which there are few well-documented cases. One example[16] is $K_4[Mo(CN)_7] \cdot 2H_2O$, which has $g_{\|} = 2.103$ and $g_{\perp} = 1.973$, but its exact geometry is uncertain. Compounds (**B**) have rather low μ_{eff} values [around 1.3 BM (Table 1)].

In CH_2Cl_2 solution at 100 K the ESR spectrum of $[Mo(SBu^n)_2(dppe)_2][BPh_4]$ shows a rhombic signal with no resolved ^{95}Mo or ^{31}P hyperfine coupling [Table 5 and Fig. 2(b)]. In thf solution, however, hyperfine coupling can be seen on the g_2 tensor [Fig. 2(a)] whose resolution depends upon time. Thus, if the spectrum is run immediately on freezing an unresolved spectrum as in Fig. 2(b) is seen. On leaving the sample at 100 K and recording spectra at various times after the initial freezing time, hyperfine structure slowly resolves. If the sample is then allowed to thaw quickly at room temperature and then refrozen, the same time-dependent effect is seen (Fig. 3). This sequence could be repeated many times without significant loss of signal intensity.

A noticeable difference in g_1 is seen between spectra for R = alkyl as opposed to those for R = aryl. For R = C_6H_4X-4, two g_1 values are seen (g_1 and g_1' in Table 5). The ratio of the heights of g_1 and g_1' is not constant. There appears to be no shift of g values with time, solvent or variation of X in C_6H_4X-4.

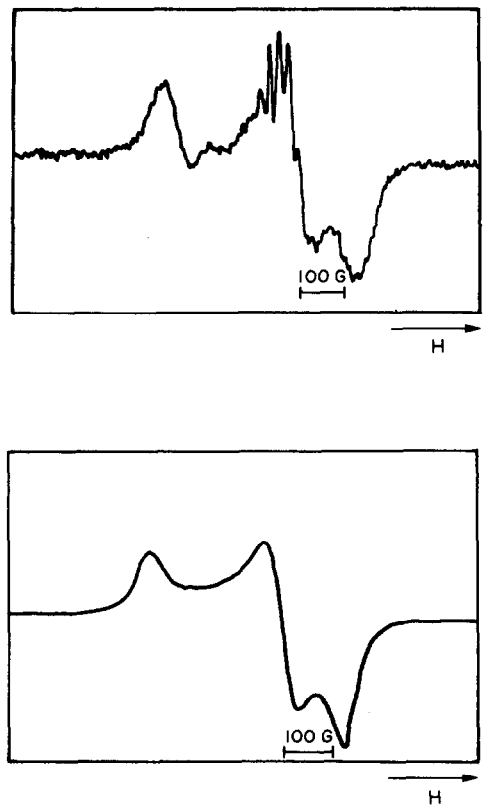

Fig. 2. ESR spectra of *trans*-$[Mo(SBu^n)_2(dppe)_2][BPh_4]$: (a) frozen thf solution, and (b) frozen CH_2Cl_2 solution.

The reason for the solvent dependence of hyperfine coupling is not clear. Possibly there is some distortion of the *trans*-geometry of compounds (**B**) induced by this solvent, but a full explanation requires a much more detailed study.

CONCLUSION

The series of thiolate complexes of Mo(II), *trans*-[$Mo(SR)_2(dppe)_2$](**A**) show electronic properties which depend upon the R group of the thiolate and are transmitted primarily by a σ-inductive mechanism, although π-electron release from S cannot be ruled out. One-electron oxidation of compounds (**A**) gives a series of low-spin complexes of Mo(III) which show an unusual solvent dependence in their ESR spectra.

EXPERIMENTAL

All air-sensitive materials were handled using standard Schlenk techniques under pure dinitrogen. All solvents were rigorously dried and distilled under dry dinitrogen prior to use. All other reagents were analytical grade and used without further purification. The complexes *trans*-[$Mo(N_2)_2(diphos)_2$] (diphos = dppe or dmtpe) were prepared by published methods.[1,2,6]

IR spectra were determined by Pye Unicam SP2000 or Perkin–Elmer SP3-200 instruments. NMR spectra were measured on a JEOL FX90Q spectrometer and electronic spectra on a Perkin–Elmer Lambda 5 UV–visible spectrophotometer. Conductivities were obtained with a Portland Electronics P310 conductivity bridge. Magnetic susceptibilities were determined with a Faraday balance. Cyclic voltammetric measurements were made using an EG and G(PAR) Model 174A polarographic analyser in conjunction with a Bryans 2400 XY recorder in a conventional[14,15] three-electrode cell at Pt-wire electrodes in thf–0.2 mol dm^{-3} $[NBu_4][BF_4]$. ESR spectra were recorded by Dr D. Lowe (AFRC, Unit of Nitrogen Fixation) on a Bruker ER200 instrument with an Oxford ESR 900 cooling system using liquid nitrogen as coolant. Microwave power = 2.06 mW, field modulation intensity = 5 G, microwave frequency = 9.45 GHz, and temperature = 125 K with thf or CH_2Cl_2 solutions of *ca* 4×10^{-4} molarity. Micro-analyses were performed by Mrs A. G. Olney (University of Sussex) and Mr C. Macdonald (AFRC, Unit of Nitrogen Fixation). Mr Macdonald also carried out NMR spectroscopic measurements.

Analytical data for the compounds prepared are shown in Table 1. Typical preparations of these compounds are given below.

Bis[*bis*(*diphenylphosphino*)*ethane*]*bis*(4 - *chloro* - *benzenethiolate*)*molybdenum*(*II*) [$Mo(SC_6H_4Cl\text{-}4)_2(dppe)_2$]

The complex *trans*-[$Mo(N_2)_2(dppe)_2$] (0.3 g, 0.32 mmol) and HSC_6H_4Cl-4 (0.14 g, 0.97 mmol) in thf (20 cm^3) were heated to 60°C for 1.5 h under dinitrogen, to give a red solution. Hexane (40 cm^3) was added and the solution left at −4°C for *ca* 3 h to give a red microcrystalline product. The solid was filtered, washed with hexane (3×10 cm^3) and dried *in vacuo*. The product was analytically pure *trans*-[$Mo(SC_6H_4Cl\text{-}4)_2(dppe)_2$] (0.2 g, 0.17 mmol, 54%).

Bis[*bis*(*diphenylphosphino*)*ethane*]*bis*(4 - *chloro* - *benzenethiolate*)*molybdenum*(*III*) *tetraphenylborate*, [$M(SC_6H_44\text{-}Cl)_2(dppe)_2][BPh_4$]

trans-[$Mo(SC_6H_44\text{-}Cl)_2(dppe)_2$] (0.2 g, 0.2 mmol) was suspended in methanol (20 cm^3) and $FeCl_3$ (0.15 g, 0.9 mmol) was added. The purple product, [$Mo(SC_6H_44\text{-}Cl)_2(dppe)_2][FeCl_4$], precipitated and was filtered, washed with methanol (2×10 cm^3) and

dried *in vacuo*. This complex was converted to its tetraphenylborate analogue by suspension in methanol and stirring with $NaBPh_4$ (0.1 g, 0.3 mmol) for *ca* 0.5 h. The resultant purple solid was filtered, washed with methanol (3×10 cm^3) and dried *in vacuo*. Recrystallization from thf–methanol gave purple, microcrystalline $[Mo(SC_6H_4$-$Cl)_2(dppe)_2][BPh_4]$ (0.15 g, 0.1 mmol, 52%).

Crystallographic studies

Crystal data. $C_{60}H_{66}MoP_4S_2 \cdot H_2O$, M = 1089.07, monoclinic, a = 25.605(5) Å, b = 12.055(2) Å, c = 19.637(4) Å, β = 107.08(2)°, U = 5793.4 Å^3, space group $C2/c$ (No. 15), Z = 4, D_c = 1.25 g cm^{-3}, D_m not measured, $F(000)$ = 2280, μ(Mo-K_α) = 4.3 cm^{-1}.

Data collection. Enraf–Nonius CAD4 diffractometer, Mo-K_α radiation, graphite monochromator θ–2θ scan mode, 1.0° < 25°, 10,522 data measured, reduced to 5100 unique reflections, 3671 observed [$I > 2.5\sigma(I)$]; data corrected for absorption and crystal decay (intensity of reference reflection dropped by 9%).

Structure solution and refinement. The structure was solved by the heavy-atom method and refined by full-matrix least squares to a final R factor of 0.041 {weighting scheme used: $\omega = 1/[\sigma^2(F_o) + 0.05F_o^2]$}. Non-hydrogen atoms were assigned anisotropic thermal parameters. The positions of the hydrogen atoms were calculated from geometrical criteria. They were not refined but were included in the structure factor calculations with fixed-temperature factors of 5.0 Å^2. Difference electron density maps revealed a disordered water molecule. The two positions for the oxygen atom were allocated fixed occupancies of 0.5 and the positional and anisotropic thermal parameters were allowed to refine freely. The C(28)—C(29)—C(30) bond lengths together with the high-temperature factors and diffuse electron density indicate severe thermal motion of C(29) and C(30). Attempts to restrict the terminal portion of the chain to a more reasonable geometry resulted in extremely high thermal parameters for C(29) and C(30) and these were therefore allowed to refine freely. Their refined positions are, therefore, ones which produce a minimum R factor.

(*Received* 14 *June* 1985)

Abstract—The synthesis, crystal structure, spectroscopic and electrochemical properties of tris(quinoxaline-2,3-dithiolato)molybdate(IV), $[Mo(qdt)_3]^{2-}$, are reported. This complex undergoes reversible protonation on the ligand nitrogen atoms and the triply protonated species $[Mo(Hqdt)_3]^{+}$ has also been isolated and characterized as its chloride salt.

Complexes of quinoxaline-2,3-dithiolate (qdt) with many of the later transition metals have been synthesized.[1,2] However, the only report of qdt complexes of molybdenum merely describes the observation of molybdenum(V) species in solution by EPR spectroscopy; the complexes reported were not isolated.[3]

Dithione Dithiol

Fig. 1. Tautomers of H_2qdt.

EXPERIMENTAL

The ligand 1,4-dihydroquinoxaline-2,3-dithione (H_2qdt) was synthesized by the method of Furst and Morrison.[4] This compound is only sparingly soluble in most organic solvents and is less acidic than normal thiols because it exists as the dithione rather than the dithiol form (Fig. 1).

Addition of H_2qdt to a stirred suspension of $[MoO_2(acac)_2]$[5] (3:1) in 98% H_2SO_4 produced an intensely coloured, bottle green solution. Rapid dilution of this solution with H_2O precipitated a green powder which dissolved in methanolic NaOH to give a purple solution. Addition of $[PPh_4]Br$ to this solution precipitated $[PPh_4]_2[Mo(qdt)_3]\cdot H_2O$ as purple, needle-like crystals in *ca* 50% yield. Recrystallization from MeCN by controlled evaporation in air gave large rectangular crystals which proved suitable for structure determination by X-ray crystallography. $[PPh_4]_2[Mo(qdt)_3]\cdot H_2O$ crystallizes in the monoclinic space group $P2_1/c$ with unit cell dimensions $a = 20.15(2)$ Å, $b = 14.014(5)$ Å, $c = 23.53(2)$ Å, and $Z = 4$. The structure of the anion is shown in Fig. 2.

RESULTS AND DISCUSSION

The geometry about molybdenum is almost perfectly trigonal prismatic; the average Mo—S distance is 2.393 Å, the average intra-ligand S—S distance is 3.127 Å, and the average inter-ligand S–S separation is 3.142 Å. The ligands show only very slight deviations from planarity and the molybdenum atom lies within each of the ligand planes; thus the anion has overall D_{3h}-symmetry. This structure was unexpected as it is unlike that of the valence isoelectronic complex tris(maleonitrile-

[c] Nujol mull.

dithiolato)molybdate (IV),[6] $[Mo(mnt)_3]^{2-}$, which has an MoS_6 core with a geometry intermediate between that of an octahedron and a trigonal prism. Also, the structure of $[Mo(qdt)_3]^{2-}$ differs from that of the trigonal prismatic dithiolene complex tris(benzene-1,2-dithiolato)molybdate(VI),[7] $[Mo(bdt)_3]$, in which the molybdadithiolene rings are puckered and the molybdenum atom does not lie within the ligand planes.

The electrochemical behaviour of $[Mo(qdt)_3]^{2-}$ in MeCN has been investigated by cyclic voltammetry at a Pt working electrode. The complex undergoes a reversible one-electron oxidation at −0.19 V, an irreversible one-electron oxidation at +0.56 V and a reversible one-electron reduction at −1.70 V. (Potentials are relative to the ferrocene–ferricenium couple at 0.0 V.) The reversible oxidation occurs at a potential at which oxidation should be readily accomplished by chemical oxidants. Thus, addition of iodine to solutions of $[Mo(qdt)_3]^{2-}$ in CH_2Cl_2 or MeCN produces an olive green colouration and a molybdenum(V) EPR signal (g = 2.002, A = 32 G) consistent with the formation of $[Mo(qdt)_3]^{-}$.

Acidification of a solution of $[Mo(qdt)_3]^{2-}$ in MeCN with HCl causes a colour change from purple to turquoise and the immediate precipitation of $[Mo(Hqdt)_3]Cl$. The absorption maxima of the UV–visible spectra of $[Mo(qdt)_3]^{2-}$ and $[Mo(Hqdt)_3]^{+}$ are listed in Table 1 and selected bands from the IR spectra of $[PPh_4]_2[Mo(qdt)_3]\cdot H_2O$ and $[Mo(Hqdt)_3]\cdot Cl$ are given in Table 2. From the IR data and by analogy with the well-characterized nickel complexes of qdt[8,9] it is considered that each

COMPLEXES OF Mo(VI) WITH LACTIC, THIOLACTIC AND THIOMALIC ACIDS STUDIED BY NMR SPECTROSCOPY

M. MADALENA CALDEIRA and VICTOR M. S. GIL†

Department of Chemistry, University of Coimbra, Coimbra, Portugal

(*Received* 25 *June* 1985)

Abstract—Proton and ^{13}C evidence is presented on the number, stoichiometry, geometry and relative stability of the complexes formed in the systems Mo(VI) + L-lactic acid, Mo(VI) + D,L-thiolactic acid and Mo(VI) + D,L-thiomalic acid in aqueous solutions at pH values in the range 3–8. In particular, 1:2 complexes are always formed and, in addition, complexes of higher metal content are detected in the case of thiolactic and thiomalic acids.

NMR spectroscopy has proved to be a powerful technique in speciation studies of complexation of oxoions with hydroxycarboxylic acids and related ligands.[1–3] This paper deals with the application of ^{1}H and ^{13}C NMR to the title compounds. Whenever possible, comparison with the corresponding W(VI) systems is also made.

RESULTS AND DISCUSSION

Mo(VI) + L-*lactic acid*

When sodium molybdate is added to an aqueous solution of L-lactic acid, a new set of peaks appear in the ^{1}H NMR spectrum corresponding to bound ligand. The spectra of free and bound ligand are of the A_3X type,

$$\underset{A_3}{CH_3}—\underset{X}{CH(OH)}—CO_2H,$$

with relative shifts that are slightly pH-dependent; for pH* = 5.1 they are $\Delta\delta(X) = 0.740$ and $\Delta\delta(A) = 0.072$ ppm, when going from free to bound lactic acid, with $\delta(X) = 4.12$ and $\delta(A) = 1.34$ ppm. Complexation occurs for pH less than about 8 and its extent increases on lowering the pH. For pH $\lesssim$ 3, the NMR signals broaden, presumably due to extensive polymerization.

The big shift undergone by the X signal is a clear indication of the involvement of the hydroxyl group in chelation to Mo(VI) together wth the CO_2H group. This conclusion is supported by the ^{13}C shifts observed on complexation (Table 1).

The presence of only one complex in the pH range 3–8, irrespective of molar ratios and concentrations (up to 1 M in the complexing species) is supported also by the observation of only one peak of bound molybdenum in the ^{95}Mo NMR spectrum of an aqueous solution of sodium molybdate and L-lactic acid (0.5–0.5 M, pH 5.7).‡ This peak has a linewidth of 80 Hz and lies 84 ppm to high frequency relative to the signal of MoO_4^{2-}(aq) as external reference.

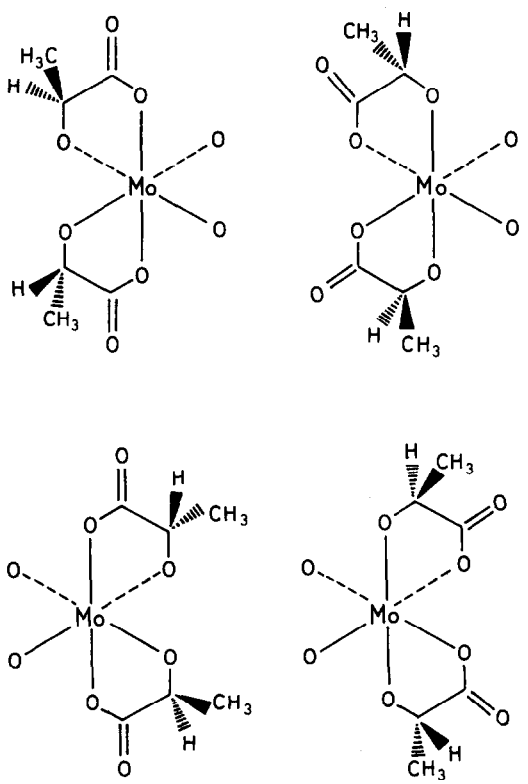
† Author to whom correspondence should be addressed.

‡ This spectrum was kindly obtained by M. T. Nunes (LNETI, Sacavem, Lisbon) on a Brucker WT-80 FY spectrometer.



From the relative intensities of the signals in the proton NMR spectra of mixtures of equimolar solutions of sodium molybdate and L-lactic acid, Job's plots for the bound ligand were obtained which clearly show the composition of the complex to be 1 : 2 (metal : ligand) (see also Refs 4–7). Preliminary studies also lead to a 1 : 2 stoichiometry for W(VI)–lactic acid complexation, but now an additional (weaker) complex is also found.

For a pH* = 4.5 and the metal concentrations used (0.01–0.04 M), the main Mo(VI) species present in solution is the heptamolybdate ion $Mo_7O_{24}^{6-}$.[8] We can thus write the following equation for the formation of the complex (the ligand, represented by H_2Y, is almost completely ionized at this pH[9]):

$$Mo_7O_{24}^{6-} + 14HY^- + 6H^+ \rightleftharpoons 7MoO_2Y_2^{2-} + 10H_2O.$$

This equation assumes that the OH group loses H^+ on complexation. A crude estimate based on the NMR spectral intensities leads to a value of −49 for the pK of formation of the complex.

Preliminary Raman spectroscopic evidence[10] shows that the dioxomolybdenum(VI) group, MoO_2, has a *cis* configuration, as expected. The magnetic equivalence of the two ligand molecules requires a C_2-configuration of the complex. The four possible structures are as follows:

Mo(VI) + D,L-*thiolactic acid*

A similar study was performed with D,L-thiolactic acid,

$$\underset{A_3}{CH_3}—\underset{X}{CH(SH)}—CO_2H,$$

as ligand. Again, the extent of complexation decreases upon increasing pH, there being no evidence of complexation for pH above *ca* 8.5. Due to broadening effects and more extensive oxidation of the acid to the disulphide at low pH, the study was limited to the pH range 3–8.5.

Three complexes were detected. The observed proton shifts upon complexation of the acid are, for pH* = 5.6, as follows: $\mathbf{a}_1$, $\Delta\delta(X) = 0.580$ ppm, $\Delta\delta(A) = 0.050$ ppm; $\mathbf{a}_2$, $\Delta\delta(X) = 0.545$ ppm, $\Delta\delta(A) = 0.062$ ppm; **b**, $\Delta\delta(X) = 0.460$ ppm, $\Delta\delta(A) = 0.040$ ppm.

Three different sets of lines due to bound ligand are also observed in the ^{13}C NMR spectrum. The shifts for various pH values are given in Table 2. It is clear that the sulphydryl group is involved in complexation. The carboxyl groups are also bound to the metal in ligands $\mathbf{a}_1$ and $\mathbf{a}_2$, but the small shift observed in **b** seems to indicate the contrary in this case. In addition, there is a much bigger shift of *C*H(SH) than in $\mathbf{a}_1$ and $\mathbf{a}_2$ and an unexpected (low-frequency) shift of the methyl signal of about −5 ppm.

A Job's plot for $\mathbf{a}_1 + \mathbf{a}_2$ (no separate integration of $\mathbf{a}_1$ and $\mathbf{a}_2$ was possible) shows a clear maximum at 1 : 2, which suggests 1 : 2 complexation, as in the case of the Mo(VI)–lactic acid system. Comparison with this system when active and racemic lactic acid are

used leads us to propose that $\mathbf{a}_1$ and $\mathbf{a}_2$ correspond to DD (or LL) and DL diastereoisomers. As far as complex **b** is concerned, a firm conclusion could not be reached because, when its concentration is a maximum (at 2:1), there is a comparable concentration of the 1:2 complexes present. However, there is little doubt that it has a higher metal content, being either a 1:1 or a 2:1 complex. We recall that the ^{13}C shifts indicate a stronger involvement of the SH group in complex **b** and no participation of CO_2H in complexation. A 2:2 species having two S bridges between the Mo atoms could fit the data, but we can offer no further support for this hypothesis.

Mo(VI)+(D,L)-*thiomalic acid*

The proton NMR spectra are now of the ABX type,

$$\underset{\text{AB}}{\text{CO}_2\text{H—CH}_2\text{—CH(SH)—CO}_2\text{H.}}\quad \underset{\text{X}}{}$$

Depending on pH, four complexes are now detected: one complex (**a**) is only present at pH above *ca* 5, whereas another complex (**c**) only appears at pH less than *ca* 5. Two other (similar) species ($\mathbf{b}_1$ and $\mathbf{b}_2$) occur in the whole pH range covered (2.5–8.5). The chemical shifts of the X proton observed on complexation are 0.5–0.7 ppm, whereas those for the AB part lie between 0.05 and 0.3 ppm.

Table 3 shows the ^{13}C shifts observed for pH* 4.0 and 7.0. The shifts to high frequency of the methyne carbon signal and those of the α-carboxyl group are consistent with the involvement of the S atom and of that carboxyl group in bonding to Mo(IV). A similar shift is also recorded for the β-carboxyl group in the case of complex **c**. It thus seems that in complexes **a**, $\mathbf{b}_1$ and $\mathbf{b}_2$ the ligand acts as bidentate (forming five-membered rings), whereas it has a terdentate function in complex **c**.

Job's curves for complexes **a**, $\mathbf{b}_1+\mathbf{b}_2$ (no separate integration was possible in all solutions) and **c** are shown in Figs 1 and 2. The maximum at the molar ratio 1:2 for $\mathbf{b}_1+\mathbf{b}_2$ suggests a 1:2 composition for these complexes; **a** and **c** are species of higher Mo content, possibly a 1:1 and a 2:1 complex, respectively. These stoichiometries are the same as those that occur in the complexation of Mo(VI) with malic acid.[11–13] They differ from those for W(VI)+thiomalic acid[1] insofar as the complexes in this case are 1:2 at any pH (above 3), only a small concentration of a species involving terdentate ligand being observed.

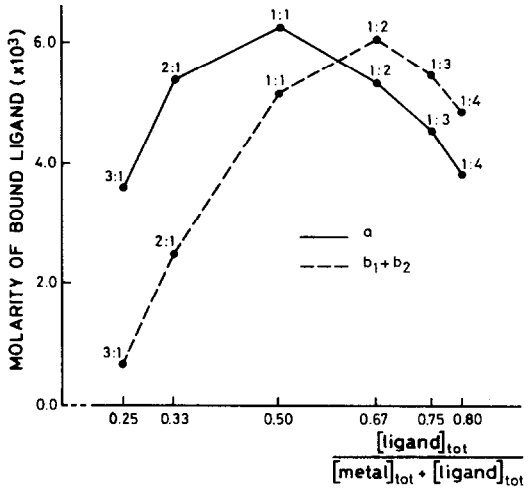

Fig. 1. Job's curves based on proton NMR spectral intensities for the system Mo(VI)+D,L-thiomalic acid. Total concentration of complexing species 0.050 M (D_2O solutions, 1 M in NaCl, pH* 7.0, temperature 275 K).

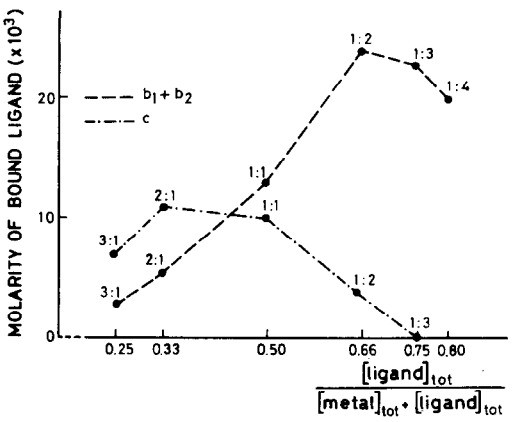
[b] Relative to free ligand.



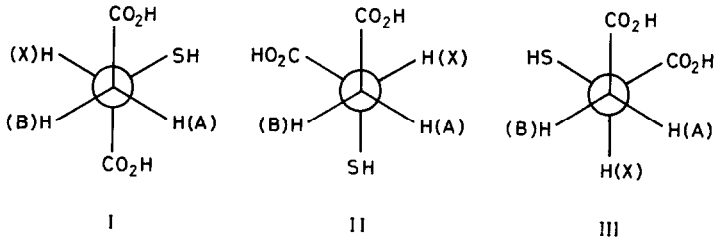


Fig. 2. Same as Fig. 1 with pH* 4.0.

The analysis of the various ABX spectra leads to the coupling constants and chemical shifts given in Table 4. The values of the vicinal coupling constants for **a**, $\mathbf{b_1}$ and $\mathbf{b_2}$ at pH 7.0 show that the rotational isomer **I**, which is the most stable[14,15] for the free acid (in the rotational isomeric state approximation) becomes even more favoured in the complexes; in fact, J_{AX} increases and J_{BX} decreases thus implying an essentially *trans* arrangement of A and X and a *gauche* arrangement of B and X. When lowering the pH, $J_{AX} \simeq J_{BX}$ for thiomalic acid, which means that form **II** is stabilized relative to **I**; however, in complexes **a**, $\mathbf{b_1}$ and $\mathbf{b_2}$ although J_{AX} is smaller than it is at pH 7.0, we have again $J_{AX} > J_{BX}$ in accordance with form **I** being stabilized by complexation. We can thus conclude that in complexes **a**, $\mathbf{b_1}$ and $\mathbf{b_2}$, where the ligand acts as bidentate, the ligand conformation is close to **I** at high pH (the β-carboxyl group is then fully ionized) and undergoes a slight distortion at low pH.

Complex **c**, with $J_{AX} \simeq J_{BX}$ and values typical of a *gauche* arrangement of the vicinal H atoms, has the ligand essentially in conformation **III**. This is the appropriate conformation for a terdentate function of thiomalic acid bonded to a Mo atom, which was independently indicated by the ^{13}C shifts. If complex **c** is a 2:1 species, then it probably is a 4:2 dimer as is the case of a complex of Mo(VI) with L-malic acid characterized by X-ray diffraction.[16] Evidence that it is a polymeric species comes from the fact that dilution of the solutions at pH 4 causes a noticeable decrease in the corresponding relative spectral intensities.

EXPERIMENTAL

D_2O solutions were used throughout. The concentrations of the molybdate solutions were established by weight and the acid solutions were standardized by potentiometry. The pH was

adjusted by addition of solutions of DCl and NaOD; the pH* values quoted are the direct pH-meter readings (room temperature) after standardization with aqueous (H_2O) buffers. Whenever necessary (for the application of Job's method) the ionic strength was kept approximately constant by using NaCl. In order to minimize air oxidation of the mercapto acids, N_2 was run through the solutions during preparation and the NMR tubes were sealed under a nitrogen atmosphere.

The ^1H and ^{13}C spectra were obtained on a Varian XL-200 NMR spectrometer. The latter were recorded using proton-decoupling techniques with suppression of the nuclear Overhauser effect; in this manner, temperature fluctuations of the sample were reduced to *ca* $\pm$ 1°C. Most ^1H NMR spectra were run at low temperature (275 K) as signals are sharper than at room temperature, due to slower exchange processes. Dioxane and DSS were used as internal references, respectively, for ^{13}C and ^1H shifts.

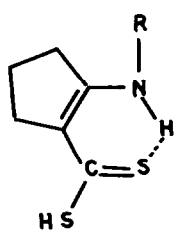
SEVEN- AND EIGHT-COORDINATED COMPLEXES OF Mo(V) AND Mo(IV) WITH 2-AMINO-1-CARBODITHIOATO LIGANDS: SYNTHESIS, SPECTRA AND ELECTROCHEMISTRY

MUKTIMOY CHAUDHURY



Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta 700 032, India

(*Received* 28 *June* 1985)

Abstract—Electrochemical half-wave potentials, charge-transfer absorption, ESR and magnetic properties are reported for a series of seven-coordinated Mo(V) (**1a–d**) and eight-coordinated Mo(IV) (**2a–d**) complexes with 2-alkylaminocyclopent-1-ene-1-dithiocarboxylato ligands (HL). The Mo(IV) compounds constitute the first reported example of a series of complexes with MoS_8 chromophore having a spin-triplet ground state. Electrochemical oxidation of **2c** is quite interesting as it involves a single-step reversible two-electron transfer involving an Mo(IV)–Mo(VI) couple.

A good deal of recent excitement has centered in the area of molybdenum–sulfur coordination chemistry due to some recent interesting results obtained from various chemical and spectroscopic studies[1,2] and Mo-EXAFS data[3–5] which led to a unique delineation for the metal binding sites of different molybdoenzymes. These enzymes are known to catalyse a number of important biological oxo-transfer reactions where valence of molybdenum cycles between Mo(VI) and Mo(IV) states in their reaction with substrates and subsequent reactivation.[6,7] As a part of our systematic approach to study the structure–redox activity relationship of molybdenum compounds with varying degree of sulfur coordination,[8–10] we recently have reported that[9,10] 2-aminocyclopent-1-ene-1-dithiocarboxylic acid (HL^1) binds molybdenum through disulfur chelation, forming a number of monomeric compounds of types $Mo(VI)O_2(L^1)_2$, $Mo(V)O(L^1)_3$ and $Mo(IV)(L^1)_4$, where oxygen atoms are successively removed from the metal's coordination sphere by various oxo-transfer reactions. The electrochemical results clearly indicate that when the same ligand system is used to bind the molybdenum center, oxygen atoms of the oxomolybdenum species have a definite role to play in guiding the nature of the electrode process. The kinetics of electron transfer get increasingly sluggish as more and more oxygen atoms are ligated to the metal center.

In this paper I would like to report the synthesis, spectroscopic and electrochemical studies of some seven- and eight-coordinated monomeric molybdenum complexes in the oxidation states V and IV using 2-alkylaminocyclopent-1-ene-1-dithiocarboxylic acid (HL^2–HL^5) as the $(S,S)^-$ donor metal-binding substrate:

HL

where R = H (HL^1), R = C_2H_5(HL^2), R = C_3H_7 (HL^3), R = C_4H_9 (HL^4) and R = C_6H_{13} (HL^5).

EXPERIMENTAL

Materials

Where available, AR or spectroscopic grade solvents were employed. Standard distillation techniques were employed to further purify and dry

solvents. *n*-Propylamine, *n*-butylamine and *n*-hexylamine were of >99% purity (K. Light) and distilled over KOH prior to use. All other chemicals used were reagent grade unless otherwise noted.

Synthesis

The ligands (HL^1–HL^5) were prepared by known procedure.[11–13] All manipulations involving Mo(V) and Mo(IV) compounds were carried out under an atmosphere of purified dinitrogen. MoO_2L_2[9] and $MoOCl_2L_2$[10] were prepared as described elsewhere.

$MoO(L^2)_2(L^1)$ (**1a**). In a three-necked flask equipped with a reflux condenser and a dropping funnel 0.25 g (0.5 mmol) of $MoO_2(L^2)_2$ was suspended in methanol (30 cm^3). To the stirred suspension was added dropwise a solution of HL^1 (0.18 g, 1.1 mmol) in methanol (20 cm^3) over a period of 45 min. The resulting solution was warmed to 40°C and the stirring was continued for 4h. During this period, the color of the solution changed from red to black through an intermediate red-brown stage. After cooling, the black microcrystalline product was filtered, washed with chloroform–hexane [1 : 2 (v/v)] mixture (4 × 10 cm^3) and finally dried *in vacuo*. The purity of the product was checked by TLC. Yield 65%.

Other $MoO(L)_2(L^1)$ complexes [L = L^3 (**1b**), L^4 (**1c**) and L^5 (**1d**)] were prepared following the same procedure with yields of 50–70%.

$Mo(L^2)_2(L^1)_2$ (**2a**). In a three-necked flask, fitted with a reflux condenser and a dropping funnel, was placed a suspension of finely ground $MoOCl_2(L^2)_2$ (0.28 g, 0.5 mmol) in methanol (30 cm^3). The stirred suspension was warmed to 40°C and a solution of HL^1 (0.35 g, 2.2 mmol) in methanol (40 cm^3) was added dropwise over a period of 45 min. After the end of the addition, the stirring was further continued for 4h. The solution was then cooled to room temperature and the black-violet product formed was filtered, washed with 1 : 3 (v/v) chloroform–hexane mixture (4 × 10 cm^3) and finally dried *in vacuo*. The purity of the product was checked by TLC. Yield 60%.

The complexes (**2b–2d**) with other ligand derivatives (HL^3–HL^5) were synthesized in a similar manner. Yields 55–70%.

All the reported compounds gave satisfactory analytical results.

Physical measurements

Room-temperature EPR spectra for solutions [1 : 10 (v/v) DMF–$CHCl_3$] were recorded at X-band frequency on a Varian E-109 Spectrometer equipped with a 100-kHz field modulation unit. Cyclic voltammetry (CV), differential pulse voltammetry (DPV) and coulometric measurements were made using a PAR model 370-4 electrochemistry systems. A Metrohm E410 hanging mercury drop electrode and a mercury pool electrode were used as the working electrodes for CV and coulometric work, respectively. All measurements were performed for DMF solutions at 298 K. The potentials are referenced to a saturated calomel electrode and are uncorrected for junction potentials. The details of electrochemical and various other physical measurements have been described elsewhere.[9,10]

RESULTS AND DISCUSSION

Using the redox coordinating ability of 2-aminocyclopent-1-ene-1-dithiocarboxylic acid (HL^1),[9,10] various monomeric Mo(V) and Mo(IV) complexes of types $MoO(L)_2(L^1)$ (**1a–1d**) and $Mo(L)_2(L^1)_2$ (**2a–2d**) were prepared from $MoO_2(L)_2$ and $MoOCl_2(L)_2$ (L = L^2–L^5), respectively, by oxo-transfer reactions. Their elemental analyses are in good agreement with the assigned formulations. The compounds are air-stable in the solid state but slowly decompose in solution.

IR spectral features of these compounds are relatively straight forward and almost identical, except in the region 1000–850 cm^{-1}. While for Mo(V) compounds (**1a–1d**) a strong band appears at ~950 cm^{-1} assignable to ν(MO=O) stretching,[14] the absence of similar band in the Mo(IV) compounds suggests complete removal of the oxo group from the metal's coordination sphere. The compounds also show a single sharp carbon–sulfur stretching in the ~830 cm^{-1} region due to ν_{asym}(CSS) with no evidence for splitting indicating a bidentate (*S,S*) mode of chelation by the ligands.[15] The appearance of a low frequency band in the region 350–380 cm^{-1} is attributed to a ν(Mo—S) vibration.[16]

Electronic spectra

An important feature of all these Mo(V) (**1a–1d**) and Mo(IV) (**2a–2d**) compounds is their intense red color in DMF solution, owing to electronic transitions in the region 850–300 nm. Bands occurring below 400 nm are due to internal ligand transitions.[13] Spectral data (Table 1) of $MoO(L)_2(L^1)$ (**1a–1d**) are consistent with the $(4d_{xy})^1$ electronic ground state ($^2B_2$) for Mo(V). Detailed interpretations of these data for similar Mo(V) complexes are given elsewhere.[9,10] Electronic spectra of the Mo(IV) compounds (**2a–2d**) in DMF solution are complex in nature (Table 2), containing

five intense bands in addition to the high-energy π–π^* internal ligand transitions.[13] The spectral features are closely comparable to those reported for many Mo(IV) compounds containing the MoS_8 chromophore.[17–20] Most of these transitions are tentatively assigned to the charge-transfer type (L → M) because of their high extinction (ε) values (2000–3700 M^{-1} cm^{-1}).

Magnetic-moment and ESR data

The room-temperature magnetic-moment and ESR data for the Mo(V) compounds are listed in Table 1. The magnetic-moment values ($\mu_{eff} \sim 1.60$ BM) are quite close to the spin-only value for a d^1-system. Their ESR spectra contain a strong central line due to the 75% Mo isotopes with $I = 0$ and six satellite lines arising from the hyperfine interaction of the unpaired electron with ^{95,97}Mo nuclei of spin $\frac{5}{2}$. The observed $\langle g \rangle$ values are somewhat higher and $\langle A \rangle$ values significantly lower compared to those of other Mo(V) complexes with different donor atom sets,[21] the reason for which may be the polarizable nature of sulfur ligands.[22]

So far as the magnetic behavior is concerned, Mo(IV) compounds are really novel because of their spin-triplet ground state. Their room-temperature susceptibilities lie between 2.35 and 2.77 BM (Table 2). Till now, apart from a few scattered examples,[23,24] most of the reported Mo(IV) complexes with MoS_8 chromophore have been diamagnetic.[17–20] Possible reason(s) for this unusual paramagnetism will be described elsewhere.[11]

Electrochemistry

Electrochemical behavior of $Mo(L)_2(L^1)_2$ compounds in DMF–0.1 M TEAP solution are shown in Fig. 1 and the relevant electrochemical data are summarized in Table 2. Apart from **2c** the electrochemical behavior of the other three compounds are almost identical, each involving two nearly reversible waves [Fig. 1(a)], one due to reduction ($E_{1/2}$ −0.42 V) and the other due to oxidation ($E_{1/2}$ −0.2 V). In each case, the scan was initiated from −0.3 V and the nature of the voltammograms remains practically identical, irrespective of the scan direction. The currents observed by DPV or CV for the two steps are of equal height, indicating an identical number of electrons in each step. Reversibility of both the electron-transfer processes [couples (1) and (2)] and single-electron involvement in the reduction process [couple (1)] are confirmed from CV and coulometric measurements (Table 2).[10] The electron stoichiometry determination for the oxidation step [couple (2)] by potentiostatic coulometry did not yield satisfactory results due to constant coulomb counts. However, on the basis of CV, DPV and coulometric results, the following reactions may be assigned:

$$[Mo(III)(L)_2(L^1)_2]^- \overset{e^-}{\rightleftharpoons} [Mo(IV)(L)_2(L^1)_2]^0, \quad (1)$$

$$[Mo(IV)(L)_2(L^1)_2]^0 \overset{e^-}{\rightleftharpoons} [Mo(V)(L)_2(L^1)_2]^+. \quad (2)$$

For **2c** the reduction behavior is essentially identical to other Mo(IV) compounds (Fig. 1), involving a reversible Mo(IV)–Mo(III) single-

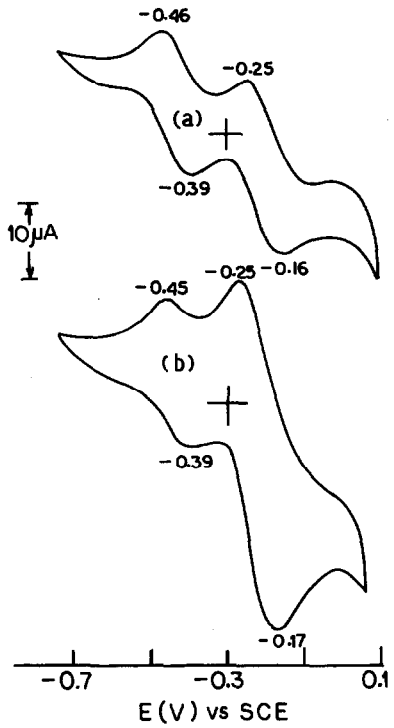

Fig. 1. Cyclic voltammograms (at a hanging mercury drop electrode, $V = 50$ mV s^{-1}) of $Mo(L^2)_2(L^1)_2$ (a) and $Mo(L^4)_2(L^1)_2$ (b). The voltammetric features of **2b** and **d** are almost identical to (a).

electron transfer ($E_{1/2}$ −0.42 V). However, its oxidation behavior is quite unique as it involves a reversible one-step two-electron transfer comprising Mo(IV)–Mo(VI) states {couple (3) [Fig. 1(b)]}. Like other Mo(IV) compounds, a meaningful coulometric result was not obtained for this electron-transfer process. Nevertheless, the CV and DPV current heights for this wave are twice that of the reduction process, indicating that two electrons are transferred in couple (3):

$$[Mo(IV)(L^4)_2(L^1)_2]^0 \overset{2e^-}{\rightleftharpoons} [Mo(VI)(L^4)_2(L^1)_2]^{2+}. \quad (3)$$

Similar redox behavior involving a simultaneous two-electron transfer is well known for many biochemical reactions catalysed by molybdo-enzymes.[6,7]

SYNTHESIS OF A NEW CLASS OF Mo–Fe–S CLUSTERS CONTAINING THE MoS_2Fe_2 UNIT

K. S. BOSE,* P. E. LAMBERTY,† J. E. KOVACS,† E. SINN* and B. A. AVERILL*‡

(*Received* 3 *July* 1985)

Abstract—A new synthetic route to Mo–Fe–S clusters related to nitrogenase has been developed, in which the bridging sulfides originate with the iron reagent (rather than with MoS_4^{2-}, as is the case for other known Mo–Fe–S clusters). This route produces clusters containing the novel $Mo(\mu_3\text{-}S)_2Fe_2$ structural unit, which is only the third known type of such a cluster (in addition to those containing the "linear" MoS_2Fe and "cubane" $MoFe_3S_4$ units). Reaction of the $[Fe_2S_2(CO)_6]^{2-}$ dianion with $MoCl_5$ has been found to produce at least four new clusters, including two Fe–S carbonyl clusters and two novel Mo–Fe–S clusters, including **I**. Complex **I**, isolated as the Ph_4As^+ salt, has been identified as the $[MoOFe_5S_6(CO)_{12}]^{2-}$ dianion by a single-crystal structure determination: space group $P2_1/n$, monoclinic, $Z = 4$; $a = 14.127(6)$ Å, $b = 17.818(5)$ Å; $c = 26.802(18)$ Å, $\beta = 94.51(2)°$, $V = 6726$ Å^3; current $R = 8.9\%$, $R_w = 9.4\%$; 2768 unique data with $F^2 > 3\sigma(F^2)$. Complex **I** can also be prepared in higher yield from the reaction of $MoOCl_3 \cdot 2THF$ with excess $[Fe_2S_2(CO)_6]^{2-}$ or $[Fe_4S_4(CO)_{12}]^{2-}$.

Recent efforts in a number of laboratories have been directed at the preparation of synthetic models[1] for the Fe–Mo cofactor (FeMo-co) of nitrogenase.[2] To data, two relevant types of synthetic Mo–Fe–S clusters have been prepared, containing the "cubane" $MoFe_3S_4$[1,3] and "linear" MoS_2Fe[1,4] structural units. The former include both double-[5–7] and single-cubane[8] clusters of stoichiometry $[Mo_2Fe_6S_8(\mu_2\text{-}L)_3(L')_6]^{3-,5-}$ (L = RS^- or RO^-, L′ = RS^- or ArO^-) and $[MoFe_3S_4(cat)(SR)_3L]^{2-,3-}$ (cat = substituted catecholate, L = any of a variety of ligands). Typical examples of the latter include the $[S_2MoS_2FeL_2]^{2-}$ [L = ArS^-,[9(a)–(c)] ArO^-[9(d),(e)] or OAc^-[9(f)]], $[S_2MoS_2FeS_2Fe(SAr)_2]^{3-}$[9(e),10] and $[Cl_2FeS_2MoS_2FeCl_2]^{2-}$[11] ions. Of these, the single cubanes display the most convincing similarity to FeMo-co in electronic properties[2(b),8(b)] and Mo EXAFS spectra,[2(b),5(c),12,13] while certain linear complexes[9(e)] provide the closest approximation to the Fe EXAFS of FeMo-co.[12,14] No synthetic complex yet prepared, however, bears a convincing similarity to FeMo-co in stoichiometry, collective electronic properties, and structural features.

All of the Mo–Fe–S clusters mentioned above are obtained by the reaction of MoS_4^{2-}[15] with various iron salts. Although MoS_4^{2-} is obtained upon acid degradation of the MoFe protein of nitrogenase,[16] its role in the biosynthesis of FeMo-co remains to be demonstrated. Accordingly, we have focussed on the development of new synthetic routes to Mo–Fe–S clusters, utilizing reagents in which the sulfide originates with the Fe species in order to increase the likelihood of obtaining new structural types, rather than variants on familiar systems. We report herein the synthesis and structure of a new type of Mo–Fe–S cluster containing the $Mo(\mu_3\text{-}S)_2Fe_2$ structural unit; it represents the first example of an Mo–Fe–S cluster related to nitrogenase whose synthesis does not require MoS_4^{2-}. While this manuscript was in preparation, a report of the synthesis and structure of a related complex, the $[MoFe_3S_6(CO)_6]^{2-}$ ion, appeared.[17]

EXPERIMENTAL

All operations were carried out under an atmosphere of purified dry dinitrogen.

‡ Author to whom correspondence should be addressed.

$MoOCl_3 \cdot 2THF$ was prepared as described previously.[18]

Preparation of $(Ph_4As)_2[MoOFe_5S_6(CO)_{12}]$, $(Ph_4As)_2I$

Method A. A solution of $Li_2[Fe_2S_2(CO)_6]$[19] was prepared by the addition of 1 M $LiEt_3BH$ (6.0 mmol) in THF to a solution of $Fe_2S_2(CO)_6$[20] (2.91 mmol) in 75 cm^3 THF at −78°C. To the deep green solution at −78°C was slowly added a solution of $MoOCl_3 \cdot 2THF$[18] (0.96 mmol) in 7 cm^3 MeCN. The solution was allowed to warm to room temperature and stirred for 1 h, after which the solvent was removed *in vacuo* at room temperature. The solid residue was dissolved in 10 cm^3 MeCN, $Ph_4As^+Cl^-$ (2.8 mmol) in 50 cm^3 MeOH was added, and the solution was maintained at −20°C overnight. The black microcrystalline solid was separated by filtration, washed with MeOH, and recrystallized by dissolving in 10 cm^3 MeCN or 7 cm^3 DMF, followed by addition of *ca* 50 cm^3 MeOH and cooling to −20°C overnight to afford black crystals of $(Ph_4As)_2[MoOFe_5S_6(CO)_{12}]$ (45% based on Mo). The compound is air-stable in the solid state, but was stored under N_2. Calc. for $C_{60}H_{40}As_2Fe_5MoO_{13}S_6$: C, 42.8; H, 2.4; As, 8.9; Fe, 16.6; Mo, 5.7; S, 11.4%. Found: C, 42.3; H, 2.4; As, 10.0; Fe, 16.6; Mo, 5.7; S, 11.3%.

Method B. A solution of $Li_2[Fe_4S_4(CO)_{12}]$[21] was prepared by addition of 1 M $LiEt_3BH$ (3.0 mmol) in THF to a solution of $Fe_2S_2(CO)_6$[20] (2.91 mmol) in 75 cm^3 THF at −78°C over 10 min, followed by maintaining the deep green solution at 0°C for 1 h, addition of 7 cm^3 DMF, and reduction of the volume *in vacuo* at room temperature to *ca* 20 cm^3. To this solution at room temperature was slowly added a solution of $MoOCl_3 \cdot 2THF$[18] (0.72 mmol) in 10 cm^3 MeCN. After stirring for 1 h, the volume was reduced *in vacuo* at room temperature to *ca* 7 cm^3, $Ph_4As^+Cl^-$ (2.8 mmol) in 50 cm^3 MeOH was added, and the solution was cooled to −20°C overnight. The black crystalline product was isolated and recrystallized as in method A (55% based on Mo). The products obtained via the two methods were identical in all respects. Found: C, 42.6; H, 2.5; Fe, 16.8%.

X-ray structure determination

Crystals of $(Ph_4As)_2I$ were obtained by diffusion of *i*-PrOH into an MeCN–*i*-PrOH solution of $(Ph_4As)_2I$ at room temperature under reduced pressure. Several crystals were mounted and sealed in glass capillaries, and the one giving the best diffraction pattern was used for the data collection.

Table 1. Crystal data and data collection procedures for $(Ph_4As)_2[MoOFe_5S_6(CO)_{12}]$

Formula	$C_{60}H_{40}As_2Fe_5MoO_{13}S_6$
Formula weight (amu)	1686
Crystal form	Monoclinic
Space group	$P2_1/n$
a (Å)	14.127(6)
b (Å)	17.818(5)
c (Å)	26.802(18)
β (°)	94.51(2)
V (Å^3)	6726
Z	4
Temperature (°C)	22
ρ_c (g cm^{-3})	1.67
μ (cm^{-1})	25.2
Radiation	Graphite-monochromated Mo-K_α $\lambda(\alpha_1) = 0.7093$ Å
Scan range	$1.50 < 2\theta < 49.00°$
Scan type	θ–2θ
Unique data	6097
Unique data with $F^2 > 3\sigma(F^2)$	2768

Crystal data and data collection procedures are summarized in Table 1.

Cell dimensions and space group data were obtained by standard methods on an Enraf–Nonius CAD-4 diffractometer. The θ–2θ scan technique[22(a)] was used to record the intensities of all nonequivalent reflections for which $1.5 < 2\theta < 49°$. Scan widths were calculated as $(A + B \tan \theta)°$, where A is estimated from the mosaicity of the crystal and B allows for the increase in peak width due to $K\alpha_1$–$K\alpha_2$ splitting. The values of A and B used were 0.8 and 0.35, respectively.

The intensities of three standard reflections showed a gradual decrease with X-ray exposure to about 63% of the original values. The data set was scaled to correct for this. The raw intensity data were corrected for Lorentz polarization and absorption. Of the 6097 independent reflections, there were 2768 with $F^2 > 3\sigma(F^2)$, where $\sigma(F^2)$ was estimated from counting statistics.[22(b)] These data were used in the final refinement of the structural parameters.

A three-dimension Patterson synthesis was used to determine the heavy-atom positions, which phased the data sufficiently well to permit location of the remaining nonhydrogen atoms from Fourier syntheses. Full-matrix least-squares refinement was carried out as previously described.[22(a)] Anisotropic temperature factors were introduced for the nonhydrogen atoms. Further Fourier difference functions permitted location of the non-methyl hydrogen atoms, which were included in the

refinement for four cycles of least squares and then held fixed.

The model converged with $R = 8.9\%$ and $R_w = 9.4\%$. A final Fourier difference map was featureless. A listing of atomic coordinates and calculated thermal parameters is available as supplementary material.* The principal programs used are as previously described.[22(a)]

RESULTS AND DISCUSSION

Synthesis

Previous studies in our laboratory[23] have demonstrated that the reaction of the $[Fe_2S_2(CO)_6]^{2-}$ dianion with Mo halides is unexpectedly complex. Under conditions similar to those described in method A, at least four new cluster products can be isolated from the reaction of $MoCl_5$ with excess $[Fe_2S_2(CO)_6]^{2-}$, as shown in Scheme 1; similar results are obtained with $MoCl_4$.[23]

The structures of suitable salts of anions **I** and **II**[24] have been solved by single-crystal X-ray structure determinations, while structure determinations on salts of **III** and **IV** are in progress.

Because of the complexity of this reaction mixture, which makes isolation of pure compounds in reasonable yields difficult, alternative syntheses of all four clusters have now been developed.[23–25] The presence of the Mo=O group in **I** suggests that it arises via oxygen abstraction[26] from the THF cosolvent in Scheme 1; consequently, syntheses employing reagents containing the MoO unit were explored. Of the systems examined, the compound $MoOCl_3 \cdot 2THF$[18] is the most promising, due to its solubility in polar organic solvents. Treatment of $MoOCl_3 \cdot 2THF$ in MeCN with a THF solution of 3 equivalents of $[Fe_2S_2(CO)_6]^{2-}$[19] (method A) or 2 equivalents of $[Fe_4S_4(CO)_{12}]^{2-}$[21] (method B) affords salts of anion **I** in 45–55% yield based on Mo. Method A requires generation of the $[Fe_2S_2(CO)_6]^{2-}$ anion *in situ*, while method B utilizes the $[Fe_4S_4(CO)_{12}]^{2-}$ ion, which can be stored as the solid Ph_4As^+ salt for prolonged periods. The latter may therefore be slightly more convenient.

The structure of anion **I** (see below) contains an FeS_2 unit in addition to discrete $[Fe_2S_2(CO)_6]^{2-}$ units. The former must arise from a rearrangement of the $Fe_2S_2(CO)_6$ core. Related rearrangements are required to account for the formation of **II** and **III** as well. Further discussion of the complex solution chemistry leading to the formation of **I–III** is deferred until studies on the latter two compounds are completed.[24,25] Preliminary evidence from elemental analysis and spectroscopic results suggests that complex **IV** contains the $[Mo_2O_4]^{2+}$ core ligated by $[Fe_2S_2(CO)_6]^{2-}$ units similar to that in **I**.

Structure of **I**

The best crystal of $(Ph_4As)_2$**I** available did not diffract well enough to permit a high-resolution structure of the material. One of the two Ph_4As^+ cations was found to be positionally disordered, and the CO groups are more poorly resolved than is usual for such compounds. The latter may be due to disorder or to partial loss of CO during data collection, reducing the coordinated carbonyls to $<100\%$ occupancy. Some of the phenyl group carbon atoms of the disordered Ph_4As^+ were not included in the calculations at the current stage of refinement. The crystallographic results thus suffice for elucidation of the structure of **I**, but bond distances and angles are subject to standard deviations somewhat larger than desirable.

The structure of the $MoOFe_5S_6$ core of **I** is shown in Fig. 1; carbonyl ligands on Fe1, Fe2, Fe4 and Fe5 have been omitted for clarity. Three key structural features are immediately apparent: (i) the novel $Mo(\mu_3\text{-}S)_2Fe_2$ unit (Fig. 1, right-hand side); (ii) the $Fe_3(\mu_3\text{-}S)_2$ unit attached to Mo via two μ_2-sulfides (Fig. 1, left-hand side); and (iii) the Mo=O unit. The overall coordination about Mo is a distorted square

* Atomic positional and thermal parameters, and lists of F_c/F_o, have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

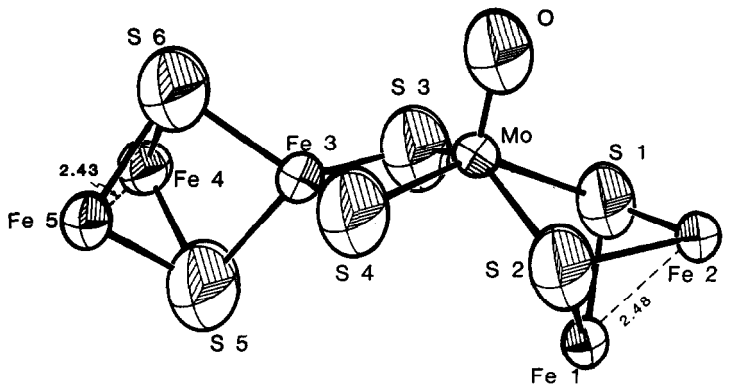

Fig. 1. An ORTEP drawing of the $MoOFe_5S_6$ core of **I**, showing the atomic labelling scheme and selected distances. The carbonyl groups have been omitted for clarity.

pyramidal $MoOS_4$ array. Selected bond distances and angles are given in Table 2.

The $Mo(\mu_3\text{-}S)_2Fe_2$ portion of **I** represents the first example of an Mo–Fe–S cluster related to nitrogenase that does not contain either the $MoFe_3(\mu_3\text{-}S)_4$ (cubane) or $Mo(\mu_2\text{-}S)_2Fe$ (linear) fragments. Within this unit, the Fe—Fe, Fe—S, and S···S distances are comparable to those observed for $Fe_2(\mu\text{-}SEt)_2(CO)_6$,[27] $(\mu\text{-}RS)(\mu\text{-}RHgS)Fe_2(CO)_6$[28] and $[Fe_4S_4(CO)_{12}]^{2-}$.[21] The acute SMoS angle (70.8°) is significantly smaller than that observed in $Ge[S_2Fe_2(CO)_6]_2$[29] (86.4°), the only other structurally characterized $Fe_2S_2(CO)_6$ chelate. It is also substantially smaller than that observed within the $Fe_3S_2(CO)_6$ portions of **I** and $[MoFe_3S_6(CO)_6]^{2-}$ (**V**)[17] (84.2 and 85.6°, respectively), suggesting that coordination to Mo results in a preference for an unusually small bite angle. This indicates that the $[Fe_2S_2(CO)_6]^{2-}$ and dithiocarbamate ($R_2NCS_2^-$) ligands have similar spatial constraints and may result in similar chemistry at the Mo. Attempts to prepare analogs to, for example, $Mo(CO)_2(R_2dtc)_2$,[30(a)] and to explore related ligand binding reactions[30(b)] are underway. The Mo···Fe1,2 distances are >3.3 Å, consistent with the absence of significant metal–metal interactions.

The $Fe_3(\mu_3\text{-}S)_2$ unit in **I** is very similar to that recently reported for **V**.[17] The triply bridging sulfides in **I** are asymmetrically located, with the bonds to Fe3 being slightly (*ca* 0.04 Å) longer than those to Fe4,5. A comparison of the bond distances between the unique iron and the bridging sulfides to Mo in **I** and **V** reveals that those in **I** are ~0.04 Å shorter than those in **V**, consistent with a higher formal valence for the unique Fe in **I** than in **V** (see below). The Mo—Fe3 distance is only 2.72 Å, similar to that found in other MoS_2Fe units,[1,4] and is within the range where direct metal–metal interactions must be considered.

Table 2. Selected bond distances (Å) and angles (°) for $(Ph_4As)_2[MoOFe_5S_6(CO)_{12}]$

Distance

		S6—Fe5—S5	85.1(5)
		S6—Fe4—S5	83.4(5)

The Mo=O distance of 1.63 Å is one of the shortest reported for any monooxomolybdenum species[31] {cf. $[MoO(SPh)_4]^-$, 1.70 Å;[32] and $MoO(n\text{-}Pr_2dtc)_2$, 1.695 Å[33]}. The distorted square pyramidal coordination and short Mo=O bond are perhaps most consistent with a Mo(V) formulation, but are also consistent with Mo(IV).[31]

Physical and spectroscopic results

Solutions of **I** in polar organic solvents are brown, due to several poorly-resolved absorptions in the UV and visible regions: λ_{max} [ε (M^{-1} cm^{-1})] 330 (1.27×10^4), 459 (8.52×10^3), 544 (sh), 624 (sh) (MeCN). At this time, assignment to specific S → M charge-transfer or *d–d* transitions is not possible.

The IR spectrum of **I** in MeCN solution shows three very strong bands, at 2040, 2005 and 1967 cm^{-1}. These are diagnostic of the presence of the $Fe_2S_2(CO)_6$ unit.[19,21,29] IR spectra of the solid Ph_4As^+ salt of **I** in Nujol mulls show a strong absorption at 924 cm^{-1}. This is attributable to the Mo=O group, and is in the same range as those reported for $[MoO(SPh)_4]^-$ (931–940 cm^{-1})[18] or $MoO(Et_2dtc)_2$ (962 cm^{-1}).[34] It is, however, not consistent with the unusually short Mo=O distance, which would be expected to produce an IR stretch at higher energy.[31]

Room-temperature magnetic susceptibility measurements give a value of $\mu_{eff}^{corr} = 5.20$ BM for solid $(Ph_4As)_2$**I**. This indicates the presence of four unpaired electrons ($S = 2$) and is consistent with either of two possible formulations for the MoS_2Fe unit (assuming that all Fe atoms coordinated to three carbonyl ligands are formally Fe(I)): (a) Mo(VI) (d^0) plus high-spin Fe(II) (d^6), or (b) Mo(V) (d^1) antiferromagnetically coupled to high-spin Fe(III) (d^5).

The question of oxidation states is best addressed by ^{57}Fe Mössbauer spectra, which have been measured for solid $(Ph_4As)_2$**I** at 4.2 K in zero applied field. The spectra consist of two overlapping quadrupole doublets in a 4:1 area ratio: doublet 1 (more intense), $\delta = 0.07$ mm s^{-1}, $\Delta E_Q = 0.70$ mm s^{-1}; doublet 2, $\delta = 0.35$ mm s^{-1}, $\Delta E_Q = 1.6$ mm s^{-1}. Doublet 1 has parameters typical of $Fe_2S_2(CO)_6$ and related compounds.[23,24,35] Doublet 2, on the other hand, has parameters that are more typical of high-spin Fe^{3+} than high-spin Fe^{2+}. For example, the isomer shift* of 0.35 mm s^{-1} is very close to that of oxidized *Clostridium pasteurianum* rubredoxin (0.32 mm s^{-1})[36] and $[Fe_2S_2(S_2\text{-}o\text{-}xyl)_2]^{2-}$ (0.29 mm s^{-1}).[37] In particular, the parameters differ significantly from those observed for

$$[S_2MoS_2Fe(SPh)_2]^{2-}\ ^{9(b),(c)}$$

and

$$[S_2MoS_2FeCl_2]^{2-},^{9(b)}$$

for which a predominantly ferrous description has been suggested, and for the corresponding unique Fe site in **V**.[17]

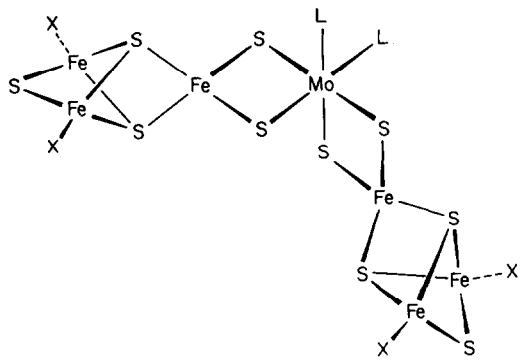

Fig. 2. A possible structure for the FeMo-cofactor of nitrogenase, based on the chemistry described in this paper.

Conclusions

Based on the available data, complex **I** is best formulated as containing a strongly antiferromagnetically coupled Fe(II)(μ-S)$_2$Mo(V)=O core, each metal ion of which is further coordinated by an $[Fe_2S_2(CO)_6]^{2-}$ unit. The resulting complex provides the first structurally characterized example of the novel Mo(μ_3-S)$_2$Fe$_2$ unit, as well as providing an example of an Fe$_3$(μ_3-S)$_2$ unit attached to Mo via bridging sulfides. It also appears to be the most complex oxomolybdenum–Fe–S cluster reported. The stability and ease of formation of the Mo(μ-S)$_2$Fe$_3$(μ_3-S)$_2$ unit, two examples of which, prepared via different synthetic routes, now exist, suggest that it might well be a potential structural fragment in the FeMo-co of nitrogenase; one possible structure for FeMo-co based on this chemistry is shown in Fig. 2. Synthetic efforts aimed at preparing complexes related to this model are in progress.

*The chemical shift data in this work are reported vs metallic Fe at room temperature. The data in Ref. 37 have been corrected by +0.12 mm s^{-1} to correct for the 4.2-K source temperature used in that work.

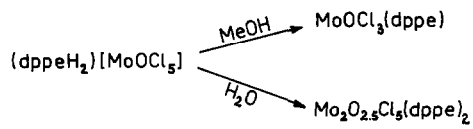
(*Received* 11 *June* 1985)

Abstract—Synthesis, properties and application of chloromolybdate anion salts with $[HP(Ph)_2(CH_2)_2P(Ph)_2H]^{2+}$ are described.

Many phosphine complexes are active and specific homogeneous catalysts.[1] Our recent positive results in the application of Mo complexes with bis(diphenylphosphine)ethane (dppe) as homogeneous catalysts of olefin epoxidations with organic hydroperoxides[2] encouraged us to discover new Mo complexes with dppe and to develop a new, simple and effective synthesis route. We present here our new synthesis of Mo complexes with dppe via the phosphonium compound. This method proved to be advantageous. First, synthesis proceeds in an acidic-water medium. Second, the large phosphonium cation, $dppeH_2^{2+}$, precipitates and stabilizes many Mo anions in various oxidation states. Third, phosphonium compounds of $dppeH_2^{2+}$ could easily be converted into phosphine complexes.

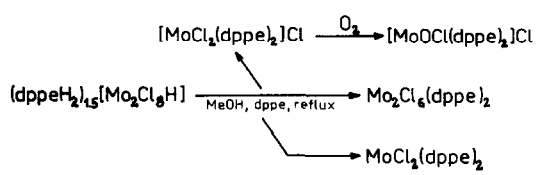


EXPERIMENTAL

A Mo(V) phosphonium salt was obtained by reaction of $[MoOCl_5]^{2-}$ (prepared according to Palmer[3]) with dppe solution in concentrated HCl. The salt, $(dppeH_2)[MoOCl_5]$ (**I**), was isolated as a light-green amorphous powder, stable in dry air, but moisture sensitive. Prolonged storage of this compound (as well as of the others described below) in air, especially under moisture, causes its conversion to the complex with phosphine oxide, in this case to $MoOCl_3(dppeO_2)$.

* Author to whom correspondence should be addressed.

RESULTS AND DISCUSSION



I is paramagnetic (1.74 BM) and insoluble in most solvents. **I** could easily be converted into phosphine complexes[4] (Scheme 1):

Scheme 1.

The quantitatively prepared $MoOCl_3(dppe)$ is the brown isomer of the compound synthesized earlier by another method.[5]

Mo(III) phosphonium salts were obtained by adding dppe solution in concentrated HCl to freshly prepared solutions of $[Mo_2Cl_8H]^{3-}$[6] and $[Mo_2Cl_9]^{3-}$.[7] The salts obtained, $(dppeH_2)_{1.5}[Mo_2Cl_8H]$ (**II**) and $(dppeH_2)_{1.5}[Mo_2Cl_9]$ (**III**), are diamagnetic, insoluble in most solvents, and quite stable in dry air. **II** proved to be a convenient precursor for the synthesis of some Mo phosphine complexes with dppe[8] (Scheme 2):

Scheme 2.

Table 1. Analytical data (wt %)

Compound	Mo		C		Cl	
	Found	Calc.	Found	Calc.	Found	Calc.
I	13.5	13.92	44.7	45.25	25.0	25.74
II	17.7	17.82	43.0	43.47	26.2	26.34
III	17.0	17.27	42.1	42.12	28.4	28.72
IV	9.7	9.43	46.8	46.03	21.3	20.72
V	14.1	14.65	48.0	47.65	21.8	21.66
VI	14.8	15.04	49.1	48.93	21.8	22.24

The above procedure does not yield the analogous phosphonium salt with the $[MoCl_6]^{3-}$ anion. However, we have synthesized crystalline $(dppeH_2)_{1.5}[MoCl_6]\cdot 6H_2O$ (IV) and its crystallographic structure was determined.[9] This structure confirmed the postulated formula for the cation, $[HP(Ph)_2(CH_2)_2P(Ph)_2H]^{2+}$.

Reaction between green Mo(III) solution (prepared according to Palmer[3]) and dppe solution in 8 N HCl produced a sky-blue precipitate of the phosphonium salt $(dppeH_2)_2[Mo_2(OH)_2Cl_8]$ (V), which was oxygen- and moisture-sensitive. This compound, unlike previously described dimeric Mo(III) di-μ-hydroxo complexes[10] is paramagnetic (1.8 BM per Mo atom, practically temperature-independent). This suggests that the structure of the $Mo(OH)_2Mo$ fragment in this complex is not planar. The possibility of such a structure was confirmed by Cramer *et al.*[11]

The freshly precipitated V solvolysed with methanol and ethanol is converted to the pink phosphine complex initially formulated as $Mo_2(OH)_2(dppe)_2Cl_4$.

A Mo(II) phosphonium complex, $(dppeH_2)[Mo_2Cl_8]$ (VI), also air- and moisture-sensitive, was obtained by a similar procedure. During its synthesis in 7–8 N HCl solution, the formation of a green complex, α-$Mo_2Cl_4(dppe)_2$, identical to a compound obtained earlier[12] was observed. This is the first case of the direct synthesis of a phosphine complex from the acidic-water solutions observed by us. Analytical data for the Mo phosphonium complexes are listed in Table 1.

Electronic spectra of isolated phosphonium salts are similar to Mo complexes of similar structure (Table 2).

The IR spectra of these compounds exhibit, besides absorption characteristic of the dppe ligand, bands at 2400 cm^{-1}, assigned to ν(P—H) stretching vibration, and ~900 cm^{-1}, assigned to δ(P—H) deformation vibrations. The IR spectrum of V shows an additional band at ~980 cm^{-1}, typical of the $Mo(OH)_2Mo$ fragment.[13]

Positive results obtained in applying the phosphonium and phosphine Mo complexes as olefin epoxidation catalyst,[2,14] as well as the fact that during this reaction the initial compounds are converted into $MoO_2(diol)(dppeO_2)$, allowed us to expect to obtain effective catalysts heterogenized on polymer carriers, functionalized by the phosphonium groups.

^{95}Mo NMR STUDIES OF SOME CARBONYLATE ANIONS

E. C. ALYEA,* A. MALEK and J. MALITO

Guelph–Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, Department of Chemistry and Biochemistry, Guelph, Ontario, Canada N1G 2W1

(*Received* 17 *June* 1985)

Abstract—^{95}Mo NMR chemical shifts are reported for a range of molybdenum(0) carbonylate anions of the type $[Mo(CO)_5X]^-$ (X = halide or pseudohalide). The dimethylsulphoxide solution data substantiate the existence of more than one product, unexpected products and ambidentate pseudohalogen bonding modes. The sensitivity of the ^{95}Mo NMR chemical shifts to the ligand field and polarizability properties of the anions in the $[Mo(CO)_5X]^-$ complexes results in an over 500 ppm range of values (−1980 to −1435 ppm); the shielding order is $H^- > CN^- > I^- > NCO^- > NCS^- > NCSe^- > Br^- > N_3^- > NO_2^- > Cl^- > O_2CH^- > O_2N^- > OCH_3^-$. Species arising from the reaction of $Mo(CO)_6$ with hydroxide ion have been previously implicated in the homogeneous catalysis of the water-gas shift reaction; the utility of ^{95}Mo NMR spectroscopy in identifying some of these products is also described.

^{95}Mo NMR spectroscopy is now well established as a sensitive probe of both electronic and structural effects in diamagnetic molybdenum complexes.[1] The chemical shift range for ^{95}Mo for all oxidation states is *ca* 7000 ppm, with resonances for Mo(0) compounds extending *ca* 2000 ppm to higher frequency from the most shielded value {−2123 ppm for $Na[CpMo(CO)_3]$}. We have previously[2] studied the ^{95}Mo NMR spectra of a series of substituted molybdenum carbonyls, $Mo(CO)_{6-n}L_n$ (n = 1–3, L = N, P, As or Sb donor ligands). Subsequent work[3] demonstrated the usefulness of ^{95}Mo NMR spectroscopy in characterizing a variety of unstable ionic complexes of the type [Cat][$Mo(CO)_5$L] and [Cat][$Mo(CO)_4$L–L] (Cat = NH_4, Na or K; L or L–L = dithiocarbamato, xanthato or phosphorodithioato). The present study extends our identification of molybdenum(0) carbonylate anions to a variety of $[Mo(CO)_5X]^-$ (X = pseudohalide) complexes. Particular interest focuses on the anionic molybdenum carbonyl species generated by the reaction of $Mo(CO)_6$ with hydroxide ion since they have been implicated in the homogeneous catalysis of the water-gas shift reaction (WGSR).[4,5] A preliminary report of this study has been published.[6]

* Author to whom correspondence should be addressed.

EXPERIMENTAL

^{95}Mo NMR spectra were recorded for naturally abundant (15.7 atom %) samples using a Bruker WH-400 NMR spectrometer in the pulsed Fourier transform mode. The spectra were obtained at ambient temperature with the probe specifically tuned for ^{95}Mo at 26.08 MHz using a field strength of 9.3956 T. The external standard was aqueous 2 M K_2MoO_4 at pH 11. The pulse width was normally in the 50–100 μs range for the 90° pulse, but other parameters varied widely, though typically the resolution was better than 5 Hz per point. Parameters used for the observation of the ^{95}Mo NMR spectrum of the possible products arising from the reaction of $Mo(CO)_6$ and $NaBH_4$ in dimethylsulphoxide (DMSO) solution are listed as a typical example: sweep width 29,412 Hz, data points 16 K, pulse width 50 μs, line broadening 25 Hz, number of scans 1871, resolution 3.6 Hz per point; the signal occurring at −1941 ppm (no other peaks were observed) has a linewidth at half height of 50 Hz and a signal-to-noise ratio of 50.

Samples were prepared *in situ* under dinitrogen using *ca* 0.1 mol dm^{-3} DMSO solutions of the alkali metal salt or hydroxide and $Mo(CO)_6$ in 1 : 1 molar ratios. Transfer to septum-sealed 10-mm NMR

tubes via a syringe was effected after warming the solutions at 60–65°C until a colour change and/or IR spectroscopy indicated an appreciable conversion to the carbonylate anion. Both the concentrations and the reaction times (typically ½–5 h) varied considerably for the samples. Solution IR spectra were also normally obtained on diluted samples subsequent to NMR analyses to ensure the integrity of the solutions, which were assumed to be air-sensitive. Matched CaF_2 or KBr sealed cells of 0.2-mm path length were used in conjunction with a Perkin–Elmer 180 grating IR spectrophotometer.

The sodium salts of $[HMo_2(CO)_{10}]^-$, $[HMoCr(CO)_{10}]^-$ and $[HMoW(CO)_{10}]^-$ were produced *in situ* in THF or DMSO following the method of Hayter.[7] The solutions were reduced to near dryness under reduced pressure to remove volatile by-products before dilution for ^{95}Mo NMR and IR measurements.

RESULTS AND DISCUSSION

The molybdenum carbonylate anions $[Mo(CO)_5X]^-$ (X = halide) are stable well-characterized species that have been long used as precursors in the synthesis of $Mo(CO)_5L$ complexes.[8] Earlier ^{95}Mo NMR studies[3,9] established that the chemical shifts of these d^6 species follow a 'normal halogen dependence',[10] in contrast to an inverse correlation observed for the $[MoE_4]^{2-}$ anions (E = O, S or Se) and $[MoO_2]^{2+}$ complexes.[11] Investigations on other $[Mo(CO)_5X]^-$ (X = pseudohalide) species are less extensive, though IR spectroscopy has shown the existence of more than one product with a given anion,[12] unexpected products,[13] and ambidentate pseudohalogen bonding modes.[14] Our success in utilizing ^{95}Mo NMR spectroscopy to identify unstable $[Mo(CO)_5L]^-$ and $[Mo(CO)_4L\text{–}L]^-$ (L or L–L = dithiocarbamato, xanthato or phosphorodithioato) anions, generated *in situ* in warm DMSO solution,[3] led us to this ^{95}Mo NMR investigation of the products formed by reacting $Mo(CO)_6$ with pseudohalides and hydroxide ions under similar conditions. Formation of the anionic products was monitored using the IR carbonyl region since a three-band pattern with a strong band near 1920 cm^{-1} is diagnostic of the presence of these pentacarbonyl species.[3,15] In the case of BH_4^-, CN^-, NCO^- and the halide ions, IR spectroscopy indicates only the pentacarbonyl product in the DMSO reaction mixture, and thus the corresponding observation of just one peak in the ^{95}Mo NMR spectrum leads to a reasonably unambiguous assignment. With the other anions employed in this study, the complexity of the IR spectra of the reaction mixtures showed only that two or more products had formed, and the identification of the species that actually exist in solution was more clearly suggested by observation of the ^{95}Mo resonances. Table 1 lists the ^{95}Mo NMR chemical shifts and their tentative assignments for the carbonylate anions of the type $[Mo(CO)_5X]^-$ formed in this study.

The spread of 545 ppm in the ^{95}Mo chemical shift resonances indicates the high sensitivity of the NMR method to the environment of the pseudooctahedral molybdenum atoms. The nephelauxetic term in the Ramsey expression[1] for the paramagnetic shielding appears to be dominant, since polarizable anions (H, CN or I) give the highest observed shielding whereas the more electronegative or harder anions (oxygen donor ions) lead to molybdenum being deshielded. The importance of the ΔE term was obvious for other series of substituted molybdenum carbonyls[2] and thus the ligand field strength of the anion is surely also an important influence on the observed range of chemical shifts for the present carbonylate anions. For example, although the data clearly differentiates between the NCO, NCS and NCSe anions, the relative contribution of π-acceptor ability and polarizability factors must remain debatable. We include the chemical shifts[3] for the species involving unidentate $S_2P(OEt)_2$, S_2CNPh_2 and S_2CNMe_2 anions in Table 1 for the sake of comparison and note their similarity to the values observed with several *N*-donor anions. We previously assigned a peak at

Table 1. ^{95}Mo NMR chemical shifts for some molybdenum(0) carbonylate anions of the type $[Mo(CO)_5X]^-$

X[a]	$\delta(^{95}Mo)$ (ppm)	X[a]	$\delta(^{95}Mo)$ (ppm)
H	−1980	Br[b]	−1540

I[b]	−1660	N_3	−1523
$S_2P(OEt)_2$[c]	−1626	NO_2	−1514
NCO	−1604	Cl[b]	−1513
NCS	−1596	O_2CH	−1495
S_2CNPh_2[c]	−1596	O_2N	−1435
NCSe[d]	−1590	OCH_3	−1435

[a] Solutions prepared *in situ* in DMSO solution, except Cl (CH_2Cl_2), Br and I (CD_2Cl_2), and OMe (THF).

[b] Previously reported, see Refs 2 and 9.

[c] Previously reported.[3]

[d] The major peak at −1438 ppm is an alternative assignment; other minor peaks occur at −1887, −1867, −1735, −1603, −1590, −1452 and −1360 ppm (see text).

−943 ppm to $[Mo(CO)_5F]^-$ and found that the ^{95}Mo NMR spectrum for the reaction of $NaBF_4$ with $Mo(CO)_6$ in DMSO solution also gave a resonance in the same region. It is more probable that a polynuclear hydroxo-species is responsible for the −943 ppm peak, considering its downfield position as compared to those for the other halide species and the fact that reaction mixtures of hydroxyl ion with $Mo(CO)_6$ always show a peak at −943 ppm.

The existence of more than one product, suggested by the observance of more than three IR carbonyl bands, was verified by the ^{95}Mo NMR data for reactions of $Mo(CO)_6$ with NaN_3, KCNS, KCNSe, NaOMe, $NaNO_2$, NaO_2CH and NaOH or KOH (*vide infra*). The second peak of lower intensity observed for the azide reaction can be attributed to the formation of the isocyanate group since the only peak found in the reaction mixture of NaNCO with $Mo(CO)_6$ also occurs at −1604 ppm; this reaction has previously been followed by IR spectroscopy.[13] Similarly, IR studies suggested that NCS-bridged binuclear species as well as *N*-bonded mononuclear species were formed in the reaction of the thiocyanate ion with $Mo(CO)_6$.[14] We assign the major peak at −1596 ppm to the $[Mo(CO)_5NCS]^-$ ion, whereas the minor peak at −1370 ppm may be due to the bridged species or, alternatively, the *S*-bonded mononuclear isomer. Some of the peaks observed for the DMSO solution containing KSeCN and $Mo(CO)_6$ are reasonably identified as unreacted $Mo(CO)_6$ (−1867 ppm), $[Mo(CO)_5CN]^-$ (−1887 ppm), $[Mo(CO)_5NCSe]^-$ [−1590 ppm or −1438 ppm (the major peak)], $[Mo(CO)_5NCO]^-$ (−1603 ppm); other minor peaks suggest the presence of *Se*-bonded and bridging species (−1438 and −1360 ppm). Whilst the major peak that occurs in the ^{95}Mo NMR spectrum of a THF solution of NaOMe and $Mo(CO)_6$ is assigned to the presence of the $[Mo(CO)_5OMe]^-$ ion, the weak broad peak at −1784 ppm remains unassigned. The two equal intensity peaks found in the case of the reaction of $NaNO_2$ with $Mo(CO)_6$ in warm DMSO solution are assigned to $[Mo(CO)_5NO_2]^-$ (−1514 ppm) and $[Mo(CO)_4O_2N]^-$ (−1435 ppm). The occurrence of bidentate nitrito coordination is suggested by the IR spectrum [peaks at 2050(w), 1970(s), 1925(vs, b) and 1850(s)] but the presence of monodentate *O*-bonded nitrito groups cannot be ruled out.

^{95}Mo NMR chemical shifts for some molybdenum carbonylate anions generated in polar solvents by the addition of hydroxide ion to $Mo(CO)_6$ are listed in Table 2. The $[Mo_2(CO)_{10}H]^-$ species is also the only product of the reaction of $NaBH_4$ with $Mo(CO)_6$ in warm DMSO solution, as previously identified by IR studies.[4,7] Masters *et al.*[16] previously reported the resonance for $[Mo_2(CO)_{10}H]^-$ at −1937 ppm (THF solution). We observe formation of the hydrido-bridged species in reactions of hydroxyl or formate ions with $Mo(CO)_6$. In the case of the reaction of NaO_2CH with $Mo(CO)_6$, the $[Mo(CO)_5O_2CH]^-$ ion is the major species formed, and we note that there is no indication of the presence of $[Mo(CO)_5H]^-$. This was surprising in that recent investigations[4] of these systems (albeit in nonpolar media) suggested that the $[Mo(CO)_5H]^-$ ion was the primary product of the decarboxylation of the $[Mo(CO)_5O_2CH]^-$ ion. Darensbourg and Rokicki[4] showed that the latter ion was readily formed by bubbling CO_2 through a solution of $[Mo(CO)_5H]^-$. We find that $[Mo_2(CO)_{10}H]^-$ generated *in situ*[7] in THF or DMSO solution reacts with CO_2 under ambient conditions to produce $[Mo(CO)_5O_2CH]^-$, identified by IR, ^{1}H and ^{95}Mo NMR spectroscopy. The characteristic IR and ^{1}H NMR peaks due to coordinated formato peaks are observed at 1600 cm^{-1} and 8.55 ppm, respectively.[4,7,17] It is nevertheless interesting to note that the major initial product of the reaction of hydroxyl ion with $Mo(CO)_6$ in DMSO solution is $[Mo(CO)_5H]^-$ {major peak at −1980 ppm; minor peaks at −1940 and −943 ppm are assigned to $[Mo_2(CO)_{10}H]^-$ and a polynuclear hydroxo-species, respectively}. Longer reaction times give rise to peaks at −1544 ppm (unidentified) and at −1495 ppm {$[Mo(CO)_5O_2CH]^-$}. The complexity of the interrelationships of the various species is of current interest[4,5,17] due to the implication of the system in the homogeneous catalysis of the WGSR. Our continuing investigations of these species employing ^{95}Mo NMR spectroscopy will be reported later.

Table 2. ^{95}Mo NMR chemical shifts for some molybdenum(0) carbonylate anions generated in polar media

Anion[a]	$\delta(^{95}Mo)$ (ppm)	Solvent
$[HMo(CO)_5]^-$	−1980	DMSO
$[HMo_2(CO)_{10}]^-$	−1941	DMSO
	−1940	CH_3CN
	−1937[b]	THF
$[HMoW(CO)_{10}]^-$	−1916	THF
$[HMoCr(CO)_{10}]^-$	−1872	THF
$[Mo(CO)_5(O_2CH)]^-$	−1495	DMSO
	−1494	THF
	−1491	CH_3CN

[a] Solutions prepared *in situ* in given solvent.
[b] Previously reported.[16]

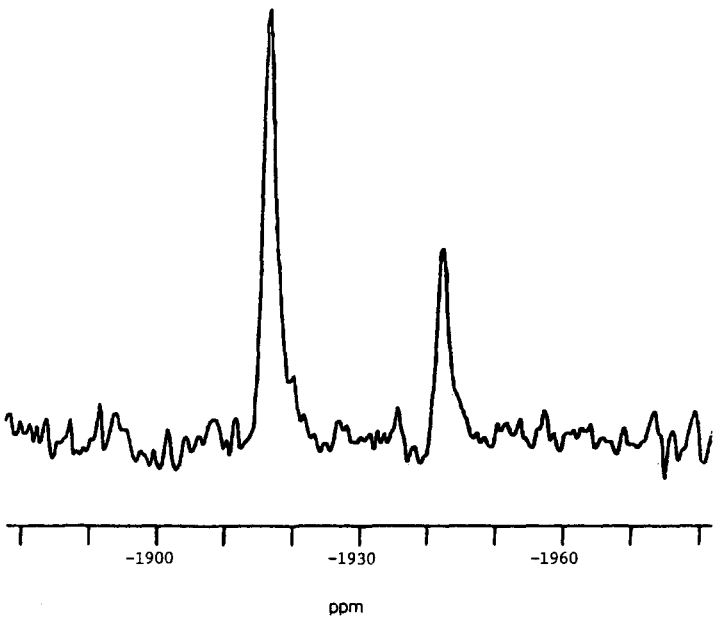

Fig. 1. The ^{95}Mo NMR spectrum of $[HMoW(CO)_{10}]^-$ (−1916 ppm) and $[HMo_2(CO)_{10}]^-$ (−1942 ppm), generated *in situ* in a 2:1 molar ratio in THF solution.[7]

Hayter[7] demonstrated earlier that one molybdenum atom in $[Mo_2(CO)_{10}H]^-$ could be replaced by a W or Cr atom: ^{1}H NMR spectroscopy showed a statistical distribution of homonuclear to heteronuclear species. Observations of the species generated in THF solution by ^{95}Mo NMR spectroscopy shows that the substitution of W or Cr atoms results in the Mo atom being deshielded. The spectrum for the W case is shown in Fig. 1. The trend is consistent with, but opposite to, the order reported[7] for the hydride chemical shifts.

(*Received in revised form* 22 *July* 1985)

Abstract—A variety of dinuclear Mo(V), Mo(IV), Mo(III) and Mo(I) complexes, and tri- and tetranuclear homo- and heterometallic complexes of molybdenum have been studied by ^{95}Mo NMR. The Mo(V) complexes, $Cp'_2Mo_2Y_2(\mu\text{-}X)_2$ (Y = O or S, X = S or Se, Cp′ = η^5-C_5Me_5), exhibit resonances in the −93 to 478 ppm region, the chemical shifts being sensitive to changes in the oxygen, sulfur and selenium content of the coordination spheres. The Mo(IV) complexes, $Cp'_2Mo_2(\mu\text{-}X)_2(\mu\text{-}X_2)$ (X = S or Se), and their derivatives exhibit resonances in the 382–790 ppm region: isomers of $Cp'_2Mo_2(\mu\text{-}S)_2(\mu\text{-}SH)_2$ which differ in the arrangement of the bridging ligands were also detected. Dinuclear Mo(III) complexes of the form Mo_2L_6 (L = amido, alkoxy or alkyl ligand) exhibit very deshielded resonances (2430–3624 ppm). The complexes $Cp_2Mo_2\{\mu\text{-}S_2C_2(CF_3)_2\}_2$ and $Cp_2Mo_2(CO)_2\{\mu\text{-}S_2C_2(CF_3)_2\}_2$ (Cp = η^5-C_5H_5) exhibit resonances consistent with their formulation as distinct Mo(III) and mixed-valence Mo(IV–II) complexes, respectively. The Mo(I) complexes exhibit resonances which are very sensitive to the bond order of the Mo–Mo bond: the resonances of the $L_2Mo_2(CO)_6$ complexes (L = Cp, −1856 ppm; L = Cp′, −1701 ppm) are more than 1800 ppm more shielded than the triply metal–metal bonded complexes, $L_2Mo_2(CO)_4$ (L = Cp, 182 ppm; L = Cp′, 133 ppm). The molybdenum containing homo- and heterometallic complexes exhibit resonances in the −133 to −1619 ppm region. The Fe_2Mo_2 cubane complex, $Cp'_2Mo_2Fe_2(\mu_3\text{-}S)_4(CO)_4$, exhibits a resonance at −506 ppm. The ease of observation of the sulfurized complexes suggests that ^{95}Mo NMR may be a valuable technique for the study of hydrodesulfurization processes.

In recent years the characterization of coordination and organometallic complexes of molybdenum by ^{95}Mo NMR spectroscopy has developed rapidly. In general, the measurement of the spectra of Mo(VI), Mo(II) and Mo(0) complexes has become routine, and the chemical-shift ranges and halogen dependencies of such complexes are well-defined.[1] For these oxidation states the ability of ^{95}Mo NMR to monitor solution processes,[2,3] to distinguish diastereomers[4–6] and to aid solid–solution structure correlations[7] has also been demonstrated.

In contrast, the study of Mo(V), Mo(IV), Mo(III) and Mo(I) complexes has been limited or nonexistent. ^{95}Mo NMR investigations of Mo(V),

* Author to whom correspondence should be addressed.

Mo(III) and Mo(I) complexes are restricted to spin-paired $(Mo_2)_n$ species possessing the diamagnetism necessary for NMR observation. Mo(V) complexes possessing *syn*- and *anti*-$[Mo_2O_2(\mu\text{-}X)_2]^{2+}$ (X = O or S) structural cores exhibit resonances in the 320–982-ppm region,[3,8] the chemical shifts being sensitive to changes in the stereochemistry of the core, e.g. *syn*- and *anti*-$[Mo_2O_4L_2]^{2+}$ (L = 1,4,7-triazacyclononane) exhibit resonances at 586 and 342 ppm, respectively.[3] Dinuclear Mo(IV) complexes have not been studied by ^{95}Mo NMR, although an extensive study of complexes possessing the $[Mo_3O_4]^{4+}$ core has been reported.[8,9] Our recent investigation of mononuclear oxo-Mo(IV) complexes by ^{95}Mo NMR[10] has established an enormous range of chemical shifts (3180 to −1309[11] ppm)* and linewidths (80[11] to >5000 Hz) for mononuclear Mo(IV) complexes. To date, complexes of Mo(III) have not been studied by ^{95}Mo NMR, and only one Mo(I) complex, $Cp_2Mo_2(CO)_6$[12] (hereafter, Cp = η^5-C_5H_5, Cp′ = η^5-C_5Me_5), has been investigated by this technique.

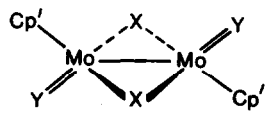
Here we report the ^{95}Mo NMR spectra of 22 dinuclear metal–metal bonded complexes of Mo(V), Mo(IV), Mo(III) and Mo(I). This work describes the first ^{95}Mo NMR data for dinuclear complexes of Mo(IV) and Mo(III) and expands upon the single previous result[12] for Mo(I). In addition, preliminary studies on several homo- and heterometallic molybdenum cluster compounds are presented. The compounds investigated are relevant to studies involving hydrodesulfurization and bioinorganic catalysis.

EXPERIMENTAL

Sample preparation

The complexes were prepared by literature methods or slight modifications thereof: a guide to the source of each complex is given in Table 1. Solutions of air-sensitive samples were prepared under anaerobic conditions using dried and deoxygenated solvents. Concentrations in the range 3–100 mM were employed.

Instrumentation



The ^{95}Mo NMR spectra were recorded on a Bruker WM250 spectrometer equipped with a 10-mm molybdenum probe and operating at 16.3 MHz. To reduce the effects of probe ringing[1] a Doty Scientific duplexer and pre-amplifier with a 16 MHz center was inserted between the probe and the Bruker broadband pre-amplifier. The duplexer was gated off during the pulse and for 5 μs thereafter. With this arrangement the pre-acquisition delay was reduced to 100 μs. The transmitter output was amplified with a Heathkit SB-201 (1-kW) linear amplifier. The input was attenuated to give a 26-μs 90° pulse. A 2 M $Na_2[MoO_4]$ solution in D_2O, effective pH 11, was used as external reference.

RESULTS AND DISCUSSION

The ^{95}Mo NMR data are summarized in Table 1, along with a guide to the structure and source of each complex. Structural formulae for the complexes are given in the appropriate sections.

Mo(V) complexes

Singly metal–metal bonded dinuclear Mo(V) complexes possessing the *anti*-$[Mo_2Y_2(\mu\text{-}X)_2]^{2+}$ core[13,14] exhibit resonances in the −93 to 478 ppm region. With the exception of $Cp'_2Mo_2S_2(\mu\text{-}S)_2$ (**2**),[14] these complexes are more shielded than previously

X=S, Y=O (**1**)
X=S, Y=S (**2**)
X=Se, Y=O (**3**)

studied dinuclear Mo(V) analogues.[3,8] The oxo complex, $Cp'_2Mo_2O_2(\mu\text{-}S)_2$ (**1**),[14] exhibits the most shielded resonance of the series at −93 ppm. Considerable deshielding of the ^{95}Mo nuclei occurs upon replacement of the Mo=O_t (t = terminal) groups of **1** by Mo=S_t: the resonance of **2** (478 ppm) is deshielded by 571 ppm compared to the oxo complex **1**. The deshielding influence of the Mo=S_t group has been previously observed in complexes such as $[MoX_4]^{2-}$[15] and $MoX_2(R_2NO)_2^2$ (X = O or S): for these types of complexes, conversion of each Mo=O_t group to Mo=S_t results in a deshielding of *ca* 500 and 700 ppm, respectively. Similarly, a deshielding of *ca* 320 ppm results upon successive replacement of Mo=S_t groups by Mo=Se_t groups.[2,15(b)] However, comparison of **1** and $Cp'_2Mo_2O_2(\mu\text{-}Se)_2$ (**3**) reveals that replacement of the μ-S ligands by μ-Se ligands deshields the ^{95}Mo nuclei by only *ca* 230 ppm. A reduced deshielding effect of 203 ppm has also been observed upon replacement of the μ-O ligands of $[Mo_2O_4(\text{L-cysteinate})_2]^{2-}$ by μ-S ligands.[8] These trends show that the substitution of bridging vs terminal atoms can be readily distinguished by ^{95}Mo NMR.

* The values given in Ref. 11 are for $[Mo(CN)_8]^{4-}$.

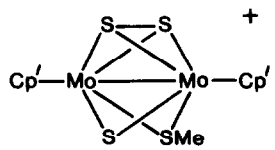
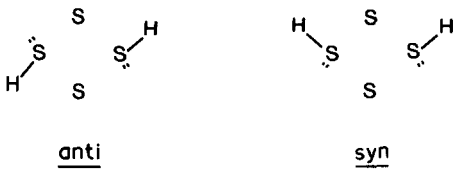
[a] At ambient temperature in CH_2Cl_2 solvent unless otherwise specified.
[b] All Mo(III) complexes, except **16** and **17**, were studied in toluene.
[c] d = doublet, s = singlet.

Mo(IV) complexes

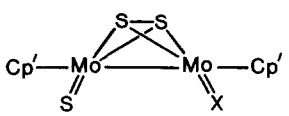


The $Cp'_2Mo_2(\mu\text{-}S)_2(\mu\text{-}S_2)$ complex (**4**)[16] exhibits a resonance at 440 ppm whereas the selenium analogue, $Cp'_2Mo_2(\mu\text{-}Se)_2(\mu\text{-}Se_2)$ (**5**),[17] exhibits a relatively deshielded resonance at 770 ppm. The 330-ppm deshielding observed upon complete replacement of μ-S ligands by μ-Se ligands is also small compared to that expected for the exchange of a similar number and type of terminal ligands (cf. **1** and **3**). Hydrogenation of **4** results in an isomeric mixture of **6**,[18] which exhibits two resonances at 714 and 728 ppm. This is consistent with the previous detection, by ^{1}H NMR, of two isomers in the analogous

X=S (**4**) or Se (**5**)



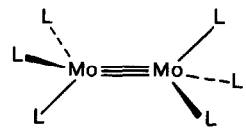
R=H (**6**) or Me (**7**)



8

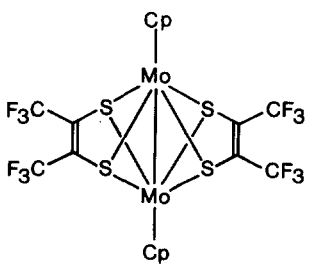
$(MeCp)_2Mo_2(\mu\text{-}S)_2(\mu\text{-}SH)_2$ complex.[19] For the *trans* isomer[19] two arrangements of the bridging SH ligands are possible (*anti* and *syn* below). The bis-μ-

methylthiolate complex (**7**), having a chemical shift of 790 ppm, has been crystallographically characterized as the *anti* isomer.[20] The reaction of **4** with methyl iodide results in the methylation of one μ-S group:[18] the resulting cationic complex, **8**, exhibits a slightly shielded resonance at 382 ppm. The chemical shifts of **6** and **7** reflect the opening of the $\mu\text{-}S_2^{2-}$ ligand to form two deshielding $\mu\text{-}S^{2-}$ ligands.



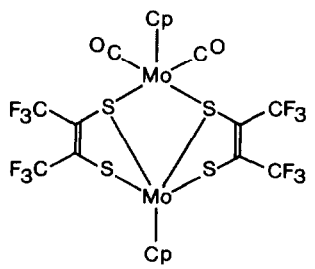
Complex **4** is converted, at 45°C in toluene, to $Cp'_2Mo_2S_2(\mu\text{-}S_2)$ (**9**):[16] the transformation of the

two $\mu\text{-}S^{2-}$ ligands into two terminal S^{2-} ligands leads to a deshielding of the ^{95}Mo nuclei and the observation of a resonance at 756 ppm for **9**. A by-product of this reaction, the unsymmetrical complex $Cp'_2Mo_2OS(\mu\text{-}S_2)$ (**10**),[16] provides a nice example of the deshielding influence of the Mo=S_t group relative to Mo=O_t. For **10**, the two resonances at −54 and 699 ppm may be readily assigned to the Mo=O_t and Mo=S_t centers, respectively. The 753-ppm shielding difference observed here is similar in magnitude to that observed elsewhere.[2]



Mo(III) complexes

A wide variety of diamagnetic Mo(III) dimers having general formulae Mo_2L_6 ($L = NR_2^-, OR^-$ or R^-) have been reported by Chisholm[21,22] and Wilkinson:[23] we have initiated a study of these complexes, their derivatives and their tungsten analogues. The complexes Mo_2L_6 [$L = NMe_2^-$ (**11**), $OCHMe_2^-$ (**12**), $OCH_2CMe_3^-$ (**13**), $OCMe_3^-$ (**14**) or $CH_2SiMe_3^-$ (**15**)] exhibit resonances over the chemical-shift range 2430–3624 ppm, a very deshielded portion of the known chemical-shift



range.[1] Only one other class of metal–metal-bonded complex, quadruply bonded Mo(II) dimers, possesses more deshielded resonances (3227–4148 ppm).[1] The shielding of the ^{95}Mo nuclei increases in the order alkyl < 3°-alkoxide < 1°- and 2°-alkoxide < dialkylamide. The *N*- and *O*-donor ligand complexes exhibit a narrow range of chemical shifts while the chemical shift of the silyl derivative **15**[23] is quite disparate.* Accounting for such observations will provide a critical test for developing theoretical treatments of ^{95}Mo chemical-shift data. The linewidths of the Mo(III) resonances range from 120 to 1320 Hz, contrasting with the generally broad resonances of Mo(II) dimers.[1]

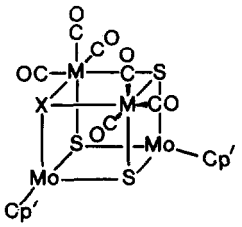
The μ-dithiolene complexes **16** and **17** exhibit readily observable resonances. The singly metal–metal bonded **16** [Mo—Mo = 2.584(1) Å[25]]

16

17

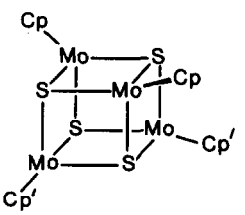
exhibits a deshielded resonance at 2301 ppm ($W_{1/2}$ = 37 Hz). The relatively shielded position compared to the triply metal–metal bonded M_2L_6 complexes is consistent with a similar trend found in the Mo(I)

* The similarly disparate ^{183}W NMR chemical shifts of $W(CXMe_3)(CH_2XMe_3)_3$ (X = C, 2867 ppm; X = Si, 3613 ppm) support a general deshielding influence for β-Si substitution.[24]



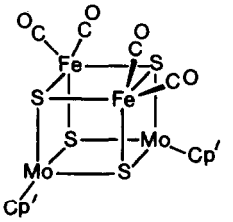
complexes below. A structure determination of **17** revealed two distinctly different molybdenum environments and a Mo... Mo interatomic distance of 3.256(1) Å,[25] indicative of a localized Class I mixed-valence complex in the Robin and Day classification.[26] The ^{95}Mo NMR spectrum of **17** is consistent with this formulation as only one peak at −789 ppm is observed. This peak is likely to be due to the $CpMo(II)(CO)_2$ moiety, while that due to the Mo(IV) fragment remains unobserved due to its rapid relaxation time.[10] Supporting this contention, the complexes

$$CpMo(CO)_2(S_2CNEt_2),\ CpMo(CO)_2(S_2COEt)$$



and

$$CpMo(CO)_2\{C(CF_3)=C(CF_3)C(O)SMe\}$$



resonate at −544, −559 and −845 ppm, respectively.[27]

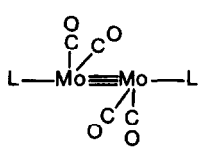
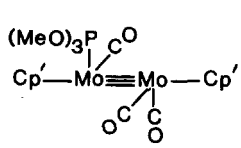
Homo- and heterometallic cubanes and related complexes

We have recently undertaken an NMR investigation of new homo- and heterometallic complexes of molybdenum and catalytically or biologically relevant co-metals such as cobalt, nickel (hydrodesulfurization) and iron (nitrogenase). Complexes **23**–**27** exhibit narrow, readily observable ^{95}Mo NMR resonances in the shielded portion of the chemical-shift range. Complexes **23**–**25** possess two environments for molybdenum and each exhibits two resonances of equal intensity: these have been assigned as described below. The shielded resonances of other carbonylmolybdenum(0) complexes[1] permits the assignment of the −1256 ppm resonance



Mo(I) complexes

To date, the ^{95}Mo NMR spectrum of only one Mo(I) complex has been reported: the metal–metal singly bonded species $Cp_2Mo_2(CO)_6$ (**18**) exhibits a relatively shielded resonance at −1856 ppm.[12] In a similar spectral region, we have observed the resonance of $Cp'_2Mo_2(CO)_6$ (**19**)[29] at −1701 ppm. Remarkably, the metal–metal triply bonded complexes, **20** and **21**, exhibit resonances which are deshielded by over 1800 ppm compared to **18** and **19**: the tetracarbonyl complexes, **20**[28] and **21**,[30,31] exhibit resonances at 182 and 133 ppm, respectively. We have also studied the unsymmetrical triply bonded complex **22**,[32] which exhibits two resonances, a doublet (J_{Mo-P} = 412 Hz) at 373 ppm and a singlet at 154 ppm. The J value is *ca* 120 Hz higher than any previously observed value:[1] coupling of the ^{31}P nucleus to both Mo nuclei was not discerned.



of **23**[33] to the $Mo(CO)_3$ moieties of this complex. The resonance at −558 ppm is therefore due to the Cp'Mo moieties. The μ_3-O ligand in **24**[20] is expected to shield the Mo center to which it is bound (relative to μ_3-S) and thus the −265 and −471 ppm resonances of this complex are assigned to μ_3-S-Mo and μ_3-O-Mo centers, respectively (compare **9** and **10**). The presence of a *ca* −500 ppm resonance attributable to μ_3-S-coordinated Mo in complexes **23** and **26** raises the possibility that the −471-ppm resonance of **24** is due to the μ_3-S-coordinated Mo center. This latter assignment is contrary to all previously observed shielding trends for $Mo{=}X_t$ and μ-X (X = O or S) ligand complexes[2,8,15] and, therefore, seems unlikely. Definitive assignment of the resonances of **24** awaits data for complexes such as $Cp'_2Mo_2Cr_2(\mu_3\text{-}X)_4(CO)_6$ (X = O or S). A

L=Cp (**18**) or Cp' (**19**)

L=Cp (**20**) or Cp' (**21**)

22

shielding effect of Cp relative to Cp′ is observed in resonances in the shielded portion of the chemical shift range (e.g. **18** and **19**) and on this basis the resonances of **25**[34] at −1444 and −1619 ppm are ascribed to Cp′- and Cp-bearing Mo atoms, respectively.

The paramagnetism of most Fe–Mo–S cubane and double-cubane cluster complexes has prevented their study by ^{95}Mo NMR. The diamagnetism of Fe–Mo–S clusters derived from **4** and $Fe_2(CO)_9$ make them attractive candidates for assessing the NMR properties of more biologically pertinent centers. Complex **26**[33] exhibits a single sharp resonance at −506 ppm, 946 ppm more shielded than the precursor **4**. The data for **26** provide evidence that μ_3-S ligands shield the molybdenum nuclei compared to μ-S and S_t ligands. The resonance of **27**[33] at −133 ppm is also shielded due to conversion of the μ-S ligands into μ_3-S ligands.

CONCLUSION

The ability of terminal X^{2-} (X = O or S) ligands to effect predictable changes in the chemical shifts of ^{95}Mo NMR resonances has been confirmed in this study. Moreover, new deshielding trends may be discerned from the data presented herein, e.g. the deshielding ability of bridging ligands involved in this study increase in the order μ-S_2^{2-} < μ-SH < μ-SMe < μ-S < μ-Se and μ_3-O < μ_3-S.

There also appears to be a deshielding effect upon increasing the bond order of the metal–metal bond. While changes in the coordination sphere accompany such reactions, the concomitant change in chemical shift is often not accounted for by these changes alone. The most dramatic example of this effect involves the pairs **18–20** and **19–21** where singly and triply bonded species differ in chemical shift by over 1800 ppm.

The ready detection and differentiation of sulfidomolybdenum complexes by ^{95}Mo NMR provides encouragement for the application of this technique to the study of hydrodesulfurization catalysis. The hydrodesulfurization reaction is an important catalytic process for the purification of petroleum products.[35] The reaction, exemplified by the equation below, involves the

$$RSH + H_2 \rightarrow RH + H_2S$$

hydrogenolysis of organosulfur compounds, and is most often effected by heterogeneous catalysts containing sulfided Mo and Co species supported on alumina. Both metal and sulfide ions have been proposed as active sites in the hydrodesulfurization reaction: the ability of sulfide ligands to react with hydrogen and other small molecules is exemplified by complexes such as **6–8** and **26** and **27**. Species such as **6–8** are important model complexes for reactivity and mechanistic studies of hydrodesulfurization.[19] Due to their narrow linewidths, the resonances of these species are readily detected even at concentrations of ^{95}Mo as low as 0.5 mM. Thus ^{95}Mo NMR may prove valuable in the characterization of solution species and intermediates, and for monitoring the course of homogeneous hydrodesulfurization systems.

PATTERNS OF ^{95}Mo SHIELDING IN ORGANOMETALLIC AND INORGANIC CHEMISTRY

RUTH A. GRIEVES and JOAN MASON*

Department of Chemistry, The Open University, Milton Keynes MK7 6AA, U.K.

(*Received* 2 *July* 1985)

Abstract—Reasonable ^{95}Mo NMR properties, a good shift dispersion, centrality in the Periodic Table, the great variety of organometallic and inorganic bond types, and comparisons with (electronic) excitation energies and ionization energies, allow in-depth examination of the determinants of the metal nuclear shielding. Exceptions to the normal correlation of decrease in shielding with increase in oxidation number are found at the top of the shielding range {for Mo(VI) in $[MoCp_2H_3]^+$} and at the bottom end [for Mo(II) in quadruply-bonded dimers with axial ligands]. The decrease in shielding with increase in bond order, Mo—Mo > Mo=Mo > Mo≡Mo > Mo≣Mo, contrasts with the sequence C—C < C≡C < C=C in carbon resonance. All these exceptions, however, prove the "spectrochemical" rule of decrease in shielding with decrease in ligand field splitting, with dependence also on nephelauxetic effects. Various sequences of ligand dependence of the ^{95}Mo shift show that nephelauxetic effects may reinforce or oppose spectrochemical influences, both in inorganic compounds (in which the two influences have differing periodicities) and in organometallic compounds.

^{95}Mo has a reasonable natural abundance (15.7%), NMR receptivity (better than for ^{13}C) and quadrupole moment (-0.019×10^{-28} m^2, similar to that for ^{14}N). Only in viscous solutions, large molecules, or unusually unsymmetrical electronic environments (as in some Mo≣Mo compounds), are the lines uncomfortably broad, and a sizeable ^{95}Mo literature has developed within the last 5 years.[1] By comparison ^{183}W, although a spin-$\frac{1}{2}$ nucleus, has a sufficiently low magnetogyric ratio that the lower sensitivity and working frequencies (with attendant problems of probe ringing) have tended to limit NMR studies.[1] We have observed a shift range of 7250 ppm for molybdenum, interestingly with high oxidation numbers at both extremes (as also for ^{183}W, with a shift range of 11,000 ppm[1]). Because of the large shift dispersion, NMR spectroscopy of the metal nucleus can be helpful in preparative and mechanistic work, and the shift relationships contain particularly interesting information on spectrochemical and nephelauxetic effects of the ligands.

RESULTS

Patterns of ^{95}Mo *shielding*

High shielding is often associated conceptually with low oxidation numbers and negative charge, probably as a lingering influence of proton (and ^{13}C) NMR spectroscopy. In fact we have observed the highest recorded ^{95}Mo shielding for the bent sandwich hydride $[MoCp_2H_3]^+$,† in which the metal is Mo(VI), formally d^0, and the complex is positively charged. Somewhat lower shielding is observed for the dihydride $[MoCp_2H_2]$ containing Mo(IV), formally d^2 (cf. Table 1); similarly the highest ^{183}W shielding so far has been observed for $[WCp_2H_2]$.[2] It is a general observation that the effect on the transition-metal nucleus shielding of a small difference in charge on the complex as a whole is relatively small.

As to the overall pattern, high ^{95}Mo shielding is

observed[1,3] in piano-stool compounds, complexes with strong ligands such as CO, phosphite, phosphine etc., and sandwich compounds. The shielding then decreases in the ligand sequence[4] $CN^- > N_2 > NO^+ > NNR^+$ (diazenido)[5] > NNR_2^{2-} (hydrazido)[5] > O-ligands > S-ligands (thiolate-bridged dimers,[6] thiomolybdates etc.) > Se ligands etc.[1] In the polyhapto ring compounds (piano-stool or sandwich) the shielding decreases with increase in ring size, with ring alkylation, and from closed to open π systems of the same hapticity.[7] In Mo–Mo bonded compounds, like ligands being compared, the ^{95}Mo shielding decreases in the sequence Mo—Mo > Mo=Mo > Mo≡Mo > Mo≡Mo (Table 4), in contrast to the well-known C—C > C≡C > C=C sequence in carbon shielding.

The very lowest metal shielding has been observed for the quadruply bonded carboxylate dimers, $[M_2(O_2CR)_4]$, for both molybdenum[8] and tungsten.[9] In ^{95}Mo resonance we have found that attachment of an axial ligand such as pyridine to molybdenum in $[Mo_2(O_2CCF_3)_4]$ decreases the shielding further, whereas in quadruply-bonded compounds of molybdenum with phosphine and halide ligands the ^{95}Mo shielding is several hundred ppm greater than in the carboxylates, as shown in Tables 2 and 3.

DISCUSSION

Spectrochemical and nephelauxetic influences on the metal nucleus shielding

The shielding of the transition-metal nucleus can be related to frontier orbital splittings and to nephelauxetic effects by a ligand field "atom-in-a-molecule" formulation of shielding theory.[10,11] In its simplest form, for comparisons of complexes of the same (high) symmetry:

$$\delta \propto \langle r^{-3} \rangle_d / \Delta E,$$

in which the constant of proportionality subsumes the angular momentum terms which depend on the local electronic symmetry (with unquenching by the magnetic field). The effective excitation energy, ΔE, which is the HOMO–LUMO gap for paramagnetic circulations in the magnetic field, is normally the ligand field splitting, the *d–d* excitations being magnetic dipole allowed. For lower symmetries the imbalance of charge in the valence shell augments paramagnetic circulations (and a summation over two or more terms with appropriate ΔE may be necessary). The radial term $\langle r^{-3} \rangle_d$, the inverse cube of the valence *d*-electron radius, is the one appropriate to a dipolar phenomenon such as magnetism.

Thus the energy term gives a spectrochemical ligand dependence to the metal nucleus shift, and the radial term gives a quasi-nephelauxetic dependence: the deshielding is the greater the smaller the excitation energy, and the closer the paramagnetic circulation to the resonant nucleus.

The high metal shielding observed for the cyclopentadienyl hydrides is clearly related to the very strong ligand field. Particularly interesting is the effect of protonation of $[MoCp_2H_2]$, d^2. This increases the metal shielding by 450 ppm, with removal of the relatively low-energy *d–d* circulation as the *d*-electron lone pair forms a bond to hydrogen (cf. the increase in ^{57}Fe shielding by 1109 ppm from ferrocene to $[FeCp_2H]^+$ in $BF_3 \cdot H_2O$ solvent[12]). The increase in metal shielding may be compared with the increase by 100 ppm or more on protonation of nitrogen in a delocalized system (in pyridine, for example) with removal of the low-energy $n \rightarrow \pi^*$ circulation.[13]

Lower oxidation states. For d^6 octahedral complexes of molybdenum, variation of a ligand Y in $[Mo(CO)_5Y]^q$ complexes[1] produces an approxi-

mate sequence of increase in metal shielding:

$$\text{py} < \text{amines} \sim \text{MeCN} < \text{Cl}^- < \text{S-ligands} \sim \text{Br}^- < \text{I}^- < \text{PPh}_3 < \text{AsPh}_3 < \text{PR}_3 \sim \text{CO} < \text{P(OMe)}_3 \sim \text{SbPh}_3 \quad \text{(range 480 ppm).} \quad (1)$$

{The higher symmetry of $[\text{Mo(CO)}_6]$ influences the position of CO in this series: thus molybdenum is deshielded by 500 ppm in $[\text{Mo}\{\text{P(OMe)}_3\}_6]$[2] relative to $[\text{Mo(CO)}_6]$.} Similarly, comparison of *trans* complexes with a $(\text{dppe})_2$ or related P_4 core produces a sequence:

$$=\text{NNR}_2^{2-} < \text{N}{=}\text{NR}^+ < \text{NO}^+ < \text{N}_2 \lesssim \text{PhCN} < \text{C}_2\text{H}_4 < \text{RNC} < \text{CO} \quad \text{(1600 ppm range).} \quad (2)$$

[Again, effects of symmetry are significant: thus the presence of a chelating phosphine such as dppe may increase the metal shielding by 100–300 ppm relative to corresponding monodentate ligands, in this case $(\text{PPh}_2\text{R})_2$.] For anionic *trans*-ligands in hydrazido(2−), diazenido and nitrosyl phosphine complexes the molybdenum shielding increases as:[5]

$$\text{OPh}^- < \text{Br}^- < \text{SPh}^- \lesssim \text{I}^- < \text{OH}^- < \text{N}_3^- \sim \text{NCO}^- \sim \text{NCS}^- < \text{CN}^- \quad \text{(range 285 ppm).} \quad (3)$$

In piano-stool carbonyl complexes of Mo(II),[14,15] $[\text{MoCp(CO)}_3\text{Y}]$ compounds produce the sequence for the Y ligand:

$$(\text{CMe}{=}\text{CMe}_2)^- < \text{Cl}^- < \text{Br}^- < \text{I}^- < \text{Me}^- < (\text{Hg}/2)^- < \text{MoCp(CO)}_3^- < \text{H}^- < \text{SnMe}_3^- \quad \text{(1240 ppm range)} \quad (4)$$

closely resembling the corresponding series in ^{183}W resonance, with 1640 ppm from Cl^- to SnMe_3^-.[2] If we allow for the deshielding of ^{95}Mo with increase in ring size, and with ring alkylation, the bent sandwich Mo(II) compounds in Table 1 give the series:

$$\text{Cl}^- < \text{MeCN} < \text{CO} < \text{PMe}_3 < \text{H}^- \quad \text{over a 750 ppm range.} \quad (5)$$

In each series the ordering shows an overall resemblance to the spectrochemical series (small ΔE corresponding to low shielding) *insofar as ligating atoms from the same row of the Periodic Table are being compared.* A notable difference from the spectrochemical ordering is the high position of ligands from lower rows of the Periodic Table. The metal shielding increases as Cl < Br < I, P < As < Sb, C ≪ Sn etc. (cf. Kidd's "normal halogen dependence"[16]), sequences related to increase in the radial term $\langle r^{-3}\rangle_d$, and to increase in polarizability and nephelauxetic effects with increase in size of the ligating atom. These relationships have been the subject of long discussion for many transition nuclei, notably ^{59}Co, ^{51}V etc.[10,11,16,17] With the heaviest ligating atoms relativistic (spin-polarization) effects are significant, acting in the same direction as nephelauxetic effects.[11]

Within a series for a particular ligating atom, also, a "spectrochemical" sequence may be evident, such as $\text{PPh}_3 < \text{PR}_3 < \text{P(OR)}_3$ (over a range of 120 ppm) in series (1), with increase in π-acceptor ability. The piano-stool $[\text{MoCp(CO)}_2\text{S}\frown\text{S}]$ compounds,[14] however, follow an opposite sequence, $\text{S}_2\text{P(OEt)}_2^- < \text{S}_2\text{CSEt}^- < \text{S}_2\text{CNR}_2 < \text{S}_2\text{COEt}$ (over a range of 220 ppm), perhaps because of an increase in π-donor ability and nephelauxetic effect. A similar sequence is observed for Mo(0) $[\text{Mo(CO)}_4\text{S}\frown\text{S}]^-$ compounds, though with indications of the opposite sequence in the corresponding pentacarbonyl compounds (both over a smaller range).[18]

It needs to be pointed out that effects of the energy term (ligand field splittings, in the present instance) and of the radial term are likely to reinforce, for comparisons of ligating atoms from the same row of the Periodic Table, although (as is better known) they are in opposition for ligating atoms from different rows. Ligand field splittings depend strongly on the ligating atom, increasing as[19] I < Br < Cl < S < F < O < N < C < H, and Se < S < O (although N < P ~ As, since back-bonding increases the splitting). Nephelauxetism in optical spectroscopy is related to decrease in electron repulsion parameters, corresponding to decrease in $\langle r^{-1}\rangle_d$.[19] It tends to increase (with decrease in electronegativity of the ligand) across the row of the ligating atom as F < O < N < C, but down the group, Cl < Br < I etc. The difference in the two periodicities has been obscured by the historical development of the field.[10] The early reports were of linear δ/λ (*d–d*) relationships, and only subsequently was it discovered that heavier ligands gave lines of decreased slope, corresponding to decrease in $\langle r^{-3}\rangle_d$ terms. In practice the slopes of the lines for ligating atoms from the same row are commonly determined by "spectrochemical" effects reinforced by nephelauxetism.[10,11] Some quantification of nephelauxetic effects on ^{59}Co shielding in terms of electron repulsion parameters has now been initiated.[20]

Polyhapto organo-ligands. It would be particularly helpful if light could be thrown on nephelauxetic and spectrochemical effects of polyhapto organic

ligands, since *d–d* bands in the electronic spectra are frequently masked by strong charge-transfer bands. Tsuchida *et al.*[21] derived the sequence of increase in hypsochromic effect (ligand field strength) Bz < Cp^- < CO from the electronic absorption spectra of chromium complexes (also PhNC < MeNC < CN^- < CO). Comparisons of sandwich or piano-stool complexes with a variety of polyhapto ligands shows that the ^{95}Mo shielding decreases with increase in ring size, with alkylation of the ring, from closed to open π systems (with the same hapticity) and with extension of the π-system.[3,7] Further information is available from comparisons of metal and ligand shielding, excitation and ionization energies, substituent effects etc.[3] In some of these comparisons it seems likely that spectrochemical and nephelauxetic effects may be opposed (even though the ligating atom is carbon in each case). Thus increase in ring size disfavours the forward bonding (as the $2p\pi$ HOMO energies drop below *d*-orbital energies), decreasing the ligand field splitting and the metal shielding. On the other hand, ring enlargement favours the back-bonding (as the $2p\pi^*$ LUMO energies approach the *d*-orbital energies) with increased nephelauxetic effect.

Higher oxidation states. Fairly low shielding is observed for Mo(VI) in molybdates, decreasing sharply in the sequence $[MoO_4]^{2-}$ > $[MoS_4]^{2-}$ > $[MoSe_4]^{2-}$ over a range of 3150 ppm, as the low-energy absorption moves to longer wavelengths in the visible spectrum. Although the formal configuration is d^0, the shielding is still dominated by *d–d* circulations, with ligand-to-metal $(\sigma+\pi)$-delocalization (as demonstrated in explanation of the temperature-independent paramagnetism and electronic spectra of $[MnO_4]^-$ and related ions,[22] and the ^{17}O shielding pattern in these tetroxo species[23]). Large differences in shift are commonly found when ΔE values are small, as relatively small differences bulk large.

The very low shielding observed for quadruply-bonded Mo(II), as in Tables 2 and 3, can be related to small *d–d* excitation energies and to considerable asymmetry of charge in the valence shell which also broadens the lines. The decrease in molybdenum shielding from the phosphine halides to the carboxylates follows the "spectrochemical" ordering, as does the deshielding with increase in acid strength. Among the phosphine halides the increase in molybdenum shielding Cl^- < Br^- < I^- (over a range of 90 ppm) is a quasi-nephelauxetic order, but relativistic effects of the heavier halogens are implicated[24] since much of the increase is from the bromide to the iodide. The failure to observe a resonance for $[Mo_2Cl_4(dmpe)_2]$ is explained by the paramagnetism of this compound, in which the small bite of the bridging ligand induces a twist angle of 40° from the eclipsed position.[25]

In the M≡M orbital ladder ($\sigma < \pi < \delta < \delta^* < \pi^* < \sigma^*$) magnetically active excitations are of $\sigma \leftrightarrow \pi$, $\pi \leftrightarrow \delta$ (etc.) type. Rather little is known of these as they are likely to be overlaid by stronger (electric dipole allowed) transitions, but some $\delta \rightarrow \pi^*$ transitions have been assigned.[26,27] At the same time, quite good δ/λ relationships may be found between nuclear magnetic shielding and $(\Delta E)^{-1}$ values for magnetically inactive excitations when these vary in parallel with the active ones (as found for ^{17}O shielding in transition-metal tetroxo compounds.[23]) Such correlations are evident in Tables 2 and 3. As the ^{95}Mo shielding in the phosphine halides decreases, so does the energy of all the electronic spectral bands[28] and of the δ and π p.e. bands,[29] and also the ^{31}P shielding. For the carboxylate dimers the relationships are more complex. The ionization energy of the δ and π bands increases[30] as the ^{95}Mo shielding decreases, both within the series (with increase in inductive effect of the carboxylate) and relative to the phosphine halides. The latter increase is evident also in the SCF-Xα-SW calculated energies, which however indicate a decrease for the σ-Mo—Mo orbital ionization energy from phosphine halide to carboxylate,[27,29] decreasing $\sigma \leftrightarrow \pi$ and $\sigma \leftrightarrow \delta$ excitation energies.

The addition of two axial pyridine ligands to the trifluoroacetate dimer lengthens the Mo≡Mo bond (from 2.09 to 2.13 Å), and lowers the Mo≡Mo stretching frequency (from 397 to 367 cm^{-1}).[31] At the same time the low-energy absorption goes to longer wavelengths as the orbital overlap and splitting are reduced, and the ^{95}Mo shielding decreases by over 300 ppm as shown in Table 3. These are corresponding indications of decrease in ^{95}Mo shielding with better-coordinating solvents, e.g. from chlorinated solvents or toluene to thf.

Deshielding of ^{95}Mo *with increase in metal–metal bond order*

According to Table 4, if due regard is paid to the influence of the ligands in question (albeit bridging[6,32,33] or semi-bridging in some examples), it seems likely that the ^{95}Mo shielding decreases steadily with increase in bond order (from 1 to 4) in metal–metal bonds. This sequence seems reasonable in view of the decrease in overlap from σ- to π- to δ-orbitals, and the decrease in electronic symmetry with increase in multiplicity (indeed, the linewidths tend to increase in this sequence).

Particularly interesting is the contrast with ^{13}C resonance, since alkyne carbon is much more highly shielded than alkene carbon. The chemical shifts are

Table 4. Dependence of ^{95}Mo shielding on Mo–Mo bond order

6, 123 and 72 ppm, respectively, for C_2H_6, C_2H_4 and C_2H_2. There is, however, a special reason for high shielding in alkynes, since the C_∞- or D_∞-symmetry allows of free diamagnetic circulation about the bond axis.[34] This is not possible in transition-metal complexes because of the higher coordination number.

EXPERIMENTAL

^{95}Mo measurements were made when possible on a JEOL FX90Q spectrometer, with a pre-acquisition delay of 0.5 ms to reduce the effects of probe ringing. Typical repetition times were of the order of 0.2 s. Higher sensitivity was needed for the quadruply-bonded compounds because of the broader lines and insufficient solubility, and for these a Bruker WH400 spectrometer was used. Manipulation of most of the compounds was carried out in the absence of oxygen, usually under nitrogen.

Acknowledgements—We thank Drs J. N. Verpeaux, V. Patel and A. Izquierdo and Mr S. K. Habron for the loan of samples, Dr J. C. Green for counsel, Drs E. Curzon and O. W. Howarth for spectra run on the WH400 spectrometer at Warwick University, and the S.E.R.C. for the provision of the high-field spectrometer.

(*Received* 17 *June* 1985)

Abstract—EPR spectra of fluid and frozen toluene solutions of $MoOLX_2$, where L = hydrotris(3,5-dimethylpyrazolyl(borate), and X = Cl, SEt, OMe or NCS, at both *X*- and *Q*-band frequencies, have been simulated on the basis of C_s-symmetry for the molecules. The non-coincidence of the *g*- and *A*-tensor axes are discussed in terms of the probable *d*-orbital mixings caused by the low-symmetry ligand fields in these molecules.

The point symmetry of a metal complex determines which metal *d*-orbitals are allowed to intermix. Such intermixing will determine whether or not the principal axes of the *g*- and metal ion *A*-tensors coincide. Complexes with no symmetry elements (C_1) or with an inversion centre (C_i) are *not required* to have any of the principal *g*- or *A*-tensor axes coincident, whilst those with a two-fold axis (C_2), or a mirror plane (C_s) or with C_{2h} point symmetries are *required* to have *one* of the principal *g*- and *A*-tensor axes coincident. A group of complexes which conform, or very closely approximate, to the C_s point group are $MoOLX_2$ where X = Cl, SEt, OMe or NCS, and L = the tridentate anion, hydrotris(3,5-dimethylpyrazolyl)borate. The mirror plane includes the molybdenum, the terminal oxo atom, and the nitrogen atom of the ligand L which is *trans* to the oxo group. The mirror plane bisects the X—Mo—X angle. In the case of X = NCS in the solid state the existence of a mirror plane in the molecule is a crystallographic requirement.[1]

EPR spectra of frozen toluene solutions of each of the above complexes at both *X*- and *Q*-band frequencies have been successfully simulated on the basis of C_s-symmetry. In this symmetry the axes of the coincident *g*- and *A*-tensor elements are *required* to be perpendicular to the mirror plane. The spectrum simulations were achieved via the spin-Hamiltonian eqn [(1)] and using methods based on those outlined previously:[2,3]

$$\mathcal{H} = \beta H(g_{xx}\hat{S}_x + g_{yy}\hat{S}_y + g_{zz}\hat{S}_z) + A_{XX}\hat{S}_X\hat{I}_X + A_{YY}\hat{S}_Y\hat{I}_Y + A_{ZZ}\hat{S}_Z\hat{I}_Z, \quad (1)$$

where the axes of the *g*-tensor (*x*, *y*, *z*) may not coincide with the axes of the *A*-tensor (*X*, *Y*, *Z*). The simulations in general use the parameters g_{xx}, g_{yy}, g_{zz}, A_{XX}, A_{YY} and A_{ZZ}, and the three Euler[4] angles, α, β and γ which are used to transform the *A*-tensor into the *g*-tensor axis system (in the case of C_s-symmetry only α is needed). In addition to the *g* and *A* tensor elements the principal linewidth parameters W_{xx}, W_{yy} and W_{zz} with axes coincident with the *g*-tensor axes are also included. Values of the parameters to give best fits (by eye) are given in Table 1. It should be noted that erroneous values of A_{ii} may be obtained in these low-symmetry compounds if the observed splittings between the hyperfine lines are used directly from either the *X*- or *Q*-band spectra. For example, for $MoOLCl_2$ direct measurement from the *X*-band spectrum gives A_{ZZ} = 74 G and A_{XX} = 76 G, whereas the simulation requires 78 and 42 G, respectively. Thus in this case a casual interpretation of the spectrum suggests that the *A* values are nearly axially symmetric but in a completely different sense from that obtained from the simulated spectrum.

					(40.1)	(83.2)	(39.6)			

[a] Values in parentheses are in G.
[b] Single-crystal data from Ref. 5.

An example of a complex which only approximates to C_s-symmetry, but which is strictly C_1-symmetry, is $MoOCl_3(hmpa)_2$, where hmpa = tris(dimethylamino)phosphineoxide. Diluted single-crystal EPR studies[5] on this compound revealed a total lack of coincidence between the principal g and A tensor axes (see Table 1). However, the principal values of the A tensor were close to metal ligand directions and in particular the largest value of A, A_{ZZ}, was nearly coincident with the terminal Mo=O vector. For this reason, and also by analogy with higher-symmetry systems,[6,7] in the present compounds we assign the largest hyperfine values to A_{ZZ} with the Z-axis parallel to Mo=O. In Table 1 the direction perpendicular to the mirror plane is chosen as the coincident y- and Y-axes.

In C_s-symmetry, with the y-axis as specified above, the allowed d-orbital mixings are:

$$\begin{aligned}
\phi_1 &= a_1 d_{x^2-y^2} + b_1 d_{xz} + c_1 d_{z^2},\\
\phi_2 &= a_2 d_{x^2-y^2} + b_2 d_{xz} + c_2 d_{z^2},\\
\phi_3 &= e_3 d_{xy} + f_3 d_{yz},\\
\phi_4 &= e_4 d_{xy} + f_4 d_{yz},\\
\phi_5 &= a_5 d_{x^2-y^2} + b_5 d_{xz} + c_5 d_{z^2}.
\end{aligned} \tag{2}$$

Assuming ϕ_1 to be the groundstate for these d^1 systems then the separation between ϕ_1 and any other orbital ϕ_i ($i = 2, 3, 4$ or 5) is defined as Δ_i. The relationship between the orbital mixings and the g- and A-tensor elements can be derived using Abragam and Bleaney's[8] perturbation equation. Working in a diagonal A-tensor axis framework, and ignoring terms in $\xi P/\Delta_i$ in the A-tensor elements, enables us to make a semi-quantitative estimate of some of the orbital mixing coefficients. ξ is the metal single electron spin–orbit coupling constant and $P = g_e g_n \beta_e \beta_n \langle r^{-3} \rangle$. For example, in $MoOL(NCS)_2$ the very small value of g_{xz} (= −0.009) coupled with the near equality of A_{YY} and A_{XX} require c_1 to be essentially zero and $b_1 \ll a_1$. Values of $a_1^2 = 0.9999$, $b_1^2 = 0.0001$ and $c_1^2 = 0.0000$ and $P = -39 \times 10^{-4}$ cm^{-1} give $A_{ZZ} = 67.8(67.8) \times 10^{-4}$ cm^{-1}, $A_{XX} = 33.9(30.0) \times 10^{-4}$ cm^{-1}, $A_{YY} = 34.0(30.8) \times 10^{-4}$ cm^{-1}, $A_{XZ} = -0.016(0.000) \times 10^{-4}$ cm^{-1}, where the values in parentheses are the experimental values. Thus in the case of the thiocyanato compound the groundstate is almost entirely composed of the metal $d_{x^2-y^2}$-orbital. The rotation of the g-tensor axes from those of the A-tensor has its origin in the d-orbital mixing in ϕ_3 and ϕ_4. Under the action of spin–orbit coupling this mixing causes g_{xz} to be non-zero. The mixing in ϕ_3 and ϕ_4 has been related[9] to the angle α. Using the criterion in Ref. 9, and on the basis of the sign of our g_{xz}, we would expect $\phi_3 = 0.891 d_{xy} + 0.454 d_{yz}$ and $\phi_4 = -0.454 d_{xy} + 0.891 d_{yz}$. As pointed out previously[9] this large amount of mixing implies that ϕ_3 and ϕ_4 are fairly close in energy. The similarity in the angle α required in the spectrum simulation for each of the compounds studied suggests a similar degree of d-orbital mixing in ϕ_3 and ϕ_4 in all of them. Furthermore, the relatively small anisotropies in g_{xx} and g_{yy}, and in A_{XX} and A_{YY}, indicate that the groundstate of each compound almost exclusively involves only $d_{x^2-y^2}$ of the metal d-orbitals. These conclusions imply that the MoOL moiety is the dominant factor in determining the part of the electronic structure which influences the EPR behaviour of each of these compounds.

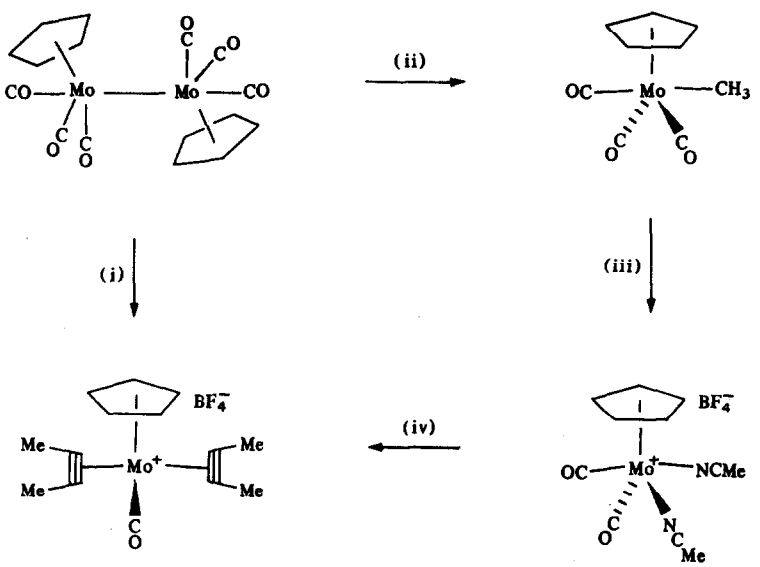
MOLYBDENUM-CENTRED CARBON–CARBON BOND FORMATION REACTIONS

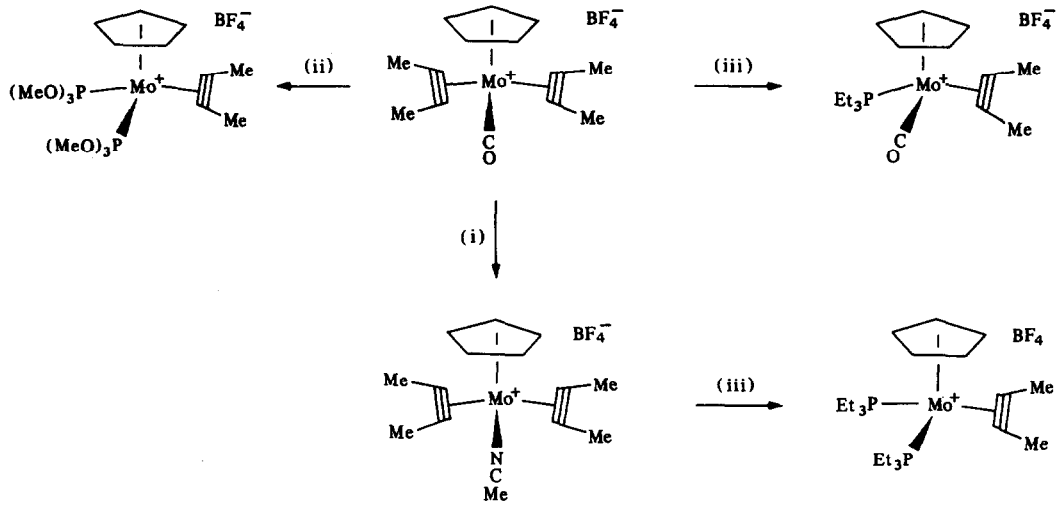
MICHAEL GREEN

Department of Inorganic Chemistry, School of Chemistry, University of Bristol, Bristol BS8 1TS, U.K.



(*Received* 19 *June* 1985)

Abstract—The chemistry of the bisalkyne molybdenum complexes $[Mo(L)(\eta^2\text{-}RC_2R)_2(\eta\text{-}C_5H_5$ or $\eta^5\text{-}C_9H_7)][BF_4]$ (L = CO or MeCN) is described. The reaction of the carbonyl cation with *o*-diphenylphosphinostyrene affords an alkyne–alkene complex which is transformed into a 1,3-diene complex in refluxing MeCN via C—C bond formation and a 1,3-H shift, whereas the acetonitrile species with cyclo-octatetraene and cyclo-heptatriene undergo $(6+2)\pi$ addition reactions with the co-ordinated alkyne. Addition of one electron to the acetonitrile cation leads to novel alkyne-linking reactions at two molybdenum centres.



Recently[1] we have been exploring the chemistry of an interesting group of cationic alkyne molybdenum complexes in which the alkyne functions as either a three- or a four-electron donor. The starting point for our investigation was the molecule

$$[Mo(CO)(\eta^2\text{-}MeC_2Me)_2(\eta\text{-}C_5H_5)][BF_4]$$

(Scheme 1), which was readily available from the redox cleavage of the Mo—Mo bond present in $[Mo_2(CO)_6(\eta\text{-}C_5H_5)_2]$ with $AgBF_4$ in the presence of but-2-yne. An alternative synthesis which can be extended to alkynes carrying reactive functional groups such as $SiMe_3$,[2] makes use of the lability of the cation *cis*-$[Mo(NCMe)_2(CO)_2(\eta\text{-}C_5H_5)][BF_4]$, and has the advantage that it avoids the use of expensive silver salts. The methodology can be readily extended to allow easy access to the more reactive corresponding η^5-indenyl complexes.

Scheme 1. (i) $AgBF_4$, CH_2Cl_2, MeC_2Me; (ii) Na–Hg, MeI; (iii) $HBF_4 \cdot Et_2O$, CH_2Cl_2, −78°C, MeCN; (iv) MeC_2Me, CH_2Cl_2.

Scheme 2. (i) Reflux MeCN; (ii) $P(OMe)_3$, CH_2Cl_2; (iii) PEt_3, CH_2Cl_2.

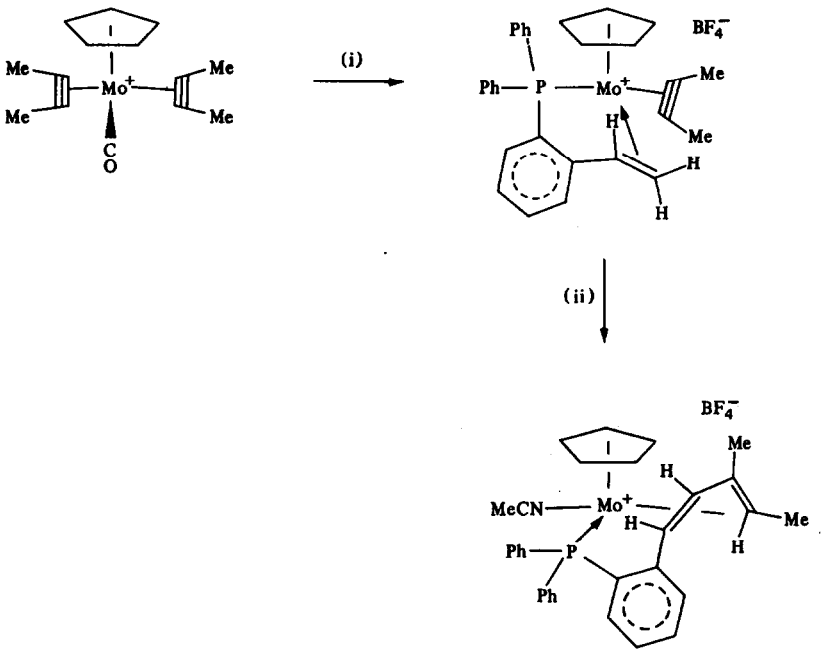
These monocarbonylbis(alkyne) complexes are reactive towards donor ligands. In refluxing acetonitrile in the presence of but-2-yne the remaining carbon monoxide is readily displaced by acetonitrile forming a member of a potentially interesting group of molecules,

$$[Mo(NCMe)(\eta^2\text{-}MeC_2Me)_2(\eta\text{-}C_5H_5)][BF_4]$$

(Scheme 2). Trimethylphosphite also reacts rapidly with this cation at room temperature, but this leads instead to displacement of both carbon monoxide and one of the co-ordinated alkynes: generalization of this reaction provides access to the cations

$$[Mo\{P(OMe)_3\}_2(\eta^2\text{-}RC_2R)(\eta\text{-}C_5H_5$$

or $\eta^5\text{-}C_9H_7)][BF_4]$ where the alkyne is a four-electron donor to the molybdenum centre. The corresponding bisphosphine-substituted monoalkyne cations can only be synthesized by reacting the acetonitrile complexes with a phosphine, the reaction of



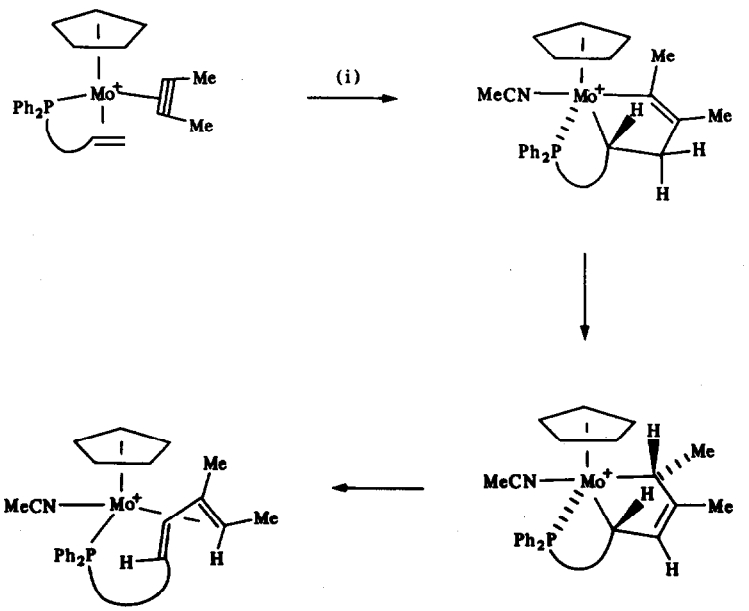
$$[Mo(CO)(\eta^2\text{-}RC_2R)_2(\eta\text{-}C_5H_5)][BF_4]$$

with PR_3 affording the asymmetric cations

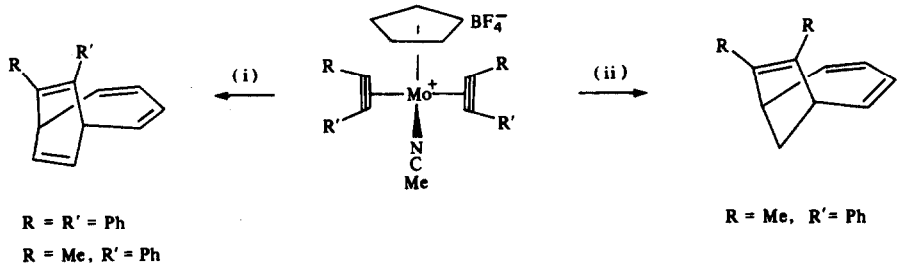
$$[Mo(CO)(PR_3)(\eta^2\text{-}RC_2R)(\eta\text{-}C_5H_5)][BF_4].$$

When this type of reaction was extended to *o*-diphenylphosphinostyrene an interesting cation was obtained which was thought from examination of the NMR spectra to contain a co-ordinated alkene and a four-electron alkyne[3] (Scheme 3). This was confirmed by X-ray crystallography which showed that the molybdenum atom is bonded to an $\eta\text{-}C_5H_5$, an η^2-bonded but-2-yne, and a chelating *o*-diphenylphosphinostyrene ligand, where the C—C vectors of the co-ordinated alkyne and alkene lie essentially parallel to the Mo—P axis. This is a potentially interesting molecule since it has been suggested[4–6] that oxidative coupling of co-ordinated alkynes and alkenes to form a metallacyclopenta-2-ene is a key step in the metal-catalysed cyclocotrimerization of alkynes and alkenes. When this cation was heated under reflux in acetonitrile solution an orange crystalline complex was formed, which was identified by X-ray crystallography as the illustrated 1,3-diene complex (Scheme 3). Examination of the solution NMR spectra showed the existence of two conformational isomers differing only in the orientation of the 1,3-diene relative to the $Mo(NCMe)(P)(\eta\text{-}C_5H_5)$ fragment. Thus, co-ordination of acetonitrile appears to promote oxidative coupling of the co-ordinated alkyne and alkene: however, this is then followed by an apparent 1,3-hydrogen shift affording the 1,3-diene cation (Scheme 4). It is interesting to note that some years ago Pauson and Khand[7] reported that alkenes carrying strong electron-withdrawing groups (CN and CO_2Et) react with the transversely bonded alkyne complex $[Co_2(\mu\text{-}PhC_2H)(CO)_6]$ to give conjugated 1,3-dienes, a reaction which resembles in some respects the processes which occur at a molybdenum centre.

In view of these observations we then examined the reaction of the labile bisalkyne acetonitrile molybdenum cations with cyclo-octatetraene and cycloheptatriene in the belief that we might see analogous behaviour to that found with the *o*-diphenylphosphinostyrene system. However, when the cations $[Mo(NCMe)(\eta^2\text{-}PhC_2Ph)_2(\eta\text{-}C_5H_5$ or $\eta^5\text{-}C_9H_7)][BF_4]$ are reacted with an excess of cyclo-octatetraene in refluxing acetonitrile an organic compound is formed which was identified as a



Scheme 3. (i) *o*-Diphenylphosphinostyrene, (ii) reflux MeCN.



substituted bicyclo[4.2.2]decatetraene.[8] Both the η-cyclopentadienyl and the corresponding η^5-indenyl cations are catalysts for the transformation of diphenylacetylene and cyclo-octatetraene into the decatetraene. The catalytic reaction could also be extended to the synthesis using phenylprop-2-yne, and, significantly, an analogous reaction occurred between

$$[Mo(NCMe)(\eta^2\text{-}PhC_2Me)_2(\eta\text{-}C_5H_5)][BF_4]$$

and cycloheptatriene affording a bicyclo[4.2.1]nona-2,4,7-triene (Scheme 5). Thus, these observations suggest that a formally forbidden $6\pi_s + 2\pi_s$ reaction is occurring at a molybdenum centre, and it is

Scheme 4. (i) Reflux MeCN.

Scheme 5. (i) Alkyne + C_8H_8, reflux MeCN; (ii) alkyne + C_7H_8, reflux MeCN.

possible that this involves a stepwise rather than a concerted addition of the alkyne to co-ordinated C_8H_8 or C_7H_8. Recently, it has been reported[9] that norbornadiene(cycloheptatriene)ruthenium(0) reacts with ethyne in a stoichiometric reaction to afford norbornadiene(bicyclo[4.2.1]nona-2,4,7-triene)ruthenium(0).

In contrast, when the but-2-yne complex

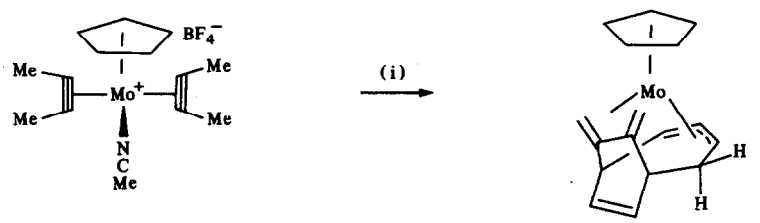
$$[Mo(NCMe)(\eta^2\text{-}MeC_2Me)_2(\eta\text{-}C_5H_5)][BF_4]$$

was reacted in an analogous manner with C_8H_8 in MeCN a *neutral* air-stable crystalline molybdenum complex was formed. An X-ray crystal structure determination revealed that a complex C_{12} ligand had been formed by formal $(6+2)\pi$ addition of but-2-yne to co-ordinated C_8H_8, but, instead of a 7,8-disubstituted bicyclo[4.2.2]decatetraene being displaced, as happens with the corresponding reactions of PhC_2Ph and PhC_2Me, hydrogen migration occurs *via* the metal, followed by proton loss to give a complex containing η^4-1,3-diene and η^3-allyl ligands (Scheme 6).

This type of molecule had not been obtained before and it was obviously interesting to examine the reactivity towards protons. Addition of CF_3SO_3H in CH_2Cl_2 to the η^5-indenyl species gave dark brown crystals of

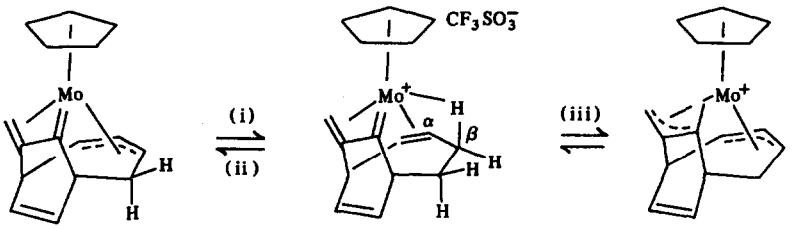
$$[Mo(C_{12}H_{14})(\eta^5\text{-}C_9H_7)][CF_3SO_3]$$

showing a high-field ^1H NMR signal (−80°C, CD_2Cl_2) at −7.83 ppm. A low-temperature X-ray structural analysis showed the cation geometry illustrated in Scheme 7. Protonation has occurred at one of the terminal allyl carbons transforming the η^3-allyl moiety into an alkene. The resultant unsaturation at the molybdenum centre is then relieved by an agostic *endo*-C–H interaction.[10] This interaction models the initial stage (**B** in Scheme 8) of a metal-assisted 1,3-hydrogen shift.[11] In this context it is interesting to note the shortening of the allylic C–C bond [to 1.471(8) Å] *prior* to C–H bond cleavage, and the non-planar geometry of the four-centre Mo–C_α–C_β–H system [dihedral angle 27(3)°]. This latter feature is in marked contrast to other β-agostic interactions, where M–C_α–C_β–H angles are < 17°, but rather close to that in $[IrCl(PPh_3)_2(\eta^3\text{-}C_3H_4Ph)(H)]$,[12] a model for **C** in Scheme 8. It is interesting that in solution at room temperature a dynamic process occurs, which involves reversible transfer of the agostic hydrogen to an end carbon of the 1,3-diene system (see Scheme 7).



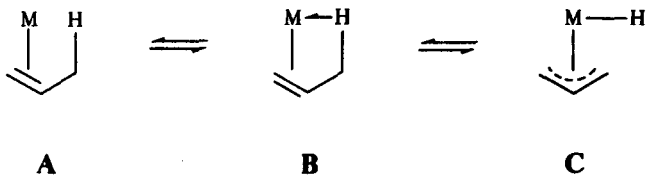
When the cation

$$[Mo(NCMe)(\eta^2\text{-}MeC_2Me)_2(\eta\text{-}C_5H_5)][BF_4]^1$$



is reacted with Na or Mg amalgam, or $Na[Fe(CO)_2(\eta\text{-}C_5H_5)]$ in tetrahydrofuran (THF) an apparent one-electron reduction occurs, resulting in the formation of an octamethyloctatrienediylidenedimolybdenum complex

$$[Mo_2\{\mu\text{-}(\eta^1,\eta^3,\eta^2,\eta^3,\eta^1\text{-}C_8Me_8)\}(\eta\text{-}C_5H_5)_2]$$



where the C_8 chain begins and ends with σ-bonds to one molybdenum.[13,14] This reaction is interesting in the context of the Reppe synthesis[15] of [8] annulene, cyclo-octatetraene, where a nickel salt catalyses the cyclotetramerization of ethyne. Remarkably, despite the advances which have been made in the last 40 years in organometallic chemistry, we still do not

Scheme 6. (i) + C_8H_8, reflux MeCN.

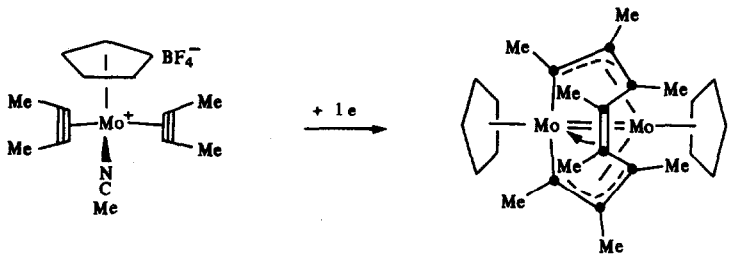
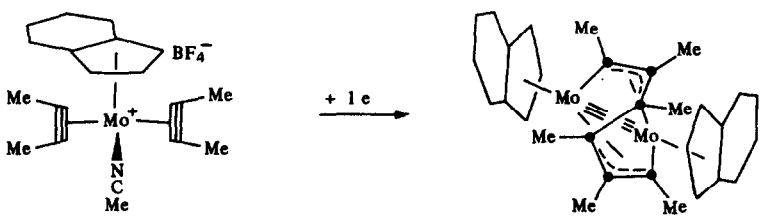


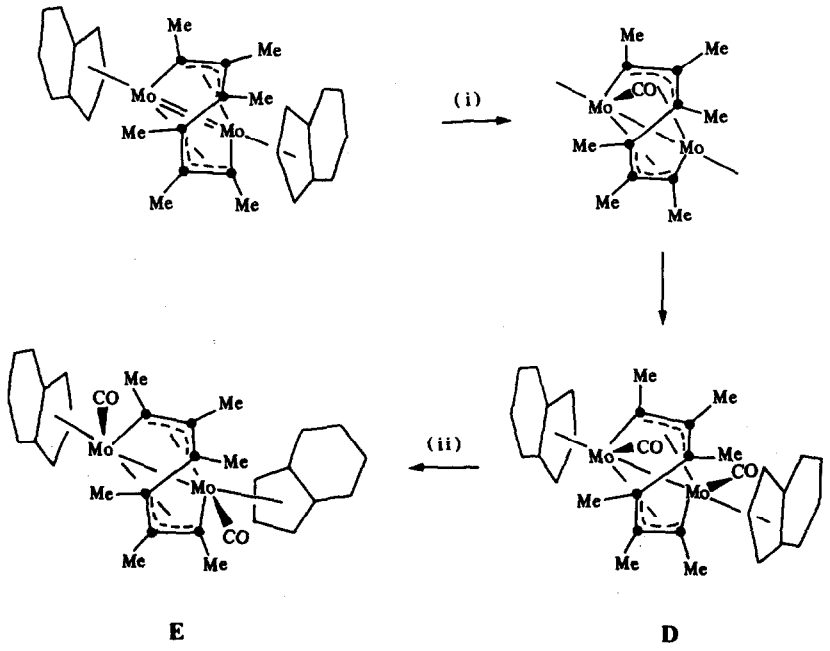
Scheme 8. Metal-mediated alkene isomerization.

understand the mechanism[16] of Reppe's reaction. Recently attention has focused on reaction pathways which involve the linking of ethyne molecules at two adjacent metal centres.[17,18] Hence the interest in the reaction illustrated in Scheme 9.



When a THF solution of the indenyl analogue

$[Mo(NCMe)(\eta^2\text{-}MeC_2Me)_2(\eta^5\text{-}C_9H_7)][BF_4]$



was reacted with a suspension of Na or Mg amalgam a green crystalline air-sensitive material was formed, which was identified by NMR and X-ray crystallography as a three-alkyne "fly-over" complex[19] (Scheme 10) with C_2-symmetry. In contrast, with the molecule $[Mo_2\{\mu\text{-}(\eta^1,\eta^3,\eta^2,\eta^3,\eta^1\text{-}C_8Me_8)\}(\eta\text{-}C_5H_5)_2]$, the three-alkyne "fly-over" complex is reactive towards carbon monoxide, forming a kinetically controlled isomer (**D**) (Scheme 11) at room temperature and the thermodynamic product (**E**) in refluxing hexane. These isomeric dicarbonyl complexes were identified by NMR and X-ray crystallography, and it is interesting that the reaction with carbon monoxide results in a lengthening of the Mo–Mo bond from a triple [Mo(1)–Mo(2) 2.306(2) Å] to a single [Mo(1)–Mo(2) 2.933(1) Å in (**D**)] bond with a consequent uncoiling of the C_6 "fly-over" array.

From studies on the thermal reaction of alkynes with complexes of the type

$$[Mo_2(\mu\text{-alkyne})(CO)_4(\eta\text{-}C_5H_5)_2]$$

it has been suggested that alkynes can sequentially link at two metal centres, and in particular it was proposed that three-alkyne "fly-over" complexes are the immediate precursors of the dinuclear C_8 species.

$$[Mo_2\{\mu\text{-}(\eta^1,\eta^3,\eta^2,\eta^3,\eta^1\text{-}C_8R_8)\}(\eta\text{-}C_5H_5)_2]$$

(R = H, Ph or CO_2Me) (Scheme 12).[18] It was therefore important to examine the reactivity of the structurally characterized three-alkyne "fly-over" complex

$$[Mo_2\{\mu\text{-}(\eta^1,\eta^3,\eta^3,\eta^1\text{-}C_6Me_6)\}(\eta^5\text{-}C_9H_7)_2]$$

towards but-2-yne. Since the octamethyl dimolybdenum complex

$$[Mo_2\{\mu\text{-}(\eta^1,\eta^3,\eta^2,\eta^3,\eta^1\text{-}C_8Me_8)\}(\eta\text{-}C_5H_5)_2]$$

is formed rapidly at room temperature then it might be expected that, if the cyclopentadienyl analogue of the C_6 "fly-over" complex was indeed a precursor of

$$[Mo_2\{\mu\text{-}(\eta^1,\eta^3,\eta^2,\eta^3,\eta^1\text{-}C_8Me_8)\}(\eta\text{-}C_5H_5)_2],$$

then the η^5-indenyl complex should rapidly react with but-2-yne, and it would be expected that this reaction would be facilitated from slippage (η^5 to η^3) of the indenyl ligand. However, the three-alkyne "fly-over" proved to be unreactive towards but-2-yne. Thus suggests that, in the case of the methyl-substituted systems, three-alkyne "fly-over" complexes and octatrienediylidenedimolybdenum species are *not* formed sequentially, but instead arise from competitive reaction pathways which are available to some earlier intermediates in the reaction sequence.

CYCLIC CARBENE COMPLEXES OF THE TYPE *cis*-MI[$\overline{CN(Me)(CH_2)_nCH_2}$](CO)$_2$($\eta$-$C_5H_5$) (M = Mo, n = 2 OR 3; M = W, n = 2): THEIR SYNTHESES AND REACTIONS OF THE MOLYBDENUM SYSTEMS WITH $LiEt_3BH$

VALERIE A. OSBORN and MARK J. WINTER*

Department of Chemistry, The University, Sheffield S3 7HF, U.K.

(*Received* 17 *June* 1985)

Abstract—Treatment of [M(CNMe)(CO)$_2$(η-C_5H_5)]$^-$ with I[CH_2]$_{n+1}$I provides the cyclic carbene species *cis*-MI[$\overline{CN(Me)(CH_2)_nCH_2}$](CO)$_2$($\eta$-$C_5H_5$) (M = Mo, n = 2 or 3; M = W, n = 2), the molybdenum examples of which undergo reaction with $LiEt_3BH$, so forming the compounds *cis*-Mo[η^2-$\overline{CH(CH_2)_{n+1}N(Me)}$](CO)$_2$($\eta$-$C_5H_5$).

Cyclic carbene complexes of the 2-oxacyclopentylidene ligand are well known and available by several synthetic strategies,[1–5] in particular through the reaction of N^- with Mo[$(CH_2)_3X$](CO)$_3$(η-C_5H_5) (X = Br or I) which leads to

trans-Mo(N)(CO)$_2$[$\overline{CO(CH_2)_2CH_2}$]($\eta$-$C_5H_5$)

(N = I, CN or SPh).[6] The first step in this reaction is a migratory insertion of the alkyl group $(CH_2)_3X$ to a *cis* carbonyl induced by the nucleophile N^-, this is followed by a ring-closing reaction of the ensuing anionic acyl. Although there are several examples of carbene synthesis by this type of ring closure reaction for molybdenum there are fewer involving tungsten, owing to the relative difficulty of achieving insertion for [WR(CO)$_3$(η-C_5H_5)] systems.[7]

We recently communicated the synthesis of the five-membered cyclic carbene

cis-MoI[$\overline{CN(Me)(CH_2)_2CH_2}$](CO)$_2$($\eta$-$C_5H_5$)

(**1**) through a related process involving migration of the same $(CH_2)_3X$ alkyl group to the isonitrile of an intermediate

Mo[$(CH_2)_3$I](CNMe)(CO)$_2$(η-C_5H_5).[8]

One interesting feature of the molecule and a related acyclic analogue

MoI[C(NHMe)Me](CO)$_2$(η-C_5H_5)[9]

is their *cis* stereochemistry; all the related

MX(CO)$_2$[C(OR^1)R^2](η-C_5H_5)

(M = Mo or W) complexes are *trans*[10–12] and there is a possibility that any *cis–trans* isomerization is sterically blocked by the methyl group although electronic factors also need to be considered. As complexes of the six-membered ring 2-oxacyclohexylidene are few and far between,[4,13] it is normally necessary to induce ring closure through silver cation assisted halide removal at the acyl stage.[13]

We now report a facile six-membered ring carbene molybdenum complex synthesis, facile synthesis of a tungsten carbene complex through an isonitrile insertion reaction, and preliminary results of reactions of some of these carbene complexes with $LiEt_3BH$.

RESULTS AND DISCUSSION

Addition of I[CH_2]$_4$I to a solution containing[14,15] [Mo(CNMe)(CO)$_2$(η-C_5H_5)]$^-$ gives rise to a dark coloured reaction mixture from which the only isolable product is the spectroscopically characterized

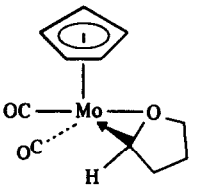
cis-MoI[$\overline{CN(Me)(CH_2)_3CH_2}$](CO)$_2$($\eta$-$C_5H_5$)

(**2**) (21%). The IR spectra of **1** and **2** are very similar, while both ^{1}H and ^{13}C NMR spectra suggest that **2** is very closely related to **1**, differing only in the extra CH_2 in the carbene ring. Complex **2** does not crystallize readily, accounting for the low isolated

* Author to whom correspondence should be addressed.

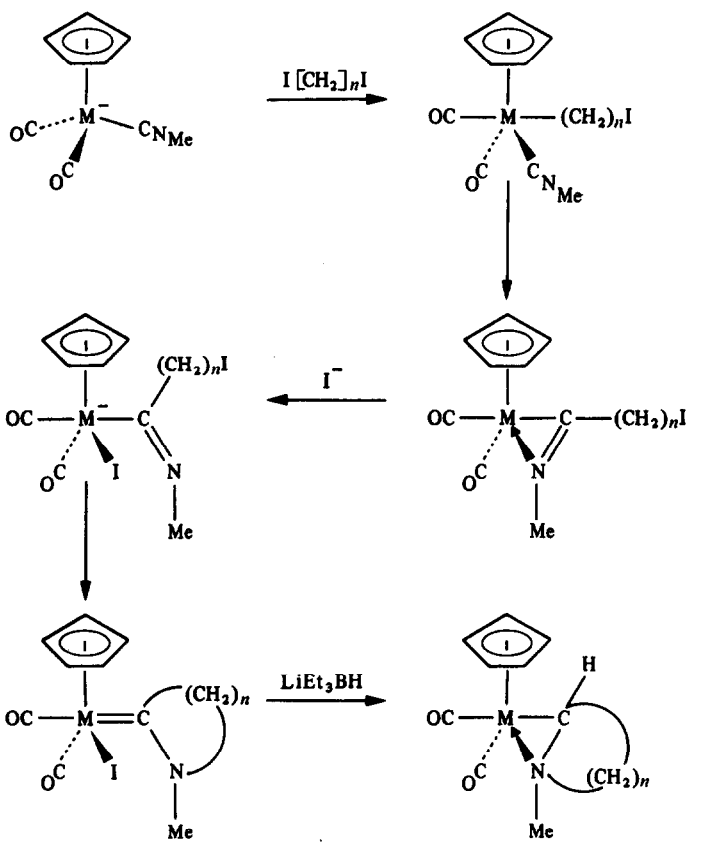
yield, but the reaction itself proceeds rather cleanly, as indicated by the IR spectrum of the reaction mixture. The ease of formation of **2** is accounted for by the ease with which alkyl groups migrate to coordinated isonitrile (Scheme 1).[16–18]

Treatment of a solution containing



$$[W(CNMe)(CO)_2(\eta\text{-}C_5H_5)]^-$$

with $I[CH_2]_3I$ results in a smooth reaction leading after workup to the single product



$$cis\text{-}WI[\overline{CN(Me)(CH_2)_2CH_2}](CO)_2(\eta\text{-}C_5H_5)$$

(3) (65%), whose spectroscopic properties are comparable to those of the molybdenum analogue.[8] In common with similar compound systems the chemical shifts of the carbene and carbonyls are at a somewhat higher frequency than those of the molybdenum analogues, that of the carbene by a considerable amount.[19,20] These signals are assigned by inspection of their $^1J(WC)$ couplings; ^{13}C NMR: $\delta(C_6D_5CD_3)$ 245.1 [s, CO, $^1J(WC)$ 146 Hz], 240.9 [s, W=C, $^1J(WC)$ 101 Hz] and 237.1 [s, CO, $^1J(WC)$ 154 Hz]. The two signals with comparable coupling constants are assumed to arise from carbonyls while the unique signal with a low coupling constant is assigned to the carbene.

We recently communicated the structure of an

4

1 M = Mo, $n = 3$
2 M = Mo, $n = 4$
3 M = W, $n = 3$

5 M = Mo, $n = 3$
6 M = Mo, $n = 4$

Scheme 1.

unusual complex (**4**) arising in the reaction of

trans-MoI(CO)$_2$[$\overline{CO(CH_2)_2\overline{CH_2}}$]($\eta$-$C_5H_5$)

with $LiEt_3BH$.[21] Complexes **1** and **2** undergo related reactions with $LiEt_3BH$. Addition of $LiEt_3BH$ to solutions of **1** or **2** leads to the isolation of, respectively,

Mo(CO)$_2$[η^2-$\overline{CH(CH_2)_3\underline{N}(Me)}$]($\eta$-$C_5H_5$)

(**5**) (36%) or

Mo(CO)$_2$[η^2-$\overline{CH(CH_2)_4\underline{N}(Me)}$]($\eta$-$C_5H_5$)

(**6**) (10%). Both these compounds are fully spectroscopically characterized, in particular the J(HH) coupling constants extracted from the ^{1}H NMR spectrum of **5** are virtually identical to those of **4**, indicating a very similar geometry for the ligated ring system. It is likely that formation of **4** proceeds by direct attack of the hydride reagent at the carbene (followed by loss of I^- as the oxygen atom enters the coordination sphere of the metal) rather than initial coordination at the metal or carbonyl followed by an inter- or intramolecular hydride transfer process.[22] Since we have not attempted to spectroscopically identify any intermediates in these reactions we assume a similar mechanism here.

Compound **4** undergoes O—Mo bond cleavage on attack by PPh_3, resulting in

trans-Mo[η^1-$\overline{CH(CH_2)_3\underline{O}}$](CO)$_2$($PPh_3$)($\eta$-$C_5H_5$).[21]

While one might expect a similar lability for the N—Mo bond of **5** and **6**, in the event neither compound undergoes reaction with PPh_3, even during prolonged heating at reflux in tetrahydrofuran. However reaction is observed for both **5** and **6** with H_2SO_4; thus treatment of **5** with acid results in the rapid decomplexation of the cycle as *N*-methyl pyrrolidine, $\overline{CH_2N(Me)[CH_2]_2\overline{CH_2}}$ (43%) (characterized and quantified by GLC and GC–mass spectrometry), together with formation of unidentified metal species. In a similar fashion H_2SO_4 treatment of **6** results in the evolution of *N*-methyl piperidine, $\overline{CH_2N(Me)[CH_2]_3\overline{CH_2}}$ (54%).

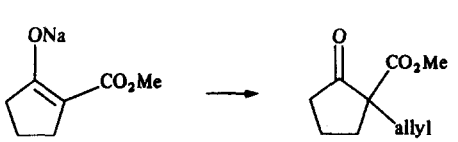
MOLYBDENUM-MEDIATED CARBON–CARBON BOND FORMATION

B. J. BRISDON, D. W. BROWN and C. R. WILLIS*

School of Chemistry, University of Bath, Claverton Down, Bath BA2 7AY, U.K.

(*Received* 19 *June* 1985)



Abstract—Reaction of $(CH_2)_nCH{=}CHCHBr$ (n = 3–5) with sodium pentan-2,4-dionate (Napda) in the presence of catalytic quantities of $Mo(CO)_4$bipyridine leads to high yields of the coupled products $\{(CH_2)_nCH{=}CHCH\}_2$ as mixtures of two diastereoisomers, with little or no alkylated derivative $(CH_2)CH{=}CHCHpda$. Up to 50% of the molybdenum present was recovered as $[MoBr(CO)_2(\eta^3\text{-}CH{\cdots}CH{\cdots}CH(CH_2)_n(bipyridine)]$ in reactions involving 3-bromocyclohexene and 3-bromocycloheptene. η^3-Allyl complexes $[MoX(CO)_2(\eta^3\text{-}C_5H_7O)]$ (where X = Cl or Br), formed by alkoxycarbonylation of the propargyl entity, were also isolated from the reaction of $[MoX(CO)_3(bipyridine)]^-$ anions with propargyl halides in methanol, and yielded dimethyl methylsuccinate on treatment with $NaBH_4$.

Several molybdenum(0) carbonyl derivatives including $Mo(CO)_4$bipy (bipy = bipyridine) have been shown recently to be effective catalysts for allylic alkylation reactions.[1] The intermediacy of metal–allyl species in catalytic cycles has been inferred from the known interaction between allyl halides and some $Mo(CO)_4L_2$ species to yield $[MoX(CO)_2(\eta^3\text{-allyl})L_2]$ (where X = halide)[2] and from stoichiometric reactions, involving attack by a carbon nucleophile on two of these neutral allyl complexes, which yield the same products as the catalytic reactions [eqns (1) and (2)]:

$$Mo(CO)_4L_2 + allylX \rightarrow MoX(CO)_2(\eta^3\text{-allyl})L_2 + 2CO \quad (1)$$

(L_2 = bipy and other N-donor ligands),

$MoCl(CO)_2(\eta^3$-allyl$)L_2$ +

(2)

(L_2 = bipy or bis(diphenylphosphino)ethane).

Although the allyl substituent, the solvent and the nature of L_2 have a marked effect on the reaction in terms of rate and regioselectivity, only alkylated products have been reported as arising from these reactions.[1]

Under only slightly different reaction conditions, we have observed that treatment of $[MoCl(CO)_2(\eta^3\text{-}C_3H_5)bipy]$ with the pentan-2,4-dionate (pda) anion in the presence of pyridine (py) results in ligand exchange with no evidence of nucleophilic attack on the allyl moiety [eqn (3)][3]:

$$[MoCl(CO)_2(\eta^3\text{-}C_3H_5)bipy] + Napda + py \rightarrow [Mo(CO)_2(\eta^3\text{-}C_3H_5)(pda)py] + NaCl. \quad (3)$$

Both the solid-state structure and the dynamic behaviour of the product were reported subsequently.[4] In view of these results, we decided that the generality of the molybdenum-catalysed allylic alkylation reaction required probing. In this paper we describe reactions in which molybdenum catalysed homo coupling rather than alkylation occurs under very similar conditions to those described by Trost and Lautens.[1] We also include a brief account of our preliminary results on the interactions of propargyl halides with molybdenum carbonyl complexes, which also result in new C—C bond formation.

* Author to whom correspondence should be addressed.

RESULTS AND DISCUSSION

In view of the anomolous behaviour of the pda anion, as noted above, we first examined the interaction of this carbanion with the neutral complexes $[MoBr(CO)_2(\eta^3\text{-cyclohexenyl})L_2]$ [L_2 = bipy (**1**) or diphos (**2**)], which were readily prepared by the stoichiometric reaction between $[MoBr(CO)_2(\eta^3\text{-cyclohexenyl})(NCMe)_2]$[5] and the appropriate bidentate ligand in acetonitrile. Using tetrahydrofuran or toluene as solvent, unreacted **1** or **2** could be recovered exchanged even after reaction for several hours under reflux. At higher temperatures (boiling *n*-butylacetate), complex **1** decomposed completely yielding $Mo(CO)_4$bipy and free bipy as isolable products. However, in the presence of py this same complex reacted in boiling tetrahydrofuran to afford $[Mo(CO)_2(\eta^3\text{-cyclohexenyl})(pda)py]$ in high yield. Thus in these stoichiometric reactions between pda and complex **1** or **2**, we obtained no evidence of allylic alkylations resulting from nucleophilic attack on the coordinated cyclic allyl ligand, although attack at the metal centre of **1** could be induced under certain conditions.

We next investigated the reaction of 3-bromocyclohexene with the pda anion both in the presence and absence of $Mo(CO)_4$bipy. In the absence of the molybdenum complex, the expected product 3-(cyclohex-2-enyl)pentan-2,4-dione was formed in *ca* 15% yield after 0.5 h and *ca* 40% yield after 15 h of reaction in refluxing toluene. In the presence of a 10 mol % of $Mo(CO)_4$bipy, reaction in boiling toluene was complete in 0.5 h, but this time the major product (*ca* 60%) was 3,3′-bicyclohexenyl. Reducing the metal complex concentration had no significant effect on the rate or direction of the reaction. Reversed-phase HPLC and ^{13}C NMR spectroscopy established the presence of *dl* and *meso* forms of the bicyclic product, and showed, rather surprisingly, that no significant diastereoselectivity had occurred in the coupling reaction. The alkylated product 3-(cyclohex-2-enyl)pentan-2,4-dione was isolated as a minor component of the reaction mixture. The only inorganic complex which could be recovered from the reaction mixture and identified with certainty was complex **1**, but strong IR evidence for a non-carbonyl-containing molybdenum–pda entity was also obtained. Under similar conditions, but in the absence of Napda, $Mo(CO)_4$bipy reacted with 3-bromocyclohexene to form a complex mixture of organics, together with impure $MoBr_4$bipy. No detectable amount of the allyl complex (**1**) was found in the reaction mixture. Furthermore, reaction of **1** with excess 3-bromocyclohexene in refluxing toluene did not yield 3,3′-bicyclohexenyl, and **1** remained unchanged at the end of the reaction. Thus the pda anion plays a key role in determining both the inorganic and organic products in this molybdenum-catalysed allylic coupling reaction.

In view of the excellent coordinating properties of the pda anion, and the IR evidence referred to above, it is tempting to postulate the intermediacy of metal–pda complex(es) in the catalytic cycle, and indeed greatly reduced yields of 3,3′-bicyclohexenyl were obtained if pda was replaced by a less effective metal-complexing agent such as $[EtO_2CCH_2CO_2]^-$. However, neither $Mo(CO)_4$bipy nor $Mo(CO)_4$ diphos appear to react with Napda in refluxing toluene in the absence of an allyl halide, nor have we been able to isolate a definite pda complex from any of the catalytic reactions. We find that several other molybdenum complexes (Table 1) also catalyse this homo coupling reaction, although less efficiently than $Mo(CO)_4$bipy, and we tentatively suggest that the metal complex facilitates halogen transfer from the cyclohexenyl bromide to the pda anion which is oxidized in the course of the reaction. In most other metal-assisted reductive coupling reactions, the oxidized product is a metal species,[6] although several examples of organic anions acting as a source of hydride in catalytic cycles are documented.[7]

In order to explore the synthetic utility of this facile coupling reaction, we extended our investigations to other cyclic allyl halides, and found that high yields of 3,3′-bicycloalkenes could also be obtained for seven- and eight-membered ring systems (Table 1). As judged by the integrals of well-resolved, like ^{13}C, atoms, the bicycloheptenyl was obtained again as a 1 : 1 mixture of two diastereoisomers, whereas the bicyclooctenyl was isolated in an approximately 5 : 4 mixture. ^{13}C NMR shift values indicate that the double bonds in the latter compound had the *Z*-configuration.

In both the cyclohexenyl- and cycloheptenyl bromide reactions, a significant proportion of the molybdenum present in the reaction mixture (up to 50%) was converted to the $[MoBr(CO)_2(\eta^3\text{-allyl})bipy]$ species. The identity of the allyl complexes (where $n = 3$ or 4) were confirmed by their independent synthesis from $Mo(CO)_3(NCMe)_3$. However, the preformed allyl complex $[MoBr(CO)_2(\eta^3\text{-}\overline{CH\cdots CH\cdots CH(CH_2)_5})(bipy)]$ differed in its spectroscopic properties from those of the molybdenum-containing species isolated after the catalytic cycle involving cyclooctenyl bromide.

In view of the results obtained from $(\overline{CH_2)_n(CH{=}CHCHBr}$ systems, we decided to extend our investigations to $CH{\equiv}CCH_2X$ (X = Cl or Br) in order to determine whether propargyl

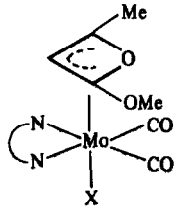


Table 1. Molybdenum-catalysed coupling reactions of $(\overline{CH_2)_nCH{=}CHCH}Br$ (n = 3–5) in the presence of Napda[a]

Metal complex	n	Yield of $\{(CH_2)_nCH{=}CHCH\}_2$ (%)	Yield of $(\overline{CH_2)_nCH{=}CHCH}$pda (%)
$Mo(CO)_4$bipy	3	63	20
$Mo(CO)_6$	3	24	22
[$Mo(CO)_2(\eta^3$-cyclohexenyl)(pda)py]	3	30	23
$Mo(CO)_4$diphos	3	—	45[b]
$Mo(CO)_4$bipy	4	61	12
$Mo(CO)_4$bipy	5	90	—

[b] Reaction time of 2.5 h.

alkylation or coupling reactions could also be effected by molybdenum complexes. Reaction of $CH{\equiv}CCH_2X$ with Napda in the presence of a 10 mol% of $Mo(CO)_4$bipy in refluxing toluene yielded a complex and irreproducible mixture of organics together with molybdenum-containing decomposition products. In the absence of Napda, little reaction occurred in boiling toluene, tetrahydrofuran or dioxan. However, the more nucleophilic $[MoX(CO)_3bipy]^-$ anions reacted cleanly with a methanolic solution of the corresponding propargyl halide to yield a *cis*-dicarbonylmolybdenum complex as an unstable brown solid. Analytical and IR data established that the complex had the composition $[MoX(CO)_2bipy(C_5H_7O_2)]$, and that the coordinated $C_5H_7O_2$ ligand exhibited a strong CO absorption at *ca* 1665 cm^{-1}. It has been shown previously that σ-propargylic molybdenum, tungsten and manganese carbonyl complexes are alkoxycarbonylated in methanol to yield organometallics containing the η^3-2-$MeO_2CC_3H_4$ ligand,[8] but the ^1H NMR data for $[MoCl(CO)_2(bipy)(C_5H_7O_2)]$ (which was of poor quality because of the low solubility of the complex in common solvents), indicate that structure **A** rather than **B** is appropriate for these complexes.

A

B

In an attempt to further define the structure of the $C_5H_7O_2$ ligand, the chloro-complex was reacted with $NaBH_4$ in methanol at −78°C. Column separation of the organic products yielded dimethyl methylsuccinate as the major constituent. Although the mechanism by which this product is formed is unknown, the carbon skeleton of dimethyl methylsuccinate can be readily derived from a complex with structure **A** via hydride attack and CO insertion reactions.

Finally, we would note that, in this two-stage reaction, two new C—C bonds are formed with the overall transformation of a linear three-carbon chain into an isopentane derivative:

$$CH{\equiv}CCH_2X \xrightarrow[NaBH_4 \text{ in MeOH (2)}]{Ph_4P[MoX(CO)_3bipy] \text{ in MeOH (1)}} MeO_2CCH_2CHMeCO_2Me.$$

Further mechanistic and synthetic investigations of this unusual reaction are in progress.

EXPERIMENTAL

All preparations involving metal carbonyl derivatives were performed in an atmosphere of dry N_2 gas using solvents and liquid reagents freed from moisture and oxygen by standard procedures. The starting materials $Mo(CO)_4$bipy, $Mo(CO)_4$diphos, $Ph_4P[MoX(CO)_3(bipy)]$ (where X = Cl or Br) and $(\overline{CH_2)_nCH{=}CHCH}Br$ (where n = 3–5) were prepared by standard literature procedures.[9–11]

IR spectra in the region 200–4000 cm^{-1} were recorded on a Perkin–Elmer 597 spectrophotometer. ^1H and ^{13}C NMR spectra were measured in $CDCl_3$ unless otherwise stated using JEOL PS 100 and FX 90Q FT instruments respectively with $SiMe_4$ as internal standard. Carbon types were identified by the INEPT technique but quoted as if determined by

off-resonance decoupling thus: δ (multiplicity, relative intensity and assignment).

Preparation of

$[MoBr(CO)_2(\eta^3\text{-}\overline{CH{=}CH{=}CH(CH_2)}_n(bipy)]$

(*where* $n = 3$–5)

A solution of $Mo(CO)_6$ (0.528 g, 2×10^{-3} mol) in MeCN (20 cm^3) was heated under reflux for 24 h. To the cooled reaction mixture was added dropwise, with stirring, a solution of the allyl bromide (2×10^{-3} mol) in MeCN (5 cm^3). The resulting suspension of $[MoBr(CO)_2(\eta^3\text{-}\overline{CH\cdots CH\cdots CH(CH_2)}_n)(NCMe)_2]$ was stirred at room temperature with 2,2′-bipy (0.312 g, 2×10^{-3} mol) dissolved in MeCN (5 cm^3). The products were isolated in 64, 77 and 44% yields, respectively, for $n = 3$, 4 or 5 after cooling the reaction mixture in ice for 0.5 h. Found for $[MoBr(CO)_2(\eta^3\text{-}\overline{CH\cdots CH\cdots CH(CH_2)}_3(bipy)]$: C, 46.1; H, 3.8; N, 5.75%. Calc. for $C_{18}H_{17}N_2O_2BrMo$: C, 46.1; H, 3.62; N, 5.97%. ν(CO) (Nujol) 1920 and 1835 cm^{-1}. Found for $[MoBr(CO)_2(\eta^3\text{-}\overline{CH\cdots CH\cdots CH(CH_2)}_4(bipy)]$: C, 47.2; H, 3.80; N, 5.75%. Calc. for $C_{19}H_{19}N_2O_2BrMo$: C, 47.2; H, 3.93; N, 5.80%. ν(CO) (Nujol) 1920 and 1835 cm^{-1}. Found for $[MoBr(CO)_2(\eta^3\text{-}\overline{CH\cdots CH\cdots CH(CH_2)}_5(bipy)]$: C, 48.5; H, 4.40; N, 5.63%. Calc. for $C_{20}H_{21}N_2O_2BrMo$: C, 48.3; H, 4.23; N, 5.63%. ν(CO) (Nujol) 1935 and 1850 cm^{-1}.

Preparation of

$[MoBr(CO)_2(\eta^3\text{-}\overline{CH\cdots CH\cdots CH(CH_2)}_3)(diphos)]$

A mixture of

$[MoBr(CO)_2(\eta^3\text{-}\overline{CH\cdots CH\cdots CH(CH_2)}_3)(NCMe)_2]$

(1.0 g, 2.5×10^{-3} mol) and diphos (1.0 g, 2.5×10^{-3} mol) in MeOH (20 cm^3) was heated under reflux for 0.75 h. The solution was allowed to cool to room temperature whereupon an orange crystalline solid precipitated. The product was collected by filtration, washed with MeOH and dried *in vacuo*. Yield 1.34 g (75%). Found for $[MoBr(CO)_2(\eta^3\text{-}\overline{CH\cdots CH\cdots CH(CH_2)}_3)(diphos)]$: C, 57.6; H, 4.81%. Calc. for $C_{34}H_{33}P_2O_2BrMo$: C, 57.4; H, 4.64%. ν(CO) (Nujol) 1925 and 1830 cm^{-1}.

Preparation of

$[Mo(CO)_2(\eta^3\text{-}\overline{CH\cdots CH\cdots CH(CH_2)}_3)(pda)py]$

A mixture of Napda (0.104 g, 8.53×10^{-4} mol), $[MoBr(CO)_2(\eta^3\text{-}\overline{CH\cdots CH\cdots CH(CH_2)}_3)(bipy)]$ and pyridine (1.5 cm^3) was heated with acetone (5 cm^3) for 15 h during which time the deep red colour of the solution lightened to a pale orange. After cooling, solid NaBr was removed by filtration and the filtrate treated with deaerated water (10 cm^3). Most of the acetone present in the solution was removed with a stream of N_2 gas and the product allowed to crystallize overnight at 0°C. After filtering, the solid was washed with water and dried *in vacuo*. Yield *ca* 50%. Found: C, 52.1; H, 5.20; N, 3.81%. Calc. for $C_{18}H_{21}NO_4Mo$: C, 52.6; H, 5.10; N, 3.41%. ν(CO) (Nujol) 1820 and 1910 cm^{-1}.

Molybdenum-mediated coupling reactions of

$(\overline{CH_2)_nCH{=}CHCH}Br$

(*where* $n = 3$–5)

The general procedure used is illustrated by reference to 3-bromocyclohexene in the presence of Napda and $Mo(CO)_4$bipy. Other reactions were carried out in an analogous manner.

3-Bromocyclohexene (10.1 g, 0.063 mol) was added dropwise to a stirred suspension of $Mo(CO)_4$bipy (5.05 g, 0.014 mol) and Napda (7.66 g, 0.063 mol) in dried oxygen-free toluene. The resulting mixture was stirred and heated under reflux for 0.5 h in an atmosphere of N_2 gas. After cooling, the reaction mixture was filtered and the solvent removed under reduced pressure. The resulting brown oil was chromatographed on 100–200-mesh florisil using hexane as eluant. The product, 3,3′-bicyclohexenyl,[12] was isolated as a colourless oil. Yield 3.22 g (63%). ^{13}C NMR data, mixture of diastereoisomers: 22.4 (t, 49, both C-4s), 25.5 (t, 63, both C-5s), 26.1 (t, 39, both C-6s), 40.3 (d, 45, both C-3s), 127.7 and 128.0 (d, 36, C-1s), and 130.5 and 130.7 (d, 28 and 38, C-2s).

3,3′-Bicycloheptenyl[13] was isolated as a mixture of diastereoisomers in a total yield of 61%. ^{13}C NMR data: 27.0 (t, 97, both C-6s), 28.9, 30.6, 31.2, 31.4 and 31.5 (t, 61, 55, 43, 48 and 61, C-4s, C-5s and C-7s, *not* respectively and with one coincidence), 45.6 and 46.0 (d, 42 and 39, C-3s), 131.4 and 131.7 (d, 37, C-1s), and 136.2 and 136.5 (d, 42 and 45, C-2s).

(*Z*)-(*Z*)-3,3′-bicyclooctenyl was prepared similarly in a 90% yield. ^{13}C NMR data* on the mixture of diastereoisomers. Diastereoisomer **A**: 26.1 (t, 54, C-

* For each diastereoisomer, the C′ set of carbons is identical to the unprimed set and so is included in the data given.

5), 27.4 (t, 75, C-8 and C-7), 29.7 (t, 46, C-6), 34.4 (t, 48, C-4), 40.9 (d, 38, C-3), 129.4 (d, 49, C-1) and 134.4 (d, 47, C-2). Diastereoisomer **B**: 26.0 (t, 43, C-5), 27.0 (t, 69, C-8 and C-7), 30.0 (t, 40, C-6), 34.6 (t, 31, C-4), 41.3 (d, 30, C-3), 129.3 (d, 31, C-1) and 133.2 (d, 37, C-2).

Preparation of 3-*(cyclohex-2-enyl)pentan-2,4-dione*

3-Bromocyclohexene (0.49 g, 2.5×10^{-3} mol) was added dropwise to a stirred suspension of Napda (0.30 g, 2.5×10^{-3} mol) in toluene (5 cm^3). The resulting mixture was heated under reflux for 15 h and then cooled to room temperature and filtered. Toluene was evaporated from the filtrate under reduced pressure to yield the product as a light brown oil (*ca* 40%). The same product was formed more readily (4 h) using MeOH as solvent, and was purified by column chromatography. Found: C, 73.3; H, 8.90%. Calc. for $C_{11}H_{16}O_2$: C, 73.3; H, 8.90%. ^{13}C NMR data: 20.8 (t, 64, C-5'), 25.0 (t, 50, C-4'), 26.8 (t, 53, C-6'), 29.6 and 30.0 (q, 40 and 36, C-1 or C-5), 35.6 (d, 49, C-3'), 74.8 (d, 64, C-3), 127.3 (d, 46, C-1'), 129.9 (d, 61, C-2'), and 203.4 and 203.6 (s, 10 and 9, C-2 or C-4).

Preparation of $[MoX(CO)_2(\eta^3\text{-}C_5H_7O_2)(bipy)]$ (*where* X = Cl *or* Br)

Propargyl halide ($8{,}45 \times 10^{-3}$ mol) was added dropwise to a stirred suspension of $PPh_4[MoX(CO)_3(bipy)]$ (8.45×10^{-3} mol) in dried oxygen-free MeOH at −17°C. The reaction mixture was stirred for 0.5 h at −17°C and then allowed to warm to room temperature and stirred for a further 0.5 h. The brown product was filtered, washed with cold MeOH and dried *in vacuo*. Yield 40% for X = Cl or Br. Found: C, 45.7; H, 3.50; N, 6.49%. ν(CO) (Nujol) 1995, 1930 and 1665 cm^{-1}. Calc. for $C_{17}H_{15}N_2O_4ClMo$: C, 46.1; H, 3.39; N, 6.33%. Found: C, 41.8; H, 3.09; N, 5.76%. Calc. for $C_{17}H_{15}N_2O_4BrMo$: C, 41.9; H, 3.08; N, 5.75%. ν(CO) (Nujol) 1995, 1930 and 1665 cm^{-1}. Both products decomposed on standing and were only sparingly soluble in CH_2Cl_2 or CH_3NO_2. The ^1H NMR spectrum of the chloro-complex was recorded in CD_2Cl_2: δ (ppm) 2.54 (q, J = 2 Hz, 1, CH), 3.08 (s, 3, OMe), 3.15 (d, J = 2 Hz, 3, CMe) and 7.5–8.7 (m, 8, aromatics).

Reaction of $[MoBr(CO)_2(\eta^3\text{-}C_5H_7O_2)(bipy)]$ *with* $NaBH_4$

Solid $NaBH_4$ (1.07 g, 0.028 mol) was stirred for 1 h with a suspension of $[MoBr(CO)_2(\eta^3\text{-}C_5H_7O_2)(bipy)]$ (6.90 g, 0.014 mol) in MeOH (250 cm^3) held at −78°C. The mixture was then allowed to warm to room temperature and stirring was continued for a further 0.3 h. Methanol was removed at reduced pressure to leave a gum which was extracted with Et_2O. After filtration and evaporation of the solvent, the crude oil was chromatographed on 63–200-mesh silica using 6:1 petroleum/ether–ethyl acetate as eluant. Careful fractionation yielded 0.16 g of pure dimethylmethylsuccinate.[14]

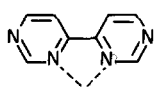
MONO- AND BINUCLEAR MOLYBDENUM CARBONYL COMPLEXES WITH CHARGE-TRANSFER ABSORPTIONS IN THE NEAR IR

WOLFGANG KAIM,* SYLVIA ERNST and STEPHAN KOHLMANN

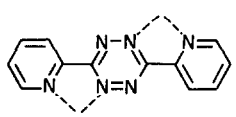
Institut für Anorganische Chemie der Universität, Niederurseler Hang, D-6000 Frankfurt am Main 50, F.R.G.

(*Received* 18 *June* 1985)



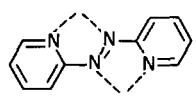
Abstract—Molybdenum(0) carbonyl complexes with very long wavelength charge-transfer absorptions (λ = 700–1000 nm) have been obtained via lowering of the complex lowest unoccupied molecular orbital, viz. by using strongly π-accepting α-diimine ligands, and via raising of the metal highest occupied molecular orbital, viz. by employing the electron-rich metal fragment $Mo(P^nBu_3)_2(CO)_2$. The electronic structures of these compounds were studied by electron and IR spectroscopy, by cyclic voltammetry and by ESR of the anion radicals.

Intense absorptions in the visible region have long been observed for molybdenum carbonyl complexes of α-diimines such as 1,10-phenanthroline,[1] 2,2′-bipyridine,[2] diazabutadienes,[3] pyridine-carbaldimines,[4] 2,2′-bipyrimidine,[5] 2,2′-bipyrazine,[6] 4,4′-bipyrimidine (bpm) (**1**)[7] and 3,3′-bipyridazine.[8] Although binuclear tetracarbonylmolybdenum complexes of 2,2′-bipyrimidine[5] and dicarbonylbis (phosphane)molybdenum complexes of 2,2′-bipyridine[9,10] exhibit long-wavelength absorption maxima up to 675[5] and 810 nm[9], respectively, we set out to push this limit further into the near-IR region of the spectrum in order to understand the interactions between metal fragments and highly π-electron-deficient ligands. Furthermore, there is a need for photocatalyzing absorbers in that spectral region since most photosensitizers used so far have absorption maxima at far smaller wavelengths.[11]



Two approaches to obtain molybdenum carbonyl complexes with metal-to-ligand charge-transfer (MLCT) absorptions in the near IR are described here, employing specially designed α-diimine ligands which have rather positive reduction potentials and are not yet commercially available.

(i) The $Mo(P^nBu_3)_2(CO)_2$ fragment with a rather high lying metal-centered HOMO (highest occupied molecular orbital)[12] was coordinated to the ligand **1** which was recently established to be the best π-acceptor among the bidiazines with α-diimine structure.[7]



(ii) Mono- and binuclear tetracarbonylmolybdenum complexes of the ligands 3,6-di-2-pyridyl-1,2,4,5-tetrazine [**2** (dptz)] and azo-2,2′-bipyridine [**3** (abpy)] were studied: both these potentially binucleating bis(chelate) ligands contain the azo function —N=N— and are, therefore, highly π-electron-deficient.[13]

1 (BPM)

2 (DPTZ)

3 (ABPY)

Electron and IR spectroscopy as well as cyclic voltammetry allow an assessment of the energy levels relevant to the CT transitions; in addition, ESR studies of the anion radicals help to establish the character of the half-occupied molecular orbital, i.e. the LUMO (lowest unoccupied molecular orbital) of the neutral complex.

RESULTS AND DISCUSSION

Table 1 summarizes the spectroscopic data which are relevant to the electronic structures of the complexes. The data from this table and the absorption spectrum shown in Fig. 1 illustrate that the first approach, i.e. raising the metal-centered HOMO via PR_3 introduction in the *cis*-position

leads indeed to compounds with very low-energy charge-transfer absorptions. Compared to corresponding 2,2′-bipyridine complexes (λ_{max} = 810 and 524 nm in benzene[9]) the bpm complex $Mo(bpm)(P^nBu_3)_2(CO)_2$ exhibits a bathochromically shifted first and a hypsochromically shifted second allowed CT absorption: the latter is assigned to a transition from the metal orbitals to the second lowest unoccupied molecular orbital (SLUMO) of ligand **1**.[10]

The shifts relative to the corresponding tetracarbonylmolybdenum complex[7] are mainly due to a strongly raised HOMO level, as indicated by the considerably lowered oxidation potential (Table 1), while the reduction potential of the complex has been shifted to a much lesser extent. In agreement with previous results on such α-diimine complexes[9,10] we observe a very small positive solvatochromism[15] for the near-IR (NIR) band: however, we do not attribute this phenomenon to a reversal of the transition character (MLCT → LMCT[10]); it rather seems that phosphine substitution in such complexes leaves the ground state less polarized and/or the excited state more polarized, and eventually this may turn the negative into a positive solvatochromism. Support for this explanation comes from an

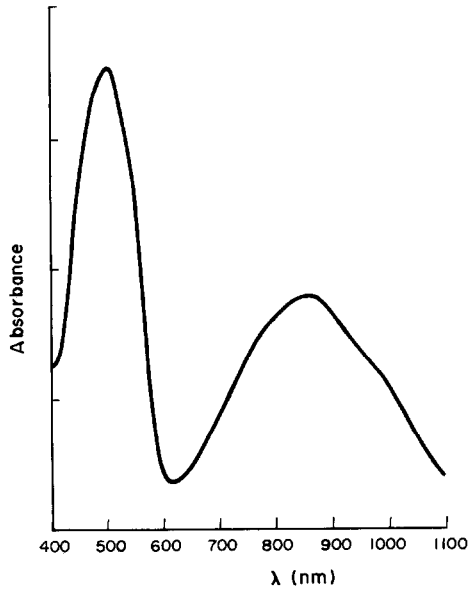

Fig. 1. VIS–NIR absorption spectrum of *cis*-$Mo(P^nBu_3)_2(CO)_2(bpm)$ in hexane.

ESR study of the anion radical complex $Mo(P^nBu_3)_2(CO)_2(bpm^{\cdot-})$ which clearly shows (Fig. 2) a similarity to the tetracarbonylmolybdenum complex radical,[7,8] except for a large ^{31}P coupling[9] originating from hyperconjugative (π^*/σ^*_{Mo-P}) spin transfer to the ^{31}P nuclei in the *cis*-position.[16,17] These results indicate that the MO which has taken up an electron still has a predominantly π^* (bpm) character.

Finally, a comparison of CO stretching frequencies between bpm (Table 1) and 2,2'-bipyridine dicarbonyl complexes [ν(CO) = 1818 and 1745 cm^{-1} in CS_2[9]] also illustrates the better back-bonding behaviour of the former ligand; the favourable combination of good π-acceptor *and* σ-donor properties of bpm[7] becomes manifest through relatively high values of ν(CO).

In the second approach, mono- and binuclear tetracarbonylmolybdenum(0) complexes of the very π-electron-deficient ligands **2** and **3** were prepared.[13] Whereas the mononuclear species have CT absorptions still in the visible region, the binuclear complexes absorb between 810 and 950 nm, exhibiting high extinction coefficients (ε) of $\sim 10^4$–10^5 $M^{-1}\,cm^{-1}$ and negative solvatochromism (Table 1). These extremely low-energy transitions are primarily the result of an additional lowering of the π^*-acceptor levels by double $Mo(CO)_4$ coordination: electrochemical data (Table 1) show that the binuclear complexes are reduced at potentials similar to that of the saturated calomel reference electrode (SCE)!

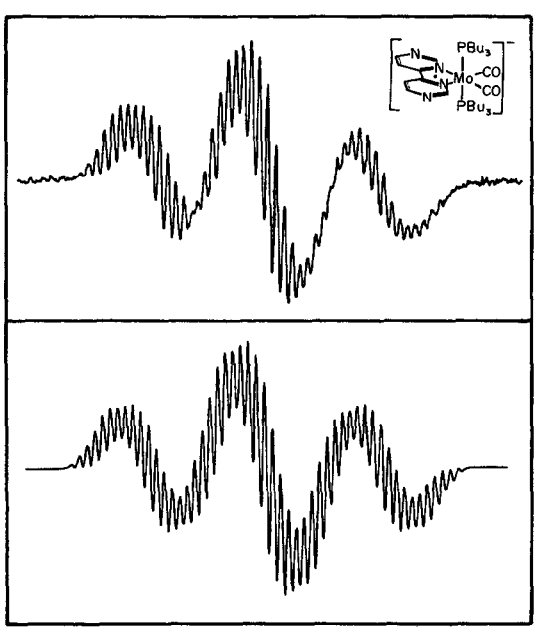

Fig. 2. Experimental (top) and computer-simulated (bottom) ESR spectrum of the anion radical complex *cis*-$Mo(P^nBu_3)_2(CO)_2(bpm^{\cdot-})$, generated with potassium in THF. The high-field component of the ^{31}P triplet is severely affected by anisotropic line broadening. Computer simulation parameters: $a_{^{31}P} = 1.974$ mT (2P), $a_N = 0.283$ mT (2N), $a_N = 0.24$ mT (2N), $a_H = 0.14$ mT (4H), line width 0.06 mT, $g = 2.0024$.

Reversible reduction occurring at such positive potentials has allowed us to obtain persistent anion radical complexes by chemical reductants such as potassium metal in THF. These radical products were readily prepared from the binuclear tetracarbonylmolybdenum species: however, the anion radical complex $Mo_2(CO)_8(abpy)^{\cdot-}$) displayed a very complex ESR hyperfine pattern, indicating extensive spin delocalization on to the pyridine rings. On the other hand, the spectrum of the complex $Mo_2(CO)_8(dptz^{\cdot-})$ is comparatively simple (Fig. 3), showing interaction of the unpaired electron only with the two pairs of ^{14}N nuclei in the central tetrazine ring and with the magnetically active ($I = \frac{5}{2}$) molybdenum isotopes $^{95,97}Mo$. The larger of the two ^{14}N coupling constants is assigned to the two metal-coordinated nitrogen centers of the tetrazine ring because of Hückel MO calculation results[18] and because of the general increase of $a_{^{14}N}$ upon molybdenum carbonyl coordination.[17,19–21] Since both isotopes ^{95}Mo (15.8% natural abundance) and ^{97}Mo (9.6% natural abundance) have similar magnetic moments and identical nuclear spins ($I = \frac{5}{2}$), they have not been treated separately. According to statistics,[17,18] the probabilities of the three possible isotope combinations are 0.557 for the species with no $^{95,97}Mo$ isotopes, 0.379 for the complex with one magnetically active isotope $^{95,97}Mo$, and 0.064 for the species where both molybdenum centers have a nuclear spin of $\frac{5}{2}$. The combination with one isotope $^{95,97}Mo$ gives rise to observable satellites (Fig. 3) due to further splitting of the main spectrum into a sextet ($I = \frac{5}{2}$).

Thus, the paramagnetic compound $Mo_2(CO)_8(dptz^{\cdot-})$ represents another example of binuclear molybdenum carbonyl complexes with bridging anion radical ligands: previously studied complexes have included pyrazine and 4,4'-bipyridine,[19,20] quinoxaline, phenazine and 1,2-bis(pyridyl)ethene,[20] 2,1,3-benzochalcogenadiazole[21] and 2,2'-bipyrimidine[17] anion radicals. Some apparently related radical complexes reported recently[22] have not been analyzed in detail. In all analyzed cases, the results for the ligand-centered singly occupied molecular orbital (SOMO), the LUMO of the neutral complex, confirm the assignment of the intense low-energy absorption as a metal-to-ligand ($\pi^* \leftarrow d$) CT transition.

The very unusual electronic situation in the binuclear tetracarbonylmolybdenum complexes with the dptz and abpy ligands is also reflected by

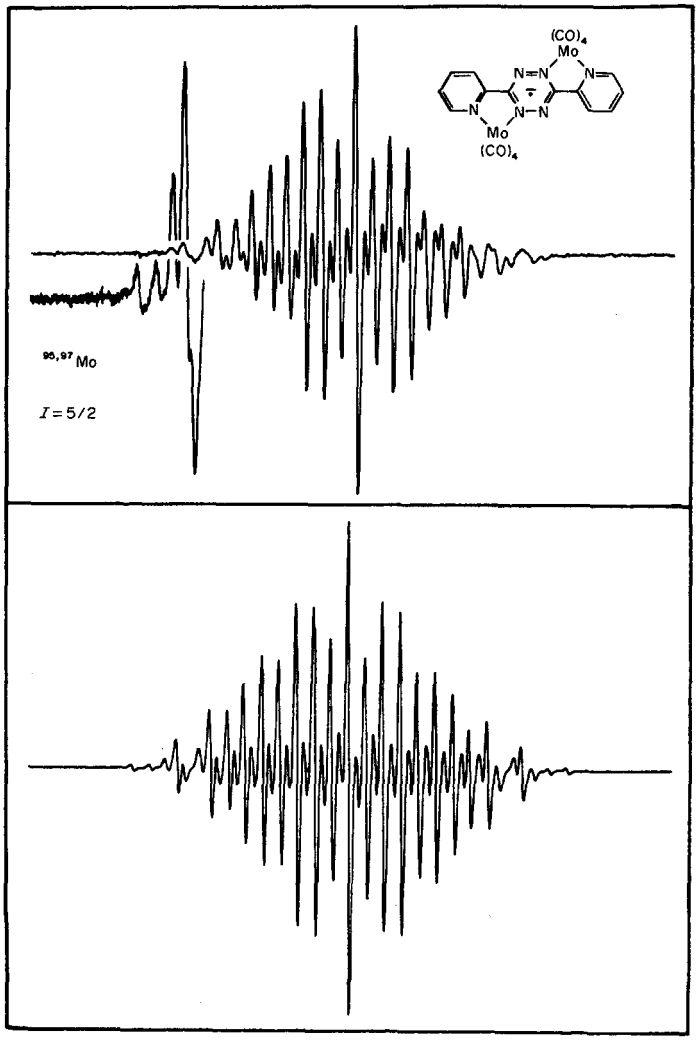

Fig. 3. Experimental (top) and computer-simulated (bottom) ESR spectrum of the anion radical complex $Mo_2(CO)_8(dptz^{\cdot-})$ in THF, counterion K^+. The amplified wing section (top) reveals $^{95,97}Mo$ isotope coupling. Computer simulation parameters: $a_N = 0.640$ mT (2N), $a_N = 0.418$ mT (2N), $a_{^{95,97}Mo} = 0.220$ mT (2 Mo, 25.4% natural abundance), line width 0.05 mT, $g = 2.0045$.

their carbonyl stretching frequencies; the four IR-active vibrational transitions are compressed into a frequency range of only 110 cm^{-1} (Table 1). Force constant calculations according to the Cotton–Kraihanzel method[23] yield values of $k_1 = 14.43$, $k_2 = 15.70$ and $k_i = 0.16$ mdyn $Å^{-1}$, and indicate unusually[6,24] strong back-bonding with these highly π-electron-deficient α-diimine ligands.

EXPERIMENTAL

The molybdenum complexes were prepared and studied taking the usual precautions, excluding air, moisture and intense light. Spectra were recorded on the following instruments: Pye Unicam SP 1800 (VIS absorption spectra), Perkin–Elmer Lambda 9 (NIR absorption spectra), Perkin–Elmer 283 B (IR spectra), Varian E9 (ESR spectra), Bruker WH 270 (^1H NMR spectra), and PAR 173/175 (cyclic voltammetry). Anion radical complexes were generated by potassium reduction of the neutral complexes in THF *in vacuo*: computer simulations of the spectra were performed on an HP 72220 S plotter using the VAX 750/11 and the available program.[25] Microanalyses were carried out by Prof. W. Ried and his staff at this Department.

Ligands **1–3** were prepared according to known procedures.[7,13] The complex $Mo(P^nBu_3)_2(CO)_2(bpm)$ was obtained from **1**[7] and $Mo(P^nBu_3)_3(CO)_2(CH_3CN)$ by the method of tom Dieck *et al.*[9] and was purified by recrystallization from toluene–acetonitrile. Dark-blue crystals. Yield 87%. ^1H NMR (C_6D_6): δ 0.79 (m, 18H), 1.09 (m,

24H), 1.32 (m, 12H), 7.05 (d, 2H), 7.94 (d, 2H), 10.40 (s, 2H). Found: C, 57.07; H, 8.40; N, 7.70%. Calc. for $C_{34}H_{60}MoN_4P_2O_2$: C, 57.13; H, 8.46; N, 7.83%. Tetracarbonylmolybdenum complexes of ligands **2** and **3** were synthesized from tetracarbonyl(η^2,η^2-bicyclo[2.2.1]hepta-2,4-diene)molybdenum and the ligands in toluene.[13]

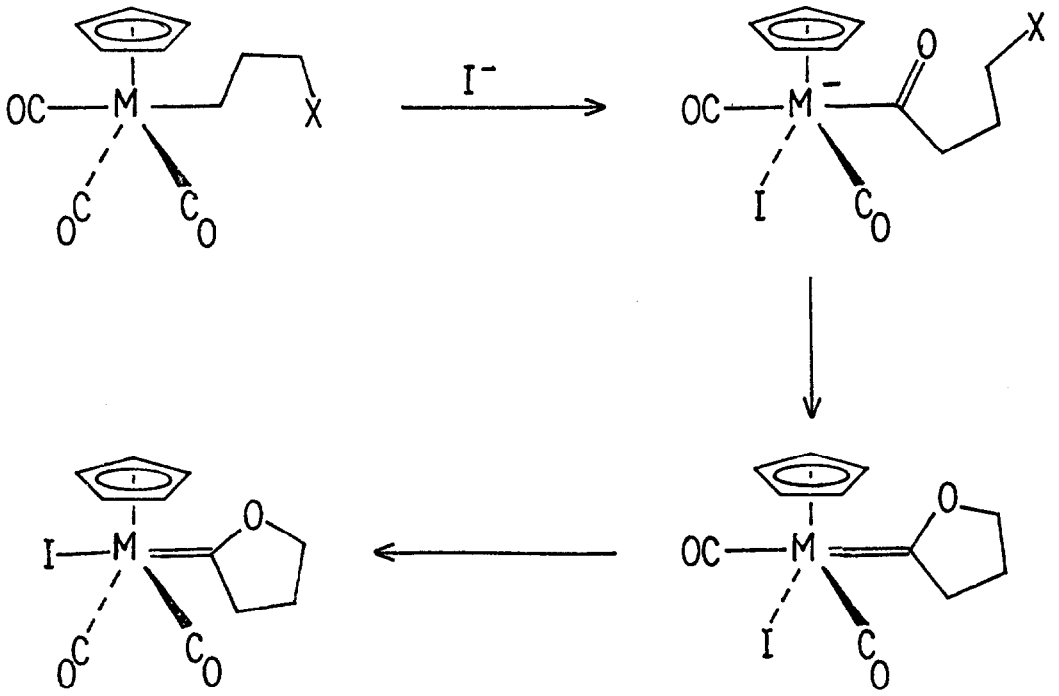
ACETALDEHYDE COMPLEXES OF MOLYBDENUM

J. TREVOR GAUNTLETT and MARK J. WINTER*

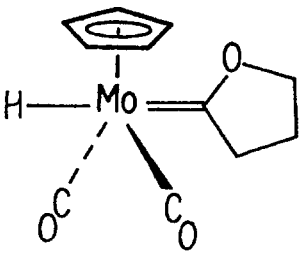
Department of Chemistry, The University, Sheffield S3 7HF, U.K.



(*Received* 17 *June* 1985)

Abstract—Addition of $LiEt_3BH$ to a solution of $MoMe(CO)_3(\eta\text{-}C_5H_5)$ allows the successive observation of the formyl alkyl $[Mo(CHO)Me(CO)_2(\eta\text{-}C_5H_5)]^-$, the hydrido acyl $[Mo(COMe)H(CO)_2(\eta\text{-}C_5H_5)]^-$, and the ultimate product, a species formulated as a complex of coordinated acetaldehyde, $[Mo(CO)_2(\eta^2\text{-}MeCHO)(\eta\text{-}C_5H_5)]^-$. All three anions are spectroscopically characterized. Addition of MeI to the acetaldehyde complex in the presence of PPh_3 or CO results in smooth formation of *trans*-$MoMe(CO)_2(PPh_3)(\eta\text{-}C_5H_5)$ or $MoMe(CO)_3(\eta\text{-}C_5H_5)$ together with the evolution of acetaldehyde; the latter case is therefore a stoicheiometric synthesis of acetaldehyde. The reaction of $PhCH_2Br$ with $[Mo(CO)_2(\eta^2\text{-}MeCHO)(\eta\text{-}C_5H_5)]^-$ provides a high-yield synthesis of $Mo(CO)_2(\eta^3\text{-}CH_2C_6H_5)(\eta\text{-}C_5H_5)$ while the η^3-allyl complex $Mo(CO)_2(\eta^3\text{-}C_3H_5)(\eta\text{-}C_5H_5)$ is formed in the corresponding reaction of allyl bromide. The position of alkylation is different using $[Me_3O][BF_4]$ and the primary product $Mo(\eta^2\text{-}CHMeOMe)(CO)_2(\eta\text{-}C_5H_5)$ arises from alkylation of the aldehyde oxygen atom. This species reacts with PPh_3 with O → Mo bond cleavage and formation of $Mo(CHMeOMe)(CO)_2(PPh_3)(\eta\text{-}C_5H_5)$. According to the conditions of workup the cationic ylide complex $[Mo(CHMePPh_3)(CO)_2(PPh_3)(\eta\text{-}C_5H_5)][BF_4]$ can also be formed. Reaction of $[Mo(\eta^2\text{-}MeCHO)(CO)_2(\eta\text{-}C_5H_5)]^-$ with several oxidizing agents, such as Fe(III), $[Fe(\eta\text{-}C_5H_5)_2]^+$, $[C_7H_7]^+$ or $[Mo(CO)_3(\eta\text{-}C_7H_7)]^+$, leads to the η^2-acetaldehyde complex $Mo_2(CO)_4(\mu\text{-}\eta^2\text{-}MeCHO)(\eta\text{-}C_5H_5)_2$ in which the carbon atom of the aldehyde is bound to a single metal but the oxygen atom bridges both metal atoms. Formally the aldehyde is a four-electron donor to the dimolybdenum system. The same product arises in the reaction of both $[M(CO)_3(\eta\text{-}C_5H_5)][BF_4]$ (M = Mo or W) with $[Mo(CO)_2(\eta^2\text{-}MeCHO)(\eta\text{-}C_5H_5)]^-$, no heterobimetallic aldehyde compounds are formed suggesting that $Mo_2(CO)_4(\mu\text{-}\eta^2\text{-}MeCHO)(\eta\text{-}C_5H_5)_2$ is formed after an initial electron-transfer process.

A short time ago we reported syntheses of cyclic carbene complexes **1** and **2** through the iodide-induced cyclization of $M([CH_2]_3X)(CO)_3(\eta\text{-}C_5H_5)$ (**3**) (Scheme 1).[1,2] Other nucleophiles such as CN^-, SPh^- or $[W(CO)_3(\eta\text{-}C_5H_5)]^-$ are suitable for this cyclization[2–4] and a related reaction leading to a cationic species is also known.[5,6] Perhaps naively we thought that a nucleophilic hydride source might induce a similar such cyclization so forming a hydride carbene of type **4**. It occurred to us that such a species might react with nucleophiles and that it would be possible to observe hydride to carbene migrations. This is important since, although such processes are often invoked to explain aspects of carbene chemistry, well-defined examples are rare.



One such hydride source is $LiEt_3BH$. In fact, the major isolated product from the reaction of $LiEt_3BH$ and **3** is compound **5** rather than **4**.[7] It is possible to view formation of **5** as proceeding by an analogous cyclization step forming the hydrido carbene **4** which subsequently undergoes a hydride to carbene migratory insertion reaction in which the ring oxygen atom functions as an intramolecular source of nucleophile (Scheme 2, path A). Compound **5** is also obtained from the reaction of carbene **1** with $LiEt_3BH$, although probably by a different mechanism.[8] These processes are quite complex and one of the ways we attempted to understand these results was to initiate a study on the interactions of hydride-donor reagents with molybdenum complexes containing simpler alkyl functions. A suitable reaction is that of $MoMe(CO)_3(\eta\text{-}C_5H_5)$ (**6**) with

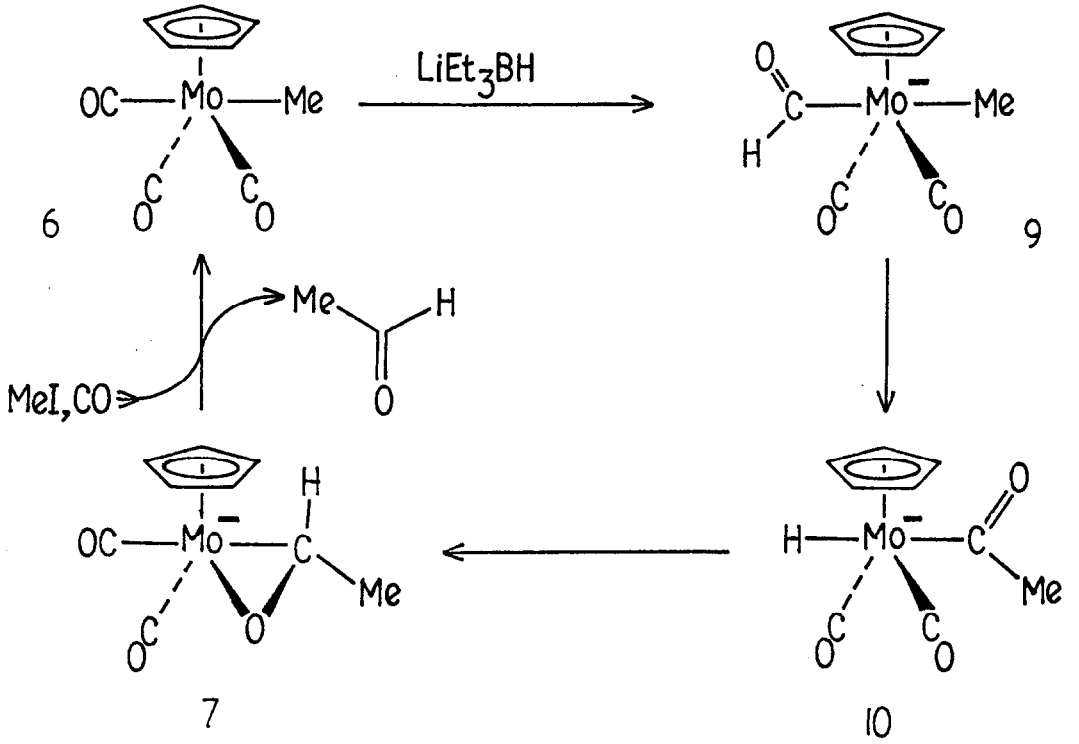


Scheme 2. Two possible pathways for the formation of $\overline{Mo[\eta^2\text{-}CH(CH_2)_3O]}(CO)_2(\eta\text{-}C_5H_5)$ from the reaction of $Mo[(CH_2)_3Br](CO)_3(\eta\text{-}C_5H_5)$ with $LiEt_3BH$.

$LiEt_3BH$, the initial aim being to identify the position of hydride attack at the metal complex.

This reaction proceeds readily at room temperature and the ultimate product is a spectroscopically characterized anion formulated as $[Mo(CO)_2(\eta^2\text{-}MeCHO)(\eta\text{-}C_5H_5)]^-$ (7).[9,10] We have succeeded in isolating **7** with a 12-crown-4 lithium complex as counter ion as a solid but have yet to obtain suitable crystals for X-ray analysis. Until we have a crystal structure of this molecule we choose to depict this molecule with the representation **7**, a metalla-oxirane, in common with representations of other aldehyde or ketone complexes that have been crystallographically characterized.[11–14] However, the alternative representation as **8** also seems reasonable. It is noteworthy that the IR spectrum of the crown complex is identical to that of the parent species in THF solution, suggesting that **7** exists as solvent-separated ion pairs in solution rather than contact ion pairs. It is also possible to write dimeric structures for this species: such a possibility is currently being examined but the chemistry of **7** delineated thus far can be rationalized satisfactorily using **7** as a representation.

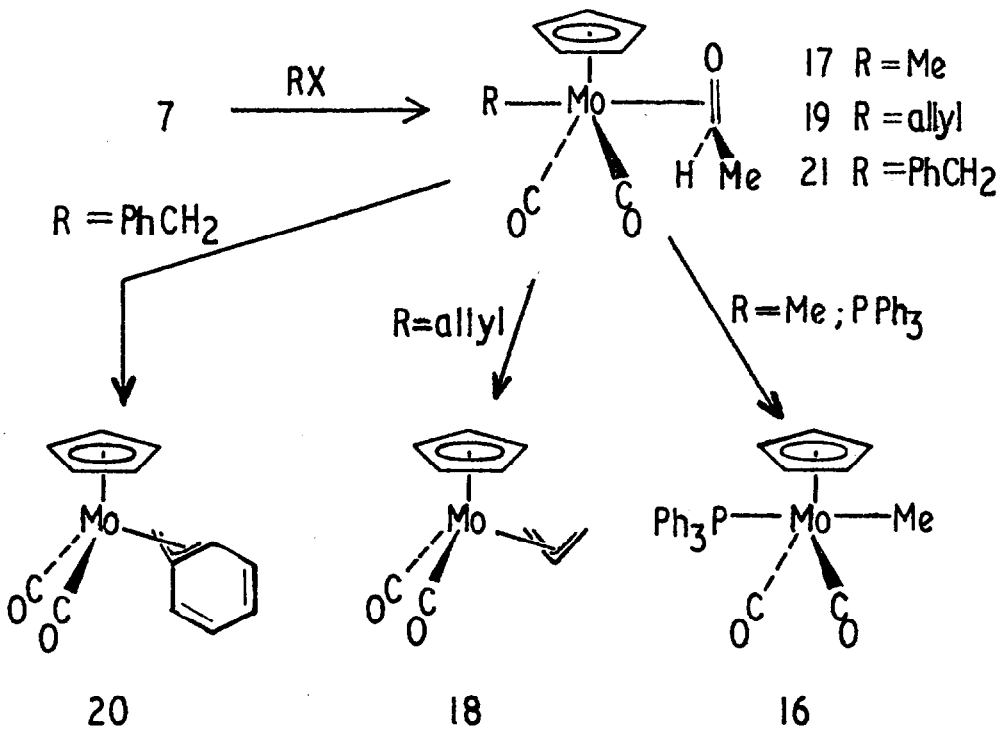
The anion **7** is not the primary product: by initiating the reaction at −78°C and allowing the reaction to warm slowly to room temperature it is possible to identify two intermediates, the formyl alkyl **9** and the hydrido acyl **10** (Scheme 3) by monitoring the ^1H and ^{13}C NMR and the IR spectra at low temperatures.[9,10] Formyl complexes arising from hydride additions to carbonyls are now well-known, although there are comparatively few molybdenum examples.[15–18] They are characterized by high-frequency signals in the ^1H NMR spectrum,[19] in this case a signal is observed at δ 14.3. The relative intensities of the bands in the carbonyl IR spectrum[20] and the presence of only a single carbonyl signal in the ^{13}C NMR spectrum are in accord with the *trans* geometry depicted. The

Scheme 3. Stoicheiometric synthetic cycle for acetaldehyde based on $MoMe(CO)_3(\eta\text{-}C_5H_5)$.

rearrangement to the hydrido acyl is unusual although there are some examples of complexes containing both hydride and acyl ligands.[21–24] Compound **10** is characterized by a low-frequency signal (δ −5.15), indicative of a metal hydride. We presume that the driving force converting **9** to **10** is the higher bond energy associated with an Mo—H bond relative to an Mo—alkyl bond. Compound **10** undergoes a formal migration of the hydride to the acyl carbon (one could also view this as a hydride to carbenoid atom migration). We do not yet know whether this step is inter- or intramolecular. The important feature of this last step is that a hydride ligand and an acyl ligand combine at a metal to produce a ligated aldehyde.

The closely related complexes $[Mo(CO)_2(\eta^2\text{-}RCHO)(\eta\text{-}C_5H_5)]^-$ (**11**, R = Et; and **12**, R = CH_2Ph) are formed in the reactions of $MoR(CO)_3(\eta\text{-}C_5H_5)$ with $LiEt_3BH$. Although not fully spectroscopically characterized the IR spectra in the carbonyl region, at least, are identical to that of **7** in THF.

Formation of **7** in this reaction allows us to comment on the formation of **5** in the reaction of **1** with $LiEt_3BH$. There are two items of information relevant here. The results of monitoring by low-temperature NMR spectroscopy suggest that the initial product is a formyl complex (**13**) [δ(THF) 14.2]. The results of IR monitoring clearly shows that the ultimate product, **5**, is produced at the expense of an intermediate whose IR spectrum in the carbonyl region is identical to that of **7**. This species is almost certainly **14**. Although we have not unambiguously identified a hydride resonance in the NMR spectrum of this reaction upon warming it does seem likely that **15** is an intermediate by analogy to the formation of **7**. Therefore, compound **5** is formed through ring closure from an anionic aldehyde complex **14** (Scheme 2, path B) rather than migration of hydride to a carbene ligand (Scheme 2, path A).



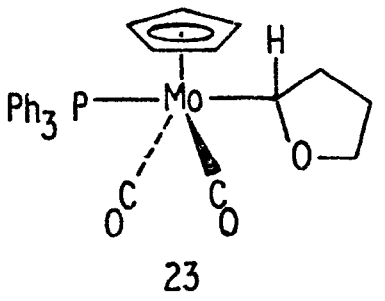
Having established a working model for the mechanism of formation of **5** an investigation of the chemistry of **7** was clearly required, with views to contrasting its reactivity with that of $[Mo(CO)_3(\eta\text{-}C_5H_5)]^-$, to see if the aldehyde could be liberated, and to determine whether a modified system could catalytically generate aldehydes.

Addition of MeI to a THF solution containing **7** results in a very slow reaction whose only identified ultimate product is a low yield of **6**, some of which at least arises from reaction of the very small quantities of $[Mo(CO)_3(\eta\text{-}C_5H_5)]^-$ generally present in solutions of **7** with MeI. Even a prolonged reaction time does not result in any observed products in the reaction of **7** with PPh_3: in particular, there is no tendency for the PPh_3 to exchange with the MeCHO

ligand in the anion **7**.[10] However, when **7** is treated with MeI in the presence of PPh_3 the phosphine complex *trans*-$MoMe(CO)_2(PPh_3)(\eta\text{-}C_5H_5)$ (**16**) is formed smoothly. We regard this as proceeding by nucleophilic replacement of the I^- of MeI by anion **7**, giving an undetected intermediate $MoMe(CO)_2(MeCHO)(\eta\text{-}C_5H_5)$ (**17**) (Scheme 4) from which MeCHO is evolved through substitution of the labile MeCHO by the two-electron ligand PPh_3. An alternative two-electron ligand is provided by CO itself. Addition of MeI to a solution of **7** maintained under a CO atmosphere (1 atm) provides the alkyl **6** in very good yield, together with MeCHO, which may be analysed by GLC and GC–mass spectrometry.[10] These two reactions probably share the same intermediate (**17**). The last result is particularly interesting in that it closes a stoicheiometric cycle for the synthesis of acetaldehyde (Scheme 3).

Both these two reactions employ an external or intermolecular source of a two-electron ligand. It is also possible to arrange matters so that the new two-electron ligand is provided by an intramolecular source. Addition of allyl bromide to a solution of **7** swiftly results in formation of the known η^3-allyl derivative, $Mo(CO)_2(\eta^3\text{-}C_3H_5)(\eta\text{-}C_5H_5)$ (**18**), isolated in moderate yield after chromatography and crystallization.[25] The probable intermediate is **19**, a labile complex from which MeCHO is displaced by intramolecular attack of the pendant ene group at the metal. An interesting related phenomenon is observed in the reaction of **7** with benzyl bromide. Here the major product is the η^3-benzyl $Mo(CO)_2(\eta^3\text{-}CH_2Ph)(\eta\text{-}C_5H_5)$ (**20**), isolated in 64% yield after chromatography and crystallization. This is a known compound,[26] but the previous synthesis is of low yield and relatively arduous. The η^1-benzyl $Mo(\eta^1\text{-}CH_2Ph)(CO)_3(\eta\text{-}C_5H_5)$ is isolated in very low yield as a byproduct, probably arising from reaction of the small quantities of $[Mo(CO)_3(\eta\text{-}C_5H_5)]^-$ present in the solution of **7** with $PhCH_2Br$. Compound **20** will be formed from the intermediate **21**: in this case the aromatic ring itself is the intramolecular source of nucleophile.

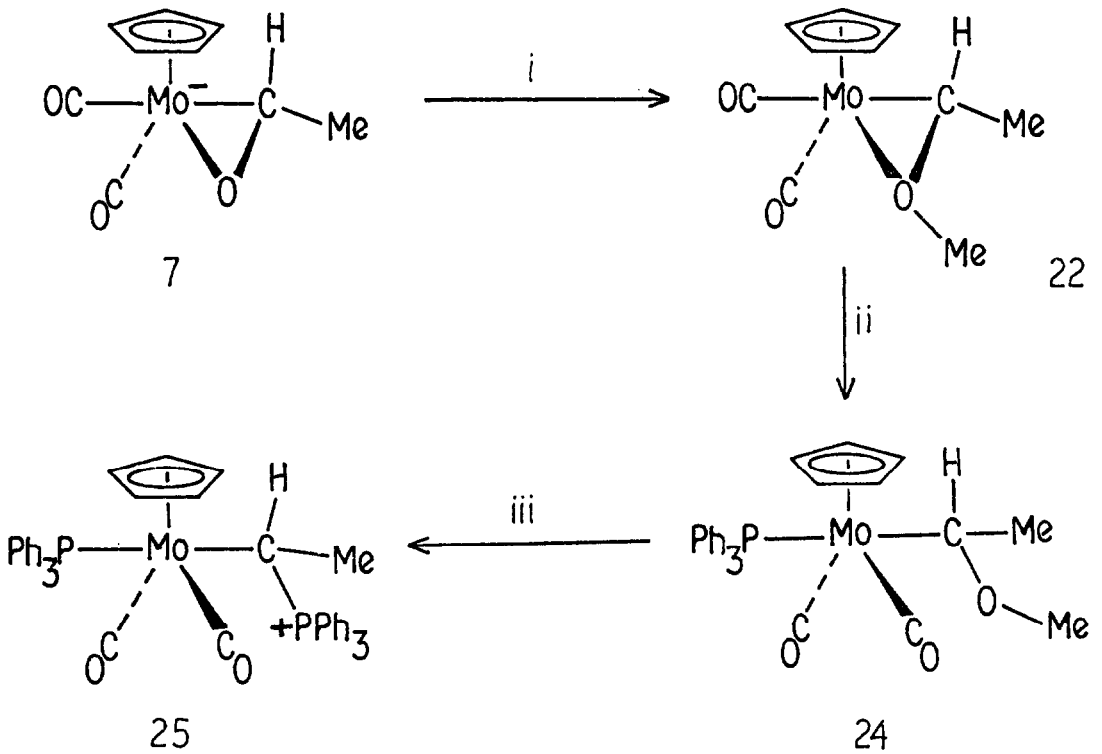
These reactions rely upon the nucleophilic replacement of halide from an organic halide: effectively this is the formal addition of an R^+ group to the metal. Another source of R^+ is provided by the reagent $[Me_3O][BF_4]$, but it is quite common for it to display a different reactivity with organotransition-metal substrate when compared to RX. This is the case here. Addition of solid $[Me_3O][BF_4]$ to a THF solution of **7** at −78°C followed by warming towards ambient temperature provides a solution whose IR spectrum in the carbonyl region is superimposable upon that of **5**, suggesting that methylation occurs at the oxygen



Scheme 4. Reactions of $[Mo(\eta^2\text{-}MeCHO)(CO)_2(\eta\text{-}C_5H_5)]^-$ with C_3H_5Br, $PhCH_2Br$ and MeI–PPh_3.

atom and that the product is **22**. Regrettably the product is extremely sensitive to air and decomposes upon attempted chromatography, so it remains unisolated as a pure material.

Compound **5** reacts with PPh_3 to give **23**, in which the Mo ← O bond is cleaved by the two-electron PPh_3 ligand. This is entirely reasonable, since one can regard the oxygen–molybdenum interaction in **5** as an ether coordinated to a metal and therefore expected to be very labile. Analogus behaviour is observed for **22**, supporting the structural assignment.



This reaction is conveniently carried out by allowing a solution of **7** in THF to warm up from −78°C to ambient temperature in the presence of solid PPh_3 and solid $[Me_3O][BF_4]$. Neither reagent is particularly soluble under these conditions, but during the time taken to warm up the IR spectrum of the reaction mixture changes first to one indicating formation of **22** (that is, identical to the IR spectrum of the reaction involving $[Me_3O][BF_4]$ alone) but whose bands in turn are replaced by two new bands typical of a *trans*-$MoR(CO)_2(PPh_3)(\eta\text{-}C_5H_5)$ molecule and which overlap with those of the cyclic alkyl **23**. Provided the reaction mixture is filtered through alumina to remove excess $[Me_3O][BF_4]$

23

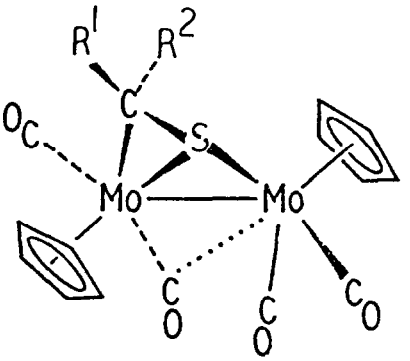
before removal of solvent the expected *trans*-$Mo(CHMeOMe)(CO)_2(PPh_3)(\eta\text{-}C_5H_5)$ (**24**) is isolable, although somewhat reactive. The ^1H NMR spectrum of **24** is informative and, in particular, a signal {$\delta(CDCl_3)$: 5.15 [d of q, 1 H, J(HH) 6.5, J(HP) 3 Hz]} is as expected for the CH proton coupled to the protons of the methyl group and the *trans* P atom.

If the reaction is not filtered prior to solvent removal a further reaction proceeds (during workup) with excess $[Me_3O][BF_4]$ and a cationic ylide (**25**) is isolable along with lesser quantities of other minor neutral products. We believe that attack of excess $[Me_3O][BF_4]$ upon **24** removes the OMe^- function (Scheme 5) and the resulting transient cationic

Scheme 5. Reactions of $[Mo(\eta^2\text{-}MeCHO)(CO)_2(\eta\text{-}C_5H_5)]^-$ with $[Me_3O][BF_4]$–PPh_3. (i) $[Me_3O][BF_4]$ alone, (ii) $[Me_3O][BF_4]$ and PPh_3 (filtration before solvent removal), and (iii) $[Me_3O][BF_4]$ and PPh_3 without filtration before solvent removal.

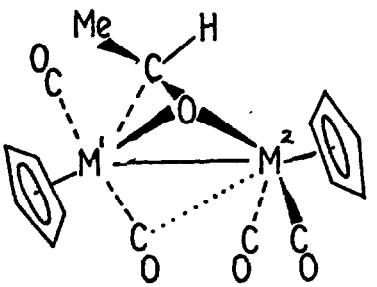
alkylidene is stabilized by a second molecule of PPh_3.

Clearly $[Me_3O][BF_4]$ alkylates **7** preferentially at the oxygen of coordinated acetaldehyde rather than at the metal as is the case for MeI although there is evidence for alkylation at the metal to a very minor degree, small quantities of the known methyl complex $MoMe(CO)_2(PPh_3)(\eta\text{-}C_5H_5)$ (**16**) are also isolable from the reaction.[27,28]



The product obtained by oxidation of **7** with any one of several oxidizing agents was unexpected to us. Addition of, for instance, $[Fe(\eta\text{-}C_5H_5)_2]^+$ to a THF solution of **7** results in the formation of **26** in 11% yield. The structure of **26** is the subject of an X-ray crystallographic study[29] and shows the MeCHO ligand to bridge the dimolybdenum centre in an asymmetric fashion. There is also a semi-bridging carbonyl of the type known for many related molecules of Mo_2 and W_2.[30–34] The Mo–Mo bond length is consistent with a single Mo–Mo bond.[34,35] One can view the bonding as coordination of the C=O bond to one molybdenum atom and donation of an oxygen lone pair to the second. Acetaldehyde therefore functions as a four-electron ligand in this molecule. The analogous complex $Mo_2(CO)_4(\mu\text{-}\eta^2\text{-}PhCH_2CHO)(\eta\text{-}C_5H_5)_2$ is also available by oxidation of the benzyl species (**12**).

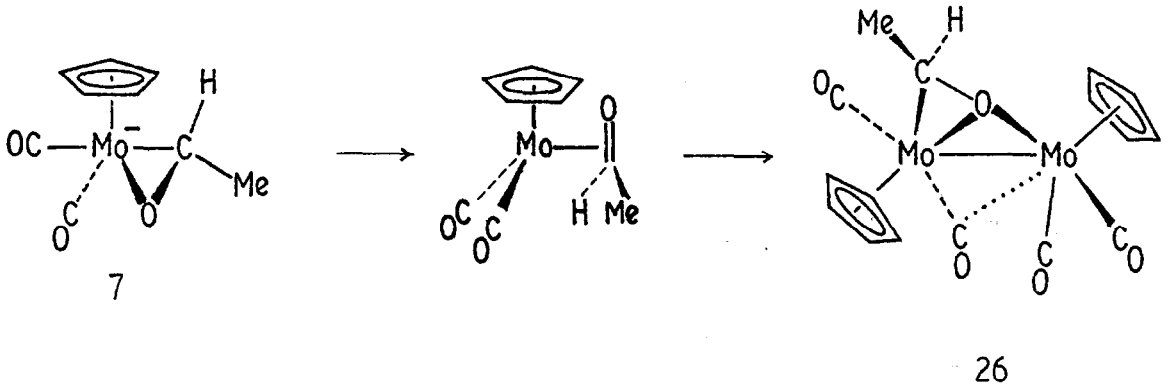
In a formal sense, this molecule is an addition product of MeCHO across the Mo–Mo triple bond of $[Mo(CO)_2(\eta\text{-}C_5H_5)]_2$. However, we have, as yet, been unable to synthesize the molecule by this route either by photochemical or thermal means. There is literature precedent for some sulphur-containing analogues. Addition of $R^1R^2C{=}S$ takes place smoothly across dimolybdenum of $[Mo(CO)_2(\eta\text{-}C_5H_5)]_2$ for a wide range of R^1 and R^2 to give species **27** with a Mo_2CS core whose structure is completely analogous to the Mo_2CO core of **26**.[36] These molecules are fluxional on the NMR time scale upon warming but analogous behaviour is not observed for **26** since decomposition occurs upon warming to 60°C in C_6D_6.



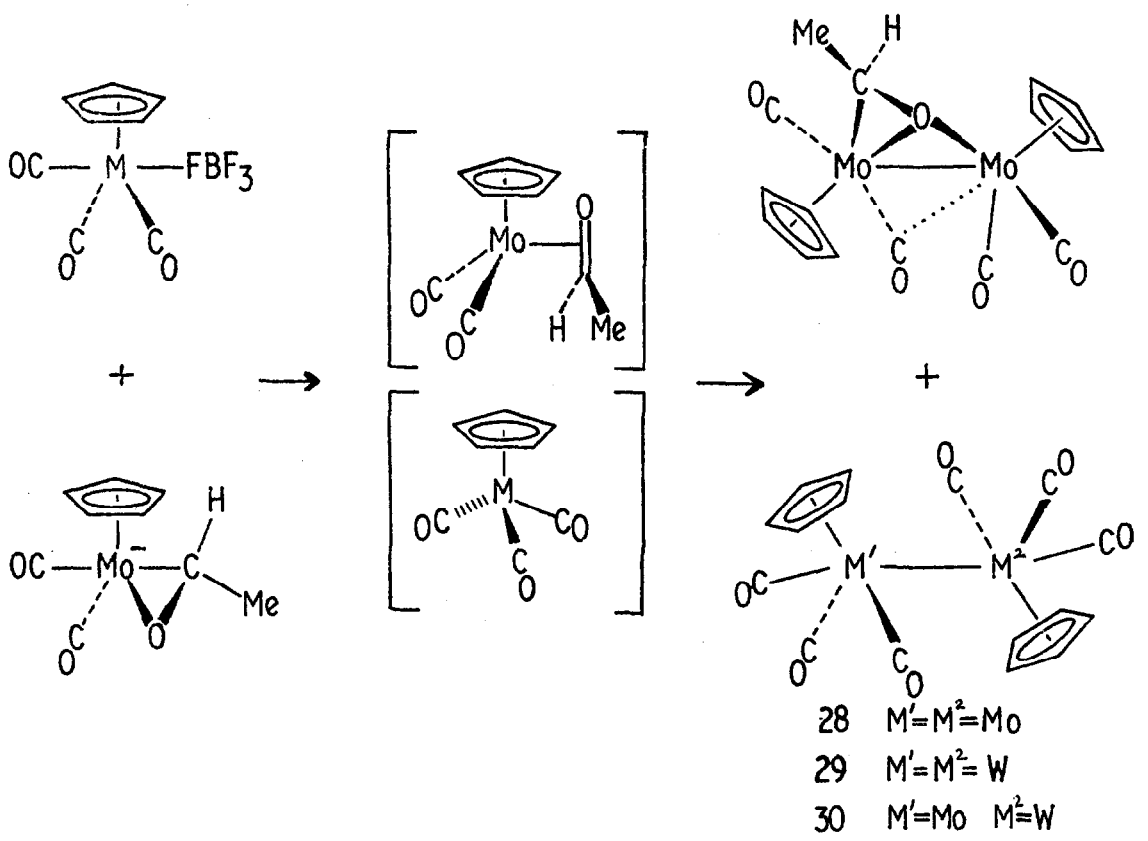
One possibility for the reaction mechanism is for the oxidizing agent to accept an electron from the anion **7**, giving a 17-electron species (Scheme 6) which dimerizes with loss of MeCHO to give **26**. In support of this acetaldehyde is detected in the reaction mixture by GC–mass spectrometry.

Other one-electron acceptors such as Fe(III), $[C_7H_7]^+$ or $[Mo(CO)_3(\eta\text{-}C_7H_7)]^+$ provide the same product but in each case there are byproducts whose nature depends upon the actual oxidizing agent employed.

Reaction of $[Mo(CO)_3(\eta\text{-}C_5H_5)][BF_4]$[37] with **7** in THF similarly results in the formation of **26** (21%), together with quantities of $[Mo(CO)_3(\eta\text{-}C_5H_5)]_2$ (**28**) (13%), but in this case there is the question as to whether both Mo atoms of **26** originate from the anionic species or one from each reagent. This question is probably answered by the result of employing $[W(CO)_3(\eta\text{-}C_5H_5)][BF_4]$[37] in place of the Mo cation. The only product containing an aldehyde ligand isolated is **26**, containing two Mo atoms. There is no sign of either of the two possible heterobimetallic species **31** or **32**. The other products isolated from chromatography are all three complexes, $(\eta\text{-}C_5H_5)(OC)_3M^1\text{-}M^2(CO)_3(\eta\text{-}C_5H_5)$ (**28–30**). This implies that **26** is formed by an electron-transfer process as for the other oxidizing agents. The formation of all these three possible hexacarbonyl compounds can be rationalized similarly and by making the assumption that when the 17-electron



27



31 M^1=Mo, M^2=W

32 M^1=W, M^2=Mo

species combine in all possible permutations to form metal–metal bonds (Scheme 7) one or two moles of acetaldehyde are then lost and disproportionation reactions give the isolated hexacarbonyls. In no case is it necessary to invoke a direct metal–metal bond formation between **7** and $[W(CO)_3(\eta\text{-}C_5H_5)][BF_4]$ as the initial step, but this does not dismiss this possibility as accounting for at least some of the heterobimetallic product.

Scheme 6. Reaction of $[Mo(\eta^2\text{-MeCHO})(CO)_2(\eta\text{-}C_5H_5)]^-$ with $[Mo(CO)_3(\eta\text{-}C_5H_5)][BF_4]$.

Scheme 7. Reaction of $[Mo(\eta^2\text{-MeCHO})(CO)_2(\eta\text{-}C_5H_5)]^-$ with $[W(CO)_3(\eta\text{-}C_5H_5)][BF_4]$.

(*Received* 11 *June* 1985)

Abstract—$[MoCl(\eta^3\text{-}C_3H_5)_3]_2$ reacts with donor ligands (L) with cleavage of the chloride bridges to give $[MoCl(L)(\eta^3\text{-}C_3H_5)_3]$ complexes from which the halide may be substituted by an alkyl group through reaction with Grignard reagents. Metathetical replacement is observed upon treatment with silver acetate or thallium acetylacetonate. The ^1H NMR spectra of these tris(η^3-allyl)molybdenum complexes indicate that the three allyl groups are magnetically inequivalent and asymmetrically bonded to the metal atom. This is borne out by a crystal-structure determination of $[MoOAc(\eta^3\text{-}C_3H_5)_3]$. Treatment of the chloride with bidentate chelating ligands leads to ionic species of the type $[Mo(L\text{–}L)(\eta^3\text{-}C_3H_5)_3]^+X^-$, while the product of the reaction with lithium in the presence of trimethylphosphite is $[Mo\{P(OMe)_3\}_3(\eta^3\text{-}C_3H_5)_2]$.

The remarkable growth of organomolybdenum chemistry in the last 15 years has taken place with the practical exclusion of tetra(η^3-allyl)molybdenum as a starting material—even though this complex was first reported in 1963.[1] This is particularly surprising since it was clearly realized at the start of the renaissance of modern organo-transition-metal chemistry that a very profitable approach is to study those complexes in which the metal interacts solely with labile organic ligands as opposed to more conventional systems stabilized by the less labile η-cyclopentadienyl and CO groups.[2] The reason for this neglect is probably two-fold: firstly, tetra(η^3-allyl)molybdenum is not as easy to prepare as some of the other homoleptic η^3-allyl-transition-metal complexes, e.g. bis(η^3-allyl)nickel, and secondly having a filled metal valence shell it might be expected to be relatively inert.

We have developed an improved synthesis of tetra(η^3-allyl)molybdenum while the isolation of $[MoCl(\eta^3\text{-}C_3H_5)_3]_2$ from the reaction with HCl has provided a new entry into the chemistry of the η^3-allyl-molybdenum system. Some initial results have been mentioned in a preliminary communication.[3]

RESULTS AND DISCUSSION

The original preparation of $[Mo(\eta^3\text{-}C_3H_5)_4]$ (**1**) from $MoCl_5$ and allylMgCl suffers from irreproducibility, low yield (0–20%) and contamination with an equal amount of the dark green dimer $[Mo_2(\eta^3\text{-}C_3H_5)_4]$.[1,2,4,5] These disadvantages can be largely compensated by reacting $MoCl_4 \cdot 2THF$[6] with a slight excess of allylMgCl at room temperature in ether: **1** is obtained in a reproducible 40% yield as a yellow crystalline solid practically uncontaminated by the dimer [eqn (1)]. **1** is stable for short periods in

$$MoCl_4 \cdot 2THF + 4C_3H_5MgCl \xrightarrow[-\ 2THF]{-\ 4MgCl_2} \underset{\mathbf{1}}{[Mo(\eta^3\text{-}C_3H_5)_4]} \quad (1)$$

air and may be sublimed in a high vacuum at 60–70°C. It is soluble in all common solvents and may be recrystallized from pentane or ethanol.

Tetra(η^3-allyl)molybdenum is chemically rather inert towards nucleophiles and could be recovered

* Author to whom correspondence should be addressed.

unchanged from reactions with ethylene [50 atm, room temperature (rt), 24 h], butadiene (rt, 24 h), C_5H_5Na (Na : Mo = 2 : 1, rt, 70 h), toluene (85°C, 5 h), $P(OMe)_3$ (neat, 65°C, 5 h) and LiMe (rt). In addition no reaction was observed with cyclopentadiene (20 h, 50°C), H_2 (1 atm, rt) or MeI (4 days, rt) while treatment with CBr_4 or H_2SO_4 led to decomposition. A slight reaction was observed with CO : after 24 h at rt under 100 atm of CO a trace of $Mo(CO)_6$ was formed with liberation of 1,5-hexadiene.

Reaction with gaseous HCl in pentane at −70°C, however, led to the quantitative formation of a pink solid which decomposes above −30°C and which analyses as the chloride **2** [eqn (2)]. A related iodide

$$2[Mo(\eta^3\text{-}C_3H_5)_4] + 2HCl \xrightarrow{-2C_3H_6} \langle(\text{—Mo(Cl)(Cl)—Mo—})\rangle_3 \quad (2)$$

2

complex could be isolated from the reaction with iodine in ether at −40°C. **2** is practically insoluble in the common organic solvents and could not be characterized by NMR spectroscopy. Its formulation as a dimer with bridging chloride atoms follows from the chemistry described below and established organometallic practice.

2 dissolves in methanol at −30°C to give a yellow solution from which, however, the starting material could be isolated by cooling to −78°C. Similar behaviour is observed if a few drops of water are added to a THF suspension of **2**, implying the equilibrium shown as eqn (3) in which reaction with

$$\mathbf{2} + 2L \rightleftharpoons \langle(\text{—Mo(Cl)(L)})\rangle_3 \quad (3)$$

3

the methanol or water causes rupture of the chloride bridges. The bond formed by *P*- or *N*-donor ligands is apparently stronger than that formed by *O*-donor ligands and in the case of the reactions of **2** with NCMe, pyridine, $P(OMe)_3$ and PMe_3 it proved possible to isolate the adducts **3** as yellow solids which decompose above −30°C. The structure of these adducts follows from the ^1H NMR spectra which are discussed in the following section : the 3-allyl groups are magnetically inequivalent and asymmetrically bonded to the metal. The reaction with *P*-donor ligands is not general and steric factors apparently determine whether reaction occurs. That with PMe_3 [cone angle (θ) = 118 ± 4°][7] is slower than that with $P(OMe)_3$ (θ = 107 ± 2°) while larger ligands such as $P(OPh)_3$ (θ = 121 ± 10°), PPh_3 (θ = 145 ± 2°) and PCy_3 (θ = 179 ± 10°) fail to react.

The chloride bridges in **2** can also be cleaved by reaction of a toluene suspension with $AlCl_3$: a violet solution results whose ^1H NMR spectrum suggests the formation of **4** [eqn (4)] : Addition of ether to this

$$\mathbf{2} + AlCl_3 \longrightarrow 2\langle(\text{—Mo(Cl)(Cl)})\rangle_3\text{—}AlCl_2 \quad (4)$$

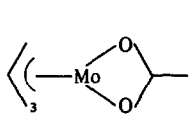
4

solution leads to precipitation of the starting material. Similar behaviour has been previously reported upon reaction of $[MoCl(\eta^3\text{-}C_3H_5)(\eta^6\text{-}C_6H_6)]$ with $AlEt_2Cl$ and $AlEtCl_2$.[8,9]

Addition of excess acetonitrile to **2** followed by $TlBF_4$ leads to formation of an ionic tris(η^3-allyl) molybdenum-bis-ligand complex [eqn (5)]. Related

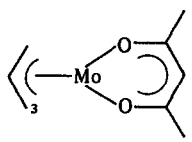
$$\mathbf{2} + 4MeCN \xrightarrow[-2TlCl]{2TlBF_4} 2\langle(\text{—Mo(NCMe)(NCMe)})\rangle_3^{+}\,BF_4^- \quad (5)$$

complexes have been isolated from reactions involving ethylenediamine and bis(dimethylphosphino)ethane, but not with the sterically more demanding tetramethylethylenediamine or bis(dicyclohexylphosphino)ethane.



A series of molybdenum–alkyl complexes (**5**) have been isolated by reacting the PMe_3 and $P(OMe)_3$ adduct **3** with Grignard reagents [eqn (6)]. Here

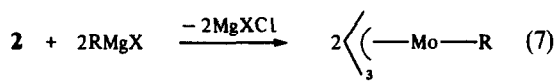
$$\langle(\text{—Mo(Cl)(PR}_3)\text{—})\rangle_3 + R'MgX \xrightarrow{-MgXCl} \langle(\text{—Mo(R')(PR}_3)\text{—})\rangle_3 \quad (6)$$



3 **5**

again steric requirements make themselves apparent in that, although methyl, ethyl and allyl complexes stabilized by PMe_3 could be isolated, no reaction was observed with Pr^{i}MgCl.

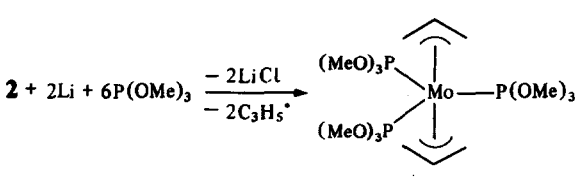
Metathetical replacement of the chloride occurs if **2** is treated with silver acetate and thallium acetylacetonate to give **6** and **7**. The crystal structure of **6** is described in a following section. Treatment of



6

7

the chloride **2** with Grignard reagents, in the absence of donor ligands, results in the formation of molybdenum–alkyl systems containing bridging (or agostic)[10] β-hydrogen atoms [eqn (7)]. The



(7)

ramifications of this reaction will be the subject of a subsequent publication.[11] The reaction of **2** with sodium or thallium cyclopentadienide which results in the formation of the paramagnetic complex $[Mo(\eta^3\text{-}C_3H_5)_2(\eta^5\text{-}C_5H_5)]$ has already been reported.[3]

In an attempt to prepare a $[MoL(\eta^3\text{-}C_3H_5)_3]$ complex, the chloride **2** was reduced with lithium powder in the presence of trimethylphosphite. However, reduction to Mo(II) occurred and the isolated product has the composition

$$[Mo\{P(OMe)_3\}_3(\eta^3\text{-}C_3H_5)_2].$$

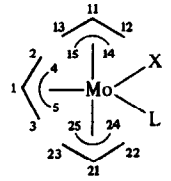
The ^{31}P NMR spectrum of this molecule consists of the characteristic signals for an A_2B spin system while the ^1H NMR spectrum shows that both allyl groups are magnetically equivalent and asymmetrically bonded to the metal atom suggesting the structure **8** [eqn (8)], in which the metal occupies a trigonal bipyramidal environment.

8 (8)

NMR SPECTROSCOPIC INVESTIGATIONS

The following qualitative description of the structures of the complexes **3**–**7** is based on their low-temperature, 400-MHz ^1H NMR spectra. In all of these complexes the three allyl groups are unique and bonded as η^3-ligands to the Mo atom. The terminal C atoms of each group are inequivalent and as a result the six *syn*- and six *anti*-protons are magnetically inequivalent and can be readily distinguished by their characteristic coupling constants. The results have been brought together in Table 1. Coupling between the P atom and the allylic protons are observed for **3** [L = PMe_3 or $P(OMe)_3$] and **5**, indicating that, under the measurement conditions, ligand dissociation is not occurring. In the case of the pyridine adduct **3** (L = py), the ^1H chemical shifts of the ligand molecule do not exclude unambiguously that dissociation is occurring. The protons of the Mo σ-bonded C atom in **5** (L = PMe_3) (34 and 35, see Table 1) are diastereotopic: however, since the three allyl groups are also inequivalent, a distinction between a quasi-tetrahedral and a square planar arrangement of the ligands around the metal atom cannot be made. That the structures of **3**–**7** in solution are similar to that observed in the crystal for the acetate **6** (see following section) is, however, underlined by detailed ^1H NMR studies using magnetization transfer difference spectroscopy[12] carried out for the $AlCl_3$ adducts **4** and **6** and the acetylacetonate complex **7** (Fig. 1).

Spectrum B in Fig. 1 suggests that the *meso*-C atoms of the η^3-allyl groups containing protons 21–25 and 1–5 are directed at each other. This is supported by the NOE interaction of the *syn*-proton 23 with the *syn*-proton 3 (spectrum C). This experiment also establishes the mutual arrangement of the protons in both of these allyl groups. The arrangement of the third allyl group (having protons 11–15) relative to these follows from spectrum D which establishes that the *syn*-proton 13 is in close proximity to the *anti*-proton 25 of the neighbouring allyl group. The proximity of the *syn*-proton 12 to the *anti*-proton 4 follows from spectrum E which also establishes the arrangement of the methyl groups in the acetylacetonate ligand, while the close proximity of the *meso*-proton 11 to this group follows from spectrum F.



The η^1-allyl complex **5** (L = PMe_3), in contrast to $[Pd(PMe_3)(\eta^1,\eta^3\text{-allyl})_2]$,[13] exhibits no exchange between the η^1- and η^3-allyl groups (up to 273 K at 200 MHz). However, in the case of the complexes $[MoClAlCl_3(\eta^3\text{-}C_3H_5)_3]$ (**4**) and **7** magnetization transfer difference spectroscopy at 243 and 263 K, respectively, show the existence of slow exchange processes which in both cases lead to an equilibration of two of the allyl groups. This exchange, which involves all three proton types (*meso*, *syn* and *anti*), will be discussed in detail for **7**. The spectra of this complex at 263 K show that, in the third allyl group (having protons 21–25, see Fig. 1), the *syn*- and *anti*-protons 23 and 25 exchange. This, which is presumably the result of the familiar η^1–η^3-allyl rearrangement, generates a free coordination site at the molybdenum and is followed by rearrangement of the acetylacetonate group and

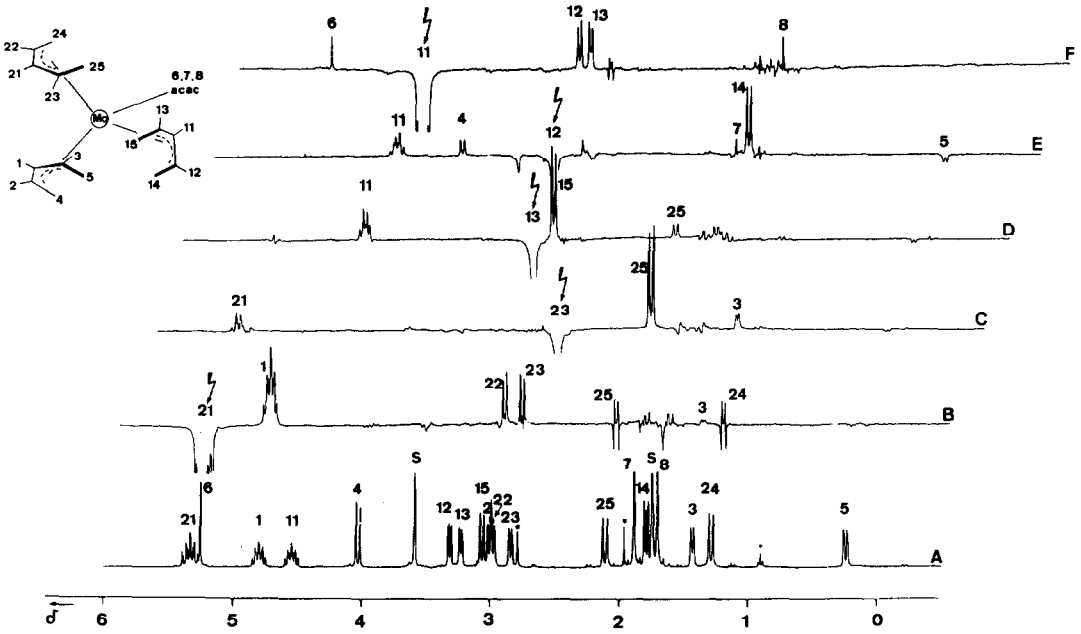
[c]



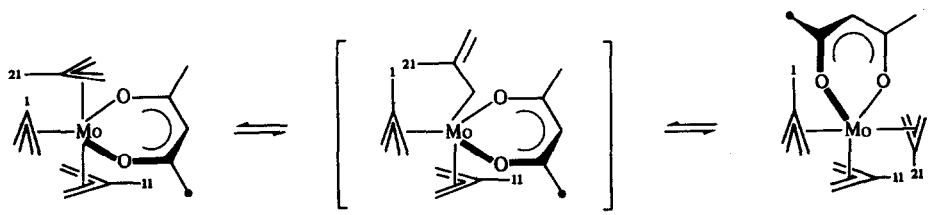


Fig. 1. 400-MHz ^{1}H NMR spectra of 7 at 233 K. (A) Normal spectrum. B–F nuclear-Overhauser difference spectra (the saturated signal is indicated by an arrow); signals for neighbouring protons appear in the difference spectra as positive signals (spectrum E shows a negative NOE for proton 5). S, solvent; *, impurity.

(9)

recomplexation of the allyl group [eqn (9)]. As a result the protons 11–15 now occupy the environment originally held by protons 1–5. In addition, an exchange of the methyl groups of the acetylacetonate group has occurred which is experimentally observed. A similar effect is found for the $AlCl_3$ adduct **4** but, in this case, the most plausible explanation involves rotation of the third allyl group about the Mo–allyl coordination axis which would lead to the observed pair-wise equilibration in this group of the *syn*- and *anti*-protons.

THE MOLECULAR STRUCTURE OF 6

The molecular structure of **6**, was determined by a single-crystal X-ray structural investigation and is shown in Fig. 2 with the atomic labelling scheme. Table 2 contains bond lengths and angles, and the positional parameters of all the atoms are given as supplementary data.

The coordination geometry about the molybdenum atom is defined by the mid-points (D1, D2 and D3) of the three allyl groups as well as by the mid-point (D4) of the acetate ligand (see footnote in Table 2 for the definition of the mid-points). The resulting six bond angles involving the metal atom may be divided into two groups: whereas two angles are significantly larger than the tetrahedral value [D1–Mo–D3 (140.0°) and D2–Mo–D4 (141.6°)], the remaining four angles have an average value of *ca* 96° (see Table 2). The molecular geometry can thus be best described as a distorted tetrahedron.

The three allyl groups are bonded unsymmetrically to the metal atom as indicated by non-equivalent C—C and Mo—C bond distances (see Table 2). The allyl group C6–C7–C8 opposite to the acetate group is least distorted with Mo—C6 and Mo—C8 differing only by 0.01 Å (±3 ESD). For the

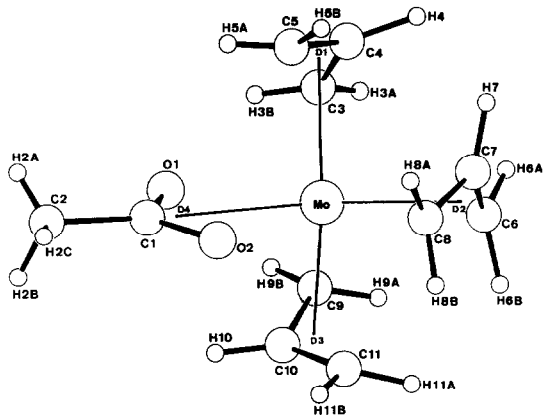

Fig. 2. Molecular structure of $[MoOAc(\eta^3\text{-}C_3H_5)_3]$.

C1...H1O	2.67(2)	H31...H9A	2.88(3)
O1...H3B	2.41(2)	H3A...H9B	2.76(3)
O1...H5A	2.40(2)	H3B...H9B	2.50(3)
O1...H9B	2.90(2)	H4...H6A	2.57(3)
O1...H1O	2.42(2)	H4...H7	1.95(3)
O2...H5A	2.88(2)	H5B...H7	2.61(3)
O2...H1O	2.83(2)	H5B...H8A	2.68(3)
O2...H11B	2.67(2)	H6A...H9A	2.78(3)
		H6B...H9A	2.42(3)
		H6B...H11A	1.97(3)
		H8B...H11A	2.45(3)
		H8B...H11B	2.48(4)

remaining allyl groups, this distortion is more pronounced, being 0.05 Å for Mo—C9 vs Mo—C11 and 0.02Å for Mo—C3 vs Mo—C5. All C—C distances lie, however, within the normal range for η^3-allyl systems. The observed asymmetry is a result of the different electronic and steric environment of each ligand. The relative positioning of the allyl groups can be described by the dihedral angles between their planes: 32.2° between C3–C4–C5 and C6–C7–C8, 46.6° between C3–C4–C5 and C9–C10–C11 and 64.3° between C6–C7–C8 and C9–C10–C11. The planar acetate group is also non-symmetric in its bonding to the molybdenum, with O2 being 0.016 Å closer to the metal than atom O1. The plane defined by C1–C2–O1–O2 (±0.002 Å) forms an angle of 76.5° with that of the allyl group C6–C7–C8 and angles of 48.8 and 23.5° with the allyl groups C3–C4–C5 and C9–C10–C11, respectively.

Intramolecular contacts smaller than 3.0 Å are shown in Table 3. Severe crowding of the four ligands

Table 2. Bond lengths (Å) and angles (°) with ESDs in parentheses[a]

[a] D1 = mid-point of allyl group C3–C4–C5, D2 = mid-point of allyl group C6–C7–C8, D3 = mid-point of allyl group C9–C10–C11, and D4 = mid-point of acetate O1–C1–O2.

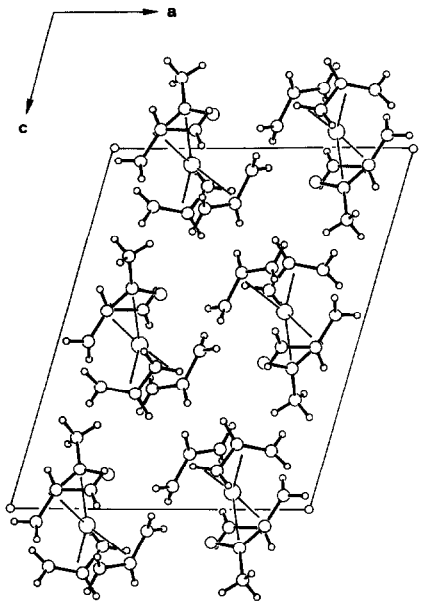

Fig. 3. View of the unit cell as projected onto the plane *ac*.

around the metal is indicated by short contacts between the hydrogen atoms of all three allyl groups and of the acetate group. The two shortest contacts, H4...H7 1.95(3) and H6B...H11A 1.97(3) Å, are much smaller than the sum of the van der Waal's radii for hydrogen atoms (2.4 Å).

No unusually short intermolecular contacts (< 3.0 Å) between non-hydrogen atoms are observed within the unit cell (see Fig. 3).

EXPERIMENTAL

All experiments were carried out under an argon atmosphere. Solvents (ether, THF, toluene and pentane) were dried and freed from dissolved oxygen by distillation form $Na[AlEt_4]$. CH_2Cl_2 and acetonitrile were dried over CaH_2, and acetone over P_2O_5.

^1H NMR spectra were measured with Bruker WP 80 (80-MHz) and WH 400 (400-MHz) instruments. ^{31}P NMR spectra were measured with a Bruker WP 80 (32.4-MHz) instrument. Mass spectra were measured with a Varian CH 5 instrument.

Microanalysis was carried out by Dornis and Kolbe, Microanalytical Laboratory, Mülheim a. d. Ruhr.

$[Mo(\eta^3\text{-}C_3H_5)_4]$ (1)

$MoCl_4 \cdot 2THF$[6] (20 g, 52.37 mmol) was added in three batches to a stirred solution of allylMgCl in diethyl ether (660 cm^3, 0.38 M) at room temperature. The reaction mixture was cooled to 0°C and stirred overnight. The solvent was evaporated and the residue extracted with pentane at room temperature. Air was bubbled through the resulting green solution for *ca* 2 min in order to decompose traces of $[Mo_2(\eta^3\text{-}C_3H_5)_4]$ and then filtered through an Avicell bed. The yellow solution was concentrated *in vacuo* and cooled under argon. Lemon-yellow crystals were deposited which were collected, dried *in vacuo* and stored at −30°C. Yield 5.72 g (42% of theoretical value). Found: C, 55.2; H, 8.0; Mo, 36.7%. Calc. for $C_{12}H_{20}Mo$: C, 55.4; H, 7.8; Mo, 36.9%.

$[MoCl(\eta^3\text{-}C_3H_5)_3]_2$ (2)

Dry gaseous HCl was bubbled slowly through a pentane solution of **1** (0.72 g, 2.76 mmol) and stirred at −70°C. A bright pink precipitate was formed and treatment was continued until the mother liquor became colourless. The solid was collected at −70°C, washed with pentane and ether and dried in a high vacuum at −50°C. Yield 0.7 g (quantitative). Found: C, 42.6; H, 5.6; Cl, 13.9; Mo, 37.8%. Calc. for $C_9H_{15}ClMo$: C, 42.5; H, 5.9; Cl, 13.9; Mo, 37.7%.

$[MoI(\eta^3\text{-}C_3H_5)_3]$

Iodine (3.17 g, 12.5 mmol) in ether was added slowly to a solution of **1** (3.25 g, 12.5 mmol) in 100 cm^3 of ether stirred at −60°C. The reaction mixture was allowed to reach −40°C for 1 h and the resulting brown precipitate was isolated at −60°C, washed with ether, dried in a high vacuum and stored at −78°C. Yield 3.89 g (90% of theoretical value). Found: C, 31.5; H, 4.5; Mo, 27.8; I, 36.2 (rest)%. Calc. for $C_9H_{15}IMo$: C, 31.2; H, 4.4; Mo, 27.7; I, 36.7%.

$[MoOAc(\eta^3\text{-}C_3H_5)_3]$ (6)

2 (2.30 g, 9.04 mmol) was dissolved in CH_2Cl_2 and treated with a 50% excess of silver acetate (2.2 g) at −20°C. The solution was stirred for a further 20 h. The solvent was removed *in vacuo* and the residue extracted with pentane at −10°C. The concentrated pentane solution was cooled to −78°C and the resulting yellow crystalline precipitate isolated, dried in a high vacuum and stored at −30°C. Yield 1.51 g (60% of theoretical value). The compound decomposes slowly at room temperature and rapidly at 57°C. Found: C, 48.4; H, 6.6; Mo, 35.2%. Calc. for $C_{11}H_{18}O_2Mo$: C, 48.5; H, 6.7; Mo, 35.3%. MS: *m/z* 280 [M^+], 238, 195. ^1H NMR spectrum: see Table 1.

$[Moacac(\eta^3\text{-}C_3H_5)_3]$ (7)

2 (1.04 g, 4.09 mmol) was suspended in 30 cm^3 THF at −78°C and Tlacac (1.55 g, 5.11 mmol) in

THF was added. A yellow-brown suspension was formed which was stirred overnight at −78°C. The reaction mixture was filtered through Avicel and the solvent removed in a high vacuum. The residue was taken up in pentane at −40°C and the solution cooled to −78°C. A yellow solid precipitated which was isolated and dried in a high vacuum at −78°C. Yield 0.60 g (46.2% of theoretical value). Found: C, 52.9; H, 6.7; Mo, 30.4%. Calc. for $C_{14}H_{22}O_2Mo$: C, 52.8; H, 6.9; Mo, 30.2%. ^{1}H NMR spectrum: see Table 1.

[MoCl(NCMe)(η^3-C_3H_5)$_3$] (**3**, L = MeCN)

2 (0.40 g, 1.54 mmol) was added to MeCN (10 cm^3) at −30°C to give a yellow suspension. The solution was concentrated to *ca* 3 cm^3 and CH_2Cl_2 added. The resulting solution was concentrated at −30°C to give yellow crystals which were washed with MeCN at −30°C, dried in a high vacuum and stored at −30°C. Yield 0.36 g (80% of theoretical value). Found: C, 44.6; H, 6.1; Cl, 11.9; N, 4.8; Mo, 32.6%. Calc. for $C_{11}H_{18}ClNMo$: C, 44.7; H, 6.1; Cl, 12.0; N, 4.7; Mo, 32.6%. The ^{1}H NMR spectrum showed the presence of isomers and was not analysed in detail.

[MoCl(py)(η^3-C_3H_5)$_3$] (**3**, L = py)

This was prepared similarly, in 80% yield, as orange crystals soluble in CH_2Cl_2 and which decompose above −30°C. Found: C, 50.4; H, 6.0; Cl, 10.6; N, 4.3; Mo, 28.6%. Calc. for $MoC_{14}H_{20}NCl$: C, 50.4; H, 6.0; Cl, 10.6; N, 4.2; Mo, 28.8%. ^{1}H NMR spectrum: see Table 1.

[MoCl(PMe_3)(η^3-C_3H_5)$_3$] (**3**, L = PMe_3)

This was prepared similarly, in 59% yield, as a yellow solid. Found: Cl, 11.1; P, 9.8; Mo, 30.5%. Calc for $C_{12}H_{24}ClPMo$: Cl, 10.7; P, 9.4; Mo, 29.0%. ^{1}H NMR spectrum: see Table 1. ^{31}P NMR (32.4 MHz, d_8-THF, rt): δ −5.5.

[MoCl{P(OMe)$_3$}(η^3-C_3H_5)$_3$] [**3**, L = P(OMe)$_3$]

This was prepared similarly, in 60% yield, as a yellow solid from ether. Found: C, 38.2; H, 5.9; Cl, 9.3; P, 8.3; Mo, 25.4%. Calc. for $C_{12}H_{24}O_3ClPMo$: C, 38.1; H, 6.4; Cl, 9.4; P, 8.2; Mo, 25.3%. ^{1}H NMR: see Table 1. ^{31}P NMR (32.4 MHz, CD_2Cl_2, −30°C): δ 146.4.

[MoMe{P(OMe)$_3$}(η^3-C_3H_5)$_3$] (**5**; R = OMe, R′ = Me)

2 (0.16 g, 0.63 mmol) was suspended in ether (30 cm^3) at −30°C and treated successively with P(OMe)$_3$ (1 cm^3, 8.48 mmol) and MeMgI (0.29 cm^3 in ether, 0.63 mmol) to give a yellow suspension. The solvent was removed *in vacuo* and pentane (80 cm^3) added. The solution was filtered, concentrated, cooled to −78°C and the yellow precipitate was isolated and dried in a high vacuum at −78°C. Yield 0.10 g (44% of theoretical value). Found: Mo, 27.2; P, 8.9%. Calc. for $C_{13}H_{27}OPMo$: Mo, 26.8; P, 8.7%. ^{1}H NMR: see Table 1. ^{31}P NMR (32.4 MHz, d_6-acetone, −30°C): δ 159.4.

[MoMe(PMe_3)(η^3-C_3H_5)$_3$] (**5**; R = Me, R′ = Me)

This was prepared similarly, in 34% yield, by reacting [MoCl(PMe_3)(η^3-C_3H_5)$_3$] with MeMgI in ether. Found: Mo, 30.3; P, 10.1%. Calc. for $C_{13}H_{27}PMo$: Mo, 31.0; P, 10.0%. ^{31}P NMR (32.4 MHz, d_8-THF, −80°C): δ 3.8.

[MoEt(PMe_3)(η^3-C_3H_5)$_3$] (**5**; R = Me, R′ = Et)

This was prepared similarly, in 63% yield, as a yellow solid by reacting [MoCl(PMe_3)(η^3-C_3H_5)$_3$] with EtMgI in ether. Found: Mo, 29.1; P, 9.2%. Calc. for $C_{20}H_{29}PMo$: Mo, 29.6; P, 9.6%. ^{31}P NMR (32.4 MHz, d_6-acetone, −30°C): δ 2.3.

[Mo-η^1-C_3H_5(PMe_3)(η^3-C_3H_5)$_3$] (**5**; R = Me, R′ = C_3H_5)

This was prepared similarly as a yellow solid by reacting **2** successively with PMe_3 and allylMgCl in ether at −78°C. Found: Mo, 28.9; P, 9.3%. Calc. for $C_{15}H_{29}PMo$: Mo, 28.6; P, 9.2%. ^{1}H NMR spectrum: see Table 1. ^{31}P NMR (32.4 MHz, d_6-acetone, −30°C): δ 1.6.

[Mo-η^1-C_3H_5{P(OMe)$_3$}(η^3-C_3H_5)$_3$] (**5**; R = OMe, R′ = C_3H_5)

This was prepared similarly in 83% purity (NMR) by reacting [MoCl{P(OMe)$_3$}(η^3-C_3H_5)$_3$] with allylMgCl in ether at −78°C. ^{31}P NMR (32.4 MHz, d_6-acetone, −60°C): δ 159.6.

[Mo(NCMe)$_2$(η^3-C_3H_5)$_3$]$^+$$BF_4^-$

MeCN (2 cm^3) was added to **2** (0.65 g, 2.56 mmol) at −30°C. CH_2Cl_2 (30 cm^3) was added to the yellow suspension followed by $TlBF_4$ (0.74 g, 2.56 mmol). The reaction was stirred overnight at −30°C, filtered and the resulting orange solution concentrated, treated with cold ether and cooled to −78°C. A yellow precipitate was formed which was isolated and dried in a high vacuum. Yield 0.64 g (64% of theoretical value). Found: Mo, 24.6; N, 7.1; F,

19.7%. Calc. for $C_{13}H_{21}BF_4N_2Mo$: Mo, 24.7; N, 7.2; F, 19.6%.

A related PF_6 complex was prepared, as yellow crystals, by reacting $[MoI(\eta^3\text{-}C_3H_5)_3]_2$ with MeCN and $AgPF_6$ in ether–CH_2Cl_2 at −30°C. Yield 60%. Found: C, 35.1; H, 5.3; N, 6.2; Mo, 20.5%. Calc. for $C_{13}H_{21}PF_6N_2Mo$: C, 35.0; H, 4.7; N, 6.3; Mo, 21.5%.

$[Mo(H_2NC_2H_4NH_2)(\eta^3\text{-}C_3H_5)_3]^+PF_6^-$

This was prepared similarly as a yellow compound in low yield by reacting **2** with ethylendiamine and NH_4PF_6 in CH_2Cl_2. Found: Mo, 22.8; N, 6.7; P, 7.2; F, 27.3%. Calc. for $C_{11}H_{23}F_6PN_2Mo$: Mo, 22.6; N, 6.6; P, 7.3; F, 26.9%.

$[Mo(Me_2PC_2H_4PMe_2)(\eta^3\text{-}C_3H_5)_3]^+BF_4^-$

This was prepared similarly, in 51% yield, by reacting **2** with $Me_2PC_2H_4PMe_2$ and $TlBF_4$ in CH_2Cl_2. Found: Mo, 20.7; P, 13.5; F, 16.3%. Calc. for $C_{15}H_{31}BF_4P_2Mo$: Mo, 21.1; P, 13.6; F, 16.7%. ^{31}P NMR (32.4 MHz, d_6-acetone, −80°C): δ 48.0/44.7 ($J_{P,P}$ 45.2 Hz).

$[Mo\{P(OMe)_3\}_3(\eta^3\text{-}C_3H_5)_2]$ (**8**)

2 (0.36 g, 0.71 mmol) was treated at −30°C with $P(OMe)_3$ (3 cm^3) and the resulting yellow precipitate dissolved in THF (30 cm^3). Excess Li powder (0.5 g) was added and the mixture stirred at −30°C for 4 h. The reaction mixture was filtered and the solution evaporated to dryness and the residue washed with pentane (5 × 10 cm^3) at −78°C. Extraction with ether at −30°C gave a yellow solution from which yellow crystals were obtained after concentration and cooling. These were dried in a high vacuum at −30°C. Yield 0.67 g (70% of theoretical value). The complex decomposes slowly at rt and rapidly at 70–75°C. Found: C, 32.9; H, 7.1; P, 16.9; Mo, 17.4% Calc. for $C_{15}H_{37}O_9P_3Mo$: C, 32.7; H, 6.8; P, 16.9; Mo, 17.4%. MS: *m/z* 552 [M^+], 428 [$M^+ - P(OMe)_3$], 302 [$M^+ - 2P(OMe)_3/2H$]. ^{31}P NMR (32.4 MHz, *d*-toluene, −30°C): AB_2 spin system [δ_A 193.6, δ_{B_2} 176.4 ($J_{P,P}$ 58.1 Hz)]. ^1H NMR (0°C, d_8-toluene, 233 K):* δ 5.61 (H1, m), 2.58 (H2, m), 2.72

(H3, m), 1.91 (H4, m), 1.53 (H5, m), 3.49 (H6, d), 3.33 (H7, t); $J_{1,2}$ 6.5 Hz, $J_{1,3}$ 6.3 Hz, $J_{1,4}$ 9.3 Hz, $J_{1,5}$ 8.9 Hz, $J_{2,3}$ 3.5 Hz, $J_{2,4}$ 0 Hz, $J_{3,5}$ 0 Hz, $J_{2,P}$ 0 Hz, $J_{3,P}$ 15.8 Hz, $\sum J_{4,P}$ 13.5 Hz, $\sum J_{5,P}$ 11.7 Hz, $J_{6,P}$ 9.8 Hz, $\sum J_{7,P}$ 9.1 Hz).

The same complex (^{31}P NMR) was formed on treating **2** with $LiAlH_4$ followed by extraction with pentane at $-10°C$ as well as in the reaction of $[MoCl\{P(OMe)_3\}(\eta^3\text{-}C_3H_5)_3]$ with allylMgCl. The product of the reaction of **2** with PMe_3 and Li in THF at $-30°C$ could not be isolated analytically pure but presumably has an analogous structure. ^{31}P NMR (32.4 MHz, d_6-acetone $-30°C$): A_2B spin system [δ_{A_2} 9.1, δ_B 5.0 ($J_{P,P}$ 34.1 Hz)].

Experimental details of the X-ray structural determination are summarized in Table 4. A single crystal of **6**, recrystallized from methanol, was mounted in a glass capillary under argon and maintained at low temperature (100 K) for all subsequent measurements. Two independent data sets were collected (see Table 4) and equivalent reflections were averaged ($R_{av} = 0.019$) to give 4894 unique observed data. These were assigned sigmas from counting statistics and used in the subsequent solution and refinement of the structure.

The Mo atom position was deduced from a Patterson map, and a phased Fourier synthesis revealed all non-hydrogen atoms. In a difference Fourier synthesis following the anisotropic refinement of the heavier atoms, the allylic hydrogen atoms could be located. Three hydrogen atoms bonded to C2 were placed at calculated positions. All the hydrogen atoms were included in the final stages of the refinement, convergence being obtained at $R = 0.025$ ($R_w = 0.037$). In addition to several locally written programs, the following programs were used: TRACER by Lawton and Jacobson for cell reduction; Sheldrick's SHELX-76 for Fourier calculations and initial least-squares refinement; GFMLS, a highly modified version of ORFLSD, by Hirshfeld, Coppens, Leiserowiz and Rabinovich for subsequent full-matrix least-squares refinement; Davis' DAESD for bond distance and angle calculations, XANADU by Roberts and Sheldrick for best-plane and torsion angle calculations; and Johnson's ORTEP for the molecular drawings.

ACTIVATION OF H_2 AND SO_2 BY Mo AND W COMPLEXES: FIRST EXAMPLES OF MOLECULAR-H_2 COMPLEXES, SO_2 INSERTION INTO METAL–HYDRIDE BONDS, AND HOMOGENEOUS HYDROGENATION OF SO_2

G. J. KUBAS† and R. R. RYAN

Los Alamos National Laboratory, University of California, Los Alamos. NM 87545, U.S.A.

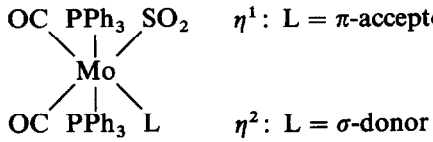
(*Received* 3 *July* 1985)

Abstract—Our recent work on small-molecule activation by low-valent organometallic Mo and W complexes is summarized. Stereochemical control of Mo–SO_2 coordination geometry has been achieved since the SO_2 in $Mo(CO)_2(PPh_3)_2(SO_2)(L)$ can bind as a σ-base (η^1), as a π-acid (η^2), or as an isomeric mixture of *both forms* merely by fine-tuning the donor–acceptor nature of the single *cis* ligand, L. Modification towards bulky phosphines led to a synthetic pathway to the formally 16-electron complexes, $M(CO)_3(PR_3)_2$ (R = Cy or Pr^i), the structures of which show agostic M···H—C interaction. This weak interaction can readily be supplanted by others, including the first example of coordination of molecular H_2. Neutron diffraction studies of $W(CO)_3(PPr^i_3)_2(\eta^2\text{-}H_2)$ show that W—H = 1.89(1) Å and H—H = 0.82(1) Å. ^1H NMR of the HD complex provides a useful spectroscopic diagnostic for molecular coordination (J_{HD} = 33.5 Hz). Complete H–D isotopic exchange occurs for $D_2 + H_2$ complex, even in the solid state. Reductions of SO_2 by hydrides and H_2 have been studied. Addition of SO_2 to solutions of $(\eta^5\text{-}C_5R_5)M(CO)_3H$ [R = H (= Cp) or Me (= Cp*)] produced $(\eta^5\text{-}C_5R_5)M(CO)_3(SO_2H)$, the first example of SO_2 insertion into an M—H bond. The —S(O)(OH) complexes are thermally unstable, decomposing at 25–75°C to SO_2 reduction products, including water and sulfido–oxo cluster complexes. A dithionite-bridged complex, $[Cp^*Mo(CO)_3]_2(\mu\text{-}S_2O_4)$, has also been obtained from the hydride–SO_2 reaction. Homogeneous catalysis of SO_2 reduction by H_2 has been effected using $[Cp^*Mo(\mu\text{-}S)(\mu\text{-}SH)]_2$ catalyst. Clean conversion to sulfur and water occurs in chlorobenzene–butanol at 1–3 atm and 25–100°C at a rate of up to 350 catalyst turnovers h^{-1}. Weak bases such as Et_3N and ROH greatly increase the rate.

Our recent findings and those of others indicate that low-valent group 6 organometallic complexes are well-suited for studies of the activation of SO_2, molecular H_2,[1] C—H,[2] and O—H[3] bonds, and also of the stereochemical control of metal–ligand (e.g. Mo–SO_2) coordination geometry.[4] Indeed, $Cr(CO)_5$ has been well recognized as a prototype mononuclear transition-metal fragment,[5] forming complexes with weak ligands such as methane in low-temperature matrices.[6] Formally 16-electron complexes, of which $M(CO)_3(PCy_3)_2$ is an example,[2,7] have been found that offer a similar type of chemistry with the advantage of room-temperature adduct stability conferred by the bulky phosphines. Because of this stability, the first examples of molecular-H_2 complexes have been characterized as isolable, crystalline solids.[1]

In this paper we summarize much of our recent work on small-molecule activation by Mo and W complexes. In general, both metals give similar chemistry, but, since the W complexes possess greater thermal and air stability, they often were more readily characterized. Our research has emphasized SO_2–transition-metal chemistry, with recent work directed towards SO_2 reduction. The pursuit of this goal led to the recent serendipitous

† Author to whom correspondence should be addressed.



discovery of the W and Mo dihydrogen complexes. Little is known about the elementary steps of SO_2 reduction, and we have found that Mo complexes offer an excellent opportunity for studying stepwise reactions of SO_2 with hydrogen and hydride ligands. The overall goal of our efforts, in addition to understanding the mechanistic processes which occur during SO_2 reduction on heterogeneous catalysts, has been to develop a *homogeneous* catalytic SO_2 reduction cycle.

COORDINATION OF SO_2 TO Mo(0) AND W(0) COMPLEXES

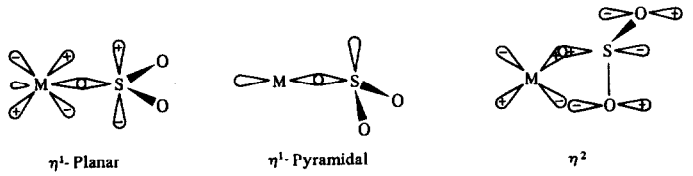
The primary focus of our research has been the synthesis, structure, bonding and reaction chemistry of transition-metal–SO_2 complexes.[4(b)] The diversity of bonding modes exhibited by SO_2–metal complex interactions is unequalled by any other ligand, making SO_2 a remarkably versatile bonding probe for transition-metal complexes. Studies of octahedral d^6 complexes of the group 6 metals have contributed much to our understanding of SO_2 coordination. In particular, the ability of SO_2 to coordinate in an η^1-planar or η^2 (S,O-bonded) fashion to Mo(0) and W(0) has been advantageous in regard to our understanding of the π-acceptor ability of SO_2. Insight into the reactivity of coordinated SO_2, for example the basicity of the uncoordinated oxygen atom in η^2-SO_2, has also been obtained.

Interestingly, $Mo(CO)_3(phen)(SO_2)$ and $Mo(CO)_2(bipy)(SO_2)_2$ contain η^2-SO_2 ligands,[8] whereas η^1-planar SO_2 was found in all previously structurally characterized SO_2 complexes of d^6-metals.[4(b)] A large variety of d^6 Mo– and W–SO_2 complexes has since been systematically synthesized and characterized to determine the extent and nature of stereochemical control of the metal–SO_2 bonding geometry.[4,9] For d^6-complexes in general, and Mo(0) and W(0) in particular, the η^1-planar and η^2 geometries have been observed whereas the η^1-pyramidal has not and is not expected on the basis of simple orbital participation schemes, i.e.

η^2 fashion, depending upon the nature of L:[4]

η^1: L = π-acceptor

η^2: L = σ-donor



The bonding mode is remarkably sensitive to fine-tuning just *one* ligand and for the complex containing L = alkylisocyanide the coexistence of both an η^1-planar SO_2 isomer and an η^2-SO_2 isomer in apparent equimixture was observed. This is the first direct observation of spontaneous linkage isomerism of coordinated SO_2, although it has been implicated in reactions of coordinated SO_2. From these and related studies the following conclusions may be drawn:

(a) The η^2-geometry involves more M → SO_2 π-donation and less SO_2 → M σ-donation than does the η^1-planar case. The η^2-geometry is, therefore, generally discouraged by strongly π-accepting ligands and encouraged by strongly σ-donating ligands.

(b) The existence of a D–M–A (D = donor or weak π-acceptor, A = acceptor) conformation *cis* to SO_2 promotes η^2-bonding and dictates the orientation of the S—O_m bond: in all cases, the sulfur atom lies closest to the acceptor ligand (e.g. CO).

The latter can be attributed to a polarization of π-electron density toward the better π-accepting ligands in the plane *cis* to the SO_2. The unsymmetrical η^2-SO_2 ligand is oriented to best compete for the π-electron density with the sulfur atom nearer the carbonyls since the $2b_1$ acceptor orbital is largely sulfur *p* in character with a smaller oxygen *p* contribution.

The coordinated SO_2 in the Mo complexes is neither reversibly bound nor reactive with oxygen to form sulfato complexes. For those complexes containing η^1-planar SO_2, this behavior is consistent with the majority of known η^1-planar SO_2 complexes of all metal coordination types. The behavior of the η^2-complexes, however, is in contrast

η^1- Planar η^1- Pyramidal η^2

Control of the SO_2 bonding mode has been achieved by the proper choice of the σ-donating vs π-accepting ancillary ligands as well as their geometric disposition with respect to the SO_2. For example, the SO_2 ligand in *cis,trans*-$Mo(CO)_2(PPh_3)_2(SO_2)(L)$ has been found to coordinate in either η^1-planar or to that of η^2-SO_2 in four- and five-coordinate complexes.[4(b)] One important difference between the octahedral η^2-SO_2 complexes and the lower-coordinate systems is the inaccessibility of the η^1-pyramidal SO_2 bonding mode in the octahedral complexes. In general, the η^1-pyramidal SO_2

geometry is not far removed energetically from that of the η^2-geometry for the four- and five-coordinate η^2-SO_2 complexes. The great majority of η^1-pyramidal SO_2 complexes contain reversibly bound SO_2 and react with oxygen to give sulfato complexes.[4(b)] Thus, an intermediate species containing an η^1-pyramidal SO_2 might be involved in the reversible coordination of SO_2 and sulfato reaction of the four- and five-coordinate η^2-SO_2 complexes. For the octahedral η^2-SO_2 systems, such a reaction pathway would be blocked by the very high energy of the η^1-pyramidal species and, in general, d^6 η^2-complexes do not react with O_2 to form sulfates.

Since the discovery of η^2-SO_2 bonding in transition-metal complexes,[10] there has been considerable interest in this bonding mode and in the extent to which S—O bond activation actually occurs and whether it can be exploited in reaction chemistry studies. This form of coordinated SO_2 has shown some intriguing examples of reactivity quite different from that presently known for the η^1-planar, η^1-pyramidal or bridging SO_2 coordination modes. The bonding of η^2-SO_2 has been suggested to primarily involve π-donation from the metal to the LUMO of SO_2, which is antibonding with respect to the S—O bond and bonding with respect to the O–O interaction.[4(b)] This type of interaction would be expected to lengthen S—O distances, increase the terminal oxygen basicity, and enhance coordination by Lewis acids. The complex

$$Ru(CO)_2(PPh_3)_2(\eta^2\text{-}SO_2 \cdot SO_2) \text{ (I)}$$

was found to contain a second SO_2 coordinated as a Lewis acid to the terminal oxygen of the η^2-SO_2 (Fig. 1).[11] It exhibits the longest coordinated S—O bond and the lowest ν(SO) value of any of the reported η^2-SO_2 complexes.[4(b)] An unusual reactivity was observed: the complex slowly reacted with excess SO_2 in the absence of oxygen to generate the bidentate sulfate complex[12] $Ru(SO_4)(CO)_2(PPh_3)_2$ (the same complex that was obtained on reaction of **I** with molecular oxygen[13]) plus PPh_3S and an unidentified ruthenium species which appeared to contain bridging carbonyls. The only products obtained in the presence of excess PPh_3 are $Ru(SO_4)(CO)_2(PPh_3)_2$ and PPh_3S. In an attempt to explore the effect of enhanced basicity of the ancillary ligand, a variety of complexes of the type $Ru(CO)_2(SO_2)(PR_3)_2$ were prepared where PR_3 = (A) triphenylphosphine, (B) *p*-tolyldiphenylphosphine, (C) tribenzylphosphine, and (D) tricyclohexylphosphine. For A–C the reactivity is essentially identical with $\sim$10% of the corresponding SO_4 complexes formed in 2 days in SO_2-saturated benzene solutions. For D, a different complex was isolated after 1 day which analyzes for $Ru(CO)_2(S_2O_4)(PCy_3)_2$ and is monomeric by solution molecular weight studies. Since this species continues to react and generate the sulfato complex, $Ru(CO)_2(SO_4)(PCy_3)_2$, it appears likely that this is an intermediate in the reaction and that the reaction should be depicted as $M^0(SO_2 \cdot SO_2) \rightarrow M^{2+}(S_2O_4)^{2-} \rightarrow M^{2+}(SO_4)^{2-} + \frac{1}{8}S_8$ (the S_8 reacts with PR_3 to form SPR_3). At this point there appears to be no clear trend in the reactivity that can be related to the phosphine basicity, but other factors such as steric effects could dominate.

Other studies of Mo–SO_2 complexes have produced well-defined illustrations of the basicity of

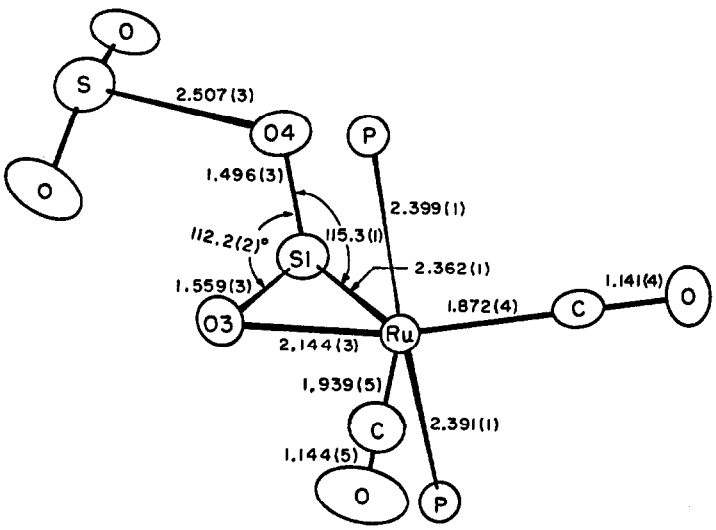


Fig. 1. Structure of $Ru(CO)_2(PPh_3)_2(\eta^2\text{-}SO_2 \cdot SO_2)$.

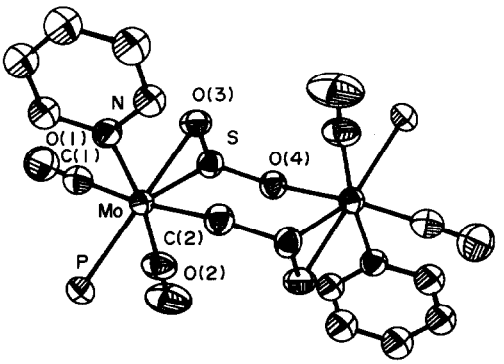

Fig. 2. Structure of $[Mo(CO)_2(PPh_3)(py)(SO_2)]_2$.

the terminal oxygen of η^2-SO_2. The structure of $[Mo(CO)_2(PPh_3)(py)(SO_2)]_2$ showed the first example of SO_2 coordinated to metals by way of all three of its atoms (Fig. 2).[4(a),14] This complex was spontaneously formed in solution from $Mo(CO)_2(PPh_3)_2(pyridine)(\eta^2\text{-}SO_2)$ by loss of PPh_3. Thus, the terminal oxygen of the η^2-SO_2 ligand in this complex apparently possesses sufficient basicity to displace PPh_3, a surprising result since PPh_3 is an excellent ligand. Even more striking is the finding that the dimer will precipitate in the presence of a large excess of pyridine, a strong competing ligand, and is not readily cleaved by pyridine and other strongly basic ligands. The low solubility of $[Mo(CO)_2(pyridine)(PPh_3)(\mu\text{-}SO_2)]_2$ may provide some driving force for its formation, but nonetheless the Mo–O bond [Mo—O(4)] must be relatively strong (bond length = 2.24 Å) and indeed is only 0.05 Å longer than that for Mo—O(3). Further indication of the oxygen basicity in Mo–SO_2 complexes was given by Schenk and Baumann,[9] who reported O-silylation of both η^1- and η^2-complexes.

An interesting series of complexes of the type $Mo(CO)_2L_3(SO_2)$ (L = $PMePh_2$ or $CyNH_2$) has been synthesized and found to contain η^1-planar SO_2. The geometry was unexpected because the presence of three σ-donating ancillary ligands would appear to favor η^2-bonding. The X-ray crystal structure of $Mo(CO)_2(CyNH_2)_3(SO_2)$ revealed that the cyclohexylamine ligands coordinate in *facial* fashion.

The most intriguing feature of this complex was found to be its novel reactivity with oxygen:

$$Mo(CO)_2(CyNH_2)_3(SO_2) + O_2 \xrightarrow[(H_2O)]{DMSO} [CyNH_3]_2[SO_4] + 2CO + [CyNH_3][Mo_xO_y].$$

The production of *uncoordinated* sulfate from SO_2 complexes has not been observed and a catalytic method for SO_2 oxidation to sulfate would be of considerable interest. However, the mechanism may involve reaction of dissociated ligands since SO_2 and $CyNH_2$ were found to give $[CyNH_3][HSO_3]$ in DMSO, and air-oxidation of the bisulfite to sulfate was catalyzed by the molybdate coproduct of the reaction. Thus, it is probable that oxidation of the metal with concomitant ligand loss occurs initially, followed by reaction of SO_2, $CyNH_2$ and H_2O to give bisulfite and eventually sulfate.

ACTIVATION OF H—H AND C—H BONDS: MOLECULAR-H_2 COMPLEXES

The discovery[2,7] of a facile synthetic pathway to stable 16-electron complexes, $M(CO)_3(PCy_3)_2$ (M = Mo or W), has provided an unparalleled opportunity to study small-molecule activation, in particular the first examples of molecular-H_2 complexes.[1] The complexes are the only ones of which we are aware that activate *both* H—H and C—H bonds. The synthesis evolved serendipitously from our work on Mo–SO_2 complexes, specifically *mer,trans*-$Mo(CO)_3(PR_3)_2(SO_2)$.[4(a)] During attempts to optimize their preparation from *fac*-tricarbonyl complexes containing labile ligands, $M(CO)_3$(cycloheptatriene) was found to be a viable precursor to formally coordinatively unsaturated species:

$$M(CO)_3(cycloheptatriene) + 2PCy_3 \xrightarrow[argon]{ether} M(CO)_3(PCy_3)_2 + C_7H_8.$$

The observation of the striking deep blue-purple color of the 16-electron complexes was a key factor in their identification.

The stability of the complexes is largely a result of the well-known steric demands imposed by bulky phosphine ligands. The labile cycloheptatriene in the starting complex, $M(CO)_3$(cycloheptatriene), occupies *three* coordination sites but is effectively displaced by only *two* phosphine ligands, thereby opening up the sixth coordination site. Because of the phosphine bulk, the cycloheptatriene is squeezed out of the coordination sphere of the metal. The phosphine size must, of course, be large enough such that three cannot easily fit around the metal in an octahedral array, but curiously the synthesis succeeds for PCy_3, PPr^i_3 and PCy_2Pr^i, but not for other phosphines with similar cone angles. The use of smaller phosphines results in the formation of $Mo(CO)_3(PR_3)_3$.

The structure of $W(CO)_3(PCy_3)_2$ shows the addition of a distal phosphine hydrogen to the metal coordination sphere (Fig. 3). This agostic interaction

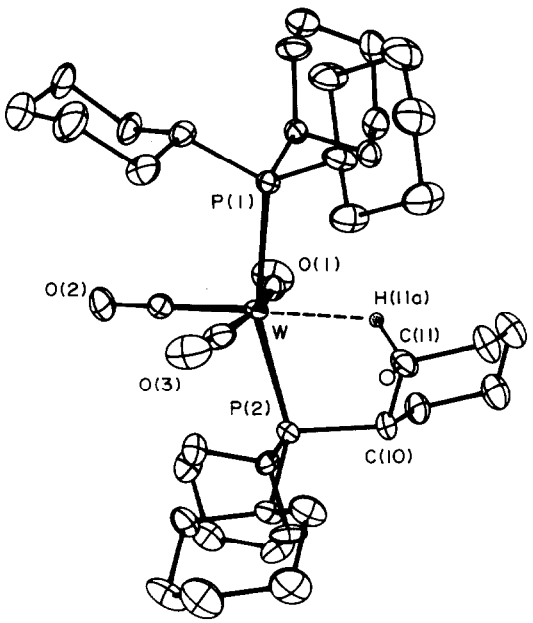

Fig. 3. Structure of $W(CO)_3(PCy_3)_2$.

[ν(CH) = 2552 cm^{-1}] is the first well-defined example of its type for an alkylphosphine. Importantly the highly distorted geometry about P(2)

$$[W—P(2)—C(9) = 122.0(2)°,$$

and

$$W—P(2)—C(10) = 99.0(2)°]$$

is evidence that the tungsten atom exerts a strong *attractive* force upon the (11a) atom. Note that this is in distinct contrast with several other coordinatively unsaturated complexes in which hydrogen atoms from coordinated phosphine groups are located near the open site about the metal. For example, the triphenylphosphine ligands in both $RhHCl(SiCl_3)(PPh_3)_2$[15] and $RuCl_2(PPh_3)_3$[16] have normal, undistorted geometries. LaPlaca and Ibers[16] attribute the particular location of ring hydrogen atoms near the metal in these complexes to "geometric" effects, rather than any true metal–hydrogen bonding interactions. The same is apparently true in the case of the Mo(CO)(diphos)$_2$ (diphos = diphenylphosphinoethane) molecule,[17] another example of a formally five-coordinate complex with a group 6 metal.

Although refinement of the hydrogen atom positions was unsuccessful, the idealized position of the activated hydrogen atom is *ca* 2.17 Å from the metal [W—C(11) = 2.943(6) Å]. The overall structure of the PPr^i_3 analogue is basically similar, although disorder hampers precise description of the crucial distorted portion of the molecule.

$M(CO)_3(PR_3)_2$ readily "add" donor ligands, which displace the C—H group from the metal center. The resultant *mer,trans*-$M(CO)_3(PR_3)_2L$ can contain reversibly bound donors (e.g. H_2, N_2, C_2H_4 and H_2O) or irreversibly bound groups (e.g. CO, SO_2 and pyridine).

As with other unsaturated complexes, the ability to bind additional ligands is strongly influenced by steric factors. For example, as also found for Mo(CO)(diphos)$_2$,[17] the complexes coordinate primary but not secondary or tertiary amines. Other ligands which fail to form isolable adducts include propylene, cyclohexene, butadiene, C_2F_4 and furan. Nevertheless, certain strong ligands, such as phosphines (e.g. PPh_3) and phosphites, will form adducts despite their relative bulkiness. Also, in spite of the strong Lewis acidity of the metal atom in $M(CO)_3(PR_3)_2$, it has been shown that CO_2 does not add, even in liquid CO_2.[3] A hydrido-bicarbonate complex, $W(CO)_3(PCy_3)_2(H)(HCO_3)$, has been suggested as the result of reaction with "wet" CO_2.[3] The same authors propose that the H_2O complex is a precursor to the bicarbonate and contains hydrido–hydroxo ligands resulting from oxidative addition. This activation of O—H bonds by Mo and W is a promising area for exploration also.

Molecular-H_2 *coordination*

The activation of hydrogen by transition-metal complexes, i.e. oxidative addition to form hydride complexes, has been well studied because of its importance in catalysis. The geometry of approach of the H_2 molecule to the metal ("end-on" or "side-on") has long been the subject of discussion,[18] and recent theoretical studies favored sideways addition to a 16-electron ML_5 center.[5] The existence of transient side-on molecular-H_2 coordination has been proposed, particularly in "direct hydrogen transfer" reaction processes,[19] but until our work a well-characterized molecular-H_2 complex had not been isolated. Spectroscopic evidence for $Cr(CO)_5(H_2)$ (stable at low temperature but short-lived at 25°C) has recently been observed,[20] and, several years prior to this, we reported novel complexes, $M(CO)_3(PCy_3)_2(H_2)$ (M = Mo or W), with unusual IR features.[7] These room-temperature stable complexes, along with $W(CO)_3(PPr^i_3)_2(H_2)$, were then shown to contain the η^2-H_2 ligand,[1] one of the last "holdouts" in the realm of small-molecule coordination. More importantly, the H_2 complexes (including newly reported examples[21]) represent incipient oxidative addition of a diatomic molecule, giving an unprecedented opportunity for study.

The complexes are readily synthesized in excellent yields from the 16-electron precursors,

$M(CO)_3(PR_3)_2$, or directly from $M(CO)_3$ (cycloheptatriene) and PR_3 under H_2. As for $M(CO)_3(PR_3)_2$, the complexes could be formed only for $R_3 = Cy_3$, Pr^i_3 or Cy_2Pr^i. The H_2 ligand readily dissociates reversibly in solution although crystals of the complexes can be handled even in air for short periods. X-ray structural studies revealed an octahedral geometry for $W(CO)_3(PPr^i_3)_2(H_2)$ and the H_2 molecular ligand was first observed by room-temperature neutron diffraction studies at the Los Alamos Pulsed Neutron Source. Subsequent low-temperature neutron studies[21(d)] at both the Brookhaven National Laboratory and Los Alamos were necessary in order to properly model a disorder in one of the phosphino ligands and resulted in the determination, with resonable precision, of H—H and W—H distances of 0.82(1) and 1.89(1) Å (Fig. 4). The H_2 is symmetrically bonded parallel to the P—W—P axis, and the overall coordination geometry is nearly octahedral. Similarly X-ray structural studies of $M(CO)_3(PCy_3)_2(H_2)$ demonstrated an octahedral geometry. Refinement of preliminary neutron diffraction data, despite a disorder of H_2 and CO due to centrosymmetry at the metal, show the H_2 to be bound in a similar fashion to that in the PPr^i_3 analog. It should be noted that the structures of a series of group 6 *hydride* complexes, including $MoH_2(PMe_3)_5$, all showed non-octahedral phosphine positions.[22]

Spectroscopic studies confirmed the structural data, and a useful NMR diagnostic for molecular-H_2 coordination, was found to be the value of J_{HD} for the monodeuterated species, e.g. $W(CO)_3(PPr^i_3)_2(HD)$. The ^1H spectrum (90 MHz) of the H_2 complex showed only a single broad major* resonance at *ca* −4 ppm from 70 to −80°C, but the HD complex gave a 1:1:1 triplet with $J_{HD} = 33.5$ Hz (Fig. 5). This value is an order of magnitude larger than that for, say, hydride and deuteride compounds and is 77% of that for HD gas (43.2 Hz).[23] Solid-state ^2H NMR studies shows that, for $W(CO)_3(PPr^i_3)_2(D_2)$, the D_2 undergoes rotational motion about the metal–D_2 axis at a rate greater than 130 kHz at ambient temperature.

IR spectroscopy provided the first hint of molecular-H_2 coordination, and subsequent thorough IR and Raman examinations of the H_2, HD and D_2 complexes located four of the six

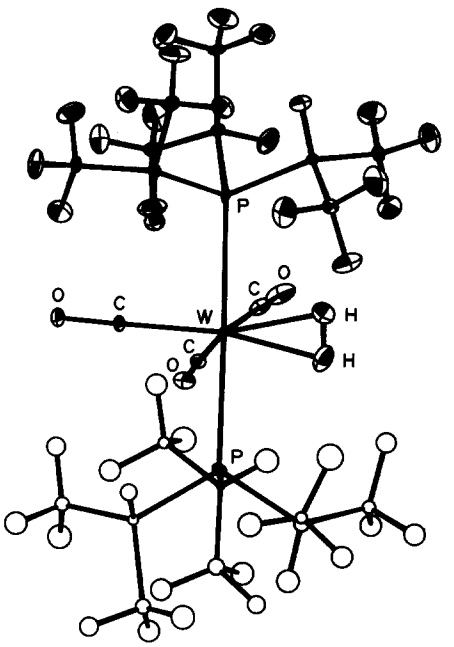

Fig. 4. Structure of $W(CO)_3(PPr^i_3)_2(H_2)$.

fundamental modes expected for η^2-H_2 (Table 1). The use of fully deuterated PCy_3 enabled location of ν(HH) as a weak, broad band at 2690 cm^{-1} in the Nujol mull IR spectrum of

$$W(CO)_3[P(C_6D_{11})_3]_2(H_2)$$

(Fig. 6). This value is some 1500 cm^{-1} lower than that of free H_2. Failure to observe ν(HH) in the Raman experiments may have been due to sample decomposition (even at 77 K). The electronic spectrum of $W(CO)_3(PPr^i_3)_2(H_2)$ shows a band at 364 nm.

In regard to the chemistry of the coordinated H_2, isotopic exchange has been found to occur between $W(CO)_3(PR_3)_2(H_2)$ and D_2 gas in both solution and

Table 1. Vibrational frequencies [ν (cm^{-1})] for solid $W(CO)_3(PCy_3)_2(H_2)$ and isotopically substituted species[a]

* A minor (*ca* 15–20%) resonance appears on cooling or on changing to higher field (200 MHz). This resonance, which coalesces with the major peak at or above room temperature, is a triplet ($J = 38$ Hz) in certain temperature ranges, suggesting P–H coupling and the possibility of a hydride form in equilibrium with the H_2 form.[21(c)]

[a] IR samples were Nujol mulls; Raman samples were enclosed in capillaries and excited by the 5682-Å line of a Kr laser. Similar results were obtained for the P-*i*-Pr_3 analogues.

[b] Partially obscured. ν(HH) was relatively clear in the $P(C_6D_{11})_3$ analogue.

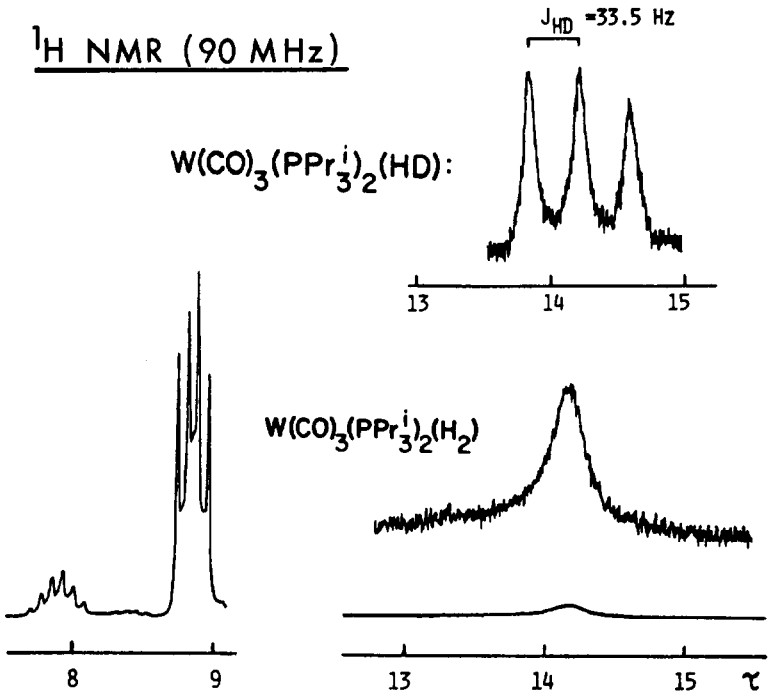

Fig. 5. ^{1}H NMR spectra in C_6D_6 at 35°C.

solid states at 20°C, giving within days a statistical mixture of H_2, HD and D_2 species. Neither the phosphine nor solvent hydrogen atoms exchange. At this point the mechanism for this process is unknown. The solid–gas scrambling is particularly interesting since transient phosphine dissociation cannot be providing vacancies for coordination of a second H_2 and D_2 molecule. The H_2 complexes do not catalyze hydrogenation of ethylene under mild conditions (toluene, 1 atm, 20°C), presumably because of limited available coordination sites (i.e. steric crowding by the phosphines).

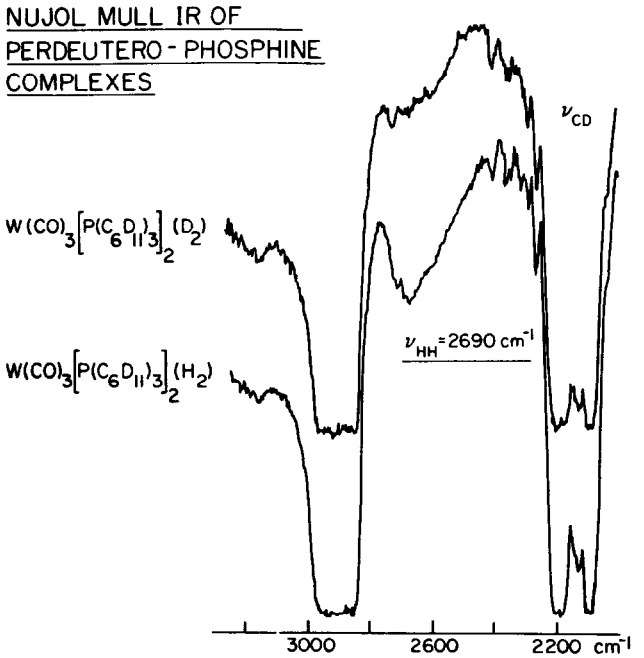

Fig. 6. IR spectra of $W(CO)_3[P(C_6D_{11})_3]_2(H_2)$ and D_2 species.

Theoretical calculations of H_2 binding in the model complex, $W(CO)_3(PH_3)_2(H_2)$, indicate that the observed conformation of the complex is stable by 16.8 kcal mol^{-1} relative to $W(CO)_3(PH_3)_2 + H_2$.[24] The conformation with the H—H rotated by 90° was only 0.3 kcal mol^{-1} less stable, in agreement with the NMR results, indicating only a small barrier to rotation. The studies also indicated that the bonding of H_2 to the metal involves primarily σ-donation to the metal, with very little backbonding into the σ^*-orbital of H_2. For the minimum-energy structure the H—H distance was 0.79 Å, close to that observed (0.82 Å) although the W—H distances were longer than those determined (2.15 vs 1.89 Å).

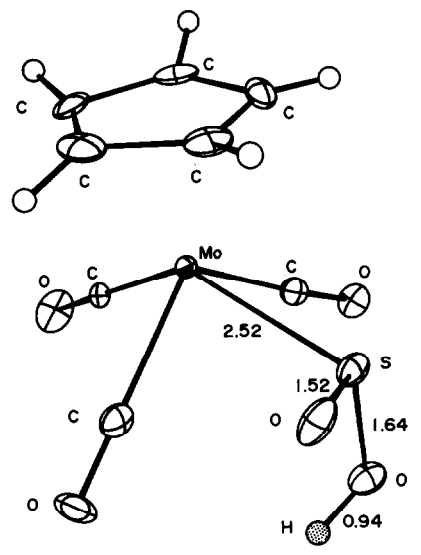
Two obvious questions arise: do more H_2 complexes exist and why do $M(CO)_3(PR_3)_2(H_2)$ coordinate dihydrogen while $MoH_2(PMe_3)_5$[22(a)] and related complexes[22] proceed to the hydride? We now have evidence that the known 16-electron complex $Mo(diphos)_2(CO)$,[17] which contains a weak M···H—C interaction, gives very similar H_2 complexes.[21(c)] Thus complexes which weakly coordinate a distal hydrogen atom are clearly excellent candidates for H_2 coordination. While the bulkiness of the phosphine ligands is no doubt important in determining whether the H_2 is arrested rather than cleaved by the metal, other factors are also involved. The electronic influence of the ligand *trans* to H_2 may be crucial, judging by the fact that the H_2 complexes [including $Cr(CO)_5(H_2)$] contain *trans*-CO while none of the structurally-characterized group 6 polyhydrides[22] contain any CO ligands at all. These principles may not apply to other metal systems,[21(b)] and only the discovery of further examples of H_2 coordination will provide understanding.

REDUCTION OF SO_2 BY GROUP 6 METAL HYDRIDES AND HYDROGEN

Hydride reduction: insertion of SO_2 into a metal–hydride bond

The reduction of SO_2 with H_2 or other agents such as CO to give sulfur and H_2O is an attractive method for SO_2 conversion. In the objectives of our studies of transition-metal–SO_2 complexes, we include metal systems that will act as catalysts for the reduction of SO_2 or will provide models for the elementary steps in a catalytic cycle. Transition-metal–hydride complexes have been shown to be important intermediates in catalytic cycles involving hydrogenation of organic substrates. Thus, in seeking homogeneous systems to catalytically or stoichiometrically hydrogenate SO_2, we are examining the reactions of metal–hydride complexes with SO_2. Much of our work has focused upon molybdenum and tungsten complexes as these metals are abundant, nonstrategic, and contained in proven catalysts in industrial processes.

A wide variety of reaction types have been found depending on the nature of steric and electronic factors. The system Cp_2MH_2 (M = Mo or W) cleanly and rapidly reduced SO_2 to $Cp_2M(S_2O_3)$ and H_2O, representing partial reduction of the SO_2.[25] Strong acids such as HCl convert $Cp_2M(S_2O_3)$ to H_2O, SO_2 and new types of cationic metal–sulfur complexes[25] in a manner similar to the conversion of ionic thiosulfate to H_2O, SO_2 and S_8. We speculate that a well-defined color change upon the addition of SO_2 to Cp_2MoH_2 may be due to adduct formation which is then followed by SO_2 insertion into the Mo—H bond. SO_2 inserts into the metal–hydride bond in $C_5H_5M(CO)_3H$ (R = H or Me; M = Mo or W) to form $(C_5R_5)M(CO)_3(SO_2H)$.[26] The reaction occurs readily at room temperature, and the insertion product precipitates upon addition of SO_2 to a concentrated solution of $(C_5R_5)M(CO)_3H$ in organic solvents. X-ray crystallography of $CpMo(CO)_3(SO_2H)$ confirmed that an S-bound insertion occurred (Fig. 7). Although both S–O distances are significantly longer than that normally found in SO_2 complexes (*ca* 1.45 Å)[4(b)] the difference in the two distances [S–O(1) = 1.637(6), S–O(2) = 1.515(6)] is sufficient to indicate that the H atom is bound to O(1). A peak appeared in the difference maps near O(1) and refined to a chemically reasonable position for an H-atom if the thermal parameter was fixed. *Sulfinate* ligands bound to transition metals have been



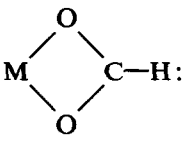


Fig. 7. Structure of $CpMo(CO)_3(SO_2H)$.

structurally characterized for *S*-sulfinates or *O*-sulfinates[27,28] with an alkyl or aryl bound to the sulfur and spectroscopic evidence exists for *O,O*-sulfinate and those of the type M—S(O)—OR.[29] The present study affords the first structural characterization of the latter type as well as the first direct evidence for insertion into a M—H bond.

The complexes $(C_5R_5)M(CO)_3(SO_2H)$ can be considered to be metallo analogues of organic sulfinic acids. RSO_2H.[30] A metallo *sulfonic* acid, $CpFe(CO)_2[S(O)_2OH]$, is known,[31] but is not a result of an insertion reaction. There appears to be no well-characterized precedent for the SO_2H^- ligand (or free anion) although a sulfinate structure, $Ru(SO_2H)_2(PPh_2Me)_3$, was tentatively formulated for the product of the $RuH_2(PPh_2Me)_4$–SO_2 reaction.[32] In contrast with SO_2, insertion of CO_2 into metal–hydride bonds is well known and results in metal–oxygen coordination,

M—O—C(O)H or 

definitive identification of a metallocarboxylic acid, M—C(O)—OH, derived by CO_2 insertion is lacking.[33]

For the reaction:

$$(C_5R_5)Mo(CO)_3H + SO_2 \xrightarrow{\text{solvent}} (C_5R_5)Mo(CO)_3(SO_2H)$$

the solution equilibrium lies far to the left; NMR shows that SO_2 readily extrudes on dissolution, unless excess SO_2 is present. $Cp^*Mo(CO)_3(SO_2H)$ ($Cp^* = C_5Me_5$) in liquid SO_2 at −40°C shows a broad resonance for the OH proton at δ 3.89, which shifts on addition of H_2O, reflecting proton exchange. A weak, broad IR stretch near 2550 cm^{-1} is assigned to ν(OH), on the basis of ^2H and ^{18}O substitution.

The mechanism of the SO_2 insertion may be a *concerted* process, involving attack on the coordinated hydride, analogous to the attack on α-carbon proposed for the alkyl analogues, $CpM(CO)_3S(O)_2R$.[34] It is reasonable that SO_2 initially coordinates to the hydride much as it does to metal-bound halides and pseudohalides.[4(b)]

A significant finding in terms of SO_2 reduction is the thermal instability of the solid complexes, which undergo auto-redox within 1 day [25°C for $CpMo(CO)_3(SO_2H)$, and 55–75°C for the W and Cp* analogues] to products indicative to S(IV) → S(II−) reduction and metal oxidation:

$$(C_5R_5)M(CO)_3(SO_2H) \xrightarrow{\Delta} [(C_5R_5)M(CO)_3]_2 + [(C_5R_5)MS_xO_y]_n + H_2O + CO.$$

A complex mixture of sulfido and oxo–sulfido complexes generally resulted, although for R = Me and M = Mo, the reaction was cleaner, yielding $[(C_5Me_5)MoO(\mu\text{-}S)]_2$[35] and a species analyzing as "$(C_5Me_5)_3Mo_3S_2O_4$" (see Fig. 8). Prolonged reactions of solutions of $(C_5R_5)M(CO)_3H$ with SO_2 in 4 : 1 stoichiometry also gave reduction of SO_2, and for R = Me and M = Mo the products were nearly identical to those for thermolysis of the SO_2 complex. Thus it would appear that the insertion complexes are logical intermediates in the SO_2 reduction. A possible further (or alternate) intermediate has also been isolated and structurally characterized. A solution-unstable dithionite-bridged complex, $[(C_5Me_5)Mo(CO)_3]_2(\mu\text{-}S_2O_4)$

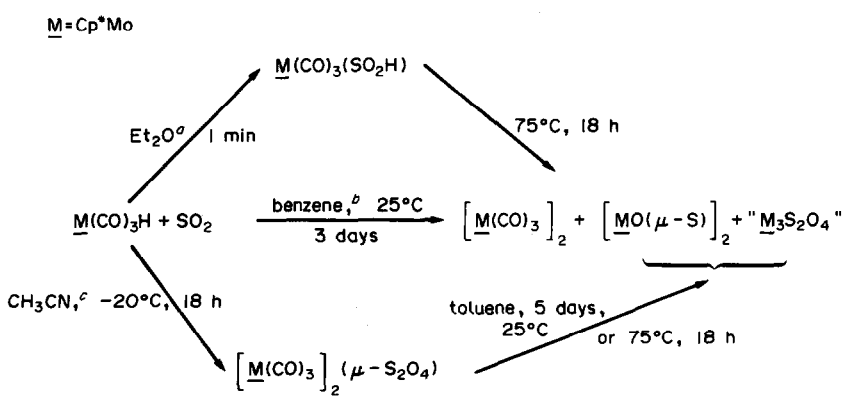

Fig. 8. Reactions of $Cp^*Mo(CO)_3H$ with SO_2.

(Fig. 9), crystallized slowly at −20°C from dilute CH_3CN solutions of $Cp^*Mo(CO)_3H$ containing excess SO_2. No H_2 was produced in this or any other of the hydride–SO_2 reactions; the hydride protons transfer to an oxygen atom to form H_2O. Conceivably, the dithionite species is produced by S—S coupling of two deprotonated $Cp^*Mo(CO)_3(SO_2H)$ fragments (an oxidation step is also required). The dithionite decomposes in solution, converting within minutes to a series of products. After several days, only two major products formed (plus CO and CO_2): the same two oxo–sulfido complexes produced from thermolysis of the insertion product or prolonged solution reaction of $(C_5Me_5)Mo(CO)_3H$ and SO_2. Thermolysis of the solid dithionite at 75° C for 18 h gave the same complexes, along with CO and CO_2 (from transfer of oxygen to CO).

The S-bound dithionite represents the first structurally characterized example of its type although this geometry had been proposed for $[CpFe(CO)_2]_2(S_2O_4)$ and $[M(CO)_5]_2(S_2O_4)$ (M = Mn or Re).[36] The S—S bond distance of 2.266(1) Å for the C_{2h} S_2O_4 is shorter than that found in $Na_2S_2O_4$ and other structures with C_{2v} $S_2O_4^{2-}$ ion (2.35–2.39 Å).[37] These unexpectedly long distances have generally eluded attempts at theoretical description. The S—S distance in the Mo complex is significantly longer than that in diphenyl disulfone [2.193(1) Å],[38] the only other structure we know of for which the S_2O_4 moiety is found in approximate C_{2h}-symmetry.

As previously mentioned, the prolonged solution reactions of SO_2 and $(C_5R_5)M(CO)_3H$ in all cases eventually yield a mixture of sulfido and/or oxo metal complexes and water as a result of SO_2 reduction. The nature of the final products depends on the metal, R group, solvent, temperature and hydride:SO_2 ratio. For example, whereas $[CpW(CO)_3]_2(\mu\text{-S})$[39] is found to be both the major as well as the initially observed sulfur-containing product for M = W, the Mo analogue is unstable and rapidly decomposes in solution with CO loss to a *mixture* of sulfide products. Complexes of the type $[Cp^*M(CO)_3]_2S$ are *not* observed for the Cp* systems, but rather *oxo-containing* products such as $[Cp^*MO(\mu\text{-S})]_2$ are prevalent in hydride–SO_2 reactions. However, for M = W, a *double* sulfide-bridged complex, $[Cp^*W(CO)_2(\mu\text{-S}\cdot SO_2)]_2$, with a strong sulfide–$SO_2$ interaction can also be isolated (Fig. 10).[39] The different products isolated in these reactions may thus merely reflect different stabilities rather than major differences in mechanisms.

Summarizing, the SO_2H unit appears to be inherently unstable, certainly when coordinated to transition metals [reduction of SO_2 by $(\mu\text{-}H_2)Os_3(CO)_{10}$ is also believed to proceed via an SO_2H complex][40] and also in sulfinic acids, RSO_2H,

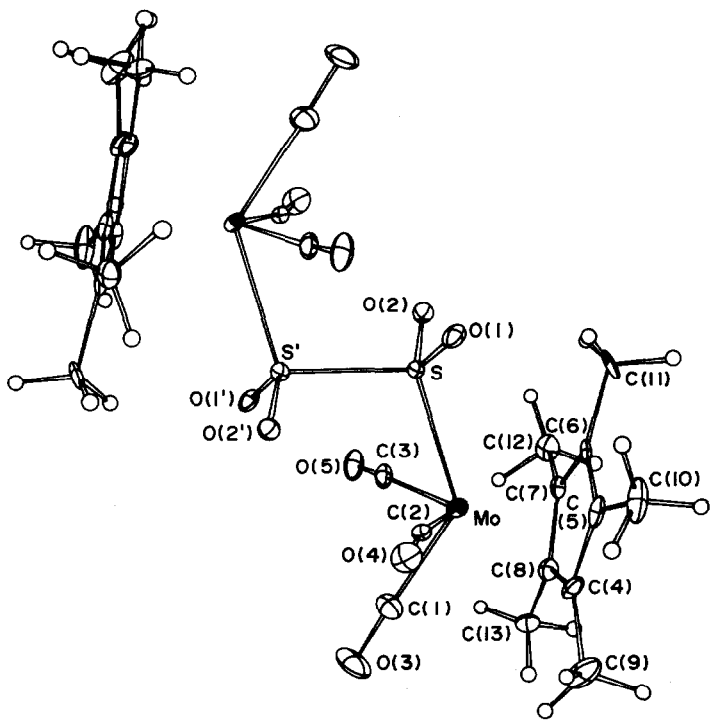

Fig. 9. Structure of $[Cp^*Mo(CO)_3]_2(S_2O_4)$.

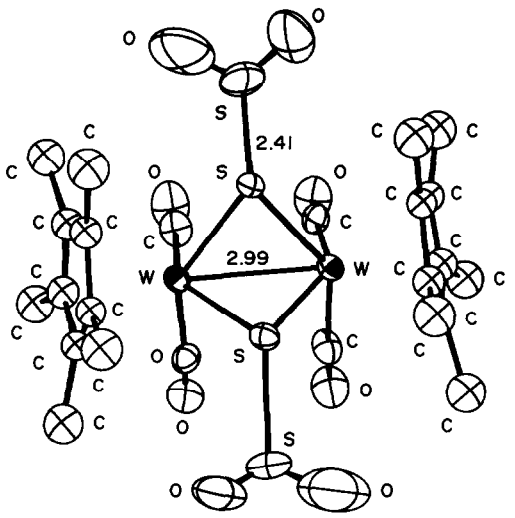

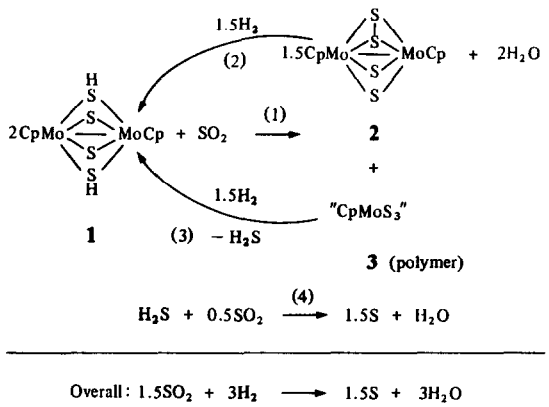

Fig. 10. Structure of $[Cp^*W(CO)_2(\mu\text{-}S \cdot SO_2)]_2$.

which readily disproportionate at 25–75°C.[30] One can conclude that the SO_2H ligand is even more reactive in solution since it could not be observed spectroscopically except at low temperature, where its reactivity was suppressed. Thus, the SO_2H species would appear to be a key intermediate in the reduction of SO_2 by hydrogen-containing complexes.

Hydrogen reduction of SO_2: the first example of a catalytic homogeneous system

Reduction of SO_2 by H_2 over heterogeneous catalysts is known. An effective heterogeneous catalyst has been found to be Ru–Al_2O_3 which readily and cleanly promoted hydrogenation to sulfur and H_2O under mild conditions (150°C, 1 atm), without catalyst poisoning.[41] Catalysis of SO_2 reduction by transition-metal species is a difficult problem in homogeneous systems because of catalyst poisoning by sulfur. As seen in the previous section, metal sulfides and oxysulfides readily form and no well-defined homogeneous systems catalyzed by transition-metal complexes have been reported. However, a possible means to circumvent the sulfiding problem was suggested by a reaction of SO_2 with a metallothiol complex, $[W(CO)_5(SH)]^-$, in which elemental sulfur was found to be produced. Instead of using metal-bound hydrogen to reduce SO_2, one could conceivably use the active hydrogen contained in *SH groups* ligated to a sulfur-saturated metal center. Furthermore, a remarkable addition of hydrogen to a dinuclear sulfur-bridged molybdenum complex to form a metallothiol $[(Me_nCp)MoS(SH)]_2$ (**1**) has been described in the literature.[42] This SH complex has been found[42] to homogeneously catalyze the reaction of sulfur with H_2 in $CHCl_3$ solution to form H_2S, and one could easily envision extension to SO_2 reduction. Experiments have indeed confirmed room-temperature reaction of $SO_2 + H_2$, in a closed flask, to give elemental sulfur and H_2O under mild conditions (25–75°C, 1–3 atm of H_2). The *stoichiometric* reaction of SO_2 with **1** (no H_2) produces $(Me_nCp)_2Mo_2(\mu\text{-}S)_2(\mu\text{-}S_2)$ (**2**), an insoluble sulfur-rich species $(Me_nCpMoS_3)_x$ (**3**), and H_2O. Both **2** and **3** readily react with H_2 to regenerate **1**, and H_2S is also generated from the excess sulfur in **3**. In the catalytic system, H_2S is produced but rapidly reacts with unconsumed SO_2 via the Claus reaction to give the observed products, sulfur and H_2O. The mechanism of the catalysis conceivably involves the above reactions (see Scheme 1) but is obviously quite complex in nature.

Scheme 1.

If the catalysis is terminated at or before complete SO_2 consumption, sulfur is the product. If the reaction is allowed to continue (assuming excess H_2 is present), the S_8 is hydrogenated to H_2S as the final product. Actually, a parallel catalytic cycle based on SO_2 reduction by H_2S produced from the S_8–H_2 reaction undoubtedly occurs in addition to the cycle shown in the Scheme 1. Importantly, the catalyst is stable to oxygenation by SO_2, although the presence of atmospheric oxygen results in $(Me_5Cp)_2Mo_2(O)S_3$[43] being formed.

Both reaction (1) and the overall catalysis have been carefully studied in regard to variations in reaction conditions (Table 2). In both instances, SO_2 reduction proceeds at a slow rate if $CHCl_3$ is used as solvent. However, the rate of catalysis increases several hundred fold (e.g. from 0.4 to 355 turnovers h^{-1}) if weakly basic solvents such as alcohols and/or catalytic amounts of Bronsted bases such as amines are present in the catalyst solution. For example, using only 0.04 mmol of **1**, 6.1 mmol of SO_2 is cleanly reduced by H_2 (27 mmol, ~3 atm) in 34 min at 75°C in 1:1 butanol–chlorobenzene (25 cm^3) containing

Table 2. Summary of catalytic reactions of SO_2 (3–8 mmol) and H_2 (12–17 mmol) to give sulfur and H_2O[a]

Solvent	Catalyst $[Me_nCpMoS(SH)]_2$	Temperature (°C)	P_{H_2} (atm)	Reaction time (h)	Catalyst turnovers h^{-1} (average)[b]

[a] Magnetically-stirred in a closed 250- or 500-cm^3 flask, using 0.04–0.1 mmol catalyst in 25–50 cm^3 of solvent.
[b] Based on SO_2 consumption (assuming 2 mmol of catalyst converts 1.5 mmol SO_2).
[c] 0.1 cm^3 (0.42 mmol).
[d] 0.025 cm^3 (0.105 mmol).

0.1 mmol of Bu_3N. Similar rate enhancements by weak bases occur for reaction (1) and the Claus reaction [(4)], which also is very slow in $CHCl_3$ but is known[44] to be promoted by donor solvents (e.g. H_2O and alcohols) and weak bases. If $CHCl_3$ is the solvent for the catalysis, the Claus reaction occurs inefficiently mainly along the upper flask walls (sulfur deposition is observed) where H_2O (from SO_2 reduction) condenses and acts to promote it. If alcohols or small amounts of amines are present in the catalyst solution, the H_2S–SO_2 reaction [(4)] occurs rapidly and completely in the solution phase. In this context, the reactivities of $(\mu\text{-}SH)_2Fe_2(CO)_6$ and $Cp_2Ti(SH)_2Mo(CO)_4$ have been found to be also promoted by bases such as amines.[45] The mechanism for base promotion of reaction (1) may be proton abstraction followed by electrophilic attack of SO_2 on S^-. In this regard, the complex μ-$SH[W(CO)_5]_2^-$ was found to be much more reactive to heterocumulenes (e.g. MeN=C=O) in its deprotonated form,[46] and SO_2 is a type of heterocumulene. Alternatively, initial coordination of SO_2 to the sulfur atom of the SH ligand, similar to Lewis acid coordination of SO_2 to SR ligands in L_nCuSR,[47] could occur. In both cases, base-assisted proton transfer to an oxygen atom could result in formation of an $MSSO_2H$ group, giving what amounts to insertion of SO_2 into the S—H bond. Since, as discussed above, the SO_2H unit is unstable in both RSO_2H and the MSO_2H complexes, the proposed $MSSO_2H$ group would likewise be expected to decompose with eventual formation of H_2O and polysulfide (S_n^{2-}). This is precisely what is observed [reaction (1) of Scheme 1)], since the sulfur-rich product, **3**, almost certainly contains polysulfide. The implications of the above chemistry, which has recently been reported,[48] could extend to hetereogeneous sulfide catalysts such as hydrodesulfurization catalysts. Thus, we plan to investigate such catalysts for SO_2 reduction and to determine whether bases promote reaction.

Acknowledgements—This work was performed under the auspices of the Department of Energy, Division of Chemical Sciences, Office of Basic Energy Sciences. We thank Drs P. J. Vergamini and H. J. Wasserman for structural data on the H_2 complexes.

ISOTOPIC ^{18}O EXCHANGE BETWEEN SOLVENT WATER AND AQUO MOLYBDENUM IONS

GARRY D. HINCH, DONALD E. WYCOFF and R. KENT MURMANN*

Department of Chemistry, University of Missouri, Columbia, MO 65203, U.S.A.

(*Received* 17 *June* 1985)

Abstract—Recent applications of ^{18}O transfer and kinetic exchange experiments coupled with X-ray crystal structures has led to the establishment or confirmation of aqueous structures of some aqueous molybdenum ions. The mechanisms by which molybdenum-coordinated OH_2, OH^- and O^{2-} are exchanged with solvent are not well-understood. Now there are several ions which have been carefully studied and some suggestions as to mechanism can be made. A summary of oxygen transfer and kinetic exchange studies is made for the aquo ions MoO_4^{2-}, $Mo_2O_4^{2+}$, $Mo_3O_4(OH_2)_9^{4+}$ and several of their complexes. Interpretation of oxygen transfer accompanying reduction to lower oxidation states gives some structural and kinetic information about the reduced ion. Some new data are presented on complexes of these oxidation states which allow an estimate of the rate behavior of oxo and bridged-hydroxo groups in the neutral and basic region not accessible with the uncomplexed aquo ion.

Studies on the isotopic ^{18}O exchange between solvent water and aquo, hydroxo or oxo groups coordinated to metal ions can give information about the number of oxygens of a particular type surrounding the metal ion, the number of different types of bound oxygens, the kinetic properties of these oxygens and the mechanism by which exchange occurs. A knowledge of the oxygen exchange reaction kinetics for an aquo ion:

$$n(H_2O^*) + [M(OH_2)_n]^{z+} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} n(H_2O) + [M(^*OH_2)_n]^{z+}$$

is necessary for an understanding of substitution reactions of the ion. Likewise, for an oxo ion or hydroxy-bridged species, the rate of isotopic exchange may be closely related to the rates of substitution reactions on it.

Isotopic ^{18}O methods utilizing mass spectrometry are very precise and accurate even by today's standards but are not suitable for rapid exchanges. In a few cases reactions with $t_{1/2}$s of less than 2 s have been kinetically studied but under usual experimental conditions half-times of greater than 1 min are needed for accurate results. Thus other methods such as NMR, IR, sound absorption, laser Raman and mass spectra of the parent molecule or fragment are used when applicable for the more rapid exchanges.

The forerunners in this field were Cohn and Urey (1938)[1] and Hall and Alexander (1940).[2] The area was significantly advanced by the innovative studies of Taube *et al.* (1950–)[3] and since that time a slow stream of results has been published by a few small groups throughout the world. A review[4] appeared in 1982 covering all metals and some generalizations were suggested for predicting rate laws along with mechanistic interpretations. Since that time, new results have been obtained on molybdenum aquo species and complexes and offer an insight into the structural and kinetic variety obtainable with this metal. Thus we will describe the results of the application of ^{18}O tracer and exchange techniques to the aqueous ions of molybdenum.

EXPERIMENTAL

In most cases, two types of measurements are made: (a) determination of the number of oxygens coordinated to a metal which are slow to exchange, and (b) measurement of the rate of exchange of those oxygen atoms. For both types the basic experiment is the same. A solution of the ion to be studied at

* Author to whom correspondence should be addressed.

equilibrium is treated with a small quantity of highly enriched ^{18}O water to change the overall ^{18}O content of the solvent. At times very close to that of mixing (experiment a) or at later times (experiment b) either the solvent or the complex ion is sampled. Generally the complex ion is sampled and its total ^{18}O content measured. For this purpose it is necessary to be able to quickly remove the ion from solution, as a well-defined solid, at low temperature without losing or catalyzing the exchange of the oxygens under investigation. The precipitate should be non-hydrated, form very quickly and once formed not exchange its oxygen with the solvent during the period of collection, purification and drying. Its exact composition has to be known either from analysis or better from a single-crystal X-ray determination.

For isotopic analysis, the oxygen in the solid salt has to be converted to a pure simple gas. CO_2 is generally used and the conversion to it done in a non-quantitative manner by heating the sample with $Hg(CN)_2$ and $HgCl_2$ in a sealed glass tube for an hour at 425°C.[5] During this time all oxygens become isotopically equivalent and the CO_2 is separated from the other products by preparative gas chromatography. After further purification in a vacuum line the 46/(44 + 45) ratio is measured with a mass spectrometer. Generally the enrichments are low [less than 3× normal (0.6%)] and ratio measurements can be made to 0.1% of enriched minus normal. Usually it is necessary to know the enrichment of the solvent which is accomplished by the equilibration of a portion of it (3 days, 25°C) with a small amount of CO_2 in a sealed tube, separating and measuring the ^{18}O content of the purified CO_2. From the amounts of water and CO_2 and the isotopic fractionation factor the solvent enrichment is calculated.[6]

The rate of exchange for a single exchange is first-order (McKay plot),[7] i.e. ln $(1-F)$ vs time is linear, slope = k_{obs} and:

$$R = k_{obs}\left(\frac{ab}{a+b}\right) = k[\,]^n[\,]^m\ldots,$$

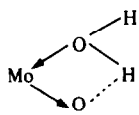
where a and b are the concentrations of exchanging oxygen atoms and solvent oxygen atoms, respectively. Nonlinear behavior of McKay plots is indicative of a chemical reaction occurring or more than one type of oxygen in the ion under study.

RESULTS AND DISCUSSION

Mo(VI)

The first aqueous molybdenum ion to be kinetically studied by ^{18}O techniques was MoO_4^{2-}, a tetrahedral ion which appears to be monomeric in the moderately alkaline region.[8,9] The latter study,[9] which included WO_4^{2-} was restricted to the alkaline region so as not to involve protonated species or oligomers derived from them. Von Felton *et al.*[9] precipitated the ion with Ba^{2+} as anhydrous $BaMoO_4$ and the zero-time exchange was essentially zero, suggesting that the only important ion in solution has four oxygens surrounding it and that the precipitate has all of the characteristics, which were given earlier, necessary for a quantitative study. The isotopic measurement was carried out on highly purified CO obtained by inductively heating the salt with graphite in a vacuum system.

The half-time for exchange was short, in the region of 5–20 s at 5°C and followed the rate equation:



$$R/[MoO_4^{2-}] = k_0 + k_1[OH^-]$$

rather well over the range

$$[OH^-] = 3\text{–}150 \times 10^{-3}\ \text{M}.$$

The activation parameters were $\Delta H^* = 62.8(2.5)$ and 70.3(5.0) kJ M^{-1} and $\Delta S^* = -43.5(9)$ and $-2.5(13)$ J K^{-1} M^{-1} for k_0 and k_1, respectively.

The k_0 term for MoO_4^{2-} and WO_4^{2-} are nearly the same, about 0.4 s^{-1} in the region of 25°C but much larger than that for CrO_4^{2-}, which is about 3×10^{-7} s^{-1}. The main difference is attributed to the larger values for the enthalpy of activation with CrO_4^{2-}, reflecting the "tighter" Cr—O bonds compared to those of Mo(VI) or W(VI). The similarity of the molybdenum and tungsten rates is fortuitive due to an unusually large negative ΔS^* for tungsten which compensates for its small value for ΔH^*. The kinetic solvent H/D isotope effect for k_0 is 3.6 and for k_1 is 2.3, about the same as for the tungsten analogue, suggesting proton transfer in the rate-determining steps. An isokinetic graph, ΔH^* vs ΔS^*, for k_0 for three tetrahedral ions, WO_4^{2-}, MoO_4^{2-} and ReO_4^{-},[10] is linear, suggesting a common rate-determining step. It is suggested that the mechanism for the k_0 term is of the solvent-assisted dissociative

type, while for the k_1 term the metal ion expands its coordination sphere as the yl-oxygen leaves. Since it has not been possible to determine the order with respect to water, a more precise suggestion as to the mechanism cannot be made. A wide and important region of study for this ion is left open, that of the neutral and faintly acid areas. Here $HMoO_4^-$ would be expected to dominate the kinetic expression and the rate should be accelerated dramatically as we

approach acidic conditions similar to that seen for other oxy-anions. Interpretation of ^{18}O results would be highly dependent on knowing the exact species and their concentration as a function of pH and total [Mo].

Mo(V)

The next study described is for the ion $MoOCl_5^{2-}$, at the other extreme of the acid–base scale.[11] The ion exists only at high [acid] and $[Cl^-]$ according to spectral studies. Structural information about the ion in solution comes from analysis, X-ray crystal structures and spectral evidence, mostly in the solid state. The ^{18}O exchange studies could be conducted without interference from other forms of Mo(V) in 9.2 M HCl down to 2.6 M HCl + 8.9 M LiCl. Cs_2MoOCl_5 was used as the precipitating agent and CO_2 as the analyzed gas. The zero-time exchange showed about 5% induced exchange which could not be reduced by experimental variations. Since the structure of the anhydrous precipitated salt is known from X-ray diffraction and analysis and essentially no exchange takes place after short times of contact with enriched solvent, the ion cannot expand its coordination number with solvent water in solution. For instance $[Cl_5Mo(OH)_2]^{2-}$ cannot form reversibly. The experiment also proved that there is 1.0 ± 0.1 slowly exchanging oxygen in the aqueous ion.

The rate of isotopic oxygen exchange is slow, $t_{1/2}$ = 1–2 h, and is dependent on [acid], $[Cl^-]$ and $[MoOCl_5^{2-}]$. At constant ionic strength (LiCl) (12.1 M), k_{obs} was nearly constant from 2 to 10 M HCl but increased significantly between 10 and 13 M. Increased $[Cl^-]$ decreased k_{obs} if the acidity was below 10 M but not if above. A plot of k_{obs} vs $[MoOCl_5^{2-}]$ at constant [HCl] (12.1 M) showed a linear relationship with the intercept zero at $[MoOCl_5^{2-}] = 0$. The best fit to all of the data was given by the expression:

$$R = k_1[MoOCl_5^{2-}]/[Cl^-] + k_2[MoOCl_5^{2-}]^2[HCl].$$

In these very concentrated solutions one cannot confidently conclude mechanistic paths from the form of the rate equation. However the first term, k_1, is consistent with an aquation equilibrium step followed by the rate-determining isotopic exchange. The intermediate aquo ion has been isolated and its solid structure determined (Fig. 1).[14] The rate-determining step would be of the internal electronic rearrangement (IER) type which requires a labile water or OH^- group *cis* or *trans* to the yl-oxygen. The second term, k_2, requires two complex ions and a

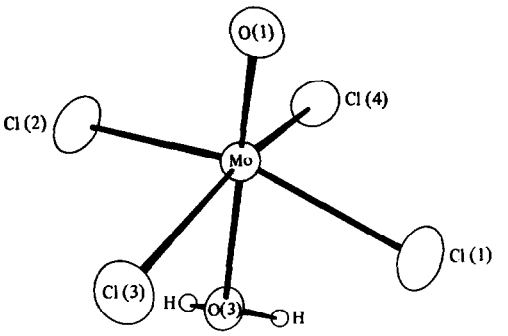


Fig. 1. ORTEP drawing of $[MoOCl_4(OH_2)]^-$.

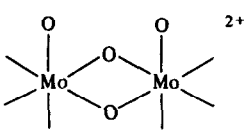


positive acid effect in the activated state. A reasonable explanation of this data lies in first protonating a complex ion forming a hydroxo complex and then a slowly reversible reaction would produce a bridged oxo complex and cause isotopic exchange:

$$[Cl_5MoO]^{2-} + H^+_{aq.} \overset{K}{\rightleftharpoons} [Cl^5MoOH]^-,$$

$$H^+ + [Cl_5MoOH]^- + [Cl_5MoO]^{2-} \overset{k_2}{\rightleftharpoons} [Cl_5Mo{-}O{-}MoCl_5]^{2-} + H_2O.$$

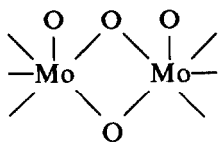
There is ample evidence for the protonation of dioxo complexes in $[Re(en)_2O_2]^+$, $[Mo(CN)_4O_2]^{4-}$, and more recently even with $VO^{2+}(aq)$.[12] Dimerization in hydrolyzed Mo(V) solutions has been postulated even in strongly acid solutions[13,14] (HCl) and it dominates the chemistry in dilute acid or neutral solution.[15] $[MoOBr_5]^{2-}$ follows essentially the same behavior but is slightly faster. This more rapid rate probably reflects the greater tendency toward hydrolysis. This suggests that stronger ligands, i.e. SCN^- or chelating ligands ($EDTA^{4-}$) would lower the rate of yl-oxygen exchange.

Over a wide range of mildly acidic solutions, Mo(V) exists almost exclusively as a dimer, aquated $Mo_2O_4^{2+}$. The evidence behind this formulation is its diamagnetism, ion exchange properties, spectral properties and X-ray solid structures of complexes. The present evidence supports a dimeric *cis*-structure with three distinguishable oxygen types.

Measurement of the rate of oxygen exchange with this ion was complicated by the fact that no precipitating agents were known with reasonably suitable properties. It was found[16] that during the conversion to the $EDTA^{4-}$ complex (whose X-ray

structure is known), no isotopically different solvent oxygen was introduced and the resulting ion could be quantitatively and quickly removed from solution with $[Pt(en)_3]^{4+}$. Thus one could "follow" the yl and bridging oxygens, but not the coordinated water since it was replaced by $EDTA^{4-}$. Also, once formed, all oxygens of $[Mo_2O_4(EDTA)]^{2-}$, including those of the organic ligand, are very slow to exchange even in solution. For this conversion the time-zero induced exchange average was 2.9(1.5)%.[16] This established that the 4.0(0.1) oxygens attached to Mo in $[Mo_2O_4(EDTA)]^{2-}$ came from the first-coordination sphere of Mo(V)(aq) and not from the solvent. The two types of oxygen proved to have quite different exchange rates over a wide range of conditions. At 0°C in 0.5 M H^+, 2.04(6) oxygens exchange rapidly with a half-time of about 4 m. The slowly exchanging oxygens were also counted and found to number 1.98(3) and the exchange half-time at 40°C was about 70 h in 0.5 M acid. The McKay plots were highly linear for the fast oxygens but the rate appeared to increase with time for the slow oxygen exchange. The non-linear behavior could easily be removed by having Hg(1) present which reduces Mo(VI). It was thought that either disproportionation or oxidation with traces of oxygen generated Mo(VI), which catalyzed the exchange. The slow oxygens were shown to increase their exchange rates with increasing $[MoO_4^{2-}]$ in the 1–3 mM range and so the exchange is very sensitive to it.

The fast oxygens were shown to be the yl-oxygens by laser-Raman IR spectroscopy where the spectrum was taken in 90% ^{18}O water before and after the fast oxygens exchanged. Assignment of the 950-cm^{-1} region to the yl-oxygen and the 760-cm^{-1} region to the bridging oxygen was done on the basis of the spectra of solid complexes. Only the yl-oxygen, 950 cm^{-1}, changed in a short time.



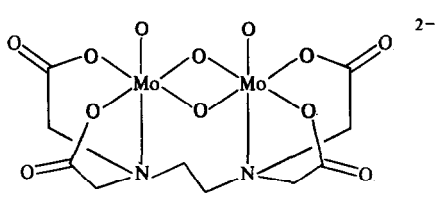
The yl-oxygen exchange showed an invariance to $[Mo_2O_4^{2+}]$ and [acid] in the ranges 0.002–0.039 and 0.01–3.1 M, respectively, and increasing $[Cl^-]$ lowered the rate constant by only a small amount. The latter effect could not be separated from that due to ionic strength changes.

On the other hand the bridging oxygens followed the rate law:

$$R/[Mo_2O_4^{2+}] = k[H^+]^2,$$

with the rate decreasing as the ionic strength or $[Cl^-]$ increased.

The yl-oxygen exchange was thought to occur through a solvent-assisted dissociative path or an IER mechanism utilizing the waters in the other coordinating positions. The bridging oxygen exchange was thought to occur through the H^+-assisted reversible opening of the



ring, breaking either one or both of the bridging bonds. The activation parameters for the bridging oxygens are $\Delta H^* = 108.1(6.7)$ kJ M^{-1}, $\Delta S^* = 1.7(0.8)$ J M^{-1} K^{-1}. At 0°C the calculated $t_{1/2}$ for the bridging oxygens is about 3 years in 1.0 M acid.

With respect to the $[monomer]^2/[dimer]$ equilibrium value, it can be shown from the ^{18}O data that K for the dissociation to the monomer cannot be greater than 4×10^{-6} at 40°C. This is in agreement with the essentially complete diamagnetic properties of Mo(V) solutions in dilute acid media.

Nothing firm is known about the exchange rate of the coordinated waters. Substitution for them with NCS^-,[17] EDTA[18] or ox^{-2} is quite fast but, as we note with Mo(IV), this does not necessarily mean that the water exchange is equally rapid. However, at the present time all available evidence points to a relative high lability for the coordinated waters.

Complexes of $Mo_2O_4^{2+}$

The EDTA complex of Mo(V), $[Mo_2O_4(EDTA)]^{2-}$ is a well-studied, well-behaved ion. In water solution, 0.07 M, pH 4.67, at 80°C the maximum exchange on any oxygen in yl- or bridging positions after 4.25 days was 1%. In acetic acid–acetate ion buffer at pH = 4.00 (other conditions the same) 83% of the yl-oxygen enrichment remains and essentially no bridging oxygen exchange occurs in the same time. In these experiments the yl-oxygens had 96% of the enrichment of the bridging oxygens as determined experimentally.

In strongly basic media only one type of oxygen exchanges, presumably the yl-oxygen.[19] At 25°C, $k = 4 \times 10^{-4}$ s^{-1} at a pH of 12.96 and the only major term in the rate equation is first order in $[OH^-]$. Considerable decomposition occurs during the kinetic experiments in basic media. Of all the complexes of $Mo_2O_4^{2+}$, that of $EDTA^{4-}$ is by far the most stable to exchanging either type of oxygen.

In order to ascertain the effect of the organic bridge

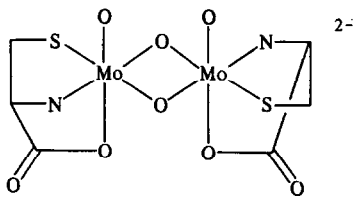


Fig. 2. $[Mo_2O_4(cysteine)_2]^{2-}$.

between the two metal ions in $Mo_2O_4^{2+}$ the complex $[Mo_2O_4(l+\text{ cysteine})_2]^{2-}$ was studied (Fig. 2). This ion showed a relatively rapidly exchanging pair of oxygens which follow first-order behavior well and a much slower pair which seemed to be somewhat erratic (Fig. 3). The velocity of both reactions were mildly affected by pH changes. At 25°C and a pH of 6.0, k_1 was 5.5×10^{-4} s^{-1}, while at pH 7.5 it equalled 4.0×10^{-4} s^{-1} (see Table 1). k_2 was 3.6×10^{-6} and 1.6×10^{-5} s^{-1}. In a stronger base, pH > 9 the rate of exchange had a positive $[OH^-]$ dependency.[19]

The sulfur-bridged analogue $[Mo_2O_2S_2(l+\text{ cysteine})_2]^{2-}$ gave values for the yl-rate constant of about half that of the oxygen-bridged complex under comparable, nearly neutral, conditions (Table 2).

However, this is highly misleading since the oxygen- and sulfur-bridged complexes behave differently in other ways. For instance the pH dependence shows a maximum k at a pH of about 6.5 for the oxygen-bridged complex, while the sulfur-bridged complex follows the rate equation (Fig. 4):

$$R/[\text{complex}] = k_0 + k_1[OH^-].$$

At 25.0° C, $\mu = 0.30$ with $LiClO_4$, $k_0 = 1.0(3) \times 10^{-4}$ s^{-1} and $k_1 = 5.1(3) \times 10^3$ m^{-1} s^{-1}. Another rather startling difference is the salt effect. From Table 1 one sees only a small ionic strength effect while Table 2 shows a very large effect. For instance for the sulfur analogue at 25°C the half-time changes from 1.0 to 120 min on increasing the ionic strength from 0.033 to 0.50 with NaCl. While the direction of this effect is the same for the oxygen- and sulfur-bridged complexes, the magnitude is not.

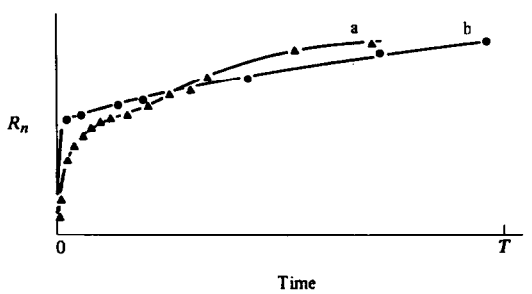

Fig. 3. Change in ^{18}O content of $[Mo_2O_4(cysteine)_2]^{2-}$ with time: pH = 7.75 (a) or 6.05 (b) (buffered). Point T = 3000 min for a, or 6000 min for b.

Table 1. pH Dependence of the fast and slow exchange for $[Mo_2O_4(cysteine)_2]^{2-}$ [a]

pH	k_1 (s^{-1})	k_2 (s^{-1})
6.05	5.5×10^{-4}	3.6×10^{-6}
6.27	7.0×10^{-4}	7.6×10^{-6}
7.09	5.8×10^{-4}	1.2×10^{-5}
7.75	2.8×10^{-4}	2.2×10^{-5}

[a] [complex] = 0.040 M, I = 0.50 M NaCl, buffer = 2,6-lutidine–HCl except at pH 7.75 (2,4,6-trimethylpyridine–HCl), pH ± 0.10, temperature 25.00 ± 0.03°C.
[b] I = 0.68 M NaCl.

The abnormal behavior of the bridging oxygen exchange for $[Mo_2O_4(cysteine)_2]^{2-}$ as shown in Fig. 3 is not understood. The increase in the rate of isotopic exchange shortly after the first type of oxygen has been exchanged suggested a chemical change which is autocatalytic and which also results in oxygen exchange. We have been trying to see if this effect is related to the catalytic effect of these solutions toward olefin hydrogenation.

A study of the ion $[Mo_2O_4(ox)_2(OH_2)_2]^{2-}$ was undertaken because it does not contain the additional bridge between the metal ions and also has a water in an equatorial position (Fig. 5). ^{18}O

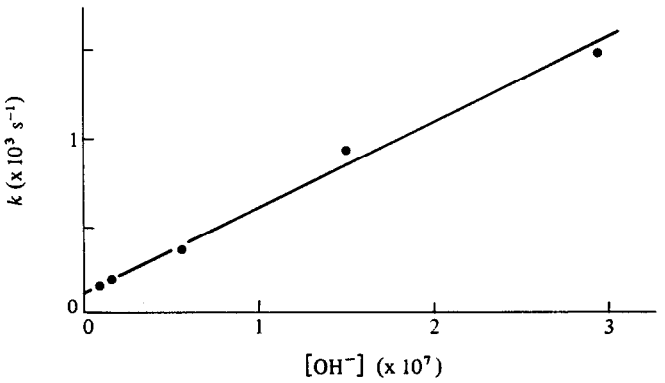

Fig. 4. Rate constants for O-exchange with $[Mo_2O_2S_2(cysteine)_2]^{2-}$ at 25°C.

exchange with this ion shows a single first-order plot corresponding to 4.0(1) oxygens and the other two oxygens exchange at least 1000 times slower. It was shown that the exchanging oxygens are yl-type *and* the coordinated waters and they cannot be distinguished from one another. In the pH region 3.8–5.1 the observed rate constant increased by about 50%. At a pH of 5.0 and 25°C the value of k was about 7×10^{-6} s^{-1}. The activation parameters at pH = 5.05, [ox^{2-} buffer] = 0.01 M, [complex] = 0.08 M, are $\Delta H^* = 88.3(1.2)$ kJ M^{-1} and $\Delta S^* = -46.9(1.0)$ J M^{-1} K^{-1}.

At this point it may be useful to try to generalize the features which appear to determine the rate of yl- and bridge oxygen exchange when they are coordinated to Mo(V). The latter appear in general to exchange very slowly. In either high acid or base the reaction proceeds more rapidly but even here the half-time is still in the many minutes to an hour range. Complexation of the positions normally occupied by water in the aquo ion by negative ions does not affect the bridging oxygen exchange rate strongly. However there is a suggestion that the coordination of a sulfur atom in a equatorial position does increase the bridging oxygen exchange rate probably due to a *trans*-effect. The yl-oxygens exchange more rapidly and are more affected by the other coordinated ligands and by solution conditions. While the rate of exchange is generally independent of acidity it is often sensitive to basic conditions. However this base sensitivity and the magnitude of the k_0 term seems to be related to water molecule(s) coordinated in one or more of the other octahedral positions. In the $EDTA^{4-}$ complex, such a water is not available and so the rate is quite slow while with cysteine the carboxyl oxygen *trans* to the yl-oxygen is reversibly exchanged for water at a fairly rapid rate. For the oxalato complex neither the water nor the yl-oxygen are very rapid or very slow to exchange but their rates appear to be related in some way. We suggest that the application of the IER mechanisms gives a reasonable explanation of their experimental behavior. In it a proton transfer from a water to yl-oxygen followed by metal ion electronic rearrangement effectively exchanges the OH_2 to $=O$ positions. If the (coordinated water)-isotopic exchange with solvent is rate-determining and the IER rate is roughly of the same order of magnitude or faster then the two types of oxygen atoms would appear to exchange at the same rate as is found. This approach also would suggest that any ligand which replaces water in either the equatorial or apical positions would lower the rate of yl-oxygen exchange, which is generally found.

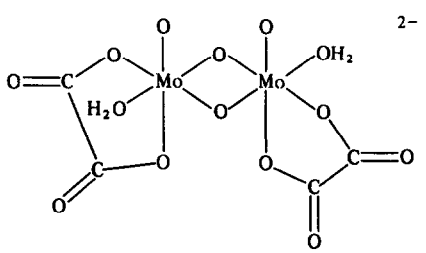

Fig. 5. $[Mo_2O_4(ox)_2(OH_2)_3]^{2-}$.

Mo(IV)

The first conclusive evidence that the +4 oxidation state of molybdenum in aqueous solution was a trimer (Fig. 6) came from ^{18}O studies directed toward measuring the rates of oxygen exchange.[20,21] Again the main problem was finding a method of precipitating the anhydrous ion quickly from aqueous solution at low temperatures. While not ideal, tetramethyl ammonium thiocyanate gave a solid complex which served this purpose. The NCS^- complexed very rapidly (and at the same time slowed down the exchange) and the $(CH_3)_4N^+$ salt of $[Mo_3O_4(NCS)_9]^{5-}$ precipitated. Within 2 min at

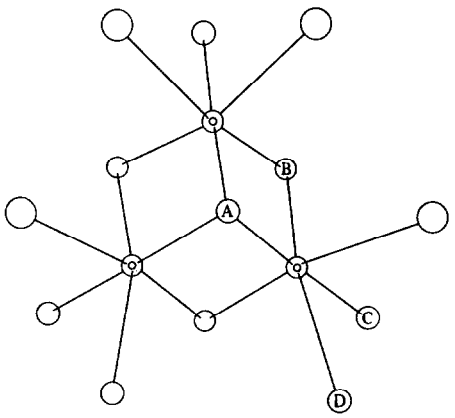

Fig. 6. $Mo_3O_4^{4+}$(aq).

0°C the majority of the precipitation took place, too short at time for rearrangement to occur. With ^{18}O enrichment in the solvent, at minimal contact times, the portion of enrichment transferred to the solid was less than 5% of that possible. Since the crystal structure of the precipitated solid[22] contained the Mo_3O_4 core all of the oxygens (four) in that core had to exchange slowly in solution. That Mo environment, shown in Fig. 6, contains two types of oxygen: one capping, and three bridging in addition to solvent water. Furthermore, it was possible to convert $Mo_3O_4^{4+}$(aq) through this sequence:

$$\rightarrow [Mo_3O_4(NCS)_9]^{5-} \rightarrow Mo_3O_4^{4+} \rightarrow [Mo_3O_4(ox)_3(OH_2)_3]^{2-} \rightarrow Mo_3O_4^{4+} \rightarrow [Mo_3O_4(SCN)_9]^{5-},$$

with less than 4% core oxygen exchange with the solvent. Even more remarkable, and a fact of considerable importance, is the transfer of $Mo_3O_4^{4+}$ core oxygens through the sequence $Mo_3O_4^{4+}$(aq) → Mo(hydroxide)↓ → $Mo_3O_4^{4+}$(aq), where at least 96% oxygen retention occurred. One usually expects extreme base catalysis of oxygen exchange but apparently that only occurs for the waters not the core oxygens.

Type A oxygen (Fig. 6) exchanges at a rate significantly faster than type B. At 30°C the half-life is about 4 days in 1.0 M acid and the number of oxygens exchanged at this rate was 1.1(1). The rate was not affected significantly by small acidity (0.8–1.2 M) or $[Mo_3O_4^{4+}]$ (0.08–0.14 M) changes.

Type B oxygen exchange (bridging) is very slow in 1.1 M CH_3SO_3H. Only a fraction of the total exchange occurred in 534 days at 25°C. During this period, appreciable oxidation occurred to Mo(V) but its presence did not cause rapid exchange. The half-life was estimated to be 5 ± 2 years and is not highly sensitive to acidity.

Type C water exchange was investigated by following the loss in enrichment in

$$[Mo_3O_4(*OH_2)_6(*OH_2)_3]^{4+}.$$

The ion was converted rapidly to

$$[Mo_3O_4(ox)_3(*OH_2)_3]^{2-},$$

whose crystal structure was determined as the easily precipitated $[Pt(en)_2]^{2+}$ salt. A count of the number of waters exchanging gave 3.0(2), suggesting that the exchanging waters were correctly identified. Of course, since the other six waters (type D) are replaced upon forming the complex no information about them can be obtained. The half-time for C type water exchange is about 1 h at 25°C in 1.0 M CH_3SO_3H. The reaction rate was not sensitive to light or $[Mo_3O_4]^{4+}$, increased slightly with ionic strength and was not affected by 10^{-4} M $Mo_2O_4^{2+}$ or MoO_4^{2-}. The rate constant was sensitive to pH and followed the rate law:

$$k_{obs} = k_0 + k_{oh}/[H^+].$$

The k_{oh} term most likely occurs through hydrolysis of one of the D-type waters leading to a lowered charge on the ion and an increased rate constant. The activation parameters were nearly the same for both terms, being $\Delta H^* = 100$ kJ M^{-1} and $\Delta S^* = 30$ J M^{-1} K^{-1} (averaged). The high value for ΔS^* suggests appreciable dissociative character leading to the activated state.

The effect of other complexing agents in the D-positions on the exchange rates of the C waters was estimated for Cl^-, NCS^- and ox^{2-}. With Cl^- the effect is a small decrease as Cl^- increases while NCS^- is much more effective in lowering the rate. This is probably due to its large association constants and the larger number of positions occupied for a particular concentration. The *tris*-oxalato complex had to be studied in less acidic media to retain the coordinated oxalate ion and to prevent oxygen exchange on the carboxylic acid groups. Actually there was a slight increase in rate constant with the oxalate complex but this is probably due in large part to the large change in acidity. Thus D water replacement by another ligand appears to cause a lowering of $k_{exch.}$, at least in the acid region.

Efforts to measure the exchange rate for type D waters utilized $[Mo(CN)_8]^{4-}$ as a precipitating agent. This reaction is not clean and neither the reaction nor the product are ideal for this type of experiment. Nevertheless, several runs gave half-times of about 25(5) min at 0°C in 1.2 M acid. This is remarkably slower than anticipated, especially since the NCS^-,[23] ox^{2-} and $EDTA^{4-}$[24] complexes form much more rapidly. Ion pairing must be extremely important in H_2O replacement by anions.

Table 3.

Oxygen type	Protons	Mo—O(av.) (Å)	Approximate $t_{1/2}$[a] [temperature (°C)]
A	0	2.020(3)	1×10^5 (0)
B	0	2.916(7)	2×10^8 (22)
C	2	2.163(3)	2×10^5 (0)
D	2	2.26(2)[b]	1×10^3 (0)

[a] 1 MH^+.
[b] This value comes from the SCN^- complex structure.

The exchange rates under nominal conditions are compared with metal–oxygen distances in the solid state in Table 3.

Oxygen transfer upon reduction of $Mo_3O_4^{4+}$(aq)

It has been conclusively demonstrated[24–26] that $Mo_3O_4^{4+}$(aq) can be reduced to two, well-defined, ions, $Mo(IV)(III)_2$ and $Mo(III)_3$, which all evidence show to be trimeric. It is of interest to know if the $Mo_3O_4^{4+}$ core remains intact in these ions. Toward this purpose the following sequence of reactions were carried out[21] utilizing ^{18}O enrichment in the core oxygens of $Mo_3O_4^{4+}$(aq):

$$Mo_3O_4^{4+} \rightarrow Mo(IV)(III)_2 \text{ or } Mo(III)_3$$
$$\rightarrow Mo_3O_4^{4+} \rightarrow [Mo_3O_4(ox)_3(OH_2)_3]^{2-}.$$

Reduction was accomplished either electrolytically or with zinc metal at 20(1)°C with identical results. In all cases, greater than 93% and as high as 97% retention of all four oxygens was found. Furthermore in one experiment a solution of $Mo(III)_3$ was allowed to exchange with solvent at room temperature for *2 months* and no (±3%) exchange was detected. Clearly the trimeric structure including the core oxygens exists in these reduced ions and solvent oxygen does not replace or become equivalent to them over a long time even though protonation no doubt takes place.

Oxygen transfer upon reduction of $[Mo_2O_4(EDTA)]^{2-}$

A similar study was made on the electrolytic and Zn(Hg) reduction products of $[Mo_2O_4(EDTA)]^{2-}$. It has been shown[27,28] that this produces $[Mo_2O_2(OH)_2(EDTA)]^{4-}$ and, when using Zn(Hg) as the reductant, an intermediate tetramer $[Mo(III)(IV)]_2$ was observed. Oxidation back to the original complex was accomplished with O_2. Using an acetate buffer at a pH of 4.95 and electrolytic reduction times of 3–24 h the core oxygen retention was 70–79(2)%. When carried out in enriched solvent with reduction times of 3–24 h, 75(2)% of the core oxygen was retained. This corresponds to 0.98(5) of four oxygens reaching isotopic equilibrium with the solvent.

When using Zn(Hg) (for reduction), the isotopic oxygen transfer was constant with time for at least 29 h. Thus the reduced ion does not exchange (±3%) in that time. A significantly higher transfer of solvent oxygen did occur which corresponds to 1.68(5) oxygens, out of four, becoming equivalent to that in the solvent. The interpretation of these results is still tentative and relates to the intermediates (tetramers) formed in the oxidation back to the starting material and the tetrameric $[Mo(III)(IV)_2]_2$ formed in the Zn(Hg) reduction.

STRUCTURE, BONDING AND ACID–BASE PROPERTIES OF PROTONATED MONOMETALATE IONS AND POLYMETALATE IONS FORMING CHAINS OR RINGS OF CORNER-SHARING MO_4 TETRAHEDRA OF TRANSITION METALS OF GROUPS V AND VI—A THEORETICAL APPROACH

KARL-HEINZ TYTKO

Institut für Anorganische Chemie, Universität Göttingen, 3400 Göttingen, F.R.G.

(*Received* 17 *June* 1985)

Abstract—It is shown that statements in the literature on the state of the mono- and diprotonated monomolybdate (and monotungstate) species in aqueous solution based on the pK_a values of the species disagree with the rules on the acid strength of oxoacids of Pauling and Ricci. A new approach to explain the protonation behaviour of the monochromate, monovanadate, monomolybdate and monotungstate species and to account for the enhanced basicity and stability of the polymetalate ions formed by corner-sharing MO_4 tetrahedra is given. The decisive feature is seen in the resonance structures of the tetrahedral and octahedral monomers and tetrahedral polymeric species in which positive and negative charges are separated, the negative charges being located on terminal oxygen atoms, thus enhancing the basicity of the species. The resonance structures in question are favoured by the size of the oxoanions (large distances between the charges) and by coordinated H_2O molecules (in the case of the octahedrally coordinated monomers) which facilitate separation of the charges by acceptance of the positive charge. Double bonds inside the chain are decisive for the enhanced stability of the polymeric species.

The state of the protonated monomolybdate and monotungstate species in aqueous solution is a matter of controversial discussions. The "real" formulae of $HMoO_4^-$ and H_2MoO_4 have been proposed to be

$[MoO(OH)_5]^-$,[1–10] $[MoO_2(OH)_3(H_2O)]^-$,[11,12]

$[MoO_3(OH)(H_2O)_2]^-$,[13] $[MoO_3(OH)]^-$ [14,15]*

and

$Mo(OH)_6$,[1–7,9,14,15]* $[MoO_2(OH)_2(H_2O)_2]$,[12,13]

and analogously the formulae

$[Mo(OH)_5(H_2O)]^+$,[3,4,7,16–19]

$[MoO_2(OH)(H_2O)_3]^+$ [12]

and

$[Mo(OH)_4(H_2O)_2]^{2+}$ [17]

have been suggested for the products of further protonation. Similar propositions have been made for corresponding tungstate species (cf. Refs 13 and 20). These propositions have been made to explain abnormal values of pK_a,[1–10] ΔG^o and ΔS^o,[14,15] ^{95}Mo and ^{97}Mo magnetic resonance observations,[11] or to account for the prevalence of a *cis*-MoO_2 unit[11,12] or the rapid aggregation processes in oxomolybdenum(VI) solutions.[13] For protonated monochromate and monovanadate species, however, only the tetrahedral structure is proven (cf. Refs 21 and 22).

The difficulties in establishing the state of the protonated monomolybdate and monotungstate ions in solution arise from the very low concentrations in which these species appear so that the usual methods of investigation cannot be applied.

In the present paper it will be shown that all statements in the literature on the coordination number of the mono- and diprotonated monomolybdate and monotungstate ions based on the pK_a values are incorrect and a new interpretation

* A tetrahedral monoprotonated monomolybdate ion $[MoO_3(OH)]^-$ and an octahedral diprotonated monomolybdate ion $Mo(OH)_6$ have also been proposed on the basis of computed Coulomb interaction energies.[41]

of the observed pK_a values and the enhanced basicity and stability of the polymetalate ions formed by corner-sharing MO_4 tetrahedra will be given.

INCOMPATIBILITY OF THE STATEMENTS IN THE LITERATURE FOR THE FIRST PROTONATION STEPS OF THE MONOMOLYBDATE ION WITH THE RULES ABOUT THE ACID STRENGTH OF THE ACIDS $MO_m(OH)_n$

The scheme mostly preferred for the first two protonation steps of the monomolybdate ion is, according to the literature:[1-10]

$$MoO_4^{2-} \overset{+H^+ \; +2H_2O}{\rightleftharpoons} [MoO(OH)_5]^- \overset{+H^+}{\rightleftharpoons} Mo(OH)_6. \quad (1)$$

Although this scheme has been postulated to explain the experimentally observed acid constants of the mono- ($pK_a \approx 3.7$, cf. Ref. 13) and diprotonated ($pK_a \approx 3.8$, cf. Ref. 13) monomers according to Pauling's and Ricci's rules[23,24] about the acid strength of the acids $MO_m(OH)_n$, it clearly contradicts these rules. As Table 1(a) shows, the observed pK_a of ≈ 3.8 for the diprotonated monomer differs strongly from that expected for the formulations in eqn (1), namely ≈ 9.0. On the other hand the observed pK_a of ≈ 3.7 for the monoprotonated monomer is similar to that expected for the tetrahedral acids HMO_4^- (considering the difference between non-metal and transition-metal oxoacids) [see Table 1(d)]. Therefore the formulation of the monoprotonated monomer in eqn (1) is incorrect and should be written $[MoO_3(OH)]^-$. The experimentally determined ΔG^o and ΔS^o values for the two reaction steps have also been interpreted to show the presence of the species $[MoO_3(OH)]^-$.[14,15] The diprotonated monomer, however, cannot be the species $[MoO_2(OH)_2]$. The expected pK_a of ≈ -3 [Table 1(c)] differs considerably from that observed, namely ≈ 3.8. Therefore the formulation $Mo(OH)_6$ might be correct from this point of view. This formulation, however, contradicts a rule according to which isopolymetalate ions built up by MO_6 octahedra cannot be centrosymmetric with the inversion centre on an M atom as a consequence of the great tendency for *cis*-location of π-interactions and a *trans*-effect in each of the MO_6 octahedra.[25,26] This rule should also apply to the octahedrally coordinated monomeric species. A similar view has also been

Table 1. Acid constants of some relevant oxoacids, $MO_m(OH)_n$, according to the literature (transition-metal oxoacids in parentheses)

Acid–base	pK_a

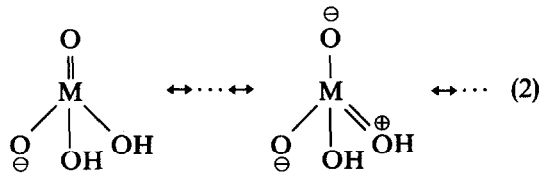
expressed by other authors.[11,12] The formula $[MoO_2(OH)_2(H_2O)_2]$ has been proposed to account for the rapid aggregation processes in molybdate solutions.[13]

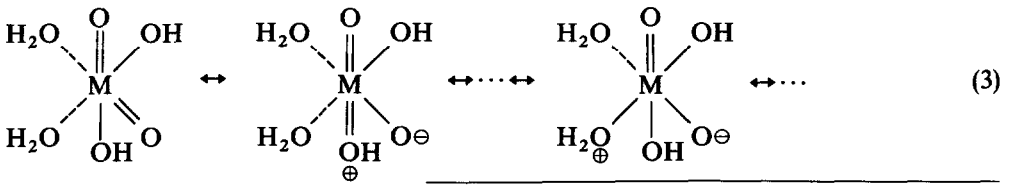
FUNDAMENTAL STATEMENTS TO EXPLAIN STRUCTURE, BONDING AND ACID–BASE PROPERTIES OF THE SPECIES UNDER DISCUSSION



The following considerations are fundamentally based on four statements:

(1) The validity of the well-known relations between the acid constants and the formulae $MO_m(OH)_n$ of the acids detected by Pauling and Ricci[23,24] is assumed as a general principle. That means the basicity of a species depends mainly on the average number of terminal O atoms which are available for each negative charge.

(2) Each O atom forms, summed over the various bonds, two covalent bonds unless its charge is compensated ionically by cations. The group VI elements form, summed over the various bonds, six covalent bonds, and the group V elements five covalent bonds, as is the case with the polymetalate ions (cf. Refs 27–29).



(3) The coordination number of the central metal cation of the metalate ion depends upon the radius of the metal cation (space requirements of the O-containing ligands) and upon the protonation state of the metalate ion (organization of more space for additional ligands).

(4) The resonance of type:

(2)

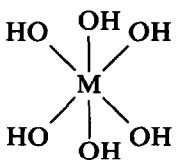
in the case of the tetrahedrally coordinated M atoms and:

(3)

in the case of the octahedrally coordinated M atoms enhances the basicity of the species by charge separation and offers an excellent possibility for charge delocalization being a stabilizing factor. It is favoured by the size of the monomeric species, since in this case charge separation is favoured (larger distances between the charges), which is also favoured by coordinated H_2O molecules.

RESULTS FOR THE PROTONATED MONOMETALATE IONS

The monomeric species of main-group and subgroup elements of groups VI and V and their experimentally determined protonation constants considered in this paper are listed in Table 2 together with the ionic radii of the central atoms of the oxoanions.



The enhanced basicity of the transition-metal oxometalate ions in general

The oxometalate ions of the transition metals are larger (also, the *d*-orbitals are more accessible[30]) and therefore show a greater tendency to undergo a charge separation than the non-metal oxoanions according to the schemes shown in Figs 1 and 2(a) by which the basicity of the species is enhanced. In this way the two to four orders of magnitude larger protonation constants of the unprotonated and protonated monometalate ions (compared with those of the corresponding main-group elements) can be explained.

The further enhanced basicity of the octahedrally coordinated oxometalate ions

Octahedrally coordinated monomers have been discussed in the literature for the mono- and diprotonated molybdate[1–10] and tungstate ions.[1,13,20] However, as has been shown above, the pK_a values of the monopronated monomers are in accordance with a tetrahedral coordination while those of the diprotonated monomers are in disaccord with a tetrahedral coordination. Extension of the coordination sphere of the metal atom can occur by coordination of two H_2O molecules, in this case opening up the possibility for an enhanced stabilization and enhanced basicity by resonance according to the schemes shown in Fig. 2(b).

The structure

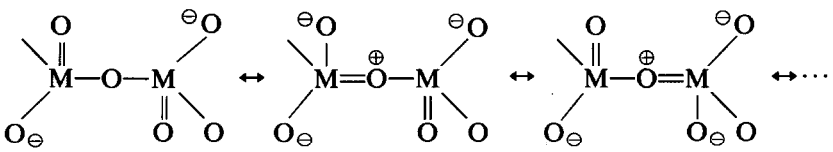
log K_p						3.2[40]

[a] See Table 1.



often proposed in the literature,[1–7,9,14,15] cannot be stabilized by resonance nor is its basicity enhanced. We therefore propose the protonation scheme:

$$MoO_4^{2-} \overset{+H^+}{\rightleftharpoons} [MoO_3(OH)]^- \overset{+H^+ \; +2H_2O}{\rightleftharpoons} [MoO_2(OH)_2(H_2O)_2]$$

$$\overset{+H^+}{\rightleftharpoons} [MoO(OH)_3(H_2O)_2]^+ \overset{+H^+}{\rightleftharpoons} [Mo(OH)_4(H_2O)_2]^{2+}, \qquad (4)$$

in which, in each case, the most basic O atoms (those bearing a negative charge, namely the terminal ones) become protonated [see Fig. 2(b)].*

explains the enhanced basicity and stability of the polymetalate ions (polychromate and polyvanadate ions) forming chains or rings of corner-sharing MO_4 tetrahedra, compared with the analogous non-metal polyanions (polysulphate and polyphosphate ions):

(5)

RESULTS FOR THE POLYMETALATE IONS FORMING CHAINS OR RINGS OF CORNER-SHARING MO_4 TETRAHEDRA

The above-mentioned resonance enhancing the basicity of the tetrahedral oxoanions [eqn (2)] also

These polymeric metalate ions are stabilized by the double bonds *inside* the chain. Due to the smaller size of the corresponding non-metal ions and, consequently, a higher repulsion energy the higher charged resonance formulae, and hence these polymeric species, are less favoured.

* The contribution of the coordinated H_2O molecules to the stabilization of the diprotonated monomer with respect to the basicity of the monoprotonated monomer would correspond to ≈ 3.8 pK_a units, as the difference between the experimentally observed pK_a of ≈ 3.8 and the average pK_a of the main-group oxoacids $MO_2(OH)_2$ [≈ -3, see Table 1(c)], corrected by ≈ 3 pK_a units (2–4, see above) for the change from a non-metal to a transition-metal oxoacid.

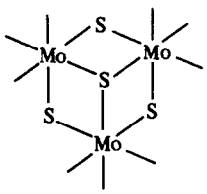
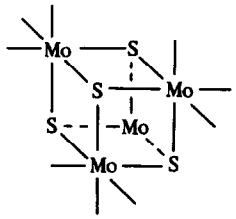
PREPARATION OF TRIANGULAR AND CUBIC MOLYBDENUM CLUSTERS AS AQUA IONS



P. KATHIRGAMANATHAN, M. MARTINEZ and A. G. SYKES*



Department of Inorganic Chemistry, The University, Newcastle upon Tyne NE1 7RU, U.K.

(*Received* 8 *July* 1985)

Abstract—Further use of an electrochemical procedure for the formation of triangular and cubic molybdenum cluster complexes as aqua ions is reported.

Details of the preparation of green coloured aqua ions, $[Mo_3S_4(H_2O)_9]^{4+}$ and $[Mo_4S_4(H_2O)_9]^{5+}$, in high yields (60 and 30% of Mo) in a single electrochemical experiment have recently been reported.[1] The method involves reduction of the

Mo(V) complex di-μ-sulphidobis-[1-cysteinato-molybdate(V)], $Na_2[Mo_2S_2O_2(cys)_2]\cdot 3H_2O$,[2] in 2 M HCl under N_2 (or Ar) at a Hg pool electrode (−0.85 V vs NHE) for 12 h. The dark brown product is then diluted to $[H^+] = 0.30$ M and 2 l of 0.5 M *p*-toluenesulphonic acid (HPTS) added. After leaving to stand in air for 24 h the solution is loaded onto a Dowex column and the 4+ and 5+ products eluted with 2 and 3 M HPTS, respectively.[1] It is now evident that there is some sort of interaction of Hg with $Mo_3S_4^{4+}$, and the spectrum obtained is more like that of $[Mo_3OS_3(H_2O)_9]^{4+}$. The crystal structure of $[Mo_4S_4(edta)_2]^{3-}$ and other Mo_4S_4 complexes have been determined.[3] A similar procedure with $Na_2[Mo_2O_4(cys)_2]\cdot 5H_2O$ gives the red product $[Mo_3O_4(H_2O)_9]^{4+}$ (~20% of Mo), which is now well-characterized,[4] and $[Mo_4O_4(H_2O)_{12}]^{5+}$ (~3% of Mo). The triangular complexes are known to have apical μ_3-ligands.[5]

With some modification the above procedure has now been extended to the preparation of selenido and tellurido analogue complexes. Those with Se were prepared by electrolytic reduction (−0.85 V) of $[Mo_2O_4(cys)_2]^{2+}$ (4×10^{-2} M, 70 ml) in the presence of Se powder (2 g), first in H_2O (12 h), and then for a further period with HCl adjusted to 0.5 M (36 h). The brown solution obtained is again left in air for 24 h. Dowex 50W X2 column chromatography gives yellow-green products, which can be eluted with 2 M HPTS (37% of Mo) and 3 M HPTS (8%), respectively. Thiocyanato complexes have been prepared and analysed. The aqua ions have absorption peaks for $Mo_3Se_4^{4+}$ (375 and 625 nm) and $Mo_4Se_4^{5+}$ (380 sh and 500 sh). There is also a substantial yield of the μ_3-selenido complex $Mo_3O_3Se^{4+}$. A similar procedure with tellurium (3 g) has been used to prepare tellurido complexes. Assuming these to be analogue complexes, the absorption peaks are for $Mo_3Te_4^{4+}$ (390 and 632 nm) and $Mo_4Te_4^{5+}$ (380 and 636 nm).

From the electrolysis of pairs of $Mo(V)_2$ complexes from $[Mo_2O_4(cys)_2]^{2-}$, $[Mo_2O_3S(cys)_2]^{2-}$ and $[Mo_2O_2S_2(cys)_2]^{2-}$ in equimolar amounts, triangular and cubic complexes with mixed μ(O) and μ(S) ligands are obtained as aqua ions. The range of triangular complexes general formula $[Mo_3O_xS_{4-x}(H_2O)_9]^{4+}$, including three prepared by Shibahara *et al.*,[6] is now complete, and includes symmetrical complexes $Mo_3O_4^{4+}$, $Mo_3SO_3^{4+}$, $Mo_3OS_3^{4+}$ and $Mo_3S_4^{4+}$, and unsymmetrical complexes $Mo_3SO_3^{4+}$, $Mo_3S_2O_2^{4+}$ (two forms) and $Mo_3S_3O^{4+}$.[7] All are in oxidation state Mo(IV)$_3$.† Selected UV–visible spectra (Fig. 1) indicate a gradual shift in peak positions to higher wavelengths with increasing sulphide content. Cyclic voltammograms (Fig. 2) give reversibility for each of the triangular complexes. Constant-potential coulometry done at potentials slightly more negative than the respective reduction peak potential shown in the cyclic voltammogram gives three electron reductions per cluster.

† The complex $Mo_3S_4^{4+}$ has also been prepared by Cotton and his colleagues from $M(CO)_6$.

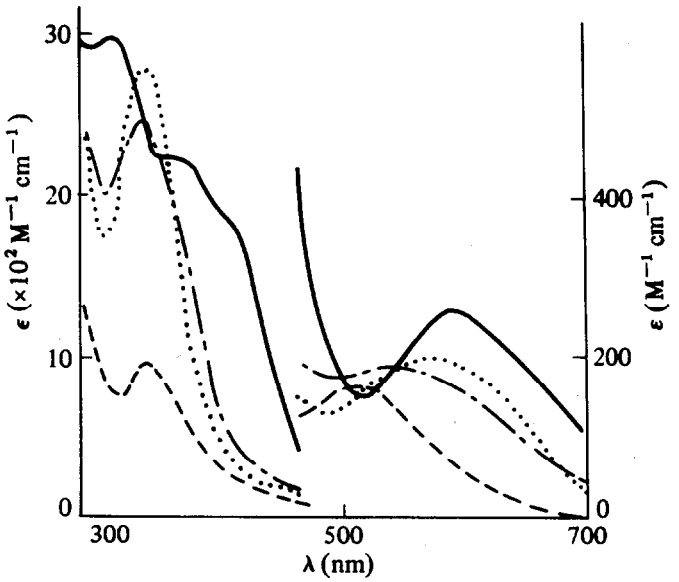

Fig. 1. UV spectra of the unsymmetrical triangular $Mo(IV)_3$ aqua ions $Mo_3O_3S^{4+}$ (– – –), $Mo_3O_2S_2^{4+}$ (two μ_2-sulphido ligands) (– · – · –), $Mo_3O_2S_2^{4+}$ (μ_2-S and μ_3-S ligands) (· · · · ·) and $Mo_3OS_3^{4+}$ (——) in 2 M HPTS.

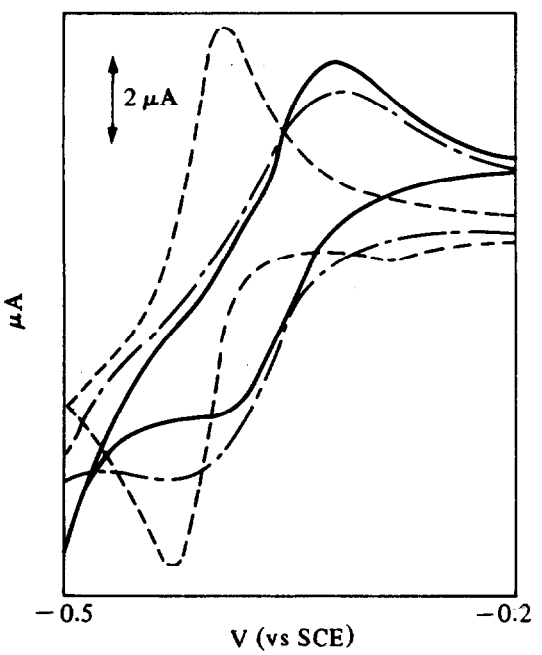

Fig. 2. Cyclic voltammograms of the $Mo(IV)_3$ aqua ions $Mo_3O_3S^{4+}$ (μ_3-sulphido) (– – –), $Mo_3OS_3^{4+}$ (μ_3-sulphido) (– · – · –) and $Mo_3S_4^{4+}$ (——) in 2 M HPTS at a hanging mercury electrode.

Similar electrochemical preparative procedures are currently under investigation to obtain W and Nb aqua ions. A range of aqua ions including $W_2O_4^{2+}$ (yellow),[8] $W_3O_4^{4+}$ (orange),[9] $W_4O_5^{5+}$ (brown-red) and a W(III) containing (green) ion have been identified in varying amounts depending on conditions employed which are at present being more carefully defined. In other related work there is evidence for formation of an aqua ion of niobium in oxidation state less then V, and preliminary results indicate a mixed-valence trimeric structure.

AQUEOUS Mo(IV): FORMATION, DISPROPORTIONATION AND PROPERTIES

G. P. HAIGHT* and K. M. RAHMOELLER†

University of Illinois, Urbana, IL 61801, U.S.A.

(*Received* 28 *June* 1985)

Abstract—A number of reactions relating to the solution chemistry of Mo(IV) are discussed.

Aqueous Mo(IV) has been the subject of many conflicting reports and speculations since 1940.[1] For example: (1) Mo(IV) has been deduced to be the active catalyst in reductions of inert oxoanions present in low, steady-state concentrations arising from its disappearance by a second-order disproportionation reaction.[2] Recently, *stable* $MO_3O_4^{4+}$ has been found to be inert to such catalysis.[3] (2) $Mo^{3+}(aq)$ is reported[4] to be oxidized to 90% $Mo_2O_4^{2+}$ and 10% $Mo_3O_4^{4+}$ with O_2, whereas we find a potential break for 100% formation of $Mo_2O_4^{2+}$ when the reaction is done rapidly. (3) Up to 70% $Mo_3O_4^{4+}$ can be formed when $Mo_2O_4^{2+}$ is reduced by Cr^{2+},[4] while earlier reports and our potentiometric titrations yield only Mo(III) as $Mo_2(OH)_2^{4+}$ with the same reducing agent.

In this paper we present evidence for the rapid disproportionation in H_2O of Mo(IV) monomers, dimers and polymeric chlorides without direct formation of stable, inert $Mo_3O_4^{4+}$, which forms only by slow conproportionation of Mo(V) or Mo(VI) with Mo(III), and by oxidation of $Mo_2(OH)_2^{4+}$ via the formation of mixed-valence oligomers from which $Mo_2O_4^{2+}$ and $Mo_3O_4^{4+}$ both form. Slow conproportionation of $Mo_2O_4^{2+}$ and $Mo_2(OH)_2^{4+}$ appears to account for varying amounts of $Mo_3O_4^{4+}$ being observed in systems reacting over long periods.[1,3] It is too slow to be a factor in potentiometric titrations used in this study.

DISPROPORTIONATION OF Mo(IV)

$MoCl_4$, $(Et_4N)_2MoCl_6$ and

$$(NH_4)_2[MoCl_4(SnCl_3)_2]$$

each catalyze the reduction of NO_3^- or ClO_4^- by Sn(II) giving kinetics similar to reactions initiated by Mo(VI).[1] Addition of each of these compounds to water or aqueous acid results in rapid disproportionation of Mo(IV):

$$12MoCl_4 + 12H_2O \rightarrow 3Mo_2O_4^{2+} + 2Mo_3Cl_{12}^{3-} + 24H^+ + 24Cl^-, \quad (1)$$

$$2MoCl_6^{2-} + 2H_2O \overset{\text{(seconds)}}{\rightleftharpoons} 2MoCl_5(OH_2)^{-1} + 2Cl^- \rightleftarrows MoOCl_5^{2-} + Mo(OH_2)Cl_5^{2-} + 2H^+, \quad (2)$$

$$2MoCl_4(SnCl_3)_2^{2-} + 2H_2O \leftrightarrows 2SnCl_3^- + \tfrac{1}{3}Mo_3Cl_{12}^{3-} + \tfrac{1}{2}Mo_2O_4^{2-}. \quad (3)$$

The driving force appears to be the formation of Mo(V)≡O multiple bonds. $MoOCl_5^{2-}$ is the Mo(V) product in ≥9 M HCl, but hydrolyzes to $Mo_2O_4^{2+}$ in dilute acid. $Mo_3Cl_{12}^{3-}$ has been identified by its UV–visible spectrum‡ and the kinetics of its dissociation (to be reported elsewhere):

$$Mo_3Cl_{12}^{3-} + 6H_2O \xrightarrow{k_1} 3[MoCl_4(H_2O)_2^-] \text{(minutes)} \xrightarrow{H_2O} Mo(OH_2)_6^{3+} \text{(hours)}, \quad (4)$$

$$3Mo_2O_4^{2+} + 6Mo^{3+} \xrightarrow{H_2O} 4Mo_3O_4^{4+} \quad \text{(hours)}. \quad (5)$$

* Author to whom correspondence should be addressed.

† Present address: Physical Chemistry Department, General Motors, Detroit, MI 48089, U.S.A.

‡ The Mo(III) product could not be isolated from solution due to its rapid dissociation. $Mo_2Cl_9^{3-}$ and $Mo_3Cl_{12}^{3-}$ both exhibit similar visible spectra and dissociation kinetics, although $Mo_3Cl_{12}^{3-}$ appeared a better match. A partially aquated form of $Mo_2Cl_9^{3-}$ could be the initial product of $MoCl_4$ disproportionation or of $Mo_3Cl_{12}^{3-}$ dissociation: however, stoichiometry and spectra dictate a preference for $Mo_3Cl_{12}^{3-}$.[5]

Hydrolysis of dinuclear[6] and trinuclear Mo(IV) alkoxides[7] led to disproportionation only for the dimeric species, which apparently dissociates on hydrolysis:

$$2[Mo(OEt)_4] \xrightarrow{H_3O^+} Mo_2O_4^{2+} + 2Mo^{3+}_{(aq)}, \quad (6)$$

$$3H_3O^+ + Mo_3O(OEt)_9^+ \rightarrow Mo_3O_4^{4+} + 9EtOH. \quad (7)$$

It appears unlikely that oxidation or reduction of monomeric Mo(III) or Mo(V) will result in direct formation of $Mo_3O_4^{4+}$.

OXIDATION OF Mo(III)

$Mo(H_2O)_6^{3+}$, $Mo_2(OH)_2^{4+}$ and various complexes of the latter have been titrated to potentiometric endpoints using oxidants Ce^{4+}, $Cr_2O_7^{2-}$, NO_3^-, VO^{2+}, ClO_3^-, ClO_4^-, $Co(C_2O_4)_3^{3-}$ and O_2 (bubbled rapidly until a potential change occurs) to discover pathways to and around $Mo_3O_4^{4+}$. Product analyses of species present at endpoints have made delineation of likely pathways possible.

Oxidation of $Mo^{3+}(aq)$ *(monomeric)*

The half reaction:

$$2Mo^{3+} + 4H_2O \rightarrow Mo_2O_4^{2+} + 8H^+ + 4e^- \quad (8)$$

describes the overall result of all oxidations of monomeric Mo^{3+} at the first potential break. Ce^{4+} and $Cr_2O_7^{2-}$ could effect further oxidation and a second potential break for:

$$Mo_2O_4^{2+} \rightarrow 2MoO_2^{2+}(aq) + 2e^-. \quad (9)$$

ClO_4^- is initially inert,[8] exhibiting autoacceleration as Mo(V) is formed. Since Mo^{3+}, a d^3 ion, must lose electrons from two different t_{2g}-orbitals, and Mo(IV) is known to disproportionate fast, the following mechanism leading to 100% formation of Mo(V) is compelling:

$$Mo^{3+} + [Ox] \rightarrow Mo(IV), \quad (I)$$

$$2Mo(IV) \rightarrow Mo^{3+} + Mo{\equiv}O^{3+}, \quad (II)$$

$$2Mo{\equiv}O^{3+} + 2H_2O \rightarrow Mo_2O_4^{2+} + 4H^+. \quad (III)$$

Scheme 1.

Mo(IV) could be oxidized directly with the same overall result:

$$Mo(IV) + Ox \rightarrow O{\equiv}Mo(V). \quad (IIa)$$

If oxidation (with O_2) is done *slowly*, $Mo_2O_4^{2+}$ may react with Mo^{3+} to give variable amounts of $Mo_3O_4^{4+}$ by reaction (5).[3]

OXIDATION OF $Mo_2(OH)_2^{4+}$

Using all the above oxidants as titrants and conproportionation with Mo(VI) give a surprising potential break at average oxidation state for Mo of +4.5. At the endpoint it is possible to separate and identify $Mo_2O_4^{2+}$ and $Mo_3O_4^{4+}$, with half of the molybdenum in each species:[1,9]

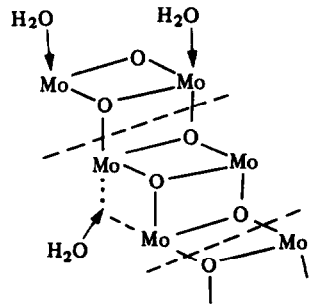
$$6Mo_2(OH)_2^{4+} \xrightarrow{[Ox]} 2Mo_3O_4^{4+} + 3Mo_2O_4^{2+} + 12H^+ + 18e^-, \quad (10)$$

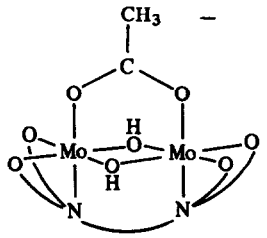
$$2H_2O + 3Mo_2(OH)_2^{4+} + 6Mo(VI) \rightarrow 2Mo_3O_4^{4+} + 3Mo_2O_4^{2+} + 10H^+. \quad (11)$$

Using ^{95}Mo NMR for isotopic labelling it is found that half of the molybdenum in each product of reaction (11) originates in each reactant. Complete scrambling of Mo, the stoichiometry and the need to use dimeric Mo_2(III) all suggest a build up of mixed-valence oligomers, from which the two very stable products may form.

STERIC HINDRANCE TO OLIGOMERIZATION

If this mechanism is correct, complexation of the $Mo_2(OH)_2^{4+}$ should prevent formation of these intermediates by removal of coordination sites necessary for oligomerization, and new stoichiometries could result. In the cases of the oxidation of the EDTA and TACN (1,4,7-triazacyclononane) complexes of $Mo_2(OH)_2^{4+}$, $Mo_2O_4^{2+}$ complexes become the dominant, if not the only, product of potentiometric titration. The $[Mo_2(OH)_2EDTA]$ complex can be partially oxidized (no potential break) to $Mo_4O_6(EDTA)_2^{4-}$. The latter may be titrated to $[Mo_2O_4EDTA]^{2-}$ as the only product. If





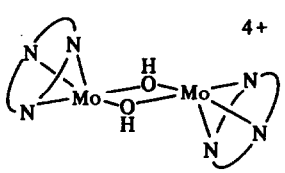


Fig. 1. Oligomer fragment showing how water-assisted cleavage of an $(Mo_2O_2)_n$ oligomer could produce both $Mo_2O_4^{2+}$ and $Mo_3O_4^{4+}$. If $n = 12$ the observed stoichiometry is realized. The dashed lines indicate how trimers and dimers may be obtained from a simply constructed intermediate.

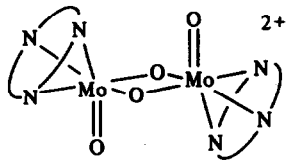
placed in acid, EDTA dissociates and the undetermined aquation product(s) are oxidized to $Mo_3O_4^{4+}$ and $Mo_2O_4^{2+}$ in the usual 2:3 ratio. In the special case of oxidation by Mo(VI), deviations from the $3Mo_2O_4^{2+} + 2Mo_3O_4^{4+}$ stoichiometry also occur. With EDTA as ligand (I), only the $Mo_3O_4^{4+}$



I

core forms. That direct formation of $Mo_3O_4^{4+}$ is permitted only in this case suggests that addition of more than one Mo(VI) to $Mo_2(OH)_2^{4+}$ to form oligomers is preferred to trimer formation in the absence of steric hindrance from ligands. With TACN as ligand, oxidation of *anti*-$Mo_2(OH)_2(TACN)_2^{4+}$ (II) with Mo(VI) gives *anti*-$Mo_2O_4(TACN)_2^{2+}$ (III) which slowly isomerizes[10] to

II

III

the more common *syn*-$Mo_2O_4(TACN)_2^{2+}$. No $Mo_3O_4^{4+}$ forms. Apparently the steric hindrance prevents formation of even the Mo(IV) trimer, allowing Mo(VI) no other role than as a simple oxidant.

REDUCTION OF Mo(VI) AND Mo(V)

Potentiometric titrations of Mo(VI) in 1 M methylsulfonic acid using Cr^{2+} and V^{2+} gave two breaks for the reactions:

$$2Mo(VI) + 2e^- \xrightarrow{H_2O} Mo_2O_4^{2+}, \quad (12)$$

$$6H^+ + Mo_2O_4^{2+} + 4e^- \rightarrow Mo_2(OH)_2^{4+} + 2H_2O. \quad (13)$$

Quick product separation and analysis showed no formation of $Mo_3O_4^{4+}$ at intermediate stages of the titration. Investigation of conditions and time of contact between Mo(III) products and Mo(V) reactants may yet reveal favorable conditions for forming $Mo_3O_4^{4+}$ by reduction of $Mo_2O_4^{2+}$ and/or Mo(VI).

CONCLUSIONS

Most Mo(IV) aquo or oxo species disproportionate in water making assembly of stable, inert $Mo_3O_4^{4+}$ cores difficult. However, special pathways and slow conproportionations do lead to $Mo_3O_4^{4+}$, making it very likely that minor differences in experimental procedure will give different stoichiometries for appearently similar redox processes.

KINETIC STUDIES ON THE REACTIONS OF AQUA Mo^{3+} WITH O_2 AND ClO_4^-

ELAINE F. HILLS and A. G. SYKES*

Department of Inorganic Chemistry, The University, Newcastle upon Tyne NE1 7RU, U.K.

(*Received* 1 *July* 1985)

Abstract—Kinetic studies are reported for two fundamental reactions of the hexaaquamolybdenum(III) ion with O_2 and ClO_4^-.

Previously the reaction of O_2 with aqua metal ions Cr^{2+},[1] V^{2+},[2] Fe^{2+} [3] and U(IV),[4] have been studied, and there are extensive investigations of the reactions of O_2 with a range of Co(II),[5] Cu(I)[6] and Ru(II)[7] complexes. In the case of Mo^{3+}, the oxidation state of the metal ion changes by $2e^-$ to give Mo(V), a feature which is relevant also to the V^{2+}, Cr^{2+} (possibly) and U(IV) studies. However, with V^{2+} and Cr^{2+} in excess the final product is the III state ion, and the oxidation of U(IV) is believed to proceed with intermediate formation of U(V).

The reaction of Mo^{3+} with O_2 in *p*-toluenesulphonic acid (HPTS) solutions, $I = 2.0$ M (LiPTS), is summarized by eqn (1):

$$2Mo^{3+} + O_2 + 2H_2O \rightarrow Mo_2O_4^{2+} + 4H^+, \quad (1)$$

where $Mo_2O_4^{2+}$ is the di-μ-oxo Mo(V) ion, $[Mo_2O_4(H_2O)_6]^{2+}$.[8] Even when there is a deficiency of Mo^{3+}, the reaction conforms to this equation. Use of isotopically labelled O_2, followed by IR spectroscopy of the isolated $Mo_2O_4^{2+}$ product, has demonstrated that some and possibly all of the ^{18}O is taken up in the di-μ-oxo positions.[9] At 25°C, with Mo^{3+} in large excess, three stages are observed by stopped-flow spectrophotometry, and an intense yellow coloured intermediate is formed which we choose to write as MoO_2Mo^{6+}, consistent with minimal-composition requirements. The oxidation state of the Mo in this intermediate is uncertain, and is presumably in the III–V range. There is no evidence for formation of aqua $Mo(IV)_3$ [or any as yet unidentified monomeric or dimeric Mo(IV) aqua ion] as an intermediate, except on bubbling O_2 through a solution of Mo^{3+} (2.3×10^{-2} M), when ~10% of red $Mo(IV)_3$ is obtained.

The kinetics of the decay of the intermediate at the 395-nm peak ($\varepsilon = 2300$ M^{-1} cm^{-1} per dimer), give rate constants, k_{3obs}, which can be expressed as in eqn (2):

$$k_{3obs} = \frac{K_1K_2k_3[Mo^{3+}]^2}{1 + K_1[Mo^{3+}] + K_1K_2[Mo^{3+}]^2}. \quad (2)$$

The various constants (in 2 M HPTS) are as defined in eqns (3)–(5):

$$Mo^{3+} + O_2 \rightleftharpoons MoO_2^{3+} \quad (K_1 = 360\ M^{-1}), \quad (3)$$

$$MoO_2^{3+} + Mo^{3+} \rightleftharpoons MoO_2O^{6+} \quad (K_2 = 535\ M^{-1}), \quad (4)$$

$$MoO_2Mo^{6+} \rightarrow \text{products} \quad (k_3 = 0.23\ s^{-1}). \quad (5)$$

Applications of a non-rigorous consecutive treatment to the last two, and then the first two stages has provided estimates of the rate constants for eqns (3) and (4). Refinement has been carried out using KINSIM for consecutive equilibria.[10] Rate constants k_1 (180 M^{-1} s^{-1}) and k_2 (42 M^{-1} s^{-1}) are in excess of previous substitution rate constants for Mo^{3+}. With O_2 in excess of Mo^{3+} an alternative route for conversion of MoO_2^{3+} to $Mo_2O_4^{2+}$ has been identified.

Taube[11] has recently reviewed the reactivity of reducing metal ions (Ti^{3+}, V^{2+}, V^{3+} and Ru^{2+}) with ClO_4^-. Notable examples in which no reaction occurs are with Cr^{2+}, Eu^{2+} and Sn^{2+}. In all cases in which reaction takes place, it appears that an oxo product, the VO^{2+} aqua ion in the case of V^{2+} and V^{3+}, is formed. With Mo^{3+} there are no stable mononuclear oxo products, since Mo(IV) exists as the trimeric $Mo_3O_4^{3+}$ ion[12] and Mo(V) as dimeric $Mo_2O_4^{2+}$. Transient monomeric aqua ions having the required structure cannot however be ruled out.

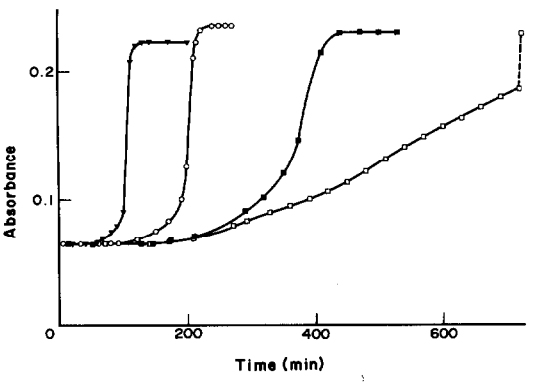

Fig. 1. Absorbance changes at 385 nm for the reaction (25°C) of Mo^{3+} (4.3×10^{-3} M) with ClO_4^- at $[H^+] = 0.30$ M, $I = 1.0$ M (LiPTS). Concentrations of perchlorate (introduced as $LiClO_4$) were: 0.20 (□), 0.30 (■), 0.50 (○) and 0.70 (▼).

This situation results in more complicated kinetics as indicated below.

The kinetics with ClO_4^- (≥ 0.2 M) in excess monitored by $Mo(V)_2$ formation is characterized by slow initiation, rapid propagation and termination (Fig. 1). No evidence was obtained for formation of either $Mo(III)_2$ or $Mo(IV)_3$ as intermediates. At 25°C solutions of Mo^{3+}, $(2.2–8.6) \times 10^{-3}$ M, have been found to exhibit no apparent reactivity with ClO_4^- (0.2–0.7 M) over a period of at least 0.5 h (and as long as 3 h for $[HClO_4] = 0.2$ M), after which a complete reaction can be observed in as little as 1 h, e.g. with $[ClO_4^-] = 0.7$ M, $[H^+] = 0.3$ M, $I = 2.0$ M (LiPTS). For the procedure used and in the absence of ClO_4^-, there was no detectable reaction of Mo^{3+} over 4 h.

Overall, the reaction is faster at higher $[ClO_4^-]$, higher $[Mo^{3+}]$, and at the higher $[H^+]$ in the range investigated. The length of the initiation period is dependent on whether the source of ClO_4^- is $LiClO_4$ or $HClO_4$ (slower rates) at constant $[H^+]$. Details of the precise mechanism remain uncertain. The features displayed are quite different to all previous studies.

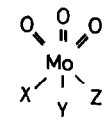
THE ELECTROCHEMISTRY OF A DIMERIC AND TWO MONOMERIC *CIS*-TRIOXOMOLYBDENUM(VI) COMPLEXES CONTAINING CYCLIC TRIAMINE LIGANDS IN PROTIC AND APROTIC MEDIA: MODEL COMPOUNDS FOR THE ACTIVE SITE IN FORMATE DEHYDROGENASE



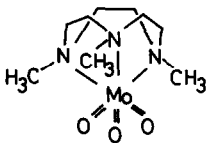
WILLY HERRMANN and KARL WIEGHARDT*

Lehrstuhl für Anorganische Chemie I der Ruhr-Universität, D-4630 Bochum, F.R.G.

(*Received* 7 *June* 1985)

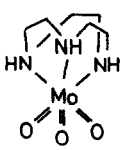
Abstract—The electrochemistry of two monomeric *cis*-trioxomolybdenum(VI) complexes containing cyclic triamine ligands *N,N',N''*-trimetyl-1,4,7-triazacyclononane (L) (**1**) or 1,4,7-triazacyclononane (L') (**2**) has been studied in protic (CH_3SO_3H) and aprotic media (DMF) by cyclic voltammetry at an HMD electrode. **1** and **2** are quasi-reversibly reduced by a $2e^-, 4H^+$ step in acidic solutions to give monomeric $[LMo(IV)O(OH_2)_2]^{2+}$ and $[L'MoO(OH_2)_2]^{2+}$, which in the case of **1** is further reduced to a monomeric Mo(III) species which then undergoes a reversible chemical reaction (dimerization?). In contrast, reduced **2** undergoes chemical reactions (dimerization or trimerization of $[L'MoO(OH_2)_2]^{2+}$ or comproportionation reactions) due to the fact that the unmethylated cyclic amine in **2** is sterically less demanding. **1** and **2** are redox-inactive in DMF (+1.0 to −1.7 V vs Ag–AgCl at a Pt or a glassy-carbon electrode). Dimeric $[L_2Mo_2O_5](PF_6)_2$, **3**, is reversibly reduced to a $Mo(V)_2$ dimer ($2e^-, 2H^+$ process) and, finally, to a $Mo(III)_2$ dimer ($4e^-, 4H^+$) in 0.1 M CH_3SO_3H at an HMD electrode, contrasting with the behavior in aprotic medium (DMF, Pt electrode), where two reversible one-electron transfer processes generating the blue, mixed-valence species Mo(VI)/(V) and an $Mo(V)_2$ dimer have been observed.

A number of enzymes containing monomeric Mo(VI), Mo(V) or Mo(IV) have been characterized and the structures of their first coordination spheres have been elucidated with an encouraging degree of certainty by EXAFS and EPR-spectroscopy.[1–3] While the oxidized forms of the enzymes sulfite oxidase, xanthine oxidase and nitrate reductase appear to have a *cis*-dioxomolybdenum(VI) or a *cis*-oxosulfidomolybdenum(VI) moiety in common, there is evidence for a *cis*-trioxomolybdenum(VI) entity in the enzyme formate dehydrogenase (CO_2 reductase) isolated from *Clostridium pasteurianum*.[4,5] Interestingly, and in contrast to the afore-mentioned enzymes, there is no evidence for coordination by sulfur ligands. Instead, additional oxygen or nitrogen ligands were found and a plausible structure of the active site has been proposed. These observations have lead to increasing efforts to synthesize simple low molecular weight model complexes of molybdenum which mimic spectroscopic and reactivity patterns of these enzymes.[1,2,6] Extremely useful information concerning the catalytic activity of enzymes and their



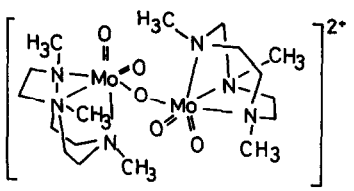
X,Y,Z = O, N

model compounds have been obtained from electrochemical studies, which have focussed to a great extent on *cis*-dioxomolybdenum complexes.[7–17] To date no such study has been carried out on simple monomeric *cis*-trioxomolybdenum(VI) complexes with the exception of the aqua-ion $MoO_3(OH_2)_3$.[18] This is due to the fact that, until very recently, stable monomeric complexes with this entity were not available. Thus



* Author to whom correspondence should be addressed.

(dien)MoO_3[19] (dien = diethylenetriamine) is known to undergo ligand dissociation in aqueous solution,[20] and $[(nta)MoO_3]^{3-}$ (nta = nitrilotriacetate) dimerizes in acidic solution.[21]



We have prepared two *cis*-trioxomolybdenum(VI) complexes **1** and **2** using the small tridentate cyclic macrocycles *N,N',N''*-trimethyl-1,4,7-triazacyclononane and 1,4,7-triazacyclononane.[22] **1** and **2** are stable in acidic aqueous solution and no ligand dissociation has been observed even in 2 M $HClO_4$.

1

2

3

We report here a cyclic voltammetric study of **1** and **2** in an aprotic medium and in acidic (CH_3SO_3H) solution. In addition, we have further investigated the electrochemistry of the dimer **3**[23] in a protic medium.

RESULTS

Electrochemistry of 1, 2 *and* 3 *in aprotic media*

The monomeric complexes **1** and **2** were found to be redox-inactive in acetonitrile (0.1 M TBA-PF_6 supporting electrolyte) at a Pt-button or glassy-carbon electrode in the potential range +1.0 to −1.7 V vs Ag–AgCl. Even in aqueous 0.1 M KNO_3 no reaction has been observed.

In contrast, binuclear $\mathbf{3}(PF_6)_2$ in acetonitrile has been shown previously to be reduced in two reversible one-electron reactions yielding an intensely blue mixed-valence species Mo(VI)/Mo(V) and, finally, a yellow dimer of Mo(V), which is a strong reductant:[23]

$$\begin{aligned}&[L_2Mo_2O_5]^{2+} + e^- \rightleftharpoons [L_2Mo_2O_5]^+ \\ &+ e^- \rightleftharpoons [L_2Mo_2O_5], \\ &E_1 = -0.77\ \text{V}, \\ &E_2 = -1.88\ \text{V vs } Fc^+\text{–Fc}.\end{aligned} \qquad (1)$$

Electrochemistry of 1 *in acidic solution* (*pH* 0.3–1.3)

The cyclic voltammogram (CV) of **1** in 0.1 M CH_3SO_3H, at a hanging mercury drop electrode (HMDE) (Fig. 1) consists of two reduction and one oxidation wave in the potential range +0.3 to −0.8 V vs normal hydrogen electrode (NHE). The second reduction wave (peak c) is less intense than the first (a) and it reduces the height of oxidation peak b. In a reduced range (+0.3 to −0.30 V) only one reduction and one oxidation wave are observed (peaks a and b).

In Table 1 the diagnostic criteria of the CV in the potential range +0.3 to −0.3 V for peaks a and b are summarized and they are commented on as follows:

(1) The reduction potential, E_p^a, and the oxidation potential, E_p^b, are shifted to more cathodic and anodic potentials, respectively, with increasing scan rates: it is a symmetrical shift of *ca* 38 mV in going from 50 mV s^{-1} to 1.0 V s^{-1}.

(2) For the peak half-width potential, $E_{p/2}^a$, a small cathodic shift (maximum 25 mV) with increasing scan rates (0.5–1.0 V s^{-1}) is observed, whereas $E_{p/2}^b$ appears to be independent of the scan rate.

(3) The peak potential difference, ΔE_p^{ab}, increases with increasing scan rates (ΔE_p = 100 mV s^{-1} and 176 mV at 1.0 V s^{-1}), indicating a substantial kinetic inhibition of the electron-transfer process.

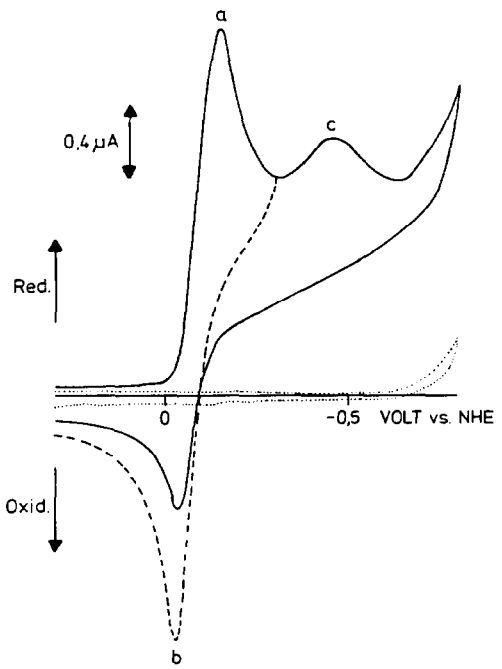


Fig. 1. CV of **1** in 0.1 M CH_3SO_3H (HMDE 25°C, scan rate 100 mV s^{-1}) in the potential range +0.3 to −0.3 V (broken line) and +0.3 to −0.8 V vs NHE (solid line).

[d] Peak half-width of peaks a and b (Fig. 1).
[e] Peak potential difference between peak a and peak b.
[g] Formal redox potential $(E_p^a - E_p^b)/2$.
[h] Reduction potential of peak c.

(4) The formal redox potential $E_{1/2}$ $[(E_p^a - E_p^b)/2]$ (−0.075 V vs NHE) is *independent* of the scan rate.

These diagnostic criteria are indicative of a quasi-reversible redox wave. Although the rather large peak potential difference ($|E_p^a - E_p^b| = \Delta E_p^{ab}$) seems to point to a one-electron transfer; the peak half-width potential differences, $|E_p^a - E_{p/2}^a|$ and $|E_p^b - E_{p/2}^b|$ (especially the latter), indicate a two-electron transfer process which is kinetically inhibited ($|E_p^b - E_{p/2}^b|$ is 0.048 V at a scan rate of 50 mV s^{-1}).

The current functions, CF^a and CF^b, are nearly identical indicating that the same number of electrons is transferred. In addition, the current ratio, I_p^b/I_p^a, and $E_{1/2}$ are independent of the scan rate. Therefore, a quasi-reversible reduction of **1** by two electrons yielding a monomeric Mo(IV) species is proposed. Coulometric measurements would settle this point unambiguously but have not been possible due to adsorption effects of **1** at the mercury pool electrode. Similar effects have been reported for $MoO_3(OH_2)_3$ in 2.0 M CF_3SO_3H at a mercury electrode.[18]

In the extended potential range to −0.8 V (Fig. 1) the second reduction peak c observed shifts to more cathodic potentials with increasing scan rates (E_p^c = −0.435 to −0.52 V vs NHE at scan rates of 0.05–1.0 V s^{-1}). Peak c has no influence on $|E_p^a - E_{p/2}^a|$, $|E_p^b - E_{p/2}^b|$ and ΔE_p^{ab} but a marked reduction of the current of the oxidation peak b is evident. Whereas in the potential range 0.3 to −0.3 V the peak current function of peak b, CF^b, is independent of the scan rate a *decrease* is observed in the extended range with *increasing* scan rate. This is paralleled by a decreasing I_p^b/I_p^a in the extended and a constant ratio (1.1) in the reduced range (Fig. 2). This behavior is typical for an E_rC_r mechanism for reduction peak a and a C_rE_r mechanism for oxidation peak b.[26]

The nature of this equilibrium reaction has been investigated in the following manner: if the potential is kept constant for 15, 30, 45 and 60 s at a potential of the returning point of −0.3 V during a normal cyclic voltammetry experiment in the *reduced* potential range (+0.3 to −0.3 V), I_p^b/I_p^a remains constant (1.1) independent of the delay times chosen. In contrast, during the same experiment but with a potential at the returning point of −0.65 V I_p^b/I_p^a decreases to 0.56 at a scan rate of 50 mV s^{-1} (0.39 at 200 mV s^{-1}) (Fig. 2). These values are also independent of the delay times at the returning point and are identical to those in continuously scanned CV experiments.

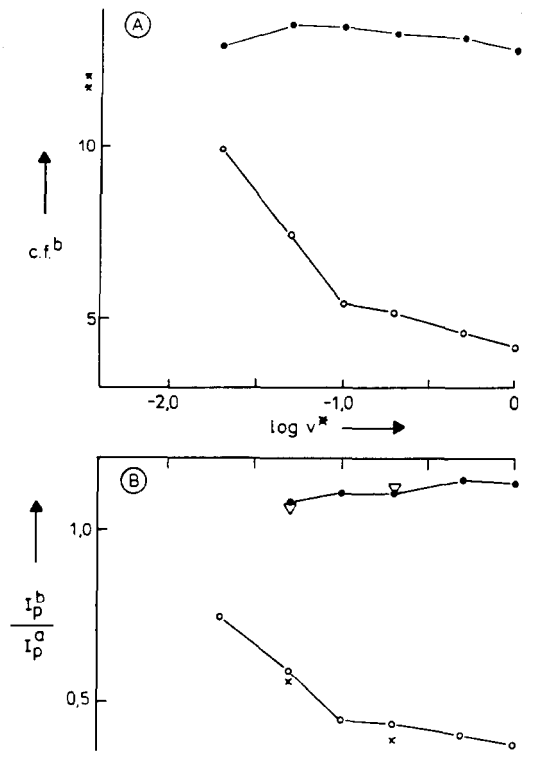

Fig. 2. Plots of CF^b (A) and I_p^b/I_p^a (B) vs the logarithm of the scan rate of **1** in 0.1 M CH_3SO_3H: (●——●) potential range +0.3 to −0.3 V vs NHE, and (○——○) potential range +0.3 to −0.8 V vs NHE.

These observations allow the following conclusions to be made.

(1) The equilibrium reaction occurs after the second reduction.

(2) The reaction is reversible (CF decreases with increasing scan rates).

(3) The equilibration reaction is fast on the time scale of a cyclic voltammetric experiment.

It has not been possible to evaluate the number of electrons transferred at the second reduction step, c, from a coulometry experiment nor from values of $|E_p^c - E_{p/2}^c|$, but the peak current function, CF^c, does indicate a one-electron transfer reaction (3.3–5.4 $\mu A\ V^{-1/2}\ s^{1/2}\ mmol^{-1}\ l$).

Thus the redox scheme of **1** may be summarized at this point by eqn (2):

$$\mathbf{1} \underset{-2e^-}{\overset{+2e^-}{\rightleftharpoons}} \text{Mo(IV)} \overset{+e^-}{\rightleftharpoons} \text{Mo(III)} \rightleftarrows \text{Mo(III)}_2(?). \quad (2)$$

In the following section the pH dependence of this scheme will be investigated. The CVs of four solutions were recorded and diagnostic criteria were evaluated ($[H^+]$: 0.5, 0.2 or 0.1; 0.05 M CH_3SO_3H: the ionic strength was adjusted to 0.5 M with KNO_3). The data are summarized in Table 1. CVs were again recorded in the reduced (0.3 to −0.3 V) and extended (0.3 to −0.8 V) potential range. The behaviour of the diagnostic criteria E_p^a, $E_p^b = f(v)$, $\Delta E_p = f(v)$ and $E^f = f(v)$ is identical in all four solutions and confirms the results presented above: the reduction peak a and the oxidation peak b correspond to a quasi-reversible two-electron transfer process. Both peaks shift with increasing pH to more cathodic potentials. The formal redox potential E_{exp}^f as a function of pH is expressed as in eqn (3):

$$E_{exp}^f(\text{V vs NHE}) = +0.055 - 0.110\text{pH}. \quad (3)$$

According to eqn (4) the number of protons involved in this step is calculated to be four if the number of electrons transferred is two:

$$E_{exp}^f = E_{1/2} - 0.059\frac{m}{n}\text{pH}, \quad (4)$$

where m = number of protons, and n = number of electrons.

The quasi-reversible first reduction of **1** may be written as:

$$\text{LMo(VI)O}_3 + 4H^+ + 2e^- \rightleftarrows [\text{LMo(IV)O(OH}_2)_2]^{2+}. \quad (5)$$

Both monomeric species are stable—at least on the time scale of a cyclic voltammetry experiment. It is noted that the nature of the supporting electrolyte does not change this picture: CVs in 0.5 M HCl are identical to those measured in CH_3SO_3H. Thus no rapid substitution reactions of the Mo(IV) species are observed. The data available for the second irreversible reduction peak c do not allow a clear-cut interpretation, although the diagnostic criteria do indicate a rapid equilibration reaction to occur after this reduction step. Also the pH dependence of reduction peak c is not conclusive and has not been investigated further. Thus the following redox scheme has been established for **1**:

$$\text{LMo(VI)O}_3 \underset{-4H^+,2e^-}{\overset{+4H^-,2e^-}{\rightleftharpoons}} [\text{LMoO(OH}_2)_2]^{2+} \overset{+1e^-}{\rightleftharpoons} \text{Mo(III)} \rightleftarrows \text{Mo}_2\text{(III)}\ (?). \quad (6)$$

Electrochemistry of **2** *in acidic solution*

The CV of **2** (Fig. 3) measured in 1.0 M CH_3SO_3H exhibits features resembling those of **1** in 0.1 M CH_3SO_3H, but also significant differences are detected. Apart from the reduction peaks (a′ and c′) and the oxidation peak (b′) two additional irreversible waves (e′ and f′) are observed. The small reduction peak e′ has no detectable chemical influence on the form and intensity of all other peaks,

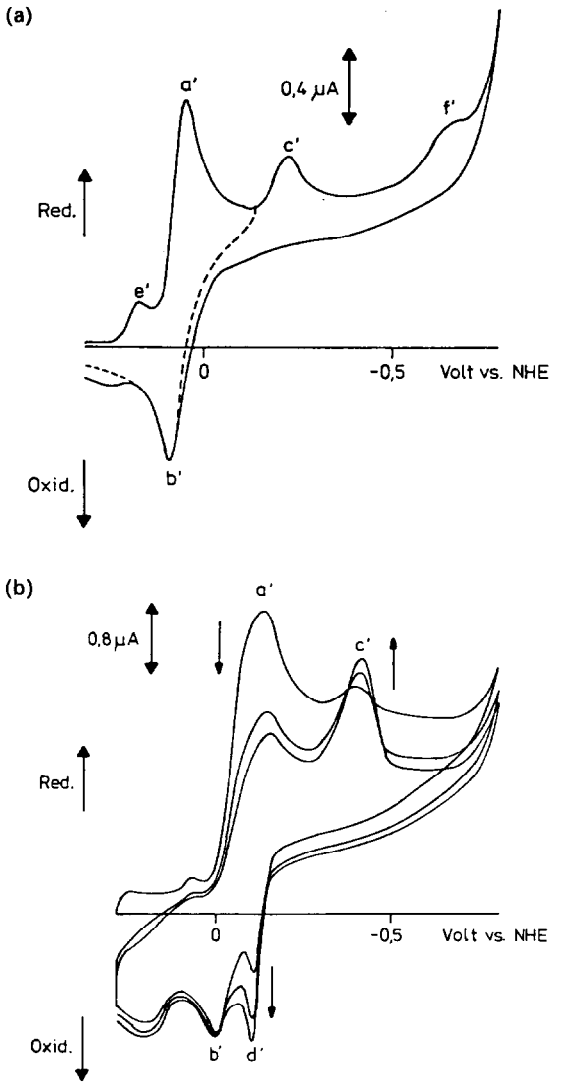

Fig. 3. (A) CV of **2** in 1.0 M CH_3SO_3H (HMD E, 25°C, $v = 50$ mV s^{-1}) in the potential range +0.3 to −0.8 V (solid line) and +0.3 to −0.15 V (broken line). (B) CV of **2** in 0.1 M CH_3SO_3H ($v = 50$ mV s^{-1}, 25°C, HMDE): three consecutive scans.

its potential is independent of pH and its intensity is so small that a diffusion-controlled charge transfer of the actual sample can be ruled out. It is either due to a small impurity of **2** or—more likely—an adsorption effect at the surface of the stationary mercury electrode. Diagnostic criteria for the reduction peak a' indicate a quasi-reversible two-electron transfer: the peak half-width potential $|E_p^{a'} - E_{p/2}^{a'}|$ is 0.034 V at a scan rate of 20 mV s^{-1} and 0.046 V at 500 mV s^{-1}: the peak current function in this range of scan rates is 10.3–8.4 μA $V^{-1/2}$ $s^{1/2}$ $mmol^{-1}$ l. The same results are obtained for the oxidation peak b', but there is a significant difference in the voltammetric behaviour of **1** and **2** concerning peaks a and b and a' and b'. The current function of peak b' is a function of the sweep rate both in the extended potential range (+0.3 to −0.80 V) *and* in the reduced range (+0.3 to −0.15 V), contrasting with the behaviour of peak b of **1**. The oxidation current of b' increases with increasing sweep rate and, consequently, the peak current ratio, $I_p^{b'}/I_p^{a'}$, increases. *This indicates that a chemical reaction occurs after the first reduction of* **2** *in contrast to* **1** *where a chemical reaction has been observed only after the second reduction step.* The half-wave potential, $(E_p^{a'} + E_p^{b'})/2$, varies linearly with pH over the range 0.3–1.5 and it is deduced that the first two-electron redox process involves four protons.

Therefore, we propose that again a monomeric Mo(IV) aqua complex is generated according to eqn (7), which irreversibly undergoes subsequent chemical reactions:

$$L'MoO_3 + 4H^+ + 2e^- \rightleftarrows [L'MoO(OH_2)_2]^{2+}. \quad (7)$$

In contrast to **1** the voltammetric behaviour of **2** in 0.1 M CH_3SO_3H is less ideal especially if the sweep rate is decreased. Therefore, it was not possible to study the nature of the subsequent chemical reaction in detail and to establish the exact nature of the products involved. Nevertheless, Fig. 3 nicely shows that upon repetitive scanning (50 mV s^{-1}) in the potential range +0.3 to −0.8 V the heights of the reduction peak c' and the oxidation peak d' increase, whereas peaks a' and b' decrease.

In keeping in line with the known chemistry of Mo(VI)–Mo(V)– and Mo(IV)–oxo complexes containing sterically non-demanding ligands it appears to be likely that $[L'MoO(OH_2)_2]^{2+}$ either comproportionates with **2** to yield a dimeric Mo(V)–oxo species [eqn (8)]:

$$[L'Mo(IV)O(OH_2)_2]^{2+} + L'Mo(VI)O_3 \rightarrow [L'_2Mo(V)_2O_5] + H_2O + 2H^+, \quad (8)$$

or, alternatively, simply dimerizes or trimerizes $\{[L'_3Mo(IV)_3O_4]^{4+}$ (?)$\}$ [eqn (9)]:

$$x[L'Mo(IV)O(OH_2)_2]^{2+} \xrightarrow{x=2} [L'_2Mo_2O_2(OH)_2]^{2+} + 2H_2O + 2H^+$$
$$\xrightarrow{x=3} [L'_3Mo_3O_4]^{4+} + 5H_2O + 2H^+. \quad (9)$$

The formation of *syn*- or *anti*-$[L'_2Mo(V)_2O_4]^{2+}$ species can be ruled out since their electrochemistry does not resemble any aspect of the present investigation.[27] It is noted that the trimer $[L'_3Mo_3O_4]^{4+}$ and its tungsten analogue have been synthesized and isolated as $ZnBr_4^{2-}$ salts.[28]

Electrochemistry of **3** *in acidic solution*

The CV of **3** in 0.1 M CH_3SO_3H at an HMD E in the potential range +0.4 to −0.8 V vs NHE is shown in Fig. 4. Two reduction peaks, a and c, and two oxidation peaks, b and d, are observed. Peaks e and f are due to a small impurity of **1** which is generated during the synthesis of **3**. The redox potential and pH dependence of the latter are identical with those of **1**. **1** is *not* produced via conceivable oxo-bridge cleavage process of **3** (or any other chemical reaction during the cyclic voltammetry experiment) as is readily deduced from multiple-scanning CVs. In fact, we have no evidence for a monomer–dimer equilibrium of **1** and **3** in acidic aqueous solution.

The potentials of peaks a and b are independent of the scan rate: the peak half-widths of 43 and 37 mV as well as the peak potential difference, $|E_p^a - E_p^b|$, of 47 mV are indicative of a reversible two-electron transfer reaction. The corresponding diagnostic criteria for peaks c and d are slightly dependent on the sweep rate ($E_{cd}^f = -0.216$ to -0.224 V at scan rates of 20–200 mV s^{-1}). The peak half-width and the peak potential difference would agree with a quasi-reversible two-electron transfer but the peak current function, CF^c, is twice as large as the corresponding value for CF^a (as is CF^d compared with CF^b). Therefore, we conclude that the second reduction step involves a quasi-reversible four-electron transfer reaction. The current peak ratios I_p^b/I_p^a and I_p^d/I_p^c are independent of the scan rate but deviate from the expected value of 1.0 due to experimental difficulties in defining proper basis lines in the CV.

These results are supported by coulometric measurements. At a controlled potential of −0.05 V vs NHE 2.05±0.1 electrons per dimeric **3** are transferred. During the electrolysis the colour of the solution changes to yellow. Reoxidation yields again a colourless solution of **3** (via electrolysis or oxygen). Electrolyses at more negative potentials (−0.60 V vs NHE) yielded 5.5±0.5 transferred electrons per dimer.

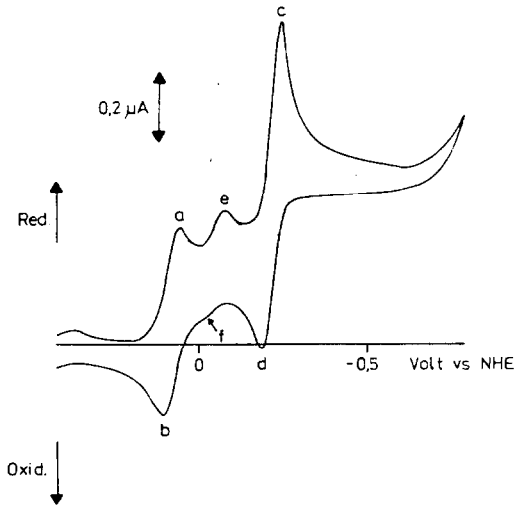

Fig. 4. CV of $3(PF_6)_2$ in 0.1 M CH_3SO_3H (HMDE, 25°C, $v = 20$ mV s^{-1}).

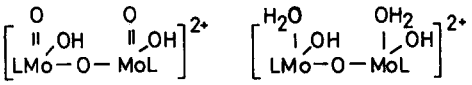
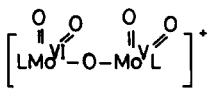
The dependences of the formal redox potentials E_{ab}^f and E_{cd}^f as a function of pH have been investigated ($I = 0.1$ M, $LiClO_4$–$HClO_4$; HMDE; 20°C). In the pH range 1.1–3.1 linear dependences have been observed according to eqns (10) and (11):



$$E_{ab}^f(\text{V vs NHE}) = +0.12 - 0.056\text{pH}, \quad (10)$$

$$E_{cd}^f(\text{V vs NHE}) = -0.185 - 0.054\text{pH}. \quad (11)$$



Thus the first reduction wave involves $2e^-$ and $2H^+$ and the second wave involves $4e^-$ and $4H^+$. This leads to the following reaction scheme [eqn (12)]:

$$Mo(VI)_2 \underset{-2e^-,2H^+}{\overset{+2e^-,2H^+}{\rightleftharpoons}} Mo(V)_2 \underset{-4e^-,4H^+}{\overset{+4e^-,4H^+}{\rightleftharpoons}} Mo(III)_2. \quad (12)$$

We propose structures **A** and **B** for the dimeric $Mo(V)_2$ and $Mo(III)_2$ species generated in acidic solution. Interestingly, **3** is reduced in alkaline

aqueous solutions (pH > 7) via a one-electron transfer to produce the blue, paramagnetic mixed-valence species Mo(VI)Mo(V) (**C**). The same species is formed in aprotic media (DMF and CH_3CN).[23]

This species is also generated chemically by reduction of **3** with $NaBH_4$ in oxygen-free aqueous solution. Figure 5 shows the EPR spectrum of such a solution at 20°C. The spectrum clearly shows that the unpaired electron is delocalized over both molybdenum atoms.

Concluding remarks

The electrochemistry of various monomeric *cis*-dioxomolybdenum(VI) complexes has in the past been studied in aprotic media.[7–17] In virtually all these cases one-electron reductions yielding Mo(V) complexes have been established with subsequent complications due to dimerization reactions affording diamagnetic $Mo(V)_2$ dimers. Since the molybdenum-containing enzymes react *in vivo* in

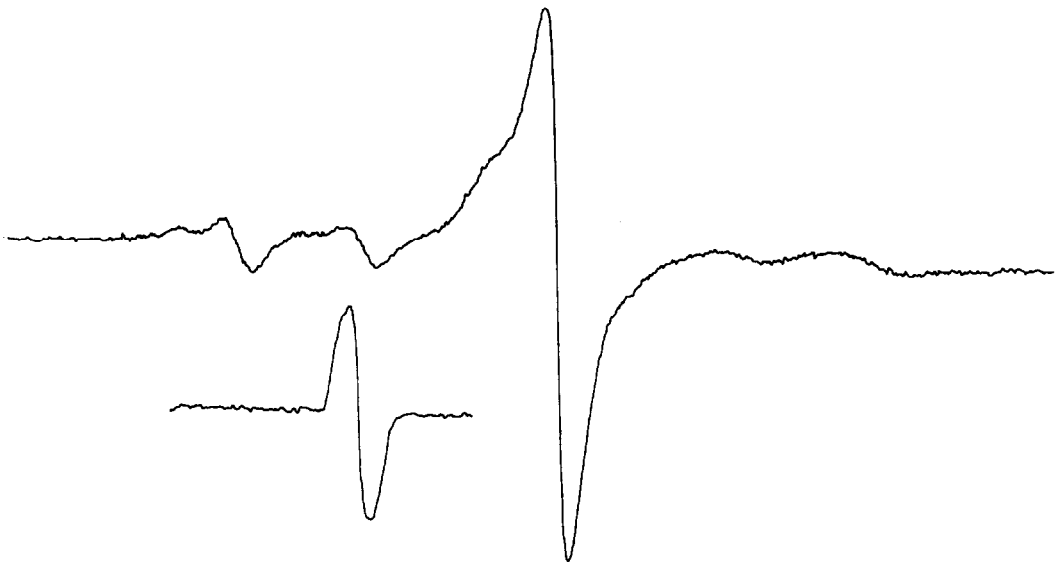


Fig. 5. EPR spectrum of $[L_2Mo_2O_5]^+$ in aqueous solution at 20°C ($g = 1.958$).

aqueous solution where protons and electrons are available, electrochemical studies of model compounds in aqueous solution over a wide range of pH should complement the above studies.

To the best of our knowledge **1** represents the first example where a stable monomeric Mo(IV) species, $[LMoO(OH_2)_2]^{2+}$ is generated by a reversible $2e^-$, $4H^+$ step. Paggett and Anson[18] have shown previously that the protonated form of $MoO_3(OH_2)_3$ in strongly acidic solution is reduced by a $1e^-$, $2H^+$ step generating a monomeric Mo(V) aqua-ion which rapidly dimerizes to the well-known, diamagnetic $Mo(V)_2$ aqua ion. Schultz *et al.*[9,24] have shown that *cis*-dioxo-bis(catecholato)molybdenum(VI) is reduced in acidic solution to monomeric Mo(V) ($1e^-$, $2H^+$) and Mo(III) species ($2e^-$, $2H^+$). No evidence for Mo(IV) intermediates has been found.

EXPERIMENTAL

The preparations of complexes **2** and **3** have been described previously.[22,23]

cis - *Trioxo*(N,N',N'' - *trimethyl* - 1,4,7 - *triazacyclononane*)*molybdenum*(*VI*) (**1**)

To a slurry of MoO_3 (0.75 g, 5 mmol) in water (25 cm^3) *N,N',N''* - trimethyl - 1,4,7 - triazacyclononane[24] (1.7 g, 10 mmol) was added with stirring and gently warmed until a clear colourless solution was obtained. This solution was rapidly poured into an ethanol–ether mixture (1 : 1, 100 cm^3) at room temperature. The colourless precipitate was filtered off, washed with ethanol and air dried (yield 1.1 g). The crude product was recrystallized from hot CH_2Cl_2 to give colourless plates of **1**. Calc. for $(C_9H_{21}N_3)MoO_3 \cdot 0.5H_2O$: C, 34.3; H, 6.71; N, 13.3; Mo, 30.4%. Found: C, 34.1; H, 6.7; N, 13.2; Mo, 30.3%.

Apparatus

CVs were recorded with Princeton Applied Research equipment, which included the model 264 A potentiostat–galvanostat/programmer, the electrochemical cell SM 303 A and an X–Y recorder (Kipp & Zonen). As a working electrode a stationary mercury drop (HMDE, 0.010 cm^2) was employed: a Pt-wire auxiliary electrode and the reference electrode (Ag–AgCl in saturated NaCl) completed the standard three-electrode system. Potentials were measured at 25 ± 0.5°C under an argon atmosphere. Solutions were $\sim 10^{-3}$ M in sample and 0.1 M in supporting electrolyte. Potentials were corrected to the NHE by adding 0.200 V to the measured potential.

Coulometric measurements were made in a Metrohm electrolysis cell at a mercury pool electrode, with an Ag wire as a counter electrode and the reference electrode (Ag–AgCl in saturated NaCl). The Ag wire was in a 0.1 M $LiClO_4$ solution which was separated from the working solution by a diaphragm. The potential was controlled during electrolysis by a potentiostat Model 173 equipped with the coulometry modul M 179 (PAR).

COMPLEXATION BETWEEN MOLYBDENUM(VI) AND CITRATE: A POTENTIOMETRIC AND CALORIMETRIC INVESTIGATION

J. J. CRUYWAGEN* and R. F. VAN DE WATER

Department of Chemistry, University of Stellenbosch, Stellenbosch, 7600 South Africa

(*Received* 11 *June* 1985)

Abstract—The molybdenum(VI)–citrate system has been investigated in the pH_c range 7.5–2.0 by potentiometric and enthalpimetric titrations at 25°C in 1 M NaCl. The potentiometric data were treated with the computer program MINIQUAD taking into account side reactions of molybdate and citrate with hydrogen ions. A reaction model comprising the complexes $(1,1,1)^{4-}$, $(1,1,2)^{3-}$, $(1,1,3)^{2-}$, $(2,1,4)^{3-}$ and $(2,1,5)^{2-}$ gave a satisfactory description of the data; the numbers refer to the values of p, q and r in the general formula $(MoO_4^{2-})_p(Cit^{3-})_q(H^+)_r$. The enthalpy and entropy changes for the formation of these complexes were calculated from the enthalpimetric data using the values of the now known formation constants. Equilibrium constants as well as enthalpy and entropy changes for the successive protonations of citrate have also been determined.

Although complex formation between molybdenum(VI) and citrate in acid solution has been reported by many workers[1–9] very little is known about the composition and stability of the complexes. Several authors[1,3–6] have suggested the existence of complexes with a molybdenum : citrate ratio of 1 : 1 but there is disagreement about the number of protons involved. Complexes with molybdenum : citrate ratios of 1 : 2 and 2 : 1 have also been proposed.[4,7,8] A number of 1 : 1 complexes with charge 2− have been isolated[8] by crystallization with cations such as Ba^{2+}, Pb^{2+} and Ag^+. Recently a bridged dinuclear complex of composition $M_2[Mo_2O_5OH(H_2O)(C_6H_5O_7)]\cdot 0.5H_2O$ where M is K^+ or NH_4^+, was synthesized and its photochemical decomposition studied.[9]

To determine the exact stoichiometry of the complexes in solution in this ternary multi-equilibrium system is difficult. In addition to complexation both citrate and molybdate are protonated upon acidification, while molybdate can also form several isopoly ions.[10] All these simultaneous equilibria have to be taken into account in the interpretation of experimental results if the complexes are to be correctly identified. This can best be done by equilibrium analysis through computer treatment of suitable data. A comprehensive potentiometric investigation was therefore carried out and the equilibrium data analyzed with the program MINIQUAD[11] to establish the compositions and stability constants of the molybdenum(VI)–citrate complexes. This paper also reports the results of a calorimetric investigation of the complexation equilibria in which the enthalpy and entropy changes for the formation of the various complexes have been determined.

EXPERIMENTAL

Reagents and solutions

All reagents were of analytical grade (Merck p.a.) and solutions were prepared with water obtained from a Milli-Q system. Sodium molybdate and sodium chloride solutions were prepared from the recrystallized salts. These solutions and sodium citrate solution were standardized gravimetrically by evaporating known volumes to dryness and heating at 160°C to constant weight. Potassium hydrogen phthalate was used to standardize a sodium hydroxide solution. Hydrochloric acid and citric acid solutions were standardized by titration with the sodium hydroxide solution.

Potentiometric measurements

Potentiometric titrations were carried out at 25°C in 1 M (Na)Cl medium by either adding hydrochloric acid to molybdate–citrate mixtures or adding sodium hydroxide to molybdate–citric acid–hydrochloric acid mixtures. A stream of purified nitrogen was passed through 1.0 M sodium chloride and then bubbled slowly through the reaction vessel to stir the solution and to exclude carbon dioxide from the system. The molybdate : citrate ratios were 4:1, 1:1 and 1:4 for molybdenum(VI) concentrations of 0.01, 0.04 and 0.05 M. A total of 389 data points obtained from 12 titrations, some in duplicate, were used in the computations. The free hydrogen ion concentration, h, was determined by measuring the potential to ± 0.2 mV with a Radiometer PHM64 research pH-meter using a Ross electrode. The following equation was applied for the calculation of the hydrogen ion concentration from the measured potential, E:

$$E = E^o + 59.16 \log h. \quad (1)$$

A value for E^o was determined before each experiment by titration of 1 M sodium chloride with a (0.1 M hydrochloric acid + 0.90 M sodium chloride) solution, and checked afterwards by a single e.m.f. measurement of the solution used to determine E^o. The titration data were considered acceptable only if the difference between the E^o values was $\leqslant 0.3$ mV. The Ross electrode proved to be very stable and the difference was usually $\leqslant 0.2$ mV.

The first three dissociation constants of citric acid were also determined by potentiometric titration at 25°C in 1 M (Na)Cl medium as described previously.[12]

Calorimetric measurements

An isothermal titration calorimeter, Tronac Model 550, described elsewhere[13,14] was used for the measurements. The titrant, either sodium hydroxide or hydrochloric acid was added with a 2.5-cm^3 Gilmont precision microburet at constant speed to 20 cm^3 (or in some experiments 25 cm^3) solution in the reaction vessel. The number of heat pulses supplied by the control heater (displayed in digital form and printed) was obtained during fixed time intervals, typically 100 s. The speed of titrant delivery was dictated by the concentrations of the reagents and amount of heat involved. In a typical run 30 readings were taken during the addition of 2.5 cm^3 titrant at a speed of 0.05 cm^3 min^{-1}.

The following experiments were carried out:

(a) titration of 0.1 M citrate with 1 M hydrochloric acid;

(b) titration of 0.05 M molybdate and 0.05 M citrate with 1 M hydrochloric acid; and

(c) titration of 0.01 M molybdate, 0.01 M citric acid and 0.02 M hydrochloric acid with 0.5 M sodium hydroxide.

The control heater of the calorimeter is calibrated electrically. The system was checked by determining the enthalpy change for the neutralization of 0.01 M sodium hydroxide with 0.1 M hydrochloric acid. After correction for the heat of dilution a value of 55.9 kJ mol^{-1} was obtained, in good agreement with 56.0 kJ mol^{-1} reported by Hale *et al.*[15] for ionic strength 0.01 M.

All the solutions used in the titrations were made 1.0 M with respect to chloride by addition of sodium chloride. To correct for heat of dilution of the titrant, blank titrations were carried out in each case.

RESULTS AND DISCUSSION

Complexes and formation constants

The results of a number of representative potentiometric titrations are shown as normalized curves in Fig. 1 where P is plotted against pH_c. The

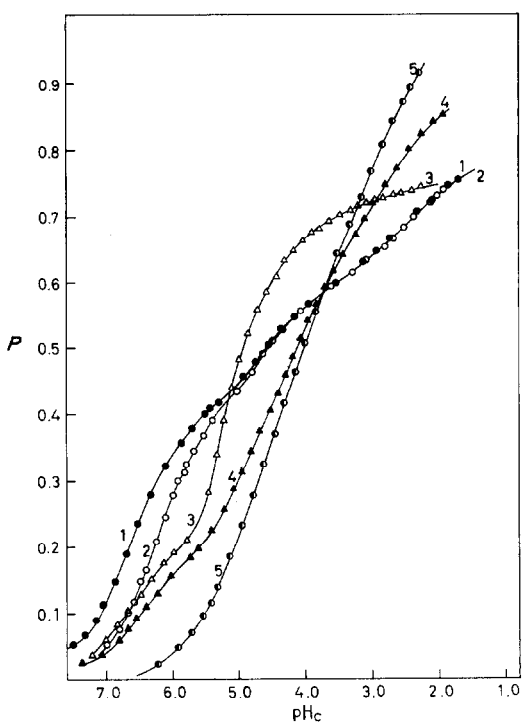

Fig. 1. P as a function of pH_c ($-\log h$) for some representative potentiometric titrations: (1) $B = C = 0.05$ M; (2) $B = C = 0.01$ M; (3) $B = 0.04$ M, $C = 0.01$ M; (4) $B = 0.01$ M, $C = 0.04$ M; and (5) $C = 0.02$ M.

function P, which represents the fraction of the total negative charge neutralized by protonation, is given by:

$$P = \frac{H-h}{2B+3C}, \quad (2)$$

where H, B and C are the total analytical concentrations of hydrogen ions, molybdate and citrate respectively. These normalized curves give some useful preliminary information about the system. For example, complexation at high pH_c is indicated by higher P values than that caused by protonation of citrate or molybdate alone. In the pH_c range 2–3, on the other hand, citrate and molybdate are more easily protonated than the complex species. Furthermore, the inflections shown by the curves at pH values of 6, 5 and 3.5 indicate the presence of at least three relatively stable complexes with charges corresponding to P values of about 0.2, 0.4 and 0.6.

The equilibria for the various possible complex formation reactions can be represented by the general equation:

$$p\mathrm{MoO_4^{2-}} + q\mathrm{Cit^{3-}} + r\mathrm{H^+} \rightleftharpoons (\mathrm{MoO_4^{2-}})_p(\mathrm{Cit^{3-}})_q(\mathrm{H^+})_r. \quad (3)$$

For brevity a complex with overall formation constant β_{pqr} is denoted by the stoiciometric coefficients p, q and r which define its composition, i.e. $(p,q,r)^{(2p+3q-r)}$. The computer program MINIQUAD[11] was used to examine various reaction models, taking the well-known R factor (derived from the error square sum) as a measure of the agreement between experimental and calculated data. The program also calculates χ^2 which should have a value of less than 12.6 at the 95% confidence level. In practice, however, χ^2 is often greater than 12.6.[16] Protonation and condensation equilibria of uncomplexed molybdate were taken into account using known equilibrium constants for 1 M sodium chloride medium.[17] The following six species were included in the computations: $HMoO_4^-$, $Mo(OH)_6$, $Mo_7O_{24}^{6-}$, $HMo_7O_{24}^{5-}$, $H_2Mo_7O_{24}^{4-}$ and $Mo_8O_{26}^{4-}$.

Equilibrium constants pertaining to 1 M sodium chloride, needed to provide for the protonation of the three carboxylate groups of citrate, were determined in separate titrations. Using MINIQUAD to treat the data, the following values for the constants were obtained (error limits 3σ):

$\log \beta_{011} = 5.12 \pm 0.01$, $\log \beta_{012} = 9.17 \pm 0.01$,

$\log \beta_{013} = 11.94 \pm 0.01$ ($R = 0.0021$, $\chi^2 = 11.32$).

These values can be compared with the extrapolated values for the constants in 1 M sodium perchlorate medium,[18] namely 5.22, 9.36 and 12.2.

In the case of a three-component system, a great number of species derived from various possible combinations of p, q and r values must be considered in the computer treatment of equilibrium data before a reaction model can be proposed with confidence. For the present system the most logical starting point was to test a model comprising only mononuclear complexes. Since P varies from ~0.05 to 0.75 for the pH_c range investigated, the following four complexes, $(1,1,1)^{4-}$, $(1,1,2)^{3-}$, $(1,1,3)^{2-}$ and $(1,1,4)^-$, corresponding to P values of 0.2, 0.4, 0.6 and 0.8, respectively, were included in the model. With these complexes a reasonable fit was obtained ($R = 0.0090$ and $\chi^2 = 349.5$). However, in addition to the rather large value of χ^2, the agreement between the experimental and calculated data for titrations where molybdate was in excess was unsatisfactory. This finding suggested that some polynuclear complexes might also be present.

Dinuclear molybdo-oxalate complexes, $(2,2,5)^{3-}$ and $(2,2,6)^{2-}$, have been shown to exist in solution[19,20] whereas the potassium salt of the $(2,2,6)^{2-}$ complex has been isolated previously.[21] In view of this and the recent synthesis of the potassium and ammonium salts[9] of the molybdo-citrate complex, $(2,1,5)^{2-}$, the next step was to introduce species with $p = 2$ and values of either 1 or 2 for q, while r was varied with the restriction that species with a negative charge greater than 6− were neglected. Inclusion of the two dinuclear complexes $(2,1,4)^{3-}$ and $(2,1,5)^{2-}$ in the model resulted in a considerable decrease in the sum of squares and a very good fit ($R = 0.0045$ and $\chi^2 = 10.1$). These species were accepted at the expense of the $(1,1,4)^-$. Most of the other complexes tried, were rejected by the program (β-negative) or occurred in such low concentrations that their inclusion in the model was not justified. The $(2,1,3)^{4-}$ complex, for example, was accepted and resulted in a slightly lower sum of squares but also caused a small increase in χ^2 ($R = 0.0043$ and $\chi^2 = 12.7$). The standard deviation of its formation constant, however, was rather high ($\log \beta_{213} = 22.0 \pm 0.1$) and the maximum concentration only 5.7% of the total molybdenum concentration. This complex is, therefore, not included in the reaction model.

Complexes with $p = 3$ or 4 and $2 \leqslant q \leqslant p$ were also tested in an attempt to further improve the above model; species with p values of up to at least 4 merited inclusion in the model in view of the tetranuclear complex of molybdenum(VI) with malic acid, i.e. $(4,2,10)^{4-}$, which has been isolated recently as a caesium salt.[22] Again complexes with a negative charge greater than 6− were not considered and r values were chosen accordingly. A few complexes with $p = 5$ or 6 were tried, e.g. $(5,2,12)^{4-}$,

Table 1. Formation constants and thermodynamic quantities for the various molybdenum(VI)–citrate complexes in 1 M (Na)Cl ($T = 298$ K)

Complex	($\log \beta_{pqr} \pm 3\sigma$)	ΔG (kJ mol^{-1})	ΔH^o (kJ mol^{-1})	$T\Delta S^o$ (kJ mol^{-1})
$(1,1,1)^{4-}$	8.25 ± 0.02	-47.1	-49.4 ± 0.4 $(49 \pm 1)^a$	-2.3
$(1,1,2)^{3-}$	15.08 ± 0.01	-86.1	-60.2 ± 0.2 (60 ± 1)	25.9
$(1,1,3)^{2-}$	19.66 ± 0.02	-112.2	-67.4 ± 0.2 (65 ± 2)	44.8
$(2,1,4)^{3-}$	27.27 ± 0.18	-155.6	-124 ± 6	31.6
$(2,1,5)^{2-}$	31.86 ± 0.05	-181.9	-125.9 ± 0.3 (128 ± 2)	56.0

[a] Figures in parentheses refer to reverse titration (see text).

$(6,2,13)^{5-}$ and $(6,3,15)^{6-}$, which have P values of 0.75, 0.72 and 0.71, respectively. None of these complexes, however, could help to improve the model; some were rejected by the program while others caused a failure in linear minimization[11] or an increase in the error square sum.

The reaction model, therefore, accepted as giving the best description of the data consists of the following five species: $(1,1,1)^{4-}$, $(1,1,2)^{3-}$, $(1,1,3)^{2-}$, $(2,1,4)^{3-}$ and $(2,1,5)^{2-}$. The formation constants are listed in Table 1. The value of 8.25 for $\log \beta_{111}$ can be compared with a value of 8.4 estimated from polarographic measurements at 2°C.[6] No values for any of the other equilibrium constants are available from the literature. However, the agreement between the protonation constants of the $(1,1,2)^{3-}$ and $(2,1,4)^{3-}$ complexes, $10^{4.58}$ and $10^{4.59}$, is noteworthy and these values also tally with those of the first two protonation constants of citrate, namely $10^{5.12}$ and $10^{4.05}$. The distribution of the various species as a function of pH_c for an equimolar (0.05 M) solution of molybdate and citrate is shown in Fig. 2. Under these conditions the $(2,1,4)^{3-}$ complex is present at relatively low concentrations, but with molybdate in excess as in the case of a 4:1 ratio of molybdate to citrate, the maximum relative concentration attained by this complex is 17.4% (in terms of molybdate). It is seen that the $(1,1,2)^{3-}$ and $(1,1,3)^{2-}$ complexes are major components in the system and are the species responsible for the inflections at $P = 0.4$ and 0.6 in the titration curves (Fig. 1).

Thermodynamic quantities

The amount of heat measured during the isothermal titration of molybdate and citrate with hydrochloric acid, Q (corrected for heats of dilution),

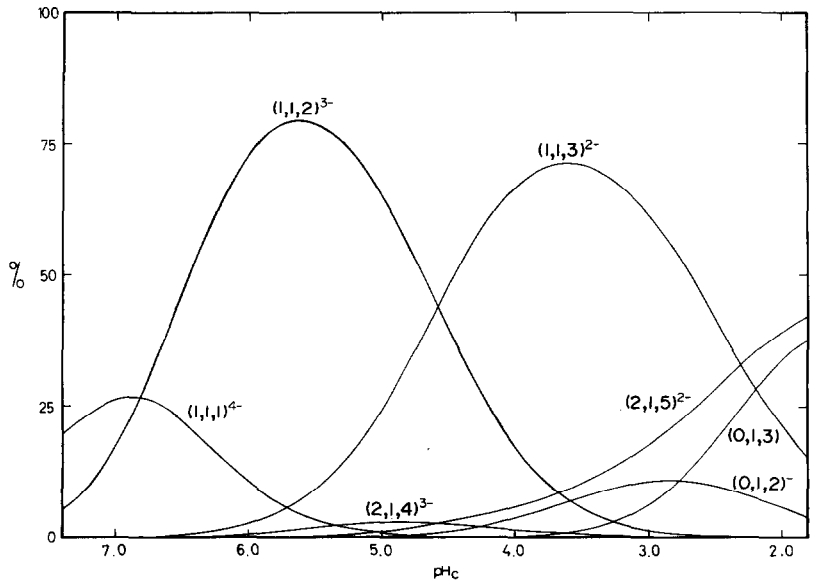

Fig. 2. Concentration of various species expressed as a percentage of the total concentration of molybdate [or citrate for $(0,1,2)^-$ and (0,1,3) species] as a function of pH_c for the enthalpimetric titration of an equimolar solution of molybdate and citrate (0.05 M) with 1 M hydrochloric acid.

Table 2. Thermodynamic quantities for the protonation of citrate in 1 M (Na)Cl ($T = 298$ K)

	ΔG^o (kJ mol^{-1})	ΔH^o (kJ mol^{-1})	$T\Delta S^o$ (kJ mol^{-1})
First protonation	−29.2	−1.32	27.9
Second protonation	−23.1	−4.45	18.6
Third protonation	−15.8	−4.29	11.5

is given by

$$Q = \sum n_{pqr}\Delta H^o_{pqr}, \quad (4)$$

where n_{pqr} is the number of moles formed and ΔH^o_{pqr} is the molar enthalpy change for a given species (p,q,r) at 25°C in 1 M sodium chloride medium. Values for n_{pqr} at each titration point were calculated from the concentrations of the species obtained by simultaneous solution (using Newton's method)[23] of the three mass balance equations:

$$B = b + \sum p\beta_{pqr}b^p c^q h^r, \quad (5)$$

$$C = c + \sum q\beta_{pqr}b^p c^q h^r, \quad (6)$$

$$H = h + \sum r\beta_{pqr}b^p c^q h^r, \quad (7)$$

where b, c and h are the free concentrations of MoO_4^{2-}, Cit^{3-} and H^+, respectively. The set of linear equations thus obtained from corresponding Q and n values were solved for the unknown ΔH^o_{pqr} parameters following a least-squares procedure.[24]

Under the conditions chosen for the enthalpimetric titrations (molybdate : citrate ratio 1 : 1) the protonation and condensation equilibria of molybdate could be neglected. The heat involved in the protonation of citrate, however, had to be taken into account in the calculations since the maximum concentration of the protonated species was, respectively, 3.6, 11 and 34% of the total citrate concentration. Since ΔH^o values for these species have been reported only for ionic strengths $\leqslant 0.15$ and furthermore show a clear dependence on ionic strength,[18,25] especially ΔH^o_{011}, values pertaining to 1 M sodium chloride were evaluated from data collected in separate titrations. These values and the other thermodynamic parameters for the protonation of citrate are given in Table 2. When the ΔH^o values of this investigation are compared with those reported[25] for ionic strength 0.15, namely 1.7, −3.3 and −4.7 kJ mol^{-1} for the three successive protonation steps, it is seen that ΔH^o_{011} is the most affected by the increase in ionic strength. Both enthalpy and entropy values are quite normal for this type of protonation reaction.[26] A characteristic feature is the decreasing trend in $T\Delta S^o$ values with successive protonation.

The thermodynamic parameters for complex formation are listed in Table 1. Because of the low concentration of the $(2,1,4)^{3-}$ complex under the conditions of the enthalpimetric titration [$\leqslant 5.8\%$ (Fig. 2)] ΔH^o_{214} could not be determined with the same accuracy as the other enthalpy values. To obtain a higher concentration of this complex relative to the mononuclear complexes, molybdate must be in excess of citrate. Under such conditions, however, reactions of the MoO_4^{2-}–H^+ subsystem can no longer be neglected and corrections will have to be applied for the enthalpies concerned. Although ΔH^o values for some of these reactions have been determined[27–30] a complete and reliable set of values for 1 M sodium chloride required to provide for heat effects of all these equilibria are not as yet* available.

To verify the reliability of the ΔH^o_{pqr} values, a reverse titration (in duplicate) was done in which a mixture of molybdate, citric acid and hydrochloric acid was titrated with sodium hydroxide. For this experiment the total amount of heat measured (corrected for heats of dilution) is given by:

$$Q = n_a\Delta H^o_w + \sum n_{pqr}(\Delta H^o_{pqr} + r\Delta H^o_w),$$

where n_a is the number of moles of free acid neutralized and ΔH^o_w is the enthalpy change for the formation of water. A value of 56.1 kJ mol^{-1} for ΔH^o_w pertaining to 1 M sodium chloride was determined in a separate titration. The ΔH^o_{pqr} values were computed according to the procedure described above except that ΔH^o_{214} was fixed at the value determined in the forward titration; the lower concentrations of molybdate and citrate used as well as the fact that fewer data points were collected during the reverse titration (28 instead of 77) precluded its inclusion as an unknown parameter. These ΔH^o_{pqr} values (shown in parentheses in Table 1) agreed well, within the 3σ error limits, with those obtained from the results of the forward titration.

The themodynamic parameters for the $(1,1,2)^{3-}$ complex are comparable to those determined[20] for the molybdenum(VI)–oxalate complex $(1,1,2)^{2-}$,

* A calorimetric study of molybdenum(VI) equilibria in this laboratory is nearing completion.

i.e. $\Delta G^o = -77.7$, $\Delta H^o = -59.5$ and $T\Delta S^o = 18.2$ kJ mol^{-1}.

The relatively large negative enthalpy change for complex formation can be ascribed to additional bond energy arising from an increase in coordination number of molybdate from four to six. The value -49.4 kJ mol^{-1} for the enthalpy of formation for the $(1,1,1)^{4-}$ complex, for instance, is nearly the same as the enthalpy change (-46.5 kJ mol^{-1}) for the second protonation of molybdate where an expansion of coordination number was indicated by the observed thermodynamic quantities.[28] The small negative value for $T\Delta S^o_{111}$ may be rationalized as follows: a loss of entropy should accompany complex formation, but this loss will be opposed by a gain in entropy caused by the weaker hydration of the complex than that of the smaller reacting species, especially that of the hydrogen ions. The ΔH^o values for the stepwise protonation of the complexes are negative and comparable to that of citrate itself, while the positive $T\Delta S^o$ values are typical for a reaction of hydrogen ions with anions.[26]

In the structure proposed[9] for the potassium salt of the $(2,1,5)^{2-}$ complex, the hydroxyl oxygen and the β-carboxylate of citrate is coordinated to one molybdenum atom while an α-carboxylate is coordinated to the other molybdenum of the dimeric unit. It is most likely that citrate also coordinates tridentate via the same groups in the formation of the mononuclear complexes.

(*Received* 14 *June* 1985)

Abstract—Aqueous acidic solutions of Mo(VI), Mo(V) and Mo(IV) form 1 : 1 complexes with bromanilic acid [H_2B (2,5-dibromo-3,6-dihydroxy-1,4-benzoquinone)], which is a quinonic ligand, easily reducible to 1,4-dibromo-2,3,5,6-tetrahydroxybenzene (H_4B). The electrolysis of the H_2B–Mo(VI) complex yielded first the H_2B–Mo(V) complex, and second a mixture of Mo(V) and H_4B. The Mo(V) was finally reduced to Mo(III). In contrast, only two polarographic waves were observed, the second one corresponding to the reduction of Mo(V) to Mo(III). The first wave (3 F mol^{-1}) was attributed to the simultaneous reduction of H_2B and Mo(VI) by the two-step catalytic process:

$$H_2B + 2H^+ + 2e \rightarrow H_4B, \quad (1)$$

$$2Mo(VI) + H_4B \rightarrow 2Mo(V) + H_2B. \quad (2)$$

The stoichiometry of step (2) was demonstrated in an independent experiment. The electronic spectra of the three complexes showed that the ligand had a fully deprotonated structure. A charge-transfer band was observed at about 400 nm in the Mo(V) and Mo(IV) complexes. It agreed with the hypothesis of increasing electron transfer to the ligand from the molybdenum atom as the oxidation number decreased. It resulted eventually in an effective redox reaction with Mo(III) according to eqn (3):

$$H_2B + Mo(III) \rightarrow H_4B + Mo(V). \quad (3)$$

Molybdenum in its various oxidation states is implicated in many redox reactions, which sometimes are of great biological importance. This prompted early research on its electrochemistry in aqueous medium, which is now quite well understood.[1–4] However, this element reacts in most cases in the form of complex species rather than as the more simple aqua ions. Recent studies have been devoted to the influence of ligands like catechol[5] or aminopolycarboxylic acids[6] on the redox behaviour of molybdenum couples.

In such cases, the complexation modified the respective stabilities of the oxidized and reduced forms, but did not play any part in the electron transfer itself, since the ligands were not reducible.

The aim of this work was to investigate the possibility of effective ligand assistance to the electron transfer. We chose a quinonic ligand, since the electrochemical reversibility of many quinone–hydroquinone couples is known to be excellent. The

synthesis and stability of the Mo(VI) complexes of bromanilic acid (H_2B) (2,5-dibromo-3,6-dihydroxy-1,4-benzoquinone) have been described earlier.[7] This paper presents the preparation and electrochemistry of the related complexes of Mo(V) and Mo(IV).

EXPERIMENTAL

Chemicals

Sodium molybdate (Prolabo) and H_2B (Eastman) were used as obtained. All other products were of reagent grade.

Mo(VI) solutions were prepared by dissolving weighted sodium molybdate in distilled water. They were standardized against standard Fe(II) solutions by redox titration in phosphoric acid, according to the method of Rao and Sagi.[8]

Mo(V) solutions were prepared by electrolysis of Mo(VI) solutions in 3 M HCl {$C = 0.2$ M, potential (E) $= -0.4$ V [saturated calomel electrode (SCE)]}.

They were standardized by UV analysis ($\lambda = 295$ nm, $\varepsilon = 1750$ l mol^{-1} cm^{-1}).

Mo(III) solutions were prepared by electrolysis of Mo(V) solutions in 3 M HCl [$C = 0.2$ M, $E = -1.0$ V(SCE)].

Their purity was checked by polarography. Since the green solutions obtained initially became red after some days because of the formation of chloro complexes, only fresh solutions were used in this work.

Mo(IV) solutions were prepared following the method of Souchay *et al.*,[9] as slightly modified:

$$\text{Mo(V)} + \text{Mo(III)} \xrightarrow[2\text{ h, }80°\text{C}]{1\text{ M HCl}} 2\text{Mo(IV)} \quad (C = 0.05\text{ M}).$$

They were standardized by redox titration.

Purified dinitrogen was bubbled through the solutions in order to avoid aerial oxidation.

Apparatus

Polarographic measurements were made in a water-jacketed cell kept at 298 K. A Tacussel PRG-3 three-electrode polarograph was used, with a platinum wire counter electrode and an SCE as reference electrode. The height of the mercury column was 50 cm.

Electrolysis were performed in a water-jacketed two-compartment cell kept at 298 K. The compartments were separated by a medium-porosity glass frit. The cathode was a mercury pool (40 cm^2). The anode was a platinum sheet of similar surface. The current source was a Tacussel PRT 20/2 potentiostat. The quantity of electricity was measured by a Tacussel IG-4 integrator. After each electrolysis, an aliquot of the solution was withdrawn and examined spectrophotometrically.

UV spectra were recorded on a Unicam SP 800 B spectrophotometer, using quartz cells of 0.1 cm width. A Metrohm E 353 B pH-meter was used for pH measurements, with Metrohm EA 120 X glass electrodes.

RESULTS AND DISCUSSION

Electrochemical behaviour of the ligand

H_2B behaves like a typical quinone at the mercury electrode. It forms with its reduction product H_4B (1,4-dibromo-2,3,5,6-tetrahydroxybenzene) a reversible redox couple: $H_4B \rightleftharpoons H_2B + 2H^+ + 2e$.

The variation in the half-wave E ($E_{1/2}$) when the pH increases is shown on Fig. 1. The normal redox E of the H_4B–H_2B couple = 210 mV(SCE). Two breaks occur on the diagram at the pK_a values of H_2B (p$K_1 = 0.22$ and p$K_2 = 2.70$) determined by UV spectroscopy.[7] Other breaks are found at the pK_a values of H_4B.

Because of the fast oxidation of H_4B at high pH, these values could not be precisely measured spectroscopically. The spectrum of molecular H_4B was nevertheless obtained. This species is colorless and absorbs only in the UV ($\lambda = 295$ nm, $\varepsilon = 300$ l mol^{-1} cm^{-1}).

Electroreduction of the Mo(VI)–bromanilate complex

The electrochemical behaviour of the complexes of H_2B with Mo(VI), Mo(V) and Mo(IV) was studied in acidic medium (pH $\leqslant$ 2.5) in which they were particularly stable. In consequence, the reduction product of the ligand was always present as the molecular species H_4B and the free ligand was

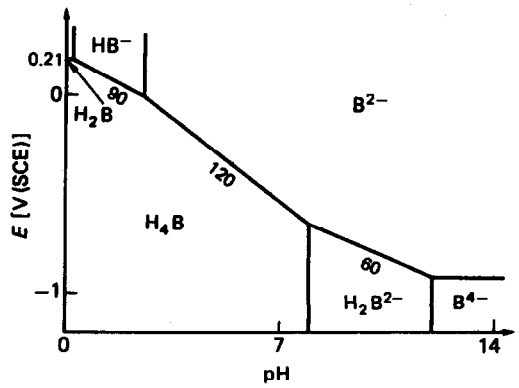

Fig. 1. Electrochemical diagram of H_2B and its reduced form H_4B ($t = 25$°C). Slopes of lines in mV.

mainly the HB^- ion. On the other hand, the structure of the ligand in all three complexes was very close to that of the B^{2-} ion, as proved by comparison of their UV spectra (Fig. 5).

In chloroacetate buffer (pH = 2.50, I = 1 M), we prepared a 10^{-3} M solution of the 1 : 1 bromanilate–Mo(VI) complex which is almost undissociated at this pH.[7] A typical polarogram of the complex was composed of two waves, A and B (Table 1). The three-electron wave, A, was somewhat ill-defined. The two-electron wave, B, was very similar to the reduction wave of uncomplexed Mo(V) under the same conditions: 2 F mol^{-1} and $E_{1/2} = -0.61$ V(SCE).

The electrolysis of the solution was performed on the plateau of wave A [$E = -0.5$ V(SCE)]. The colour of the solution shifted from purple to brown. When 1 F mol^{-1} had been absorbed, wave B remained unchanged, while wave A had decreased by 33%. It was verified that the brown solution contained the bromanilate–Mo(V) complex described hereafter, identical to a sample prepared by mixing the ligand and Mo(V) at the same pH.

The electrolysis was continued until the complete disappearance of wave A occurred, which needed the absorption of another 2 F mol^{-1}. Wave B was thus slightly shifted to $E_{1/2} = -0.56$ V(SCE) and the anodic wave of H_4B appeared. A UV spectrum of the reduced solution confirmed the complete reduction of H_2B to H_4B. A second electrolysis was then made on the plateau of wave B [$E = -0.9$ V(SCE)]. Another 2 F mol^{-1} were needed for this wave to disappear, and the observation of a new anodic wave [$E_{1/2} = -0.20$ V(SCE)] characteristic of uncomplexed Mo(III) in the same conditions.

Reaction between Mo(VI) and H_4B

The results of the electrolysis on the plateau of wave A disagreed with those of the polarographic study, in which wave A indicated a reduction of the complex by three electrons. It should have yielded a mixture of Mo(V) and H_4B, and H_2B was indeed reducible at the $E_{1/2}$ of wave A. On the contrary, the electrolysis showed a two-step reduction:

$$Mo(VI) + e \rightarrow Mo(V),$$

$$H_2B + 2e + 2H^+ \rightarrow H_4B.$$

In order to reconcile the two experiments, we assumed that the first reduction product was H_4B, which rapidly reduced Mo(VI) to Mo(V) in a subsequent step. This hypothesis was verified by reducing the ligand H_2B alone to H_4B under the same conditions as previously, and then introducing known amounts of a standard Mo(VI) solution in the colorless solution. A brown colour rapidly appeared, indicating the formation of the bromanilate–Mo(V) complex.

The stoichiometry of this reaction was determined by a polarographic study, with complete exclusion of aerial dioxygen in order to avoid the oxidation of either H_4B or Mo(V).

Figure 2 represents the variations in the intensities of the polarographic waves vs the ratio q ([Mo(VI)]/[H_4B]) in chloroacetate buffer (pH 2.50). The wave heights refer to 1 mole of H_4B. When q increased, the anodic wave of H_4B decreased and two cathodic waves appeared. They were identified as the waves A and B found previously in the case of the H_2B–Mo(V) complex. Wave B had an intensity of 4 F mol^{-1} H_4B because free Mo(V) is reduced at the same E as complexed Mo(V). It can be seen that the reaction was complete for $q = 2$, when the anodic wave of H_4B disappeared. The reaction could thus be written:

$$2Mo(VI) + H_4B \rightarrow H_2B + 2Mo(V) + 2H^+.$$

Table 1. Polarographic waves of the ligand and of the complexes of Mo(VI), Mo(V) and Mo(IV)[a]

Species	Wave	Intensity (F mol^{-1})	$E_{1/2}$ [V(SCE)]	pH
H_2B	Cathodic	2	−0.02	2.5
H_4B	Anodic	2	−0.02	2.5
Mo(VI) complex	A	3	−0.10	2.5
	B	2	−0.63	
Mo(V) complex	A	2	−0.10	2.5
	B	2	−0.63	
Mo(IV) complex	A	2	0.03	2.0
	B	1	−0.47	

[a] Conditions: t = 25°C, and I = 1.0 M (chloroacetate buffer).

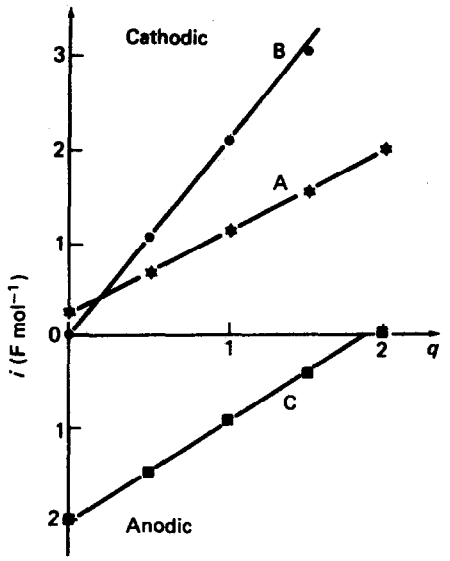

Fig. 2. Stoichiometry of the reduction of Mo(VI) by H_4B. Intensity (i) of the polarographic waves at $t = 25°C$, pH = 2.50, and $q = [Mo(VI)]/[H_4B]$. (A) Wave A ($E_{1/2} = -0.10$ V), (B) Wave B ($E_{1/2} = -0.63$ V), and (C) anodic wave of H_4B ($E_{1/2} = -0.02$ V).

Interpretation of the electrochemical behaviour of complexes

Wave A of the H_2B–Mo(V) complex is easy to account for: it corresponds to the reduction of the ligand released near the electrode by the dissociation of the complex. This is why its $E_{1/2}$ is lower than that for the free ligand [$E_{1/2} = -0.10$ instead of -0.02 V(SCE) at pH 2.5].

Wave B corresponds to the reduction of Mo(V) released at the E of wave A, when the reduced ligand loses its complexing ability. In consequence, it is almost identical to that of free Mo(V). The same interpretation can be applied to wave B of the H_2B–Mo(VI) complex. On the other hand, the existence of the three-electron wave A of the Mo(VI) complex is more difficult to explain, since free Mo(VI) is not reducible at its $E_{1/2}$. We cannot exclude the possibility of a dissociation of the complex near the electrode, releasing a monomeric species of Mo(VI) which would be more reducible than the free polymeric Mo(VI). However, the more probable explanation involves a catalytic reduction of Mo(VI) by the reduced form of the ligand H_4B, following the scheme:

$$H_2B + 2e + 2H^+ \rightarrow H_4B,$$

$$H_4B + 2Mo(VI) \rightarrow 2Mo(V) + H_2B + 2H^+,$$

which results in the following overall reduction of Mo(VI):

$$2Mo(VI) + 2e \rightarrow 2Mo(V).$$

Finally, wave A of the Mo(VI)–H_2B complex would be due to the simultaneous reduction of H_2B (2 F.mol^{-1}) and Mo(VI) (1 F mol^{-1}) in a 1 : 1 ratio.

A detailed study of the parameters of wave A could not be done in order to demonstrate its catalytic character, since the plateau was not horizontal and its height could not be measured with sufficient accuracy. Final evidence for the catalytic nature of wave A was found in the identity of the $E_{1/2}$ of waves A in the Mo(VI) and Mo(V) complexes. Since wave A of the Mo(V) complex is ascribed to the reduction of the dissociated ligand, and because the two complexes are of almost identical stability (as shown below), one can expect wave A of the Mo(VI) complex to be found at the same E as the Mo(V) complex.

Stability of the Mo(V)–bromanilate complex

The composition of this species was determined by spectrophotometry. The mole ratio method showed the formation of a 1 : 1 complex. A typical plot of the absorbance variation vs addition of Mo(V) to H_2B is given in Fig. 3, showing that the complex is very stable at pH 2.00.

In the presence of a two-fold excess of Mo(V), we verified that the complex was almost undissociated between pH 1 and 4. However, its spectrum changed with acidity and an isosbestic point was observed ($\lambda = 357$ nm, $\varepsilon = 10{,}000$ 1 mol^{-1} cm^{-1}). This was related to an acid–base equilibrium between two species only, identified as C_1 (present at pH < 2) and C_2 (present at pH > 4.3). Knowing the molar absorbances of pure C_1 and C_2, we obtained the proportions of C_1 and C_2 as a function of pH, and calculated the pK_a value for the equilibrium:

$$C_1 \rightleftharpoons C_2 + H^+,$$

$$pK_a = 3.00 \pm 0.05 \quad (t = 25°C,\ I = 1.0\ M).$$

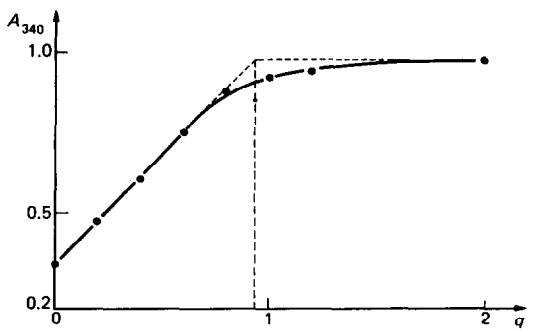

Fig. 3. Composition of the bromanilate–Mo(V) complex at pH 2.00: $[H_2B] = 5 \times 10^{-4}$ mol 1^{-1}, $t = 25°C$, $I =$ 1 M ($HCOO^-$), $\lambda = 340$ nm, cell length = 1 mm and $q = [Mo(V)]/[H_2B]$.

Since only *one* proton was exchanged per mol of complex, we were led to assume a monomeric formula for both C_1 and C_2, as for the related Mo(VI) species.[7] It is shown below that this hypothesis gave satisfactory results for the stability constant of the Mo(V) "acidic" complex. However, free aqua Mo(V) is generally thought to be dimeric[10] in acidic medium.

The nature of the "basic" complex C_2 could not be investigated directly because of the precipitation of Mo(V) hydroxide at pH > 4.5. This is why we studied the formation of the C_1 complex in perchloric acid medium. We found that an invariant equilibrium constant could be calculated only if the complexation was assumed to involve monomeric Mo(V):

$$\mathrm{Mo(V)} + \mathrm{H_2B} \rightleftharpoons \mathrm{C_1} + n\mathrm{H^+},$$

with a formation constant, K:

$$K = \frac{[\mathrm{C_1}][\mathrm{H^+}]^n}{[\mathrm{Mo(V)}][\mathrm{H_2B}]},$$

and a conditional constant,[11] K':

$$K' = \frac{[\mathrm{C_1}]}{[\mathrm{Mo(V)}][\mathrm{H_2B}]} = \frac{K}{[\mathrm{H^+}]^n}.$$

The analytical concentrations of the complex C_1 and the free ligand H_2B were measured spectrophotometrically. Free Mo(V) was obtained by difference from total Mo(V). The results in several acidic media are given in Table 2. It can be seen that $n = 2$.

Assuming that the monomeric Mo(V) is present as the cation MoO_2^+, the formation of C_1 could be written:

$$\mathrm{MoO_2^+} + \mathrm{H_2B} \rightleftharpoons [\mathrm{MoO_2B}]^- + 2\mathrm{H^+}$$

(water molecules are omitted).

The formula of C_2, the conjugate base of C_1, could thus be written as $[MoO_2(OH)B]^{2-}$.

The equilibrium constants for the complexation of Mo(VI) and Mo(V) in aqueous perchloric acid:

$$\mathrm{Mo(VI)}: \mathrm{HMoO_3^+} + \mathrm{H_2B} \rightleftharpoons [\mathrm{MoO_3HB}]^- + 2\mathrm{H^+},$$

$$\mathrm{Mo(V)}: \mathrm{MoO_2^+} + \mathrm{H_2B} \rightleftharpoons [\mathrm{MoO_2B}]^- + 2\mathrm{H^+},$$

can be compared in Table 2. As expected from Pearson's[12] considerations on increasing "hard" character of metal ion with increasing oxidation number, the Mo(VI) complex is more stable than the Mo(V) complex.

The Mo(III)–bromanilate reaction

The electroreduction of the Mo(V)–bromanilate complex could not result in the formation of a Mo(III) complex because the ligand was reduced before Mo(V) at the mercury drop electrode. In fact, the examination of redox potentials of the couples of molybdenum and the H_4B–H_2B couple revealed that the ligand H_2B was thermodynamically reducible by Mo(III). Owing to the irreversibility of the redox steps involving molybdenum, it was not possible to predict whether Mo(V) or Mo(IV) would be the oxidation product.

We investigated the reaction in the same conditions as above (chloroacetate buffer, pH 2.00), by titrating a 10^{-3} M solution of H_2B by a standard solution of Mo(III) present in its dimeric form.[13] The reaction was very fast and measurements were made 2 min after the addition of Mo(III).

Figure 4 represents the variations of the intensities of the polarographic waves vs the ratio $q([\mathrm{Mo(III)}]/[\mathrm{H_2B}])$ in chloroacetate buffer of pH 2.00.

When q increased, the cathodic wave of the ligand (species HB^-) decreased while the anodic wave of H_4B appeared. The reduction ratio was exactly equal to q and was complete for $q = 1$.

Thus, each molybdenum atom was oxidized by one ligand molecule, which indicated a two-electron

Table 2. Complexes of H_2B with Mo(VI) and Mo(V): variation in the conditional stability constants with acidity[a]

Complex	$[HClO_4]$ (mol l^{-1})	$[NaClO_4]$ (mol l^{-1})	K' (l mol^{-1})	K ($K' \cdot [H^+]^2$) (mol l^{-1})
Mo(V)	0.50	1.50	15,200 + 450	3800 ± 100
	1.00	1.00	3800 ± 120	3800 ± 120
	2.00	0.00	1080 ± 80	4300 ± 300
Mo(VI)	1.00	1.00	7000 ± 300	7000 ± 300
	2.00	0.00	1875 ± 100	7500 ± 400

[a] Condition: $t = 25°C$. K' is the conditional stability constant (see text).

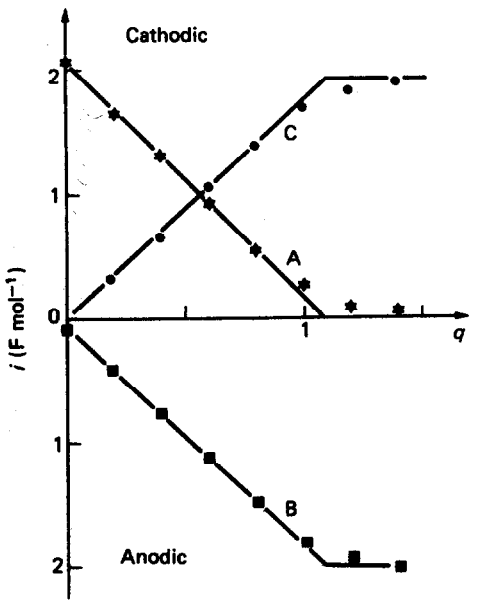

Fig. 4. Stoichiometry of the reduction of H_2B by Mo(III). Intensity (i) of the polarographic waves at $t = 25°C$, pH = 2.00, and $q = [Mo(III)]/[H_2B]$. (A) cathodic wave of H_2B ($E_{1/2} = 0.03$ V), (B) anodic wave of H_4B ($E_{1/2} = 0.03$ V), and (C) sum of waves at $E_{1/2} = -0.45$ and -0.65 V.

transfer:

$$Mo(III) + H_2B + 2H^+ \rightarrow H_4B + Mo(V).$$

Further evidence for the formation of Mo(V) was given by the simultaneous appearance of two cathodic waves ($E_{1/2} = -0.45$ and -0.65 V, sum of intensities = 2 F mol^{-1}). The unexpected transient wave at $E_{1/2} = -0.45$ V could be due either to some formation of intermediate Mo(IV) from the mixture of Mo(III) and Mo(V) or to the preliminary oxidation of Mo(III) to a species of Mo(V) which rapidly turned into "classical" Mo(V). The resulting Mo(V) rapidly complexed the remaining H_2B to give the already described Mo(V)–H_2B complex. Accordingly, we observed in the solution spectrum a transient band ($\lambda = 330$ nm) which had a maximum intensity for $q = 0.5$ and which disappeared at $q = 1$. This finding was in agreement with the formation of a 1:1 complex between H_2B and Mo(V).

Discussion of the redox reduction of Mo(III)

Like most oxidizing agents, H_2B oxidized Mo(III) to Mo(V) and the Mo(IV) state could not be detected. On the other hand, reduction of organic substrates by Mo(III) is not common. The literature gives scanty examples in the cases of nitro and nitroso compounds[14] and methylene blue.[15]

We could not find any spectral evidence of complex formation preceding the redox reaction between Mo(III) and H_2B. Such complex formation was expected to be slow, since d^3 ions like Mo(III) have high crystal-field stabilization energies which slow down their substitution rates.[16] Accordingly, complexes of Mo(III) with oxygenated ligands have been shown to be stable in the case of acetylacetone[17] and EDTA,[18] and the complexation of monomeric Mo(III) by thiocyanate ions has been reported to be slow.[19]

Because the reduction of H_2B by Mo(III) was very fast, it could lead to the conclusion that the electron transfer occurred without preliminary complexation of the metal ion. In other words, the mechanism would belong to the "outer-sphere" type.

The Mo(IV)–bromanilate complex

Neither the electroreduction of the Mo(VI) and Mo(V) complexes of the bromanilate ion nor the oxidation of Mo(III)–ligand mixtures allowed us to obtain the corresponding Mo(IV) complex. Thus we investigated the direct reaction between H_2B and Mo(IV) prepared independently.

In contrast with the fast reactions of the ligand with Mo(VI) and Mo(V), the spectral evolution of mixtures of H_2B and Mo(IV) was found to be surprisingly slow. It indicated a probable two-step process, since the absorbance increased rapidly at $\lambda = 340$ nm, and then more slowly. The second evolution defined an isosbestic point ($\lambda = 320$ nm) which did not belong to the spectrum of the initial mixture of the reactants. It could be due to the use of a slight excess of Mo(IV), but, when the concentration of Mo(IV) was lower than that of ligand, the reaction became extremely slow and was obscured by a slow oxidation of the complex.

As expected if the final spectrum was characteristic of the Mo(IV) complex, its absorbance increased with the pH and the initial concentration of Mo(IV).

At pH 2, the mole ratio method indicated that the complex was likely to have a 1:1 composition. Its formation was almost complete when a two-fold excess of Mo(IV) was used. A polarogram recorded in the same conditions as before (pH 2, chloroacetate buffer, $C = 10^{-3}$ mol l^{-1}) presented two cathodic waves (Table 1):

(1) wave A, corresponding to the bielectronic reduction of the ligand released near the electrode by the complex dissociation; and

(2) wave B, very close to that of free Mo(IV),[9,20] corresponding to the reduction of Mo(IV) to Mo(III).

The intensity of wave B gave clear evidence that we were actually dealing with a Mo(IV) species. We did

not attempt to calculate its stability constant, because its slow formation made it difficult to know if the equilibrium was reached (without aerial oxidation of the complex) and because its structure was probably polynuclear. Indeed, a dimeric[21] structure had long been accepted for the free aquo ion and this species was recently shown to be trimeric.[22,23]

The corresponding cluster, $[Mo_3O_4]^{4+}$, was also observed[24] in the related oxalate[25] and EDTA complexes.[26] However, another series of complexes containing a $[Mo_3O_2]^{8+}$ central group has recently been described.[27] Owing to these results, the sluggishness of the complexation of Mo(IV) could be due to some sort of structural reorganization of the molybdenum coordinating centre. Other examples can be found in the slow reactions of Mo(IV) with tartrate[28] and thiocyanate[29] ions. More surprisingly, in the latter case, the kinetic data could only be rationalized by assuming that free and complexed Mo(IV) species were monomeric.[29]

Charge-transfer spectra of the complexes

The electronic spectra of the complexes of Mo(VI), Mo(V) and Mo(IV) are compared in Fig. 5. The main bands, situated near $\lambda = 335$ nm, are quite similar in wavelength and intensity to that of the uncomplexed bromanilate ion B^{2-} ($\lambda = 334$ nm, $\varepsilon = 26{,}500$ l mol^{-1} cm^{-1}). They can be attributed to electronic transitions occurring inside the ligand cycle, which possess an important aromatic character.[7] Thus the ligand is fully deprotonated in all three complexes.

A remarkable phenomenon is the occurrence of a charge-transfer band at about $\lambda = 400$ nm, which increases in intensity as the oxidation state of molybdenum decreases. It can be attributed to a transition of an electron from an excited metal orbital to an antibonding π-orbital of the ligand. As pointed out by Orgel[30] such an electronic transition is redox in type, the metal being oxidized and the ligand reduced. This was demonstrated in the present case since a more reducing metal ion, like Mo(III), indeed reduced the ligand H_2B to H_4B. This sort of process is much less common than the inverse phenomenon in which the ligand reduces the metal ion. Its observation in the present study gives much support to the invoked participation of the ligand to the redox reactions of the molybdenum atom.

In this respect, our results contrast strongly with those reported on the electrochemistry of Mo(VI) complexes formed with non-reducible ligands.[5,6] They exemplify a peculiar type of redox process in molybdenum chemistry, in which the ligand functions as a redox catalyst.

ELECTROCHEMICAL STUDIES OF MOLYBDATE AND THIOMOLYBDATES

JINGFENG YOU, DAXU WU and HANQIN LIU*

Fujian Institute of Research on the Structure of Matter, Chinese Academy of Sciences, Fuzhou, Fujian, China

(*Received* 2 *July* 1985)

Abstract—The cyclic voltammogram of sodium molybdate in weak acid solution exhibits two main reduction waves, one at −0.8 V (SCE) from the $[Mo_7O_{24}]^{6-}$ anion and the other at −1.3 V (SCE) from $[MoO_4]^{2-}$. The former is quasi-reversible and relates to three oxidation waves. The thiomolybdates give only one irreversible reduction wave at about −1.1 V (SCE). The reduction mechanism has also been discussed.

The molybdate anion in weak acid solution polymerizes to form different species, e.g. $[MoO_4]^{2-}$, $[Mo_2O_7]^{2-}$, $[Mo_7O_{24}]^{6-}$ etc., depending on the pH values. The thiomolybdate anions, $[MoO_xS_{4-x}]^{2-}$ ($x = 0$–3), prepared from molybdate are important reactants in synthesizing molybdenum complexes. During the investigation of iron–molybdenum–sulfur compounds it is found that the redox behavior of molybdate and thiomolybdate anions is complicated and should be studied in detail in various reaction mediums, including aqueous solution at various pH values and different organic solvents.

EXPERIMENTAL

^{95}Mo NMR spectra were recorded at 310 K on a Varian FT-80A NMR. ESR signals were determined by a Brüker ER-420 spectrometer.

The cyclic voltammeter used is composed of a DHE-1 electrochemical multipurpose instrument and an X–Y recorder or a Gould OS 4200 memorized oscilloscope. The cyclic voltammogram was performed with the three-electrode system: a platinum auxiliary electrode, an SCE reference electrode, and a working electrode. In aqueous solution, a hanging mercury drop electrode was used as a working electrode and its surface area was about 0.04 cm^2. With the organic solvent, a platinum electrode with 0.12 cm^2 area was adopted. The experiments were carried out under a dinitrogen atmosphere.

Analytical grade $Na_2[MoO_4]$ and $(NH_4)_6[Mo_7O_{24}]$ were used without further purification. $[NH_4]_2[MoS_4]$, $Cs_2[MoOS_3]$, $[NH_4]_2[MoO_2S_2]$ and $K_2[MoO_3S]$ were prepared according to the method indicated in the literature.[1,2] All samples were checked by ^{95}Mo NMR, UV–Vis and IR spectrometry to ensure their purity.

RESULTS AND DISCUSSION

Cyclic voltammogram of $Na_2[MoO_4]$, with $Na_2[SO_4]$ (1.0 M) as its supporting electrolyte, exhibits four reduction and three oxidation waves in aqueous buffer solution in a pH range of 7.0–3.0. The reduction waves pc1, pc2, pc3 and pc4 are at −0.2, −0.4, −0.8 and −1.3. V (SCE), respectively. The three oxidation waves, pa1, pa2 and pa3, are located at −0.6, −0.4 and 0.0 V (SCE), respectively. Figure 1 shows a typical example. HAc–NaAc, $(CH_2COOH)_2$ or $Na_2[B_4O_7]$, are used as buffer solutions. Cyclic voltammograms are very similar no matter what type of buffer solution is used, but the pH value must be kept between 7 and 4.

Molybdate anions, $[MoO_4]^{2-}$ and $[Mo_7O_{24}]^{6-}$, are in equilibrium in aqueous solution:

$$7[MoO_4]^{2-} + 8H^+ \rightleftharpoons [Mo_7O_{24}]^{6-} + 4H_2O. \quad (1)$$

* Author to whom correspondence should be addressed.

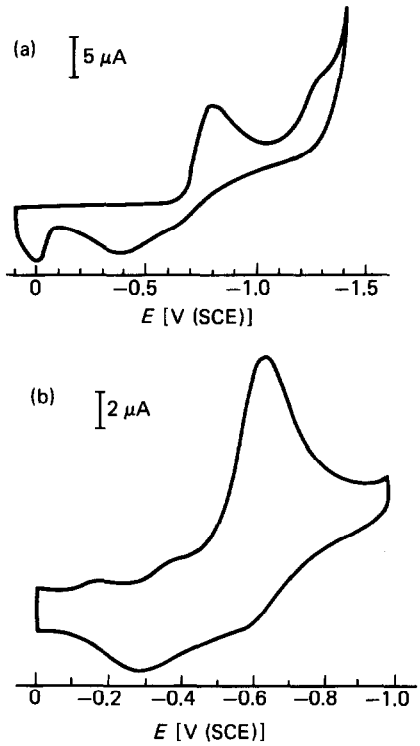

Fig. 1. Cyclic voltammogram of $Na_2[MoO_4]$ with $Na_2[SO_4]$ (1.0 M), in NaAc–HAc (0.1 N) in aqueous solution. (a) $C = 2.24\,mM\,l^{-1}$, pH = 5.77, $v = 0.14\,V\,s^{-1}$. (b) $C = 2.25\,mM\,l^{-1}$, pH = 4.87, $v = 0.055\,V\,s^{-1}$.

In weak acid solution, however, the equilibrium is shifted to the right as indicated by ^{95}Mo NMR spectroscopy. The sharp ^{95}Mo NMR peak of $[MoO_4]^{2-}$ begins to broaden at pH = 7.0 and a second broad peak appears at 45 ppm downfield of the first peak. This second peak is assigned to the anion of $[Mo_7O_{24}]^{6-}$, which dominates in solutions at pH $\leqslant$ 5.7.

The ratio of peak currents, i_{pc3}/i_{pc4}, depends on the pH value and scan rate as shown in Fig. 2. This ratio increases with the concentration of $Na_2[MoO_4]$. Therefore, it can be seen that pc3 and pc4 do not come from the same species, nor do they come from the consequent reduction products. The fact that the peak current function, I_{pc3} ($\equiv i_{pc3} \cdot v^{-1/2} \cdot ([MoO_4]^{2-})^{-1}$), increases with the decrease of pH value suggests that the reduction wave of pc3 is associated with the species $[Mo_7O_{24}]^{6-}$ and that of pc4 with the species $[MoO_4]^{2-}$. As indicated in eqn (1), a decrease in pH value will result in more $[Mo_7O_{24}]^{6-}$ species, or tend to increase the molar ratio of $[Mo_7O_{24}]^{6-}/[MoO_4]^{2-}$. Further evidence for the above assignment is that thiomolybdate anions, which exist in a monomolybdenum form at pH

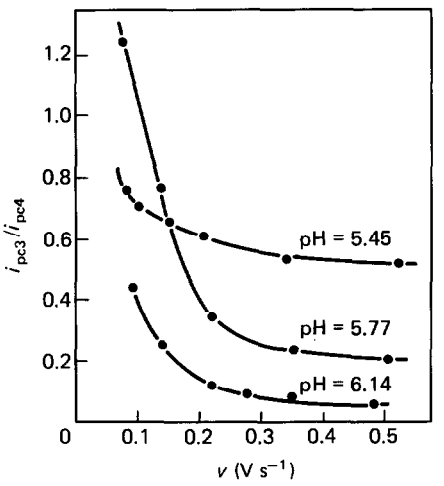

Fig. 2. i_{pc3}/i_{pc4} vs scan rate v at various pH values.

= 6.0, exhibit only one irreversible reduction wave at about −1.1 V (SCE). In a solution of NaAc–HAc (pH = 6.0) with $Na_2[SO_4]$ (1.0 N) as its supporting electrolyte, the irreverisble reduction waves, E_{pc}, are at −1.33, −1.12, −1.06, −1.07 and −1.08 V (SCE) for $Na_2[MoO_4]$, $K_2[MoO_3S]$, $[NH_4]_2[MoO_2S_2]$, $Cs_2[MoOS_3]$ and $[NH_4]_2[MoS_4]$, respectively. The assignment of pc3 and pc4 to different species in equilibrium state can also be indicated by the fact that $I_{pc3} + I_{pc4}$ is constant at each pH value as shown in Fig. 4.

With controlled-potential coulometry at −0.900 V(SCE), it is found that the reduction wave of pc3 is a two-electron process. In this process, some diamagnetic precipitates are found, which have been

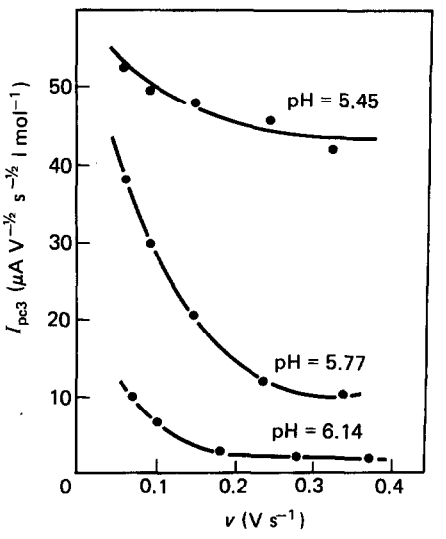

Fig. 3. I_{pc3} vs scan rate v at various pH values.

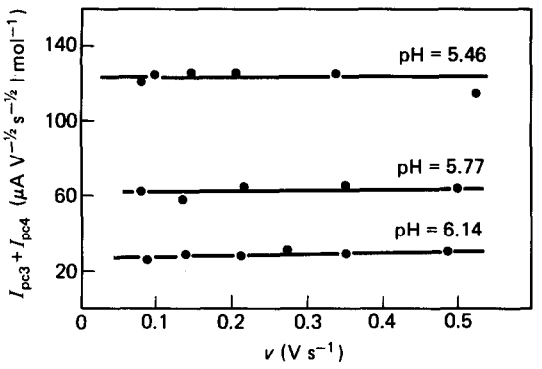

Fig. 4. $I_{pc3}+I_{pc4}$ vs scan rate v at various pH values. $[Na_2MoO_4] = 2.21$ mmol l^{-1}.

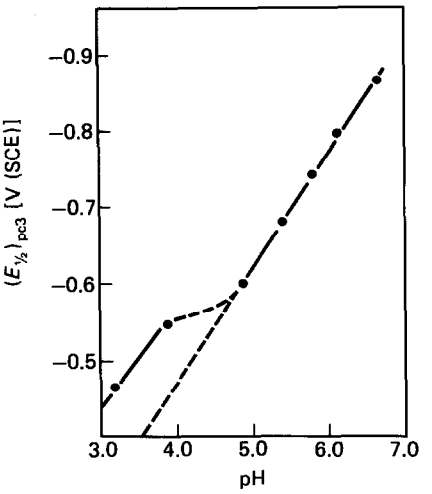

Fig. 5. Plot of $E_{1/2}$ vs pH.

confirmed by our magnetic susceptibility measurement. The two-electron process has also been confirmed by the slope method:[3]

$$\alpha \cdot n = \frac{RT}{F} \cdot \frac{1}{K},$$

where K is the slope of the plot E_{pc3} vs ln $\sqrt{v}$. The average $\alpha \cdot n$ determined by this method is 0.93 $\pm$0.19. If $n = 2$, then $\alpha = 0.465$, which is a reasonable value.[3]

By limiting the scan range, all oxidation waves, pa1, pa2 and pa3, are quasi-reversible vs the reduction wave pc3. The sum of the peak area of the three oxidation waves is equal to that of pc3 in the cyclic voltammogram.

As indicated by eqn (1), since pc4 is associated with $[MoO_4]^{2-}$, I_{pc4} should have decreased as the pH value dropped. In fact, however, as pc4 is a catalytic wave to evolve hydrogen gas, I_{pc4} actually increases as the pH value is lowered. The cross-over of the two curves at lower pH values can thus be explained.

As shown in Fig. 4, $I_{pc3}+I_{pc4}$ increases as the pH is lowered. This is an indication that proton transfer might be involved in the reduction process. By extrapolation of E_{pc3} to $v = 0$ and subtracting 15 mV, the half-wave potential $(E_{1/2})_{pc3}$ can be established for each pH value. A straight line has been obtained by plotting $E_{1/2}$ vs pH as shown in Fig. 5. The line can be expressed as:

$$(E_{1/2})_{pc3} = 0.130 - 0.150 \text{ pH}, \quad 4.8 < \text{pH} < 6.7.$$

The number of protons involved in the reduction process is $(150/60) \times 2 = 5$.

In conclusion, molybdate and thiomolybdates can be reduced more easily if they first polymerize to form molecules composed of two or more molybdenum atoms before the reduction takes place. This fact also agrees with the result of Pan *et al.*[4] Mo(VI) in molybdate and thiomolybdates is generally reduced to Mo(IV) in weak acid solution involving protonation. In general, polymerization, protonation or ligation change the coordination number of molybdenum in the compounds, thereby making the reduction easier.

REDOX REACTIONS BETWEEN COMPLEXES OF MOLYBDENUM AND IRON

H. DIEBLER* and C. MILLAN†

Max-Planck-Institut für Biophysikalische Chemie, 34 Göttingen-Nikolausberg, F.R.G.

(*Received* 30 *June* 1985)

Abstract—Several redox reactions between complexes of molybdenum (oxidation states III–VI) and iron in aqueous solution have been investigated with respect to their stoichiometry, kinetics and mechanism. The reactions include the oxidation of Mo^{3+} and $Mo_2O_4^{2+}$ by Fe^{3+}, and of $Mo_2O_4^{2+}$, $Mo_2O_2S_2^{2+}$ and $Mo_3O_4^{4+}$ by $Fe(phen)_3^{3+}$ (phen = 1,10-phenanthroline). The reduction of Mo(VI) by Fe(II) in 8 M HCl and of $Mo(CN)_8^{3-}$ by Fe^{2+} have also been investigated. Three separate reaction steps were detected in the oxidation of Mo^{3+} to Mo(VI) and in the reduction of $Mo(CN)_8^{3-}$ by Fe^{2+}. In the oxidation of $Mo_2O_4^{2+}$ by Fe^{3+}, and of $Mo_2O_4^{2+}$ and $Mo_3O_4^{4+}$ by $Fe(phen)_3^{3+}$, however, only one reaction effect was observed. The rate equations reveal that, in these reactions, the transfer of the first electron represents the rate-determining step. The rate constants of individual electron-transfer steps are discussed in terms of mechanisms, thermodynamic effects and the nature of the coordinating ligands.

All of the Mo enzymes also contain Fe, and it has been suggested that direct electron transfer occurs between the Mo and Fe centers in some of these enzymes during the catalytic action.[1] In order to learn more about the general features of redox processes between Mo and Fe compounds, we have studied the kinetics of a series of redox reactions between simple complexes of these two metal ions. The reactions include the oxidation of Mo^{3+} and $Mo_2O_4^{2+}$ by Fe^{3+}, of $Mo_2O_4^{2+}$, $Mo_2O_2S_2^{2+}$ and $Mo_3O_4^{4+}$ by $Fe(phen)_3^{3+}$ (phen = 1,10-phenanthroline), and the reduction of Mo(VI) by Fe(II) and of $Mo(CN)_8^{3-}$ by Fe^{2+}.

EXPERIMENTAL

Solutions of the metal complexes used have been prepared and standardized according to procedures described in the literature.[2] All solutions were kept and handled under an atmosphere of N_2. Absorption measurements were carried out by means of a Cary 118C spectrophotometer. The kinetics of the redox processes were followed spectrophotometrically using a Cary 118C spectrophotometer, a stopped-flow apparatus or a temperature-jump apparatus. The latter two instruments had been built at our institute. The reaction signals of the stopped-flow and relaxation measurements were stored in a transient recorder (Datalab DL 905 or DL 920) and evaluated either by means of an electronic simulator (developed by Dr C. R. Rabl) or by computer fitting procedures. At least three individual measurements were made with each solution studied.

RESULTS

Mo(VI) + Fe(II)

In accordance with reported redox potentials[3] Mo(VI) is reduced to Mo(V) by Fe(II) in strong HCl solution, e.g. 8 M HCl. Under these conditions Mo(VI) is present in the form of MoO_2Cl_2[4] and Mo(V) as $MoOCl_5^{2-}$ (or H_2MoOCl_5).[5] The Mo(V) complex is of a green colour and its solution shows absorption maxima near 450 and 710 nm. Spectrophotometric titrations of Mo(VI) with Fe(II) in 8 M HCl confirmed the 1 : 1 stoichiometry and revealed that the equilibrium is far to the side of the products.

The kinetics of the fast redox reaction were studied

by means of the stopped-flow technique with a large excess of Fe(II) (0.01–0.1 M) over Mo(VI) (0.001–0.005 M). The reaction was monitored at 710 nm, following the formation of Mo(V). In all experiments a single exponential reaction curve was observed (half-lifes 2.5–18 ms). The dependence of the apparent first-order rate constant on the concentration of Fe(II) is shown in Fig. 1. The straight line passes through the origin (i.e. the back reaction is negligible) and yields a second-order rate constant:

$$k = 3.6 \times 10^3\ M^{-1}\ s^{-1}\ (20°C, 8\ M\ HCl).$$

$Mo_2O_4^{2+} + Fe^{3+}$

In dilute $HClO_4$ Mo(V) exists in form of a dimer of structure $(H_2O)_3MoO(\mu\text{-}O)_2OMo(H_2O)_3^{2+}$,[6] usually abbreviated by $Mo_2O_4^{2+}$. Spectrophotometric titrations of $Mo_2O_4^{2+}$ with Fe^{3+} at 384 nm (an absorption maximum of $Mo_2O_4^{2+}$) indicated a stoichiometry according to:

$$Mo_2O_4^{2+} + 2Fe^{3+} \rightleftharpoons 2Mo(VI) + 2Fe^{2+}, \quad (1)$$

with the equilibrium far to the side of the products [the predominant form of Mo(VI) under the conditions of this study is a monomeric cationic species,[7] $HMoO_3^+$].

The kinetics of this reaction have been investigated with a large excess of Fe^{3+} (0.01–0.04 M) over $Mo_2O_4^{2+}$ (0.001 M) and at H^+ concentrations of 0.4–1.5 M ($HClO_4$), and ionic strength (I) of 2.0 M ($NaClO_4$). The reaction was monitored at 450 nm, observing the decrease in $[Mo_2O_4^{2+}]$. Only one reaction effect was detected (half-lifes 8–90 s). Plots of $\log(A_t - A_\infty)$ vs t were linear for more than 90% of the reaction. The dependence of the pseudo first-order rate constant on $[Fe^{3+}]$ is shown in Fig. 2 for various H^+ concentrations. The apparent second-order constant (slopes of Fig. 2) depends on $[H^+]$ as shown in Fig. 3. The data reveal that the rate equation is of the form:

$$-d[Mo_2O_4^{2+}]/dt = (k_a + k_b/[H^+]) \times [Mo_2O_4^{2+}][Fe^{3+}], \quad (2)$$

with $k_a \leqslant 0.2\ M^{-1}\ s^{-1}$ and $k_b = 1.27\ s^{-1}$ (25°C, $I = 2.0$ M).

The overall reaction [eqn (1)] is assumed to proceed by a step-wise transfer of two electrons from

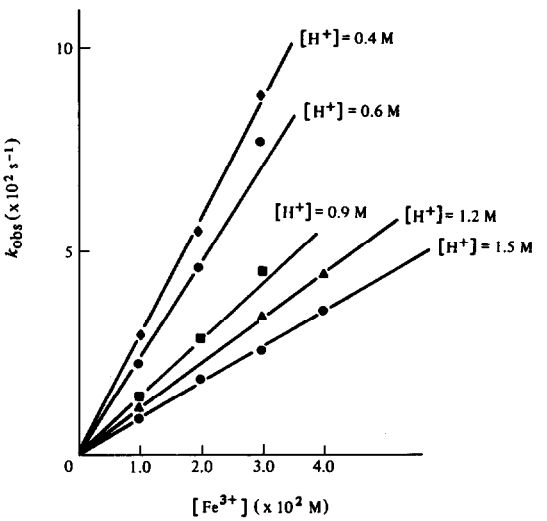

Fig. 2. Oxidation of $Mo_2O_4^{2+}$ by Fe^{3+}. Dependence of the pseudo first-order rate constant on $[Fe^{3+}]$ and $[H^+]$ [25°C, $I = 2.0$ M ($NaClO_4$)].

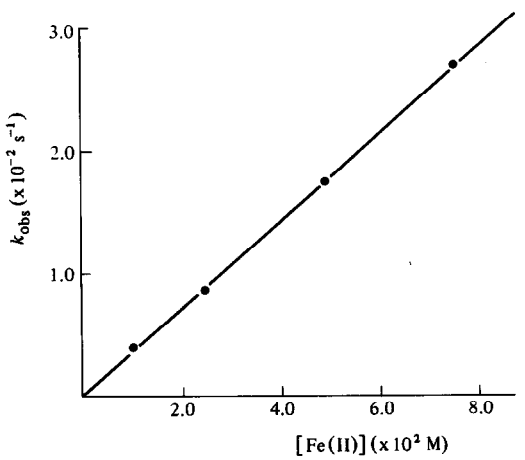

Fig. 1. Reduction of Mo(VI) by Fe(II). Dependence of the apparent first-order rate constant on [Fe(II)] (20°C, 8 M HCl).

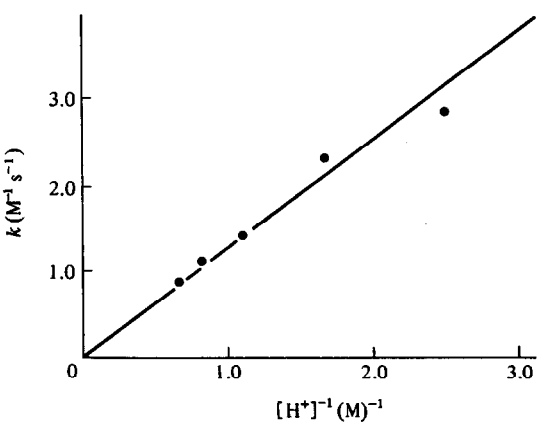

Fig. 3. Oxidation of $Mo_2O_4^{2+}$ by Fe^{3+}. Dependence of the apparent second-order rate constant on $[H^+]^{-1}$ [25°C, $I = 2.0$ M ($NaClO_4$)].

the Mo(V) dimer to two Fe(III), with Mo(V)Mo(VI) as a steady-state intermediate. The form of eqn (2) clearly demonstrates that the first electron-transfer step is rate-determining in the overall reaction. Assuming that the term with $k_b/[H^+]$ [eqn (2)] indicates a reaction path in which $Mo_2O_4^{2+}$ is oxidized by $FeOH^{2+}$, this interpretation yields, with a K_H ($[FeOH^{2+}][H^+]/[Fe^{3+}]$) of 1×10^{-3} M^{-1} (25°C, $I = 2$ M),[8] a second-order rate constant (k) of 1.3×10^3 $M^{-1}\,s^{-1}$ for the oxidation by $FeOH^{2+}$.

$Mo_2O_4^{2+} + Fe(phen)_3^{3+}$

Measurements of the kinetics of the oxidation of $Mo_2O_4^{2+}$ by the phen complex of Fe(III) have been carried out either with the Mo(V) dimer in excess (1.1×10^{-4}–1.1×10^{-3} M) over Fe(III) (5.6×10^{-5} M) or with Fe(III) in excess (5×10^{-5}–2.6×10^{-4} M) over $Mo_2O_4^{2+}$ (5×10^{-6}–1×10^{-5} M): $[H^+] = 0.5$–1.5 M ($HClO_4$), $I = 2.0$ M ($NaClO_4$). The strong absorption of the Fe(II) product at 510 nm was used in order to follow the reaction. Both series of measurements conform to the rate law:

$$d[Fe(II)]/dt = 2k_1[Fe(III)][Mo_2O_4^{2+}], \quad (3)$$

with $k_1 = k_a + k_b/[H^+]$.

The form of the rate law demonstrates that the first electron-transfer step (rate constant k_1) is again the rate-determining process. The studies with excess of $Mo_2O_4^{2+}$ yielded $k_a = 13.5\,M^{-1}s^{-1}$, and $k_b = 9\,s^{-1}$, and those with excess of $Fe(phen)_3^{3+}$ gave $k_a = 11.5$ $M^{-1}s^{-1}$, and $k_b = 4\,s^{-1}$. The two values of k_a are in fair agreement but those of k_b differ appreciably. In case of excess of Fe(III) the low reactant concentrations slow down the redox process (half-lifes 170–740 s) and some spontaneous decomposition of the Fe(phen) complexes occurs during the time of the reaction.[9] Therefore, the results of this series may be considered as less reliable. The moderate variation of the rate with $[H^+]$ can be assigned to a contribution of the reaction path $Mo_2O_4(H_2O)_5OH^+ + Fe(phen)_3^{3+}$. Similar results had been reported by Cayley *et al.*[10] for this system under conditions somewhat different from ours: $k_a = 31\,M^{-1}s^{-1}$, $k_b = 6.0\,s^{-1}$ [$I = 1.0$ M ($LiClO_4$)].

$Mo_2O_2S_2^{2+} + Fe(phen)_3^{3+}$

The structure of this Mo(V) species is analogous to that of the oxo complex, $(H_2O)_3MoO(\mu\text{-}S)_2OMo(H_2O)_2^{2+}$.[11] The rate of its oxidation by $Fe(phen)_3^{3+}$ is rather low and some spontaneous decomposition of the Fe(phen) complexes occurs during the time of the reaction. High concentrations of $Mo_2O_2S_2^{2+}$ were used (1.8×10^{-3}–8.1×10^{-3} M) in order to enhance the rate of reaction. A reaction curve (510 nm) is shown in Fig. 4. The final value of the absorbance corresponds to practically complete reduction of the Fe(III) complex. Contrary to all other systems described so far, the reaction curves are not exponential. This behaviour can be accounted for either by a change in the rate-determining step during the reaction or by the formation of a non-steady-state intermediate. Important information can be evaluated very conveniently from the initial rate of reaction. The initial slopes of the reaction curves are given by:

$$(dA/dt)_o = k[Mo_2O_2S_2^{2+}] \times [Fe(III)]_o\varepsilon_{Fe(III)}. \quad (4)$$

The dependence of $(dA/dt)_o$ on $[Mo_2O_2S_2^{2+}]$ yields $k = 0.8$ $M^{-1}s^{-1}$ (25°C, 1 M $HClO_4$). If k_1 denotes the rate constant of the first electron-transfer step, then $k = k_1$ in the non-steady-state model (formation of a true intermediate) and $k = 2k_1$ if steady-state conditions are maintained and a change in the rate-determining step occurs.

$Mo_3O_4^{4+} + Fe(phen)_3^{3+}$

In aqueous solution Mo(IV) exists in the form of trimeric species characterized by a $Mo_3O_4^{4+}$ core.[12] Spectrophotometric measurements of $Mo_3O_4^{4+}$–$Fe(phen)_3^{3+}$ mixtures (510 nm, 1 M HCl indicated a stoichiometry of the redox reaction according to:

$$6Fe(phen)_3^{3+} + Mo_3O_4^{4+} \rightleftharpoons 6Fe(phen)_3^{2+} + 3Mo(VI). \quad (5)$$

The reaction curves observed in the kinetic studies {$[Mo_3O_4^{4+}] = 4 \times 10^{-5}$–$2.2 \times 10^{-4}$ M, $[Fe(phen)_3^{3+}] = 4 \times 10^{-5}$ M, 25°C, 1.0 M HCl, $I = 2.0$ M (NaCl), 510 nm} were always single

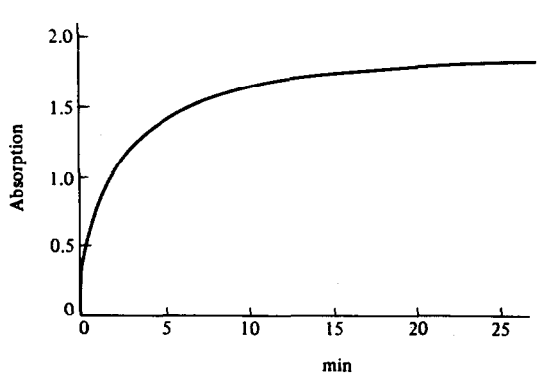

Fig. 4. Oxidation of $Mo_2O_2S_2^{2+}$ by $Fe(phen)_3^{3+}$. Reaction curve with $[Mo_2O_2S_2^{2+}] = 8.1 \times 10^{-3}$ M and $[Fe(phen)_3^{3+}] = 1.8 \times 10^{-4}$ M (25°C, 1.0 M $HClO_4$, $I = 1.0$ M, $\lambda = 510$ nm).

exponentials and the apparent first-order rate constant depends on $[Mo_3O_4^{4+}]$ as shown in Fig. 5. The results reveal a rate law of the form:

$$d[Fe(II)]/dt = 6k_1[Mo_3O_4^{4+}][Fe(III)], \quad (6)$$

which indicates that the first electron-transfer process is rate-determining. For this step a rate constant (k_1) of 51 $M^{-1} s^{-1}$ [25°C, 1 M HCl, I = 2.0 M (NaCl)] is obtained.

$$Mo(H_2O)_6^{3+} + Fe(H_2O)_6^{3+}$$

The monomeric aquo ion $Mo(H_2O)_6^{3+}$ is stable only in strongly acidic non-complexing solutions.[13] The results of a spectrophotometric titration of Mo^{3+} with Fe^{3+} in 1 M *p*-toluenesulfonic acid (HPTS) at 450 nm (at this wavelength the absorption of the Fe species is very small) is shown in Fig. 6. Obviously the Mo(III) is first oxidized to Mo(V) and then to Mo(VI). The spectrum at the position of the first break is that of the Mo(V) dimer, $Mo_2O_4^{2+}$.

In the kinetic studies of the oxidation of Mo^{3+} by Fe^{3+} (stopped-flow techniques, λ = 450 nm), three reaction effects were observed with Fe^{3+} in excess: a fast one in the millisecond range, and two slower ones with half-lifes of seconds. The fast effect describes the disappearance of Mo^{3+}. The rate law of this process was found to be:

$$-d[Mo^{3+}]/dt = k_f[Mo^{3+}][Fe^{3+}], \quad (7)$$

with $k_f = 1.3 \times 10^3$ $M^{-1} s^{-1}$ (25°C, 1 M HPTS).

The nature of the first true intermediate (between Mo^{3+} and $Mo_2O_4^{2+}$) is unknown. Equation (7) demonstrates, however, that the rate-determining step on the way to this intermediate is given by:

$$Mo^{3+} + Fe^{3+} \xrightarrow{k_f} Mo(IV) + Fe^{2+}. \quad (8)$$

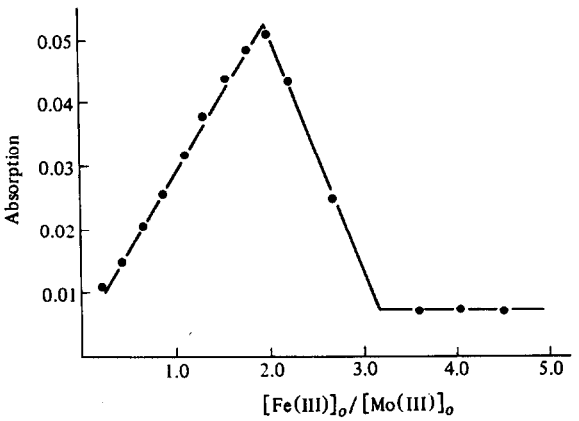

Fig. 6. Spectrophotometric titration of 2.3×10^{-3} M Mo^{3+} with 0.6 M Fe^{3+} (25°C, 1.0 M HPTS, I = 1.0 M, λ = 450 nm).

An experimental curve of the two slower processes is shown in Fig. 7. The decrease in and recovery of the signal intensity reflect the formation and disappearance of $Mo_2O_4^{2+}$. The final part of the curve is described by a single exponential function and a rate constant (k) of 0.5 $M^{-1} s^{-1}$ (1 M HPTS, I = 1.0 M) has been evaluated for the oxidation of the intermediate $Mo_2O_4^{2+}$ by Fe^{3+} in these experiments. This value is consistent with the one which was determined directly [see above, k = 1.27 $M^{-1} s^{-1}$ (1 M $HClO_4$, I = 2.0 M)], since like-charged reactants are expected to react with a higher rate at the higher ionic strength.

Attempts were made to fit the total experimental curve (Fig. 7) with the help of a computer program based on a four-step mechanism of the type Mo(III) → Mo(IV) → Mo(V) → $Mo(V)_2$ → Mo(V)Mo(VI)

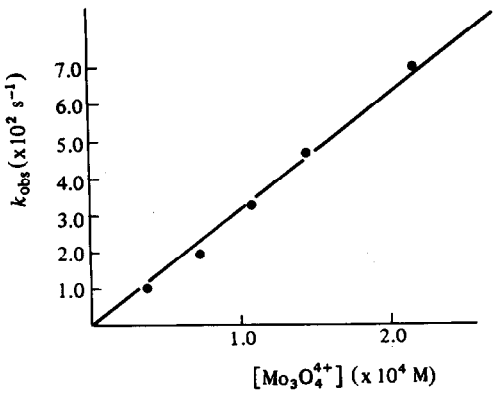

Fig. 5. Oxidation of $Mo_3O_4^{4+}$ by $Fe(phen)_3^{3+}$. Dependence of the apparent first-order rate constant on $[Mo_3O_4^{4+}]$ [25°C, 1.0 M HCl, I = 2.0 M (NaCl)].

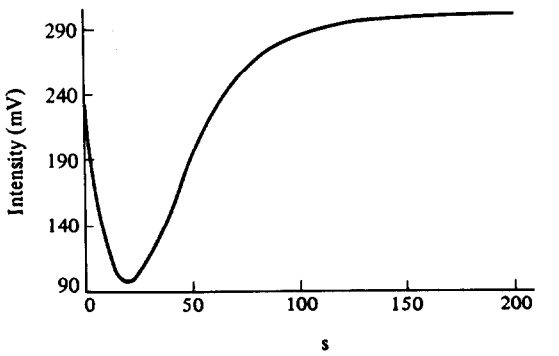

Fig. 7. Oxidation of Mo^{3+} by Fe^{3+}. Reaction curve with $[Mo^{3+}] = 1.2 \times 10^{-3}$ M and $[Fe^{3+}]$ = 0.045 M (25°C, 1.0 M HPTS, I = 1.0 M, λ = 450 nm).

and assuming that: (a) either monomeric Mo(IV), or (b) monomeric Mo(V) is the first true intermediate. Neither assumption gave a very good fit [although (a) was better than (b)], deviations occurring in particular near the intensity minimum. Possibly the neglect of all back reactions is not justified, or the assumed mechanism is incorrect.

$Mo(CN)_8^{3-} + Fe^{2+}$

The product of the reduction of $Mo(CN)_8^{3-}$ by Fe^{2+} was identified by its spectrum to be $Mo(CN)_8^{4-}$. A spectrophotometric titration in 0.1 M $HClO_4$ confirmed the expected 1:1 stoichiometry. Thus:

$$Fe^{2+} + Mo(CN)_8^{3-} \overset{K_r}{\rightleftharpoons} Fe^{3+} + Mo(CN)_8^{4-}. \quad (9)$$

A quantiative evaluation of the spectrophotometric data yielded a value for K_r of 11.7 [25°C, 0.1 M $HClO_4$, I = 1.0 M ($NaClO_4$), 387 nm].

In studies of the kinetics of reaction (9) by stopped-flow techniques ($[Mo(CN)_8^{3-}] = 2 \times 10^{-5}$ M, $[Fe^{2+}] = 1 \times 10^{-4}$–$6 \times 10^{-4}$ M), one reaction effect in the millisecond range was detected. The absorbance at the starting point of this reaction (λ = 387 nm) is not that calculated from the initial concentration of $Mo(CN)_8^{3-}$ and it is concluded that other reaction steps precede the one observed by the stopped-flow method. This was confirmed by studies with the temperature-jump relaxation technique which showed that there are two more reaction effects, one in the microsecond range (τ = 100–400 μs) and one with a time constant <0.2 μs (cable T-jump). The results demonstrate that the reaction does not proceed by an outer-sphere path, and the following three-step inner-sphere mechanism is considered:

$$\text{(a)} \quad Mo(V) + Fe(II) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Mo(V)Fe(II),$$

$$\text{(b)} \quad Mo(V)Fe(II) \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} Mo(IV)Fe(III), \quad (10)$$

$$\text{(c)} \quad Mo(IV)Fe(III) \underset{k_{-2}}{\overset{k_3}{\rightleftharpoons}} Mo(IV) + Fe(III).$$

Steps (a) and (c) involve inner-sphere substitution processes, the time constants of which should be measurable by the techniques used. Therefore, the extremely rapid process was assigned to step (b), yielding $1/\tau_b = k_2 + k_{-2} > 5 \times 10^6$ s^{-1}. This very fast effect is not observed in the absence of Fe(II) and Fe(III), i.e. it is not due to a protonation reaction of the $Mo(CN)_8$ species.

The relaxation time of the microsecond effect depends on the concentration of Fe(II) but is independent of [Fe(III)]. This effect is assigned to step (a), to which the rapid equilibrium (b) is coupled. Then, with [Fe(II)] $\gg$ [Mo(V)]:

$$1/\tau_a = k_{-1}/(1 + K_2) + k_1[Fe(II)], \quad (11)$$

where $K_2 = k_2/k_{-2}$. A plot of $1/\tau_a$ vs [Fe(II)] gave $k_1 = 1.15 \times 10^6$ M^{-1} s^{-1} [3.0°C, 0.1 M $HClO_4$, I = 1 M ($NaClO_4$)]. (In order to reduce cavitation effects, the T-jump experiments were carried out at low temperature.)

The slow effect is assigned to step (c) with (a) and (b) as preequilibria. It is evaluated more conveniently from the stopped-flow rather than from the T-jump measurements. The apparent first-order rate constant is given by:

$$\frac{1}{k_{obs}} = \frac{1 + K_2}{k_3 K_2} + \frac{1}{k_3 K_1 K_2 [Fe(II)]}. \quad (12)$$

A plot of $1/k_{obs}$ vs $1/$[Fe(II)] yielded $k_3 K_1 K_2 = 3.2 \times 10^5$ M^{-1} s^{-1}. $K_1 K_2$ was determined from K_r and K_3 ([Mo(IV)Fe(III)]/[Mo(IV)][Fe(III)]) = 172 M^{-1} (obtained during this study by spectrophotometric measurements), leading finally to $k_3 = 160$ s^{-1}, and $k_{-3} = 2.75 \times 10^4$ M^{-1} s^{-1}.

DISCUSSION

The rates of individual reaction steps which have been determined during this study are summarized in Table 1. The mechanism of the reduction of Mo(IV) by Fe(II) in 8 M HCl is uncertain, but Cl^- is known to be a good bridging ligand and an inner-sphere mechanism may tentatively be assumed. It can safely be excluded that the formation of the precursor complex (inner- or outer-sphere) is rate-limiting, since both the diffusion-controlled encounter of the reactants and substitution at an Fe(II) center are very rapid processes. Thus, either the electron-transfer step or (in the case of an inner-sphere mechanism) the dissociation of the successor complex must be rate-limiting. An additional complication arises from the fact that the overall reaction includes ligand exchange processes ($MoO_2Cl_2 \rightarrow MoOCl_5^{2-}$).

The interesting point in the oxidation of $Mo_2O_4^{2+}$ by Fe^{3+} is the origin of the term showing a $1/[H^+]$ dependence. Three possible mechanisms may be considered: (a) $FeOH^{2+}$ reacts with the Mo(V) dimer via an efficient inner-sphere path with OH^- bridging;[14] (b) $Mo_2O_4(H_2O)_5OH^+$ reacts with $Fe(H_2O)_6^{3+}$ by an OH^--bridged inner-sphere path; and (c) reaction via inner-sphere structures which result from rate-determining substitution of a terminal oxygen of $Mo_2O_4^{2+}$ at $Fe(H_2O)_5OH^+$ and $Fe(H_2O)_6^{3+}$, respectively. A comparison with other Fe^{3+} and $FeOH^{2+}$ reactions[15] disfavours (b) and (c).

Table 1.

Reaction	Rate constant ($M^{-1} s^{-1}$)	Conditions
$MoO_2Cl_2 + Fe(II) \rightarrow MoOCl_5^{2-} + Fe(III)$	3.6×10^3	20°C, 8 M HCl
$Mo_2O_4^{2+} + Fe^{3+} \rightarrow Mo(V)Mo(VI) + Fe^{2+}$	$\leqslant 0.2$	25°C, I = 2 M ($NaClO_4$)
$Mo_2O_4^{2+} + FeOH^{2+} \rightarrow Mo(V)Mo(VI) + Fe^{2+}$	1.3×10^3	25°C, I = 2 M ($NaClO_4$)
$Mo_2O_4^{2+} + Fe(phen)_3^{3+} \rightarrow Mo(V)Mo(VI) + Fe(phen)_3^{2+}$	13	25°C, I = 2 M ($NaClO_4$)
$Mo_2O_2S_2^{2+} + Fe(phen)_3^{3+} \rightarrow Mo(V)Mo(VI) + Fe(phen)_3^{2+}$	0.8 or 0.4	25°C, 1 M $HClO_4$
$Mo_3O_4^{4+} + Fe(phen)_3^{3+} \rightarrow Mo(IV)_2Mo(V) + Fe(phen)_3^{2+}$	51	25°C, 1 M HCl, I = 2 M (NaCl)
$Mo^{3+} + Fe^{3+} \rightarrow Mo(IV) + Fe^{2+}$	1.3×10^3	25°C, 1 M HPTS
$Mo(CN)_8^{3-} + Fe^{2+} \rightarrow [(CN)_7Mo(V)CNFe(II)]^-$	1.1×10^6	3°C, 0.1 M $HClO_4$, I = 1 M ($NaClO_4$)
$[(CN)_7Mo(V)CNFe(II)]^- \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} [(CN)_7Mo(IV)CNFe(III)]^-$	$k_2 + k_{-2} > 5 \times 10^6 s^{-1}$	
		3°C, 0.1 M $HClO_4$, I = 1 M ($NaClO_4$)
$[(CN)_7Mo(IV)CNFe(III)]^- \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} Mo(CN)_8^{4-} + Fe^{3+}$	$k_3 = 160 s^{-1}$	25°C, 0.1 M $HClO_4$, I = 1 M ($NaClO_4$)
	$k_{-3} = 2.7 \times 10^4$	25°C, 0.1 M $HClO_4$, I = 1 M ($NaClO_4$)

Thus interpretation (a) is considered to be the most likely. The results of Sasaki *et al.*[16] on substitution at $Mo_2O_4(H_2O)_6^{2+}$ indicate that the replacement of water at the Mo(V) dimer may well be the rate-determining step in mechanism (a).

The oxidation processes involving $Fe(phen)_3^{3+}$ must proceed, of course, by outer-sphere pathways. The higher rate of the oxidation of $Mo_2O_4^{2+}$ by $Fe(phen)_3^{3+}$ (13 $M^{-1} s^{-1}$), compared to the oxidation by $Fe(H_2O)_6^{3+}$ ($\leqslant 0.2 M^{-1} s^{-1}$, probably also outer-sphere), is easily rationalized in terms of Marcus' theory: $Fe(phen)_3^{3+}$ is the stronger oxidizing agent (higher ΔG^o), and the Fe–phen complexes have a much higher self-exchange rate than the Fe–aquo complexes.[17]

The rate of oxidation of $Mo_2O_2S_2^{2+}$ by $Fe(phen)_3^{3+}$ is more than one order of magnitude lower than that of $Mo_2O_4^{2+}$. The low reductive power of $Mo_2O_2S_2^{2+}$ is observed also in other cases: $Mo_2O_2S_2^{2+}$ is not noticeably oxidized by air, and, after the addition of Fe^{3+}, no oxidation was found to occur within 24 h. Obviously the μ-thio ligands stabilize the Mo(V) state relative to Mo(VI) more than the μ-oxo ligands.

The rate of the first electron-transfer step in the oxidation of $Mo_3O_4^{4+}$ by $Fe(phen)_3^{3+}$ was found to be 51 $M^{-1} s^{-1}$ in 2 M chloride solution. While these studies were in progress, a paper by Harmer *et al.* appeared[18] which reported on the kinetics of this reaction in perchlorate solution (they had managed to keep $Mo_3O_4^{4+}$ stable in the presence of ClO_4^-) and gave a rate constant of only 0.47 $M^{-1} s^{-1}$. Since spectrophotometric studies had provided evidence for the coordination of Cl^- to the trimeric Mo(IV) ion[19] in chloride solution

$$[Mo_3O_4(H_2O)_{9-n}Cl_n^{+(4-n)}],$$

it is probably the strong reduction of the electrostatic repulsion which provides most of the rate enhancement in the chloride medium.

The reaction between Mo^{3+} and Fe^{3+} in non-complexing media is also strongly retarded by electrostatic repulsion. Using an (educated) estimate of 4×10^{-2} M^{-1} for the outer-sphere association constant under our conditions, the first-order rate constant of the outer-sphere precursor complex $[k_1 (k/K_0)]$ is $\approx 1.3 \times 10^3/0.04 = 3 \times 10^4 s^{-1}$. This value is by orders of magnitude too high for substitution at Fe^{3+}[15] or Mo^{3+}.[13] It has to be concluded, therefore, that this redox reaction proceeds by an outer-sphere path.

Finally, the rate constants for the formation of the inner-sphere complexes Mo(V)CNFe(II) from $Mo(CN)_8^{3-} + Fe^{2+}$ ($k_1 = 1.1 \times 10^6$ $M^{-1} s^{-1}$) and Mo(IV)CNFe(III) from $Mo(CN)_8^{4-} + Fe^{3+}$ ($k_{-3} = 2.7 \times 10^4$ $M^{-1} s^{-1}$) appear reasonable for substitution at $Fe(H_2O)_6^{2+}$ and $Fe(H_2O)_6^{3+}$, respectively, if the charge effects are taken into account. The electron transfer within the inner-sphere complex is fast, $k_2 + k_{-2} > 5 \times 10^6 s^{-1}$. This might have been expected, since cyano ligands are known to be very good electron-transferring groups. For instance, the outer-sphere reduction of $Mo(CN)_8^{3-}$ by $Fe(CN)_6^{4-}$ occurs with a second-order rate constant of 3×10^4 $M^{-1} s^{-1}$ and that of $Mo(CN)_8^{3-}$ by $W(CN)_8^{4-}$ with one of 5×10^6 $M^{-1} s^{-1}$.[20] Considering the charge type of these reactions (-3 and -4), the first-order electron-transfer rates within the encounter com-

plexes (i.e. through two layers of CN^- ligands) are estimated to be near 1×10^7 s^{-1} and 1×10^9 s^{-1}, respectively.

MOLYBDATES IN AQUEOUS CORROSION INHIBITION—III. EFFECTS OF MOLYBDATE IN THE ANODIC FILMING OF STEEL

A. J. BENTLEY,* L. G. EARWAKER,* J. P. G. FARR,† M. SAREMI and A. M. SEENEY

Department of Metallurgy and Materials and *Department of Physics, University of Birmingham, Birmingham B15 2TT, U.K.

Abstract—Molybdates inhibit the aqueous corrosion of steel. We show that molybdate can promote film formation, extend the anodic passive range, and lower the residual passive current. By *in situ* analysis for molybdenum on electrode surfaces we find that MoO_4^{2-} is adsorbed weakly but copiously in some films. The mechanism of corrosion inhibition by molybdates is discussed.

The literature on the effects of molybdate in the protection of steel from aqueous corrosion grows slowly. An overall view is obscured by the variety of experimental conditions adopted by different workers, and early fundamental work does not directly relate to probable situations in the field.[1] In Fig. 1 a brief comparison is presented of the anodic behaviours of mild steel prepared by: (i) etching (E), and (ii) metallographic polishing (A), and (iii) by cleansing without removing its native oxide (NO). Simulated cooling water (SCW) is used, containing realistic amounts of Cl^- and SO_4^{2-} in the aerated state.[2] In Fig. 2 it is shown that MoO_4^{2-} is an anodic passivator, effective even when the steel is in its more active condition. However, although promising, these effects are too mild to be of immediate use to the corrosion engineer; their significance is mechanistic.

In practice a wide range of corrosion inhibitors is applied to the protection of steel. Many inhibitors are filming agents, protecting the anodically polarised surface under specific conditions for film formation and maintenance, so that formulations for water treatment are rarely, if ever, simple. Nevertheless, examples can be presented of significant improvements in the passivation of steel by well-known and new film-formers, in conjunction with molybdate. Once the respective appropriate conditions for the formation and maintenance of the primary films are provided, the additional presence of molybdate has several general effects and therefore some common mechanisms can be sought. A summary of filming agents tested previously has been given elsewhere.[1] Further examples are given in Fig. 3.

Experiments have involved: (i) the measurement of test electrode potentials, (ii) linear sweep voltammetry,[3] (iii) a.c. electrode impedance measurements,[4] and (iv) surface analysis. Results show that molybdate can promote film formation, extends the anodic passive range and lowers the residual passive current; furthermore it reduces the trans-passive current and can induce the repassivation of pits when corrosive potentials are relaxed. However in *ex situ* analytical experiments only small amounts of Mo are found on electrode surfaces, especially those that have not undergone an active–passive transition.[3] It has now been possible to make *in situ* elemental analyses on test electrodes in a thin-layer cell, using proton-induced characteristic X-ray emission.[5] The technique is shown in Figs 4 and 5 and some results are presented in Fig. 6. It is found that MoO_4^{2-} is adsorbed weakly but copiously in some films, depending on the electrochemical conditions.

Some conclusions can be drawn regarding mechanisms of corrosion inhibition. First, the protectiveness of the composite passivating films in which MoO_4^{2-} is adsorbed is consistent with the effect of molybdate on the ion-selectivity of hydrous ferric oxide films in chloride solutions, demonstrated by Sakashita and Sato[6] (although adsorption probably involves the outer filming agent which is itself adsorbed on residual underlying metal oxide). The net effect is that a barrier is presented, under fairly specific conditions of pH, the presence of accompanying cations, and temperature, to aggress-

ive anions such as Cl^- and SO_4^{2-}. When pitting does occur the MoO_4^{2-} concentrated on the surface from considerable dilution in the bulk water is released by the establishment of cathodic potentials around the localized anodes. It concentrates within pits as do other anions and in a locally acidic environment[7] neutralizes Cl^- by the formation of oxysalts[4] or by stabilizing a chloride salt film.[8]

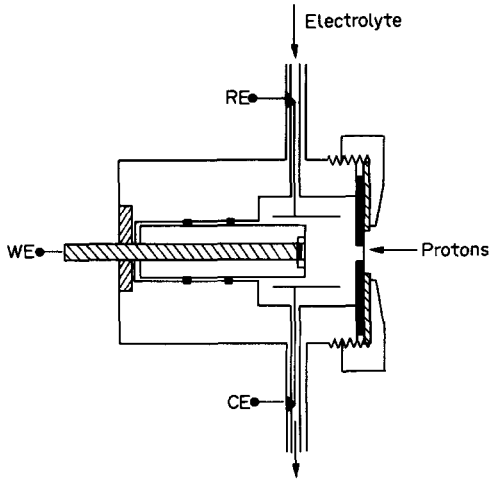

Fig. 4. Thin-layer cell for *in situ* analysis of electrochemically controlled surfaces (CESA). The working electrode (WE) is withdrawn to permit free circulation of dilute electrolyte. For analysis it is moved forward so that a thin (5-μm) electrolyte layer remains between it and the window. A titanium window functioned satisfactorily as a counter electrode (CE). RE = reference electrode.

(*Received* 1 *July* 1985)

Abstract—It has been nearly 50 years since molybdate compounds were first identified and used practically as corrosion inhibitors. They are now recognized as amongst the most broadly applicable of inhibitors chiefly because of their efficacy to protect both ferrous and nonferrous metals and their very low toxicity. This review summarizes fundamental and applied studies dealing with molybdate inhibition and includes descriptions of their practical applications. It also summarizes certain of their physical and chemical properties and emphasizes those environmental aspects relevant to their use in corrosion inhibition.

Corrosion-inhibiting[1] behaviour was first attributed to the molybdate anion in 1939. That year, two patents were issued which described the utilization of soluble molybdates in alcohol–water antifreezes to protect automobile cooling systems from corrosion.[2,3] While still used in antifreezes, molybdate corrosion inhibition has been extended to a diverse variety of other practical applications. Though many specific reports have been published on molybdate corrosion inhibition, the subject has received but a single brief review.[4] The present review is the first of a series that will cover both fundamental and applied aspects of molybdate inhibition, it includes a section on the environmental and regulatory factors which favour its commercial application.

PROPERTIES OF MOLYBDATES

Simple molybdates have the general formula M_2MoO_4, and contain the discrete tetrahedral ion MoO_4^{2-} in both their solid form and in aqueous solution. The chemistry and properties of Mo(VI) aquo ions are described elsewhere.[5–10] The simple alkali metal and ammonium salts, which are readily water-soluble, are most commonly used in corrosion inhibition. The calcium, zinc and strontium molybdates have only slight water solubility, but this property makes them attractive as corrosion-inhibiting paint pigments. In contrast to its congener Cr(VI), the simple Mo(VI) oxyanion is a very weak oxidant, a property rendering the simple molybdates compatible in most systems containing easily oxidized functional organic substances.

The tetrahedral simple molybdate species which is stable in neutral and alkaline solutions condenses and polymerizes upon acid hydrolysis to octahedral Mo_7 and Mo_8 species. The condensation occurs in definite steps and begins at approximately pH 6 to form the heptamolybdate ($Mo_7O_{24}^{6-}$) ion, which reaction is complete by pH 4.5. Between pH 2.9 and 1.5, condensation to $Mo_8O_{28}^{4-}$ is complete. At pH 0.9, the isoelectric point, molybdic acid ($MoO_3 \cdot H_2O$) precipitates, and at still lower pH the cationic dioxomolybdenum(VI) species (MoO_2^{2+}) forms. The type of molybdate species present in solution will vary with pH as indicated and also with concentration.[11]

Pourbaix[12] has used established equilibrium relations to develop potential–pH equilibrium diagrams for many metal–water systems at 25°C and

* Author to whom correspondence should be addressed.

included those for Mo and Fe. Kodama and Ambrose[13] superimposed these diagrams to show that simple molybdate is not an oxidizer of the ferrous ion, a conclusion arrived at experimentally in early studies by Robertson[14] and Pryor and Cohen.[15]

ENVIRONMENTAL ASPECTS OF MOLYBDATE USE IN CORROSION INHIBITION

Commercial acceptance of any inhibitor for a given application is dependent on a variety of techno-economic factors, and also on its environmental acceptability or safety. Molybdates are one of relatively few inorganic inhibitors not considered to be toxic pollutants. Because of this, and their efficacy, molybdates are increasingly being substituted for inhibitors such as chromate, nitrite, phosphate and borate.

Biochemical role

Molybdenum has long been identified as a micronutrient essential to plant life,[16,17] and as playing a major biochemical role in animal health as a constituent of several important enzyme systems.[18,19] Several studies have indicated that molybdenum-deficient diets may be associated with the incidence of various forms of cancer.[20–24]

Molybdenum toxicity

Unlike many other transition metals, molybdenum has been described as having an extremely low or even negligible toxicity.[25] Sax[26] reviewed molybdenum and states that "Molybdenum and its compounds are said to be somewhat toxic, but in spite of their considerable use in industry, industrial poisoning by molybdenum has yet to be reported." In a recent listing of the potential carcinogenicity of metal ions,[27] molybdenum compounds are shown in the lowest potentially carcinogenic category.

Molybdenosis in ruminants was identified in the early 1930s, and has since been explored extensively.[28] It was found that molybdenum was not causing a direct toxic effect in ruminants, but that high dietary molybdenum resulted in depleted body copper levels. The resulting malady was manifested as that of copper deficiency. Today, the molybdenosis risk in ruminants is routinely avoided by copper supplementation.[29] It has been shown that aquatic species, in general, are relatively insensitive to molybdenum from sodium molybdate. Bluegill, rainbow trout, channel catfish, fathead minnow, water flea and scud exposed to varying concentrations showed no effect at levels ranging from 1800 $mg\,l^{-1}$ for the water flea and scud to 7500 $mg\,l^{-1}$ for the channel catfish.[30]

The U.S. Occupational Safety and Health Administration[31] and the Mining Safety Health Administration[32] have adopted threshold limit values (TLV) for worker exposure to various airborne chemicals. The most recent TLV published by the American Conference of Government Industrial Hygienists 1984–1985[33] show the time-weighted average TLV for soluble molybdenum particulates as 5 $mg\ m^{-3}$ and for insoluble particulates as 10 $mg\,m^{-3}$. For comparison, the TLV for total particulates in the nuisance dust category is also shown as 10 $mg\ m^{-3}$.

Impact of federal regulations on molybdenum use

From an environmental perspective, five statutes, and their associated regulations, govern the use and disposal of chemicals within the United States. These are the Safe Drinking Water Act,[34] the Resource Conservation and Recovery Act (RCRA),[35] the Clean Water Act (CWA),[36] the Comprehensive Environmental Response Liability Act,[37] and the Toxic Substances Control Act (TSCA).[38] Molybdenum is not a regulated parameter under any of these statutes. The TSCA requires all existing chemical substances be registered. Sodium molybdate has been assigned a Chemical Abstract Service number of 7631-95-0 but has not been selected for toxicity testing. Under the RCRA, molybdenum is neither a listed hazardous waste nor a hazardous constituent. Section 311 of the CWA lists 299 substances as hazardous if spilled in waterways. No molybdenum compound is included.

In summary, sodium molybdate and other molybdates free of accompanying toxic elements or compounds, exhibit an environmental compatibility within the framework of their commercial utilization as a corrosion inhibitor.

APPLICATION OF MOLYBDATES IN CORROSION INHIBITION

The application of molybdates in corrosion inhibition is increasing rapidly. The purpose of this section is to indicate some significant fields; full reviews will be published elsewhere.

Engine coolants

Important early references are 2, 3 and 39. For the application to aluminium and its alloys see Refs 40–47. Antifreezes are covered in patents,[40,48–50] papers[43,47,51,52] and company specifications (e.g. Ref. 53).

Paints

The earliest relevant reference is to zinc tungstate;[54] molybdenum compounds were first used as pigments,[55] and much later for their corrosion inhibition.[56–67] Molybdates can also be usefully incorporated in to an anodized aluminium surface.[67–70] More recently inhibiting combinations of molybdate with other pigments have been developed.[71–82] There is an extensive literature on paint formulation.[61,67,83–117]

Cooling waters

Quite small quantities of molybdate have been reported to be effective in reducing the corrosiveness of cooling waters[56,118,119] and even brine.[56] To match the efficiency of chromate[120] a variety of synergistic systems have been tried.[121–166] This is a developing field with considerable challenges from the unhappy juxtaposition of incompatible alloys and metals and from the variable quality of cooling waters.

Metal-working fluids

Nitrite has been the established inhibitor of the rusting of machinery tooling and workpieces, often used with alkanolamines. It is now being replaced because of the risk of carcinogenic nitrosamine formation.[167] Molybdate allows the partial[168–170] or, in complex formulations, the complete replacement of nitrite[171–173] and it can be cost-effective.[174]

SYNERGISTS OF MOLYBDATE INHIBITION

In commercial practice combinations are used to take advantage of synergisms between inhibitors and to cope with multi-metal systems.

The molybdate–nitrite synergistic combination has been applied to engine antifreeze,[2] to open or fully aerated[127] and closed or partially de-aerated[151,163] recirculating cooling water, primer paints,[109] metal-working fluids[169,170,173] and coal-water slurries.[175] It was shown that the effect of molybdate in this combination was to reduce the critical current density and of nitrite to reduce passive current density during the inhibition of mild steel.[176] The pitting potential was also increased. Another study dealing with this combination showed oxygen is needed for the synergism to be operative, at a minimum concentration between 1 and 2.5 mg l^{-1}.[163]

Cathodic inhibitors are synergists of molybdate inhibition.[177] In neutral or alkaline solutions, these cations can stifle the cathodic reaction of the corrosion process, usually through the formation of an adherent, insoluble oxide, hydroxide or carbonate film. Ni^{2+}, Mn^{2+} and, most efficiently, Zn^{2+} synergize molybdate inhibition of steel in aerated, neutral and alkaline cooling tower water.[135] Ca^{2+}, another cathodic inhibitor usually present as hardness in cooling water, significantly increased the corrosion protection of steel already synergistically inhibited with MoO_4^{2-}–Zn^{2+}.[128] Anodic–cathodic polarization curves for steel in a neutral, low-hardness cooling water are shown in Refs 157 and 176, Zn^{2+} produces an increase in the slope of the cathodic curve, but the synergism is evident from a noble shift in the critical potential for passivation even though the passive region remains unaffected. It was proposed that Zn^{2+} adsorbs and blocks the cathodic sites as proposed previously[178] for Zn^{2+} in dilute acid solution.

Numerous other substances have been identified as synergists of molybdate inhibition. Among these are the copper alloy inhibitors benzotriazole and tolyltriazole. The corrosion inhibition of steel and aluminium in cooling water were found to be synergized with either triazole used with molybdate at weight ratios of between 1:2.5 and 1:5, respectively.[130] The molybdate–triazole combination has also been used to protect ferrous and nonferrous metals in automotive antifreezes.[39] Chromate strongly synergizes the molybdate inhibition of both ferrous and nonferrous metals[118] and this combination is still used in some cooling-water treatments in locales where a low level of chromate is tolerable. Another widely used synergistic combination is molybdate–organic phosphonate.[127,128,134,138,142,164,179–181] A further benefit was found to be derived when inorganic phosphate and benzotriazole were added to the molybdate–organic phosphonate.[182] Inorganic phosphates themselves are also synergistic with molybdate.[156] Equal weight parts of either sodium tripolyphosphate ($Na_5P_3O_{10}$) or hexametaphosphate [$(NaPO_3)_6$] and sodium molybdate were reported to be more protective of steel than these phosphates with chromate.[183] Finally, many examples are reported of organic inhibitors that are synergistic with molybdate for the protection of ferrous and nonferrous metals.[155,169,170,173,174]

THE MECHANISM OF THE INHIBITION OF CORROSION OF STEEL BY MOLYBDATE

An understanding of the effects of molybdate in promoting or providing inhibition in the field

depends on the establishment of a laboratory phenomenology to match the industrial experience that has been reviewed in previous sections. Extensive laboratory work is necessary to identify the controlling factors in particular situations of corrosion or protection, to form a basis for a diagnostic approach to "real" situations. Progress has been slow; at present, model experiments and existing theory permit useful discussion of corrosion inhibition by molybdates, *inter alia*, on steel in neutral and alkaline aqueous systems containing mild oxidants.

Phenomenology

Surface. The steel surface that is merely degreased and thoroughly washed retains its "native" oxide. This is not an ideal start-point for a purely electrochemical experiment but it is realistic and therefore it is considered here. On mild steel the native oxide may be up to 0.1 μm thick and its composition and structure is still a matter for research. Earlier work was oriented towards the identification of Fe_2O_3 and Fe_3O_4 crystalline phases in aged oxide layers.[184] Recently there has been a growing interest in the non-crystalline or "gel-like" parts of the surface film. Thus X-ray absorption fine structure experiments[185,186] suggest a marked difference between *in situ* formed films and *ex situ* structures. There is agreement with results from the use of other techniques,[187–190] notably Mössbauer spectroscopy, that films formed in moist air contain hydrogen or hydroxyl and that desiccation and increasing crystallinity are features of ageing.[186] The product of an electrolytic active–passive transition is a gel-like structure approaching FeO·OH molecular composition.[191] There is some agreement on the absence of Fe(II) in such films. The difference between such electrochemically passivated films and the "native" oxide seems largely in the degree of crystallinity; the native oxide undoubtedly contains variable proportions of crystalline to uncrystalline FeO·OH and some hydration; furthermore it may have a variable porosity due to its history of ageing and desiccation.

There are, therefore, three distinguishable experimental situations:

(i) The active–passive transition, which involves the filming of an initially oxide-free surface at a critical potential or current. Molybdate and any co-reagents may interact with the anodic steel surface (which is likely to be hydroxylated in both acid and alkali[192–195] or they may effect the solubility of the initially formed Fe(II) species.

(ii) Where the passivation is by formation of a gel-like FeO·OH film, molybdate and co-reagent may be incorporated from its initiation, or in a subsequent process.

(iii) The modification of an existing native oxide, as must often occur in "real" situations.

Electrochemistry. The cathodic effect of Mo(VI) appears to be insignificant in corrosion or its prevention. Its behaviour as an anodic inhibitor, especially in conjunction with other "primary" film formers, is manifest[196,197] in:

(i) measurements of corrosion potentials;

(ii) potentiostated current–voltage measurements, including linear sweep voltammetry; and

(iii) a.c. impedance measurements.

With some reservations, it is concluded[196,197] from laboratory experiments that:

(i) Mo(VI) promotes the passivation of active steel, by more effective film formers than itself;

(ii) it reduces the passivation current, i.e. the leakage current through the passivating film;

(iii) it extends the anodic passive range, i.e. it shifts the pitting potential to more anodic values; and

(iv) it promotes the repassivation of the pits produced during anodic excursions in to transpassivity.

Presence of Mo *on the surface.* The detection and estimation of molybdenum in surface films on metals, including steel, has proved difficult. XPS, Auger Spectroscopy, SIMS and Rutherford backscattering of α-particles have been applied successfully *ex situ*.[152,156,198,199]

It seems generally true that, from whatever inhibitor formulation, most Mo is found on steel surfaces that have undergone active–passive or passive–active transitions. Mo yields on previously passivated surfaces soaked in Mo(VI)-bearing water have been low, regardless of the *ex situ* analytical techniques applied. Recent *in situ* analyses,[200] have shown that this is because Mo(VI) is weakly, if copiously, adsorbed; there are considerable handling losses *in ex situ* analyses.

Mechanism

Molybdate. There is no evidence at present that Mo(VI) modifies the kinetics or dissolution mechanism of active, film-free iron. It seems likely that the promotion of active–passive transition is due to the early formation of insoluble Fe(III) molybdate which contributes to the necessary electrode polarization.[12]

Impedance measurements, in particular, show that Mo(VI) stabilizes the native oxide on unetched

steel. This oxide is slowly dissolved by aggressive cooling waters; but the electrode impedance actually increases in the presence of molybdate. Various theories have been proposed to account for this.[201–204] Currently there is acceptance that molybdate is adsorbed on the porous oxide surface, probably by processes of ion exchange. This adsorption produces a layer impermeable to other anions, particularly to Cl^- and SO_4^{2-}. The theory, whilst plausible, has limited experimental support.[191,205] However, it is consistent with much that is known about the adsorption of anions and cations on FeO·OH mineral species.[206,207] The nature of the oxide surface is subject to on-going research. There is dispute concerning the extent to which associated water is structured, the significance of porosity, the identification of adsorption sites and the nature of the adsorption bond.[208–213] For the present purpose, agreement that the isoelectric point for FeO·OH is about or above pH 8 suggests that moderate alkalinity is necessary to optimize MoO_4^{2-} ion exchange. It may also be concluded that the usefulness of Mo(VI) in the absence of co-passivators should not be underrated. That Mo(VI) is not a strong passivator does not exclude it from being effective in improving the barrier properties of oxide or, indeed, other films.

Molybdate with other film formers: synergism. The behaviour of molybdate in conjunction with other film-forming agents is more difficult to discuss because the surface chemistries of these substances are specific and there may also be complexing between Mo(VI) and other electrolyte species. Often, usefully synergistic compounds provide a primary passivating film more readily than does Mo(VI) on its own, or even in the presence of oxidant. Given the correct chemical conditions, the addition of molybdate promotes primary film formation, reduces the passive current (i.e. increases the impedance of the passivated surface) and extends the anodic range of passivation. Very much better barrier films than the Mo(VI)-bearing native oxide are obtained on mild steel. Usually the chemistry of filming involves the deposition of the filming agent on to native oxide. However with some surface-active chelating agents, the native oxide seems to be displaced and thinner passive films result.[214] The behaviours of citrate and phosphate, each in the presence of Mo(VI), contrast interestingly.[157] Very protective but thin films are obtained with citrate; good protection with Mo(IV)–orthophosphate involves much thicker layers.[120,122,157] It appears impossible to generalize about the interaction of Mo(VI) and the primary film formers; nevertheless, in many cases it seems that the improvement in passivation does come from such interactions rather than from exchange on the surface of underlying oxide as previously described. Again the Mo(VI) is held weakly and is readily released by perturbations in the electrode conditions.

Molybdate in anodic pits. It is common to all the Mo(VI)-passivated systems explored in the transpassive condition (with or without synergists) that Mo is readily found in pits, by *ex situ* analytical techniques. Such observations have been made in corrosion experiments conducted up to 250°C.[215] The molybdenum species in pits are agreed to be inhibiting, slowing down pit growth and presumably ensuring that some incipient pits do not reach a critical condition for continued growth. A general mechanism of inhibition is not agreed. Adsorption of molybdate on the pit wall is supported in Sugimoto and Sawada[216] and Kodama and Ambrose.[217] However conditions in an active pit are conducive to the accumulation of molybdate with, for example, Cl^-, and to low pH. A pH of 3.5 within a pit has been reported[218] for an external, bulk pH from 2 to 10. In more concentrated neutral NaCl solutions the pit pH has been reported[219] to be below 1.0, and the Cl^- concentration rose to 6.2 M. These conditions are consistent with the formation of molybdochloride that may hydrolyse to a molybdate-stabilized oxide film when the anodic pitting condition relaxes.[215,220]

Thus the repassivation of steel in the presence of molybdate involves transfer of the anion from its accumulation in surface films, to the pit. One may speculate that release from the composite film is due to the establishment of cathodic conditions around the pit.[221]

THE NATURE OF AMIDE LIGATION TO THE METAL SITES OF FeMoco

M. ANTON WALTERS, STEPHEN K. CHAPMAN and WILLIAM H. ORME-JOHNSON*

Department of Chemistry, Massachusetts Institute of Technology, Cambridge, MA 02139, U.S.A.

(*Received* 18 *June* 1985)

Abstract—The nature of the ligation of *N*-methylformamide (NMF) to the metal sites of FeMoco has been investigated. The IR spectrum of FeMoco in NMF shows an intense band at 1600 cm^{-1} which we assign to the ν(C=O) stretch of ligated NMF. This frequency is characteristic of *N*-deprotonated amide ligands, indicating that NMF ligation to FeMoco is predominantly through nitrogen. Hence NMF behaves as an anionic ligand. The importance of the amide functionality for FeMoco extraction has been further examined and a new extracting agent, 2-pyrrolidinone, has been employed. We hypothesize that, in the MoFe-protein, the primary coordination of the cofactor is via deprotonated backbone amide ligands.

Nitrogenase catalyses the reduction of dinitrogen to ammonia. The enzyme system consists of two separately purifiable proteins; the MoFe-protein and the Fe-protein.[1] The MoFe-protein (which has a molecular weight of about 240,000 and an $\alpha_2\beta_2$ subunit pattern[2]) contains two iron–molybdenum cofactors known as FeMoco.[2] The composition of FeMoco has been reported to be $MoFe_6S_{8-9}$.[3] FeMoco was first isolated by Shah and Brill[4] by extraction from acid-denatured MoFe-protein into *N*-methylformamide, NMF. Until now NMF and formamide have been the only extracting agents which reliably separate FeMoco from the MoFe-protein. We have investigated why NMF is so successful in the extraction of FeMoco, and report here on vibrational studies designed to elucidate the manner in which NMF ligates the metal sites of FeMoco. Based on our results we have developed a hypothesis as to the properties essential for extraction of the cofactor from the MoFe-protein.

The amide I [ν(C=O)] band of secondary amides is estimated to have a potential-energy distribution of 70–80% pure C=O stretch.[5,6] It is, however, coupled to the central C—N stretch and the N—H stretch, and can be affected, via electron delocalization, by hydrogen bonding[5–7] or deprotonation[8–10] of the amide nitrogen. The ν(C=O) band is observed in the range 1680–1630 cm^{-1} in the solid and liquid states of the pure secondary amide, and 1700–1650 cm^{-1} in dilute non-hydrogen bonding solution. These ranges are characteristic of both the *cis* and *trans* forms of secondary amides.[5] Vibrational studies of metal–amide complexes have shown that the ν(C=O) frequency is sensitive to the type of ligation of amides, which sometimes exhibit linkage isomerism. Using the carbonyl stretching frequency as a marker band in Fourier-transform IR (FT-IR) experiments, we reported here on the nature of the amide–metal bond in the NMF-extracted FeMoco where NMF acts as a solvent and as a ligand[11] for the cofactor metal centers.

MATERIALS AND METHODS

Anaerobicity

Manipulations of FeMoco were carried out either in a Vacuum/Atmosphers model M040-1 glove box (helium atmosphere) or by Schlenck line techniques. Unless otherwise specified, solutions of FeMoco were 1 mM in sodium dithionite. Stock 1 M sodium dithionite solutions were 0.25 M in potassium hydroxide.

Cell growth and protein purification

In this work, the conditions for growth and derepression of nitrogenase synthesis in *Azotobacter vinelandii* were as previously described.[1] A *nif B* mutant of *Klebsiella pneumoniae* (used to provide *nif B*$^-$ MoFe-protein for FeMoco assays) was grown using medium (b) described by Hawkes and Smith.[12] Nitrogenase proteins were purified (with minor modifications) and assayed by previously published procedures.[1]

FeMoco extraction, concentration and characterisation

FeMoco was isolated using modifications of methods already described.[3,4] All solutions were 2 mM in sodium dithionite, and maintained at 4°C where possible. Solutions were thoroughly vortexed at each step to ensure complete mixing. Purified MoFe-protein [40–50 mg in 0.5 cm^3 of 0.025 M Tris–HCl (pH 7.4), 0.25 M NaCl] was diluted six-fold in doubly distilled water. To this solution was added 0.1 cm^3 of 1.0 M citric acid, whereupon the solution turned green. After 3 min the solution was neutralized by the addition of 0.4 cm^3 of 0.5 M Na_2HPO_4, causing the protein to precipitate. After ~30 min the protein was separated by centrifugation at ~120 *g* for 10 min. The (colourless) supernatant was removed and the pellet resuspended in 0.5 cm^3 of dimethylformamide (DMF) (Aldrich) by vortexing for ~5 s. The protein was again separated by centrifugation (~600 *g* for 10 min) and the DMF wash repeated. After DMF washing, 0.5 cm^3 of NMF (Aldrich) was added and the sample vigorously vortexed for ~5 min and chilled in an ice bath for 5–10 min. The protein was removed by centrifugation (~1400 *g* for 10 min) and the clear green coloured FeMoco solution collected. The NMF extraction step was repeated twice after which no further colour was observed in the extract. The extracted FeMoco was concentrated to 0.2–0.3 cm^3 using a vacuum distillation procedure already described,[1] and then filtered to remove solid impurities. Extractions using 2-pyrrolidinone (Aldrich) were carried out as above but at room temperature because of the higher melting point of this amide (20°C). 2-Pyrrolidinone was recrystallized before use.

For FT-IR experiments, NMF-extracted FeMoco samples were concentrated either to dryness or almost to dryness on zinc selenide plates using vacuum distillation. Typical solutions were ~0.3 mM in FeMoco, 2.0 mM in sodium dithionite, and 0.5 mM in potassium hydroxide, before concentration. Fully desalted samples (no dithionite or potassium hydroxide present) were prepared by passage of the concentrated FeMoco solution down a Sephadex G-10 (Pharmacia) column equilibrated with degassed NMF.

Specific activities of FeMoco were determined by enzymatic assays of reconstituted *nif B*$^-$ Kp1 (crude extract). Activities of FeMoco used for FT-IR experiments were in the range 180–220 nmol C_2H_2 reduced min^{-1} (nmol Mo)$^{-1}$. Samples used for FT-IR studies displayed the characteristic FeMoco EPR spectrum. Fe/Mo ratios for FeMoco were determined by atomic absorption spectroscopy as previously described,[3] and were found to be in the region of 7–8 for most samples.

Preparation of sodium NMF (NaNMF) and N-deuterated NMF

NaNMF, $NaHC(O)NCH_3$, was prepared by the method of Fones:[13] 1 g (17 mmol) of NMF was added to sodium dried xylene under nitrogen. To this 0.4 g (17 mmol) sodium hydride was added and the mixture refluxed overnight under nitrogen. The product was washed with ethyl ether, vacuum dried and stored in a dry box. Yield 89%. Calc.: C, 29.6; H, 5.0; N, 17.3; Na, 28.3%. Found: C, 29.3; H, 4.7; N, 17.0; Na, 28.1%.

N-deuterated NMF, $HC(O)NDCH_3$, was produced by the addition of 3.0 ml D_2O to 6.6 g NMF followed by distillation to remove H_2O and HOD. This was repeated three times yielding a product for which >95% H–D exchange was determined by ^1H NMR (methyl group singlet at 2.8 ppm) and IR [ν(N—D) 2471 cm^{-1}].

FT-IR studies: instrumentation and procedures

IR spectra were recorded at 2-cm^{-1} resolution using Nicolet 7199 and 60SX FT-IR spectrometers, with KBr optics and MCT detectors. During data collection, sample cells were maintained at room temperature in a dry-air or nitrogen-purged atmosphere. For studies involving NMF-extracted FeMoco, anaerobic cells with zinc selenide windows (Harrick Scientific) were used. All other data were obtained using demountable cells with sodium chloride windows.

RESULTS AND DISCUSSION

The spectrum of the FeMoco–NMF complex prepared as a dry film in an IR cell is shown in Fig. 1. The vibrational bands above 2000 cm^{-1} are assigned to predominantly N—H and C—H stretching vibrations based on a simple group frequency analysis. The broad band at 3246 cm^{-1} appears in the region where ν(N—H) of amides and ν (O—H) of hydroxyl generally occur.[14] When NMF is replaced by exchange with N-deuterated NMF, or when the

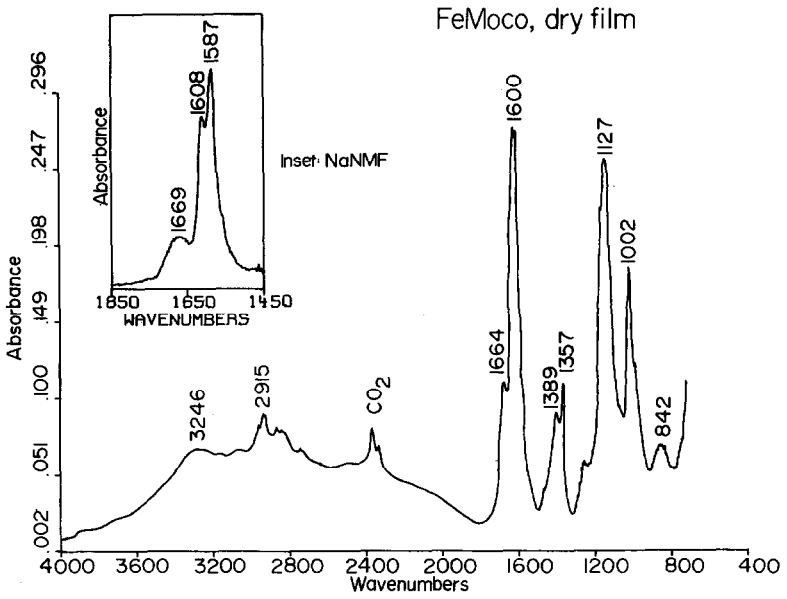

Fig. 1. FT-IR spectrum of FeMoco–NMF complex, 2-cm^{-1} resolution. The sample was prepared as a dry film on the inner face of one of the zinc selenide windows of an anaerobic sample cell. Inset: FT-IR spectrum of NaNMF as a Nujol mull.

FeMoco solution is desalted chromatographically on a Sephadex G-10 column, the positions of the bands above 2000 cm^{-1} are unaffected. Similarly, these bands appear in the spectra of FeMoco solutions isolated from MoFe-protein in either D_2O or H_2O buffer. Accordingly, the 3246-cm^{-1} band is tentatively assigned to a ν(N—H) stretch, possibly from an amino acid, which may be present in preparations of FeMoco obtained by the methods employed in this study. The weak, sharp peaks in the 3000-cm^{-1} region are due primarily to the formyl and methyl C—H stretching vibrations of NMF.[6]

The FeMoco–NMF complex exhibits a prominent vibrational band at 1600 cm^{-1} in its IR spectrum indicative of NMF bonding as an *N*-deprotonated, *N*-bound ligand to certain of the metal centers of FeMoco. Support for this assignment is provided by numerous spectroscopic investigations of transition-metal–amide complexes. In a study of a series of cobalt(III) pentaamine–amide complexes which included two linkage isomers of formamide (Table 1), Balahura and Jordan[10] reported a large ν(C=O) frequency decrease of 65 cm^{-1} (relative to free hydrogen bonding NMF) for one complex with formamide as an *N*-bound, *N*-deprotonated anionic ligand. For other complexes incorporating neutral DMF or formamide, ν(C=O) differed little from the carbonyl frequencies of the free ligands. The large frequency decrease in the *N*-bound anionic ligand was attributed to an enhanced contribution from the resonance structure incorporating an N=C—O^- linkage. A similar explanation for the lowering of a carbonyl stretching frequency was presented by Rosenberg[15] and Kieft and Nakamoto[9] in their studies of bis(glycinamido)copper(II) monohydrate. The occurrence of NMF as a deprotonated anionic ligand in the FeMoco–NMF complex is consistent with the suggestion by Yang *et al.*[11] that NMF in alkaline media is more effective than acidic NMF in extracting FeMoco from its protein matrix. The weak band at 1665 cm^{-1} is likely due to excess NMF solvate judging from its frequency and the decrease in its intensity with extensive sample drying. It may however arise from a normal mode of anionic NMF since the intensity pattern of the carbonyl region

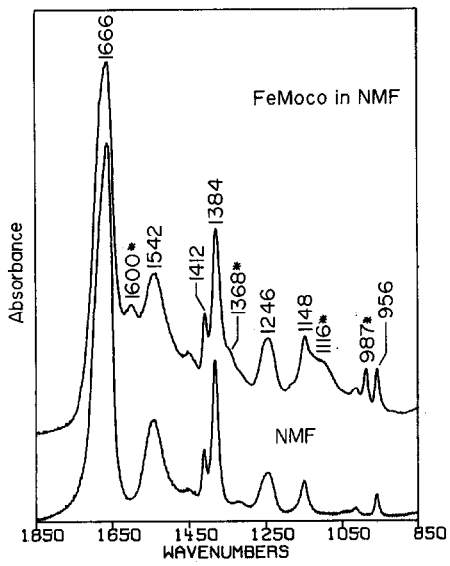

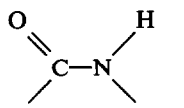

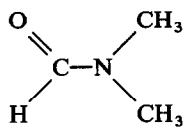

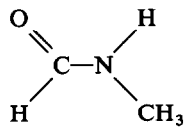

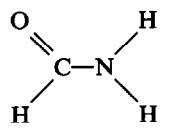

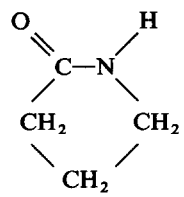

Fig. 2. Top: FT-IR spectrum of FeMoco in NMF, 2-cm^{-1} resolution. The sample was prepared as a liquid film and placed as in Fig. 1. Asterisks denote vibrational bands unique to the FeMoco–NMF complex. Bottom: FT-IR spectrum of NMF solution used for the preparation of FeMoco sample.

bands appearing in the spectrum of the FeMoco–NMF complex bear a resemblance to those of NaNMF (Fig. 1).

Bands occurring in the region below 1600 cm^{-1} cannot be assigned in detail without recourse to a normal-mode analysis. Further isotopic labeling studies currently underway should aid in this effort. However, we assign the intense band at 1127 cm^{-1} to dithionite or one of its reaction products. This follows from the observation that the 1127-cm^{-1} band is not seen in desalted samples in which dithionite has been removed.

Significantly, after anaerobic NMF extraction of FeMoco, the nature of NMF bonding was found to be independent of the physical state of FeMoco. The carbonyl stretching frequency was identical for FeMoco prepared as a dry film either under fully anaerobic conditions or after prolonged exposure to oxygen prior to drying, despite the fact that rapid and complete activity loss occurs upon exposure of FeMoco to air. Typically, we found that samples of the cofactor could not be resuspended in NMF after they had been taken to dryness. In a somewhat more demanding experiment, an NMF solution of FeMoco was concentrated on a zinc selenide IR plate resulting in a liquid thin film which could be rediluted for cofactor specific activity measurements following IR data acquisition. The data obtained in this manner are shown in Fig. 2 along with a solvent reference spectrum. The bands unique to the FeMoco solution spectrum are the same as those observed in the dry film spectrum, indicative of *N*-bound anionic NMF ligation to FeMoco in the

Table 2. Extractants for FeMoco

		Required for extraction
DMF		Does *not* extract
NMF		Extracts well
Formamide		Extracts poorly
Pyrrolidinone		Extracts well

solution state. A 30% decrease in FeMoco specific activity was recorded following IR measurements, most likely the result of oxygen damage. This, however, does not alter the conclusions about the mode of NMF bonding to FeMoco.

The results of our vibrational studies on NMF-extracted FeMoco suggested that other primary and secondary amides should be suitable for the extraction and stabilization of FeMoco. Support for this has been provided by the successful extraction of FeMoco using the cyclic amide 2-pyrrolidinone. The extraction of FeMoco from acid-denatured protein using 2-pyrrolidinone (at 25°C) works equally as well as NMF. In parallel experiments the yields of recovered FeMoco were almost the same (varying between 50 and 70% in both cases) for NMF and 2-pyrrolidinone extracts. Using 2-pyrrolidinone, an average Fe/Mo ratio of 7 ± 1 was obtained for FeMoco extracts. The average specific activity of these samples was 190 ± 30 nmol C_2H_2 reduced min^{-1} (nmol of Mo)$^{-1}$. Both the Fe/Mo ratio and average activity of FeMoco in 2-pyrrolidinone are identical to the values found for FeMoco in NMF (see Materials and Methods for Fe/Mo ratio and activity of NMF-extracted FeMoco samples). Cofactor extracted using 2-pyrrolidinone also exhibits an EPR spectrum identical to that obtained by NMF extraction.

The fact that the cyclic amide 2-pyrrolidinone is able to extract FeMoco indicates that other amides should also be suitable. Presumably the pK_a of the neutral amide is important in this context, and may help to explain why formamide extracts less well than NMF and 2-pyrrolidinone. A summary of the amides used in FeMoco extractions is shown in Table 2.

In conclusion, it would appear from our vibrational studies that NMF is ligated to FeMoco via deprotonated nitrogen, thus contributing significantly to the overall negative charge of the FeMoco–NMF complex. An earlier report[11] suggesting that NMF is the predominant ligand of isolated FeMoco is consistent with the results of this work, but we cannot rule out the occurrence of additional ligands. Further, it has been shown that, in addition to NMF, other secondary amides, e.g. 2-pyrrolidinone, are readily able to extract FeMoco. The results of FT-IR and extraction experiments have implications for the nature of FeMoco binding in the protein. We suggest that FeMoco resides in a protein site where it is bound by deprotonated backbone peptide nitrogens. Work is in progress on this topic. The suggestion of deprotonated amide coordination by the protein is of course very different to the type of binding of 4Fe–4S clusters, for example, which are typically held in the protein by thiolate linkages. Rawlings *et al.*[16] reported that, based on EPR measurements, benzenethiol binds to cofactor, and Burgess *et al.*[17] have quantiated this at one thiolate per Mo atom. The occurrence of FeMoco coordination to the protein via deprotonated peptide nitrogens, a novel feature in proteins, as well-precedented in the coordination chemistry of transition-metal ions.[18]

(*Received* 4 *July* 1985)

Abstract—Structural, oxidation–reduction and compositional probes of the iron–molybdenum cofactor (FeMoco) from the MoFe protein of *Azotobacter vinelandii* nitrogenase have been undertaken, via a variety of physicochemical techniques, to gain insight into the nature of this entity. Using highly concentrated (> 1 mM) solutions of extruded FeMoco in *N*-methylformamide (NMF), details of its oxidation–reduction behavior have been garnered for the first time. A combination of cyclic voltammetry, potentiometry and electron paramagnetic resonance (EPR) spectroscopy has shown that, of the two "quasi-reversible", couples observed, the more-positive couple (at *ca* −0.3 V vs NHE) corresponds to the "oxidized"-to-"semi-reduced" change as demonstrated by the production of the unique $S = \frac{3}{2}$ EPR signal of FeMoco on titration through this couple with aliquots of aqueous dithionite. Plots of EPR intensity vs added electrons and Nernst plots of these data are consistent with the involvement of a single electron in this process. The more negative couple at *ca* −1.0 V may well involve the substrate-reducing state of FeMoco. No synthetic Mo–Fe–S–O compound has yet been found which duplicates these electrochemical properties. X-ray absorption spectroscopy studies at the Mo *K*-edge of similar highly concentrated FeMoco solutions have produced high-quality data in terms of the near-edge (XANES) spectra. Comparisons with similar data sets from FeMoco bound within the protein matrix indicate some (but not radical) structural flexibility or variability around the Mo site. The XANES of a variety of synthetic Mo compounds, which fall into three major categories: (i) Mo in an approximately tetrahedral environment, e.g. $[Fe(MoS_4)_2]^{3-}$, which exhibits two inflection points on the Mo absorption edge at *ca* 20,004 and 20,010 eV; (ii) Mo in all-sulfur, pseudo-octahedral environment, e.g. the dicubane $[Mo_2Fe_6S_8(SEt)_9]^{3-}$, which has a single inflection point at *ca* 20,010 eV; and (iii) Mo in a mixed sulfur–oxygen, pseudo-octahedral environment, e.g. $[Mo_2Fe_6S_8(SEt)_6(OMe)_3]^{3-}$, which has two inflection points at *ca* 20,012 and 20,020 eV, have also been obtained. The XANES of FeMoco, both within and outside the protein, show a marked similarity to those of compounds of the third category, indicating Mo nearest neighbors of 3O (or N) and 3S from anionic ligands. These results are consistent with the structural data derived from the deconvolution of the EXAFS of similar extruded and protein-bound FeMoco samples. Oxidative decomposition studies of isolated FeMoco are also consistent with a coordination environment of only three S atoms around Mo.

* Author to whom correspondence should be addressed.

The iron–molybdenum cofactor (FeMoco) is the extruded, putative N_2-reducing site of the enzyme nitrogenase.[1] The MoFe protein component of nitrogenase contains two such cofactors, each of which accounts for one Mo, *ca* 50% (six–eight atoms) of the Fe and probably eight or nine S atoms[2–4] arranged in a cluster, so far unrecognized elsewhere in biology.[3–10] Structural, oxidation–reduction and compositional probes of the FeMoco from the MoFe protein of *Azotobacter vinelandii* nitrogenase have been undertaken, via a variety of physical and chemical techniques, to gain insight into the nature of this entity. These probes include a combination of cyclic voltammetry, potentiometry and electron paramagnetic resonance (EPR) spectroscopy, X-ray absorption spectroscopy (XAS) and the oxidative elicitation and trapping of thiomolybdates.

Inasmuch as a major function of FeMoco is to transfer electrons to the substrate, experiments designed to characterize its electrochemical behavior have been undertaken both to determine the extent to which the redox properties of extruded FeMoco correlate with those of FeMoco bound within the intact MoFe protein and to establish correspondence between oxidation levels and spectroscopic properties. Herein, the redox properties of isolated FeMoco, as characterized by both cyclic voltammetry (CV) and chemical redox titrations with voltammetric, potentiometric and EPR spectroscopic monitoring, are discussed.[11] As part of our continuing XAS studies of the Mo environments in nitrogenase,[6,12] good quality Mo *K*-edge X-ray data have been collected for both the dithionite-reduced state of the MoFe protein and free FeMoco and a variety of Mo compounds, including bimetallic clusters of several structural types. These XANES of FeMoco and the synthetic clusters are compared and, together with the EXAFS data, provide a more detailed insight into the structure at the Mo site of the native cluster. These compositional insights are in line with the results of the oxidative decomposition of FeMoco, in the presence and absence of trapping agents, when trithiomolybdate is elicited.

EXPERIMENTAL

Materials

The synthetic Mo compounds were prepared by methods in the indicated literature references.

The MoFe protein of *A. vinelandii* was purified to homogeneity as described previously.[13] The specific activity of the protein samples used was always >2000 nmol C_2H_2 reduced min^{-1} (mg protein)$^{-1}$.

FeMoco was prepared from such protein by the large-scale HCl–NaOH modification[3] of the original isolation method.[2] *N*-methylformamide (NMF) extracts were concentrated either by vacuum distillation[13] followed by centrifugation to separate solid material or by column chromatography on DE-52 DEAE cellulose (Whatman) in NMF.[11] Sample solutions had [Mo] = 0.6–1.7 mM, Fe/Mo = 6.05–7.10, and activities in the UW45 reconstitution assay[2] of 224–276 nmol C_2H_2 reduced min^{-1} (ng-atom Mo)$^{-1}$. All sample solutions were 1–2 mM in $Na_2S_2O_4$. Sample integrity was monitored by activity determinations, which revealed $<10\%$ decrease after XAS and electrochemical measurements. Similarly, the before and after EPR spectra (at 10 K) were virtually identical and corresponded to those of previous preparations.[3,9]

XAS measurements

All data were acquired at the Stanford Synchrotron Radiation Laboratory under dedicated synchroton radiation production conditions. Spectra were calibrated with Mo foil, with the first inflection point in the edge absorption spectrum taken as 20,003.9 eV. Synthetic compounds were measured as solids at ambient temperature. Spectra of MoFe protein and FeMoco samples were obtained in aqueous buffer at 2–4°C and NMF solutions at -15 to -25°C, respectively. All measurements were performed under anaerobic conditions. Second derivatives of the absorbance vs energy were obtained by differentiation of a third-order polynomial fit to the data over an interval of ± 3.5 eV on each side of a data point.

Electrochemistry and chemical redox titrations

CV and chemical redox titrations were conducted in a small-volume (100 cm^3) cell that consisted of a Teflon collar threaded onto the shaft of an inverted glassy carbon (working) electrode (Bioanalytical Systems, West Lafayette, IN). A Pt wire auxiliary electrode was inserted through the Teflon collar. The reference electrode, a miniature Ag–AgCl (1M KCl) electrode (MI-401, Microelectrodes Inc., Londonderry, NH), was immersed directly in the sample solution at the time of measurement. The Teflon cell was evacuated for 12–24 h in the antechamber of the glove box before use. About 50–75 cm^3 of FeMoco solution was transfered to the cell for electrochemical measurements. For chemical titrations, appropriate quantities of aqueous 0.02 M $Na_2S_2O_4$ were mixed with aliquots (350-cm^3) of FeMoco solution. Sixty microliters were then transferred to the electrochemical cell and the

remainder to a matched quartz EPR tube and frozen 10 min after dithionite addition. The equilibrium potential was determined by measuring the potential difference between the glassy carbon and Ag–AgCl electrodes. Cyclic voltammograms were generated with a Bioanalytical Systems CV-1B potentiostat. All electrochemical and recording equipment was connected to the cell by shielded cable passing through an air-tight seal in the glove box. Except as noted, all potentials have been corrected to NHE.

Oxidative decompositions

Two experimental protocols were used. In a typical dioxygen-titration experiment, FeMoco (4 cm^3 of an NMF solution of 50–60 μM in Mo) in a suitable spectroscopic cell was treated with successive measured aliquots (100–350 cm^3) of air. The visible spectrum (350–800 nm) was monitored until invariant after each addition and then recorded. The final treatment of all samples was bubbling with dioxygen for 2 min. Again, a final spectrum was recorded, when stable. In all cases, visible absorption bands at 465 and 395 nm were observed, consistent with the formation of $[MoOS_3]^{2-}$.

The second procedure involved mixing aliquots of chromatographically purified FeMoco (300–500 cm^3 of a >1 mM in Mo anaerobic NMF solution) with an excess of $(Ph_3P)_2CuNO_3$ (10 mg) in acetonitrile in air. Red, but poorly formed, crystals developed after several days at 5°C to leave a colorless solution. Visible (λ_{max} 380 nm in $CHCl_3$) and IR [ν(Mo=O) 910 cm^{-1}, ν(Mo—S—Cu), 445, 452 cm^{-1}] spectroscopy are consistent with the cubane[14] formulation $[OMo(CuPPh_3)_3S_3Br]$.

RESULTS AND DISCUSSION

Oxidation–reduction properties

The FeMoco within the protein exhibits three oxidation states: (i) FeMoco(s-r), the EPR-active, $S = \frac{3}{2}$ semi-reduced form that is produced and maintained in the presence of excess $Na_2S_2O_4$; (ii) FeMoco(ox), with $S = 0$ and EPR-silent, prepared by dye oxidation of FeMoco(s-r); and (iii) FeMoco(red), the integer spin, EPR-silent, substrate-reducing state, achieved only in the full nitrogenase system.[15–17] The MoFe protein does not exchange electrons directly with an electrode, but requires redox mediators, such as the viologens.[17] Even then, its redox couples exhibit considerable hysteresis. The average potentials for the two couples in the *A. vinelandii* MoFe protein are -0.17 and -0.465 V vs NHE,[17] although the latter, being the substrate turnover potential, may be too positive because it neglects any contribution from the energy-yielding ATP hydrolysis that is mandatory for catalysis.

Because shifts[18] of *ca* -0.4 V in redox potential are experienced by [4Fe–4S] clusters upon transfer from an aqueous protein matrix into an organic solvent (as a synthetic analogue), by analogy, waves at *ca* -0.57 and -0.87 V vs NHE, respectively, were sought in cyclic voltamograms of isolated FeMoco. In fact, cyclic voltammetry of oxidized, EPR-silent FeMoco does show two reduction processes, one beginning at *ca* -0.4 V vs NHE and a second at *ca* -1.1 V with the related oxidation waves occurring at -0.21 and -0.85 V, respectively, in reasonable agreement with the predictions. Thus, oxidized cofactor appears to be interconverted with its semi-reduced form by reduction at *ca* -0.4 V and oxidation at *ca* -0.2 V to give a formal potential of -0.3 V. The second quasi-reversible redox process has a formal potential of -1.00 V. If these processes correspond directly to those of protein-bound FeMoco, this second wave represents reduction to the substrate-reducing state. Because the separation of the oxidation and reduction waves is in the range of 120–240 mV (at $v = 0.1$ V s^{-1}), some charge-transfer irreversibility accompanying the cofactor reductions is indicated in line with the hysteresis associated with the protein-bound FeMoco redox processes. The mean values of the current parameter for reduction of FeMoco(s-r), following electrochemical reduction of FeMoco(ox), and for oxidation of FeMoco(s-r), produced by the one-electron chemical reduction of FeMoco(ox), are 331 and 284 $\mu A\ s^{1/2}\ V^{-1/2}\ cm^{-2}\ mM^{-1}$, respectively, when the Mo concentration is corrected for the 78% EPR activity exhibited by the samples. These two values are not unreasonable for one-electron transfers in NMF (cf. 375 $\mu A\ s^{1/2}\ V^{-1/2}\ cm^{-2}\ mM^{-1}$ for methyl viologen in NMF) and support a one-electron stoichiometry for both redox processes.

To confirm the one-electron stoichiometry, a sample of EPR-silent FeMoco was titrated with sodium dithionite while monitoring the CV, potentiometric and EPR spectroscopic responses. The initial rest potential was -0.23 V. As dithionite was added: (i) the solution rest potential shifted from values more positive than -0.3 V to more negative values, (ii) the primary reduction current decreased and the primary oxidation current increased, and (iii) the $S = \frac{3}{2}$ EPR signal developed to maximum intensity after addition of 0.78 electrons (g-atom Mo)$^{-1}$. A Nernst plot of these data had a potential at half-intensity of -0.30 V and a reciprocal slope of 65 mV ($n = 0.91$ at 25°C).

The foregoing results demonstrate that FeMoco is converted from its oxidized to semi-reduced state by

a chemically reversible, one-electron transfer. Based on the similarity in potentials and our ability to monitor oxidized and reduced species during the course of these titrations, this chemical process is the same as that observed by direct CV measurements.

Attempts to determine the electrochemical behavior in 0.1 M $[Et_4N]Br$–NMF of $[Fe_4S_4(SPh)_4]^{2-}$,[18] $[Fe(MoS_4)_2]^{3-}$,[19] $[Fe(WS_4)_2]^{3-}$,[19] and $[Mo_2Fe_6S_8(SPh)_9]^{3-}$[20] were made, but each of these molecules either decomposes in NMF or exhibits behavior so different from its reported electrochemistry in other solvents that a significant chemical change must have taken place. Thus, these compounds cannot be closely correlated models for FeMoco. A model with two quasi-reversible redox couples separated by 0.7 V at *ca* −0.3 and −1.0 V vs NHE in a polar aprotic solvent or at *ca* +0.1 and −0.6 V vs NHE in aqueous solution could indicate close correlation with FeMoco. Perusal of electrochemical data reported for Mo–Fe–S–O cluster complexes, however, shows that none fully satisfy this criterion, although of course, no data set was collected in NMF.

Structural insights

The most incisive structural information on FeMoco has come from XAS.[6,12,21,22] XAS is the general term used to describe both the edge, near (or above) edge (XANES) and extended fine structure (EXAFS) regions of the X-ray absorption spectrum. The edge and XANES regions, collectively referred to as XANES herein, provide insights into the geometric and electronic state of the absorbing atoms, while the EXAFS region provides metrical details of the coordination sphere around the absorber. Comparisons of the XANES of a variety of Mo compounds with those from FeMoco, both within and free of the MoFe protein, show a distinct correlation between the shapes of the absorption edge features and the environment of nearest-neighbor atoms around the Mo atom. The Mo compounds investigated constitute an extensive set of mononuclear compounds and both linear and cubane cluster types, in which two–four sulfide and one–three Fe atoms are within bonding distances of the Mo atom. Certain examples contain thiolates and alkoxides coordinated to the Mo atom also. The XANES of these synthetic compounds fall into three distinct subsets, which correlate with certain attributes of their structures.

Members of the first subset contain $[MoS_4]^{2-}$ as the common unit. Compounds examined were $[NH_4]_2[MoS_4]$,[23,24] $[X_2FeMoS_4]^{2-}$ (X = PhS[25] or Cl[26]), $[(Cl_2Fe)_2MoS_4]^{2-}$[27] and $[Fe(MoS_4)_2]^{3-}$.[19,28] Spectral features are identical, within the experimental limitations, for all compounds up to 20,020 eV. Inflection points occur near 20,004 and 20,011 eV, corresponding to a lower energy shoulder and the principal absorption edge discontinuity, respectively. Corresponding low-energy features have been observed in the XANES of all compounds containing terminal Mo=O or Mo=S groups.[21,22]

The second subset consists of the double cubanes

$$[Mo_2Fe_6S_8(SEt)_9]^{3-}\ ^{29,30}$$

and

$$[Mo_2Fe_7S_8(SEt)_{12}]^{3-/4-}\ ^{29,31}$$

plus $Mo(S_2C_6H_4)_3$.[32] The common feature of this category is the $Mo–S_6$ coordination unit. The spectra reveal a single inflection point at *ca* 20,011 eV for all compounds corresponding to the principal absorption discontinuity.

The third group consists of the single cubane

$$[MoFe_3S_4(SEt)_3Fe(cat)_3]^{3-}\ ^{33}$$

and the methoxy-bridged dicubane

$$[Mo_2Fe_6S_8(SEt)_6(OMe)_3]^{3-},^{30,34}$$

both with MoS_3O_3 coordination units of effective C_{3v}-symmetry. The inflection point of the principal absorption discontinuity occurs at 20,012–20,013 eV, which is slightly, but consistently, higher than those for the second subset and may result from the lower polarizability of the O ligands relative to S. In contrast to the previous subsets, these curves also exhibit a shoulder at higher energies.

Because of this observed association between the XANES of the Mo compounds and the structures of the first shell of the Mo atom's nearest neighbors, information about the Mo site of nitrogenase may be obtained by a comparison of XANES spectra. The XANES appears to be more sensitive to the atoms and chemical nature of the bonds between the Mo and its neighbors than to metrical and symmetry variations. Thus, close correspondence of the XANES from the sample of interest to that from a standard implies structural and chemical similarity more than identity, while a difference in the XANES is an unequivocal indication of a structural difference. The XANES of the FeMoco samples are very similar to one another and have their inflection points, the principal absorption discontinuity, at 20,012–20,013 eV with a shoulder at 20,018–20,020 eV. On the basis of the comparisons of XANES of the synthetic compounds and the nitrogenase samples in the region 20,000–20,020 eV, the following unambiguous conclusions can be drawn concerning the Mo site structure in the enzyme and cofactor. It is most closely approached by those compounds

possessing MoS_3O_3 coordination units with Mo–O bond lengths in the 2.1–2.2-Å range. This similarity indicates that the nearest neighbors of Mo in nitrogenase consist of a significant number of both singly bound hard and soft ligands. Any changes in the structure resulting from the extraction of FeMoco from the protein must be sufficiently small so that the basic structure is conserved. These conclusions based on XANES studies are completely consistent with and complementary to results from Mo EXAFS studies.[6,12]

Support for these conclusions was sought through the controlled oxidative degradation of FeMoco. These efforts were based on a previous report that thiomolybdates were released from the intact MoFe protein by the appropriate acid–base treatment[35] and our observation that FeMoco is decomposed with respect to its iron atoms by dioxygen.[3] Thus, when FeMoco was subjected to controlled dioxygenation in a spectral cell with monitoring over 350–800 nm, the initial, virtually featureless FeMoco spectrum showed some striking changes. First, a feature at 500–600 nm appeared, possibly due to a species containing an Mo–S–Fe unit,[10,19] followed by a general absorbance decrease over the whole range. The final spectrum had, as its only major absorption bands, absorbances at 465 and 395 nm, which are characteristic of $[MoOS_3]^{2-}$.[23] A steeply rising background starting at *ca* 400 nm, however, made quantitative spectral simulation difficult, but at least 75% (and maybe all) of the released thiomolybdates must be $[MoOS_3]^{2-}$. Confirmation of this conclusion was obtained when a $(PPh_3)_2Cu$ trap was employed for the released thiomolybdate. The red crystals, which formed when FeMoco was mixed with an aerobic $(PPh_3)_2CuNO_3$ solution, were shown to be $[OMo(CuPPh_3)_3S_3Br]$ by a combination of visible, IR and Raman spectroscopies, plus X-ray data from the poorly diffracting crystals. Even though these last data were severely limited by the poor crystal quality, they clearly showed the basic cubane structure of the molecule and the presence of bromide.

A reasonable interpretation of these data is that FeMoco contains an MoS_3 core, consistent with our EXAFS results.[6,12] In fact, these data constitute a refinement in that they firm up the number of S neighbors to Mo in extruded FeMoco, the softest parameter from the EXAFS investigation, by clearly distinguishing between the two possibilities of 3 and 4. A comparison of these data with the mixture of tetra- and tri-thiomolybdates observed on treatment of the intact MoFe protein[35] suggests that, again in line with the EXAFS results, a real difference exists in the first coordination sphere of Mo within and outside the protein matrix.

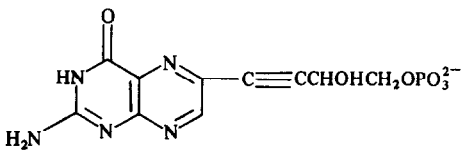
STUDIES ON THE OXIDATION STATE OF MOLYBDOPTERIN

K. V. RAJAGOPALAN,* STEVEN KRAMER and SUSAN GARDLIK

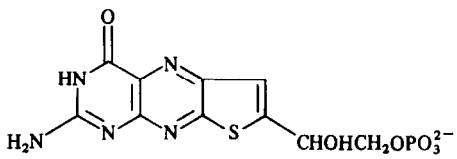
Department of Biochemistry, Duke University Medical Center, Durham, NC 27710, U.S.A.

(*Received* 26 *June* 1985)



Abstract—Molybdopterin, the organic component of the molybdenum cofactor common to all molybdenum-containing enzymes except nitrogenase, is proposed to contain two vicinal thiols capable of complexing Mo. The pterin ring is in an unknown state of reduction in the active cofactor. We have used subtractive difference spectroscopy for examining the reduction state of the pterin in sulfite oxidase and xanthine oxidase under rigorously anaerobic conditions in 6 M guanidinium chloride. It is concluded that the molybdopterin is in the tetrahydro form in both enzymes. Alkylation of molybdopterin with iodoacetamide in denatured samples of sulfite oxidase yields a derivative which contains two alkyl groups per phosphate and is in the tetrahydro form. These findings are in accord with the proposed presence of two thiols in the cofactor, and provide additional evidence for the state of reduction in the pterin.

The Mo cofactor common to all hydroxylase-type molybdoenzymes is functionally identified as a substance which can be released from purified Mo-containing proteins by any of a variety of denaturation techniques and is then capable of reconstituting the apoprotein of nitrate reductase in extracts of *Neurospora crassa nit-1* cells.[1] Studies on degradation products of the cofactor in our laboratory have shown that the organic component of Mo cofactor is a novel pterin with a phosphorylated 4-carbon side chain, postulated to contain a pair of vicinal sulfhydryl groups.[2] The extreme instability of the Mo cofactor, especially under oxidizing conditions, has been interpreted to be due to the oxidation of a reduced form of pterin, termed molybdopterin, present in the active cofactor. The structures of two major oxidized derivatives of molybdopterin, termed form A and form B, and of urothione, a urinary metabolite of Mo cofactor,[2] are shown in Fig. 1 along with the proposed structure of the Mo cofactor.



Studies on sulfite oxidase have shown that molybdopterin is bound tightly but non-covalently to the protein, is present in a stoichiometry of 1 : 1 : 1 with respect to protein subunit and Mo, and does not contain the thiophene ring present in form B and urothione.[3] Examination of the phosphate content and yield of form A from several molybdoenzymes has shown that all of the enzymes studied contain one molybdopterin per subunit.[4] The fact that molybdopterin can be isolated in a form which retains most of its activity and is virtually devoid of amino acids rules out the presence of a peptide in the Mo cofactor.[5] To date there is no evidence for the presence of any organic constituent other than molybdopterin in the cofactor.

As shown in Fig. 1D, we have proposed that Mo is complexed to molybdopterin via the vicinal sulfhydryl groups.[2] Evidence for the existence of a complex has been derived from our demonstration that the Mo cofactor released from denatured sulfite oxidase at pH 7 is fully active in the *nit-1* reconstitution assay in the absence of extraneous Mo for a short duration whereas cofactor released at pH 8 is devoid of activity in the absence of molybdate.[6] The Mo cofactor relased at pH 7.0 is rendered molybdate-dependent by treatment with Hg^{2+} and other sulfhydryl reagents, indicating thiolate ligation of the Mo in the cofactor.[6] The marked protection afforded by arsenite against inactivation by sulfhydryl reagents presumably reflects the strong binding of arsenite to the vicinal SH groups in the cofactor.[7]

Fig. 1. Structures of molybdopterin and derivatives.

More recently, we have initiated investigations on the oxidation state of molybdopterin in several enzymes. The electronic spectra of pterins are well documented, and can be used to differentiate oxidized, dihydro and tetrahydro forms. In the case of molybdoenzymes the spectral intensities of the protein and of the other prosthetic groups are so much greater than those of pterins that direct observations of the spectral features of molybdopterin is not possible.

The simplest catalytically active Mo protein, the Mo domain of rat liver sulfite oxidase, displays an absorption spectrum[8] which is largely due to the weak chromophore resulting from the binding of Mo(VI) to thiolate ligands, and does not provide information about the state of reduction of the pterin ring in the active cofactor. It is therefore necessary to disrupt the structure of the chromophore before assessing the spectral properties of the pterin.

The extreme instability of Mo cofactor after separation from Mo proteins, leading to loss of activity and generation of multiple species, has made it impossible as yet to isolate the active material in a homogenous state for structural and spectroscopic studies. We have therefore devised procedures for examining the spectral properties of uncomplexed molybdopterin in sulfite oxidase and xanthine oxidase under denaturing conditions. We have also characterized an alkylated inactive derivative prepared from sulfite oxidase and the results are presented here.

METHODS

Alkylation of molybdopterin

Chicken liver sulfite oxidase (10–20 mg/ml) in 0.05 M phosphate buffer, pH 7.8, was mixed with 10 volumes of dimethyl sulfoxide containing 1 mM sodium EDTA and 10 mM sodium ascorbate. The solutions were made anaerobic prior to mixing by repeated evacuation and flushing with oxygen-free nitrogen. After 5 min at room temperature an aliquot was removed for assay of molybdopterin activity by the *nit-1* reconstitution system. At this time, a 100-fold molar excess of an anaerobic solution of iodoacetamide was added to the mixture. After 2 h at room temperature the sample was applied to an *aerobic* QAE-Sephadex column. The column was washed with 0.01 N acetic acid and the carboxamidemethylated molybdopterin (cam-MPT) could then be eluted, together with the ascorbate, with 0.01 N HCl. This material was rapidly frozen in a dry ice–ethanol bath and lyophilized overnight.

The lyophilized material was redissolved in 4 cm^3 of 50 mM ammonium acetate and the cam-MPT was purified by reverse-phase HPLC using an Alltech C18 column and a Spectra-Physics SP8700 solvent delivery system. All HPLC solvents were continuously sparged with helium (ultra high purity grade). Two peaks of cam-MPT were obtained by this procedure. The material in the second peak was rapidly converted to the material in the first peak if precautions to exclude oxygen were not taken dur-

ing fraction collection. Further purification of this, more oxidized, cam-MPT derivative was then accomplished by reverse-phase HPLC using 5% MeOH–95% 100 mM triethylamine with 100 mM acetic acid, pH 6.8, as the mobile phase.

The material in the second peak was pure after reverse-phase HPLC in ammonium acetate and was collected in anaerobic serum vials or cuvettes. Absorption spectra were obtained on a Shimadzu UV-240 spectrophotometer.

For proof of alkylation, as well as the determination of the stoichiometry of the reaction, 0.01 mCi of [1-^{14}C]iodoacetamide (New England Nuclear) was included in the initial iodoacetamide solution. Phosphate analysis of cam-MPT was done by the method of Ames.[9]

Preparation of apo-xanthine oxidase

Apo-xanthine oxidase was made by dialyzing the enzyme against deaerated 6 M guanidine–HCl and 10 mM DTT, pH 7.0, for 24 h, then against 6 M guanidine HCl, pH 7.0, for 48 h.

Difference spectra

To obtain the difference spectrum of the pterin, a solution of apo-xanthine oxidase in 6 M guanidine–HCl (pH 7.0), 1 mM EDTA, and an appropriate amount of FAD was used as the reference against an anaerobic solution of fully active xanthine oxidase in 6 M guanidine–HCl and 1 mM EDTA, pH 7.0. The active enzyme solution was made anaerobic by flushing with nitrogen for 20 min.

Absorption and difference spectra were obtained using a Shimadzu UV240 spectrophotometer. Fluorescence spectra were obtained with an Aminco–Bowman spectrofluorometer.

RESULTS

The UV–visible absorption spectrum of xanthine oxidase is largely composed of the contributions of the Fe/S centers and flavin, and of the protein itself. The spectral properties of the active Mo center of the enzyme are not known, but may be similar to that of the Mo domain of sulfite oxidase.[8] In the presence of 6 M guanidine–HCl, the Fe/S centers and the Mo—S bonds are destroyed, and the resulting spectrum should be the sum of those of the protein, free FAD and free molybdopterin. By using a reference sample containing matching concentrations of molybdopterin-free apoprotein and FAD it should be possible to isolate the absorption spectrum of the pterin in the sample cuvette. Such a difference spectrum of molybdopterin in xanthine oxidase is shown in Fig. 2, along with that of tetrahydrobiopterin in guanidine–HCl. The difference spectrum is clearly that of a tetrahydropterin, with an extinction coefficient appropriate for a stoichiometry of one molybdopterin per subunit. Under the conditions of this experiment the FAD remained fully oxidized, suggesting that the tetrahydro form is the native oxidation state of molybdopterin in xanthine oxidase. Similar results were also obtained in the case of sulfite oxidase. Thus we conclude that in both xanthine oxidase and sulfite oxidase the pterin ring of molybdopterin is in the fully reduced state, as shown in Fig. 1D.

Alkylated molybdopterin

When sulfite oxidase was denatured by addition of 10 volumes of dimethyl sulfoxide and then treated with iodoacetamide, the Mo cofactor activity of the preparation was abolished in about 2 h. No loss of activity occurred in the absence of iodoacetamide. The inactivated molybdopterin was isolated from the mixture by procedures described in Methods. Figure 3 shows the HPLC elution pattern of the sample eluted from the QAE-Sephadex with 0.01 N HCl. The large peak representing unabsorbed material was mainly ascorbate. The peaks labeled A and B both contained radioactivity from the [^{14}C]iodoacetamide. When the two fractions were collected in anaerobic containers and re-examined by HPLC, their elution properties were unaltered. However, if the fractions were collected in air, material from peak B was wholly converted to the

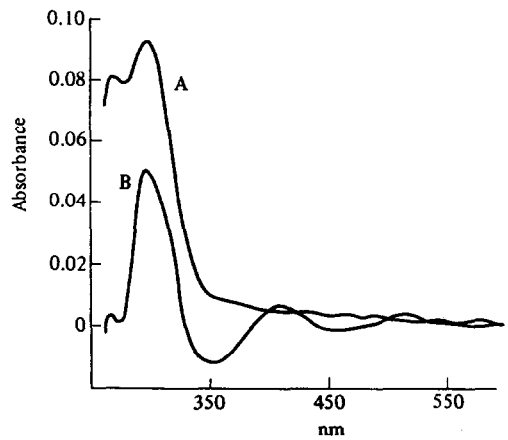

Fig. 2. Difference spectrum (B) of molybdopterin of bovine milk xanthine oxidase in 6 M guanidine–HCl. The sample cuvette contained 1.4 mg/ml of xanthine oxidase, while the reference cuvette contained equivalent concentrations of apoprotein and FAD. Spectrum A is that of tetrahydrobiopterin under the same conditions.

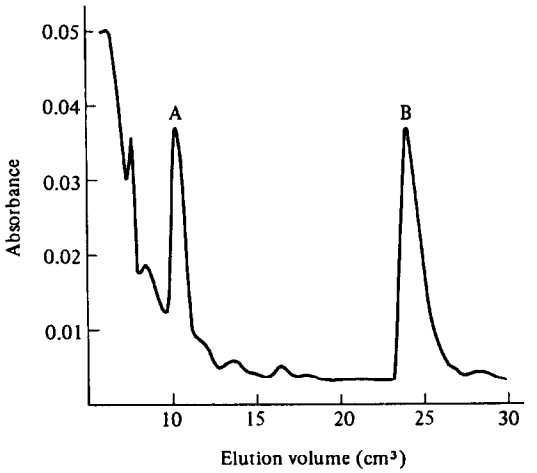

Fig. 3. HPLC analysis of alkylated molybdopterin. Conditions for HPLC are described in Methods. The elution profile was monitored at 280 nm using a Spectra-Physics 8440 detector.

earlier eluting form. These results showed that peak A represents the oxidized form of peak B.

The absorption spectrum of anaerobically collected peak B material is shown in Fig. 4, and corresponds to that of a tetrahydropterin. Air oxidation in the cuvette resulted in an altered absorption spectrum identical to that of the peak A sample, presumably a fully oxidized form.

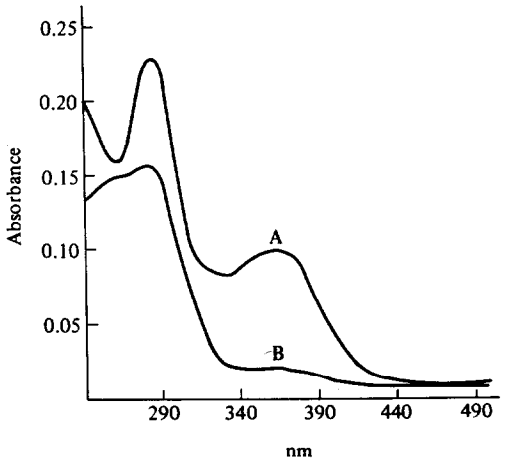

Fig. 4. Absorption spectrum of cam-MPT in 100 mM triethylamine–acetic acid, pH 6.8, containing 5% methanol. Spectrum B is that of the anaerobic sample corresponding to peak B in Fig. 3. Spectrum A was recorded after complete oxidation in air, and is identical to that displayed by material from peak A in Fig. 3.

DISCUSSION

The data presented here indicate that the Mo cofactor present in xanthine oxidase as well as in sulfite oxidase contains the metal complexed to the tetrahydro form of molybdopterin. The procedure used for difference spectroscopy was designed to eliminate steps which could lead to oxidative modification of the pterin. Artifactual reduction of an oxidized form to a tetrahydro form is considered unlikely because of the absence of exogenous reductants and the observation that the FAD of the xanthine oxidase sample remained fully oxidized during the time of the experiment. In the case of sulfite oxidase, further support for this is derived from the isolation of the alkylated pterin in the tetrahydro state.

The reaction of two molecules of iodoacetamide with each molecule of molybdopterin supports the proposed presence of two vicinal SH groups in active molybdopterin. We are currently carrying out mass spectroscopic studies on cam-MPT and hope to obtain unequivocal evidence for the proposed structure of molybdopterin.

PROPERTIES OF THE MOLYBDENUM DOMAIN OF NITRATE REDUCTASE

MICHAEL J. BARBER* and LARRY P. SOLOMONSON

Department of Biochemistry, University of South Florida, College of Medicine, Tampa, FL 33612, U.S.A.

(*Received* 17 *June* 1985)

Abstract—Partial reduction of the complex metalloflavoprotein nitrate reductase resulted in the appearance of a triad of Mo(V) EPR signals with a g_{av} of approximately 1.97. The precise g values and lineshapes were dependent upon the pH of the medium and the presence of anions. Potentiometric titrations revealed that midpoint potentials for both the Mo(VI)–Mo(V) and Mo(V)–Mo(IV) redox couples were pH-dependent. Treatment of the native enzyme with a specific inactivating protease from corn yielded two fragments of M_r 280,000 and 28,000. The large fragment contained Mo and heme whereas the small fragment contained FAD.

Nitrate reductase (NR) catalyses the rate-limiting step, the two-electron reduction of NO_3^- to NO_2^-, in the pathway of nitrate assimilation.[1] The enzyme from *Chlorella vulgaris* has been purified to homogeneity and found to contain Mo, in combination with a substituted pterin cofactor,[2] FAD and a b_5-type cytochrome prosthetic group in a 1:1:1 stoichiometry per subunit (M_r = 96,000) of the homotetrameric native enzyme.[3] Reducing equivalents from the physiological donor, NADH, enter the enzyme at the FAD domain and are transferred to the acceptor, NO_3^-, via the Mo center.

The initial spectroscopic studies of the enzyme have demonstrated that a variety of Mo(V) EPR signals can be elicited following partial reduction of the enzyme with either NADH or dithionite, some of which show superhyperfine coupling to an exchangeable proton.[3]

EXPERIMENTAL

NR was purified to homogeneity from *C. vulgaris* as previously described[4] using standard growth media or medium enriched in ^{95}Mo. Enzyme activities were monitored as previously described,[4] purified NR exhibiting a specific activity of >80 units mg^{-1} (NADH:NR) and an A_{280}/A_{413} ratio of <1.8. NR was extensively dialysed into zwitterionic buffers and stored at 77 K. NR was cleaved into its domain fragments by treatment with purified corn inactivator protease[5] [3.3 μg protease (mg enzyme)$^{-1}$] at 25°C until >95% inactivation of NADH:NR activity was achieved. Protein fragments were separated by chromatography on Sephacryl S-300. EPR samples, prepared using controlled reduction techniques and potentiometric titrations were performed as previously described.[3,6] EPR spectra were recorded using a Varian E109 spectrometer equipped with a variable-temperature accessory and operating at 9 GHz. g values were determined with reference to Mn–DPPH and xanthine oxidase "resting I" standards. Double integrations of EPR spectra were performed as described by Barber and Siegel[6] using CuEDTA as standard.

RESULTS AND DISCUSSION

Low-temperature EPR spectra of oxidized, native NR showed no signals due to Mo(V). However, partial reduction of the enzyme with dithionite yielded the spectra shown in Fig. 1. While the form of the Mo(V) spectrum was complex and was observed to vary between samples, particularly those containing anions such as chloride or phosphate, in zwitterionic buffers two major species were detected, the proportions of each dependent upon the pH. At low pH (7.0), a rhombic spectrum was identified that

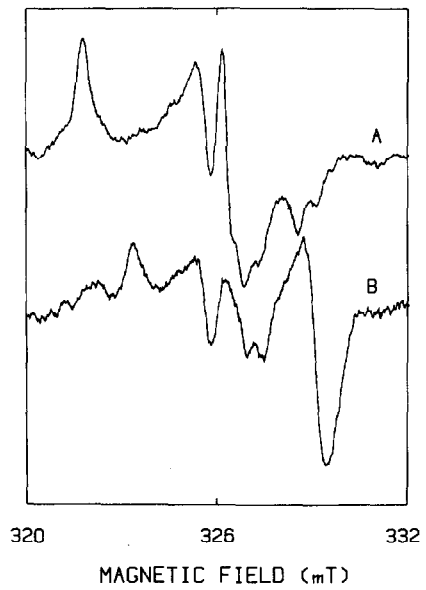

Fig. 1. EPR spectra of the Mo center in NR. (A) NR (11.5 μM heme) in 50 mM MOPS buffer containing 0.1 mM EDTA (pH 7.0) was poised at -57 mV in the presence of mediator dyes (14 μM) using dithionite as reductant. (B) NR (8.3 μM heme) in 50 mM CHES buffer containing 0.1 mM EDTA (pH 9.0) was poised at -132 mV in the presence of mediator dyes (20 μM). Spectra were recorded at 173 K using 10-mW microwave power and a modulation amplitude of 0.25 mT. The field scale corresponds to a microwave frequency of 8.985 GHz.

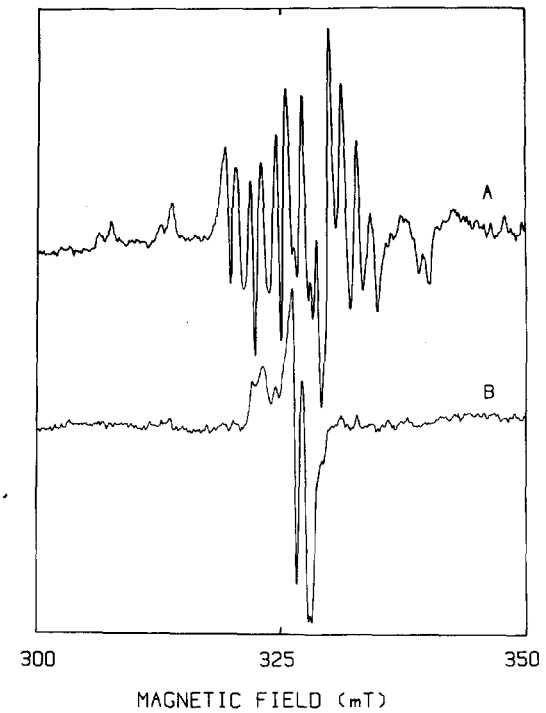

Fig. 2. EPR spectra of ^{95}Mo-containing NR. (A) NR (23 μM heme), purified from *C. vulgaris* grown on a medium enriched in $^{95}MoO_4^{2-}$, in 50 mM MOPS buffer containing 0.1 mM EDTA and 200 mM KCl (pH 7.0) was poised at -49 mV in the presence of mediator dyes (100 μM). (B) NR (9 μM heme) was poised at -37 mV under identical conditions as for spectrum A. EPR spectra were recorded under conditions described in Fig. 1, except that for spectrum A, the microwave power and modulation amplitude were increased to 30 mW and 0.4 mT, respectively. The field scale corresponds to a frequency of 8.984 GHz.

showed no evidence for superhyperfine coupling to protons and exhibited g values of $g_1 = 1.995$, $g_2 = 1.967$ and $g_3 = 1.954$ ("low pH"). At alkaline pH (9.0), a second rhombic species was detected, again showing no superhyperfine coupling, with g values of $g_1 = 1.985$, $g_2 = 1.952$ and $g_3 = 1.949$ ("high pH"). At low pH and in the presence of anions such as chloride, a third Mo(V) species was observed with g values of $g_1 = 1.995$, $g_2 = 1.968$ and $g_3 = 1.966$. In contrast to the "low pH" and "high pH" species, the "anion" signal showed superhyperfine coupling to a single, exchangeable, proton with coupling constants of $A_1 = 1.2$ mT, $A_2 = 1.1$ mT and $A_3 = 1.5$ mT. Similar signals were obtained in the presence of phosphate and fluoride. Confirmation that this signal was due to Mo(V) was achieved by purifying NR from *Chlorella* grown on a medium enriched with $^{95}MoO_4^{2-}$. Partial reduction of the enzyme yielded a broad, complex EPR signal centered around $g = 1.98$ that showed multiple lines with those occurring at extreme low and high field resolved into doublets (Fig. 2). ^{1}H and ^{95}Mo hyperfine coupling constants were estimated to be of the order of 1.2–1.3 and 5.5–6.0 mT, respectively. In addition to perturbing the EPR parameters of the Mo center, anions were also observed to stimulate the NADH : NR activity of the enzyme without affecting the NADH : CR activity. Whilst phosphate exhibited the greatest stimulation of activity, corresponding to nearly a four-fold increase at pH 7 (50 mM phosphate), both chloride and fluoride caused similar effects, though of lower magnitude. At pH 9, stimulation of NADH : NR activity was also observed.

The behavior of the Mo(V) EPR signals during potentiometric titrations of the native enzyme at pH 7 and 9 are shown in Fig. 3. At high potential, Mo(V) was undetectable: however, as the potential was decreased the Mo(V) signals were observed to appear, to reach maximum intensity at -40 (pH 7) and -130 mV (pH 9), corresponding to approximately 38% conversion of Mo to the quinquivalent state, and to decrease at more negative potentials. No change in the lineshape of

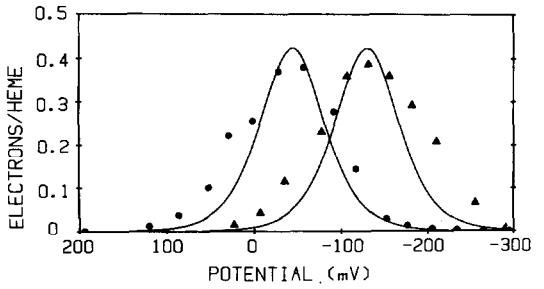

Fig. 3. Behavior of the Mo(V) EPR signal during potentiometric titrations. (●) NR (11.5 μM heme) in 50 mM MOPS buffer containing 0.1 mM EDTA (pH 7.0) was poised at various potentials using dithionite as reductant in the presence of mediator dyes (14 μM). (▲) NR (8.3 μM heme) in 50 mM CHES buffer containing 0.1 mM EDTA (pH 9.0). The curves fitted to the data points correspond to redox processes involving two, consecutive, one-electron redox steps with potentials, pH 7: Mo(VI)–Mo(V) = −34 mV and Mo(V)–Mo(IV) = −54 mV; pH 9: Mo(VI)–Mo(V) = −120 mV and Mo(V)–Mo(IV) = −140 mV.

either the "low pH" or "high pH" signals was observed throughout the course of either titration. Behavior of this type is typical of a reduction process involving two, consecutive, one-electron redox steps corresponding to the reactions:[7]

$$\text{Mo(VI)} \overset{E_1}{\longleftrightarrow} \text{Mo(V)} \overset{E_2}{\longleftrightarrow} \text{Mo(IV)},$$

with E_1 and E_2 corresponding to the midpoint potentials of the Mo(VI)–Mo(V) and Mo(V)–Mo(IV) couples. Values obtained for these couples at pH 7 and 9 were $E_1 = -34$ and -120 mV and $E_2 = -54$ and -140 mV, respectively. The shift in the position of the titration curve to lower potential with increasing pH and the corresponding decrease in both Mo redox couples indicates the involvement of protons in both redox steps. Values of ΔE/pH of -43 mV for both couples would indicate that reduction of Mo(VI) to Mo(V) and Mo(V) to Mo(IV) involve the addition of one electron and one proton in each reaction.

Incubation of native NR at room temperature in the presence of an isolated corn inactivator protease was observed to result in the time-dependent abolition of both NADH:NR and NADH:CR activity, whereas, in contrast, $MV^{\cdot+}$:NR activity remained unchanged. Chromatographic separation of the fragments produced following proteolysis yielded two fragments. The first, eluting just behind the column void volume, exhibited $MV^{\cdot+}$:NR activity, corresponded to an M_r of 280,000, comprised four identical polypeptide chains and was referred to as the "large fragment". Comparison of the visible spectra of this fragment (Fig. 4B) with that of the native enzyme (Fig. 4A) showed the characteristic bands corresponding to the presence of a cytochrome component. Addition of NADH failed to reduce the heme center but reduction could be ahieved using dithionite. In addition, controlled reduction of the fragment with dithionite yielded an EPR signal identical to that of the native enzyme, due to the formation of Mo(V) and indicating that the "large fragment" contained both the Mo and cytochrome components. In contrast, the "small fragment" (Fig. 4C) showed visible maxima at 390, 413 and 455 nm (the peak at 413 nm indicating contamination with a small amount of residual

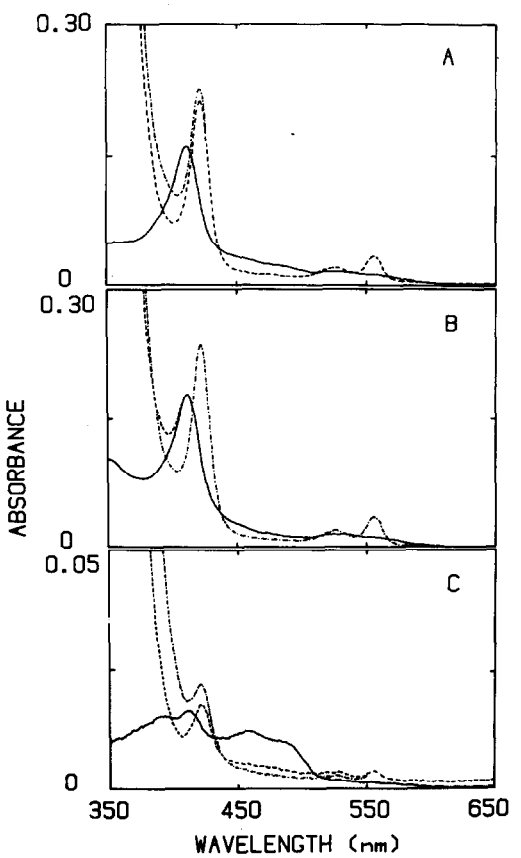

Fig. 4. Visible spectra of NR and the fragments obtained following treatment with corn inactivator protease. (A) (——) NR (0.88 μM heme) in 80 mM potassium phosphate buffer containing 0.15 mM EDTA, 0.5 M KCl and 0.15 mM DTE (pH 7.8); (– – –) enzyme reduced with NADH (1 mM); and (–·–·–) enzyme reduced with dithionite (1 mM). (B) (——) Large fragment (1 μM heme) in the same buffer as A, (– – –) large fragment reduced with NADH (1 mM), and (–·–·–) large fragment reduced with dithionite (1 mM). (C) (——) Small fragment in same buffer as A, (– – –) small fragment reduced with NADH (1 mM), and (–·–·–) small fragment reduced with dithionite (1 mM).

heme), was reduced by NADH, exhibited an M_r of 28,000 and showed no quaternary structure. These results indicate that the "small fragment" contained both a functional NADH-binding site and the FAD prosthetic group and represented a small flavin domain that could be readily cleaved from the main protein structure without destroying its functionality with respect to nitrate reduction. In addition, an intact flavin domain is essential for the transfer of reducing equivalents from NADH to heme and Mo.

(*Received* 17 *June* 1985)

Abstract—The molybdoenzyme NADH–nitrate reductase (NADH–NR) (EC 1.6.6.1) has been purified 3400-fold, by a multi-stage procedure, to homogeneity from spinach (*Spinacea oleracea* L.). The enzyme had a specific activity of 102 μmol NO_2^- produced min^{-1} mg^{-1}. Denaturing electrophoresis revealed two subunits of molecular weight 110,000 and 120,000 and was substantially free of proteolytic degradation products. Extinction coefficients of the functional haem were 127 mM at 412 nm (oxidized) and 172 mM at 423 nm (NADH-reduced). A set of monoclonal antibodies was raised to the pure NR. Six selected for further cloning were all γG type and bound to five distinct and one overlapping site on the enzyme. The various activities of the NR (NADH-oxidizing and nitrate-reducing) were differentially inhibited by the monoclonal antibodies. NADH–NR activities of extracts of roots and leaves of a variety of species were inhibited to different extents.

Nitrate reductase (NR) (EC 1.6.6.1) from higher plants is the rate-limiting enzyme in the assimilation of inorganic nitrogen.[1–3] In most of the species examined, NR has a preference for NADH† as the electron donor to reduce nitrate to nitrite and also displays two partial activities: (1) a dehydrogenase function, reducing one-electron donors such as cytochrome *c* with NADH; and (2) nitrate reduction with $FMNH_2$ and $MV^{\cdot}$ as donors. The dehydrogenase function is independent of the molybdenum prosthetic group (molybdo-pterin) and the nitrate-reducing function is independent of the NADH donation site. From the few species examined, NR has been shown to have a molecular weight of 200,000–250,000, made up of two subunits of approximately 100,000 plus the molybdo-pterin complex. It has prosthetic groups of FAD, cytochrome b_{557} and molybdenum and electron flow occurs via these three components (see Fig. 1). The enzyme is unstable both *in vivo* and *in vitro* and has been purified from relatively few species.[4–8] Native electrophoresis (PAGE) of purified NR often results in a single protein band which is enzymically active: however, denaturing electrophoresis (SDS–PAGE) reveals multiple bands.[1,9,10] These are due to the presence of proteolytically nicked subunits which remain associated with the enzyme during its purification and the occurrence of these fragments can be decreased by using protectants against

proteolysis.[11] The stability of NR means that purifications result in small yields, the 200 μg kg^{-1} reported here being one of the best. A study of the structure and function of the enzyme is therefore restricted. Our ability to purify NR,[12] and the knowledge that NR is a good antigen,[13] led us to attempt the preparation of a set of McAbs which would have potentially a four-fold use: (1) large-scale purification by affinity chromatography, (2) probes for the molecular structure, (3) quantification of the enzyme in the presence of impurities, and (4) intracellular localization. We report here further characterization of the six McAbs previously obtained.[21]

MATERIALS AND METHODS

Spinach plants (*Spinacea oleracea* L., cv. Noorman) were grown under greenhouse conditions using a nutrient flow technique and Long Ashton nitrate nutrient.[14] Leaves were taken from plants 6–8 weeks old and frozen at −20°C before use. Enzyme activities of NR, NADH–NR, NADH–cytochrome *c* reductase (NADH–cyt *c* Rase) and $FMNH_2$–NR used standard methods.[15] MV–NR used 0.2 mM MV instead of FMN.

Electrophoresis was done in vertical gel slabs using the standard formulations for a 3.75% stacking gel (pH 6.8), 7.5% resolving gel (pH 8.8) and reservoir buffer (pH 8.3) as described for native PAGE[16] and SDS–PAGE.[17] Protein samples (10–50 μg) were made either 10% with glycerol (native PAGE) or heated for 3 min at 90°C with an equal volume of 2% SDS, 5% mercaptoethanol, 10% glycerol in 62.5 mM Tris buffer (pH 6.8) (SDS–PAGE). Bromophenol blue was used as the marker dye. Molecular weights were estimated from the mobility of standard proteins. Gels were stained with 1% Coomassie brilliant blue R250. Vertical gel strips were cut from the gel slabs for scanning spectrophotometrically.

Enzyme extraction and purification used modifications of our earlier method.[4] All operations were done at 4°C and buffers contained 1 mM EDTA. Frozen spinach leaves were macerated with 1 volume of 5 mM phosphate buffer (pH 7.5) containing 10 μM leupeptin.[11] The macerate was filtered through muslin and centrifuged to remove debris. Nucleic acids were precipitated by the addition of streptomycin sulphate [5 mg (g leaf)$^{-1}$] and removed by centrifuging. The supernatant was made 50% saturated with $(NH_4)_2SO_4$ and the precipitate collected, redissolved in 5 mM phosphate buffer (pH 7.5) and desalted on Sephadex G 25 for chromatography on hydroxapatite. The column was washed with 5 mM phosphate buffer and the NR-containing fraction eluted with 100 mM phosphate buffer (pH 7.5) containing 10 μM FAD and 5% $(NH_4)_2SO_4$. The NR fraction was concentrated by precipitation with 50% saturated $(NH_4)_2SO_4$, the precipitate redissolved in 100 mM phosphate buffer (pH 7.5) containing 10 μM FAD and 50 mM KCl, and submitted to molecular sieve chromatography (Biogel A 1.5 m). Active fractions were precipitated as before, redissolved in 5 mM phosphate buffer (pH 7.5) containing 10 μM FAD and applied slowly to a column of blue–Sepharose. After removal of unbound material the column was inverted and bound NR eluted using 100 mM phosphate buffer (pH 7.5) containing 10 μM FAD and 150 μM NADH. The NR was concentrated by precipitation and the chromatography repeated, including the inversion technique, using 5′-AMP–Sepharose.[12] Active fractions were retained separately.

Female rats were injected with 200 μg of pure NR followed by booster injections after 37 and 62 days. Response to the antigen was measured by the ability of the antiserum to inhibit the NADH–NR of a suitably diluted NR preparation.[13] Hybrid myelomas were derived from spleen cells of rats showing a strong positive response to NR, by fusion[18] with either rat myeloma lines Y3Agl 2.3[19] or YB 2/3.0 Ag20.[20] Supernatants from confluent cultures were tested for McAb activity by an ELISA. Selected positive cell lines were either frozen or cloned.[21] Cell lines giving positive ELISA supernatants were also tested for their ability to inhibit activities of NR after a 1-h incubation at 4°C.

Antibodies were labelled with [^{3}H]lysine by incubating cell lines in labelled culture media and secreted immunoglobulins were analysed by SDS–PAGE after reduction with 2-mercaptoethanol.[22]

Competition between McAbs for the same site on the NR protein used ^{3}H-labelled McAbs diluted with each of the unlabelled McAbs. The mixtures were incubated overnight with NR attached to PVC plates. Counts obtained were plotted against volume of unlabelled McAb.

RESULTS AND DISCUSSION

The purification of NR from 2 kg of spinach leaves is summarized in Table 1. The final product was 400 μg of a 3400-fold purified enzyme having a nominal specific activity of 102 units of activity (mg protein)$^{-1}$. This figure was obtained with the commonly used protein standard, bovine serum albumin (BSA). However, BSA is known to behave in an abnormal manner with the assay reagent used[23] and the resultant specific activity has been shown to be 30% too high compared with using NR as its standard,[24] i.e. a corrected figure of 71.4. Based on the purification data, the initial enzyme activity and the final recovery (5.6%), spinach leaves contained approximately 3.5 mg NR (kg fresh weight)$^{-1}$. Although the recovery figure is low, this is a substantial improvement on most other attempted large-scale purifications. The destruction of NR during all chromatography stages[25] has been considerably decreased by the inclusion of FAD in the buffers and particularly by inverting the columns in the last two affinity chromatography stages.[12]

The light absorption spectrum of the pure NR (Fig. 2) shows a Soret band at 412 nm typical of NRs so far isolated from eukaryotic sources.[1–3] The 280:412 nm ratio is now approximately 2:1. The functional nature of the haem was confirmed by reducing the NR with NADH, resulting in a shift of the Soret to 423 nm and the appearance of α and β bands at 557 and 523 nm. Reoxidation with nitrate led to the production of nitrite and a reversion of the spectrum back to the native oxidized form. Extinction coefficients (mM) of the haem, based on a molecular weight of 200,000 were 127 (412 nm) (oxidized) and 172 (423 nm), 17.5 (525 nm) and 29 (557 nm) (NAHD-reduced). These coefficients are similar to those reported for NR from *Chlorella*.[26] Native PAGE of purified NR typically resulted in only one protein band[1,9,10] after both blue- and 5'-AMP–Sepharose. In both cases this band also displayed NADH–NR activity. However, SDS–PAGE resulted in multiple banding of the post blue–Sepharose-purified NR (Fig. 3A) similar to previous reports,[4,9–11] but the post 5'-AMP–Sepharose NR revealed only a doublet (Fig. 3B) corresponding to molecular weights of 110,000 and 120,000 with trace amounts (< 10%) of smaller proteins. This result has been recently confirmed by other workers[27] who regarded spinach NR as consisting of two equal sized subunits of molecular weight 120,000 and the doublet resulting from the loss of a small peptide by proteolysis. Identity of both bands as being related to NR was confirmed by cross-reaction with McAbs to the enzyme. It seems, therefore, that 5'AMP–Sepharose is capable of removing associated proteolytically nicked peptides from the NR.

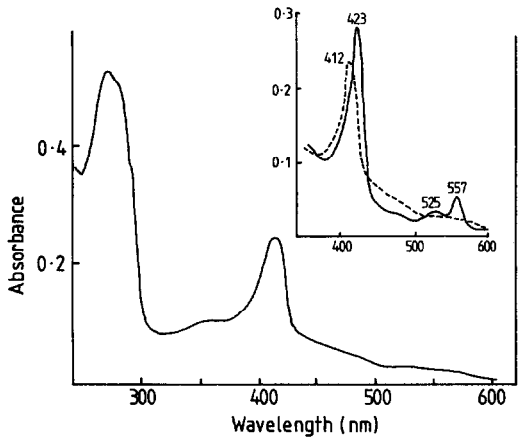

Fig. 2. Absorption spectrum of purified NR.[12] Sample contained 400 μg ml^{-1} in 5 mM phosphate buffer at pH 7.5 and was measured at room temperature. Insert shows the effect of reduction with NADH (——) and reoxidation with nitrate (– – –) on the haem.

Table 1. Purification of NR from spinach leaves (crude extract obtained from 2 kg of frozen leaves)

Stage	Total activity (mol NO_2^- produced min^{-1})	Specific activity	Purification factor
Crude extract	367	0.03	1.0
Streptomycin	272	0.02	0.8
$(NH_4)_2SO_4$	243	0.02	0.8
Hydroxyapatite	139	0.20	6.7
Biogel A 1.5 m	82	0.22	7.1
Blue–Sepharose	42	7.14	224.5
5'-AMP–Sepharose	30	65.68	2189.1
Best fraction	21	102.96	3431.9

Antisera were obtained from rats injected with pure NR inhibited NADH–NR activity, the dilution required for 50% inhibition varied six-fold. Non-immune serum had no inhibitory properties.

Cells obtained as a result of fusion of rat spleen cells with myeloma cells[18] were cultured and exudates tested by ELISA for the presence of McAbs. Those giving a positive were subcultured and samples stored in liquid N_2. Negative ELISA cultures were stopped. From the celll cultures 24 were ELISA-positive, 16 from Y3Agl 2.3 and eight from YB3/3.0 rat myelomas. Of these, six, designated AFRC MAC 74–79, were selected for cloning in soft agar and further growth.[21]

Analysis by SDS–PAGE of [^{3}H]lysine-labelled

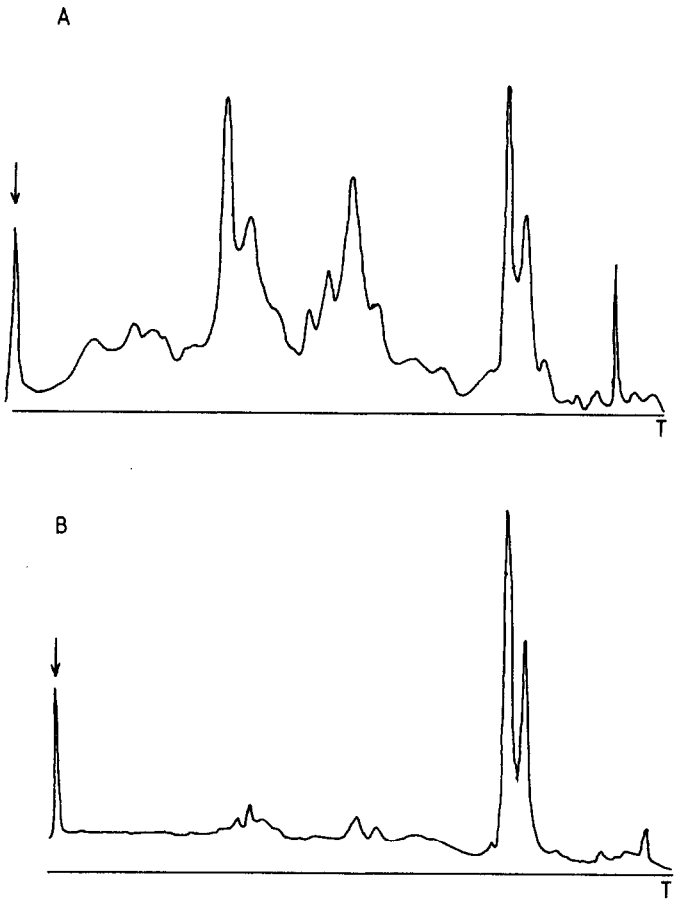

Fig. 3. Gel scan of subunit of 20 μg of purified NR separated by SDS–PAGE and stained with Coomassie brilliant blue R250.[12] (A) Post blue–Sepharose and (B) best fraction of post 5′-AMP–Sepharose. T = top of gel. ↓ bromophenol blue marker.

McAbs showed that MAC 77–79 were all heavy-chain class γ. However, attempts to purify the McAb using protein A–Sepharose were not successful, presumably because the IgGs were of a subclass not recognized by protein A.[28]

Competition of one McAb with the others, for a particular antigenic site on NR, over a limited dilution range of 10 : 1–1 : 20, showed that MAC 76 and 77 were mutually competitive and therefore bound at the same or overlapping sites. They also had the same enzyme inhibitory properties (see below). MAC 74, 75, 78 and 79 were non-competitive and, therefore, bound at unique sites on the NR.

Antibodies were concentrated either by pressure filtration, using a 20,000 cut-off ultrafiltration membrane, or by precipitation with $(NH_4)_2SO_4$ at 50% saturation followed by resolution and dialysis to remove salt. Equal volumes of the McAbs and a suitably diluted semi-purified NR were incubated at 4°C for 1 h before determining residual activities. The results (Table 2) show that MAC 74, 76 and 77 strongly and MAC 75 weakly inhibit all nitrate-reducing (terminal) activities of NR (NADH–NR, $FMNH_2$–NR and MV–NR) while MAC 78 and 79 inhibit NADH acceptor activities (NADH–NR and NADH–cyt *c* Rase) (see Fig. 1). Preliminary tests using pure NR indicate that MAC 78 binds close to the NADH site, inhibiting both acceptor activities equally, while MAC 79 binds closer to the cyt *c* site and preferentially inhibits the NADH–cyt *c* Rase activity.

Inhibition of terminal activities resulted in a stimulation of acceptor activities and vice versa, possibly as a result of binding of the McAbs affecting the changes in tertiary structure of the enzyme on reduction.

Crude extracts of roots and leaves of both spinach and a variety of other species (barley, wheat, oats, marrow, pea, oilseed rape and cucumber) were tested against McAbs for inhibition of their NADH–NR activity. While all the McAbs which inhibited the terminal activities of spinach (MAC 74–77) were effective to varying degree with the other species, indicating a partial recognition, only MAC 74 was

Table 2. Inhibition of NR activities by McAbs (effect of McAbs MAC 74–79 on the various activities of a semi-purified NR from spinach leaves)

	Residual activity[a]			
McAb	NADH–NR	NADH–Cyt *c* Rase	$FMNH_2$–NR	MV–NR
74	9	120	15	20
75	75	115	55	45
76	16	120	17	26
77	17	100	28	26
78	55	59	150	105
79	73	73	124	86

[a] Results are expressed as % of control activities obtained after equal volumes of supernatant and a suitably diluted NR preparation were incubated for 1 h at 4°C.

inhibitory in every case and was obviously directed against an invariant site on the NR. MAC 78 and 79 was only effective against spinach and marrow NR (to some extent), which may be due to a greater variation in structure at this end of the molecule.

Although McAbs have been raised to a number of plant proteins this is one of the few cases reported of McAbs against a higher-plant enzyme. We feel that McAbs are particularly useful as probes of protein structure and although MAC 74–79 gave negative ELISAs against xanthine dehydrogenase, the isolation of an McAb against the molybdo-pterin complex which is common to a number of molybdoenzymes (NR, xanthine dehydrogenase and sulphite oxidase)[29] would be particularly useful. It may be present amongst the remaining 18 cell lines yet to be cloned.

THE LIGAND ENVIRONMENT OF MOLYBDENUM IN THE MOLYBDENUM COFACTOR, INVESTIGATED BY EPR

G. N. GEORGE, T. R. HAWKES, G. D. JONES and R. C. BRAY*

School of Chemistry and Molecular Sciences, University of Sussex, Brighton BN1 9QJ, U.K.

(*Received* 1 *July* 1985)

Abstract—Frozen-solution EPR studies of Mo(V) in the active molybdenum cofactor, in the form of a complex with thiophenol, have been carried out in extension of the work of Hawkes and Bray (*Biochem. J.* 1984, **222**, 587). Isotopic substitution with ^{95}Mo, ^{17}O and ^{2}H, and computer simulations of the spectra were employed. C_s-symmetry and weak coupling to exchangeable ^{17}O and ^{2}H nuclei are indicated. A local structure for the molybdenum environment in the cofactor is suggested.

The structures of molybdoenzymes[1] such as xanthine oxidase,[2] nitrate reductase[3] and sulphite oxidase,[3] have been extensively investigated by EPR of Mo(V). Molybdenum in all molybdoenzymes other than nitrogenase is present as the molybdenum cofactor, but work on this essential constituent of the enzymes has lagged behind that on the enzymes because of its instability. Degradation studies[4] of the cofactor indicate it to be a reduced pteridine derivative, with molybdenum attached to a side chain via sulphur ligands. In earlier work we have shown that under rigorously anaerobic conditions the active cofactor may be extracted[5] from xanthine oxidadase in the presence of dithionite and converted[6] as a thiophenol complex to the Mo(V) state in 80–100% yield. In this procedure, thiophenol presumably displaces cysteinyl ligands from the protein. Frozen-solution EPR spectra indicated a well-defined species, whose parameters were reported as $g_{\|} = 2.0258$ and $g_{\perp} = 1.9793$. We now report additional EPR studies[7] on this species, involving isotopic substitution experiments, which permit important structural conclusions to be derived.

EXPERIMENTAL

Molybdenum cofactor activity was measured[5] by complementation of apo-nitrate reductase of the *nit-1* mutant of *Neurospora crassa*. The cofactor was extracted[5] in the presence of dithionite from purified xanthine oxidase into dimethylsulphoxide containing approximately 5% H_2O and converted,[6] in the presence of 0.1 M thiophenol, to the Mo(V) state by controlled oxidation. EPR spectra of frozen samples were recorded and simulated.[2] Enrichment[2] with stable isotopes involved starting from xanthine oxidase incubated in ^{2}H- or ^{17}O-enriched water, or from enzyme prepared following *in vivo* enrichment with ^{95}Mo.

RESULTS

The EPR spectra of the thiophenol complex of the molybdenum cofactor are illustrated in Fig. 1. Spectra were recorded both at 9 [Fig. 1(a)] and 35 [Fig. 1(b)] GHz. The spectra, plotted on a g value scale, are indistinguishable from one another and indicate an accurately axial g-tensor.

Experiments carried out using ^{17}O-enriched water showed definite broadening of the spectrum. This was particularly apparent in the $g_{\perp}$-region of the spectrum. Broadening corresponded (for one oxygen ligand) to $A(^{17}O)_{\perp} = 0.4$ mT. Similar experiments employing ^{2}H-enriched water gave smaller, though almost certainly definite, broadening, corresponding in this case (again assuming a single ligand) to $A(^{2}H)_{\perp} = 0.3$ mT.

Figure 2 illustrates the spectrum of the ^{95}Mo cofactor at 9 GHz. The experimental spectrum is shown in Fig. 2(a). The signal-to-noise ratio is considerably better than that achieved in our earlier

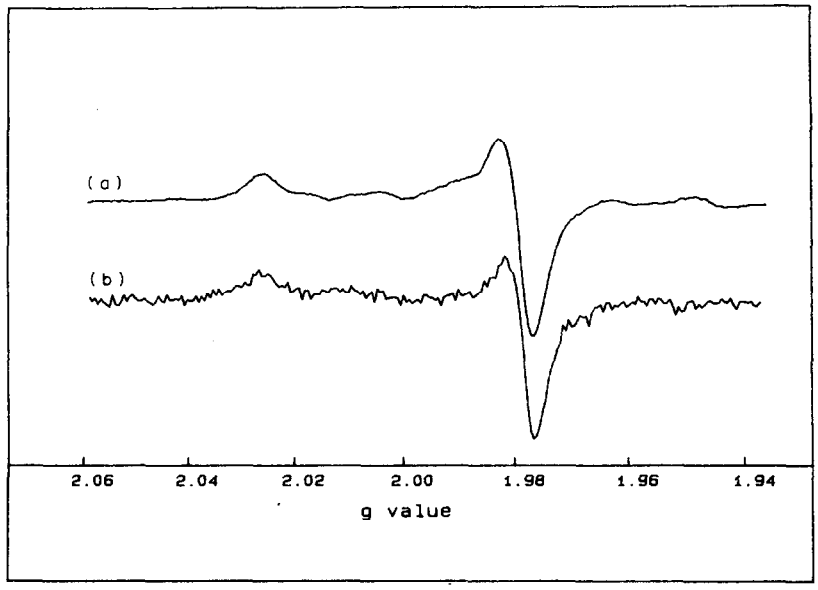

Fig. 1. EPR spectra of the thiophenol complex of the molybdenum cofactor at 9 (a) and 35 (b) GHz. The spectra are plotted on a g-value scale. Spectra were recorded at about 120 K.

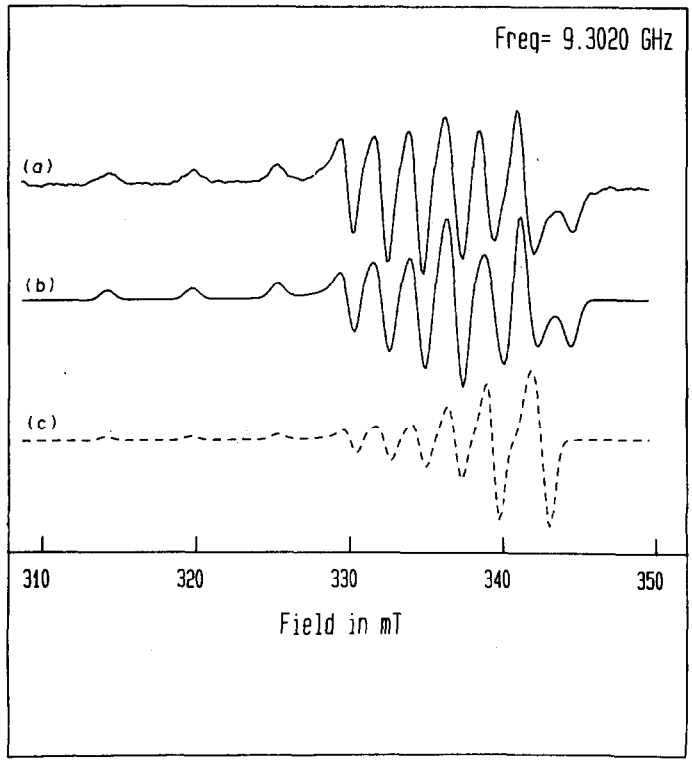

Fig. 2. EPR spectrum of the ^{95}Mo cofactor–thiophenol complex. (a) Experimental spectrum, corresponding to 100% enrichment with the isotope, obtained by subtracting a small amount of the spectrum of unenriched cofactor from that of the enriched sample. The computer simulation (b) was obtained by using the following parameters: $g_{xx} = 1.9779$, $g_{yy} = 1.9779$, $g_{zz} = 2.0260$, $A_{xx} = 64$, $A_{yy} = 64$, $A_{zz} = 159$ (hyperfine couplings in MHz); $\alpha_{xz} = 12°$ (angle of non-coincidence of the axes of g and A, convention of Rose). The unsatisfactory simulation (c) was based on the same parameters, except that $\alpha_{xz} = 0°$ was assumed.

work.[6] We were able to produce an accurate simulation [Fig. 2(b)] of the spectrum by using the parameters as listed in the caption. It was necessary to introduce a single angle of non-coincidence of the axes of g and A. If coincident axes were assumed, a totally inadequate simulation [Fig. 2(c)] was obtained. Conversely, if additional angles of non-coincidence of the axes, greater than about 5°, were introduced, then the fit became significantly worse.

DISCUSSION

The finding that the thiophenol complex of the molybdenum cofactor shows an axial g-tensor and one rather than two angles of non-coincidence of the axes of g and A, is in contrast to the situation[8] for various EPR-active species from molybdoenzymes. Current data are most readily interpreted[7] (cf. Refs 9–11) in terms of local C_s-symmetry at the molybdenum centre. Most of the enzyme species showing[3,12,13] coupling to ^{17}O and ^{2}H are presumed to contain a hydroxyl ligand of molybdenum, and we therefore assume that this is the case for the cofactor–thiophenol complex. Furthermore, the EPR parameters are comparable to those expected for an oxo complex of molybdenum having sulphur ligands. Combining these facts, we suggest the structure shown in Fig. 3 as a likely one for the cofactor–thiophenol complex.

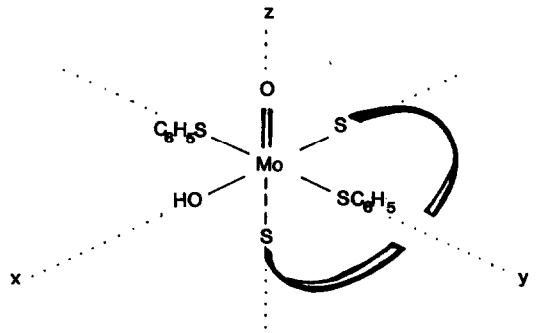

Fig. 3. Suggested co-ordination of molybdenum in the thiophenol complex of the molybdenum cofactor. The axes of A are approximately along the bond directions, as indicated, with the xz plane as the mirror plane. The curved line represents the organic part of the cofactor, co-ordinated to the metal via axial and equatorial sulphur atoms. In the enzyme the thiophenol ligands would presumably be replaced by cysteinyl residues from the protein.

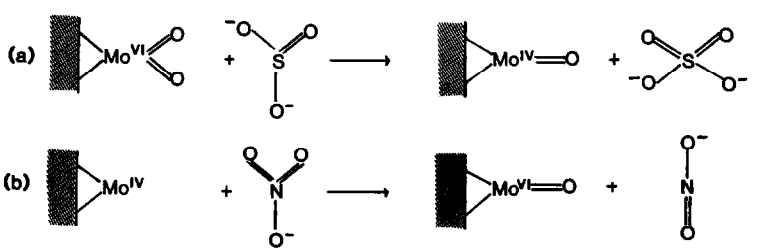
THE NATURE OF THE HIGH-pH–LOW-pH TRANSITION IN SULPHITE OXIDASE AND NITRATE REDUCTASE

R. C. BRAY



School of Chemistry and Molecular Sciences, University of Sussex, Brighton BN1 9QJ, U.K.

(*Received* 1 *July* 1985)

Abstract—The structures of the molybdenum centres in nitrate reductase and sulphite oxidase, and their reactions with substrates, are discussed in the light of work in the literature on model compounds and of work on the enzymes by EXAFS and EPR spectroscopy. EXAFS indicates that the metal in Mo(VI) states of the enzymes bears more oxo ligands than it does in Mo(IV) states. This is consistent with the enzymes functioning by oxo transfer mechanisms, shuttling between Mo(VI) and Mo(IV) states. The relevance of EPR work on the structures of Mo(V) states of the enzymes is discussed. EPR provides information complementary to that from EXAFS. At the same time, because of the complexities in the enzymes that it reveals, EPR indicates that caution needs to be exercised in interpreting EXAFS data. EPR shows that, for both enzymes, two different forms of the Mo(V) state are in pH- and anion-dependent equilibrium. In the low-pH forms the metal bears hydroxyl and anion ligands. The structure of the high-pH form is less certain but recent work indicates that it, too, may contain a hydroxyl ligand.

This paper summarizes recent work relating to the catalytic reactions occurring at the molybdenum centres of the enzymes sulphite oxidase and nitrate reductase. Particular emphasis is placed on sulphite oxidase from chicken liver and on nitrate reductase from anaerobically grown *Escherichia coli*, and on studies of these enzymes in the author's laboratory by EPR spectroscopy of Mo(V). The enzymes are involved respectively in catabolism of sulphur-containing amino acids prior to excretion as sulphate, and in the reduction of nitrate utilized under anaerobic conditions as an energy source. Oxidation–reduction centres, present in the enzymes in addition to molybdenum and involved in reaction with the second substrates and in electron transfer to or from molybdenum, are haem in sulphite oxidase, and haem and iron–sulphur in nitrate reductase. The very closely related nitrate reductase from *Pseudomonas aeruginosa* will not be discussed here, nor will the quite similar assimilatory nitrate reductases from spinach and *Chlorella vulgaris*, though some EPR studies have been reported[1–3] on each of these enzymes.

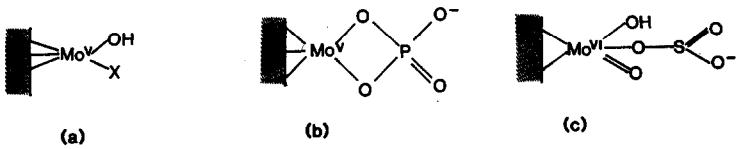
EXAFS data[4,5] on the enzymes under consideration and oxo-transfer studies on model compounds[6–8] indicate reactions to be overall as illustrated in Scheme 1. The numbers of oxo groups shown in the oxidized and reduced forms of the enzymes are those indicated by EXAFS. The reactions as formulated are consistent with

Scheme 1.

theoretical studies,[9] which indicate particular stability for molybdenum species having a single oxo group. (Note that EXAFS indicates an extra oxo ligand in *Chlorella* nitrate reductase in comparison with the *E. coli* enzyme. There may, however, be uncertainties relating to interpretation of published EXAFS data, because effects of anions on the enzymes, as discussed below, were not taken into account. It must be remembered that EXAFS does not distinguish, for example, S from Cl or P.)

EPR has been more successful[10] than EXAFS in identifying ligands of molybdenum in molybdoenzymes. However, the question arises as to what EPR can tell us about sulphite oxidase and nitrate reductase, since the catalytic reactions as formulated in Scheme 1 indicate involvement of Mo(IV) and Mo(VI), whereas EPR studies provide information only on Mo(V). Accepting that EPR might give information only indirectly relevant to the catalytic reactions, we note, nevertheless, the method's utility for unambiguous identification of ligands through studies of hyperfine couplings, and its considerable potential for yielding additional structural information (e.g. Ref. 11).

Molybdenum in enzymes may be titrated reversibly from the Mo(VI) state, through Mo(V), to Mo(IV) and the two redox potentials controlling these processes may be evaluated (e.g. Ref. 12). The enzymes generally show a maximum of about 40% conversion of molybdenum to the Mo(V) state. Oxidized sulphite oxidase gives rise[13] to Mo(V) signals within a few tens of milliseconds or less, on adding the substrate, sulphite. This no doubt results from reduction to Mo(IV), followed by rapid partial transfer of electrons to other centres. Nitrate reductase shows Mo(V) signals when isolated, these probably corresponding to enzyme molecules locked in a "dead-end" state, with the rest of the molecule oxidized, and unable to donate the single electron to nitrate. Signals from the enzyme may be increased[14] by addition of dithionite. The above facts indicate both that EPR is highly relevant to mechanistic studies of the enzymes and that their Mo(V) states may well be in rapid equilibrium with Mo(IV) or Mo(VI) states, or perhaps with both of these.



EPR data relating to the structures of chicken liver sulphite oxidase and *E. coli* nitrate reductase will be considered together. It has been known[15] for some years that the molybdenum centres of the enzymes, when in the Mo(V) oxidation state, exist in high- and low-pH forms, distinguished by different EPR spectra. The low-pH signals show well-resolved hyperfine coupling from a single proton (A_{av} about 1 mT) exchangeable with the solvent, whereas the high-pH spectra show no such coupling and have slightly different g values, with lower values of g_{av}. pK values for interconversion between the species were given[16,17] as 8.2 and 8.3, respectively, for sulphite oxidase and nitrate reductase.

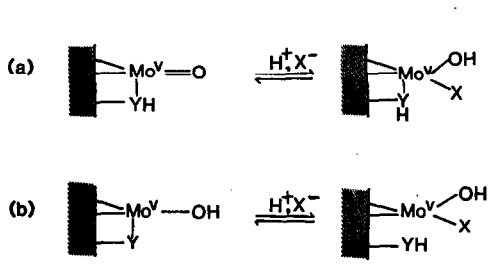
All currently available data are consistent with the low-pH species having the structure shown in Scheme 2(a), with the molybdenum atom bearing a hydroxyl ligand and an anion ligand. Evidence for this is as follows.

Interconversion between the species has been found to depend on the anion concentration as well as on the pH. Particularly for sulphite oxidase, it was shown[13] that a 10-fold increase in chloride concentration had the effect of increasing the apparent pK value for the interconversion by 1 pH unit. Variation in the nature of the anion ligand causes (particularly for nitrate reductase[14]) small changes in the form of the low-pH EPR spectrum, with different ligands each giving slightly different g and A values. With fluoride as a ligand, hyperfine coupling to ^{19}F ($A_{av} = 0.71$ mT for nitrate reductase[14] and about 0.5 mT for sulphite oxidase[13]) is observed.

The characteristic large and predominantly isotropic hyperfine coupling from a proton in the low-pH spectrum disappears on dissolving the enzymes in ^2H_2O. Coupling for this proton, for example[14] in the nitrate complex of nitrate reductase [$A(^1H) = 1.46, 1.11, 1.09$ mT], is comparable in magnitude and in extent of anisotropy with coupling of the proton from a hydroxyl ligand of molybdenum in irradiated molybdate crystals[18] [$A(^1H)$ 0.96, 0.71, 1.32 mT]. The latter seems a good model for the enzymes and appears to be the only authenticated report in the literature of EPR work on a Mo(V)—OH compound.

Evidence for oxygen as a ligand has been provided[19,20] by substitution studies with ^{17}O,

Scheme 2.



carried out by dissolving the enzymes in enriched water. Spectra have not so far been evaluated in detail, in contrast to those for similar species from xanthine oxidase, for which ^{17}O couplings and angular relationships have been evaluated.[21] Nevertheless coupling is clearly detectable in the low-pH species from sulphite oxidase. Though so far no ^{17}O substitution has been reported for nitrate reductase, there seems no reason to doubt that for both enzymes, the structure of the low-pH species is that of Scheme 2(a).

Still further support for the structure of Scheme 2(a) has been obtained from studies of the phosphate complex of sulphite oxidase. This is believed to have the structure given in Scheme 2(b). When the pH of samples of sulphite oxidase is decreased in the presence of a mixture of phosphate and chloride ions, then the high-pH species is replaced progressively, as the pH value decreases, by a mixture of the low-pH chloride species and the phosphate species, with the relative proportions of these depending on the ratio of the concentrations of the two ions.[13] The spectrum of the phosphate complex is unlike that of other anion complexes in that it shows[22] no coupling to protons. Furthermore, on dissolving in ^{17}O-enriched water there is no change in the spectrum. However, if ^{17}O-enriched phosphate is employed, using ordinary water as solvent, then coupling to this nucleus is clearly seen[23] in the spectrum. The data are thus fully consistent with the structure of Scheme 2(b), in which phosphate acts as a bidentate ligand, in contrast to the monodentate ligand, X^-, in Scheme (2a). Phosphate is an inhibitor of sulphite oxidase and the structure of Scheme 2(b) seems particularly significant since it is analogous to a plausible intermediate in the enzyme's action on sulphite.

We now turn to the structure of the high-pH species. The signal from this is not affected by anions but is affected[19,20] (for sulphite oxidase) by ^{17}O-enriched water. Until quite recently it was assumed that in the signal-giving species the hydroxyl and anion ligands of the low-pH species had been replaced by an oxo group. However, recent work casts some doubt on this. For nitrate reductase, although this was overlooked in the original work,[17] use of ^2H_2O as solvent results[14] in a significant sharpening of the high-pH spectrum. This means that there must be a coupled proton in the signal-giving species, though the coupling is not sufficient to result in resolved splittings. The data are explicable[14] in terms of a single coupled proton with $A(^1H)$ 0.38, 0.32, 0.33 mT.

A comparably coupled proton also exists in the high-pH species from sulphite oxidase, though here its effects on the spectrum are of a more subtle nature. This proton manifests[24] itself by producing features in the spectrum due to "spin flip" transitions, in which the spin of the coupled proton flips simultaneously with that of the unpaired electron. Such transitions[25] (not previously observed in a biological system) result in shoulders which are not easily saturated on raising the microwave power, and which appear on either side of EPR lines, separated from one another by twice the proton NMR frequency, i.e. by 1.0 mT at the fields in question (9 GHz). These spectral features, disappearing in ^2H_2O are observable[13] in the high-pH spectrum of sulphite oxidase, being particularly apparent at the g_1 feature. Detailed interpretation by George[24] reveals that the proton is coupled quite reasonably strongly to molybdenum [$A(^1H)$ 0.4, 0.4, 0.7 mT]. However, splittings or broadening effects of the proton on the spectrum are effectively lost, due to magic angle effects in relation to non-coincidence of the axes of g and A.

In the light of the above data were not able to elucidate unambiguously the structure of the high-pH species. Possible alternative schemes for the high-pH–low-pH transition are given in Scheme 3(a) and (b). Scheme 3(a) is an adaptation of an earlier scheme,[13] with the high-pH species bearing an oxo ligand replaced by a hydroxyl in the low-pH species. The hydroxyl proton "seen" in the low-pH species is the one whose dissociation controls the pK. An additional ligand, Y, bears the more weakly coupled proton of the high-pH species. In the low-pH species, although this second proton is still present, its coupling is supposed to have become undetectably small due to the change of structure. In the alternative, Scheme 3(b), molybdenum bears a hydroxyl ligand in both high- and low-pH species, whose proton is strongly coupled in the low-pH and less so in the high-pH species. In this scheme[24] the ligand Y, present in the high-pH species, dissociates from the metal in formation of the low-pH species, being replaced by the anion X^-, with Y becoming protonated. It is dissociation of this proton, which is not detectably coupled to molybdenum, that controls the pK. In partial analogy with Scheme 3(b), work[26] with model compounds has shown that a ligand of molybdenum (in this case a nitrogen atom)

Scheme 3.

may be reversibly protonated and deprotonated, between species having quite distinct EPR parameters, with the proton apparently not showing coupling to molybdenum in either. Bearing in mind the substantial magnitude of the proton coupling [$A(^1H)_{av} = 0.5$ mT] in the high-pH species from sulphite oxidase, Scheme 3(b) tends to be favoured in the author's laboratory. Though further variations of schemes for the high-pH–low-pH transition could be suggested, it is important to note that in principle, a combination of careful EPR studies with ^{17}O and EXAFS should certainly be capable of distinguishing between the alternatives of Scheme 3(a) and (b).

In attempting to relate the EPR data to the enzyme mechanisms (Scheme 1), we need to bear a number of points in mind. It is perhaps surprising that there seems to have been a lack of detailed steady-state kinetic studies on these enzymes, particularly of studies taking proper account of the two-substrate nature of the reactions. Such work could in principle establish basic points such as whether pK values in the enzymes, or in the substrates, or both, control the profiles (cf. Refs 13 and 17) of enzyme activity against pH. At the present time we have no more than hints as to whether activity of the enzymes shows anion-dependent pK values analogous to the ones detected by EPR. Nor do we know, for instance, whether the true substrate of sulphite oxidase is SO_3^{2-} or HSO_3^-. Steady-state kinetic studies might also provide information as to whether anion inhibitors bind to oxidized or reduced forms of the enzymes. Perhaps more definitively, pre-steady-state kinetic studies could establish whether the oxidation or the reduction step of the turnover is rate-limiting for the enzymes. Only if reaction of substrates with molybdenum is rate-limiting are subtle changes to the structure of the molybdenum centre likely to be crucial to turnover rates.

Mo(V) complexes such as those of the low-pH forms of Scheme 3 might arise by replacement of oxo groups of Mo(VI) species by anions, as in electrochemical reactions[6,7] of model compounds. It is attractive to think of EPR-detectable anion-bearing species from the enzymes as being analogous in structure to complexes of the enzymes with substrate molecules, formed before reaction takes place. Binding of substrate to molybdenum might occur via an increase in co-ordination number. On the other hand, in the case of sulphite oxidase, should it be that the true substrate is HSO_3^-, this could react by addition across a Mo(VI)—oxo bond to give the species of Scheme 2(c). For nitrate reductase, an anion ligand in the Mo(IV) form might simply be exchanged for nitrate. Starting from such species, plausible oxo transfer mechanisms can readily be written.

Complexities revealed by EPR work, particularly in relation to anion effects, make it clear that caution needs to be used in interpreting most published EXAFS work on molybdoenzymes, since this seems not to have been taken into account. It should be added that EPR has provided no support for the suggestions[5] that *E. coli* nitrate reductase carries a relatively heavy atom, "X", 2.8 Å from Mo. If this atom were paramagnetic, as are most of the possible candidates such as iron, it would be coupled to Mo, and there are no indications whatever of this in the EPR data. The enzyme shows Mo(V) EPR spectra quite typical of the metal in all other molybdoenzymes (other than nitrogenase). Whether additional EXAFS studies will substantiate the existence of "X" remains to be seen.

Thus it is particularly desirable that further work by EXAFS should take account of effects of pH and anions on the enzymes. Additional studies, by both EPR and EXAFS, should also seek more carefully than hitherto to relate the species being studied to kinetic data on the enzymes. The way seems open for work leading to considerably deeper understanding than at present exists of these enzymes.

Acknowledgements—I thank my co-workers, as listed in the references, for their part in the published work described. I also thank Dr G. N. George for discussions and Dr S. Cramer for drawing my attention to Ref. 9. The work was supported by grants from the MRC and the SERC.

BIOLOGICAL CONTRIBUTIONS TO MINERAL CYCLING IN NATURE WITH REFERENCE TO MOLYBDENUM

BRUCE C. KELLEY

Biotechnology Australia Pty Ltd, P.O. Box 20, Roseville, NSW 2069, Australia

(*Received* 10 *June* 1985)

Abstract—While the biological functions of molybdenum have been well studied, the mobilization of this element from its mineral hosts is poorly understood. This in part results from the low solubility product of molybdenum disulphide, its peculiar electronic structure which resists chemical and biological attack, and its toxicity to the growth of metal sulphide leaching bacteria. However, considering the low concentrations of molybdenum in many natural systems, chemoautotrophic and thermophilic acidophiles may make significant contributions to the molybdenum cycle in nature. The physiology and metabolism of these organisms is discussed in relation to metal sulphide dissolution, with special reference to molybdenum disulphide.

A variety of naturally occurring elements, including iron, sulphur and molybdenum, bear similarities in their ability to form a variety of chemical compounds and to participate in electron-transfer reactions through valence-state transitions. These attributes contribute to the important biological functions of these elements in living organisms, and, in turn, provide the basis for the microbial cycling of a large number of mineral elements in nature. The present discussion is not centred on the structure and function of the metalloproteins involved in such oxidation–reduction reactions, but rather on the contribution of specialized microorganisms in oxidizing large amounts of inorganic compounds and therefore their involvement in mineral transformations. There have been many excellent reviews on this subject,[1–7] to which the reader is directed.

Unlike the major mineral elements, molybdenum transformations have received little attention despite the importance of molybdenum in a diversity of living systems. As stated above, the chemolithotrophic bacteria represent important biological mediators of mineral ore solubilization. Although these bacteria exhibit a low tolerance to soluble molybdenum,[8] they may still make considerable contributions to molybdenum transformation on a global scale, particularly when the low concentration of molybdenum in natural systems is considered. In addition, the recently recognized tolerance of thermoacidophilic microorganisms to relatively high levels of molybdenum[9,10] and their contribution to the increased mobilization of this element is important from both the biological and industrial viewpoint. This paper aims to provide a simplified overview of the metabolism of the chemolithotrophic bacteria, and their contribution to the mobilization of biologically and industrially important elements, with specific reference to molybdenum.

SULPHIDE MINERAL DEGRADATION

The microbially-assisted degradation of sulphide-based minerals is a biochemical process which involves a complex interaction between organisms, medium and mineral surfaces. Since the initial demonstrations of the contribution of iron-oxidizing bacteria[11,12] to mineral sulphide dissolution, the majority of studies on the biodegradation of minerals have centred on the activities of the acidophilic chemolithotrophic bacterium *Thiobacillus ferrooxidans*. However, in a natural leaching environment it is likely that a diverse group of organisms are involved in a series of complex interactions, as discussed by Lundgren and Malouf.[7] The extent to which sulphide mineral degrades depends on the development of a microbial pH succession,[13] which in turn is influenced by factors

Table 1. Examples of iron- and sulphur-oxidizing bacteria associated with mineral sulphide ores

Temperature profile	Microorganism	Growth mode
Mesophile	*T. ferrooxidans*	Oxidizes reduced iron and sulphur compounds, autotrophic
	T. thiooxidans	Oxidizes sulphur and reduced sulphur compounds, e.g. $S_2O_3^{2-}$ and S^{2-}; autotrophic
	Leptospirillum ferrooxidans	Oxidizes reduced iron only; autotrophic
Moderate thermophile	Unnamed	Oxidizes iron, sulphur and mineral sulphides at 50°C; organic compound requirement
Extreme thermophile	*Sulfolobus*	Oxidizes iron, sulphur and mineral sulphides at 55–85°C; can use CO_2, simple organic compounds or is heterotrophic

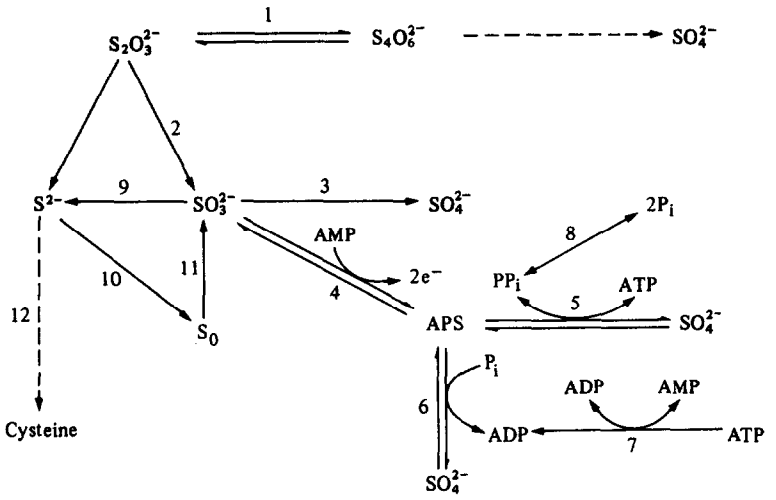
including the physical and chemical characteristics of the mineral, climatic conditions and the availability at reaction sites of water, oxygen and carbon dioxide. The complex microbial associations which develop on the minerals are dominated by the organisms with sulphur and iron-oxidizing abilities which possess tolerance to high levels of acidity and high concentrations of heavy metals. Some examples of important microorganisms involved in leaching metals from mineral sulphide ores are listed in Table 1. These types of organisms exhibit diversity with respect to the nature of their energy sources for growth, their carbon requirements, temperature and pH optima for growth. An important ubiquitous and well-studied member of the natural consortium is *T. ferrooxidans* and aspects of this organism's physiology and metabolism are briefly discussed below.

PHYSIOLOGY OF *T. FERROOXIDANS*

T. ferrooxidans is a Gram-negative rod and displays optimum growth at pH 2.0–2.5 and at temperatures of 25–35°C. Energy for growth is derived from the oxidation of reduced valence state iron and sulphur compounds. Carbon dioxide is the sole source of carbon for growth and the organism prefers the ammonium ion as the nitrogen source, although the ability to fix dinitrogen has been reported.[14]

CARBON METABOLISM

T. ferrooxidans is obligatorily dependent on carbon dioxide as a source of cellular carbon. Indeed, the growth of this organism is sensitive to many organic acids. This probably relates to the large transmembrane pH gradient operating in organisms with an internal pH near neutrality and growing in a highly acidic environment. Such a pH gradient may permit the accumulation of weak acids into the cell cytosol,[15,16] resulting in cytosolic acidification and death.



The carbon metabolism of *T. ferrooxidans* is characteristic of a chemolithotroph. Carbon dioxide assimilation is via the Calvin–Benson cycle, catalysed by the enzyme ribulose bisphosphate carboxylase.[17–19] The metabolism of carbon by this organism has recently been reviewed in brief by Ingledew.[16] A more detailed review on this subject is provided by Matin.[15] The Krebs cycle in *T. ferrooxidans* is incomplete and therefore cannot assume its generally recognized catabolic role in generating energy and reducing power. Instead, the Krebs cycle performs a biosynthetic role, providing carbon skeletons for the synthesis of amino acids. Poly(β-hydroxybutyrate) represents the major storage product in this organism.[16]

SULPHUR METABOLISM

The biochemical pathways of sulphur oxidation are quite complex. The oxidation of inorganic sulphide to sulphate can be simply represented as follows:[1]

$$S^{2-} \rightarrow S^{6+} + 8e^{-}. \quad (1)$$

As discussed by Torma,[1] a series of intermediate products are formed during this oxidative process, although intermediate-product identification may not be possible due to chemical instability. A simplified scheme of sulphur metabolism in *T. ferrooxidans* is presented in Fig. 1. The oxidative metabolism of inorganic sulphur compounds has been discussed at length by Tuovinen.[20] Thiosulphate may be oxidized directly to tetrathionite by the thiosulphate-oxidizing enzyme. Alternatively, thiosulphate is oxidized by initial

Reaction	Enzyme
1	Thiosulphate - oxidizing enzyme
2	Rhodanese
3	AMP - independent sulphite oxidase
4	APS - reductase
5	ATP - sulphurylase
6	ADP - sulphurylase
7	Adenylate kinase
8	Pyrophosphatase
9	Sulphite reductase
10	Sulphide oxidase
11	Sulphur - oxidizing enzyne
12	*O*-acetylserine sulphydrase

Fig. 1. Simplified scheme of inorganic sulphur compound metabolism in *T. ferrooxidans*.

rhodanese-catalysed cleavage to sulphide and sulphite (Fig. 1). The latter chemical species probably represents a key metabolite in this rather complex sequence of reactions.[1] Sulphite in turn may be oxidized to sulphate by the enzyme AMP-independent sulphite oxidase[20] in an energy-linked process. An alternative pathway would involve the production of adenosine-5′-sulphatophosphate (APS) by the enzyme APS-reductase. APS in turn would be coupled to substrate-level phosphorylation by ADP-sulphurylase and adenylate kinase activities[20] (Fig. 1). Thus sulphate and ATP would result.

The reductive assimilation of sulphur into cellular protein in this organism has also been discussed by Tuovinen.[20] During growth on ferrous iron, sulphate is actively assimilated into APS[21] prior to its reduction via sulphite and sulphide into cellular protein.[20] During growth on thiosulphate, however, the cleavage of this compound provides a continual source of sulphide which can be incorporated into cellular protein.[20,22] Under these conditions, the major pathway of thiosulphate utilization would probably proceed in the oxidative direction[20] via APS-reductase to ultimately produce sulphate and ATP (Fig. 1).

The structure–function relationships and oxidative mechanisms of the sulphur pathway are discussed in detail elsewhere.[23,24]

IRON METABOLISM

Under optimum conditions, *T. ferrooxidans* grows aerobically at pH 2.0 with an electron-transport chain operating between the two half-reactions as follows:

$$2Fe^{2+} \rightarrow 2Fe^{3+} + 2e^- \quad (2)$$

$$2e^- + \tfrac{1}{2}O_2 + 2H^+ \rightarrow H_2O \quad (3)$$

$$\text{Sum: } 2Fe^{2+} + \tfrac{1}{2}O_2 + 2H^+ \rightarrow 2Fe^{3+} + H_2O \quad (4)$$

The steady-state E_h during growth of the Fe^{2+}–Fe^{3+} couple is about +770 mV and that of the $\frac{1}{2}O_2$–H_2O couple at the cytosolic pH (pH 5.5–6.0) is +890 mV.[16,25] There is, therefore, little energy available to the cell from this oxidative reaction. Chemolithotrophic bacteria that use high redox

potential substrates which are energetically unfavourable typically rely on a high throughput of electrons along the electron-transport chain. High oxidase rates, up to 10 times those reported for beef heart mitochondria,[16] are achieved since the cells develop high concentrations of some electron-transport components. As pointed out by Ingledew,[16] the copper protein rusticyanin, which is the proposed primary electron acceptor of the respiratory chain, accounts for approximately 5% of the total cell protein, while for cytochrome *c* the figure more closely approximates 10%. The components of the electron-transport chain have received considerable study.[16,26,27]

Since the Fe^{2+}–Fe^{3+} couple is so electropositive (+770 mV), it is not possible to directly reduce NADP ($NADP^+$–NADPH, $E_o = -320$ mV). Reduced pyridine nucleotides are essential for cellular processes such as carbon dioxide fixation. The mechanism of NADPH production is assumed to be via an energy-dependent reversal of electron flow. Such a process, while generally documented in chemolithotrophs,[16] has only been observed on two occasions in *T. ferrooxidans*.[28,29] Ingledew[16] provides an excellent discussion on the thermodynamics and possible mechanism of reversed electron transport in this organism.

The nature of the electron-transport chain operating during iron oxidation can now be considered. Most of the electron flux occurs between Fe^{2+} and O_2 while less than 10% of the electrons flow "uphill" from Fe^{2+} to NADP.[16] The electron-transport chain has been modelled[16,25] and can be summarized as follows. Fe^{2+} is oxidized outside of the cell membrane. Cytosolic oxidation of Fe^{2+} would not be expected to occur since the cytosolic pH (5.5–6.0) would favour rapid autooxidation of the Fe^{2+} substrate and chemical precipitation of the Fe^{3+} product. Both rusticyanin and cytochrome *c* are considered as soluble components of the periplasmic space.[25] Ingledew *et al.*[25] consider that one of the multiple forms of cytochrome *c* present may be bound to the cell membrane as is the terminal oxidase, cytochrome a_1, where O_2 reduction occurs at the inner or cytosolic surface of the cell membrane.

Although the components involved in reversed electron transport have yet to be fully identified or purified, the respiratory studies of DiSpirito and Tuovinen[30] provide some insight into the comprehensive pathways of electron transport accompanying Fe^{2+} oxidation.

ENERGY GENERATION

The relationship between electron flow and ATP generation in *T. ferrooxidans* has been discussed in terms of the chemi-osmotic theory.[16,25,31] The chemi-osmotic hypothesis broadly proposes that electron transfer along an H^+-impermeable membrane results in a translocation of H^+ out of the cell. This occurs as a function of the spatial distribution of respiratory chain components which can therefore be considered as redox-coupled H^+ pumps. The energy from the oxidative reaction (substrate oxidation) is thus translocated and conserved as an electrochemical gradient. This proton motive force is made up of a chemical and an electrical component and is responsible for driving H^+ back into the cell via a reversible ATPase which in turn drives the phosphorylation of ADP.[16,25,31] In *T. ferrooxidans*, the chemi-osmotic theory is also invoked,[16,25,31] although the component contributions to the proton motive force are different. The acidity of external medium coupled with the neutrality of the cytosol provides a large and favourable chemical potential of H^+ into the cell. The organism thus uses the acidic environment to its advantage, generating a transmembrane pH gradient by internal proton consumption (reduction of oxygen at the cytosol–cell membrane interface) and using this gradient for the synthesis of ATP via the reversible ATPase system. This therefore represents a simple chemi-osmotic model that does not postulate redox-coupled proton pumps, and is consistent with the environment in which the organism lives.

MICROBIAL LEACHING

The dissolution of a large number of metal sulphides has been shown to be bacterially assisted. Examples of some of the more common sulphides have been considered by Manchee[4] and Ehrlich[5] and include arsenopyrite (AsFeS), orpiment (As_2S_3), bismuthite (Bi_2S_3), enargite [$Cu_3(As,Sb)S_4$], chalcopyrite ($CuFeS_2$), bornite (Cu_5FeS_4), covellite (CuS), chalcocite (Cu_2S), tetrahedrite ($Cu_8Sb_2S_7$), marcasite (FeS), pyrite (FeS_2), molybdenite (MoS_2), pentlandite [$(NiFe)_9S_8$], millerite (NiS), galena (PbS), uraninite (UO_2) and sphalerite (ZnS). The metal sulphides resist bacterial attack to varying degrees[2] and it is of interest that molybdenite is quite recalcitrant.[2] For discussions on the leaching of various metal sulphides together with appraisals of commercial leaching methods, the reader is directed to a large number of excellent reviews.[1–4,7,32]

MECHANISMS OF MICROBIAL DEGRADATION OF SULPHIDE MINERALS

Iron plays a key role in mineral sulphide degradation. Thus, attempts to demonstrate "direct"

bacterial oxidation of mineral sulphides must necessarily exclude iron.

In an iron-free environment, Torma and Bosecker[6] found that the rate of metal dissolution was proportional to the solubility product of the respective metal sulphide. Thus metal sulphide dissolution at the mineral surface provides the sulphide moiety as the oxidizable substrate for the bacterial metabolic system:[6]

$$MS \rightleftharpoons M^{2+} + S^{2-}, \quad (5)$$

where M = bivalent metal.

Torma and Bosecker[6] further suggested that substrate dissociation from the mineral surface, rather than bacterial attachment, is the prerequisite for bacterial oxidation of the insoluble metal sulphides.

In an elegant series of experiments, Tributsch and Bennett[33,34] also demonstrated that metal sulphides with high solubility products are good substrates for bacterial leaching. However, other conditions also apply, such as an excess of holes in the valence band or electron extraction by Fe^{3+} (see later). Thus, in the absence of iron, protons (H^+) were shown to play a central catalytic role in the mechanism of bacterial oxidation of metal sulphides.[33,34] Proton-catalysed reactions chemically break surface bonds, including electronic-state transitions into the forbidden energy gap. This leads to the formation of weakly bonded $SH^{\delta-}$ groups which are, in turn, removed from the sulphide surface through complex formation with an unidentified molecular carrier used by the bacterium.[33,34]

As indicated above, iron is often associated with the leaching system. Indeed, one of the most important naturally occurring growth substrates for *T. ferrooxidans* is the iron sulphide mineral, iron pyrites (FeS_2), which is often associated with other more valuable minerals. Iron is brought into solution by the aqueous oxidation of pyrite by molecular oxygen. In an excellent review, Lowson[35] identifies three reaction paths for pyrite oxidation, namely bacterial, chemical and electrochemical, restricting discussion to the latter two. The chemical oxidation path is a three-step process:

(i) the oxidation of pyrite by molecular oxygen:

$$2FeS_2 + 7O_2 + 2H_2O \rightarrow 2FeSO_4 + 2H_2SO_4; \quad (6)$$

(ii) the oxidation of ferrous iron to ferric iron by molecular oxygen, which is thought to be the rate-limiting step;

(iii) the oxidation of pyrite by ferric iron.

Thermodynamic data predicts sulphate formation[35,36] as shown in eqn (7):

$$FeS_2 + 7Fe_2(SO_4)_3 + 8H_2O \rightarrow 15FeSO_4 + 8H_2SO_4. \quad (7)$$

However, in acid ferric medium, elemental sulphur is often produced[4,36] [see eqn (8)]:

$$FeS_2 + Fe_2(SO_4)_3 \rightarrow 3FeSO_4 + S_0. \quad (8)$$

The electrochemical pathway is the summation of two half-cell reactions:[35]

(i) the cathode:

$$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O, \quad (9)$$

(ii) the anode:

$$FeS_2 + 8H_2O \rightarrow Fe^{3+} + 2SO_4^{2-} + 16H^+ + 15e^-. \quad (10)$$

Both the chemical and electrochemical reactions make important contributions to localized iron environments in nature.[35] In the natural environment, the large number of physical–chemical parameters involved would greatly influence the kinetics and direction of pyrite dissolution.

Thus, the bacterium is presented with reduced iron and sulphur compounds as energy sources for growth:

$$4FeSO_4 + O_2 + 2H_2SO_4 \rightarrow 2Fe_2(SO_4)_3 + 2H_2O, \quad (11)$$

$$2S_0 + 3O_2 + 2H_2O \rightarrow 2H_2SO_4. \quad (12)$$

The products of these reactions, ferric sulphate and sulphuric acid, provide an excellent means of dissolving a variety of mineral sulphides by what is sometimes termed the "indirect" mechanism of bacterial attack:

$$MS + Fe_2(SO_4)_3 \rightarrow MSO_4 + 2FeSO_4 + S_0, \quad (13)$$

where M = bivalent metal.

The ferrous sulphate produced can be recycled as a bacterial-growth substrate [see eqn (11)].

When ferric iron is present, there is less need to break chemical bonds in the mineral sulphide surface by proton interaction,[33,34] although proton concentration is critical to maintain ferric iron solubility. Ferric iron may directly break chemical bonds by extracting electrons from the valence band of the sulphide provided that energetic constraints are met.[33,34] This may provide an efficient means of sulphide oxidation.

In the natural leaching system, it is likely that all of these parameters, including the solid state, chemical and electrochemical properties of the mineral sulphide, the presence or absence of iron,

particularly trivalent iron, and the proton concentration are important in the relationship between *T. ferrooxidans* and the mineral sulphide.

MOLYBDENUM MINERALS

Molybdenum does not occur in the free state in nature. There are two recognized ores of molybdenum, namely molybdenite (MoS_2) and wulfenite ($PbMoO_4$). Molybdenite is the chief ore of molybdenum and is relatively widely distributed, frequently occurring in small veins or scattered as small flakes, and often associated with granites and pegmatities. The chief source is the U.S., with smaller but significant producers including the U.S.S.R., Chile, China, Canada, Japan and Norway.

Geologically, molybdenum exhibits two important valence states, +4 and +6. The lower valence state is largely limited to molybdenite, while the higher valence state is characteristic of molybdates formed in surface environments. The weathering of molybdenum minerals yields molybdate ion in solution, chiefly as MoO_4^{2-} at pH values above 5 or 6, and $HMoO_4^-$ at lower pH values. Thus molybdenum is probably present in soils chiefly as absorbed molybdate (MoO_4^{2-}). The successful use of soil molybdenum content analysis as a geological prospecting tool for molybdenum would indicate that molybdenum in soils is largely dependent on parent mineral content.

The complex area of molybdenum mineral weathering, speciation, chemistry, soil solution transport, interaction with other materials and adsorption in relation to physico-chemical parameters will not be considered here.

APPLICATIONS OF MOLYBDENUM

Industrial

The industrial uses of molybdenum are largely confined to metallurgical applications (90%), of which the iron and steel industry accounts for some 70% of the total usage. Steels (carbon, stainless, alloys and specialized), cast irons, superalloys and other welding alloys are important end products of molybdenum. The use of molybdenum lies in its enhancement of strength, toughness, wear and corrosion resistance. Non-metallurgical applications include lubricants, catalysts in petroleum refining processes, paint and dye pigments, and chemical usage in flame retardants and smoke suppressants. When considering major end use product areas, molybdenum applications extend to machinery (35%), transportation (20%), oil and gas (15%), chemicals (11%), electrical (9%) and miscellaneous (10%).

Biological

The biological significance of molybdenum is extremely well-documented and will only be briefly mentioned here. Molybdenum represents an important metal component of a variety of enzymes that are found in micro-organisms, plants and animals. Examples of the reactions catalysed by molydoproteins are shown in Table 2. The suitability of molybdenum as a participant in electron-transfer reactions is attributable to its complex chemical properties. Molybdenum can undergo two-electron transfers and possesses some four oxidation states which appear biologically relevant, namely +6, +5, +4 and +3. Molybdenum transitions between +6 and +4 oxidation states have been reported but it is likely that a variety of electron-transfer reactions operate between the various oxidation states. The molybdenum-containing cofactor, which is common to the different molybdo-enzymes, will be covered in detail by other participants at this Symposium.

BIOLOGICAL LEACHING OF MOLYBDENITE

The microbiological leaching of molybdenite (MoS_2) by chemolithotrophic bacteria has been generally reported as follows:[1]

$$2MoS_2 + 9O_2 + 6H_2O \rightarrow 2H_2MoO_4 + 4H_2SO_4. \quad (14)$$

Recently, Lyalikova and Lebedeva[37] implied that different microorganisms may oxidize different moieties of the molybdenite molecule. The chemolithotrophic bacteria would oxidize the sulphur moiety[1] [see eqn (14)]. However, molybdenum chemistry could predict the following reaction:[37]

$$2MoS_2 + 9O_2 + 2H_2O \rightarrow 2(MoO_2 \cdot SO_4) + 2H_2SO_4. \quad (15)$$

Their calculations[37] showed that the oxidation of molybdenum dioxide would provide sufficient energy for growth of an autotrophic organism. Such a culture of molybdenum-oxidizing bacteria was obtained, growing on molybdenum dioxide as substrate:

$$MoO_2 + O_2 \rightarrow MoO_3. \quad (16)$$

Indeed, their evidence suggested that molybdenite was oxidized by two microorganisms, one that oxidized molybdenite and the other molybdenum dioxide.[37] This interesting observation, together

Table 2. Reactions catalysed by molybdoproteins

Enzyme	Conversion catalysed
Nitrogenase	Nitrogen → two ammonia
Nitrate reductase	Nitrate → nitrate
Chlorate reductase	Chlorate → chlorite
Tetrathionate reductase	Tetrathionate → two thiosulphate
Thiosulphate reductase	Thiosulphate → sulphite + sulphide
Sulphite oxidase	Sulphite → sulphate
Xanthine oxidase	Xanthine → uric acid
Formate dehydrogenase	Formate → bicarbonate
Carbon monoxide oxidoreductase	Carbon monoxide → carbon dioxide
Acetaldehyde oxidase	Acetaldehyde → acetate

with identification and characterization of the organisms involved, awaits further examination.

Historically, Bryner and Anderson[38] first provided conclusive evidence that molybdenite can be oxidized by autotrophic bacteria or by their reaction products. In the presence of undefined bacterial cultures, a seven-fold increase in molybdenite dissolution was observed over sterile controls. Soluble molybdenum was present in a 1:4 ratio of penta- and hexavalent forms. In the presence of pyrite, a significant increase in molybdenum sulphide oxidation was observed, indicating the importance of indirect mechanisms of molybdenite solubilization. Such mechanisms have been discussed above. Indeed, the contribution of direct (Fe^{3+}-independent) bacterial attack cannot be determined from these early studies[38] as no efforts were made to totally exclude iron from the system.[38]

The use of mesophilic chemolithotrophic microorganisms in leaching molybdenite is largely restricted due to the toxicity to growth of such organisms by soluble molybdenum.[8,38,39] In a comprehensive study,[8] molybdenum was shown to be lethal to *T. ferrooxidans* at concentrations above 5 mg l^{-1}. Variations in tolerance to different metals were coupled to the type of oxidizable substrate.[8] While oxidizing thiosulphate, the organism was more sensitive to heavy metals than when oxidizing iron. It has recently been shown[40] that the presence and oxidation of ferrous iron may afford a protective effect on *T. ferrooxidans* from a range of heavy metals, particularly cobalt. The alleviation of inhibition by toxic metals of iron oxidation by non-inhibitory concentrations of disodium ethylenediamine tetraacetic acid (EDTA) has also been recently evaluated.[41] The picture for molybdenum, however, remains unclear and further studies aimed at elucidating the lethal effects and mechanism of action of this metal have not been forthcoming.

In commercial leaching operations involving toxic metal species such as molybdenum, the use of protective agents such as EDTA would be unlikely to be practical from economic considerations. A remote or two-stage operation physically separating the bacterial generation of ferric iron from the chemical or indirect interaction with the mineral sulphide ore in question may provide the basis for a leaching process.[3,32] However, the relative ease with which other base metals, particularly copper-, zinc- and nickel-based minerals, are leached has tended to limit research input into molybdenum solubilization and recovery.

Attempts to enhance molybdenite oxidation have been recently successful through the use of high-temperature sulphur-oxidizing bacteria of the genus *Sulfolobus*. As early as 1966, Brierley[42] first reported the isolation of an organism resembling *Sulfolobus* from an acid thermal spring drainage in Yellowstone National Park. Detailed characterization of these acidophilic thermophiles was later presented by Brock *et al.*,[43] who demonstrated that *Sulfolobus* represents a new genus of bacterium characterized as a facultative autotroph with distinctive morphology and growing on sulphur or a variety of sulphur compounds. Growth was further characterized by a low pH optimum (2–3) and temperatures ranging from 55 to 85°C. The organism originally isolated by Brierley[42] was examined in greater detail[44] and found to closely resemble *Sulfolobus* as described by Brock *et al.*[43] Unlike *Sulfolobus* however, the isolate oxidized ferrous iron in addition to sulphur and was unable to use yeast extract as an energy source.[44] Nevertheless, growth on iron and sulphur substrates was enhanced by the provision of yeast extract (0.02%).[44]

In applying this *Sulfolobus*-like organism to mineral sulphide substrates, Brierley and Murr[9] first demonstrated the ability of acido-thermophilic bacteria to leach molybdenite. In a preliminary report,[9] molybdenite concentrates could be oxidized

in the presence of the thermophilic isolate in shake flask experiments. Maximum yields (13.3% yield after 30 days) were observed in the presence of yeast extract (0.02%) and ferrous sulphate (1%). Over similar times, uninoculated controls reported only 0.1% molybdenum recovery. The organism therefore exhibited a unique tolerance to relatively high levels of molybdenum, far in excess of that previously reported for mesophilic chemoautotrophic bacteria.[8] In addition, scanning electron micrograph analysis showed isolate attachment to molybdenite fines.[9] The use of scanning electron microscopy as a tool in bioextractive research was further highlighted by the demonstration of microcolony formation on molybdenite fines,[45] although attachment was not clearly indicated. In a more specific study,[46] attempts were made to correlate mineral properties of molybdenite with the attachment of *Sulfolobus* to find out whether attachment was random or specifically related to mineral surface characteristics. No correlation could be found between bacterial attachment and dislocation lines or structural abnormalities on the mineral surface, thus leading the authors to conclude that crystal dislocations probably do not play an important role.[46] Brierley,[2] however, has questioned the validity of this conclusion based on insufficient mineralogical and chemical definition of the material used, the possibility of a contribution to dislocation lines through the inclusion of gangue mineral, and artificial defect introduction resulting from thin-section preparation. Brierley[2] clearly indicates that dislocations represent active sites of crystal changes which may provide obvious benefits for effective biological or chemical exploitation and that further work is required before bacterial attachment to molybdenite fines is more clearly understood. Indeed, the whole area of a bacterial attachment mechanism relating to a large number of mineral ores awaits resolution.

In any commercial operation where molybdenum may be present as a major or minor component of the mineral being extracted or its associated gangue, the use of chemoautotrophic bacteria may be in doubt, due to the low tolerance to molybdenum of these organisms.[8] The improved leaching of molybdenite by *Sulfolobus*[9] therefore provided the stimulus for further demonstrations of biologically catalysed molybdenum solubilization. In a detailed study, Brierley[10] reported on the tolerance of *Sulfolobus* to high concentrations of soluble molybdenum. Initial studies[9] showed that tolerance to hexavalent molybdenum at 60°C was high, although the tolerance varied according to whether the cells were actively growing or not. Oxygen uptake studies[10] revealed that cell respiration was only slightly impaired at 2.0 g l^{-1} (21 mM) Mo(VI). The organism was still capable of active growth at a soluble molybdenum concentration of 0.75 g l^{-1} (7.8 mM). As reported above, the maximum tolerance of chemoautotrophic *Thiobacilli* is approximately 0.005–0.09 g l^{-1}.[8]

The high-temperature organism was further evaluated in batch reactor studies designed to evaluate the leaching of a variety of molybdenite-containing materials.[10] Molybdenite waste and tailings could not be leached due to the acid-consuming nature of the associated gangue minerals which displaced the pH above physiologically favoured conditions. No attempts were made to maintain the pH (2–3) by pH control. High grade (7.3% molybdenum) run-of-mine ore could be successfully leached.[10] Molybdenite concentrate was also biologically leached in a batch reactor system at 60°C. The maximum dissolution observed over a 30-day period was 26.5 mg Mo l^{-1} day^{-1} (13.3% yield) and required the addition of yeast extract (0.02%) and ferrous sulphate (1%). In batch reactors, a biphasic kinetic leaching pattern was established with a gradual cessation of molybdenite leaching.[10] This effect, ascribed to the build-up of inhibitory products in the liquor, could be overcome by the operation of a semi-continuous process, replacing the medium periodically with fresh leaching solution. Brierley[10] argues that industrial processes, reliant on continuous liquor flows, would eliminate this problem of toxic product build up. A variety of organic compounds were tested for their ability to stimulate leaching.[10] The highest rates were obtained with either yeast extract or sucrose, provided ferrous iron was present. Indeed, the presence of ferrous sulphate was most important in molybdenite oxidation, whereas sulphur was inhibitory.[10] When ferrous iron was replaced by pyrite, soluble molybdenum levels were reduced if the pyrite concentration exceeded 50% of total solid substrate. This was considered to be due to preferential pyrite oxidation or precipitation of ferrimolybdite.[10] The latter possibility might also be expected to occur when soluble ferrous iron is included.

During the course of these experiments, Brierley[10] made the interesting observation that the organism reduced soluble oxidized hexavalent molybdenum to molybdenum blue, the pentavalent state, while oxidizing sulphur. In a recent publication,[47] the anaerobic reduction of molybdenum by *Sulfolobus* species was investigated. Both *Sulfolobus brierleyi* and *S. acidocaldarius* oxidized sulphur aerobically and anaerobically, simultaneously inducing a blue colouration in the medium attributable to a reduced form of molybdenum.[48] The results[47] indicated that

Sulfolobus may be using Mo(VI) as an electron acceptor, as previously discussed by Brierley.[2] The generation of pentavalent molybdenum even under aerobic conditions was considered likely due to the poor solubility of oxygen at 60°C. The complexity of the structures of Mo(VI) and Mo(V) in solution under these conditions, coupled with the enhancing effect of aluminium on Mo(VI) reduction,[47] has not as yet permitted elucidation of this proposed redox couple. Appropriate controls excluded the possibility of chemical effects and it would therefore appear that the reduction requires the intervention of these unique bacteria or their reaction intermediates or products.

The ability of these high-temperature bacteria to enhance molybdenum dissolution, coupled with apparent molybdenum reduction under microaerophilic or anaerobic conditions, enhances the metabolic versatility of these unique organisms. In addition, these findings further implicate the importance of the biological molybdenum cycle in nature.

CONCLUSIONS

Although molybdenum is regarded as a rare metal, it is distributed widely in nature and occurs as independent mineral deposits. While molybdenum has many practical uses and is commercially a valuable commodity, the real significance of this element lies in its biological functions which are common across a diversity of life forms. Indeed, it represents an essential functional component in a large number of biochemical systems.

While much is now known of the complex chemistry and biochemistry of molybdenum, the mobilization of this element from its mineral hosts through natural weathering and biodegradative processes remains poorly understood. There may be several reasons for this. Molybdenite is considered to be quite recalcitrant or resistant to biological attack.[2] This in turn probably relates to the low solubility product of molybdenum disulphide.[34] This compound is a layer-type transition metal sulphide with a peculiar electronic structure which does not favour a chemical reaction with protons, and is therefore extremely resistant against bacterial attack and chemical oxidation.[34] Mesophilic chemolithotrophs are generally most implicated in the biologically assisted dissolution of metal sulphides, yet these organisms show low tolerance to soluble molybdenum.[8,38,39] The extreme thermophiles show greater tolerance[9,10] and have been shown to enhance molybdenite solubilization and to mediate valence-state transitions between soluble molybdenum species through as yet unknown mechanisms. However, the difficulties associated with working with such mesophilic and thermophilic bacteria, coupled with the problems outlined above and the complex solution chemistry of molybdenum, may have tended to restrict progress in this area of research.

The gradual depletion of natural high-grade resources of some specific elements may necessitate the development of alternative extractive technologies. Thus biological mining is likely to find applications in the extraction of high-value metals from low-grade zones of mineralization. Conventional approaches may be more severely limited by economic constraints related to mineral deposit size and value. Future research may well be directed by industrial demands towards the mobilization and recovery of more exotic mineral elements, including molybdenum. This can only help to contribute to our increased understanding of the biological significance and cycling of molybdenum in nature.

OXIDATIVE BREAKDOWN OF POLYMERIC PLUTONIUM(IV) HYDROXIDE BY CERIUM(IV)

D. J. SAVAGE* and T. W. KYFFIN

Dounreay Nuclear Power Development Establishment, Caithness KW14 7TZ, U.K.

(*Received* 4 *February* 1985; *accepted after revision* 27 *July* 1985)

Abstract—The breakdown of polymeric plutonium(IV) hydroxide (plutonium colloid) by cerium(IV) has been studied spectrophotometrically by monitoring the formation of plutonium(VI). Reaction rate variations were studied with changes in cerium(IV), acid and plutonium colloid concentrations. A reaction mechanism involving the formation of $[Ce_2O(OH)_2]^{4+}$ and its reaction with the polymer surface to produce two plutonium(V) ions is postulated to explain the observed kinetic data, in particular the maximum in the reaction rate at around 0.3 M nitric acid.

Plutonium(IV) cations hydrolyse under conditions of low acidity to form either a hydrous oxide precipitate or more frequently a colloidal "solution" of polymeric hydroxide. The conditions for colloid formation have been studied by several authors.[1–5] The process can be represented by eqns (1) and (2):

$$Pu^{4+} + 4H_2O \rightleftharpoons Pu(OH)_4 + 4H^+, \quad (1)$$

$$nPu(OH)_4 \rightarrow (PuO_2)_n + 2nH_2O. \quad (2)$$

Reactions (1) and (2) must be incomplete to provide the charge necessary to stabilize the colloid.

Reversal of the hydrolysis and polymerization occurs at increased acidity. Normally the breakdown of plutonium colloid is very slow[1,5] because of the difficulty in reversing the polymerization reaction (2). It has been shown that the rate of reconversion into ionic forms, in nitric acid solution, increases with nitric acid strength and decreases with colloid age.[1] The depolymerization rate is significantly increased by anions which complex plutonium(IV) strongly.[5] The fluoride ion is outstandingly effective in this respect; for example, aged colloid is completely reconverted to ionic plutonium species in less than 5 min at 20°C using 0.4 M nitric acid containing 0.05 M fluoride. Consequently, fluoride is often employed in the analysis of solutions which may contain colloidal plutonium hydroxide.[6]

The exceptional effectiveness of fluoride ions is believed to arise from their small size and high charge density, permitting them to penetrate the colloid molecules by replacing hydroxyl groups. Their ability to complex with plutonium(IV) then results in removal of a plutonium atom from the colloid molecule with the lower polarizability of fluoride inhibiting bridging-bond formation between plutonium atoms.

A common analytical technique for plutonium measurement is to oxidize the plutonium to plutonium(VI) with cerium(IV) and to measure the plutonium(VI) spectrophotometrically at 831 nm.[6–8] During attempts to extend this technique to the estimation of plutonium(IV) colloid concentrations by performing the measurements with and without a fluoride pretreatment, it was obvious that cerium(IV) was itself capable of converting polymeric plutonium(IV) hydroxide into simple plutonium(IV) cations. The mechanism for this reaction is obviously different from that postulated for fluoride. This paper studies the conversion of colloidal plutonium(IV) hydroxide to ionic species by reaction with cerium(IV). An examination of the relationship between the cerium(IV) concentration, the plutonium concentration and the acidity dependence of the reaction has been used in an attempt to elucidate a probable reaction mechanism.

EXPERIMENTAL

Plutonium(VI) *measurement*

Cerium(IV) is a strong oxidant ($E^\ominus = 1.6$ V in dilute nitric acid)[9] and will oxidize ionic plutonium species to plutonium(VI). This reaction has been used in a titrimetric analytical procedure[10] and as

* Author to whom correspondence should be addressed.

the basis of a spectrophotometric technique.[6–8] The latter technique was used in this study to follow the breakdown of plutonium colloid by monitoring the formation of the plutonium(VI) peak at 831 nm, using a Perkin–Elmer Hitachi 200 spectrophotometer.

Preparation of plutonium colloid

The polymeric plutonium hydroxide solutions were prepared by heating a plutonium nitrate solution (of known plutonium concentration and free acidity) with a little hydrogen peroxide to form plutonium(IV), neutralizing most of the free acid with sodium hydroxide and diluting to known volume to give about 2.5 mg plutonium cm^{-3} and about 0.02 M calculated free acidity. The stock solutions were apple green.

The ionic plutonium content of these colloid solutions was checked by measuring the visible spectrum at 477, 567, 603 and 831 nm, corresponding to the absorption maxima of plutonium(IV), plutonium(V), plutonium(III) and plutonium(VI), respectively. The only ionic plutonium found was plutonium(VI), which ranged from 1 to 12% of the total plutonium present, depending upon the batch.

Depolymerization rate measurement

The breakdown of plutonium colloid was examined by adding ceric ammonium nitrate in dilute nitric acid of the desired strength. Aliquots of plutonium colloid stock were added and the mixture was then diluted to volume and transferred to the spectrophotometer. The reaction time was the elapsed time from adding the plutonium colloid aliquot.

Initial reaction rates were calculated from the first measurement of ionic plutonium(VI), which was normally obtained 3 min after initiating the reaction, corrections being made for the ionic plutonium present in the original colloid sample.

RESULTS

Cerium(IV) *oxidation of plutonium*(IV)

The oxidation of plutonium(IV) by cerium(IV) can be expressed as follows:

$$Pu^{4+} + 2H_2O + 2Ce^{4+} \rightleftharpoons PuO_2^{2+} + 4H^+ + 2Ce^{3+}. \quad (3)$$

It follows from this equation that the kinetics of the reaction may be slow and that both the equilibrium and rate should vary with acidity. The acid dependence of the reaction has been observed in other applications[10] although the redox potential is nearly independent of the acidity between 0.5 and 2 M nitric acid.[9]

Some preliminary measurements of the rate of this reaction were made in order to assess the minimum acceptable concentrations of cerium(IV) in the depolymerization rate measurements. Oxidation of any ionic plutonium must be more rapid than the breakdown of plutonium colloid.

The time required for oxidation of plutonium(IV) with cerium(IV) was estimated at a range of acidities. The results for the oxidation of a 0.00059 M plutonium(IV) solution at 16 ± 1°C are shown in Table 1. These show that, with decreasing acidity, progressively lower cerium(IV) concentrations are required to oxidize 99% of the plutonium present within 5 min.

Reaction of cerium(IV) *with colloidal plutonium*(IV)

Some typical plots of the proportion of colloid converted to plutonium(VI) vs reaction time are shown in Figs 1 and 2. These show that the time for

the reaction to reach 50% pf completion is in the region 5–30 min. The data in Fig 1 show that the reaction rate varies with the colloid batch or age, under identical experimental conditions. Figure 2 shows that, for one batch of colloid, the breakdown rate varies with both cerium(IV) concentration and solution acidity.

Cerium(IV) does not form complexes with plutonium(IV) but it does produce plutonium(VI) from polymeric plutonium(IV) hydroxide. If it is assumed that reversal of the hydrolysis–polymerization reaction by acid is still involved, a reaction of the type:

$$(PuO_2)_n \xrightarrow{H^+} nPu^{4+} \xrightarrow{Ce^{4+}} nPuO_2^{2+} \qquad (4)$$

is probable. In this case the initial rate of breakdown is expected to be given by an expression of the type:

$$-\frac{dPu_c}{(dt)_{init}} = k[Ce(IV)]^x[H^+]^y[Pu_c]^z, \qquad (5)$$

where [ ] represents the concentrations (or, more strictly, activities) of the reacting species, Pu_c represents colloidal plutonium(IV), and x, y and z are simple exponents. Thus, a plot of log

$$-\frac{dPu_c}{(dt)_{init}} \text{ vs log } [Ce(IV)]$$

at constant cerium(IV) and plutonium colloid concentrations should be a straight line of slope x. Similar plots vs log $[H^+]$ and $[Pu_c]$ should give y and z, respectively.

Initial reaction rates were calculated for the first 3 min of the reaction at $16 \pm 1°C$. Colloid of the same batch and age was used for all measurements of any one variable so that it was valid to express $[Pu_c]$ by the actual plutonium concentration.

The maximum acceptable measured initial rate is limited by the requirement of an approximately constant plutonium colloid concentration during the period of measurement, and by the experimentally imposed limit of about 3 min between reaction initiation and measurement. Rates up to about 1×10^{-6} mol l^{-1} s^{-1} have been used to this work.

The minimum rate is limited by the requirement that the plutonium(VI) produced by colloid breakdown can be measured in the presence of the

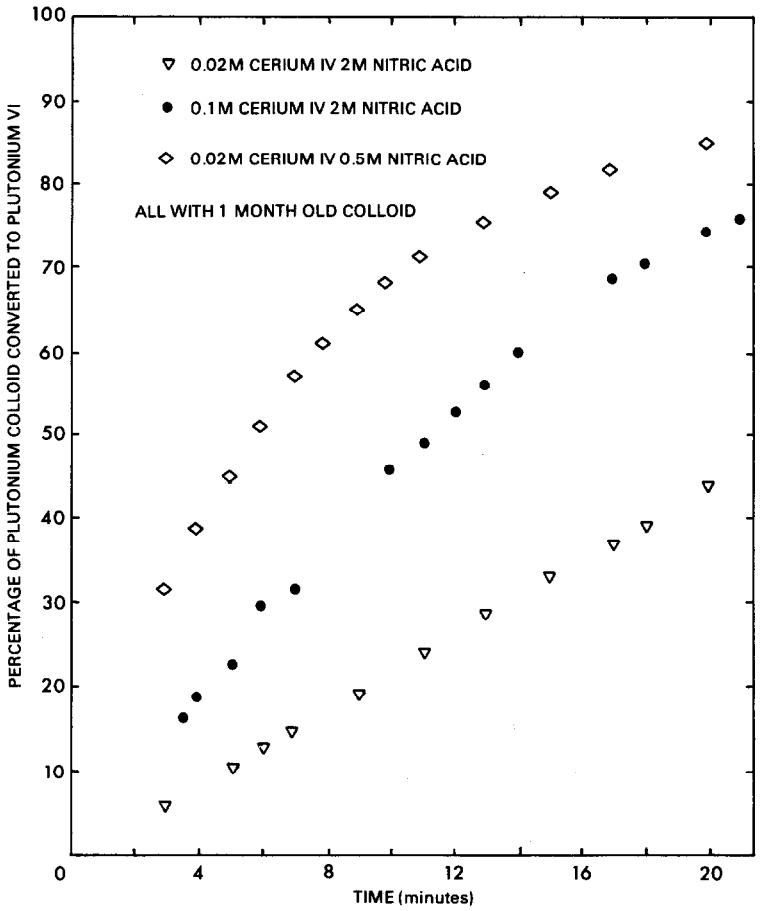

Fig. 2. Conversion of plutonium colloid to plutonium(VI) by cerium(IV).

plutonium(VI) present initially. This limitation becomes critical when the rate falls below about 1.5×10^{-7} mol of plutonium l^{-1} s^{-1}.

The minimum cerium(IV) concentration is limited by the requirement that any plutonium(IV) present is almost completely oxidized during the reaction period. This is particularly important at acidities above 1 M. The data in Table 1 have been used to assess the minimum acceptable concentration. At low acidities the cerium(IV) concentration is limited by the stoichiometric requirement of 2 mol of cerium(IV) per mol of plutonium.[1]

The results for the variation of the initial rate with cerium(IV) concentration (Fig. 3), at various fixed acidities between 0.05 and 3 M, lie on a series of approximately parallel lines with a slope of about 0.5. More detailed examination of the calculated slopes, listed in Table 2, shows that the value alters systematically with acidity.

The results for the variation of the initial rate with acidity, at various fixed cerium(IV) concentrations (Fig. 4), lie on a series of approximately parallel curves. Although the practical limitations discussed above mean that some curves are incomplete, it is obvious that they pass through a definite maximum at about 0.3 M acid. At acidity levels above 0.5 M, the plots become straight lines with a negative slope close to unity. The results are listed in Table 2.

The variation of initial rate with plutonium colloid concentration, at various fixed acidities and constant cerium(IV) concentration, gives parallel straight lines, with a slope of unity, as shown in Fig. 5 and Table 2.

Thus, for acidities between 0.5 and 3 M, the breakdown rate can be expressed approximately by the equation:

$$-\frac{dPu_c}{(dt)_{init}} = k[H^+]^{-1}[Ce(IV)]^{0.5}[Pu_c].$$

Reversal of the hydrolysis reaction by acid, as initially postulated, is not a rate-limiting reaction. The dependence of colloid breakdown on both cerium(IV) concentration and the hydroxyl concentration of the acid solution suggests that a cerium(IV) hydroxide species may be involved and the rate maximum at 0.3 M acid suggests that

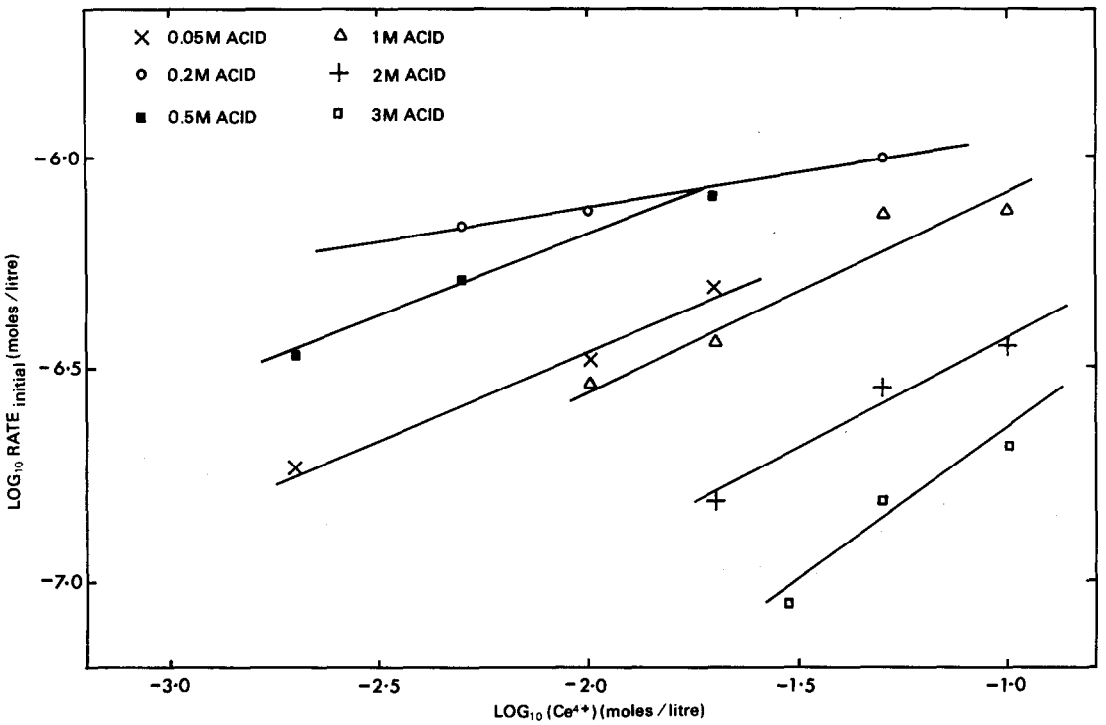

Fig. 3. Variation of plutonium colloid breakdown rate with cerium(IV) concentration at various acidities.

a rate-limiting species reaches its maximum concentration under such conditions.

DISCUSSION

It is first necessary to consider the probable cerium(IV) species present in low nitric acid media, when nitrate complexing and hydrolysis can take place simultaneously.

Although anionic nitrate complexes are formed in 6 M nitric acid, the nitrate complexing is weak, with equilibrium constant values of about 1 (0.6,[11] 2[12] and 0.2[13]) reported for the first nitrate complex.

Using a mean value for

$$K_1 \{[Ce(IV)NO_3]/Ce(IV)][NO_3]\}$$

of 1, the ratio of cerium(IV) nitrate complex to uncomplexed cerium(IV) is 0.3 in 0.3 M nitrate

solution. Thus, about 80% of cerium(IV) is uncomplexed by nitrate in 0.3 M nitrate solution, and nitrate complexing can be largely ignored.

Hardwick and Robertson[14] deduce that cerium(IV) exists as a mixture of Ce^{4+}, $[Ce(OH)]^{3+}$ and a dimer, probably $(Ce–O–Ce)^{6+}$, with equilibrium constants of:

$$K = \frac{[Ce(OH)^{3+}][H^+]}{[Ce^{4+}]} = 5.2$$

and

$$K_1 = \frac{[(Ce–O–Ce)^{6+}]}{[Ce(OH)^{3+}]^2} = 16.5.$$

These data apply at 25°C and in ionic strength of 2, although they show that the equilibria are not greatly affected by either temperature or ionic strength. The data are consistent with measurements of the cerium(III)–cerium(IV) redox potential.[9]

Other works[15,16] have assumed that hydrolysis does not involve the formation of dimers. They have shown that, in 2 M perchloric acid, formation of the first hydrolysis complex $[Ce(OH)]^{3+}$ is almost complete, and that the equilibrium constant for the second hydrolysis step:

$$K_2 = \frac{[\{Ce(OH)_2\}^{2+}][H^+]}{[Ce(OH)^{3+}]}$$

has a value of 0.6[15] or 0.2.[16] Thus at about 0.3 M acid the second hydrolysis species has become more important than the first. Further hydrolysis can occur. The extent of this will obviously increase at low acidities, and therefore the second hydrolysis species will pass through a concentration maximum.

Cerium(IV) has been shown to exist as oxo- or hydroxo-bridged dimers even in 6 M nitric acid, with equilibrium constant values for

$$2Ce(IV) \rightleftharpoons [Ce(IV)]_2$$

reported as 17[17,18] and 20.[19]

It follows that both the first and second hydrolysis species are unlikely to exist in significant quantities as monomers.

The dimerization of the first hydrolysis species can be represented by:

$$2[Ce(OH)]^{3+} \rightleftharpoons [Ce(IV)–O–Ce(IV)]^{6+}.$$

If a similar reaction is envisaged for the second hydrolysis species then:

$$2[Ce(OH)_2]^{2+} \rightleftharpoons [HO–Ce(IV)–O–Ce(IV)–OH]^{4+} + H_2O.$$

Since the dimer $(Ce_2O)^{6+}$ will predominate over the monomer, this suggests that the actual course of the hydrolysis may involve:

$$(Ce_2O)^{6+} \overset{OH^-}{\rightleftharpoons} [Ce_2O(OH)]^{5+} \overset{OH^-}{\rightleftharpoons} [Ce_2O(OH)_2]^{4+}$$

rather than formation of $[Ce(OH)_2]^{2+}$.

Danesi[20] studied the hydrolysis of cerium(IV) in a 3 M sodium nitrate medium, assuming that in 1 M acid unhydrolysed species only are present. The data discussed above suggest that a significant proportion (about 25%) will be present as monomeric or dimeric hydrolysis species under these conditions. Danesi[20] calculated that the hydrolysis proceded via two dimeric species and finally formed a polymeric species, and he gave stability constant data for this formation. He also stated that the work would not distinguish between unhydrolysed cerium(IV) and the first hydrolysis product in 1 M acid. In the latter case, the hydroxide content of the hydrolysis species would be increased. Calculation of the variation of these species with acidity shows that the intermediate species passes through a concentration maximum (see Fig. 6) at about 0.1 M acid in a 3 M nitrate solution. Reduction of the total nitrate concentration to the levels used in this work will reduce the extent of nitrate complexing, and so shift the hydrolysis to higher acidities.

Thus, the literature data suggest that, in 0.3 M nitric acid, cerium(IV) exists predominantly as the dimer of the second hydrolysis stage, i.e. as $[Ce_2O(OH)_2]^{4+}$ or a closely related species, and that this species will pass through a concentration maximum close to this acidity. As 0.3 M is the acidity at which the rate of the oxidative breakdown of plutonium colloid reaches a maximum, if follows that $[Ce_2O(OH)_2]^{4+}$ is probably the active cerium species.

The structural similarities of cerium(IV) and plutonium hydroxides suggests that the cerium(IV) hydroxide can combine with hydroxyl sites on the surface of the plutonium hydroxide polymer to form plutonium–oxygen–cerium groups similar to the normal metal–oxygen–metal bonding of the polymer. The redox reaction can then proceed by transfer of an electron from the plutonium oxygen bond to the cerium oxygen bond on the other side of the same oxygen atom with simultaneous oxygen–metal cleavage. Two routes are possible. With the involvement of one electron transfer per plutonium atom, the hydroxide polymer is converted into ionic plutonium(V):

$$(PuO_2)_n + nCe^{4+} \rightarrow n(PuO_2)^+ + nCe^{3+},$$

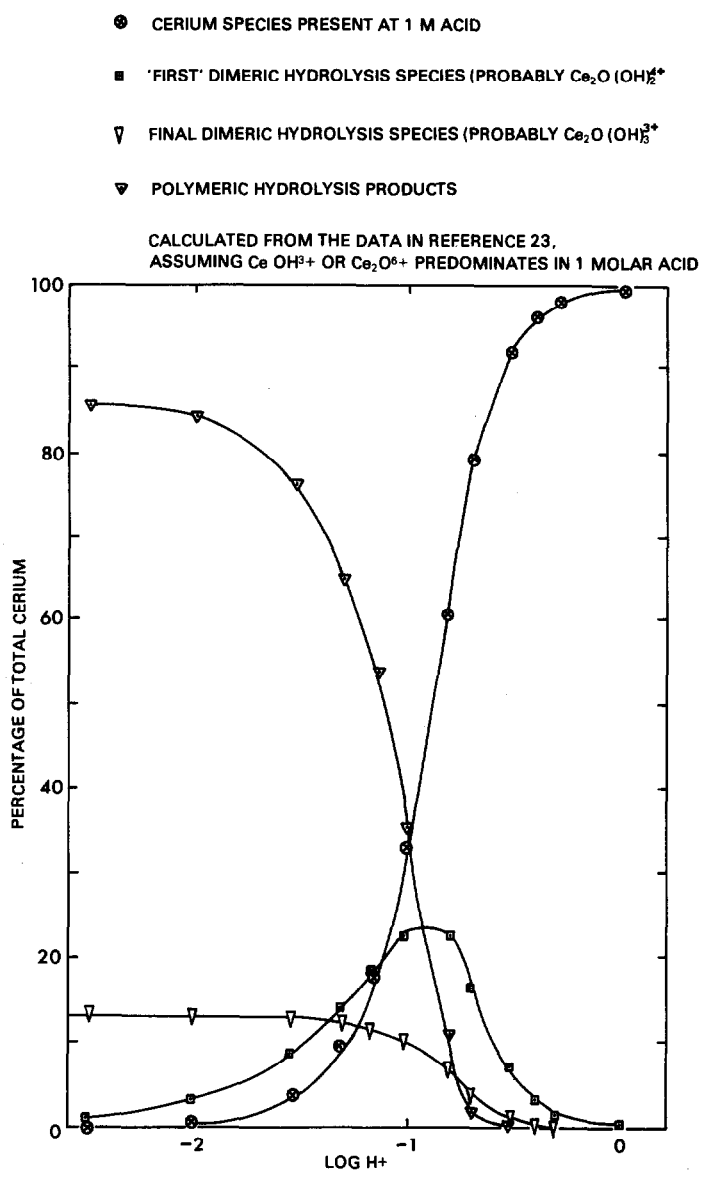

Fig. 6. Variations of cerium species with acidity.

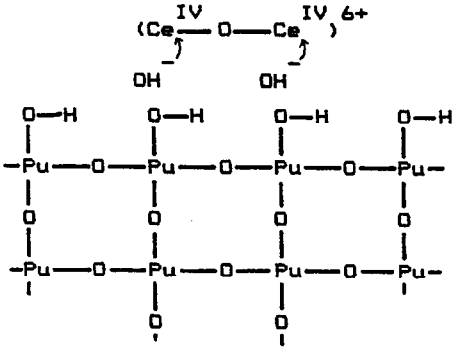
which will be rapidly oxidized[21] to plutonium(VI) in solution, while the transfer of two electrons per plutonium atom will produce ionic plutonium(VI) $(PuO_2)^{2+}$ directly.

If one dimeric cerium(IV) molecule reacts with two hydroxyl groups and two plutonium sites on the colloid surface (probably in two stages), to form a transition complex which breaks to form two free plutonium(V) ions in solution which are themselves rapidly oxidized, the limiting reaction in 0.5–3 N HNO_3 becomes:

$$2\,\text{Pu sites} + (Ce_2O)^{6+} + 2OH^- \rightarrow 2(PuO_2)^{2+} + [Ce_2O(OH)_2]^{2+},$$

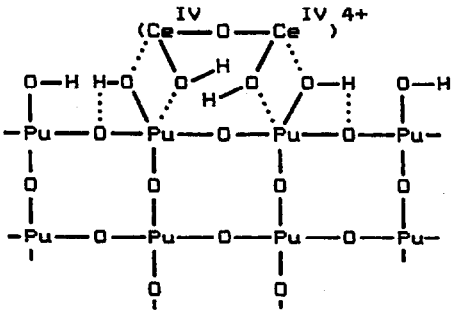
and the measured rate will be:

$$\frac{dPu_5}{dt} = -\frac{dPu_c}{dt} = k[(Ce_2O)^{6+}]^{0.5}[OH^-][Pu_c].$$



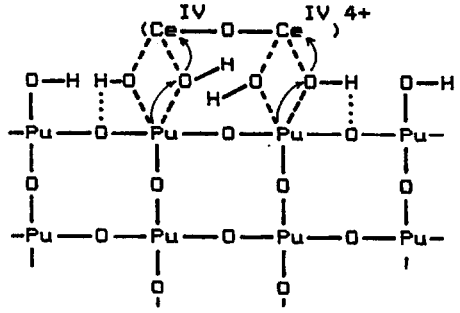
Therefore, as the oxidation of plutonium(V) to plutonium(VI) is rapid, the observed rate will be:

$$\frac{dPu_6}{dt} = k[Ce(IV)]^{0.5}[H^+]^{-1}[Pu_c],$$

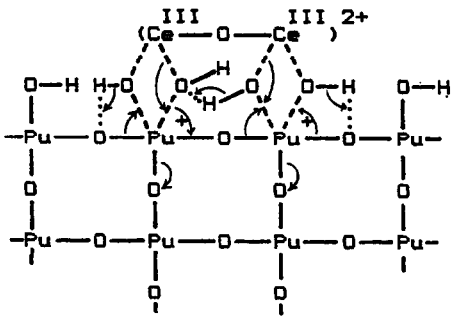


which is identical with the expression which fits the observed data for a colloid batch. The reaction of one dimeric cerium(IV) molecule with the plutonium colloid to produce two free plutonium(V) ions in

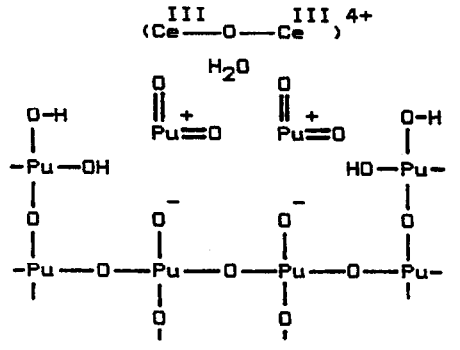
solution is therefore the probable reaction route, with $[Ce_2O(OH)_2]^{4+}$ as the reacting species.



A probable reaction pathway for the depolymerization is:



REACTANTS



REACTIVE INTERMEDIATE

CHARGE TRANSFER

BREAKDOWN OF COMPLEX

PRODUCTS

$$PuO_2^{+} + Ce^{4+} \longrightarrow PuO_2^{2+} + Ce^{3+}$$

OXIDATION OF Pu^{V} (RAPID)

This involves the formation of an intermediate activation complex.

The proposed mechanism is consistent with the steady change in cerium(IV) concentration dependence with acidity (see Table 2). In 3 N nitric acid solution the proportion of monomeric cerium(IV) species will be higher (because of nitrate complexing and reduced hydrolysis) and reactions of the type $2Ce(IV) \rightleftharpoons [Ce(IV)]_2$ may contribute to the overall rate. At lower acidities, this type of reaction will be less important, and some of the plutonium colloid may even be oxidized by a polymeric rather than by a dimeric species.

CONCLUSIONS

Cerium(IV) reacts with polymeric plutonium hydroxides to simultaneously breakdown the polymer and oxidize the plutonium to plutonium(VI). The rate of breakdown increases with cerium(IV) concentration, but decreases with increasing acidity above 0.5 M nitric acid. The experimental data between 0.5 M and 3 M nitric acid

will fit a rate expression:

$$\text{Rate} = k[\text{Pu}][\text{Ce(IV)}]^{0.5}[\text{H}^+]^{-1}.$$

The rate of breakdown passes through a maximum at about 0.3 M nitric acid. Literature data suggests that, in 0.3 M nitric acid, cerium(IV) exists largely as a dimeric hydrolysis species, probably $[\text{HO–Ce(IV)–O–Ce(IV)–OH}]^{4+}$. A reaction mechanism is postulated which will fit both the observed maximum in the reaction rate, and the observed rate equation at higher acidities. $Ce_2O(OH)_2$ combines with the polymer surface through hydroxyl bridges to two plutonium atoms. Simple electron transfer in these bridges simultaneously reduces two cerium atoms to cerium(III), oxidizes two plutonium atoms to plutonium(V), and breaks the oxygen–metal bonds holding the plutonium atoms to the polymer. At acidities higher than 0.5 M nitric acid, cerium(IV) probably exists as $(Ce_2O)^{6+}$. Before the oxidative breakdown can proceed, reactions such as $(Ce_2O)^{6+} + 2OH^- \rightleftharpoons [Ce_2O(OH)_2]^{4+}$ are necessary to form the reactive species and contribute to the rate-controlling step in the 0.5–3 M nitric acid range, to explain the inverse acidity dependence.

THEORETICAL STUDY OF THE STATIC JAHN–TELLER EFFECT—II* THREE-MODE VIBRONIC COUPLING IN OCTAHEDRAL HALOCOMPLEXES WITH TRIPLY DEGENERATE ELECTRONIC STATES

PETER PELIKÁN, MARTIN BREZA and ROMAN BOČA†

Departments of Physical Chemistry and Inorganic Chemistry, Slovak Technical University, CS-812 37 Bratislava, Czechoslovakia

(*Received* 10 *July* 1985; *accepted* 27 *July* 1985)

Abstract—A new analytic formula for the adiabatic potential surface of the three-mode vibronic coupling T_{2g}–$(a_{1g}+e_g+t_{2g})$ in octahedral systems with triply degenerate electronic states was obtained. This formula includes linear and quadratic vibronic terms as well as the harmonic and anharmonic part of normal vibrations. The necessary potential constants (seven vibronic and nine force constants) were evaluated from the numerical maps of adiabatic potential surfaces (APS) by applying a non-linear regression analysis. Numerical calculations of APS were obtained for nine hexahalo complexes using the CNDO–UHF method.

The theory of vibronic coupling is able to predict an analytic form of the adiabatic potential surface (APS) in the presence of electron degeneracy. Considerations resulting in an analytic form of the APS for triply degenerate electronic states in the reference octahedral configuration have been published by many authors.[2–15] They were used in interpreting the physical and chemical properties of various materials where the Jahn–Teller effect occurs. The electric and magnetic polarization, the spectroscopic characteristics in the ESR, NMR, electron and ionization spectroscopy, problems of stereochemistry, crystallochemistry and chemical reactivity belong to them. Nevertheless, those considerations were based only on the two-mode vibronic coupling scheme T–$(e+t_2)$ or they were limited only to linear vibronic and quadratic force constants.

In this paper the analytic form of the APS has been derived for a more complete three-mode coupling scheme T–(a_1+e+t_2). Moreover, the vibronic coupling constants as well as the quadratic and cubic force constants have been calculated for some hexahalo complexes of the first-row transition metals by a purely theoretical, non-empirical way. They resulted from a non-linear regression analysis applied to a numerical map of the APS calculated by the CNDO–UHF version of the MO–LCAO–SCF method.

METHOD

The approach used below closely resembles the method outlined for the doubly degenerate electronic terms.[16,17] It may be summarized by the following points.

(i) For the three-state strong coupling case the unperturbed (zero-order) wave function stands:

$$\Psi^0 = \theta_u(r,[Q^0])\chi_u(Q)+\theta_v(r,[Q^0])\chi_v(Q) + \theta_w(r,[Q^0])\chi_w(Q) = \theta_u^0\chi_u + \theta_v^0\chi_v+\theta_w^0\chi_w, \quad (1)$$

where $\theta_u(r,[Q^0])$ are the electronic wave functions and $\chi_u(Q)$ are the vibration functions, r and Q being the electron and nuclear coordinates, respectively. The reference configuration of nuclei is denoted by $[Q^0]$.

(ii) The APS $W(Q)$ is obtained as a root of the secular equation:

$$\det\begin{pmatrix} U_{uu}-W; & U_{uv}; & U_{uw} \\ U_{vu}; & U_{vv}-W; & U_{vw} \\ U_{wu}; & U_{wv}; & U_{ww}-W \end{pmatrix} = 0. \quad (2)$$

The matrix elements U_{uv} contain a Taylor expansion

* For Part I, see Ref. 1.

† Author to whom correspondence should be addressed.

of the Hamiltonian $H_{uv} = \langle\theta_u^0|\hat{H}(r,Q)|\theta_v^0\rangle$:

$$U_{uv} = E_u^0\delta_{uv} + H_{uv}^{(1)} + H_{uv}^{(2)} + \cdots + E_{uv}^{(2)} + \cdots \quad (3)$$

as well as the energy correction originating from the higher orders of the perturbation theory, where a weak vibronic coupling with excited states is considered.[18] The latter term is neglected.

(iii) The Hamiltonian in the frozen-nuclei approximation contains the electronic kinetic energy ($\hat{T}_e$), the interelectronic repulsion ($\hat{V}_{ee}$), the electron–nuclear attraction ($\hat{V}_{eN}$) and the internuclear repulsion ($\hat{F}_{NN}$):

$$\hat{H}(r,Q) = \hat{T}_e(r) + \hat{V}_{ee}(r) + \hat{V}_{eN}(r,Q) + \hat{F}_{NN}(Q). \quad (4)$$

Therefore, its Taylor terms $[H_{uv}^{(n)}]$ may be split into the electron–nuclear part, $V_{uv}^{(n)}$, and the purely nuclear (scalar) part, $F_{uv}^{(n)}$:

$$H_{uv}^{(n)} = V_{uv}^{(n)} + F_{uv}^{(n)}\delta_{uv}. \quad (5)$$

They are:

$$V_{uv}^{(n)} = \frac{1}{n!}\sum_{k_1\ldots k_n}^{m}\left\langle\theta_u^0\left|\left[\frac{\partial^n\hat{V}_{eN}(r,Q)}{\partial Q_{k_1}\ldots\partial Q_{k_n}}\right]_0\right|\theta_v^0\right\rangle \Delta Q_{k_1}\ldots\Delta Q_{k_n}, \quad (6)$$

$$F_{uv}^{(n)} = \frac{1}{n!}\sum_{k_1\ldots k_n}^{m}\left[\frac{\partial^n\hat{F}_{NN}(Q)}{\partial Q_{k_1}\ldots\partial Q_{k_n}}\right]_0\Delta Q_{k_1}\ldots\Delta Q_{k_n}\delta_{uv}. \quad (7)$$

(iv) The symmetrized normal vibration coordinates may be chosen as the internal displacement coordinates, $\Delta Q = Q - Q^0$, each of them belonging to a γ class of the Γ representation of the molecular symmetry group in the reference configuration. The matrix elements $V_{uv}^{(n)}$ are expressible via the reduced matrix elements $X(\Gamma_u,\Gamma_v;\Gamma_{k_1},\ldots,\Gamma_{k_n})$ and the Clebsch–Gordan (Wigner) coefficients which have been tabulated.* Consequently, the APS becomes a function of a limited number of vibronic constants.

(v) Having derived an analytic form of the APS, the problem of the evaluation of the potential constants appears. First, a numerical map, $W(Q_1,\ldots,Q_m)$, of the APS is to be obtained by a quantum-chemical calculation of the total molecular energy for fixed nuclear coordinates. Then the regression of calculated points of the APS $W^c(Q_i)$ on its analytic form will proceed. The fitting is realized by the least-squares method with weighing:

$$\mathscr{F} = \sum_i [W^c(Q_i) - W^a(Q_i)]^2 w_i^2 = \min, \quad (8)$$

where $W^a(Q_i)$ are the approximate energies calculated for a trial set of potential constants from the analytic form of the APS. The statistical weights (w_i) were chosen in accordance with the metric weighing concept:

$$w_i = \left(\sum_k Q_k^2\right)^{-1/2}, \quad (9)$$

* The linear term is reduced according to the Wigner–Eckart theorem as:

$$V_{uv}^k = \langle\theta_u^0|[\partial\hat{V}(r,Q)/\partial Q_k]_0|\theta_v^0\rangle = X(\Gamma_u,\Gamma_v;\Gamma_k)C^{\Gamma_u\Gamma_k\Gamma_v}_{\gamma_u\gamma_k\gamma_v}.$$

The reduction of a quadratic term, V_{uv}^{kl}, needs a successive decomposition of the operator part, $[\partial^2\hat{V}(r,Q)/\partial Q_k\partial Q_l]_0$, according to the Wigner formula.[19]

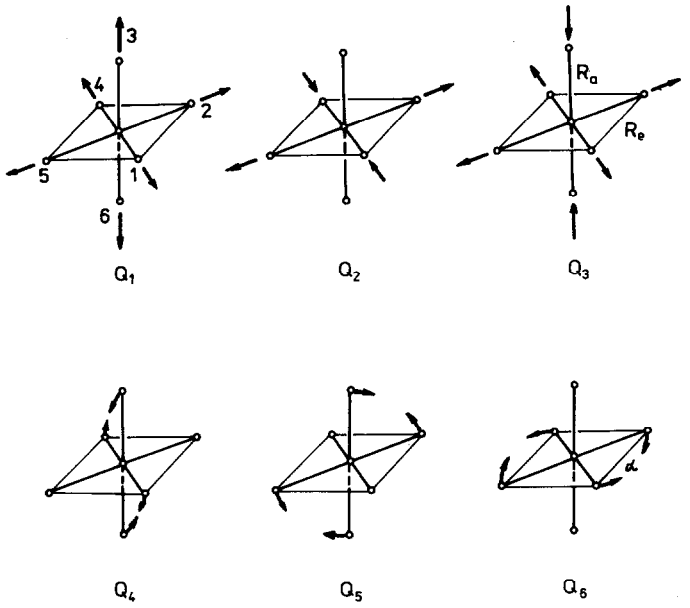

Fig. 1. Some internal and normal vibration coordinates of octahedral systems.

where Q_k is a set of displacement coordinates for a given point of the APS (Fig. 1).

VIBRONIC COUPLING $T_{2g}(a_{1g}+e_g+t_{2g})$

The octahedral system ML_6 has 15 normal modes of vibration belonging to the a_{1g} (coordinate Q_1), e_g (Q_2 and Q_3), t_{2g} (Q_4, Q_5 and Q_6), t_{2u}, t'_{1u} and t''_{1u} irreducible representations. Notice, the relation:

$$[\Gamma_t \times \Gamma_t] = A_{1g}+E_g+T_{2g} \tag{10}$$

holds for a symmetrized direct product of t-type irreducible representations ($t = t_{1g}$, t_{2g}, t_{1u} or t_{2u}). Therefore, the linear vibronic term $V^k_{uv} = \langle\theta^0_u|[\partial\hat{V}(r,Q)/\partial Q_k]_0|\theta^0_v\rangle$ is reduced to a non-zero element only if the representation of Q_k is contained in the reducible representation of $[\Gamma_{t_{2g}} \times \Gamma_{t_{2g}}]$. Consequently, only the coordinates Q_1-Q_6 are vibronic active in the linear coupling. The reduction of quadratic terms V^{kl}_{uv} according to the Wigner formula[19] gave one of the principal results of this paper:

$$\begin{aligned}
\mathbf{V}^{(1)}+\mathbf{V}^{(2)} = \mathbf{C}_1\Big[& X_a Q_1 + \frac{1}{2}X_{aa}Q_1^2 \\
& + \frac{1}{2\sqrt{2}}X_{ee}(Q_2^2+Q_3^2) \\
& + \frac{1}{2\sqrt{3}}X_{tt}(Q_4^2+Q_5^2+Q_6^2)\Big] \\
& + \mathbf{C}_2\Big[X_e Q_2 + X_{ae}Q_1Q_2 + \frac{1}{2\sqrt{2}}X_{ee}(Q_2^2-Q_3^2) \\
& + \frac{1}{2\sqrt{2}}X_{tt}(Q_5^2-Q_4^2)\Big] \\
& + \mathbf{C}_3\Big[X_e Q_3 + X_{ae}Q_1Q_3 + \frac{1}{2\sqrt{2}}X_{ee}2Q_2Q_3 \\
& + \frac{1}{2\sqrt{2}}X_{tt}(Q_4^2+Q_5^2-2Q_6^2)\Big] \\
& + \mathbf{C}_4\Big[X_t Q_4 + X_{at}Q_1Q_4 \\
& + \frac{1}{2}X_{et}Q_4(\sqrt{3}Q_2-Q_3) - \frac{1}{\sqrt{2}}X_{tt}Q_5Q_6\Big] \\
& + \mathbf{C}_5\Big[X_t Q_5 + X_{at}Q_1Q_5 \\
& - \frac{1}{2}X_{et}Q_5(\sqrt{3}Q_2+Q_3) - \frac{1}{\sqrt{2}}X_{tt}Q_4Q_6\Big] \\
& + \mathbf{C}_6\Big[X_t Q_6 + X_{at}Q_1Q_6 \\
& + \frac{1}{2}X_{et}2Q_3Q_6 - \frac{1}{\sqrt{2}}X_{tt}Q_4Q_5\Big].
\end{aligned} \tag{11}$$

Here X_e, X_t, X_{aa}, X_{ee}, X_{tt}, X_{ae}, X_{at} and X_{et} are the reduced matrix elements of a given symmetry ($a = a_{1g}$, $e = e_g$, $t = t_{2g}$). The matrices $\mathbf{C}_1$–$\mathbf{C}_6$ are formed by the Wigner coefficients in the space of the original triplet of electronic functions:

$$\mathbf{C}_1 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad \mathbf{C}_2 = \frac{\sqrt{3}}{2}\begin{pmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \end{pmatrix},$$

$$\mathbf{C}_3 = \frac{1}{2}\begin{pmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 2 \end{pmatrix},$$

$$\mathbf{C}_4 = \frac{-1}{\sqrt{2}}\begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}, \quad \mathbf{C}_5 = \frac{-1}{\sqrt{2}}\begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix},$$

$$\mathbf{C}_6 = \frac{-1}{\sqrt{2}}\begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

The expansion of the internuclear repulsion up to the cubic terms for the six vibronic active coordinates is:

$$\begin{aligned}
\mathbf{F}^{(1)}+\mathbf{F}^{(2)}+\mathbf{F}^{(3)} = \mathbf{C}_1\Big\{ & F_a Q_1 \\
& + \frac{1}{2}F_{aa}Q_1^2 + \frac{1}{2\sqrt{2}}F_{ee}(Q_2^2+Q_3^2) \\
& + \frac{1}{2\sqrt{3}}F_{tt}(Q_4^2+Q_5^2+Q_6^2) + \frac{1}{6}F_{aaa}Q_1^3 \\
& + \frac{1}{12}F_{eee}(3Q_2^2Q_3-Q_3^3) \\
& + \frac{1}{3\sqrt{2}}F_{aee}Q_1(Q_2^2+Q_3^2) \\
& + \frac{1}{3\sqrt{3}}F_{att}Q_1(Q_4^2+Q_5^2+Q_6^2) \\
& - \frac{1}{2\sqrt{6}}F_{ttt}Q_4Q_5Q_6 \\
& - \frac{1}{6\sqrt{3}}F_{ett}[Q_4^2(Q_3-\sqrt{3}Q_2) \\
& + Q_5^2(Q_3+\sqrt{3}Q_2) - 2Q_6^2Q_3]\Big\}.
\end{aligned} \tag{12}$$

The vibronic Hamiltonian considered here has the form:

$$\mathbf{U} = E^0\mathbf{1} + \mathbf{V}^{(1)} + \mathbf{V}^{(2)} + \mathbf{F}^{(1)} + \mathbf{F}^{(2)} + \mathbf{F}^{(3)}. \quad (13)$$

Since it contains a scalar part, i.e. terms standing by the Wigner matrix $\mathbf{C}_1 = \mathbf{1}$, the APS becomes:

$$\begin{aligned} W(Q_1, Q_2, Q_3, Q_4, Q_5, Q_6) &= \varepsilon_i + E^0 \\ &+ \frac{1}{2}K_{aa}Q_1^2 + \frac{1}{2}K_{ee}(Q_2^2 + Q_3^2) \\ &+ \frac{1}{2}K_{tt}(Q_4^2 + Q_5^2 + Q_6^2) + T_{aaa}Q_1^3 \\ &+ T_{aee}Q_1(Q_2^2 + Q_3^2) \\ &+ T_{att}Q_1(Q_4^2 + Q_5^2 + Q_6^2) \\ &+ T_{eee}Q_3(3Q_2^2 - Q_3^2) \\ &+ T_{ttt}Q_4Q_5Q_6 + T_{ett}[Q_4^2(Q_3 - \sqrt{3}Q_2) \\ &+ Q_5^2(Q_3 + \sqrt{3}Q_2) - 2Q_6^2Q_3]. \end{aligned} \quad (14)$$

The vibronic correction term (ε_i) is obtained as the lowest eigenvalue of the symmetric matrix V defined by the elements:

$$\begin{aligned} V_{11} &= \frac{1}{2}A_e(Q_3 - \sqrt{3}Q_2) \\ &+ \frac{1}{2}B_{ee}(Q_2^2 - Q_3^2 - 2\sqrt{3}Q_2Q_3) \\ &+ \frac{1}{2}Z_{ae}Q_1(Q_3 - \sqrt{3}Q_2) \\ &+ \frac{1}{\sqrt{6}}B_{tt}(-2Q_4^2 + Q_5^2 + Q_6^2), \\ V_{12} &= A_tQ_6 - Z_{et}Q_3Q_6 \\ &+ Z_{at}Q_1Q_6 + B_{tt}Q_4Q_5, \\ V_{13} &= A_tQ_5 + \frac{1}{2}Z_{et}Q_5(Q_3 + \sqrt{3}Q_2) \\ &+ Z_{at}Q_1Q_5 + B_{tt}Q_4Q_6, \\ V_{22} &= \frac{1}{2}A_e(Q_3 + \sqrt{3}Q_2) \\ &+ \frac{1}{2}B_{ee}(Q_2^2 - Q_3^2 + 2\sqrt{3}Q_2Q_3) \\ &+ \frac{1}{2}Z_{ae}Q_1(Q_3 + \sqrt{3}Q_2) \\ &+ \frac{1}{\sqrt{6}}B_{tt}(Q_4^2 - 2Q_5^2 + Q_6^2), \\ V_{23} &= A_tQ_4 + \frac{1}{2}Z_{et}Q_4(Q_3 - \sqrt{3}Q_2) \\ &+ Z_{at}Q_1Q_4 + B_{tt}Q_5Q_6, \\ V_{33} &= -A_eQ_3 - B_{ee}(Q_2^2 - Q_3^2) \\ &+ \frac{1}{\sqrt{6}}B_{tt}(Q_4^2 + Q_5^2 - 2Q_6^2) \\ &- Z_{ae}Q_1Q_3. \end{aligned} \quad (15)$$

In the final formulas, eqns (14) and (15), $A_e = -X_e$ and $A_t = -X_t/\sqrt{2}$ are the linear vibronic constants; $B_{ee} = -X_{ee}/2\sqrt{2}$, $B_{tt} = X_{tt}/2$, $Z_{et} = -X_{et}/\sqrt{2}$, $Z_{ae} = -X_{ae}$ and $Z_{at} = -X_{at}/\sqrt{2}$ are the quadratic vibronic constants; $K_{aa} = F_{aa} + X_{aa}$, $K_{ee} = (F_{ee} + X_{ee})/\sqrt{2}$ and $K_{tt} = (F_{tt} + X_{tt})/\sqrt{3}$ are the harmonic force constants; and $T_{aaa} = F_{aaa}/6$, $T_{eee} = F_{eee}/12$, $T_{ttt} = -F_{ttt}/2\sqrt{6}$, $T_{aee} = F_{aee}/3\sqrt{2}$, $T_{att} = F_{att}/3\sqrt{3}$ and $T_{ett} = -F_{ett}/6\sqrt{3}$ are the anharmonicity constants.* Moreover, the relation:

$$K_a = X_a + F_a = \langle\theta_u^0|[\partial\hat{H}(r, Q)/\partial Q_1]_0|\theta_u^0\rangle = 0 \quad (16)$$

holds for the optimum octahedral geometry where this gradient component vanishes.

NUMERICAL APPLICATION

The semiempirical CNDO–UHF method was used[20–22] for the total-energy calculation of systems systematically displaced from the octahedral geometry. The numerical map of the APS $W^c(Q_1, Q_2, Q_3, Q_4, Q_5, Q_6)$ obtained in this way contains *ca* 80 points for each system under study. The energy cut-off for the total molecular energy was 10^{-4}–10^{-5} eV.

Calculations were performed for nine hexahalo complexes having a triply degenerate electronic state in the reference octahedral configuration: MnX_6^{4-} in $^2T_{2g}$ state, CoX_6^{3-} in $^5T_{2g}$ state and CoX_6^{4-} in $^4T_{1g}$ state with X = F, Cl or Br.

The evaluation of potential constants—nine force constants and seven vibronic constants—occurring in the analytic form of the APS [eqns (14) and (15)] is not a trivial problem. The minimization procedure [eqn (8)] represents a non-linear optimization of 16 parameters. A rapid convergence was obtained by splitting the whole process into the linear and the non-linear part. The procedure was accelerated by successive optimizations of selected potential constants for some cuts of the APS.

The results of the regression are listed in Table 1. Each quantity is presented to a significant number of digits (the order of the last number being higher

* The cubic terms T_{ijk} in reality partly include the third-order vibronic coupling terms V^{ijk}, i.e. those terms which are reduced by the Wigner matrix $\mathbf{C}_1$. Therefore, both the F_{ijk} and K_{ijk} notations are left and the T_{ijk} notation is used in this sense.

[a] E_{JT} is the Jahn–Teller stabilization energy. Coordinates are illustrated in Fig. 1.

than the standard deviation). Some statistical characteristics, namely the correlation coefficient ρ (> 0.997) and the discrepancy factor R (< 0.07), imply that the form of the functional dependence for the total energy used is correct.

To open the discussion of numerical applications it must be mentioned that the CNDO/2 version of the MO–LCAO–SCF method used has its quantitative limitations. For example, the stretching force constants are overestimated by a factor of two and the vibronic constants are probably underestimated. The latter originates in the approximation of the $\hat{V}(r, Q)$ operator through an average of coulomb integrals in the CNDO/2 method. Consequently, the Jahn–Teller distortions and stabilization energies may be understimated. Nevertheless, valuable conclusions from data listed in Table 1 can be drawn. They will be discussed together with calculated characteristics of the extremum points of the APS as they appear in Table 2.

(i) The quadratic vibronic coupling constants Z_{ae}, Z_{at} and Z_{et} adopt significant values; they are of the same order as the vibronic constants B_{ee} and B_{tt}. Thus, the importance of these terms is clearly demonstrated.

(ii) The neglect of the a_{1g} admixture in the vibronic coupling ($Z_{ae} = Z_{at} = 0$) makes the regression considerably worse: ρ becomes lower and the R-factor higher. Analogically, the neglect of anharmonicities of normal vibrations ($T_{ijk} = 0$) leads to dramatic changes in the quality of the regression. Notice, these terms used to be omitted in the majority of papers where only $T\text{–}(e + t_2)$ coupling is considered.

(iii) The harmonic force constants fulfil the relation $K_{aa} > K_{ee}$. Thus, the e_g-mode (tetragonal distortion) is a softer mode relative to the a_{1g}-mode (symmetric stretching), so that the distortion is easier.

(iv) Three types of energy minima exist on the APS: the tetragonal minima along the e_g-mode (D_{4h}-symmetry), the trigonal minima along the t_{2g}-mode (D_{3d}-symmetry) and the mixed-type, orthorhombic minima (D_{2h}-symmetry).[23]

(v) The coordinates of extremum points are determined by the vibronic and force constants. If only the tetragonal distortions are considered, the corresponding cut of the APS adopts an explicit form:

$$W(Q_1, Q_3) = \mathbf{C}_1\left(W^0 + \frac{1}{2}K_{aa}Q_1^2 + \frac{1}{2}K_{ee}Q_3^2\right) - \mathbf{C}_2\frac{1}{2\sqrt{2}}X_{ee}Q_3^2 + \mathbf{C}_3(X_eQ_3 + X_{ae}Q_1Q_3), \quad (17)$$

where the anharmonicity terms were omitted. The coordinates of the stationary points are evaluated from the vanishing-gradient condition: $(\partial W/\partial Q_1)_0 = (\partial W/\partial Q_3)_0 = 0$. They are:

$$Q_3^0 = (C_3)_{ii}\frac{A_e}{K_{ee}}\left[1 - \frac{(C_3)_{ii}^2Z_{ae}^2}{K_{aa}K_{ee}} - \frac{2(C_2)_{ii}B_{ee}}{K_{ee}}\right], \quad (18)$$

$$Q_1^0 = (C_3)_{ii}Q_3^0Z_{ae}/K_{aa}. \quad (19)$$

Now, some trends in Tables 1 and 2 become more clear. It is seen that the coordinate Q_3^0 is proportional to A_e and the coordinate Q_1^0 to Z_{ae}. The a_{1g} admixture in the vibronic coupling manifests itself in the nonzero value of Z_{ae} and, consequently, in the shift of the coordinate Q_1^0. This effect was never discussed before.

(vi) The calculated degree of tetragonal distortion of Q_3 (~ 0.001–0.013) (in units of 10^{-10} m) for T_{1g} and T_{2g} reference states is much lower in comparison with analogous complexes having the E_g electronic state where a Q_3 of ~ 0.017–0.076 is predicted by the same method.[17] The trigonal distortions ($\Delta\alpha$) are 0.1–1.0°.

(vii) Although the absolute values of the degree of distortion are underestimated by the simple CNDO method used, the trends in the calculated force constants, vibronic constants, coordinates of stationary points and the Jahn–Teller stabilization energies seem correct. The solid state, however, contributes to these quantities as well and it probably manifests itself in an amplification of the degree of distortion.

ROLE OF CYANIDE IN REACTION WITH *CIS*-DICHLOROBIS(2,2'-BIPYRIDINE)Co(III) CHLORIDE IN WATER

G. SCHIAVON* and F. MARCHETTI

Istituto Chimico "G. Ciamician", Bologna University, Italy

(*Received* 11 *October* 1984; *accepted* 27 *July* 1985)

Abstract—Although cyanide does not substitute chloride in the *cis*-dichlorobis (ethylenediamine)Co(III) cation in water, it does so in the analogous 2,2'-bipyridine-containing complex.

Many years ago, Chan and Tobe[1] reported that, according to experimental conditions, the reaction between *trans*-$[Co(en)_2Cl_2]Cl$ (en = ethylenediamine) and KCN in aqueous solution led to the formation of *trans*-$[Co(en)_2(OH)Cl]^+$ or products resulting from the disproportionation or redox-catalyzed reactions. In no case was the substitution of one or both chlorine atoms in the substrate by cyanide verified.

However the substitution of one atom of labile chlorine, by cyanide was realized by Chan and Tobe[1] with the reaction between *trans*-$[Co(en)_2(SO_3)Cl]$ and KCN in aqueous solution. This result together with that of Ray and Sarma,[2] who obtained the *cis*-$[Co(en)_2(CN)_2]^+$ by means of the reaction in water between KCN and $[Co(en_2(S_2O_3)_2]^-$, led Chan and Tobe[1] to the conclusion that the presence of SO_3^{2-} and $S_2O_3^{2-}$ groups assists the entry of cyanide (for unknown reasons at the time) into the Co(III) coordination sphere.

The *trans*-$[Co(en)_2(SO_3)CN]$ obtained by Chan and Tobe,[1] after being treated with concentrated HCl, gave the *trans*-$[Co(en)_2(CN)Cl]^+$ cation.[1]

Ohkawa *et al.*[3] prepared afterwards the form *cis*-$[Co(en)_2(CN)X]^+$ ($X = Cl^-$, Br^- or I^-), starting from *cis*-$[Co(en)_2(SO_3)CN]$ and the suitable halogen acid.

In 1969 Maki and Sakuraba[4] reported the preparation of mixed cyano-Co(III) complexes and, among others, that of *cis*-$[Co(bpy)_2(CN)_2]^+$ (bpy = 2,2'-bipyridine), *cis*-$[Co(phen)_2(CN)_2]^+$ (phen = 1,10-phenanthroline) and

$$cis\text{-}[Co(en)_2X(CN)]^{n+},$$

where $X = NO_2^-$, SO_3^{2-}, H_2O or CN^-. In the first two cases, the substrate was the corresponding dichloro-complex, while, for ethylenediamine-containing complexes, the substrate was the corresponding $[Co(en)_2XCl]^{n+}$ complex. In every case the cyano-group was supplied by an AgCN saturated solution. According to the AA the substitution of labile chloride by cyanide was made possible by the low concentration, thus realized, of the entering ligand.

On the other hand Palade *et al.*[5] prepared and characterized the *cis*-$[Co(phen)_2(CN)_2]^+$ cation by heating an aqueous solution of the corresponding dichloro-complex mixed with a 3% aqueous solution of KCN.

We have prepared and characterized

$$cis\text{-}[Co(bpy)_2(CN)Cl]^+$$

by the reaction between *cis*-$[Co(bpy)_2Cl_2]^+$ and KCN in aqueous solution and with a molar ratio between the reagents of 1 : 1.† When the molar ratio between the dichloro-complex and KCN was 1 : 2, the nucleophilic substitution product was the *cis*-$[Co(bpy)_2(CN)_2]^+$ cation.

From the chlorocyano-complex we have obtained, always in aqueous solution, the *cis*-$[Co(bpy)_2(CN)OH]^+$ cation with LiOH (1 : 1), and the *cis*-$[Co(bpy)_2(CN)_2]^+$ cation with KCN (1 : 1).

We have also performed molar conductance measurements on 5×10^{-4} M aqueous solutions of

$$cis\text{-}[Co(bpy)_2(CN)Cl]ClO_4,$$

$$cis\text{-}[Co(bpy)_2(CN)OH]ClO_4$$

* Author to whom correspondence should be addressed.

† We have already quoted the *cis*-$[Co(bpy)_2(CN)Cl]^+$ cation in Ref. 6 as an intermediate product in the preparation of the *cis*-$Co(bpy)_2(SO_3)CN$ compound.

and

$$cis\text{-}[Co(bpy)_2(CN)_2]ClO_4.$$

In all cases, the value for the molar conductance was 92 Ω^{-1} cm^2, which is peculiar to a uni-univalent electrolyte. However, while the specific conductivity was constant with time in the last two cases, the specific conductivity of solution of *cis*-$[Co(bpy)_2(CN)Cl]ClO_4$ slowly increased at 25°C. This fact indicates that the aquation reaction is taking place.

It seems evident that the cyano-group entering the coordination sphere of the dichloro-complex containing 2,2'-bipyridine, to substitute one or two chlorine atoms in aqueous solution, is due to the presence of the two aromatic α-diimine molecules. In fact it is known that, in octahedral complexes containing ammonia or amines having a hydrogenated (therefore protonatable) nitrogen atom, the reaction is always "base-catalyzed" when the entering ligand is, as in the case of CN^-, a relatively strong base. The process is of S_N1cb type and the product of the nucleophilic substitution reaction is the corresponding hydroxo-complex as verified by Chan and Tobe.[1]

With the aromatic α-diimines coordinating by two pyridine-like nitrogen atoms, the catalysis fails and the competition: hydroxide ion-entering ligand is overcome by the cyano-group, because of its higher nucleophilicity.

We must also consider the fact that 2,2'-bipyridine, unlike ethylenediamine, is a potential π-acceptor[7] and belongs to the class of "soft" bases as does the cyano-group. Therefore, between the latter and the two molecules of aromatic α-diimines a mutual stabilizing effect takes place, which Jørgensen called "symbiosis".[8] To this symbiosis phenomenon could also be referred the function developed by the SO_3^{2-} and $S_2O_3^{2-}$ groups in favouring the substitution of the labile Cl^- by CN^- in the Co(III) octahedral coordination sphere.[1]

Finally, even though 2,2'-bipyridine is a weaker σ-donor than ethylenediamine, the stabilities of its coordination complexes are greater.[9]

EXPERIMENTAL

Conductivity measurements were carried out on an Analytical Control model 101 conductivity meter. IR spectra of Nujol mulls were recorded on a Perkin–Elmer 397 spectrophotometer.

cis-*Dichlorobis*(2,2'-*bipyridine*)Co(III) *chloride*

This was prepared and purified according to Palade's method.[10]

cis - *Chlorocyanobis*(2,2' - *bipyridine*)Co(III) *per - chlorate*

To an aqueous solution of *cis*-dichlorobis(2,2'-bipyridine)Co(III) chloride dihydrate (1.5 g, 2.9 mmol in 130 cm^3 of water) an aqueous solution of KCN (0.189 g, 2.9 mmol in 2 cm^3 of water) was dropwise added with stirring at room temperature. The red-brown colour of the solution turned to orange. By adding solid $LiClO_4$ a pink precipitate was obtained, which was filtered, washed with ethyl alcohol and ether, and recrystallized from hot water [yield 1.1 g (70%)]. (Found: C, 47.3; H, 3.0; N, 13.5%. $CoC_{21}H_{16}N_4Cl_2O_4$ requires: C, 47.35; H, 3.00; N, 13.15%.) Its IR spectrum shows a band at ν = 2140 cm^{-1} attributed to the cyano-group coordinated to the metal.

cis - *Hydroxycyanobis*(2,2' - *bipyridine*)Co(III) *perchlorate*

To an aqueous solution of *cis*-chlorocyanobis(2,2'-bipyridine)Co(III) perchlorate (0.6 g, 1.13 mmol in 350 cm^3 of hot water) an aqueous solution of LiOH (0.027 g, 1.13 mmol in 10 cm^3 of water) was added. To the warm solution a saturated solution of $LiClO_4$ was added. On cooling the concentrated solution a brownish-yellow precipitate was obtained, which was filtered, washed with water, ethanol and ether, and recrystallized from hot water [yield 0.38 g (65%)]. (Found: C, 49.4; H, 3.1; N, 13.3%. $CoC_{21}H_{17}N_5ClO_5$ requires: C, 49.05; H, 3.31; N, 13.62%.) Its IR spectrum shows the band of cyanide coordinated at ν = 2140 cm^{-1} and two bands at ν = 1670 and 1630 cm^{-1}, which can be attributed to the hydroxide ion coordinated to the metal, since these two bands do not appear in the IR spectra of the other compounds examined.

cis-*Dicyanobis*(2,2'-*bipyridine*)Co(III) *perchlorate*

(a) To an aqueous solution of *cis*-chlorocyanobis(2,2'-bipyridine)Co(III) perchlorate (0.5 g, 0.94 mmol in 330 cm^3 of hot water) was added the equivalent amount of KCN dissolved in a minimum amount of water. By adding solid $LiClO_4$, and cooling, a yellow precipitate followed which was filtered, washed with water, ethanol and ether, and recrystallized from hot water [yield 0.42 g (86%)]. (Found: C, 50.4; H, 3.0; N, 16.3%. $CoC_{22}H_{16}N_6ClO_4$ requires: C, 50.50; H, 3.06; N, 16.07%.) Its IR spectrum shows a cyano-group band at ν = 2140 cm^{-1}.

(b) To an aqueous solution of *cis*-dichlorobis(2,2'-bipyridine)Co(III) chloride dihydrate (0.5 g, 0.97 mmol in 50 cm^3 of water) was added a solution of KCN in a minimum amount of water (0.126 g,

1.94 mmol). Proceeding as in (a), we obtain the same compound, characterized by elemental analysis, IR spectrophotometrical and conductivity measurements.

ROLE OF CYANIDE AS A BRIDGING LIGAND IN *CIS*-AQUOCYANOCo(III) COMPLEXES CONTAINING 2,2′-BIPYRIDINE AND 1,10-PHENANTHROLINE

G. SCHIAVON,* F. MARCHETTI and M. PATRIKAKI

Istituto Chimico "G. Ciamician", Universita' di Bologna, Bologna, Italy

(*Received* 27 *June* 1985; *accepted* 16 *September* 1985)

Abstract—*Cis*-aquocyanobis(2,2′-bipyridine)Co(III) and *cis*-aquocyanobis(1,10-phenanthroline)Co(III) cations present in their IR spectra a cyano-group band in a Nujol mull at $\nu = 2200\ cm^{-1}$. To justify the shift in the frequency from 2140 to 2200 cm^{-1} of cyanide in these compounds, we have hypothesized that the cyano group is a bridge between the metal atom and one hydrogen atom of the water molecule in the *cis* position on the Co(III) coordination sphere.

We have previously reported[1] the kinetics of the aquation reactions of *cis*-$[Co(bpy)_2(CN)Cl]^+$ (**1**) (bpy = 2,2′-bipyridine) and

cis-$[Co(phen)_2(CN)Cl]^+$ (**2**)

(phen = 1,10-phenanthroline), and the preparation of compound **1**.[2]

We now report the preparation of compound **2** and the aquocyano derivatives of **1** and **2**.

Just as for **1**, the *cis*-$[Co(phen)_2(CN)Cl]^+$ complex can be prepared by the reaction in water between *cis*-$[Co(phen)_2Cl_2]^+$ and KCN. As in the case of the bpy-containing complex (**1**), so in the present case the aromatic α-diimine (phen) is the ligand which assists, since with it no "base-catalysed" process of the type S_N1cb is possible, the cyanide's entry into the coordination sphere of Co(III), by virtue of the analogy between phen and cyanide, both soft bases and π-acceptor ligands (Jørgensen "symbiosis"[3]).

Both of the chlorocyano complexes (**1** and **2**) have very low values for the aquation rate constant at 25°C,[1] compared to the corresponding *cis*-dichloro and *cis*-chloronitro complexes.

Furthermore, neither Ag^+ nor Hg^{2+} is able to cause a fast hydrolysis. However, addition of minute amounts of $[Co(N–N)_2(CN)Cl]$ (N–N = bpy or phen) results in immediate hydrolysis of the *cis*-chlorocyano in the *cis*-aquocyano complex.

This faster aquation reaction is manifested by the fact that, on treating the reaction mixture with solid $LiClO_4$, a precipitate was obtained which has an IR spectrum with two cyano-group bands at $\nu = 2200$ and 2140 cm^{-1}, indicating the presence of two compounds. By ion exchange chromatography of the reaction mixture we obtained two fractions. The first one gave the *cis*-$[Co(N–N)_2(CN)Cl]^+$ cation characterized by elemental analysis, which has an IR spectrum with the cyano-group band at $\nu = 2140\ cm^{-1}$. The second fraction gave the *cis*-$[Co(N–N)_2(CN)OH_2]^{2+}$ cation, characterized by elemental analysis, which has an IR spectrum with the cyano-group band at $\nu = 2200\ cm^{-1}$, and two new bands at $\nu = 465$ and $450\ cm^{-1}$, which we have attributed to the water molecule coordinated to the metal.

We have justified the frequency $\nu(CN) = 2200\ cm^{-1}$ in the IR spectra of the aquocyano cation derivatives from **1** and **2**, admitting that, since the cyano group and the water molecule are *cis* to each other, with no possibility of *cis–trans* isomerization at all for the complexes, a hydrogen bond was formed between the free nitrogen end of the coordinated cyanide and the oxygen atom of the water molecule. In this way the cyanide bridged, intermolecularly, the cobalt atom and the proton. From there the stretching frequency of the coordinated cyano-group shifted to higher values.

It is known, in fact, that a nitrogen atom at the free end of coordinated cyanide can be engaged in the formation of a bond with: (a) a metal atom, as in the case of binuclear or bridged cyano complexes;[4] (b) a proton;[5] and (c) a Lewis acid, as in the case of BF_3 (acid–base adducts).[6] In every case the stretching

* Author to whom correspondence should be addressed.

frequency of the coordinated cyanide is shifted to a higher value.

EXPERIMENTAL

cis-Dichlorobis (1,10-phenanthroline) Co(III) chloride

This was prepared according to Ref. 7.

cis - Chlorocyanobis(1,10 - phenanthroline)Co(III) chloride

To an aqueous solution of *cis*-dichlorobis(1,10-phenanthroline)Co(III) chloride (2 g, 3.8 mmol in 10 cm^3 of water) an aqueous solution of KCN (0.25 g, 3.8 mmol in 2 cm^3 of water) was added dropwise, with stirring at room temperature. The purple solution turned to a yellow-orange color. Solid LiCl was added to the reaction mixture, which was then concentrated to a small volume. By adding ethanol and ether (1 : 1) a pale pink precipitate followed, which was recrystallized from water (yield 1.29 g, 65%). Found: C, 58.3; H, 3.0; N, 13.4. $CoC_{25}H_{16}N_5Cl_2$ requires: C, 58.1; H, 3.1; N, 13.6%. Its IR spectrum shows a cyano-group band at $\nu = 2140\ cm^{-1}$.

cis - Aquocyanobis(1,10 - phenanthroline)Co(III) perchlorate

Minute amounts of *cis*-chlorocyanobis(1,10-phenanthroline)Co(II), opportunely prepared, were added to a solution of *cis*-chlorocyanobis(1,10-phenanthroline)Co(III) chloride (1.96 g, 3.8 mmol in 20 cm^3 of water). The cationic species were absorbed at the top of a column of Amberlite 15 (H) (30 × 1 cm) and eluted, first with 0.1 M HCl and then with 4 M $HClO_4$. The first eluate gave, on adding solid $LiClO_4$, a pale hazel colored precipitate of *cis*-$[Co(phen)_2(CN)Cl]ClO_4$. Found: C, 52.1; H, 2.9; N, 11.9. $CoC_{25}H_{16}N_5Cl_2O_4$ requires: C, 51.7; H, 2.8; N, 12.1%. Its IR spectrum shows a cyano-group band at $\nu = 2140\ cm^{-1}$.

The second eluate, yellow-orange in color, gave, on adding solid $LiClO_4$, a pale-pink precipitate of *cis*-$[Co(phen)_2(CN)OH_2](ClO_4)_2$. Found: C, 45.2; H, 2.8; N, 10.7. $CoC_{25}H_{18}N_5Cl_2O_9$ requires: C, 45.3; H, 2.7; N, 10.6%. Its IR spectrum shows a cyano-group band at $\nu = 2200\ cm^{-1}$ and two bands at $\nu = 465$ and $450\ cm^{-1}$, which we have attributed to the water molecule coordinated in the *cis* position with respect to the cyanide in the octahedral coordination sphere of Co(III).

cis - Chlorocyanobis(2,2' - bipyridine)Co(III) perchlorate

This was prepared according to Ref. 2.

cis-Aquocyanobis(2,2'-bipyridine)Co(III) perchlorate

Minute amounts to *cis*-$[Co(bpy)_2(CN)Cl]$, opportunely prepared, were added to a solution of *cis*-$[Co(bpy)_2(CN)Cl]ClO_4$ (0.66 g, 1.24 mmol in 250 cm^3 of water). The red-orange color of the solution immediately turned to orange-yellow. After 30 min the solution was filtered. From the pale-orange filtrate an orange precipitate was obtained by adding solid $LiClO_4$. The precipitate was redissolved in hot water and the cationic species were absorbed at the top of a column of Amberlite 15 (H). The eluate with 0.1 M $HClO_4$, which was nearly colorless, was discarded. The eluate with 4 M $HClO_4$, orange-yellow in color, after concentration in a water bath, and on adding solid $LiClO_4$, gave a pale-yellow precipitate, which was washed with water, ethanol and diethyl ether, and recrystallized from hot water. Found: C, 41.7; H, 3.0; N, 11.2. $CoC_{21}H_{18}N_5Cl_2O_9$ requires: C, 41.0; H, 2.1; N, 11.4%. Its IR spectrum shows the cyano-group band at $\nu = 2200\ cm^{-1}$ and two bands at $\nu = 465$ and $450\ cm^{-1}$, attributed to the water molecule coordinated to the metal.

(*Received* 15 *March* 1985; *accepted after revision* 27 *July* 1985)

Abstract—The reactions of nitrosyl halides NOX (X = Cl, Br or Br_3) and N_2O_3 with $RuCl_3(H_2O)_3$ and $RhCl_3(H_2O)_3$ in the presence of 2,2′-bipyridine and 1,10-phenanthroline results in the formation of neutral nitrosyl complexes of types $Ru(NO)X_3(L–L)$ and $Rh(NO)X_2(L–L)$ (L–L = 2,2′-bipyridine or 1,10-phenanthroline).

Nitrosyl halides NOX (X = Cl or Br) besides nitric oxide have been used as nitrosylating agents in the synthesis of transition-metal nitrosyl complexes.[1–15] In this paper the reactions of nitrosyl chloride, nitrosyl bromide, nitrosyl tribromide and N_2O_3 with $RuCl_3(H_2O)_3$ and $RhCl_3(H_2O)_3$ in the presence of 2,2′-bipyridine and 1,10-phenanthroline are described. The structure of the resulting nitrosyl complexes are proposed on the basis of IR, UV, visible and magnetic measurements, and elemental analysis.

EXPERIMENTAL

All the chemicals used were of chemically pure or AnalaR grade. All solvents were dried by standard procedures and distilled just prior to use.

NOX (X = Cl, Br or Br_3) and N_2O_3 were prepared by the literature methods.[16–19]

Reaction of NOX (X = Cl, Br *or* Br_3) *with* $RuCl_3(H_2O)_3$ *in the presence of L–L* (*L–L = 2,2′-bipyridine or 1,10-phenanthroline*)

A saturated solution of NOCl in dichloromethane (50 cm^3) was added to an ethanolic solution of $RuCl_3(H_2O)_3$ (0.2 g) and the resulting mixture was refluxed for 30 min. A solution of L–L (0.8 g) in 20 cm^3 ethanol was added to the above solution and the reaction mixture was again refluxed for 15 min. Brown shining crystals of $[Ru(NO)Cl_3(L–L)]$ were separated out, which were washed with ethanol and diethylether, and dried in air.

By a similar procedure, the reaction of NOBr and $NOBr_3$ in dichloromethane (10 cm^3, *ca* 2 M) with $RuCl_3(H_2O)_3$ in the presence of L–L gave brown shining crystals of $[Ru(NO)Br_3(L–L)]$. These were filtered and washed with ethanol and diethylether, and dried in air.

Reaction of N_2O_3 *with* $RuCl_3(H_2O)_3$ *in the presence of L–L* (*L–L = 2,2′-bipyridine or 1,10-phenanthroline*)

A saturated green solution of N_2O_3 in dichloromethane (20 cm^3) was added with stirring to 20 cm^3 of an alcoholic solution of $RuCl_3(H_2O)_3$ (0.2 g) and the resulting mixture was refluxed for 30 min. A solution of L–L (0.8 g) in 20 cm^3 ethanol was added. It was refluxed for 15 min. Brown crystals of $[Ru(NO)Cl_3(L–L)]$ were separated out which were centrifuged, washed with ethanol and diethylether, and dried in air.

Reaction of NOX (X = Cl, Br *or* Br_3) *with* $RhCl_3(H_2O)_3$ *in the presence of L–L* (*L–L = 2,2′-bipyridine or 1,10-phenanthroline*)

A saturated solution of NOCl in dichloromethane (50 cm^3) was added dropwise to a stirred ethanolic

* Author to whom correspondence should be addressed.

solution of $RhCl_3(H_2O)_3$ (0.25 g) and the resulting mixture was refluxed for 40 min. A solution of L–L (1.0 g) in 20 cm^3 ethanol was added to the above solution and the reaction mixture was again refluxed for 15 min. Red-brown shining crystals of $[Rh(NO)Cl_2(L–L)]$ were separated out which were washed with ethanol and diethylether, and dried in air.

By a similar procedure, the reaction of NOBr and $NOBr_3$ in dichloromethane (10 cm^3, *ca* 2 M) with $RhCl_3(H_2O)_3$ in the presence of L–L gave red-brown shining crystals of $[Rh(NO)Br_2(L–L)]$. These were centrifuged, washed with ethanol and diethylether, and dried in air.

Reaction of N_2O_3 *with* $RhCl_3(H_2O)_3$ *in the presence of L–L (L–L = 2,2′-bipyridine or 1,10-phenanthroline)*

A saturated green solution of N_2O_3 in dichloromethane (20 cm^3) was added with stirring to 20 cm^3 of an ethanolic solution of $RhCl_3(H_2O)_3$ (0.2 g) and the resulting solution was refluxed for 1 h. A solution of L–L (1.0 g) in 20 cm^3 ethanol was added. It was again refluxed for 15 min. Red-brown crystals of $[Rh(NO)Cl_2(L–L)]$ were separated out which were centrifuged, washed with ethanol and diethylether, and dried in air.

Carbon, hydrogen and nitrogen analyses of the complexes were performed by the Microanalytical Section of the Indian Institute of Technology, New Delhi, India. The halogen estimations were carried out by standard methods.[20] For estimation of phosphorus, samples were decomposed with Na_2O_2, sugar and $NaNO_3$ in a Parr bomb crucible, extracted with water and, after adding conc. H_2SO_4, heated till the evolution of SO_3 fumes ceased. Extraction with H_2O and filtration, if necessary, were carried out. Phosphorus was estimated gravimetrically as ammonium phosphomolybdate. The IR spectra of the samples were recorded with a Perkin–Elmer Model 580 spectrophotometer in the range 4000–250 cm^{-1}. Samples were prepared as KBr pellets. The electronic spectra (ruthenium complexes in dichloromethane and rhodium complexes in nitrobenzene solution) were recorded on a Varian 634 S spectrophotometer. The magnetic measurements were made on a Gouy balance. Conductivity measurements of the compounds were made on a Remi Conductivity Meter type 2LH with milimolar solutions in nitrobenzene. All the compounds are found to be non-conducting.

RESULTS AND DISCUSSION

The reactions of NOX with $MCl_3(H_2O)_3$ (M = Ru or Rh) in the presence of ligands L–L (L–L = 2,2′-bipyridine or 1,10-phenanthroline) resulted in the formation of $\{MNO\}^6$ complexes of types $[Ru(NO)X_3(L–L)]$ and $[Rh(NO)X_2(L–L)]$ in about 60% yield, respectively, as:

$$RuCl_3(H_2O)_3 + NOX + L–L \rightarrow [Ru(NO)X_3(L–L)] + \cdots$$

$$RhCl_3(H_2O)_3 + NOX + L–L \rightarrow [Rh(NO)X_2(L–L)] + \cdots$$

Ruthenium nitrosyl complexes

All the complexes are air-stable, diamagnetic and sparingly soluble in dichloromethane, nitrobenzene and pyridine. The IR spectra of the complexes show a sharp band in the region 1830–1840 cm^{-1} due to ν(NO), at 335 cm^{-1} due to ν(Ru—Cl), and bands due to 2,2′-bipyridine or 1,10-phenanthroline. Complexes with a similar composition, $[Ru(NO)Cl_3(L–L)]$, but with a higher nitrosyl stretching frequency [ν(NO) = 1880 cm^{-1}], have been reported previously.[21] The corrected nitrosyl stretching frequencies [ν'(NO)] according to Ibers' rules[22] fall above 1620 cm^{-1}, which indicates a linear bonding of the nitrosyl group. The diamagnetic behaviour and linear bonding mode of the nitrosyl group suggest that the oxidation state of the metal ion is 2^+ and these complexes are regarded as complexes between Ru(II) and NO^+. The ruthenium ion thus has a d^6 electronic configuration.

The visible spectra of the complexes show three bands around 18,000, 20,700 and 26,000 cm^{-1}. However, the extinction coefficients of these bands are much higher compared to the ones found normally for octahedral complexes. These may be charge-transfer bands[23] [$d\pi \rightarrow \pi^*$ (NO), halogen $\rightarrow d\pi$ or $d\pi \rightarrow \pi^*$ (L–L)]. However, the bands at 18,000 and 20,700 cm^{-1} may be *d–d* singlet $\rightarrow$ singlet transitions, in which case the intensity of the bands may arise due to: (i) the covalent nature of the complex, and (ii) the lowering of the symmetry of the molecule whereby the centre of symmetry is lost.

Rhodium nitrosyl complexes

All the complexes are air-stable, diamagnetic, red-brown solids, insoluble in benzene and dichloromethane, and soluble in nitrobenzene and pyridine. The IR spectra of the complexes exhibit absorption bands at 1625 cm^{-1} due to ν(NO), at 350 cm^{-1} due to ν(Rh—Cl) and bands due to 2,2′-bipyridine and 1,10-phenanthroline. The diamagnetic behaviour suggests that the rhodium in the complexes is present either in a 1^+ [Rh(I)–NO^+] or a 3^+ [Rh(III)–NO^-] oxidation state. The determi-

[b] All complexes decompose without melting.

nation of the ν(NO) according to Ibers' rules showed this band at *ca* 1600 cm^{-1}, i.e. below 1620 cm^{-1}. This is evidence of the presence of a bent nitrosyl group. Thus, the formal oxidation state of rhodium in these complexes is 3^+, [Rh(III)–NO^-] and not 1^+, [Rh(I)–NO^+]. For penta-coordinated mononitrosyl complexes of group VIII transition metals, square-pyramidal and trigonal bipyramidal geometries with bent apical and linear equatorial nitrosyl bonding, respectively, have been found from X-ray structural determination[24] and theoretical calculations.[25] Thus, the structures of $Rh(NO)X_2(L–L)$ (X = Cl or Br, L–L = 2,2′-bipyridine or 1,10-phenanthroline) are probably square-pyramidal with bent apical nitrosyl bonding. The visible spectra of the complexes show two bands around 20,400 and 23,500 cm^{-1}. The extinction coefficients are high and these bands may be charge-transfer bands.

Abstract—By means of the neutron diffraction method the atomic arrangement of a zinc–tellurite glass with composition 80% TeO_2 + 20 mol % ZnO has been studied. Analysis of the radial distribution functions (RDF_{exp} and RDF_{model}) shows the presence of some changes in the basic structural units at the glass transition. Approximately 35% of the Te atoms conserve the same coordination state as in the α-TeO_2 crystal structure. The remaining Te atoms are of lower coordination. The Gaussian distribution of the O—O distances of the first coordination sphere ($\bar{R}$ = 2.95 Å) indicates an increasing assymmetry of TeO_4, TeO_{3+1}, TeO_3 and ZnO_{4+1+1} polyhedra. The observed variations of the Te—Te, Te—second O and O—second O distances greater than 3.0 Å have an essential contribution to tellurite melt amorphization. An attempt is made to give a stereochemical representation of the glass structure on the basis of the obtained RDF_{exp}.

Tellurium(IV) oxide in combination with ZnO forms stable glasses. Data on glass properties are reported in the literature.[1,2] Because of the wide glass-formation range which is close to the extremum for binary tellurite glasses, the ZnO–TeO_2 system is used as a basis for multicomponent optical glass synthesis.[3,4] For example the influence of $ZnCl_2$ and ZnO on the refractive indices and the dispersion coefficients of the glasses in the TeO_2–WO_3, TeO_2–BaO and TeO_2–Na_2O systems have been discussed.[5–7] The above-mentioned indicate undoubtedly the existence of a practical interest in the zinc-tellurium-containing systems as a choice of compositions for superheavy optical flint glasses.[8–11] Apart from their applications there is a lack of data on structural investigations of these glasses in the literature.

In the present work we have investigated the short range order of a tellurite glass with composition 80% TeO_2 + 20 mol % ZnO.† The presence of atoms of significantly different atomic numbers in the investigated sample, $_8$O, $_{30}$Zn and $_{52}$Te, necessitated the use of the neutron diffraction method. The nuclei of O, Te and Zn have similar scattering amplitudes ($b_O = 0.580 \times 10^{-14}$ m, $b_{Zn} = 0.570 \times 10^{-14}$ m, $b_{Te} = 0.580 \times 10^{-14}$ m) and therefore the measured diffuse scattering intensity will be sensitive to the light oxygen nuclei distribution. Hence the experimental radial distribution function (RDF_{exp}) will contain information about the O—O distances.

EXPERIMENTAL

Phase diagram

The phase diagram of the TeO_2–ZnO system is well known.[12] Phase analysis confirms the existence

* Authors to whom correspondence should be addressed.

† All compositions are given in mol %.

of two compounds, namely $Zn_2Te_3O_8$ (monoclinic) and $ZnTeO_3$ (orthorhombic), in accordance with Hanke's data.[13,14] The eutectic point is located in the TeO_2-rich region at 21% ZnO and a temperature of 590°C. The electron microscopic investigations of the glasses do not establish phase separation in the system.[12]

Materials and glass synthesis

Materials used (TeO_2 and ZnO) were of Analar grade. The X-ray diffraction study of the initial TeO_2 material shows that there was only a paratellurite (α-TeO_2) polymorphous phase. A batch of 50 g of the material placed in a Pt crucible was directly melted in an electric furnace. Melting was achieved in a dry-air atmosphere at a temperature of 750°C for 40 min. The glass melt was quenched to room temperature by pouring on to a copper mold. The bulk glass sample had not been additionally tempered or thermally treated. After glass density measurements (5.283 g cm^{-3}) the sample was crushed and directly investigated by the neutron diffraction method.

Methods

Neutron diffraction patterns were obtained by a diffractometer installed at the WWR-M reactor (LINPH, U.S.S.R.). The experimental spectrum was taken at a constant step of $2\theta = 0.1°$ in the angular range $2\theta \in [4.125°]$. The wavelength of the monochromatic neutron beam was $\lambda = 1.113$ Å. The points required for Fourier transformation distributed at a constant $\Delta Q = 0.05$ Å^{-1} ($Q = 4\pi \sin\theta/\lambda$) were calculated by a parabolic interpolation of the experimental data. The obtained curve, presented in Fig. 1, shows the characteristic behaviour of glassy substances with broad diffusion maxima located in the range 0.4–10 Å^{-1}. For establishing the normalized diffraction intensity [$i(Q)$]:

$$i(Q) = [I(Q) - I_\infty]/(I_\infty - I_0) \qquad (1)$$

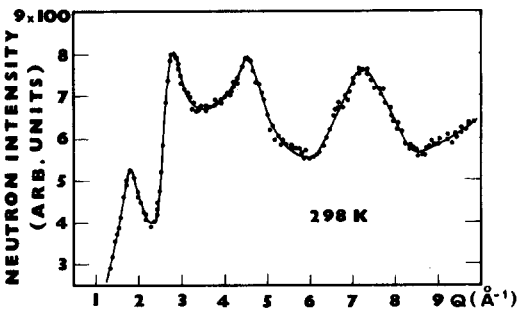

Fig. 1. Intensity of diffracted neutrons as a function of Q at room temperature.

the values of the structurally independent coherent scattering (I_∞) and the multiple and incoherent scattering (I_0) should be evaluated. As shown in Ref. 15, I_∞ is found from the constant integral intensity theorem:

$$\int_0^\infty Q^2 I(Q)\, dQ = \int_0^\infty Q^2 I_\infty\, dQ. \qquad (2)$$

I_0 is defined from the formulae in Ref. 16, while μR is experimentally measured by passing a thin neutron beam along the diameter of the cylindrical powder sample. For elimination of the influence of the upper limit of the Fourier integral on the RDF curve the modifying function:

$$M(Q) = \sin\frac{Q\Delta}{2}\Big/\frac{Q\Delta}{2} \qquad (3)$$

proposed by Lorch,[17] where $\Delta = 2\pi/Q_{max}$ has been used. The RDF is a sum of $m(m+1)/2$ interatomic distributions, where m is the number of different kinds of atoms. It is necessary to note that the neutron diffraction experiment by itself does not permit a unique interpretation of the RDF_{exp}. This problem may partially be solved by a model approach consisting in the selection of such an initial structure, whose RDF is comparable with the experimentally obtained RDF curve for a glass sample. This approach has been used in the present work.

RESULTS

The measured diffraction spectrum is shown on Fig. 1. Four well-expressed diffraction maxima are observed at Q values of 1.8, 2.8, 4.5 and 7.2 Å^{-1}, respectively. The last maximum is symmetrically broadened. Performing the Fourier transformation we obtain the $F(R)$ function presented in Fig. 2 (curve 1). The calculated, up to $R = 10$ Å, $F(R)$ curve has nine peaks, two of which (P3 and P5) are not well resolved (see Fig. 2). The $F(R)$ function maxima are due to maxima in the atomic density at: P1 (1.95 Å), P2 (2.90 Å), P3 (3.90 Å) (diffuse), P4 (4.65 Å), P5 (5.20 Å) (unresolved), P6 (5.80 Å), P7 (7.15 Å), P8 (8.0 Å) and P9 (9.0 Å). The accuracy of determination of the position of the P1–P4 peaks is $\Delta R \leqslant 0.03$ Å and for peaks P5–P9 it is 0.10 Å. From our former structural investigations on tellurite glasses[18,19] it is known that peaks P1–P6 are sensitive to the influence of the second component in the glass and are shifted towards lower R values. This kind of R value lowering is especially evident in cases when the second component possesses a stable cation–anion coordination and has a high bond strength. The peak shift is illustrated in Fig. 2.

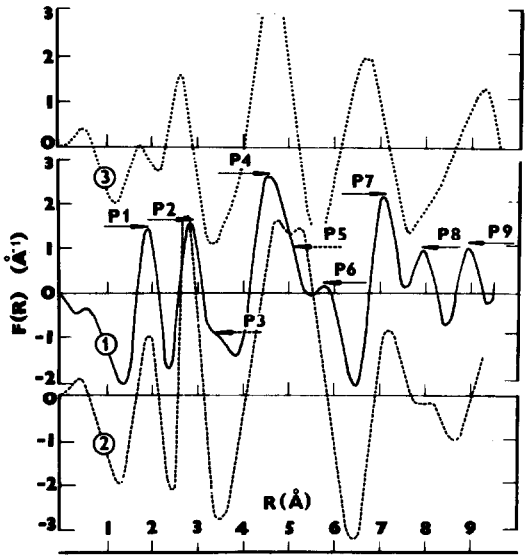

Fig. 2. Comparison between Fourier transform curves of the normalized intensity [$i(Q)$] glasses with compositions: 80% TeO_2 + 20% ZnO (curve 1), 80% TeO_2 + 20% Li_2O (curve 2)[19] and 80% TeO_2 + 20% P_2O_5 (curve 3).[18]

Figure 3 represents a comparison of the RDF_{model} curves for ZnO and α-TeO_2. There is an essential difference in the O—O distance distributions; curve 1, peak P2 at 3.35 Å, curve 2, peak P2 at 2.85 Å.

DISCUSSION

The RDF_{exp} is shown in Fig. 4 (curve 1). For a comparison and a more reliable interpretation of the results, RDF_{model} curves for an 80% TeO_2 + 20% ZnO glass (curve 2), and for $Zn_2Te_3O_8$ (curve 3), are also shown in Fig. 4.

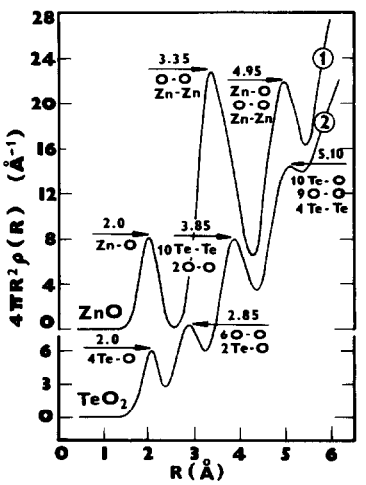

Fig. 3. Model RDF curves of ZnO (curve 1) and α-TeO_2 (curve 2).

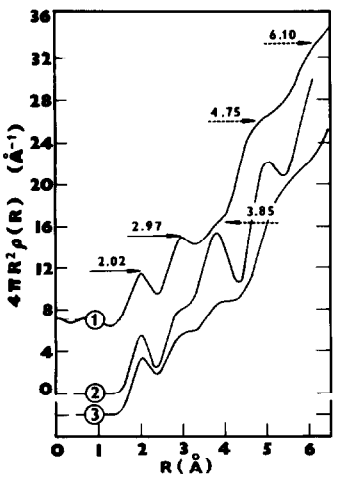

Fig. 4. A comparison of the RDF_{exp} (curve 1) of the glass investigated with the RDF_{model} (curve 2) of a glass with composition 80% TeO_2 + 20% ZnO and the RDF_{model} (curve 3) of $Zn_2Te_3O_8$ atomic density.

The RDF_{exp} curve

$$\left[4\pi R^2 \sum_i^m \sum_j^m n_i \bar{b}_i \bar{b}_j Z_{ij}(R)\right]$$

[Fig. 4 (curve 1)], where

$$\bar{b}_i = \frac{b_i}{\sum_i^m n_i b_i^2}$$

and $Z_{ij}(R)$ is the partial distribution of j-atoms around i-atoms, exhibits well-expressed coordination maxima located at R_1 = 2.02 Å (peak P1), R_2 = 2.97 Å (peak P2) and two unresolved maxima at 3.85 (peak P3) and 4.75 Å (peak P4), respectively. The interpretation of the peaks at ~5.8–6.1, 7.2, 8.0 Å etc. in Fig. 2 (curve 1) includes large uncertainties. That is why our discussion will be confined to the first four maxima, since these peaks carry the most essential information about the short-range order in the glasses.

On the basis of Te(IV), O(II) and Zn(II) ion radii of 0.83, 1.36 and 0.83 Å, respectively, we may claim that the P1 maximum is due to the contribution of the Te–O and Zn–O interatomic distances. This conclusion is supported by the fact that the main building units of the initial crystal structures persist to a great extent in the vitreous state too. This tendency exists even for metal–metalloid glasses which have been considered until recently as entirely disordered.[20] According to Lindqvist[21] the basic structural unit in α-TeO_2 is derived from a TeO_4 trigonal bipyramid with two equal Te—O_{eq} distances of 1.90 Å and two equal Te—O_{ax} distances of 2.08 Å. For the ZnO polyhedron the Zn—O distance ($\bar{R}_{Zn-O}$) in the ZnO_4 tetrahedron is 1.98 Å.

In general, the RDF_{model} curves are of the type:

$$4\pi R^2\rho_{ij}(R) = \sum_k \frac{Z_{ij}(R_k)}{\sqrt{2\pi\sigma(R_k)}} \times \left(\frac{R}{R_k}\right)^2 \exp\left[-\frac{R-R_k}{2\sigma(R_k)}\right]^2, \quad (4)$$

where it is supposed that $\sigma(R) \sim \sqrt{R}$, i.e. the structural diffusion model[22] is valid. The coordination numbers of the kth coordination spheres of radius R_k were calculated on the basis of the α-TeO_2, ZnO and $Zn_2Te_3O_8$ crystal structures. Summing the RDF_{model} for α-TeO_2 and ZnO (presented in Fig. 3) in accordance with their molar ratio (80 : 20) we have obtained the additive RDF (curve 2) given in Fig. 4. Figure 4 also shows the RDF_{model} for $Zn_2Te_3O_8$ (curve 3). Since peak P1 is a result of the distribution of the Te—O and Zn—O distances of the first coordination sphere we could define the type and degree of deformation of the building units in the glass. Taking into account the location of the composition in the phase diagram,* according to the "level rule" it follows that, in the sub solidus region at temperatures below the eutectic temperature (596°C), there should coexist two solid phases, TeO_2 and $Zn_2Te_3O_8$. By summing the RDF_{model} of α-TeO_2 [Fig. 3 (curve 2)] and $Zn_2Te_3O_8$ [Fig. 4 (curve 3)] in a 5 : 1 ratio we have obtained the resultant RDF_{model} curve for the 80% TeO_2 + 20% ZnO glass given in Fig. 5.

The comparison of the RDF_{exp} with the RDF_{model} curves for the 80% TeO_2 + 20% ZnO glass, calculated in two ways, and with the model curve for $Zn_2Te_3O_8$, for R smaller than 3 Å, shows that the main structural units in the glass are similar to those in paratellurite plus zinc–tellurite and they are predominantly those of $Zn_2Te_3O_8$. The experimentally obtained coordination number value of Te atoms in the investigated glass is 3.35.

From the average values of the interatomic distances $\bar{R}_{Te-O}$ (1.99 Å) for α-TeO_2[21] and $\bar{R}_{Te(1)-O}$ = 1.97 Å, $\bar{R}_{Te(2)-O}$ = 2.05 Å and $\bar{R}_{Zn-O}$ = 2.19 Å in $Zn_2Te_3O_8$[23] we obtained for the theoretical position of P1 a value of 2.03 Å. This value is in good correlation with that experimentally obtained by us (2.02 Å for P1 from curve 1 in Fig. 4). This coincidence shows that the shortest interatomic distances are conserved and the glass network is built on the basis of paratellurite and zinc–tellurite cation–oxygen networks. This is a good confirmation of our previous results for TeO_2-rich compositions (located in the initial crystallization field for TeO_2) or located in the eutectic point region.[18,19,24,25] It was established that TeO_4 polyhedra in tellurite glasses exhibit a clear tendency towards deformation and mobility of one of the Te—O_{ax} bonds. Due to the lack of a center of symmetry in the polyhedron this axial bond can easily undergo an elongation to a value greater than 2.2 Å. In this case we assume that there is a 3+1 coordination state for the Te atom. An analogous stereochemical surrounding of the Te atom has also been reported for glasses in the TeO_2–B_2O_3 system.[26] Zemann[27] stated that the axial bond in the crystalline tellurites is not strictly defined and can vary from 2.08 to 2.98 Å. According to the literature[28,29] however, it can exceed the upper limit of 2.9 Å. For example, for $BaTeO_3$(II) Te(1) the fourth Te—O distance is 3.25 Å, while for $BaTeO_3$(II) Te(3) it is 3.40 Å. An extreme case of elongation of the fourth Te—O bond was reported for $K_2TeO_3 \cdot 3H_2O$,[30] possessing three Te—O distances of 1.85 Å and a fourth one of 3.87 Å. It is obvious that in this case we cannot speak about four-coordination of the Te atom, but rather should consider typical TeO_3 groups. It has been established[27] that the three shortest Te–O distances vary from 1.78 to 2.15 Å,[27,29] which shows a relatively unstable configuration. From this review, it is clear that there is no strongly defined cation–anion structure, the oxygen atoms lie at different distances, influenced by both internal and external factors.

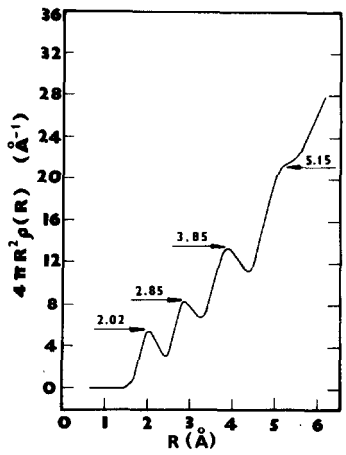

Fig. 5. RDF_{model} curve of a glass, obtained by summing up in 5 : 1 ratio curve 2 from Fig. 3 and curve 3 from Fig. 4.

On the basis of the discussion above and the data obtained for the coordination number of Te atoms, we may accept that there are approximately 35% of the Te atoms in the glass in the form of a TeO_4 configuration and 65% of the Te atoms in the form of

* Our composition choice is based on two concepts: (1) a correlation with the eutectic composition, where stable glasses of important practical use are synthesized; and (2) a comparison with glass structural data of other systems at the same molar ratio.

a TeO_{3+1} and/or a TeO_3 stereochemical surrounding. With the aid of this method a sharp boundary between these two states cannot be drawn.

While the position of the first coordination maximum in the RDF_{model} shows a good coincidence with the observed position in the glass, the RDF_{model} in the 2.5–4.5 Å region is essentially different from the experimental one. In particular, there is considerable disagreement in the interval 3.5–4.5 Å, in which the Te–Te, Te—second O, Zn—Zn and Zn—second O distances are located. Peak P2 is mainly due to the contribution of the O—O distances. While, for α-TeO_2, it is located at 2.83 Å, for the ZnO RDF_{model} P2 is observed at 3.35 Å. This great difference in the O—O distances of both basic polyhedra building the glass network leads to a broadening of the P2 maximum. This is established by the RDF_{exp} as well as by the RDF_{model} curves (see Fig. 4). The P2 in RDF_{exp} is observed at 2.9 Å. This elongation of distances is greater than 2.85 Å and the increase in the minimum between P2 and P3 (unresolved) is predominantly due to the O—O distances in the ZnO polyhedra (see Fig. 3). At the position of the expected minimum, the ZnO RDF curve has its maximum contribution. Due to these oppposite tendencies in the resultant RDF_{model} and RDF_{exp} curves, the minimum is smoothed over and even disappears; only a fluctuation in the region around 3.25 ± 0.4 Å remains in the RDF curves in Fig. 4.

In agreement with our previous results[18,19,24,25] there is also an unresolved peak, P3, which is mainly due to the Te—Te distribution. RDF_{exp} shows that the distances of approximately 3.9 Å are considerably changed. Te—Te, Te—Zn, O—second O and Te—second O are bonds with such distances. The broadening of peak P3 shows that it is one of the main structural characteristics of the glass transition.

What are the basic structural changes taking place at distances greater than 3.0 Å? Greater than this value there are many differences in number and specific influence on the RDF interatomic distances. It was established that the Te—Te distances are the most sensitive to the transition to the glassy state. This may be explained by the fact that the shortest Te—Te distance in α-TeO_2 is 3.76 Å. This long distance between the two heavy metal cations leads to an assumption that some weak metal bonds are present. A comparison[11,31,32] carried out of the bond energy (D_{R-R}) in some glass formers shows that it decreases in the sequence:

B_2O_3	P_2O_5	SiO_2	GeO_2	As_2O_3	TeO_2
R_k (Å)					
0.20	0.35	0.41	0.53	0.43	0.56
$\bar{R}_{R-O}$ (Å)					
1.26	1.52	1.55	1.63	1.80	1.99
D_{R-R} (kcal mol^{-1})					
—	51.3	42.2	37.6	32.1	33.0

It is established that the Te atoms have the greatest ion radius and the biggest mass, the highest value of average Te–O distance and the lowest Te—Te bond energy, near to that of As—As in As_2O_3. We should like to note here that, during the glass transition, the $\bar{R}_{Te-Te}$ of 3.80 Å between two tellurite–oxygen chains (see Fig. 6) is not preserved. This is due to the fact, that along the *c*-axis in paratellurite there are channels which are able to incorporate even the second-component polyhedra.*
