where the intermediate species would be a quaternary complex with two hydrogen peroxide molecules coordinated to the apical positions [or one molecule in the case of eqn (2)]. Another possible intermediate would consist of a *cis* apical–equatorial coordination of two hydrogen peroxide molecules, the amino acid remaining as monodentate a ligand. However, as were already pointed out, these reac-

tion pathways disagree with the competitive inhibitory properties of the free amino acid. Moreover, the reaction order for this species, -1.3, strongly suggests that a simultaneity of the above proposed mechanisms would be feasible.

On summary, although it is possible that there exist some steric effects on these catalytic reactions, arising from the particular coordination environments provided by the chiral ligands, evidence with respect to this point was not found. The structural features of the secondary ligand seem to influence the catalytic behavior mainly by thermodynamic stability effects which rule the availability of accessible coordination sites on the metal ion.

(*Received* 14 *November* 1985; *accepted* 19 *December* 1985)

Abstract—Bond indices (I) have been calculated, using the CNDO-based molecular-orbital bond index method, for real and hypothetical *closo* borane species, $B_nH_n^{c-}$ ($n = 5$–12; $c = 0$, 2 or 4), and used to infer their relative stabilities by means of the bond index (I)–bond enthalpy [E (kJ mol^{-1})] equations E(B—B) = 297.9I(B—B), and E(B—H) = 374.8I(B—H). For the species able to tolerate $n+2$ skeletal electron pairs ($n = 8$, 9 or 11) in closed-shell electronic configurations, estimates of the relative stabilities of alternative *nido* structures for the anions $B_nH_n^{4-}$ have been made. Detailed assessments of the changes in bond index with electron numbers for particular edge types for $B_nH_n^{c-}$ species ($n = 8$, 9 or 11; $c = 0$, 2 or 4) have been carried out, providing quantitative confirmation of earlier qualitative predictions, and showing that generally for the "normal" *closo* $B_nH_n^{2-}$ species addition or removal of an electron pair leads to the same type of polyhedral distortion, because, where the HOMO of $B_nH_n^{2-}$ is bonding for a particular edge, the LUMO is antibonding.

This paper is concerned with the strength of the cluster bonding in some systems that may be regarded as exceptions to the general rules linking boron cluster shapes to formula types and so to skeletal electron numbers. In particular, we shall consider some clusters in which n skeletal atoms are held together in a *closo* polyhedral arrangement even though bound by other than the usual ($n+1$) skeletal electron pairs, and shall probe quantitatively the bonding consequences of their electron deficits or surpluses, testing the qualitative predictions we have made earlier about such systems.[1–3]

The well-established link between the skeletal shapes and electron numbers of borane clusters[4–12] can be summarized as follows. $B_nH_n^{2-}$ anions ($n = 6$–12), neutral carboranes [$C_2B_{n-2}H_n$ ($n = 5$–12)] and related clusters, with $n+1$ skeletal bond pairs to hold their n skeletal atoms together, have *closo* deltahedral structures whose symmetries (as many MO treatments[13–19] have shown) generate $n+1$ strongly bonding MOs with substantial HOMO–LUMO energy gaps. Figure 1 shows these *closo* shapes of the $B_nH_n^{2-}$ species ($n = 5$ as yet unknown, $n = 6$–12) and gives the edge distances used in calculations. More open *nido* or *arachno* structures, based on the deltahedra with $n+1$ or $n+2$ vertices, are generally found for n-atom clusters with $n+2$ or $n+3$ skeletal bond pairs, respectively, one or two vertices (respectively) being left vacant. Their polyhedral fragment structures generate the same number of bonding MOs as the complete deltahedra.

Here, we shall be concerned with exceptions to these generalizations in which n-atom clusters with *closo* shapes are held together by n or $n+2$ skeletal electron pairs. Examples of the former include

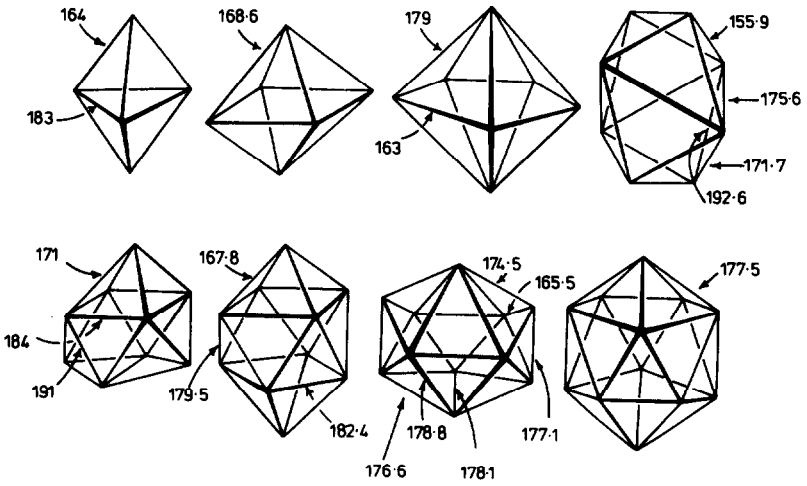

Fig. 1. All *closo* polyhedra showing interatomic distances used in calculations.

B_8Cl_8,[20] B_9Cl_9[21] and $(\eta^5\text{-}C_5H_5)_4Co_4B_4H_4$,[22] held together by one pair of electrons fewer than the norm. On the other hand, Bi_9^{5+} [23] and $(\eta^5\text{-}C_5H_5)_4Ni_4B_4H_4$[24,25] are of the latter type, with *closo* structures rather than the *nido* shapes expected. We have elsewhere[1-3] noted that the frontier orbital degeneracies of these D_{2d} dodecahedral and D_{3h} tricapped trigonal prismatic clusters allow them to be compatible with n, $n+1$ or $n+2$ skeletal electron pairs (the same being true in principle for C_{2v} octadecahedral clusters shaped like $B_{11}H_{11}^{2-}$) although the most effective bonding is presumably achieved with $n+1$ skeletal electron pairs (though calculations to test this quantitatively have not to our knowledge previously been carried out). We also pointed out that the subtle differences in bond lengths between $B_8H_8^{2-}$ and B_8Cl_8, or between $B_9H_9^{2-}$ and B_9Cl_9, were qualitatively explicable in terms of the bonding or antibonding nature of particular B–B edge links in the HOMOs of $B_8H_8^{2-}$ or $B_9H_9^{2-}$.

Below, we attempt to place on a quantitative basis the consequences, for *closo* clusters, of having n or $n+2$ instead of $n+1$ skeletal electron pairs. For the purpose, we use the CNDO-based molecular-orbital bond index (MOBI) method developed by Armstrong *et al.*[26] which in a previous paper[27] we employed to estimate skeletal bond enthalpies [E(B—B)] for the *closo* borane anions, $B_nH_n^{2-}$ (n = 5–12), using the following relationships (already known to be compatible with published thermochemical data for various boranes[28]) to link E(B—B) (kJ mol^{-1}) to bond indices (I):

$$E(\text{B—B}) = 297.9I(\text{B—B})$$

and

$$E(\text{B—H}) = 374.8I(\text{B—H}).$$

RESULTS AND DISCUSSION

In reporting and discussing the results of our MOBI calculations, we consider in turn the following issues:

(a) the degeneracies of the frontier orbitals of *closo*-$B_nH_n^{2-}$ anions;

(b) the variations in total $I(\Sigma I)$ and enthalpies (ΣE) of *closo*-$B_nH_n^{c-}$ species (c = 0, 2 or 4) with their skeletal electron pair numbers $\left(n+\frac{c}{2}\right)$;

(c) the influence of $\left(n+\frac{c}{2}\right)$ on individual bond lengths and indices; and

(d) the relative energies of *closo* and *nido* structures for $B_nH_n^{4-}$ anions (n = 7, 8, 9 or 11).

Frontier-orbital degeneracies

Figure 1 shows the D_{2d}-, D_{3h}- and C_{2v}-skeletons of the *closo* borane anions $B_8H_8^{2-}$, $B_9H_9^{2-}$ and $B_{11}H_{11}^{2-}$. For our calculations, atomic coordinates for $B_8H_8^{2-}$ and $B_9H_9^{2-}$ were taken from published structures of salts of these anions.[15] For the hypothetical neutral hydrides B_8H_8 and B_9H_9 we used the boron coordinates found in X-ray crystallographic studies of B_8Cl_8[20] and B_9Cl_9,[21] substituting B—H bonds of length 116 pm for the B—Cl bonds. Atomic coordinates for $B_{11}H_{11}^{2-}$ were derived from the published structure of the $[B_{11}H_{10}SMe_2]^-$ anion,[29] with a B—H unit (bond length 116 pm) replacing the $BSMe_2$ unit. The non-degeneracy of the frontier orbitals that allows these systems to tolerate n, $n+1$ or $n+2$ skeletal electron

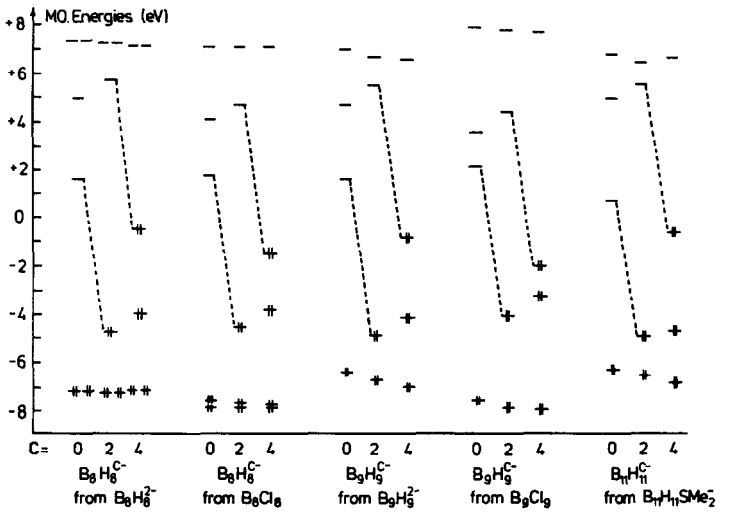

Fig. 2. Frontier-orbital energies of $B_8H_8^{2-}$, $B_9H_9^{2-}$ and $B_{11}H_{11}^{2-}$.

pairs is confirmed by our calculations (Fig. 2). Removal of electron pairs from these anions to generate neutral B_nH_n species (n atoms, n pairs) or addition of electron pairs to them, to generate $B_nH_n^{4-}$ anions (n atoms, $n+2$ pairs) would leave closed-shell, spin-paired electronic configurations and hence give rise to potentially stable species.

As expected for colourless species that are not easily reduced, the HOMO–LUMO gaps for the $B_nH_n^{2-}$ dianions are large (8.3–10.4 eV). If one bonding MO is left unfilled, as in the case of neutral B_nH_n molecules, the $(n+1)$th skeletal bonding MO, formerly the HOMO of $B_nH_n^{2-}$, increases markedly in energy relative to the nth skeletal bonding MO, so preserving a significant HOMO–LUMO energy gap of *ca* 7.4–9.6 eV for the hypothetical neutral B_nH_n species (Fig. 2).

In order to check the sensitivity of MO energies and degeneracies to the atomic coordinates used, we also calculated the energies of the MOs of hypothetical B_nH_n species using the atomic coordinates found experimentally for $B_nH_n^{2-}$ anions. As expected, the degeneracies (which reflect the symmetries) were unaffected, though orbital energies changed slightly. For example, the HOMO of B_8H_8 is calculated to have an energy of -7.62 eV using the boron coordinates of B_8Cl_8, but of -7.06 eV using the boron coordinates of $B_8H_8^{2-}$.

Addition of an electron pair to a *closo*-$B_nH_n^{2-}$ species to generate a hypothetical *closo*-$B_nH_n^{4-}$ anion fills the former's slightly antibonding LUMO. Again, orbital energy changes with occupancy leave substantial (7.0–9.3 eV) HOMO–LUMO gaps for these hypothetical $B_nH_n^{4-}$ species ($n = 8$, 9 or 11).

By contrast, MOBI calculations[27] on other *closo*-$B_nH_n^{2-}$ anions ($n = 5$, 6, 7, 10 or 12) using experimentally determined[30–32] or estimated[27] ($n = 5$ or 7) atomic coordinates confirmed that their frontier orbitals are degenerate. Adding an electron pair to any of these dianions, or removing an electron pair, would generate a paramagnetic species prone to distortion to remove the HOMO degeneracy. (Actually, use of the published atomic coordinates for $B_{10}H_{10}^{2-}$ [31] and $B_{12}H_{12}^{2-}$,[32] which show slight departures from idealized D_{4d}- and I_h-symmetries, respectively, causes a slight splitting of the frontier orbitals that vanishes if idealized symmetries are used.)

ΣI *and* ΣE *of* closo-$B_nH_n^{c-}$ *species* (c = 0, 2 *or* 4)

Tables 1 and 2 list the B—B and B—H I calculated for the real and hypothetical *closo*-$B_nH_n^{c-}$ systems considered in this work. Table 1 presents data for systems with $n = 8$, 9 or 11, i.e. those systems that are either known to tolerate other than $n+1$ skeletal electron pairs, or may reasonably be expected to do so for the orbital degeneracy reasons just outlined. Table 2 presents data for systems with $n = 5$, 6, 7, 10 or 12, for which the presence of n or $n+2$ skeletal electron pairs (i.e. when $c = 0$ or 4) would leave frontier orbitals incompletely filled.

Entries in the second, third and fourth columns in both tables record the following: $\Sigma I(\text{B—B})_{\text{adj}}$, the sum of the bond indices between nearest neighbour (adjacent) boron atoms, i.e. for all of the boron–boron polyhedral edge bonds; $\Sigma I(\text{B—B})_{\text{all}}$, the sum of *all* of the (skeletal) boron–boron links, including pairwise cross-polyhedral interactions as well as polyhedral edge interactions; and $\Sigma I(\text{B—H})$, the sum of the n B—H I for each species.

The fifth column in each table lists figures that

reflect the efficiency with which the $2n+c$ electrons formally available for skeletal bonding are used in these systems, by listing the mean boron–boron I per skeletal electron pair. The next column shows how effectively the n electron pairs notionally available for B–H bonding are used, and the final three columns convert these total bond indices into total bond enthalpies using the equations[28] already referred to, i.e. E(B—B) = 297.9I(B—B), and E(B—H) = 374.8I(B—H).

Considering first the data in Table 1, and comparing entries for the "normal" $(n+1)$ skeletal pair systems ($B_nH_n^{2-}$) with those (B_nH_n) containing only n skeletal electron pairs, we see that:

(i) the $n+1$th skeletal electron pair does indeed contribute significantly to the skeletal bonding, albeit to a lesser extent than the other n "skeletal" pairs already present;

(ii) this same $(n+1)$th electron pair, formally a skeletal bond pair, apparently has slight B–H *antibonding* character in that its presence correlates with a slight (2–3%) decrease in ΣI(B—H);

(iii) the cross-polyhedral boron–boron interactions in these systems, as represented by the difference between $\Sigma I(\text{B—B})_{\text{all}}$ and $\Sigma I(\text{B—B})_{\text{adj}}$, are of little significance [$<2.5\%$ of $\Sigma I(\text{B—B})_{\text{all}}$] for the normal $B_nH_n^{2-}$ anions but of rather more significance [still $<5\%$ of $\Sigma I(\text{B—B})_{\text{all}}$] for the neutral B_nH_n species; and

(iv) the total energy of the B—B and B—H bonds in the $B_nH_n^{2-}$ anions is greater than that of the hypothetical B_nH_n species, though only marginally so (difference $<0.6\%$).

The entries in Table 1 relating to hypothetical $B_nH_n^{4-}$ anions show that the extra electron pair such species possess compared to the normal *closo*-$B_nH_n^{2-}$ anions strengthens the cross-polyhedral boron–boron interactions while leaving the polyhedral edge bonding essentially little changed overall, though individual edge bonds change markedly in strength, as shown below. However, the concomitant *decrease* in the total boron–hydrogen I (and consequent loss of boron–hydrogen bond energy) is more than sufficient to offset completely the marginal strengthening of the skeletal bonding, leaving the overall effect of this $(n+2)$th pair of electrons *anti*bonding.

A qualitatively similar but quantitatively more pronounced picture emerges from an examination of the data in Table 2, which show, as expected, that the *closo*-$B_nH_n^{2-}$ clusters, containing $n+1$ bond pairs that are attributable to skeletal (boron–boron) bonding and n bond pairs attributable to boron–hydrogen bonding, are those that make best use of their electrons. The relatively strongly bonding nature of the $(n+1)$th pair of skeletal electrons is reflected in the marked reduction in bond energy when this pair is removed going from $B_nH_n^{2-}$ to the hypothetical neutral B_nH_n species though since the bond indices and enthalpies of the latter were calculated using the atomic coordinates of the dianions, not on optimized structures, the bonding nature of the $(n+1)$th skeletal pair will actually be rather less than the figures in Table 2 suggest.

An interesting implication of the figures in Table 2 is that, of the $B_nH_n^{2-}$ anions therein, $B_{10}H_{10}^{2-}$ appears to be the best candidate for oxidation to a neutral B_nH_n species, in that it is calculated to lose the least bond energy on removal of two electrons.

The influence of skeletal electron numbers on individual polyhedral edge lengths and I

Earlier[1-3] we pointed out that the differences between the skeletal geometries of the dodecahedral $B_8H_8^{2-}$ [15] and B_8Cl_8,[20] or of the tricapped trigonal prismatic $B_9H_9^{2-}$ [15] and B_9Cl_9,[21] could qualitatively be understood in terms of the polyhedral edge-bonding or edge-antibonding characteristics of their $(n+1)$th skeletal bonding MOs, which are occupied, as the HOMOs, in the hydride $B_nH_n^{2-}$ dianions but empty in the neutral halides, B_nCl_n: loss of electrons that bond specific edges causes those edges to lengthen on going from $B_nH_n^{2-}$ to B_nCl_n; on the other hand, edges for which those same electrons were antibonding contract. The bond indices calculated in the present study confirm these qualitative changes, and reveal the extent to which specific edge bonds are strengthened or weakened. Results for systems with 8, 9 or 11 skeletal atoms are discussed in turn below.

D_{2d} *dodecahedral* closo *octaboranes*, $B_8H_8^{c-}$ (c = 0, 2 *or* 4)

The four distinct types of polyhedron edge in the D_{2d} dodecahedral octaborane clusters B_8Cl_8[20] and $B_8H_8^{2-}$,[15] labelled w, x, y and z in Fig. 3, differ in length as summarized in Table 3. Figure 3 and Table 3 also illustrate the edge-bonding or edge-antibonding characteristics of the frontier orbitals. The HOMO of $B_8H_8^{2-}$, empty in B_8Cl_8, is *bonding* for edges of types w, y and z, but *antibonding* for those of type x. Conversely, the LUMO of $B_8H_8^{2-}$, which would be filled in a hypothetical D_{2d} $B_8H_8^{4-}$ cluster (or in an isoelectronic neutral D_{2d} dodecahedral carborane, $C_4B_4H_8$) is *antibonding* for edges of types w, y and z, but *bonding* for edges of type x. Whether a pair of electrons is added to or

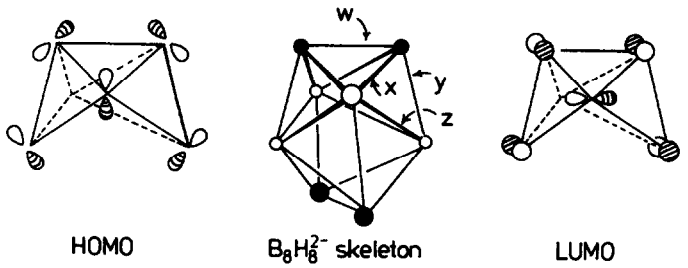

Fig. 3. $B_8H_8^{2-}$ shape, and HOMO and LUMO.

removed from $B_8H_8^{2-}$, provided the D_{2d} *closo* dodecahedral shape is retained, the same type of distortion is expected. Edges of types *w*, *y* and *z* will lengthen, while those of type *x* will contract.

Such changes in edge bond strengths, which incidentally make the skeletal atom geometry of B_8Cl_8 a realistic model for that of the hypothetical $B_8H_8^{4-}$ anion, are clearly reflected in the *I* calculated for the four edge types and listed in Table 3. Calculations of edge *I* were carried out for B_8H_8, $B_8H_8^{2-}$ and $B_8H_8^{4-}$ using both B_8Cl_8[20] and $B_8H_8^{2-}$[15] skeletal atom geometries, to explore the extent to which the *I* were dependent on the interatomic distance used. The *I* calculated for B_8H_8 and $B_8H_8^{4-}$ using the B_8Cl_8 skeletal atom coordinates, and those calculated for $B_8H_8^{2-}$ using its measured skeletal atom coordinates, are the *I* considered the more apt of the pair listed for each system.

That the calculated *I* are influenced more by changes in electron numbers than by subtle changes in interatomic distances is shown by the sets of data in Table 3 that relate to a common structure for B_8H_8, $B_8H_8^{2-}$ and $B_8H_8^{4-}$, whether that structure be that of the B_8Cl_8 or the $B_8H_8^{2-}$ skeleton.

The structural changes expected to accompany two-electron oxidation or reduction of D_{2d} dodecahedral $B_8H_8^{2-}$ with retention of *closo* geometry incidentally result in an overall *expansion* of the dodecahedron, the atoms of lower coordination number (those connected to each other by edges of type *w*) moving out from the centre more than those of higher coordination number, stretching the polyhedron along the two-fold axis connecting the midpoints of the edges of type *w*.

D_{3h} *tricapped trigonal prismatic* closo *nonaboranes*, $B_9H_9^{c-}$ (c = 0, 2 *or* 4)

The three distinct types of polyhedron edge in the D_{3h} tricapped trigonal prismatic nonaborane clusters B_9Cl_9[21] and $B_9H_9^{2-}$,[15] labelled *f*, *g* and *h* in Fig. 4, differ in length as summarized in Table 4. Figure 4 and Table 4 also illustrate the edge-bonding or edge-antibonding characteristics of the frontier orbitals. The HOMO of $B_9H_9^{2-}$, empty in B_9Cl_9, is clearly *bonding* for edges of types *g* and *h*, but *antibonding* for those of type *f*. Conversely, the LUMO of $B_9H_9^{2-}$, which would be occupied in a hypothetical

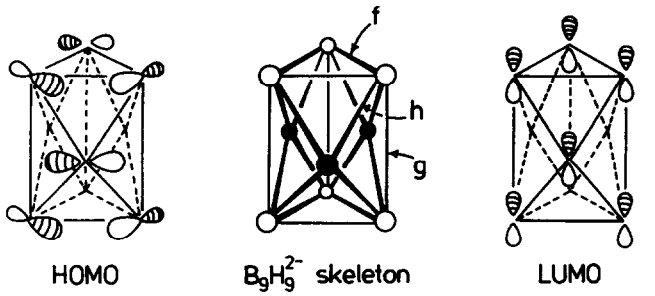

Fig. 4. $B_9H_9^{2-}$ shape, and HOMO and LUMO.

$B_9H_9^{4-}$ cluster, and is indeed occupied by one electron in the tricapped trigonal prismatic Sn_9^{3-} anion,[33] and by two electrons in the tricapped trigonal prismatic Bi_9^{5+} cation,[23] is clearly *bonding* for edges of type *f* but *antibonding* for those of type *g*. Its bonding/antibonding character with respect to edges of type *h* is less clearly deducible from the lobal characteristics of its AOs, and was referred to earlier by us[1-3] as *antibonding*, in contrast to the description of Critchlow and Corbett[33] who in considering the Sn_9^{3-} anion found the singly-occupied HOMO to be *bonding* with respect to edges of type *h*.

The *I* data in Table 4 shed useful light on this and other issues. Whatever the bonding or antibonding character of the LUMO for edges of type *h*, one feature is clear. This is that two-electron oxidation *or* reduction of a cluster such as $B_9H_9^{2-}$, provided that a tricapped trigonal prismatic structure is retained, will cause the trigonal prism to become elongated along its three-fold axis, but thinner. This conclusion is reinforced by the *I* for edges of types *f* and *g* given in Table 4, which increase and decrease, respectively, on going from $B_9H_9^{2-}$ to B_9H_9 or $B_9H_9^{4-}$, when appropriate sets of skeletal atom coordinates are used. (If a particular structure, whether using the atomic coordinates of B_9Cl_9 or of $B_9H_9^{2-}$, is retained for all the calculations of bond indices, the *I* calculated for edges of type *g* remains essentially unchanged going from $B_9H_9^{2-}$ to B_9H_9.)

As regards edges of type *h*, these are clearly weakened going from $B_9H_9^{2-}$ to B_9H_9 as the edge-bonding power of two electrons is lost. Going from $B_9H_9^{2-}$ to $B_9H_9^{4-}$, these same edges are calculated to be strengthened a little if a B_9Cl_9-type structure

[b] Distance to capping boron; *h* for capping carbon is 161 pm.

[c] This anion is very distorted,[35] with one long prism edge, *g*. For the others, the *f*/*g* ratio is 0.94.

[d] Figures in parentheses relate to B_9Cl_9 skeletal geometry, others to $B_9H_9^{2-}$ geometry; the more apt are in **bold print**.

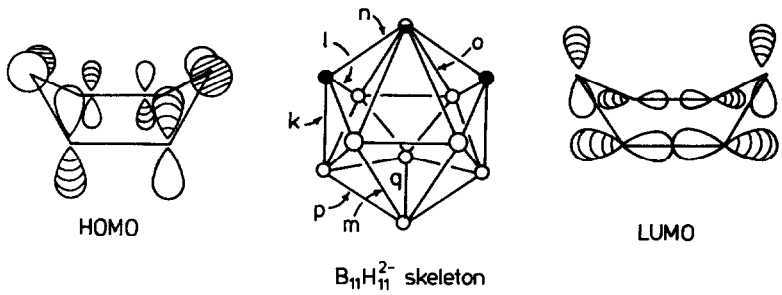

Fig. 5. $B_{11}H_{11}^{2-}$ shape, and HOMO and LUMO.

is assumed for both species, but to be weakened a little if the $B_9H_9^{2-}$ structure is assumed for both species. Making the more reasonable comparison between $B_9H_9^{2-}$, with its known structure, and $B_9H_9^{4-}$ with a skeletal atom arrangement like that of B_9Cl_9, we find the edges of type *h* to suffer negligible change in bond index—the increase from 0.663 for $B_9H_9^{2-}$ to 0.667 for $B_9H_9^{4-}$ cannot be regarded as significant. We conclude that the LUMO of $B_9H_9^{2-}$ is essentially *nonbonding* for these edges.

In addition to the interatomic distances for B_9Cl_9 and $B_9H_9^{2-}$ given in Table 4, structural data for the related tricapped trigonal prismatic clusters $C_2B_7H_9$,[34] Ge_9^{2-},[35] Sn_9^{3-} [33] and Bi_9^{5+} [23] are included for purposes of comparison. Direct comparison of interatomic distances for clusters of atoms of such different sizes as boron, germanium, tin and bismuth is of little value, so the ratio, *f*/*g*, of the prism edge lengths is given to facilitate comparison. The longer, thinner prism of B_9Cl_9 compared with $B_9H_9^{2-}$ is reflected in its smaller *f*/*g* ratio (0.87, cf. 1.04 for $B_9H_9^{2-}$); Sn_9^{3-} and Bi_9^{5+} likewise have low *f*/*g* ratios. However, values of *f*/*g* less than unity cannot be taken as uniquely characteristic of tricapped trigonal prismatic clusters with "anomalous" electron numbers, as shown by the *f*/*g* ratio of 0.91 for the "normal" *closo* cluster Ge_9^{2-} anion,[35] though it should be acknowledged that this ion is significantly distorted from idealized D_{3h}-symmetry in the crystal.

C_{2v} *octadecahedral* closo *enneaboranes*, $B_{11}H_{11}^{c-}$ (c = 0, 2 *or* 4)

The 11-vertex *closo* borane systems are far less well documented than the 8- and 9-vertex systems just considered. The structure of the anion $B_{11}H_{11}^{2-}$ has not yet been determined crystallographically, though that of the derivative $[B_{11}H_{10}SMe_2]^-$ [29] provides a good guide to its likely interatomic distances (Fig. 5, Table 5).

In principle, because its frontier orbitals (Fig. 5) are nondegenerate, the $B_{11}H_{11}^{2-}$ anion could tolerate two-electron oxidation or reduction while retaining its *closo* deltahedral shape, albeit with modified interatomic distances, though no 11-atom *closo*-shaped clusters with 11 or 13 skeletal electron pairs have to our knowledge been characterized to date. In order to get some feeling for the manner in which

[a] See Fig. 5.

[b] Skeletal atom coordinates as for $[B_{11}H_{10}SMe_2]^-$.[29]

they would be expected to differ from $B_{11}H_{11}^{2-}$, we carried out *I* calculations on $B_{11}H_{11}$, $B_{11}H_{11}^{2-}$ and $B_{11}H_{11}^{4-}$, assuming for each a structure like that of $B_{11}H_{11}^{2-}$, itself deduced from the published structure[29] of $[B_{11}H_{10}SMe_2]^-$ by replacement of the SMe_2 ligand by a hydrogen ligand. The results are given in Table 5.

Detailed interpolation of the data in Table 5 is not justified, since the calculations for $B_{11}H_{11}$ and $B_{11}H_{11}^{4-}$ have been carried out using the structure of $B_{11}H_{11}^{2-}$, making no allowance for the expected distortions. Nevertheless, the nature of these distortions can be inferred from the calculated *I*, in that edges experiencing an increase in *I* on electron pair addition or removal may be expected to shorten relative to those of $B_{11}H_{11}^{2-}$, while those experiencing a decrease in *I* may be expected to lengthen.

Thus, in the hypothetical *closo* hydride, $B_{11}H_{11}$, or chloride, $B_{11}Cl_{11}$, the edges of types *k*, *m*, *n* and *q* are expected to be slightly shorter than their counterparts in $B_{11}H_{11}^{2-}$, while edges of types *l*, *o* and *p* are expected to be longer, type *l* showing the most marked change.

Qualitatively similar changes relative to $B_{11}H_{11}^{2-}$ are expected for a *closo* $B_{11}H_{11}^{4-}$ species, i.e. edges of types *k*, *m*, *n* and *q* shorter than in the parent $B_{11}H_{11}^{2-}$, edges of types *l*, *o* and *p* longer. From this we can infer that, as with $B_8H_8^{2-}$ and $B_9H_9^{2-}$, so with $B_{11}H_{11}^{2-}$, for the edges for which the HOMO is bonding, the LUMO is antibonding, and vice versa.

Our data incidentally allow the symmetries of the frontier orbitals of $B_{11}H_{11}^{2-}$ to be identified for the first time. The HOMO is A_2, the LUMO A_1.

Relative energies of closo *and* nido *structures for* $B_nH_n^{4-}$ *anions* (n = 8, 9 *or* 11)

So far in this paper we have been considering the bonding consequences of changing the numbers of electrons of *closo* clusters while retaining *closo* geometries, paying particular attention to systems with 8, 9 or 11 skeletal atoms whose nondegenerate frontier orbitals allow closed-shell electronic configurations for neutral B_nH_n entities (effectively already known in the form of the chlorides B_8Cl_8 and B_9Cl_9) and for $B_nH_n^{4-}$ tetra-anions (unknown as *closo* species, but known in protonated or metallated form as *nido* species based on deltahedra with $n+1$ vertices). In this final section we use the MOBI method to compare the energies of such hypothetical *closo* structures with likely alternative *nido* structures for $B_8H_8^{4-}$, $B_9H_9^{4-}$ and $B_{11}H_{11}^{4-}$.

Our results are summarized in Table 6, which lists the total B—B and B—H *I* calculated for the various possible structures for these tetra-anions, and the *E* they imply, calculated using the relationships $E(B—B) = 297.9I(B—B)$ kJ mol^{-1}, and $E(B—H) = 374.8I(B—H)$ kJ mol^{-1}.[28]

For $B_8H_8^{4-}$, we compare the results for a *closo* species with what we regard as the most plausible skeletal structure (like that of B_8Cl_8), with *nido* structures derived from the $B_9H_9^{2-}$ skeleton by removal of one or other of the two types of capping BH^{2+} units, or by removal of one of the more highly coordinated BH^{2+} units from a prism vertex site (Fig. 6) (*nido* boranes are generally found to have skeletons based on deltahedra with the *most highly* coordinated vertex vacated). Interestingly, in all

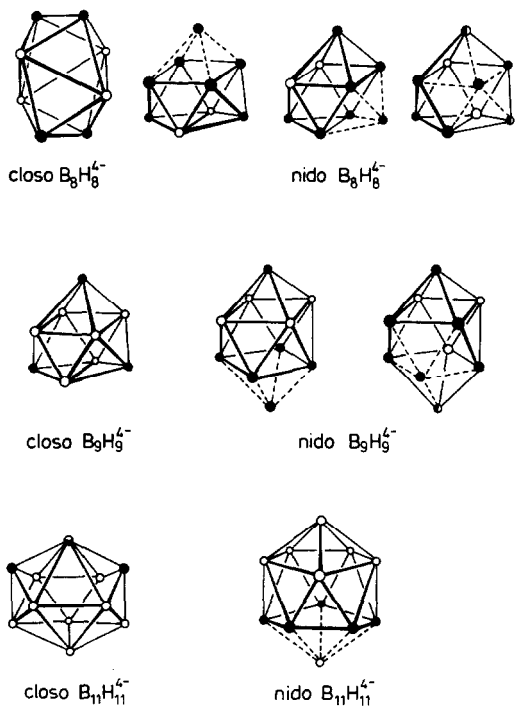

Fig. 6. Alternative *nido* shapes for $B_8H_8^{2-}$, $B_9H_9^{2-}$ and $B_{11}H_{11}^{2-}$.

cases, the skeletal I, ΣI(B—B), are very similar, as are the BH I, ΣI(B—H), and when these are converted into E, we find only very small differences in total E, E_{total}, between these alternative structures. Our conclusion is that the hypothetical *closo* structure we have been considering for $B_8H_8^{4-}$ may indeed by a plausible possible structure for such an anion or isoelectronic analogues such as $C_4B_4H_8$, Sn_8^{4-} etc., even if slightly more stable *nido* alternatives exist, so the *closo* geometry could provide at least a low-energy intermediate/transition state through which *nido* species might readily rearrange.

Similar conclusions can be drawn concerning the feasibility of a *closo* structure for $B_9H_9^{4-}$. Indeed, the *closo* structures already known for salts of the Sn_9^{3-} anion and the Bi_9^{5+} cation show that in certain systems the *closo* structure may actually be preferred to *nido* alternatives, though the influence of the counter-ions in such salts should not be ignored.

For $B_{11}H_{11}^{4-}$, since in icosahedral *closo*-$B_{12}H_{12}^{2-}$ all 12 BH units are equivalent, there is only one feasible *nido* structure with which to compare our hypothetical *closo* structure. Again, the difference in E_{total} is calculated to be very small, surprisingly so since the skeleton assumed for the calculation on *closo*-$B_{11}H_{11}^{4-}$ was that of the normal $(n+1)$-skeletal pair species $[B_{11}H_{10}SMe_2]^-$,[29] no allowance being made for the expected distortions.

The above results for $B_nH_n^{4-}$ species (n = 8, 9 or 11) for which *closo* structures are feasible alternatives to *nido* ones can be contrasted with those for other $B_nH_n^{4-}$ species (n = 5, 6, 7, 10 or 12) for which they are not. For example, comparing the results for a *closo*-$B_7H_7^{4-}$ species (using bond lengths predicted earlier[27] for $B_7H_7^{2-}$) with those for a *nido*-$B_7H_7^{4-}$ one (derived from *closo*-$B_8H_8^{2-}$ by removal of the high-coordinate BH^{2+} capping unit) shows severe weakening of cluster bonding in the former [ΣI(B—B) = 8.65 and 9.81, respectively]. As the exo-B—H bonding is of very comparable strength in both [ΣI(B—H) = 6.25 and 6.26, respectively], the effect of this is to make the *closo* structures energetically extremely unfavourable (E_{total} = 4919 and 5267 kJ mol^{-1}, respectively).

MODES OF COORDINATION OF 1,2-AMINOTHIOLS IN ORGANOTIN(IV) COMPLEXES, AS DEMONSTRATED BY ^{119}Sn, ^{15}N AND ^{13}C NMR SPECTROSCOPY

BHIM SEN SARASWAT* and JOAN MASON†

Department of Chemistry, The Open University, Milton Keynes MK7 6AA, U.K.

(*Received* 29 *November* 1985; *accepted* 19 *December* 1985)

Abstract—Three series of organotin(IV) cysteamine complexes have been prepared in which the 1,2-aminothiol may be monodentate, chelating or bridging, on the ^{119}Sn, ^{15}N or ^{13}C NMR spectroscopic and other physical evidence. Triorganotin(IV) complexes $[SnR_3(SCH_2CH_2NR'_2)]$ (R = Me, Bu^n or Ph; R′ = H, Me or Et) are monomeric and the aminothiol monodentate in non-coordinating solvents. Dialkyltin(IV) chloro complexes $[SnR_2Cl(SCH_2CH_2NR'_2)]$ (R = Me, Et, Bu^n or Oct^n; R′ = H, Me or Et), however, are monomeric with chelation of the aminothiol, like the SnR_2Cl complex of ethyl cysteinate, although nitrogen ligation is hindered by *N,N*-dialkylation. These solution properties contrast with the polymeric solid structures that are likely for $[SnR_2Cl(SCH_2CH_2NH_2)]$ complexes with R = Me or Et, though not for R = Bu^n or Oct^n. Dialkyltin bis-cysteamine complexes $[SnR_2(SCH_2CH_2NR'_2)_2]$ (R = Me, Et, Bu^n or Oct^n; R′ = H or Et) show an intermolecular association as neat liquids and in non-coordinating solvents, increasingly with concentration, but again, nitrogen ligation is hindered by tertiary amino groups. The ^{15}N results usefully complement those from ^{119}Sn and ^{13}C NMR spectroscopy.

The chemistry of organotin(IV) compounds with strongly ligating sulphur and possibly ligating nitrogen is of interest in view of the biocidal activity of triorgano-$[R_3SnX]$ and diorgano-$[R_2SnX_2]$ tin compounds.[1,2] Particularly effective R groups in $[R_3SnX]$ are Me, Et, Pr^n, Bu^n and Ph. Remarkably, each is effective against different living species, the toxicity decreasing with increase in alkyl-chain length beyond C_4. Detailed mechanisms are obscure, but $[R_3SnX]$ compounds (which inhibit mitochondrial oxidative phosphorylation) and $[R_2SnX_2]$ compounds (which inhibit α-ketoacid oxidation) are known to combine with thiol and dithiol groups, respectively, in proteins and enzymes. There is interest also in organotin compounds with nitrogen ligands for cancer chemotherapy.[1,2] Some organotin(IV) complexes with sulphur-containing aminoacid or other biological ligands have been studied,[3–7] and corresponding inorganic complexes.[8] Less information is available, however, on aminothiol complexes, although certain cysteamine (2-aminoethanethiol) derivatives are reported, $[SnMe_2Cl(SCH_2CH_2NH_2)]$[4,5] and $[SnR_3(SCH_2CH_2NH_2)]$, with R = Me[5] or Bu^n.[6]

To explore effects of changes in the coordination sphere and in the organo groups, we undertook the preparation and characterization of three series of organotin(IV) cysteamine compounds, $[SnR_2Cl(SCH_2CH_2NR'_2)]$, $[SnR_3(SCH_2CH_2NR'_2)]$ and $[SnR_2(SCH_2CH_2NR'_2)_2]$, with R = Me, Et, Bu^n, Oct^n or Ph, and R′ = H, Me or Et (cf. Table 1), and related compounds of known structure for comparison, the cysteinato complex (**1**),[9,10] and $[SnR_2(SAT)]$ (**3**).[3] Depending on the balance of steric and electronic effects the aminothiol may be mono- or bidentate, chelating or bridging, and the tin may increase its coordination number with electronegative substituents, but not if the ligands are too bulky. Information on solid-state structures is available from X-ray crystallography, vibrational spectroscopy, and Mössbauer quadrupole splittings.[2,11] In solution, however, the structures may differ, they may depend

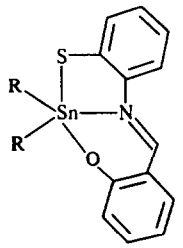
on the solvent, and there may be fluxionality. We have used the ^{119}Sn shift and one-bond coupling to carbon as evidence for the tin coordination number,[12] and the nitrogen coordination shift for the nitrogen ligation.[13] The tin shielding increases markedly with increase in coordination number,[14–17] from $\delta = 50$–100 ppm for trialkyltin thiolates with four-coordinate tin[18] to -204 ppm for $[SnMe_2Cl(S_2CNEt_2)]$ with five-coordinate tin and to -336 ppm for $[SnMe_2(S_2CNEt_2)_2]$ with six-coordinate tin.[16] There is a similar marked increase in $^1J(^{119}Sn$–$^{13}C)$: in trialkyltin compounds, from 330–390 Hz for four-coordinate to 450–480 Hz for five-coordinate tin, and in dialkyltin compounds, from 370–480 Hz for four-coordinate to 900–970 Hz for six-coordinate tin.[19] The absolute $J(^{119}Sn$–$^{13}C)$ values in alkyltin groups usually decrease as $^1J > {}^3J > {}^2J > {}^4J$.[12] Little nitrogen NMR work has been reported for nitrogen attached to tin: some ^{15}N shifts and $^1J(^{119}Sn$–$^{15}N)$ values for stannatranes[20] and $SnMe_3$ derivatives of aniline,[21] and ^{14}N shifts in trimethylstannylamines.[22]



RESULTS AND DISCUSSION

The organotin cysteamine complexes are thermally stable but slowly oxidize in air to give organic sulphides, signalled by extra ^{13}C peaks.

Triorganotin(IV) cysteamine complexes

As shown in Table 2, the ^{119}Sn shifts do not vary greatly with concentration, and fall in the range 70–90 ppm as for trialkyltin thiolates,[17,18] in which tin is four-coordinate. Similarly the $^1J(^{119}Sn–^{13}C)$ values resemble those for four-coordinate compounds such as $[SnMe_3Cl]$ (386 Hz) and $[SnBu_3Br]$ (330 Hz), decreasing slightly with increase in alkyl-chain length.[19] Four-coordination of tin is supported also by the small differences ($\Delta\delta$) in ^{15}N shift from the free to the coordinated ligand, measured in saturated solutions (cf. Table 5). These differences, however, are all in the direction of deshielding, consistent with very weak coordination to tin (although hydrogen bonding was suggested[23] for the aminostannanes $[SnMe_{4-n}(NR_2)_n]$, with R = Me or Et). The neat liquids are not particularly viscous, but show increases in tin shielding and in $^1J(^{119}Sn–^{13}C)$ which suggest some associative process. The increase in shielding is largest (32 ppm) for the least hindered compound, $[SnMe_3(SCH_2CH_2NH_2)]$; it is 15 ppm for $[SnMe_3(SCH_2CH_2NMe_2)]$, in which the nitrogen is less basic and more hindered, the butyltin compounds showing smaller increases. For comparison, the addition of excess pyridine to $[SnMe_3Cl]$ (these forming a trigonal bipyramidal adduct in the solid state) increases the tin shielding[24] by 170 ppm and $^1J(^{119}Sn–^{13}C)$ by 100 Hz.[19] Thus weak and exchanging coordination of nitrogen to tin is likely for these cysteamine complexes as neat liquids.

The phenyltin compounds, also, are seen to be four-coordinate in Table 2. Tin shifts and coupling constants are normally higher with phenyl compared to alkyl substituents:[15,25] e.g. $\delta(Sn)$ −40 to −120 ppm and $^1J(^{119}Sn–^{13}C)$ 550–660 Hz for four-coordinate tin, cf. −180 to −250 ppm and 750–850 Hz for five-coordinate tin (or 600–650 Hz, depending on the coordination geometry).[15] The ^{119}Sn parameters resemble those for thiolates, e.g. −62 ppm for $[SnPh_3SPr^i]$[25] and 566 Hz for $[SnPh_3SPr^n]$.[15] The increaase in tin shielding in thf solvent probably reflects some thf coordination, and the nitrogen deshielding (by 4 ppm) is likely to arise from hydrogen bonding to thf.

Diorganochlorotin(IV) cysteamine complexes

The presence of the electronegative chloro substituent is expected to favour five-coordinate tin for the compounds in Table 3. A chelate structure in the solid state has been demonstrated for **1**,[3] as for **2**.[9,10] An amino-bridged polymeric structure, however, is likely for $[SnMe_2Cl(SCH_2CH_2NH_2)]$ on the Mössbauer and IR evidence.[5] We could not dissolve this or the analogous diethyltin compound in non-coordinating solvents, including chloroform or benzene. They are sparingly soluble in methanol, but fairly soluble in dmf and dmso. With longer alkyl chains, however (R = Bu^n or Oct^n) the compounds are soluble in chloroform and benzene, and our experiments showed them to be monomeric in freezing benzene.

The tin shifts and coupling constants of all the $(SCH_2CH_2NH_2)$ compounds in Table 3 are consistent with five-coordination and chelation. A tin shift of −92 ppm is observed[14] for the chelate complex of 8-quinolinol, $[SnMe_2Cl(8\text{-quin})]$, in which tin forms part of a five-membered ring. Four-coordinate tin is deshielded by *ca* 60 ppm in a five-membered stanna-alkane or stanna-thioalkane ring as in $[SnMe_2(CH_2)_4]$ or $[SnMe_2(SCH_2CH_2S)]$, relative to open-chain analogues such as $[SnMe_2(SEt)_2]$;[26] but effects of angular distortion should be smaller in trigonal bipyramidal geometry, since the relevant (equatorial–axial) angle is already reduced from the tetrahedral angle. There is some additivity of substituent effects (for four-coordinate tin), e.g. the tin shifts for Me_2Sn bound to nitrogen

[a] Relative to external $SnMe_4$, high-frequency positive.
[b] Line-width at half height.
[c] Observed in ^{13}C spectrum.
[d] Shift (high-frequency positive) relative to the appropriate free ligand $HSCH_2CH_2NR_2$ (R = H, Me or Et), measured in the solvent recorded, usually in saturated solution. Only one ^{15}N resonance was observed in each case (cf. Table 5).

and sulphur in six-membered ring compounds $[Me_2SnZ]_3$, where Z is NEt or S, are intermediate between those in $[Me_2SnS]_3$ (128 ppm) and $[Me_2SnNEt]_3$ (76 ppm).[16]

The nitrogen coordination shifts of 10–13 ppm are as expected for bonding to tin: nitrogen in amines is commonly deshielded by a few ppm on replacement of Me by $SnMe_3$,[20–22] a similarly small deshielding being observed on quaternization by H or R[27] (cf. also Table 5). The $^1J(^{15}NH)$ coupling constant of 54 Hz observed for the dibutyltin compound clearly shows coordination to tin: it is larger than any two- or three-bond ^{15}NH coupling constant, but smaller than those observed for free amines (*ca* 65 Hz) or alkylammonium (*ca* 75 Hz). The reduced ^1J value is consistent with reduction in *s*-character of the NH bonding orbitals and in the effective nuclear charge of the nitrogen when bonded to an electropositive atom; cf. $^1J(^{15}NH) = 66$ Hz in $[(Me_3Si)_2NH]$,[28] also the increase in $^1J(SnC)$ with a chloro substituent on tin.[19] The failure to resolve fine structure for the homologous compounds is most likely due to exchange. This is found to be twice as fast for NH_2 as for NH groups in phenylhydrazines, for which a dimeric transition state with a four-membered N_2H_2 ring was proposed.[29] Interactions with a polar solvent, also, may wash out fine structure.

For the $[SnR_2Cl(SCH_2CH_2NH_2)]$ complexes, therefore, the NMR parameters show nitrogen coordinating to tin, and their insensitivity to concentration in non-coordinating solvents, and the evidence for monomolecularity, suggest a chelate structure (**3**), as found for **1** in the solid.[3] This has a distorted trigonal bipyramidal configuration with the more electronegative ligating atoms in the apical positions, as generally found for $[SnR_3X_2]$ compounds, following Bent's rule.[1] The $[SnR_2Cl(SCH_2CH_2NH_2)]$ compounds with R = Me or Et are then polymeric in the solid and monomeric in solution, the tin shifts and coupling constants indicating further coordination to tin in dmf solution.

The complexes in which the amino group is dialkylated clearly differ. With *N,N*-diethylation of

[a–d] As for Table 2.
[e] Triplet, $^1J(^{15}NH) = 54$ Hz.
[f] Reference 4.

$[SnBu^n_2Cl(SCH_2CH_2NH_2)]$, tin is deshielded by 44 ppm, the nitrogen coordination shift vanishes, and $^1J(^{119}Sn-^{13}C)$ is reduced from 555 to 404 Hz, as appropriate for four-coordinate tin. The carbon bonded to tin also reflects a change in the coordination sphere (Table 6): the shielding increases by 2.7 ppm, whereas dialkylation of nitrogen has little effect on the α-carbon shielding in four-coordinate $[SnR_3(SCH_2CH_2NH_2)]$ compounds. Comparable results are obtained with *N,N*-diethylation of $[SnMe_2Cl(SCH_2CH_2NH_2)]$, but interestingly, the NMe_2 compound shows evidence of some *N*-ligation. The presence of the alkyl groups would be expected to reduce the basicity of the amino group, and sterically hinder the coordination, as before. Again, the shifts are insensitive to dilution in non-coordinating solvents, so intermolecular interactions are unimportant. The broadening of the tin resonance in the dibutyltin complex suggests some fluxional process.

Diorganotin(IV) bis-cysteamine complexes

The *bis*-cysteamine complexes differ from both categories of *mono*-cysteamine complexes. Only one tin resonance is observed, but the shielding decreases with dilution, by up to 70 ppm from the neat liquid to 0.05 M solution (Table 4). The neat liquids are very viscous. In freezing benzene, 0.06 M $[SnBu^n_2(SCH_2CH_2NH_2)_2]$ shows evidence of intermolecular association, which increases with concentration, whereas the corresponding *N,N*-diethyl compound is monomeric at 0.08 M. Similarly, at higher concentrations of the ($SCH_2CH_2NH_2$) compounds the tin shifts and tin–carbon coupling constants are appropriate for five-

coordination, but with dialkylation of the amino group the ^{119}Sn shift shows the dibutyltin compound to be four-coordinate in the neat liquid and in 0.1 M solution in chloroform.

Again, the singularity of the ^{119}Sn, ^{13}C and ^{15}N spectral lines can be explained by sufficiently fast exchange, as can the variation in ^{119}Sn and ^{15}N shifts with concentration. There is some trend towards broader lines at higher concentrations. The ^{15}N shifts fall midway between the values for coordinated and uncoordinated nitrogen (cf. Tables 3 and 5). The presence of a dynamic equilibrium is supported also by the increase in tin shielding by 15 ppm when a concentrated solution of the diethyltin complex is cooled to 230 K.

As shown in Table 4, $[SnEt_2(SCH_2CH_2NH_2)_2]$ forms an adduct in solution in $(Me_2N)_3PO$ in which the tin shielding ($\delta - 78$ ppm) is comparable with that in the self-associated systems. The increase of 201 ppm in the shielding relative to the four-coordinate NEt_2 complex with $\delta = 123$ ppm, resembles the increase of 207 ppm when $[SnMe_3Cl]$ is dissolved in $(Me_2N)_3PO$.[12]

EXPERIMENTAL

Organotin chlorides, cysteamine hydrochloride, *N*-dimethyl- and *N*-diethylcysteamine hydrochlorides, L-cysteine ethyl ester hydrochloride and *S*-methylcysteamine were commercial samples. All solvents were dried by standard methods and moisture was excluded throughout the manipulations. Free ligands were obtained by the reaction of ligand hydrochlorides with sodium methoxide in dry methanol under nitrogen. After filtration of sodium chloride, the ligands were purified by subli-

were prepared by reported methods. Microanalyses were done at the Open University and at Butterworth laboratories.

Synthesis of complexes

Complexes **1**–**3** in Table 1, **15** and **16** were prepared by the reaction in methanol of organotin(IV) chlorides with equimolar amounts of the sodium salt of the ligand prepared *in situ*. After the filtration of the sodium chloride the complexes crystallized out on standing overnight, in 60–80% yield. $[SnMe_2Cl(SCH_2CH_2NH_2)]$[4,5] also was prepared by this method. Complexes **4**–**6** were prepared similarly with Pr^iOH as solvent. After the filtration of sodium

chloride the complexes were isolated by evaporation of the filtrate under reduced pressure. Complexes **7–14** are somewhat air-sensitive, and were synthesized by the reaction of organotin(IV) chlorides with the sodium salt of the ligand in stoichiometric ratio under a nitrogen atmosphere in a mixture of methanol and benzene as solvent. After filtration of sodium chloride the excess solvent was removed under reduced pressure. Complexes **8–10** were further purified by distillation under reduced pressure. Complexes **7** and **11** decompose on distillation and so were used undistilled for spectral measurements. Complex $[SnMe_3(SCH_2CH_2NMe_2)]$[31] also was prepared by this method and purified by distillation under reduced pressure.

Molar masses were determined (as appropriate) by depression of the melting temperature of benzene.

NMR spectroscopy

Non-coordinating solvents were used unless a coordinating solvent was necessary for solubility. ^{119}Sn and ^{13}C spectra were measured on a JEOL FX90Q spectrometer at 27°C in 10-mm sample tubes. The ^{119}Sn–^{13}C coupling constants were obtained from satellites in the carbon spectra in about 250 pulses for neat liquids, or up to 6000 pulses for concentrated solutions. ^{117}Sn–^{13}C couplings were observed at the same time in the expected ratios. ^{15}N spectra were measured in natural abundance on 15-cm^3 samples on a Bruker WH180 spectrometer, in 25-mm sample tubes.

CONCLUSION

The sensitive balance of electronic and steric factors involved in the coordination of 1,2-aminothiol ligands to organotin(IV) is demonstrated by the differences between the three series of complexes reported here, between the primary and tertiary amino groups, and, interestingly, between complexes of the same type but with different alkyl-chain lengths. Although the nitrogen coordination shifts are not very large they are characteristic of the coordination mode; there is a periodic dependence of nitrogen shielding on the nature of the ligating atom, such that larger shifts are observed with other metals.[13] Nitrogen NMR spectroscopy is therefore a useful indicator of ligation, particularly with metals less amenable than tin to NMR spectroscopy, and if coupling to nitrogen can be observed.

Acknowledgements—We thank Dr P. J. Smith of the International Tin Research Institute for gifts of organotin chlorides, Dr Fred Armitage for a recipe for $[SnMe_3Cl]$, the S.E.R.C. for the provision of widebore 180-MHz facilities for natural-abundance ^{15}N NMR, Mr Maurice Cooper for running the ^{15}N spectra, and Mr Gordon Howell for ^{119}Sn and ^{13}C spectra run at the Open University.

CATIONIC COMPLEXES OF TRIMETHYLPLATINUM(IV) WITH TRIDENTATE LIGANDS—I. PREPARATION AND CHARACTERIZATION OF COMPLEXES FROM A RANGE OF THIO, SELENO, THIO-SELENO, AMINO-THIO AND AMINO-SELENO LIGANDS

EDWARD W. ABEL, KENNETH KITE* and PHILLIP S. PERKINS

Department of Chemistry, University of Exeter, Exeter EX4 4QD, U.K.

(*Received* 6 *December* 1985; *accepted* 20 *December* 1985)

Abstract—The new ionic complexes $[PtMe_3\{MeE(CH_2)_nE'(CH_2)_nEMe\}]^+X^-$ [$n = 3$; E = E′ = S: $n = 2$; E = Se or S; E′ = O, S, Se or —SS—: X = I, BPh_4 or BF_4] and $[PtMe_3(H_2NCH_2CH_2)_2E']^+BF_4^-$ [E′ = O or —SS—] have been prepared and characterized by molar-conductivity measurements and ^1H NMR spectroscopy. The hitherto unreported ligands $[(MeE(CH_2)_n)_2E']$ ($n = 3$; E = E′ = S: $n = 2$; E = Se; E′ = O or S or Se: $n = 2$; E = S; E′ = Se] have been characterized by ^1H NMR and ^{77}Se NMR (where appropriate), and by mass spectroscopy.

Extensive studies in this department on the fluxional properties of complexes of trimethylplatinum(IV) with bidentate chalcogen donors[1] have been exclusively concerned with neutral systems in which a halide counter ion has been coordinated to the metal. The extension to tridentate chalcogen donor ligands is appealing for a number of reasons. The comparatively few reported complexes of *fac*-$PtMe_3$(IV) in which one ligand occupies all three *trans* sites are limited to nitrogen and oxygen donors, i.e. with pyrazolylborates[2] $\{[(C_3H_3N_2)_nBH_{4-n}]^-\}$ ($n = 3$ or 4), with tris(1-pyrazolyl)methane and tris(2-pyridyl)methane,[3] and with imidodiacetate, its *N*-methyl analogue, and nitrilotriacetate.[4] Complexes with two tridentate Schiff base ligands containing one SMe and two nitrogen donor groups have been shown to lead to interesting stereochemistry at the metal.[5] The steric requirement that the methyl groups have a *fac*-orientation,[6] and therefore a *fac*-disposition of *trans* ligands might be expected to impose constraints on the fluxionality which are not observed in the bidentate system. We have explored these possibilities using ligands of general formula $MeE(CH_2)_nE'(CH_2)_nEMe$, where E and E′ are chalcogen donor atoms, with three potential inverting centres, and for comparative purposes the ligands $(H_2NCH_2CH_2)_2E'$, where E′ = O or —SS—, having only one such centre. In this paper we report the preparation and characterization of the ligands and their $PtMe_3$(IV) complexes with appropriate counter ions.

EXPERIMENTAL

The following were made by literature methods: trimethylplatinum iodide[7] and sulphate,[8] dimethyldiselenide,[9] 2-chloro-1-methylthioethane,[10] β,β′-dichloroethylsulphide[11] and β-methylthioethylmercaptan.[12] 3-Chloro-1-methylthiopropane was prepared in 70% yield (b.p. 163–165°C) in an analogous manner to 2-chloro-1-methylthioethane but using 3-hydroxy-1-methylthiopropane in place of 2-hydroxy-1-methylthioethane. β,β′-Dichloroethyloxide [b.p. 66–70°C (15 mmHg)] and β,β′-dichloroethylselenide [b.p. 95–97°C (15 mmHg)] were made in 47 and 45% yield in a similar manner to β,β′-dichloroethylsulphide, using the oxygen and selenium analogues of β-thiodiglycol, respectively, and HCl in place of $SOCl_2$ in the selenide preparation. The characterization of these precursors is summarized in Table 1. The ligands 2,5,8-trithianonane {b.p. 113°C (0.5 mmHg) [lit.[13] 118°C (1.0 mmHg)]} and 2,5,6,9-tetrathiadecane {b.p. 117°C (0.02 mmHg)

[lit.[14] 160–162°C (<0.5 mmHg)]} were made by literature methods. 2,6,10-Trithiaundecane [b.p. 111°C (0.02 mmHg)] and 2,8-dithia-5-selenononane [b.p. 82°C (0.005 mmHg)] were prepared in 35 and 70% yield, respectively, in a similar manner to 2,5,8-trithianonane,[13] but using 3-chloro-1-methylthiopropane instead of 2-chloro-1-methylthioethane for the formed ligand, and sodium selenide in place of sodium sulphide for the latter.

2,8-*Diseleno-5-oxynonane.* To approximately 300 cm^3 of freshly distilled, anhydrous liquid ammonia was added dimethyldiselenide (4.56 g, 48.5 mmol) followed by sodium metal (2.27 g, 98.7 mmol), and the mixture stirred under reflux until a permanent blue tinge was observed. To this mixture was added β,β'-dichloroethyloxide (6.45 g, 45.1 mmol) over 20 min, and stirring was continued with slow ammonia evaporation until a slurry remained. Water and chloroform (100 cm^3 of each) were added, and the organic layer was removed and dried over magnesium sulphate. Removal of the solvent followed by vacuum distillation gave a malodorous pale yellow oil [b.p. 45–49°C (0.03 mmHg)] (4.7 g, 63%).

The following were prepared similarly with the modifications noted: 2,8-diseleno-5-thianonane [b.p. 112°C (0.175 mmHg), 93%] using β,β'-dichloroethylsulphide for β,β'-dichloroethyloxide; 2,5,8-triselenononane [b.p. 91°C (0.017 mmHg), 43%] using β,β'-dichloroethylselenide for β,β'-dichloroethyloxide; and 2,8-dithia-5-oxynonane [b.p. 45–49°C (0.03 mmHg), 63%] [lit.[15] 97°C (4 mmHg)] using dimethyldisulphide instead of dimethyldiselenide.

2,2′-*Oxybis(ethylamine) and cystamine.* These ligands were obtained as their dihydrochloride salts from Aldrich Chemical Co. Ltd, the free amine being recovered by bubbling dry ammonia gas through a suspension of the salt in chloroform, maintaining anhydrous conditions throughout. Subsequent filtration and removal of solvent gave the product. The amines gave molecular ions at m/z 105 and 152, respectively.

The same general method was used for the preparation of each of the iodide salts, the following being typical.

[(2,5,8-*Trithianonane*)*trimethylplatinum*(IV) *iodide*]. A solution of trimethylplatinum(IV) iodide (500 mg, 1.36 mmol*) and 2,5,8-trithianonane (250 mg, 1.37 mmol) in chloroform (27 cm^3) was refluxed overnight. Concentration to *ca* 5 cm^3 and addition of light petroleum (40–60°C) precipitated a pale yellow solid. Recrystallization from dichloromethane–light petroleum gave the pure product (190 mg, 25%).

The tetrafluoroborate salts were prepared by the following general method.

[(2,8 - *Dithia* - 5 - *oxynonane*)*trimethylplatinum*(IV) *tetrafluoroborate*]. To a solution of trimethylplatinum(IV) sulphate tetrahydrate (170 mg,

* Based on the molar unit $PtMe_3I$.

0.262 mmol) in acetone (10 cm^3) was added 2,8-dithia-5-oxynonane (90 mg, 0.54 mmol), producing a dense white precipitate. A solution of sodium tetrafluoroborate (80 mg, 0.73 mmol) in water (4 cm^3) was added, and the mixture refluxed for 8 h, then concentrated to *ca* 7 cm^3. Addition of water (10 cm^3) and dichloromethane (10 cm^3) gave a two-phase system. The lower organic layer was removed and dried over magnesium sulphate. Removal of the solvent gave a white solid, which was recrystallized from dichloromethane–carbon tetrachloride to give the pure product (110 mg, 42%). For the nitrogen-containing ligands, methanol replaced acetone, and the products were recrystallized from chloroform.

The tetraphenylborate salts were made by an analogous method, using sodium tetraphenylborate for sodium tetrafluoroborate. The crystalline salts were sparingly soluble in chlorocarbons and acetone, but dissolved readily in dimethylsulphoxide and dimethylformamide.

100-MHz ^1H NMR spectra were obtained using either a JEOL MH-100 spectrometer operating in the continuous-wave mode under internal field-frequency lock conditions, or a JEOL PS/PFT-100 spectrometer operating in the Fourier transform mode. The latter instrument was also used to obtain the ^{77}Se NMR spectra at 19 MHz. A JES-VT-3 variable-temperature unit was used to control the probe temperature.

Mass spectra were obtained on a single-focusing VG-Micromass MM-30 spectrometer interfaced with a Pye 104 gas chromatograph. Electron ionization was employed using potentials of 70 and 18 eV with probe temperature of 200 or 145°C. Chemical ionization was used to observe molecular ions for the amine ligands.

Conductivity measurements were made on approximately 1×10^{-3} M solutions in acetone using a Doran conductivity bridge.

RESULTS AND DISCUSSION

The ligands $[MeE(CH_2)_n]_2E'$ ($n = 3$, E = E′ = S; $n = 2$, E = S, E′ = O, S, —SS— or Se; $n = 2$, E = Se, E′ = O, S or Se), and $[(H_2NCH_2CH_2)_2E']$ (E′ = O or —SS—) are malodorous viscous oils with high boiling points. They were characterized by mass spectroscopy, and by ^1H NMR and ^{77}Se NMR spectra (Table 2). Characteristic resonances for the SMe and SeMe protons were seen at *ca* 2.15 and *ca* 2.03 ppm, respectively, the latter showing coupling to ^{77}Se ($^2J = 11$ Hz, intensity 7%). The ^{77}Se NMR data showed that Se nuclei in CH_2SeCH_3 groups ($\delta = 60$–129 ppm) invariably resonate at lower frequencies than in $—CH_2SeCH_2—$ groups ($\delta = 211$–253 ppm). The $—CH_2—$ protons in both S and Se mixed ligands give non-first-order multiplets, showing that these chemically different groups exhibit magnetic equivalence at 100 MHz. The mass spectra showed excellent correlation between theoretical and observed fragments. An ionization potential of 18 eV was necessary to observe the molecular ion of the disulphide ligands, as a potential of 70 eV gave spectra whose most intense signals corresponded to fragments resulting from the cleavage of the disulphide bond. Electron ionization on the amine ligands produced typical primary amine fragments, but chemical ionization was needed to observe the molecular ion of $(H_2NCH_2CH_2)_2O$.

The $PtMe_3$(IV) complexes (Table 3) were made initially as iodide salts by refluxing $[PtMe_3I]_4$ with the ligands in chloroform. These salts readily dissolve in spectroscopic solvents, but dissociate in solution on heating to give covalent species with coordinated iodide. The BPh_4^- salts made from $[(PtMe_3)_2SO_4 \cdot 4H_2O]$ showed no tendency to dissociate in solution, but had limited solubility. Changing the counter ion to BF_4^- gave complexes which had good solubility and high temperature stability. This type of non-coordinating anion was also necessary to observe oxygen coordination with the O-containing ligands. Ether-type oxygen does not usually bond to transition metals unless it is part of a chelate ligand.[16–18] Attempts to make tridentate O-coordinated complexes were not successful with I^- or SO_4^{2-} as counter ions, the ligand coordinating in a bidentate manner with non-bonded oxygen. However, when the anion-bound complexes were refluxed with $NaBF_4$, oxygen replaced the anion to give the ionic tridentate complexes. All the compounds are pale yellow or white crystalline solids with sharp melting points. Molar-conductivity measurements in acetone gave values lying within the range for typical 1:1 electrolytes (92–199 Ω^{-1} cm^2 mol^{-1}),[19] and elemental analyses are also consistent with the ionic formulation in Fig. 1.

Structural confirmation was provided by ^1H

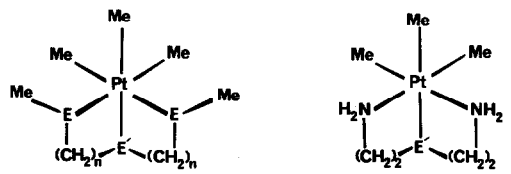

Fig. 1. Structures of the cationic complexes $[PtMe_3\{MeE(CH_2)_nE'(CH_2)_nEMe\}]^+$ [$n = 3$; E = E′ = S; $n = 2$; E = S or Se, E′ = O, S or Se: $n = 2$; E = S, E′ = —SS—] and $[PtMe_3(H_2NCH_2CH_2)_2E']^+$ [E′ = O or —SS—].

[c] Coupled to ^{77}Se.
[d] Melting point of dihydrochloride salt.

NMR spectra at temperatures where chalcogen–methyl inversion is fast (for **I–IV** and **VI–VIII**) (Table 4). For compound **V** the central O atom dissociates before Se inversion is fast, and the spectrum at low temperatures is complicated by the presence of four configurational isomers. The spectra of the complexes in Table 4 consist of three regions associated with the —CH_2— protons (δ = 3.0–4.2 ppm), the E–Me protons (δ = 2.3–2.5 ppm) and the Pt–Me protons (δ = 0.8–1.3 ppm). The methylene protons give non-first-order multiplets. Chalcogen–methyl signals show the typical three-bond coupling to ^{195}Pt ($^3J \sim 14$ Hz) and are easily identified. Se–Me signals are also coupled to ^{77}Se ($^2J \sim 8.0$ Hz).

[b] Numbering as in Table 3.

[c] Signals for the NH_2 protons.

The Pt–Me signals at highest field are most diagnostically useful, as the $^2J(^{195}Pt–^1H)$ values are highly sensitive to the *trans* ligand.[6] In all but the disulphide complexes a mirror plane relates two of the Pt–Me groups, as the chelate rings will be in an averaged planar conformation,[20] so that two signals (ratio 2 : 1) are seen. The ^2J values for Me *trans* to S and Se are in the same narrow range (65.9–67.3 Hz), as was found for the complexes with the bidentate ligands $[PtMe_3(MeE(CH_2)_nEMe)X]$ (E = S or Se, n = 2 or 3, X = halide). Where direct comparison is possible (compounds **I**, **IIIa** and **VII**) the values are significantly lower for the tridentate ligands, indicating stronger Pt–chalcogen bonding.[21] Comparison of **I** with **IIIa** also shows that ^2J is slightly lower for the six-membered ring complexes, just as was found for the bidentate compounds. There is practically no difference between the ^2J values for Pt–Me groups *trans* to the same chalcogen when that atom is terminal compared to when it is in the middle of the chain.

When oxygen is the *trans* atom (**II** and **IX**), the expected[22,23] much higher ^2J values for the Pt–Me signals (81.6 and 83.4 Hz) demonstrate the inherent weakness of the Pt–O bond evident in its ready displacement by coordinating anions (see above). When a disulphide S atom is the donor (**VIII** and **X**), ^2J values of 68.8 and 67.9 Hz show the somewhat weaker Pt–S bonds compared to Pt–S(thioether), though they are stronger than those found in the dinuclear complexes $[(PtMe_3X)_2MeSSMe]$[6] for which ^2J is 71.6–73.8 Hz. No evidence for a 1,2-shift was found in the spectra of the disulphide complexes (E′ = —SS—). This would necessarily introduce a plane of symmetry, and in both **VIII** and **X** all three Pt–Me groups are distinct, as are the two S–Me groups in **VIII** and the NH_2 groups in **X**. Separate five- and six-membered rings are clearly present. Coupling constants for Pt–Me *trans* to sp^3-hybridized nitrogen are in the expected range[23] {e.g. 69.8 Hz in $[PtMe_3(H_2NCH_2CH_2)_2NH]^+$}.[5]

A full DNMR study of the complexes shows the presence of configurational isomers at temperatures where inversion at the chalcogen atoms is slow, and their fluxional behaviour will be discussed in detail elsewhere.

POLAROGRAPHIC REDUCTION OF AQUEOUS SULFUR DIOXIDE

W. L. REYNOLDS* and YU YUAN

Chemistry Department, University of Minnesota, Minneapolis, MN 55455, U.S.A.

(*Received* 23 *September* 1985; *accepted* 7 *January* 1986)

Abstract—Direct- and alternating-current polarograms of aqueous $SO_2 \cdot OH_2$ solutions show four reduction waves, more than previously reported. Waves I and II probably result from the electroreduction of $SO_2 \cdot OH_2$ and HSO_3^-, respectively; these two waves completely overlap at pH 1 but are partially resolved at higher pH values due to different pH dependence. Reduction of $SO_2 \cdot OH_2$ involves two electrons and two H^+ ions and the initial product is probably sulfoxylic acid, H_2SO_2. This product can disproportionate to S^0 and $SO_2 \cdot OH_2$ in very acidic media (pH $\leqslant$ 1) and, in the limit, double the reduction current of $SO_2 \cdot OH_2$. Reduction of HSO_3^- appears to occur via two paths: one is a two-electron three-H^+ ion path and the other is a one-electron one-H^+ ion path. The former dominates at pH $\leqslant$ 3 and probably produces H_2SO_2; the latter dominates at pH > 4 and may produce SO_2^-. H_2SO_2 in less acidic media can react with HSO_3^- to yield dithionite species (such as $H_2S_2O_4$, $HS_2O_4^-$ and $S_2O_4^{2-}$) and HSO_2 and SO_2^- by dissociation of the dithionite species. Waves III and IV are believed to result from reduction of HSO_2 and SO_2^-, respectively, to H_2SO_2 species.

Several investigations on the reduction of sulfur dioxide, $SO_2 \cdot OH_2$, in aqueous solution at a mercury electrode have reported two waves in acidic media and no waves in neutral or slightly alkaline media. There has been much disagreement in the interpretation of these results. Gosman[1] postulated that in acidic media only undissociated sulfurous acid, i.e. $SO_2 \cdot OH_2$, is reduced, that it is reduced by a one-electron reduction to the S(III) state with subsequent dimerization to $H_2S_2O_4$, that in neutral or alkaline solutions $S_2O_4^{2-}$ disproportionates to SO_2^{2-} and SO_2 and that the SO_2 so produced is reduced by a two-electron reduction directly to SO_2^{2-} in the second wave. This explanation for the second wave is incorrect for the following reason: the pH controls the disproportionation of 2S(III) to S(II) and SO_2, and at the pH values where the disproportionation occurs the limiting current due to S(IV) → S(III) reduction in the first wave will be increased (doubled in the limit) by a kinetic current contribution from the disproportionation. At the limit all SO_2 reaching the electrode is effectively reduced to S(II) at potentials more positive than the potential where the second wave is observed. Consequently when the potential of the second wave is reached and direct reduction of SO_2 to S(II) can occur there will be little change in the current due to SO_2 → S(II) reduction. Experimentally there is no evidence of the limiting current in the first wave increasing with increasing pH as the disproportionation increasingly produces more SO_2.

Kolthoff and Miller[2] found that the first wave in 0.1 M HNO_3 was a two-electron reduction and postulated reaction (1) as the electrode reduction:

$$SO_2 + 2H^+ + 2e^- \rightarrow H_2SO_2. \qquad (1)$$

They also postulated that, of the two waves seen at pH 6, the first was due to reduction of HSO_3^- to HSO_2 and the second to reduction of $S_2O_4^{2-}$ (from dimerization and ionization of HSO_2) to thiosulfate, $S_2O_3^{2-}$.

Čermak[3] postulated that the first wave was a one-electron reduction of SO_2 to HSO_2 followed by a rapid disproportionation of $2HSO_2 \rightarrow SO_2 + H_2SO_2$ to make it appear that the first wave was a two-electron reduction of SO_2 to H_2SO_2 and that the second wave was a direct two-electron reduction of SO_2 to H_2SO_2. The objection to this explanation

* Author to whom correspondence should be addressed.

of the waves follows much the same lines as the objection to Gosman's explanation: if the disproportionation of the S(III) electroreduction product to H_2SO_2 and SO_2 is so rapid as to make the first wave appear to be a two-electron reduction then there will be little or no current increase when the potential for the direct two-electron reduction is reached.

Jacobsen and Sawyer[4] postulated that the first wave was a two-electron reduction as given in reaction (1) and that the second wave was due to adsorption of a reduction product of SO_2 with partial inhibition of SO_2 reduction.

Here we report the detection of four polarographic reduction waves and their interpretation.

EXPERIMENTAL

Chemicals

Reagent-grade sodium metabisulfite, $Na_2S_2O_5$, was used as a source of SO_2 and HSO_3^- and was obtained from Matheson, Coleman & Bell. It was analysed using an excess of standard iodine solution which was back-titrated with standard sodium thiosulfate solution; it was found to be $99.7 \pm 0.66\%$ pure in seven analyses. All other acids and salts used as supporting electrolytes, buffer components or to establish ionic strength were reagent-grade and were used without further purification. The de-ionized water used in preparing solutions gave typical residual currents.

Apparatus

A Princeton Applied Research Model 170 Electrochemistry System was used to record current–voltage data. An IBM Instruments Inc. electrolysis cell with a saturated calomel electrode (SCE) as the reference electrode, a dropping mercury electrode (dme) as the indicator electrode and a Pt wire as the third electrode were used. All solutions in this cell were de-aerated by passage of N_2 gas prior to the addition of a known quantity of sulfite by microsyringe through a port sealed with a self-sealing rubber septum. The rate of N_2 gas flow over the solution after sulfite addition was reduced to minimize SO_2 loss but yet maintain a positive N_2 gas pressure inside the cell. The loss of SO_2 from the cell during the recording of any one polarogram was not sufficient to invalidate the results but was detectable in very acidic solutions over a half-hour period. Consequently measurements of limiting currents at a series of sulfite concentrations or mercury column heights were performed in times much less than half an hour or a series of freshly prepared solutions was used. All currents used in calculations were corrected for residual current.

At a mercury column height of 70.0 cm the mercury flow rate was 2.650 mg s^{-1} with the capillary tip on the mercury pool surface, the drop time was 3.84_6 s at -0.50 V vs (SCE), and the drop surface area was 0.0400 cm^2 at the maximum drop size.

Maximum suppressors were not used and maxima did not occur. Sodium dodecylsulfate, a surfactant, was added only to test the effect, if any, on polarographic waves suspected of being due to adsorption effects.

RESULTS AND DISCUSSION

Direct-current (dc) polarography

$pH < 1.3$. At H^+ concentrations in the range 0.10–4.0 M HCl at a constant ionic strength of 4.0 M or at variable ionic strength in the range 1.0–4.0 M, there was only one reversible two-electron reduction wave, hereafter referred to as wave I. The customary plots of $\log [i/(i_l - i)]$ vs $-E$ gave slopes of approximately $+33.8$ V^{-1}, i.e. the inverse of 0.05915/2, where i and i_l are the maximum current at voltage E and the maximum limiting current, respectively, corrected for the residual current.

In a 0.10 M HCl + 3.90 M KCl medium the value of I_{max}, the diffusion current constant at maximum current, for SO_2 was 7.14 ± 0.09. Although the slope of the $\log [i/(i_l - i)]$ vs E plot was independent of pH in the pH range under discussion, the height of the SO_2 reduction wave was dependent on the pH. The height of the wave rapidly increased with increasing H^+ concentration at constant ionic strength and reached a limiting value in 4.0 M HCl of approximately twice its height in 0.10 M HCl. Hence it is likely that electrode reaction (1) is followed by the overall disproportionation reaction (2):

$$2H_2SO_2 \rightarrow S^0 + SO_2 + 2H_2O, \qquad (2)$$

which is acid-catalysed so that the wave height asymptotically approaches twice the height of wave I in the absence of reaction (2). Thus, at pH < 1.3 the mechanism of SO_2 reduction is EC_{dis} where the electrode reaction is followed by disproportionation of S(II) to S(0) and S(IV). The classic example of this mechanism is the reduction[5] of U(VI) to U(V) at the dme followed by disproportionation of U(V) to U(IV) and U(VI); the limiting current for the $U(VI) + e^- \rightarrow U(V)$ reduction wave is doubled by quantitative disproportionation of U(V).

The value of i_l in 1.0 M HCl increased somewhat more slowly than $h^{1/2}$, the square root of the mer-

cury column height, as expected if reaction (2) was partly limiting the SO_2 supply at this acidity.

Orlemann and Kern[6] have given a quantitative treatment, subject to some assumptions, of the EC_{dis} mechanism and derived equation (3):

$$\frac{1}{(\bar{i}_l-\bar{i}_d)^{1/2}}=\left(\frac{0.2tk}{\bar{K}_R}\right)^{1/2}\left(\frac{\bar{i}_l}{\bar{i}_i-\bar{i}_d}-2\right), \qquad (3)$$

where $\bar{i}_d$ is the diffusion current, averaged over the lifetime of the drop, that would be obtained in the absence of the disproportionation reaction, $\bar{i}_l$ is the limiting current in the presence of the disproportionation averaged over the drop lifetime, t is the drop time, k is a rate constant for the disproportionation reaction and $\bar{K}_R$ is the Ilkovic constant for the product of the electrode reaction (calculated using average diffusion currents). It was assumed in the derivation, and it is assumed here, that the diffusion coefficients of oxidized and reduced species in the electrode reaction are equal so that $\bar{K}_R = \bar{K}_0$. The experimental values of i_l, i_d, t, K_R and HCl concentration are given in Table 1, as are the value of k calculated from eqn (3). The maximum values of i_l, $i_l - i_d$ and K_R for currents at the end of the droplife were converted to average values for use in eqn (3) as explained in the original derivation.[6] When the rate constants in Table 1 were expressed as:

$$\log k_j = \log k_o + n \log [H^+]_j$$

a least-squares treatment of the data gave $n = 2.93 \pm 0.03$ and $k_o = 21.9 \pm 0.5$ (mmol dm^{-3})$^{-4}$ s^{-1}, so that k is approximately given by:

$$k = k_o[H^+]^3 \text{ (mmol dm}^{-3})^{-1}\text{ s}^{-1}.$$

This dependence on the cube of the H^+ concentration accounts for the rapid decrease in the rate of the disproportionation reaction with increasing pH so that at pH > 1.3 reaction (2) contributes negligibly to the electrochemical behavior of SO_2.

The value of I_{max} in 4.00 M HCl was 13.98 ± 0.29. If this number is divided by 2 to give I_{max} for SO_2 reduction in the absence of reaction (2) then one obtains:

$$I_{max} = 6.99 \pm 0.15 = 708nD^{1/2}.$$

Thus D, the diffusion coefficient of SO_2, in this medium is found to be $(2.44 \pm 0.10) \times 10^{-5}$ cm^2 s^{-1}. This value is somewhat larger than the value of 2.04×10^{-5} cm^2 s^{-1} reported by Kolthoff and Miller[2] for 0.10 M HNO_3. Some uncertainties surround the latter value because in 0.10 M H^+ the SO_2 is approximately 12% ionized and because the behavior of the very unstable H_2SO_2 in reducible HNO_3 is unknown. In 4.0 M HCl there is an entirely negligible amount of SO_2 ionized and there is no evidence that Cl^- affects the stoichiometry of reaction (2). The value of the limiting current was not affected by ionic strength changes or by Cl^- ion concentration changes when the KCl concentration was increased from 0.0 to 3.0 M in SO_2 solutions containing 1.00 M HCl.

Table 1. Kinetic data for disproportionation reaction (2)[a]

[HCl] (mol dm^{-3})	i_l (μA)	k [(mmol dm^{-3})$^{-1}$ s^{-1}]
4.00	33.5	—
2.00	31.5	165.3
1.00	28.7	21.9
0.75	26.9	9.73
0.50	23.5	2.80

[a] $t = 3.846$ s, $i_d = 16.7$ μA, $K_R = 16.7$ μA (mmol dm^{-3})$^{-1}$.

In chronopotentiometric studies Jacobsen and Sawyer[4] found that the quantity $i\tau^{1/2}$ increased linearly with τ, the transition time, at pH < 1.5 and that this increase became more pronounced at pH 0. These authors also observed elemental sulfur formation, as did we, in the electrolysis cell in these very acidic solutions. Hence they suggested reaction (2) as an explanation.

1.3 < pH < 3. As noted by previous investigators the SO_2 reduction wave lost its reversible character at pH values somewhat greater than 1.0. The cause of this irreversibility in the reduction does not appear to have been determined. We found that, as the pH increased, the plots of log $[i/(i_l - i)]$ vs $-E$ became S-shaped, that the S-character of the plot increased at first, that the slope of the upper branch of the plot decreased faster than the slope of the lower branch and that at approximately pH 4.5–5.0 the plot became linear again. There were two overlapping waves present, namely waves I and II, both of which shift to more negative potentials as pH increases. The overlapping waves can be analysed by the methods of Ružić and co-workers.[7] The $E_{1/2}$ values for the two waves and the corresponding pH values are given in Table 2. When these $E_{1/2}$ values were plotted against pH it was found that the least-squares straight-line relationships were given by:

$$(E_{1/2})_I = (-0.272 \pm 0.007) - (0.065 \pm 0.003)\text{pH}$$

for wave I and by:

$$(E_{1/2})_{II} = (-0.254 \pm 0.006) - (0.099 \pm 0.002)\text{pH}$$

for wave II. Thus wave I involves two protons in the reduction; this is evidence in support of reaction

Table 2. Half-wave potentials of waves I and II as a function of pH

(1) which has not been forthcoming heretofore. Wave II involves three protons and we propose reaction (4) for this reduction:

$$HSO_3^- + 3H^+ + 2e^- \rightarrow H_2SO_2 + H_2O. \quad (4)$$

The reduction waves for SO_2 and its conjugate base HSO_3^- can be treated in the manner in which the reduction waves for pyruvic acid and its conjugate base, the pyruvate ion, have been treated.[8-10] The pH at which i_{l1}, the limiting current for wave I, is reduced to one-half its value at pH 1.2 (where only wave I is present) is approximately 2.7. This pH value yields[8,9] $k_{h,r}$, the heterogeneous second-order rate constant for recombination of H^+ and HSO_3^-, equal to 792 cm mol dm^{-3} s^{-1}. The homogeneous second-order rate constant, k_r, for the recombination is related to $k_{h,r}$ by the equation:

$$k_r = \frac{K_{a1}}{D} k_{h,r}^2$$

where K_{a1} is the first acid ionization constant of SO_2. The values of 1.4×10^{-2} mol dm^{-3} for K_{a1}^{11} and 2.4×10^{-5} cm^2 s^{-1} for D yield $k_r = 3.7 \times 10^8$ (mol dm^{-3})$^{-1}$ s^{-1}, which is between the values of 2×10^8 (mol dm^{-3})$^{-1}$ s^{-1} reported by Eigen *et al.*[12] from relaxation measurements and 2.5×10^9 (mol dm^{-3})$^{-1}$ s^{-1} reported by Betts and Voss[13] from isotope exchange rate measurements.

$5.8 \leqslant pH \leqslant 7.4$. In this pH range in KH_2PO_4+NaOH and $Na_2B_4O_7$+HCl buffers we observed three waves which we designated waves II, III and IV. Kolthoff and Miller[2] used the former buffer to obtain pH 6.0 but reported only two waves. Wave I due to undissociated $SO_2 \cdot OH_2$ had completely disappeared because the SO_2 content was entirely negligible. Wave II due to HSO_3^-, the major sulfite species, had so decreased in height as to strongly suggest that the electrode reaction was now a one-electron reduction so that reaction (4) no longer represents the HSO_3^- electrode reaction in this pH range. The change in the electroreduction reaction of HSO_3^- is discussed further in the section on alternating-current (ac) polarography. Reaction (2) has become entirely negligible and reactions (5) and (6) are now important for any H_2SO_2 formed by two-electron reduction of HSO_3^-:

$$H_2SO_2 + HSO_3^- \rightarrow HS_2O_4^- + H_2O, \quad (5)$$

$$H_2SO_2 + SO_3^{2-} \rightarrow S_2O_4^{2-} + H_2O. \quad (6)$$

In addition to proton transfer reactions between $S_2O_4^{2-}$, $HS_2O_4^-$ and $H_2S_2O_4$ there exist the dissociations of $H_2S_2O_4$ in reaction (7) and/or $S_2O_4^{2-}$ in reaction (8), and proton transfer between HSO_2 and SO_2^- to be considered:

$$H_2S_2O_4 \rightleftarrows 2HSO_2, \quad (7)$$

$$S_2O_4^{2-} \rightleftarrows 2SO_2^-. \quad (8)$$

The S–S bond length in $S_2O_4^{2-}$ is[14,15] 239 pm and is much longer than the S–S bond length[15] of 221 pm in $S_2O_5^{2-}$ which dissociates completely[16] and rapidly at millimolar concentrations in aqueous solutions according to reaction (9):

$$S_2O_5^{2-} + H_2O \rightleftarrows 2HSO_3^-. \quad (9)$$

The first-order rate constant for dissociation of $S_2O_4^{2-}$ at 25°C was found to be[17] 2.5 s^{-1} at pH 6.5 and 1.8 s^{-1} in 0.1 M NaOH, so that the half-life for dissociation to $2SO_2^-$ is of the order of 0.28 s and the drop time of the electrode was approximately 14 half-lives. During the formation of each drop at potentials where all SO_2^- reaching the electrode is reduced, the dissociation in reaction (8) could be

displaced sufficiently to the right to yield an easily observable current depending on the concentration of $S_2O_4^{2-}$ in the reaction volume near the electrode surface. We postulate that polarographic waves III and IV are due to electroreduction of HSO_2 and SO_2^-, respectively, according to overall reactions (10) and (11):

$$HSO_2 + H^+ + e^- \rightarrow H_2SO_2, \quad (10)$$

$$SO_2^- + e^- \rightarrow SO_2^{2-}. \quad (11)$$

Because the undissociated form of a weak acid is usually reduced at a more positive potential than the conjugate base form we believe that pH-dependent wave III is due to reaction (10) and that pH-independent wave IV is due to reaction (11). Since wave IV is independent of pH over a wide pH range the electroreduction does not involve any protons in the rate-determining step. Furness[18] observed a small reduction wave at approximately the potential of wave IV in 0.1 M NaOH solutions of $Na_2S_2O_4$ which he concluded was due to a reducible species derived from $Na_2S_2O_4$, and which had a large temperature dependence typical of a kinetically controlled wave.

We were unable to quantitatively obtain the pH dependence of wave III by dc polarography because of the spread-out nature of wave III and its overlapping with wave II.

The wave labelled IV here was assigned by Jacobsen and Sawyer[4] to an inhibited electrode reaction because the presence of 0.001% dodecylamine perchlorate eliminated the wave. We found that the presence of 0.001% sodium dodecylsulfate, which is also a surfactant, did not eliminate or decrease either wave III or wave IV. It is unlikely that either of these waves is due to an adsorbed layer of a reduction product which is either desorbed at the potential of the waves or penetrated by the electroactive species. A further argument against the adsorption origin of waves III and IV is that the waves do not appear when their potential is reached until the pH is sufficiently high for reactions such as (5) and (6) to occur.

Ac polarography

For 3.0 mmol dm^{-3} SO_2 in 1.00 M HCl and 1.00 M ionic strength the peak current, I_p, in an ac polarogram was proportional to $v^{1/2}$, the square root of the frequency, up to 25 Hz, then increased less rapidly than $v^{1/2}$ and was independent of frequency above *ca* 640 Hz. Since I_p is proportional to $v^{1/2}$ for reversible waves and independent of v for irreversible waves[19] the electrode reaction for SO_2 reduction apparently becomes irreversible within the approximate range of times set by these frequency limits. However there seems to be some degree of irreversibility even at a frequency of 10 Hz because the peak width at half-height is approximately 70 mV, greater than $90/n$ or 45 mV for a reversible two-electron reduction.

At pH 2.27 the peaks for waves I and II for SO_2 and HSO_3^- reduction, respectively, are plainly evident (although overlapping) and no peaks for waves III and IV are present.

At pH 2.86 a low, broad peak for wave III appears in the ac polarogram but a peak for wave IV does not.

At pH 4.00 the four peaks for waves I–IV inclusive can be seen as shown in Fig. 1. The peaks for waves I–III overlap. The SO_2 reduction occurring in wave I now makes only a modest contribution. The HSO_3^- reduction occurring in wave II makes

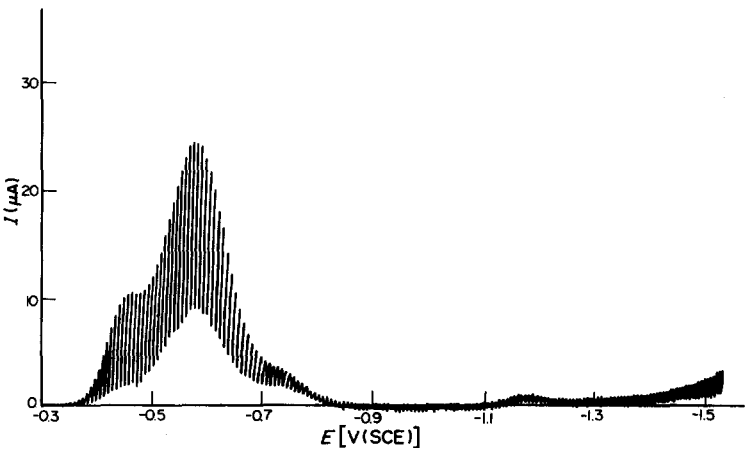

Fig. 1. Ac polarogram of 0.020 mol dm^{-3} sulfur dioxide in acetic acid–KOH buffer: pH 4.0, ionic strength 4.0 M, 25°C.

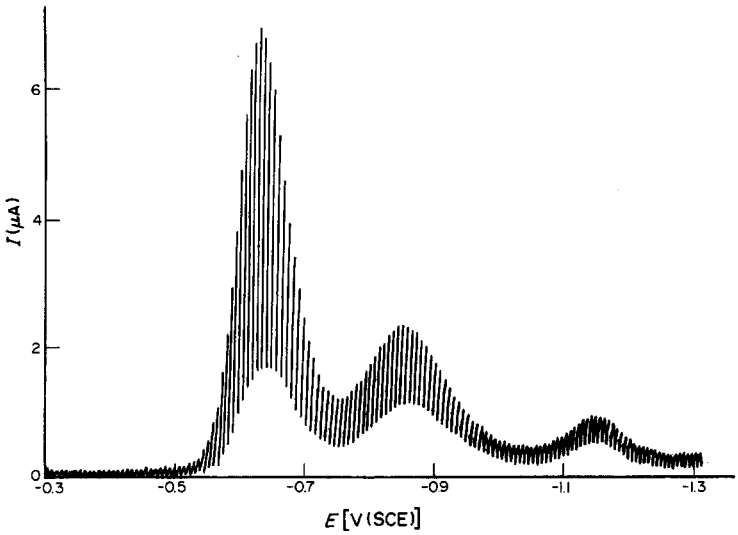

Fig. 2. Ac polarogram of 0.020 mol dm^{-3} sulfur dioxide in acetic acid–KOH buffer: pH 5.89, ionic strength 4.0 M, 25°C.

the major contribution to the current because at this pH sulfite is virtually all present as HSO_3^-. The product H_2SO_2 of the electroreduction of HSO_3^- reacts with HSO_3^- to yield some HSO_2 via reactions (5) and (7). The HSO_2 produced in this way and its conjugate base SO_2^- are reduced via reactions (10) and (11), and so contribute to waves III and IV, respectively. More HSO_2 and SO_2^- can be formed in another manner and also contribute to waves III and IV. Apparently the electroreduction of HSO_3^- can proceed by more than one path, the different paths having different H^+ ion dependencies and different numbers of electrons. The path with $[H^+]^3$ dependence in the pH range 1.3–3 was not experimentally detectable at pH 4. Instead the H^+ ion dependence became approximately first-order because $(E_{1/2})_{II}$ for wave II shifted from −0.55 V at pH 3.0 to approximately −0.583 V at pH 4.0, or −0.033 V per pH unit. At pH 5.89 the peak for wave II was shifted to −0.638 V (as shown in Fig. 2) or by −0.029 V per pH unit from its position at pH 4.0. At the same time the height of wave II is greatly decreased as observed by Kolthoff and Miller[2] for this pH range. It is clear that reaction (4) no longer represents the electroreduction of HSO_3^- in this pH range. Instead we suggest reaction (12):

$$HSO_3^- + H^+ + e^- \rightarrow SO_2^- + H_2O, \qquad (12)$$

a one-electron reduction (as suggested by Kolthoff and Miller[2]) with first-order H^+ ion dependence.

At pH 4.0 the peak for wave III was at −0.72 V and at pH 5.89 it was at −0.85 V. The shift was approximately −0.069 V per pH unit, indicating a $[H^+]^2$ dependence for the electrode reaction. The product of the HSO_3^- reduction in these very weakly acidic solutions must pick up two H^+ ions for the electrode reaction to occur so we suggest reaction (13) for wave III:

$$SO_2^- + 2H^+ + e^- \rightarrow H_2SO_2. \qquad (13)$$

Reaction (13) is really reaction (10) written differently. Therefore the SO_2^- produced from both the two-electron three-H^+ and one-electron one-H^+ reductions of HSO_3^- will be reduced in wave III by the same electrode process. It is expected that the recombination reaction between H^+ and SO_2^- can proceed at rates comparable to the rates of recombination of H^+ with other mononegative conjugate bases. The shift from a two-electron to a one-electron reduction of HSO_3^- should not be too surprising since one-electron reductions of SO_2 take place at a dme in dimethyl sulfoxide,[20] an aprotic solvent. Perhaps the shift can occur in water when the proton concentration is sufficiently small.

The peak for wave IV is not shifted by the pH change from 4.0 to 5.89.

At pH 7.4 all peaks have disappeared, as have all dc polarographic waves because reducible SO_2 and HSO_3^- are not present at sufficiently high concentrations.

PREPARATION AND X-RAY CRYSTAL STRUCTURE OF $[Pd_2(\mu\text{-}O_2CMe)_2(C_6H_5)_2(PPh_3)_2]$, A BINUCLEAR ACETATE-BRIDGED PALLADIUM(II) PHENYL COMPLEX FORMED BY P—C BOND CLEAVAGE OF TRIPHENYLPHOSPHINE

MICHAEL B. HURSTHOUSE,* OLIVIER D. SLOAN, PETER THORNTON* and NIGEL P. C. WALKER

Department of Chemistry, Queen Mary College, Mile End Road, London E1 4NS, U.K.

(*Received* 10 *January* 1986; *accepted* 27 *January* 1986)

Abstract—The new binuclear complex $[Pd_2(\mu\text{-}O_2CMe)_2(C_6H_5)_2(PPh_3)_2]$ is formed when $[Pd_3(O_2CMe)_6]$ reacts with PPh_3 in methanol. An X-ray crystal structure analysis shows the complex to comprise two square planar palladium(II) atoms bridged by two acetate ligands in a *cis* fashion. The phosphine and phenyl ligands on each metal atom adopt positions which are mutually *trans* to the equivalent ligand on the other metal atom, so that the complex has an approximate two-fold axis perpendicular to the plane of the four acetate oxygens. The NMR (^1H, ^{13}C and ^{31}P) spectra are reported.

The comparatively few reports of P—C bond cleavage of triaryl phosphines in the presence of metal compounds have usually involved reactions which can be considered as oxidative additions, so that a zerovalent metal is oxidized to the bivalent state with the formation of complexes of aryl and/or dialkylphosphido ligands.[1] The formation of aryl intermediates has also been suggested during the alkylation of alkenes[2] and during the formation of biphenyl in reactions involving $[NiClR'(PR_3)_2]$,[3] $[NiCl_2(PPh_3)_2]$[4] or $[Pd(O_2CMe)_2(PPh_3)_2]$,[5] and must also occur when the latter complex is used to phenylate styrene.[6]

These suggestions are now confirmed by our finding that the solution obtained by the reaction of $[Pd_3(O_2CMe)_6]$ with triphenylphosphine in methanol produces the new binuclear aryl complex $[Pd_2(\mu\text{-}O_2CMe)_2(C_6H_5)_2(PPh_3)_2]$, which has been characterized by NMR spectroscopy and X-ray crystallography. The ^1H NMR spectrum ($CDCl_3$) shows only a broad singlet, δ 1.32, for acetate protons and a complex multiplet, δ 6.5–7.5, for phenyl protons, but in the broad-band-decoupled ^{13}C spectrum the acetate carbons are found at δ 24.04 ($\underline{C}H_3CO_2$) and 147.4 ($CH_3\underline{C}O_2$), the triphenylphosphine carbons at 127.9 (*m*), 130.0 (*p*), 132.0 (P—$\underline{C}$) and 134.7 (*o*), and the phenyl carbons at 123.2 (*p*), 126.8 (*m*) and 137.3 (*o*), though the carbon bound to palladium was not detected. The ^{31}P spectrum shows a singlet (δ 29.03, with reference to H_3PO_4).

EXPERIMENTAL

NMR spectra were obtained on Bruker WP-80 (^1H) and WM-250 (^{13}C and ^{31}P) spectrometers, and the IR spectrum on a Perkin–Elmer 577 spectrophotometer.

Di-μ-acetatodiphenylbis(triphenylphosphine)dipalladium(II)

$[Pd_3(O_2CMe)_6]$ (0.19 g, 0.30 mmol) and triphenylphosphine (0.67 g, 2.6 mmol) were dissolved in methanol (75 cm^3) and the solution refluxed for 10 min. The red-brown solution was cooled and allowed to evaporate slowly in air until a black crystalline solid was deposited and a clear solution remained (approximately 36 h). Yield 0.19 g (41%). Found: C, 61.1; H, 4.5; P, 6.8; Pd, 22.0%. $C_{26}H_{23}O_2PPd$ requires: C, 61.9; H, 4.6; P, 6.1; Pd, 21.1%. IR spectrum: 3050(m) (aromatic C—H), 1575(vs) [$\nu_{as}(CO_2)$], 1440(s) (P—Ph), 1414(vs) [$\nu_s(CO_2)$], 1376(s) (C—H sym. def.), and 750–690(s) (aromatic o.o.p. bending).

Crystal data

$C_{52}H_{46}O_4P_2Pd_2$, $M = 1008.8$, monoclinic, $a = 11.104(2)$ Å, $b = 24.135(5)$, Å, $c = 17.193(3)$ Å, $\beta = 99.51(2°)$, $U = 4544.3$ Å^3, space group $P2_1/n$, $Z = 4$, $D_c = 1.474$ g cm^{-3}, $F(000) = 2048$, λ(Mo-K_α) = 0.71069 Å, μ(Mo-K_α) = 8.11 cm^{-1}.

Data collection

Unit cell parameters were determined and intensity data collected at room temperature on an Enraf–Nonius CAD4 diffractometer using graphite-monochromated Mo-K_α radiation and an ω–2θ scan procedure.[7] 8634 data ($1.5 \leqslant \theta \leqslant 25°$) were measured of which 7983 were unique and 6096 considered observed [$I \geqslant 1.5\sigma(I)$]. Monitoring of three intensity control reflections showed no crystal decomposition.

Structure solution and refinement

The structure was solved via the heavy-atom method. After least-squares refinement with isotropic temperature factors for all non-hydrogen atoms the DIFABS empirical method of absorption correction[8] was applied. Following refinement using anisotropic thermal parameters for all atoms and with constraints on the phosphine phenyl rings to retain regular hexagonal geometry a difference-Fourier map revealed the location of most of the hydrogen atoms on the phenyl and methyl groups. All hydrogen atoms on the phenyl rings were included in refinement with a common refined isotropic temperature factor for each ring and constaints to main regular geometry. The methyl-group hydrogens were also subjected to constraints to retain tetrahedral geometry and assigned group isotropic temperature factors.

The final full-matrix least-squares refinement was carried out with unit weights and gave the following R-factor values: $R = \Sigma|\Delta F|/\Sigma|F_o| = 0.056$ and $R_w = [\Sigma|\Delta F|^2/\Sigma|F_o|^2] = 0.069$.

All computations were made using SHELX76[9] on a DEC VAX-11/750. Fractional atomic coordinates, thermal parameters, full lists of bond lengths and angles, and lists of F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are avilable on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

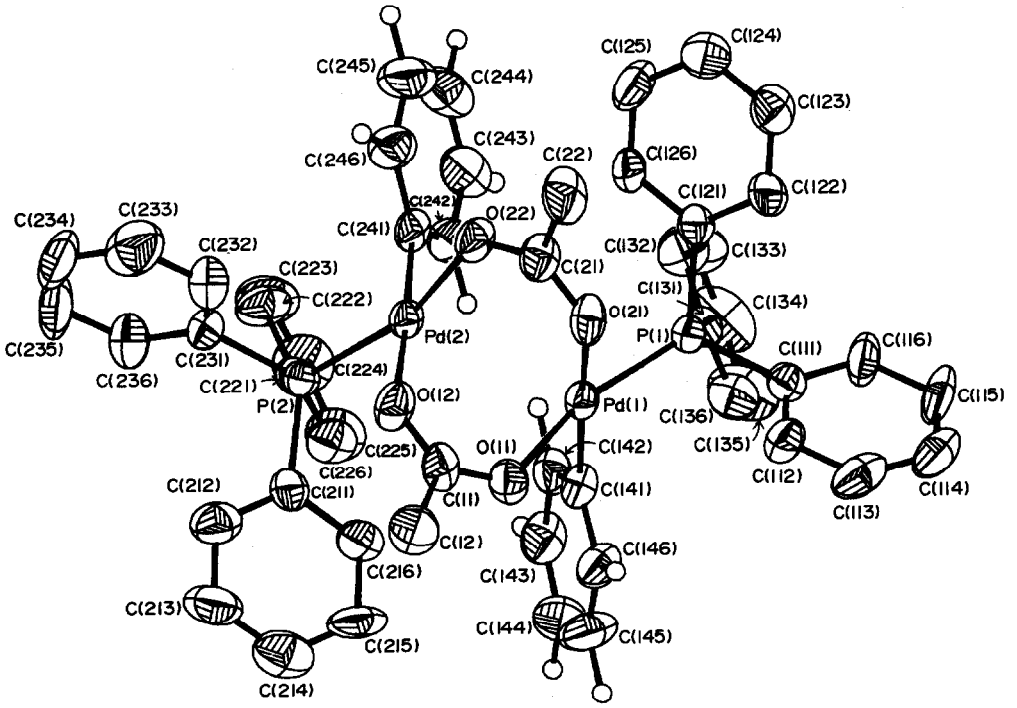

Fig. 1. The crystal structure of $[Pd_2(O_2CMe)_2(C_6H_5)_2(PPh_3)_2]$ with hydrogens on the phosphine phenyl rings and methyl groups omitted for clarity. The thermal ellipsoids are drawn to include 50% probability [E. K. Davies, SNOOPI program for drawing crystal structures, University of Oxford (1983)].

DISCUSSION

The molecular structure is illustrated in Fig. 1. Selected bond lengths and angles are given in Table 1. The two palladium atoms are linked by two *syn–syn* acetate bridges, with the acetate oxygens adopting a *cis*-configuration at the square planar palladium(II) atoms, as in $[Pd_2(O_2CMe)_2Cl_2(Me_2PPh)_2]$.[10] The other two coordination sites on each palladium are occupied by a phenyl group and a triphenylphosphine ligand with the coordinated atoms remaining within 0.4 Å of planarity at both palladiums. The bulky phosphines are kept well apart by these two PdO_2CP planes being splayed at an angle of 38° and a torsion angle between the phosphorus atoms across the Pd–Pd axis of 115°. By comparison the torsion angle between the bonded carbon atoms of the phenyl groups [C(141) and C(241)] is 85°. There is no question of a Pd—Pd bond with these atoms 3.079 Å apart.

Concerning the formation of our compound, we

note that the P—C bond fission has, unusually, not come from an oxidative addition. Our reaction has similarities to the recent finding[11] that triphenylphosphine is cleaved by $[Ru_2(PhCONH)_4Cl]$ to give $[Ru_2Ph_2(PhCONH)_2\{Ph_2POC(Ph)N\}_2]$. In that example the diphenylphosphido group becomes attached to the benzamide residue, but in our reaction the Ph_2P units must form some soluble compound, possibly a palladium complex (our yield is 41%), which we have not identified. We have also found that the assertion[12] that palladium(II) carboxylates decompose when warmed in alcohols is incorrect.

Acknowledgements—We thank the S.E.R.C. for financial support, including provision of instruments and computing facilities and a C.A.S.E. studentship (O.D.S.) with the valued collaboration of ICI Petrochemicals and Plastics Division. We are also grateful to Ms J. Elliott (King's College, London) for ^{13}C and ^{31}P NMR spectra, and to Dr R. J. Errington for helpful discussions.

SOLVENT EXTRACTION OF METAL IONS FROM AQUEOUS SOLUTIONS CONTAINING *N,N,N',N'*-ETHYLENEDIAMINETETRAACETIC AND RELATED ACIDS—II.* La(III) AND DIETHYLENETRIAMINEPENTAACETIC ACID

FAWZI H. AL-DABBAGH and JOSEPH I. BULLOCK†

Department of Chemistry, University of Surrey, Guildford GU2 5XH, U.K.

(*Received* 23 *January* 1986; *accepted* 10 *February* 1986)

Abstract—In the absence of a competing anion, $[La(DTPA)]^{2-}$ was extracted from aqueous phases in the pH ranges 1–3 by the perchlorate salt of the primary amine Primene JM-T. The addition of small amounts of SO_4^{2-} to the aqueous phases depressed the extraction of La to near zero. As the SO_4^{2-} concentration was increased further, D_{La} increased to values greater than that found in the absence of SO_4^{2-}; this was caused by a change in the mechanism of extraction and $[La(SO_4)_2]^-$ became the extracted species.

The extraction of lanthanides(III) from aqueous phases containing aminepolycarboxylic acids at low pH into Primene JM-T and other amines in the absence of a complexing inorganic anion has long been supposed[1–3] to occur through anions such as $[Eu(DTPA)]^{2-}$. If much SO_4^{2-} is also present then the $[Ln(SO_4)_2]^-$ complexes are said to be extracted[4] with the organic acids acting as aqueous-phase masking agents since, for example, an increase in the complexone concentration actually depressed the extraction of the lanthanide. The present study was aimed at demonstrating these assertions using, as example, the extraction of La from H_5DTPA solution. Throughout the abbreviation DTPA refers to a non-specific form; for specific cases charges are included. A comparison with the U(IV) system is offered.

EXPERIMENTAL

Materials

Primene JM-T was described before.[5] All other materials, including diluents, were of high quality.

Extraction experiments

All were repeated at least twice and two samples for analysis were taken from each aqueous phase. The reproducibility of the D_{La} values was 10% or better. D_{La} was determined by analysis of the initial and equilibrium aqueous phases only using xylenol orange.[6] All concentrations of La were determined in the presence of the same aqueous-phase components as used in the extractions.

Solutions of Primene JM-T and its salts were made up as before.[5] La solutions were prepared by dissolving La_2O_3 in perchloric acid and, after dilution, adjusting the pH with sodium or ammonium hydroxides; pH was measured with calibrated Philips PW 9148 or 9409 meters. All quoted pH values refer to the equilibrium aqueous phases.

RESULTS AND DISCUSSION

There are major differences between the species formed by La(III) and U(IV) with amine-polycarboxylate anions in the pH range 1–3. The formation constants for La(III) are much smaller, giving rise to a considerable amount of free La ion; it is thus possible that a second complexing agent could, by interacting with the free La ion, produce a competing mechanism of extraction which would be unimportant in the U(IV) systems.[5] Also, protonated forms such as $[La(H \cdot DTPA)]^-$ are found but similar U(IV) species are unknown. Further, hydrolysis of the complexes will occur at a lower pH for U(IV) than La(III). With regard to the formation of ternary complexes with a second

Table 2. Extraction data for La(III): variation of D_{La} with pH and SO_4^{2-} concentration

Series 1.	Primene JM-T perchlorate[a] [La(III)–$HClO_4$, pH 2, $D_{La} = 0.00$] $H_5DTPA = La(III) = 5.00\times10^{-4}$ mol dm^{-3}						
pH	1.45	1.70	2.00	2.40	2.70		
D_{La}	0.02	0.09	0.13	0.18	0.23		
Series 2.	Primene JM-T perchlorate[a] (H_5DTPA absent) $SO_4^{2-} = 0.05$ mol dm^{-3}; $La(III) = 5.00\times10^{-4}$ mol dm^{-3}						
pH	1.68	2.23	2.90	3.58			
D_{La}	0.24	0.29	0.83	1.06			
Series 3.	Primene JM-T perchlorate[a]; pH 2.80 $La = H_5DTPA = 5.02\times10^{-4}$ mol dm^{-3}						
SO_4^{2-}	0.000	0.005	0.010	0.020	0.030	0.040	0.050
D_{La}	0.19	0.13	0.04	0.25	0.48	0.54	0.67

[a] Primene JM-T = 0.033 mol dm^{-3}.

ligand, for example SO_4^{2-}, the formation constants:

$$M^{n+} + xSO_4^{2-} \rightleftharpoons [M(SO_4)_x]^{(2x-n)-}$$

are about two orders of magnitude smaller for La(III) ($I = 0.5$ mol dm^{-3}; La(III):[7] $\log K_1 = 1.77$, $\log \beta_2 = 2.66$; U(IV):[8] $\log K_1 = 3.42$, $\log \beta_2 = 5.82$). By analogy the formation constants for mixed-ligand complexes, e.g. $[M(DTPA)SO_4]^{a-}$, are likely to be lower for M = La ($a = 4$) than for M = U ($a = 3$). Speciation in the La and U(IV) systems is shown in Table 1.

Extraction of La(III) *from DTPA solution by Primene JM-T perchlorate (solvent xylene)*

As expected no extraction was found at pH 2 from a solution of La(III) in perchloric acid. Extraction was found from La(III)–DTPA solution and increased as the pH was raised towards 3 (Table 2, series 1) in keeping with the results given in Table 1. Extraction[5] from U(IV)–DTPA was more marked at the lower pH values. An amine dependence experiment (Table 3, series 1) gave a plot of log D_{La} against log [Primene JM-T] with a slope of 1.81 which would suggest that $[La(DTPA)]^{2-}$ was the extracted species.

Extraction of La(III) *from solutions containing* SO_4^{2-} *by Primene JM-T perchlorate or sulphate (solvent xylene)*

La(III)–SO_4^{2-}. In the presence of 0.05 mol dm^{-3} SO_4^{2-}, La(III) was more strongly extracted into Primene JM-T perchlorate at a given pH (Table 2, series 2) than from DTPA solution containing no SO_4^{2-}. Further, when Primene JM-T sulphate was used with an aqueous phase containing 0.5 mol dm^{-3} SO_4^{2-} at pH 2 there was no detectable La present in the equilibrium aqueous phase. The results strongly suggest the extraction of $[La(SO_4)_2]^-$ {there is evidence[11] for the extraction of both $[La(SO_4)_2]^-$ and $[La(SO_4)_3]^{3-}$}.

La(III)–DTPA–SO_4^{2-}. The addition of small amounts of SO_4^{2-} to aqueous phases containing La(III)–DTPA at pH 2.80 reduced D_{La} (Table 2, series 3) for extraction into Primene JM-T perchlorate to almost zero near 0.01 mol dm^{-3} SO_4^{2-}. It is possible that a non-extractable, mixed-ligand complex, e.g. $[La(DTPA)(SO_4)]^{4-}$, was formed. In an earlier study,[12] lanthanide(III) mixed-ligand complexes with DTPA and iminodiacetate were not found but subsequent[13,14] studies identified such complexes with phthalate, malonate, tartrate and malate. Since $[La(EDTA)(H_2O)_3]^-$ is nine-coordinate,[15] coordination numbers greater than 8 involving DTPA are possible. The slope of an amine dependence plot [0.005 mol dm^{-3} SO_4^{2-} (Table 3, series 2a)] was 2.13 which implied that $[La(DTPA)]^{2-}$ was extracted at low SO_4^{2-}. On increasing the SO_4^{2-} concentration further (Table 2, series 3), D_{La} began to increase to values greater than that found in the absence of SO_4^{2-}. The slope of the amine dependence plot [0.05 mol dm^{-3} SO_4^{2-} (Table 3, series 2b)] became 1.01. This suggested a change in the extraction mechanism with $[La(SO_4)_2]^-$ as the new extracted species. This was confirmed by bringing the SO_4^{2-} concentration in each of the equilibrium aqueous phases at pH 2.80 from Table 2 (series 3) to 0.5 mol dm^{-3} and re-extracting with Primene JM-T sulphate when all the residual La was extracted. Titration of the new equilibrium aqueous phases for DTPA with zinc ions clearly showed (Table 4, series 1) that, in the initial extractions from the higher SO_4^{2-} concentrations, the equilibrium organic-phase La concentration was much greater than that of DTPA. $[La(DTPA)]^{2-}$ cannot be the only extracted species across the whole SO_4^{2-} concentration range and a change in mechanism to give predominantly organic-phase $[La(SO_4)_2]^-$ must occur. It is of interest to note that the weakly complexing SO_4^{2-} can compete so successfully with DTPA for the metal ion in the solvent extraction system. In our experiments, La and H_5DTPA were introduced at the same concentration and so, if free La is present at the prevailing pH (Table 1), so must free DTPA. In the absence of La and SO_4^{2-}, DTPA species exchange to a considerable extent with organic-phase perchlorate (Table 4, series 2) and this might well have a synergic influence on the successful competition of SO_4^{2-} over DTPA for the available aqueous-phase La. The reextraction experiments (Table 4, series 1), showed that at low SO_4^{2-} concentrations the initial, equilibrium organic phases contained more DTPA than La. Such exchanges of DTPA and perchlorate are not important in the U(IV) systems since the aminepolycarboxylate complexes are completely formed at the prevailing aqueous-phase pH.

COMMUNICATION

SYNTHESIS, FORMATION CONSTANTS AND REACTIONS OF CATIONIC RHODIUM(I) COMPLEXES OF NITRILES

MYOUNG KIE LEE, IN BUM KIM, HWA-KUN PARK, SOON HEUM PARK and CHONG SHIK CHIN*

Department of Chemistry, Sogang University, CPO Box 1142, Seoul 121, Korea

(*Received* 29 *July* 1985; *accepted after revision* 20 *January* 1986)

Abstract—Reactions of $Rh(ClO_4)(CO)(PPh_3)_2$ with nitriles produce new cationic rhodium(I) complexes, $[RhL(CO)(PPh_3)_2]ClO_4$ [L = CH_3CN (**1**), $CH_3CH_2CH_2CN$ (**2**) or C_6H_5CN (**3**)], whose spectral data suggest that the nitriles are coordinated through the nitrogen atom. Formation constants for the reaction $Rh(ClO_4)(CO)(PPh_3)_2 + L \rightleftharpoons [RhL(CO)(PPh_3)_2]ClO_4$, have been measured to be 1.01×10^5 M^{-1} (CH_3CN), 1.07×10^5 M^{-1} ($CH_3CH_2CH_2CN$) and 2.59×10^4 M^{-1} (C_6H_5CN) at 25°C in monochlorobenzene. The differences in the formation constants for the different nitriles seem to be predominantly due to differences in ΔH (not to differences in ΔS). The nitriles in **1–3** are readily replaced with nitrogen base ligands (unsaturated nitriles and pyridine) and PPh_3.

The synthesis, physical properties and chemical reactivities of cationic rhodium(I) complexes of saturated nitriles[1–3] and iridium(I) complexes of unsaturated[4–6] and saturated[7] nitriles, $[ML(CO)(PPh_3)_2]ClO_4$ (M = Rh or Ir, L = unsaturated or saturated nitriles), have been reported recently. This communication reports the synthesis, formation constants with thermodynamic parameters, and reactions of new cationic rhodium(I) complexes of saturated and aromatic nitriles.

Addition of nitriles (L) into the yellow solution of $Rh(ClO_4)(CO)(PPh_3)_2$ in benzene at 25°C under nitrogen resulted within 5 min in yellow-orange microcrystals of $[RhL(CO)(PPh_3)_2]ClO_4$ [eqn (1)]:†

$$Rh(ClO_4)(CO)(PPh_3)_2 + L \rightarrow [RhL(CO)(PPh_3)_2]ClO_4, \quad (1)$$

where L = CH_3CN (**1**), $CH_3CH_2CH_2CN$ (**2**) or C_6H_5CN (**3**). Complexes **1–3** are stable in the solid state in air and in solution under nitrogen at 25°C, and soluble in polar solvents (chloroform, dichloromethane and acetonitrile) and insoluble in non-polar solvents (benzene and hexane). The molar-conductance values (110–120 Ω^{-1} cm^2 mol^{-1}) of **1–3** (5.0×10^{-5} M in dichloromethane) suggest that the complexes are 1 : 1 electrolytes.‡

IR spectral data (Table 1) unambiguously show that nitriles in complexes **1–3** are coordinated to rhodium through the nitrogen atom, and not through the π-system of the nitrile group. It is well-known that ν(CN) for a nitrile increases upon coordination through the nitrogen atom,[8–10] while it decreases significantly upon coordination through the π-system of the nitrile group.[10] A broad and strong absorption band at *ca* 1100 cm^{-1} (not listed in Table 1) observed for all the complexes is attributable to the anionic tetrahedral ClO_4 (T_d) group,[11]

* Author to whom correspondence should be addressed.

† One drop (*ca* 0.75 mmol) of a nitrile (CH_3CN, $CH_3CH_2CH_2CN$ or C_6H_5CN), 1.20 g (0.26 mmol) of $Rh(ClO_4)(CO)(PPh_3)_2$ and 10 cm^3 of benzene were used. The yellow-orange crystals were collected by filtration, washed with benzene (5 cm^3) and hexane (15 cm^3), and dried *in vacuo*. The yield was *ca* 85% based on $[RhL(CO)(PPh_3)_3]ClO_4$ [L = CH_3CN (**1**), $CH_3CH_2CH_2CN$ (**2**) or C_6H_5CN (**3**)]. Found: C, 59.5; H, 4.8; N, 1.6%. Calc. for $RhC_{39}H_{33}NClO_5P_2$ (**1**): C, 58.8; H, 4.2; N, 1.8%. Found: C, 60.7; H, 4.4; N, 1.7%. Calc. for $RhC_{41}H_{37}NClO_5P_2$ (**2**): C, 59.8; H, 4.5; N, 1.7%. Found: C, 62.6; H, 3.9; N, 1.7%. Calc. for $RhC_{44}H_{35}NClO_5P_2$ (**3**): C, 61.6; H, 4.1; N, 1.6%.

‡ The molar conductance of a standard 1 : 1 electrolyte, $[(C_3H_7)_4N]PF_6$, in dichloromethane at 25°C was measured to be 110 Ω^{-1} cm^2 mol^{-1}.

Table 1. IR (in Nujol), electronic absorption (in monochlorobenzene) and ^1H NMR (in $CDCl_3$) spectral data for $[RhL(CO)(PPh_3)_2]ClO_4$ [L = CH_3CN (**1**), $CH_3CH_2CH_2CN$ (**2**) or C_6H_5CN (**3**)]

2	0.23 (t, CH_3), 0.75 (m, CH_3CH_2), 1.83 (t, CH_2CN)		
3	*ca* 7.5 (m, C_6H_5)		

[a] Weak. $\Delta\nu$(CN) = ν(CN) of coordinated nitrile − ν(CN) of free nitrile.
[b] Very strong.
[c] At 25°C under nitrogen in the presence of excess corresponding L.
[d] At 25°C at 60 MHz. All complexes (**1–3**) show a multiplet due to the phenyl protons of PPh_3 at *ca* 7.5 ppm. Relative to TMS.

which supports the view that the complexes are 1 : 1 electrolytes as confirmed by the conductance measurements. It is noticed in Table 1 that ν(CO) for the CH_3CN complex (**1**) is lower than those of other nitrile complexes.

Electronic absorption spectral data (Table 1) also suggest that **1–3** are four-coordinated rhodium(I) complexes and the nitriles in **1–3** are coordinated through the nitrogen atom. It is well-known that the four-coordinated rhodium(I) complexes $RhA(CO)(PPh_3)_2$ [A = monodentate nitrogen base ligand such as NCO, NO_2, NCS or $N(CN)_2$][12] and $[RhL(CO)(PPh_3)_2]ClO_4$ (L = monodentate nitrile coordinated through the nitrogen atom)[3] show an absorption band at 365–383 nm (ε 3400–4300).

The observed chemical shifts of the nitrile protons in **1** and **2** (Table 1) and the ratios (not given in Table 1) of the phenyl protons of PPh_3 to nitrile protons clearly indicate a $RhL(PPh_3)_2$ (L = CH_3CN or $CH_3CH_2CH_2CN$) moiety in **1** and **2**. It is seen in Table 1 that all protons of nitriles in **1** and **2** showed upfield shifts relative to those of the free nitriles as observed for related rhodium(I) and iridium(I) complexes of nitriles coordinated through the nitrogen atom.[2,3,6] The spin coupling between ^{103}Rh and the protons of coordinated nitriles has not been observed for the complexes prepared in this study.

Formation constants and thermodynamic parameters have been determined for eqn (2):*

$$Rh(ClO_4)(CO)(PPh_3)_2 + L \rightleftharpoons [RhL(CO)(PPh_3)_2]ClO_4 \quad (2)$$

where L = CH_3CN, $CH_3CH_2CH_2CN$, C_6H_5CN.

It is noticed in Table 2 that the formation constant of **3** is smaller than those of **1** and **2**, which seems to be predominantly due to differences in ΔH (not to differences in ΔS).

Nitriles in **1–3** are readily replaced by nitrogen and phosphorus base ligands according to eqn (3):

$$[RhL(CO)(PPh_3)_2]ClO_4 + L' \rightarrow [RhL'(CO)(PPh_3)_2]ClO_4 + L, \quad (3)$$

where L = CH_3CN, $CH_3CH_2CH_2CN$ or C_6H_5CN; and L′ = $CH_2{=}CHCN$,[1] $CH_2{=}C(CH_3)CN$,[3]

* Formation constants for eqn (2) were determined in the same manner as described for the formation constants of $[RhL(CO)(PPh_3)_2]ClO_4$ (L = unsaturated nitriles coordinated through the nitrogen atom).[3] The molar conductances of **1–3** in monochlorobenzene are practically zero, indicating that the ionization $[RhL(CO)(PPh_3)_2]ClO_4 \rightarrow [RhL(CO)(PPh_3)_2]^+ + ClO_4^-$ is negligible, while that in dichloromethane is 110–120 Ω^{-1} cm^2 mol^{-1}, suggesting that the complexes undergo complete ionization. A similar observation was previously reported for the related complexes of unsaturated nitriles[3] and $Rh(ClO_4)(CO)(PPh_3)_2$.[11]

Table 2. Formation constants and thermodynamic parameters for the reaction $Rh(ClO_4)(CO)(PPh_3)_2 + L \rightleftharpoons [RhL(CO)(PPh_3)_2]ClO_4$ (L = CH_3CN, $CH_3CH_2CH_2CN$ or C_6H_5CN) in monochlorobenzene

L	Formation constant[a] (M^{-1})	ΔH^b (kcal mol^{-1})	ΔS (cal mol^{-1} deg^{-1})
CH_3CN	1.01×10^5	-7.3 ± 0.8	-2 ± 3
$CH_3CH_2CH_2CN$	1.07×10^5	-7.3 ± 0.4	-1 ± 1
C_6H_5CN	2.59×10^4	-6.7 ± 0.1	-2 ± 0.3

[a] At 25°C.
[b] In the region of 25–55°C.

$CH_2{=}CHCH_2CN$,[3] *cis,trans*-$CH_3CH{=}CHCN$,[3] PPh_3[13] or C_5H_5N.[13]

The reactions of **1–3** with unsaturated aldehydes, however, do not produce $[Rh(RCH{=}CHCHO)(CO)(PPh_3)_2]ClO_4$ (R = H or CH_3), which are readily formed by the reactions of $Rh(ClO_4)(CO)(PPh_3)_2$ with $RCH{=}CHCHO$.[14]

(*Received* 10 *December* 1985; *accepted* 28 *February* 1986)

Abstract—Crystals of the complex $Ni(NCS)_2 \cdot 2Ph_3P$ are triclinic with $a = 7.939(4)$ Å, $b = 10.457(5)$ Å, $c = 11.474(5)$ Å, $\alpha = 111.08(3)°$, $\beta = 74.56(3)°$ and $\gamma = 92.25(3)°$. X-ray data for 2692 independent observed reflections were collected and the structure determined by Fourier methods and refined to $R = 0.038$. The nickel geometry is square planar with the triphenylphosphine ligands occupying *trans* positions. A feature of the structure is the large value (173.3°) for the Ni–N–C angles.

Structures have previously been determined for a number of nickel complexes containing tertiary phosphine ligands showing the presence of tetrahedral coordination about the central atom for the halide complexes.[1,2] The related thiocyanates are often square planar,[3] but, in a number of cases, octahedral coordination has been found as a result of both intra- and intermolecular interactions.[4] No data are available for the simple bis(triphenylphosphine) adduct of nickel thiocyanate and, in the context of general nickel stereochemistry, it was of interest to investigate its structure.

EXPERIMENTAL

The compound was prepared by treating a mixture of $Ni(NO_3)_2 \cdot 6H_2O$ with 2 mol of potassium thiocyanate in ethanol with an excess of triphenylphosphine. Crystals suitable for X-ray analysis were obtained by slow recrystallization from ethanol solution. Found: C, 65.2; H, 4.3; N, 4.0%. Calc. for $C_{38}H_{30}N_2NiP_2S_2$: C, 65.3; H, 4.2; N, 4.0%.

Crystal data

$C_{38}H_{30}N_2NiP_2S_2$, $M = 698.7$, triclinic, $a = 7.939(4)$ Å, $b = 10.457(5)$ Å, $c = 11.474(5)$ Å, $\alpha = 111.08(3)°$, $\beta = 74.56(3)°$, $\gamma = 92.25(3)°$, $U = 855$ Å^3, $Z = 1$, $D_c = 1.36$ g cm^{-3}, $F(000) = 362$, space group $P\bar{1}$, Mo-K_α radiation, $\lambda = 0.7107$ Å, $\mu = 8.07$ cm^{-1}, crystal size $1.3 \times 0.2 \times 0.35$ mm^3, rotating about *a*.

Structure determination

Data were collected using a Hilger and Watts four-circle diffractometer for 3211 reflections of which 2692 with $I > 3\sigma(I)$ were observed. Data reduction and subsequent crystallographic calculations used the CRYSTALS programs;[5] scattering factors were those for neutral atoms.[6] As the unit cell contains one molecule of the complex, the nickel atom lies on a centre of symmetry ($\frac{1}{2}, \frac{1}{2}, \frac{1}{2}$). The refinement converged at $R = 0.112$ with isotropic and $R = 0.038$ with anisotropic thermal parameters, and the hydrogen atoms placed (but not refined) at their calculated positions. The final atomic co-ordinates, temperature factors, observed and calculated structure factors, and torsion angles have been deposited as supplementary data with the

DISCUSSION

Important bond distance and angle data are collected in Table 1 and Fig. 1 shows the molecular structure and atom-numbering scheme. The complex forms isolated molecules; there are no intermolecular Ni...S interactions within 3.8 Å. The geometry about nickel is square planar [N(1)–Ni(1)–P(1) 92.08° and N(1)–Ni(1)–P(1′) 87.92°] and, as the metal atom lies on a centre of symmetry, the complex is necessarily the *trans* isomer. In keeping with the hardness of Ni^{2+}, the thiocyanate group is bonded via nitrogen. Surprisingly, the softer Pd^{2+} ion also bonds via nitrogen in $Pd(NCS)_2 \cdot 2Ph_3P$,[7] but via sulphur in $Pd(SCN)_2 \cdot 2Ph_2MeP$.[3]

Important features of the structure are the closeness to planarity of the $NiP_2(NCS)_2$ system and the large value (173.7°) for the Ni(1)–N(1)–C(1) angle. In the former, the maximum deviation of any atom [N(1) and N(1′)] from the best plane through the nine atoms is 0.01 Å. Both features can be interpreted in terms of π-bonding between nickel and nitrogen and, in agreement, the Ni(1)–N(1) bond length is short (1.819 Å). The isothiocyanate group is linear with distances in the expected ranges; the Ni–P distance is also as expected.

BOOK REVIEW

Gmelin Handbook of Inorganic Chemistry, 8th Edition. Cu—Organocopper Compounds, Part 1, Organocopper Compounds. 1985, 2 illus., x + 470 pp., hard cover, DM1725, Springer, Berlin, ISBN 3-540-93517-7.

This is the second Gmelin Handbook on Organocopper compounds. Part 2, published in 1983, dealt with the metal dialkylcuprates, or "homocuprates", R_2CuM. Part 1 now covers the mono-organic copper(I) compounds RCu and RCu,MX or RCuX,M (the "heterocuprates").

These organocopper compounds have become widely used as sources of nucleophilic organic groups, particularly in substitution reactions with alkyl, vinyl or acyl halides, or propargyl sulphonates or carboxylates, or in conjugate additions to enones, and the reactivity can be modulated by the addition of metal halides such as BF_3, or of ligands such as sulphides or amines.

However, these compounds are often thermally unstable and very reactive towards oxygen and moisture, and few have been isolated and fully characterized. More usually the heterocuprates are formed in solution from an equimolar mixture of CuX and MR (organolithium or Grignard reagent), and their composition and degree of aggregation in solution may vary with the reaction conditions. In this volume, the compounds are therefore assigned the simplest formula as derived from the stoichiometry of the preparation, unless there is firm evidence for a different specific structure.

The first major section covers the compounds RCu (R = alkyl, alkenyl and aryl). These compounds often separate from organic solvents at low temperatures as coloured (often yellow to red), sometimes explosive solids. The perfluoroalkyl compounds are unusual in that they can be prepared from the perfluoralkyl iodides and activated copper, and, once formed, are not readily hydrolysed. The preparation, spectra, structure and chemical behaviour are clearly presented; for example the section on MeCu covers 8 pp. and includes 66 references. Families of related compounds are tabulated, and information on the more important members is amplified by extensive footnotes.

The next sections then deal in a similar way with the complexes with lithium salts, RCu,LiX (154 pp.) and with magnesium salts, RCu,MgX_2 (118 pp.). The most important part here is the extensive tabulation of the synthetic applications of these compounds in their reactions with organic halides, R′Y, to couple together the two organic groups to form RR′ (often with allylic or propargylic rearrangement within R′).

The complexes formed with salts of copper, silver, gold, zinc, tin, aluminium and titanium are then covered more briefly, then there is a substantial section (23 pp.) on the enhancement of reactivity which is obtained in the presence of boron compounds. The final sections deal with the modulation of the reactivity of the organocopper compounds by ligands such as dioxane, dialkylsulphides, amines and phosphines.

The text, as in all current volumes of Gmelin, is wholly in English, and the layout of the text and tables is excellent in the usual sanserif typeface. The formal literature closing date is the end of 1983, but some 1985 references are included. The authors are J. Faust, J. Füssel and H. Somer, and the editors J. Füssel and A. Slawisch.

This will be an invaluable source of reference to anyone who becomes involved in the application of organocopper compounds in organic synthesis, which is a rapidly expanding field. Unfortunately, at a price of DM1725 (£530, U.S. $750) it will be beyond the reach of many libraries.

SYNTHESES AND CHARACTERIZATION OF $[Ru(\eta^5\text{-}C_5H_5)(AsPh_3)(L)X]$ AND $[Ru(\eta^5\text{-}C_5H_5)(AsPh_3)(L)(MeCN)]^+_mY^-$ (L = PPh_3 OR $AsPh_3$; X = F, Cl, Br, I, CN, H OR $SnCl_3$; Y = $HgCl_3$, Zn_2Cl_6 OR BPh_4; m = 1 OR 2)

KOLLIPARA MOHAN RAO, LALLAN MISHRA* and UMESH CHANDRA AGARWALA†

Department of Chemistry, Indian Institute of Technology, Kanpur 208016, India

(*Received* 23 *September* 1985; *accepted* 19 *December* 1985)

Abstract—The syntheses of the complexes $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(L)X]$ (L = PPh_3 or $AsPh_3$; X = Cl, F, Br, I, H, CN or $SnCl_3$) and $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(L)(MeCN)]^+Y^-$ (Y = $HgCl_3$, BPh_4 or Zn_2Cl_6) are described. They were characterized by elemental analyses, IR, UV and visible, PMR spectroscopy, X-ray powder diffraction, and mass spectral studies.

The potential chemical reactivities of the complexes $[(\eta^5\text{-}C_5H_5)RuX(PR_3)_2]$ (X = Cl, Br or I; R = Me or Ph) with various heterocyclic bases, dienes, trienes, NOX (X = Cl, Br, Br_3 or NO_2) etc. have recently received considerable attention in the chemical literature.[1–10] Interest in these molecules stems from the reactions of the substitution-reaction products which they show because of the close proximity of sterically hindered two trialkyl or triaryl phosphine molecules. It has recently been demonstrated that $[(\eta^5\text{-}C_5H_5)RuCl(PPh_3)_2]$ undergoes a substitution reaction under refluxing conditions for a very long period, giving $[(\eta^5\text{-}C_5H_5)RuCl(AsPh_3)_2]$ in good yield. Since, in our previous papers,[8,9] the substitution of one molecule of PPh_3 by a heterocyclic base like pyridine has been reported, it is anticipated that substitution reactions should proceed through stepwise replacement of one molecule by another. It was, therefore, of interest to extend our investigations of substitution reactions and to attempt to synthesize mixed complexes $\{[(\eta^5\text{-}C_5H_5)RuX(A)(B)]$ (A = PPh_3, $AsPh_3$ or $SbPh_3$; B = PPh_3, $AsPh_3$ or $SbPh_3$)$\}$, and to interconvert them. In this paper we describe the syntheses of these complexes, which have been characterized by chemical analyses, spectroscopic studies (IR, PMR and mass), the powder X-ray method, and by magnetic-susceptibility measurements.

EXPERIMENTAL

All the reagents were Analar or of chemically pure grade. All the solvents were dried and distilled before use. The reactions were carried out under a dry and pure nitrogen atmosphere. $[(\eta^5\text{-}C_5H_5)RuCl(PPh_3)_2]$, $[(\eta^5\text{-}C_5H_5)RuCl(AsPh_3)_2]$ and $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)_2H]$ were prepared by the literature methods.[7,11]

Preparation of complexes

(*A*) *Preparation of monochloromonocyclopentadienylmonotriphenylphosphine monotriphenylarsine ruthenium(II)* $\{[(\eta^5\text{-}C_5H_5)RuCl(AsPh_3)(PPh_3)]\}$ (**1**). A solution of $[(\eta^5\text{-}C_5H_5)RuCl(PPh_3)_2]$ (0.500 g, 7.0×10^{-4} mol) and $AsPh_3$ (0.4 g, 1.3×10^{-4} mol) in 60 cm^3 benzene was heated to reflux for 25 h. The resulting solution was concentrated to near dryness, the residue extracted by CH_2Cl_2 and the complex precipitated from the extract by using petroleum ether. It was centrifuged and purified by recrystallization from CH_2Cl_2–petroleum ether. It was filtered, washed with petroleum ether, and dried. The orange-yellow complex **1** was analysed (yield *ca* 78%).

(*B*) *Preparation of monohydridomonocyclopentadienylmonotriphenylarsine monotriphenylphosphine ruthenium(II)* $\{[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)H]\}$. (i) *Using* NaOMe–MeOH. A mixture of the orange-yellow coloured complex **1** (0.1 g, 1.3×10^{-4} mol) and sodium metal (0.20 g, *ca* 0.009 g atm) in 15

*Present address: S.C.P.G. College, Ballia 277001, India.
†Author to whom correspondence should be addressed.

cm^3 methanol was heated to reflux until all the starting material was dissolved (*ca* 20 min) with the simultaneous formation of a precipitate from the solution near the glass surface, which was separated by centrifugation, washed with small quantities of methanol, and dried *in vacuo*. It was identified as $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)H]$ by analyses (yield *ca* 50%).

(ii) *Using* NaOEt–EtOH. The hydrido derivative was also prepared by the same procedure as given in B(i), except that ethanol (15 cm^3) was used in place of methanol. The yellow complex was collected and identified by chemical analyses and by comparing it with that prepared in B(i). Both samples were found to be identical.

(*C*) *Preparation of mono(fluoro, bromo or iodo)-monocyclopentadienylmonotriphenylarsine monotriphenylphosphine ruthenium(II)* $\{[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)X]$ (X = F, Br *or* I)$\}$. (i) *Using* HX (X = F, Br *or* I). A yellow suspension of $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)H]$ (0.1 g, 1.4×10^{-3} mol) in methanol (15 cm^3) was treated with concentrated HX (five or six drops). Immediately, the yellow suspension dissolved to form a light yellowish-orange coloured solution which was stirred for about 10 min, whereby a brownish-orange precipitate deposited. It was collected by centrifuging the solution, washed with methanol and ether, and dried *in vacuo*. On analysis it was identified as $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)X]$ (yield *ca* 90%).

(ii) *Using* KX (X = Br *or* I). Complexes of $[(\eta^5\text{-}C_5H_5)RuX(AsPh_3)(PPh_3)]$ (X = Br or I) were also prepared by heating under reflux a solution of $[RuCl(AsPh_3)_4(PPh_3)(\eta^5\text{-}C_5H_5)]$ (0.1 g, 1.3×10^{-4} mol) in ethanol (20 cm^3) with KX (0.200 g, *ca* 0.17 mol) for 1 h, whereupon brownish-orange crystals were deposited. These were separated by centrifuging the solution, washed with water, methanol and diethyl ether, and dried. On analysis the complex was identified as $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)X]$ (X = Br or I) (yield *ca* 80%).

(iii) *Using* MeI. The iodo analogue of the complex was prepared by the procedure described in C(i) by treating $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)H]$ (0.1 g, 1.4×10^{-4} mol) with methyl iodide (five or six drops) in methanol (10 cm^3). The resulting complex was identified as $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)I]$.

(iv) The bromo analogue $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)Br]$ was also prepared by heating to reflux a solution of $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)_2Br]$ (0.1 g, 1.2×10^{-4} mol) in ethanol (30 cm^3) with $AsPh_3$ (0.1 g, 3.3×10^{-4} mol) for 15 h, whereupon brown crystals were deposited. These were separated by centrifuging the suspension, washed with ethanol, diethyl ether and petroleum ether. The complex was dried and identified as the bromo derivative (yield *ca* 70%).

(*D*) *Preparation of monocyclopentadienylmonotriphenylarsine monotriphenylphosphinetrichlorotin ruthenium(II)* $\{[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)SnCl_3]\}$. A mixture of $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)Cl]$ (0.1 g, 1.3×10^{-4} mol) and tin(II) chloride (0.05 g, 2.5×10^{-4} mol) was heated to reflux in 15 cm^3 of benzene to which 20 cm^3 of methanol was added. After about half an hour yellow crystals had appeared, which were separated by centrifugation. The centrifugate was further concentrated by heating on a water bath whereby more compound appeared in the concentrate. It was centrifuged, recrystallized from CH_2Cl_2–petroleum ether, washed with petroleum ether, and dried *in vacuo*. The complex was identified as $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)SnCl_3]$ (yield *ca* 60%).

(*E*) *Preparation of monocyanomonocyclopentadienylmonotriphenylarsine monotriphenylphosphine ruthenium(II)* $\{[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)CN]\}$. A mixture of $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)Cl]$ (0.1 g, 1.3×10^{-4} mol) and excess KCN (0.2 g, 3.3×10^{-3} mol) was heated under reflux for 4–5 h in methanol (20 cm^3), whereupon greenish-yellow crystals separated, which were centrifuged. The centrifugate was further concentrated, yielding more of the complex as precipitate. The complex was centrifuged, washed with water, methanol and ether, and dried *in vacuo*. It was identified as $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)CN]$ (yield *ca* 50%).

(*F*) *Preparation of monocyclopentadienylmonotriphenylarsine monotriphenylhosphineacetonitrile ruthenium(II) cationic salts* $\{[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)(MeCN)]^+X^-$ (X = BPh_4, $HgCl_3$ *or* Zn_2Cl_6)$\}$. (i) *Tetraphenylborate salt.* Addition of sodium tetraphenylborate (0.05 g, 1.1×10^{-4} mol) to a solution of $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)Cl]$ (0.07 g, 1.0×10^{-4} mol) in 20 cm^3 acetonitrile, followed by heating for about 20 min under reflux, yielded a yellow solution, which was filtered. The filtrate was concentrated to nearly one-third of the volume ($\sim$5 cm^3). Ether was then added to the concentrate, whereby the complex precipitated. It was then centrifuged and recrystallized from acetonitrile–ether. It was washed with ether and dried *in vacuo*. The complex was identified as $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)(MeCN)]BPh_4$.

(ii) *Trichloromercurate salt.* The reaction was carried out by a procedure similar to that described in F(i) except that mercury(II) chloride was used instead of sodium tetraphenylborate to obtain $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)(MeCN)]HgCl_3$.

(iii) *Hexachlorodizincate salt.* The reaction was carried out by a procedure similar to that described

in F(i) except that zinc(II) chloride was used instead of tetraphenylborate to obtain $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)(MeCN)]_2Zn_2Cl_6$.

The corresponding $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)_2X]$ (X = Cl, Br, I, CN or $SnCl_3$) complexes have also been prepared using the same procedures as described in the above sections.

Interconversions (*Scheme* 1)

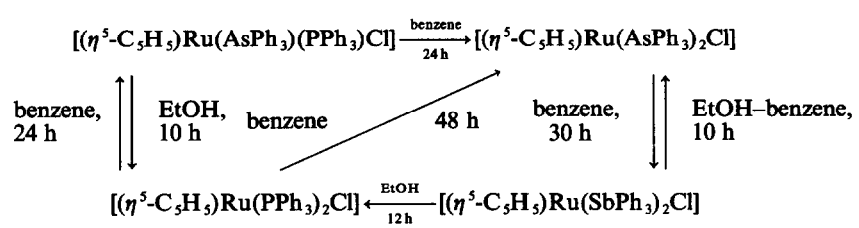
Conversion of $[(\eta^5\text{-}C_5H_5)Ru(SbPh_3)_2Cl]$ *to* $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)_2Cl]$. A mixture of $[(\eta^5\text{-}C_5H_5)Ru(SbPh_3)_2Cl]$ (prepared by a method described elsewhere)[13] (0.1 g, 1.1×10^{-4} mol) and triphenylarsine (0.1 g, 3.3×10^{-4} mol) was refluxed in 20 cm^3 benzene for 12 h. The resulting orange solution was evaporated to dryness, and the residue extracted with 10 cm^3 of dichloromethane. Excess petroleum ether was added to the extract to give the corresponding arsine complex. It was identified by comparing its spectral and analytical data with those of the authentic sample, and by determining the mixed melting point.

Conversion of $[(\eta^5\text{-}C_5H_5)Ru(SbPh_3)_2Cl]$ *to* $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)_2Cl]$. A mixture of $[(\eta^5\text{-}C_5H_5)Ru(SbPh_3)_2(Cl]$ (0.1 g, 1.1×10^{-4} mol) and triphenylphosphine (0.1 g, 3.8×10^{-4} mol) was refluxed in 30 cm^3 of ethanol for 10 h. The resulting solution was evaporated to nearly 5 cm^3, whereby an orange crystalline precipitate appeared. It was centrifuged, washed with ethanol, recrystallized from CH_2Cl_2–petroleum ether, and dried *in vacuo*. The complex was identified as $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)_2Cl]$.

Conversion of $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)Cl]$ *to* $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)_2Cl]$. A mixture of $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)Cl]$ (0.1 g, 1.3×10^{-4} mol) and triphenylphosphine (0.1 g, 4.0×10^{-4} mol was refluxed in 20 cm^3 ethanol for 12 h. The resulting solution was filtered and the filtrate was concentrated to 5 cm^3, whereby an orange crystalline precipitate appeared. It was filtered, washed with ethanol and diethyl ether, and dried *in vacuo*. The complex was identified as $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)_2Cl]$.

Conversion of $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)Cl]$ *to* $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)_2Cl]$. A mixture of $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)Cl]$ (0.5 g, *ca* 6.5×10^{-4} mol and triphenylarsine (0.2 g, 6.4×10^{-4} mol) was refluxed in benzene (20 cm^3) for 24 h. The solution was then centrifuged and the centrifugate evaporated to near dryness. The residue was extracted with CH_2Cl_2, and excess petroleum ether was added to the extract to yield a crystalline product which was identified as $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)_2Cl]$.

Physical measurements



Carbon, hydrogen and nitrogen analyses were carried out by the Microanalytical Laboratory of the I.I.T., Kanpur, India. The percentage of halide in the sample was determined by the standard method[12] in the filtrate obtained after fusing the sample with the fusion mixture, extracting it with distilled water and filtering it. IR, UV and visible, ^1H NMR, ^{31}P NMR and mass spectra, magnetic measurements and powder X-ray data were determined by the methods described elsewhere.[13] The results are given in Table 1. All the complexes were found to be diamagnetic. The molecular weight of complex **1** was determined by using a Knauer vapour pressure osmometer.

RESULTS AND DISCUSSION

The analytical data of the yellowish-orange, air-stable complex **1** and other substitution products suggested that their formula was $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)X]$. Complex **3** was obtained as a result of the substitution reaction of $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)_2Cl]$ with triphenylarsine. It was found to be highly soluble in $CHCl_3$ and CH_2Cl_2, partially soluble in ethanol, methanol and diethyl ether, and insoluble in petroleum ether and *n*-hexane. This formulation was further confirmed by the results of the following experiments:

(i) Its experimentally determined molecular weight (752) by osmometer as against the theoretical value of 770.

(ii) By the presence of peaks in its mass spectrum

Scheme 1. Interconversion of various complexes.

[a] d = decomposition.
[b] YO = yellowish-orange, B = brown, OR = orange-red, Y = yellow, YG = yellowish-green, BR = brick-red.
[c] Solvent $CDCl_3$. Aromatic protons of the other coligands appeared in the region of δ 7–8 as broad multiplets, and in the case of acetonitrile additional signals in the δ-1.8–2.0 region were observed due to the methyl protons.

with m/z values of 306, 262 and 201, corresponding to $AsPh_3$, PPh_3 and [RuCpCl], respectively. (Since the purpose of this study was just to detect the presence of $AsPh_3$ and PPh_3 fragments, no attempt has been made to explain other relatively less intense peaks.)

(iii) Complex **1** was subjected to substitution reactions which led to the scission of the Ru—Cl bond and yielded $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)X]$ as substituted products (X = Br, I, F, CN or $SnCl_3$) (Table 1).

(iv) Reactions between complex **1** and zinc or mercury(II) chlorides in acetonitrile produced a rapid colour change from orange to yellow of the solution from which stable yellow complexes were isolated. They were initially thought to be 1:1 adducts of the Ru complex acting as a Lewis base. Further investigations revealed that the products were salts of the cation $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)(MeCN)]^+$. The cationic nature has been tested by ion exchange studies.

It has been observed that, by refluxing a solution of $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)Cl]$ with either PPh_3 or $AsPh_3$, it was possible to convert them to the known compounds $[(\eta^5\text{-}C_5H_5)Ru(MPh_3)_2Cl]$ (M = P or As). These reactions have been further extended and the PPh_3 or $AsPh_3$ can easily be substituted by triphenylstibine ($SbPh_3$) simply by refluxing the solution of $[(\eta^5\text{-}C_5H_5)Ru(MPh_3)_2Cl]$ (M = P or As) with $SbPh_3$. It has, however, been observed that the time of refluxing for the substitution reaction of the complex having PPh_3 as a coligand with $AsPh_3$, was much longer compared to the complex having a $AsPh_3$ as coligand. This could possibly be due to the similarity of some of the chemical properties of the alternate elements in a group.[14] This is, however, a tentative explanation.

The properties of the substitution products of $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)Cl]$ and $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)(MeCN)]^+$ are given in Table 1. Their formulae have been assigned on the basis of the chemical analyses and other properties discussed below.

IR spectra

The IR spectra of all the complexes exhibited two bands of medium intensity in the 840–850- and 420-cm^{-1} regions, corresponding to the C—H out-of-plane and skeletal bending modes of the C_5H_5 ring, respectively, besides the characteristic bands[15] of triphenylphosphine and triphenylarsine (1490, 1440, 1100, 750, 700 and 535 cm^{-1}). Since the band positions due to the phenyl groups of $AsPh_3$ and PPh_3 in their IR spectra do not appreciably vary it was difficult to distinguish the presence of both triphenylarsine and triphenylphosphine in the same complexes by the IR spectra. However, it has been observed that all the phenyl bands in the IR spectra of the complexes $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)X]$ were relatively broader compared to those found in $[(\eta^5\text{-}C_5H_5)Ru(MPh_3)_2X]$ (M = P or As). This broadness could possibly be taken tentatively as evidence for the presence of both $AsPh_3$ and PPh_3 in the complexes, as indicated by other experiments. The IR spectra of all the complexes displayed a characteristic pattern of three bands decreasing in intensity from 535 to 495 cm^{-1}, which suggests the presence of a triphenylphosphine- or triphenylarsine-coordinated ligand.[16] Spectra of the cyanato and hydrido complexes exhibited medium-intensity, slightly broad bands at 2050 and 1950 cm^{-1}, assigned to ν(CN) and ν(Ru—H), respectively,[7,8,17] confirming the presence of a CN^- or H^- ion bonded to ruthenium in the complexes.

It is interesting to observe that the ν(CN) band in all complexes having a coordinated isonitrile around 2100 cm^{-1} is very weak. A low value of the transition moment is usually observed in these type of complexes.[18,19] In the 400–200-cm^{-1} region bands assignable to $[Zn_2Cl_6]^{2-}$ and $[HgCl_3]^-$ anions, besides those due to ν(Ru—Cl), have been observed. In the spectrum of the mercury derivative a band at 285 cm^{-1}, assigned to the asymmetric mode in $[HgCl_3]^-$, and for the zinc complex the characteristic bands of $[Zn_2Cl_6]^{2-}$ at 335, 305, 252 and 242 cm^{-1}, were present. The positions and relative intensities of the $[Zn_2Cl_6]^{2-}$ bands were found to be similar to those observed in the IR spectra of the solutions of the complexes B^+MCl_3 (B = bipyBPh$_2$, M = Zn or Hg), where it has been suggested[20] that the zinc is present as the bridged $[Zn_2Cl_6]^{2-}$ rather than the mononuclear $[ZnCl_3]^-$ anion.[21]

^{1}H *NMR spectra*

^{1}H NMR spectra of all the complexes showed a sharp resonance in the δ-4.0–4.5 region. The sharp singlet in this region is characteristic of π-bonded cyclopentadiene. The aromatic group on the triphenylphosphine and triphenylarsine ligands showed broad complex resonances in the usual range of δ 7.0–8.0 for the C_6H_6 protons. The integrated intensity ratio of the signals of C_5H_5 and MPh_3 (M = P or As) (1:6) corresponded to the ratio of the number of hydrogen atoms of the cyclopentadienyl anion and the sum of those present in triphenylphosphine and triphenylarsine. It was reported earlier that a sharp resonance in the NMR spectra of $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)_2Cl]$ and $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)_2Cl]$ appears at δ 4.0 and 4.2 (Fig. 1), respectively.[1] The presence of a peak at δ 4.1 in

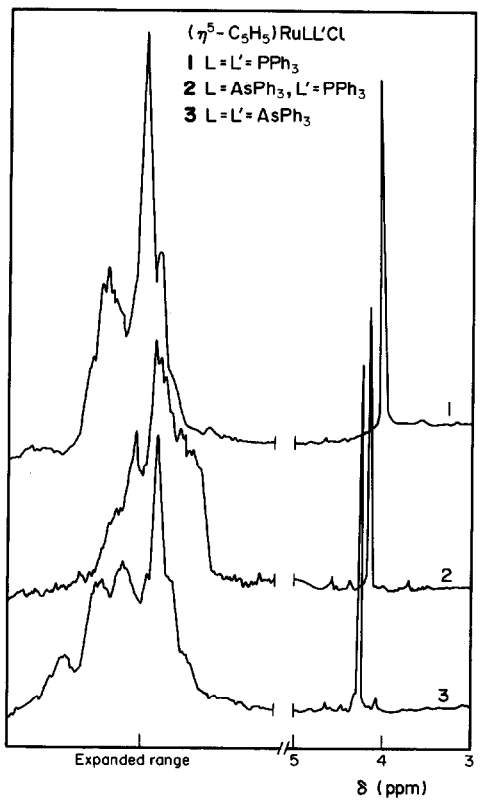

Fig. 1. ^{1}H NMR spectra of Ru complexes.

the complex $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)Cl]$, therefore, suggests the environment of the cyclopentadienyl protons to be different from that in the former two complexes. Furthermore, the presumption that the complex $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)Cl]$ is a 1.1 mixture of $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)_2Cl]$ and $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)_2Cl]$ is also not tenable because of the fact that the NMR spectra of the mixture is expected to exhibit two independent peaks due to cyclopentadienyl protons at δ 4.0 and 4.2, one for each component of the mixture. The presence of only one sharp peak at δ 4.1 suggests only one type of electronic environment around the cyclopentadienyl protons. Further, the spectra of all the complexes showed a broad multiplet in the region of δ 7.8 different from the one present in the spectra of triphenylphosphine and triphenylarsine complexes. The spectra of latter two together did not match the one of complex **1** in the region of δ 7.0, indicating again that it is not a mixture of the phosphine and arsine complexes. In the case of the acetonitrile complexes, an additional signal in the δ-1.8–2.0 region was observed for the methyl protons. ^{31}P NMR exhibited a sharp resonance at δ 39.01, indicating the presence of at least one triphenylphosphine molecule in our complex. The literature indicates one single sharp ^{31}P signal in $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)_2Cl]$ at δ 38.6, indicating the presence of two symmetrical triphenylphosphine molecules.[22] The shifting of the signal in our complex towards a lower value by about δ 0.5 suggests that triphenylphosphine in our complex has different surroundings than in $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)_2Cl]$. These data, along with those of other physical measurements, further confirm the formula to contain one molecule each of triphenylphosphine and triphenylarsine.

Magnetic moments and electronic spectra

All the complexes were found to be diamagnetic, indicating spin pairing. The symmetry of the donor atoms around the metal centre in all these complexes may be considered to be distorted octahedral, based upon the assumption that the cyclopentadienyl group occupies three coordinate sites, or distorted tetrahedral if the perpendicular axis of the C_5-ring is considered to occupy one position. The diamagnetism of the complexes is, however, strongly suggestive of the former alternative, because of the definite possibility of there being spin-free complexes in a tetrahedral environment.

The position of the absorption bands shown in the UV and visible region of the electronic spectra of complex **1** were at 375 nm and a shoulder at 455 nm due to a M → L charge-transfer band. When we compared complex **1** with the $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)_2Cl]$ complex the absorption band showed red shifts.

The powder X-ray photograph of complex **1** is found to be identical to that of $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)_2Cl]$ and $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)_2Cl]$ as far as peak positions are concerned. However, the peak intensities were different from those of the phosphine and arsine analogues as expected because of the difference in the scattering power of P and As. It suggests that these three complexes are isomorphous and the same structure may be assigned to the complex $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)Cl]$ as to $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)_2Cl]$.

CONCLUSIONS

From the above discussion it is postulated that, during the substitution reaction of $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)_2Cl]$ by $AsPh_3$ to yield $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)_2Cl]$ the phosphine molecules are not both simultaneously substituted by two molecules of triphenylarsine, but the reaction proceeds by a stepwise mechanism with the formation of a stable intermediate complex having one molecule of phosphine and one molecule of arsine as coligands. Various derivatives of the $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)$

$(PPh_3)X]$ (X = Br, I, CN or $SnCl_3$) have been prepared and characterized. Their structures are assumed to be the same as those of their respective phosphine analogues. Although it has also been observed that phosphine, arsine and stibine analogues of the complexes $[(\eta^5\text{-}C_5H_5)Ru(MPh_3)_2Cl]$ (M = P, As or Sb) can be interconverted simply by refluxing the complex with the appropriate compound (MPh_3), the substitution of phosphine or stibine involves a much shorter time of refluxing compared to that of arsine.

Abstract—Homo-trinuclear complexes of general formula $[M_3LCl_2(H_2O)_3]$ [M = Mn(II), Co(II) or Ni(II); H_4L = bis-(resacetophenone)-2,6-dipicolinoyldihydrazone] have been synthesized. The ligand acts as a tetrabasic nonadentate (N_5O_4) chelating agent. The complexes have been characterized on the basis of elemental-analysis, electrical-conductance and IR spectral data.

In recent years, an increasing number of homo-binuclear or homo-bimetallic complexes of first-row-transition metal ions with a variety of binucleating ligands have been studied.[1,2] The majority of these complexes involve two metal ions in similar environments of four-, five- or six-coordination. Very few examples are known in which each of the two metal ions possesses a different stereochemistry and spin-state.[3,4] A number of trimeric or tetrameric bivalent metal complexes involving multidentate ligands of varied denticity are known.[4,5] All these complexes could be obtained as a result of the tendency of the metal ions to polymerize the organic-ligand systems. However, it appears that no trinuclear or trimetallic complexes of trinucleating ligands of type M_3L, $M_2M'L$ or $MM'M''L$ are known in which one ligand molecule coordinates three ions of the same or different metal ions. In this paper we report the isolation of homo-trinuclear complexes of Mn(II), Co(II) and Ni(II) with bis-(resacetophenone)-2,6-dipicolinoyldihydrazone ($rdphH_6$). The complexes are characterized on the basis of elemental-analysis, electrical-conductance and IR spectral data.

EXPERIMENTAL

The dimethyl ester of dipicolinic acid was procured from Midland Yorkshire Tar Distillers Ltd, U.K. All other chemicals used were of A.R. grade and the solvents were purified before use.

The molar-conductance and magnetic measurements, and IR spectra, were recorded as earlier.[6] The elemental analyses were carried out at I.I.T., New Delhi.

2,6-Dipicolinoyldihydrazine ($dphH_2$) was synthesized by refluxing the dimethyl ester of dipicolinic acid (0.1 mol) with hydrazine hydrate (0.2 mol, 99%) for 2 h on a water bath. The product, on repeated crystallization from hot water, gave colourless needles (m.p. 285°C). The ligand, $rdphH_6$, was prepared by the condensation of $dphH_2$ with resacetophenone in methanol on a water bath for 2 h (Fig. 1). Straw-coloured crystals of $rdphH_6$ were formed with a sharp m.p. at 340°C. Found: C, 59.5; H, 4.5; N, 15.1%. Calc. for $C_{23}H_{21}N_5O_6$: C, 59.6; H, 4.5; N, 15.1%. The purity of the ligand was confirmed by thin-layer chromatography.

For trinuclear complexes, the metal salt (0.003 mol) was dissolved in ethanol (50%, 75 cm^3) and the ligand (0.001 mol) was added to it slowly with constant stirring. The mixture was refluxed for about 4 h on a water bath. The pH of the mixture was then raised to ~8 by adding alcoholic potassium hydroxide and the mixture was then digested on a water bath for about 1 h. The solid complex that separated was filtered, washed successively with water and ethanol (50%), and dried *in vacuo* at room temperature.

RESULTS AND DISCUSSION

The analytical results for the complexes (Table 1) indicate that they possess a 3:1 metal–ligand stoichiometry. The molar-conductance values in

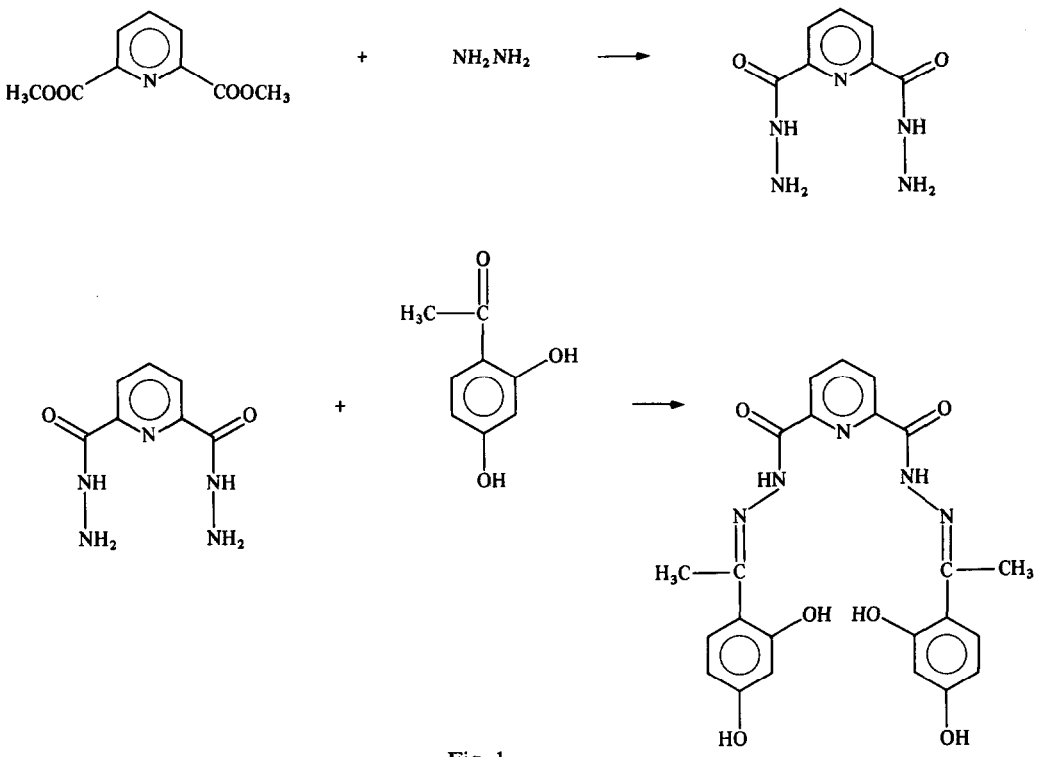

Fig. 1.

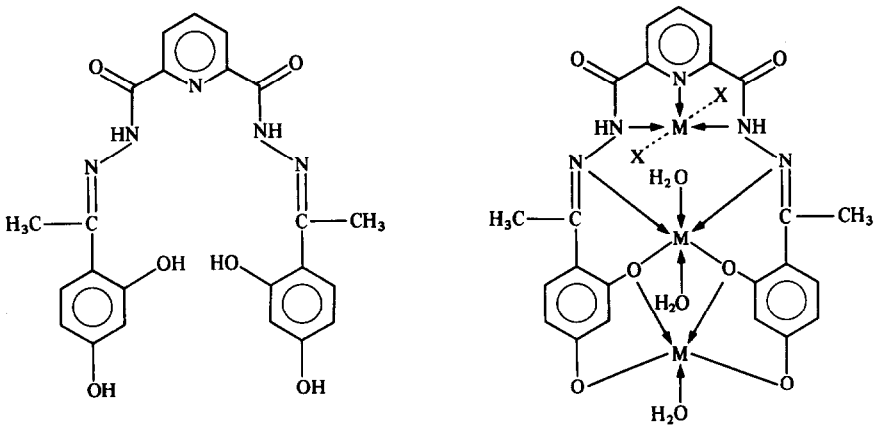
DMF are consistent with the non-electrolytic nature of the complexes.

The magnetic moments (Table 1) at 293 K indicate that the values are appreciably lower than those observed for the high-spin metal ions, possibly due to metal–metal interaction and anti-ferromagnetic exchange in the complexes,[7] but measurements over a temperature range are required.



The important IR spectral bands along with their assignments for the ligand and their complexes are discussed here. These assignments are based on the study of the metal complexes of 2,6-dphH_2 and its hydrazones.[8,9] The IR spectra of the ligand show two bands at 3360 and 2625 cm^{-1} assigned to ν(OH) phenolic groups and ν(OH---N=C) intramolecular hydrogen bonding,[10] respectively. These bands disappear in the complexes, indicating bond formation between metal and phenolic oxygen atoms after deprotonation. Two other bands occurring at 1550 and 1260 cm^{-1}, due to phenolic ν(C—O) and δ(C—O), respectively, in the ligand, shift to ~1580 and ~1300 cm^{-1}, respectively, in the complexes. This indicates that these complexes possess oxo-bridges provided by the phenolic oxygen atoms. The presence of oxo-bridging is further supported by the presence of weak-intensity bands in the 790–810-cm^{-1} region in the complexes.[11] A weak band at ~515 cm^{-1} may be assigned to ν(M–O) vibrations.[11]

The bands appearing at 1670, 1480, 1290, 690 and 450 cm^{-1} may be assigned to amide-**I** [ν(CO)], amide-**II** [ν(CN)+δ(NH)], amide-**III**

Table 1. Analytical data, conductances and magnetic moments of the complexes of rdphH_6 (L = rdphH_2 = $C_{23}H_{17}N_5O_6$)

Complex	Colour	M.p. (°C)	Found (calc.) (%) C	H	N	Cl	Metal	Λ_M (Ω^{-1} cm^2 mol^{-1})	μ_{eff} (BM)

Ligand

Fig. 2.

[ν(CN)+δ(NH)], amide-**IV** (C=O in-plane deformation) and amide-**VI** (C=O out-of-plane deformation) vibrations, respectively,[8,9] in the free ligand. These bands appear in the 1680–1685-, 1440–1450-, 1305–1310-, 705–710- and 465–470-cm^{-1} regions, respectively, in the complexes. The upward shift in amide-**I**, amide-**III**, amide-**IV** and amide-**VI**, and downward shift in amide-**II** bands are compatible with a secondary amide-nitrogen coordination to a metal atom. A broad band at 3300 cm^{-1} in the free ligand and the complexes due to ν(NH) indicates that this group remains intact during complexation. A medium band at 1620 cm^{-1} attributable to ν(C=N) of the azomethine group in the ligand appears at a lower frequency (1605 cm^{-1}) in the complexes, indicating the coordination of imino-nitrogen to the metal atom.[12] The bands appearing at 440, 435 and 450 cm^{-1} may be assigned to ν(Mn–N), ν(Co–N) and ν(Ni–N) vibrations, respectively.

The pyridine-ring vibrations most affected on its coordination to a metal atom include 8a (pyridine-ring deformation), 8b (pyridine-ring breathing), 6a (in-plane ring deformation) and 16b (out-of-plane ring deformation).[13] In the free ligand, these vibrations occur at 1595, 1060, 640 and 420 cm^{-1}, respectively. These bands appear at higher frequencies (*ca* 1600, 1080, 660 and 450 cm^{-1}, respectively) in the complexes. The upward shift in these vibrations of the pyridine ring indicates its coordination with a metal atom.[14] The medium bands appearing at 250, 265 and 260 cm^{-1} may be assigned to ν(Mn–Py), ν(Co–Py) and ν(Ni–Py) vibrations, respectively.

The bands appearing at 300, 310 and 305 cm^{-1} may be assigned to ν(Mn–Cl), ν(Co–Cl) and ν(Ni–Cl) vibrations, respectively.[10] Four new bands appear in the 3430–3440-, 1615–1620-, 795–800- and 520–545-cm^{-1} regions attributable to ν(OH), δ(OH), $\delta\nu$(H_2O) and $\delta\omega$(H_2O) vibration modes, respectively, of the coordinated water molecules in the complexes.[10]

On the basis of the preceding discussion it appears that the ligand acts as a nonadentate chelating agent having coordination sites at one pyridine-nitrogen, two azomethine-nitrogen, two secondary-amide-nitrogen and four phenolic oxygen atoms (Fig. 2).

(*Received* 10 *July* 1985; *accepted after revision* 2 *January* 1986)

Abstract—The kinetics of the reactions of Ru(II) complexes with $CS_2N_3^-$ ions were studied spectrophotometrically. The formation rate constants data for *trans*-$[Ru(NH_3)_4L(CS_2N_3)]$ are 2.2×10^2, 1.8×10 and $1.3 \times 10^2\ M^{-1}\ s^{-1}$ for L = SO_3^{2-}, HSO_3^- and $P(OEt)_3$), respectively [μ = 1.0 M ($NaCF_3COO$), 25°C]. Under the same experimental conditions, the values of k^{-1} (specific rate for the aquation reaction) are 1.5×10^{-2}, 5.0×10^{-2} and $4.5 \times 10\ s^{-1}$ for L = SO_3^{2-}, HSO_3^- and $P(OEt)_3$, respectively. The free-energy change (ΔG^+) for the systems where L = $P(OEt)_3$ and SO_3^{2-} are in agreement within the experimental error. It was observed that the affinity of the $CS_2N_3^-$ ion decreases with the increasing π-acidity of the auxiliary ligand L. The order of affinity of the $CS_2N_3^-$ ion for the Ru(II) center studies is $SO_3^{2-} > HSO_3^- > P(OEt)_3 > SO_2$.

The compound 1,2,3,4-thiatriazole-5-thiolate acid [HCS_2N_3] (pK = 1.5, μ = 1.0) is the first member of the thiatriazole series. Its chemistry is worthy of study.

After the development of adequate preparation, storage[1] and analytical determination methods[2,3] for the 1,2,3,4-thiatriazole-5-thiolate ion ($CS_2N_3^-$) (Fig. 1), studies have been carried out on its complexing properties[3,4] and electron-transfer reactions.[5]

The data obtained thus far on formation constants,[4] electrochemical measurements[5–8] and chemical reactivity[9–11] suggest a soft-base character for the $CS_2N_3^-$ anion.

The Ru(II) centers (soft acids) are inert to substitution reactions. The substitution of the NH_3 group from the $[Ru(NH_3)_5(H_2O)]^{2+}$ complex from a position *trans* to water by an auxiliary ligand L, with π-acid character transforms the π-electron density of the central atom, strikingly affecting the metal capacity for back-donation.[12–15] Because of this characteristic, Ru(II) tetraammines represent excellent models for the study of the chemical behaviour of the $CS_2N_3^-$ ion as a ligand towards metal centers of different acidity.

In the course of the investigation of the reactivity of Ru(II) ammines, soft acids, and of HCS_2N_3 chemistry, we report here some results on the $[Ru(NH_3)_5(H_2O)]^{2+}$–$CS_2N_3^-$ and *trans*-$[Ru(NH_3)_4L(H_2O)]$–$CS_2N_3^-$ systems, where L = SO_3^{2-} and $P(OEt)_3$.

EXPERIMENTAL

Solvents and reagents

(a) Imidazole (imN): *puriss* grade 99% (Aldrich) was used as supplied. (b) Triethyl phosphite

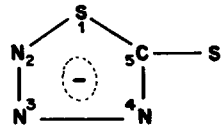

Fig. 1. Structure of the $CS_2N_3^-$ ion.

* Address to whom correspondence should be addressed.

$[P(OEt)_3]$ (Aldrich) was purified by distillation over metallic sodium as usual.[16]

The purification of carbon disulphide and sodium azide and the preparation and storage of sodium 1,2,3,4-thiatriazole-5-thiolate have been previously described.[1,4,6] Solvents were purified and dried by standard methods.[17,18] All other chemicals were of analytical purity and used as supplied.

Ru *complexes*

$[Ru(NH_3)_5(H_2O)](PF_6)_2$,[19] $[Ru(NH_3)_6]Cl_2$,[20] $[Ru(NH_3)_5Cl]Cl_2$,[21] *trans*-$[Ru(NH_3)_4SO_2Cl]Cl$[22] and *trans*-$[Ru(NH_3)_4(P(OEt)_3)_2](PF_6)_2$[14] were synthesized as described in the literature.

Apparatus and methods

Spectra. UV and visible spectra were recorded on a Varian–Tectron spectrophotometer, model 635.

Kinetic experiments. Slow reactions were followed using the same spectrophotometer. An Aminco–Morrow stopped-flow apparatus was used for rapid reactions. The reactions were studied with ligand concentrations $\geqslant$ 10-fold that of the complex. Under these conditions, in all experiments, pseudo-first-order rate constants (k_{obs}) were obtained. These were determined graphically by plotting $\log(A_\infty - A_t)$ vs time, where A_∞ was the final absorbance value and A_t the absorbance at time t. Rate constants were reproducible to within $\pm 5\%$. The plots of k_{obs} vs $[CS_3N_3^-]$ are linear with a positive intercept. The observed pseudo-first-order rate constant for approach to equilibrium in reaction (1):

$$\textit{trans}\text{-}[Ru(NH_3)_4L(H_2O)] + CS_2N_3^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \textit{trans}\text{-}[Ru(NH_3)_4L(CS_2N_3)] + H_2O, \quad (1)$$

where L = SO_3^{2-}, $P(OEt)_3$, HSO_3^- or NH_3, is given by the expression:

$$k_{obs} = k_1[CS_2N_3^-] + k_{-1}.$$

Values of k_1 and k_{-1} were calculated from the slope and intercept of plots of k_{obs} vs $[CS_2N_3^-]$.

The rate constant for aquation of *trans*-$[Ru(NH_3)_4L(CS_2N_3)]$ in some cases was measured using a high excess (100 times) of a competitor ligand, imN, to eliminate the reverse reaction according to the following scheme:

$$\textit{trans}\text{-}[Ru(NH_3)_4L(CS_2N_3)] + H_2O \xrightarrow[\text{slow}]{k_{-1}} \textit{trans}\text{-}[Ru(NH_3)_4L(H_2O)] + CS_2N_3^-, \quad (2)$$

$$\textit{trans}\text{-}[Ru(NH_3)_4L(H_2O)] + \text{imN} \xrightarrow{\text{fast}} \textit{trans}\text{-}[Ru(NH_3)_4L(\text{imN})] + H_2O. \quad (3)$$

The pH was adjusted by using buffers as follows. For $[Ru(NH_3)_4P(OEt)_3(H_2O)]^{2+}$, pH = 3.0 ($HCF_3COO$); $[Ru(NH_3)_4(SO_3)(H_2O)]^{2+}$, pH = 9.0 ($NaHCO_3$) and $[Ru(NH_3)_4(HSO_3)(H_2O)]^{2+}$, pH = 3.7 and 4.7 ($NaCH_3COO$–$HCH_3COO$). Ionic strengths (1.0 M) were adjusted in all cases with sodium trifluoroacetate. The temperature was adjusted before each experiment. Due to the air sensitivity of Ru(II) complexes all manipulations were carried out in an inert atmosphere of argon or nitrogen.

The equilibrium constants (K_{eq}) were evaluated by the k_1/k_{-1} ratio. For some cases, K_{eq} were calculated also by using the method described by Babko and Pilipenko,[23] employing the following expressions:

$$P = \frac{C_z''}{C_z'} = \frac{A_2}{A_1}, \quad C_z' = \frac{C_x(C_L'' - PC_L')}{P(C_L'' - C_L')},$$

and (4)

$$K_{eq} = \frac{PC_z'}{(C_x - PC_z')C_L''},$$

where C_x = initial concentration of metallic ion, C_L' and C_L'' = the ligand concentrations, C_z' and C_z'' = the complex concentration in the ligand's solutions where the concentrations are C_L' and C_L'', respectively, and A_1 and A_2 = the absorbance values of complex solutions C_z' and C_z''.

The activation parameters quoted were calculated by unweighted least-squares analysis of specific rate data over three temperatures, employing Eyring's equations[24,25] from plots of $\log(k/T)$ vs $1/T$.

RESULTS

The reactions of *trans*-$[Ru(NH_3)_4L(H_2O)]$ and the $CS_2N_3^-$ ion were studied under pseudo-first-order conditions. The experimental data for the k_{obs} are summarized in Table 1. The values of k_1, k_{-1} and K_{eq} are listed in Table 2.

For L = SO_2, HSO_3^- and SO_3^{2-}, the substitution reactions were studied over a wide range of hydrogen ion concentrations.

The coordinated sulfite adopts several forms as a function of pH,[21] according to the scheme:

$$[Ru(NH_3)_4SO_2(H_2O)]^{2+} \underset{+H^+}{\overset{-H^+}{\rightleftharpoons}} [Ru(NH_3)_4HSO_3(H_2O)]^+ \underset{+H^+}{\overset{-H^+}{\rightleftharpoons}} [Ru(NH_3)_4SO_3(H_2O)]. \quad (5)$$

[b] pH = 4.7.
[c] pH = 3.7.
[d] Determined by the method described by Babko and Pilipenko.[23]

Within a low-pH range (1.15–3.15) the Ru complex is present as sulphur dioxide, whereas the predominant form at pH values higher than 6.0 is the sulfite.

In order to obtain more accurate data, the k_{-1} values were also determined from the aquation reactions on $[Ru(NH_3)_4SO_3(CS_2N_3)]^-$, using imN as the competitor ligand.

The *trans*-$[Ru(NH_3)_4SO_2(H_2O)]^{2+}$ complex ion exists[13] in aqueous solutions since $C_{H^+} > 10^{-3}$ M. The complete conversion of the HSO_3^- into the SO_2 form occurs in the medium where $C_{H^+} = 0.5$ M. Under these conditions, the $CS_2N_3^-$ ion is protonated.[4] The solution formed by mixing the above reagents as $C_{H^+} = 10^{-1.8}$ M and $C_{H^+} = 1.0$ M shows an absorption band at 390 nm ($\varepsilon = 2 \times 10^3$ $M^{-1}\,cm^{-1}$). In the case where $C_{H^+} = 10^{-1.8}$ M, the

first possibility is coordination either by nitrogen N-4 or by the extracyclic sulphur atom, whereas, when $C_{H^+} = 1.0$ M, with the sulphur atom protonated,[4] coordination must occur by nitrogen (Fig. 1).

Spectrophotometric measurements at 390 nm in solutions where $C_{H^+} = 10^{-1.8}$ permit estimation of the order of magnitude of the equilibrium constant:

$$trans\text{-}[Ru(NH_3)_4SO_2(H_2O)]^{2+} + HSCSN_3 \rightleftharpoons [Ru(NH_3)_4SO_2(HSCSN_3)]^{2+} + H_2O, \quad (6)$$

which must be lower than 10 M^{-1}.

Since the pseudo-halide $CS_2N_3^-$ is unstable in acidic media[1] where $C_{H^+} > 10^{-3}$ M, these studies were discontinued.

For L = $P(OEt)_3$, the reactions were studied at pH = 3.0 and at temperatures of 5.0, 15.0 and 25.0°C. Figure 2 shows a plot of k_{obs} vs $[CS_2N_3^-]$. The results are summarized in Table 3. As for the SO_3^{2-} system, the k_{-1} values obtained from graphic extrapolation were too close to the origin (Fig. 3).

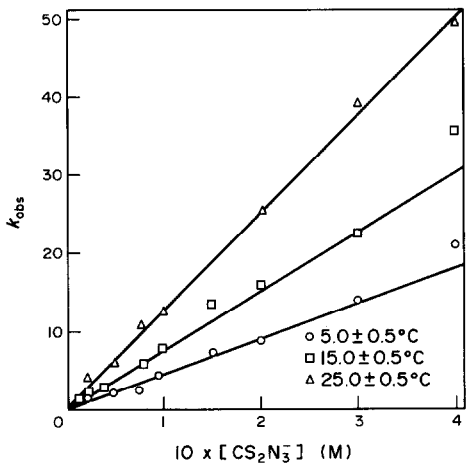

Fig. 2. Dependence of the observed constant, k_{obs} on the concentration of the ligand for the formation of the *trans*-$[Ru(NH_3)_4P(OEt)_3(CS_2N_3)]^+$ complex. $\mu = 1.0$ M, pH = 3.0.

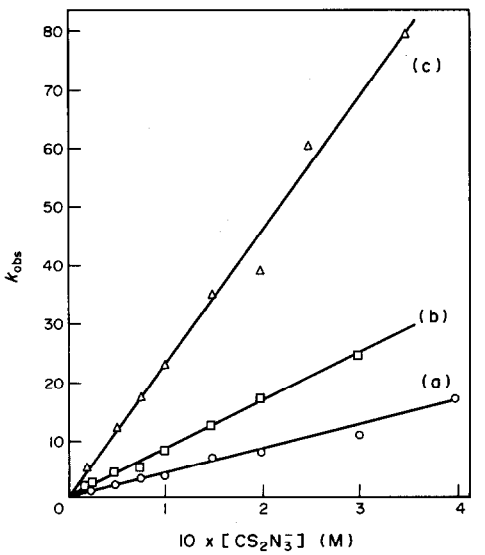

Fig. 3. Dependence of the observed constant, k_{obs} on the concentration of the ligand for the formation of the *trans*-$[Ru(NH_3)_4SO_3(CS_2N_3)]^-$ complex, $\mu = 1.0$ M, pH = 9.0. (a) 5.0±0.5°C. (b) 15.0±0.5°C. (c) 25.0±0.5°C.

Thus, to obtain better data for k_{-1}, the aquation of *trans*-$[Ru(NH_3)_4P(OEt)_3(CS_2N_3)]^+$ was studied in the presence of imN as the competitor ligand. The results of this method are in good agreement with those obtained by *trans*-$[Ru(NH_3)_4P(OEt)_3(CS_2N_3)]^+$ aquation.

In the case where L = NH_3, solutions of $CS_2N_3^-$ and $[Ru(NH_3)_5H_2O]^{2+}$ mixed in acidic medium in the absence of oxygen develop a reddish colour.

The electronic spectrum exhibits two peaks at 510 and 430 nm. However, when the spectrum is taken on the stopped-flow time scale, another peak is observed at 460 nm. This absorption band at 460 nm does not grow in the same proportion as the other two but disappears after 10 s.

DISCUSSION

[b] pH = 9.0 ($NaHCO_3$).
[c] pH = 3.0 (HCF_3COO). The $\Delta G^{\pm}_1$ and $\Delta G_1^{\ddagger}$ data have an uncertainty of ±2 kcal mol^{-1}.

SO_3^{2-} are in agreement within the experimental error. The substitution reactions for the Ru(II) ammines, 18-electron systems, are governed mainly by dissociative activation. Thus, although no evidence for rate saturation has been observed for the systems dealt with in the present study, these reactions, by analogy with data observed for other Ru(II) systems,[13,14] are supposed to occur by a dissociative mechanism.

Except for the pentaammineaquoruthenium(II) complex ion, all other Ru(II) complexes behave as a monocoordinative center, mainly owing to the *cis*-delabilizing effects of the SO_2, HSO_3^-, SO_3^{2-} and $P(OEt)_3$ ligands. For the $[Ru(NH_3)_5(H_2O)]^{2+}$–$CS_2N_3^-$ system, two bands are initially observed at 428 and 514 nm, probably due to the *cis*-ammonia labilization.

As judged from continuous-variation plots at several wavelengths, the product of the reaction between $[Ru(NH_3)_5(H_2O)]^{2+}$ and $CS_2N_3^-$ has a stoichiometry of 1:1. The labilization of the *cis*-ammonia and the decomposition of the ligand, probably assisted by the metal center, are additional complications in the substitution process of the $[Ru(NH_3)_5(H_2O)]^{2+}$ complex ion. This system is currently under study and the results will be published elsewhere.

The λ_{max} for the metal–ligand charge-transfer band (MLCT) observed for the P(III)–Ru(II)–$CS_2N_3^-$ and S(IV)–Ru(II)–$CS_2N_3^-$ complexes are 390, 390, 410 and 420 nm for $P(OEt)_3$, SO_2, HSO_3^- and SO_3^{2-}, respectively. The shift on the λ_{max} for the MLCT band in such complexes is related to the availability of the Ru(II) $4d_\pi$-electrons for back-bonding with $CS_2N_3^-$: the lower the energy of the transition, the stronger the back-bonding Ru(II) → $CS_2N_3^-$.

Based on the energy of MLCT bands, the order of the π-acidity of the auxiliary ligands L coordinated to the Ru(II) center in L–Ru(II)–$CS_2N_3^-$ complexes is:

$$NH_3 < SO_3^{2-} < HSO_3^- < SO_2 \sim P(OEt)_3.$$

The affinity of the L–Ru(II) centers with respect to the $CS_2N_3^-$ ion, measured by the formation constants of derivatives L–Ru(II)–$CS_2N_3^-$ decreases with increasing π-acidity of the auxiliary ligand L, and the affinity order is

$$SO_3^{2-} > HSO_3^- > P(OEt)_3 > SO_2.$$

The studies on Ru(II) and Ru(III) aquopentaammine systems, although limited, showed that the mercaptide ligands, RS^-, are very strong σ-donors and weak π-acids. However, this does not seem to be the behaviour of $CS_2N_3^-$, a weak σ-base. The HCS_2N_3 acid has a pK_a of 1.5 and exhibits properties of mercaptans. The order of Ru(II) center affinity towards $CS_2N_3^-$ strongly suggests that the π-bonding is important in such systems.

Comparing $CS_2N_3^-$ with other pseudo-halides,[27] with respect to the *trans*-$[Ru(NH_3)_4P(OEt)_3(H_2O)]^{2+}$ ion affinity the following order can be established: $SCN^- < N_3^- < CS_2N_3^- \ll CN^-$. The position of 1,2,3,4-thiatriazole-5-thiolate in this series is close to CN^-, a biphilic ligand, a strong σ-base and a strong π-acid.

Another point that deserves comment is the binding site of the $CS_2N_3^-$ anion. The affinity of $CS_2N_3^-$ toward several metal cations and the chemical reactivity of this anion suggest the sulphur atom to be the reactive center.[4,6] Quantum mechanical calculations for this molecule[28] have shown that the electron density in N-4 and the extracyclic sulphur are not very different. Although the sulphur is more basic than the nitrogen atom, and considering the soft-base character of $CS_2N_3^-$ in the $[Ru(NH_3)_5(H_2O)]^{2+}$ system, the possibility of coordination also through nitrogen with the formation of a chelate ring should not be ruled out. Investigations in this direction are currently in progress and will be reported later.

REACTIONS OF 2,5-PYRROLEDIYLBIS[*N*-(*o*-HYDROXYPHENYLALDIMINE)] WITH SOME METAL IONS

H. A. TAYIM,* A. S. SALAMEH† and U. S. I. MERI

Department of Chemistry, University of Petroleum and Minerals, Dhahran, Saudi Arabia

(*Received* 20 *August* 1985; *accepted after revision* 2 *January* 1986)

Abstract—The novel Schiff-base 2,5-pyrrolediylbis[*N*-(*o*-hydroxyphenylaldimine)] (SBH_2) has been synthesized by the condensation of 2,5-pyrroledicarboxaldehyde and *o*-aminophenol. The reactions of the Schiff-base with several transition- and post-transition-metal ions have been investigated. The Schiff-base reacts as a tetradentate dianion without deprotonation of the pyrrole. The complexes $M(SB)\cdot nH_2O$ have been isolated and characterized with $n = 1$, 2 or 3; SB is the dianion of the Schiff-base; and M = divalent Mn, Co, Ni, Cu, Zn, Pd, Cd, Pb or UO_2. The binuclear complexes $M(SB)MX_2$ for M = Cu, X = NO_3, and M = Ni or Pd, X = Cl, have also been isolated.

We have recently reported the reactions of 2,5-pyrroledicarboxaldehyde with several transition-metal ions as an introduction to the investigation of the chemistry of the Schiff-base derived from the condensation of this dialdehyde with *o*-aminophenol and *o*-aminobenzenethiol.[1] The present report deals with the reactions of metal ions with 2,5-pyrrolediylbis[*N*-(*o*-hydroxyphenylaldimine)] synthesized from the reaction of 2,5-pyrroldicarboxyaldehyde with *o*-aminophenol.

EXPERIMENTAL

Preparation of 2,5-*pyrrolediylbis*[N-(o-*hydroxyphenylaldimine*)] (SBH_2)

To a solution of 3.00 g 2,5-pyrroledicarboxaldehyde[2] in 50 cm^3 of hot water a solution of 6.11 g *o*-aminophenol in 50 cm^3 hot water was added dropwise through a dropping funnel with continuous stirring of the reaction mixture. The reaction temperature was kept at about 85°C throughout the reaction time of 2 h. The crude solid product that separated was filtered off and recrystallized from hot benzene. The product is golden yellow (m.p. 184–185°C). Yield 5.00 g (67%). It is insoluble in water, ether and hexane; and soluble in DMF, DMSO, chloroform, ethanol, hot benzene, toluene, dioxane and methylene chloride.

Reaction of the Schiff-base SBH_2 *with some metal ions*

The following general procedure was followed in the reactions of the Schiff-base with each of $MnCl_2\cdot 4H_2O$, $CoCl_2\cdot 6H_2O$, $NiCl_2\cdot 6H_2O$, $Ni(acac)_2\cdot(H_2O)_2$, $Cu(NO_3)\cdot 3H_2O$, Cu(acac)OCH_3, $Zn(CH_3COO)_2\cdot 2H_2O$, $Zn(acac)_2\cdot 2H_2O$, $PdCl_2$, $Pd(PhCN)_2Cl_2$, $Cd(CH_3COO)_2\cdot 2H_2O$, $SnCl_2\cdot 2H_2O$, $Pb(CH_3COO)_2$ and $UO_2(CH_3COO)_2\cdot 2H_2O$. To a stirred solution of 0.400 g (1.31 mmol) of SBH_2 in 50 cm^3 ethanol, a solution of an equimolar amount of the reactant metal salt or complex was added slowly. An immediate reaction took place as indicated by the change in colour or the formation of a precipitate. The reaction mixture was stirred overnight. The product was then filtered off and washed with ethanol and petroleum ether, respectively.

Dioxane was used as a solvent for the Schiff-base in the reaction of $Cu(NO_3)_2\cdot 3H_2O$. The salt was dissolved in the minimum amount of water. In the few cases where the salt did not dissolve in ethanol, the solid salt was added slowly to the solution of the Schiff-base. The colours of the products were dark red, dark brown or reddish brown. The Mn(II) complex was deep orange. The yields ranged between 50 and 62% except for $PdCl_2$ and

$MnCl_2 \cdot 4H_2O$ where the yield was only 15%. The molecular mass was determined for the product from the reaction of the Schiff-base with $Cu(NO_3)_2 \cdot 3H_2O$ by mass spectrometry using a JEOL DX 300 instrument. Calc. for $C_{18}H_{11}N_5O_8Cu_2$: 552; found: 551.

RESULTS AND DISCUSSION

The investigation of Schiff-bases derived from 2,5-pyrroledicarboxaldehyde has only recently been started,[3] apparently due to the difficulty of synthesizing the dialdehyde.[2] The reaction of the dialdehyde with *o*-aminophenol readily yields the corresponding Schiff-base SBH_2. The proposed structure (**I**) of the Schiff-base is substantiated by elemental analysis and physico-chemical evidence. Found: C, 71.0; H, 5.1; N, 13.8%: Mol. wt (in $CHCl_3$) 301. Calc. for $C_{18}H_{15}N_3O_2$: C, 70.8; H, 4.9; N, 13.8%; mol. wt 305. The IR spectrum shows ν(OH) at 3400(m), ν(NH) at 3300(s), ν(C=C) at 1650(s) and ν(C=N) at 1615(s).

The Schiff-base has four potential donor atoms: the two azomethine nitrogens and the two phenolate oxygens. Models show that all these donor atoms are simultaneously accessible to a metal ion when the phenolate hydrogens are ionized. The pyrrole nitrogen is another potential donor site if it were deprotonated. Investigation of the reactions of 2,5-pyrroledicarboxaldehyde has shown that this may happen only in appreciably basic media. The dialdehyde itself did not afford transition-metal complexes in neutral media, i.e. under reaction conditions similar to those used in the present investigation. It was not surprising, therefore, to find that the Schiff-base behaved in its reaction with all the metal ions that have been investigated as a dianionic tetradentate ligand $(SB)^{2-}$. Complexes of

SBH_2

divalent metal ions have thus been isolated and characterized. They are formulated as $M(SB)\cdot nH_2O$ (M = Mn, Ni, Cu, Zn, Cd or Pd; $n = 1$: M = Zn; $n = 2$: M = Co or Pd; $n = 3$). The uranyl complex $UO_2(SB)\cdot 4H_2O$ and the tin complex $Sn(SB)Cl_2$ have also been synthesized. The formulae of these complexes are supported by elemental analyses (Table 1) and by spectral evidence. In all these complexes the ligand is tetradentate bonded to the metal through the azomethine nitrogens and the phenolate oxygens. The C=N stretching band in the complexes is lowered by 10–30 cm^{-1} relative to its value in the free Schiff-base, suggesting bonding of the azomethine nitrogens to the metal atom. The ν(NH) observed in the IR spectra of all the complexes around 3300 cm^{-1} supports the fact that the pyrrole is not deprotonated. Moreover, a ν(OH) around 3400 cm^{-1} was observed in the IR spectra of the hydrated complexes.

The colours of the complexes are all intense and dark, varying between red and brown. Even the Mn(II) complex has a deep orange color. This may be due to extensive delocalization of electrons over the skeleton of the planar Schiff-base dianion. The coordination sphere may be completed by solvent molecules or by ions [e.g. $Sn(SB)Cl_2$], whenever this is called for by the nature of the metal ion involved.

Cu(II), Ni(II) and Pd(II) also afforded solvated binuclear complexes of the form $[M(SB)MX_2\cdot$ solvent], where X = NO_3 for Cu(II), and Cl for Ni(II) and Pd(II). In these complexes the species M(SB) behaves as a neutral bidentate ligand that bonds to the other metal atom through the two phenolate oxygens, each of which still has two lone pairs of electrons, even after forming the M(SB) species. In other words, the phenolate oxygens bridge the two metal atoms. The binuclear nature of these complexes is confirmed by molecular weight determination by mass spectrometry.

The behaviour of SBH_2 is similar to the behaviour of the analogous Schiff-base derived from 2,6-pyridinedicarboxaldehyde in every aspect,[4] including the formation of the binuclear complexes. Even the colours, solubilities and melting points of the complexes of both Schiff-bases are very similar. This supports our previous suggestion[4] that the pyridine nitrogen is not involved in bonding to the metal in the complexes of the Schiff-base derived from 2,6-pyridinedicarboxaldehyde.

SYNTHESIS AND CHARACTERIZATION OF Bi(III) COMPLEXES OF 2-AMINOBENZENETHIOL

E. CASASSAS* and T. VISA

Department of Analytical Chemistry, Facultat de Química, Universitat de Barcelona, Av. Diagonal, 647, Barcelona 08028, Spain

(*Received* 17 *September* 1985; *accepted* 7 *January* 1986)

Abstract—Bi(III) complexes with 2-aminobenzenethiol were studied, and the preparation and properties of the new compound tris(2-ammoniumbenzenethiolato)bismuth(III) chloride are reported. Spectral and emf data are consistent with the zwitterionic nature of the ligand. A mercury-bis(2-aminobenzenethiolato)mercury(II) electrode is proposed and used to follow the relative changes in 2-aminobenzenthiol concentration along the course of the complexometric titration of Bi(III) ion with this ligand.

Several solid metal derivatives (normal salts, complex salts and chelates) of 2-aminobenzenethiol (2-abt) are described in the literature. Water-insoluble complexes formed by the Bi(III) ion and 2-abt have been studied by different authors,[1–4] although only Alonzo isolated and analyzed a compound with a well-defined stoichiometry. According to Alonzo, this complex compound is obtained by reacting Bi(III) carbonate suspended in methanol with 2-abt. Other inorganic Bi(III) salts, particularly the trihalides, yield several different products, coloured from orange to red, which have various melting points and lack a defined stoichiometry. In this paper, the preparation of two different Bi(III)–2-abt compounds is described. They are obtained from strongly acidic solutions (hydrochloric acid containing) of Bi(III) nitrate, and are formed within narrow pH ranges during the progressive neutralization of these solutions with sodium hydroxide. The characterization of the two Bi(III)–2-abt compounds and some of their properties (solubility in different solvents, and UV and IR absorption spectra) are also described.

The equilibria in solution which lead to the formation of both bismuth complexes cannot be studied from emf measurements if an indicator glass electrode is used, because it lacks the required precision since, in the strongly acidic reaction medium, the deprotonation of the mercapto group due to its binding to the bismuth atom does not yield any significant acidity change. An emf-based study requires, then, the direct measurement of either the free-ligand concentration or the free-metal-ion concentration during the course of the complexation, and this requires the use of an electrode in the presence of a mercury complex of the implied ligand. An electrode of this type was introduced by Reilley and Schmid[5] to follow potentiometrically a wide variety of complexometric titrations using EDTA in which the electrode was used as an indicator either for the free ligand or for a metal ion different from mercury. This type of electrode has been used with other complexing agents than EDTA. Thus, Galkina *et al.*[6] used a mercury electrode in the presence of 2-mercaptobenzothiazole (HR) or, better, in the presence of the complex HgR_2, for the potentiometric determination of metal ions such as those of nickel, cadmium and lead. They showed that the measured electrode potential is linearly related to the free-ligand concentration. Later, Rusina *et al.*[7] used the same electrode for the determination of several other ions with HR, and established that the electrode potential is determined by the equilibrium $Hg + HR = HgR + H^+ + e^-$.

Similarly, a mercury electrode in the presence of 2-abt is now shown to be useful for following the complexometric titration of the Bi(III) ion (in a citrate-containing medium) with 2-abt as the titrant, since its potential is a linear (although not fully Nernstian) function of the free-ligand concentration. The electrode behaviour allows the confirmation of the 1 : 3 stoichiometry of the new Bi complexes.

EXPERIMENTAL

Commercially available reagents and solvents were used without further purification, except when otherwise stated.

Bi(III) nitrate solution

5.224 g (1.077×10^{-2} mol) of bismuth nitrate pentahydrate (Merck, analytical-reagent grade) is dissolved in 25 cm^3 of conc. hydrochloric acid (approx. 0.30 mol), and 100 cm^3 of water are added. From the resulting solution, which is 8.64×10^{-2} mol l^{-1} in Bi(III) and 2.40 mol l^{-1} in hydrochloric acid, bismuth basic salts do not precipitate.

2-abt solution

8.85 g (7.07×10^{-2} mol) of 2-abt (Aldrich, analytical-reagent grade), previously distilled under nitrogen atmosphere, at reduced pressure (less than 1 mmHg), is dissolved in 250 cm^3 of ethanol plus 250 cm^3 of water, both solvents previously deaerated by prolonged bubbling of nitrogen gas into them. The resulting solution is 14.14×10^{-2} mol l^{-1} in 2-abt (as determined iodatometrically) and it is colourless. It is stored in a nitrogen atmosphere and sheltered from light.

*C and H were analyzed by automated microanalytical techniques, and S, N, Cl and Bi by the following methods:

Mercapto sulphur. After destruction of the complexes by strong acid attack, the HS group was titrated with potassium iodate in the presence of excess iodide and starch as indicator.[8]

Nitrogen. Semimicro-Kjeldahl mineralization and titration.

Bismuth. This was gravimetrically determined as Bi_2O_3. Semimicro samples were calcined to 750°C and the residue was weighed as Bi_2O_3.

Chloride. Chloride was potentiometrically titrated with silver nitrate as a titrant and a Ag–AgCl indicator electrode. A weighed amount of the complex trichloride was decomposed by treatment in the cold with 15 cm^3 of 1.0 mol l^{-1} sodium hydroxide solution, with constant stirring by nitrogen bubbling, for several hours. A dirty pale-yellow insoluble residue, supposed to be mainly bismuth(III) hydroxide, was filtered off and the pure yellow filtrate, once acidified with 10 cm^3 of conc. nitric acid, was titrated with silver nitrate solution. Two potential steps are obtained in the titration curve; the amount of chloride was calculated from the titrant volume needed to proceed from the first to the second potential step.

Synthesis of 2-abt–Bi(III) complexes from hydrochloric acid containing solutions

The solid 2-abt–Bi(III) complexes were obtained through neutralization with sodium hydroxide of the strongly acidic solution resulting from mixing the two solutions described before, according to the following procedures:

Preparation of the complex salt tris(2-ammoniumbenzenethiolato)bismuth(III)chloride [$Bi(SC_6H_4NH_3)Cl_3$] (*complex* I). Into a 1:1 mixture of the two solutions described before, which is of a very intense orange colour, stirred by nitrogen bubbling and maintained in a nitrogen atmosphere, a 1.00 mol l^{-1} sodium hydroxide solution was slowly added, until a microcrystalline orange-yellow precipitate formed. This precipitate was rapidly filtered through a No. 3 sintered-glass filter. The clear and transparent filtrate has a pH lower than 2.0 and is also orange-coloured, but much weaker in colour than before precipitation. The solid collected on the filter was repeatedly washed with a water–ethanol mixture [3:2 (v/v)]. Without any recrystallization it is dried in a vacuum desiccator.

*Elemental analysis.** Found: C, 31.3; H, 3.3; N, 5.7; S, 14.1; Cl, 15.2; Bi, 30.8%. Calc for $Bi(SC_6H_4NH_3)Cl_3$: C, 31.3; H, 3.1; N, 6.1; S, 13.9; Cl, 15.4; Bi, 30.2%.

Preparation of the complex tris(2-aminobenzenethiolato)bismuth(III) [$Bi(SC_6H_4NH_2)_3$] (*complex* II). To the filtrate from the precipitation of the later complex trichloride, further additions of 1.00 mol l^{-1} sodium hydroxide solution were slowly made, while the stirring by nitrogen bubbling was continued, until a spongy orange-red precipitate formed. Additions of sodium hydroxide solution were continued drop by drop until the precipitation was complete, but care must be taken not to exceed pH 4.0. The solid was filtered off through a No. 4 sintered-glass filter, repeatedly washed with a water–ethanol mixture [3:2 (v/v)], and dried in a vacuum desiccator.

Elemental analysis. Found: C, 37.3; H, 3.1; N, 7.5; S, 16.1; Cl, traces: Bi, 35.2%. Calc for $Bi(SC_6H_4NH_2)_3$: C, 37.2; H, 3.1; N, 7.2; S, 16.5; Cl, 0.0; Bi, 35.9%.

The chemical process in chloride determination as described is as follows. The yellow colour of the acidified solution is due to the presence of organic matter proceeding from the 2-abt in the complex. During the sodium hydroxide treatment, the ligand 2-abt is set free and is first quantitatively oxidized to disulphide; later on in the strongly basic medium the latter dismutates into the mercaptide anion RS^-, and a higher oxidation product, e.g. the sulphenate anion RSO^-. The UV spectrum of the final

basic solution, actually, shows the absorption maximum at 297.5 nm which is characteristic of 2-abt. The presence of 2-abt in the acidified solution used for the chloride titration with silver nitrate is also shown by the potentiometric results: the titration curve shows two potential steps, the first one corresponding to the end-point of the precipitation of the silver mercaptide and the second one which is the end-point of the precipitation of silver chloride. In this way, the sulfur content in the complex can be also evaluated. A mean value for the sulfur content in the complex trichloride of 13.2% resulted, with a relative error of 4% be defect, losses being assignable to 2-abt oxidation during the acidification process.

RESULTS AND DISCUSSION

Some physical properties of both bismuth complexes have been determined (solubility in several solvents of different polarities, and spectral properties in the UV–VIS and IR ranges) and emf measurements have been used to study complex formation as well as the conversion of complex I into complex II. The results are discussed as follows.

Solubility

The following solvents were tested: benzene, carbon tetrachloride, chloroform, ethanol, dioxane, carbon disulphide, pyridine, dimethylformamide, dimethyl sulphoxide and water. At a concentration of 1 mg ml^{-1} both complexes are soluble in pyridine, dimethylformamide and dimethyl sulphoxide; complex II is also soluble in dioxane.

UV–VIS absorption spectrophotometry

Solutions of complex I in pyridine show absorption maxima at 400 and 305 nm, in DMF at 387.5, 300 and 267.5 nm, and in DMSO at 400 and 290 nm. The absorption maxima of solutions of complex II are: in pyridine at 400 and 301 nm, in DMF at 400, 277.3 and 267.5 nm, in DMSO at 400 and 295 nm, and in dioxane at 400, 280, 226 and 215.4 nm. Both complexes seem to have the same chromophore group, responsible for the absorption maxima at 400 nm. In complex I the amino group is protonated and cannot coordinate to the metal ion, whereas, in principle, in complex II the situation is the reverse. The evidence afforded by Alonzo[4] and the observed spectral behaviour discount the participation of the amino group in the binding of bismuth in complex II and, therefore, invalidate a chelate structure for this complex. The constancy of the absorption band at 400 nm in the different solvents can be taken as a proof that both complexes have a common mercaptide structure, and that the actual common chromophore must be $[BiS_3]$.

IR absorption spectra

The IR spectrum of complex II was described by Alonzo:[4] that of complex I (obtained either from a KBr pellet or a Nujol mull) shows significant differences, all of which can be assigned to the protonation of the amino group.

Thus, the two bands at 3440 and 3320 cm^{-1} in the spectrum of complex II, which appear at 3440 and 3360 cm^{-1} in the 2-abt spectrum, and which are assigned to the stretching vibrations of NH_2 in the spectrum of complex I are changed into a set of three bands at 3440, 2900 and 2600 cm^{-1}, characteristic of the protonated amino group.[9] Similarly, the zone of the NH_2-deformation bands is changed as a result of protonation: thus, whereas the 2-abt spectrum shows a very strong band at 1618 cm^{-1} and complex II one strong band at 1598 cm^{-1} and a medium-intensity band at 1580 cm^{-1}, the spectrum of complex I has a family of bands at 1610 cm^{-1} (strong), 1555 cm^{-1} (medium), 1540 cm^{-1} (medium) and 1511 cm^{-1} (medium). It must be mentioned that the symmetry properties of complex I, which is a chloride, can be changed on compacting it with potassium bromide to form the pellet used for IR measurements, as observed by Burger[10] in several cases, as a result not only of chloride substitution but even of the entering of bromide into the co-ordination sphere of the metal ion. In the spectrum from the Nujol mull, the mentioned family of bands appears at 1600, 1543, 1538 and 1500 cm^{-1}.

Features which are common to the spectra of both complexes are the following: the band assigned to stretching of the C–S bond (at 680 cm^{-1} in 2-abt), appearing at 675 cm^{-1}; the lack of a band due to SH stretching (which appears at 2537 cm^{-1} in the spectrum of 2-abt); the series of weak bands between 290 and 250 cm^{-1}, which has been assigned for complex II[4] to the Bi–S bond; and, finally, an unassigned band of medium intensity at 815 cm^{-1} (complex I) or at 801 cm^{-1} (complex II).

Potentiometric study of the reaction of Bi(III) with 2-abt

The amount of mercury suitable to form the pool which will act as electrode was left during several hours in contact with an acidic 2-abt solution (about 0.02 mol l^{-1} in 2-abt and between 1.0 and 2.0 M in perchloric acid) in 1 : 1 (v/v) water–ethanol, with constant bubbling of a nitrogen-gas stream.

The contact solution was then extracted, the pool washed with a diluted perchloric acid solution in water–ethanol and the following cell assembled:

$$\text{Treated Hg} \left| \begin{matrix} \text{test solution in} \\ \text{water–ethanol} \end{matrix} \right| \left| \text{NaCl, AgCl} \right| \text{Cl}$$

The cell contains a measured volume of test solution, which contains A mol l^{-1} 2-abt and H mol l^{-1} perchloric acid, was kept under a nitrogen atmosphere, and was connected to the reference half-cell through a Wilhelm-type salt bridge containing 1 M $NaClO_4$ in 1 : 1 water–ethanol. The concentration of 2-abt in the test solution was initially zero, and was increased by successive additions of a 10^{-1}–10^{-2} mol l^{-1} 2-abt solution from a buret. The cell emf was measured with a Radiometer pH-meter PHM64 (precision ± 0.1 mV). After each 2-abt addition the emf reading was taken when stabilized, which happens in less than 1 min (if the mercury has been pretreated as prescribed, but not if clean mercury was used for the electrode construction).

The following behaviour was observed. For each of the potentiometric runs successively done using the same mercury electrode, emf readings showed a linear dependence on log [2-abt] within the 2-abt concentration ranges shown in Table 1. The values of the parameters m and n in the expression $E = m + n \log$ [2-abt] which produce the best fit to the experimental points for each one of the potentiometric runs in a series, together with their correlation coefficients, are given at Table 1. It is observed that in each case linearity is acceptable, but that reproducibility is not. In the first runs, the slope n lies usually in the range of 100–130 mV; when the same mercury pool is used again the numerical value of the slope in each run falls to a value of about 60 mV. The value of the standard potential of the electrode is not wholly reproducible: after the abnormal first run, E^o stabilizes at about 320–340 mV, as is also shown in Table 1.

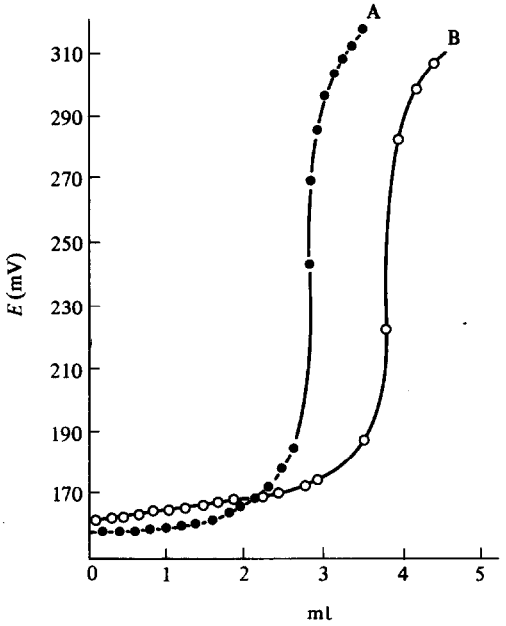

Fig. 1. Titration curves of Bi(III) aqueous solutions, in a citrate buffer of pH 3.50, with a 2-abt titrant solution in 1 : 1 (v/v) water–ethanol, as followed with a treated-mercury indicator electrode. (A) Titration of 20.0 cm^3 of 6.214×10^{-3} mol l^{-1} Bi(III). Titrant: 0.1395 mol l^{-1} 2-abt. (B) Titration of 20.0 cm^3 of 5.579×10^{-3} mol l^{-1} Bi(III). Titrant: 0.0901 mol l^{-1} 2-abt.

The observed behaviour clearly shows that, although the cell employing a treated-mercury electrode cannot be used to calculate the free concentration of ligand in equilibrium with the Bi ion, for instance, because the values of the parameters m and n show slight changes from run to run, it can actually be used to follow the *relative* changes in 2-abt concentration along the course of a potentiometric titration of the Bi ion with 2-abt solution as a titrant. That this is actually the case is shown by the two curves in Fig. 1, which are examples of the titration curves of bismuth(III) chloride solutions which contain excess chloride ion buffered

Table 1. Observed response of a treated-mercury electrode in 2-abt solutions (1.0 mol l^{-1} in $HClO_4$) in 1 : 1 (v/v) water–ethanol

Experiment No.	2-abt concentration range (10^{-3} mol l^{-1})	No. of points	E^o (mV) m	Slope (mV) n	Correlation coefficient

5	2.40–7.50	7	321.3	63.15	0.9953

Table 2. 2-abt/Bi(III) ratio in complex **II**, as determined from potentiometric titrations with 2-abt of 20.0 cm^3 of a Bi(III) solution buffered with citrate

Experiment No.	pH	Bi(III) concentration (mmol l^{-1})	2-abt concentration (mol l^{-1})	Titrant volume (cm^3)	2-abt/Bi(III) ratio
1	3.5	6.214	0.1395	2.80	3.14
2	3.5	5.579	0.0901	3.80	3.06
3	3.5	5.579	0.0901	3.90	3.14
4	3.9	5.432	0.0400	8.64	3.18
5	4.0	7.390	0.0400	11.80	3.19

with citrate at pH 3.5. The potential jump at the end-point is very steep and covers a potential range of over 100 mV.

These properties were used to check the stoichiometric ratio 2-abt : Bi in the new complexes. Complex **I** formation, occurring at pH lower than 2.0 and producing a non-quantitative precipitation of bismuth ion, cannot be followed by potentiometric means with this aim. Complex **II** formation, which is quantitative, occurs at a higher pH and, in order to avoid bismuth hydrolysis or hydroxocomplex precipitation, the potentiometric study must be done in the presence of a suitable complexing agent, such as citrate. The experiment was performed as follows.

Bi(III) solutions were prepared from samples of pure Bi_2O_3 accurately weighed and dissolved in the minimum amount of conc. hydrochloric acid. The resulting solution was made 2.0 mol l^{-1} in sodium citrate, and sodium hydroxide and water were added until the desired pH (in the range 3.5–4.0) was reached and up to volume. This solution was introduced into the potentiometric cell, deaerated with nitrogen gas and titrated with a 2-abt solution in 1 : 1 (v/v) water–ethanol that was previously adjusted to the same pH. The concentration of the titrant was previously determined by titration with potassium iodate.[8] After each titrant addition, emf readings were taken when stabilized. An orange-red spongy precipitate of complex **II** formed during the titration. From the end-point detected in the titration curve the amount of 2-abt reacted and the stoichiometric ratio of reactants in complex **II** were evaluated, as shown in Table 2. The results for the 2-abt/Bi ratio, although they are a little too high, due perhaps to 2-abt co-precipitation or auto-oxidation, confirm the 3 : 1 stoichiometry previously found from the results of elemental analysis.

Conversion of complex **I** *into complex* **II**

The major chemical difference between the two bismuth complexes stems from the amino group of 2-abt, which is protonated in complex **I** and unprotonated in complex **II**. In free 2-abt, the log of the protonation constant for the amino group is $\log K_{H2} = 2.63$.[11] In complexed 2-abt the value of this protonation constant cannot be very different. Then, if the solid complex **I** is suspended in water and shaken for some minutes, an acid–base equilibrium is established (pH is stabilized at about 2.5). The equilibrium can be shifted by titration with sodium hydroxide and complex **I** will be converted into complex **II**.

Three samples of complex **I** (55.0, 50.5 and 35.9 mg) were suspended in water and, after shaking for 30 min, the suspension was potentiometrically titrated with sodium hydroxide solution using a glass-electrode indicator. During the course of the titration, the aspect of the suspended solid actually changes to that of complex **II**, but near the end-point a new change begins to be apparent to a brown denser solid. Since at the end-point emf readings show a steep jump in pH from about 4 to about 11, it is likely that some mixed hydroxocomplex formation takes place. The amounts of sodium hydroxide reacted in the titration of the three mentioned samples were 0.1653, 0.1820 and 0.1199 mmol, respectively, leading to ratios of hydrogen ion titrated per mol of complex **I** equal to 2.08, 2.49 and 2.29, respectively. The conversion into complex **II** is not quantitative in any case, the theoretical value of 3.0 not being reached due to the heterogeneous nature of the phases implied in the acid–base equilibrium.

Abstract—A number of ruthenium(II) complexes of some polydentate O–N, O–O and O–N–O donors in the form of 2-methyl-3-substituted (3*H*)-quinazolin-4-ones have been synthesized and studied. The reaction between $RuCl_2(DMSO)_4$ and the uninegative bidentate ligands yielded complexes of the type $Ru(DMSO)_2(O–O)_2$ (O–O = MHQ, PHQ, MHEQ, MHPQ or MCMQ), displacing only two DMSO groups along with chlorides, whereas the neutral bidentate ligands gave $RuCl_2(O–N)_2$ (O–N = MAQ, PAQ, MANQ, PANQ, MAAQ, MAPQ, MPQ or PPQ), displacing all the DMSO groups. A uninegative terdentate ligand (MHAQ) with O–N–O donors, however, yielded a bis chelate of ruthenium(II).

Quinazolone and its derivatives are widely known for their anti-tubercular,[1] anti-convulsant,[2] anti-amoebic[3] and anti-allergic[4,5] properties. The chelating tendency of these compounds is little known except for a few publications involving similar ligands.[6–8] We report here the synthesis of a series of neutral ruthenium(II) complexes obtained by the reaction of $RuCl_2(DMSO)_4$ with various 2,3-disubstituted quinazolones represented in Fig. 1, where X is invariably a donor group and R a methyl or phenyl group.

EXPERIMENTAL

All analytical data are collected in Table 1. IR and proton NMR spectral data are presented in Tables 2 and 3. The ligands were prepared by reported methods[9–17] (Table 1). The complex $RuCl_2(DMSO)_4$ was prepared by a published method.[18] Elemental analyses and other physical measurements were carried out as reported earlier.[19]

General method for the preparation of ruthenium(II) complexes

The complex, $RuCl_2(DMSO)_4$ (0.2 g) was suspended in toluene (30 cm^3) and refluxed for 1 h with about 4 mol excess of the appropriate ligand in methanol (10 cm^3). During the period of refluxing the whole suspension dissolved, resulting in a clear solution, which was then evaporated under reduced pressure to remove the excess solvent. The residue was treated with diethylether, when the solid complex precipitated. This was filtered off, washed several times with diethylether, dried and recrystallized from methanol–ether to give a pure complex. Yields 50–70%. The complexes are highly soluble in methanol, ethanol and other organic solvents.

[d] The ν(C=N) of quinazoline and pyridyl rings in the MPQ and PPQ ligands.

RESULTS AND DISCUSSION

The complex, $RuCl_2(DMSO)_4$ is an excellent precursor for the synthesis of many new ruthenium(II) complexes and the reactions involving this complex are mainly of the displacement type.[18,19] The reaction of this complex with 2-methyl-3-substituted (3*H*)-quinazolin-4-ones at reflux temperature in toluene was rapid and gave good yields of the complexes. Depending on the nature of the chelate this complex undergoes a variety of reactions. Uninegative bidentate ligands such as MHQ, PHQ, MHEQ, MHPQ and MCMQ yielded $Ru(DMSO)_2(O–O)_2$ and neutral bidentate ligands such as MAQ, PAQ, MANQ, PANQ, MAAQ, MAPQ, MPQ and PPQ gave $RuCl_2(O–N)_2$. A bis chelate of type $Ru(O–N–O)_2$ was also obtained when $RuCl_2(DMSO)_4$ was reacted with a large excess of uninegative terdentate ligand MHAQ. All the complexes were isolated as crystalline, air-stable compounds. The yields are high and the reactions generally faster when the 2-position is substituted by a methyl rather than a phenyl group. Molar conductivities are found in the range of 16–22 mho $cm^2 mol^{-1}$, indicating their non-electrolytic nature[20] (Table 1). All are diamagnetic ruthenium(II) complexes.

The most important bands occurring in the IR

[a] Free-ligand values are given in parentheses. 100-MHz spectra in $CDCl_3$ solutions with $Si(CH_3)_4$ as internal reference.

[b] s, singlet; m, multiplet; br, broad.

[c] The peaks in the range δ 3.0–3.5 are broad and correspond to CH_3 protons of DMSO in complexes **1–5**.

[d] Due to the OH of the carboxylic group in the MCMQ ligand.

[e] Due to NH/NH_2.

[f] Due to the amide CH_3 (δ 2.9) and —NH— (δ 4.2) protons of the MAAQ ligand.

[g] Due to the OH group.

of the free ligands and their metal complexes have been compared in order to ascertain the bonding sites in ligands (Table 2). A strong band corresponding to ν(C=O) at 1700 cm^{-1} of the quinazolone ring is shifted to lower wavenumbers by 35–50 cm^{-1} in the IR of all the complexes, indicating that the carbonyl oxygen is invariably coordinated to ruthenium(II).[21]

The bands due to ν(OH) observed in the IR of MHQ, PHQ, MHEQ, MHPQ and MCMQ disappeared completely in their complexes, confirming the coordination of these ligands by deprotonation.[22,23] The presence of DMSO in complexes **1–5** was characterized by its ν(S=O), which occurs as a strong band in the 1050–1100-cm^{-1} region, corresponding to the S-bonded DMSO ligands[18,24] (Table 2).

The NMR spectra of complexes **1–5** bear general resemblances to those of free ligands; nevertheless some differences are evident because of co-

ordination (Table 3). A single intense signal in the δ-3.0–3.5 region in complexes **1–5** with a downfield shift of about 0.7–0.9 ppm from that of free DMSO may be assigned to the S-bonded DMSO ligands coordinated in a *trans* manner.[18] The resonances due to OH groups of MHQ, PHQ, MHEQ, MHPQ and MCMQ totally disappear in their complexes.

The ligands MAQ, PAQ, MANQ, PANQ, MAAQ, MAPQ, MPQ and PPQ with mixed-donor centres (O–N) are neutral and react with $RuCl_2(DMSO)_4$ to give neutral complexes of type $RuCl_2(O–N)_2$ (**6–13**). The IR spectra confirms the absence of DMSO groups in all these complexes. The ν(N—H) frequencies of the NH_2 group in MAQ, PAQ and MAPQ were reduced by about 40 cm^{-1} upon coordination in complexes **6**, **7** and **11**.[25] On the other hand, the ν(N—H) of —NH— in MANQ, PANQ and MAAQ were lowered by 40–80 cm^{-1} in complexes **8–10**[26] (Table 2). In complex **10**, the shift in the ν(N—H) band to the lower side is more pronounced, supporting coordination through the amide nitrogen.[27] The band at 1640 cm^{-1} due to the ν(C=N) of quinazolone remains unaltered in the IR of complexes **12** and **13**, whereas the band at 1610 cm^{-1} due to the ν(C=N) of pyridine undergoes a lower shift of 40–50 cm^{-1}, suggesting coordination through the pyridine nitrogen.[28]

A broad signal around δ 6.2 in the proton NMR spectra of MAQ, PAQ and MAPQ due to $—NH_2$ protons undergoes a downfield shift to δ 8.1–8.2 in complexes **6**, **7** and **11**, as the primary amine nitrogen is bonded to the metal ion. Similarly, a large downfield shift of 1.8 ppm is observed in complexes **8** and **9**, compared to the free-ligand values at δ 6.5 and 6.6, respectively. Further, a very large downfield shift of δ 4.2 was observed when coordination occurred via the amide nitrogen in complex **10**.

MHAQ binds as a uninegative terdentate ligand in the complex $Ru(MHAQ)_2$ (**14**). Besides IR evidence, proton NMR data also confirm this type of coordination (Table 3). There is a large downfield shift observed for the —NH— proton in MHAQ and the signal merged with those of aromatic protons at δ 7.22–9.00 has been identified by means of D_2O exchange studies.

STABILITY AND SPECTRAL CHARACTERISTICS OF THE U(VI)–ALIZARIN MAROON–THIOSALICYLIC ACID TERNARY COMPLEX

MOHAMED M. SELEIM, KAMAL A. IDRISS,* MAGDA S. SALEH and ELHAM Y. HASHEM

Department of Chemistry, Faculty of Science, Assiut University, Assiut, Egypt

(*Received* 15 *July* 1985; *accepted after revision* 27 *January* 1986)

Abstract—The stability constant of the ternary U(VI) complex containing alizarin maroon (azm) and, as a second ligand, thiosalicylic acid (tsa) in a 1 : 1 : 1 molar ratio was determined by potentiometric titration in 40% (v/v) ethanol–water medium [$I = 100$ mmol dm^{-3} ($NaClO_4$), 25 ± 0.1°C]. For the equilibrium, $U(azm)_2 + U(tsa)_2 \rightleftharpoons 2U(azm)(tsa)$, the corresponding constant, $\log X$, was found to be 2.80 (0.27). The constant given in parentheses is due to $\Delta \log K = \log K^{U(tsa)}_{U(azm)(tsa)} - \log K^{U}_{U(azm)}$. The absorption spectra of the U(azm)(tsa) ternary complex were investigated and a sensitive method was developed for the microdetermination of uranium based on the formation of this complex. The solution spectrum of the ternary complex gave an absorption band at 630 nm over the pH range 5.8–7.4. The ternary system conformed Beer's law between 5.9 and 66.6 μg cm^{-3} uranium with a molar absorptivity of 2×10^4 l mol^{-1} cm^{-1}. The IR spectra of the mono- and biligand complexes were also studied.

It has already been recognized that the stability of mixed-ligand complexes is strongly dependent on the kind of donor atoms available and the possibility of π-bond formation.[1] Since S is one of the more important donor atoms, being able to form σ- and π-bonds,[2] it seems of interest to study the binding behaviour of this atom in ternary complexes. The strongest and most common binding site in this respect is proffered by the thiol group.

Thiosalicylic acid (tsa), widely known for its analytical applications, has two possible coordination sites, namely the sulphydryl (SH) and carboxyl (COOH) groups. Although it was reported that tsa forms stable binary complexes with some metal ions[3–5] yet mixed-ligand complexes involving this reagent as one of the ligands are scarce. No studies have yet been reported on ternary systems containing tsa and an acid anthraquinone dye.

In this paper, the mixed-ligand complex of U(VI) with azm (3-amino-1,2-dihydroxyanthraquinone) and tsa was investigated potentiometrically. An Irving and Rossotti pH-titration technique[6] and its modifications[7,8] were employed, the aim being to establish the equilibria existing in solution and to characterize the ternary stability constant of the U(VI)–azm–tsa complex. Measurements were made at 25 ± 0.1°C, and $I = 100$ mmol dm^{-3} ($NaClO_4$) in 40% (v/v) ethanol. The absorption and vibrational spectra of the mixed-ligand complex were also investigated. Fundamental conditions for the spectrophotometric determination of U(VI) using the U(VI)–azm–tsa ternary system were established.

EXPERIMENTAL

Analytical-grade reagents and deionized water (or pure ethanol) were used for preparation of solutions. 10^{-3} mol dm^{-3} stock solutions of azm or tsa were prepared by dissolving the accurately weighed amount of the reagent in ethanol. A solution of U(VI) (5×10^{-3} mol dm^{-3}) was prepared using AnalaR uranyl nitrate and standardized as recommended.[9] Standard solutions of NaOH (0.1 mol dm^{-3}) and $HClO_4$ (2.5×10^{-2} mol dm^{-3}) were also prepared. More dilute solutions of the reagents were obtained as required by accurate dilution. Buffer solutions and solutions of diverse ions used for interference studies were all prepared as mentioned elsewhere.[10]

* Author to whom correspondence should be addressed.

All pH-metric titrations were carried out at 25±0.1°C using an Orion (M 601 A) digital pH-meter with a combined glass–calomel electrode. The ionic strength of solutions was kept constant at 100 mmol dm^{-3} ($NaClO_4$). Measurements were carried out in a 40% (v/v) ethanol–water medium. Correction of pH readings in this medium was made as described previously.[11] The absorption spectra of solutions were recorded on a Pye–Unicam SP 8000 spectrophotometer in the range 350–750 nm using 1-cm matched stoppered quartz cells. IR spectra of organic ligands and their solid chelates were recorded as CsBr discs on a Perkin–Elmer 251 IR spectrophotometer.

Dissociation constants of the ligands and stability constants of the binary and ternary complexes

The previous work[12,13] from this laboratory on the acid dissociation of azm in aqueous solution and in water–organic solvent mixtures indicated that the predominate form of this reagent in acid solutions of pH 2–6 is the monocationic species (H_3A^+), which undergoes stepwise ionization on increasing the pH of solution. In this work, the proton association constant $pK^H_{H_3A}$ and the dissociation constant $pK^H_{H_2L}$ of azm in 40% (v/v) ethanol were determined by titrating 50 cm^3 of 2.5×10^{-3} mol dm^{-3} $HClO_4$ and $NaClO_4$ (I = 100 mmol dm^{-3}) in the presence and absence of the ligand (10^{-4} mol dm^{-3}) with standard carbonate-free NaOH (1.05×10^{-2} dm^{-3}).

The dissociation constant of tsa ($pK^H_{H_2L}$) corresponding to the ionization of the carboxyl hydrogen was also determined under the same experimental conditions. The value for pK^H_{HL} as reported by Kumar *et al.*[14] was 9.52. Table 1 gives the values of dissociation constants of azm and tsa as depicted from the titration graphs. The stability constant of the binary complexes were calculated from titration graphs in which the metal : ligand ratio was 1 : 2. The conditions for the measurements were the same as for the acidity constants. Titrations of solutions without ligand were used as a basis for the evaluation. The conditions of measurements for the titrations of the ternary complex were the same as for the binary ones, but the solutions contained equivalent amounts of azm, U(VI) and tsa. The evaluation of the titration curves was done using curves obtained using the same solutions but without tsa. Multiple titrations were carried out for each system. The uncertainties given in Tables 2 and 3 are 3 times the standard deviation.

Table 1. Negative logarithms of the acidity constants of the ligands

azm	6.45±0.03	5.07	11.52
tsa	4.60±0.02	3.72	8.32

RESULTS AND DISCUSSION

The stoichiometry of the complexes formed during the interaction of U(VI) with azm (H_3A^+) was established from the magnitude of the proton displacement, which was determined by titrating solutions containing the ligand against standard alkali in the absence and presence of different molar quantities of U(VI). The potentiometric titration graph for azm in the cationic form (H_3A^+) (Fig. 1) shows

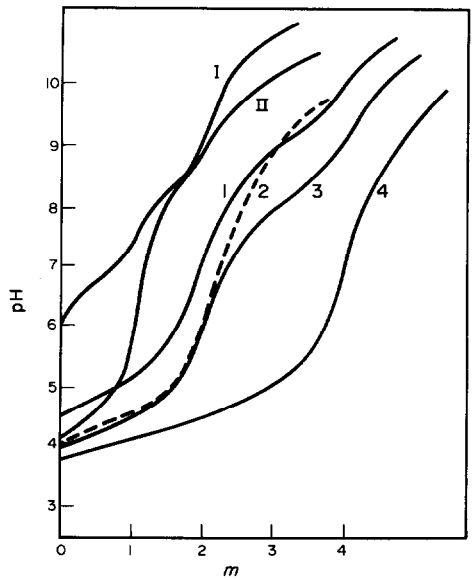

Fig. 1. Potentiometric titration curves of binary and ternary complex systems of U(VI) [I = 100 mmol dm^{-3} ($NaClO_4$), 25±0.1°C, 40% (v/v) ethanol]. For curves I and II, the abscissa represents mol of alkali added per mol of ligand (*a*). (I) azm, (II) tsa, (1) 1 : 1 U(VI)–azm, (2) 1 : 1 U(VI)–tsa, (3) 1 : 2 U(VI)–tsa, (4) 1 : 1 : 1 U(VI)–azm–tsa.

[e] Equation (11).

a moderate inflection at $a = 1$ followed by a steep inflection at $a = 2$ (where a is the number of mol of base added per mol of ligand). The constants $pK^{H}_{H_3A}$ and $pK^{H}_{H_2A}$ corresponding to the stepwise dissociation of the ligand are given in Table 1.

The titration graph for a system containing a 1:2 molar ratio of U(VI) and azm exhibits two inflections at $m = 2$ and 4 (m = mol of base added per mol of metal ion), indicating the formation of mono and bis-binary complexes, the corresponding equilibria may be represented as follows

$$U + azm \rightleftharpoons U(azm), K^{U}_{U(azm)}; \quad (1)$$

$$U(azm) + azm \rightleftharpoons U(azm)_2, K^{U(azm)}_{U(azm)_2}. \quad (2)$$

The formation constants were calculated taking into account the species H, H_3A, H_2A, HA, U, U(HA) and $U(HA)_2$, where H_2A is the neutral form of azm.

The titration curve for a system containing a 1:2 molar ratio of U(VI) and tsa (H_2L), exhibits two inflections at values of $m = 2$ and 4, respectively, indicating the stepwise formation of 1:1 and 1:2 binary complexes. The corresponding constants for equilibria (3) and (4) were calculated:

$$U + tsa \rightleftharpoons U(tsa), K^{U}_{U(tsa)}; \quad (3)$$

$$U(tsa) + tsa \rightleftharpoons U(tsa)_2, K^{U(tsa)}_{U(tsa)_2}. \quad (4)$$

The potentiometric titration graph for the ternary system containing U(VI), azm and tsa in a 1:1:1 molar ratio exhibits a single steep inflection at $m = 4$. The overall stability constant for the complexation equilibrium (5) was calculated taking into account the species H, H_3A, H_2A HA, H_2L, HL, L, U, U(HA), $U(HA)_2$, UL, UL_2 and U(HA)L:

$$U + azm + tsa \rightleftharpoons U(azm)(tsa), \beta^{U}_{U(azm)(tsa)}. \quad (5)$$

However, most of the species already taken into account occur only at a very low concentration. Calculations were carried out only with the species H, H_2L, HL, L, U(HA) and U(HA)L, assuming that, in a 1:1 mixture of the metal ion and azm, the formation of a U(azm) (1:1) complex is complete.

The stability constants of a ternary system are defined by eqns (6)–(8). The overall stability constant $\beta^{U}_{U(azm)(tsa)}$, which was determined experimentally, is connected with $K^{U(tsa)}_{U(azm)(tsa)}$ and $K^{U(azm)}_{U(azm)(tsa)}$ by eqns (9) and (10), respectively:

$$U + azm + tsa \rightleftharpoons U(azm)(tsa), \quad \beta^{U}_{U(azm)(tsa)} = [U(azm)(tsa)]/[U][azm][tsa]; \quad (6)$$

$$U(tsa) + azm \rightleftharpoons U(tsa)(azm), \quad K^{U(tsa)}_{U(tsa)(azm)} = [U(tsa)(azm)]/[U(tsa)][(azm)]; \quad (7)$$

$$U(azm) + tsa \rightleftharpoons U(azm)(tsa), \quad K^{U(azm)}_{U(azm)(tsa)} = [U(azm)(tsa)]/[U(azm)][tsa]; \quad (8)$$

$$\log K^{U(tsa)}_{U(tsa)(azm)} = \log \beta^{U}_{U(tsa)(azm)} - \log K^{U}_{U(tsa)}; \quad (9)$$

$$\log K^{U(azm)}_{U(azm)(tsa)} = \log \beta^{U}_{U(azm)(tsa)} - \log K^{U}_{U(azm)}. \quad (10)$$

Stability of U(VI)–azm–tsa ternary complex

One way to quantify the stability of ternary complexes is according to eqn (11):[15]

$$\Delta \log K_U = \log K^{U(tsa)}_{U(tsa)(azm)} - \log K^{U}_{U(azm)} = \log K^{U(azm)}_{U(azm)(tsa)} - \log K^{U}_{U(tsa)}. \quad (11)$$

i.e. by comparing the differences in stability, e.g. for the reaction between U(tsa) and azm.

The value of $\Delta \log K_U$ is the logarithm of the equilibrium constant of eqn (12):

$$U(tsa) + U(azm) \rightleftharpoons U(azm)(tsa) + U. \quad (12)$$

In general, negative value for $\Delta \log K_U$ [eqn (11)] is expected, since usually $K^{M}_{ML} > K^{ML}_{ML_2}$. This is in accordance with the statistical values obtained for the coordination of two different bidentate ligands to a regular and to a distorted octahedral coordination sphere, i.e. $\Delta \log K_{oh} = -0.4$ and $\Delta \log K_{do} \simeq -0.9$, respectively.[16]

The other approach commonly used to quantify the stability of a ternary complex is based on the equilibrium constant, X, as defined by eqn (13)[17,18]

[log X may be calculated according to eqn (14)]:

$$\begin{aligned} &U(azm)_2 + U(tsa)_2 \rightleftharpoons 2U(azm)(tsa), \\ &X = [U(azm)(tsa)]^2/[U(azm)_2][U(tsa)_2]; \end{aligned} \quad (13)$$

$$\begin{aligned} \log X &= 2\log \beta^{U}_{U(tsa)(azm)} - [\log \beta^{U}_{U(azm)_2} \\ &\quad + \log \beta^{U}_{U(tsa)_2}] \\ &= [\log K^{U(azm)}_{U(azm)(tsa)} - \log K^{U(tsa)}_{U(tsa)_2}] \\ &\quad + [\log K^{U(tsa)}_{U(tsa)(azm)} - \log K^{U(azm)}_{U(azm)_2}]. \end{aligned} \quad (14)$$

The statistical value for log X is for all geometries of the coordination sphere of a metal ion the same and is 0.6.[18,19]

According to our results, the formation of U(VI)–azm and U(VI)–tsa binary complexes and the complex equilibrium for the U(VI)–azm–tsa ternary system can be represented by the following schemes:

U(VI)–azm complexes:

$$UO_2^{2+} + H_3A^+ \rightleftharpoons [UO_2(HA)]^+ + 2H^+, \quad K^{U}_{U(azm)}; \quad (15)$$

$$[UO_2(HA)]^+ + H_3A^+ \rightleftharpoons [UO_2(HA)_2] + 2H^+, \quad K^{U(azm)}_{U(azm)_2}. \quad (16)$$

U(VI)–tsa complexes:

$$UO_2^{2+} + H_2L \rightleftharpoons [UO_2(L)] + 2H^+, \quad K^{U}_{UL}; \quad (17)$$

$$[UO_2(L)] + H_2L \rightleftharpoons [UO_2(L)_2]^{2-} + 2H^+, \quad K^{UL}_{UL_2}. \quad (18)$$

U(VI)–azm–tsa ternary system:

$$UO_2^{2+} + H_3A^+ + H_2L \rightleftharpoons [UO_2(HA)L]^- + 4H^+, \quad \beta^{U}_{U(azm)L}; \quad (19)$$

$$[UO^2(HA)]^+ + H_2L \rightleftharpoons [UO_2(HA)L]^- + 2H^+, \quad K^{U(azm)}_{U(azm)L}; \quad (20)$$

$$[UO_2(HA)_2] + [UO_2L_2]^{2-} \rightleftharpoons 2[UO_2(HA)(L)]^-, \quad X. \quad (21)$$

Comparing the curves resulting from the titration of U(VI) and tsa in a molar ratio of 1 : 1 with that where, in addition, azm was present (ratio 1 : 1 : 1) one can observe that the deprotonation of tsa in the ternary system occurs at a lower pH. This means that the ternary complex is more stable than the corresponding binary one, and we shall obtain a positive Δ log K value in this case. The results obtained for the formation of the U(VI)–azm–tsa ternary complex are given in Table 3. The constant log $\beta^{U}_{U(azm)L}$, which is due to the overall equilibrium [eqn (19)] was determined from the experimental data. By using the results given in Table 3, the values of $\Delta \log K_U$ [eqn (11)] and log X [eqns (13) and (14)] were calculated.

Spectrophotometric study of the ternary complex of U(VI) *with azm and tsa*

Absorption spectra and optimum pH. The visible spectra of azm exhibit a main absorption band at $\lambda = 470$ nm within the pH range 4–6.5. This band undergoes a reasonable shift to longer wavelengths on adding a U(VI) solution. The spectra of the U(VI)–azm 1 : 1 complex with reagent blank as reference are characterized by an absorption band at $\lambda = 590$ nm. A tsa solution (10^{-4} mol dm^{-3}) shows no measurable absorbance above 400 nm. In the pH range 4.5–6.5, the absorption spectrum of the U(VI)–tsa 1 : 1 complex was characterized by an absorption band at $\lambda = 420$ nm. The solution containing equimolar concentrations of azm and tsa undergoes a change in colour, from yellow to pink, when mixed with the U(VI) solution. The spectrum of the reaction mixture against a blank solution containing the same concentration of the two ligands shows an apparent decrease in the absorption at 470 nm and exhibits a new band at 630 nm (cf. Fig. 2). The latter band is unambiguously due to the formation of a mixed-ligand complex of U(VI) with the maximum colour development attained in the pH range 5.8–7.4. Job's method of continuous variation[20,21] was applied to establish the composition of the ternary U(VI)–azm–tsa complex. The molar fractions of two of the components were varied continuously, keeping their combined concentration constant, and keeping the third component in a large excess for all solutions

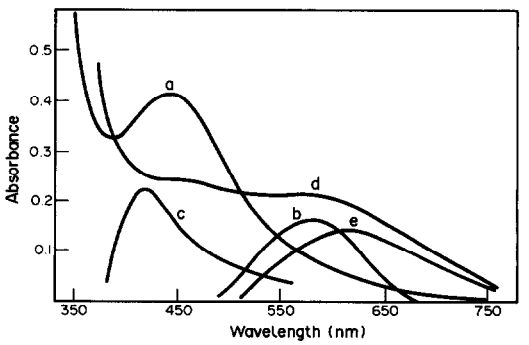

Fig. 2. Absorption spectra of U(VI)–azm–tsa ternary complex in 40% (v/v) ethanol [pH = 6.0, U(VI) = 1×10^{-4} mol dm^{-3})]: (a) azm and azm–tsa (both give the same spectrum), (b) 1 : 1 U(VI)–azm (vs azm), (c) U(VI)–tsa (vs tsa), (d) 1 : 1 : 1 U(VI)–azm–tsa (vs buffer containing 40% ethanol), (e) 1 : 1 : 1 U(VI)–azm–tsa (vs reagent blank).

in the series. Under these conditions, the ternary system was modified to a quasi binary system. The results graphically shown in Fig. 3 indicate that the overall U(VI)–azm–tsa complex has a 1 : 1 : 1 composition at the pH of the study. The stoichiometry of the ternary system was also determined by applying the mole-ratio method.[22]

Spectrophotometric determination of U(VI)

An aliquot of an acidic sample solution containing 148–714 μg of U(VI) was transferred to a 25-cm^3 calibrated flask and subsequently 2 ml of 10^{-3} mol dm^{-3} azm were added. The pH was adjusted to pH 6.2 with buffer solution and then 2 ml of 10^{-3} mol dm^{-3} tsa was introduced. The solution was diluted to volume with doubly distilled water and the requisite amount of pure ethanol. After thoroughly mixing the reaction mixture, the absorbance was measured at 630 nm against a reagent blank similarly prepared but containing no uranium.

Effect of diverse ions. To determine the effect of diverse ions on the determination of uranium, solutions were prepared containing 178.5 μg of U(VI) and varying concentrations of each ion to be tested. The uranium was then determined under the optimum conditions as described in the given procedure. The presence of 18 mg (100-fold excess) of the following ions caused no interference: Li^+, K^+, Na^+, Ba^{2+}, Ca^{2+}, Sr^{2+}, Mg^{2+}, Zn^{2+}, Mn^{2+}, Cd^{2+}, Pb^{2+}, Br^-, Cl^-, SO_4^{2-}, SO_3^{2-}, NO_3^-, NO_2^-, CN^-, tartarate, citrate, tetraborate and oxalate. The negative interference due to Al^{3+}, Cu^{2+}, Fe^{3+} and Ni^{2+} was completely eliminated by the addition of 1.0 ml M EDTA solution. Of the anions investigated, F^-, HPO_4^{2-} and S^{2-} caused a serious negative error even when reduced to only 10-fold excess.

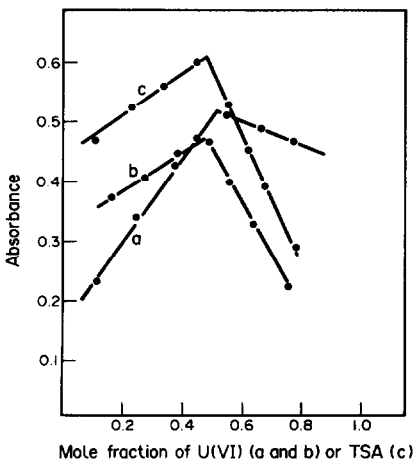

Fig. 3. Job's plots: (a) U(VI)–tsa (in presence of excess azm), (b) U(VI)–azm (in presence of excess tsa), (c) tsa–azm [in present of excess U(VI)].

Calibration graph and reproducibility. The system followed Beer's law over the range 2.5×10^{-5}–2.8×10^{-4} mol dm^{-3} of U(VI). The molar absorptivity was 2×10^4 l mol^{-1}. Eight identical samples each with a final U(VI) concentration of 1.5×10^{-4} mol dm^{-3} were treated according to the recommended procedure and their absorbance were measured. The mean absorbance was 0.350, with a standard deviation of 0.005 absorbance units.

IR spectra of the single and mixed-ligand complexes of U(VI) *with azm and/or tsa*

The solid 1 : 1 chelates of uranyl ion with azm or tsa as well as the 1 : 1 : 1 UO_2^{2+}–azm–tsa ternary complex were isolated and characterized. The IR spectra of the pure ligands were also recorded. The aim is to examine the salient features of the IR spectrum of the mixed-ligand complex (Fig. 4).

The IR spectrum of the UO_2^{2+}–azm (1 : 1) complex exhibits a band in the vicinity of 3480 cm^{-1}, which denotes the assignment of ν(NH). The band at 3380 cm^{-1} which corresponds to the ν(OH) of the bonded group is shifted to a lower frequency (3300 cm^{-1}) in the complexed ligand. The band becomes broadened and less intense. The spectrum indicates an overlap of the bounded ν(C=O) with ν(C=C) near 1600 cm^{-1}, and a red shift is observed. This indicates that the quinone structure is influenced by the substituents, that is to say it lowers the C=O character and increases the C=C bond order. The bands observed at 1440 and 1270 cm^{-1} in the spectrum of the free ligand, azm, suffer a red shift on complexation with the metal ion. The frequency shift of the former band was more or less in good agreement with the change in the reduced mass of the vibrating atoms. The intensity of this band decreases due to the displacement of a proton from one OH group on complex formation.

The band at 2520 cm^{-1} in the spectrum of tsa corresponds to the ν(S—H) stretching vibration. The disappearance of this band in the UO_2^{2+}–tsa and UO_2^{2+}–azm–tsa complexes confirms that the sulphydryl hydrogen is replaced by the metal and, consequently, coordination through sulphur is achieved in these complexes. The carbonyl stretching frequency at 1876 cm^{-1} in tsa appears at 1620–1650 cm^{-1} in its binary and ternary chelates, respectively, whereas the ν(C=O) band position is blue-shifted. The coordination of the uranyl ion with tsa in the ternary complex seems, therefore, to be carried out through the carbonyl oxygen of the

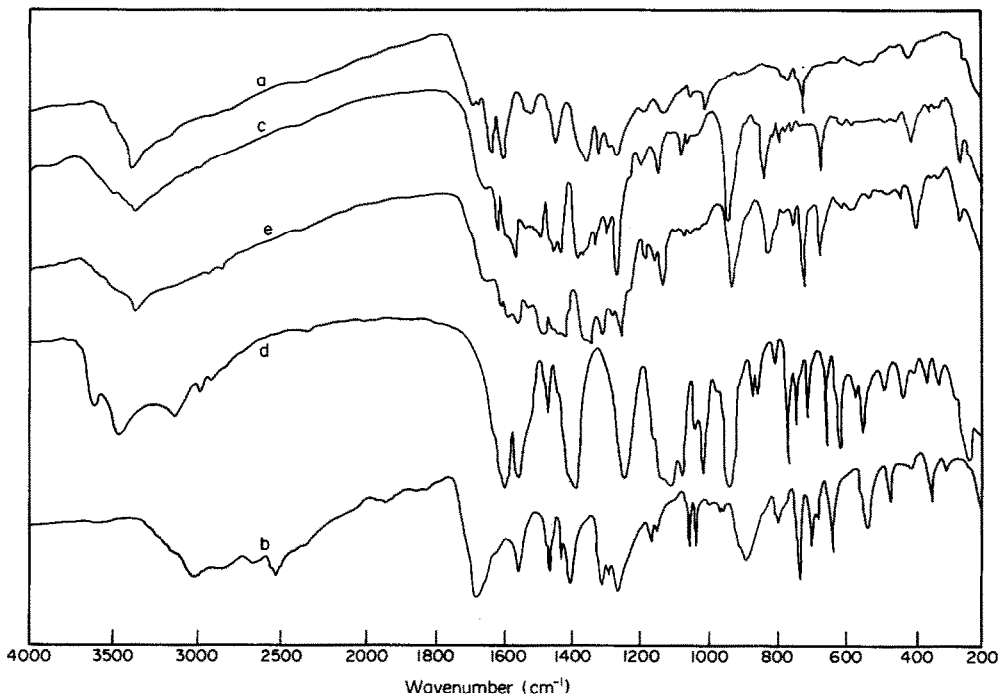

Fig. 4. IR spectra of binary and ternary complexes of U(VI): (a) U(VI)–azm, (b) U(VI)–tsa, (c) 1 : 1 U(VI)–azm, (d) 1 : 1 U(VI)–tsa, (e) 1 : 1 : 1 U(VI)–azm–tsa.

carboxyl group. Similar behaviour was reported elsewhere[23,24] for the Ni(II) complexes of tsa.

The IR spectrum of the ternary complex exhibits a band at 3300 cm^{-1}, which denotes the assignment of ν(OH). The appearance of the hydroxyl stretching frequency in the spectrum of UO_2^{2+}–tsa complex give additional evidence that the coordination through the hydroxyl oxygen of the carboxyl group is not taking place in the complex under investigation.

(*Received* 20 *August* 1985; *accepted after revision* 27 *January* 1986)

Abstract—The reactions of the sulphite radical anion, $SO_3^{\bar{\cdot}}$, which was generated either from a Ce^{4+}–$NaHSO_3$ system at pH 2.5 or from a Ti^{3+}(ethylenediaminetetraacetic acid)–H_2O_2–Na_2SO_3 system at pH 9 in aqueous solutions, with some olefinic compounds were investigated by use of a rapid-mixing flow technique coupled with ESR which can detect the radicals having a lifetime of 5–100 ms. The $SO_3^{\bar{\cdot}}$ radical could add to the C=O double bond in the olefinic compounds in both acidic and alkaline aqueous solutions, although the $SO_3^{\bar{\cdot}}$ radical is more active in acidic conditions than in alkaline conditions. From the observed hyperfine splitting constants of the $SO_3^{\bar{\cdot}}$ adducts of the olefinic compounds, the preferred conformation of the adducts was discussed.

It is well known that the rapid-mixing flow technique coupled with electron spin resonance (ESR) is very useful to detect the short-lived radicals having a lifetime longer than a few milliseconds. By use of this technique we have reported that the sulphite radical anion, $SO_3^{\bar{\cdot}}$, which is generated from a Ce^{4+}–$NaHSO_3$ system in acidic aqueous solutions, can add to compounds having C=C[1], C≡C[2] and C=S[3] bonds to give the corresponding secondary radicals. Also, in alkaline aqueous solutions at pH 9, the same radical species, $SO_3^{\bar{\cdot}}$, which is obtained from a Ti^{3+}(ethylenediaminetetraacetic acid)–H_2O_2–Na_2SO_3 system, can add to uracil derivatives having a C=S bond[4] and to nitroalkane *aci*-anions having C=N bonds.[5] Further, we have found that the reactive characteristics of the oxy anion radicals of sulphur ($SO_2^{\bar{\cdot}}$, $SO_3^{\bar{\cdot}}$ and $SO_4^{\bar{\cdot}}$) are different from each other and reported that these differences of the reactivity towards the organic substrates may be caused by the difference in the distribution of the unpaired electron density of each radical anions.[6]

In previous papers,[1,6] we briefly described that the $SO_3^{\bar{\cdot}}$ radical can add some olefinic compounds in acidic aqueous solutions. We have further examined the reactions of the $SO_3^{\bar{\cdot}}$ radical with olefinic compounds in both acidic and alkaline aqueous solutions by use of the rapid-mixing flow technique coupled with ESR in order to discuss the preferred conformation of the $SO_3^{\bar{\cdot}}$ adducts of the olefinic compounds. In this paper, we would like to report these results.

EXPERIMENTAL

Materials

$Ce(NO_3)_4 \cdot 2NH_4NO_3$, $NaHSO_3$, $TiCl_3$ [20% (v/v)], ethylenediaminetetraacetic acid (EDTA) and Na_2SO_3 were purchased from Wako Pure Chemical Industries Ltd and used without further purification. H_2O_2 (30%) was obtained from Mitsubishi Gas Chemical. Organic substrates were purchased from a commercial source and used without further purification. Sulphuric acid, NaOH, NH_4OH and

* Author to whom correspondence should be addressed.

other chemical reagents were of commercial GR grade.

ESR measurements

ESR measurements were carried out on a JEOL-PE-1X ESR spectrometer (X-band) with 100-kHz field modulation in conjunction with a JEOL mixing chamber. In the Ti^{3+}(EDTA)–H_2O_2–Na_2SO_3 system a T-shaped cell which enabled three reagents to mix almost simultaneously was used.[4] This apparatus enabled us to detect radicals having a lifetime of 5–100 ms. The hyperfine coupling constants and g values were calibrated by comparison with an aqueous solution of Fremy's salt ($g = 2.0055$, $a^N = 13.0$ G),[7,8] in a capillary tube attached to the sample.

Procedure

All solutions were prepared from triply distilled water, and their pH was adjusted by an aqueous solution of sulphuric acid, NaOH or NH_4OH.

For the generation of the SO_3^- radical in acidic aqueous solutions, $Ce(NO_3)_4 \cdot 2NH_4NO_3$ and $NaHSO_3$ were used. To investigate the reactions of the SO_3^- radical with organic substrates, two aqueous solutions were mixed: one (a) contained 0.01 M Ce^{4+} acidified by sulphuric acid and the other (b) 0.1 M $NaHSO_3$ containing various organic substrates of 0.02–0.3 M concentrations.

For the generation of the SO_3^- radical in alkaline aqueous solutions,[4,5,9] $TiCl_3$ (20%), H_2O_2 (30%) and Na_2SO_3 were used. The conditions for oxidation with and without an added organic substrate were the same except that, in the latter case, only two of the three entry ports into the mixing chamber were employed and the third solution referred to below was omitted. Three solutions were prepared: the first solution (c) contained 0.01 M Ti^{3+}, 0.01 M EDTA and 0.1 M Na_2SO_3; the second (d) contained 0.05 M H_2O_2; the third (e) contained the organic compounds (0.1 M). Aqueous ammonia was added to the first and the third solution to give a pH of 9.

RESULTS

Reactions of the SO_3^- radical with olefinic compounds in an acidic medium

The secondary radicals were detected when maleic acid, acrylic acid, methacrylic acid, crotonic acid, 3,3-dimethylacrylic acid and vinyl acetate, respectively, were added to the Ce^{4+}–$NaHSO_3$ system, as described previously.[1,6] The assigned structures and the ESR parameters were summarized in Table 1, along with those of the OH adducts of the corresponding olefinic compounds, which were obtained by oxidation with the Ti^{3+}–H_2O_2 system. For comparison, Fig. 1 shows the ESR spectrum observed by the reaction of SO_3^- with maleic acid.

Under the same experimental conditions, only very weak unanalysable resonance was detected with allyl alcohol, styrene and cinnamyl alcohol, and there was no detectable ESR absorption with the following compounds: acrylamide, acrolein, crotonaldehyde and acrylic acid methyl ester.

Reactions of the SO_3^- radical with olefinic compounds in an alkaline medium

When solutions of Ti^{3+} and EDTA, H_2O_2 and Na_2SO_3 were mixed in the cavity of the ESR spectrometer, the pH after mixing being 9, a singlet absorption line due to the SO_3^- radical was observed.[4] Since, when either Ti^{3+} or H_2O_2 was omitted, no ESR spectrum could be observed, the SO_3^- radical may be formed by one-electron oxidation of the sulphite ion by the hydroxyl radical (OH·) which is generated by the reaction of Ti^{3+} ion with H_2O_2[11] [eqns (1)–(4)], taking into consideration the pK of HSO_3^-:[12]

$$Ti^{3+} + H_2O_2 \rightarrow Ti^{4+} + HO^- + HO\cdot, \quad (1)$$

$$HO\cdot + HSO_3^- \rightarrow H_2O + SO_3^-, \quad (2)$$

$$HSO_3^- \rightleftarrows SO_3^{2-} + H^+, \quad (3)$$

$$HO\cdot + SO_3^{2-} \rightarrow HO^- + SO_3^-. \quad (4)$$

Maleate ion. When the maleate ion was added as the third solution and allowed to react with the solution mentioned above, the signal intensity of

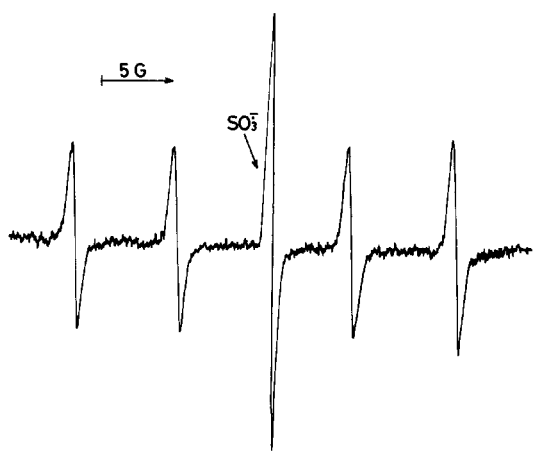

Fig. 1. ESR spectrum observed by the reaction of the SO_3^- generated from Ce^{4+}–$NaHSO_3$ with maleic acid at pH 2.5.

Table 1. ESR spectra of radicals formed by addition of the SO_3^- radical to olefinic compounds

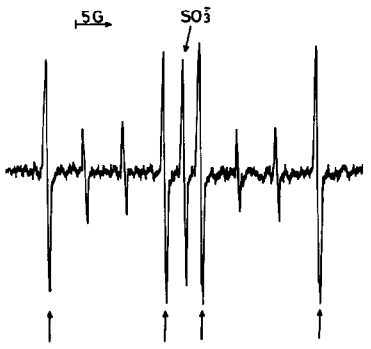
[a] A. L. J. Beckwith, *Aust. J. Chem.* 1972, **25**, 1887.

the SO_3^- radical considerably decreased, and another two ESR signals due to the different radical species were observed as shown in Fig. 2. The ESR spectrum of a doublet of a doublet [$a^H(1) = 20.4$ G and $a^H(1) = 15.6$ G] shown by the arrows (Fig. 1) is almost identical to that of the radical (**I**) formed by the reaction of the OH radical with maleate ion.[13] Thus, the radical species giving the ESR spectrum shown by the arrows was identified as the OH adduct (**I**).



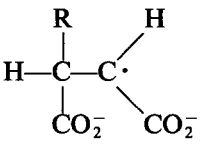


Fig. 2. ESR signal observed when the SO_3^- radical is generated in the presence of the maleate ion. It comprises overlapping spectra for $^-O_3SCH(CO_2^-)\dot{C}HCO_2^-$ and $HOCH(CO_2^-)\dot{C}HCO_2^-$ (marked ↑).

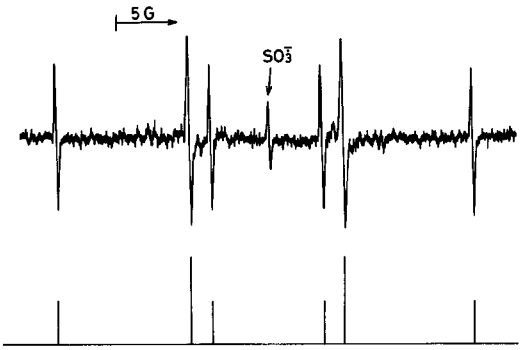
Since the other ESR spectrum consisting of a doublet of a doublet [$a^H(1) = 20.4$ G and $a^H(1) = 5.2$ G] resembles that of the SO_3^- adduct of maleic acid observed in acidic medium,[6] this radical species was identified as the SO_3^- adduct (**II**).

I: R = OH
II: R = SO_3^-

The fact that the two radical species, the OH adduct (**I**) and the SO_3^- adduct (**II**), could be observed in the Ti^{3+}(EDTA)–H_2O_2–Na_2SO_3 system indicates that the rate of addition of the OH radical to the maleate ion is almost the same as that of the oxidation of SO_3^{2-} by the OH radical, and that the decay rates are similar.

Acrylate ion. When the acrylate ion was mixed with the SO_3^- radical, the ESR signal intensity of the SO_3^- radical decreased and a new ESR signal was observed at $g = 2.0033$ (Fig. 3). This spectrum can be analysed in terms of the following parameters: $a^H(1) = 13.0$ G and $a^H(2) = 11.25$ G.



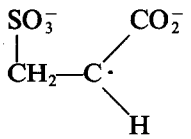


Fig. 3. ESR spectrum obtained by the reaction of the acrylate ion with the SO_3^- radical generated from Ti^{3+}(EDTA)–H_2O_2–Na_2SO_3 at pH 9.0.

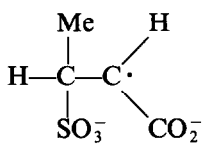

Since the spectral pattern is similar to that of the SO_3^- adduct of acrylic acid,[6] the radical species can be assigned to the SO_3^- adduct (**III**).

III

Methacrylate ion. When the methacrylate ion was added to the Ti^{3+}(EDTA)–H_2O_2–Na_2SO_3 system, an unanalysable ESR spectrum was observed, although the SO_3^- adduct of methacrylic acid was observed in an acidic medium (Table 1).

Crotonate ion. When the crotonate ion was reacted with the SO_3^- radical, a weak ESR spectrum similar to that obtained by the same reaction in acidic medium was observed. This spectrum was analysed as follows: $a^H(1) = 19.6$ G, $a^H(1) = 6.1$ G and $a^H(3) = 0.95$ G. This radical species was assigned to the SO_3^- adduct (**IV**).

IV

3,3-*Dimethylacrylate ion.* No ESR spectrum was observed for the reaction of the SO_3^- radical with the 3,3-dimethylacrylate ion, although the SO_3^- adduct was observed in an acidic medium (Table 1).

Vinyl acetate. The same ESR spectrum as observed in acidic medium was obtained by the reaction of the SO_3^- radical with vinyl acetate at pH 9.

Under the same experimental conditions, there was no detectable ESR absorption with the following compounds: styrene, cinnamyl alcohol, acrylamide, acrolein, crotonaldehyde and acrylic acid methyl ester.

The ESR parameters observed during the reaction of the SO_3^- radical with olefinic compounds are summarized in Table 1, along with the OH adducts of the corresponding olefinic compounds for comparison.

DISCUSSION

From Table 1, it is apparent that the SO_3^- radical can easily add to the C=C double bond of olefinic compounds to yield SO_3^- adducts. Further, it is indicated from Table 1 that the SO_3^- radical is more active in an acidic medium than in an alkaline medium.

From the radical structures assigned here (Table 1), it is also suggested that the addition reactions of the SO_3^- radical are influenced by the steric hindrance. That is, for acrylic acid and its anion, crotonic acid and its anion, and 3,3-dimethylacrylic acid, the SO_3^- radical adds to the *C*-terminal of the C=C bond far from the carboxyl or carboxylate group, whereas the OH radical adds to both sides of the C=C bond. These results indicate that the bulky SO_3^- radical is more sensitive to steric hindrance than the OH radical.

The facts that the radical concentration of the SO_3^- adduct obtained by the reaction of the SO_3^- radical with the crotonate ion was very low and that no secondary radical was observed from the reaction of the SO_3^- radical with the 3,3-dimethylacrylate ion indicate that the addition reactions of the SO_3^- radical in an alkaline medium are affected by the electrostatic repulsion between the SO_3^- and the carboxylate group.

The α-proton-splitting constants of the SO_3^- adducts are almost the same as those of the OH adducts (Table 1). However, the β-proton-splitting constants of the SO_3^- adducts are less than those of the OH adducts, except for that of vinyl acetate (Table 1). Since the hyperfine splitting constants of the β-proton reflect the radical conformation,[14,15] it is suggested that the conformations of the SO_3^- adducts are different from those of the OH adducts.

It is known that the sensitivity of the hyperfine splitting from the β-proton to the dihedral angle between the orbital of the unpaired electron and the β-C—H bond has continued to provide a useful probe for the study of the radical conformation.

Generally, the hyperfine splitting constant due to the β-proton could be represented by eqn (5):

$$a(\beta\text{-H}) = B_0 + B\cos^2\theta, \qquad (5)$$

where θ is the dihedral angle between the orbital of

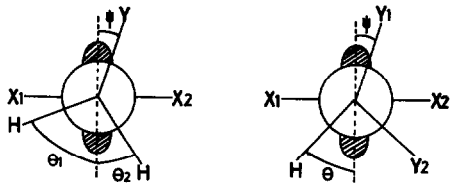

Fig. 4. Sterical conformation: $YCH_2\dot{C}X_1X_2$ (a) and $Y_1Y_2CH\dot{C}X_1X_2$ (b).

the unpaired electron and the β-C—H bond, and B_0 and B are constants. In this equation, since B_0 is approximately zero, $a(\beta\text{-H})$ is mainly dependent on $\cos^2\theta$.

From Table 1, we can divide the conformations of the SO_3^- adducts into two groups: one is the conformation having two protons, such as acrylic acid, its anion and vinyl acetate, as shown in Fig. 4(a), and the other having one proton such as maleic acid, its anion, and crotonic acid and its anion, as shown in Fig. 4(b). Thus, we consider the representative example for each group.

First, we consider the SO_3^- adduct of the acrylate ion ($X_1 = H$, $X_2 = CO_2^-$) as the radical shown in Fig. 4(a). Each dihedral angle of the SO_3^- adduct ($Y = SO_3^-$) is represented by ψ, θ_1 and θ_2, and the corresponding dihedral angles of the OH adduct ($Y = OH$) are represented by ψ', θ'_1 and θ'_2, as shown in Fig. 4(a). Since the SO_3^- group is larger than the OH group, the steric hindrance towards the carboxylate group is larger in the SO_3^- group than in the OH group. Then, $\psi < \psi' < 90°$. These results lead to $\cos^2\psi' < \cos^2\psi$, and, then, for the dihedral angle of the two β-protons of the rest, the following equation is obtained:

$$\frac{1}{2}(\cos^2\theta_1+\cos^2\theta_2) = \cos^2\theta < \cos^2\theta'$$

$$= \frac{1}{2}(\cos^2\theta'_1+\cos^2\theta'_2), \qquad (6)$$

where θ and θ' are the average dihedral angle of the SO_3^- adduct and the OH adduct, respectively. When eqn (6) is substituted in eqn (5), we obtain $a(\beta\text{-H})$ for the SO_3^- adduct $< a(\beta\text{-H})$ for the OH adduct.

The conformation of the SO_3^- adduct of acrylic acid is considered to be the same as mentioned above.

For the SO_3^- adduct of the vinyl acetate, no difference in the values of $a(\beta\text{-H})$ for both adducts can be detected. This result suggests that the conformations of both adducts are almost the same.

In these radicals, represented as $YCH_2\dot{C}X_1X_2$, we can calculate the ψ value from the observed $a(\alpha\text{-H})$ and $a(\beta\text{-H})$, according to Fischer's method.[14] As a result, in the acrylate ion, the calculated ψ value is 28 and 52° for the SO_3^- adduct and the OH adduct, respectively. In acrylic acid, ψ is 23 and 23° for the SO_3^- adduct and the OH adduct, respectively. In vinyl acetate, ψ is 9 and 5° for the SO_3^- adduct and the OH adduct, respectively. These results indicate that, when the C—S bond of the SO_3^- adduct approaches the orbital of the unpaired electron, the conformation of the SO_3^- adduct is energetically most stable.

Next, we consider the conformation of the SO_3^- adduct of the crotonate ion ($X_1 = H$, $X_2 = CO_2^-$) as the radical shown in Fig. 4(b). The dihedral angles of the SO_3^- adduct ($Y_1 = SO_3^-$, $Y_2 = CH_3$) are represented by ψ and θ, and the corresponding dihedral angles of the OH adduct ($Y_1 = OH$, $Y_2 = CH_3$) are represented by ψ' and θ', respectively, as shown in Fig. 4(b). Since the results for the adduct from the crotonate ion and the SO_3^- radical can be understood in a similar way as explained by the SO_3^- adduct of the acrylate ion, $\psi < \psi' < 90°$. Then, since $\cos^2\psi > \cos^2\psi'$, for the remaining dihedral angles $\cos^2\theta < \cos^2\theta'$. Therefore, from eqn (5), the $a(\beta\text{-H})$ of the SO_3^- adduct $< a(\beta\text{-H})$ of the OH adduct. The results for the SO_3^- adducts from maleic acid, maleate ion and crotonic acid can be understood similarly.

In these adducts, represented by $Y_1Y_2CH\dot{C}X_1X_2$, since there are two β-substituents without a proton, it is difficult to calculate the value of the ψ.[16] However, the fact that a large reduction in the hyperfine splitting of the β-proton in the SO_3^- adduct was observed indicates that in these adducts the conformation in which the dihedral angle between the C_β—H bond and the orbital of the unpaired electron approaches 90° is energetically lowest.

SINGLE-HALIDE ANIONS IN PHOSPHORUS(V) HALIDE COMPLEXES: A RAMAN INVESTIGATION

ARTHUR FINCH, PETER N. GATES* and ALAN S. MUIR

Department of Chemistry, Royal Holloway and Bedford New College, Egham Hill, Egham, Surrey TW20 0EX, U.K.

(*Received* 27 *November* 1985; *accepted* 27 *January* 1986)

Abstract—Phosphorus(V) chloride and bromide complexes containing single-halide anions are surveyed in terms of characteristic phosphonium ion Raman shift patterns. Methods of preparation of Phase III phosphorus pentachloride are reviewed and some modes of formation proposed. The nature of the phosphonium cation–single-halide anion interaction is discussed on the basis of observed Raman shifts. With trihalide anions, similar shifts are observed but are strongly dependent on anion symmetry.

Structurally, solid phosphorus pentachloride and phosphorus pentabromide are very different, viz. $[PCl_4^+][PCl_6^-]$[1–3] and $[PBr_4^+][Br^-]$[4–6] respectively. The significant difference is the presence of the single-bromide ion in the pentabromide, the PBr_6^- ion being unknown. In addition, a well-documented modification (Phase III) of phosphorus pentachloride exists, in which the presence of a single-chloride anion is inferred,[7–16] i.e. $[PCl_4^+]_2[PCl_6^-][Cl^-]$. Raman spectroscopy affords a convenient and clear distinction between the two forms of PCl_5; the chief differences on passing from $[PCl_4^+][PCl_6^-]$ to $[PCl_4^+]_2[PCl_6^-][Cl^-]$ are: (i) a large increase in the intensities of the PCl_4^+ modes relative to those of PCl_6^- (Fig. 1) and, (ii) a low-frequency shift of *ca* 20 cm^{-1} in the $\nu_1(a_1)$ (symmetric) and $\nu_3(e)$ (antisymmetric) stretching frequencies of the PCl_4^+ ion (Table 1). In phosphorus pentabromide, which already contains a single-bromide ion, formation of PBr_4^+ complexes with polyatomic anions leads to *high*-frequency shifts in the ν_1- and ν_3-modes of the cation. Examples of this effect for PCl_4^+ and PBr_4^+ are summarized in Table 1.

EXPERIMENTAL

All preparations and manipulations were carried out in an atmosphere of dry nitrogen. Chemicals of the best available commercial grade were used, generally without further purification, except for Et_4NCl which was recrystallized from ethanol by addition of diethyl ether, followed by drying at 50°C and storage *in vacuo* over P_4O_{10} until required.[17] Halogenated solvents were dried over 4-Å molecular sieves.

$[PCl_4^+][SbCl_6^-]$ and $[PCl_4^+][AlCl_4^-]$ were prepared from PCl_5, with $SbCl_5$ and $AlCl_3$, respectively, in CH_2Cl_2 as solvent, using modifications of established methods.[18,19] $[PBr_4^+][BBr_4^-]$ was prepared by reaction of PBr_5 and BBr_3 in CH_2Cl_2 as previously described.[20] A novel complex, $[PCl_4^+]_2[BCl_4^-][Cl^-]$, was prepared by reaction of PCl_3, BCl_3 and Cl_2 (in 2:1:1 molar ratio) in $AsCl_3$, and is described in detail elsewhere.[21,22] Phase III phosphorus pentachloride ($[PCl_4^+]_2[PCl_6^-][Cl^-]$) was usually prepared by recrystallization of Phase II PCl_5 from CH_2Cl_2 in the presence of a small quantity of Br_2.[15] Several other methods of obtaining this complex were found during the course of this work, and are summarized in Table 2. On one occasion, use of a larger quantity of Br_2 during recrystallization of Phase II PCl_5 from CH_2Cl_2, followed by sudden cooling, yielded a very unstable yellow aggregate which could not be analysed.

Halide analyses were performed potentiometrically following hydrolysis; in all cases, analytical results were within 0.4% of calculated values.

Raman spectra were obtained on solid samples sealed in glass capillaries using a Coderg PHO spectrometer equipped with a Coherent Radiation argon laser with excitation at 514.5 nm.

RESULTS AND DISCUSSION

Formation of Phase III PCl_5

Although a variety of procedures (Table 2) have yielded Phase III (metastable) PCl_5 very little is understood about the mechanism of formation of the isomer. ^{31}P NMR studies[14] have suggested that the conversion of Phase II to Phase III may proceed *via* a selective decomposition of PCl_6^-, ions at least in the solid state.

The present Raman study has provided some insight into the mode of formation involved in some of the chemical methods of preparation. Probably the most convenient reliable method is the recrystallization of Phase II PCl_5 from CH_2Cl_2 in the presence of small (typically $< 5\%$) quantities of Br_2. The Raman spectrum of a typical sample prepared in this way is compared with that for Phase II PCl_5 in Fig. 1. In one experiment, where a stoichiometric quantity of Br_2 was present, a very unstable yellow solid was isolated. Raman wavenumbers and assignments for these species are given in Table 3, together with those of saturated solutions of PCl_5 and Et_4NCl in Br_2. Spectra are shown in Figs 2 and 3. Earlier ^{31}P NMR work has shown that PCl_4^+ is the only phosphorus-containing moiety in a solution of PCl_5 in Br_2,[23] and this is supported by the present observation of bands at 178, 250, 452 and 655 cm^{-1} in the Raman spectrum. The only additional band, a strong, broad scattering centred at 278 cm^{-1}, is reasonably assigned to a species such as Br_2Cl^-. This is supported by an almost identical feature in the spectrum of Et_4NCl in Br_2. It should be noted that the $\nu_1(a_1)PCl_4^+$ mode occurs at 452 cm^{-1} in the PCl_5 in Br_2 solution, consistent with those of other complexes containing a polyhalide counter ion (Table 1). On this basis the Raman spectrum clearly indicates the presence of PCl_4^+, PCl_6^- and Br_2Cl^- ions in the unstable material. This complex underwent progressive decomposition in the laser beam, resulting in the formation of Phase III PCl_5; this was evident from the reduction in intensity of bands at 360 cm^{-1} (ν_1 PCl_6^-) and 280–284 cm^{-1} (ν_2 PCl_6^- and ν_1 Br_2Cl^-) together with a shift in $\nu_1(a_1)$ PCl_4^+ from 450 to 440 cm^{-1}. These observations strongly suggest that the unstable yellow complex is an intermediate species in the formation of Phase III from Phase II PCl_5. This process could be represented as follows:

$$PCl_5 + Br_2 \rightarrow [PCl_4^+][ClBr_2^-],$$

$$[PCl_4^+][ClBr_2^-] + [PCl_4^+][PCl_6^-] \rightarrow [PCl_4^+]_2[PCl_6^-][Cl^-] + Br_2. \quad (1)$$

Such a scheme seems reasonable, assuming the instability of the Br_2Cl^- ion in an environment

other than Br_2. In an additional experiment, Phase II PCl_5 was recrystallized from Br_2 alone, resulting in a dark red unstable aggregate, the Raman spectrum of which could not be obtained; pumping of this material yielded a pale yellow solid with a Raman spectrum identical to that of Phase III PCl_5. In an earlier report,[7] powder X-ray analysis of a yellow material, $PCl_{4.66}Br_{0.33}$, was consistent with a formulation $8PCl_4^+4PCl_6^-4Br^-$ per unit cell. This is probably an analogue of Phase III PCl_5, with Br^- substituted for Cl^-, i.e. $[PCl_4^+]_2[PCl_6^-][Br^-]$ Unfortunately no Raman data for this are reported and attempts to repeat the synthesis in this laboratory were unsuccessful.

It is interesting to compare the effects of the different halogens on the recrystallization of Phase II PCl_5 from CH_2Cl_2. Cl_2 has no effect, and I_2 leads to the formation of $[PCl_4^+][ICl_2^-]$. In terms of the proposed trihalide intermediate (see above for the Br_2 case), Cl_2 interacts negligibly at ambient temperatures, where the Cl_3^- ion is relatively unstable, whereas I_2 leads to the formation of the well-known ICl_2^- salt. Thus, in terms of intermediate trihalide ion stability, Br_2Cl^- probably represents a borderline case. When Phase II PCl_5 was recrystallized from liquid Cl_2 no change to Phase III occurred, consistent with the extreme instability of any intermediate.

Recrystallization of Phase II PCl_5 from anhy-

drous liquid HCl also produced Phase III. A previous Raman study[24] of PCl_5 dissolved in liquid HCl indicated that the ions present in solution are PCl_4^+ and HCl_2^-. The cation is characterized by bands at *ca* 188, 244, 445 and 645 cm^{-1}, and the anion by a strong band at *ca* 2600 cm^{-1} (frequencies estimated from Fig. 3 in Ref. 24). A similar scheme to (1) could account for the formation of Phase III:

$$PCl_5 + HCl \rightarrow [PCl_4^+][HCl_2^-],$$

$$[PCl_4^+][HCl_2^-] + [PCl_4^+][PCl_6^-] \rightarrow [PCl_4^+]_2[PCl_6^-][Cl^-] + HCl. \quad (2)$$

The instability of the HCl_2^- with loss of HCl during the recrystallization would provide the driving force for the process.

Recrystallization from CCl_4 can also produce Phase III PCl_5, although in this case the nature of any analogous intermediate is less clear. An adduct $2PCl_5 \cdot CCl_4$ has been reported[25] but attempts to isolate it in these laboratories have so far been unsuccessful. The preparations of P_2Cl_9Br (formulated as $[PCl_4^+]_6[PCl_3Br^+]_2[PCl_6^-]_4[Br^-]_4$[26]), and of $[PCl_4^+]_2[BCl_4^-][Cl^-]$,[21,22] are both solvent-dependent; both complexes can be prepared in $AsCl_3$ but not in CH_2Cl_2, and it seems probable that some intermediate species involving PCl_5 and $AsCl_3$ are involved.

Nature of the interaction between a cation and a single-halide or trihalide anion

As mentioned above, the chief manifestations of cation perturbation when a single-halide or trihalide anion is present are low-frequency shifts and intensity changes. When PCl_5 changes from Phase III to Phase II the intensity (I) ratio, $[I(\nu_1\, PCl_4^+)]/[I(\nu_1\, PCl_6^-)]$, decreases by a factor of approximately 10; this cannot be accounted for simply on the basis of the change in the $PCl_4^+ : PCl_6^-$ ratio (2 : 1 in Phase III and 1 : 1 in Phase II). These effects seem to be general in these types of compounds, having also been observed in mixed-halogen phosphonium cations ($PCl_nBr_{4-n}^+$, $1 \leqslant n \leqslant 3$)[11,20,26] and mono-, di- and trimethylphosphoranes and derivatives.[21] Unfortunately there is a paucity of X-ray data, which exist only for PBr_4Br and $PBr_4^+Br_3^-$.

In PBr_5, the PBr_4^+ ion is a nearly regular tetrahedron with all PBr distances in the range 213–217 pm,[6] consistent with earlier work.[4,5] Each Br^- ion is surrounded by four Br atoms, each from a different cation, with interaction distances averaging 312 pm, i.e. less than the van der Waals' separation, thus indicating a significant anion–cation interaction but with no reduction of the T_d-symmetry of the cation. In $PBr_4^+Br_3^-$ a tetrahedral cation (angles in the range 107–110°) with all P—Br distances between 216 and 218 pm is found.[27] The Br_3^- ion is almost linear but with one bond of 239 pm (cf. 228 pm in Br_2) and the other of 291 pm. The extended terminal Br atom is much closer to the Br atoms of surrounding cations than to the other two anion Br atoms. Each elongated end of the Br_3^- ion has four close Br neighbours (each from a different cation) within the 310–340 pm range, whereas all other nearest approaches were *ca* 390 pm. As the van der Waals' radius of Br is 195 pm, significant interaction is indicated, although again there is no perturbation

of the T_d-symmetry of PBr_4^+, consistent with the observed Raman spectra. These data give a clue to the origin of the shifted Raman frequencies. The close approach of the single-halide[4–6] or polyhalide[27] anion indicates some interaction, probably resulting in weakening of the P—X bonds and consequent reduction in stretching frequencies. From Table 1 it can be seen that the low-frequency shifts (relative to $[PBr_4^+][BBr_4^-]$) for both $[PBr_4^+][Br^-]$ and $[PBr_4^+][Br_3^-]$ are very similar (24 and 22 cm^{-1},

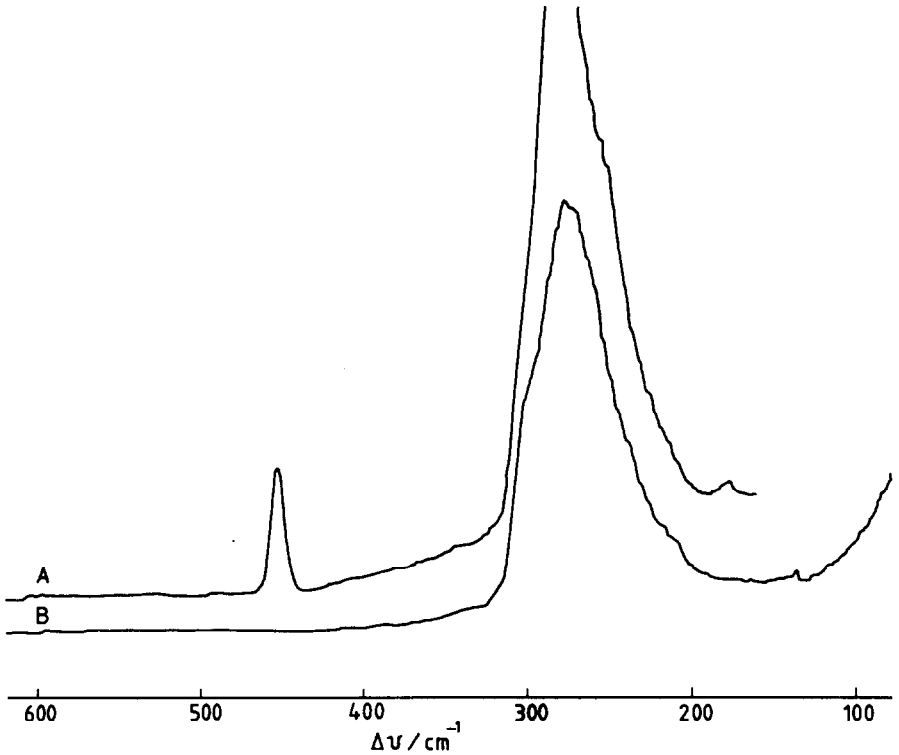

Fig. 3. Raman spectra of Br_2 solutions of PCl_5 (A) and Et_4NCl (B).

respectively), suggesting a similar anion–cation interaction. However, when the symmetric ($D_{\infty h}$) IBr_2^- ion replaces the asymmetric Br_3^- species, the shift is reduced to 15 cm^{-1}, suggesting a weaker anion–cation interaction. A similar trend in shifts can be seen in the series $[PCl_4^+][PCl_6^-]$, $[PCl_4^+][ICl_2^-]$ (where the ICl_2^- is symmetric) and $[PCl_4^+]_2[PCl_6^-][Cl^-]$, presumably arising from similar interactions, although the structures of these species must be quite different from the Br analogues. The very significant intensity increases of the PCl_4^+ stretching modes in Phase III PCl_5 must reflect an enhanced P—Cl bond polarizability derivative arising from interaction of PCl_4^+ with the single Cl^- ion. Another manifestation of the interaction is observed in the ^{31}P magic angle rotation NMR spectra of some of the complexes, in which very significantly broader phosphonium ion resonances occur when single-halide ions are present.[21,28] This is probably due to a closer cation–single halide approach, leading to increased dipolar interaction and consequent line-broadening.

The stretching frequencies of the trihalide ion in some complexes are also informative. In $[PBr_4^+][Br_3^-]$, a Br—Br stretching mode of the Br_3^- ion ($C_{\infty v}$-symmetry) occurs at 252 cm^{-1}, only *ca* 50 cm^{-1} less than that in liquid Br_2 at 308 cm^{-1}.[29–31] Symmetric ($D_{\infty h}$) Br_3^- ions are also known in which the Br—Br symmetric stretch (ν_1, Σ_g^+) occur at a much lower frequency, typically 168 cm^{-1}.[31] Hence in the less symmetric ($C_{\infty v}$) Br_3^- ion, the mode at 252 cm^{-1} may be regarded as essentially a weakened Br—Br stretching mode in the species Br—Br...Br^-. The proposed Br_2Cl^- ion in the PCl_5–Br_2 and Et_4NCl–Br_2 systems is probably similar to this. The strongest mode is at 280 cm^{-1} (Table 3) which is even closer to that in Br_2, suggesting that the Cl^-------Br—Br interaction is very weak, consistent with its apparent instability.

Acknowledgements—We thank Professor R. K. Harris and Mr A. Root (University of East Anglia) for solid-state NMR data, and Humberside County Council for provision of a Research Assistantship (A.S.M.).

THERMODYNAMIC STUDIES ON IODINE(III) COMPOUNDS

B. M. DERAKHSHAN, A. FINCH* and P. N. GATES

Chemistry Department, Royal Holloway and Bedford New College, Egham, Surrey TW20 0EX, U.K.

(*Received* 27 *November* 1985; *accepted* 28 *February* 1986)

Abstract—The standard enthalpies of aqueous hydrolysis of $I_2Cl_6(c)$ and $I_2(CH_3COO)_6(c)$ have been determined as -59.3 ± 3.4 and -57.1 ± 2.0 kJ mol^{-1}, respectively, leading to the estimates of the standard enthalpies of formation $\{\Delta H_f^{\ominus}[I_2Cl_6(c)] = -179.8 \pm 4.0$ and $\Delta H_f^{\ominus}[I_2(CH_3COO)_6(c)] = -2101.6 \pm 9.0$ kJ mol^{-1}, respectively$\}$. A thermometric titration of I_2Cl_6 with aqueous $AgNO_3$ has been used to investigate the mechanism of the hydrolysis reaction.

Notwithstanding its electronegative character, iodine forms numerous species in which formal positive oxidation states are found. Thus I_n^+ ($n = 2, 3$ or 5) species in non-aqueous solutions, interhalogen cations (e.g. $ICl_2^+AlCl_4^-$), neutral polyhalogens (e.g. I_2Cl_6) and crystalline polyhalides (e.g. $MICl_2$ and $MICl_4$ where M = Group I metal or alkylammonium) are well documented;[1] considerable synthetic, structural and thermodynamic data are available. In addition, several tervalent iodine compounds such as the iodine triacylates $(RCOO)_3I$ and IPO_4[2,3] are known. $(CH_3COO)_6I_2$, in particular, has been used as a regio- and stereospecific reagent in alkene synthesis;[4,5] indications of a bridged, dimeric structure for this compound have been adduced from Mössbauer studies.[6] Thermodynamic data on these species are limited to an early, but meticulous, study of I_2Cl_6,[7] and to some polyhalide species.[8] We report here measurements leading to an estimation of the standard enthalpy of formation ($\Delta H_f^{\ominus}$) of iodine(III) chloride (I_2Cl_6) and $(CH_3COO)_6I_2$. Further, via a thermometric titration procedure, we define the sequential stages of hydrolysis of I_2Cl_6.

EXPERIMENTAL

Preparation of compounds

I_2Cl_6. Chlorine gas was liquefied at −78°C and powdered iodine added with stirring (2 h). Excess chlorine was allowed to evaporate at room temperature to leave orange-yellow needles of I_2Cl_6. Found: Cl, 44.7; I, 54.2%. Calc.: Cl, 45.6; I, 54.4%.

$(CH_3COO)_6I_2$. Powdered iodine (7.05 g, 0.05 mol) was added to glacial acetic acid (10.0 g, 0.16 mol) in the presence of acetic anhydride (15 cm^3). On addition of fuming nitric acid (6 cm^3) a yellow solution developed, from which yellow iodine triacetate precipitated on cooling. The compound was filtered and dried *in vacuo*, and stored in the absence of light. Found: I, 42.0%. Calc.: I, 41.8%.

Calorimetry

Enthalpies of aqueous hydrolysis ($\Delta H_h^{\ominus}$) were measured in the ampoule-breaking mode using a commercial isoperibol calorimetric system (LKB model 8700), the performance of which was periodically checked using the enthalpy of neutralization of tris(hydroxymethyl) methylamine in an excess of HCl. The apparatus for the thermometric titration of I_2Cl_6 with $AgNO_3$(aq) has been described previously.[9]

RESULTS

Values for $\Delta H_h^{\ominus}$ are summarized in Table 1 for reactions (1) and (2), and $\Delta H_f^{\ominus}$ of the compounds were calculated on the basis of eqns (3) and (4):

$$5I_2Cl_6(c) + 18H_2O(l) \rightarrow 2I_2(c) + 6IO_3^-(aq) + 36H^+(aq) + 30Cl^-(aq), \quad (1)$$

[b] Uncertainties calculated using a Student's *t*-distribution at the 99.5% level.

$$5(CH_3COO)_6I_2(c)+18H_2O(l) \rightarrow 2I_2(c) + 6IO_3^-(aq)+6H^+(aq)+30CH_3COOH(aq), \quad (2)$$

$$5\Delta H_f^\ominus[I_2Cl_6(c)] = 6\Delta H_f^\ominus[IO_3^-(aq)] + 30\Delta H_f^\ominus[Cl^-(aq)]+2\Delta H_f^\ominus[I_2(c)] + 36\Delta H_f^\ominus[H^+(aq)]-18\Delta H_f^\ominus[H_2O(l)]-5\Delta H_h^\ominus, \quad (3)$$

$$5\Delta H_f^\ominus[(CH_3COO)_6I_2(c)] = 6\Delta H_f^\ominus[IO_3^-(aq)] + 2\Delta H_f^\ominus[I_2(c)]+30\Delta H_f^\ominus[CH_3COOH(aq)] + 6\Delta H_f^\ominus[H^+(aq)]-18\Delta H_f^\ominus[H_2O(l)]-5\Delta H_h^\ominus, \quad (4)$$

using the following ancillary data (all values in kJ mol^{-1}):

$$\Delta H_f^\ominus[IO_3^-(aq)] = -221.3\pm4.0;^{10}$$

$$\Delta H_f^\ominus[Cl^-(aq)] = -167.08\pm0.004;^{10}$$

$$\Delta H_f^\ominus[H_2O(1)] = -285.83\pm0.004;^{11}$$

$$\Delta H_f^\ominus(CH_3COOH)(3000H_2O) = -487.0\pm1.0.^{12}$$

DISCUSSION

Hydrolysis of I_2Cl_6

The excellent agreement between the definitive value (based on heat capacity measurements) of Lamoureaux and Giauque[7] for the $\Delta H_f^\ominus$ of I_2Cl_6 and that calculated from the present solution calorimetric measurements (-89.29 ± 0.10 and -89.89 ± 1.9 kJ mol^{-1}, respectively) supports the view that the hydrolytic reaction proceeds as in eqn (1). The possibility of significant polyhalide formation, e.g. ICl_2^-, and reversibility under the prevailing experimental conditions, is unlikely.

Sequential reaction of I_2Cl_6 *with* $AgNO_3$

As shown in Fig. 1, the aqueous reaction between I_2Cl_6 and $AgNO_3$ is clearly sequential and may be quantitatively rationalized as follows. All the chloride ions are first precipitated, followed by reaction of iodine to give iodide and iodate ions. AgI then precipitates immediately ($K_{sp} \sim 10^{-16}$), together with some $AgIO_3$ ($K_{sp} \sim 10^{-8}$). This is followed by precipitation of the remaining iodate when conditions, e.g. pH, allow the solubility product to be exceeded. These processes may be summarized as follows:

$$30Cl^- + 30Ag^+ \rightarrow 30AgCl\downarrow, \quad (i)$$

$$2I_2+2H_2O+4Ag^+ \rightarrow \frac{10}{3}AgI\downarrow+\frac{2}{3}AgIO_3\downarrow+4H^+, \quad (ii)$$

$$6IO_3^- + 6Ag^+ \rightarrow 6AgIO_3\downarrow. \quad (iii)$$

The overall reaction is hence:

$$3I_2Cl_6+24AgNO_3+12H_2O \rightarrow 18AgCl+2AgI+4AgIO_3+24HNO_3. \quad (iv)$$

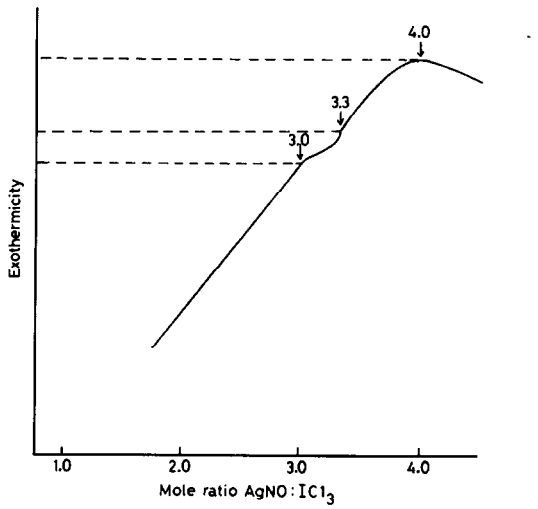

Fig. 1. Thermometric titration of ICl_3 with aqueous $AgNO_3$.

That reactions (i)–(iii) proceed discretely and sequentially is shown by the positions of the projections of the inflections on the abscissa of the thermometric reaction trace at $Ag^+ : IO_3^-$ mole ratios of 3 : 1, 3.33 : 1 and 4 : 1, respectively. In each case the position on the ordinate (energy) axis relevant to these points was quantitatively and unequivocally assignable to the precipitation of the appropriate mass of product, viz. AgCl, AgI and $AgIO_3$, respectively, via the literature values of the appropriate $\Delta H_f^\ominus$; details are given elsewhere.[13] Finally, the validity of eqn (iv) was further confirmed by acidimetric back titration of the nitric acid produced.

Hydrolysis of $(CH_3COO)_6I_2$

Combustion studies, routinely applied to organic compounds using a conventional static bomb calorimeter, cannot be applied to iodine(III) organic compounds in view of the uncertainties in defining the final state. The good agreement in results reported above for I_2Cl_6, compared with independent measurements,[7] and its clear chemical similarity to $(CH_3COO)_6I_2$ on hydrolysis, give confidence that a solution–reaction procedure is appropriate for determination of $\Delta H_f^\ominus$. Presumably comparable sequential processes are likely in reductive hydrolyses, as with $AgNO_3$ and I_2Cl_6. The substantial negative value for $\Delta H_f^\ominus (CH_3COO)_6I_2$ does not, of course, reflect reactive stability.

SYNTHESIS, CHARACTERIZATION AND ^{1}H NMR STUDIES OF $[Co(en)_2(malH)_2]ClO_4 \cdot H_2O$

C. CHATTERJEE,* MARIE STEPHEN, RAKESH KUMAR and SUBROTO DAS

Department of Chemistry, Indian Institute of Technology, Powai, Bombay 400076, India

(*Received* 9 *December* 1985; *accepted* 27 *January* 1986)

Abstract—The *trans*-$[Co(en)_2(malH)_2]ClO_4 \cdot H_2O$ complex was prepared by the reaction of sodium hydrogen malonate with $[Co(en)_2(H_2O)_2](ClO_4)_3$ in the presence of a large concentration of perchlorate ion. It showed a three-band visible spectrum ($\lambda\lambda_{max}$ 357, 448 and 542.6 nm), diagnostic of a *trans*-MA_4B_2 system and gave characteristic IR bands as expected for a *trans*-bisethylenediamine cobalt(III) complex. The ^{1}H NMR spectrum in DMSO-d_6 revealed a broad band at 5.8 ppm assignable to the amino hydrogen and a single band at 2.68 for the ethylene group of the chelate ring. The $\rangle CH_2$ group of the hydrogen malonate ion appeared as a sharp singlet at 2.95 ppm and integration showed the presence of two bimalonate groups. The reactive methylene protons were found to be exchangeable. Ion association by counter ions of the complex ion in DMSO-d_6 showed no preference among amino protons. This is as expected for *trans* complexes with D_{2h}-symmetry.

In the anation reaction of *cis*-$[Co(en)_2(OH_2)_2]^{3+}$ with the bimalonate ion[1] the product expected is $[Co(en)_2(mal)]^+$. However, at low pH (~2.5), instead of getting complete conversion the absorbance at the end of the reaction does not match the spectral data of $[Co(en)_2(mal)]^+$. Some side reactions occur which could be due to formation of the *trans* product. The *trans* product separates out on standing for a long time from the reactant solution containing excess sodium perchlorate.

The synthesis of *trans* compounds with dicarboxylate as the unidentate group are very rare and hence justifies detailed characterization. Carunchio *et al.*[2] reported the synthesis of *trans*-$[Co(en)_2(malH)(H_2O)]^{2+}$ in solution and hence characterization was confined to the liquid phase only. The isolation of the title complex in the solid state allowed extensive and systematic structural investigations.

EXPERIMENTAL

Preparation of the complexes

$[Co(en)_2(CO_3)]ClO_4$ was prepared following the method described in the literature.[3] *cis*-$[Co(en)_2(H_2O)_2](ClO_4)_3$ was obtained by acidifying $[Co(en)_2(CO_3)]ClO_4$ with a slight excess of perchloric acid.

trans-$[Co(en)_2(malH)_2]ClO_4 \cdot H_2O$

This was synthesized by the addition of excess sodium hydrogen malonate (0.1 M) to an aqueous solution (50 cm^3) of *cis*-$[Co(en)_2(H_2O)_2]ClO_4$ (0.005 M). The pH of the solution was adjusted to ~2.5 followed by addition of the requisite quantity of sodium perchlorate such that the final concentration of perchlorate ion in the solution was $\geqslant$ 2.0 M. After digesting the reaction mixture at 70°C for 4 h the solution was allowed to evaporate slowly at room temperature. The reddish violet crystals of *trans*-$[Co(en)_2(malH)_2]ClO_4 \cdot H_2O$ separated out on standing. The product was recrystallized twice from acidified aqueous solution and washed successively with water, ethanol and ether and finally dried in air. Found: C, 23.6; H, 4.7; N, 11.2%. Calc. for $[CoC_{10}H_{22}N_4O_8]ClO_4 \cdot H_2O$: C, 23.9; H, 4.4; N, 11.4%.

Physical measurements

IR spectra of the complex in KBr were recorded using Nicolet model FTIR Spectrometer. A. Shimadzu 260 UV–visible spectrophotometer was

* Author to whom correspondence should be addressed.

employed for recording electronic absorption spectra. ^{1}H NMR spectra were recorded on a Varian-XL 100 spectrometer operating at 100 MHz. The spectra were obtained either in deuterium oxide (Aldrich, 99.8 atom % D minimum) or in perdeuteriodimethyl sulphoxide (Me_2SO-d_6, 99.9 atom % D minimum) with an internal reference of sodium 2,2-dimethyl-2-siliapentane-5 sulfonate or tetramethyl silane, respectively. Thermogravimetric analysis (TGA) was carried out using a Dupont thermal balance at a heating rate of 5°C min^{-1} under a nitrogen atmosphere.

RESULTS AND DISCUSSION

Carunchio *et al.*[2] isolated a mixture of *cis*- and *trans*-$[Co(en)_2(mal)(OH)]$ during the base hydrolysis of the $[Co(en)_2(mal)]^+$ ion. The *trans* species was separated from the *cis* isomer chromatographically. Acidification of the *trans*-hydroxo species led to the synthesis of the *trans*-$[Co(en)_2(malH)(H_2O)]^{2+}$ ion characterized in the solution phase. The complex in the present investigation contains two hydrogen malonate ions in the *trans* position. Preliminary investigation reveals that the aquation of the complex in weakly acidic medium leads to the initial formation of *trans*-$[Co(en)_2(malH)(H_2O)]^{2+}$ followed by the isomerization of the latter to the *cis*-$[Co(en)_2(malH)(H_2O)]^{2+}$ product. The isolation of the title complex in the solid state thus enabled detailed characterization by various physical techniques. The present data will add knowledge in the chemistry of *trans*-dicarboxylate bisethylenediamine complexes.

Protonation equilibrium studies

Acid dissociation constants of the *trans*-$[Co(en)_2(malH)_2]ClO_4 \cdot H_2O$ complex at 25°C and ionic strength 1.0 mol dm^{-1} were determined from conventional pH-metric titrations against a carbonate-free sodium hydroxide solution using pH M-64 research pH meter (Radiometer, Copenhagen). The pK_a values computed were $pK_1 = 3.0 \pm 0.05$ and $pK_2 = 4.10 \pm 0.1$, respectively.

Electronic absorption spectrum

Wilkins and Williams[4] have summarized the use of electronic absorption spectroscopy to distinguish between *cis*- and *trans*-cobalt(III) isomers based on crystal field considerations as established by Ballhausen and Jorgensen,[5] Moffit and Ballhausen,[6] and Yamatera.[7] The visible spectrum of the complex *trans*-$[Co(en)_2(malH)_2]^+$ in dilute perchloric acid showed absorption maxima corresponding to *d–d* transitions at 357, 448 and 542.6 nm respectively. The three absorption band spectrum (Fig. 1 and Table 1) is diagnostic of a *trans* configuration for the hexacoordinate complex of type MA_4B_2. In the *trans* isomer the $^1A_1 \rightarrow {}^1T_1$ transition was split and the principal band shifted to a lower energy. The low extinction coefficients of *d–d* bands (Table 1) also suggests the *trans* configuration for the complex. For the present system and for the *trans*-$[Co(en)_2(H_2O)(malH)]^{2+}$ ion the extinction coefficient corresponding to the shorter wavelength (357 nm) is higher than that of the longest-wavelength band (542–546 nm) while for *cis*-$[Co(en)_2(H_2O)(malH)]^{2+}$ and *cis*-$[Co(en)_2(mal)]^+$ ions the reverse trend is observed.[2]

IR spectrum

The IR spectrum of the complex in KBr pellets (Fig. 2) revealed two strong bands at 1581 and 1729 cm^{-1} attributable to the carbonyl stretching frequencies of the coordinated and free carboxyl groups, respectively. Morris and Busch[8] while

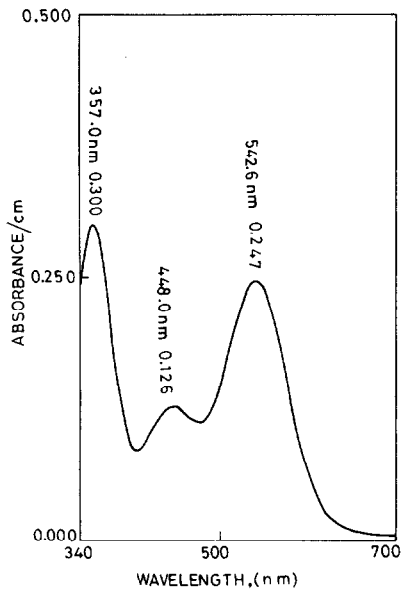

Fig. 1. Electronic spectrum of *trans*-$[Co(en)_2(malH)_2]ClO_4 \cdot H_2O$ in 0.05 mol dm^{-3} $HClO_4$. [Complex] = 0.004 mol dm^{-3}.

studying the IR spectra of *cis*- and *trans*-dichloro- and dinitro-bisethylenediamine cobalt(III) complexes, observed a characteristic difference in the N—H bending mode between the isomers. *Cis* complexes showed splitting of the band in the region 1640–1570 cm^{-1} while no splitting is observed for the corresponding *trans* isomer. The title complex $[Co(en)_2(malH)_2]^+$ shows only one peak at 1581 cm^{-1}, whereas *cis*-$[Co(en)_2(mal)]^+$ shows two absorptions at 1571 and 1621 cm^{-1}. On the basis of

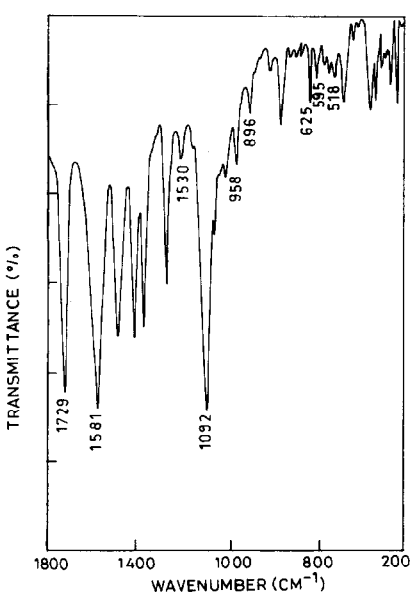

Fig. 2. IR spectrum of *trans*-$[Co(en)_2(malH)_2]ClO_4 \cdot H_2O$.

IR spectra of several *cis*- and *trans*-diacido bisethylenediamine cobalt(III) complexes, Chamberlain and Bailar[9] suggested that only one N—H wagging frequency appears in the range 1120–1150 cm^{-1} for the *trans* but two for the corresponding *cis* isomers. A single peak at 1130 cm^{-1} for the complex under investigation strongly suggests the *trans* configuration. The peak at 1130 cm^{-1} appears as a shoulder along with the major absorption band due to the perchlorate ion at 1092 cm^{-1}. Baldwin[10] in the course of their spectral studies on *cis*- and *trans*-bisethylenediamine cobalt(III) complexes noted a consistent variation of spectra with configuration in the CH_2 rock region (870–910 cm^{-1}) of the chelate ring. Here again, the complexes with the *cis* configuration showed two bands whereas a single band was observed for the *trans* isomers. In accordance with a *trans* configuration the title complex exhibited only one band at 896 cm^{-1}. Hughes and McWhinnie[11] obtained a satisfactory correlation with the number of peaks and the configuration of the isomers in the region 500–610 cm^{-1} where Co–N stretching modes occur. In this region no *trans* isomer has more than three strong bands whereas four bands were exhibited by the *cis* isomers. The bands for the *trans* isomers are generally evenly spaced, whereas in the *cis* complexes they appear in two separate groups. The band at 561 cm^{-1} is attributable to the Co—O of the Co–malH bond. It is evident from Fig. 2 that the *trans* complex reveals only three bands at 595, 540 and 518 cm^{-1}, whereas four bands at 592, 580, 533 and 520 cm^{-1} are exhibited by *cis*-$[Co(en)_2(mal)]ClO_4$. Prominent IR peaks due to perchlorate ions are observed at 1092, 958 and 625 cm^{-1} and the evidence obtained from IR studies is thus consistent with a *trans* configuration for the title complex.

^{1}H NMR *spectrum*

The ^{1}H NMR spectrum offers conclusive proof of the configuration of the isomers in solution. The *cis* and *trans* isomers of $[Co(en)_2X_2]^+$ ions have different symmetry properties, and this factor appears to govern the difference in their NMR spectra. The *cis* isomers possess C_2-symmetry with the two-fold axis in the plane of cobalt and the two X groups. As a result the $\diagdown CH_2$ protons become equivalent provided the cobalt–ethylenediamine rings have the same conformation. In case of relatively rigid conformers an ABCD pattern could be seen in D_2O. If an average conformer is observed an A_2B_2 system should appear since the protons on

either side of each cobalt–ethylenediamine ring would experience different fields. The amine hydrogens in the *cis* configuration also undergoes splitting and gives rise to four peaks in ideal situations. In *trans* isomers, however, with D_{2h}-symmetry, the amine protons and methylene protons of ethylenediamine appear as singlets. A similar situation is observed in dipolar aprotic solvents, such as DMSO-d_6. Both the number and the intensity of NH signals may be rationalized in terms of overall stereochemistry. In the *trans* complexes all the protons are equivalent due to the rapid conformational interchange and hence only one signal is observed. For the *cis* compound the different NH absorption are attributed to the orientation of the NH protons with respect to the rest of the ions.

Figure 3 illustrates the NMR spectra of the title complex in DMSO-d_6 and D_2O solvents. The spectrum of the title complex in DMSO-d_6 exhibited a broad band of eight-proton intensity at δ 5.8 ppm which is assignable to the amine hydrogens of ethylenediamine. The absorptions at δ 2.95 and 2.68 ppm are assigned to the CH_2 absorptions of hydrogen malonate and ethylenediamine, respectively, on the basis of their integrated intensities (1 : 2). The sharp signal at 2.95 ppm is indicative of the equivalence of the two protons of the methylene moiety of the hydrogen malonate ion. A similar pattern was also observed in D_2O (Fig. 3b).

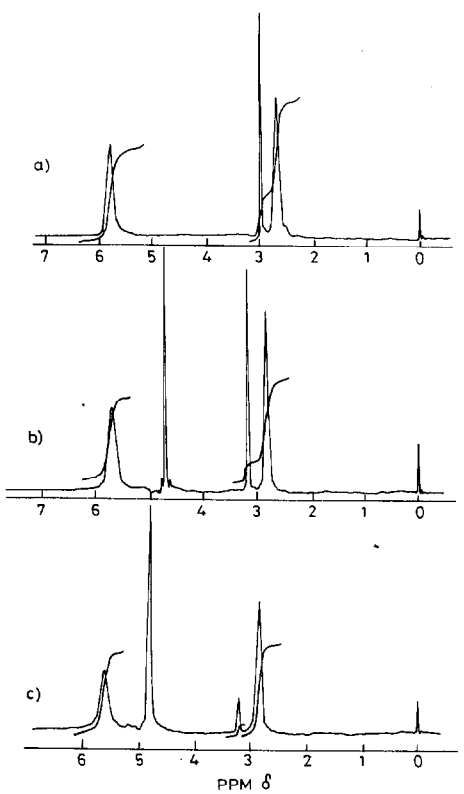

Fig. 3. PMR spectra of *trans*-$[Co(en)_2(malH)_2]ClO_4 \cdot H_2O$ in: (a) DMSO-d_6, (b) D_2O, and (c) D_2O and DCl.

Proton exchange

The amine protons of metal amine complexes undergo fast H–D exchange when dissolved in D_2O. In contrast, no appreciable exchange of amine protons in the title complex was observed under identical conditions. As the H–D exchange of the amine proton is always base-catalysed the lack of proton exchange can be attributed to the presence of free carboxylic acid groups contribution to the residual acidity. The reactive methylene protons of the malonate groups are found to exchange at a fast rate in both acidic and alkaline D_2O. Such an exchange of methylene hydrogen in the coordinated malonate group has been reported by several workers.[12]

Ion association

Directional association of ions with amine protons in metal complexes as inferred from NMR spectra is a fascinating subject and yields valuable information as regards the three-dimensional structure of the complex in solution. Ion association occurs when counter anions bind with an ionizable hydrogen of the coordinated ligands in the complex ion. The counter ions are known to associate with amine hydrogens via hydrogen bonding. Association by hydrogen bonding causes a reduction in electron density on the bonded hydrogen atom and the NMR signal moves downfield. The downfield shift increases with increasing amount of counter ions. The most interesting and important fact is that the association of the counter anion with a complex cation is stereoselective. The selection based on electrostatic consideration suggests that, since the anion carries a negative charge, it will approach the complex cation along the C_2-axis from the side opposite to the acido group present in the complex. Yoneda *et al.*,[13] while studying the ion association of amine hydrogens in *cis*-$[Co(en)_2X_2]^+$ systems, found that the NH *trans* to X was most sensitive to ion association. In *trans*-$[Co(en)_2X_2]^+$ such a preference is not expected since all the amine hydrogens are *cis* to X. In order to test the above generalization for differentiating the *cis* and *trans* configurations, ion association studies were carried out by the addition of lithium chloride to the complex ion dissolved in DMSO-d_6. As expected all the amine hydrogens

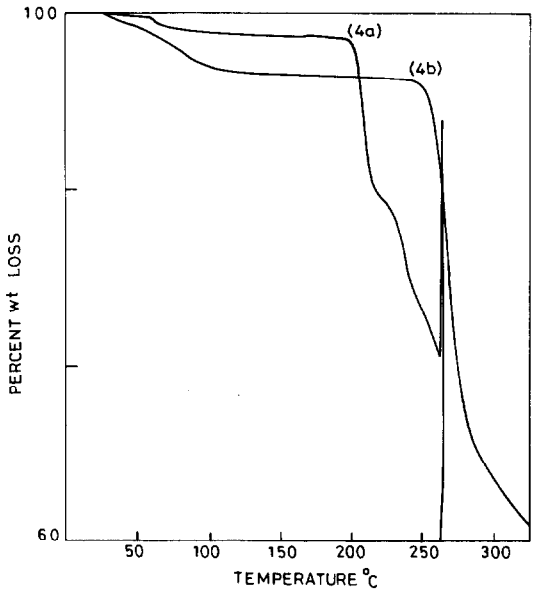

Fig. 4. Thermal analysis of: (a) *trans*-$[Co(en)_2(malH)_2]ClO_4 \cdot H_2O$, and (b) $[Co(en)_2mal]Cl \cdot 2H_2O$.

moved downfield together. The downfield shift was only 0.3 ppm even in the presence of a large excess of lithium chloride as against a 1–2-ppm shift of amine protons *trans* to X in *cis*-$[Co(en)_2X_2]^+$. A larger downfield shift is indicative of a higher association constant of *cis* complexes in a dipolar aprotic solvent.

Thermal studies

The thermal data (Fig. 4) show that the title compound decomposed in multiple steps. The first step was due to the loss of one water molecule at 75°C (found = 3.3%, calculated for % water in $[Co(en)(malH)_2]H_2O_4 \cdot H_2O$ = 3.58). The second step at 215°C could be attributed to the loss of two CO_2 molecules. This most probably occurred due to decarboxylation from free carboxylic acid groups in the complex [found (% loss) = 17.6, calculated for loss of two CO_2 molecules = 17.51]. The third step at 255°C is decarboxylation of the coordinated carboxylate group with total decomposition of the complex which occurred through an *explosion* as shown by the break in the line in Fig. 4a. The TGA of the chelated malonate complex $[Co(en)_2(mal)]Cl \cdot 2H_2O$ (Fig. 4b) shows a one-step decomposition at 267°C. In the chelated complex it shows that decarboxylation occurs at a higher temperature.[14]

Abstract—The Re(V) complexes $[Re(L)_2O_2]^+$ [L = en (1,2-diaminoethane) or pn (1,3-diaminopropane)] are reduced irreversibly near −1.5 V (SCE) in a neutral or basic aqueous solution, but protonation causes a significant anodic shift of ~+1 V. No oxidation is observed in aqueous solution before the solvent limit (~+1 V) at solid electrodes but oxidation of $[Re(en)_2O_2]^+$ with OH in pulse radiolysis experiments generates a Re(VI) intermediate which decays by first-order kinetics (k_d 2.5×10^4 s^{-1}), apparently by rate-determining ligand loss. Reduction with e_{aq}^- likewise forms transient d^3-Re(IV) complexes which show first-order decay (6×10^3 s^{-1} for en, 9×10^3 s^{-1} for pn), ultimately to ReO_2. Transient intermediates were characterized by their electronic spectra, which for d^3-Re(IV) complexes are qualitatively similar to Cr(III) and known octahedral Re(IV) complexes with different donor ligands.

The known chemistries of rhenium and technetium are similar.[1,2] The latter element has attracted a deal of recent interest, largely as a result of the importance of compounds of technetium as radiopharmaceuticals.[2,3] This interest has caused the coordination chemistry of this synthetic element to be investigated more extensively than that of rhenium. Nevertheless, the latter element is inherently easier to work with on a large scale and the study of its chemistry and reactions may have implications for reactions of the former. With simple saturated multidentate amines, both elements form hexacoordinate dioxo complexes with the metal in oxidation state V. Although various amines have been coordinated to Tc(V),[2] only the 1,2-diaminoethane (en) and 1,3-diaminopropane (pn) complexes of Re(V) are well-characterized.[4–9]

The dioxorhenium(V) diamine compounds are known to protonate in aqueous acid (presumably oxo to hydroxo),[4,8] and appear to undergo a one-electron reduction below −1 V in aqueous solution,[9] although redox properties have not been investigated extensively. Since a one-electron reduction would lead to d^3-Re(IV), and this electronic configuration is inherently inert, it was of interest to investigate this reduction in detail by electrochemical and pulse radiolytic means. Further, the prospect of oxidation to presumably labile d^5-Re(VI) exists. This paper reports the pulse radiolysis and pH-dependent voltammetry of dioxobis(diamine)rhenium(V) cations in aqueous solution.[10]

EXPERIMENTAL

Syntheses

Bis(1,2-*diaminoethane*)*dioxorhenium*(V) *chloride*. This complex was prepared by the oxidation of a mixture of K_2ReCl_6 (3 g) in 90% en (15 cm^3) with air as previously described,[4] and recrystallized from water and alcohol as yellow-green microcrystals (1.6 g, 70%). Found: C, 13.0; H, 4.3; N, 14.9%. Calc. for $C_4H_{16}ClN_4O_2Re$: C, 12.8; H, 4.3; N, 15.0%.

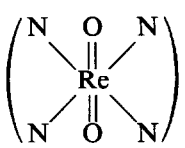
Bis(1,3 - *diaminopropane*)*oxohydroxorhenium*(V) *chloride*. This complex was prepared as above,

* Author to whom correspondence should be addressed.

except that recrystallization from dilute acidic solution (pH ~ 2) gave the purple oxohydroxo complex in similar yield. Found: C, 16.7; H, 4.9; N, 12.8%. Calc. for $C_6H_{21}Cl_2N_4O_2Re$: C, 16.4; H, 4.8; N, 12.8%.

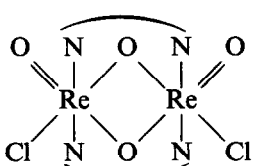
Bis(1,4 - *diaminobutane*)*dichlorotetraoxodirhenium*(V). Attempts to reproduce the above syntheses with 1,4-diaminobutane (bn) yielded a black neutral product in the initial step following addition of acetone. Spectroscopy and microanalysis were most consistent with formulation as a dimer, the complex being isolated with the ·KCl·acetone formulation. Found: C, 16.0; H, 3.8; N, 7.2; Cl, 12.8%. Calc. for $C_8H_{24}Cl_2N_4O_4Re_2 \cdot KCl \cdot (CH_3)_2CO$: C, 16.2; H, 3.7; N, 6.9; Cl, 13.0%.

Physical methods



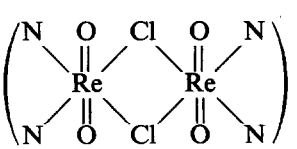
IR spectra were recorded as KBr discs using a Perkin–Elmer 3-300 spectrometer. Electronic spectra were recorded using an Hitachi 220A spectrophotometer. The pK_a values for the hydroxo/oxo forms of the pn complex were determined spectrophotometrically at several wavelengths in the visible region using either a range of acids of known concentration or a range of buffers of known pH.

Polarography at a dropping mercury (DME) or a static mercury drop electrode, and cyclic voltammetry at either a hanging mercury drop electrode (HMDE) or a glassy carbon electrode, was performed on dilute aqueous solutions ($\sim 10^{-3}$ M) under an inert argon atmosphere. A conventional three-electrode system was employed with a platinum wire auxiliary electrode and a silver–silver chloride or SCE reference electrode. Electrochemical controllers employed were either BAS Model 27 or Amel Model 457 units.



Pulse radiolysis experiments were conducted using the 1-MeV electron accelerator facility and optical system previously described.[11] The system was calibrated by thiocyanate dosimetry.[12] Complexes in triply-distilled water at concentrations $\leqslant 10^{-3}$ M were reacted with e_{aq}^- or OH radical. For e_{aq}^-, an N_2-purged solution containing 0.1 M *t*-butyl-alcohol as an OH radical scavenger was used; for OH, the solution was purged with N_2O to capture e_{aq}^- by converting e_{aq}^- to OH, thus effectively doubling the yield of OH radical. Initial and final optical-density changes were measured at 5–25-nm intervals from signal-averaged data over the range 220–700 nm. This permitted construction of the absorption spectra of intermediate and decay products. Kinetics of the decay processes were followed at several wavelengths in the UV–visible region. Formation rate constants for reaction with e_{aq}^- ($G_e = 2.7$) were determined by monitoring the decay kinetics of e_{aq}^- at 580 nm in the presence of different concentrations of complex. The rate constant for formation with OH ($G_{OH} = 5.5$) was determined by competition kinetics with KSCN. The radiolytically generated e_{aq}^- is a powerful reducing agent ($E^\ominus = -2.8$ V), while the OH radical is a powerful oxidizing agent ($E^\ominus = \sim +2$ V); the reaction conditions in these experiments determine that the oxidation and reduction processes initiated are definitively one-electron in character.

RESULTS AND DISCUSSION



Reaction of $ReCl_6^{2-}$ with en or pn and oxygen at room temperature yields the bis(diamine)dioxorhenium(V) compounds in high yield. The crystal structure of $[Re(en)_2O_2]^+$ has been determined,[7] and the Re(V) ion is monomeric and essentially octahedral, with a *trans*-dioxo configuration and chelated diamines (**I**). While five- and six-membered chelates readily lead to monomers with structure **I**, attempts to repeat the synthesis with bn yielded a black and possibly polymeric compound. Although detailed characterization was not pursued, IR spectroscopy is indicative of diamine coordination and bound oxo groups, and microanalysis best fits a formulation as a dimer of stoichiometry $[Re_2(bn)_2Cl_2O_4]$. Possible structures are **II**, where the bridging diamine may be appropriate with the longer-chain bn, or else a bridging chloro species such as **III**. Both

I

II

III

oxo and chloro bridges are known for rhenium,[1] and a structure like **III** could be viewed as an intermediate in the synthesis of **I**. Further work with this compound is warranted, but in this case we intended to concentrate on the definitive monomeric Re(V) diamines formed with en and pn.

The electronic spectra of the dioxorhenium(V) monomers are markedly pH-dependent, as observed previously.[8] Maxima for both diamine complexes at three different acidities apparently corresponding to three different species are collected in Table 1. From these spectra, at least two acid dissociation steps are apparent in aqueous solution; spectroscopic pK values determined were $pK_1 = 3.2$ and $pK_2 = -0.7$ for the pn complex, which agree well with values of 3.26 and -0.9 previously determined for the en complex.[8] The complexes decompose only very slowly in aqueous acid at room temperature, but decompose more rapidly in strong aqueous base. Allowed electronic transitions for octahedral d^2 are $^3T_{1g}(F) \rightarrow {}^3T_{2g}(F)$, $^3T_{1g}(F) \rightarrow {}^3T_{1g}(P)$ and $^3T_{1g}(F) \rightarrow {}^3A_{2g}(F)$; the latter probably does not contribute to transitions in the visible region for first-row V(III).[113] Observed transitions in third-row Re(V) may relate to the first-row case, and should be similar in octahedral d^2-W(IV), although electronic spectroscopy of neither third-row metal ion has been extensively studied.[1] The significant shifts in absorption maxima with acidity fit best with protonation of the O^{2-} ligand to OH^-, since these ligands differ in their position in the spectrochemical series. Considerable diminution in $d\pi$–$p\pi$ interactions to the M—O bonding is also expected from O^{2-} to OH^-.[14] The pH-dependent polarography supports in part ligand protonation. Previously, protonation/deprotonation shifts in metal-centred redox couples of approximately 1 V have been observed for octahedral third-row metal complexes of Pt(IV) and Os(IV).[15,16] Here, the $[Re(en)_2O_2]^+$ complex at neutral pH exhibits an irreversible reduction near -1.5 V (SCE) at the DME; this shifts to a quasi-reversible couple at -0.5 V at pH $\sim$ 1, paralleling the earlier observations.

Voltammetry of the dioxorhenium(V) complexes (Table 2) shows that reduction occurs well below -1 V on both mercury and solid-billet electrodes in neutral solution. Previously, polarography in aqueous chloride media of the $[Re(en)_2O_2]^+$ complex, some with added ethylenediamine, reported a reversible one-electron couple at or near -1.15 V (SCE).[9] This does not agree completely with the current results in ClO_4^- media, nor does the assertion in that note that the $Re(en)Cl_4$ compound is formed equate with the concept of reversibility. Notably, the polarography in acid defined a quasi-reversible couple which is a volt more cathodic than the wave in neutral solution (Fig. 1) for both complexes. The significant shift in potential observed at the mercury electrode was not reproduced clearly at a glassy carbon electrode where the wave is poorly-defined and irreversible, so it is likely that the former couple is not a simple metal-centred process, but involves some specific interaction with the metal electrode surface. In aqueous solution, no oxidation of Re(V) is observed at solid electrodes before the solvent limits of $\sim +1$ V.

It is only with the powerful oxidant OH in the pulse radiolysis experiments that an oxidation reaction is observed. Rapid formation (Table 3) of an apparently Re(VI) complex occurs upon reaction of OH with $Re(en)_2O_2^+$. The transience exhibits an absorbance maximum at 320 nm, with no detectable absorbances in the visible region (Fig. 2). The decay of this transience is quite rapid, and first-order in nature. Disproportionation of Re(VI) with second-order kinetics is the expected mode of decay, and has been observed for Re(VI) generated by reduction of ReO_4^- with e_{aq}^-.[17] The first-order process observed here implies that ligand loss is the

$$\downarrow k_{dissoc}$$

$$\text{oxo Re species} \xrightarrow{fast} Re(V) + Re(VII).$$

Alternatively, hydrogen abstraction from the amine ligand may be the first step, with intramolecular electron transfer to form an Re(VI) species which then undergoes ligand dissociation and disproportionation reactions. Like ReO_4^{2-}, the Re(VI) species generated in this reaction is not stable. Earlier studies of chemical oxidation of $[Re(en)_2O_2]^+$ to Re(VII) showed that the ReO_2 core remains intact,[5] so a like process probably holds in this one-electron oxidation, with amine loss the possible kinetically significant process.

While stable hexacoordinate Re(VI) is unlikely and its instability therefore not unexpected, the case for Re(IV) complexes is much stronger. Firstly, Re(IV) is a member of the d^3-family, and this is an inherently inert electronic configuration. Secondly, the present and previous voltammetry experiments lend some support to the existence of oxorhenium(IV) diamines. Finally, there are extant a range of examples of monomeric, octahedral Re(IV) compounds,[1,18–20] albeit not commonly with *N*-donor ligands. Known Re(IV) compounds usually contain

a halide or mixed halide, and O- or P-donors. The *trans*-$Re(acac)_2Cl_2$[19] and $Re(diphos)Cl_4$ [diphos = 1,2-bis(diphenylphosphino)ethane][20] compounds have been characterized by X-ray crystal structure analyses, and exhibit octahedral or distorted octahedral geometries. Since both Re(V) and Re(IV) commonly occur as hexacoordinated species, the addition of an electron to Re(V) should be accommodated without any requirement for marked geometric change.

Addition of e_{aq}^- to $[Re(en)_2O_2]^+$ and $[Re(pn)_2O_2]^+$ is rapid (Table 3), generating an intermediate which absorbs in the visible region. Two maxima are observed in each case (Fig. 3), and the spectra are qualitatively similar to those of octahedral d^3-Cr(III), and resemble somewhat the spectrum of *trans*-$Re(acac)_2Cl_2$ [maxima at 500 nm ($\varepsilon = 260$ M^{-1} cm^{-1}), 420 nm ($\varepsilon = 810$) and 330 nm ($\varepsilon = 1600$) reported,[18] the two low-energy maxima possible arising from splitting in the tetragonal field] despite the variation from a distorted O_4Cl_2 chromophore to a presumably N_4O_2 chromophore. Rapid formation of an Re(IV) complex is also supported by the expectation that the alternative of a saturated ligand radical would not absorb in the visible region. Decay of the intermediate Re(IV) complex occurs on the millisecond timescale by a first-order process which is presumed to involve amine ligand dissociation. Disproportionation is not consistent with the observed kinetic behaviour, nor is it expected for d^3-Re(IV), given the stability of ReO_2.

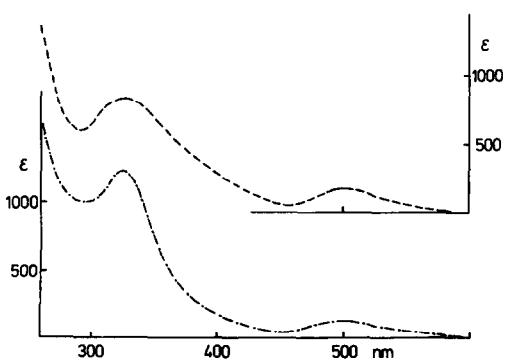

Fig. 3. Electronic spectra of the transient d^3-Re(IV) complexes formed from reaction of $[Re(en)_2O_2]^+$ (upper) and $[Re(pn)_2O_2]^+$ (lower) with e_{aq}^- in neutral aqueous solution.

The ultimate decomposition product was expected to be the cinnamon-coloured hydrate of ReO_2, and absorbance of visible light in aged solutions from continuous-pulse experiments is consistent with the expectation. It is known that decay of radiolytically-generated Mn(IV) amine complexes produces MnO_2 following decay,[21] so an analogy can be drawn. Further, decomposition of Re(IV) compounds such as $[Re(OH)Cl_5]^{2-}$ in aqueous solutions yield ReO_2 as the only stable product.[22] The immediate product of the decay in this case does not absorb in the visible region, however, so ReO_2 is not the initial decay product. Complexed species such as $Re(en)(OH)_4$, $Re(enH)(OH)_5$, $Re_2(en)(OH)_8$ or oxo analogues may form initially. The amine coordination chemistry of rhenium is strictly limited, so we are unable to establish the structure of this unstable species. It is notable that d^3-complexes of both Mn(IV)[21] and Re(IV) with saturated *N*-donor ligands apparently occupying four coordination sites decay relatively quickly. Apparently *N*-donor-saturated ligands do not form stable complexes with any metal in the +4 oxidation state in the manganese triad. This accords with the known chemistry, although whether this instability extends to unsaturated imine *N*-donors remains untested.

THE DECOMPOSITION OF POTASSIUM BIS(CARBONATO)DIAMMINECOBALTATE(III) AND THE KINETICS OF THE BRIDGE CLEAVAGE REACTIONS OF A HYDROXY-BRIDGED DIMER IN AQUEOUS PERCHLORIC ACID*

XIAOHONG LING and KENNETH E. HYDE†

Department of Chemistry, State University of New York, College at Oswego, Oswego, NY 13126, U.S.A.

(*Received* 10 *September* 1985; *accepted after revision* 28 *January* 1986)

Abstract—The decomposition of the title complex in aqueous perchloric acid solution has been investigated. A rapid decarboxylation yields an unexpected product tentatively identified as a μ-hydroxo-dicobalt(III) complex by its cation exchange column and UV–vis spectral characteristics. A dimeric structure with two carbonate bridges is proposed for the title complex and it is suggested that each carbonate bridge uses only one oxygen atom for bridging. The di-μ-carbonato complex, similar to a monodentate carbonato complex, is suggested to decarboxylate with carbon–oxygen bond rupture, leaving the oxygen bridges intact. The product $[(NH_3)_2(H_2O)_2Co(OH)_2Co(H_2O)_2(NH_3)_2]^{4+}$ undergoes both water-induced and acid-catalyzed bridge cleavage reactions in two successive steps, ultimately forming *cis*-$[Co(NH_3)_2(H_2O)_4]^{3+}$ via a singly bridged intermediate. Under the experimental conditions $\{[H^+] = 0.1$–2.0 M; $I = 2.0$ M ($NaClO_4$), 40°C$\}$, the k_{obsd} for both steps shows the same form: $k_{fast} = (2.20 \pm 0.18) \times 10^{-4} + (3.70 \pm 0.15) \times 10^{-4}[H^+]$ and $k_{slow} = (2.90 \pm 1.02) \times 10^{-5} + (11.85 \pm 0.83) \times 10^{-5}[H^+]$. These results are compared with those for the acid-catalyzed bridge cleavage reactions of other μ-hydroxo complexes.

The current status of the work on carbonato metal complexes has been recently reviewed.[1] The kinetics and mechanisms for the decarboxylation of monodentate[1,2] and bidentate[1,3,4] monocarbonato complexes have been adequately investigated. Recent kinetic studies have dealt with the decarboxylation reactions of bis(carbonato) complexes[5–7] and complexes that contain a bridging carbonato[8] ligand.

It was the original objective of the present study to investigate in detail the kinetics of the acid-catalyzed decarboxylation reaction of another bidentate bis(carbonato)cobalt(III) complex *cis*-$K[Co(NH_3)_2(CO_3)_2]$. However, the first observable decarboxylation product has been found to be entirely different from those observed for the decarboxylation of the $[Co(py)_2(CO_3)_2]^-$ and $[Co(en)(CO_3)_2]^-$ ions. The unusual behavior of the ammine complex is that the decarboxylation reaction produces condensed complexes presumed to be hydroxy-bridged dimers. These undergo further decomposition in aqueous perchloric acid. As a result, we have turned our attention to the kinetic study of the acid-catalyzed bridge cleavage reaction of a μ-hydroxo-dicobalt(III) complex. Limited kinetic data have permitted us to obtain the experimental rate law for this reaction. The kinetic behavior of the ion investigated in this work has been compared with those of some other similar tri-, di- and monohydroxy-bridged cobalt(III) complexes and a possible mechanism is suggested.

EXPERIMENTAL

Synthesis of cis-$K[Co(NH_3)_2(CO_3)_2]$

The title complex was prepared by a method similar to that reported previously.[9–11] Since several modifications have been incorporated in our synthesis, it is reported in detail below.

Approximately 35 g of $KHCO_3$ was mixed with

* This article is based in part on the M.S. thesis of XL submitted to the State University of New York, College at Oswego (1985).

† Author to whom correspondence should be addressed.

30 cm^3 of water, and the resulting slurry was kept cool in an ice bath. Separately, 12 g of $CoCl_2 \cdot 6H_2O$ was dissolved in 10 cm^3 of hot water, and 27 cm^3 of cold 30% H_2O_2 was added to this solution after it had been cooled in an ice bath. The Co^{2+}–H_2O_2 solution was added dropwise, with constant stirring, to the cold $KHCO_3$ slurry. The resulting green solution was quickly filtered by suction and the filtrate, potassium tris(carbonato)cobaltate(III) solution, was kept at 0°C in an ice bath. To this cold green solution was added 6 g of ammonium carbonate and the mixture was warmed with stirring in a water bath at 45°C until the color of the solution changed from dark green to dark blue. This process took about 35 min. The vessel containing the warm solution was immediately dipped into an ice bath and kept at 0°C for 20 min. Addition of approximately 200 cm^3 of cold methanol to the cooled solution caused precipitation. The initial precipitate was removed by suction filtration and discarded. The filtrate stood for about 2 h at room temperature and additional precipitation occurred during this period. Filtration of this mixture gave the crude product. The crude product was dissolved in a minimum amount of water and was reprecipitated with pure methanol. Repeating this reprecipitation procedure yielded the final product.

The purity of the product was verified by the experimentally determined carbonate : cobalt(III) ratio of 2.02 : 1 and a good agreement between the obtained spectral parameters and the literature values (see Table 1). The result of chemical analysis for each element, with the exception of oxygen, was close to that calculated for $K[Co(NH_3)_2(CO_3)_2]$. (Found : Co, 23.2; C, 9.4 and 9.3; H, 2.5 and 2.6; N, 10.9; O, 26.5 and 23.9%. Calc. : Co, 23.4; C, 9.5; H, 2.4; N, 11.1; O, 38.1%.) We take this elemental analysis as additional evidence for the reasonable purity of the final product. The stoichiometry *cis*-$K[Co(NH_3)_2(CO_3)_2]$ is assigned to this compound.

[a] The proposed decarboxylation product in this work. See the text for the stoichiometric assignment.

It indicates that there is no hydrate. The same complex has been reported to possess zero[9] or one[10] water of hydration.

Synthesis of cis-$[Co(NH_3)_2(H_2O)_4]^{3+}$

A small amount of *cis*-$K[Co(NH_3)_2(CO_3)_2]$ was dissolved in 1.5 M $HClO_4$. The resulting purple solution was kept at room temperature for 1 week. The *cis*-$[Co(NH_3)_2(H_2O)_4]^{3+}$ ion was purified by passing an acidic solution of this ion through a cold cation exchange column. The spectral parameters for *cis*-$[Co(NH_3)_2(H_2O)_4]^{3+}$ are reported in Table 1.

Cation exchange column procedures

A 1.5 × 3 cm column of Bio-Rad Dowex 50w-X2 cation exchange resin (200–400-mesh hydrogen form) with a cooling jacket 8 cm in length was employed for all the column chromatographic experiments. The column separation run started with prewashing the resin bed with at least two bed volumes of eluant and precooling the column to 0°C. All the exchange column experiments were performed at this temperature using 1.5 M $HClO_4$ as the eluant.

Analytical procedures

The cobalt concentration of a solution was determined spectrophotometrically using the procedure as described by Kitson.[12]

Carbon dioxide analysis was used in the determination of the stoichiometric carbonate content and in the estimate of the decarboxylation rate of the *cis*-$[Co(NH_3)_2(CO_3)_2]^-$ ion.

In the procedure for the investigation of decarboxylation rate, an amount (80–130 mg) of *cis*-$K[Co(NH_3)_2(CO_3)_2]$ was transferred to a dry flask previously thermostated to the desired temperature (0°C). This was followed by adding 20 cm^3 of 0°C 1.00 M $HClO_4$ [I = 2.0 M ($NaClO_4$)]. The start of the time measurement coincided with the addition of the acid. Dry nitrogen, free from carbon dioxide, passed through the reaction solution. The evolved carbon dioxide was carried by the nitrogen stream to the absorption system where it was absorbed by a standardized barium hydroxide solution. The absorption system was disconnected from the reaction system immediately after a selected time of 5 min. The excess barium hydroxide was titrated with standard hydrochloric acid to the phenolphthalein end point.[13]

By a slightly modified procedure, the bound carbonate content of the complex cations separated in the cation exchange column experiments was determined.

Kinetic measurements

The kinetic runs were followed by means of a CARY 14 spectrophotometer. Temperature control was maintained to within ±0.1°C by a thermostated circulating bath. A preliminary kinetic run was made at an acidity of 1.00 M [I = 2.0 M ($NaClO_4$)] and at 40°C by repeating the wavelength scan (from 600 to 280 nm) at certain time intervals. No isosbestic point was found.

Most kinetic data was obtained by recording the change in absorbance of the reaction solution at 315 nm as a function of time. To begin a run, a weighed sample (about 10 mg) of *cis*-$K[Co(NH_3)_2(CO_3)_2]$ was quickly dissolved in 20.0 cm^3 of $HClO_4$–$NaClO_4$ solution with appropriate acidity and at the temperature of the run. The resulting purple solution was immediately transferred to a cell contained in the thermostated cell compartment. In all kinetic runs, the reaction solution was monitored until the absorbance at 315 nm had decreased to a value below an A_∞ calculated from the known cobalt(III) concentration and the experimentally determined molar absorptivity of the product *cis*-$[Co(NH_3)_2(H_2O)_4]^{3+}$ (ε = 9.0 M^{-1} cm^{-1}).

RESULTS

The carbon dioxide analysis performed during the acid-catalyzed decomposition of the ammine–carbonato complex has shown conclusively that the loss of two carbon dioxides from each cobalt(III) center is complete in less than 5 min at 0°C and at an $[H^+]$ of 1.0 M. It is is assumed that the time span of 5 min corresponds to at least five half-lives, then an appropriate estimate of the pseudo-first-order rate constant would be 1×10^{-2} s^{-1}. This sets the lower limit for the decarboxylation rate constant at 0°C. This result is not unexpected. It has indicated that, under the experimental conditions of this work, the decarboxylation rate is too fast to be studied in detail by our techniques.

When *cis*-$K[Co(NH_3)_2(CO_3)_2]$ was dissolved in ~5 cm^3 of cold 1.5 M $HClO_4$ (0°C) and the resulting purple solution was immediately charged on the cold column, two bands appeared. A period of about 45 min was needed for removal of the first band from the column. Based on these experimental conditions and the observation that the loss of both carbonates from *cis*-$[Co(NH_3)_2(CO_3)_2]^-$ in 1.0 M $HClO_4$ is complete in less than 5 min at 0°C, we conclude that the species separated by our cold

column must not be a carbonato complex. In the spectrum of the very early portion of the band (leading 14 cm^3), there is a very strong absorbance peak at 315 nm. This peak around 300 nm has been proposed[14] to be indicative of the existence of hydroxy-bridged cobalt(III) dimers. The latter portions of the same band indicate the presence of a peak around 370 nm and a decrease in absorbance at 315 nm. This column experiment was repeated several times and the results were reproducible. They invariably indicated that the later the band portion was collected, the more evident was the peak at 370 nm and the less evident was the peak at 315 nm. This observation suggests poor separation and/or slight decomposition of the initial decarboxylation product during the cold column separation.

Compared with the column characteristics of the standard cations $[Co(NH_3)_4(H_2O)_2]^{3+}$, $[Co(NH_3)_5Cl]^{2+}$ and $[Co(NH_3)_4(NO_2)_2]^{+}$ the species contained in the first band appear to behave as 3+ charged cations. However, the components in this band need not have identical charges. It is not unreasonable for us to deduce that less eluant volume is required to elute a dimer (larger molecular size) than that needed for a same charged monomer (smaller size). It is therefore probable that a mixture of some hydroxy-bridged dimers with 3+ and/or higher charges are components of this first band.

The 620-cm^3 volume of eluant failed to elute the very small second band. No further attempts were made to obtain detailed information about the column and spectral characteristics of this very sluggish band which probably contains polymers with charges higher than 4+.

When the purple solution that resulted from dissolving *cis*-$K[Co(NH_3)_2(CO_3)_2]$ in ~ 5 cm^3 of 1.5 M $HClO_4$ was incubated for 1 week at room temperature, cold column separation showed only one band. This band behaved as a 3+ charged monomer. The leading, middle and trailing portions of this band exhibited nearly identical visible spectra and these spectra are in good agreement with that reported for *cis*-$[Co(NH_3)_2(H_2O)_4]^{3+}$.

Table 1 summarizes the spectral parameters in UV–vis range for the cobalt(III) complexes characterized in this work. The values previously published for some other similar cobalt(III) complexes are also listed in the same table for convenient comparison. Although caution has been used to minimize further decomposition of the initial decarboxylation product, the absorbance of the 315-nm peak still proved to be unreproducible. Therefore, the extinction coefficients reported in Table 1 for the proposed decarboxylation product (μ-hydroxo dimer) only can be assumed to be estimates.

In an extended kinetic run on the total decomposition of *cis*-$[Co(NH_3)_2(CO_3)_2]^{-}$, the observed A_∞ at 315 nm was smaller than the A_∞ calculated for the *cis*-$[Co(NH_3)_2(H_2O)_4]^{3+}$ ion ($\varepsilon = 9.0$ M^{-1} cm^{-1}), the expected final cobalt(III) product of the acid-catalyzed hydrolysis reaction. This observation suggests additional decomposition of *cis*-$[Co(NH_3)_2(H_2O)_4]^{3+}$. This further reaction is attributed to the slow reduction of the *cis*-$[Co(NH_3)_2(H_2O)_4]^{3+}$ ion to Co^{2+} species.

In the data treatment for a typical kinetic run, the calculated A_∞ was used and the plot of $\log(A_t - A_\infty)$ vs time showed a curvature at the beginning corresponding to an induction period, after which the plot became linear. These features suggest that the decomposition of the initial decarboxylation product occurs in two or more successive steps and that the relative rates of the slowest two steps (hereafter called fast step and slow step) are such that each step can be studied separately.

The pseudo-first-order rate constants for the slow step were obtained from the slopes of the later portions (linear for at least two half-lives) of the plots of $\log(A_t - A_\infty)$ vs time. An alternative method also was used to calculate the observed rate constants. This method involved a nonlinear least-squares computer fit of the absorbance–time data to the equation $A_t = (A_0 - A_\infty)e^{-kt} + A_\infty$. Both methods gave identical values within experimental uncertainty of the observed rate constants for the slow step. These values are shown as k_{slow} in Table 2. The A_∞ evaluated by the computer program agreed with the calculated A_∞ used in the conventional plot method to within 1.3%.

The observed rate constants that correspond to the fast step were extracted from the data as follows. The linear portions of the $\log(A_t - A_\infty)$ vs time plots

Table 2. Pseudo-first-order rate constants for the bridge cleavage reactions of $[(NH_3)_2(H_2O)_2Co(OH)_2Co(H_2O)_2(NH_3)_2]^{4+}$ in aqueous perchloric acid solutions at 40°C [$I = 2.0$ M ($NaClO_4$)]

$[H^+]$ (M)	k_{fast} (s^{-1})	k_{slow} (s^{-1})
0.1001	2.32×10^{-4}	5.29×10^{-5}
0.4010	3.90×10^{-4}	7.27×10^{-5}
1.002	5.94×10^{-4}	1.32×10^{-4}
1.507	7.94×10^{-4}	2.05×10^{-4}
2.006	9.45×10^{-4}	2.76×10^{-4}

$k_{fast} = k_a + k_b[H^+]$: $k_a = (2.20 \pm 0.18) \times 10^{-4}$
$k_b = (3.70 \pm 0.15) \times 10^{-4}$
$k_{slow} = k_c + k_d[H^+]$: $k_c = (2.90 \pm 1.02) \times 10^{-5}$
$k_d = (11.85 \pm 0.83) \times 10^{-5}$

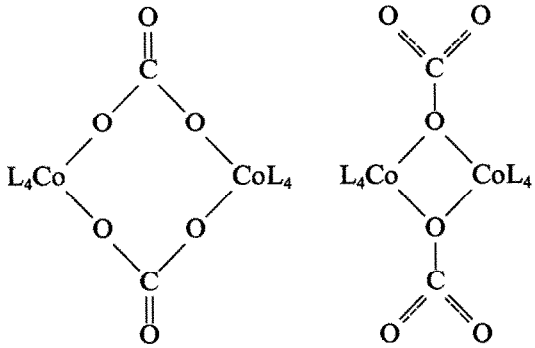
were back extrapolated. The differences between the original values of $A_t - A_\infty$ and the back extrapolated values were plotted vs time in a semilogarithmic manner. These plots were linear for at least four half-lives and the corresponding slopes[15] gave the pseudo-first-order rate constants for the fast step (shown as k_{fast} in Table 2).

It is seen from Table 2 that, in the range of hydrogen ion concentration investigated, the observed rate constants for both steps show a simple first-order dependence on hydrogen ion concentration of the following forms:

$$k_{fast} = k_a + k_b[H^+], \quad (1)$$

$$k_{slow} = k_c + k_d[H^+]. \quad (2)$$

The values of k_a, k_b, k_c and k_d were evaluated by using a least-square computer program and are given in Table 2.



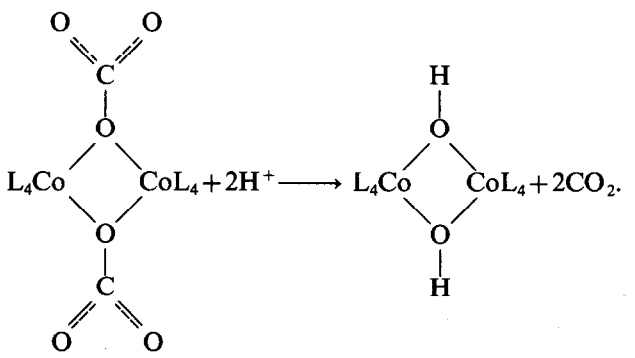
DISCUSSION

Our exchange column experiments have suggested a binuclear species, the μ-hydroxo-dicobalt(III) cation, as the first observable decarboxylation product of *cis*-$[Co(NH_3)_2(CO_3)_2]^-$. This behavior is in marked contrast to that of the $[Co(py)_2(CO_3)_2]^-$ and $[Co(en)(CO_3)_2]^-$ ions,[6,7] both of which give the corresponding monomeric tetraquo cobalt(III) complexes as the initial decarboxylation products. Now we concern ourselves with some possibilities for the structure of the reactant carbonato complex and the stoichiometry of the decarboxylation reaction that produces the hydroxy-bridged dimer.

One possibility is that the hydroxy-bridged dimer is produced from the acid-catalyzed decarboxylation reaction of a monomeric reactant, *cis*-$[Co(NH_3)_2(CO_3)_2]^-$. For the convenience of discussion, we have assumed this monomeric bis(carbonato)diamminecobaltate(III) ion earlier in this report. However, this proposal of a monomeric bidentate carbonato complex reactant may be refuted. The monomeric diaquo complex is always the observed decarboxylation product during the decomposition of a bidentate carbonato-cobalt(III) complex in acidic solution. Moreover, no precedent has been found for the formation of μ-hydroxo dimers from the corresponding monomeric aquo complexes in strongly acidic medium.

Another possibility is that the reactant carbonato complex is, itself, dimeric. Both monomeric and dimeric cobalt(III) complexes have been proposed to exist under the conditions usually used for the preparation of bis(carbonato) complexes[16] and it has been noted that acidification of these complexes yields hydroxy-bridged species.[17–20] These findings encourage us to propose a dimeric reactant with two carbonate bridges. However, there are two different binding modes for the carbonate bridges and hence two quite different structures for the dimeric reactant. One (structure **I**) may be thought to contain two triatomic bridging carbonate groups in a form that is somewhat analogous to that found in a bidentate carbonato complex. The other (structure **II**) contains carbonate groups with monoatomic oxygen bridges. These bridging carbonate groups may be viewed as being analogous to those found in a monodentate carbonato complex.

Previous work[8] on some μ-carbonato complexes in which the carbonate bridging is as shown in dimer **I** has indicated that the dimer possesses the same decarboxylation kinetic behavior as that of a bidentate carbonato complex.



I **II**

Assuming that this conclusion is applicable in the present work, dimer **I** is not expected to behave differently from the monomeric carbonato complex in its acid-catalyzed decarboxylation reaction. Both carbonato bridges would decarboxylate with metal–oxygen bond breaking and a monomeric aquo product is to be expected.

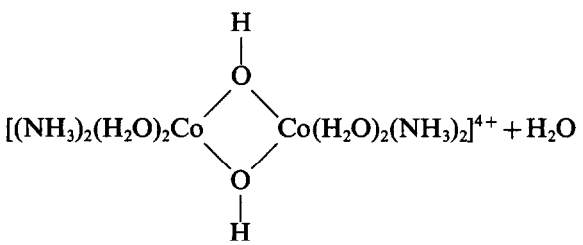
To explain the formation of the binuclear μ-hydroxo product, dimer **II** seems to be a proper candidate. Although there has been no report of a cobalt(III) complex in which a single oxygen of a carbonate group bridges a pair of adjacent cobalt atoms, such a structure has been reported for several other metal ions.[1] It is also interesting to note that the μ-carbonatobis(pentaammine)cobalt(III) ion exhibits decarboxylation kinetics[21] similar to that observed for the monodentate $[Co(NH_3)_5CO_3]^+$ ion. The authors suggest the triatomic carbonate bridge (dimer **I**) for the complex of unknown structure. We suggest that the observed kinetic behavior of this complex is consistent with that expected for a monatomic carbonate oxygen bridge (dimer **II**). The following scheme [eqn (3)] is consistent with the decarboxylation mechanism of monodentate carbonato complexes and provides a

pathway which only involves oxygen–carbon bond breakage for the acid-catalyzed formation of the di-μ-hydroxo dimer:

$$L_4Co(O_2CO)CoL_4 + 2H^+ \longrightarrow L_4Co(OH)CoL_4 + 2CO_2. \quad (3)$$

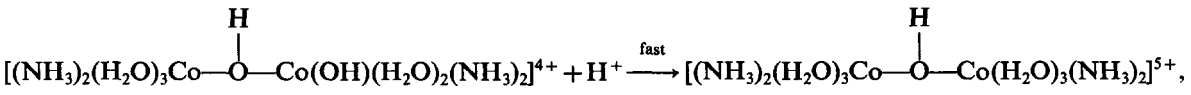
The total reaction stoichiometry for the acid-catalyzed decarboxylation may be represented by eqn (4):

$$[(NH_3)_2(CO_3)Co(CO_3)_2Co(CO_3)(NH_3)_2]^{2-} + 6H^+ + 2H_2O \rightarrow [(NH_3)_2(H_2O)_2Co(OH)_2Co(H_2O)_2(NH_3)_2]^{4+} + 4CO_2. \quad (4)$$



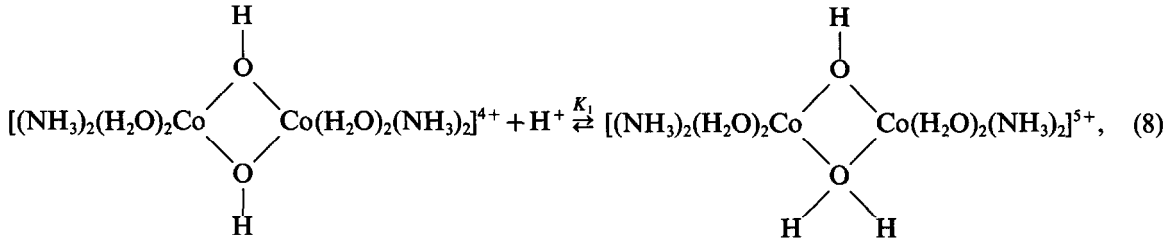
Our kinetic data obtained at 40°C are consistent with the hydrolysis of a hydroxy-bridged dimer formed as the initial decarboxylation product. The data suggests that the acid-catalyzed bridge cleavage reaction of $[(NH_3)_2(H_2O)_2Co(OH)_2Co(H_2O)_2(NH_3)_2]^{4+}$ takes place in two successive steps of the form:

$$\text{dimer} \xrightarrow{k_1} \text{intermediate} \xrightarrow{k_2} \text{monomer}. \quad (5)$$

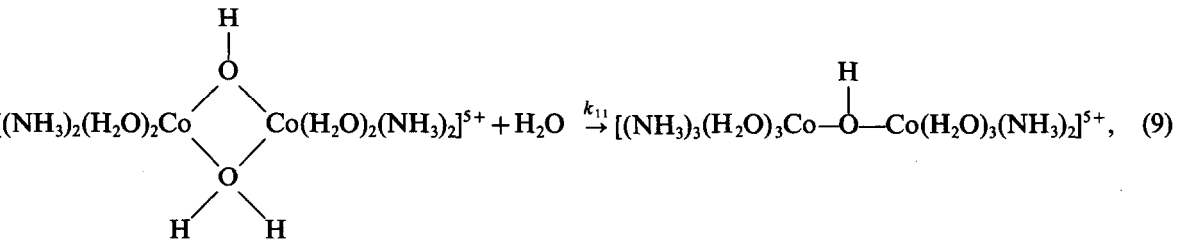


The relative rates of these two steps are such that each step can be treated separately. This type of stepwise bridge cleavage of di-μ-hydroxo complexes has been observed previously for the cationic species $N_4Co(OH)_2CoN_4]^{4+}$ (N ≡ NH_3[22] or $\frac{1}{2}$en[23,24]) and the anionic $[(NTA)Co(OH)_2Co(NTA)]^{2-}$ ion (NTA ≡ $[N(CH_2COO)_3]^{3-}$).[25] It has been suggested that simultaneous fission of two hydroxo bridges is improbable[23] and that the corresponding diaquo mono-μ-hydroxo dimeric species acts as an intermediate in the course of the complete cleavage reaction.[22–26] For the reaction of the $[(en)_2Co(OH)_2Co(en)_2]^{4+}$ ion, the existence of a short-lived singly bridged intermediate has been kinetically identified,[23] while the $[(NTA)(H_2O)Co(OH)Co(H_2O)(NTA)]^-$ ion produced as the intermediate during the bridge cleavage of the di-μ-hydroxo complex has been spectrally characterized.[25] In both cases, the singly bridged intermediates have been proven to exist in an appreciable concentration and the two consecutive cleavage steps can be treated separately.

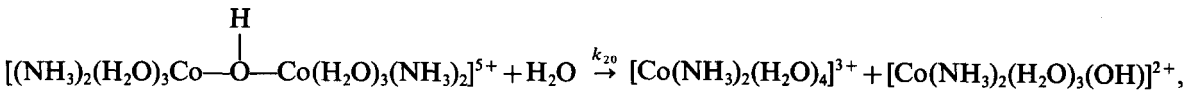
In the present study, it is assumed that a similar situation exists for the $[(NH_3)_2(H_2O)_2Co(OH)_2Co(H_2O)_2(NH_3)_2]^{4+}$ ion where the mono-μ-hydroxo intermediate, $[(NH_3)_2(H_2O)_3Co(OH)Co(H_2O)_3(NH_3)_2]^{5+}$, is formed in an appreciable concentration as the product of the first hydroxo bridge fission. The similar mono-μ-hydroxo complex ion[27] $[(NH_3)_5Co(OH)Co(NH_3)_5]^{5+}$ undergoes an acid-catalyzed bridge cleavage reaction with a kinetic form[28] ($k_{obsd} = k_a + k_b[H^+]$) similar to that obtained in this work.



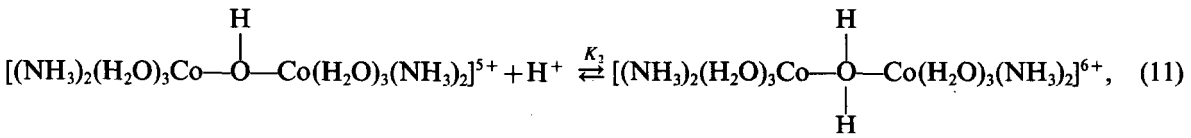
On the assumption that the singly bridged intermediate is produced in an appreciable concentration during the acid-catalyzed cleavage reactions of the di-μ-hydroxo complex, we suggest the following mechanism which is similar to that proposed by Harris and Meloon:[25]



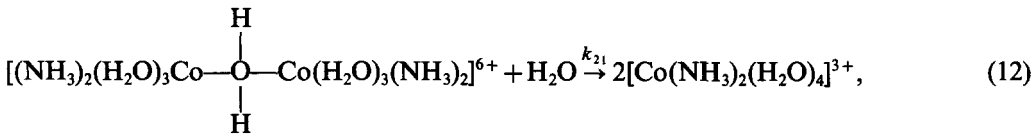
$$\xrightarrow{k_{10}} [(NH_3)_2(H_2O)_3Co{-}O{-}Co(OH)(H_2O)_2(NH_3)_2]^{4+}, \quad (6)$$



(7)



(8)



(9)

(10)

(11)

(12)

(13)

This mechanism leads to the simplified form of the observed rate constants:

$$k_1 = k_{10} + k_{11}K_1[H^+], \quad (14)$$

$$k_2 = k_{20} + k_{21}K_2[H^+]. \quad (15)$$

These have the same hydrogen ion concentration dependence as our experimental forms [eqns (1) and (2)].

By comparison of our simple first-order rate laws with the more complicated one generalized by Harris and Meloon[25] for the acid-catalyzed cleavage reactions of μ-hydroxo complexes:

$$k_{obsd} = (k_0 + k_1K_1[H^+ + k_2K_1[H^+]^2)/(1 + K_1[H^+]), \quad (16)$$

we can see the following kinetic features exhibited by the cleavage reactions of $[(NH_3)_2(H_2O)_2Co(OH)_2Co(H_2O)_2(NH_3)_2]^{4+}$ and $[(NH_3)_2(H_2O)_3Co(OH)Co(H_2O)_3(NH_3)_2]^{5+}$ in strong aqueous perchloric acid solution.

(a) For both the $[(NH_3)_2(H_2O)_2Co(OH)_2Co(H_2O)_2(NH_3)_2]^{4+}$ and the $[(NH_3)_2(H_2O)_3Co(OH)Co(H_2O)_3(NH_3)_2]^{5+}$ complex ions, the water-assisted paths symbolized by k_{10} and k_{20} [eqns (6) and (10)] play a significant role in the bridge cleavage reactions.

(b) The protonations of the highly charged cationic di-μ-hydroxo reactant and mono-μ-hydroxo intermediate are not very effective ($K_1[H^+] \ll 1$ and $K_2[H^+] \ll 1$). The same situation also exists for

the $[(NH_3)_3(H_2O)Co(OH)_2Co(H_2O)(NH_3)_3]^{4+}$ and $[(NH_3)_5Co(OH)Co(NH_3)_5]^{5+}$ ions.[28,29]

(c) In the rate-determining bridge cleavage steps, both protonated dimers (doubly bridged and singly bridged) undergo bridge fissions dominantly by the water-assisted paths represented by k_{11} and k_{21} [eqns (9) and (12)]. No contribution from the acid-catalyzed path represented by the $k_2K_1[H^+]^2$ term in eqn (16) is detected in the present cases.

The magnitudes of the rate constants obtained for the two successive bridge cleavage steps are such that one is slightly larger than the other. Moreover, both of the rate constants exhibit the same hydrogen ion concentration dependence. As a result, the assignment of the observed rate constants (k_{fast} and k_{slow}) to the individual cleavage steps [k_1 and k_2 in eqn (5)] is not obvious. However, there are two points noted by previous study[29] that can provide some basis for the rate constant assignment. Firstly, the cleavage rate of a singly bridged complex is comparable to or slightly faster than that of a doubly bridged complex. Secondly, in the cleavage reactions of singly bridged complexes, the water-assisted path usually makes a more significant contribution than that path makes in the cleavage reactions of multiply bridged complexes. This observation has been ascribed to the presence of additional bridge(s) that may help to retain the binuclear structure. Thus stretching of the metal–hydroxo bond is less likely to lead to bridge fission.

On inspection of the magnitudes of the rate constants for the water-induced and acid-catalyzed reactions, we should assign k_{slow} to the first bridge cleavage reaction of the di-μ-hydroxo reactant [k_1 in eqns (5) and (14), $k_{10}/k_{11}K_1 \simeq 0.255$] and k_{fast} to the bridge cleavage reaction of the mono-μ-hydroxo intermediate [k_2 in eqns (5) and (15), $k_{20}/k_{21}K_2 \simeq 0.60$]. In spite of these arguments, we must acknowledge the possibility that k_{fast} may correspond to the cleavage of the di-μ-hydroxo reactant and k_{slow} to the cleavage of the mono-μ-hydroxo intermediate. Usually the fast and slow reactions do conform to the first and second stages of a consecutive reaction sequence.

(*Received* 14 *February* 1985; *accepted after revision* 28 *January* 1986)

Abstract—The anion–cation interactions that take place in several room-temperature haloaluminate molten salts were investigated by using NMR spectroscopy. The systems studied were $AlCl_3$–1-(1-butyl)pyridinium chloride, $AlCl_3$–1-methyl-3-ethylimidazolium chloride and $AlBr_3$–1-methyl-3-ethylimidazolium bromide. The ion–ion associations in these systems were examined by studying the ^1H and ^{13}C chemical shifts of the nuclei on the organic cations as a function of melt composition. Investigations conducted in basic melts, i.e. those melts with an aluminium halide mole fraction less than 0.5 and where the anion–cation interactions have been found to be most extensive, suggested that, in contrast to previous work, ion–ion interactions in these solvents involve more than just simple ion-pair formation. A model is proposed which considers that each cation may interact with two or more anions and vice versa to form oligomeric chains of alternating cations and anions. The latter model is shown to provide a more realistic interpretation of the experimental chemical shift data than a model based on simple ion-pair formation.

Mixtures of certain organic halide salts and $AlCl_3$ or $AlBr_3$ are liquid at room temperature. These ionic liquids have been used as electrolytes for electrochemical cells and as solvents for a variety of fundamental studies employing inorganic and organic solutes.[1–3] Raman spectroscopy[4] and ^{27}Al NMR spectroscopy[5,6] indicate that the melts consist of an organic cation and one or two anions (AlX_4^- and X^- or $Al_2X_7^-$), depending on the melt composition, i.e. the relative proportion of organic halide salt to aluminum halide. Structure imparted to these ionic liquids by associations between the organic cation and the anions may play an important role in transport processes[7] and the physical properties of the melts.[8]

In previous papers we showed that ^1H and ^{13}C NMR spectroscopy could be used to detect ion–ion interactions in the 1-methyl-3-ethylimidazolium chloride–$AlCl_3$ melt (MeEtImCl–$AlCl_3$).[6,9,10] Taulelle and Popov conducted similar studies in 1-(1-butyl)pyridinium chloride–$AlCl_3$ (BuPyCl–$AlCl_3$).[11] It was concluded from these investigations that changes in the chemical shifts of nuclei on the organic cations were best explained by extensive, probably complete, anion–cation associations.

Taulelle and Popov[11] observed a linear dependence of chemical shifts with changes in the apparent $AlCl_3$ mole fraction (N) over a small range of composition in basic melt. The greatest changes in chemical shifts with composition of the melt are observed in basic melts, i.e. compositions where the organic halide salt is in excess over the aluminum halide.[6,9–11] Therefore, only basic melts were considered here since the effects of interest are more pronounced in these than in acidic melts. In the present study we examined the ^1H and ^{13}C chemical

shifts for the BuPyCl–$AlCl_3$, MeEtImCl–$AlCl_3$, and MeEtImBr–$AlBr_3$ melts over the entire basic composition range ($0 < N < 0.50$). In contrast to the results of Taulelle and Popov,[11] these measurements have indicated a decided non-linear dependence of chemical shifts on N in all of the systems that were examined. The impact of these observations on the formulation of models used to represent anion–cation interactions in room-temperature haloaluminate melts is described. This work also extends our earlier results in the MeEtImCl–$AlCl_3$ system[10] in which proton chemical shifts were reported over the limited composition range $0.33 < N < 0.50$.

EXPERIMENTAL

Reagents

BuPyCl,[12] MeEtImCl[13] and $AlCl_3$[14] were prepared and purified as previously described. MeEtImBr was synthesized by combining equal amounts of 1-methylimidazole and ethyl bromide in a flask fitted with a drying tube and allowing the mixture to react slowly. When the reaction was complete, the resulting salt was purified by the same procedure used to purify the chloride analog. $AlBr_3$ (Fluka, puriss grade) was sublimed *in vacuo* a minimum of 3 times before use. The melts were prepared by weighing and mixing the components in argon or nitrogen filled dry boxes.

NMR measurements

NMR spectra were obtained on a JEOL FX90Q spectrometer in 5-mm diameter tubes. Chemical shifts were externally referenced to dimethyl sulfoxide in a concentric capillary. In order to ensure that all samples remained liquid throughout the entire range of compositions that were studied the chloride melts were run at 150°C, and the bromide melts were run at 120°C. All spectra were qualitatively similar to those reported previously.[6,10,11]

RESULTS AND DISCUSSION

The variation in chemical shifts with N reported in previous studies[6,9–11] were explained by assuming that the organic cation was in fast exchange between more than one environment. Thus, the chemical shifts could be described by a population-weighted average:

$$\delta_{obs} = \sum_{i=1}^{n} \delta_i X_i \qquad (1)$$

where δ_i and X_i are the chemical shifts and mole fractions of the cations in the ith environment, respectively. Taulelle and Popov[11] attempted to explain this effect in the BuPyCl–$AlCl_3$ melt by considering two environments which resulted from ion-pair interactions between the $BuPy^+$ cation and the two different anions present in the basic melt (Cl^- and $AlCl_4^-$). In this case eqn (1) becomes:

$$\delta_{obs} = \delta_1 Y_1 + \delta_4 Y_4, \qquad (2)$$

where Y_1 and Y_4 are the anion fractions of Cl^- and $AlCl_4^-$ which may be calculated from the equations:

$$Y_1 = \frac{1-2N}{1-N}.$$

$$Y_4 = \frac{N}{1-N}.$$

Taulelle and Popov[11] state that Y_1 and Y_4 are essentially linear functions of N, which explains why they obtained linear chemical shifts as a function of N. However, eqn (2) is approximately linear for only small ranges of N. Figure 1 shows that Y_1 and Y_4 are both non-linear with N when the entire basic composition range is considered. The chemical-shift data for the $BuPy^+$ cations reported in Ref. 11 were taken over a range of N too small to permit detection of deviations from linearity.

Wilkes and coworkers[6,10] considered two associations for each anion and cation in the MeEtImCl–$AlCl_3$ melt which results in three environments for the $MeEtIm^+$ cation. In this case eqn (1) becomes:

$$\delta_{obs} = \delta_2 Y_1^2 + \delta_5 2 Y_1 Y_4 + \delta_8 Y_4^2. \qquad (3)$$

The subscripts associated with each δ denote the magnetic environment for the cation containing the nucleus under observations (*vide infra*).

The chemical shift behavior of the nuclei at the 2,6- and 4-positions on the $BuPy^+$ cation and the 2-position on the $MeEtIm^+$ cation in chloroaluminate

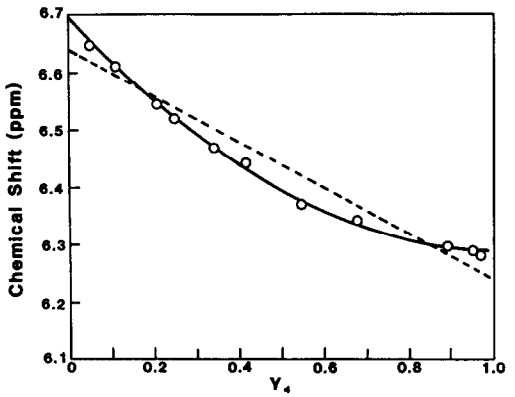

Fig. 2. Chemical-shift dependence on melt composition for ^1H at ring position 4 in BuPyCl–$AlCl_3$ binary melts. Lines are predicted according to eqn (4) (----) and eqn (5) (——). Y_4 is the anion fraction of $AlCl_4^-$.

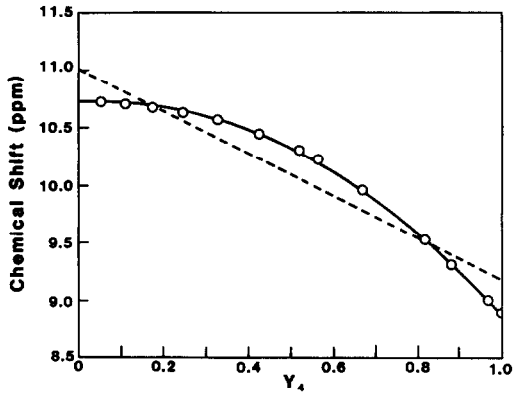

Fig. 4. Chemical-shift dependence on melt composition for ^1H at ring position 2 in MeEtImCl–$AlCl_3$ binary melts. Lines are predicted according to eqn (4) (----) and eqn (5) (——). Y_4 is the anion fraction of $AlCl_4^-$.

and bromoaluminate melts as a function of N are shown in Figs 2–7. In the past such data have been plotted with N as the abscissa. However, it is more advantageous to plot such data against the ion fraction of $AlCl_4^-$ as the abscissa. With this treatment eqn (2) becomes linear in Y_4:

$$\delta_{obs} = \delta_1 + (\delta_4 - \delta_1)Y_4, \quad (4)$$

while eqn (3) becomes quadratic in Y_4:

$$\delta_{obs} = \delta_2 + (2\delta_5 - 2\delta_2)Y_4 + (\delta_8 - \delta_5 + \delta_2)Y_4^2. \quad (5)$$

It should be noted that it is much easier to compare a linear equation like eqn (4) with a quadratic function like eqns (5) than to compare two non-linear, non-polynomial functions like eqns (2) and (3).

The chemical-shift data for the nuclei in Figs 2–7 are not linear in Y_4; thus, one can predict with relative certainty that eqn (4) will be inadequate for representing data that is obtained over a large composition range. In order to test this supposition statistically the data in Figs 2–7 were fitted to eqns (4) and (5). Two coefficients were adjustable in each equation. The parameter δ_2 in eqn (5) was calculated from the experimental chemical-shift data for the $N = 0$ composition, i.e. pure molten organic halide salt. The quality of the fits to eqns (4) and (5) was examined quantitively by calculating the Hamilton R-factors for each of the fits. The R-factor test is an accepted statistical method for comparing the quality of fits to different non-linear relationships and provides quantitive criteria that can be used to reject one model in favor of another.[15] One model may be selected over another at a specified confidence level by testing the ratio of R-factors against values appearing in statistical tables (see the appendix of Ref. 15). If the experimental value of the R-factor ratio exceeds the value listed in the statistical table, then it is possible to choose one model over the other. Table 1 compares the fits of the δ_{obs} data from Figs 2–7 to eqns (4) and (5). The

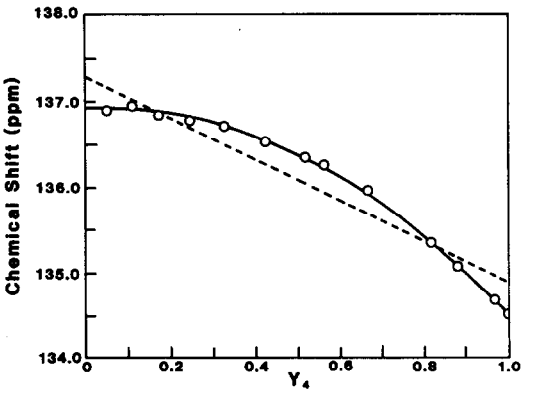

Fig. 5. Chemical-shift dependence on melt composition for ^{13}C at ring position 2 in MeEtImCl–$AlCl_3$ binary melts. Lines are predicted according to eqn (4) (----) and eqn (5) (——). Y_4 is the anion fraction at $AlCl_4^-$.

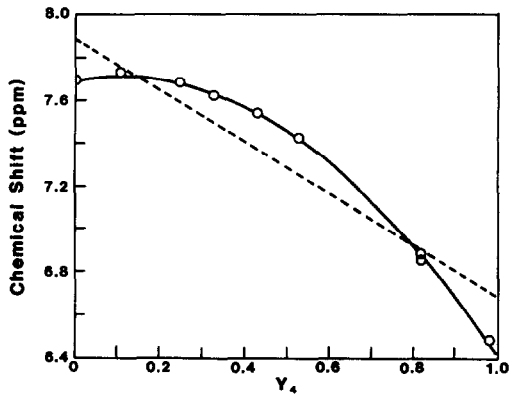

Fig. 6. Chemical-shift dependence on melt composition for ^1H at ring position 2 in MeEtImBr–$AlBr_3$ binary melts. Lines are predicted according to eqn (4) (----) and eqn (5) (——). Y_4 is the anion fraction of $AlBr_4^-$.

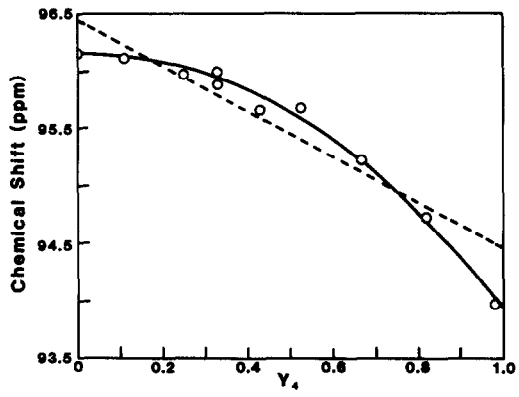

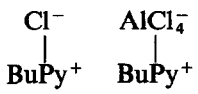

Fig. 7. Chemical-shift dependence on melt composition for ^{13}C at ring position 2 in MeEtImBr–$AlBr_3$ binary melts. Lines are predicted according to eqn (4) (----) and eqn (5) (——). Y_4 is the anion fraction of $AlBr_4^-$.

results given in this table clearly show that the fit to eqn (5) is superior to that for eqn (4). The nuclei that were examined in this study were chosen because they exhibit large changes in chemical shift with N. Other nuclei exhibit similar chemical shifts, but the dependences on N are less pronounced. In some cases the experimental error for measurement of the chemical shift is of the same order of magnitude as the observed change in the chemical shift with N. This makes comparison of the two models difficult, and the chemical shifts of these nuclei are not discussed here. However, in no case was the fit to eqn (4) found to be superior to that to eqn (5).

The important difference between data that fit eqns (2) or (4) and data that fit eqns (3) or (5) is in the number of ion–ion interactions that are considered for each ion. The data obtained by Taulelle and Popov, which appear to fit eqns (2) or (4) best, imply that simple ion-pairs are formed:

1 **4**

[a] Ring position–nucleus.

[b] Calculated according to Ref. 15.

[c] From tables in Ref. 15, b = number of adjustable parameters = 2, N = number of data points minus b, α = confidence level = 99.5%.

Our data for the $BuPy^+$ and $MeEtIm^+$ cations obtained in a variety of melts over a much larger composition range appear to fit best to the model represented by eqn (3). This implies that each cation interactions specifically with two anions and vice versa:

2 **5** **8**

These species need not be discrete but may be envisaged as portions of oligomeric chains of alternating cations and anions. The complexes proposed here are conceptually similar to the multi-ion pyridinium complexes which were reported by Angell and Schuppert[16] in the PyH–$AlCl_3$ system (PyH = hydropyridinium), e.g. $(PyH\ldots\ Cl\ldots HPy)^+$. However, the ion–ion interactions that occur in the systems studied here must arise via a purely electrostatic mechanism rather than through a hydrogen-bonding process since the latter is structurally precluded.

CONCLUSION

The chemical-shift data of Taulelle and Popov[11] were measured over too small a range of compositions to clearly establish the model represented by eqn (2). This is not to belie the importance of their conclusion that significant anion–cation interactions occur in the room-temperature chloroaluminate melts. Data which cover a wider composition range indicate that the anion–cation interactions that take place in these melts are considerably more complex than predicted by Taulelle and Popov. The "structures' represented by **2**, **5** and **8** appear more likely than those represented by **1** and **4** in the room-temperature haloaluminates melts examined in this study.

(*Received* 16 *December* 1985; *accepted* 28 *January* 1986)

Abstract—The complex "$Cu(SO_4)(btaH)_4 \cdot 2H_2O$" (btaH = benzotriazole) deposited as deep blue crystals from aqueous $CuSO_4 \cdot 5H_2O$–H_2SO_4–btaH solutions has been shown by X-ray diffraction methods to be a *mono*hydrate $[Cu(SO_4)(H_2O)(btaH)_3 \cdot btaH]$. The crystals contain five-coordinate, tetragonal pyramidal $Cu(SO_4)(H_2O)(btaH)_3$ units and bridging btaH molecules linked together by a three-dimensional array of H-bonding interactions.

The ability of benzotriazole (btaH) (I) to inhibit corrosion in copper and copper alloys has focused attention on btaH complexes of the transition metals in general, and of copper in particular.[1] Numerous copper–btaH complexes have been synthesized and several—notably $[Cu_5(bta)_6(acac)_4]$[2] and $[Cu_5(bta)_6(CNBu^t)_4]$[3]—have been shown to possess unusual structures in which btaH ligands adopt a variety of coordination modes. Copper–btaH complexes of indeterminate structure reported in the literature include the blue derivative "$Cu(SO_4)(btaH)_4 \cdot 2H_2O$" which crystallizes from aqueous solutions of $CuSO_4 \cdot 5H_2O$–H_2SO_4–btaH.[4] Vibrational, electronic and ESR spectra have been reported for this complex but only tenuous ideas, based on mono- and bidentate btaH ligands, have been advanced concerning its structure.[4] The fact that copper(II) complexes have a strong tendency to tetragonal distortion {cf. $[Cu(NH_3)_4(H_2O)_2]^{2+}$} coupled with the observation that btaH molecules participate readily in H-bonding led us to speculate that the complex $Cu(SO_4)(btaH)_4 \cdot 2H_2O$ might involve tetragonally distorted copper(II) with weakly bound axial water and/or sulphate ligands, as in the parent $CuSO_4 \cdot 5H_2O$, together with an equatorial set of four N^2-coordinated btaH ligands

Scheme 1.

linked via N^1—H---N^3 hydrogen bonds to form an N_4-macrocycle similar in shape and form to the very stable phthalocyanin ligand. To test this hypothesis we have undertaken an X-ray diffraction study of the complex as part of our current work on the coordination chemistry of btaH and related ligands. The results of this investigation, which are presented below, do not support our original hypothesis but establish that the complex is really a *mono*hydrate $[Cu(SO_4)(H_2O)(btaH)_3 \cdot btaH]$ with a novel structure based on $Cu(SO_4)(H_2O)(btaH)_3$ units and bridging non-coordinated btaH molecules linked together by a three-dimensional array of H-bonding interactions.

EXPERIMENTAL

The complex was prepared by the literature method,[4] crystallizing readily from aqueous $CuSO_4 \cdot 5H_2O$–H_2SO_4–btaH solutions as dark blue, air-stable plates. IR data were in good agreement with those originally reported.[4] Since the complex

* Authors to whom correspondence should be addressed.

is reported to react on attempted solubilization in water to form a green amorphous mass, recrystallization was not undertaken.

X-ray crystallography

The crystal used for X-ray work was sealed under nitrogen in a thin-walled glass capillary. After preliminary photography, unit cell and intensity data were obtained using a CAD4 diffractometer and graphite-monochromatized Mo-K_α radiation ($\lambda = 0.71069$ Å) following standard procedures.[5] The structure was solved via use of the heavy-atom method and full-matrix least-squares; non-hydrogen atoms were assigned anisotropic thermal parameters; hydrogen atoms were refined freely with isotropic thermal parameters, except those of the btaH ligands which were all assigned to a common refined μ_{iso} value.

Crystallographic data are as follows: $Cu(SO_4)(H_2O)(C_6H_5N_3)_4$, $C_{24}H_{22}N_{12}O_5SCu$, formula weight = 654.15, monoclinic, $a = 7.294(3)$ Å, $b = 19.744(3)$ Å, $c = 19.227(5)$ Å, $\beta = 82.97(3)°$, $U = 2748.1$ Å^3, space group $P2_1/c$, $Z = 4$, $D_c = 1.58$ g cm^{-3}, μ(Mo-K_α) = 9.3 cm^{-1}, $T = 295$ K. 5381 data were recorded, giving 4828 unique, 3207 observed [$I > 1.5\sigma(I)$]. Number of parameters = 462, weighting scheme $\omega = 1/[\sigma^2(F_o)+0.0005g(F_o)^2]$. Final R $(= \Sigma|\Delta F_o|/\Sigma F_o) = 0.0457$, $R_W = [\Sigma_W|\Delta F|^2/\Sigma_W F_o^2]^{1/2} = 0.0417$. Atomic scattering factors calculated from data in Ref. 6. Final atomic positional and thermal parameters, and lists of F_o/F_c values have been deposited as supplementary material with the Editor from whom copies are available on request.*

RESULTS AND DISCUSSION

The structures of the $Cu(SO_4)(H_2O)(btaH)_3$ unit and the associated btaH molecule are shown in Fig. 1, together with the atomic numbering scheme. Two views of the unit cell contents illustrating molecular packing and H-bonding interactions, are shown in Figs 2 and 3. Selected bond lengths and angles are given in Table 1.

Coordination about copper

The copper atom has a tetragonal pyramidal coordination (Fig. 1) with an apical H_2O ligand. The basal coordination positions are occupied by

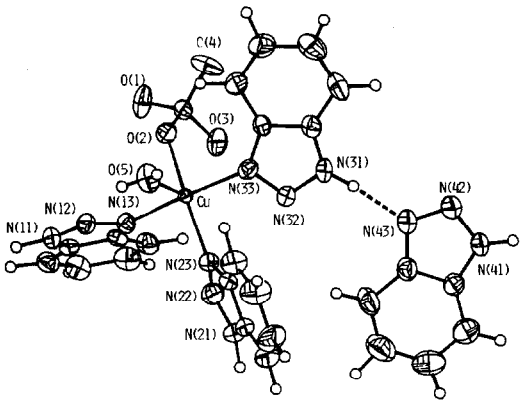

Fig. 1.

a monodentate sulphate and three N^3-coordinated btaH molecules. The copper atom is slightly displaced (0.157 Å) from the basal plane towards the apical H_2O ligand. The apical Cu—OH_2 bond [2.202(5) Å] is elongated relative to equatorial Cu—OH_2 bonds (*ca* 1.95–2.01 Å)[7] but less so than similar bonds in tetragonal bipyramidal copper(II) structures, values for which fall in the range *ca* 2.31–2.64 Å.[8,9] The Cu—OSO_3 distance [1.980(5) Å] is typical for equatorially coordinated sulphate[7] and the Cu—N distances [1.990(5), 2.009(5) and 2.019(5) Å] are similar to those previously recorded for related copper(II)–btaH structures.[10,11] An interesting feature of the structure is the co-existence of a non-coordinated btaH molecule and what would appear to be a relatively unhindered vacant coordination site at the copper

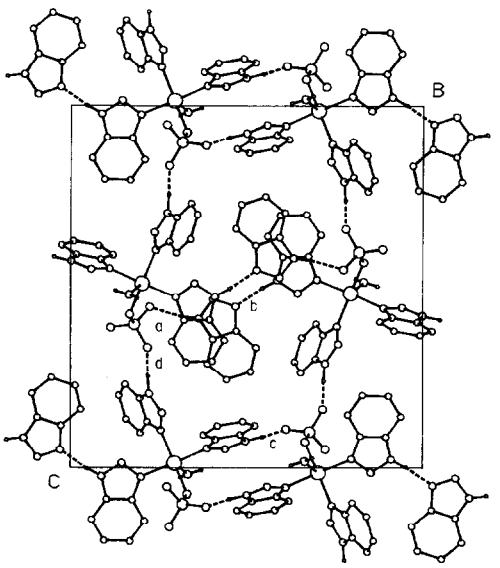

Fig. 2.

*Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

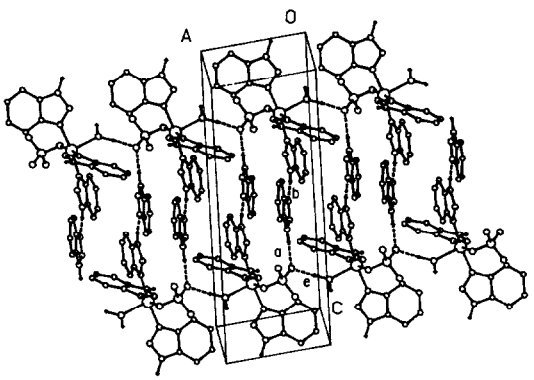

Fig. 3.

centre in the free molecule. However, in the crystal structure this site is partially blocked by the O(3) atom of the sulphate group [O(3)···Cu = 3.175 Å]. Presumably the presence of the fourth btaH is a requirement for the formation of this strong three-dimensional H-bonded crystal structure.

BtaH ligands

The molecular dimensions of the coordinated btaH ligands are in close agreement with those previously reported for related Cu(II)–btaH structures.[10,11] The most noticeable difference is a lengthening of the N^2—N^3 distances (1.326, 1.334 and 1.335 Å) in the N^3-coordinated btaH ligands relative to those found for the non-coordinated btaH in the present structure [1.300(6) Å] and for the free btaH molecule [1.310(4) Å].[12] Structural parameters recorded for the non-coordinated btaH are in good agreement with data previously reported for the free ligand.[12]

Sulphate ligand

The sulphate tetrahedra are irregular with the S—O bond length being greatest [1.489(4) Å] for the oxygen involved in coordination to the copper. For the terminal S—O bonds the bond lengths increase as participation of the oxygen in H-bonding interactions increases.

Molecular packing and H-*bonding interactions*

The $Cu(SO_4)(H_2O)(btaH)_3$ polyhedra are linked by bridging non-coordinating btaH molecules which H-bond to coordinated sulphate [N(41)—H(41)···O(3), N···O = 2.764 Å] (a, Figs 2 and 3), and to coordinated btaH ligands [N(43)···H(31)—N(31), N···N = 2.731 Å] (b, Figs 2 and 3). The polyhedra are further linked by H-bonding interactions between coordinated sulphate and coordinated btaH [O(1)···H(11)—N(11), O···N = 2.687 Å (c, Fig. 2); O(4)···H(21)—N(21), O···N = 2.666 Å (d, Fig. 2)] and between coordinated sulphate and coordinated water [O(3)···H(52)—O(5), O···O = 2.764 Å] (e, Fig. 3) to generate a three-dimensional H-bonding network. The presence of a non-H-bonded hydrogen atom on the coordinated aquo ligand presumably accounts for the very characteristic strong, sharp IR absorption which occurs at *ca* 3620 cm^{-1}.

The preference shown for the observed structure over the macrocyclic alternative described above no doubt reflects in part the tendency of btaH to coordinate through N^3 rather than N^2. However, examples of N^2–btaH coordination are known: pertinent examples include the copper complexes $[Cu_5(bta)_6(acac)_4]$[2] and $[Cu_5(bta)_6(CNBu^t)_4]$.[3] It therefore seems probable that the very extensive H-bonding interactions found for the observed structure are a significant factor in tilting the thermodynamic balance against the "macrocyclic" structure in the present instance.

REACTIVITIES OF TETRAHALOSILANES AND SILANE WITH SULPHUR TRIOXIDE

B. S. SURESH and D. K. PADMA*

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 560012, India

(*Received* 30 *July* 1985; *accepted* 4 *February* 1986)

Abstract—Reactions of tetrahalosilanes [SiX_4 (X = F, Cl or Br)] and silane (SiH_4) with sulphur trioxide (SO_3) have been studied under different experimental conditions. Each of the silanes behaves differently in accordance with the bond energy of the Si—X bond. While SiF_4 remains unreactive even at 600°C, $SiCl_4$ reacts with SO_3 at 500°C giving rise to hexachlorodisiloxane [$(SiCl_3)_2O$] as the major product. In contrast $SiBr_4$ and SiH_4 react with SO_3 at room temperature and below room temperature, respectively, yielding silica as one of the products of reaction. In all cases the SO_3 is reduced to sulphur dioxide.

In continuation of our work on the reactions of silicon compounds, we found that silicon halides lend themselves for a good comparative study of their reactivities towards oxygen-containing compounds.[1–4] In the present system, a study has been made of the reactions of silicon tetrahalides [SiX_4 (X = F, Cl or Br)] and silane (SiH_4) towards sulphur trioxide (SO_3).

EXPERIMENTAL

Materials and methods

Standard methods of preparation were adopted for the preparation of SiH_4,[5] SiF_4,[5] $SiBr_4$[6] and SO_3.[7] Commercially available $SiCl_4$ was purified by repeated distillation and the fraction boiling at 55.5–56°C was collected and stored.

IR spectra of solids were recorded on a Perkin–Elmer Model 599 spectrophotometer, in a Nujol mull or a KBr matrix, and those of gases were recorded using a 10-cm gas cell fitted with KBr windows. IR spectra of liquids were recorded using conventional liquid cells.

Reaction of SiF_4 *with* SO_3. SiF_4 (~1.0 mmol) was placed in an evacuated reaction vessel and SO_3 (~5.0 mmol) was introduced into the vessel. The reactants were heated at various temperatures up to 600°C. The IR spectra shows only the reactants with a small amount of sulphur dioxide (SO_2) and complete absence of any other expected compounds such as sulphuryl fluoride and hexafluorodisiloxane.

Reaction of $SiCl_4$ *with* SO_3. $SiCl_4$ (~2.0 mmol) was introduced into the reaction vessel containing SO_3 (~8.0 mmol). SO_3 dissolved in $SiCl_4$ to give a clear solution. The reactants were heated to various temperatures. It was observed that no detectable reaction took place below 500°C. At 500°C (12 h), hexachlorodisiloxane [$(SiCl_3)_2O$] and SO_2 were formed as the volatile products. When the reaction was cooled to about −10°C the reaction mixture became yellow, indicating the presence of chlorine. This was further confirmed by separating chlorine at −30°C and reacting with solid potassium iodide to liberate iodine. All the volatile products were removed by gradual pumping till the IR (gas phase) showed no volatile compounds. A nonvolatile colourless liquid was left behind. The IR spectrum of its solution in CCl_4 showed absorption bands in the regions 630–650 and 1100–1250 cm^{-1} which could be assigned to ν(Si—Cl) and ν(Si—O) vibrations. These can be attributed to the formation of higher chlorosiloxanes in the reaction mixture. A white solid product deposited at the bottom of the reaction vessel was identified as silica by IR spectroscopy and chemical tests.

Reaction of $SiBr_4$ *with* SO_3. $SiBr_4$ (~2.0 mmol) was placed in a reaction vessel and SO_3 (~8.0 mmol) was introduced into the vessel. As soon as the two reactants came into contact with each other, brown fumes of bromine started evolving which

increased with time. The reaction mixture was kept at room temperature for about 12 h. The gas-phase IR spectra showed the presence of only SO_2. All the volatile products (SO_2, bromine and SO_3) were pumped off. A white solid was left behind in the reaction vessel. This was found to be silica by chemical tests and spectral analysis.

Reaction of SiH_4 *with* SO_3. SiH_4 (~4.0 mmol) was placed in a reaction vessel and kept frozen at liquid-nitrogen temperature. SO_3 (~20.0 mmol) was introduced into the vessel. The liquid-nitrogen bath was withdrawn and the reaction mixture was allowed to attain room temperature over a period of 1 h. The IR spectrum of the gaseous component shows only SO_2 and the complete absence of SiH_4 or any other higher siloxanes such as disiloxane. All the volatile products were transferred into another trap and treated with alkaline cadmium acetate solution and shaken well. No yellow precipitate was formed, indicating the absence of hydrogen sulphide (H_2S) among the reaction products. The reaction vessel was found to contain tiny droplets of a colourless nonvolatile liquid which was identified to be sulphuric acid (H_2SO_4) and a deposited white solid which was characterized as silica.

RESULTS AND DISCUSSION

From the experimental observations described above it can be seen that silicon tetrahalides and SiH_4 react differently with SO_3. SiF_4 remains unreactive even at elevated temperatures. This lack of reactivity can be attributed more to kinetic parameters rather than to thermodynamic feasibility as the reaction $SiF_4 + 2SO_3 \rightarrow SiO_2 + 2SO_2F_2$ is thermodynamically favourable ($\Delta G^{\ominus} = -42.3$ kcal mol^{-1}). This kind of nonreactivity by SiF_4 has been observed also with oxides of nitrogen.[8]

On the other hand, the other silicon compounds react with SO_3 with varying degrees of ease. $SiCl_4$ undergoes reaction only at 500°C giving rise to $(SiCl_3)_2O$ as the major product of the reaction. The minor products are polychlorosiloxanes and silica. The reactions should involve radical cleavage followed by oxidation and fragmentation to account for the formation of chlorine and higher siloxanes:

$$2SiCl_4 + SO_3 \xrightarrow{500°C} Cl_3Si{-}O{-}SiCl_3 + SO_2 + Cl_2,$$

$$3[Cl_3Si{-}O{-}SiCl_3] + SO_3 \xrightarrow{500°C} 2[SICl_3{-}O{-}SiCl_2{-}O{-}SiCl_3] + SO_2 + Cl_2,$$

$$SiCl_3{-}O{-}SiCl_2{-}O{-}SiCl_3 + 4SO_3 \xrightarrow{500°C} 3SiO_2 + 4SO_2 + 4Cl_2.$$

It is of interest to point out here that the formation of chlorine and SO_2 has been observed in reactions of sodium chloride with SO_3:[9]

$$SO_3 + 2NaCl \xrightarrow{350°C} Na_2S_2O_7 + SO_2 + Cl_2.$$

The reaction of $SiBr_4$ with SO_3 occurs at room temperature with the liberation of bromine and formation of silica, indicating that radical cleavage is not predominant. The SO_3 is reduced to SO_2 and the overall reaction may be represented as follows:

$$SiBr_4 + 2SO_3 \xrightarrow{25°C} SiO_2 + 2SO_2 + 2Br_2.$$

SiH_4 undergoes oxidation below room temperature with the formation of silica. The SO_3 is reduced only to SO_2 and not to H_2S. The hydrogen part of silane is oxidized to water, which further combines with unreacted SO_3 to form H_2SO_4:

$$SiH_4 + 4SO_3 \xrightarrow[\text{room temperature}]{\text{below}} SiO_2 + 2H_2O + 4SO_2,$$

$$2H_2O + 2SO_3 \rightarrow 2H_2SO_4.$$

It is clear from the above results that there is clear gradation in the ease with which the Si—X bonds (X = F, Cl, Br or H) are attacked and replaced by Si—O bonds. While Si—F is not attacked even at elevated temperatures, Si—Cl is cleaved at about 500°C. Si—Br is oxidized to Si—O at room temperature and the Si—H bond is converted to Si—O below room temperature. This trend is in accordance with the bond energies: Si—F > Si—Cl > Si—Br ~ Si—H.

(*Received* 17 *December* 1985; *accepted* 10 *February* 1986)

Abstract—Several new, pentacoordinated, triorganoantimony bis-selenocyanates [$R_3Sb(SeCN)_2$ (R = Me, Ph, *p*-$CH_3C_6H_4$, *p*-ClC_6H_4, *p*-F-C_6H_4 or C_6F_5)], tetraorganostibonium selenocyanates [$R_3R'Sb(SeCN)$ (R = R′ = Ph; R = Ph, and R′ = —CH_2—CH=CH_2)] and μ-oxy-bis(triarylantimony) bis-selenocyanates {[Ar_3Sb—O—$SbAr_3$]$(SeCN)_2$ (Ar = Ph, *p*-$CH_3C_6H_4$, *p*-ClC_6H_4 or *p*-FC_6H_4)} have been synthesized from potassium selenocyanate and the corresponding organoantimony halide (chloride and/or bromide) in the presence of the phase-transfer catalyst 18-crown-6, and characterized. Spectroscopic evidence suggested an *iso* structure (Sb—NCSe). The compounds were also obtained in the absence of 18-crown-6 but in lower yields. Some of these compounds were found to exhibit a significant biological activity.

Despite a considerable interest in the chemistry of selenocyanate derivatives of the main-group elements, and a variety of metal and metalloids for which such derivatives have been synthesized, synthetic routes for the corresponding selenocyanate compounds of group V elements (As, Sb and Bi) have been neglected.[1–9] During the course of our investigations on the oxidative addition, cleavage and metathetical reactions of tertiary aryl antimony(V) compounds,[10–12] it was observed that, except for a single reference by Challenger *et al.*[1] describing the synthesis and isolation of Ph_2Bi(III)SeCN obtained through the reaction of triphenyl bismuth and selenium bis-selenocyanate [$Se(SeCN)_2$], there are no references on any aspect of the selenocyanate derivatives of group V elements (P, As, Sb and Bi) in either oxidation state (+3 and +5).[8,9] Attempts to demonstrate the existence and isolation of $Ph_3Sb(V)(SeCN)_2$ by the same authors were unsuccessful.[1] In view of the scarcity of the data and the enhanced antimicrobial activity expected for such compounds, it was considered worthwhile to make a systematic study of organoantimony(V) selenocyanates.

The present work describes the synthesis of triarylantimony(V) bis-selenocyanates [$Ar_3Sb(SeCN)_2$ (Ar = Ph, *p*-FC_6H_4, *p*-$CH_3C_6H_4$ or C_6F_5)], and symmetrical and unsymmetrical tetraorganoantimony [$Ph_4Sb(V)$ and $Ph_3(CH_2$=CH—$CH_2)Sb(V)$] selenocyanate obtained using the phase-transfer catalyst (PTC) 18-crown-6. In addition to this, μ-oxy-bis(triarylantimony) bis-selenocyanates {[Ar_3Sb—O—$SbAr_3$]$(SeCN)_2$} have also been prepared.

On the basis of some previous studies and the present work it has been safely concluded that, except for the heaviest element in a group (Hg, Tl, Pb and Bi), all the preceding elements (In, Sn, Sb and Te), including other lighter members of the group studied so far, have the *iso* structure. A few compounds have been tested, and found to exhibit a significant biological activity.

EXPERIMENTAL

Triorganoantimony dihalides [R_3SbX_2 (R = Me, Ph, *p*-$CH_3C_6H_4$, *p*-ClC_6H_4, *p*-FC_6H_4 or C_6F_5; X = Cl and/or Br)[8,10–13] and μ-oxy-bis(triarylantimony) dihalides [(Ar_3Sb—O—$SbAr_3$)X_2 (Ar = Ph, *p*-$CH_3C_6H_4$, *p*-ClC_6H_4 or *p*-FC_6H_4)][14,15] were synthesized by the reported methods.

Tetraphenylstibonium bromide was obtained by the treatment of triphenyl stibine with bromobenzene in the presence of aluminium chloride[16] while triphenyl(allyl)stibonium bromide was prepared by the reactions of triphenylantimony dibromide with allyl magnesium bromide (1 mol) (m.p.

204°C). Found: C, 52.1; H, 4.0%. Calc. for $C_{21}H_{20}SbBr$: C, 53.2; H, 4.2%.

Potassium selenocyanate and 18-crown-6 (used as a PTC) were Fluka products and dried before use.

All the solvents were purified and dried by standard procedures and reactions were carried out under strictly anhydrous conditions.

IR spectra were recorded in the range 4000–200 cm^{-1} by using KBr/CsI pellets on a Perkin–Elmer spectrophotometer. The molar conductance of 10^{-3} M solutions was determined at 25°C with a Phillips PR-9500 conductivity assembly. Molecular weights were determined cryoscopically in benzene using a Beckmann thermometer of accuracy ±0.01°C.

Typical experimental details of the reactions are described below. Relevant IR assignments and analytical data are listed in Tables 1–3.

Preparation of triorganoantimony(V) diselenocyanate

Triphenylantimony dichloride (0.424 g, 1 mol) and potassium selenocyanate (0.248 g, 2 mol) in benzene (60 cm^3) were stirred at room temperature in the presence of a catalytic amount of 18-crown-6 (0.01 mmol) for 4–6 h. Potassium chloride was filtered off and the solvent was removed *in vacuo* to afford a brownish pink solid, which was recrystallized from petroleum ether (40–60°C) and characterized as triphenylantimony bis-selenocyanate (m.p. 155–157°C, yield 83%).

Similarly, compounds **I–VI** were synthesized from triorganoantimony dihalide (chloride or bromide) and potassium selenocyanate in a 1:2 molar ratio in the presence of 18-crown-6.

Preparation of tetraorganostibonium selenocyanate

Tetraphenylstibonium bromide (0.510 g, 1 mol) and potassium selenocyanate (0.124 g, 1 mol) were mixed in anhydrous benzene and stirred for 3 h at room temperature in the presence of 18-crown-6 (0.01 mmol) under a nitrogen atmosphere. Potassium bromide was filtered off and the filtrate was concentrated to dryness *in vacuo* followed by the

addition of petroleum ether (20 cm^3) (40–60°C) to yield light brown crystals of tetraphenylstibonium selenocyanate (m.p. 139°C, yield 84%).

Triphenyl(allyl)antimony selenocyanate was also prepared in an analogous manner (m.p. 161°C, yield 80%).

Tetraphenylstibonium selenocyanate in 40% yield was also synthesized without the PTC from tetraphenylstibonium bromide and potassium selenocyanate in benzene. However, a crystal of NaOH was added at the beginning of the reaction to check the decomposition of KSeCN. The NaOH was recovered after the usual work up of the reaction.

Preparation of μ-oxy-bis(triarylantimony) bis-selenocyanate

The title compounds (**IX–XII**) were synthesized from potassium selenocyanate and the corresponding μ-oxy-bis(triarylantimony) dichloride in a 1:2 molar ratio under conditions similar to those described for triphenylantimony bis-selenocyanate. The analytical data for the compounds are given in Table 1.

RESULTS AND DISCUSSION

Organoantimony(V) selenocyanates [$R_nSb(SeCN)_{5-n}$] are obtained in excellent yield by the interaction of potassium selenocyanate with the corresponding organoantimony dichloride or dibromide in a 1:2 molar ratio in the presence of the PTC 18-crown-6:

$$R_3SbX_2 + 2KSeCN \xrightarrow[\text{benzene}]{\text{PTC}} R_3Sb(SeCN)_2 + 2KX, \quad (1)$$

where R = Me, Ph, *p*-$CH_3C_6H_4$, *p*-ClC_6H_4, *p*-FC_6H_4 or C_6F_5; X = Cl or Br;

$$R_3R'SbX + KSeCN \xrightarrow[\text{benzene}]{\text{PTC}} R_3R'Sb(SeCN) + KX, \quad (2)$$

where R = R′ = Ph; R = Ph, and R′ = —CH_2—CH=CH_2. μ-Oxy-bis(triarylantimony) bis-selenocyanates are obtained in an analogous manner:

$$(R_3Sb—O—SbR_3)X_2 + 2KSeCN \xrightarrow[\text{benzene}]{\text{PTC}} (R_3Sb—O—SbR_3)(SeCN)_2 + 2KX, \quad (3)$$

where R = Ph, *p*-$CH_3C_6H_4$, *p*-ClC_6H_4 or *p*-FC_6H_4.

Compounds in equations (1)–(3) can also be obtained in the absence of the PTC but the yield of the product is invariably low. All the organometal selenocyanates in fact tend to decompose on prolonged stirring or heating without completion of the reaction, and the yields of the desired products are poor. However, the use of the PTC 18-crown-6 not only reduced the time of the reaction but also enhanced the yield considerably.

The analytical and molecular-weight data, and the melting points of the investigated compounds are recorded in Table 1. The compounds are, generally, coloured crystalline solids but are moisture-sensitive and tend to decompose on storage. Except for trimethylantimony bis-selenocyanate, they are moderately soluble in common organic solvents. $Me_3Sb(SeCN)_2$ (**I**) is insoluble in benzene and chloroform but soluble in acetonitrile. The molecular-weight data showed that all the compounds are monomeric in benzene. The equivalent conductances of these compounds in nitrobenzene (10^{-3} M solutions) and acetonitrile (Table 3) indicate their non-ionic nature.[17] The observed non-mass-sensitive frequencies associated with the various modes of vibration of aromatic groups are in conformity with the reported frequencies and hence are not discussed here.[9–12] IR absorptions associated with the various internal modes of vibration of the selenocyanate group have been identified and indicate the nature of the bonding.

IR spectra have been widely used to establish the distinction between the two isomeric forms. Selenocyanates, like thiocyanates, are capable of exhibiting bonding isomerism and can exist either in the normal or the *iso* form. They give rise to three fundamental modes of vibration in their IR spectra, two of which are ν(C=N) and ν(C—Se) while the third is due to a deformation mode of δ(NCSe). The observations made so far by the various groups of workers indicate that the position and intensity of the peaks vary with the nature of metal. Thus, Aynsley *et al.*[3] have shown that organolead selenocyanates have a sharp single ν(C=N) stretch at 2100 cm^{-1}, indicating that the selenocyanate group is selenium-bonded to the lead atom. On the other hand, the corresponding tin compounds show a broad band at 2108 cm^{-1}, which in $CHCl_3$ resolves into a weak band at 2144 cm^{-1} and a broad band of strong intensity at 2055 cm^{-1}, suggesting the *iso* structure for these compounds.[3] A similar conclusion has been arrived at in the case of $(CH_3)_3Si(NCSe)$.[4] Interestingly enough, on the basis of their ν_{as}(C=N) being a single sharp peak about 2100 cm^{-1}, $Ar_2Tl(III)SeCN$ are interpreted as having the normal[5] form while, in sharp contrast to this, $Bu_2M(III)SeCN$[6] (M = Ga, In or Te) have been shown to possess an *iso* form [ν_{as}(C=N) = 2040 cm^{-1})]. Organotellurium selenocyanates, irrespective of the nature of the organic group attached to the tellurium, have the *iso* structure.[7] Except for the synthesis of diphenylbismuth(III) selenocyanate[1] no synthetic route and IR data are available on the selenocyanate derivatives of group VB elements.[8,13]

In the IR spectra of all the selenocyanate derivatives of arylantimony(V) reported herein there is a sharp band of strong intensity in the range 2050–2090 cm^{-1}. No appreciable shifting was observed in ν_{as}(C=N) when the IR spectra were recorded in a $CHCl_3$ solution and thus the observed frequencies, both in the solid state and in chloroform, listed in Table 1 are consistent with an *N*-bonded NCSe group consonant with the usual *iso* structure of the thiocyanate counterpart of the antimony(V) derivatives.[9] In addition to this, absorption of medium-to-weak intensity in the region 610–650 cm^{-1} also supports the *iso* structure of the newly synthesized compounds.[18,19] In the case of aryl derivatives the deformation mode δ(NCSe) could not be assigned with certainty due to the overlapping of the Sb—C stretching (*Y*-mode) present in the same region. However, a tentative assignment has been made both for the δ(NCSe) deformation mode and for the Sb—N bending mode. Compound **I** exhibits a medium-intensity band at 575 cm^{-1}, which can safely be assigned to the equatorial ν_{as}(Sb—C) mode on the basis of a comparison with earlier studies on pentacoordinated methylantimony derivatives [Me_nSbX_{5-n} (n = 3 or 4, X = halide or pseudohalide)].[9]

A noticeable feature of the IR spectra of all the triarylantimony bis-selenocyanate compounds is the absence of an ν_{sym}(Sb—C) absorption corresponding to the *t*-mode which should be located in the region 250–300 cm^{-1} as reported by earlier workers.[9,10,20] The ν_{as}(Sb—C) absorption corresponding to the *Y*-mode is intermixed with the δ(NCSe) band and appears as a strong band in the range of 455–485 cm^{-1}. A medium-intensity band appearing at about 740 cm^{-1} in the case of μ-oxy-bis(triarylantimony) bis-selenocyanates may be assigned to Sb—O—Sb stretching.

The proton magnetic resonance spectra recorded

on an EM 360L Varian spectrometer in $CDCl_3$ containing TMS as an internal indicator, for a representative compound $(CH_3C_6H_4)_3Sb(SeCN)_2$ showed a singlet due to the CH_3 protons (δ 2.88 ppm) and a multiplet due to the phenyl-ring protons centred at δ 8.50–7.80 ppm. The integration of the peaks was consistent with the proposed formulation.

Thus, on the basis of the IR, NMR, molecular and conductance data, triarylantimony(V) bis-selenocyanates may be assigned a pentacoordinated trigonal bipyramidal structure with the two selenocyanate groups at the apical positions while the aryl groups occupy the equatorial positions. Stibonium selenocyanate [$R_4Sb(NCSe)$] may also be assigned a pentacoordinated covalent structure while a trigonal bipyramidal structure containing an oxygen bridge (Sb—O—Sb) can be proposed for the oxy-bridged organoantimony(IV) selenocyanates.

On the basis of the present and some previous studies on the selenocyanate derivatives of non-transition elements as discussed above, it may reasonably be concluded that the heaviest element organometal selenocyanates in a group, viz. Hg, Pb or Tl, have the normal structure (M—SeCN) while all the preceding elements, including the lighter elements (Sn, In, Sb, Te or Si) exist in the *iso* form (M—NCSe).

All the selenocyanate compounds of antimony have repulsive odours and cause headaches on exposure. A few representative compounds were tested for biocidal activity and were found to possess significant bactericidal and fungicidal activities, details of which will be published elsewhere.

Acknowledgement—We are thankful to the Head of the Chemistry Department, Lucknow University, Lucknow, for providing the necessary laboratory facilities, the Director RSIC, Lucknow, for obtaining IR spectra, and the Council of Scientific and Industrial Research, New Delhi, for a pool officership to K.S. and a JRF to R.R.

OXOVANADIUM(IV) COMPLEXES OF CARBOHYDRAZONES AND THIOCARBOHYDRAZONES

O. P. PANDEY

Department of Chemistry, University of Gorakhpur, Gorakhpur 273001, India

(*Received* 8 *May* 1985; *accepted* 24 *February* 1986)

Abstract—Oxovanadium(IV) complexes $\{[VOL_2(H_2O)]SO_4$ (L = ligand derived by the condensation of carbohydrazide or thiocarbohydrazide with benzaldehyde, *o*-nitrobenzaldehyde, anisaldehyde, cinnamaldehyde, acetophenone and 2-acetylpyridine)$\}$ have been synthesized and characterized by elemental analysis, room-temperature magnetic moment, electrical-conductance, electronic, IR and ESR studies. The complexes are hexacoordinate and have a distorted octahedral structure.

Metal complexes of semicarbazide and semicarbazones (thiosemicarbazide and thiosemicarbazones) have attracted much attention due to their activity against smallpox, virus diseases and certain kinds of tumour.[1] Some papers on oxovanadium(IV) complexes with these ligands have also reported certain striking structural features.[2–5] However, very little attention has been paid to the coordination behaviour of the next highest homolog in the series (carbohydrazide and thiocarbohydrazide).[6,7] Oxovanadium(IV) complexes of carbohydrazones and thiocarbohydrazones have been prepared and studied to learn whether coordination to the metal ion still occurs through the sulphur or oxygen atom (as in thiosemicarbazones and semicarbazones) or whether advantage is taken of the available nitrogen donors to form a coordination sheath consisting of only nitrogen atoms.

EXPERIMENTAL

Carbohydrazide and thiocarbohydrazides were prepared as reported in the literature.[7,8] The hydrazones were synthesized by the usual method using ethanol as the solvent.[9,10]

Preparation of complexes

The following general method was used. A hot ethanolic solution of the respective ligand (0.1 mol) and a hot water–ethanol solution of the metal salt (0.05 mol) were mixed together and boiled under reflux on a water bath for *ca* 2 h. The solution was then concentrated to half of its original volume and, on cooling, a brown, blue or green coloured precipitate separated out, which was filtered, washed with ethanol and dried in an oven at 80°C (yield 60–72%).

Analytical procedures

Microanalyses for carbon and hydrogen were performed by the C.D.R.I., Lucknow, and by the Department of Chemistry, B.H.U., Varanasi. Nitrogen was estimated by Kjeldahl's method. Vanadium was estimated as its oxide by the standard gravimetric method.

Physical measurements

Conductance measurements were done using a Toshniwal conductivity bridge type CL O1/O1A. Solid-state IR spectra were recorded with Beckman AccuLab-9 and Perkin–Elmer 621 spectrophotometers. Magnetic measurements were performed by the Faraday method using ferrous ammonium sulphate as the calibrant. The electronic spectra were recorded on Rissian C ϕ10 and Beckman DU-2 automatic recording spectrophotometers. The ESR spectra of polycrystalline samples were recorded on a Varian E_4-EPR spectrometer operating at 9.4-GHz and 100-KHz field modulation and phase-sensitive detection. The instrument was calibrated using DPPH powder.

RESULTS AND DISCUSSION

Elemental analyses (Table 1) reveal that all the complexes have the general composition $[VOL_2(H_2O)]SO_4$. The complexes are soluble in dimethylformamide, dimethylsulphoxide and nitrobenzene. Electrical-conductivity measurements in DMF show that the complexes behave as 1 : 2 electrolytes. The presence of one coordinated water molecule has been confirmed from the TGA studies which show weight loss at 170–180°C.

Magnetic moments and electronic spectra

The spin–orbit coupling (λ) for oxovanadium(IV) complexes is positive[11] and magnetically dilute oxovanadium(IV) complexes should exhibit magnetic moments very close to the spin-only magnetic moment of 1.73 BM[12] expected for an $S = \frac{1}{2}$ system. All the complexes exhibit magnetic moments in the 1.68–1.72 BM range corresponding to one unpaired spin.

Intepretation of the electronic spectra of oxovanadium(IV) complexes is a subject of continuing investigation and discussion. Three spin-allowed transitions, $b_2 \rightarrow e_\pi^* ({}^2B_2 \rightarrow E)$, $b_2 \rightarrow b_1 ({}^2B_2 \rightarrow {}^2B_1)$ and $b_2 \rightarrow a_1 ({}^2B_2 \rightarrow {}^2A_1)$, are expected for distorted octahedral oxovanadium(IV) complexes according to the energy level schemes suggested by Ballhausen and Gray,[13] Selbin[14] and Lever.[15] The present complexes exhibit all three *d–d* transitions in the 12,100–14,500-, 15,000–17,300- and 22,800–24,900-cm^{-1} regions which are assigned to the $b_2 \rightarrow e_\pi^* ({}^2B_2 \rightarrow E)$, $b_2 \rightarrow b_1 ({}^2B_2 \rightarrow {}^2B_1)$ and $b_2 \rightarrow a_1 ({}^2B_2 \rightarrow {}^2A_1)$ transitions, respectively, according to the above schemes.

On the basis of data available, it appears that these complexes have tetragonally distorted octa-

hedral structures. Various ligand field parameters (*Dq*, *Ds* and *Dt*) have been calculated by making use of the energy level diagram suggested by Lever,[15] which are also consistent with a tetragonally distorted stereochemistry for the complexes. The negative *Dt* values may presumably be due to weak σ-bonding but still more to a π-bonding ability since *Dq* and *Ds* are positive. The thiocarbohydrazone derivatives have higher *Dq* values compared to corresponding carbohydrazone complexes. This is in line with the higher position of sulphur compared to oxygen in the spectrochemical series.

However, it may be pointed out that these parameters are inadequate, for *Dq* is the measure of the in-plane ligand field only and *Dt* does not take into account an off-diagonal fourth-order contribution. These shortcomings of classical Hamiltonian parameters have recently been overcome by Lever *et al.* by advancing a normalized spherical harmonic (NSH) Hamiltonian.[16,17] In the NSH Hamiltonian, all these parameters are capitalized to relate them to the corresponding crystal field parameters. The NSH and classical parameters are related as:[17]

$$DS = -7Ds,$$

$$DT = \left(\frac{7\sqrt{15}}{2}\right)Dt,$$

$$DQ = (6\sqrt{21})Dq - \left(\frac{7\sqrt{21}}{2}\right)Dt.$$

There are several advantages of NSH Hamiltonian theory: (a) the theory takes into account an off-diagonal contribution to *Dt*; (b) *DQ* is a measure of the average ligand field experienced by the metal ion, unlike the classical *Dq* which is the measure of in-plane field only; and (c) the parameters of the NSH theory are independent of the coordinate system used for the calculations and may be compared with the crystal field or angular overlap parameters to determine the restrictions of these values. The values of different NSH parameters for the present complexes are given in Table 2.

Further, the *DT*/*DQ* ratio has been shown to be a good measure of the degree of tetragonal distortion.[18] The values of *DT*/*DQ* for these complexes (Table 2) lie in the range 0.18–0.21. These values are much lower than the limiting value (0.4226), a value postulated for the square planar complexes, the limiting case of tetragonally distorted complexes. This small value indicates that the complexes are weakly distorted.

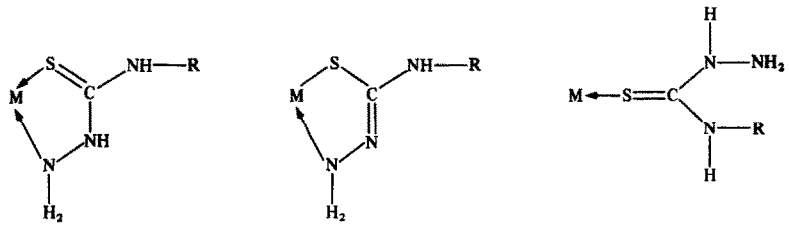
[a] Abbreviations as in Table 1.

ESR spectra

ESR signals are observed readily for oxovanadium(IV) complexes because of the prevalence of a less than cubic symmetry, which results in a longer relaxation time. An isotropic spectrum is obtained at room temperature.



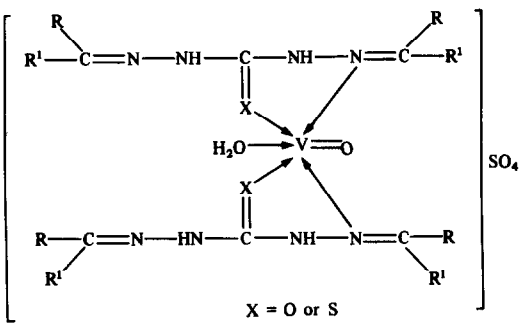
g values are listed in Table 1. They are lower than the free-electron value (2.0023) as expected for a d^1-system and this is related to the spin–orbit interaction of the ground state with a low-lying excited state. The decrease in the free-electron value is an approximate measure of the ligand field strength; the stronger the ligand field the smaller the decrease in the g value relative to the free-electron value. In the present study, the g-values of thiocarbohydrazone complexes are higher than those of carbohydrazone complexes. This also indicates the thiocarbohydrazone complexes possess a higher ligand field than carbohydrazone complexes. The line width is observed in the 240–260-G range.

IR spectra

Thiocarbohydrazone derivatives. The major interest in the preparation of these complexes is the attachment of the Schiff base ligand derived from thiocarbohydrazide. The IR spectra of thiocarbohydrazide and its complexes with several metals (Zn, Cd, Hg, Fe, Co, Ni and Pd) have been studied by Burns by carrying out a normal-coordinate analysis of the free ligand.[7] The thiocarbohydrazide molecule was treated as though it had C_{2v}-symmetry. X-ray crystallographic studies[19–21] have identified structures **1**–**3**. Recently, Singh *et al.*[22] and Srivastava *et al.*[23] have synthesized Mn(II), Ni(II), Cu(II), Zn(II), Pd(II), Pb(II) and Sn(IV) complexes with thiocarbohydrazones and concluded that the ligand can be pentadentate, quadridentate or tetradentate. The coordination behaviour of these ligands depends upon the nature of metal ion, the reaction conditions and the pH of the medium.

The ligands show one medium-intensity band and one weak band at *ca* 3270 and 1650 cm^{-1}, assignable to ν(NH) and δ(NH) of the secondary amine group.[7] These bands persist in the spectra of the complexes, indicating the non-coordination of the amino group. The ν(C=N) absorption at *ca* 1630–1600 cm^{-1} in the spectra of the ligands appears as a split band on complexation with one band located almost at the original position (due to uncoordinated C=N) and the other shifted to a lower frequency (*ca* 1590–1580 cm^{-1}), arising from the coordinated C=N. The splitting of ν(C=N) suggests that only one of the azomethine nitrogen atoms is involved in coordination.[24,25] The ν(C=S) band[22] appearing at 820–790 cm^{-1} in the spectra of the ligands is of medium intensity at 760–740 cm^{-1} in the spectra of the complexes. This shift to a lower wavenumber suggests that the thioamide sulphur is one of the bonding sites in the complexes.[25] Medium- or weak-intensity bands at *ca* 980, *ca* 460 and *ca* 400–380 cm^{-1} are tentatively assigned to ν(V=O), ν(V—N) and ν(V—S), respectively.

Carbohydrazone derivatives. Compared with thiocarbohydrazide derivatives, very few reports are available on the coordination behaviour of carbohydrazide[6,26–28] and, particularly, no study has been done on Schiff bases derived from carbohydrazide. The ligands carbohydrazones show one medium-intensity band at *ca* 3250 cm^{-1} due to ν(NH) of the secondary amino group which remains almost at the same position in oxovanadium(IV), indicating its non-involvement in coordination.[28] The carbohydrazones contain a —CONH— grouping and should show amide group vibrations. These are observed[27] at *ca* 1700 cm^{-1} [amide I, ν(C=O)], 1500 cm^{-1} [amide II, ν(CN)+δ(NH)], 1260–1220 cm^{-1} [amide III, δ(NH)] and 680–660 cm^{-1} [amide IV, ϕ(C=O)]. In the oxovanadium(IV) complexes, all these bands except amide I show upward shifts (~60–20 cm^{-1}), whereas the amide-I band shows a downward shift (~35–25 cm^{-1}). These changes in amide group vibrations indicate that the amide oxygen (ketonic) takes part in coordination to the metal atom.[27] This has further been confirmed by the appearance of new bands at *ca* 480–470 cm^{-1} assignable to ν(V—O).[29] The IR spectra of all carbohydrazones show a strong band at 1610–1600 cm^{-1} which may be due to the vibration of the azomethine linkages. In the complexes, this band is



1 **2** **3**

found to be split into two with one almost at the same position and the other at a lower frequency (~1585–1570 cm^{-1}), indicating that only one of the azomethine nitrogens is involved in coordination.[25] The ν(V—N) vibration is observed at *ca* 460–440 cm^{-1}. The bands due to the ν(V=O) vibration occur in the 980–960 cm^{-1} region. The position of this band in different complexes clearly indicate that the ν(V=O) frequency depends upon the nature of substituent present in the ring, i.e. electron-withdrawing groups cause a lowering of the ν(V=O) frequency, and vice versa.

The carbohydrazone and thiocarbohydrazone derived from 2-acetylpyridine show bands at *ca* 1570, 600 and 420 cm^{-1} which may be assigned[27,30] to 8a (pyridine ring deformation), 6a (in-plane ring deformation) and 16b (out-of-plane ring deformation). In their complexes, all these bands persist, indicating the non-coordination of pyridine nitrogen to vanadium atoms.

In addition to these, the presence of an ionic sulphate group in these complexes has been confirmed[31] by the appearance of three bands at *ca* 1130 cm^{-1} (ν_3), 930 cm^{-1} (ν_1) and 650 cm^{-1} (ν_4). The absence of the ν_2-band and the non-splitting of ν_3-band indicates that T_d-symmetry still holds.[31]

Thus, on the basis of above discussion, the following structures may be assigned to the different complexes:

(*Received* 20 *November* 1985; *accepted* 24 *February* 1986)

Abstract—The crystal structure of rubidium pentabromodistannate(II) ($RbSn_2Br_5$) is determined. The crystals are tetragonal and contain four formula units in a cell of dimensions $a = 8.442(2)$ Å, and $c = 14.754(3)$ Å with $D_c = 4.54$ g cm^{-3}, and $D_m = 4.44$ g cm^{-3}. The structure was solved in the space group *I*4/*mcm*. Unlike $NaSn_2F_5$, which contains discrete $[Sn_2F_5]^-$ ions, the structure is a layered lattice consisting of two-dimensional polymeric $(Sn_2Br_5)_n^{n-}$ layer units separated by Rb ions. The Sn and bridging Br atoms lie in planes perpendicular to the *c*-axis at $c = 0$ and $c = \frac{1}{2}$. Each Sn atom is surrounded by two bridging Br atoms, at 3.105(1) Å, in the plane of the polymer network and by two terminal Br atoms, at 2.755(3) Å, symmetrically above and below the network plane. The bridging Br atoms are surrounded by four equatorial Sn atoms and by two axial Rb atoms in the direction of the *c*-axis at 3.688(1) Å. The positions of the non-bonding orbitals on the Sn(II) atoms suggest that the lone pairs could be partly delocalized within the polymeric network. The ^{119}Sn Mössbauer data for $RbSn_2Br_5$ are interpreted in the light of its structural data.

The presence of stereochemically active lone pairs of electrons in Sn(II) species usually results in a distorted environment around the Sn atom.[1] The most common type of distortion found has a trigonal pyramidal distribution of three nearest-neighbour Sn–ligand bonds and three longer essentially non-bonding contacts completing a distorted octahedral environment. The longer contacts arise because close approach of the ligands to the tin is prevented along directions in which the lone pairs point. In the less common distorted four pyramidal environment, the Sn atom has two short bonds to ligands and two bonds of greater length than those normally found in Sn(II) compounds as nearest-neighbour contacts. Although most Sn(II) compounds have low-symmetry lattices, a few structures have tin in high-symmetry regular octahedral sites. Such environments are found in compounds containing heavier halide and chalcogenide ions, in which the distorting effects of the non-bonding electron pair, on the Sn atom, are removed by a population of solid-state bands arising from overlap of the empty halide or chalcogenide orbitals. Recent evidence has also shown that the direction in which lone-pair orbitals point can lead to some delocalization of the non-bonding electrons into cluster orbitals.[2]

In most examples in which Sn(II) forms complex ions with ligands, the triligandstannate(II) species

* Author to whom correspondence should be addressed.

is the stable and predominant ion. Crystal structures of a number of alkali metal trichloro- and trifluoro-stannates(II) have been determined.[3] The only known structure of a pentahalodistannate(II) complex, however, is that of $NaSn_2F_5$, in which an F atom bridges two SnF_2 groups to form discrete $[Sn_2F_5]^-$ ions.[4] There is, however, a considerable difference in the nature of bonds formed between Sn and F, and those formed between Sn and other halogen atoms.[1] We now describe the first structure determination of a pentahalogenodistannate(II) with a halide other than fluoride.

EXPERIMENTAL

Preparation

Rubidium pentabromodistannate(II) ($RbSn_2Br_5$) was prepared by mixing the appropriate quantities of RbBr and $SnBr_2$ dissolved in the minimum amount of boiling water containing tin metal and a few drops of HBr to minimize oxidation and hydrolysis, respectively. The resulting mixture was evaporated to give a clear yellow solution from which white rhomboid plates formed on cooling. These were collected and dried, *in vacuo*, over silica gel. The whole process was carried out under N_2 to minimize oxidation. A single crystal was selected from the bulk material to obtain the cell data.

X-ray crystal structure

Crystal data. $RbSn_2Br_5$, $M = 722.37$, tetragonal, space group $I4/mcm$ (No. 140), $a = b = 8.442(2)$ Å, $c = 14.754(3)$ Å, $U = 1051.48$ Å^3, $Z = 4$, $D_c = 4.56$ g cm^{-3}, $D_m = 4.44$ g cm^{-3}, $F(000) = 1248$. μ(Mo-K_α) = 275.31 cm^{-1}, $\gamma = 0.7107$ Å, $R = 0.058$. Intensity data were collected with a Philips PW1100 four-circle diffractometer by use of monochromatized Mo-K_α radiation. Intensity data for 365 independent tetragonal reflections were observed and of these 284 with $I > 3\sigma(I)$ were used in subsequent calculations. Data were corrected for Lorentz and polarization factors but not for absorption. The structure was solved via the heavy-atom method and refined successfully in the centrosymmetric space group $I4/mcm$. All atoms were refined with anisotropic temperature factor coefficients, giving a final R value of 0.058. Calculations were performed using "SHELX-76"[5] and unit-cell projections were obtained using "PLUTO".[6] The final atomic positions and anisotropic thermal parameters and lists of F_o/F_c values have been deposited with the Editor.* A projection of the unit cell is shown in Fig. 1. Bond lengths and angles are in Table 1.

^{119}Sn *Mössbauer spectra*

The ^{119}Sn Mössbauer data were recorded, at 80 K, using a $CaSnO_3$ source, on a Cryophysics MS102 spectrometer with a multi-channel analyser and fitted to Lorentzian distributions.

Thermal analysis

TG/DTA data were obtained over the temperature range, ambient to 600°C, using a Stanton Redcroft STA-780 Simultaneous Thermal Analyser. $RbSn_2Br_5$ decomposes above its melting point of 290°C.

RESULTS AND DISCUSSION

The arrangement of the Sn and bridging Br(1) atoms is such that they constitute a two-dimensional polymeric network perpendicular to the c-axes at $c = 0$ and $c = \frac{1}{2}$. The remaining Br(2) atoms lie symmetrically above and below the plane of the network forming terminal Sn—Br bonds. The resultant layer structure (Fig. 1) consists of two-dimensional polymeric $(Sn_2Br_5)_n^{n-}$ anionic layers separated by Rb ions lying symmetrically above and below Br(2) in the direction of the c-axis. The formation of the polymeric $(Sn_2Br_5)_n^{n-}$ network is in sharp contrast to the discrete $[Sn_2F_5]^-$ units found in $NaSn_2F_5$.

The Sn atoms in the structure are in distorted square pyrimidal environments with two long bonds to bridging Br(1) atoms within the plane of the polymeric network and two terminal bonds to Br(2) atoms symmetrically positioned above and below the plane of the network (Fig. 2). The distorted square pyramidal environment of the Sn atoms shown in Fig. 3 has an Sn—Br(2) bond length of 2.755(3) Å, typical of strong Sn—Br bonding interactions, and Sn—Br(1) bond lengths of 3.105(1) Å that are shorter than those found in Sn_3BrF_5[7] (3.29–3.35 Å) and which were considered to be non-bonding. The bridging Br(1) atoms are surrounded by four equatorial Sn atoms at distances of 3.105(1) Å and by two axial Rb atoms in the direction of the c-axis at 3.688(1) Å. The terminal Br atom, Br(2), is surrounded by one Sn at 2.75 Å, two Sn atoms at 3.49 Å, two Rb atoms at 3.60 Å, and two Br atoms at 3.84 and 3.97 Å.

The Sn–Br network perpendicular to the c-axis

* Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

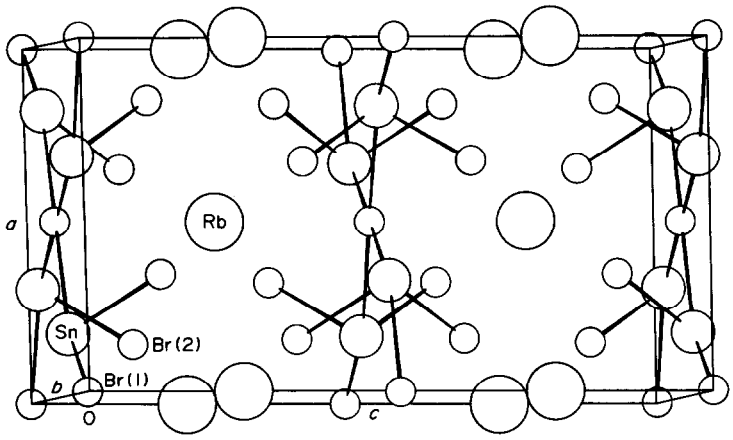

Fig. 1. Unit-cell contents of $RbSn_2Br_5$.

consists of interlocked puckered planar eight-membered Sn_4Br_4 rings. The Sn–Sn distances across the rings are 4.26 and 7.68 Å. The positions of the terminal Br atoms cause the lone pair orbitals on the Sn atoms to lie in the plane of the ring. It is interesting to note that the lone pairs on the Sn atoms point directly towards one another across the shortest Sn–Sn distance in the ring. This distance of 4.261(5) Å is too long to permit direct interaction between the filled non-bonding orbital on one Sn atom and the empty orbital on the opposite Sn atom, but they are close enough to the terminal Br atoms above and below the plane, directed along the longer Sn–Sn distance of the ring, to enable interaction between the lone-pair orbitals on Sn and the empty *d*-orbitals of Br. Taking the radius of the *s*-orbitals on the Sn atom as 2.05 Å and the empty *d*-orbitals on Br as 2.4 Å,[8] a significant overlap between the filled Sn orbitals and the Br *d*-orbitals is suggested. The effect of this would be to delocalize some of the lone-pair electron density on the Sn atoms into a two-dimensional band structure produced by overlap of empty Br *d*-orbitals within the planar ring network. The unusual Br(2)—Sn—Br(2) angle of approximately 90° is consistent with the suggested delocalization because it would provide the best arrangement of Br atoms to ensure a maximum overlap of the lone pairs on Sn and the empty Br *d*-orbitals. Such solid-state effects would not be possible in Sn–F networks because of the absence of suitable *d*-orbitals on the F to produce a delocalized band system and this may account for the formation of discrete $[Sn_2F_5]^-$ ions in $NaSn_2F_5$ rather than the polymeric network structure in $RbSn_2Br_5$.

The delocalization of non-bonding Sn electrons in $RbSn_2Br_5$ forms part of a range of interactions involving the non-bonding pairs that are known to have important consequences in certain Sn(II) compounds. The types of interactions range from dimer formation in $Sn[CH(SiMe_3)_2]_2$,[9] where the stability and structure of the material arises from interactions between the lone pair of one Sn atom with the empty orbital on the other Sn atom in the dimer, cluster formation of Sn atoms around the halogens in $K_3Sn_2(SO_4)_3X$ (X = Br or Cl),[2] where the distorting effects of the lone-pair orbitals pointing towards the halide ions are removed by delocalization of the Sn electron density into the cluster orbitals, to the population of solid-state bands by

non-bonding electrons that accounts for the optical and electrical properties of compounds such as $CsSnBr_3$[10] and SnO,[8] where the non-bonding orbitals are delocalized into three-dimensional and adjacent-layer Sn bands, respectively.

The ^{119}Sn Mössbauer shift of 3.91(6) mm s^{-1} for the complex $RbSn_2Br_5$ is only slightly lower than that of its parent compound $SnBr_2$ (δ = 3.98 mm s^{-1}). This slight decrease in shift can be described in terms of the existence of $SnBr_2$ units in the structure of $RbSn_2Br_5$ bridged by Br atoms. The quadrupole splitting of 0.89(5) mm s^{-1} is consistent with the unsymmetrical arrangement about the Sn atom with two short and two long Sn—Br bonds found in this structure.

(*Received* 6 *January* 1986; *accepted* 24 *February* 1986)

Abstract—The apparent stability constants (K) of the cryptates $[Ag \cdot C21C_5]^+$ and $[Na \cdot C21C_5]^+$ ($C21C_5$ = 4,7,13-trioxa-1,10-diazabicyclo[8.5.5]eicosane) have been determined in a range of solvents. For $[Na \cdot C21C_5]^+$ log (K/dm^3 mol^{-1}) = 2.87, 3.72, 3.76, 3.98, 5.08 and 5.12 at 298.2 K in dimethylformamide, pyridine, methanol, acetone, acetonitrile and propylene carbonate, respectively, in the presence of 0.05 mol dm^{-3} tetraethylammonium perchlorate supporting electrolyte. These values are substantially lower than those observed for $[Na \cdot C211]^+$ (C211 = 4,7,13,18-tetraoxa-1,10-diazabicyclo-[8.5.5]eicosane) and this is attributed to the presence of one less oxygen atom in $C21C_5$ than in C211. A similar relationship is observed for $[Ag \cdot C211]^+$ and $[Ag \cdot C21C_5]^+$, where, for the latter cryptate, log (K/dm^3 mol^{-1}) = 5.19, <2, 7.62, 8.58 and 4.55 at 298.2 K in dimethylformamide, pyridine, methanol, acetone and acetonitrile, respectively.

As part of a study of cryptates[1–3] we have determined the apparent stability constants (K) of sodium and silver cryptates formed with the cryptand 4,7,13-trioxa-1,10-diazabicyclo[8.5.5]eicosane ($C21C_5$) in dimethylformamide, pyridine, methanol, acetone, acetonitrile and propylene carbonate in order to determine the effect on cryptate stability of the replacement of an oxygen atom in 4,7,13,18-tetraoxa-1,10-diazabicyclo[8.5.5]eicosane (C211) by a methylene unit. (The low solubilities of $C21C_5$ and $[Na \cdot C21C_5]ClO_4$ in water precluded a study in this solvent.) In the solid state both [Na(C211)NCS] and [Na($C21C_5$)NCS] exist in the *exclusive* form in which Na^+ resides above the face of the 15-membered ring delineated by two nitrogens and three oxygens (hereafter referred to as the N_2O_3 face), and the nitrogen of NCS^- is within bonding distance of Na^+.[2] ($[Li \cdot C211]I$[4] and $[Li \cdot C21C_5]NCS$[3] exemplify the *inclusive* form of cryptates in which the metal ion is totally encapsulated within the cryptand.) ^{13}C NMR spectra[1,2] of the perchlorate analogues of both of the above cryptates are consistent with the retention of the *exclusive* form of the cryptate in solution, and it is probable that solvent largely displaces perchlorate from the first coordination sphere of Na^+. Thus in this study $[Na(C211)]^+$ and $[Na(C21C_5)]^+$ denote the *exclusive* form of the cryptate in which Na^+ resides above the N_2O_3 face of the cryptand and at the same time retains part of its solvation shell. There appear to be no published structural studies of the analogous Ag^+ cryptates, but as the effective six-

coordinate ionic radius[5] of Ag^+ (1.15 Å) is greater than that of Na^+ (1.02 Å), and the diameters[6] of the C211 and $C21C_5$ cavities or crypts are 1.6 Å, it is expected that $[Ag \cdot C211]^+$ and $[Ag \cdot C21C_5]^+$ should exist in the *exclusive* form on the basis of these relative sizes.

EXPERIMENTAL

Materials

The cryptand $C21C_5$ was prepared as previously described and its purity was determined to be at least 98.5% by ^{13}C NMR spectroscopy.[2] Tetraethylammonium chloride (BDH) was converted to tetaethylammonium perchlorate through ion exchange of chloride on Amberlite IRA-400 resin in the hydroxide form followed by precipitation of the perchlorate with perchloric acid. This was followed by two recrystallizations from water, and vacuum drying at 335 K for 24 h to produce tetraethylammonium perchlorate which was stored over P_4O_{10} *in vacuo*. Sodium and silver perchlorate (Fluka) were dried *in vacuo* at 335 K for 48 h and were stored over P_4O_{10}. Dimethylformamide, pyridine, methanol, acetone, acetonitrile and propylene carbonate (BDH) were purified and dried as described in the literature[7] and were stored over Linde 3A molecular sieves under dry nitrogen.

Stability constant (K) *determinations*

K were determined titrimetrically at 298.2 ± 0.02 K in a water-jacketed Princeton Applied Research vessel under a dry nitrogen stream which both stirred the titration solution and prevented the ingress of moisture. Solutions for titration were 0.05 mol dm^{-3} in tetraethylammonium perchlorate background electrolyte, and were prepared in glove boxes under dry nitrogen. $[Ag \cdot C21C_5]^+$ K were determined from the potentiometric titration of 25 cm^3 of 10^{-3} mol dm^{-3} $AgClO_4$ solution with 10^{-2} mol dm^{-3} $C21C_5$ solution. The titration was monitored through a silver wire electrode and a reference electrode consisting of a silver wire in a 10^{-2} mol dm^{-3} $AgClO_4$ solution in the titration solvent. The titration vessel and the reference electrode were linked through a salt bridge containing 0.05 mol dm^{-3} tetraethylammonium perchlorate in the solvent under study. Cell potentials were measured using an Orion Research 701A digital analyser and were accurate to ±0.2 mV. The electrode response was calibrated in each solvent by measuring the potentials of solutions of known Ag^+ concentration in the presence of 0.05 mol dm^{-3} tetraethylammonium perchlorate, and encompassing the Ag^+ concentration range encountered in the $[Ag \cdot C21C_5]^+$ titration. Plots of potential (E) in mV against log$[Ag^+]$ were linear with slopes ($= k$) in the range 55–65 mV consistent with eqn (1):

$$E = E_o + k \log[Ag^+]. \quad (1)$$

K for $[Ag \cdot C21C_5]^+$ were determined from $[Ag^+]$ derived from the titrations by eqn (1) using methods of calculation described in the literature.[8] The derived K appear in Table 1.

In dimethylformamide, methanol, acetone and acetonitrile the K for $[Na \cdot C21C_5]^+$ were determined using a competitive-equilibrium method from the literature.[9,10] K_{Na} for the equilibrium

Table 1. Log (K/dm^3 mol^{-1}) for sodium and silver cryptates in the presence of 0.05 mol dm^{-3} tetraethylammonium perchlorate in a range of solvents at 298.2 K

Solvent	D_N[a]	Log (K/dm^3 mol^{-1}) at 298.2 K for the cryptates[b]			
		$[Na \cdot C21C_5]^+$[c]	$[Na \cdot C211]^+$[d]	$[Ag \cdot C21C_5]^+$[c]	$[Ag \cdot C211]^+$[d]
Dimethylformamide	26.6	2.87	5.2	5.19	8.6
Pyridine	33.1	3.72	—	<2	—
Methanol	19.0	3.76	6.1	7.62	10.6

[b] Error in log (K/dm^3 mol^{-1}) is ±0.10 for data obtained in this study except for $[Ag \cdot C21C_5)^+$ in methanol where it is ±0.02.

[c] This study.

[d] Data from Ref. 12.

shown in eqn (2) may be determined by eqn (3) if K_{Ag} is known:

$$[Na \cdot C21C_5]^+ + Ag^+ \overset{K'}{\rightleftharpoons} [Ag \cdot C21C_5]^+ + Na^+, \quad (2)$$

$$K' = \frac{K_{Ag}}{K_{Na}} = \frac{[Ag \cdot C21C_5^+][Na^+]}{[Na \cdot C21C_5^+][Ag^+]}. \quad (3)$$

Thus, using the previously described apparatus, 25 cm^3 of 10^{-3} mol dm^{-3} $AgClO_4$ solution were titrated with a solution 10^{-2} mol dm^{-3} in both $NaClO_4$ and $C21C_5$. The derived K_{Na} data appear in Table 1.

Only a small potential change was observed for the $[Ag \cdot C21C_5]^+$ system in pyridine consistent with $\log (K_{Ag}/dm^3\ mol^{-1}) < 2$, and as a consequence K_{Ag} could not be accurately determined by the direct titration of Ag^+ employed in this study. Despite several purifications of propylene carbonate, $AgClO_4$ solutions in this solvent rapidly turned brown, and as a result no Ag^+ titrations were attempted.

The K of $[Na \cdot C21C_5]^+$ in pyridine and propylene carbonate were determined by direct Na^+ titration using the equipment employed in the Ag^+ titrations with the silver wire electrode replaced by a Radiometer G502 specific sodium ion electrode. The response of the electrode was calibrated and the $[Na \cdot C21C_5]^+$ titrations were carried out in a similar manner to that described for the $[Ag \cdot C21C_5]^+$ titrations, and the derived $\log (K_{Na}/dm^3\ mol^{-1})$ values appear in Table 1. All titrations were carried out in duplicate.

RESULTS AND DISCUSSION

In the solid state Na^+ is bound to the N_2O_3 face of the cryptand in $[Na \cdot C21C_5 \cdot NCS]$ with Na—N (cryptand) distances of 2.576(3) and 2.759(4) Å, and Na—O distances of 2.297(2), 2.340(3) and 2.356(2) Å.[2] In $[Na \cdot C211 \cdot NCS]$ Na^+ is also bound on the N_2O_3 face with Na—N(cryptand) distances of 2.492(17) and 2.478(13) Å, and Na—O distances of 2.289(14), 2.324(13) and 2.433(19) Å, and a fourth Na—O distance of 2.662(9) Å.[2] Thus although both cryptates exist in the *exclusive* form the fourth oxygen of $[Na \cdot C211 \cdot NCS]$ opposite the N_2O_3 face, above which Na^+ is sited, is still within bonding distance of Na^+. It is therefore expected that this fourth oxygen should have a significant influence on the stability of $[Na \cdot C211]^+$ in solution. Apart from the displacement of the anion (which in this study is perchlorate instead of thiocyanate) from its binding site with Na^+, it is anticipated that the *exclusive* structures observed in the solid state are largely retained in solution as indicated by ^{13}C NMR studies.[1,2] There are potentially two alternative forms of *exclusive* $[Na \cdot C211]^+$ in which Na^+ binds either to one of the equivalent 15-membered N_2O_3 faces of C211 (as observed in the solid state) or to the smaller 12-membered N_2O_2 face. The stability constants characterizing the crown ether complexes $[Na \cdot 12C4]^+$ in methanol and propylene carbonate are 10–100 times less than those observed for $[Na \cdot 15C5]^+$.[11] As the number of donor atoms and ring sizes of the two crown ethers are similar to those of the N_2O_2 and N_2O_3 faces of C211 it seems probable that these faces will exhibit similar relative propensities for binding Na^+ and hence that $[Na \cdot C211]^+$ will exist predominantly with Na^+ bound to a N_2O_3 face in solution. In the case of $C21C_5$ it is unlikely that the 12-membered N_2O or the 15-membered N_2O_2 faces will compete effectively with the 15-membered N_2O_3 face as Na^+-binding sites. Thus any differences in the stabilities of $[Na \cdot C21C_5]^+$ and $[Na \cdot C211]^+$ should predominantly reflect differences in binding of Na^+ on the N_2O_3 faces of the two cryptands.

Values of $\log (K/dm^3\ mol^{-1})$ for $[Na \cdot C21C_5]^+$ [eqn (4)] and $[Ag \cdot C21C_5]^+$, and $[Na \cdot C211]^+$ and $[Ag \cdot C211]^+$ from the literature[12] are given in Table 1. It is seen that the K characterizing $[Na \cdot C21C_5]^+$ [eqn (4)]:

$$Na^+ + C21C_5 \underset{k_d}{\overset{k_f}{\rightleftharpoons}} [Na \cdot C21C_5]^+ \quad (k_f/k_d = K) \quad (4)$$

is several orders of magnitude less than that characterizing $[Na \cdot C211]^+$ in the four common solvents studied, and that a similar relationship holds for $[Ag \cdot C21C_5]^+$ and $[Ag \cdot C211]^+$. This indicates the importance of the fourth oxygen in C211 in the competition between the cryptand and the solvent for Na^+- and Ag^+-binding sites. It is seen that K for $[Na \cdot C21C_5]^+$ increases as the Gutmann donor number (D_N)[13] decreases for the oxygen donor solvents in the sequence: dimethylformamide (26.6), methanol (19.0), acetone (17.0), and propylene carbonate (15.1), where D_N is shown in parentheses. A similar increase in K is seen for the nitrogen donor solvents pyridine (33.1) and acetonitrile (14.1), but whereas K observed in acetonitrile fits roughly into the sequence observed for the oxygen donor solvents, the K observed in pyridine is greater than expected on the basis of its high D_N. This is probably a consequence of the position of the *N*-donor atom in the pyridine ring causing substantial steric hindrance towards bonding with Na^+. In general it is expected that the electron-donating abilities indicated for the solvents by D_N will be modified by their steric characteristics. Similar variations of stability with the nature of the solvent have been observed for other cryptates.[12]

The kinetic origins of the differences in K for $[Na \cdot C21C_5]^+$ and $[Na \cdot C211]^+$ in dimethylformamide are apparent from the respective k_f (298.2 K) (2.14×10^7 and 1.92×10^6 $dm^3\ mol^{-1}\ s^{-1}$) and k_d (298.2 K) (2.88×10^4 and 12.1 s^{-1}) values.[1,2] Clearly the much greater dissociation rate of $[Na \cdot C21C_5]^+$ accounts predominantly for its lower stability in dimethylformamide, but a detailed mechanistic analysis must await the availability of kinetic data in other solvents.

In the oxygen donor solvents both silver cryptates are seen to be substantially more stable than their sodium analogues despite Na^+ being characterized by the smaller effective six-coordinate ionic radius[5] (1.02 Å), and therefore expected to fit further into the cryptand cavity and form a more stable cryptate than the larger Ag^+ (1.15 Å). This suggests that this difference in stability may arise from differences in bonding. While Na^+ has no directional bonding characteristics Ag^+ tends to form two strong coaxial bonds consistent with a greater degree of covalency in the bonding of the latter metal.[14] The reversal of the relative magnitudes of K for the sodium and silver cryptates with the change from oxygen donor solvents to nitrogen donor solvents indicates that the latter solvents compete more effectively with the cryptates for binding sites on Ag^+ than do the oxygen donor solvents. This is consistent with the known characteristic of Ag^+ for binding nitrogen donor atoms in preference to oxygen donor atoms in the formation of complexes;[14] and also with the observation that the ion–solvent interaction of Ag^+ (in comparison with Na^+) with acetonitrile is much stronger than with dimethylformamide, methanol or propylene carbonate.[12]

PREPARATION OF A NOVEL POLYMERIC LIGAND CONTAINING A TETRAAZA MACROCYCLE SUPPORTED ON POLYSTYRENE, AND SEPARATION OF COPPER(II) AND NICKEL(II)

YASUHIRO NAKAJIMA, MANABU FUJIWARA, TAKAYUKI MATSUSHITA and TOSHIYUKI SHONO*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565, Japan

(*Received* 6 *January* 1986; *accepted* 24 *February* 1986)

Abstract—The novel polymeric ligand containing the tetraaza macrocycle as a pendant group was prepared by the reaction of 2,7,12,14-tetramethyl-1,4,8,11-tetraazacyclotetradeca-1,5,7,12-tetraene with iodomethylstyrene–divinylbenzene copolymer beads. The content of the ligand in the polymer was 0.75 mmol g^{-1} under the optimum conditions. The complexation of this polymer with copper(II) and nickel(II) in water under heterogeneous conditions in a batch system showed that it can bind copper(II) selectively by complex formation with the tetraaza macrocycle. The capacity for copper(II) was found to depend on the pH, ionic strength and ethanol content of the sample solutions. Moreover, the separation of nickel(II) and copper(II) was achieved in a column system.

Tetraaza macrocyclic compounds such as porphyrins and cyclam are important as models for metal enzymes in biological chemistry, so the properties of their metal complexes have been investigated in detail.[1–4] Recently, tetraaza macrocyclic compounds have been applied to selective extractants for transition-metal ions.[5–10] We have previously reported that the polymeric ligands, which were prepared by the reaction of 5,7,12,14-tetramethyl-1,4,8,11-tetraazacyclotetradeca-1,5,7,12-tetraene (L) with diisocyanates {OCN—R—NCO [R = $(CH_2)_6$ or $C_6H_5CH_2C_6H_5$]}, can be applied to a selective adsorbent for copper(II).[11]

In this paper, we describe the preparation and complexing ability of the polymeric ligand, in which L was incorporated covalently to polystyrene beads as a pendant group toward transition-metal ions such as copper(II) and nickel(II). In a column system, copper(II) and nickel(II) were found to be separated satisfactorily.

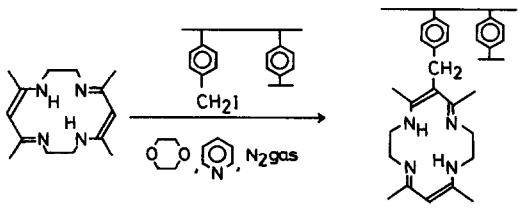
EXPERIMENTAL

Materials



All reagents were of reagent grade. 1,4-Dioxane was refluxed over sodium and distilled. It was kept over sodium. Acetone was refluxed over calcium sulfate and distilled. Other solvents were purified in the usual manner. Water was deionized.

Measurements

IR spectra were recorded on a Hitachi 215 grating spectrophotometer. Atomic absorption spectra were obtained using a Nippon Jarrell Ash AA-1. The pH of the sample solution was measured with a Hitachi–Horiba F-8DP pH meter.

Preparation of polymeric ligand

The macrocyclic ligand was prepared according to the method of a previous paper.[12] The polymeric ligand was prepared as shown in Scheme 1.

Scheme 1. Preparation of the polymeric ligand.

Preparation of the iodomethylstyrene polymer

Five grams of chloromethylstyrene–5% divinylbenzene copolymer beads obtained from Mitsubishi Kasei Co. Ltd was suspended in acetone–1,4-dioxane (45 cm^3–15 cm^3) and stirred at room temperature for 3 h. To this suspension was added sodium iodide (5.0 g) and the mixture refluxed for 24 h in the dark. After cooling to room temperature, it was filtered and washed with acetone and water several times, and dried *in vacuo*. The reaction was found to occur almost quantitatively.

Incorporation of L into polymer beads

The iodomethylstyrene–divinylbenzene copolymer (10.0 g) was suspended in 1,4-dioxane (400 cm^3) and stirred at room temperature for 2 h under a nitrogen atmosphere. To this suspension was added a 1,4-dioxane solution (100 cm^3) of L (21.4 g) and dried pyridine (15 cm^3), which was then stirred at 70°C for 24 h. After cooling to room temperature, it was filtered and washed with chloroform and acetone several times. The resulting beads were dried *in vacuo*. Found: C, 48.8; H, 4.5; N, 4.2%.

Procedure for binding of metal ion in a batch system

Binding of metal ions in a batch system was carried out by using a 10-cm^3 test tube (with a stopper) which contained an aqueous solution of metal(II) acetate [copper(II) or nickel(II)] and polymer beads (*ca* 1×10^{-5} unit mol). The test tube was shaken for an appropriate time (from 1 to 48 h) at room temperature by using a shaker. After shaking, polymer beads were separated with decantation and the solution was diluted with water, and the concentration of the metal(II) ion remaining in it was determined by atomic absorption spectrometry. To investigate the effect of the ethanol content in the sample solution, the separated solution, with water added if necessary, was evaporated very slowly at 80°C to remove the ethanol. The residual solution was diluted with water, and the concentration of copper(II) remaining in it was determined by atomic absorption spectrometry.

Procedure for separation of metal(II) ions in a column system

Separation of copper(II) and nickel(II) ions in a column system was carried out under the following conditions. A column (i.d. = 10 mm) was packed with 3 g of the polymer beads which were fully swollen in advance. A mixed solution of copper(II) and nickel(II) {[metal(II)] = 1×10^{-3} M} was eluted at a flow rate of 0.2 $cm^3\ min^{-1}$. Eluates were fractionated into 2-cm^3 portions and diluted with water to determine the concentration of the eluted metal(II) ions.

RESULTS AND DISCUSSION

Characterization of the polymeric ligand

Figure 1 shows the IR spectra of the iodomethylstyrene–divinylbenzene copolymer, the tetraaza macrocycle and the polymeric ligand. The characteristic bands due to the tetraaza macrocycle were observed 1620, 1565 and 665 cm^{-1} for the spectrum of the polymeric ligand, indicating that the macrocycles were supported on the copolymer. The content of the macrocycle was calculated to be 0.75 mmol g^{-1}, based on the nitrogen content in the elemental analysis.

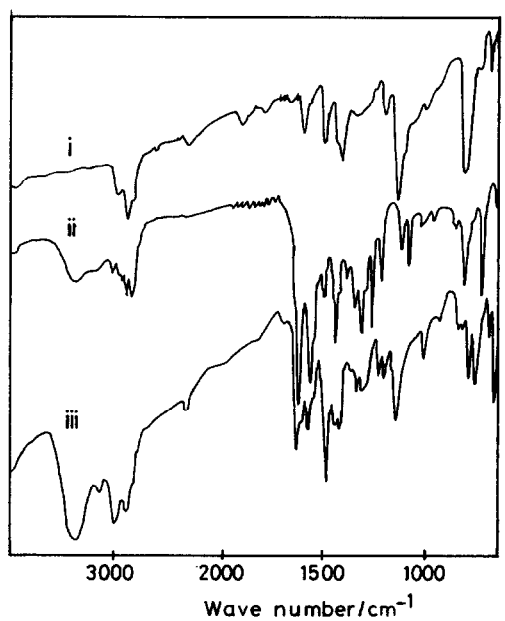


Fig. 1. IR spectra of iodomethylstyrene–divinylbenzene copolymer (i), tetraaza macrocycle (ii) and polymeric ligand (iii) in KBr disc.

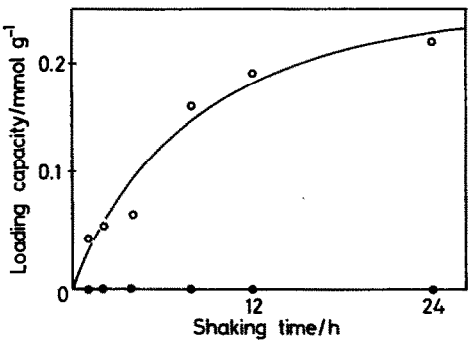

Fig. 2. Effects of shaking time on the loading capacity of the polymeric ligand for copper(II) (○) and nickel(II) (●). pH, 5.6; metal(II) acetate, 1×10^{-3} M (10 cm^3); polymeric ligand, 10 mg.

Effect of shaking time on the loading capacity in the batch system

Figure 2 shows the effect of shaking time on the loading capacity of the polymeric ligand for copper(II) and nickel(II) in the batch system at pH = 5.6 without a buffer solution. The loading capacity for copper(II) reached 0.23 mmol g^{-1} after shaking for 24 h. On the other hand, no nickel(II) was bound to the polymer after shaking for 24 h. This result indicates that this polymeric ligand possesses a high selectivity to copper(II). Thus, we have studied its binding ability for copper(II) in detail.

Effect of pH on the loading capacity

Figure 3 shows the effect of the pH of the sample solution on the loading capacity of the polymeric ligand for copper(II) ion. The pH values were adjusted by using acetate buffer solutions (0.02 M) from 3.5 to 5.6 and by the addition of appropriate amount of 0.25 M hydrochloric acid or sodium hydroxide solution below 3.5 or above 5.6, respectively.

The capacity for copper(II) increased gradually with increasing pH of the copper(II) solution. It should be noticed that a capacity of 0.12 mmol g^{-1} was obtained even at pH = 3.0. At this pH the corresponding monomeric tetraaza macrocycle could not bind copper(II).[8] This result can be explained as follows: the binding of copper(II) may take place on both the exterior and the interior of the polymer beads. The binding sites on the interior should be surrounded by a hydrophobic environment due to the polystyrene backbone. Thus, the hydrogen ion concentration on the interior is considered to be lower than those on the exterior and in the bulk solution. Therefore, a relatively slight effect of pH on the loading capacity was observed by lowering the pH of the bulk solution.

Effect of ionic strength

Figure 4 shows the effect of the ionic strength of the sample solution on the loading capacity for copper(II), which was carried out under the following conditions: the concentration of the copper(II) ion was 1.0×10^{-3} M, and the shaking time was 48 h. The ionic strength of the sample solution was varied from 0.0 to 3.0 by the addition of sodium nitrate.

The loading capacity for copper(II) decreased with increasing ionic strength and reached a constant value of 0.07 mmol g^{-1} above 2.5. The coexisting ionic salts in large amounts influence more or less the results for the solvent extraction and the adsorption on the resins: they exert a negative effect

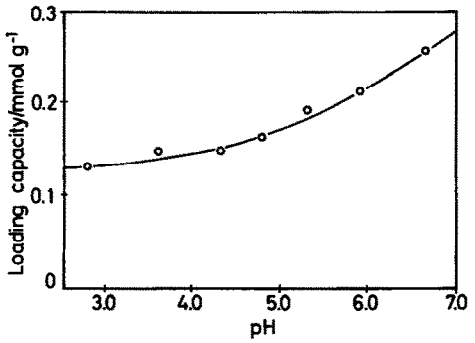

Fig. 3. Effect of pH on the loading capacity of the polymeric ligand for copper(II). Shaking time, 48 h; copper(II) acetate, 1×10^{-3} M (10 cm^3); polymeric ligand, 10 mg.

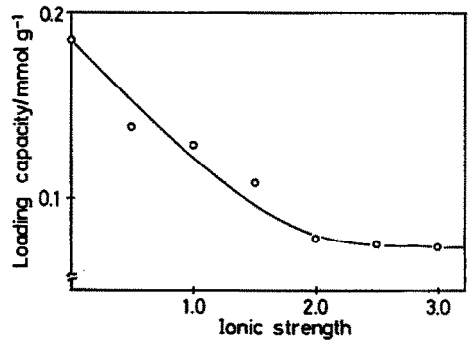

Fig. 4. Effect of ionic strength on the loading capacity for copper(II). Shaking time, 48 h; copper(II) acetate, 1×10^{-3} M (10 cm^3); polymeric ligand, 10 mg. Ionic strength was adjusted by the addition of sodium nitrate.

on the metal binding by weakening the interaction between the metal ion and the chelating agents, but they exert a positive effect on it by desolvation around the metal ion to be captured. In the present system, the former process may operate effectively.

Effect of the ethanol content in the sample solution

Figure 5 shows the effect of the ethanol content in the sample solution on the loading capacity for copper(II). The concentration of the copper(II) ion was 1.0×10^{-3} M and the ethanol content varied from 0 to 100 vol %. The shaking time was 48 h.

The loading capacity for copper(II) increased from 0.18 to 0.73 mmol g^{-1} as the ethanol content in the sample solution was increased from 0 to 100 vol %. These results indicate that the complexation of the polymeric ligand with copper(II) is accelerated by the addition of ethanol. It has been already pointed out that the addition of an appropriate organic solvent to an aqueous sample solution results in a strong retention of ions on ion-exchange resins.[13-15] Such behavior has been ascribed to a decreasing tendency for hydration in a mixed solvent, in which the metal ions can interact easily with the binding sites. In the present case, a similar effect operates and accelerates the complexation of copper(II) with the tetraaza macrocycles of the polymeric ligand. Of course, other factors, such as the swelling of the polymer beads, should increase the capacity.

Recovery of copper(II) ion from copper(II)-loading polymer beads with hydrochloric acid

We have examined the recovery of copper(II) bound in the polymeric ligand by treatment with hydrochloric acid. Figure 6 shows the effect of the shaking time on the recovery of copper(II) ion with 0.01 M hydrochloric acid. The recovery of copper(II) ion gradually increased and reached 21.4% after shaking for 24 h. The low percentage of recovery is explained by a slight pH dependence of the binding ability because of the hydrophobicity of the polymer support (see Fig. 3).

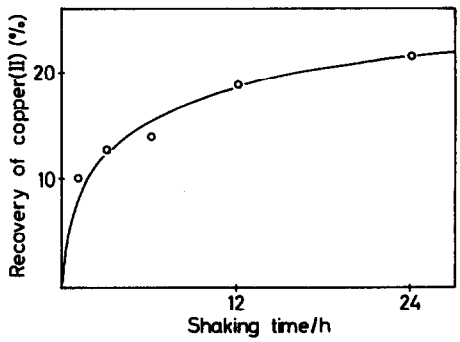

Fig. 6. Effect of shaking time on the recovery of copper(II) from copper(II)-loading polymer beads with 0.01 M hydrochloric acid.

Separation of copper(II) and nickel(II) in the column system

We have applied the polymeric ligand for separation of copper(II) and nickel(II) ions by using a column. Figure 7 shows the breakthrough curves of the copper(II) and nickel(II) ions under the conditions described in Experimental. The nickel(II) ion was rapidly eluted and the concentration in the effluents reached the feed concentration of 1×10^{-3} M. On the other hand, the copper(II) ion was completely adsorbed on the polymer beads and began to elute when the effluent volume exceeded 70 cm^3.

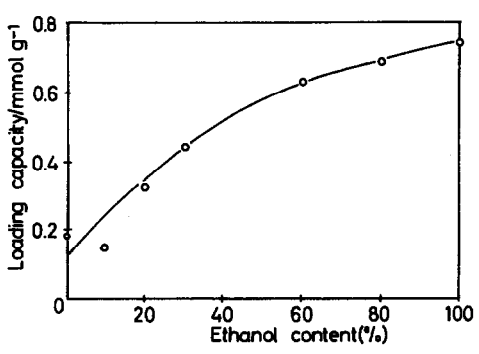

Fig. 5. Effect of ethanol content in the sample solution on the loading capacity for copper(II). Shaking time, 48 h; copper(II) acetate, 1×10^{-3} M (10 cm^3); polymeric ligand, 10 mg.

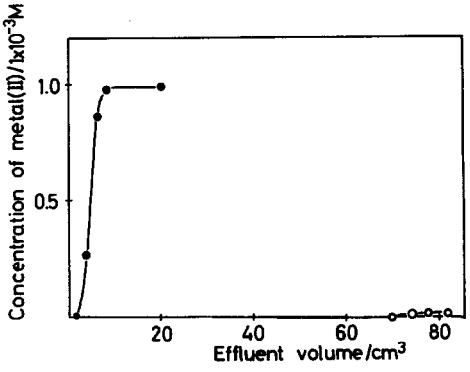

Fig. 7. Breakthrough curves for copper(II) (○) and nickel(II) (●) in the column system. Feed concentration of metal(II), 1×10^{-3} M; pH, 5.5; flow rate, 0.2 cm^3 min^{-1}; polymeric ligand, 3.0 g (dry).

This result indicates that this polymer ligand has a high selectivity to copper(II) ion, consistent with the results obtained in the batch system.

THEORETICAL STUDY OF THE STATIC JAHN–TELLER EFFECT—III. TYPE OF VIBRONIC COUPLING IN HEXAHALO COMPLEXES*

MARTIN BREZA, PETER PELIKÁN and ROMAN BOČA†

Departments of Inorganic and Physical Chemistry, Slovak Technical University, CS-812 37 Bratislava, Czechoslovakia

(*Received* 14 *January* 1986; *accepted* 24 *February* 1986)

Abstract—Three types of vibronic coupling in hexacoordinate complexes are compared: the T_{ig}–$(a_{1g}+e_g)$ type in the group O_h, the E_g–$(a_{1g}+e_g)$ type in the group D_{3d}, and the E_g–$(a_{1g}+b_{1g})$ type in the group D_{4h}. It is shown that the group with the highest symmetry (O_h) does not imply the best model of vibronic coupling. Numerical applications were obtained for 29 complexes of the MX_6^q type having a triply degenerate electronic state in an octahedral geometry on the CNDO–UHF level of the MO–LCAO–SCF method. Characteristics of these Jahn–Teller active systems are calculated and discussed.

The Jahn–Teller effect (JTE) has been studied by many authors using various methods. Nevertheless, only a small number of publications deal with quantitative calculations in this field. In our previous papers[1–4] the hexahalo complexes of the first-row transition metals have been investigated by means of the semiempirical MO–LCAO–SCF methods in the CNDO and INDO versions. As a result, the vibronic coupling constants and the vibrational force constants have been calculated as parameters of the adiabatic potential surface (APS). Recently, using group theory, a complete classification of the possible symmetries, which may exist for the JTE, has been published.[5,6] We applied the principle of a step-by-step descent in symmetry (symmetry elements being lost) synchronous with a step-by-step splitting of degenerate electron terms. Accordingly, the symmetry group O_h with triple degenerate electron terms (T_{1g}, T_{2g}, T_{1u} and T_{2u}) is split to its first-level subgroups: cubic (T_h, T_d and O), hexagonal (D_{3d}) or tetragonal (D_{4h}). If the electronic terms still remain degenerate, the splitting continues to the corresponding second-, third- and fourth-level subgroups, respectively (Fig. 1). One possible pathway of distortion is shown in Fig. 2 for the tetragonal pattern. The central-atom effect [the proton number influence of the central atom M, as well as the oxidation state (q) and spin state (m) of the complex] and the ligand field effect represent factors which determine the final ground-state geometry of the system. The central problem of this paper may be formulated as follows. The vibronic coupling in hexacoordinate systems may be of the T_{2g}–$(a_{1g}+e_g+t_{2g})$ type within the O_h-group, the E–$(a_1+b_1+b_2)$ type for the D_4-group, the E–(a_1+e) type for the C_3-group etc. Many possibilities are relevant. Therefore the scope of this paper is to clear up which type of vibronic coupling actually operates in hexacoordinate complexes.

METHOD

The types of vibronic coupling have been studied by Griffith[7] who concluded that only three types (except icosahedral groups) may occur. They are:

(i) the three-mode coupling T–(a_1+e+t_2) for cubic groups with triple degenerate electron terms (T_d, T_h, T, O_h and O);

(ii) the three-mode coupling E–$(a_1+b_1+b_2)$ for groups D_{4h}, C_{4v}, C_{4h}, C_4, D_4, S_4 and D_{2d};

(iii) the two-mode coupling E–(a_1+e) for the remaining groups having doubly degenerate electron terms. Some subscripts (u or g and 1 or 2)

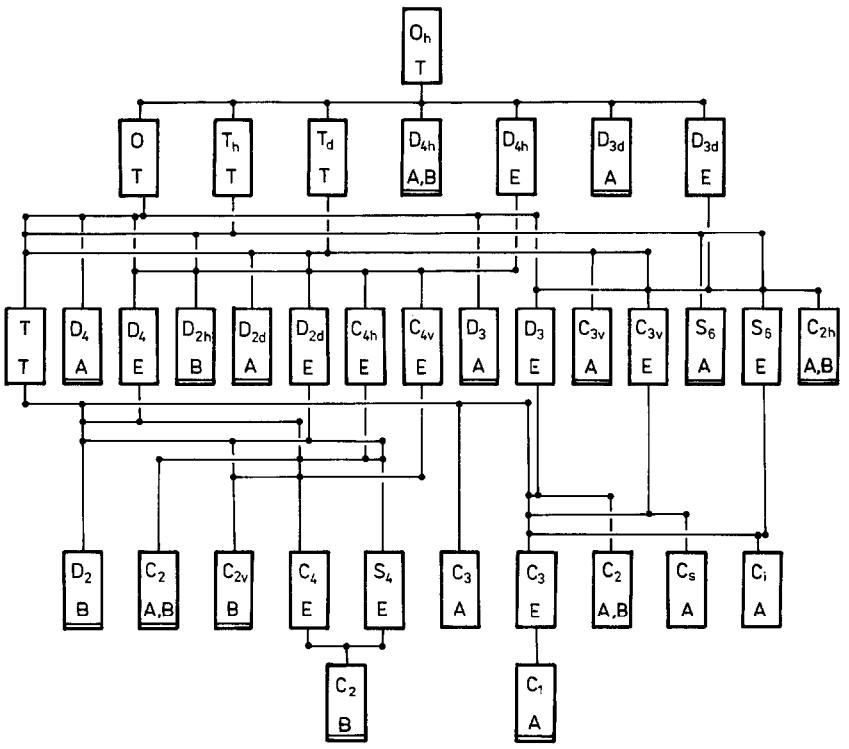

Fig. 1. Pattern of the octahedral system distortions.

for the symbols of irreducible representations are omitted here for simplicity. The a_1-mode (the totally symmetric coordinate) is usually deleted from consideration since it has no influence on the linear approximation of the electron–nuclear operator $\hat{V}(q, Q)$. Nevertheless, this mode is coupled with the other vibronic active modes in the quadratic approximation of $\hat{V}(q, Q)$, so that this degree of freedom has to be considered.

Using the degenerate perturbation theory an analytic formula for the APS can be derived:

$$W(\ldots Q_k \ldots) = E^0 + F(\ldots Q_k \ldots) + \varepsilon_i. \qquad (1)$$

The second term is the usual Taylor expansion along vibrational coordinates (Q_k) with the restriction that each component spans the totally symmetric representation. The vibronic correction term arises from the secular equation:

$$\det\{V_{mn} - \varepsilon_i \delta_{mn}\} = 0, \qquad (2)$$

with ε_i being the lowest eigenvalue of the electron–nuclear operator matrix (**V**) in the space of degenerate electronic functions. The actual shape of the APS depends on the individual type of vibronic interaction.

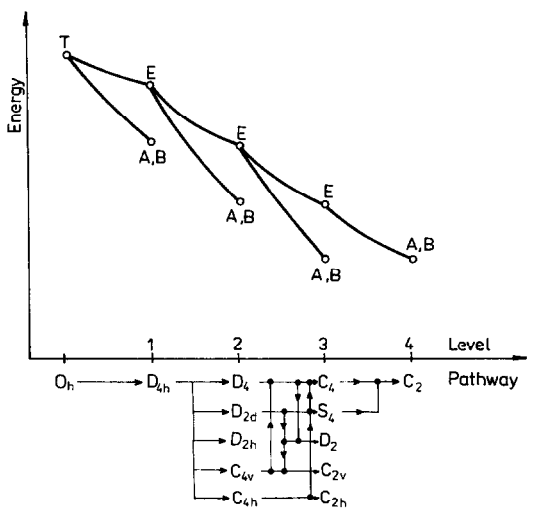

Fig. 2. Energy profile of octahedral system distortions for the tetragonal pattern.

Type 1

Vibronic interaction T_{ij}–$(a_{1g} + e_g + t_{2g})$ for the reference group O_h ($i = 1$ or 2, $j = u$ or g). The symmetrized normal coordinates span the a_{1g} (Q_1), e_g (Q_2 and Q_3) and t_{2g} (Q_4–Q_6) irreducible rep-

resentations. The APS adopts a form:

$$\begin{aligned}W(Q_1,Q_2,Q_3,Q_4,Q_5,Q_6)&=\varepsilon_i+E^0+K_aQ_1+\tfrac{1}{2}K_{aa}Q_1^2+\tfrac{1}{2}K_{ee}(Q_2^2+Q_3^2)\\&+T_{aaa}Q_1^3+T_{aee}Q_1(Q_2^2+Q_3^2)\\&+T_{att}Q_1(Q_4^2+Q_5^2+Q_6^2)\\&+T_{eee}Q_3(3Q_2^2-Q_3^2)+T_{ett}[Q_4^2(Q_3\\&-\sqrt{3}Q_2)+Q_5^2(Q_3+\sqrt{3}Q_2)\\&-2Q_3Q_6^2]+T_{ttt}Q_4Q_5Q_6.\end{aligned}\tag{3}$$

V is defined by the elements ($V_{mn}=V_{nm}$):

$$\begin{aligned}V_{11}&=\tfrac{1}{2}(A_e+Z_{ae}Q_1)(Q_3-\sqrt{3}Q_2)\\&+\tfrac{1}{2}B_{ee}(Q_2^2-Q_3^2-2\sqrt{3}Q_2Q_3)\\&+\frac{1}{\sqrt{6}}B_{tt}(-2Q_4^2+Q_5^2+Q_6^2),\\V_{12}&=(A_t+Z_{at}Q_1)Q_6+B_{tt}Q_4Q_5-Z_{et}Q_3Q_6,\\V_{13}&=(A_t+Z_{at}Q_1)Q_5+B_{tt}Q_4Q_6\\&+\tfrac{1}{2}Z_{et}Q_5(Q_3+\sqrt{3}Q_2),\\V_{22}&=\tfrac{1}{2}(A_e+Z_{ae}Q_1)(Q_3+\sqrt{3}Q_2)\\&+\tfrac{1}{2}B_{ee}(Q_2^2-Q_3^2+2\sqrt{3}Q_2Q_3)\\&+\frac{1}{\sqrt{6}}B_{tt}(Q_4^2-2Q_5^2+Q_6^2),\\V_{23}&=(A_t+Z_{at}Q_1)Q_4+B_{tt}Q_5Q_6\\&+\tfrac{1}{2}Z_{et}Q_4(Q_3-\sqrt{3}Q_2),\\V_{33}&=-V_{11}-V_{22}\\&=-(A_e+Z_{ae}Q_1)Q_3-B_{ee}(Q_2^2-Q_3^2)\\&-\frac{1}{\sqrt{6}}B_{tt}(Q_4^2+Q_5^2-2Q_6^2).\end{aligned}\tag{4}$$

The following parameters are contained in the APS: K_e = the linear vibration constant (it vanishes in equilibrium geometry), K_{ii} = harmonic force constants of ith vibration, T_{ijk} = cubic vibration constants, A_e and A_t = linear vibronic constants for e_g and t_{2g} active vibrations, B_{ee} and B_{tt} = quadratic vibronic constants, and Z_{ij} = quadratic vibronic constants which couple vibrations of different symmetry.

Type 2

Vibronic interaction E_i–$(a_{1g}+b_{1g}+b_{2g})$ for the reference group D_{4h} ($i=u$ or g). In this case the APS has the form:

$$\begin{aligned}W(Q_1,Q_2,Q_6)&=\varepsilon_i+E^0+K_aQ_1+\tfrac{1}{2}K_{11}Q_1^2\\&+\tfrac{1}{2}K_{22}Q_6^2+T_{aaa}Q_1^3\\&+T_{a11}Q_1Q_2^2+T_{a22}Q_1Q_6^2,\end{aligned}\tag{5}$$

with the vibronic correction originating from the explicit solution of the 2×2 secular equation:

$$\varepsilon_i=-[(A_1-Z_{a1}Q_1)^2Q_2^2+(A_2-Z_{a2}Q_1)^2Q_6^2]^{1/2}.\tag{6}$$

Its parameters have the same meanings as for type 1.

Type 3

Vibronic interaction E_i–$(a_{1g}+e_g)$ for the reference group O_h or D_{3d} ($i=u$ or g). For the APS it holds that:[3]

$$\begin{aligned}W(Q_1,Q_2,Q_3)&=\varepsilon_i+E^0+K_aQ_1\\&+\tfrac{1}{2}K_{aa}Q_1^2\\&+\tfrac{1}{2}K_{ee}(Q_2^2+Q_3^2)\\&+T_{aaa}Q_1^3+T_{aee}Q_1(Q_2^2+Q_3^2)\\&+T_{eee}(3Q_2^2-Q_3^2)Q_3,\end{aligned}\tag{7}$$

with the vibronic term:

$$\begin{aligned}\varepsilon_i=-[&(A_e-Z_{ae}Q_1)^2(Q_2^2+Q_3^2)\\&+B_{ee}^2(Q_2^2+Q_3^2)^2\\&+2B_{ee}(A_e-Z_{ae}Q_1)Q_3(Q_3^2-3Q_2^2)]^{1/2}.\end{aligned}\tag{8}$$

A significant simplification is obtained when restricting only to vibration coordinates Q_1 and $Q_x=Q_3$ ($Q_x=Q_22/\sqrt{3}$ for group D_{4h}). This means that only a certain cut of the APS will be considered. The APS adopts a uniform shape:

$$\begin{aligned}W(Q_1,Q_x)&=s(A_x-Z_{ax}Q_1)Q_x+sB_{xx}Q_x^2+E^0\\&+K_aQ_1+\tfrac{1}{2}K_{aa}Q_1^2\\&+\tfrac{1}{2}K_{xx}Q_x^2\\&+T_{aaa}Q_1^3+T_{axx}Q_1Q_x^2-T_{xxx}Q_x^3.\end{aligned}\tag{9}$$

In reality this represents:

(i) the vibronic interaction T_{2g}–$(a_{1g}+e_g)$ for the reference group O_h ($s=+1$ and -0.5, respectively; $Z_{ax}=-Z_{ae}$);

(ii) the vibronic interaction E_g–$(a_{1g}+b_{1g})$ for the reference group D_{4h} ($s=\pm1$, $Z_{ax}=Z_{a1}$, $T_{axx}=T_{a11}$, $T_{xxx}=0$, $B_{xx}=0$);

(iii) the vibronic interaction E_g–$(a_{1g}+e_g)$ for the reference group D_{3d} ($s=\pm1$, $Z_{ax}=Z_{ae}$).

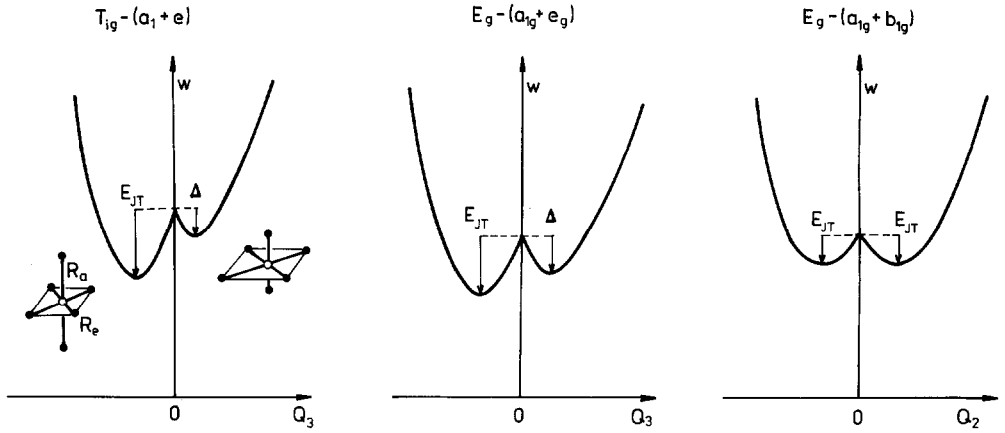

Fig. 3. Double-minimum form of the APS for three cases of vibronic coupling.

The positive values of s hold for an elongated bipyramid and the negative values for the compressed form (Fig. 3).

RESULTS AND DISCUSSION

A study of the type of vibronic coupling has been carried out for 29 complexes of the $^m[MX_6]^q$ type ($X = F^-$, Cl^- or Br^-). These systems are characterized in Table 1. The following procedure has been applied to each system.

(i) The total molecular energy was calculated for selected geometries of the complex so that a two-dimensional numerical map of $W^c(Q_1, Q_x)$ was obtained. The semiempirical CNDO–UHF version[8,9] of the MO–LCAO–SCF method was applied for this purpose. The energy cut-off was 10^{-5} eV.

(ii) A least-squares fitting was used so that the functional:

$$\mathscr{F} = \sum_i w_i^2[W_i^c(Q_1, Q_x) - W_i^q(Q_1, Q_x)]^2 = \min \tag{10}$$

was minimized. The metric weighting concept was applied with $w_i^2 = 1/(\sum_k Q_k^2)$. The procedure is fast owing to the simple (linearizable) form of function (9).

(iii) As a result of the least-squares method, the force constants (K_a, K_{aa}, K_{xx}, T_{aaa}, T_{axx} and T_{xxx}) and the vibronic constants (A_x, B_{xx} and Z_{ax}) have been calculated. They determine the extremal points of the APS (Q_1^0 and Q_x^0). Consequently, the Jahn–Teller stabilization energies (E_{JT}) were obtained: $E_{JT} = W(Q_1 = 0, Q_x = 0) - W(Q_1^0, Q_x^0)$.

The results of the least-squares fitting are collected in Table 2. 33–42 points of the APS were used in the regression. It is concluded that the best model of vibronic coupling corresponds to the highest value of N_ρ (the number of nines in the correlation coefficient ρ), the lowest value of the discrepancy factor and the highest E_{JT}. These conditions are fulfilled only for 11 complexes (from the total number of 29 systems) if the vibronic coupling $T_{ig}-(a_{1g}+e_g)$ within group O_h is considered. The vibronic coupling $E_g-(a_{1g}+e_g)$ within group D_{3d} is a better model for 15 complexes. This result is of great significance, because the group with the highest symmetry (O_h) does not imply the best model of vibronic coupling in each case. In the light of this conclusion Liehr's first postulate[10] needs

[a] N_ρ = number of nines in the correlation coefficient (e.g. $N_\rho = 6$ for $\rho = 0.9999998$), R = discrepancy factor $\{[\Sigma_i(W_i^c - W_i^a)^2/\Sigma_i(W_i^a)^2]^{1/2}\}$ in %, E_{JT} = Jahn–Teller stabilization energy in meV, Δ = stabilization energy of the second extremum (saddle point) in meV. The N_ρ value is underlined for the best description.

modification. The proposed statement is that the strong vibronic coupling operates in the presence of electron degeneracy within the group which is not necessarily of the highest symmetry. It implies the hypothesis of the existence of vibronic coupling in the group of lowest symmetry with degenerate electron terms. Moreover, our results represent excellent arguments for the theory of a step-by-step descent in symmetry by the classification of possible symmetries of the Jahn–Teller systems.[5,6]

The following conclusions can be drawn from Table 3.

(i) The non-zero values of K_a, Z_{ae} and Q_1^0 parameters are mutually interrelated. The greater the vibronic coupling constant Z_{ae} (this couples the vibration modes of different symmetry), the greater is the $|Q_1^0|$ value—a deviation from the optimum octahedron. This effect, however, is not substantial since Q_1^0 typically has values of 10^{-14} m.

(ii) The Jahn–Teller distortions may be characterized by the Q_3^0 parameter. Its values span the range of 10^{-13}–10^{-12} m. Higher distortions occur in M(III) complexes compared to M(II) systems. The values of $|Q_3^0|$ are also functions of the polarity of the metal–ligand bond: they decrease within the series M(III)—F, M(III)—Cl and M(III)—Br, and increase within the series M(II)—F, M(II)—Cl and M(II)—Br. Since the values of Q_3^0 are negative for the energy minimum, the elongated form of the tetragonal bipyramid represents the equilibrium geometry of the complexes under study.

(iii) $|Q_3^0|$ as well as E_{JT} are functions of the quadratic vibronic constant B_{ee} [$\sim \partial^2 \hat{V}(q, Q)/\partial Q_3^2$]. These

quantities are probably underestimated by the simple CNDO method used. Their trends, however, seem to be correct. A more sophisticated *ab initio* approach does not come into consideration at present, because of the large number of geometries—over 1000—in this study.

(iv) The harmonic force constants fulfil the relation $K_{ee} < K_{aa}$, so that the tetragonal distortion along the $Q_3(e_g)$ mode is much easier than the symmetric stretching $Q_1(a_{1g})$. Thus $Q_3(e_g)$ might be considered as a soft mode. The cubic force constants (T_{aaa}, T_{aee} and T_{eee}) adopt significant values so that the anharmonicity effects are not negligible.

These conclusions are valid not only for iron complexes included in Table 3 but also for the other systems characterized in Table 1.

SYNTHESIS AND CHARACTERIZATION OF $Rh_2\{Ph(2\text{-}pyr)N\}_4$: A PRECURSOR TO A DIRHODIUM(III) DICATION CONTAINING AN Rh–Rh BOND

DEREK A. TOCHER* and JOANNE H. TOCHER

Department of Chemistry, University College London, 20 Gordon Street, London WC1H 0AJ, U.K.

(*Received* 23 *January* 1986; *accepted* 24 *February* 1986)

Abstract—$Rh_2\{Ph(2\text{-}pyr)N\}_4$ has been prepared from hydrated rhodium trichloride and the sodium salt of 2-anilinopyridine in ethanol. The dark green air-stable compound has been characterized by analytical and spectroscopic measurements. The complex undergoes two facile one-electron oxidations at moderate potentials. The dication, $[Rh_2\{Ph(2\text{-}pyr)N\}_4]^{2+}$, formally contains two Rh(III) ions and a double Rh–Rh bond.

The one-electron oxidation of neutral binuclear Rh(II) compounds to the corresponding monocations, in which the mean oxidation state per Rh is 2.5, is well established[1–3] and results in a formal increase in Rh–Rh bond order from 1.0 to 1.5. The most extensively electrochemically studied series of dirhodium(II) complexes have been the tetracarboxylates ($Rh_2(O_2CR)_4L_2$).[4–14] Investigations into the electro-oxidation and electro-reduction reactions of $Rh_2(O_2CR)_4$ complexes in a number of solvents have shown that the midpoint potentials depended on the identify of both the carboxylate and the solvent.[9] Carboxylates possessing electron-withdrawing substituents were more difficult to oxidize than those with electron-donating substituents and a linear relationship between oxidation potentials and Taft polar substituents constants has been observed. The potential for electro-oxidation of a given $Rh_2(O_2CR)_4$ complex was inversely related to the solvent's donor ability.[9] Investigations into the 1:1 and 1:2 Lewis base adducts[10,14] of $Rh_2(O_2CR)_4$ complexes have shown that the 1:2 adducts are more easily oxidized than the corresponding 1:1 adducts. The shifts in potential observed in these studies are in accord with expectations based on the model of Rh–Rh interactions put forth by Kawamura and Nakatsuji.

The impetus for this work was the observation that, on replacing bridging carboxylate ions by amidates,[15–19] that is changing the immediate coordination sphere about the $[Rh_2]^{4+}$ core from one of eight oxygen atoms to one comprising four oxygen and four nitrogen atoms, a shift in oxidation potentials to values which are 700–1000 mV less positive is observed. For example, the parent acetate complex $Rh_2(O_2CCH_3)_4$ undergoes a quasi-reversible one-electron oxidation at a potential of +1.17 V (SCE) in acetonitrile, while the amidate $Rh_2(HNC(O)CH_3)_4$ undergoes a corresponding oxidation at +0.15 V (SCE).[19] Similar observations have been made for other pairs of dirhodium(II) compounds. In the two amidate-bridged compounds $Rh_2(C_6H_5NC(O)CH_3)_4$ and $Rh_2(HNC(O)CH_3)_4$ this shifting of oxidation potentials to less positive values is sufficiently dramatic that a second oxidation wave is brought into the available solvent range.[18,19] These new one-electron oxidations occur at potentials >1.40 V (SCE), unfortunately too close to the solvent background for any further characterization of the doubly oxidized products to be feasible.

The substitution of a further four nitrogen atoms for the remaining four oxygens of the amidates ought to result in the further shifting of the oxidation potentials to less positive values and an increase in the relative stability of both the singly and doubly oxidized products. To test this hypothesis we have prepared a new dirhodium(II) complex, $Rh_2\{Ph(2\text{-}pyr)N\}_4$, in which the immedi-

* Author to whom correspondence should be addressed.

ate coordination sphere about the $[Rh_2]^{4+}$ core comprises eight nitrogen atoms. This complex undergoes two facile one-electron oxidations at moderate potentials. Although we have been unable to isolate the cations, $[Rh_2\{Ph(2\text{-}pyr)N\}_4]^{+/2+}$, they have been characterized spectroelectrochemically. This paper reports the synthesis and full characterization of the dirhodium(II) precursor and discusses its electron-transfer behaviour. A preliminary report of the redox behaviour of this compound has already appeared.[20]

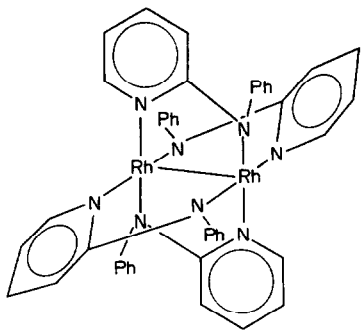
EXPERIMENTAL

Physical measurements

IR spectra were recorded in the region 4000–240 cm^{-1} on a Perkin–Elmer 983 spectrophotometer using Nujol mulls on CsI plates. The ^1H NMR spectrum was recorded on a Varian XL200 spectrometer. Electronic spectra were recorded in the range 1600–400 nm on a Varian 2390 spectrophotometer. Molecular weights were determined in acetone on a Perkin–Elmer Hitachi (model 115) osmometer calibrated with benzil. Mass spectra were by the University of London Intercollegiate Research Service at the School of Pharmacy.

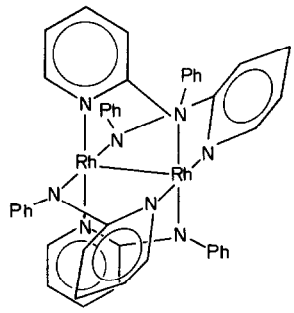
Voltammetric studies employed a Metrohm E506 potentiostat interfaced with a Metrohm E505 cell-stand utilizing a three-electrode geometry. The working electrode consisted of either a dropping mercury electrode or a platinum wire electrode (Metrohm EA 285). A non-aqueous Ag–AgCl–Cl^-, CH_2Cl_2 electrode, separated from the bulk of the solution by a fritted glass disk, was used as a reference electrode (Metrohm EA 441/5), and a platinum wire as an auxiliary electrode. Cyclic voltammetric (CV) measurements also employed a Metrohm E612 VA Scanner in conjunction with a Hewlett–Packard 7035B XY recorder. Current–voltage curves were recorded at scan rates of 0.02–0.50 $V\,s^{-1}$. The solvents used for the electrochemical measurements were CH_2Cl_2 and dimethylsulphoxide. The solvents contained 0.5 M tetra-*n*-butylammonium tetrafluoroborate ($TBABF_4$) as supporting electrolyte. Deaeration of the solutions was carried out before commencing the experiment, and a stream of nitrogen was passed throughout. All potentials are reported with respect to the Ag–AgCl electrode, against which ferrocene is oxidized at a potential of +0.60 V. Spectroelectrochemistry was performed in an O.T.T.L.E. cell which had an optical path length of 0.10 cm. Time-resolved spectra were obtained using a Varian 2390 spectrophotometer.

Synthesis



Sodium metal (0.46 g, 20.0 mol) was added to a solution of 2-anilinopyridine (3.42 g, 20.0 mmol) in ethanol (50 cm^3). The solution was stirred until all the sodium was dissolved (*ca* 15 min). To the homogeneous solution was added $RhCl_3 \cdot 3H_2O$ (0.50 g, 1.9 mmol). The resulting mixture was refluxed under N_2 for 3 h, after which time a microcrystalline dark green precipitate had formed. The precipitate was filtered off and recrystallized from MeOH. The final product was then extracted with the minimum volume of CH_2Cl_2 and then reprecipitated by addition of cold EtOH. The solid was dried *in vacuo* at room temperature. Yield 0.44 g (52%). Found: C, 59.4; H, 4.4; N, 12.7%. Calc. for $Rh_2(C_{11}H_9N_2)_4$: C, 59.8; H, 4.1; N, 12.7%. IR spectrum (Nujol mull, CsI plates); 1601 (s), 1584 (m), 1531 (w), 1508 (s), 1294 (s), 1229 (m), 1160 (w), 1015 (m), 858 (w), 743 (s), 709 (m), 529 (s), 506 (m), and 376 (w) cm^{-1} (s = strong, m = medium, w = weak). Electronic spectrum (1600–400 nm in CH_2Cl_2): 1015 ($\varepsilon = 2160\ dm^{-3}\ mol^{-1}\ cm^{-1}$), 579 (770), and 476 (sh). ^1H NMR [CD_2Cl_2 solvent, $(CH_3)_4Si$ reference]: δ 6.5–8.5 ppm (complex multiplets). Mass spectrum: *m/z* 882, $[Rh_2\{Ph(2\text{-}pyr)N\}_4]^+$; 713, $[Rh_2\{Ph(2\text{-}pyr)N\}_3]^+$; 544, $[Rh_2\{Ph(2\text{-}pyr)N\}_2]^+$; 441, $[Rh\{Ph(2\text{-}pyr)N\}_2]^+$; and 375, $[Rh_2\{Ph(2\text{-}pyr)N\}]^+$. Molecular weight (osmometrically in acetone): 864 (1.0×10^{-3}), and 894 (0.79×10^{-3} mol dm^{-3}), calc. 882. The complex is soluble in a wide range of common organic solvents.

RESULTS AND DISCUSSION



The anion derived from 2-anilinopyridine has previously been observed to coordinate across both Mo and W quadruple bonds,[21] across the Os–Os triple[22] bond, in the complex $Os_2\{Ph(2\text{-}pyr)N\}_3Cl_3$, and across the $Ru^{2.5}Ru$ bond[23] in the complex $Ru_2\{Ph(2\text{-}pyr)N\}_4Cl$. The geometry of the last complex was unusual in that all four of the asymmetric ligands adopted the same orientation about the $Ru^{2.5}Ru$ bond. Earlier attempts to prepare the Rh complex $Rh_2[Ph(2\text{-}pyr)N]_4$ by reaction of $RhCl_3 \cdot nH_2O$ with Na[Ph(2-pyr)N] were unsuccessful. When the reactants were combined in a 1 : 4 molar ratio a red solution was formed. Treatment of that solution with pyridine resulted in the deposition of orange crystals which were identified crystallographically as $RhCl_2py_2[(C_6H_4)(2\text{-}pyr)NH]$.[24] In this complex the 2-anilinopyridinato ligand is not only coordinated through the pyridine nitrogen atom but also through an *ortho* carbon atom of

the phenyl group, thus forming a six-membered metallocyclic ring. However when $RhCl_3 \cdot 3H_2O$ and Na[Ph(2-pyr)N] are refluxed in EtOH, in a molar ratio of *ca* 1:10, for 2–3 h a dark green solution is formed, together with a dark precipitate. The recrystallization and subsequent extraction of this precipitate leads ultimately to the isolation of a complex with the empirical formula $Rh\{Ph(2\text{-}pyr)N\}_2$. The ^1H NMR spectrum in CD_2Cl_2 solvent only contains signals in the region δ 6.5–8.5 ppm. Considerable overlapping of these multiplets is observed and we have not attempted to assign the resonances to individual protons on the phenyl or pyridyl rings. Importantly no N—*H* resonance was observed in the range 0–20 ppm. The absence of a proton on the amine nitrogen atom is confirmed by the IR spectrum. The free ligand 2-anilinopyridine contains a ν(N—H) stretching band at 3231 cm^{-1}, which is absent from the IR spectrum of the complex. The IR spectrum of the *ortho*-metallated complex, $Rh_2Cl_2py_2[(C_6H_4)(2\text{-}pyr)NH]$, contained bands at 1522 and 1570 cm^{-1} which were characteristic of the metallated phenyl ring.[24–26] Analogous bands are absent from the spectrum of this complex, although several other strong bands do occur in the region 1500–1600 cm^{-1}. A strong band at 1604 cm^{-1} can be assigned to the skeletal vibrations of the pyridyl rings. Strong bands in the regions 700–850 and 500–540 cm^{-1} are also characteristic of bridging 2-anilinopyridinato anions.[22,23]

The binuclear nature of the product has been confirmed by a variety of techniques. The mass spectrum contains a strong parent-ion peak at *m/z* 882 corresponding to the binuclear cation $[Rh_2\{Ph(2\text{-}pyr)N\}_4]^+$. The successive loss of three of the bridging ligands, to give peaks at *m/z* 713, 544 and 375, is also observed, together with peaks due to the mononuclear fragment cations $[Rh\{Ph(2\text{-}pyr)N\}_3]^+$ and $[Rh\{Ph(2\text{-}pyr)N\}_2]^+$, at *m/z* 610 and 441, respectively. The complex was sufficiently soluble in acetone for its molecular weight to be determined by osmometry. Values obtained agree well with the proposed dimeric formulation (see Experimental). When four asymmetric ligands bridge a dimetal unit a total of four different geometric isomers are possible.[23] However, as we have observed that $Rh_2\{Ph(2\text{-}pyr)N\}_4$ does not readily form axial adducts, this suggests that a close approach to the sixth coordination site of each rhodium is not facile. It is likely that the presence of two pendant phenyl groups would be sufficient to block axial coordination and hence it appears reasonable to suggest that the molecule adopts structure **1** or **2**. The former arrangement of bridging ligands has been observed for the Mo and W complexes $M_2\{Ph(2\text{-}pyr)N\}_4$,[21] while the *trans* disposition of two 2-anilinopyridine anionic ligands, both orientated in the same direction, has been observed in the mixed-ligand complex $Ru_2Cl(O_2CCH_3)_2\{Ph(2\text{-}pyr)N\}_2 \cdot Ph(2\text{-}pyr)NH$.[27]

CV and linear alternating-current voltammetric (ACV) measurements were made in several solvents at a Pt electrode. Figure 1 shows the voltammetric

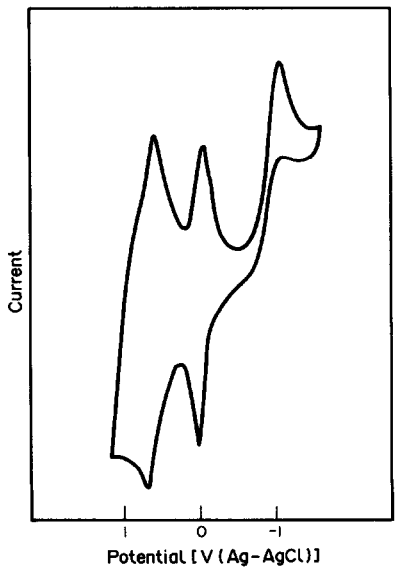

Fig. 1. Voltammetry of $Rh_2\{Ph(2\text{-}pyr)N\}_4$ in CH_2Cl_2. Scan rate = 100 mV s^{-1} (CV). Potentials vs Ag–AgCl reference electrode (against which ferrocene is oxidized at +0.60 V).

response of $Rh_2\{Ph(2\text{-}pyr)N\}_4$ in CH_2Cl_2. Clearly the complex undergoes two oxidation processes in the potential range 0.0–0.8 V as well as being reduced at −1.13 V. The electrochemical oxidation of $Rh_2\{Ph(2\text{-}pyr)N\}_4$ to the cation $[Rh_2\{Ph(2\text{-}pyr)N\}_4]^+$ is straightforward and uncomplicated at $E_{1/2} = +0.07$ V. Diagnostic plots of $E_p - E_{p/2}$ and $E_p^a - E_p^c$ are in the range predicted for a one-electron transfer.[28] The peak current is proportional to the square root of the scan rate and $i_{p,a}/i_{p,c} = 1$, indicating a diffusion-controlled one-electron transfer. The second oxidation, the mid-point potential of which is +0.72 V, is chemically reversible, although apparently characterized by sluggish heterogeneous charge-transfer kinetics. Hence, although $i_{p,a}/i_{p,c} = 1.0$ at all scan rates, ΔE_p $(E_p^a - E_p^c) = 100$ mV at $v = 50$ mV s^{-1}, and increases to 140 mV at 500 mV s^{-1}. In contrast to the oxidation behaviour of the dimer the reduction could be characterized as an irreversible process. A broad peak was obtained on the forward sweep and no peak was observed on the backward sweep. Neither scanning very rapidly nor recording the voltammograms at low temperatures improved the reversibility of this reduction wave. Analogous irreversible reduction waves have been reported for other dirhodium(II) complexes.[9,29] The one-electron nature of both oxidation processes was indicated by the ACV peak widths at half height and confirmed by comparison of the diffusion-limited currents with that of a known quantity of ferrocene, as measured by stirred voltammetry. On the basis of the observed data, the following description is proposed for the oxidation/reduction of $Rh_2\{Ph(2\text{-}pyr)N\}_4$:

$$\begin{array}{ccc} Rh_2\{Ph(2\text{-}pyr)N\}_4 & \xrightarrow{+e} & [Rh_2\{Ph(2\text{-}pyr)N\}_4]^- \\ {\scriptstyle +e}\uparrow\downarrow{\scriptstyle -e} & & \downarrow \\ [Rh_2\{Ph(2\text{-}pyr)N\}_4]^+ & & \text{decomposition products} \\ {\scriptstyle +e}\uparrow\downarrow{\scriptstyle -e} & & \\ [Rh_2\{Ph(2\text{-}pyr)N\}_4]^{2+} & & \end{array}$$

Repeated attempts to isolate the mono- and dication, through chemical or electrochemical oxidation, have generally been unsuccessful. Hence we have of necessity characterized the cations $[Rh_2\{Ph(2\text{-}pyr)N\}_4]^{+/2+}$ *in situ* by controlled potential oxidation of $Rh_2\{Ph(2\text{-}pyr)N\}_4$ in an optically transparent cell sited in the beam of an electronic spectrophotometer.

The steady-state spectra obtained at potentials of −0.10, +0.20 and +0.85 V are illustrated in Fig. 2. These spectra (1, 2 and 3) correspond to $Rh_2\{Ph(2\text{-}pyr)N\}_4$, $[Rh_2\{Ph(2\text{-}pyr)N\}_4]^+$ and $[Rh_2\{Ph(2\text{-}pyr)N\}_4]^{2+}$, respectively, the band maxima and extinction coefficients of which are presented in Table 1. The transitions which occur upon sequential oxidation are totally reversible since the spectra obtained upon controlled potential reduction of the oxidized species were identical with those observed initially. The appearance of two isosbestic points in the time-resolved spectra obtained in carrying out reduction/oxidations is consistent with the 1:1 interconversions of reduced and oxidized forms of the complex. For completeness we have carried out a controlled-potential reduction, at −1.2 V, in the spectroeletrochemical cell. The steady-state spectrum obtained is illustrated by curve 4 in Fig. 2. A

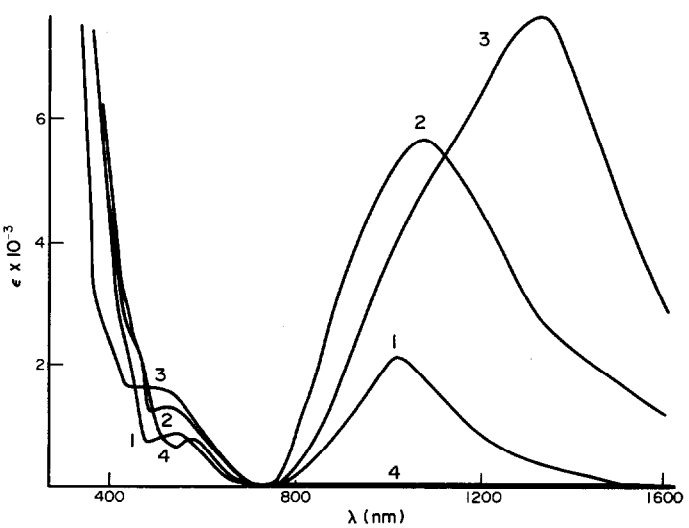

Fig. 2. Steady-state electronic absorption spectra obtained at potentials of −0.10 V (1), +0.20 V (2), +0.85 V (3), and −1.20 V (4), in CH_2Cl_2–0.5 M $TBABF_4$.

Table 1. Spectral characterization of $[Rh_2\{Ph(2\text{-}pyr)N\}_4]^n$ ($n = -1$, 0, 1 or 2) complexes

Complex	λ_{max} of major peaks (nm) [ε (dm^{-3} mol^{-1} cm^{-1})]
$Rh_2\{Ph(2\text{-}pyr)N\}_4$	1025 (2165), 579 (770), 476 (sh)
$[Rh_2\{Ph(2\text{-}pyr)N\}_4]^+$	1066 (5680), 525 (1235), 480 (sh)
$[Rh_2\{Ph(2\text{-}pyr)N\}_4]^{2+}$	1365 (7730), 500 (1545), 430 (sh)
"$[Rh_2\{Ph(2\text{-}pyr)N\}_4]^{1-}$"	595 (700)

controlled-potential reoxidization did not result in the quantitative regeneration of the spectrum of the neutral molecule. This observation together with the absence of isosbestic points in the time-resolved spectra are consistent with our earlier deductions on the irreversible nature of this electron-transfer step.

The electronic spectrum of each of the species $[Rh_2\{Ph(2\text{-}pyr)N\}_4]^{0/+/2+}$ contains a moderate-to-strong band in the near-IR region of the electronic spectrum. The magnitude of the associated extinction coefficients suggests that these bands are due to a charge-transfer process, and we will not discuss them further. The electronic spectrum of each of the species in question contains a single distinct band in the visible portion of that spectrum together with a series of shoulders at higher energy. The neutral molecule is characterized by a band at 579 nm ($\varepsilon = 770$ dm^{-3} mol^{-1} cm^{-1}). Upon oxidation to the monocation that band moves to a higher energy, 525 nm, and increases in intensity. Further shifting and gain in intensity, to 500 nm and $\varepsilon = 1545$ dm^{-3} mol^{-1} cm^{-1}, accompanies the formation of the dication.

To attempt to make a detailed assignment of the electronic transitions for this complex, based upon extrapolation from the theoretical results[13,30–34] obtained for the tetracarboxylates, $Rh_2(O_2CR)_4$, would be foolish. However, from the observations we have made, some useful general conclusions may be drawn. If the neutral dirhodium(II) complex, having no axial ligands, has the normal electronic ground state configuration $\sigma^2\pi^4\delta^2\delta^{*2}\pi^{*4}$, then the first electron to be removed by oxidation is likely to originate in the π^* molecular orbital. Thus the mono-oxidized product, $[Rh_2\{Ph(2\text{-}pyr)N\}_4]^+$, formally contains a $Rh\overset{1.5}{—}Rh$ bond, with the electronic configuration $\sigma^2\pi^4\delta^2\delta^{*2}\pi^{*3}$. In view of the smooth and reversible changes which occur in the electronic spectrum upon sequential oxidation, and which are consistent with the retention of the dimeric cage structure, we would suggest that the second electron removed also originated in the π^* molecular orbital. Hence the dication $[Rh_2\{Ph(2\text{-}pyr)N\}_4]^{2+}$ has the electronic configuration $\sigma^2\pi^4\delta^2\delta^{*2}\pi^{*2}$, and contains a $Rh\overset{2}{—}Rh$ bond.

FACTORS AFFECTING THE FORMATION OF ALCOHOL AND ALKOXO COMPLEXES IN THE REACTIONS OF OXOMOLYBDENUM(V) TETRAPHENYLPORPHYRIN WITH VARIOUS ALCOHOLS IN DICHLOROMETHANE

MIYUKI MIURA, TAIRA IMAMURA* and MASATOSHI FUJIMOTO*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060, Japan

(*Received* 6 *January* 1986; *accepted* 4 *March* 1986)

Abstract—The addition of alcohols to dichloromethane solution of Mo(V)O(tpp)Br (tpp = *meso*-tetraphenylporphinato) causes three-step reactions. The products in the first, second and third stages of the reactions are solvated, alcohol and alkoxo complexes, respectively. *t*-Butyl alcohol does not afford the corresponding alcohol complex. The most important factor controlling the formation of alcohol complexes is the bulkiness of the alcohol molecules.

Recently we reported the formation of an Mo(V) tetraphenylporphyrin (tpp) alcohol complex {[Mo(V)O(tpp)(ROH)]$^+$X$^-$ (X = Br or NCS)} and an alkoxo complex [Mo(V)O(tpp)OR] in the reaction of alcohols such as methanol and ethanol with Mo(V)O(tpp)X in dichloromethane.[1] In these reactions the following three factors are thought to be important: (1) the change in the values of the dielectric constants of the mixed solvents, (2) the basicity of the mixed solvents and the acidity of the coordinated alcohols, and (3) the bulkiness of the alcohol molecules.

In the present study, the reactions of Mo(V)O(tpp)Br with various alcohols and water were followed by electronic spectral measurements to find out the most important factors affecting the formation of the alcohol and alkoxo complexes, or driving those formation reactions.

EXPERIMENTAL

Mo(V)O(tpp)Br was prepared by the method previously reported.[1] Alcohols were purified by the usual methods. Dichloromethane was especially carefully purified. Visible absorption spectra were measured at 25±0.1°C with an Hitachi 808 spectrophotometer. ESR spectra were recorded on a JEOL JES-FE1X spectrometer at 25°C. All sample solutions were prepared and measured in the dark to avoid photochemical reductions of the complexes.[2,3]

RESULTS AND DISCUSSION

The addition of a trace amount of methanol [(0.02% (v/v)] to the dichloromethane solution of Mo(V)O(tpp)Br (1.1×10^{-5} mol dm^{-3}) causes a shift in the Soret band[4] from 510 to *ca* 508 nm (first stage of the reaction). This spectral shift was too small to confirm its presence in the previous study.[1] The presence of this first stage was confirmed in the present study by detailed electronic spectral measurements for the reaction systems between Mo(V)O(tpp)Br and various alcohols. Further addition of methanol yields a complex showing bands at 478, 600, and 645 nm (second stage). This spectral change shares isosbestic points with the final spectrum of the first stage. An Asmus plot[5] for this spectral change indicated that the complex formed in the first stage reacts with methanol with a 1:1 molar ratio. The absorption spectrum of the complex in the presence of a large excess of methanol (third stage) has bands at 454, 581 and 621 nm. This absorption spectrum agrees with that of the methoxo complex synthesized independently. The formation of the methoxo complex is accel-

* Authors to whom correspondence should be addressed.

erated by the addition of a trace amount of superoxide (O_2^-) which acts as a base to remove a proton from methanol.[1] ESR measurements showed that the oxidation state of the central molybdenum of the complexes formed in these three stages was +5: the ESR signal with nine lines due to the coupling of $^{92,94,96,98,100}Mo(d^1, I = 0)$ and four nitrogen atoms of the porphyrin ring was observed around $g = 1.967$. Therefore, there is no change in the oxidation state of molybdenum in these reactions with alcohols. These results suggest that the reaction of Mo(V)O(tpp)Br with alcohol in dichloromethane proceeds in three steps [(1)–(3)]:

$$\mathrm{Mo(V)O(tpp)Br} \overset{\mathrm{ROH}}{\rightleftharpoons} [\mathrm{Mo(V)O(tpp)Br}]_s \quad (\mathrm{s} = \text{solvation}), \quad (1)$$

$$[\mathrm{Mo(V)O(tpp)Br}]_s + \mathrm{ROH} \overset{K_1}{\rightleftharpoons} [\mathrm{Mo(V)O(tpp)(ROH)}]_s^+ \mathrm{Br}^-, \quad (2)$$

$$[\mathrm{Mo(V)O(tpp)(ROH)}]_s^+ \mathrm{Br}^- \overset{\mathrm{ROH}}{\rightleftharpoons} [\mathrm{Mo(V)O(tpp)OR}]_s + \mathrm{HBr}. \quad (3)$$

The solvation of the methoxo complex $Mo(V)O(tpp)OCH_3$ formed in the third stage is suggested by the shift of the UV-absorption peak of the synthesized complex $Mo(V)O(tpp)OCH_3$ from 341 to 322 nm when the dichloromethane solution contains 1% (v/v) methanol.

The electronic spectra of the alcohol and alkoxo complexes for various alcohol systems have almost the same peaks in the visible region. Table 1 shows the formation constants (K_1) obtained from the Asmus plots, the alcohol concentrations required for the 50% formation of alkoxo complexes, and the acidity and dielectric constants (D) of the pure alcohols. For the formation reactions of the alcohol complexes the difference in the acidity among those alcohols may not be the main consideration because dissociation of a proton from alcohols is unnecessary for the formation of the corresponding alcohol complexes. The methanol, ethanol and 1-propanol complexes are formed completely in dichloromethane containing 1, 10 and 2% (v/v) of the respective alcohols. The addition of these amounts of the alcohols causes only small changes in D [from 8.93 (pure CH_2Cl_2) to 9.2, 10.4 and 9.4 for the respective reaction systems]. This result suggests that the change in D is not an important factor in the formation of alcohol complexes. The smaller ligands such as water, methanol, ethanol and 1-propanol yield the aqua or alcohol complexes easily. The bulky *t*-butyl alcohol yields no alcohol complex, indicating that the bulkiness of the alcohol is the most important factor in the formation of alcohol complexes. This in turn suggests that the alcohol complexes have the structure shown in Fig. 1. The CPK model shows that alcohols which are longer and more bulky than 1-propanol destabilize the alcohol complexes.

More than 60% of the initial amount of the Mo(V) complex Mo(V)O(tpp)Br exists as alkoxo complexes under the conditions of 20% (v/v) methanol–dichloromethane or 40% (v/v) propanol–

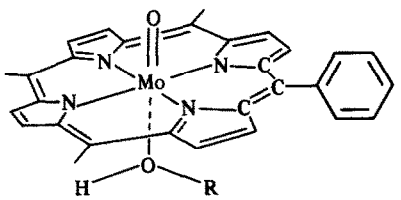

Fig. 1. Proposed structure of the alcohol complexes.

dichloromethane (D = 13.6 and 13.4, respectively). However, in 90% (v/v) butyl alcohol (D = 16), the yield of the alkoxo complex is only 12%. These results reveal also that the change in D of the mixed solvents is not an important factor for the formation of alkoxo complexes. Table 1 shows that smaller ligands such as water and methanol easily yield their aqua and methoxo complexes, respectively. 2-Propanol, presumed to be a bulky ligand, yields simultaneously alcohol and alkoxo complexes with a low concentration of alcohol. The more bulky *t*-butyl alcohol does not give an alcohol complex due to steric hindrance but gives an alkoxo complex with increasing concentration, which indicates that the *t*-butoxo complex is more stable sterically than the *t*-butyl alcohol complex. These results suggest that the size and bulkiness of the alcohol molecule are very important in determining the equilibria of reactions (2) and (3). The small size of the alcohol affects the formation of the alkoxo complex via the alcohol complex. The direct driving force for the formation of the alkoxo complex from the corresponding alcohol complex in the third stage may be a combined action of the acidity of the coordinated alcohol and the basicity of the solvent alcohol.

HYDROGENATION OF IMINES BY RHODIUM–PHOSPHINE COMPLEXES

CINDY J. LONGLEY, TERENCE J. GOODWIN and GEOFFREY WILKINSON*

Chemistry Department, Imperial College, London SW7 2AY, U.K.

(*Received* 1 *May* 1986; *accepted* 19 *May* 1986)

Abstract—The hydrogenation of imines using $RhCl(PPh_3)_3$ and $[Rh(PPh_3)_2(diene)]PF_6$ as catalyst precursors is effective at room temperature under 1 atm of hydrogen, using alcohols as solvents. A water–diethylether phase-transfer system has been used for a solid imine. A catalytic cycle featuring hydrogen bonding between a coordinated alcohol and an imine, and involving a dialkylamido intermediate, is proposed.

Although rhodium–phosphine complexes have long been used in the reduction of carbon–carbon and carbon–oxygen double bonds by molecular hydrogen,[1] the reduction of carbon–nitrogen double bonds has been less well studied.[1,2] Rhodium–phosphine catalysts have been used to reduce imines via catalytic hydrosilylations,[3] but the use of metal carbonyl compounds has received more attention. For example, $Co_2(CO)_8$ under H_2+CO (1 : 1) at 100 bar and 95°C,[4] $Fe(CO)_5$ under CO (100 bar) at 100°C in the presence of NaOH or Et_3N,[5] Cr, Mo or W hexacarbonyls in MeOH containing NaOMe under H_2 (100 bar) at 60–160°C,[6] and $Fe(CO)_5$ in alcohols with and without organic bases under H_2 (100 bar) at 150°C[7] are found to be effective systems for the reduction. Rhodium–phosphine systems at temperatures above 40°C and > 10 bar pressure (H_2) have also been studied by Markó,[8] whilst $[Rh(diop)(nbd)]^+$ [diop = 2,3 - *O* - isopropylidene - 2,3 - dihydroxy - 1,4 - bis(diphenylphosphino)-butane, nbd = norbornadiene] has been employed without great success for asymmetric reduction.[9] Grigg *et al.*[10] have proposed a hydride-transfer mechanism for the reduction of imines by a $RhCl(PPh_3)_3$–Na_2CO_3 mixture in refluxing propan-2-ol, where $RhH(PPh_3)_4$ was suggested to be the effective catalyst.

We now show that $RhCl(PPh_3)_3$ or a cationic species, $[Rh(PPh_3)_2(diene)]^+$, can be used to reduce imines at 25°C and 1 atm H_2, provided that the solvent is an alcohol; large amounts (> 10 g) of imine can be reduced in a water–diethylether system using phase-transfer catalysis. $RhH(CO)(PPh_3)_3$, which has been used as a homogeneous hydrogenation catalyst in the selective reduction of carbon–carbon multiple bonds,[11] is effective in the reduction of imines under synthesis gas (1 : 1, 70 bar) in hot ethanol or toluene (95°C). Hydrogen alone was ineffective under these conditions, even in the presence of excess PPh_3.

RESULTS AND DISCUSSION

Hydrogenation of $RhCl(PPh_3)_3$ or $[Rh(PPh_3)_2(nbd)]PF_6$ in methanol, ethanol or higher alcohols gives a pale yellow or colourless solution, respectively, which on addition of imine becomes deep orange. On stirring under 1 atm H_2 at room temperature a stoichiometric amount of gas is absorbed and the imine reduced as in Table 1. For $RhCl(PPh_3)_3$ the orange solution reverts to yellow on completion of the reduction, but for the cationic species a brown solution is formed; such solutions tend to decompose and deposit rhodium metal, especially if fresh imine is added. No reduction occurs in acetone, dimethylformamide or acetonitrile, and addition of even small amounts (< 5%) of benzene to the alcohol severely inhibits reduction. Reductions in hexane–diethylether require temperatures > 50°C and pressures > 40 bar [cf. Ref. 8 where benzene–methanol (1 : 1) was used].

Although solvent effects in homogeneous hydrogenation are well-known,[1] the requirement for pure

alcohols is unusual and the fact that other polar but non-hydrogen-bonding solvents are unsuitable suggests that hydrogen bonding may be important. Support is provided by observation of effective reduction even in aqueous alcohols.

A proposed cycle is shown in Fig. 1. It would normally be the N atom of the imine that would act as donor, but intramolecular hydrogen bonding as in **A** in Fig. 1 could lead to η^2-C,N bonding of the imine. Protonation of the imine nitrogen might be expected to have the same effect; however attempts to reduce $[RNH{=}CHR']^+$ failed probably because such a cationic substrate would have little tendency to bond a cationic metal species. H transfer to the imine in Fig. 1 would produce the dialkylamido species (**B**). This corresponds to the alkoxide intermediate species proposed in the reduction of ketones,[12] where we suggest that initial H-transfer occurs only to a η^2-ketone. A second hydride transfer to N would then give the coordinated amine complex (**C**), which, on oxidative addition of H_2, eliminates amine. The details of the cycle could, of course, differ from those in Fig. 1 in that the imine could coordinate to a rhodium(I) species which then undergoes oxidative addition of H_2, some of the species need not be solvated and the amine could be displaced by solvent etc. The rate of reduction is affected by the nature of the solvent alcohol, as illustrated in Table 1. For example, reduction is faster in propan-1-ol than in propan-2-ol, probably because steric crowding around the hydroxyl group in the latter restricts hydrogen bonding to the imine.

The formation of a dialkylamido intermediate, $[PhCH_2N(Ph)Cr(CO)_5]^-$, has also been proposed by Markó *et al.*[6] in the hydrogenation of imines using $[HCr(CO)_5]^-$; for $[HFe(CO)_4]^-$ it was suggested that interaction with $[PhCH{=}NHPh]^+$ gave an Fe—C σ-bonded species, $[Fe(PhCHNHPh)H(CO)_4]$.

The hydrogenolysis of a model dialkylamido complex is illustrated by the interaction of hydrogen with the complex $Rh[N(SiMe_3)_2](PPh_3)_2$.[13] A green solution of the complex immediately becomes yellow-brown on exposure to hydrogen, and $(Me_3Si)_2NH$ is formed quantitatively along with rhodium hydride species. Metal–nitrogen bond cleavage resulting in amine elimination has been established[14] in reactions of the type:

$$L_nM(NR_2)+L_mM'H \rightarrow L_nM{-}M'L_m+R_2NH,$$

but not previously, as far as we are aware, with dihydrogen.

Attempts to confirm the proposed reduction mechanism (Fig. 1) by performing the reaction under deuterium were not very successful. Only about 50% incorporation of D at the α-carbon atom in the product amine was observed; also the proportion of ROD in the solvent increased. This is due to D_2–ROH exchange processes, like those encountered by Schrock and Osborn[12] in ketone hydrogenation. Indeed such an exchange is observed on stirring alcohol solutions of the catalyst under D_2, in the absence of imine.

The results in Table 1 show that the rate of reduction decreases with increased steric crowding around the C=N bond. The higher activity of the cationic species relative to $RhCl(PPh_3)_3$ may be due to the possibility, in the former, of forming intramolecular hydrogen-bonded intermediates where both imine and alcohol are bound to the metal (as in **A**), whereas for $[RhCl(PPh_3)_2(H)_2(imine)]$ hydrogen bonding must be intermolecular. Also cationic

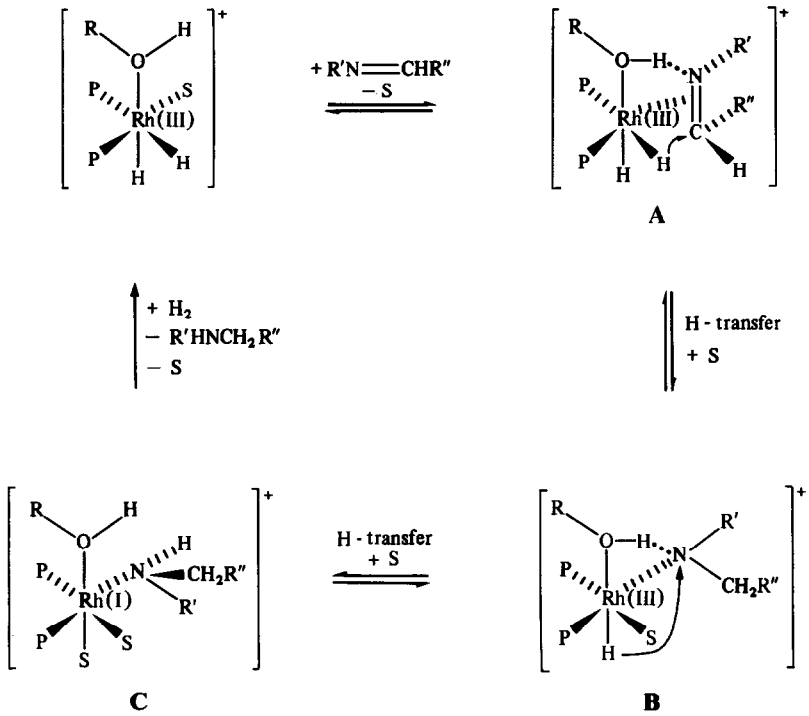

Fig. 1. Proposed cycle for catalytic hydrogenation of imines on cationic rhodium–triphenylphosphine complex. S = alcohol.

species are known to have a greater ability to reduce unsaturated linkages.

The relative insolubility of $RhCl(PPh_3)_3$ in alcohols precludes the use of this catalyst for reduction of large amounts of imine (> 10 g), since large volumes of solvent are required. The decomposition of the cationic catalysts in the presence of high concentrations of imine/amine makes them unsuitable for large-scale reductions. However, for the solid imine *N*-benzylidenephenylamine, phase-transfer permits the rapid reduction of relatively large amounts of imine. However, for liquid imines the reduction is very slow. Other two-phase systems such as polyethylene glycol–H_2O and toluene–H_2O were found to be ineffective.

EXPERIMENTAL

$RhCl(PPh_3)_3$,[15] $[Rh(PPh_3)_2(diene)]PF_6$[16] and $Rh[N(SiMe_3)_2](PPh_3)_2$[13] were prepared according to the literature. *N*-benzylidenemethylamine and *N*-benzylideneisopropylamine were from Lancaster Synthesis Ltd, *N*-benzylidenephenylamine and *N*-benzylidenebenzylamine were prepared by condensation of benzaldehyde with the appropriate amine in ethanol. Triton X-100 was from BDH Chemicals Ltd. Reagent grade solvents were purified by standard methods. Hydrogen was purified using an Englehard "Deoxo" catalyst.

Typical hydrogenation of imine in alcohols

$[Rh(PPh_3)_2(nbd)]PF_6$ (0.06 g, 0.07 mmol) in absolute ethanol was stirred vigorously under 1 atm hydrogen for 1 h. *N*-benzylidenemethylamine (1 g, 8.4 mmol) was added and the stirring continued until hydrogen uptake was complete (gas burette). Concentrated HCl (0.8 cm^3, 10 mmol) was added and the solution reduced to dryness. The solid was dissolved in the minimum amount of ethanol (*ca* 5 cm^3) and diethylether added dropwise until precipitation of the amine hydrochloride was complete; the white solid was collected, washed sparingly with ethanol–ether (1 : 1) and ether, and air dried. Yield 1.2 g (91%).

Free *N*-benzylmethylamine was liberated from the hydrochloride salt by dissolution in the minimum amount of 5 M NaOH (*ca* 5 cm^3) and extracting into ether. The ethereal extracts were dried over Na_2SO_4 and the ether removed under reduced pressure to give the amine. Yield 0.91 g (89%).

Hydrogenation using $RhH(CO)(PPh_3)_3$

$RhH(CO)(PPh_3)_3$ (0.06 g, 0.065 mmol) and *N*-benzylidenephenylamine (1 g, 5.52 mmol) were stirred in toluene (or ethanol) at 95°C under $CO+H_2$ (1 : 1, 70 bar) in a Berghof thermostatted autoclave for *ca* 48 h. The solution was cooled, evap-

orated and the solid dissolved in ethanol (*ca* 5 cm^3); concentrated HCl (1 cm^3, 13 mmol) was added followed by diethylether to precipitate the amine hydrochloride. The free amine was liberated as above.

Hydrogenation using phase-transfer catalysis

$[Rh(PPh_3)_2(cod)]PF_6$ (cod = cycloocta-1,5-diene) (0.2 g, 0.23 mmol) was stirred in diethylether (10 cm^3). Water (50 cm^3), then *N*-benzylidenephenylamine (5 g, 28 mmol) and Triton X-100 (0.1 cm^3) were added, and the mixture vigorously stirred under hydrogen until uptake was complete (*ca* 10 h). Concentrated HCl (3 cm^3, 36 mmol) was added and the solution evaporated under reduced pressure. The solid was dissolved in the minimum amount of hot ethanol (*ca* 20 cm^3) and after cooling precipitation of the amine hydrochloride was completed by slow addition of ether. The white crystals were collected, washed sparingly with ethanol–ether (1 : 1) and ether, and air dried. Yield 4.8 g (80%). The free amine was liberated as above.

COMPARATIVE STUDY OF IRON(III) PHOSPHATE, ARSENATE, ANTIMONATE, SELENITE, MOLYBDATE AND TUNGSTATE

P. S. THIND and J. S. GANDHI*

Department of Chemistry, Guru Nanak Dev University, Amritsar 143005, India

(*Received* 24 *June* 1985; *accepted after revision* 28 *May* 1986)

Abstract—Six water-insoluble compounds of iron(III) have been synthesized by mixing solutions of ferric nitrate and the acidic oxides of elements of Groups V and VI. These compounds have been characterized on the basis of chemical-analysis, pH titration, thermogravimetry, solid-reflectance, IR and Mössbauer studies. Their chemical, thermal and ion-exchange characteristics have been compared.

Since the classical work of Amphlett,[1] numerous synthetic inorganic ion-exchangers have been synthesized and their properties studied. However, the methods of preparation of the same ion-exchanger by different workers are not always the same. It has been shown that the selectivity of an inorganic ion-exchanger depends not only upon its composition but also upon the pH at which the precipitation is performed. It is important that the various ion-exchangers should be synthesized again under the same conditions and their properties studied. Szirtes *et al.*,[2] as well as Qureshi *et al.*,[3,4] have made interesting studied of the phosphates of titanium, zirconium and chromium, and compared their ion-exchange properties. Furthermore, iron(III) phosphate,[5] arsenate,[6] antimonate,[7] tungstate[8] and molybdate have been synthesized and used for the separation of metal ions. In this investigation these iron(III)-based ion-exchangers have been used for a comparison of their spectroscopic, chemical, thermal and ion-exchange properties.

EXPERIMENTAL

Reagents

The ferric nitrate, ammonium dihydrogen phosphate, sodium tungstate, sodium selenite and sodium arsenate used were of L.R grade. Antimony pentachloride solution (sp. gr. 2.30) was diluted with 4 M hydrochloric acid to obtain solutions of the required concentration. All other reagents were of analytical grade.

Preparation

The iron(III) compounds have been synthesized under similar conditions to facilitate comparison (Table 1). The reagents given in column 2 were mixed in the volume ratios given in column 3. The pH of the reaction mixture was adjusted by adding an alkali or acid solution. Iron(III) hydroxide was prepared by adding ammonia solution to aqueous 0.10 M ferric nitrate. The gelatinous precipitates obtained were washed by decantation, filtered off, washed again with distilled water and then dried at 40°C. Aging always affects the properties of this type of inorganic ion-exchanger.[10] Therefore, all the precipitates were kept for 24 h with the reaction mixture at room temperature. The dried product was immersed in 0.1 M nitric acid to remove the foreign ions adsorbed during the preparation. Finally, the exchangers were washed with demineralized water to remove the excess acid, and dried again at 40°C.

Analytical procedures

A 0.20-g portion of the exchanger was dissolved in concentrated hydrochloric acid. Iron(III) was estimated as oxide, phosphate by the phospho-molybdate method, molybdate by the quinolinol

method, selenium by reducing it to the element, tungstate by the dithiol method, and arsenate and antimony by titrimetric methods.

To determine the solubility of the iron(III) compounds, 0.20 g of the exchanger was shaken for 24 h with 20 cm^3 of the solution concerned. The undissolved exchanger was filtered off and in the filtrate iron was determined spectrophotometrically by the 1,10-phenanthroline method. Phosphorus, molybdenum, tungsten, antimony and selenite were also determined spectrophotometrically. All the cations used for distribution studies were determined using EDTA.

RESULTS

Various properties of iron(III) compounds are given in Table 1. All these compounds remain as stable gels in water. The gels crack on immersion in water, with slight evolution of heat.

Ion-exchange capacity

The ion-exchange capacity of various iron(III)-based ion-exchangers was determined by column operation: 1 g of the exchanger in the H^+-form was loaded in a glass column with a glass wool support and washed with a 1.0 M sodium nitrate solution; 400 cm^3 of effluent was collected in each case, at the rate of 5–10 drops min^{-1}. The liberated hydrogen ions were titrated against standard alkali solution.

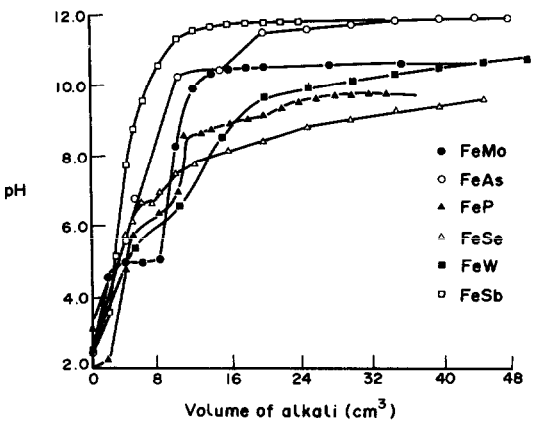

Fig. 1. pH titrations of different iron(III)-based ion-exchangers.

The ion-exchange capacity of different materials dried at various temperatures was also determined (Table 1).

pH titrations

The pH titrations with 0.1 N sodium hydroxide solutions were performed by the added-salt method: 0.2 g of the exchanger was kept in contact with varying volumes of the base and the salt solutions for about 24 h (Fig. 1).

Density measurements

The density (d) of the dry ion-exchanger has been calculated from the following formula[11] on the basis

of the measured data:

$$d = \frac{mS}{(M-M')+m},$$

where m is the weight of the exchanger, M is the weight of the pyknometer filled with water, M' is the weight of the pyknometer containing the ion-exchanger and water, and S is the density of water at the temperature of the measurements (25°C). The results of density measurements are given in Table 1.

Spectroscopic studies

The diffuse electronic spectra of the iron(III)-based ion-exchangers were recorded in the range 200–600 nm using magnesium oxide as the standard reflector.

The IR spectra of the ion-exchangers in the range 4000–200 cm^{-1} were recorded on a SP3-300 Pye-Unicam spectrophotometer using potassium bromide pellets.

Mössbauer spectra of the ion-exchangers were recorded at room temperature (25 ± 1°C) using a Mössbauer spectrometer MBS-35 (ECIL, India) having a multichannel analyser (480 channels, MCA-38B type using ^{57}Co source at constant acceleration). Sodium nitroprusside was used as the reference and the values of isomer shift have been quoted with respect to it. The results are given in Table 2.

X-ray photographs of the powder samples were taken using a Debye–Scherrer camera of radius 57.3 mm. A thick paste of the sample with "Quick-Fix" was shaped in the form of a thin solid rod of about 0.3 mm diameter and about 1 cm in length. It was mounted on the axis of the camera and the incident beam of X-rays was directed at right angles to this axis. The X-rays were produced from a Phillips generator of the type PW-1720. Cu-K_α radiation was used for taking the photographs.

Absorption studies

The K_d values for inorganic ions have been determined for the phosphate, molybdate, tungstate and selenite of iron(III) in demineralized water. The loading of cations for the system was less than 3% of the experimental ion-exchange capacity. The equation used was:

$$K_d = \frac{I-F}{F} \times \frac{20}{0.2} \text{ cm}^3 \text{ g}^{-1},$$

where I is the volume of 0.025 M EDTA needed to titrate the original cation solution, and F is the volume of 0.025 M EDTA needed for titration after equilibrium. The total volume of the equilibrating solution was 20 cm^3 and the amount of exchanger taken was 0.20 g. The results are given in Fig. 2.

DISCUSSION

All the six salts of iron(III) reported here were first prepared under varying conditions. The conditions of preparation finally chosen were those which appeared to give reproducible and fairly stable products. These conditions were adhered to in all preparations to facilitate comparison. The results for the chemical compositions of the phosphate, arsenate, antimonate, molybdate, tungstate and selenite are given in Table 1. Iron(III) arsenate, antimonate and tungstate have almost the same ion-exchange capacity but their chemical composition is quite different. Iron(III) molybdate has the highest ion-exchange capacity, which may be attributed to the hydrolysis of the exchanger in an aqueous system. Iron(III) selenite has the lowest ion-exchange capacity. The values of the ion-exchange capacity and chemical composition of all the iron(III) exchangers given in Table 1 are almost similar to those reported earlier.[5–9]

A comparison of the chemical stabilities of iron(III)-based ion-exchangers is presented in Fig.

Table 2. Isomer shifts and quadrupole splitting of various iron(III) compounds[a]

Compound	Drying temperature	Isomer shift (mm s^{-1})	Quadrupole splitting (mm s^{-1})
Iron(III) molybdate	RT[b]	0.68	0.48
Iron(III) selenite	RT	0.60	0.44
Iron(III) phosphate	RT	0.70	0.44
Iron(III) antimonate	RT	0.66	0.44
Iron(III) arsenate	RT	0.59	0.19

[a]The uncertainty in measurement is ±0.03 mm s^{-1}.
[b]Room temperature.

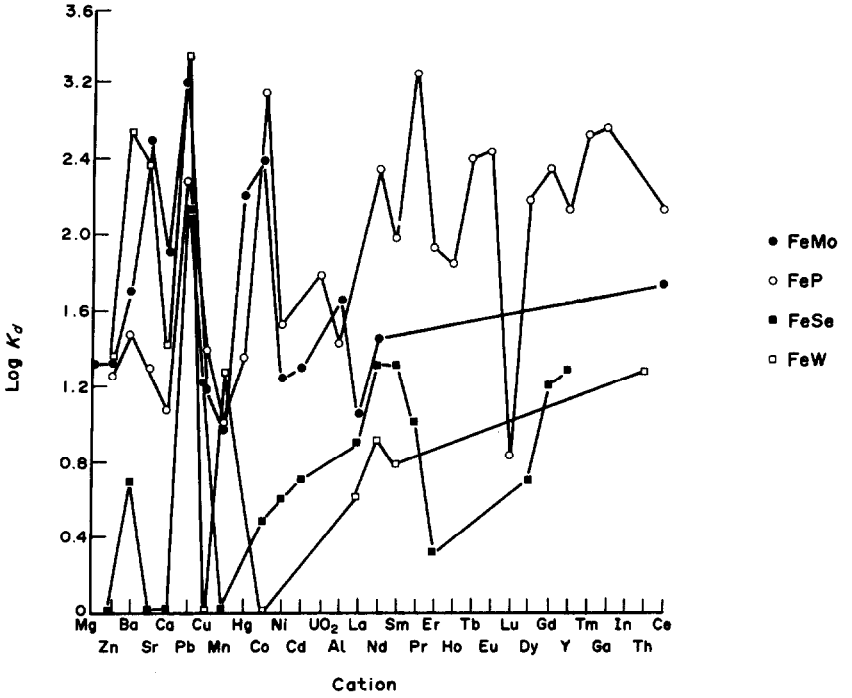

Fig. 2. Log K_d as function of metal ion.

2. Figure 3 gives an idea of the chemical stability of the materials. It is found that iron(III) tungstate is the most stable chemically in the lower-pH range while iron(III) selenite is the most stable in a neutral medium.

From Fig. 1, it can be seen that the exchange of sodium ions begins at acidic pH values and continues at the alkaline pH values. With iron(III) antimonate, no exchange of sodium ions takes place in acidic media, but it does at alkaline pH values.

The IR absorption bands observed for all six compounds are found to be identical. The materials show their characteristic bands in the range 350–700 cm^{-1}, in addition to the usual bands for interstitial water and the OH stretch. On increasing the drying temperature, the bands for water and the OH groups disappear, and this pattern is followed by all the exchangers discussed in the paper.

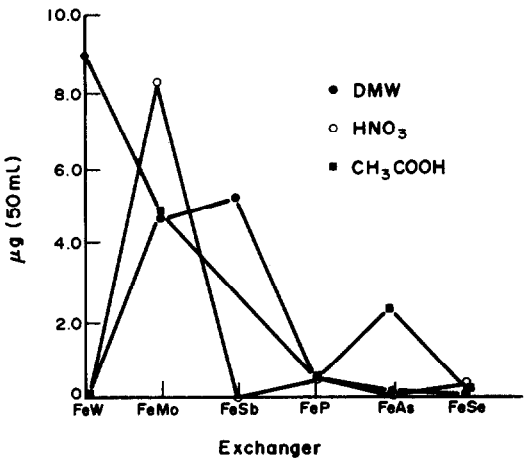

Fig. 3. Solubility as function of ion-exchanger.

The purpose of the present Mössbauer investigation of the amorphous substances of iron(III)-based ion-exchangers was to elucidate the bonding character between the iron and the anionic group in the material as shown in an earlier paper.[12]

The Mössbauer spectra of all the iron(III) compounds consist of a doublet at room temperature (25±2°C) (Table 2). The isomer shift values (0.59–0.70 mm s^{-1}) indicate that these compounds are high-spin with oxidation state +3. The quadrupole-splitting values show their distortion from the cubic symmetry around the iron nucleus. The peaks are broad (being 2–3 times the natural line width of the source), indicating more than one type of octahedral site. From Mössbauer data, it is concluded that iron atoms are surrounded predominantly by oxygen atoms. Therefore, relatively similar values of isomer shifts were observed for all the compounds.

X-ray powder photographs show that all the six compounds in hydrogen dried at 40°C are amorphous.

The Fe:Sb ratio by chemical analysis is 1:2.98. On heating, the oxides are produced, which should

Table 3. Possible separation on iron(III) compounds

Compound	Possible separations

Table 4. Separation factors of some important pairs of cations on iron(III)-based ion-exchangers

Separation factor	Iron(III) molybdate	Iron(III) selenite	Iron(III) antimonate	Iron(III) tungstate	Iron(III) phosphate
α_{Pb}^{Sn}	30.4	132	8.2	38.2	10.5
α_{Pb}^{Ba}	13.0	26.4	2.0	2.5	6.3
α_{Pb}^{La}	56.6	16.5	0.0	220	—
α_{Pb}^{Cu}	42.2	7.7	0.0	879	7.8
α_{Pb}^{Ni}	36.9	33	1.2	—	5.7
α_{Sr}^{Hg}	15.3	—	1.4	—	—
α_{Sr}^{Cd}	15.8	5	0.6	—	—
α_{Sr}^{Mn}	33.6	0	2.9	12.7	1.9

be in the same mole ratio. Allowing for experimental error, this may be rounded off to a 1:3 ratio. Therefore, the empirical formula weight for $Fe_2O_3 \cdot 3Sb_2O_5$ is approximately 1130. The total weight loss on heating is 12.5%, so, if n is the number of mol of water per mol of "mixed oxide", then $1800n/(1130+18n) = 12.5$, and $n = 8.97$. Again, allowing for error in the TG work, we can write the formula as $Fe_2O_3 \cdot 3Sb_2O_5 \cdot 9H_2O$ (formula weight 1292). The cation exchange capacity on the basis of two protons per formula weight is $2000/1292 = 1.54$ meq g^{-1}. The Fe:W ratio by chemical analysis is 1:1, corresponding to a molecular formula of $Fe_2O_3(H_2WO_4)_2 \cdot 2H_2O$, and the Fe:As ratio by chemical analysis is found to be 2:5, corresponding to a molecular formula of $Fe_2O_3 \cdot 2.5As_2O_3 \cdot 5H_2O$. The structure of iron(III) phosphate, iron(III) molybdate and iron(III) selenite are similar, as reported earlier.[5,9]

A comparison of the K_d values of metal ions on these exchangers in demineralized water shows some outstanding features (Fig. 2). Thus, the antimonate has the highest ion uptake of the six exchange materials studied. This may be due to the fact that amorphous antimony oxide has the largest number of free exchange sites available for the metal ions to be adsorbed. The lanthanides have the lowest K_d values for iron(III) tungstate, their highest K_d values being for iron(III) antimonate as expected. In the case of the tungstate the highest K_d value is for Pb^{2+}, which shows high K_d values on almost all the exchangers. In the case of the phosphate, Th^{4+} is totally adsorbed. This is a characteristic feature of iron(III) phosphate because all the other exchangers have a very low affinity for Th^{4+}. Some possible separations on the basis of K_d values for iron(III) exchangers are given in Table 3. The arsenate and tungstate of iron(III) are useful for the separation of alkaline earth metal ions. The corresponding phosphate and antimonate are useful for the separation of thorium from other cations. The difficult separation of Ga^{3+} and Al^{3+} is possible on arsenate and antimonate columns. Separation factors of some important pairs of cations on these exchangers, given in Table 4, also prove the utility of these materials. Therefore, the insoluble iron(III) compounds may be used to achieve separation. Their chief advantage is that they are inexpensive and are easy to prepare.

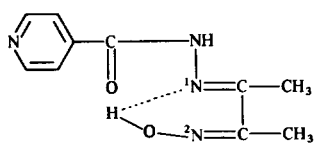
(*Received* 17 *December* 1985; *accepted after revision* 28 *May* 1986)



Abstract—The synthesis and characterization of Co(II), Ni(II), Cu(II), Zn(II), Cd(II) and UO_2^{2+} complexes of biacetylmonoxime isonicotinoylhydrazone (BMINH) are reported. Elemental-analysis, magnetic, thermal and spectral (IR, visible and NMR) measurements have been used to characterize the complexes. IR spectral data show that the ligand behaves in a bidentate and/or tridentate manner. An octahedral structure is proposed for the Ni(II) complexes, while a square-planar structure is proposed for both Co(II) and Cu(II) complexes, on the basis of magnetic and spectral measurements.

We reported earlier[1–3] on complexes of both aliphatic and aromatic hydrazone–oximes, but no work has been traced concerning a hydrazone–oxime containing a heterocyclic moiety. In this paper we report the preparation and characterization of some new metal complexes derived from biacetylmonoxime isonicotinoylhydrazone (BMINH), with dipositive transition metal ions. All the observations and data confirm that the behaviour of BMINH is quite different from those reported earlier.[1–3] In addition, the investigation of BMINH as a type of hydrazone–oxime-containing heterocyclic moiety as well as the importance of the isonicotonic acid residue for the treatment of tuberculosis provided an impetus for this study.

RESULTS AND DISCUSSION

The solid complexes isolated are quite stable in air and insoluble in common organic solvents, but easily soluble in dimethylformamide (DMF) and dimethylsulphoxide. The molar conductivities in DMF at 25°C are in the range indicating[4] a non-electrolytic nature for all complexes except the $[Ni(BMINH)(H_2O)_2(C_2H_5OH)]Cl_2$ and $[Mn(BMINH)(H_2O)_2]Cl_2$ complexes, which have high values which suggest that they are 1:2 electrolytes.

The most characteristic features of the IR spectrum of BMINH have been determined by a careful comparison of the spectrum of BMINH with both isonicotinic acid hydrazide and biacetylmonoxime. The spectrum of BMINH, in Nujol, shows three bands at 1675, 1635 and 1575 cm^{-1} assigned to $\nu(CO)$, $\nu(CN^1)$ and $\nu(CN^2)$, respectively. The strong band observed at 940 cm^{-1} in the spectrum of the ligand, which is absent in the spectrum of isonicotinic acid hydrazide is mainly attributed to the $\nu(NO)$ vibration. In addition, the two bands at 3320 and 3170 cm^{-1} in the spectrum of the ligand are assigned to the oxime NOH and NH groups, respectively. The presence of $\nu(OH)$ as a shoulder at a low wavenumber suggests intramolecular hydrogen bonding. The broad but weak bands in the 1910–2000- and 2200–2400-cm^{-1} regions can be taken as additional evidence for the presence of intramolecular hydrogen bonding (O—H . . N)[5] as shown below:

*Author to whom correspondence should be addressed.

The NMR spectrum of BMINH in d_6-DMSO shows two signals at δ 11.0 and 10.4 ppm (i.e. downfield from TMS), which disappear upon adding D_2O. These two signals are therefore assigned to *anti*- and *syn*-oxime NOH protons, respectively. The *syn*:*anti* ratio was found to be 1:1, indicating that the percentages of free and hydrogen-bonded OH are identical. Additionally, a signal at δ 8.25 ppm is assigned to the NH proton, and this also disappeared upon adding D_2O.

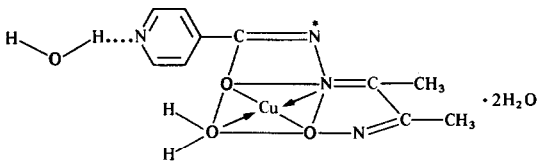
The IR spectra of the complexes [Cu(BMINH)Br_2]$2H_2O$ and [Mn(BMINH)$(H_2O)_2$]Cl_2 show that the ligand behaves as bidentate coordinating via the azomethine nitrogen (CN^1) and the carbonyl oxygen (CO) in the keto form, forming a five-membered ring around the metal ion. The mode of complexation is suggested by the negative shift of both ν(CO) and $\nu(CN^1)$ vibrations to a lower wavenumber as well as the positive shift of ν(N—N). The new bands observed at *ca* 470 and *ca* 410 cm^{-1} are assigned to ν(M—O)[6] and ν(M—N),[7] respectively.

In addition, the ligand acts as a bidentate in the complexes [Cd(BMINH)Cl_2]$2H_2O$ and [Cu(BMINH)Cl_2]C_2H_5OH, coordinating via the azomethine nitrogen of both the hydrazone (CN^1) and the oxime (CN^2) groups. The bonding sites are assigned on the basis of the following evidence: the negative shift of the CN^1 band to a lower wavenumber as well as the positive shift of the band due to CN^2; the CO band remains unaffected as observed in the IR spectrum of the free ligand; a new band is observed at *ca* 405 cm^{-1}, which is assigned to ν(M—N);[7] and the NMR spectrum of the [Cd(BMINH)Cl_2]$2H_2O$ complex shows signals due to the protons of the NOH and NH groups.

Moreover, the ligand coordinates in a bidentate manner via the azomethine nitrogen (CN^1) and the enolized carbonyl oxygen with the displacement of a hydrogen atom from the latter group. This behaviour is found in the [Co(BMINH–H)Ac]$4H_2O$ complex. This mode of complexation is supported by the following observations: the disappearance of ν(CO) with the simultaneous appearance of new bands at 1170 and 1620 cm^{-1}, assignable to ν(C—O)[8] and ν(C=N*), respectively; and the negative shift of $\nu(CN^1)$ together with the positive shift of ν(N—N). The new bands observed at *ca* 470 and *ca* 380 cm^{-1} are assigned to ν(M—O)[6] and ν(M—N),[7] respectively. The observation of two bands at 1590 and 1440 cm^{-1} attributable to ν_{as} and ν_s of the acetate group as well as the great difference (150 cm^{-1}) between those two bands indicates a bidentate nature for the acetate group.

The existence of water of hydration for [Co(BMINH–H)Ac]$4H_2O$ was confirmed by thermal analysis. The thermal-analysis results show that the mass loss up to 225°C corresponds to the removal of four water molecules. This indicates that the four water molecules are identical and exist in the outer coordination sphere.

On the other hand, the ligand may act in a tridentate way, coordinating via the azomethine nitrogen of both the hydrazone (CN^1), and the oxime (CN^2), and the carbonyl oxygen in the keto form. This behaviour is found in the case of the [Ni(BMINH)$(H_2O)_2(C_2H_5OH)$]Cl_2 complex. This mode of coordination is supported by the negative shifts of the CO group and the azomethine nitrogen of both the hydrazone (CN^1) and the oxime (CN^2) groups. The bands in the low-frequency region at *ca* 480 and *ca* 375 cm^{-1} are assigned to ν(M—O)[6] and ν(M—N)[7] vibrations, respectively.



In addition, the ligand may behave in a tridentate way, coordinating via the azomethine nitrogen of the hydrazone (CN^1), the CO and the deprotonated NOH groups. This behaviour is found in [UO_2(BMINH–H)$_2$], [Cd(BMINH–H)$_2$] and [Zn(BMINH–H)Br]H_2O complexes. The mode of chelation is supported by the following evidence: the negative shifts of both the CO and the azomethine (CN^1) vibration bands to lower wavenumbers; the disappearance of ν(OH) together with the positive shift of ν(NO) to higher wavenumbers; the appearance of new bands in the 450–470- and 430–370-cm^{-1} regions, assignable to ν(M—O)[6] and ν(M—N),[7] respectively; and the disappearance of the signals due to the proton of the oxime group in the NMR spectra of those complexes.

The uranyl complex exhibits three bands at 930, 480 and 265 cm^{-1}, assigned to ν_3-, ν_1- and ν_4-vibrations, respectively, of the dioxouranium ion.[9] The force constant (F) for bonding sites of the U=O vibration is calculated by the method of McGlynn *et al.*[10] and the value (F_{UO}) is found to be 7.139 mdynes $Å^{-1}$.

The ligand may also behave in a tridentate way, coordinating via the azomethine nitrogen (CN^1), the oxime oxygen (NOH) and the carbonyl oxygen in the enol form (=C—OH), with displacement of two hydrogen atoms from the latter two groups. This behaviour is observed in the [Cu(BMINH–2H)$(H_2O)_2$]$2H_2O$ and [Ni(BMINH–2H)·$(H_2O)_2(C_2H_5OH)$] complexes. The mode of complexation is supported by the following evidence: the disappearance of the bands at 3320 and 1675 cm^{-1} attributable to ν(OH) and ν(CO) vibrations, respectively, with the simultaneous appearance of new bands at *ca* 1240 and

1645 cm^{-1}, assigned to ν(C—O)[8] and ν(C=N*), respectively; the negative shift of $\nu(CN^1)$ to a lower wavenumber and the positive shift of ν(NO) to a higher wavenumber; and the appearance of new bands in the low-frequency region at 440–420 and 395–375cm^{-1}, assigned to ν(M—O)[6] and ν(M—N),[7] respectively.

The presence of water molecules in the $[Cu(BMINH–2H)(H_2O)_2]2H_2O$ complex was confirmed by thermal analysis. The results show that there are three types of water molecules. Firstly, the mass loss up to 214°C corresponds to the removal of two loosely bound water molecules. Secondly, the mass loss up to 308°C corresponds to the removal of another water molecule. This water molecule may be hydrogen bonded to the pyridine nitrogen as shown in structure **I**. Thirdly, the mass loss up to 328°C corresponds to the removal of a water molecule of coordination.

I

The magnetic moments and electronic spectra of the complexes are listed in Table 1. The electronic spectra (Nujol) of the Ni(II) complexes, $[Ni(BMINH)(H_2O)_2(C_2H_5OH)]Cl_2$ and $[Ni(BMINH–2H)(H_2O)_2(C_2H_5OH)]$, show two bands in the 14,080–15,670- and 25,640–25,120-cm^{-1} regions, assignable to $^3A_{2g} \rightarrow {}^3T_{1g}(F)$ and $^3A_{2g} \rightarrow {}^3T_{1g}(P)$ transitions,[11] respectively. The calculated values of Dq, B, β and ν_2/ν_1 (Table 2) lie in the same range as reported for the octahedrally coordinated Ni(II) ion.[12] The position of ν_1 is calculated theoretically.[12] The values of the magnetic moment (3.15–2.96 BM) are additional evidence for an octahedral structure. The magnetic-moment value (2.37 BM) for $[Co(BMINH–H)Ac]4H_2O$ falls in the range reported for a square-planar structure. The presence of a characteristic band at *ca* 19,200 cm^{-1} further supports the square-planar configuration.[13] The electronic spectra of the complexes $[Cu(BMINH–2H)(H_2O)_2]2H_2O$, $[Cu(BMINH)Cl_2]C_2H_5OH$ and $[Cu(BMINH)Br_2]2H_2O$ show broad bands with maxima in the 14,800–13,700-cm^{-1} range, due to the $^2B_{1g} \rightarrow {}^2A_{1g}$ transition, and a shoulder in the 22,400–22,600-cm^{-1} range, in a square-planar configuration.[14] The band in the 25,900–25,600-cm^{-1} range may be due to a charge transfer, probably, d–π^*.[15] In addition, the magnetic-moment values (2.15–2.05 BM) can be taken as additional evidence of the square-planar configuration.[16] The low value of the magnetic moment (1.57 BM) for the complex $[Cu(BMINH–2H)(H_2O)_2]2H_2O$ may be explained on the basis of the existence of a polymeric structure including copper–copper interaction.

EXPERIMENTAL

All the chemicals were of analytical grade (BDH) and used as supplied. The ligand (BMINH) was prepared as reported earlier.[2] The metal complexes with the general formula $M(BMINH)X_2 \cdot nY$ [M = Ni(II), Cu(II), Cd(II) or Mn(II); X = Br or Cl; Y = H_2O or C_2H_5OH; and n = 0–2] were prepared by refluxing equimolar amounts of BMINH and hydrated metal salts in absolute ethanol for 0.5–1 h, whereas the complexes $[Zn(BMINH–H)Br]H_2O$ and $[Ni(BMINH–2H)(H_2O)_2(C_2H_5OH)]$ were prepared by the same method but in the presence of sodium acetate as a buffering agent. The complexes with the formulae $[Cd(BMINH–H)_2]$, $[Co(BMINH–H)Ac]4H_2O$, $[Cu(BMINH–2H)(H_2O)_2]2H_2O$ and $[UO_2(BMINH–H)_2]$ were prepared using the metal acetate or sulphate in doubly distilled water, except for the uranyl complex which was prepared in absolute ethanol.

Table 1. Spectral and magnetic data of BMINH complexes

Compound	Magnetic moment (μ_{eff}) (BM)	Electronic spectra ($cm^{-1} \times 10^3$); ligand field bands
$[Ni(BMINH)(H_2O)_2(C_2H_5OH)]Cl_2$	3.15	14.08, 25.64; Dq = 843, B = 963, β = 0.920, ν_2/ν_1 = 1.67
$[Ni(BMINH–2H)(H_2O)_2(C_2H_5OH)]$	2.96	15.67, 25.12; Dq = 990, B = 740, β = 0.71, ν_2/ν_1 = 1.58
$[Co(BMINH–H)Ac]4H_2O$	2.37	19.2
$[Cu(BMINH)Cl_2]C_2H_5OH$	2.05	13.7, 22.4 (sh), 25.9 (CT)
$[Cu(BMINH)Br_2]2H_2O$	2.15	14.8, 22.4 (sh), 25.6 (CT)
$[Cu(BMINH–2H)(H_2O)_2]2H_2O$	1.57	14.7, 22.6 (sh), 25.9 (CT)

The products were filtered off and washed with ethanol and diethyl ether, and finally dried in a vacuum desiccator over anhydrous calcium chloride. The results of elemental analysis together with some physical properties are listed in Table 2.

The analyses for the metals and halide were carried out by the standard method.[17] Carbon and hydrogen contents were performed by the Microanalytical Unit at Mansoura University. Magnetic moments were obtained at room temperature (25°C) by Gouy balance using $Hg[Co(SCN)_4]$ as a calibrating agent at Alexandria University. IR spectra were recorded on an SP 2000 IR spectrophotometer as Nujol mulls between CsI plates. Electronic spectra were recorded on an SP 1800 spectrophotometer. Molar conductivities in DMF at room temperature were measured using a Tacussel conductivity bridge type CD6NG. Proton magnetic resonance spectra were carried out on a Varian EM 360 (60-MHz) spectrophotometer. Thermal-analysis measurements were carried out with a thermoanalyser GDTD 16 (Setaram, Lyon, France) at Mansoura University.

^{11}B-^{11}B COSY NMR STUDIES OF DERIVATIVES OF THE OCTAHYDROTRIBORATE ANION, $[B_3H_7(X)]^-$ AND $[B_3H_6(X)_2]^-$

(*Received* 30 *January* 1986; *accepted* 28 *May* 1986)

Abstract—2-D ^{11}B–^{11}B correlation (COSY) spectra have been obtained on the series of monosubstituted and disubstituted octahydrotriborate anions, $[B_3H_7(X)]^-$ (X = Cl, NCS, NCSe, $NCBH_3$, $NCBH_2Cl$, $NCBPh_3$, $NCBH_2CN$, NCB_3H_7 or CNB_3H_6Cl) and $[B_3H_6(Cl)(X)]^-$ (X = Cl, NCS, $NCBH_2Cl$ or NCB_3H_7). All monosubstituted derivatives and $[B_3H_6(Cl)_2]^-$ showed a coupling correlation between the substituted and unsubstituted borons. The unsymmetrically disubstituted derivatives showed only one coupling correlation, between the borons carrying the substituents. The absence of other correlations is attributed to relaxation phenomena. The correlations are independent of the solid-state structural type.

The use of 2-D boron–boron correlation NMR spectroscopy (^{11}B–^{11}B COSY) as a probe in the study of boron hydride derivatives is now well established, and has been shown to give valuable information relating to boron atom connectivities.[1–4] Most of the published work has concentrated on polyhedral systems and it was found that generally only boron atoms which were directly bonded (by two-centre–two electron bonds) displayed couplings, whereas borons linked by bridging hydrogens usually showed no evidence for coupling. Only two compounds, 1,2,3-$[C_6Me_6]FeEt_2C_2B_3H_5$ and 2-$(C_5H_5)CoB_4H_8$, have shown evidence for coupling between borons linked by bridging hydrogens.[2]

In earlier work we prepared[5–7] a series of derivatives of the octahydrotriborate anion, of general types $[B_3H_7X]^-$ and $[B_3H_6X_2]^-$, in which several structural types were observed (Fig. 1).[8–11]

Evidence of ^{11}B–^{11}B couplings was only occasionally found in the previous 1-D ^{11}B NMR studies of these and related systems; in compounds in which the coupling could be observed, the coupling constants were found to be of the order of 8–20 Hz.[12] However, for most of the compounds, the quadrupolar relaxation mechanism resulted in broad lines without resolution of the ^{11}B–^{11}B couplings; indeed in many cases even the larger ^{11}B–^{1}H couplings of *ca* 35 Hz were only detectable after resolution enhancement techniques were applied to the free-induction decay signals prior to Fourier transformation.[12,13]

It was therefore apparent that this series of compounds, examined by the ^{11}B–^{11}B COSY technique, offered a unique opportunity to study the relationship of observation of ^{11}B–^{11}B coupling to the structural and bonding parameters in the triborate cage. In this work we have extended these NMR studies to include the results of ^{11}B–^{11}B COSY NMR spectra, and now compare the data with observed structures.

EXPERIMENTAL

115.55-MHz ^{11}B NMR spectra were recorded in $CDCl_3$ solutions using a Bruker WH 360 NMR spectrometer fitted with an Aspect 2000 computer. Homonuclear correlation spectra were obtained using the COSY-90 $D1$-90°-t_1-90°-AQ sequence,[14] where $D1$ is the recycling delay to allow complete relaxation (usually 0.1 s is adequate) and t_1 is the interpulse delay. The increment Δt_1, by which t_1 is successively increased during the COSY experiment, is controlled by the dwell time, and hence by the spectrum width. Broad-band decoupling was applied during runs.

Typically 128 FIDs were acquired with 512 words of data for each. Acquisition times ranging from 0.013 to 0.036 s were used. After Fourier transformation the spectra comprised a 256 × 256-word $F1 \times F2$ matrix. The COSY spectra are presented as contour maps. The contour levels were selected by examination of both the $F1$ and $F2$ projections, and setting the lowest contour threshold just above the average noise level. All COSY spectra were symmetrized.

The compounds, prepared as previously described,[5-7] were obtained as $[N(PPh_3)_2]^+$ salts of the $[B_3H_7(Cl)]^-$, $[B_3H_7(NCS)]^-$, $[B_3H_7(NCSe)]^-$, $[B_3H_7(NC)BH_3]^-$, $[B_3H_7(NC)BPh_3]^-$, $[B_3H_7(NC)BH_2(CN)]^-$, $[B_3H_7(NC)B_3H_7]^-$, $[B_3H_6(Cl)_2]^-$, $[B_3H_6(Cl)(NCS)]^-$ and $[B_3H_6(Cl)(NC)B_3H_7]^-$ anions.

RESULTS AND DISCUSSION

The recent advent of ^{11}B–^{11}B COSY as a viable technique in the study of boranes and their derivatives[1-4] has meant that it is now possible in many cases to study interactions between boron nuclei in the solution phase. Previously such interactions were rarely examinable by solution methods such as NMR, and any information was derived from solid-state studies such as X-ray crystallography. Clearly the possibility of carrying out such studies in both phases should provide an important insight into the nature of these materials. Since several structural types of compound had been established in the solid state by X-ray crystallography, it was of interest to determine whether the COSY spectra would distinguish these in solution, or whether fluxional character and quadrupolar relaxation effects would predominate and make solution characterization of structural type unfeasible. Previous 1-D NMR studies had yielded values of ^{11}B–^{11}B coupling constants for a few of the compounds in deuteroacetonitrile solution, but studies in deuterochloroform in general resulted in an increased efficiency of quadrupolar relaxation and hence a failure to resolve this coupling. Because many of the anionic triborane derivatives undergo reactions such as ligand–solvent exchange in acetonitrile solutions, the ability to derive coupling information from chloroform solutions would also be valuable. Homonuclear correlation spectroscopy provides a means by which such information may be derived.

The compounds which have been studied are listed in Tables 1 and 2, which also indicate the solid-state structure adopted by those compounds which have been examined crystallographically.

All the monosubstituted triborane derivatives have ^{11}B NMR spectra which comprise two signals of relative intensities 2:1, and correlations between these occur in all cases. A typical spectrum is given in Fig. 2 for the $[B_3H_7(NC)B_3H_7]^-$ anion, in which the two triborane units each give correlations, and are independent of each other. Since correlations are observed regardless of the solid-state structure, it is apparent that significant electron density exists between all three boron atoms, possibly as a result of the fluxional character.

In the disubstituted triboranes, the symmetrical $[B_3H_6(Cl)_2]^-$ anion showed a COSY correlation between the resonances of the unsubstituted boron (of intensity 1) and the two borons carrying substituents (of relative intensity 2) (Fig. 3). Each of

the unsymmetrical disubstituted anions exhibited ^{11}B spectra which comprised three resonances of relative intensity 1:1:1. [See, for example, the spectrum of $[B_3H_6(Cl)NCS]^-$ in Fig. 4.] However, the COSY spectra revealed only one correlation; this occurs between the low-frequency resonance (which is assigned to the *N*-coordinated boron) and the sharper of the two high-frequency resonances.

The broad high-frequency resonance which occurred near δ 4.1 in all the compounds was earlier[6] assigned to the chlorine-substituted boron atom. However, it appears probable that it should rather be assigned to the unsubstituted boron since its shift varied very little over all the compounds. The fact that only one correlation is observed may at first sight be interpreted as evidence for a direct B—B bond between the substituted atoms, except for the fact that coupling is observed between the unsubstituted boron and those carrying chlorine substituents in $[B_3H_6Cl_2]^-$. The apparent absence of coupling with the broad boron resonance is the unsymmetric derivatives may be a result of the experimental COSY conditions, and in particular on the magnitude of the incremental time (Δt_1) by which the interpulse delay is successively increased. Δt_1 values, optimized between 2.5×10^{-4} and $5 \times$

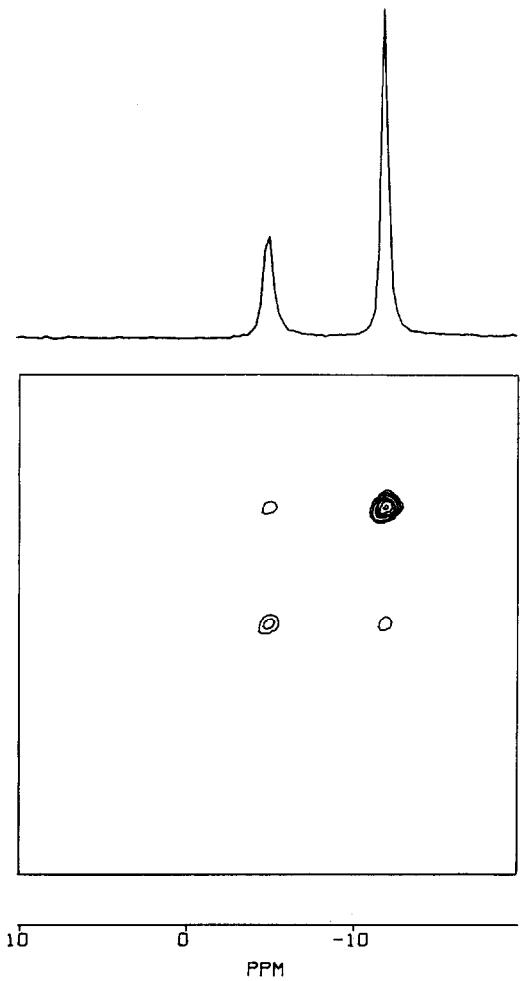

Fig. 3. 2-D COSY and 1-D ^{11}B–{^1H} spectra of $[B_3H_6(Cl)_2]^-$.

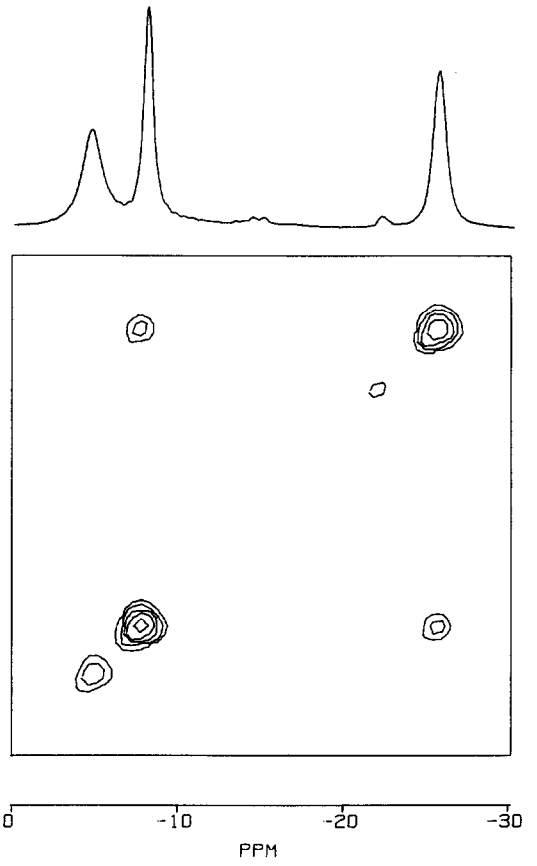

Fig. 4. 2-D COSY and 1-D ^{11}B–{^1H} spectra of $[B_3H_6(Cl)(NCS)]^-$.

10^{-5} s {for $[B_3H_7(NC)BPh_3]^-$} were found necessary in order to observe correlations with broad lines. It had been observed previously[3] that in the COSY spectra of the $[B_9H_{13}L]^-$ anions (L = NCS or NCSe) the high-frequency broad resonance of B(7) was not observed even along the diagonal. We have now reexamined the COSY spectra of $[B_9H_{13}(NCSe)]^-$ using a shorter value of Δt_1, and have now detected the resonance due to B(7) together with couplings from this signal. The COSY spectrum is now completely analogous to that of $B_9H_{13}(SMe_2)$.[3]

The COSY results for the triborane derivatives thus show that both mono- and disubstituted derivatives have significant *s*-electron density between all three boron atoms in the solution studies in which low-energy fluxional behaviour occurs. The failure to observe coupling with the broad resonance of the unsymmetrical disubstituted compounds is probably a result of fast relaxation resulting in broad, low-intensity signals, whose FIDs decay significantly in the time-scale of the pulse train. Effects of relaxations have been referred to previously by Grimes.[2]

The COSY spectra of the bridge-cyanide species $[B_3H_7(NC)B_3H_7]^-$ and $[B_3H_6(Cl)(NC)B_3H_7]^-$ also give unambiguous support for the structures and assignments of these compounds which were reported earlier on the basis of 1-D ^{11}B and ^{11}B–{^1H} measurements.[7]

PERTURBED γ–γ DIRECTIONAL CORRELATIONS AND THE COORDINATION CHEMISTRY OF Hf: NEW ASPECTS OF THE BEHAVIOUR OF Hf IN THE PRESENCE OF HIGH FLUORIDE CONCENTRATIONS

P. BODE,* M. DE BRUIN and R. W. HOLLANDER†

Interuniversity Reactor Institute and †Delft University of Technology,
Department of Applied Physics, Mekelweg 15, 2629JB Delft, The Netherlands

(*Received* 24 *March* 1986; *accepted* 7 *May* 1986)

Abstract—In solutions of Hf at high fluoride concentrations, the γ–γ directional correlation of ^{181}Hf remains almost unperturbed. This result differed strongly from earlier observations of a strong perturbation in such systems, explained as a consequence of the formation of Hf–F polymers. It was shown that in these investigations the role of the Na^+ ion had been overlooked, and that these strong perturbations are due to the formation of $Na_5Hf_2F_{13}$.

Information on the chemical and/or physical environment of decaying radionuclides can be obtained by measuring the directional correlation between γ-rays emitted in cascade.[1] In an investigation of the relation between the observed γ–γ directional correlation and the chemical form of radioactive atoms in aqueous solutions, PDC experiments were carried out with ^{181}Hf in the presence of fluoride.‡ It was reported earlier[3,4] that with increasing F^-/Hf atomic ratios, the directional correlation becomes strongly perturbed. This was explained as a result of the formation of Hf–F polymers, either present as a macromolecule in solution, or as a precipitate.

However, recent measurements of Hf and F in solution yielded results which differ strongly from the observations mentioned above. Even for very high F^-/Hf atomic ratios up to 120 we found that the directional correlation remains almost unperturbed (Fig. 1), and no precipitation was observed. Closer examination of the experimental procedures showed that the essential difference between the two series of experiments was the way the fluoride was applied to the Hf solution. In our recent experiments, fluoride was added as an HF solution, whereas de Bruin *et al.* used an NaF solution. This indicates that, in their investigations of the Hf–F system, the role of the Na^+ ion might have been overlooked.

Therefore we have carried out a study of the nature of the precipitate as described by de Bruin *et al.* It was prepared by adding NaF to a solution of $HfOCl_2 \cdot 8H_2O$ in 1 N $HClO_4$; the crystals were isolated by centrifugation and rinsed with ethanol. After reactor irradiation, the time-differential PDC spectrum was recorded (Fig. 2). The interaction is obviously caused by a static, randomly oriented field gradient. Fitting of the experimental data leads to values of $\omega_Q = 87.9 \pm 0.8 \times 10^6\ s^{-1}$ and $\eta = 0.41 \pm 0.02$. These values are in agreement with the values reported by Hollander[4] for a similar precipitate, also assumed to be a Hf polyfluoride: $\omega_Q = 100.3 \pm 0.9 \times 10^6\ s^{-1}$ and $\eta = 0.37 \pm 0.01$. Mayer *et al.*[5] found similar results for single crystals of $(NH_4)_2HfF_6$: $\omega_Q = 80.3 \times 10^6\ s^{-1}$ and $\eta = 0.43$.

The existence of Na_xHfF_y compounds in Hf–Na–F systems has been described by different authors.[6–8] The agreement between our TDPDC results and the values found by Mayer for a compound of the M_xHfF_y type strongly suggests that the precipitate is a Na_xHfF_y compound.

*Author to whom correspondence should be addressed.

‡The PDC spectrometer has been described elsewhere.[2]

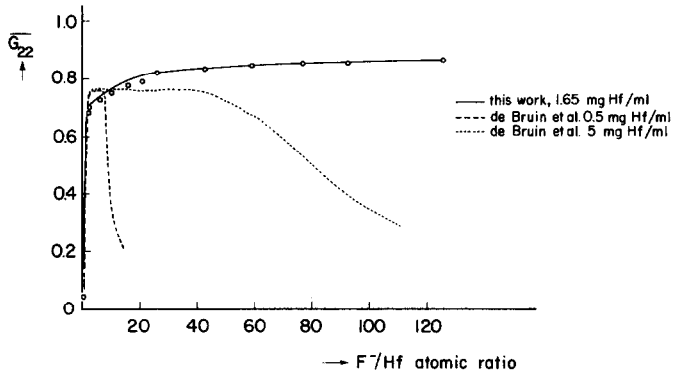

Fig. 1. Time-integral perturbation factor ($\overline{G_{22}}$) as function of the ratio of F^- to Hf atoms present in the source.

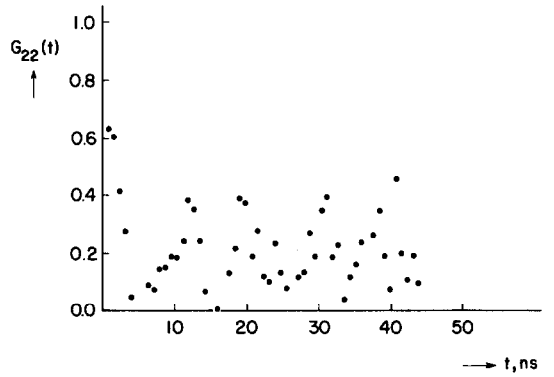

Fig. 2. Time-differential PDC spectrum of the precipitate.

Elemental analysis of the precipitate was carried out by instrumental neutron activation analysis. The major constituents were found to be Na (16.22%) and Hf (50.14%), corresponding to an Hf:Na atomic ratio of 2.5:1. In addition, the X-ray diffraction pattern was determined. From these data, the substance was identified as $Na_5Hf_2F_{13}$, which is in excellent agreement with the results from I.N.A.A.

The identification of the precipitate as $Na_5Hf_2F_{13}$ also explains the high-power relation between the inverse time constant of the change in the anisotropy after addition of F^- to the Hf solution, and the free fluoride concentration.[3,4] Under the experimental conditions used by these authors, $[F^-]$ almost equals $[Na^+]$, which makes $[F^-]$ proportional to $[Hf^{4+}]^{-9}$. The decrease in $[Hf^{4+}]$ due to precipitation of $Na_5Hf_2F_{13}$ is reflected by the anisotropy; the inverse time constant of the change in the anisotropy therefore corresponds to changes in the rate of decrease of $[Hf^{4+}]$, and is proportional to $[F^-]^9$.

CONCLUSIONS

The results from the work described in this paper strongly suggests that in the presence of fluoride ions no polymerization of Hf and F^- occurs at high F^-/Hf atomic ratios. Earlier reported suggestions of the existence of such an $(HfF_{x+1})_n$ polymer in Hf–F systems on the basis of results of directional correlation measurements can be associated with the formation of $Na_5Hf_2F_{13}$ due to the presence of Na^+ ions in the investigated systems.

Acknowledgement—We are indebted to Mr N. M. van der Pers of the Delft University of Technology, Department of Metallurgy, for carrying out the X-ray diffraction analysis.

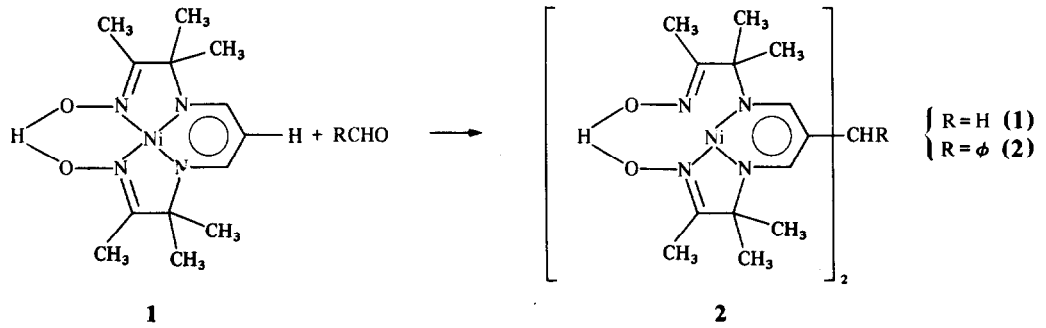
UNUSUAL REACTIVITY OF A QUASI-AROMATIC Ni(II),2N,3C HETEROCYCLE

R. KENT MURMANN,* ELMER O. SCHLEMPER and MICHAEL S. TEMPESTA

Department of Chemistry, University of Missouri—Columbia, MO 65211, U.S.A.

(*Received* 27 *September* 1985; *accepted after revision* 20 *January* 1986)

Abstract—[Ni(PnAO)-6H]°, a Ni,2N,3C-pseudoaromatic heterocycle is shown to be highly reactive at the central carbon atom toward most aldehydes and ketones, giving with CH_2O, for example, a dimer having the formula [Ni(PnAO)-7H]$_2$-CH_2 whose X-ray crystal structure as well as ^{13}C and ^1H NMR spectra are presented.



We recently reported[1] the X-ray crystal structure of [Ni(PnAO)-6H]° (**1**),† an "aromatic" Ni(II),2N,3C heterocycle and two products of its acid hydrolysis. These studies led to uncovering its remarkable reactivity towards aldehydes which we report herein. "Aromatic" behavior in complexes has been studied since about 1965.[2] A symposium on "aromaticity, pseudoaromaticity and antiaromaticity" was held in 1970,[3] and reactions involving delocalized M,2N,3C complexes with O_2,[4] nitriles,[5] alkynes[6] and isocyanates[7] are known. The present discovery is likely to revitalize this area because the planar complex described is much more reactive than any previously seen, and a reaction with aldehydes has not previously been reported. This also relates to the facile P alkylation for Ni,2N,2P complexes[8] and to the acylation of similar ligands.[9] The "aromatic" nature of **1** is indicated by the short Ni–N bond distances, the C–N and C–C distances, and the ^{13}C and ^1H NMR spectral data (Table 1). These are consistent with strong π-orbital overlap between the six ring atoms resulting in the downfield chemical shifts observed in ^{13}C and ^1H NMR caused by ring current effects. Comparison of the NMR chemical shift of **1** (11-H, δ 7.04; 12-H, δ 5.07; C-11, δ 147.7; C-12, δ 93.3) with the analogous pyrimidine δ values[10] (4-H, δ 8.78; 5-H, δ 7.36; C-4, δ 156.4; C-5, δ 121.4) indicates that 12-H and C-12 are found considerably upfield, the direct result of a high electron density at C-12.

The nucleophilic C-12 position of the Ni,2N,3C aromatic ring of **1** has a similar reactivity to that of the indole[11] C-3 (3-H, δ 6.45; C-3, δ 102.1[10]) position, and to other related organic molecules. The planar Ni(II) complex is very stable to dissociation or ligand replacement even in 1–2 M acid and reactions take place preferentially on the electron-rich C-12 site. Initial indication of this came with the preparation of the C-12 —NO_2, —NO, and —Cl derivatives (**2–4**) under mild conditions.[12,13] Additional evidence came with the discovery of the self-reaction of **1** in acid media at slightly elevated temperatures and long reaction times to give a 3C-bridged conjugated dimer.[1] The subsequent demonstration that malondialdehyde was the reactant (produced by the hydrolysis of the parent complex **1**) suggested that less reactive aldehydes and ketones might also condense under mild, acidic conditions.

Our recent discovery that formaldehyde and benzaldehyde react with **1** within a few minutes at room temperature in *ca* 0.002 M HCl [CH_3CN–H_2O (1 : 4) as the solvent] to give a single (2 : 1) product points out the unusual reactivity and the chemical potential for this remarkable complex compound (Scheme 1). We have isolated and identified the

Scheme 1.

products of the reaction of **1** with CH_2O and ϕCHO and have shown the reaction to be analogous to that of aldehydes with indole.[11] The dimer is produced in a two-step reaction; under the conditions of preparation* the second reaction is very fast and no intermediate is found. The X-ray crystal structure† (Fig. 1) of product **5** shows the very planar nature of the mononuclear unit with a strong H-bond and aromatic type distances within the quasi-aromatic ring.‡ Except for the geminal methyls which are roughly mirrored across the planes, maximum deviations from least-squares planes thru the four coordinated nitrogen atoms are 0.060(7) and 0.139(6) Å for the atoms in each of the two subunits. The dihedral angle between those planes is 77° while the C12–C14–C12′ bond angle is 113.5(6)°. The twist as measured by the dihedral angles (89.1 and 86.5°) between the rings and the C12–C14–C12′ plane is minimal, indicative of a near mirror relationship of the monomers. The "aromatic" nature of the ring is reflected in the very short Ni–N distances [average 1.836(5) Å] which can be compared with the Ni–N(amine) distance of 1.937(5) Å in the unoxidized parent,[14] $[Ni(PnAO-H)]^+$, and with a comparable distance of 1.838(5) Å in the monomer.[1] The average C–N distance [1.313(6) Å] and the average C–C distance [1.397(14) Å] also reflect the aromatic nature of the very planar rings [maximum deviation 0.013(5) Å]. All other distances are normal including the short O—O hydrogen bonds between oxime hydrogens (2.398 Å).

Utilizing other reaction conditions we have determined that **1** is very reactive towards most aldehydes and ketones, to diazo reagents and to oxidized dimethylphenylenediamine. In some of the compounds we have prepared there is conjugation thru the bridge between the metal ion centers giving rise to intense charge-transfer bands in the visible region. These dye-like materials appear to be extremely stable both in solution and in the solid state. Some success has been obtained in replacing Ni(II) with other metal ions and further studies are now underway. Furthermore the unusual stability of this planar complex may allow the formation of styrene type polymers in which the stacked planar rings should give products with unique spectral and electronic properties. The oxidation–reduction properties of planar nickel complexes are of special interest in terms of their catalytic applications.[15] Of considerable significance is the expected facile conjugation thru C-12 of **1** to biologically interesting molecules.

* Preparation of **5** is accomplished by dissolving 80 mg of **1** in 5.0 cm^3 of CH_3CN and adding two drops (0.10 cm^3) of 1.0 M HCl. The slight change in color is due to protonation of the oxime intramolecular hydrogen bond. Addition of water to a volume of 25.0 cm^3 gives a clear orange solution which is treated with two–six drops (0.1–0.3 cm^3) of aqueous 37% CH_2O solution. Within a few minutes crystals of **5** begin to form and after a few hours are collected on a filter (yield *ca* 85% of theory). The product **5** can be recrystallized from CH_3CN–H_2O mixtures, giving well-formed orange-red crystals. The phenyl derivative **6** is prepared in an analogous fashion.

†Supplemental material available: Tables of fractional coordinates, thermal parameters, and bond distances and angles.

‡The dinuclear complex $[Ni_2O_4N_8C_{27}H_{44}]\cdot CH_3CN$ crystallizes from acetonitrile in space group $P2_12_12_1$ with $a = 8.241(3)$ Å, $b = 17.456(6)$ Å, $c = 23.919(7)$ Å, $V = 3441(2)$ Å^3, $Z = 4$, $D_c = 1.357$ g cm^{-3}, and $M_r = 703.2$. 4538 reflection intensities were measured by the θ–2θ scan technique with an Enraf–Nonius CAD-4 diffractometer using Mo-K_α radiation. Absorption correction involved a range of transmission from 0.927 to 1.0. The structure was solved by Patterson and Fourier methods, and refined by full-matrix least-squares methods with hydrogen atoms in "idealized", fixed positions (important hydrogen atoms including those on the bridging methylene were located from difference Fourier syntheses). The final agreement factors for 2949 observations with $F_o^2 > 2\sigma(F_o^2)$ on minimization of the $\Sigma w(|F_o|-|F_c|)^2$ were $R_F = 0.035$ and $R_{wF} = 0.037$. Additional structural details will be published with the structure of the ϕCHO product **6**.

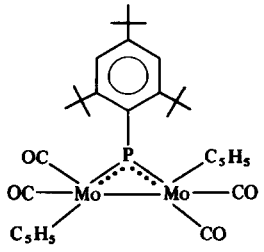
Abstract—The reaction of $ArPCl_2$ (Ar = 2,4,6-*t*-$Bu_3C_6H_2$) with $K[Mo(CO)_3(\eta\text{-}C_5H_5)]$ affords Ar(H)PP(Cl)Ar (**1**), $ArP[Mo(CO)_2(\eta\text{-}C_5H_5)]_2$ (**2**), ArP=PAr, $ArPH_2$ and Ar(H)PP(H)Ar. By means of X-ray crystallography, it was established that the Mo_2P ring of **2** involves a planar phosphorus geometry, a slight degree of Mo–P multiple bonding, and a Mo—Mo single bond. Thermolysis of the original reaction mixture produced the P_2Mo ring compound $ArPP(H)(Ar)[\mu^2\text{-}Mo(CO)_2(\eta\text{-}C_5H_5)]$ (**3**). The structure of **3** was determined by X-ray diffraction.



There are several examples of complexes of the type $R_2P{\cdots}ML_n$ which imply three-electron donation by phosphorus and thus a modicum of metal–phosphorus multiple bonding.[1] We describe a new type of interaction in which the $3e^-$ donation involves *two* phosphorus atoms.

A THF solution of $ArPCl_2$ (Ar = 2,4,6-*t*-$Bu_3C_6H_2$) was treated with two equivalents of $K[Mo(CO)_3(\eta\text{-}C_5H_5)]$ at −78°C and allowed to warm slowly to 25°C. ^{31}P NMR spectroscopic assay of the reaction mixture revealed the presence of ArP=PAr,[2] $ArPH_2$,[3] Ar(H)PP(H)Ar,[3] and two new compounds, ArP(H)PP(Cl)Ar (**1**) and $ArP[Mo(CO)_2(\eta\text{-}C_5H_5)]_2$ (**2**). Separation of the reaction mixture by column chromatography (silica gel–*n*-hexane) resulted in the isolation of **2** (22% yield), but caused the decomposition of **1**. However, the identity of **1** as ArP(H)PP(Cl)Ar was established by the following facts: (i) the ABX ^{31}P NMR spectrum for **1** ($\delta_{P_A}+111$, $\delta_{P_B}-30$, $^1J_{P_AP_B}=300$, $^1J_{P_BH}=224$, $^2J_{P_AH}=5$ Hz) is very similar to that of $(Me_3Si)_3CP(H)P(Cl)C(SiMe_3)_3$,[4] and; (ii) **1** can be produced (42% yield) (in admixture with smaller quantities of $ArPH_2$, ArP(H)PP(H)Ar and ArP=PAr) by slow addition of ArPHLi to $ArPCl_2$ in THF solution at 0°C. Compound **2** (δ_P+687) was identified as a bridging phosphinidene complex by X-ray crystallography (Fig. 1). Within experimental error, the geometry at phosphorus is trigonal planar and the Mo–P bond lengths [average 2.306(8) Å] are somewhat short and thus indicative of a slight degree of metal–phosphorus multiple bonding. The Mo–Mo bond length [3.220(8) Å], on the other hand, corresponds to a bond order of unity. The foregoing structural features for **2** are similar to those of $ArP[Co(CO)_3]_2$ (**4**).[5] While there are several

1

2

examples of complexes of the type $RP(ML_n)_2$ featuring $16e^-$ organometallic moieties,[7] the significance of **2** and **4** is that they involve $15e^-$ fragments.

Thermolysis of the original reaction mixture (refluxing toluene, 30 min) caused the disappearance of the ^{31}P resonance due to **1** and the emergence of a new ABX pattern attributed to **3** ($\delta_{P_A} - 151$, δ_{P_B} 0.2, $^1J_{P_AP_B} = 541$ Hz, $^1J_{P_AH} = 401$ Hz, $^2J_{P_AH} < 1$ Hz). Compound **3** can also be prepared

3

(in >90% yield) by the thermal reaction of **1** with $K[Mo(CO)_3(\eta\text{-}C_5H_5)]$, thus suggesting its origin in the previous reaction. Purification of **3** was effected by column chromatography (silica gel–*n*-hexane) and the compound was identified by X-ray crystallography (Fig. 2) and NMR spectroscopy.* Hydrogen H_x was not detected in the X-ray study due to poor crystal quality; however, its presence was clear from the ABX ^{31}P NMR spectrum. Examination of the geometry around P_B indicates that H_x is pointed away from the Mo–P_B bond. The simplest way to visualize the bonding in **3** is to consider it as a complex of the (as yet unprepared)[6] anion, $[ArP_A\text{–}P_B(H)(Ar)]^-$, in which P_A and P_B serve as one- and two-electron donors, respectively. The

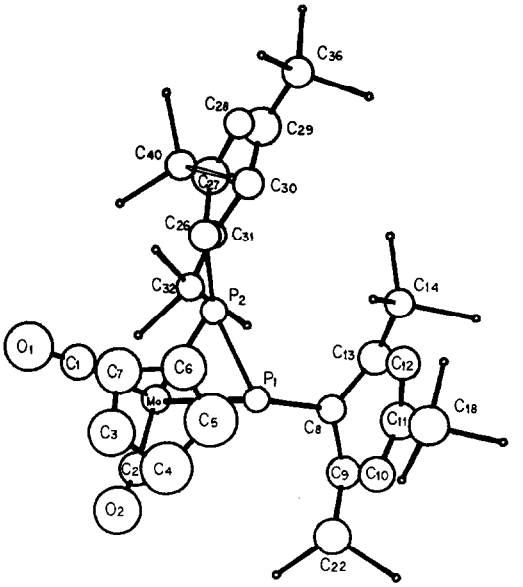

Fig. 2. ORTEP view of **3** showing the atom-numbering scheme. Important parameters: Mo–P(1) = 2.696(6) Å, Mo–P(2) = 2.389(7) Å, P(1)–P(2) = 2.145(8) Å, P(1)–Mo–P(2) = 49.4(2)°, P(2)–P(1)–Mo = 57.8(2)°, P(1)–P(2)–Mo = 72.8(3)°, P(2)–P(1)–C(8) = 103.0(8)°, P(1)–P(2)–C(26) = 124.2(7)°.

*Crystal data for **2**: $C_{32}H_{39}Mo_2O_4P$; $M = 710.52$. Crystal data: monoclinic, $P2_1/c$ (No. 14); $a = 13.429(2)$ Å, $b = 13.705(2)$ Å, $c = 17.072(2)$ Å, $\beta = 97.62(1)°$; $V = 3114$ Å^3, $Z = 4$, $D_c = 1.515$ g cm^{-3}.

Crystal data for **3**: $C_{43}H_{63}MoO_2P_2$; $M = 769.87$. Crystal data: monoclinic, $P2_1/c$ (No. 14); $a = 20.456(3)$ Å, $b = 11.501(3)$ Å, $c = 18.380(6)$ Å, $\beta = 97.80(2)°$; $V = 4284$ Å^3, $Z = 4$, $D_c = 1.194$ g cm^{-3}.

Intensity data: Enraf–Nonius CAD-4F diffractometer, ω–2θ scan modes in the range $2.0 \leqslant 2\theta \leqslant 50.0°$; 3007 and 3298 unique reflections for **2** and **3**, respectively. The structure of **2** was solved by direct methods while that of **3** was solved by Patterson and difference Fourier technqiues. The structures of **2** and **3** were refined (full matrix, least squares) by using 2127 and 2940 data, respectively. Final residuals (R) were 0.0870 and 0.1030 for **2** and **3**, respectively. Atomic positional and thermal parameter coefficients, full lists of bond lengths and angles and lists of F_o/F_c values for **2** and **3** have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

P_A–Mo distance [2.389(7) Å] corresponds to a bond order of unity. The P_B–Mo bond [2.696(6) Å] is somewhat longer than normal; nevertheless, the presence of such a bonding interaction is evident from, for example, the acute Mo–P_A–P_B angle [57.8(2)°]. Interestingly, the P_A–P_B distance [2.145(8) Å] is ~0.06 Å shorter than that of a P—P single bond, suggesting a slight multiple-bond character. This results should not be over-interpreted given the mediocre quality of the crystal structure. Nevertheless, it is interesting to note that the implication of modest multiple bonding is consistent with the large $^1J_{P_AP_B}$ coupling constant.[8]

SYNTHESIS AND CHARACTERIZATION OF OXOMOLYBDATE CLUSTERS CONTAINING COORDINATIVELY BOUND ORGANO-DIAZENIDO UNITS: THE CRYSTAL AND MOLECULAR STRUCTURE OF THE HEXANUCLEAR DIAZENIDO-OXOMOLYBDATE, $(NBu^n_4)_3[Mo_6O_{18}(N_2C_6H_5)]$

TZE-CHEN HSIEH and JON A. ZUBIETA*

Department of Chemistry, State University of New York at Albany, Albany, NY 12222, U.S.A.

(*Received* 31 *October* 1985; *accepted after revision* 4 *March* 1986)

Abstract—$(NBu^n_4)_3[Mo_6O_{18}(N_2C_6H_5)]$ has been obtained by treating $(NBu^n_4)_2[Mo_6O_{19}]$ with an equivalent amount of phenylhydrazine in benzene. X-ray crystallography reveals the identity of the deep red crystalline material as a polymolybdate species incorporating a coordinatively bound organo-diazenido unit. The anion $[Mo_6O_{18}(N_2C_6H_5)]^{3-}$ is structurally similar to the precursor $[Mo_6O_{19}]^{2-}$, with the terminally bound phenyldiazenido group replacing a terminal oxo unit of the hexamolybdate moiety. $(NBu^n_4)_3[Mo_6O_{18}(N_2C_6H_5)]$ crystallizes in the orthorhombic space group *Pmcn* with $a = 17.162(3)$ Å, $b = 17.577(3)$ Å, $c = 23.860(4)$ Å, $V = 7197.7(8)$ Å^3, $Z = 4$, and $D_c = 1.56$ g cm^{-3} [$\mu = 10.60$ cm^{-1}, Mo–K_α ($\lambda = 0.71069$ Å)]. Solution and refinement based on 2118 reflections with $I_o \geqslant 3\sigma(I_o)$ gave a final reisdual of 0.080.

In view of their metal oxide like structures and high molecular weights, the interactions of isopolyanions with small organic molecules are of considerable interest in the development of models for the interactions of organic substrates with catalytic oxide surfaces.[1–3] Although a number of polymolybdate structures incorporating oxygen-donating organic ligands have been described,[4,5] examples of isopolymolybdates containing nitrogen-donating ligands are rare indeed.[6] We have shown that phenylhydrazine reacts with isopolymolybdate clusters in a condensation-type reaction to yeild organo-diazenido-polymolybdate species with tetranuclear, $[Mo_4O_8(OR)_2(N_2C_6H_5)_4]^{2-}$, or octanuclear, $[Mo_8O_{20}(N_2C_6H_5)_6]^{4-}$, frameworks, depending on reaction conditions.[7–9] Since the solvent often influences the stability of the various isopolymolybdate aggregates, it is not surprising that variation in reaction solvent should yield novel compositions for organo-diazenido-derivatized polymolybdates. Herein, we report the isolation and structural identification of the first example of a derivatized polymolybdate structurally related to the $[Mo_6O_{19}]^{2-}$ unit[10] through replacement of a terminal oxo group by an organodiazenido unit, $[Mo_6O_{18}(NNC_6H_5)]^{3-}$.

Reaction of a suspension of $(NBu^n_4)_2[Mo_6O_{19}]$ in dry benzene with an equivalent amount of phenylhydrazine and triethylamine results in an intense red solution after 3 h of reflux. Slow evaporation yields dark red crystals of rhombic habit. The material analyzed for $(NBu^n_4)_3[Mo_6O_{18}(NNC_6H_5)]$,† and exhibited an IR spectrum which confirmed the presence of the coordinated phenyldiazenido units [ν(N–N) 1588 cm^{-1}] and displayed a pattern characteristic of terminal and bridging oxo groups [ν(Mo–O$_t$) 935 cm^{-1}, ν(Mo–O$_b$) 790 cm^{-1}]. The electronic spectrum shows three bands in the UV, with maxima at 215, 295 and 335 mμ, and visible transitions at 390 and 525 mμ, the latter, presumably, associated with the $[Mo(NN_6H_5)]$ chromophore.

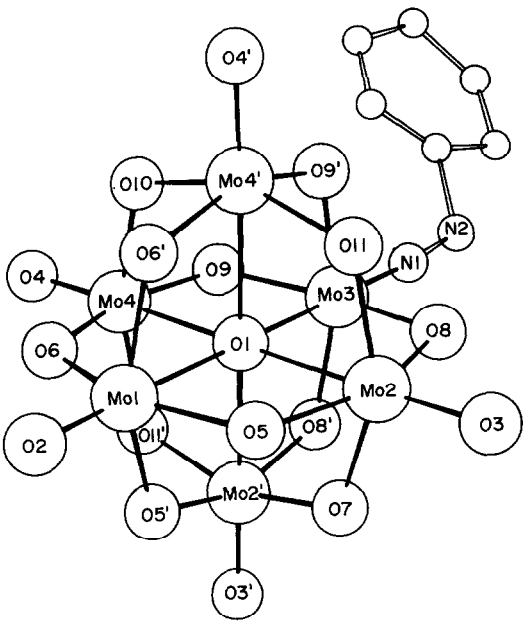
† Elemental analysis: Found: C, 37.8; H, 6.5; N, 4.0%. Calc. for $C_{54}H_{113}Mo_6N_5O_{18}$: C, 38.2; H, 6.7; N, 4.3%.

Crystal data

$C_{54}H_{113}Mo_6N_5O_{18}$, $M = 1695.6$, orthorhombic space group *Pmcn*, $a = 17.162(3)$ Å, $b = 17.577(3)$ Å, $c = 23.860(4)$ Å, $U = 7197.7(8)$ Å, $Z = 4$ (based on the hexanuclear unit), $D_c = 1.56$ g cm^{-3}. 2118 reflections of 4321 collected were used in the structural analysis (Mo-K_α radiation, $R = 0.08$, error of fit = 1.67).*

The X-ray structure† confirms the presence of discrete hexanuclear units incorporating a single coordinatively bound phenyldiazenido group, $[Mo_6O_{18}(NNC_6H_5)]^{3-}$, as illustrated in Fig. 1. In contrast to the previously reported structures of phenyldiazenido-derivatized polymolybdates,[7-9] $[Mo_6O_{18}(NNC_6H_5)]^{3-}$ is structurally similar to the precursor hexamolybdate $[Mo_6O_{19}]^{2-}$.[10] While the structural integrity of the hexanuclear core is maintained, a single phenyldiazenido group has substituted for the terminal oxo unit of Mo3.

The geometry of the hexanuclear core of molybdenum atoms is distorted from the idealized octahedral symmetry displayed by the $[Mo_6O_{19}]^{2-}$ precursor as a consequence of phenyldiazenido substitution at Mo3. The Mo3–O1 bond distance is significantly shorter than the average of the the other Mo–O1 distances, 2.16(1) in contrast to 2.35 Å (average). A consequence of the Mo3–O1 bond contraction is a small lengthening of the Mo3–O(bridging) bond distances. The short Mo3–N1 distance and the linearity of the Mo3–N1–N3 valence angle are consistent with the description of the phenyldiazo linkage as the three-electron donation $-N_2R^+$ structure. However, the Mo3–N1 and N1–N2 distances imply a significant contribution of resonance form **II** to the overall structure of the [Mo–N_2R] unit, in contrast to other diazenido derivatives of polymolybdates which display metrical parameters approaching the idealized structure **I**.



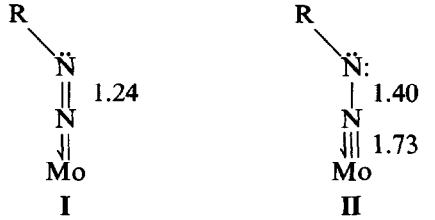


Fig. 1. ORTEP view of the structure of the molecular anion $[Mo_6O_{18}(NNC_6H_5)]^{3-}$, showing the atom-labelling scheme. Relevant bond lengths (Å) and angles (°): Mo3–O1 = 2.15(1), Mo3–O8 = 1.98(1), Mo3–O9 = 2.01(2), Mo3–N1 = 1.76(2), N1–N2 = 1.31(3), O1–Mo3–N1 = 179.2(10), O9–Mo3–N1 = 100.1(9), O8–Mo3–N1 = 101.8(9), O8–Mo3–O9 = 158.1(7), Mo3–N1–N2 = 178.7(19). Average values of the non-derivatized Mo sites: Mo–O_t = 1.68(2), Mo–O_b = 1.93(2), Mo–O_c = 2.35(1), O_c–Mo–O_t = 178.5(9), O_b–Mo–O_c = 76.9(7), and O_t–Mo–O_b = 103.2(9); where O_t, O_b and O_c refer to terminal, bridging, and central oxo groups, respectively. The atoms Mo1, Mo3, O1, O3, O7 and O10, and the entire phenyldiazenido unit, lie on a crystallographic mirror plane passing through the $[Mo_6O_{18}(NNC_6H_5)]^{3-}$ unit at $x = 0.2500$.

The complex is electrochemically active in common with type **I** polymolybdates, displaying a reversible one-electron oxidation at +0.076 V followed by a quasi-reversible one-electron oxidative process at +0.842 V.‡ Controlled-potential electrolysis at +0.3 V results in a dramatic color change from pale red to intense violet, accompanied in the

*The atomic coordinates for this work are available on request from the Director of the Cambridge Crystallographic Data Centre, Cambridge CB2 1EW. Any request should be accompanied by the full literature citation for this communication.

†One cation lies in the crystallographic mirror plane at $x = 0.2500$, such that N12 and C31–C38 occupy positions on the plane and C39–C42 rest in general positions. The cation exhibits disorder about the mirror plane, evidenced by significant residuals (1.5–1.8 e Å^{-3}) above and below the plane positions of C33, C34, C37 and C38. Thermal parameters associated with C41 and C42 also suggest a degree of disorder. Since various models assigning partial populations to these positions failed to yield a significantly improved fit, we have reported the model with carbon atoms located at the positions of major intensity with unit populations and unconstrained thermal parameters.

‡$[Mo_6O_{19}]^{2-}$ exhibits successive one-electron reductions at −0.85 and −1.70 V.[11]

electronic spectrum by the disappearance of the 390-mμ transition and the appearance of a band at 439 mμ. The electrochemically generated oxidized species $[Mo_6O_{18}(NNC_6H_5)]^{2-}$ is paramagnetic, and details of the magnetic properties and the EPR spectrum will be presented in subsequent publications.

ANNOUNCEMENT

METALS IN OLEFIN POLYMERIZATION SYMPOSIUM

This symposium will be held in Denver, CO, U.S.A. (5–10 April 1987) at the 193rd American Chemical Society National Meeting. For further information or to submit contributions, contact: Dr Steven D. Ittel or Dr Andrew H. Janowicz, Central Research and Development Department, E. I. du Pont de Nemours & Co., Inc., Experimental Station, E328, Wilmington, DE 19898, U.S.A.

The symposium will focus on catalyst preparation, catalytic and stoichiometric reactions, mechanistic aspects, and novel applications of:

Coordination polymerization by late transition metals,

Effect of transition metals in free-radical polymerizations,

Group transfer polymerizations,

Ziegler–Nata catalysis,

Polymerizations by organolanthanides,

Main-group metals in polymerizations,

Other appropriate applications of metals in polymer chemistry.

VII. SUMMARY AND FUTURE PROSPECTS 1694

I. INTRODUCTION

Complexes of transition metals with sulphur–nitrogen (S–N) ligands,* e.g. $MoCl_5 \cdot S_4N_4$[1] and $TiCl_4 \cdot S_4N_4$,[2] were first described in the early part of this century. The topic enjoyed some popularity in the 1950s, primarily due to the pioneering work of Becke-Goehring and co-workers in Germany and a review by Weiss was published in 1966.[3] The structural characterization of these compounds was a difficult task, however, due to the lack of suitable physical techniques, and progress was slow. Furthermore, unlike boron or phosphorus chemistry, the advent of NMR spectroscopy in the 1960s had little impact on the advancement of the subject since neither sulphur nor nitrogen have readily amenable NMR nuclei. In the 1970s there was a dramatic increase in interest in S–N chemistry.[4] X-ray crystallography has played the major role in providing essential structural information and, in the last 5 years, our knowledge of metal complexes has progressed to the point where a review of the subject is timely. It is particularly appropriate during the sesquicentennial anniversary (1985) of the discovery of tetrasulphur tetranitride S_4N_4,[5] the precursor of the first metal complexes with S–N ligands.

This review is limited to complexes of metals with *inorganic* S–N ligands such as binary sulphur nitrides and S–N anions, thiazyl halides (NSX), S–N oxides, and sulphur imides, $[(SNH)_x]$. It does not include complexes with *organic* ligands in which the donor sites are sulphur and nitrogen. Complexes between metals and the binary sulphur nitrides SN, S_2N_2 and S_4N_4, which are treated first, can be considered as typical Lewis acid–Lewis base adducts in which the ligand is bonded to the metal via a nitrogen atom. Complexes of thiazyl halides NSX (X = F, Cl or Br), which are covered in the next section, can be viewed in a similar way. A discussion of S–N oxides as ligands follows, for which coordination through oxygen or, less frequently, nitrogen is observed. Attachment to the metal via sulphur atoms is exhibited by sulphur imides, e.g. $S_4N_4H_4$, in which the nitrogen atoms are three-coordinate (cf. two-coordinate nitrogen in sulphur nitrides). The last section covers the important class of compounds known as cyclometallathiazenes, represented by the general formula MS_xN_y. In these complexes the metal ion is a constituent of an S–N ring and the ligand can be considered as a binary S–N anion.

In keeping with the current state of knowledge of the subject the major emphasis of the review will be on synthetic methods and structural information.

* The use of parentheses (or a period) in molecular formulae to distinguish between complexes in which the thiazene unit is bonded as a neutral ligand to the metal and those in which the metal is part of a thiazene ring should be noted. For example, $M(S_2N_2)$ (or $M \cdot S_2N_2$) represents an adduct of disulphur dinitride (Section II.2), whereas MS_2N_2 signifies a five-membered metallathiazene ring (Section VI.1). This distinction does not apply when the metal is part of more than one ring system, i.e. for a spirocyclic metal centre.

II. COMPLEXES OF SULPHUR NITRIDES

II.1. *Thionitrosyl complexes*

The chemistry of transition-metal–thionitrosyl complexes up to 1981 has been surveyed by Roesky and Pandey.[6] Accordingly, after a general introduction, this section will focus on publications that postdate that review. Recent investigations by Hursthouse *et al.*[7] have shown, however, that earlier claims of the preparation of a number of rhodium–thionitrosyl complexes[8–10] cannot be substantiated. Consequently, a reinterpretation of some of the earlier work is warranted and is included in this section.

II.1.*A. Preparation.* Unlike NO, the monomeric NS molecule has only a transient existence and it cannot be used to prepare thionitrosyl–metal complexes. The NS molecule is, however, stabilized by coordination to a transition metal. The following metals are known to form thionitrosyl complexes: Cr, Mo, W, Mn, Tc, Re, Fe, Ru, Os, Co, Rh and Ir.

The tetramer S_4N_4 is a potential source of the SN monomer, but there is only one example of the preparation of a metal–thionitrosyl complex from S_4N_4.[11] The reactions of S_4N_4 with certain transition-metal halides in methanol give complexes originally formulated as $M(NS)_4$ (M = Ni, Co or Fe),[12] but later shown to be $M(S_2N_2H)_2$[13,14] (see Section VI.2). Some poorly characterized products described as metal thionitrosyls, e.g. NiS_4N_4,[15] CoS_4N_4,[16] $Mo(CO)S_5N_5$,[17] $Fe(CO)(S_4N_4)$[18] and $Co_2(CO)(S_4N_4)$,[19] have been obtained from S_4N_4 and metal carbonyls, but structural information is lacking. In fact, treatment of the latter cobalt complex with NO gives the cyclometallathiazene $(NO)_2CoS_3N$ (Section VI.3).[20] The first M–NS complex was prepared in 1974 by the reaction of molybdenum nitrido complexes with sulphur or propylene sulphide.[21,22] Since then several other synthetic approaches to metal–thionitrosyl complexes have been discovered and examples of each of these are discussed below.

(a) *Reactions of nitrido complexes with* S_2Cl_2

This preparative route was first used for the synthesis of Re– and Os–thionitrosyl complexes.[23,24] It has recently been extended to the preparation of Tc(I) and Tc(II) complexes:[25]

$$L_3TcCl_2N + S_2Cl_2 \rightarrow L_3TcCl_x(NS),$$

where L = $PhMe_2P$ and $x = 2$ or 3.

(b) *Reactions of* NS^+ *salts with transition-metal complexes*

This approach has the potential to become a general method of synthesis but only a few thionitrosyl complexes have been obtained from NS^+ salts.[26,27] The latter can be generated *in situ* from $(NSCl)_3$ and $AgPF_6$:[26]

$$(C_6H_6)Cr(CO)_3 + [NS][PF_6] \xrightarrow{MeCN} [Cr(NS)(MeCN)_5][PF_6]_2,^{26}$$

$$[CpFe(CO)_2SO_2][AsF_6] + [NS][AsF_6] \longrightarrow [CpFe(CO)_2NS][AsF_6]_2 + SO_2,^{27}$$

$$[Re(CO)_5SO_2][AsF_6] + [NS][AsF_6] \longrightarrow [Re(CO)_5NS][AsF_6]_2 + SO_2.^{27}$$

(c) *Reactions of* $(NSCl)_3$ *with anionic metal–carbonyl complexes*

The first organometallic-thionitrosyl complex was prepared by the addition of $(NSCl)_3$ in THF to $[CpCr(CO)_3]^-$ at $-78°C$[28,29] and the corresponding C_5Me_5 derivative has been obtained in a similar way:[30]

$$Na[CpCr(CO)_3] + \tfrac{1}{3}(NSCl)_3 \rightarrow CpCr(CO)_2NS + CO + NaCl.$$

The analogous Mo or W complexes could not be prepared in this way, however, due to preferential oxidation of the $[CpM(CO)_3]^-$ anion to the dimer $[CpM(CO)_3]_2$ by $(NSCl)_3$.[28,29] This problem has

been overcome recently by replacement of Cp with the hydridotris(3,5-dimethylpyrazolyl)borate ligand:[31]

$$K[HB(Me_2Pz)_3M(CO)_3] + (NSCl)_3 \xrightarrow{THF} HB(Me_2Pz)_3M(CO)_2NS + [HB(Me_2Pz)_3M(CO)_2]_2S,$$

where M = Mo or W.

(d) *Halide abstraction from coordinated* NSF *or* NSCl

The reaction of $[Re(CO)_5NSF][AsF_6]$ with AsF_5 provides a source of $[Re(CO)_5NS]^{2+}$,[32] but method (b) is prefered for the preparation of this cation.[27] Complexes containing two NS ligands have been prepared by chloride abstraction from coordinated NSCl ligands:[33]

$$OsCl_4(NSCl)_2 + Ph_4AsCl \xrightarrow{CH_2Cl_2} [Ph_4As][OsCl_4(NS)(NSCl)]$$
$$GaCl_3\downarrow \uparrow Ph_4AsCl$$
$$OsCl_4(NS)_2$$

(e) *Reactions of* $(NSCl)_3$ *with transition-metal halides*

This method could be a versatile route to M–NS complexes and it has been applied recently to an improved synthesis of Ru and Os complexes:[33]

$$(Ph_3P)_3MCl_2 + \tfrac{1}{3}(NSCl)_3 \xrightarrow{THF} (Ph_3P)_2M(NS)Cl_3,$$

where M = Ru (55%) or Os (46%).

As indicated in subsequent sections, however, the reactions of transition-metal halides with $(NSCl)_3$ can give rise to a wide range of compounds including S_2N_2 adducts, NSCl complexes, cyclometallathiazenes or salts containing binary or chlorinated S–N cations. It should also be noted that the reactions of triphenylphosphine–rhodium complexes (or Ph_3P itself) with $(NSCl)_3$ produce Ph_3PNH and $[Ph_3PNH_2]Cl$,[7] not thionitrosyl complexes.[8–10]

(f) *Reactions of* S_4N_4 *with transition-metal halides or nitrides*

Very recently the first examples of the preparation of transition-metal–thionitrosyl complexes from S_4N_4 have been reported.[11] The reaction of $ReNCl_4$ with S_4N_4 in the presence of Ph_4AsCl gives $[Ph_4As]_2[ReCl_4(NS)(NSCl)] \cdot CH_2Cl_2$. In contrast, it should be noted that the reaction of $WNCl_3$ with S_4N_4 produces the cyclometallathiazene $[Cl_3WS_2N_3]_2$ (Section VI.4.A). The preparation of $[Ph_4As][Re(NS)Cl_5]$ from S_4N_4 and Re_2Cl_{10}, followed by treatment with Ph_4AsCl, has also been described:[11]

$$Re_2Cl_{10} + S_4N_4 \xrightarrow[CH_2Cl_2]{Ph_4AsCl} [Ph_4As][Re(NS)Cl_5].$$

The M–NS complexes that have been reported since 1981 and the methods used in their preparation are listed in Table 1.

II.1.*B. Structure and bonding.* Although more than 70 metal–thionitrosyl complexes have been described, X-ray structural data are available for only six (Table 2). The M—N≡S unit is essentially linear in all six compounds and, unlike metal nitrosyls, there are no confirmed examples of complexes containing either bent- or bridging-thionitrosyl ligands. From a comparison of the IR data [ν(CO) and ν(NX)] of the series of d^6-metal complexes $[CpM(CO)_2NX]^{n+}$ (M = Cr, $n = 0$; M = Mn, $n = 1$; M = Fe, $n = 2$; X = O or S) it is apparent that the comparative acceptor abilities of NO^+ and NS^+ depend on the charge density in the complex. The former behaves as a stronger π-acceptor in the Mn and Fe complexes.[27]

II.1.*C. Spectroscopic studies.* The bands attributed to the ν(NS) stretching mode of new metal–thionitrosyl complexes are given in Table 1. They fall within the broad range 1065–1390 cm^{-1}. Complexes that absorb in the 1110–1130-cm^{-1} region were considered earlier to contain bent, terminal NS ligands,[6] and a series of Rh complexes with an IR band at 1118 ± 3 cm^{-1} were claimed to be thionitrosyl complexes on the basis of analytical data and IR evidence.[8–10] However, the data

[a] See Section II.1.A for description of methods a–f.

[b] Prepared by ligand exchange reactions.

[c] Prepared by treatment of neutral complexes $M(NS)Cl_3$ (M = Ru or Os) with Ph_4ECl (E = P or As) or NH_4Cl.

given in Table 2 indicate that there is no correlation between ν(NS) and the MNS angle and more recent work has identified the source of this IR band to be $[Ph_3PNH_2]Cl$, an impurity that is formed from the reaction of triphenylphosphine–rhodium complexes with $(NSCl)_3$.[7]

A bridging-thionitrosyl group has been attributed to complexes of type $[Rh(NS)X_2L]_2$ (X = Cl or Br, L = Ph_3P or Ph_3As) on the basis of an IR band at 840 cm^{-1},[6] but a reinvestigation of the reaction of $[Rh(NO)(PPh_3)_3]$ with $(NSCl)_3$ gave Ph_3PO and $[Ph_3PNH_2]Cl$[7] and not

$[Rh(NS)Cl_2(Ph_3P)]_2$ as reported previously.[9] Thus the existence of Rh complexes containing bridging-thionitrosyl ligands is questionable.

^{13}C and ^{14}N NMR data have been reported for three pairs of metal–nitrosyl/thionitrosyl compounds.[40] Only small changes in the ^{13}C NMR chemical shifts of CO ligands are observed. However, the ^{14}N chemical shifts increase by as much as 49 ppm for an NS complex compared to the analogous NO complex and the ^{95}Mo chemical shift in $HB(Me_2Pz)_3Mo(CO)_2NX$ (X = O or S) increases by >550 ppm when NO is replaced by NS. This deshielding of both the ^{95}Mo and ^{14}N nuclei has been attributed to a decrease in the energies of the low-lying excited states for the M–NS complexes. The bathochromic shifts observed in the UV–visible spectra of M–NS complexes and earlier data from photoelectron spectra[41] provide support for this explanation of the NMR data.

II.1.*D. Reactions.* Several reactions of transition-metal–thionitrosyl complexes have been reported since 1981. Rh complexes containing the NSCl and NSF ligands were prepared by nucleophilic halide addition to the thionitrosyl ligand in the dicationic complex $[Re(CO)_5NS][AsF_6]_2$ (Section III.3.A). The reactivity of $Ru(NS)X_3L_2$ complexes (X = Cl or Br; L = PPh_3, $AsPh_3$, $SbPh_3$ or pyridine) towards NOCl, NOBr and N_2O_3 in the presence of excess L was investigated. In all cases displacement of the thionitrosyl group occurred and the products were nitrosyl and nitrosyl-nitrato (from N_2O_3) complexes of the general formulae $Ru(NO)X_3L_2$ and $Ru(NO)(NO_3)X_2L_2$.[34] Similarly, the reaction of $Co(NS)Cl_3(PPh_3)_2$ with NOCl or NOBr resulted in the formation of $Co(NO)XCl_2(PPh_3)_2$ (X = Cl or Br).[39]

II.2. *Complexes of disulphur dinitride* (S_2N_2)

The smallest cyclic sulphur nitride, S_2N_2, is usually prepared by pyrolysis of S_4N_4 in the vapour phase using a silver catalyst.[42] More recently, several alternative preparative routes have been reported.[43–45] Although S_2N_2 has attracted attention as the precursor of the conducting polymer $(SN)_x$,[46] the coordination chemistry of this simple ligand is not well developed, probably due to the difficulties involved in handling an explosively labile compound. In fact, the first transition-metal complex, polymeric $(\mu\text{-}S_2N_2)[Cu(CH_3CN)Cl_2]_2$, was not reported until 1980.[47]

II.2.*A. Preparation.* Complexes of S_2N_2 have been prepared by the reactions of transition-metal halides with a variety of S–N precursors. Examples of each preparative route are given below.

(a) *Direct reaction with* S_2N_2

This method has only been reported for $TiCl_4 \cdot S_2N_2$.[48]

(b) *Cleavage of* S_4N_4

The reaction of S_4N_4 with Lewis acids can result in cleavage of the eight-membered S_4N_4 ring to give S_2N_2 as a complex with the Lewis acid. This transformation occurs readily with aluminium trihalides [Al_2X_6 (X = Cl[49] or Br[50])]. It has also been reported for $CuCl_2$,[47] VCl_4[51] and the adduct $TiCl_4 \cdot S_4N_4$:[48]

$$2TiCl_4 \cdot S_4N_4 \xrightarrow{125°C} 2TiCl_4 \cdot S_2N_2 + S_4N_4.$$

The yield in the above reaction is quantitative, but the procedure is hazardous.

(c) *Ligand exchange*

This synthetic approach is potentially of general application but to date there is only one example:[48]

$$(Ph_3P)_2(CO)_2RuCl_2 + (\mu\text{-}S_2N_2)(AlCl_3)_2 \rightarrow [(Ph_3P)_2(CO)_2(S_2N_2)RuCl][AlCl_4] + \tfrac{1}{2}Al_2Cl_6.$$

(d) *Elimination of* SO_2 *from* $S(NSO)_2$

Although S_2N_2 cannot be obtained by pyrolysis of $S(NSO)_2$, the elimination of SO_2 from this

precursor in the presence of $TiCl_4$ gives $TiCl_4 \cdot S_2N_2$ in 95% yield:[48]

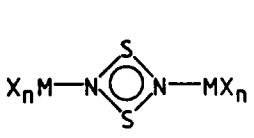
$$S(NSO)_2 + TiCl_4 \xrightarrow{CH_2Cl_2} TiCl_4 \cdot S_2N_2 + SO_2.$$

(e) *Reduction of* $(NSCl)_3$ *or* $S_3N_2Cl_2$

The reactions of chlorides of Groups 4–6 with $(NSCl)_3$ or $S_3N_2Cl_2$ have proved to be a rich source of transition-metal complexes with S–N ligands. In certain cases S_2N_2 complexes are obtained,[52,53] but this route can also give rise to cyclometallathiazenes (Section VI.4) or complexes of thiazyl chloride (Section III.3):

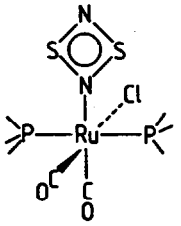
$$[Ph_4As][VCl_5] + (NSCl)_3 \xrightarrow{CH_2Cl_2} [Ph_4As]_2[(\mu\text{-}S_2N_2)(VCl_5)_2] \xrightarrow{(NSCl)_3} [Ph_4As][(S_2N_2)VCl_4]$$

(f) *Thermolysis of thiazyl chloride complexes*



Thermolysis of the complexes $MCl_5(NSCl)$ (M = Nb or Ta) results in the reductive elimination of Cl_2 to give S_2N_2-bridged complexes:[54]

$$2MCl_5(NSCl) \xrightarrow{\Delta} (\mu\text{-}S_2N_2)(MCl_5)_2 + Cl_2,$$



where M = Nb or Ta.

The known S_2N_2 complexes of transition metals and the methods used in their preparation are summarized in Table 3.

II.2.*B. Structural studies.* In Table 4 the pertinent X-ray structural data for S_2N_2 complexes of transition metals are compared with the corresponding data for S_2N_2 complexes of Lewis acids and the free ligand. In all but one of these complexes S_2N_2 acts as a bidentate, bridging ligand with nitrogen atoms as the donor sites **1**. The geometry of the coordinated S_2N_2 molecule is not substantially different from that of the square planar free ligand.[42] The S–N bond lengths remain essentially equal at *ca* 1.64 Å and the bond angles at S and N are *ca* 85 and *ca* 95°, respectively. The one exception is $[(Ph_3P)_2(CO)_2(S_2N_2)RuCl][AlCl_4]$ in which the S_2N_2 ligand is monodentate (**2**).[48] Significant differences in the S—N bond lengths are observed for this complex (Table 4), possibly due to a short, intramolecular S—Cl contact of 2.918(4) Å.

1

2

II.3. *Complexes of tetrasulphur tetranitride* (S_4N_4)

There have been numerous claims of the preparation of adducts of S_4N_4 with transition-metal halides, e.g. WCl_4,[1] $MoCl_5$[1] and $TiCl_4$,[2] in the early literature, and in 1978 these complexes were documented in a survey by Alange and Banister.[58] At that time structural assignments were based on IR spectra and chemical analyses. The fact that $WX_4 \cdot S_4N_4$ (X = Cl[1,58] or Br[59]) was obtained from the reactions of S_4N_4 with tungsten *hexa*halides suggests the occurrence of redox reactions. Indeed more recent investigations have revealed that, in addition to adduct formation, treatment of S_4N_4 with transition-metal halides can lead to fragmentation of the S_4N_4 ring to give S_2N_2 complexes (Section II.2), or redox reactions with the formation of S–N cations or cyclometallathiazenes (Section VI.4). Thus claims of the preparation of S_4N_4 complexes must be viewed with circumspection unless they are supported by X-ray structural characterization.

II.3.*A. Preparation.* Adducts of S_4N_4 with transition-metal halides may be prepared by direct combination of the components in inert solvents such as CH_2Cl_2 or CCl_4. In the case of the Cu complexes, $CuCl_2 \cdot S_4N_4$[60,61] and $CuX \cdot S_4N_4$ (X = Cl[60] or Br[62]), methanol or acetonitrile were used as solvents. However, the reactions of several other transition-metal halides with S_4N_4 in methanol result in the formation of five-membered MS_2N_2H rings [M = Co, Ni, Pd or Pt (see Section VI.2)].

The interaction of $FeCl_3$ with S_4N_4 in various solvents has been studied by several groups and provides a good example of the delicate balance between simple adduct formation and the occurrence of redox reactions. The adducts α- and β-$FeCl_3 \cdot S_4N_4$ have been prepared in CCl_4.[63,64] In CH_2Cl_2,

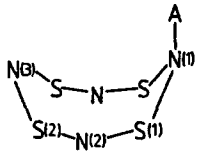
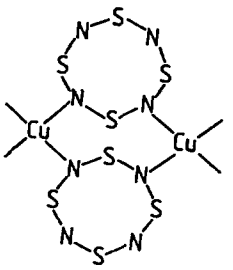
[a] These complexes are polymeric.



[b] The S_2N_2 ring exhibits positional disorder in this anion.

however, S_4N_4 is oxidized to give $[S_6N_4][FeCl_4]_2$ and other products.[65] The same reaction has also been reported to give a salt of the S_4N_4 radical cation, $[S_4N_4][FeCl_4]$,[66] but the structural parameters of the cation are very similar to those of $[S_4N_4H]^+$ in $[S_4N_4H][BF_4]$.[67]



Treatment of S_4N_4 with VCl_4 in CH_2Cl_2 produces $VCl_4 \cdot S_2N_2$, but the primary product of this reaction is the cyclometallathiazene $[Cl_2VS_2N_3]_n$.[51] Similar redox reactions to give $[Cl_3MS_2N_3]_2$ (M = Mo or W) occur when S_4N_4 reacts with Mo_2Cl_{10} or WCl_6 in CH_2Cl_2 (Section VI.4).

The reaction of S_4N_4 with $IrCl(CO)(Ph_3P)_2$ in benzene gives the dark red crystalline complex $IrCl(CO)(Ph_3P)(S_4N_4)$ of unknown structure.[68] Two poorly characterized compounds, $L_2Pt(S_4N_4)$ [L = PPh_3 or $P(OPh)_3$], have been isolated from the interaction of S_4N_4 with the zero-valent Pt complexes, L_4Pt.[69]

II.3.*B. Structural studies.* The structures of five 1 : 1 adducts of S_4N_4 with transition-metal halides have been determined by X-ray crystallography: $TaCl_5 \cdot S_4N_4$,[70] $FeCl_3 \cdot S_4N_4$ (α- and β-modifications),[63,64] $CuCl \cdot S_4N_4$,[60] $CuBr \cdot S_4N_4$[62] and $CuCl_2 \cdot S_4N_4$.[60,61] The molecular structures of $TaCl_5 \cdot S_4N_4$ and $FeCl_3 \cdot S_4N_4$ are similar to those of adducts with Lewis acids, $S_4N_4 \cdot SbCl_5$,[59] $S_4N_4 \cdot BF_3$[71] and $S_4N_4 \cdot AsF_5$,[72] and the protonated species $[S_4N_4H]^+$.[67] In all cases the S_4N_4 ligand is coordinated via one of the nitrogen atoms. The structural consequence of this coordination is the disruption of the cross-ring S—S bonds of S_4N_4 to give a boat-shaped eight-membered ring with approximately coplanar sulfur atoms (**3**), and a remarkable regularity in S–N bond distances (Table 5). Oakley and co-workers have analyzed this structural rearrangement in the light of MNDO MO calculations on various conformations of $[S_4N_4H]^+$.[67] The effect of protonation is to localize π^*-electrons into the skeletal bonds to the protonated nitrogen as indicated by the relatively long S(1)–N(1) bonds. The resulting structure is susceptible to ring contraction reactions to give the five-membered ring $[S_3N_2NH_2]^+$,[73] cf. reactions of S_4N_4 with acid anhydrides to give S_3N_2NR (R = CF_3 or CCl_3).[4] In view of the structural resemblance between $[S_4N_4H]^+$ and $S_4N_4 \cdot A$ (A = an acceptor molecule), it is conceivable that the disruption of the S_4N_4 ring by transition-metal halides to give S_2N_2 complexes or cyclometallathiazenes is a related process.

3

4

A different coordination mode is exhibited by S_4N_4 in the three Cu complexes $CuCl \cdot S_4N_4$,[60] $CuBr \cdot S_4N_4$[62] and $CuCl_2 \cdot S_4N_4$ (**4**).[60,61] The first two are isostructural and form polymers in which $[Cu—X]_n$ chains (X = Cl or Br) are bridged via 1,3-bidentate S_4N_4 ligands. Surprisingly, the conformation and structural parameters for these bidentate ligands are not significantly different from those of uncoordinated S_4N_4. A very similar type of coordination was found for $CuCl_2 \cdot S_4N_4$. In

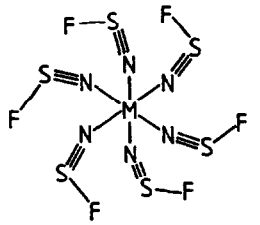
this one-dimensional chain structure octahedrally surrounded Cu atoms are bridged by Cl and 1,3-bidentate S_4N_4 ligands.

III. COMPLEXES OF THIAZYL HALIDES

Four thiazyl halides, NSF, NSCl, NSBr and NSF_3, have been used as ligands in transition-metal complexes. In addition, a number of complexes with the related $[NSOF_2]^-$ ligand have been described.



III.1. *Thiazyl fluoride* (NSF)

The chemistry of NSF and thiazyl trifluoride (NSF_3) has been surveyed in a recent review by Glemser and Mews.[74] The microwave spectrum of NSF indicates a bent structure,[75] cf. SO_2. It is most conveniently generated by decomposition of $FC(O)NSF_2$ or $Hg(NSF_2)_2$,[74] but the combination of moisture-sensitivity and thermal instability make it a difficult substance to handle. Thiazyl fluoride can be stabilized by coordination to a transition metal, however, and such complexes are conveniently prepared in liquid SO_2. This solvent is readily displaced from a metal site by weakly nucleophilic ligands and two homoleptic NSF complexes have been synthesized by this route:[76]

$$[M(SO_2)_2][AsF_6]_2 + 6NSF \rightarrow [M(NSF)_6][AsF_6]_2 + 2SO_2,$$

where M = Co or Ni.

Both complexes have been characterized by IR spectroscopy and X-ray diffraction (**5**) (Table 6).[77,78] The IR stretching frequencies ν(SN) and ν(SF) occur at higher wavenumbers and the S–N and S–F distances are significantly shorter than those in the free ligand, indicating an increase in S–N and S–F bond strength upon coordination.

5

An orange-red cationic NSF complex of Re has also been prepared by replacement of coordinated SO_2 with NSF:[79]

$$[Re(CO)_5SO_2][AsF_6] + NSF \xrightarrow[SO_2]{-30°C} [Re(CO)_5NSF][AsF_6] + SO_2.$$

This product has been used as a source of the corresponding thionitrosyl complex via halide abstraction (Section II.1.A).[32] It is also a useful intermediate for the synthesis of complexes of

[b] Reference 76.

other thiazyl halides, via halogen exchange,[41] and *N,N*-dialkylthiazylamides, by reaction with Me_3SiNMe_2:[81]

$$[Re(CO)_5NSF][AsF_6] + Me_3SiNMe_2 \xrightarrow[-30°C]{SO_2} [Re(CO)_5NSNMe_2][AsF_6] + Me_3SiF.$$

III.2. *Thiazyl trifluoride* (NSF_3) *and the difluorosulphoximide anion* $\{[NSOF_2]^-\}$

NSF_3 is more thermally stable and easier to handle than NSF. It can be obtained by fluorination of NSF or $FC(O)NSF_2$ with AgF_2.[74] On the basis of spectroscopic data, NSF_3 has a distorted tetrahedral structure.[74] The synthetic approach to transition-metal complexes of NSF_3 is similar to that described above for NSF derivatives:[82]

$$[M(SO_2)_2][AsF_6]_2 + 4NSF_3 \rightarrow [M(NSF_3)_4][AsF_6]_2 + 2SO_2,$$

where M = Mn, Fe, Co, Ni or Cu.

The IR spectra of NSF_3 complexes show a large increase in ν(SN) and ν(SF) compared to free NSF_3 (Table 7) and an X-ray structural determination of $[Mn(NSF_3)_4][AsF_6]_2$ has confirmed the proposed shortening of the S–N and S–F bonds in the coordinated NSF_3 ligands.[83] In fact the S–N bond distance in these complexes [1.365(11) Å] is essentially the same as that in the NS^+ cation [1.361(6) Å in $NS^+SbF_6^-$ at 293 K].[84] The vibrational spectra of $[Mn(NSF_3)_4][AsF_6]_2$ and $[Re(CO)_5NSF_3][AsF_6]$ have been discussed elsewhere in detail.[85]

The strengthening of S–N and S–F bonds in coordinated NSF and NSF_3 is in marked contrast to the behaviour of NS^+ and other ligands such as CO and PF_3. According to SCF calculations this effect can be ascribed to the increased net positive charge on sulphur resulting from removal of electrons from the thiazyl group.[86]

The synthesis of a cationic NSF_3 complex of Re has been reported and the product has been characterized by IR and ^{19}F NMR spectroscopy:[87]

$$[Re(CO)_5SO_2][AsF_6] + NSF_3 \xrightarrow{SO_2} [Re(CO)_5NSF_3][AsF_6].$$

The reaction of $AgAsF_6$ with excess NSF_3 affords unstable $[Ag(NSF_3)_2][AsF_6]$, which readily loses NSF_3 *in vacuo* to give the stable complex $[Ag(NSF_3)][AsF_6]$.[82]

The $[NSOF_2]^-$ anion is isoelectronic with NSF_3. The salts $[Ph_4E][NSOF_2]$ (E = P or As)[88] can be used for the preparation of anionic transition-metal complexes $[M(NSOF_2)_4]^{2-}$ (M = Hg, Co or Pt).[89] The reaction of $M(CO)_5Br$ (M = Mn or Re) with $AgNSOF_2$[90] at low temperature gives $M(CO)_5(NSOF_2)$,[91] which decompose at <20°C (M = Mn) and 90°C (M = Re) to give dinuclear compounds, $[M(CO)_4(\mu\text{-}NSOF_2)]_2$. The structures of $Re(CO)_5(NSOF_2)$[92] and $[Mn(CO)_4(\mu\text{-}NSOF_2)]_2$[92,93] have been shown by X-ray crystallography to contain terminal and bridging $NSOF_2$ groups, respectively. In both cases the ligand is coordinated to metal centres by the nitrogen atom.

III.3. *Thiazyl chloride* (NSCl) *and thiazyl bromide* (NSBr)

The first transition-metal complexes of NSCl were discovered by Dehnicke and co-workers in 1982[94] and within a few years these compounds have become a well-established group of S–N

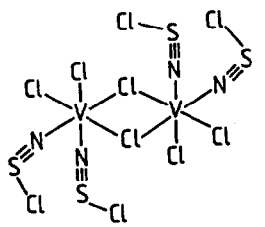
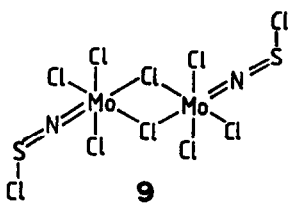
complexes. The bonding in metal–NSCl complexes can be described in terms of resonance structures **6** and **7**. Spectroscopic and X-ray structural data indicate that structure **6** is dominant in most transition-metal–NSCl complexes and that the metal–ligand interaction is stronger than in the transition-metal complexes of NSF.

6 **7**



Monomeric NSCl is formed as a greenish-yellow gas by heating $(NSCl)_3$ *in vacuo* or in an inert-gas stream.[95] It has not been used for reactions with transition-metal complexes, probably due to its tendency to trimerize in the condensed state. In fact, the trimer $(NSCl)_3$ has proved to be a convenient starting material for the preparation of M–NSCl complexes. Monomeric NSBr has been prepared in the gas phase by the pyrolysis of S_4N_3Br and characterized by its IR spectrum.[96] The trimer $(NSBr)_3$ is unknown. The various routes available for the synthesis of M–NSX (X = Cl or Br) complexes are described below and summarized in Table 8.

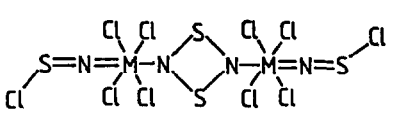
III.3.*A*. *Preparation.*



(a) *Reaction of* $(NSCl)_3$ *with metal halides*

The reaction of $(NSCl)_3$ with anhydrous metal chlorides in solvents such as CH_2Cl_2 or CCl_4 is the most general route to M–NSCl complexes. In some cases $POCl_3$ is used as a solvent to dissolve the metal chloride. Some MCl_n–$(NSCl)_3$ reactions are quite complicated and give rise to other S–N complexes, e.g. cyclometallathiazenes (Section VI.4).

Red crystalline 1 : 1 complexes, $MCl_5(NSCl)$ (M = Nb[97] or Ta[54]) are formed from MCl_5 (M = Nb or Ta) and $(NSCl)_3$, whereas VCl_4 yields a dimeric species $[VCl_3(NSCl)_2]_2$ (**8**).[55] $ReCl_5$ reacts with $(NSCl)_3$ in $POCl_3$ solution to give $ReCl_4(NSCl)(POCl_3)$[98] and $ReCl_3(NSCl)_2(POCl_3)$.[94,98]



8

9

Several M–NSCl complexes have been isolated from reactions of molybdenum and tungsten chlorides with $(NSCl)_3$, but the nature of the products is dependent on subtle changes in reaction conditions (solvent, stoichiometry etc.). The dimeric complexes $[MCl_4(NSCl)]_2$ (M = Mo[99] or W[100]) (**9**) are obtained from $(NSCl)_3$ and Mo_2Cl_{10} or WCl_6, respectively, in CH_2Cl_2. In $POCl_3$ solution the solvated complex $MoCl_4(NSCl)(POCl_3)$ is formed.[99] When the $MoCl_5$: NSCl molar ratio is 1 : 2, a complex containing a bridging S_2N_2 ligand (**10**) (M = Mo) is obtained. [56] The W analogue $(\mu\text{-}S_2N_2)[WCl_4(NSCl)]_2$ (**10**) (M = W), is formed in addition to $[WCl_4(NSCl)]_2$[100] and $[Cl_3WS_2N_3]_2$ (Section VI.4) in the reaction of WCl_6 with $(NSCl)_3$ in CCl_4. A better synthesis of **10** (M = W) is the thermolysis of $[N(SCl)_2][WCl_5(NSCl)]$.[56]

10

An anionic NSCl complex, $[N(SCl)_2][MoCl_5(NSCl)]$ is also obtained in low yields from $(NSCl)_3$ and Mo_2Cl_{10} or $MoCl_4$ in CH_2Cl_2 suspension.[90] The cyclometallathiazene $[Cl_3MoS_2N_3]_2$ (Section VI.4) is formed as a by-product in this reaction.

Treatment of $OsCl_5$ with $(NSCl)_3$ in $CCl_4/POCl_3$ produces $OsCl_4(NSCl)$.[102]

[a] See Section III.3.A for description of methods a–f.
[b] Reaction of S_4N_4 with a metal nitridochloride.

(b) *Reaction of* $S_3N_2Cl_2$ *with metal halides*

$S_3N_2Cl_2$ has been used less frequently than $(NSCl)_3$ for the synthesis of M–NSCl complexes, but the following reaction proceeds in high yield:[56]

$$WCl_6 + S_3N_2Cl_2 \xrightarrow{CCl_4} [N(SCl)_2][WCl_5(NSCl)].$$

The reaction of $ReCl_5$ with $S_3N_2Cl_2$ produces the dimeric species $[ReCl_3(NSCl)_2]_2$ (**11**) in CH_2Cl_2 suspension or $ReCl_3(NSCl)_2(POCl_3)$ in $POCl_3$ solution.[103] The latter complex has also been obtained from $ReCl_5(POCl_3)$ and $(NSCl)_3$.[94,98]

11

(c) *Halide addition to neutral* M–NSCl *complexes*

Some of the metal complexes prepared from $(NSCl)_3$ and anydrous metal chlorides [method (a)] are powdery, insoluble materials, e.g. $OsCl_4(NSCl)_2$[102] and $[ReCl_3(NSCl)_2]_2$.[103] They can, however,

be converted to soluble, more easily crystallized anionic NSCl complexes by treatment with R_4PCl or R_4AsCl (R = Me or Ph). A typical example is the reaction of $ReCl_3(NSCl)_2(POCl_3)$ with Ph_4AsCl in CH_2Cl_2 to give $[Ph_4As][ReCl_4(NSCl)_2] \cdot CH_2Cl_2$.[94,98] The neutral compound can be regenerated by treatment of the anionic complex with $GaCl_3$. Similarly, $MoCl_4(NSCl)(POCl_3)$ and $[WCl_4(NSCl)]_2$ yield $[R_4E][MoCl_5(NSCl)]$ (R_4E = Ph_3MeP or Ph_4As)[99] and $[Ph_4As][WCl_5(NSCl)]$,[94] respectively. The bridging S_2N_2 ligand in **10** (M = W) can also be displaced by chloride ion:[56]

$$(\mu\text{-}S_2N_2)[WCl_4(NSCl)]_2 + 2Ph_4PCl \rightarrow 2[Ph_4P][WCl_5(NSCl)] + S_2N_2.$$

A complex containing a thionitrosyl ligand in addition to coordinated NSCl, $[Ph_4As]$ $[OsCl_4(NS)(NSCl)]$, is prepared by the reaction of $OsCl_4(NSCl)_2$ with Ph_4AsCl.[33]

Halide addition also occurs in the reaction of $[WCl_4(NSCl)]_2$ with sulphur dichloride in boiling CCl_4:[56]

$$[WCl_4(NSCl)]_2 + SCl_2 \rightarrow [N(SCl)_2][WCl_5(NSCl)].$$

Hartmann *et al.*[81] have described three other synthetic approaches, which can be applied to the preparation of metal complexes of either NSCl or NSBr.

(d) *Halide addition to coordinated* NS

$$[Re(CO)_5NS][AsF_6]_2 + CsX \xrightarrow{SO_2} [Re(CO)_5NSX][AsF_6] + CsAsF_6,$$

where X = Cl or Br.

(e) *Insertion of* NS^+ *into metal–halogen bonds*

$$Re(CO)_5X + [NS][AsF_6] \xrightarrow{SO_2} [Re(CO)_5NSX][AsF_6],$$

where X = Cl or Br.

(f) *Halogen exchange at coordinated* NSF

$$[Re(CO)_5NSF][AsF_6] + \tfrac{1}{4}SiX_4 \xrightarrow{SO_2} [Re(CO)_5NSX][AsF_6] + \tfrac{1}{4}SiF_4,$$

where X = Cl or Br.

These methods, particularly (e), appear to be capable of wider application and preliminary studies have shown that other metal halides, e.g. $CpCr(NO)_2Cl$ and Cp_2TiCl_2, react similarly with $[NS][AsF_6]$, but crystalline products have not been isolated.[81]

III.3.*B. Spectroscopic and structural studies.* The IR spectra of M–NSCl complexes have been discussed in detail. Complexes in which the resonance structure **6** is dominant show a characteristic strong band at 900–1000 cm^{-1},[56,94,98–102] which has been assigned to ν_{as}(MNS). The IR spectra of compounds with a larger contribution from resonance form **7** show ν(N≡S) bands at 1290–1360 cm^{-1}. These include $NbCl_5(NSCl)$,[97] $TaCl_5(NSCl)$,[54] $[VCl_3(NSCl)_2]_2$[55] and $[Re(CO)_5(NSCl)][AsF_6]$.[41] The dimeric structures of $[ReCl_3(NSCl)_2]_2$,[103] $[VCl_3(NSCl)_2]_2$[55] and $[MoCl_4(NSCl)]_2$[99] were deduced from IR data.

X-ray structural data for six M–NSCl complexes are compared in Table 9 with the corresponding data for the free ligand determined by spectroscopic methods. Both the S–N bond length and the N–S–Cl angle for $NbCl_5(NSCl)$ are very similar to those of uncoordinated NSCl indicating that resonance form **7** is predominant for this complex. The average Nb–N distance of 2.264 Å is consistent with a weak interaction. By contrast, in four of the other complexes the S–N bond lengths are significantly longer and the N–S–Cl angle is smaller than those of free NSCl, suggesting that resonance form **6** is the best representation in these cases. The short metal–nitrogen distances support this interpretation.

III.3.*C. Reactions.* In this section only those reactions in which the NSCl ligand is replaced or modified will be mentioned.

Table 9. X-ray structural data for M–NSCl complexes

Complex	M–N (Å)	N–S (Å)	S–Cl (Å)	M–N–S (°)	N–S–Cl (°)	Reference

[a] The two sets of data refer to two crystallographically independent molecules.

[b] The two sets of data refer to the two crystallographically inequivalent NSCl ligands.

[c] The Cl atom of the NSCl ligand is disordered and statistically belongs to both sulphur atoms with an occupation probability of 50%.

[d] The molecular dimensions of NSCl(g) were obtained from an analysis of its microwave spectrum.

(a) *Synthesis of nitrido compounds from* NSCl *complexes*

The conversion of coordinated NSCl into a nitrido ligand provides a useful new synthesis of transition-metal nitrides. The first example was the reaction of $ReCl_4(NSCl)(POCl_3)$ with Ph_4AsCl which affords the known complex $[Ph_4As][ReNCl_4]$ in good yield.[98] Treatment of $ReCl_4(NSCl)(POCl_3)$ with triphenylphosphine results in the formation of $ReNCl_2(PPh_3)_2$ (65% yield).[99] $[MoCl_4(NSCl)]_2$ was found to be an excellent precursor for the synthesis of nitrido complexes. Thermolysis leads to $MoNCl_3$ and anionic nitrido complexes are obtained by reaction with chloride ion:[99]

$$[MoCl_4(NSCl)]_2 \xrightarrow[10^{-3}\,\text{torr}]{130^\circ C} 2MoNCl_3 + 2SCl_2,$$

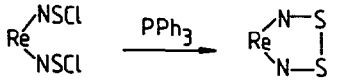
$$[MoCl_4(NSCl)]_2 + 2Cl^- \rightarrow 2[MoNCl_4]^- + 2SCl_2.$$

(b) *Formation of anionic halide complexes*

The weakly coordinated NSCl ligand in thiazyl chloride complexes of V, Nb and Ta is easily replaced by chloride ions:[54,55]

$$MCl_5(NSCl) + Ph_4AsCl \rightarrow [Ph_4As][MCl_6],$$

where M = Nb or Ta.



This reaction has no synthetic value, however, since the resulting anionic chloro complexes are more easily prepared directly from the corresponding metal chlorides.

(c) *Other reactions*

The NSCl ligands in $[VCl_3(NSCl)_2]_2$ are readily replaced by $POCl_3$ to give $[VCl_3(POCl_3)_2]_2$.[55] The thermolysis of $MCl_5(NSCl)$ (M = Nb or Ta) at 100°C under normal pressure yields dinuclear complexes containing a bridging S_2N_2 ligand (Section II.2.A).

The most interesting reaction of coordinated NSCl ligands has been reported for the complex

$ReCl_3(NSCl)_2(POCl_3)$. Reduction of the two NSCl ligands with triphenylphosphine results in the coupling of adjacent thionitrosyl groups with formation of a novel metallathiazene ring, $[Ph_3PCl][Cl_4ReN_2S_2]$[104] (Section IV.1).

IV. COMPLEXES OF SULPHUR–NITROGEN OXIDES

In contrast to the numerous reports of transition-metal complexes of NSCl and, to a lesser extent, NSF (Section III), there is only one confirmed example of a complex of the isoelectronic NSO^- ion. The S–N oxides $S(NSO)_2$, S_3N_2O and $S_4N_4O_2$ form adducts with silver(I) in which coordination occurs via oxygen or nitrogen (or both) atoms.

IV.1. *The thionylimide anion* (NSO^-) *and thionyl imide* (HNSO)

Potassium thionylimide (KNSO) is readily prepared from Me_3SiNSO and potassium *t*-butoxide in THF,[105] but this salt has not been used in the preparation of transition-metal derivatives. A complex described as $Co(NSO)Cl_2[P(OPh)_3]_2$, on the basis of elemental analyses and IR spectra, was isolated when the solution obtained from the reaction of $CoH[P(OPh)_3]_4$ with $(NSCl)_3$ in THF was oxidized in air.[106] The complicated IR spectrum was interpreted in terms of an *N*-bonded thionitrito ligand $\{(CoN(O)S]^-\}$,[106] but structural information is not available. The first confirmed example of a transition-metal complex of $[NSO]^-$ was reported in 1984.[107] The reaction of $CsNSO_2$[108] with $RhH(CO)(PPh_3)_3$ in acetonitrile yields *trans*-$Rh(CO)(NSO)(PPh_3)_2$ and Ph_3PO. The unbranched $[NSO]^-$ ligand is coordinated to rhodium via nitrogen with a bond angle of 122.5° at sulphur and N–S and S–O bond lengths of 1.480(12) and 1.509 (10)Å, respectively, indicative of double bonds.[107]

HNSO can be prepared by the reaction of $SOCl_2$ with ammonia in the gas phase.[109] It polymerizes rapidly in the condensed phase. The *cis*-thionylimide structure (**12**) is lower in energy than the isomeric thiazyl-*S*-hydroxide form, HOSN (**13**),[110] according to the best *ab initio* MO calculations.[111] The calculated isomerization energy is 9.5 ± 5.0 kcal mol^{-1}.[111]

12 **13**

The reaction of $(Ph_3P)_4$ Pt with $S_4N_4H_4$ in benzene–acetone gave a complex formulated as $(Ph_3P)_2Pt(S_2N_2H_2)$ on the basis of elemental analysis and UV–visible spectra,[69] but subsequently described as *cis*-bis(thionylimide-*O*)bis(triphenylphosphine)platinum(II), $(Ph_3P)_2Pt(OSNH)_2$, as a result of an X-ray structural determination.*[112,113] The bond lengths quoted for the coordinated OSNH ligands [d(SO) = 1.341(17) and 1.258(11) Å; d(SN) = 1.452(19) and 1.485(19) Å] are not very reliable, but they are remarkably short compared to those found by spectroscopic methods for the free ligand [d(SO) = 1.451 Å; d(SN) = 1.512 Å].[114]

The reaction of an aqueous solution of K_2PtCl_4 with $S_4N_4H_4$ in acetone is reported to give $Pt(OSNH)_2(S_2N_2H_2)$ on the basis of analytical data and IR and ^1H NMR spectra.[115] This compound would formally be a complex of the otherwise unknown $[S_2N_2H_2]^{2-}$ dianion and structural confirmation is awaited with interest.

Two approaches to the directed synthesis of thionylimide complexes have been reported recently.[116] The first involves quantitative displacement of coordinated SO_2 by preformed HNSO:

$$[M(CO)_5SO_2][AsF_6] + HNSO \xrightarrow[-50°C]{SO_2} [M(CO)_5HNSO][AsF_6] + SO_2,$$

where M = Mn or Re.

* The positions of the hydrogen atoms were not determined with certainty so the ligands could be either OSNH (**12**) or HOSN (**13**). However, the complex is a derivative of Pt(0) rather than Pt(II) since both **12** and **13** are neutral ligands.

The complex $[Ni(HNSO)_4][AsF_6]_2$ has also been prepared by this procedure.[116]

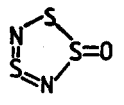
The second method involves nucleophilic displacement of fluoride ion from coordinated NSF by OH^- using trimethyltin hydroxide as the reagent:

$$[Re(CO)_5NSF][AsF_6] + Me_3SnOH \xrightarrow[-30°C]{SO_2} [Re(CO)_5HNSO][AsF_6] + Me_3SnF.$$

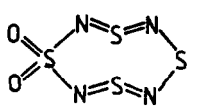
The IR spectra of the Re complexes obtained by these two different routes are identical. Thus it seems reasonable to conclude that the ligand is present in the HNSO form. Furthermore, the second procedure would be expected to give an *N*-coordinated product.

The coordination chemistry of the organic ligands (ArNSO) and the related sulphur diimides (RNSNR) has been reviewed recently.[117]

IV.2. *Bis(thionylimino)sulphur* $[S(NSO)_2]$



The acyclic S–N oxide $S(NSO)_2$ (**14**) is readily prepared from Me_3SiNSO and sulphur dichloride at reflux in the absence of a solvent.[118] The reaction of $S(NSO)_2$ with $AgAsF_6$ in SO_2 gives the polymeric complex $[Ag_4\{S(NSO)_2\}_9][AsF_6]_4 \cdot SO_2$ in which there are two crystallographically independent Ag atoms.[119] One is octahedrally coordinated by the terminal oxygens of six $S(NSO)_2$ ligands, while the other is unsymmetrically coordinated by the nitrogen atoms of three $S(NSO)_2$ ligands. The *cis,trans*-geometry of the two SNSO units of the free ligand[120,121] is unchanged upon coordination and the mean S(II)—N and S(IV)–N bond lengths of 1.649(21) and 1.530(23) Å, respectively, indicate that the localization of single and double bonds is also retained.[119]



14

IV.3. S_3N_2O *and* $S_4N_4O_2$

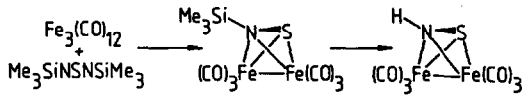
The cyclic S–N oxides S_3N_2O (**15**) and $S_4N_4O_2$ (**16**) are obtained by the reaction of $S_3N_2Cl_2$ with formic acid or $SO_2(NH_2)_2$, respectively.[122] The former is a red liquid while the latter is an orange-yellow crystalline solid. In the octahedral complex $TiCl_4(S_3N_2O)_2$ coordination occurs through oxygen,[123] whereas in complexes with silver(I), $[Ag(S_3N_2O)_2][AsF_6]$[124] and $[Ag(S_4N_4O_2)_4][AsF_6]$,[125] the nitrogen atoms are bound to the metal. In the latter case all the coordinated nitrogen atoms are adjacent to the sulphur(VI) centre.

15

16

V. COMPLEXES OF SULPHUR IMIDES

The cyclic sulphur imides S_7NH, 1,3-, 1,4- and 1,5-$S_6(NH)_2$, 1,3,5- and 1,3,6-$S_5(NH)_3$, and $S_4N_4H_4$ are eight-membered rings derived formally from cyclo-S_8 by the replacement of one or more sulphur atoms by NH groups.[126] They differ fundamentally from the cyclic sulphur nitrides in that the nitrogen atoms are three-coordinate. These ring systems adopt a crown conformation, like cyclo-S_8, and the geometry about the nitrogen atoms in S_7NH[127] and $S_4N_4H_4$[128] is essentially planar suggesting that the lone pair of electrons on nitrogen is involved in π-bonding to neighbouring sulphur atoms. Consistent with this view the known coordination complexes of $S_4N_4H_4$ involve bonding to the metal via sulphur atoms. Transition-metal complexes of the other cyclic sulphur imides are unknown.

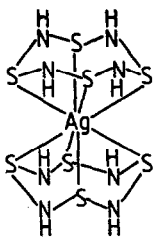


V.1. *Sulphur imide* (SNH)

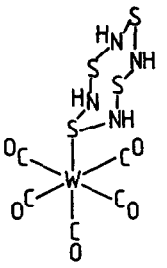
SNH, the parent molecule of the unstable organic thionitroso compounds, is not known in the free state. *Ab initio* MO calculations suggest that the sulphur imide form (**17**) should be more stable than the thiazyl isomer (**18**).[129]

17 **18**

In 1984 Herberhold and Bühlmeyer[130] reported a complex in which HNS is stabilized by coordination as a six-electron ligand to two metal centres. The reaction of $Me_3SiNSNSiMe_3$ with $Fe_3(CO)_{12}$ in *n*-hexane at reflux gave $(Me_3SiNS)Fe_2(CO)_6$ (**19**) (51%), which was converted quantitatively to $(HNS)Fe_2(CO)_6$ (**20**) by chromatography on silica gel. Treatment of **20** with diazomethane yielded $(CH_3NS)Fe_2(CO)_6$ (92%), a member of a class of compounds, $(RNS)Fe_2(CO)_6$ (R = *t*-Bu, *p*-$CH_3C_6H_4$ or C_6H_5), that were discovered earlier.[131,132]



19 **20**



The mononuclear complexes $(RNS)Cr(CO)_5$ (R = Me_2N or Ph_2N), in which the ligand is bonded to the metal via sulphur, have been prepared and structurally characterized.[133,134]

V.2. *Tetrasulphur tetraimide* ($S_4N_4H_4$)

$S_4N_4H_4$ is easily made by reduction of S_4N_4 in benzene with methanolic $SnCl_2 \cdot 2H_2O$ at 80°C.[135] The coordination chemistry of $S_4N_4H_4$ is not well developed and only a few transition-metal derivatives have been described. A rather unstable silver(I) complex, $S_4N_4H_4 \cdot 2AgNO_3$, was reported by Meuwsen in 1931.[136] More recently adducts of $S_4N_4H_4$ with $AgClO_4$ in three different stoichiometries (2 : 1, 1 : 1 and 1 : 2) have been isolated.[137] The X-ray structure of $[Ag(S_4N_4H_4)_2][ClO_4] \cdot 1.5H_2O$ showed that the Ag atom is coordinated to all four sulphur atoms of two $S_4N_4H_4$ crowns in a sandwich-type structure (**21**).[138] The Ag atom is displaced sideways from the central position and the ligands are tilted with an angle of 20.4° between the two S_4 planes.

21

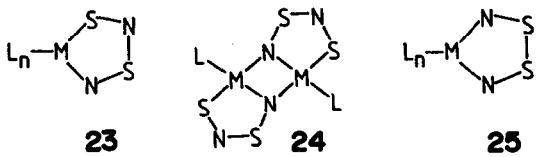
22

Organometallic derivatives of types $(S_4N_4H_4)M(CO)_5$ and μ-$(S_4N_4H_4)[M(CO)_5]_2$ (M = Cr or W) have been prepared by the reaction of $S_4N_4H_4$ with $(CO)_5M(THF)$:[139]

$$S_4N_4H_4 + 2(THF)M(CO)_5 \rightarrow (\mu\text{-}S_4N_4H_4)[M(CO)_5]_2 + 2THF.$$

An X-ray structural determination of $(S_4N_4H_4)W(CO)_5$ (**22**) showed that the monodentate $S_4N_4H_4$ is coordinated to the metal by a sulphur atom. Unlike the S_4N_4 adducts (Section II.3), coordination has little effect on the geometry or structural parameters of $S_4N_4H_4$. The crown conformation of the eight-membered ring is retained and the average S–N bond lengths [1.685(8) Å] and bond angles at sulphur [109.1(4)°] and nitrogen [120.9(4)°][12] are not substantially different from those reported for the free ligand [*d*(SN) = 1.665(1) Å; NSN = 109.3(1)°; SNS = 124.2(2)°].[128]

It should be mentioned that several compounds have been reported in which either two or



four hydrogen atoms of $S_4N_4H_4$ have been replaced by transition metals, e.g. $S_4N_4H_2(CuCl)_2$,[140] $S_4N_4H_2[Cu(NO_3)]_2$,[140] $Cu_4S_4N_4$,[140] $Ag_4S_4N_4$[140] and $Hg_4S_4N_4$.[141] However, it has not been established whether the S_4N_4 ring is retained in these complexes. It is conceivable that they are derivatives of the $[S_2N_2H]^-$ or $S_2N_2^{2-}$ anions, respectively (see Sections VI.1 and VI.2).

VI. CYCLOMETALLATHIAZENES AND RELATED COMPLEXES

A cyclometallathiazene is defined here as a ring system consisting only of sulphur and nitrogen, and one or more metal atoms.* As indicated in Table 10, cyclometallathiazenes can be formally considered as complexes between cationic-metal fragments and binary S–N anions in which both the sulphur and nitrogen atoms are two-coordinate.[142] With only two exceptions, S_3N^- [143,144] and SN_2^{2-},[145] these S–N anions have not been characterized as the free anion. Complexes of the hypothetical $[S_2N_2H]^-$ anion, which do not fall within this definition of cyclometallathiazenes, are also included in this section because of their close relationship to MS_2N_2 rings and historical importance (*vide infra*). The metals that are known to form a particular metallathiazene ring are also indicated in Table 10 together with the dates of the discovery and of the first X-ray structural determination for each system.

VI.1. MS_2N_2

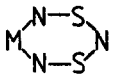
The five-membered cyclometallathiazenes MS_2N_2 can be regarded as derivatives of the dianion of disulphur dinitride, $S_2N_2^{2-}$, for which simple salts are unknown. Several mononuclear MS_2N_2 rings (**23**) have been described, but the S_2N_2 unit can also be part of a binuclear structure (**24**). Very recently the first example of the isomeric heterocycle (**25**) has been reported (Section III.3).[104]

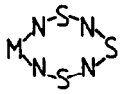
23 **24** **25**

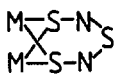
VI.1.*A. Preparation.* With a few exceptions most rings of type **23** have been synthesized by the reaction of various metal complexes with S_4N_4. Indeed the first example of a cyclometallathiazene was of this type. In 1904 Ruff and Geisel[146] reported the reaction of S_4N_4 with PbI_2 in liquid ammonia and the isolation of green, crystalline $PbS_2N_2(NH_3)$. The coordinated NH_3 can be removed by heating at 80–90°C *in vacuo* to give red-brown, highly explosive PbS_2N_2.[140,147,148] Small amounts of crystalline PbS_2N_2 can also be obtained by the reaction of a mixture of $Pb(NO_3)_2$ and S_4N_4 in $CHCl_3$ suspension with NH_3.[149]

S_4N_4 is readily cleaved by complexes containing metals in low oxidation states to give MS_2N_2 rings. For example, the reaction of $CpCo(CO)_2$ or, preferably, CpCo(COD) with S_4N_4 in benzene produces $CpCoS_2N_2$ as black, air-stable crystals.[150,151] $(C_5Me_5)CoS_2N_2$ has been prepared from $(C_5Me_5)Co(CO)_2$ by a similar reaction:[151]

$$2CpCo(COD) + S_4N_4 \rightarrow 2CpCoS_2N_2 + 2COD.$$







The mononuclear complex $(Ph_3P)_2PtS_2N_2$ is obtained on treatment of $(Ph_3P)_2Pt(C_2H_4)$ with S_4N_4 or $S(NSO)_2$:[152]

$$\left.\begin{array}{l}(Ph_3P)_2Pt(C_2H_4) + \tfrac{1}{2}S_4N_4 \\ (Ph_3P)_2Pt(C_2H_4) + S(NSO)_2\end{array}\right\} \xrightarrow{-SO_2} (Ph_3P)_2PtS_2N_2.$$

The cationic complex $[(Ph_2PCH{=}CHPPh_2)_2IrS_2N_2][BPh_4]\cdot 0.5Me_2CO$ was isolated in 60% yield from the reaction of $[(Ph_2PCH{=}CHPPh_2)_2Ir(CO)][BPh_4]$ with S_4N_4 in THF after recrystallization from acetone–*n*-Bu_2O.[153]

* See footnote on p. 1662.

Table 10. Metallathiazene ring systems and the corresponding S–N anions

Ring system[a]	Corresponding S–N anion[b]	Metal	Year of discovery (first X-ray structure)
	$S_2N_2^{2-}$	Co, Ir, Ni, Pd, Pt (Pb)	1982 (1982)
	$S_2N_2^{4-}$	Re	1984 (1984)
	$[S_2N_2H]^-$	Co, Ni, Pd, Pt	1953 (1958)
	$\boxed{S_3N^-}$	Co, Ni, Pd, Pt, Cu, Ag, Au	1958 (1966)
	$S_2N_3^{3-}$	V, Mo, W	1983 (1983)
	$S_3N_4^{2-}$	Ti	1983 (1983)
	$S_4N_3^-$	Pt	1981 (1981)
	$\boxed{SN_2^{2-}}$	Hg	1904 (1984)
	$S_3N_2^{2-}$	Pd	1966 (1982)

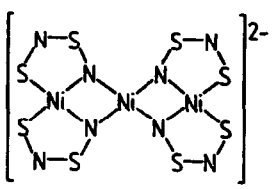
[a] The rings are represented as structural frameworks showing those atoms which are bonded to each other on the basis of X-ray structural data, since it is unlikely that valence bond structures give an adequate description of the bonding in these π-electron-rich systems.

[b] Only the species in boxes are known as the free anions.

It seems reasonable to conclude that the formation of mononuclear MS_2N_2 rings from low-valent metal complexes involves initial coordination of S_4N_4 to the metal centre, which promotes cleavage of S_4N_4 to S_2N_2 (Section II.2), followed by oxidative addition to the metal.

An anionic nickel complex containing two $S_2N_2^{2-}$ chelate ligands has been prepared by a different approach. $Ni(S_2N_2H)_2$ is deprotonated by KOH in methanol to give red $K_2[Ni(S_2N_2)_2]$.[154] Monoanions of $Ni(S_2N_2H)_2$, which also contain an $S_2N_2^{2-}$ ligand, will be discussed in Section VI.2.C.

Recently a number of complexes have been reported in which one of the metal-bonded nitrogens of each MS_2N_2 ring is also coordinated to a second metal centre to give a dimer (**24**). An anionic complex of this type, $K_2[(NiS_2N_2)_2(CN)_2]$, which is readily converted to the crystalline Ph_4As^+ salt, was prepared from $Ni(S_2N_2H)_2$ and KCN in MeOH in the presence of $KHCO_3$.[155] The mononuclear complex $K[(CN)_2NiS_2N_2H]$ is obtained in the absence of $KHCO_3$.



Neutral dinuclear MS_2N_2 complexes have been described for Ni, Pd and Pt. Treatment of $[(Ph_3P)_2Ni(C_3Ph_3)][ClO_4]$ with S_4N_4 in CH_2Cl_2 gives red-brown $[(Ph_3P)NiS_2N_2]_2$ (**24**) (M = Ni, L = Ph_3P) in low yield.[156] The analogous palladium complex is obtained in 50% yield from

$(Ph_3P)_2Pd(C_2H_4)$ and S_4N_4:[156]

$$2(Ph_3P)_2Pd(C_2H_4)+S_4N_4 \rightarrow [(Ph_3P)PdS_2N_2]_2+2Ph_3P+C_2H_4.$$

The products isolated from the platinum(0)–S_4N_4 system are dependent on reaction conditions. As indicated above, the yellow mononuclear complex $(Ph_3P)_2PtS_2N_2$ is formed from $(Ph_3P)_2Pt(C_2H_4)$ and S_4N_4 in a 2:1 molar ratio in CH_2Cl_2–ether.[152] When the reaction is carried out in THF or benzene using a 1:1 molar ratio, the red-brown dinuclear complex $[(Ph_3P)PtS_2N_2]_2$ (**24**) (M = Pt, L = Ph_3P) and a yellow complex, tentatively identified as $(Ph_3P)_3(PtS_2N_2)_2 \cdot C_6H_6$, were obtained.[156] By contrast, two poorly characterized compounds formulated as $(Ph_3P)_2PtS_2N_2$ and $(Ph_3P)_2Pt(S_4N_4)$ were obtained from the reaction of $(Ph_3P)_4Pt$ and S_4N_4 in benzene.[69*] It is well known, however, that $(Ph_3P)_4Pt$ dissociates to give free Ph_3P in solution and the reaction of Ph_3P with S_4N_4 in benzene produces the red compound $Ph_3P{=}N{-}S_3N_3$.[157] The formation of the latter compound as one of the products of the $(Ph_3P)_4Pt$–S_4N_4 reaction has been confirmed recently.[158]

An interesting trinuclear anion containing MS_2N_2 units (**26**) was described by Weiss in 1984. $Ni(S_2N_2H)_2$ reacts with $NiCl_2 \cdot 6H_2O$ in methanol in the presence of Ph_4POH to give crystalline $[Ph_4P]_2[Ni_3(S_2N_2)_4]$.[159]

26

VI.1.*B. Structural studies.* The structures of four transition-metal complexes of the $S_2N_2^{2-}$ ion have been determined by X-ray crystallography. The bond lengths and bond angles for these cyclometallathiazenes are compared in Table 11 with the corresponding data for PbS_2N_2 and $PbS_2N_2(NH_3)$, the latter being more reliable. Although the uncertainties are large for several of these structures, the S–N bond lengths exhibit similar trends with the exception of $(Ph_3P)_2PtS_2N_2$. The S(1)–N(1) distances (1.65–1.78 Å) are significantly longer than the S(2)–N(1) (1.56–1.58 Å) and S(2)–N(2) bond lengths (1.51–1.55 Å) indicating a localization of π-bonding within the thiazene unit. The former distance approximates to a single bond whereas the latter two are close to double-bond values.

VI.2. MS_2N_2H

Complexes of the hypothetical $[S_2N_2H]^-$ anion represent the largest and best characterized group of S–N ring systems containing a transition metal. The preeminent example is $Ni(S_2N_2H)_2$, which was discovered in 1953 by Goehring and Debo.[15] The reaction of $Ni(CO)_4$ with S_4N_4 produced an amorphous black material which, on extraction with organic solvents, yielded a soluble purple complex formulated as $Ni(NS)_4$, "nickel tetrathionitrosyl".[15,16] Subsequently, Piper[13,14] demonstrated the presence of N–H in this complex by IR and ^1H NMR spectroscopy. Chemical evidence was also consistent with the existence of an acidic proton.[13,14,160]

VI.2.*A. Preparation.* Complexes of the type $M(S_2N_2H)_2$ are known for Co, Ni, Pd and Pt. All four compounds are usually prepared from S_4N_4 and the anhydrous metal chlorides, but there are differences in the experimental details especially for the Pt derivative and some improvements in the established procedures have been reported recently.[161] $Ni(S_2N_2H)_2$ is readily obtained in 50–70% yields from the reaction of S_4N_4 with anhydrous $NiCl_2$ in methanol.[19,161,162] The hydrated salt, $NiCl_2 \cdot 6H_2O$, has also been used for this synthesis, but no yields were given.[163] In a similar manner $Co(S_2N_2H)_2$[15,19,160,161] and $Pd(S_2N_2H)_2$[161] are prepared in 23 and 26% yields, respectively, from $CoCl_2$

* The formulation $(Ph_3P)_2PtS_2N_2$ is based on analytical data (C, H, N and S) which are well outside of the normally acceptable limits for satisfactory analyses.

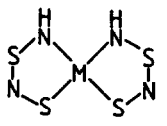


Table 11. X-ray structural data for MS_2N_2 rings

Bond distance (Å)	M = Pb[a]	M = Pb(NH$_3$)[a]	M = Co(C$_5$H$_5$)[b]	M = Pt(PPh$_3$)$_2$[c]	M–L = Ni–CN$^-$[d]	M–L = Pt(PPh$_3$)[e]

or $PdCl_2$ and S_4N_4 in methanol. The preparation of $Pt(S_2N_2H)_2$ from $PtCl_2$ and S_4N_4 was found to be unreliable because of the varying quality of commercial $PtCl_2$.[161] It was first prepared from H_2PtCl_6 and S_4N_4 in aqueous DMF,[164,165] but the most convenient synthesis involves the reaction of Na_2PtCl_6 with S_4N_4 in boiling methanol in the presence of $Na_2S_2O_4$. This method produces blue, crystalline $Pt(S_2N_2H)_2$ in 15% yield. The $M(S_2N_2H)_2$ complexes are usually isolated by preparative TLC or column chromatography on silica gel in order to separate them from the by-products $M(S_2N_2H)(S_3N)$ and $M(S_3N)_2$ (Section VI.3).

VI.2.*B. Structural and spectroscopic studies.* The structures of $Ni(S_2N_2H)_2$ (α-[166] and β-[163] modifications), $Pd(S_2N_2H)_2$[166] and $Pt(S_2N_2H)_2$[167,168] have been determined by X-ray crystallography. The MS_2N_2H units are planar and the hydrogen atom is bonded to the nitrogen atom that is coordinated to the metal. Two structural isomers, *cis* (**27**), and *trans* (**28**), are possible for $M(S_2N_2H)_2$ but only the *cis*-configuration has been found. The greater stability of the *cis* isomers is consistent with CNDO MO calculations for $Ni(S_2N_2H)_2$ and $Pd(S_2N_2H)_2$.[169]

27

28

Calculations of atomic-charge densities in $Ni(S_2N_2H)_2$ indicate that the nitrogen attached to Ni has a lower negative charge than the other nitrogen atom while the sulphur attached to the metal is less positively charged than the other sulphur. This prediction is in agreement with the core binding energies for $Ni(S_2N_2H)_2$ determined by X-ray photoelectron spectra.[170,171] For the palladium complex, however, there is a disagreement between the calculated and experimental charge densities.[169,172]

The mass spectra of $M(S_2N_2H)_2$ (M = Co, Ni, Pd or Pt) show the parent molecular ions, thus confirming the $M(S_2N_2H)_2$ stoichiometry. The predominant fragmentation pattern is the successive loss of SN units.[173]

An ESR spectrum has been obtained for $Co(S_2N_2H)_2$ and detailed studies have revealed the presence of a spin equilibrium between high- ($S = \frac{3}{2}$) and low-spin ($S = \frac{1}{2}$) cobalt(II).[161]

^1H and ^{13}C NMR spectra have been reported for a number of tricyclic derivatives of $Ni(S_2N_2H)_2$ in which the hydrogen atoms have been substituted by bridging organic groups.[174]

The near- and far-IR and Raman spectra of $M(S_2N_2H)_2$ (M = Co, Ni, Pd or Pt),[161,173,175,176] $Ni(S_2N_2H)(S_2N_2CH_3)$[176] and *trans*-$Ni(S_2N_2CH_3)_2$[176,177] have been studied in detail. Isotope shift data for $Co(S_2N_2D)_2$,[176] $Ni(S_2N_2D)_2$,[176,177] $^{62}Ni(S_2N_2H)_2$[177] and $^{62}Ni(S_2N_2CH_3)_2$[177] have been obtained to aid in the vibrational assignments.

The electronic spectra of $M(S_2N_2H)_2$ (M = Co, Ni, Pd or Pt) have been measured and the absorption maxima were found to be independent of solvent.[161] The high extinction coefficients suggest that the observed transitions arise from ligand-localized electrons. On the basis of studies of the resonance Raman spectrum of $Ni(S_2N_2H)_2$, the absorption maximum at 570 nm was assigned to a metal-to-ligand charge-transfer transition.[178] It should be noted that CNDO calculations for the free ligand $[S_2N_2H]^-$ indicate the presence of low-lying π^*-orbitals on the ligand.[161]

VI.2.*C. Reactions.* The $M(S_2N_2H)_2$ complexes undergo a variety of reactions that are largely dependent on the reactivity of the NH protons. These reactions are conveniently divided into three types: (a) deprotonation, (b) substitution of imide protons, and (c) displacement of $[S_2N_2H]^-$. Since $Ni(S_2N_2H)_2$ is more readily available in large quantities than the Co, Pd or Pt derivatives, most of the reactions have been carried out with the Ni complex. Only four derivatives of $Co(S_2N_2H)_2$ are known and no reactions of $Pd(S_2N_2H)_2$ or $Pt(S_2N_2H)_2$ have been reported.

(a) *Deprotonation*

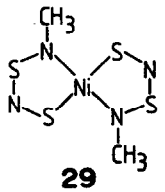
The NH protons in $Ni(S_2N_2H)_2$ are acidic and can be determined quantitatively by titration with MeMgI.[160] Piper determined the pK_1 value to be 10.9 by titration of $Ni(S_2N_2H)_2$ with NaOH in ethanol–water (2:1).[13] The first crystalline products of deprotonation were described recently by Weiss.[154] Double deprotonation occurs with KOH in methanol to give the red salt $K_2[Ni(S_2N_2)_2]$ (Section VI.1). Crystalline brown salts of the monoanion $[Ni(S_2N_2H)(S_2N_2)]^-$ are obtained when

$Ni(S_2N_2H)_2$ is deprotonated with R_4NOH (R = Me, Et or *n*-Bu) or Ph_4EOH (E = P or As).[154] Protonation of the mono- or dianions regenerates $Ni(S_2N_2H)_2$:

$$Ni(S_2N_2H)_2 + OH^- \rightarrow [Ni(S_2N_2H)(S_2N_2)]^- + H_2O,$$

$$Ni(S_2N_2H)_2 + 2OH^- \rightarrow [Ni(S_2N_2)_2]^{2-} + 2H_2O.$$

The X-ray crystal structure of $[Ph_4As][Ni(S_2N_2H)(S_2N_2)]$ has been determined.[154] The structural parameters are very similar to those of the parent molecule $Ni(S_2N_2H)_2$.[163,166]

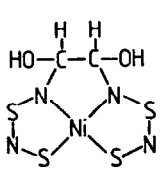


$Ni(S_2N_2H)_2$ also reacts with methyl-lithium[179,180] or silver nitrate,[179,181] to give uncharacterized lithium and silver salts of the anions $[Ni(S_2N_2H)(S_2N_2)]^-$ and $[Ni(S_2N_2)]^{2-}$, which have been used in substitution reactions (*vide infra*).

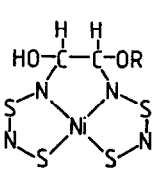
(b) *Substitution of imide protons*

The NH protons in $Ni(S_2N_2H)_2$ are readily substituted by organic groups and more than 30 derivatives have been synthesized. In addition to mono- and disubstitution products there are a number of tricyclic compounds in which both hydrogen atoms are replaced by a bridging organic group. These are all listed in Table 12, which also indicates those derivatives for which X-ray structural data are available.

Both $Ni(S_2N_2H)_2$ and $Co(S_2N_2H)_2$ can be deuterated by treatment with a large excess of D_2O in THF. The products, $Ni(S_2N_2D)_2$[175,176] and $Co(S_2N_2D)_2$[176] have been used in studies of the vibrational spectra of these complexes.

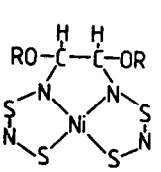


The simple alkyl derivatives $Ni(S_2N_2H)(S_2N_2CH_3)$, $Ni(S_2N_2H)(S_2N_2C_2H_5)$ and $Ni(S_2N_2CH_3)_2$ have been prepared by the reaction of an intermediate silver salt, formulated as "$(Ni(S_2N_2Ag)_2$", with the appropriate alkyl iodide.[180] The dimethyl derivative, $Ni(S_2N_2CH_3)_2$, is also obtained by treatment of $Ni(S_2N_2H)_2$ with KOH and methyl iodide in THF[177] and deserves special mention because it is the only structurally characterized $M(S_2N_2R)_2$ derivative with a *trans*-configuration (**29**).[180]



29

Both mono- and dibenzoyl derivatives, as well as small amounts of $Ni(S_2N_2C_6H_5)(S_2N_2H)$, are obtained on addition of benzoyl chloride to "$Ni(S_2N_2Li)_2$".[181] $Ni(S_2N_2C(O)NHC_6H_5)(S_2N_2H)$ has been synthesized from $Ni(S_2N_2H)_2$ and C_6H_5NCO and characterized by an X-ray structure analysis.[182] Two different monosubstitution products have been isolated from $Ni(S_2N_2H)_2$ and formaldehyde. In acetone solution $Ni(S_2N_2CH_2OH)(S_2N_2H)$ is formed.[183] When the reaction is carried out in methanol one solvent molecule is incorporated to give $Ni(S_2N_2CH_2OCH_3)(S_2N_2H)$, which has been characterized by X-ray diffraction.[184]



The largest group of $Ni(S_2N_2H)_2$ derivatives are tricyclic compounds in which the NH protons are replaced by a bridging group. The additional ring can have five, six or seven members. The tricyclic complexes **30**, **31** and **32** are obtained from $Ni(S_2N_2H)_2$ and glyoxal under various conditions (**31** and **32** are formed in the presence of alcohols).[174,183,185,186] The Co analogue of **30** has also been reported.[183] During chromatography on alumina the complexes **31** eliminate water to give **33**.

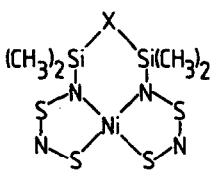
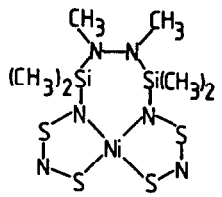
As a result of the two chiral carbons in the bridging group, the complexes **30–32** have diastereomers, which have been separated into their *meso* and *racemic* forms by chromatography on silica gel in the case of **32a**[174,185] and **32b**.[185]

Tricyclic compounds with a nitrogen-containing bridge (**34**) have been prepared by the condensation reaction of $Ni(S_2N_2H)_2$ with formaldehyde in the presence of primary amines[174,183,187–190] or methanol and ammonia [**34d** (R = CH_3OCH_2)].[188,189] Complex **35** is obtained similarly from $Ni(S_2N_2H)_2$ and acetaldehyde in the presence of ammonia.



34

a R=CH_3
b R=C_2H_5
c R=$CH_2C_6H_5$
d R=CH_2OCH_3



35

Finally, several tricyclic complexes with a silicon-containing bridging group have been reported.[191,192] Derivatives of type **36** are obtained by the reaction of $M(S_2N_2H)_2$ (M = Co or Ni) with 1,3-dichlorodisiloxanes or 1,3-dichlorodisilazanes in THF. Compound **37** was prepared similarly from $Ni(S_2N_2H)_2$ and 1,2-bis(chlorodimethylsilyl)dimethyl-hydrazine.

37

(c) *Displacement of* $[S_2N_2H]^-$

There are a few examples of reactions in which the $[S_2N_2H]^-$ ligand is displaced from the metal site. A complex formulated as $(en)_2NiS_2N_2H$ has been obtained from the reaction of $Ni(S_2N_2H)_2$ with ethylenediamine (en) in acetone.[194] The monomeric nature of this complex is questionable in view of its insolubility in organic solvents. The anion $[(CN)_2NiS_2N_2H]^-$, prepared by treatment of $Ni(S_2N_2H)_2$ with KCN in methanol,[155] has been structurally characterized by X-ray crystallography.[195] It was first synthesized from $K_4[Ni_2(CN)_6]$ and S_4N_4 in methanol.[196]

Recently it was found that $Ni(S_2N_2H)_2$ can be a useful precursor for the synthesis of cyclic S–N compounds. The reaction of $Ni(S_2N_2H)_2$ with S_2Cl_2 affords S_4N_2 in 57% yield:[197]

$$Ni(S_2N_2H)_2 + S_2Cl_2 \xrightarrow[Et_3N]{THF} S_4N_2.$$

Similarly, $COCl_2$ and $SOCl_2$ react with $Ni(S_2N_2H)_2$ to give the five-membered ring systems S_2N_2CO and S_3N_2O, respectively.[197]

VI.3. MS_3N

Transition-metal complexes containing the five-membered MS_3N ring are an important and rapidly growing class of cyclometallathiazenes. With the exception of **25** they differ from the other ring systems discussed in this section in the presence of an S–S bond.

VI.3.*A. Preparation.* There are three approaches available for the systhesis of MS_3N derivatives.

(a) *Reactions of* S_4N_4 *with metal halides (or metal carbonyls) in methanol*

This method is not very satisfactory but it is of historical significance. The MS_3N ring system was first discovered in 1958 by Piper,[14] who isolated $Ni(S_2N_2H)(S_3N)$ and $Ni(S_3N)_2$, in addition to

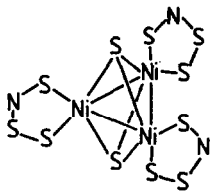
the known complex $Ni(S_2N_2H)_2$ (Section VI.2), by chromatographic separation of the mixture obtained when S_4N_4 reacts with anhydrous $NiCl_2$ in methanol. The yield of $Ni(S_3N)_2$ from 10 g of S_4N_4 was 0.009 g (0.04% based on S)! Subsequently it was found that all preparations of $M(S_2N_2H)_2$ (M = Co, Ni, Pd or Pt) produce small amounts of $M(S_2N_2H)(S_3N)$ and $M(S_3N)_2$.[161,165,198] The following complexes have been isolated from the appropriate reaction mixtures by chromatography on silica gel: $Co(S_2N_2H)(S_3N)$,[165,198] $Co(S_3N)_2$,[165,198] $Pd(S_2N_2H)(S_3N)$,[165] $Pd(S_3N)_2$,[165,198] $Pt(S_2N_2H)(S_3N)$,[161,165] and $Pt(S_3N)_2$.[161,165] Although some improvements in the preparative procedures have been reported,[165] the yields are generally very low.

The unsymmetrical complexes $M(S_2N_2H)(S_3N)$ have been shown to disproportionate on contact with silica or alumina or on heating.[165,198] This disproportionation reaction has been used to prepare pure samples of $M(S_3N)_2$ (M = Co[198] or Pt[165]) that are not accessible by other routes:

$$2M(S_2N_2H)(S_3N) \rightarrow M(S_2N_2H)_2 + M(S_3N)_2.$$

The complex $(NO)_2CoS_3N$ was obtained in 12% yield on treatment of the insoluble black material obtained from the reaction of $Co_2(CO)_8$ and S_4N_4 with nitric oxide.[20]

(b) *Reactions of* S_3N^- *with metal halides*



Crystalline salts of the S_3N^- anion are readily prepared by treatment of $[PPN][S_4N]$[199] or $[Ph_4As][S_4N]$[200] with triphenylphosphine in acetonitrile.[143,144] The metathetical reaction of this anion with metal halides represents the most direct synthesis of the MS_3N system, but this approach is frequently thwarted by competing redox reactions.[144] The reaction of $[PPN][S_3N]$ with $NiBr_2$ in acetonitrile does, however, produce $Ni(S_3N)_2$ in 30% yield, and smaller amounts of $Co(S_3N)_2$ have been obtained by this route.[144] The surprising feature of these reactions is that complexes of the $[S_2N_2H]^-$ anion are also formed as minor products.

Salts of the S_3N^- anion have been used for the synthesis of the first MS_3N rings containing copper or silver.[201] The reaction of $[PPN][S_3N]$ with CuCl in acetonitrile gives good yields of either $[PPN][ClCuS_3N]$ or $[PPN][Cu(S_3N)_2]$, depending on the stoichiometry. The corresponding Ag complex $[PPN][Ag(S_3N)_2]$ was prepared from $AgNO_3$ in a similar manner. Treatment of the anion $[ClCuS_3N]^-$ with triphenylphosphine gives the neutral complex $(Ph_3P)_2CuS_3N$ in 81% yield.[201] The same complexes are obtained when $[PPN][S_4N]$ is used instead of $[PPN][S_3N]$:[202]

$$[PPN][S_3N] + CuCl \rightarrow [PPN][ClCuS_3N] \xrightarrow{2Ph_3P} (Ph_3P)_2CuS_3N + PPNCl.$$

(c) *Reactions of* S_7NH *with metal halides in the presence of a base*

In view of the ready avilability of S_7NH (from the reaction of sodium azide with sulphur in HMPA),[203] this approach potentially provides the easiest access to the MS_3N ring system. It can be regarded as the *in situ* generation of S_4N^-, since this anion is produced on deprotonation of S_7NH with a base.[204] The first application of this method was reported by Weiss in 1982.[205] The trigonal–bipyramidal-cluster anion $[(NiS_3N)_3S_2]^-$ (**38**) was obtained from the reaction of S_7NH with $NiCl_2 \cdot 6H_2O$ in methanol in the presence of KOH. It was isolated and structurally characterized (X-ray) as the black *n*-Bu_4N^+ salt. When $Ni(CN)_2$ was used instead of $NiCl_2$ for this reaction, $K[(CN)_2NiS_3N]$ was isolated in addition to **38**.[206] The crystalline salt $[Me_4N][(CN)_2NiS_3N]$ was also prepared directly from $Ni(CN)_2$, S_7NH and Me_4NCl in methanol in the presence of aqueous ammonia.[206]

38

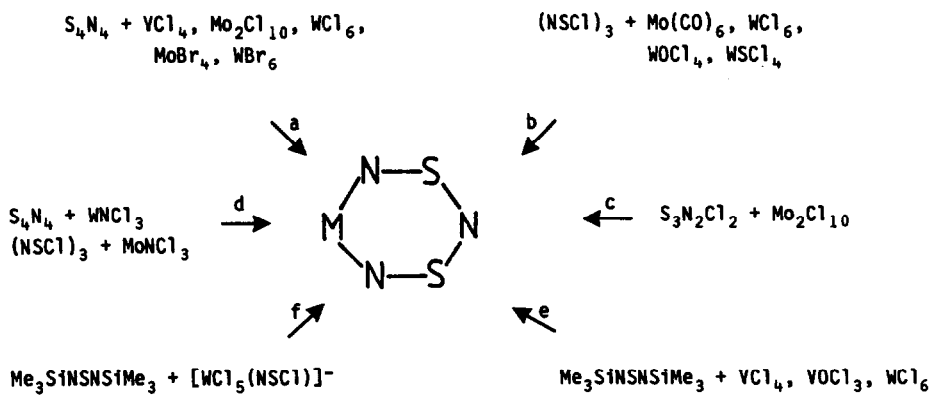
Simple syntheses of $[Ph_4As][ClCuS_3N]$ and $[Ph_4As][Cu(S_3N)_2]$ from S_7NH and $CuCl_2 \cdot 2H_2O$ in the presence of Ph_4AsOH have also been reported.[206] A trigonally coordinated copper complex, $(Ph_3PS)CuS_3N$, was isolated in low yield from the reaction of $(Ph_3P)CuCl$ with S_7NH in methylene chloride (without a base).[207] Finally the gold complex, Cl_2AuS_3N has been prepared in 21% yield by treatment of S_7NH with *n*-BuLi in the presence of $HAuCl_4$ in diethyl ether.[208]

VI.3.*B. Structural studies.* The structures of five MS_3N and two $M(S_3N)_2$ ring systems have been determined by X-ray crystallography and the pertinent bond lengths and bond angles are summarized in Table 13. The bidentate S_3N^- ligand is always bonded to the metal via two sulphur atoms. The MS_3N ring exhibits unequal S–N bond lengths. In most cases the S(1)–N distance is substantially longer than S(2)–N, but the opposite effect is observed for $(Ph_3P)_2CuS_3N$ and $[PPN][Cu(S_3N)_2]$.[201] The reversal of this trend in the latter complex is particularly puzzling since the more usual order, d[S(1)–N] > d[S(2)–N], was found for the Ph_4As^+ salt of the same anion.[206] The S–S bond distances fall within the range 1.95–2.06 Å.

VI.4. MS_2N_3

The discovery of complexes containing the six-membered MS_2N_3 ring is one of the most recent and significant developments in transition-metal S–N chemistry. The first example, polymeric $[Cl_2VS_2N_3]_n$, was reported in 1983 by Roesky *et al.*[51] and it has quickly become apparent that the MS_2N_3 system represents an important class of cyclometallathiazenes.

VI.4.*A. Preparation.* Six different methods have been used to prepare the MS_2N_3 ring and examples of each of these are discussed below and summarized in the following reaction scheme.



(a) *Reactions of* S_4N_4 *with transition-metal halides*

As indicated in previous sections, the reactions of S_4N_4 with transition-metal halides can give rise to a variety of S–N complexes including simple adducts (Section II.3), complexes of S_2N_2 (Section II.2) or cyclometallathiazenes (Sections VI.2, VI.3, VI.6 and VI.8). In certain cases, the MS_2N_3 ring system is formed as the major product.

A black, crystalline polymer $[Cl_2VS_2N_3]_n$ is obtained by heating the crude product from the reaction of VCl_4 with S_4N_4 at 110°C *in vacuo*.[51] The dark brown, microcrystalline dimers $[Cl_3MS_2N_3]_2$ (M = Mo or W) have been synthesized similarly from Mo_2Cl_{10} or WCl_6 and S_4N_4 in methylene dichloride.[210] The anionic complex $[PPN][Cl_4WS_2N_3]$ can be prepared from WCl_6 and S_4N_4 in the presence of PPNCl.[211]

(b) *Reactions of metal carbonyls or halides with* $(NSCl)_3$

The reaction of a metal carbonyl with $(NSCl)_3$ was first described by Wynne and Jolly in 1968.[17] Treatment of $Mo(CO)_6$ with $(NSCl)_3$ in CH_2Cl_2 yielded a dark brown, microcrystalline solid, formulated as $MoS_3N_3Cl_3$ on the basis of chemical analyses. Similar reactions with $Cr(CO)_6$ or

[a] Atomic-numbering scheme:

[b] In $[Ph_4As][Cu(S_3N)_2]$.
[c] In $[PPN][Cu(S_3N)_2]$.

$W(CO)_6$ were reported to give non-stoichiometric products.[17] A recent reinvestigation of these reactions revealed that "$MoS_3N_3Cl_3$" is in fact $[Cl_3MoS_2N_3]_2$.[210] This complex and the W analogue can be isolated in good yields from the reactions of $M(CO)_6$ (M = Mo or W) with $(NSCl)_3$. It appears, however, that the outcome of metal carbonyl–$(NSCl)_3$ reactions depends on subtle variations of experimental details since Dehnicke and co-workers obtained $(\mu\text{-}S_2N_2)[Cl_3MS_2N_3]_2$ (M = Mo or W) from the corresponding metal carbonyls and $(NSCl)_3$ under slightly different conditions.[212] The bromo derivatives $(\mu\text{-}S_2N_2)[Br_3MS_2N_3]_2$ have been prepared from $MoBr_4$ or WBr_6 and S_4N_4.[212]

A quantitative yield of $[Cl_3WS_2N_3]_2$ is obtained when $WOCl_4$ or $WSCl_4$ is allowed to react with $(NSCl)_3$ in CH_2Cl_2.[213] The reaction of $(NSCl)_3$ with excess $VOCl_3$ at 130°C in the absence of a solvent provides an improved synthesis of $[Cl_2VS_2N_3]_n$ in almost quantitative yield.[214] When $(NSCl)_3$ is present in excess, however, a thiazyl chloride adduct of $Cl_2VS_2N_3$ is obtained. This complex has been assigned a dimeric structure on the basis of IR spectroscopic data:[214]

$$VOCl_3 + \tfrac{4}{3}(NSCl)_3 \xrightarrow{CH_2Cl_2} \tfrac{1}{2}[Cl_2VS_2N_3(NSCl)]_2 + SOCl_2 + Cl_2.$$

(c) *Reactions of transition-metal halides with* $S_3N_2Cl_2$

Only one example of the preparation of an MS_2N_3 ring from $S_3N_2Cl_2$ has been reported. When Mo_2Cl_{10} is heated with $S_3N_2Cl_2$ in CH_2Cl_2 a low yield of $[Cl_3MoS_2N_3]_2$ is obtained.[210] In contrast, the analogous reaction of WCl_6 with $S_3N_2Cl_2$ yields $[WCl_4(NSCl)]_2$ (Section III.3.A).

(d) *Reactions of nitrido complexes with* S_4N_4 *or* $(NSCl)_3$

Transition-metal nitrido complexes have been used in two syntheses of MS_2N_3 rings. A quantitative yield of $[Cl_3MoS_2N_3]_2$ is obtained when $MoNCl_3$ is treated with $(NSCl)_3$ in CCl_4.[213] Although $MoNCl_3$ does not react with S_4N_4, the preparation of $[Cl_3WS_2N_3]_2$ from $WNCl_3$ and S_4N_4 in CH_2Cl_2 has been reported.[210] The formation of the WS_2N_3 ring in this reaction can be viewed as the cycloaddition of $WNCl_3$ with S_2N_2 (generated as an intermediate by cleavage of S_4N_4).[210]

(e) *Reactions of transition-metal halides with* $Me_3SiNSNSiMe_3$

Bis(trimethylsilyl)sulphur diimide ($Me_3SiNSNSiMe_3$) is a convenient reagent for the synthesis of certain MS_2N_3 rings from the appropriate transition-metal halide.[210] The reaction of WCl_6 with $Me_3SiNSNSiMe_3$ yields $[Cl_3WS_2N_3]_2$ as the major product, identified by conversion to the anion $[Cl_4WS_2N_3]^-$ by treatment with Ph_4AsCl (*vide infra*). Under identical conditions, Mo_2Cl_{10} gives $MoNCl_3$ and only a trace of $[Cl_3MoS_2N_3]_2$. The polymer $[Cl_2VS_2N_3]_n$ is obtained from $Me_3SiNSNSiMe_3$ and VCl_4 or $VOCl_3$ in CH_2Cl_2.[210]

(f) *Cyclization of transition-metal halide–*NSCl *complexes with* $Me_3SiNSNSiMe_3$

The cyclization of complexes of the type $MCl_x(NSCl)$ by treatment with $Me_3SiNSNSiMe_3$ potentially represents a controlled synthesis of the MS_2N_3 ring. One example, the reaction of $[Ph_4As][WCl_5(NSCl)]$ with $Me_3SiNSNSiMe_3$ in CH_2Cl_2 to give $[Ph_4As][Cl_4WS_2N_3]$ in 51% yield, has been reported.[210]

The known cyclometallathiazenes of type MS_2N_3 and the methods used in their preparation are summarized in Table 14.

VI.4.*B. Structural and spectroscopic studies.* The X-ray crystal structures of three monomeric (**39**) and two dimeric MS_2N_3 systems (**40** and **41**) have been reported. The structural data are compared with those of the related heterocycle $Ph_2PS_2N_3$ in Table 15. The thiazene segment of the ring in the three mononuclear complexes and in $[Cl_2VS_2N_3]_n$, like that in $Ph_2PS_2N_3$,[216] is planar while the metal atom is tilted out of the plane. The VS_2N_3 ring in $[Ph_4As]_2[\{VS_2N_3(N_3)_3\}_2] \cdot CH_2Cl_2$ is entirely planar.[214] The endocyclic bond angles at the metal in the MS_2N_3 are in the range 93–96° reflecting the octahedral geometry at the metal centre, whereas the bond angle at the approximately tetrahedral phosphorus atom in $Ph_2PS_2N_3$ is 115.8(2) Å. Consequently, the angles at the metal-bonded nitrogens in MS_2N_3 (129–141°) are substantially larger than the corresponding bond angles

Table 14. Preparative methods for MS_2N_3 rings

[a] Complexes obtained by the reactions of certain MS_2N_3 systems with Cl^- or MeCN are discussed in Section VI.4.C.

[b] See Section VI.4.A for description of methods a–f.

(120–121°) in $Ph_2PS_2N_3$. Nevertheless, the average S–N bond distance (1.58–1.59 Å) is similar to that in $Ph_2PS_2N_3$ [d(S–N) = 1.575 Å] for all MS_2N_3 systems and the bond angles at the unique nitrogen (125–129°) are uniformly larger than the bond angles at sulphur (108–118°). Calculations of the π-charge density in the model compound $H_2PS_2N_3$ suggest that the internal salt model $[H_2P]^+[S_2N_3]^-$ is a useful approximate description. However, NMR studies (^{51}V or ^{95}Mo) and magnetic susceptibility measurements of MS_2N_3 systems indicate oxidation states of +5 for V and +6 for Mo and W.[210] Thus these cyclometallathiazenes should be regarded as complexes of the hypothetical trianion $S_2N_3^{3-}$.

The IR spectra of MS_2N_3 complexes have been discussed elsewhere in detail.[210,213,214] This information has been used to deduce a dimeric structure for $[Cl_2VS_2N_3(NSCl)]_2$ {**40** [M = V(NSCl), X = Cl]},[214] and different dimeric structures [**40** (MX = $MoCl_3$, X = Cl) and **41** (M = WCl_3)], for $[Cl_3MS_2N_3]_2$.

VI.4.*C. Reactions.* A characteristic reaction of the cyclometallathiazenes $Cl_xMS_2N_3$ is the addition of chloride ions to give anionic complexes, which are frequently more tractable than their neutral precursors. Both mononuclear and dinuclear anionic complexes have been prepared in this way:[210,213,214]

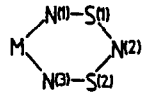
$$[Cl_3MS_2N_3]_2 + 2Ph_4ECl \xrightarrow{CHCl_3} 2[Ph_4E][Cl_4MS_2N_3],$$

where M = Mo or W, and E = P or As.

$$\frac{2}{n}[Cl_2VS_2N_3]_n + 2Ph_4AsCl \rightarrow [Ph_4As]_2[(Cl_3VS_2N_3)_2].$$

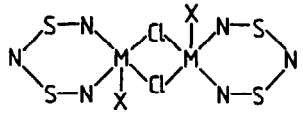
On the basis of IR data the anion $[(Cl_3VS_2N_3)_2]^{2-}$ was assigned a nitrogen-bridged dimeric structure [**41** (M = VCl_3^-)], analogous to the structurally characterized azido complex {**41** [M = $V(N_3)_3]^-$}, which is obtained by treatment of $[Ph_4As]_2[(Cl_3VS_2N_3)_2]$ with a slurry of silver azide in CH_2Cl_2. The black, crystalline azido complex is not shock-sensitive, but explodes on heating.

The dimers $[Cl_2MS_2N_3]_2$ (M = Mo or W) also reacts with acetonitrile to give crystalline, monomeric adducts of type $Cl_3MS_2N_3(CH_3CN)$.[210,215]



VI.5. MS_3N_4

The only example of the eight-membered MS_3N_4 ring system, in which one sulphur atom of S_4N_4 is replaced by a transition metal, was isolated from the following reaction in 16% yield (after chromatography) by Oakley *et al.* in 1983:[217]



$$Cp_2Ti(CO)_2 + S_4N_4 \xrightarrow{THF} Cp_2TiS_3N_4.$$

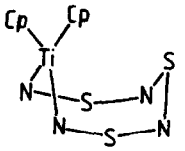
39

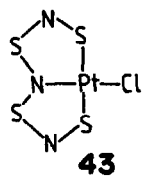


40

41

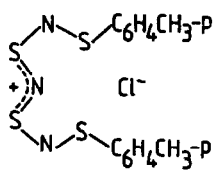
This synthesis can be viewed as an oxidative-addition reaction of a low-valent, early-transition-metal complex to give a titanium(IV) complex of the acyclic $S_3N_4^{2-}$ anion. The latter species is unknown as the free anion but the trimethylsilyl derivative, $Me_3SiNSNSNSNSiMe_3$, has been prepared.[218]

The cyclometallathiazene $Cp_2TiS_3N_4$ (**42**) is structurally related to $S_4N_4O_2$.[219] Both eight-membered rings adopt a boat conformation that is less puckered in $Cp_2TiS_3N_4$ than in $S_4N_4O_2$. The variations in S–N bond lengths suggest a somewhat different electronic structure in the two rings.[217]



42

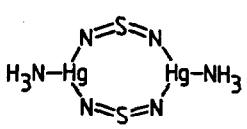
VI.6. MS_4N_3



The only representative of the MS_4N_3 ring system, $ClPtS_4N_3$ (**43**), was prepared in 1981 in 10% yield by the following reaction:[220]

$$cis\text{-}PtCl_2(NCC_6H_5)_2 + S_4N_4 \xrightarrow[\text{reflux}]{\text{toluene}} ClPtS_4N_3.$$

The MS_4N_3 ring is formally derived from the hypothetical $S_4N_3^-$ ion, which is coordinated to platinum as a tridentate ligand via the two terminal sulphur atoms and the central nitrogen atom (**43**). A very similar geometry was found for the S_4N_3 unit in 1,7-di-*p*-tolyltetrasulphurtrinitrogen chloride (**44**).[221] The $ClPtS_4N_3$ molecule is planar and forms stacks along the *a* axis, but there are no significant interactions between neighbouring molecules.

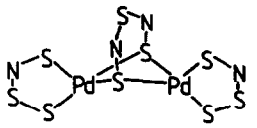


43

44

VI.7. $M_2S_2N_4$

In 1904 the reaction of HgI_2 with S_4N_4 in liquid ammonia was reported to give a yellow, crystalline product of empirical formula $HgN_2S \cdot NH_3$.[146] Eighty years later Weiss and Martan[222] showed that this product is in fact a mercury(II) derivative of the SN_2^{2-} anion, which has recently been characterized as its potassium salt, K_2SN_2.[145] The molecule consists of a planar eight-membered ring in which two Hg atoms are bridged by —NSN— units (**45**). Each Hg atom is bonded to an NH_3 ligand, and the nitrogen atoms of these ligands lie on opposite sides of the molecular plane. In addition, each Hg atom is linked to a nitrogen atom of an adjacent ring to give a two-dimensional network. The Hg–Hg distance of 3.106 Å is slightly longer than that in α-Hg.

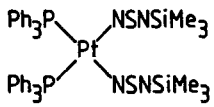


45

There are no transition-metal analogues of this ring system, but the recently described *cis*-$Pt(NSNSiMe_3)_2(PPh_3)_2$[223] could prove to be a useful precursor for the synthesis of such bimetallic cyclometallathiazenes.

VI.8. $M_2S_3N_2$

The reactions of transition-metal halides with S_4N_4 in methanol usually produce $M(S_2N_2H)(S_3N)$ and $M(S_3N)_2$ (M = Co, Ni, Pd or Pt) as minor products in addition to $M(S_2N_2H)_2$ (Section VI.2.A). In the case of Pd, Weiss and Thewalt[198] reported the formation of a red product formulated as "PdS_4N_2". The same product was also observed by other workers in the reaction of $PdCl_2$ with S_4N_4,[161] but it was not characterized further until an X-ray structural analysis in 1982 revealed it to have the composition $(S_3N)_2Pd_2S_3N_2$ (**46**).[224]



46

This molecule consists of two PdS_3N rings bridged by the two terminal sulphur atoms of a planar S_3N_2 unit. The coordination around the Pd atoms is approximately square planar, but the small PdSPd angles [77.1(1)°] and the Pd–Pd distance of 2.921(2) Å (cf. 2.751 Å in metallic Pd) indicate a significant Pd–Pd interaction.

No other complexes of the hypothetical $S_3N_2^{2-}$ ion have been described.

VI.9. *Related complexes*

The reaction of $(Ph_3P)_2Pt(C_2H_4)$ with $Me_3SiNSNSiMe_3$ in benzene produces the square planar complex *cis*-$Pt(NSNSiMe_3)_2(PPh_3)_2$ (**47**) in 44% yield.[223]

47

In view of the well-known reactivity of Si–N linkages towards metal halides, this complex offers obvious potential for the synthesis of novel cyclometallathiazenes.

Finally, it should be mentioned that a brown crystalline product formulated as $NiSN_3[P(OPh)_3]_2 \cdot 2H_2O$ (on the basis of analytical data) was isolated from the reaction of $Ni[P(OPh)_3]_4$ with S_4N_4 in benzene.[225] This compound is not well-characterized and awaits structural conformation. It is considered formally to be a Ni(II) complex of the hypothetical SN_3^{2-} ion,[225] and, as such, it would represent the only example of a cyclometallathiazene derived from a *paramagnetic*, binary S–N anion (Table 10).

VII. SUMMARY AND FUTURE PROSPECTS

Although considerable progress has been made in the synthesis and structural determination of transition-metal complexes of inorganic S–N ligands, particularly in the last 5 years, the subject is still at an early stage of development. A large number of complexes have been structurally characterized, but little is known about their electronic structures or chemical reactivity. A change in the emphasis of investigations from the synthesis of novel systems with unusual structures towards an understanding of the unique properties which S–N ligands confer on metal sites could advance the topic from the status of "chemical curiosities" to the forefront of coordination chemistry. The current interest in the role of coordination complexes of sulphur ligands in certain areas of bioinorganic chemistry and heterogeneous catalysis provides an incentive for such studies. The following avenues of investigation are likely to be fruitful in achieving a more prominent role for cyclometallathiazenes: (a) MO calculations of electronic structures; (b) electrochemical studies of redox behaviour; (c) investigation of reactivity towards electrophiles, nucleophiles and unsaturated substrates; and (d) preparation and catalytic activity of heterobimetallic or metal cluster complexes

containing S–N ligands. The directed synthesis of transition-metal–S–N polymers with interesting solid-state properties is another exciting possibility.

STUDIES ON THE MIXED-LIGAND COMPLEXES OF CADMIUM–IMIDAZOLE–CITRATE SYSTEMS USING DIFFERENTIAL-PULSE POLAROGRAPHY

A. M. Y. JABER

University of Petroleum and Minerals, UPM, Box No. 650, Dhahran 31261, Saudi Arabia

(*Received* 26 *September* 1985; *accepted* 6 *November* 1985)

Abstract—Differential-pulse polarography has been used to study the simple and mixed-ligand complexes of cadmium–imidazole–citrate systems in solution. Using the graphical DeFord–Hume and Schaap–McMasters treatments the overall stability constants, β_{ij}, for the mixed-ligand complexes were found to be: $\log \beta_{11} = 5.89$, $\log \beta_{12} = 6.38$, $\log \beta_{21} = 7.38$, $\log \beta_{22} = 7.08$, $\log \beta_{31} = 8.38$, and $\log \beta_{41} = 9.00$. The equilibria between the various mixed-ligand species coexisting in the solution together with their stepwise stability constants are also given.

Imidazole is an important material in biological systems since it is the nucleus in the amino acid histidine which, in turn, binds to metal ions in several metalloproteins, such as haemoglobin. The complexing properties have therefore been widely studied. For example, among the electroanalytical methods, successive association constants of imidazole with some transition-metal ions have been investigated using potentiometric[1–7] or polarographic methods.[8–13] Potentiometry was utilized for imidazole complexes with cadmium,[2–4], copper,[3–7] nickel,[1,3,7] cobalt,[3,7], zinc[3,5,7] and manganese(II).[3,7] On the other hand, conventional dc polarography was used to evaluate the consecutive stability constants of imidazole with cadmium[8–10] and copper.[8] The stability constants of the mixed-ligand complexes of cadmium,[11] copper[8] and europium[12] in the presence of tartrate and succinate, respectively, have also been reported.

This study concerns the consecutive stability constants for the simple and mixed-ligand complexes of Cd–imidazole–citrate systems using differential-pulse polarography. The graphical method of DeFord and Hume[14] has been used in assessing the stability constants of the simple complex (Cd–imidazole and Cd–citrate) systems, and the Schaap–McMasters[15] graphical method has been used to assess the stability constants of the mixed-ligand complexes (Cd–imidazole–citrate system).

THEORY OF STABILITY CONSTANT DETERMINATION

Heath and Hefter[16] have modified the DeFord–Hume treatment for determining the consecutive stability constants for the simple complexes for use with differential-pulse polarography instead of conventional dc polarography. In this modification, it is assumed that the shift in the half-wave potential, $(E_{1/2})_s - (E_{1/2})_c$, is equal to the shift in the differential-pulse peak potential, $(E_p)_s - (E_p)_c$ (the subscripts s and c refer to the simple and complex ions, respectively). Thus, the modified DeFord–Hume $F_0(X)$ is expressed as follows:

$$F_0(X) = \sum \beta_n C_L^n$$

$$= \text{antilog} \left\{ 0.434 \frac{nF}{RT} [(E_p)_s - E_p)_c] + \log (i_p)_s/(i_p)_c \right\},$$

where β_n is the overall stability constant for the nth complex, C_L is the analytical concentration of the ligand which is always taken in large excess over the metal ion concentration, and is, therefore, considered as the total ligand concentration, and i_p is the peak height of the differential-pulse wave. Apart from this modification, the DeFord–Hume treat-

ment for consecutive stability constant evaluation was followed.

Similarly, the Schaap and McMasters function, $F_{00}(XY)$,[15] might be modified for differential-pulse polarography:

$$F_{00}(XY) = \beta_{MX_iY_j}[X]^i[Y]^j$$

$$= \text{antilog}\left[\frac{0.434nF}{RT}\Delta E_p + \log\,(i_p)_s/i_p)_c\right],$$

where $\beta_{MX_iY_j}$ is the stability constant of the mixed-ligand complex, involving ligands X and Y. The concentration of one of the ligands is kept constant while the other is varied. The concentration of each ligand should individually be in excess with respect to the analytical concentration of the metal ion. i and j refer to the number of ligands associated in each mixed-ligand complex. Stability constants of the mixed-ligand complexes can then be determined as described by Schaap and McMasters.

EXPERIMENTAL

Polarograms were recorded by the Princeton Applied Research Polarographic Analyzer Model PAR 274A in conjunction with the EG and G Static Mercury Electrode Model 303 with a three-electrode system (Pt wire counter electrode and Ag–AgCl reference electrode) and X–Y recorder (Re 0074). The differential pulse mode was used with a modulation amplitude of 25 mV, scan rate of 2 mV s^{-1}, drop time of 0.5 s, and a full-scale sensitivity of 1 μA.

A glass double-walled cell was used with thermostated water circulating at 25±0.1°C. Sample solutions were purged with nitrogen gas for 8 min. The nitrogen was passed through a bottle containing vanadyl chloride solution followed by another containing distilled water for it to be saturated with water vapour.

General reagent grade imidazole, analytical reagent grade cadmium nitrate and trisodium citrate (Fischer), polarographic grade sodium nitrate and mercury (Merck), and deionized double distilled water were used.

Sample solutions (20.0 cm^3) were 1.0 mol dm^{-3} with respect to sodium nitrate for maintaining the ionic strength, 2.0×10^{-5} mol dm^{-3} with respect to cadmium nitrate, and of variable concentrations with respect to either imidazole (0.0–1.8 mol dm^{-3}) or trisodium citrate (0.0–0.90 mol dm^{-3}) for the simple complex systems. For the mixed-ligand complexes, polarograms were recorded for three series of solutions containing fixed citrate concentrations of 0.10, 0.20 and 0.45 mol dm^{-3}, with the imidazole concentration being varied in each case in the range 0.0–0.50 mol dm^{-3}. Imidazole of appropriate concentrations was either added to separate sample solutions or spiked into the same sample solution.

RESULTS AND DISCUSSION

Cd–imidazole system

E_p and i_p (for five sample solutions), were in the range 0.614–0.624 V (0.619±0.0043 V) and 120.7–129.5 divisions (125.8±3.2 divisions), respectively. Each 25.5 divisions correspond to 0.1 μA. It has been reported[8,11] that the polarographic reduction of Cd–imidazole complexes in potassium nitrate medium is reversible, with $n = 2$. The reversibility is confirmed in this study by measuring the half-peak width of the differential-pulse polarograms. Values of 51–52 mV were found for all of the polarograms recorded for either Cd or Cd–imidazole in 1.0 mol dm^{-3} sodium nitrate medium. This is consistent with the prediction of Parry and Osteryoung[17] where, for a fully reversible two-electron reduction with an applied-pulse amplitude of 25 mV, there will be a peak width of 49.5 mV.

Figure 1 shows that the maximum number of imidazole ligands associated with cadmium in the concentration range 0.0–1.8 mol dm^{-3} imidazole is 6, indicating that six stability constants can be determined. However, except for one[10] of the pre-

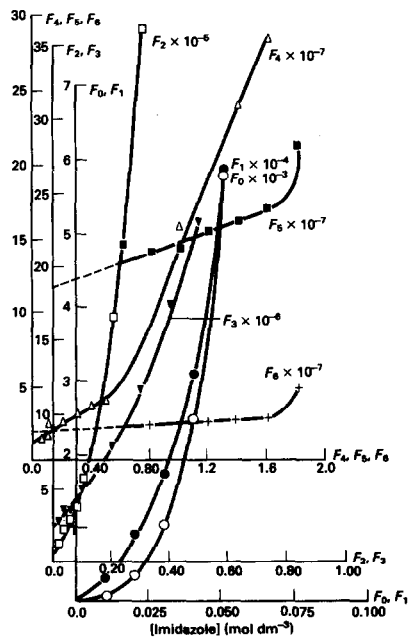

Fig. 1. Plots of the simple functions, F_i, vs imidazole concentration.

2.78	4.85	6.43	7.15	8.08	7.18	This study

[a]This study was carried out using potentiometry, while the remaining literature data were obtained with conventional dc polarography.

vious studies,[4,8,11] only four stability constants have been reported. Table 1 shows that the values of the consecutive stability constants obtained in this study are comparable with those obtained previously.[4,8,10,11] However, the β_6 for $Cd(imid)_6$ is much less than that obtained by Jensen.[10] This may be due to the activity effect, since Jensen's main concern was to determine the activity coefficients at the various imidazole concentrations and then to use them in calculating the stability constants.

Polarograms recorded on a sample solution containing 1.0 mol dm^{-3} sodium nitrate and 2.0×10^{-5} mol dm^{-3} cadmium nitrate, with spiked quantiaties of 1.0 mol dm^{-3} imidazole solution to yield imidazole concentrations of 0.0–9.5×10^{-2} mol dm^{-3} permitted the evaluation of just four stability constants owing to the low imidazole concentration. The log stability constants obtained are: $\beta_1 = 2.83$, $\beta_2 = 4.81$, $\beta_3 = 6.32$, and $\beta_4 = 7.36$, values which are consistent with those of the separate-solution method (Table 1).

Cd–citrate system

The half-peak width of each of the polarograms recorded for the Cd–citrate system over a citrate concentration range of 0.0–0.90 mol dm^{-3} in 1.0 mol dm^{-3} sodium nitrate medium is found to be in the range 51–52 mV, indicating a fully reversible two-electron reduction. It can be concluded from Fig. 2 that three species of the Cd–citrate complexes exist within the concentration range studied, namely, $[Cd(cit)]^-$, $[Cd(cit)_2]^{4-}$ and $[Cd(cit)_3]^{7-}$, with log stability constants of: $\beta_1 = 3.00$, $\beta_2 = 4.08$, and $\beta_3 = 4.47$.

The data were also treated according to Lingane,[18] whereby ΔE_p was plotted vs log $C_{citrate}$, when a line consisting of three segments was obtained. The log values of the consecutive stability constants deduced from the plot were: $\beta_1 = 3.11$, $\beta_2 = 4.08$, and $\beta_3 = 4.32$, with coordination numbers of 1.2, 1.8 and 2.3. This confirms the presence of three complex species. The log stability constants of cadmium with citric acid have previously been reported[19] as: $\beta_1 = 3.15$, and $\beta_2 = 4.54$. The existence of three Cd–citrate complexes have also been recently reported.[20]

Mixed-ligand Cd–imidazole–citrate system

Since the maximum number of imidazole species that can associate with cadmium is 6, and the maximum number of citrate ions is 3, imidazole can be considered as monodentate and the citrate ion as bidentate. Consequently, the Schaap and McMasters treatment for the mixed-ligand complexes can be written as follows:

$$F_{00}(XY) = A + B[X] + C[X]^2 + D[X]^3 + E[X]^4 + F[X]^5,$$

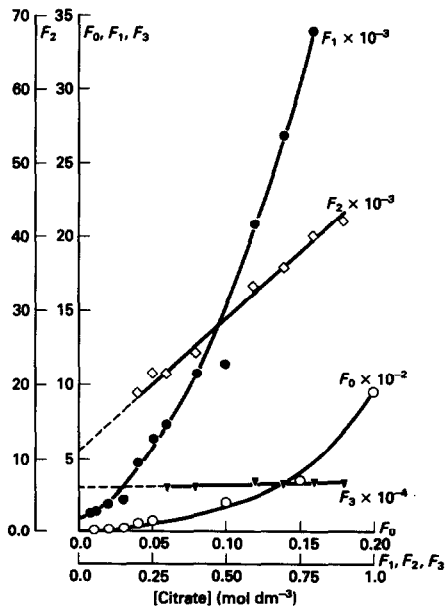

Fig. 2. Plots of the simple functions, F_j, vs citrate concentration.

where:

$$A = \beta_{00} + \beta_{01}[Y] + \beta_{02}[Y]^2 + \beta_{03}[Y]^3,$$

$$B = \beta_{10} + \beta_{11}[Y] + \beta_{12}[Y]^2,$$

$$C = \beta_{20} + \beta_{21}[Y] + \beta_{22}[Y]^2$$

$$D = \beta_{30} + \beta_{31}[Y],$$

$$E = \beta_{40} + \beta_{41}[Y],$$

$$F = \beta_{50}.$$

This predicts the coexistence of about 14 complexes in solutions containing both ligands. X and Y refer to imidazole and citrate ligands, respectively. In the stability constants β_{00}, the first subscript refers to the number of imidazole ligands while the second refers to the number of citrate ligands. According to Schaap and McMasters,[15] the function F_{00} is plotted vs imidazole, for calculating the parameter A. The other functions, F_{i0} ($i = 1, 2, 3, \ldots$ etc.) will also be calculated, and the other parameters (B, C, D, E and F) are evaluated. These parameters are calculated at three different citrate concentrations, that is, 0.10, 0.20 and 0.45 mol dm^{-3}. Calculation of the stability constants of the mixed-ligand complexes will then be possible.

The differential-pulse polarograms recorded for the mixed-ligand system at the concentration ranges of the ligands studied gave peak half-widths of 51–52 mV, and again suggests a two-electron reversible reduction. Polarograms also indicate that the negative shift, ΔE_p, for the mixed-ligand complex system is much more than those for the simple systems under the same conditions. For example, ΔE_p for the Cd–imidazole–citrate complex at 0.20 mol dm^{-3} imidazole and 0.20 mol dm^{-3} citrate is 179 mV, whereas ΔE_p for the simple Cd–imidazole and Cd–citrate systems at a ligand concentration of 0.20 mol dm^{-3} is 140 and 84 mV, respectively. This emphasizes that mixed-ligand complexes are formed.

The differential-pulse polarographic data at the three citrate concentrations are summarized in Table 2. Other data were obtained for two sample solutions containing 1.0 mol dm^{-3} sodium nitrate, 2.0×10^{-5} mol dm^{-3} cadmium nitrate, and a fixed citrate concentration of 0.10 mol dm^{-3} for one and 0.45 mol dm^{-3} for the other. Imidazole was spiked into the sample solution to give concentrations in the 0.0–9.5×10^{-2} mol dm^{-3} range and polarograms recorded for the mixed-ligand complexes after each addition. The results are reported in Table 3.

The values of F_{00}, F_{10}, F_{20} and F_{40} were calculated according to Schaap and McMasters and plotted vs the imidazole concentration. Graphs for the first set of data (the separate-solution method) are represented in Figs 3–5. The values for A, B, C, D, E and F estimated from the figures at the different citrate concentrations are given in Table 4. Values of parameter A given in Table 4 (5.5×10^2, 1.0×10^3 and 6.0×10^3) are in reasonable agreement with those calculated (2.5×10^2, 9.20×10^2 and 5.6×10^3, respectively) from the stability constants of the simple Cd–citrate system obtained in the experiment. Also, the value of parameter F obtained from Fig. 5 is in good agreement with that ex-

pected from the equation $F = \beta_{50}$ ($\beta_{50} = 1.2\times10^{8}$) (Table 1).

Stability constants of the mixed-ligand Cd–imidazole–citrate complex system were calculated using the parameter values estimated at three different citrate concentrations. The individual values of these stability constants and their log values are given in Table 5. Of course, the negative values of the stability constants for some complexes in Table 5 indicate that such complexes do not exist in the solution at the particular citrate concentration range. For example, the mixed-

[a]Values shown in Nos 1, 2 and 3 are calculated from the data obtained at citrate concentrations of 0.10 and 0.20, 0.10 and 0.45, and 0.20 and 0.45 mol dm^{-3}, respectively. Values in No. 2a are derived from Table 3 at 0.10 and 0.45 mol dm^{-3} citrate.

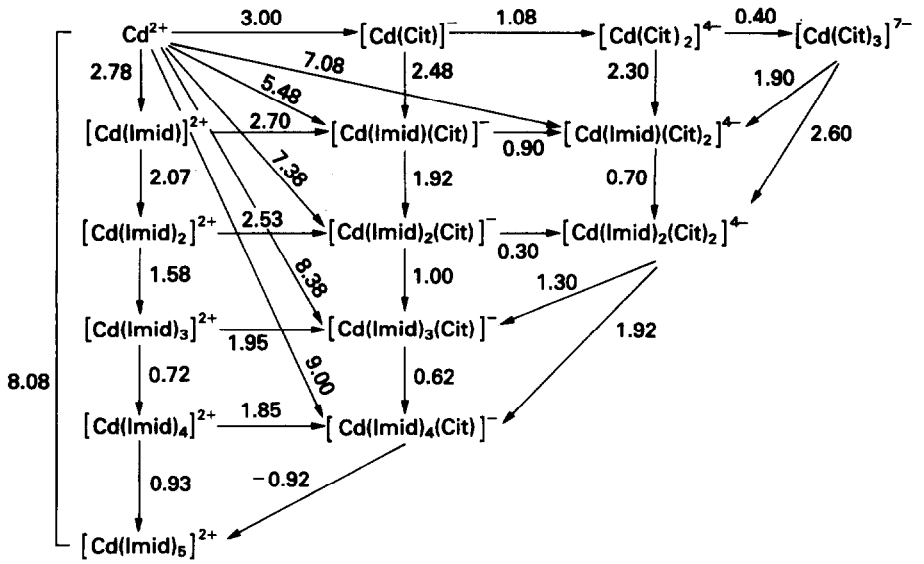

Fig. 6. Schematic diagram showing the equilibria in the mixed-ligand system and log k values for these equilibria.

ligand species $[Cd(imid)\cdot(cit)_2]^{2-}$ and $[Cd\cdot(imid)_2\cdot(cit)_2]^{4-}$ appeared in the solution only in high citrate concentration ranges.

The equilibria between the various species existing in the mixed-ligand system together with the log stepwise stability constant values (log k) are represented schematically in Fig. 6. The log k values indicate that it is easier to add the $[Cit]^{3-}$ ligand to the binary complex $[Cd(imid)]^{2+}$ (log $k = 2.70$) than to add it to the complex $[Cd(cit)]^{-}$ (log $k = 1.08$). However, addition of the imidazole ligand to the binary complex $[Cd(cit)]^{-}$ (log $k = 2.48$) is easier than adding it to the species $[Cd(imid)]^{2+}$ (log $k = 2.07$). This indicates that the tendency for formation of the mixed-ligand complex is favoured. It is also obvious from the schematic diagram (Fig. 6) that it is possible to replace citrate in the saturated mixed-ligand complex, while there is no tendency for replacing imidazole by citrate except for the species $[Cd(imid)_5]^{2+}$ (log k value is negative) which in any case probably does not coexist with the mixed-ligand complexes. This also indicates that the citrate ligand is much weaker than the neutral ligand, imidazole. These results are consistent with those reported earlier for other mixed-ligand complex systems, namely, Cd–imidazole–tartrate,[11] Cd–ethylenediamine–oxalate[15] and Cd–trimethylenediamine–succinate.[20]

Acknowledgements—I am grateful to the University of Petroleum and Minerals for supporting this research project (UPM proposed CY/Imidazole/83) and to Mr E. Michanowsky for assistance with the polarographic measurements. The constructive comments by Dr J. D. R. Thomas of UWIST, Cardiff, are much appreciated.

LONG-RANGE NUCLEAR SPIN–SPIN COUPLING BETWEEN ^{11}B AND ^{13}C, ^{29}Si OR ^{119}Sn: A PROMISING TOOL FOR STRUCTURAL ASSIGNMENT

BERND WRACKMEYER

Institut für Anorganische Chemie, Meiserstraße 1, D-8000 München 2, F.R.G.

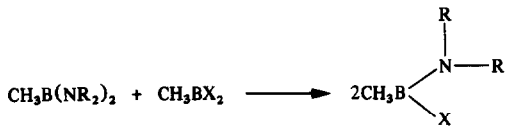
(*Received* 4 *June* 1985; *accepted* 20 *December* 1985)

Abstract—The influence of unresolved long-range nuclear spin–spin coupling [$^nJ(^{11}B–X)$ ($n > 1$; X = ^{13}C, ^{29}Si or ^{119}Sn)] on X resonances has been studied for aminoboranes (**1** and **2**), haloboration (**3** and **4**), hydroboration (**5**) and organoboration products of alkynes (**6** and **7**). The differential broadening of X resonances in the X NMR spectra arising from $^nJ(^{11}B–X)$ (most obvious for X = ^{119}Sn) shows a qualitatively useful pattern of various coupling pathways. $|^2J(^{13}CN–^{11}B)|$ in **1** and **2** appears to be sensitive to the nature of the *trans*-ligand and to the ring size. In many alkenylboranes (**3**, **4**, **5b** and **d**, **6** and **7**) the magnitude of the coupling constants across the C=C double bond follows the trend $|^2J(^{11}B–X)| \sim |^3J(^{11}B–X)|_{cis} < |^3J(^{11}B–X)|_{trans}$. An increasing number of electropositive substituents at the C=C double bond causes an increase in the magnitude of $|^3J(^{11}B–X)|_{cis,trans}$. If there are only organyl groups or hydrogen attached to the C=C double bond, as in the hydroboration products of alkynes (**5a** and **c**) $|^nJ(^{13}C–^{11}B)|$ appears to be too small with respect to $[T_{Q(^{11}B)}]^{-1}$, and the differential broadening was negligible under the experimental conditions used.

The ever increasing complexity of boron compounds under investigation requires efficient methods for rapid structural assignment. Multinuclear NMR methods, in addition to routine ^1H and ^{11}B NMR[1,2] measurements, appear to be particularly suitable for this purpose as they frequently provide decisive information on the composition and structure of the compounds in question.[3] Apart from chemical-shift data (δ) for various nuclei present in boron compounds in solution we are dealing with indirect nuclear spin–spin coupling (J) and relaxation phenomena (T_1 and T_2). Obviously, the δ values contain much structural information which can be used as soon as a sufficiently large set of data exists. The measurement of relaxation times (T_1 and T_2) for nuclei X (X = ^{13}C, ^{29}Si or ^{119}Sn) with $I = \frac{1}{2}$ is still a tedious non-routine procedure if one aims for accurate values, and their interpretation is not at all straightforward.

However, the relaxation behaviour of quadrupolar nuclei such as ^{11}B ($I = \frac{3}{2}$) in solution (assuming that the quadrupolar mechanism is dominant, $T_1 = T_2$, and that the motional narrowing limit applies) is somewhat more simple. Furthermore, the quadrupolar relaxation rate of the ^{11}B nucleus influences the appearance of the resonance of X with $I = \frac{1}{2}$[4] (scalar relaxation of the second kind).

That means that the scalar ^{11}B–X spin–spin coupling, $^nJ(^{11}B–X)$, will be completely averaged only by very rapid quadrupolar relaxation of the ^{11}B nucleus or if its absolute magnitude is very small [$|J(^{11}B–X)|T_{Q(^{11}B)}2\pi \ll 1$]. In the case of a slower quadrupolar relaxation or larger values of $|J(^{11}B–X)|$ more or less broadened X resonances [$|J(^{11}B–X)|T_{Q(^{11}B)}2\pi < 1$] or partially resolved ^{11}B–X spin–spin coupling [$|J(^{11}B–X)|T_{Q(^{11}B)}2\pi > 1$] will be observed. The main interest has been focused so far on values of $^1J(^{11}B–X)$[1–3,5,6] which frequently lead to partially resolved or to severely broadened X resonances. Except for favourable cases, such as a highly symmetric environment of boron (e.g. in borates[3,6,7]), the $^nJ(^{11}B–X)$ coupling constants ($n > 1$) are in general not resolved, neither in the ^{11}B nor in the X NMR spectra. In ^1H NMR spectra of boron compounds there are numerous examples

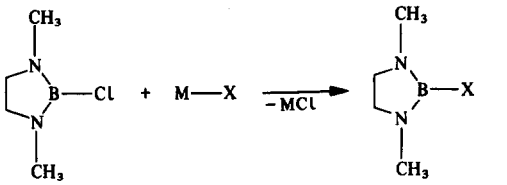


of slightly broadened ^1H resonances which can be sharpened in appropriate ^1H–$\{^{11}B\}$ heteronuclear double-resonance experiments. This has been used to evaluate $^nJ(^{11}B$–$^1H)$ coupling constants ($n = 2$ and 3),[8] to assign specific ^1H resonances in aryl- or alkenylboranes,[9] or to relate ^1H and ^{11}B resonances in mixtures of compounds.[10]

Bearing in mind the multinuclear NMR approach we have studied ^{13}C, ^{29}Si and ^{119}Sn NMR spectra of various boranes in order to obtain experimental evidence for the influence of long-range ^{11}B–X coupling [$^nJ(^{11}B$–X)] ($n > 1$). For this first systematic study we have selected compounds for which there is little or no doubt about the assignment of the ^{13}C, ^{29}Si and ^{119}Sn resonances. The compounds studied represent various active research areas in boron chemistry as they are aminoboranes (**1** and **2**) and products of haloboration (**3** and **4**), hydroboration (**5**) and organoboration (**6–8**).

RESULTS AND DISCUSSION

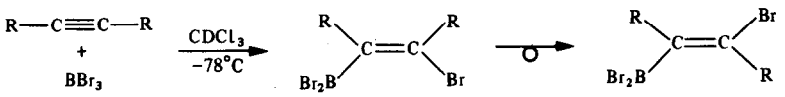
Synthesis



The aminoboranes **1** were prepared according to eqn (1):[11]

(1)

1	X	R
a	CH_3O	CH_3
b	CH_3S	CH_3
c	Br	C_2H_5



The reaction of **2c**[12] with metalated groups X led to the aminoboranes **2a**,[11(b),13] **b**,[14] **c**[15] and **d**[5] [eqn (2)]:

(2)

2	X	M
a	CH_3	Li
b	$Si(CH_3)_3$	Li
c	$NHCH_3$	Li
d	$SeCH_3$	Na

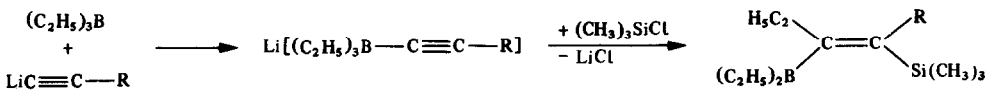
Haloborations[16–18] (**3** and **4**) were carried out by adding slowly a slight excess (10%) of BBr_3 in $CDCl_3$ to a $CDCl_3$ solution of the alkyne at $-78°C$. The reaction was monitored by NMR (^{11}B and ^{13}C). The haloboration products were not isolated.

(3)

3 **4**

R = C_2H_5 (**a**), C_3H_7 (**b**) or C_4H_9 (**c**)

Hydroboration of alkynes to compounds **5** was performed as described previously:[19–22]



(4)

5

R = C_2H_5 (**a**), or $Si(CH_3)_3$ (**b**)

5	R^1	R^2
c	C_2H_5	C_2H_5
d	H	$Si(CH_3)_3$

Organoboration reactions were conducted either by the reaction of triethyl-alkynylborates with $(CH_3)_3SiCl$[23] [eqn (4)] or by direct organoboration of alkynylstannanes[24] [eqn (5)]:

(5)

6

R = CH_3 (**a**), or $Si(CH_3)_3$ (**b**)

$(C_2H_5)_3B + (CH_3)_3Sn{-}C{\equiv}C{-}R \longrightarrow$ **6** (6)

6

R = CH_3 (**c**), H (**d**), $Si(CH_3)_3$ (**e**), $Ge(CH_3)_3$ (**f**), or $Sn(CH_3)_3$ (**g**)

Isomers (**7**) of compounds **6** are either formed already during the synthesis of **6** (**7d** and **e**) or they can be obtained by UV irradiation or standing in daylight:[25]

7a (UV, 20 h, ~ 10%)

R = CH_3 (**b**), H (**c**), $Si(CH_3)_3$ (**d**), or $Ge(CH_3)_3$ (**e**) (7)

R = CH_3 (**f**), or H (**g**)

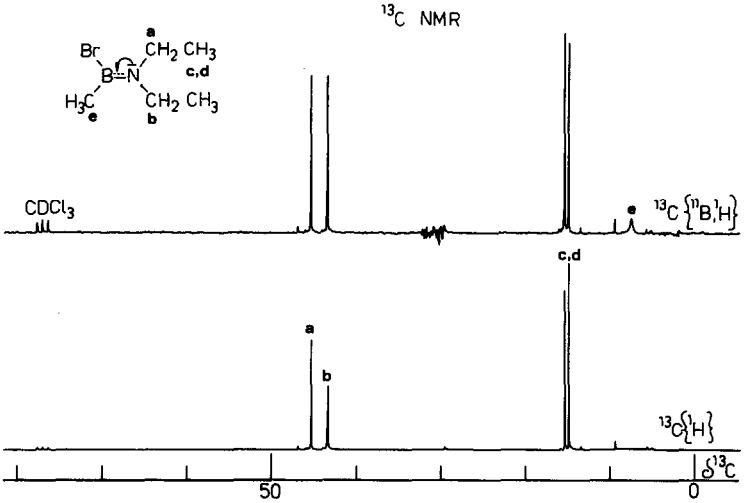
7h

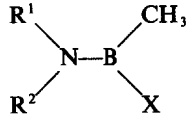
All the relevant NMR data of the compounds studied are given in Tables 1–4.

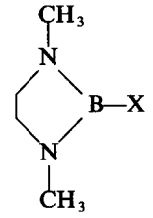
^{13}C *NMR*

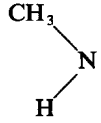
The origin of differential broadening in ^{13}C NMR spectra can be traced to the scalar interaction with the ^{11}B nucleus either by measuring the ^{13}C NMR spectra at different temperatures (affecting the quadrupolar relaxation rate) or by heteronuclear triple-resonance experiments (^{13}C–{^1H–^{11}B}). Since our NMR facilities enable us to perform the latter experiments, we can prove unambiguously the influence of the ^{11}B nucleus if there is another quadrupolar nucleus such as ^{14}N present. This is shown in Fig. 1 for compound **1c** and similar experiments have been carried out for the other compounds studied.

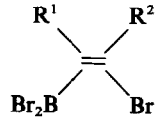
In the case of **1** it appears that the greater value of the geminal coupling constant $^2J(^{11}CN{-}^{11}B)$











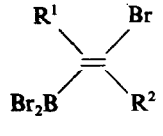


Fig. 1. 50.3-MHz ^{13}C NMR spectra of diethylamino-bromo-methylborane (**1c**). Simultaneous ^1H and ^{11}B decoupling leads to significant sharpening of the ^{13}C(b) resonance (and, of course, the $B\underline{C}H_3$–^{13}C resonance appears); the assignment of the ^{13}C(a and b) resonances is based upon the similarity between $\delta[^{13}C(a)]$ and $\delta[^{13}C(NCH_2)]$ in $Br_2BN(C_2H_5)_2$[36] and between $\delta[^{13}C(b)]$ and $\delta[^{13}C(NCH_2)]$ in $(CH_3)_2BN(C_2H_5)_2$.[36]

[a] Assignment of ^{13}C (R^1 and R^2) resonances in **5a** and **c** is based on ^1H-coupled ^{13}C NMR spectra assuming $|^3J(^{13}C–^1H)| > |^2J(^{13}C–^1H)|$: $C_8H_{14}B$ = 9-borabicyclo[3.3.1]nonyl.

[b] Values of $J(^{29}Si–^{13}C)$ are given in parentheses.

[c] $^1J(^{13}C–^1H) = 152.5$ Hz.

[d] $^3J(^{29}Si–^{29}Si) = 6.2$ Hz.

[e] $^1J(^{13}C–^1H) = 126.8$ Hz.

[f] $^1J(^{13}C–^1H) = 151.5$ Hz.

can be assigned for ^{13}C *trans* to an electronegative substituent X. Considering the behaviour of $^2J(^{13}C^{\alpha}–^1H)$ in substituted alkenes, $XC^{\alpha}H=CH_2$,[26] large changes in the magnitude of $|^2J(^{13}CN–^{11}B)|$ are not entirely surprising. In contrast to **1**, there is no appreciable influence of electronegative groups X (Cl or N<) on the linewidth of the $^{13}C(NCH_2)$ resonance in 1,3-dimethyl-1,3,2-diazaborolidines (**2**). In all cases studied the $^{13}C(NCH_3)$ resonances exhibit much more residual broadening (removable by ^{11}B decoupling) than the $^{13}C(NCH_2)$ resonances. However, in the five-membered ring system it is conceivable that contributions from $^2J[^{13}C(NCH_2)–^{11}B]$ and $^3J[^{13}C(NCH_2)–^{11}B]$ cancel each other.

Recently, haloboration reactions have received renewed attention with respect to their stereochemistry[17] and their application in synthesis.[18] In this context we have already pointed out briefly the effect of ^{11}B decoupling for assignment purposes in ^{13}C NMR spectra[17(b)] and we report here on compounds **3** and **4** in more detail. The 1,2-haloboration proceeds stereospecifically *cis* to compounds **3** which slowly rearrange to the *trans*-products (**4**). Our $^{13}C–\{^1H–^{11}B\}$ experiments show that the magnitude of the coupling constants $|^{2,3}J(^{13}C–^{11}B)|$ across the C=C double bond increases in the order: $|^2J(^{13}C–^{11}B)| \sim |^3J(^{13}C–^{11}B)_{cis}| < |^3J(^{13}C–^{11}B)_{trans}|$.

Although many hydroboration products have been used *in situ* for conversion into other products by various procedures,[27] we note an increasing tendency for complete characterization of hydroboration products prior to further use in organic syntheses.[28,29] In general, ^{13}C NMR is very helpful in this respect[3,6] and we wanted to find out whether differential broadening by long-range coupling $[^nJ(^{13}C–^{11}B)]$ across C=C double bonds can be of diagnostic value. We have studied the boranes **5a** and **b**, which may be regarded as typical examples as far as the relaxation of the ^{11}B nucleus is concerned [$T_{Q(^{11}B)}$ for **5a** = 8.5×10^{-4} s, for **5b** = 4.3×10^{-4} s]. However, in both compounds we did not observe any appreciable line broadening originating from $^nJ(^{13}C–^{11}B)$ ($n > 1$). Since a digital resolution of 0.1 Hz/point was used and a linewidth of the $^{13}C(C_2H_5)$

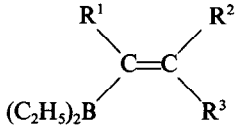
signals of the order of 0.3–0.4 Hz was found we found an $^nJ(^{13}C-^{11}B)$ ($n = 2$ or 3) of < 5 Hz in **5a** and **b**.

It is well known that the magnitude of $^3J(HH)_{trans}$ or $^3J(HH)_{cis}$ increases with increasing number of electropositive groups attached to the C=C double bond. Therefore, we studied the organoboration products carrying one $Si(CH_3)_3$ or $Sn(CH_3)_3$ group at the C=C double bond. Indeed there is a distinct broadening (*ca* 0.3 Hz) of the ^{13}C-resonance signal of the methyl group *trans* to the ^{11}B nucleus in **6a** and **c**. In **7a**, **b**, **f** and **g** the linewidths of all relevant ^{13}C resonances are equal within the error of determination (± 0.2 Hz).

The ^{11}B quadrupolar relaxation rate in compounds **6a** and **c**, and **7a**, **b** and **f**, is similar to that in **5a** and **b**. Hence, it follows that $|^3J(^{13}C-^{11}B)|_{trans}$ increases in the presence of an $Si(CH_3)_3$ or $Sn(CH_3)_3$ group at the C=C double bond. Considering that it was possible to observe effects from $|^3J(^{13}C-^{11}B)|_{trans}$ in the haloboration compounds **3** [$T_{Q(^{11}B)}$ for **3d** (8.6×10^{-4} s) is very similar to $T_{Q(^{11}B)}$ for **5a** (8.5×10^{-4} s)] we conclude that electronegative substituents at the site of the boron atom also induce an increase in the magnitude of $|^3J(^{13}C-^{11}B)|_{trans}$.

In spite of the encouraging results the deduction of reliable data for $^nJ(^{13}C-^{11}B)$ coupling constants from these experiments is not straightforward. Several more or less convincing assumptions are involved: (i) the line shape of the ^{13}C resonances is exactly Lorentzian, (ii) relaxation time $T_{1(^{11}B)} = T_{2(^{11}B)} = T_{Q(^{11}B)}$, (iii) the contributions to the linewidth of the ^{13}C resonances in question arising from the species containing the ^{10}B isotope (*ca* 20%) can be evaluated accurately,[8(b)] (iv) different inhomogeneity broadening in two consecutive experiments (^{11}B-decoupled on-resonance and off-resonance) can be neglected, (v) digital resolution introduces small errors, and (vi) the values of the linewidth of the ^{11}B resonance are sufficiently accurate. Even if we believe that some of these assumptions [e.g. (i), (ii) and (iii)] are permissible in a semiquantitative treatment the error which is introduced considering all the other factors is fairly large. Thus, we calculate[8] a value of 9.5 ± 4 Hz for $|^3J(^{13}C-^{11}B)|_{trans}$ in **3a**. Clearly, some contributions to the error will become smaller with increasing values of $^nJ(^{13}C-^{11}B)$ and/or with decreasing linewidth of the ^{11}B resonance (e.g. **1c**: $h_{1/2} = 80$ Hz, **3a**: $h_{1/2} = 180$ Hz, and **3d**: $h_{1/2} = 370$ Hz). However, for the compounds studied we find that the values of $^nJ(^{13}C-^{11}B)$ ($n = 2$–4) range from 0 to *ca* 12 Hz, and that an error of *ca* ± 3–5 Hz is realistic. Therefore, we are left with the qualitative experimental evidence described.

However, as we aim primarily for the comparison of the absolute values of $|^nJ(^{13}C-^{11}B)|$ within the same molecule differential broadening effects as described may well serve as a guide for assignment. The comparison of effects arising from $|^nJ(^{13}C-^{11}B)|$ for different types of compounds is possible only in a crude qualitative way as pointed out for the haloboration, hydroboration and organoboration products.



^{29}Si *NMR*

Silanes obtained via organoboration (**6a**, **b** and **e**, and **7d**) or hydroboration (**5b** and **d**) have been studied by ^{29}Si NMR using pulse sequences for refocused INEPT[30] or DEPT (with ^1H decoupling).[31] This helps to circumvent the problem of long and unpredictable ^{29}Si relaxation times and it guarantees an acceptable signal:noise ratio within a reasonably short time.[32] Figure 2 shows the ^{29}Si NMR spectrum for compound **5b** in $CDCl_3$ as a representative example. Running the ^{29}Si NMR spectrum of **5b** in pentane solution shows that both ^{29}Si resonances are more broadened owing to the slower quadrupolar relaxation rate in solvents of lower viscosity [$h_{1/2}(^{11}B) = 1450$ Hz in $CDCl_3$, 510 Hz in pentane]. Consequently, the ^{29}Si signals become equally broad if the spectrum of **5b** is recorded at -40°C, as the result of a much increased quadrupolar relaxation rate of the ^{11}B nucleus at lower temperature [$h_{1/2}(^{11}B) > 3000$ Hz in $CDCl_3$, -40°C].

Compound **5b** has been studied previously by ^1H, ^{11}B, ^{13}C and ^{29}Si NMR.[20] We observe very similar δ values but we find that several of the reported coupling constants are wrong. Thus, both ^1H and ^{29}Si NMR (^1H-coupled) show that, for the olefinic hydrogen atom, $|^3J(^{29}Si-^1H)|_{trans} = 21.3$ Hz and $|^2J(^{29}Si-^1H)| = 4.6$ Hz (the literature[20] gives a single value for $^2J(^{29}Si-^1H)$ of 26 Hz]. Both $^2J(^{29}Si-^1H)$ values for the $Si(CH_3)_3$ for groups are 6.55 ± 0.1 Hz. Very accurate values of $^1J(^{29}Si-^{13}C)$ can be obtained from the ^{29}Si NMR spectrum (Fig. 2). The value for $|^1J(^{29}Si-^{13}C)|$ of 57.3 Hz for the olefinic carbon atom attached to boron deviates significantly from the data in the literature (50 Hz[20]). There is no indication for a large geminal coupling [$^2J(^{29}SiC(B)-^{13}C)$], for which a value of 45 Hz has been given.[20] In addition, we can assign ^{29}Si satellites to $^3J(^{29}Si-^{29}Si)_{cis} = 6.2$ Hz, although these lines (AB-spin system) have a distorted phase in the DEPT experiment.

The amount of broadening of the ^{29}Si resonances in **5b** and **6b**, and **6a** and **7a**, together with the known quadrupolar relaxation rate of the ^{11}B nucleus suggests that $|^2J(^{29}Si-^{11}B)| \sim |^3J(^{29}Si-$

Table 4. ^{11}B, ^{13}C, ^{29}Si and ^{119}Sn NMR data of some organoboration products for the detection of long-range ^{11}B–X spin–spin coupling[ab]

[a] Positions of ^{13}C, ^{29}Si and ^{119}Sn resonances broadened most significantly by long-range ^{11}B–X spin–spin coupling are given in italics.
[b] Values of $^1J(^{29}Si–^{13}C)$ are given in parentheses, and values of $^1J(^{119}Sn–^{13}C)$ in square brackets.
[c] $^2J(^{29}Si–^{29}Si) = 8.6$ Hz.
[d] $^2J(^{119}Sn–^{29}Si) = 93.0$ Hz.
[e] $^2J(^{119}Sn–^{119}Sn) = 943.0$ Hz.
[f] $^2J(^{119}Sn–^{29}Si) = 92.1$ Hz.

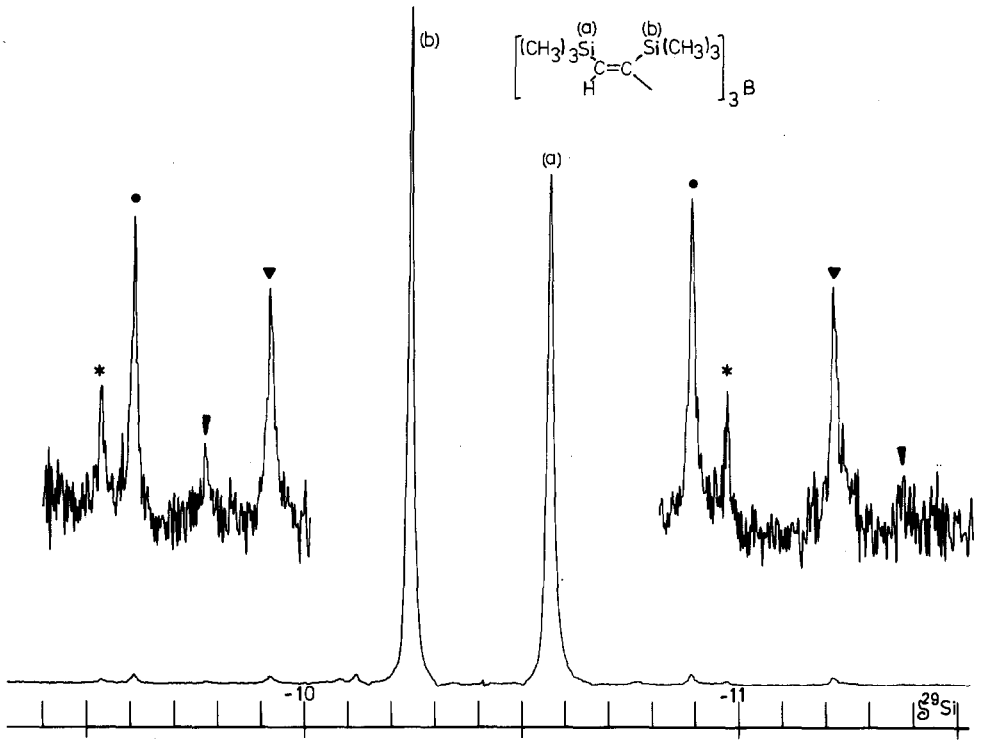

Fig. 2. 39.76-MHz ^{29}Si NMR spectrum [DEPT with ^{1}H decoupling,[31] $^{2}J(^{29}Si–^{1}H) = 6.5$ Hz] of tris[1,2-bis(trimethylsilyl)ethenyl]borane (**5b**); ^{13}C satellites are marked and serve for the assignment of the ^{29}Si resonances (a) and (b) by comparison with the values of $^{1}J(^{29}Si–^{31}C)$ from ^{13}C NMR spectra; the integral intensities of resonances (a) and (b) are 1:1 and the digital resolution was 0.02 Hz/point.

$^{11}B)|_{cis} > |^{3}J(^{29}Si–^{11}B)|_{trans}$, similar to the finding for $^{13}C–^{11}B$ long-range coupling. Furthermore, measurement of ^{29}Si and ^{11}B linewidths for **5d**, **6a** and **7a** indicate that the magnitude of $|^{3}J(^{29}Si–^{11}B)|_{cis,trans}$ is smaller than in compounds **5b** and **6b** with two $(CH_3)_3Si$ groups linked to the C=C double bond.

^{119}Sn *NMR*

The stannanes studied here showed significantly broadened ^{119}Sn resonances. The sharpening of these ^{119}Sn resonances at −40°C proves that $^{n}J(^{119}Sn–^{11}B)$ is the source of this broadening. Figure 3 shows the ^{119}Sn NMR spectrum of **6g** as a typical example. Since isomerization of the alkenylstannanes **6c–f** occurs readily in daylight or much faster with UV irradiation the application of ^{119}Sn NMR to follow these processes is clearly indicated. Figure 4 demonstrates this in the case of compound **6d**, which rearranges mainly into **7c**, **g** and **h**. The ^{119}Sn resonance of pure **6d** is known and the linewidth indicates that in **7g** the $Sn(CH_3)_3$ group and the boryl group are also in a mutual *cis*-position. In contrast, the greater linewidth of the ^{119}Sn resonances in **7c** and **h** suggest a mutual *trans*-position for both groups. Together with the pattern of $\delta(^{119}Sn)$ values[33] a preliminary assignment of the structures is possible. In the present examples we have confirmed all assignments by ^{1}H and ^{13}C NMR evidence. However, both ^{1}H and ^{13}C NMR suffer from a somewhat restricted choice of the solvent and sometimes there is a severe overlap of resonances in the spectral area of interest, in particular when mixtures of similar compounds are studied. Although, numerous techniques (such as 2D NMR[34]) are available today to deal with most of these shortcomings the NMR parameters of hetero-nuclei can be of great advantage for obtaining fast reliable information. In contrast to previous investigations [60-MHz ^{1}H NMR[24(a)]] it was easy now to prove that at ambient temperature the mixture of compounds **6e** and **7d** consists mainly (>95%) of **7d** rather than **6e**. The broad ^{119}Sn resonance of **7d** [$h_{1/2}(^{119}Sn) \sim 100$ Hz] with respect to **6e** [$h_{1/2}(^{119}Sn) \sim 30$ Hz) is convincing proof. In this case ^{119}Sn NMR is superior to ^{29}Si NMR because the much smaller differential broadening in the ^{29}Si

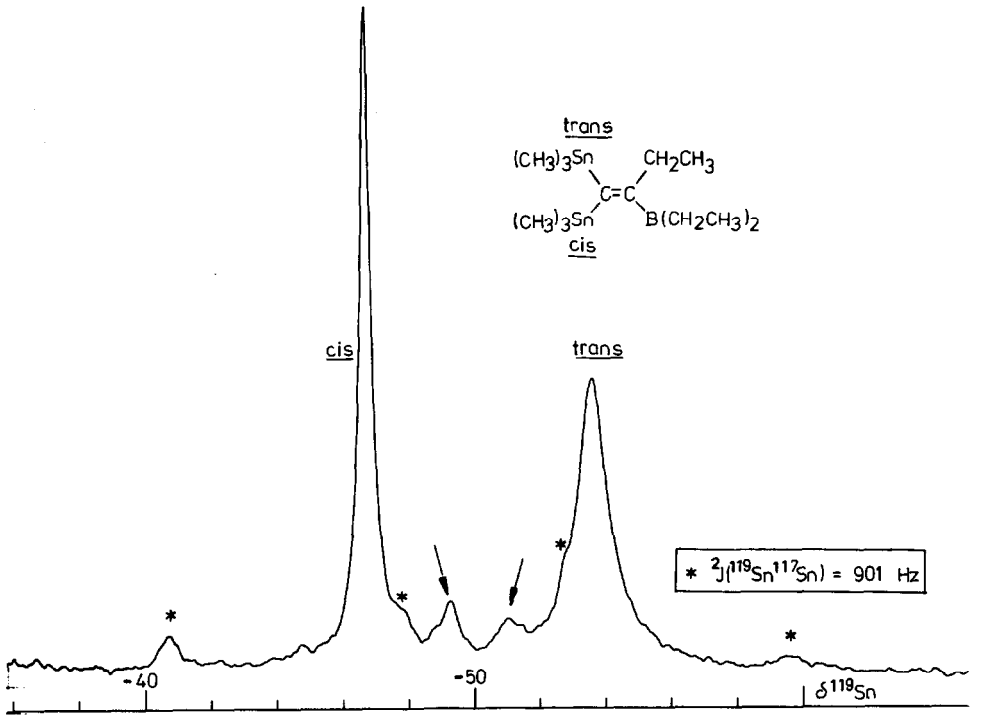

Fig. 3. 74.63-MHz ^{119}Sn NMR spectrum (^1H-decoupled) of 1,1-bis(trimethylstannyl)-2-diethylboryl-1-butene (**6g**); ^{117}Sn satellites are marked with asterisks. The inner lines of the ^{119}Sn satellite AB spectrum are marked with arrows; the calculation of the position of the other lines (low-intensity) agrees with a value for $^2J(^{119}Sn–^{119}Sn)$ of 943 Hz, obtained by multiplication of $^2J(^{119}Sn–^{117}Sn)$ with $\gamma_{(^{119}Sn)}/\gamma_{(^{117}Sn)} = 1.0465$.

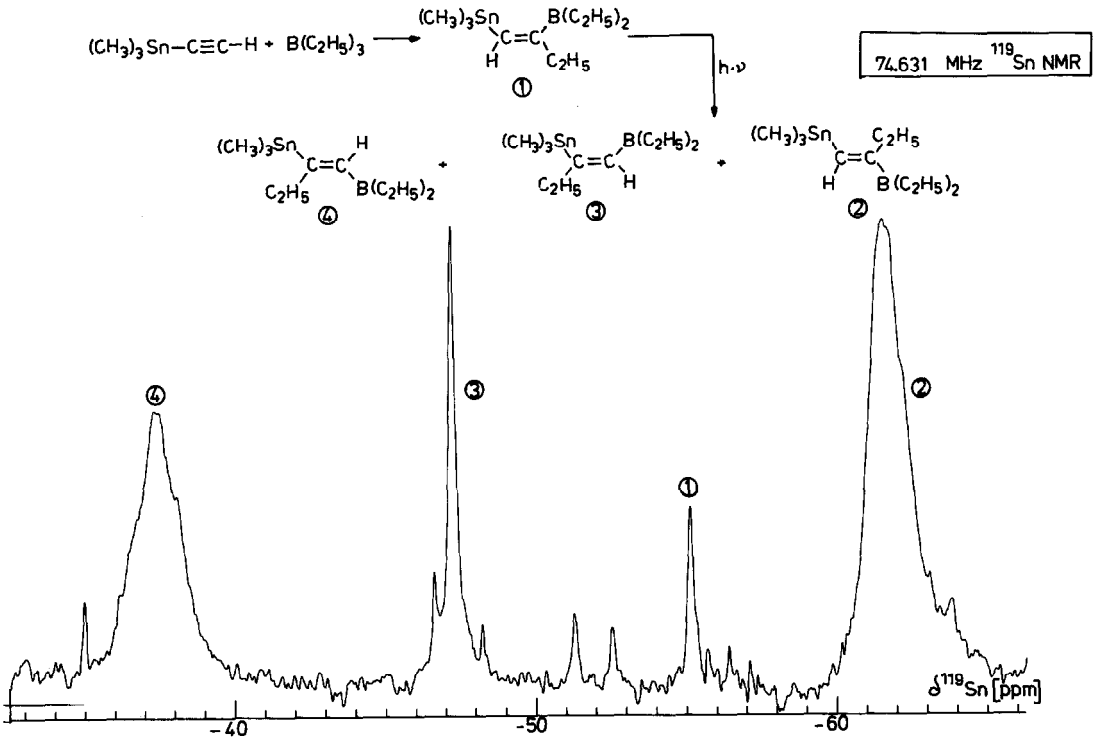

Fig. 4. 74.63-MHz ^{119}Sn NMR spectrum (^1H-decoupled) of the reaction mixture obtained from pure 1-trimethylstannyl-2-diethylboryl-1-butene[24(a)] (**6d**) signal ①, after standing in daylight for several weeks. The structural assignment of the main components, **7c**, ②, **7h**, ③, and **7g**, ④, of this mixture is based on conclusive information from ^1H and ^{13}C NMR.

NMR spectrum is difficult to observe owing to an isomer ratio > 9.5 : 1.

We evaluate[8] the magnitude of coupling constants $^3J(^{119}Sn-^{11}B)_{cis,trans}$ at the C=C double bond in the order of *ca* 40–50 Hz [$|^3J(^{119}Sn-^{11}B)|_{cis}$ in **6c** and **d**, and **7g**], *ca* 60–70 Hz [$|^3J(^{119}Sn-^{11}B)|_{cis}$ in **6e**, **f** and **g**], 75–85 Hz [$|^3J(^{119}Sn-^{11}B)|_{trans}$ in **6g**, and **7d** and **e**]. This is the same trend as has already emerged from ^{13}C and ^{29}Si NMR studies of similar types of compounds.

Conclusions

The experiments and results described and discussed show that long-range ^{11}B–X coupling is a promising tool for structural assignment, complementing the information from other NMR parameters. However, in general it is difficult to deduce accurate values of $^nJ(^{11}B-X)$ from linewidth measurements which is, probably, one of the reasons that these effects have not been discussed in detail for nuclei other than protons in the past. There is no need to emphasize the importance of the differential broadening arising from $^nJ(^{119}Sn-^{11}B)$ in the ^{119}Sn NMR spectra (see Figs 3 and 4). We have demonstrated that these effects, although they are much smaller, can be useful in ^{13}C and ^{29}Si NMR too. In this context, it is important to point out that the unambiguous assignment in the cases of ^{13}C and ^{29}Si NMR requires careful setting of the spectral parameters (see Experimental).

EXPERIMENTAL

Most of the compounds studied have been prepared following literature methods (**1a–c**;[11] **2a**,[11,13] **b**,[14] **c**,[15] **d**;[5] **5a**,[19] **b**,[20] **c**,[21] **d**;[22] **6a** and **b**,[23] **6c–g**[24]). The haloboration products **3** and **4** have been studied in the reaction solution and their structure was deduced from ^{11}B and ^{13}C NMR data. The compounds **7**, isomers of compounds **6**, were studied in the mixtures. The structural assignment of the isomers is based on combined ^1H, ^{11}B, ^{13}C, ^{29}Si or ^{119}Sn NMR evidence. In the case of **6a** 20 h of UV irradiation (Hg high-pressure lamp TQ 150, Hanau) was necessary for ~10% conversion into **7a**. In the case of **6c** standing in daylight for 60 days produced the isomers **7b** and **f** in a ratio of ~ 2 : 3. Similarly, in the case of **6d** standing in daylight for 5 days leads primarily to the formation of **7c**; **7g** and **h** are formed only after several weeks (see Fig. 4). The handling of all compounds required careful exclusion of oxygen and moisture.

All NMR spectra were recorded with a Bruker WP 200 NMR spectrometer, equipped with two frequency synthesizers, a multinuclear unit and a selective ^{13}C probehead, modified for ^{11}B decoupling. The ^{11}B-decoupling power used was 4–6 W and the efficiency of the experiment could be checked by the sharpening of ^{13}C resonances broadened by one-bond $^{13}C-^{11}B$ coupling. As the overall signal : noise ratio appeared to be somewhat dependent on the setting of the ^{11}B-irradiating frequency (probably a result of imperfect filtering of ^{13}C and ^{11}B frequencies in the decoupler and observe channel, respectively) no attempt was made to obtain quantitative data by comparison of ^{11}B-on-resonance- and ^{11}B-off-resonance decoupled spectra. Since the amount of residual broadening is dependent on all other experimental conditions (temperature, solvent and concentration) these data would not be very meaningful, anyhow.

The values of $h_{1/2}(^{11}B)$ increase with decreasing temperature as expected assuming that quadrupolar relaxation is dominant for the ^{11}B nucleus. The condition $T_{1(^{11}B)} = T_{Q(^{11}B)}$, with $T_Q = [\pi h_{1/2}(^{11}B)]^{-1}$ was checked by inversion recovery T_1 measurements[35] for several boranes (**1c**, **2c**, **3a**, **5a**, and **6a** and **c**). The values of $T_{1(^{11}B)}$ agreed within ±10%. In general, sharpening by ^{11}B decoupling, as shown in Fig. 1, was considered as proof for the origin of the broadening in ^{13}C NMR spectra. The digital resolution was selected according to the experimental linewidth in order to enable the correct assignment of broadened with respect to unbroadened or less broadened lines: ^{13}C: 0.2 Hz/point or better, ^{29}Si: 0.1 Hz/point; ^{119}Sn: 0.6 Hz/point.

The δ values given are referred to external BF_3–$O(C_2H_5)_2$ [$\delta(^{11}B)$]; to external $(CH_3)_4Si$ [$\delta(^{13}C)$ ($CDCl_3$) = 77.0, $\delta(^{13}C)$ (C_6D_6) = 128.0], [$\delta(^{29}Si)$]; to external $(CH_3)_4Sn$ [$\delta(^{119}Sn)$]. The spectra were recorded from samples in 10-mm tubes (o.d.) at 27–28°C in $CDCl_3$ or C_6D_6 [10–25% (w/v)].

(*Received* 2 *December* 1985; *accepted* 28 *January* 1986)

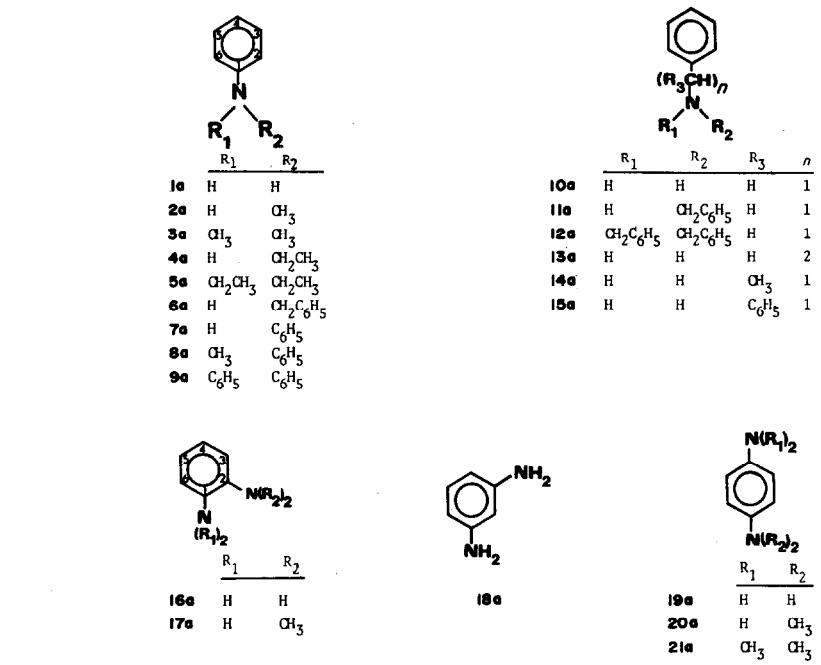
Abstract—^{1}H and ^{11}B NMR spectroscopy was applied to mono- and bisborane adducts derived from aryl-, benzyl-, phenethyl- and phenylenediamines, but no simple relationship was established between the spectroscopic data and the nature of the N—B bond. Comparative studies of the affinity of aromatic amines to BH_3 by equilibria reactions may be of great value in establishing a scale of relative basicity.

Although it is known that the order of reactivity among the BH_3–aliphatic amine adducts is closely related to their N—B bond strength[1] and that borane–arylamine complexes are rendered less stable due to steric and electronic effects,[2] there are, to our knowledge, no systematic studies of a series of aryl-, benzyl-, phenethyl- and phenylenediamine adducts.

Previous studies of aromatic amine borane complexes include bisdiphenylaminoborane,[3] the bifunctional hydride 1-pyrrolylborane–tetrahydrofuran complex,[4] pyrrolylborane–pyridine[4] and the exceptionally reactive diphenylamineborane,[5] where the aromatic groups were shown to weaken coordination of the nitrogen atom, thus making it more acidic and reactive as well as commercially attractive.[6] More recently, Brown[2] reported the use of phenylamine complexes as unique hydroborating and reducing agents, finding that the order of reactivity and consequently the stability of the adduct formed may be explained in terms of base strength.

It seemed of interest, therefore, to investigate the influence of *N*-alkyl, *N*-benzyl and *N*-aryl substituents on the strength of the N → B bond. Furthermore, these spectroscopic studies provide evidence for the relative affinity of these compounds to BH_3.

RESULTS AND DISCUSSION



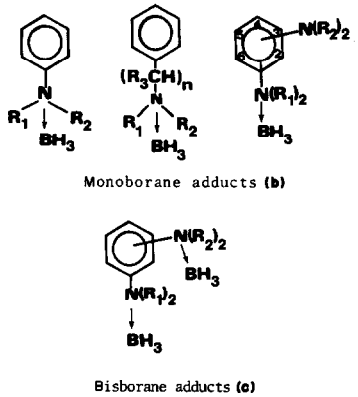
Reactions of amines **1a–21a** (Scheme 1) with borane or diborane were carried out and the resulting adducts were studied. Borane *N*-arylamine (**1b–7b**), *N*-benzylamine (**10b–12b**, **14b** and **15b**) and *N*-phenethylamine (**13b**) complexes were prepared by addition of a 1:1.25 BH_3:THF molar ratio to the corresponding amines (**1a–7a** and **10a–15a**) (Scheme 2). For compounds **1b** and **7b** immediate isolation is required to avoid formation of the bisaminoboranes **1d** and **7d**. On the other hand, compound **8b** was prepared by reaction of *N*-diphenylamine **8a** with diborane (~30:1) in benzene and was found to decompose upon evaporation to dryness, while compound **9b** was not obtained. Compound **12b** was not soluble enough to obtain NMR spectra.

Evidence of the formation of mono- (**16b–21b**) and bisborane adducts (**16c–21c**) (Scheme 2) derived from phenylenediamines (**16a–21a**) was provided by NMR when a 1:1 or 2:1 amine:BH_3 ratio was used. Complexes **19b**, **19c**, **21b** and **21c** were isolated as solid compounds. All of the borane derivatives were moisture-sensitive. Coordination of BH_3 to one of the nitrogen atoms allowed observation of electronic and steric effects induced at the aromatic ring. It was found that coordination causes a decrease in basicity of the remaining free amino group, thus rendering it less reactive to a second BH_3 molecule.

^{11}B *NMR studies*

Aryl-, benzyl- and phenethylamines. It has been described previously[7] that ^{11}B chemical shifts can be used as criteria for measuring the relative strength of the N—B dative bond. However, careful obser-

* Author to whom correspondence should be addressed.



Scheme 1.

vation of Table 1 reveals that this does not hold for compounds **1b–8b**, **10b**, **11b** and **13b–15b**, since, for example, the **3b–8b** and **2b–4b** pairs, which differ considerably in basicity, show nearly identical ^{11}B chemical shifts.

Martin and coworkers[8] have also demonstrated that in the case of borane adducts of aniline and aminopyridines it is not only the density around the boron atom that exerts an influence on the ^{11}B δ but also paramagnetic anisotropic effects and hydrogen bonding.

Inspection of Table 1 shows clearly that for compounds **1b–8b**, **10b**, **11b** and **13b–15b** the shifts are not dependent on the nature of the substituent on the nitrogen atom, but rather tertiary amines (**3b** and **8b**) are shifted to lower fields than secondary (**2b**, **4b**, **7b** and **11b**) or primary (**1b**, **10b** and **13b–15b**) ones. A methyl (**3b**) or phenyl (**8b**) group produces the same variation on the chemical shift, indicating similar steric effects. This effect is considerably higher than those with an ethyl substituent group (**4b** and **5b**).

Scheme 2.

The importance of steric effects on the stabilities of the addition compounds is clearly established by considering **7a** and **8a**, which have pK_a values in water of 0.85[9(a)] and 0.86,[9(b)] respectively. It was found that **7a** reacts with BH_3·THF immediately, while complexation of **8a** must be carried out directly with diborane, implying the presence of greater steric hindrance.

Substitution at the β-carbon in primary benzyl- and phenethylamineboranes (**10b** and **13b–15b**) did not affect considerably the ^{11}B δ ($\Delta\delta = 1.3$ ppm). This observation is in contrast with cyclic systems[10] in which ^{11}B chemical shifts were highly dependent on steric effects.

Phenylenediamines. Table 1 summarizes the ^{11}B chemical shifts of phenylenediamineborane adducts (**16b** and **c**–**21b** and **c**). The data show that mono- or bisborane substitution has little effect on the shifts. As shown by ^1H, *o*-phenylenediamine (**16a**) on addition of BH_3·THF afforded mono- (**16b**) and bisborane (**16c**) adducts, both with a similar ^{11}B chemical shift (−18 ppm). Observation of the ^{11}B spectra of **16b** and **16c** showed that these adducts undergo an intramolecular reaction with

the formation of a cyclic compound (**16e**)[11] (23.75 ppm) (Scheme 3).

The ^{11}B spectra of the *o*-phenylenediamine derivative (**17b**) and the *p*-phenylenediamine derivative (**20b**) showed two quartets at −7 ppm ($(CH_3)_2N:BH_3$) and −17 ppm ($H_2N:BH_3$) in the ratios shown in Scheme 4. On standing at room temperature an additional broad signal at ~26 ppm was attributed to the bisaminoboranes **17d** and **20d** (Scheme 4). The bisborane adducts **17c** and **20c** obtained by addition of two equivalents of $BH_3 \cdot THF$ also decomposed in solution, giving **17d** and **20d** as shown by the appearance of the signal at ~26 ppm.

The initial ratios of **17b** to **17b′** (20:80%) and **20b** to **20b′** (45:55%) are different, probably due to structural effects.

The formation of a kinetic (**20b′**) and a thermodynamic (**20b**) product is suggested due to an increase in the size of the signal for **20b** (45 → 67%) and a decrease in **20b′** (55 → 33%) on standing for 3 h at room temperature.

Formation of mono- and bisadducts derived from *o*-phenylenediamines (**16a** and **17a**) suggests that there is no appreciable steric hindrance in such systems. On the other hand, the *m*- and *p*-phenylenediamine derivatives (**18b** and **c**, and **19b** and **c**) polymerize on standing in solution at room temperature and were not further investigated.

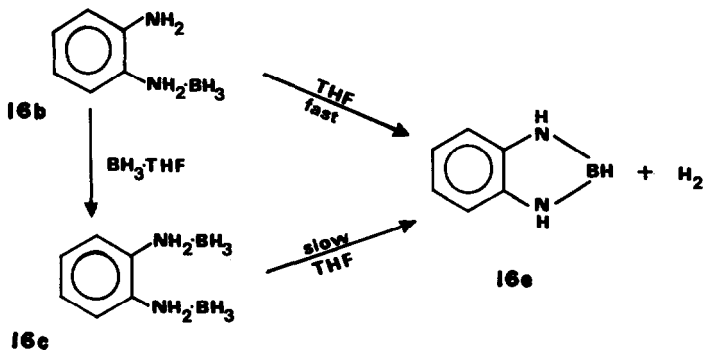
^{1}H *NMR studies*

Aryl-, benzyl- and phenethylamines. The ^{1}H NMR resonances of borane adducts **1b–7b**, **10b**, **11b** and **13b–15b** are summarized in Table 2 together with the literature values for **1a–15a**. The data show that the *N*-aryl-coordinated species **1b–7b** show a *considerable* downfield shift, particularly for the *o*-protons while the benzyl and phenethylamine derivatives (**10b**, **11b** and **13b–15b**) are essentially unaffected. In general δ for the aliphatic groups remained invariant ($\Delta\delta$ 0.05–0.2 ppm).

Freezing of N-inversion in **4b–6b**, **10b**, **11b** and **13b** was evident in the ^{1}H spectra which showed complex patterns due to the presence of diastereotopic protons. Also, an increased complexity of the aromatic proton multiplicities for **1b**, **2b**, **4b** and **6b** was observed.

N-dimethyl- and *N*-diethylaniline adducts (**3b** and **5b**) undergo large downfield shifts for the *o*-hydrogens, due to steric effects, while, the *m*- and *p*-hydrogens show shifts similar to benzene.

It has been shown that HCNH coupling constants are observed only when the nitrogen involved is a weak base[12] and the N—H dissociation is very slow ($pK_a < 1.3$).[13] In this study, although the HCNH couplings were observed for **2b**, **6b**, **11b**, **13b** and **15b**, the complexity of the systems allowed measurements only for **2b** and **15b** (Table 2).



Phenylenediamines. As already mentioned, ^{1}H NMR spectroscopy allowed reliable detection of mono- and bisboranephenylenediamine adducts (**16b** and **c–21b** and **c**) (Table 3). In these cases adduct formation causes large downfield shifts of the aromatic and —NH($\Delta\delta \cong 3$ ppm) resonances

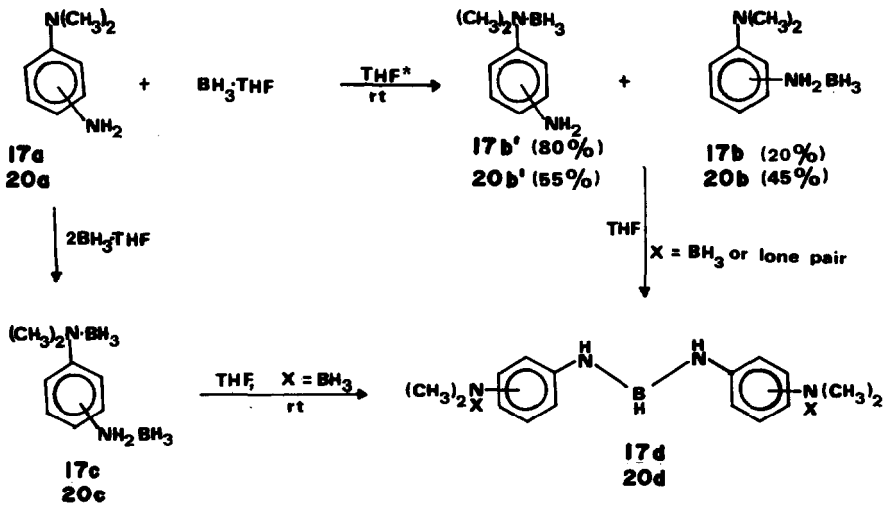
of the **c** species, while the methyl signals are less affected. The aromatic protons in the *p*-substituted species **19b** and **21b** show A_2X_2 systems, while **19c** and **21c** are singlets, as are **19a** and **21a**.

The selective formation of the monoadduct is indicative of a decrease in the electron donating of nitrogen after monocoordination, thus rendering the remaining amino group less basic. This fact has also been observed in *p*-substituted aniline studies.[14]



IR studies

As far as the IR spectra of the borane adducts are concerned (Table 4) the bands attributed to B—H (2200–2450 cm^{-1}), B—N (1100–1200 cm^{-1})[15] and N—H (3120–3324 cm^{-1}) were analyzed to obtain information concerning the influence of the charge on the boron and nitrogen atoms on the frequency of the corresponding vibrations[16] as well as the effect of various substituents on the nitrogen.

Table 4 shows that the asymmetric B—N stretching bands of borane adducts derived from primary amines (**10b**, **13b**, **14b** and **15b**) show very similar frequencies (1167–1170 cm^{-1}) while a delocalization effect is evident in the aniline derivative **1b**, where the corresponding band appears at 1139 cm^{-1}, the secondary amine derivatives (**2b**, **4b**, **6b**, **7b** and **11b**) being in the 1137–1165 cm^{-1} region. Arylamines having different electron-releasing alkyl substituents on the nitrogen (**2b**, **4b** and **6b**) showed identical B—N frequencies (1160 cm^{-1}).

In the case of tertiary amines (**3b**, **5b** and **12b**) the B—N frequency appeared between 1165 and 1176 cm^{-1}, except for the weakly basic complex **8b** (1100 cm^{-1}). This observation indicates that there is no direct correlation between absorption frequency and stability.

It is interesting to notice that the IR spectra of mono- (**19b** and **21b**) and bisborane adducts (**19c**

Scheme 4. *17c or **20c** could be another precursor of **17d** or **20d**, respectively, but according to monoboration selectivity may be less probable.

and **21c**) of phenylenediamines show distinct frequencies depending on whether one or two molecules of BH_3 are coordinated (Table 4). Also the free amino group in the monoborane adducts (**19b** and **21b**) produces a stronger N–B coordination with respect to the bisborane adducts (**19c** and **21c**). Compounds **16–18** and **20** were not analyzed due to superposition of solvent bands.

The data summarized in Table 4 allow us to conclude that, although the arylamine adducts are more affected than the benzyl or phenethyl derivatives, there is not a straightforward correlation between the strength of the B—N bond and the observed IR frequency.

Study of the relative affinity of aromatic amines to BH_3 *by equilibria reactions*

Early qualitative studies of molecular addition compounds of amine with BF_3[17] and $B(CH_3)_3$[18] established the importance of steric effects on the stabilities of the addition compounds. Subsequent equilibria studies by calorimetric measurements,[19] IR[20] and, more recently, ^{11}B NMR[21] techniques, have been helpful not only in studying steric effects, but also in understanding the mechanisms involved in these reactions.

Here, we have chosen arylamine adducts (**1b–7b**) for a detailed study of the base strength and steric

effects on NMR shifts. As mentioned before the base strength of the amines has little effect on ^{1}H and ^{11}B shifts. It can be shown, however, that a study of different equilibria in solution between arylaminoboranes (**1b–7b**) and aromatic amines (**1a–7a**) can be successfully carried out using NMR techniques. The results of equilibria are summarized (Table 5), the data showing that the extent of complexation reflects the relative basicity or affinity of each amine for BH_3.

The experiments were conducted by adding a stroichiometric amount of $BH_3 \cdot THF$ (2 M) to a solution of amine at $-78°C$ in THF (^{11}B NMR) or TDF (^{1}H NMR) under a nitrogen atmosphere, followed by addition of one equivalent of the second amine. The solution was then stirred until it reached room temperature. Exactly the same procedure using the reverse order of addition of the amines was also carried out as described in Scheme 5; a good agreement between both experiments was observed in all cases. Moreover, integration of the area under the ^{11}B NMR peak allowed us to obtain a rough estimate of the species present in solution. However, in some cases, the ^{11}B resonances of the adducts possessed similar chemical shifts or were too broad to allow a clear distinction of the aminoboranes. In such cases, a qualitative estimation of the equilibrium was made by ^{1}H NMR (Table 5).

Attempts to study the equilibrium reaction between benzyl- or phenethylamine and their borane derivatives were unsuccessful due to a strong $N \rightarrow BH_3$ coordination.

According to Table 5, it can be concluded that the base strength of the aromatic amine studied decreases in the following order: **2a**(130) > **1a**(100) > **4a**(90) > **3a**(30) > **7a**(5.6) ≅ **5a**(5) > **6a**(1) (relative to **6a**).

The above results clearly demonstrate that: (a) as the number of aryl substituents increases the affinity of the amine for the borane molecule decreases; and (b) in secondary amines, this N—B bond strength increases in the following order: $CH_3 > CH_2CH_3 > C_6H_5 > CH_2C_6H_5$; while in tertiary amines, the trend is $(CH_3)_2 > (CH_2CH_3)_2 > (CH_3)(C_6H_5) > (C_6H_5)_2$.

Table 5. Relative affinity of aromatic amines to BH_3 by equilibria reactions[a]

[a] As described in text and Scheme 5. Values in parentheses are % of the adduct formed.

In terms of base strength and the stability of the adduct formed, we can conclude that these aromatic adducts studied are more reactive than the aliphatic ones and therefore potentially useful reagents in synthesis.[1]

Finally, the spectroscopic methods employed suggest that we must be careful in the interpretation of the nature of the N—B bond since there is not a direct relationship between the chemical-shift or frequency data obtained and the basicity of the aromatic amines.

EXPERIMENTAL

^{11}B NMR spectra were recorded on a Varian XL-100A (32.1 MHz). ^{1}H NMR spectra were obtained with a Varian EM-390 spectrometer. Chemical shifts are relative to $BF_3 \cdot Et_2O$ and TMS. IR were

Scheme 5.

obtained on a Nicolet MX-1-FT spectrophotometer.

Dry solvents were distilled under dry nitrogen just before use: THF from $LiAlH_4$, hexane and benzene from sodium metal. Diborane and $BH_3 \cdot THF$ were prepared by published procedures.[22] Reagents were commercially available samples used without previous purification. All reactions were carried out under a dry nitrogen atmosphere.

General procedure for the preparation of N-*borane amine adducts* (**1–7b** *and* **10–15b**) *and the mono- and bisborane adducts* (**19b** *and* **c**, *and* **21b** *and* **c**)

To a stirred and ice-cooled solution of the amine (10 mmol) in 4 cm^3 of THF, a 2.0 M $BH_3 \cdot THF$ (15 mmol for amines **1a–7a** and **10a–15a**; 10 and 25 mmol for the mono- and bisadducts of phenylenediamines **19a** and **21a**, respectively) was added dropwise. Immediately, after the addition, the solvent and excess of $BH_3 \cdot THF$ were removed at reduced pressure, affording quantitative yields of the crude adducts.

The same procedure was carried out with phenylenediamines **16a–18a** and **20a**. However, attempts to isolate the corresponding adducts **16b** and **c**, **17c**, **18b** and **c** and **20c** were unsuccessful, and they were directly studied in THF solution.

N-*diphenylmethylamineborane* (**8b**)

Amine **8a** (0.13 g, 0.71 mmol) was dissolved in benzene (4 cm^3). The solution was stirred at 8°C and diborane 35:1 diborane:amine molar ratio was passed through the solution for ~3 h. Isolation was not carried out, because removal of the solvent under reduced pressure led to decomposition.

PREPARATION AND CHARACTERIZATION OF OCTACYANOMOLYBDATES(IV AND V) AND OCTACYANOTUNGSTATES(IV AND V) WITH 2,2′-BIPYRIDYLIUM CATION

J. SZKLARZEWICZ, A. SAMOTUS* and A. KANAS

Faculty of Chemistry, Jagiellonian University, Kraków, Poland

(*Received* 8 *November* 1985; *accepted* 27 *January* 1986)

Abstract—Reaction of protonated 2,2′-bipyridine (bpy) with octacyanometalates(IV and V), $[M(CN)_8]^{n-}$ (M = Mo or W, $n = 3$ or 4), gave the following complexes: $\{(bpyH)_3[M(CN)_8]\cdot 4H_2O\}$, $\{(bpyH)_3(H_3O)[M(CN)_8]\cdot H_2O\}$, $\{(bpyH_2)_2[W(CN)_8]\cdot 3H_2O\}$ and $\{(bpyH_2)K_2[W(CN)_8]\cdot 2H_2SO_4\cdot 7H_2O\}$. These salts were characterized by electron absorption and reflectance spectrometry, IR, Raman and ESR spectrometry, thermogravimetry and differential thermal analysis, cyclic voltammetry and potentiometry. The solubility of the salts in water and some polar organic solvents has been measured. The intensively coloured salts of molybdenum(IV) and tungsten(IV) have been discussed in terms of the $bpyH^+$–$[M(CN)_8]^{4-}$ ion pairs, which exhibit an outer-sphere electron transfer between adjacent redox sites.

The ability of octacyanometalates(IV and V) (M = Mo or W) to form compounds with several metallic and organic cations is well-established.[1] These compounds are characterized by a cation-dependent crystal structure[2] and a strong tendency to ion-pair formation in solution.[3] In the course of a study on the photochemistry of octacyanometalates(IV and V) we became involved in an investigation of the interaction of complex anions with several cations.[4] By interaction of $[M(CN)_8]^{n-}$ ($n = 3$ or 4) with 2,2′-bipyridine (bpy) in acidic aqueous solution we obtained a series of new bipyridylium salts[5] and found evidence of a cation–anion association in aqueous and non-aqueous solutions. Accordingly, ion-pair or outer-sphere complexes of type $bpyH^+$–$[M(CN)_8]^{4-}$ which are characterized by an optical charge-transfer (CT) transition represent a new class of photochemically active systems. In this paper we have described the preparation and physicochemical properties of the salts $\{(bpyH)_3[M(CN)_8]\cdot 4H_2O\}$, $\{(bpyH)_3(H_3O)[M(CN)_8]\cdot H_2O\}$, $\{(bpyH_2)_2[W(CN)_8]\cdot 3H_2O\}$, and $\{(bpyH_2)K_2[W(CN)_8]\cdot 2H_2SO_4\cdot 7H_2O\}$.

EXPERIMENTAL

Reagents and general procedure

All synthetic work was performed in red light under an argon atmosphere. Because of the low solubility of the 2,2′-bipyridylium salts in water the general method of preparation was the metathetical reaction of potassium octacyanides obtained as described earlier[6] with protonated bpy in aqueous solution of various acidity. Bpy (c.p.a. POCh) was recrystallized from 50% ethanol. The purity was checked by measuring the IR spectra before and after crystallization (m.p. = 70.5 ± 0.5°C).

Syntheses

Tris (2,2′-bipyridylium) octacyanomolybdate(V) tetrahydrate, $\{(bpyH)_3[Mo(CN)_8]\cdot 4H_2O\}$ (A). Method (a). To an aqueous solution of $K_3[Mo(CN)_8]$ (*ca* 0.02 M) 0.25 M bpy in 0.5 M H_2SO_4 was slowly added with mixing, resulting in the precipitation of light yellow crystals which were then filtered off and washed with water, methanol, and finally with diethyl ether.

Method (b). The saturated solution of $\{(bpyH)_3(H_3O)[Mo(CN)_8]\cdot H_2O\}$ (*vide infra*) in 0.5 M H_2SO_4 was oxidized with potassium per-

manganate resulting in the precipitation of the less soluble salt of molybdenum(V). The solid obtained was collected by filtration and recrystallised twice from water. Found: C, 53.4; H, 3.9; N, 23.7; Mo, 11.4; CN^-, 24.0; H_2O (1), 8.2; H_2O (2), 8.4; bpy, 55.1%. Calc.: C, 53.7; H, 4.2; N, 23.1; Mo, 11.3; CN^-, 24.5; H_2O, 8.4; bpy, 55.2%.

Tris (2,2′-*bipyridylium*) *octacyanotungstate*(V) *tetrahydrate*, $\{(bpyH)_3[W(CN)_8]\cdot 4H_2O\}$ (**B**). The procedure was analogous to the preparation of $\{(bpyH)_3[Mo(CN)_8]\cdot 4H_2O\}$ [methods (a) and (b)], resulting in the precipitation of white crystals. Found: C, 48.4; H, 3.5; N, 21.4; W, 19.9; H_2O (1), 7.7; H_2O (2), 8.0; bpy, 49.3%. Calc.: C, 48.6; H, 3.9; N, 20.9; W, 19.7; H_2O, 7.6; bpy, 50.0%.

Tris (2,2′-*bipyridylium*) *hydroxonium octacyanomolybdate*(IV) *monohydrate*, $\{(bpyH)_3(H_3O)[Mo(CN)_8]\cdot H_2O\}$ (**C**). In a typical preparation, 1.24 g (2.5 mmol) of $K_4[Mo(CN)_8]\cdot 2H_2O$ was dissolved in 50 cm^3 of water and a solution of 1.95 g (12.5 mmol) of bpy in 50 cm^3 of 0.5 M H_2SO_4 was added dropwise. The solution changed the colour from yellow to orange, and after stirring a yellow crystalline precipitate was formed. The product was filtered off, washed with water, methanol and ether, and dried at room temperature. The product when dried for about 3 days lost 8–10 water molecules, changing in colour from yellow to pale-orange. Found: C, 56.2; H, 3.9; N, 24.5; Mo, 11.7; CN^-, 25.4; bpy + H_2O, 62.3%. Calc.: C, 56.1; H, 3.9; N, 24.1; Mo, 11.8; CN^-, 25.5; bpy + H_2O, 62.0%.

$\{(bpyH)_3(H_3O)[Mo(CN)_8]\cdot H_2O\}$ when dried *in vacuo* over P_4O_{10} at room temperature lost 2.2% of its weight. This corresponds to the loss of one water molecule (calc. loss for one H_2O = 2.2%).

Tris (2,2′-*bipyridylium*) *hydroxonium octacyanotungstate*(IV) *monohydrate*, $\{(bpyH)_3(H_3O)[W(CN)_8]\cdot H_2O\}$ (**D**). To 1.46 g (2.5 mmol) of $K_4[W(CN)_8]\cdot 2H_2O$ in 50 cm^3 of water a solution of 1.95 g (12.5 mmol) of bpy in 50 cm^3 of water was slowly added, causing a change in colour from yellow to red and the precipitation of pale-red crystals. After 1 day the crystals were filtered off, washed 3 times with water, methanol and ether, and dried at room temperature. The crystals turn brown upon drying together with the loss of 6–7 mol of water per mol of complex. Found: C, 50.9; H, 3.6; N, 21.8; W, 20.4; CN^-, 22.6; bpy + H_2O, 55.3%. Calc.: C, 50.6; H, 3.6; N, 21.8; W, 20.4; CN^-, 23.1; bpy + H_2O, 56.1%. H_2O calc. for two water molecules should be 4.0% whereas the found H_2O (2) = 1.7%, which means that only one water molecule can be removed by isothermal dehydration.

Bis (2,2′-*bispyridinium*) *octacyanotungstate*(IV) *trihydrate*, $\{(bpyH_2)_2[W(CN)_8]\cdot 3H_2O\}$ (**E**). 2.0 g (7.7 mmol) of $K_4[W(CN)_8]\cdot 2H_2O$ was dissolved in approximately 5 cm^3 of water and a solution of 1.7 g (10.9 mmol) of bpy in 18 cm^3 of 7 M H_2SO_4 was slowly added. The solution changed in colour to a deep red-brown. After 3 days standing in a refrigerator (under argon) the resulting black crystals were filtered off, carefully washed with diethyl ether, and dried at room temperature. Found: C, 45.5; N, 21.3; W, 24.6; H_2O (2), 7.4; bpy, 44.3%.* Calc.: C, 45.1; N, 22.0; W, 24.1; H_2O, 7.2; bpy 41.0%.

$\{(bpyH_2)K_2[W(CN)_8]\cdot 2H_2SO_4\cdot 7H_2O\}$ (**F**). To 2.92 g (5 mmol) of $K_4[W(CN)_8]\cdot 2H_2O$ in 4 cm^3 of water a solution of 1.56 g (10 mmol) of bpy in 20 cm^3 of H_2SO_4 (1 : 1) was slowly added. Red-brown crystals were filtered off and carefully washed with diethyl ether. Found: C, 23.6; H, 3.0; N, 14.4; SO_4^{2-}, 22.2; WO_3+K_2O, 34.0; H_2O (2), 12.8%. Calc.: C, 22.7; H, 3.0; N, 14.8; SO_4^{2-}, 20.2; WO_3+K_2O, 34.3; H_2O, 12.2%.

Analytical methods

Carbon, nitrogen and hydrogen were determined by organic microanalysis (in the presence of $PbCrO_4$). Molybdenum and tungsten were determined gravimetrically as MO_3 after thermal decomposition of the sample (except for salt **F** for which the sum of the oxides WO_3+K_2O was determined gravimetrically). Water was determined by thermal gravimetric analysis, H_2O (1), and by isothermal dehydration *in vacuo* over P_4O_{10}, H_2O (2). Bpy was determined by thermal gravimetric analysis. In the case when water and bpy were removed together the sum, bpy + H_2O, was determined by thermal gravimetric analysis. Cyanide ions were determined by Volhard's method after photochemical decomposition of the sample in alkaline solution. Sulphate ions were determined gravimetrically as $BaSO_4$. The presence of potassium in salt **F** was found by flame photometry.

Solubility of the salts in water and organic solvents was determined at 21.5 (±0.5)°C in two ways: (i) by measuring UV–visible spectra of saturated solution and assuming for calculations molar extinction coefficients as given in Table 1, and (ii) gravimetrically by evaporation of the saturated solution to dryness.

Physical measurements

Electronic absorption and reflectance spectra were recorded on a Specord UV–visible spectrometer (Zeiss). IR spectra in the 400–4000- and 100–500-cm^{-1} ranges were recorded on a Zeiss

* Partial decomposition of the sample was observed.

UR-10 spectrophotometer and a "Digilab" interferometric spectrometer FTS-14,* respectively. Samples were prepared as Nujol mulls, KBr pellets and/or as thin films on polyethylene. Raman spectra were recorded with a Cary 82 spectrometer* using the 514.5-nm exciting line. The thermogravimetric (TG) and differential thermal analysis (DTA) analyses were performed under argon with a heating rate of 2 and 5°C min^{-1} on a Mettler thermoanalyser.* ESR spectra were recorded with a SE/X-25 spectrometer* (Poland) using $(bpyH)_3[M(CN)_8]\cdot 4H_2O$ as a standard for estimation of the content of M(V) in the M(IV) complexes. Potentiometric titrations were carried out by using a Radelkis pH-meter, Model OP-211 standardized in the usual way. Cyclic voltammograms† were scanned using approximately 10^{-3} M solutions of the complexes in 0.1 M KCl with a conventional three-electrode setup as described elsewhere.[7] A platinum working electrode was used. The formal reduction potentials for the reversible couples were taken as the means of the anodic and cathodic peaks. Formal reduction potentials reported are all vs a normal hydrogen electrode (NHE).

RESULTS AND DISCUSSION

Synthesis and analysis

It was found that by addition of bpy to an acidic aqueous solution of octacyanometalates(IV and V) various complexes with protonated bpy as a cation can be isolated. The reaction of $[M(CN)_8]^{3-}$ gave white (W) and pale-yellow (Mo) crystals of $(bpyH)_3[M(CN)_8]\cdot 4H_2O$. The complexes are paramagnetic with an ESR spectrum typical for d^1-M(V) octacyanides.[8] Salts **A** and **B** behave as strong acids giving, during titration with NaOH, a single potential jump (Fig. 1), corresponding to the simultaneous neutralization of all $bpyH^+$ cations. The presence of the $bpyH^+$ cation is clearly seen in the electronic spectra due to the intensive interligand bands in the UV region. The thermal decomposition of the organic cation which occurred at a lower temperature than for the complex anion can also be used for analytical purposes.

Interestingly, the reaction between $[M(CN)_8]^{4-}$ and bpy in an acidic aqueous medium gives an intensively coloured solution, orange (Mo) or

* Measurements were performed in the Regional Laboratory of Physicochemical Analyses and Structural Research of Jagiellonian University, Kraków, Poland.

† Measurements were performed in the Department of Inorganic Chemistry I of Ruhr University, Bochum, F.R.G.

red (W), from which coloured crystals of $\{(bpyH)_3(H_3O)[M(CN)_8]\cdot H_2O\}$ can be isolated. The d^2-$[M(CN)_8]^{4-}$ complexes should be diamagnetic but **C** and **D** contain *ca* 0.1 and 2.5%, respectively (see Table 2), of paramagnetic d^1-M(V). Potentiometric titrations with a standard NaOH solution clearly indicate two different types of protons with a molar ratio of 1:3 (Fig. 1). UV spectra give evidence of three protonated bpy per mol of salt. The assumption that the one additional proton is bound to one water molecule in the crystals was based on the following results: (i) under isothermal dehydration over P_4O_{10} only one water molecule was released, (ii) under thermal dehydration (see Table 1) the second water molecule was released together

[b] Bands in Raman spectrum.

with decomposition products of $bpyH^+$, and (iii) the IR spectra show the shoulder at 1700 cm^{-1} characteristic of the H_3O^+ bending mode. It should be mentioned that the X-ray structure determination of $\{[HN(C_2H_5)_3]_2[H_3O]_2[Mo(CN)_8]\}$[9] shows the existence of the H_3O^+ ion in the solid state.

Using more acidic solutions two other tungsten salts have been obtained: black **E** and red-brown **F**, the formulae of which are consistent with the analytical data, potentiometric (Fig. 1), TG (Table 1) and spectroscopic (Table 3) results. The last salt seems to be similar to a known adduct of tungstocyanide acid $\{H_4[W(CN)_8]\cdot 4HCl\cdot 12H_2O\}$.[10] Both salts contain some W(V): 28.8% (**E**) and 1.7% (**F**) (Table 3). The same synthetic procedure carried out to obtain molybdenum analogues of **E** and **F** caused the decomposition of the complex anion.

Several attempts were made to prepare the tetra(2,2′-bipyridylium) salts. However, such salts have not been obtained, most probably due to the steric reasons.

TG and DTA analyses

A summary of TG and DTA results is given in Table 1. In the temperature range investigated (20–350°C) the endothermic peaks and the weight loss are mainly due to the evolution of water and the decomposition of bpy. **A** and **B** began to lose water of hydration at about 40°C, giving two endothermic peaks in the temperature ranges 50–60 and 75–85°C, which correlates well with the loss of three and then one molecule of water per atom of metal (H_2O/M). The $bpyH^+$ cations decomposed at a much higher temperature with T_{max} (DTA peak maximum temperature) changing in the order W > Mo salt.

[a] Reflectance spectra.
[b] Estimated from ESR spectra using **A** or **B** as standards.
[c] Apparent molar extinction coefficient.
[d] Band obtained from differential spectra.

There is a distinct difference in the behaviour of **A** and **B** and **C** and **D**. The latter salts seem to be strongly hydrogen bonded and on heating the release of water proceeded simultaneously with the decomposition of organic cations and even, at a higher temperature, complex anions. The separation between T_{max} for dehydration and decomposition of $bpyH^+$ for **E** is similar to that for **A** and **B**. This is consistent with the proposed formula with a diprotonated bpy and no H_3O^+ ion.

Spectra

Data for prominent bands in the IR and Raman* spectra are summarized in Table 2. The most characteristic bands are seen in the range 2180–2200 cm^{-1} (CN stretching), 1600–1700 cm^{-1} (H_2O and/or H_3O^+ bending), 1400–1600 cm^{-1} (ring C=N and C=C stretching, and ring H bending), 1200–1300 cm^{-1} (ring stretching and NH bending), 700–800 cm^{-1} (out-of-plane bending of the aromatic C—H), 300–500 cm^{-1} (M—C stretching and M—CN bending) and 100–200 cm^{-1} (C—M—C bending).

A and **B** show ν(CN) bands which are essentially identical to that of $M'[M(CN)_8]\cdot xH_2O$ ($M' = Na^+$, K^+, Rb^+, Cs^+ or $[(C_4H_9)_4N]^+$)[3(a),11] as well as the bands typical for $bpyH^+$ with a probable cissoid geometrical configuration.[12,13] The electronic spectra of the complexes in the solid state and in solution (Table 3) also exhibit bands characteristic of the component ions.[14,15] This clearly indicates that no significant interaction occurs between the $bpyH^+$ and $[M(CN)_8]^{3-}$ moieties.

C and **D** show a reduced number of ν(CN) bands and a shift of the maxima to higher frequencies in comparison with the $[M(CN)_8]^{4-}$ of D_{2d}-symmetry[16] (Table 2). The electronic spectrum of the complexes in the solid state exhibits a very broad band in the visible region, which may be due to an overlapping of the *d–d* band of $[M(CN)_8]^{4-}$ and the outer-sphere, intervalence CT (OSCT) band for the $bpyH^+$–$[M(CN)_8]^{4-}$ ion pair (Table 3 and Fig. 2). In solution the ion pair also exhibits a relatively low-energy absorption band visible to the eye as orange (Mo) or red (W) in a sufficiently concentrated solution of the ions. The band obtained from the differential spectrum is approximately Gaussian in shape and has a maximum at about 490 nm (Fig. 2). The extinction coefficient of the OSCT band for **D** seems to be higher than that of **C**, and at a higher concentration of both ions and in methanolic solution an increase in absorbance is observed in accordance with the increasing extent of ion-pair formation.

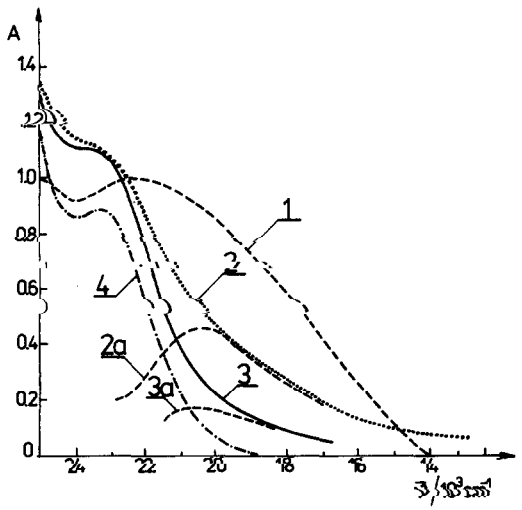

*Fig. 2. Reflectance spectrum (1) and absorption spectra of 0.0038 M solution of **B** ($d = 2$ cm) in CH_3OH (2) and H_2O (3) in comparison with the spectrum of $K_4[W(CN)_8]$ of the same concentration (4). The differential spectra 2a [(2)–(4)] and 3a [(3)–(4)] are given by dashed lines.*

The IR spectra in the solid state as well as the electronic spectra in solution clearly indicate the presence of monoprotonated bpy (the same bands as for **A** and **B**). On the other hand the IR spectra together with the potentiometric measurements are indicative of the H_3O^+ cation (weak band at *ca* 1700 cm^{-1}).

Salts **E** and **F** exhibit less IR bands in the 700–1600-cm^{-1} range than the other salts. This implies the presence of diprotonated bpy, $[bpyH_2]^{2+}$, which seems to occur in a transoid configuration[12,13] (the C_{2h} *trans*-configuration has a centre of symmetry, thus eliminating approximately half of the vibrational degrees of freedom from IR activity). After dissolution in water, the brown (**E**) and black (**F**) salts give electronic spectra identical to that of **D** due to the shift of the proton-transfer equilibria to the right

$$[bpyH_2]^{2+} + H_2O \rightleftharpoons bpyH^+ + H_3O^+.$$

Solubility

The solubility results for salts **A–D** in water and various polar organic solvents at 20 (±1)°C are shown in Table 4. The solubility of **A** and **B**

* The Raman spectra were obtained only for **A** and **B**. In the other cases decomposition of the complexes occurred under a 514-nm laser light.

Table 4. Solubility data (mmol dm^{-3}) and formal redox potentials (V) in various solvents at 20°C

	Solubility					
Solvent	A	B	C	D	E(A/C)	E(B/D)
H_2O	2.6	2.6	18.0	19.2	0.78	0.51
CH_3OH	3.3	8.6	2.8	8.4	0.58	0.32
C_2H_5OH	1.3	1.6	0.25	0.33	—	—
CH_3CN	2.6	2.6	0.06	0.21	0.51	0.26
DMSO	[a]	[a]	—	—	0.19	−0.06

[a] Solubility higher than 10 mmol dm^{-3}.

decreases in the order: DMSO > CH_3OH > H_2O ~ CH_3CN > C_2H_5OH, whereas that for **C** and **D** decreases in the order: H_2O > CH_3OH > C_2H_5OH > CH_3CN. In all cases the solubility of tungsten compounds is higher than that of molybdenum species.

Cyclic voltammetry

Electrochemical properties of octacyanometalates(IV) with protonated bpy as a cation in aqueous solution are in accord with those expected on the basis of existing data for $[M(CN)_8]^{n-}$.[17] The voltametric half-wave potentials vs NHE are presented in Table 4. The Mo and W complexes exhibit in water a couple, corresponding to a reversible one-electron oxidation at *ca* 0.78 and 0.51 V, respectively. Additionally these salts show an irreversible reduction at *ca* −0.38 V, most probably connected with a one-electron reduction of the $bpyH^+$ cation.

Standard redox potentials of the $[M(CN)_8]^{4-}$–$[M(CN)_8]^{3-}$ couple are solvent-dependent and decrease in the order: H_2O > CH_3OH > CH_3CN > DMSO. It seems that the changes are mainly due to preferential ion pairing with one redox component. The data in DMSO suggest that at least the W complex would be very air-sensitive because of the negative potential at which it is oxidized.

A fuller account of the electrochemical behaviour of $[M(CN)_8]^{n-}$ with various counter ions in water and in some polar organic solvents will be given elsewhere.[18]

THE ^{1}H NMR SPECTRA AND FLUXIONAL BEHAVIOUR OF $[Mo(\eta\text{-}C_5H_5)(CO)(CNR)_3][PF_6]$ COMPLEXES (R = Me, Et, Pr^i OR Bu^t): THE X-RAY STRUCTURE OF $[Mo(\eta\text{-}C_5H_5)(CO)(CNBu^t)_3][PF_6]$

GERARD LAWLESS, GERARD McNALLY and A. R. MANNING*

(*Received* 16 *October* 1985; *accepted* 19 *February* 1986)

Abstract—A 3D X-ray diffraction study on a single crystal of $[Mo(\eta\text{-}C_5H_5)(CO)(CNBu^t)_3]^+[PF_6]^-$ shows that it contains an octahedral anion and a cation with a four-legged piano-stool ligand arrangement. The other $[Mo(\eta\text{-}C_5H_5)(CO)(CNR)_3][PF_6]$ salts (R = Me, Et or Pr^i) have similar spectra and hence similar structures to the above. Their ^{1}H NMR spectra at 270 MHz show that they are non-fluxional at room temperature with separate signals due to the CNR ligands *cis* to CO and that *trans* to it with the former always appearing at the greater δ values. The differences in chemical shifts are greater for the α- than for the β-protons, and decrease in the order: R = Me > Et > Pr^i. This suggests that, although a single resonance is observed for the Bu^t protons of $[Mo(\eta\text{-}C_5H_5)(CO)(CNBu^t)_3][PF_6]$ even at −60°C, it is due to identical ^{1}H chemical shifts for *cis* and *trans* ligands rather than to fluxionality. This conclusion is confirmed by the ^{13}C NMR spectra of the salts. However, at elevated temperatures fluxional interchange of these *cis*- and *trans*-CNR ligands is unambiguously observed for R = Et and Pr^i, with a coalescence temperature of 43°C when R = Et. The resonances due to the cyclopentadienyl protons are singlets, except when R = Me. Then it has two unequal components separated by 0.52 Hz which coalesce at *ca* 50°C.

Previously we reported the preparation of a series of $[Mo(\eta\text{-}C_5H_5)(CO)(CNR)_3][PF_6]$ salts which have IR spectra that are consistent with the four-legged piano-stool structure for the cations (Fig. 1). Their ^{1}H NMR spectra at 60 or 100 MHz in $CDCl_3$ solution indicated that these two types of alkyl isocyanide ligands interchanged rapidly on the NMR time-scale.[1] However a reinvestigation of the spectra at higher field has shown that the original data were of too low a quality to support such an interpretation, and that the cations are not fluxional at room temperature when R = Me, Et or Pr^i, and also probably not when R = Bu^t. ^{13}C NMR spectra confirm this viewpoint. On warming, $[Mo(\eta\text{-}C_5H_5)(CO)(CNEt)_3]^+$ and its CNPr^i counterpart become fluxional. The structure of $[Mo(\eta\text{-}C_5H_5)(CO)(CNBu^t)_3][PF_6]$ has been determined by a single-crystal X-ray diffraction study and shown to be that which was proposed previously.[1]

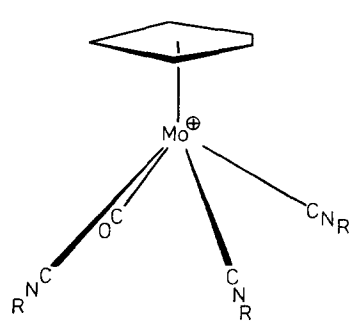

Fig. 1. Proposed structure of $[Mo(\eta\text{-}C_5H_5)(CO)(CNR)_3]^+$ cations.

EXPERIMENTAL

The preparation of the $[Mo(\eta\text{-}C_5H_5)(CO)(CNR)_3][PF_6]$ salts has been described for R = Me, Pr^i and Bu^t.[1] $[Mo(\eta\text{-}C_5H_5)(CO)(CNEt)_3][PF_6]$ was prepared similarly and isolated as an analytically pure, microcrystalline yellow solid.

NMR spectra were obtained using a JEOL GX-270 spectrometer in CD_2Cl_2, $CDCl_3$ or $(CD_3)_2CO$. All chemical shifts were measured with respect to Me_4Si or residual solvent peaks. The spectra are summarized in Table 1.

Crystal data

$C_{21}H_{32}F_6MoN_3OP$, $M = 583.47$, orthorhombic, $a = 11.438(3)$ Å, $b = 13.831(3)$ Å, $c = 17.631(4)$ Å, $\alpha = \beta = \gamma = 90°$, $U = 2789.2$ Å^3, $Z = 4$. $D_c = 1.39$ g cm^{-3}, $F(000) = 1191.99$, $\lambda(\text{Mo-}K_\alpha) = 0.71069$ Å, $\mu = 5.21$ cm^{-1}, space group $P2_12_12_1$. All intensity data were obtained as described by Alyea *et al.*[2] on a Hilger & Watts Y290 diffractometer. Unit-cell parameters were determined by a least-squares fit of θ values between 12 and 20° measured on the diffractometer. The data were collected by the θ–2θ method within the range $2 < \theta < 24°$. Intensities were corrected for Lorentz and polarization effects but not for extinction or absorption. Standard reflections showed an intensity variation of less than 2%. A total of 971 unique reflections with $I > 5\sigma(I)$ were obtained. The observed structure factors were placed on a common scale by the K curve method. Neutral atom-scattering factors were taken from Ref. 3 (hydrogen atoms) and Ref. 4 (others), whilst the anomalous dispersion correction factors for non-hydrogen atoms were taken from Ref. 5.

All calculations were carried out on a Dec-2060 computer. The structure was solved by direct methods (MULTAN)[6] which located both Fe atoms in the asymmetric unit. The other non-hydrogen atoms were located in difference-Fourier maps. Calculated hydrogen atom positions were included in the refinement which was carried out by full-matrix least-squares procedures (SHELX)[7] in which $\Sigma\ \omega(|F_o|-|F_c|)^2$ were minimized with weights (ω) for each reflection being given by $\omega = 0.4701(\sigma^2|F_o|+0.0064|F_o|^2)^{-1}$. The carbon atoms C_1–C_5 of the cyclopentadienyl ligand were constrained to a rigid pentagon during refinement; only the Mo and P atoms were allowed to vibrate anisotropically. The number of variable parameters was 135. The final R value was 0.0593 and R^1 $[= \{\Sigma\ \omega(|F_o|-|F_c|)^2/\Sigma\ \omega(|F_o|^2)\}^{1/2}] = 0.0633$. The final-difference map showed no electron densities >0.64 e Å^{-3}.

Final atom coordinates and isotropic thermal parameters, observed and calculated structure factors, and anisotropic atomic thermal parameters have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Structure of $[Mo(\eta\text{-}C_5H_5)(CO)(CNBu^t)_3][PF_6]$

An irregular single crystal of this compound was grown from hot benzene solution and subjected to

an X-ray diffraction study. The unit cell contains discrete octahedral $[PF_6]^-$ anions and $[Mo(\eta\text{-}C_5H_5)(CO)(CNBu^t)_3]^+$ cations (Fig. 2), with no unusual anion–cation interactions as the shortest such contact is $F_6\cdots H(202)$ at 2.55 Å. The ligand distribution and interligand bond angles in the cation (Table 2) are similar to those found in a wide variety of $[Mo(\eta\text{-}C_5H_5)(L)_3X]$ complexes.[8] The Mo—CO distance of 1.90(2) Å is rather short {cf. 1.980(4)–2.009(6) Å in $[Mo(\eta\text{-}C_5H_5)(CO)_3Cl]$ in Ref. 8} which correlates well with the low ν(CO) frequency of 1928 cm^{-1},[1] indicative of extensive Mo to CO back-bonding. The Mo—CNBu^t distances are comparable with that found in $[Mo_2(\eta\text{-}C_5H_5)_2(CO)_5(CNMe)]$ [2.05(1)Å][9] and there are no significant differences between the two ligands *cis* to CO and the unique one *trans* to it.

NMR spectra of $[Mo(\eta\text{-}C_5H_5)(CO)(CNR)_3][PF_6]$

The ^1H NMR spectra of these salts in CD_2Cl_2 or $CDCl_3$ solutions show resonances due to alkyl and cyclopentadienyl protons (Table 1). The latter were usually singlets at *ca* δ 5, but for $[Mo(\eta\text{-}C_5H_5)(CO)(CNMe)_3][PF_6]$ in $CDCl_3$ solution two unequal ($\sim$100 : 85) resonances were observed, one at δ 5.3362 and the other at δ 5.3382. Although their separation of 0.52 Hz is very close to the limits of the resolution of the spectrometer, this does not appear to be an artifact. It is reproducible and is also observed in acetone-d^6 solution, but here the resonances are much broader and the weaker component is, apparently, much weaker than in $CDCl_3$ solution so that it appears only as a shoulder to lower δ on the stronger. A possible explanation for these observations is that it is due to the presence of ion-paired species in equilibrium with free anions and cations. Alternatively it may be due to isomerism within the cation arising as a consequence of the two different *trans*-MeNC—Mo—L angles (L = CO or CNMe). However, neither suggestion is completely convincing. In both cases the interconversion processes involved might be expected to have low energies of activation and to be fluxional on the NMR time-scale at room temperature, whereas the two cyclopentadienyl signals only coalesce at *ca* 50°C and do not change on cooling below 20°C.

Previously it was indicated that the ^1H resonances of the alkyl groups R were consistent with fluxional cations undergoing rapid interchange of *cis*- and *trans*-RNC ligand as two sets of such resonances

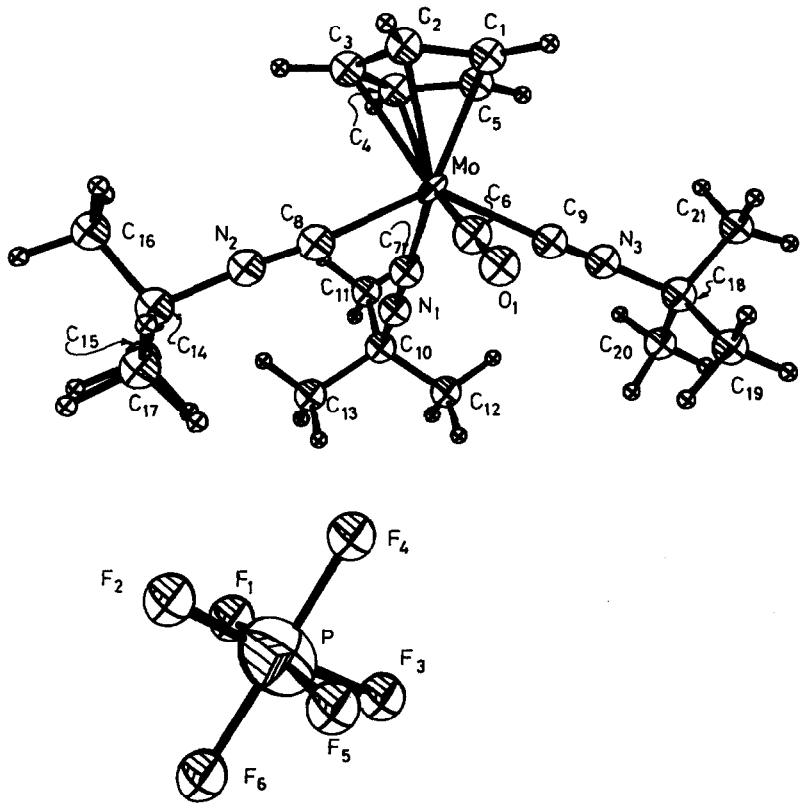

Fig. 2. Structure of $[Mo(\eta\text{-}C_5H_5)(CO)(CNBu^t)_3]^+$ and $[PF_6]^-$ in the crystal [C. K. Johnson, Oak Ridge National Laboratory (Report) ORNL (U.S.) 1986 ORNL-3794 (revised 1971)].

were not observed.[1] This is incorrect as at higher field in $CDCl_3$ solution at 21°C the ^1H NMR spectrum of $[Mo(\eta\text{-}C_5H_5)(CO)(CNMe)_3][PF_6]$ shows two well-defined singlets having relative intensities of 2:1 due to *cis*- and *trans*-MeNC ligands, respectively. In contrast, the alkyl protons of $[Mo(\eta\text{-}C_5H_5)(CO)(CNBu^t)_3]^+$ showed only a sharp singlet even at −60°C. The $[Mo(\eta\text{-}C_5H_5)(CO)(CNEt)_3]^+$ and $[Mo(\eta\text{-}C_5H_5)(CO)(CNPr^i)_3]^+$ cations occupy intermediate positions between these two extremes. In the first there are two resolved quartets due to the CH_2 and two triplets due to the CH_3 protons. Double-irradiation experiments cause both the quartets and triplets to each collapse to two singlets having an intensity ratio of 2:1. Those due to the CH_3 protons are less well resolved than those due to the CH_2. In the $CNPr^i$ cation the quintet due to the CH protons of the Pr^i group clearly have unequal components which are not completely resolved, whilst the doublet due to the CH_3 protons show shoulders. In all instances the less intense resonances due to the single RNC ligands *trans* to CO lie at lower δ than those due to the two which are *cis*.

On inspection of the spectra (Table 1) it can be seen that the differences in chemical shift between the corresponding protons of *cis*- and *trans*-RNC ligands is always greater for those on the α-carbon atoms ($\Delta\alpha$) than those on the β-carbon atoms ($\Delta\beta$), and for both they decrease along the series R = Me > Et > Pr^i. Thus it is very likely that when R = Bu^t $\Delta\beta$ is so small that it cannot be detected at the field strength employed, and that $[Mo(\eta\text{-}C_5H_5)(CO)(CNBu^t)_3]^+$ actually behaves in the same way as the other cations.

The conclusions are supported by the ^{13}C NMR spectra of the salts at 21°C (Table 1). Apart from the singlet resonances due to the cyclopentadienyl (*ca* δ 91) and carbonyl (*ca* δ 241) ligands, there are also resonances due to the α- and, where appropriate, β-carbon atoms of the R groups. There are always two of these with markedly unequal intensities.

Thus even when R = Bu^t there are two CNR environments which are not interchanging rapidly on the NMR time-scale. Again the chemical shift differences are always smaller for the β- than the α-carbon atoms. As for the protons, the former decrease

in the order: R ⩭ Me ≫ Et > Bu^t, but the latter increase in the order: R = Et < Bu^t. The absolute ^{13}C chemical shifts (δ) for both α- and β-carbon atoms increase for R = Me < Et < Bu^t. The resonances due to the isocyanide carbon atoms are very weak but two can always be detected. Although one is sharp the other is much broader and when R = Bu^t at least it appears to be a triplet. Unfortunately, further studies on this unexpected and not readily explicable observation have been prevented by solubility and stability problems.

Fluxionality in $[Mo(\eta\text{-}C_5H_5)(CO)(CNEt)_3][PF_6]$

The site exchange of the ligands (L) in $[M(\eta\text{-}C_5H_5)(L)_4]$ derivatives has been shown to be a facile process especially for $[Mo(\eta\text{-}C_5H_5)(CO)_2(L)X]$ and $[Mo(\eta\text{-}C_5H_5)(CO)(L)_2X]$ systems.[10] Therefore the temperature dependence of the ^1H NMR spectrum of $[Mo(\eta\text{-}C_5H_5)(CO)(CNEt_3)][PF_6]$ was investigated. In $CDCl_3$ solution at 51°C the signals due to the CH_2 and CH_3 protons of the EtNC ligands are a sharp quartet and triplet, respectively. Double irradiation causes these to become sharp singlets. On cooling these broaden and separate each into the two components observed at 21°C (see above). The coalescence temperature for the CH_2 methylene protons, where the two signals were separated by 4.05 Hz, was 43°C. Faller and Anderson have suggested[10] that these site exchange processes proceed via intermediates which have a trigonal bipyramidal arrangement of the five ligands with η-C_5H_5 at an apical site. A similar mechanism probably operates in the $[Mo(\eta\text{-}C_5H_5)(CO)(CNR)_3]^+$ cations.

The two CNMe signals for $[Mo(\eta\text{-}C_5H_5)(CO)(CNMe)_3][PF_6]$ do not coalesce before the upper temperature limit for chloroform is reached (~55°C). However noticeable peak broadening, which is reversible, has taken place and it is clear that exchange of the two types of CNMe ligands is taking place.

EXTRACTION EQUILIBRIUM BETWEEN PRIMARY AMINE PRIMENE 81R AND IRON(III) SULPHATE

F. J. ALGUACIL* and S. AMER

Centro Nacional de Investigaciones Metalúrgicas, Avda. Gregorio del Amo n° 8, Ciudad Universitaria, 28040 Madrid, Spain

(*Received* 6 *January* 1986; *accepted* 24 *February* 1986)

Abstract—The extraction equilibrium between aqueous iron(III) sulphate solutions and amine Primene 81R was studied. The results show that the free amine extracts iron(III) from these solutions. The extracted complex has been isolated and can be represented by the stoichiometric formula $4RNH_2 \cdot Fe_2(SO_4)_3$. The extraction reaction is almost independent of temperature and change in the diluent of the organic phase. On the basis of spectral studies a structure for the extracted complex is suggested.

The extraction of iron(III) from aqueous sulphate solutions by amines has been extensively studied before.[1–3] However, in all the above studies the extracting agent was the corresponding amine sulphate because it seems that the free amine can not extract iron(III) from these aqueous solutions.

Thus, the amine Primene 81R sulphate extracts iron(III) from aqueous sulphate solutions in the form of two well-defined complexes, depending on the extraction temperature,[4,5] although a previous study[5] has shown that as the sulphuric acid concentration in the aqueous phase decreases the amine Primene 81R extracts iron(III), and when no free sulphuric acid was present in the aqueous phase the amine also extracts this metallic ion. Thus, it can be concluded that the free amine extracts iron(III) because when there is no sulphuric acid the amine is in the free form.

It has been shown that several amines extract iron(III) and cobalt(III) from oxalate media when they are in the free form,[6] and also a primary amine named Primene JMT extracts uranium from sulphate solutions to form the complex $(RNH_3)_2UO_2(OH)_2SO_4$.[7] These results show that it is possible that the amines extract several metallic ions from aqueous solutions when they are acting in the free form and not as the amine salts.

The purpose of the present investigation was to study in detail the new liquid–liquid $Fe_2(SO_4)_3$–amine Primene 81R extraction system, when the amine is present as a free base. The objective was also to isolate and identify the compound extracted in the organic phase as a new contribution to understanding the extraction chemistry of amines.

EXPERIMENTAL

The amine Primene 81R used in this work was obtained as a commercial mixture from Rohm & Haas Co., Philadelphia, PA. This amine is a branched-chain, tertiary-carbon amine and its composition is >99% primary aliphatic amine, having the general structure $R_1R_2R_3$—C—NH_2, where the total carbon atom number is 12–14. The experimental molecular weight was 200, as calculated from the titration of various amine solutions, in ethanol, with standard hydrochloric acid using a Beckman 3560 pH-meter.

Kerosene was supplied by CAMPSA with the following specifications: % aromatics, ~20; density (20°C), 0.780 g cm^{-3}; boiling point, >140°C. All other chemicals were reagent grade.

Extractions were carried out by the following procedure. Equal volumes of Primene 81R solutions diluted in kerosene and iron(III) sulphate solutions were placed in separatory funnels, thermostatted at the required temperature, and mechanically shaken. On completion of the extraction the phases were separated and iron(III) in the organic phase was then stripped with 3 M sulphuric acid.

Iron(III) in both phases was determined volu-

* Author to whom correspondence should be addressed.

metrically with potassium dichromate. Sulphate was determined gravimetrically as barium sulphate.

The diluent of the saturated organic phases was evaporated under reduced pressure to yield a dark-red waxy solid residue. This was recrystallized from an ethanol–acetone mixture to yield an orange solid, which was dried in a desiccator over $CaCl_2$.

The solid melts at 140°C. Found: Fe, 9.2; SO_4^{2-}, 23.6; C, 51.3; N, 4.6; H, 9.0%. Calc. for $4RNH_2 \cdot Fe_2(SO_4)_3$: Fe, 9.3; SO_4^{2-}, 24.0; C, 52.1; N, 4.7; H, 10.0%.

IR measurements on the solid were carried out using Unicam SP3-200S and Perkin–Elmer 682 spectrophotometers with cesium iodide windows. Nujol and hexachlorobutadiene mulls were used. The UV spectra were obtained using a Beckman DB-GT spectrophotometer with 1-cm SiO_2 cells.

RESULTS AND DISCUSSION

Influence of sulphuric acid concentration

Figure 1 shows the results obtained by studying iron(III) sulphate extraction with organic phases of amine Primene 81R [10 and 5% (v/v) in kerosene] in dependence on the initial sulphuric acid concentration in the aqueous phase at temperatures of 25 and 50°C.

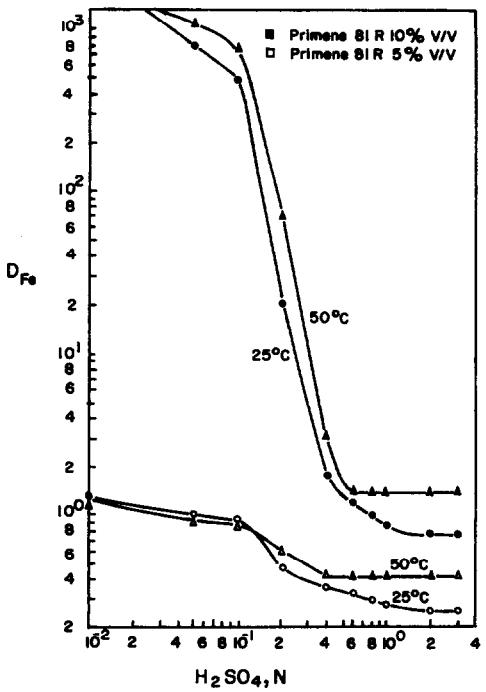

Fig. 1. Effect of sulphuric acid concentration on the extraction of iron(III) by amine Primene 81R. *Aqueous phase*: 0.179 M iron(III) solution.

It can be seen that in the extraction of $Fe_2(SO_4)_3$ with amine Primene 81R solutions the iron(III) concentration in the organic phases decreases with increasing sulphuric acid concentration in the aqueous phase. These results show that the amine bisulphate which formed at high acid concentration does not extract iron(III). The constancy of the results obtained at 50°C for a >6 N sulphuric acid concentration independent of the initial amine concentration is due to the formation of an amine salt that can be represented with the stoichiometric formula $5(RNH_3)_2SO_4 \cdot 3RNH_3HSO_4$, which is not formed at lower temperatures.[5,8]

Iron(III) extraction tends to be greatest when the sulphuric acid concentration is zero, that is in the case when all of the amine in the organic phase is in the form of the free base. This indicates that the extraction agent for iron(III) in the case of amine Primene 81R is the free amine in addition to the amine sulphate.

In order to achieve a clarification of this phenomenon the present investigation was carried out with aqueous solutions that contained no sulphuric acid.

Influence of the diluent

The present study was carried out with solutions of amine Primene 81R [10 and 5% (v/v)] in three diluents which present a great influence on the extraction of iron(III) sulphate by amine Primene 81R sulphate:[9] kerosene, benzene and chloroform. These organic phases were shaken for 10 min with an aqueous sulphate solution of 0.358 M iron(III) at 25°C. Time studies indicated that complete equilibration was obtained after about 5 min shaking, almost independent of the diluent.

The results obtained are shown in Table 1. It can be seen that in this system the change in the diluent of the organic phase does not have a great influence on the iron(III) extraction. The same result was

Table 1. Influence of diluent on the extraction of iron(III) by amine Primene 81R[a]

	Amine [5% (v/v)]	Amine [10% (v/v)]
Diluent	Fe(III) [g (l organic phase)$^{-1}$]	Fe(III) [g (l organic phase)$^{-1}$]
Kerosene	5.63	11.36
Benzene	5.63	11.36
Chloroform	5.63	11.36

[a] *Aqueous phase*: 0.358 M iron(III) solution. Temperature = 25°C.

obtained at higher temperatures. This behaviour is different from that observed with the amine Primene 81R sulphate.[10] From here onwards the only diluent studied for the organic phase was kerosene because it gave a better phase separation time when compared with the other diluents studied.

Influence of modifiers

The addition of a modifier to overcome the third-phase and emulsion tendencies in a solvent extraction system is a common practice. In this paper the use of *n*-alcohols as modifiers for the amine Primene 81R–iron(III) sulphate system was investigated, the alcohols chosen for this study were *n*-butanol, *n*-hexanol, *n*-octanol and *n*-decanol.

Table 2 presents the results obtained by shaking equal volumes of a 0.358 M iron(III) aqueous solution with an amine Primene 81R [10% (v/v) in kerosene] solution with different modifiers. The results show that the highest concentration values of iron(III) on the organic phase were obtained with *n*-decanol independent of the extraction temperature, it seems that the shorter the carbon organic chain of the modifier the less iron(III) is extracted by the amine. Table 2 shows the phase separation time at temperatures of 25 and 50°C. The best results are always obtained with *n*-decanol although at 50°C the experimental time is shorter than those obtained at the lower temperature for the four modifiers studied. Figure 2 shows the iron(III) concentration in the organic phase vs the *n*-decanol concentration in this phase. It can be seen that the presence of a small amount of *n*-decanol improves the extraction of iron(III) which is a new tendency found in this system because it is known that modifiers have a depressant effect on metal extraction.[11]

The maximum extraction was obtained when using 5% (v/v) *n*-decanol, although the differences in the range 4–7.5% (v/v) are small. This range of concentrations is independent of temperature and the initial amine Primene 81R concentration.

Thus, the following study was made using organic phases containing a concentration of *n*-decanol half that of the amine [expressed as % (v/v)].

Table 2. Effect of modifiers on the extraction of iron(III) by amine Primene 81R[a]

Study of extraction kinetics and influence of temperature

Kinetics studies have been carried out on the effect of various initial iron(III) sulphate concentrations on shaking time, keeping the iron(III) concentration constant.

The results obtained are shown in Fig. 3 for temperatures of 25 and 50°C, plotting the iron(III) concentration in the organic phases vs the equilibration time when an organic phase of amine Primene 81R [10% and 5% (v/v) in kerosene] was shaken with different aqueous iron(III) solutions.

An almost complete independence of temperature and amine concentration equilibrium was reached in 3 min, and from Fig. 3 can be seen that at 25°C in the organic phase a considerable amount of iron(III) is extracted compared to the extraction at the higher temperature, although there are no significant differences between the results obtained for the two temperatures when more diluted

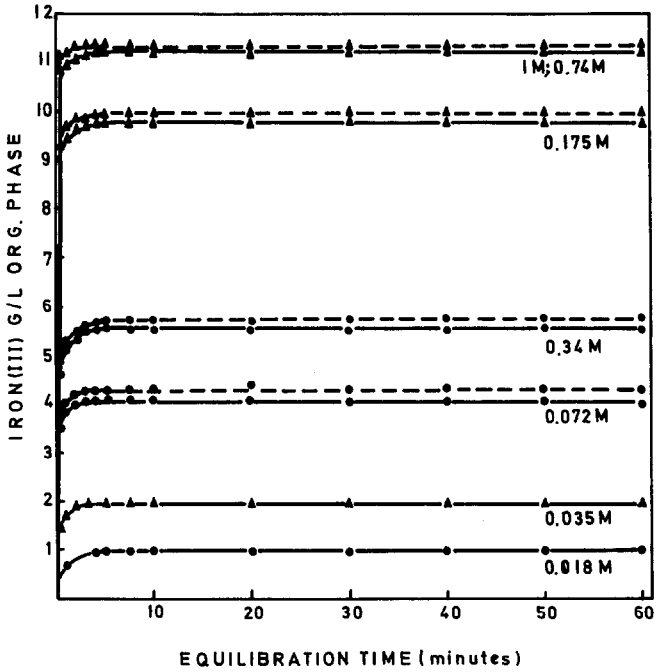

Fig. 3. Kinetics of iron(III) extraction by amine Primene 81R [(▲) 10% (v/v), and (●) 5% (v/v) in kerosene]. Influence of various iron(III) concentrations in the aqueous phase. Broken line, 25°C; continuous line, 50°C.

iron(III) concentrations were studied. Increasing iron(III) concentrations in the aqueous phase up to 1 M have no influence on the organic-phase load, indicating that there is not a species change in the organic phase at high aqueous iron(III) concentrations.

Figure 4 plots the relationship between the iron(III) loaded in the organic phase and the extraction temperature for organic phases which contain different amine Primene 81R concentrations in kerosene shaken with an aqueous phase of 0.358 M iron(III) for 10 min.

From Fig. 4 it can be seen that there is practically no change in the iron(III) concentration loaded in the organic phases at different temperatures, indicating that a complex with the same stoichiometry is extracted over the range of temperatures studied. This result differs from those obtained with amine Primene 81R sulphate which extracts two well-defined iron(III) complexes, depending on the extraction temperature.[4,12]

Temperature has a great influence on the phase separation time as can be seen in Fig. 5, in which this variable is plotted vs temperature for the experimental points obtained with 10% (v/v) amine Pri-

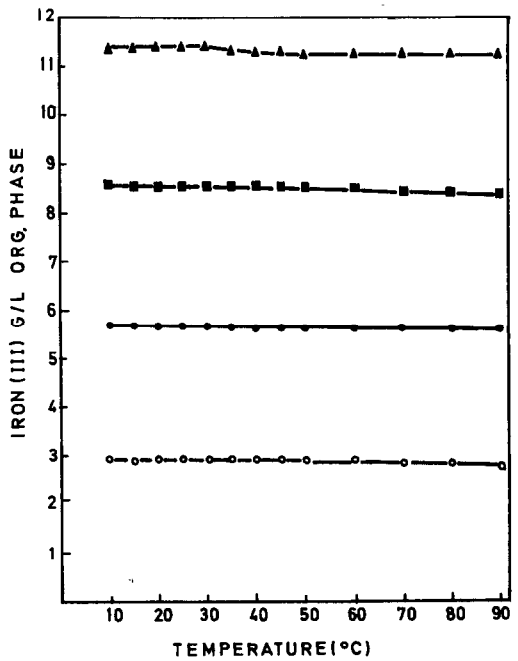

Fig. 4. Influence of temperature on the extraction of iron(III) by amine Primene 81R [(▲) 10% (v/v), (■) 7.5% (v/v), (●) 5% (v/v), and (○) 2.5% (v/v) in kerosene]. *Aqueous phase*: 0.358 M iron(III) solution.

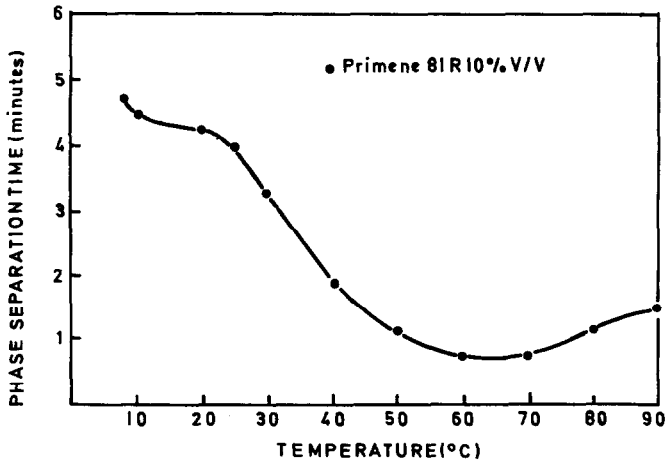

Fig. 5. Variation in the phase separation time with extraction temperature. *Aqueous phase*: 0.358 M iron(III) solution. *Organic phase*: Primene 81R [10% (v/v) in kerosene].

mene 81R. As the temperature increases the separation time decreases progressively until 70°C, at which a long time is required; similar results were also obtained with other initial amine concentrations.

Extraction equilibrium isotherms

Figure 6 shows loading isotherms for the extraction of iron(III) with amine Primene 81R [10 and 5% (v/v) in kerosene] in equilibrium with aqueous iron(III) sulphate solutions at 25 and 50°C; the shaking time in all cases was 10 min. At saturation loading the results show that the amine Primene 81R/iron(III) concentration ratio appears to approach 2 almost independently of temperature. Neither of the curves show an upward swing above the initial loading level as has been shown with amine sulphates.[12] This result supported the previous suggestion that there is no species change in the organic phase at high iron(III) concentrations.

Several sulphuric acid titrations on equilibrated aqueous phases show that no acid is liberated by iron(III) extraction as occurs with the extraction by means of amine Primene 81R sulphate; this result suggests that the extraction mechanism may differ from that proposed for the amine sulphate.

Figure 7 shows the relationship between the molar ratio of iron(III) concentration in the organic phase to the amine Primene 81R concentration vs the iron(III) concentration in the aqueous phase. From Fig. 7 it can be seen that the limiting ratio obtained is near to 0.5, corresponding to $[Fe(III)]_{org}/[RNH_2]_{org} = 0.5$. This ratio is similar to that obtained from extraction loading curves shown in Fig. 6.

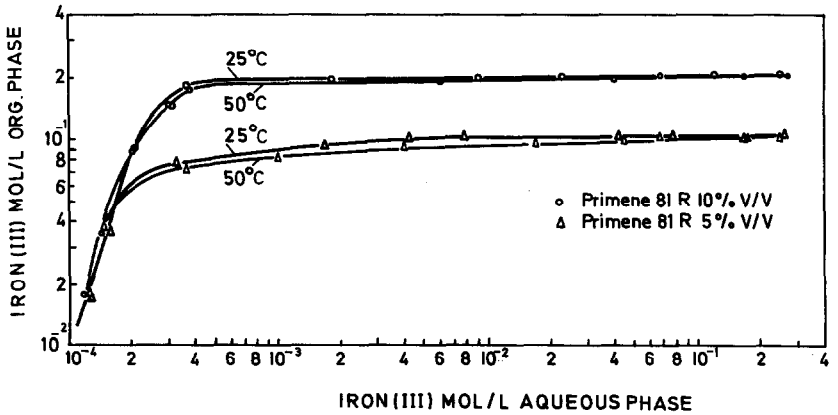

Fig. 6. Equilibrium extraction curves for iron(III) extracted by amine Primene 81R. Effect of the initial amine concentration. *Aqueous phase*: solutions containing various concentrations of iron(III) sulphate. *Organic phase*: Primene 81R [(○) 10% (v/v), and (△) 5% (v/v) in kerosene].

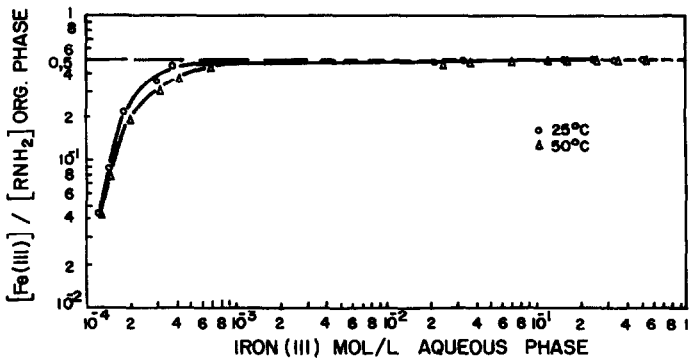

Fig. 7. Variation in the molar ratio [Fe(III)]/[RNH_2] in the organic phase with molar [Fe(III)] in the aqueous phase. *Organic phase*: Primene 81R [10% (v/v) in kerosene].

The sulphate analysis of the organic phase indicated that the molar ratio of the sulphate concentration to the iron(III) concentration in the organic phase is equal to 1.5.

According to the above experimental data the following extraction reaction of iron(III) sulphate by amine Primene 81R, acting as a free base, is suggested:

$$4RNH_{2org} + Fe_2(SO_4)_{3aq} \rightleftarrows 4RNH_2 \cdot Fe_2(SO_4)_{3org} \quad (1)$$

This extraction reaction being independent of temperature and different to those proposed with amine Primene 81R sulphate and other amine sulphates indicates that the amine acting as a free base extracts iron(III) sulphate by means of a well-defined complex.

Reagent concentration dependence

The study of the reagent dependence was carried out by shaking a 0.358 M iron(III) aqueous solution and different organic phases for 10 min at a temperature of 25°C. The results are shown in Fig. 8 in which the iron(III) concentration loaded in the organic phase is plotted against the initial amine concentration. There is a proportional relationship between the two values represented; thus, from Fig. 8 unknown amine Primene 81R concentrations can be determined by comparing values for the iron(III) concentration extracted with those shown in Fig. 8. The same result is obtained when the extraction is carried out at 50°C or other temperatures.

Spectra and structure of the complex

The UV spectrum obtained in kerosene of the isolated amine Primene 81R–iron(III) complex shows a band at about 307 nm ($\varepsilon \sim 3240$) that can be assigned to the species $[FeSO_4]^+$ and possibly $[Fe(SO_4)_2]^-$, as the $[FeSO_4]^+$ species absorbs at about 305–310 nm whereas the $[Fe(SO_4)_2]^-$ species appears to have an absorption maximum at 300 nm. Although it seems that the observed band is near to the $[FeSO_4]^+$ species it is possible that the spectrum of the compound in kerosene solution showed a contribution from both iron(III) species.

The molar extinction coefficient value is higher than those reported in aqueous solution for these species.[13] However, Good *et al.*[14] have found that in certain chloroform–amine solutions the spectra of ionic transition-metal complexes have higher extinction coefficients than the same ion in aqueous

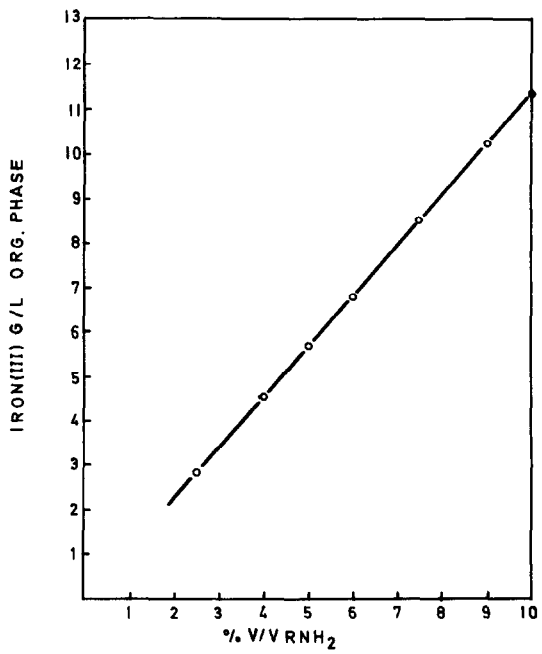

Fig. 8. Variation in iron(III) extracted in the organic phase with initial amine concentration in the organic phase. *Aqueous phase*: 0.358 M iron(III) solution.

solution. These will be probably due to certain interactions between the diluent and such species. This phenomenon has also been observed with the iron(III)–amine Primene 81R sulphate complexes extracted at different temperatures.[12]

The IR spectrum of the complex shows a band at 3400 cm^{-1} that can be assigned to the N—H stretching vibration of the amine group, and also two bands at 2950 and 2850 cm^{-1} assigned to the C—H stretching vibrations (antisymmetrical and symmetrical modes, respectively) of the carbon chains.

In the 1200–900-cm^{-1} zone the spectrum shows bands at 1175, 1135 (weak) and 1010 cm^{-1} that can be due to sulphate groups acting as bidentate ligands (C_{2v}-symmetry) and a band at 1105 cm^{-1} that can be assigned to the sulphate group with T_d-symmetry.[15] Also, a very weak band at 950 cm^{-1} can be assigned to the sulphate group with a C_{2v}-symmetry. This band is probably hidden by the broad band at 1010 cm^{-1}. At 1220 cm^{-1} there is a band which is probably due to the C—N vibration of the amine group and at about 1615 cm^{-1} a band assigned to the N—H deformation vibration of the amine group is also observed.

Molecular-weight values, obtained by cryoscopic measurements in benzene, of the iron(III) complex at various concentrations are presented in Table 3. They show that the complex is a monomer in benzene solution if based on the $4RNH_2 \cdot Fe_2(SO_4)_3$ formula.

From the data obtained the structure shown in Fig. 9 can be suggested for the amine Primene 81R–iron(III) complex. In this structure the stoichiometry of two iron(III) atoms for each of the four amine Primene 81R molecules deduced from the extraction reaction (1) and established by analysis remains constant and the iron(III) appears to

Table 3. Degree of association of the amine Primene 81R–iron(III) complex

Diluent	Molecular weight	Concentration (mM)	Degree of association[a]

STUDY OF THE AMINE PRIMENE 81R SULPHATE–$Fe_2(SO_4)_3$ EXTRACTION EQUILIBRIUM SYSTEM AT LOW TEMPERATURES

F. J. ALGUACIL* and S. AMER

Centro Nacional de Investigaciones Metalúrgicas, Avda. Gregorio del Amo n° 8, Ciudad Universitaria, 28040 Madrid, Spain

(*Received* 2 *December* 1985; *accepted* 28 *February* 1986)

Abstract—The extraction of iron(III) from aqueous sulphate solutions by Primene 81R sulphate at low temperatures was studied as a function of iron(III) and amine sulphate concentrations. In the range of temperatures between 8 and 5°C a complex with the stoichiometric formula $4(RNH_3)_2SO_4 \cdot [Fe(OH)SO_4]_2$ is extracted. The extraction reaction may occur by adduct formation between the amine sulphate and the species $[Fe(OH)SO_4]_2$ from the aqueous phase and not by an anion exchange reaction. The extracted complex is a monomer in benzene solution; the spectral study suggests that the $[Fe(OH)]_2^{4+}$ unit is present in its structure and the sulphate groups act as bidentate ligands.

The extraction of iron(III) from aqueous sulphate solutions with amine sulphates has been extensively studied. Baes[1] had studied the iron(III) extraction from acidic sulphate solutions by a secondary amine sulphate; Cattrall and West[2] have shown that the secondary amine di(3,5,5-trimethylhexyl)amine extracts iron(III) by means of a complex with the stoichiometric formula $(R_2NH_2)_2[FeOH(SO_4)]_2$, where R is 3,5,5-trimethylhexyl.

The extraction of iron(III) from aqueous solutions with primary amine sulphate has also been reported. Thus Cattrall and Reverill[3] investigated the extraction of iron(III) by means of the primary amines 3,5,5-trimethylhexylamine and *n*-dodecylamine. The extraction of iron(III) from sulphate solutions with primary amines has been reported by Seeley[4,5] and Ishimori[6] in extraction survey studies, and Schultze *et al.*[7] reported their investigations concerning the extraction of iron(III) from concentrated aluminium sulphate solutions by different types of amines.

The extraction of iron(III) by Primene 81R sulphate at 50°C or higher temperatures has been studied before,[8,9] showing that the extracted complex presents a stoichiometric formula represented by $3(RNH_3)_2SO_4 \cdot [Fe(OH)SO_4]_2$. All the above studies have been carried out at 20°C or higher temperatures and no data are available about the extraction of iron(III) at lower temperatures.

It has been shown, therefore, that the iron(III) extraction by the primary amine Primene 81R sulphate is temperature-dependent,[10] and in the range of temperatures between 8 and 5°C it seems that a complex with a different stoichiometry than that presented by the complex described above was extracted.

Thus, the purpose of the present paper was to study in detail the extraction equilibrium system between iron(III) sulphate and Primene 81R sulphate in kerosene at low temperatures as a new contribution to understanding the iron(III) extraction behaviour of amine sulphates, this being the first time that an extraction system at these temperatures has been described.

EXPERIMENTAL

Chemicals

The amine Primene 81R used in the investigation was obtained from Rohm & Haas Co., Philadelphia, PA; its composition is >99% primary aliphatic amine, having the general structure $R_1R_2R_3$—C—NH_2, where the total carbon atom number is 12–14. The experimental molecular weight was 200, as calculated from the titration of various amine solutions, in ethanol, by standard

* Author to whom correspondence should be addressed.

sulphuric and hydrochloric acid using a Beckman 3560 pH-meter.

Kerosene was supplied by CAMPSA with the following specifications: boiling point, >140°C; % aromatics, ~20; density (20°C), 0.780 g cm^{-3}. All other chemicals were reagent grade.

Procedure

Extractions were carried out by the following procedure. Equal volumes of Primene 81R solutions diluted in kerosene with *n*-decanol as modifier [in a proportion of half the initial amine concentration, expressed as % (v/v)] and iron(III) sulphate solutions containing the stoichiometric concentration of sulphuric acid to form the amine sulphate[8] were placed in separatory funnels, thermostatted at 8±0.1°C, and mechanically shaken. On completion of the extraction, the phases were separated and iron(III) in the organic phase was then back-extracted with 3 M sulphuric acid solutions.

Iron(III) in both phases was determined volumetrically with potassium dichromate; the acidity of the equilibrated aqueous phases was determined with sodium hydroxide solutions using methyl orange as indicator; the procedure followed was: an aliquot of the aqueous phase was treated with sufficient standard sodium hydroxide solution to precipitate all the iron(III) in the form of the hydroxide, and to neutralize free sulphuric acid formed in the extraction reaction. After filtration of the solid and carefully washing it, the solution was titrated with standard hydrochloric acid using methyl orange as indicator. Sulphuric acid concentrations were then calculated from all these values. The accuracy of this procedure was checked by the use of known-concentration solutions of either iron(III) or sulphuric acid. Sulphate was determined gravimetrically as barium sulphate.

The diluent of the saturated organic phases was evaporated under reduced pressure to yield a dark-red waxy solid residue. This was recrystallized from a methanol–acetone mixture to yield a dark-red solid. The compound was dried in a desiccator over $CaCl_2$ and P_4O_{10}.

The solid decomposes at 190°C. Found: Fe, 4.7; SO_4^{2-}, 23.1; C, 53.1; N, 4.7; H, 10.2%. Calc. for $4(RNH_3)_2SO_4 \cdot [Fe(OH)SO_4]_2$: Fe, 4.8; SO_4^{2-}, 24.7; C, 53.6; N, 4.81; H, 10.7; O, 1.4%.

IR measurements of the solid were carried out in Unicam SP-1100 and Perkin–Elmer 682 spectrophotometers using cesium iodide windows. Nujol and hexachlorobutadiene mulls were used. UV spectra were obtained in a Beckman DB-GT spectrophotometer using 1-cm SiO_2 cells.

RESULTS AND DISCUSSION

Study of extraction kinetics

Influence of the iron(III) concentration in the aqueous phase. Isotherms for the extraction of iron(III) by 0.203 M Primene 81R sulphate in kerosene and 5% (v/v) *n*-decanol from aqueous iron(III) sulphate solutions are presented in Fig. 1 (temperature of 8°C).

The experimental values obtained from these curves indicated that the equilibrium was reached within 10 min and the change between 10 min and 1 h is quite small, although at high iron(III) concentrations there are no significant differences between 1 and 10 min or 1 h.

The curves did not show the upward swing above the initial loading plateau shown in other amine systems.[5] Thus, it can be concluded that in the Primene 81R sulphate–iron(III) extraction system there is not a species change at high aqueous iron(III) concentration.

Influence of equilibration time. Kinetic studies have also been carried out on the effect of different initial aqueous iron(III) concentrations on the equilibration time, keeping the iron(III) concentration constant each time. The results obtained at 8°C are shown in Fig. 2, plotting the iron(III) concentration in the organic phase vs equilibration time, for an organic phase of 0.203 M amine Primene 81R sulphate in kerosene shaken with different aqueous iron(III) solutions.

At 8°C equilibrium was reached in 5 min for all compositions of the aqueous phase. Temperature has no influence on equilibrium extraction between 8 and 5°C. Increasing concentrations of iron(III) in the aqueous phase up to 1 M have no influence on the organic-phase composition. This result was in

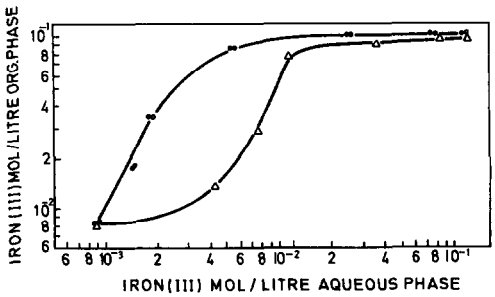

Fig. 1. Equilibrium loading curves for iron(III) extraction by Primene 81R sulphate in kerosene. *Organic phase*: 0.203 M Primene 81R sulphate in kerosene and 5% (v/v) *n*-decanol. *Aqueous phase*: solutions containing various concentrations of $Fe_2(SO_4)_3$. *Contact*: equal volumes equilibrated for: (△) 1 min, (●) 10 min, or (○) 1 h.

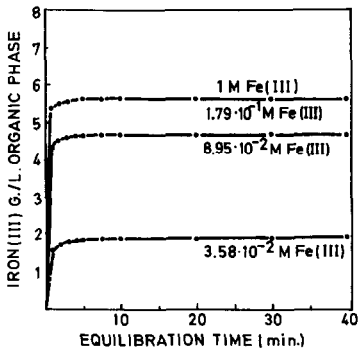

Fig. 2. Kinetics of iron(III) extraction by 0.203 M Primene 81R sulphate. Effect of varying initial iron(III) concentrations in the aqueous phase and equilibration time.

accordance with those obtained previously showing the absence of the upward swing of the curves in Fig. 1. Increasing equilibration time has no influence on the loading of the organic phase.

Extraction isotherms

Loading isotherms for the extraction of iron(III) with 0.0254, 0.0508, 0.1015 and 0.203 M amine Primene 81R sulphate in kerosene, in equilibrium with aqueous iron(III) sulphate solutions at 8 ± 0.1°C, are shown in Fig. 3. The results obtained show that at saturation loading the amine sulphate/iron(III) concentration ratio appears to approach 2. Neither of the curves shows an upward swing above this loading level as mentioned before.

Sulphuric acid titration of the equilibrated aqueous phase shows that 1 mol of sulphuric acid is liberated for every 2 mol of iron(III) extracted by Primene 81R sulphate as shown by experimental

Table 1. Experimental values of acid liberated by the extraction of iron(III) (organic phase: 0.203 M Primene 81R sulphate, temperature 8°C)

$[Fe(III)]_{org}$ (mM)	$[H_2SO_4]_{aq}$ (mM)	$[Fe(III)]_{org}/[H_2SO_4]_{aq}$
8.1	4.1	1.98

34.0	16.9	2.01
84.2	41.9	2.01
100.0	50.3	1.99
101.0	50.5	2.00
	Average	2.00

values in Table 1 for a 0.203 M amine sulphate concentration.

Figure 4 shows the relationship between the molar ratio of the iron(III) concentration in the organic phase to the Primene 81R concentration vs the iron(III) concentration in the aqueous phase; it can be seen that the limiting ratio obtained is equal to 0.25, corresponding to $[Fe(III)]_{org}/[RNH_2]_{org} = 0.25$. If the amine concentration is transformed into amine sulphate concentration, this value is 0.5, as $[RNH_2]_{org} = 2[(RNH_3)_2SO_4]_{org}$ for this system.[8] This molar ratio is similar to those obtained from curves in Fig. 3.

According to the experimental data, the following extraction reaction for iron(III) sulphate by Primene 81R sulphate in the range of temperatures between 8 and 5°C is suggested:

$$4(RNH_3)_2SO_{4(org)} + Fe_2(SO_4)_{3(aq)} + 2H_2O \rightleftarrows 4(RNH_3)_2SO_4 \cdot [Fe(OH)SO_4]_{2(org)} + H_2SO_{4(aq)}. \quad (1)$$

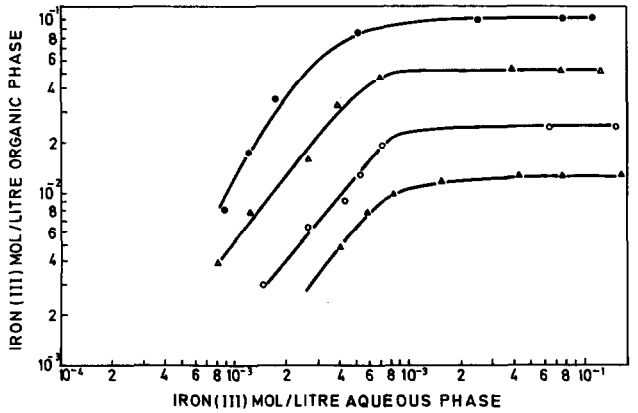

Fig. 3. Equilibrium loading curves for iron(III) extraction by Primene 81R sulphate. Effect of amine sulphate concentration. *Organic phase*: (●) 0.203 M, (△) 0.1015 M, (○) 0.0508 M, (▲) 0.0254 M amine sulphate in kerosene and *n*-decanol [5, 2.5, 1.25 and 0.63% (v/v), respectively]. *Aqueous phase*: aqueous solutions containing various concentrations of $Fe_2(SO_4)_3$. *Contact*: equal volumes were equilibrated for 10 min.

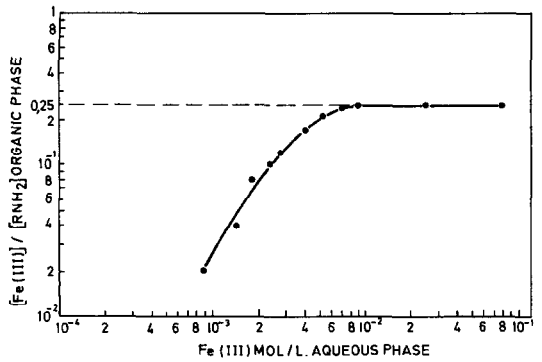

Fig. 4. Variation in the molar ratio [Fe(III)]/[RNH_2] in the organic phase with molar [Fe(III)] in the aqueous phase. *Organic phase*: 0.203 M Primene 81R sulphate.

It seems that an adduct is formed as suggested in other systems described by other authors, with the extraction of an iron(III) compound similar to those described before with other amine sulphates,[1-3] but different from the extracted species described for other primary amines.[5] The results obtained show that the structure of the amine sulphate will define the way in which iron(III) is extracted into the organic phase, and not the type of amine (i.e. primary, secondary, ...), because several primary and secondary amines (like those studied in this paper and in Refs 1–3 and 9) extract iron(III) in the form of a hydroxylated species of this metallic ion, whereas another primary amine named Primene JMT extracts iron(III) in a complex with no iron(III)-hydroxylated species.[5] The results obtained also show that the Primene 81R sulphate can extract iron(III) from aqueous sulphate solutions even at low temperatures, the mechanism of the extraction being similar to that described for the same amine sulphate at higher temperatures; the extraction reaction can be related as an adduct formation and not as an anion exchange reaction, this being the first time that the extraction behaviour of an amine sulphate at this temperature has been described.

Reagent concentration dependence

This study was carried out by shaking a 0.179 M iron(III) aqueous solution and different organic phases for 10 min at 8°C. The results obtained are shown in Fig. 5, in which the iron(III) concentration in the organic phase is plotted against the initial amine sulphate concentration. It can be seen that there is a proportional concentration relationship between both values until an approximately 0.2 M Primene 81R sulphate concentration. Thus, from Fig. 5 unknown amine sulphate concentrations can be determined by comparing values for the iron(III)

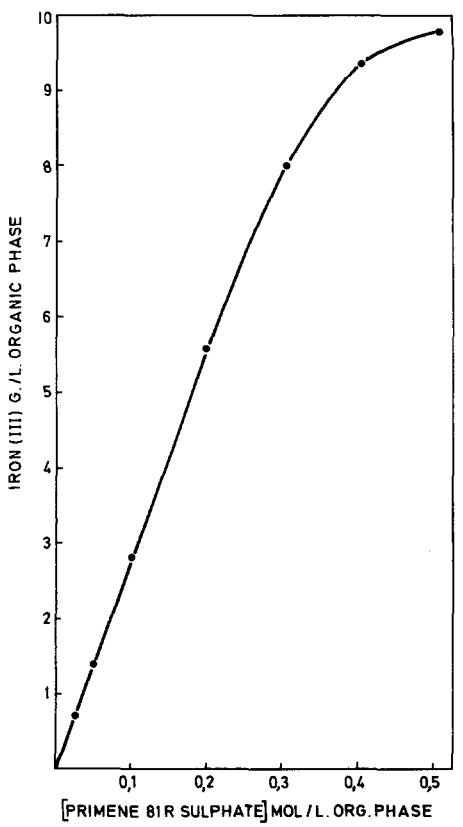

Fig. 5. Variation in iron(III) loading in the organic phase with initial Primene 81R sulphate concentration in the organic phase. *Aqueous phase*: 0.179 M iron(III) solution in sulphate media.

extracted in the organic phase with those shown in Fig. 5.

Figure 6 shows the relationship between the ratio of iron(III) to the amine sulphate concentration in the organic phase vs the initial Primene 81R sulphate concentration at 8°C. It shows that, when the organic phase is saturated with this metallic ion, the maximum value of this relationship is independent of the initial amine sulphate concentrations, this value being equal to the ratio 0.50 or 1/2. This maximum value is equal to that previously obtained from Fig. 4, indicating that, at least at saturation loading, an organic complex with constant stoichiometry was extracted. When there is an excess Primene 81R sulphate concentration the ratio decreases progressively.

The variation in the iron(III) distribution coefficient with the amine sulphate concentration is shown in Fig. 7 at 8°C (equilibrium time in all cases was 10 min). The results show that as the amine sulphate concentration increases the slope of the curves defined by $\log D_{Fe}$ vs log [Primene 81R sulphate] decreases progressively, indicating aggregation of the amine sulphate.

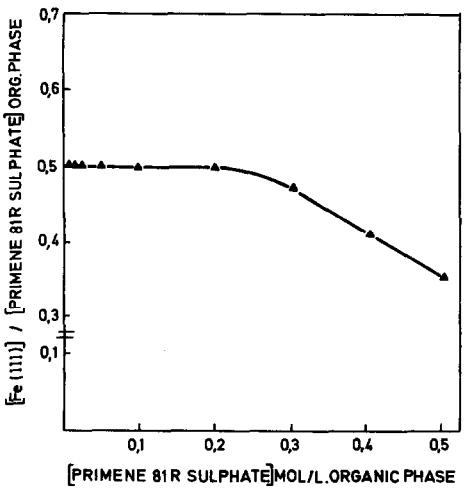

Fig. 6. Variation in the molar ratio [Fe(III)]/[Primene 81R sulphate] in the organic phase with initial amine sulphate concentration. *Aqueous phase*: 0.179 M iron(III) solution in sulphate media.

Equations describing the extraction equilibrium may be derived by considering the following equilibria:

(1) The formation of amine sulphate and distribution of the amine salt between the aqueous and the organic phases:

$$2RNH_{2(org)} + H_2SO_{4(aq)} \rightarrow (RNH_3)_2SO_{4(org)},$$

$$4(RNH_3)_2SO_{4(org)} \rightleftarrows 4(RNH_3)_2SO_{4(aq)},$$

$$K_1 = \frac{[(RNH_3)_2SO_4]^4_{aq}}{[(RNH_3)_2SO_4]^4_{org}}. \quad (2)$$

(2) The hydrolysis of iron(III) in the aqueous phase:

$$2Fe^{3+}_{(aq)} + 2H_2O \rightleftarrows [Fe(OH)]^{4+}_{2(aq)} + 2H^+_{(aq)},$$

$$K_2 = \frac{[[Fe(OH)]^{4+}_2]_{aq}[H^+]^2_{aq}}{[Fe^{3+}]^2_{aq}[H_2O]^2}. \quad (3)$$

(3) The formation of the species $[Fe(OH)SO_4]_2$ in the aqueous phase:

$$[Fe(OH)]^{4+}_{2(aq)} + 2SO^{2-}_{4(aq)} \rightleftarrows [Fe(OH)SO_4]_{2(aq)},$$

$$K_3 = \frac{[[Fe(OH)SO_4]_2]_{aq}}{[[Fe(OH)]^{4+}_2]_{aq}[SO^{2-}_4]^2_{aq}}. \quad (4)$$

(4) The formation of the complex in the aqueous phase:

$$4(RNH_3)_2SO_{4(aq)} + [Fe(OH)SO_4]_{2(aq)} \rightleftarrows 4(RNH_3)_2SO_4 \cdot [Fe(OH)SO_4]_{2(aq)},$$

$$K_4 = \frac{[4(RNH_3)_2SO_4 \cdot [Fe(OH)SO_4]_2]_{aq}}{[(RNH_3)_2SO_4]^4_{aq}[[Fe(OH)SO_4]_2]_{aq}}. \quad (5)$$

(5) And the distribution of the complex between the aqueous and the organic phases:

$$4(RNH_3)_2SO_4 \cdot [Fe(OH)SO_4]_{2(aq)} \rightleftarrows 4(RNH_3)_2SO_4 \cdot [Fe(OH)SO_4]_{2(org)},$$

$$K_5 = \frac{[4(RNH_3)_3SO_4 \cdot [Fe(OH)SO_4]_2]_{org}}{[4(RNH_3)_2SO_4 \cdot [Fe(OH)SO_4]_2]_{aq}}. \quad (6)$$

The combination of the expressions for the five equilibrium constants by rearrangement and substitution gives an expression of the equilibrium constant of the overall extraction reaction shown in eqn (1). This K may be deduced as:

$$K = \frac{[4(RNH_3)_2SO_4 \cdot [Fe(OH)SO_4]_2]_{org}[H^+]^2_{aq}[SO^{2-}_4]_{aq}}{[(RNH_3)_2SO_4]^4_{org}[Fe^{3+}]^2_{aq}[SO^{2-}_4]^3_{aq}[H_2O]^2}, \quad (7)$$

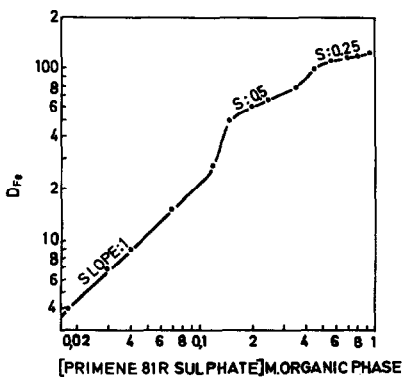

Fig. 7. Dependence of the iron(III) extraction coefficient on the organic-phase concentration of Primene 81R sulphate. *Aqueous phase*: aqueous solution of 0.179 M iron(III) in sulphate media.

in which K is the overall equilibrium constant and molar concentrations are used. If it is assumed that all the iron(III) in the organic phase is in the form of the complex given in eqn (7), and the iron(III) concentration in the aqueous phase is proportional to the iron(III) concentration as described in eqn (1), eqn (7) is transformed into eqn (8):

$$D_{Fe} = \frac{K[SO^{2-}_4]^2_{aq}[(RNH_3)_2SO_4]^4_{org}}{[H^+]^2_{aq}}. \quad (8)$$

From this equation eqn (9) is obtained:

$$\log D_{Fe} = 4\log[(RNH_3)_2SO_4]_{org} + \log K', \quad (9)$$

where K' is the overall constant.

It has been shown[5] that in the case of extraction by a primary amine this equation must be corrected by introducing a value named j, which represents

the number of free amine sulphate molecules per aggregate; hence:

$$\log D_{Fe} = \frac{n}{j}\log [(RNH_3)_2SO_4]_{org} + \log K', \quad (10)$$

in accordance with eqn (9). n is the number of amine Primene 81R sulphates associated with each iron(III).

Consequently, in a representation of $\log D_{Fe}$ vs log [Primene 81R sulphate] as in Fig. 7, the slope of the curves (n/j) will be dependent on the iron(III) complex stoichiometry and on the extractant aggregation. From Figs 3 and 6 is can be deduced that the value of n in this extraction system is 2 for the present complex stoichiometry [eight molecules of amine or four of the amine sulphate per two iron(III)]. Thus the slope $n/j = 1$ in Fig. 7 at low extractant concentrations gives an average Primene 81R sulphate aggregation of approximately 2, and the slope $n/j = 0.25$ at higher amine sulphate concentrations suggests an aggregation of approximately 8. These experimental data are in accordance with those obtained about the aggregation of primary amine sulphates.[11]

From the experimental values presented in this work it can be deduced that when iron(III) is extracted by Primene 81R sulphate at 8°C there is a deaggregation of the amine sulphate, which is much larger at low amine sulphate concentrations in the organic phase.

Spectra and structure of the complex

The IR spectrum of the complex shows four bands at 1180, 1125, 1035 and 985 cm^{-1}, which are consistent with those expected for the sulphate group acting as a bidentate ligand.[12] The spectrum also shows a band at 3025 cm^{-1} assigned to the N—H stretching vibration of the amine group and a band at 1220 cm^{-1} that can be assigned to the C—N vibration of the amine group. A band that can be assigned to the O—H group linked to iron(III) appears at about 3600 cm^{-1}, whilst the absence of a band in the region 1600–1650 cm^{-1} suggests the absence of water in the complex and implies that the band at 3600 cm^{-1} is only due to the O—H group.

The UV spectrum in kerosene of the isolated iron(III)–Primene 81R complex shows a band at about 335 nm. It has been suggested[13] that at certain iron(III) concentrations the iron(III)-hydroxylated species dimerizes to give the $[Fe(OH)]_2^{4+}$ species which shows an absorption peak at 335 nm. The dimer species must be considered with hydroxyl groups bridging two iron(III) ions.

Table 2. Degree of association of the amine Primene 81R sulphate–iron(III) complex extracted at 8°C

Solvent	Concentration (mM)	Molecular weight	Degree of association[a]
Benzene	12.51	2365	1.0
Benzene	25.01	2346	1.0
Benzene	50.02	2330	1.0

[a] Based on the empirical formula $4(RNH_3)_2SO_4 \cdot [Fe(OH)SO_4]_2$, corresponding to a molecular weight of 2330.

The value of the molar extinction coefficient at 335 nm is about 3887 (complex concentration = 3.91×10^{-5} M) which is different to that reported for these species in aqueous solutions. It has been shown[14] that in solutions of certain amines in chloroform, the spectra of several complexes of metals have higher extinction coefficients than those obtained in aqueous solutions, although the absorption maxima and character of the spectra will be constant. It is possible that this change is due to the different diluents and to certain interactions between the solvent and metallic species. The phenomenon observed in this paper has also been observed in other amine systems.[2,3,9]

Molecular-weight values, obtained by cryoscopic measurements in benzene of the iron(III) complex with Primene 81R sulphate, at various concentrations, are presented in Table 2. They show that the complex is a monomer in benzene solution if based on the $4(RNH_3)_2SO_4 \cdot [Fe(OH)SO_4]_2$ unit.

From the data obtained the structure shown in Fig. 8 can be suggested for the iron(III)–Primene 81R sulphate complex extracted in the range of temperatures between 8 and 5°C. In this structure the stoichiometry of two iron(III) atoms per four amine sulphate groups deduced above from the extraction reaction (1), and established by analysis, remains constant. Each iron(III) presents a coordination number of 6, similar to the coordination observed for this ion in similar complexes.[3,9]

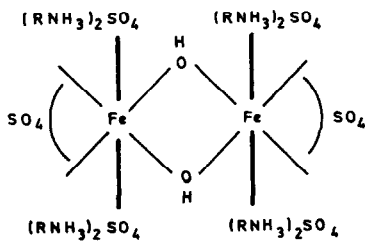

Fig. 8. A possible structure of the iron(III)–Primene 81R sulphate complex.

PREDICTED STABILITIES OF MONATOMIC ANIONS IN WATER AND LIQUID AMMONIA AT 298.15 K

STEVEN G. BRATSCH* and J. J. LAGOWSKI

Department of Chemistry, The University of Texas, Austin, TX 78712, U.S.A.

(*Received* 3 *January* 1986; *accepted* 28 *February* 1986)

Abstract—Critically evaluated experimental and theoretical atomic electron affinities are assembled and used to derive thermodynamic properties of gas-phase monatomic anions throughout the Periodic Table. The stabilities (as ΔG_f^o) of these anions in water and liquid ammonia are calculated by a semiempirical electrostatic model. The predictions are compared with experimental observations where possible.

The ability of some metals to form "simple" anions represents a new and unusual area of inorganic chemistry. Monatomic metal anions (M^-) known in nonaqueous solvents and/or crystals include Na^-, K^-, Rb^-, Cs^-[1–3] and Au^-.[4,5(a),6]

Chemical intuition may serve as a guide in determining which metals should form anions. However, a significant advancement in our understanding of simple metal anions would be the calculation of their thermodynamics of formation in solution or crystals. In previous papers,[7–9] we have applied a semiempirical electrostatic model to the estimation of the stability of monatomic anions of the alkali metals, lanthanides and actinides in water and liquid ammonia at 298.15 K. In the present work we apply our model to the remaining elements of the Periodic Table. With the exception of about a dozen borderline cases, our results serve to identify those elements which are expected to form thermodynamically stable simple anions in solution under standard-state conditions.

The standard Gibbs free energy of formation of a solvated monatomic anion M^- [ΔG_f^o (M^-, solv)] is defined as the standard Gibbs free energy change for the reaction:

$$M(\text{std state}) + 0.5H_2(g) \rightarrow M^-(\text{solv}) + H^+(\text{solv}), \quad (1)$$

where H^+(solv) is a shorthand for the various cationic hydrogen species (e.g. H_3O^+, $H_9O_4^+$ etc., in water, and NH_4^+ in liquid ammonia). Based on experimental halide data,[7] we have previously derived the relationships:

$$\Delta G_f^o(M^-, \text{aq}) = \Delta G_f^o(M^-, \text{g}) - \frac{56.1}{r_{M^-} - 0.017} + 451, \quad (2)$$

$$\Delta G_f^o(M^-, \text{am}) = \Delta G_f^o(M^-, \text{g}) - \frac{50.3}{r_{M^-} - 0.017} + 354, \quad (3)$$

for anions in aqueous and ammonia solutions, respectively, at 298.15 K. In eqns (2) and (3), ΔG_f^o is in kJ mol^{-1} and r_{M^-} is the crystal anionic radius in nm.[10] The term in eqns (2) and (3) involving r_{M^-} represents a simple, semiempirical way of relating the standard Gibbs free energy of solvation of M^- in water or liquid ammonia to the ionic radius. In order to calculate the stability of a monatomic anion in water or liquid ammonia by eqn (2) or (3), we require ΔG_f^o (M^-, g) and an estimate for r_{M^-}.

THERMODYNAMICS OF GAS-PHASE ANIONS AT 298.15 K (TABLE 1)

Standard enthalpies of formation of monatomic gases [ΔH_f^o (M, g)] and standard entropies of the elements in their standard states [S^o (M, std state)] at 298.15 K have been taken from familiar references[11,12] and therefore have not been tabulated. Experimental atomic electron affinities [EA (M)] have been taken from the recent review by Hotop and Lineberger.[13]

[a] Reference 13, except as noted.
[b] Anion electron configuration (Ref. 13 and this work).
[c] Equation (4). ΔH_f^o (M, g) from Ref. 11 or 12 except for M = Tc, Po and At [estimated (620, 180 and 100 kJ mol^{-1})] (this work).
[d] Equation (5).
[e] S^o (M, std state) from Ref. 11 or 12 except for M = Tc, Po and At [estimated (33, 60 and 65 J K^{-1} mol^{-1})] (this work). S^o (e^-) accounted for in $\Delta G_f^o = \Delta H_f^o - T\Delta S_f^o$.
[f] Arbitrary convention.
[g] Estimated (this work).

We have estimated the EAs where necessary by methods discussed by Zollweg.[14] All atomic ionization potentials [IP (M)] and atomic and cationic promotion energies (ΔE) required for these methods have been taken from Moore's tables.[15,16]

He, Ne, Ar, Kr *and* Xe

These were derived by quadratic extrapolation of isoelectronic sequences, correcting for ΔE [M^{2+}, $(n-1)d^1 \rightarrow ns^1$] for M = Sc, Y and La.

Be, Mg, Zn, Cd *and* Hg

These were derived by extrapolation of the EA of *p*-block elements by comparison with the IP of the following element (an isoelectronic process).

Ca (3d), Sc (3d), Mn (3d), Sr (4d), Y (4d), Tc, Lu (5d), Hf, Re *and* Po

These were calculated by horizontal analysis.[14]

Ca (4p), Sr (5p), Ba, Lu (6p) *and* Rn

These were estimated by vertical extrapolation.

Mn (4p)

This was assumed to lie between Ca (4*p*) and Zn.

The standard enthalpies of formation and standard entropies of gas-phase anions M^- have been calculated by:[17(a),(b)]

$$\Delta H_f^o(M^-, g) = \Delta H_f^o(M, g) - EA(M) - 2.5RT, \quad (4)$$

$$S^\circ(M^-, g) = 1.5R\ln(\text{at wt}) + R\ln(2J+1) + 108.745, \quad (5)$$

where ΔH_f° is in kJ mol^{-1} and S° is in J K^{-1} mol^{-1}. J in eqn (5) is the total angular-momentum quantum number (L–S coupling) and $2J+1$ is the electronic-spin multiplicity.[18,19]

Finally, ΔG_f° (M^-, g) values in Table 1 have been calculated by ΔH_f° (M^-, g) $- T\Delta S_f^\circ$ (M^-, g), using S° (e^-) = 20.87 J K^{-1} mol^{-1}.[17(c)]

CRYSTAL ANIONIC RADII AND PREDICTED STANDARD GIBBS FREE ENERGIES OF FORMATION OF ANIONS IN WATER AND LIQUID AMMONIA AT 298.15 K (TABLE 2)

Crystal anionic radii have been calculated by an extension of a method used for lanthanides and actinides:[8,9]

$$r_{M^-} = \frac{A}{q+B} + C, \quad (6)$$

where q equals the number of np, $(n-1)d$ or $(n-2)f$ electrons in the anion. The basis for q is the orbital type being filled in accordance with the Aufbau principle. B equals 6, 10 or 14 for anions of the p-, d- or f-block elements, respectively, and A and C are determined by fitting to certain "key" values. "Key" anionic radii have been assumed for the alkalides ($q = 0$) [Ref. 5(b) and this work], the halides ($q = 6$) (Ref. 10 and this work), and the copper and zinc subgroups ($q = 10$ and 1, respectively) [Ref. 5(c) and this work]. Irregularities in electron configurations (e.g. Pd^- is $4d^{10}5s^1$, not $4d^95s^2$) have been ignored in assigning q. Noble-gas anionic radii are probably the least certain because they have been extrapolated by using $q = -1$.

Pauling[10] has calculated the hydride ionic radius by the extrapolation of an isoelectronic sequence. Alternately, one may subtract the appropriate cationic radius from the measured metal–hydrogen distance in the alkali hydride crystals.[20(a)] Both results are given in Table 2.

Crystallographic measurements[21(a)] and spectroscopic correlations[5(c)] indicate that r_{Au^-} is about

[h] Using the more stable ΔG_f° (M^-, g) from Table 1.

0.02 nm *smaller* than r_{At^-} which occurs later in the same period. The difference is probably related to the presence of 6*p* electrons in the valence shell of the latter ion which are absent in Au^-. The isovalent cationic radii of the late *d*-block transition metals are also often somewhat smaller than those of the post-transition elements of the same period.[10,21(a)] Therefore, we postulate that a small (but possibly abrupt) increase in crystal anionic radius occurs on the initial filling of the *np* orbitals following the *d*-block transition metals, i.e. between the copper and zinc subgroups.

We estimate that anionic radii calculated by eqn (6) are probably reliable to about 0.02 nm; thus, the third decimal place in the anionic radius is significant only in a relative sense between adjacent elements.

Predicted standard Gibbs free energies of formation of monatomic anions M^- in water and liquid ammonia at 298.15 K are presented in Table 2 [calculated by eqns (2) and (3)]. The corresponding standard electrode potentials [E^o (M–M^-)] are also given.

DISCUSSION

The standard Gibbs free energy change at 298.15 K for the reaction:

$$0.5H_2(g) \rightarrow e^-(solv) + H^+(solv) \qquad (7)$$

is about 267 kJ mol^{-1} in water[22] and 186 kJ mol^{-1} in liquid ammonia.[5(d)] Therefore, for the reaction:

$$M(\text{std state}) + e^-(solv) \rightarrow M^-(solv) \qquad (8)$$

to be spontaneous at unit activity, ΔG_f^o (M^-, solv) must be less than these quantities. From Table 2, this requirement is met for the halogens, chalcogens, sodium and gold in either solvent, and also for lithium, silver and bismuth in water.

However, the formation of M^- from M depends not only on reaction (8) being both thermodynamically and kinetically feasible but also on all possible decomposition routes being prohibited for either thermodynamic or kinetic reasons. Thus, we expect anions of lithium, sodium, silver, gold and bismuth to be rapidly oxidized by water and not be detectable. Also, the existence of Na^- in liquid ammonia is doubtful, perhaps because the correction for activity effects in this solvent is very large (*vide infra*), but also perhaps because other combinations such as $Na^+ + 2e^-$, $Na^+e^- + e^-$ and/or $e^-Na^+e^-$ are thermodynamically favored.[1-3] Monatomic anions M^- of the chalcogens, although predicted to be stable in terms of reaction (8), should dimerize, forming O_2^{2-}, S_2^{2-} etc.

On the other hand, if ΔG^o for reaction (8) is positive, M^- might still be formed by an alternate route which does not involve the free element M, provided the decomposition kinetics are slow. In addition, other negative oxidation states may be stable (e.g. Pb_9^{4-} and Sb_7^{3-} in liquid ammonia) even if M^- is not.

The following values (in kJ mol^{-1}) are typical for the *d*-block transition metals:

$$\Delta H_f^o(M, g) = 500 \pm 200,$$

$$EA(M) = 60 \pm 70,$$

$$\Delta G_{solv}^o(M^-) = -260 \pm 30$$

[based on eqns (2) and (3)].

These figures indicate that the *variations* in transition-metal anion stability are determined mainly by ΔH_f^o (M, g), and that EA (M) and ΔG_{solv}^o (M^-) have a relatively minor influence. For example, although the electron affinity of platinum is only 0.2 eV less than that of gold, and the standard Gibbs free energies of solvation of the anions should be similar, Pt^- is predicted to be unstable in solution, because strong bonding in the metal forces reaction (8) to the left. On the other hand, anionic mercury is calculated to be almost stable in terms of reaction (8), the extreme volatility of the metal nearly compensating for the negative electron affinity.

The fictitious "rhenide" ion is known today to be a hydride species,[20(b),21(b)] although it is still incorrectly written as Re^- in some modern publications (e.g. Ref. 12). Table 2 indicates that authentic $Re^-(solv)$ should be extremely unstable.

Noble-gas anions are probably unstable in solution because the anionic radii are so large that solvation is not sufficiently exothermic to compensate for the negative electron affinities. If our EA (M) and anionic radius estimates are accurate, anionic helium is the most probable species. Zollweg[14] has derived noble-gas electron affinities from experimental excited-state EAs with estimated corrections to the ground state. By combining Zollweg's EA values with estimated anionic radii, Blake and Clack[23] have concluded that neon is the noble gas most likely to form anions (as Cs^+Ne^-).

Some of the information presented in this paper may have other applications in addition to predictions on anions in water and liquid ammonia. For example, Table 1 serves as a convenient reference of critically evaluated electron affinities and gas-phase anion thermodynamics for the entire Periodic Table (except the lanthanides and actinides). Table 2 offers an internally consistent set of anionic radii for all elements. These data may be used in structural predictions for solids containing metal anions or in crystal lattice energy calcu-

lations. Finally, for those who are interested only in qualitative trends, the standard electrode potentials provided in Table 2 should serve as approximate indicators of the stability of metal anions in other chemical systems (i.e. other solvents and crystals) because the *order* of anion stability is not expected to change radically in moving from one system to another.

Reliability of predictions of ΔG_f° (M^-, *solv*)

The atomic EAs which have been estimated in this work are mostly believed to be uncertain by about 0.2 eV, thereby contributing about 20 kJ mol^{-1} to the uncertainty in the standard Gibbs free energies of formation of M^- in solution. A similar contribution to the uncertainty is believed to be generated by the choice of crystal anionic radii.

We have not considered ligand field stabilization effects for transition-metal anions with partially filled $(n-1)d$ orbitals. Such effects should be small because the $(n-1)d$ electrons should be largely shielded from their environment by the overlying *ns* electrons. The situation is therefore not analogous to that found for transition-metal cations.[17(d),20(c)]

The validity of eqns (2) and (3) can be tested by comparison of our predicted ΔG_f° (M^-, solv) with experimental measurements or observations for those elements where errors due to the choice of EA (M) or r_{M^-} should be small. For example, Peer[5(e)] has reported E_{NH_3} [Au−Au(−I)] = −1.48 V (relative to the hydrogen electrode) in 0.1 M KI at 233 K. Because this potential does not take ion pairing (i.e. K^+Au^-) into account, the standard-state value $E^\circ_{NH_3}$ ($Au-Au^-$) must be more negative; thus ΔG_f° (Au^-, am) [reaction (1)] is greater than 143 kJ mol^{-1} at 233 K. By comparison with the standard entropies of the halides in liquid ammonia,[24] and correcting for the atomic weight of gold, we estimate ΔS_f° (Au^-, am) = -200 ± 20 J K^{-1} mol^{-1} at 298.15 K. Neglecting the unknown heat capacity correction, we derive ΔG_f° (Au^-, am) to be greater than 156 kJ mol^{-1} at 298.15 K. Therefore, our predicted value in Table 2 is probably in error by less than 30 kJ mol^{-1}.

Alkali metal anions are unknown in liquid ammonia,[1-3] despite the fact that ΔG_f° (Na^-, am) is calculated to be less than 186 kJ mol^{-1} (Table 2). However, a correction for activity effects[7] reveals that an impossibly high concentration of sodium metal would be required to produce a solution of Na^- under standard-state conditions (unit activity) in liquid ammonia.

On the basis of these considerations, we surmise that the uncertainty in our predictions of ΔG_f° (M^-, solv) could be as great as 50–60 kJ mol^{-1} in a few instances, but more typically about 30 kJ mol^{-1}. The greatest uncertainties in ΔG_f° (M^-, solv) are probably for hydride anion (due to the uncertainty in the anionic radius) and for the anions of the noble gases (due to the uncertainty in the anionic radii and the electron affinities). Nevertheless, with the exception of about a dozen borderline cases, one can predict whether a given metal anion should be thermodynamically stable in water or liquid ammonia. A more detailed approach which considers the specific anion–solvent interaction, perhaps as a sum of many terms, would be required to resolve the borderline cases.

(*Received* 5 *February* 1986; *accepted* 4 *March* 1986)

Abstract—Variable-temperature ^{119}Sn Mössbauer spectroscopic (VTMS) data for six tin phthalocyanine (pc) derivatives have been collected in order to ascertain the restrictions imposed by the macrocyclic ring on the vibrational motion of the tin atom. Thermal condensation of $[(t\text{-Bu})_4\text{pc}]\text{Sn(OH)}_2$ yields the co-facially stacked polymer $\{[(t\text{-Bu})_4\text{pc}]\text{SnO}\}_n$ which can be distinguished in the VTMS experiment by the enhanced rigidity of its structure.

A considerable amount of research effort has been directed towards the synthesis of organic and metal–organic molecular systems which have metal-like electrical, magnetic and optical properties.[1] Among the best known of the "1-D metals" are the organic charge-transfer compounds, e.g. tetrathiafulvalene–tetracyanoquinodimethane,[2] and square planar metal species, e.g. $K_2Pt(CN)_4$[3] and Ni(pc) (pc = phthalocyanine).[4] This latter class forms molecular stacks in the solid, yielding a conduction pathway by overlap of d_{z^2}-orbitals along the metal spine. More recent work has sought to overcome the unpredictable and largely uncontrollable intermolecular packing forces which determine whether or not stacks are formed by linking square planar metal complexes with axially-oriented bridging groups, e.g. M(pc)F (M = Al or Ga),[5] Fe(pc)pyrazine[6] and Co(pc)CN.[7] For main-group elements, Marks *et al.*[8] have shown that thermal condensation of silicon, germanium or tin phthalocyanine dihydroxide yields the oxo-bridged co-facial stack $[M(pc)O]_n$, e.g.

(1)

While these compounds are themselves semiconductors, partial oxidation with molecular halogens

* Author to whom correspondence should be addressed.

yields materials with metallic conductivities of *ca* $1\ \Omega^{-1}\ cm^{-1}$.

Our recent work utilizing variable-temperature Mössbauer spectroscopy (VTMS) as a lattice structure probe has shown that the technique is a good indicator of both polymer formation and the three-dimensional spacial disposition of atoms along the polymer backbone, i.e. rod, zig-zag, "S"-shaped and helical.[9] As such, VTMS seems ideally suited to assess reactions of the type shown in eqn (1), which leads to a stack of molecules linked by a central polymer strand. However such experiments cannot be viewed against the backdrop of systematics for simple molecular species[9,10] since the rigid macrocycle might itself be expected to significantly influence the lattice dynamics of the coordinated metal. In this report we quantify this "macrocyclic effect", and subsequently show how VTMS can be a useful probe of stack formation.

EXPERIMENTAL

The solvents quinoline and 1-chloronaphthalene were vacuum distilled from BaO before use; pyridine was dried over sodium hydroxide and distilled under a dry dinitrogen atmosphere. Anhydrous stannous chloride was obtained commercially (BDH) and used without further purification. (pc)$SnCl_2$,[11] (pc)SnI_2,[12] (pc)Sn[12] and [(*t*-Bu)$_4$pc]$SnCl_2$[13] were prepared by published procedures. IR, Mössbauer and (for the more soluble *t*-butylated compounds) ^{1}H NMR and UV–VIS spectroscopic data are in excellent agreement with those previously reported. The insolubility and involatility of the unsubstituted macrocyclic derivative makes purification of products difficult and microanalysis data* are on occasion low in carbon. The Mössbauer spectrum of (pc)Sn indicated that the presence of a resolved Sn(IV) impurity of *ca* 7% [assuming equal recoil-free fractions for the Sn(II) and Sn(IV) species], which could not be separated.

4-t-*Butyl*-o-*xylene* (2)

This was prepared by alkylation of *o*-xylene (**1**) with *t*-butyl chloride and iron(III) chloride as reported previously.[14] *o*-Xylene was removed from the reaction mixture by fractional distillation (15-cm packed column) at atmospheric pressure; the column was removed and the desired product distilled at 208°C (yield 52%).

4-t-*Butyl phthalic acid* (3)

The synthesis of this follows the general procedure of Hanack.[13] To a refluxing, mechanically stirred solution of **2** (32.8 g, 20 mmol) in a mixture of pyridine (250 cm^3) and water (80 cm^3) was added potassium permanganate (169.5 g, 1.07 mol) over a 1.5-h period such that reflux was maintained without external heating. At the conclusion of the addition, the solution was heated at reflux for a further 30 min. Ethanol (30 cm^3) was added to the hot solution, which was then allowed to cool to room temperature and filtered. The filtrate was concentrated to *ca* one-third its volume, treated with conc. HCl (80 cm^3), extracted with ether, and the extract washed with water and dried over anhydrous $MgSO_4$. The viscous oil which results after solvent evaporation was crystallized using a 1:1 chloroform–petroleum ether mixture (yield 24.6 g, 55%).

4-t-*Butyl phthalic anhydride* (4)

3 (24.6 g, 0.11 mol) was refluxed in acetic anhydride (70 cm^3) for 1 h. After cooling, the solution was filtered, the filtrate concentrated to *ca* 20 cm^3 and allowed to crystallize at −10°C. The resulting white solid was purified by sublimation at *ca* 80°C/1 mmHg to yield **4** (16.0 g, 71%).

(2,9,16,23 - *Tetra* - t - *butylphthalocyaninato)tin dihydroxide* (8)

[(*t*-Bu)$_4$pc]$SnCl_2$ (**7**) (500 mg) was heated at reflux for 6 h in a solution of NaOH (2.4 g) in 5:1 ethanol–water (60 cm^3). After cooling, a dark blue solid was isolated by filtration, redissolved in chloroform and washed several times with water. The organic phase was separated, dried over anhydrous $MgSO_4$, and the product [**8** (240 mg, 50%)] recovered by evaporation of the solvent. Found: C, 64.2; H, 5.7; N, 11.6%. Calc. for $C_{48}H_{50}N_8O_2Sn$: C, 64.8; H, 5.7; N, 12.6%.

Poly-(2,9,16,23-*tetra*-t-*butylphthalocyaninato)stannoxane* (10)

A sample of **8** (250 mg) was heated under dynamic vacuum at 330°C for 30 min. The resulting solid was washed with chloroform until the wash-

* (pc)$SnCl_2$: Found: C, 52.0; H, 2.1; N, 15.6%. Calc. for $C_{32}H_{16}Cl_2N_8Sn$: C, 54.8; H, 2.3; N, 16.0%. (pc)SnI_2: Found: C, 43.5; H, 1.9; N, 12.5%. Calc. for $C_{32}H_{16}I_2N_8Sn$: C, 43.4; H, 1.8; N, 12.6%. [(*t*-Bu)$_4$pc]$SnCl_2$: Found: C, 59.1; H, 5.3; N, 11.6%. Calc. for $C_{48}H_{48}Cl_2N_8Sn$: C, 62.2; H, 5.2; N, 12.1%.

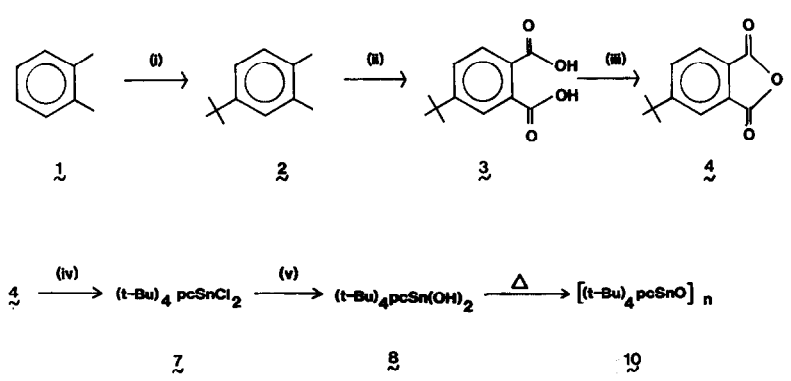
ings were colourless. The black microcrystalline product was insoluble in organic solvents.

^{119}Sn *VTMS*

Details of our Mössbauer spectrometer, cryostat and temperature controller, along with the method of data manipulation, are given elsewhere.[15] Samples containing 0.5–1.0 mg ^{119}Sn cm^{-2} were used, and data acquisition was *ca* 12 h per spectrum; temperature stability was ± 0.1 K for the duration of data collection.

RESULTS AND DISCUSSION

Syntheses



Tin phthalocyanine derivatives [(pc)Sn and (pc)SnX_2 (X = Cl or I)] were synthesized by published procedures. The dichloride is obtained from refluxing anhydrous $SnCl_2$ and *o*-phthalonitrite in 1-chloronaphthalene,[11] and can subsequently be reduced to the divalent species (pc)Sn by reaction with additional $SnCl_2$ in quinoline.[12] (Phthalocyaninato)tin diodide is prepared in an oxidative addition reaction between (pc)Sn and I_2 in 1-chloronaphthalene.[12] All three species are only sparingly soluble in organic solvents, and are hence difficult to purify and characterize. Their solubility in such media can be greatly enhanced by preparation of the peripherally substituted tetra-(*t*-butyl)phthalocyanine compounds, which follows the route used by Hanack and is shown in Scheme 1.[13] This increase in solubility also facilitates the hydrolysis of the dichloride (**7**) to the dihydroxy-species (**8**):

$$[(t\text{-Bu})_4\text{pc}]SnCl_2 + 2OH^- \rightarrow [(t\text{-Bu})_4\text{pc}]Sn(OH)_2 + 2Cl^- \quad (2)$$

The ν_a(Sn—Cl) absorption at 300 cm^{-1} for **7** is absent in the reaction product, and is replaced by a new band at 562 cm^{-1} which we assign to ν_a(Sn—O) on the basis of data for (pc)$Sn(OH)_2$ [ν_a(Sn—O) = 564 cm^{-1}].[11] The stannol (**8**) can be dehydrated to give the condensed polymer (**10**) by heating under a dynamic vacuum at 330°C:

$$[(t\text{-Bu})_4\text{pc}]Sn(OH)_2 \xrightarrow{330°C} \{[(t\text{-Bu})_4\text{pc}]SnO\}_n + H_2O. \quad (3)$$

The black, stannoxane polymer (**10**), unlike other *t*-butylated phthalocyanine derivatives studied, is totally insoluble in organic solvents. The dehydration process is accompanied by decomposition of the tin(IV) species, as noted by other workers for a similar reaction with (pc)$Sn(OH)_2$.[11,16] Decomposition is evidenced by the presence of an absorption of *ca* 10% of total intensity in the Mössbauer spectrum of **10**, with an isomer shift (IS) of 3.05 mm s^{-1} and a quadrupole spitting (QS) of 1.71 mm s^{-1}, indicative of tin in the +2 oxidation state. The similarity of these parameters, and indeed the temperature dependence of the Mössbauer recoil-free fraction (f) also, to data for (pc)Sn (Table 1) make it tempting to assign the decomposition product as [(*t*-Bu)$_4$pc]Sn; however other workers have found this compound to be soluble in organic solvents, and extremely light- and oxygen-sensitive.[13] Clearly, the exact nature of the decomposition product must remain as yet uncertain. Characterization of **10** is difficult. Its polymeric nature is suggested by its insolubility in common solvents, but its IR spectrum is very similar to that for **8**, other than that well-dispersed mulls proved difficult to obtain leading to a poor signal: background resolution. Our assignment of **10** as an oxo-bridged polymer rests largely on the temperature dependence of its Mössbauer spectrum, as described below.

Scheme 1. Preparative route to soluble tetra-(*t*-butyl)phthalocyanine compounds. Reagents: (i) $FeCl_3$ and *t*-BuCl, (ii) $KMnO_4$ and HCl, (iii) $(CH_3CO)_2O$, (iv) $SnCl_2$ and urea, and (v) NaOH.

Table 1. Mössbauer spectroscopic data for tin phthalocyanine (pc) derivatives[a]

	Compound	IS (mm s^{-1})	QS (mm s^{-1})	Γ_1[b]	Γ_2[b]	10^2a (K^{-1})
5	(pc)$SnCl_2$[c]	0.26	0.90	1.06	1.20	1.10
6	(pc)SnI_2[d]	0.45	1.21	1.26	1.17	0.67
7	[(*t*-Bu)$_4$pc]$SnCl_2$	0.25	0.89	1.00	1.10	1.06
8	[(*t*-Bu)$_4$pc]$Sn(OH)_2$	0.18	0.64	1.02	1.20	1.15
9	(TPP)$Sn(OH)_2$ · solv[e,f]	0.07	0.66	1.04	0.89	1.19
10	{[(*t*-Bu)$_4$pc]SnO}$_n$[g]	0.10	0.67	0.98	1.37	0.36
11	(pc)Sn[h,i]	2.80	1.43	1.28	1.26	1.40

[a] IS and QS data were recorded at 78 K, and are ±0.02 and 0.04 mm s^{-1}, respectively.
[b] Full width at half height for the low (Γ_1) and high (Γ_2) velocity wings of the doublet spectrum.
[c] Literature:[17] IS = 0.28, and QS = 0.99 mm s^{-1}.
[d] Literature:[17] IS = 0.45, and QS = 0.99 mm s^{-1}.
[e] α,β,γ,δ-Tetraphenylporphyrinatotin dihydroxide-bis(chloroform)-bis(carbon tetrachloride) solvate.
[f] Reference 19.
[g] Also contains a tin(II) impurity (~10%): IS = 3.05, and QS = 1.71 mm s^{-1}; 10^2a = 1.35 K^{-1}.
[h] Literature:[17] IS = 2.78, and QS = 1.40 mm s^{-1}.
[i] Also contains a tin(IV) impurity (<10%): IS = −0.10, and QS = 0.00 mm s^{-1}.

Mössbauer spectroscopy

Mössbauer spectroscopic data for tin phthalocyanine complexes are given in Table 1. IS and QS data for known compounds are in good agreement with literature values.[17] IS data for the series $(R_4pc)SnX_2$ (R = H or *t*-Bu; X = O, Cl or I) decrease with increasing electronegativity of X, concomitant with increasing *s*-electron density withdrawal from tin. Both IS and QS data for $(R_4pc)SnCl_2$ (R = H or *t*-Bu) are identical within experimental error, indicating, reasonably, that peripheral substitution of the macrocycle by alkyl groups has no appreciable effect on the electronic environment at the tin nucleus. The temperature dependence of *f* for compounds **5–11** is also given in Table 1, where:

$$a = -\frac{d\ln f}{dT} = -\frac{d\ln A}{dT}, \qquad (4)$$

and A is the area under the Mössbauer spectral envelope. Since:

$$f(T) = \exp[-\langle x(T)^2\rangle/\lambda\!\!\!^{-2}], \qquad (5)$$

and

$$\frac{df(T)}{dT} = \frac{d\exp[-6E_RT/k\theta_D^2]}{dT}, \qquad (6)$$

where $\langle x(T)^2\rangle$ is the mean-square amplitude of vibration of the tin at temperature T, $\lambda\!\!\!^{-}$ the wavelength of the Mössbauer transition divided by 2π, E_R the Mössbauer recoil energy and θ_D the Debye temperature of the lattice, plots of $\ln A$ vs T are linear and indicative of the tightness with which the tin atom is held in the lattice, with values of a decreasing with increasing lattice rigidity. Data for **8** and **10** are shown pictorially in Fig. 1, and typify the quality of data for all compounds.

Aided by a classification of tin polymers based upon the spacial disposition of atoms within the polymer backbone, we[9] and others[10] have shown broadly that non-associated lattices or lattices comprising "S"-shaped (Class 3) or helical (Class 4) polymers show $10^2a > 1.3$ K^{-1} and typically *ca* 1.8 K^{-1}. The value of a also depends on the strength of the intermolecular bond, and to a less well-defined extent the mass of the vibrating unit containing the Mössbauer atom (usually the whole molecule) although the variation due to this phenomenon is usually relatively small. VTMS data for **5–8**, all of which can be assumed to exist as discrete molecules within the solid lattice as has been shown for $(pc)SnCl_2$,[18] have $10^2a \sim 1.0$ K^{-1}, with $(pc)SnI_2$ somewhat lower at 0.67 K^{-1}. We ascribe this inhibition on the vibrational motion of the cavity-located tin in these monomers, which is akin to that in Class 2 or weakly-bridged Class 1 polymer systems,[9] to the restraining effect of the rigid, bulky phthalocyanine ring. The value of 10^2a for the related solvated tetraphenylporphyrin derivative $(TPP)Sn(OH)_2$ (1.19 K^{-1})[19] suggests that these findings can be generalized to a "*macrocyclic effect*". The lower 10^2a value for **6** (0.67 K^{-1}) is probably due to the mass effect of the two heavy iodine atoms in the axial sites on the metal coordination polyhedron. The structure of (pc)Sn is known, and

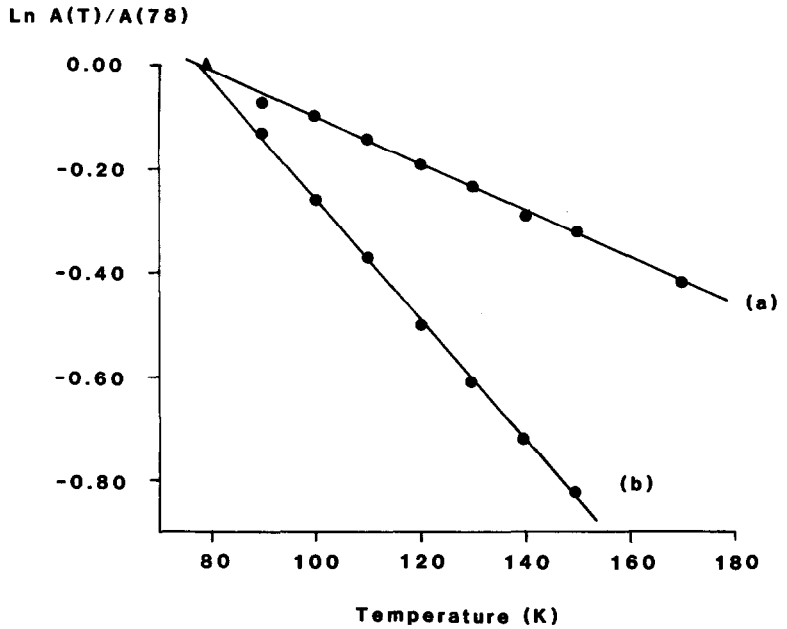


Fig. 1. Variable-temperature Mössbauer spectroscopic data for: (a) $\{[(t\text{-Bu})_4\text{pc}]\text{SnO}\}_n$, and (b) $[(t\text{-Bu})_4\text{pc}]\text{Sn(OH)}_2$. Normalization of the data is to facilitate intersample comparison. The point ▲ (78, 0.00) is common to both plots.

shows that the larger tin(II) atom cannot be accommodated within the macrocycle cavity, so that the metal lies 1.11 Å above the plane of the four isoindole nitrogens and that the macrocycle is slightly deformed away from tin to a "saucer" shape.[20] Such an environment for the metal "sitting-atop" the phthalocyanine reduces the *macrocyclic effect* and is entirely consistent with the increased 10^2a value of 1.40 K^{-1}.

The insoluble material $\{[(t\text{-Bu})_4\text{pc}]\text{SnO}\}_n$ has a significantly lower 10^2a value (0.35 K^{-1}) than any of the other compounds studied, and in particular its monomeric precursor (**8**) ($10^2a = 1.15$ K^{-1}). The reduction in vibrational freedom for tin in **10** clearly results from the formation of strong, covalent, single-atom linkages between tin–pc units to form a co-facially stacked polymer, which is rod-like (Class 1) with respect to the O—Sn—O—Sn—O backbone. In view of the difficulties encountered in monitoring the condensation reaction shown in eqn (1) (*vide supra*), VTMS seems a particularly useful diagnostic technique. Comparative VTMS data for other Class 1 tin polymers is unfortunately limited, due to the relative rareness of this architecture in tin chemistry. Class 1 polymers do seem a feature of associated tricyclohexyltin systems probably due to the steric demands of the bulky hydrocarbons, but while Cy_3SnCl ($10^2a = 1.40$ K^{-1}) and Cy_3SnF ($10^2a = 0.91$ K^{-1}) are both of this type[9] the rigidity of the lattice in each case is somewhat offset by a long Sn—X (X = Cl or F) bridging interaction (3.30 and 3.32 Å, respectively).[21,22] Cy_3SnOH appears to have a strongly bonded Class 1 mode of association ($10^2a = 0.66$ K^{-1})[9] but crystallographic confirmation of this assignment is still awaited.

CONCLUSIONS

In the light of the data presented, the effects of an embracing, rigid macrocycle on the vibrational freedom of the cavity-metal have been assessed and provide additional correlations between structure and VTMS behaviour. In addition, the VTMS technique has been shown to be a useful probe of the formation of co-facially stacked metallomacrocycle polymers, and should be applicable to a variety of such systems providing they contain a Mössbauer-active metal. We are currently pursuing this assertion with respect to coordination polymers of iron(II) phthalocyanine.

STABILITY CONSTANTS OF PALLADIUM(II) COMPLEXES WITH THIO- AND DITHIODIACIDS

J. COELLO, S. HERNÁNDEZ CASSOU* and H. ITURRIAGA MARTÍNEZ†

Departamento de Química Analítica, Facultad de Ciencias, Universidad Autónoma de Barcelona, Bellaterra, Barcelona, Spain

(*Received* 7 *February* 1986; *accepted* 4 *March* 1986)

Abstract—The formation of complexes between palladium(II) and 3,3′-thiodipropanoic (TDPA) and 3,3′-dithiodipropanoic (DTDPA) acids has been studied by using spectrophotometric methods in acidic aqueous media with a constant ionic strength of 0.5 M $(Na^+, H^+)ClO_4^-$. The stoichiometry of the detected complexes is 1 : 1 and 1 : 2 (metal : ligand) for the Pd–TDPA system, and 2 : 1 and 1 : 1 for the Pd–DTDPA system. The spectrophotometric characteristics and equilibrium constants for the different species have been calculated with the LETAGROP–SPEFO computer program.

A general survey of the methods for determining palladium indicates that sulphur compounds, thioether in particular, are commonly employed reagents,[1–3] while no attempt has been made to use 3,3′-thiodipropanoic (TDPA) and 3,3′-dithiodipropanoic (DTDPA) acids. Between these two ligand families and some divalent cations, a number of spectrophotometric studies have already been reported in the literature,[4–7] but no information exists about the palladium complex. Because of the increasing interest in platinum group metal compounds[3,8] and following our previous research with thio- and dithiodiacids,[9–11] a fundamental spectrophotometric study of the interaction between palladium(II) aqueous ion and the mentioned diacids was carried out in a perchlorate medium to establish the different complex species formed in acidic solution and evaluate their stability constants.

EXPERIMENTAL

Apparatus

The absorption spectra and quantitative absorbance measurements were obtained at 25°C with a Perkin–Elmer 554 spectrophotometer, employing 1-cm quartz cells. The reference cell solution had always the same matrix composition as the sample cell solution, except for the ligand and metal content.

The measurement of pH was done with a glass electrode (Radiometer G-202) using a Radiometer PHM-64 pH meter. The reference electrode was a saturated calomel electrode (Radiometer K-401) immersed in a salt bridge containing a 0.5 M $NaNO_3$ solution.

Reagents

TDPA (Merck for synthesis) was recrystallized twice from water, and DTDPA (Aldrich, analytical reagent grade) 3 times in the same manner from ethanol. The final purity of both ligands was 99.9%, as determined by acid–base titration of carboxylic groups with standardized sodium hydroxide. Sodium perchlorate was prepared from sodium carbonate and perchloric acid.[12] All other products were of analytical reagent grade. All solutions were prepared with double distilled water.

Standard palladium perchlorate solution. Palladium(II) perchlorate solution was prepared from $PdCl_2$ (Spanish Society of Noble Metals), precipitating palladium oxide twice and dissolving it in perchloric acid (Carlo Erba R.P.E.) as has been previously described.[13] The absence of chloride was checked by measuring the absorbance of the final

* Present address: Departamento de Química Analítica, Facultad de Química, Universidad de Barcelona, Barcelona, Spain.

† Author to whom correspondence should be addressed.

solution at 420 nm.[13] The chloride content was always less than 10^{-5} M. The concentration of palladium was determined gravimetrically by the dimethylglyoxime method and the total acidity was determined by passing the solution through a cationic resin column (Merck I) and titrating it with standard sodium hydroxide solution.

Preliminary studies

Spectral characteristics. Palladium perchlorate solutions showed two absorption bands, a small one at 370 nm and a higher and more intense one at around 200 nm.

Aqueous spectra of both ligands showed the carboxylic peak at 200–205 nm while the DTDPA solutions showed another peak corresponding to the disulphide group at 247 nm.

The Pd–TDPA system showed two peaks 225 and 270 nm, depending on the metal/ligand ratio, while Pd–DTDPA showed two broad bands about 260 and 330 nm; the solutions in both cases were acidic.

Variation of absorbance with pH. The study of the effect of pH changes on the absorbance of palladium complexes was done by adjusting the pH in the range 0.5–12 with sodium hydroxide and perchloric acid.

The absorbance values of solutions containing 9×10^{-5} M palladium and metal/ligand ratios of 1.3 and 0.1 for TDPA systems, and 2 and 0.5 for DTDPA systems, remained constant when pH = 3. The spectra from solutions with a pH greater than 3 showed shifts to lower wavelengths and new absorption bands that could be attributed to mixed complexes with hydroxide ion.

On this basis, a pC_H of 1.3 was chosen for the next studies in order to avoid problems with hydro complexes.

Variation of absorbance with time. The change in the absorbance was followed in solutions with Pd/TDPA ratios of 1.25, 0.3 and 0.1, and with Pd/DTDPA ratios of 1, 0.5 and 0.16. The total concentration of palladium was 1×10^{-4} M for TDPA complexes and 7.5×10^{-5} M for those of DTDPA. This study indicates that absorbances were stable for 6 h for Pd–TDPA system and for between 90 min and 5 h for DTDPA complexes.

Number and stoichiometry of complexes. The composition of different complexes formed was studied with a fixed pC_H of 1.3 by two well-known spectrophotometric methods: continuous-variation[14] and molar-ratio.[15] Because of the absorption of the metal and ligands at the complexes wavelengths, the experimental absorbances were corrected by subtracting the absorption corresponding to the metal and ligands as if they remained free in solution without complexation. These two graphical methods defined two complexes, 1 : 1 and 1 : 2 metal : ligand ratios and peaks at 225 and 275 nm, respectively, for Pd(II)–TDPA, and a polynuclear 2 : 1 and a mononuclear 1 : 1 complex for Pd(II)–DTDPA, this last one predominantly absorbing with a 340-nm band.

The TRIANG[16] numerical program was applied to confirm the number of absorbing species. Three species (which were assigned as 1 : 1 and 1 : 2 complexes and free ligand) were found for Pd–TDPA, and two (mononuclear 1 : 1 and polynuclear 2 : 1) for Pd–DTDPA, by employing an error matrix for both systems in the range of 0.002–0.008.

RESULTS AND DISCUSSION

Data were obtained from the absorbance measurements of solutions shown in Table 1. The ionic strength was always kept constant with perchloric acid and sodium perchlorate to 0.5 M (Na^+, H^+)ClO_4^-. Table 1 specifies the characteristics of these series and Figs 1 and 2 show the absorption spectra corresponding to one series of each system. The absorbance values were read at 275, 270, 240, 230 and 225 nm after 60 min for Pd–TDPA complexes, and at 340, 330, 267, 260 and 247 nm after 2 h for Pd–DTDPA.

Treatment of the experimental data

Some of the wavelengths which characterize the complexes were absorbed by palladium ion and ligands whose molar absorptivities had to be previously calculated under the same experimental conditions as the complexes. These were obtained from the slope of straight lines by representing the absorbance at each particular wavelength vs the metal (or ligand) concentrations. The values can be observed in Table 2. The molar absorptivities at wavelengths higher than 270 nm were averaged between the most and least concentrated solutions because of their very low absorbance values. The linearity ranges were 1×10^{-5}–1×10^{-4} M for palladium and 7×10^{-5}–2×10^{-3} M for TDPA and DTDPA.

Graphical methods. The small range of ligand concentration in which the absorbances of the complexes of the TDPA system grew induced us to think that the stepwise constants were high. On this basis, it was assumed that the whole ligand was complexed in the solutions with metal excess and its concentration was equal to that of the Pd(TDPA) species. Thus, an equation can be derived as

Table 1. Experimental conditions of the series needed to study Pd–TDPA and Pd–DTDPA systems [$I = 0.5$ M $(Na^+, H^+)ClO_4^-$, $T = 25°C$]

Total palladium (mol l^{-1})	Total hydrogen (mol l^{-1})	Total ligand (mol l^{-1})	Number of solutions

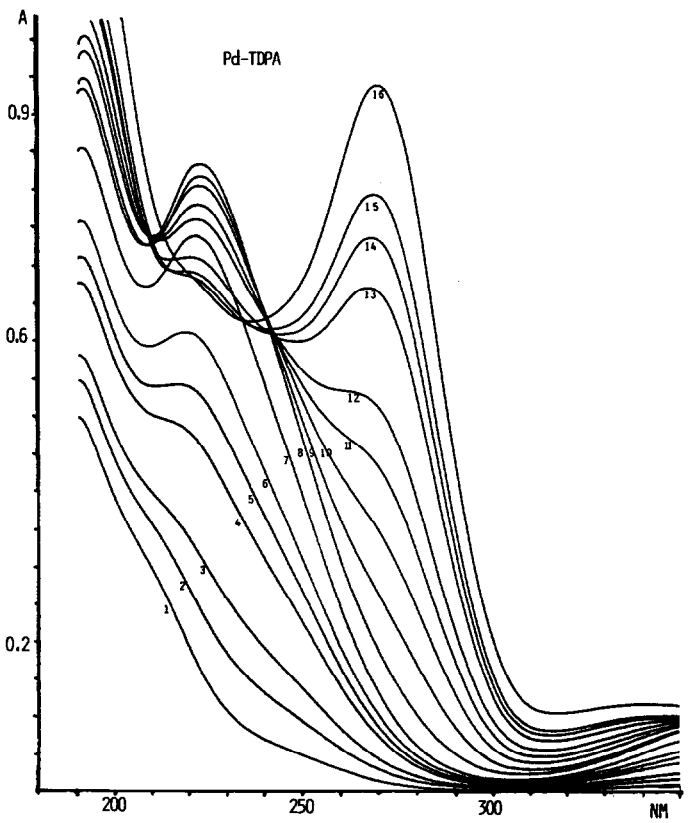

Fig. 1. Absorption spectra for the Pd–TDPA system. Palladium concentration was 7.4×10^{-5} M in all solutions and ligand concentration was: (1) 6×10^{-6} M, (2) 1.3×10^{-5} M, (3) 2.0×10^{-5} M, (4) 3.3×10^{-5} M, (5) 3.9×10^{-5} M, (6) 4.5×10^{-5} M, (7) 5.9×10^{-5} M, (8) 7.2×10^{-5} M, (9) 7.8×10^{-5} M, (10) 8.5×10^{-5} M, (11) 9.1×10^{-5} M, (12) 9.8×10^{-5} M, (13) 1.11×10^{-4} M, (14) 1.18×10^{-4} M, (15) 1.24×10^{-4} M, and (16) 1.44×10^{-4} M.

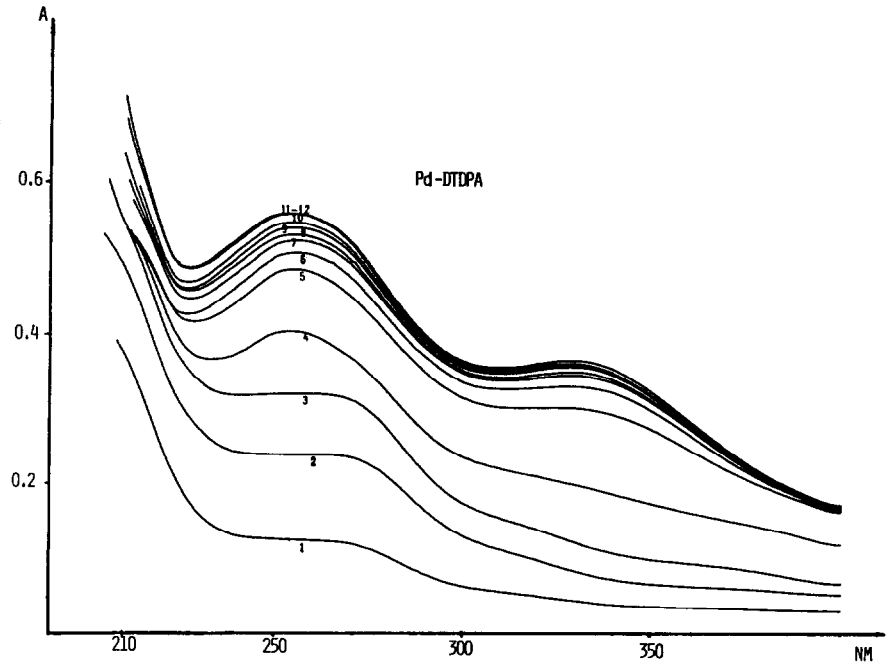

Fig. 2. Absorption spectra for the Pd–DTDPA system. Palladium concentration was 5.3×10^{-5} M in all solutions and ligand concentration was: (1) 1.0×10^{-5} M, (2) 2.0×10^{-5} M, (3) 3.0×10^{-5} M, (4) 4.0×10^{-5} M, (5) 6.0×10^{-5} M, (6) 8.0×10^{-5} M, (7) 1.00×10^{-4} M, (8) 1.20×10^{-4} M, (9) 1.40×10^{-4} M, (10) 1.60×10^{-4} M, (11) 1.80×10^{-4} M, and (12) 2.00×10^{-4} M.

follows:

$$A_{exp} - \varepsilon_{Pd}(C_{Pd} - C_{TDPA}) = A_1 = \varepsilon_{Pd(TDPA)}C_{TDPA}, \quad (1)$$

where C_{Pd} and C_{TDPA} are the total concentrations of palladium and ligand, respectively, and A_{exp} is the experimental absorbance of the solution. In a similar way, the molar absorptivities of the complex $Pd(TDPA)_2$ were deduced from solutions with $C_{TDPA} : C_{Pd} \geqslant 2$. Now, all the metal would be complexed and the $Pd(TDPA)_2$ species would predominate, in which case eqn (2) is obtained:

$$A_{exp} - \varepsilon_{TDPA}(C_{TDPA} - 2C_{Pd}) = A_2 = \varepsilon_{Pd(TDPA)_2}C_{Pd}. \quad (2)$$

The molar absorptivities, $\varepsilon_{Pd(TDPA)}$ and $\varepsilon_{Pd(TDPA)_2}$, were found by plotting A_1 vs C_{TDPA} and A_2 vs C_{Pd}, respectively (Fig. 3 and Table 3). The molar absorptivities of the Pd–DTDPA system (Table 3) were obtained analogously to that of the Pd–TDPA system by eqns (3) and (4):

$$A_{exp} - \varepsilon_{Pd}(C_{Pd} - 2C_{DTDPA}) = A_3 = \varepsilon_{Pd_2(DTDPA)}C_{DTDPA}, \quad (3)$$

$$A_{exp} - \varepsilon_{DTDPA}(C_{DTDPA} - C_{Pd}) = A_4 = \varepsilon_{Pd(DTDPA)}C_{Pd}. \quad (4)$$

Numerical methods. The LETAGROP computer program (spectrophotometric version SPEFO[17]) was used to treat experimental data (absorbances

and concentrations of the metal, hydrogen and ligands). The minimized function was:

$$U = \sum_{1}^{NP} \sum_{1}^{NW} (A_{calc} - A_{exp})^2, \qquad (5)$$

where NP and NW are the number of experimental points and wavelengths, respectively, and $A_{calc} - A_{exp}$ the difference between the theoretical absorbance calculated by the program from the proposed model and the measured experimental absorbance. The molar absorptivities, previously calculated by graphical methods, were the initial input values; this was followed by the refinement of the equilibrium constants with fixed molar absorptivities. The output was a set of initial constants, which were recalculated in a final cycle by minimizing both the constants and the molar absorptivities. The computer treatment was simultaneously applied at five wavelengths to the experimental data of Table 1. The final computer values of the constants and molar absorptivities are listed in Tables 4 and 3, respectively. The overall formation constants for the system $pPd^{2+} + qH^+ + rL^{2-} \rightleftarrows Pd_pH_qL_r^{(2p+q-2r)+}$ are expressed as log $(\beta_{pqr} \pm 3\sigma_\beta)$ where σ is the standard deviation. If 3σ is greater than 0.20 then the program writes the maximum value of log $(\beta \pm 3\sigma)$. Other models (2:2, 2:4 and 4:2) for both systems were tried but did not improve the U function, and as a result were rejected.

Table 3 shows agreement between numerical and graphical methods except for the polynuclear complex of DTDPA. This difference can be explained by looking at Fig. 4 which corresponds to the species distribution diagrams calculated by the computer program HALTAFALL.[18] The species Pd(DTDPA) is always present in the metal concentration range studied and in consequence its absorbance can not be neglected as it was assumed in the graphical calculation. The diagram for the TDPA complexes is independent of the free concentration of palladium in solution while that of DTDPA depends on the metal because a polynuclear complex, $Pd_2(DTDPA)$, is present.

The stepwise constants (K_i) listed in Table 4 have been calculated from the overall constants (Table 4) and the ligand protonation constants.[10] These K_i values are greater than those of the corresponding complexes of d^{10} metal ions, e.g. Ag(I) and Hg(II), and divalent cations, e.g. Cu(II), Ni(II), Cd(II)...[11,19-21] due to the high affinity between sulphur atoms (soft ligands) and palladium(II) (soft cation).

In the experimental hydrogen concentration ($pC_H = 1.3$) the ligands are totally protonated (more than 99.9%) and the palladium site reaction with hydroxide ion, if we follow Baes and Mesmer,[22] is small in these conditions [log $\alpha_{Pd(OH)} = 0.04$]. The number of hydrogens associated to a given complex can not be directly ascertained because absorbance variations were not observed in the pH range 1–3 which was fixed to minimize the hydroxospecies of palladium. Although, the comparison between silver(I) complexes of TDPA and DTDPA[11,21] and palladium(II) complexes of the present work admits as a conclusion that the ligands are totally protonated, as in the case of silver, and can be represented as $Pd_i(H_2L)_j^{2i+}$. Some data can be given to explain this similarity. The mononuclear complexes of the

final models proposed coincide with those previously found for silver(I).[11,21] The possibility of polynuclear species for both palladium(II) with ligands containing disulphide groups and silver(I) with dithiopropanoic acid has already been pointed out;[11,23] in this case, the polynuclear 2:1 Pd–DTDPA complex would agree with it. Table 4 shows that the logarithmic difference between the constants of the mononuclear 1:1 and 1:2 Pd–TDPA complexes is 1.82 while for the silver system it was 1.11;[11] then, by following Arhland's theory, this value, smaller than 2, would indicate there is no d_π–d_π bonding between palladium and sulphur. There is also agreement if TDPA and DTDPA mononuclear 1:1 complexes are compared for a particular metal ion system; these differences,

expressed in logarithmic units, are 1.48 (Table 4) and 1.26[24] for palladium(II) and silver(I) complexes, respectively. The stepwise constant of $Pd(TDPA)_2$ is 1.82 logarithmic units smaller than that of the first complex Pd(TDPA), and would be explained by steric hindrance when a second bulky molecule of the ligand approximates the Pd(TDPA) species. The trend is always that the constants from TDPA species are greater than those similar to DTDPA.

Taking into account all previous considerations and keeping in mind the analogous behaviour of both ligands with respect to silver(I) and palladium(II), it can be assumed that, under the experimental conditions, the metal–ligand coordination seems to occur mainly through the sulphur donor atoms, where the remaining carboxylic groups are protonated and practically without any interaction with the metal ion.

Abstract—Prolonged reaction of CF_3COOH with $Mo(CO)_3(P(OCH_3)_3)_3$ in CH_2Cl_2 yields the dimer $[Mo(CO)_2(\mu(O)P(OCH_3)_2)P(OCH_3)_3CF_3COO]_2$ in low yield. The complex has been characterized by the usual spectroscopic methods and by an X-ray crystal structure determination. The molybdenum atoms are linked by two O–P bridges, the six-membered dimetallacycle adopting a twisted-boat conformation. Each molybdenum is seven-coordinated and has a capped trigonal prism geometry, the capping position being occupied by an oxygen atom of the bridging $OP(OCH_3)_2$ group. A mechanism similar to the well-known Michaelis–Arbuzov rearrangement is proposed and substantiated by the concomitant apparition of CF_3COOCH_3 during the reaction.

Protonation of zero-valent molybdenum complexes is a well-documented method for the preparation of heptacoordinate molybdenum hydrido complexes. In previous studies we have shown that the reaction of $Mo(CO)_2(PR_3)_4$ ($R = CH_3$) produced the cations $[MoH(CO)_2(PR_3)_4]^+$.[1] However, in the case of $Mo(CO)_3(PR_3)_3$, the reaction is highly dependent on the nature of the R group. When R = Me, $[MoH(CO)_3(PMe_3)_3]^+CF_3COO^-$ is obtained first, and a longer reaction time leads to $Mo(CO)_2(PMe_3)_3(CF_3COO)_2$, a heptacoordinated complex containing two monodentate trifluoroacetate ligands.[2] In the case of the more bulky R = Et, dissociation of a phosphine occurs to give $Mo(CO)_2(PEt_3)_2(CF_3COO)_2$, which contains one monodentate and one bidentate trifluoroacetate group.[3] Furthermore, the protonation of $Mo(P(OCH_3)_3)_6$ was first shown to produce $[MoH(P(OCH)_3)_6]^+$,[4] but only in low yield, the major product of the reaction being a complex containing a dimethoxyphosphino group $[Mo(P(OCH_3)_2)(P(OCH_3)_3)_5]^+$.[5] In this paper, we describe the results of the protonation of $Mo(CO)_3(P(OCH_3)_3)_3$ and the unexpected formation of a new heptacoordinate dinuclear complex.

RESULTS AND DISCUSSION

The reaction of $Mo(CO)_3(P(OCH_3)_3)_3$ with excess CF_3COOH in CH_2Cl_2 produced a yellow solution from which, by precipitation with methanol and recrystallization, we could isolate a low

yield (*ca* 10%) of yellow crystals analyzing for $Mo_2(CO)_4(P(O)(OCH_3)_2)_2(P(OCH_3)_3)_2(CF_3COO)_2$. The IR spectrum showed four bands at 1960(m), 1890(s), 1865(m) and 1610(w) cm^{-1}. The latter was attributed to the chelating trifluoroacetato ligands. The ^1H NMR spectrum only shows two doublets in a 2:3 ratio at δ 3.59 (J_{PH} 11.5 Hz) and 3.82 ppm (J_{PH} 12 Hz). Finally, the ^{31}P NMR spectrum consists of two doublets in a 1:1 ratio at δ 176.18 and 136.50 ppm (J_{PP} 50.3 Hz). Since these data did not allow an unambiguous proposition of structure for the complex, an X-ray crystal structure determination was undertaken. The results are shown in Fig. 1 and Tables 1 and 2.

The complex is a centrosymmetric dimer containing two heptacoordinated molybdenum units linked by two R_2P–O bridges. The geometry around each molybdenum is that of a capped trigonal prism.[6] The capping position is occupied by O(3)′, the oxygen atom of the bridging R_2PO group. The capped quadrilateral face contains the CF_3COO^- ion acting as a bidentate group [O(9) and O(10)], one CO ligand [C(2)] and one R_2PO group [P(1)]. The remaining edge contains one CO [C(1)] and one $P(OCH_3)_3$ [P(2)] molecule. The two coordinated phosphorus groups on each molybdenum atom are *cis* to one another in agreement with the low P–P coupling constant observed by ^{31}P NMR. The conformation of the dimetallacycle (—Mo—P—O—)$_2$ is that of a twisted boat. The bond lengths are all in the usual range except for Mo—O(9) and Mo—O(10) which are significantly longer than other known Mo—O distances (usually in the range 2.09–2.15 Å),[7] probably indicating a weakly bonded trifluoroacetato group. There is no significant difference between the Mo—P(1) and the Mo—P(2) bond [2.420(1) and 2.402(1) Å, respectively]. The bridging P—O distance [P(1)—O(3)] is shorter than other phosphite P—O bonds [1.526(3) Å vs 1.57–1.59 Å], suggesting that the bond has a significant π-bond character as in related complexes.[8,9] Finally, the Mo–Mo distance is very long [4.563(1) Å] and precludes any kind of metal–metal interaction. This type of bridging R_2PO group is not very usual and so far examples have been found only in manganese, rhenium and platinum chemistry.[10] In molybdenum chemistry, this structure can be related to that of other heptacoordinate dimers bridged by oxygen-containing ligands such as the carbonato-bridged complex $[Mo(\mu\text{-}CO_3)(CO)(PMe_2Ph)_3]_2$[11] (Mo...Mo = 4.95 Å) or the μ-SO_2 derivative $[Mo(\mu\text{-}SO_2)(CO)_2(py)(PPh_3)]_2$.[12]

As a whole, the formation of this complex

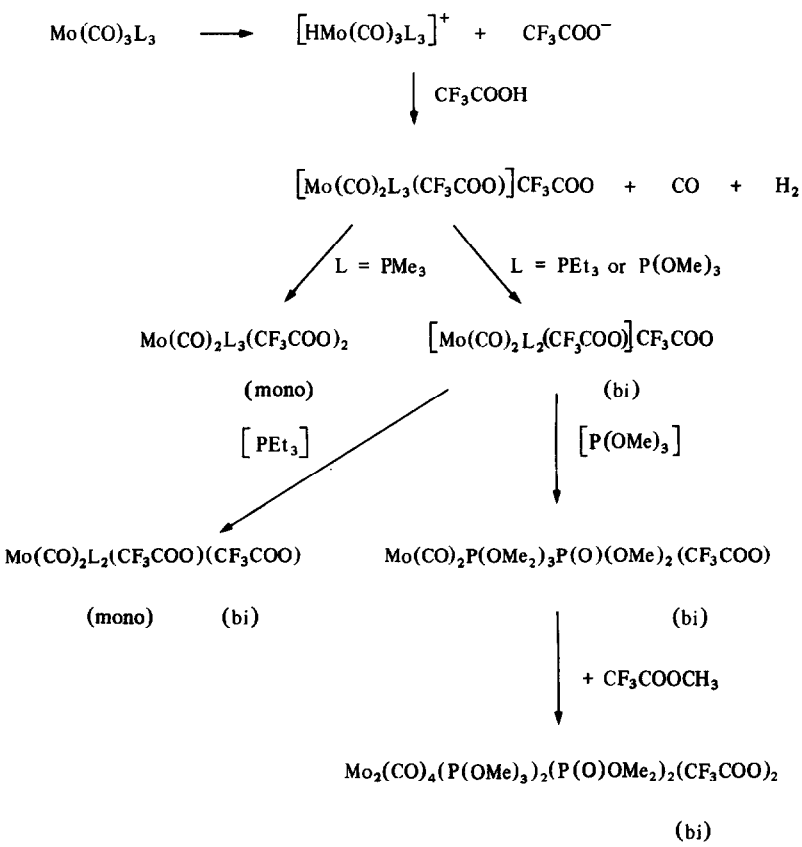
seemed surprising and we tried to elucidate its mechanism. A study by Haines and Nolte[13] has shown that the reaction of $[CpMo(CO)_3]_2$ with excess $P(OCH_3)_3$ led eventually to a 1:1 mixture of $[CpMo(CO)_2(P(OCH_3)_3)(P(O)(OCH_3)_2)]$ and $[CpMo(CH_3)(CO)_2(P(OCH_3)_3)]$ through an ionic derivative $[CpMo(CO)_2(P(OCH_3)_3)_2][CpMo(CO)_3]$. Actually, our mechanism is probably very similar and also similar to the well-known Michaelis–Arbuzov type rearrangement of phosphites in the presence of alkyl halides. Thus in both cases formation of a cationic species containing a phosphorus in a tetrahedral environment is observed followed by rupture of an O—C bond and migration of the alkyl group on the anionic species [eqns (1) and (2), respectively]:



$$[CpMo(CO)_2(P(OR)_3)_2][CpMo(CO)_3] \rightarrow [CpMo(CO)_2(P(OR)_3)(P(O)(OR)_2)] + CpMo(CO)_3R, \quad (1)$$

$$P(OR)_3 + R'X \rightarrow [R'P(OR)_3]X \rightarrow R'P(O)(OR)_2 + RX. \quad (2)$$

Concerning our reaction (Scheme 1) we assume that in the presence of excess CF_3COOH, as for similar complexes with other ligands, formation of a diacetato complex is observed on which one trifluoroacetate could be weakly bonded, thus leading to an ionic species. One methyl group should then transfer to the CF_3COO^- anion and indeed ^1H NMR monitoring of the reaction shows the formation of CF_3COOCH_3. Finally, the complex $Mo(P(O)(OCH_3)_2)(CO)_2(P(OCH_3)_3)(CF_3COO)$ which has eliminated CO {formation of $Mo(CO)_4[P(OCH_3)_3]_2$ is also observed in this reaction} dimerizes in order to achieve an 18-electron configuration around the molybdenum. This type of complex containing weakly bonded trifluoroacetate ligands and easily broken bridges,[14] thus easily producing vacant sites of coordination, can be very important for reactivity and catalytic studies.

EXPERIMENTAL

IR spectra were recorded in solution in CH_2Cl_2 or as Nujol mulls on a Perkin–Elmer 257 grating

Scheme 1. Proposed mechanism for the reactions of $Mo(CO)_3(PR_3)_3$ complexes with CF_3COOH (mono means a monodentate trifluoroacetate group, bi a bidentate trifluoroacetate group).

diffractometer. ^1H and ^{31}P NMR were recorded on a WM250 Bruker (250 and 101.22 MHz, respectively) operating in the Fourier transform mode with TMS and external H_3PO_4 (85% in D_2O) as reference, respectively. All operations were carried out under dry nitrogen and solvents were carefully degassed before use.

Preparation of $Mo_2(\mu\text{-}P(O)(OCH_3)_2)_2(CO)_4(P(OCH_3)_3)_2(CF_3COO)_2$

$Mo(CO)_3(P(OCH_3)_3)_3$ (2 g, 3.63 mmol) was added to a mixture of CF_3COOH (10 cm^3, excess) and CH_2Cl_2 (20 cm^3) and the resulting yellow solution was stirred at room temperature for 24 h. Methanol (20 cm^3) was then added and the mixture was cooled to −18°C, thus producing a yellow precipitate. After filtration, the precipitate was washed several times with methanol and dried *in vacuo*. It was then recrystallized from CH_2Cl_2, affording yellow crystals of the complex (yield *ca* 10%). Occasionally, the first crystalline product obtained in very low yield was $Mo(CO)_4(P(OCH_3)_3)_2$.

Found: C, 21.7; H, 3.0; P, 12.4; F, 11.4%. Calc. for $MoC_9F_3H_{15}O_{10}P_2$: C, 24.0; H, 3.0; P, 12.1; F, 11.2%.

Crystal structure

Crystal data. $Mo_2P_4F_6O_{20}C_{18}H_{30}$, molecular weight = 996.19, orthorhombic, $a = 24.439(3)$ Å, $b = 8.861(1)$ Å, $c = 16.688(2)$ Å, $V = 3613.8(6)$ Å^3, space group *Pbcn* (D_{2h}^{14}—No. 60), $Z = 4$; $\rho_m = 1.83$ g cm^{-3}, $\rho_c = 1.831$ g cm^{-3}; $F(000) = 1984$; $\lambda = 0.71069$ Å; $\mu(\text{Mo-}K_a) = 9.70$ cm^{-1}.

Data collection and solution. Intensity data were collected on a crystal of dimensions $0.31 \times 0.29 \times 0.27$ mm using θ–2θ scans ($3.2 < 2\theta < 52.0°$) with a variable scan speed of 2.93–29.3° min^{-1} and a scan width of 0.8° below $K\alpha_1$, to 0.8° above $K\alpha_2$ on a Syntex $P2_1$ diffractometer. From a total of 3581 measured reflections, 2572 with $I > 3\sigma(I)$ were considered observed and used in the structure solution and refinement. Two standard reflections (040; 1200) monitored every 100 measurements showed only minor fluctuations during data collection. Data were cor-

rected for Lorentz and polarization effects but not for absorption.

The molybdenum atom was located in a Patterson synthesis and the light atoms via a subsequent Fourier map. Refinement of all non-hydrogen atoms with isotropic parameters gave an R value of 0.095 ($R = \Sigma \| F_o| - |F_c\| / \Sigma |F_o|$). Refinement with anisotropic thermal parameters reduced R to 0.042. A difference Fourier synthesis at this stage revealed disorder of the CF_3 group. F(3) was found to be resolvable into two centres while the other fluorine atoms apparently possessed singular sites. Inclusion of the F(3) disorder into the refinement led to convergence at $R = 0.038$ with the weighted residual $R_w = 0.046$ $\{R_w = [\Sigma\ w(|F_o| - |F_c|)^2 / \Sigma\ w(|F_o|)^2]^{1/2}\}$. An empirical weighting scheme of the form $w^{-1} = 2.52 - 0.0225|F_o| + 0.00029|F_o|^2$ was used in the final cycles of refinement. A final difference Fourier synthesis indicated maximum residuals of 0.6 e Å^{-3} in the vicinity of the CF_3 and —OMe groups. Scattering factors were taken from the *International Tables*,[15] including both the real and imaginary components of the anomalous dispersion for molybdenum. Computer programs used have been described elsewhere.[16] Final atomic coordinates and other crystallographic data have been deposited with the Editor and atomic coordinates have been sent to the Cambridge Crystallographic Data Centre.

(*Received* 29 *August* 1985; *accepted* 11 *March* 1986)

Abstract—An electronic structure of *closo*-six-apex metal carbonyl clusters is proposed, based on a comparison with Stone's description of *closo*-borane clusters. From this, and by comparison with B_5H_9, a description of the occupied cluster orbitals of *nido*-five-apex metal carbonyl clusters is proposed and found to agree well with calculations on $Fe_5(CO)_{15}C$ and $Fe_5H(CO)_{14}N$. The photoelectron spectrum of the nitride is presented. The role of the interstitial atom and the chemical stabilities of the compounds are discussed.

The existence of metal carbonyl clusters with geometries analogous to borane clusters has been well rationalized in a phenomenological manner by Wade's rules[1] and the "isolobal–isoelectronic" description of Hoffmann and Mingos.[2] For example Wade's rules state that the $Fe(CO)_3$ group can replace a BH group in a borane cluster without changing the cluster geometry, and the Hoffmann–Mingos description shows that these two groups are "isolobal–isoelectronic" in the manner shown in Fig. 1. The BH group has three "atomic" orbitals (AOs) and two electrons available for cluster bonding, the $Fe(CO)_3$ group has three similarly oriented orbitals and two electrons not accounted for by carbonyl bonding or metal lone pairs. On the basis of these "rules" the observed octahedral arrangements of metal atoms in $[Fe_6(CO)_{16}C]^{2-}$ or $Co_6(CO)_{16}$ can be compared with *closo*-$B_6H_6^{2-}$, and the square-based pyramidal arrangement in $M_5(CO)_{15}C$ (M = Fe, Ru or Os) with *nido*-B_5H_9.

In this paper we consider the application of Stone's theoretical description[3] of the electronic structure of *closo*-boranes to analogous metal clusters. This is not a phenomenological description and counts among its successes the first *a priori* explanation of the triangular faced polyhedral geometries of the $B_nH_n^{2-}$ anions stabilized by the occupation of $n+1$ cluster-bonding molecular orbitals (MOs). As Stone's theory may justifiably be considered as the basis of the phenomenological descriptions, it should, by implication, be useful in analogous metal clusters. We investigated this by replacing the BH groups used in Stone's discussion with metal carbonyl groups and then tested the results by comparison with self-consistent charge calculations and the photoelectron spectrum of $Fe_5(H)(CO)_{14}N$. We are particularly interested in the role of the interstitial main-group atom found in many clusters since it appears to be significant in the stability of the clusters.

Stone has demonstrated that for $B_nH_n^{2-}$ the basis set of $3n$ AOs [two tangential (π) and one radial (σ) per BH group (Fig. 1)] generate three groups of n MOs. These are separable in the limit of spherical symmetry to which all *closo*-borane geometries

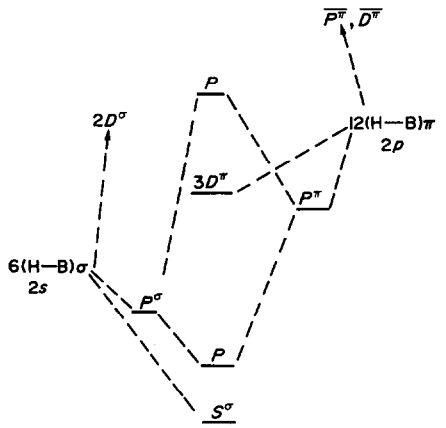

Fig. 2. Schematic of the MO diagram of $B_6H_6^{2-}$.

approximate, hence the tangential/radial labels. The n radial AOs produce n MOs with spherical harmonic properties which are labelled $S^\sigma, P^\sigma, D^\sigma \ldots$ in order of increasing energy (the spherical degeneracy is usually lifted by the molecular symmetry). The $2n$ tangential AOs produce two groups of n MOs, both with tensor harmonic properties but differing in parity, labelled P^π, $D^\pi, \ldots$, and $\overline{P^\pi}$, $\overline{D^\pi}$. . . . One major distinction is that the radial AOs have a predominantly boron $2s$ composition and are therefore lower in energy than the tangential AOs which are almost pure boron $2p$. This leads to the MO diagram for $B_6H_6^{2-}$ shown in Fig. 2. The extent of P^σ–P^π mixing in the symmetry of the anion is a matter of debate[4] but is not critical in the following argument. The seven occupied cluster MOs of the $B_6H_6^{2-}$ anion are S^σ, $3P$, $3D^\pi$. Stone developed energy equations for each type of MO that showed that the orbitals are most stable when the geometry of the cluster is a triangular faced polyhedron.

EXPERIMENTAL

$Fe_5(CO)_{15}C$[5] and $Fe_5(H)(CO)_{14}N$[6] were prepared by literature methods and identified by their IR and mass spectra. The photoelectron spectrum of $Fe_5(H)(CO)_{14}N$ was measured on an apparatus described previously.[7] The solid was introduced into the ionization region and heated to 90°C, at which temperature the vapour pressure was sufficient to give a count rate of 1500 counts s^{-1}. The spectrum was calibrated using the known ionizations of N_2 and H_2O (introduced with the sample). The IR spectrum of the sample was unchanged after recovery at room temperature and therefore decomposition was assumed to be insignificant. [Attempts to measure the spectra of $Fe_5(CO)_{15}C$, $Os_5(CO)_{15}C$ and $Os_6(CO)_{17}C$ all failed as the room-temperature vapour pressure was too small and slight heating led to rapid decomposition in each case.]

All calculations were performed using Hoffmann's FORTICON 8 program extended to accept the large number of AOs involved.[8] The geometries used were symmetrized geometries based on average experimental bond lengths and angles.[6,9] This resulted in relative dispositions of the carbonyl ligands which were different to the experimental ones but this was necessary in order to simplify the assignment of the MOs. Calculations with geometries approaching the experimental ones produced insignificant changes in orbital energies and suggest that symmetrization is not an important source of error.

RESULTS AND DISCUSSION

Attempts to construct a diagram similar to Fig. 2 for a *closo*-six-apex metal carbonyl cluster, e.g. "$[Fe_6(CO)_{18}]^{2-}$", are immediately complicated by the composition of the $Fe(CO)_3$ AOs of Fig. 1. The σ- and π-symmetry type orbitals have a predominantly iron $3d$ composition and should therefore have similar energies. Mingos has shown[10] that the calculation gives the orbital energy of the σ-lobe as higher than that of the π-lobes. This is the reverse of the BH order. One would therefore construct a diagram such as Fig. 3(a) for this compound, noting that the energy spread over the seven orbitals is small. Educing reasons why the unfavourable AO energies should produce the required occupied MOs is a matter of tentative guess-work but could be based on the possibly greater overlap of the radial lobes than of the tangential ones. Conversely, this is probably a good argument for the non-existence of "$[Fe_6(CO)_{18}]^{2-}$". One has however to account for the existence of the isoelectronic clusters $Co_6(CO)_{16}$, $[Co_6(CO)_{15}]^{2-}$ and $[Co_6(CO)_{14}]^{4-}$ which have the expected octahedron of cobalt atoms.[11]

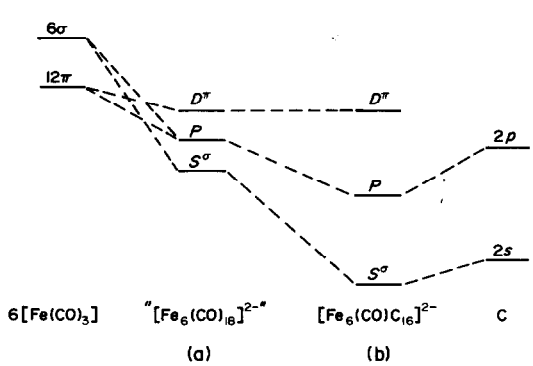

Fig. 3.

Extended Hückel calculations on the $M(CO)_3$ group (M = Mn, Fe or Co) show that the σ–π-lobe energy separation is 2.09, 1.92 and 1.21 eV in that order and, therefore, the $Co(CO)_3$ unit is a much better starting point for achieving an MO diagram such as Fig. 3(a) than the $Fe(CO)_3$ unit. In Mingos's extended Hückel[12] calculation on $[Co_6(CO)_{14}]^{4-}$ the seven cluster-bonding orbitals are identifiable in the group of high-energy occupied MOs and are all within 1 eV of the highest-energy MO (HOMO).

The MOs of Fig. 3(a) can be made to resemble those of Fig. 2 more closely by the introduction of an interstitial atom with a corresponding reduction of the number of carbonyl ligands, e.g. the carbon atom in $Fe_6(CO)_{16}C^{2-}$. The symmetries of the AOs of the interstitial atom allow interaction only with the S^σ and P MOs of the metal carbonyl cluster. This should result in the MO diagram of Fig. 3(b), with a stable bonding S^σ MO predominantly on the carbon atom, and a stabilized set of P-orbitals. The actual energy and composition of these latter MOs are unpredictable at this level of description. The P^σ/P^π composition of the metal carbonyl P-orbitals is unknown as is the relative energy of the carbon atom $2p$ orbitals.

One immediate experimental corollary of Fig. 3 is the different stability and chemical reactivity of metal clusters with and without interstitial atoms. If a perturbation can displace one or more of the cluster-bonding MOs to the virtual-orbital set, particularly one of the S^σ, P orbitals which we have shown[13] are the more important bonding orbitals of the boranes, then the cluster will open up and become labile, losing its closed deltahedral geometry. This is far more probable for clusters without interstitial atoms and such clusters are consistently less stable and more reactive than those with interstitial atoms. Some of the above discussion has been addressed at a qualitative level by Wade.[14]

It is the utility of Fig. 3 that we now wish to investigate through calculations and spectroscopic work on *nido*-five-apex iron carbide and nitride clusters. As these compounds are analogous to *nido*-B_5H_9 we first briefly review the cluster-bonding MOs of the borane. The B_5H_9 geometry is related to $B_6H_6^{2-}$ by deletion of one of the apices of the octahedron. It also has the same number of cluster-bonding MOs. Figure 4 shows the MOs of both molecules calculated using the MNDO method.[4] The energy separations of the three types of orbitals are large. Stone's labels S^σ, P and D^π are clearly valid for B_5H_9, particularly if the bridging hydrogens are ignored. Only the P_z-orbital is seriously affected by apex deletion and has become extensively mixed with a P^π-orbital. We expect the

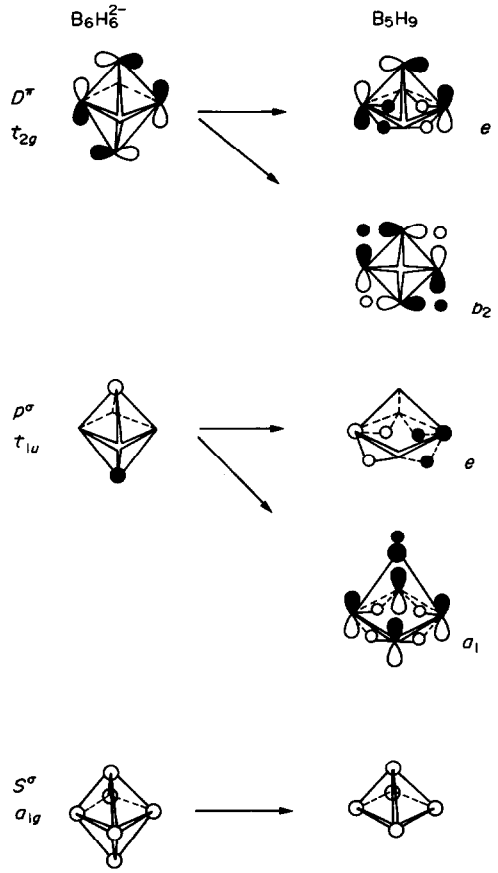

Fig. 4. Correlation of the cluster-bonding orbitals of $B_6H_6^{2-}$ and B_5H_9.

orbitals of $Fe_5(CO)_{15}C$ and $Fe_5(H)(CO)_{14}N$ to resemble these orbitals, together with a significant contribution from the basal carbon or nitrogen atom to the S^σ and P MOs.

A self-consistent charge calculation was performed on $Fe_5(CO)_{15}C$ in the C_s-symmetry shown in Fig. 5. This was necessary in order to simplify the assignment of the MOs. It is worth noting that the molecule has 97 occupied valence MOs: 15 Fe "lone pairs" which include any Fe → CO π^*-back-bonding, and 75 carbonyl orbitals (these can be subdivided into 15 5σ which include Fe ← CO σ-donation, 30 of type 1π, and 15 each from $4\sigma^*$ and 3σ), and the seven cluster orbitals. The calculation shows the 18 HOMOs to be 40–60% localized on the metal atoms, whilst only four lower-energy orbitals are more than 15% metal-localized (*vide infra*). The C_s-symmetry is only a small perturbation to the C_{4v} metal atom framework for these orbitals and the symmetries of the 18 orbitals are exactly those expected from the 15 lone-pair orbitals and the three D^π cluster orbitals. Figure 5 shows the energy spread of these orbitals. The non-degenerate orbitals are given their C_s labels (it is impossible in

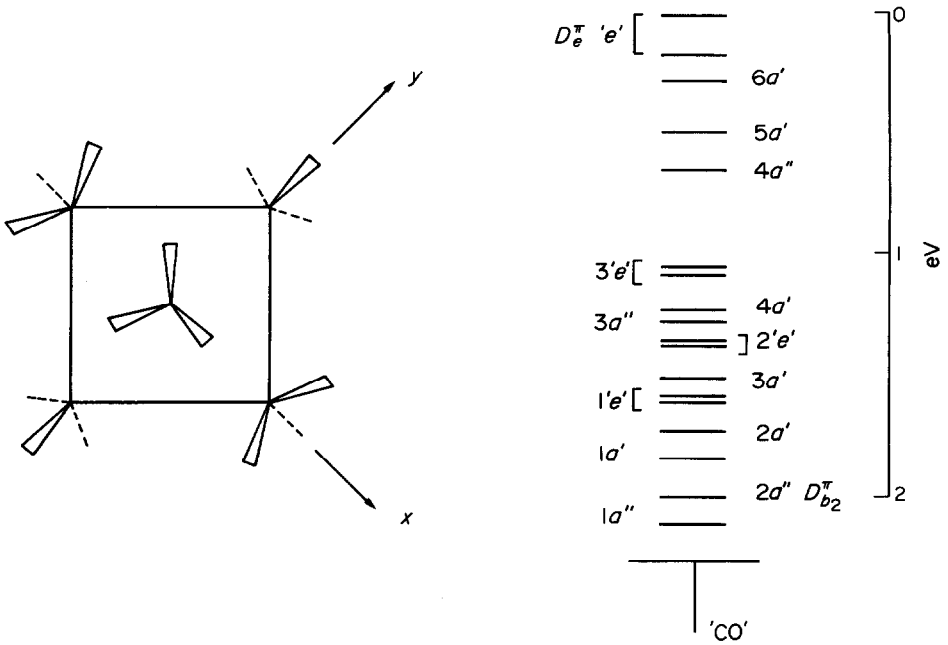

Fig. 5. Geometry of $Fe_5(CO)_{15}C$ used in calculation and the energy separations and assignments of the 18 HOMOs calculated.

a number of cases to identify their C_{4v} parentage) and the four C_{4v} degenerate pairs are labelled '*e*' (and transform as two *a'* in C_s) as these are least perturbed by the lower symmetry. Inspection of the composition allows the clear assignment of the cluster-bonding orbitals indicated in Fig. 5, and illustrated in Fig. 6. Comparison of the D_e^π and $D_{b_2}^\pi$ of Fig. 6 with those of B_5H_9 shows that the borane comparison is valid through to the composition of the orbitals. The D^π-orbitals have contributions from atoms not involved in the borane orbitals, arising from mixing with lone pairs of the same symmetry, particularly those perpendicular to the Fe–C direction. Such orbitals are labelled D^δ in Stone's description[3] and should be non-bonding. However the mixing has the effect of dèstabilizing the D_e^π pair, causing them to be the HOMOs of the molecule, and stabilizing the $D_{b_2}^\pi$ by antibonding and bonding interactions, respectively. The D^π labels are based on majority composition but are not unique. Clearly some lone-pair orbitals (particularly 3'*e'* and 4*a''*) have D^π character. Calculations on $Fe_5(CO)_{15}C$ in geometries closer to experimental enhance the mixing and it is impossible to assign even majority D^π or lone-pair character to individual orbitals.

Hoffmann[5] has reported an energy level diagram for "$[Ru_6(CO)_{18}]^{2-}$" and $[Ru_6(CO)_{16}C]^{2-}$ similar to Fig. 3, and determined using extended Hückel calculations. The orbitals corresponding to S^σ and *P* orbitals are not stabilized to anything like the extent that we find for $Fe_5(CO)_{15}C$. This is a consequence of the lack of charge-iteration in his calculation which we have previously shown[16] is necessary to account reasonably for metal–main-group atom interactions.

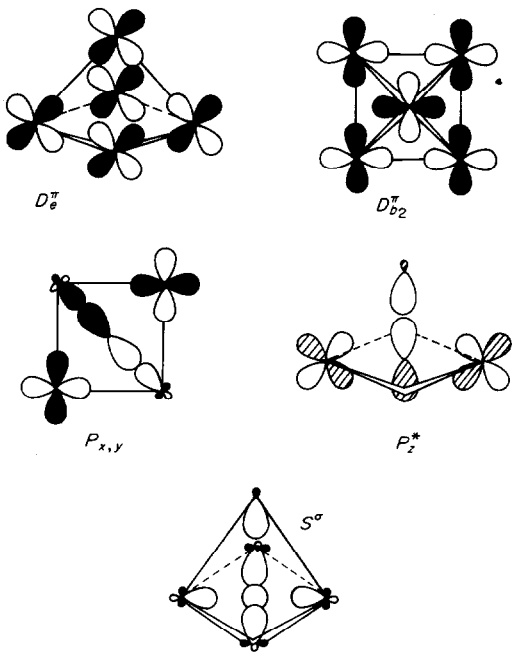

Fig. 6. Major components of the cluster-bonding orbitals of $Fe_5(CO)_{15}C$. * Represents a section through the *xz* plane; a similar contribution occurs in the *yz* plane (not shown).

Figure 7 shows a schematic of all the valence energy levels of $Fe_5(CO)_{15}C$ and $Fe_5(H)(CO)_{14}N$. The 18 orbitals discussed above are followed by three blocks of carbonyl orbitals as shown. The three P and the S^σ cluster orbitals are easily identified at 7 and 20 eV below the HOMOs as they have large contributions from the basal carbon atom (60%) and the metal atoms (25% $P_{x,y}$, and 30% P_z and S^σ), and are shown in Fig. 6. The comparison of these orbitals with the related MOs of B_5H_9 is remarkably good. The metal σ hybrids ($3d_{z^2}$, $4s$, $4p_z$) substitute for the boron $2s$ orbital and the component of $P_{x,y}$ from the bridging hydrogens of B_5H_9 is supplied by the basal metal atoms not directly interacting with the carbon $2p$ orbital. Again the P_z-orbital is the one least like its *closo* precursor and is mixed with a P^π-orbital on the basal metal atoms. The carbon $2s$ and $2p$ contributions to these four orbitals are exactly those expected from the discussion of Stone's theory above. These four orbitals are insensitive to changes of the geometry of the carbonyl ligands unlike the D^π-orbitals. Provided the square-based pyramidal geometry of the metal atoms is maintained the orbitals have the composition shown.

In a similar manner a calculation on $Fe_5(H)(CO)_{14}N$ in a geometry very close to the experimental one shows that the lower symmetry completely mixes the D^π and lone-pair orbitals so that no assignment can be made for the top 18 orbitals. The S^σ- and P-orbitals of the nitride are very similar to the carbide ones, only somewhat lower in energy. There appears to be nothing significant about the nature of the basal bridging carbonyls and hydrogen atom of this molecule. Their orbitals are calculated to be mixed with those of the terminal carbonyls, the hydrogen mainly in the (5σ, 1π) group.

Figure 8 shows the photoelectron spectrum of

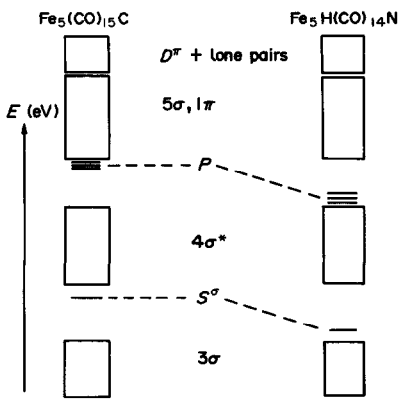

Fig. 7. Schematic of the valence orbitals of $Fe_5(CO)_{15}C$ and $Fe_5(H)(CO)_{14}N$.

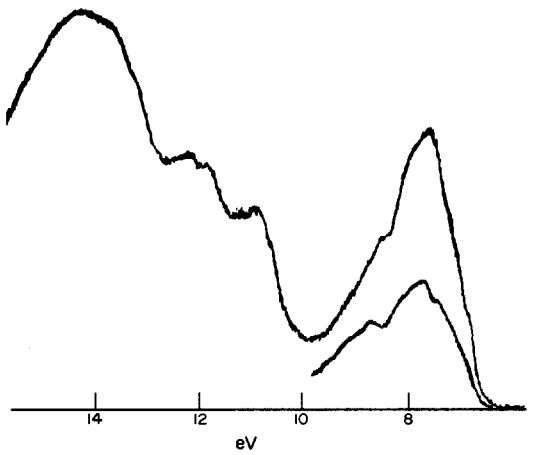

Fig. 8. He(I) photoelectron spectrum of $Fe_5(H)(CO)_{14}N$.

$Fe_5H(CO)_{14}N$. To the authors' knowledge no other molecule containing five metal atoms has been studied by gas-phase PES. The spectrum is remarkably structured for so large a molecule. The low-energy '$3d$' band (6.5–9.5 eV) has a width similar to that predicted by the calculation and is followed by a carbonyl band (10–15 eV) corresponding to the (5σ, 1π) group of MOs. No useful measurements could be made below 17 eV. There is clearly no possibility of identifying individual ionizations in the '$3d$' band. The structure observed in the 10–13-eV region of the carbonyl band is unusual, and could be related to the bridge-bonded carbonyl and hydrogen ligands. Ionizations due to MOs localized on bridging hydrogens have been observed at 12.5 eV[17] but apparently no spectra of molecules with symmetrically bridging carbonyls have been reported and assigned. The spectra of $Fe_2(CO)_6(C_4H_4)$ and $Fe_3(CO)_8(C_4H_4)$, which both contain semi-bridging carbonyls, have been reported.[18] These carbonyls are found to contribute to the HOMOs of the molecules, unlike the above, and also to a number of MOs in the -12 to -13 eV binding-energy region.

The calculations suggest that the D^π-orbitals are very sensitive to the carbonyl position. This is realized in practice as a considerable variety of carbonyl arrangements have been observed. This sensitivity is not surprising as the lone-pair orbitals formed from ($4p$, $3d$) hybridization of opposite phase to the π AOs of Fig. 1 are the ones most likely to provide d–π^* backbonding interaction. Provided the D^π-lone-pair mixing does not displace any D^π component to the virtual-orbital set then none of the cluster-bonding contributions from these orbitals is lost. The energy gap between occupied and virtual orbitals is small. The calculations

predict a HOMO–LUMO gap of 0.8 eV and the absorption spectra of $[Fe_6(CO)_{16}C]^{2-}$ and $Fe_5(CO)_{15}C$ both show electronic absorptions as low as 1 eV in energy. As the low-energy virtual orbitals are calculated to be largely metal-localized the loss of cluster bonding due to mixing of D^{π} with lone pairs is a distinct possibility.

Due to the experimental indistinguishability of D^{π} and lone-pair orbitals, the calculated sensitivity to carbonyl position, and the possibility of mixing with virtual lone-pair orbitals we are of the opinion that the D^{π}-orbitals are probably not very important in determining the strength of the overall cluster bonding. If the D^{π}-orbitals were critical to the structure of the clusters one might expect them to be far less sensitive to rearrangement of the carbonyl ligands than is indicated by the calculations. This observation is in accord with our recent work[13] on *closo*-six-apex borane and carborane clusters where we concluded that the D^{π}-orbitals are very weakly bonding but are important in defining the shape of the molecule, the stability being due essentially to the S^{σ}- and P-orbitals. The structure[20] of $[Co_6(CO)_{14}C]^-$ appears to support this opinion. The cluster has one Co—Co distance (2.96 Å) that is almost too long to be considered as bonding. The D^{π} interactions of this region of the cluster have clearly been disrupted yet the cluster retains a basically octahedral arrangement of metal atoms.

The interaction of S^{σ} and P metal orbitals with the interstitial atom is relevant to earlier work we reported on $Fe_5(CO)_{15}C$ and the related metalloboranes 1- and 2-$Fe(CO)_3B_4H_8$ and 1,2-$Fe_2(CO)_6B_3H_7$.[21] We observed that the radial hybrid ($4s$, $4p_z$, $3d_{z^2}$) metal lobes in the metalloborane molecules were shown to make little contribution to the cluster bonding, whereas they were important in the carbide cluster. The energy separation of this lobe from the boron $2s$ orbital is too large to allow an effective interaction and the metal component of cluster bonding is achieved almost entirely by the H-lobes. In $[Fe_2(CO)_6B_3H_7)]$ there are insufficient boron atoms to construct the S^{σ} and P MOs, and one of the P-orbitals is lost, presumably replaced by a metal–metal σ-bonding orbital constructed from the two metal σ-lobes. This would account for the orientation of the carbonyl ligands more towards the metal–metal axis than the cluster centre.

CONCLUSIONS

The following general statements can be made on the basis of the above discussions, even allowing for the approximate nature of the calculations employed.

(1) Stone's theory and terminology can be transferred from boranes to metal clusters, and underpins the "borane analogy" summarized by Wade's and Hoffmann and Mingos's description of the molecules considered.

(2) The group of metal-localized orbitals at the top of the orbital stack of a metal cluster will contain $4n+1$ orbitals [$3n$ lone pairs$+(n+1)$ cluster orbitals] or $4n-3$ orbitals if the cluster involves an interstitial atom. n is the number of apices of the related *closo*-borane geometry.

(3) Only in highly symmetric metal clusters, of which $Co_6(CO)_{14}^{4-}$ is the only obvious example, could cluster or lone-pair character be clearly distinguishable in this top group of MOs. It is therefore difficult to conceive of any experimental measurement on the valence orbitals to demonstrate the application of Stone's theory to these clusters.

(4) For clusters with an interstitial atom four cluster MOs are low in energy, one (S^{σ}) much lower than the other three (P). These MOs have a large contribution from the interstitial atom and are the major source of stability in such clusters.

(5) Clusters with interstitial atoms should be more likely to have chemistries based on retention of cluster geometry and should be more stable than related clusters without interstitial atoms. This applies equally to *closo*, *nido* or *arachno* systems, but may be more marked in the latter, e.g. there are no *arachno*-Fe_4 compounds known which do not have an interstitial atom.

As a final comment we note that there must be a minimum cluster size capable of accommodating an interstitial atom. Taking main-group atoms as interstitials, the p-orbitals of the atom will be clearly destabilized by too small a cluster, negating the stabilizing interaction discussed above. A *closo*-Fe_5 trigonal bipyramidal cluster would have an Fe—C distance of 147 pm, which is unreasonably small ($r_C = 77$ pm and $r_{Fe} = 112$ pm) whilst for the Fe_6 octahedron the distance is 187 pm {cf. Fe—C lengths in $[Fe_6(CO)_{16}C]^{2-}$ of 189 ± 8 pm}, very close to the optimum. The smallest metal clusters observed of *closo*, *nido* or *arachno* type, e.g. $[Fe_4(CO)_{12}C]^{2-}$, are all based on the octahedron.

(*Received* 25 *November* 1985; *accepted* 11 *March* 1986)

Abstract—*N,N*-dimethylanilinium β-octamolybdate dihydrate has been synthesized in acidic aqueous solution. The compound has been identified by using TG, DTG, IR and ^{1}H NMR techniques. It crystallizes in the triclinic system, space group $P\bar{1}$, $Z = 1$, $a = 11.755(3)$ Å, $b = 11.836(5)$ Å, $c = 10.498(2)$ Å, $\alpha = 105.29(2)°$, $\beta = 81.56(3)°$, $\gamma = 115.24(3)°$, $V = 1273.4(8)$ Å, $D_o = 2.23(1)$ Mg m^{-3}, $D_x = 2.23$ Mg m^{-3}, $R = 0.029$ and $R_w = 0.032$ for 5259 observed reflexions. Two crystallographically independent $[C_8H_{12}N]^+$ cations, one water molecule and one centrosymmetric β-octamolybdate polyanion are present in the asymmetric unit. Hydrogen bonds of types N—H···O and O—H···O seem to stabilize the structure.

In a previous paper[1] we reported the crystal structure of anilinium β-octamolybdate dihydrate. Anilinium and *N,N*-dimethylanilinium anhydrous salts were first described by Andreu.[2] The study of these compounds is part of a general investigation of anilinium, *N*-alkylanilinium and *N,N*-dialkylanilinium polymolybdates. Some of these salts may play an important role as possible catalysts in redox reactions, and also show photochemical properties.

EXPERIMENTAL

A suspension of MoO_3 (5.0 g) and distilled water (850 cm^3) was stirred and heated, and *N,N*-dimethylanilinium (5.0 cm^3) was added. After evaporating, the resulting slightly turbid solution (pH = 3.5) was cooled and filtered. Crystals of *N,N*-dimethylanilinium octamolybdate dihydrate (**I**) appeared in the solution. The light blue prismatic crystals were washed with ether, ethanol and water, and finally dried in air. They were found to be stable to air, light and X-ray exposure.

Compound **I** appeared to be a dihydrate: Found: Mo, 44.9; C, 22.5; H, 3.0; N, 3.3%; weight loss at 570°C, 32.6%; Calc. for $(C_8H_{12}N)_4Mo_8O_{26}\cdot 2H_2O$: Mo, 44.9; C, 22.5; H, 3.1; N, 3.3%; weight loss at 570°C, 32.6%.

Thermogravimetric analyses were performed on a Perkin–Elmer TGS-2 thermobalance at a heating rate of 5°C min^{-1} in a nitrogen stream under atmospheric pressure. The IR spectra were recorded in KBr pellets on a Beckman IR-4240 spectrophotometer (4000–250 cm^{-1}). ^{1}H NMR spectra were recorded in deuterated DMSO solution using TMS as the internal standard on a Perkin–Elmer R-12 B instrument (60 MHz).

Crystal data are shown in Table 1. Cell parameters were obtained by least-squares fit from 30 Bragg angles measured for both positive and nega-

Number of observed reflexions	5259 for $I > 3\sigma(I)$
R and R_w	0.029 and 0.032

tive θ values. 7317 independent reflexions measured up to $\theta = 30°$ on a CAD4 diffractometer with Mo-K_α radiation. There was no absorption correction. 5259 reflexions with $I > 3\sigma(I)$ were considered as observed. Scattering factors for neutral atoms and anomalous dispersion effects for Mo are from *International Tables for X-ray Crystallography*.[3] The structure was refined by full-matrix least-squares analysis using unit weights (H atoms as isotropic fixed contributors). Difference syntheses confirmed the existence of H atoms attached to N and O atoms. The remaining H atoms of the *N,N*-dimethylanilinium cations were located at their expected positions (broad maxima in the $\Delta\rho$ maps). Final-discrepancy indices are given in Table 1.

Final atomic coordinates, isotropic or equivalent

isotropic temperature factors, lists of F_o/F_c values, anisotropic thermal parameters for non-H atoms and hydrogen contacts have been deposited with the Editor as supplementary material.*

Most calculations were performed using the XRAY 76 system[4] running on a VAX 11/750 computer.

RESULTS AND DISCUSSION

The thermal decomposition of the compound shows its hydrated state. The two water molecules are lost in one step (70–130°C). There are seven stages in the total thermal decomposition, the final product being identified as MoO_3 by IR and its powder diffraction pattern. The formation of MoO_3 corresponds to the residue weight obtained in the chemical analysis.

N,N-dimethylanilinium octamolybdate dihydrate exhibits a very similar spectrum to anilinium β-octamolybdate dihydrate. Only small differences have been appreciated in the region of 2800 cm^{-1} due to the presence of the methyl groups linked to the N atom, and one band at 1450 cm^{-1} corresponding to C—H bending (methyl groups). The C—N stretching vibrations give two peaks at 1150 and 1200 cm^{-1}.

^1H NMR spectra show a multiplet between 6.3 and 7.2 ppm due to the aromatic protons. There is a signal at 2.8 ppm attributed to the methyl protons. A broad signal at 5.1 ppm is assigned to exchanging protons linked to the N atoms with the water protons.

The structure solution confirms that compound I contains discrete β-$Mo_8O_{26}^{4-}$ anions, $[C_8H_{12}N]^+$ cations and water molecules.

The β-octamolybdate polyanion is built up of eight distorted MoO_6 octahedra sharing edges and corners. A schematic drawing of the polyanion with atom labelling is shown in Fig. 1.

The Mo—O bond lengths within the MoO_6 octahedra are listed in Table 2 together with those from anilinium octamolybdate dihydrate and the idealized polyanion.

The O—O distances and O—Mo—O bond angles are displayed in Table 3. The degree of distortion of MoO_6 octahedra, estimated by eqns (1)–(3) are summarized in Table 3:

$$\Delta_1 = \frac{1}{6}\sum[(R_i - R)/R]^2, \quad (1)$$

Table 2. Mo—O bond lengths (Å) in compound I, anilinium octamolybdate dihydrate and the idealized polyanion

[a] Idealized polyanion (2/*m* symmetry) obtained from octamolybdates with ESDs ⩽ 0.006 Å from Mo—O bond lengths: salts of ammonium,[5] melaminium,[6] di-μ-aqua-tetrakis[μ-(methanol)-(methanol) sodium],[7] 3-ethylpyridinium,[8] 4-ethylpyridinium,[9] 3-methylpyridinium,[10] pyridinium,[11] anilinium[1] and *N,N*,-dimethyl anilinium.

$$\Delta_e = \frac{1}{12}\sum[(D_i - D)/D]^2, \quad (2)$$

$$\Delta_\alpha = \frac{1}{3}\sum[(\alpha_i - 180)/180]^2, \quad (3)$$

where R_i = individual Mo—O distance, R = mean Mo—O distance, D_i = individual O—O distance, D = mean O—O distance, and α_i = individual O—Mo—O_{trans} angle.

Plotting Δ_α vs Δ_e we can obtain the linear-regression formula $\Delta_\alpha = 0.0035 + 0.833\Delta_e$ with a correlation coefficient (r) of 0.993. Mo2, Mo3 and Mo4 octahedra present a similar degree of distortion. The Mo1 octahedron is the least distorted because of its central position in the polyanion.

* Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

A NEW TREND IN THE SYNERGISTIC EXTRACTION OF RARE-EARTH(III) COMPLEXES WITH VARIOUS β-DIKETONES AND 1,10-PHENANTHROLINE

SHIGETO NAKAMURA and NOBUO SUZUKI*

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980, Japan

(*Received* 6 *January* 1986; *accepted* 11 *March* 1986)

Abstract—The synergistic extraction of rare-earth (RE) [La(III), Sm(III), Tb(III) and Lu(III)] complexes, with three β-diketones (HA) [hexafluoroacetylacetone (Hhfa), pivaloyltrifluoroacetone (Hpta) and benzoylacetone] in the presence of a bidentate ligand (S), 1,10-phenanthroline, in benzene was investigated. The general composition of the adducts formed is expressed as $RE(A)_3S$. $RE(A)_3(S)_2$ is also observed in La–Hhfa, La–Hpta and Sm–Hhfa systems. The adduct formation constants $\beta_{s,1}$ and $\beta_{s,2}$ and the synergistic extraction constants $K_{ex,s,1}$ were determined. The trend of these constants is discussed in terms of the RE(III), β-diketone, neutral bidentate ligand and organic solvent.

The well-known synergistic effect in solvent extraction involves the enhancement of the extraction of a metal ion with an acidic chelating agent by the addition of a neutral ligand. Many studies have been carried out on the synergistic extraction using a neutral unidentate ligand, such as tributylphosphate (tbp) or trioctylphosphine oxide (topo). Compared with those, the systematic study of the synergistic extraction system involving a neutral bidentate ligand is sparse. We have investigated the synergistic extraction of bivalent and tervalent metal ions with several β-diketones and different bidentate heterocyclic amines in nonpolar organic solvents.[1–5] In a previous paper, the synergistic extraction of several rare-earth ions [RE(III)] with various β-diketones and 2,2′-bipyridine (bpy) was carried out, and a remarkable enhancement by bpy was observed.[5] Further investigation of the synergistic extraction using other bidentate ligands seemed to be of much interest and necessary to make the specific enhancement more clear.

In the present paper, the synergistic extractions of several RE(III) complexes with hexafluoroacetylacetone (Hhfa), pivaloyltrifluoroacetone (Hpta) and benzoylacetone (Hba) in the presence of 1,10-phenanthroline (phen) in benzene were investigated. This system was expected to show a larger synergistic effect than the bpy system, by analogy with the investigation of Tm(III)–thenoyltrifluoroacetone (Htta)–phen, bpy.[3] The adduct formation constant and extraction constant were determined and discussed together with those in acetylacetone (Hacac)–phen systems.[2,4]

EXPERIMENTAL

Materials and apparatus

Radioactive solutions of ^{140}La, ^{153}Sm, ^{160}Tb and ^{177}Lu were prepared as described previously.[4,5] Hhfa was distilled in the presence of P_4O_{10}. Reagent-grade Hba, Hpta and phen were used as obtained. Benzene was stirred with conc. sulfuric acid, washed with water and distilled after drying. Unless otherwise stated, reagents used were of guaranteed reagent grade. The γ-activity of each radioisotope was measured with an NaI(Tl) well-type scintillation detector.

Procedure

An aqueous solution (6 cm^3) containing 10^{-7}–10^{-5} M RE(III) labelled with its radioisotope was placed in a 30-cm^3 centrifuge tube with a ground-glass stopper. In the Hba systems, 2×10^{-3}–2×10^{-2} M sodium citrate was added to prevent hydrolysis. A benzene solution (6 cm^3) containing 10^{-4}–10^{-1} M β-diketone and 10^{-6}–10^{-3} M phen was added and shaken for 1–3 h at 25°C, then centrifuged. An aliquot was taken from each phase, the γ-activity

was measured, and the distribution ratio of the metal was calculated as the radioactivity ratio. The pH of the aqueous phase was adjusted with 5×10^{-3}–10^{-2} M piperazine-*N*,*N*′-bis(2-ethanesulfonic acid) and sodium hydroxide solution, and the equilibrium pH value was measured immediately after shaking. The ion strength was adjusted to 0.1 with sodium perchlorate.

Equilibrium equations

The distribution ratio (D_0) of a tervalent cation (M^{3+}) with a chelating extractant (HA) can be expressed as follows;

$$D_0=\frac{[\overline{MA_3}]}{[M^{3+}]+\sum[MA_n^{3-n}]}=\frac{P_{MA_3}\beta_3[A^-]^3}{1+\sum\beta_n[A^-]^n}, \quad (1)$$

where the bar denotes the organic phase, β_n the formation constant of MA_n^{3-n} in the aqueous phase, P_{MA_3} the partition coefficient of MA_3, and A^- the chelating anion in the aqueous phase. Often the extraction constant (K_{ex}) is given for the overall extraction reaction as:

$$M^{3+}+3\overline{HA}\rightleftharpoons\overline{MA_3}+3H^+,$$

$$K_{ex}=\frac{[\overline{MA_3}][H^+]^3}{[M^{3+}][\overline{HA}]^3}=\left(\frac{K_{HA}}{P_{HA}}\right)^3P_{MA_3}\beta_3, \quad (2)$$

where K_{HA} and P_{HA} denote the acid dissociation constant and the partition coefficient of HA, respectively. In the lower-concentration region for A^-, the intermediate chelates in the aqueous phase can be neglected in eqn (1), and D_0 is related simply to K_{ex} by the following equation:

$$D_0=K_{ex}\left(\frac{P_{HA}}{K_{HA}}\right)^3[A^-]^3. \quad (3)$$

In the synergistic extraction of M^{3+} with HA and a neutral ligand (S) the distribution ratio (D) can be expressed as follows:

$$D=\frac{[\overline{MA_3}]+\sum[\overline{MA_3S_m}]}{[M^{3+}]+\sum[MA_n^{3-n}]}$$

$$=\frac{P_{MA_3}\beta_3[A^-]^3(1+\sum\beta_{s,m}[\bar{S}]^m)}{1+\sum\beta_n[A^-]^n}, \quad (4)$$

where $\beta_{s,m}$ is the adduct formation constant in the organic phase corresponding to the following equilibrium:

$$\overline{MA_3}+m\bar{S}\rightleftharpoons\overline{MA_3S_m},$$

$$\beta_{s,m}=\frac{[\overline{MA_3S_m}]}{[\overline{MA_3}][\bar{S}]^m}. \quad (5)$$

From eqns (1) and (4), the following simple relationship is obtained:

$$D/D_0=1+\sum\beta_{s,m}[\bar{S}]^m. \quad (6)$$

If only MA_3S_m is the dominant species in the organic phase, D/D_0 depends on the mth power of $[\bar{S}]$. When the extraction is made from an aqueous phase containing an auxiliary complexing agent, e.g. the citrate ion in the extraction with Hba, we have to introduce an additional complex formation in eqns (1) and (4), but we finally arrive at the same equation.[5]

The synergistic extraction constant ($K_{ex,s,m}$) is defined by the following equilibrium:

$$M^{3-}+3\overline{HA}+m\bar{S}\rightleftharpoons\overline{MA_3S_m}+3H^+,$$

$$K_{ex,s,m}=\frac{[\overline{MA_3S_m}][H^+]^3}{[M^{3+}][\overline{HA}]^3[\bar{S}]^m}=\left(\frac{K_{HA}}{P_{HA}}\right)^3P_{MA_3}\beta_3\beta_{s,m}. \quad (7)$$

$K_{ex,s,m}$ can be calculated from the following relationship derived from eqns (2) and (7):

$$K_{ex,s,m}=K_{ex}\beta_{s,m}. \quad (8)$$

RESULTS AND DISCUSSION

Synergistic extraction with Hhfa and phen

The synergistic extraction of La(III) with various Hhfa concentrations and a constant phen concentration in benzene at a fixed pH was carried out, and plots of the logarithm of the distribution ratio against the logarithm of the hfa^- concentration are shown in Fig. 1. The equilibrium hfa^- concentration in the aqueous phase was calculated as follows:

$$[A^-]=\frac{C_{HA}}{(P_{HA}+1)[H^+]/K_{HA}+1}, \quad (9)$$

where C_{HA} denotes the initial Hhfa concentration. The literature values of K_{HA} and P_{HA} were adopted, i.e. $\log K_{HA}=-4.46$ and $\log P_{HA}=-1.91$.[6] A large synergistic enhancement can be observed by comparing the plots of $\log D_0$ in the absence of phen in Fig. 1. The plots for the synergistic extraction system give a straight line with a slope of 3.0. Therefore, it is proved that three molecules of hfa^- participate in the synergistic extraction of La(III).

Plots of $\log D/D_0$ against $\log[\bar{S}]$ in the synergistic extraction of La(III), Sm(III) and Lu(III) with Hhfa and various phen concentrations are shown in Fig. 2. The equilibrium phen concentration in the organic phase was calculated from the following

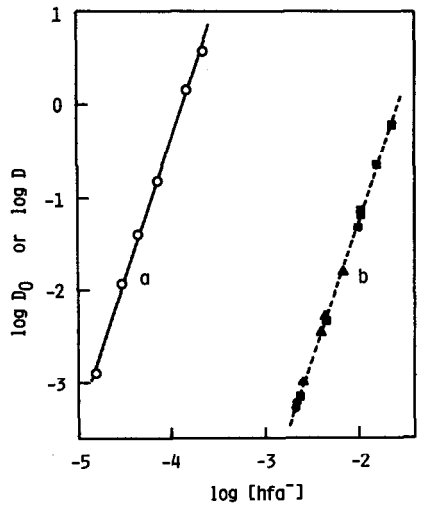

Fig. 1. Distribution ratio of La(III) as a function of hfa^- concentration in the presence and absence of phen in benzene. (a) 2.46×10^{-4} M phen, pH 3.38. (b) Without phen: (■) 10^{-1} M Hhfa, (▲) 3×10^{-2} M Hhfa, and (●) 10^{-2} M Hhfa.[5]

equation:

$$[\bar{S}] = \frac{C_S}{1+(1+[H^+]/K_{HS})/P_S}, \qquad (10)$$

where C_S denotes the initial phen concentration.

The acid dissociation constant of protonated phen (K_{HA}) and the partition coefficient of phen (P_S) were determined photometrically,[2] i.e. $\log K_{HS} = -5.04$ and $\log P_S = 0.78$. The values of D_0 were calculated from eqn (3) using K_{ex} summarized in Table 1. The plots for Lu(III) in Fig. 2 give a straight line with a slope of 1.0, and this shows, from eqn (6), that the chelate : phen mole ratio of the adduct is 1 : 1, and no evidence for the formation of a higher adduct, such as $Lu(hfa)_3(phen)_2$, is observed. The plots for La(III), however, give a straight line with a slope of 2.0, which suggests that a 1 : 2 adduct between the chelate and phen forms in this concentration range for phen. In most synergistic extraction studies of RE(III) with β-diketone and a neutral unidentate ligand, such as the RE(III)–Htta–tbp system,[7] and the La(III), Eu(III), Tb(III), Lu(III)–benzoyltrifluoroacetone (Hbfa)–topo, tbp, hexanol system,[8,9] the dominant species involves three molecules of β-diketone ligand and two molecules of neutral ligand, and the coordination number of the central metal of the adduct seems to be eight, which is confirmed by an X-ray crystallographic study of a similar adduct, $Nd(tta)_3(tppo)_2$ (tppo is triphenylphosphine oxide).[10] If phen acts as a bidentate ligand, the preferential formation of the adduct

Table 1. Extraction constants (K_{ex}) in RE(III)–HA–benzene systems, and adduct formation constants ($\beta_{s,m}$) and synergistic extraction constants ($K_{ex,s,1}$) in RE(III)–HA–phen–benzene systems

HA	RE(III)	Log K_{ex}	Log $\beta_{s,1}$	Log $\beta_{s,2}$[a]	Log $K_{ex,s,1}$
Hhfa	La	−2.91[b]	(9.03)[c]	15.92	(6.12)

[a] A dash denotes that no observation of the adduct formation of $RE(A)_3(phen)_2$ was obtained under the given experimental conditions.

[b] From our previous work.[5]

[c] Calculated from eqn (11).

[d] K_{ex} for Hacac are evaluated from eqn (2) (see text).

[e] From our previous work.[4]

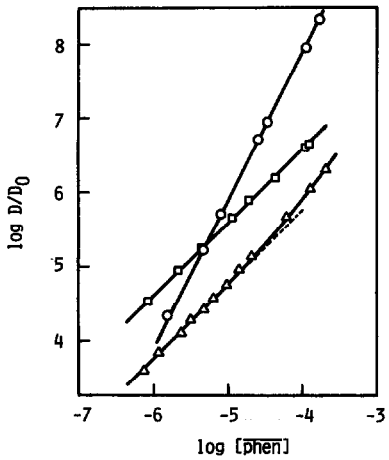

Fig. 2. Effect of phen concentration in benzene on the synergistic extraction of RE(III) with Hhfa ($[Hhfa]_{init} = 10^{-3}$ M): (○) La, pH 3.3; (△) Sm, pH 3.5; and (□) Lu, pH 3.3.

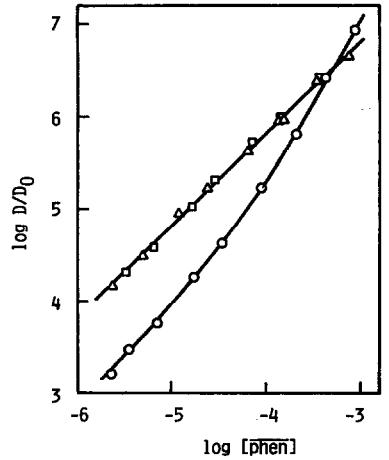

Fig. 3. Effect of phen concentration in benzene on the synergistic extraction of RE(III) with Hpta ($[Hpta]_{init} = 10^{-3}$ M): (○) La, pH 5.4; (△) Sm, pH 4.5; and (□) Lu, pH 4.1.

involving three β-diketone ligands and one phen ligand is understandable. In fact, the same type of adduct was observed in the synergistic extraction of RE(III) with β-diketone and a bidentate ligand, e.g. $RE(acac)_3phen$ (RE = La, Nd, Sm, Tb, Tm or Lu[2,4]) and $Tm(tta)_3S$ (S = phen, bpy or 2,9-dimethyl-1,10-phenanthroline[3]). In the synergistic extraction of La(III) with Hhfa and bpy, however, the possibility of the formation of a higher adduct, such as $La(hfa)_3(bpy)_2$, was also pointed out.[5] The plots for the present La(III)–Hhfa–phen system clearly give a straight line with a slope of 2.0. This is a very interesting result and a typical example of a higher adduct involving an acidic chelating agent and a bidentate ligand, such as $La(hfa)_3(S)_2$, though the coordination stereochemistry cannot be clear.

In Fig. 2, the plots for Sm(III) in the lower-concentration range for phen give a straight line with a slope of 1.0, but those in the higher-concentration range for phen deviate positively from the straight line. This suggests that, in the lower-concentration range for phen, the 1 : 1 adduct between the metal chelate and phen is predominantly formed, and in the higher-concentration range for phen a mixture of the 1 : 1 adduct and a higher adduct (possibly a 1 : 2 adduct) are present. The adduct formation constants, $\beta_{s,1}$ for $RE(hfa)_3phen$ and $\beta_{s,2}$ for $RE(hfa)_3(phen)_2$, are calculated from eqn (6) by the least-squares method and listed in Table 1.

Synergistic extraction with Hpta and phen

The synergistic extraction of La(III), Sm(III) and Lu(III) with Hpta and phen in benzene was carried out and the plots of $\log D/D_0$ against $\log [\overline{phen}]$ are shown in Fig. 3. The values of D_0 were calculated from eqn (3) using K_{ex} values in Table 1, and the quoted values of p_{HA} and K_{HA}, i.e. $\log P_{HA} = 2.15$ and $\log K_{HA} = -7.01$.[6] The plots for Sm(III) and Lu(III) give straight lines with a slope of 1.0, which suggests that a single adduct, $RE(pta)_3phen$, is formed. For La(III), however, the plots give curved lines having two asymptotes with a slope of 1.0 in the lower-concentration region for phen and a slope of 2.0 in the higher-concentration region for phen, corresponding to the formation of $La(pta)_3phen$ and $La(pta)_3(phen)_2$. The adduct formation constant $\beta_{s,1}$ and $\beta_{s,2}$ are listed in Table 1.

Synergistic extraction with Hba and phen

The extraction of La(III), Sm(III), Tb(III) and Lu(III) with Hba in the presence and absence of phen in benzene was carried out, and the plots of $\log D/D_0$ against $\log [\overline{phen}]$ are shown in Fig. 4. These plots for each RE(III) give a straight line with a slope of 1.0, which suggests that only one adduct, $RE(ba)_3phen$, is formed. The adduct formation constants are listed in Table 1.

Comparison of the adduct formation constants

Adduct formation constants involving neutral bidentate ligands are very large, e.g. $\beta_{s,1}$ for Hpta and Hhfa is about 10^9–10^{11}, and $\beta_{s,2}$ for La(III)–Hhfa reaches 10^{16}. Few synergistic extractions with a chelating extractant and a neutral ligand, in which the adduct formation constant exceeds 10^{15}, have been reported.[9,11,12] The $\beta_{s,1}$ and $\beta_{s,2}$ for phen are

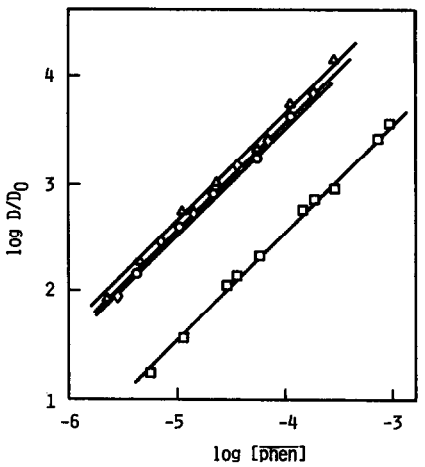

Fig. 4. Effect of phen concentration in benzene on the synergistic extraction of RE(III) with Hba in the presence of citrate: (○) La, 2.7×10^{-2} M Hba, 2×10^{-3} M citrate, pH 9.3; (△) Sm, 2.7×10^{-2} M Hba, 2×10^{-3} M citrate, pH 8.7; (◇) Tb, 2×10^{-2} M Hba, 1×10^{-2} M citrate, pH 8.9; and (□) Lu, 2×10^{-2} M Hba, 2×10^{-2} M citrate, pH 8.9.

larger than those for bpy.[5] In Fig. 5, $\log\beta_{s,1}$ for phen is plotted against $\log\beta_{s,1}$ for bpy in corresponding combinations of RE(III) and β-diketones, together with those in the Hacac systems.[4] These plots indicate a good linear relationship and give a straight line with a slope of 1.02. This relationship can be approximated by the following equation:

$$\log\beta_{s,1}(\text{phen}) = \log\beta_{s,1}(\text{bpy}) + 3.42(\pm0.08). \quad (11)$$

The above relationship may be interpreted as follows. The thermodynamic adduct formation constant ($\beta^o_{s,1}$) can be related to the apparent one ($\beta^x_{s,1}$) by introducing the activity coefficient (γ) of the solute in the organic phase, in terms of the mole fraction scale:

$$\beta^o_{s,1} = \beta^x_{s,1}\frac{\gamma_{MA_3S}}{\gamma_{MA_3}\gamma_S}, \quad (12)$$

where the subscripts MA_3S, MA_3 and S denote adduct, chelate and neutral ligand, respectively. Further, $\beta^o_{s,1}$ can be related to the standard chemical potential (μ^o) of the solute in its pure liquid state:

$$-2.303RT\log\beta^o_{s,1} = \mu^o_{MA_3S} - \mu^o_{MA_3} - \mu^o_S. \quad (13)$$

From eqns (12) and (13), $\beta^x_{s,1}$ can be written as follows:

$$\log\beta^x_{s,1} = -(\mu^o_{MA_3S} - \mu^o_{MA_3} - \mu^o_S)/2.303RT - (\log\gamma_{MA_3S} - \log\gamma_{MA_3} - \log\gamma_S). \quad (14)$$

Here, the adduct formation constant on the mole fraction scale is connected with that on the molar-concentration scale under the assumption that the concentration of each solute is low enough:

$$\beta^x_{s,1} = \beta_{s,1}\frac{1000}{V_o}, \quad (15)$$

where V_o denotes the molar volume of the solvent. Then, from eqns (14) and (15), $\beta_{s,1}$ for phen can be related to that for bpy by the following equation:

$$\log\beta_{s,1}(\text{phen}) = \log\beta_{s,1}(\text{bpy}) + A + B, \quad (16)$$

where:

$$A = (\mu^o_{MA_3bpy} - \mu^o_{MA_3phen})/2.303RT + (\log\gamma_{MA_3bpy} - \log\gamma_{MA_3phen}), \quad (17)$$

$$B = (\mu^o_{phen} - \mu^o_{bpy})/2.303RT + (\log\gamma_{phen} - \log\gamma_{bpy}). \quad (18)$$

From a simple comparison of eqns (11) and (16) we can get the relationship:

$$A + B = 3.42. \quad (19)$$

Here B, as shown in eqn (18), is constant for a given organic solvent and not dependent on the adduct, but substantially A takes different values with different adducts in the same organic solvent. The constant value (3.42) for $A+B$ for two adducts in a given organic solvent suggests that the value of A is negligibly small compared with B or practically constant for these adducts. In eqn (17) the chemical potential of the adducts is not known, but the chemical-potential term of A may take a constant value, and the activity coefficients of the adducts with phen and bpy may be nearly equal, considering that both adducts involve three molecules of the same β-diketone and one molecule of heterocyclic amine with a similar structure.

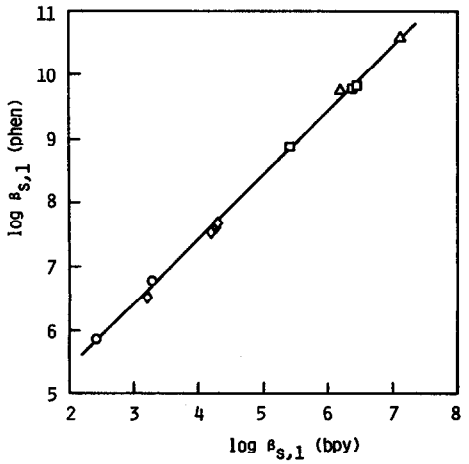

Fig. 5. Correlation of $\log\beta_{s,1}$ between phen and bpy systems: (△) Hhfa, (□) Hpta, (◇) Hba, and (○) Hacac.

The activity of a nonelectrolyte solute (a_c) in an organic solvent can be expressed, based on the regular solution theory,[13] as:

$$\ln a_c = \ln X_c + \frac{V_c}{RT}\phi_o^2(\delta_c - \delta_o)^2, \quad (20)$$

where X, ϕ and δ denote the mole fraction, the volume fraction and the solubility parameter, respectively, and the subscripts c and o the solute and the organic solvent, respectively. When the concentration of solute is very low, ϕ_o is approximately unity. Accordingly, the activity coefficient can be written as follows:

$$\log \gamma_c = \frac{V_c}{2.303RT}(\delta_c - \delta_o)^2. \quad (21)$$

Therefore, the following equation can be obtained:

$$\log \gamma_{MA_3bpy} - \log \gamma_{MA_3phen} = \frac{V_{MA_3bpy}}{2.303RT}(\delta_{MA_3bpy} - \delta_o)^2 - \frac{V_{MA_3phen}}{2.303RT}(\delta_{MA_3phen} - \delta_o)^2. \quad (22)$$

It seems that the value for this equation varies with different solvents. However, in the limiting case, in which V_{MA_3bpy} and δ_{MA_3bpy} are assumed to be equal to V_{MA_3phen} and δ_{MA_3phen}, respectively, the value of eqn (22) is zero. The molar volume of the bpy adduct is close to that of the phen adduct, because the molar volumes of bpy and phen are close to each other (134 cm^3 mol^{-1} for bpy and 142 cm^3 mol^{-1} for phen).[14] The solubility parameters of the phen and bpy adducts may be approximated to each other, considering the similarity in the intermolecular force of the phen adduct and the bpy adduct; hence, the value of eqn (22) will be negligibly small. This means that A takes a constant value governed only by μ^o, and $A+B$ takes a constant value.

The same relationship for eqns (16) and (19) seems to hold good in the Tm(III)–Htta–phen, bpy–benzene system, that is $\log \beta_{s,1} = 9.93$ (phen) and 6.58 (bpy), a difference of 3.35 (close to 3.42), but in another solvent system [Tm(III)–Htta–phen, bpy–cyclohexane] $\log \beta_{s,1} = 11.76$ (phen) and 7.57 (bpy), a difference of 4.19.[3] To understand the solvent effect in eqn (16), the activity coefficient terms in eqns (17) and (18) must be discussed, but, as discussed above, practically the activity coefficient term in eqn (18) is highly dependent on the nature of the solvent. We tried to estimate the activity coefficient of a neutral bidentate ligand in the organic solvent as follows. The partition coefficient of a solute expressed on the mole fraction scale (P_c^x) is related to the activity coefficient of the solute in the organic phase (γ_c) and in the aqueous phase ($\gamma_{c,a}$):

$$P_c^x = \frac{X_c}{X_{c,a}} = \frac{\gamma_{c,a}}{\gamma_c}. \quad (23)$$

From eqns (18) and (23) the following equation is derived:

$$B = (\mu^o_{phen} - \mu^o_{bpy})/2.303RT + (\log \gamma_{phen,a} - \log \gamma_{bpy,a}) + (\log P^x_{bpy} - \log P^x_{phen}). \quad (24)$$

The chemical-potential term is a constant and the activity coefficient terms in the aqueous phase ($\gamma_{phen,a}$ and $\gamma_{bpy,a}$) are also constant; hence, we can derive the same type of equation as eqn (16), including an overall constant (c):

$$\log \beta_{s,1}(phen) = \log \beta_{s,1}(bpy) + (\log P^x_{bpy} - \log P^x_{phen}) + C, \quad (25)$$

where:

$$C = (\mu^o_{MA_3bpy} - \mu^o_{MA_3phen})/2.303RT + (\mu^o_{phen} - \mu^o_{bpy})/2.303RT + (\log \gamma_{phen,a} - \log \gamma_{bpy,a}) = 2.15. \quad (26)$$

The constant C can be simply estimated as 2.15 by subtracting the value of $\log P^x_{bpy} - \log P^x_{phen}$ for benzene, which is determined experimentally,[3] from the constant value of 3.42 in eqn (11). This relationship is expected to apply in many other organic solvent systems which have no specific solute–solvent interaction. That is, the phen adduct formation constant in any organic solvent can be predicted from the bpy adduct formation constant by eqn (25). For example, in a cyclohexane solvent system, eqn (25) can be rewritten as follows by knowing $\log P_{bpy}$ and $\log P_{phen}$:[3]

$$\log \beta_{s,1}(phen) = \log \beta_{s,1}(bpy) + 4.26. \quad (27)$$

The experimental value of $\beta_{s,1}$ in the Tm(III)–Htta–bpy–cyclohexane system is 7.57;[3] hence, $\beta_{s,1}$ for the Tm(III)–Htta–phen–cyclohexane system is calculated as 11.83, which is in good agreement with the experimental value of 11.76.[3]

The value of $\beta_{s,1}$ for phen in the La(III)–Hhfa–benzene system could not be obtained under the present experimental conditions. $\beta_{s,1}$ is estimated from eqn (11) using the experimental $\beta_{s,1}$ for bpy, i.e. $\log \beta_{s,1}(bpy) = 5.61$;[5] hence, $\log \beta_{s,1}$ for phen is calculated as 9.03 (Table 1). The proportion of $La(hfa)_3phen$ to $La(hfa)_3(phen)_2$ in the organic phase can be calculated by using $\beta_{s,1}$ and $\beta_{s,2}$ as

only 10%, even at a concentration of 10^{-6} M phen, which is why $\beta_{s,1}$ cannot be determined experimentally by the present extraction technique.

The logarithmic values of $\beta_{s,1}$ are plotted in order of RE(III) atomic number in Fig. 6. A similar tendency is also observed in the bpy systems.[5] The values of $\beta_{s,1}$ for a given RE with different β-diketones increase in the order Hacac < Hba < Hpta $\leqslant$ Hhfa. This is in accord with the order of K_{HA}, i.e. $10^{-8.88}$ (Hacac)[15] < $10^{-8.39}$ (Hba) < $10^{-7.01}$ (Hpta) < $10^{-4.46}$ (Hhfa),[6] and may be the reverse of the chelate formation constants of RE(III) with these β-diketones, which is also observed in the synergistic extraction system involving a unidentate neutral ligand.[9] As to the central metal, in the Hacac and Hba systems, $\beta_{s,1}$ trends to decrease with increasing RE atomic number, and this tendency has been observed in most of the synergistic extraction studies using a unidentate neutral ligand; e.g. $\beta_{s,2}$ in the RE(III)–Htta–tbp and RE(III)–Hbfa–topo systems.[7-9] On the other hand, in Hpta and Hhfa systems, $\beta_{s,1}$ tends to increase with increasing RE(III) atomic number. How this characteristic trend is governed by the chelating agents is not yet known. This trend cannot be completely elucidated, but seems to be simply explained as follows. A stronger coordination of a chelating ligand ($acac^-$ or ba^-) to the central metal ions, in accordance with a larger chelate formation constant for RE(III) of higher atomic number, accompanies a lesser ability to accept a further addition of a neutral bidentate ligand for a RE(III) chelate of higher atomic number. On the other hand, the RE(III) chelate with hfa^-, with a very weak coordination ability considering the quite large acid dissociation constant of Hhfa, has a residual ability to accept

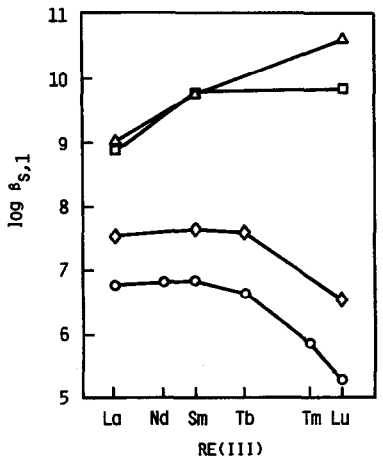

Fig. 6. Plots of adduct formation constants in RE(III)–HA–phen–benzene systems in order of RE atomic number: (△) Hhfa, (□) Hpta, (◇) Hba, and (○) Hacac.

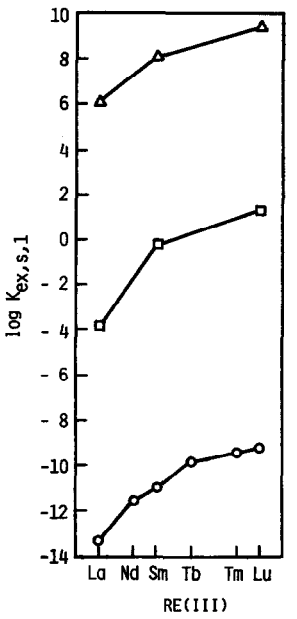

Fig. 7. Plots of synergistic extraction constants in RE–HA–phen systems in order of RE atomic number: (○) Hacac, (□) Hpta, and (△) Hhfa.

further coordination of the quite strong base of a neutral bidentate ligand. The difference between $\log\beta_{s,1}$ for Lu(III) and that for La(III) [$\Delta\log\beta_{s,1}$(Lu–La)] varies with different β-diketones, and its order of magnitude is -1.49 (Hacac) < -1.00 (Hba) < 0.95 (Hpta) < 1.57 (Hhfa), which accords with the order of the acid dissociation constant of β-diketones.

A secondary adduct containing two molecules of phen, $RE(A)_3(phen)_2$, is observed in limited extraction systems such as the La(III)–Hhfa, Sm(III)–Hhfa and La(III)–Hpta systems. $\beta_{s,2}$ for La(III)–Hhfa is larger than that for La(III)–Hpta, but secondary-adduct formation for Sm(III) is observed only in the system involving Hhfa. The secondary adduct seems to be formed in the system involving β-diketones with a larger acid dissociation constant. The successive adduct formation constant ($K_{s,2}$) of $RE(A)_3(phen)_2$ is calculated from the ratio $\beta_{s,2}/\beta_{s,1}$. Log $K_{s,2}$ is 6.89 for $La(hfa)_3(phen)_2$, 3.61 for $Sm(hfa)_3(phen)_2$ and 4.19 for $La(pta)_3(phen)_2$. $K_{s,2}$ is much influenced by the central metal of the adduct, and tends to be smaller the larger the RE atomic number.

Comparison of the synergistic extraction constants

The synergistic extraction constant ($K_{ex,s}$) is often used as a simple measure of the extractability of a metal ion in a synergistic extraction. $K_{ex,s,1}$ calculated from eqn (8) are listed in Table 1 and plotted in order of RE(III) atomic number in Fig.

Table 2. Differences in the logarithmic values of the extraction constants, adduct formation constants and synergistic extraction constants between Lu(III) and La(III) systems

HA	$\Delta \log K_{ex}$(Lu–La)	$\Delta \log \beta_{s,1}$(Lu–La)	$\Delta \log K_{ex,s,1}$(Lu–La)
Hhfa	1.71	1.57	3.28
Hpta	4.26	0.95	5.21
Hacac	5.62	−1.49	4.13

7. For this calculation, K_{ex} in the Hhfa and Hpta systems were the experimental values[5] and K_{ex} in the Hacac system was estimated from eqn (2) using P_{MA_3}[16] and the quoted values of P_{HA}, K_{HA} and β_3: $\log P_{MA_3} = -2.17$ (La), -2.12 (Nd), -1.89 (Sm), -1.60 (Tb), -0.63 (Tm), and -0.32 (Lu);[16] $\log P_{HA} = 0.74$;[17] $\log \beta_3 = 10.91$ (La), 12.60 (Nd), 12.95 (Sm), 14.04 (Tb), 14.29 (Tm), and 14.68 (Lu).[18] The $K_{ex,s,1}$ values for a given metal are in the order Hacac < Hpta < Hhfa. This is understandable as the result of the similar increasing trend of both K_{ex} and $\beta_{s,1}$: Hacac < Hpta < Hhfa. $K_{ex,s,1}$ for each β-diketone increases with increasing RE atomic number. This is a result of the increase in both K_{ex} and $\beta_{s,1}$ in the same way in the Hhfa and Hpta systems. In the Hacac systems, the tendency of $\beta_{s,1}$ reverses, but K_{ex} is quite large, to fully compensate for a small reverse change in $\beta_{s,1}$. Here, the difference between $\log K_{ex,s,1}$ for Lu(III) and that for La(III) can be calculated:

$$\Delta \log K_{ex,s,1}(\text{Lu–La}) = \log K_{ex,s,1}(\text{Lu}) - \log K_{ex,s,1}(\text{La}) = \Delta \log K_{ex}(\text{Lu–La}) + \Delta \log \beta_{s,1}(\text{Lu–La}), \quad (28)$$

where:

$$\Delta \log K_{ex}(\text{Lu–La}) = \log K_{ex}(\text{Lu}) - \log K_{ex}(\text{La}). \quad (29)$$

$\Delta \log K_{ex}$ and $\Delta \log K_{ex,s,1}$ are sometimes taken as the separation factors of two metal ions in an extraction with an acidic chelating agent and a synergistic extraction, respectively. The calculated values of $\Delta \log K_{ex,s,1}$(Lu–La) are listed in Table 2, together with $\Delta \log K_{ex}$(Lu–La) and $\Delta \log \beta_{s,1}$(Lu–La). In the Hacac system, $\Delta \log K_{ex,s,1}$(Lu–La) is smaller than $\Delta \log K_{ex}$(Lu–La), but in the Hpta and Hhfa systems, $\Delta \log K_{ex,s,1}$(Lu–La) are larger than $\Delta \log K_{ex}$(Lu–La). It has been generally believed that synergistic extraction makes the separation of metals worse, compared with extraction with a chelating ligand only. In the Hpta and Hhfa systems involving the bidentate neutral ligand phen, however, the separation factor can be improved by synergistic extraction. This suggests a further possibility of synergism in separation science. $\Delta \log K_{ex,s,1}$ as the sum of $\Delta \log K_{ex}$(Lu–La) and $\Delta \log \beta_{s,1}$(Lu–La) are in the order Hhfa < Hacac < Hpta. This order does not agree with either that of $\Delta \log K_{ex}$(Lu–La) or $\Delta \log \beta_{s,1}$(Lu–La), because the order of $\Delta \log K_{ex}$(Lu–La) is the reverse of that of $\Delta \log \beta_{s,1}$(Lu–La). This means that the theoretical prediction of a synergistic extraction involving an acidic chelating agent and a neutral bidentate ligand is not so easy, and further systematic investigation is required.

(*Received* 5 *February* 1986; *accepted* 11 *March* 1986)

Abstract—The dimethylpyrazole derivative of *N*,*N*′-dimethylethylenediamine, viz. 1,6-bis(3′,5′-dimethylpyrazol-1′-yl)-2,5-diazahexane (debd), forms coordination compounds with the transition-metal ions Co(II), Ni(II), Cu(II) and Zn(II) in the presence of a halide and a perchlorate anion of stoichiometry $[M(debd)X(H_2O)_n]ClO_4$ ($n = 0$ or 1). The ligand is always tetradentate. With cobalt and nickel six-coordinate compounds are formed. With copper and zinc five-coordinate compounds are formed. The compounds have been characterized by spectroscopic and magnetic methods (IR, ligand field, ESR and NMR).

Currently, much attention is given to the coordinating behaviour of pyrazole-containing ligands,[1–3] especially in relation to modelling active sites of metalloenzymes.[4–6] To obtain a better understanding of the coordinating possibilities of this type of ligand, we recently reported about a series of metal complexes with the ligand 1,6-bis (3′,5′ - dimethylpyrazol - 1′ - yl) - 2,5 - dimethyl - 2,5 - diazahexane (debd) (Fig. 1).[7] With transition-metal ions in combination with the anions NCS^- and N_3^-, six-coordinated metal compounds of formula $M(debd)X_2$ were formed with the anions in the *cis*-position. With the larger anions Cl^- and Br^- only compounds with the relatively large metal ions Mn^{2+} and Cd^{2+} could be isolated, which most likely originates from steric effects.[7,8]

When using this type of compound as metalloenzyme models, there should be the possibility of coordinating and binding reversibly small ligands, in addition to the larger debd ligand. We therefore extended the earlier investigation of the $[M(debd)]^{2+}$ unit, and tried to coordinate Cl^- and Br^- to other metals than Mn^{2+} and Cd^{2+}, with the aim of obtaining a better insight into the restrictions

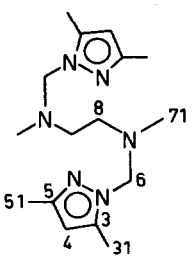

Fig. 1. Schematic drawing of the ligand debd, indicating the numbering used.

of the debd ligand. This paper describes the synthesis and characterization of such compounds: Cu^{2+} and Zn^{2+} yield five-coordinated compounds with only one bound Cl^- and Br^-, whereas Ni^{2+} and Co^{2+} yield six-coordinated compounds, in which water occurs as an additional ligand. Such a water ligand also occurs in the enzymes carboxypeptidase[9] and alcohol dehydrogenase.[10]

EXPERIMENTAL

Starting materials

Commercially available solvents and hydrated metal salts were used. The ligand debd was syn-

* Author to whom correspondence should be addressed.

thesized as described[7,11] by the condensation of *N*-hydroxymethyl-3,5-dimethylpyrazole and the amine *N,N'*-dimethylethylenediamine (Janssen Chimica) using acetonitrile as the solvent. The ligand was obtained as a yellow oil. The purity was checked by NMR. The ligand was used without further purification.

Synthesis of the complexes

The compounds $[MCl(debd)(H_2O)]ClO_4$ (M = Ni or Co) and $[CuX(debd)]ClO_4$ (X = Cl or Br) were synthesized by adding a hot solution of 5 mmol of debd in 15 cm^3 ethanol to a solution of the appropriate metal halide (2.5 mmol) and the appropriate metal perchlorate (2.5 mmol) in 15 cm^3 of hot ethanol. The compounds separated from the solution as microcrystalline material (Ni or Co compounds) or powders (Cu compounds) upon standing. The compounds $[ZnX(debd)]ClO_4$ (X = Cl or Br) were prepared by adding a hot solution of 6 mmol of debd in 15 cm^3 methanol to a hot solution of 3 mmol of $Zn(ClO_4)_2$ and 3 mmol of the appropriate zinc halide in 15 cm^3 of methanol. The compounds crystallized from the solution upon standing. Cu-doped zinc compounds were prepared by adding a small amount of copper salt to the solution of the zinc salts.

CAUTION: perchlorate salts may yield explosive mixtures. Although no accidents concerning perchlorates occurred during this research, perchlorates should only be prepared in small amounts and be handled with adequate care.[12]

Spectroscopic methods

IR spectra (4000–180 cm^{-1}) were recorded on a Perkin–Elmer PE580 instrument, using KBr pellets and Nujol mulls between NaCl discs or polyethene discs (low frequencies).

Electronic spectra were measured on a Perkin–Elmer UV330 instrument, operating in the diffuse-reflectance mode with MgO as a reference. ESR spectra were measured in a Varian E-3 EPR spectrometer, using a 9.5-GHz microwave bridge. The solid, powdered samples were measured at ambient temperature and at 77 K; methanolic solutions were measured as frozen glasses at 77 K.

All NMR spectra were measured in deuterated dmso solutions. Proton NMR spectra were recorded on a JEOL LNM PS100 instrument, operating at 99.5 MHz, externally locked and using TMS as an internal reference. ^{13}C NMR spectra were recorded on a JEOL JEC 980B instrument, operating at 50.1 MHz, using ^2H as an internal lock and dmso as an internal reference (39.500 ppm downfield from TMS).

X-ray powder diffraction patterns were obtained using a Guinier-type camera.

Elemental analyses were performed at the microanalytical laboratory of the University College, Dublin, Republic of Ireland.

Conductivities were measured of 10^{-3} M solutions in CH_3NO_2, using a Seibold LTB conductor.

RESULTS AND DISCUSSION

The compounds, obtained from the reaction between the debd ligand and a 1 : 1 mixture of MCl_2 and $M(ClO_4)_2$ (M = Ni or Co), can be formulated as $[MCl(debd)(H_2O)]ClO_4$. Their IR spectra are practically identical, as well as their X-ray powder diffraction patterns, indicating a very similar structure for both compounds. Their IR spectra are, except for the perchlorate vibrations, remarkably similar to the spectra of the $M(debd)X_2$ compounds,[7] indicating a similar *cis*-symmetrical configuration for the coordinated debd ligand. The electronic spectra show typical octahedral features (see Tables 1 and 4) with ligand field parameters in agreement with an $N_4(Cl)O$ chromophore.[13] The strong, sharp ν(O—H) near 3500 cm^{-1} in the IR spectra strongly suggests the coordination of a water molecule to the metal.[14,15] Vibrations at 222 cm^{-1} (Co) and 238 cm^{-1} (Ni), assigned to the ν(M—Cl) indicate terminal metal–halogen bonds.[16] The magnetic susceptibility, measured down to 4 K (Table 2), shows only a very small temperature dependence, probably originating from zero-field effects. Dimeric structures would be expected to show much stronger effects.[17,18] Even though these data in itself cannot exclude the presence of halogen-bridged dimeric structures, they strongly support the assignment of a monomeric structure to the compounds. The combination of data leads to the conclusion that these compounds have a monomeric, *cis*-octahedral structure with both a water molecule and a chloride ion coordinated to the metal, in addition to the tetradentate debd ligand.

The compounds $[CuCl(debd)]ClO_4$ and $[CuBr(debd)]ClO_4$ should have mutually very similar structures, as can be concluded from their almost identical IR spectra and X-ray powder diffraction patterns. Their conductance values in solution agree with 1 : 1 electrolytes[19] (see Table 1), suggesting the coordination of the halogen anion, and not the perchlorate anion, to the metal ion, as is also seen from the sharp Cl—O vibrations in the IR spectrum. The elemental analysis does not suggest the presence of water, nor is there any indication of coordinated

Table 1. Colours, IR and X-ray types, melting points, molar conductivities and elemental analyses of the debd compounds

water in the IR spectra. The values for the ν(Cu—X) vibrations (see Table 3) also suggest a five-coordinated structure rather than a six-coordinated structure.[14,16,20] The ESR and ligand field data (Tables 4 and 5) are in agreement with a square pyramidal five-coordinated structure.[21,22] When the steric constraints of the ligand and the known structure of the Cu(debd)$(NCS)_2$ compound[23] are considered, the four nitrogen ligands probably form the basis of the pyramid, with the halide ion on top.

The compounds [ZnCl(debd)]ClO_4 and [ZnBr(debd)]ClO_4 are mutually isostructural, which can be concluded from the similarity of IR spectra and X-ray powder diffraction patterns. Their NMR [^{1}H and ^{13}C (see Table 6)] spectra are also remarkably similar, confirming the structural similarity of the compounds. The elemental analysis does not suggest the presence of water, nor do the ^{1}H NMR spectra show any resonances due to water. The conductivity data suggest 1 : 1 electrolytes[19] (see Table 1), indicating the coordination of the halide anion. These data suggest a five-coordinated structure for the zinc compounds also. The ESR spectrum of the Cu-doped [ZnBr(debd)]ClO_4 compound is of the 'reversed' type,[22,24] indicating a d_{z^2} ground state, and suggesting a trigonal bipyrimidal structure for the zinc compounds. The sterical constraints of the debd ligand, in combination with the simple NMR spectra, suggest a structure similar to the structure of the six-coordinated compounds M(debd)X_2,[7] with the halide occupying one equatorial coordination site.

Concluding remarks

The steric constraints of the debd ligand greatly influence its coordination possibilities. Octahedral, six-coordinated compounds are formed only with a limited combination of metals and anions.[7] The adaptability of the Cu(II) ion allows relief of the steric interaction by elongation of the Cu—N(pyrazole) bonds[23] in the compound Cu(debd)$(NCS)_2$. This flexibility also allows the formation of the described five-coordinated copper compounds. With zinc similar five-coordinated compounds are also formed. With cobalt and nickel, chloride and water are coordinated to the [M(debd)]$^{2+}$ moiety. The bromide analogues could not be isolated, which can be explained by the steric requirements of the ligand (bromide being larger than chloride).

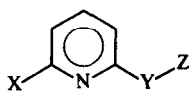
(*Received* 10 *January* 1985; *accepted* 11 *March* 1986)

Abstract—The dark purple title compound was prepared by reaction of $Ru_2Cl(O_2CCH_3)_4$ with molten 6-fluoro-2-hydroxypyrine (Hfhp) in quantitative yield. Crystals of composition $Ru_2Cl(fhp)_4$ were obtained by slow diffusion of hexane into a CH_2Cl_2 solution of the compound. The crystals belong to the tetragonal space group *I4mm* with the following unit-cell dimensions: $a = b = 10.890(2)$ Å, $c = 13.178(4)$ Å, $\alpha = \beta = \gamma = 90.0°$, $V = 1562.8(6)$ Å^3, and $Z = 2$. The $Ru_2Cl(fhp)_4$ molecule, which has crystallographic *4mm* (C_{4v}) symmetry, contains a diruthenium(II,III) unit with a metal–metal bond order of 2.5. The four bridging fhp ligands across the Ru_2 unit are oriented in one direction to form a polar molecule. The coordination spheres of the two ruthenium atoms [Ru(1) and Ru(2)] are $Ru(2)N(1)_4$ and $Ru(1)Cl(1)O(1)_4$, respectively. The axial site on Ru(1) is blocked by four F(1) atoms. The Ru(1)—Ru(2), Ru(2)—Cl(1), Ru(2)—O(1) and Ru(1)—N(1) distances are 2.284(1), 2.427(3), 1.971(2) and 2.089(4) Å, respectively. The electronic spectrum of the compound in CH_2Cl_2 shows two strong bands at 522 nm ($\varepsilon = 4720$ M^{-1} cm^{-1}) and 355 nm ($\varepsilon = 3770$ M^{-1} cm^{-1}). Cyclic voltammetry of $Ru_2Cl(fhp)_4$ in CH_2Cl_2 in the presence of 0.1 M $[N(C_2H_5)_4]ClO_4$ at 100 mV s^{-1} shows two quasireversible metal-centered one-electron oxidation and reduction processes at +1.68 V ($\Delta E_p = 120$ mV) and −0.01 V ($\Delta E_p = 126$ mV), respectively, vs an Ag–AgCl reference electrode.



Recent work from this laboratory has shown[1–7] that the formation of a new class of metal–metal multiple bonded complexes of type $M_2(NY)_4$ (**1**), where NY is ligand **2** bridging across the pair of metal atoms, is governed by the presence of a strong axial coordination as well as the bulk of X and Z on the bridging ligand. The discovery of compounds having a polar arrangement of ligands was first reported[1] in 1983 from our laboratory. It was found[1,2] that in $M_2(fhp)_4L$ (M = Cr, Mo, W or Rh; L = THF or Me_2SO) the four bridging fhp ligands are oriented in the same direction. The axial coordination is on to the metal which is bonded to four O atoms. This unprecedented sort of arrangement was surprising because earlier structural studies had shown that a 2:2 (or, rarely, a 3:1) arrangement of ligands occurs in chp and mhp complexes.[7–11]

Subsequent reports[3–6] from this laboratory on

F	O	H	Hfhp
Cl	O	H	Hchp
Me	O	H	Hmhp

the diruthenium(II,III) complexes have shown that Hhp, PhNHpy and Hchp ligands also form complexes $Ru_2Cl(hp)_4(Hhp)$ (**3**), $Ru_2Cl(PhNpy)_4$ and $Ru_2Cl(chp)_4$ (**4**) having a polar arrangement of bridging ligands. Our attempts to prepare a polar $Ru_2Cl(mhp)_4$ were unsuccessful, although we were able to prepare a new mixed-ligand complex, $Ru_2Cl(O_2CCH_3)_2(mhp)_2 \cdot 0.5CH_2Cl_2$.[5] The reported[12] structure of $Ru_2(mhp)_4 \cdot CH_2Cl_2$, a diruthenium(II,II) complex, has a 2:2 type of ligand arrangement, but there is no axial ligand.

3

4

Among ligands of type **2**, i.e. 2-hydroxypyridine and its derivatives, the bulk of X plays an important steric role in determining the coordination geometry of the metal atoms. When X = H(Hhp), the axial Cl coordination is on the metal which is coordinated to four nitrogen atoms, thus freeing the other axial site for coordination by a neutral Hhp ligand,[3] which forms a hydrogen bond to one bridging hp ligand. When X = Cl (Hchp), there is a basic change in the deployment of the ligands.[4] Now the axial coordination is to the metal atom bonded to four oxygen atoms, while the other axial site is blocked by four bulky Cl atoms. The presence of four Cl atoms close to each other also causes a twist of the ligand arrangement with an approximate torsion angle of 19°. A similar polar twist is also observed[3] in $Ru_2Cl(PhNpy)_4$. In the situation where X = Me, the polar arrangement of the ligands would result in a considerably greater twist compared to that in $Ru_2Cl(chp)_4$ because of the greater bulk of Me over Cl, and we could not isolate $Ru_2Cl(mhp)_4$.[5] Using Hfhp as a bridging ligand we have prepared the $Ru_2Cl(fhp)_4$ complex. The steric bulk of F lies between that of H and that of Cl, and thus we were interested to learn the extent of twist, if any, and the effect of fhp on the Ru—Ru and Ru—Cl bond lengths in $Ru_2Cl(fhp)_4$.

In this paper we report that we have succeeded with the synthesis and structure of the new diruthenium(II,III) complex, $Ru_2Cl(fhp)_4$, and that it does have a polar arrangement of bridging ligands. The present study is part of our systematic investigations to understand the role of steric and electronic factors responsible in the formation of polar molecules in which two metal atoms are in completely different coordination environments.

EXPERIMENTAL

Materials

$Ru_2Cl(O_2CCH_3)_4$ was prepared by following a literature procedure.[13] The ligand 6-fluoro-2-hydroxypyridine (Hfhp) was kindly supplied by the Dow Chemical Co.

Preparation of $Ru_2Cl(fhp)_4$

A mixture of 0.12 g of $Ru_2Cl(O_2CCH_3)_4$ and 0.50 g of Hfhp was heated at 130°C for 2 h under a dinitrogen atmosphere. The color of the melt changed from brown to deep purple. Excess ligand was removed by sublimation *in vacuo* at 130°C. The purple solid, obtained in quantitative yield, was dissolved in 20 cm^3 of CH_2Cl_2 and the solution filtered. A 5-cm^3 portion of the filtrate was placed in a test tube and 10 cm^3 of hexane was carefully placed on top of the CH_2Cl_2 solution, maintaining as much as possible a distinct interface between the two layers. Slow diffusion of hexane into the CH_2Cl_2 solution gave dark-coloured, large crystals in quantitative yield.

Found: C, 35.2; H, 2.0; N, 8.1%. Calc. for $Ru_2Cl(fhp)_4$: C, 35.0; H, 1.7; N, 8.2%. The compound is soluble in common organic solvents other than hexane. Electronic spectrum in CH_2Cl_2 solvent: λ_{max} = 522 nm (ε = 4720 M^{-1} cm^{-1}), 420 nm (shoulder), and 355 nm (ε = 3770 M^{-1} cm^{-1}).

Measurements

The elemental analysis was obtained from Galbraith Laboratories, Inc. The electronic spectrum was recorded on a Cary 17D spectrophotometer. Electrochemical measurements were carried out in

CH_2Cl_2 solutions in the presence of 0.2 M tetrabutylammonium perchlorate as a supporting electrolyte under an argon atmosphere with a Bioanalytical Systems, Inc. Model BAS 100 Electrochemical Analyser instrument in connection with a Bausch & Lomb, Houston Instruments Model DMP 40 digital plotter. In a three-electrode cell system, a platinum disk Model BAS MF 2032 and a platinum wire were used as working and auxiliary electrodes, and a BAS MAF 2020 Ag–AgCl was used as reference electrode. All potentials were referenced to the Ag–AgCl electrode at 22 ± 1°C and are uncorrected for junction potentials.

X-ray crystallographic procedures

Pertinent crystallographic data are given in Table 1. The structure of a single crystal of size 0.6 × 0.6 × 0.5 mm, mounted on a glass fiber, was determined by using general procedures prescribed in the literature.[14]* Measurement of the unit-cell constants and data collection were performed on a Nicolet P3 diffractometer equipped with graphite-monochromated Mo-K_α (λ = 0.71073 Å) radiation. Lorentz, polarization and absorption corrections were applied to the data. Systematic absences from the preliminary data collection, which was performed in the 2θ range 20–30°, revealed *I*-center-

* Calculations were done on the VAX-11/780 computer in the Department of Chemistry, Texas A&M University, College Station, Texas with a VAX-SDP software package.

ing, and during subsequent data collection the $h+k+l = 2n$ restriction was applied. There was no decay of the crystal during 12.1 h of exposure time. The systematic absences in the data are consistent with all of the space groups *I*422, *I*4*mm*, $I\bar{4}m2$ (or $I\bar{4}2m$) and *I*4/*mmm*. With $Z = 2$ and the anticipated structure, only *I*4*mm* was acceptable for an ordered structure, and accordingly it was used to begin the process of solving and refining the structure. It proved to be entirely satisfactory and is doubtless correct. The positions of the two ruthenium atoms, one of which was placed at the origin, were obtained from the Patterson function, which along with data set seemed to be more consistent with the space group *I*4*mm*. The remaining non-hydrogen atoms were found using least-square refinements and difference Fourier maps.

The asymmetric unit consists of two metal atoms, one Cl atom, and one fhp ligand. Ru(2) and Cl are at the special position 0, 0, *z*, while all the other atoms are at the special position *x*, *x*, *z*. All the atoms were refined anisotropically and in the last cycle 394 data with $I > 3\sigma(I)$ were used to refine 57 parameters, to final values of $R = 0.0288$ and $R_w = 0.0383$. The final difference Fourier map had the highest peak with 0.60 *e* Å^{-3}.*

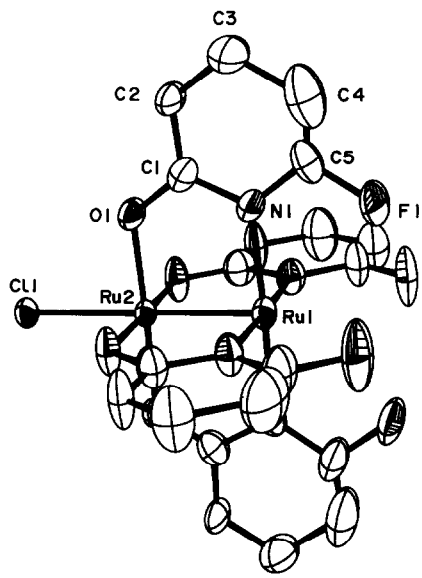

Fig. 1. ORTEP view of $Ru_2Cl(fhp)_4$ molecule with atoms represented by thermal vibration ellipsoids at the 50% level. The atom-labeling scheme in this molecule is defined.

RESULTS

Molecular structure

Selected bond distances and angles are listed in Table 2, and an ORTEP view of the molecule is shown in Fig. 1.

A C_4-axis coincides with the linear Cl(1)—Ru(2)—Ru(1) chain, and there are vertical mirror planes containing the fhp ligands and bisecting the angles between them. Thus, all the atoms belonging to the asymmetric unit lie in one plane, and the molecular symmetry is rigorously 4*mm* (C_{4v}). The molecule has a diruthenium(II,III) unit bridged by four fhp ligands in a fashion that gives rise to a polar arrangement of ligands. The coordination geometry of Ru(2) is octahedral with $Ru(1)O(1)_4Cl(1)$ while the other ruthenium atom, Ru(1), is square pyramidal (virtually octahedral with one empty site) with a $Ru(2)N(1)_4$ coordination sphere. The axial position on this Ru is empty because of the array of four F(1) atoms, which form a square with its plane normal to the Cl(1)—Ru(2)—Ru(1) axis screening this axial site.

The Ru(1)—Ru(2) distance in $Ru_2Cl(fhp)_4$ is 2.284(1) Å. The metal–metal distances found[3–5] in other diruthenium(II,III) complexes having a polar arrangement of ligands show little variation, lying between 2.278 and 2.286 Å. Among diruthenium tetracarboxylates,[15–19] the Ru—Ru distance ranges from 2.248 to 2.292 Å. The longest Ru—Ru bond length of 2.296 Å is known [20] in $Ru_2Cl(4\text{-}Cl\text{-}C_6H_4CONH)_4 \cdot CH_3OH$. The Ru(2)—Cl(1), Ru(2)—O(1) and Ru(1)—N(1) distances in $Ru_2Cl(fhp)_4$ are 2.427(3), 1.971(2) and 2.089(4) Å, respectively. The Ru—Cl distance is quite short compared to those in $Ru_2Cl(O_2CR)_4$, which are typically ~2.55 Å. It is our general observation that, in diruthenium complexes with only one axial site occupied by a Cl atom and the other one empty, the Ru—Cl bond lengths are in the range 2.419–2.443 Å.

Electronic spectra

The visible absorption spectrum of $Ru_2Cl(fhp)_4$ in CH_2Cl_2 displays one strong band at 522 nm ($\varepsilon = 4720$ M^{-1} cm^{-1}). At 355 nm, there is another moderately strong absorption with $\varepsilon = 3770$ M^{-1} cm^{-1}. The shoulder observed at 420 nm is weak. The spectrum is shown in Fig. 2.

Among polar diruthenium(II,III) complexes, the low-energy band position is found to be sen-

* Tables of atomic coordinates, structure factors, anisotropic thermal parameters and a complete list of bond distances and angles have been deposited with the Editor at Queen Mary College and at the Cambridge Crystallographic Data Centre.

sitive to the nature of the bridging ligand. The shift towards higher energy follows the order hp > fhp > chp > mhp > PhNpy. The metal–metal distance increases in the same order. For comparison, the Ru—Ru and Ru—Cl distances in polar diruthenium(II,III) complexes along with their low-energy electronic spectral data are presented in Table 3.

While we observed two bands in the electronic spectrum of $Ru_2Cl(fhp)_4$, the spectra $Ru_2Cl(chp)_4$ and $Ru_2Cl(O_2CCH_3)_2(mhp)_2$ exhibit[4,5] several bands. In $Ru_2Cl(chp)_4$, a low-energy band at 680 nm with $\varepsilon = 980\ M^{-1}\ cm^{-1}$ is present along with three higher-energy shoulders at 440, 380 and 340 nm. The electronic spectrum of the mixed-ligand complex $Ru_2Cl(O_2CCH_3)_2(mhp)_2$ also shows[5] three additional bands and shoulders at 460 nm, 378 nm ($\varepsilon = 1540\ M^{-1}\ cm^{-1}$) and 292 nm ($\varepsilon = 8070\ M^{-1}\ cm^{-1}$).

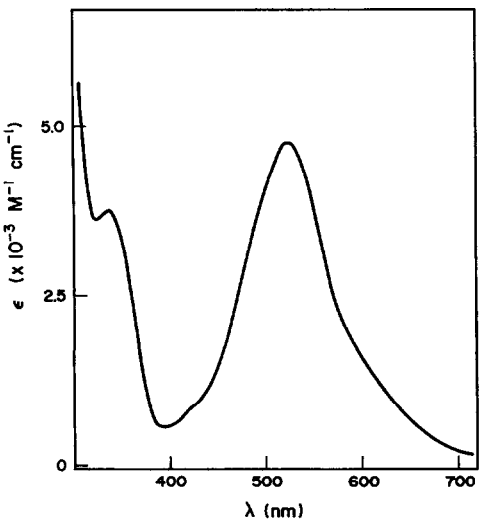

Fig. 2. Electronic spectrum of $Ru_2Cl(fhp)_4$ in CH_2Cl_2.

The diffuse-reflectance spectrum of $Ru_2Cl(O_2CCH_3)_4$ studied by Clark and Franks is known[21] to have a maximum at 21,600 cm^{-1} (*ca* 462 nm). The presence of this band was also observed by Martin *et al.*[19] in the polarized electronic spectra for tetraacetate. From the SCF-Xα-SW calculation done on $[Ru_2(O_2CR)_4]^+$ complexes, Norman *et al.*[22] assigned this band to an allowed $O(\pi) \rightarrow \pi^*(RuRu)$ transition. If we consider that the band observed by us in $Ru_2Cl(O_2CCH_3)_2(mhp)_2$ at 460 nm has the same origin as in tetracarboxylates, the intense lower-energy band could be assigned to the transition involving the bridging mhp ligands and the $\pi^*(RuRu)$. This argument is supported by the presence of only one intense band in the range 480–764 nm having $\varepsilon > 3000\ M^{-1}\ cm^{-1}$ in these polar complexes. The band observed at 17,900 cm^{-1} (*ca* 558 nm) in $Ru_2Cl(O_2CCH_3)_4$ was assigned by Norman *et al.* to a $Cl \rightarrow \pi^*(RuRu)$ or $Cl \rightarrow \sigma^*(RuRu)$ transition. The band observed near 400 nm in the polar complexes could have the same origin. The observed shift of this band position from the tetracarboxylato to these polar compounds could be due to shortening of the Ru—Cl bond in the latter complexes.

Electrochemistry

The electron-transfer behavior of $Ru_2Cl(fhp)_4$ was studied in CH_2Cl_2 solution by cyclic voltam-

Table 3. Comparison of the Ru—Ru and Ru—Cl distances and the band maximas in polar diruthenium(II,III) complexes

Compound	Ru—Ru (Å)	Ru—Cl (Å)	λ_{max} (nm) [ε (M^{-1} cm^{-1})]	Reference
$Ru_2Cl(hp)_4(Hhp)$	2.286(1)	2.558(2)	480 (4690)	3
$Ru_2Cl(fhp)_4$	2.284(1)	2.427(3)	522 (4720)	This work
$Ru_2Cl(chp)_4 \cdot CH_2Cl_2$	2.281(1)	2.443(2)	536 (4740)	4
$Ru_2Cl(O_2CCH_3)_2(mhp)_2 \cdot 0.5CH_2Cl_2$	2.278(2)	2.419(5)	550 (3370)	5
$Ru_2Cl(PhNpy)_4$	2.275(3)	2.437(7)	764 (6910)	3

metry. In the voltage scan range of +2.0 to −2.0 V, two voltammograms were observed at −0.01 and +1.68 V with ΔE_p values of 126 and 120 mV, respectively, at a scan rate of 100 mV s^{-1}. The $i_{p,a}/i_{p,c}$ ratio of the voltammograms equals unity at scan rates of 100–500 mV s^{-1} indicating a quasireversible electron-transfer process. One-electron stoichiometry as well as the nature of the process, as given in eqn (1):

$$[Ru_2Cl(fhp)_4]^+ \underset{-e^-}{\overset{+e^-}{\rightleftharpoons}} Ru_2Cl(fhp)_4$$

$$E_{1/2} = +1.68\ V\ (\Delta E_p = 120\ mV)$$

$$\underset{-e^-}{\overset{+e^-}{\rightleftharpoons}} [Ru_2Cl(fhp)_4]^-, \quad (1)$$

$$E_{1/2} = -0.01\ V\ (\Delta E_p = 126\ mV)$$

were determined by controlled-potential coulometry. Both processes are believed to be metal-centered.

These results, when compared with electrochemical studies done on other polar diruthenium(II,III) species,[6] show that the redox properties of all compounds with 2-hydroxypyridine and its derivatives as bridging ligands tend to be similar. However, a considerable shift towards a lower potential for both the processes occurs on changing ligand coordination from O,N to N,N, e.g. in $Ru_2Cl(PhNpy)_4$ the processes occur at +0.50 V (ΔE_p = 60 mV) and −0.75 V (ΔE_p = 67 mV).

DISCUSSION

With the preparation and structural characterization of $Ru_2Cl(fhp)_4$ we have obtained further experimental evidence to corroborate our previous arguments concerning the reasons why certain binuclear species adopt the completely polar arrangement of ligands. We have argued that for a ligand of type **2** (or any other such as PhNpy, which also would place bulky groups near the axial site on the M_2 core), the 2 : 2 arrangement is disfavored because it prevents the formation of a strong axial ligand bond at *either* end. Indeed, in many cases it would preclude the formation of even weak axial bonds. With the polar arrangement, one strong axial bond can be formed, although, of course, the formation of a second axial bond is then entirely ruled out. A second factor, however, is whether the four blocking groups, X in **2**, can all be accommodated at one end. When X = H there is no problem at all, and it is possible to obtain a compound, **3**, in which the axial Cl ion is bound to the end of the M_2 unit where all of the X groups are. In this case, there is also an axial ligand at the other end that forms a hydrogen bond, and it is likely that the Cl^- ligand is forced to the other end because the hydrogen-bonded ligand has a strong preference for the end where hydrogen bond formation is possible.

In our previous work we next went to the chp ligand, where X is much larger, namely Cl. Here, again, the polar arrangement was adopted (see **4**), but apparently with difficulty, since the Cl...Cl nonbonded contacts are close and seem to induce some twisting about the Ru—Ru axis to yield a slight increase in these distances. At this point, two predictions were implied. (1) If the X groups were to be made even larger, say CH_3 groups, adoption of a polar $Ru_2(NY)_4Cl$ structure could become impossible. (2) If the X groups were to be made somewhat smaller than Cl, say F atoms, then a polar $Ru_2(NY)_4Cl$ structure would be adopted without any twisting. The first of these predictions is of limited usefulness since its verification requires the "proof of a negative", which isn't possible. Nevertheless, its correctness is supported (not proved) by the finding that $Ru_2(O_2CCH_3)_4Cl$ could be converted only to $Ru_2(O_2CCH_3)_2(mhp)_2Cl$, and not all the way to $Ru_2(mhp)_4Cl$.

What we are now reporting is proof of the correctness of the second prediction. We have demonstrated that $Ru_2(fhp)_4Cl$ can be made, that it has the polar structure, and that there is no twist about

the Ru—Ru bond. In fact, in the crystal the angle of twist is rigorously zero.

SYNTHESIS AND STRUCTURE OF COBALT(II) SQUARATE CHLORIDE

O. St. C. HEADLEY and L. A. HALL*

Department of Chemistry, University of the West Indies, St. Augustine, Trinidad

(*Received* 25 *February* 1986; *accepted* 24 *March* 1986)

Abstract—Cobalt(II) squarate chloride $[Co(HC_4O_4)(Cl)(C_2H_5OH)]_2 \cdot C_2H_5OH$ has been synthesized by reacting ethanolic solutions of $CoCl_2 \cdot 6H_2O$ and squaric acid in a nitrogen atmosphere. Analysis of the spectroscopic data, magnetic-susceptibility and weight loss measurements suggests that the complex is five-coordinate.

We have recently reported the synthesis of the two five-coordinate squarate complexes, iron(II) and nickel(II) squarate chlorides, from ethanolic solution.[1] We have now synthesized cobalt(II) squarate chloride which is apparently also five-coordinate.

EXPERIMENTAL

Chemicals

Squaric acid was obtained from Aldrich, recrystallized once from water and dried at approximately 100°C. Analar $CoCl_2 \cdot 6H_2O$ obtained from BDH was used as received. Analar grade ethanol (BDH) was redistilled over CaO prior to use.

Preparation of the complex

Squaric acid (0.34 g, 3.0 mmol) was dissolved in 200 cm^3 of hot ethanol through which a continuous stream of dry nitrogen was being passed. Cobalt(II) chloride-6-water (1.20 g, 3.0 mmol) was then dissolved in a similar volume of hot degassed ethanol and the solution quickly added to the squaric acid solution. After mixing, the passage of nitrogen was continued for about 5 min. Following filtration, the purple complex which separated out from a blue solution was transferred to a glass manifold in a nitrogen-filled glove bag. Found: C, 29.4; H, 4.9; Cl, 13.1; Co, 22.0%. Calc. for $C_{14}H_{20}Cl_2Co_2$: C, 30.4; H, 3.6; Cl, 12.8; Co, 21.3%.

* Author to whom correspondence should be addressed.

Instrumentation

The IR spectra were recorded on a Perkin–Elmer model 983 spectrophotometer. Nujol was used as the mulling agent and "saran wrap" as window material for the spectrum between 600 and 180 cm^{-1}. The UV–VIS–NIR reflectance spectra were done on a Varian 2300 spectrophotometer. Magnetic-susceptibility measurements were performed using a Newport magnetic balance. $HgCo(SCN)_4$ was used as the susceptibility standard. The TGA curve was obtained on a Netzsch STA 409 thermogravimetric analyser.

Analyses

The carbon and hydrogen analyses were done by Mikroanalytisches Labor Pascher. Cobalt was determined by atomic absorption spectrophotometry using a Pye–Unicam SP9 spectrophotometer while chlorine was determined gravimetrically.[2]

RESULTS AND DISCUSSION

The UV–VIS–NIR spectrum (Fig. 1) shows bands at 27,000, 13,300–23,300 and 5300–10,000 cm^{-1}. Two weak bands occur at about 4300 and 4700 cm^{-1}. The band between 13,300 and 23,300 has a fine structure in addition to a shoulder at about 14,000 cm^{-1}. These bands can be explained in terms of the energy-level diagram for five-coordinate cobalt(II) obtained by Norgett *et al.*[3] The broad absorption band between 5300 and 10,000

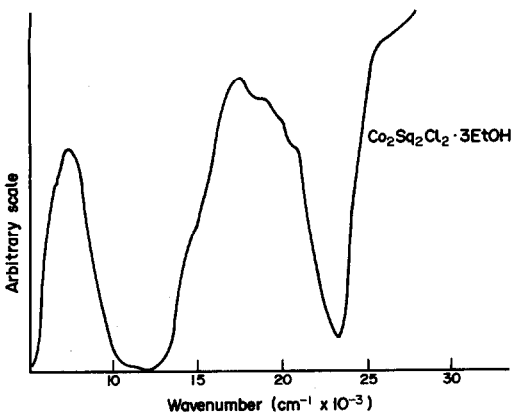

Fig. 1. Electronic spectrum of $Co_2Sq_2Cl_2 \cdot 3EtOH$ ($Sq = C_4O_4H^-$).

cm^{-1} has been assigned to $(e'')^4(e')^3 \rightarrow (e'')^3(e')^4$, while the absorptions between 13,300 and 23,300 cm^{-1} have been assigned to $(e'')^4(e')^3 \rightarrow (e'')^4(e')^2 a_1^1$. The band at 27,000 cm^{-1} has been assigned to the $(e'')^4(e')^3 \rightarrow (e'')^3(e')^3 a_1^1$ transfer. The three bands predicted to occur at about 20,000 cm^{-1} are actually observed in the spectrum of cobalt(II) squarate chloride. These bands make up the fine structure in the 13,300–23,300-cm^{-1} region and occur at 19,100, 19,800 and 20,800 cm^{-1}, respectively. The bands at 14,800 and 17,400 cm^{-1} have been attributed to the one-electron transitions predicted to occur at energies of 16,100 and 18,200 cm^{-1} by Norgett's model. The complex thus appears to be five-coordinate.

In the IR spectrum of cobalt(II) squarate chloride (Table 1), the broad band between 1500 and 1700 cm^{-1} has been assigned to C—C and C—O stretching modes. The peaks at 750, 1100, 1150 and 2250 cm^{-1}, and the band between 2600 and 2700 cm^{-1} are assumed to be absorptions due to squarate since they all appear in the spectrum of squaric acid and/or the squarates.[4-7] The peak at 1800 cm^{-1} is attributed to C=O stretching. The broad band between 3100 and 3600 cm^{-1} is assumed to be due to the O—H stretching of hydrogen-bonded hydroxyl groups from both ethanol and squarate. The peak at 1050 cm^{-1} has been assigned to a C—C—O stretching mode of ethanol while the peak at 875 cm^{-1} is assumed due to be an out-of-plane-bonded deformation. The Co—O stretching gives rise to peaks at 446 and 530 cm^{-1}, respectively.[8] Peaks at 215 and 225 cm^{-1}, and the broad band at 250–300 cm^{-1} have been assumed to be due to bridging chloride.[9]

The following structure is proposed:

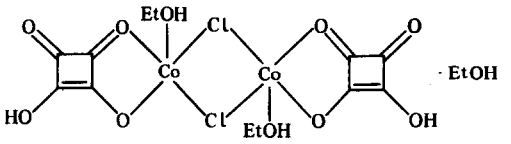

Table 1. IR spectroscopic data for $[Co(HC_4O_4)(Cl)(C_2H_5OH)]_2 \cdot C_2H_5OH$

Frequency[a] (cm^{-1})	Assignment
3100–3600 s, b	O—H stretch
2600–2700 w, b	Overtone and/or combination bands due to squarate
2250 m, sh	Overtone of peak at approximately 1100 cm^{-1}
1800 w, sh	C=O stretch
1500–1700 b	C—C and C—O stretching
1260 m, sh	O—H bending and C—O stretching of the ethanol molecule
1150 vw	Bands due to squarate
1100 s, sh	
1050 m, sh	C—C—O stretching of ethanol molecule
875 m, sh	Out-of-plane O—H bonded deformation
750 s, sh	C—O deformation due to squarate
530, 446 s, sh	M—O stretching
250–300 m, b	M—Cl bridging
225 s, sh	
215 s, sh	

[a] s = strong, sh = sharp, w = weak, vw = very weak, b = broad, and m = medium.

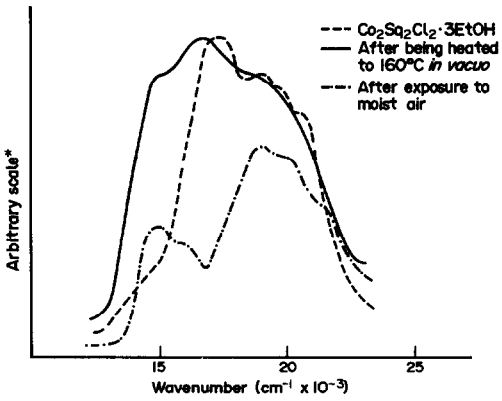

Fig. 2. Changes in the electronic spectra of $Co_2Sq_2Cl_2 \cdot 3EtOH$ due to changes in environment (Sq = $C_4O_4H^-$). * Peak heights are not intended to show relative intensities.

When cobalt(II) squarate chloride is exposed to the atmosphere it turns pink. The UV–VIS spectrum of the exposed complex shows broad bands at 13,300–16,700 and 17,000–23,300 cm^{-1}. The band at 13,300–17,000 cm^{-1} has a fine structure while the band at 17,000–23,300 cm^{-1} has a shoulder on the high-frequency side at about 21,600 cm^{-1}. These bands at 13,300–16,700 and 17,000–23,300 cm^{-1} have been assigned to the $^4T_{1g} \rightarrow {}^4A_{2g}$ and $^4T_{1g}(P)$ transitions of octahedral cobalt(II).

If cobalt(II) squarate chloride is heated *in vacuo* it turns blue. The UV–VIS spectrum of the heated substance has a broad band extending from 12,800 to 23,300 cm^{-1} which, although poorly resolved, has two maxima at 15,600 and 16,700 cm^{-1}, and a shoulder at 18,900 cm^{-1}. This broad band is assumed to be due to the $^4A_2 \rightarrow {}^4T_1(P)$ transition of tetrahedral cobalt(II).

A comparison of the UV–VIS spectra of cobalt(II) squarate chloride before exposure to the atmosphere, after exposure to the atmosphere and after heating at 160°C *in vacuo* is given in Fig. 2. The complex therefore appears to become octahedral on exposure to the atmosphere due to the coordination of water and tetrahedral due to loss of coordinated ethanol when heated *in vacuo*.

The hydrogen analysis of cobalt(II) squarate chloride is about 36% higher than expected and this has been attributed to solvent contamination as was observed for nickel(II) and iron(II) squarate chloride.[1]

The thermal weight loss curve for $[Co(HC_4O_4)(Cl)(C_2H_5OH)]_2 \cdot C_2H_5OH$ shows weight losses of 19.4 and 10.3% at about 180 and 250°C, respectively. This could be interpreted in terms of the sequential loss of the two coordinated ethanol molecules (16.7% calculated) and "lattice" ethanol (8.3% calculated). The differences between the theoretical and experimental weight losses have been assumed to be due to solvent contamination.

Cobalt(II) squarate chloride has a magnetic moment of 5.30 BM. This relatively high value could be due to clathrated solvent molecules.[6] However, high-spin five-coordinate cobalt(II) complexes with square-pyramidal geometry have similar magnetic moments.[10]

Abstract—The synthesis of the borohydride complexes $(dmpe)_2CrH(\eta^2\text{-}BH_4)$ (**A**) [dmpe = 1,2-bis(dimethylphosphino)ethane], $(Me_3P)_3WH_3(\eta^2\text{-}BH_4)$ and $(Me_2PhP)_3ReH(\eta^1\text{-}BH_4)(\eta^2\text{-}BH_4)$ are reported. ^1H and ^{31}P NMR spectra show that all the molecules are non-rigid, undergoing metal–hydride exchanges. The heavy-atom structure of **A** has been confirmed by X-ray crystallography.

A variety of transition-metal hydrido aluminohydrides[1] have dimeric structures of types **1** and **2** with five-coordinate Al. Borohydrides where boron is four-coordinate are commonly monomeric with $M(\mu\text{-}H_n)BH_{4-n}$ groups,[2(a)] although bridge groups are known.[2(b)] The patterns of non-rigid behaviour in the two types of complex according to ^1H and ^{31}P NMR spectra also differ considerably. The only borohydrides that have aluminohydride analogues are those of bis(pentamethylcyclopentadienyl)titanium(III)[3] and tris(trimethylphosphine)ruthenium(II).[4] We now report on some other borohydrides whose comparable aluminohydrides have been characterized in order to allow spectroscopic and structural comparison.

RESULTS AND DISCUSSION

Chromium

The diamagnetic aluminohydride made from $(dmpe)_2CrCl_2$ [dmpe = 1,2-bis(dimethylphosphino)ethane] and $LiAlH_4$ is $[(dmpe)_2HCr(\mu\text{-}H)_2AlH(\mu\text{-}H)]_2$.[5] Interaction of the chloride with an excess of $NaBH_4$ in diethylether–tetrahydrofuran (thf) leads to bright red crystals of $(dmpe)_2HCr(\eta^2\text{-}BH_4)$ (**A**). The IR spectrum shows strong bands typical of terminal B—H groups at 2460 and 2430 cm^{-1}, as well as a band at 2060 cm^{-1} due to Cr—H. A weaker band, *ca* 1650 cm^{-1}, is a bridging hydride stretch. Unlike the aluminohydride the compound is paramagnetic ($\mu_M = 2.49$ BM) with low-spin Cr(II) (d^4). The ^1H NMR spectrum contains many broadened peaks due to the CH_3 and CH_2 protons of dmpe [δ −13.5 ppm (P-C$\underline{H}_2$) and −15.6 ppm (P-C$\underline{H}_3$]; the hydrides appear as three separate peaks at δ −25.5, −29.4 and −33.5 ppm.

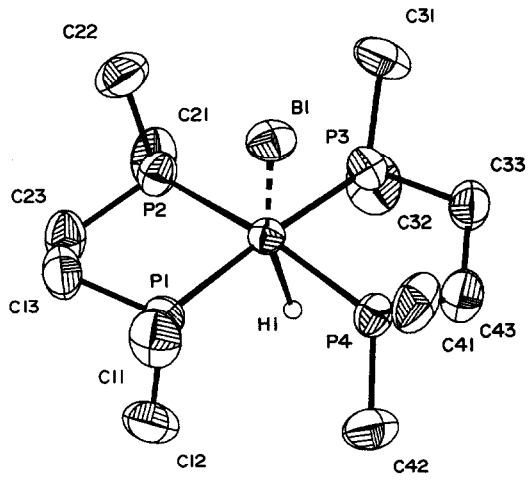

Fig. 1.

The structure of the compound is illustrated in Fig. 1; selected bond lengths and angles are given in Table 1. The BH_4 hydrogens were not located and we presume that this group is disordered with respect to these atoms. The main features of this typical $M(dmpe)_2L_2$ "octahedral" structure are the Cr—P bond lengths, which, at 2.321–2.346(6) Å, lie to the lower end of the range found for other Cr(II) $(dmpe)_2$ complexes,[6] and the slight bending down of the equatorial Cr—P bonds away from the BH_4 group [B...Cr—P = 94.4–97.2(4)°]. Otherwise, the geometry is as expected, with P—Cr—P chelate angles of 83(1)° and P—C distances of 1.82–1.8(2) Å.

Tungsten

The addition of $LiBH_4$ to an ether suspension of $WCl_4(PMe_3)_3$[7] results in a bright orange solution that yields the hexane-soluble $(Me_3P)_3H_3W(BH_4)$ (**B**).

The IR spectrum of the compound clearly shows various stretches due to terminal and bridging hydrides. A strong doublet at *ca* 2450 cm^{-1} [ν(B—H_b)] along with a broad signal at 1800 cm^{-1} [ν(B—H_b)] is indicative of a bidentate borohydride,[3] while a terminal metal hydride stretch at 2060 cm^{-1} is in the region expected for tungsten.[8] Although complex **B** undoubtedly has a geometry around the tungsten similar to that in the aluminohydride $[(Me_3P)_3H_3W(\mu\text{-}H)_2AlH(\mu\text{-}OBu^n)]_2$,[9] the tungsten hydride stretch in the latter is appreciably shifted and appears as part of a strong hydride envelope in the region 1800–1600 cm^{-1}. The remaining IR bands in **B** can be assigned to various phosphine stretches and deformations.

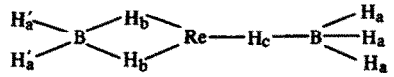
At room temperature the exchange between terminal M—H and bridging M(μ-H)B hydrides occurs rapidly on the NMR time scale. There is a broad singlet at δ −2.33 ppm which, on cooling decoalesces to give two broad signals at δ −0.13 ppm (B—H) and −6.25 ppm [W(μ-H)B].

Whereas in aluminohydrides the exchange between terminal M—H and bridging M(μ-H)Al hydrides is usually facile at room temperature, the equivalent exchange process for the borohydride compound occurs only at about +50°C. The process is typical of borohydride[2,3] with the BH_4 peaks coalescing with the metal hydride resonance (δ −7.80 ppm), to give a broad singlet (−4.62 ppm).

The $^{31}P\text{-}\{^1H\}$ NMR spectrum comprises a singlet with ^{183}W satellites [δ = −21.6 ppm, J(P–^{183}W) = 140 Hz]. When the phosphine protons are selectively decoupled the signal becomes a binomial quartet [J(P–H) = 26.0 Hz], indicating the presence of three terminal metal hydrides. No coupling is observed at room temperature due to the bridging hydrides.

Rhenium

The aluminohydride $[(Me_2PhP)_3H_2Re(\mu\text{-}H)_2Al(\mu\text{-}H)]_2$ has been described.[9] The interaction of $LiBH_4$ with $ReCl_3(PMe_2Ph)_3$ in Et_2O yields the bright orange, hexane soluble complex $(Me_2PhP)_3HRe(BH_4)_2$ (**C**).



The IR spectrum indicates the presence of two different terminal B—H_t hydride environments: a strong doublet at 2530 cm^{-1} due to B—H_t stretching in a bidentate η^2-BH_4 unit plus a higher-frequency band at 2390 cm^{-1} in the region assigned to η^1-BH_4 terminal B—H_t stretches.[2,3] Two stretches are present in the Re—H stretching region (1960 and 1895 cm^{-1}). However this is not inconsistent with the proposed formulation as two bands are also observed in the complex $(Ph_2MeP)_3HRe(\mu\text{-}H)_3AlMe_2$,[10] which has been crystallographically characterized as having three bridging Re(μ-H)Al hydrides and one terminal Re—H hydride. Two broad peaks in the IR spectrum at 1700 and 1610 cm^{-1} are probably due to bridging hydrides whilst the remaining peaks between 1500 and 400 cm^{-1} are attributed to phosphine vibrations.

In addition to PMe_2Ph bands the ^1H NMR spectrum contains a broad singlet (δ −2.70 ppm), due to the two BH_4 groups, and a quartet [δ −4.60 ppm, J(P–H) = 34.6 Hz] due to the terminal Re—H. As with complex **B** the exchange between metal hydride and borohydride groups occurs only at > 75°C. On cooling to −20°C the BH_4 peak merges with the base line, whilst at −50°C three new peaks appear: a broad singlet at *ca* −1.6 ppm assigned B—H_a (see **3**) and two broad peaks at δ −5.30 and −13.70

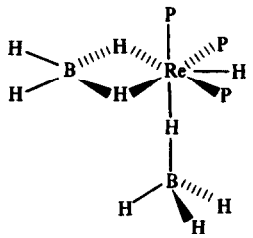
ppm due to $Re(\mu\text{-}H_b)B$ and $Re(\mu\text{-}H_b)B$ hydrides, respectively. The $^{31}P\text{-}\{^1H\}$ NMR spectrum, a singlet at room temperature, splits into a doublet when the phosphine protons are selectively decoupled [δ −24.6 ppm, J(P–H) = 32 Hz].

3

At −50°C the $^{31}P\text{-}\{^1H\}$ spectrum is a doublet and a triplet [δ −22.5 and −24.5 ppm, respectively, J(P–P′) = 10.6 Hz]. Hence it appears that the compound contains both η^1 and η^2 units. This appears to be the first example of this situation in a transition-metal complex. However, examples of complexes containing both η^3 and η^2 units have been reported.[11] The η^1- and η^2-BH_4 groups undergo mutual exchange as well as each having a separate $B\text{—}H_t \rightleftharpoons B\text{—}H_b$ equilibrium. These two exchange processes are probably closely related. If the exchange between bridging and terminal hydrides in the η^2-BH_4 unit involves a unidentate intermediate [eqn (1)]:



(1)

then the vacant site on the rhenium can be occupied by a hydride from either BH_4 group.

Pathways involving unidentate groups have been used to explain the stereochemical non-rigidity in compounds such as $Al(BH_4)_3$.[12]

The coordinate geometry about rhenium can be described as a pentagonal bipyramid (**4**) with one

phosphine and the unidentate borohydride occupying axial sites.

4

In this conformation the inter-exchange between the two different BH_4^- units can readily occur, whilst the energy required to initiate the exchange with the terminal rhenium hydride is large due to the *equatorial* arrangement.

EXPERIMENTAL

Microanalyses were by Pascher Laboratories, Bonn. Melting points were determined in sealed capillaries and are uncorrected. IR spectra were recorded in the region 4000–400 cm^{-1} on a Perkin–Elmer 683 grating spectrometer in Nujol mulls. NMR spectra were recorded on a JEOL FX90Q spectrometer [δ values in ppm relative to $SiMe_4$ (^1H) and 85% H_3PO_4 external (^{31}P) in d^8-toluene].

All manipulations were carried out under argon. Solvents were distilled and degassed before use.

trans - (*Hydrido*)(η^2 - *tetrahydroborato*)*bis*[1,2 - *bis*(*dimethylphosphino*)*ethane*]*chromium*(II) (A)

Excess solid $NaBH_4$ was added to a solution of $CrCl_2(dmpe)_2$ (0.40 g, 0.94 mmol) in Et_2O–thf (50+40 cm^3) at −78°C. The mixture was warmed slowly and stirred at room temperature for 12 h, when the solution became dark red brown. Removal of solvent and extraction of the brown solid with hexane (40 cm^3), filtration and concentration of the solution, followed by cooling to −20°C gave small red-brown needles which on crystallization from toluene (20 cm^3) gave large red prisms. Yield 0.5 g (60%). M.p. 183°C (decomp.). Required for $C_{12}H_{37}BCrP_4$: C, 39.1; H, 10.0; B, 2.0; P. 33.7%. Found: C, 36.6; H, 9.1; B, 2.98; P, 31.4%.

IR: 2460s, 2430s, 2060m, 1650br.w, 1290m, 1260s, 1200m, 1140m, 1130m, 1120w, 1060s, 950s, 930s, 890w, 860m, 770m, 765m, 730m, 700m, 670w and 650w cm^{-1}.

NMR: ^1H: −13.5 (8H, br.s, P-C$\underline{H}_2$). −15.6 (24H, br.s, P-C$\underline{H}_3$), −25.5, −29.4 and −33.5 [5H, Cr—H, Cr(μ-H)B and B—H].

Trihydrido(η^2 - *tetrahydroborato*)*tris*(*trimethyl* - *phosphine*)*tungsten*(IV) (B)

Solid $WCl_4(PMe_3)_3$ (1.00 g, 1.81 mmol) was added to a suspension of $LiBH_4$ (0.17 g, 7.73 mmol) in Et_2O (50 cm^3) at −78°C and the stirred mixture warmed to room temperature. After stirring for *ca* 6 h the solvent was removed and the red solid extracted with hexane (2 × 3 cm^3). Reduction in volume and cooling (−20°C) yielded orange crystals. Yield 0.41 g (53%). M.p. 180°C (decomp.). Required for $C_9H_{34}BP_3W$: C, 25.1; H, 7.9; B, 2.6; P. 21.6%. Found: C, 24.9; H, 7.8; B, 2.6; P, 22.0%.

IR: 2495s, 2420s, 2060m, 1800br.m, 1410m, 1295m, 1275s, 1140w, 940s, 850s, 800br.m, 915 and 660s cm^{-1}.

NMR: ^1H (298 K): 1.40 [27H, d, J(P–H) = 7.0 Hz, P-C$\underline{H}_3$]; −2.33 [4H, br.s, W(μ-H)B and B—H]; −7.80 (3H, br.s, W—H). ^{31}P–{^1H}: −21.6 [br.s with tungsten satellites, J(P–W) = 140 Hz].

Hydrido bis(η^1,η^2 - *tetrahydroborato*)*tris* (*dimethylphenylphosphine*)*rhenium*(III) (C)

To a cooled (0°C) suspension of $LiBH_4$ (0.20 g, 9.09 mmol) in Et_2O (40 cm^3) was added $ReCl_3(PMe_2Ph)_3$[13] (1.70 g, 2.41 mmol). The mixture was refluxed gently for *ca* 2 h, and the resulting orange solution evaporated *in vacuo*. Extraction of the residue with hexane (3 × 30 cm^3), removal of the solvent and crystallization of the solid from toluene resulted in several batches of bright orange crystals. Yield 1.09 g (72%). M.p. 84°C (decomp.). Required for $C_{24}H_{42}B_2ReP_3$: C, 45.6; H, 6.7; B, 3.5; P, 14.7%. Found: C, 45.0; H, 6.5; B, 3.4; P, 14.5%.

IR: 3080w, 2530s, 2520s, 2405s, 2390s, 1920s, 1850w, 1895w, 1435s, 1405m, 1290s, 1280s, 1100s, 1030m, 940vs, 905s, 860m, 840m, 800m, 750m, 740s, 720m, 700s, 675m, 480m and 415m.

NMR: ^1H (298 K): 7.29 (15H, m, P-C$_6\underline{H}_5$), 1.35 (18H, s, P-C$\underline{H}_3$), −2.70 [8H, br.s, Re(μ-H)B and B—H], −4.60 [1H, q, J(P–H) = 34.6 Hz, Re—H]. ^{31}P–{^1H}: −24.6(s).

Crystallographic studies

Crystals of $CrH(BH_4)(dmpe)_2$ were sealed under argon in thin-walled glass capillaries for X-ray examinations. The orientation matrix, and associated cell dimensions, and intensity data were obtained at 293 K following previously described procedures,[14] using an Enraf–Nonius CAD4 diffractometer operating in the ω–2θ scan mode, and graphite-monochromatized Mo-K_α radiation [λ(Mo-K_α) = 0.71069 Å]. The structure was solved via the heavy-atom method and refined by full-

matrix least squares,[15] with scattering factor data taken from Ref. 16. All non-hydrogen atoms were refined anisotropically. The chromium-bonded hydrogen atom was experimentally located and refined isotropically; hydrogens on the dmpe carbon atoms were inserted in idealized positions (C—H = 0.98 Å) and assigned a fixed U_{iso} of $1.2U_{equ}$ of the parent carbon atom. The BH_4 hydrogens could not be located and were not included.

Crystal data. $C_{12}H_{37}BCrP_4$, molecular weight = 368.13, orthorhombic, $a = 18.290(3)$ Å, $b = 9.299(2)$ Å, $c = 12.374(2)$ Å, $V = 2104.6$ Å space group $Pna2_1$, $d_c = 1.16$ g cm^{-3}, $Z = 4$, μ(Mo-K_α) = 8.17 cm^{-1}, 2245 intensities measured, 1949 unique and 1332 observed [$F_o > 2\sigma(F_o)$]. 167 parameters, $R = 0.56$, $R_\omega = 0.057$, weights = $1/[\sigma^2(F)+0.0002F_o^2]$.

Final atomic parameters, full lists of bond lengths and angles and F_o/F_c values have been deposited as supplementary material with the Editor from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

CHROMIUM(III)–CITRATE COMPLEXES: A STUDY USING ION EXCHANGE AND ISOTACHOPHORESIS

G. ABBAY and T. W. GILBERT*

Department of Chemistry, University of Cincinnati, Cincinnati, OH 45221, U.S.A.

(*Received* 2 *December* 1985; *accepted* 18 *March* 1986)

Abstract—Aqueous solutions containing equimolar chromium(III) and citric acid at various total concentrations and pH values were fractionated by weak ion exchange on amino-propyl-derivatized silica and by isotachophoresis. The chromium : citrate combining ratios were determined by liquid scintillation spectrometry. Of the approximately 15 solution species formed, the six major species were found to contain chromium and citrate in a ratio of 1 : 1. Possible structures of these complexes are discussed.

Hydroxycarboxylic acids are effective complexing agents for metals and are useful pH buffers. As a result, many industrial and analytical separation processes employ these ligands. Citric acid, because of its high solubility and low cost, is particularly widely used. However, its solution chemistry with metals can be complicated since it is known to form complexes containing metal ions of different identity (heteronuclear or mixed-metal complexes).[1–4] Our initial purpose was to study such complexes using chromatographic techniques. The kinetic inertness provided by the use of chromium(III) as one of the metals should permit separation of the mixed species on the chromatographic time scale. This work is our preliminary study of chromium(III) with citric acid alone.

Although the complexation of chromium(III) with citrate has long been recognized, documentation has been sparse. In all studies to date, chromium(III) has been reported to combine with citrate in a 1 : 1 molar ratio.[1,5,6] In the one attempt made to estimate equilibrium constants of formation, the species CrL, $[Cr(OH)L]^-$ and $[Cr(OH)_2L]^{2-}$ were postulated, where L represents the trivalent citrate anion.[6] Equilibrium measurements alone cannot establish unambiguously whether protons are liberated from water molecules in the inner coordination sphere of the chromium or from the very weak hydroxyl groups (pK *ca* 16) of the citric acid. The involvement of the hydroxyl groups of several hydroxycarboxylic acids through dissociation and coordination to metal ions is now well-established[7,8] and is most likely also occurring here. The only other combining ratio previously demonstrated is that of 2Cr : 1 citrate. However, to form this complex, the presence of a large excess of the weakly binding ligand, acetate, was required.[1] These conditions do not pertain to the present experiments.

Through analogy to the reaction of vanadyl(IV) and copper(II) ions with citric acid which showed the release of four equivalents of protons per citric acid reacted,[9] it was reasoned that the chromium(III) citrate complex should be anionic at pH values greater than 4.5. Preliminary experiments using a polystyrene–DVB anion exchanger (Aminex A-27) showed this to be the case. Five components could be resolved from the reaction mixtures but even at elevated temperatures 4 h were required for the separation. Consequently, it was decided to try a weak amino-bonded silica exchanger which should have faster exchange kinetics and improved resolving power. In addition, for confirmation of results, a capillary isotachophoresis apparatus was constructed and used for the separation of the same reaction mixtures.

EXPERIMENTAL

The chromatographic system consisted of an Altex Model 100A high-pressure pump and a Model 153 UV detector operated at 254 nm with a 0.008-cm^3 flow cell. A Knauer column (250 × 4.6 mm) was slurry packed with 5-μm Spherisorb amino-bonded phase using a Haskel pneumatic

* Author to whom correspondence should be addressed.

pump. Counting experiments using ^{51}Cr tracer and ^{14}C-labeled citric acid were done using a Packard Model 3320 liquid scintillation spectrometer.

Isotachophoresis experiments were done on an instrument constructed using the design principles outlined by Everaerts *et al.*[10] A 30-kV power supply with an associated high-voltage controller were commercial units (Bertan Associates, Model 210-30P). The potential-gradient detector was of new design.[11]

A stock solution of chromium(III) was prepared from hexaquochromium(III) perchlorate (G. F. Smith), assayed, and diluted to 0.30 M. An equimolar stock solution of citric acid was prepared by dissolving AR grade monohydrated crystals in water. Mobile phases were made from sodium perchlorate (AR) and tris(hydroxymethyl)aminomethane (primary standard). They were adjusted as required to specific pH values with perchloric acid and sodium hydroxide using a Beckman Zeromatic pH meter. All solutions were filtered through 0.5-μm Millipore membrane filters.

Two sets of sample solutions were prepared which were equimolar in chromium(III) and citric acid. The first set had different levels of chromium(III) and citric acid (0.0060, 0.060 and 0.30 M) but a constant pH of 5.5. The second set was 0.060 M in chromium and citric acid, but had different pH values (4.5, 5.0, 5.5 and 6.0). Because of the slow substitution kinetics of hexaquochromium(III) ions, the solutions were made up slightly under volume to permit pH adjustment as the reactions proceeded. They were kept in a water bath at 45°C until the desired pH value of each solution could be achieved. After cooling and dilution to final volume, the pH values were checked again. This procedure required from 46 to 60 h in the water bath to accomplish.

RESULTS AND DISCUSSION

The reaction of equimolar solutions of chromium(III) and citric acid results in a mixture of products of unexpected complexity. Depending on the solution and chromatographic conditions, 15 or more species can be resolved. Figure 1 shows a typical chromatogram, and indicates the six major peaks selected for study.

Figure 2 shows the chromatograms obtained at different concentration levels obtained from reacting equimolar quantities of chromium(III) and citric acid at pH 5.5. Three things should be noticed: first, the reaction mixtures are exceedingly complicated. Only chromium(III) perchlorate, citric acid, and a little sodium hydroxide for pH adjustment, were used in their preparation. Even the minor peaks are reproducible from run to run and from preparation to preparation. Second, the later eluting peaks are relatively much favored over the earlier peaks as the overall concentration increases. Finally, the retention times of all the peaks are constant and independent of the overall con-

centration. In order to make direct comparisons of the chromatograms, the peak heights of the six major peaks were normalized to account for the different concentration levels and detector sensitivities employed (Fig. 3).

To study the effect of pH on the yields of the six major solution species, a second set of solutions were prepared and subjected to chromatographic separation. As can be seen from Fig. 4, the same pattern of peaks is obtained in each chromatogram. The retention and the resolution of the peaks decrease as the pH of the solutions increases. This is to be expected, and has nothing to do with the chemistry of the chromium–citrate reaction. It is caused by the decrease in the number of exchange sites of the weak anion exchanger with increasing pH. Again, through a process of normalization of the peak heights to a common exchange capacity of the exchanger, comparisons of the relative amounts of the six peaks can be made (Fig. 5). It can be seen that the first peak eluted is strongly favored at lower pH values, whereas the last three peaks are favored at higher pH values. Peaks 2 and 3 do not seem to be significantly affected.

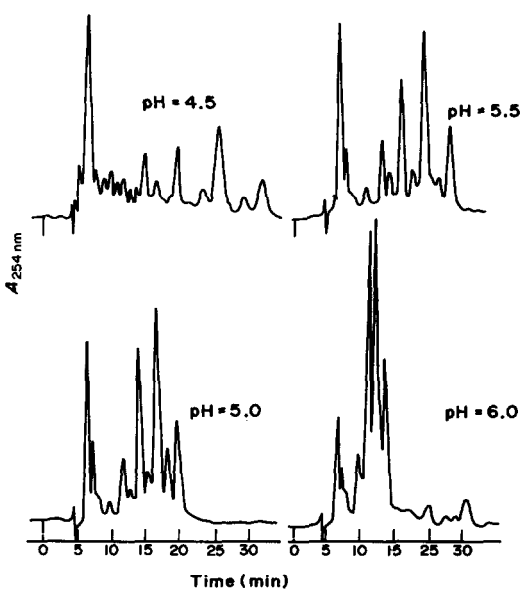

Fig. 4. Effect of pH on peak distribution of equimolar (0.060 M) chromium(III)–citrate solutions. Other conditions as in Fig. 1.

In a series of experiments duplicating the conditions of Fig. 1, ^{51}Cr tracer and ^{14}C-labeled citric acid were incorporated into the reaction mixture. By placing a NaI crystal scintillator flow-through detector in series with the UV detector, a two-channel recording of the chromatographic separation was possible. A chromatogram closely similar to Fig. 1 was obtained from the UV detector, and a second chromatogram from the rate counter showed the same peaks as the UV detector. In addition, the peaks were in the same proportion as in the UV trace. This shows that all the peaks in the chromatogram contain chromium since the crystal was totally unresponsive to ^{14}C, and, further, that the molar absorptivity of the chromium in the separated species is approximately constant.

In another experiment, the six major peaks shown in Fig. 1 were collected as separate fractions, treated with Universal Scintillation Cocktail (Fisher Scientific Co.) and counted with a liquid scintillation spectrometer. It was found that it was not possible to separate completely the emissions of the two isotopes by energy window selection, and so the fractions were counted at 14-day intervals. The activity decreases could be attributed solely to the ^{51}Cr (half-life 27.8 days). A simple calculation from the decay curve then gave the activities of the

Table 1. ^{51}C and ^{14}C activities in separated fractions

Peak No.[a]	Counts per unit time		Normalized counts[b]		Activity ratio
	^{51}Cr	^{14}C	^{51}Cr	^{14}C	(^{51}Cr : ^{14}C)

[b] Peak 2 counts are each assigned to unity.

two isotopes at the time of separation. In Table 1 are shown the counts obtained on each of the fractions corresponding to the six major chromatographic peaks. When the counts are normalized, it is seen that the ratio of chromium to citric acid in each fraction is approximately constant. Since all previous studies have indicated a 1 : 1 combining ratio, it is evident that chromium and citrate are present in this ratio in each one of the species separated.

In order to verify the surprising finding of so many different species formed from so few reactants, another high-performance separation technique was sought. For this product mixture, isotachophoresis seemed the most promising. It differs from chromatography in several important aspects. First, it is a single-phase technique, with no partitioning into or onto a second solid or liquid phase. The basis for separation is totally different; separation is achieved through the differential migration of ionic species according to their effective mobilities in an electric field. If the migrating ions are kinetically inert toward dissociation, then their effective mobilities will be characteristics of the species, and will depend on their charges, solvation and masses. If, in addition, there are present acidic or basic groups which can associate or dissociate, then the effective mobility will be a function of the solution pH as well. When a true isotachophoretic condition is achieved through the appropriate selection of leading and terminating electrolytes and pH, the step heights will be characteristic of the species migrating, and the zone lengths will be proportional to the amounts of the various sample constituents. An important feature of isotachophoresis is that the zone boundaries are self-sharpening. A consequence of this is that the method is useful for minor sample constituents since they are actually concentrated into narrow zones with the same step positions and heights that they would have as major components of the sample.

Figure 6 shows a typical isotachopherogram of an equimolar chromium(III)–citrate mixture. The direct recording of the detector signal (curve A) clearly shows the presence of six major steps. In addition, the derivative trace (curve B) reveals the presence of five or six more zones of minor constituents. It was hoped that the isotachophoretic zones could be correlated one by one with the chromatographic peaks obtained by the ion exchange separation. Unfortunately, our attempts at this were not successful, and only descriptive general conclusions could be reached (*vide infra*). However, it is clear that both separation methods reveal with

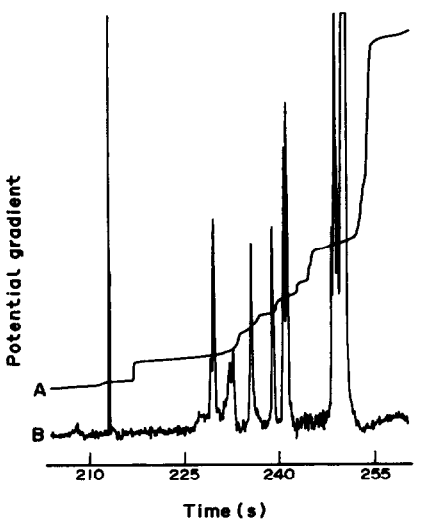

Fig. 6. Isotachopherogram of equimolar (0.024 M) chromium(III)–citrate at pH 5.0. Curve A is the direct signal from the potential gradient detector. Curve B is the electronically obtained and simultaneously recorded derivative of curve A. Curve B is displaced slightly to the left of curve A. For other conditions, see Table 2.

Table 2. Summary of isotachophoresis data on equimolar chromium(III)–citrate mixtures[a]

Concentration of mixture (M)	Sample size (mm^3)	pH[b]	Zones detected	First zone (% of total)	Six major zones (% of total)
0.012	4.0	5.0	14	45	87

comparable efficiency the complicated nature of the reaction of chromium(III) with citric acid.

Table 2 summarizes the results of other isotachophoretic separations of reaction products in which the reactants differed in concentrations and pH values. For reasons related to ionic charge and size, we believe the first isotachophoretic zone is due to a species responsible for one of the later eluting chromatographic peaks. It is seen that both increasing concentration and increasing pH favors its formation. This is the same behavior exhibited by the late eluting chromatographic peaks.

There are many structures for mononuclear and dinuclear complexes of chromium(III) and citric acid which can be drawn exhibiting 1:1 stoichiometry. Some suggestions which seem chemically reasonable and which can be constructed with space-filling molecular models are shown in Fig. 7. The mononuclear structure **I**, as shown, has a net charge of −1. However, simple dissociation of protons from the water molecules in the primary hydration shell could increase the charge. Such differently charged species would not be separable by either technique since they would be in rapid dynamic equilibrium. It is the loss of coordinated water and not the change in protonation which is the slow process.[12] Structure **II** incorporates the dioxo or dihydroxo bridge arrangement which is

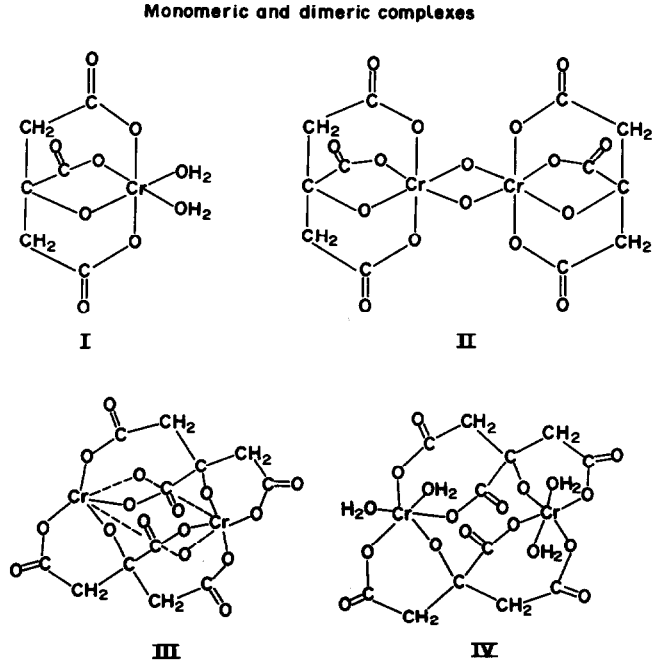

Fig. 7. Postulated structures for chromium(III)–citrate complexes.

well-established in chromium chemistry.[13,14] For the dioxo structure shown, the charge is -6; for the dihydroxo species it would be -4. Again, the protonation equilibria should be rapid and the species inseparable. However, numerous possibilities for isomerization exist which depend on how the citrates coordinate about the chromium nuclei. Structure **III** utilizes only citrate bridges between the chromiums; structure **IV** uses both citrate and oxo bridges. These structures are not written in the belief that these are necessarily the actual species separated in these experiments, but only to indicate how such a complicated mixture could originate. The possibilities for geometric isomers in these structures are many, and it has been shown that geometric isomers of chelated chromium(III) are readily separated by reversed-phase liquid chromatography.[15] Similarly, it would be expected that different spacial geometries would also influence ion exchange partition and effective mobilities.

In conclusion, it should be noted that the results of Tripathy and Patnaik[6] on the formation constants of chromium(III)–citrate complexes were done at a concentration level of about 8 mM in chromium and over a pH range from 3 to 8. Our results clearly show the formation of significant amounts of polynuclear complexes under such conditions. Furthermore, it is uncertain that equilibrium had been achieved since the constants were reported for 25°C and no mention of slow reaction kinetics was made. The constants reported should, therefore, be regarded with great skepticism.

Abstract—The extraction of Cu(II) from 5.0 M lithium chloride solutions using tri-*n*-dodecylammonium chloride (TLAHCl) dissolved in toluene was studied at 25°C. The data were treated both graphically, by the normalized-curves methods, and numerically using the LETAGROP–DISTR program. In both cases, the extraction of copper was best explained by the formation of the species $(TLAHCl)_2CuCl_2$ and $(TLAHCl)_5CuCl_2$ in the organic phase. The formation constants for the different species were obtained at different ionic strengths (1.0–5.0 mol dm^{-3}) and correlated using the specific-interaction theory.

The extraction of metals from chloride solutions by long-chain amines has been studied under a great variety of experimental conditions.[1] The extraction of copper by cationic[2–6] and anionic extractants[7–17] from acidic chloride solutions has been studied by several workers, focusing the attention on the speciation in the organic phase and the influence of the chloride ion concentration on the extraction.

The extraction of metals is generally dependent on the composition of the aqueous phase. However, the extraction data for a given system can be used for other aqueous-phase compositions (e.g. different feed solutions) if a correlation of the data to the variation in the aqueous-phase composition could be made. Speciation studies generally consider only the variation of the reacting species, but the presence of non-reacting ions [expressed by the ionic strength (I)] affecting the metal extraction is normally neglected.

Recently, we started a program for a systematic study of the extraction of metals from chloride solutions.[17–19] The extraction of copper from solutions with different chloride concentrations ($[Cl^-] = 1.0$, 2.0 or 3.0 mol dm^{-3}) was reported.[17] The study was extended to include the extraction of copper from solutions with constant I (5.0 mol dm^{-3}) and different chloride concentrations. In the present paper, the work is extended to a chloride concentration of 5.0 mol dm^{-3}.

EXPERIMENTAL

Reagents and solutions

Tri-*n*-dodecylammonium chloride (TLAHCl) was prepared and purified as described in Ref. 20.

Toluene (Merck p.a.) was washed with 0.1 M NaOH, H_2O, 0.1 M HCl and, finally, double distilled water before use.

Copper chloride (Merck p.a.) was purified by recrystallization.

Lithium chloride (Merck p.a.) was recrystallized twice before use as described in Ref. 21.

The organic phase was prepared by dissolving TLAHCl in toluene. The total TLAHCl concentration was varied from 0.05 to 0.265 mol dm^{-3}. The composition of the aqueous phase was $[Cu(II)] = B$ mol dm^{-3}, $[H^+] = A$ mol dm^{-3}, $[Li^+] = 5-2B-A$ mol dm^{-3} and $[Cl^-] = 5.0$ mol dm^{-3}. The total Cu(II) concentration was varied

* Author to whom correspondence should be addressed.

from 0.05 to 0.021 mol dm^{-3}, whereas the hydrogen ion concentration was maintained constant at 10^{-2} mol dm^{-3}.

Distribution measurements

Experiments were carried out at 25°C by shaking equal volumes of both phases using stoppered glass tubes for 3 h. The Cu(II) concentration in the aqueous phase was determined by titrations with EDTA using Fast Sulphon Black as indicator.[22] The organic phase was dissolved in ethanol and the copper was titrated with EDTA using PAN as indicator.[23]

RESULTS AND DISCUSSION

The distribution coefficient of the metal (D) defined as:

$$D = [\text{Cu(II)}]_{org}/[\text{Cu(II)}]_{aq} \quad (1)$$

was determined as a function of the total concentration of TLAHCl at a given total initial Cu(II) concentration in the aqueous phase. The experimental data (log D vs log $[\text{TLAHCl}]_{tot}$) are plotted in Fig. 1. The extraction of Cu(II) can be formally described by the following reaction:

$$n[\text{TLAHCl}]_{org} + Cu^{2+} + 2Cl^- \rightarrow (\text{TLAHCl})_n CuCl_{2org}. \quad (2)$$

In the aqueous phase, the activity coefficients of the different species may be regarded as constant since I was maintained at a constant value. For the organic phase, ideal behaviour is assumed as the concentrations of the reacting species are low. The possible coextraction of water is formally neglected. Experiments using different Cu(II) concentrations indicate the absence of polynuclear complexes in the organic phase.

The equilibrium constant for reaction (2) can be written as:

$$K_n = [(\text{TLAHCl})_n CuCl_2]_{org} [\text{TLAHCl}]_{org}^{-n} [Cl^-]^{-2} [Cu^{2+}]^{-1}. \quad (3)$$

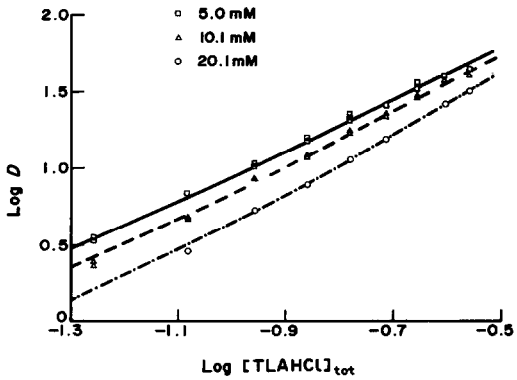

Fig. 1. Experimental points presented as log D vs log-$[\text{TLAHCl}]_{tot}$. Curves are drawn using the constants given in Table 1.

TLAHCl in toluene was found to form trimers:[24]

$$3(\text{TLAHCl})_{org} \rightarrow (\text{TLAHCl})_{3org} \quad (4)$$

and an aggregation constant (log Q) of 2.7 ± 0.1.

The formation constants of the aqueous copper chloride complexes (β_i) are defined as:

$$\beta_i = [CuCl_i^{2-i}][Cu^{2+}]^{-1}[Cl^-]^{-i} \quad (5)$$

and their values at the different Is were calculated from Ref. 25 using the specific-interaction theory. The interaction coefficients used are summarized in Table 1, and the log β_i calculated are given in Table 2.

As $V_{org} = V_{aq}$, the mass balance conditions are:

$$[\text{TLAHCl}]_{tot} = c + 3Qc^3 + \sum nK_n b l^2 c^n, \quad (6)$$

and

$$[\text{Cu(II)}]_{tot} = [\text{Cu(II)}]_{org} + [\text{Cu(II)}]_{aq}, \quad (7)$$

where:

$$[\text{Cu(II)}]_{org} = D(1+D)^{-1}[\text{Cu(II)}]_{tot} = \sum K_n b l^2 c^n, \quad (8)$$

$$[\text{Cu(II)}]_{aq} = (D+1)^{-1}[\text{Cu(II)}]_{tot} = [Cu^{2+}] + \sum [CuCl_i^{2-i}] = b(1 + \sum \beta_i l^i), \quad (9)$$

Table 1. Interaction coefficients (kg mol^{-1}) used in the calculation of log β_i

ε (Cu^{2+}, ClO_4^-) = 0.32[a]	ε ($CuCl^+$, ClO_4^-) = 0.29[b]	ε ($CuCl^+$, Cl^-) = 0.14[c]
ε (Cu^{2+}, Cl^-) = 0.08[a]	ε ($CuCl_3^-$, Na^+) = 0.14[b]	ε ($CuCl_3^-$, Li^+) = 0.29[b]
ε (Cl^-, Na^+) = 0.03[a]	ε ($CuCl_n^{2-}$, Na^+) = 0.22[c]	ε ($CuCl_n^{2-}$, Li^+) = 0.43[b]
ε (Cl^-, Li^+) = 0.10[a]		

[a] Values taken from Ref. 31.

[b] Values taken from Ref. 32, assuming the same values for Cu^{2+} and Zn^{2+}.

[c] Values also taken from Ref. 32, but assumed to be one-half of the related ones.

Table 2. Values of the equilibrium constants for the copper chloro complexes calculated using the specific-interaction theory

I	Log β_1	Log β_2	Log β_3	Log β_4	Log α
5 M ($NaClO_4$)	0.40	0.06	−0.05	−1.60	
5 M (LiCl)	0.17	−0.99	−1.51	−3.04	−1.19
3 M (LiCl)	0.13	−1.60	−1.68	−3.17	−0.77
2 M (LiCl)	0.13	−1.84	−1.71	−3.20	−0.59
1 M (LiCl)	0.19	−1.99	−1.67	−3.18	−0.41

and

$$[Cl^-]_{tot} = [Cl^-]_{aq} + [Cl^-]_m. \quad (10)$$

$[Cl^-]_{tot}$ is the total initial chloride concentration in the aqueous phase, $[Cl^-]_{aq}$ is the total chloride in the aqueous phase at equilibrium, and $[Cl^-]_m$ is the total chloride extracted together with the copper.

It follows that:

$$[Cl^-]_m = 2[(TLAHCl)_nCuCl_2]_{org} = 2[Cu(II)]_{org}, \quad (11)$$

and

$$[Cl^-]_{aq} = l + \sum i[CuCl_i^{2-i}]. \quad (12)$$

b, l and c are the free equilibrium concentrations of Cu^{2+}, Cl^- and TLAHCl, respectively.

Using eqns (1), (8) and (9) D can be written as:

$$D = \sum K_n l^2 c^n (1 + \sum \beta_i l^i)^{-1}. \quad (13)$$

The data were treated using both graphical and numerical methods, for the determination of the extracted copper species and their constants.

Graphical treatment

Assuming that only one species containing copper is formed in the organic phase, eqn (13) could be rewritten as:

$$\log D = \log K_n (1 + \sum \beta_i l^i)^{-1} + N \log c + 2 \log l, \quad (14)$$

and

$$\log D = \log K_n' + N \log c \quad (15)$$

where K_n' is a conditional constant defined by:

$$K_n' = K_n l^2 (1 + \sum \beta_i l^i)^{-1}. \quad (16)$$

Different n values will thus represent different species.

Models with $n = 2$, 3, 4 and 5 were considered. As the total copper concentration is much smaller than total chloride concentration, it is possible to assume, as a first approximation, that the free $[Cl^-]$ (l) is equal to the total chloride. For each case the free [TLAHCl] (c) was calculated using eqns (6) and (8). For the model to be accepted, a plot of $\log D$ vs $\log c$ should yield a straight line with a slope equal to the assumed n. None of the models fulfill this condition. This indicates that more than one species containing copper may be present in the organic phase.

In further treating the data, the variation in free $[Cl^-]$ as a result of copper extraction was considered.

A conditional distribution coefficient (D') may be defined as:

$$D' = D(1 + \sum \beta_i l^i) l^{-2}, \quad (17)$$

and eqn (13) is rewritten as:

$$D' = \sum K_n c^n. \quad (18)$$

Using $[Cu(II)]_{aq}$, $[Cl^-]_{aq}$ can be calculated from eqns (10) and (11). l can be calculated for each point by solving the copper and chloride mass balance equations using the values of the chloro complex formation constants.

In order to determine the free TLAHCl, the term $\sum n K_n b l^2 c^n$ in eqn (6) was estimated using the approximation:

$$\sum n K_n b l^2 c^n \approx \nu \sum K_n b l^2 c^n \approx \nu [Cu(II)]_{org}, \quad (19)$$

where ν is the average number of TLAHCl molecules bound to the metal in the organic phase. In this case, from the slopes obtained in the treatment considering only one species, a value for ν of 3.5 seems acceptable.

The TLAHCl mass balance equation can then be written as:

$$[TLAHCl]_{tot} = c' + 3Qc'^3 + 3.5[Cu(II)]_{org}, \quad (20)$$

where c' is the free ammonium salt concentration.

Assuming two copper-containing species do exist

in the organic phase, eqn (18) can be written as:

$$D' = K_p c'^p + K_s c'^s \quad (p < s), \tag{21}$$

or

$$D'/K_p c'^p = 1 + (K_s c'^{s-p})/K_p. \tag{22}$$

A normalized variable is defined by:

$$V^r = (K_s/K_p)c'^r, \tag{23}$$

where $r = s - p$. The normalized function (Y) is thus obtained:

$$Y = 1 + V^r. \tag{24}$$

By plotting log Y vs log V a set of curves is thus obtained for different r values. Superimposing the plot of log Y vs log V on the experimental curve $\log(D'/c'^p)$ vs $\log c'$, and, with vertical and horizontal translations of the curves, it may be possible to obtain the position of the best fit. By reading off the differences:

$$\log(D'/c'^p) - \log Y = \log K_p \tag{25}$$

and

$$(\log V - \log c') = (\log K_s - \log K_p)/r \tag{26}$$

the values of the formation constants are obtained.

Two different models were considered. First, assuming $p = 3$, c' was calculated using $v = 3.5$. In the second model ($p = 2$) a better fit was obtained. The same graphical treatment was applied to an earlier study.[17] It was found that the data were better explained by the present model. The plots showing the best fits for the different ionic strengths are presented in Fig. 2. A summary of the values of the constants graphically obtained are given in Table 3.

Computer calculations

The experimental data at 5.0 mol dm^{-3} ionic strength were treated by using the LETAGROP–DISTR program.[26] In this treatment the error-square sum defined by eqn (27) is minimized:

$$U = \sum_{N_p} (\log D_{calc} - \log D_{exp})^2. \tag{27}$$

The standard deviation [σ (log D)] is defined as:

$$\sigma(\log D) = (U/N_p)^{1/2}, \tag{28}$$

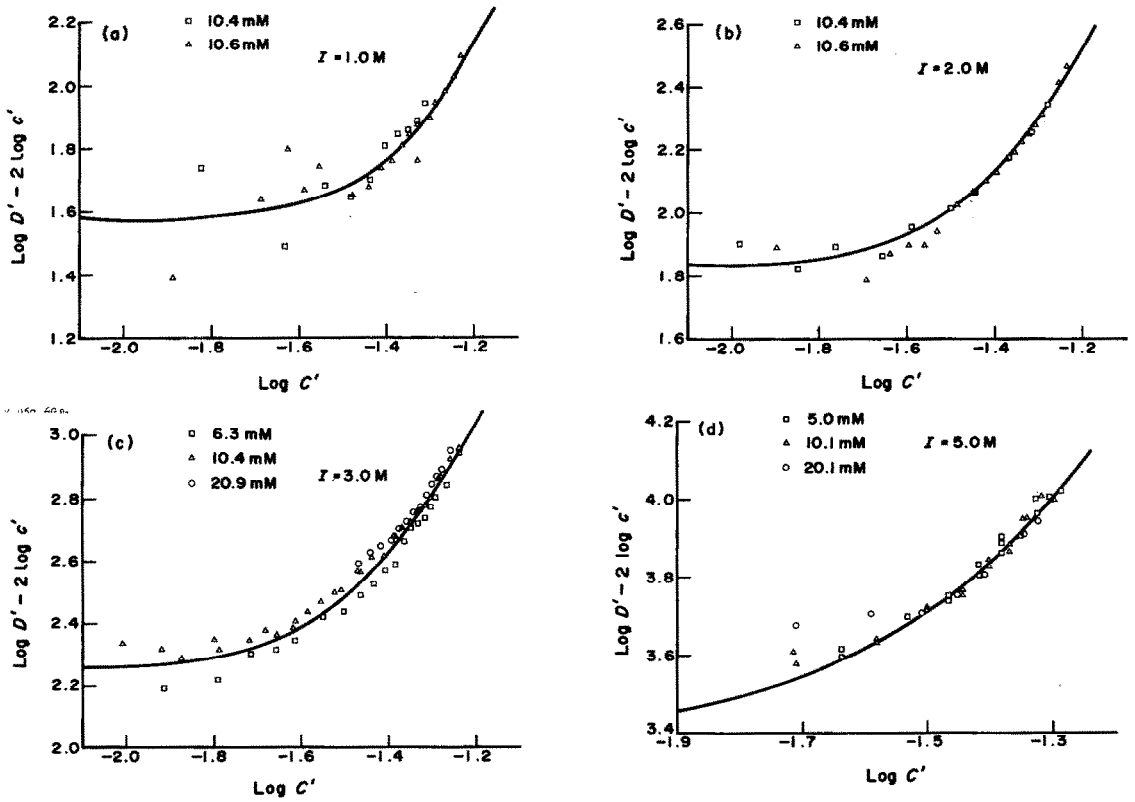

Fig. 2. Plot of $\log D' - 2\log[\text{TLAHCl}]_{free}$ vs $\log[\text{TLAHCl}]_{free}$ calculated from eqn (20) for different ionic strengths (I): (a) $I = 1.0$ M, (b) $I = 2.0$ M, (c) $I = 3.0$ M, and (d) $I = 5.0$ M. The continuous lines are the normalized functions log Y vs log V with $r = 3$. $c' = [\text{TLAHCl}]_{free}$.

5	2 1 2	3.46	3.43±0.02			2.24±0.02
	5 1 2	7.81	7.83±0.03	0.0160	0.0200	6.64±0.03

[a] Values of the constants are given with $\pm 3\sigma$ (log K).

where N_p is the total number of experimental points used in the calculations.

The model suggested in the earlier study as well as that proposed from the graphical treatment were considered. Other species were also assumed and their effect on the goodness of the fit was examined. The best fit of the data was obtained with the model $(TLAHCl)_2CuCl_{2\,org} + (TLAHCl)_5CuCl_{2\,org}$.

The data of Ref. 17 were also subjected to the computer treatment and the model suggested at 5.0 mol dm^{-3} was also found to give a better fit for the lower chloride concentrations.

The results obtained are summarized in Table 3.

Dependence of K_n *on the ionic strength*

The results of the Cu(II) extraction studies at different Is indicate that the composition of the extracted species is independent of I, whereas the formation constants of the different species vary with I.

In order to correlate the values of the equilibrium constants to I, the specific-interaction theory, developed by Guggenheim[27] and Scatchard,[28] was used. In this approach the activity coefficient (γ_i) of an ion of charge Z_i in a solution of I may be expressed as:

$$\log \gamma_i = -Z_i^2 D(I) + \sum \varepsilon(i,k) m_k. \quad (29)$$

The summation is made over all ions (k) present in the solution at molality m_k. $D(I)$ is the Debye–Hückel term $A\sqrt{I}/(1+1.5\sqrt{I})$, with $A = 0.5107$ at 25°C, while the ε terms, called interaction coefficients, are equal to zero if ions i and k are of the same charge sign.

Assuming ideality in the organic phase, the dependence of β^I on I is given by:

$$\log \beta^I = \log \beta^0 - (\Delta z^2 A\sqrt{I})/(1+1.5\sqrt{I}) + \sum \varepsilon(i,k) I_k, \quad (30)$$

with

$$\Delta z^2 = \sum n_j z_j^2 - \sum p_l z_l^2, \quad (30a)$$

where n_j denotes the stoichiometric coefficients of the reacting ionic species of charge Z_j [Cu^{2+} and Cl^- in eqn (2)], p_l is the coefficient of the ionic species of charge Z_l formed in reaction (2), and β^0 represents the formation constant at zero I in the molal scale.

It is possible to define a conditional constant (K'_n) for reaction (2) that describes the equilibria without taking into account the copper chloro complexes in the aqueous phase:

$$K'_n = K_n \alpha, \quad (31)$$

where α is the fraction of the free copper concentration:

$$[Cu^{2+}] = [Cu(II)]_{tot}\alpha, \quad (32)$$

and

$$\alpha = (1 + \sum \beta_i l^i)^{-1}. \quad (33)$$

The log α values at different Is (on the molar scale) are given in Table 2, and the calculated log k_n are summarized in Table 3.

In this case, for the equilibrium given by eqn (2) the species in the organic phase are non-ionic. It follows that $\Delta z^2 = 6$, and eqn (30) can be written as:

$$\log K_n^{\prime I} + 6A\sqrt{I}/(1+1.5\sqrt{I}) = \log K_n^{\prime 0} + \sum \varepsilon I, \quad (34)$$

where:

$$K_n'^0 = [(TLAHCl)_nCuCl_2]_{org}[Cu^{2+}]^{-1}[Cl^-]^{-2}[TLAHCl]^n_{org}, \quad (35)$$

and

$$\sum \varepsilon = \varepsilon(Cu^{2+}, Cl^-) + 2\varepsilon(Cl^-, Li^+). \quad (36)$$

Plotting $\log K_n'^I + 6D(I)$ vs I a straight line should be obtained with an intercept equal to $\log K_n'^0$ and a value for the slope given by eqn (36).

To correlate the constants it is necessary first to transform them to the molality scale. The concentration C (in mol dm^{-3}) of a solute with molecular weight M_w is expressed in units of molality, knowing the density of the solution (ρ), by using the expression:

$$m = C/(\rho - 10^{-3}CM_w). \quad (37)$$

For the species present in the organic phase, their concentration is very small and the term $10^{-3}CM_w$ is assumed to be negligible, and thus the density of the pure solvent can be used.[29] In the aqueous phase, the density of the solution is considered equal to the density of the ionic medium. The values have been taken from Ref. 30.

The experimental points have been plotted in Fig. 3 and fitted to a straight line with a weight $W = \sigma^{-2}$, where σ is the standard deviation of the extraction constants of reaction (2) given in Table 3. The obtained values of the constants (on the molar scale) are $\log K_2'^0 = 1.97 \pm 0.06$ and $\log K_5'^0 = 6.33 \pm 0.10$.

Slope values [0.31 ± 0.01 for $(TLAHCl)_2CuCl_2$, and 0.32 ± 0.02 for $(TLAHCl)_5CuCl_2$] agree with the ε values tabulated in Ref. 31 and given in Table 1.

The distribution diagram of the different species containing copper is plotted in Fig. 4.

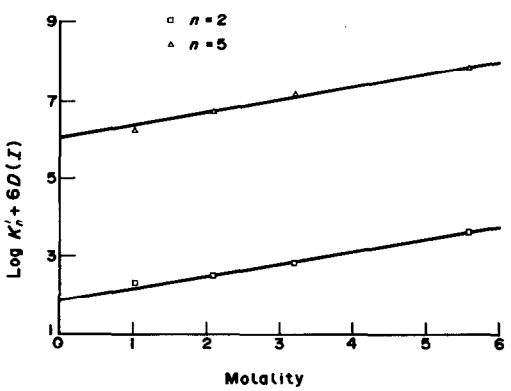

Fig. 3. Plot of $\log K_n' + 6A\sqrt{I}/(1+1.5\sqrt{I})$ [$D(I)$] vs ionic strength. The intercepts are $\log K_2'^0 = 1.89 \pm 0.06$, and $\log K_5^0 = 6.07 \pm 0.10$ (on the molal scale).

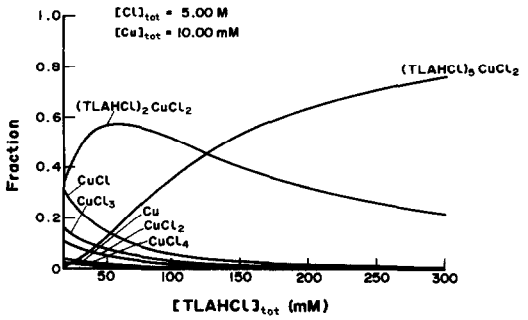

Fig. 4. Distribution of the species containing copper at different $[TLAHCl]_{tot}$.

SYNTHESIS AND CHARACTERISTIC STUDIES OF TIN(II) AND TIN(IV) COMPLEXES OF MACROCYCLIC SCHIFF BASES

ANIL VARSHNEY and J. P. TANDON*

Department of Chemistry, University of Rajasthan, Jaipur 302004, India

(*Received* 30 *January* 1986; *accepted* 18 *March* 1986)

Abstract—Equimolar reactions of tin (II) chloride, tin(IV) chloride or dimethyltin dichloride with macrocyclic Schiff bases lead to the formation of a new series of tin(II) and tin(IV) complexes. An attempt has been made to prove the structures of the resulting complexes on the basis of elemental analysis, conductance measurements, molecular-weight determination, and electronic, IR and multinuclear magnetic resonance (^{1}H, ^{13}C and ^{119}Sn) spectral studies.

Apart from some recent papers dealing with tin(II) and tin(IV) adducts with various crown ethers[1–5] no work has been reported on the tin(II) and tin(IV) macrocyclic Schiff base complexes. In view of this, it was considered of interest to synthesize and characterize tin(II) and tin(IV) derivatives of these ligands, and the results of these investigations are reported in this paper.

EXPERIMENTAL

All the reactions were carried out under an anhydrous and oxygen-free nitrogen atmosphere. Stannous chloride was dehydrated by dissolving it into acetic anhydride.[6] The ligands (2,3,8,9-tetraphenyl-1,4,7,10-tetraazacyclododeca-1,3,7,9-tetraene and 2,3,8,9 - tetraphenyl - 5,12 - dimethyl - 1,4,7,10 - tetraazacyclododeca-1,3,7,9-tetraene) were prepared by mixing ethylenediamine or 1,2-propylenediamine with an alcoholic solution of benzil in a 1 : 1 molar ratio followed by the addition of 6 cm^3 of concentrated hydrochloric acid. The resulting solution was refluxed for about 2 h on a waterbath and kept overnight. A light yellow crystalline solid precipitated out, which was recrystallized from ethanol. The ligands are also soluble in carbon tetrachloride, chloroform, methanol, DMF and DMSO (m.p. 159 and 96°C).

The complexes were analysed as reported earlier[7,8] and the IR spectra were recorded on a Perkin–Elmer 577 IR spectrophotometer in the region 4000–200 cm^{-1} using KBr optics. The electronic spectra (in methanol) were taken on a Toshniwal spectrophotometer. A Perkin–Elmer (Model R-12B) spectrometer was used for obtaining the PMR spectra employing $CDCl_3$ as the solvent and TMS as the internal standard.

Molar-conductance measurements were made in anhydrous dimethylformamide at 36 ± 1°C using a Systronics conductivity bridge Model 305. Molecular-weight determinations were carried out by the Rast Camphor method. ^{13}C and ^{119}Sn NMR spectra were recorded on a 90-MHz JEOL NMR spectrometer using $CHCl_3$ as the solvent, and TMS and TMT as the internal standards.

Synthesis of tin(II) *and tin*(IV) *complexes*

To a weighed amount of tin(II) chloride, tin(IV) chloride or dimethyltin dichloride was added the calculated amount of ethylenediamine or 1,2-propylenediamine and benzil in a 1 : 2 : 2 molar ratio, using tetrahydrofuran or benzene as the reaction medium in an oxygen-free nitrogen atmosphere. The color of the contents immediately changed from light yellow to dark yellow. The solution was stirred using a magnetic stirrer for *ca* 1 h. The excess solvent was removed from the filtrate and the compound was finally dried *in vacuo* at a bath temperature of 40 ± 5°C after being repeatedly washed with dry cyclohexane.

RESULTS AND DISCUSSION

Reactions of tin(II) chloride, tin(IV) chloride and dimethyltin dichloride with ethylenediamine or 1,2-propylenediamine and benzil in a 1 : 2 : 2 molar ratio afford adducts of types $SnCl_2 \cdot L$, $SnCl_4 \cdot L$ and $Me_2SnCl_2 \cdot L$ (L = a macrocyclic Schiff base). These

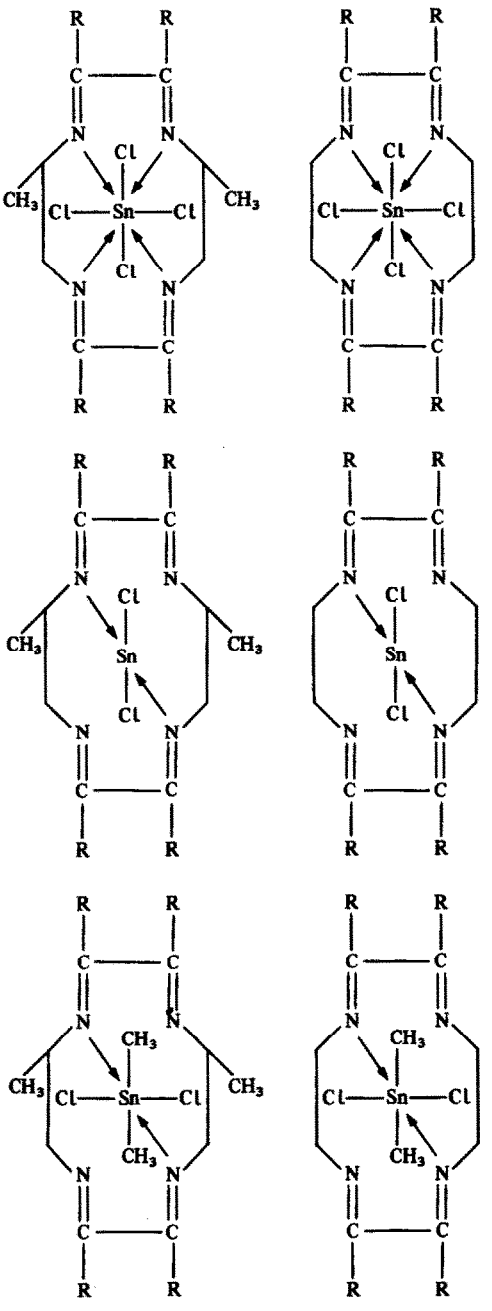
adducts are soluble in solvents like methanol, DMSO and chloroform, but insoluble in benzene.

The molar conductance of 10^{-3} M solutions of these adducts in DMF lies in the range 10–20 Ω^{-1} cm^2 mol^{-1}, indicating their non-electrolytic nature. The molecular weights of the adducts determined by the Rast Camphor method correspond with the formula weight, indicating their monomeric nature.

In the electronic spectra of the ligands, a band is observed at *ca* 218 nm, which may be assigned to the "1*B*" band of the phenyl ring. This undergoes a bathochromic shift due to complexation and is observed at *ca* 220 nm in the complexes. Similarly, the ligand chromophore C=N, which absorbs at *ca* 290 nm, shifts to a higher wavelength and is observed at 296 nm. The band in the spectrum of the ligand at *ca* 340 nm is likely to be the secondary band of the benzene and this shifts to 370 nm in the complexes possibly due to polarization of the C=N bond caused by the metal–ligand interaction.



The strong ligand band around 1620 cm^{-1} assignable to C=N is shifted to a higher wavenumber in the spectra of the adducts and this indicates coordination of the ligand through the nitrogen atom of the azomethine group.[9] The new bands around 430 and 600 cm^{-1} in the complexes could be assigned to $\nu(N \rightarrow Sn)$ and $\nu(C—Sn)$,[10] respectively. In the PMR spectra of the adducts in DMSO-d_6, the signals at δ 2.25 and 8.15 ppm have been assigned to methyl and methine protons, respectively. These signals appear downfield compared to the corresponding signals (δ 2.10 and 8.00 ppm) of the ligands, indicating coordination of the ligands to the tin via the azomethine nitrogen. The proton signals due to phenyl groups are observed in the range δ 6.5–7.6 and shift downfield, lending further support to the above mode of coordination.

In the ^{13}C NMR spectra of the ligands, the presence of four signals at δ 167.2, 168.2, 169.5 and 170.2 ppm may be due to all the four azomethine carbons. All these four signals shift downfield (δ 169.2, 170.3, 170.6 and 171.31 ppm, respectively) in the case of tin(IV) chloride adducts, indicating the coordination of all four nitrogens to the tin atom. However, in the case of tin(II) chloride adducts, out of the four signals originally observed, only two signals (δ 167.2 and 169.5 ppm) shift downfield (δ 168.3 and 170.3 ppm), indicating the coordination of only two of these nitrogens to the tin.

The compound $SnCl_4 \cdot C_{34}H_{32}N_4$ gives a sharp signal at δ −638 ppm in the ^{119}Sn NMR spectrum, which is far below the value reported for tin(IV) chloride (δ −150 ppm).[11] On this basis an antiprismatic eight-coordinate structure similar to the tin phthalocyanine system[12] may be proposed for this complex.

The compound $SnCl_2 \cdot C_{34}H_{32}N_4$ gives a sharp signal at δ −576 ppm in the ^{119}Sn NMR spectrum, which is below the reported value for tricoordinated hydrated tin(II) chloride.[13] Therefore, a four-coordinate square pyramidal geometry can be proposed for the resulting tin(II) complex.

Furthermore, the presence of a sharp signal at δ −250 ppm in the ^{119}Sn NMR spectrum of the tin(IV) complex $Me_2SnCl_2 \cdot C_{34}H_{32}N_4$ can be attributed to an octahedral six-coordinate geometry as also reported earlier.[14] On the basis of the above evidence, the following tentative structures can be assigned to these newly synthesized derivatives:

where R = C_6H_5

TRANS-BIS(DIFLUOROBORONDIMETHYLGLYOXIMATO) COBALT(III) COMPLEXES CONTAINING IMIDAZOLE AND CHLORIDE OR THIOCYANATE AS AXIAL LIGANDS

JAYANTA K. DAS and KAILASH C. DASH*

Department of Chemistry, Utkal University, Vani Vihar, Bhubaneswar 751004, India

(*Received* 11 *November* 1985; *accepted* 18 *March* 1986)

Abstract—Halo- and pseudohalocobaloxime complexes $[Co(DH)_2(Im)(X)]$ (X = Cl or CNS), containing imidazole (Im) or its derivatives, interact with $BF_3 \cdot Et_2O$ to form a series of cobalt(III) complexes, $[Co(DBF_2)_2(Im)(X)]$, that contain a 14-membered macrocyclic ligand. These light coloured microcrystalline solid complexes, stable under ordinary conditions, were characterized on the basis of elemental analyses, conductivity measurements, electronic, IR, NMR and mass spectra, and thermogravimetric and cyclic voltammetric studies, and are shown to possess a six-coordinated *trans*-octahedral configuration. The mass spectra do not reveal any molecular-ion peak whereas the results of thermolyses reveal the decreased stability of these complexes compared to the corresponding cobaloximes and yield polymeric intermediates, and finally forming Co_3O_4 as the end product. Cyclic voltammetric studies show four reductive waves and an oxidative wave, confirming an oxidation number of III for the central cobalt atom.

The study of macrocyclic-ligand systems is of importance in view of their presence in many biologically significant naturally occurring metal complexes, such as the metallo proteins, vitamin B_{12} and chlorophyll etc. In these macrocyclic complexes both the metal ion and the size of the ring play an important role.[1] Investigation of macrocyclic complexes of cobalt(III) throws light on different aspects of stereochemistry,[2–4] molecular rearrangement and electrochemistry[5,6] etc. In view of the biological significance of imidazole (Im), a fundamental component of enzymes and proteins[7,8] and of cobaloximes, which simulate the reactions of vitamin B_{12} and are of importance in vitamin B_{12} "model chemistry",[9,10] we have been studying the syntheses and the stereochemical as well as biochemical behaviour of Im-containing cobaloxime complexes with the general formulae $[Co(DH)_2(L)(X)]$ (DH = the monoanion of dimethylglyoxime; X = Cl, CNS, CNSe, N_3, ClO_4, BF_4, NO_2, NO_3 etc.; L = Im, benzimidazole and their different substituted derivatives).[11–15] The report of Schrauzer[16] on the reactivity of $BF_3 \cdot Et_2O$ with bis(dimethylglyoximato)nickel(II) $[Ni(DH)_2]$ to form the yellow planar macrocyclic complex bis(difluoroborondimethylglyoximato) nickel(II) $[Ni(DBF_2)_2]$ prompted us to synthesize and elucidate the stereochemistry and stability of six-coordinated cobalt(III) complexes, $[Co(DBF_2)_2(L)(X)]$† (X = Cl or CNS, L = Im or its derivatives), containing a similar 14-membered macrocyclic ligand and resembling the corrin system. These complexes are derived by the reaction of $BF_3 \cdot Et_2O$ with the parent cobaloximes containing an Im base.

EXPERIMENTAL

Materials

Im and its substituted derivatives were used as supplied by M/s BASF, Ludwigshafen, F.R.G. $Co(NO_3)_2 \cdot 6H_2O$, $CoCl_2 \cdot 6H_2O$, KCNS and DH_2

* Author to whom correspondence should be addressed.

† Throughout this paper DH_2 represents neutral dimethylglyoxime and DH^- its monoanion, DBF_2^- represents the monoanion of the macrocylic boronic ester ligand difluoroborondimethylglyoxime (1,8-diboro-1,1,8,8-tetrafluoro-2,7,9,14-tetraoxa-3,6,10,13-tetraaza-4,5,11,12-tetramethyl cyclotetradeca-3,5,10,12-tetraene) and the archaic symbolism CNS indicates only the presence of thiocyanate without specifying its mode of bonding.

were BDH reagents. $BF_3 \cdot Et_2O$ was distilled before use.

Syntheses of cobaloxime complexes

Chloro- and thiocyanatocobaloxime complexes of type $[Co(DH)_2(X)(L)]$ containing Im ligands were synthesized by bubbling air into a mixture of the appropriate cobalt(II) salt, dimethylglyoxime (DH_2) and Im in a ratio of 1:2:2 in EtOH, for a period of 1–6 h, depending on the nature and position of the substituents in the Im ring.[11,15]

Syntheses of macrocyclic complexes, $[Co(DBF_2)_2(X)(L)]$

Difluoroboro-bridged macrocyclic complexes of cobalt(III) were obtained by the reaction of the corresponding cobaloxime complexes in dry ether with freshly distilled boron trifluoride etherate. After completion of the reaction, usually marked by colour change (8–16 h), the reaction vessel was allowed to stand overnight and the product, collected on a glass frit, was washed with ether and dried *in vacuo*. The desired product was purified by recrystallization of the product from hot acetonitrile or a water–alcohol mixture. A typical method of synthesis of one of the complexes is detailed below.

Synthesis of $[Co(DBF_2)_2(Cl)(Im)]$. 0.5 g of the chloro(imidazole)bis(dimethylglyoximato)cobalt(III) complex, $[Co(DH)_2(Cl)(Im)]$, was suspended in 15–20 cm^3 of dry ether to which 1.5–2.0 cm^3 of freshly distilled boron trifluoride etherate was added very slowly with constant stirring. The stirring was continued till a definite colour change from greenish-yellow to light pink was observed, indicating the formation of the difluoroborondimethylglyoxime complex (6 h). However, the process was continued for a further 2 h in order to ensure the completion of the reaction. The reaction mixture was allowed to settle overnight and the product, collected on a sintered glass by filtration, was repeatedly washed with dry ether. The microcrystalline solid product thus obtained was recrystallized from hot acetonitrile. The reaction seems to proceed in the following manner:

$$2CoCl_2 \cdot 6H_2O + 4DH_2 + 4Im + \tfrac{1}{2}O_2 \rightarrow 2[Co(DH)_2(Cl)(Im)] + 2Im \cdot HCl + 13H_2O \quad (1)$$

$$[Co(DH)_2(Cl)(Im)] + 2BF_3 \cdot Et_2O \rightarrow [Co(DBF_2)_2(Cl)(Im)] + 2HF + 2Et_2O. \quad (2)$$

Analyses

Cobalt was estimated volumetrically by the method of Laitenen and Burdett.[17] Chlorine and sulphur were determined gravimetrically as AgCl and $BaSO_4$, respectively, after alkaline oxidative fusion. Microanalytical data of C, H and N were obtained from Inorganic Chemistry Institute, Technical University, Munich, F.R.G.

Electrolytic conductance, and electronic and IR spectra

Electrolytic conductance of the complexes was determined at room temperature in $MeNO_2$ and MeOH solutions (*ca* 10^{-3} M) with an ELICO conductivity bridge type CM 82 and a dip type cell with a cell constant of 0.5. Electronic spectra in dilute MeOH solutions ($\sim 10^{-3}$–10^{-5} M) were recorded in a Varian 634 spectrophotometer, and IR spectra in the 4000–400-cm^{-1} region were recorded as KBr discs or a Nujol mull in a Perkin–Elmer 337 grating spectrometer.

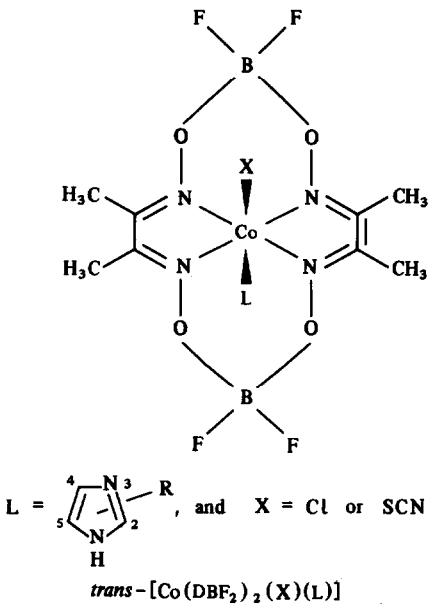
NMR spectra

NMR spectra of the complexes were recorded in CD_3NO_2 and DMSO-d_6 media in a Bruker spectrometer operating at 80.13 MHz.

Thermolysis

Thermal decomposition of the complexes was carried out using a Shimadzu DT 30 instrument which records T, TG and DTA simultaneously with a heating rate of 10°C min^{-1}.

Mass spectra



Mass spectra of the compounds were recorded in a Varian CH-7 MAT spectrometer operating at an electron energy of 70 eV. The instrument was maintained at 473 K and the emission current was 300 μA.

Cyclic voltammogram

Cyclic voltammograms of the complexes were run in MeCN using Pt as the working electrode and tetraethyl ammonium perchlorate (TEAP) as the supporting electrolyte, using a PAR model 370-4 electrochemistry system along with a PAR model 174A polarographic analyser, a PAR model 175 Universal programmer and a Houston Instruments RE 0074 XY recorder.

RESULTS AND DISCUSSION

Cobaloxime complexes containing imidazole and chloride or thiocyanate as axial ligands, $[Co(DH)_2(X)(L)]$ (L = Im or a substituted Im, X = Cl or CNS), interact with $BF_3 \cdot Et_2O$ in dry ether to form *trans*-[chloro(imidazole)bis(difluoroborondimethylglyoximato)cobalt(III)] complexes, $[Co(DBF_2)_2(Cl)(L)]$, and *trans*-[thiocyanato(imidazole) bis (difluoroborondimethylglyoximato)cobalt(III)] complexes, $[Co(DBF_2)_2(SCN)(L)]$, where the protons of the $[Co(DH)_2]^+$ moiety are replaced by BF_2 groups (see Scheme 1). These complexes contain the 14-membered tetradentate macrocyclic *N*-donor (N_4) ligand, 1,8-diboro-1,1,8,8-tetrafluoro-2,7,9,14-tetraoxa-3,6,10,13-tetraaza-4,5,11,12-tetramethyl cyclotetradeca-3,5,10,12-tetraene (DBF_2^-) occupying the four planar positions, with the imidazole base and chloride or thiocyanate ion bonded orthogonally. All the complexes reported in this work are presented in Table 1, along with analytical and other characterizing data. The molar-conductance values [Λ_M (Ω^{-1} cm^2 mol^{-1})] in MeOH and $MeNO_2$ at room temperature support the non-ionic nature of the complexes,[17] indicating coordination of Cl^- and SCN^- to the cobalt centre. However, slightly higher values obtained in some cases may be

Scheme 1.

due to the solvolytic effect of the solvent or due to partial ion-pair formation in solution.

The ligand field spectra of complexes in a MeOH medium are identical to each other and exhibit a peak of weak to moderate intensity at ~ 18,000 cm^{-1} due to the $^1A_{1g} \rightarrow {}^1T_{1g}$ transition, characteristic of a pseudo-octahedral cobalt(III) d^6 system.[18] The more intense band in the 40,500–42,500-cm^{-1} region is attributable to the intraligand $\pi \rightarrow \pi^*$ transition of the coordinated oxime group, whereas an ill-defined shoulder in the 31,000–34,000-cm^{-1} region arises due to the possible $d_\pi(Co) \rightarrow \pi^*(DH^-)$ MLCT transition.[19,20] However, the LMCT band, as seen in the case of the parent cobaloxime complexes,[11,15] is not observed in these macrocyclic complexes.

A systematic investigation of the IR spectra of free DH_2 and chloro- or thiocyanato(imidazole) cobaloximes, and the macrocyclic complexes derived from them, revealed the coordination of difluoroborondimethylglyoximate, an Im ligand and the ambidentate SCN^- group. In these macrocyclic complexes the prominent IR absorption frequencies are located in almost the same position, indicating that variation of the base does not greatly affect the IR spectra. However, variations to a certain extent are observed in the IR frequencies of cobaloximes and the corresponding macrocyclic complexes due to the presence of the BF_2 groups. The difluoroboro-bridged macrocyclic complexes $[Co(DBF_2)_2(X)(L)]$ and $Ni(DBF_2)_2$ do not exhibit any weak band in the 1700–1800-cm^{-1} region characteristic of δ(O—H···O) of the hydrogen bridge in these systems.[21] $BF_3 \cdot Et_2O$, being a more effective reagent for the synthesis of the fully closed $Ni(DBF_2)_2$ complex[22] than BF_4^- ($NaBF_4$),[16] has interacted with the O—H···O group of cobaloximes to form boron-bridged complexes containing the O—BF_2—O group, and this observation also provides further evidence for the presence of a hydrogen bridge in the parent cobaloxime complexes.

The ν(C⋯N) frequency of free DH_2 observed at 1620 cm^{-1} is shifted to a lower wavenumber (1560–1570 cm^{-1}) in the parent cobaloxime complexes, as reported earlier,[11–15] causing a higher conjugation of the dioxime chelate ring, accounting for its increased stability.[23] However, the ν(C⋯N) of the synthesized macrocyclic difluoroborondimethylglyoximato complexes, observed as a sharp and intense band at about 1600–1625 cm^{-1}, is consistent with earlier observations,[24–26] indicating that the CN stretching frequency is less affected in these complexes, and may be due to the attachment of the electronegative fluorine atoms to the electronically poor boron atom. While free DH_2 has no band at ~1240 cm^{-1}, a sharp intense band was observed in $Ni(DH)_2$ and all the cobaloxime complexes at 1240 cm^{-1}, in addition to the band at 1090 cm^{-1} due to the ν(N—O) of the ionized N—OH group of DH_2,[27] indicating the non-equivalent nature of the two N—O bonds.[28] All these difluoroboro-bridged macrocyclic complexes exhibit two bands at ~1240 cm^{-1} and in the 1100–1120-cm^{-1} region due to ν(N—O), the former remaining almost unaffected while the latter experiences a positive shift.

The vibrational spectra of these complexes in the 1200–700-cm^{-1} range demonstrates the presence of the BF_2 group in the 14-membered macrocyclic ring system. All these complexes exhibit an intense band at 1005–1030 cm^{-1}, assignable to the ν(B—F) frequency, and two other bands of reduced intensity at 1190–1200 and 830–850 cm^{-1}, attributable to ν(B—O) vibrations.[16,24] A band of moderate intensity observed at ~750 cm^{-1}, either as a singlet or as an ill-defined doublet, is assigned to the vibration of the —BF_2 group.[29] All these observations indi-

cate the presence of the $[Co(DBF_2)_2]^+$ group in a square plane, making room for the orthogonal coordination of the imidazole base and an anion to the cobalt(III) centre to complete the octahedron. The ν(Co—N) stretching frequencies observed at 515 and 430 cm^{-1} indicate the coordination of the oximate group and the Im base, respectively, to the cobalt(III) ion.[11–15]

The vibrational spectra also helps in deciphering the mode of attachment of the ambidentate CNS^- group.[30,31] The CNS^- group in thiocyanato(imidazole) cobaloxime complexes contains Co—S bonding[11] even though cobalt(III) (a typical hard acid) is expected to coordinate through the *N*-end of the CNS^- group.[31] These macrocyclic complexes containing the thiocyanate ion exhibit a sharp and strong band at about 2100–2120 cm^{-1} due to the ν(C≡N) of the CNS^- group, indicating Co—S bonding. The ν(C—S) is somewhat obscured by the ν(B—O) and the deformation vibration of BF_2. However, the δ(NCS) observed at 450 cm^{-1} further confirms the Co—S bonding. Even though the ν(Co—Cl) has not been located due to the limitations of instrument, the analytical and Λ_M values unambigously prove the coordination of the Cl^- to the Co(III) ion.

NMR spectra

Even though the ^1H NMR chemical shifts of the cobaloxime complexes have established a *trans* structure for the cobaloxime complexes, $[Co(DH)_2(X)(L)]$,[11,13,33–36] not much information is available on the ^1H NMR spectra of the macrocyclic complexes derived from them. The methyl protons of free DH_2 observed as a sharp singlet at 1.98 ppm has undergone a clear downfield shift of about 0.4 ppm in $[Co(DBF_2)_2]^+$ and is now observed at ~ 2.30 ppm as a sharp singlet, characteristic of the four equivalent methyl groups, indicating their *trans* structure. The methyl protons of DH_2 were located in similar position in $Co(DH)_2^+$ complexes containing imidazole and an anion.[33] Thus, the replacement of the oxime protons by $—BF_2$ groups does not affect the original *trans* structure of the parent cobaloximes. The ^1H NMR spectra of uncoordinated Im exhibit two separate signals in an intensity ratio of 1:2 at 7.82 ppm due to H-2 and 7.14 ppm due to H-4 and H-5 protons. On coordination, the equivalence of H-4 and H-5 is lost and two separate signals are observed. These macrocyclic complexes containing an Im ligand show ^1H NMR signals at 7.5, 7.2 and 6.5 ppm due to the H-2, H-4 and H-5 of Im, respectively, indicating its coordination to the metal ion.

The poor solubility of these complexes in suitable solvents precluded the measurement of good-quality ^{13}C NMR spectra.

Cyclic voltammetric studies

Even though polarographic reductions of cobaloxime complexes have been reported[9,10,37,38] the electrochemical oxidation has received much less attention,[39] and more so in the case of the difluoroborondimethylglyoximate cobalt(III) complexes, $[Co(DBF_2)_2]^+$. The electrochemical behaviour of a series of the cobalt(III) macrocyclic complexes containing imidazole and the SCN^- group as axial ligands have been investigated by cyclic vol-

[a] Conditions are as follows: scan rate, 0.05 V s^{-1}; solute concentration, $\sim 3.0 \times 10^{-3}$ M; supporting electrolyte, TEAP: the reported E_{pc} values are uncorrected for junction potentials.

tammetric studies in acetonitrile solution using TEAP as the supporting electrolyte and the results are shown in Table 4, and Figs 1 and 2. Invariably all these complexes exhibit three or four reductive responses on the negative side of the saturated calomel electrode (SCE) under identical conditions in contrast to our earlier observation of five reductive waves for azido(imidazole) cobaloxime complexes.[40] The first three reductions may be due to the reduction of cobalt(III) → cobalt(II), cobalt(II) → cobalt(I), and cobalt(I) → cobalt(0), whereas the fourth one corresponds to the reduction of the ligand.[10] The reductions of these complexes which take place at a lower potential may be due to the presence of the —BF_2 group in close proximity to the metal centre. However, all these observations clearly indicate the existence of cobalt

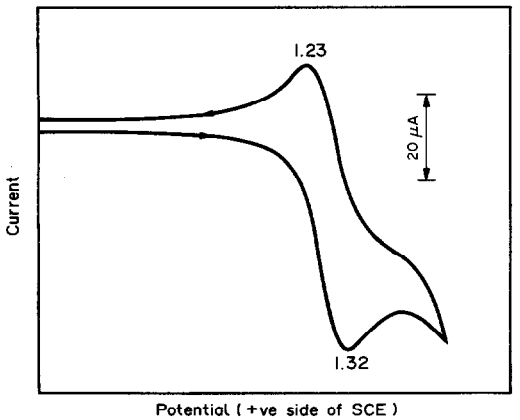

Fig. 1. Cyclic voltammogram of *trans*-$[Co(DBF_2)_2(SCN)(Im)]$ in acetonitrile solution (positive side of SCE).

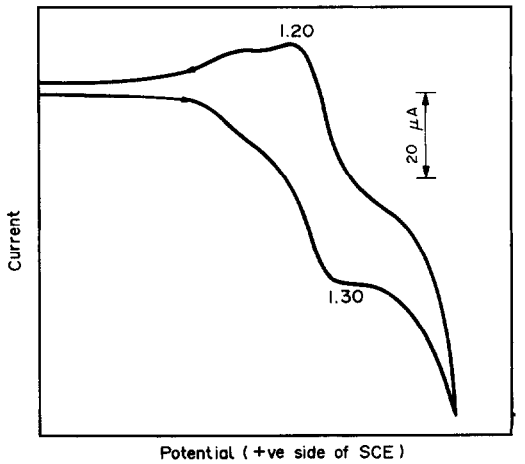

Fig. 2. Cyclic voltammogram of *trans*-$[Co(DBF_2)_2(SCN)(1\text{-MeIm})]$ in acetonitrile solution (positive side of SCE).

in the III state unlike the presence of cobalt(II) in the alkylcobaloxime complexes.[10] Just like azido-(imidazole) cobaloximes,[40] all these complexes record a reversible oxidative peak at about +1.0 V (Pt electrode) which may be due[41] to the one-electron oxidation of cobalt(III) → cobalt(IV).

Mass spectra and thermal analyses

A comparative investigation of the mass spectral studies of free DH_2, $Ni(DH)_2$ and $[Co(DBF_2)_2(Cl)(Im)]$ was made to gain information about the stability and the metal–ligand interactions in these complexes. It reveals that molecular-ion peaks are observed for both DH_2 and $Ni(DH)_2$, but not for the macrocyclic complex, just like the precursor cobaloxime complexes,[42] indicating the comparable stability of the parent cobaloximes and the derived macrocyclic complexes. However, the thermal-decomposition studies establish the lower thermal stability of these complexes relative to the parent cobaloximes. All these macrocyclic complexes on heating decompose, giving polymeric intermediates, and finally forming Co_3O_4 as the ultimate end product.

ELECTROCHEMICAL REACTIONS OF SOME POLYHYDRIC ALCOHOLS AT A COPPER ANODE

J. S. BANAIT* and P. K. PAHIL

Chemistry Department, Punjabi University, Patiala 147002, India

(*Received* 6 *November* 1985; *accepted* 18 *March* 1986)

Abstract—The reactions of some polyhydric alcohols have been carried out at a copper anode and the reaction products have been identified by chemical analysis and IR spectral studies. All the reactions have been found to yield copper(II) glycolates with almost 100% current efficiency.

Though electrochemical methods have been used extensively in synthetic organic chemistry,[1–5] little efforts have been made in applying this technique for the synthesis of inorganic and organometallic compounds in spite of the fact that electrochemical properties of such compounds have been widely studied.[6–8] In this report the reactions of ethylene glycol, glycerol, 1,2-propandiol, phloroglucinol and 2-mercaptoethanol at a copper anode are described.

EXPERIMENTAL

Material and equipment

N,N-dimethylformamide (DMF) was distilled and dried over molecular sieves, and was used as solvent in these electrochemical studies. Ethylene glycol, glycerol, 1,2-propandiol, phloroglucinol and 2-mercaptoethanol were used as supplied. Tetrabutylammonium chloride (Bu_4NCl) (Reidel Pure) was dried under reduced pressure and elevated temperature, and was used as a supporting electrolyte.

An H-type electrolysis cell made of Pyrex glass was used to carry out the electrochemical reactions. The cathode and anode compartments were separated from each other by a sintered disc of G-3 porosity. Volume of one of the compartments was almost 3 times that of the other one.

Platinum foil (1 × 1 cm) was used as a cathode. A thick layer of copper had been deposited electrochemically[9] on a sheet of copper (5 × 5 × 0.2 cm) in order to ensure the purity of the anode material.

Direct current was obtained with the help of a Toshniwal electrophoresis power supply.

The solution of the polyhydric alcohol (5 g) in 250 cm^3 of DMF was taken in the electrolysis cell. A copper plate freshly electroplated with copper was dipped in the larger compartment and platinum foil in the other one. Necessary connections were made with the power supply and potential across the electrodes was than adjusted so that a current of about 20 mA passed through the cell. The electrolytic cell can be represented as:

$$Pt^{(-)}|DMF+R(YH)_n+Bu_4NCl|Cu^{(+)} \quad (1)$$

where $Pt^{(-)}$ is the platinum cathode, $Cu^{(+)}$ is the copper anode, and $R(YH)_n$ is the polyhydric alcohol/thiol, i.e. Y represents oxygen or sulphur atom in $R(YH)_n$. Electrolysis was carried out for 6 h. A green coloured solid separated out in the anode compartment which was filtered, washed repeatedly with dry ether, and dried *in vacuo*.

IR spectra of the products were scanned on a Beckman IR-20 spectrophotometer in Nujol using sodium chloride plates in the region 4000–600 cm^{-1} and polythene plates in the region 600–200 cm^{-1}.

Copper contents in the products were estimated volumetrically.[9]

RESULTS AND DISCUSSION

Solutions of ethylene glycol, glycerol, 1,2-propandiol, phloroglucinol and 2-mercaptoethanol have been electrolyzed at a sufficiently high potential so that a current of about 20 mA passes through the solution. The electrolytic characteristics have been summarized in Table 1.

* Author to whom correspondence should be addressed.

Table 1. Electrolytic characteristics, and analytical and other relevant data of the electrolysis processes

Polyhydric alcohol	Potential (V)	Product	Colour	Current efficiency [eq (Faraday)$^{-1}$]	Percentage of copper	
					Found	Required
Ethylene glycol	15	$C_2H_4O_2Cu$	Bluish green	0.95	51.0	51.4
Glycerol	15	$C_3H_6O_3Cu$	Bluish green	1.00	41.2	41.4
1,2-Propandiol	10	$C_6H_6O_2Cu$	Parrot green	0.98	46.6	46.2
Phloroglucinol	10	$C_6H_4O_3Cu$	Dark green	0.95	33.3	33.9
2-Mercaptoethanol	10	$C_2H_4(O)SCu$	Brownish green	0.98	44.7	45.5

The products of the electrochemical reactions are insoluble in most of the commonly used organic solvents, and are also hygroscopic. The copper contents in these compounds (determined volumetrically) correspond to the respective copper(II) glycolates of these polyhydric alcohols. All the relevant data are recorded in Table 1.

IR spectral data of the products recorded in the 4000–200 cm^{-1} region reveal that all the compounds of polyhydric alcohols show characteristic absorption bands in the 1020–1060 and 520–560 cm^{-1} regions, which correspond to ν(C—O) and ν(Cu—O) stretching frequencies, respectively.[10,11] The IR spectrum of the copper(II) compound of 2-mercaptoethanol shows absorption bands at 1040, 550, 650 and 315 cm^{-1}, which are due to ν(C—O), ν(Cu—O), ν(C—S) and ν(Cu—S) stretching modes, respectively.[10–13] The IR data, therefore, confirm that the products of the present electrochemical reactions are copper(II) glycolates/thiolates, and thus support the analytical data.

Current efficiencies of these reactions have also been determined and are recorded in Table 1. Perusal of Table 1 reveals that the current efficiencies of all these systems vary from 0.95 to 1.00 eq (Faraday)$^{-1}$ showing thereby that the reactions leading to the formation of copper(II) glycolates are the predominant reactions of these systems. The reaction scheme can be written as:

At the cathode:

$$R(YH)_n + 2e^- \rightarrow (YH)_{n-2}RY^{2-} + H_2(g). \quad (2)$$

At the anode:

$$(YH)_{n-2}RY^{2-} + Cu^{(+)} \rightarrow [(YH)_{n-2}RY_2]Cu + 2e^-, \quad (3)$$

where $(YH)_{n-2}RY^{2-}$ is the dianion of the polyhydric alcohol/thiol.

In recent years, the use of pure metals as reagents has increased through the development of the vapour-phase synthetic technique, which of course needs very sophisticated apparatus and the reaction is carried out at a very high temperature. In contrast, these electrochemical reactions have been carried out at room temperature with all the advantages of using routine laboratory apparatus and metals as reagents.

Such high values of current efficiencies, the use of simple laboratory apparatus and reagents, and, moreover, a direct method[13] compared to the usual synthetic method suggest that these electrochemical methods can be commercially used for the preparation of copper(II) glycolates/thiolates.

SPECTRAL STUDIES ON THE MAGNETICALLY ANOMALOUS Ni(II) COMPLEXES OF SUBSTITUTED PHENYLAZO-2,4-DINITROSORESORCINOL COMPOUNDS

MAMDOUH S. MASOUD,* ALI EL-DISSOUKY and ENAS E. GHATWARY

Chemistry Department, Faculty of Science, Alexandria, Egypt

(*Received* 12 *September* 1985; *accepted after revision* 28 *May* 1986)

Abstract—Hydrated Ni(II) chloride reacts with new substituted phenylazo-2,4-dinitrosoresorcinol ligands to give complexes with stoichiometry $[NiCl_nL(H_2O)]$ ($n=0$ or 1, and L is the anion of the ligand). These complexes have room-temperature μ_{eff} in the 1.77–2.66-BM/Ni range. The planar $\rightleftharpoons$ tetrahedral equilibrium for these complexes is proved by electronic spectral studies either in a Nujol mull or in a 1,2-dichloroethane solvent. The ligation properties of these complexes by the Lewis bases pyridine or 2-picoline point to the formation of a distorted octahedral configuration. The calculated ligand field parameters are related to the electronic characters of the ligands and the Lewis bases. The IR spectra show that all the titled ligands (except the *o*-carboxy compound) are monobasic bidentate, coordinated to the nickel ion *via* the enolized phenolic oxygen and the azo-nitrogen atoms. The *o*-carboxy compound acts as dibasic tridentate in the coordination.

In view of the role played by nitroso complexes in body systems, delineation of the nature of the metal binding and stereochemistry in nitroso complexes seems to be interesting.[1] The azo compounds have also gained much attention because of their use as models of biological systems.[2] In our laboratory, the coordinating behaviour and chemical equilibria of some nitroso[3–8] and azo[9–14] compounds have been investigated in depth. However, no structural chemistry and coordinating studies have been reported for ligands containing both azo and nitroso functional groups. The major interests of this paper are: (i) the synthesis of new substituted phenylazo-2,4-dinitrosoresorcinol (**I**) ligands, (ii) the synthesis of Ni(II) complexes derived from these ligands, (iii) assigning the stereochemistry of the complexes based on the electronic-spectra and magnetic-susceptibility measurements, and (iv) knowing the mode of bonding in these complexes from the IR spectral data.

*Author to whom correspondence should be addressed.

EXPERIMENTAL

Preparation of the organic ligands

2,4-Dinitrosoresorcinol was prepared according to the method outlined by Orndorff and Nichols.[15] I were obtained by direct diazotization of the aniline derivatives (*o*-toluidine, *o*-chloroaniline, *o*-aminobenzoic acid, *m*-toluidine, *m*-chloroaniline and *m*-nitroaniline), followed by coupling with 2,4-dinitrosoresorcinol. The compounds were characterized by their elemental analyses given in Table 1.

Preparation of the Ni(II) *complexes*

These were prepared according to the general method, viz.: to a suspension of 0.025 mol of the ligand in 50 cm^3 absolute ethanol, 0.01 mol of hydrated $NiCl_2$ in 20 cm^3 absolute ethanol was added. The reaction mixture was refluxed with stirring for 6–8 h. On cooling the polycrystalline solid precipitated in each case was filtered off, washed several times with ethanol followed by ether, and dried *in vacuo* over P_4O_{10}.

The nickel content was determined by the

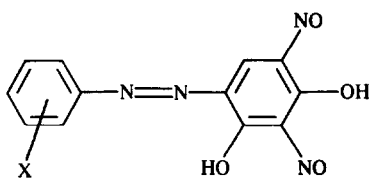
complexometric-titration procedure.[16] Carbon, nitrogen, hydrogen and chloride contents were estimated at the Microanalytical Laboratory at Cairo University, Cairo, Egypt. The data are collected in Table 1.

Physical measurements

The diffuse-reflectance and solution spectra were recorded using a CARY 14 spectrophotometer. Magnetic measurements were carried out using the Gouy method.[17] The KBr IR spectra were made with Unicam SP 1025 and SP 3-100 spectrophotometers equipped with NaCl prisms.

RESULTS AND DISCUSSION

The interaction of **I** with hydrated $NiCl_2$ in ethanol gave complexes of stoichiometry $[NiCl_nL(H_2O)]$ ($n = 0$ or 1, and L is the anion of the ligand). The complexes are brown or brownish red in colour. They are stable in air and are partially soluble in water and in most organic solvents but freely soluble in Lewis bases such as pyridine and 2-picoline.



The room-temperature μ_{eff} of all the complexes exhibit anomalous values in the range 1.77–2.66 BM (Table 2). These values are lower than those for octahedral, tetrahedral or high-spin five-coordinate Ni(II) complexes. They may be consistent with those of low-spin five-coordinate Ni(II) complexes. Bis-halo-bisphosphino and bis(salicylaldiminato)nickel(II) complexes with anomalous magnetic moments exist in a planar–tetrahedral mixture in the solid state and/or in solution.[18] It was proved that several four-coordinated Ni(II) complexes give a diamagnetic–paramagnetic mixture in the same crystalline solid.[19] This was referred to the change in the effective ligand field acting on Ni(II) by melting, grinding or dissolving the complexes.[20] Accordingly, the Ni(II) complexes under investigation can be assumed to exist in a mixture in the solid state.

The solid-reflectance and 1,2-dichloroethane solution spectra of the prepared Ni(II) complexes were recorded in the 5000–30,000-cm^{-1} range. The

I

II

X = *o*-COOH, *o*-Cl, *o*-CH_3, *m*-Cl, *m*-CH_3 or *m*-NO_2

data are summarized in Table 2. The solid spectra are identical to those obtained for the solutions and exhibit bands in the 5000–5300- $[\nu_1(^3T_1 \rightarrow {}^3T_2)]$, 6750–6900- $[\nu_2(^3T_1 \rightarrow {}^3A_2)]$ and 18,000–19,000-cm^{-1} regions. These spectral data are very similar to those of square planar–tetrahedral configurations[21–23] in either the solid state or solution. The second band is for an idealized tetrahedral symmetry. The third band can be attributed to a composite of the tetrahedral $\nu^3[^3T_1 \rightarrow {}^3T_1(P)]$ transition and the lowest-energy spin-allowed transition of the planar isomer, presumably the $^1A_{1g} \rightarrow {}^1B_{1g}$ transition. The existence of the planar transitional band together with those of tetrahedral geometry were made evident by comparison with the spectra of similar complexes.[20–24] The following equation[21] is applied:

$$N_t = 100\mu_{obs}^2/3.3,$$

where N_t is % tetrahedral, μ_{obs} is the measured effective magnetic moment and 3.3 is the value of the magnetic moment for standard tetrahedral Ni(II) complexes. The N_t values are given in Table 2, where the effect of the substituents on the stereochemistry of the complexes is shown. For the *o*-substituents, the N_t value increases in the sequence: -Cl > $-CH_3$ > -COOH. This could be explained by the steric, electronic requirement and/or their chelating properties. The lower N_t value of the tridentate *o*-carboxy-containing complex can be related to its strong steric requirement enhancing the existence of the planar form. The order of increasing N_t value for the *m*-substituents follows the order: $-NO_2$ > -Cl > $-CH_3$. The N_t values are used to calculate the molar extinction coefficient of the tetrahedral geometry in the 6720–6900-cm^{-1} region where the planar molecules do not absorb. This is done by using the following equation:[21]

$$N_t = 100\varepsilon_{max}^{max}/42,$$

where the integer 42 is the molar extinction coefficient of the peak around 6700–6950 cm^{-1} for the pure pseudo-tetrahedral Ni(II) complexes. The ε values are in the order *m*-NO_2 > *m*-Cl > *m*-CH_3 > *o*-Cl > *o*-CH_3 > *o*-COOH. This is the same sequence as for N_t. The data are summarized in Table 2. Accordingly, the significant property of the ligand fields is the existence of a well-defined trend in the energies of ν_2 and the planar component of ν_3. This is related to the electronic requirements of their positions and the relative percent of the isomers are varied. The data are collected in Table 2 with a direct relation between ν_2 and N_t from one side and an inverse relation between ν_3 and N_t from the other side. The ν_3 combination bands provide a measure of the frequency trend of the planar *d–d* transition for the following reasons: (i) the intensity increases as N_t decreases, and (ii) the trend in ν_3 energies is opposite to that in ν_2.

The electronic spectra of the Ni(II) complexes in solutions in the Lewis bases pyridine or 2-picoline are given in Table 2. The spectra of all complexes are quite different from those recorded in either 1,2-dichloroethane or by solid reflectance. This indicates a strong interaction with the Lewis base

molecules. All spectra consist of four major bands with maxima at 9185–10,500, 11,000–13,000, 15,000–15,400 and 23,000–24,400 cm^{-1}. These are consistent for tetragonally distorted octahedral Ni(II) complexes.[25,26] The bands at 9185–10,500, 15,000–15,400 and 23,000–24,400 cm^{-1} are assigned to $\nu_1[^3A_{2g} \rightarrow {}^3T_{2g}(P)]$, $\nu_2[^3A_{2g} \rightarrow {}^3T_{1g}(F)]$ and $^3A_{2g} \rightarrow {}^3T_{1g}(P)$ transitions, respectively. In this symmetry, two spin-forbidden transitional bands may be observed and assigned to $^3A_{2g} \rightarrow {}^1E_g(D)$ and $^3A_{2g} \rightarrow {}^1E_g(G)$ transitions. Therefore, the band in the 11,000–13,000-cm^{-1} region could be assigned to the spin-forbidden transitions. Furthermore, the observed splitting in the ν_2 and ν_3 absorption bands suggests the presence of a distortion of the idealized symmetry.[27] The calculated ligand field parameters are given in Table 3. The Dq values for the Ni(II) complexes under investigation lie in the 918.5–1050-cm^{-1} region, indicating an intermediate ligand field position of our ligands in the nephelauxetic series [the Dq values found in octahedral Ni(II) complexes[27] vary between 6400 and 12,700 cm^{-1}]. The values of B' for all the adduct complexes are in the 629–731-cm^{-1} region, lower than that of the free Ni(II) ion (1030 cm^{-1}). The reduction in the B' values could be taken as a criterion for the amount of covalency in these complexes. This could also be explained on the basis that the e_g-electrons are σ-antibonding and spend some time on the ligand. The t_{2g}-electrons may become π-bonding or antibonding, and will also spend some of its time on the ligand. Such delocalization will increase the mean distance between the d-electrons and thereby reduce the value of B'. The ratio $\beta = B'/B_o$ is used to indicate the amount of reduction of B_o (for the free ion). According to the values of β given in Table 3, a covalent-character bonding in our complexes can

[b]For H_2L_1 etc. see Table 1.

be assumed (ionic ligands form complexes with β values very close to the unity). From the Dq, B' and β values, our ligands can be arranged in the order: *o*-Cl > *m*-CH_3 > *m*-Cl > *o*-COOH > *o*-CH_3 > *m*-NO_2 with the same Lewis base.

IR spectra

The ligands gave characteristic spectral regions as follows:

(i) 3531–2938 cm^{-1} due to the intramolecular hydrogen-bonded OH group overlapping with oximic OH stretching.[28] Such a region is due to a hydrogen-bonding effect or water molecules (Table 4).

(ii) 1695–1611 cm^{-1} due to ν(C=O), absent in all complexes.

(iii) 1600–1570 cm^{-1} due to free ν(N=N), affected on complexation, i.e. the azo group contributes in the structure of the complex compound.

(iv) 990–950 cm^{-1} due to ν(=NOH). This in turn verifies the phenomenon of tautomerism.

(v) 950–860 cm^{-1} due to hydrogen bonding. This finding is parallel to that present in the stretching spectral region. Therefore, structure **II** could be assumed for these ligands.

For the carboxy system, the following are noticed:

(i) A strong and broad band at 3460 cm^{-1} is present due to the presence of intramolecular O···H—O between the —C=O and —COOH of one molecule and the —OH group of another.

(ii) The presence of band (i) beside that in the range 980–870 cm^{-1} is assigned to intramolecular bonds between the —C=O and —OH of the oxime. The presence of strong bands at 1570–1430 cm^{-1} could be used to assign the presence of the azo group in an azobenzene-like structure in a *trans* configuration.[29] This region is affected on complexation, i.e. the azo group takes part in the complex compound. The absence of bands in the free ligand at 1490 and 1400 cm^{-1} is due to the lack of N=O. The carboxylate radical is identified by the presence of two bands at 1685 and 1655 cm^{-1} (a strong and weak feature, respectively), due to ν(C=O) and $\nu_{asym}(COO^-)$, in turn. The first is absent and the second is red-shifted on complexation.

Generally, the bidentate nature for all the ligands—except that of the carboxy ligands—is based on the interaction of the azo and phenolic oxygen with nickel. The carboxy ligands are tridentate, i.e. the azo, hydroxy and carboxy groups all attach to Ni(II).

ELUCIDATION OF STRUCTURES OF *NIDO*-7-CB_8H_{12} AND $B_9H_{12}^-$ BY TWO-DIMENSIONAL ^{11}B–^{11}B NMR SPECTROSCOPY

S. HEŘMÁNEK,* J. FUSEK, B. ŠTÍBR, J. PLEŠEK and T. JELÍNEK

Institute of Inorganic Chemistry, Czechoslovak Academy of Sciences, 250 68 Řež near Prague, Czechoslovakia

(*Received* 6 *December* 1985; *accepted after revision* 28 *May* 1986)

Abstract—The product of the thermal decomposition of 4-CB_8H_{14} is, according to two-dimensional (2-D) ^{11}B–^{11}B NMR spectroscopy, 7-CB_8H_{12}. An analogous structure stems from the 2-D NMR for $B_9H_{12}^-$. A new approach to the estimation of distribution of bonds in borane skeletons is proposed on the grounds of positions of individual signals in the given ^{11}B NMR spectrum and documented in the distribution of bonding electrons in $B_9H_{12}^-$ and 7-CB_8H_{12}.

In earlier papers[1,2] we have described a pyrolytic preparation of a new *nido*-CB_8H_{12} carbaborane (**1**) from 4-CB_8H_{14}. The ^{11}B and ^1H NMR spectra (^{11}B, 32.1-MHz; ^1H, 100-MHz) offered two possible structures [**2** and **3** (Fig. 1)] exhibiting five ^{11}B signals of relative areas 1:2:2:2:1 and two types of H-bridges of relative intensity 2:1. Structure **2** was consistent with the ease of dehydrogenation while structure **3** corresponded to the character of the ^{11}B NMR spectrum in the light of our ^{11}B NMR empirical rules.[3] A definite decision was believed to require an x-ray diffraction study. The importance of a solution of this problem was enhanced by finding that the carbaborane discussed (**1**) has a ^{11}B NMR spectrum similar in character to that of the isoelectronic $B_9H_{12}^-$ anion (**4**).[1] This "^{11}B NMR isospectrality"[4] indicated that both compounds are structurally very similar, and for both the distribution of H-bridges as in **3** and **4** was preferred.[1]

EXPERIMENTAL

The measured 7-CB_8H_{12} and $B_9H_{12}N(CH_3)_4$ compounds were prepared according to the literature[2] and Ref. 5, respectively.

NMR spectra were measured using a Varian XL-200 NMR spectrometer (^{11}B, 64.184-MHz; ^1H, 200-MHz). The locked spectra of **1** were recorded in $CDCl_3$, and those of $B_9H_{12}N(CH_3)_4$ in CD_3COCD_3. Referencing was to an external $BF_3 \cdot O(C_2H_5)_2$ for ^{11}B and an internal TMS for ^1H.

For two-dimensional (2-D) ^{11}B–^{11}B NMR spectroscopy, the COSY pulse sequence was used to generate the t_1, t_2 matrix (512 × 512 for **1** and 256 × 256 for **4**). The spectra were obtained utilizing a standard Varian XL-200 software "HOMCOR" pulsed sequence. For **1** the following acquisition parameters were used: acquisition time (AT) = 0.051 s, relaxation delay (D1) = 0.2 s, sweep width (SW) = 5000 Hz, number of transitions (NT) = 32; $B_9H_{12}^-$: AT = 0.032 s, D1 = 0.2 s, SW = 4000 Hz, NT = 32. The resulting COSY spectra were line-narrowed (using resolution enhancement = 0.003 and apodization function = 0.01), symmetrized, and recorded using a Nicolet Zeta 1553 plotter.

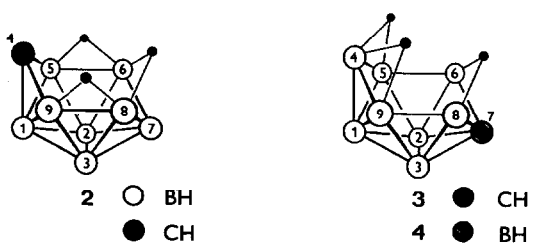

Fig. 1. Structure of CB_8H_{12} and $B_9H_{12}^-$: (a) proposed structure of **2**, and (b) proposed and found structures of 7-CB_8H_{12} (**3**) and $B_9H_{12}^-$ (**4**).

RESULTS AND DISCUSSION

CB_8H_{12}

With the introduction of 2-D ^{11}B–^{11}B NMR spectroscopy[6] the above-mentioned problem was simplified to searching for the presence or absence of an interaction (i.e. of a cross-peak) between two atoms both represented by signals of intensity 1 at 6.46 and −54.43 ppm. As shown in Fig. 2, their cross-peak is unambiguously present, which confirms both the formerly preferred[1] rearranged structure **3** and the importance of the ^{11}B NMR empirical rules.[3]

Structure **3** was further confirmed by a detailed NMR study of **1** (shown in Fig. 3). Selective ^1H decoupling by the frequency corresponding to an H-bridge of intensity 1 (−5.5 ppm) unequivocally demonstrated the loss of μH coupling at B(6,8) (Fig. 3c) while the selective ^1H decoupling by the frequency of the H-bridge of intensity 2 (at −3.1 ppm) resulted in a simultaneous loss of μH coupling at B(5,9) and B(4) (Fig. 3d). A distinct μH splitting of the B(6,8) signal at −27.57 is also in agreement with the "μH rule", according to which this phenomenon is observed with signals of B atoms which bear μH, and are either joined to a C-vertex[7] or are connected with an adjacent B atom by a classical B—B bond. The ^{11}B NMR characteristics and the assignment of all signals are summarized in Table 1.

In the pyrolysis of 4-CB_8H_{14}, deuterated to a great extent in the 2,3- and partly in the 6,8-positions, a derivative of **3**, deuterated partially in positions B(1,2,3,6,8) was obtained. This denied the mechanism based on a rotation of the inner B(1,2,3) triangle[1] and another rearrangement mechanism has to be proposed.

$B_9H_{12}^-$

Under similar conditions to **1**, a 2-D ^{11}B–^{11}B NMR spectrum of the isoelectronic $B_9H_{12}^-$ anion was obtained (Fig. 4), which enabled us to propose structure **4** and make a complete ^{11}B signal

6,8	−35.00	148	−27.57	173, 47	7.43	Vicinal
1	−52.74	153	−54.43	160	−1.69	*Meta*

assignment (Table 1). The ^{11}B NMR spectrum of **4** is almost identical with that of Siedle *et al.*[8] measured in CD_3CN. The structure **4** determined in this work substantiated the Coordination Number Pattern Recognition Theory of Williams, who preferred structure **4** on those grounds.[9]

A graphical correlation of ^{11}B NMR spectra[10] of the $B_9H_{12}^-$ and 7-CB_8H_{12} *nido* compounds (Fig. 5) indicates an observable vicinal shift of ^{11}B signals of the adjacent B(2,3) and B(6,8) atoms, and an

outstanding antipodal shift (23.7 ppm) of the opposite B(4) atom caused by the partially positive C-vertex.[10]

Distribution of bonds in $B_9H_{12}^-$ *and* 7-CB_8H_{12}

Nido boranes and their derivatives can be described by a set of styx formulae[11] composed of H-bridges (s), three-center (t) and classical (y) bonds, and of *endo*-hydrogens (x). The isoelectronic $B_9H_{12}^-$ and 7-CB_8H_{12} compounds discussed can be expressed by two distinct tautomeric styx formulae [3530 (**5** and **6**) and 2621 (**7**)], differing in number of B—H—B bridges and BH_2 groups. Each tautomeric formula is, moreover, a hybrid of many canonical resonance formulae, differing in the dislocation of styx-given bonds. From all these, three representative formulae (**5**–**7**) were elected to show possible boundary arrangements in particular parts of these skeletons (Fig. 6).

Up to now, the choice of optimum formulae was a matter of quantum chemical calculations based on X-ray structural analysis. In the case of $B_9H_{12}^-$ these attempts were unsuccessful due to the disorder of the measured crystals.[8] Difficulties in obtaining suitable crystals, long-term measuring and computing, and further complications were the reason why a new approach was looked for.

Almost 10 years ago, a series of empirical rules was presented[3,12] which give a mutual relationship of the ^{11}B NMR chemical shift of an observed B* atom with the position of the center of a bond connecting two adjacent skeletal atoms. It was stated that "shielding" increases (or, probably better, paramagnetic deshielding decreases) in the order shown in Fig. 7.

A tight relation between the ^{11}B chemical shift of a given skeletal atom and the distribution of bonding electrons in front or behind the imaginary connecting line of a couple of adjacent skeletal atoms is illustrated for three compounds [$B_{10}H_{14}$ (**9**), 4,6-$C_2B_7H_{13}$ (**10**) and 4-$(CH_3)_2SB_9H_{13}$ (**11**)] (Fig. 8) which have marked parts of the molecule analogous with those in **3** or **4**. These three compounds were elected due to the correct assignment of all signals (see values in ppm) and a very probable distribution of bonds in **9** and **10**, estimated by quantum chemical calculations and visualized by fractional bonds.

A confrontation of ^{11}B chemical shifts of the key atoms B(1) (−16.24 ppm) and B(4) (−52.74 ppm) in $B_9H_{12}^-$ with chemical shifts of B atoms enclosed in dashed boxes for compounds **9** and **10** allows one to prefer a classical B—B bond (see **5** and **7**) to two partial three-center bonds (**6**) between B(1) and B(4). Similarly, the chemical shift of −10.47 ppm of

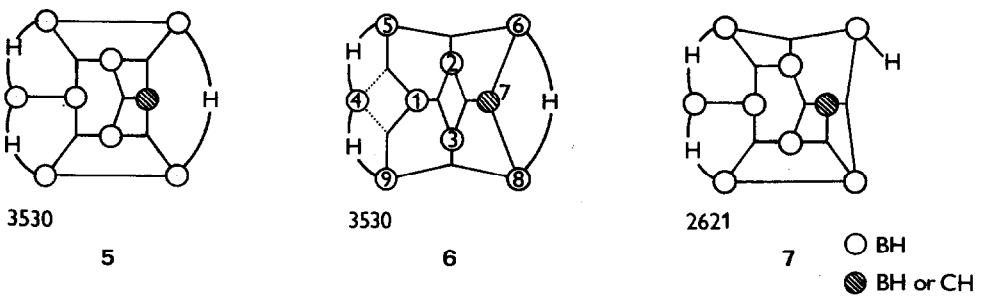

Fig. 6. Selected representative valence structures of $B_9H_{12}^-$ and 7-CB_8H_{12}.

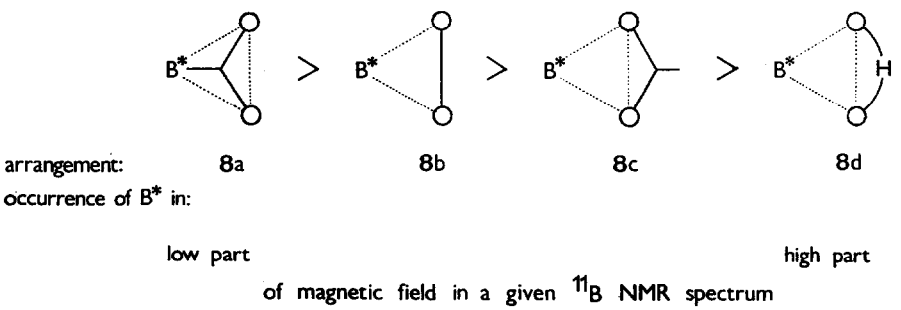

Fig. 7. Relation between the position of the B* signal in a given ^{11}B NMR spectrum and the location of the center of bonding electrons connecting two neighboring atoms (○). Individual bond arrangements are ordered according to the decreasing deshielding of B*.

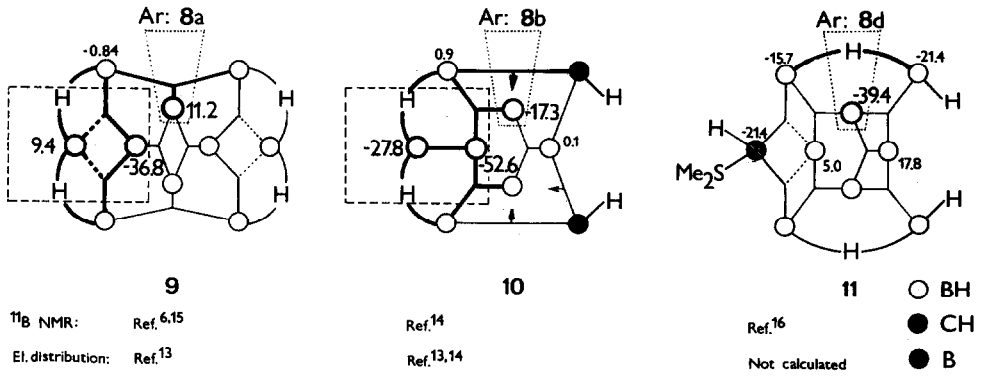

Fig. 8. Bonding schemes of $B_{10}H_{14}$ (**9**), 4,6-$C_2B_7H_{13}$ (**10**) and 4-$(CH_3)_2SB_9H_{13}$ (**11**). Bond arrangements (Ar) governing ^{11}B chemical shifts of particular atoms are marked by bold contours, and are enclosed in dashed or dotted boxes.

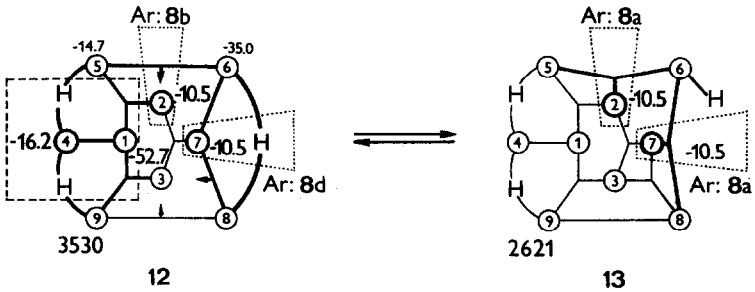

Fig. 9. Distribution of bonding electrons in $B_9H_{12}^-$ deduced from the ^{11}B chemical shifts of B(1,2,4,7) atoms. The analogous distribution is expected for 7-CB_8H_{12}.

the B(2,3) atoms, and its occurrence in the low part of the given spectrum favors a hybrid of a three-center bond and a classical bond in the areas B(2,5,6) and B(3,8,9) (cf. dotted boxes in **9** and **10**). The presence of a B—H—B bridge between B(6) and B(8) is controversial [cf. the relatively low δ value (-10.47 ppm) of the B(7) atom]. This seeming discrepancy can be easily explained by assuming an alternating occurrence of the B—H—B bridge and BH_2 group in this area, i.e. the existence of both tautomers (**12** and **13**) in equilibrium and, consequently, alternating arrangements (**8d** and **8a**) at B(7), averaging a generally high shift (**8d**) (-40 ± 10 ppm) and a low shift (**8a**) (10 ± 10 ppm) to the average value of -10.5 ppm. The tautomers **12** and **13** are expressed by localized valence structures composed of fraction bonds distributed in such a manner as to reflect ^{11}B chemical shifts of individual B atoms and their bonding surroundings (Fig. 9).

With the 7-CB_8H_{12} carborane, taking into account changes brought about by the effect of the 7-C heteroatom (see Fig. 5), we can consider its ^{11}B NMR spectrum to be analogous to that of $B_9H_{12}^-$. For 7-CB_8H_{12} a $BH_2 \rightleftharpoons$B—H—B tautomerism is also present, stemming from the relative low ^{13}C δ value of 31.06 ppm, which corresponds to a ^{11}B δ value of *ca.* -20 ppm.[15] On the grounds of the relationships discussed a tautomerism of structures **12** and **13** with a 7-C vertex is proposed.

CONCLUSIONS

(i) The thermal origin of 7-CB_8H_{12}, leading to a transformation of the four- to the five-coordinated carbon vertex, supports the idea that the thermodynamically best isomers are those "with bridge hydrogens in optimal positions and carbons in next best positions"[9] (Williams' rules 2 and 3).

(ii) This work substantiated the preference for a five-membered face with *nido* nine-vertex borane and heteroborane compounds.

(iii) This study has confirmed a tight relationship between the location of bonding electrons and the chemical shift of individual vertex atoms.

(iv) A new approach to the estimation of a distribution of bonding electrons in the framework of borane and heteroborane molecules, based on argument (iii), is proposed.

Acknowledgements—We thank Drs J. Schraml and V. Blechta for very valuable help concerning the preparation of 2-D measurements.

A FACILE SYNTHESIS AND PROPERTIES OF QUINONE FROM A POLYVALENT PORPHYRIN, TETRAKIS(3,5-DI-*TERT*-BUTYL-4-HYDROXYPHENYL)PORPHYRIN

TOSHIHIKO OZAWA* and AKIRA HANAKI

National Institute of Radiological Sciences, 9-1, Anagawa-4-chome, Chiba-shi 260, Japan

(*Received* 3 *March* 1986; *accepted* 28 *May* 1986)

Abstract—The quinone 5,15-di-(3,5-di-*tert*-butyl-4-hydroxyphenyl)-10,20-di-(3,5-di-*tert*-butyl-4-quinomethane)porpho-10,20-dimethene (**2**) was obtained in high yield by the oxidation of the polyvalent porphyrin tetrakis(3,5-di-*tert*-butyl-4-hydroxyphenyl)porphyrin (**1**) with an Mn^{2+}–O_2 system in dimethylformamide. **2** was reduced to **1** by ascorbic acid or hydroquinone.

In a preceding paper,[1] we described how the polyvalent porphyrin tetrakis(3,5-di-*tert*-butyl-4-hydroxyphenyl)porphyrin (**1**) was oxidized by the superoxide ion (O_2^-) to give the corresponding quinone, 5,15-di-(3,5-di-*tert*-butyl-4-hydroxyphenyl)-10,20-di-(3,5-di-*tert*-butyl-4-quinomethene)porpho-10,20-dimethene (**2**). Further, Milgrom[2] reported that **2** was obtained by aerial oxidation of **1** in basic solutions. However, the yield of **2** was somewhat low in both systems (50.1 and 60%, respectively). Then, we tried to obtain **2** in high yield and found that the Mn^{2+}–O_2 system is suitable for preparing **2** in extremely high yield. Furthermore, it is of interest that the oxidation product, **2**, is very stable, whereas other porphyrins, such as tetraphenylporphyrin and hydroxyporphyrin, undergo further redox or ring-opening reactions during oxidation steps.[3,4] Traylor *et al.*[5,6] reported that **2** is reduced quantitatively to **1** in chloroform ($CHCl_3$) by stannous chloride or aqueous sodium dithionite but not reduced by *p*-cresol and other phenols. We intended to examine the reduction of **2** by use of some organic reducing agents and found that ascorbic acid and hydroquinone can reduce **2** to **1**. We report these results in this paper.

EXPERIMENTAL

Materials

1 was prepared as described previously.[1] $CuCl_2 \cdot 2H_2O$, $FeCl_3$, $MnCl_2 \cdot 2H_2O$ and $CoCl_2$ were obtained from Wako Pure Chemical Industries Ltd. Potassium superoxide was purchased from Alfa Products, Inc. Dicyclohexyl-18-crown-6 was purchased from Nippon Soda Ltd and used without further purification. L-Ascorbic acid and hydroquinone were obtained from Wako Pure Chemical Industries Ltd and Nakarai Chemicals Ltd, respectively, and used as received. α-Tocopherol (vitamin E) was purchased from Aldrich. Other reagents were commercially available. $CHCl_3$ was distilled and passed through a neutral alumina column prior to use. Other solvents were distilled prior to use.

Spectral measurements

Visible absorption spectra were recorded at room temperature with a Union Giken SM-401 spectrophotometer. ESR spectra were obtained at room temperature or at 77 K with a JEOL-PE-1X (X-band) ESR spectrometer with 100-kHz field modulation. ESR parameters were obtained by comparison with 1,1-diphenyl-2-picrylhydrazyl ($g = 2.0036$) and a standard Mn^{2+}–MgO

Table 1. Reaction mode of **1** with some metal ions

Valence change	Reduction potential[a] (V)	Reaction mode
$Cu(II)+e^- \rightarrow Cu(I)$	0.153	Incorporation
$Fe(III)+e^- \rightarrow Fe(II)$	0.77	Incorporation
$Mn(III)+e^- \rightarrow Mn(II)$	1.51	Oxidation
$Co(III)+e^- \rightarrow Co(II)$	1.842	Incorporation

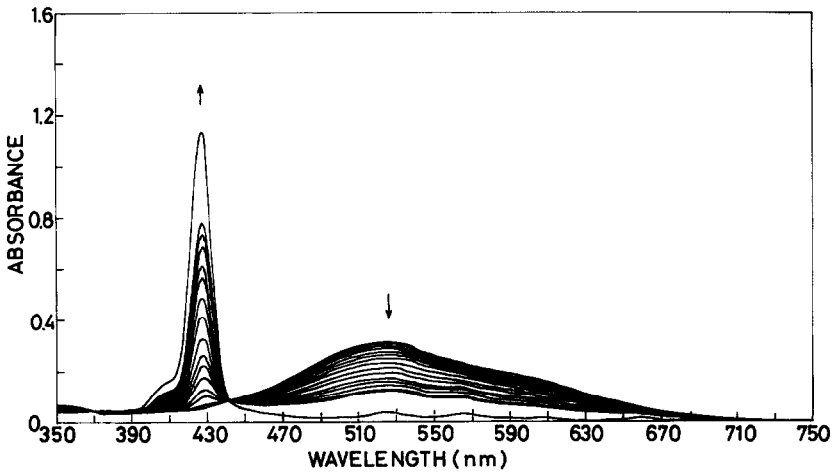
powdered marker. IR spectra were recorded on a JASCO IRA-1 IR spectrometer. The ^1H NMR spectra were recorded on a JEOL JNM-FX-100 spectrometer in $CDCl_3$ solution with tetramethylsilane as an internal standard.

Synthesis of **2**

2 was prepared by the oxidation method using Mn^{2+}–O_2 as follows: **1**[7-9] (0.944 g, 0.84 mmol) was dissolved in 200 cm^3 of dimethylformamide (DMF) and the solution was heated to flux. $MnCl_2 \cdot 2H_2O$ (0.664 g, 4.1 mmol) was added to this refluxing solution and the reaction mixture was further refluxed for 15 min. The formation of **2** was checked spectrophotometrically. After completion of the reaction, the reaction mixtures were evaporated to dryness by a rotary evaporator and the residues were dissolved in a minimum amount of $CHCl_3$. This solution was placed on a column packed with dry activated alumina (neutral, Woelm) and chromatographed with $CHCl_3$ as eluant. The first eluate, a reddish fraction, was the unreacted **1**, and the second purple eluate was collected and concentrated to dryness. The residue was recrystallized from $CHCl_3$–petroleum ether (b.p. 60–70°C) to give dark-green microcrystals. The yield was 0.899 g (95.2%, based on porphyrin). Found: C, 75.9; H, 8.3; N, 5.1%. Calc. for $C_{76}H_{92}N_4O_4 \cdot 4H_2O$: C, 76.2; H, 8.4; N, 4.7%. M.p. > 300°C. Their spectroscopic data were identical to those of **2**.[1,2,5] ^1H NMR ($CDCl_3$): δ (ppm) 1.35 (s, *m*-^{t}Bu); 6.71 (s, *p*-OH); 7.40 (s, *o*-H); and 8.92 (s, pyrrole H). IR ($CHCl_3$) (cm^{-1}): 3700 and 3520 (OH), and 1600–1610 cm^{-1} (carbonyl C=O). Visible ($CHCl_3$): 522 nm (log ε = 5.09).

RESULTS AND DISCUSSION

2 was almost quantitatively prepared from the oxidation of **1** by Mn^{2+}–O_2 in DMF in comparison with the oxidation by superoxide ion in dimethyl sulphoxide[1] or aerial oxidation in basic solutions.[2] That is, the yield of **2** was 95.2% in the Mn^{2+}–O_2 oxidation, 50.1% in the superoxide oxidation and 60% in the aerial oxidation, respectively. Other metal ions such as Fe^{3+}, Cu^{2+} and Co^{2+} did not oxidize **1** in air, but were incorporated into **1** to yield the corresponding metalloporphyrins.[10] These results may be explained by the reduction potentials of metal ions (Table 1).[11] Both Cu^{2+} and Fe^{3+} ions having low reduction potentials cannot oxidize **1** and are incorporated into the cavity of **1**. The Co^{2+} ion is hardly oxidized by O_2 to the Co^{3+} ion which has a high reduction potential and is incorporated into the cavity of **1**. On the other hand, since in basic



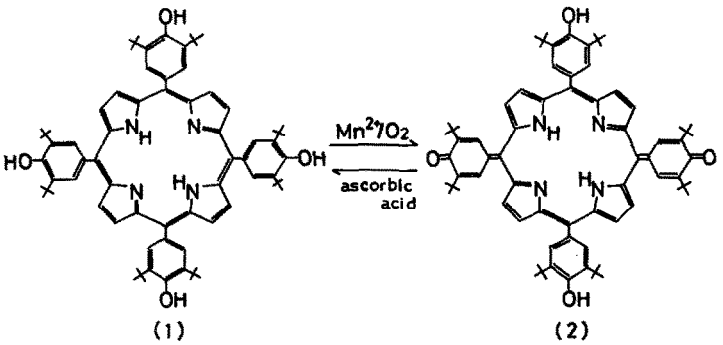


Fig. 1. Visible spectral changes accompanying the reduction of **2** to **1** by ascorbic acid in $CHCl_3$ solution at 25°C. Concentrations: **2** = 2.57×10^{-6} mol dm^{-3}, and ascorbic acid = 1.87×10^{-5} mol dm^{-3}. Time after mixing (min): 0, 5, 10, 20, 30, 40, 60, 90, 120, 150, 180, 210, 240 and 270. The final spectrum was recorded after 20 h.

Scheme 1.

media Mn^{2+} ion is easily oxidized by O_2 to the Mn^{3+} ion, which has a high reduction potential,[12] the Mn^{3+} ion formed from the oxidation of the Mn^{2+} ion by O_2 in DMF can oxidize **1** to give **2**. From these results, it is indicated that the Mn^{2+} ion is a suitable reagent for preparing a high yield of **2** in basic media such as DMF.

2 shows a very broad absorption spectrum (λ_{max} = 522 nm, $\log \varepsilon = 5.09$) in $CHCl_3$. When ascorbic acid in ethyl alcohol–H_2O (9:1) was added to a $CHCl_3$ solution of **2**, spectral changes were observed as shown in Fig. 1. The final spectrum showed five absorption bands (λ_{max} = 427, 525, 563, 606 and 658 nm) and was identical with that of **1** in $CHCl_3$. This result indicates that **2** can be reduced by ascorbic acid to **1**.

The same spectral changes were observed upon the reaction of hydroquinone with **2**, although its reaction rate was slower than that between **2** and ascorbic acid. α-Tocopherol (vitamin E) which is known to act as an antioxidant in living organs did not reduce **2**. Traylor *et al.*[5,6] reported that **2** is reduced by stannous chloride or sodium dithionite but not reduced by *p*-cresol and other phenols. These results suggest that **2** has less oxidizing ability.

In the reaction of **2** with ascorbic acid, the reaction shown in Scheme 1 may be assumed.

Both the semiquinone radical and the ascorbic acid free radical,[13,14] which are anticipated as reaction intermediates, could not be detected by ESR spectrometry. This result suggests that the reduction of **2** does not involve the formation of stable semiquinone radicals or, if the semiquinone radical could be formed, its lifetime should be too short to be detected by ESR spectrometry.

We are now further investigating the reductions of **2** by other organic or inorganic substrates.

OPTICALLY ACTIVE COBALT(III) COMPLEXES OF 1,4,8,11-TETRAAZACYCLOTETRADECANE COORDINATED IN A FOLDED CONFIGURATION

MATSUO NONOYAMA,* TAKAKO YAMAGUCHI and HIDEKO KIMIJIRI

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464, Japan

(*Received* 11 *March* 1986; *accepted* 28 *May* 1986)

Abstract—Some optically active cobalt(III) complexes of 1,4,8,11-tetraazacyclotetradecane (L) coordinated in a folded (*cis*) configuration, $[CoL(XY)]^{n+}$ [XY = (*R*)-propylenediamine ($n = 3$), (*S*)-alanine ($n = 2$) or acetylacetone ($n = 2$)], have been prepared and separated into isomers by column chromatography. These complexes are characterized spectroscopically and absolute configurations are assumed based on the circular-dichroism spectra.

A wealth of investigations have been carried out for complexes of tetraazamacrocycles but only a small part of the investigations participates in complexes coordinated with tetraazamacrocycles in a folded (*cis*) configuration.[1] Optically active complexes of the folded tetraazamacrocycles have been studied quite sparingly.[2,3] 1,4,8,11-Tetraazacyclotetradecane (cyclam), one of the most widely used tetraazamacrocycles coordinated in a folded configuration, exists in two enantiomers.[3,4] Configurational chirality results from an alternating displacement of five- and six-membered chelate rings around a central metal ion, but it is impossible to assign a simple Δ or Λ description to either enantiomer. The secondary nitrogen atoms are chiral and can be described in terms of *R* or *S* (Fig. 1). In a preliminary paper,[5] we have reported on an optically active complex, $[Co(en)(cyclam)]^{3+}$ (en = ethylenediamine), and in this paper we describe some new optically active cobalt(III) complexes coordinated with cyclam in a folded (*cis*) configuration.

RESULTS AND DISCUSSION

Reactions of *trans*-$[CoCl_2(cyclam)]Cl$ with bidentate ligands (XY) [XY = (*R*)-propylenediamine (pn), (*S*)-alanine (ala) or acetylacetone (Hacac)] in hot dimethylsulfoxide gave $[Co(XY)(cyclam)]^{n+}$ complexes. Isomers of the pn and ala complexes were separated by chromatography on an SP Sephadex C-25 column[6] with an aqueous solution of disodium hydrogen phosphate as an eluent (Table 1, where abbreviations for the complexes are given). The acac complex was optically resolved also by chromatography with an aqueous solution of sodium antimony tartrate as an eluent (Table 1). By this method $[Co(en)(cyclam)]^{3+}$ was previously resolved.[5]

The chemical shifts of methyl groups in the ^1H NMR spectra are given in Table 1. Two isomers (P+) and (P−) can not be distinguished by the ^1H

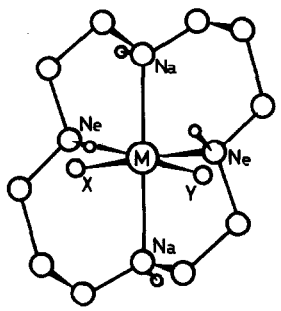

Fig. 1. Structure of Λ(en) and Δ(tn) (*RRRR*, *δδ*)-[Co(XY)(cyclam)]. Λ(en) and Δ(tn) represent, respectively, the chirality with respect to the pair of en or tn rings of cyclam, *R* the chirality of N atoms, and *δ* a *gauche* conformation of en rings (tn = trimethylenediamine). The structure of the Δ(en) and Λ(tn) (*SSSS*, *λλ*)-isomers is just the mirror image of the one shown.

[a] L = cyclam.

NMR spectra. To identify the isomers, the ^{13}C NMR spectra were measured (Table 2). The numbers of ^{13}C signals are small for (E+) and (C+), and this consists with the presence of a two-fold axis in these complexes. The spectra are in agreement with the proposed structure (Fig. 1) and the bidentate ligands are shown to be coordinated in the usual manner.

The pn and en complexes are pink despite a CoN_6 chromophore and the ala complex with a $CoON_5$ chromophore is red. These colours are different from those of $[Co(en)_3]^{3+}$ and $[Co(ala)(en)_2]^{2+}$, respectively, with the same chromophore. The absorption spectral patterns of the cyclam complexes are very similar to those of the corresponding bis(ethylenediamine) complexes, $[Co(XY)(en)_2]^{n+}$ (Table 3), but the following two points should be noted. Substitution of the $(en)_2$ part by cyclam results in a lowering of the energies ($\tilde{\nu}_{max}$) of the *d–d* transitions, and in a significant enhancement of the molar extinction coefficients ($\log \varepsilon$). The first point is in contrast with the fact that the ligand field of a secondary amino group is usually stronger than that of a primary one.[7] The weakened ligand field of cyclam compared with that of the $(en)_2$ part should be caused by distortions of an octahedral ligand field: connection of the $(en)_2$ part with two trimethylene chains produces strains and crowds around a central metal ion if cyclam adopts a folded configuration, as revealed for

$[Co(en)(cyclam)]^{3+}$ by X-ray analysis[4] (an axial N_a—Co—N_a bond angle of 173° is reported). The distortions should also be reflected in the higher molar extinction coefficients. Similar complexes of a smaller-size macrocycle, $[Co(XY)(cyclen)]^{n+}$ (cyclen = 1,4,7,10-tetraazacyclododecane), have higher molar extinction coefficients and lower-energy *d–d* transitions than the corresponding cyclam ones.[8] More pronounced distortions in $[Co(XY)(cyclen)]^{n+}$ [where the $(en)_2$ part is connected with two ethylene chains] have been shown by X-ray analysis.[9,10]

It is interesting to compare the electronic spectra of the cyclam complexes with those of an unsaturated analogue, for instance 5,12-dimethyl-1,4,8,11-tetraazacyclotetradeca-4,11-diene (L1). The L1 complexes with en, ala and acac show ν_{max} of *d–d* transitions at higher energies, which are nearly comparable with those of the $(en)_2$ analogues.[11] L1 is more compact due to the presence of unsaturated C=N bonds. In the cyclam complexes there are more non-bonding intra- and inter-chelate ring repulsions, which may characterize in part the spectral properties.

All the complexes are chiral and their circular-dichroism (CD) spectra are measured (Table 3, Figs

2 and 3). The CD spectra of the two isomers (P+) and (P−) are roughly opposite in pattern, suggesting that the two are pseudoenantiomers. The pattern of (P+) is very similar to that of (E+). The absolute configuration of (E+) was previously assumed to be Λ(en) (Fig. 1, XY = en).[5] The absolute configuration of (P+) is, therefore, Λ(en). The marked difference in intensity of the CD spectra of (P+) and (P−) is explained as follows.

A preferred λ-conformation of (*R*)-pn shows a CD spectrum due to a vicinal effect {for instance, $[Co(pn)(NH_3)_4]^{3+}$ shows ν_{ext} at 19.3 ($\Delta\varepsilon = -0.063$) and 21.7 $(+0.34)\times 10^3\,cm^{-1}$ in the first *d–d* transition region (Fig. 2)}.[12] This interferes in the CD spectra caused by a chiral Δ(en) or Λ(en) configuration of the fragment "[Co(XY)(cyclam)]". The CD spectra of the fragment can, roughly, be estimated by that of (E+) since an en chelate ring is usually flexible in solution. For the (P+) isomer, assumed to have a Λ(en) configuration, the vicinal effect of (*R*)-pn acts in a contradictory way (Fig. 2) (the vicinal CD spectrum of (*R*)-pn is reversed in sign compared with the CD spectrum of (E+)[5] and should reduce the intensity of the spectrum of (P+)). For (P−), on the contrary, the vicinal CD is additive to the CD spectrum of (E−) [the spectrum of (E−) is just the mirror image of that of (E+)] and then the spectrum of (P−) is enhanced.

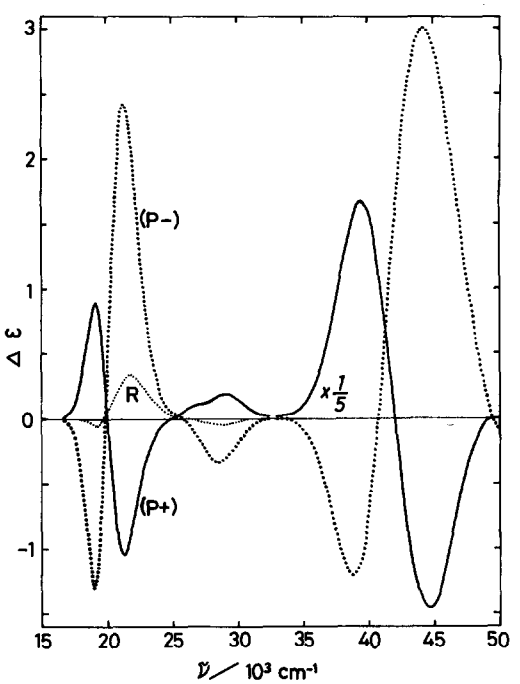

Fig. 2. CD spectra of: (P+) $(+)_D$-[Co(pn)(cyclam)] $(ClO_4)_3$, (P−) $(-)_D$-[Co(pn)(cyclam)]$Cl_3\cdot 3H_2O$ and (R) $[Co(R\text{-pn})(NH_3)_4]^{3+}$ in H_2O.

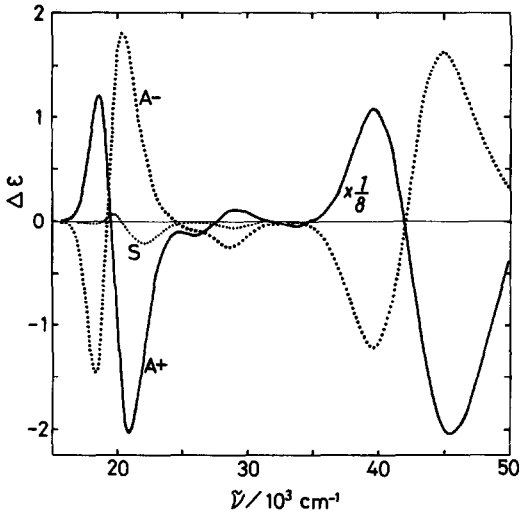

Fig. 3. CD spectra of: (A+) $(+)_D$-[Co(ala)(cyclam)] $(ClO_4)_2$, (A−) $(-)_D$-[Co(ala)(cyclam)]$(ClO_4)_2$ and (S) $[Co(S\text{-ala})(NH_3)_4]^{2+}$ in H_2O.

The two five-membered chelate rings of Λ(en)-[Co(XY)(cyclam)] [where the chirality of all the secondary amino groups is *R* (Fig. 1)] adopt a δ *gauche* conformation as revealed by X-ray structural analysis.[4] The chelate ring of (*R*)-pn is usually fixed to a λ-conformation due to a preferred equatorial orientation of the methyl substituent. For the (P+) [Λ(en)] isomer, therefore, the three five-membered chelate rings are in a set of λδδ conformations, that is, an *ob* lel_2 set, and the (P−) [Δ(en)] isomer has a set of λλλ conformations (lel_3). The lel_3 set is the most stable in energy.[13] The difference in energy between (P−) and (P+) is reflected in the formation ratio (P−)/(P+) (85/15). The assignment of Λ(en) to (P+) is compatible with these observations.

The CD spectra of (A+) and (A−) are also of pseudoenantiomers and that of (A+) is similar in pattern to that of (E+) suggesting a similar absolute configuration [Λ(en)] for (A+). The different intensity of the CD spectra between (A+) and (A−) can be explained similarly as for the case of (P+) and (P−), considering the vicinal CD spectrum of (*S*)-ala {the spectrum of [Co(ala)$(NH_3)_4]^{2+}$ is given in Fig. 3}.[14] A preferred equatorial orientation of a methyl substituent results in a δ-conformation of the chelate ring of (*S*)-ala, although less packered than that of pn.[13] (A+) is shown to exist in a Λ(en) [δδδ (lel_3)] configuration, while (A−) is Δ(en) [δλλ (*ob* lel_2)]. This may reflect the slightly preferred formation of (A+) [the formation ratio (A+)/(A−) = 57/43].

In the first *d–d* transition region, the CD spectral pattern of (C+) is similar to that of (E+) and Λ(en)

is tentatively assigned to (C+), but, in the UV region, there are absorptions due to an acac ligand and the CD pattern in this region can not be simply compared with that of (E+) or (A+). In the CD spectra of $[Co(XY)(cyclam)]^{n+}$ the higher-energy component {corresponding to the A_2-component of $[Co(en)_3]^{3+}$} of the first *d–d* transition ($^1A_{1g} \rightarrow {}^1T_{1g}$ in O_h) is intensified compared with that of the corresponding $[Co(XY)(en)_2]^{n+}$ (Table 3). The differences are considered to originate in part from the presence of extra six-membered chelate rings and of chiral amino groups in cyclam. The above discussion is based on the assumption that the CD spectra are, to a first approximation, caused only by five-membered chelate rings in a *gauche* conformation, and that contributions from six-membered rings in a chair conformation are, compared to those of five-membered ones, sufficiently small to be ignored. We expect that the chiral structures of these complexes of cyclam will be confirmed by X-ray structural analysis.

EXPERIMENTAL

Measurements

Measurements were carried out by methods reported previously.[8] ^{13}C NMR spectra were recorded on a JNM FX-100 spectrometer and dioxane was used as an internal standard (δ = 67.8 ppm). Chemical shifts were given relative to tetramethylsilane (TMS).

Preparation

(P+) $(+)_D$-$[Co(pn)(cyclam)](ClO_4)_3$ *and* (P−) $(-)_D$-$[Co(pn)(cyclam)]Cl_3 \cdot 2H_2O$. To a hot dimethylsulfoxide solution (30 cm^3) of 1.5 mmol of (*R*)-pn·2HCl and 3.0 mmol of 1,8-diazabicyclo-(5.4.0)-7-undecene (DBU) was added 1.0 mmol of *trans*-$[CoCl_2(cyclam)]Cl$ and the mixture was heated on a steam bath for several minutes until the complex had reacted to give an orange-red solution. The solution was diluted with 100 cm^3 of 0.01 M hydrochloric acid and adsorbed on a short column of SP Sephadex C-25. The column was washed with 0.1 M hydrochloric acid and eluted with 1.0 M hydrochloric acid. The eluant was evaporated and, in order to separate isomers, readsorbed on a column (150 cm × 3 cm ϕ) of SP Sephadex C-25. The column was developed with a 0.2 M aqueous solution of disodium hydrogenphosphate to give two pink-orange bands; the former one was more deeply coloured. The two bands were collected separately and diluted with water (10 times the volume of the eluant of the respective band). The diluted solutions were adsorbed on a short column of SP Sephadex C-25 and washed sufficiently with 0.03 M hydrochloric acid. The column was eluted with 1 M hydrochloric acid and concentrated to a small volume. From the first band, upon addition of ethanol, pink $(-)_D$-$[Co(pn)(cyclam)]Cl_3 \cdot 2H_2O$ was obtained. From the latter band, upon addition of lithium perchlorate (1 mmol) followed by ethanol, pink $(+)_D$-$[Co(pn)(cyclam)](ClO_4)_3$ was obtained. The relative yield of $(-)_D/(+)_D$ was about 85/15.

(A−) $(-)_D$- and (A+) $(+)_D$-$[Co(ala)(cyclam)](ClO_4)_2$. To a hot dimethylsulfoxide solution (40 cm^3) of 2 mmol of (*S*)-ala and 2 mmol of DBU was added 1 mmol of *trans*-$[CoCl_2(cyclam)]Cl$ and the mixture was heated for about 10 min on a steam bath with occasional stirring until the complex had reacted. The resultant red solution was treated as above and the short column used first was washed and eluted, respectively, with 0.1 and 1.0 M aqueous solutions of lithium chloride. Upon development two red bands appeared and then each eluant was diluted with water (30 times the volume of the respective eluant). The column used last was washed as above with 0.01 M aqueous solution of lithium chloride and eluted with a 1.0 M aqueous solution of lithium perchlorate. Addition of ethanol to the concentrated eluants gave the red $(-)_D$-isomer (from the former band) and the $(+)_D$-isomer (from the latter band). The formation ratio $(-)_D/(+)_D$ was about 43/57.

(C+) $(+)_D$- *and* (C−) $(-)_D$-$[Co(acac)(cyclam)](ClO_4)_2$. This complex was prepared similarly to $[Co(ala)(cyclam)]^{2+}$ by using acetylacetone instead of ala and, for optical resolution, this was adsorbed on a column (150 cm × 3 cm ϕ) of SP Sephadex C-25. The column was eluted with a 0.15 M aqueous solution of sodium antimony tartrate to give two slightly overlapping red bands. The overlapping part was subjected to rechromatography. The front and rear parts were treated as for $[Co(ala)(cyclam)]^{2+}$. From the front part the red $(+)_D$-isomer and, from the rear, the $(-)_D$-isomer were obtained.

(E+) $(+)_D$-$[Co(en)(cyclam)]Cl_3 \cdot 1\frac{1}{4}H_2O$. This[5] was prepared by a method similar to that for $[Co(pn)(cyclam)]^{3+}$ by using en instead of pn·2HCl and DBU, and optically resolved similarly to $[Co(acac)(cyclam)]^{2+}$.

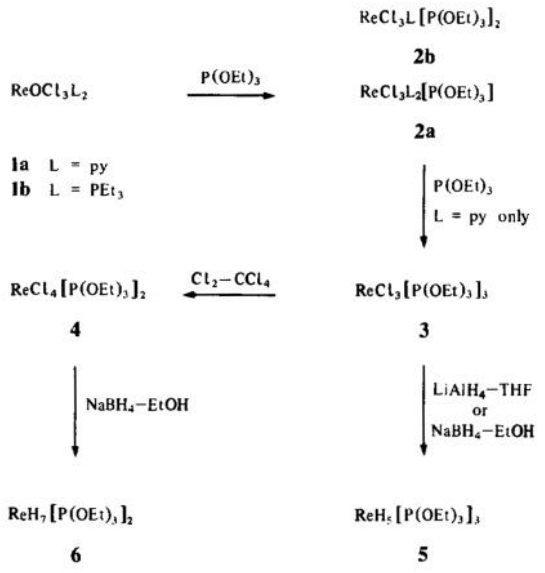
Abstract—The preparation and characterization of some Re(III), Re(IV) and Re(V) chloro phosphite complexes are reported. Both Re(III) and Re(IV) complexes react with sodium borohydride, yielding the corresponding polyhydrides, $ReH_5[P(OEt)_3]_3$ and $ReH_7[P(OEt)_3]_2$. The thermal and photochemical reactivity of these complexes is described.

The chemistry of rhenium phosphine complexes is well developed but the chemistry of the analogous rhenium phosphite complexes is a relatively unexplored area. To date, there have been only a few reports in the literature concerning rhenium phosphites.[1] Different reactivities of metal phosphite complexes relative to the phosphine analogs as a result of different electronic and steric properties[2] have prompted us to pursue the synthesis of these rhenium compounds. In this paper the improved synthesis of $ReCl_3[P(OEt)_3]_3$ (**3**) as well as several new rhenium triethyl phosphite compounds are reported (Scheme 1).



In a preliminary account the synthesis of **3**, starting from $ReOCl_3(PPh_3)_2$ was reported.[3] However, chromatographic isolation of **3** often resulted in lower yield, because of its sensitivity to air in solution.† Thus an alternative synthetic method was sought. It was found that the reaction of $ReOCl_3py_2^{1(a)}$ (**1a**) and excess $P(OEt)_3$ in boiling benzene gave high reproducible yields of **3** *without chromatographic separation*.‡ Shorter reaction times (about 15 h) yielded the partially substituted *trans*, *mer*-$ReCl_3py_2[P(OEt)_3]$ (**2a**) shown in Scheme 1. Spectroscopic data are consistent with the assigned geometry.§ Similarly the synthesis of **3** was attempted using *cis*-$ReOCl_3(PEt_3)_2^4$ (**1b**) since the volatility of the byproduct ($OPEt_3$) should also facilitate the separation of **3**. After 4.5 h of reflux in benzene an eight-fold excess of $P(OEt)_3$ reacts with

*Authors to whom correspondence should be addressed.

†Preliminary data suggest that **3** reacts with O_2 in hexane to form blue crystals of $ReOCl_3[P(OEt)_3]_2$. IR (Nujol mull): 975 cm^{-1}. Calc. for $C_{12}H_{30}O_7Cl_3P_2Re$: C, 22.5; H, 4.7; Cl, 16.6; P, 9.7%. Found: C, 22.1; H, 4.3; Cl, 16.5; P, 10.0%.

‡**1a** (1.4 g, 30 mmol) was refluxed in benzene (30 cm^3) with a 20-fold excess of $P(OEt)_3$ under N_2 for 36 h. The yellow solution was evaporated to dryness and additionally vacuum (8×10^{-3} hPa) dried overnight. The solid (**3**) was recrystallized from a hexane–pentane solution (yield 87%).

§IR (Nujol): ν(Re—Cl) (cm^{-1}) 307s, 267m and 250m. ^1H NMR ($CDCl_3$, 25°C): δ (TMS) (ppm) 3.05 (t, J = 7 Hz, 9H, CH_3); 4.06 (t, J = 7.7 Hz, 2H, py); 4.94 (d, J = 5.9 Hz, 4H, py); 10.15 (q, J = 7 Hz, 6H, CH_2); and 17.28 (t, J = 6.8 Hz, 4H, py).

Scheme 1. Synthesis of rhenium phosphite compounds.

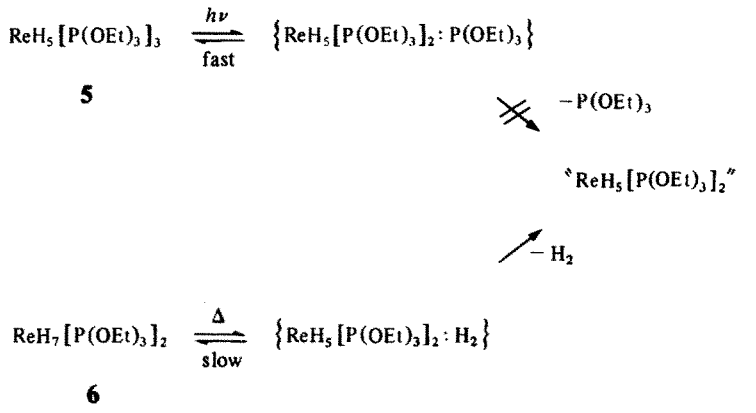
1b to form *cis*, *mer*-$ReCl_3(PEt_3)[P(OEt)_3]_2$ (**2b**).* Surprisingly, even after prolonged reflux (48 h) in benzene with an excess of $P(OEt)_3$, no further phosphine substitution of **2b** is observed (^1H NMR). Most probably, the extent of these substitution reactions is controlled both by electronic effects and the geometry of the reacting complexes. These newly synthesized Re(III) complexes (**2a** and **b**) exhibit the expected contact-shifted signals in the ^1H NMR spectrum as a result of the temperature-independent paramagnetism.[5]

It has been shown that Re(III) chloro phosphines can be oxidized easily to Re(IV) complexes by treatment with chlorine.[6] A similar chemistry was observed when **3** reacted with Cl_2 in CCl_4.† Spectroscopic data suggest the formation of *trans*-$ReCl_4[P(OEt)_3]_2$ (**4**) in this reaction.

The successful isolation and characterisation of the chloro phosphite complexes (**3** and **4**) provided a unique opportunity to prepare the corresponding hydrido phosphite complexes of rhenium, and to compare their reactivity with well-known phosphine analogs. A general procedure[7] can be applied for the preparation of these polyhydrides. The pentahydride $ReH_5[P(OEt)_3]_3$ (**5**)‡ can be synthesized from **3** by treatment with $LiAlH_4$ in the THF, or with $NaBH_4$ in EtOH at ambient temperature. From **4**, $ReH_7[P(OEt)_3]_2$ (**6**)§ can be obtained by means of $NaBH_4$ treatment in EtOH at room temperature (see Scheme 1). In both cases the reaction mixtures were stirred until the characteristic colours of **3** (yellow) and **4** (red) disappeared, leaving a colourless slurry. The solvent was then removed *in vacuo* and the polyhydride was extracted into benzene from the solid residue. The two polyhydride products (**5** and **6**) are to our knowledge the first examples of high oxidation state rhenium hydride phosphites.

The photochemistry of $ReH_5(PMe_2Ph)_3$ has been well characterized.[8] The reactive intermediate was determined, via isolation of reaction products and laser flash photolysis, to be the unsaturated $ReH_5(PMe_2Ph)_2$.[8(c)] A similar chemistry was expected from **5**. However, being thermally unreactive (65°C, 12 h in C_6D_6) as its phosphine analog, the photolysis of **5** in benzene-d_6 solution also showed no net reaction after 8 h.‖ Likewise, photolysis in the presence of eight molar equivalents of PEt_3 in benzene gave no net reaction (^1H NMR). On the contrary, the thermal chemistry of **6** follows the typical reactivity patterns observed in other heptahydride rhenium compounds.[9] Thus, heating a C_6D_6 solution of **6** results in H/D exchange (^1H NMR) as well as in a growth of the new hydride quintet [$\delta -6.8$, $J(P-H) = 8.6$ Hz], indicative of the formation of $Re_2H_8[P(OEt)_3]_4$.[8(a)] This type of reactivity suggests the transient character for $ReH_5[P(OEt)_3]_2$.

The lack of an observable reactivity during the photolysis of **5** and thermal reactivity of **6** is astonishing, especially since both precursors should generate the same transient species, $ReH_5[P(OEt)_2]_2$. The obvious difference between **5** and **6**



*IR (Nujol): ν(Re—Cl) (cm^{-1}) 311s, 283m and 257m. ^1H NMR (C_6H_6): δ (ppm) 2.33 and 2.79 (t and t, J = 7 Hz, 9H and 9H, CH_3); 7.0 and 10.74 (q and q, J = 7 Hz, 6H and 6H, CH_2) [indicating a non-equivalent $P(OEt)_3$]; 5.5 (q, J = 7.2 Hz, 6H, CH_2); and 8.0 (t, J = 7.2 Hz, 9H, CH_3).

†Chlorine gas was slowly bubbled through a CCl_4 solution of **3** (0.5 g) for 1 h. To the resulting red solution a small amount of MeOH was added and red crystals were isolated after cooling down to −20°C (yield 50%). The high solubility of **4** precludes further isolation. Calc. for $C_{12}H_{30}O_6Cl_4P_2Re$: C, 21.2; H, 4.6; Cl, 21.5%. Found: C, 22.0; H, 5.0; Cl, 21.7%. Scheme 2. Curly brackets indicate species in solvent cage.

is the type of ligand extruded from the coordination sphere of the metal complex. With the available data it can be concluded that, in the photochemical case, a back-reaction with photoextruded $P(OEt)_3$ is favoured over a reaction with added substrate (C_6D_6 or PEt_3). In the thermal case (**6**), further reaction with added substrate is observed (H/D exchange and dimerization) (see Scheme 2). It seems that the observed reactivity is dependent upon the rate of diffusion of the extruded ligand [$P(OEt)_3$ or H_2] out of the solvent cage, thereby allowing "naked" $ReH_5[P(OEt)_3]_2$ to react with additional reagents.

ANNOUNCEMENTS

FIFTH INTERNATIONAL SYMPOSIUM ON PLATINUM AND OTHER METAL COORDINATION COMPOUNDS IN CANCER CHEMOTHERAPY

The University of Padua, Faculty of Pharmacy and Consiglio Nazionale delle Ricerche are organizing this Symposium which will be held at Hotel Sheraton Orologio, Abano Terme, Padua, Italy (29 June–2 July 1987).

Scientific program

The following provisional topics are expected:

Session A: Biochemistry of platinum complexes in cancer chemotherapy.

Session B: Pharmacological mechanisms of cisplatinum action.

Session C: Clinical applications of platinum complexes.

Session D: Advances in antitumor research with non-platinum complexes.

Session E: Development of new metal coordination compounds: synthesis and characterization.

Session F: Toxicology of metal coordination complexes as antitumor agents.

Presentation

The conference will have the following format:
(1) Plenary and session lectures.
(2) Regular papers.
(3) Poster sessions.

Language

The official language of the conference will be *English.*

Public information

The proceedings of the conference will be published in a special volume to appear after the closing of the Symposium by *Martinus Nijhoff, Boston.* A collection of abstracts will be circulated during the Symposium.

Registration fee

(1) Active participants: U.S. $270.
(2) Non-active participants: U.S. $100.

The registration fee for active participants will cover coffees and lunches throughout the Symposium, the social dinner, the sightseeing tour, and publication of the Volume of Proceedings.

The non-active participants will be offered the social dinner and the sightseeing tour to the countryside.

For further information contact: P. Uguagliati, Dipartamento Scienze Farmaceutiche, Via Marzolo, 5, 35131 Padua, Italy.

7th FECHEM CONFERENCE ON ORGANOMETALLIC CHEMISTRY

This Conference will be held in Toledo, Spain (31 August–5 September 1987).

Scope

The Conference will be concerned with all aspects of synthesis, structure and applications of organometallic compounds. The scientific programme will include invited plenary lectures and poster sessions.

The number of Conference participants will be limited according to FECHEM rules.

Location

The Conference will be held in Toledo which is easily accessible from Madrid (70 km) by bus or train. Regular public buses connect Barajas Airport with bus and train terminals in Madrid.

ANNOUNCEMENTS

FIFTH INTERNATIONAL SYMPOSIUM ON PLATINUM AND OTHER METAL COORDINATION COMPOUNDS IN CANCER CHEMOTHERAPY

The University of Padua, Faculty of Pharmacy and Consiglio Nazionale delle Ricerche are organizing this Symposium which will be held at Hotel Sheraton Orologio, Abano Terme, Padua, Italy (29 June–2 July 1987).

Scientific program

The following provisional topics are expected:

Session A: Biochemistry of platinum complexes in cancer chemotherapy.

Session B: Pharmacological mechanisms of cisplatinum action.

Session C: Clinical applications of platinum complexes.

Session D: Advances in antitumor research with non-platinum complexes.

Session E: Development of new metal coordination compounds: synthesis and characterization.

Session F: Toxicology of metal coordination complexes as antitumor agents.

Presentation

The conference will have the following format:
(1) Plenary and session lectures.
(2) Regular papers.
(3) Poster sessions.

Language

The official language of the conference will be *English.*

Public information

The proceedings of the conference will be published in a special volume to appear after the closing of the Symposium by *Martinus Nijhoff, Boston.* A collection of abstracts will be circulated during the Symposium.

Registration fee

(1) Active participants: U.S. $270.
(2) Non-active participants: U.S. $100.

The registration fee for active participants will cover coffees and lunches throughout the Symposium, the social dinner, the sightseeing tour, and publication of the Volume of Proceedings.

The non-active participants will be offered the social dinner and the sightseeing tour to the countryside.

For further information contact: P. Uguagliati, Dipartamento Scienze Farmaceutiche, Via Marzolo, 5, 35131 Padua, Italy.

7th FECHEM CONFERENCE ON ORGANOMETALLIC CHEMISTRY

This Conference will be held in Toledo, Spain (31 August–5 September 1987).

Scope

The Conference will be concerned with all aspects of synthesis, structure and applications of organometallic compounds. The scientific programme will include invited plenary lectures and poster sessions.

The number of Conference participants will be limited according to FECHEM rules.

Location

The Conference will be held in Toledo which is easily accessible from Madrid (70 km) by bus or train. Regular public buses connect Barajas Airport with bus and train terminals in Madrid.

Accommodation

Student rooms will be available for triple, double or single occupancy at "Convento de S. Juan de la Penitencia" and "Castillo de S. Servando". Rooms will also be reserved at various hotels.

Fees

The price will be 30,000 Pes. including: registration, lodging in student rooms, meals and social activities.

Extra payment will be required for hotel lodging.

1. INTRODUCTION

The tetrahydroaluminate ion, AlH_4^-, has been used widely as a reducing agent in organic chemistry.[1–3] The Li^+ and Na^+ salts are the most common in use, but other ionic group I and II metal tetrahydroaluminates have been made.[4] Until recently there have been few examples of transition-metal aluminohydride† complexes reported in the literature, in contrast to the wide range of transition-metal borohydride complexes.[5] This is unexpected in light of the extensive use of $MAlH_4$ (M = Na or Li) in the synthesis of transition-metal hydrides,[6,7] e.g. eqns (1) and (2):

$$(\eta^5\text{-}C_5H_5)Ru(PPh_3)_2Cl \xrightarrow{LiAlH_4,\ Et_2O} (\eta^5\text{-}C_5H_5)Ru(PPh_3)_2H,^{8} \quad (1)$$

$$ReOCl_3(PPh_3)_2 \xrightarrow[MeOH]{LiAlH_4,\ thf} ReH_7(PPh_3)_2,^{9} \quad (2)$$

as well as their use as cocatalysts with early transition-metal halides and complex halides, in catalytic hydrogenation and in polymerization.[10,11]

This review reports recent advances in the field of covalent transition-metal aluminohydrides, and compares their structure and chemistry, where relevant, to that of analogous borohydride complexes.

2. RANGE OF ALUMINOHYDRIDE COMPLEXES

The majority of known transition-metal aluminohydride complexes (Table 1) are stabilized by tertiary phosphines (both uni- and bidentate) or by η^5-cyclopentdienyl ligands (including those with alkyl substituents). However, only a few metal aluminohydrides, $[M(AlH_4)_n]$, have been reported[12] and their structures have yet to be confirmed by X-ray crystallography.

* Author to whom correspondence should be addressed.

† The term aluminohydride has been adopted throughout this article so as to include all complexes with the $M(\mu\text{-}H)_2Al$ unit and not just those of AlH_4^-. Where aluminohydride complexes contain hydrides terminal to the metal, besides any bridges to aluminium, these are called alumino-polyhydrides.

[a] Cp = η^5-C_5H_5, Cp–Cp = $CH_2(\eta^5$-$C_5H_4)_2$, Cp* = η^5-C_5Me_5, Cp′ = η^5-C_5H_4Me, dmpe = 1,2,-bis(dimethylphosphino)ethane; tmeda = tetramethylethylenediamine.

[b] No structural data are implied by the given formula.

[c] The references chosen are those containing synthetic and spectroscopic details.

[d] Elemental analysis is assumed for all isolable products.

The complexes so far characterized are of the *d*-group transition elements but lanthanide and actinide complexes should be capable of existence.

3. SYNTHESIS OF ALUMINOHYDRIDE COMPLEXES

The synthesis of transition-metal aluminohydrides is most readily accomplished by the reaction of a metal halide complex with $LiAlH_4$ in ethers. Reduction of the metal may also occur as in eqn (3):

$$(\eta^5\text{-}C_5H_5)_2Nb(IV)Cl_2 \xrightarrow[Et_2O]{LiAlH_4} (\eta^5\text{-}C_5H_5)_2Nb(III)AlH_4.^{26} \quad (3)$$

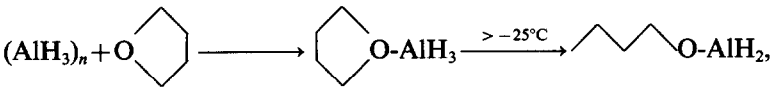
If the number of halides replaced is greater than one, and no reduction of the metal occurs then an aluminohydride, containing terminal metal hydrides, as well as those bridging to aluminium, may be formed [eqn (4)]:

$$(Me_3P)_4Ru(II)Cl_2 \xrightarrow[Et_2O]{LiAlH_4} [(Me_3P)_3HRu(II)(\mu\text{-}H)_2Al(H)(\mu\text{-}H)]_2.^{37} \quad (4)$$

In this case insoluble AlH_3 is formed along with LiCl as products.

The actual mechanism for the formation of co-ordinated AlH_4^- complexes may not be simply a substitution of halide for AlH_4^-. From calorimetric and ESR studies Bulychev *et al.*[17] have proposed a mechanism for the formation of $(\eta^5\text{-}C_5H_5)_2Ti(\mu\text{-}H)_2AlH_2$ from $(\eta^5\text{-}C_5H_5)_2TiCl_2$ which involves the formation of various species containing halides attached to the aluminium atom, e.g. $[(\eta^5\text{-}C_5H_5)_2Ti(\mu\text{-}H)_2AlHCl]_2$. Such species can be trapped by addition of MeCN and isolation of the resulting imine complex.[28]

The choice of solvent has been found to be very important in determining the final product. Thus reactions may proceed in thf but not in Et_2O [eqns (5) and (6)]:



$$(Me_3P)_4OsCl_2 \xrightarrow[Et_2O]{LiAlH_4} \quad (5)$$

$$(Me_3P)_4OsCl_2 \xrightarrow[thf]{LiAlH_4} [(Me_3P)_3HOs(AlH_4)]_2.^{37} \quad (6)$$

However, in certain cases the aluminohydride reacts with thf to produce bridging *n*-butoxo groups, contained in an $Al(\mu\text{-}OBu^n)_2Al$ unit [eqn (7)]:

$$[(Me_3P)_3H_3WAlH_4]_2 \xrightarrow{thf} [(Me_3P)_3H_3W(AlH_3OBu^n)]_2.^{32} \quad (7)$$

The interaction of AlH_3 with thf has been known for some time[39] [eqn (8)]:

(8)

and leads to a source of *n*-butoxo groups via ring cleavage.

The use of aluminium alkyl hydrides or alkoxyhydrides has also been successful in the formation of the $M(\mu\text{-}H)_2Al$ unit [eqns (9) and (10)]:

$$(\eta^5\text{-}C_5H_5)_2NbCl_2 \xrightarrow{LiAlH_2Et_2} (\eta^5\text{-}C_5H_5)_2NbH_2AlEt_2, \quad (9)$$

$$(dmpe)_2TaCl_2 \xrightarrow{LiAlH_2(OC_2H_4OMe)_2} [(dmpe)_2TaH_2Al(O(CH_2)_2OMe)_2]_2.^{27} \quad (10)$$

Where a suitable halide starting material is unavailable, the exchange of a BH_4^- group by an AlH_4^- group can lead to an aluminohydride [eqn (11)]:

$$(\eta^5\text{-}C_5Me_5)_2TiBH_4 \xrightarrow{LiAlH_4} [(\eta^5\text{-}C_5Me_5)_2TiAlH_4]_2.^{23} \quad (11)$$

Alternatively, instead of $LiAlH_4$, $(AlH_3)_n$ can be used with a metal halide to produce the

$M(\mu\text{-}H)_2Al$ unit [eqn (12)]:

$$(\eta^5\text{-}C_5H_5)_2TiCl_2 \xrightarrow[Et_2O]{AlH_3} (\eta^5\text{-}C_5H_5)_2Ti(\mu\text{-}H)_2AlCl_2 \cdot OEt_2.^{18} \quad (12)$$

Recently, borohydrides have been synthesized by the addition to metal polyhydrides of BH_3.[40] Although no "AlH_4^-" complexes have been made by this route,[30] several $M(\mu\text{-}H)_nAlMe_2$ complexes have been synthesized from the addition of $AlMe_3$ to rhenium polyhydrides[36] [eqn (13)]:

$$(Me_2PhP)_2ReH_7 + AlMe_3 \longrightarrow (Me_2PhP)_2H_4Re(\mu\text{-}H)_2AlMe_2 + CH_4.^{36} \quad (13)$$

Hydrolysis of these aluminohydrides results in the formation of the original polyhydride. It may be possible to use AlH_3 to produce an aluminohydride from easily obtainable polyhydrides.

Trialkylaluminium compounds are well known as Lewis acids,[42] and will coordinate with donors such as amines, phosphines, ethers and thioethers.[42] Similarly, the Lewis case nature of certain metal hydrides facilitates the synthesis of a series of aluminohydrides[30,31] [eqn (14)]:

$$(\eta^5\text{-}C_5H_5)_2WH_2 + AlMe_3 \longrightarrow [(\eta^5\text{-}C_5H_5)_2W(\mu\text{-}H)_2AlMe_3]. \quad (14)$$

As with borohydrides, the stability of aluminohydrides with respect to thermal decomposition is most likely both thermodynamic and kinetic. This includes the stability of the complex with respect to a metal hydride and aluminium trihydride,† i.e. eqn (15):

$$M^{n+}AlH_4^- \longrightarrow M^{n+}H^- + AlH_3. \quad (15)$$

Bulky or chelating ligands may be used to impede the decomposition process.[38]

4. VIBRATIONAL SPECTROSCOPY

IR and Raman spectroscopy have been widely used in the assignment of the structure of many transition-metal borohydrides.[5]

For aluminohydrides it is more difficult to assign the IR bands due to hydride-containing ligands because of serious overlapping of different stretches. In general, for terminal transition-metal hydrides ν(M—H) appear in the range 1500–2100 cm^{-1},[7] whilst bridging hydrides are in the 1550–1650 cm^{-1} range (M—H—M).

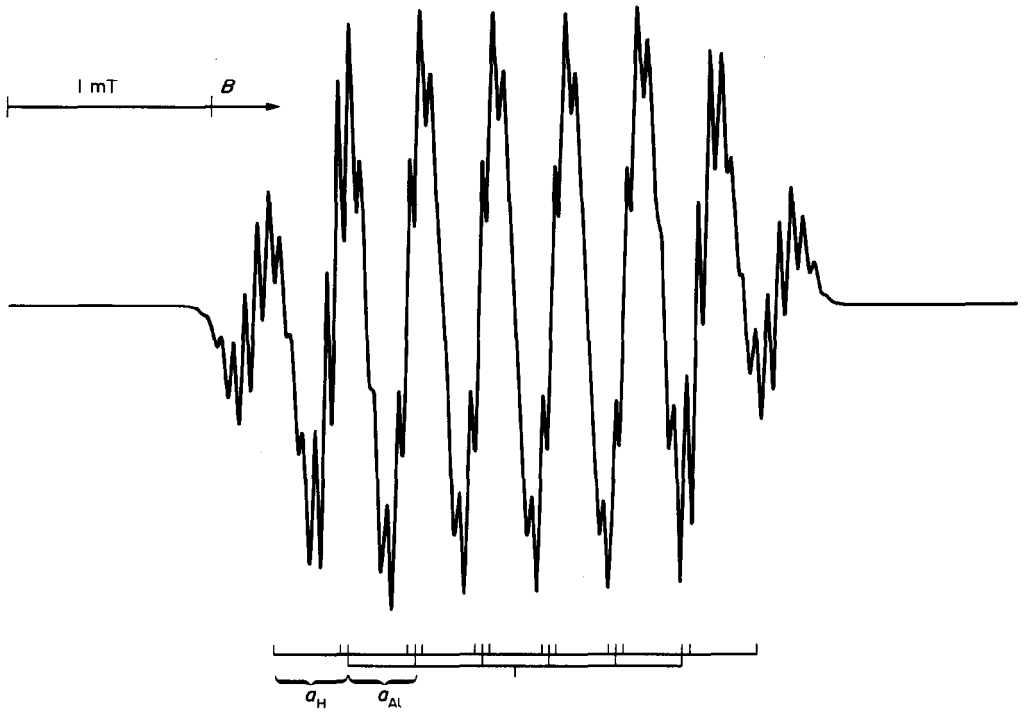
Terminal Al—H stretches can vary in position, 1700–1850 cm^{-1} [ν(Al—H)] being common.[19] Bridging $M(\mu\text{-}H)Al$ stretching frequencies depend on the transition metal present, and, because of this, the values quoted in the literature vary widely from *ca* 1200 cm^{-1}[19] to as high as *ca* 1800 cm^{-1}.[36] It has also been noted[19] that more than one stretch is associated with the $Ti(\mu\text{-}H)_2Al$ unit, e.g. $[(\eta^5\text{-}C_5H_5)_2Ti(\mu\text{-}H)_2AlHCl \cdot Et_2O]$[19] {1150 and 1250 cm^{-1} [$\nu(TiH_2Al)$], and 1340 sh and 1470 sh cm^{-1} [ν(TiHAl)]}. Even in complexes containing only bridging $M(\mu\text{-}H)Al$ hydrides more than one peak has been observed, e.g. in $[(dmpe)_2Ta(\mu\text{-}H)_2Al(OC_2H_4OMe)(\mu\text{-}OC_2H_4OMe)]_2$[27] (1605 and 1646 cm^{-1}). The reason for the multiplicity of bridging hydride stretches may be allied to the asymmetrical nature of the hydride bridge, as found by X-ray crystallography (Section 8).

The IR spectrum is thus very difficult to assign, although the hydride envelope is very characteristic compared with metal hydrides.[6] For the present, IR spectra must be used in conjunction with other techniques to assign the structure of many aluminohydrides.

5. ESR STUDIES

The majority of known aluminohydrides are diamagnetic, making NMR spectroscopy (where solubility and stability permits) the most convenient method of study (see Section 6). However, the most widely studied system has been the paramagnetic titanium(III) species obtained from the reaction of $[(\eta^5\text{-}C_5H_5)_2TiCl]_2$ with $LiAlH_4$.[17,42]

† The reaction of $(dmpe)_2FeCl_2$ with two equivalents of $LiAlH_4$ in Et_2O results, at low temperature, in a yellow aluminohydride, characterized by its IR spectrum, but on warming the solution becomes colourless and only the dihydride $(dmpe)_2FeH_2$ can be isolated.[28]



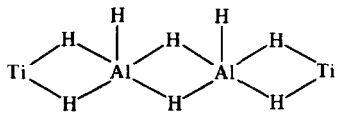


Fig. 1. Computer-simulated ESR spectrum of $(\eta^5\text{-}C_5H_5)_2Ti(AlH_4)$ (using data obtained from Ref. 44) $a_{Al} = 0.36$ mT, $a_H = 0.40$ mT, and $a_{H(Cp)} = 0.056$ mT.

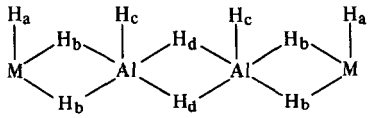
Early studies on what was considered to be $(\eta^5\text{-}C_5H_5)_2TiAlH_4$ showed a single signal ($g = 1.979$) coupled to the ^{27}Al nucleus ($I = \frac{5}{2}$)[43] with the hyperfine coupling due to two protons just discernable as 1:2:1 triplets. High-resolution spectra showed this coupling clearly (Fig. 1), as well as super-hyperfine splitting due to interaction with the nuclear spins of the cyclopentadienyl protons.[44,45]

ESR has also been used as a probe in the study of unisolable intermediates in the formation of $(\eta^5\text{-}C_5H_5)_2TiAlH_4$.[42,46]

On isotopic substitution of H by D there is a broadening in the spectra at room temperature;[45] however, no explanation was given. In the light of recent X-ray crystallographic studies[23,32,35] it is reasonable to propose a dimeric structure containing a bridging $Ti(\mu\text{-}H)_2Al(H)(\mu\text{-}H)_2Al(H)(\mu\text{-}H)_2Ti$ unit (**1**)



1

A distorted trigonal bipyramidal geometry around the aluminium is most probable (see Section 8), with one bridging $Ti(\mu\text{-}H)Al$ hydride axial and the other equatorial.[23,32,35] At room temperature the bridging $Al(\mu\text{-}H)Al$ and terminal Al—H hydrides would be fluxional[33] (see Section 7). This exchange process would alter the bridging $Ti(\mu\text{-}H)Al$ environments from axial to equatorial, and vice versa. In a given conformation the coupling constants due to the $Ti(\mu\text{-}H)Al$ hydrides would not be identical ($a_{Heq} \neq a_{Hax}$). On passing to the other conformations these coupling constants would be exchanged. Such a process would obviously be affected by replacement of hydrogen by deuterium and result in a broadening of the signal, as is observed.[43]

ESR has been useful in studying some unisolable aluminohydride complexes such as $\{(n\text{-}C_4H_9)_3P\}_2Ni(\mu\text{-}H)_2Al(C_2H_5)_2$,[38] whose structure has been proposed on the basis of the observed spectrum.

6. NMR SPECTROSCOPY

Transition-metal hydride resonances in the hydride region normally lie to high field of Me_4Si (δ 0 to -30 ppm). This has been attributed to strong shielding of the ^1H nuclear by *d*-electrons of the metal.[47] In aluminohydrides the terminal M—H_a resonances, where present (for labelling see **2**) do indeed appear to be in this region, as do the bridging M(μ-H_b)Al resonances (Fig. 2).

2

The latter appear upfield of the former. The shift in general is dependent on the number of transition-metal *d*-electrons (the greater the number the higher field the signal).

Where aluminohydrides contain phosphorus donor ligands the hydride signal is spin–spin coupled to the ^{31}P nucleus. Since these compounds are generally non-rigid at room temperature (see Section 7) a binomial multiplet of $n+1$ lines, due to n phosphines bound to the metal, results.

Any terminal Al—H_c and Al(μ-H_d)Al resonances present appear at δ 4–6 ppm as a very broad singlets (Fig. 2), sometimes the line width is such that the signals may be lost in the base line.[26] The broadening of all hydride peaks is most probably ascribed to the large quadrupole moment of ^{27}Al.

The fluctional behaviour of the hydrides will be discussed later (Section 7).

NMR spectroscopy also makes it possible to determine the hydride multiplicity in an aluminohydride where there are terminal metal hydrides present, i.e. alumino-polyhydrides. Two general methods can be used. It is possible to integrate and compare the area of the hydride resonance with that of the ligand protons. However, there are two drawbacks to this method: (1) the relaxation time of the hydride may be different from those of the ligand protons, thus reducing the accuracy of the integration; and (2) the aluminohydride may be hydrolysed by any residual moisture in the deuterated solvent to give a polyhydride [see Section 9(ii)]. Although the M—H signal will be at a different shift from that in the aluminohydride, the signal due to the ligand will not vary greatly, thus making the integration difficult to measure accurately.

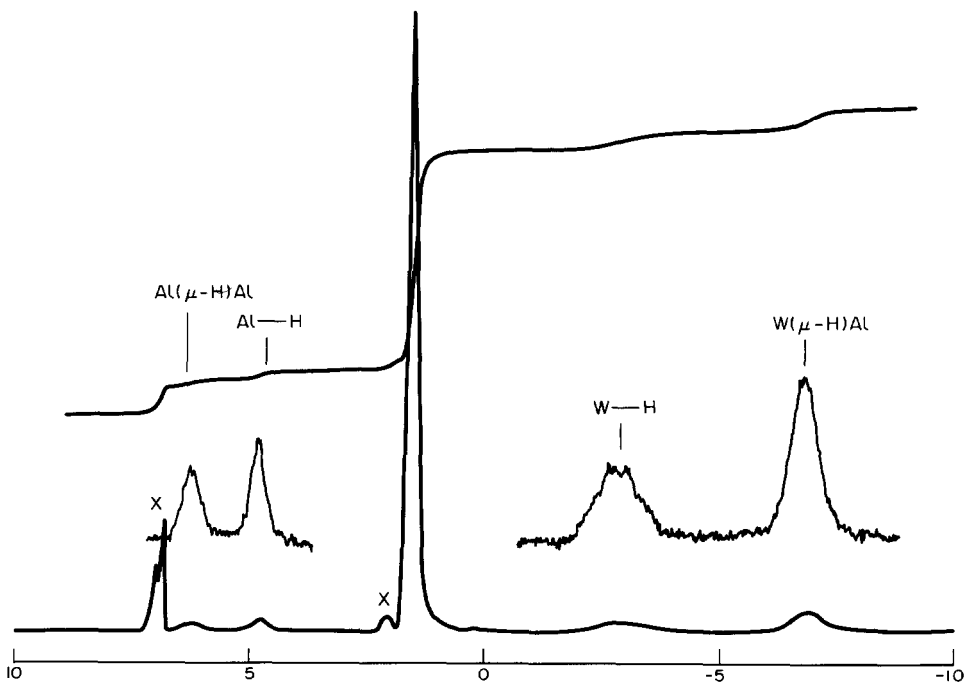


Fig. 2. ^1H NMR spectrum (203 K) of $[(Me_3P)_3H_3W(\mu\text{-}H)_2Al(H)(\mu\text{-}H)]_2$. X denotes peak due to the solvent, d^8-toluene.

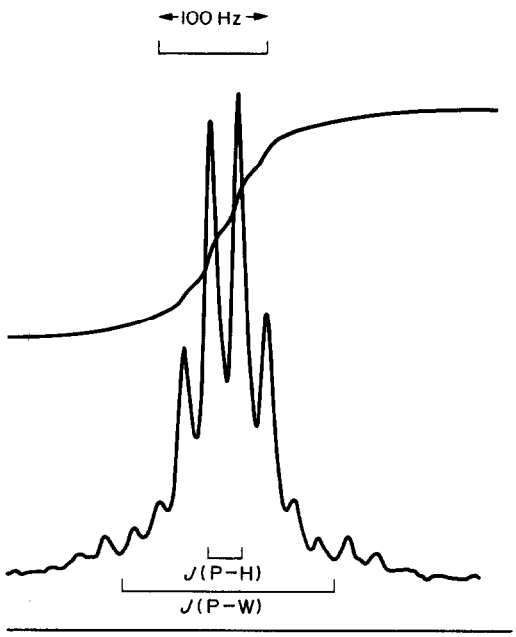

Fig. 3. ^{31}P NMR spectrum of $[(Me_3P)_3H_3W(\mu\text{-}H)_2Al(H)(\mu\text{-}H)]_2$ with only the phosphine P—$C\underline{H}_3$ protons decoupled. J(P–H) = 25.4 Hz, and J(P–W) = 199.4 Hz.

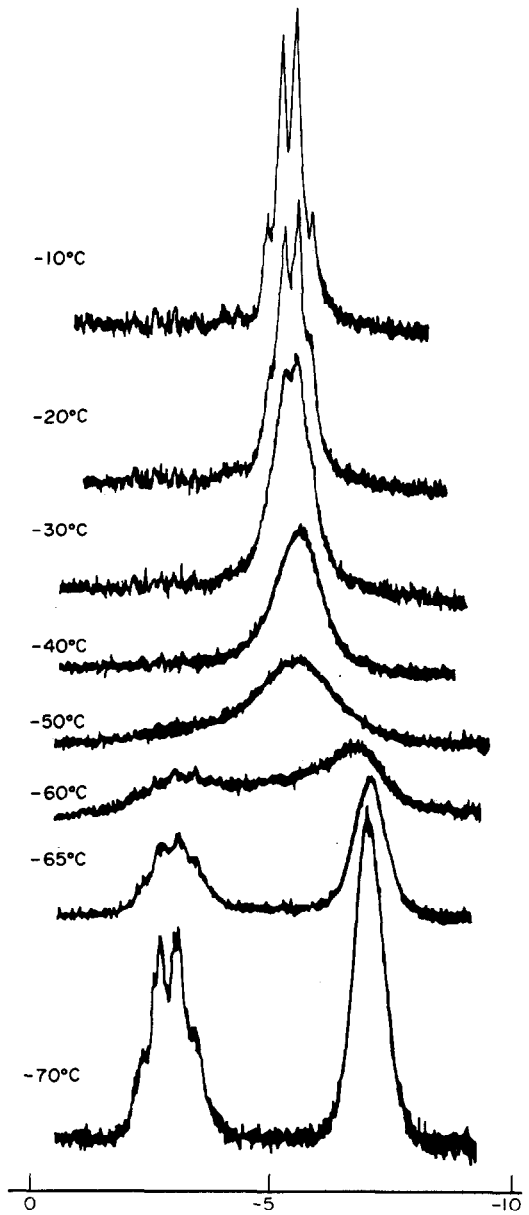
When phosphorus donors are present, the ^{31}P NMR spectrum is a more reliable method for the determination of hydride multiplicity. On selective decoupling the phosphine protons only the M—H and M(μ-H)Al hydrides will interact with the phosphorus nuclei, thus giving a multplet of $n+1$ lines (for n hydrides) (Fig. 3). This is in contrast to borohydrides where no coupling is observed for the bridging M(μ-H)B hydrides. The multiplet may not in fact be binomial, depending on the stereochemistry of the metal and its fluxional behaviour.[37]

A further tool in the structural characterization of aluminohydrides has been the use of ^{27}Al NMR spectroscopy. Although ^{27}Al possesses a large quadrupole moment[48] narrow lines in the NMR spectra can be obtained. The line width depends on the geometry of the substituents around the aluminium nucleus. X-ray crystallography indicates that the aluminium centres have a five-coordinate distorted trigonal bipyramidal geometry.[23,33] Given the low symmetry, large line widths would be expected and are indeed found.[32,37] Only relatively few five-coordinate aluminium species are known; of these a series of alkoxy-aluminium compounds have ^{27}Al NMR spectra[47] of comparable position and line width. All the complexes so far studied have given broad singlets in the region 50–70 ppm with line widths of 4000–5000 Hz. It is interesting to note that the AlH_5^- complexes such as $[(Me_3P)_3H_3W]_2AlH_5$[33] have similar positions and line widths, suggesting that the aluminiums in the M(μ-H)$_2$Al(H)(μ-H)$_2$Al(H)(μ-H)$_2$M unit do not interact with each other's quadrupole moment.

7. FLUXIONAL BEHAVIOUR

The fluxional behaviour of transition-metal borohydrides has been well studied by NMR spectroscopy.[5] At room temperature the bridging M(μ-H)B and terminal B—H hydrides commonly undergo rapid intramolecular exchange, but seldom undergo exchange with any transition-metal terminal M—H hydrides that may also be present in the molecules. Exchange has been observed, but only at elevated temperature, e.g. in $RuH(BH_4)(PMe_3)_3$[50] and $OsH_3(BH_4)(PR_3)_2$ (R = c-C_5H_9).[51]

By contrast the terminal M—H_a and bridging M(μ-H_b)Al hydrogen atoms (see **2** for labelling) in aluminohydrides undergo exchange at room temperature. Using NMR spectroscopy this exchange can be studied (Fig. 4). From the low-temperature NMR data the activation energy can be calculated[32,37] the magnitude of which is dependent upon the environment around the metal centre[32] and whether any rearrangement of the ancillary ligands is required.[37] A *fac* arrangement around the



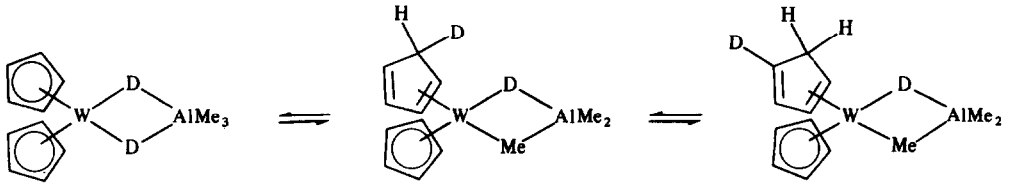


Fig. 4. Variable-temperature ^{1}H NMR spectra of $[(Me_3P)_3W(\mu\text{-}H)_2AlH(\mu\text{-}OBu^n)]_2$ over the region 0 to -10 ppm vs Me_4Si in d^8-toluene solvent.[52]

transition metal, as in *fac*-$[(Me_3P)_3HRu(\mu\text{-}H)_2Al(H)(\mu\text{-}H)]_2$,[37] allows for a very labile M—H_a and M(μ-H_b)Al exchange, which appears equally rapid in complexes with bulkier phosphines.[37] A consequence of this is that the aluminohydride may adopt a different stereochemistry around the metal, in contrast to the analogous borohydride[29,37] so as to accommodate this exchange process.

The dimeric nature of most aluminohydrides allows for an exchange between terminal Al—H_c and bridging Al(μ-H_d)Al hydrides (no analogous exchange in borohydrides has been reported). The activation energy of this exchange process (*ca* 50 kJ mol^{-1}) appears to be independent of the sterochemistry around the metal and is readily stopped at low temperature. As yet no mechanism has been proposed.

Where cyclopentadienyl ligands are used to stabilize aluminohydrides a third type of exchange is observed. That is, between the bridging M(μ-H)Al and cyclopentadienyl ring hydrides. A study of the deuterated complexes show that isotopic scrambling occurs.[26,28] Bruno *et al.*[31] have proposed a

mechanism involving hydride transfer from the metal to the cyclopentadienyl ring [eqn (16)]:

(16)

However, the analogous exchange observed in $(\eta^5\text{-}C_5H_5)_2M(BH_4)$ complexes[53] suggests that a hydrogen is transferred from the ring to the transition metal and from there onto the boron.

NMR experiments involving line broadening have been used to estimate the energy and rate of the exchange for borohydrides. However, no line broadening is observed in the complexes $(\eta^5\text{-}C_5H_5)_2NbAlD_4$[26]† and $[(\eta^5\text{-}C_5H_4Me)_2Ta(\mu\text{-}D)_2Al(D)(\mu\text{-}D)]_2$,[28] although it has been noted that thf slows the rate of exchange, perhaps by blocking the vacant sites on the aluminium or metal.

8. X-RAY STRUCTURAL STUDIES OF METAL ALUMINOHYDRIDES

A knowledge of the structure and configuration of a series of compounds contributes immensely to an understanding of their physical and chemical properties. Unfortunately for transition-metal aluminohydrides and hydrides in general, the most common solid-state structural technique, single-crystal X-ray diffraction, may not allow hydrogen atoms to be accurately located except in special cases. This is because the magnitude of X-ray scattering is approximately proportional to the square of the atomic number of the atoms in the compound.

Whereas borohydrides have been studied by a variety of structural techniques, including gas-phase electron diffraction,[54] single-crystal neutron diffraction,[55] broad-line nuclear magnetic resonance,[56] as well as X-ray diffraction.

The study of aluminohydrides, which are not volatile, has so far been confined to X-ray diffraction. The crystal structure of $LiAlH_4$, as determined by X-ray diffraction,[57] shows the aluminium to be four-coordinate with a tetrahedral arrangement of four hydrides (Fig. 5). These hydrides can be divided into two types μ_2- (bridging one lithium and one aluminium) and μ_3-

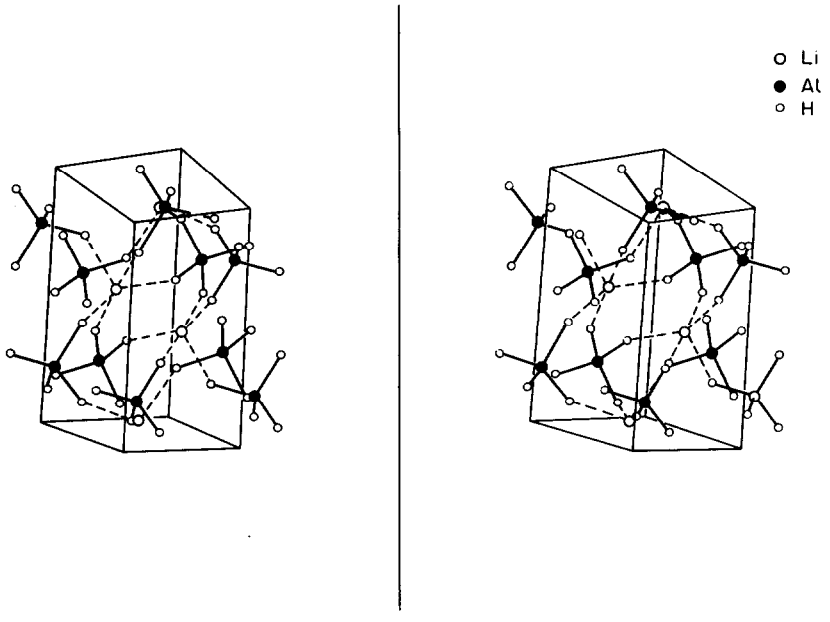

Fig. 5. Stereo pair view (*ca* along *c*) of unit cell of $LiAlH_4$: *a*-axis horizontal and *b*-axis vertical. The μ_3-hydrides are on the *b*- and *c*-faces (coordinates obtained from Ref. 57).

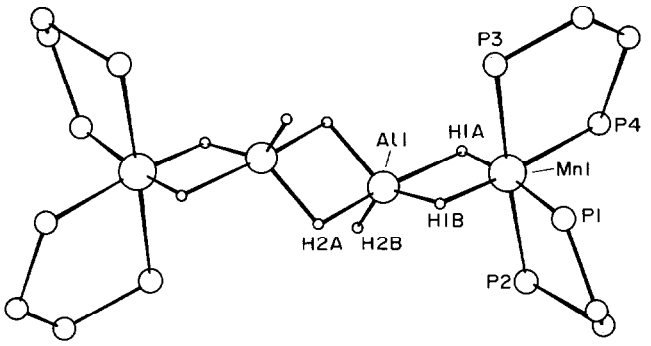
† Although this complex was formulated[26] from ^1H NMR spectroscopy to be monomeric it is undoubtedly isostructural with the dimeric tantalum complex.[28]



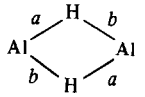


Fig. 6. Structure of $[(dmpe)_2Mn(\mu\text{-}H)_2Al(H)(\mu\text{-}H)]_2$. The methyl groups and methylene protons have been omitted for clarity (coordinates obtained from Ref. 35).

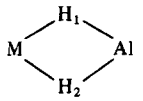
(bridging two lithiums and one aluminium). The Al—H bond distances vary between 1.516(27) and 1.578(26) Å.

The tetrahedral geometry around boron, as present in KBH_4,[58] is maintained throughout transition-metal borohydride chemistry. This does not, however, appear to be the case for aluminohydrides where a four-coordinate complex is the exception.



The first tetrahydridoaluminate complex to be crystallographically characterized, $[(dmpe)_2Mn(\mu\text{-}H)_2Al(H)(\mu\text{-}H)]_2$,[34,35] was found to be a centrosymmetric dimer containing a $Mn(\mu\text{-}H)_2AlH(\mu\text{-}H)_2Al(H)(\mu\text{-}H)_2M_2$ core (Fig. 6). The aluminium atoms adopt distorted trigonal bipyramidal geometries, with one bridging $Al(\mu\text{-}H)Al$ and one bridging $Mn(\mu\text{-}H)Al$ hydride occupying the axial positions around each aluminium. The Mn—H distances in the $Mn(\mu\text{-}H)_2Al$ unit are equal, and shorter than the two Al—H distances. The central $Al(\mu\text{-}H)_2Al$ unit is assymetric with the long and short distances differing by about 0.3 Å (**3**)

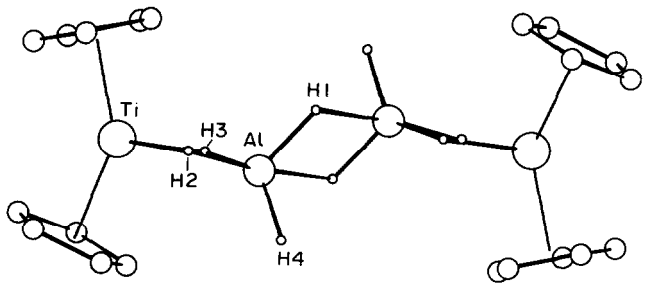
3

	a (Å)	*b* (Å)
$[(dmpe)_2Mn(\mu\text{-}H)_2Al(H)(\mu\text{-}H)]_2$	1.510(30)	1.804(28)
$[(C_5Me_5)_2Ti(\mu\text{-}H)_2Al(H)(\mu\text{-}H)]_2$	1.56(1)	1.94(1)

The asymmetry of the $Al(\mu\text{-}H)_2Al$ unit has also been observed in the complex $[(\eta^5\text{-}C_5Me_5)_2Ti(\mu\text{-}H)_2Al(H)(\mu\text{-}H)]_2$.[23] The coordination geometry around the aluminium is again distorted trigonal bipyramidal (Fig. 7). However, unlike the manganese complex the $Ti(\mu\text{-}H)_2Al$ unit is asymmetric (**4**) with one hydrogen nearer the aluminium than the other. As with the majority of bis-η^5-cyclopentadienyl complexes of titanium, the geometry is pseudo tetrahedral, with the aluminium atom located on the C_2-axis of the "sandwich".

4

	M—H_1 (Å)	M—H_2 (Å)	Al—H_1 (Å)	Al—H_2 (Å)
$[(C_5Me_5)_2Ti(\mu\text{-}H)_2Al(H)(\mu\text{-}H)]_2$	1.92(1)	1.86(1)	1.63(1)	1.70(1)
$[(Me_3P)_3H_3W]_2AlH_5$	1.771(61)	1.653(82)	2.020(61)	1.802(80)



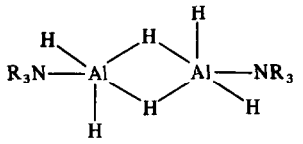


Fig. 7. Molecular structure of $[(\eta^5\text{-}C_5Me_5)_2Ti(\mu\text{-}H)_2Al(H)(\mu\text{-}H)]_2$ using the atom coordinates of Ref. 23. The methyl groups have been omitted for clarity.

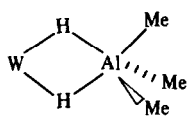
The bridging $M(\mu\text{-}H)_2Al(H)(\mu\text{-}H)_2Al(H)(\mu\text{-}H)_2M$ unit found in these compounds is similar to those proposed for the amine adducts of AlH_3[59] (**5**), and appears to be a common feature of aluminohydride complexes.[29,37]



5

When a chelating amine such as tetramethylethylenediamine (tmeda) forms adducts with AlH_3 an infinite chain structure is found to be of preference,[60] each "link" consisting of an $-\{AlH_3(tmeda)\}-$ unit. Bulychev *et al.*[21] have reported the X-ray crystal structure of the complex $[(\eta^5\text{-}C_5H_5)_2Ti(\mu\text{-}H)_2AlH_2]_2 \cdot \mu\text{-tmeda}$ (Fig. 8), where two $(\eta^5\text{-}C_5H_5)_2TiH_2AlH_2$ moieties are bonded via a bidentate tmeda ligand by donor–acceptor N–Al bonds. The coordination polyhedron at the aluminium is distorted trigonal bipyramidal with the nitrogen and one of the bridging $Ti(\mu\text{-}H)Al$ hydrides occupy axial positions on each aluminium.

The similarity of these transition-metal aluminohydrides to alanes suggests that, whereas it is correct to consider transition-metal borohydrides as consisting of L_nM^+ and BH_4^- moieties, similar models for aluminium analogues are not as accurate. It may be wiser to consider the complexes as being derived from a donor–acceptor complex of $L_nM\text{-}H$ and AlH_3, rather than L_nM^+ and AlH_4^-.

This Lewis acid–base representation is substantiated by the complex $(\eta^5\text{-}C_5H_5)_2W(\mu\text{-}H)_2AlMe_3$,[31] whose structure consists of the basic $(\eta^5\text{-}C_5H_5)_2WH_2$ unit coordinating to the Lewis acid $AlMe_3$ (**6**)

6

Dimers may also be formed with bridging alkoxides, in an $Al(\mu\text{-}OR)_2Al$ unit. The complex $[(dmpe)_2Ta(\mu\text{-}H)_2Al(OC_2H_4OMe)(\mu\text{-}OC_2H_4OMe)]_2$[27] contains both terminal Al–OR and bridging $Al(\mu\text{-}$

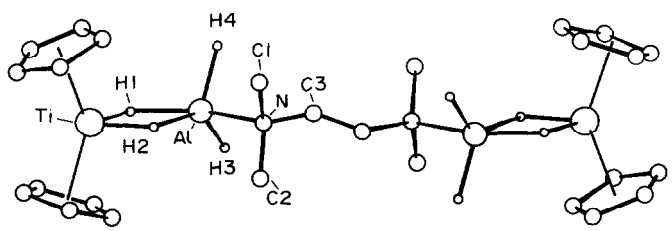


Fig. 8. Molecular structure of $[(\eta^5\text{-}C_5H_5)_2Ti(\mu\text{-}H)_2AlH_2]_2 \cdot$ tmeda. The organic H atoms have been omitted for clarity (coordinates from Ref. 21).

OR)Al groups (R = CH_2CH_2OMe). Interestingly the Ta atom adopts a distorted square-based pyramidal coordination with the four phosphorus atoms forming the basal plane while a $(\mu\text{-H})_2Al$ unit occupies the apex. This is in contrast to the closely related manganese complex, $[(dmpe)_2Mn(\mu\text{-H})_2Al(H)(\mu\text{-H})]_2$,[34,35] where the stereochemistry around the manganese is octahedral. The angle between the normal to the P_4 plane and the Ta–Al vector is 16.1°, suggesting that the $Ta(\mu\text{-H})_2Al$ unit is not planar as is the case for the manganese[35] and titanium[23] complexes. Steric factors could account for the change in stereochemistry. Certainly, steric hindrance caused by bridging *n*-butoxide groups in the complex $[(Me_3P)_3H_3W(\mu\text{-H})_2Al(H)(\mu\text{-OBu}^n)]_2$[32] is the probable reason for the adoption of a pseudo *cis* geometry, as opposed to the *trans* geometry found in other complexes[23,34] (**7**):

7

Compounds with alkyl groups on the aluminium do not show any ability to dimerize and remain as monomers. The X-ray crystal structure of $(MePh_2P)_2H_4Re(\mu\text{-H})_2AlMe_2$[36] has been determined and reveals a planar P_2ReAl (Fig. 9) framework with vertical (non-crystallographic) C_2-symmetry. The aluminium atom lies on the C_2-axis, similar to that found in $[(\eta^5\text{-}C_5Me_5)_2Ti(\mu\text{-H})_2Al(H)(\mu\text{-H})]_2$.[23] Of the six metal-bound hydrogen atoms found, two are unequivocally terminal to rhenium, and the remaining four hydrides are in the Re... Al internuclear region. However, these four can be subdivided into two pairs, two with short distances to Al [1.79(8) and 2.02(12) Å], and the other two with long non-bonding distances to Al [2.50(8) and 2.22(9) Å]. The latter are comparable to the non-bonding distance between the aluminium and the hydrogen atom in the $AlMe_2$ group [2.63(23)–2.62(14) Å].

From this result it is proposed that the aluminium is bound to the rhenium by two bridging hydrides. The aluminium adopts a tetrahedral geometry, with the MeAlMe plane being close to perpendicular (98.2°) to the H–Re–H plane.

In the closely related complex $[(Ph_2MeP)_3HRe(\mu\text{-H})_3AlMe_2]$[36] the aluminium is five-coordinate with three bridging $Re(\mu\text{-H})Al$ hydrides (Fig. 10) off-set from the Re... Al vector. The $Re(\mu\text{-H})_3Al$ bridge is entirely asymmetric with one hydride being equidistant from the aluminium and rhenium [Re—H = 1.73(5) Å, Al—H = 1.76(5) Å] atoms, the others being closer to the rhenium (Re—H_{av} = 1.54 Å, Al—H_{av} = 2.02 Å).

All the structures so far discussed have a transition metal/aluminium ratio of 1. However, the complex $[(Me_3P)_3H_3W(\mu\text{-H})_2Al(H)(\mu\text{-H})_2WH_3(PMe_3)_3]$[33] contains two tungsten atoms, bridged by a single aluminium (Fig. 11), in what can be regarded as a bis-adduct of the Lewis acid AlH_3 with $WH_4(PMe_3)_3$, or with equal validity two $[WH_3(PMe_3)_3]^-$ units joined by a bridging AlH_5^- unit. The asymmetric $W(\mu\text{-H})_2Al$ units (**4**) are near to being planar whilst the geometry around the aluminium approximates quite well to a trigonal bipyramid.

It is likely that the third hydride bridge occurs in order to enable the aluminium to become pentacoordinate. However, the complex $(Me_3P)_3H_2W(\mu\text{-H})_3AlCl_2(NMe_3)$[28] contains a symmetrical $(\mu\text{-H})_3$ bridge (see **8**) but here the aluminium is six-coordinate octahedral, no doubt a reflection of the greater electron-withdrawing effect of the two chlorides.

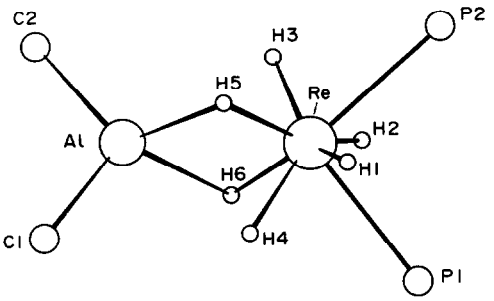

Fig. 9. Molecular structure of $(Ph_2Me)_2H_4Re(\mu\text{-H})_2AlMe_2$ using the atomic coordinates of Ref. 36. The methyl H atoms, as well as the organic groups attached to phosphorus, have been omitted for clarity.

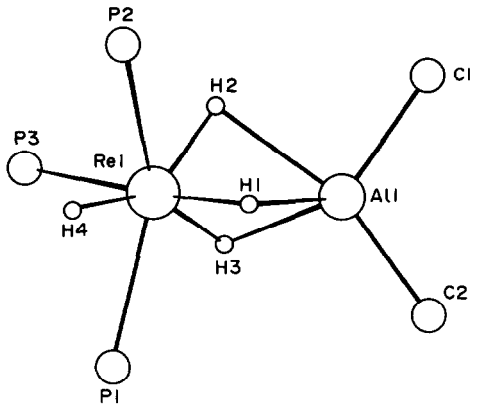

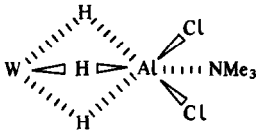

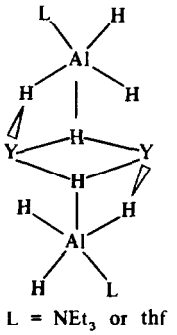

Fig. 10. Molecular structure of $(Ph_2MeP)_3HRe(\mu\text{-}H)_3AlMe_2$ (atomic coordinates from Ref. 36). Methyl hydrogens and organic groups attached to phosphorus have been omitted.

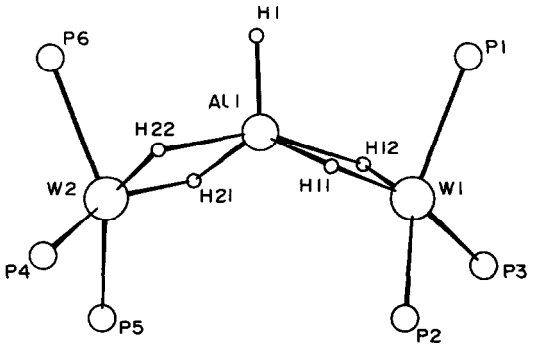
8

A complex with a similar bridge $[(\eta^5\text{-}C_5Me_5)_2Ti(\mu\text{-}H)_2Al(H)(\mu\text{-}H)_2Ti(\eta^5\text{-}C_5Me_5)_2]$[23] has also been reported.

A series of aluminohydride complexes of yttrium,[13,14] $\{[(\eta^5\text{-}C_5H_5)_2Y(\mu_3\text{-}H)][(\mu\text{-}H)AlH_2L]\}_2$ (L = thf or NEt_3) have been synthesized and their structures solved by X-ray crystallography (**9**).

9

These compounds were reported to be "the first representatives of aluminium hydride compounds involving three-coordinate hydrogen atoms". However, it should be noted that similar bridging hydrides have been found in $LiAlH_4$ (Fig. 5). Each $(\eta^5\text{-}C_5H_5)_2Y$ sandwich is bridged by two μ_3-hydrides to two aluminiums. Each aluminium is linked to one of the yttriums by a μ_2-hydride. The yttrium and aluminium atoms are coplanar, along the bisecting plane of the $(\eta^5\text{-}C_5H_5)_2Y$ wedge.



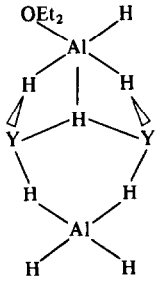


Fig. 11. Structure of $[(Me_3P)_3H_3W]_2AlH_5$. Only the hydrogens attached to Al (terminal and bridging) have been located with reasonable certainty.

As is common, the aluminium is a distorted trigonal bipyramid, with the axial position occupied by the solvent molecule and the μ_3-hydride.

The monosolvated complex $[(\eta^5\text{-}C_5H_5)_2YAlH_4]_2 \cdot OEt_2$[13] is of interest because it contains both four- and five-coordinated aluminiums (**10**). The four-coordinate geometry is a distorted tetrahedron with two of the hydrides bridging to different yttriums. The five-coordinate aluminium exists as the expected trigonal bipyramidal geometry.

10

These yttrium complexes are best considered as alane adducts of $[(\eta^5\text{-}C_5H_5)_2Y(\mu\text{-}H)]_2$. This representation is supported by the formation of an alane adduct of $[(\eta^5\text{-}C_5H_5)_2Y(\mu\text{-}Cl)]_2$[61] containing $Y(\mu\text{-}H)Al$ bridges linking alternate aluminium and yttrium fragments in an infinite chain.

The structural properties of aluminohydrides thus differ substantially from those of analogous borohydrides in several ways; whereas borohydrides are four-coordinate and tetrahedral, the majority of aluminohydrides are five-coordinate with trigonal bipyramidal aluminium. This ability of aluminium to become five-coordinate most probably arises from hybridization, involving one of the low lying 3*d* orbitals, along with the 3*s* and 3*p* orbitals. To achieve five-coordination the aluminohydrides are required to form dimers with a metal/aluminium ratio of either 1 or 2.

Borohydrides have been found to have a variety of bridges $[M(\mu\text{-}H)_nB$ ($n = 1$, 2 or 3)], but aluminohydrides are mainly bridged by two $M(\mu\text{-}H)Al$ units, even when "spare" terminal M—H hydrides are present.[32] The only case for three bridging hydrides is when the compound is precluded from forming a dimer by terminal alkyl groups.[36] The hydrides in the $M(\mu\text{-}H)_2Al$ bridge are asymmetric, reflecting the difference between axial and equatorial sites on the aluminium, as opposed to equivalent sides on the tetrahedral borohydrides.

9. REACTION CHEMISTRY OF ALUMINOHYDRIDES

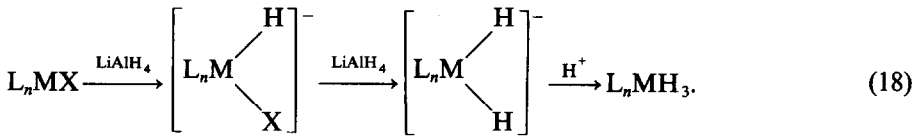
Although several trends can be found the study of the reactivity of transition-metal aluminohydrides is in its infancy.

(i) *Thermal degradation*

When the complex $[(\eta^5\text{-}C_5Me_5)_2Ti(\mu\text{-}H)_2AlH(\mu\text{-}H)]_2$[23] is stored for any length of time in solution decomposition occurs to give the complex $[(\eta^5\text{-}C_5Me_5)_2Ti]_2AlH_5$[23] along with aluminium and hydrogen. A similar reaction is observed when the complex $[(Me_3P)_3H_3W(\mu\text{-}H)_2Al(H)(\mu\text{-}H)]_2$ is refluxed in hexane for a few hours, the product being $[(Me_3P)_3H_3WAlH_5$.[32] The proposed mechanism for the decomposition of the titanium complex [eqn (17)] would seem to be stoichiometric:

$$[(\eta^5\text{-}C_5Me_5)_2Ti(\mu\text{-}H)_2Al(H)(\mu\text{-}H)]_2 \rightarrow [(\eta^5\text{-}C_5Me_5)_2Ti]_2AlH_5 + Al + \tfrac{3}{2}H_2. \quad (17)$$

However, NMR studies[28] of the decomposition of the tungsten compound indicate that the reaction is far more complicated.



If the unsubstituted cyclopentadienyl complex is used further decomposition occurs with recombination of basic hydride hydrogens and acidic protons of the Cp rings to give a polycyclic complex, $[(\eta^5\text{-}C_5H_5)_2Ti(\mu\text{-}H)_2Al(\mu\text{-}H)(\eta^1:\eta^5\text{-}C_5H_4)TiCp(\mu\text{-}H)]_2$,[22] whose structure has been found by X-ray crystallography.

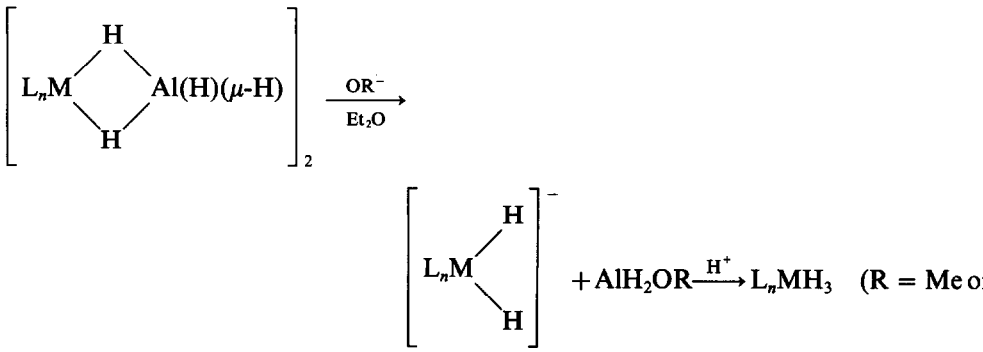
(ii) *Hydrolysis*

In general the aluminohydride complexes are moisture-sensitive, yielding on hydrolysis the

appropriate polyhydride.[29,32,36] Thus the addition of MeOH or H_2O to a diethyl ether solution of $[(dmpe)_2HCr(\mu\text{-}H)_2Al(H)(\mu\text{-}H)]_2$[29] yields the polyhydride $(dmpe)_2CrH_4$.[62]

$LiAlH_4$ has been widely used in the synthesis of transition-metal polyhydrides.[6] Often the formal oxidation state of the metal in the product is higher than in the starting material, usually a halide. That is, there is an apparent oxidation by what is normally regarded as a reducing agent. Davies *et al.*[63] attempted to explain this by the mechanism of eqn (18):

$$L_nMX \xrightarrow{LiAlH_4} \left[L_nM(H)(X)\right]^- \xrightarrow{LiAlH_4} \left[L_nM(H)_2\right]^- \xrightarrow{H^+} L_nMH_3. \quad (18)$$



However, in the light of hydrolysis studies on aluminohydrides,[29] is appears that these are, in fact, intermediates in the synthesis of polyhydrides as in eqn (19):

$$L_nMX \xrightarrow{LiAlH_4} [L_nM(\mu\text{-}H)_2Al(H)(\mu\text{-}H)]_2 \xrightarrow{H_2O} L_nMH_3. \quad (19)$$

The formation, prior to hydrolysis, of yellow solutions in the synthesis of $IrH_5(PR_3)_3$[64] and of orange solutions in the synthesis of $[(\eta^5\text{-}C_5H_4Me)_2TaH_3]$[65] have been noted but without comment on the possibility of intermediate aluminium-containing species. In some cases (e.g. the tantalum one) the oxidation state of the metal is the same both in the starting material and the product. Two possibilities can be considered: (a) direct attack of H^- on L_nMCl_m with no formation of an aluminohydride, or (b) reduction of the metal halide complex to give an aluminohydride followed by oxidation during hydrolysis. The reaction of $TaCl_5$ with two equivalents of LiC_5H_4Me followed by addition of three equivalents of $LiAlH_4$ yields $[(\eta^5\text{-}C_5H_4Me)_2Ta(III)(\mu\text{-}H)_5Al(H)(\mu\text{-}H)]_2$: hydrolysis of this complex then gives the trihydride.[28]

The actual mechanism for the hydrolysis of the aluminohydride is as yet not certain. Deuteration studies indicate that the $M(\mu\text{-}H)_2Al$ bridge is cleaved either symmetrically,[29,32] i.e. one hydride is retained on the transition metal and one on the aluminium, or asymmetrically,[26,28] i.e. both hydrides are retained on the transition metal.

The asymmetric cleavage may result from initial nucleophilic attack on the five-coordinate aluminium atom followed by protonation of the resulting hydrido anion [eqn (20)]:

$$\left[L_nM(H)_2Al(H)(\mu\text{-}H)\right]_2 \xrightarrow[Et_2O]{OR^-} \left[L_nM(H)_2\right]^- + AlH_2OR \xrightarrow{H^+} L_nMH_3 \quad (R = Me \text{ or } H). \quad (20)$$

(iii) *Reaction with Lewis bases*

There is a wide variety of aluminium–nitrogen complexes[41] formed via Lewis acid–base interactions. Whereas borohydrides readily react with simple trialkyl amines, NR_3, no such reaction has been observed for aluminohydrides.[27,28] However, if a chelating amine such as tmeda is used the reactivity is increased.

Addition to tmeda to a toluene solution of $[(\eta^5\text{-}C_5H_5)_2TiAlH_4]_n$ yields the bridged species $[(C_5H_5)_2TiAlH_4]_2\mu$-tmeda.[21] In other cases the insoluble adduct $(tmeda \cdot AlH_3)$ is produced along with an aluminohydride containing a single AlH_5^{2-}-bridge between two transition-metal units[32,37] [eqn(21)]:

$$[(Me_3P)_3HRu(\mu\text{-}H)_2Al(H)(\mu\text{-}H)]_2 \xrightarrow[Et_2O]{tmeda} [AlH_3 \cdot tmeda]_n + [(Me_3P)_3HRu]_2AlH_5.[38] \quad (21)$$

(iv) *Reaction with organo* C≡N *and* C=N *bonds*

The reduction of organic nitriles with $LiAlH_4$ has been widely used in organic synthesis.[66]

Interaction of MeCN with $[(Me_3P)_3H_3W(\mu\text{-}H)_2Al(H)(\mu\text{-}H)]_2$ yields the imine-bridged complex $[(Me_3P)_3H_3W(\mu\text{-}H)_2Al(H)(\mu\text{-}N{=}CH{-}Me)]_2$[28] containing a four-membered Al–N ring system. On hydrolysis acetaldehyde is liberated along with $(Me_3P)_3WH_6$.

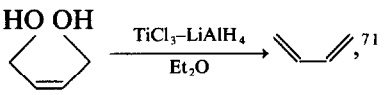
Interestingly, the complex $[(Me_3P)_3H_3W]_2AlH_5$ does not react with nitriles even at elevated temperatures, suggesting that it is the bridging $Al(\mu\text{-}H)Al$ hydrides that become incorporated into the imine.

The reaction of imines (R'N=CHR) with a WCl_6–$LiAlH_4$ mixture yields a mixture of tertiary and secondary amines,[67] but the authors have not considered an aluminohydride intermediate in the proposed mechanism.

(v) *Reaction with lithium alkyls*

Addition of alkyllithium reagents to $[(Me_3P)_3H_3W(\mu\text{-}H)_2Al(H)(\mu\text{-}H)]_2$ yields the polyhydride anion $\{[(Me_3P)_3WH_5]Li\}_4$.[68]

The aluminohydride acts in an analogous way to $AlH_3 \cdot NR_3$[69] [eqn (22)] with attack by the nucleophile at the unsaturated five-coordinate aluminium:



$$AlH_3 \cdot NR_3 + LiR \rightarrow AlH_2R \cdot NR_3 + LiH. \tag{22}$$

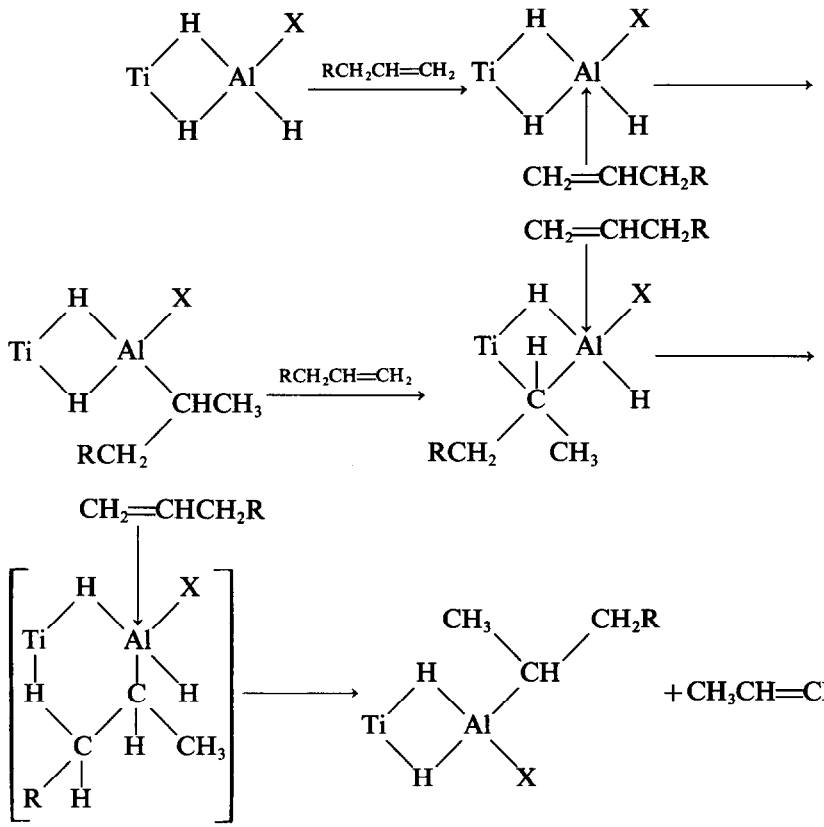
(vi) *Uses in catalysis*

Although so far studies on reactions of isolated aluminohydrides are few, their *in situ* use in catalytic systems has been known for some time.

Mixtures of titanium halides ($TiCl_4$ and $TiCl_3$) with aluminium hydride species have been successfully used as Ziegler–Natta catalysts in the polymerization of alkenes,[10,11] as well as in a range of other organic transformations [eqns (23) and (24)]:

$$2R_2C{=}O \xrightarrow[Et_2O]{TiCl_3\text{–}LiAlH_4} R_2C{=}CR_2,^{70} \tag{23}$$

,[71] (24)



although little is known of the exact nature of the catalytic intermediates.

Mixtures of $[(\eta^5\text{-}C_5H_5)TiCl]_2$ and $LiAlH_4$ have been used for a variety of catalytic processes. With a Ti/Al ratio of 1 [i.e. a complex formulated as "$Cp_2Ti(\mu\text{-}H)_2AlH_2$"] the maximum activity for the isomerization of α-olefins is observed and for which a mechanism involving the coordination of the olefin to the coordinatively unsaturated aluminium atom has been proposed[72] [eqn (25)].

It should be noted that all these studies *assume a monomeric structure*; however in the light of crystallographic results discussed above, the active species may be dimeric.[23] If this is the case the aluminium is still unsaturated (maximum coordination 6[41]) and so this mechanism is still feasible.

Using a Ti/Al ratio of 2[73] the catalytic system can be used to hydrogenate α-olefins as well as cyclohexene and benzene.[74] ESR data suggest that the reactive species is a complex of the formula $[(\eta^5\text{-}C_5H_5)_2Ti]_2AlH_4X$ (X = hal or H).[10] This has been confirmed by studying the catalytic and spectroscopic properties of the crystallographically characterized complex $[(\eta^5\text{-}C_5Me_5)_2Ti]_2AlH_5$.[23]

It should be noted that other aluminohydrides have shown little or no ability to act as catalysts.[27,28]

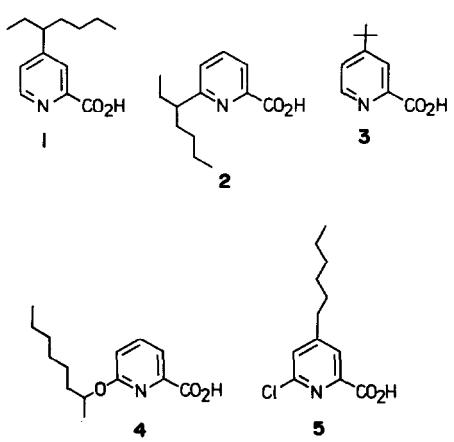
(*Received* 3 *October* 1985; *accepted* 11 *November* 1985)

Abstract—Alkyl-substituted pyridine-2-carboxylic acids have been found to be efficient reagents for the extraction of Cu^{2+}, Fe^{3+}, Co^{2+} and Ni^{2+} from aqueous sulfate solutions at pH 1.7. The effects of the position and the nature of the substituent are discussed.

Considerable attention has been devoted to the development of chelating agents for liquid–liquid extraction of metal ions.[1–3] In particular, reagents capable of extracting base metals at low pH conditions are of great interest for the recovery of metals from acidic leach solutions.



We have recently reported on the syntheses and extracting properties of substituted quinoline-2-carboxylic acids.[4,5] Since pyridine-2-carboxylic acid, picolinic acid, also forms stable complexes with a variety of metal ions,[6] we prepared substituted pyridine-2-carboxylic acids to investigate their extracting properties, and herewith the results of this investigation are described.

RESULTS

Reagent **1**, 4-(3-heptyl)pyridine-2-carboxylic acid, was prepared, along with the isomer 6-(3-heptyl)pyridine-2-carboxylic acid (**2**), by radical alkylation[7] of 2-cyanopyridine with 2-ethylhexanoic acid, followed by hydrolysis. Compound **1** is stable under acidic conditions—no degradation was observed during 60 days at pH 1. It is essentially insoluble in water but is readily soluble in various organic solvents (37.5 g of **1** can be dissolved in 100 ml of Shellsol A + 20% decanol).

The reagents were tested for their ability to extract Cu^{2+}, Zn^{2+}, Ni^{2+}, Co^{2+}, Fe^{2+}, Cd^{2+}, Fe^{3+} and K^+ from aqueous sulfate solutions of mixtures of metal ions into an organic phase. The results are reported as $pH_{1/2}$ values (Table 1), which were calculated from the concentrations of metal ions measured by atomic absorption spectrophotometric analysis of the aqueous phase after extraction.

Inspection of Table 1 reveals that compound **1** is an effective reagent for the extraction of Cu^{2+} and Fe^{3+} in particular but also for Ni^{2+} and Co^{2+} at low pH. A slightly higher affinity for Ni^{2+} than for

*Authors to whom correspondence should be addressed.
†Present address: Boliden Kemi AB, Box 902, S-25109 Helsingborg, Sweden.

Co^{2+} is shown. The Ni^{2+}–Co^{2+} selectivity can be increased slightly by using a 2:1 mixture of 2-ethylhexanoic oxime[8] and **1** in toluene. This mixture extracts 100% of Ni^{2+} and 25% of Co^{2+} at pH 1.83.

The 6-substituted isomer **2** is much less efficient, extracting only minor amounts of all metal ions, with the exception of Cu^{2+}, at pH values below 2.5 ($pH_{1/2}$ for Cu^{2+} is 2.0). Reagent **3**, however, which was prepared analogously to **1**, showed extracting properties (Table 1) similar to those of **1**.

Compounds **4** and **5** were also tested as reagents for extraction of metal ions into a chloroform phase. Neither reagent extracted metal ions below pH 2. For solutions with pH values between 2 and 3, Cu^{2+} was extracted; the $pH_{1/2}$ values for Cu^{2+} were 3.1 and 2.4 for **4** and **5**, respectively.

Measurements were made of the distribution of metal ions at pH 2 between an aqueous phase containing varying concentrations of a single metal ion (Cu^{2+}, Fe^{3+}, Fe^{2+}, Ni^{2+}, Co^{2+} or Zn^{2+}) and an organic phase of equal volume containing **1**. Using a 5% solution of reagent **1** in Shellsol A+20% decanol as a modifier, maximum loadings of 8.4, 4.5, 3.6 and 4.5 g metal dm^{-3} of Cu^{2+}, Zn^{2+}, Fe^{2+} and Fe^{3+}, respectively, were obtained. A third phase formed when Ni^{2+} and Co^{2+} were extracted from concentrated solutions (>*ca* 3.9 and 4.8 g metal dm^{-3}, respectively). In chloroform, about the same loadings of Ni^{2+} and Co^{2+} could be obtained, but the distributions of metal ions between the two phases were somewhat less favorable.

The rates of the extraction of Cu^{2+}, Fe^{3+} and Zn^{2+} from 2 mM aqueous solutions of single metal sulfates at pH 2 by reagent **1** in an equal volume of chloroform were determined by measuring the concentrations of metal ions in the aqueous phase at intervals. From this data it was concluded that 98% of Cu^{2+} was extracted within 1 min, while $t_{1/2}$ for Zn^{2+} was *ca* 0.8 min and for Fe^{3+} *ca* 1 min.

Ligand **1** could be regenerated from the Zn^{2+} and Cu^{2+} complexes by treatment with 1 and 4 M H_2SO_4, respectively.

Table 1.

	Reagent[a]				
	1	**2**	**3**	**4**	**5**
Cu^{2+}	<0.8	2.0	0.3	3.1	2.4
Zn^{2+}	2.1	[b]	2.4	[b]	[b]
Ni^{2+}	1.2	[b]	1.5	[b]	[b]
Co^{2+}	1.7	[b]	2.2	[b]	[b]
Fe^{2+}	1.9	[b]	2.5	[b]	[b]
Fe^{3+}	<0.9	[b]	<0.8	[b]	2.6
Cd^{2+}	2.5	[b]	[b]	[b]	[b]
K^{+}	[b]	[b]	[b]	[b]	[b]

[a]The extractions were performed with equal volumes of an aqueous phase containing initially 2 mM metal sulfates and a 20 mM chloroform solution of the reagent.

[b]Less than *ca* 5% extraction at pH 2 corresponding to $pH_{1/2} > 2.8$ for divalent metal ions.

DISCUSSION

Pyridine-2-carboxylic acid forms stable complexes with a variety of metal ions. Because the parent compound is water soluble, it cannot be used as a reagent for liquid–liquid extraction. Introduction of a lipophilic group to the molecule provides a more suitable reagent. With a heptyl chain or even a tertiary butyl group as the lipophilic substituent, a reagent with the desired properties was achieved. Attempts to prepare picolinic acids with longer chains resulted in considerably lower yields. Therefore, these products were not tested.

The position of the lipophilic group on the pyridine nucleus is important, as shown by the different extraction performances of the isomers **1** and **2**. The poor extracting ability of **2** compared to **1** is probably due to steric hindrance in the complexing region. The electronic nature of the substituent also seems to be of importance since compound **4** extracts less Cu^{2+} than **2**. This effect may, at least in part, be due to a reduced electron donor ability of the nitrogen atom caused by the electron-withdrawing alkoxy substituent. The same effect may also explain the poor extracting properties of **5**.

Several reagents have recently been developed for liquid–liquid extraction of Ni^{2+} and Co^{2+}.[8–12] These reagents are usually only efficient at conditions above pH 2 however. The reagent reported here can be used for the efficient extraction of these two metal ions at lower pH, though it is not useful for separation of the two ions. We have recently found that the selectivity of quinoline-2-carboxylic acids for different metal ions is greatly influenced by the electronic and steric nature and the position of the substituents,[4] and it can therefore be expected that the same factors are operative among pyridine-2-carboxylic acids. We are currently studying such effects, particularly on the Ni^{2+}–Co^{2+} selectivity.

EXPERIMENTAL

Instrumentation

All melting points are uncorrected. IR spectra were recorded on a Perkin–Elmer 257 spectrometer and mass spectra were run on an LKB 9000 spectrometer. NMR spectra were recorded on a Bruker

WP 200 spectrometer at 200 MHz and on a Varian EM 360 instrument at 60 MHz. A Perkin–Elmer 603 atomic absorption spectrophotometer was used for metal determinations.

Elemental analyses were performed by Mikro Kemi AB in Uppsala and are within 0.4%.

Preparation of substituted picolinic acids

1 *and* **2**. $(NH_4)_2S_2O_8$ (28.85 mmol) in water (40 cm^3) was added over 15 min to a mixture of 2-cyanopyridine (19.23 mmol), 2-ethylhexanoic acid (96.15 mmol), $AgNO_3$ (1.923 mmol) and 1 M H_2SO_4 (58 cm^3) at 70°C. After stirring for 3 h at 70°C the mixture was poured into ice-water, neutralized with 25% NH_3 (40 cm^3) and extracted with CH_2Cl_2 (2×100 cm^3). The organic phase was washed with 5% NaOH (100 cm^3) and dried ($MgSO_4$). Evaporation afforded 3.56 g of crude product which was chromatographed on silica gel (235 g) with CH_2Cl_2 as the mobile phase to give 2-cyano-4-(3-heptyl)pyridine (59%) and 2-cyano-6-(3-heptyl)pyridine (11%). Alternatively, the cyanopyridines could be separated by crystallization from diethyl ether–petroleum ether. 2-Cyano-4-(3-heptyl)pyridine: IR (film): 3050, 2960–2850, 2230 and 1595 cm^{-1}. NMR (CCl_4): δ 0.6–1.0 (6H, *m*, CH_3), 1.0–2.0 (8H, *m*, CH_2), 2.65 [1H, *tt*, $J = 6$ Hz, C*H*(Et)Bu], 7.3 (1H, *dd*, $J = 5$ and 2 Hz, 5-pyridyl), 7.5 (1H, *s*, 3-pyridyl) and 8.55 (1H, *d*, $J = 5$ Hz, 6-pyridyl). Analysis: C, H and N. 2-Cyano-6-(3-heptyl)pyridine—IR (film): 3050, 2960–2850, 2230 and 1590 cm^{-1}. NMR (CCl_4): δ 0.6–1.0 (6H, *m*, CH_3), 1.0–2.0 (8H, *m*, CH_2), 2.65 [1H, *tt*, $J = 6$ Hz, C*H*(Et)Bu], 7.25 (1H, *dd*, $J = 9$ and 2 Hz, 5-pyridyl) and 7.35–7.9 (2H, *m*). Analysis: C, H and N.

2-Cyano-4-(3-heptyl)pyridine (9.32 mmol) and KOH (93.2 mmol) were reacted in ethylene glycol (50 cm^3) at 130°C. After 3 days, the pH was adjusted to 3 and the mixture extracted with $CHCl_3$ (3×50 cm^3). The organic phase was washed with H_2O (2×100 cm^3), dried ($MgSO_4$) and the solvent evaporated to give the product (**1**) as a yellow oil that slowly crystallized (84%, m.p. 100.5–102.5°C). IR (KBr): 3420, 3050, 2960–2850, 2600–2300, 1700 and 1600 cm^{-1}. MS *m/z* (rel. int.): 222(0.5), 221(0.5), 150(62), 146(44), 132(32), 118(36), 106(38), 104(34), 29(42), 28(100) and 27(32). ^{1}H NMR [$(CD_3)_2CO$]: δ 0.6–1.0 (6H, *m*, CH_3), 1.0–1.4 (4H, *m*, CH_2), 1.4–1.9 (4H, *m*, CH_2), 2.4–2.95 (1H, *m*, CH-py), 7.5 (1H, *dd*, $J = 6$ and 2 Hz), 8.0 (1H, *d*, $J = 2$ Hz), 8.65 (1H, *d*, $J = 6$ Hz) and 9.5 (1H, *s*, OH). Analysis: C, H and N.

2-Cyano-6-(3-heptyl)pyridine was hydrolysed in the same manner to give **2**.

4-t-*Butylpyridine*-2-*carboxylic acid* (**3**). This compound was prepared the same way as **1** from 2,2-dimethylpropionic acid and 2-cyanopyridine, followed by hydrolysis (33% overall yield). M.p. 90–91°C. IR (KBr): 2960, 1720 and 1600 cm^{-1}. MS *m/z* (rel. int.): 164(43), 135(100), 120(52), 118(33) and 28(40).

2-(2-*Carboxy*-6-*pyridyloxy*)*octane* (**4**). This compound was prepared by reaction of 2-cyano-6-chloropyridine (1.33 g, 9.6 mmol) with 2-octanol (1.24 g, 9.6 mmol) in monoglyme (50 cm^3) in the presence of NaH (0.46 g, 19.1 mmol) at 80°C for 1.5 h. Addition of water, extraction with diethyl ether and flash chromatography [ethyl acetate–petroleum ether (7 : 93)] gave 2-(6-cyano-2-pyridyloxy)octane (55%), which was hydrolysed (KOH–EtOH–H_2O, 80°C, 24 h) to give **4** (93%). IR (film): 3300, 2960–2850 and 1710 cm^{-1}. MS *m/z* (rel. int.): 251(3), 140(100). ^{1}H NMR (CCl_4): δ 0.6–1.95 (16H, *m*), 5.20 [1H, *m*, OC*H*(CH_3)C_6H_{13}], 6.75–7.0 (1H, *m*, 5-pyridyl), 7.65–7.85 (2H, *m*, 3- and 4-pyridyl) and 10.5 (1H, *s*, OH).

6-*Chloro*-4-(n-*hexyl*)*pyridine*-2-*carboxylic acid* (**5**). 4-(*n*-Hexyl)-pyridine, obtained from 4-picolyl lithium and 1-bromopentane, was treated with sodium amide followed by HCl–$NaNO_2$ to give 4-(*n*-hexyl)-2-chloropyridine. This product was treated with 3-chloroperbenzoic acid to give the *N*-oxide, which was reacted with $(CH_3)_2SO_4$ followed by NaCN and the product finally hydrolysed to give **3**. IR (KBr): 3400–3100, 3060, 2960–2850, 1725 and 1600 cm^{-1}. MS *m/z* (rel. int.): 243(31), 241(67), 171(80), 153(80), 142(30), 140(100), 127(42), 125(37), 43(100), 41(80) and 17(90). ^{1}H NMR ($CDCl_3$): δ 0.7–1.0 (3H, *m*, CH_3), 1.0–2.0 (8H, *m*, CH_2), 2.7 (2H, *t*, $J = 7$ Hz, CH_2-py), 7.4 (1H, *s*, 5-pyridyl), 8.0 (1H, *s*, 3-pyridyl) and 9.85 (1H, *s*, OH). Analysis: C, H and N.

Metal extraction tests

Aqueous solutions of mixtures of metal sulfates (Cu^{2+}, Zn^{2+}, Ni^{2+}, Co^{2+} and Fe^{2+}, or Cu^{2+}, Zn^{2+}, Ni^{2+}, Co^{2+} and Cd^{2+}, or Cu^{2+}, Zn^{2+}, Fe^{3+}, Cd^{2+} and K^+), *ca* 2 mM in each metal ion, at pH *ca* 2 or 4 were agitated with equal volumes of 20 mM organic solutions of the appropriate reagent until equilibrium was reached. The two phases were then separated by centrifugation and the amount of metal present in the aqueous phase was determined by atomic absorption spectrophotometry.

Acknowledgements—All metal extraction tests were performed by Ms Kerstin Högberg at the Department of Inorganic Chemistry, Royal Institute of Technology. This work was supported by the Swedish Board for Technical Development.

Abstract—4-Vinyl pyridine (4-Vp) reacts with $RuHClCO(PPh_3)_3$ (I) in THF to give $RuHClCO(PPh_3)_2$(4-Vp) (II), which reacts with sodium derivatives of bidentate chelating ligands to afford substitution products, $[RuH(CO)(PPh_3)_2(L)]$. The bidentate ligands used are 2-hydroxybenzaldehyde, 2-hydroxy-3-methoxybenzaldehyde, trifluorothenoylacetone and 8-hydroxyquinoline. Insertion reactions of the Ru—H bond of II with activated olefins such as acrylonitrile [giving $RuCl(CO)(CH_3CHCN)(PPh_3)_2$(4-Vp)], 2-vinyl pyridine, dimethyl fumarate and monobromodiethyl fumarate have been carried out to obtain chelated Ru–C bonded complexes. $RuCl_2(PPh_3)_3$ reacts with an excess of 4-Vp to give an octahedral ruthenium addition complex containing two vinyl pyridine ligands. The dimer $[RuClCO(CH_3CHCN)(PPh_3)$(4-Vp)$]_2$ is obtained by the reaction of $[RuClCO(CH_3CHCN)(PPh_3)_2]_2$ with an excess of 4-Vp. Stereochemical assignments have been made for these new complexes on the basis of IR and ^1H NMR data.

Substitution reactions of carbonylchlorohydridotris(triphenylphosphine)ruthenium(II) (I) with ligands like phosphines, phosphites, phosphinites and phosphonates have been studied by various workers,[1,2] but there have been no reports regarding reactions using nitrogen bases. It has been observed that because of the strong *trans* bond weakening effect of the hydride ligand, complex I readily undergoes substitution at the *trans* site with the above bases, giving neutral monosubstituted products. Douglas and Shaw[3] have observed that no detectable displacement of phosphine took place even when an excess of 4-methyl pyridine was added to a complex similar to I. In continuation of our work on reactions of ruthenium hydrido complexes,[4,5] we now report a new range of ruthenium(II) complexes containing 4-vinyl pyridine.

EXPERIMENTAL

The ruthenium complex $[RuHCl(CO)(PPh_3)_3]$ (I) was prepared as described by Robinson *et al.*[6] The organic ligands were commercially available and their purities checked. Solvents were freshly distilled after careful drying and degassed prior to use. Reactions were performed under nitrogen and worked up *in vacuo* or under nitrogen. Elemental analyses were done by the microanalysis group of the laboratory. IR spectra were taken in Nujol mulls, KBr pellets or in chloroform solution in a Perkin–Elmer 599 grating spectrophotometer. ^1H NMR spectra were recorded in $CDCl_3$ on Varian FT 80A and Bruker WH 90 spectrometers.

(*a*) *Carbonylchlorohydrido bis(triphenylphosphine)*4-*vinyl pyridine ruthenium* (II)

Freshly distilled 4-vinyl pyridine (0.21 g, 2mmol) was added to a suspension of I (0.238 g, 0.25 mmol) in THF (20 cm^3) in a Schlenk tube. The solution was magnetically stirred at 25°C for 24 h to obtain a light brown precipitate. This was filtered through a sintered glass disc in air and washed with hexane (10 cm^3, 3 times) and kept *in vacuo* at 1 mm pressure for 2 h. Yield 0.155 g (78%).

(*b*) *Carbonylhydrido(salicylaldehydato)bis(triphenylphosphine) ruthenium*

To a suspension of sodium salicylaldehyde [prepared from salicylaldehyde (0.037 g, 0.3 mmol) and oil-free sodium hydride (0.008 g, 0.33 mmol)] in THF (30 cm^3) was added II (0.2 g, 0.25 mmol), and the mixture was stirred for 12 h at 25°C, after which the solvent was removed under reduced pressure.

* NCL Communication No. 3811.

† Author to whom correspondence should be addressed.

The residue was extracted with benzene, centrifuged, and the solvent again removed under reduced pressure. The mass was washed with hexane (10 cm^3, 3 times), crystallized from a benzene–hexane [1 : 1 (v/v)] mixture and dried at 0.1 mm pressure for 2 h. The yellow microcrystalline solid weighed 0.12 g (78%). Other chelated ruthenium derivatives have been prepared similarly.

(*c*) *Carbonylchloro*(1 - *cyanoethyl*) *bis*(*triphenylphosphine*)4-*vinyl pyridineruthenium*

Freshly distilled acrylonitrile (0.106 g, 2 mmol) was added to a suspension of **II** (0.2 g, 0.25 mmol) in THF (30 cm^3), and the mixture was magnetically stirred at 25°C for 24 h. The resulting clear brown solution was evaporated to dryness *in vacuo* and the mass thus obtained was washed 3 times with small lots of hexane and the solid crystallized from a benzene–hexane mixture. Yield 0.17 g (82%).

(*d*) *Carbonylchloro - bis*(*triphenylphosphine*)2 - (2′ - *pyridyl*)*ethyl ruthenium*

To a suspension of **II** (0.2 g, 0.25 mmol) in THF (30 cm^3) was added 2-vinyl pyridine (0.105 g, 1 mmol), and the mixture stirred for 14 h and processed to obtain a light green crystalline solid. Yield 0.17 g (85%). Reactions with fumarates have been carried out similarly.

(*e*) *Carbonylchlorodithioformato - bis*(*triphenylphosphine*)*ruthenium*

To a suspension of **II** (0.2 g, 0.25 mmol) in benzene (20 cm^3) was added carbon disulphide (5 ml) and the mixture was kept at room temperature for 24 h. The yellow crystals separated were filtered, dried *in vacuo* and recrystallized from a dichloromethane–hexane mixture. Yield 0.15 g (78%).

(*f*) *Carbonylchloro*(1 - *cyanoethyl*)*triphenylphosphine*)4-*vinyl pyridineruthenium dimer*

$[RuCl(CO)(CH_3CHCN)(PPh_3)_2]$ (0.19 g, 0.25 mmol) was suspended in THF (25 cm^3) and was reacted with 4-vinyl pyridine (0.105 g, 1 mmol) by stirring at room temperature for 24 h. The red solution obtained was processed as in (c) to obtain a dark red crystalline solid. Yield 0.12 g (83%).

(*g*) *Dichloro - bis*(*triphenylphosphine*)*bis*(4 - *vinyl pyridine*)*ruthenium*

To a suspension of $RuCl_2(PPh_3)_3$ (0.19 g, 0.25 mmol) in benzene (30 cm^3) was added an excess of 4-vinyl pyridine (0.22 g, 2 mmol), the mixture was stirred for 24 h at ambient temperature, and then refluxed for 4 h to obtain a clear red solution. It was then processed as in (c) to get a red microcrystalline solid. Yield 0.21 g (93%).

RESULTS AND DISCUSSION

The hydrido complex **I** reacts smoothly with 4-vinyl pyridine (freshly distilled, monomer) in THF at ambient temperature to afford the neutral monosubstituted product **II**. This colourless microcrystalline solid is stable towards air, is soluble in chloroform and dichloromethane, and insoluble in hexane (Table 1).

The IR spectrum of compound **II** shows a strong band at 1900 cm^{-1} due to $\nu(C{\equiv}O)$ and a medium-intensity band at 1990 cm^{-1} arising from $\nu(Ru{-}H)$ (Table 2). In the starting hydrido complex (**I**) the corresponding vibrations are at 1922 and 2020 cm^{-1}, respectively.[6] Low-frequency shifts are expected when triphenylphosphine situated *trans* to the hydrido ligand is substituted by a strong σ-donating ligand like 4-vinyl pyridine having little π-accepting ability. The coordination of the ligand to ruthenium is through its nitrogen lone pair and not through the vinylic π-system as seen from the vinylic CH and CH_2 out-of-plane deformations at 995 and 935 cm^{-1}, respectively.[7]

The high-field proton NMR spectrum of the compound comprises a triplet centred at δ −13.52 [$^2J(PH)_{cis}$ = 20 Hz], which suggests that the hydride is *cis* to two equivalent phosphorus atoms as shown in Fig. 1.

The chlorine substitution in complex **II** has been carried out using the sodium derivatives of bidentate ligands like 2-hydroxybenzaldehyde (salicylaldehyde), 3-methoxy-2-hydroxybenzaldehyde (*o*-vanillin), 8-hydroxyquinoline (oxine) and trifluorothenoylacetone in THF medium. The chelated derivatives are obtained in good yield by the elimination of chlorine and 4-vinyl pyridine (Table 1):

$$RuHCl(CO)(PPh_3)_2(4\text{-}Vp) + NaL \rightarrow RuH(CO)(PPh_3)_2(L) + NaCl + 4\text{-}Vp.$$

These are freely soluble in benzene and chloroform,

[a] Abbreviations: 4-Vp, 4-vinyl pyridine; Sal-H, salicylaldehyde; *o*-Vanil-H, *o*-vanillin; Oxine-H, 8-hydroxyquinoline; Tftac-H, trifluorothenoylacetone; 2-Ep, 2-ethyl pyridine; PPh_3, triphenylphosphine.

and insoluble in hexane; but the solution stability is poor in all cases. The same products were obtained by the reaction of $[RuHCl(CO)(PPh_3)_3]$ with the sodium salts of the respective bidentate ligands.

The IR spectra of the chelated complexes (Table 2) show clearly that the ligands are coordinated. The $\nu(C{\equiv}O)$ has been shifted to a higher frequency except in the case of 8-hydroxyquinoline derivative, suggesting less electron density at ruthenium atom as a result of chelate formation. There is not a considerable change in the ν(Ru—H) mode.

^{1}H NMR spectra (Table 2) of these derivatives exhibit triplets due to coupling of the Ru—H proton with two *cis* phosphorus atoms. Two triplets of equal intensity having very similar chemical shifts are observed for the complexes suggesting the existence of two isomers. Separation of these isomers was attempted by column chromatography using a variety of elutants. The yellow fraction obtained by elution with benzene gave similar ^{1}H NMR signals as the unchromatographed starting material, suggesting that the isomers are not resolved probably because of their very close R_f values. Attempts to elute out the isomers using other solvents also failed. The two isomers can have the structures shown in Fig. 2(a) and (b). However, in the case of the 8-hydroxyquinoline derivative, the resonance due to the Ru—H proton in the major isomer is at δ −9.85 (80%) and the minor isomer at δ −14.85 (20%). The resonance at δ −9.85 arises from the structure (Fig. 3) as the σ-donating oxine nitrogen is *trans* to the π-acceptor carbonyl ligand. This is in good agreement with the reduction in $\nu(C{\equiv}O)$ in this complex.

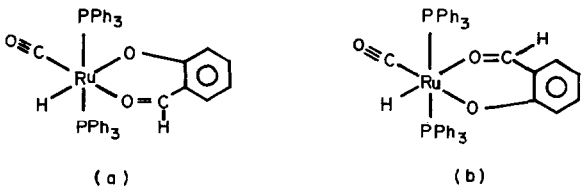

Fig. 2.

Complex II has been reacted with activated olefins in THF at ambient temperature to give Ru–C-bonded mononuclear insertion compounds. The olefins used are acrylonitrile, dimethyl fumarate and bromodiethyl fumarate. Acrylic esters did not yield any pure isolable product:

$$[RuHCl(CO)(PPh_3)_2(4\text{-}Vp)] + CH_2{=}CHCN \rightarrow [RuCl(CO)(CH_3CHCN)(PPh_3)_2] + 4\text{-}Vp.$$

The IR spectrum of the 1-cyanoethylruthenium complex lacks a ν(Ru—H) mode at 1990 cm^{-1} and shows a strong band at 1925 cm^{-1} due to the terminal carbonyl group. The ν(CN) is at 2230 cm^{-1}, confirming the non-involvement of a nitrile group in coordination. The vinylic $\delta(CH_2)$ is at 935 cm^{-1} as in the starting hydrido complex.[5] The ^{1}H NMR spectrum shows two doublets due to methyl resonance at δ 0.17 and 0.43 [^3J(HH) = 8 Hz] with

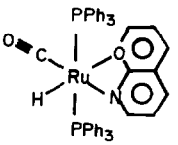

Fig. 3.

Table 2. IR (ν in cm^{-1}) and proton NMR (δ in ppm) data of new ruthenium(II) complexes

S. No.	Compound	ν(C≡O)	ν(Ru—H)	ν(C=O)/(C=N)	ν(Ru—H)	Other NMR resonances

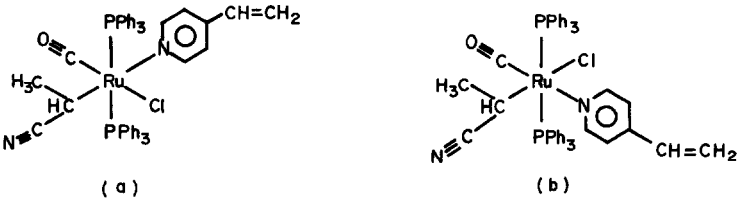

Fig. 4.

relative intensities of 2:1, suggesting the presence of two isomers. A high-field shift for methyl protons is expected when a strong σ-donating nitrogen is situated at the *trans* position. The tertiary methine proton, $\rangle$CH, resonates at δ 2.43 as a multiplet. The δ values for vinylic protons of major and minor isomers are well separated and they resonate between δ 5.4 and 6.7. All these data suggest the stereochemistry of the complex shown in Fig. 4.

2-Vinyl pyridine adds to the Ru—H bond in **II** to give the compound $[RuCl(CO)(CH_2CH_2C_5H_4N)(PPh_3)_2]$ with the elimination of 4-vinyl pyridine. The same compound has been synthesized by Hiraki *et al.*[8] by the reaction of **I** with 2-vinyl pyridine [reported: m.p. 170°C, ν(C≡O) 1908 cm^{-1}, chemical shift δ 1.8 t, 2.6 t for CH_2] and on the basis of IR and NMR data the stereochemistry is suggested to be as shown in Fig. 5.

The hydrido complex **(II)** reacts with carbon disulphide in a benzene medium at ambient temperature to yield the insertion product $[RuCl(CO)(S_2CH)(PPh_3)_2]$ as an air-stable yellow-crystalline solid; 4-vinyl pyridine is eliminated.

$$[RuHCl(CO)(PPh_3)_2(4\text{-Vp})] + CS_2 \rightarrow [RuCl(CO)(S_2CH)(PPh_3)_2] + 4\text{-Vp}.$$

When the same reaction is carried out in refluxing benzene (7 h), a red product which is a 1:1 mixture of two isomers, as seen from the ^1H NMR spectrum, was obtained. Fractional crystallization of the product separated the less soluble yellow isomer. From the mother liquor pure isomers could not be obtained even by using chromatographic techniques.

The IR spectrum of the yellow product shows bands at 1235 and 930 cm^{-1}, attributable to δ(HCS) and $\nu_{as}(CS_2)$, respectively, which suggests the presence of a chelated dithio ligand.[9,10] The ^1H NMR spectrum comprises a triplet at δ 11.88 [^4J(PH) ~ 8 Hz] due to the coupling of a dithioformate proton (S_2CH) with *trans* phosphorus nuclei. The following structure (Fig. 6) is proposed; an X-ray crystal study is underway.

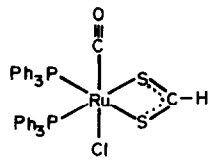

Fig. 6.

This compound has been found to be identical with that prepared by Robinson and Sahajpal[11] by the insertion reaction of $[RuHCl(CO)(PPh_3)_3]$ with carbon disulphide in refluxing benzene for 30 min [reported: m.p. 214–216°C, ν(C≡O) 1958 cm^{-1}, $\nu(S_2CH)$ 1230 and 920 cm^{-1}, chemical shift δ 11.87 t, $^4J(PH)_{trans} = 8$ Hz].

Ligand substitution reaction of the dimer $[RuCl(CO)(CH_3CHCN)(PPh_3)_2]_2$[8] with excess 4-vinyl pyridine yields the monosubstituted dimeric derivative $[RuCl(CO)(CH_3CHCN)(PPh_3)(4\text{-Vp})]_2$. The IR spectrum of the dimer shows ν(CN) at 2200 cm^{-1} and ν(C≡O) at 1920 cm^{-1}. The ^1H NMR spectrum comprises two doublets due to methyl protons, which suggests the presence of isomers.

$RuCl_2(PPh_3)_2$ reacts with excess 4-vinyl pyridine in refluxing benzene to afford the red air-stable compound $[RuCl_2(PPh_3)_2(4\text{-Vp})_2]$. The IR spectrum shows bands characteristic of 4-vinyl pyridine. In the lower-frequency region two weak bands observed at 350 and 330 cm^{-1} suggest *cis* coordination of chlorine atoms to ruthenium as shown in Fig. 7.

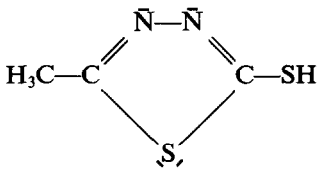
2-MERCAPTO-5-METHYL-1,3,4-THIADIAZOLE AS A LIGAND IN Ru(III), Rh(III), Os(III) AND Ir(III) TRICHLORIDE COMPLEXES



A. C. FABRETTI* and A. GIUSTI

Department of Chemistry, University of Modena, 41100 Modena, Italy

(*Received* 3 *March* 1986; *accepted* 24 *March* 1986)

Abstract—Some 2-mercapto-5-methyl-1,3,4-thiadiazole complexes of Rh(III), Ir(III), Ru(III) and Os(III) have been prepared and characterized by chemical-analysis, conductometric, room-temperature magnetic-moment, electronic, IR, EPR and thermogravimetric measurements. From the magnetic properties it was derived that the above ligand forms low-spin complexes with all the metal ions. The position and multiplicity of the metal–halogen stretching modes in the far-IR region have been investigated. The wavelengths of the principal electronic absorption peaks have been accounted for in terms of the crystal field theory and the various parameters have been calculated.

As a part of a series of investigations into the behaviour of heterocyclic ligands[1] we have considered 2-mercapto-5-methyl-1,3,4-thiadiazole (mttz) which has, besides the three-heteroatoms of the five-membered ring, another potential binding site such as the exocyclic sulphur atom. These ligands exist in —N=C—SH or —NH—C=S forms, exhibiting a thiol⇔thione equilibrium. However, we have established that the thione form dominates in the solid state. The coordination compounds of this ligand with some metal of the VIII group, such as Ru(III), Rh(III), Os(III) and Ir(III), have been prepared and studied

EXPERIMENTAL

Preparation of the complexes

The mttz derivatives were prepared by reaction of an ethanolic–hydrochloric solution of the metal chloride with an ethanolic solution of the ligand in an M : L ratio of 1 : 3. The same result was obtained without HCl.

Any attempt to prepare inner complexes in basic media caused the precipitation of the metal hydroxide.

Analysis

Carbon, nitrogen, sulphur and hydrogen were determined using a Carlo-Erba 1106 analyser.

The electrical conductances of the complexes were measured in DMF. The IR spectra were recorded with a Perkin–Elmer 180 spectrophotometer as KBr disks or Nujol mulls on polyethylene. The electronic spectra were recorded with a Shimadzu MPS 50L spectrometer either in DMF or in the solid state. EPR spectra were recorded at X-band frequencies on a Varian E-9 spectrometer at room and liquid-nitrogen temperatures on the powdered samples. The TGA and DTG measurements were carried out on a Mettler TA 3000 system; a scan rate of 10°C min^{-1} was used.

RESULTS AND DISCUSSION

The new compounds prepared in the present investigation are listed in Table 1.

The molar conductances in 10^{-3} M DMF solution are in the 15–24 Ω^{-1} mol^{-1} cm^2 range indicating the nonelectrolytic nature of the compounds.

Table 1. Analytical data for the complexes

Compound	Colour	Found (calc.) (%) N	C	H	S	H_2O
$RhLCl_3 \cdot H_2O$	Orange	7.8 (7.8)	10.1 (10.1)	1.5 (1.6)	18.2 (17.8)	4.2 (4.0)
$IrLCl_3 \cdot H_2O$	Mustard	6.1 (6.2)	8.0 (8.0)	1.2 (1.3)	13.8 (14.3)	4.9 (5.0)
$RuL_{2.5}Cl_3$	Black	13.0 (13.0)	17.0 (16.8)	2.0 (1.9)	30.1 (29.8)	
$OsL_{2.5}Cl_3$	Brown	11.5 (11.2)	14.6 (14.4)	1.5 (1.6)	25.3 (25.6)	

This is consistent with the stoichiometry assumed for the complexes on the basis of analytical data. The rhodium and iridium complexes are diamagnetic while the ruthenium and osmium complexes have magnetic moments at room temperature of 1.6 and 1.5 BM, respectively. These values are slightly below the spin-only value. The EPR spectra of the powdered mttz ruthenium and osmium complexes consist in each case of a single broad signal with a peak-to-peak separation of about 1000 G either at room or liquid-nitrogen temperature, proving that the metals are in the oxidation state III. No detailed analysis of any spectrum is possible. The g_o values are 2.112 and 2.135 for ruthenium and osmium complexes, respectively.

IR spectra

The ligand mttz does not show any ν(SH) band in the 2600–2500-cm^{-1} region, in which this stretching frequency is generally expected.[2]

In order to verify the thioketo form of the ligand deuteration of the molecule has been carried out by refluxing for several hours and evaporating to dryness from a CH_3OD solution. Of the four ligand bands at 3120(sh), 3050(s), 2975(m) and 2865(s) cm^{-1} three are still present in the deuterated form at 3055(mw), 2980(w) and 2875(m) cm^{-1}, and may be assigned to ν(CH) modes, while a new very strong polyhumped band centred at 2260(vs) cm^{-1} is assignable to the ν(ND) mode, the corresponding ν(NH) band at 3120 cm^{-1} disappears, giving a ν(NH)/ν(ND) ratio of 1.38. Other bands sensitive to deuteration [1448(vs), 973(m) and 763(vs) cm^{-1}, which shift, respectively, to 1342(vs), 930(s), and 557 (vs) and 529 (s) cm^{-1}] are principally NH and ND vibrational bands.

It may therefore be concluded that the ligand is mainly in the thioketo form.

The ν(NH) frequency and the other NH vibration bands of the ligand remain practically unchanged upon complexation; this result excludes a NH coordination of the ligand to the metal ion.

The ligand band at 1550(sm) cm^{-1}, which shows only a very small frequency decrease on deuteration to 1540(ms) cm^{-1} and may be assigned mainly to a ν(C=N) mode, is shifted to 1542–1538 cm^{-1} in the complexes. This small frequency lowering should indicate a weak coordination of the ligand in the complexes though the unprotonated nitrogen atom. In the case of ruthenium and osmium derivatives a shoulder at 1550 cm^{-1} is still present in the spectra. This should mean a double behaviour of the ligands in the cited complexes. On the contrary, the ligand band at 1268(vs) cm^{-1} to which an important ν(C—N) contribution may be assigned[2] increases to 1295–1305 cm^{-1} in the complexes in agreement with the electronic shift $HN\overset{\curvearrowright}{-}C\overset{\curvearrowright}{=}S \rightarrow M$ due to a coordination of the ligand through its thiocarbonylic sulphur atom. Consequently some frequencies lowering are observed in the complexes for the bands in the 1070–760-cm^{-1} region [1070(vs) → 1043–1050(vs) and 763(vs) → 755–758(s)], in which a ν(C=S) contribution may be located.

In the far-IR spectra five new bands are located in the 348–248-cm^{-1} region which can be assigned to ν(M—Cl), ν(MS) and ν(MN) vibrations in agreement with data of other similar compounds.[4–6]

The sixth new band at 223(m) cm^{-1} for rhodium and iridium derivatives can be attributed to a M—OH_2 vibration mode (Table 2).

Visible spectra

Almost the same spectra for the complexes are found either in DMF solution or in Nujol mulls.

The rhodium mttz complex shows two bands at 19.6 and 24.4 kK, expected for spin-allowed transitions to the $t_{2g}^5 e_g^1$ configuration. The ligand field bands are large but not obscured by charge-transfer absorptions. The $10Dq$ and B' values, as calculated from the position of these bands by means of the following equations[7]—$\nu_1 = \Delta - 4B' + 86(B')^2/\Delta$ and $\nu_2 = \Delta + 12B' + 2(B')^2/\Delta$—are reported in Table 2 and are well within those found for other trivalent rhodium complexes.[4,5,8–11]

These bands are in the wavelength range expected for chromophores containing S, N, Cl and O.

Table 2. Significant IR bands (cm^{-1}) for the complexes

	ν(OH)	ν(M—Cl)	ν(M—S)	ν(M—L)
$RhLCl_3 \cdot H_2O$	3440s	329s, 303m, 297m	347sh	275m 223m
$IrLCl_3 \cdot H_2O$	3415s	320s, 304s, 280sh	348sh	262 m 223m
$RuL_{2.5}Cl_3$		319s, 289s, 278s	362m	248sh
$OsL_{2.5}Cl_3$		330sh, 309sh, 280s	373m	248sh

Table 3. Electronic spectra and ligand field parameters (kK) of low-spin metal(III) complexes

	$^1A_{1g} \rightarrow {}^1T_{1g}$	$\rightarrow {}^1T_{2g}$	$\rightarrow {}^3T_{1g}$	ν_1/ν_2	Δ	B'	β					
$RhLCl_3 \cdot H_2O$	19.6	25.0	14.9	1.27	20.5	0.373	0.52					
$IrLCl_3 \cdot H_2O$	22.0	28.5	16.4	1.29	23.0	0.453	0.69					
	$^2T_{2g} \rightarrow {}^4T_{1g}$	$\rightarrow {}^4T_{2g}$	$\rightarrow {}^2A_{2g}, {}^2T_{1g}$	$\rightarrow {}^2E_g$		$\rightarrow {}^2T_{1g}, {}^2T_{2g}$		$\rightarrow {}^2A_{1g}$		B	C	$10Dq$
				Obs.	Calc.	Obs.	Calc.	Obs.	Calc.			
$RuL_{2.5}Cl_3$	15.4	19.4	21.5	24.5	25.9	28.6	28.5	32.2	31.0	0.500	1.530	24.0
$OsL_{2.5}Cl_3$	17.9	20.8	23.8	27.8	27.1	29.4	28.9	32.5	30.7	0.363	1.604	26.1

As for the iridium complex the two observed absorption bands are in the range expected for the two spin-allowed transition ν_1 and ν_2, from the ground state $^1A_{1g}$ (Table 3). The band at 16.4 kK (14.9 kK for the rhodium complex) can be attributed to the spin-forbidden $^1A_{1g} \rightarrow {}^3T_{1g}$ transition.[8,10,12,13]

The B' values are of the order of 0.52 and 0.69% of the free ion values in the rhodium and iridium derivatives, respectively, suggesting a considerable orbital overlap with a strong covalency in the metal–ligand σ-bond.

In the spectra of $Ru(mttz)_{2.5}Cl_3$ complex six maxima or shoulders are present; the low intensity of these transitions suggests that they are crystal field transitions and they appear to be characteristic of octahedral complexes of ruthenium(III).[14,15] The two broad low-intensity bands at 15.4 and 19.4 kK are assigned to the spin-forbidden transitions, while the remaining bands are assigned to transitions to doublet states.

On the basis of the following energy levels for low-spin d^5 ions in an octahedral environment:[15]

$^2T_2$	t^5	0
$^4T_1$	t^4e	$10Dq-5B-4C$
$^4T_2$	t^4e	$10Dq+3B-4C$
$^6A_1$	t^3e^2	$20Dq-15B-10C$
$^2A_2, {}^2T_1$	t^4e	$10Dq-2B-C$
^2E	t^4e	$10Dq+7B-C$
$^2T_1, {}^2T_2$	t^4e	$10Dq+12B-C$
$^2A_1$	t^4e	$10Dq+17B-C$

The assignments are given in the Table 3 together with the parameters $10Dq$, B and C.

It is not possible to measure the intensity of the $^2T_2(t^5) \rightarrow {}^6A_1(t^3e^2)$ transition because it corresponds to the highly forbidden transition of the double-electron excitation ($\Delta S = +2$).

As shown in Table 2, the calculated energies for the excited configuration $t_{2g}^4 e_g^1$ fall in the same region as the observed transitions, supporting the suggested configuration.

As for the Os(III) derivative the metal is in a t_{2g}^5-configuration; the two bands at lower wavenumbers are assigned to the two spin-forbidden transition $^2T_2 \rightarrow {}^4T_1$ and $^2T_2 \rightarrow {}^4T_2$ (Table 3). The low-intensity bands between 23.8 and 32.5 kK are transitions from the ground state to doublet states $t_{2g}^4 e_g^1$. These transitions are characteristic of Os(III) octahedral complexes.

The relative low magnetic moments of Ru(III) and Os(III) derivatives at room temperature are probably due to some electron exchange between metal ions though a bridging ligand molecule.

Thermal behaviour of the complexes

The thermogravimetric analysis shows in the case of rhodium and iridium compounds a weight loss in the range 50–140°C (Table 1) due to water molecules. Over 140°C the compounds begin to decompose, leaving M_2O_3 as decomposition products.

REACTIONS OF DITHIOCARBAMATES OF DIMOLYBDENUM—II. REACTION OF MOLYBDENUM ACETATE WITH TWO EQUIVALENTS OF DITHIOCARBAMATE

D. M. BAIRD* and S. D. CROLL

Department of Chemistry, Western Illinois University, Macomb, IL 61455, U.S.A.

(*Received* 17 *February* 1986; *accepted after revision* 1 *May* 1986)

Abstract—Reaction of molybdenum acetate with two equivalents of sodium diethyl dithiocarbamate in methanol results in the tetrakis-substituted $Mo_2(dtc)_4$ (dtc = dithiocarbamate). Exposure of this product to the atmosphere produces $Mo_2O_3(dtc)_4$.

Recently we reported the structure of $Mo_2(Pdtc)_2(OAc)_2TPPO$ (Pdtc = pyrroledithiocarbamate, TPPO = triphenylphosphineoxide).[1] This compound was obtained from reaction of molybdenum acetate with four equivalents of Pdtc. The product of this reaction was later reacted with TPPO in benzene in order to produce higher-quality crystals. A major feature of the structure was the fact that only two of the acetates had been replaced by dithiocarbamates. In addition this was the first example of a dimolybdenum complex with bridging dithiocarbamates.

When four equivalents of dialkyldithiocarbamate are reacted with molybdenum acetate $Mo_2(dtc)_4$ is formed.[2,3] This compound probably has the molybdenum acetate structure with all four of the dithiocarbamates bridging the quadruply bonded dimolybdenum unit. This species, however, rearranges to form an unusual complex in which two of the dithiocarbamate ligands have been reduced by the molybdenum atoms, producing two bridging sulfides and two thiocarboxamide groups (Fig. 1).[3,4]

The structure of $Mo_2(Pdtc)_2(OAc)_2$ led us to wonder what the structure of a complex with two dialkyldithiocarbamates and two acetates would be. Would the two dithiocarbamates simply act as bridging ligands to give a product analogous to the product obtained when pyrroledithiocarbamate was used or would the two dithiocarbamates be reduced and give a product with two bridging sulfides, two thiocarboxamides and two bidentate acetates (see Fig. 2)?

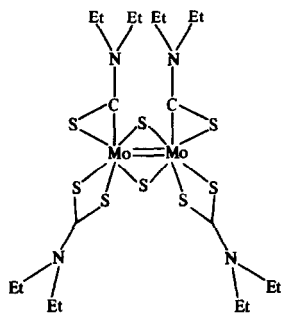

Fig. 1.

The results of a study of reaction (1), that is the reaction of molybdenum acetate with two equivalents of diethyl dithiocarbamate, are presented in this paper.

$$Mo_2(OAc)_4 + 2Na(dtc) \rightarrow Mo_2(dtc)_4 + \tfrac{1}{2}Mo_2(OAc)_4. \quad (1)$$

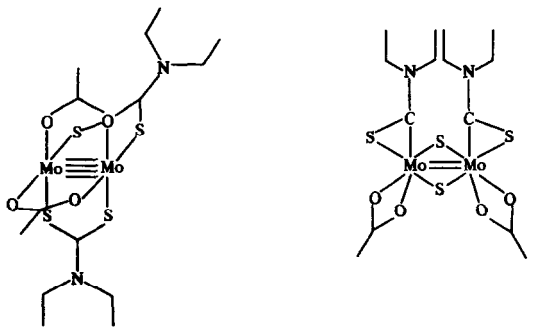

Fig. 2.

EXPERIMENTAL

Materials and methods

Molybdenum acetate was prepared by the method of Wilkinson.[5] Sodium diethyldithiocarbamate tris hydrate was purchased from Fisher Chemical Co. and was used as received. All reactions were performed under an Ar atmosphere using standard Schlenk techniques. Methanol was dried by refluxing over calcium sulfate for 2 h. It was then distilled onto fresh calcium sulfate, where it was stored.

Spectroscopic measurements

Electronic absorption spectra were recorded on a Hitachi 100A spectrophotometer or a Perkin–Elmer 552, in methylene chloride solutions. IR spectra were obtained on a Perkin–Elmer 621 spectrophotometer as KBr pellets which were prepared under inert conditions. NMR were taken on a JOEL 90 in $DCCl_3$.

Reactions

In a typical reaction molybdenum acetate was added to two equivalents of sodium diethyldithiocarbamate which had been dissolved is dry degassed methanol according to reaction (1). A green precipitate formed immediately. After stirring the mixture for about 30 min the green material was filtered under Ar. The material was then left with the filter system open to the atmosphere overnight. The contact with air produced $Mo_2O_3(dtc)_4$.

RESULTS

Upon reaction of molybdenum acetate with two equivalents of sodium diethyldithiocarbamate in dry degassed methanol a green precipitate forms immediately. Unreacted molybdenum acetate is visible in the mixture and upon filtration. The conditions used here are the same as those that have been used to produce $Mo_2(dtc)_4$ in other laboratories.[2–4] The green precipitate formed in reaction (1) reacts with even the smallest traces of oxygen to form a purple $Mo_2O_3^{4+}$ complex. This latter reaction is so facile that it was difficult to perform analyses on the green species. As a result the green compound was allowed to react slowly with air and analyses were performed on the purple species. Solution samples were prepared by dissolving the purple compound and then filtering out unreacted $Mo_2(OAc)_4$. It was assumed that if the green complex had the formula $Mo_2(dtc)_2(OAc)_2$ then the purple species would be $Mo_2O_3(OAc)_2(dtc)_2$ by analogy with the reaction of $Mo_2(dtc)_4$ with oxygen, which has been reported to produce $Mo_2O_3(dtc)_4$.[2,3]

IR, electronic-absorption and NMR analyses of the purple complex obtained from reaction (1) showed it to be $Mo_2O_3(dtc)_4$. In each case spectra were identical to those obtained from an authentic sample of $Mo_2O_3(dtc)_4$ prepared by the method of Newton.[6] The NMR spectrum of the purple complex showed only resonances from the ethyl groups of the dithiocarbamates. The possibility of acetate resonance lies under these ethyl resonances can be ruled out by the integration which shows a 1 : 1.48 ratio of ethyl $-CH_3$ ($\delta = 1.295$) to ethyl $-CH_2$ ($\delta = 3.857$) protons. This compares with a theoretical ratio of 1 : 1.5. The IR spectrum of the purple species obtained from reaction (1) is identical to the IR spectrum of the authentic $Mo_2O_3(dtc)_4$ compound. This is particularly important for the 1500–1600-cm^{-1} region, where acetate vibrational frequencies may be observed. The electronic-absorption spectra of $Mo_2O_3(dtc)_4$ from both sources show bands at 380 and 510 nm. The source of these bands has been discussed.[6,7]

DISCUSSION

These results suggest that either a dimolybdenum species which has had one or two acetates replaced by a dialkyldithiocarbamate is more reactive to substitution by a further dithiocarbamate than molybdenum acetate itself or precipitation of $Mo_2(dtc)_4$ drives the equilibria in Scheme 1 toward that complex.

$$Mo_2(OAc)_4 + dtc^- \rightleftarrows Mo_2(OAc)_3(dtc) + OAc^-,$$

$$Mo_2(OAc)_3(dtc) + dtc^- \rightleftarrows Mo_2(OAc)_2(dtc)_2 + OAc^-,$$

$$Mo_2(OAc)_2(dtc)_2 + dtc^- \rightleftarrows Mo_2(OAc)(dtc)_3 + OAc^-,$$

$$Mo_2(OAc)(dtc)_3 + dtc^- \rightleftarrows Mo_2(dtc)_4 + OAc^-.$$

Scheme 1.

In either case it becomes difficult to isolate our target product, $Mo_2(OAc)_2(dtc)_2$. It seems unlikely at this point that an equilibrium control of the product is involved since $Mo_2(OAc)_4$ is not very soluble in methanol. During the reaction yellow $Mo_2(OAc)_4$ crystals are always visible. There is no evidence that the $Mo_2(OAc)_4$ has gone into solution and come back out. That is, much of the $Mo_2(OAc)_4$ is never involved in the reaction scheme.

In conclusion we have shown that the reaction of $Mo_2(OAc)_4$ with two equivalents of dialkyldithiocarbamate in methanol produces $Mo_2(dtc)_4$, which, upon exposure to air, gives $Mo_2O_3(dtc)_4$. We are initiating a study of the kinetics of this reaction system in order to determine

if the product is obtained due to an increased lability of acetates on a dimolybdenum unit that has already been substituted with dithiocarbamate.

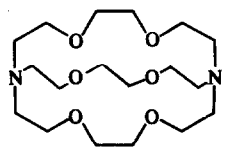
^{133}Cs NMR STUDY OF THE CRYPTAND-222–Cs^+ COMPLEX IN BINARY SOLVENT MIXTURES

GHOLAMHOSSEIN ROUNAGHI and ALEXANDER I. POPOV*

Department of Chemistry, Michigan State University, East Lansing, MI 48824, U.S.A.

(*Received* 9 *January* 1986; *accepted after revision* 1 *May* 1986)



Abstract—The formation constants of the cryptand-222 complex with the cesium ion were studied by ^{133}Cs NMR measurements in four binary solvent systems: acetone–dimethylsulfoxide (Me_2CO–Me_2SO), acetonitrile (MeCN)–Me_2SO, propylene carbonate(PC)–Me_2SO and PC–dimethylformamide (DMF). In the neat solvents the formation constant increases in the order Me_2SO < DMF < Me_2CO < PC < MeCN, which is the inverse order of their solvating abilities as given by the Gutmann donor number. In binary mixtures the stabilities varied monotonically with the composition. As expected, there is no correlation between the stabilities of the complexes and the dielectric constant of the medium. It seems that, for aprotic solvents with similar Pearson basicities and in the absence of ion pair formation, the donor ability of a binary solvent mixture can be qualitatively predicted from the donicities of the two solvents and the composition of the mixture.

In recent years it has become abundantly clear that solvent properties exert a very significant influence on the thermodynamics and kinetics of all reactions in solutions and, in particular, on the complexation reaction between a metal ion and a neutral or a charged ligand. At least two solvent properties play a particularly important role, the solvating ability *vis-à-vis* the metal ion *and* the ligand, and the dielectric constant which influences not only the coulombic forces between the ion and a charged ligand but also may complicate the system by promoting competition from ion pair formation.

While the dielectric constant of a solvent is a readily measured quantity, its donor properties are evaluated much less readily. A number of empirical scales have been proposed,[1] each with its own set of advantages and disadvantages. However, until our fundamental knowledge of the liquid state improves dramatically, we have to rely on empirical approaches for the estimation of the solvating power of solvents.

In a case of alkali ion complexes with macrocyclic ligands (crown ethers and cryptands) the Gutmann donicity scale[2] is particularly useful,[3] provided the dielectric constant of the solvent is high enough to prevent ion pair formation and that, in the case of alkali cations, the solvents are not "soft" bases.[4] With the above provisos, the stability constant is an inverse function of the donor number.[3,4]

In a previous paper[5] we reported a study of the Cs^+ ion complexes with the crown ethers dibenzo-21-crown-7 and dibenzo-24-crown-8 in several mixed solvents. It was of interest to us to extend these studies to cesium cryptates where the interaction between the cation and the ligand is much stronger and, therefore, the influence of the solvent may be less apparent. The work described below involved a study of the Cs^+ ion complex with cryptand-222 (C222) (**1**) which was selected as the probe since the behavior of this complex in neat solvents is rather well-known. A total of four binary systems and five organic solvents, acetone (AC), acetonitrile (AN), dimethylformamide (DMF), dimethylsulfoxide (DMSO) and propylene carbonate (PC), were used. These solvents were selected so as to give a respectable range of donicities and yet with sufficiently high dielectric constants as to avoid ion pair formation. All of these solvents can be classified as "hard" bases.

EXPERIMENTAL

The macrobicyclic ligand C222 (E.M. Laboratories, Inc.) was purified by two recrystallizations from *n*-hexane and then vacuum dried for several ways. Cesium thiocyanate (Rocky Mountain Research, Inc.) was recrystallized from methanol and dried *in vacuo* at 50°C for 48 h. After drying, it was stored in a vacuum desiccator over granulated barium oxide.

AC (Fisher Scientific Co.), DMSO (Fisher), PC (Aldrich) and AN (Mallinckrodt) were purified and dried by previously outlined procedures.[5] DMF (Mallinckrodt) was refluxed over night under reduced pressure over calcium hydride, then fractionally distilled; the middle 60% fraction of the distillate was further dried over freshly activated molecular sieves (Linde type 4 A). Karl Fischer titration, and gas chromatography (in the case of AC) showed the water content of all of the solvents to be less than 100 ppm.

Most ^{133}Cs NMR measurements were carried out on a Bruker WH-180 spectrometer in the Fourier transform mode at a field of 42.3 kG and a frequency of 23.62 MHz. Some of the data were obtained with a Varian DA-60 spectrometer with a multinuclear probe at a field of 14.09 kG and 7.87 Mz. The details are given in a previous paper.[5]

In all cases the exchange of the Cs^+ ion between the complexed and the free sites was fast at the temperature and the frequency of the measurement. Assuming that only the 1 : 1 complex is formed, the population-averaged chemical shift is given by:

$$\delta_{obs} = \delta_f X_f + \delta_c X_c, \quad (1)$$

where δ_f and δ_c are the resonances corresponding to the free and the complexed Cs^+ ion, respectively, and X_f and X_c are the corresponding mole fractions of the two species. Equation (1) is combined with the equilibrium constant expression to yield:[6]

$$\delta_{obs} = [(KC_M - KC_L - 1) + (K^2C_L^2 + K^2C_M^2 - 2K^2C_LC_M + 2KC_M + 2KC_L + 1)^{1/2}]\left(\frac{\delta_f - \delta_c}{2KC_M}\right) + \delta_c. \quad (2)$$

C_M and C_L are the *total* concentrations of the metal ion and the ligand, respectively, and K is the formation constant.

Our procedure involves substitution of the experimental parameters, δ_{obs}, δ_f, C_M and C_L, into the equation, and varying K and δ_c until the calculated chemical shifts correspond, within experimental error, to the measured values. A nonlinear least-squares curve-fitting program KINFIT[7] was used for the calculations.

RESULTS AND DISCUSSION

Complexation of the cesium ion with C222 was studied in AC–DMSO, AN–DMSO, PC–DMSO and PC–DMF binary systems at the probe temperature (32°C). As an example, results obtained in the PC–DMF system are shown in Fig. 1 and the data are shown in Table 1. A similar behavior was observed in other systems, i.e. as the mole fraction of AC, AN and PC is increased in the AC–DMSO, PC–DMSO and AN–DMSO mixtures, the plots show a more pronounced curvature, indicating the formation of a more stable complex.

The values of the formation constants of the complex in the neat solvents are given in Table 2. The data obtained in the mixed solvents are summarized in Table 3. These data show, for example, that the values of the stability constants increase as the concentration of DMSO and DMF in binary mixtures is lowered. In strongly solvating solvents, such as DMSO and DMF, complex formation is rather scant, while in solvents with medium donicities, such as AC, PC and AN, a more stable complex is formed. These results parallel the behavior observed by Mei *et al.*[3] for cesium ion complexes with cryptands in various neat nonaqueous solvents. From these data it is seen that the solvating ability, as defined by Gutmann, agrees well with the behavior of the Cs^+ ion cryptate in various mixed nonaqueous solvents.

The limiting chemical shifts of the cesium–cryptate complex depends on the composition of the mixed solvents. It can be concluded, therefore, that the Cs^+ inside the C222 cavity is not completely shielded from the influence of the medium, and that there is still some direct contact between the solvent molecule and the cation. The crystal structure of the C222 · Cs^+ complex showed that the Cs^+ ion is slightly larger than the equilibrium size of the ligand cavity.[8] When the ligand penetrates the cavity it somewhat distorts the ligand. ^{133}Cs NMR studies on this complex in a variety of solvents showed[3,9] that, at room temperature, the cation does not completely penetrate the ligand cavity and forms an "exclusive" complex where a portion of the complexed cation is exposed to the solvent and, therefore, its ^{133}Cs resonance is solvent-dependent.

Table 2. Formation constants of the C222 · Cs^+ complex in neat solvents at 32°C

Solvent	Dipole moment	Donor number[a]	Log K_f

The variations of the formation constants of the C222 · Cs^+ complex as a function of solvent composition in AC–DMSO, AN–DMSO, PC–DMSO and PC–DMF mixtures are shown in Figs 2 and 3. It is interesting to note that in AC–DMSO solutions the variation of the stability constants of the cesium–cryptate complex with the solvent composition is not significant at low AC concentration (from 0 to ~15 mol % AC), suggesting that in these

solutions the metal ion, and possibly the ligand, are solvated only by DMSO. At higher contents of the AC, however, there is a substantial increase in the formation constants. It seems reasonable to assume that upon addition of more AC to the system, the DMSO molecules in the first solvation shell of the Cs^+ ion are gradually replaced by the AC molecules. Since AC is a much weaker solvating solvent than DMSO, the stability of the complex is enhanced by a diminished competition of the solvent for the metal ion.

The above results indicate that the concept of solvent donicity and the predictive ability of the donor numbers holds true at least for the binary solvent systems we investigated. It seems likely that the above generalization will hold in other solvent systems with similar properties, e.g. acid–base

character, hydrogen-bonding ability and large enough values of dielectric constants to prevent a significant amount of ion pairing. It should be noted, however, that many systems are complicated by the solvation of the ligand. This ligand–solvent interaction can have a sizable effect on the stability constants of complexes.[10] It is obvious, however, that much additional work is needed to elucidate the behavior of solvent mixtures.

TRIMETALLIC COMPLEXES OF FERROCENYLENE BIS[MERCURY(II)THIOCYANATE]

P. P. SINGH* and D. S. GUPTA

Department of Chemistry, M.L.K. College, Balrampur 271201, India

(*Received* 20 *August* 1985; *accepted after revision* 7 *May* 1986)

Abstract—$[Fe(C_5H_4HgSCN)_2M(NCS)_2]$ complexes were prepared by reacting ferrocenylene bis[mercury(II)thiocyanate] with $M(NCS)_2$ [M = Co(II), Ni(II), Cu(II) or Zn(II)]. Their adducts of general formula $[Fe(C_5H_4HgSCN)_2M(NCS)_2L]$ were prepared by reacting ferrocenylene bis[mercury(II)thiocyanate] and $M(NCS)_2L_2$ (L = morph or en). All compounds were characterized by elemental analyses, and molar-conductance, IR and electronic spectral studies. These studies indicated that the geometry around the metal is tetrahedral for cobalt and zinc, and octahedral for nickel and copper. Both types of complex have a thiocyanate-bridged structure.

Ferrocene derivatives have been used as ligands towards certain metal ions. The resulting complexes have two different metals.[1,2] Bimetallic complexes having moieties other than ferrocene have also been reported.[3] In this paper we present a new series of complexes containing three different metals by involving ferrocenylene bis[mercury(II)thiocyanate] (FBMT).

EXPERIMENTAL

Reagent grade solvents were purified before use. $M(NCS)_2$ (M = Co, Ni, Cu or Zn) were prepared by reacting their respective nitrates with KNCS in ethanol. $M(NCS)_2L_2$ [L = morph or en] were prepared by direct reaction of morph or en with $M(NCS)_2$ in ethanol. Morph, en and dimethylsulphoxide (DMSO) were used from fresh bottles FBMT was prepared by mercuration of ferrocene as described below.

Preparation of FBMT

To a solution of ferrocene (18.4 g, 0.1 mol) in benzene (96 cm^3), a solution of mercuric acetate (32.8 g, 0.1 mol) in methanol (360 cm^3) was added drop by drop over a period of 1 h with continuous stirring. The stirring was further continued for 0.5 h. To this solution a solution of KNCS (9.7 g, 0.1 mol) in distilled water (10 cm^3) was added and stirred for 0.5 h. An orange yellow precipitate was obtained which was filtered through a Buchner funnel, washed with petroleum ether and dried *in vacuo*. This compound was a mixture of ferrocenyl mercury thiocyanate (FMT) and FBMT. From the mixture FBMT was separated by Soxhlet extraction using 1,2-dichloroethane as solvent. The extraction was repeated with 1,2-dichloroethane 7 or 8 times till the extract became colourless. On vacuum evaporation of the extract impure FMT was obtained. The residue was FBMT, which was purified by dissolving in DMSO, followed by addition of water. The compound was filtered, washed with petroleum ether and dried *in vacuo*. The purity of the compound was tested by elemental analyses and IR spectral measurements. The FBMT so obtained was used as ligand.

FBMT: m.p. 145°C (d). Found: N, 4.0; S, 9.1; Hg, 56.9%. Calc.: N, 4.0; S, 9.1; Hg, 57.1%.

Preparation of complexes

$[Fe(C_5H_4HgSCN)_2M(NCS)_2L_x]$ *adducts* [M = Co(II), Ni(II), Cu(II) *or* Zn(II); L = 2*morph or en*]. $[Fe(C_5H_4HgSCN)_2]$ (1 mmol) was dissolved in 30 cm^3 of DMSO and the solution was diluted with 100 cm^3 of acetone. To this solution, 1 mmol solution of $M(NCS)_2 \cdot 2L$ in 25 cm^3 acetone was added and stirred for 36 h. Solid compound was formed in each case, which was filtered, washed with acetone and dried *in vacuo*. The complexes were purified by dissolving in DMSO and isolating them by addition of water.

$[Fe(C_5H_4HgSCN)_2M(NCS)_2]$: *Lewis acids* (M = Co *or* Ni). The compounds were prepared by heating the morpholine complexes $[Fe(C_5H_4HgSCN)_2 M(NCS)_2(morph)_2]$ *in vacuo* for about 80 h at 60°C. The morpholine was given off leaving behind the compounds of general formula $[Fe(C_5H_4HgSCN)_2M(NCS)_2]$. The compounds were purified by first dissolving in acetone and isolating them by addition of petroleum ether.

$[Fe(C_5H_4HgSCN)_2M(NCS)_2$ (M = Cu *or* Zn). 0.7 g of FBMT was dissolved in 30 cm^3 of DMSO and diluted with 100 cm^3 of ethanol. To this solution a solution of an equimolar quantity of $M(NCS)_2$ in 25 cm^3 of acetone was added and stirred for 36 h. Solid compound was formed in each case, which was filtered, washed with acetone and dried *in vacuo*. The compounds were recrystallized from an acetone–ethanol mixture.

Analyses of the complexes

The complexes were analysed for cobalt as anthranilate, nickel as dimethylglyoximate, sulphur as sulphate and mercury as sulphide, gravimetrically. Nitrogen was estimated by the semimicro Kjeldahl's method. Analytical results are presented in Table 1.

Physical measurements

The molar conductances of the complexes were measured in DMSO using a Philips conductivity bridge model PR-9500. Electronic spectra were recorded as Nujol mulls or in DMSO (solution phase) on a Pye–Unicam SP-5-500 spectrophotometer in the range 250–999 nm. IR spectra were recorded as Nujol mulls or KBr pellets on a Pye–Unicam SP-3-300 spectrophotometer in the range 4000–200 cm^{-1}. The molecular weights were determined by the cryoscopic method using DMSO.

RESULTS AND DISCUSSION

The IR spectra of FBMT were recorded in Nujol and DMSO. The mull spectra show the presence of three bands at 2190, 2120 and 2100 cm^{-1} in the ν(C—N) region, two bands at 730 and 720 cm^{-1} in the ν(C—S) region and two bands at 460 and 410 cm^{-1} in the δ(NCS) region. In solution phase only two bands at 2120 and 2100 cm^{-1} are observed, and the band at 2190 cm^{-1} disappears. This shows that FBMT is a dimer like CH_3HgSCN in the solid phase[4] through bridging as shown in Fig. 1. In the solution phase the bridge is ruptured and it becomes a monomer as shown below.

Lewis acids

On reaction with $M(NCS)_2$ FBMT forms complexes of general formula $[Fe(C_5H_4HgSCN)_2 M(NCS)_2]$. These complexes have been referred to as Lewis acids. The IR spectra indicate that the ν(C—N) stretching band moves from 2120 in FBMT to 2190 cm^{-1} in the Lewis acid. The ν(C—S) and δ(NCS) bands change their positions to 790 and 480 cm^{-1}, respectively. The positions of these bands are indicative of the presence of bridging thiocyanate group.[3] A band is also observed in the region 2070 cm^{-1} which is assigned to *N*-bonded terminal thiocyanate arising from M—NCS.[5] These changes indicate that the thiocyanate of FBMT becomes bridged by coordination through its free *N*-end to the M of $M(NCS)_2$. The electronic spectral data as presented in Table 2 indicate that cobalt is in tetrahedral and the nickel is in octahedral geometry in their Lewis acids. The octahedral geometry in case of the nickel Lewis acid is perhaps acquired by axial coordination of thiocyanate group of other molecule of adjacent layer.[7] Copper perhaps also acquires octahedral geometry through similar axial coordination in its Lewis acid. The IR spectra of the zinc Lewis acid have close similarity with the cobalt Lewis acid. The zinc has also a preference for tetrahedral geometry; hence it can be presumed that the geometry around this metal is also tetrahedral. The molar-conductance data show that they are non-conducting in nature. On the basis of the above results the following structures (Figs 2 and 3) can be proposed

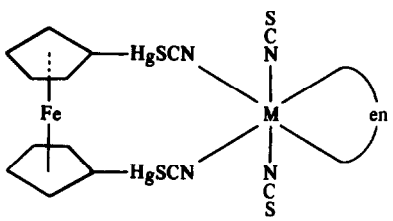
for the Lewis acids. Since a single crystal could not be grown the proposed structures are tentative.



Adducts $[Fe(C_5H_4HgSCN)_2M(NCS)_2L_x$ (L = *morph or en*, x = 1 *or* 2)

FBMT on reaction with $M(NCS)_2L_2$ forms adducts of general formula $[Fe(C_5H_4HgSCN)_2 M(NCS)_2L_x$. The IR spectra of these adducts show that there is no significant change in the positions of ν(C—N), ν(C—S) and δ(NCS) on adduct formation as compared to the Lewis acid. However, a negative shift in the position of ν(M—NCS) is observed when M is cobalt and zinc. This change in ν(M—NCS) is on account of change in geometry of the metal ions from tetrahedral to octahedral. It has earlier been observed that a change in geometry causes a negative shift in the ν(M—NCS) band.[8,9] The geometry around nickel and copper remains the same on adduct formation, hence the changes in the positions of ν(M—NCS) in these cases are insignificant. This shows that the basic structure of the Lewis acid is retained and the change is only in the coordination geometry. The electronic spectral data are presented in Table 2.

The spectral band positions and spectral parameters favour octahedral geometry around cobalt and nickel. Since the infrared spectra of the complexes of zinc and copper have close similarity with cobalt and nickel complexes, it has been presumed that they too have octahedral geometry around M. All the adducts are non-conducting in DMSO solution. On the basis of the above studies the following structures (**IIIa** and **IIIb**) can be proposed for the adducts.

TERNARY COMPLEXES OF 5′-CYTIDINE MONOPHOSPHATE AND CYTOSINE WITH SOME BIOLOGICALLY IMPORTANT SECONDARY LIGANDS

PULIMAMIDI RABINDRA REDDY* and B. MADHUSUDHAN REDDY

Department of Chemistry, Osmania University, Hyderabad 500007, India

(*Received* 30 *October* 1985; *accepted after revision* 7 *May* 1986)

Abstract—Potentiometric equilibrium measurements have been made at 35°C for the interaction of 5′-cytidine monophosphate and Cu(II), Ni(II), Zn(II), Co(II), Mn(II), Mg(II) and Ca(II) with biologically important secondary ligands (glycine, oxalic acid, histidine and histamine) in a 1:1:1 ratio. Similar studies with cytosine were carried out for comparison. For the above systems, the ternary complexes are found to be more stable than the corresponding binary complexes. The Δ log K values for 1:1:1 complexes of metal–5′-cytidine monophosphate (or cytosine) with aromatic ligands are more positive compared to the corresponding complexes with aliphatic ligands. This is explained in terms of "stacking phenomenon" that occur between the two aromatic moieties of the primary and secondary ligands in solution.

Nucleotides contain a heterocyclic nitrogenase base (either purine or pyrimidine derivative), a pentose sugar and the phosphate moiety. Because of the presence of these three components, which offer a large number of potential binding sites for metal coordination, the study of metal interactions with these molecules becomes very important and interesting from the view point of a bioinorganic chemist. A large number of papers have appeared on metal–nucleotide complexes[1–15] to explore the nature of the bonding. One method of approach is the study of ternary complexes of these molecules especially with biologically important ligands, as these systems mimic many biological reactions.

The ternary complexes of pyrimidine nucleotides are less known compared to purine nucleotides. The solid dimeric and polymeric complexes of uridine 5′-monophosphate[16,17] and cytidine-5′-monophosphate[18–20] (5′-CMP) were reported earlier. However, in solution only the ternary complexes of 5′-CMP with Ni(II) and L-tryptopan were reported.[11] In view of this we have undertaken a detailed investigation of the interaction of 5′-CMP with various divalent metal ions and biologically important ligands (glycine, oxalic acid, histidine and histamine). We have also studied the similar interactions with cytosine, the simplest example of metal–nucleic base interactions, for comparison. These studies we hope will help in the correct assignment of the coordination sites on nucleic acid components in the absence and presence of the phosphate residue, which adds a new dimension to the metal-bonding concept.

EXPERIMENTAL

5′-CMP, cytosine, glycine, histidine and histamine were obtained from Sigma Chemical Co. (U.S.A.) and oxalic acid from Fluka (Switzerland). Transition and alkaline earth metal ions were of AnalaR grade and were standardized volumetrically by titration with disodium salt of EDTA in the presence of a suitable indicator as outlined by Schwarzenbach.[21] Carbonate-free sodium hydroxide was prepared by the method of Schwarzenbach and Biedermann.[22]

The experimental conditions and procedures in this work were similar to those described in our earlier publication.[23]

CALCULATIONS AND RESULTS

Dissociation constants

The acid dissociation constants of the 5′-CMP, cytosine, glycine, oxalic acid, histidine and his-

tamine were calculated by the usual algebraic method.

Formation constants

To calculate the stability constants of the ternary complexes of Ni(II), Zn(II) and Co(II) with 5′-CMP and histidine in a 1 : 1 : 1 ratio the following equations were employed [eqns (1)–(12)] (charges are omitted for clarity):

$$M+H_2L+H_2A \rightleftharpoons MLA+4H^+, \quad (1)$$

together with the related equilibria:

$$M+L+A \overset{K^M_{MLA}}{\rightleftharpoons} MLA, \quad (2)$$

$$K^M_{MLA} = \frac{[MLA]}{[M][L][A]}, \quad (3)$$

$$[L] = \frac{\alpha Q}{XQ+YP}, \quad (4)$$

$$[A] = \frac{\alpha P}{XQ+YP}, \quad (5)$$

$$[M] = [A]P \quad \text{or} \quad [L]Q, \quad (6)$$

$$[MLA] = T_M - [M], \quad (7)$$

$$\alpha = (4-m)T_L - [H^+] + [OH^-], \quad (8)$$

$$Q = \frac{[H^+]^2}{K_aK_{2a}} + \frac{[H^+]}{K_{2a}} + 1 \quad (9)$$

$$Y = \frac{4[H^+]^2}{K_aK_{2a}} + \frac{3[H^+]}{K_{2a}} + 2 \quad (10)$$

using K_a and K_{2a} of 5′-CMP,

$$P = \frac{[H^+]^2}{K_aK_{2a}} + \frac{[H^+]}{K_{2a}} + 1 \quad (11)$$

$$X = \frac{4[H^+]^2}{K_aK_{2a}} + \frac{3[H^+]}{K_{2a}} + 2 \quad (12)$$

using K_a and K_{2a} of histidine.

These equations [(1)–(12)] were also employed to calculate the stability constants of the ternary complexes of Ni(II), Zn(II) and Co(II) with 5′-CMP and histamine in a 1 : 1 : 1 ratio.

To calculate the stability constants of the ternary complexes of Cu(II), Ni(II), Zn(II), Co(II), Mn(II), Mg(II) and Ca(II) with 5′-CMP and oxalic acid the following equations were used:

$$M+H_2L+H_2A \rightleftharpoons MHLA+3H^+ \quad (13)$$

together with the related equilibria:

$$M+HL+A \overset{K^M_{M(HL)A}}{\rightleftharpoons} MHLA, \quad (14)$$

$$K^M_{M(HL)A} = \frac{[MHLA]}{[M][HL][A]}. \quad (15)$$

The calculation of the constant $K^M_{M(HL)A}$ was done by the method described in our earlier publication.[24] These equations [(13)–(15)] were also employed to calculate the stability constants of Cu(II), Mg(II), Mn(II) and Ca(II) with 5′-CMP and histidine or histamine in the buffer region between $m = 0$ and $m = 3$.

In order to calculate the stability constants of Cu(II), Ni(II), Zn(II), Co(II), Mn(II), Mg(II) and Ca(II) with 5′-CMP and glycine in a 1 : 1 : 1 ratio the following equations were used:

$$M+H_2L+H_2A \rightleftharpoons M(HL)(HA)+2H^+ \quad (16)$$

together with the related equilibria:

$$M+HL+HA \rightleftharpoons M(HL)(HA), \quad (17)$$

$$K^M_{M(HL)(HA)} = \frac{[M(HL)(HA)]}{[M][HL][HA]}, \quad (18)$$

where HL is the monoanion of 5′-CMP and HA is neutral glycine.

The calculation of the constants $K^M_{M(HL)(HA)}$ was done by the equations given in our previous paper.[24] These equations were also employed to calculate the stability constants of Cu(II), Ni(II) and Co(II) with 5′-CMP and glycine in a 1 : 1 : 1 ratio in the buffer region between $m = 2$ and $m = 4$.

For the ternary metal(II) ion–5′-CMP–oxalic acid complexes in the buffer region between $m = 3$ and $m = 4$ the following equations were used:

$$M(HL)A \rightleftharpoons MLA+H^+, \quad (19)$$

together with the related equilibria:

$$M+L+A \overset{K^{M(HL)A}_{MLA}}{\rightleftharpoons} MLA, \quad (20)$$

$$K^{M(HL)A}_{MLA} = \frac{T_M - [M]}{[M][L]}. \quad (21)$$

$K^{M(HL)A}_{MLA}$ was calculated by the equations given in our earlier paper.[25] These equations [(19)–(21)] were also employed for Zn(II), Mn(II), Mg(II) and Ca(II) with 5′-CMP and glycine in a 1 : 1 : 1 ratio in the buffer region between $m = 2$ and $m = 3$, and also for Cu(II), Mn(II), Mg(II) and Ca(II) with 5′-CMP and histidine or histamine in a 1 : 1 : 1 ratio in the region between $m = 3$ and $m = 4$.

All the above calculations were done by a CASIO PB 100 Personel Computer with suitable programmes.

DISCUSSION

The proton dissociation constants of the ligands 5′-CMP, cytosine, glycine, oxalic acid, histidine and histamine are presented in Table 1.

Table 2 presents the stability constants of ternary

complexes of cytosine with glycine, oxalic acid and histamine. Table 3 gives the ternary complexes of 5′-CMP with glycine, oxalic acid, histamine and histidine. Among the ternary complexes of divalent metal ions and cytosine [only Cu(II) constants can be compared] the following order is observed with various secondary ligands: histidine[26] > histamine > glycine > oxalic acid. This is in accordance with the aromaticity and the nature of the donor atoms of these ligands.[25,27–29]

It is important here to mention briefly the various factors that influence the formation of ternary complexes in solution. In ternary systems the interligand interactions have been found to be most effective in deciding the stability of the ternary complexes along with other factors like the nature of the metal ion, the geometry of the metal complex and the solvent effects, etc. However, it should be mentioned here that these interactions (interligand) are highly specific and selective. The effects of charge neutralization, the π-accepting capacity of the secondary ligand and the stacking interactions are usually quantified in terms of $\Delta \log K$. $\Delta \log K$ is the difference between the overall 1 : 1 : 1 ternary complexes

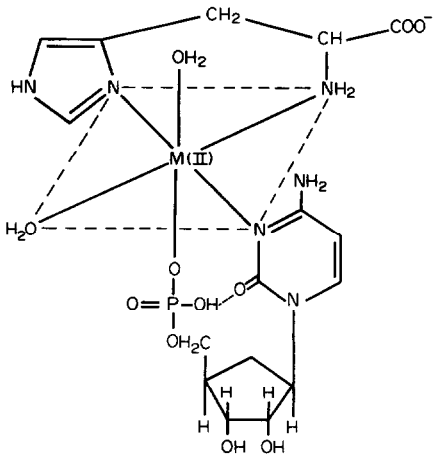

Fig. 1. Tentative structure of M(II) : 5′-CMP : histidine (1 : 1 : 1) illustrating the histamine-like coordination and stacking interaction.

and the corresponding 1 : 1 binary complexes. Since $\Delta \log K$ is derived from two different constants it is also a constant but varies with temperature like any other constant. The $\Delta \log K$ values for the various systems studied are given in Table 4.

It can be seen from the Table 4 that the $\Delta \log K$ values are positive for all the systems. First, let us compare the $\Delta \log K$ values for the systems where interligand interactions are absent (glycine and oxalic acid systems of cytosine). The corresponding values with 5′-CMP could not be computed owing to the formation of different types of complexes in binary and ternary systems. The $\Delta \log K$ values for Cu(II)–cytosine–glycine are more positive than for the Cu(II)–cytosine–oxalic acid complexes; for the rest of the metal ions the data could not be computed. This is due to the involvement of mixed

donor atoms in metal coordination in the case of glycine system (enhancement of stability on coordination with mixed N/O atoms compared to pure O/O and N/N atoms). Similar results were also reported for other related systems.[24,28,30] This is further supported by electrostatic molecular potential calculations.[31] In the case of systems where interligand interactions are expected (histidine and histamine systems of cytosine and 5′-CMP), the Δ log K values of histidine are less positive than the corresponding values of histamine for all the metal ions with cytosine as well as 5′-CMP. This trend is exactly the reverse of that observed in their respective binary complexes. In 1:1 complexes histidine forms more stable complexes than histamine as it is known to behave as a terdentate ligand. However, in ternary complexes the data suggest that histidine is acting as a bidentate ligand. Then the interesting question that arises is which is the donor group that is not involved in metal binding in ternary system. It is likely that the histidine may act in a histamine-like manner involving amino and imidazole groups for metal-bonding and hydrogen-bond type of interaction between the histidine C(=O)—O and the —NH_2 of 5′-CMP takes place. As a result the C(=O)—O group is kept away from the metal. Although we do not have definite evidence for this, similar observations were made earlier in the case of metal–ATP–histidine[32] and metal–cytidine–histidine complexes.[25] Such an interaction is known to disfavour the formation of ternary complexes in solution by an entropy factor as the ligands become more rigid as a consequence of a bridge between two non-coordinating groups (amino and carboxylate groups), and also due to the different degrees of solvent interaction with the metal ion. This may be the reason for the less positive values of Δ log K in histidine complexes compared to the histamine in both cytosine and 5′-CMP systems.

It is of interest and important here to compare the Δ log K values of cytosine and 5′-CMP systems (histidine and histamine) with that of cytidine.[25] The Δ log K values of 5′-CMP are more positive, followed by cytidine and cytosine. Higher values in the case of the 5′-CMP system are due to the presence of the phosphate moiety, which is the strongest donor group. The more positive values of cytidine compared to cytosine may be due to the presence of an additional donor atom in the latter which may exert an influence on the donor atom which is being chelated and this accounts for its lower stability. The magnitudes of Δ log K values of all the systems indicate that the stacking interaction, which is

expected to occur between the pyrimidine ring of the primary ligand and imidazole ring of the secondary ligands, is most effective for accounting the extra stability found in ternary systems.

Based on the above conclusions we propose Fig. 1 as the structure for metal–5′-CMP–histidine. This structure allows: (i) minimum steric hindrance between two ligands, and (ii) there is a hydrogen-type bonding between the OH of phosphate and the C(2)—O of the imidazole ring. The stacking is possible as both the ligands are only two bond distances apart. Though many studies in solution favoured the phosphate group rather than the purine or pyrimidine base as the primary metal-binding site, the simultaneous binding of a metal ion to base and phosphate was reported for the modified mononucleotides of transfer RNA.[33] Consequently, we have also involved N(3) along with phosphate oxygen in metal bonding as it allows the required stacking interaction.

VIBRATIONAL SPECTRUM OF $[(CD_3)_3S]I$ AND NORMAL COORDINATE CALCULATIONS FOR $[(CH_3)_3S]^+$ AND $[(CD_3)_3S]^+$ CATIONS

KOYO AIDA, SHIN KUSAKA, TAKASHI UEDA,* HISASHI SHIBUYA† and YOSHIKA IMAI‡

(*Received* 6 *January* 1986; *accepted* 7 *May* 1986)

Abstract—IR (4000–30 cm^{-1}) and Raman (4000–0 cm^{-1}) spectra of $[(CD_3)_3S]I$ have been observed, together with those of $[(CH_3)_3S]I$. By assuming a C_{3v} molecular symmetry for the cations $[(CH_3)_3S]^+$ and $[(CD_3)_3S]^+$, all the active fundamentals of $[(CD_3)_3S]^+$ have been assigned and normal coordinate calculations have been carried out by a symmetry force field for $[(CH_3)_3S]^+$ and $[(CD_3)_3S]^+$. The strength of the S—C and C—H bonds in the compound has been compared with that in dimethyl sulfide by using their valence stretching force constants.

During the course of a vibrational spectroscopic study on dimethyl sulfide–boron trihalide adducts,[1] we were interested in the extent to which the bond strength of the ligand is influenced by adduct formation. It is of interest to investigate such influence encountered in other dimethyl sulfide adducts. Dimethyl sulfide reacts with some alkyl halides to form sulfonium compounds. The sulfonium compound contains a sulfonium ion which can be regarded as an adduct between a carbonium ion and dimethyl sulfide. Therefore, the study has now been extended to trimethylsulfonium iodide which is one of the simplest sulfonium compounds.

Although the vibrational spectra of trimethylsulfonium halide have been observed by Creighton *et al.*,[2] no vibrational spectra of the deuterated compounds have been reported. They also carried out the normal coordinate calculations, without the data of the isotopic compounds. However, in order to obtain more reliable force constants, the calculations should be made including the data of isotopic molecules. In this paper we report the vibrational spectra of $[(CD_3)_3S]^+$ and the normal coordinate calculations for $[(CH_3)_3S]^+$ and $[(CD_3)_3S]^+$. Since the trimethylsulfonium iodide is easily prepared and the spectra of sulfonium compounds do not depend on an anion, with a few exceptions, no study has been made on other trimethylsulfonium compounds in this work.

EXPERIMENTAL

Trimethylsulfonium iodide was prepared by the reaction of dimethyl sulfide with methyl iodide in a sealed glass tube at room temperature. The white solid was deposited after a day. The crude compound was recrystallized from ethanol and dried over P_4O_{10} *in vacuo*: m.p. 209.5–212°C (lit.[2] 211–212.5°C). The deuterated compound was prepared in the same manner using $(CD_3)_2S$ and CD_3I: m.p. 209–211°C.

IR (4000–400 cm^{-1}) and far-IR (400–30 cm^{-1}) spectra were recorded on Hitachi 345 and Hitachi FIS-III spectrophotometers, respectively. The spectra were observed in Nujol and hexachlorobutadiene mulls.

Raman spectra (4000–0 cm^{-1}) were recorded in the solid state on a JEOL-JRS-S1 spectrophotometer equipped with an He–Ne laser. The spectra were also measured in aqueous solutions in order to obtain qualitative polarizations.

RESULTS AND DISCUSSION

The crystal structure for the compound was examined by an X-ray diffraction method.[3] Though the study had revealed that the SC_3 skeleton has a C_{3v} symmetry, no information about the configuration of the methyl groups was obtained owing to the low X-ray scattering power of a hydrogen atom. We assumed that each methyl group is staggered to the neighbouring C—S bonds for the free sulfonium ion. Therefore its overall symmetry is also C_{3v}. Under this symmetry, 33 normal vibrations divide into $7a_1+4a_2+11e$. The a_1 and e modes are active in both the IR and Raman spectra and the a_2 modes inactive in both.

No discussion about the vibrational spectra and the assignments for the light compound seems to be necessary, since they were almost the same as those reported by Creighton *et al.*[2]

Table 1 shows the observed IR and Raman frequencies and their assignments for $[(CD_3)_3S]^+$. The assignments of the fundamentals were made by taking into consideration those of $(CD_3)_2S$[4] and $(CD_3)_3P$.[5] Trimethylphosphine is isoelectronic with the trimethylsulfonium ion. But there is also no need to discuss them except for the modes which are observed below 400 cm^{-1}.

Three modes (a_1 and e SC_3 deformations and an e methyl torsion) are expected to be observed below 400 cm^{-1}. We have observed three Raman bands at 269, 243 and 153 cm^{-1} in the solution spectrum. Though the correct polarization measurement for the band at 269 cm^{-1} is difficult owing to the overlap of the band at 243 cm^{-1}, the 269-cm^{-1} band

w = weak, s = strong, vw = very weak, vs = very strong, m = medium, sh = shoulder, p = polarized, dp = depolarized, asym. = asymmetric, sym. = symmetric, str. = stretch, def. = deformation.

seems to be polarized. Therefore, we assigned the band to the a_1 SC_3 deformation (ν_7). Thus the 243- and 153-cm^{-1} bands should be due to the e modes. Considering their intensity and the assignments for the light compound, we assigned the 243-cm^{-1} band to the e SC_3 deformation (ν_{21}) and the 153-cm^{-1} to the e torsion (ν_{22}). For $[(CH_3)_3S]I$ the former mode was observed at 284 cm^{-1} and the latter at 209 cm^{-1} in the solution Raman spectrum. The ratio 209/153 is 1.37 which is close to that expected for the methyl torsion, while 284/243 is 1.17 which is too small for the torsion.

The normal coordinate calculations were performed for the a_1 and e modes using programs designed by Watari.[6] Molecular parameters used here were based on the X-ray data,[3] except for those of methyl group which were assumed: r(C—S) = 1.83 Å, r(C—H) = 1.093 Å, $\angle CSC = 103°$, $\angle SCH = \angle HCH = 109°28'$. The least-squares refinements were carried out in terms of the symmetry force constants, which were fitted to the observed fundamental frequencies, for the two isotropic molecules, simultaneously. The observed frequencies used in the calculation were obtained from the Raman spectra for the aqueous solution except for ν_{18} for $[(CH_3)_3S]^+$ and ν_4 and ν_{17} for $[(CD_3)_3S]^+$. ν_{18} for $[(CH_3)_3S]^+$ was obtained from the IR spectrum and ν_4 and ν_{17} from the Raman spectrum in the solid.

Table 2. Description of the symmetry coordinates for trimethylsulfonium ion

Table 2 shows the description of the symmetry coordinate which needs in order to describe the potential energy distributions. Table 3 shows the observed and calculated frequencies and potential energy distributions for $[(CH_3)_3S]^+$ and $[(CD_3)_3S]^+$. The average errors between the observed and calculated frequencies are 0.70 and 0.54% for a_1 and e modes, respectively. The proposed assignments for $[(CH_3)_3S]^+$ and $[(CD_3)_3S]^+$ are supported by the potential energy distribution shown in Table 3. Table 4 shows symmetry force constants from the last cycle in the least-squares refinement, together with their statistical errors.

[a]The stretching force constants are given in N cm^{-1}, the deformation force constants in 10^{-16} N cm rad^{-2}, and the stretching–deformation interaction constants in 10^{-8} rad^{-1}. The subscript number i in $F_{i,i}$ (diagonal element) corresponds with that in S_i in Table 2. $F(\sigma)$ means the statistical error.

The S—C and C—H valence stretching force constants were 3.1 ± 0.06 and 4.8 ± 0.035 N cm^{-1}, respectively. These were calculated from the symmetry force constants in Table 4. The S—C force constant is slightly smaller than that of dimethyl sulfide reported by Levin and Pearce;[7] 3.4 ± 0.08 N cm^{-1}, while the C—H force constant is slightly larger than 4.7 ± 0.05 N cm^{-1} [7] in dimethyl sulfide. Though many investigators reported the force constants of dimethyl sulfide, it seems to be reasonable to be compared with Levin–Pearce's force constants, because the force constants were calculated by using a valence force field and their statistical errors were also reported. These force constants show that upon adduct formation the S—C bond of dimethyl sulfide is weakened but the C—H bond strengthened, indicating that adduct formation influences the C—H bonds as well as the C—S bonds. For the C—S bonds, this is consistent with what might be expected from their bond distances; 1.83 Å in trimethylsulfonium iodide,[3] 1.802 Å in dimethyl sulfide.[8]

SPECTROSCOPIC *CIS*-INFLUENCES IN OCTAHEDRAL TIN(IV) *MESO*-TETRAPHENYLPORPHYRIN COMPLEXES

DENNIS P. ARNOLD

Chemistry Department, Queensland Institute of Technology, G.P.O. Box 2434, Brisbane 4001, Australia

(*Received* 6 *January* 1986; *accepted* 7 *May* 1986)

Abstract—Visible absorption and ^{1}H NMR spectra have been measured for a series of octahedral tin(IV) porphyrin complexes Sn(TPP)X_2, where TPP is *meso*-tetraphenylporphyrin and X is Cl, OH, OMe, OAc, NO_3, ClO_4, Br, I, NCS and OC_6H_4-*p*-Me. The tin–proton coupling constants to the β-pyrrole protons decrease from 19.2 Hz (X = ClO_4) to 9.9 Hz (X = OMe), and for the oxygen-bound ligands, correlate well with the basicity of the ligands. The halides do not fit this relationship, perhaps because of π-bonding effects. The chemical shifts of the β-protons also depend on the nature of X, and vary from 9.35 (X = ClO_4) to 9.04 (X = OC_6H_4-*p*-Me) ppm. Increasing basicity of X causes red shifts in the visible spectra, as well as a decrease in the molar absorption coefficient ratio ($\varepsilon_\beta/\varepsilon_\alpha$) for the visible absorption bands. Tin–proton coupling constants for the axial ligands OH, OMe and OAc are reported. The complex Sn(TPP)$(ClO_4)_2$ exhibits unusual NMR behaviour in $CDCl_3$ solutions, possibly due to self-aggregation.

NMR spectra of diamagnetic metalloporphyrins containing spin-$\frac{1}{2}$ magnetically active metal ions have been exploited to a limited extent in structural and reactivity studies. Various data for thallium(III),[1–3] mercury(II),[3] phosphorus(V),[4] platinum(II)[5–7] and tin(IV)[8–11] complexes of octaethylporphyrin (OEP) and tetraphenylporphyrin (TPP) have been published, including some metal–^{1}H and metal–^{13}C coupling constants. Some data have also been forthcoming on the NMR properties of proton-bearing axial ligands in tin(IV) complexes,[8–11] including interesting long-range couplings between axial OH protons and ^{13}C nuclei on the porphyrin periphery.[8] Studies of five-coordinate indium(III) porphyrins have revealed correlations between the donor strengths of axial ligands and electro- and spectrochemical properties,[12] although the absence of a spin-$\frac{1}{2}$ isotope necessarily restricted the NMR data to chemical shifts.

The present study was undertaken to evaluate the utility of coupling constants involving ^{117}Sn and ^{119}Sn in studies of the chemistry of these metalloporphyrins, in particular with respect to the reactions of axial ligands. In this paper, the syntheses, visible absorption and ^{1}H NMR spectra of a series of octahedral Sn(IV) TPP complexes (Fig. 1) are reported, and correlations between spectroscopic properties and the nature of the axial ligands are discussed.

RESULTS AND DISCUSSION

IR spectra

Complexes containing IR-active axial ligands exhibited the expected bands in solid-state spectra (Table 1). The hydroxo ligands in **2** were identified by a weak, sharp doublet at 3590 and 3610 cm^{-1}.[8] The low frequency of the ν(CN) band in the spectrum of **9** suggests that the thiocyanate ligands are N-bound.[13] NMR data support this conclusion (see below).

The situation with the O-bound ligands in complexes **3**, **5** and **6** is less clear. It appears that, especially for **3**, both unidentate and bidentate ligands are present in the solid state. In Zr(OEP)$(OAc)_2$, bands at 1560, 1460 and 690 cm^{-1} were assigned to chelating acetates, while in Sn(OEP)$(OAc)_2$, bands at 1640 and 1380 cm^{-1} indicated unidentate ligands.[14] Intermediate coordination has been found crystallographically for In(OEP)(OAc) which absorbs at 1570 and 1405 cm^{-1}.[15]

[b]IR in KBr disc.
[c]ε given relative to *Q*(1,0) band.
[d]All bands broad, shoulders at *ca* 434 and 604 nm.

Complex **3** shows bands for both types (Table 2), while the NMR spectrum of a solution of the same material showed only single Sn-porphyrin and acetate methyl signals. The situation for the dinitrato analogue (**5**) is similarly ambiguous from the IR spectrum.[13] A poorly resolved envelope of bands from 1135 to 960 cm^{-1} for **6** is consistent with O-bound perchlorate ligands.[13–16]

Visible absorption spectra

The spectra (Table 1) of all the complexes except (**8**) are typical of Sn(IV) porphyrins, and exhibit the "normal" type of metalloporphyrin spectrum.[17] The compounds are displayed in Table 1 in order of increasing red shift of the α band. The other bands show a similar trend, although shifts for the

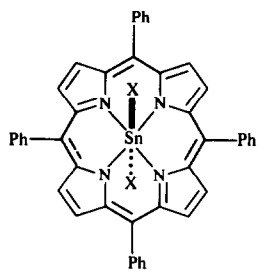
Soret band are very small. Gouterman *et al.*[18] studied a smaller series of Sn(etioporphyrin-I)X_2 complexes (X = F, OCOPh, OH, Cl, Br, I) and found a similar red shift of the α band. The complex (**8**) is somewhat unstable in $CHCl_3$ solution, but it is clear that it exhibits an unusual spectrum, in that the bands are all broadened and have reduced ε_{max} compared with the other compounds. Both the instability and the spectral differences were noted for Sn(Etio-I)I_2, and to a lesser extent for Sn(Etio-I)Br_2.[18] The red shift for **8** is such that the solid appears almost black and thin films of the solution are greenish, while all the others appear red, purple or violet.

The second parameter which changes significantly over the series is the ratio of the molar absorption coefficients for the β and α bands ($\varepsilon_\beta/\varepsilon_\alpha$). A general relationship between red shift and decreasing ratio is clear, but the trend is not smooth. With the exception of X = ClO_4, the O-donors show a rough dependence of $\varepsilon_\beta/\varepsilon_\alpha$ on the strength of their conjugate acids. As discussed under NMR spectra below, the positions of the halides are exceptional. The behaviour of complex **6** may reflect aggregation (see below). The limit of these trends is probably Sn(TPP)$(CH_2SiMe_3)_2$ reported by Pommier *et al.*[10] The powerful σ-donor ligands cause a red shift of the α band to 660 nm, and a reduction of $\varepsilon_\beta/\varepsilon_\alpha$ to *ca* 0.5. A parallel series of TPP complexes is In(TPP)R, where R was varied from ClO_4 through Cl and increasingly basic alkyl groups to *t*-butyl.[12] The α-band shifted from 595 to 639 nm, and $\varepsilon_\beta/\varepsilon_\alpha$ decreased from 1.94 to 0.72. A striking difference appears, however, on perusal of the data for the electron-rich macrocycles OEP and Etio-I. The same red shift trend is evident in In(OEP)R, but the effect on $\varepsilon_\beta/\varepsilon_\alpha$ is large, and in the opposite sense to that the TPP series, viz. 0.96 (ClO_4) to 3.78 (t-Bu).[12] This reversal is also present in Sn(Etio-I)X_2, for which the ratio changes from 0.87(X = F) to 1.77(X = I),[18] and in Tl(OEP)X_2, where $\varepsilon_\beta/\varepsilon_\alpha$ varies from 1.18 (X = $OCOCF_3$) to 1.54 (X = CN).[1] Such an inversion has been noted before in comparisons of OEP and TPP complexes for different metal ions. A high value of $\varepsilon_\beta/\varepsilon_\alpha$ for TPP complexes generally indicates more stable metal ion coordination, as expected in this series for weaker donors such as NO_3, whereas the opposite is found for OEP complexes.[19] A theoretical explanation has apparently not yet been advanced.

^1H NMR spectra

The relevant ^1H data for complexes **1–10** are displayed in Table 2, together with comparable literature data. The spectra are typical of TPP metal



Formula	Number in text	X
	**1**	Cl
	2	OH
	3	OAc
	4	OMe
	5	NO_3
	6	ClO_4

complexes, consisting of singlet β-pyrrole resonances at lowest field, the *meso*-phenyl groups in the normal regions of 8.3 and 7.8 ppm, and signals for proton-containing axial ligands at high field. The β-pyrrole and axial ligand (X = OH, OMe, OAc) signals are flanked by Sn satellites due to coupling with ^{119}Sn and ^{117}Sn (spin-$\frac{1}{2}$, abundances 8.6 and 7.6%, respectively). Although the ^1H spectra of various Sn(IV) porphyrin complexes, e.g. Sn(OEP)X_2 (X = Cl, OMe, OPh, OAc)[9,20,21] and Sn(TPP)X_2 (X = Cl, OH)[8] have been reported, Sn—H coupling information has been unavailable until recently,[8] presumably because of signal-to-noise problems. With the advent of high-field FT instruments, such information is now accessible even for very insoluble complexes.

Sn–H coupling constants

The compounds are listed in Table 2 in order of decreasing magnitude of ^4J(Sn–H) for the β-pyrrole signals. Individual couplings to ^{119}Sn and ^{117}Sn were not resolved so average values are given. If only O-bound ligands are considered, it is apparent that a representative selection of such ligands is present, spanning a wide range of donor abilities. Moreover, the coupling constants for this smaller set show a good correlation ($r = 0.991$, $n = 6$) with the pK_as of the conjugate acids[22] of the ligands (Fig. 2). This dependence may be useful in structural assignment and reactivity studies. The halides, however, do not fit this correlation, although they span a very small pK_a range, and changes in J are small. The difference in ^4J(Sn–H) for two of the complexes, i.e. **1** and **2**, has been recorded by Milgrom and Sheppard.[8] The larger value of J for X = Cl was attributed to the tendency of that ligand to engage in p_π–d_π bonding, which causes an increase in σ-overlap in the Sn–N bonds.[8] However, ^4J(Sn–H) for **8** (X = I) is slightly less than that for **1**, while the effects of π-bonding would be expected to be greater, since the 5*p* orbitals of I should be more compatible with the empty Sn 5*d*

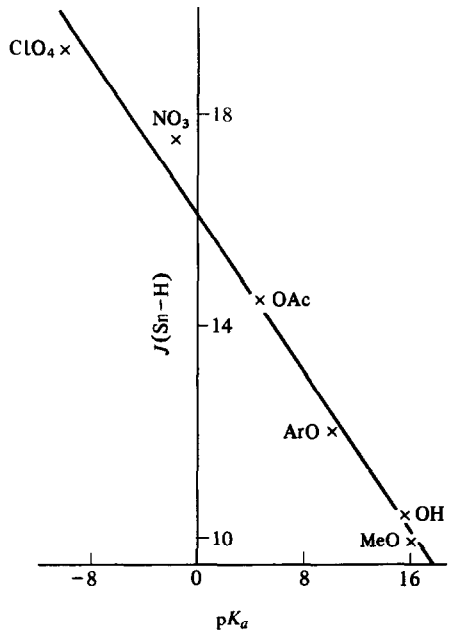

Fig. 2. Dependence of ^4J(Sn–H) (Hz) for β-pyrrole protons in Sn(TPP)X_2 complexes on the pK_a of the conjugate acids HX.

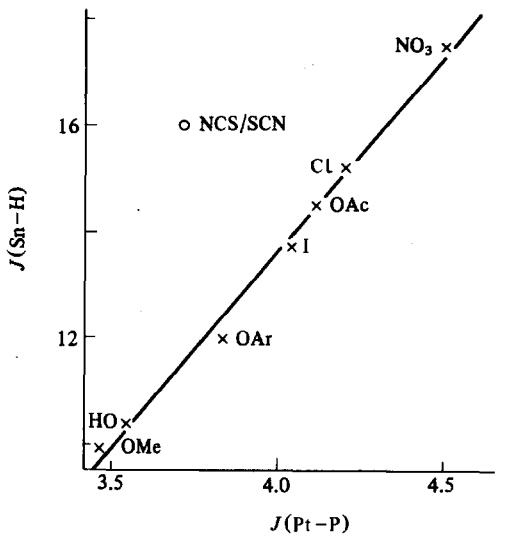

Fig. 3. Plot of ^4J(Sn–H) (Hz) for β-pyrrole protons in Sn(TPP)X_2 complexes vs ^1J(Pt–P) (kHz) in PtX(Me)(dppe) complexes [from Ref. 23, in which ArO = *p*-(MeO)C_6H_4O]. (NCS/SCN point not included in linear-regression analysis.)

orbitals than are the 3*p* orbitals of Cl. It appears, therefore, that both increased π-donation (e.g. for the halides) and increased σ-donation (for the oxygen ligands) cause a weakening of the Sn–N bonds, which is transmitted to the peripheral protons, thus decreasing ^4J(Sn–H). Transmission of electronic effects to the β-pyrrole protons in TPP complexes has been attributed mainly to contact interactions between the electrons of the σ-bonds in the macrocycle.[1-7]

Where the two series have ligands X in common, a surprising correlation ($r = 0.996$, $n = 7$) (Fig. 3) exists between ^4J(Sn–H) in Sn(TPP)X_2 and ^1J(Pt–P)(*trans* to X) in PtX(Me)(dppe) [dppe = 1,2-bis(diphenylphosphino)ethane].[23] A naive inference is that these ligands in two completely different families of compounds are exerting similar influences on very different coupling constant types. Here the *cis*-influence in the Sn(IV) series operates in the same sense as the *trans*-influence in the Pt(II) series, which is often not the case when comparisons are made within a single type of complex, e.g. [Pt(Ar)$(PEt_3)_3$]BF_4.[24] While very little can be concluded from such an obscure comparison, perhaps the σ-transmission arguments above are reinforced by it. Interestingly, the thiocyanate point lies well off the line, suggesting again that it is N-bonded in **9**, since it has been convincingly argued that it is S-bonded in the Pt series.[23]

β-Pyrrole chemical shifts

These chemical shifts show a similar dependence on ligand basicity, with weaker bases causing downfield shifts. A plot of ^4J(Sn–H) against δ (Fig. 4) indicates a good correlation ($r = 0.993$, $n = 8$), if the points for X = OH and OMe are excluded. Since the *J* values for these complexes fit well with the pK_a dependence, these chemical shifts seem anomalous. Literature data for X = OH are closely comparable with the present ones.[8] Inclusion of the β-pyrrole chemical shift for Sn(TPP)$(CH_2CH_3)_2$, *ca* 8.8 ppm,[11] indicates a continuation of the upfield shift for even more basic ligands. A similar dependence on the base strength of X has been reported for the chemical shifts of the β-pyrrole protons in In(TPP)X and the *meso*-protons in In(OEP)X complexes.[12]

Other NMR data

The protons in axial ligands appear at high field because of their location within the shielding zone of the macrocycle. Such chemical shifts for phenoxy, acetoxy and methoxy protons have been observed for Sn(OEP)X_2 complexes,[9] but Sn–H coupling constants were not reported. Recently, both δ and *J*(Sn–H) data were given for (**2**).[8] The trend of ^3J(Sn–H) > ^2J(Sn–H) > ^4J(Sn–H) evident in the series is similar to that observed for organotin(IV) compounds.[25] The OH ligand is subject to proton exchange with water, since marked broad-

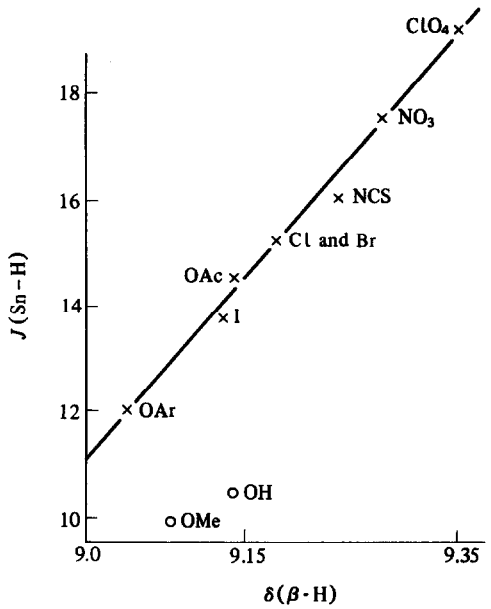

Fig. 4. Plot of ^4J(Sn–H) (Hz) vs chemical shift [δ (ppm)] for β-pyrrole protons in Sn(TPP)X_2 complexes. (OH and OMe points not included in linear-regression analysis.)

ening and a downfield shift occur when the $CDCl_3$ is not specially dried.

Complex **6** exhibits unusual behaviour in $CDCl_3$ solutions which is not apparent for any of the other compounds. A fresh solution of **6** in $CDCl_3$ shows two sets of peaks. The data in Table 2 refer to one set, which remains sharp. The other signals ($\delta_{pyrrole}$ 9.13, ^4J(Sn–H) = 13.5 Hz, δ_{ortho} 8.1, $\delta_{meta,para}$ 7.75) are broader. On standing for less than 24 h, a purple precipitate appears, accompanied by the loss of these broad peaks. The peaks assigned to the monomeric complex (**6**), whose δ and J values are internally consistent with those of the rest of the series, gradually disappear as precipitation continues. In acetone-d_6 and pyridine-d_5 solutions, single species exhibiting sharp peaks are present (δ 9.56, J = 18.0 Hz and δ 9.35, J = 13.2 Hz, respectively), and no precipitation occurs over many days. The precipitate can be dissolved in acetone to give a solution whose visible spectrum is virtually identical with that of the original solid **6** in acetone. Washing the precipitate with $CHCl_3$ slowly dissolves some of it, producing a spectrum very similar to that of the supernatant in $CDCl_3$. This behaviour seems consistent with aggregation in the weakly polar solvent, which does not occur in acetone or pyridine. Perhaps intermolecular perchlorate bridges are formed, leading to oligomerization. These phenomena are under investigation.

EXPERIMENTAL

General

^{1}H NMR spectra were recorded on the Bruker CXP-300 F.T. instrument at the Brisbane NMR Centre, Griffith University, using $CDCl_3$ as solvent. Preliminary spectra were obtained on a Varian EM-360 spectrometer. UV–visible spectra were recorded on a Varian DMS-100 spectrometer in $CHCl_3$ solutions. IR spectra were obtained on a Jasco IR-810 instrument in either Nujol mulls or KBr pellets. Microanalyses were carried out by the Microanalytical Service, University of Queensland. The ligand *meso*-tetraphenylporphyrin (TPP) was prepared and purified ("chlorin-free") by the literature method.[26] Inorganic salts were A.R. grade.

Preparations of Sn(TPP)X_2

X = Cl. This complex was prepared according to the literature[27] and recrystallized from $CHCl_3$–hexane to yield violet crystals.

X = OH. A solution of Sn(TPP)Cl_2 (100 mg) in CH_2Cl_2 (10 cm^3) was stirred with basic alumina (Woelm, activity IV, 2 g) for 15 min. The suspension was filtered through a short column of the same alumina, eluting with CH_2Cl_2. The major red–purple band was collected and concentrated, and then hexane was added to yield maroon microcrystals (70 mg, 73%), which were dried at 70°C under vacuum (< 1 mmHg).

X = OMe. A suspension of Sn(TTP)Cl_2 (50 mg) in dry $CHCl_3$–MeOH [1 : 1 (v/v), 10 cm^3) was stirred under dry N_2 with basic alumina (Woelm, activity IV, 1 g). After 10 min, the suspension was percolated through a short column of the same alumina, eluting with dry MeOH. The major band was collected, concentrated and cooled to yield the product as maroon microcrystals (25 mg, 50%), which were dried under vacuum at room temperature and stored in a desiccator. This material was shown to be >95% pure by ^{1}H NMR.

X = OAc. A mixture of Sn(TPP)Cl_2 (110 mg), AgOAc (130 mg) and glacial acetic acid (25 cm^3) was heated under reflux for 3 h, filtered while hot, then left at room temperature for 3 days. White crystals of excess AgOAc were removed by filtration, then the volume was reduced and hexane was added to yield shiny purple crystals, shown by NMR to be contaminated with acetic acid. Grinding and vacuum drying (70°C, < 1 mmHg) gave a maroon powder, which was recrystallized from CH_2Cl_2–hexane to yield shiny violet prisms. (Found: C = 67.7, H = 4.1, N = 6.5.

$C_{48}H_{34}N_4O_4Sn$ requires C = 67.9, H = 4.0, N = 6.6%.)

X = NO_3. A mixture of $Sn(TPP)Cl_2$ (70 mg) and $AgNO_3$ (70 mg) was refluxed in dry benzene (25 cm^3) for 3 h. Precipitated AgCl was removed by filtration, the solution was evaporated to dryness, and the residue was recrystallized from $CHCl_3$–hexane to give purple microcrystals in nearly quantitative yield. Recrystallization from CH_2Cl_2–hexane gave shiny purple prisms. (Found: C = 62.2, H = 3.4, N = 9.7. $C_{44}H_{28}N_6O_6Sn$ requires C = 61.8, H = 3.3, N = 9.8%.)

X = ClO_4. A solution of $Sn(TPP)Cl_2$ (80 mg) in dry benzene (10 cm^3) was stirred at 55°C. A solution of $AgClO_4$ (82 mg) in dry benzene (3 cm^3) was added, and stirring was continued at 55°C for 30 min. The purple complex and AgCl precipitated, leaving a bluish-purple supernatant. All solids were collected by filtration, then the porphyrinic materials were extracted by washing the residue with successive small portions of boiling $CHCl_3$, and filtering the resulting solution through Celite. Hexane was added and the solution concentrated to yield violet prisms (64 mg, 69%). Recrystallization from CH_2Cl_2–hexane gave maroon microcrystals. (Found: C = 56.7, H = 3.2, N = 5.8. $C_{44}H_{28}Cl_2N_4O_8Sn$ requires C = 56.8, H = 3.0, N = 6.0%.)

X = Br. A solution of $Sn(TPP)(ClO_4)_2$ (33 mg) in acetone (10 cm^3) was treated with LiBr (30 mg). The purple precipitate was collected after 30 min stirring, washed with acetone and dried. Recrystallization from CH_2Cl_2–hexane gave violet prisms (20 mg, 63%). (Found: C = 59.3, H = 3.2, N = 6.2. $C_{44}H_{28}Br_2N_4Sn$ requires C = 59.3, H = 3.2, N = 6.3%.)

X = I. A solution of $Sn(TPP)(ClO_4)_2$ (30 mg) in acetone (5 cm^3) was treated with KI (20 mg). Sparkling black prisms (21 mg, 66%) were formed directly from the reaction mixture, and were collected, washed with acetone and dried. Recrystallization from CH_2Cl_2–hexane gave very dark green crystals with a purple reflectance. (Found: C = 54.7, H = 2.9, N = 5.9. $C_{44}H_{28}I_2N_4Sn$ requires C = 53.6, H = 2.9, N = 5.7%.)

X = NCS. A solution of $Sn(TPP)(ClO_4)_2$ (30 mg) in acetone (5 cm^3) was treated with KSCN (20 mg). The mixture was stirred for 30 min, then filtered to yield purple crystals which were washed with acetone and dried (15 mg, 55%). Recrystallization from CH_2Cl_2–hexane gave glistening purple prisms. (Found: C = 63.7, 65.9; H = 3.2, 3.5; N = 9.6, 9.3. $C_{46}H_{28}N_6O_2Sn$ requires C = 65.7, H = 3.3, N = 9.9%.)

X = OC_6H_4-*p*-Me. A mixture of $Sn(TPP)(OH)_2$ (26 mg), *p*-cresol (20 mg) and benzene (5 cm^3) was stirred and refluxed for 1 h. The solvent was removed by distillation then the product was dissolved in CH_2Cl_2 and precipitated with hexane (19 mg, 59%). Recrystallization from CH_2Cl_2–hexane gave dark maroon microcrystals. [Found: C = 72.8, H = 4.4, N = 5.9. $C_{58}H_{42}O_2N_4Sn$ requires C = 73.7, H = 4.5, N = 5.9%.)

Acknowledgements—I thank Mr P. Comino and Dr P. Barron for assistance with the NMR spectrometer.

KINETICS OF FORMATION OF INTERMEDIATES IN SILVER ION ASSISTED AQUATIONS

HERVINE MILLER

Chemistry Department, University of the West Indies, Cave Hill, Barbados

(*Received* 31 *January* 1986; *accepted* 7 *May* 1986)

Abstract—There is kinetic evidence for the formation of $[Co(NH_3)_5NCSAg_3]^{5+}$ in the interaction of $[Co(NH_3)_5NCS]^{2+}$ with Ag^+ in aqueous solution, with pseudo-first-order formation rate constant $k = 0.158\ s^{-1}$ for the forward reaction in the following equation at 25°C and $[Ag^+]$ in the range $1.23–5.0 \times 10^{-2}$ mol dm^{-3} and 0.10 ionic strength ($NaClO_4$):

$$[Co(NH_3)_5NCSAg_2]^{4+} + Ag^+ \xrightarrow{k} [Co(NH_3)_5NCSAg_3]^{5+}.$$

Additionally, the formation constant, β_2, for $[Co(NH_3)_5NCSAg_2]^{4+}$ has been determined to be $\log \beta_2 = 4.717$. For the $[Rh(NH_3)_5I]^{2+}$–Ag^+ reaction there is evidence of an outer-sphere interaction with rate constants of $k_2 = 670\ dm^3\ mol^{-1}\ s^{-1}$ at 25°C and 0.10 ionic strength. This outer-sphere species undergoes further reaction to give the silver ion containing intermediates of the aquation reactions.

As part of the study of the silver ion assisted aquation of pentaammine metal(III) complexes, it seemed worthwhile to examine whether rates of formation of the intermediates in these reactions could be measured by conventional stopped-flow techniques. Evidence for the existence of species of the type $\{[M(NH_3)_5X]_mAg_n\}^{(m+n)+}$, where M = Cr(III), Co(III) or Rh(III); X = I^- or NCS^-; $m = 1$ or 2; and $n = 1$, 2 or 3, had previously been obtained from spectrophotometric,[1,2] potentiometric[2,3] and kinetic[4,5] studies, all of which indicated a stepwise complex formation. For Cr(III)[6] and Co(III)[1] solids having $m = 1$ and $n = 1$ or 2 have been isolated and characterized but analogous Rh(III) compounds have not been isolated to date. The stability constants, K_1, for the 1:1 adducts are of the order of $\log K_1 = 3.0$[3] and the rates of aquation for the pure pentaammine and its silver adducts are negligible at room temperatures.

Kinetics of the reactions of $[Co(NH_3)_5NCS]^{2+}$ and $[Rh(NH_3)_5I]^{2+}$ with silver ions in aqueous solution were examined at 25°C and the results are herein reported.

EXPERIMENTAL

Analytical-grade reagents and deionized or double-distilled (all-glass) water, as solvent, were used throughout. Acidopentaammine complexes and silver and sodium perchlorate solutions were prepared as previously reported.[1,2]

The drive syringes of a Durrum stopped-flow spectrophotometer were filled with reaction solutions of composition as follows.

Solution 1: $AgClO_4$ (variable concentration), $HClO_4$ to pH ~3 and $NaClO_4$ to ionic strength 0.10. Solutions were filtered using Millipore 0.45-μm filter disc together with a Millipore Swinney adapter to remove any traces of colloidal silver chloride.

Solution 2: pentaammine (fixed concentration), $HClO_4$ to pH ~3 and $NaClO_4$ to ionic strength 0.10, such that on 1:1 dilution the reaction mixture had the desired $[Ag^+]$ and [pentaammine].

The solutions and the reaction chamber were thermostatted at 25.0°C in diffuse light or near darkness. Concentrations of pentaammine were chosen such that absorbance at the monitoring wavelength was *ca* 0.5.

Photometric adjustments were made with solution 1 as blank and the reactions were monitored at 263 nm and 255 nm for $[Co(NH_3)_5NCS]^{2+}$ and $[Rh(NH_3)_5I]^{2+}$, respectively. At these wavelengths the difference between the spectra of the pure pentaammine solutions and of those containing silver ions was optimum. Typical absorb-

ance changes for the concentrations used were 0.03–0.05 units.

Multiple determinations of the absorbance vs time plots were done at each silver ion concentration and an average taken by superimposing the oscilliscope traces. For the $[Rh(NH_3)_5I]^{2+}$ reaction a few determinations were done at the same temperature using a modified Zeiss PMQII spectrophotometer[7] to confirm that the stopped-flow apparatus had not produced spurious results. In addition, by measuring the absorbance, A_∞, corresponding to the infinity values of the first and subsequent reactions which take place the spectra of the intermediates could be obtained. Wavelength was varied from 250 to 325 nm with Ag^+ solution used as reference solution for the photometric adjustments. A new reaction run was done at each wavelength.

All component parts of the stopped-flow system had to be thoroughly cleaned with EDTA, followed by repeated rinsings with water, so as to desorb any silver ions. Failure to do this or to reduce the amount of light reaching the apparatus resulted in the well-known photochemical changes of the silver solution and "blackening" of the equipment. This risk of damage to expensive equipment severely limited the scope of this study.

RESULTS AND DISCUSSION

Figure 1 shows a typical oscilloscope trace for the reaction of $[Co(NH_3)_5NCS]^{2+}$ with silver ions and represents not less than eight superimposed plots of absorbance vs time. Data from such plots yielded good first order kinetics

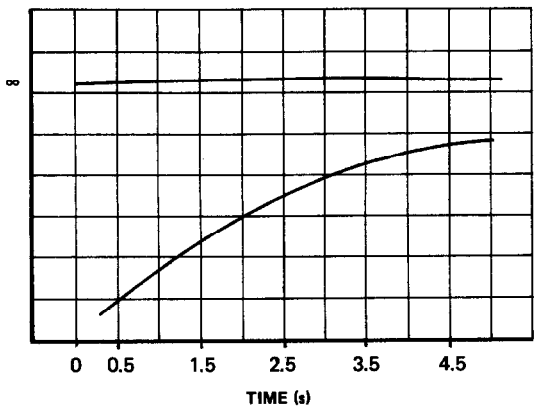

Fig. 1. Typical oscilloscope trace of absorbance vs time for the $[Co(NH_3)_5NCS]^{2+}$–Ag^+ reaction. $[Ag^+]_{total} = 1.25 \times 10^{-2}$ mol dm^{-3}. $[Co(NH_3)_5NCS^{2+}]_{total} = 2.5 \times 10^{-4}$ mol dm^{-3}.

Table 1. Observed rate constants, k_{obs}, for the $[Co(NH_3)_5NCS]^{2+}$–Ag^+ interaction at 25°C and 0.10 ionic strength ($NaClO_4$)

$10^2[Ag^+]^a$ (mol dm^{-3})	1.23	2.48	3.73	4.98
$10^2 k_{obs}$ (s^{-1})	3.5	6.1	7.2	8.3

[a]Corrected for complete formation of $[Co(NH_3)_5NCSAg]^{3+}$.

over more than three half-lives. The pseudo-first-order rate constants, k_{obs}, in Table 1 for $[Co(NH_3)_5NCS]^{2+} = 2.50 \times 10^{-4}$ mol dm^{-3} and $[Ag^+]_{total} = 1.25\text{–}5.0 \times 10^{-2}$ mol dm^{-3} are reproducible to within 2%.

Under the reaction conditions, $[Ag^+] \gg [Co(NH_3)_5NCS]^{2+}$, it is assumed that $[Co(NH_3)_5NCSAg]^{3+}$ is completely formed within the mixing time given its known formation constant, $\log K_1 = 3.350$[3] and the concentration of the reacting species. From previous[1] spectrophotometric data under similar conditions, complexes $\{[Co(NH_3)_5NCS]_mAg_n\}^{(2m+n)+}$ formed would be expected to have values of $m = 1$ and $n > 2$ and, by analogy with the Ag^+–SCN^- system, n should not exceed 4. On the basis of these observations the formation of $[Co(NH_3)_5NCSAg_3]^{5+}$ is postulated as follows:

$$[(NH_3)_5CoNCSAg]^{3+} + Ag^+ \overset{K_2}{\rightleftharpoons} [(NH_3)_5CoNCSAg_2]^{4+} \text{ (fast)}, \quad (1)$$

$$[(NH_3)_5CoNCSAg_2]^{4+} + Ag^+ \overset{k}{\rightleftharpoons} [(NH_3)_5CoNCSAg_3]^{5+} \text{ (slow)}. \quad (2)$$

For this reaction scheme the observed pseudo-first-order rate constants, k_{obs}, would be given by eqn (4)

$$k_{obs} = \frac{kK_2[Ag^+]}{1 + K_2[Ag^+]}. \quad (3)$$

The predicted linearity of the $1/k_{obs}$ vs $1/[Ag^+]$ plots has been observed and linear regression analysis of the data yields values of $k = 0.158$ s^{-1} and $K_2 = 23.3$ dm^3 mol^{-1}. This leads to a value of $\log \beta_{12} = 4.717$, where $\beta_{12} = K_1K_2$, for the overall stability constant of $[Co(NH_3)_5NCSAg_2]^{4+}$ which has been isolated as the nitrate.[1] This value is several orders or magnitude lower than for similar Hg^{2+} complexes,[8] as is the trend when Ag^+ and Hg^{2+} values have been compared for similar reactions.

For $[Rh(NH_3)_5I]^{2+}$ the reaction with Ag^+ under

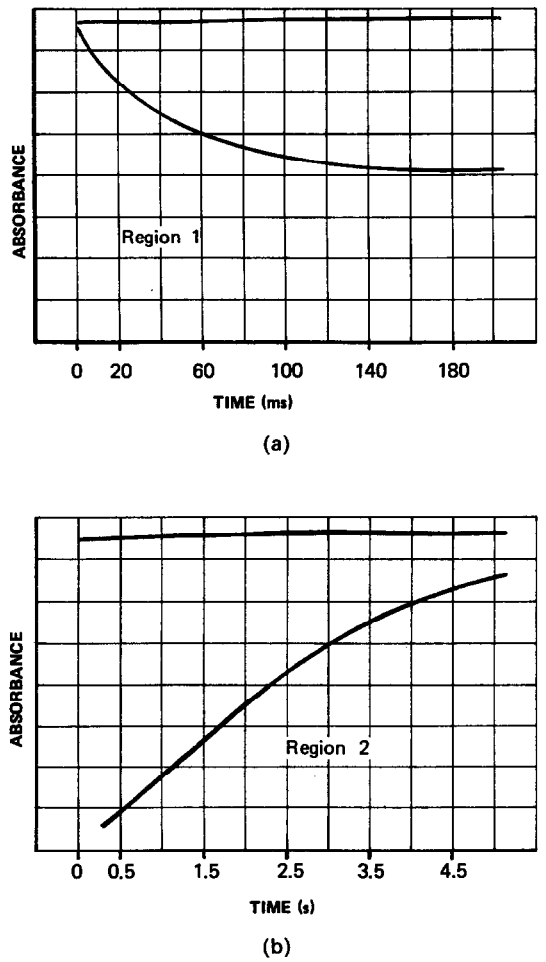

Fig. 2. Typical oscilloscope traces of absorbance vs time for the $[Rh(NH_3)_5I]^{2+}$–Ag^+ reaction. $[Ag^+]_{total} = 1.25 \times 10^{-2}$ mol dm^{-3}. $[Rh(NH_3)_5I^{2+}]_{total} = 8.0 \times 10^{-5}$ mol dm^{-3}.

similar conditions is more complex. The absorbance vs time plots seem to be divisible into two regions as in Fig. 2 which shows typical oscilloscope traces for this reaction. Good first-order kinetics were observed for both regions 1 and 2 and the pseudo-first-order rate constants k and k' respectively are in Table 2 for $[Rh(NH_3)_5I^{2+}] = 8.0 \times 10^{-5}$ mol dm^{-3} and $[Ag^+] = 0.50$–5.0×10^{-2} mol dm^{-3}. The rate constants are reproducible to better than 5%. The data for region 1 show that k varies linearly with Ag^+ over the range studied, thus indicating a true bimolecular association with second-order rate constant, k_2, of 670 dm^3 mol^{-1} s^{-1}. Such a value may result from an outer-sphere interaction of the two cations. This interpretation of the experimental data is based on the observed decrease in absorbance and a comparison with other bimolecular association reactions for example Cr^{2+}–V^{2+} charge-transfer reactions[9] for which the second-order rate constants are lower and $\sim 1.2 \times 10^2$ dm^3 mol^{-1} s^{-1}. The more favourable charge product of +2 for the Ag^+–$Rh(NH_3)_5I^{2+}$ interaction may account for this higher value of k_2. Furthermore, associations of this type are well-known precursors in many substitution and redox reactions and represent the first relaxation process in the formation of the intermediate species. The interaction of the iodine atom with Ag^+ should increase the Rh—I bond distance in the reactant and lead to the observed decrease in the absorbance of the charge-transfer bands. Supporting evidence is obtained from A_∞ vs wavelength plots which showed a small shift to longer wavelength with a broad maximum at *ca* 283 nm, indicating that the intermediate at this stage is different from those previously reported[2] as Ag^+-containing species.

Table 2. Observed rate constants for the $[Rh(NH_3)_5I]^{2+}$–Ag^+ interaction at 25°C and 0.10 ionic strength ($NaClO_4$)

10^2[Ag][a] (mol dm^{-3})	Region 1 k (s^{-1})	Region 2 k' (s^{-1})
0.50	20.0	0.243
1.25	23.9	0.260
2.50	34.3	0.160
5.00	49.8	0.124

[a]Initial $[Ag^+]$.

For region 2 a two-fold decrease of the pseudo-first-order rate constant, k', with the 10-fold increase in $[Ag^+]$, is observed, but no detailed mechanistic evaluation is possible with this limited data. However, these reactions must lead to complexes of the type $[Rh(NH_3)_5IAg_n]^{n+2}$ (n = 1, 2 or 3) as these are thermodynamic products of the interaction. Under the reaction conditions complexes should have all three values of n.[2]

There is evidence to support these complex species as the intermediates in the silver ion assisted aquation of $[Rh(NH_3)_5I]^{2+}$. For example, Boyce *et al.*[5] reported data (Table 9) which show good linear free energy correlation between the aquation rate contants, k_n, and the formation constants, K_n, of these complexes. If it is assumed, as suggested[10] for metal ion assisted aquations, that the formation constants, K', for the leaving groups [eqn (4)] are related to those for the reacting complexes [eqn (5)]:

$$[Ag_{n-1}I]^{(n-2)+} + Ag^+ \overset{K'}{\rightleftharpoons} [Ag_nI]^{(n-1)+}, \quad (4)$$

$$[Rh(NH_3)_5IAg_{n-1}]^{n+1} + Ag^+ \overset{K_n}{\rightleftharpoons} [Rh(NH_3)_5IAg_n]^{n+2}, \quad (5)$$

by eqn (6):

$$K_n = b + mK' \quad (6)$$

and that b is sufficiently small to allow for the approximation in eqn (7) to be valid:

$$K_n = mK' \quad (7)$$

then the data of Boyce *et al.*[5] are well reproduced by eqn (8):

$$\log k_n = 1.52 + 1.37 \mathrm{p}K_n \quad (8)$$

with standard deviations of 0.026 an 0.030 in slope and intercept, respectively. A slope > 1 is indicative of a dissociative mechanism often encountered for other Rh(III) equations.

It is, therefore, reasonable to assume that the outer-sphere complex, initially formed, rearranges or reacts further with Ag^+ to give such intermediates, the spectra of which corresponds to those in other studies.[2]

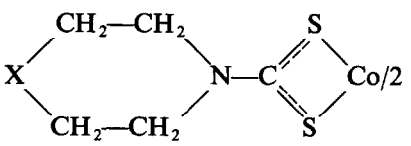
(*Received* 17 *February* 1986; *accepted* 7 *May* 1986)



Abstract—The X-ray photoelectron spectra of a series of Co(II) dithiocarbamate complexes have been studied. Data confirmed the substantial identity of the electronic structure of the chromophores throughout the series, and Co2$P_{3/2}$ BE values of 780.1 eV are in good agreement with the expectation on the base of Feltham–Brant scale. Shake-up satellites associated with the Co2$P_{3/2}$ photoelectron line have been investigated and compared with magnetic moments.

Application of X-ray photoelectron spectroscopy (XPS) to the investigation of the electronic structure of molecules has become a widely accepted technique. The transition metals as a group show such interesting properties as variable valence, paramagnetism and a highly diverse stereochemistry. Hence, they are ideally suited for XPS studies by probing directly the electronic environment of transition metal or ion.

Dithiocarbamate have properties which make them useful in applications including vulcanization accelerators, fungicides and pesticides among others.[1]

Several structural studies of metal dithiocarbamates have been published.[2–4] It has been recognized that the ligand forms a four membered chelate ring with delocalization of electrons over the S_2CN moiety. X-ray photoelectron spectroscopy has not been used as much as other techniques to investigate metal dithiocarbamates. Jørgensen and Berthou[5] reported data for Cu(II) and Ni(II) dithiocarbamate. Perry and Geanangel[6] reported about tin diethyl- and dimethyl dithiocarbamates. Frost *et al.*[7] studied several diethyldithiocarbamates giving particular emphasis to the satellite structure. Best *et al.*[8] investigated sulfur behaviour in Fe, Mo diethyl- and Co(III) dimethyldithiocarbamates. Van Attekum and Trooster[9] studied the X-ray induced decomposition of gold (III) dimethyl- and *n*-propyl dithiocarbamates. Walton[10] reviewed the sulfur behaviour in the metal dithiocarbamates among others. Chang and Cheng[11] examined the Cu(II), Pb(II) and Sn(IV) diethyldithiocarbamates reporting a procedure to decompose the C1*S* signal into three components in order to get a more accurate spectra calibration.

More recently Payne *et al.*[12,13] and Liesegang and Lee[14] reported data on IR–XPS chemical shifts correlations for eleven disubstituted Cu(II) and Ni(II) dithiocarbamates in which they found strong effects of the substituents on the binding energies, specially for sulfur, attributing its changes to the reverse movement of electronic charge towards the S atom. With the aim of correlating XPS spectra with chemical properties, and following a systematic XPS investigation of metal dithiocarbamates, we already examined a series of Cu(II) and Ni(II) dithiocarbamates.[15,16] In the present work we extended our study to the series of quadratic complexes of Co(II), **1**,

EXPERIMENTAL

Synthesis

The cobalt(II) complexes:

where X = CH_2 (piperidinedithiocarbamate = Pipdtc),
HN (piperazinedithiocarbamate = Pzdtc),
CH_3N (*N*-methylpiperazinedithiocarbamate = Mepzdtc),
O (morpholinedithiocarbamate = Morphdtc),
S (thiomorpholinedithiocarbamate = Timdtc),
C_6H_5—CH (4-phenylpiperidinedithiocarbamate = 4Ph-pipdtc),
C_6H_5—N (phenylpiperazinedithiocarbamate = Ph-N-pzdtc)

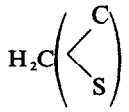
were prepared and purified, according to previous literature reports, by some of us[17–20] and on the basis of their properties were classified as low spin Co(II) compounds.

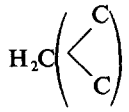
Spectral measurements

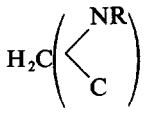
The X-ray photoelectron spectra were measured using a VG ESCA-3 MKI spectrometer employing $AlK_{\alpha 1,2}$ X-rays ($h\nu$ = 1486.6 *eV*). Samples were deposited as thin powder films on gold bearing plates, whose $Au4f_{7/2}$ signal at 84.0 eV was used as reference. Samples proved to be essentially stable under X-rays (typical power 12 kV × 10 mA). Vacuum in the analysis chamber was typically 1×10^{-9} torr, and the resolution was about 1.6 eV on the $Au4f_{7/2}$ line. Gaussian curve fitting was performed by computer program. Quantitative evaluation of atomic ratios, in the XPS sampling layer, was achieved by analysis of the XPS signal intensity of solid Co(II) dithiocarbamates and by using the Scofield's atomic cross-sections values[21] together with the $E_k^{1/2}$ dependence of mean free-path values and $E_k^{-1/2}$ dependence of luminosity factors. As the sensitivity factors gave results not in agreement with the nominal formulas, further measurements were performed on two standard compounds: $CoSO_4$ and $[Co(NH_3)_5CO_3]NO_3$, and a factor of 1.6 was found to adjust the sensitivity factors for S, N, C and O with respect to Co, giving results in agreement with the expected composition. The application of this factor 1.6 to the dithiocarbamate compounds gave good quantitative values, within the usual range of ±20%.

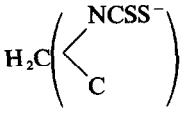
No attempts were made to clean the sample, by ion bombardment, in order to avoid decomposition.

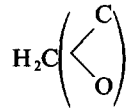
The referencing procedure based on Cl*S* of contamination carbon taken at 285.0 eV[22] cannot be applied here in a simple way, as we have described previously,[15,16] due to the fact that position and shape of the Cl*S* signal vary according to the different kind of C atoms present in the ligands. A significant assignment can be obtained only identifying the actual Cl*S* components and assigning them to a consistent and transferable scheme like that reported in Table 1. The same procedure was used by Chang and Cheng.[11]

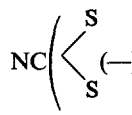


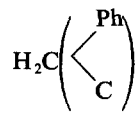


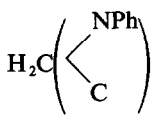












RESULTS

The data obtained in the present study are summarized in Table 2 and typical spectra are reported in Fig. 1. To our knowledge this is the first investigation of Co(II) dithiocarbamates. Frost *et al.*[7] studied the octahedral diamagnetic Co(III) diethyldithiocarbamate complex and Best *et al.*[8] reported about sulfur for the same Co(III) complex. The former authors found for $Co2p_{3/2}$ and S2*p* lines the presence of weak satellites at 5.2 eV and 6.0 eV, respectively, attributable to shake-up process, they noted also that the Co spin-orbit splitting ($2P_{1/2}$, $2P_{3/2}$) of 14.9 eV was in agreement with that measured for diamagnetic Co(III) compounds.

In this work, the low spin Co(II) compounds show intense broad additional lines to higher binding energy of the $Co2p_{1/2}$, $2P_{3/2}$ lines attributable to shake-up process. These satellites are separated by 6.3 ± 0.1 eV (ΔE) from the parent peaks throughout the series of Co(II) compounds, shift of comparable magnitude with the Frost *et al.*[7] value for Co(III) diethyl derivative of 5.2 ± 0.3 eV. Co2*p* additional lines are broad and their intensity, along the series, falls between 12.7 and 44.5% of the total intensity of $Co2p_{3/2}$ signal. It is most notable that they occur with significant intensity only in the case of the paramagnetic cobalt(II) complexes. In our case, for instance, I_{sat} for $Co(Timdtc)_2$ is about 20.5% of the total intensity of $Co2p_{3/2}$, whilst for the analogous Co(III) compound $Co(Timdtc)_3$, we found $I_{sat} \sim 1.4\%$ probably due to some impurity of Co(II) on the surface.

Moreover, for the same two compounds, the $2p_{1/2}$, $2p_{3/2}$ energy separation observed is close to 16.0 eV for the paramagnetic cobalt(II) whilst the diamagnetic cobalt(III) complex shows a separation of only 15.0 eV in agreement with the literature reports.[7,23–25]

Several authors[7,23-30] suggest that satellites depend on whether the central metal atom has unpaired electrons or not and Borod'ko *et al.*[26] suggest that satellite intensities correlate with the spin density on the Co atoms in paramagnetic species or, less accurately, with the magnetic moments. More recently however, Perera *et al.*[31] reported that a strong shake-up satellite is favored by two factors: "(a) the amounts of charge transferred from the ligand to the metal and (b) whether or not the central ion component of the mainly ligand orbital is small before ionization".

Moreover, they pointed out also that the most important requirement for the presence of satellites in the photoelectron spectra of transition metal compounds is an incompletely filled 3*d* subshell, it does not matter whether the compound is paramagnetic or diamagnetic.

A tentative correlation between magnetic moments values (μ) and Co2$p_{3/2}$ satellites did not give very good results. Co(Pipdtc)$_2$ for instance shows an intensity of satellites (I_{sat}) too high with respect to the others, and in the meantime Co(4PhPipdtc)$_2$ and Co(PhNPzdtc)$_2$ show an I_{sat} too low. This might be perhaps due to the different amount of the surface contamination of Co(III) species, which can be caused by oxidation of Co(II) complexes or formed during the preparation. These surface contamination can reduce the satellite lines in intensity.

In a previous paper[15] we found a good relationship between I_{sat} and magnetic moment values for a series of Cu(II) dithiocarbamates. The spectra for Cu2$p_{3/2}$ showed satellites whose intensity throughout the series varied between 17 and 23% of the total intensity ($I_{sat} + I_{main\ peak}$), and their position was about 10.5 eV higher BE than the main 2*p* line, that is in good agreement with the Frost *et al.*[7] data for Cu(II) diethyldithiocarbamate. It is not in agreement with Payne *et al.*[13] who studied a series of Cu(II) dithiocarbamates and did not find any satellites structure for Cu2$p_{3/2}$.

For the Co complexes, additional signals were also observed for S2*p* lines at about 6.6 eV from the main line, like those we already observed for Cu(II) and Ni(II) dithiocarbamates;[15,16] Frost *et al.*[7] attributed these peaks to shake-up satellites. However, an alternative interpretation is that some of these "satellites" might be due to the formation of small amounts of high oxidation state sulfur contaminations.

The electronic structure of the central metal chromophores [CoS_4] appears, on XPS evidence, substantially similar for all the Co(II) dithiocarbamates investigated here, and practically independent on the nature of the remote substituent X. As it can be seen from Table 2, binding energies do not vary largely and are essentially stable throughout the series of planar Co(II) compounds studied.

The Co2$p_{3/2}$ signals fall at 780.1 $\pm$ 0.2 eV for all the investigated Co(II) compounds, a value which is in good agreement with the predicted value (779.6 eV) of the additive ligand contribution model by Feltham and Brant.[32] The BE value for S2*p* fall at 162.0 $\pm$ 0.2 eV throughout the series; this value is within the values reported by Walton (161.7–162.9)[10] and indicates the absence of any strong effect due to the remote substituent X. The sulfur BE value is lower than the average values reported for the analogous Cu(II) and Ni(II) dithio-

carbamates[15,16] (162.0 against 162.2 and 162.5, respectively). The N1*S* BE value of 399.8 ± 0.2 eV is the same already reported for Cu(II) and Ni(II) dithiocarbamates[15,16] and confirms the insensitivity of the electronic structure of the bonding functions to the groups substituted in X position.

These findings and those already reported for the Ni(II) and Cu(II) series of dithiocarbamates[15,16] are not in agreement with Payne *et al.*[13] who studied Ni(II) and Cu(II) dithiocarbamates and reported that by substituting CH_2 with O in remote position of the ligand (e.g. by substituting piperidinedithiocarbamate with morpholinedithiocarbamate) the BE shift (ΔE_b) was: (a) 1.24 eV for Cu2$p_{3/2}$, 1.18 eV for S2*p* and (b) 1.43 eV for Ni2$p_{3/2}$, 2.96 for S2*p*, 1.4 for N1*S* for the copper and the nickel series, respectively.

We would not expect such a binding energy shift for such a substitution.

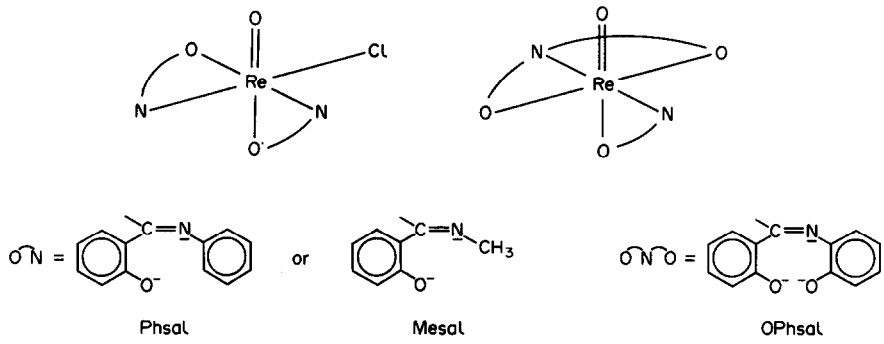
Abstract—The cathodic and anodic behaviour of rhenium(V) complexes, characterized by the ReO^{3+} core, with bidentate and tridentate Schiff base ligands, has been studied in acetonitrile solvent. Cyclic voltammetry and controlled potential coulometry were the main electroanalytical techniques employed to define the electrode processes. Electrolyses were also carried out with the aim to identify the nature of the reduced and oxidized products. In particular, it was possible to isolate and characterize new rhenium(VI) complexes, containing the group ReO^{4+}, and the possibility of obtaining stable rhenium(IV) complexes has also been proved.

Our previous electrochemical studies have been devoted to complexes of rhenium in oxidation states ranging from +1 to +4.[1–3] Oxidizing or reducing these compounds, containing ligands such as carbon monoxide and different phosphines, we were able to prepare and characterize unusual rhenium compounds, as well as to define the electrode mechanisms through which they are formed. Since rhenium is known to assume a wide range of possible oxidation states (from −1 to +7) our attention has now turned toward complexes with the metal in higher oxidation states. In addition to the interest of the chemistry of the complexes of this metal, a further appealing aspect lies in the growing importance of ^{99m}Tc in nuclear medicine; our previous electrochemical studies on complexes of rhenium and technetium[1–6] have allowed us to draw out useful comparisons, as well as to gain, on the basis of the studies on the complexes of the first metal, important suggestions on the properties of those of the latter element.



Relatively simple procedures are requested to synthesize rhenium(V) complexes containing the ReO^{3+} core; this atomic group involves specific interesting chemical properties and the resulting complexes exhibit quite satisfactory stability.[7–10] We report here electrochemical studies on Schiff base rhenium(V) complexes of the type $[ReOCl(BSB)_2]$ and [ReO(TSB)(BSB)] where BSB = *N*-methylsalicylideneiminate or *N*-phenylsalicylideneiminate and TSB = *N*-(2-oxidophenyl)salicylideneiminate.

Our aim is to elucidate both anodic and cathodic electrode mechanisms, as well as to characterize the final electrolysis products in which ReO^{2+} or ReO^{4+} cores may be present.

EXPERIMENTAL

Acetonitrile (MeCN) (Fluka-Burdick & Jackson, distilled in glass) was used without further puri-

Scheme 1.

fication, storing it under nitrogen on 0.3 nm molecular sieves (Union Carbide).

$NaClO_4$ supporting electrolyte was prepared by neutralizing $HClO_4$ with Na_2CO_3; then it was twice crystallized from hot water and dried at 110°C. $[NEt_4]ClO_4$(TEAP)(C. Erba) supporting electrolyte was dried in a vacuum oven at 50°C and used without further purification.

99.99% pure nitrogen was bubbled through the solutions before the electrochemical tests, in order to remove oxygen.

The synthesis of the studied complexes has been described elsewhere.[7,8,10]

In the voltammetric tests the polarizing unit was a PAR 170 Electrochemistry System; voltammograms were recorded either with a Linseis LY 1800 pen recorder or with a Hewlett-Packard 1223 A storage oscilloscope, depending on the potential scan rate. The stationary working electrode was either a platinum disc (geometrical area of about 5 mm^2) or a gold sphere freshly covered with mercury; they both were surrounded by a platinum spiral counter electrode; the saturated calomel electrode—reference electrode—was connected with the working electrode compartment through a salt bridge ending in a Luggin capillary.

In the controlled potential electrolyses an AMEL model 552 potentiostat with an associated AMEL model 558 coulometer were used; these tests were carried out in an H-shaped cell with anodic and cathodic compartments separated from each other by a sintered glass disc. A platinum gauze was used as working electrode while the auxiliary electrode was a mercury pool.

In the voltammetric as well as in the coulometric experiments, TEAP was used as supporting electrolyte. $NaClO_4$ was employed in exhaustive electrolyses performed with the aim to recover the reduction or oxidation products.

All electrochemical measurements were carried out at 25 ± 0.1°C. The reference electrode was an aqueous saturated calomel electrode (SCE); however, after performing the voltammetric tests, biscyclopentadienyl iron(*II*) was added to the solutions in order to refer the calculated $E'_{1/2}$ to $E'_{1/2}$ of this "internal reference" redox couple. In this way, the measured quantity results are unaffected by variable liquid junction potential at the aqueous–organic solvents interface.

In order to isolate the electrolysis products, namely the cathodic reduction products, different procedures were followed for the different compounds. In particular, the solutions after reduction of $[ReOCl(BSB)_2]$ complexes were dried removing MeCN solvent under reduced pressure and the resulting solids were washed with $CHCl_3$ to solubilize the rhenium complexes; after filtering, this last solvent was also removed and the pure solid was analyzed by elemental analysis, IR spectroscopy and magnetic moment measurement. All these recovery procedures were performed carefully avoiding the presence of oxygen and by using deaerated solvents. A similar procedure was followed for the reduction products of [ReO(TSB)(BSB)]; however, it was observed that decomposition and/or reoxidation of the electrolysis products could be avoided only if the solid obtained after removal of MeCN was treated with a very small amount of a protic solvent, typically ethanol.

IR spectra were recorded on a Perkin-Elmer model 580B spectrometer. Magnetic moment measurements were performed with an Oxford Instrument.

RESULTS AND DISCUSSION

$[ReOCl(BSB)_2]$

Cathodic behaviour. Figure 1 reports the voltammetric behaviour of the complex $[ReOCl(Phsal)_2]$ in acetonitrile solution. A first reversible elec-

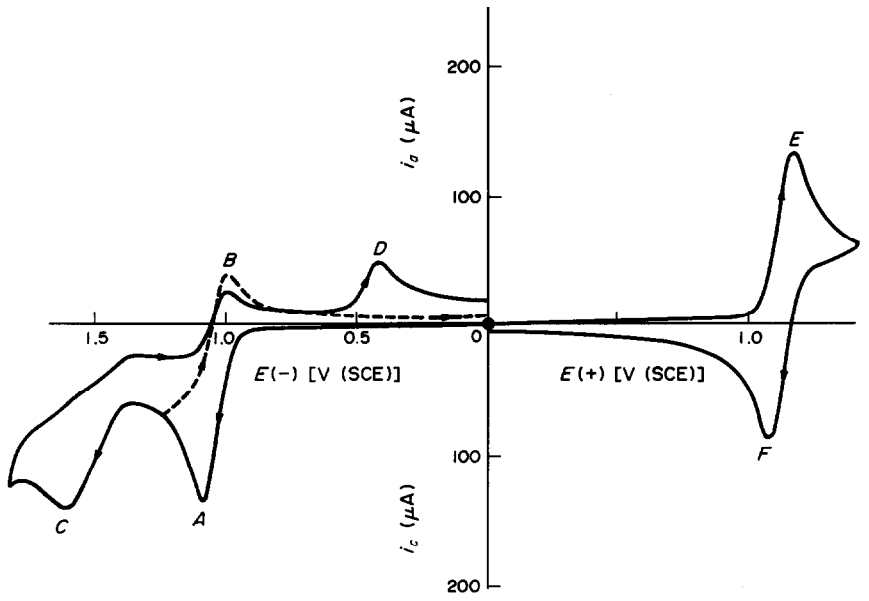

Fig. 1. Cyclic voltammograms recorded on a 4.9×10^{-3} M [ReOCl(Phsal)$_2$], 0.1 M TEAP, and MeCN solution. Platinum working microelectrode; potential scan rate, 0.2 V s^{-1}. (●) Starting potential.

trode reduction leads to a species which is stable enough on the short voltammetric time scale (the ratio of backward to forward peak currents relative to the peaks system A–B is always quite near to one). Exhaustive coulometric electrolyses at peak A lead to a consumption of 1 mol of electrons per mole of starting compound. Voltammetric curves recorded on the electrolysed solutions show a further reduction peak at potential values quite near those of peak C; in addition, the reduced complex is oxidizable at an anodic peak, rather low in height, which corresponds to peak D of Fig. 1, but no peak is recorded at the potential of peak B.

Oxidizing the reduced solutions at a potential only just less cathodic than those where oxidation of the starting complex occurs, this last can be regenerated with a good yield (*ca.* 60–70%).

The analysis of the reduced solutions reveals the presence of free chloride ions; accordingly, performing electrolyses using $NaClO_4$ as supporting electrolyte, NaCl is precipitated. Moreover, from these solutions the reduced rhenium complex can be recovered and characterized following the procedure described above. The elemental analysis data are as follows (found: C, 52.4; H, 3.4; N, 4.8. Calc. for $C_{26}H_{20}ReN_2O_3$: C, 52.5; H, 3.4; N, 4.7%). Two most significant data can be drawn from the IR spectra. The ν(Re—Cl) absorption, located at 311 cm^{-1} in the spectrum of the starting complexes, is now absent, in agreement with the presence of free chloride ions in the reduced solution. On the contrary the ν(Re=O) is still present, at a wavenumber value quite close to that for the starting complex (960 cm^{-1}). Magnetic susceptibility measurements on solid samples at room temperature lead to $\mu_{eff.} = 1.96$ B.M., in agreement with a d^3 configuration in a square pyramidal environment, as reported by Hoffman *et al.*[11]

The compound is soluble in EtOH, CH_2Cl_2, $CHCl_3$ and MeCN, and insoluble in Et_2O and C_6H_6. However, it slowly decomposes in chlorinated solvents and no physico-chemical measurements could be performed on these solutions.

Accordingly with the reported data the more probable configuration can be the one in Fig. 2. The stereochemical position of the two bidentate Schiff base in the horizontal square pyramidal plane can be deduced from the possible reaction mechanism leading to the product. In fact after the electrode reaction the chlorine atom is the most probable leaving group. The substitution with the phenolic oxygen of the ligand allows the formation of the product without the detaching of the whole ligand and consequently the reproduction of the starting compound both by electrochemical and chemical oxidation.

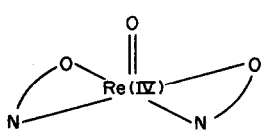

Fig. 2. Schematic drawing of the rhenium(IV) compound obtained by cathodic reduction of [ReOCl(Phsal)$_2$]. $\widehat{NO}$ = Phsal.

On the basis of these findings, the electrode reduction mechanism at peak A can be summarized as follows:

$$[ReOCl(Phsal)_2] + e^- \rightleftarrows [ReOCl(Phsal)_2]^- \quad (1)$$

$$[ReOCl(Phsal)_2]^- \rightarrow [ReO(Phsal)_2] + Cl^- \quad (2)$$

Since oxidation of $[ReO(Phsal)_2]$ to the starting compound requires the uptake of a chloride ion in a 1 : 1 ratio, it is reasonable that the regeneration of $[ReOCl(Phsal)_2]$ can occur only with a non-quantitative yield. The slowness of the chemical reaction following the reduction charge transfer step allows the evaluation of $E'_{1/2}$ for the couple $[ReOCl(Phsal)_2]/[ReOCl(Phsal)_2]^-$, which results equal to -1.43 V (referred to $E'_{1/2}$ of the ferricinium ion/ferrocene couple).

As to the electrode process occurring at peak C, it involves the uptake of one further electron, but this reduction is followed by irreversible decomposition reactions leading to products which could not be identified.

$[ReOCl(Mesal)_2]$ exhibits an electrochemical behaviour which is only qualitatively similar to that of the corresponding Phsal complex. In fact, the cathodic reduction of $[ReOCl(Mesal)_2]$ shows some significant differences; as to the voltammetric behaviour, the anodic peak directly associated to the first cathodic one does not result, at any potential scan rate, as high as required for a backward to the forward peak-currents-ratio equal to one. In particular, this ratio increases increasing the potential scan rate, reaching unity only for a high enough value of this experimental parameter. Also in this case, in controlled potential coulometries at potentials of the first reduction peak, 1 mol of electrons per mole of starting complex is spent, and chloride ions are present in the solution. The voltammograms of these electrolyzed solutions show that the product can be further reduced corresponding to a peak with $(E_p)_c \simeq -1.55$ V vs SCE and oxidized at a peak ($(E_p)_a \simeq +0.6$ V vs SCE) with a small directly associated cathodic peak. Also in this case we have tried to isolate the reduction product following the same procedure, but when $CHCl_3$ is used it is quickly converted to the starting complex. Nevertheless, since after reduction insoluble NaCl is recovered, also in this case the same reduction mechanism, previously outlined for $[ReOCl(Phsal)_2]$, can be hypothesized, even if the voltammetric data agree with a faster release of the chloride ion by the electrogenerated anionic species. On the basis of the trend of the backward to forward peak currents ratio at varying the potential scan rate,[12] a half-life time of about 0.2 s (at 25 ± 0.1°C) can be evaluated for the directly electrogenerated species. Cyclic voltammograms recorded at high enough potential scan rate, allow us to calculate $E'_{1/2}$, $[ReOCl(Mesal)_2]/[ReOCl(Mesal)_2]^- = -1.54$ V (vs $E'_{1/2}$ of the couple ferricinium ion/ferrocene).

As to the reduction and oxidation processes this reduced compound undergoes, while its further reduction, involving the consumption of 1 mol of electrons per mole of starting complex, does not lead to any stable rhenium complex, electrode oxidation at a potential of $+0.7$ V vs SCE allows one to regenerate the starting compound at a yield higher than 60%. It must be taken into account that the presence in the solution of free chloride ions, which strongly adsorb on the platinum electrode surface, prevents the recording of completely reliable voltammetric curves in the anodic potential region, as well as carrying out satisfactory electrolysis tests at those potentials.

As regards the electrode reduction of both the studied $[ReOCl(BSB)_2]$ complexes, completely similar results are obtained by using a mercury microelectrode, with respect to both shape and location of the cathodic voltammetric peaks, as well as to the trend of the peak currents ratio at varying the potential sweep rate. These facts allow us to conclude that the charge transfer occurs via an outer sphere electrode mechanism.[13]

Anodic behaviour. As shown in Fig. 1, $[ReOCl(Phsal)_2]$ undergoes a reversible electrode oxidation. Controlled potential coulometries reveal it is a one-electron oxidation; furthermore, the charge transfer is not complicated by any following chemical reaction, neither on the voltammetric nor on the exhaustive electrolysis time scale. In fact, the ratio between backward and forward peak currents is equal to one for any potential scan rate and, even more significantly, cyclic voltammetry after exhaustive oxidation shows the same reversible peaks system (see Fig. 3). Of course, peak F is first recorded in a forward cathodic scan starting at a potential of about $+1.5$ V vs SCE and peak E is recorded as an associated peak if the potential scan direction is reversed after traversing peak F. If, on the contrary, the cathodic scan goes on, the peaks systems reported in the cathodic potentials region of Fig. 1 are recorded, suggesting that the starting complex is regenerated at the potentials of peak F. Accordingly, exhaustively reducing, at the potentials of peak F, solutions of $[ReOCl(Phsal)_2]$ previously oxidized at peak E, the starting compound is regenerated with a yield very near 100%.

Quite a similar behaviour is exhibited by the compound $[ReOCl(Mesal)_2]$, as regards both voltammetric and coulometric–voltammetric results.

These findings allow us to propose a method to prepare via electrochemical procedures stable

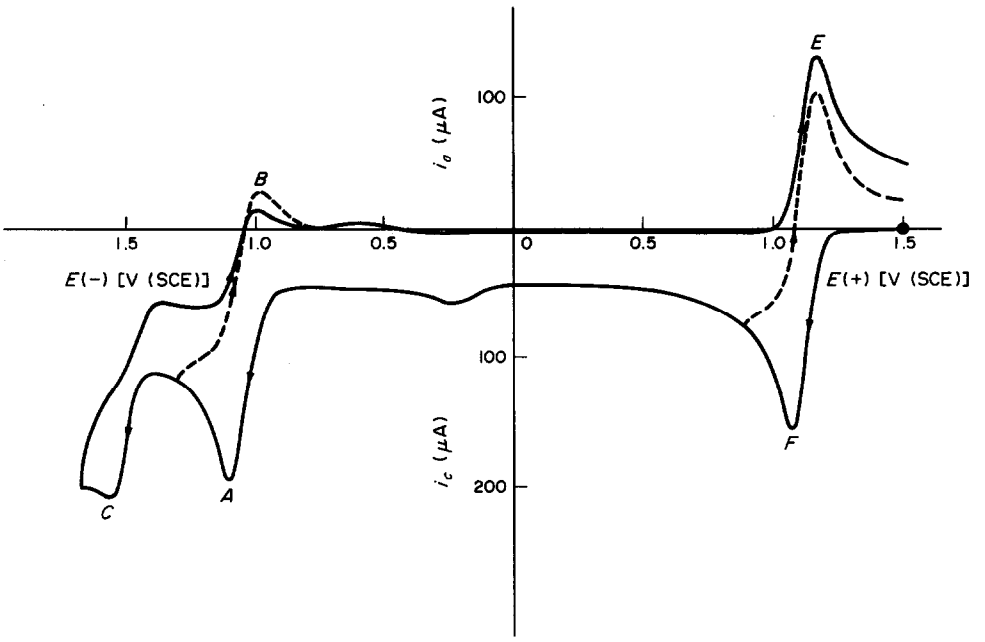

Fig. 3. Cyclic voltammograms recorded on a 4.9×10^{-3} M [ReOCl(Phsal)$_2$] solution, previously oxidized exhaustively in correspondence to peak E of the curve in Fig. 1. Same experimental conditions as for the voltammograms in Fig. 1. (●) Starting potential.

rhenium(VI) complexes containing the ReO^{4+} core.

On the basis of the voltammetric tests the following $E'_{1/2}$ values can be calculated: $E'_{1/2}$, $[ReOCl(Phsal)_2]^+/[ReOCl(Phsal)_2] = +0.76$ V; $E'_{1/2}$ $[ReOCl(Mesal)_2]^+/[ReOCl(Mesal)_2] = +0.67$ V (vs $E'_{1/2}$ of the couple ferricinium ion/ferrocene).

[ReO(TSB)(BSB)]

Cathodic behaviour. Figure 4 illustrates the voltammetric behaviour of [ReO(OPhsal)(Phsal)] in acetonitrile solution. It is evident that no anodic response directly associated to the cathodic peak A can be recorded at the potential scan rate employed to draw the figure (0.2 V s^{-1}). Only at sweep rates higher than 2 V s^{-1} the peak attributable to the oxidation of the species primarily formed at the electrode can be noted, with a relative height progressively increasing at increasing the scan rate. On the basis of the dependence on this last experimental parameter of the ratio $(i_p)_{backward}/(i_p)_{forward}$, of the results of a series of voltammetric measurements

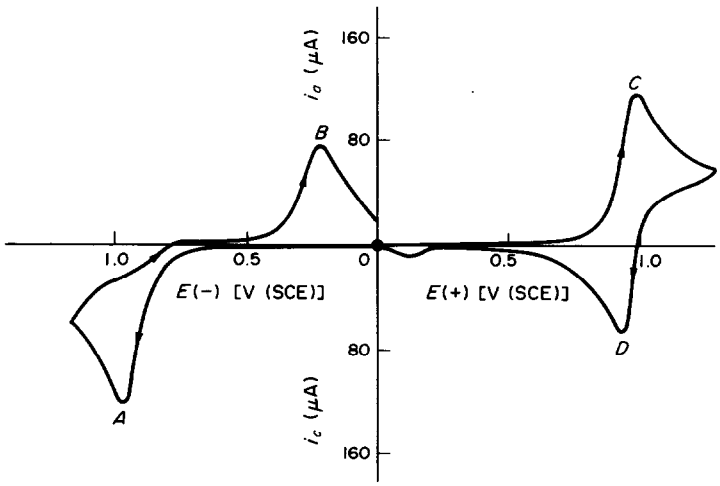

Fig. 4. Cyclic voltammograms recorded on a 4.5×10^{-3} M [ReO(OPhsal)(Phsal)], 0.1 M TEAP, and MeCN solution. Platinum working microelectrode; potential scan rate, 0.2 V s^{-1}. (●) Starting potential.

with different depolarizer concentrations, of chronoamperometric tests and, finally, of the coulometric datum (1 mol of electrons per mole of electrolyzed compound is spent), it is possible to conclude that the electrode reduction consists in an EC mechanism, were a one-electron reversible charge transfer is followed by a first order irreversible chemical reaction. The cyclic voltammetric curves at different potential scan rates allow us to estimate a half-life time of about 25 ms for the short-lived electrogenerated species. The $E'_{1/2}$ value of the couple [ReO(OPhsal)(Phsal)]/[ReO(OPhsal)(Phsal)]$^-$ can be estimated only approximately ($\simeq -1.33$ vs $E'_{1/2}$ of the couple ferricinium ion/ferrocene).

Voltammetric curves recorded on the exhaustively electrolyzed solutions appear as those shown in Fig. 5. During a sweep starting at the potential of the electrolyses performed, peak B is recorded. By switching the potential after traversing this anodic peak, peak A, attributable to the reduction of the complex [ReO(OPhsal)(Phsal)], is recorded. If, on the contrary, the anodic sweep continues towards more positive potentials, the same peaks (system C/D) recorded on solutions of the starting complex, can be noted. Accordingly, electrolysing the reduced solutions at a potential of 0.0 V vs SCE, the starting complex is quantitatively regenerated through the consumption of 1 mol of electrons per mole of compound.

Solutions of the starting compound were also exhaustively reduced in order to identify the final electrolysis products. As we have already mentioned in the Experimental section, through the usual procedure involving dissolution of the reduction product in $CHCl_3$, even if it was carried out in carefully deoxygenated media, we did not manage to avoid that the compound partially decomposed and partially regenerated the starting complex. However, the product was stabilized by treating it with ethanol. Recalling that the voltammetric results suggest that the primary reduction product, [ReO(OPhsal)(Phsal)]$^-$, undergoes a fast chemical reaction leading to a complex that, by oxidation regenerates the starting compound, we can suppose that the chemical reaction consists in the release by the metal centre of one phenolic site of the tridentate ligand, as a consequence of the reduced positive charge on rhenium. On the other hand if, through electrode oxidation, we increase back the rhenium oxidation state, the initial situation is re-established. In this context, the role of the protic solvent in stabilizing the reduction product may consist in the protonation of the free phenolic site. Accordingly, the solubility of the product in MeCN results is noticeably lower after protonation.

The elemental analysis data are as follows (found: C, 44.9; H, 2.7; N, 3.9. Calc. for

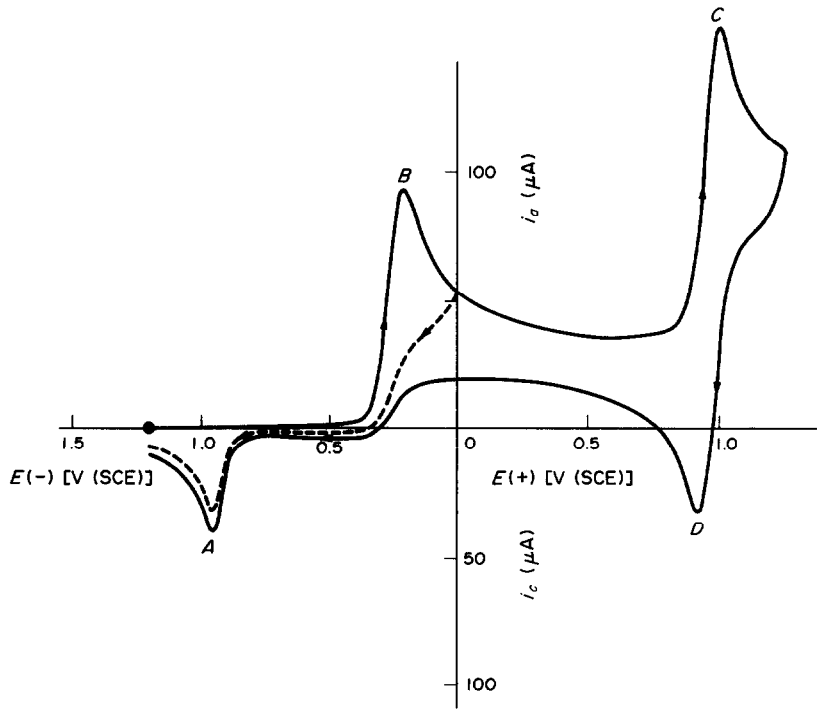

Fig. 5. Cyclic voltammograms recorded on a 4.5×10^{-3} M [ReO(OPhsal)(Phsal)] solution, previously reduced exhaustively at peak A of the curve in Fig. 4. Same experimental conditions as for the voltammograms in Fig. 4. (●) Starting potential.

$C_{26}H_{20}ReN_2O_4$: C, 51.1; H, 3.3; N, 4.6%). The compound could not be further purified owing to the continuous transformation back to the starting complex. For this reason the elemental analyses are not in agreement with the formulation but the C:N:H ratio are consistent with the presence of two ligands in the product and presumably the impurities are due to inorganic compounds.

IR spectra of the recovered reduction products show a significant lowering of the wavenumber of the ν(Re=O) absorption (a shift of about 50 cm^{-1}). This result is in apparent disagreement with that obtained on the reduction product of [ReOCl(Phsal)$_2$], but a weakening of the Re=O bond can be explained assuming the formation of an intramolecular hydrogen bond.

On these bases, and considering, as reported above, only the leaving of the phenolic groups, we propose the formulation reported in Fig. 6 for the product of the [ReO(OPhsal)(Phsal)] reduction.

The compound is soluble in EtOH, MeOH and MeCN and insoluble in Et_2O and pentane; moreover, it easily regenerates the starting complex in CH_2Cl_2, $CHCl_3$, C_6H_6 and acetone.

The results obtained with the complex [ReO (OPhsal)(Mesal)] are only qualitatively similar. Apart from the exact values of the potentials at which the different peaks are recorded, Fig. 4 is still useful to discuss the electrochemical behaviour of this compound. The main differences lie in the lower stability of the electrogenerated species [ReOCl (OPhsal)(Mesal)]$^-$ (half-life time of about 5 ms), and in the value of $E^r_{1/2}$ for the couple [ReO (OPhsal)(Mesal)]/[ReO(OPhsal)(Mesal)]$^-$, which resulted equal to about -1.37 V (vs $E^r_{1/2}$ of the couple ferricinium ion/ferrocene).

Also in this case the reduced solution can be reoxidized at a potential noticeably anodic in respect to the potentials of the cathodic peak (see, qualitatively, peak B in Fig. 5), regenerating quantitatively the starting complex.

The recovery of the reduction product has been more difficult in respect to the corresponding Phsal complex, because it exhibits a marked tendency to regenerate the starting compound if only small traces of oxidizing agents such as oxygen or water, are present. It was only possible to recover a mixture of starting complex and reduced product. IR spectra of this mixture show a first ν(Re=O) band at 924 cm^{-1}, attributable to the reduction product and a second ν(Re=O) band at 957 cm^{-1}, due to the starting complex. The formulation of this compound can be assumed as reported in Fig. 6 by analogy with the previous one.

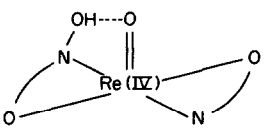

Fig. 6. Proposed scheme for the rhenium(IV) molecule obtained by cathodic reduction of [ReO(OPhsal)(Phsal)], after treatment with ethanol. $\widehat{NO}$ = Phsal and $\widehat{ONOH}$ = HOPhsal.

Also for these tridentate–bidentate compounds, completely similar results are obtained using mercury as the working electrode material.

Anodic behaviour. As Fig. 4 shows for the complex [ReO(OPhsal)(Phsal)], both the [ReO(TSB) (BSB)] compounds undergo reversible oxidation. The oxidized species are stable on the voltametric time scale, so much so that backward to forward peak ratios equal unity also at the lowest (50 mV s^{-1}) potential scan rate used. Controlled potential electrolyses allows one to ascertain that the electrode processes involve a one-electron charge-transfer; however the oxidized species are not stable at the longer electrolysis times and voltammetric tests after electrolyses do not show the peak system C/D giving any interesting information about the presence in the solution of some particular rhenium complex either. Many attempts to recover the oxidation products have been performed. Unfortunately, even if different procedures have been tried, a brown oil was always obtained and all attempts to obtain crystalline products has failed.

On the basis of the voltammetric data it is possible to evaluate $E^r_{1/2}$, [ReO(OPhsal)(Phsal)]$^+$/[ReO(OPhsal)(Phsal)] = +0.57 V, and $E^r_{1/2}$, [ReO (OPhsal)(Mesal)]$^+$/[ReO(OPhsal)(Mesal)] = +0.53 V (vs $E^r_{1/2}$ of the couple ferricinium ion/ferrocene).

As a final consideration, let us observe that the relative values of the $E^r_{1/2}$ calculated for the eight redox couples identified result in agreement with the different electron withdrawing effects of methyl and phenyl groups. In fact, both as regard [ReOCl(BSB)$_2$] and [ReO(TSB)(BSB)], the resulting $E^r_{1/2}$ values for neutral/anionic and cationic/neutral redox couples are more positive for BSB = Phsal than for BSB = Mesal.

From the recovery products point of view, the complexes have shown the presence of Re=O oxo moiety. This fact is particularly important if it is considered that the Re=O group was found in the same complex with rhenium atom in three different oxidation states: VI, V and IV.

To date the principal example of the ReO^{4+} core was given by the complex $[ReOCl_5]^-$ [14,15] and in a few of its substitution products.[16] The ReO^{2+} core was never clearly authenticated.

In particular the oxo oxygen in the fourth oxi-

dation state was always considered bound to a hydrogen atom, for example in the $[Re(OH)Cl_3(PEt_2Ph)_2]$ compound reported by Duatti *et al.*[17] and the formal oxidation state of oxogroup was −1. Concerning the $[ReO(BSB)_2]$ complexes, only phenyl protons can interact with the oxo group, while in the case of [ReO(TSB)(BSB)] complexes a phenolic hydrogen can bind Re=O; however, in both cases oxo group is considered in −2 formal oxidation state.

Abstract—The complex formation of Co(II), Ni(II), Zn(II) with aminopyrophthalone was studied by means of electronic, IR, EPR and ^{1}H–NMR spectroscopy. It was established that with Co(II) and Ni(II) two isomeric complexes are formed in contrast to Zn(II) and Cu(II) complex formation. On the basis of the spectral data obtained the coordination mode and structure of the complex species are assumed.

We have already studied the complexation properties of some derivatives of 1,3-indandione, namely of 2-(2-pyridyl)-1,3-indandione or pyrophthalone (PPH), 2-(2-quinolyl)-1,3-indandione or quinophthalone (QPH) and 3-amino-2-(2-pyridyl)-indenone or iminopyrophthalone (IPH) towards some transition metal ions.[1–3] These ligands are used as dyes, organic semiconductors, and anti-inflammatory and anaesthetic agents.[4–8] The structure of the pyrophthalone and iminopyrophthalone complexes with Cu(II)—one of the most important biometals, was studied in detail.[1,2] In the present paper the results obtained for the Co(II), Ni(II) and Zn(II) complexes of iminopyrophthalone are reported, emphasizing mainly the mode of coordination of the ligand.

EXPERIMENTAL

The electronic and IR spectra were obtained on recording spectrometers "Specord UV–vis", "Specord 71 IR", VEB Carl Zeiss-Jena and Perkin-Elmer 983 (CsI discs, spectral range 4000–200 cm^{-1}). The EPR spectra were recorded on X-band EPR-spectrometer ERS-220 (G.D.R.), the ^{1}H–NMR on FT–NMR spectrometer "Bruker WP-200". The HPLC experiments were performed on Perkin-Elmer LC system consisting of a series of four solvent delivery system connected with 8-μl flow cell of 550 SE UV–Vis spectrometer.

Synthetic procedures

IPH was obtained and purified as described previously.[1] The complexes $Co(IP)_2$, $Ni(IP)_2$ and $Zn(IP)_2$ were obtained in slightly acidic medium (pH ~ 4–5) mixing ethanolic solution of IPH (5×10^{-3} M) with water solution of the corresponding metal salt [$M''Cl_2$ or $M''(NO_3)_2$] at 40°C (metal to ligand ratio 1 : 2). The corresponding complexes were precipitated after careful neutralization of the solution with 0.1 M NaOH. The products

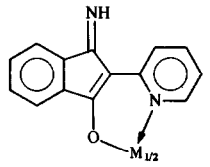
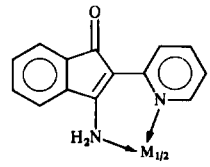
were filtered off, washed with ethanol and dried for a week over P_2O_5 under low pressure.

Analytical data



Elemental analysis of N was provided according to Kjeldahl (treatment for 12 h). Nickel and zinc were determined complexometrically at pH 10 and indicators murexide for nickel and eriochrom T for zinc after ashing the sample and dissolving the residue in HNO_3 (2:1). Cobalt was determined photometrically with nitroso-R-salt at $\lambda = 500$ nm after wet oxidative destruction of the sample with conc. HNO_3, evaporation near dryness and dissolving the residue in water.

RESULTS AND DISCUSSION



The analytical data obtained show that the complexes thus formed have a metal to ligand ratio of 1:2. Their formation is connected with the appearance of a new band in the visible spectra of the complexes (see Table 1).

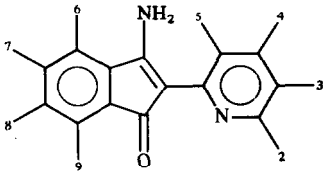
In order to obtain some structural information IR, EPR and ^{1}H–NMR investigations were provided. In Table 2 the IR data obtained for the complexes studied together with that for $Cu(IP)_2$[1] are presented.

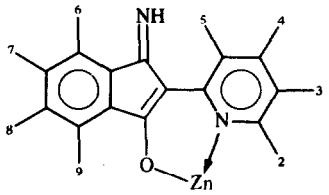
It is evident that the IR spectral data for $Zn(IP)_2$ are very similar to that of $Cu(IP)_2$, showing a similarity of their mode of coordination as well. For $Cu(IP)_2$ chelation through enolic oxygen and nitrogen atom from the pyridyl ring (str. I) has been found. By means of EPR and magnetic susceptibility data a depressed tetrahedral or rhombic symmetry with slightly mis-aligned tetragonal axes was assumed.[1,2]

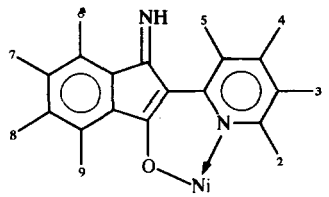
I

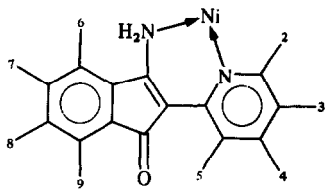
II

The IR data for the Co(II) and Ni(II) complexes show the simultaneous presence of carbonyl, imino- and amino (ν^s and ν^{as}) vibrations. Therefore simultaneous formation of two isomeric complexes (str. I and II) of Co(II) and Ni(II) should be assumed. These results are in agreement with the HPLC and ^{1}H–NMR data obtained. The chromatograms of Cu(II) and Zn(II) complexes show one single peak, while these of Co(II) and Ni(II) complexes show two peaks (Fig. 1), thus suggesting the presence of two isomeric species.









The ^{1}H–NMR data obtained for $Ni(IP)_2$ and $Zn(IP)_2$ in the range 0–20 ppm together with that

of IPH were assigned[1] and summarized in Table 3. They are also consistent with the conclusions made above.

The comparison of IPH and $Zn(IP)_2$ spectra indicates on the Zn(II) chelation through enolic oxygen and nitrogen from pyridyl ring. In $Zn(IP)_2$ spectrum instead of NH_2 doublet at 9.26 and 10.23 ppm[1] a new peak at 10.1 ppm due to =NH group appears. The doublet of H_2 proton is strongly shifted and the multiplet due to $H_{6/9}$ protons is affected as well, namely a doublet at 7.70 ppm is observed, assigned to the H_6 proton and the new peak at 8.93 ppm should be assigned to the H_9 proton. The shifts of the H_2 and H_9 protons signals indicates the coordination of Zn(II) to the neighbouring N- and O-atoms respectively.

In the $Ni(IP)_2$ spectrum a greater number of signals is observed. A new low-field doublet (14.4 and 14.9 ppm) is present due most probably to coordinated NH_2 group and an =NH singlet is also observed indicating the presence of the other isomer. In this case the H_2 proton neighbouring the pyridyl nitrogen is also shifted as well as the signals due to H_5 and H_9. For H_9 two different peaks are observed, due most probably to the H_9 protons of the two isomers.

The EPR study of the $Co(IP)_2$ complex [powder sample, diamagnetically diluted with $Zn(IP)_2$] in the range 700–5700 Oe at −190°C showed that only one almost isotropic singlet line ($g = 2.002 \pm 0.001$) was observed, thus proving the oxidation state +2 for the complex. According to the literature data[11] the EPR results show that for the $Co(IP)_2$ complex a planar structure seems more likely than a tetrahedral one.

The fact that Co(II) and Ni(II) are forming two isomeric complexes with IPH in contrast to Cu(II) and Zn(II) is rather surprising taking into account the very close values of their ionic radii.[12] Most probably the simultaneous formation of the two

different types of complexes with Co(II) and Ni(II) is due to a proper steric orientation and energy level of the nitrogen atom orbitals of NH_2 group, for which overlapping with *d*-orbitals only of Co(II) and Ni(II) is possible.

SYNTHESIS AND CRYSTAL STRUCTURE OF A NEW NICKEL(II)–TERPYRIDINE COMPLEX: [Ni(terpy)(NO_2)(ONO)(H_2O)]

ROBERTO CORTES, M. ISABEL ARRIORTUA, TEOFILO ROJO,* XAVIER SOLANS† and DANIEL BELTRAN‡

Departamentos de Química (Inorgánica) y Cristalografía, Universidad del País Vasco, Aptdo. 644, 48080 Bilbao, Spain

(*Received* 28 *January* 1986; *accepted* 7 *May* 1986)

Abstract—The compounds Ni(terpy)$Cl_2 \cdot 3H_2O$ and $NaNO_2$ react readily in aqueous solution to give the complex [Ni(terpy)(NO_2)(ONO)(H_2O)], which has been structurally characterized by an X-ray diffraction study. The hexacoordinate nickel atom bonds to three nitrogen atoms of the terpyridine ligand, to a "nitro" group, to a "nitrite" group and to a water molecule. Distortion from an octahedron to a trigonal prism, for the complex, has been evaluated. An infrared study of the complex has been carried out and shows bands of nitro and nitrite coordination. Magnetic study reveals a Curie–Weiss behavior, giving an effective magnetic moment at room temperature 3.12 B.M.

The nitrite group is unusual because of the number of different ways in which it can coordinate to a metal.[1] As a monodentate ligand it can bond via either nitrogen or oxygen, while as a bidentate ligand it can chelate or bridge either via nitrogen and oxygen or via a single oxygen atom. The factors influencing the type of nitrite coordination adopted are often delicately balanced.

The ligand 2,2′:6′,2″-terpyridine(terpy) forms two types of complexes when it reacts with one bivalent transition metal in 1:1 ratio, M(terpy)X_2 and [M(terpy)X]Y (X, Y = (pseudo)halide or counterion). The former leads to discrete monomeric molecules,[2,3] while the latter gives rise to polynuclear species in which the X atom acts as a bridging ligand, causing magnetic interactions.[4]

In recent years the work carried out in our laboratories has been based on the coordination studies of both types of complex to explain their physical properties. Only one structure of a monoterpyridine nickel(II) complex has been reported so far.[5]

In order to advance this work we have studied this Ni–nitrite complex.

RESULTS AND DISCUSSION

The crystal consists of single molecules with an hexacoordinate stereochemistry around the nickel atom, resulting from bonding to a quasi-planar tridentate ligand, to a "nitro" group, to a "nitrite" group and to a water molecule. The results of the single crystal X-ray diffraction study are summarized in Table 1 and the molecular structure is shown in Fig. 1.

The main distortions from octahedral geometry are caused by the tridentate ligand which subtends angles at nickel of 77.8 and 78.1°. Intermolecular hydrogen bonds are present in the compound [O(w)—H(w)...O1($-x$, $1-y$, $-z$) 2.84(3) Å, H(w)..O1 2.00(4) Å, ∠O(w)—H(w)...O1 179.46°; O(w)—H(w)′...O4($-x$, $1-y$, $1-z$) 2.85(6) Å, H(w)′...O4 2.09(6) Å, ∠O(w)—H(w)′...O4 162.79°].

Values obtained for bond distances and angles in the terpy ligand are in good agreement with those in the literature.[6,7]

It could be expected that the N—O bond distance in the nitrite involving the oxygen atom closer to the metal increases in length, while for the less strongly bonded oxygen it decreases.[1] On the con-

trary, the observed N—O bond distance for the metal bonded oxygen is 1.203(4) Å while for the other is 1.242(4) Å.

This can probably be explained on the basis of intermolecular hydrogen bonds between the water molecule and the free oxygen of the nitrite group.

Distortion from an octahedron to a trigonal prism (Δ) for the complex has been examined using the Muetterties and Guggenberger description[8] by comparison of the observed dihedral angles (δ) formed by the normal to adjacent polytopal faces with those of the ideal octahedron ($\Delta = 0$) (see Table 2); the value $\Delta = 0.09$ indicates that the $[NiN_4O_2]$ polyhedron is close to octahedral.

The infrared spectrum of the complex, pelleted in KBr, has been recorded in the hope that the

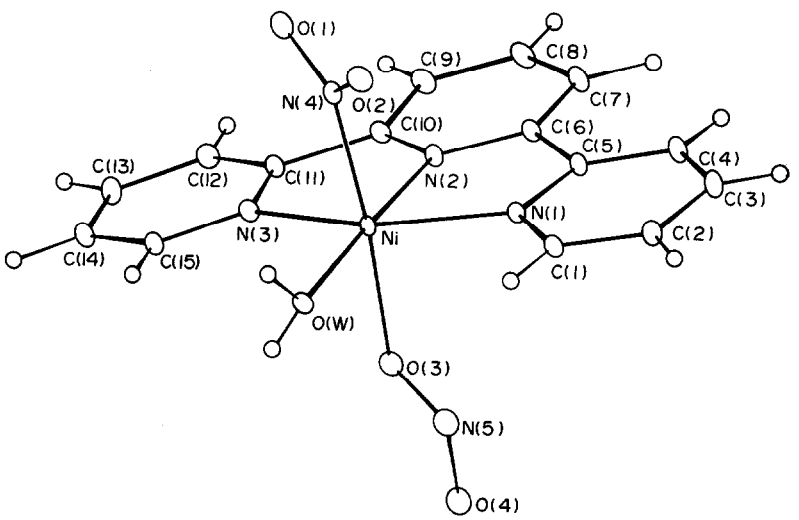

Fig. 1. Molecular structure of the complex Ni(terpy)$(NO_2)(ONO)(H_2O)$ showing the atom-numbering scheme.

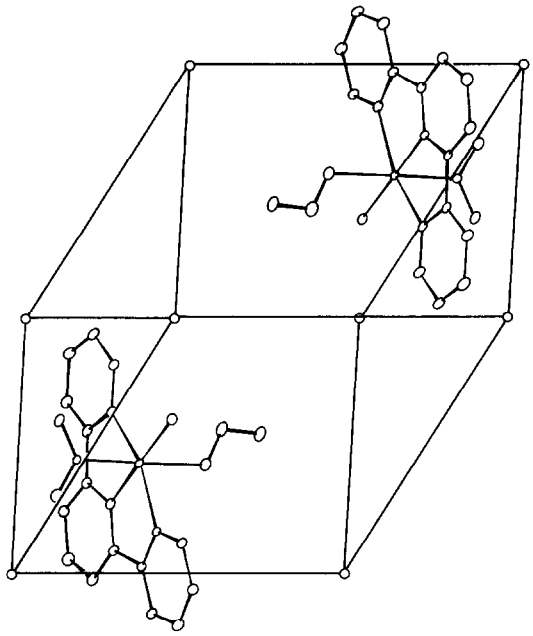

Fig. 2.

"nitrite" and "nitro" peaks could be identified and used for the study of the relationship between the vibrational frequencies and the internal geometry of the nitrite ion.

The general effect of coordination via nitrogen is to raise the frequency of both $\nu_{as}(NO_2)$ and $\nu_s(NO_2)$ from the free ion values of 1328 cm^{-1} and 1260 cm^{-1} respectively. Coordination via oxygen may be expected to raise the frequency of $\nu_{as}(NO_2)$ and to lower that of $\nu_s(NO_2)$.[1]

The IR spectrum of Ni(terpy)(NO_2)(ONO)(H_2O) in the N—O stretching region has two bands due to nitro group at 1303 $cm^{-1}(\nu_{as})$ and 1274 $cm^{-1}(\nu_s)$; bands at 1358 $cm^{-1}(\nu_{as})$ and 1128 $cm^{-1}(\nu_s)$ may be attributed to "nitrite" group.[9]

Table 2. Distortion Δ^a of the $[NiN_4O_2]$ polyhedron

Dihedral angle	Polyhedron: Octahedron (°)	Polyhedron: NiN_4O_2 (°)	Polyhedron: Trigonal prism (°)

δ_6	70.5	55.4[N(1)—N(2)—O(3)—N(3)]	90
Δ	0	0.09	1

[a] Δ is calculated using the following formula:

$$\Delta = \sum \frac{[\delta b_1 - \delta b_{1\,oct}]}{846} + \sum \frac{[\delta b_2 - \delta b_{2\,oct}]}{594} + \sum \frac{[\delta_i - \delta_{oct}]}{234}.$$

Susceptibility measurements over a temperature range 77–300 K obey the Curie–Weiss law. The effective magnetic moment at room temperature is 3.12 B.M.

EXPERIMENTAL

Synthesis of the complex

[Ni(terpy)(NO_2)(ONO)(H_2O)] was prepared by mixing the complex Ni(terpy)$Cl_2 \cdot 3H_2O$, synthesized by us,[10] with an excess of sodium nitrite in aqueous solutions. Red crystals of the compound were obtained by slow evaporation of this solution, and then washed with acetone and dried *in vacuo*. The red colour may be indicative of nitro-coordination for nickel(II) complex. (Found: C, 45.0; H, 3.4; N, 17.5. $NiC_{15}H_{11}N_3N_2O_4H_2O$ requires C, 44.8; H, 3.2; N, 17.4%.)

Crystal structure determination

Crystals grow as red needles from aqueous medium. Diffracted intensities were collected at room temperature on a Phillips PW 1100 four-circle diffractometer using a crystal of dimensions $0.08 \times 0.02 \times 0.42$ mm.

Of the total 2777 reflections, measured to $2\theta \leqslant 50$ ($\omega - 2\theta$ scans) 2087 had $I \geqslant 2.5\sigma(I)$, and only these were used in the refinement of the structure after the data had been corrected for Lorentz and polarization effects, not for absorption.

Crystal data. Ni($C_{15}H_{11}N_3$)(NO_2)(ONO)(H_2O), $M = 402.1$, triclinic, $a = 9.079(2)$, $b = 9.430(2)$, $c = 10.683(3)$ Å, $\alpha = 76.61(3)$, $\beta = 70.73(2)$, $\gamma = 68.02(2)°$, $U = 794.5(3)$ Å^3, space group: $P\bar{1}$, $Z = 2$, $D_x = 1.68$ g cm^{-3}, $F(000) = 410$, Mo-K_α X-radiation (graphite monochromated), $\lambda = 0.7106$ Å, μ(Mo-K_α) = 12.63 cm^{-1}.

The structure was solved by direct methods, using the 1980 version of MULTAN. It was refined isotropically and also anisotropically using the program SHELX 76.[11] The positions of the hydrogen atoms were determined from the difference Fourier synthesis.

Refinement converged at $R = 0.030$ ($Rw = 0.031$) with a weighting scheme of the form $w = [\sigma^2(F_0) + 0.00035(F_0)^2]^{-1}$ giving a satisfactory weight analysis. A final electron density difference synthesis showed no peaks >0.3 e Å^{-3}. All computations were carried out on an IBM 3083 computer. Atomic scattering factors and anomalous dispersions corrections were taken from Ref. 12. The atomic coordinates of this work are available on request from the Editor and have also been deposited with the Cambridge Crystallographic Data Centre.

Magnetic measurements

Magnetic susceptibility measurements were performed with a Faraday type magnetic microbalance between 77–300 K.

THE NITROSATION OF ANILINE WITH $Zn(py)_2(ONO)_2$

ANNA G. McKENNA* and JAMES C. FANNING†
Department of Chemistry and Geology, Clemson University, Clemson, SC 29634, U.S.A.

(*Received* 27 *January* 1986; *accepted* 8 *May* 1986)

Abstract—Diazoaminobenzene (DAAB) formed slowly when aniline was reacted with $Zn(py)_2(ONO)_2$ in dichloroethane at 60°. The rate of reaction was followed by measuring the DAAB concentration spectrophotometrically at 353 nm. Complex concentrations ranged from 5 to 30 mM, while those of aniline were from 100 to 900 mM. The kinetic data were explained by a mechanism involving a pre-equilibrium, wherein aniline displaced a nitrite ion from the zinc complex. This was followed by a slow reaction of the free nitrite ion with the solvent, forming a highly reactive nitrosating species.

It has been previously communicated that metal nitrite complexes with O-bound nitrite, the nitrito form, are capable of efficiently nitrosating secondary amines in organic solvents.[1] In an attempt to show that the reaction also occurs with primary amines, dinitritobis(pyridine)zinc, $Zn(py)_2(ONO)_2$, was reacted with aniline at 60° in dichloroethane (DCE) under a nitrogen atmosphere and in the absence of light. The reaction which slowly produced the intensely colored N-coupled diazoaminobenzene (DAAB), $C_6H_5N{=}NN(H)C_6H_5$, was followed spectrophotometrically. The Zn complex was used since it has the potential to form nitrito complexes in solution. In the solid state the nitrite groups are bound in a bidentate manner.[2] In solution, one end of the nitrite might be expected to be displaced from the labile Zn(II) ion. The complex dissolved readily in DCE and was colorless. Also, the Zn(II) ion was felt to be less likely to bind to the azo product than transition metal ions and thus not change the character of the reaction as it proceeded.

EXPERIMENTAL

$Zn(py)_2(ONO)_2$ was prepared according to the procedure of Goodgame *et al.*[2] and gave satisfactory analysis. The aniline and DCE were distilled prior to use and protected from moisture and light.

For the nitrosation reactions, 50 cm^3 of the complex solution were transferred to a 75 cm^3 two neck flask. Twenty-five cm^3 of the aniline solution were placed in a vented dropping funnel. The dropping funnel was inserted into one neck of the flask and a stopcock into the other neck. The system was purged with nitrogen and the complex solution heated in a constant temperature bath for 15 min before adding the amine solution. The reaction was carried out in a nitrogen atmosphere and protected from light. Under a stream of nitrogen, the stopcock was removed and a septum inserted. Fractions of 50 to 200 μl were removed at various times, diluted to 2 cm^3 and the visible spectra measured. A Bausch and Lomb Spectronic 2000 was used for these measurements.

A 50 cm^3 solution, 3.0 mM in complex and 80.0 mM in aniline, was allowed to stand for 3 h at 60°. The solution was then shaken with conc. aqueous NH_3 to destroy the complex, followed by dilute HCl to remove the amine and pyridine. After washing the organic layer, drying it and removing the DCE under vacuum, the infrared, ultraviolet–visible, and mass spectral properties of the product were obtained. They matched those of DAAB synthesized by the method of Vogel.[3] In DCE, DAAB has an absorption band at 353 nm (ε 20,000 cm^{-1} M^{-1}) and obeys the Beer–Lambert law over the concentration range used in these experiments. The 353 nm band did not shift during the reaction, indicating that no rearrangement occurred to form p-aminoazobenzene (4-(phenylazo)-benzenamine) which absorbs at 384 nm. p-Aminoazobenzene was synthesized from DAAB by heating it in aqueous acid.[3]

RESULTS AND DISCUSSION

The nitrosation reaction was carried out at complex concentrations ranging from 5 to 30 mM and over an aniline concentration range of 100 to 900 mM. Figure 1 shows the concentration of DAAB vs time for a 30 mM $Zn(py)_2(ONO)_2$/600 mM aniline solution with added DAAB (2.1 mM) and without it. The curves are essentially parallel for over 300 min showing that no significant decomposition of DAAB occurred during the early part of the reaction. For this reason most of the kinetic runs were followed for about 300 min. Attempts to obtain the theoretical yield of DAAB were unsuccessful, probably because of DAAB decomposition.

The overall reaction for the formation of DAAB in the early stages can be considered to be:

$$Zn(py)_2(ONO)_2 + 2C_6H_5NH_2 \rightarrow Zn(py)_2(ONO)(OH) + C_6H_5N_2N(H)C_6H_5 + H_2O.$$

No evidence for the zinc product exists and it is quite probable that one or both pys are exchanged with the excess aniline. As the reaction proceeds both nitrites probably react; however, DAAB may decompose or convert to p-aminoazobenzene. The 30 mM $Zn(py)_2(ONO)_2$/600 mM aniline reaction after 27 h showed spectrophotometric evidence of a 47% conversion of total nitrite into DAAB.

A mechanism which is able to explain the kinetic data is as follows:

$$MX + A = MA + X \quad \text{pre-equilibrium, } K \quad (1)$$

$$X + \text{solvent} \rightarrow B \quad \text{slow step, } k \quad (2)$$

$$B + A \rightarrow \text{DAAB} + \text{other products} \quad \text{fast} \quad (3)$$

Step (1) involves the reactant complex (MX) with a substitutionally labile nitrite (X), displaced by the amine (A) in a rapidly established pre-equilibrium having an equilibrium constant, K. The nitrite then reacts with solvent in a pseudo-first order slow step with a rate constant, k, to produce an intermediate (B). B reacts with amine to produce, in a series of fast reactions, DAAB and other products. From the relationship

$$-\frac{d[MX]}{dt} = \frac{d[X]}{dt} = -k[X] = -\frac{kK[MX][A]}{[MA]} \quad (4)$$

and the assumptions that $[A] \sim [A]_0$, the initial amine concentration, and that the initial MX concentration, $[MX]_0$, is equal to the sum of the concentrations of MX and MA, eqn (5) may be derived.

$$[MX]_0 \ln\left(\frac{[MX]}{[MX]_0}\right) + [MX]_0 - [MX] = -kK[A]_0 t. \quad (5)$$

Initially $[MX] = [MX]_0 - [\text{DAAB}] - [X]$; however, as [DAAB] increases,

$$[MX] \sim [MX]_0 - [\text{DAAB}]. \quad (6)$$

Substituting (6) into (5) gives

$$[MX]_0 \ln\left(1 - \frac{[\text{DAAB}]}{[MX]_0}\right) + [\text{DAAB}] = -kK[A]_0 t. \quad (7)$$

Thus a graph of the left side of eqn (7) vs time should result in a straight line with a slope of $-kK[A]_0$ after the reaction has proceeded for a given period of time.

The plots of eqn (7) for solutions with an initial aniline concentration of 600 mM and zinc complex concentrations of 5.2, 11, 20 and 30 mM are shown in Fig. 2. At the lower concentrations a longer time was required to reach the linear region of the reaction. The slopes of the linear region are approximately equal [average value: $(-1.18 \pm 0.08) \times 10^{-4}$ mM s^{-1}]. Table 1 gives the slopes for each experiment. The slopes from the experiments where the initial zinc complex concentration is 11 mM are shown plotted against the initial aniline concentrations in Fig. 3. An approximate linear relationship results (slope: -1.67×10^{-7} s^{-1}; intercept: 8.8×10^{-6}; correlation coefficient: 0.95) with a

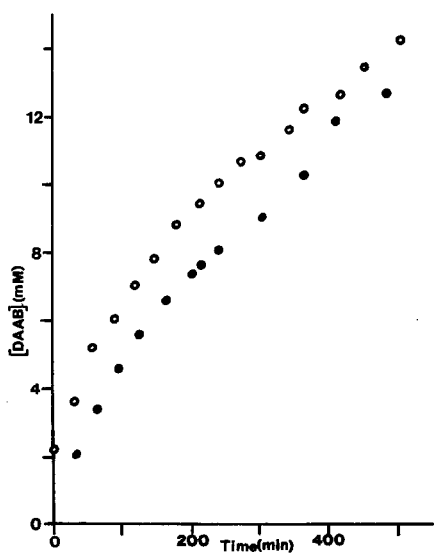

Fig. 1. The concentration of DAAB vs time (min) for the reaction of 30.0 mM $Zn(py)_2(ONO)_2$ and 600 mM aniline at 60° in DCE with added (2.1 mM) DAAB (○) and without added DAAB (●).

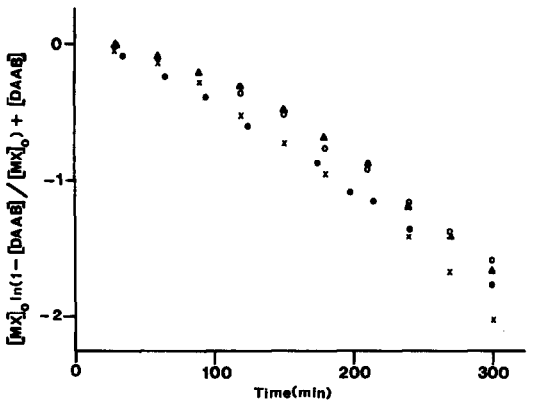

Fig. 2. The function,

$$[MX]_0 \ln\left(1-\frac{[\text{DAAB}]}{[MX]_0}\right)+[\text{DAAB}],$$

vs time (min) for the experiments with 600 mM aniline and 30 (●, A); 20 (×, C); 11 (○, D); and 5.2 mM (△, F) $Zn(py)_2(ONO)_2$ nitrosation reactions. Letters refer to experiments listed in Table 1.

near zero intercept. Because of the relatively long time (>60 min) required to reach the linear region of the reaction with low concentrations of aniline and complex, the slopes for these concentrations were somewhat inexact.

An initial slope method was also used to examine the kinetics. If it is assumed that $[A] \sim [A]_0$ and, for the initial stages, that $[MA] = [X] = \sqrt{K[MX]_0[A]_0}$, then using eqn (4), a first-order relationship results

$$\frac{d[MX]}{dt} = -kK^{1/2}\sqrt{\left(\frac{[A]_0}{[MX]_0}\right)}[MX].$$

Therefore, the experimental initial first-order rate constant

$$k_e = kK^{1/2}\sqrt{\left(\frac{[A]_0}{[MX]_0}\right)}$$

or

$$\ln(k_e) = 0.5\ln\left(\frac{[A]_0}{[MX]_0}\right)+\ln(kK^{1/2}).$$

To obtain k_e, $\ln([MX]_0-[\text{DAAB}])$ vs time plots were made and the initial slope, equal to k_e, determined. The k_e values are given in Table 1.

A log–log plot of k_e vs $[A]_0/[MX]_0$ is shown in Fig. 4. An increase in k_e with an increase in the ratio was found. The slope of the best line drawn through the points is 0.46 ± 0.11 (90% confidence limit). Thus, the expected slope of 0.5 is well within this limit. The intercept is -12.07 which makes $kK^{1/2}$ equal to 5.7×10^{-6}. Using this value and the slope of the line in Fig. 3 (-1.67×10^{-7}), equal to $-kK$, allows a rough calculation of K (9×10^{-4}) and k (2×10^{-4} s^{-1}).

The excess aniline in each solution is expected to produce partial, if not total, substitution of the two pyridines bound to the labile zinc ion. An estimate of the amount of *bis*-aniline complex may be made

if the equilibrium constant for the reaction:

$$ZnL(py)_2^n + 2A = ZnL(A)_2^n + 2py$$

is known. It may be calculated from stability constant data. Such data are not available for the nitrite complex used in this study; however, data are available for two very different zinc complexes and the calculated equilibrium constant values are quite similar. When L is the acetylacetonate anion; n, zero; and the solvent benzene at 20°, the equilibrium constant is 1.2×10^{-2}.[4] When L is $(H_2O)_x$; n, +2; and a 30° aqueous solution with an ionic strength of 0.1 is used, the equilibrium constant is 8×10^{-3}.[5]

Assuming a value of 1×10^{-2} for the equilibrium

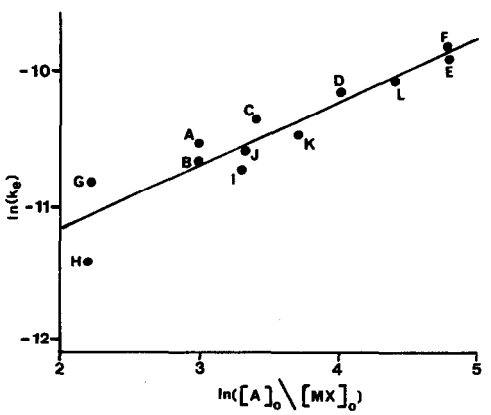

Fig. 4. $\ln(k_e)$ vs $\ln([A]_0/[MX]_0)$ for the $Zn(py)_2(ONO)_2$/aniline reactions given in Table 1. $[A]_0$ and $[MX]_0$ are the initial aniline and zinc complex concentrations and k_e is the initial first-order rate constant. constant when $Zn(py)_2(ONO)_2$ has both pyridines replaced by aniline, the per cent of *bis*-aniline product was calculated for the solutions with the highest aniline/complex ratio (expts E and F) and the lowest ratio (expts G and H). Experiments E and F with 5 mM complex and 600 mM aniline would have 97% *bis*-aniline product; while expts G and H with 11 mM complex and 100 mM aniline would have 45% *bis* product.

Thus, it appears that for most of the solutions, the *bis*-aniline complex is a major, if not predominant, reactant species in solution. If the $[A]_0$ values were adjusted by subtracting $2[M]_0$, the slopes and correlation coefficients of the lines shown in Figs 3 and 4 were unaffected.

At this time we believe the free nitrite ion leads to the eventual production of DAAB. Ongoing work in our laboratory and other work[6] has shown that nitrite salts in DCE and dichloromethane react with the solvent to produce, as yet, an unidentified product which appears to have a high nitrosating potential. The product is probably a nitrite ester, RONO, resulting from the substitution of a chloride by a nitrite on a solvent molecule.[6]

The bound nitrite does not appear to have appreciable reactivity with the solvent. Heating an 11 mM zinc complex solution at 60° for 24 h prior to making it 300 mM in aniline results in only small changes in the eqn (7) slope and k_e (expt. I) compared to a solution with comparable concentrations and reacted in the normal manner (expt. J).

The kinetic data were examined in detail with a number of models which involved the direct nitrosation of aniline by the zinc nitrite complex. The models considered varying amounts of pyridine substitution by aniline and aniline displacement of one end of the bidentate nitrite. Most of the models predicted that the complex would react with first order kinetics and that the aniline would have an order dependent on the model. Since an excess of aniline was used for the experiments, the data were treated with first order kinetics, and second order as well, but to no avail. These models were unable to explain all of the collected data. Only the solvent reaction model presented here was able to give a complete explanation. We are now seeking a solvent for the complex which would not participate in the nitrosation reaction and would allow the complex to serve as a direct nitrosating agent of amines.

The nitrito complex, $Co(NH_3)_5ONO^{2+}$ has been shown to nitrosate water[7] and azide ions[8] in aqueous solution. The inert complex is considered to be the active nitrosating agent for the azide ions and not involve the solvent.

The primary *N*-nitrosamine, $C_6H_5N(H)NO$, is expected to be formed as part of eqn (3). Reactions

leading to the formation of the diazonium product, DAAB, from the nitrosamine are fast even at temperatures well below 60°. Aziz *et al.*[9] have discussed recently the nitrosation of aniline by N_2O_4 and have outlined a nitrosation pathway producing the diazonium ion, $C_6H_5N_2^+$. DAAB forms by the attack of this ion on an aniline molecule.

The 60° reaction temperature was the optimum temperature for this study. Both decreasing and increasing the temperature by 10° showed a sharp decrease in the rate of DAAB production. At 70° considerable DAAB decomposition occurred.

The presence of water in the DCE resulted in an increase in rate (expt. M). Since water is a product of the reaction, it should cause an increase in rate as the reaction proceeds.

Abstract—$Zr(O_3PONa)_2 \cdot nH_2O$ can be prepared as a single crystalline phase by direct precipitation in the presence of HF. This material is a powder. When a single crystal of α-HZrP is exchanged with Na^+, $Zr(O_3PONa)_2 \cdot nH_2O$ is obtained as a powder-like crystal. The zero level Weissenberg photograph shows a monoclinic symmetry; the unit cell ($a = 0.900$ nm, $b = 1.059$ nm, $c = 2.210$ nm and $\beta = 117.12°$) contains eight formula units $Zr(O_3PONa)_2 \cdot 3H_2O$. This is doubled with respect to α-HZrP.

Crystalline $Zr(O_3POH)_2 \cdot H_2O$ (α-HZrP) is the most important member of the acid salts of quadrivalent metals. It is used as an ion exchanger.[1,2] When the proton is exchanged by transition metals a heterogeneous catalyst is produced.[3–5] When it is exchanged by organic cations stable aqueous suspensions can be prepared, which open new ways for applications.[6,7]

A limitation to the extension of our knowledge about zirconium phosphates is the lack of accurate structural data. A detailed structure has been published for α-HZrP.[8] Half exchanged and fully exchanged alkali metal zirconium phosphates are only known as powders.[9–11] In this note we describe our efforts to obtain single crystals of $Zr(O_3PONa)_2 \cdot nH_2O$ and their characterization.

EXPERIMENTAL

Direct precipitation

The precipitation of sodium exchanged α-zirconium phosphate was based on the HF method for the synthesis of α-HZrP.[12] 4.2 g $ZrOCl_2 \cdot 8H_2O$, 3 g NaCl and 3 or 4 cm^3 HF 40% are dissolved in 27 or 26 cm^3 water respectively. The HF/Zr molar ratio is 5.2 and 6.9 respectively. To this solution 11.6, 23.2 or 116 g $Na_2HPO_4 \cdot 2H_2O$, dissolved in 100 cm^3 water, was added to obtain a P/Zr molar ratio of 5, 10 or 50 respectively. P stands for sodium phosphate. The reaction mixture was stirred on a waterbath at 330–335 K for 2 weeks. The reaction product was washed with water and freeze-dried.

To prepare large crystals the temperature of the reaction mixture with HF/Zr = 5.2 and P/Zr = 50 was increased from 325 to 360 K at a rate of 2° per day and kept at 360 K for 1 week.

In a second set of synthesis reactions $NaH_2PO_4 \cdot 2H_2O$ was used instead of $Na_2HPO_4 \cdot 2H_2O$. 10.2 g or 20.4 g $NaH_2PO_4 \cdot 2H_2O$, dissolved in 100 cm^3 water, were added to the solution of $ZrOCl_2$, HF and NaCl. The P/Zr ratio was 5 or 10 respectively. These reaction products were air-dried instead of freeze-dried.

Ion exchange

Large α-HZrP crystals (particle size of about 1 mm) were synthesized as described by Alberti *et al.*[13] 0.5 g of these α-HZrP crystals were equilibrated with 100 cm^3 NaCl 0.1 M and 40 cm^3 NaOH 0.1 M for 2 weeks. The exchanged crystals were air-dried. The best crystal out of about 30 examined under microscope was used for single crystal X-ray analysis.

Crystalline α-HZrP powder was prepared by direct precipitation as described by Alberti and Torracca.[12] The sodium-exchange was performed in the same way as for the large α-HZrP crystals. Part of the exchanged powder was freeze-dried, the other part was air-dried. These samples were used as references for the NaZrPs formed by direct precipitation.

* Author to whom correspondence should be addressed.

Techniques

X-ray powder diffraction (XRD) patterns (Ni-filtered Cu K_α radiation) were obtained with a modified Siemens type F diffractometer [automated and equipped with a position-sensitive detector (M. Braun)]. The X-ray patterns of the synthesized or ion-exchanged products were identified by comparison with published spectra.[9,14,15]

Oscillation and zero level Weissenberg photographs were taken from several α-HZrP and NaZrP crystals (plates with mean size approximately 0.2 mm).

RESULTS AND DISCUSSION

Direct preparation of $Zr(O_3PONa)_2 \cdot nH_2O$

Large single crystals of α-HZrP can be prepared in the presence of HF because the slow decomposition of $ZrF_n^{(4-n)+}$ is the rate-determing step. When the same synthesis conditions are applied with NaH_2PO_4 or Na_2HPO_4 instead of H_3PO_4 the crystalline phases given in Table 1 are obtained. These are present as powders. In no case did we obtain large crystals. The XRD patterns of the samples 1, 3, 4 and 7 (Table 1) are given in Fig. 1 as examples together with the patterns of $Zr(O_3PONa)_2 \cdot H_2O$ and $Zr(O_3PONa)_2 \cdot 3H_2O$, obtained by Na^+-exchange of α-HZrP powder.

With Na_2HPO_4 pure phases of $Zr(O_3PONa)_2 \cdot nH_2O$ are obtained with HF/Zr and P/Zr ratios of 5.2 and 10 to 50 respectively. At lower P/Zr ratios or higher HF/Zr ratios mixtures of phases or zirconium fluorides are obtained. With NaH_2PO_4 no pure single phase could be isolated.

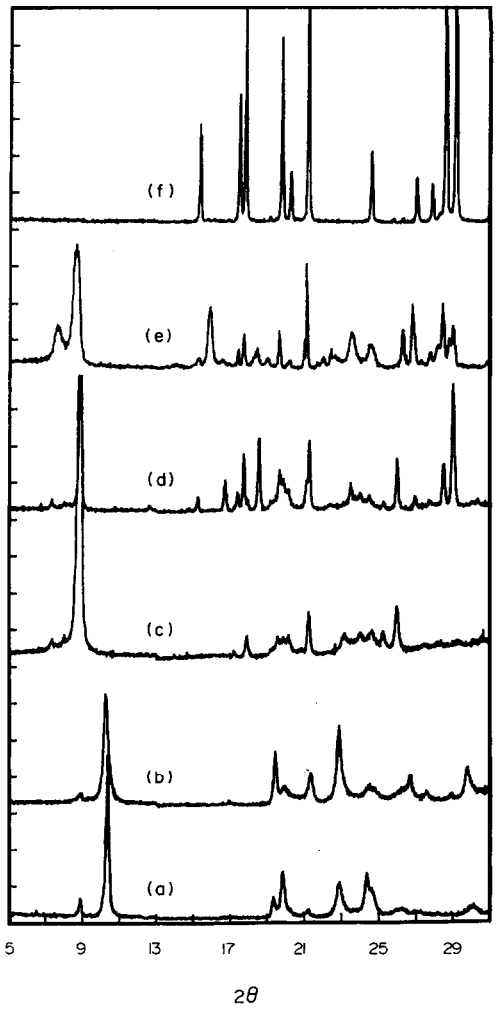

Fig. 1. XRD patterns of $Zr(O_3PONa)_2 \cdot H_2O$ (a), sample No. 3 (b), $Zr(O_3PONa)_2 \cdot 3H_2O$ (c), sample No. 1 (d), sample No. 7 (e) and sample No. 4 (f).

Table 1. Reaction products obtained by direct precipitation from a solution with given reagent concentrations

Sample No.	P[a] source	Zr(IV) (M)	HF (M)	P (M)	Product
1	$Na_2HPO_4 \cdot 2H_2O$	0.10	0.52	0.5	D,[b] β-$Na_5Zr_2F_{13}$
2		0.10	0.52	1.0	E
3		0.10	0.52	5.0	E
4		0.10	0.69	0.5	β-$Na_5Zr_2F_{13}$
5		0.10	0.69	1.0	Na_3ZrF_7
6	$NaH_2PO_4 \cdot 2H_2O$	0.10	0.52	0.5	D, A, Na_3ZrF_7
7		0.10	0.52	1.0	D, A, β-$Na_5Zr_2F_{13}$

[a] P stands for sodium phosphate.

[b] The phases are identified by letters as defined in Ref. 9. A stands for $Zr(O_3PONa)(O_3POH) \cdot 5H_3O$. D stands for $Zr(O_3PONa)_2 \cdot 3H_2O$. E stands for $Zr(O_3PONa)_2 \cdot H_2O$.

The failure to obtain large single crystals can be attributed to the following two reasons.

(1) The interlayer distance of $Zr(O_3PONa)_2 \cdot H_2O$ is 1.18 nm (as derived from the supposed d_{002} reflections in the XRD patterns[9]). This is too large for efficient interlayer cohesion. Cleavage of α-HZrP crystals during the exchange with Na^+ was indeed observed by Alberti *et al.*[13]

(2) The maximum concentration of an aqueous solution of sodium phosphates is 5 M, i.e. only half of the concentration of phosphoric acid needed to obtain large single crystals of α-HZrP[13] (the crystal size increased with increasing phosphoric acid concentration).

Ion-exchanged $Zr(O_3PONa)_2 \cdot 3H_2O$

Single crystals of α-HZrP were ion-exchanged with Na^+ as described in the experimental section. The oscillation photograph parallel to the *b*-axis of a single crystal of $Zr(O_3PONa)_2 \cdot 3H_2O$ is shown in Fig. 2.

A first observation is a deterioration of the diffraction pattern, which could be expected already from a visual inspection of the crystal which is no longer transparent. In view of the pronounced disintegration of the crystals upon exchange, the oscillation photograph shown in Fig. 2 is consistent with a diffraction pattern of domains which are more or less oriented in a parallel fashion. This is also evident on the Weissenberg photograph. A second observation is a doubling of the *b*-axis. Although the most intense spots are still those of the original α-HZrP material (figure not shown), weak but definite spots consisting of *h*,*k*/2,*l* lines emerge, indicating a doubling of the *b*-axis.

The unit cell parameters could be derived from the Weissenberg photograph (Table 2) and the *a*-axis was chosen so as to coincide with the original *a*-axis. This is reasonable in view of the fact that the zirconium phosphate layers will be less affected than the interlayer spacing. (The original *b*-axis was indeed still predominant although symmetry lowering is obvious and no indication was found for a doubling of the *a*-axis.) The *c*-axis was chosen so as to reproduce the d_{001} spacing observed in the XRD patterns (Fig. 1c) (*i.e.* $c \sin \beta$).

It is remarkable that the widening of the diffraction spots is anisotropic: only the *b*-axis is affected. The structural changes due to K^+-exchange ($ZrHK(PO_4)_2$[16]) are indeed restricted to a shift of the layers along the *b*-axis (apart of course from a swelling due to the intercalation of the cations).

From the available information on systematic extinctions, the probable spacegroup is $P2_1/c$, such as was found also for all other structures investigated: [$ZrKH(PO_4)_2$[16] and $Zr(O_3PONH_4)_2$[17]].

The resulting unit cell volume, *V*, of $Zr(O_3PONa)_2 \cdot$

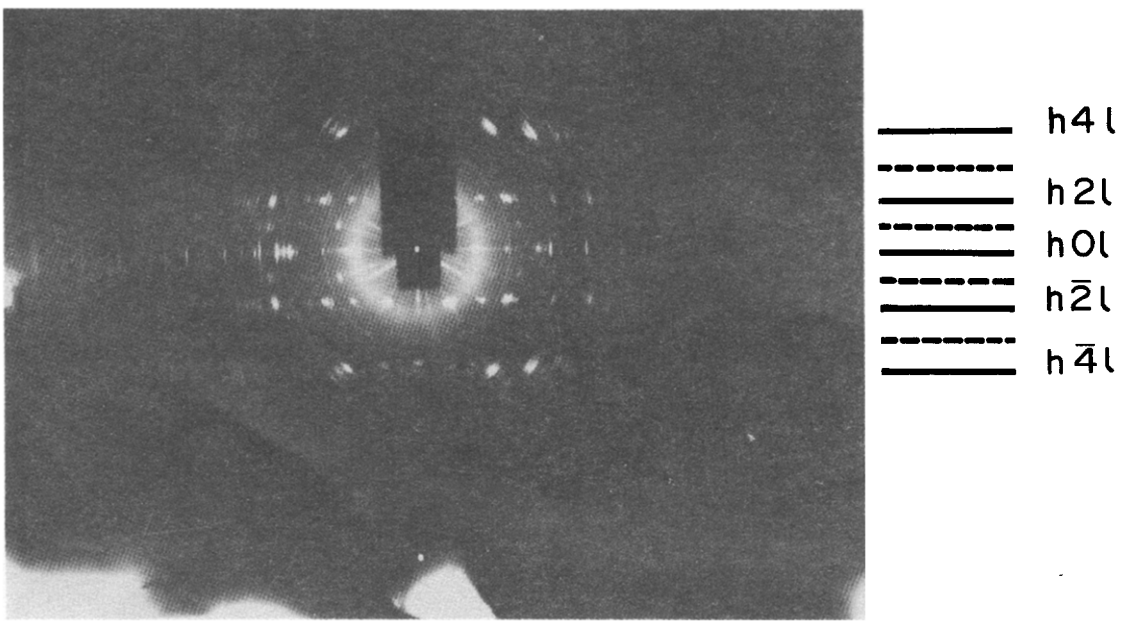

Fig. 2. Oscillation photograph of a single crystal of $Zr(O_3PONa)_2 \cdot 3H_2O$.

Table 2. Unit cell dimensions of zirconium phosphates

	$Zr(O_3PONa)_2 \cdot 3H_2O$	α-HZrP[8]
a, nm	0.900	0.9060
b, nm	1.059	0.5297
c, nm	2.210	1.5414
β, deg	117.12	101.71
V, nm^3	1.875	0.7243

$3H_2O$ is more than doubled with respect to the unit cell volume of α-HZrP (Table 2). The unit cell possesses eight formula units $Zr(O_3PONa)_2 \cdot 3H_2O$ or $Z = 8$ and, to be compatible with the symmetry, four non-equivalent phosphate groups must be present in the asymmetric unit.

UNEXPECTED REACTION OF SULFUR DICHLORIDE WITH [Cr(CO)$_5$THF]: A Cr(III) PRODUCT WITHOUT CARBON MONOXIDE AS LIGAND

CARLOS DÍAZ

Universidad de Chile, Facultad de Ciencias, Casilla 653, Santiago, Chile

(*Received* 20 *August* 1985; *accepted after revision* 8 *May* 1986)

Abstract—The reaction of SCl_2 with the complex Cr(CO)$_5$THF produces a solid which does not contain carbonyl groups. Elemental analysis, IR and diffuse reflectance spectra as well as magnetic and chemical properties and deuterium substitution experiment suggest the formula [Cr(H_2O)(THF)(SCl_2)Cl_3]·2THF.

It is well-known that the reaction of the complex [Cr(CO)$_5$THF], photochemically generated, with neutral ligands L gives rise to the formation of monosubstituted complex [Cr(CO)$_5$L].[1–3] This method has been especially useful in the synthesis of the [M(CO)$_5$L] complexes with L = sulfur(II) ligand.[4] The reaction of [Cr(CO)$_5$THF] with sulfur dichloride yielded a product which contained no carbon monoxide ligand, and the details of this reaction are reported here.

RESULTS AND DISCUSSION

Although all results are consequent with the formulation [Cr(H_2O)(THF)(SCl_2)Cl_3]·2THF for the product of the reaction of SCl_2 with [Cr(CO)$_5$THF] a definitive determination of the structure of complex by a crystal X-ray analysis was not possible because the insolubility or decomposition of the compound in organic solvent precluded the growing of a suitable single crystal.

The addition of sulfur dichloride to a tetrahydrofuran solution of [Cr(CO)$_5$THF] gave a pink–violet solid whose IR spectra showed no carbonyl bands but surprisingly did show the characteristic bands of coordinated water.

In Table 1 are shown the frequencies observed for this compound. In addition to the three fundamental modes of the water molecule in the spectra are observed the typical—and expected—rocking and wagging modes of coordinated H_2O.[5,6] The Cr—OH_2 stretching frequency is assigned at 490 cm^{-1}, according with the frequencies observed in other chromium–water compounds.[5]

The presence of the coordinated water is confirmed by the use of heavy water in the THF at the

[b] Tetrahydrofuran uncoordinated.

start. In this case the bands at 3290 (νOH) and 1610 (δOH) shifted to 2410, 2340 and 1110 cm^{-1} respectively on deuteration (see Table 1). The ratios of the frequencies are very close to the expected value of $(\nu_H/\nu_D)^{1/2} = 1.41$.

Also in the spectra are observed the bands of tetrahydrofuran coordinated. The frequencies corresponding to ν(C—O—C)$_{as}$ and ν(C—O—C)$_s$ in free tetrahydrofuran are lowered 61 and 56 cm^{-1} respectively by coordination, behavior characteristic of this ligand linked to $CrCl_3$.[7,8]

A thermogravimetric analysis of the complex agree with the formulation suggested, containing THF solvation molecules. The weight-loss curve reveals that the tetrahydrofuran began to escape at 60°C, behavior typical of organic solvate molecules.*

Because THF and water do not absorb in the 650–200 range, the broad band at 510–490 cm^{-1} may be assigned to SCl_2 modes; e.g. $[PdCl_2(SCl_2)_2]$ 510–530 cm^{-1},[9] $[N(SCl)_2][Re_2Cl_9]$ 512, 494 cm^{-1},[10] $[TaCl_5 \cdot NSCl]$ 493 cm^{-1},[11] $[N(SCl)_2][NbCl_6]$ 514, 492,[11] $[SCl_3][AlCl_4]$ 516, 530 cm^{-1}.[12] The band at 330 cm^{-1} with shoulders at 310 and 290 cm^{-1} can be attributed to Cr—Cl stretching vibrations and Cr—S stretching vibration, by comparison with the assignment for the following complexes: $CrCl_3$, 315 cm^{-1}; $CrCl_3(THF)_3$ 369, 340, 311 cm^{-1} and $CrCl_3 \cdot (Py)_3$ 364, 341, 307 cm^{-1}.[13] The Cr—S stretching vibration occurs at 310–360 cm^{-1}.[14]

The magnetic moment of the complex is 3.87 B.M. which is close to the spin-only value for three unpaired electrons, and typical of Cr(III) complexes.

The electronic spectra of the complex, obtained by diffuse reflectance (Fig. 1), show three ligand-field bands (one with splitting). The energies and relative intensity of these bands is similar to that found in Cr(III) complexes with a nearly regular octahedral stereochemistry, but belonging strictly to lower symmetry.[15]

Although the complex has four different types of ligand and hence should have a symmetry lower than D_{4h} or C_{4v}, it can be treated as approximately belonging to D_{4h} (with two chlorides in *trans* position) if each different ligand, SCl_2, H_2O, THF and Cl can be averaged in considering the ligand fields.[15] Following this analysis the bands have been assigned in terms of D_{4h} nomenclature (see Fig. 1).

Further the similar spectral and magnetic data of the complex with those for $CrCl_3$[16] and other

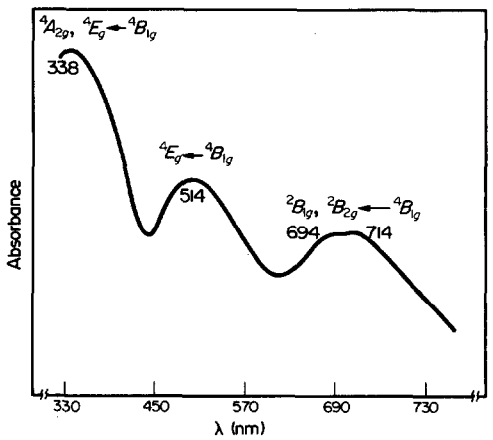

Fig. 1. Reflectance diffuse absorption spectra of $[Cr(H_2O)(THF)(SCl_2)Cl_3] \cdot 2THF$.

$[CrCl_3L_2]_2$ complexes[13] support the presence of three chloride coordinated to chromium(III). In spite of the nucleophilic characteristic expected from the lone pair on sulfur and chlorine atoms of SCl_2 only a reduced number of unstable adducts $AlCl_3 \cdot SCl_2$, $FeCl_3 \cdot SCl_2$ and $SbCl_5 \cdot SCl_2$ are known.[18] Recently iridium, platinum, palladium and osmium complexes with SCl_2 as ligand have been reported.[9]

The formulation of a Cr(III) complex from the hexacarbonylchromium(0) can be understood if we consider a possible oxidation of Cr(0) with the chlorine, presumably formed in the disproportionation of SCl_2.[19] Moreover this could explain the coordination of chloride toward chromium.

EXPERIMENTAL

$Cr(CO)_6$ (Aldrich) was used without prior purification. Sulfur dichloride (Fluka) was distilled with a few drops of PCl_3 prior to use, and the fraction boiling at 58–60°C collected. Tetrahydrofuran was dried with sodium. IR and diffuse reflectance spectra were obtained by using the Perkin–Elmer 621 and Pye–Unicam SP 1800 spectrophotometers respectively. Magnetic moment was measured in a Cahn Ventron model RTS apparatus by the Faraday method. Correction for the diamagnetism of the ligand was made by using Pascal's constants. Reactions were done in a N_2 atmosphere.

Reaction of $[Cr(CO)_5THF]$ with SCl_2. A solution of 1 g of $Cr(CO)_6$ in ca. 60 cm^3 THF was irradiated (UV lamp, Hanau, medium pressure, 150 W) for 100 min at room temperature.[4] Then, a solution of 3.2 g of SCl_2 was added dropwise and the mixture stirred for 30 min. Immediately carbon monoxide was evolved. Solvent was then evaporated under reduced pressure leaving behind a pink–violet solid. This was dried *in vacuo* for 3 h and stored in a

* Unfortunately no other information was obtained from the thermal decomposition weight-loss curve because a horizontal weight level was not observed.

Schlenk apparatus under argon. The compound is hygroscopic and has a pungent odor. In organic solvents it is insoluble or decomposes. m.p. 124–125°C. Found: C, 29.5; H, 5.2; S, 5.6; Cr, 10.8. Calc. for $C_{12}H_{26}O_4Cl_5SCr$; C, 30.2; H, 5.4; S, 6.7; Cr, 10.9%. Chromium analyses were done by oxidation of sample with HNO_3 followed by oxidation of the solution to $Cr_2O_7^{2-}$ with $NaBiO_3$ and titration with Fe^{2+}.

The presence of sulfur dichloride in the complex is confirmed by the reaction of the Cr(III)—SCl_2 compound with copper perchlorate hexahydrate in acetonitrile to give the $[Cu(CH_3CN)_2]ClO_4$. This redox reaction is characteristic for SCl_2 and other sulfur(II) compounds.[17]

Reaction of $[Cr(H_2O)(THF)(SCl_2)Cl_3]\cdot 2THF$ with $Cu(ClO_4)_2\cdot 6H_2O$. 0.14 g of the Cr(III) complex in CH_3CN, was added dropwise over 0.42 g of the copper salt in the same solvent, with stirring and ambient temperature. A small amount of green solid formed, was filtered and by evaporation of the solvent the white crystalline complex $[Cu(CH_3CN)_4]ClO_4$ was obtained, and identified by IR.[17]

(*Received* 9 *December* 1985; *accepted* 8 *May* 1986)

Abstract—The structure of the complex $Co(NIPA)_3(ClO_4)_2$ has been determined by X-ray diffraction analysis and found to be very close to that of the corresponding OMPA complex. The magnetic susceptibilities of the OMPA and NIPA complexes have been measured by a thermomagnetic method and have allowed the calculation of $\chi_\parallel$ and $\chi_\perp$, the susceptibilities along the principal axes of the complexes. The magnetic properties of the isomorphous nickel compounds have been studied for comparison. Results give evidence for the greater magnetic anisotropy of the NIPA complexes.

In an earlier publication[1] we reported the results of a NMR study on stereochemically non-rigid paramagnetic tris-chelate complexes of cobalt(II) with the two ligands: octamethylpyrophosphoramide [OMPA: $(NMe_2)_2P(O)OP(O)(NMe_2)_2$] and nonamethylimidodiphosphoramide [NIPA: $(NMe_2)_2P(O)NMeP(O)(NMe_2)_2$]. These complexes, studied as perchlorate salts dissolved in a solvent mixture of deuterated nitromethane and dichloromethane, exhibit two signals corresponding to the terminal *N*-methyl groups. This inequivalence is due to the D_3 symmetry of the complexes in which these two substituents occupy diastereotopic positions. In spite of a very similar structure of the ligands which differ only by the bridging group between the phosphorus atoms, the chemical shifts of the proton NMR spectra were found quite different. For example, at −36°C, the values are 12.69 and −8.87 ppm for $Co(OMPA)_3^{2+}$ against 18.65 and −19.47 ppm for $Co(NIPA)_3^{2+}$.

As the chemical shifts depend essentially on dipolar interactions between the electron spin of the metal ion and the nuclear spin of the observed nuclei, they are governed by two factors, a geometrical one and a magnetic one. The former term is related to the positions of the hydrogen atoms in the complex and the latter to the difference of magnetic susceptibilities $\chi_\parallel$ and $\chi_\perp$ along the principal axes of the complex (C_3 and C_2 respectively). In our previous study, we assumed that the structures of the two complexes were strictly identical on the basis of powder diagram studies[2,3] which indicated isomorphous compounds. We therefore concluded that the observed differences between the chemical shifts were due to a variation of the magnetic anisotropies on going from one complex to another. Considering the similar structure of the ligands, these results seemed rather surprising. We therefore decided to reexamine the complete geometry of $Co(NIPA)_3(ClO_4)_2$ by X-ray diffraction on a single crystal to verify if minor variations in the structure could account for the observed phenomena. In addition magnetic measurements were performed on these and the corresponding nickel(II) compounds to complete the study.

EXPERIMENTAL

Materials

The complexes $Co(NIPA)_3(ClO_4)_2$, $Co(OMPA)_3(ClO_4)_2$, $Ni(NIPA)_3(ClO_4)_2$ and $Ni(OMPA)_3(ClO_4)_2$

‡ Author to whom correspondence should be addressed.

were prepared as described before.[1,2,4] Crystals of the NIPA complex were obtained by recrystallization from an anhydrous acetone solution.

All manipulations were carried out under purified argon in a glove box because of the hygroscopic character of the compounds. The crystal of $Co(NIPA)_3(ClO_4)_2$ was sealed in a Lindeman glass capillary for the crystallographic study. $Ni(NIPA)_3(ClO_4)_2$ powder was put in a tight box between two beryllium windows for the crystallographic data collection.

Magnetic measurements

Thermomagnetic measurements for the complexes $Co(NIPA)_3(ClO_4)_2$, $Co(OMPA)_3(ClO_4)_2$, $Ni(NIPA)_3(ClO_4)_2$ and $Ni(OMPA)_3(ClO_4)_2$ were performed between 4.2 and 300 K in a S.Q.U.I.D. magnetometer (SHE, minimum detectable magnetization: 2×10^{-8} emu) and in a vibrating sample magnetometer (PAR, minimum detectable magnetization: 5×10^{-5} emu). The sample was warmed up in an applied field of 10 kOe and the susceptibility was recorded as a function of temperature.

Susceptibility data are reported on a molar basis in c.g.s. units. Effective moments as well as the molar magnetizations are given in Bohr magnetons:

$$M = \chi_m H/N\beta$$

where N is Avogadro's number, χ_m the molar susceptibility, H the applied field and β is the Bohr magneton. The data are corrected for the diamagnetism of the sample holder and that of the ligand.

Crystallographic measurements

The data for the compounds as well as the experimental and refinement parameters are given in Table 1.

$Co(NIPA)_3(ClO_4)_2$. The crystal of $Co(NIPA)_3(ClO_4)_2$ was a hexagonal prism elongated along the [001] crystallographic axis. Cell dimensions were adjusted by a least-squares procedure applied to the setting angles of 25 reflections measured with the indicated diffractometer with graphite-monochromated CuK_α radiation at room temperature. A correction was applied to the data according to the linear decrease of the three standards. Empirical absorption corrections were calculated by using the program DIFABS.[5]

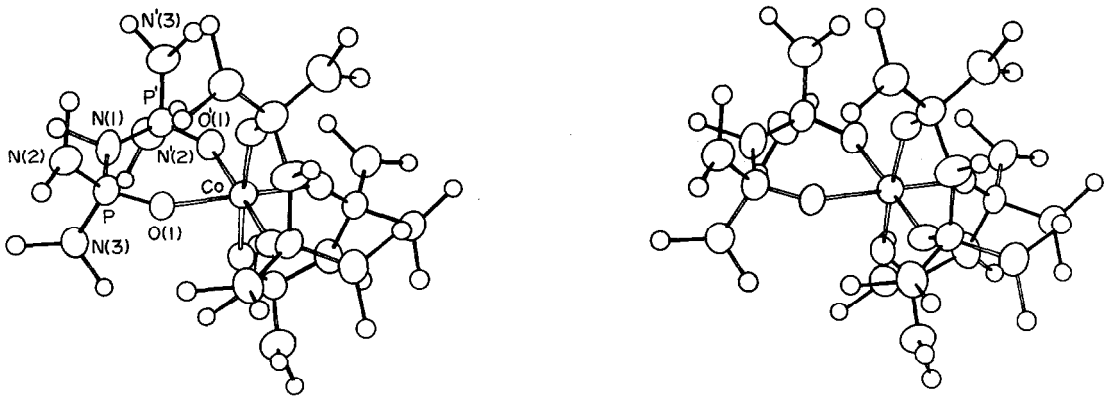

Fig. 1. Stereoscopic ORTEP[12] view of the complex $Co(NIPA)_3(ClO_4)_2$.

$Ni(NIPA)_3(ClO_4)_2$. The box containing the powder was rotated to minimize the effects of possible preferred orientation. Diffraction data were collected on the diffractometer with quartz-monochromated CuK_α radiation at room temperature. The observed reflections may be indexed with a trigonal cell similar to that of $Co(NIPA)_3(ClO_4)_2$. Cell dimensions were adjusted by a least-squares procedure[6] applied to all the measured reflections. Intensities were recorded on paper and measured by planimetry. The 19 observed peaks are stemming from 47 non zero reflections measured until $2\theta = 41°$.

Solution and refinement of structures

$Co(NIPA)_3(ClO_4)_2$. The cobalt and phosphorus atoms were located from Patterson maps. These atoms are found on the same sites as those in the Co—OMPA complex structure.[7] Therefore we placed the other atoms in the cell correspondingly. The carbon bound to the central nitrogen was located by difference Fourier synthesis. The positions of hydrogens were calculated after checking on difference Fourier maps.

N(1) and C(1) are located on a C_2 axis, an incompatible symmetry for a methyl group. Therefore we must attribute a half multiplicity to the three hydrogens H(Cl). The fit is good ($R < 5\%$) for the centrosymmetric hypothesis $P\bar{3}c1$. Taking into account that the absorption corrections are not perfect, we think it is not reasonable to choose the $P\bar{3}c1$ group without the C_2 axis leading to a non-statistic interpretation. Moreover, the zero-moment test of Howells *et al.*[8] shows a typical centric distribution.

Difference maps obtained with all atoms except the perchlorate oxygens had areas of residual electron density corresponding to more than one ClO_4 tetrahedron. However it was impossible to refine some of these positions without observing an unacceptable increase of their thermal parameters. Therefore we decided to place only the O(2)–O(3) tetrahedron for which the disorder is expressed by somewhat anisotropic thermal parameters.

A full-matrix least-squares refinement[9] [on $\Sigma w(\Delta F)^2$] including a weighting scheme, $w = 1/(\sigma^2(F_0) + 0.0016F^2)$, converged to $R = 0.048$ and $R_w = 0.052$ with anisotropic thermal parameters for non-H atoms and isotropic temperature factors (equivalent to those of bonded atoms) for hydrogens. Atomic scattering factors were taken from the *International Tables for X-ray Crystallography*.[10]

Final positional and thermal parameters and a list of calculated and observed factors have been deposited as supplementary data with the Editor, from whom copies are available on request.*

$Ni(NIPA)_3(ClO_4)_2$. At first, all the atoms were located in the corresponding sites of the Co—NIPA structure with isotropic thermal parameters equal to those of the latter. Taking into account the restricted number of independent data, we only refined the positions of atoms of the chelate ring by a least-squares procedure[11] which minimizes the quantity $U = \Sigma(I_0 - I_c)^2$. When several reflections overlapped, the sum of their intensities was taken as a unique value. The refinement is checked by the decrease of U and yielded $R = \Sigma(I_0 - I_c)/\Sigma I_0 = 7\%$. The positions of refined atoms and a list of calculated and observed intensities are available as supplementary data.

RESULTS AND DISCUSSION

Structures

The geometry of $Co(NIPA)_3(ClO_4)_2$ including the atomic numbering scheme of one ligand is illustrated by the stereoscopic ORTEP view[12] of Fig. 1.

* Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

[a] Ref. 7.

For greater clarity, the methyl groups are plotted as small spheres. Table 2 summarizes bond lengths and angles. The cobalt ion is octahedrally surrounded by six oxygen atoms stemming from three ligands related by a C_3 axis. The O—Co—O angles in Table 3 indicate small deviations from octahedral geometry. Each ligand presents a *cis* conformation [dihedral angle O(1)—P—P′/P—P′—O′(1) = 3.1°] contrary to the free ligand NIPA in the solid state.[13] The O, P and N atoms of each chelate ring are almost coplanar, the Co^{2+} ion being situated in the plane (Table 4) corroborating infrared and Raman measurements.[2] Least-squares planes calculations show that all nitrogen atoms have a trigonal planar hybridization.

The results of the crystallographic study about $Ni(NIPA)_3(ClO_4)_2$ are not significantly different from those of $Co(NIPA)_3(ClO_4)_2$ (see comparison of distances in Table 3 taking into account the standard deviations). Therefore we can consider that the two structures are isomorphous.

Table 3 also compares distances and angles in the complexes $Co(NIPA)_3(ClO_4)_2$ and $Co(OMPA)_3(ClO_4)_2$. Co—O,P—O lengths and O—Co—O angles are very similar. Obviously distances and angles concerning the central atoms of the chelate ring [N(1) for NIPA and O(2) for OMPA] are clearly different.

Table 4. Deviations of the different atoms of the chelate ring from the least-squares plane in the complex $Co(NIPA)_3(ClO_4)_2$

Atom	d (Å)
O(1)	−0.022(3)
P	0.021(1)
N(1)	0.0
P′	−0.021(1)
O′(1)	0.022(3)
Co	0.0

Therefore we conclude that the environment of the metal ion (Co or Ni) is very similar in the two considered complexes.

Magnetic measurements

Once the exact structure of the NIPA complex had been established we could recalculate the geometrical term $\langle(3\cos^2\theta-1)/r^3\rangle$ for the hydrogen atoms of the N-methyl groups, in the same way as for the OMPA complex, θ representing the angle between the C_3 axis and the vector connecting the cation to the observed atom and r being the distance between them. Following the method described in Ref. 1, we could subsequently determine the contribution of the pseudo-contact shifts δ_{pc} to the total chemical shift δ_p. From the knowledge of δ_{pc}, we could compute $\Delta\chi$, the difference between the magnetic susceptibilities along the $C_2(\chi_\perp)$ and $C_3(\chi_\parallel)$ axes respectively, according to the relation:

$$\delta_{pc} = (\chi_\parallel - \chi_\perp)\left\langle \frac{3\cos^2\theta-1}{r^3} \right\rangle.$$

The results are summarized in Table 5 and show a good agreement with those obtained previously. This study confirms our earlier conclusion that the OMPA complex is magnetically by far less anisotropic than the NIPA complex. (For example, at −36°C, $\Delta\chi = 5.31\times10^{-3}$ and 10.80×10^{-3} Å^3 for the complexes of OMPA and NIPA respectively.)

Table 5. Mean magnetic susceptibilities $\langle\chi\rangle$ and differences $\Delta\chi$ between transverse ($\chi_\perp$) and longitudinal ($\chi_\parallel$) magnetic susceptibilities (in 10^{-3} Å^3) for the complex $Co(NIPA)_3(ClO_4)_2$ as well as $\chi_\parallel$ and $\chi_\perp$, at different temperatures, calculated from the NMR results of Ref. 1 and the crystallographic data and magnetic measurements of this work

T (K)	$\langle\chi\rangle$	$\Delta\chi$	$\chi_\parallel$	$\chi_\perp$
194.5	18.93	14.95	8.96	23.91
222	16.28	12.37	8.04	20.41
230	15.63	11.46	7.99	19.45
237	15.10	10.80	7.90	18.70
247	14.39	10.12	7.64	17.76

This trend is not actually reflected by the values of magnetic moments measured by Joesten *et al.*[14] for the OMPA complex (5.24 B.M.) and by the authors for Co—NIPA (5.08 B.M.). Since these measurements had been made at room temperature only, we decided to determine them more accurately by thermomagnetic analysis. Plots of the reciprocal molar susceptibility, χ_m^{-1}, and effective magnetic moments, μ_{eff}, vs temperature are shown in Fig. 2(a) and (b), the arrows indicating the corresponding

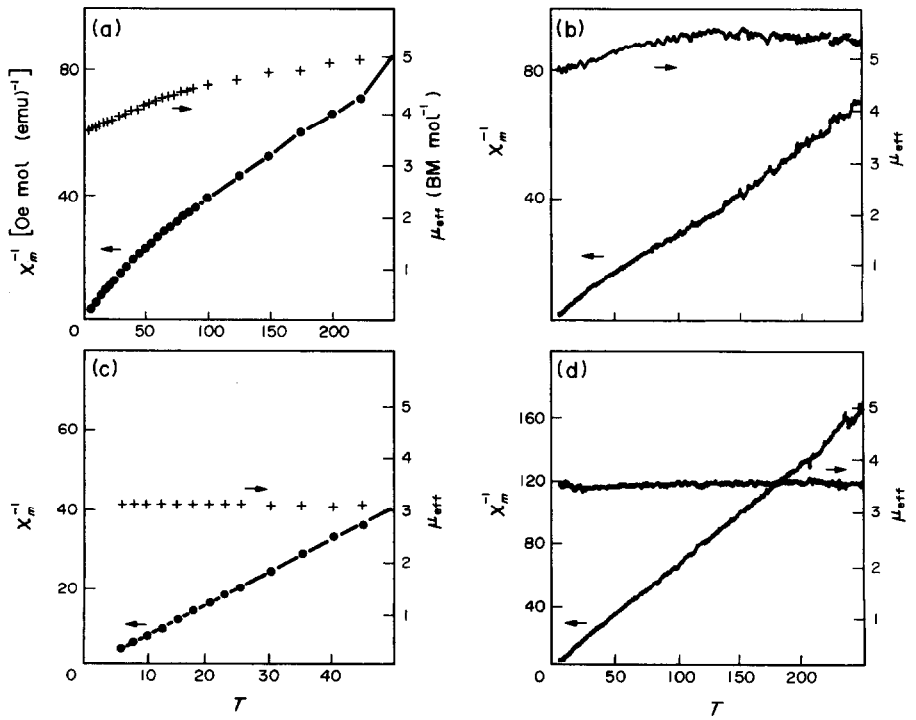

Fig. 2. Plots of χ_m^{-1} and μ_{eff} vs temperature (T) for $Co(OMPA)_3(ClO_4)_2$ (a), $Co(NIPA)_3(ClO_4)_2$ (b), $Ni(OMPA)_3(ClO_4)_2$ (c), and $Ni(NIPA)_3(ClO_4)_2$ (d). The arrows designate the corresponding axes. (Values corrected for T.I.P. terms.)

axes. μ_{eff} was calculated from the relation:

$$\mu_{eff}^2 = \frac{3k}{N\beta^2}\chi_m T = 8\chi_m T$$

where k is the Boltzmann constant.

For these complexes, the inverse magnetic susceptibility vs temperature curve presents a curvature towards the T axis and does not follow a Curie law. The effective magnetic moment calculated for the Co—NIPA complex, is at any temperature greater than that of the OMPA compound. It tends towards a maximum of 5.5 B.M. above 125 K and is nearly constant at higher temperatures. For the Co—OMPA complex, the effective magnetic moment reaches a maximum of 5.1 B.M. at about 240 K.

In our previous publication[1] we had used a single value of $\langle\chi\rangle$ determined at 300 K, and assumed that the product $\langle\chi\rangle \cdot T$ was constant at different temperatures. On the base of the results mentioned above, we decided to recalculate $\chi_\perp$ and $\chi_\parallel$ from the relations $\Delta\chi = \chi_\perp - \chi_\parallel$ and $\langle\chi\rangle = (\chi_\parallel + 2\chi_\perp)/3$ for each temperature of the NMR experiments of Ref. 1. The results are shown in Tables 5 and 6. The magnetic susceptibilities along the C_3 axis are found very similar whereas those perpendicular to it differ significantly.

The magnetic behaviour found for these Co complexes is characteristic for the $^4T_{1g}$ ground term and that for the complexes of OMPA and NIPA with the Ni^{2+} ion is characteristic for the $^3A_{2g}$ ground term, as shown in Fig. 2(c) and (d).

In the case of these nickel chelates, the variation of the magnetic susceptibility with temperature follows practically a Curie law. An additional small constant T.I.P. (Temperature Independent Paramagnetism) is due to a contribution from the A_{2g} term and related to the energy separation $10D_q$ between the $^3A_{2g}$ and $^3T_{1g}$ levels by the equation[15]

$$\chi_{T.I.P.} = 8N\beta^2/|10D_q|.$$

Table 6. Mean magnetic susceptibilities $\langle\chi\rangle$ and differences $\Delta\chi$ between transverse ($\chi_\perp$) and longitudinal ($\chi_\parallel$) magnetic susceptibilities, as well as $\chi_\parallel$ and $\chi_\perp$ (in 10^{-3} Å^3) for the complex $Co(OMPA)_3(ClO_4)_2$ at different temperatures, calculated from the NMR results of Ref. 1 and the magnetic measurements of this work

T (K)	$\langle\chi\rangle$	$\Delta\chi$	$\chi_\parallel$	$\chi_\perp$
190.5	14.31	5.39	10.72	16.11
208	13.36	5.46	9.72	15.18
221	12.76	5.46	9.12	14.58
237	12.10	5.31	8.56	13.87
252	11.56	5.07	8.18	13.25

To estimate this contribution, we measured the diamagnetism of NIPA alone and that of the sample holder. The data were corrected for these diamagnetic contributions.

The experimental susceptibilities were fitted according to:

$$\chi = \frac{C}{T} + \chi_{T.I.P.}$$

The values for $\chi_{T.I.P.}$ calculated in this way are 280×10^{-6} e.m.u. mol^{-1} for $Ni(OMPA)_3(ClO_4)_2$ and 288×10^{-6} e.m.u. mol^{-1} for $Ni(NIPA)_3(ClO_4)_2$. The corresponding results for D_q are approximately 746 cm^{-1} and 724 cm$^{-1} \pm 40$ cm^{-1}, respectively. They agree with the values determined spectrophotometrically by Joesten *et al.*[4,14], e.g. 726 (or 731, Ref. 16) and 727 cm^{-1}.

A difference in the magnetic behaviour of the NIPA complex compared to the corresponding OMPA compound however, is also verified in this case of magnetically "normal" complexes. Temperature independent values of μ_{eff} can be obtained for the nickel compounds: 3.14 B.M. for $Ni(OMPA)_3(ClO_4)_2$ and 3.45 B.M. for $Ni(NIPA)_3(ClO_4)_2$ (compared to 3.26 B.M. determined by Joesten *et al.*[14]). The corresponding g values are 2.22 and 2.44. On the base of powder diffraction data,[2,16] it can be ascertained that the two nickel compounds are of nearly identical structure and that they are both in turn very close to the corresponding cobalt complexes (cf. Table 3).

CONCLUSION

The results of these studies confirm our previous hypothesis concerning the different magnetic properties of OMPA complexes compared to NIPA compounds although their structures are very similar as verified by X-ray diffraction analysis. We had noticed also that the complexes of the two ligands did not show the same behaviour as far as the intra and intermolecular exchange reactions are concerned, the OMPA being much more labile than NIPA. Thermodynamic stabilities, too, differ significantly between complexes of a given ion with the two ligands.[17] These facts could be explained either by a difference in the nature of the metal–ligand bonds (i.e. a more important electron delocalization in the case of OMPA)—although contradictory to the observation of rigorously the same metal–oxygen distances in the two cobalt complexes—or, the distance of closest approach being limited by the crowding of ligands around the ion, by a different charge-distribution in the ligands, leading to a stronger interaction with the cation in the case of NIPA.

BIS[BIS{(DIPHENYLPHOSPHINYL)METHYL}ETHYL PHOSPHINATE]BIS(ETHANOL) COPPER(II) PERCHLORATE: SYNTHESIS, CRYSTAL AND MOLECULAR STRUCTURE

MARIJA HERCEG,* PAVICA BRONZAN-PLANINIĆ, HENRIKA MEIDER and BORIS MATKOVIĆ

"Rudjer Bošković" Institute, 41001 Zagreb, Croatia, Yugoslavia

(*Received* 6 *January* 1986; *accepted* 8 *May* 1986)

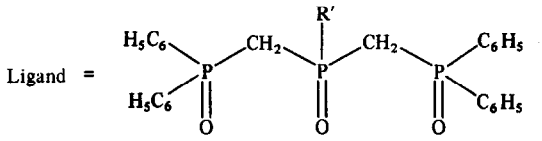
Abstract—Bis[bis{(diphenylphosphinyl)methyl}ethyl phosphinate]bis(ethanol) metal(II) perchlorate complexes, where metal = Co, Ni or Cu, have been prepared by the reaction of metal perchlorates and bis[(diphenylphosphinyl)methyl]ethyl phosphinate, (RPOEt), in absolute ethanol. The crystal structure of the copper complex is triclinic, space group $P\bar{1}$, $a = 13.688(7)$ Å, $b = 14.424(10)$ Å, $c = 9.865(2)$ Å, $\alpha = 110.43(4)°$, $\beta = 90.13(2)°$, $\gamma = 115.54(4)°$, $V = 1619.8$ Å^3, $Z = 1$ and refined to $R = 0.048$ ($R_w = 0.057$). The structure consists of complex cations surrounded by perchlorate anions. Two RPOEt ligands and two ethanols are coordinated to the copper atom situated at the centre of symmetry 0, 0, 0. The RPOEt ligand is bidentate [Cu—O distances 1.969(4) Å, 2.312(4) Å], but the third oxygen atom from phosphoryl bonds is hydrogen bonded [2.669(6) Å], to the oxygen atom of ethanol molecule coordinated to the copper at 1.988(4) Å. The conformations of the ligand and chelate rings, magnetic data, molar conductance values, infrared and electronic spectra are given.

The synthesis of some cobalt(II), nickel(II) and copper(II) perchlorate[1] and chloride [2,3] complexes with tripod organophosphorus compounds, was reported previously. The types of ligands, together with their abbreviations, are portrayed in Scheme 1.

The preparation of ligands RPOEt, RPPh and RPOH was reported before.[4,5] Bis[(diphenylphosphinyl)methyl]ethyl phosphinate (RPOEt) is the ligand studied in the present work. It has three phosphoryl groups bridged by methylene groups. Another ligand consisting of three phosphoryl groups bridged by methylimido groups is dodecamethyl diimidotriphosphoramide, named TRIPA, $[(CH_3)_2N]_2P(O) \cdot NCH_3 \cdot [(CH_3)_2N]P(O) \cdot NCH_3 \cdot P(O)[(CH_3)_2N]_2$.[6–8] In the complexes: $[Er(TRIPA)_2(NO_3)](NO_3)_2$ and $[Ca(TRIPA)(NO_3)_2(H_2O)]$ TRIPA acts as tridentate ligand.[8]

The ligands RPOEt, RPPh and RPOH are potentially tridentate too. Conformation analyses revealed that RPPh acts preferentially as a bidentate ligand, but the possibility that this ligand is a tridentate complexing agent was not excluded.[9] No structure of any complex with RPOEt, RPPh and RPOH has been reported yet.

Formulae of investigated complexes are: $[Co(RPOEt)_2(C_2H_5OH)_2](ClO_4)_2$, $[Ni(RPOEt)_2(C_2H_5OH)_2](ClO_4)_2$ and $[Cu(RPOEt)_2(C_2H_5OH)_2](ClO_4)_2$. These compounds were characterized by chemical analysis, infrared and electronic spectra, magnetic and conductivity measurements. X-ray structure determination has been carried out on $[Cu(RPOEt)_2(C_2H_5OH)_2](ClO_4)_2$.



EXPERIMENTAL

The ligand, bis[(diphenylphosphinyl)methyl] ethyl phosphinate (RPOEt) was prepared according to the literature data.[5]

For conductivity measurements nitrobenzene was purified by the method of Taylor and Kraus.[10] All other solvents were analytical grade reagents dried over molecular sieves without further purification.

Physical measurements and the instrumentation employed have been already described.[1] The correction for the diamagnetism of the ligand was made with the use of Pascal's constants.[11] All physical

$(C_{26}P_3O_3H_{24}R')$

If R′ is OC_2H_5, the ligand is bis[(diphenylphosphinyl)methyl]ethyl phosphinate (RPOEt)

If R′ is C_6H_5, the ligand is bis[(diphenylphosphinyl)methyl]phenylphosphine oxide (RPPh)

If R′ is OH, the ligand is bis[(diphenylphosphinyl)methyl]phosphinic acid (RPOH)

Scheme 1.

measurements were carried out immediately after recrystallization.

Preparation of complexes

The complexes $[M(RPOEt)_2(C_2H_5OH)_2](ClO_4)_2$ (M = Co, Ni, Cu) were obtained by the reaction of metal(II) perchlorate and ligand, both dissolved in absolute ethanol and mixed together in a molar ratio of 1:2. As all three complexes were obtained exactly in the same manner, only detailed preparation of $[Cu(RPOEt)_2(C_2H_5OH)_2](ClO_4)_2$ is given: 0.371 g $Cu(ClO_4)_2 \cdot 6H_2O$ (1 mmol) was dissolved in 4 cm^3 of hot absolute ethanol, filtered and added slowly into a hot, filtered solution of 1.054 g RPOEt (2 mmol) in 10 cm^3 abs. ethanol. After one day the product was filtered and washed with absolute ethanol and diethylether. The complexes were recrystallized by dissolving in hot 96% ethanol. The solution was refluxed for an hour, filtered and allowed to stand in a covered beaker for 2 days. The crystals were then collected by filtration and washed with small portions of abs. ethanol. The yield was about 80%. Found: Cu, 4.4; P, 13.4; Cl, 5.2. Calc. for $[Cu(RPOEt)_2(C_2H_5OH)_2](ClO_4)_2$: Cu, 4.5; P, 13.3; Cl, 5.1%. Found: Co, 4.2; P, 13.3; Cl, 5.1. Calc. for $[Co(RPOEt)_2(C_2H_5OH)_2](ClO_4)_2$: Co, 4.0; P, 13.3; Cl, 5.1%. Found: Ni, 4.1; P, 13.5; Cl, 5.1. Calc. for $[Ni(RPOEt)_2(C_2H_5OH)_2](ClO_4)_2$: Ni, 4.2; P, 13.3; Cl, 5.1%.

Crystallography

Pale bluish, almost colourless crystals of $[Cu(RPOEt)_2(C_2H_5OH)_2](ClO_4)_2$, suitable for crystallographic study, were obtained by slow careful cooling of a hot 96% ethanolic solution of the recrystallized complex. Pink crystals of the corresponding cobalt complex and greenish crystals of Ni complex obtained in the same way, were not large enough for crystallographic study. However, X-ray powder patterns of the three compounds are similar and indicate a close structural relationship.

The crystals are unstable and were kept in a desiccator over ethyl alcohol. Crystallographic parameters are given in Table 1. Three-dimensional intensity data were collected at room temperature with a Philips PW 1100 diffractometer. As a check on the stability of diffractometer and of the crystal three standard reflections ($00\bar{1}$; $\bar{1}11$; $\bar{2}2\bar{2}$) were monitored periodically. The intensities were corrected with ZOAK program[12] for Lorentz and polarization effects.

The structure was solved by vector and difference Fourier methods. The calculations included both f' and f'' for anomalous dispersion effects of Cu, Cl, P, O and C atoms.[13] The positions of H atoms were calculated from geometrical criteria and included in the structure factor calculations at the end of isotropic refinement. They were given the calculated isotropic temperature factors $B(H) = 1.6B(C) - 2$. Neither positional nor temperature parameters were refined for H atoms. All non-hydrogen atoms were refined anisotropically. The function minimized in least-squares refinement was $w(|F_0| - |F_c|)^2$. The weighting function applied was $w = 1/\sigma^2(F_0)$, a weighting scheme of type 9 from the XRAY system.[14] The scattering factors of Cromer and Mann[15] were used for non-H and those of Stewart *et al.*[16] for H atoms. The final residuals are $R = 0.048$, $R_w = 0.057$. The goodness of fit dropped from $S = 1.531$ to $S = 1.007$ by applying scale factor for weights, SCALWT = 0.43.[14] The largest shift/error in the final cycle is 0.48. Calculations were performed on a Univac 1100 computer at the University Computing Centre, Zagreb with XRAY 76 system.[14] Final positional and thermal parameters and structure factors have been deposited as supplementary material.

RESULTS AND DISCUSSION

and bond angles are given in Tables 2 and 3, respectively; C—C distances and C—C—C angles in peripheral phenyl rings are available as supplementary material.*

The structure consists of complex cations surrounded by perchlorate anions. Two RPOEt ligands and two ethanols are coordinated to the copper atom. The polyhedron around the copper is tetrahedrally distorted octahedron. The RPOEt ligand is bidentate, but the third phosphoryl oxygen atom is hydrogen bonded to the oxygen atom of ethanol molecule coordinated to the copper.

One terminal and the central P=O group of RPOEt ligand are coordinated to the copper at two unequal distances [1.969(4) and 2.312(4) Å] thus permitting an extended conformation of the ligand, with the torsion angle about one of the central bonds, C(91)—P(3), of 171.9(3)°, the O(1)—Cu—O(3) chelate angle of 90.0(1)° and O(1)···O(3) bite of 3.036(4) Å. The conformation about the other central bond, P(3)—C(93), is gauche, with a torsion angle −78.6(4)°, the O(3)···O(5) distance is 3.269(5) Å and the P(1)—P(3)—P(5) virtual angle is 120.14(6)°. The valence angle on the bridging carbon atom which is involved in the six-membered chelate ring, P(1)—C(91)—P(3) is larger than the corresponding angle in the non coordinated part of the ligand, P(3)—C(93)—P(5), 113.9(3),° vs 112.1(3)°. The

* Supplementary material, available from the Editor, includes: tables of atom parameters, equivalent isotropic and anisotropic temperature factors, observed and calculated structure factors, bond distances and angles within peripheral phenyl rings and those including hydrogen atoms, as well as equations of least-squares planes. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

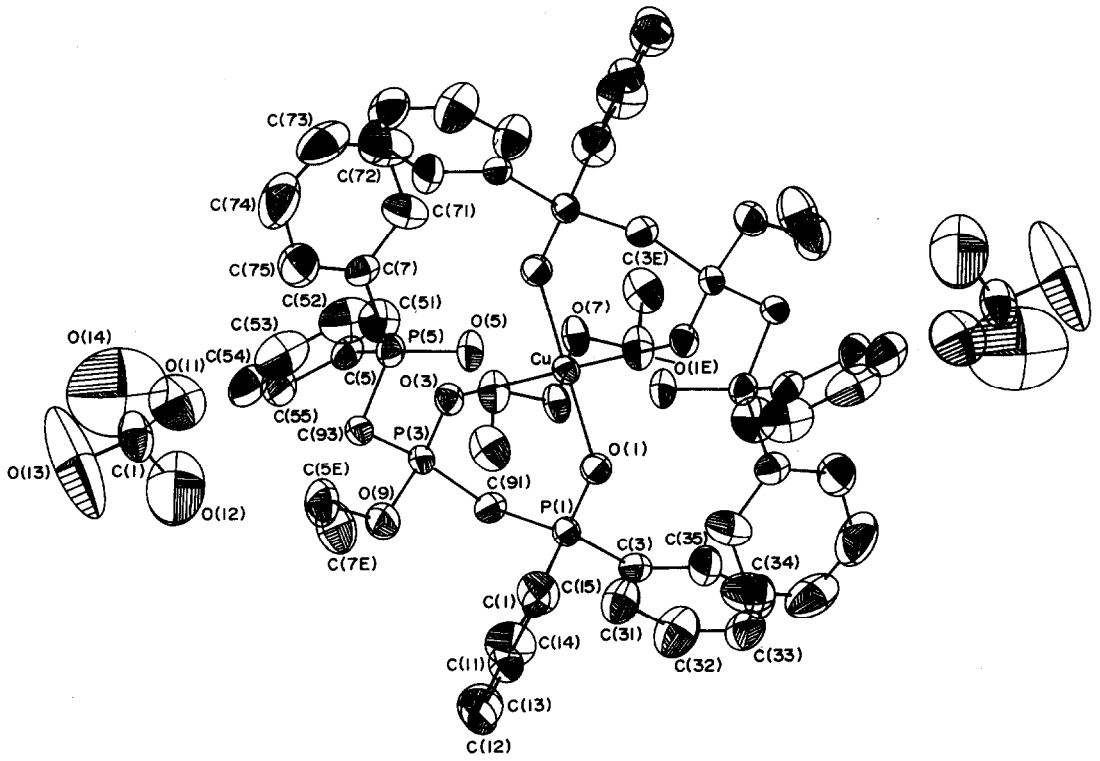

Fig. 1. Molecular geometry and atom-labelling scheme for the molecule $[Cu(RPOEt)_2(C_2H_5OH)_2](ClO_4)_2$.

intracation hydrogen bond, O(5)···H—O(7) of 2.669(6) Å with H—O(7) of 1.092(4) Å and the angle on H of 179.6(2)° may be responsible for this.

Taking into account the O(5)···H—O(7) hydrogen bond, there are two chelate rings in one asymmetric unit, around the copper atom. The conformation of the six-membered Cu—O(1)—P(1)—C(91)—P(3)—O(3) ring may be described following Cremer and Pople[17] by the amplitude of pucker $Q = 0.633(4)$ Å and pseudorotational phase angles $\varphi = 176.4(3)°$ and $\theta = 78.5(3)°$. P(1) and O(3) lie on one side and O(1) and P(3) on the other side of the least-squares plane through the P(3), O(3), O(1), P(1) atoms of the ring. The deviation of ring atoms from this plane is −0.009(2) Å for P(1); 0.009(2) Å for P(3), 0.030(4) Å for O(1) and −0.029(4) Å for O(3).[18] Cu and C(91) are well above the plane, 0.337(2) Å and 0.689(5) Å respectively. After Boeyens[19] this conformation is near boat $B_{4,1}$ ($\varphi = 180.0°$, $\theta = 90.0°$). The torsion angles are given in Table 4.

Table 2. Some important bond distances (Å)

Cu—O(1)	1.969(4)	P(1)—O(1)	1.496(5)
Cu—O(3)	2.312(4)	P(1)—C(91)	1.796(5)
Cu—O(7)	1.988(4)	P(1)—C(1)	1.782(6)
O(7)—C(1E)	1.448(5)	P(1)—C(3)	1.796(4)
O(9)—C(5E)	1.476(6)	P(3)—O(3)	1.475(5)
C(1E)—C(3E)	1.490(9)	P(3)—O(9)	1.568(4)
C(5E)—C(7E)	1.468(11)	P(3)—C(91)	1.808(4)
Cl(1)—O(11)	1.370(9)	P(3)—C(93)	1.798(6)
Cl(1)—O(12)	1.345(10)	P(5)—O(5)	1.492(3)
Cl(1)—O(13)	1.320(10)	P(5)—C(93)	1.809(6)
Cl(1)—O(14)	1.332(14)	P(5)—C(5)	1.794(7)
		P(5)—C(7)	1.791(6)

The second ring could be considered as eight membered, Cu—O(3)—P(3)—C(93)—P(5)—O(5)···H—O(7), or seven membered if geometrically determined H atom is excluded. This seven membered ring is rather puckered. There is a significant deviation of the ring atoms from the least-squares plane through the O(5), O(7), Cu and O(3) atoms of the ring. The atom O(5) is 0.028(5) Å, Cu 0.015(3) Å on one side and the atom O(7) is 0.047(5) Å, O(3) 0.026(5) Å on the other side of the plane. The other ring atoms are P(3) 1.046(3) Å, C(93) 0.493(6) Å above and P(5) 0.463(3) Å below the plane. Torsion angles are given in Table 4. The O(3)···O(7) bite distance is 2.948(5) Å and the corresponding angle on the copper atom is 86.2(1)°. The longest copper–

[a] The atoms marked with a prime correspond to positions obtained by using the transformation $-x, -y, -z$.

oxygen bond distance [2.312(4) Å] involves the central phosphoryl bond which is the shortest one [1.475(5) Å]. The two peripheral phosphoryl bonds are equal, 1.496(5) and 1.492(3) Å. The bond distances and angles of the ligand (Tables 2 and 3) are close to the values found before in the crystal structures of diphenylphosphinic acid,[20] diphenylthiophospinic acid,[21] sodium salt of monomethyl ester of fosfomycin,[22] or sodium salts of bis(diphenylphosphinyl) methane.[23,24] The smooth differences in P—C bonds along the backbone of the ligand (Table 2) seem to have similar causes as, for instance, the differences in P—O bonds along the backbone of $P_3O_{10}^{5-}$ anion in the crystal structures of condensed triphosphates or the differences in $P—N_{bridge}$ bonds in TRIPA · H_2O (Table 5).

As is usual in phosphine oxides and related compounds, distortion of phosphorus coordination tetrahedra is observed i.e. the $C_{sp^3}—P—C_{sp^3}$ angle decreases to 105.7(3)° while O=P—O angle increases to 115.5(2)°. The two angles involving oxygen from the ethoxy group, $O—P—C_{sp^3}$ are quite different, 102.8(2)° vs 105.7(2)°.

All three oxygen atoms from P=O groups lie on the same side of the plane through the three phosphorus atoms at various distances, O(1) at −1.489(5) Å, O(3) at −1.473(5) Å and O(5) at −0.399(5) Å, with O(1)···O(3) and O(3)···O(5)

[b] Mn, Cu and Cd compounds seem to be isostructural.

distances of 3.036(4) Å and 3.269(5) Å, respectively. The plane through phenyl ring C(1) to C(15) is almost parallel to the plane through O(3) P(3), O(9) [dihedral angle of 4.7(3)°], and perpendicular to the plane through P(1), P(3), P(5) [dihedral angle of 89.5(2)°]. The acute angle between the plane through phenyl ring C(3) to C(35) and the plane through C(1) to C(15) is 73.9(2)°. The plane through the phenyl ring C(5) to C(55) is roughly parallel to the plane through O(5), O(7), O(3), Cu, O(3)′, O(7)′, O(5)′ [Table 3, dihedral angle of 9.3(2)°]. The acute angle between the plane through phenyl ring C(7) to C(75) and the plane through C(5) to C(55) is 74.4(3)°.

The cation–anion interactions seem to be rather weak. Cation–anion distances shorter than 3.6 Å are given in Table 6.

Physical properties

Magnetic data of the cobalt(II) and nickel(II) complexes (Table 7) are indicative of spin-free octahedral compounds. The effective moment of the copper(II) complexes is more or less independent of the stereochemistry.

Molar conductance values observed (Table 7) are close to those expected for 2 : 1 electrolytes.

The intensity, position and shape of the absorption bands in the electronic spectra (Table 7) are typical of octahedral cobalt(II) and nickel(II) complexes. The broad asymmetric band in the near IR region in the spectrum of copper(II) complex appearing at 855 nm can be compared with the spectra of known tetragonally distorted octahedral copper(II) complexes.

Infrared spectral data (Table 8) are in good agreement with the X-ray structural determinations. The most important absorption bands in the spectra of the ligand and its complexes in the range of 4000–620 cm^{-1} are those of P═O, than OH and C—O vibrations from the coordinated ethanol and of ClO_4-ion vibrations. The spectrum of the ligand exhibits three strong absorption bands assigned to P═O stretching vibrations. The maximum at 1245

cm^{-1} assigned to the P=O stretching vibration of the central phosphoryl group, and the maximum appearing at 1220 cm^{-1} are shifted to lower wave numbers (1210–1162 cm^{-1}). Data observed indicate that in all isolated metal complexes the central P=O group as well as one of the exterior P=O groups are involved in complex formation. Positions of the maxima of the central P=O group vibrations indicate stronger bonding of the ligand to the cobalt(II) and nickel(II) than to the copper(II) ion. The maximum assigned to P—OC_2H_5 vibrations appearing in the spectrum of the ligand RPOEt at 1035 cm^{-1} is not shifted in the spectra of the complexes. That means that this group is not

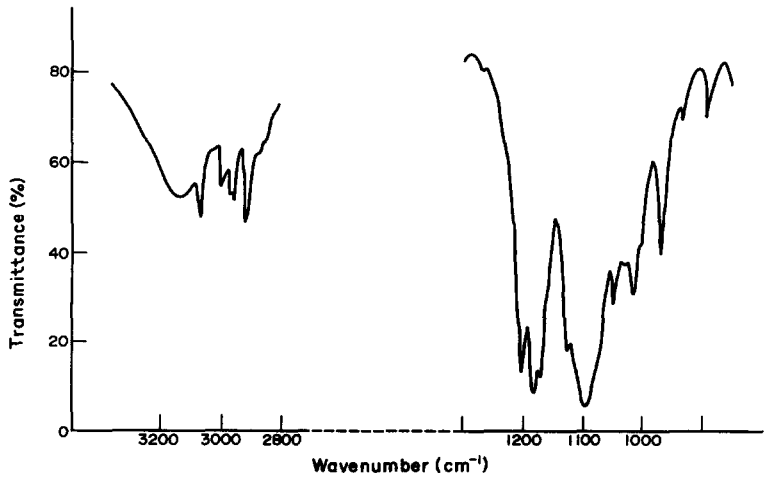

Fig. 2. IR absorption spectrum of $[Co(RPOEt)_2(C_2H_5OH)_2](ClO_4)_2$.

involved in complex formation. Maxima of the OH vibrations assigned to the coordinated ethanol indicate stronger coordination of ethanol in the copper(II) (3030 cm^{-1}) than in the nickel(II) and cobalt(II) (3130 cm^{-1}) complexes. The weaker coordination of ethanol in the cobalt(II) and nickel(II) complexes is the reason for the rather high instability of these complexes and the faster replacement of ethanol by water than in the case of the copper(II) compound. The most important absorption bands of $[Co(RPOEt)_2(C_2H_5OH)_2](ClO_4)_2$ are presented in Fig. 2.

Abstract—The reaction of hydrogen sulphide with $[Co(H_2O)_6](BF_4)_2$ and triethylphosphine in the presence of sodium tetraphenylborate or tetrabutylammonium hexafluorophosphate gave the paramagnetic clusters $[Co_6(\mu_3\text{-}S)_8(PEt_3)_6](Y)$ ($Y = BPh_4$, (**1**), PF_6, (**2**)). These compounds can be easily reduced by sodium naphthalenide to the diamagnetic species $[Co_6(\mu_3\text{-}S)_8(PEt_3)_6]\cdot 2C_4H_8O$ (**3**). The molecular structures of **1** and **3** have been established by single-crystal X-ray diffraction methods. Crystal data: (**1**) space group $P\bar{1}$, $a = 19.481(9)$, $b = 15.562(7)$, $c = 12.390(6)$ Å, $\alpha = 92.70(8)$, $\beta = 94.50(7)$, $\gamma = 94.10(9)°$, $Z = 2$, (**3**) space group $R\bar{3}$, $a = 11.780(6)$ Å, $\alpha = 92.50(7)°$, $Z = 1$. Both structures were solved by the heavy atom method and refined by full-matrix least-squares techniques to the conventional R factors values of 0.050 for **1** and 0.044 for **3** on the basis of 4251 and 1918 observed reflections, respectively. The two clusters $[Co_6(\mu_3\text{-}S)_8(PEt_3)_6]^{1+,0}$ are isostructural, the inner core consisting of an octahedron of cobalt atoms with all the faces symmetrically capped by triply bridging sulphur atoms. Each metal centre is additionally linked to a triethylphosphine group so that each cobalt atom is co-ordinated by four sulphur atoms and one phosphorus in a distorted square pyramidal environment. The addition of one electron whilst leaving unchanged the geometry of the inner framework, induces small changes in the structural parameters, the average Co—Co and Co—P distances being 2.794 (3) and 2.162 (2) Å for **1** and 2.817 (3) and 2.138 (2) Å for **3** respectively. Electrochemistry in non-aqueous solvents shows the electron-transfer sequence

$$[Co_6S_8(PEt_3)_6]^0 \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} [Co_6S_8(PEt_3)_6]^+ \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} [Co_6S_8(PEt_3)_6]^{2+} \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} [Co_6S_8(PEt_3)_6]^{3+}.$$

The tricationic species is stable only in the short time of cyclic voltammetric tests.

In recent years polynuclear metal-sulphide complexes have attracted great interest, owing to their importance both in industrial and enzymatic catalysis.

On the one hand, metal-sulphur-clusters could be regarded as models for heterogeneous metal-sulphide catalysts[1,2] and on the other hand it is well known that it is mainly of electron transfer the biological function of the iron-sulphur proteins, which, as electron carriers, satisfy electron supply or removal in the enzymatic catalysis.[3]

Electrochemistry of metal-sulphur clusters can play an important role in determining both ther-

* Author to whom correspondence should be addressed.

modynamic and kinetic aspects of their redox changes. For instance, in order to model iron-sulphur compounds able to mimic iron-sulphur proteins a great deal of study has been devoted to test the ability of these compounds to undergo one-electron charge transfers, and to compare the relevant redox potentials with those of iron proteins.[4]

Holm *et al.* succeeded in the synthesis of iron-sulphur clusters through the "spontaneous self-assembly" reactions, from mixture of appropriate reactants.[5] Later such strategy appeared suited for the synthesis of other systems.[6]

Recently, we succeeded in the synthesis of unprecedented metal sulphur clusters such as $[Ni_9(\mu_4\text{-}S)_3(\mu_3\text{-}S)_6(PEt_3)_6](BPh_4)_2$[7] and $[Fe_6(\mu_3\text{-}S)_8(PEt_3)_6](BPh_4)_2$[8] by the reaction of H_2S with nickel(II) or iron(II) ions in the presence of monotertiary phosphines. The first complex, which is diamagnetic, has a confacial bioctahedral skeleton, whereas the second, which is paramagnetic with six unpaired electrons in the cluster unit, at room temperature, has an octahedral face-capped geometry. Interestingly these two geometries are closely related to the structures present in some molybdenum chalcogenide crystal noteworthy for their particular electron conductor ability (Chevrel phases).[9]

In this paper we report the synthesis, the single-crystal X-ray structure determinations and the electrochemical properties of the cobalt clusters $[Co_6(\mu_3\text{-}S)_8(PEt_3)_6](BPh_4)$ (**1**) and $[Co_6(\mu_3\text{-}S)_8(PEt_3)_6]\cdot 2C_4H_8O$ (**3**).

Preliminary reports of this work have been already published.[10,11]

EXPERIMENTAL

Chemicals were generally used as purchased. Tetrahydrofuran was distilled over $LiAlH_4$ under nitrogen. Commercial grade dichloromethane, benzene, absolute ethanol and *n*-butanol were used without purification.

Synthesis of $[Co_6(\mu_3\text{-}S)_8(PEt_3)_6](BPh_4)$ (1)

A deoxygenated solution of $[Co(H_2O)_6](BF_4)_2$ (0.68 g, 2 mmol) in 20 cm^3 of ethanol was added to a deoxygenated solution of PEt_3 (0.71 g, 6 mmol) in 30 cm^3 of dichloromethane, under a nitrogen atmosphere and hydrogen sulphide was bubbled through, at room temperature, for 10 min. The resulting dark-brown solution was stirred overnight under a slight stream of nitrogen; then sodium tetraphenylborate (0.34 g, 1 mmol) was added. The solution was filtered and the filtrate was evaporated in air, at room temperature. After ca. 12 h dark brown crystals together with colourless crystals and a dark powder separated. This material was filtered and treated with boiling benzene (ca. 200 cm^3) in which only the brown crystals dissolved. The resulting solution was filtered and 20 cm^3 of *n*-butanol was added. By slow evaporation of the solvent in air, at room temperature, large dark brown crystals precipitated; they were collected on a filter, washed with *n*-butanol and then with petroleum ether and dried *in vacuo*; yield 0.17 g (31%). Found: C, 43.8; H, 7.1; Co, 21.3; S, 15.5. Calc. for $C_{60}H_{110}BCo_6P_6S_8$: C, 44.0; H, 6.8; Co, 21.6; S, 15.7%.

Synthesis of $[Co_6(\mu_3\text{-}S)_8(PEt_3)_6](PF_6)$ (2)

A deoxygenated solution of $[Co(H_2O)_6](BF_4)_2$ (0.68 g, 2 mmol) in 20 cm^3 of *n*-butanol was added to a deoxygenated solution of PEt_3 (0.71 g, 6 mmol) in 30 cm^3 of acetone, under a nitrogen atmosphere and hydrogen sulphide was bubbled through, at room temperature for 10 min. The resulting dark-brown solution was stirred overnight under a slight stream of nitrogen; then tetrabutylammonium hexafluorophosphate (0.39 g, 1 mmol) was added. The solution was filtered and the filtrate was evaporated in air, at room temperature until dark brown crystals separated. These were filtered and recrystallized from methylene chloride and *n*-butanol. Large dark brown crystals were obtained, which were collected in a filter, washed with *n*-butanol, and then with petroleum ether and dried *in vacuo*; yield 0.095 g (21%). Found: C, 29.3; H, 6.3; Co, 23.7. Calc. for $C_{36}H_{90}Co_6F_6P_7S_8$: C, 29.5; H, 6.2; Co, 24.1%.

Synthesis of $[Co_6(\mu_3\text{-}S)_8(PEt_3)_6]\cdot 2C_4H_8O$ (3)

Sodium naphthalenide (0.025 g, 0.16 mmol) in 15 cm^3 of thf was added to a solution of $[Co_6(\mu_3\text{-}S)_8(PEt_3)_6]BPh_4$ (0.2 g, 0.12 mmol) in 30 cm^3 of thf with stirring, at room temperature. Then the solution was allowed to stand and crystals, rapidly formed (10 min), were isolated; yield 0.15 g (86%). Found: C, 36.5; H, 7.5; Co, 23.7. Calc. for $C_{44}H_{106}Co_6O_2P_6S_8$: C, 36.1; H, 7.3; Co, 24.2%.

Physical methods

Conductivity and magnetic susceptibilities measurements were carried out by previously described methods.[12]

Electrochemistry

Acetonitrile and dichloromethane solvents (Burdik and Jackson, distilled in glass, UV grade) were

used as received. Tetraethylammonium perchlorate (Carlo Erba) and tetrabutylammonium perchlorate (Fluka) supporting electrolytes were dried in a vacuum oven and used without further purification. Bis(η-cyclopentadienyl)iron(II) (Alfa Products) was used as purchased. Extra pure nitrogen was used to remove oxygen from tested solutions. Electrochemical techniques were carried out using a PAR model 170 Electrochemistry System as polarizing unity; the recording device for potential scan rates higher than 0.5 V s^{-1} was a Hewlett–Packard model 1123 A storage oscilloscope. Cyclic voltammetry and chronoamperometry were performed both with a gold sphere working microelectrode freshly covered with a thin mercury layer, and with a platinum sphere working microelectrode; the working electrode was surrounded by a platinum-spiral counter-electrode. The potential of the working microelectrode was probed by a Luggin capillary reference electrode compartment. Controlled potential coulometric tests were performed in a H-shaped cell with anodic and cathodic compartments separated by a sintered glass disc. The working macroelectrode was either a mercury pool or a platinum gauze. A mercury pool was used as counter electrode. In these tests an Amel potentiostat model 551, with an associated coulometer Amel integrator model 558, were used. In all electrochemical tests an aqueous saturated calomel electrode (SCE) was used as reference electrode. The temperature was controlled at 20 ± 0.1°C.

X-ray data collection

Diffraction data were collected at room temperature on a Philips PW 1100 automatic diffractometer. Unit cell parameters for compound **1** and **3** were determined from the least squares refinement of the setting angles of 20 and 24 accurately centred reflections, respectively. Crystal data and data collection details are reported in Table 1. After cor-

rection for background the intensities were assigned standard deviations calculated by using for the instability factor k the value of 0.03.[13] Intensity data were corrected for Lorentz and polarization effects and for absorption.[14]

Solution and refinement of the structures

All the calculations were carried out on a SEL 32/77 computer by using the SHELX-76[14] and ORTEP[15] programs. Atomic scattering factors of the appropriate neutral atoms were taken from ref. 16 for the non-hydrogen atoms and from ref. 17 for hydrogen atoms. Both the $\Delta f'$ and $\Delta f''$ components of anomalous dispersion were included for all non-hydrogen atoms.[18] The refinement was based on F_0, the function minimized being $\Sigma w(|F_0|-|F_c|)^2$, where $w = 1/\sigma^2(F_0)$. The structure of both compounds was solved by the heavy atom method. Several Fourier maps revealed all the non hydrogen atoms and for compound **3** the disordered solvating tetrahydrofuran molecule. Full-matrix least-squares refinements were carried out by using anisotropic thermal parameters only for cobalt, sulphur and phosphorus. The phenyl rings of the tetraphenylborate were treated as rigid groups. The hydrogen atoms were introduced in calculated positions but not refined. The tetrahydrofuran molecule was refined as rigid group with population parameter of 1/3. The refinement converged at R and R_w factors value of 0.050 and 0.051 for **1** and 0.044 and 0.045 for **3** respectively. R and R_w are defined as $\Sigma||F_0|-|F_c||/\Sigma|F_0|$ and $[\Sigma w(|F_0|-|F_c|)^2/\Sigma w|F_0|^2]^{1/2}$. Final difference Fourier maps did not show any feature. Final atomic coordinates for both compounds, tables of thermal parameters and lists of F_0/F_c have been deposited with the Editor as supplementary material.*

RESULTS AND DISCUSSION

Synthesis

The reaction of H_2S with $[Co(H_2O)_6]^{2+}$, in the presence of PEt_3 (Co/P $\cong$ 1/3), at room temperature, affords the cluster ion $[Co_6(\mu_3\text{-}S)_8(PEt_3)_6]^+$ which can be isolated as tetraphenylborate **1** or hexafluorophosphate **2** salt. A large excess of PEt_3, with respect to the stoichiometry of the final product, is necessary in order to prevent the precipitation of the binary cobalt sulphide. The reaction occurs in air, the initial stage being carried out under a nitrogen atmosphere only to prevent the phosphine oxidation.

At the end of the reaction the metal atoms are formally oxidized, the cobalt mean oxidation state being +2.83. A similar formal oxidation was previously observed during the formation of the clusters $[Ni_9(\mu_4\text{-}S)_3(\mu_3\text{-}S)_6(PEt_3)_6]^{2+}$ and $[Fe_6(\mu_3\text{-}S)_8(PEt_3)_6]^{2+}$ with final mean oxidation states of +2.22 and +3.0 for nickel and iron respectively.

Unfortunately we were not able to identify all of the reaction products and the oxidant.

The complex **1** can be easily reduced in thf solution by sodium naphthalenide to form the uncharged species $[Co_6(\mu_3\text{-}S)_8(PEt_3)_6]\cdot 2C_4H_8O$, **3** (Scheme 1).

$$[Co_6(\mu_3\text{-}S)_8(PEt_3)_6]^+ + NaC_{10}H_8 \rightarrow [Co_6(\mu_3\text{-}S)_8(PEt_3)_6] + Na^+ + C_{10}H_8$$

Scheme 1.

The clusters **1** and **2** are air stable both in the solid state and in solution. They are very soluble in polar organic solvents such as acetone, dichloromethane, nitroethane, in which they behave as 1 : 1 electrolytes. **1** is also soluble in warm benzene. The complex **3**, which is practically insoluble in the common organic solvents, is indefinitely stable under nitrogen.

The complex **1** and **2** are paramagnetic with bulk magnetic moments of 2.10 and 2.14 μ_B *per* cluster unit, at room temperature, respectively. This result, which indicates one unpaired electron for the cluster agrees with the presence of an odd total electrons number in the cation. The uncharged cluster is diamagnetic.

Description of the structures

Compound **1** is constructed of discrete $[Co_6(\mu_3\text{-}S)_8(PEt_3)_6]^+$ cations and $[BPh_4]^-$ anions. Figure 1 shows a perspective view of the cation and selected bond distances and angles are reported in Tables 2 and 3. Compound **3** consists of discrete cluster units with interspersed molecules of tetrahydrofuran. Table 4 lists selected bond distances and angles of the uncharged species, while Fig. 2 shows the inner core of **1** and **3**.

The structure determination has shown that both the monopositive and the neutral species retain the same $M_6S_8P_6$ framework as the previously described iron derivative $[Fe_6(\mu_3\text{-}S)_8(PEt_3)_6]^{2+}$.[8] The inner core of the two clusters consists of an octahedron of cobalt atoms with all the faces symmetrically capped by triply-bridging sulphur atoms. Moreover

* Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

each metal atom is linked to a triethylphosphine group along the body diagonal of the octahedron. Each metal atom is therefore surrounded by four sulphur and one phosphorus atom in a distorted square pyramidal environment and it is additionally linked to other four metal atoms. Alternatively the Co_6S_8 unit may be described as a cube of sulphur atoms with the metal atoms in the face centred positions.

The monocation has no crystallographic symmetry imposed, however the deviations of the M_6 unit from a regular octahedron are small. As a matter of fact no systematic distortions are present: the Co—Co distances range from 2.771 (2) to 2.808 (2) Å and the Co—Co—Co angles, which fall in the ranges 59.2 (1)–60.5 (1)° and 89.4 (1)–90.6 (1)° are very close to the values of 60.0 and 90.0 for perfect octahedral symmetry. The crystallographic symmetry of the neutral species is C_{3i} and in this case the deviations of the inner core from the O_h symmetry are even smaller, the Co—Co—Co angles being equal within the experimental errors to the ideal values.

The comparison of the geometries of the monocharged and neutral derivatives shows a small difference in the average Co—Co distance which goes from 2.794 (3) to 2.817 (2) Å. Moreover the Co—S distances in **1** and **3** are equal within the experimental errors, while the Co—P bond distance in the neutral species is shorter, 2.138 (2) Å, than that in the monocation, 2.162 (2) Å (av). No other features or distortions are observed between the two cluster units.

Therefore the addition of one electron, whilst leaving unchanged the geometry of the inner framework, induces small variation in the metal–metal interactions and in the Co—P distances, but does not affect the metal sulphur bonds, which are the actual stabilizing factors of the metal framework.[7] In this connection it is noteworthy that the values of the Co—Co distances are rather long if compared with those reported for other cobalt clusters[6,19,20] and may be related to the high valence electron numbers (97 and 98) of these cobalt clusters. Indeed

the class of the well-known octahedral carbonyl clusters possesses an electronic configuration of 86 valence electrons.[21] A fully comparable value of Co—Co distance, 2.811 (1) Å, was found for $[Co_6(\mu_3\text{-}S)_8(CO)_6]$ which is isoelectronic with **3**.[22]

Of great interest is also the comparison of these

cating that the increase of the total electron number results in a lengthening of the metal–metal distances with a parallel decrease of the M–P distances and to a lesser extent of the M–S ones. A larger sensitivity to the redox changes has been found for the terminal Co—S distances than for the bridging ones in $[Co_8S_6(SPh)_8]^{-4,-5}$ [6] in which the metal and sulphur positions are reversed with respect to those in **1** and **3**.

Other changes in the structural parameters associated with the variation of the electron numbers are reported in Table 5: all the reported mean structural parameters vary monotonically, with the number of electrons. Augmenting the electron density the separations between the metals in *trans* positions become larger in such a way that the metal atoms lying at the face centred positions of the sulphur cubes are pushed out, the deviations of the metal atoms from the S_4 planes going from 0.27 to 0.45 Å. Moreover the triply-bridging sulphur becomes more flat, the M–S–M average angle going from 71.2 (1)° to 78.2 (2)° and the average S–S edge going from 3.154(8) to 3.095 (2) Å.

The concomitance of the above changes is such that, augmenting the number of electrons, the M_6S_8 becomes more similar to a ball than to a cube encompassing an octahedron.

Electrochemistry

The electrochemical behaviour of the polinuclear monocation (**1**) has been studied by cyclic voltammetry. The relevant responses at a platinum

electrode both in CH_2Cl_2 and MeCN solutions are shown in Fig. 3.

As it can be seen the cluster gives rise to three oxidation and one reduction processes in both solvents, the only significant difference being the insolubility in MeCN of the product electrogenerated in correspondence of peak F, which is desorbed and reoxidized at the potentials of peak H, well anodic with respect to the potentials of peak G recorded in CH_2Cl_2 solvent. Controlled potential coulometric experiments showed that both the anodic process occurring at peak A and the cathodic one occurring at peak F involve the consumption of 1 mol of electrons per mole of starting compound. On the contrary in the electrolysis directly performed at potentials of peak B, the anodic current abruptly falls after the consumption of 2 mol of electrons per mole of starting compound, but it remains significantly higher than the background current up to the overall consumption of 4 mol of electrons per mole of starting compound. Finally coulometric experiments in correspondence to peak C in MeCN solvent, where the solvent discharge does not interfere, show the consumption of a number of electrons higher than 30 per molecule of the starting compound.

The analysis of cyclic voltammetric responses with scan rate[23] varying from 0.02 to 100 V s^{-1} showed the following features. The anodic process occurring at peak A involves an uncomplicated one-electron reversible charge transfer, which slightly departs from reversibility criteria only at scan rates higher than 5 V s^{-1}, probably because of some uncompensated solution resistance; in fact ΔE_p gradually increases from the theoretical value of 59 to 90 mV in the scan rate range 5–100 V s^{-1}. On the basis of its peak height, also the anodic process occurring at peak B involves a one-electron charge transfer in the cyclic voltammetric time scale; however, in the scan rate range 0.02–1 V s^{-1}, the diagnostic parameters i_{pc}/i_{pa}, which is lower than unity, and $i_{pa}/v^{1/2}$, which decreases, show it to be complicated by following chemical reactions, while at scan rates higher than 1 V s^{-1} it appears as an uncomplicated one-electron reversible charge transfer slightly departing from reversibility at scan rates higher than 5 V s^{-1}. On the other hand potential-step chronoamperometric experiments in the time range 0.002–3 s reveal this anodic process to be a one-electron charge transfer up to 2 s (i.e. $i \times t^{1/2}$ is constant), then the number of electrons involved increases. In summary, all voltammetric data indicate that the second anodic process can be described according to a complicated electrode mechanism in which more than one chemical reactions are interposed between more than two one-electron charge transfer (ECEC...); however in the cyclic voltammetric time scale the first coupled chemical reaction is enough slow that the electrode mechanism can be considered to approach a more simple EC mechanism.

The anodic process occurring at peak C is a multi-electron charge transfer (its peak height is seven times higher than that of peak A or B), totally irreversible in character.

Finally the cathodic process occurring at peak F in CH_2Cl_2 solvent, involves an uncomplicated one-electron charge transfer, having a degree of reversibility lower than the first two anodic processes. In fact ΔE_p gradually increases from 86 to 200 mV in the scan rate 0.02–100 V s^{-1}.

The whole of electrochemical data have to be interpreted in these terms: (i) the peak system A/E is due to the reversible oxidation of the monocation

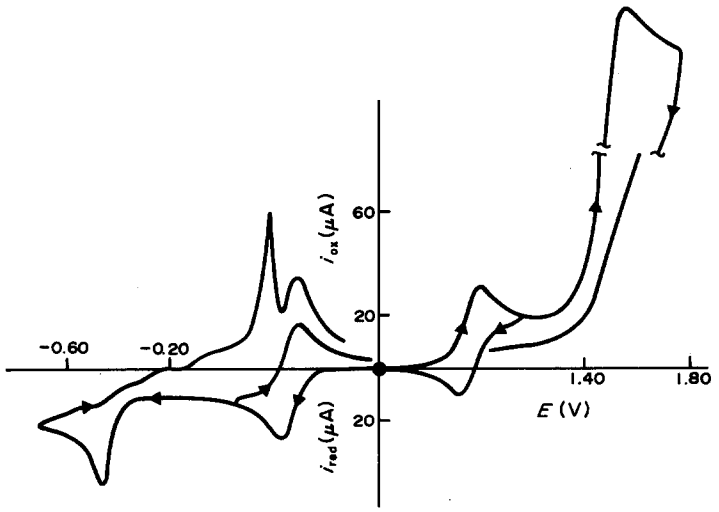

Fig. 4. Cyclic voltammogram at a platinum microelectrode recorded on a MeCN solution of $[Co_6(\mu_3\text{-}S)_8(PEt_3)_6](PF_6)$ (2.38×10^{-5} mol) containing $(NEt_4)(ClO_4)$ (0.1 mol dm^{-3}) after exhaustive electrolysis at +0.5 V (2.3 C spent) at a platinum working macroelectrode. Scan rate 0.2 V s^{-1}. (●) Starting potential.

cluster to the corresponding dication (1+/2+). As it can be seen from Fig. 4 this dication is a quite stable product; (ii) the peak system B/D is due to the reversible oxidation of the cluster dication to the corresponding trication (2+/3+), which however is stable only on the short times of the cyclic voltammetric test. In fact, assuming that the first chemical reaction coupled to the 2+/3+ charge transfer (very likely the decomposition of the trication cluster) is an irreversible first-order chemical reaction, it is possible to evaluate, by the method of Nicholson and Shain,[24] an half-life of about 5 s for the electrogenerated trication; (iii) peak C is likely due to the anodic oxidation of the triethylphosphine ligand. In fact free PEt_3 oxidizes irreversibly at $E_p = +1.34$ V in MeCN/$(NEt_4)(ClO_4)$ (0.1 mol dm^{-3}) solution; and (iv) the peak system F/G (or F/H) is due to the reversible reduction of the starting polinuclear monocation to the corresponding neutral form (1+/0), previously obtained by chemical reduction.

Table 6 summarizes the redox potentials of the cluster under study in the two employed solvents. In order to eliminate variable diffusion potentials arising at the aqueous/non-aqueous interface of the aqueous reference electrode, and in the attempt to make comparable the potential data in different solvents, we used ferrocene as an internal standard,[25] so that potentials vs the solvent-independent ferrocenium/ferrocene couple are also reported. It must however be taken into account that the ferrocenium/ferrocene couple is also nominally independent from the solvent, in fact it shows a formal electrode potential, $E^{\circ\prime}$, of +0.49 V in CH_2Cl_2, and of +0.40 V in MeCN. Therefore a shift in potential values of about 0.1 V towards more negative values is expected in passing from CH_2Cl_2 to MeCN. As it can be seen the shift is higher for what concerns the 2+/3+ couple.

Since thermodynamic redox potentials are directly related to the relative energies of the HOMO/LUMO levels, it can be speculated that in CH_2Cl_2 solvent the difference in energy between the HOMO and LUMO levels is of about 82 kJ mol^{-1} for the monocation cluster, as well as of about 105 kJ mol^{-1} for the dication cluster. In MeCN the difference is of about 91 kJ mol^{-1} for the dication, clearly indicating that the solvation terms involved in HOMO/LUMO levels[26] are different for the two solvents here used, so making this type of calculations a useful, but rough estimate of the involved orbital energies. A comparison with the

Table 6. Formal electrode potential (in V vs SCE) for the electron transfer series exhibited by $[Co_6(\mu_3\text{-}S)_8(PEt_3)_6]^+$. Potential values in parentheses refer to the ferrocenium/ferrocene couple

Solvent	1+/0	1+/2+	2+/3+

redox chemistry of the very similar cluster $[Co_8S_6(SPh)_8]^{-}$[46] in MeCN solvent is shown in Scheme 2.

$$[Co_8S_6(SPh)_8]^{5-} \underset{}{\overset{-1.12\,V}{\rightleftharpoons}} [Co_8S_6(SPh)_8]^{4-}$$

$$\overset{-0.52\,V}{\rightleftharpoons} [Co_8S_6(SPh)_8]^{3-}$$

$$[Co_6S_8(PEt_3)_6]^{0} \overset{\sim -0.5\,V}{\rightleftharpoons} [Co_6S_8(PEt_3)_6]^{+}$$

$$\overset{+0.25\,V}{\rightleftharpoons} [Co_6S_8(PEt_3)_6]^{2+}$$

$$\overset{+0.95\,V}{\rightleftharpoons} [Co_6S_8](PEt_3)_6]^{3+}$$

Scheme 2.

A first glance indicates that the Co_6S_8 core offers a more rich availability of one-electron charge transfers than the Co_8S_6 core. The relevant redox potentials are shifted towards more positive values, probably because of the presence of terminal uncharged triethylphosphine groups in the title compound with respect to the negatively charged benzene thiolate groups in $[Co_8S_6(SPh)_8]^{4-}$.

In spite of the electrochemical stability of the dipositive species we were unable so far to isolate it in the solid state.

(*Received* 24 *January* 1986 ; *accepted* 8 *May* 1986)

Abstract—The synthesis and characterization of the [M(dmit)(phen)] complexes [M = Pd(II), Pt(II); H_2dmit = 4,5-dimercapto-1,3-dithiole-2-thione; phen = 1,10-phenanthroline) and of the iodinated [M(dmit)(phen)]I compounds are described. The conductivity of [M(dmit)(phen)] increases upon oxidation by a factor of 10^6, and is ca. 5×10^{-3} $ohm^{-1}\,cm^{-1}$ for the [M(dmit)(phen)]I compounds. The nature of the iodine species in these solids is determined by UV–visible and resonance Raman spectroscopies. The only polyiodide present is I_3^- and, thus, the charge distribution can be expressed as $[M(dmit)(phen)]^{0.33+}[I_3^-]_{0.33}$.

One of the strategies which can be employed for synthesizing highly conductive low-dimensional materials derives from the observation that halogenation of certain solids greatly increases their electrical conductivity. An extraordinary large variety of such conductive halogenated, and especially iodinated, materials has been studied,[1,2] including organic systems, transition metal complexes and polymers.

In these materials, iodine species reported to exist are I_2, I^-, I_3^- and I_5^-. Since the first Raman spectroscopic studies by Kiefer and Bernstein,[3] and Kaya and coworkers[4] on I_3^- species dissolved in methanol, this technique has been widely used[5–13] in the study of this anion for the following reasons :

(i) The existence of intense allowed electronic transition of the type $\sigma \rightarrow \sigma^*$ and/or $\pi \rightarrow \sigma^*$ gives rise to resonance Raman spectra which are greatly enhanced, by excitation in the visible, and generally characterized by a very intense ν_1 mode ($\nu_{sym}I_3^-$) and the activity of a $n\nu_1$ overtone progression.

(ii) Less intense additional signals observed in ordinary Raman and resonance Raman conditions have found various structural interpretations and have also been assigned to vibrational modes of several I_4^{2-}, I_5^- or I_6^{2-} polyiodides. However, the asymmetric linear configuration $C_{\infty v}$ seems now well established for I_3^- in solution.

(iii) The formation and the existence of I_3^- species in iodinated compounds, such as conductive complexes,[1,2,10,11] are clearly evidenced by resonance Raman scattering spectra, in spite of their very dark colour. In this respect, I_2 (ca. 210–180 cm^{-1}) and I_3^- (116–106 cm^{-1}) species are clearly discriminated by vibrational spectroscopy.

In the course of previous investigations on highly conductive bis(dithiolato) metal complexes[14] we have prepared mixed-ligand mononuclear complexes of the type [M(dmit)(Phos)$_2$] (M = Ni(II), Pd(II), Pt(II)); H_2dmit = 4,5-dimercapto-1,3-dithiole-2-thione; (Phos)$_2$ = dppe or $(PPh_3)_2$.[15] Several

* Author to whom correspondence should be addressed.

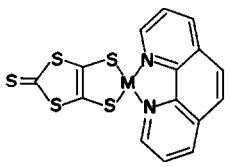

Fig. 1. [M(dmit)(phen)] complexes.

attempts to oxidize these complexes with iodine or bromine have failed to produce any conductive materials. This was probably due to steric effects of the $(Phos)_2$ ligands, precluding the stacking of the molecules. For example, in the crystal structure of [Pt(dmit)(dppe)] the Pt atom displays a distorted square planar configuration but there is no close stacking of the molecules.[16]

In order to circumvent this difficulty, we have studied the effect of replacing in such $[M(dmit)L_2]$ complexes the $(Phos)_2$ ligand by more planar bidentate ligands such as 2,2′-bipyridine[17] and 1,10-phenanthroline (phen). We report here the synthesis and characterization of the [M(dmit)(phen)] complexes [M = Pd(II), Pt(II)] (Fig. 1) and of the conductive [M(dmit)(phen)]I derived compounds, and the results of a resonance Raman study of these iodinated materials.

EXPERIMENTAL

(1) *Starting materials*

The benzoil salt $dmit(COPh)_2$ is prepared following the method of Steimecke and coworkers.[18] $[PdCl_2(phen)]$ and $[PtCl_2(phen)]$ were prepared following ref. 19. All reactions were carried out under inert atmosphere conditions unless otherwise stated. C, H, N analyses were carried out on a Carlo Erba instrument.

(2) *Synthesis of the* [M(dmit)(phen)] *complexes* [M = Pd(II), Pt(II)]

The $dmit^{2-}$ anion is generated in solution by reaction of $dmit(COPh)_2$ with 2 mol equivalent of sodium methoxide at room temperature. To the resulting solution is added 1 mol equivalent of the appropriate $[MCl_2(phen)]$ solid complex, and the solution refluxed for 5 h. A brown-to-reddish microcrystalline powder precipitates from the reaction mixture and after cooling is collected by filtering, washed with ethanol and dried under vacuum over silicagel. Yields were ca. 60%. Both compounds are insoluble in most common organic solvents but DMF, in which they are slightly soluble, precluding further purification by recrystallization. Analytical data are gathered in Table 1.

(3) *Iodine oxidation and synthesis of* [M(dmit)(phen)]I *compounds* [M = Pd(II), Pt(II)]

These compounds were prepared by mixing a solution of iodine in DMF (two-fold excess) with a solution-slurry of the corresponding [M(dmit)(phen)] complex in DMF. After stirring the reaction mixture for 30 min, the resulting dark brown precipitate is filtered out, and washed with methanol, hexane and, finally, several times with CCl_4 until no traces of iodine could be detected in the washing solvent. The solid was finally dried under vacuum. Yields were ca. 70%. Analytical data are gathered in Table 1.

(4) *Physical measurements*

IR spectra (4000–600 cm^{-1}) were recorded as KBr pellets with a Beckman IR-20A spectrophotometer. UV–visible spectra were recorded as KBr pellets with a 5230-UV Beckman spectro-

photometer. Electrical conductivities were estimated on compressed pellets as described in ref. 20.

Low frequency (10–650 cm^{-1}) resonance Raman spectra were obtained using a Coderg T800 triple monochromathor and a Spectra Physics Argon (5145 Å, model 171) or Krypton (6471 Å, model 2020) Laser. The detector was a RCA/C 31034 photomultiplier coupled with a photon counting device. Low excitation Laser powers were used ($P_0 \leqslant 60$ mW) because of the strong absorption of the compounds in this wavelength range (see electronic absorption spectra). The compounds were grinded as solid polycrystalline mixtures in KCl (ca. 6% w/w) and the samples were attached to rapidly rotating discs (ca. 2000 rpm) in order to avoid any local heating: under these conditions no decomposition was observed over long periods. The asymmetry of the Raman lines was checked by varying the amplification ratio and the spectral resolutions (between 1.6 and 3 cm^{-1}).

RESULTS AND DISCUSSION

The [M(dmit)(phen)] complexes [M = Pd(II), Pt(II)] were obtained by reaction of the corresponding [MCl_2(phen)] with the $dmit^{2-}$ anion generated in solution from [dmit($COPh)_2$] and methanolate. These complexes were characterized by elemental analysis (Table 1) and IR spectroscopy. Most of the observed IR bands are due to the coordinated ligands. The most characteristic absorptions, observed between 1500 and 1400 cm^{-1}, 840cm^{-1} and 700 cm^{-1} in the spectra of [M(dmit)(phen)] are mainly ring vibrations similar to corresponding bands of the coordinated 1,10-phenanthroline in [MCl_2(phen)].[21] On the other hand, new strong bands at ca. 1050 and 1030 cm^{-1} appear in the spectra of the [M(dmit)(phen)] complexes and are easily assigned to the typical ν(C⋯S) stretching frequencies of the dmit ligand.[15,18,22]

The [M(dmit)(phen)] complexes are slightly soluble in DMF. Reaction of a solution-slurry of these complexes with iodine dissolved in DMF yields the corresponding [M(dmit)(phen)]I compounds. The stoichiometry of both compounds is assigned from elemental analysis data (Table 1). Very little information can be gained from the IR spectra of these iodinated materials which show very few intense and broad bands (Fig. 2). However, the broad absorption bands near 1100 and 1250 cm^{-1} are similar to those observed in a number of other conductive systems.[23,24] Such features in the IR spectra of narrow band semiconductor or metallic materials, should be explicitly attributed to electron–molecular vibration interaction and not generically to an electron–phonon interaction.[24]

As a matter of fact, the [M(dmit)(phen)]I compounds exhibit a fairly high compaction powder conductivity at room temperature: ca. 5×10^{-3} $ohm^{-1}\,cm^{-1}$. The conductivity of the corresponding [M(dmit)(phen)] starting complexes being lower than 10^{-9} $ohm^{-1}\,cm^{-1}$, this means that iodination results in an increase of the conductivity by a factor of at least 10.[6]

It can be inferred from the conductivity increase and the peculiar features of the IR spectra that iodination of [M(dmit)(phen)] leads to partially oxidized materials. A first indication on the nature of the iodine species present in these solids and, hence, the degree of the charge transfer can be found in the UV–visible spectra: it is known that the intense absorption maximum for a chain of I_3^- ions is in the 550 nm region,[1,25] whereas chains of I_5^- give rise to an absorption maximum at ca. 700 nm.[1,26] In

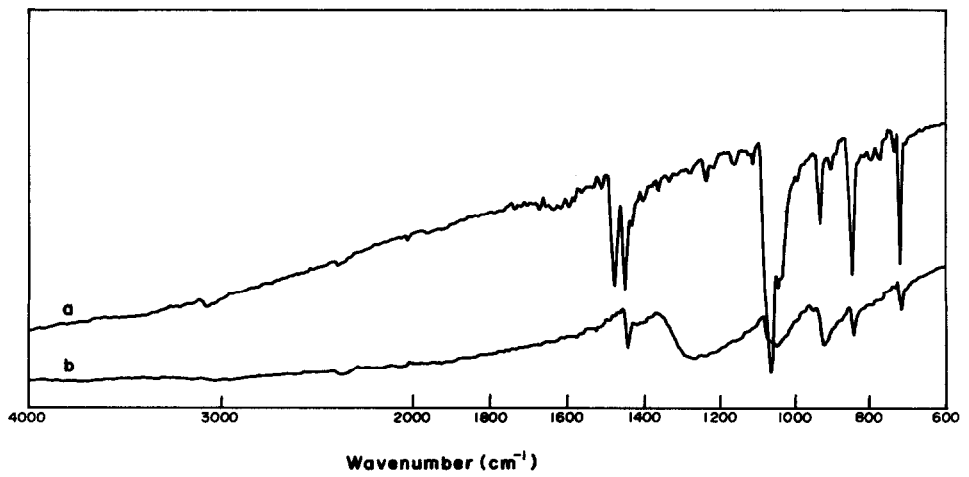

Fig. 2. IR spectra of: (a) [Pt(dmit)(phen)], and (b) [Pt(dmit)(phen)]I.

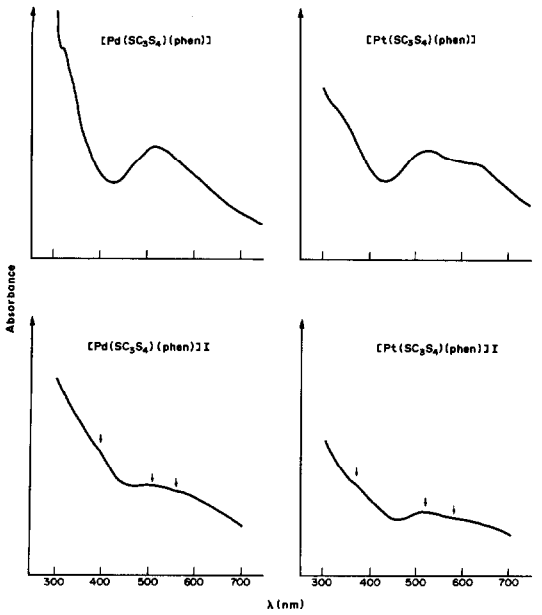

Fig. 3. UV–vis absorption spectra (KBr pellets) of [M(dmit)(phen)] and [M(dmit)(phen)]I compounds (M = Pd or Pt) (dmit = SC_3S_4).

our case (Fig. 3), whereas the unoxidized [M(dmit)(phen)] complexes exhibit weak d–d absorptions at ca. 520 and 325 nm for M = Pd and ca. 625, 530 and 325 nm for M = Pt, the oxidized [Pd(dmit)(phen)]I compound exhibits broad intense absorption at ca. 510 nm with shoulders at ca. 550 and 400 nm. Likewise the [Pt(dmit)(phen)]I compound exhibit a very broad asymmetric absorption maximum centred at ca. 525 nm with shoulders at ca. 575 and 375 nm. These observations agree with those previously reported for [M(dmit)(bipy)]I[17] and are consistent with the presence of I_3^- species in the studied compounds.

A definitive answer to this question is given by resonance Raman spectroscopy.

The Raman spectra of both platinum and palladium complexes are quite similar and only those obtained for the platinum complex are shown in Fig. 4. All the observed band-wavenumbers and proposed assignments are gathered in Table 2, together with their relative intensities and band-widths (FWHM).

The spectra exhibit essentially a very intense band at 105 cm^{-1}, characteristic of the $\nu_1(\Sigma^+)$ mode of I_3^- species and some weaker and broader progressions $n \times \nu_1$ of this mode as far as $n = 6$. Using the classical expressions $\nu(n)/n = (\omega e + \omega eXe) + \omega eXe \times n$ and the plots of $\nu(n)/n$ vs n, where n is the vibrational quantum number, the following spectroscopic constants have been estimated, $\omega e = 104.8\ cm^{-1}$ and $\omega eXe \simeq +0.4\ cm^{-1}$ (Fig. 5). These values are in agreement with those reported in several previous studies.[3–7]

It is noteworthy that weaker additional signals are also detected at 52 cm^{-1} (lattice mode), 148 cm^{-1} (ν_3, Σ^+), 170 cm^{-1} ($2 \times \nu_2$) and 254 cm^{-1} ($\nu_1 + \nu_3$) while the high frequency mode at 514 cm^{-1} is likely to be due to the stretching ν(C=S) mode of the $SC_3S_4^{2-}$ ligand. The very low intensity of the

ν_3 mode for both exciting radiations used indicates that the I_3^- species have probably a nearly symmetric linear structure. At this point, these resonance Raman results confirm that I_3^- is the only polyiodide present in these partially oxydized compounds. Finally, large broadenings of the bands due to the overtones and asymmetric profiles are clearly evidenced on the recorded spectra even using high resolution conditions. This must reflect coupling to lattice modes or vibrational dephasing. Assuming linear coupling to lattice modes, we would expect a linear dependence on the linewidth on n,[5] whereas vibrational dephasing would introduce a n^2 dependence.[27] Our results indicate a behaviour roughly linear upon n, confirming the large contribution of the first mechanism.[5,8] Nevertheless, "hot band" processes may also make a significant contribution since the profiles are always asymmetric on the high frequency side ($\omega eXe > 0$)[17,28] and the asymmetries generally disappear when cooling the samples to 20–10 K.[5,8]

EXTRACTION OF CADMIUM(II) BY ORGANOPHOSPHORUS COMPOUNDS

I. CASAS, N. MIRALLES, A. SASTRE* and M. AGUILAR

Departament de Química, Escola Tècnica Superior d'Enginyers Industrials de Barcelona, Universitat Politècnica de Catalunya, Diagonal 647, 08028 Barcelona, Spain

(*Received* 19 *February* 1986; *accepted* 8 *May* 1986)

Abstract—The extraction of cadmium(II) by di-(2-ethylhexyl) phosphoric acid dissolved in tetradecane from aqueous chloride and perchlorate solutions has been studied at 25°C. The distribution of the metal has been determined as a function of metal and DEHPA concentrations. Distribution data have been treated both graphically and numerically using the program LETAGROP-DISTR (*Acta Chem. Scand.* 1971, **25**, 1521) and the composition of the extracted species into the organic phase has been determined. The extraction constants for these species are given in Table 1.

This work is part of a series dealing with the extraction of divalent metal ions by organophosphorus extractants dissolved in commercial diluents.[2,3] The aim of this work is to investigate the different systems and describe them in terms of species and equilibrium constants, in order to establish if speciation in the organic phase may be utilized to design metal separation methods.[4]

The extraction of cadmium(II) by di-(2-ethylhexyl) phosphoric acid (henceforth DEHPA in the text and HA in formulas) has been studied under a great variety of experimental conditions. Most of the work is connected with the separation of cadmium and zinc in different media[5–8] and less emphasis has been placed on equilibrium studies. It seems from these studies that extraction reaction models proposed by different authors do not agree with each other—probably because of different experimental conditions.

Thus, while Grimm and Kolarik[9] found the species $CdA_2(HA)_3$ in the extraction of cadmium(II) from chloride solutions by DEHPA dissolved in *n*-dodecane, Rice *et al.*[5] studied the extraction of Zn(II), Cd(II) and Hg(II) from sulphate solution by different extractants and reported species of composition $MA_2(HA)_2$ in organic phase, even though data for cadmium do not exactly fit the proposed model. According to these authors this may probably be due to the polymerization reactions, or else perhaps due to activity coefficient variations.

On the other hand Baes[10] in a review on the extraction of metal ions by dialkylphosphoric acid gives some constants for the extraction of $CdA_2(HA)_2$ in different diluents, although these constants were estimated from the work of several investigators and corrected for toluene as solvent.

All these results make us think that new distribution data may contribute to the clarification of the uncertainties in the composition of Cd–DEHPA-extracted species at low metal loading, as well as give new information on organophosphorus extractants.

Under these circumstances, a detailed study of the extraction of Cd(II) by DEHPA in tetradecane is undertaken. The object of this is to describe the metal extraction in terms of species and extraction constants.

EXPERIMENTAL

Reagents

Di-(2-ethylhexyl) phosphoric acid (DEHPA = HA)—supplied by BDH. Its purity was determined by potentiometric titration in an 80% ethanol solution of the acid with NaOH 0.1 mol dm^{-3} using Gran plots.[11] Purity was found to be 98.2%

Tetradecane—supplied by PETRESA, is a commercial hydrocarbon of the following characteristics:

* Author to whom correspondence should be addressed.

Density at 15°C	0.768
Aromatic content, ppm	215
Water content, ppm	50 max.
Boiling point at 760 mmHg	253.7°C.
Distribution (%)	
C_{13}	1.2
C_{14}	98.2
C_{15}	0.1.

Tetradecane was washed with NaOH 0.1 mol dm^{-3}, distilled water, HCl 0.1 mol dm^{-3} and finally distilled water until no evidence of chloride ions in the aqueous solution.

Sodium chloride and sodium perchlorate—used as ionic medium, were prepared as described in ref. 12.

Perchloric acid and hydrochloric acid.—Merck p.a. were used without further purification. A stock solution of both acids was prepared and standardized against HgO and NaI.[13]

Cadmium perchlorate—was prepared from cadmium oxide (Probus p.a.) and perchloric acid (Merck p.a.) as described in ref. 14. The cadmium concentration of the stock solution was determined by complexometric titration with EDTA using eriochrome black T as indicator.[15] The perchlorate concentration of the stock solution was determined as described elsewhere.[3]

Cadmium chloride—Merck p.a. was used without further purification. A stock solution was prepared and analysed as cadmium perchlorate.

Extraction procedure

All experiments were carried out at 25°C. The phases in contact had the following composition:

Aqueous phase:	
$(Na^+, H^+, Cd^{2+})ClO_4^-$	1.0 mol dm^{-3}
$(Na^+, H^+, Cd^{2+})ClO_4^-$	0.1 mol dm^{-3}
$(Na^+, H^+, Cd^{2+})Cl^-$	0.1 mol dm^{-3}
Organic phase:	DEHPA in tetradecane.

The extractant concentrations were varied from 0.010 to 0.150 mol dm^{-3}.

Volumes (15 cm^3) of each phase was shaken out mechanically in stoppered glass tubes for 30 min. This time was enough to reach equilibrium and the tubes were then centrifuged.

Metal content in both phases were determined by atomic absorption spectrometry or by complexometric titration with EDTA. The metal in organic phase was stripped from an aliquot by dilute nitric acid and determined in the same way.

RESULTS

The distribution coefficient of cadmium(II) between the organic and aqueous phases was obtained directly as the ratio of the total cadmium concentration in both phases

$$D = \frac{[Cd(II)]_{(org)}}{[Cd(II)]_{(aq)}}. \quad (1)$$

When only DEHPA was present in the initial organic phase, values of D were determined as a function of both the total concentration of DEHPA and pH, for different total concentrations of metal in either chloride or perchlorate media.

The results are plotted in Figs 1 and 2 as $\log D - 2pH$ *vs* total DEHPA concentration for different ionic media.

Treatment of data

Graphical treatment. The extraction of cadmium with cationic extractant (DEHPA) may be described by the following general reaction

$$Cd^{2+} + mHA_{(org)} \rightarrow CdA_2(HA)_{m-2} + 2H^+ \quad (2)$$

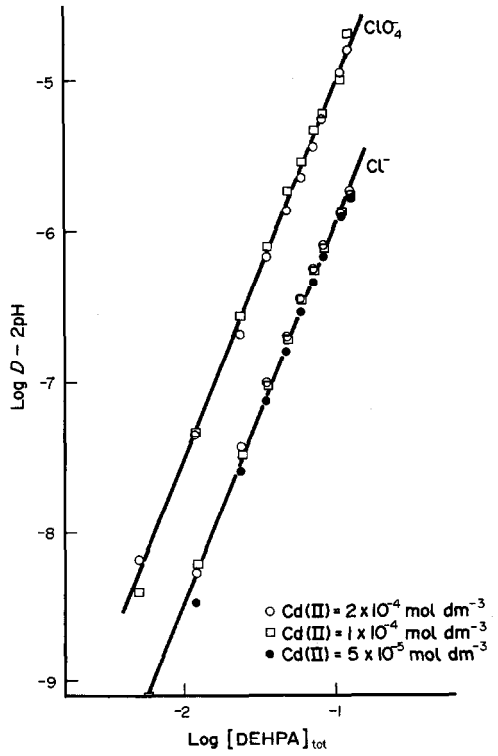

Fig. 1. $\log D - 2pH$ plotted as a function of the total DEHPA concentration in tetradecane at 0.1 mol dm^{-3} ionic strength in chloride and perchlorate media. The full-drawn lines have been calculated using the constants given in Tables 1 and 2.

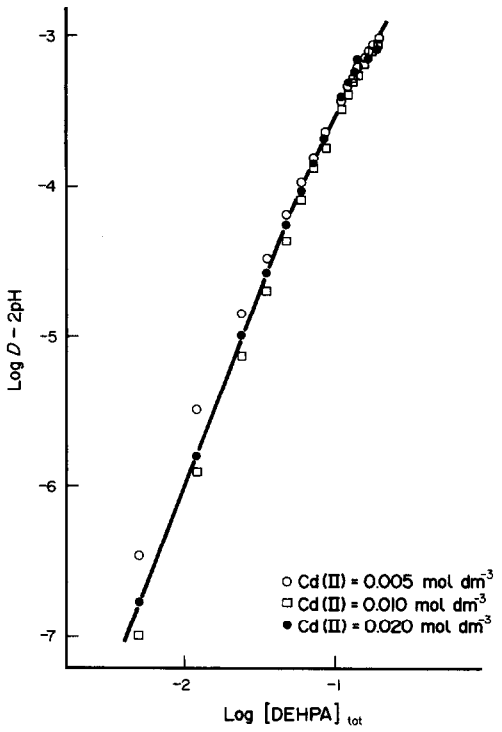

Fig. 2. Log $D-2$pH plotted as a function of the total DEHPA concentration in tetradecane at 1.0 mol dm^{-3} ionic strength in perchlorate medium. The full-drawn lines have been calculated using the constants given in Tables 1 and 2.

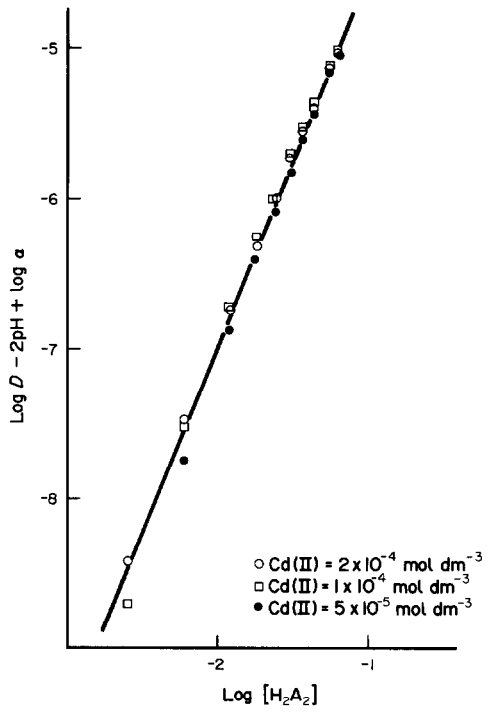

Fig. 3. Log $D-2$pH$+\log\alpha$ plotted as a function of free DEHPA concentration in tetradecane at 0.1 mol dm^{-3} ionic strength in chloride medium. The curve has been calculated from eqn (14) with $m = 4$ or 5, and $L = 0.01$.

where HA refers to di-(2-ethylhexyl) phosphoric acid and β_{1m} is the formation constant, defined by

$$\beta_{1m} = \frac{[CdA_2(HA)_{m-2}]_{(org)}[H^+]^2}{[Cd^{2+}][HA]^m_{(org)}}. \qquad (3)$$

Polynuclear cadmium(II) complexes in the organic phase have been excluded because plots log $D-2$pH$+\log\alpha$ *vs* log $[H_2A_2]$ are independent of cadmium concentration (Figs 3–5).

As a starting model, taking into account the previous findings for similar systems,[3] two species of the type $CdA_2(HA)_2$ and $CdA_2(HA)_3$ may be assumed.

Then the distribution coefficient becomes

$$D = \frac{[CdA_2(HA)_2]_{(org)} + [CdA_2(HA)_3]_{(org)}}{[Cd(II)]_{(aq)}}$$

$$= \frac{[HA]^2_{(org)}\beta_{14}[H^+]^{-2} + [HA]^3_{(org)}\beta_{15}[H^+]^{-2}}{\alpha} \qquad (4)$$

where α is the ratio $[Cd(II)]_{(aq)}/[Cd^{2+}]$.

Since no complexes are formed between cadmium and perchlorate ions, $\alpha = 1$ in this ionic medium.

In chloride solutions α can be written as

$$\alpha = 1 + \beta_1[Cl^-] \qquad (5)$$

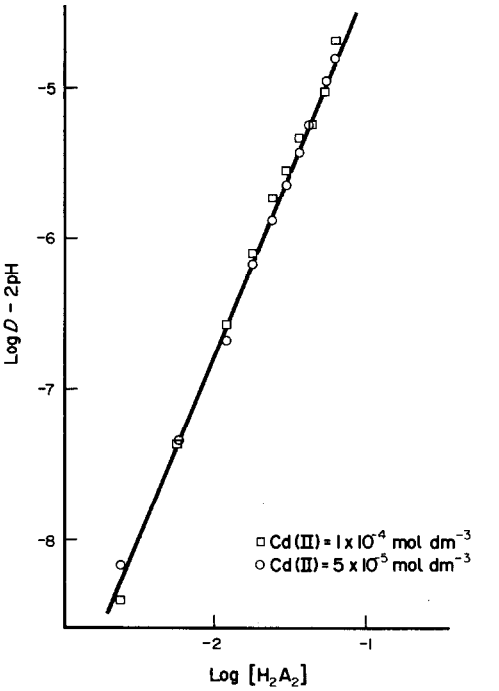

Fig. 4. Log $D-2$pH plotted as a function of free DEHPA concentration in tetradecane at 0.1 mol dm^{-3} ionic strength in perchlorate medium. The curve has been calculated from eqn (14) with $m = 4$ or 5, and $L = 0.01$.

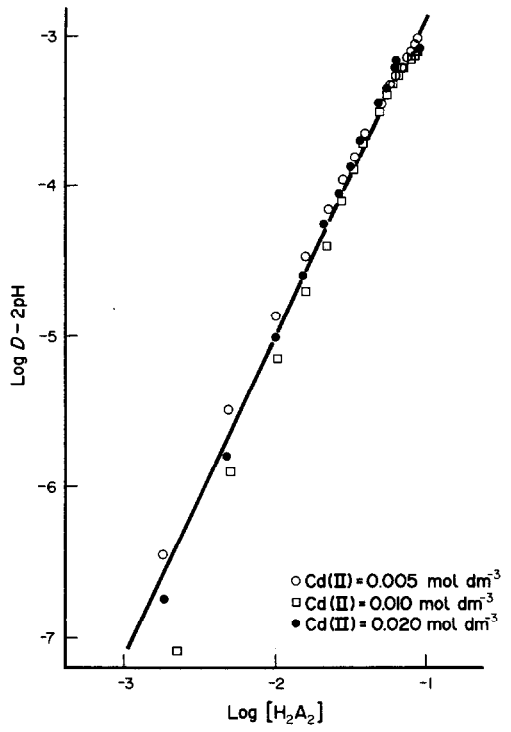

Fig. 5. Log $D-2$pH plotted as a function of free DEHPA concentration in tetradecane at 1.0 mol dm^{-3} ionic strength in perchlorate medium. The curve has been calculated from eqn (14) with $m = 4$ or 5, and $L = 0.2$.

where β_1 is the formation constant of the cadmium–chloride complex. The value of β_1 was taken from ref. 16.

Considering the dimerization equilibrium of DEHPA represented by

$$2HA_{(org)} \rightleftharpoons H_2A_{2(org)} \tag{6}$$

$$K_D = \frac{[H_2A_2]_{(org)}}{[HA]^2_{(org)}}. \tag{7}$$

Equation (4) becomes

$$D\alpha[H^+]^2 = \beta_{14}K_D^{-2}[H_2A_2]^2_{(org)} + \beta_{15}K_D^{-5/2}[H_2A_2]^{5/2}_{(org)} \tag{8}$$

in which D is expressed as a function of the dimer concentration. The K_D value was taken from ref. 17.

$[H_2A_2]_{(org)}$ values may be calculated from the mass action law

$$[HA]_{tot} = 2[H_2A_2]_{(org)} + [H_2A_2]^{1/2}_{(org)}K_D^{-1/2} + m[Cd(II)]_{(org)} + [HA]_{(aq)}. \tag{9}$$

Considering the high value of K_D and the low water solubility of DEHPA, values of $[H_2A_2]_{(org)}$ can be calculated for different m, as

$$[H_2A_2]_{(org)} = \frac{[HA]_{tot}}{2} - \frac{mD}{2(1+D)}[Cd(II)]_{tot}. \tag{10}$$

Two new variables u, Y and a parameter L may be defined as

$$u = \beta_{15}^{2/5}K_D^{-1}[H_2A_2]_{(org)} \tag{11}$$

$$L = \beta_{14}\beta_{15}^{-4/5} \tag{12}$$

$$Y = D\alpha[H^+]^2. \tag{13}$$

Substituting in eqn (8), we get

$$Y = Lu^2 + u^{5/2}. \tag{14}$$

By means of eqn (14), a set of curves of $\log Y = f(\log u)$ were constructed for different L values and were compared to the experimental $(\log D - 2\text{pH} + \log\alpha) = f(\log [H_2A_2]_{(org)})$ curves for perchlorate and chloride media. Thus, by superimposing these curves on the theoretical model function, a position was found by lateral translation along the abscissa, where the experimental curves coincide with one of the theoretical curves.

By reading off the difference

$$\log u - \log [H_2A_2]_{(org)} = 2/5 \log \beta_{15} - \log K_D \tag{15}$$

$\log \beta_{15}$ was determined.

The best fit was found for $L = 0.2$ in perchlorate 1.0 mol dm^{-3} and $L = 0.01$ for perchlorate and chloride 0.1 mol dm^{-3} (Figs 3–5), and β_{14} was then calculated using eqn (12). The results are given in Table 1.

Theoretical functions were also constructed on the assumption of the existence of the species with $m = p$ and $m = p+1$ (p = 2–5) but the fit to the experimental curve was not acceptable.

Numerical treatment. A refinement of the model obtained was performed using the program LETAGROP-DISTR.[1] In this program, the

computer searches for the best set of formation constants that would minimize the error square sum, defined by

$$U = \sum (\log D_{exp} - \log D_{calc})^2 \qquad (16)$$

where D_{exp} is the distribution ratio of cadmium determined experimentally and D_{calc} is the calculated D value obtained by solving the mass balance equations, assuming a certain set of species and constants. The program also calculates the standard deviation $\sigma(\log D)$, defined by

$$\sigma(\log D) = \left[\sum \frac{(\log D_{exp} - \log D_{calc})^2}{N_p}\right]^{1/2}. \qquad (17)$$

The equilibrium constants for the different DEHPA species in the two-phase system used in the present work are given in Table 2. The calculations were performed in two steps. First, the model and the constants β_{14}, β_{15} obtained from graphical treatment were used as starting values and U was then calculated and minimized. Furthermore, several other calculations with LETAGROP-DISTR were carried out, in order to investigate the possibility of finding other sets of complexes which could improve the fit of the experimental data.

The results are given in Table 3. The values of the minimum U and the standard deviation $\sigma(\log D)$ are shown for each set tried. The lowest error squares sum was obtained for the model $CdA_2(HA)_2$ and $CdA_2(HA)_3$ derived graphically in both chloride and perchlorate media.

Finally, the distribution of cadmium in organic phase between the two species $CdA_2(HA)_2$ and $CdA_2(HA)_3$ have been calculated with the program HALTAFALL[22] using the constants given in Table 1.

CONCLUSIONS

The results of the present work, summarized in Table 1, indicate that the extraction of Cd(II) from different media (Cl^-, ClO_4^-) may be explained assuming the formation in the organic phase of two species of composition $CdA_2(HA)_2$ and $CdA_2(HA)_3$. This conclusion may explain the observed fractionary slope (2.4) for both chloride and perchlorate media in the plots $\log D - 2pH + \log \alpha$ *vs* $\log [H_2A_2]$ at low Cd/DEHPA ratio where the predominant species is $CdA_2(HA)_3$ (Figs 3, 4). As the ratio Cd/DEHPA increases, slope tends to approximate to 2 and the predominance of the species $CdA_2(HA)_2$ seems to be evident (Fig. 5).

As seen in Fig. 6, the species $CdA_2(HA)_3$ becomes predominant for Cd/DEHPA < 0.1, while for ratio

K_1 and K_2 are the formation constants of $CdA_2(HA)_2$ and $CdA_2(HA)_3$ defined by

$$K_1 = \frac{[CdA_2(HA)_2]_{org}[H^+]^2}{[Zn^{2+}][H_2A_2]^2_{org}} \quad \text{and} \quad K_2 = \frac{[CdA_2(HA)_3]_{org}[H^+]^2}{[Zn^{2+}][H_2A_2]^{2.5}_{org}}$$

respectively, and β_{14} and β_{15} are the formation constants of reaction (2) calculated from expression $\beta_{14} = K_D^2 K_1$ and $\beta_{15} = K_D^{2.5} K_2$.

[a] Corrected and standardized value per toluene as solvent.[10]

[b] Tentatively acceptable value of the constant reviewed by Kolarik.[21]

[c] Conditional constants.

Cd/DEHPA > 0.1 the predominant species in organic phase is $CdA_2(HA)_2$.

In this sense the reaction model and constants in Table 1 represent a more complete description and in certain ways may unify the results of some other authors.[5,9,10] Finally, although information on extraction constants for this system is scarce, constants quoted in Table 1 seem to be within the broad range of values given in the literature (Table 4).

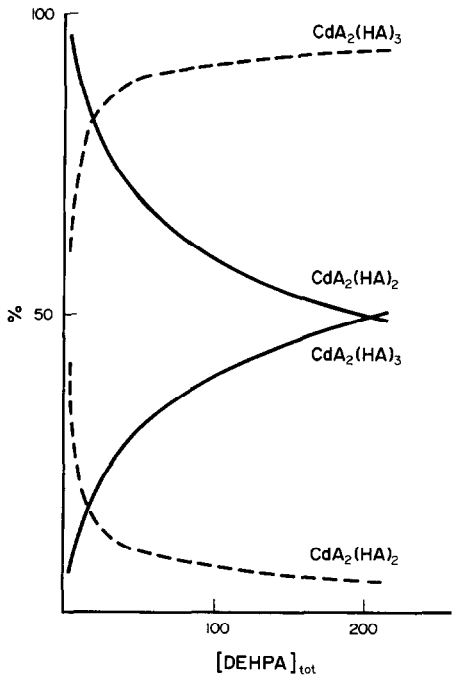

Fig. 6. Fraction of $CdA_2(HA)_2$ and $CdA_2(HA)_3$ plotted as a function of the total DEHPA concentration in organic phase: (----) Cd/DEHPA > 0.1, and (·····) Cd/DEHPA < 0.1.

(*Received* 26 *February* 1986; *accepted* 8 *May* 1986)

Abstract—*N*-Mercaptoethylated derivatives of macroporous polystyrene resins functionalized with diethylenetriamine or pyridylamines have been synthesized. The resin with higher sulfur content reveals better selectivity toward 'soft' metal ions. Concentration of Ag(I) and Hg(II) has been examined by the column containing the present chelating resins.

Chelating polymer resins involving sulfur donor atoms have attracted much attention from the analytical and environmental points of view because of their high selectivity toward heavy metal ions.[1] Recently we have synthesized the chelating resins in which various amines are immobilized onto crosslinked polystyrene beads.[2,3] The aminated resins were found to be convenient substrates for the preparation of multidentate *N*-derivatives particularly when the ligand contains the primary amino groups.[4,5] *N*-Mercaptoethylated derivatives of poly(ethylene-grafted-styrene) have been prepared and the complexation properties examined.[1a] This paper describes the mercaptoethylation of the polymer-bound diethylenetiramine (dien) or pyridylamines where amino and imino nitrogens are available for the *N*-substitution, respectively. The adsorption characteristics of the resins for heavy metal ions and the column concentration of Ag(I) and Hg(II) have been examined.

EXPERIMENTAL

Materials

Macroporous styrene–10%-divinylbenzene copolymer beads (60–100 mesh, Mitsubishi Chemical Co.) were used as the polymer matrix. The surface area and the mean pore radius of the resin are 7.5 $m^2 g^{-1}$ and 720 Å, respectively. The beads were chloromethylated (Cl: 17.5%) followed by functionalization with dien or pyridylamines as described in the literature.[2–4]

Resin **1**. Resin beads containing dien (17 g, 0.05 mol of dien) were swollen in toluene (60 cm^3) and heated to 60°C. While stirring, ethylenesulfide (12.5 g, 0.21 mol) in toluene (40 cm^3) were added over 20 min. A few drops of *n*-butanethiol were added to each toluene solution in order to avoid the polymerization of ethylenesulfide.[6] The reaction mixture was heated at 120°C for 6 h, then filtered. The resin beads were washed successively with toluene, ethanol and diethyl ether and dried *in vacuo* at 50°C. Yield: 27.8 g.

Resins **2** *and* **3**. These were obtained using a similar procedure with much longer reaction time (30 h) to that for the resin **1** using the resins functionalized with *N*-[2-(2-pyridyl)ethyl]ethylenediamine and 2-pyridylmethylamine, respectively.

Equilibrium adsorption capacity

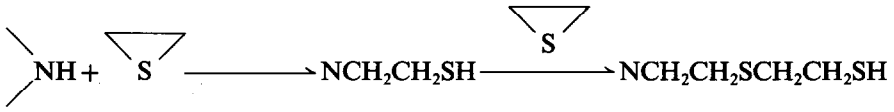
Typically, 100 mg of dry resin was added to 100 cm^3 of metal ion solution of various pH and the mixture was shaken at room temperature. After equilibrium was attained, the concentration of the remaining metal ion in the supernatant was analyzed by atomic absorption spectroscopy.

Column breakthrough experiment

Resin **1** was swollen with water and poured onto a glass column. Then about 500 ppm of metal ion

* Author to whom correspondence should be addressed.

solution [Ag(I) or Hg(II)] of appropriate pH were passed through the column continuously at a rate of 1.5 $cm^3 min^{-1}$. The effluent was fractionated into 15-cm^3 portions and the amount of metal ion was determined. The adsorbed Ag(I) and Hg(II) were released from the resin by elution with 3% thiourea in 2 mol dm^{-3} of sulfuric acid and 2 mol dm^{-3} of hydrochloric acid, respectively.



Measurements

Metal ion concentration was determined with a Shimadzu atomic absorption/flame photometer model AA-610S. The analysis of Hg(II) was carried out with a Hiranuma HG-1 flameless atomic absorption apparatus.

RESULTS AND DISCUSSION

Preparation and characterization of the resins

The analytical data of the resins are summarized in Table 1. Total sulfur content in resin **1** is approximately equal to that of the calculated value assuming that each of the dien moiety has reacted with 4 moles of ethylenesulfide. The parent dien-bound resin contains free amino groups since the ligand is linked to polymer uniquely through the imino nitrogen.[3,4] Therefore two sets of the amino groups in each dien unit can be available for the *N*-substitution. The iodometric titration[1b] demonstrated that resin **1** contains *ca* 3.7 mmol of thiol (—SH) group per gram of the resin which corresponds to approximately 60% of the total sulfur in the resin. This indicates that some of the sulfur atoms are not present in the form of a thiol group probably because successive reactions took place at the thiol terminal in the resin as shown below.

A similar procedure for the preparation of resin **1** was applied to the resins functionalized with pyridylamines in which imino nitrogens are available for the *N*-substitution. The lower sulfur content in the resulting resins may be attributed to the unfavourable steric environment around the imino nitrogens. It has been pointed out that the yields of this type of reactions are affected by the presence of bulky substituents on the nitrogen atom.[7] Imino groups in the pyridylamine-bound resins locate between bulky polymer matrix and pyridyl group, and hence access of ethylenesulfide would be restricted.

Equilibrium adsorption capacity

Figures 1 and 2 show the equilibrium adsorption capacity *vs* pH profiles for resins **1** and **2**. Resin **1** does not show clear pH dependence on the adsorption capacity in the pH range 1–8 irrespective of the metal ions examined. The resin prefers to associate with heavy metal ions such as Ag(I), Hg(II) and Mo(VI) while it has lower affinity for the common

Table 1. Analytical data of the chelating resins

Resin	Parent resin	N content %N (mmol g^{-1})	S content %S (mmol g^{-1})
1	PS-CH_2-N($CH_2CH_2NH_2$)$_2$	6.4 (4.6)	21.7 (6.8)
2	PS-CH_2-$NHCH_2CH_2NHCH_2CH_2$-(pyridyl)	7.4 (5.3)	5.4 (1.7)
3	PS-CH_2NHCH_2-(pyridyl)	7.2 (5.1)	3.0 (0.9)

PS = polystyrene resin.

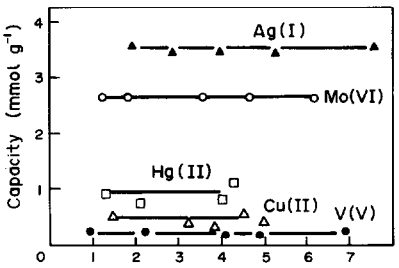


Fig. 1. Equilibrium adsorption capacity of resin **1** as a function of pH.

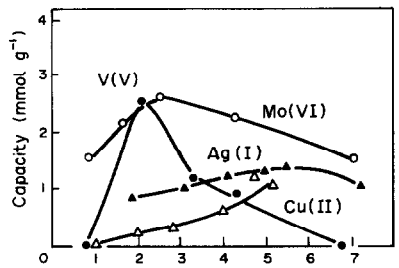

Fig. 2. Equilibrium adsorption capacity of resin **2** as a function of pH.

metal ions including alkaline, alkaline earth ions, Ni(II), Co(II), Fe(II) and Zn(II). The capacity for Ag(I) is nearly equal to the thiol content estimated by iodometry indicating that each thiol group coordinates to Ag(I) in a 1 : 1 molar ratio. The adsorbed Ag(I) and Hg(II) were released almost quantitatively from the resin by elution with acidic thiourea solution. The resin showed reproducible capacity upon several adsorption and regeneration cycles. On the contrary, when alkaline solution was employed to release metal ions, as in the case of Mo(VI), gradual oxidation of thiol group to disulfide took place.[8] However the resin capacity was restored upon treatment with a reducing agent such as $NaHSO_3$ solution.

Resin **2** whose sulfur/nitrogen ratio is much lower than resin **1** showed rather distinct pH dependence for the adsorption capacity. Lowering of sulfur content coincides with the decrease in Ag(I) capacity and increase in Cu(II) capacity. It seems that the adsorption characteristics of the resin **2** are much like the parent aminated resin due to low reaction conversion.

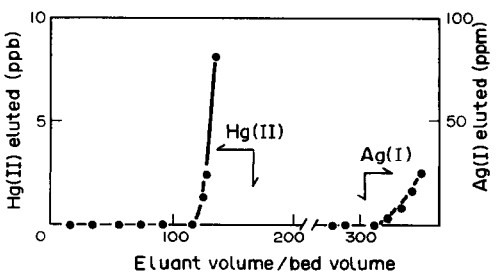

Fig. 3. Column adsorption of Hg(II) or Ag(I) using resin **1**. Breakthrough profiles were obtained in the separated experiments.

Column adsorption of Hg(II) and Ag(I)

Resin **1** has been applied to the adsorption of Hg(II) and Ag(I) by column operation since the adsorption rates for these metal ions are sufficiently rapid, i.e. equilibrium was attained within 30 min under batchwise procedure. Macroporous resins have numerous pores inside the beads which allow facile diffusion of metal ions into the polymer matrix.

When the Hg(II) solution (500 ppm, pH = 3.5) containing a seawater level of sodium chloride was passed through the column of resin **1** (⌀1.3 × 7.5 cm, 5 g), no detectable amount of Hg(II) was found in the eluate until the breakthrough point (Fig. 3). The amount of Hg(II) adsorbed at the breakthrough point was 0.54 mmol per gram of resin. A similar procedure using the column (⌀1.0 × 4.9 cm, 2 g) was applied to the solution containing 500 ppm of Ag(I) (pH = 4.1). About 300 bed volumes of the feed solution could be passed through the column without any leakage of Ag(I) into the effluent. The capacity at the breakthrough point was found to be 2.5 mmol per gram of resin. The adsorbed ions were recovered in a concentrated form on elution with acidic thiourea solution and the regenerated column could be used repeatedly.

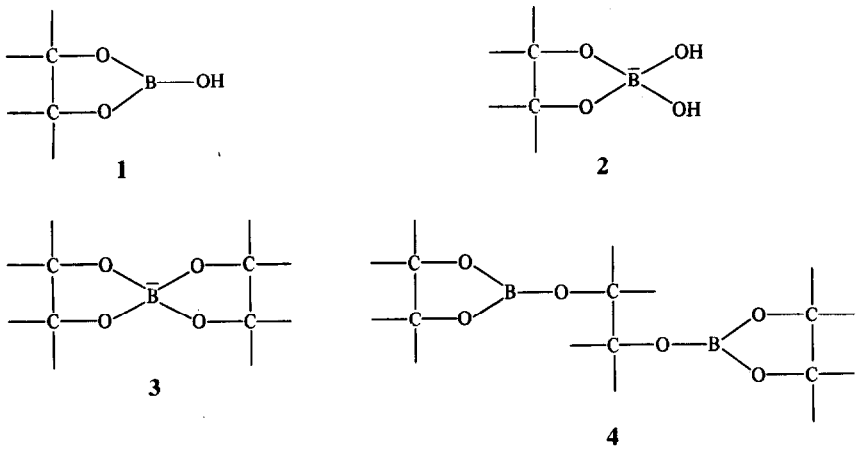
(*Received* 3 *March* 1986; *accepted* 8 *May* 1986)

Abstract—A new synthesis of bis-catechol spiroborate and its analogs are described. Not only five- but also six- and seven-membered spiroborates are obtained. The reaction mechanisms are also discussed.

The reaction of boric acid or borate salts with diols has directed chemists' attention to examine stereochemical and structural problems of the diols, and to evaluate the equilibrium constants for a number of diol–boric acid reactions.[1–4] As Scheme I shows, the reaction system frequently involves complicated equilibria between several types of compounds such as the cyclic ester (**1**) and ionized, strongly acidic complexes in which one boron atom is associated with one (**2**) or two (**3**) molecules of the diol.[1,3,5,6] A type of compound (**4**) can also be formed directly from the diol and boric acid.[7] In general, the use of excess amounts of boric acid gave **1** and **2**, whereas the use of excess amounts of diol gave **3** and **4**, predominantly.[7] When boric acid and a diol are used in equimolecular amounts under alkaline conditions, very often **2** can be isolated in crystalline form from water,[7] except for pinacol as a diol which gives a type of compound **3**.[8]



Böeseken[1] and Meulenhoff[9] synthesized bis-catechol spiroborate complexes such as **6**, **7a** and **7b** from the reaction of catechol (**5a**) with potassium borate, and the reaction of **5a** with boric acid and aniline or pyridine in molar ratio of 2 : 1, and 2 : 1 : 1, respectively (Scheme II). However, some of catechols such as pyrogallol (**5b**) and 2,3-dihydroxybenzaldehyde (**5d**) cannot give compounds of type **7** by Meulenhoff's method, and some of the compounds such as 2,2′-dihydroxydiphenyl are insoluble in water. Since there are no reports on preparation of such bis-catechol spiroborate complexes using amine borane, we report here a new method for synthesizing bis-catechol spiroborate (**9a**) and its analogs in organic solvents using 2-amino-4-methylpyridine borane (Scheme III).

EXPERIMENTAL

Melting points were determined by using a Yamato Scientific stirred liquid apparatus and are uncorrected. PMR spectra were run on a Varian EM-90 (90 MHz) spectrometer with $(CD_3)_2SO$ as the solvent and $(CH_3)_4Si$ as the internal standard. Elementary analyses (C, H, N) of all compounds described here were performed on a Perkin–Elmer 240B instrument.

Bis-catechol spiroborate (**9a**)—A solution of 2-amino-4-methylpyridine borane (**8**, 0.6 g, 4.9 mmol) in 10 cm^3 of triethyl orthoformate was added to a solution of catechol (0.5 g, 4.54 mmol) in 10 cm^3 of triethyl orthoformate with stirring. After 2 min, precipitates were filtered off, and washed with ether to give a pure **9a** in 73% yield, m.p. 207–209°C (decomp.). Found: C, 64.4; H, 5.1; N, 8.3%. Calc.

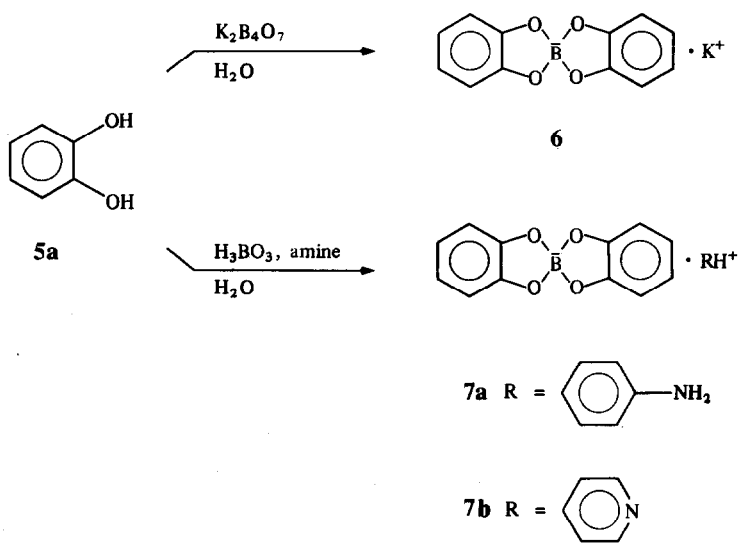
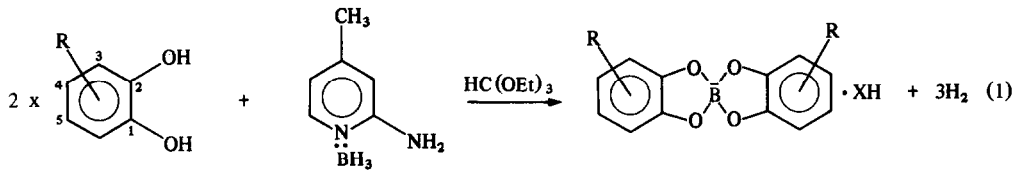


Scheme I.

for $C_{18}H_{17}BN_2O_4$: C, 64.3; H, 5.1; N, 8.3%. PMR: δ 2.30 (3H, s, CH_3), 6.47 (8H, s, benzene), 6.67 (1H, d, 5-H of pyridine ring), 6.70 (1H, s, 3-H of pyridine ring), 7.73 (3H, b, NH_2 and $\overset{+}{N}H$), 7.78 (1H, d, 6-H of pyridine ring).



Bis-pyrogallol spiroborate (**9b**)—A solution of **8** (0.4 g, 3.28 mmol) in 10 cm^3 of triethyl orthoformate was added to a solution of pyrogallol (0.5 g, 3.96 mmol) in 10 cm^3 of triethyl orthoformate with stirring. After 1 min, precipitates were filtered off and washed with chloroform to give pure **9b** in 89% yield, m.p. 84–85°C(decomp.). Found: C, 52.2; H, 4.1; N, 6.9%. Calc. for $C_{18}H_{17}BN_2O_6 \cdot CHCl_3$: C, 51.9; H, 4.1; N, 6.6%. PMR: δ 2.27 (3H, s, CH_3), 6.00–6.70 (8H, m, benzene and 3(5)-H of pyridine ring), 7.40 (5H, b, OH, NH_2 and $\overset{+}{N}H$), 7.78 (1H, d, 6-H of pyridine ring).

Bis(3,4-*dihydroxytoluene*) *spiroborate* (**9c**)—A solution of **8** (0.5 g, 4.10 mmol) in 10 cm^3 of triethyl orthoformate was added to a solution of 3,4-dihydroxytoluene (0.5 g, 4.03 mmol) in 10 cm^3 of triethyl orthoformate with stirring. After 2 min, precipitates were filtered off and washed with carbon tetrachloride to give pure **9c** in 55% yield, m.p. 209–211°C(decomp.). Found: C, 66.1; H, 5.9; N, 7.8%. Calc. for $C_{20}H_{21}BN_2O_4$: C, 66.0; H, 5.8; N, 7.7%. PMR: δ 2.15 (6H, s, CH_3 of benzene ring), 2.30 (3H, s, CH_3 of pyridine ring), 6.28 (6H, s, benzene), 6.67 (1H, d, 5-H of pyridine ring), 6.70 (1H, s, 3-H of pyridine ring), 7.70 (3H, b, NH_2 and $\overset{+}{N}H$), 7.77 (1H, d, 6-H of pyridine ring).

Bis(2,3-*dihydroxybenzaldehyde*) *spiroborate* (**9d**)—To a solution of 2,3-dihydroxybenzaldehyde (1 g, 7.24 mmol) in 50 cm^3 of ether was added trimethyl borate (0.4 g, 3.85 mmol) and the mixture was stirred for 3 min. A solution of 2-amino-4-methylpyridine (0.4 g, 3.70 mmol) in 10 cm^3 ether was added to the above solution with stirring. After

Bis(2,3-*dihydroxybenzylalcohol*) *spiroborate* (**9e**)—Amine borane **8** (2 g, 16.4 mmol) was gradually added to a solution of 2,3-dihydroxybenzaldehyde (2 g, 14.5 mmol) in 50 cm^3 of chloroform with stirring. The mixture was stirred at room temperature overnight. Precipitates were filtered off, and dried to give pure **9e** in 83% yield, m.p. 111–112°C(decomp.). Found: C, 59.6; H, 5.3; N, 6.9%. Calc. for $C_{20}H_{21}BN_2O_6 \cdot 1/3H_2O$: C, 59.7; H, 5.4; N, 7.0%. PMR: δ 2.33 (3H, s, CH_3), 4.43 (2H, s, CH_2), 5.40–8.40 (5H, b, OH, NH_2 and $\overset{+}{N}H$), 6.30–6.80 (8H, m, benzene and 3(5)-H of pyridine ring), 7.77 (1H, d, 6-H of pyridine ring).

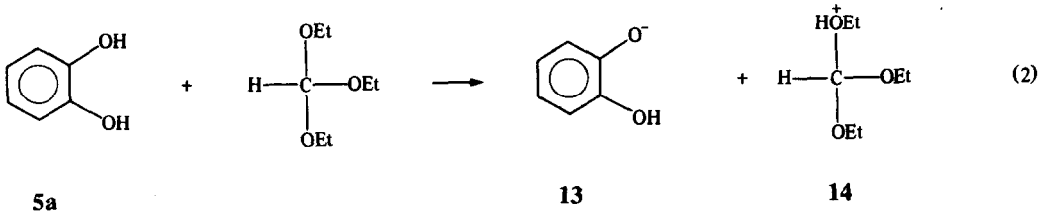
Bis(2,3-*dihydroxynaphthalene*) *spiroborate* (**10**)—A solution of **8** (0.2 g, 1.85 mmol) in 10 cm^3 of triethyl orthoformate was added to a solution of 2,3-dihydroxynaphthalene (0.2 g, 1.25 mmol) in 10 cm^3 of triethyl orthoformate with stirring. After 40 min, precipitates were filtered off and washed with chloroform to give pure **10** in 78% yield, m.p. 248–250°C(decomp.). Found: C, 69.0, 5.1; N, 6.2%. Calc. for $C_{26}H_{21}BN_2O_4 \cdot H_2O$: C, 68.7; H, 5.1; N, 6.2%. PMR: δ 2.28 (3H, s, CH_3), 6.60–8.00 (18H, m, all protons except for methyl protons).

Bis(*salicylic acid*) *spiroborate* (**11a**)—A solution of **8** (0.9 g, 7.4 mmol) in 36 cm^3 of triethyl orthoformate was added to a solution of salicylic acid (1.5 g, 7.4 mmol) in 36 cm^3 of triethyl orthoformate with stirring. After 10 min, precipitates were filtered off and washed with carbon tetrachloride to give

pure **11a** in 36% yield, m.p. 176–178°C(decomp.). Found: C, 60.4; H, 4.2; N, 6.9%. Calc. for $C_{20}H_{17}BN_2O_6 \cdot 1/3H_2O$: C, 60.3; H, 4.5; N, 7.0%. PMR: δ 2.30 (3H, s, CH_3), 6.70 (1H, d, 5-H of pyridine ring), 6.73 (1H, s, 3-H of pyridine ring), 6.80 (2H, d, 3-H of benzene ring), 6.87 (2H, t, 5-H of benzene ring), 7.43 (2H, dt, 4-H of benzene ring), 7.77 (2H, b, NH_2), 7.80 (2H, dd, 6-H of benzene ring), 7.80 (1H, d, 6-H of pyridine ring), 13.00 (1H, b, $\overset{+}{N}H$).

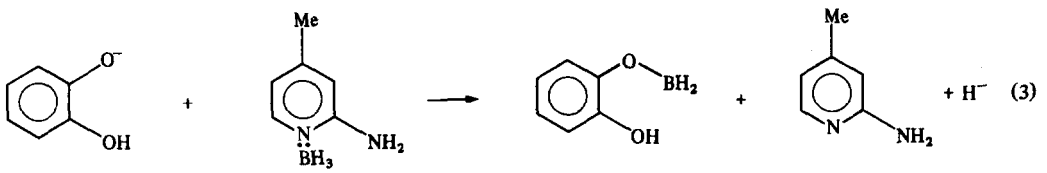
Bis(2,6-dihydroxybenzoic acid) spiroborate (**11b**)—To a solution of **8** (0.2 g, 1.64 mmol) in 10 cm^3 of triethyl orthoformate was added 2,6-dihydroxybenzoic acid (0.25 g, 1.62 mmol) with stirring. After 30 min, precipitates were filtered off and washed with carbon tetrachloride to give pure **11b** in 70% yield, m.p. 239–240°C(decomp.). Found: C, 54.8; H, 4.0; N, 6.4%. Calc. for $C_{20}H_{17}BN_2O_8 \cdot 3/4H_2O$: C, 54.9; H, 4.3; N, 6.4%. PMR: δ 2.30 (3H, s, CH_3), 6.28 (2H, d, 3-H of benzene ring), 6.32 (2H, d, 5-H of benzene ring), 6.70 (1H, d, 5-H of pyridine ring), 6.73 (1H, d, 3-H of pyridine ring), 7.30 (2H, t, 4-H of benzene ring), 7.77 (2H, b, NH_2), 7.80 (1H, d, 6-H of pyridine ring), 11.67 (2H, s, OH), 13.00 (1H, b, $\overset{+}{N}H$).

Bis(2,2′-dihydroxydiphenyl) spiroborate (**12**)—A solution of **8** (0.5 g, 4.1 mmol) in 10 cm^3 of triethyl orthoformate was added to a solution of 2,2′-dihydroxydiphenyl (0.5 g, 2.69 mmol) in 10 cm^3 of triethyl orthoformate with stirring. After 3 min, precipitates were filtered off, and washed with carbon tetrachloride to give pure **12** in 92% yield, m.p. 246–248°C(decomp.). Found: C, 73.7; H, 5.2; N, 5.9%. Calc. for $C_{30}H_{25}BN_2O_4$: C, 73.8; H, 5.2; N, 5.7%. PMR: δ 2.23 (3H, s, CH_3), 6.60 (1H, d, 5-H of pyridine ring), 6.63 (1H, s, 3-H of pyridine ring), 6.77–7.43 (16H, m, benzene), 7.60 (3H, b, NH_2 and $\overset{+}{N}H$), 7.67 (1H, d, 6-H of pyridine ring).



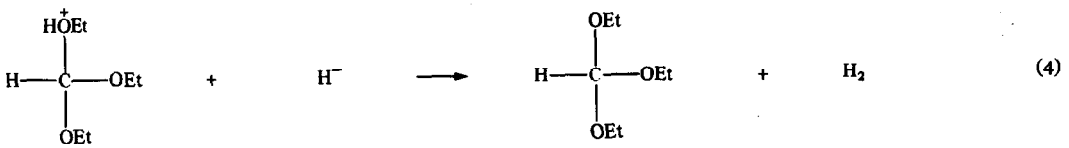
RESULTS AND DISCUSSION

When 2-amino-4-methylpyridine borane (**8**) was reacted with **5a** for a few minutes in chloroform in the presence of triethyl orthoformate, **9a** was precipitated. The use of excess amounts of the amine borane in this reaction gave **9a** in a better yield. Since the oxygen atoms of **9a** originate in **5a**, types of compounds **1** and **2** which are often associated with **3** in boric acid–diol equilibria can never be formed. The compound **9a** was entirely the same one as that obtained by Meulenhoff's method. Similarly, compounds **9b**, **9c** and bis(2,3-dihydroxynaphthalene) spiroborate (**10**) were obtained from **5b**, **5c** and 2,3-dihydroxynaphthalene, respectively. It is worth noting that these reactions were subjected to the presence of the orthoester. Namely, when **5a** was treated with **8** in chloroform for 1 h, no reaction occurred, however, when triethyl orthoformate was added to the above mixed solution (or was used as a solvent), **9a** was soon precipitated. These results indicate that the initiation of the reaction is due to taking up the phenolic proton of **5a** by the orthoester. We propose the reaction mechanisms in Scheme IV. Since ethanol was not detected in the reaction by mass analyses, the role of the orthoester might be that of the Lewis base as shown in eqn (2). Although solvents such as ether, acetal and tetrahydrofuran (THF) might be thought of as the Lewis bases in these reactions, they did not afford these spirane types of complexes. This fact indicates that these solvents cannot take up a proton from the weak acid to produce a catechol anion **13**. The anion **13** would react with the amine borane **8** to give **15** which readily cyclizes to catechol borane (**16**) with liberation of hydrogen gas. The compound **16** would react with **5a** to yield a spirane type acid (**17**) which can form **9a** with 2-amino-4-methylpyridine. The overall reaction is summarized in eqn (1). Since it is known that *o*-aminophenol in place of **5a** readily affords **18**[10] by the reaction with **16** which was readily available through the rapid reaction of **5a** with borane in THF,[11] eqn (6) would be reasonable.



Although an orthoester was essential for eqn (1), there was one exception where **5d** was reacted with **8** in chloroform to give a reduced spiroborate (**9e**) as shown in Scheme V. The initial step of the reaction would be in the reduction of the aldehyde group which takes up a proton from the hydroxy group and a hydrogen anion from **8** to afford **19**. The reduced compound **19** would readily form compound **20**, then, **9e** was obtained through reactions [eqns (9)–(13)] like those described in Scheme IV. Compound **9d** was obtained by the reaction of **5d** with trimethyl borate and 2-amino-4-methylpyridine.

Our method was used to synthesize other spiroborates (**10**, **11a**, **11b** and **12**) from the corresponding diols. The structures of all compounds obtained here were determined by proton magnetic resonance (PMR), but the optical resolution was not done for the racemic spiroborates. Isolation of **12** is specially interesting because a boron-assisted synthesis of the macrocyclic host molecules containing convergent hydroxy groups (**24**) has recently been reported where the key intermediates were assumed to be as in structure **23** but they had not been isolated (Scheme VI).[12]



Recently, R(+)- and S(−)-1,1′-bi-2-naphthol have been recognized to be effective constituents of a chiral hydride reagent exemplified by Noyori's

BINAL-H,[13] and a new microbial resolution of the racemic binaphthols has been reported[14] instead of a classical tedious resolution method.[15] On the other hand, since there is a possibility of producing a spiroborate (**25**) as a type of R(+)·B·R(+) or S(−)·B·S(−) complex by the reaction of **8** with the corresponding racemic binaphthols, we attempted to isolate **25**, however, the 2-amino-4-methylpyridinium salt of the binaphthol was obtained instead. This result indicates that the dihedral angle of the diol and the distance between the two oxygen atoms of the binaphthol in the solvent are outside the requirements for the formation of the spiroborate, namely 0° to 60° for the angle and 2.2 to 2.5 Å for the distance.[16]

In conclusion, 2-amino-4-methylpyridine borane (**8**) which is stable and readily prepared in aqueous media[17] was found to be a useful alternative to boric acid to produce spiroborate complexes in organic solvents without yielding types of compounds **1**, **2** and **4**.

THE PAIRING PRINCIPLE IN TENSOR SURFACE HARMONIC THEORY: DEFINITION OF A GENERAL CLASS OF *N*-ATOM *POLAR DELTAHEDRA* WITH *N* SKELETAL ELECTRON PAIRS

R. L. JOHNSTON and D. M. P. MINGOS*

Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford OX1 3QR, U.K.

(*Received* 20 *March* 1986; *accepted* 8 *May* 1986)

Abstract—A general group theoretical criterion, based on the Pairing Principle in Stone's Tensor Surface Harmonic Theory, is presented for *polar deltahedra* with $3p+1$ ($p = 1, 2, 3, \ldots, X$) atoms and belonging to the C_3, C_{3v}, T and T_d point groups. These clusters are characterised by N ($N = 3p+1$) skeletal bonding molecular orbitals and examples of such clusters with $N = 4$, 7 and 10 atoms are discussed. This treatment follows on from the group theoretical analysis presented by Fowler, but the *polar deltahedral* generalisation follows from a group theoretical restriction not previously recognised.

In a recent paper Fowler[1] described a theoretical analysis for high nuclearity deltahedral boranes B_NH_N ($N > 12$) and confirmed Lipscomb's[2] earlier conclusion that a certain number of these molecules should be characterised by N rather than the usual $N+1$ skeletal electron pairs.[3] Fowler showed that these unconventional deltahedra did not represent accidental departures from the $N+1$ skeletal electron pair rule,[3] but formed the basis of a more general pattern. Within the framework of Stone's Tensor Surface Harmonic Theory[4] and utilising some elegant group theoretical methods developed by Ceulemans[5] and Quinn,[6] Fowler[1] concluded that the unconventional electron counts arose because the polyhedra belonged to the C_3, C_{3v}, T and T_d point groups and discussed some specific examples with 16, 19 and 22 boron atoms.

It is the purpose of this paper to demonstrate that the examples discussed by Fowler[1] form part of a wider pattern arising from a further group theoretical restriction which applies to this specific class of deltahedron. Furthermore, the conclusions we have arrived at are corroborated by some structurally characterised examples of lower nuclearity metallaboranes.[7]

Fowler[1] has concluded that a group theoretical criterion for symmetry-induced departures from the $N+1$ skeletal electron pair rule arises for clusters where the irreducible representations spanned by the L^π and $\bar{L}^\pi$ tangential molecular orbitals contain an odd number of self-conjugate E representations. He showed that this arises for *closo* clusters in just two cases:

(1) T or T_d clusters with an odd number of sets of four equivalent cage atoms.
(2) C_m or C_{mv} ($m \geqslant 3$) clusters with an odd number of cage atoms on the C_m axis.

It is not, however, geometrically feasible to have a *closo*-deltahedron with an odd number of cage atoms on the principal rotation axis C_m with $m > 3$, because square, pentagonal and higher faces would be generated. For $m > 3$ the polyhedra are actually *nido* and fit the rule with their well-known count of $(N+2)$ skeletal electron pairs. Only when $m = 3$ does the principal axis also pass through a triangular face and we define such polyhedra as *polar deltahedra* (see Fig. 1 for examples). If the principal axis bisects a deltahedral edge the point group is restricted to C_{2v}, C_2 or C_s and the L^π and $\bar{L}^\pi$ orbitals do not contain E representations so that the group theoretical criterion arising from the pairing principle cannot be rigorously applied.

In a C_3 or C_{3v} deltahedron there are p sets (layers) of symmetry-related atoms lying in planes perpendicular to the C_3 axis, consequently the total

* Author to whom correspondence should be addressed.

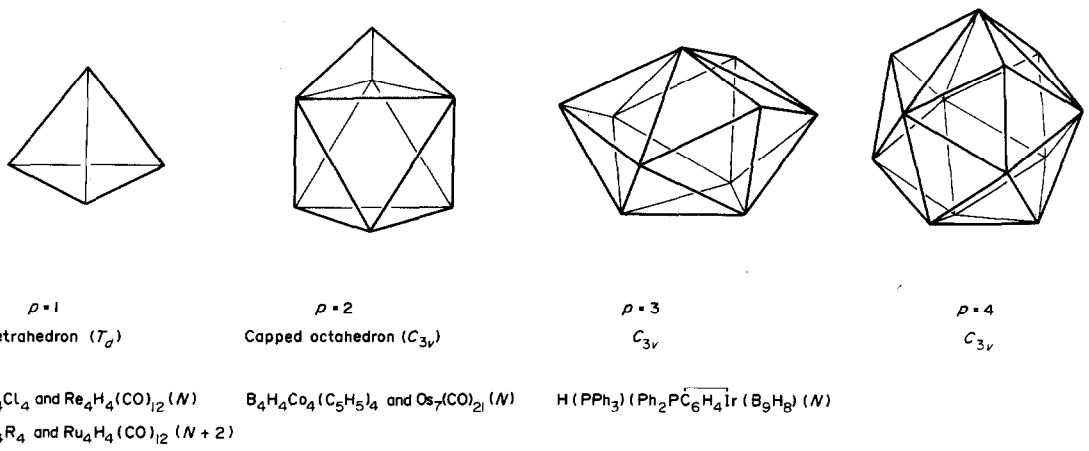

Fig. 1. Examples of polar deltahedral clusters with either N or $N+2$ skeletal bonding molecular orbitals.

number of atoms in *polar deltahedra* must be $3p+1$. The higher symmetry T or T_d possibilities arise from the occurrence of three additional threefold symmetry axes, but those deltahedra with anomalous electron pairs (N or $N+2$ skeletal electron pairs) also possess $3p+1$ atoms (one atom on each of these axes) and so may be classified as *polar deltahedra*. There is therefore a general class of *polar deltahedra* with $N = 3p+1$ atoms which are characterised by N bonding skeletal molecular orbitals.

Fowler[1] has discussed some examples of hypothetical boranes, with 16 ($p = 5$, T_d), 19 ($p = 6$, C_{3v}) and 22 ($p = 7$, T_d) atoms, which have N bonding skeletal molecular orbitals in agreement with his analysis. In Fig. 1 we illustrate examples of lower nuclearity *polar deltahedra* with $3p+1$ atoms which emerge as a result of our more general treatment. The occurrence of N (or $N+2$) electron pairs in the tetrahedron ($p = 1$) has been discussed by Fowler,[1] the capped octahedron ($p = 2$) is not known for B_NH_N but the *isolobal* analogue $[Co_3(\eta^5\text{-}C_5H_5)_3B_4H_4]$, studied by Grimes,[8] has the predicted geometry. Similarly for 10-atom clusters ($p = 3$) metalloboranes and metallocarboranes with 10 skeletal electron pairs have been reported by Greenwood and Kennedy[9] and described by Baker[10] as *hyper-closo*. For $p = 4$ the C_{3v} geometry has not been observed to date but molecular orbital calculations indicate the likelihood of a C_{3v} cluster with 13 skeletal electron pairs[11] (Lipscomb's calculations[2] on an alternative C_{2v} structure predict the usual ($N+1 = 14$) skeletal electron pair count).

This group theoretically based rule for *polar deltahedra* can be derived simply for axial point groups in the following manner. For each of the p triangles of symmetry-related atoms, the L^σ orbitals give rise to A_1 and E irreducible representations. The L^σ orbitals of a cluster belonging to an axial point group can be obtained by combining the L^σ orbitals of its constituent orbits (i.e. sets of symmetry-related atoms).[6] Quinn has also shown that the π_θ components of L^π and $\bar{L}^\pi$ can be derived by using the L^σ orbitals as generator functions with a basis set of p_θ^π orbitals rather than radial orbitals. In group theoretical terms this corresponds to the direct product:

$$\Gamma_{\pi_\theta} = \Gamma_\sigma \otimes \Gamma_z.$$

The π_φ components are generated by taking the π_θ components and rotating the p orbitals on each atom by 90° (in the same sense) about a radial vector. This process corresponds to the action of the parity inversion operator. This operator ($\hat{\varepsilon}$) belongs to the irreducible representation (Γ_u°) which is antisymmetric with respect to all improper rotations (including inversion and reflections) of the point group. In axial point groups the symmetry of the parity inversion operator is given by the direct product

$$\Gamma_u^\circ = \Gamma_z \otimes \Gamma_{R_z}.$$

Thus the component is obtained from the L orbitals by taking the following direct product:

$$\Gamma_{\pi_\varphi} = \{\Gamma_\sigma \otimes \Gamma_z\} \otimes \{\Gamma_z \otimes \Gamma_{R_z}\} = \Gamma_\sigma \otimes \Gamma_{R_z}$$

(in terms of Stone's Tensor Surface Harmonic Theory this is not surprising since the component p^φ atomic orbitals are defined such that their positive lobes follow the direction of R_z). A summary of this information is shown below

$$\begin{array}{ccc} \{\Gamma_\sigma\}L^\sigma & \xrightarrow{\otimes\Gamma_z} & (L^\pi/\bar{L}^\pi)_\theta\{\Gamma_{\pi_\theta}\} \\ & \searrow^{\otimes\Gamma_{R_z}} & \downarrow \hat{\varepsilon} \otimes \Gamma_u^\circ \\ & & (\bar{L}^\pi/L^\pi)_\varphi\{\Gamma_{\pi_\varphi}\}. \end{array}$$

In the C_{3v} point group $\Gamma_z = A_1$ and $\Gamma_{R_z} = A_2$, for axial groups in general Γ_z and Γ_{R_z} are one-dimensional. Since $E \otimes A_1$ or $E \otimes A_2 = E$ then for every E function in L^σ there will be one in L^π and one in $\bar{L}^\pi$. The total number of E representations in the $L^\pi/\bar{L}^\pi$ orbitals is therefore even ($2p$). When considering polyhedra with vertices lying on the C_3 axis the above method for generating $L^\pi/\bar{L}^\pi$ orbitals does not work because at the poles of a sphere an atomic p_z orbital has pure radial rather than tangential orientation (at any other position it can be resolved into radial and tangential components). To get round this problem it is merely necessary to work out the π orbitals for the non-polar structure and add the orbitals of the polar atoms. For one polar atom in C_{3v} symmetry the p^π atomic orbitals (p_x and p_y) transform as E so the *polar deltahedron* possesses in total an odd number ($2p+1$) of E representations in the $L^\pi/\bar{L}^\pi$ orbitals. As Fowler has pointed out[1] this results in an equal number (p) of bonding (L^π) and antibonding ($\bar{L}^\pi$) E functions and one self-conjugate ($L^\pi/\bar{L}^\pi$) E set which is roughly non-bonding. Occupation of these latter orbitals would lead to a cluster with ($N+2$) skeletal electron pairs but usually they are unoccupied and an N skeletal electron pair count is observed.

The arguments presented above may readily be extended to other types of polyhedra belonging to axial point groups. In general if a (*non-polar*) polyhedron belongs to an axial point group and its L^σ orbitals contain a certain number (X) of E representations then the $L^\pi/\bar{L}^\pi$ set of orbitals will contain an even number ($2X$) of E functions. Introducing one atom on the principal rotation axis (thereby generating a *polar* polyhedron) will result in an odd number ($2X+1$) of Es, one of which will be a non-bonding $L^\pi/\bar{L}^\pi$ pair. The introduction of a second atom on the principal rotation axis generates a *bipolar* polyhedron which again has an even number ($2X+2$) of Es which, for deltahedra, again split into bonding (L^π) and antibonding ($\bar{L}^\pi$) sets.

Acknowledgements—The S.E.R.C. is thanked for financial support and Dr P. W. Fowler for many helpful comments.

COMPLEXES OF NITRILOTRIMETHYLPHOSPHONIC ACID WITH COBALT, NICKEL, COPPER AND ZINC

IVAN LUKEŠ,* DANA REJŠKOVÁ, ROMAN ODVÁRKO and PAVEL VOJTÍŠEK

Department of Inorganic Chemistry, Charles University, 128 40 Prague 2, Czechoslovakia

(*Received* 25 *October* 1985; *accepted after revision* 13 *May* 1986)

Abstract—Substances of the types MH_4ntmp, $Mg_3[M(Hntmp)]_2$, M_2H_2ntmp and $Mg[M_2(Hntmp)]_2$, where M = Co, Ni, Cu, Zn and $H_6ntmp = N[CH_2PO(OH)_2]_3$ were prepared. The sodium and cesium salts of the $[Co(Hntmp)]^{3-}$ complexes were also prepared. The IR and electronic spectra and the experimental magnetic susceptibilities indicate that these are high-spin complexes. The coordination surroundings of the central atom consist of a highly distorted octahedron of the ligand oxygen atoms. The nitrogen atom is not coordinated to the central atom.

Aminoalkylphosphonic acids are interesting as analogues of natural amino acids and as chelating agents. Therefore, we have studied the preparation and the properties of the complexes of the transition metals with nitrilotrimethylphosphonic acid $N[CH_2P(O)(OH)_2]_3$ (denoted as H_6ntmp, Fig. 1). This substance has a betain structure both in solution and in the solid state.[1–6] The dissociation constants have been determined pH-metrically[7–9] and are somewhat dependent on the H_6ntmp concentration in dilute solution.[9] Complex compounds of H_6ntmp have only been studied in solution. Morozova *et al.*[10] studied the formation of 1 : 1 complexes pH-metrically and spectrophotometrically. This type of complex is formed even in acidic media, where the logarithms of the stability constants for the formation of the species $[M(H_3ntmp)]^-$ range from 4.79 to 6.35. However, only the stability constants for the formation of the complex species $[M(ntmp)]^{4-}$ (M = Co, Ni, Cu, Zn) are higher than or comparable with those for analogous complexes of nitrilotriacetic acid.[11] The preparation and a study of the H_6ntmp complexes with cobalt, nickel, copper and zinc are dealt with in the present paper.

EXPERIMENTAL

The IR spectra were obtained on a Perkin–Elmer 225 instrument in the ranges 400–4000 cm^{-1} in a Nujol mull and 2000–4000 cm^{-1} in hexachlorobutadiene. The magnetic susceptibility was measured at 298 K using the Faraday method, on a balance calibrated with cupric sulphate pentahydrate and sodium chloride. The diffusion reflectance spectra of the solid substances were obtained on a VSU-2 instrument (Zeiss, Jena) in the range 200–1200 nm, using magnesium oxide as the reference substance. The absorption electronic spectra of aqueous solutions of the substances were obtained using a Unicam SP 800 and VSU-2 instrument, from 250 to 400 nm at a concentration of 0.003 M and from 400 to 1100 nm at concentrations from 0.005 to 0.01 M, depending on the solubility of the test compounds, using 5-cm cells.

Orientative X-ray powder patterns were obtained using the Debye–Scherrer method and a Mikrometa 2 instrument (Chirana).

In the substances prepared, the alkali metals were determined by atomic absorption spectrometry, magnesium and the transition metal were determined chelatometrically after sample combustion and dissolution of the residue in hydrochloric acid; nitrogen was determined as NH_3 by distillation on mineralization of the sample. The water was determined from the weight loss from 50 to 200°C.

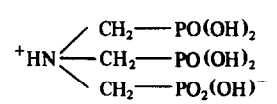

Fig. 1. Nitrilotrimethylphosphonic acid.

Preparations

H_6ntmp. The preparation of Moedritzer and Irani[12] was used and the product was isolated after crystallization from aqueous solution. The acid readily forms supersaturated oily solutions and thus the crystallization ability was tested frequently in samples taken during evaporation of the solution. The product was recrystallized in the same way from an aqueous solution.

Na_6ntmp·$3H_2O$. To a solution of 0.01 mol of H_6ntmp in 100 cm^3 water, 0.1 mol NaOH and 200 cm^3 methanol was added, thus precipitating an oily solution that was transferred to a flask, covered with 200 cm^3 methanol and refluxed. The product separated gradually in the form of small crystals that were filtered off and washed with ethanol and ether.

MH_4ntmp. Freshly precipitated and washed transition metal hydroxide (0.03 mol) was dissolved in a solution of 10 g H_6ntmp in 150 cm^3 water. The solution obtained was transferred to four times as large a volume of ethanol. The precipitate separated was filtered off, washed several times with ethanol and ether and dried over silica gel.

$Mg_3[M(Hntmp)]_2 \cdot 16H_2O$. Small crystals separated spontaneously on neutralization of a MH_4ntmp solution with sodium hydroxide to pH = 8 followed by the addition of a stoichiometric amount of $Mg(ClO_4)_2$. Only $Mg_3[Ni(Hntmp)]_2 \cdot 18H_2O$ was precipitated with methanol as above.

$Na_3[Co(Hntmp)] \cdot 6H_2O$ and $Cs_3[Co(Hntmp)] \cdot 4H_2O$. A CoH_4ntmp solution was neutralized with NaOH or $CsCO_3$ to pH 7.5–8, evaporating the solution in the air to obtain a highly viscous oil and covering the oil several times with ethanol and spreading it in a mortar. A fine product separated that was washed with ethanol and dried over silica gel.

M_2H_2ntmp. To a solution of 0.07 moles of H_6ntmp in 50 cm^3 water a suspension of the appropriate hydroxide in 200 cm^3 water was added. The hydroxide amount was stoichiometric, only a 50% excess of $Ni(OH)_2$ had to be added. On mild heating and dissolution of the hydroxide a fine product separated, was filtered off and washed with ethanol and ether.

$Mg[M_2Hntmp]_2$. Under the same conditions as M_2H_2ntmp, but the stoichiometric amount of $Mg(ClO_4)_2$ dissolved in 20 cm^3 H_2O, was added before heating the solution.

The results of analyses of the compounds prepared are given in Table 1.

RESULTS AND DISCUSSION

Nitrilotrimethylphosphonic acid forms 1 : 1 and 1 : 2 complexes with the studied metals. Complexes

of the MH_4ntmp type are readily soluble in water and can be precipitated by methanol. We tried to prepare alkaline salts of the $[M(ntmp)]^{4-}$ type, especially those of $CoH_4ntmp \cdot 4H_2O$. The salts $Na_3[Co(Hntmp)] \cdot 6H_2O$ and $Cs_3[Co(Hntmp)] \cdot 4H_2O$ were prepared by precipitation with ethanol. The analogous lithium salt could not be prepared in this way. In contrast to $CoH_4ntmp \cdot 4H_2O$, the above substances are only sparingly soluble after drying. The substances precipitated appear as X-ray amorphous. Magnesium was found to be the most advantageous external cation, probably because of its relatively weak complexes with the ligand.[13,14] The complexes $Mg_3[MHntmp]_2 \cdot 16H_2O$ crystallized from the solution, except for the Ni complex that contained 18 molecules of water. The X-ray powder patterns indicate that these substances are isostructural. The test complexes with the ligand-to-metal ratio equal to 1:2 are very poorly soluble in water and precipitate spontaneously. No pH region has been found with the 1:1 and 1:2 complexes, from which complexes $[Mntmp]^{4-}$ or $[M_2ntmp]^{2-}$, i.e. the complexes in which the last hydrogen atom is substituted, could be isolated. Complexes of the types $[MHntmp]^{3-}$ or $[M_2Hntmp]^{-}$ were always obtained (at pH < 10) or hydroxy complexes of various compositions resulted at pH > 10.

The IR spectra of the substances prepared were measured in the range 400–4000 cm^{-1}. The absorption bands have a dominant character in a region 900–1200 cm^{-1}. The bands are listed in Table 2, together with the assignment. According to the literature[9,15–18] the spectra are consistent with oxygen coordination to the metals.

The calculated effective magnetic moments are given in Table 1 for the prepared complexes of cobalt, nickel and copper and demonstrate that these are high-spin complexes.

The electronic absorption spectra of the copper complexes correspond very well to the appropriate diffuse reflectance spectra (Table 3). A broad absorption band was always found, corresponding to the transition, $\nu_1(^2T_{2g} \leftarrow {}^2E_g)$ with assumed coordination number of six. Although the band is very wide, it can be found that the band maximum for the $[Cu(Hntmp)]^{3-}$ complex type is shifted by about 500 cm^{-1} toward lower values with respect to that for the $[Cu_2(Hntmp)]^{-}$ complex type. A shoulder was found in the visible region, which is apparently connected with the complex character of the absorption band for the ν_1 transition.

With the nickel complexes, the electronic and diffusion reflectance spectra are also in good agreement, are given in Table 3 and suggest a coordination number of six. A shoulder was observed in a region 16,900–17,200 cm^{-1} for the substances $NiH_4ntmp \cdot 5H_2O$ and $Mg_3[Ni(Hntmp)]_2 \cdot 18H_2O$, which apparently corresponds to the spin-forbidden transition $^1T_{1g} \leftarrow {}^3A_{2g}$.

The character of the electronic absorption and reflectance spectra of the cobalt complexes is the

$Mg[Ni_2(Hntmp)]_2 \cdot 22H_2O$	(8.3)	13.3 (13.2)			24.4 (24.4)
$CuH_4ntmp \cdot 4H_2O$		11.0–11.6b (11.4)		16.4 (16.4)sh	
$Mg_3[Cu(Hntmp)]_2 \cdot 16H_2O$		11.1–11.5b (11.6)		16.1 (16.1)sh	
$Cu_2H_2ntmp \cdot 10H_2O$		11.4–12.2b (11.9)			
$Mg[Cu_2(Hntmp)]_2 \cdot 18H_2O$		11.4–12.0b (11.9)			

same, except for the spectrum of $CoH_4ntmp \cdot 4H_2O$. The diffusion reflectance spectrum of this compound (Fig. 2 bottom) is typical of a cobalt compound with octahedral surroundings.[19,20] In the electronic absorption spectrum and in the spectra of all the other cobalt complexes an absorption band appears in the region 12,500–11,800 cm^{-1}, which might suggest a coordination number of five (Fig. 2 and Table 3). The coordination surroundings of cobalt would be a trigonal bipyramid and the band would correspond to the $E' \leftarrow A'$ transition, or a tetragonal pyramid and the band would correspond to a transition from the ground state to the B_1 state, as, for example, in phosphinate complexes of cobalt.[21] It is difficult to establish the coordination surroundings of cobalt on the basis of these spectra, as the symmetries of a distorted octahedron in one direction and of a tetragonal pyramid are the same.

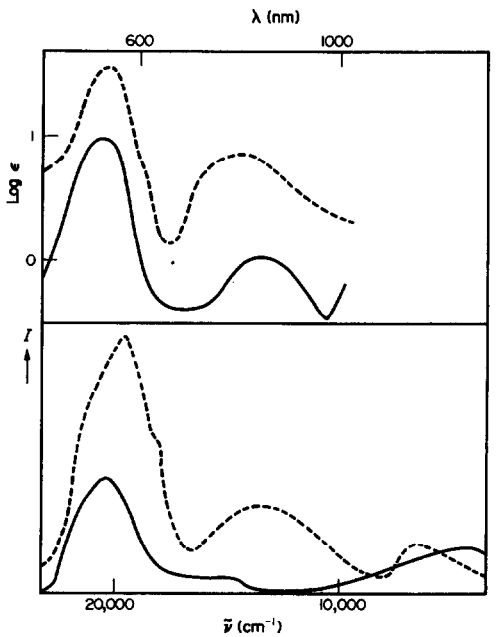

Fig. 2. Electronic absorption spectra (upper part) and diffusion reflectance spectra (lower part) of $CoH_4(ntmp) \cdot 4H_2O$ (full curve) and $Na_3[Co(Hntmp)] \cdot 6H_2O$ (broken curve).

If a justified assumption is adopted that the complexes of the $Mg_3[M(Hntmp)]_2 \cdot 16H_2O$ type are isostructural and the spectrum of $Mg_3[Cu(Hntmp)]_2 \cdot 16H_2O$, as well as those of the other complexes of copper and nickel, suggest a coordination number of six for the central atom, then the coordination number of cobalt in the studied complexes is probably also six.

The band at 8300 cm^{-1} in the diffusion reflectance spectra of the nickel complexes and the wide absorption band in the region 11,000–12,000 cm^{-1} of the copper complexes directly correspond to a value of $10Dq$. For the cobalt complexes the value, $10Dq$, was calculated according to Reedijk[22] and amounts on average to 8880 cm^{-1}. The f_L parameter, calculated from the above values for H_6ntmp, amounts to 0.98 (Co complexes); 1.00 (Ni complexes) and 1.03 (Cu complexes) and thus is comparable with the value given for H_2O.

It follows from the complex stoichiometry and from the IR spectra that the nitrogen atom is not coordinated to the central atom. The coordination surroundings are apparently a strongly distorted octahedron of oxygen atoms, which can be expected in view of the bond angles and bonding distances in the ligand alone. During the thermal decomposition

which was used to determine the water present it has been found that the studied substances are dehydrated in a single step below 100°C. In the IR spectra there is neither splitting nor a shift of the band of deformation vibration of water molecules. Hence it can be assumed that the surroundings of the central atom consist solely of the oxygen atoms of the phosphonic groups. However, coordination of water cannot be excluded with the complexes of the $[M_2(Hntmp)]^-$ type, in view of the stoichiometry.

The poor solubility of the M_2Hntmp complexes, all the prepared magnesium salts and the relatively poor solubility of the isolated $Na_3[Co(Hntmp)]\cdot 6H_2O$ complexes suggest that these substances have a polymeric character in the solid state.

TUNGSTEN–MANNITOL AND SORBITOL COMPLEXES: STRUCTURAL CHARACTERIZATION BY IR AND CARBON-13 NUCLEAR MAGNETIC RESONANCE SPECTROSCOPY

E. LLOPIS,* J. A. RAMIREZ and A. CERVILLA

Departamento de Química Inorgánica, Facultad de Químicas, Universidad de Valencia, Dr. Moliner, 50, Burjassot, Valencia, Spain

(*Received* 10 *December* 1985; *accepted after revision* 13 *May* 1986)

Abstract—Polarimetric and spectrophotometric studies of the mannitol–tungsten(VI) system show the formation of three stable complexes. Their stoichiometries, degrees of condensation and interconversion equilibria have been studied. The structure of these compounds has been investigated by ^{13}C NMR spectroscopy in aqueous solution and by IR spectroscopy in the solid state for the two species stable at pH < 7.

Although the literature contains sufficient information to establish that tungstates and molybdates interact with mannitol, or its isomer sorbitol, to form a stable species of stoichiometric ratio metal : ligand = 2 in approximately aqueous neutral solutions, no other reliable conclusions can be inferred from the reported results since there are many disagreements among them.[1–6]

We have shown in a previous publication the number, composition, degree of condensation and stability of the complex species formed between tungstate ions and sorbitol.[7]

According to Weigel *et al.*[8] for the 2 : 1 complex, the speculative structure given is a cyclic one which has a μ-oxo bond and a symmetrically bridged sorbitol molecule coordinated to each tungsten atom by two α-CHOH groups.

The main purpose of this paper has been the study in solution of the complexes which mannitol forms, in order to see whether the change of the ligand conformation has any influence on the formation of these species; this paper also deals with the structural study of these complexes by ^{13}C NMR spectroscopy. It has been possible in the same way to isolate the dinuclear species in a solid state and this has allowed its characterization by IR spectroscopy.

EXPERIMENTAL

$Na_2[W_2O_3(OH)_4(C_6H_{10}O_6)]$ *synthesis*

An aqueous solution containing the stoichiometric amounts of Na_2WO_4 and mannitol (0.5 mol dm^{-3} in mannitol) was acidified with $HClO_4$ at pH = 6.0. Addition of acetone to the solution produces the formation of a syrup at the bottom of the flask. This syrup was decanted and washed with warm absolute ethanol becoming a white powder which was dried in a dessicator over H_2SO_4(c).

Found: C, 10.1; W, 53.6%. Calc.: C, 10.1; W, 45.3%.

$Na[W_2O_3(OH)(C_6H_{11}O_6)_2]$ *synthesis*

To an aqueous solution containing Na_2WO_4, mannitol and $HClO_4$ in 1 : 1.5 : 1.5 ratio, respectively (1 mol dm^{-3} in Na_2WO_4), acetone was added and a syrup obtained that, after dehydration with absolute ethanol, was dried (lightly protected) in a dessicator over H_2SO_4(c).

Found: C, 17.4; W, 42.5%. Calc.: C, 17.7; W, 45.3%.

The rotatory power of the samples was measured with a Perkin–Elmer 141 digital photoelectric polarimeter; measurement accuracy was $\pm 0.002°$. The cell was thermostatically set at 25°C and had a length of 10 ± 0.02 cm. The measurements were

taken at five different wavelengths (589, 578, 546, 436 and 365 nm) and all these results were comparable.

The pH of the samples was measured with a Radiometer pH-meter 82 with a pH accuracy of ± 0.01. All the samples were prepared to be 1 mol dm^{-3} in $NaClO_4$ and the pH was adjusted to the required value adding the proper amounts of concentrated NaOH and/or $HClO_4$ (70%). Specific conditions of the samples are indicated in the text.

The ^{13}C NMR spectra were recorded using a Bruker AC-200 spectrometer at an operating frequency of 50.32 MHz. This instrument was also used to record 200 MHz ^1H NMR spectra.

RESULTS AND DISCUSSION

The procedures used, in the polarimetric and spectrophotometric study,[9] have been similar to the ones previously described.[7,10,11]

Table 1 summarizes the rotatory power values in the course of the acidification of a solution 0.38 mol dm^{-3} in D(−)mannitol with $HClO_4$ ($\hat{D}_{mann}$). These values are essentially independent of the pH, but they are greatly modified by addition of Na_2WO_4 1.9×10^{-2} mol dm^{-3} to the solution of D(−)mannitol, ($\hat{D}_{mann/W}$), (|Mann|/|W(VI)| = 20). The rotatory powers due to the excess of mannitol are superimposed on the values of $\hat{D}_{mann/W}$, and we can consider that the difference $\Delta\hat{D} = \hat{D}_{mann/W} - \hat{D}_{mann}$ represents the change in the rotatory power with pH produced by the complexes (Fig. 1).

Table 1. Rotatory power values (degrees) for a solution 0.38 mol in D(−)mannitol in presence (a) or absence (b) of Na_2WO_4 1.9×10^{-2} mol dm^{-3}. $\Delta\hat{D} = \hat{D}_{mann/W} - \hat{D}_{mann}$, $\lambda = 365$ nm, ionic strength in all samples $NaClO_4$ 1 mol dm^{-3}

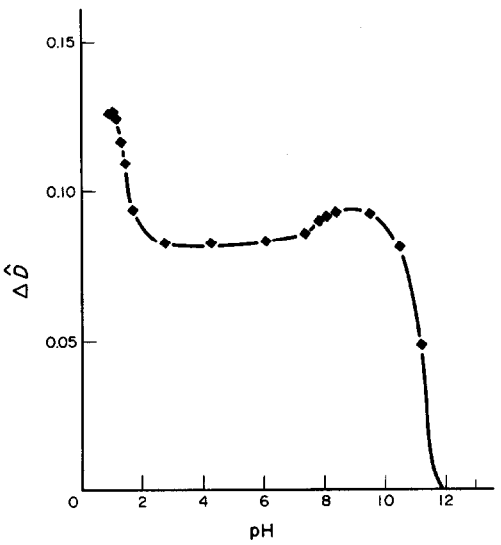

Fig. 1. Optical-activity variations as a function of pH. Excess of D(−)mannitol. $[Na_2WO_4] = 1.9 \times 10^{-2}$ mol dm^{-3}. [Mannitol] = 0.38 mol dm^{-3}. $\lambda = 365$ nm.

The existence of four breaks in curve $\Delta\hat{D}$ *vs* pH at pH = 12.0, 9.0, 5.0 and 1.0 suggests the presence of three different complex species.

From Fig. 1 values, acid equivalents needed to form every complex species, from mannitol and tungstate ions, as well as their condensation degree can be deduced.[10] On the other hand, application of the generalized Asmus and molar-ratio methods[12,13] at each pH break where only one complex species is assumed to be present, allowed a simultaneous calculation of complex composition, condensation degree and stability constant.

The above results suggest the following complexation equilibria, which agrees with those reported for the tungsten(VI)–sorbitol system[7]

$12 > pH > 9.0$

$$WO_4^{2-} + 2C_6H_{14}O_6 + H_2O \rightleftarrows [WO(OH)(C_6H_{12}O_6)_2]^- + OH^- + 2H_2O$$

$9.0 > pH > 7.0$

$$\{[WO(OH)(C_6H_{12}O_6)_2]^- + OH^-\} + H^+ + \tfrac{1}{2}H_2O \rightleftarrows [W_2O_3(OH)_4(C_6H_{10}O_6)]^{2-} + \tfrac{3}{2}C_6H_{14}O_6$$

$3.0 > pH > 1.0$

$$[W_2O_3(OH)_4(C_6H_{14}O_6)]^{2-} + C_6H_{14}O_6 + H^+ \rightleftarrows [W_2O_3(OH)(C_6H_{11}O_6)_2]^- + 3H_2O.$$

The proposed formulations are based on structural information in the literature and in previous works on related tungsten(VI) and molybdenum(VI) compounds.[11,14,15]

It should be noted that formation of $[W_2O_3(OH)L_2]^{3-}$ only occurs if an excess of mannitol is present since, in a very acidic medium, the condensation equilibria of uncomplexed tungsten(VI) are strongly favoured.

Structural characterization

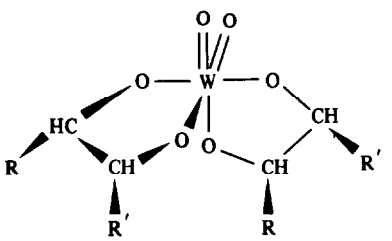
At high pH values (pH > 9.0), tungstate ion forms, mainly, a stable 1 : 2 complex

$$WO_4^{2-} + 2C_6H_{14}O_6 + H_2O \rightleftarrows [WO(OH)(C_6H_{12}O_6)_2]^- + OH^- + 2H_2O.$$

Therefore consistent with this equilibrium, the addition of sorbitol or mannitol to a solution containing WO_4^{2-} produces an increase in the pH.

The apparent stability constant of this complex has been evaluated, and a large ligand : tungsten(VI) ratio is needed to displace its formation equilibrium towards complete complex formation. That is why we think that all attempts at isolation in a pure state have been unsuccessful.

Figure 2 displays ^{13}C NMR spectrum of a solution of Na_2WO_4 0.5 mol dm^{-3} and sorbitol 2.5 mol dm^{-3} at pH = 9.5. In the presence of free sorbitol, the spectrum shows sharp and well-resolved resonances for both the bound and the free ligand, which indicates that an intermolecular exchange, if its exists, must be slow on an NMR scale.



The ^{13}C NMR signals of primary C—OH groups are found between 61 and 64 ppm and, therefore, we can suppose that they are uncoordinated. Downfield, three ^{13}C signals of secondary carbon atoms appear to be shifted about 10 ppm with respect to those of the free ligand.

For sorbitol, as a polyol having an asymmetric configuration, one signal for each carbon atom should be expected, being the ^{13}C signal of secondary C atoms located between 68 and 73 ppm. In this region, the complex species only shows a signal which is of the highest intensity.

The spectral behaviour found for this species allows us to conclude, thus, that there are only two C—OH secondary groups bonded to tungsten(VI), which causes a downfield shift in their resonances, being in agreement with other previous results.[16]

Another important fact to be pointed out concerning this spectrum is that one of two C—OH coordinated group resonances is found to be split into a doublet, which is interpreted as being due to the presence of two environments not magnetically equivalent for the sorbitol coordinated CHOH groups.

The foregoing features, usually observed for other *cis*-MO_2L_2 complexes [M = W(VI) of Mo(VI) and L being a single deprotonated chelating oxo-ligand] prompt us to propose the following structure for the complex species stable at higher pH.

I

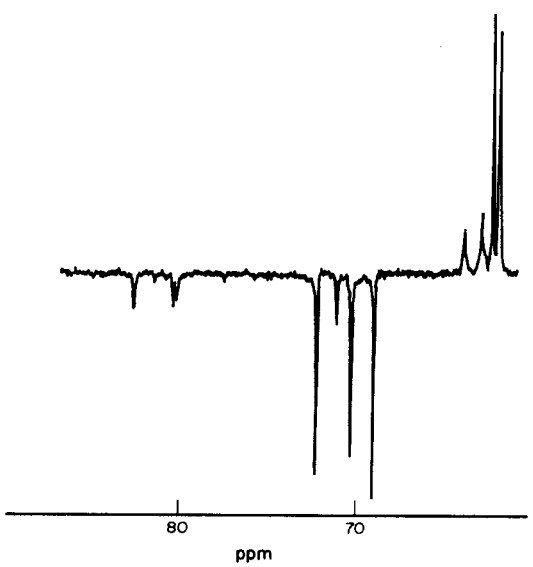


Fig. 2. DEPT ^{13}C NMR spectrum of 0.5 mol dm^{-3} Na_2WO_4 and 2.5 mol dm^{-3} sorbitol at pH = 9.5.

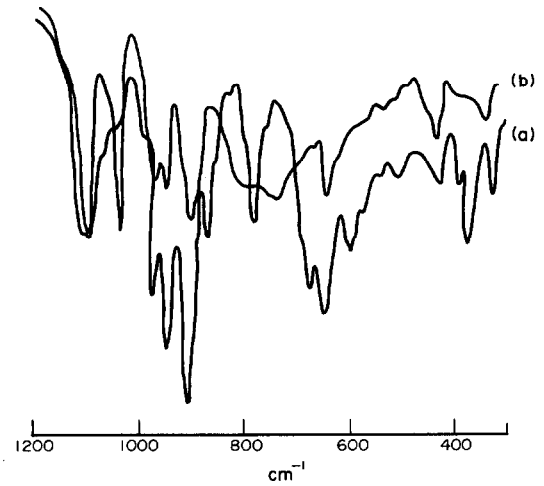
In contrast to $[WO(OH)L_2]^{2-}$, the formation reaction of the complex species $[W_2O_3(OH)_4(C_6H_{10}O_6)]^{2-}$ has a higher stability constant, and proceeds smoothly giving this species in a pure form and a good yield.

We have, thus, prepared the $Na_2[W_2O_3(OH)_4(C_6H_{10}O_6)]$ complex and observed that the IR spectrum of the solid (KBr pellet) (Fig. 3a), in the 900 cm^{-1} region, shows two strong bands at 910 and 955 cm^{-1} which indicate the presence of *cis*-WO_2 groups.[17,18] Besides these absorbances, the broad band at 660 cm^{-1} might be assigned to the stretching antisymmetric vibrations of the W—O_b—W group,[11] and the other band at 400 cm^{-1} can be assigned to a W—O_b—W symmetric bond.[19,20]

On the other hand, a solution of this complex species [for sorbitol–tungsten(VI) system] gives rise to the room temperature ^{13}C NMR spectrum shown in Fig. 4a. The number of signals which appear



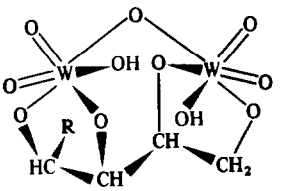


Fig. 3. IR spectra (KBr pellet) of: (a) $Na_2[W_2O_3(OH)_4(C_6H_{10}O_6)]$, and (b) $Na[W_2O_3(OH)(C_6H_{11}O_6)]$.

clearly shows the presence of two different isomers in solution, and their chemical shifts indicate that there is only a CH_2OH and a CHOH group uncoordinated in each isomer. In Table 2 we show the chemical shifts of fee and complexed ligands at different pH values.

We have observed that D-mannitol, D-sorbitol and D-gluconic acid (in excess of metal) show the same ^{13}C NMR spectrum, corresponding to the existence of two similar isomers, while adonitol (a polyol with a different conformation) is only able to form a single isomer for the complex species stable at these pH values ($3 < pH < 7$).

These observations mentioned above lead us to propose, as a more likely structure in solution, one of the structures proposed by Angus (tetrytol system C-1, C-2, C-3 and C-4), but with an alcoxy coordination in trans position to the μ-oxo bond (II).[21]

[a] Signals from free and complexed mannitol.

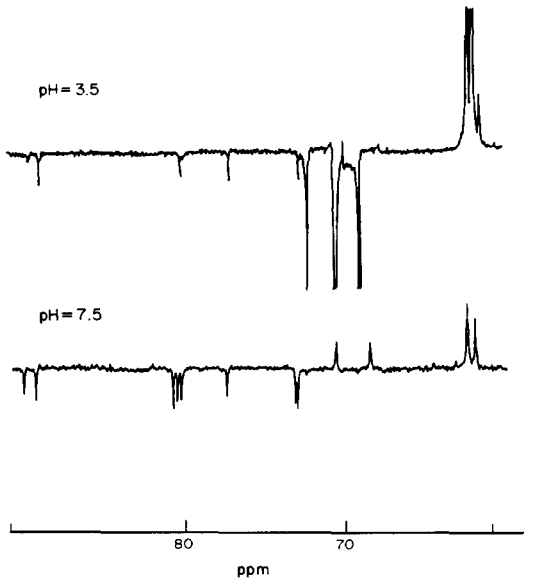

Fig. 4. DEPT ^{13}C NMR spectra of tungsten(VI)–sorbitol system in excess of ligand (pH = 3.5) and in excess of metal (pH = 7.5).

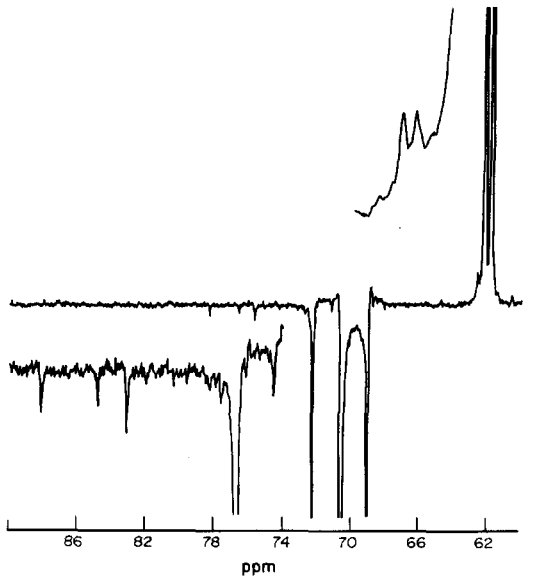

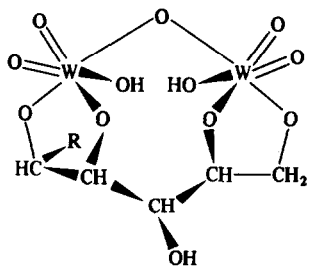

Fig. 5. DEPT ^{13}C NMR spectrum of 0.25 mol dm^{-3} Na_2WO_4 and 2.5 mol dm^{-3} sorbitol at pH = 1.0.

Concerning the structure of the second isomer, in spite of the fact that different signals are observed for each isomer at pH = 7.0 whose intensities are not temperature-dependent ($0°C < T < 90°C$), only the signals from one of these isomers are detected when the pH decreases because the signal intensities for the second isomer becomes very weak (Fig. 4).

That is why we have considered that the ligand has a different coordination to the metal in each isomer, the interconversion process being unlikely. Therefore, the second isomer for the mannitol and sorbitol complexes at this pH will be one where the ligand molecule will be coordinated by the same hydroxy terminal group (C-1) and three different CHOH groups, probably through C-2, C-4 and C-5 (III).

III

Concerning the third complex species, it has also been possible to isolate its sodium salt, which displays the IR spectrum shown in Fig. 3b. The WO_t region is similar to that found for the 2 : 1 species, but it also shows a new intense band at 1040 cm^{-1}. Bands at 1000–1100 cm^{-1} are described in a great number of complexes with hydroxo bridges[22,23] and, therefore, lead us to suggest the conversion of the M—O—M bond in a double M—O—M bridge, one of which must be protonated.

This structural change might explain the change in the stoichiometric ratio (from 2 : 1 to 2 : 2). In fact, it becomes reasonable to assume that the cyclic structure of the 2 : 1 complex is not compatible with the formation of a new μ-hydroxo bond which could agree with that a tricoordination of mannitol or sorbitol molecule to each tungsten(VI) center became easier.

This last consideration was fully corroborated in the ^{13}C NMR spectrum displayed by the complex species stable at lower pH (Fig. 5). In this spectrum, only three of the six signals expected for a coordinated sorbitol molecule are downfield shifted, whilst the other set of three resonances (one of a carbinol group and two of the terminal CH_2OH groups) are very close to the resonances of the analog groups in the free ligand, suggesting that these alcoholic groups are not coordinated.

All those results can be extended to mannitol complexes.

Acknowledgement—The authors wish to thank Mª José Viqueira for her help in the English correction of the manuscript.

Abstract—The pentaamminecobalt(III) complex with the 3-cyano-2,4-pentanedionate anion coordinated through the nitrile nitrogen has been characterized by X-ray crystallography. The crystals of $[(NH_3)_5CoNCacac](Cl)(ClO_4)\cdot 2H_2O$ are triclinic, space group $P\bar{1}$, $a = 10.245(2)$ Å, $b = 14.071(4)$ Å, $c = 6.971(2)$ Å, $\alpha = 90.03(3)°$, $\beta = 109.86(2)°$, $\gamma = 108.91(2)°$, $V = 887.1$ Å^3, $Z = 2$, $D_c = 1.64$ g cm^{-3}, $F(000) = 456$, Mo–K_α radiation, $\lambda = 0.71069$ Å, μ(Mo–K_α) = 12.7 cm^{-1}. The structure was determined by the heavy-atom method, and refined by block-diagonal least-squares calculations, $R = 0.0537$, $R_w = 0.0607$, for 2499 observed reflections. Principal dimensions are: Co—N(NH_3) *trans* to $NCacac^-$ 1.940(5), other Co—N(NH_3) 1.967(2), Co—N($NCacac^-$) 1.911(5) Å. The pendant acac moiety is best described in terms of a delocalized bond network with, for example, C—C distances in the range 1.44–1.52(1) Å. Several reactions involving this free acac group are also described including the preparation and characterization of the dimeric species pentaamminecobalt(III) - μ - (3 - cyano - 2,4 - pentanedionato) - bis(propylenediamine) cobalt(III) perchlorate.

Most metal acetylacetone (2,4-pentanedione, Hacac), complexes involve coordination of the ligand as the enolate ion to form a six-membered ring.[1] However, there are examples where the metal is bonded directly to the methine carbon leaving a pendant acac moiety.[2] Metals forming these types of complexes are second and third row transition metals, in particular platinum. Potassium chlorobis(acetylacetonato)platinate(II), contains both a bidentate chelated acac group and a methine carbon-bonded ligand.[3] For the latter arrangement, the 'free' acac is a potential donor for other metal ions.

We have been interested in metal complexes with pendant groups capable of strong interaction with redox metal ions for mechanistic studies.[4] To this end we have selectively coordinated potential chelating agents via a monodentate substituent.[5,6] For example, 3-cyano-2,4-pentanedione has been bonded to cobalt(III) through the nitrile nitrogen leaving the pendant acac available to chelate to other metal ions.[6] The structure and reactivity of this unique complex are of considerable interest in this regard. In this paper we report the X-ray crystal structure of (3-cyano-2,4-pentanedionato-*N*)-pentaamminecobalt(III) perchlorate chloride dihydrate, $[(NH_3)_5CoNCacac](Cl)(ClO_4)\cdot 2H_2O$.

Several examples of the reactivity of the pendant acac in the complex are also given.

EXPERIMENTAL

The title complex was prepared as described previously as were solutions for kinetic studies.[6]

Synthesis of pentaamminecobalt(III) - μ - (3 - *cyano* - 2,4 - *pentanedionato*) - *bis*(*propylenediamine*) *cobalt*(III) *perchlorate*, $[(NH_3)_5CoNCacacCo(tn)_2](ClO_4)_5$

Aquahydroxybis (propylenediamine) cobalt (III) perchlorate,[7] 0.074 g, and (3-cyano-2,4-pentane-

* Author to whom correspondence should be addressed.

dionato-*N*)pentaamminecobalt(III) perchlorate, 0.072 g, were dissolved in 20 cm^3 H_2O and 3 drops of concentrated perchloric acid added. The solution was stirred for 24 h at room temperature, diluted to 500 cm^3 with water and charged onto a weak acid CM–Sephadex cation exchange column. Elution with increasing concentrations of NaCl removed unreacted starting material and slowly moved a 5+ ion down the column. This species was removed from the column and isolated as the perchlorate salt.

Found: C, 14.7; H, 4.3; N, 14.4%. Calc. for $Co_2C_{12}H_{41}O_{22}N_{10}Cl_5$: C, 14.8; H, 4.2; N, 14.4%.

Infrared: $\nu_{C\equiv N} = 2240\ cm^{-1}$.

^1H NMR: *cis*-NH_3, 4.09 δ (12 H); *trans*-NH_3, 3.68 δ (3H); propylenediamine NH protons, 5.34, 5.10, 4.75, 4.57 δ (8H); propylenediamine CH protons, 2.56–1.74 δ (12H); CH_3, 2.42 δ (6H).

Kinetic studies

The reduction reactions were carried out on a Durrum Model D-110 stopped flow spectrophotometer. All reagents were handled and mixed using standard syringe techniques. The reactions were carried out under pseudo-first-order conditions (reductant in greater than 10-fold excess over oxidant). Absorbance-time data were collected and displayed using a DASAR analog–digital data storage and retrieval system (American Instruments Co.). Rate constants were obtained directly from the exponential decay traces by matching this curve with a curve generated by an exponential curve simulator. Agreement between these values and rate constants obtained from a plot of $\log(A_t - A_\infty)$ *vs* time was within 1% (A_t and A_∞ are the absorbances at time t and after the reaction was complete).

Physical measurements

Infrared spectra were obtained using a Beckman Model IR-12 spectrophotometer using KBr pellets. Proton magnetic resonance spectra were recorded with a Bruker AM-250 spectrometer.

X-ray studies

Crystal data. $C_6H_{21}CoN_6O_2 \cdot Cl \cdot ClO_4 \cdot 2H_2O$, $M = 439.14$. Triclinic, $a = 10.245(2)$ Å, $b = 14.071(4)$ Å, $c = 6.971(2)$ Å, $\alpha = 90.03(3)°$, $\beta = 109.86(2)°$, $\gamma = 108.91(2)°$, $V = 887.1$ Å^3, $Z = 2$, $D_c = 1.64\ g\ cm^{-3}$, $F(000) = 456$, Mo–K_α radiation, $\lambda = 0.71069$ Å, μ(Mo–K_α) = 12.7 cm^{-1}, Space group $P\bar{1}$.

Structure determination and refinement

Accurate cell parameters were obtained by a least-squares refinement of the setting angles of 25 reflections (with θ in the range 10–15°) measured on a Enraf–Nonius CAD4 diffractometer. Intensity data were collected by the $\omega/2\theta$ method with a small ($0.23 \times 0.38 \times 0.08$ mm) crystal to a maximum θ of 25°, and 3110 unique data were obtained. After corrections for Lorentz and polarization effects the data with $I > 3\sigma(I)$ (2499) were labelled observed and used in structure solution and refinement.

The coordinates of the Co atom were obtained from an analysis of a three-dimensional Patterson function. The remaining non-hydrogen atoms were located in the subsequent heavy-atom phased Fourier summations. It was clear from intermediate difference maps that one of the waters of hydration was disordered over two sites and this was allowed for. Refinement was by block-diagonal least-squares calculations,[8] initially with isotropic and then with anisotropic thermal parameters. A difference map computed at an intermediate stage in the refinement revealed maxima in positions expected for all the hydrogen atoms, except those in the disordered water molecule; these were then allowed for in geometrically idealized positions (C—H = 1.08 Å) and included but not refined in the final rounds of calculations. In the refinement cycles a weighting scheme of the form $w = 1/[\sigma^2 F]$ was employed. The scattering factors were taken from refs 9 and 10, and allowance was made for anomalous dispersion.[11] Refinement converged with $R = 0.0537$ and $R' = \Sigma w\Delta^2/\Sigma wF_0^2 = 0.0607$ for the 2499 observed reflections. A final difference map showed some peaks (maximum $0.69e$ Å^{-3}) near the low occupancy oxygen atom. Figure 1 is a perspective view of the cation with our numbering scheme. Final coordinates for the non-hydrogen atoms, lists of anisotropic thermal parameters, calculated hydrogen coordinates, and hydrogen-bond distances involving the ions and water molecules, together with observed and calculated structure factors have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The dimensions in the cation in $[(NH_3)_5CoN\text{-}Cacac](Cl)(ClO_4) \cdot 2H_2O$ are listed in Table 1. The crystallographic analysis demonstrates that the $[(NH_3)_5CoNCacac]^{2+}$ cation is composed of an octahedrally coordinated cobalt atom bonded to

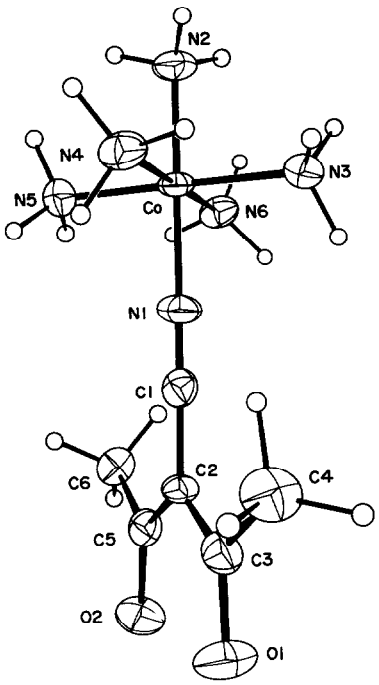

Fig. 1. An ORTEP view of the $[(NH_3)_5CoNCacac]^{2+}$ cation with our numbering scheme; ellipsoids are at the 50% level except for hydrogens which are shown as spheres of an arbitrary size.

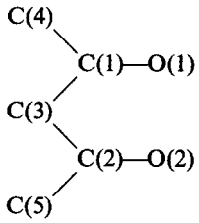
five NH_3 ligands with *cis* N—Co—N angles of 89.0°–91.3(2)°. The sixth position is occupied by the nitrile coordinated $NCacac^-$ moiety, with *cis* N—Co—N angles of 89.2°–90.3(2)°.

The Co—N(NH_3) bonds range in length from 1.940(5) to 1.968(5) Å, with the Co—N bond [1.940(5) Å] *trans* to the $NCacac^-$ moiety significantly shorter than the *cis* Co—N bonds [average = 1.967(2) Å]. The average value for the *cis* Co—N bond length agrees well with distances found in other cobalt–ammine complexes, e.g. Co—N = 1.968 Å for $Co(NH_3)_6^{3+}$.[12]

The shortening of the *trans* Co—N bond seen in the present work has been observed for a few other complexes,[13–15] notably for *sp* or sp^2 hybridized nitrogen donor ligands. In the complex $[(NH_3)_5CoNCCo(CN)_5]$ this effect has been interpreted as being due to donation of metal $d\pi$ electrons into the vacant π^*2p nitrogen orbital on the cyano ligands,[13] shifting the metal electron cloud away from the *trans* NH_3 ligand and thereby minimizing repulsion.



The cobalt–nitrile bond length of 1.911(5) Å is significantly shorter than the Co—NH_3 bond lengths, which is expected due to the *sp* hybridization of the nitrogen atom, in comparison to sp^3

[d] Ref. 16.

hybridization for the NH_3 ligands. This value compares well with the value reported for $(NH_3)_5CoNCCo(CN)_5$ of 1.920(3) Å.[13] The Co—N(1)—C(1) angle of 179.0(5)° indicates linear coordination of the NCacac ligand, and the N(1)—C(1) bond length of 1.153(7) Å is in accord with accepted values.[13]

Other bond lengths in the $NCacac^-$ ligand, along with parameters for other metal–acac complexes are summarized in Table 2. The carbonyl bond lengths in $NCacac^-$ are significantly longer than those for typical C=O bonds, and are close to the range of C=O bond lengths found in metal(acac) complexes.[16] The crystal structure of $K[Pt(acac)_2Cl]$,[3] which contains both pendant acac (methine carbon σ-bonded to Pt) and bidentate chelated acac groups, indicates that the pendant β-diketone is best represented as a keto-type structure containing single C—C and double C=O bonds (loss of delocalization). This is definitely not the case for the $NCacac^-$ ligand, as comparison of bond lengths in Table 2 indicates that the $NCacac^-$ moiety is best described in terms of a delocalized bond network, as in $Co(acac)_3$.[16] The values obtained for the methine C–carbonyl C bond lengths are intermediate between those reported for $M(acac)_3$-type complexes and the σ-bonded structure in $K[Pt(acac)_2Cl]$. A bond order greater than 1 is evident, however delocalization is not to the same degree as in $Co(acac)_3$.

The methine carbon–nitrile carbon bond length C(1)—C(2) in $NCacac^-$ [1.405(8) Å] is significantly shorter than typical carbon–carbon single bonds (1.51–1.54 Å), indicating that delocalization extends into this bond as well. This conjugated system should provide a facile pathway for electron transfer *via* π^* orbitals.

The 'bite' size, or oxygen–oxygen distance, was found to be 2.778(3) Å, which is in the middle of the range found for $M(III)(acac)_3$ complexes (M = Al, Co, Mn, Cr, Fe and V).[16]

The bonding of metal ions to the pendant keto acac group in $[Pt(acac)_2Cl]^-$ indicates that the M—O bonds in the binuclear species were weaker than typical M—O bonds in enol coordinated species.[17] Although a limited amount of π-electron delocalization is present, the bonding in the binuclear complex still involves keto coordination.

For $[(NH_3)_5CoNCacac]^{2+}$, the favourable bite size, combined with the 'enol' nature of the β-diketone, implies that metal coordination to the remote linkage may dominate in the reactions of the complex.

It has been shown that the reduction of $[(NH_3)_5CoNCacac]^{2+}$ by chromium(II) occurs by an inner-sphere mechanism where the reductant attacks at the free acac grouping.[6] The mechanism predicts that addition of non-reducing metal ions should inhibit the reduction due to competition for the chelating β-diketone moiety between reductant and the added metal ion. This prediction was investigated for the reduction of the complex by chro-

Table 3. Kinetic data for the Cr(II) reduction of $[(NH_3)_5CoNCacac]^{2+}$ in the presence of added M^{n+} [a,b]

M^{2+}	$[M^{n+}]$ (mol dm^{-3})	k_{obsd} (s^{-1})	K_M (dm^3 mol^{-1})
—	—	136	—

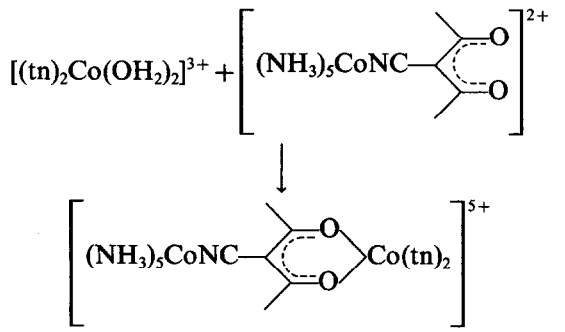
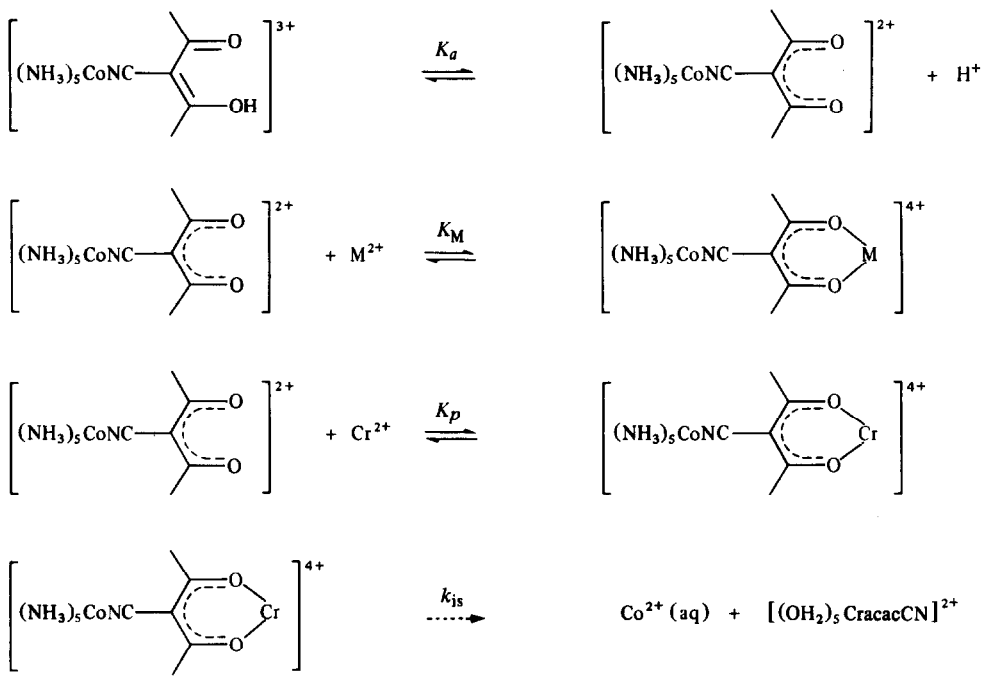
	0.1213	144	
	0.1273	138	
Mn^{2+}	0.1213	125	3±1
Ba^{2+}	0.1213	139	—

[a] Temperature = 25°C, Ionic strength = 1.00 mol dm^{-3} ($LiClO_4$).



[b] $[H^+] = 0.12$ mol dm^{-3}, $[Cr^{2+}] = 0.01335$ mol dm^{-3}, $[Co(III)] = 2.5 \times 10^{-4}$ mol dm^{-3}.

mium(II) in the presence of Ba^{2+}, Ni^{2+}, Mn^{2+}, Zn^{2+} and Co^{2+}. The data are given in Table 3. The data are consistent with the mechanism outlined in Scheme 1. The following rate equation can be derived from Scheme 1:



$$k_{obsd} = \frac{k_{is}K_p[Cr^{2+}]}{1+[H^+]K_a^{-1}+K_p[Cr^{2+}]+K_M[M^{2+}]}.$$

A plot of k_{obsd}^{-1} *vs* $[M^{2+}]$ at constant $[Cr^{2+}]$ and constant $[H^+]$ gave the expected linear plots with constant intercept and varying slopes. The values of K_M obtained from these plots are also collected in Table 3. Thus the kinetic data are also consistent with the existence of a reactive pendant acac group.

Finally, we have also shown that the parent complex can be used to prepare dimeric species. The reaction below

occurs readily in dilute acid due to the lability of the water molecules in $(tn)_2Co(OH_2)_2^{3+}$ [7,18] and the chelating ability of the free acac. The nitrile stretching frequency (2240 cm^{-1}) of the dimer shows the expected shift to higher frequency [19] when compared to that for the free ligand ($\nu_{C\equiv N}$ = 2225 cm^{-1}) or

Scheme 1.

uncomplexed nitrile in the complex $en_2Coacac–CN^{2+}$ ($\nu_{C\equiv N} = 2220\ cm^{-1}$). The NMR spectrum of the dimer in Me_2SO-d_6 shows *cis*- and *trans*-NH_3 peaks (4.09 and 3.68δ, respectively) similar to those found in $(NH_3)_5CoNCacac^{2+}$ (3.90 and 3.60δ, respectively). Also the methyl peaks in the dimer occur at 2.42δ indicating that the acac moiety is chelated as in the $en_2Coacac–CN^{2+}$ complex (2.50δ).[6]

STUDIES OF π-BONDING PERTURBATION IN THE TUNGSTEN–NITROGEN MULTIPLE BOND OF ISOPROPYLIMIDO TUNGSTEN(VI) COMPLEXES: THE CRYSTAL AND MOLECULAR STRUCTURES OF $[W(NCHMe_2)Cl_4]_2 \cdot C_6H_6$ AND $[W(NCHMe_2)Cl_5][NEt_4]$

(*Received* 11 *March* 1986; *accepted* 19 *May* 1986)

Abstract—^{13}C NMR chemical shift data for the α-carbon (δ_α) of a variety of tungsten isopropylimido complexes indicate that the extent to which the nitrogen lone pair participates in multiple bonding to tungsten depends on the form of the complex and the ligands involved. The structures of $[W(NCHMe_2)Cl_4]_2 \cdot C_6H_6$ (**1a**) and $[W(NCHMe_2)Cl_5][NEt_4]$ (**7**) which show widely different δ_α values, have been determined by single-crystal X-ray diffraction methods. Crystals of **1a** are triclinic space group $P\bar{1}$, with $a = 6.394(2)$, $b = 8.890(3)$, $c = 11.205(2)$ Å and $\alpha = 109.95(2)°$, $\beta = 98.91(2)°$, $\gamma = 93.96(2)°$; crystals of **7** are orthorhombic, space group *Pnma*, with $a = 13.667(5)$, $b = 15.152(2)$, $c = 9.432(2)$ Å. Both structures were solved by Patterson and Fourier methods and refined to an R value of 0.050 for 1325 observed data of **1a** and to an R value of 0.050 for the 1157 observed data of **7**. Complex **1a** is dimeric with a W—N bond length of 1.697(12) Å and complex **7** is monomeric with a longer W—N bond length of 1.763(16) Å. Comparison of the W—Cl bond lengths and correlations with π-bonding to make an 18-electron count, indicates that the W—N bond lengths differ in the two complexes as a result of overall π-bonding requirements.

The multiple bond of organoimido complexes (M≡NR)[1] has not shown the diversity of reactions exhibited by the related alkylidene and alkylidyne complexes (M=CHR and M≡CR)[2] and in general is comparatively unreactive. Electrophilic activity has been observed to occur for osmium organoimido complexes where the amination of olefins is now well known[3] and also in the reactions of $Cr(N\text{-}t\text{-}Bu)_2(OSiMe_3)_2$ with Ph_2Zn.[4] Nucleophilic activity has been identified in the reaction of M≡NR complexes with PhCHO to give M=O complexes and PhCH=NR[5] while $Mo(NPh)_2(S_2CNEt_2)_2$ reacts with MeBr to give $Mo(NPh)Br_2(S_2CNEt_2)_2$.[6] These reactions have mainly been identified by analysis of the organic products produced but some examples of the intermediate complexes are now emerging. The alkanolaminato osmium(VI) complex $Os_2O_4(OCMe_2CH_2NBu^t)_2$ has recently been characterised by X-ray crystallography[7] as have the amido complexes $[W_2(NHPh)_2(\mu\text{-pinacol})(pinacol)_4]$[8] and $[W(NCMe_3)(NHCMe_3)_2(benzopinacol)]$,[9] which result from protonation of an imido function.

One approach taken to increase the nucleophilicity of the imido nitrogen has been the preparation of complexes in which the maximum electron count can exceed 18 electrons, either by placing a strongly competitive π-donating ligand *trans* to the imido function as in the case of $[Re(NPhCH_3)(OEt)(S_2CNMe_2)_2]$[10] or by introducing a second imido function which is forced to act essentially as a two-electron donor (i.e. M=N̈R) as in the case of $[Mo(NPh)_2(S_2CNEt_2)_2]$.[11] Alternatively, ^{13}C NMR investigations of a series of d^0 *t*-butylimido complexes have shown that on changing the metal, the charge on the imido nitrogen atom decreases on proceeding upwards and to the right of the transition metal series.[12]

In view of these studies we were interested in

* Author to whom correspondence should be addressed.

preparing complexes of tungsten(VI) in which the reactivity of the imido ligand might be enhanced. We report here results of studies in which ligands other than the organoimido function are varied and the effect on the W—N linkage examined by ^{13}C NMR spectroscopy and X-ray crystallography.

EXPERIMENTAL

$WOCl_4$ was prepared by reaction of WO_3 with thionyl chloride[20] and trimethylphosphine by a literature method.[21] Trityl ethoxide was obtained by refluxing trityl chloride with ethanol and triethylamine in benzene and recrystallising the product from petroleum ether at −20°C. Tetraethyl ammonium chloride, sodium acetate and diethyldithiocarbamate were dried at 100°C *in vacuo* for 24 h and stored in Schlenk tubes under dry nitrogen. Lithium *t*-butoxide was prepared from *t*-butanol and *n*-butyllithium in petroleum ether. Propionitrile was dried over and distilled from calcium hydride. Petroleum ether (b.p. range 40–60°C), toluene, benzene and diethyl ether were distilled over sodium wire and dichloromethane over calcium hydride. All distillations were carried out under N_2 treated to remove oxygen and water, as were manipulations using bench-top, air-sensitive techniques.[22] IR spectra were recorded on a Perkin–Elmer 597 spectrometer, ^1H NMR on a Varian T60 Model spectrometer and ^{13}C NMR spectra on a JEOL FX60 spectrometer. Analytical data were obtained by Professor A. D. Campbell and associates, University of Otago, New Zealand. Melting points were determined in sealed tubes under N_2 on an electrothermal melting point apparatus and are uncorrected.

Hexachloro - di - μ - chlorobis(isopropylimido)ditungsten(VI) (1)

Iso-propylisocyanate (1.65 cm^3, 17.0 mmol) was added to tungsten oxytetrachloride (5.7 g, 16.7 mmol) in benzene (90 cm^3) and the resulting red solution refluxed overnight, after which it was filtered while hot and the volume reduced to *ca* 30 cm^3. On standing the product formed as orange–red crystals which were filtered, washed with cold benzene (2 × 10 cm^3) and dried *in vacuo* whereupon crystallinity was lost. The air-sensitive complex may be stored under nitrogen for several months without decomposition but traces of moisture cause the formation of a blue colouration. M.p. 158–160°C.

IR (Nujol) bands at 1650w, 1580m, 1240s, 1230s, 1150m, 1150m, 1070s, 930m, 935s, 880s, 860s, 810s, 680w, 610m, 540s, 480s, 400s, 370s, 330s, 300s, 280s; (KEL-F) 2900w, 2250w, 1570w cm^{-1}.

Tetrachloropropionitrile(isopropylimido)tungsten (VI) (2)

Propionitrile (35 cm^3) was added to hexachloro-di-μ-chlorobis(isopropylimido)ditungsten(VI) (1.2 g, 1.6 mmol) and the mixture stirred for 2 h. The orange solution was filtered, the volume reduced to *ca* 3 cm^3 and on standing at −20°C the complex formed as orange crystals which were filtered off and dried *in vacuo*. M.p. 179–183°.

IR (Nujol) bands at 2280m, 1460s, 1418m, 1364m, 1305m, 1270s, 1155w, 1110w, 1074m, 845w, 780w, 724w, 620w, 565m, 330s cm^{-1}.

Triphenylcarbonium tetrachloroethoxy(isopropylimido)tungsten(VI) (3)

Trityl ethoxide (0.5 g, 1.73 mmol) in dichloromethane (30 cm^3) was added to hexachloro-di-μ-chlorobis(isopropylimido)ditungsten(VI) (0.66 g, 8.6 mmol) suspended in dichloromethane and the mixture was stirred for 4 h. The yellow–orange solution was filtered and the solvent removed to give the complex as a gum which failed to solidify on continuous washing with petroleum ether and drying *in vacuo*. The complex was characterised by ^1H and ^{13}C NMR spectroscopy (see Table 2). Λ_m(MeCN) 107.3 ohm^{-1} cm^2 mol^{-1}.

IR (smear) bands at 3020s, 2990s, 2950s, 1575s, 1475s, 1440s, 1280m, 1350m, 1308w, 1260m, 1200m, 1180m, 1150m, 1070s, 1024s, 975s, 860s, 805s, 750s, 690s, 660s, 620s, 504w, 455w, 320s cm^{-1}.

Chlorotris(diethyldithiocarbamate)isopropylimidotungsten(VI) (4)

A suspension of sodium diethyldithiocarbamate (2.36 g, 13.8 mmol) in dichloromethane (80 cm^3) was added to a solution of hexachloro-di-μ-chlorobis(isopropylimido)ditungsten(VI) (1.32 g, 1.72 mmol) in dichloromethane (50 cm^3) and the mixture was stirred for 15 h. The yellow solution was filtered and the solvent removed to give a yellow gum which failed to solidify on extensive washing with petroleum ether. The complex was characterised by NMR spectroscopy (see Table 2).

IR (smear) bands at 3375m, 3175w, 2960s, 2920s, 2860s, 2800s, 2715m, 2620m, 2530m, 2445m, 2350w, 2220w, 2100w, 2010w, 1980w, 1920w, 1830w, 1770w, 1620m, 1580m, 1560s, 1540s, 1410s, 1380s, 1345s, 1300s, 1260s, 1220s, 1200s, 1140s, 1110m, 1090s, 1070s, 1010s, 980s, 920s, 855s, 835s, 790s, 735s, 705m, 670w, 610m, 595m, 570s, 560s, 520w, 495m, 465w, 440m, 420m, 400m, 380s, 365s,

340m, 330w, 315w, 300w, 295s, 265m, 260s, 240m cm^{-1}.

Triphenylcarbonium pentachloro(isopropylimido)tungstate(VI) (**5**)

Trityl chloride (0.44 g, 1.57 mmol) in dichloromethane (30 cm^3) was added to isopropylimidotungsten tetrachloride dimer (0.6 g, 0.78 mmol) and the mixture was stirred for 3 h. The red solution was filtered and the solvent removed to give a red gummy material which was continuously washed with petroleum ether, dried *in vacuo* and ground with a spatula until the complex was obtained as a yellow–brown powder. Λ_m(MeCN) 103.6 ohm^{-1} cm^2 mol^{-1}.

IR (Nujol) bands at 1660m, 1460s, 1445s, 1290m, 1270m, 1160m, 1100w, 1070w, 1025w, 980m, 870m, 820m, 750m, 735m, 692m, 660m, 618m, 608m, 568w, 504w, 460w, 400m, 310s, 280m cm^{-1}.

Chlorobisacetato-di-μ-acetatobis(isopropylimido)ditungsten(VI) (**6**)

Benzene (120 cm^3) was added to isopropylimido tungsten tetrachloride dimer(1.1 g, 1.44 mmol) and sodium acetate (1.0 g, 12.2 mmol) and the mixture was stirred for 4 h and then left to stand for 2 h. The solution was filtered and the solvent removed giving a yellow gum which failed to solidify on extensive washing with petroleum ether. The complex was characterised by NMR spectroscopy (see Table 2). It did not mull in Nujol or KEL-F.

Tetraethylammonium pentachloro(isopropylimido)tungstate(VI) (**7**)

Tetraethylammonium chloride (0.30 g, 1.8 mmol) in dichloromethane (30 cm^3) was added to hexachloro-di-μ-chlorobis(isopropylimido)ditungsten-(VI) (1.4 g, 1.8 mmol) in dichloromethane (60 cm^3) and the solution stirred for 2 h. The red solution was filtered and the solvent removed *in vacuo* leaving a red crystalline solid which was recrystallised from dichloromethane giving the complex as large red prisms. M.p. 154°C.

IR (Nujol) bands at 1360s, 1255s, 1210w, 1160s, 1150m, 1110w, 1070w, 1050w, 995s, 920w, 900w, 860w, 810w, 780s, 680w, 650w, 630w, 610m, 575m, 510w, 460w, 400w, 375w, 350m, 320s, 310s, 300s, 290s, 280m, 240s; (KEL-F) 2925w, 2270w, 1510w, 1460m, 1450w, 1430m, 1390m, 1370m, 1350m cm^{-1}.

Dichloro(isopropylimido)tris(trimethylphosphine)tungsten(IV) (**8**)

Isopropylimido tungsten tetrachloride dimer (1.2 g, 1.6 mmol) in benzene (100 cm^3) was added to a benzene solution (100 cm^3) of trimethylphosphine (1 cm^3, 9 mmol) and sodium–mercury amalgam (0.16 g sodium, 7 mmol; 50 g mercury) and the mixture stirred for 4 h. The blue solution was filtered from the spent amalgam, the solvent removed and the resulting solid taken up in toluene. Reducing the volume to *ca* 15 cm^3 and cooling to −20°C gave the complex as a purple crystalline solid. M.p. 118–120°C.

IR (Nujol) bands at 1410m, 1305m, 1300m, 1270s, 1260s, 1150w, 1110m, 1090m, 1070m, 1010m, 970s, 945s, 850m, 820m, 800s, 705m, 665s, 610w, 540w, 470w, 400w, 385w, 370m, 345s, 335m, 330m, 290w, 270s, 255m; (KEL-F) 2960s, 2900s, 2850m, 1450w, 1410s cm^{-1}.

Tris(t-butoxy)chloro(isopropylimido)tungsten(VI) (**9**)

Lithium *t*-butoxide (1.75 g, 22 mmol) in diethyl ether (30 cm^3) was added to a solution of isopropylimido tungsten tetrachloride (2.0 g, 2.0 mmol) in diethyl ether (40 cm^3) and the mixture was stirred for 12 h. The solution was filtered from the precipitated lithium chloride and the solvent removed to give a pale yellow crystalline solid which was extracted with petroleum ether (50 cm^3). After filtering, the volume was reduced to *ca* 5 cm^3 and the solution allowed to stand giving the complex as a colourless crystalline solid which was filtered off, washed with petroleum ether cooled to dry-ice temperature and dried *in vacuo*. M.p. 187°C decomp.

IR (Nujol) bands at 1650m, 1630m, 1610s, 1520m, 1500m, 1390m, 1260w, 1210m, 1160m, 1090w, 1020m, 950s, 935s, 900s, 860s, 840s, 820w, 800w, 660s, 575m, 480s, 465s, 410m, 365s, 340m, 260w; (KEL-F) 1455s, 1430w, 1390m, 1375s, 1365s cm^{-1}.

Tetraphenylarsonium pentachloro(isopropylimido)tungstate(VI) (**10**)

Tetraphenylarsonium chloride (1.39 g, 3.3 mmol) in dichloromethane (50 cm^3) was added to hexachloro-di-μ-chlorobis(isopropylimido)ditungsten-(VI) (1.2 g, 1.57 mmol) and the mixture was stirred for 2 h. The resulting red solution was filtered and the solvent removed to give the complex as an orange–red flaky solid which was washed several times with petroleum ether and dried *in vacuo*.

M.p. 45–50°C. The complex did not mull in Nujol or KEL-F.

Crystallographic studies

Single crystals of $[W(NCHMe_2)Cl_4]_2 \cdot C_6H_6$ (**1a**) (grown from benzene solution) and $[W(NCHMe_2)Cl_5][NEt_4]$ (**7**) (grown from dichloromethane) were sealed under nitrogen in glass capillaries and mounted on an Enraf–Nonius CAD-4 diffractometer.

Crystal data. Compound **1a**: $C_6H_{14}Cl_8N_2W \cdot C_6H_6$, $M = 843.63$, triclinic $a = 6.394(2)$, $b = 8.890(3)$, $c = 11.205(2)$ Å, $\alpha = 109.95(2)$, $\beta = 98.91(2)$, $\gamma = 93.96(2)°$, $U = 586.32$ Å^3; space group $P\bar{1}$, $Z = 1$, $D_c = 2.389$ g cm^{-3}, $F(000) = 390$, μ(Mo–K_α) = 112.7 cm^{-1}.

Crystal data. Compound **7**: $C_{11}H_{27}Cl_5N_2W$, M = 548.50, orthorhombic, $a = 13.667(5)$, $b = 15.152(2)$, $c = 9.432(2)$ Å, $U = 1953.10$ Å^3; space group *Pnma*, $Z = 4$, $D_c = 1.865$ g cm^{-3}, $F(000) = 1064$, μ(Mo–K_α) = 69.2 cm^{-1}.

Data collection. Accurate unit cell dimensions were determined by least-squares fits to the observed setting angles of 25 reflections using Mo–K_α radiation (Zr filter for $[W(NCHMe_2)Cl_4]_2 \cdot C_6H_6$, graphite monochromator for $[W(NCHMe_2)Cl_5][NEt_4]$).

Intensity data collections employed the $2\theta/\omega$ scan technique with a total background/peak count time ratio of 1/2. Reflections were counted for either 60 s or else until $\sigma(I)/I$ was 0.022 or 0.020 for the two compounds, respectively.[23] Measured data: compound **1a**, 2199 reflections ($\theta_{max} = 25°$), compound **7**, 2200 reflections ($\theta_{max} = 25°$). The intensities of three standard reflections were remeasured systematically throughout the data collections, and these showed isotropic declines to 0.35 and 0.71 of their initial values. The data were corrected for Lorentz, polarisation, crystal decay and absorption.[24]

Structure solutions and refinements. Both structures were solved by Patterson and Fourier methods and refined by the full-matrix least-squares technique.[25] The function minimised was $\sum w(|F_o| - |F_c|)^2$. Atomic scattering factors and dispersion corrections were for neutral atoms. After initial isotropic refinement, anisotropic thermal parameters were refined for the heavier atoms. In complex **7** the cation nitrogen atom occupies a crystallographic centre of symmetry with the β-carbons being related in pairs through the centre. The α-carbons are statistically disordered such that the cation spends half its time in one orientation, half its time in the alternative orientation, whilst maintaining common positions for the nitrogen and four outer carbon atoms. Such a model enables a very satisfactory refinement to be carried out in the centrosymmetric space group *Pnma*. Final residuals R and R_w were 0.050 and 0.053 for both the 1325 observed data [$I > 3\sigma(I)$] of compound **1a** and the 1157 observed data [$I > 2.5\sigma(I)$] of compound **7**.

Final atomic co-ordinates for both complexes, tables of thermal parameters, and listings of observed and calculated structure factors have been deposited with the Editor as supplementary material.*

RESULTS AND DISCUSSION

Preparation of complexes

To make ^{13}C NMR spectral comparisons with the range of known *t*-butylimido complexes we required $[W(NCMe_3)Cl_4]_2$, however, the general procedure for preparing organoimido complexes of tungsten(VI) by reacting alkylisocyanates with $[WOCl_4]$ fails with *t*-butylisocyanate.[13] We have thus restricted our studies to isopropylimido complexes, the preparation of $[W(NCHMe_2)Cl_4]_2$ (**1**) being straightforward. The preparative methods used are similar to those employed for phenylimido complexes of tungsten(VI)[13] and are shown in Fig. 1. Analytical data are contained in Table 1.

Several of the complexes persisted as gummy materials or did not analyse satisfactorily so that characterisation was made by NMR spectroscopy (Table 2). For example, reaction of **1** with eight equivalents of sodium acetate led to a green oil, the main component of which was identified as $[W(NCHMe_2)(\mu\text{-}OAc)(OAc)_2Cl]_2$ (**6**) from the presence in the ^1H NMR spectrum of three acetate group methyl resonances, a doublet for the isopropyl methyl groups and the isopropylimido methine proton septet at the characteristic shift of 6.05 ppm. In the ^{13}C NMR spectrum the isopropyl methine and methyl carbons appeared at 65.5 and 23.8 ppm, respectively, three acetate group methyl resonances were present at 22.4, 23.1 and 24.1 ppm, while there were three acetate group quaternaries at 170, 172 and 181.0 ppm, the latter resonance being in the vicinity of that characteristic of bridging acetate ligands.[14]

Reaction of **1** with eight equivalents of NaS_2CNEt_2 similarly gave an oil characterised as $[W(NCHMe_2)Cl(S_2CNEt_2)_3]_x$ (**4**) on the basis of

* Atom co-ordinates for these structures have also been deposited with the Cambridge Crystallographic Data Centre for inclusion in their data base. Copies are available on request from the Editor at Queen Mary College.

methine, methylene and methyl group proton resonances in the ratio of 1 : 12 : 24. The ^{13}C NMR spectrum suggested the presence of two species, there being two isopropylimido CH resonances and two sets of dithiocarbamate quaternary carbons. The two terminal quaternaries of each species appear at 192.8 and 196.9 ppm while two further resonances at 196.0 and 200.3 ppm are assigned to chelating or bridging dithiocarbamate ligands. Structures **4a** and **4b** are proposed on the basis of these features.

We were also interested in preparing complexes that given sufficient electron density on the imido nitrogen atom might react further to form amido complexes by the following reaction sequence:

$$[W(NCHMe_2)Cl_4]_2 + 2R{-}X \rightarrow 2[W(NCHMe_2)Cl_4X][R] \rightarrow [W(NCHMe_2R)Cl_4X].$$

Isopropylimido tungsten tetrachloride is surprisingly inert to a range of alkyl halides but the trityl

complexes $[W(NCHMe_2)Cl_4X][CPh_3]$ (X = Cl, OEt) (**5** and **3**) were readily formed but persisted as dichloromethane solvates. The complexes are 1 : 1 electrolytes in acetonitrile although the conductance values lie slightly outside the recognised lower limit. Ethoxy complex (**3**) failed to form a solid and was characterised by ^1H NMR spectroscopy, the salient features being the isopropylimido group methine proton resonance at 6.64 ppm and the ethoxide CH_2 quartet at 5.42 ppm. Both complexes apparently react further in solution but we have not yet been able to gain reliable evidence for transformation of either to an amido complex.

NMR spectra

^1H and ^{13}C NMR spectral details for the complexes are contained in Table 2. In the ^1H NMR spectra the imido ligand methine proton occurs in the region 4.5 to 7.1 ppm but as these protons may be influenced by environmental effects related to the different supporting ligands, interpretation of the shifts is not meaningful. In general however the protons are more shielded when the complexes contain oxygen or sulphur donors.

Table 2 shows the complexes arranged in descending order of the isopropylimido ligand ^{13}C NMR spectrum α-carbon resonance, relative to TMS. ^{13}C NMR studies for *t*-butylimido complexes of a range of metals[12] have shown that decreasing electron density on the nitrogen atom causes a downfield shift of the α-carbon resonance and an upfield shift for the β-carbon, the difference between the two, Δ ($\Delta = \delta_\alpha - \delta_\beta$), being used as an experimental probe for electron density on nitrogen. For the present complexes where only tungsten metal-centres are present, the position of the α-carbon resonance is used for this purpose as within experimental error the δ_α values follow the trend downwards.

The δ_α values indicate that the nitrogen lone pair participates in multiple bonding to tungsten to the greatest extent in $[W(NCHMe_2)Cl_4]_2$ (**1**). Thus the complex might be expected to show electrophilic reactivity at nitrogen with a progressive trend towards nucleophilic activity for the other complexes down the table. We note, however, that in comparison with the various *t*-butylimido complexes reported,[12] the Δ (40.1) value for $[W(NCHMe_2)Cl_5][AsPh_4]$ (**10**) compares with that of $[OsO(NBu^t)_3]$ (40.1) so that the anionic tungsten complex would still be regarded as being essentially electrophilic.

As an additional probe of small changes in electron density between nitrogen and tungsten we have obtained the methine C–H coupling constant for two complexes with widely differing δ_α values in view of the magnitude of J_{CH} for the α-carbon of substituted alkyl organic compounds being dependent on substituent electronegativity.[15] For $[W(NCHMe_2)Cl_4]_2$ (**1**) and $[W(NCHMe_2)Cl_5][NEt_4]$ (**7**), the J_{CH} values at 144.5 and 141.0 Hz, respectively, are much larger than J_{CH} for isopropylamine at 124.5 Hz, but the difference between complexes, although small, does indicate that polarisation of the W—N bond is slightly greater in the dimer. The J_{CH} values obtained compare with CH_3OH at 141.0 Hz, CH_3OPh at 143.0 Hz and CH_3NO_2 at 146.7 Hz.[15]

In order to relate ^{13}C NMR features to structural aspects, X-ray crystal structure determinations were carried out on $[W(NCHMe_2)Cl_4]_2 \cdot C_6H_6$ (**1a**) and $[W(NCHMe_2)Cl_5][NEt_4]$ (**7**).

X-ray crystallography studies

The X-ray crystal structure of $[W(NCHMe_2)Cl_4]_2 \cdot C_6H_6$ (**1a**) shows the molecule to be a dimer in which the two halves are centrosymmetrically related. Each tungsten atom adopts a distorted octahedral co-ordination geometry, consisting of three terminal chlorine atoms with a fourth chlorine forming a bridge between the two tungsten atoms. The isopropylimido ligand is terminal and lies *trans* to one of the chlorine bridges. A view of the molecule is shown in Fig. 2. Bond distances and angles are given in Table 3.

The isopropylimido ligand is essentially linear with a W—N—C(1) bond angle of 171.5(4)°. The

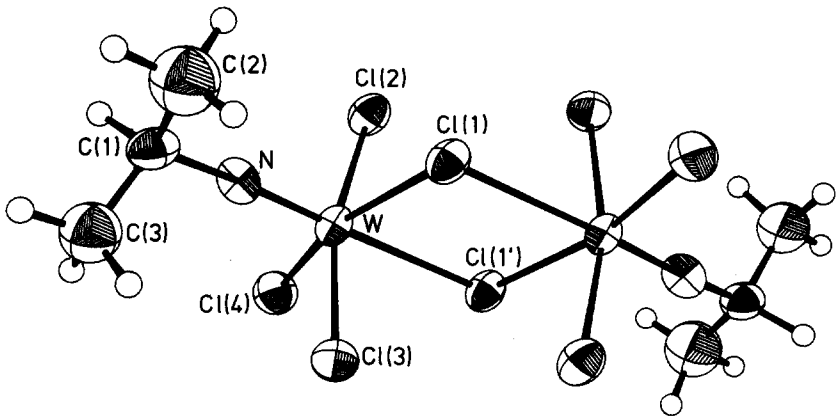

Fig. 2. $[W(NCHMe_2)Cl_4]_2$ molecule. Thermal ellipsoids have been drawn at the 50% probability level.

short W—N bond distance of 1.697(12) Å is not significantly different from the value of 1.71 Å predicted for a W—N bond acting as a four-electron donor (W≡NR).[1] The bridging chlorides are unsymmetrical in that W—Cl(1) is 2.418(4) Å whereas W—Cl(1′) is 2.736(5) Å. Since Cl(1′) is situated *trans* to the imido function, the lengthening of W—Cl(1′) is most likely due to a very strong *trans*-influence associated with the multiple bonding between tungsten and nitrogen.[13] The terminal W—Cl bond distances range from 2.285(4) to 2.310(4) Å.

Distortion from octahedral geometry in the molecule arises from chlorine atoms (1)–(4) being displaced away from the imido group, the mean N—W—Cl(*n*) angle (*n* = 1–4) being 97.8°. The tungsten atom lies 0.32 Å from the plane made by these four chlorine atoms.

The crystal structure of **7** consists of discrete tetraethylammonium cations and complex anions. The anion is monomeric with a distorted octahedral geometry. The molecule is shown in Fig. 3 and bond distances and angles shown in Table 4.

The isopropylimido ligand is again essentially linear with a W—N—C bond angle of 174.4(16)° while the W—N(1) bond length of 1.763(16) is significantly longer than that found for the parent dimer and slightly longer than those found for other organoimido complexes in which the W—N bonds are considered to have bond orders of less than 3.[1,8,13,16,17] The W—Cl bond lengths in the equatorial plane range from 2.346(3) to 2.357(5) Å while the

Cl(1)—W—Cl(3)	87.44(14)		

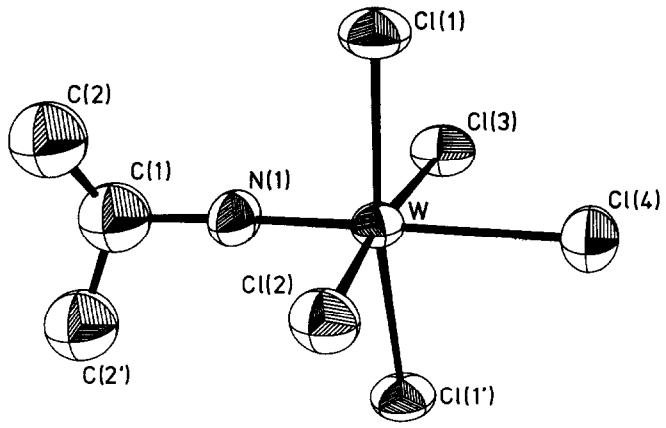

Fig. 3. $[W(NCHMe_2)Cl_5]$ anion. Thermal ellipsoids have been drawn at the 50% probability level.

W—Cl bond *trans* to the imido function is long at 2.462(5) Å. The octahedron is less distorted than in the dimer with the average of the angles between nitrogen, tungsten and the four equatorial chlorines being 93.6°. The tungsten atom lies 0.15 Å from the plane made by these four chlorine atoms.

The main point of interest in the two structures is the difference in the W—N bond lengths which at 1.697(12) and 1.763(16) differ by 0.066 Å which is at least 4 standard deviations. However the W—N—C bond angles at 171.5(9)° and 174.4(16)° are not significantly different, being essentially linear, so that the differences in bond lengths can apparently be accommodated without effecting a major change in the hybridisation state of nitrogen. By contrast in $[Mo(NPh)_2(S_2CNEt_2)_2]$[11] where one Mo—N bond is long [1.789(4) Å] and is associated with a Mo—N—C bond angle of 139.4(4)° a bond order of about 2.3 is implied but in $[\{W(NPh)(OCMe_3)_2\}_2(\mu\text{-}O)(\mu\text{-}OCMe_3)_2]$[17] a bond order of about 2.8 is suggested for a W—N bond length and W—N—C bond angle of 1.737(5) Å and 165.3(5)°, respectively. In the $[W(NCHMe_2)Cl_5]$ anion however, the W—N bond is lengthened to 1.763(16) Å without significant change to the W—N—C bond angle.

The W—N bond lengths observed in the present complexes may be explained in terms of the 18-electron rule when bonding of the other ligands is also taken into account. In the dimeric complex the bond lengths associated with the bridging chloride [2.418(4) and 2.736(5) Å] are consistent with Cl(1) acting as a one-electron donor to W and a two-electron donor to W′. The Cl(1)—W′ bond length is extremely long, as is the equivalent W—Cl(1′) bond length so that the bonding between the two halves of the molecule is weak. Assuming however that Cl(1) acts as a one- and two-electron donor to the respective tungsten atoms, the remaining terminal chlorides are one-electron donors and the

Table 4. Selected bond lengths and angles for $[W(NCHMe_2)Cl_5][NEt_4]$

	Bond length (Å)

Cl(1)—W—N(1)	93.5(1)	Cl(4)—W—N(1)	178.1(6)

imido group acts as a four-electron donor, then the electron count for the complex is 16.

Consideration of the terminal W—Cl bond lengths indicates that the two extra electrons needed to complete an 18-electron count, arise mainly from a π-contribution at Cl(4) [the W—Cl(4) bond length at 2.285(4) Å is similar to the terminal W—Cl bond lengths in $[WOCl_4]_x$[18] at 2.28 Å where an extra electron from each chlorine atom or more realistically a series of Cl⇌W—Cl canonicals involving π-bonding, is needed to achieve 18 electrons]. The contribution lies to a lesser extent from Cl(2) and Cl(3) [W—Cl bond lengths 2.310(4) and 2.307(4) Å, respectively]. The W—Cl(4) bond length also indicates that chlorine is better able to participate in π-bonding to the metal when it lies *trans* to Cl(1) in which minimal π-bonding to W occurs. As such, Cl(4) does not have to compete for π-bonding orbitals as do Cl(2) and Cl(3). Of the ligands capable of π-bonding, the imido nitrogen is apparently best able to supply electrons and this is reflected by the shortened W—N bond length [1.697(12) Å] which is similar to the predicted value of 1.71 Å for a four-electron donor.[1]

In the case of the anionic complex, more chlorine ligands are available to participate in π-bonding and this appears to relieve the need for the imido ligand to act strictly as a four-electron donor. The W—Cl(4) bond length at 2.462(5) Å is considerably longer than those in the equatorial plane as a result of the imido group *trans* influence so that little π-bonding is expected from this ligand. The remaining W—Cl bond lengths range from 2.346(3) to 2.357(5) Å, all being shorter than that found for chlorine acting as a one-electron donor in the dimeric complex, so that they represent the average of the canonicals contributing to π-bonding.

CONCLUSION

Correlation of an 18-electron count with structural details thus indicates that changes in the W—N bond length between the two complexes results mainly from overall π-bonding requirements rather than a competitive π-bonding situation *trans* to the imido function. While there are differences in the shift of the α-carbon ^{13}C NMR resonances of the imido ligands for all the complexes these can also be expected to relate to π-bonding capabilities of the other ligands present. For example, from inspections of the decreasing δ_α values in Table 1, $[W(NCHMe_2)Cl_4(NCEt)]$ (**2**), with more terminal chlorine ligands, has a lesser need for W—N π-bonding than does $[W(NCHMe_2)Cl_4]_2$ (**1**). $[W(NCHMe_2)Cl(OCMe_3)_3]_2$ (**9**) lies at the lower end of the table as the alkoxide ligand is a better π-bonding ligand than chlorine.[19] Interestingly, $[W(NCHMe_2)Cl_4(OEt)][CPh_3]$ (**3**) in which the ethoxide ligand is expected to lie *trans* to the imido function and therefore compete for π-bonding orbitals, is intermediate in the list, so that the nitrogen lone pair is not free to interact with the carbocation and otherwise produce the amido complex, $[W(NCHMe_2CPh_3)Cl_4(OEt)]$.

(*Received* 17 *March* 1986; *accepted* 19 *May* 1986)

Abstract—The X-ray structures of the complexes $Eu(NO_3)_3(Ph_3PO)_3(acetone)_2$ (**A**) (Ph_3PO = triphenylphosphine oxide) and $Eu(NO_3)_3(Ph_3PO)_2(ethanol)$ (**B**) have been solved by the heavy-atom method, by using the three-dimensional Patterson–Fourier synthesis. The crystals are both monoclinic and belong to the space group $P2_1/n$, with $Z = 4$. The cell dimensions are: $a = 27.825(4)$ Å, $b = 19.422(4)$ Å, $c = 11.238(2)$ Å, $\beta = 94.9(3)°$ for **A**; and $a = 22.193(4)$ Å, $b = 10.866(2)$ Å, $c = 17.101(3)$ Å, $\beta = 105.6(3)°$ for **B**. In both complexes the europium(III) ion is ennea-coordinated to three chelate nitrate groups and three oxygens of the Ph_3PO ligands for **A** and two of the Ph_3PO and one of the ethanol for **B**. The acetone molecules of **A** are outside the coordination sphere of the metal and disordered.

A wide interest has been shown concerning the complexes formed by europium(III), together with the other lanthanides, and various monodentate neutral ligands with O as the donor atom.[1–14] These simple ligands have been proved to be very useful in the study of the different coordination geometries which are possible for this ion, because compounds with many stoicheiometries can be obtained, depending upon the reaction conditions. Different compounds are obtained according to the binding ability of the anion and the solvent, and the experimental procedure itself. On the basis of IR, electronic and fluorescence spectra, coordination numbers and idealized geometries around the metal center have been proposed,[10,15–23] whereas few X-ray structures have been reported in the literature to support the spectroscopic results.[24–27] It therefore seemed interesting to have a series of these simple compounds for a complete study of their characteristics, and of the electronic and structural properties by absorption, fluorescence and Mössbauer effect spectroscopies, and, when feasible, by X-ray structure determinations. The goal of this research is an attempt to rationalize the effects leading to one of the various possible geometries. Therefore, several europium(III) nitrate complexes with triphenylphosphine oxide (Ph_3PO) of triphenylarsine oxide have been prepared. The use of the nitrate group as an anion is due to its good bidentate ligand behavior, and to its small bite that allows us to consider it as occupying a single coordination position. The phosphine and arsine oxides have been chosen because of the great binding ability of the O atom toward the lanthanides, enhanced by the strong electric dipole of the P–O or As–O moieties. We now report on the X-ray single-crystal structures of two of these complexes, namely $Eu(NO_3)_3(Ph_3PO)_3(acetone)_2$ (**A**) and $Eu(NO_3)_3(Ph_3PO)_2(ethanol)$ (**B**), that have characteristics typical of the whole series.

EXPERIMENTAL

The complexes were prepared as previously reported.[1] Recrystallization from acetone and ethanol, respectively, yielded crystals which were suitable for the X-ray analysis.

Crystal data

A: $EuC_{60}H_{57}N_3O_{14}P_3$, monoclinic, space group = $P2_1/n$, $a = 27.825(4)$ Å, $b = 19.422(4)$ Å, $c = 11.238(2)$ Å, $\beta = 94.9(3)°$, $U = 6050.6(5)$ Å^3, $Z = 4$, $F(000) = 2632$, $D_c = 1.415$ g cm^{-3}, $D_m = 1.40$ g cm^{-3}, $\mu = 16.1$ cm^{-1}, $M = 1289.01$.

B: $EuC_{38}H_{36}N_3O_{12}P_2$, monoclinic, space group = $P2_1/n$, $a = 22.193(4)$ Å, $b = 10.866(2)$ Å, $c = 17.101(3)$ Å, $\beta = 105.6(3)°$, $U = 3972.0(8)$ Å^3, $Z = 4$, $F(000) = 1896$, $D_c = 1.572$ g cm^{-3}, $D_m = 1.56$ g cm^{-3}, $\mu = 16.0$ cm^{-1}, $M = 940.63$.

All the data were collected on a Philips PW 1100 four-circle diffractometer at room temperature in the range $2° < 2\theta < 50°$, with graphite-monochromatized Mo-K_α radiation ($\lambda = 0.71069$ Å). For complex **A**, 11,174 reflections were measured, of which 10,607 were unique ($R_{int} = 0.017$), and 4774, considered observed following the criterion $I > 3.5\sigma(I)$, were used in the subsequent calculations. For complex **B** 7233 reflections were measured, of which 6994 were unique ($R_{int} = 0.06$) and 5625 were considered observed [$I > 3\sigma(I)$].

Both structures were solved using the heavy-atom block-diagonal least-squares refinement based on F and the function $\sum w[|F_o|-|F_c|]^2$, in which $w = 1$, was minimized. The SHELX-76 program and its scattering factors for C, N, O and P atoms were used in the refinement;[28] scattering factor data for Eu were taken from Ref. 29. In structure **A** only Eu and P atoms, and in structure **B** also N and O atoms were refined anisotropically. The final R factor for complex **A** is 0.129 and for complex **B** 0.0436. The very high R value for **A** is attributed to the large disorder of the phenyl groups and the acetone molecules.

Distances and angles between the metal center and atoms forming the coordination polyhedra are reported in Table 4; the fractional atomic coordinates, thermal parameters, and the observed and calculated structure factors have been deposited as supplementary data with Editor, from whom copies are available on request.* Perspective views of the two structures, along with the atom-numbering scheme, are shown in Figs 1 and 2.

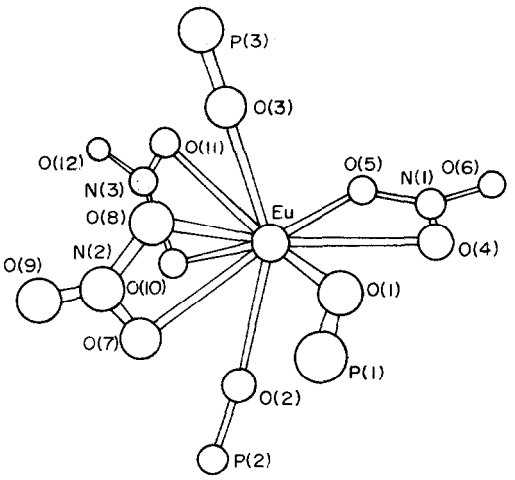

Fig. 1. Perspective view of the molecule $Eu(NO_3)_3(Ph_3PO)_3$ along with the atom-numbering scheme.

RESULTS AND DISCUSSION

The structures of both complexes are rather similar to each other: the europium(III) center is surrounded by nine O atoms, six from the three nitrate groups and three from the monodentate ligands. The nitrate groups are all bidentate as in other complexes of the 4*f* transition elements,[30–36] and as already suggested by the IR spectra.[1] The average O (nitrate)—Eu bond distances are 2.497 Å for complex **A** and 2.500 Å for complex **B**, and the O—Eu—O bond angles range between 50 and 52°, values that are close to those of related compounds.[25,26] The coordination sphere in complex **A** is completed by three phosphine oxide molecules,

* Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

while in complex **B** one of the ligands has been substituted by an ethanol molecule [the acetone molecules are not bonded to the europium(III) ion, the Eu—O (acetone) distances being over 4.0 Å]. The polyhedron surrounding the europium(III) ion does not conform to any of the common geometries found in nine-coordinate lanthanide complexes, viz. tricapped trigonal prism and monocapped square antiprism. If the nitrate groups are considered as occupying a single coordination site, the geometry of the resulting polyhedron, formed now by the three O atoms from the monodentate ligands and by three N atoms, is a highly distorted octahedron where the angles between opposite ligands range from about 151° for O—Eu—O to 176° for N—Eu—N (Table 1). The bidentate nitrate groups may be considered as symmetrically bonded to the europium(III) ion because the Eu—O bond distances differ by less than 0.10 Å from each other. For complex **A** the N—O (bonded) distance seems to be identical to the N–O (non-bonded) distance, while in complex **B** it is slightly longer as already found in other symmetrically bidentate nitrate groups.[25] The O—N—O interbond angle involving both coordinated O atoms is smaller than 120° (average values are 116 and 117°, respectively) and the other two angles are correspondingly larger (121 and 122°). The Eu—O—P bond angles on the O

atom vary from 144 to 171°, with values similar to those already found for uranyl complexes with Ph_3PO or triphenylarsine oxide.[37] It may be interesting to note that the values of this angle are widespread in the first complex (144, 163 and 171°) and much less in the second one (164 and 168°) which is also much less crowded for the substitution of a phosphine oxide molecule by an ethanol molecule.

POTENTIOMETRIC DETERMINATION OF STABILITY CONSTANTS OF INORGANIC CYCLOPHOSPHATE COMPLEXES WITH COPPER(II), CADMIUM(II) AND LEAD(II) IONS

GENICHIRO KURA

Department of Chemistry, Fukuoka University of Education, Akama, Munakata, Fukuoka 811-41, Japan

(*Received* 24 *April* 1986; *accepted* 28 *May* 1986)

Abstract—The stability constants of the complexes of cyclophosphate anions and copper(II), cadmium(II) and lead(II) ions were determined by potentiometry with the use of ion-selective electrodes. For each metal ion, the stability constant of the 1 : 1 complex increases linearly with the charge on the phosphate ion. For the same cyclophosphate ion, the stability constants also increase with increase in the crystal radii of the cation, i.e. in the order: $Cu^{2+} < Cd^{2+} < Pb^{2+}$. These results suggest that the complex formed is a typical outer-sphere type based on electrostatic forces.

Of the inorganic condensed phosphates, cyclophosphates ranging from the trimeric anion, $P_3O_9^{3-}$, through the octametric anion, $P_8O_{24}^{8-}$, with cyclic structures are very interesting electrolytes, since they have a high negative charge on their relatively compact structure.[1] These phosphates are stable for the hydrolysis reaction at ordinary temperatures in slightly acidic or basic aqueous solutions.[2–5] Protonation of cyclophosphates has been neglected provided the hydrogen ion concentration of the solutions is low,[6] and so the treatment of these cyclophosphates is easier than that of other condensed phosphates.

The interaction of cyclophosphates and several cations has already been reported by the author.[6–9] The property of the interaction was considered to be ascribed to the electrostatic force between highly negatively charged phosphate anions and cations. In this study, we have determined the stability constants of the complexes of cyclo-tri-, cyclo-tetra-, cyclo-hexa- and cyclo-octaphosphate and copper(II), cadmium(II) and lead(II) ions by potentiometry with the use of ion-selective electrodes. The mechanism of the complex formation is discussed.

In this paper, cyclophosphates are abbreviated as P_{nm}, where n is the degree of polymerization.

EXPERIMENTAL

Reagents

A standard solution of copper(II) perchlorate was prepared from copper(II) carbonate hydroxide and perchloric acid. Stock solutions of cadmium(II) and lead(II) ions were prepared from the nitrates of reagent grade.

Cyclophosphates were prepared by the usual methods[2,5] and their purity was checked by liquid chromatography.[5]

The other chemicals used in this study were reagent grade and commercially available.

The concentrations of the stock solution of the metal ions were determined by complexometric titration with EDTA.

Apparatus

Potential measurements were made with the Orion Ion Meter Model 801. As ion-selective electrodes, the Orion Model 94-29A, 94-48A and 94-82A were used for copper(II), cadmium(II) and lead(II) ion measurements, respectively. The Orion Model 90-01-00 reference electrode was also used for all potential measurements.

Procedure

The potential was measured at 25±0.1°C in a thermostatted vessel and the pH of the test solution was adjusted to 4 with $HClO_4$. The ionic strength (I) of the test solutions was adjusted by adding $NaClO_4$ as follows: $I = 0.4$ for P_{3m}, $I = 0.3$ for P_{4m}, and $I = 0.1$ for P_{6m} and P_{8m}. The concentration range of the total phosphate and metal ion in the test solutions are given below:

$[M^{2+}]_t$: 2.9×10^{-4}–1.9×10^{-2} M for the P_{3m} and P_{4m} systems, and 2.9×10^{-5}–1.9×10^{-3} M for the P_{6m} and P_{8m} systems.

$[P]_t$: 5.0×10^{-2}–3.3×10^{-2} M for the P_{3m} system, 1.3×10^{-2}–2.0×10^{-2} M for the P_{4m} system, and 6.7×10^{-4}–1.0×10^{-3} M for the P_{6m} and P_{8m} systems.

Before activity measurements the ion-selective electrodes were aged in the metal ion solution of the prescribed concentration for several hours. The electrode systems were standardized before and after each experiment using several metal ion solutions of various concentrations which covered the concentration range of interest.

For the determination of the free metal ion concentration, a titration method was applied and standardization of the electrodes was first carried out by adding metal ion to aqueous solutions free from cyclophosphates. The I of both solutions was adjusted to the prescribed values.

RESULTS AND DISCUSSION

The potential reading of the ion meter can be converted to the concentration of the metal ions when the I of the test solution is known. However, the I of the solution cannot be calculated unless the stability constant of the complex formed is determined.

This problem was solved by successive approximations as follows. At first, the I of the test solution was adjusted to an approximate value designed by adding the supporting electrolyte, and the potential was measured and converted to the free metal ion concentration by assuming that I was constant. Thus, the average number of metal ions bound to one cyclophosphate anion ($\bar{n}$) was determined, and from the formation curve thus obtained approximate stability constants were calculated and refined. Next, I was adjusted rather accurately to a constant value designed by adding the supporting electrolyte to the test solution by the calculation based on the stability constants determined above, and $\bar{n}$ was again measured. The I of the systems calculated using the stability constants finally determined agreed very closely with the prescribed value. The above two-step measurements were satisfactory for the purpose of determining the accurate stability constants.

	Log β_1	Log β_1	Log β_1	Log β_2	Log β_3	Log β_1	Log β_2	Log β_3
Cu^{2+}	1.6	2.7	4.5	7.1		5.6	8.1	
Cd^{2+}	1.8	3.3	5.0	8.3	11.1	6.2	9.6	12.6
Pb^{2+}	2.8	4.5	7.5	12.1	15.3	7.5	12.1	15.3

$\bar{n}$ can be presented as:

$$\bar{n} = \frac{[M^{2+}]_t - [M^{2+}]_{free}}{[P]_t}, \quad (2)$$

where $[M^{2+}]_t$, $[M^{2+}]_{free}$ and $[P]_t$ denote the total metal, free metal and total cyclophosphate concentration, respectively. The formation curves for the copper(II), cadmium(II) and lead(II) ion systems are shown in Figs 1–3. From these formation curves, we have determined accurate stability constants by combining the half-$\bar{n}$ method and successive approximations.

For cyclo-tri- and cyclo-tetraphosphate complexes, $\bar{n}$ is lower than 1 for all metal ions, then only 1 : 1 complex formation was assumed and the stability constant β_1 was directly calculated using the following equation:

$$\beta_1 = \frac{\bar{n}}{(1-\bar{n})[Cu^{2+}]_{free}}. \quad (3)$$

For the Cu^{2+}–P_{6m} and Cu^{2+}–P_{8m} systems, the formation of a 2:1 [copper(II):cyclophosphate ratio] complex was assumed. For the Cd^{2+}–P_{6m}, Cd^{2+}–P_{8m}, and Pb^{2+}–P_{6m} and Pb^{2+}–P_{8m} systems, the maximum number of metal ions bound to one cyclophosphate anion was assumed to be 3.

The stability constants obtained are shown in Table 1. The solid lines in Figs 1–3 are drawn using the calculation based on the stability constants in Table 1, and other points are experimentally obtained. The coincidence of both is satisfactory.

For each cyclophosphate, $\log \beta_1$ values, which are plotted in Fig. 4, increase almost linearly with their negative charge. Complex formation of cyclophosphate anion with these bivalent cations is thought to be ascribed to the electrostatic interaction. For the same cyclophosphate anion, the stability constant increases in the order: Cu^{2+} (0.72 Å) < Cd^{2+} (0.97 Å) < Pb^{2+} (1.20 Å). This order is in accord with the increase in the crystal radii. This result is compatible with a complex formation of outer-sphere type based on the electrostatic force.

SPECTROPHOTOMETRIC DETERMINATION OF FORMATION CONSTANTS OF VARIOUS TYPES OF COMPLEXES BY USE OF ANOTHER COMPETING LIGAND

EMIKO OHYOSHI

Yatsushiro National College of Technology, Hirayamashinmachi 2627, Yatsushiro, Kumamoto, 866, Japan

(*Received* 20 *May* 1986; *accepted* 23 *June* 1986)

Abstract—A method has been developed for determining the formation constants of various colored complexes, ML and ML_2, and their protonated forms, spectrophotometrically, by measuring the absorbance of all forms of the colored complexes in the absence and presence of another ligand, Y, which forms the colorless complex MY, with a known formation constant. This method is based on the competition between the two ligands, L and Y, for the metal ion. An experimental test has been done for the Zn(II)–4-(2-pyridylazo)resorcinol (PAR) (H_2L) system by using nitrilotriacetic acid (NTA) as another ligand, Y. The results showed that the concentrations of PAR used were suitable for the study of 1:2 complexes, ZnL_2, ZnL(HL) and $Zn(HL)_2$, but were too high to study the 1:1 complexes. With the aid of the formation constants of ZnL and ZnHL determined previously, the experimental data gave an approximate value for the formation constant of ZnY (Y = NTA) which agreed with the published value.

When a metal simultaneously forms various colored complexes involving protonated species, it is very difficult to estimate each species by spectrophotometry. A recent study[1] showed that the estimation of the free-ligand concentration spectrophotometrically can be used to evaluate the formation constants of both protonated and normal complexes. This method, however, is limited to the 1:1 complexes. To study a system involving 1:2 complexes, the ligand concentration must be used in large excess over the metal, and all the metal ions would thus form the colored complexes. When another ligand with which the metal forms a colorless complex having a known formation constant is added to such a system, the absorbance due to the colored complexes decreases as a result of competition between the two ligands. By measuring this decrease, which corresponds to the amount of the colorless complex, we can evaluate the equilibrium concentrations of both colored and colorless complexes, which would enable us to estimate the free metal ion concentration. Therefore, the principle seems to be analogous to that of the cation exchange method (the use of another ligand in place of the cation exchange resin) which has been useful for the analysis of various complex species.[2–5] Hughes and Martell[6] have described a method using another competing metal for determining relative stability constants by spectrophotometric determination of the positions of exchange equilibria. However, it is applicable only to a system of 1:1 complexes with a known molar absorptivity.

In this study, a spectrophotometric method has been developed for determining the formation constants of various types of colored complexes without a knowledge of any molar absorptivities by the use of another competing ligand, and applied to the Zn(II) and 4-(2-pyridylazo)resorcinol (PAR) (H_2L) system. The procedure is more rapid and simple compared to the cation exchange method.

CALCULATION OF COMPLEX FORMATION CONSTANTS

When a metal, M, reacts with a reagent, H_2L, like PAR, at relatively low pH, possible forms of the colored complexes are MHL, ML, $M(HL)_2$, M(HL)L and ML_2 (the charges are omitted for simplicity). Under conditions where the concentration of the ligand (C_L) is in large excess over that

of the metal (C_M), all the metal would be complexed. Then:

$$C_M = [MHL] + [ML] + [M(HL)_2] + [M(HL)L] + [ML_2]. \quad (1)$$

When another ligand, Y, which forms the colorless complex MY, is added to such a solution, it displaces the ligands HL and L, and the total amount of the colored complexes decreases. If we can assume that no mixed-ligand complexes are formed (this assumption will be tested later), the concentration of MY is given by:

$$[MY] = C_M - ([MHL] + [ML] + [M(HL)_2] + [M(HL)L] + [ML_2]). \quad (2)$$

Since the total amount of the colored complexes can be estimated spectrophotometrically, the relative amounts of the colorless complex and the colored complexes (all forms) at equilibrium are given by measuring the absorbance at the peak of the colored complexes before and after addition of Y, A_t and A, as follows:

$$[MY]/([MHL] + [ML] + [M(HL)_2] + [M(HL)L] + [ML_2]) = (A_t - A)/(A - A_o), \quad (3)$$

where A_o is the absorbance of the free colored ligand at the peak of the colored complexes. Using the formation constants of all the complexes, K_{MHL}, K_{ML}, $K_{M(HL)_2}$, $K_{M(HL)L}$, K_{ML_2} and K_{MY}, the dissociation constants of H_2L and HL, K_1 and K_2, and the α coefficient,[7] $\alpha_L = [L']/[L] \simeq C_L/[L]$, where [L'] is free ligand not combined with any metal (in this case $[L'] \simeq C_L$ since $C_M \ll C_L$), eqn (3) is expressed as:

$$K_{MY}[Y]/\{(K_{MHL}K_1[H] + K_{ML}K_1K_2)C_L/(\alpha_L K_1K_2) + (K_{M(HL)_2}K_1^2[H]^2 + K_{M(HL)L}K_1^2K_2[H] + K_{ML_2}K_1^2K_2^2)C_L^2/(\alpha_L K_1K_2)^2\} = (A_t - A)/(A - A_o). \quad (4)$$

It can be seen from eqn (4) that the ratio $(A_t - A)/(A - A_o)$ should be proportional to [Y] at constant pH and C_L. This linear relation can be used to prove the assumption that no mixed-ligand complexes are formed. The slope, s_1, should be given as a function of C_L or pH. When s_1 is determined at different C_L keeping pH constant, the quantity $1/(s_1C_L)$ can be expressed as a function of C_L:

$$1/(s_1C_L) = \{(K_{MHL}K_1[H] + K_{ML}K_1K_2)/(\alpha_L K_1K_2) + (K_{M(HL)_2}K_1^2[H]^2 + K_{M(HL)L}K_1^2K_2[H] + K_{ML_2}K_1^2K_2^2)C_L/(\alpha_L K_1K_2)^2\}/K_{MY}. \quad (5)$$

According to eqn (5), a plot of $1/(s_1C_L)$ vs C_L should be linear with an intercept of $(K_{MHL}K_1[H] + K_{M(HL)_2}K_1^2[H]^2 + K_{M(HL)L}K_1^2K_2[H] + K_{ML_2}K_1^2K_2^2)/(K_{MY}\alpha_L^2K_1^2K_2^2)(s_2)$. The products of $\alpha_L K_1K_2$ and y_1, and of $(\alpha_L K_1K_2)^2$ and s_2 are both given as a function of pH:

$$\alpha_L K_1K_2y_1 = (K_{MHL}K_1[H] + K_{ML}K_1K_2)/K_{MY}, \quad (6)$$

$$(\alpha_L K_1K_2)^2s_2 = (K_{M(HL)_2}K_1^2[H]^2 + K_{M(HL)L}K_1^2K_2[H] + K_{ML_2}K_1^2K_2^2)/K_{MY}. \quad (7)$$

Hence, with a knowledge of K_{MY} we can determine the formation constants of various complexes by evaluating y_1 and s_2 at different pH values. The K_{MHL} and K_{ML} values are obtained from the slope and intercept of the plot of eqn (6). The plot of eqn (7) at low values of [H] should be linear to yield K_{ML_2} as the intercept (y_2). Subtracting this intercept, y_2, from $(\alpha_L K_1K_2)^2s_2$ and dividing it by [H], we obtain:

$$\{(\alpha_L K_1K_2)^2s_2 - y_2\}/[H] = (K_{M(HL)_2}K_1^2[H] + K_{M(HL)L}K_1^2K_2)/K_{MY}. \quad (8)$$

The plot of the left-hand side of eqn (8) vs [H] gives $K_{M(HL)_2}$ and $K_{M(HL)L}$ as the slope and intercept, respectively. In this experiment, we used PAR and nitrilotriacetic acid (NTA) as the ligands H_2L and Y, respectively.

EXPERIMENTAL

Materials

All chemicals used were of reagent grade. PAR was obtained from Dojindo Chemical Co., and its

purity was checked by using thin-layer chromatography.[8] Weighed quantities of PAR and NTA were dissolved in a small volume of 1.0 M NaOH and diluted with distilled water to prepare the stock solutions of PAR (1.0×10^{-2} M) and NTA ($2.5–5.0 \times 10^{-3}$ M). A Zn(II) solution having a concentration of about 0.01 M was prepared from nitrate and standardized by EDTA titration using xylenol orange as an indicator. Sodium diethylbarbiturate and sodium nitrate were used to maintain the pH at 6.5–8 and the ionic strength at 0.1, respectively.

Procedure

An aliquot of 1.0×10^{-3} M Zn(II) solution was added using a microliter pipet to 10 cm^3 of buffered PAR solution ($5–11 \times 10^{-5}$ M), to give concentrations of $3–5 \times 10^{-6}$ M. The NTA solution was then added in small aliquots, $20–50 \times 10^{-3}$ cm^3 each. The absorbance at 500 nm (λ_{max} of the Zn–PAR is 493 nm, at which we observed a larger contribution of the free PAR absorption peak at 415 nm) was measured before any addition of the substance (A_o) and then after each addition of the metal (A_t) and the NTA solution (A) by using a Shimadzu UV-260 spectrophotometer. The variation in the absorbance due to the free PAR (415 nm) was also measured to evaluate [L′] at equilibrium, which is more accurate than C_L for using in calculation.

RESULTS AND DISCUSSION

The experiments were carried out under conditions where $C_L \gg C_M$ (L = PAR, M = Zn). The absorbance due to the Zn–PAR complex at 500 nm, $A_t - A_o$ was not varied with increasing C_L at constant pH to show all the metal ions being complexes. The apparent molar absorptivity ($\varepsilon_{Zn\text{-}PAR}$) [$= (A_t - A_o)/C_M$], which was confirmed to be unchanged with varying C_M ($3–5 \times 10^{-6}$ M), gradually decreased with decreasing pH from 8.3×10^4 (pH = 7.92) to 5.5×10^4 (pH = 5.52), suggesting that protonation of the Zn–PAR complex occurred. To analyse these complex species we used another competing ligand, NTA (Y) and studied the effect on the complexation equilibria between Zn(II) and PAR. As shown in Table 1, the absorbance due to the Zn–PAR complex (500 nm) decreases with increasing concentrations of NTA (C_Y) which is related to [Y] by the equation: $[Y] = K^H_{HY}(C_Y - [MY])/[H]$, where $K^H_{HY} = [H][Y]/[HY] = 10^{-9.719}$ and $[MY] = C_M(A_t - A)/(A_t - A_o)$. At the same time, the free PAR absorption peak (415 nm) was observed to increase. From the variation in these two peaks at relatively high pH, we concluded that only the reaction: $ZnL_2 + Y = ZnY + 2L'$ took place, i.e. no formation of the mixed-ligand complex, ZnLY, which was the assumption made in deriving equations. This was also proved by the fact that the linear character of the plots according to eqn (4) (a constant value of the slope s_1 given in Table 1) was obtained at constant pH and C_L.

Using the slope s_1, determined at different C_L, keeping pH constant, we plot the quantity $1/(s_1C_L)$ vs C_L [eqn (5)] as shown in Fig. 1. All the plots yield a linear relationship with a very small intercept (y_1), indicating that almost all the complexes have a 1:2 metal:ligand ratio under the conditions studied. Hence, both K_{MHL} and K_{ML} could not accurately be evaluated in this experiment. However, the y_1 values obtained at relatively low pH were used to test the validity of this method. According to eqn (6), with a knowledge of K_{MHL}, K^1_{ML}, K_1 and K^{10}_2, and the use of y_1 values in Fig. 1(b), we obtained values of log K_{MY} ranging from 10.3 to 10.5, which agreed with the published value of 10.44.[9] It is noted that the slope increases to a great extent with

increasing pH, suggesting that the stability of ML_2 is much larger than that of M(HL)L or $M(HL)_2$.

To study the protonation of the complex species with increasing [H], we tried to plot the product of the slope of each line (s_2) in Fig. 1 and $(\alpha_L K_1 K_2)^2$ against [H] according to eqn (7) (curve a in Fig. 2). The slope of the plot is nearly constant at low values of [H], where ML_2 and M(HL)L are present, and then gradually increases with increasing [H], indicating that formation of $M(HL)_2$ occurs. With a knowledge of K_{MY}, $K_{MY} = 10^{10.44}$,[9] K_{ML_2} could be calculated from the intercept of the linear portion of the plot (curve a). With the use of this intercept (y_2) the plot of eqn (8) yields line b in Fig. 2. By using the linear-squares method $K_{M(HL)L}$ and $K_{M(HL)_2}$ were obtained from the intercept and slope of line b. With these values the protonation constants of ML_2 and M(HL)L, $K^H_{M(HL)L}$ and $K^H_{M(HL)_2}$, were calculated by the following equations:

$$K^H_{M(HL)L} = [M(HL)L]/([ML_2][H]) = K_{M(HL)L}/(K_{ML_2}K_2), \quad (9)$$

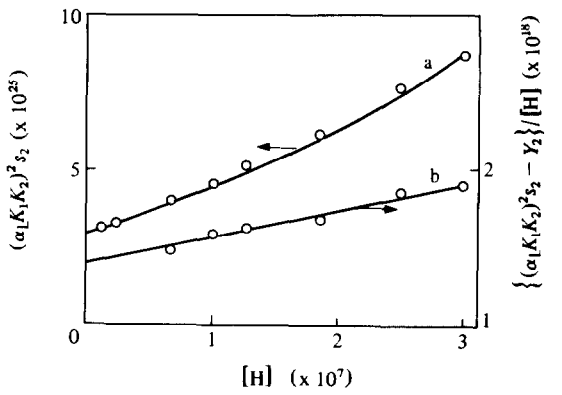

Fig. 2. Plots according to eqn (7) (a) and eqn (8) (b).

$$K^H_{M(HL)_2} = [M(HL)_2]/([M(HL)L][H]) = K_{M(HL)_2}/(K_{M(HL)L}K_2). \quad (10)$$

In Table 2, all the constants obtained are listed together with those in the literature.

From Table 2, it can be seen that the value for the protonation constant of ML_2 reported by Tanaka *et al.*[11] is much larger than ours. They measured the absorbance of a 1:2 Zn–PAR complex (at 495 nm) as a function of pH and evaluated the protonation constants and molar absorptivities of various species by means of curve fitting. The apparent molar absorptivity at 495 nm obtained in this experiment was 8.3×10^4 at pH 7.92 and 8.0×10^4 at pH 7.63. These values agreed well with the reported value of 8.1×10^4 at pH 8 in borate buffer.[12] Therefore, their evaluation for the molar absorptivity of ML_2 ($\varepsilon_{ML_2} = 9.58 \times 10^4$) seems to be too large. Another problem is that under their experimental conditions ($C_L = 7.50 \times 10^{-6}$ M) it must be considered that, with decreasing pH, transformation of the 1:2 to the 1:1 complex as well as their protonation occurs. This would result in a larger decrease in absorbance at 495 nm with decreasing pH from 8 to 7 as compared with our results ($C_L > 5 \times 10^{-5}$ M in this experiment). They assumed that protonation of a 1:2 complex only occurred, and this would make the value of $K^H_{M(HL)L}$ large.

In conclusion, this method is applicable to a study of the formation of various colored complexes without a knowledge of any molar absorptivities.

SYNTHESIS OF Tc(IV) ALCOHOLATO COMPLEXES WITH METHANOL, ETHYLENEGLYCOL AND 1,2,4-BUTANETRIOL

R. ALBERTO, G. ANDEREGG* and K. MAY

Laboratorium für Anorganische Chemie, ETH Zürich, CH-8092 Zürich, Switzerland

(*Received* 25 *June* 1986; *accepted* 7 *July* 1986)

Abstract—The preparation of three Tc(IV) alcoholato complexes: $K_2[^{99}Tc(OMe)_6]$, $K_2[^{99}Tc(glyc)_3]\cdot 3C_2H_5OH$ ($H_2glyc = CH_2OHCH_2OH$), and $K_2[^{99}Tc(butri)_2]\cdot CH_3OH$ ($H_3butri = CH_2OHCHOHCH_2CH_2OH$) is described.

Among the Tc(IV) hexahalogenocomplexes, $K_2[TcBr_6]$ shows, in contrast to $K_2[TcF_6]$ and $K_2[TcCl_6]$, an unexpectedly high solubility in methanol. The reason seems to be a partial substitution of bromide by methoxide (MeO^-) and pH measurements in water-free MeOH gave an acidic pH, according to the following equation

$$(TcBr_6]^{2-} + nCH_3OH \xrightarrow{\text{methanol}} [Tc(OCH_3)_nBr_{6-n}]^{2-} + nH^+ + nBr^- \quad (1)$$

Since Tc(IV) prefers oxygen as a donor atom, it should be possible to obtain bromide-free complex salts.

EXPERIMENTAL

KOMe was prepared by direct reaction of elemental potassium with MeOH. Solutions of KOMe in MeOH have a long shelf-life. MeOH was therefore evaporated *in vacuo* immediately prior to use.

Synthesis of $K_2[Tc(IV)(OMe)_6]$ **(I)**

$$[TcBr_6]^{2-} + 6MeO^- \xrightarrow{\text{methanol}} [Tc(OMe)_6]^{2-} + 6Br^-$$

320 mg $K_2[TcBr_6]$ (0.5 mmol) in 10 cm^3 of MeOH were added dropwise to 490 mg KOMe (7 mmol) under nitrogen. The solution discolored completely within 10 min. KBr precipitated during the evaporation to a total volume of 2 cm^3. The KBr (97%) was filtered and washed with several drops of cold MeOH. In the filtrate the solvent was removed first by a stream of dry nitrogen and then *in vacuo*. The remaining white powder was treated twice with 1 cm^3 of *t*-butanol (*t*-BuOH) to remove the excess of KOMe. The residue was washed with another portion of *t*-BuOH then with CH_3CN and dried *in vacuo*. 124 mg of a pale greenish salt was obtained. Found: K, 22.1; Tc, 26.9. Calc. for **I**: K, 21.5; Tc, 27.2%.

The ratio MeO/Tc was determined by complete hydrolysis of the complex and acidimetric titration of the obtained hydroxyl ions and was found to be 5.97. The complex is soluble in MeOH and EtOH, insoluble in other common organic solvents, it decomposes rapidly in aqueous solution, if the pH < 12 but it is stable for several days if the pH > 12. In the air, the complex changes into a red species which in turn is oxidized to pertechnetate. For this reason, an R_f value in CH_3CN–H_2O (2.5:1 v/v) could not be determined.

Synthesis of $K_2[Tc(IV)(glyc)_3]\cdot 3C_2H_5OH$ **(II)** ($glyc = OCH_2CH_2O$)

220 mg of **I** and 1.5 cm^3 of freshly distilled ethyleneglycol were mixed and transferred into an ultrasonic vibrator and **I** dissolved slowly. The substitution of MeO^- by glycolate can be scanned by paper chromatography. The educt remains at the starting point and the product shows an R_f value of 0.2. After 24 h the excess ethyleneglycol was removed by high vacuum distillation. The intense hygroscopic nature of the remaining greenish salt was attributed to missing alcohol molecules

*Author to whom correspondence should be addressed.

in the unitary crystal cell. Recrystallization from CH_3CN–EtOH (3:1 v/v) yielded 185 mg (62%) of a colorless non-hygroscopic salt. Found: K, 15.4; Tc, 19.3; C, 28.8; H, 6.1. Calc. for **II**: K, 15.8; Tc, 20.0; C, 29.1; H, 6.1%.

Synthesis of $K_2[Tc(IV)(butri)_2]\cdot CH_3OH$ **(III)** (butri = 1,2,4-*butanetriolate*)

200 mg of **I** (0.55 mmol) and 2 cm^3 of 1,2,4-butanetriol were treated as described for **II**. The resulting solution was mixed with 1 cm^3 of *t*-BuOH and left to stand overnight. The white powder which settled was filtered off and recrystallized from CH_3CN–MeOH (3:1 v/v) giving 160 mg of a white non-hygroscopic salt. Found: K, 18.1; Tc, 23.5; C, 26.2; H, 4.3. Calc. for **III**: K, 18.8; Tc, 23.8; C, 26.0; H, 4.4%.

Spectroscopic properties of the complexes:

	UV–(abs MeOH)	IR (TcO-st)(KBr)
$Tc(OMe)_6^{2-}$	$\lambda_{max} = 274$ nm	IR: $\nu = 450\ cm^{-1}$
$Tc(glyc)_3^{2-}$	$\lambda_{max} = 270$ nm	IR: $\nu = 455\ cm^{-1}$
$Tc(butri)_2^{2-}$	$\lambda_{max} = 267$ nm	IR: $\nu = 460\ cm^{-1}$

The IR band at 450 cm^{-1} can be assigned to a Tc—O stretching frequency. It lies between that of Tc—F—st (574 cm^{-1}) and that of Tc—Cl—st (330 cm^{-1}).[1] Moreover, the IR spectra agree with those of the corresponding alcohols.

DISCUSSION

It has long been known that most metal centers with significant A-character form binary complexes with alcoholates.[2–4] The feasibility of synthesizing such complexes with Tc(IV) also indicates that Tc(IV) shows a similar behavior.

It was not possible to grow crystals suitable for X-ray studies. The proof that Tc is in the +IV oxidation state had to be obtained indirectly from chemical measurements including elemental analysis. We have also synthesized known Tc(IV) complexes using **I** as starting material. The scheme below illustrates the complexes,[5,6] all of which could be produced in good yields (Hacac = acetylacetone).

As mentioned earlier, the complexes are soluble in MeOH and EtOH. **I** is stable in aqueous solution at pH > 12, **II** for pH > 10–11, and **III** for pH > 8–9. Below these limits the rate of hydrolysis increases with decreasing pH. Hydrolysis can be prevented by adding a strong ligand. This provides a useful method of synthesizing new Tc(IV) complexes directly from aqueous solution. The question arises as to the nature of the coordination of complexes **II** and **III**. It is theoretically possible, that the alcohols of crystallization are coordinated while the multidentate ligands are partially protonated and not fully coordinated. This question can be answered from a thermodynamic point of view. The significantly higher stability of **II** and **III** with respect to hydrolysis cannot be explained in the absence of chelating effects. If in these cases unidentate ligands were coordinated, hydrolysis should take place under the same conditions as for **I**.

(*Received* 18 *April* 1986; *accepted* 23 *June* 1986)

Abstract—The diglyme adduct of sodium iodide, $NaI \cdot (CH_3OCH_2CH_2)_2O$, has been structurally characterized by X-ray diffraction. It forms infinite zig-zag chains which, unlike most complexes of the salt, retain Na—I bonds. In addition, diglyme molecules bridge pairs of Na atoms through four-co-ordinate O atoms, so representing a new role for this neutral oxygen donor.

Diglyme · {di-(2-methoxyethyl)ether [$(CH_3OCH_2CH_2)_2O$]}, a high-temperature ether solvent (b.p. 162°C) which was first prepared in 1925,[1] has for many years been widely employed in both organic and inorganic synthesis.[2] A powerful sequestering agent, it is very effective in solvating cations of sodium salts, a property which facilitates reactions of "ionic" compounds in non-polar media. Research chemists engaged in structural studies of transition-metal species have found diglyme to be a particularly useful solvent as it frequently gives rise to stable, crystalline complexes: crystal structures of diglyme-containing Ti, Cr, Zr, Mo and W systems have been reported recently in the literature.[3–7]

In the course of seeking a mixed-metal cluster of Li and Na we have synthesized (unintentionally) NaI · diglyme, which to the best of our knowledge has never been previously isolated. Surprisingly, no diglyme adduct of a sodium salt (or indeed of a *simple* salt of any other alkali metal) appears to have been structurally determined by X-ray diffraction. Therefore we have carried out a structure analysis of the title compound.

EXPERIMENTAL

The method which produced NaI · diglyme was explored with a view to incorporating sodium into a lithium imide cluster, specifically the trigonal antiprismatic hexamer $[LiN{=}C(Ph)Bu^t]_6$,[8] which is readily accessible from equimolar proportions of LiPh and $Bu^tC{\equiv}N$. Accordingly, LiPh (5.0 cm^3 of a 2 M solution in ether–cyclohexane, 10.0 mmol) was added dropwise to a chilled mixture of NaI (0.5 g, 3.3 mmol) and diglyme (8.0 cm^3, 56.0 mmol) in a Schlenk tube under an atmosphere of dry, oxygen-free nitrogen. Following a vigorous reaction $Bu^tC{\equiv}N$ (1.1 cm^3, 10.0 mmol) was added, generating a crimson solution. Cooling to 0°C afforded highly moisture-sensitive, colourless, needle-like crystals, identified as $NaI \cdot (CH_3OCH_2CH_2)_2O$, m.p. 78°C; cf. NaI itself,

661°C. (Found: C, 25.7; H, 5.0; Li, 0.0; I, 43.8; Na, 8.1%. $C_6H_{14}INaO_3$ requires: C, 25.4; H, 4.9; I, 44.7; Na, 8.1; O, 16.9%.) A second product, an orange solid, has not yet been characterized.

A subsequent attempt to prepare the complex directly from anhydrous NaI and diglyme proved successful, although the crystals obtained were of an inferior quality. To effect complete dissolution of the salt a 10-fold excess of hot diglyme (80°C) was required. The complex was rapidly precipitated, however, when the solution was agitated or cooled by a few degrees.

Crystallography

$C_6H_{14}INaO_3$, $M = 284.1$, orthorhombic, *Fddd*, $a = 7.9147(3)$ Å, $b = 23.1492(7)$ Å, $c = 23.7448(8)$ Å, $V = 4350.5$ Å^3, $Z = 16$, $D_c = 1.735$ g cm^{-3}, $F(000) = 2208$, $\mu = 2.92$ mm^{-1} for Mo-$K\alpha$ radiation ($\lambda = 0.71073$ Å). Of 1179 reflections measured with a Siemens AED2 diffractometer at 293 K ($2\theta_{max} = 50°$), and corrected for absorption by semi-empirical methods, 966 were unique ($R_{int} = 0.016$), and 762 with $F > 4\sigma(F)$ were used for structure determination by Patterson and difference syntheses.[9] Blocked-cascade refinement to minimize $w\Delta^2$ [$\Delta = |F_o| - |F_c|$; $w^{-1} = \sigma^2(F)$] with anisotropic thermal parameters for non-H atoms, constrained H atoms [C—H = 0.96 Å, H—C—H = 109.5°, $U(H) = 1.2U_{eq}(C)$] and an extinction correction $F_c' = F_c/(1 + xF_c^2/\sin 2\theta)^{1/4}$ [$x = 4.0(2) \times 10^{-7}$] gave $R = 0.025$, $R' = (\Sigma w\Delta^2/\Sigma wF_o^2)^{1/2} = 0.024$, a satisfactory analysis of variance, and no significant features in a final-difference map. Tables of atomic co-ordinates and other crystallographic data have been deposited with the Editor and the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The molecular structure consists of polymeric chains (viewed end-on in Fig. 1) of NaI·diglyme units. These chains are built-up in a zig-zag arrangement (Fig. 2). Sets of parallel two-fold axes of symmetry pass through the I and O(1) atoms, with a second, perpendicular set passing through the Na atoms, both sets being perpendicular to the chain direction. Table 1 gives the important bond lengths and angles. The Na—I bonds are marginally shorter in length [3.164(1) Å] than the closest Na—I distances in the salt itself (3.231 Å),[10] reflecting the lower co-ordination state of the I atoms in the diglyme complex (i.e. 2 vs 6). The fact that Na—I bonds are retained at all is highly surprising. Normally complexation results in "solvent-separated"

ion pairs, particularly with chelating ligands like diglyme but even in the case of ligands with only one co-ordinatively active atom; X-ray structure analyses of tris(acetone)– and tris(methanol)–Na^+I^-[11,12] exemplify this point. Our structure is more akin to that of $NaI\cdot(H_2O)_2$.[13] This complex consists of sheets composed of an hexagonal array of octahedrally co-ordinated Na atoms, with each Na being linked to its three neighbouring Na atoms by a centro-symmetric pair of I atoms [at interatomic distances of 3.210(6) and 3.260(11) Å] or water molecules. The environment of the metal atoms in NaI·diglyme (Fig. 2) is likewise octahedral; two opposite sites are occupied by I atoms while oxygens from independent diglyme molecules participate in two terminal bonds to each Na. To complete the six-fold co-ordination arrangement, however, the central O atoms [O(1)] of the diglyme molecules *bridge* between pairs of Na atoms. This is the first example of μ_2-bonding involving diglyme. In common with *neutral* oxygen donors in general, diglyme usually attaches terminally, through 3-co-ordinate O atoms, to metal atoms. Examples are (diglyme)Cd[$Mn(CO)_5$]$_2$,[14] (μ_3-N_2)(η^5:η^5-$C_{10}H_8$)(η-C_5H_5)$_2$Ti$_2$[(η^1:η^5-C_5H_4)(η-C_5H_5)$_3$Ti$_2$] · [(η-C_5H_5)$_2$(diglyme)Ti] · diglyme[15] and $Mo_2(O_2CC_6H_5)_4\cdot 2$(diglyme),[16] where the ether functions as a tri-, bi- and monodentate ligand, respectively. A comparison can be made between the Na—O bridge bonds in this system and those in "washing-soda", which is composed of $[Na_2(H_2O)_{10}]^{2+}$ and CO_3^{2-} ions. In the cations, two sodium–water octahedra share an edge making eight terminal and four bridging Na—O bonds (range of lengths: in the former, 2.39–2.51 Å; in the latter, 2.31–2.49 Å).[17] The interatomic distances in the diglyme complex, refined to a final R value of 0.025 (cf. 0.18 in the decahydrate), provide a more precise comparison of the different types of Na—O bond, as those in a bridging mode are distinctly longer [2.714(2) Å] than those in a terminal arrangement [2.427(3) Å]. Finally, it should be noted that the title compound as isolated is insoluble in hydrocarbon solvents but is soluble in diglyme itself. The conclusion drawn is that excess of a strongly coordinating solvent such as diglyme cleaves the polymeric chains and presumably breaks all metal–halogen bonds, separating the metal ions to give $Na(diglyme)_x^+ \ldots I^-$ solution species.

Acknowledgements—We thank the SERC for financial support including a research grant towards crystallographic apparatus, and Professor K. Wade for helpful discussion.

VARIATION OF ACTIVATION VOLUMES FOR AQUATION OF CHLOROAMINECOBALT(III) COMPLEXES

GEOFFREY A. LAWRANCE

Department of Chemistry, The University of Newcastle, New South Wales 2308, Australia

(*Received* 6 *June* 1986; *accepted* 23 *June* 1986)

Abstract—Activation volumes for aquation of *cis*-$[Co(en)_2(NO_2)Cl]^+$, *trans*-$[Co(en)_2(CN)Cl]^+$, *cis*-α- and *cis*-β-$[Co(trien)Cl_2]^+$ have been determined, and are compared with values reported for a range of chloroaminecobalt(III) complexes. Variation of reported $\Delta V^{\neq}$ in terms of, particularly, solvation effects is discussed.

The mechanistic value of measured activation volume ($\Delta V^{\neq}_{exp}$) in reactions of coordination complexes has been the basis for extensive study.[1–6] At least for reactions involving exchanges of small neutral molecules, interpretation of $\Delta V^{\neq}_{exp}$ in terms of volume changes arising from displacement of particles at the active site seems relatively straightforward.[6] This is because motions of small neutral molecules should not involve any large changes in solvation from precursor to transition state. If we assign to the experimental activation volume separate contributions from intrinsic displacement ($\Delta V^{\neq}_{intr}$) and solvation ($\Delta V^{\neq}_{solv}$) terms, where the former term carries the mechanistically significant information, it becomes clear that interpretation of $\Delta V^{\neq}_{exp}$ values depends on small $\Delta V^{\neq}_{solv}$ components or at least an understanding of the significance of this term in various circumstances.

With ionic leaving groups, a dissociative transition state may involve formation of, or substantial motion towards formation of, a new charge centre. In polar solvents, significant electrostriction of the new charge centre with concomitant changes in molar volumes of participating solvent molecules will occur. The result is seen experimentally as a negative contribution to $\Delta V^{\neq}_{exp}$. Variation in $\Delta V^{\neq}_{exp}$ from +1.2 to −9.9 to −18.5 $cm^3 mol^{-1}$ for $[Co(NH_3)_5L]^{n+}$ hydrolysis[7,8] as L varies from OH_2 to Cl^- to SO_4^{2-} can be used to illustrate the role of electrostriction. While these complexes aquate by essentially the same mechanism, clearly $\Delta V^{\neq}_{exp}$ alone is not mechanistically definitive, being masked by solvent electrostriction terms in the latter two examples.

The significance of the problem can be gauged further by the observation that $\Delta V^{\neq}_{exp}$ for chloride aquation from a range of cobalt(III) amines vary between −10 and +11 $cm^3 mol^{-1}$.[1,8,13] Here, differences must lie not just with the central metal ion or leaving group but also with the non-leaving groups and overall charge. We have been working to extend the number of such examples for which $\Delta V^{\neq}_{exp}$ have been measured. Recently, $\Delta V^{\neq}_{exp}$ for aquation of $[Co(NH_3)_5Cl]^{2+}$, *trans*-$[Co(NH_3)_4(NH_2CH_3)Cl]^{2+}$ and $[Co(NH_2CH_3)_5Cl]^{2+}$ were compared.[13] It was found that $\Delta V^{\neq}_{exp}$ becomes more positive with increasing molar volume of the cation. Here, we report $\Delta V^{\neq}_{exp}$ for several other chloroaminecobalt(III) complexes, and examine the overall trend.

With stereochemically unconfined cobalt(III) complexes, isomerization can accompany spontaneous aquation,[14] which can make interpretation of $\Delta V^{\neq}_{exp}$ more difficult. The complexes *cis*-$[Co(en)_2(NO_2)Cl]^+$, *trans*-$[Co(en)_2(CN)Cl]^+$ and *cis*-$[Co(trien)Cl_2]^+$ were chosen for study because they are reported to undergo aquation with retention of configuration.[5–7] Hydrolyses were followed in 0.1 M $HClO_4$ on a Varian 635 spectrophotometer fitted with a high-pressure cell at a fixed wavelength and a constant temperature. Minor enhancement of observed rate constants with increased pressure were observed in all cases. Results $\{10^4 k_{obs}$ (s^{-1}) [*P*(bar)]} obtained were as follows: *cis*-$[Co(en)_2(NO_2)Cl]^+$: 3.63 ± 0.10(1), 3.78 ± 0.20 (345), 3.92 ± 0.15(690), 4.03 ± 0.10(1035), 4.23 ± 0.05 (1380); *trans*-$[Co(en)_2(CN)Cl]^+$: *cis*-α-3.10 ± 0.09(1), 3.16 ± 0.07(345), 3.20 ± 0.10(690), 3.36 ± 0.16

(1035), 3.45 ± 0.10(1380); *cis*-α-$[Co(trien)Cl_2]^+$:1.89 ± 0.06(1), 2.01 ± 0.13(345), *cis*-β-[2.19 ± 0.11(690), 2.33 ± 0.06(1035), 2.50 ± 0.10(1380). Further, aquation of *cis*-β-$[Co(trien)Cl_2]^+$ was reexamined, since deviation from first-order behaviour was more substantial than expected in the initial study,[11] limiting accuracy of determined k_{obs}. The revised results, using a different sample of complex, which yields a different $\Delta V^{\neq}_{exp}$, are for *cis*-β-$[Co(trien)Cl_2]^+$: 14.7 ± 0.4(1), 15.0 ± 0.3 (345), 15.5 ± 0.4(690), 16.1 ± 0.4(1035), 16.4 ± 0.3 (1380). Experiments were conducted at 35, 35, 27 and 25°C, respectively. Activation volumes for complexes were calculated in the usual manner,[5] and are included in Table 1, along with activation enthalpy and entropy values previously determined, and data for similar complexes.

Although in all cases chloride aquation from cobalt(III) is occurring, with the consequent expectation of a basic mechanistic constancy, it is clear from data in Table 1 that both $\Delta V^{\neq}_{exp}$ and $\Delta S^{\neq}_{exp}$ vary appreciably. Since a strictly limiting dissociative character is unlikely,[14] variations could in part reflect differing Co^{3+}–Cl^- separation in the transition state, which would affect both $\Delta V^{\neq}_{intr}$ and $\Delta V^{\neq}_{solv}$ terms. In any case, the sensitivity to particularly non-leaving groups is apparent. Variation in the series *trans*-$[Co(en)_2(X)Cl]^+$ is notable, since $\Delta V^{\neq}_{exp}$ changes with *trans*-X group from +11 cm^3 mol^{-1} (X = Cl^-) to +0.7 cm^3 mol^{-1} (X = N_3^-) to −2.0 cm^3 mol^{-1} (X = CN^-). At least for the first two, aquation occurs with some isomerization.[14] Since isomerization reactions alone in cobalt(III) chemistry can exhibit large positive $\Delta V^{\neq}_{exp}$,[18] variations observed may reflect the amount of rearrangement in the transition-state formation. The extent of bond stretching necessary to reach the transition state for aquation reactions in complexes where chelate rings exist may differ from the situation with simple ammines if molecular relaxation and rearrangement to permit a choice of geometry in the successor are involved in part in the activation process for aquation.

Except for $[Co(tren)Cl_2]^+$ and $[Co(dtcd)(N_3)Cl]^+$, all complexes show a quite close linear relationship between $\Delta V^{\neq}_{exp}$ and $\Delta S^{\neq}_{exp}$. For the $[Co(tren)Cl_2]^+$ ion, the first hydrolysis is a composite reaction since two non-equivalent sites exist, one of which may be especially labile;[19] observed $\Delta V^{\neq}_{exp}$ in this case may be less accessible to interpretation. Alone amongst the complexes, aquation of $[Co(dtcd)(N_3)Cl]^+$ involves loss from a large substituted and unsaturated macrocyclic complex, which may represent a special situation.[10] Since intrinsic and electrostrictive effects should usually contribute in a like sense to $\Delta V^{\neq}_{exp}$ and $\Delta S^{\neq}_{exp}$, a correlation between these terms is not unexpected, and has been addressed previously.[20] One interpretation of the significantly positive $\Delta V^{\neq}_{exp}$ for $[Co(tren)Cl_2]^+$ and $[Co(dtcd)(N_3)Cl]^+$ could be to assert a significant shift towards a limiting dissociative mechanism in these cases. However, there seems no special case for this assertion at least with the *trans*-$[Co(en)_2Cl_2]^+$ ion, where $\Delta V^{\neq}_{exp}$ is also large and positive;[9] thus it may not be an acceptable interpretation in general.

Reactions of cobalt(III) complexes in acid, while believed to be dissociative in nature, have rarely been considered to involve a limiting mechanism. Lifetimes of any intermediates are probably in no more than the picosecond range, which should not permit complete solvent reorganization in the activation process itself. Varying the non-leaving groups may vary the lifetime of the activated

[b]This work.

groups may vary the lifetime of the activated complex a little. In a timescale regime where solvent reorganization may be occurring at a more "leisurely" pace, the actual progress to, and "resting" period in, the transition state for a particular molecule may markedly affect the $\Delta V^{\neq}_{solv}$ component of $\Delta V^{\neq}_{exp}$ when displacement of ionic groups is involved. An increase (in a positive sense) in $\Delta V^{\neq}_{exp}$ as the size of the cation increases or the type of ligands vary may then reflect a small change in either the amount of bond extension in forming the transition state or its lifetime, or both. No abrupt change in mechanism need be considered.

Complexes with markedly positive $\Delta V^{\neq}_{exp}$, such as $[Co(en)_2Cl_2]^+$, may involve more substantial rearrangement in forming the transition state, with electrostriction of new charge centres being offset by displacement of electrostricted water molecules into the bulk solvent by motions of the non-leaving groups. There may be a prospect for examining this concept. It is known, for example, that solvolysis of $[Co(NH_3)_5(OCH\cdot N(CH_3)_2)]^{3+}$ in H_2O or $OCH\cdot N(CH_3)_2$ yields essentially identical $\Delta V^{\neq}_{exp}$,[21] perhaps indicative of small $\Delta V^{\neq}_{solv}$ contributions to $\Delta V^{\neq}_{exp}$. However, isomerizations of $[Co(en)_2(X)(OH_2)]^{2+}$ complexes, even from H_2O to D_2O as solvent,[22] show differences in $\Delta V^{\neq}_{exp}$ which probably relate to variations in $\Delta V^{\neq}_{solv}$. Variations in $\Delta V^{\neq}_{exp}$ for *trans*-$[Co(en)_2Cl_2]^+$ solvolysis compared with those for *trans*-$[Co(en)_2(CN)Cl]^+$, for example, may probe the comparative roles of $\Delta V^{\neq}_{solv}$ terms in each case. It is clear that a greater understanding of the part played by solvation terms is important for a more detailed interpretation of $\Delta V^{\neq}_{exp}$ when ionic leaving groups are involved.

COMMUNICATION

A NOVEL PALLADIUM-INDUCED EPIMERIZATION OF STEROID ALCOHOLS—A SINGLE-STEP SYNTHESIS OF EPIMERIC ALCOHOLS

B. M. CHOUDARY

Regional Research Laboratory, Hyderabad 500007, India

(*Received* 13 *May* 1986; *accepted* 23 *June* 1986)

Abstract—The epimerization of steroid alcohols is induced by the $Pd(PPh_3)_4$–*p*-benzoquinone system. A convenient method for the synthesis of epicholesterol is described.

A transannular 1,5-hydride shift via palladium complex has been proposed in the reaction of cyclohexylmethylmercury chloride with $PdCl_2$ in the presence of the $CuCl_2$–HOAc system to give 1-chloro-4-methylcyclohexane.[1] In the Wacker reaction, the oxidation of ethylene to acetaldehyde, a 1,2-hydride shift via a palladium complex, was visualized.[2] The palladium-catalysed oxidation of secondary alcohols[3] in the presence of bromobenzene could be explained by an hydride shift from alkoxy to phenyl moiety in the transient complex based on the mechanism reported in the reduction of arylhalides by sodium methoxide.[4] Palladium is also known to isomerize[5] and invert[6] allylacetates.

This communication reports the epimerization of steroid alcohols in a single step induced by the $Pd(PPh_3)_4$–*p*-benzoquinone system. The Δ^5-steroid alcohols give selectively epimeric alcohols [eqn (1); Table 1, entries 1–4] while saturated alcohols give ketones apart from corresponding epimeric alcohols [eqn (2); Table 1, entries 5 and 6].

Similarly, *trans*-4-*t*-butylcyclohexanol, a monocyclic alcohol (entry 7) is isomerized into *cis*-4-butylcyclohexanol. Incidentally, this is a convenient method for the synthesis of epicholesterol in reasonable yields as against the tedious multistep synthesis reported earlier,[7] and is the first report of the epimerization of alcohols induced by $Pd(PPh_3)_4$–*p*-benzoquinone.

EXPERIMENTAL

Measurements and materials

Spectra were recorded on Perkin–Elmer (IR), Varian A-60 (NMR) and RMU 6 (mass) spectrometers. All solvents were dried by standard procedures.

Epimerization of steroid alcohols

Clear solutions of $Pd(PPh_3)_4$ (0.004 mmol) in *m*-xylene (3 cm^3) and *p*-benzoquinone (0.008 mmol) in *m*-xylene (3 $cm)^3$ were separately injected through

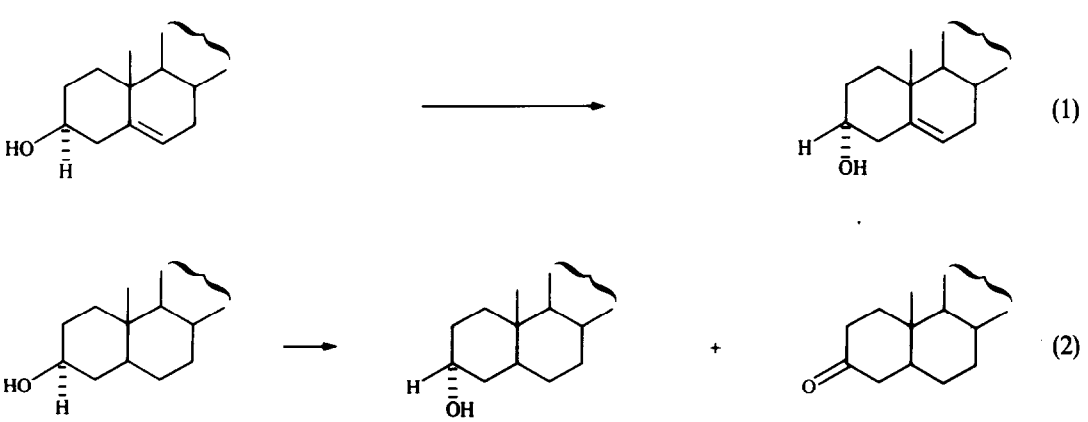

Table 1. Epimerization of steroid alcohols[a]

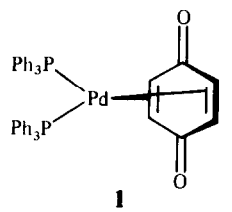
Entry	Compound	Epimeric alcohol [isolated yield (%)]	Ketone (isolated yield (%)]
1	Cholesterol	Epicholesterol (40) (50)[b]	
2	Stigmast-5-en-3β-ol	Stigmast-5-en-3-α-ol (34)	
3	Diosgenin	Epidiosgenin (15)	
4	Epicholesterol	Cholesterol (24)	
5	Cholestanol	Epicholestanol (36)	Cholestan-3-one (25)
6	Epiandrosterone	Androsterone (33)	Androstan-3,17-dione (15)
7	*trans*-4-*t*-Butylcyclohexanol	*cis*-4-*t*-Butylcyclohexanol (15)	4-*t*-Butylcyclohexanone (8)

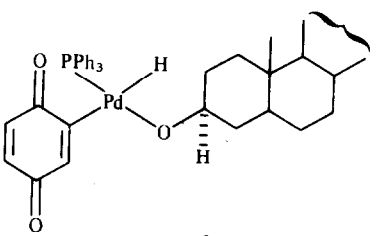
[a]All reactions were carried out under the following conditions: substrate, 0.4 mmol, $Pd(PPh_3)_4$, 0.004 mmol, *p*-benzoquinone, 0.008 mmol (entries 1–4), 0.400 mmol (entries 5–7); reaction time, 6 h; and solvent, *p*-xylene under reflux.

[b]Yield based on ^1H NMR.



a septum into a nitrogen-purged R.B. flask equipped with a magnetic stirrer and a condenser. Cholesterol (0.40 mmol) in *m*-xylene (5.0 cm^3) was injected to the homogeneous catalytic system and the reaction mixture was heated to reflux for 6 h under a nitrogen atmosphere. Then the reaction mixture was cooled, filtered and evaporated to dryness *in vacuo*. The residue was chromatographed to isolate pure compounds.

RESULTS AND DISCUSSION



The isolated yields of epimeric alcohols are given in Table 1. The products are well characterized by m.p., ^1H NMR, IR, and mass spectra, and compared with authentic samples.

The bidentate *p*-benzoquinone–$Pd(PPh_3)_4$ complex[8] (**1**) which is expected to form *in situ* may be a real catalytic species in this system since no epimerization occurs in the absence of *p*-benzoquinone. Moreover the isolation of hydroquinone and ketone from a reaction medium involving epimerization of saturated alcohols which is due to the transfer of hydrogen from steroid alcohol to *p*-benzoquinone demonstrates that the *p*-benzoquinone is part of the catalytic system. This reaction required excess *p*-benzoquinone since it acts also as a hydrogen acceptor and is converted into hydroquinone, while the catalytic amount of *p*-benzoquinone is sufficient for epimerization of Δ^5-steroid alcohols. A trace of palladium metal is deposited during the reaction. The epimerization reaction of cholesterol which gives a 1:1 epimeric ratio did not proceed further on continuation of the reaction. The epimerization may have involved hydride inversion by the activation of the carbinyl proton induced by palladium in the intermediate hydridoalkoxypalladium(II) (**2**) which can be formed from the reaction of **1** with a secondary steroid alcohol.

The hydroxyl inversion can be ruled out in view of the formation of a ketone as a side product in

1

2

saturated sterols and the absence of diene formation in unsaturated Δ^5-sterols, which is a homoallyl alcohol. The diene is formed in the epimerization reaction of allyl acetate.[6] However, further work to understand the mechanism is under progress.

(*Received* 28 *August* 1985; *accepted after revision* 27 *June* 1986)

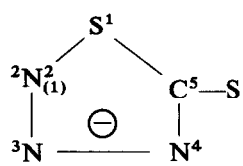
Abstract—The pseudo-halide 1, 2, 3, 4-thiatriazol-5-thiolate, in the anion and acid forms, undergoes photochemical decomposition with the formation of sulfur, nitrogen and the thiocyanate anion, with quantum yields (ϕ_{313}) of 0.13 and 0.26 for the acid and anion forms, respectively.

The synthesis,[1] analytical applications,[2] coordinative abilities,[3] oxidation reactions[4] and quantum mechanic calculations[5] for the pseudo-halide 1,2,3,4-thiatriazol-5-thiolate anion, $CS_2N_3^-$, have been already reported.

In the course of an investigation of the chemical properties of thiatriazol ring, we describe the photochemical decomposition of the $CS_2N_3^-$ and HCS_2N_3 systems.

EXPERIMENTAL

$NaCS_2N_3$ was synthesized and standardized as described previously.[1] For the photolysis studies, $NaCS_2N_3$ aqueous solutions at different hydrogen ion concentrations were irradiated at 313 nm with light of 1.58×10^{-7} Einsteins min^{-1}. The intensity of the light source was measured using ferrioxalate actinometry.[6]



After 3 min of irradiation the solutions exhibit some turbidity, probably due to the formation of colloidal sulphur. Thus, only solutions irradiated for less than 2 min were analysed for the calculation of quantum yields.

Photolysis as monitored spectrophotometrically at 313 nm. At each pH, different samples were irradiated for 15, 30, 45, 60 and 120 s each. Quantum yields were plotted vs % reaction, and extrapolated back to 0% reaction to obtain the reported quantum yield values.

RESULTS AND DISCUSSION

The absorption band[2,5] of the acid, at 313 nm, is due to a π–π^* transition ($4a''$–$5a''$). For the anion, the absorption maximum at 313 nm is assumed[2,5] to be a combination of $n \rightarrow \pi^*$ with π–π^* transitions ($12'$–$5a''$ and $4a''$–$5a''$, respectively).

Continuous photolysis of aqueous solutions of the acid and of the anion with light of 313 nm leads to the photochemical decomposition of the ring,[1,2,4,7] according to:

(1)

*Author to whom correspondence should be addressed.

The quantum yields for reaction (1) at several hydrogen ion concentrations are listed in Table 1. Since the pK_a for HCS_2N_3 is 1.5,[1] at pH values higher than 3.0 only the $CS_2N_3^-$ form is present, and in a 1.0 M $HClO_4$ solution more than 96% of the pseudo-halide is present as HCS_2N_3.

In the absence of light, the $NaCS_2N_3$ solutions are more stable than the corresponding HCS_2N_3 ones. In fact, quantum mechanical calculations[5] showed that the anion $CS_2N_3^-$ is more stable than HCS_2N_3 by 29 kcal mol^{-1}. However, under irradiation, the anion is more unstable than the acid, as indicated by the quantum yields of 0.13 and 0.26 for HCS_2N_3 and $CS_2N_3^-$, respectively.

The decomposition of the 1,2,3,4-thiatriazol ring is not a simple process. The bond orders in the ground state show a low bond order value (0.06) for the N(2)—N(3) bond in the thiatriazol ring. However, the bond orders or electron densities in the excited states of HCS_2N_3 and $CS_2N_3^-$ are not known, not allowing the identification of the first bond break in the ring.

Table 1. Quantum yields for the reaction[a]

$$CS_2N_3^- \xrightarrow{h\nu} N_2 + S + SCN^-$$

pH	0.0[b]	0.5	1.0	3.0	4.6	5.2	11.8
ϕ	0.13[c]	0.19	0.26	0.27	0.26	0.27	0.27

[a] μ = 1.0 M, $NaClO_4$, 25°C. Each ϕ value is a mean of four independent determinations with agreement better than 96%.

[b] 1.0 M $HClO_4$.

[c] Refers to the acid form.

Studies on the degradation of the thiatriazol ring as an alternative synthetic route[8] for isothiocyanate synthesis are in progress and will be reported later.

SYNTHESIS AND X-RAY STRUCTURE OF THE Mo(VI) SPECIES $Mo_4O_{12}(C_{12}H_{30}N_4S_2)_2(C_3H_7ON)_n$ ($n \approx 2$)

MICHAEL B. HURSTHOUSE and RICHARD L. SHORT

Department of Chemistry, Queen Mary College, London E1 4NS, U.K.

and

BRIAN PIGGOTT,* ALAN TUCKER and SWEE FATT WONG

Department of Chemistry, The Hatfield Polytechnic, Hatfield AL10 9AB, U.K.

(*Received* 2 *June* 1986; *accepted* 27 *June* 1986)

Abstract—Dissolution of $Mo_2O_5((CH_3)_2NCH_2CH_2NHCH_2CH_2S)_2$ in dimethylformamide results in the formation of a species without coordinated sulphur, as indicated by ^{95}Mo NMR spectroscopy. Subsequent crystallization of this solution yielded the compound $Mo_4O_{12}(C_{12}H_{30}N_4S_2)_2(C_3H_7ON)_2$ which X-ray crystallography shows to consist of a novel Mo_4O_{12} core, containing an eight-membered Mo_4O_4 ring with the two pairs of diagonal molybdenum atoms linked by disulphido-containing groups.

An X-ray structure analysis of the compound $[Mo_2O_5(Me_2NCH_2CH_2NHCH_2CH_2S)_2]$ showed it to contain the $Mo_2O_5^{2+}$ core with six-coordination about each Mo(VI) atom being completed by 2N and 1S donors.[1] This structure is very similar to that reported earlier for $[Mo_2O_5(Me_2NCH_2CH_2NHCH_2CMe_2S)_2]$.[2]

Since we are interested in the ^{95}Mo NMR spectra of $Mo_2O_5^{2+}$ species, we have recorded the spectra of these two compounds in dimethylformamide (DMF). In each case, signals were observed at approximately 330 and 125 ppm. The signal at 330 ppm we assigned to the $Mo_2O_5L_2$ species, where L is $(Me_2NCH_2CH_2NHCH_2CH_2S^-)$ or $(Me_2NCH_2CH_2NHCH_2CMe_2S^-)$. The signal at 125 ppm was presumed to indicate the presence of a second species, which we accordingly attempted to isolate. After repeated attempts we were successful in obtaining a white, crystalline air-sensitive product from a DMF solution of $Mo_2O_5(Me_2NCH_2CH_2NHCH_2CH_2S)_2$.

A subsequent X-ray study of these crystals revealed a novel structural type based on an eight-membered Mo_4O_4 ring.† The structure found is shown in the Fig. 1. The two bridging oxygens at each molybdenum are *cis* to each other, with distorted octahedral geometry being completed by two *cis* terminal oxo atoms and two *cis* amine nitrogen atoms. The Mo—O bond lengths in the ring alternate, with values of 1.80–1.81(1) and 2.11–2.13(1) Å, respectively, the longer ones being *trans* to terminal oxo functions. The corresponding bonds in the starting material are equal at 1.91 Å and

*Author to whom correspondence should be addressed at: 4 Coach Drive, Hitchin, Herts SG4 9AP.

†Crystal data: $C_{24}H_{60}N_8O_{12}S_4Mo_4(C_3H_7ON)_n$, $M_4 = 1310.99$ for $n = 2$, triclinic, space group $P\bar{1}$, $a = 12.219(2)$ Å, $b = 16.627(3)$ Å, $c = 16.847(3)$ Å, $\alpha = 60.13(1)°$, $\beta = 77.21(1)°$, $\gamma = 73.19(1)°$, $U = 2828.9$ Å^3, $Z = 2$, $D_c = 1.539$ g cm^{-3}, Mo-K_α radiation, $\lambda = 0.71069$ Å, μ(Mo-K_α) = 9.7 cm^{-1}.

The structure was solved by direct methods and refined by least squares to $R = 0.049$ for 4636 reflections with $I > 2\sigma(I)$, and with all non-hydrogen atoms in the complex anisotropic and hydrogens included in calculated positions. Atoms of the solvent molecules, which occupy three sites at approx. 70% were refined isotropically.

Tables of atomic positional and thermal parameters, bond lengths and angles and F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

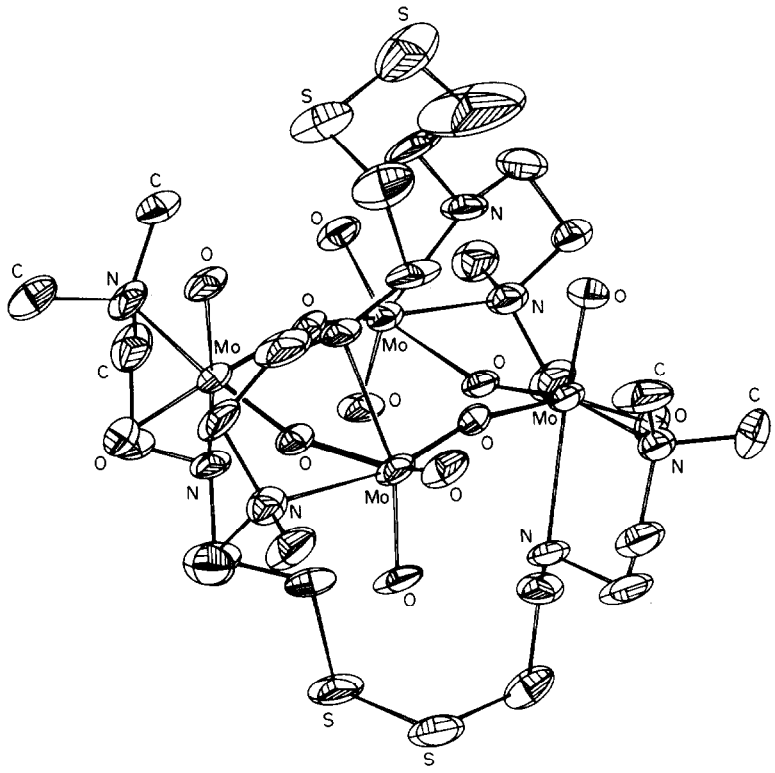

Fig. 1. Structure of the complex $Mo_4O_{12}(C_{12}H_{30}N_4S_2)_2$ Significant bond lengths (Å) are: Mo—O (bridge) = 1.80–1.81(1) (short), and 2.11–2.13(1) (long); Mo—O(oxo) = 1.71–1.73(1), and Mo—N 2.34–2.39(2).

neither of them are *trans* to a terminal oxygen.[1]

A further interesting feature of the molecule is the form of the organic ligands. Instead of these being tridentate NNS donors, as in the starting material,[1] they are now NN donors, with the displaced thiolate ends linking to form disulphide bridges. The two ligands present each connect pairs of diagonally related Mo atoms.

The structure of the title compound is loosely related to those of two other MoO ring species, the tetranuclear anion $[Mo_4O_8(OMe)_2(NNPh_4)]^{2-}$[3] and its related complex $[Mo_8O_{20}(NNPh)_6]^{4-}$[4] The former comprises a ring containing two MoO_2 and two $Mo(NNPh)_2$ units linked by Mo—O—Mo bridges, with two methoxy bridges between the $Mo(NNPh)_2$ metal atoms, whilst the latter can be described as a crown of six oxo-bridged molybdenum centres, alternately $[MoO_4]^{2-}$ and $[Mo(NNPh)_2]^{2+}$ moieties, capped above and below by oxomolybdate fragments.

Acknowledgement—We thank the SERC for support of this work.

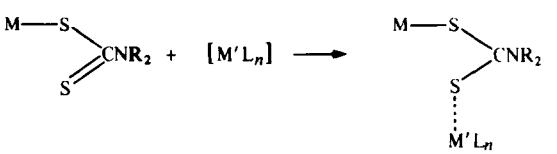
COMMUNICATION

A CONVENIENT SYNTHESIS OF $Fe(CO)_2(\eta^2\text{-}S_2CNMe_2)_2$ AND $Fe(\eta^2\text{-}S_2CNMe_2)_2$ FROM THE MONODENTATE DITHIOCARBAMATO DERIVATIVE, $[(\eta^5\text{-}C_5H_5)(CO)_3W(\eta^1\text{-}SCSNMe_2)]$ AND $Fe_2(CO)_9$

SALIL K. JHA, B. H. S. THIMMAPPA and PRADEEP MATHUR*

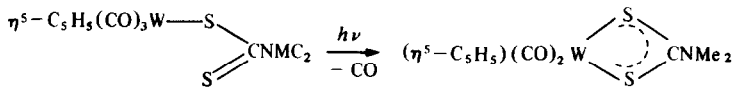


Department of Chemistry, Indian Institute of Technology, Powai, Bombay 400076, India

(*Received* 12 *May* 1986; *accepted* 7 *July* 1986)

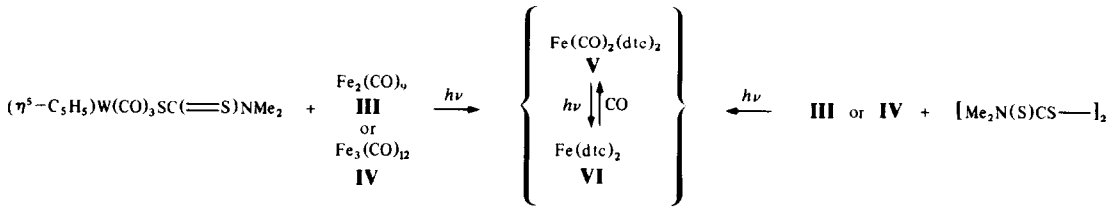
Abstract—A high yield synthesis of the carbonyl dithiocarbamato derivative $Fe(CO)_2(\eta^2\text{-}S_2CNMe_2)_2$ and $Fe(\eta^2\text{-}S_2CNMe_2)_2$ by photolysis with visible light of solutions containing $Fe_2(CO)_9$ or $Fe_3(CO)_{12}$ and $[(\eta^5\text{-}C_5H_5)(CO)_3W(\eta^1\text{-}SCSNMe_2)]$ is reported.

The chemistry of carbonyl dithiocarbamate complexes has generated considerable interest lately.[1] Derivatives of the form $(CO)_nM(dtc)_m$ with M = Rh, $n = 2$, $m = 1$; M = Fe, $n = 2$, $m = 2$; M = Mn, $n = 4$, $m = 1$; dtc = dialkyldithiocarbamate, have been prepared by reacting the sodium salts of dialkyldithiocarbamates with metal carbonyl halides or by oxidation of the metal carbonyls with tetraalkylthiocarbamoyl disulphides.[2] Other methods for the preparation of dithiocarbamate complexes include using trimethyltin thiocarbamates,[3] CS_2–CO_2 exchange on the carbamate derivatives,[4] or by reacting carbamoyl complexes of transition metals with CS_2.[5] Although most syntheses result in the dithiocarbamato ligand acting in a bidentate manner, several reports have appeared in the literature recently giving methods for preparing complexes containing monodentate dithiocarbamato ligands.[6–9]



We have been interested in investigating the reactivity of the uncoordinated sulphur atom towards additional transition metal centres (Scheme 1). The complex $[(\eta^5\text{-}C_5H_5)(CO)_3WSC(\text{—}S)NMe_2]$ (**I**), is a suitable candidate for such an investigation because: (i) it can be conveniently synthesized in good yields by irradiating with visible light solutions containing $[\eta^5\text{-}C_5H_5(CO)_3W]_2$ and tetramethylthiuram disulphide (tmtd);[6] and (ii) the dtc ligand maintains the monodentate mode of bonding unless heated strongly or photolysed with UV irradiation, which leads to formation of the dicarbonyl chelate (**II**) (Scheme 2).

Scheme 1. Reactivity of uncoordinated sulphur atom of η^1-dithiocarbamate ligand towards transition-metal centres.



We report here our findings on the reaction of (**I**) with iron carbonyl fragments $Fe(CO)_x$ generated from $Fe_2(CO)_9$ (**III**) or $Fe_3(CO)_{12}$ (**IV**) (Scheme 3). When oxygen-free toluene solutions containing **I** and **III** are irradiated with visible light under a nitrogen stream, the colour of the solution changes from orange-red to dark brown. From the photolysed solution, after column chromatography, two products have been isolated and identified on the basis of IR, NMR, UV spectra and microanalytical data as $Fe(CO)_2(\eta^2\text{-dtc})_2$ (**V**) and $Fe(\eta^2\text{-dtc})_2$ (**VI**).[2] Interestingly, Abrahamson and Freeman[6] have reported the formation of **I** from $Fe(dtc)_3$ and $[\eta^5\text{-}C_5H_5(CO)_3W]_2$. In our reaction, even after prolonged photolysis, $Fe(\eta^2\text{-dtc})_3$ is not obtained and at the end of the photolysis there is no evidence of any unreacted **I**. Irradiation of solutions

Scheme 2. Conversion of monodentate dithiocarbamato derivative (I) to the dicarbonyl chelate (II).

Scheme 3. Photolytic synthesis of $Fe(CO)_2(dtc)_2$ (V) and $Fe(dtc)_2$ (VI).

containing I and IV also yielded V and VI. There is no observable reaction between the bidentate chelate derivative $[Cp(CO)_2W(\eta^2\text{-}S_2CNMe_2)]$ and $Fe_2(CO)_9$ or $Fe_3(CO)_{12}$. The special reactivity of the monodentate dithiocarbamate ligand makes complex I a useful starting material for carbonyl dithiocarbamato derivatives; the generality of this transmetallation type of reaction is currently being investigated with other binary carbonyl complexes. We have also synthesized the dithiocarbamato derivatives V and VI by photolysing with visible light solutions containing either III or IV with tetramethylthiuram disulphide.

Pure V, on photolysis with visible light forms VI, which readily adds CO at room temperature to give V quantitatively. Thus, in the above reaction V is probably the initial product formed, but loses CO under the reaction conditions and forms VI.

The very mild conditions of our reactions appear to be advantageous, giving high yields of the carbonyl dithiocarbamato complexes and an improvement on earlier reported methods.

EXPERIMENTAL

All reactions were routinely performed under an inert atmosphere of argon using standard Schlenk techniques. The solvents were dried and distilled prior to use. IR spectra were recorded on a Perkin–Elmer 681 spectrophotometer and calibrated against polystyrene. NMR spectra were recorded on Hitachi T-60, and UV spectra on a Shimadzu 260 spectrophotometer.

Photolysis of $[(\eta^5\text{-}C_5H_5)(CO)_3W(\eta^1\text{-}SCSNMe_2)]$ *and* $Fe_2(CO)_9$

A mixture of diironnonacarbonyl (0.2 g 0.55 mmol) and $(\eta^5\text{-}C_5H_5)(CO)_3W(\eta^1\text{-}SCSNMe_2)$ (0.25 g 0.55 mmol) in 60 cm^3 of toluene solvent was irradiated with visible light for 2 h. The solvent was removed *in vacuo* and the dark brown residue was put on a silica gel column. Elution with petroleum ether–dichloromethane (50:50) gave a red-brown band identified as $Fe(\eta^2\text{-dtc})_2(CO)_2$, yield = 60%; IR (KBr): ν(CO) 1970 cm^{-1}, 2040 cm^{-1}, ν(CN) 1535 cm^{-1}, ν(CS) 995 cm^{-1}; NMR ($CDCl_3$): δ 3.28, 3.20; $\lambda_{max}(CH_2Cl_2)$: 236.8, 274.8, 383 nm. Further elution with neat dichloromethane gave the dark brown $Fe(\eta^2\text{-dtc})_2$, yield = 30%; IR (KBr): ν(CN) 1530 cm^{-1}, ν(CS) 990 cm^{-1}; NMR ($CDCl_3$): δ 3.60; $\lambda_{max}(CH_2Cl_2)$: 231, 256, 343 nm. Both complexes gave satisfactory, C, H, and N microanalysis results.

The photolysis of I and $Fe_3(CO)_{12}$ was carried out similarly to obtain $Fe(CO)_2(\eta^2\text{-dtc})_2$ and $Fe(\eta^2\text{-dtc})_2$ in yields of 60 and 30%, respectively, after 2 h. Prolonged photolysis in either reaction resulted in quantitative formation of only $Fe(\eta^2\text{-dtc})_2$ which converted back to $Fe(CO)_2(\eta^2\text{-dtc})_2$ quantitatively when a toluene solution of $Fe(\eta^2\text{-dtc})_2$ was bubbled with carbonmonoxide for 1 h.

Photolysis of $Fe_2(CO)_9$ *and tetramethylthiuram disulphide (tmtd)*

A mixture of diironnonacarbonyl (0.15 g 0.41 mmol) and tetramethylthiuram disulphide (0.1 g 0.41 mmol) in 70 cm^3 of toluene solvent was

irradiated with visible light for 0.5 h. Removal of solvent *in vacuo* and chromatographic work up as above gave $Fe(CO)_2(\eta^2\text{-dtc})_2$ and $Fe(\eta^2\text{-dtc})_2$ in yields of 66 and 30%, respectively.

The reaction of $Fe_3(CO)_{12}$ and tmtd was carried out similarly to give $Fe(CO)_2(\eta^2\text{-dtc})_2$ and $Fe(\eta^2\text{-dtc})_2$ in similar yields.

BOOK REVIEW

Gmelin Handbook of Inorganic Chemistry. Fe—Organoiron Compounds, Part A8, Ferrocene 8. Springer, Berlin, 1986. ISBN 3-540-93527-4, xiii+419 pp., DM1552. **Part B9, Mononuclear Compounds 9.** Springer, Berlin, 1985. ISBN 3-540-93522-3, ix+286 pp., DM1064. **Part B10, Mononuclear Compounds 10.** Springer, Berlin, 1986. ISBN 3-540-93523-1, ix+361 pp., DM1356. **Part C7, Polynuclear Compounds 7.** Springer, Berlin, 1986. ISBN 3-540-93530-4, xii+410 pp., DM 1488.

The burgeoning organometallic chemistry of iron has been treated well by Gmelin. Unlike any other metal, it has been granted more than one series—series A is devoted to ferrocene and its derivatives, series B to the other mononuclear compounds, and series C to polynuclear iron compounds—totalling in all 27 volumes.

Volume A8 is dedicated to disubstituted ferrocene derivatives with C-, H- and O-containing substituents. Like the other volumes, it contains useful tabulations of recent reviews. Its first 50 pp. are devoted to 1,1′-diacetyl ferrocene; the thoroughness of the Gmelin treatment is illustrated by the two closely packed pages comparing preparative routes, and the subsequent page devoted to its purification. Over 30 references are cited for its melting point. ^{1}H, ^{13}C and ^{57}Fe NMR data; Mössbauer, IR and Raman, electronic, MCD and photoelectron spectra are given, as well as crystallographic data; just as useful is the section on the reaction chemistry of diacetyl ferrocene. One section that this reviewer found particularly interesting detailed catalytic applications. Similarly, dipping into the subsequent sections (100 pp.) on other 1,1-disubstituted ferrocenes, one finds that compounds of this type have been used as polymerization catalysts, polymer stabilizers, ingredients for photosensitive photoimaging materials, treatments for iron-deficiency anaemia, and as antiknock agents. Later sections treat the 1,2- and 1,3-compounds (where two substituents co-exist on one ring), carboxylic acid, ester and acyl chloride derivatives, finishing with heterocyclic compounds with oxygen as the heteroatom. The volume concludes with a formula index covering Vols A7 (which initiated the coverage of disubstituted ferrocenes) and A8, the present one.

Volume B9 covers organometallic compounds of type $^{4}LFe(CO)_3$, in which the ligand forms four iron–carbon bonds and has ring systems with seven–nine member atoms. It begins with the seven-membered heterocyclic systems, where the N-containing heterocycles are azepines and diazepines, the less common oxygen analogues the oxepines, and one example of a B-containing ring. Much more important are the systems based on cycloheptadiene. As usual, detailed data are presented, in accessible and logical tabular form, for these and derivatives of cycloheptatriene, which are discussed subsequently. The complex structural and reaction chemistry of these complexes is clarified by the usual lucid structural diagrams. A further 90 pp. are devoted to the chemistry of the derivatives of cyclooctadiene, cyclooctatriene and cyclooctatetraene systems, as well as those of larger ring systems. Cyclooctatetraene iron tricarbonyl receives thorough treatment, including some 3 pp. discussing its NMR spectra.

Volume B10 (which includes empirical formula and ligand formula indexes to Vols B8–B10) takes on the story with complexes of trimethylene methane (and derivatives thereof): σ,π-allyl and σ,σ,π-allyl ligands. The trimethylenemethane complexes exemplified by the type $[(CH_2)_3C]Fe(CO)_3$ have attractive "piano-stool"-type structures adopting the staggered rather than the eclipsed configuration. Allyls of type  are considered next: these involve both σ- and π-bonding of the allyl moiety, either cyclic or acyclic. As usual, spectroscopic data are clearly tabulated and known molecular structures represented. The four much rarer σ,σ,π-allyls are also included. Next, consideration is given to compounds where more than one hydrocarbon "fragment" is present in the organometallic molecule. Several of the few known have not been isolated but postulated from spectroscopic data. Also included are the ferrocene analogues involving phosphole and arsole ligands, the sandwich structure having been established for molecules such as $[cyclo\text{-}PC_4H_2(CH_3)_2]_2Fe$. Slightly more complex are the diene complexes of type $(1,3\text{-diene})_2Fe \cdot L$ (where $L = PR_3$, pyridine etc.) and the analogous compounds with $L = CO$, many of which have been prepared by matrix cocondensation methods.

Volume C7 appears out of sequence, before C6, which will deal with trinuclear-type compounds up to $Fe_3(CO)_{11}$ with monodentate ligands. C7 begins with a 100 pp. devoted to $Fe_3(CO)_{12}$, commencing with a very useful survey of routes to the preparation and formation of $Fe_3(CO)_{12}$. The lengthy history of the structural determination and the IR spectra, including the controversial nature of the solution species, are discussed, along with other spectroscopic results. The reaction chemistry is broken into sections treating, successively, its reactions with elements, inorganic compounds, organic and organometallic compounds. An interesting little section deals with uses of $Fe_3(CO)_{12}$ in organic synthesis, followed by a consideration of catalytic and other uses. The next three sections of the book are concerned with compounds containing the Fe_3 unit with ligands bound, respectively, through two, three and four carbon atoms, and are relatively brief. Over 30 pp. are devoted, however, to the

many triiron compounds containing C_5-rings. What is interesting (to this reviewer) is the number of syntheses where $Fe_2(CO)_9$ and other Fe_2 compounds can be used as starting materials for the synthesis of Fe_3 derivatives, here and elsewhere. This part of the book is brought to a close with the compounds of ligands binding through six or more carbon atoms, and a number of compounds of undefined structure.

The subsequent 150 pp. are devoted to compounds with four iron atoms. It begins with a most useful survey of relevant literature (like the other volumes to at least 1984) and a synopsis of theoretical considerations underlying the bonding in the compounds. The system adopted for classification of the tetranuclear clusters is based on the number of Fe—Fe bonds, the doyen being the salts of $[Fe_4(CO)_{13}]^{2-}$, first prepared by Hieber around 1930. Another important class are the clusters $[(C_5H_5)Fe(CO)]_4^n$ ($n = -1, 0, +1$ or $+2$), with the faultless serendipitous pedigree (for organometallics) of an accidental discovery; next come the clusters with a $Fe_4E(CO)_{12}$ "butterfly" core (E = C, N, B or NC) and Fe_4MC (M = metal) cores. The clusters with four Fe—Fe bonds come next, exemplified by $Fe_4(CO)_{12}(PMe_3)_2$. Here, as elsewhere in the volume, a good deal of use is made of simplified structural diagrams in the tables of data which makes it very easy to identify individual compounds and relate them to others. Subsequent sections deal with compounds with three, two, one and no Fe—Fe bonds including the $[(C_5H_5)FeS]_4$ clusters, which are ferredoxin models. Pentanuclear compounds, best known as $Fe_5C(CO)_{15}$, hexanuclear and octanuclear derivatives follow on, completing the volume, which has both empirical formula and ligand formula indexes. (Compounds with more than eight iron atoms will be treated in Vol. C6.)

All four volumes reduce a considerable bulk of information to intelligibility and a large degree of digestibility. Though not a first choice for a rapid literature search, Gmelin remains unrivalled as a means of easy access to all published data on an individual compound. Many workers could use a period spent reading one of these volumes as a springboard to a new project.

Pergamon Journals Ltd. Printed in Great Britain

ANNOUNCEMENT

POLYHEDRON PUBLICATION AWARD

Pergamon Journals Ltd is pleased to announce the award annually of a cash prize of $1000 for the best paper published in *Polyhedron*.

The award will be made to the authors of the original research paper (not including *Polyhedron* Reports) judged to be the best on the basis of scientific originality, significance, clarity and style of presentation. The first award will be made for a paper published in Volume 6, 1987. Members of the Editorial Board will each be invited to nominate two papers for the award and the final selection will be made by an anonymous committee appointed by the Editors who themselves will not be eligible for the award.

The recipient of the first award will be notified early in 1988.
