Therefore the atomic arrangement in a zinc–tellurite glass can most accurately be described taking into account the preceding discussion, the analysis of the RDF_{exp} and RDF_{model} curves, as well as the structural building of paratellurite chains (Fig. 6) and the $Zn_2Te_3O_8$ crystal structure.† For a Te–Zn–O glass having an eutectic composition, we consider that the stereochemical structural model given in Fig. 7 is close to reality. It may be described as follows.

The experimentally established elongation of one $Te—O_{ax}$ bond in TeO_4 building units as well as the absence of a contribution to the RDF_{exp} of Te–Te, Te–Zn and O–second O pairs shows, that the connection between the two chains is weakened markedly. The RDF_{exp} [Fig. 4 (curve 1)] and the RDF_{model} [Fig. 4 (curve 3)] lead to the conclusion that both structures are similar. On the other hand, it is well known that in the $Zn_2Te_3O_8$ structure[13] $^1_\infty[Te(4)Te_2(3+1)O_8]$ chains are formed where, for one TeO_4 polyhedron, there are two TeO_3 trigonal pyramids. For the investigated glass, and on the basis of our calculations, only 35% of the Te atoms have TeO_4 surroundings. The connection between chains is accomplished by Zn atoms conventionally

* The existence of channels in tellurite minerals is well known. For example Mätzat[23] reports that for $\{(Zn,Fe)_2[TeO_3]_3\}Na_xH_{2-x} \cdot yH_2O$ there are channels 8.28 Å in diameter, while for Denningit mineral, according to Refs 33 and 34, a channel of diameter 4.97 Å is formed.

† According to Hanke,[13] in the compound $Zn_2Te_3O_8$ there are infinite chains formed, with two trigonal pyramids TeO_3 for one TeO_4E trigonal bipyramid. The central Te atom has a coordination number of 3+1 or 3 since the fourth oxygen atom is shared by the next TeO_3 pyramid at a distance of 2.41 Å. Chains are isolated from each other (R_{min} = 2.72 Å). The bond between them is formed by Zn atoms of 4+1+1 oxygen coordination: the greatest Zn—O distance is equal to 2.47 Å.

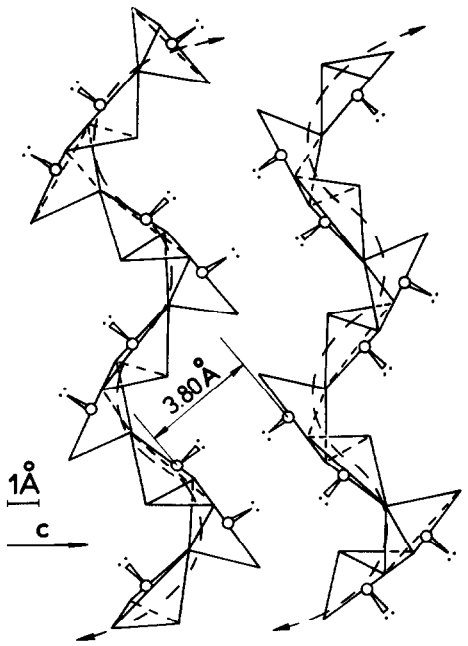

Fig. 6. Illustration of two Te–O chains in paratellurite (*c*-axis).

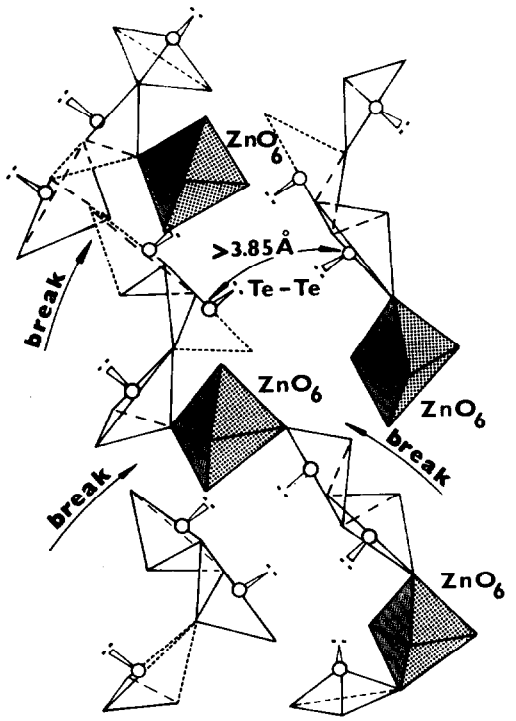
coordinated 4 + 1 + 1. Figure 7 illustrates the atomic arrangement nature of a zinc–tellurite glass with an eutectic composition. Parts of ZnO_{4+1+1} polyhedra are incorporated into and between the $^{1}_{\infty}[TeO_4 \cdot TeO_3]$ chains. In the bridging area, chains



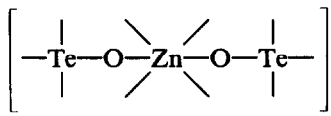


Fig. 7. Model illustrating the nature of the atomic arrangement in the investigated glass.

are weakly connected by

chains. Such a connection shows that it is probable that a number of ZnO_{4+1+1} polyhedra take site positions.

CONCLUSIONS

(1) It has been proved that there are no essential changes in TeO_4, TeO_3 and ZnO_6 polyhedra in the glass because the average value of the interatomic Te—O and Zn—O distances is preserved. It has been established that the O–O pairs in the glass at different distances greater than 2.2 Å are fixed. This causes an increase in the asymmetry of the TeO_4, TeO_{3+1} and ZnO_{4+1+1} polyhedra.

(2) The oxygen network of the glass is built of atoms at a mean distance, $\bar{R}_{O-O}$ of 2.95 Å. This value is close to the $\bar{R}_{O-O}$ of 2.85 Å for α-TeO_2. Such a small difference in the average values is probably due to the strong influence of the O—O distances in ZnO_{4+1+1} polyhedra.

(3) It has been experimentally proved that the average coordination number of the Te atoms is 3.35. Therefore it follows that approximately 35% of the Te atoms are in a TeO_4E trigonal bipyramidal surrounding and 65% of the Te atoms have a lower coordination number.

(4) It has been confirmed that the Te–Te, Te–second O and O–second O pairs in the region of 3.9 Å do not contribute significantly to the RDF_{exp}. Distances in this region are greatly changed in the glassy state and it can be accepted that they have a definitive contribution in the amorphization of tellurite melts. It is assumed that there are weak cation bonds of the Te—Te and Te—Zn type (via oxygen atoms) in the glass, connecting the different chains.

(5) The proposed model attempts to present stereochemically the atomic arrangement of the studied zinc–tellurite glass and to explain it in terms of short-range order.

Acknowlegement—We are heartily thankful to Dr V. Plahtii from the Institute of Nuclear Physics, Leningrad, for enabling us to carry out the neutron diffraction measurements.

Abstract—^{27}Al NMR isotropic chemical-shift and quadrupole-coupling data have been determined for a series of polycrystalline calcium aluminates with varying CaO/Al_2O_3 ratios. The data were derived from static and magic-angle spinning NMR spectra recorded at different magnetic field strengths up to 11.7 T. The chemical-shift and quadrupole-coupling data are discussed with regard to the crystal structure of the compounds studied. It is shown that structural effects are reflected more sensitively in the quadrupole-coupling data than in the chemical shifts. In favourable cases crystallographically different Al sites could be resolved in the NMR spectra.

^{27}Al NMR can provide structural information about the environment of the Al nuclei in polycrystalline and amorphous samples using either quadrupole-coupling data or chemical shifts. In the first case, the quadrupole moment of the Al nucleus is used as a sensitive probe for the electric field gradient (EFG) at the nuclear site. In the second case, the magnetic shielding of the aluminium by its electronic environment is investigated. Recent studies[1–3] have shown that, by employing magic-angle spinning (MAS) techniques at high magnetic fields, the second method proved to be a powerful tool for the determination of the coordination state of Al–O polyhedra. Subsequently this new method has been applied to structural studies of numerous inorganic materials including zeolites (see Ref. 4 and references cited therein), glasses,[5–7] cements,[8] clay minerals and layer silicates.[9–11]

The spread of chemical-shift values for AlO_4 tetrahedra reflects, beyond the Al coordination with oxygen atoms, more subtle influences on the Al shielding. Such influences are, for example, effects of neighbouring atoms in the second coordination sphere, cation effects and influences of the lattice geometry such as bond angles and distances.[12] For the detection of these subtle structural influences on the Al shielding a very precise determination of the chemical-shift values is necessary. Al as a quadrupolar nucleus, however, gives rise to particular experimental difficulties with regard to a determination of the actual chemical-shift values. In evaluating MAS NMR spectra of quadrupolar nuclei with non-integral spin, quadrupole-induced shift effects[13] have to be eliminated. This has been performed by means of combined high- and low-field ^{27}Al NMR measurements in the case of $LiAlO_2$ polymorphs.[14]

In the present work we extended our systematic studies of ^{27}Al chemical shifts and EFGs at the Al

* Author to whom correspondence should be addressed.

sites to a series of calcium aluminates with varying CaO/Al_2O_3 ratios. For them MAS NMR spectra and spectra of the static samples were recorded at different magnetic fields (up to the highest commercially available magnetic field strength of 11.7 T). The $CaO–Al_2O_3$ system has been extensively characterized crystallographically as well as thermodynamically.[15] De Jong *et al.*[16] have recently discussed the connectivity of the AlO_4 tetrahedra in this system. In some of these structures Al occurs at different Al sites. The present study also aims to show to what extent those different Al sites can be resolved in the ^{27}Al NMR spectra.

EXPERIMENTAL

^{27}Al NMR spectra were recorded at 1.4, 6.4, 8.45 and 11.7 T. The measurements were carried out on a Bruker-Physik CXP-200 equipped with a 8.45-T magnet (^{27}Al frequency 93.8 MHz) and on a Bruker-Physik AM 500 (11.7 T, 130.3 MHz) high-resolution NMR spectrometer (Tallinn). The measurements at 6.4 T (^{27}Al frequency 70.4 MHz) were made on a FKS 176 solid-state high-resolution NMR spectrometer (Jena). All high-field ^{27}Al NMR spectra were recorded both with static samples and with rapid MAS techniques (spinning rates 3–7 kHz). Whereas for the MAS NMR spectra usually between 100 and 1000 free induction decays (FIDs) with 1-s time intervals were accumulated, for the static spectra at lower frequencies up to 10,000 FIDs with 0.1-s time intervals were accumulated. Radio-frequency pulses of 1–2 μs duration were applied. In addition, in some cases, conventional low-field ^{27}Al NMR measurements were carried out on a wide-line NMR spectrometer at 16 MHz, recording the first derivative of the spectra. Quadrupole-coupling constants (e^2qQ/h) and asymmetry parameters (η) of the EFG at the Al sites were determined from computer simulation of the static spectra and/or the MAS NMR spectra using least-squares fitting procedures.

Chemical shifts [δ (ppm)] measured relative to an external standard of aqueous $AlCl_3$ solution are denoted by a positive sign for low-field shifts. The actual chemical-shift values (considering quadrupole-induced shift effects[13]) were obtained by different methods:

(i) directly from the fitted MAS spectra;
(ii) from the spinning sidebands of the satellite transitions;[17]
(iii) by adding a correction term which considers quadrupole-induced shifts to the experimental, field-dependent, apparent chemical-shift value of the MAS spectrum;[12,14]
(iv) from the fitted static spectrum; and
(v) from the extrapolation of the field-dependent apparent chemical shift.

In most cases satisfactory agreement was achieved with the different methods. It is clear that, for a determination of e^2qQ/h and η static low-field spectra are to be preferred, whereas most accurate chemical shifts are obtained from the MAS NMR spectra at highest fields. The resulting errors of the derived values are included in Table 1.

The samples under investigation were prepared by standard procedures and checked by X-ray powder diffraction.

RESULTS AND DISCUSSION

Table 1 contains the derived ^{27}Al chemical-shift values and quadrupole-coupling data for compounds of the $CaO–Al_2O_3$ system. The compounds in Table 1 are arranged in order of increasing CaO/Al_2O_3 ratio. The NMR data were obtained from the static and MAS NMR spectra recorded at magnetic field strengths of between 1.4 and 11.7 T. Table 1 also includes some structural data of the crystallographically different Al sites (coordination number and Al—O bond lengths).

The $CaO–Al_2O_3$ system starts with the compound $CaO \cdot 6Al_2O_3$ (CA_6).* According to Kato and Saalfeld[18] the structure of CA_6 contains five crystallographically different Al sites, namely three types of octahedral Al, a tetrahedral Al and a pentacoordinated Al. In the highfield ^{27}Al MAS NMR spectra of CA_6 three of the five types of Al sites can be detected separately. Figure 1 shows the static and the MAS NMR spectrum of CA_6 at 130.3 MHz. In addition to the signal of tetrahedral Al at 65 ppm, the spectrum exhibits two resolved signals due to octahedral Al at 9 and 16 ppm. Whereas the position of the signal at 16 ppm is nearly field-independent, the former, more intense signal is shifted to 7.5 ppm at 70.4 MHz, which is due to the above-mentioned quadrupole-induced shifts. Therefore this signal must be attributed to the more strongly distorted AlO_6 octahedra. Accordingly the signal at 9 ppm is assigned to the 12 AlO_6 octahedra per unit cell with noticeably varying Al—O distances of between 1.818 and 1.995 Å.[18] Correspondingly the signal at 16 ppm is assigned to the remaining six octahedral Al(3) and Al(4) atoms with identical and nearly identical Al—O distances, respectively. Comparison of the observed intensities of the NMR signals (about 2 : 1) confirms the assignment.

[f] Value derived from the spinning sidebands of the satellite transition.[17]

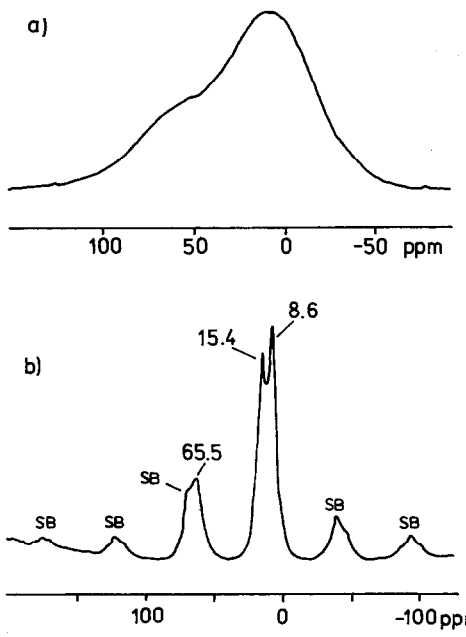

Fig. 1. ^{27}Al NMR spectra at 130.3 MHz of CA_6. (a) Static spectrum and (b) MAS spectrum; spinning sidebands (SB) are marked.

Because of the superposition of the NMR signals it was not possible to derive the e^2qQ/h and η values for the individual structural units directly from the static spectrum. Estimations of e^2qQ/h were made from the field-dependent quadrupole-induced shifts of the signals in the MAS NMR spectra (assuming $\eta = 0$).

A separate signal of the Al atoms at pentahedral sites, which should amount for 8% of the total intensity, could not be detected by NMR spectroscopy. This is obviously due to a strong quadrupolar broadening. Likewise, in the NMR spectrum of the corresponding barium aluminate, BA_6,[19] signals occur only for tetrahedral Al (at 71 ppm) and octahedral Al (at 9 ppm). A splitting of the latter signal is not observed in the NMR spectrum of BA_6.

It should be noted that the relatively low chemical-shift value for the tetrahedral Al in CA_6 correlates with the lengthened Al—O distance. We confirmed[19] this relationship in a series of compounds with related structural units.

Interpretation of recent Al-K_α measurements[20] of CA_6 which are discussed in terms of dominant penta-coordinated Al and hexa-coordinated Al (no tetrahedral Al), contrasts with the above-mentioned structure of CA_6 and with our NMR results. Apparently, this method is less favourable for the determination of the coordination state of Al in materials with mixed AlO_n polyhedra.

On increasing the CaO/Al_2O_3 ratio the next representative of the CaO–Al_2O_3 system is $CaO \cdot 2Al_2O_3$ (CA_2). The structure of CA_2 contains two types of fully condensed AlO_4 tetrahedra which share one or two, respectively, of the bridging oxygen atoms with two other tetrahedra forming so-called "triclusters".[21] It is plausible that this peculiarity of the connection of the tetrahedra, i.e. the existence of such tri-coordinated oxygen atoms adjacent to the usual bridging oxygen atoms, leads to anisotropic charge distributions at the Al sites and should produce large EFGs. Indeed, the NMR spectrum of the static sample at 70.4 MHz shows two broad, superimposed signals [see Fig. 2(a)]. The corresponding NMR spectra recorded at 93.83 and 130.3 MHz show the theoretical field dependence expected for quadrupolar lines in second-order perturbation theory. Large e^2qQ/h of 6.7 MHz with $\eta = 0.8$ and of 13 MHz with $\eta = 0$, respectively, were obtained from the computer fit of the superimposed static spectrum. According to the zero η which corresponds to axial symmetry of the EFG, we assign the latter broad signal to such AlO_4 tetrahedra having only one tri-coordinated oxygen atom. Subsequently the narrower signal is assigned to the other type of AlO_4 tetrahedra having two oxygen atoms of this type (non-axial symmetry). It should be noted that the intensity of the broad signal only amounts for about 50% of the expected value. This is probably

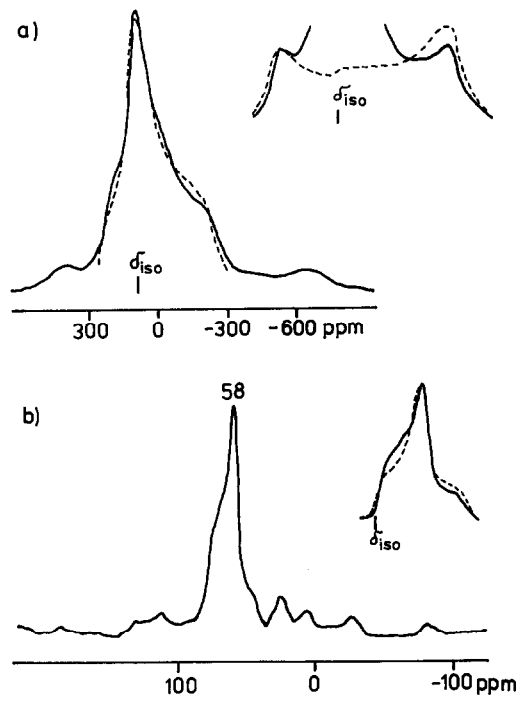

Fig. 2. ^{27}Al NMR spectra of CA_2. (a) Static spectrum at 70.4 MHz. On the right the broad component of the spectrum is shown vertically expanded. (b) MAS spectrum at 130.3 MHz [(– – –) fitted lineshape; the resulting locations of δ_{iso} are marked].

due to the fundamental difficulties in the detection of very broad lines by pulsed NMR techniques. In this connection the size of the e^2qQ/h derived for the AlO_4 tetrahedra in CA_2 is interesting since the values give an idea of the quadrupole line broadening of such "triclusters" which are also discussed as possible structural units in glasses.[7,22] The ^{27}Al MAS NMR spectrum at 130.3 MHz of CA_2 [see Fig. 2(b)] only shows the narrowed line of the AlO_4 tetrahedra with nonaxial symmetry together with spinning sidebands of the satellite transitions. The computer simulation of the MAS NMR spectrum confirms the quadrupole-coupling data derived from the static spectrum and provides a chemical-shift value of 78 ppm for this type of AlO_4 tetrahedra. For the other AlO_4 tetrahedra only a rough value of 60 ± 20 ppm can be estimated from the simulation of the broad component of the static spectrum.

At a CaO/Al_2O_3 ratio of 1.0 the compound $CaO \cdot Al_2O_3$ (CA) occurs. According to Hörkner and Müller-Buschbaum[23] the structure of CA consists of six-rings of AlO_4 tetrahedra forming two-dimensional infinite sheets. There are six different AlO_4 tetrahedra which differ only slightly in their Al—O distances.

The derivative ^{27}Al NMR spectrum at 16 MHz of the static CA sample could satisfactorily be simulated by assuming only one set of e^2qQ/h and η values.[24] This is not surprising with regard to the similarity of the geometry of the six AlO_4 tetrahedra. At higher measuring frequencies, however, shoulders appear in the MAS NMR spectra which indicate the existence of more than one signal with different chemical shifts. The MAS NMR spectrum at 130.3 MHz is shown in Fig. 3. From analysis of the spinning sidebands of the satellite transitions which are distinctly split into two peaks, chemical-shift values of 80.5 and 83.3 ppm are determined. Using these chemical-shift values and the common quadrupole-coupling data derived at low field, the MAS NMR spectrum was simulated by a superposition of two lines. As shown in Fig. 3(b), a satisfactory agreement with the experimental spectrum was achieved. As a possible reason for the two different chemical shifts the variation of the mean Al—O—Al angles (between 121 and 124°) can be discussed. However, an assignment of the two signals to distinct Al sites in the structure is not accomplished.

In the compound $4CaO \cdot 3Al_2O_3$ (C_4A_3), a sodalith-like phase, there is only one type of AlO_4 tetrahedra which form a cubooctahedron.[25] As expected the MAS NMR spectrum of C_4A_3 (not shown) exhibits only one sharp signal at 79 ppm. Compared to C_4A_3, the corresponding hydrate phase $C_4A_3H_3$ contains two kinds of AlO_4

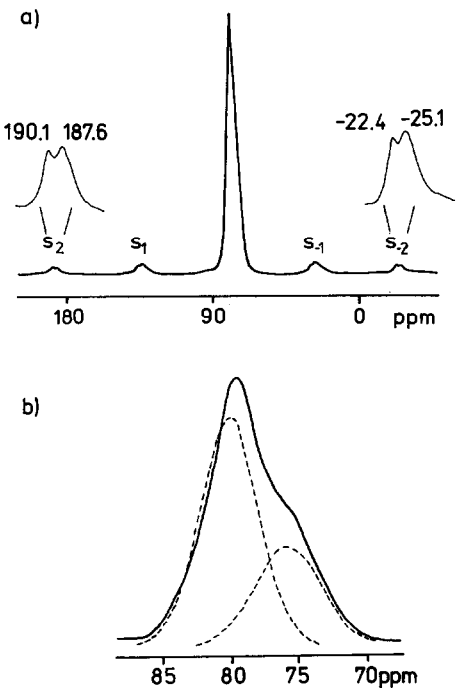

Fig. 3. ^{27}Al MAS NMR spectrum at 130.3 MHz of CA. (a) Total MAS spectrum; the second spinning sidebands of the neighboured satellite transition are shown expanded. (b) Central line of the MAS spectrum; the two signals resulting from the line separation (see text) are indicated by hatched lines.

tetrahedra, regular and distorted. Because of their different quadrupole-coupling constants the two Al sites can be resolved in the MAS NMR spectrum.[19]

At a CaO/Al_2O_3 ratio of 1.67 the compound $5CaO \cdot 3Al_2O_3$ (C_5A_3) with a structure of twisted sheets of distorted AlO_4 tetrahedra is known.[26] Unfortunately, all the samples available to us contained considerable amounts of CA. Therefore we must exclude this phase from our considerations.

The next compound to be discussed is $12CaO \cdot 7Al_2O_3$ ($C_{12}A_7$) at a CaO/Al_2O_3 ratio of 1.7. According to Bartl and Scheller[27] this compound can be formulated as

$$Ca_{12}[AlO_2]_6[AlO_{2.5}]_8.$$

In addition to the tetrahedral Al in completely connected $[AlO_2]^-$ groups, $C_{12}A_7$ also contains AlO_4 tetrahedra with one non-bridging oxygen atom (usually denoted as Q^3 groups). Correspondingly the static NMR spectra at 70.4, 93.8 and 130.3 MHz show in each case a superposition of a sharp and an extremely broad line. (Both lines show the theoretical dependence on the magnetic field.) For example, the MAS NMR spectrum at 70.4 MHz is shown in Fig. 4. From the simulation of the superimposed spectra a large

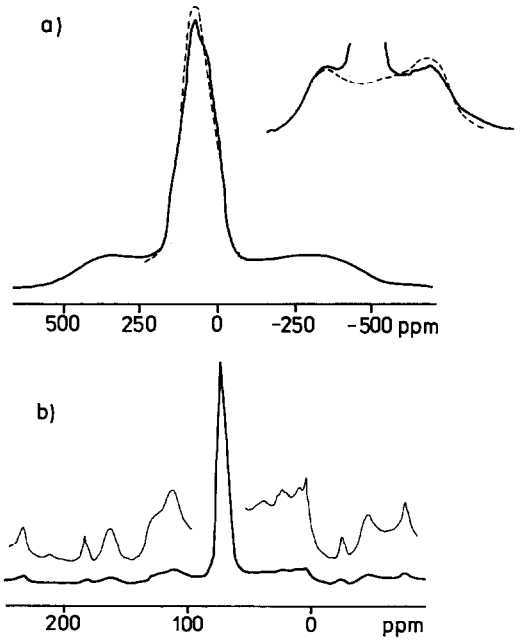

Fig. 4. ^{27}Al NMR spectra of $C_{12}A_7$. (a) Static spectrum at 70.4 MHz. On the right the vertical expansion of the broad component of the spectrum is shown [(– – –) fitted lineshape]. (b) MAS spectrum at 130.3 MHz. In addition the amplified spinning sidebands are shown.

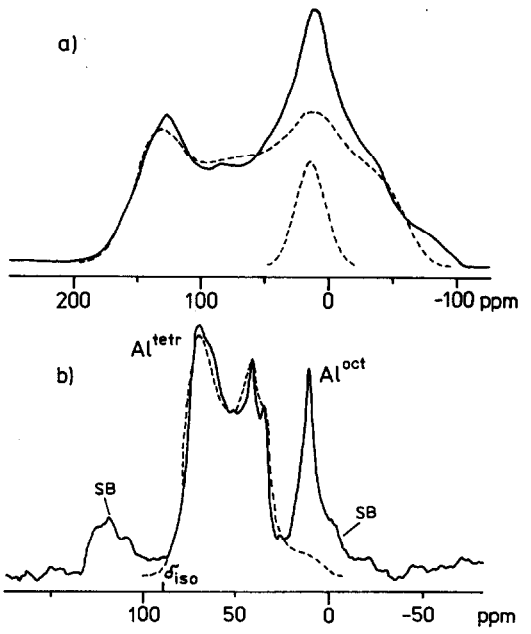

Fig. 5. ^{27}Al NMR spectra at 130.3 MHz of C_3A. (a) Static spectrum, and (b) MAS spectrum [(– – –) fitted lineshape]. The signal near 10 ppm is due to octahedral Al and indicates a partial hydration of the sample.

e^2qQ/h value of 11 MHz and a zero η (axial symmetry of the EFG tensor) results for the broad signal which is therefore assigned to the Q^3 group.

In this connection the size of the large EFG of these AlO_4 branching groups has to be emphasized. The distortion of these tetrahedra are also reflected in the shorter Al—O distance of the single terminal oxygen atom compared with the other Al—O distances of 1.78 Å.[27]

For the undistorted AlO_4 tetrahedra of $C_{12}A_7$ a chemical shift value of 79 ppm was determined from the MAS NMR spectrum at 130.3 MHz. Unfortunately, under our experimental conditions no separate line due to the Q^3 groups was observed in the MAS NMR spectrum. Therefore for the latter groups only a rough value of 85 ± 8 ppm could be estimated from the computer simulation of the corresponding static spectrum.

The last compound of the $CaO–Al_2O_3$ system is $3CaO \cdot Al_2O_3$ (C_3A) at a CaO/Al_2O_3 ratio of 3.0. In the structure of C_3A[28] there are two types of Al atoms which are arranged in six-membered rings of AlO_4 tetrahedra (Q^2 group). The NMR spectrum of the static C_3A sample is shown in Fig. 5(a). An e^2qQ/h of 9.6 MHz and an η of 0.3 result from the computer simulation of the spectrum. The derived data represent mean values for both types of AlO_4 tetrahedra which do not markedly differ in their interatomic distance bond angles.[28]

The deviation of the simulated spectrum at its peak near 10 ppm suggests a partial hydration of the C_3A sample. This suggestion is confirmed by the MAS NMR spectrum which shows, in addition to the signal of the AlO_4 groups, a sharp peak at 10 ppm obviously due to regular AlO_6 groups. The spectrum of another well-dried sample at 70.4 MHz did not show any additional signal of octahedral Al. From the simulation of the MAS NMR spectrum of C_3A at 130.3 MHz [Fig. 5(b)] a chemical-shift value of 85 ppm can be derived for the groups of the six-membered rings of AlO_4 tetrahedra. This value is in good agreement with the value determined from the simulation of the static spectrum.

CONCLUSIONS

Apart from the known influence of the coordination state of aluminium, other structural factors such as interatomic distances and bond angles cause only weak changes in the ^{27}Al chemical-shift values in the calcium aluminates studied. So, for example, only slight variations in the chemical-shift values are observed between the various AlO_4 tetrahedra with different numbers of bridging oxygen atoms. A systematic study of such condensation effects of the AlO_4 tetrahedra, which also includes the measurement of other selected

aluminates and aluminate hydrates, is given elsewhere.[19]

Compared to the chemical shift structural effects are reflected more sensitively in the e^2qQ/h and η. Therefore resolved NMR spectra were only obtained in such cases where the crystallographically different Al sites also have clearly differing EFGs.

(*Received* 15 *April* 1985; *accepted after revision* 31 *July* 1985)

Abstract—Eight polycrystalline materials of the new spinel series $Co_{1+2s}Cr_{2-3s}Sb_sO_4$ ($s = 0$, 0.10 ... 0.60 or 0.67) have been prepared and studied by X-ray powder diffraction. The series goes from $CoCr_2O_4$ ($s = 0$) to $Co_{7/3}Sb_{2/3}O_4$ ($s = \frac{2}{3}$), with a gradually increasing from 8,3346(3) ($s = 0$) to 8.5330(6) Å ($s = \frac{2}{3}$), and u slightly decreasing from 0.261 ($s = 0$) to 0.258 ($s = \frac{2}{3}$). Interatomic distances are given. The series may be thought as the result of progressive substitution of Cr^{3+} by $\frac{2}{3}Co^{2+} + \frac{1}{3}Sb^{5+}$ in the normal spinel $CoCr_2O_4$. This substitution can be total, so that $CoCr_2O_4$ *becomes* $Co_{7/3}Sb_{2/3}O_4$.

Recently the authors have suggested[1,2] that an oxide spinel constituted by three equal or different metals, M, M′ and M″, in oxidation states m, m' and m'', can be a member of the series $M_sM'_dM''_cO_4$, where $d = (8-3m''-ms+m''s)/(m'-m'')$ and $e = (3m'-8+ms-m's)/(m'-m'')$, s, d and e being positive. This suggestion has been confirmed for the series $Co_{3-s}Al_sO_4$ ($0 \leqslant s \leqslant 2$),[1] and $Mn_{1+s}Cr_{2-3s}Sb_sO_4$ ($0.05 \leqslant s \leqslant 0.30$).[2] This second series may be conceived of as the result of partial substitution of Cr^{3+} by $\frac{2}{3}Mn^{2+} + \frac{1}{3}Sb^{5+}$ in the normal spinel $MnCr_2O_4$. At first sight the mentioned substitution could be performed for s values up to $\frac{2}{3}$, but in fact it could not be accomplished for $s > \frac{1}{3}$, because in these cases a mixture of phases was found.[2]

The hypothetical series $M(II)_{1+2s}Cr_{2-3s}Sb_sO_4$ is limited by two compounds: for $s = 0$, the *chromite* MCr_2O_4; for $s = \frac{2}{3}$, the oxide $M_{7/3}Sb_{2/3}O_4$. Whereas all the *chromites* are spinels, only two $M_{7/3}Sb_{2/3}O_4$ compounds with spinel structure are known,[3] those of Co and Zn. Thus, in these two cases it seems feasible to prepare the complete series $M_{1+2s}Cr_{2-3s}Sb_sO_4$, i.e. for s values from zero up to $\frac{2}{3}$. In fact, the oxide for which M = Co and $s = 0.50$ has been described[4] as a spinel with $a = 8.499$ Å.

This paper aims to report how the series $Co_{1+2s}Cr_{2-3s}Sb_sO_4$ was prepared and the X-ray diffraction data for eight samples ($s = 0, 0.10 \ldots 0.60$ or 0.67) of the series. These data are relevant especially for the first and last members, because dark green $CoCr_2O_4$ has been known since 1927, but it has not been completely studied: according to the last investigation[5] its lattice constant a was 8.332 ± 0.005 Å, but the oxygen positional parameter (u) was not determined. On the other hand, for black $Co_{7/3}Sb_{2/3}O_4$, $a = 9.523$ Å; and $u = 0.255 \pm 0.005$, origin at center, ($\bar{3}m$), was determined[6] from the intensity ratios of some reflections.

EXPERIMENTAL

The samples were prepared from mixtures of analytical grade Co_3O_4, Cr_2O_3 and Sb_2O_3, of molar ratios Co : Cr : Sb = $(1+2s):(2-3s):s$ ($s = 0, 0.10 \ldots 0.60$ or 0.67), which were heated in air at 953, 1173, 1273, 1473 and 1500 K during 1 day. After each thermal treatment the materials were quenched and ground. Additional experimental details were as indicated elsewhere.[7] The unit-cell parameters, a,

* Author to whom correspondence should be addressed.

were refined from the 2θ values of at least eight of the last 12 reflections using the program PARAM.[8] The intensities were calculated with the program LAZY-PULVERIX,[9] using scattering factors for neutral atoms, Debye–Waller, Lorentz and polarization factors, and correction for anomalous dispersion. The arbitrarily chosen Debye–Waller factors, B_j, for the calculation of the intensities were 0.30 and 0.80 Å^2 for Sb and oxygen atoms respectively; the values 0.60 and 0.63 Å^2 for Co and Cr, respectively, were obtained from these two by interpolation of the respective atomic masses between those of oxygen and Sb. Intensities were calculated for u equal to 0.255, 0.256 ... 0.263, origin at centre, $(\bar{3}m)$, and assuming tetrahedral (a) sites occupied by Co atoms for all the samples. The disrepancy factor between observed and calculated intensities:

$$R = (\sum |I_o^{1/2} - I_c^{1/2}|)/\sum I_o^{1/2}$$

was computed after making $\sum I_o$ equal to $\sum I_c$, and taking into account all the reflections with $I_o > 5$. For each member of the series, the u value taken as observed was that leading to the smallest R.

RESULTS AND DISCUSSION

The eight samples of composition $Co_{1+2s}Cr_{2-3s}Sb_sO_4$ ($0 \leqslant s \leqslant \frac{2}{3}$) were obtained as powders coloured from dark grey blue ($s = 0$), blackish blue ($s = 0.10$ and 0.20) to black ($s = 0.30$, 0.40 ... 0.67), which gave good X-ray diffraction patterns* characteristic of spinels. The a values showed a gradual variation, confirming the existence of the series. Thus, $Co_{1+2s}Cr_{2-3s}Sb_sO_4$ ($0 \leqslant s \leqslant \frac{2}{3}$) is a series of cubic spinels, space group $Fd\bar{3}m$ (No. 227), $Z = 8$, with the a and observed u_o values which are shown in Table 1. For $CoCr_2O_4$, $Co_2Cr_{0.5}Sb_{0.5}O_4$, and $Co_{7/3}Sb_{2/3}O_4$, the observed unit-cell parameters compare with those previously determined.[4–6] Calculated intensities,* I_c, were obtained for the distribution of cations and u_o values of Table 1, where the best R factors are also shown.

Observed u_o values can be compared with those calculated, u_c, using the expression $u_c = 3r^2 + (33r^2 - 8)^{1/2} - 8/24(r^2 - 1)$, where r is the ratio of the octahedral, d_o, to the tetrahedral, d_t, M—O distances. This expression is deduced taking into account that $d_o = a(3u^2 - 2u + 3/8)^{1/2}$, and $d_t = a3^{1/2}(u - 1/8)$. Assuming the distribution of cations indicated in the supplementary material,* and the corresponding ionic radii[10] (Å), values for d_o, d_t, r and u_c are obtained.* The u_c agree acceptably with the u_o.

Table 1. Crystal data for the spinels $Co_{1+2s}Cr_{2-3s}Sb_sO_4$, with ESDs in parentheses

s	a (Å)	u_o	u_c	R
0.00	8.3346(3)	0.261	0.261	0.042
0.10	8.3461(4)	0.260	0.260	0.030
0.20	8.3783(3)	0.260	0.260	0.029
0.30	8.4187(5)	0.260	0.259	0.025
0.40	8.4577(3)	0.260	0.259	0.027
0.50	8.4909(4)	0.259	0.258	0.031
0.60	8.5185(4)	0.259	0.258	0.031
0.67	8.5330(6)	0.258	0.257	0.043

Table 2 shows the observed M—O and O—O distances at tetrahedral (a) and octahedral (d) sites. The O—O distances have been calculated from the following expressions: at tetrahedral sites, O—O = $a2^{1/2}(2u - \frac{1}{4})$; for octahedral positions, O—O = $a2^{1/2}(\frac{3}{4} - 2u)$; O—O′ = $a(4u^2 - 2u + \frac{3}{8})^{1/2}$. As can be deduced from Table 2, the distances M—O and O—O for tetrahedral positions remain unaltered along the series, equal 1.967(9) and 3.212(14) Å, respectively. The ESD obtained for these distances illustrate the precision of the method, which consists in establishing u_o and, as a function of a and u_o, the M—O and O—O distances. The mentioned ESD are those calculated for a u_o absolute error of 0.0006 units. Assuming this u_o error, from the expressions which give the distances M—O, O—O and O—O′ for octahedral sites as a function of a and u_o the following ESDs are deduced for these distances: 0.005, 0.014 and 0.0006 Å respectively.

Table 2. Observed interatomic distances (Å) in the spinels $Co_{1+2s}Cr_{2-3s}Sb_sO_4$ ($0 \leqslant s \leqslant \frac{2}{3}$).

	Tetrahedral (a) sites		Octahedral (d) sites		
s	M—O	O—O	M—O	O—O	O—O′
0.00	1.963	3.206	1.996	2.687	2.952
0.10	1.952	3.187	2.007	2.715	2.956
0.20	1.959	3.199	2.014	2.725	2.967
0.30	1.969	3.215	2.024	2.738	2.981
0.40	1.978	3.320	2.033	2.751	2.995
0.50	1.971	3.218	2.049	2.786	3.006
0.60	1.977	3.229	2.056	2.795	3.016
0.67	1.966	3.210	2.067	2.824	3.020

* The data have been deposited with the Editor and are available on request.

Table 2 shows how the tetrahedral M—O bond lengths are constant along the series, whereas the octahedral M—O distances increase with s. These results could be anticipated, because the series $Co_{1+2s}Cr_{2-3s}Sb_sO_4$ ($0 \leqslant s \leqslant \frac{2}{3}$) can be thought of as derived from the normal spinel $CoCr_2O_4$ through progressive substitution of two Cr^{3+} by two of the more voluminous cations, $\frac{2}{3}Mn^{2+} + \frac{1}{3}Sb^{5+}$. This substitution takes place at the octahedral sublattice, whereas the tetrahedral sites remain unaltered, occupied by Co^{2+} ions. Hence, the mentioned substitution has to be accomplished keeping unchanged the tetrahedral M—O distances and progressively increasing the octahedral ones.

From these results and those of the previous paper,[2] it is concluded that in the series $M_{1+2s}Cr_{2-3s}Sb_sO_4$, limited by the oxides MCr_2O_4 ($s = 0$) and $M_{7/3}Sb_{2/3}O_4$ ($s = \frac{2}{3}$), when both of these oxides are spinels, s can adopt all the values from zero to $\frac{2}{3}$, i.e. all the $\lambda+$ chromium of MCr_2O_4 can be substituted by $\frac{2}{3}M\frac{1}{3}Sb$. On the other hand, when the oxide $M_{7/3}Sb_{2/3}O_4$ is not a spinel, only half the chromium in MCr_2O_4 can be substituted, and s can vary only up to $\frac{1}{3}$.

COPPER–TUNGSTEN COMPLEXES WITH BRIDGING TOLYLMETHYLIDYNE LIGANDS: CRYSTAL STRUCTURE OF THE COMPOUND $[CuW_2(\mu_3\text{-}CC_6H_4Me\text{-}4)(CO)_4(PPh_3)(\eta\text{-}C_5H_5)_2]\cdot CH_2Cl_2$

MATHIAS MÜLLER-GLIEMANN, SIMON V. HOSKINS, A. GUY ORPEN, ANDREW L. RATERMANN and F. GORDON A. STONE

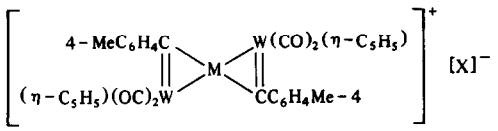
(*Received* 8 *July* 1985; *accepted* 31 *July* 1985)

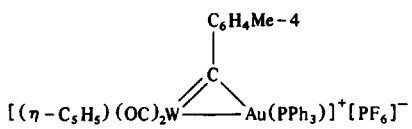


Abstract—The complexes $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ and $[Cu(NCMe)_4][PF_6]$ in dichloromethane combine to form the salt $[Cu\{W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)\}_2][PF_6]$, but the latter very readily dissociates in solution releasing the tolylmethylidynetungsten compound. The more stable salt $[CuW(\mu\text{-}CC_6H_4Me\text{-}4)(CO)_2(NCMe)(PPh_3)(\eta\text{-}C_5H_5)][PF_6]$ is obtained by addition of $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ to a dichloromethane solution of $[Cu(NCMe)_4][PF_6]$ previously treated with 1 mol equivalent of PPh_3. In the presence of additional PPh_3, however, no copper–tungsten complex is formed. Several reactions of $[CuW(\mu\text{-}CC_6H_4Me\text{-}4)(CO)_2(NCMe)(PPh_3)(\eta\text{-}C_5H_5)][PF_6]$ have been studied, but these led only to release of $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$. The compounds $[\{CuH(PPh_3)\}_6]$ and $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ react in toluene at room temperature to give $[W(CO)_2(\eta^3\text{-}CH_2C_6H_4Me\text{-}4)(\eta\text{-}C_5H_5)]$ and the new cluster compound $[CuW_2(\mu_3\text{-}CC_6H_4Me\text{-}4)(CO)_4(PPh_3)(\eta\text{-}C_5H_5)_2]$. The structure of the latter species has been established by X-ray diffraction. A CuW_2 metal triangle [Cu—W 2.640(2) and 2.610(2), and W—W 3.064(1) Å] is asymmetrically capped by a CC_6H_4Me-4 group [μ_3-C—Cu 2.130(9), μ_3-C—W 2.035(9) and 2.122(9) Å]. The copper atom is ligated by a PPh_3 molecule, and each tungsten by an η^5-cyclopentadienyl and two carbonyl groups. The copper atom is weakly co-ordinated in a semi-bridging manner by two of the CO ligands, one on each tungsten, and is also very weakly bound to a third. The molecule undergoes dynamic behaviour in solution.

The alkylidyne–tungsten compound $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ reacts with a variety of low-valent metal–ligand fragments to afford complexes with metal–metal bonds bridged by the CC_6H_4Me-4 group.[1,2] Most of the *d*-block elements are represented among the products of these reactions, and complexes of this class are also known with bonds between tungsten and copper, silver or gold. For example, the dicopper–tungsten species $[Cu_2W(\mu_3\text{-}CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)(\eta\text{-}C_5Me_5)_2]$ is obtained by treating $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ with $[Cu(thf)(\eta\text{-}C_5Me_5)]$ (thf = tetrahydrofuran).[3] Moreover, the latter reagent is sufficiently reactive to add to the unsaturated C=W bonds in $[PtW(\mu\text{-}CC_6H_4Me\text{-}4)(CO)_2(PMe_3)_2(\eta\text{-}C_5H_5)]$ and $[Pt\{W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)\}_2]$ to give, respectively, the trimetal compound $[CuPtW(\mu_3\text{-}CC_6H_4Me\text{-}4)(CO)_2(PMe_3)_2(\eta\text{-}C_5H_5)(\eta\text{-}C_5Me_5)]$ and the pentanuclear metal compound $[Cu_2PtW_2(\mu_3\text{-}CC_6H_4Me\text{-}4)_2(CO)_4(\eta\text{-}C_5H_5)_2(\eta\text{-}C_5Me_5)_2]$. In this paper we report some further studies directed towards the synthesis of complexes containing copper–tungsten bonds and bridging to tolylmethylidyne groups.

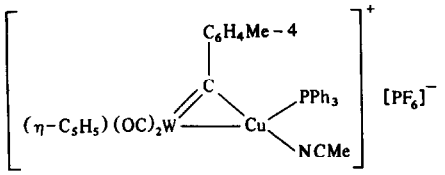
RESULTS AND DISCUSSION

In earlier work,[4] the gold- and silver–ditungsten salts **1** and **2** were prepared from $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ by treating the latter with either $[AuCl\{S\cdot(CH_2)_3\cdot CH_2\}]$, in the presence of $TlPF_6$, or $[Ag(NCMe)_4][BF_4]$, respectively. Whereas **1** is stable in thf solution, under similar conditions the silver cation readily dissociates the "carbyne–tungsten" ligands. We were interested in



establishing whether the copper–ditungsten salt (**3**) could be obtained, and if so to compare its stability in solution with those of **1** and **2**.

	M	X
1	Au	PF_6
2	Ag	BF_4
3	Cu	PF_6



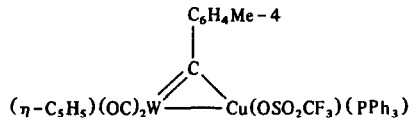
Reaction between $[Cu(NCMe)_4][PF_6]$ and $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ in CH_2Cl_2 at room temperature afforded, after addition of light petroleum, orange crystals of **3**. The IR spectrum of this product in the carbonyl region, measured in CH_2Cl_2, showed two bands (2021 and 1942 cm^{-1}) very similar to those seen in the spectra of **1** (2024 and 1969 cm^{-1}) and **2** (2020 and 1956 cm^{-1}). Not unexpectedly, in view of the salt-like nature of **1**–**3**, the carbonyl stretching bands occur at higher frequencies than the corresponding bands in the spectrum of $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ (1984 and 1906 cm^{-1}, measured in CH_2Cl_2).

Attempts to obtain NMR data for **3** led only to the observation of peaks due to free $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$. Moreover, when the IR spectrum of **3** was measured in thf solution, the only CO stretching bands observed were those due to the tolylmethylidynetungsten compounds It is thus apparent that **3** is even more labile than **2**, and that, overall, the ligating properties of the carbyne–tungsten compound decreases in the order Au(I) > Ag(I) > Cu(I).

4

Earlier we reported[5] the synthesis of the gold–tungsten salt (**4**) by treating $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ with $[AuCl(PPh_3)]$ in CH_2Cl_2 in the presence of $TlPF_6$. With the object of obtaining a copper analogue of **4**, reactions between $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ and $[Cu(NCMe)_4][PF_6]$ in the presence of PPh_3 were investigated, using CH_2Cl_2 as solvent. It was found that whether an isolable copper–tungsten complex was formed depended on the amount of PPh_3 added to the copper salt prior to addition of this reagent to a CH_2Cl_2 solution of the tolylmethylidynetungsten compound. Using one equivalent of PPh_3, the orange salt **5** could be isolated.

5

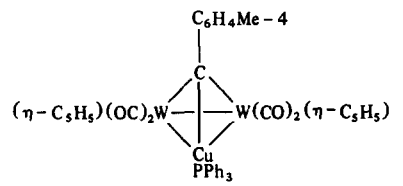


However, when two equivalents of PPh_3 were added to the copper–acetonitrile cation, or if the latter was treated with a mol equivalent of $Ph_2PCH_2PPh_2$, no reaction subsequently occurred with the tungsten compound. Not surprisingly, in view of these observations, treatment of **5** with PPh_3 regenerates $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$. Evidently, the $[Cu(NCMe)(PPh_3)]^+$ fragment is able to bond a molecule of $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ to produce **5**, whereas $[Cu(PPh_3)_2]^+$ cannot form a stable adduct with the alkylidyne–tungsten compound.

It is interesting to contrast **4** with **5**. In these species the gold and copper centres are co-ordinated by two and three ligands, respectively, assuming that the C≡W system, being akin to an alkyne,[1] occupies one co-ordination site.

Earlier it was observed that, in solution, **4** readily dissociates, affording a mixture of complexes, including the species $[Au(PPh_3)_2]^+$ and the cation of **1**.[5] Although **5** appeared to be reasonably stable in solution, allowing definitive NMR data to be obtained (see below), reactions of the copper–tungsten salt with Cl^-, I^- or CN^-, in CH_2Cl_2, led to the release of $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$. A similar decomposition of **5** occurred on treatment with SR^-, BH_4^- or H^-, or with sodium naphthalenide in the presence of CO.

Compound **5** was fully characterised spectroscopically. The IR spectrum had the expected two CO stretching bands (2014 and 1946 cm^{-1}). The ^1H NMR spectrum showed resonances due to the MeCN, Me-4 and C_5H_5 groups, and these signals had the expected relative peak intensities. The ^{31}P–$\{^1H\}$ NMR spectrum consisted of a singlet signal at δ 0.2 ppm, due to the PPh_3 ligand, and a resonance at δ −144.2 [heptet, J(PF) 713 Hz] characteristic of the anion PF_6^-. The ^{13}C–$\{^1H\}$ NMR spectrum was especially informative, with a diagnostic resonance for the μ-C nucleus at 294.9 ppm. The corresponding peak in the spectrum of **4** is observed at 292.6 ppm, and occurs as a doublet due to ^{31}P–^{13}C coupling.[5] The absence of such coupling on the bridging carbyne resonance of **5** suggests that, in the latter, the acetonitrile ligand is *transoid* to the μ-C group, with the PPh_3 ligand *cisoid*.



Treatment of the trifluoromethanesulfonate (benzene)copper complex [$Cu(SO_3CF_3)(0.5\ C_6H_6)$] with 1 mol equivalent of PPh_3 in CH_2Cl_2, followed by addition of this mixture to [$W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)$] afforded the salt **6** in which the SO_3CF_3 anion is co-ordinated to copper. The $^{13}C\text{-}\{^1H\}$ NMR spectrum showed the characteristic resonance for the bridging carbyne–carbon nucleus at δ 292.3 ppm, while the CF_3 group gave a quartet signal [J(FC) 319 Hz] at 120.2 ppm.

6

During the course of our studies we also investigated the reaction between [$W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)$] and the hexanuclear copper complex [$\{CuH(PPh_3)\}_6$].[6] It was anticipated that the product of this reaction might have been a copper–tungsten complex containing both bridging hydrido and tolylmethylidyne ligands, or alternatively, a species having a μ-CH(C_6H_4Me-4) group, if Cu–H addition across the C≡W bond occurred. In practice the reaction proceeded in an unexpected manner.

Treatment of [$W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)$] with [$\{CuH(PPh_3)\}_6$] in toluene at room temperature afforded a mixture of two products separated by column chromatography on alumina. The first eluate contained the known[7] *p*-methylbenzyltungsten complex [$W(\eta^3\text{-}CH_2C_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)$], which we have observed previously[8] as a product of reactions involving [$W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)$]. The second product was a purple crystalline compound. Examination of the ^1H NMR spectrum of this species (**7**) failed to reveal any

7

resonance attributable to the presence of a hydrido ligand in the molecule. The $^{13}C\text{-}\{^1H\}$ NMR spectrum had a resonance at δ 339.6 ppm, appearing as a doublet [J(PC) 7 Hz] with ^{183}W satellite peaks [J(WC) 94 Hz]. This signal seemed almost certainly to be due to a bridging carbon nucleus of a tolylmethylidyne group, rather than that arising from the ligated carbon of a μ-CH(C_6H_4Me-4) fragment. In confirmation of this, a fully coupled ^{13}C NMR spectrum established that no proton was attached to the carbon nucleus responsible for the resonance at δ 339.6 ppm. It was thus evident that the structure of **7** could not be resolved without a single-crystal X-ray diffraction study.

The crystals studied were grown from CH_2Cl_2, and the crystal structure consists of isolated molecules of **7** and CH_2Cl_2, in equimolar amounts, separated by normal van der Waals' contact distances. The molecular structure is illustrated in Fig. 1, and selected bond lengths and angles are given in Table 1. Molecules of **7** contain two tungsten and one copper atom forming an approximately isosceles triangle [Cu—W(1) 2.610(2), Cu—W(2) 2.640(2), and W(1)—W(2) 3.064(1) Å]. The CuW_2 triangle is asymmetrically capped by the μ_3-CC_6H_4Me-4 ligand [Cu—C(120) 2.130(9), W(1)—C(120) 2.035(9), and W(2)—C(120) 2.122(9) Å]. Each tungsten is further ligated by a η^5-cyclopentadienyl and two carbonyl ligands. The copper atom is bound to a triphenylphosphine ligand [Cu—P 2.217(3) Å]. The copper is also weakly co-ordinated by two of the carbonyl ligands [C(2)O(2) and C(10)O(10)] in a semi-bridging manner, and very weakly attached to a third [C(20)O(20)], a feature discussed further below.

The copper–tungsten bond lengths are very

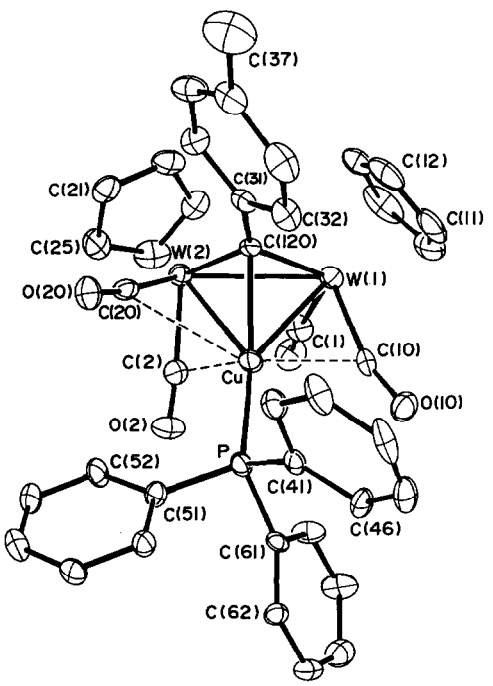


Fig. 1. The molecular geometry of [$CuW_2(\mu_3\text{-}CC_6H_4Me\text{-}4)(CO)_4(PPh_3)(\eta\text{-}C_5H_5)_2$], showing the atomic labelling scheme. All hydrogen atoms and the CH_2Cl_2 molecule have been omitted for clarity.

Table 1. Bond distances (Å) and angles (°) for the complex $[CuW_2(\mu_3\text{-}CC_6H_4Me\text{-}4)(CO)_4(PPh_3)(\eta\text{-}C_5H_5)_2]\cdot CH_2Cl_2$

similar to the Cu–W separation in [CuPtW(μ_3-CC_6H_4Me - 4)$(Co)_2(PMe_3)_2(\eta$ - $C_5H_5)(\eta$ - $C_5Me_5)$] [Cu—W = 2.648(3) Å].[3] The capping carbyne atom [C(120)] in **7** is, however, less strongly bound to copper [C(120)—Cu 2.130(9) Å] than the μ_3-C atom in [CuPtW(μ_3-CC_6H_4Me-4)$(CO)_2(PMe_3)_2$ $(\eta$-$C_5H_5)(\eta$-$C_5Me_5)$] [μ_3-C—Cu 1.96(2) Å]. The C(120)—W distances in **7** [2.035(9) and 2.122(9) Å] are similar to those found [2.035(14) and 2.050(11) Å] in the compound [$ReW_2(\mu$-Br)(μ-CC_6H_4Me-4) (μ_3-CC_6H_4Me-4)(μ-CO)$(CO)_3(\eta$-$C_5H_5)_2$].[9] The asymmetry of the C(120)—W distances in **7** is not paralled by any asymmetry in the W—μ_3-C—C_{ipso} angles [W(1)—C(120)—C(31) 131.7(7), and W(2)—C(120)—C(31) 131.2(7)°]. The Cu—C(120)—C(31) angle [121.1(6)°] in **7** is less obtuse than the W—C(120)—C(31) angles, indicating that the C_6H_4Me-4 substituent on C(120) "leans" towards the copper. A similar feature is found[3] in the structure of [CuPtW(μ_3-CC_6H_4Me-4)$(CO)_2$ $(PMe_3)_2(\eta$-$C_5H_5)(\eta$-$C_5Me_5)$], [Cu—μ_3-C—C(tolyl) 121.3(12), Pt—C—C(tolyl) 131.4(13), and W—C—C(tolyl) 128.8(13)°].

The carbonyl ligands all show non-linear geometries to a greater or lesser extent; the degree of non-linearity correlating with the interaction of the carbon atoms with the copper [W(1)—C(1)—O(1) 170.3(10), W(1)—C(10)—O(10) 163.4(9), W(2)—C(2)—O(2) 172.6(8), and W(2)—C(20)—O(20) 174.1(8)°; C(1)...W(2) 2.905(12), C(10)—Cu 2.307(10), C(2)—Cu 2.514(10), and C(20)...Cu 2.752(10) Å]. The weak Cu...C(O) interactions are presumably to allow delocalisation of electron density from the filled copper d_π-orbitals. It is noticeable that while the P–Cu vector points to the middle of the μ_3-CW_2 triangle [W(1)—Cu—P 146.2(1), W(2)—Cu—P 141.0(1), and C(120)—Cu—P 149.0(3)°] the Cu...C(O) interactions lie in a belt around the extension of this vector [P—Cu—C(10) 99.4(3), P—Cu—C(2) 105.3(2), and P—Cu...C(20) 107.1(3)°].

The binding of $AuPR_3$, $AgPR_3$ or $CuPR_3$ fragments in transition-metal clusters has been explained by the isolobal analogy between such fragments and CH_3 or H. Recently Evans and Mingos[10] have pointed out that, for $CuPR_3$ (unlike $AuPR_3$), the empty 4*p* orbitals may play a part in the bonding in addition to the *sp* hybrid orbital. This leads to the isolobal mapping:

each fragment having one valence electron and three valence orbitals (one σ and two π). The $W(CO)_2$ $(\eta$-$C_5H_5)$ fragment is isolobal with CH and hence a $(\eta$-$C_5H_5)(OC)_2W(\mu$-CC_6H_4Me-4)$W(CO)_2(\eta$-$C_5H_5)$ group would be expected to have frontier orbitals related to those of the cyclopropenyl radical (C_3H_3) albeit with lowered symmetry (C_s at most, rather than D_{3h} or C_{3v}). This argument therefore likens **7** to $C_4H_4^{2+}$, the dication of tetrahedrane. Clearly a more quantitative description of the bonding in **7** is required for understanding its stability. It is likely that the lowered symmetry of **7** due to replacement of CH by $W(CO)_2(\eta$-$C_5H_5)$, and the Cu...CO interactions, lift the degeneracy of orbitals (e.g. the HOMO of "cyclopropenyl"). Seemingly the copper 4*p* orbitals are of secondary importance, interacting with one of the "*e*" set of the μ-CW_2 "cyclopropenyl" ring π-orbitals to assist in Cu...CO bonding. Interestingly the strongest Cu—CO interaction [Cu—C(10) 2.307(10) Å] is orthogonal to the Cu—C(120) bond, and lies close to the trimetal plane.

The ^{13}C-{^1H} and ^1H NMR spectra of **7** show one cyclopentadienyl environment and two carbonyl sites present in solution. In view of the X-ray diffraction results this implies that **7** is fluxional in solution undergoing a rearrangement which brings about time-averaged C_s-symmetry on the NMR timescale. This process amounts to racemisation of the chiral structure adopted by **7** in the solid state, with the environments of C(10) and C(20), and C(1) and C(2) rendered equivalent, as shown in Scheme 1. A similar process, involving "wagging" of $Mo(CO)_2(\eta$-$C_5H_5)$ groups is responsible for related fluxionality in $[Mo_2(CO)_4(\mu$-HCCH)$(\eta$-$C_5H_5)_2]$.[11]

The formation of **7** and [W(η^3-$CH_2C_6H_4Me$-4) $(CO)_2(\eta$-$C_5H_5)$] from the reaction between [W(≡CC_6H_4Me-4)$(CO)_2(\eta$-$C_5H_5)$] and [{CuH $(PPh_3)\}_6$] evidently involves a complicated pathway, leading to an unexpected stoichiometry. Isolation of [W(η^3-$CH_2C_6H_4Me$-4)$(CO)_2$ $(\eta$-$C_5H_5)$] indicates that hydrogenation and cleavage of a C≡W tungsten bond has occurred, presumably involving hydrogen transfer from the copper reagent. The latter obviously functions as the source of the $CuPPh_3$ fragment found in **7**.

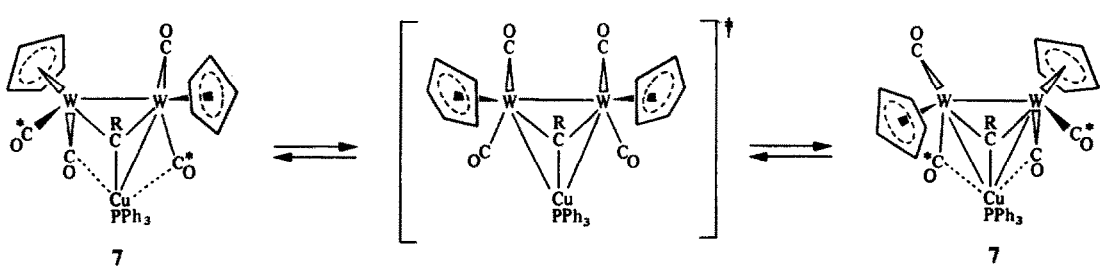
EXPERIMENTAL

The complexes [W(≡CC_6H_4Me-4)$(CO)_2(\eta$-$C_5H_5)$],[12] [{CuH$(PPh_3)\}_6$][13] and [Cu$(NCMe)_4$] $[PF_6]$[14] were prepared by published methods. The reagent [Cu(0.5 $C_6H_6)SO_3CF_3$] was obtained from Fluka. Solvents were rigorously dried before use, and all reactions were carried out in Schlenk tubes under oxygen-free nitrogen. Light petroleum refers to the fraction with b.p. 40–60°C. Alumina used in chromatography was BDH aluminium oxide (Brockman activity II).

The IR spectra were recorded with a Nicolet 10-MX FT spectrophotometer and the NMR measurements were made with a JNM-FX 90Q instrument. ^{31}P chemical shifts (ppm) are positive to high frequency of 85% H_3PO_4 (external).

Reactions involving the complex $[Cu(NCMe)_4][PF_6]$

The compounds $[Cu(NCMe)_4][PF_6]$ (0.18 g, 0.33 mmol) and $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ (0.28 g, 0.65 mmol) were stirred in CH_2Cl_2 (20 cm^3) for 30 min. The solvent was reduced *in vacuo* to *ca* 5 cm^3, and light petroleum (15 cm^3) was layered upon the CH_2Cl_2 solution. After diffusion (24 h) between the two layers, orange crystals formed. The solvent was removed with a syringe, and the crystals of $[Cu\{W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)\}_2][PF_6]$ (**3**) (0.55 g, 82%) were dried *in vacuo*; ν_{max}(CO) at 2021s and 1942m cm^{-1} (in CH_2Cl_2). When the IR spectrum was measured in thf only bands in the CO region (1983 and 1910 cm^{-1}) due to free $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ were observed.



A suspension of $[Cu(NCMe)_4][PF_6]$ (0.28 g, 0.70 mmol) in CH_2Cl_2 (10 cm^3) was treated with PPh_3 (0.19 g, 0.70 mmol) in CH_2Cl_2 (5 cm^3). The mixture was then added to $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ (0.30 g, 0.70 mmol) in the same solvent (10 cm^3), and the reactants stirred for 10 min. The solvent was removed *in vacuo* and the resulting oil treated with diethyl ether (*ca* 100 cm^3). After a few hours crystals appeared. The supernatant liquid was removed with a syringe, and the orange product washed with diethyl ether (2×10 cm^3) and dried *in vacuo*, affording orange *microcrystals* of $[CuW(\mu\text{-}CC_6H_4Me\text{-}4)(CO)_2(NCMe)(PPh_3)(\eta\text{-}C_5H_5)][PF_6]$ (**5**) (0.56 g, 83%) (Found: C, 45.3; H, 2.9%. $C_{35}H_{30}CuNO_2PW$ requires C, 45.7; H, 3.3%), m.p. 100–102°C, ν_{max}(CO) at 2014s and 1946m cm^{-1} (in CH_2Cl_2). NMR (in $CDCl_3$): ^1H, δ 2.11 (s, 3H, MeCN), 2.28 (s, 3H, Me-4), 5.71 (s, 5H, C_5H_5) and 7.17–7.49 (m, 19H, C_6H_4 and Ph); ^{13}C–$\{^1H\}$, δ 294.9 (μ-CC_6H_4Me-4), 213.6 (CO), 149.8–129.1 (C_6H_4 and Ph), 119.8 (Me*C*N), 92.7 (C_5H_5), 22.1 (Me-4) and 2.2 ppm (*Me*CN); ^{31}P–$\{^1H\}$, δ 0.2 (PPh_3) and −144.2 ppm [heptet, PF_6, J(PF) 713 Hz].

Reaction between $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ *and* $[Cu(SO_3CF_3)(0.5\ C_6H_6)]$

The reagent $[Cu(SO_3CF_3)(0.5\ C_6H_6)]$ (0.19 g, 0.70 mmol) in CH_2Cl_2 (10 cm^3) was added to a solution of PPh_3 (0.19 g, 0.70 mmol) in the same solvent (5 cm^3). The resulting mixture was then added to a CH_2Cl_2 (10 cm^3) solution of $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ (0.30 g, 0.70 mmol) with stirring for 10 min. The solvent was removed *in vacuo*, and the oily residue was treated with diethyl ether–light petroleum (1 : 1, 100 cm^3). After a few hours orange crystals appeared. The supernatant liquid was removed with a syringe and the product washed with 2×10 cm^3 portions of diethyl ether–light petroleum (1 : 1), and dried *in vacuo* to afford orange *microcrystals* of $[CuW(\mu\text{-}CC_6H_4Me\text{-}4)(OSO_2CF_3)(CO)_2(PPh_3)(\eta\text{-}C_5H_5)]$ (**6**) (0.45 g, 73%) (Found: C, 45.8; H, 3.2%. $C_{34}H_{27}CuF_3O_5PSW$ requires C, 46.3; H, 3.1%), m.p. 113–115°C, ν_{max}(CO) at 2016s and 1941m cm^{-1} (in CH_2Cl_2). NMR (in $CDCl_3$): ^1H, δ 2.21 (s, 3H, Me-4), 5.77 (s, 5H, C_5H_5) and 7.00–7.43 (m, 19H, C_6H_4 and Ph); ^{13}C–$\{^1H\}$, δ 292.3 (μ-CC_6H_4Me-4), 215.5 (CO), 149.8–128.9 (C_6H_4 and Ph), 120.2 [q, CF_3, J(FC) 319 Hz], 93.0 (C_5H_5) and 22.0 ppm (Me-4).

Reaction between $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ *and* $[\{CuH(PPh_3)\}_6]$

The compound $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ (0.18 g, 0.45 mmol) in toluene (10 cm^3) was treated with $[\{CuH(PPh_3)\}_6]$ (0.18 g, 0.09 mmol) in the same solvent (10 cm^3). The mixture was stirred for 2 h, the solvent was removed *in vacuo*, and the residue dissolved in diethyl ether–light petroleum (1 : 5, 5 cm^3) and chromatographed on

Scheme 1.

an alumina column (2 × 10 cm). Elution with diethyl ether–light petroleum (1:5) gave a red eluate which afforded the known compound $[W(CO)_2(\eta^3\text{-}CH_2C_6H_4Me\text{-}4)(\eta\text{-}C_5H_5)]$ (0.05 g, 27%), identified spectroscopically.[8] Elution of the column with diethyl ether–light petroleum (1:1) produced a purple solution. Reduction in the volume of the solvent to *ca* 5 cm^3 gave purple crystals of $[CuW_2(\mu_3\text{-}CC_6H_4Me\text{-}4)(CO)_4(PPh_3)(\eta\text{-}C_5H_5)_2]\cdot CH_2Cl_2$ (7) (0.18 g, 55%) (Found: C, 43.7; H, 2.9; Cl, 6.5; P, 2.8%. $C_{40}H_{32}CuO_4PW_2\cdot CH_2Cl_2$ requires C, 43.8; H, 3.1; Cl, 6.3; P, 2.8%), ν_{max}(CO) at 1921m, 1863s, 1908w and 1776m cm^{-1} (in toluene). NMR (in CD_2Cl_2): ^1H, δ 2.12 (s, 3H, Me-4), 5.23 (s, 10H, C_5H_5), 6.80 (m, 4H, C_6H_4) and 7.29 (m, 15H, Ph); $^{13}C\text{-}\{^1H\}$, δ 339.6 [d, μ_3-C, J(PC) 7, J(WC) 94 Hz], 235.9 [CO, J(WC) 181 Hz], 222.1 [CO, J(WC) 171 Hz], 168.4 [$C^1(C_6H_4)$], 135.8–123.2 (C_6H_4 and Ph), 90.7 (C_5H_5) and 22.1 ppm (Me-4); $^{31}P\text{-}\{^1H\}$, δ 23.3 ppm (PPh_3).

Crystal structure determination for $7\cdot CH_2Cl_2$

Crystal data for $7\cdot CH_2Cl_2$. $C_{40}H_{32}CuO_4PW_2\cdot CH_2Cl_2$, M = 1123.8, monoclinic, space group, $P2_1/c$ (No. 14), a = 10.034(4), b = 21.514(8), c = 17.964(6) Å, β = 91.73(3)°, U = 3876(2) Å^3, Z = 4, D_c = 1.93 g cm^{-3}, D_m = 1.94 g cm^{-3}, $F(000)$ = 2152 electrons, Mo-K_α X-radiation (graphite monochromator), $\bar{\lambda}$ = 0.71069 Å, μ(Mo-K_α) = 68.2 cm^{-1}. A small single-crystal (*ca* 0.45 × 0.23 × 0.25 mm) of $7\cdot CH_2Cl_2$ was glued under N_2 in a thin-walled glass capillary for diffraction study on a Nicolet *P3m* diffractometer. Intensity data were collected for a unique quadrant of reciprocal space by $\theta/2\theta$ scans of width 2.4° + $\Delta_{\alpha_1\alpha_2}$ for $4 < 2\theta < 50°$. For $2\theta > 40°$ only those reflections with 2*s* prescan counts > 25 s^{-1} were recorded. Of the 6454 data measured, 5512 remained after averaging of duplicate and symmetry related measurements, of these 4630 with $I \geqslant 1.5\sigma(I)$ were used in structure solution and refinement. An absorption correction was applied by a six-parameter fit, minimising discrepancies between 119 pairs of reflection intensities (0*kl*) and (0*kl̄*); transmission coefficients varied between 0.055 and 0.093. The structure was solved by conventional heavy-atom (Patterson and difference Fourier) methods and refined by blocked cascade full-matrix least squares. All non-hydrogen atoms were refined with anisotropic vibrational parameters, and all hydrogen atoms with fixed U_{iso} = *ca* 1.2 times U_{iso} for the bonded carbon atom. Hydrogen atoms were held in idealised geometries with C—H = 0.96 Å. Final residual indices at convergence were R = 0.044, R' = 0.052 and S = 1.09.* Weights (w) were set equal to $[\sigma_c^2(F_o)+gF_o^2]$, where g = 0.001 was chosen to minimise the variation of S with $|F_o|$.† Final electron density difference syntheses showed no features of magnitude > 1.4 *e* Å^{-3}; the largest being < 1 Å from tungsten atoms. All calculations were made on a Nicolet R3m/E structure determination system using the SHELXTL program package,[15] with complex neutral atom scattering factors taken from Ref. 16.

X-RAY CRYSTAL STRUCTURE OF MANGANESE(II) BIS(ETHYLENEDIPHOSPHINETETRAACETATO)NICKELATE(II) HEXADECAHYDRATE

J. PODLAHOVÁ,* B. KRATOCHVÍL, V. LANGER† and J. PODLAHA

Department of Inorganic Chemistry, Charles University, 128 40 Prague, Czechoslovakia

(*Received* 1 *July* 1985; *accepted* 31 *July* 1985)

Abstract—X-ray structure analysis of the title compound (diffractometer data, $R = 0.061$ for 2805 reflections) confirmed the structure proposed on the basis of spectral evidence for the series of isostructural complexes, $M_3[NiL_2](H_2O)_{16}$, where

$$H_4L = (HO_2CCH_2)_2PCH_2CH_2P(CH_2CO_2H)_2$$

and M = Mn, Fe, Co, Ni, Zn or Cd. The compound studied is monoclinic, $P2_1/c$, $a = 9.990(3)$, $b = 28.51(2)$, $c = 14.828(9)$ Å, $\beta = 94.50(5)°$, $Z = 4$. Nickel(II) is coordinated by two P,P-chelating ligand anions in a rather distorted square planar environment. The carboxyl groups of the ligand are not coordinated to nickel; three of them remain free and five are bonded, together with 10 of the total of 16 water molecules, to the manganese(II) ions. The environments of three manganese ions thus formed are all nearly octahedral but differ in the number and bonding mode of the carboxyls (monodentate and/or bridging bidentate). The carboxyl-to-manganese bonds produce a three-dimensional structure of the compound which is further stabilized by hydrogen bonding.

Ethylenediphosphinetetraacetic acid[1,2] is the formal phosphorus analogue of the familiar EDTA but, in contrast to it, coordinates metal ions in a variety of ways, depending mainly on the degree of soft character of the metal ion. For example, nickel(II) can be bonded either to phosphorus or to the carboxyl groups of the ligand (but apparently not to both types of donors simultaneously) with the formation of square planar, square pyramidal and octahedral complexes.[3] The obvious candidate for confirming this variety of structural types by X-ray structure determination is the $Ni_2L(H_2O)_8$ complex, in which two modes of nickel(II) coordination seem to be present simultaneously. It follows from spectral, magnetic and powder pattern evidence[3] that this complex belongs to the isostructural series, $M_3[NiL_2](H_2O)_{16}$, where M = Mn, Fe, Co, Ni, Zn or Cd. Since we did not succeed in preparing single crystals of $Ni_2L(H_2O)_8$ we decided to carry out the structure determination of the well-crystallized, isostructural manganese derivative.

EXPERIMENTAL

The synthesis of the complex has been described.[3]

Crystal data

$C_{20}H_{56}Mn_3NiO_{32}P_4$, $M = 1156.1$; prismatic, $0.15 \times 0.10 \times 0.30$ mm; monoclinic, $P2_1/c$, $a = 9.990(3)$, $b = 28.51(2)$, $c = 14.828(9)$ Å, $\beta = 94.50(5)°$, $V = 4210(4)$ Å^3, $D_m = 1.787(2)$ (flotation in bromoform–benzene), $D_c = 1.823$ g cm^{-3}, $Z = 4$; Syntex $P2_1$ diffractometer, Mo-K_α radiation, $\lambda = 0.71069$ Å, $\mu = 15.0$ cm^{-1}. The cell dimensions were obtained by least-squares refinement of 11 precisely centered reflections in the range $6 < \theta < 17°$. The techniques used for data collection and reduction and for solution and refinement of the structure using a SHELX76 program were the same as described previously.[4] During the early stages in the structure solution it was impossible to distinguish nickel from manganese on the basis of electron density values. Spectral and magnetic

properties,[3] however, clearly indicated that nickel is the atom that is coordinated by four phosphorus donors. This assignment was finally confirmed during anisotropic refinement which led to unreliable temperature factors if nickel was changed for manganese or vice versa. Although the positions of methylene hydrogens were obvious in the difference map, they were not included in the refinement because of limitations in the computer memory; their calculated coordinates are therefore given. All water hydrogens except four were located in the difference map and their positions were refined isotropically using one, overall value of $U_{iso} = 0.106$ Å^2. The final R values were

$$R = \sum|\Delta F|/\sum|F_o| = 0.061$$

and

$$R_w = (\sum|w\Delta F|^2/\sum w|F_o|)^{1/2} = 0.057,$$

with $w = [\sigma^2(F_o)]^{-1}$. Final atomic coordinates, thermal parameters and a list of bond lengths and angles have been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

A perspective drawing of the formula unit including intermolecular carboxylate bonds is given in Fig. 1 together with the atom numbering. Table 1 summarizes distances and angles within the metal ion environments. The structure consists of

Table 1. Distances (Å) and angles (°) within the coordination polyhedrons of the metal ions (ESDs in parentheses)

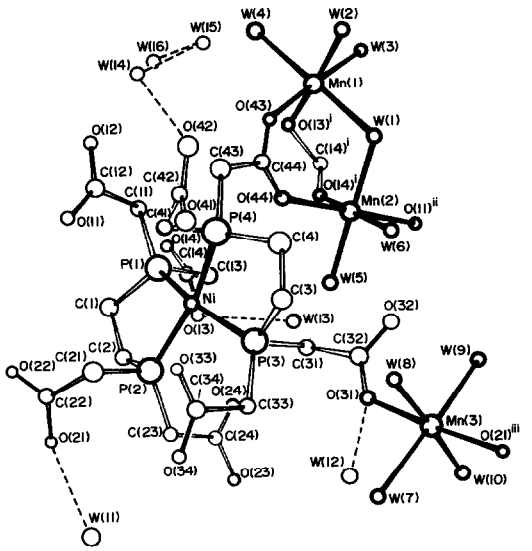

Fig. 1. Perspective view of the formula unit of the complex. W denotes an oxygen atom of a water molecule. Hydrogen atoms (omitted for clarity) are given the numbers of their bonding partners. Symmetry codes i, ii and iii correspond to [a], [b] and [c] in Table 1.

coordination polyhedra of the metal ions linked by intra- and intermolecular acetate groups, resulting in a three-dimensional network. Water molecules are of both the coordinated and lattice types and take part in extensive water-to-water and water-to-carboxylate hydrogen bonding which contributes to the stabilization of the structure.

The environment of nickel(II) is considerably distorted and can be considered as originating from a square by closing the P(1)—Ni—P(2) and P(3)—Ni—P(4) angles and twisting the appropriate PNiP planes to a dihedral angle of 29.6°, which corresponds to alternating the phosphorus atoms 0.383(3) Å below and above the mean NiP_4 plane. As the distortion of the two PNiP moieties is nearly identical and the nickel atom lies very closely within the mean plane, the effective symmetry of the coordination polyhedron approximates to D_2. Analogous but less serious distortions of this type, common in nickel(II) complexes of chelating bis(tertiary phosphines),[5] have usually been ascribed to the sterical bulk of the ligands. As can be seen from idealized geometry calculations, the unusually large distortion of the NiP_4 core found here is probably related to bonding of the acetate groups to manganese, especially through the bridging bidentate carboxyls involving C(14) and C(44). This explanation is supported by the comparison to a closely related nickel(II) complex with a little more sterically bulky phosphineacetate ligand,[4]

$HO_2CCH_2(C_6H_5)PCH_2CH_2P(C_6H_5)CH_2CO_2H$:

the P_4 core in this complex is considerably closer to the ideal square, obviously because the protonized acetate groups do not take part in any significant interaction except hydrogen bonding.

Because of its pronounced hard character, manganese(II) cannot compete with nickel(II) for the phosphorus donors; instead, it acts as the counterion to the NiL_2^{6-} anion. The three manganese ions are coordinated altogether by five carboxyl groups and 10 water molecules, forming three slightly distorted MnO_6 octahedra with an average Mn—O distance of 2.19(5) Å, average O—Mn—O angles of 90(3) and 179(4)° and a mean distance of the atoms from the octahedral equatorial planes of 0.00(3) Å. The Mn(1) and Mn(2) atoms are a part of a cluster of two octahedra sharing one axial water molecule and two *cis*-equatorial bridging bidentate carboxyl groups from two different formula units. A further monodentate carboxyl group belonging to a third formula unit is bonded to Mn(2) in the *trans*-equatorial position. The remaining coordination sites are occupied by water molecules. This arrangement strongly resembles a fragment of the structure of manganese(II) acetate tetrahydrate.[6] The Mn(3) atom belongs to a separate octahedron consisting of two axial monodentate carboxyl groups (one intramolecular and one from a fourth formula unit), completed by four equatorial water molecules. This system of carboxyl-to-manganese bonding constitutes the three-dimensional structure of the complex.

The distances and angles in the ligands are unexceptional and, compared to the free ligand,[2] reflect the coordination to the metal ions. Notably, the angles at the phosphorus atoms vary between 98.8 and 130.7° according to the distortion of the NiP_4 moiety. Both chelate rings adopt a λ-skew conformation with PCCP torsional angles of 44°. The CCOO fragments of the acetate groups are all remarkably planar and are of three different types with respect to the manganese ions: uncoordinated [involving C(24), C(34) and C(42)], monodentate to Mn(2) or Mn(3) [C(12), C(22) and C(32)] and bridging bidentate to the Mn(1), Mn(2) cluster [C(14) and C(44)]. The various environments of the carboxyl groups hardly influence, however, their geometry in any systematic and significant manner; this effect is common for many similar, extensively hydrogen-bonded carboxylate structures (see, for example, Ref. 7 for a recent review). In the present case, the C—O distances range from 1.212 to 1.279 Å [mean 1.25(2)], the O—C—O angles from 123.1 to 127.8° [mean 125(2)] and the C—C—O angles from 112.9 to 122.1° [mean 118(3)]. Undoubtedly, hydrogen bonding is the main averaging factor in the carboxylate geometry.

[i] Not found.

The O—H...O contacts which satisfy the criteria for hydrogen bonding[8] are summarized in Table 2. In general, each carboxylate oxygen except O(11), O(14) and O(44) acts as either a one- or a two-proton acceptor from water molecules. The environments of the water oxygen atoms approximate to trigonal or tetrahedral geometry and involve manganese ions as electron acceptors and carboxylate and/or water oxygen atoms as proton acceptors.

The present structure applies also for the other members of the isostructural series with Fe, Co, Ni, Zn and even Cd in place of Mn. Hence, the behaviour of the ligand towards nickel(II) is totally different from that of its nitrogen analogue, the formally similar complex of which, $Ni_2EDTA(H_2O)_6$, is composed[9] of the aquanickel(II) cations and the $Ni(EDTA)^{2-}$ anions with a hexadentate chelating ligand. Most probably, the remarkable tendency of nickel(II) to form the low-spin NiP_4 core is the factor that is mainly responsible for the difference.

(*Received* 22 *July* 1985; *accepted* 1 *August* 1985)

Abstract—Stability constants of the binary species Cr(III)–ethylenediamine, Cr(III)–succinate and mixed-ligand complex Cr(III)–ethylenediamine–succinate have been determined polarographically by the method of Sundaresan and Sundaram at 30 ± 0.2°C at a constant ionic strength [$\mu = 0.6$ M (NH_4ClO_4)]. The values of the stability constants obtained by this method are compared with those reported in the literature. The positive values of the mixing constants for the mixed-ligand complexes indicate that the mixed-ligand complexes are more stable than simple binary complexes. The reduction of the simple and mixed complexes is irreversible at a dropping mercury electrode: therefore, kinetic parameters like the standard rate constant, transfer coefficient and activation energy have also been calculated.

Mixed complexes of chromium have been studied extensively by various techniques.[1–4] After the development of Schaap and McMaster's method[5] for the determination of composition and stability constants of the mixed-ligand complexes, the polarographic technique has also received considerable attention in this field. Recently mixed-ligand complexes of certain transition metals have been studied polarographically.[6] Although, the polarographic behaviour of chromium in the presence of different electrolytes[7] and complexing agents[8,9] has been studied, a survey of the literature reveals that the mixed-ligand complex Cr(III)–ethylenediamine (en)–succinate has not been studied polarographically so far. In the present paper, the polarographic investigation of the binary and ternary complexes formed by Cr(III) with en and succinate ligands is reported using the method of Sundaresan and Sundaram.[10] Various kinetic parameters, i.e. the reaction rate constant, transfer coefficient (α) and activation energy (Q), have also been calculated in each case.

EXPERIMENTAL

Materials

All the chemicals used were of analytical grade and their solutions were prepared in conductivity water. The ionic strength (μ) was maintained constant [0.6 M (NH_4ClO_4)]. En and sodium succinate were used as

ligands. Triton X-100 (0.002%) was used as the maximum suppressor.

Apparatus and procedure

Polarograms in all instances were recorded at 30 ± 0.2°C with a manual polarograph (Toshniwal CLO2) in conjunction with a polyflex galvanometer (Toshniwal PL 50). A sturated calomel electrode (SCE) was used as the reference electrode. It was connected to the polarographic cell through a potassium chloride agar–agar bridge. The dropping mercury electrode (DME) had the following characteristics: $m^{2/3}t^{1/6} = 2.120$ mg$^{2/3}$ s$^{-1/2}$, and $h_{corr} = 30$ cm in 0.1 M NH_4ClO_4 with open circuit. Oxygen was expelled by passing a slow stream of purified nitrogen into the test solution.

RESULTS AND DISCUSSION

Cr(III) gives two well-defined reversible diffusion-controlled waves in NH_4ClO_4 with $E_{1/2} = -0.9$ V and -1.46 V vs SCE. However, in the presence of en and succinate separately it only gives a single well-defined wave. The slopes of linear plots of $\log i/(i_d - i)$ vs $E_{d.e}$ are of the order of 80 ± 1 mV in both the cases, indicating an irreversible reduction. $E_{3/4} - E_{1/4}$ values also confirm irreversible reduction of the metal complexes. The number of electrons (n) involved in the reduction process was determined by the millicoulometric method of DeVries and Kroon.[11] This gave $n = 3$ in all cases. The value of $n\alpha$ was obtained by equating the slope of the log plot to $-0.0542/n\alpha$. The values of α are given in Tables 1 and 2 for Cr(III)–en and Cr(III)–succinate systems.

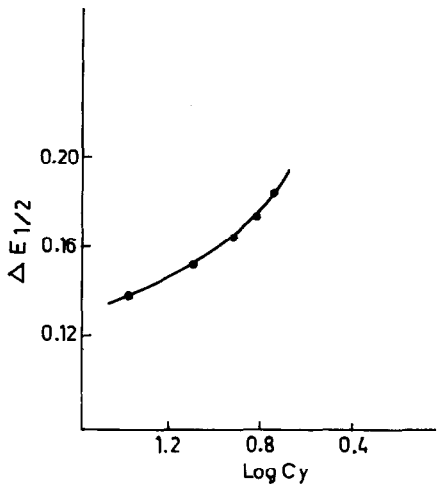

Fig. 2. Cr(III)–succinate system. Plot of log C_y vs $\Delta E_{1/2}$. Conditions as in Fig. 1.

Since these complexes are reduced irreversibly at the DME, the composition, stability constants and reaction rate constants were calculated by the method of Sundresan and Sundaram.[10] The Q of the electrode reaction was calculated by the usual relationship:[12] $Q = 577.8(5.097 - \log K_s)$ (K_s = standard rate constant). The values are summarized in Tables 1 and 2.

Cr(III)–*en and* Cr(III)–*succinate systems*

The formation of the complex is evident in both cases as the $E_{1/2}$ gets shifted to a more negative potential with increasing concentration of the ligand, en or succinate. A plot of $\Delta E_{1/2}$ vs log [X] (where X is en or succinate) was a smooth curve (Figs 1 and 2), indicating the formation of successive complexes. The function $F'(X)$ has been calculated at different concentrations of ligands and is represented in Figs 3 and 4. The analysis shows that Cr(III) reacts with these ligands in ratios of 1 : 1, 1 : 2 and 1 : 3. The values of the stability constants and K_s are given in Tables 1 and 2.

Cr(III)–*en–succinate system*

After studying simple complexes of Cr(III) with en and succinate separately, attempts have been made to study the mixed complexes of Cr(III) with en and succinate present together. The present study of these mixed complexes was carried out at two different concentrations of succinate ions. The concentration of en was varied from 0.01 to 0.07 M

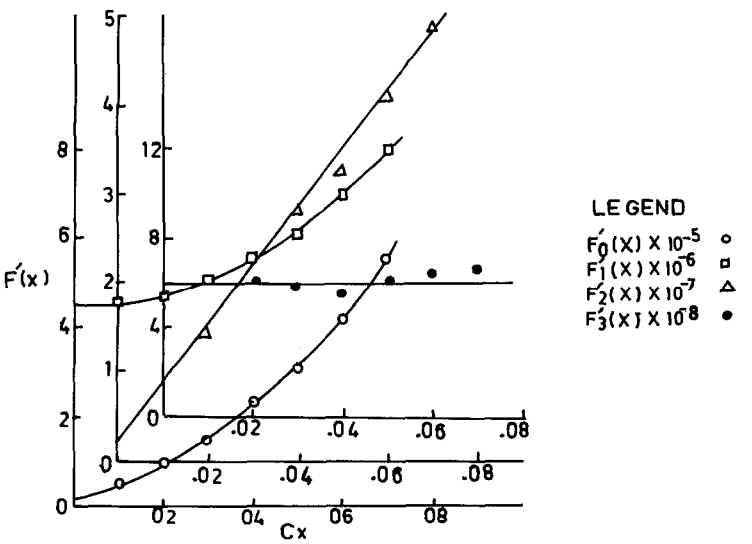

Fig. 3. Cr(III)–en system. Plot of $F'(X)$ vs C_x. Conditions as in Fig. 1.

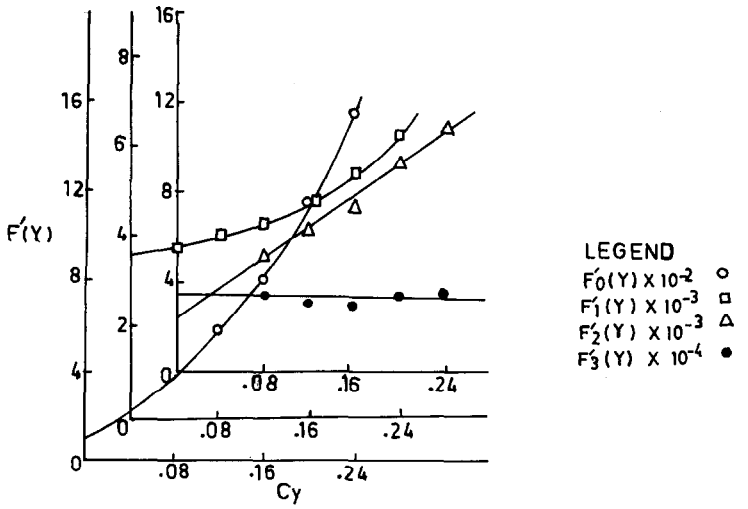

Fig. 4. Cr(III)–succinate system. Plot of $F'(X)$ vs C_y. Conditions as in Fig. 1.

(Table 3) while that of succinate was kept constant at 0.08 M in one set, series 1, and 0.16 M in the second set, series 2. The ionic strength and metal ions concentration were the same as for the binary systems. The $E_{1/2}$ values were more negative than those obtained in the absence of succinate, indicating the formation of mixed complexes. The slopes of a conventional log plot and also from $E_{3/4}-E_{1/4}$ indicate irreversible reduction: therefore, the method of Schaap and McMaster[5] cannot be applied for the determination of stability constants of this system. Hence, the method of Sundaresan and Sundaram[10] has been applied to estimate the stability constants of the mixed-ligand complexes and kinetic parameters. It is inferred that Cr(III) forms two mixed complexes $[Cr(en)(succinate)_2]^-$ (1:1:2) and $[Cr(en)_2(succinate)]^+$ (1:2:1) with the ligands.

0.05	0.346	5.81	10.20	13.40	2.28
0.06	0.354	7.90	12.00	14.16	2.02
0.07	0.362	10.73	14.33	15.48	1.92

[a] Cr(III) = 0.5 M, μ = 0.6 M (NH_4ClO_4), temperature = 30 ± 0.2°C, t = 13.6 s, $D = 2.6 \times 10^{-6}$ cm^2 s^{-1}, α = 0.308.
Series 1: $K/C = 5 \times 10^4$, $L/C = 3 \times 10^8$, $M/C = 1.6 \times 10^7$, $N/C = 1.52 \times 10^9$.
Series 2: $K/C = 7 \times 10^4$, $L/C = 3.5 \times 10^6$, $M/C = 2 \times 10^7$, $N/C = 1.98 \times 10^9$.

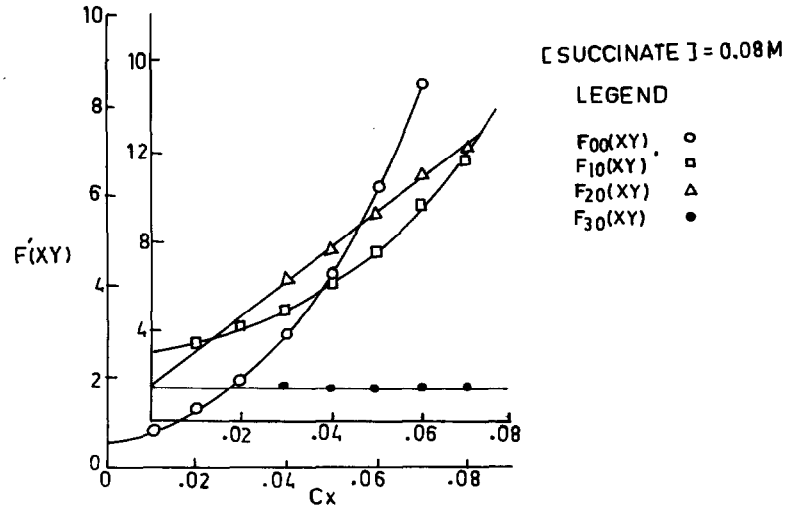

Fig. 5. Cr(III)–en–succinate system. [Succinate] = 0.08 M. Rest of the conditions as in Fig. 1.

From the plots of $F'(X,Y)$ vs C_x (concentration of en) (Figs 5 and 6, and Table 3) the following intercept values are obtained.

Series 1—[succinate] = 0.08 M:

$$K/C = 5 \times 10^4, \quad L/C = 3 \times 10^6,$$

$$M/C = 1.6 \times 10^6, \quad N/C = 1.52 \times 10^9.$$

Series 2—[succinate] = 0.16 M:

$$K/C = 7 \times 10^4, \quad L/C = 3.5 \times 10^6,$$

$$M/C = 2 \times 10^7, \quad N/C = 1.98 \times 10^9.$$

The constants K/C, L/C, M/C and N/C were evaluated graphically from the functions calculated at different concentrations of the ligand. The parameter C was obtained from the stability constants of the Cr(III)–succinate system. Hence, the parameters C, L, M and N were calculated and solved algebraically for stability constants of mixed complexes. The stability constants evaluated for the mixed-ligand complexes from intercept data are: log β_{11} = negative, log $\beta_{12} = 4.277$, and log $\beta_{21} = 5.225$. The negative value of β_{11} indicates the absence of $[Cr(en)(succinate)]^+$ in the aqueous solution. Stability constants of mixed complexes have also been calculated from the statistical consideration according to the relationship given by Tedesco and Martinez.[13] Log $\beta_{12} = 4.09$ and log $\beta_{21} = 4.96$ indicate that they are quite close to the present study.

The K_s for the reduction of mixed-ligand complexes is as calculated from the parameters C, t =

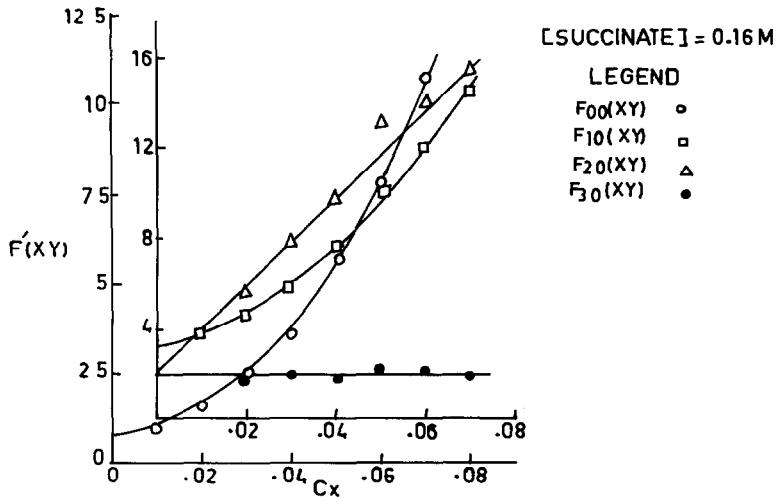

Fig. 6. Cr(III)–en–succinate system. [Succinate] = 0.16 M. Rest of the conditions as in Fig. 1.

Equilibrium	log K
1. $Cr^{3+} + en + 2(succinate)^{2-} \rightleftharpoons [Cr(en)_2(succinate)_2]^-$	4.277
2. $Cr^{3+} + 2en + succinate^{2-} \rightleftharpoons [Cr(en)_2(succinate)]^+$	5.225
3. $[Cr(succinate)_2]^- + en \rightleftharpoons [Cr(en)(succinate)_2]^-$	2.675
4. $[Cr(en)]^{3+} + 2(succinate)^{2-} \rightleftharpoons [Cr(en)(succinate)_2]^-$	1.374
5. $[Cr(en)_2]^{3+} + succinate^{2-} \rightleftharpoons [Cr(en)_2(succinate)]^+$	2.322
6. $[Cr(succinate)_3]^{3-} + en \rightleftharpoons [Cr(en)(succinate)_2]^- + succinate^{2-}$	1.536
7. $[Cr(succinate)_3]^{3-} + 2en \rightleftharpoons [Cr(en)_2(succinate)]^+ + 2(succinate)^{2-}$	3.625
8. $[Cr(en)_2]^{3+} + 2(succinate)^{2-} \rightleftharpoons [Cr(en)_2(succinate)]^+ + succinate^{2-}$	2.322
9. $[Cr(en)(succinate)_2]^- + en \rightleftharpoons [Cr(en)_2(succinate)]^+ + succinate^{2-}$	0.948

3.6 s, $D = 2.6 \times 10^{-6}$ cm^2 s^{-1} and $\alpha = 0.308$ (from log plot), and was found to be 5.97×10^{-5} cm s^{-1}. Q for the complex was found to be 53 kcal mol^{-1}.

The mixing constants[14] (K_m) for the reactions are given below:

$$[Cr(en)]^{3+} + [Cr(succinate)_2]^- \rightleftharpoons [Cr(en)(succinate)_2]^- + Cr^{3+}, \quad (1)$$

$$\tfrac{1}{2}[Cr(en)_2]^{3+} + [Cr(succinate)_2]^- \rightleftharpoons [Cr(en)(succinate)_2]^- + \tfrac{1}{2}Cr^{3+}, \quad (2)$$

$$[Cr(en)_2]^{3+} + [Cr(succinate)]^+ \rightleftharpoons [Cr(en)_2(succinate)]^+ + Cr^{3+}, \quad (3)$$

$$K_m(1) = \beta_{12}/(\beta_{10})(\beta_{02}),$$

$$K_m(2) = \beta_{12}/(\beta_{20})^{1/2}(\beta_{02}),$$

$$K_m(3) = \beta_{21}/(\beta_{20})(\beta_{01}),$$

which indicate the relative stability of mixed complexes in solution as compared to parent binary complexes. A positive value of K_m shows that the mixed complexes are more stable than simple complexes.

The results of the present study are summarized above. The numerical values show the logs of the equilibrium constants of the reactions indicated.

From these equilibrium constant values, it is evident that en can replace succinate from the mixed complex $[Cr(en)(succinate)_2]^-$ and thus the complexing tendency of en is higher than that of succinate.

PREPARATION AND SPECTROCHEMICAL PROPERTIES OF SOLUBLE VANADOPHOSPHATE POLYANIONS WITH BICAPPED-KEGGIN STRUCTURE

KENJI NOMIYA, KATSUHIKO KATO and MAKOTO MIWA*

Department of Industrial Chemistry, Faculty of Engineering, Seikei University, Musashino, Tokyo 180, Japan

(*Received* 8 *July* 1985; *accepted* 2 *September* 1985)

Abstract—Some soluble forms in aqueous and nonaqueous media of vanadophosphate with a bicapped-Keggin structure have been prepared. Some isopoly decavanadates derived during such preparations have also been reported. Their spectrochemical data (IR, UV–vis and MCD) are presented.

Vanadium is an element which can form hetero- and isopolyanions. Such vanadopolyanions are structurally distinct from the polyanions formed by elements such as molybdenum and tungsten, although the coexistence of vanadium with molybdenum, or tungsten, sometimes leads to mixed polyanions structurally related to the molybdo- or the tungstopolyanion.[1] In 1980, Sasaki *et al.*[2,3] determined the structure of the vanadophosphate polyanion by X-ray analysis, showing it to be a Keggin framework capped by two VO_5 trigonal bipyramids. The two caps occupy the *trans*-position of six pits on the surface of the Keggin framework. Confirmation of this conclusion has been obtained in the form of an insoluble guanidinium salt,

$$(CN_3H_6)_8H[PV_{14}O_{42}]\cdot 7H_2O,$$

isolated from aqueous solutions of phosphate and vanadate (P : V = 1 : 4) at pH 2.7. This salt, which is easily obtained by sodium salt metathesis, is the most suitable one for the X-ray study. However, other salts, which are soluble in aqueous and nonaqueous media, and suitable for spectrochemical studies, have been poorly characterized. In this paper, we report the preparation of a soluble vanadophosphate with counterions and show their spectrochemical data (IR, UV–vis and MCD). Furthermore, we also report briefly on the isopoly decavanadate, $[V_{10}O_{28}]^{6-}$, derived during such preparations.

EXPERIMENTAL

Preparations

$(CN_3H_6)_8H[PV_{14}O_{42}]\cdot H_2O$ (1).[3] $NaNO_3$ [4.5 g (37 mmol)] was dissolved in 25 cm^3 hot water, to which 6.2 cm^3 of 1.5 mol dm^{-3} phosphoric acid was added. The pH of the deep red solution is adjusted to 2–3 by 3 mol dm^{-3} nitric acid. Then, an aqueous solution containing 5.0 g (52.3 mmol) guanidine hydrochloride was added with stirring. Brown precipitates were immediately formed, which were insoluble in almost all solvents and could not be recrystallized. They were washed several times with ethanol and then thoroughly with water. Found: C, 5.0; H, 3.1; N, 17.8. Calc. for $(CN_3H_6)_8H[PV_{14}O_{42}]\cdot H_2O$: C, 5.0; H, 2.7; N, 17.5%.

From the coloured aqueous washings, orange needle crystals of isopoly decavanadate are obtained. Found: C, 5.0; H, 3.3; N, 17.6. Calc. for $(CN_3H_6)_6[V_{10}O_{28}]\cdot 6H_2O$: C, 5.0; H, 3.4; N, 17.7%

In the preparation of vanadophosphate, other precipitating agents could not be used in place of guanidine hydrochloride. For instance, when an aqueous solution containing tetrabutylammonium bromide was added, the tetrabutylammonium salt of decavanadate was mainly obtained. It could be recrystallized from acetonitrile. Found: C, 33.9; H, 6.7; N, 2.5. Calc. for $[(C_4H_9)_4N]_3H_3[V_{10}O_{28}]$: C, 34.2; H, 6.6; N, 2.5%.

* Author to whom correspondence should be addressed.

(K, H)$_9$[$PV_{14}O_{42}$]·nH_2O (**2**). The deep red aqueous solution obtained in the preparation of **1**, the pH of which had been adjusted to 2–3 by nitric acid, was kept at 50°C in a steam bath, to which an aqueous solution at 50°C containing 10 g KCl was slowly added. After stirring, the solution was left standing overnight at room temperature. Fine black crystals were obtained with a yield of 4.8 g. They were very soluble in water, slightly soluble in methanol and ethanol, and almost insoluble in ether, acetone and acetonitrile. In this preparation, the reaction temperature of 50°C was important: if it was lower, compound **2** was contaminated by an orange compound, potassium decavanadate, and, at room temperature, the latter became the main product.

[$(C_4H_9)_4N$]$_4H_5$[$PV_{14}O_{42}$]·$4H_2O$ (**3**). Compound **2** (3.5 g) was dissolved in water (below 50°C) and then an aqueous solution containing excess tetrabutylammonium bromide was added. After stirring at 50–60°C for a few minutes, dark brown precipitates were collected on a filter which could be recrystallized from acetonitrile. They were very soluble in acetonitrile, slightly soluble in acetone, and insoluble in water, methanol, ethanol and ether. Found: C, 31.3; H, 6.2; N, 2.3. Calc. for [$(C_4H_9)_4N$]$_4H_5$[$PV_{14}O_{42}$]·$4H_2O$: C, 31.2; H, 6.4; N, 2.3%. From the red aqueous filtrate in this preparation, the same precipitates could not be obtained again even by further addition of the aqueous solution of tetrabutylammonium bromide. The filtrate contained salts with different compositions of counterions because the evaporated solids showed the characteristic IR of vanadophosphate.

The tetrabutylammonium salt (**3**) was also obtained by another method. The red aqueous solution containing compound **2** (5 g) was passed through an H^+-ion exchange resin column (Dowex-50W) and eluted with water. The vanadophosphate was converted to the free-acid form without decomposition. The eluted aqueous solution was evaporated to a small volume and then an aqueous solution containing excess tetrabutylammonium bromide was added. After stirring at 50–60°C for a few minutes, dark brown precipitates were filtered and recrystallized from acetonitrile. Found: C, 31.2; H, 6.3; N, 2.3. Calc. for [$(C_4H_9)_4N$]$_4H_5$[$PV_{14}O_{42}$]·$4H_2O$: C, 31.2; H, 6.4; N, 2.3%.

In order to compare IR spectra, sodium decavanadate $Na_6[V_{10}O_{28}]\cdot nH_2O$ was prepared from $NaVO_3$ and glacial acetic acid by a modification described in the literature.[4]

UV–vis absorption spectra were measured on an Hitachi 340-spectrophotometer with a computer keyboard attached. The MCD spectra were recorded by a JASCO J-40AS spectropolarimeter with a 1-T electromagnet mounted on it. IR spectra were recorded by a JASCO IR-G spectrophotometer. Measurements were made at room temperature.

RESULTS AND DISCUSSION

Some salts of vanadophosphate obtained here, except the guanidinium salt, are soluble in appropriate solvents. The potassium salt (**2**) especially is very soluble in water and can be used for preparing other salts.

The acidity of the free acid of vanadophosphate obtained as a powder from the eluted solution of a cation-exchange resin column was not as strong as that of the Keggin molybdo- and tungsto-heteropolyacids. In fact, acid catalysis of the polymerization of benzyl alcohol to polybenzyl could not be observed.[5]

Generally, the maximum number of bulky tetrabutylammoniums in the counterions is significantly related to the size, rather than to the charge, of the polyanion. For instance, the maximum number is four for the Keggin heteropolyanion and six for the Dawson one. Thus, it should be noted that it is four in the bicapped-Keggin vanadophosphate.

IR spectra of vanadophosphate (D_{2d}-symmetry) with some counterions are shown in Fig. 1. The vibrational structure of the polyanion moiety is

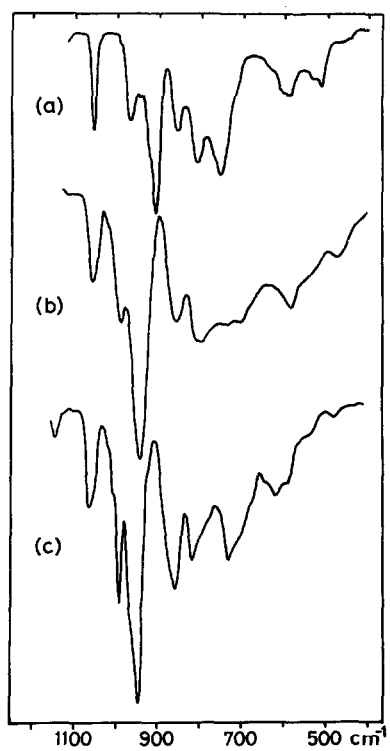

Fig. 1. IR spectra measured in KBr disk of vanadophosphates with counterions: (a) $(CN_3H_6)_8H[PV_{14}O_{42}]\cdot H_2O$, (b) (K, H)$_9$[$PV_{14}O_{42}$]·$nH_2O$, and (c) [$(C_4H_9)_4N$]$_4H_5$[$PV_{14}O_{42}$]·$4H_2O$.

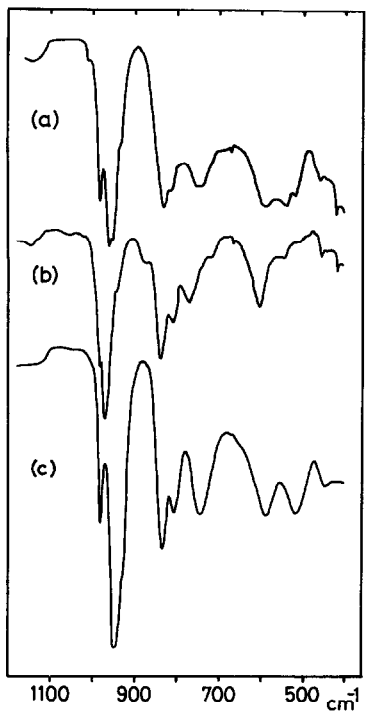

Fig. 2. IR spectra measured in KBr disk of decavanadates with counterions: (a) $(CN_3H_6)_6[V_{10}O_{28}]\cdot 6H_2O$, (b) $[(C_4H_9)_4N]_3H_3[V_{10}O_{28}]$, and (c) $Na_6[V_{10}O_{28}]\cdot nH_2O$.

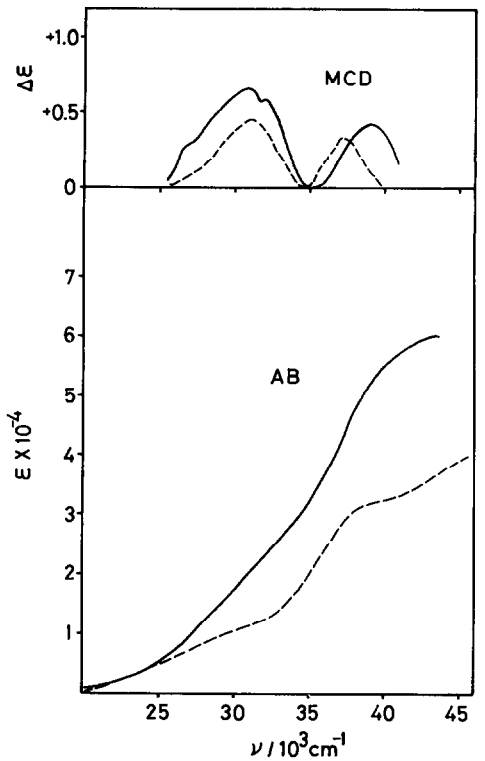

Fig. 3. Electronic absorption and MCD spectra in acetonitrile solution of $[(C_4H_9)_4N]_4H_5[PV_{14}O_{42}]\cdot 4H_2O$ (full line) and $[(C_4H_9)_4N]_3H_3[V_{10}O_{28}]$ (dashed line).

subtly changed by counterions, especially in the low-frequency region. The characteristic band at 1050–1060 cm^{-1} is due to P—O stretching and many bands in the region of 1000–500 cm^{-1} are due to the various V—O vibrations. These patterns are more complicated than those of a Keggin heteropolyanion with T_d-symmetry. The IR spectra of decavanadate are also changed by counterions, depending upon whether the proton is contained or not (Fig. 2). IR patterns of $(CN_3H_6)_6[V_{10}O_{28}]$ and $Na_6[V_{10}O_{28}]$ are very close to each other; however, they are different from that of $[(C_4H_9)_4N]_3H_3[V_{10}O_{28}]$ in the region of 850–600 cm^{-1}. These are presumably caused by either or both of two possibilities, the existence of an anion–anion interaction in the case of a small-size counterion[6] and the protonation of the surface oxygens of the polyanion.[7]

Electronic absorption and MCD spectra in acetonitrile solution are shown in Fig. 3 as full lines for $[(C_4H_9)_4N]_4H_5[PV_{14}O_{42}]\cdot 4H_2O$ and as dashed lines for $[(C_4H_9)_4N]_3H_3[V_{10}O_{28}]$. All of these absorptions and MCD are due to the V ← O charge-transfer (CT) transitions. In the absorption spectra, there is a very broad shoulder (ε *ca* 20,000) around 30,000 cm^{-1} and a strong broad band (ε *ca* 60,000) around 43,000 cm^{-1} for the vanadophosphate, and a shoulder (ε *ca* 10,000) around 30,000 cm^{-1} and a broad band (ε *ca* 32,000) around 40,000 cm^{-1} for the decavanadate. The intensities of the absorptions of vanadophosphate are larger than those of decavanadate. The absorption position of the lowest-energy CT is almost unchanged in the two vanadopolyanions; however, that of the second CT of vanadophosphate is shifted more to the high-frequency region than that of decavanadate. These tendencies are also observed in the MCD spectra, which consist of two positive components. No negative MCD component appears in this region. The MCD in the first CT region of vanadophosphate contains further components.

STEREOSELECTIVE ASSOCIATION BETWEEN OPTICALLY ACTIVE TRIS(1,10-PHENANTHROLINE)RUTHENIUM(II) AND TRIS(ACETYLACETONATO)COBALT(III) IN WATER

ETSURO IWAMOTO,* HITOKO SAITO and YUROKU YAMAMOTO

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730, Japan

(*Received* 29 *April* 1985; *accepted after revision* 2 *September* 1985)

Abstract—Stereoselective interactions between tris(acetylacetonato)cobalt(III) [$Co(acac)_3$] and optically active Λ-$(+)_{546}$-tris(1,10-phenanthroline)ruthenium(II) chloride [Λ-$[Ru(phen)_3]Cl_2$] were investigated by measuring the distribution coefficients of racemic $Co(acac)_3$ between carbon tetrachloride and water containing Λ-$[Ru(phen)_3]^{2+}$ or pure water, and the optical rotations of the aqueous phase was measured over the temperature range 10–40° C. The Λ-isomer of $Co(acac)_3$ is "salted-in" more strongly by Λ-$[Ru(phen)_3]^{2+}$ than the Δ-isomer. The association constants between Λ-$[Ru(phen)]^{2+}$ and Λ- or Δ-$Co(acac)_3$ were calculated by using the optical rotation to give $K(\Lambda\text{–}\Lambda) = 3.86$ and $K(\Lambda\text{–}\Delta) = 3.80$ at 25°C, respectively. The temperature dependence of the association constants showed that the enthalpy and entropy changes for the Λ–Λ association is slightly more positive than those for the Λ–Δ association. This was discussed from the viewpoint of hydrophobic interactions.

The optical resolution of neutral tris(β-diketonato)metal chelates has been effectively carried out by liquid column chromatography.[1–6] Recently a facile large-scale optical resolution of the neutral chelates through selective complex formation with (2*R*,3*R*)-(−)dibenzoyltartaric acid was also reported.[7] However, the enantioselective interactions in solution have not been investigated quantiatively, probably because the weak interactions make it difficult to study batchwise equilibria, although, from a theoretical point of view, chiral discrimination energies for a complex analogous to the acetylacetone complex have been discussed.[8]

Recently, we showed that the tris(1,10-phenanthroline)–iron(II) chelate cation $[Fe(phen)_3]^{2+}$ "salts-in" more tris(acetylacetonato)cobalt(III) [$Co(acac)_3$] with large positive transfer enthalpy and entropy changes than do aliphatic ions such as tetraalkylammonium ions.[9] Such large aromatic ions strongly interact with non-electrolytes in aqueous solution due to the sigificantly coupled action of the structural effects of water and a van der Waals' interaction. We also found that this interaction leads to a stereoselective interaction between the optically active Δ-$[Ni(phen)_3]^{2+}$ ion and the Δ- or Λ-isomer of $Co(acac)_3$,[10] applied to the "salting-in" chromatography to optically resolve the octahedral neutral metal chelates.[5]

In the present paper, as an extention of the above findings, we investigated the stereoselective association thermodynamically. The optical active ruthenium(II) metal chelate electrolyte Λ-$[Ru(phen)_3]Cl_2$, which does not racemize, was used in place of optically active Δ-$[Ni(phen)_3]Cl_2$, which racemizes with a rate constant of 3.35×10^{-4} min^{-1} at 25°C. The partition method with solvent extraction was used for this salting-effect study. CCl_4 was selected as a solvent because $Co(acac)_3$ is distributed in water in such a way that the concentration in water can be determined spectrophotometrically.

EXPERIMENTAL

The tris(1,10-phenanthroline)ruthenium(II) salt was prepared by refluxing an aqueous solution of ruthenium(III) chloride (0.2 mol) with sodium tartrate (0.06 mol) until a greenish brown solution resulted, and then adding 1,10-phenanthroline (0.6 mol). The heating was continued until the colour changed to a deep orange red, when the mixture was filtered. The optically active complex Λ-$(+)_{546}$-$[Ru(phen)_3](ClO_4)_2 \cdot 2H_2O$ was resolved, in a

* Author to whom correspondence should be addressed.

similar manner to the iron complex, by the method of Dwyer and Gyarfas,[11] using the above solution and antimony (+)-tartrate. The perchlorate was transformed to the more soluble chloride with a Dowex 21K anion exchange resin in the Cl^- form with as little distilled water as possible. This solution gave a molecular rotation ($[M]_{546}$) of $-20{,}300$. The concentration of $[Ru(phen)_3]^{2+}$ determined spectrophotometrically.[12] $Co(acac)_3$ was prepared by a well-established procedure.[13] CCl_4 of reagent grade was used as received. The density of solutions was measured using a digital densimeter (Anton Paar Model DMA 02D).

Partition experiments

An aqueous solution (50 cm^3) of $[Ru(phen)_3Cl_2$ was agitated with CCl_4 solution (20 cm^3) containing *ca* 0.3 g of $Co(acac)_3$ for 1 h in a thermostatted water bath (± 0.05°C). After standing for 30 min, the aqueous solution (40 cm^3) was pipetted out and shaken with CCl_4 (10 cm^3) to extract $Co(acac)_3$. After separation, the CCl_4 extract was washed with water (1 cm^3) to prevent optical contamination by $[Ru(phen)_3]Cl_2$. The CCl_4 extraction was repeated 3 times, leading to a percentage extraction of $Co(acac)_3$ of more than 99%. The absorbance at 590 nm, molecular rotation at 546 nm, and circular dichroism of each CCl_4 solution were measured at ambient temperature using an Hitachi Model 139 spectrophotometer, a Perkin–Elmer Model 141 polarimeter, and a Jasco model J-40CS polarimeter, respectively.

RESULTS AND DISCUSSION

The distribution coefficient (K_d) is defined as the ratio of the concentration (mol kg^{-1}) of $Co(acac)_3$ in the aqueous phase to that in the organic phase. The K_d value for pure water is independent of the concentration (Table 1). Thus, the variation in activity coefficients of $Co(acac)_3$ in both phases is negligible. The CCl_4 solution containing an amount (*ca* 0.3 g) of $Co(acac)_3$ was used throughout the following experiments. The temperature dependence of K_d for Λ-$[Ru(phen)_3]Cl_2$ concentrations (mol kg^{-1}) of 0, 0.0976 and 0.144 is shown in Fig. 1. Increasing the temperature results in a decrease in K_d and increasing the concentration of the ruthenium chelate cation increases K_d. Furthermore, the temperature dependence of K_d in the presence of the ruthenium chelate cation is slightly less than that in pure water. These results are compatible with the view that the non-electrolyte $Co(acac)_3$ is a hydrophobic solute which is exothermically distributed in water and is endothermically salted in by the large aromatic cation $[Ru(phen)_3]^{2+}$, as observed for the salting effect of $[Fe(phen)_3]^{2+}$.[9]

[a] Aqueous : organic volume ratio is 20 : 50.
[b] Initial amounts in 20 cm^3 of CCl_4.
[c] Obtained using the solubility ratio from Ref. 18.

The optical rotations and concentrations of $Co(acac)_3$ partitioned in the aqueous phase containing the optically active Λ-ruthenium chelate cation were measured in the CCl_4 extracts without the ruthenium cation. The $Co(acac)_3$ is back-extracted into CCl_4 by four successive extractions but no appreciable absorbance was observed in the fourth extract within experimental error. Molecular rotations of each of the three extracts are shown in Fig. 2, and, as expected, it is clearly demonstrated that the later extract gives the higher molecular rotation. Figure 3 shows a typical CD spectrum of $Co(acac)_3$ distributed in the Λ-ruthenium chelate aqueous solution which is assigned to the Λ-isomer of $Co(acac)_3$.[4] Thus, the aqueous phase with the ruthenium chelate cation contained the Λ-isomer of

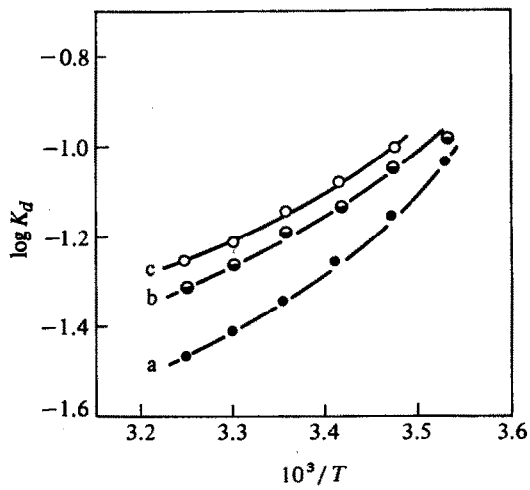

Fig. 1. Temperature (T) dependence of the distribution coefficient (K_d) of $Co(acac)_3$ between aqueous and CCl_4 phases. Concentration of $[Ru(phen)_3]^{2+}$ in water (mol kg^{-1}): (a) 0, (b) 0.0976, and (c) 0.144.

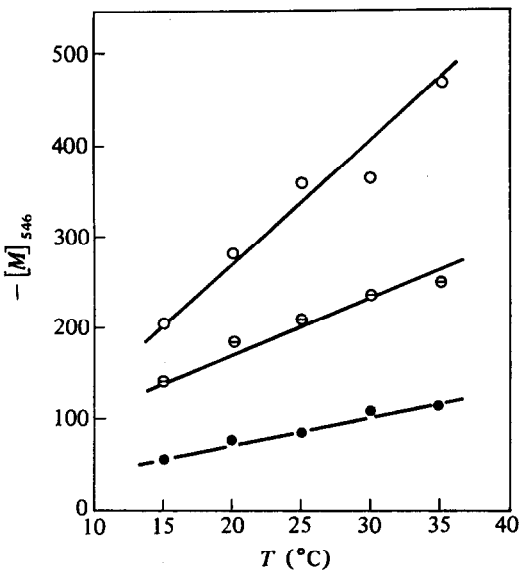

Fig. 2. Temperature (T) dependence of the molecular rotation ($[M]_{546}$) of $Co(acac)_3$ in CCl_4 extracts from the Λ-$[Ru(phen)_3]Cl_2$ solution (0.144 mol kg^{-1}). Extracts: (a) first, (b) second, and (c) third.

$Co(acac)_3$ as the excessive enantiomer, showing that the Λ–Λ pair interaction is stronger than the Λ–Δ pair interaction.

This observation is very similar to one made by Dwyer and Gyarfas.[14] Their performance was based on the view that the peripheral atoms in the tris-acetylacetone cobalt(III) complex probably carry a slight negative charge, and hence negative or anionic asymmetrical fields are associated with the antipodal form: therefore tris(ethylenediamine)cobalt(III) was selected as a multiply-charged optically active cation with which the maximum differential interaction in solution would be expected. However, our observation[9] concerning salting effects on the solubility of $Co(acac)_3$ showed that tris(ethylenediamine)cobalt(III) bromide "salts-out" it with a Setschnow coefficient (k_s) of 0.45 at 25°C but tris(1,10-phenanthroline)iron(II) bromide "salts-in" with a k_s of −2.7. These results caused us to expect that the phenanthroline complex could interact stereoselectively with $Co(acac)_3$ while the ethylenediamine complex could not. In practice we failed to observe the optical resolution of $Co(acac)_3$ by tris(ethylenediamine)cobalt(III) with the same procedure as for tris(1,10-phenanthroline)ruthenium(II). As stated later, the hydrophobic property of the optically active cation seems the most important. If the complex cation is triply-charged, even the phenanthroline complex "salts-out" $Co(acac)_3$: the k_s for tris(1,10-phenanthroline)cobalt(III) bromide is 0.21.

Table 2 summarizes the concentrations of $Co(acac)_3$ distributed in each phase for concentrations of 0.144 and 0.0976 mol kg^{-1} of the ruthenium chelate electrolyte, and the molecular rotation ($[M]_{546}$), and percentage resolution (R) in the aqueous phase, which was estimated by using an $[M]_{546}$ value of −28,920 for the complete resolution.[15]

Now we consider the association equilibria between $[Ru(phen)_3]^{2+}$ and $Co(acac)_3$ in aqueous solutions, assuming that $[Ru(phen)_3]Cl_2$ is completely dissociated and the $Co(acac)_3$ salted in by the ruthenium chelate cations is ascribed only to the association between them. The equilibria are:

$$\Lambda_{Ru}+\Lambda \rightleftharpoons \Lambda_{Ru}\Lambda, \qquad \Lambda_{Ru}+\Delta \rightleftharpoons \Lambda_{Ru}\Delta, \tag{1}$$

[c] In organic phase.

with corresponding association constants $K(\Lambda\text{–}\Lambda)$ and $K(\Lambda-\Delta)$, respectively, where Λ_{Ru} is Λ-$[Ru(phen)_3]^{2+}$, and Λ and Δ are the Λ- and Δ-isomers of $Co(acac)_3$. The total concentration of $Co(acac)_3$, C_t, is written as:

$$C_t = [\Lambda_{Ru}\Lambda] + [\Lambda_{Ru}\Delta] + C_o, \qquad (2)$$

where C_o is the concentration of $Co(acac)_3$ when the ruthenium cation is absent, and is estimated using K_d and the concentration of $Co(acac)_3$ in CCl_4, C_{CCl_4}:

$$C_o = K_d C_{CCl_4}. \qquad (3)$$

For free $Co(acac)_3$:

$$[\Lambda] = [\Delta] = C_o/2. \qquad (4)$$

The excess Λ-isomer concentration, C, is given as:

$$C = [\Lambda_{Ru}\Lambda] - [\Lambda_{Ru}\Delta] = C_t R. \qquad (5)$$

The concentration of the ruthenium complex used is larger than that of $Co(acac)_3$:

$$[\Lambda_{Ru}] \gg [\Lambda_{Ru}\Lambda] \quad \text{and} \quad [\Lambda_{Ru}\Delta]. \qquad (6)$$

Using eqns (2)–(6) and K_d values, the association constants $K(\Lambda\text{–}\Lambda)$ and $K(\Lambda\text{–}\Delta)$ were calculated and are given in the last two columns in Table 2. The thermodynamic quantities of the Λ–Λ and Λ–Δ associations at a ruthenium complex concentration of 0.144 mol kg^{-1}, at which R is greater than at 0.0976 mol kg^{-1}, were calculated from the temperature dependence of the association constants in Table 2 and tabulated in Table 3.

The association constants of around 4 is comparable with the ionic association constant for

Table 3. Theremodynamic quantities of the Λ–Λ and Λ–Δ associations for Λ-$[Ru(phen)_3]^{2+}$–$Co(acac)_3$ at 25°C[a]

Difference	−0.04	0.4	2

[a] Concentration of the ruthenium chelate cation is 0.144 mol kg^{-1}. Errors in the parameters are around 10%.

$[Fe(phen)_3]^{2+}Br^-$.[16] Considering that $Co(acac)_3$ is a non-polar non-electrolyte without the possibility of hydrogen bonding, the value seems rather large. The hydrophobic property of the tris(1,10-phenanthroline)metal(II) chelate cations[9,17] is mainly responsible for the marked association. As shown in Table 3, this association process has positive enthalpy and entropy changes and may be attributed to the resultant effect of the overlapping of their hydrophobic co-spheres: Strengthened hydrogen-bonded networks of water in the co-sphere of $Co(acac)_3$ are released by overlapping with the co-sphere of $[Ru(phen)]^{2+}$ and thereby the water molecules return to ordinary water with positive enthalpy and entropy changes.[9] The slight preference for the Λ-isomer compared to the Δ-isomer by the Λ-ruthenium chelate cation is accompanied by more positive enthalpy and entropy changes. Unfortunately, there are errors of around 10% in the free-energy and enthalpy changes and their differences between the two pairs seem unclear. However, the temperature trend for the Λ–Λ pair preference is reliable since it is based on direct measurements of the degree of chiral discrimination. These increases in enthalpy and entropy are explained by the view that the stronger van der Waals' interaction for the analogous like-chirality pair, where the three-bladed ligand planes of both of the solutes are parallel to each other if they approach along their three-fold axis, affects more favorably the co-sphere overlapping.

(*Received* 20 *June* 1985; *accepted* 2 *September* 1985)

Abstract—Raman and IR spectra were obtained of molten $AlCl_3NH_3$, $AlCl_3ND_3$ and $AlBr_3NH_3$ in addition to chloroaluminate mixtures of the $AlCl_3NH_3$. The main spectral features of the gaseous $AlCl_3NH_3$ molecules having a C_{3v}-symmetry are retained in the molten and glassy states. Some additional bands were observed both in the pure liquid and in mixtures with chloroaluminate melts. The spectra indicated that the dissociation reaction $2AlCl_3NH_3 = AlCl_4^- + [AlCl_2(NH_3)_2]^+$ occurs with $K \simeq 3 \times 10^{-3}$ (mole fraction basis). Frequency shifts found on liquefaction demonstrate that extensive hydrogen bonding takes place between $AlCl_3NH_3$ molecules. This observation is supported by the glass-forming nature of $AlCl_3NH_3$. The molecule $Al_2Cl_6NH_3$ seems to exist in binary $AlCl_3$–$AlCl_3NH_3$ melts.

The production of aluminium by electrolysis in chloroaluminate melts (Alcoa process)[1] requires high-purity $AlCl_3$ which at present is obtained by chlorination of Al_2O_3. Undesirable chlorination of hydrocarbons, however, makes this process difficult to commercialize, despite the efficient electrolysis stage. A direct dehydration of $AlCl_3 \cdot 6H_2O$ would be advantageous for the production of $AlCl_3$, and a method in analogy with the NH_3 route for the dehydration of $MgCl_2 \cdot 6H_2O$ has been suggested.[2,3] The thermal stability of $AlCl_3NH_3$ has for this reason been studied in chloride melts.[3,4]

The present paper deals with the structure of this compound in the pure state and in some neutral and acidic chloroaluminate melts, as determined by IR and Raman spectroscopy. The interpretation of the spectra benefitted from comparison with the corresponding pure bromide and deuterated compound.

An ethane-like structure has been established for $AlCl_3NH_3$ and $AlBr_3NH_3$ by mass spectroscopy and electron diffraction[5–7] in the gas phase, as well as by a single-crystal X-ray investigation.[8] It has generally been assumed that the structure is staggered, thus adopting C_{3v}-symmetry. Recent *ab initio* MO calculations verifies the increased stability of this conformation.[9,10] The IR[9] and Raman spectra[10] of the chloride vapour have been reported, and most of the spectral assignments seem to be well-established.

The spectra of the solid[9,11] glass and liquid [12,13] show features distinctly different from those of the vapour. A description of the condensed phases in terms of dissociation, association and hydrogen bonding will be discussed. To our knowledge, no structural study of molten mixtures between $AlCl_3NH_3$ and $AlCl_3$ or alkali chlorides has been presented previously.

EXPERIMENTAL

All handling of salts was done in a glove box (< 5 ppm H_2O), or *in vacuo* ($< 10^{-5}$ torr). The alkali

* Author to whom correspondence should be addressed.

chlorides (p.a., Merck), except LiCl, were purified by recrystallization from the melt. Before melting the salts were dried at 400°C *in vacuo* for 2–3 h. The purification of LiCl (p.a., Merck) and $AlCl_3$ (p.a., Fluka) and the synthesis of $AlCl_3NH_3$ from $AlCl_3$ and NH_4Cl (p.a., Merck) are described elsewhere.[4,14]

$AlCl_3ND_3$ was synthesized in the same way as $AlCl_3NH_3$ using ND_4Cl (99% D, Stohler Isotope Chemicals) and $AlCl_3$ as starting materials. $AlBr_3NH_3$ was prepared from $AlBr_3$, obtained from a reaction between Al and HBr, and NH_4Br (99.5%, Hopkin & Williams). Both $AlBr_3$ and NH_4Br were purified by 5-times distillation–sublimation. The NH_4AlBr_4 salt formed by melting together $AlBr_3$ and NH_4Br in an evacuated silica tube was distilled twice, collecting HBr in a liquid N_2 cold trap.

The properly cleaned and baked-out Raman cells were filled with pure $AlCl_3NH_3$ or the different haloaluminate melts. The cells were sealed *in vacuo* and placed in a resistance-heated furnace. The Raman spectra were recorded with two different units. The data on pure $AlCl_3NH_3$ and on the $AlCl_3NH_3$–$CsAlCl_4$ melts were recorded using an Ar^+ laser from Control Laser Corporation (15 W). The scattered light was analyzed with a double monochromator (Jobin–Yvon) and detected with an RCA-C31034 photomultiplier and PAR photon-counting electronics. The Raman spectra of the other salts were excited with a Coherent CR-8 Ar^+ laser (8 W). The laser was passed through a Claisenfilter and the scattered light was analyzed with a double monochromator (Spex Ramalog 6) and detected with an RCA-C31034 photomultiplier and photon-counting electronics. The IR emission and specular reflection spectra were recorded using a method developed by Rytter *et al.*[15–17] using a thin film between a diamond window and a gold-plated nickel backplate.

RESULTS

The Raman spectra of $AlCl_3NH_3$ (g, l and glass) are shown in Fig. 1. The gas spectrum is from Papatheodorou *et al.*[10] and is given for comparison. The $AlCl_3NH_3$ glass was obtained by quenching the Raman cell in water after the salt had been melted. If the salt was properly synthesized, the glass was stable for several weeks. The IR emission spectra of $AlCl_3NH_3$ (g, l and s) are shown in Fig. 2 together with the reflectance spectrum of $AlCl_3ND_3$(l). The Raman spectrum of $AlBr_3NH_3$(l) is given in Fig. 3. The vibrational frequencies of all the neat compounds are collected in Table 1.

To study the possible decomposition reaction:

$$2AlCl_3NH_3(l) = AlCl_4^- + [AlCl_2(NH_3)_2]^+ \quad (1)$$

mixtures of $AlCl_3NH_3$ with $MAlCl_4$ ($M^+ = Li^+$, Na^+, K^+ or Cs^+), were examined. Figures 4–6 show the intensity variations with composition for the Raman frequencies around 400 cm^{-1}.

Vapour pressure and mass spectrometric studies of KCl–$AlCl_3$–$AlCl_3NH_3$ melts[4] show that the molecules $Al_2Cl_6NH_3$ and $AlCl_3NH_3$ are stable above this melt. To verify if $Al_2Cl_6NH_3$ also exists in the melt, Raman spectra of $AlCl_3$–$AlCl_3NH_3$ molten mixtures were recorded. The results are given in Fig. 7 and Table 2.

DISCUSSION

Condensed $AlCl_3NH_3$

It is evident from Figs 1 and 2 that the main spectral features of gaseous $AlCl_3NH_3$ are preserved upon condensation. However, distinct frequency shifts takes place and some new bands appear (see Table 1). These differences are interpreted in terms of H...Cl hydrogen bonding and dissociation in the liquid. Some oligomerization or polymerization, involving aluminium with higher coordination numbers, cannot be ruled out, but seem to contribute less to the structure.

The polarized Raman bands at 418 and 349 cm^{-1} are neither seen in the gas nor in the solid.[8–11] They are attributed to the symmetric AlCl stretching vibrations of $[AlCl_2(NH_3)_2]^+$ and $AlCl_4^-$, respectively. The latter value corresponds well to data for tetrachloroaluminate melts.[19] In this context it is interesting that electrical-conductivity measurements suggest some dissociation into ionic species.[20] Further substantiation of the formation of ions is given below in a quantiative approach.

Hydrogen bonding is expected to reduce the NH stretching frequencies and give rise to broader bands.[21] In Table 1 and Fig. 1 it is seen that the antisymmetric stretch (ν_7) is reduced from 3387 to 3295 cm^{-1} and the symmetric stretch (ν_1) from 3300 to 3243 cm^{-1} upon liquefaction. These Raman shifts are accompanied by the band broadenings (FWHH) (*ca* 38 → 66 cm^{-1} and 16 → 27 cm^{-1}). The ν_1 shift is influenced by Fermi resonance with $2\nu_8$ (NH_3 antisymmetric deformation). As ν_8 is unchanged, the resonance will be stronger in the liquid. This fact accounts for the enhanced intensity of the overtone and the frequency reduction from 3195 to 3178 cm^{-1}. In contrast, hydrogen bonding strengthens the force constants involved in the symmetric NH_3 deformation and NH_3 rocking.[21] Consequently, ν_2 increases from 1263 (1261) to 1332 cm^{-1} and ν_9 from 702 (697) to 731 cm^{-1}. As shown in Table 3, these effects are larger for the glass and the solid. It is also noteworthy that the influence of hydrogen bonding

on the NH stretching frequencies is roughly twice that of complexation of ammonia.

Little is known about torsional modes of ammines, and for $AlCl_3NH_3$ with ideal C_{3v}-symmetry this vibration (ν_6) is inactive in Raman as well as in the IR. A band at 1024 cm^{-1} in the IR melt spectrum, however, can be assigned to the combination $\nu_6 + \nu_9$, thus establishing the torsion at *ca* 293 cm^{-1}. The corresponding difference band is seen as a shoulder at *ca* 440 cm^{-1}. A similar interpretation of the gas-phase spectrum yields a torsional frequency of 276 cm^{-1}.[9] The 17 cm^{-1} higher value in the liquid is a further manifestation of hydrogen bonding. Additional verification comes from the deuterated sample which gives the sum at 820 cm^{-1} and the difference at 405 cm^{-1}, implying $\nu_6 = 208$ cm^{-1} and $\nu_9 = 612$ cm^{-1}. The latter mode is seen as a broad band in the IR spectrum, whereas the shift factor for the torsion of 1.41 matches exactly the value predicted by the Teller–Redlich product rule.

Gas–liquid–glass transformation does not alter the symmetric AlCl stretch at 378 cm^{-1}, but the antisymmetric counterpart is shifted from 536 to 502 cm^{-1} (Table 3). In the $AlCl_3$ deformation and rocking region below 300 cm^{-1}, the spectral appearance changes distinctly. We will think that that originates in the H...Cl interactions. The upward shift in the symmetric deformation from 200 to 251 cm^{-1} is particularly large. The explanation may partly be that there are differences in the purity of the mode.

A related problem is detected for the AlN mode assigned[9,10] at *ca* 480 cm^{-1} in the free molecule. No likely candidates in the neighbourhood of this value are found in any of the spectra of condensed materials. Our suggestion is that this vibration is

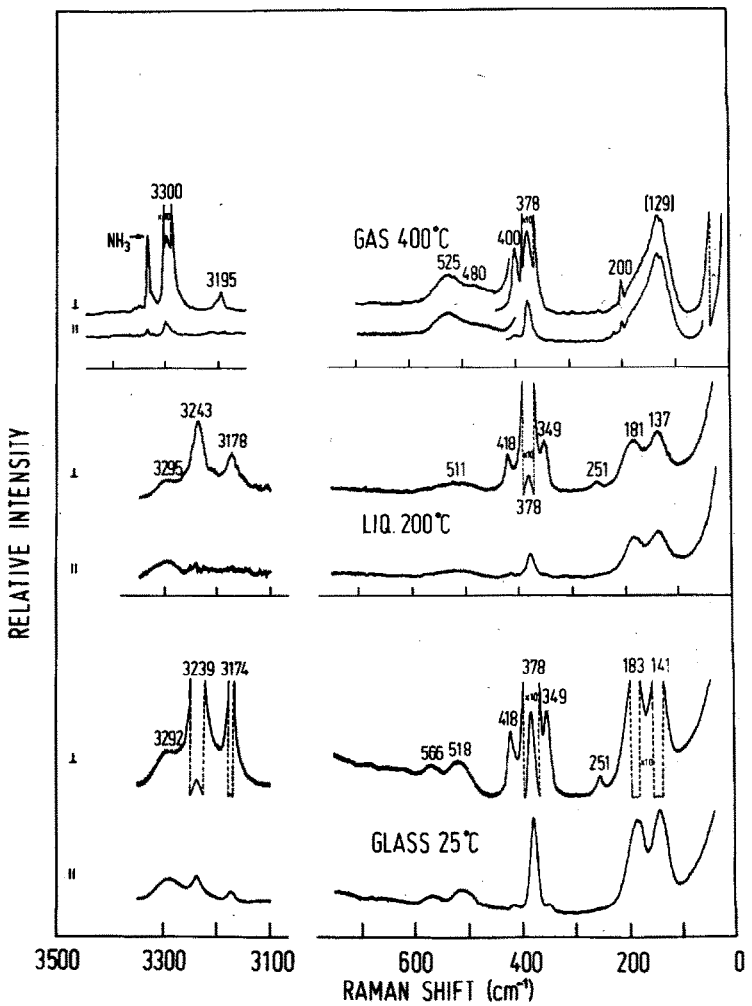

Fig. 1. Raman spectra of $AlCl_3NH_3$. The gas spectrum is from Papatheodorou *et al.*[10] For the liquid and glass spectra $\lambda_0 = 457.9$ nm, power = 400 mW, time constant (τ) = 0.06 s (except for higher frequencies of lower spectrum where $\tau = 0.3$ s), spectral slit width = 5 cm^{-1}, scan rate = 50 cm min^{-1}, chart speed = 5 cm min^{-1}.

[e] Not investigated.

[f] Glass value (see Fig. 1).

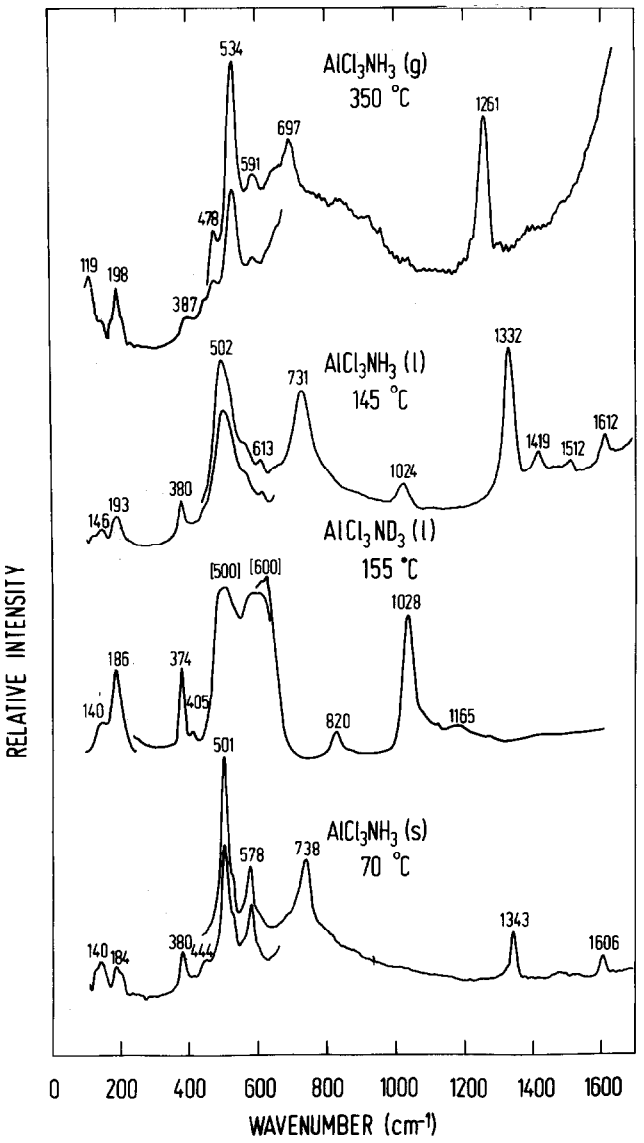

Fig. 2. IR emission spectra of $AlCl_3NH_3$ (g, l and s) and IR reflection spectrum of $AlCl_3ND_3$(l). Thick melts are used as reference.[17]

found at a higher frequency, possibly at 566 cm^{-1} (or 518 cm^{-1}) as observed in the Raman spectrum of the glass (Fig. 1); compare the shoulder at 565 cm^{-1} in the IR spectrum of the liquid and 578 cm^{-1} for the solid (Fig. 2). Presumably a synergetic effect operates. As hydrogen bonding weakens the N—H bonds, Al—N is strengthened. In turn, Al—Cl becomes weaker (chlorine will act as a better donor), the hydrogen bond stronger and N—H even weaker, cf. Gutmann's rules.[24] The result is an additional contribution to the Al—N bond strength. Alternatively, it may be observed that hydrogen bonding is expected to increase the lengths of both types of bonds adjacent to Al—N. In fact, the Al—Cl gas-phase and solid values are 2.102(5) and 2.111 Å, respectively, whereas Al—N contracts from 1.998(19) to 1.921 Å.[6,8]

Liquid $AlBr_3NH_3$

Due to insufficient distillation of the starting material, the Raman spectrum of $AlBr_3NH_3$(l) shows an appreciable amount of $AlBr_4^-$. The molten salt fundamentals of the tetrabromoaluminate ion in NH_4AlBr_4 are situated at 397 (w; ν_3, F_2), 209 (vs, p; ν_1, A_1), 113 (m; ν_4, F_2) and 74 cm^{-1} (m; ν_2, E), all of which are recognized in Fig. 3.

The interpretation of all other bands in the figure follows closely the assignments for $AlCl_3NH_3$ (g and l) and $AlBr_3NH_3$(g). As in the case for the chlor-

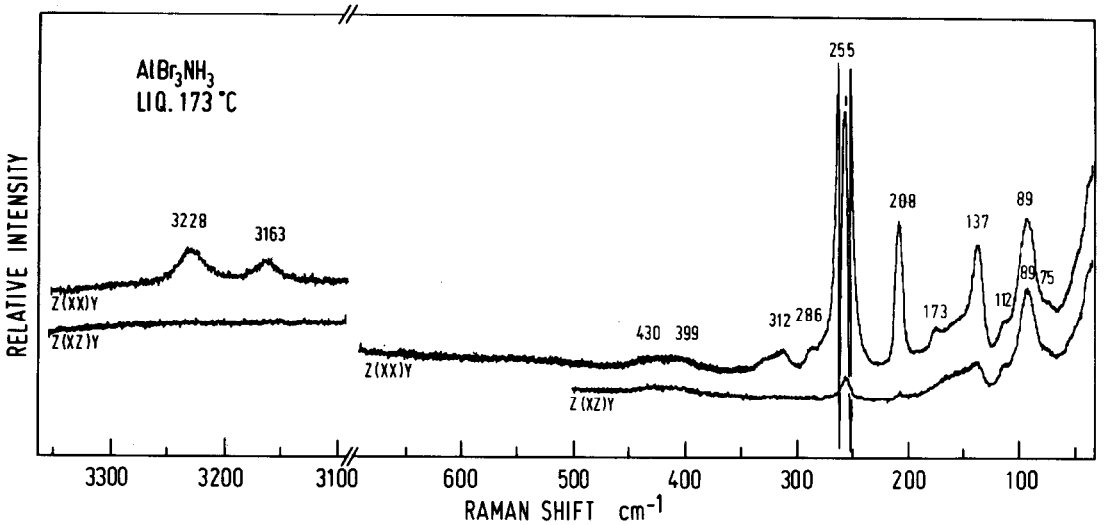

Fig. 3. Raman spectra of $AlBr_3NH_3$(l). λ_0 = 514.5 nm, power = 125 mW, τ = 1 s, scan rate = 0.2 cm s^{-1}, chart speed = 1 cm min^{-1}, spectral slit width = 8 cm^{-1}.

ide molecule, on going from liquid to gaseous $AlBr_3NH_3$ the NH symmetric stretch (ν_1) increases from 3228 to 3294 cm^{-1}, whereas the $AlBr_3$ symmetric deformation (ν_5) decreases from 173 to 149 cm^{-1}. A comparison between the $AlBr_3NH_3$(l) and $AlCl_3NH_3$(l) spectra shows that the ammonia frequencies are practically unchanged whereas the aluminium halide modes follow the mass difference. Some additional features between 310 and 350 cm^{-1} are ascribed to combinations or overtones. The AlN stretch expected in the range 450 to 550 cm^{-1} is apparently extremely weak in the Raman spectrum, although a band barely observable at *ca* 525 cm^{-1} has been attributed to this fundamental. The low intensity may be correlated with the high ionicity

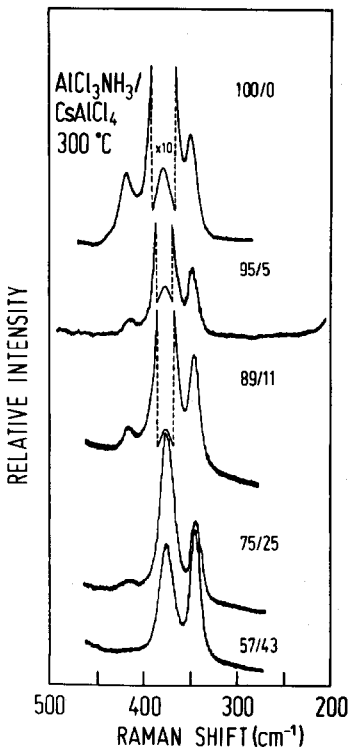

Fig. 4. Raman spectra of $AlCl_3NH_3$–$CsAlCl_4$ melts. λ_0 = 457.9 nm, power = 300 mW, τ = 0.02 s, spectral slit width = 3.5 cm^{-1}, scan rate = 50 cm min^{-1}, chart speed = 5 cm min^{-1}.

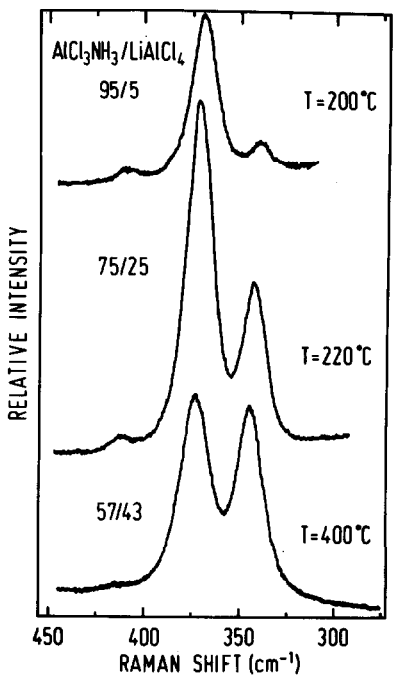

Fig. 5. Raman spectra of $AlCl_3NH_3$–LiCl melts. λ_0 = 488 nm, power = 75 mW, τ = 1 s, scan rate = 0.02 cm s^{-1}, chart speed = 0.2 cm min^{-1}, spectral slit width = 8 cm^{-1}.

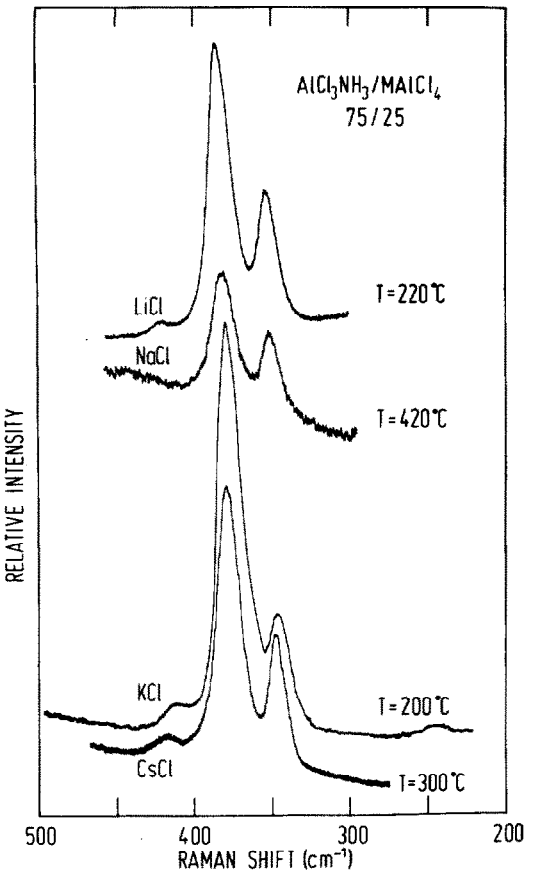

Fig. 6. Raman spectra of $AlCl_3NH_3$–$MAlCl_4$ melts (M = Li, Na, K or Cs). The polarized spectra of the LiCl- and CsCl-containing systems are run under the conditions specified in Figs 5 and 4, respectively. The spectra of the NaCl- and KCl systems are obtained with $\lambda_0 = 488$ nm, power = 30 mW, $\tau = 1$ s, scan rate = 0.5 cm s^{-1}, chart speed = 1 cm min^{-1}, spectral slit width = 8 cm^{-1}.

of the Al—N bond as found by *ab initio* MO calculations.[9] Complexation gives rise to a net flux in charge from the hydrogen to the chlorine atoms in $AlCl_3NH_3$.

Assignments for the $AlBr_3$ deformation and rocking modes must be regarded as tentative. In Table 3 it is demonstrated that the former type does not follow the same smooth trend as the corresponding NH_3 vibrations, as might be expected from differences in kinematic coupling, vibrational mixing and structural change. Note that the AlX_3 entities are transformed from planar to pyramidal during complexation. Additional support to the assignment of the AlX_3 symmetric deformation hence comes from the weak Raman intensity as this mode is inactive for free AlX_3. A special feature only for the bromide is the splitting of the $AlBr_3$ rock into one polarized and one depolarized component. This observation indicates breakdown of the ideal C_{3v}-symmetry. The explanation favoured is the 10–20% content of NH_4AlBr_4. The presence of the ammonium ion may cause a prevalence of asymmetrical hydrogen bonding.

The approximately equal melting points of $AlCl_3NH_3$ and $AlBr_3NH_3$, the higher vapour pressure of the bromide and the reduced tendency to form glass are consistent with the general belief that chlorine is a more efficient hydrogen bond donor atom than bromine. It therefore is intriguing that the spectroscopic results (Table 3) indicate that the N—H bond strength is approximately the same for both liquids. Note, however,the uncertainty due to the ν_1–$2\nu_8$ Fermi resonance that influences the position of the NH symmetric stretch.

Dissociation of $AlCl_3NH_3$

The dissociation equilibrium in eqn (1) was investigated by adding $AlCl_4^-$ in the form of $MAlCl_4$

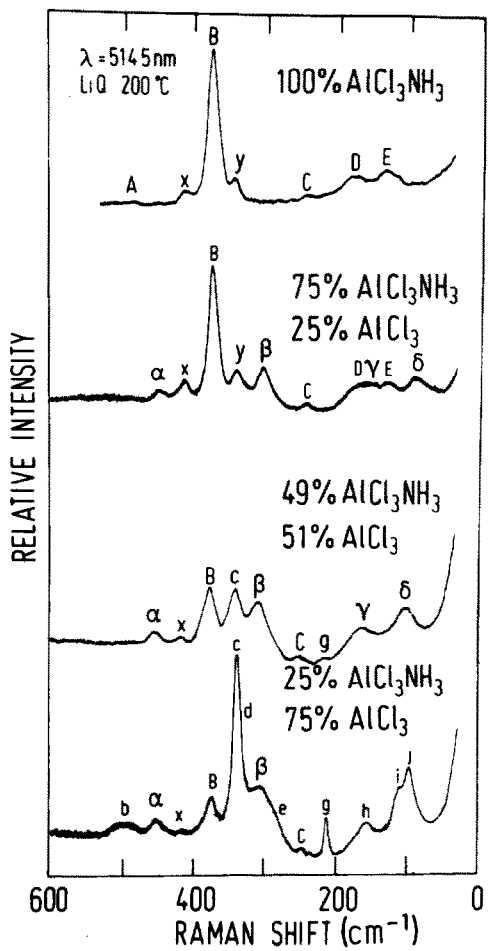

Fig. 7. Raman spectra of $AlCl_3NH_3$-$AlCl_3$ liquid mixtures at 200°C. $\lambda_0 = 514.5$ nm, power = 700 mW, $\tau = 1$ s, scan rate = 0.2 cm s^{-1}, chart speed = 1 cm min^{-1}, spectral slit width 8 cm^{-1}. [c] The symbols refer to Fig. 7. The complete set of bands a–j for molten Al_2Cl_6 is found in Ref. 19.

(M = Li, Na, K or Cs). As expected, such an addition increases the Raman intensity of the 349 cm^{-1} band (y, $AlCl_4^-$) relative to the 378 cm^{-1} band (B, $AlCl_3NH_3$) at the expense of the 418 cm^{-1} band {x, $[AlCl_2(NH_3)_2]^+$} but without any significant change in band positions.

By resolving the spectrum from 300 to 450 cm^{-1} into three bands, the peak intensities in Table 4 were obtained. Employing a procedure similar to the one used for dissociation of $Al_2Cl_7^-$,[25] it was thus possible to calculate the equilibrium constant of eqn (1). It is assumed that the intensities of the totally symmetric AlCl stretching vibration of the three species are proportional to the concentrations. Thus, a stoichiometric equilibrium constant is obtained. This constant approaches the thermodynamic value if the activity coefficients cancel, as very well may be the case. It follows that:

$$n^o_{MCl} = n_{AlCl_4^-} - n_{[AlCl_2(NH_3)_2]^+}, \quad (2)$$

$$n^o_{AlCl_3NH_3} = n_{AlCl_3NH_3} + 2n_{[AlCl_2(NH_3)_2]^+}, \quad (3)$$

$$K = \frac{n_{[AlCl_2(NH_3)_2]^+} n_{AlCl_4^-}}{n^2_{AlCl_3NH_3}} \quad (4)$$

and

$$I_B/I_y = k n_{AlCl_3NH_3}/n_{AlCl_4^-}. \quad (5)$$

Employing intensity data from two different compositions one obtains eight equations to match the six unknown concentrations, k and K. In this way, several equilibrium constants were calculated for each $MAlCl_4$–$AlCl_3NH_3$ system. The results were improved by including the intensity I_x through the relationship:

$$K = k' \frac{I_x I_y}{I_B^2}, \quad (6)$$

evaluating an average k' and recalculating K from eqn (6) for each composition.

The results given in Table 4 show an average equilibrium constant of 3.2×10^{-3}, or *ca* 5% dissociation. The deviation from the *ca* 1% value inferred from conductivity measurement[20] probably is due to reduced ionic mobilities as a result of hydrogen bonding. The calculated equilibrium constant seems to increase with tetrachloroaluminate addition. A more ionic melt enhances the dissociation of the neutral ammine into ionic species. Thus, the spectroscopic data give information on variations in the activity coefficient term. Another effect is that larger alkali ions give more ionic liquids.

The alternative dissociation reaction:

$$2AlCl_3NH_3 = AlCl_2NH_2 + NH_4^+ + AlCl_4^- \quad (7)$$

can be regarded as a mutual autoionization of $AlCl_3$ and NH_3. This possibility cannot be rejected from the spectral data or equilibrium constant calcula-

tion. Formation of a three-coordinated highly acidic aluminium atom is, however, improbable.

$AlCl_3NH_3$ *in* $AlCl_3$

The successive addition of the Lewis base NH_3 to the Lewis acid Al_2Cl_6 may be formulated as:

$$Al_2Cl_6 + NH_3 = Al_2Cl_6NH_3, \quad (8)$$

$$Al_2Cl_6NH_3 + NH_3 = 2AlCl_3NH_3. \quad (9)$$

From this it follows that the associative redistribution reaction:

$$2AlCl_3NH_3 + Al_2Cl_6 = 2Al_2Cl_6NH_3 \quad (10)$$

may play an important part when $AlCl_3NH_3$ is added to pure $AlCl_3$. In addition, formation of ionic species cannot be excluded:

$$Al_2Cl_6 + Al_2Cl_6NH_3 = [Al_2Cl_5NH_3]^+ + Al_2Cl_7^-, \quad (11)$$

$$2Al_2Cl_6NH_3 = [Al_2Cl_5(NH_3)_2]^+ + Al_2Cl_7^- \quad (12)$$

$$Al_2Cl_6NH_3 + AlCl_3NH_3 = [Al_2Cl_5(NH_3)_2]^+ + AlCl_4^-, \quad (13)$$

$$2AlCl_3NH_3 = [AlCl_2(NH_3)_2]^+ + AlCl_4^-. \quad (14)$$

In Fig. 7 and Table 2, the Raman bands have been attributed to neutral and ionic entities in the melt according to these reaction schemes. The interpretation is based on systematic intensity variations of individual or groups of bands, overall stoichiometry, the well-characterized spectra[19] of Al_2Cl_6, $Al_2Cl_7^-$,

$AlCl_4^-$ and $AlCl_3NH_3$ as well as of $[AlCl_2(NH_3)_2]^+$ and assumptions regarding frequency shifts.

In particular, it is evident that the spectrum of $AlCl_3NH_3$ (bands A–E) and its dissociation products $AlCl_4^-$ (y) and $[AlCl_2(NH_3)_2]^+$ (x) gradually disappears as Al_2Cl_6 (bands b–j) is added. That a simple mixture of the two compounds is far from the whole story, is most clearly seen by the presence of the α- and β-bands at intermediate compositions. The most straightforward interpretation of the data is in terms of eqn (10), i.e. $Al_2Cl_6NH_3$ is formed at intermediate compositions.

The striking similarities, both in frequencies and intensities, between the β-, γ- and δ-bands in Fig. 7 and the corresponding bands for $Al_2Cl_7^-$ deserve a comment. In $AlCl_3$–CsCl mixtures, the frequencies found[19] were 306, 161 and 96 cm^{-1}, which may be compared to the present values of 306, 160 and 97 cm^{-1} (Table 2). However, the symmetric AlCl terminal stretch expected for $Al_2Cl_7^-$ at 431 cm^{-1} is apparently shifted to 453 cm^{-1} (α). Besides, it seems impossible to incoporate a positive species to the required extent, although the main band of $[Al_2Cl_5(NH_3)_2]^+$ may be hidden in the y–c envelope in Fig. 7, cf. the width of the c-band for the 49–51% composition.

We conclude that $Al_2Cl_6NH_3$ is formed in the molten $AlCl_3$–$AlCl_3NH_3$ system, possibly with some dissociation into ionic species. As for the pure ammine, hydrogen bonding is of course expected to be important in these mixtures. Another result that may be inferred from Fig. 7 is that the relative concentration of $Al_2Cl_6NH_3$ is less than the concentration of $Al_2Cl_7^-$ in the alkali chloride–$AlCl_3$ melts. This difference may be caused by factors like hydrogen bonding, counterion influence and the basicity of Cl^- vs NH_3.

Abstract—On the basis of experimental data the energy levels of the central-atom orbitals in the complex $[Mo(N_2)_2(dppe)_2]$ [dppe = 1,2-bis(diphenylphosphine)ethane] were calculated. Using the diagram thus obtained the electronic configuration of the irradiation-generated ion, $[Mo(N_2)_2(dppe)_2]^-$, was determined to be as follows: $(b_{2g})^2 (e_g)^4 (b_{1g})^1$ or $(b_{2g})^2 (e_g)^4 (e_u)$. The yields from the decomposition of $[Mo(N_2)_2(dppe)_2]$ in the solid phase in a hydrogen atmosphere were determined on the basis of the decrease in band intensities at 306 and 377 nm: $G(-Mo—N_2)_{306nm} = 0.01$, and $G(-Mo—P)_{377nm} = 0.1$ (molecules per 100 eV). In toluene solution it was found that $G(-Mo—N_2) > G(-Mo—P)$. The yields observed were in accordance with the calculated levels. Using a mass spectrometer the volatile products of $[Mo(N_2)_2(dppe)_2]$ radiolysis in H_2 and O_2 atmospheres were identified as H_3N, H_4N_2, NO and N_2O. In the light of the results mentioned above (as well as the IR results) a mechanism for the radiolysis of $[Mo(N_2)_2(dppe)_2]$ in the solid phase was proposed.

Compounds of transition metals in low oxidation states with 1,2-bis(diphenylphosphine)ethane (dppe) are used in the fixation and reduction of molecular nitrogen (N_2), and the $[Mo(N_2)_2(dppe)_2]$ molecule is the subject of great interest.[1–19] Introduction of N_2 into the coordination sphere of Mo(0) may be carried out without any problem.[3] The chemical reduction of coordinated nitrogen, e.g. by using either acids or alkyl halides, is not efficient enough and is connected with the oxidation of the central atom.[20,21] Thus, the recycling of his complex in the fixation of N_2 becomes impossible without previous reduction of the central ion. The irradiation of $[Mo(N_2)_2(dppe)_2]$ by means of UV light leads to N_2 elimination.[11,22,23] N_2 may be liberated from the complex with no π-acceptor ligands (except N_2) with the help of ionizing radiation.[24]

Taking into account the low reactivity of dppe towards e_s^- [25] {which is supported by the invariability of this ligand in the irradiated $[MoOCl(dppe)_2]Cl$ complex,[26] as well as assuming, that—as in the case of the other complex—the lower-energy molecule orbitals would be filled by e_s^-} one should expect that, as a result of the irradiation of $[Mo(N_2)_2(dppe)_2]$, N_2 will not be immediately eliminated from this compound. Although the energy level sequence of the molecular orbitals in $[Mo(N_2)_2(dppe)_2]$ is not established so far, it is assumed that the a_{2u}-level [π(Mo—N_2)] is undoubtedly higher than the other potentially acceptor orbitals: e_u [π(Mo—P)], a_{1g} and b_{1g}.[22] Thus, the Mo—N_2 σ-bond is attenuated by the formation of the $[Mo(N_2)_2(dppe)_2]^-$ ion (this ion is formed through the filling of the a_{1g}-orbital), whereas attenuation of the Mo—P σ-bond is caused by the filling of the b_{1g}-orbital. Hence the determination of the yields from the destruction of both the Mo—N_2 and the Mo—P bond as a result of the irradiation as well as the suggestion of the $[Mo(N_2)_2(dppe)_2]^-$ ion electronic state should contribute to the explanation of the electron configuration either at the ground or the excited state of the $[Mo(N_2)_2(dppe)_2]$ molecule. Moreover, the determination of the gaseous pro-

ducts of radiolysis as well as the finding that the changes in the $[Mo(N_2)_2(dppe)_2]$ molecule caused by irradiation (by means of IR spectroscopy) are the purpose of this work.

EXPERIMENTAL

$[Mo(N_2)_2(dppe)_2]$ was prepared as previously described.[3] Samples (0.2 g) of $[Mo(N_2)_2(dppe)_2]$ were placed into glass tubes provided with suitable taps. The air was pumped out and the sample washed out with hydrogen, nitrogen or oxygen, then pumping out was done, and the sample filled with hydrogen, nitrogen or oxygen. Air-tight tubes with $[Mo(N_2)_2(dppe)_2]$ were irradiated in the cobalt source "Issliedowatiel" at dose rate of 6×10^{16} eV min^{-1} g^{-1} or 3.8×10^{17} eV min^{-1} ml^{-1} in toluene solution. The solutions of $[Mo(N_2)_2(dppe)_2]$ in toluene (1.2×10^{-4} mol dm^{-3}) were saturated with argon, then irradiated. The absorption bands of the unstable products of radiolysis were determined at 77 K in a frozen solution of $[Mo(N_2)_2(dppe)_2]$ in tributylphosphate (TBP) (freshly purified), saturated with argon. The non-irradiated frozen solution of $[Mo(N_2)_2(dppe)_2]$ in TBP was used as a reference. The absorption bands were measured on a Beckman 5240 spectrophotometer: the weighed portions of $[Mo(N_2)_2(dppe)_2]$ after irradiation were dissolved in tetrahydrofuran. IR spectra were taken in KBr discs on a Specord 75 spectrophotometer. The gaseous products were pumped out from the irradiation samples, and examined by means of an WSM-2 mass spectrometer using an ionization energy of 100 eV.

RESULTS AND DISCUSSION

In the frozen solution of $[Mo(N_2)_2(dppe)_2]$ in TBP, as a result of the irradiation, a low-intensity band appears at 580 nm (OD = 0.03, optical path = 1 cm), which disappears rapidly. This band may be attributed to the $(b_{1g})^1 \rightarrow (a_{1g})^1$ transition in the $[Mo(N_2)_2(dppe)_2]^-$ ion formed as a result of the interaction of e_s^- with the Mo(0) complex. The assignment of the band at 580 nm was made on the basis of Fig. 1. In the dose range up to 60 kGy no change was observed in the absorption band as well as in the frequency modes when the sample was irradiated in an N_2 atmosphere. A linear decrease in absorbance at 306 ($\varepsilon = 2.3 \times 10^4$) and 377 nm ($\varepsilon = 1.37 \times 10^4$) was observed in an H_2 atmosphere up to 60 kGy. The calculated yields from bond decomposition are as follows: $G(-Mo—N_2) =$ 0.01/100 eV [on the basis of the decrease in the band intensity at 306 nm corresponding to the charge transfer from Mo to N_2 (MLCT)] and $G(-Mo—P) = 0.1/100$ eV [on the basis of the decrease in the band at 377 nm—the charge transfer from Mo to P (MLCT)]. The vibrations in $[Mo(N_2)_2(dppe)_2]$ together with some assignments are presented in Fig. 2. The assignment was based on papers [19,27–29] as well as compared with free ligand and complex IR spectra. There were no changes observed in the frequency modes of $[Mo(N_2)_2(dppe)_2]$ irradiated in an H_2 atmosphere in comparison with those of the non-irradiated sample (the small decrease in the amount of N_2 in the complex does not reach the sensitivity limit of the IR method and so no changes in the intensity of the N_2 and Mo—N_2 vibrations were detected). Mo—P IR vibrations appear at about 350–520 cm^{-1}.[28] Assuming a D_{4h}-symmetry for the MoP_4 unit E_u [ν(Mo—P)] and A_{2u} and B_{2u} [δ(Mo—P)] IR vibrations are expected. In the 350–520-cm^{-1} region a strong variation also appears [δ(CCC) in the plane of the phenyl ring]. As follows from the above the Mo—P symmetrical vibrations appear in the Raman region, e.g. A_{1g} at 170 cm^{-1},[19] but we could not observe any Mo—P bond cleavage in the IR absorption. The lowering of the vibration frequency of N_2 (at 1970 cm^{-1}) is observed when higher doses are used. The lowering of some vibration frequencies and the appearance of new vibrations can be seen when $[Mo(N_2)_2(dppe)_2]$ is irradiated in an O_2 atmosphere (Table 1). Data in Table 1 show that the irradiation of

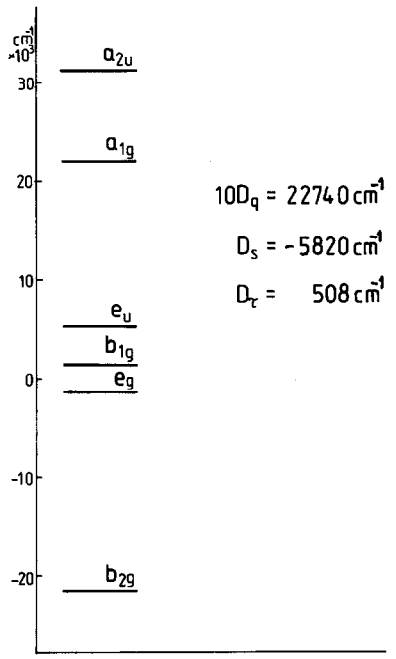

Fig. 1. Parameters of the ligand field and the energy level diagram of the central-atom orbitals for complex $[Mo(N_2)_2(dppe)_2]$, calculated on the basis of the absorption bands.

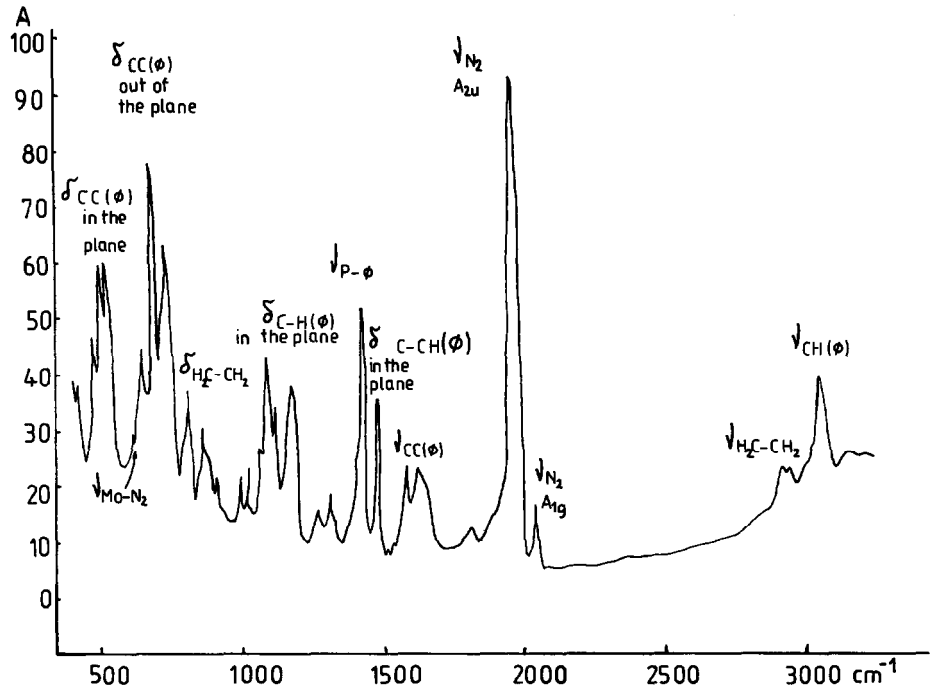

Fig. 2. IR spectrum of $[Mo(N_2)_2(dppe)_2]$ in KBr tablet.

$[Mo(N_2)_2(dppe)_2]$ in an O_2 atmosphere leads: (a) to the destruction of this compound, (b) to the addition of oxygen to the ligand fragment, and (c) to the oxidation of Mo. The relative intensities of the mass spectral peaks of both the gaseous ions and the volatile products forming as a result of the irradiation of $[Mo(N_2)_2(dppe)_2]$ in an H_2 or an O_2 atmosphere are presented in Tables 2 and 3. It follows from Tables 2 and 3 that, as a result of the irradiation of $[Mo(N_2)_2(dppe)_2]$ in an H_2 atmosphere, the nitrogen is converted partly into H_4N_2 and H_3N, and about 40% of the nitrogen liberated from the coordination sphere remains unchanged. In an O_2 atmosphere the coordinated nitrogen is converted into NO and N_2O, but about 10% of the liberated nitrogen remains unchanged. The behaviour of $[Mo(N_2)_2(dppe)_2]$ towards the ionizing radiation is different from towards UV or VIS light as shown by our results.

In the solid phase, the Mo—N_2 bond is ruptured by γ-radiation, with a lower efficiency. In the case of the Mo—P bond a higher decomposition yield is observed. γ-Irradiation of the toluene solution of $[Mo(N_2)_2(dppe)_2]$ (1.2×10^{-4} mol dm^{-3}) saturated with argon results in the following yields: $G(-Mo{-}N_2) = 0.012$ and $G(-Mo{-}P) = 0.007$ bonds/100 eV. In toluene solutions, the ionizing radiation has a similar effect to UV or VIS light, i.e. it breaks the Mo—N_2 bond. It should be noted, however, that in toluene as well as in benzene solutions the excited states of the solvent molecules (i.e. $^1B_{2u}$ and $^3B_{1u}$) are produced as a result of the irradiation. The triplet state is especially important, in which 430-nm radiation is absorbed by the solvent[30] {this region is almost covered by the ligand field transition for $[Mo(N_2)_2(dppe)_2]$}. Thus the result of the transfer of excitation energy from the solvent to the complex is the same as that of light absorption, i.e. the rupture of the Mo—N_2 bond.[11,22]

The absorption bands of $[Mo(N_2)_2(dppe)_2]$ with respect to the character of the electron transitions are

well known. The bands at 306 and 377 nm were attributed to a charge transfer from the central atom to the ligand (MLCT): Mo → P(3*d*) and Mo → $N_2(\pi^*)$.[11,31,32] The band at 440 nm was that one of LFT.[33–36] In spite of this, there is some controversy about the order of the electron levels in the *trans*-$[Mo(N_2)_2(dppe)_2]$ complex. Dubois and Hoffman,[37] on the basis of the semiempirical MO scheme suggested, that the b_{2g}-level is the highest filled level in the ground state. The configuration $(e_g)^4$ $(b_{2g})^2$ was also accepted by other authors.[33–35] The e_g-level was suggested by Chatt *et al.*[38] to be the highest filled level and this suggestion was supported by *ab initio* SCF molecular-orbital calculations.[39]

Table 3. Comparative intensities of mass spectrum peaks of the gaseous ions formed as a result of the irradiation of $[Mo(N_2)_2(dppe)_2]$ at 48 kGy, and different $O_2:N_2$ (coordinated) volume ratios, under standard conditions

The experimental results of our work[26,40] are partially in accordance with the MO diagram calculated by Murrell *et al.*[39] The radiation-induced reduction of $[MoOCl(dppe)_2]Cl$ [diamagnetic complex with $(b_2)^2$ configuration[26]] gave $[MoOCl(dppe)_2]$ with the configuration $(b_2)^2$ $(e)^1$.[40] The disproportionation of Mo(III) leads to $[MoCl_2(dppe)_2]$[26,40] with $(b_{2g})^2$ $(e_g)^2$ configuration (μ_{eff} = 2.98 BM).[26]

It is expected that the $(b_{2g})^2$ $(e_g)^4$ configuration in the diamagnetic *trans*-$[Mo(N_2)_2(dppe)_2]$ is caused by the reduction of Mo(II) to Mo(0). These experimental conclusions are in accordance with the calculations of Murrell *et al.*[39] as well as with the fact that the Mo—N_2 bond is shorter than the Mo—P bond.[9,10] The $(b_{2g})^2$ $(e_g)^4$ configuration does not contradict the fact of photodissociation of N_2 without $[Mo(N_2)_2(dppe)_2]$, because the absorption of radiation connected with the transition $^1A_1 \rightarrow {}^3E\,(b_{2g})^2\,(e_g)^4 \rightarrow (b_{2g})^2\,(e_g)^3\,(a_{1g})^1$ is the reason for the simultaneous weakness of the Mo—N_2 π-bond (decrease in the number of e_g-level electrons) as well as for the cleavage of the Mo—N_2 σ-bond (filling of the a_{1g}-level). The absorption of 440-nm radiation may also lead to the excitation $^1A_1 \rightarrow {}^3A_2\,(b_{2g})^2\,(e_g)^4$ $\rightarrow (b_{2g})^1\,(e_g)^4\,(b_{1g})^1$. Thus, the accepted first state of excitation, b_{1g}, is in accordance with the yields from $[Mo(N_2)_2(dppe)_2]$ decomposition found in toluene solution. In considering the population, the transition $^1A_1 \rightarrow {}^3E$ is more probable than $^1A_1$ $\rightarrow {}^3A_2$, so the decomposition yield of Mo—N_2 is higher than that of Mo—P. This fact is also influenced by the higher donor capacity of dppe in

comparison with that of N_2. The first excited state, b_{1g}, is in agreement with the decomposition yields of $[Mo(N_2)_2(dppe)_2]$ in the solid phase in an H_2 atmosphere. The energy level diagram of the central atom for the $[Mo(N_2)_2(dppe)_2]$ complex calculated on the basis of the experimental data {the absorption bands of $[Mo(N_2)_2(dppe)_2]$} is shown in Fig. 1. From Fig. 2 it is evident that b_{1g} is the first unfilled state. Thus, the interaction of $[Mo(N_2)_2(dppe)_2]$ with e^- leads to the configuration $(b_{2g})^2 (e_g)^4 (b_{1g})^1$ or $(b_{2g})^2 (e_g)^4 (e_u)^1$ (because of the small energy interval between the e_u- and b_{1g}-orbitals). The filling of the b_{1g} or $3d$(P) state results in the rupture of the Mo—P bond in the solid phase. The anion, $[Mo(N_2)_2(dppe)_2]^-$, formed in the solution may disappear on reaction with the cation. A reaction of this type takes place in the case of $(dppe)^-$ in CH_3OH.[25] If the a_{1g}-level is lower than b_{1g}, as assumed by Murrell *et al.*,[39] the decomposition yield of Mo—N_2 is higher than that of Mo—P in the solid phase. The band occurring in frozen TBP solution at 480 nm is well interpreted by the diagram in Fig. 1. The $(b_{1g})^1 \rightarrow (a_{1g})^1$ transition which is expected on the basis of this diagram should have an energy of 20,000 cm^{-1} (in a non-polar solvent). The experimental frequency (in a polar solvent) equals 20,800 cm^{-1}, in good agreement with the diagram. The band for the $[Mo(N_2)_2(dppe)_2]^-$ ion, in accordance with Murrell *et al*'s[39] diagram, i.e. $(a_{1g})^1 \rightarrow (b_{1g})^1$ should be at 37,100 cm^{-1}. Therefore the MO sequence calculated by Murrell *et al.*,[39] i.e.

$$3b_{2g} < 4e_g < 16a_{1g} < e_u < 4b_{1g},$$

may be changed to the following one:

$$3b_{2g} < 4e_g < 4b_{1g} < 8e_u < 16a_{1g}.$$

Taking into account the results described above, it can be noted that the radiation investigations may be applied as an essential complementary method for the determination of the electronic states of complex compounds.

In the light of the results presented the following mechanism is proposed for $[Mo(N_2)_2(dppe)_2]$ radiolysis in the solid phase in an H_2 atmosphere:

$$[Mo(N_2)_2(dppe)_2] \rightarrow M^+ + e^-, \tag{1}$$

$$[Mo(N_2)_2(dppe)_2] + e^- \rightarrow [Mo(N_2)_2(dppe)_2]^- \tag{2}$$

$$[Mo(N_2)_2(dppe)_2]^- \rightarrow [Mo(N_2)_2(dppe)] + (dppe)^-, \tag{3}$$

$$[Mo(N_2)_2(dppe)_2] + H \rightarrow \left[\begin{matrix} & N_2 & \\ Mo & & (dppe)_2 \\ & N_2H & \end{matrix} \right], \tag{4}$$

$$\left[\begin{matrix} & N_2 & \\ Mo & & (dppe)_2 \\ & N_2H & \end{matrix} \right] + H_2 \rightarrow \left[\begin{matrix} & N{-}NH_3 & \\ Mo & & (dppe)_2 \\ & N_2 & \end{matrix} \right] \text{ and } \left[\begin{matrix} & N_2 & \\ Mo & & (dppe)_2 \\ & NH{-}NH_2 & \end{matrix} \right] \tag{5}$$

$$\left[\begin{matrix} & N{-}NH_3 & \\ Mo & & (dppe)_2 \\ & N_2 & \end{matrix} \right] \rightarrow H_3N + [Mo(N_2)(dppe)_2] + N, \tag{6}$$

$$\left[\begin{matrix} & NH{-}NH_2 & \\ Mo & & (dppe)_2 \\ & N_2 & \end{matrix} \right] + H_2 \rightarrow H_4N_2 + [Mo(N_2H)(dppe)_2], \tag{7}$$

$$N + N \rightarrow N_2. \tag{8}$$

EXTRACTION OF 1:1 ELECTROLYTES FROM AQUEOUS SOLUTIONS BY RESINS CONTAINING DIBENZO-18-CROWN-6 AS ANCHOR GROUPS

ANGELA F. DANIL DE NAMOR* and ELIZABETH SIGSTAD†

Department of Chemistry, University of Surrey, Guildford, Surrey GU2 5XH, U.K.

(*Received* 1 *July* 1985; *accepted* 2 *September* 1985)

Abstract—The electrolyte concentration dependence of the distribution ratio of 1 : 1 electrolytes between resins containing dibenzo-18-crown-6 and water at 298 K was studied. The apparent equilibrium constants for the process taking place when the resin is equilibrated with aqueous solutions of different electrolytes are reported. The results obtained clearly reflect the influence of the anion on the extraction of cations by the resin containing the macrocyclic ligand.

The extraction of 1 : 1 electrolytes from water to non-aqueous solvents by the use of macrocyclic ligands is an area of considerable interest. Extraction studies of 1 : 1 electrolytes using naturally occurring antibiotics were reported by Eisenman *et al.*[1] in 1967. The discovery of synthetic macrocyclic ligands such as crown ethers[2] and cryptands[3] and their specific ion-bonding properties encouraged their use for the extraction of metal ions from aqueous to non-aqueous media.[4–27] Among the factors that should be taken into consideration in solvent extraction processes involving liquid–liquid systems and chelating agents are those concerned with the recovery of the solvent as well as the extracting material. The latter factor seems to be more relevant in the case of crown ethers and cryptands because of the relatively high cost of these ligands. Hence, the use of solid materials containing macrocyclic ligands, easily recycled, is greatly advantageous. Among these materials are those prepared by Blasius and coworkers[28–36] using crown ethers and cryptands as anchor groups. Distribution data as reported by these authors[31,36] for several 1:1 electrolytes in a water–resin system are referred to a given electrolyte concentration.

This work is concerned with measurements of distribution data at several electrolyte concentrations for a number of alkali metal salts in the water–ϕDB18C6‡ system at 25°C in order to derive an expression for the equilibrium constant for the extraction process.

EXPERIMENTAL

Resin preparation

ϕDB18C6 was prepared according to the technique suggested by Blasius *et al.*,[28] using DB18C6 (Sigma Chemical Co.), formic acid (BDH) [98% (w/v)] and formaldehyde (BDH) [37.40% (w/v)]. The product obtained was extracted with methanol (May & Baker Ltd) for 48 h, dried in a vacuum oven at 100°C for 1 day and finally milled in a mortar. It was kept in a desiccator with P_4O_{10} for a period of at least 2 weeks before use in order to ensure the minimal amount of water in the sample. The water content of the resin determined by a thermogravimetric method, using a Stanton Redcroft TG 750 thermobalance, was never greater than 2%. The percentages of C and H determined by microanalysis carried out at the University of Surrey were 68.39 and 5.95%, respectively.

Reagents used

Potassium thiocyanate (KSCN), potassium iodide (KI), potassium bromide (KBr), potassium chloride (KCl), sodium thiocyanate ($NaSCN \cdot H_2O$),

* Author to whom correspondence should be addressed.
† Present address: Universidad Nacional de Santiago del Estero, Avda Belgrano 1912(S), Santiago del Estero, Argentina.

‡ Throughout this paper we use the notation given by Blasius to indicate the resin containing dibenzo-18-crown-6 (DB18C6) as anchor group.

sodium iodide (NaI), rubidium iodide (RbI) and caesium iodide (CsI) (all BDH Analar grade) were dried at 105°C for several days before use. Potassium and sodium picrate (KPi and NaPi) were prepared by neutralizing a solution of picric acid with the corresponding hydroxide solution [5% (w/v)]. The yellow precipitate formed was then filtered off and the product obtained was twice recrystallized from water and dried for several days in a vacuum oven at 60°C.

Capacity measurements of ϕDB18C6 and 1:1 electrolytes in aqueous solution at 25°C

The resin was accurately weighed (±0.00001 g) in a plastic container. A volume (50 cm^3) of an accurately analysed aqueous solution of the electrolyte was added. The contents left in a thermostat (25 ± 0.05°C) under continuous stirring. After an overnight equilibration period an aliquot of the solution was taken and analysed. A further volume (25 cm^3) of solution was added to the resin and the container was left in a thermostat for a further period of 12 h. The procedure was followed subsequently until no further uptake of electrolyte by the resin was observed. This was done in duplicate.

Distribution experiments

To weighed samples of resin (±0.00001 g) were added known volumes of accurately analysed solutions of different electrolye concentration. The mixture was left in a water bath at 25 ± 0.05°C until equilibration was attained. Aliquot samples of the equilibrium solutions were removed and analysed by the methods described below. Blank experiments were carried out by equilibrating weighed samples of resin with water. No presence of distribuends were detected.

Methods of analysis

Halides and thiocyanates were determined by the volumetric method suggested by Vogel[37] based on the precipitation of the halide and thiocyanate by the addition of silver nitrate in the presence of an adsorption indicator like dichlorofluoroscein in the case of chlorides and thiocyanates, and eosin in the case of bromides and iodides. The results were checked by potentiometric titrations.

Picrates were analysed spectrophotometrically at 350 nm using a Pye–Unicam SP 8100 visible–UV spectrophotometer. The extinction coefficient as calculated by regression analysis of the data was 14.473 $cm^{-1}\ M^{-1}$.

RESULTS AND DISCUSSION

Distribution ratio

The value obtained in this work for the capacity of ϕDB18C6 from microanalysis (2.59×10^{-3} mol g^{-1} dry resin) is in excellent agreement with that reported by Blasius *et al.*[35] The effective capacities of ϕDB18C6 at 25°C, defined as the maximum amount of electrolyte taken up by the resin for the different 1:1 electrolytes when water is the reaction media, are reported in Table 1. Taking into account the number of crown ether units in the polymer framework as given by microanalysis data, it is quite clear from the results that, for all 1:1 electrolytes, the value of 2.59×10^{-3} mol g^{-1} of dry resin is not obtained when water is used as the solvent. This observation is again in line with results previously reported by Blasius.

The variation of the distribution coefficients at 25°C with the initial molar concentration of the alkali-metal salts is shown in Fig. 1 for KSCN, KI, KBr, KCl, NaSCN and NaI, and in Fig. 2 for KPi and NaPi. It was not possible to measure the distribution ratio for KPi at higher concentrations than 2×10^{-2} mol cm^{-3}. The solubility of this salt in water is 2.36×10^{-3}.[39] Figure 3 shows the distribution data obtained for RbI and CsI. For all the electrolytes considered distribution values generally decrease with increasing solution concentration, this effect being more pronounced for electrolytes containing large anions such as iodide, thiocyanate and picrates. The clear dependence of the distribution ratio with the initial concentration of the electrolyte in the solution phase could be attributed to an increase in interaction in the resin phase as the number of sites available for extraction decreases. The distribution data shows the influence of the anion on the extraction of the alkali-metal cations from the

aqueous solution by ϕDB18C6. Considering the potassium salts, values for the distribution coefficients are in the order $Pi^- > SCN^- > I^- > Br^- > Cl^-$. Comparison of partition data for a given cation and different anions in a water–non-aqueous media system clearly show that the transfer of the anion plays an important role in the distribution of the cation. The results obtained from distribution studies for the 1 : 1 electrolytes in the ϕDB18C6–water system shows that the distribution coefficients obtained follow the same trend as that generally observed from the free energy of transfer

data of anions (Ph_4AsPh_4B convention) from water to non-aqueous solvents.[38,39]

Extraction equilibrium constant

The resin used in this work is characterized by an anchor group (DB18C6) containing donor atoms capable of forming strong co-ordinative bonds with metal ions. Since electroneutrality must be maintained, cations and anions from the solution enter the resin phase. Provided that the electrolytes are fully dissociated in the solvent, the process taking place when a solution of 1 : 1 electrolyte ($M^+ + A^-$) is equilibrated with a resin containing an anchor group (L) may be described by:

$$M^+(aq.) + A^-(aq.) + \overline{nL} \rightarrow \overline{M^+L_nA^-}, \qquad (1)$$

where barred formulae are used to indicate the species in the resin phase. In eqn (1) n is defined as the average number of moles of crown ether units that take up 1 mol of the electrolyte from the solution phase. The n value is obtained from the ratio between the total capacity (C_T^-) as obtained from microanalysis and the effective capacity of the resin as shown in Table 1. If the molar fraction scale is chosen for the resin phase and the molar scale for the solution phase, the rational equilibrium constant (K_{ext}) for eqn (1) may be represented by:

$$K_{ext} = \frac{\bar{x}_{(M^+L_nA^-)}}{[M^+]_{aq.}[A^-]_{aq.}[1 - n\bar{x}_{(M^+L_nX^-)}]^n}, \qquad (2)$$

where $\bar{x}_{(M^+L_nA^-)}$ and $[1 - n\bar{x}_{(M^+L_nA^-)}]$ are the notations used to indicate the mole fraction of the electrolyte and ligand in the resin phase, respectively, and $[M^+]_{aq.}$ and $[A^-]_{aq.}$ are the equilibrium molar concentrations of the cation and anion in the solution phase. The rational distribution coefficient (D_R) may be defined by:

$$D_R = \frac{\bar{x}_{(M^+L_nA^-)}}{[M^+]_{aq.}}. \qquad (3)$$

Replacing eqn (3) in eqn (2) gives:

$$K_{ext} = \frac{D_R}{[A^-]_{aq.}[1 - n\bar{x}_{(M^+L_nA^-)}]^n} \quad (4)$$

Equation (5) is simply a rearranged form of eqn (2):

$$K_{ext}[1 - n\bar{x}_{(M^+L_nA^-)}]^n = \frac{D_R}{[A^-]_{aq.}}. \quad (5)$$

Taking logarithms on both sides of eqn (5), eqn (6) is obtained:

$$\log \frac{D_R}{[A^-]_{aq.}} = \log K_{ext} + \log [1 - n\bar{x}_{(M^+L_nA^-)}]^n. \quad (6)$$

According to eqn (6) a plot of log $D_R/[A^-]_{aq.}$ against log $[1 - n\bar{x}_{(M^+L_nA^-)}]^n$ should give a straight line. The intercept of this line will give log K_{ext} and the slope should be equal to unity. Figure 4 shows the plots obtained for the electrolytes KSCN, KI, KBr, KCl, KPi, NaSCN, NaI, NaPi, RbI and CsI. In all cases a linear relationship was obtained with slope values about unity which indicates that the assumptions made to derive eqn (6) seem to be reasonable. The apparent equilibrium constants (log K_{ext}) as obtained by eqn (6) for 1:1 electrolytes are presented in Table 2.

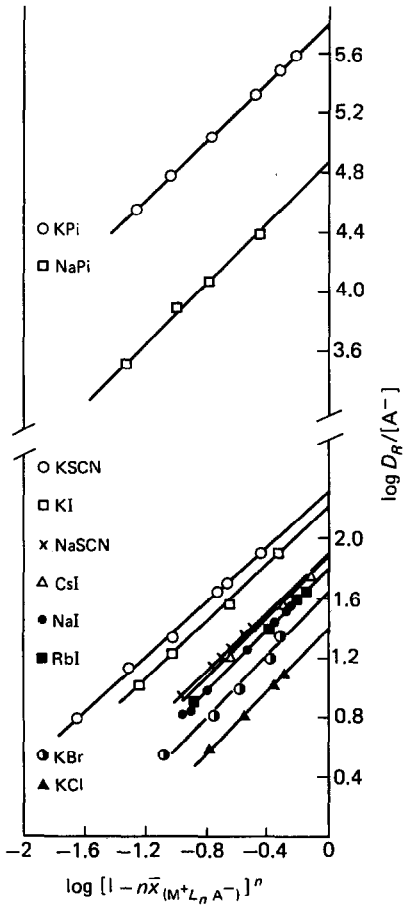

Fig. 4. Plot of log $D_R/[A^-]$ against log $[1 - n\bar{x}_{(M^+L_nA^-)}]^n$ in water at 298 K.

Table 2. Rational equilibrium constants for the extraction of 1:1 electrolytes from aqueous solutions at 298 K using eqn (6) in text

Electrolyte	log K_{ext}
KSCN	2.33
KI	2.23
KBr	1.64
KCl	1.40
KPi	5.81
NaSCN	1.91
NaI	1.84
NaPi	4.85
RbI	1.79
CsI	1.90

The equilibrium constants (log K_{ext}) reflect the selectivity of ϕDB18C6 towards the different 1:1 electrolytes. Quite remarkable is the effect of the anion on the extraction constants, particularly the picrates. An approximate evaluation can be made by taking the ratio between K_{ext} values for the electrolytes containing the same cation and different anions. It is shown that the extraction of a given cation, in this case potassium, is increased by factors of about 1.5×10^4, 8.9×10^3, 2.1×10^3 and 1.5×10^3 when picrate is the anion with respect to chloride, bromide, iodide and thiocycnate, respectively. Although the values for the extraction constants (log K_{ext}) are only apparent, the results obtained are still undoubtedly of considerable practical importance.

MIXED ISOCYANIDE–1,4-DIAZA-1,3-BUTADIENE COMPLEXES OF MOLYBDENUM AND TUNGSTEN—II.* SPECIES OF THE TYPE $[M(CO)_3(CNR)(R'\text{-DAB})]^{1+,0,1-}$

ANDREW BELL and RICHARD A. WALTON†

Department of Chemistry, Purdue University, West Lafayette, IN 47907, U.S.A.

(*Received* 8 *May* 1985; *accepted* 5 *September* 1985)

Abstract—The complexes $M(CO)_4(R'\text{-DAB})$ (M = Mo or W; R'-DAB = R'—N=CH—CH=N—R'; R' = *i*-Pr, *t*-Bu, Cy or *p*-tol) undergo substitution of a single CO ligand by isocyanide ligands RNC (R = Me, $CHMe_2$, CMe_3, C_6H_{11} or xylyl), in refluxing toluene to give *fac*-$M(CO)_3(CNR)(R'\text{-DAB})$. Synthesis of the latter complexes can also be achieved, at ambient temperature, through the use of the nitrile complexes, $Mo(CO)_3(NCMe)_3$ and $W(CO)_3(NCEt)_3$: the method involves substitution of the nitrile ligands first by R'-DAB, then by RNC. The intermediate compounds $Mo(CO)_3(NCMe)(R'\text{-DAB})$ and $W(CO)_3(NCEt)(R'\text{-DAB})$ have also been isolated and characterized. Oxidation of dark blue-purple $Mo(CO)_3(NCMe)(t\text{-Bu-DAB})$ and $Mo(CO)_3(CNR)(t\text{-Bu-DAB})$ (R = Me or CMe_3) with $[Cp_2Fe]PF_6$ in dichloromethane solution produces the paramagnetic (17-electron), orange complexes $[Mo(CO)_3(NCMe)(t\text{-Bu-DAB})]PF_6$ and $[Mo(CO)_3(CNR)(t\text{-Bu-DAB})]PF_6$, respectively. The molybdenum cations, $[Mo(CO)_3(NCMe)(t\text{-Bu-DAB})]PF_6$ and $[Mo(CO)_3(CNCMe_3)(t\text{-Bu-DAB})]PF_6$, react with two and one equivalent of *tert*-butyl isocyanide, respectively, to yield dark red *cis, trans*-$[Mo(CO)_2(CNCMe_3)_2(t\text{-Bu-DAB})]PF_6$. Reduction of *cis, trans*-$[Mo(CO)_2(CNCMe_3)_2(t\text{-Bu-DAB})]PF_6$ with cobaltocene in acetone yields the analogous dark blue zerovalent species *cis, trans*-$Mo(CO)_2(CNCMe_3)_2(t\text{-Bu-DAB})$. The compounds $[Mo(CO)(CNR)_4(t\text{-Bu-DAB})](PF_6)_2$ and $Mo(CO)_3(CNR)(t\text{-Bu-DAB})$ are produced, via a disproportionation reaction, when solutions of the cations $[Mo(CO)_3(CNR)(t\text{-Bu-DAB})]^+$ (R = Me or CMe_3) are reacted with ~three equivalents of RNC. On the other hand, the reaction between *tert*-butyl isocyanide and $[Mo(CO)_3(CNCMe_3)(i\text{-Pr-DAB})]^+$ gives seven-coordinate $[Mo(CNCMe_3)_5(i\text{-Pr-DAB})](PF_6)_2$ and $Mo(CO)_3(CNCMe_3)(i\text{-Pr-DAB})$. The ligand-based reduction of the complexes $M(CO)_3(CNR)(R'\text{-DAB})$ (M = Mo or W) is readily accessible in THF upon addition of one molar equivalent of THF-soluble $LiEt_3BH$ to yield solutions that contain the radical anions $[M(CO)_3(CNR)(R'\text{-DAB})]^{-\cdot}$. The complexes synthesized in this work have been characterized on the basis of their spectroscopic and electrochemical properties, including ESR spectral studies on the paramagnetic 17- and 19-electron complexes.

We have shown[1] that the reactions of the molybdenum(II) complexes $Mo(CO)_3(R'\text{-DAB})(SnCl_3)Cl$, where R'-DAB represents R'—N=CH—CH=N—R', with an excess of alkyl isocyanide (CNR) in the presence of KPF_6 lead to the seven-coordinate mixed isocyanide–R'-DAB species

$$[Mo(CNR)_4(R'\text{-DAB})Cl]PF_6$$

and

$$[Mo(CNR)_5(R'\text{-DAB})](PF_6)_2$$

in the case of R' = *i*-Pr or Cy. However, when the *tert*-butyl-DAB (*t*-Bu-DAB) ligand is used, such reactions proceed with the reductive elimination of the elements of $SnCl_4$ and the formation of $Mo(CO)_3(CNR)(t\text{-Bu-DAB})$. A similar reaction was used[1] to give the analogous tungsten(0) complex $W(CO)_3(CNR)(t\text{-Bu-DAB})$ in the case of R = CMe_3. We have now developed some general procedures for the synthesis of a broad range of complexes of the

† Author to whom correspondence should be addressed.

type $M(CO)_3(CNR)(R'\text{-DAB})$. In this report we give an account of these syntheses and a full characterization of these complexes, including an examination of their redox chemistry. The generation and isolation of the 17-, 18- and 19-electron species $[M(CO)_3(CNR)(R'\text{-DAB})]^{1+,0,1-}$ are described.

EXPERIMENTAL

Starting materials

The following compounds were prepared by standard literature procedures: methyl isocyanide,[2] *iso*propyl isocyanide,[3] *tert*-butyl isocyanide,[3] cyclohexyl isocyanide,[3] *N,N'*-di-*iso*-propylethylenediimine [*iso*propyl-DAB (*i*-Pr-DAB)],[4] *N,N'*-di-*tert*-butylethylenediimine (*t*-Bu-DAB),[4] *N,N'*-dicyclohexylethylenediimine [cyclohexyl-DAB (Cy-DAB)][4,5] $Mo(CO)_4(R'\text{-DAB})$ (R' = *i*-Pr, *t*-Bu or Cy).[6] The complex $W(CO)_4$(t-Bu-DAB) was prepared by heating a mixture of $W(CO)_6$ and *t*-Bu-DAB in xylene at reflux for 24 h. The work up was then identical to that described by tom Dieck.[6] Lithium triethylborohydride [1.0 M $LiEt_3BH$ in THF ("Super-Hydride"), Aldrich Chemical Co.], ferrocene, cobaltocene and 2,6-dimethylphenyl isocyanide (xylylNC, Fluka AG) were obtained from commercial sources as were all reagents and solvents. The solvents dichloromethane, acetonitrile and THF were distilled under N_2 from P_4O_{10}, CaH_2 and sodium benzophenone ketyl, respectively, before use.

The hexacarbonyls $Mo(CO)_6$ and $W(CO)_6$ were obtained from Pressure Chemical Co. and were converted into the nitrile derivatives $Mo(CO)_3(NCMe)_3$ and $W(CO)_3(NCEt)_3$ using established procedures.[7,8] For convenience in handling, these nitrile complexes were usually generated *in situ* and then reacted further with RNC or R'-DAB ligands.

Samples of the oxidizing agent ferricinium hexafluorophosphate ($[Cp_2Fe]PF_6$) were prepared as described in the literature.[9]

Reaction procedures

All reactions were carried out under a dry nitrogen atmosphere, and all reaction solvents were dried and deoxygenated prior to use by purging with N_2 gas for 15 min. In those cases where compounds were prepared by very similar procedures (see Sections A–D) details of representative preparations only will be given. In those instances where microanalytical data are not given, identification of products is based upon their spectroscopic and electrochemical properties.

A. Preparation of $Mo(CO)_3(NCMe)(R'\text{-DAB})$ (R' = *t*-Bu or Cy). (i) $Mo(CO)_3(NCMe)$(*t*-Bu-DAB). A quantity of $Mo(CO)_3(NCMe)_3$ was generated *in situ* by heating $Mo(CO)_6$ (5.0 g, 18.94 mmol) in 50 cm^3 of freshly distilled acetonitrile for 36 h. Without isolating the tris(acetonitrile) product, solid *t*-Bu-DAB (3.20 g, 18.94 mmol) was added to the pale yellow solution. The reaction mixture was stirred at room temperature for 30 min, whereupon the solution turned dark purple and a dark blue-purple microcrystalline material separated. The solid was collected by filtration and washed with diethyl ether and hexane and dried *in vacuo*. A further quantity of the product was obtained by evaporating the filtrate to dryness. Recrystallization was effected from an acetonitrile–petroleum ether mixture to give dark purple crystals having a metallic luster; yield 7.07 g (96%). Found: C, 46.5; H, 6.0. Calc. for $C_{15}H_{23}MoN_3O_3$: C, 46.3; H, 5.9%.

(ii) $Mo(CO)_3(NCMe)$(Cy-DAB). This product was prepared by a procedure analogous to that described in Section A(i): yield 92%.

B. Preparation of $W(CO)_3(NCEt)(R'\text{-DAB})$ (R' = *i*-Pr, *t*-Bu *or* Cy). (i) $W(CO)_3(NCEt)$(*i*-Pr-DAB). A 100-cm three-necked flask was charged with $W(CO)_3(NCEt)_3$ (2.0 g, 4.62 mmol) and *i*-Pr-DAB (0.711 g, 5.08 mmol). Addition of 25 cm^3 of dichloromethane by syringe and stirring the mixture under a nitrogen atmosphere resulted in the formation of a royal blue solution. The mixture was then stirred vigorously for 2 h at ambient temperature. After this period, the reaction solution was filtered to remove a small amount of a beige insoluble material, which was subsequently discarded, and the dark blue filtrate was taken to dryness under a stream of nitrogen. The purple-blue product was recrystallized from propionitrile–petroleum ether mixtures to give shiny dark purple platelets: yield 1.77 g (83%). Found: C, 36.6; H, 4.7. Calc. for $C_{14}H_{21}N_3O_3W$: C, 36.3; H, 4.5%.

(ii) $W(CO)_3(NCEt)$(*t*-Bu-DAB). Yield 74%. Found: C, 39.6; H, 5.7%. Calc. for $C_{16}H_{26}N_3O_3W$: C, 39.1; H, 5.1%.

(iii) $W(CO)_3(NCEt)$(Cy-DAB). Yield 86%. Found: C, 43.1; H, 5.3. Calc. for $C_{20}H_{29}N_3O_3W$: C, 44.2; H, 5.3%.

C. Reactions of $M(CO)_4(R'\text{-DAB})$ (M = Mo *or* W) *with isocyanides*. (i) $Mo(CO)_3(CNCMe_3)$(*t*-Bu-DAB). A mixture of $Mo(CO)_4$(*t*-Bu-DAB) (1.00 g, 2.66 mmol) and 1.2 equivalents of *tert*-butyl isocyanide (0.34 cm^3, 3.20 mmol) in 30 cm^3 of toluene was stirred for 1 h at reflux. During the reaction period, the solution turned from a dark red to a royal blue. Upon cooling the reaction solution to 0°C,

dark purple-blue crystals precipitated. The product was collected by filtration and washed with copious amounts of diethyl ether and petroleum ether prior to being dried *in vacuo*. An additional quantity of the product was obtained by taking the blue toluene filtrate to dryness and recrystallizing the product from acetone–diethyl ether: yield 0.92 g (80%). Found: C, 50.5; H, 7.1; N, 9.7. Calc. for $C_{18}H_{29}MoN_3O_3$: C, 50.1; H, 6.8; N, 9.7%.

(ii) $Mo(CO)_3(CNMe)(t\text{-Bu-DAB})$. Yield 54%. Found: C, 47.1; H, 6.0. Calc. for $C_{15}H_{23}MoN_3O_3$: C, 46.3; H, 5.9%.

(iii) $Mo(CO)_3(CNCHMe_2)(t\text{-Bu-DAB})$. Yield 63%. Found: C, 49.0; H, 7.3. Calc. for $C_{17}H_{27}MoN_3O_3$: C, 48.9; H, 6.5%.

(iv) $Mo(CO)_3(CNC_6H_{11})(t\text{-Bu-DAB})$. Yield 67%. Found: C, 52.5; H, 7.2. Calc. for $C_{20}H_{31}MoN_3O_3$: C, 52.5; H, 6.8%.

(v) $Mo(CO)_3(CNxylyl)(t\text{-Bu-DAB})$. Yield 74%. Found: C, 54.9; H, 5.7. Calc. for $C_{22}H_{29}MoN_3O_3$: C, 55.1; H, 6.1%.

(vi) $Mo(CO)_3(CNCMe_3)(i\text{-Pr-DAB})$. Yield 58%. Found: C, 47.5; H, 6.1. Calc. for $C_{16}H_{25}MoN_3O_3$: C, 47.6; H, 6.2%.

(vii) $W(CO)_3(CNMe)(t\text{-Bu-DAB})$. Yield 73%. Found: C, 45.9; H, 5.6. Calc. for $C_{15}H_{23}MoN_3O_3$: C, 46.3; H, 5.9%.

(viii) $W(CO)_3(CNCMe_3)(t\text{-Bu-DAB})$. Yield 68%. Found: C, 41.4; H, 5.8. Calc. for $C_{18}H_{29}N_3O_3W$: C, 41.6; H, 5.6%.

(ix) $W(CO)_3(CNxylyl)(t\text{-Bu-DAB})$. Yield 75%. Found: C, 46.9; H, 5.3. Calc. for $C_{22}H_{29}N_3O_3W$: C, 46.6; H, 5.2%.

D. Preparation of $M(CO)_3(CNR)(R'\text{-DAB})$ *from* $M(CO)_3(CNR)_3$ (M = M *or* W). (i) $Mo(CO)_3(CNCMe_3)(Cy\text{-DAB})$. A quantity of $Mo(CO)_3(NCMe)_3$ was prepared by heating a mixture of $Mo(CO)_6$ (3.0 g, 11.4 mmol) and 50 cm^3 of freshly distilled acetonitrile at reflux for 24 h. The reaction mixture was then allowed to cool to room temperature and Cy-DAB (2.53 g, 11.5 mmol) was added to the solution. The mixture was stirred for 15 min at ambient temperature by which time the solution had turned a royal blue color. Addition of *tert*-butyl isocyanide (1.25 cm^3, 11.8 mmol) yielded a dark purple-blue solution upon further stirring of the mixture for 15 min. Filtration of the reaction mixture afforded an olive green insoluble material, and the filtrate was taken to dryness under reduced pressure. The purple-blue crystals which resulted were recrystallized from acetone–petroleum ether and dichloromethane–hexane mixtures: yield 4.29 g (78%). Found: C, 54.0; H, 6.7. Calc. for $C_{22}H_{33}MoN_3O_3$: C, 54.7; H, 6.8%.

(ii) $Mo(CO)_3(CNCMe_3)(t\text{-Bu-DAB})$. Yield 96%. The identity of the product was confirmed by its spectroscopic and electrochemical properties which were identical to those of an authentic sample as prepared in Section C(i).

(iii) $Mo(CO)_3(CNCMe_3)(i\text{-Pr-DAB})$. Yield 84%.

(iv) $Mo(CO)_3(CNMe)(t\text{-Bu-DAB})$. Yield 75%.

(v) $Mo(CO)_3(CNCHMe_2)(Cy\text{-DAB})$. Yield 78%.

(vi) $Mo(CO)_3(CNxylyl)(i\text{-Pr-DAB})$. Yield 92%.

(vii) $Mo(CO)_3(CNxylyl)(Cy\text{-DAB})$. Yield 94%.

(viii) $Mo(CO)_3(CNCMe_3)(p\text{-tol-DAB})$. Yield 32%.

An alternative to the preceding procedure involved the reaction of the isolated mononitrile complexes $M(CO)_3(NCR)(R'\text{-DAB})$ (see Sections A and B) with one equivalent of RNC (R = Me, $CHMe_2$, CMe_3, C_6H_{11} or xylyl) at room temperature in deoxygenated dichloromethane. Representative experimental details for this synthetic method are described for the preparation of $W(CO)_3(CNCMe_3)(i\text{-Pr-DAB})$ from $W(CO)_3(NCEt)(i\text{-Pr-DAB})$.

(ix) $W(CO)_3(CNCMe_3)(i\text{-Pr-DAB})$. Typically, a quantity of $W(CO)_3(NCEt)(i\text{-Pr-DAB})$ (0.5 g, 1.08 mmol) was stirred in 15 cm^3 of dry, deoxygenated dichloromethane at room temperature. The addition of *tert*-butyl isocyanide (0.114 cm^3, 1.08 mmol) to the royal blue solution changed the reaction medium to a dark purple color. The mixture was stirred at room temperature for 6 h, and then taken to dryness under reduced pressure to yield small dark purple crystals. The product was washed with copious amounts of petroleum ether, and the solid then recrystallized from acetone–diethyl ether: yield 0.45 g (85%). Found: C, 39.5; H, 5.5. Calc. for $C_{16}H_{25}N_3O_3W$: C, 39.2; H, 5.1%.

(x) $W(CO)_3(CNxylyl)(i\text{-Pr-DAB})$. Yield 86%.

(xi) $W(CO)_3(CNCMe_3)(Cy\text{-DAB})$. Yield 91%.

(xii) $W(CO)_3(CNxylyl)(Cy\text{-DAB})$. Yield 94%.

(xiii) $W(CO)_3(CNC_6H_{11})(t\text{-Bu-DAB})$. Yield 85%.

E. Oxidation of $Mo(CO)_3(NCMe)(t\text{-Bu-DAB})$ *to* $[Mo(CO)_3(NCMe)(t\text{-Bu-DAB})]PF_6$. A 25-$cm^3$ three-necked flask was charged with $Mo(CO)_3(NCMe)(t\text{-Bu-DAB})$ (0.5 g, 1.285 mmol) and $[Cp_2Fe]PF_6$ (0.425 g, 1.285 mmol). The addition of 10 cm^3 of dry acetonitrile with stirring resulted in an immediate reaction to form a dark orange-red solution. The reaction mixture was then filtered under nitrogen to remove any insoluble materials, which were discarded, and 80 cm^3 of anhydrous diethyl ether were added to the filtrate. The bright orange crystals that precipitated after about 10 min were collected by filtration and washed with copious amounts of diethyl ether before being dried *in vacuo*: yield 0.49 g (71%). Found: C, 34.0; H, 4.9. Calc. for $C_{15}H_{23}F_6MoN_3O_3P$: C, 33.7; H, 4.3%.

The air-sensitive orange solid could be recrystallized from acetonitrile–diethyl ether and dichloromethane–diethyl ether mixtures. Orange-

red colored solutions of the complex turned colorless almost immediately upon exposure to air.

F. Oxidations of $Mo(CO)_3(CNR)(R'\text{-DAB})$. (i) $[Mo(CO)_3(CNMe)(t\text{-Bu-DAB})]PF_6$. A 15-$cm^3$ aliquot of freshly distilled dichloromethane was syringed into a flask containing $Mo(CO)_3(CNMe)(t\text{-Bu-DAB})$ (0.25 g, 0.643 mmol) and $[Cp_2Fe]PF_6$ (0.215 g, 0.650 mmol), whereupon the solution immediately changed from royal blue to dark red-orange in color. The reaction mixture was filtered under nitrogen, and addition of 50 cm^3 of anhydrous diethyl ether to the filtrate precipitated an orange solid. The product was collected by filtration, washed with diethyl ether, and dried *in vacuo*. Recrystallization from dichloromethane–diethyl ether afforded bright orange crystals of the above formulation: yield 0.254 g (74%). Found: C, 33.7; H, 4.5. Calc. for $C_{15}H_{23}F_6MoN_3O_3P$: C, 33.7; H, 4.3%.

The solid is extremely air- and moisture-sensitive in the solid state, and solutions of the complex decompose very rapidly when exposed to the air.

(ii) $[Mo(CO)_3(CNCMe_3)(t\text{-Bu-DAB})]PF_6$. Yield 82%.

Although the compounds $[Mo(CO)_3(CNR)(R'\text{-DAB})]PF_6$ (R = Me or CMe_3, R' = *t*-Bu) could be isolated as solids, their use as starting complexes in this way was inconvenient because of their extreme air sensitivity. Accordingly, when solutions of the monocations were required they were normally generated *in situ* through the reaction of $Mo(CO)_3(CNR)(R'\text{-DAB})$ with $[Cp_2Fe]PF_6$ in dichloromethane solution. These solutions were then used for reactions involving isocyanide and/or R'-DAB.

G. Preparation of cis, trans-$[Mo(CO)_2(CNCMe_3)_2(t\text{-Bu-DAB})]PF_6$. (i) *From* $[Mo(CO)_3(CNCMe_3)(t\text{-Bu-DAB})]PF_6$. A dark orange-red solution of the cation $[Mo(CO)_3(CNCMe_3)(t\text{-Bu-DAB})]PF_6$ was prepared by stirring a mixture of $Mo(CO)_3(CNCMe_3)(t\text{-Bu-DAB})$ (0.60 g, 1.39 mmol) and $[Cp_2Fe]PF_6$ (0.465 g, 1.41 mmol) in 15 cm^3 of freshly distilled dichloromethane at room temperature for 15 min. A mixture of *tert*-butyl isocyanide (0.15 cm^3, 1.42 mmol) and *t*-Bu-DAB (0.234 g, 1.39 mmol) dissolved in 15 cm^3 of dry dichloromethane was then added dropwise to the resulting solution. The orange-red solution changed to a dark red color during the addition of the reagents and CO gas evolution occurred. The reaction mixture was stirred at room temperature for 30 min, filtered, and the filtrate taken to dryness under reduced pressure. The bright red solid so obtained was washed with copious amounts of diethyl ether until the washes were colorless in order to ensure that all traces of ferrocene and unreacted $Mo(CO)_3(CNCMe_3)(t\text{-Bu-DAB})$ had been removed. The product was then recrystallized from dichloromethane–diethyl ether and acetone–diethyl ether mixtures: yield 0.77 g (88%). Found: C, 41.6; H, 6.6. Calc. for $C_{22}H_{38}F_6MoN_4O_2P$: C, 41.8; H, 6.1%.

(ii) *From* $[Mo(CO)_3(NCMe)(t\text{-Bu-DAB})]PF_6$. A sample of the complex $[Mo(CO)_3(NCMe)(t\text{-Bu-DAB})]PF_6$ (0.305 g, 0.571 mmol) was dissolved in 15 cm^3 of freshly distilled dichloromethane, and a mixture of *tert*-butyl isocyanide (0.121 cm^3, 1.15 mmol) and *t*-Bu-DAB (0.1 g, 0.595 mmol) dissolved in 15 cm^3 of dichloromethane was then added dropwise with rapid stirring. Reaction for 30 min and a work-up and purification procedure as described in Section G(i) gave crystals of *cis, trans-*$[Mo(CO)_2(CNCMe_3)_2(t\text{-Bu-DAB})]PF_6$; yield 0.31 g (85%).

H. Reduction of cis, trans-$[Mo(CO)_2(CNCMe_3)_2(t\text{-Bu-DAB})]PF_6$ *to form cis, trans-*$Mo(CO)_2(CNCMe_3)_2(t\text{-Bu-DAB})$. Dry deoxygenated acetone (15 cm^3) was syringed into a flask containing *cis, trans-*$[Mo(CO)_2(CNCMe_3)_2(t\text{-Bu-DAB})]PF_6$ (0.418 g, 0.662 mmol) and Cp_2Co (0.125 g, 0.662 mmol). The mixture was stirred at room temperature for 30 min during which time the color of the solution became turquoise blue. The solution was filtered under nitrogen to remove an olive green solid ($[Cp_2Co]PF_6$) and the clear, blue filtrate was evaporated to dryness under reduced pressure. The blue solid was recrystallized from diethyl ether–petroleum ether and dichloromethane–petroleum ether mixtures: yield 0.21 g (65%). Found: C, 53.8; H, 8.6. Calc. for $C_{22}H_{38}MoN_4O_2$: C, 54.3; H, 7.8%.

I. Reactions of $[Mo(CO)_3(CNR)(R'\text{-DAB})]PF_6$ *with isocyanides.* (i) $[Mo(CO)(CNCMe_3)_4(t\text{-Bu-DAB})](PF_6)_2$. A solution of $[Mo(CO)_3(CNCMe_3)(t\text{-Bu-DAB})]PF_6$ was generated by stirring a mixture of $Mo(CO)_3(CNCMe_3)(t\text{-Bu-DAB})$ (0.40 g, 0.928 mmol) and $[Cp_2Fe]PF_6$ (0.31 g, 0.937 mmol) in 25 cm^3 of dichloromethane at room temperature for 15 min. The dark red-orange solution was filtered under nitrogen, and three equivalents of *tert*-butyl isocyanide (0.295 cm^3, 2.784 mmol) were added dropwise to the filtrate. The reaction mixture immediately turned a dark red-purple color and CO gas was evolved. It was stirred for 1 h and then taken to dryness under reduced pressure. The purple residue was extracted with diethyl ether to yield a red solid and a royal blue ethereal solution. The red solid was collected by filtration and recrystallized from dichloromethane–diethyl ether, and finally from methanol–diethyl ether to give red-orange crystals of $[Mo(CO)(CNCMe_3)_4(t\text{-Bu-DAB})](PF_6)_2$: yield 0.38 g (45%). Found: C, 40.4; H, 6.3; N, 9.1. Calc. for $C_{31}H_{56}F_{12}MoN_6OP_2$: C, 40.7; H, 6.1; N, 9.2%.

The blue diethyl ether filtrate was evaporated to dryness under a stream of nitrogen gas and the solid recrystallized from dichloromethane–petroleum ether to give purple-blue microcrystals: yield 0.16 g (40%). This solid was identified as $Mo(CO)_3(CNCMe_3)$(*t*-Bu-DAB) on the basis of its spectroscopic and electrochemical properties which were identical to those of an authentic sample [see Section C(i)].

(ii) $[Mo(CNCMe_3)_7](PF_6)_2$. The dropwise addition of four equivalents of *tert*-butyl isocyanide (0.98 cm^3, 9.285 mmol) to a mixture of $[Mo(CO)_3(CNCMe_3)$(*t*-Bu-DAB)$]PF_6$ (1.336 g, 2.320 mmol) {formed from $Mo(CO)_3(CNCMe_3)$(*t*-Bu-DAB) (1.0 g, 2.320 mmol) and $[Cp_2Fe]PF_6$ (0.768 g, 2.320 mmol)} in 25 cm^3 of dichloromethane caused the red-orange solution to change color immediately to a dark purple-blue and evolution of CO to occur. The reaction mixture was stirred at room temperature for 6 h, and the solution then taken to dryness under reduced pressure. The residue was washed with copious amounts of diethyl ether to give a yellow powder and a royal blue ether solution. The yellow product was recrystallized from dichloromethane–diethyl ether and methanol–diethyl ether before drying it *in vacuo*: yield 1.0 g (45%). The identity of this yellow complex as $[Mo(CNCMe_3)_7](PF_6)_2$ was confirmed by comparison of its spectroscopic and electrochemical properties with those exhibited by an authentic sample.[10,11]

The ether extract was evaporated to dryness to yield a quantity of $Mo(CO)_3(CNCMe_3)$(*t*-Bu-DAB) (0.40 g), whose identity was confirmed by its spectroscopic and electrochemical properties.

(iii) $[Mo(CNCMe_3)_5$(*i*-Pr-DAB)$](PF_6)_2$. Dark red-purple crystals of this complex were obtained by a procedure analogous to that described in Section I(i) through the reaction between $Mo(CO)_3(CNCMe_3)$(*i*-Pr-DAB) (0.5 g, 1.266 mmol), $[Cp_2Fe]PF_6$ (0.42 g, 1.269 mmol), and three equivalents of *tert*-butyl isocyanide (0.40 cm^3, 3.79 mmol) in 15 cm^3 of freshly distilled dichloromethane: yield 0.65 g (50%). Found: C, 41.9; H, 6.8. Calc. for $C_{33}H_{61}F_{12}MoN_7P_2$: C, 42.1; H, 6.5%.

The work up of the blue filtrate followed by recrystallization of the product from dichloromethane–petroleum ether gave a small quantity of $Mo(CO)_3(CNCMe_3)$(*i*-Pr-DAB): yield 0.08 g (16%).

(iv) $[Mo(CO)(CNMe)_4$(*t*-Bu-DAB)$](PF_6)_2$. A brick red powder with this stoichiometry was obtained by the use of a procedure similar to that described in Section I(i) with $Mo(CO)_3(CNMe)$(*t*-Bu-DAB) (0.109 g, 0.281 mmol), $[Cp_2Fe]PF_6$ (0.093 g, 0.281 mmol) and three equivalents of methyl isocyanide (0.50 cm^3, 0.625 mmol) in 20 cm^3 of dichloromethane: yield 0.10 g (48%). Characterization was based on its IR spectral and cyclic voltammetric properties which were very similar to those of its *tert*-butyl isocyanide analogue.

J. Reaction of $[Mo(CO)_3(NCMe)$(*t*-Bu-DAB)$]PF_6$ *with* tert-*butyl isocyanide.* $[Mo(CO)(CNCMe_3)_4$(*t*-Bu-DAB)$](PF_6)_2$. A quantity of $[Mo(CO)_3(NCMe)$(*t*-Bu-DAB)$]PF_6$ (0.823 g, 1.542 mmol) was prepared from $Mo(CO)_3(NCMe)$(*t*-Bu-DAB) (0.6 g, 1.542 mmol) and $[Cp_2Fe]PF_6$ (0.51 g, 1.542 mmol) in 35 cm^3 of dichloromethane. Dropwise addition of five equivalents of *tert*-butyl isocyanide (0.81 cm^3, 7.710 mmol) to the resulting solution resulted in an immediate color change from dark red-orange to a dark purple-blue and the evolution of CO. A work up procedure identical to the one described in Section I(i) gave $[Mo(CO)(CNCMe_3)_4$(*t*-Bu-DAB)$](PF_6)_2$ (0.54 g, 38%) and $Mo(CO)_3(CNCMe_3)$(*t*-Bu-DAB) (0.37 g, 56%). These two products were identified on the basis of their spectroscopic and electrochemical properties which were identical to those exhibited by authentic samples of the compounds [see Sections C(i) and I(i)].

K. Attempted preparation of $[Mo(CNCMe_3)_5$(*t*-Bu-DAB)$](PF_6)_2$ *from* $[Mo(CO)(CNCMe_3)_4$(*t*-Bu-DAB)$](PF_6)_2$. A quantity of *tert*-butyl isocyanide (0.029 cm^3, 0.274 mmol) was syringed into a stirred red-orange solution of $[Mo(CO)(CNCMe_3)_4$(*t*-Bu-DAB)$](PF_6)_2$ (0.20 g, 0.219 mmol) in 25 cm^3 of dichloromethane. The reaction mixture was heated at reflux for 12 h, cooled to 0°C, and then taken to dryness under a stream of nitrogen. The yellow solid was collected, washed with water, diethyl ether and hexane, and recrystallized from acetone–diethyl ether: yield 0.13 g (61%). This product was deduced, on the basis of IR spectral and cyclic voltammetric data, to be $[Mo(CNCMe_3)_7](PF_6)_2$.[10,11]

L. Preparation of $Li[Mo(CO)_3(CNMe)$(*t*-Bu-DAB)$]$. Solutions that contained the molybdenum and tungsten radical anions $[M(CO)_3(CNR)(R'$-DAB)$]^{-\cdot}$ were prepared by the following general procedure. The tetrahydrofuran-soluble reducing agent $LiEt_3BH$ (1.0 M in THF; 0.15 cm^3, 0.150 mmol) was added dropwise to a solution of $Mo(CO)_3(CNMe)$(*t*-Bu-DAB) (0.060 g, 0.154 mmol) in 5 cm^3 of freshly distilled THF. The color of the solution changed almost immediately to a pale orange-yellow and gas evolution (BEt_3 and H_2) occurred as the monoanion was formed. Solutions containing the resulting molybdenum (and tungsten) radicals could be handled quite easily using conventional techniques.

Physical measurements

IR spectra were recorded as Nujol mulls between KBr plates or as dichloromethane solutions using an IBM Instruments IR/32 Fourier Transform (4800–400 cm^{-1}) spectrometer. Electronic absorption spectra were recorded on an IBM Instruments 9420 UV–Visible spectrophotometer. ^1H NMR spectra were recorded at 90 MHz on a Perkin–Elmer R-32 spectrometer. The residual protons of acetone-d_6 ($\delta = 2.05$ ppm vs TMS) were used as reference. Electrochemical measurements were made in dichloromethane solvents that contained 0.2 M tetra-*n*-butylammonium hexafluorophosphate (TBAH) as supporting electrolyte. $E_{1/2}$ values were determined as $(E_{p,a}+E_{p,c})/2$ and are referenced to the Ag–AgCl electrode at room temperature. Voltammetric experiments were performed using a Bioanalytical Systems Inc. Model CV-1A instrument in conjunction with a Hewlett–Packard Model 7035B x–y recorder. X-band ESR spectra were recorded using a Varian E-109 spectrometer.

Analytical procedures

Elemental microanalyses were performed by Dr H. D. Lee of the Purdue University Microanalytical Laboratory.

RESULTS AND DISCUSSION

Synthetic procedures and spectroscopic characterization of $M(CO)_3(CNR)(R'\text{-DAB})$

Two, high-yield, synthetic methods have been devised for the synthesis of the complexes $M(CO)_3(CNR)(R'\text{-DAB})$ (M = Mo or W; R = Me, $CHMe_2$, CMe_3, C_6H_{11} or xylyl; R′ = *i*-Pr, *t*-Bu, Cy or *p*-tol) as outlined by the sequence of reactions shown in eqns (1) and (2):

$$M(CO)_6 \rightarrow M(CO)_4(R'\text{-DAB}) \rightarrow M(CO)_3(CNR)(R'\text{-DAB}), \quad (1)$$

$$M(CO)_6 \rightarrow M(CO)_3(NCR)_3 \rightarrow M(CO)_3(NCR)(R'\text{-DAB}) \rightarrow M(CO)_3(CNR)(R'\text{-DAB}). \quad (2)$$

Representative examples, which are given in Experimental, show the generality of both procedures. Both methods are superior to that involving the reaction of $M(CO)_3(R'\text{-DAB})(SnCl_3)Cl$ (M = Mo or W) with RNC,[1] since these latter reactions proceed (via the reductive elimination of $SnCl_4$) only in the cases where R′ = *t*-Bu. As indicated in eqn (2), it is possible to isolate the blue-purple nitrile precursors $M(CO)_3(NCR)(R'\text{-DAB})$, and this has been done for a few such derivatives (M = Mo, R = Me, R′ = *t*-Bu or Cy; M = W, R = Et, R′ = *i*-Pr, *t*-Bu or Cy).

The new complexes prepared are dark blue or purple solids. They are generally stable to atmospheric oxygen in the solid state, and dissolve in organic solvents, especially the more polar ones, imparting an intense blue to purple coloration to the solution. It should be noted that the isocyanide complexes are very stable in solution, while solutions of the nitrile complexes decompose quite rapidly (even in deoxygenated solvents), thereby complicating the measurement of their solution spectral properties.

Microanalytical data, together with ^1H NMR spectral data (recorded in acetone-d_6),* confirmed the stoichiometries of these complexes. The chemical shifts of the azomethine protons indicate that the R′-DAB ligands are in the σ,σ-bidentate coordination mode.[12,13] Their IR spectra [ν(CN) and ν(CO) modes] are presented in Table 1, together with representative electronic absorption spectral data. As is often the case, the ν(CN) modes for the coordinated nitrile ligand are extremely weak in some instances not seen.[14] The IR spectra of the octahedral, diamagnetic complexes $M(CO)_3(CNR)(R'\text{-DAB})$, show a single isocyanide stretching mode at $\sim 2100\ cm^{-1}$ and three intense carbonyl stretching absorptions, both in the solid state and in solution, in the region 1940–1780 cm^{-1}. This implies that in the isocyanide complexes the three carbonyl ligands are in a *facial* arrangement and that the solid-state structure of the complexes persists in solution. Likewise, the nitrile complexes exhibit similar spectral properties and hence, most likely, possess the same rigid stereochemistry. This is also the structure of the 2,2′-bipyridine complex $Mo(CO)_3(NCEt)(bpy)$.[15]

The most noteworthy feature in the electronic absorption spectra of $M(CO)_3(CNR)(R'\text{-DAB})$ (M = Mo or W) is the intense absorption in the visible region ($\lambda_{max} \sim 580$ nm) assignable to a metal-to-ligand (R′-DAB) charge transfer. We find that the location and ε_{max} value of this band depends on the polarity of the solvent (solvatochromism) and the solvent shifts are comparable to those observed for the parent species $M(CO)_4(R'\text{-DAB})$.[16,17] An analogous metal-to-ligand charge-transfer band is found at 529 nm in the electronic absorption spectrum of $Mo(CO)_3(NCEt)(bipy)$.[15]

* Resonances due to the isocyanide and R′-DAB ligands had the correct integrated intensities [see A. Bell, Ph.D. Thesis, Purdue University (1985)].

[a] In V vs Ag–AgCl with a Pt-bead electrode and 0.2 M tetra-*n*-butylammonium hexafluorophosphate (TBAH) as supporting electrolyte. Recorded at a scan rate of 200 mV s^{-1}.

Redox properties of $M(CO)_3$(L)(R'-DAB) (M = Mo *or* W; L = RCN *or* RNC)

The electrochemical properties of these nitrile and isocyanide complexes are given in Table 2 along with some related data for the $M(CO)_4$(R'-DAB) complexes taken from Ref. 1. These results are in good agreement with those expected on the basis of existing data for $M(CO)_4$(R'-DAB) and $M(CO_3$(L)(R'-DAB) (L = PR_3, MeCN or THF).* The half-wave or peak potentials vs Ag–AgCl for 0.2 M TBAH–dichloromethane solutions were measured by the cyclic voltammetric technique, and the voltammograms of $Mo(CO)_3$(NCMe)(*t*-Bu-DAB) and $Mo(CO)_3(CNCMe_3)$(*t*-Bu-DAB) are shown in Fig. 1. In all instances the octahedral complexes exhibit a couple [$E_{1/2}$(ox)] corresponding to a one-electron oxidation (as determined by coulometry). For sweep rates 50 to 400 mV s^{-1}, these couples are characterized by $i_{p,a}/i_{p,c} \simeq 1$ and the ratio $i_p/v^{1/2}$ was constant, in accordance with diffusion control. The potential separation between the coupled anodic and cathodic peaks, ΔE_p, is close to 75 mV for a sweep rate of 200 mV s^{-1} and increases slightly with increase in scan rate. These properties are (with our cell configuration[19]) consistent with electron-transfer processes which are reversible or approach reversibility.

The tricarbonyl complexes $M(CO)_3$(NCR)(R'-DAB)(M = Mo, R = Me, R' = *t*-Bu or Cy; M = W, R = Et, R' = *i*-Pr, *t*-Bu or Cy) possess a reversible oxidation at *ca* +0.20 V (M = Mo or W) vs Ag–AgCl, and a second (irreversible) oxidation between +1.1 and +1.5 V. Two irreversible reductions at $E_{p,c} \sim -1.5$ and −1.9 V for M = Mo, and $E_{p,c} \sim -1.4$ and −1.8 V for M = W, are also found (Fig. 1). Similarly, the monoisocyanide complexes $M(CO)_3$(CNR)(R'-DAB) (M = Mo or W; R = Me,

* These electrochemical measurements[18] were made at a platinum bead electrode in 0.1 M tetraethylammonium perchlorate–acetonitrile solutions at ambient temperatures and a scan rate of 100 mV s^{-1}. Potentials were referenced to an Ag–AgCl electrode.

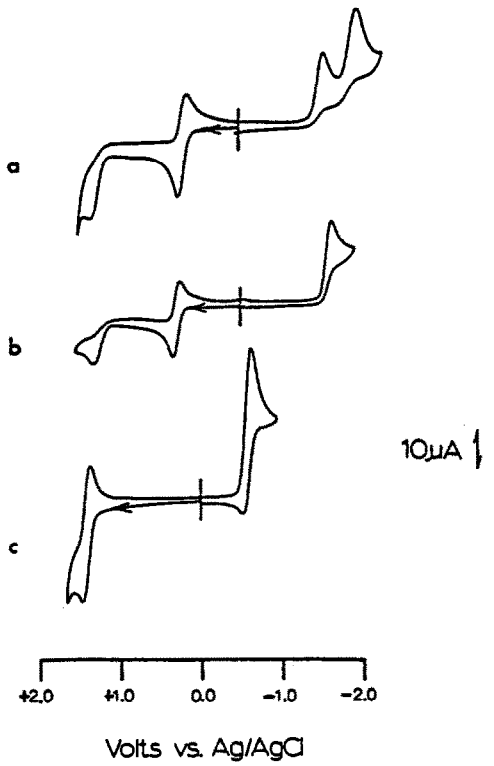

Fig. 1. Cyclic voltammograms (recorded at $v = 200$ mV s^{-1} using a Pt-bead electrode) for 0.2 M TBAH–dichloromethane solutions of: (a) $Mo(CO)_3(NCMe)(t\text{-Bu-DAB})$, (b) $M(CO)_3(CNCMe_3)(t\text{-Bu-DAB})$, and (c) $[Mo(CO)(CNCMe_3)_4(t\text{-Bu-DAB})](PF_6)_2$.

$CHMe_2$, CMe_3, C_6H_{11} or xylyl; R′ = *i*-Pr, *t*-Bu or Cy) exhibit a reversible couple at *ca* +0.30 V vs Ag–AgCl, and a second (irreversible) oxidation between +1.2 and +1.6 V is further observed. The existence of only one irreversible reduction process in the cyclic voltammogram of these complexes (at $E_{p,c} \sim -1.4$ to −1.6 V) distinguishes them from the analogous nitrile species.

In comparing the $E_{1/2}$ values of the tetracarbonyl complexes $M(CO)_4$(R′-DAB) with those of their nitrile or isocyanide derivatives (Table 2), we see that the $E_{1/2}$ values for the latter species are shifted to more negative potentials. This reflects the superior σ-donor ability of nitriles or isocyanides and/or their poorer π-accepting ability compared to CO when bound to the group 6 metals. Thus, the nitriles and isocyanides are better able to stabilize the metal(I) oxidation state relative to the CO ligand. Indeed, the bulk electrolyses of dichloromethane solutions of several $Mo(CO)_3$(L)(R′-DAB) complexes (L = MeCN or RNC) afforded solutions that contain 17-electron oxidized species. Furthermore, oxidation of the complexes $Mo(CO)_3(NCMe)(t\text{-Bu-DAB})$ and $Mo(CO)_3(CNR)$(R′-DAB) to the corresponding monocations has been achieved chemically by use of the rather mild oxidizing agent ferricinium hexafluorophosphate ($[Cp_2Fe]PF_6$). This procedure produced samples of the orange-red, crystalline, 17-electron compounds $[Mo(CO)_3(NCMe)(t\text{-Bu-DAB})]PF_6$ and $[Mo(CO)_3(CNR)(t\text{-Bu-DAB})]PF_6$ (R = Me or CMe_3) with the accompanying formation of ferrocene. The generation of the analogous tungsten monocations was not possible either by use of controlled potential electrolysis or by chemical means under the conditions we employed. This presumably attests to their reactivity and/or instability in comparison to their molybdenum congeners. While the molybdenum monocations decompose very rapidly upon exposure to oxygen, their solutions can be manipulated quite easily under nitrogen.

Relative to their neutral precursors, the monocations have IR spectra in which the ν(CO) modes shift to higher energy by 100–140 cm^{-1} (Table 3). This shift, and a similar one in the case of the ν(CN) modes of the RNC ligands, is expected because of the decrease in backbonding to the π^*-levels of the CO and RNC ligands.

The X-band ESR spectra of the paramagnetic 17-electron species were recorded at −160°C on frozen dichloromethane solutions; the measured g values are presented in Table 3, and a spectral trace of $[Mo(CO)_3(CNMe)(t\text{-Bu-DAB})]PF_6$ is shown in Fig. 2. Although some structure is apparent in the very broad signals, no semblance of hyperfine structure attributable to interaction with the coordinated nitrogens of the R′-DAB molecules is discernible.

Although the reduction processes [$E_{p,c}(1)$ and $E_{p,c}(2)$ in Table 2] which are seen in the cyclic voltammograms of 0.2 M TBAH–dichloromethane solutions of the $M(CO)_3$(L)(R′-DAB) complexes are irreversible electrochemically (Table 2 and Fig. 1), the 19-electron radical complexes $Li[M(CO)_3(CNR)(R'\text{-DAB})]$ (M = Mo or W; R = Me, CMe_3 or xylyl; R′ = *i*-Pr, *t*-Bu or Cy) have been generated chemically by utilizing the commercially available triethylborohydride reagent, viz. $LiEt_3BH$.[20] The attractiveness of this procedure is that only volatile by-products (H_2 and BEt_3) are formed, and the reducing agent is THF-soluble.

The resulting paramagnetic complexes have been characterized by X-band ESR spectroscopy (Fig. 2), and Table 4 summarizes the pertinent ESR data for the complexes. The ESR parameters indicate that the unpaired electron is centered mainly in the ligand π-system for all the radical anion complexes investigated; the coordination of the $M(CO)_3(CNR)$ moiety to the radical ligand is, however, evident from the metal isotope splittings in the ESR spectra (Fig. 2 and Table 4). Further, the ESR spectral data for

the complexes clearly distinguishes them from the previously characterized ligand radicals, and the radical anionic complxes K[M(CO)$_4$(R′-DAB)] (M = Mo or W).[18,21,22] The most prominent features of the ESR spectra can be interpreted in terms of coupling to the diazabutadiene nitrogens, azomethine protons, and protons on the alkyl substituents (i.e. R′ = *i*-Pr or Cy).

Reactivity studies

While the 18-electron neutral complexes Mo(CO)$_3$(CNR)(R′-DAB) are unreactive toward an excess of RNC or R′-DAB, activation of these complexes by a one-electron oxidation to the monocationic 17-electron species enables further substitution chemistry to be developed. Thus, the addition of dichloromethane solutions containing one equivalent and two equivalents of *tert*-butyl isocyanide, respectively, to solutions of the red-orange complexes [Mo(CO)$_3$(CNCMe$_3$)(*t*-Bu-DAB)]PF$_6$ (prepared *in situ*) and [Mo(CO)$_3$(NCMe)(*t*-Bu-DAB)]PF$_6$, gave *cis, trans*-[Mo(CO)$_2$(CNCMe$_3$)$_2$(*t*-Bu-DAB)]$^+$ with concomitant CO evolution. The dark blue neutral dicarbonyl *cis, trans*-Mo(CO)$_2$(CNCMe$_3$)$_2$(*t*-Bu-DAB) is easily prepared by the chemical reduction of the cation using cobaltocene in acetone solution. The related 2,2′-bipyridyl complex Mo(CO)$_2$(CNEt)$_2$(bpy) has been assigned a *cis, cis*-structure on the basis of its IR spectral properties.[15]

The ν(CO) and ν(CN) modes in the IR spectra of [Mo(CO)$_2$(CNCMe$_3$)$_2$(*t*-Bu-DAB)]$^{1+,0}$ complexes again proved to be useful as a means of distinguishing between the 17- and 18-electron congeners (see Table 5). The ν(CO) bands shift by between +100 and +120 cm^{-1} upon changing from the zerovalent complex to the monocation and, in addition, the ν(CN) absorption increases by *ca* 110 cm^{-1} as the formal charge on the metal complex increases; both of these shifts reflect a decrease in the π-back donation to the CO and RNC π^* molecular orbitals. The same IR spectral pattern exists for the 18-electron complex, *cis, trans*-Mo(CO)$_2$(CNCMe$_3$)$_2$(*t*-Bu-DAB) and for the oxidized species, thereby indicating that no major geometrical change is associated with the redox process (Table 5). The ^{1}H NMR spectral properties of the neutral complex support the proposed geometry and integration of 1,4-diaza-1,3-butadiene and isocyanide resonances,† together with the elemental microanalyses, showed excellent agreement with the proposed stoichiometry.

The above chemical and spectral observations are in agreement with the results of electrochemical studies which were carried out on *cis, trans*-[Mo(CO)$_2$(CNCMe$_3$)$_2$(*t*-Bu-DAB)]$^{1+,0}$ in 0.2 M TBAH–dichloromethane solution (Table 5). The substitution of one carbonyl ligand by an iso-

cyanide in $Mo(CO)_3(CNR)(R'\text{-DAB})$ to produce $Mo(CO)_2(CNR)_2(R'\text{-DAB})$ causes a change in the electrochemistry. The oxidation of $Mo(CO)_2(CNR)_2(R'\text{-DAB})$ to its monocation occurs at a lower potential [compared to that of $Mo(CO)_3(CNR)(R'\text{-DAB})$], as is expected when a carbonyl ligand is replaced by a less effective π-acceptor RNC ligand. Several electrochemical investigations have examined the *cis* ⇄ *trans* isomerizations that occur in carbonyl derivatives of the types $Mo(CO)_4(PR_3)_2$,[23] $Mo(CO)_2(P\text{–}P)_2$ [where $P\text{–}P = Ph_2P(CH_2)_nPPh_2$; $n = 1\text{–}3$[24–26] and $Mo(CO)_4(carbene)_2$[27] following their oxidation. Particularly relevant to the present case is the conversion of *cis*, *cis*-$Mo(CO)_2(CNR)_2(PR_3)_2$ to the *all trans*-isomer upon oxidation.[28] We find that no such isomerization occurs when the 18-electron complex *cis*, *trans*-$Mo(CO)_2(CNCMe_3)_2$(*t*-Bu-DAB) is oxidized. The bonding constraints and electronic properties imposed by the chelating R'-DAB ligand do not favor such a stereochemical change.

The X-band ESR spectrum of the paramagnetic species, *cis*, *trans*-$[Mo(CO)_2(CNCMe_3)_2(t\text{-Bu-DAB})]^+$, was recorded at −160°C on a frozen dichloromethane solution (Fig. 2) and the measured g values found to be as follows: $g_1 = 2.199$, $g_2 = 2.166$, and $g_3 = 1.981$.

Three equivalents of alkyl isocyanide RNC (R = Me or CMe_3) react very rapidly with the activated complexes $[Mo(CO)_3(CNR)(t\text{-Bu-DAB})]^+$ at room temperature to give the seven-coordinate molybdenum(II) complex $[Mo(CO)(CNR)_4(t\text{-Bu-DAB})](PF_6)_2$ (Fig. 1 and Table 5),* as well as the reduced starting complex $Mo(CO)_3(CNR)(t\text{-Bu-DAB})$. Disproportionation of the molybdenum(I) complex, in the presence of RNC, apparently occurs to give an intermediate, reactive, dicationic molybdenum(II) complex and the reduced product $Mo(CO)_3(CNR)(t\text{-Bu-DAB})$: the dicationic species then reacts further with RNC to yield the final product, $[Mo(CO)(CNR)_4(t\text{-Bu-DAB})]^{2+}$. The same products, $Mo(CO)_3(CNR)(t\text{-Bu-DAB})$ and $[Mo(CO)(CNR)_4(t\text{-Bu-DAB})]^{2+}$, are isolated if four equivalents of isocyanide are added to $[Mo(CO)_3(NCMe)(t\text{-Bu-DAB})]PF_6$. Upon addition of four equivalents of isocyanide to the $[Mo(CO)_3(CNCMe_3)(t\text{-Bu-DAB})]^+$ complex, the reaction proceeds to the homoleptic seven-coordinate isocyanide complex $[Mo(CNCMe_3)_7]^{2+}$ rather than to $[Mo(CNCMe_3)_5(t\text{-Bu-DAB})](PF_6)_2$. In accord with this result, when $[Mo(CO)(CNCMe_3)_4(t\text{-Bu-DAB})](PF_6)_2$ is reacted with *tert*-butyl isocyanide (one equivalent) loss of CO and *t*-Bu-DAB occurred to give the homoleptic isocyanide complex $[Mo(CNCMe_3)_7](PF_6)_2$ as a major product.

If a different 1,4-diaza-1,3-butadiene ligand is employed, namely *i*-Pr-DAB, a similar disproportionation reaction takes place, but the final molybdenum(II) product is the dication $[Mo(CNCMe_3)_5(i\text{-Pr-DAB})]^{2+}$, a species we have isolated previously[1] in a different study. Accordingly, the exact course of these reactions is dependent on the R'-DAB ligand used and this is supported by other work. Specifically, we have shown that complexes of the type $[Mo(CNR)_5(R'\text{-DAB})]^{2+}$ (R' = *i*-Pr or Cy) can be prepared by the action of RNC (R = $CHMe_2$ or CMe_3) on the seven-coordinate molybdenum(II) complexes $Mo(CO)_3(R'\text{-DAB})(SnCl_3)Cl$.[1] However, under similar conditions, the *t*-Bu-DAB derivative $Mo(CO)_3(t\text{-Bu-DAB})(SnCl_3)Cl$ undergoes reductive elimination to form the octahedral complexes $Mo(CO)_3(CNR)(t\text{-Bu-DAB})$.

(*Received* 11 *July* 1985; *accepted* 9 *September* 1985)

Abstract—New examples of $[Te(IV)(S_2C \cdot NR_2)_4]$ compounds have been synthesized (where R = Bu^i, Ph or CH_2Ph). Evidence is found from ^{125}Te NMR spectroscopy of a ligand exchange reaction involving $[Te(IV)(S_2C \cdot NR_2)_4]$ (R = Et or CH_2Ph) which has a rate comparable with the time scale of the NMR experiment. $[Te(IV)(S_2C \cdot NR_2)_4]$ undergoes a UV-promoted stoichiometric reaction with dioxygen to give TeO_2 and disulphide.

Tellurium(IV) dithiocarbamates[1,2] continue to find application as accelerators in rubber vulcanization,[3] and have also attracted the interest of crystallographers[4] who have shown the tellurium atom to be eight-co-ordinate in dodecahedral (D_{2d}) co-ordination. We have recently established that the compounds show great promise as stabilizers of polypropene[5] and report in this paper the synthesis of some new compounds which were required to assist those investigations, together with some observations of previously unreported chemical behaviour.

EXPERIMENTAL AND RESULTS

Synthesis

Quantitative yields of the following compounds were obtained via the indicated literature methods: $[Te(IV)(S_2C \cdot NMe_2)_4]$, m.p. 165°C (lit.[6] 165°C); $[Te(IV)(S_2C \cdot NEt_2)_4]$, m.p. 123–124°C (lit.[6] 124°C); $[Te(II)(S_2C \cdot NMe_2)_2]$, m.p. 265°C (lit.[7] > 250°C); $[Te(II)(S_2C \cdot NEt_2)_2]$, m.p. 162–163°C (lit.[8] 164°C).

Tetrakis(dibenzyldithiocarbamato)tellurium(IV). This compound was prepared by an adaptation of Murrill's method.[1] Sodium hydroxide (1.6 g, 0.04 mol) in water (8 cm^3) was added to TeO_2 (3.19 g, 0.02 mol) and heated to dissolve the oxide. The solution was set aside. A solution of dibenzylamine (17.8 g, 0.08 mol) in ethanol (70 cm^3) was treated with sodium hydroxide (3.2 g, 0.08 mol) in water (10 cm^3) whilst cooling and stirring. Carbon disulphide (6.08 g, 0.08 mol) was then added gradually with continued cooling over 30 min to maintain the temperature below 10°C. Water (60 cm^3) was added to dissolve the heavy precipitate, the resulting solution being added to that of sodium tellurite which had been set aside. The reaction mixture was cooled by the addition of ice. The solution was treated with HCl (5%) with continued cooling; the total volume was increased to 300 cm^3. The yellow precipitate was filtered washed and recrystallized from benzene [m.p. 160°C (dec.)]. The yield was quantitative.

Tetrakis(di-isobutyldithiocarbamato)tellurium(IV) and tetrakis(diphenyldithiocarbamato)tellurium(IV). These were prepared by a similar method.

Bis(dibenzyldithiocarbamato)tellurium(II). This was prepared by an adaptation of Foss's method.[7]

Analytical data are given in Table 1.

Reactions

Solutions of tellurium dithiocarbamates (equimolar proportions) in xylene were prepared as

* Author to whom correspondence should be addressed.

follows:

$[Te(IV)(S_2C\cdot NEt_2)_4]$
$+[Te(IV)(S_2C\cdot N(CH_2Ph)_2)_4]$,

$[Te(IV)(S_2C\cdot NEt_2)_4]+[Te(IV)(S_2C\cdot Ph_2)_4]$,

$[Te(IV)(S_2C\cdot NEt_2)_4]+[Te(IV)(S_2C\cdot Me_2)_4]$.

The solutions were refluxed for periods between 2 and 10 h and examined by thin-layer chromatography (TLC). In all cases the following species were positively identified: $[Te(IV)(S_2C\cdot NR_2)_4]$, $[Te(II)(S_2C\cdot NR_2)_2]$ and $(S_2C\cdot NR_2)_2$. There were also other spots which did not correlate to known species.

An equimolar mixture of $[Te(IV)(S_2C\cdot NMe_2)_4]$ and $[Te(IV)(S_2C\cdot NEt_2)_4]$ was heated in a sealed quartz tube for periods ranging from 10 min to 1 h. TLC examination of chloroform solutions of the cooled mixtures showed the presence of $[Te(IV)(S_2C\cdot NR_2)_4]$, $[Te(II)(S_2C\cdot NR_2)_2]$ and $(S_2C\cdot NR_2)_2$, and other unidentified species (10 min heating). The solution heated for 1 h contained no tellurium(IV) compounds.

^1H *NMR spectroscopy.* Equimolar mixtures of the following pairs of tellurium(IV) dithiocarbamates were prepared in $CDCl_3$:

$[Te(IV)(S_2C\cdot NEt_2)_4]+[Te(IV)(S_2N(CH_2Ph)_2)_4]$,

$[Te(IV)(S_2C\cdot NEt_2)_4]+[Te(IV)(S_2N\cdot Ph_2)]$.

No change in spectra was discernible with time, the observed trace being the sum of the two components.

^{125}Te *NMR spectroscopy.* Only one mixture was sufficiently soluble in $CDCl_3$ for study:

$[Te(IV)(S_2C\cdot NEt_2)_4]+[Te\{S_2C\cdot N(CH_2Ph)_2\}_4]$.

An equimolar mixture of the maximum attainable concentration was examined in a 10-mm sample tube. A broad resonance was observed with a chemical shift the average of those obtained from the single sharp resonances of the pure components. Unfortunately, cooling the mixture resulted in crystallization of the solution, rendering it unsuitable for further NMR investigation.

Photochemical reaction of $[Te(IV)(dtc)_4]$ *and* $[Te(II)(dtc)_2]$ *with dioxygen* (*dtc = dithiocarbamate*). $[Te(IV)(S_2C\cdot NEt_2)_4]$ shows an absorption maximum at 420 nm ($\varepsilon = 3.38\times10^3$) and 255 nm ($\varepsilon = 1.5\times10^5$). Irradiation of chloroform or benzene solutions of the compound in the presence of air over 14 days gave a white precipitate of TeO_2 (quantitative). Chromatography of the solution showed the presence of $(S_2C\cdot NEt_2)_2$. When concentrations were very low ($\sim10^{-6}$ M), the reaction was complete after only a few minutes. The reaction appears to be general for soluble *tetrakis*(dithiocarbamato)tellurium(IV) species and also proceeds for soluble *bis*(dithiocarbamato) tellurium(II) compounds. The reaction does not proceed in the dark nor in the absence of dioxygen.

The stoichiometry is accurately:

$$\{Te(dtc)_n\}+O_2\rightarrow TeO_2 + \frac{n}{2}(S_2C\cdot NR_2)_2 \quad (n = 2 \text{ or } 4).$$

Table 1. Analytical data for tellurium dithiocarbamates

Compound	M.p. (°C)	Colour	% C (calc.)	% H (calc.)	% N (calc.)	% S (calc.)

Physical measurements

IR spectra were measured for KBr discs with a Perkin–Elmer 599B spectrophotometer. ^{1}H NMR spectra were taken with a Perkin–Elmer R12B instrument (60 MHz) and ^{125}Te NMR spectra were obtained with a Bruker WH 90C spectrometer as previously described.[9] TLC was carried out on silica gel plates.

Pertinent spectroscopic data are given in Table 2.

DISCUSSION

The limited solubility of the well-known *tetrakis*(dimethyldithiocarbamato)tellurium(IV) in common solvents at ambient temperature led us to synthesize new, more soluble, examples (Table 1). Three aspects of the work merit brief discussion.

IR spectra

Table 2 lists characteristic frequencies for the dithiocarbamato complexes [ν(CN), ν(CS) and ν(TeS)]. In all the complexes ν(CN) is a strong band in the range 1490–1510 cm^{-1}. ν(CS) was a strong to medium band in the range 970–1010 cm^{-1}. These observations agree with previous reports.[10,11] Some workers have attempted to use solution IR data to differentiate mono- and bidentate dithiocarbamato groups:[6,12] however, since all crystallographic data to date[4,13–16] show unsymmetrically bidentate dithiocarbamato groups to be co-ordinated to tellurium it is clearly unwise to infer more from our IR data than the fact that the similarity of major spectral features of our new compounds to those of known structure implies that the new compounds belong to the same structural class.

Exchange and dissociative reactions

Simple experiments were carried out in which equimolar mixtures of *tetrakis*(dithiocarbamato) tellurium(IV) compounds were refluxed in xylene. TLC examination of the solution after periods of reflux between 2 and 10 h revealed evidence for the following decomposition:

$$[Te(IV)(S_2C\cdot NR_2)_4] \rightarrow [Te(II)(S_2C\cdot NR_2)] + R_2N\cdot C(S)S{-}S(S)C\cdot NR_2,$$

but, in addition, several spots were seen which did not correlate to known species. More rigorous conditions (sealed tube) led to total decomposition of the tellurium(IV) compound.

^{1}H NMR spectroscopy was uninformative since the spectra of equimolar mixtures of tellurium(IV) dithiocarbamates were indistinguishable from the sum of the component spectra: however, ^{125}Te NMR spectra were much more informative. The chemical shift for $[Te\{(S_2C\cdot N(CH_2Ph)_2\}_4]$ was 867.5 ppm (vs Me_2Te) in $CDCl_3$ solution and that for $[Te(S_2C\cdot NEt_2)_4]$ in the same solvent was 841.2 ppm: both resonances were sharp. An equimolar mixture of the compounds gave a *broad* band centred on 852 ppm, i.e. approximately the mean of the values for the single compounds. Unfortunately, cooling produced precipitation, but the results even as they stand clearly concur with an exchange process and hint that the unidentified spots in the TLC analysis may well correspond to mixed-ligand species.

Undue speculation as to the mechanism of exchange would not be justified, but the other data we possess suggest that a redox mechanism involving reductive elimination of disulphide from tellurium(IV) and oxidative addition of disulphide to tellurium(II) is probable.

Reaction with oxygen

During the course of this work we observed that, under the influence of UV light, the tellurium(IV) and tellurium(II) dithiocarbamates reacted with dioxygen in a clean stoichiometric reaction. This reaction could be of significance in the UV stabilization of polypropene by $[Te(IV)(S_2C \cdot NR_2)_4]$ since, not only does it help to remove oxygen, but in doing so it releases disulphide, itself a powerful antioxidant.

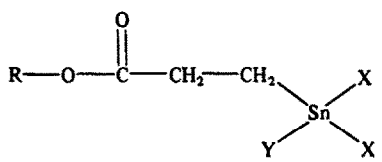
β-ALKOXYCARBONYL ALKYL TIN CHELATES—I. OXINATES AND SUBSTITUTED OXINATES: PREPARATION AND SPECTROSCOPIC STUDIES



BARUN KANTI DEB and AMIYA KANTI GHOSH*

Department of Chemistry, University of North Bengal, Darjeeling 734430, India

(*Received* 11 *March* 1985; *accepted after revision* 18 *September* 1985)

Abstract—β-Alkoxycarbonyl ethyl tin chlorides, the so-called "estertins" (a unique class of PVC stabilizer) form stable coordination complexes with bidentate ligands like oxine and substituted oxines. A number of complexes of the types R_2SnL_2, R_2SnLX, $RSnL_2X$ and $RSnL_3$, where R = $CH_3CO_2CH_2CH_2$, $C_4H_9CO_2CH_2CH_2$, $CH_3CO_2CH(CH_3)CH_2$ or $CH_3COCH_2C(CH_3)_2$, X = Cl or SCN, and L = oxine, 5,7-dichloro oxine or 5,7-dibromo oxine, have been prepared and characterized by elemental analysis, electronic, IR and PMR spectral data. Possible structural features of the isolated complexes are discussed.

Hutton *et al.*[1–3] developed a simple, relatively inexpensive and non-hazardous preparation for "estertins" having the general formula I:

R = alkyl or aryl group, Y = $ROCOCH_2CH_2$ or halogen, X = halogen

I

Subsequent work[4] has established their application as excellent PVC stabilizers with relatively low mammalian toxicities. Poller,[5] after consideration of relevant facts, suggested that reduction of Lewis acidity of the resulting organotin chloride will improve the efficiency of a stabilizer and prepared di-(4-ketopentyl)tindi(isooctyl thioglycolate), in which it was expected that the keto groups would be free in the stabilizer while co-ordinated to tin in the corresponding dichloride. They showed that the ketopentyl tin compounds are more than twice as effective in stabilization as the corresponding dialkyl tin derivatives. Lewis acidity of the β-alkoxycarbonyl alkyl tin compounds (i.e. estertins) has not been investigated extensively so far, particularly with bidentate ligands. Attempts were therefore being made to prepare such complexes. In this paper we would like to report the preparation of different types of β-alkoxycarbonyl alkyl tin complexes with oxine and substituted oxines and also their characterization by elemental analysis and electronic, IR and PMR spectral data.

EXPERIMENTAL

Synthesis

Analytical-grade reagents and dry and distilled solvents were used.

Preparation of β-alkoxycarbonyl ethyl tin chlorides and related compounds. The compounds used are of the types R_2SnCl_2 and $RSnCl_3$, where R = $CH_3CO_2CH_2CH_2$, $C_4H_9CO_2CH_2CH_2$, $CH_3CO_2CH(CH_3)CH_2$ and $CH_3COCH_2C(CH_3)_2$. All these compounds were prepared by reported methods.[1–3]

General method of preparation of complexes. Except for β-alkoxycarbonyl ethyl tin thiocyanato complexes, others were prepared by reacting stoichiometric quantities of β-alkoxycarbonyl alkyl tin chlorides and the ligands in appropriate molar ratios. The hydrochloric acid liberated was neutralized with ammonia solution (17 N) and the resulting ammonium chloride was removed by filtration. The filtrate was refluxed, concentrated and

* Author to whom correspondence should be addressed.

the complexes were isolated and purified by fractional crystallization.[6]

β-Alkoxycarbonyl thiocyanato oxinates were prepared by treating β-alkoxycarbonyl ethyl tin chloro oxinates with a suspension of potassium thiocyanate in hot ethanol.[6] Potassium chloride produced in the reaction was removed by filtration and the filtrate was concentrated. The product crystallized out was then purified.

Some typical preparations of complexes

$(CH_3CH_2CH_2CH_2)_2Sn$(5,7-dichloro oxine)$_2$

A hot benzene solution (100 cm^3) of 5,7-dichloro oxine (1.28 g, 5.98 mmol) was added to a 50 cm^3 solution of $(CH_3CO_2CH_2CH_2)_2SnCl_2$ (1.09 g, 2.99 mmol) in benzene and heated in a water bath. A few drops of ammonia solution were added and the precipitate filtered. The filtrate was refluxed for 2 h, concentrated and treated with an equal volume of methanol. The solution was refrigerated for several hours and a heavy yellow layer was produced. The layer, gummy in nature, was extracted with hot methanol, concentrated and kept overnight. Yellow crystals which appeared were purified from the same solvent.

$CH_3CO_2CH_2CH_2Sn(oxine)_2Cl$

A chloroform solution of

$CH_3CO_2CH_2CH_2SnCl_3$

(0.94 g, 3.01 mmol) and oxine (0.87 g, 6.00 mmol) was mixed and heated in a water bath for 10 min. The colour changed to deep yellow when a few drops of ammonia were added to it. After filtration the filtrate was refluxed for 2 h, concentrated to minimum volume, methanol was added, followed by refrigeration overnight. Yellow crystals separated when the solution was scratched with a spatula. The product was crystallized from the chloroform–methanol mixture.

$C_4H_9CO_2CH_2CH_2Sn(oxine)_2(SCN)$

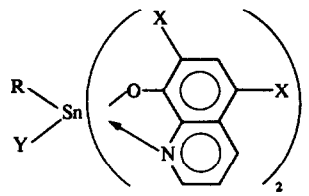
A suspension of potassium thiocyanate (0.20 g, 2.06 mmol) in hot ethanol was added to a hot solution of $C_4H_9CO_2CH_2Sn(oxine)_2Cl$ (1.14 g, 1.99 mmol) while stirring with a magnetic stirrer for an hour. Potassium chloride produced in the reaction was filtered off and the filtrate was evaporated to dryness and then extracted with chloroform. The chloroform extract was concentrated and refrigerated for a few hours. The yellow solid formed was purified by several crystallizations from ethanol.

Spectroscopic data

The electronic spectra were recorded on a Backman DU-2 spectrophotometer and/or a Pye–Unicam SP 8-300 using methanol (Uvasol, E. Merck) as the solvent. The IR spectra were recorded as Nujol mulls using a Backman IR-20 spectrophotomer equipped with KBr windows. The PMR spectra in $CDCl_3$ against internal standard TMS were recorded on a Varian EM-390 and/or Zeol, Japan, FT NMR and/or a Varian A-60 spectrophotometer.

RESULTS AND DISCUSSION

The complexes isolated in the present investigation are listed in Table 1, together with their analytical, electronic and IR spectral data. All the complexes are yellow in colour.



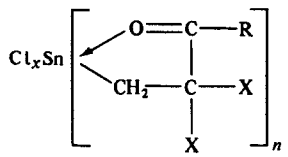
Electronic spectra

The electronic spectra of β-alkoxycarbonyl ethyl tin oxinates correspond to those of other chelated metal oxinates.[7–10] Meinema *et al.*[8] reported that the shift to a longer wavelength of the 320-nm absorption of oxine in an organometallic complex is generally considered to be a reliable indication of the presence of a chelating oxine ligand. All the spectra of oxinate complexes are characterized by a strong band in the region 370–375 nm. The 310-nm band of oxine, a π–π^* transition, suffers a bathochromic shift to 370–375 nm in all β-alkoxycarbonyl ethyl tin oxinates. The considerable shift observed in these cases and near constancy of the oxinates absorption at ~375 nm indicate strongly that a chelate formation of similar stability has taken place.[8,9] The inflexion observed in the region 310–375 nm in most oxinate complexes may be due to the presence of some free ligand produced from the rupture of the Sn—N bond in methanol.[9,11]

In substituted oxine complexes two well-separated bands are observed at ~338–340 and ~385–390 nm. From its position and intensity, the band at ~385–390 nm is supposed to be the ligand band shifted from its original position (at 324 nm), which suggests that in solution these organotin compounds contain a chelated substituted oxinate ligand.[8,13] The other band at ~338–340 nm in β-alkoxycarbonyl ethyl tin (substituted oxinates) is in the same position as the usual ^1L_b band, insensitive to changes in solvent or substituent.[13] This band may also be due to the presence of some free ligand produced in methanol[9,11] and is observed in the spectra of other metal oxinates.[8]

The large bathochromic shift of the π–π^* transition in β-alkoxycarbonyl ethyl tin oxinate and

substituted oxinate complexes is consistent with the presence of Sn ← N coordination. The complexes are, thus, structurally quite similar to other organotin oxinates[10] and may be formulated as **II**:



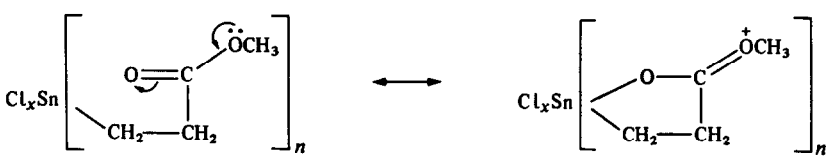
R = $CH_3CO_2CH_2CH_2$, $C_4H_9CO_2CH_2CH_2$ or $CH_3CO_2CH(CH_3)CH_2$, X = H, Cl or Br; Y = R, Cl or SCN

II

IR spectra

From the spectroscopic data (IR and PMR) and also from the fact that the carbonyl stretching frequency remains unaffected by dilution in toluene or ethereal solvents, Hutton *et al.*[1] suggested the following structure for β-alkoxycarbonyl ethyl tin chloride (**III**):

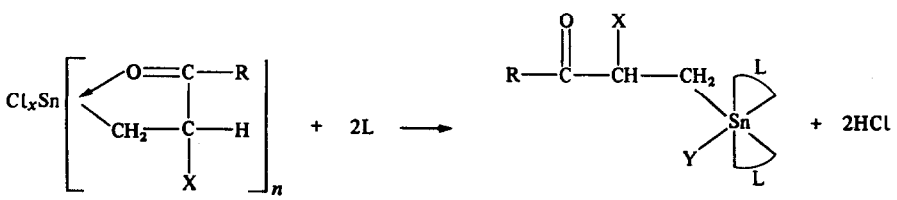
R = OCH_3, OC_4H_9 or CH_3; X = H or CH_3; x = 2 or 3; n = 1 or 2



III

They also proposed that the methoxy oxygen lone-pair electrons are also involved in the delocalization of the ester carbonyl electron density on tin and reported the intramolecular coordination as follows (**IV**):

IR spectra of all the β-alkoxycarbonyl ethyl tin oxinates and substituted oxinates (Table 1) show that the carbonyl stretching frequency of these compounds appeared at higher wavenumbers than the carbonyl frequencies in the parent Lewis acids (i.e. in β-alkoxycarbonyl ethyl tin chlorides). This indicates the nonchelating nature of the ester carbonyl group. The intramolecular carbonyl coordination of the β-alkoxycarbonyl ethyl tin chlorides is cleaved (**V**), which is indicated by the shift in the ν(C=O) frequency appearing in the region 1720–1730 cm^{-1} in all cases.



The cleavage of intramolecular carbonyl coordination is expected due to increased electron density on tin via the ligands and, also, possibly due to steric reasons.

The IR spectra of oxine and β-alkoxycarbonyl ethyl tin oxinates are very complex due to the presence of a large number of vibrational modes due to ring-stretching deformation, inplane and out-of-plane ring and CH deformation etc. In all the β-alkoxycarbonyl ethyl tin oxinates the carbonyl stretching frequency is assigned at ~1720–1730 cm^{-1}. As expected the OH stretching mode of oxine at ~3200 cm^{-1} disappeared in these complexes, confirming bonding through the oxygen atom of the ligand. Both ν(Sn—C) and ν(Sn—O) peaks appeared between 400 and 600 cm^{-1}.[12,14,15] All the spectra of the oxine complexes show, in addition to the Sn—C stretching modes, one other strong absorption band at ~520–540 cm^{-1}, which is absent in spectrum of the ligand and, therefore, may be assigned to Sn—O vibration (oxygen of the 8-OH group).[12] The presence of a number of ligand bands in the region expected for Sn—C stretching has

x = 2 or 3, n = 1 or 2

IV

R = OCH_3, OC_4H_9 or CH_3; X = H or CH_3; Y = $ROCH(X)CH_2$ or Cl; L = ligand; x = 2 or 3; n = 1 or 2

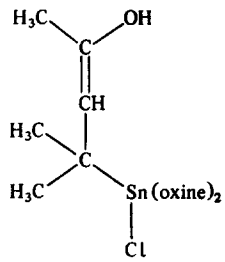
L = oxine, L^{I} = 5,7-dichloro oxine, L^{II} = 5,7-dibromo oxine, $R^{I} = CH_3CO_2CH_2CH_2$, $R^{II} = C_4H_9CO_2CH_2CH_2$, $R^{III} = CH_3CO_2CH(CH_3)CH_2$, $R^{IV} = CH_3COCH_2C(CH_3)_2$; [a,b] and [c] refer to reaction medium (chloroform, ethanol and benzene, respectively). [d,e,f,g] and [h] refer to solvent for crystallization (chloroform–methanol mixture, ethanol, benzene–methanol mixture, chloroform–benzene mixture and methanol, respectively). [i]Stirred instead of refluxing. [j]Decomposition point. [k]Calculated value in parentheses. λ_{max} in parentheses are influxions. λ_{max} in methanol of L, L^{I} and L^{II} is at 370, 324 and 325 nm, respectively.

ν(C=O) of $R^{I}_{2}SnCl_2$ at 1677 cm^{-1}, of $R^{I}SnCl_3$ at 1660 cm^{-1}, of $R^{II}_{2}SnCl_2$ at 1675 cm^{-1}, of $R^{II}SnCl_3$ at 1640 cm^{-1}, of $R^{III}SnCl_3$ at 1640 cm^{-1}, and of $R^{IV}SnCl_3$ at 1662 cm^{-1}.

created some confusion in assigning the Sn—C band of complexes in a conclusive manner. As the spectra were recorded using KBr windows, the region below 400 cm^{-1}, where the Sn ← N stretching frequency is expected,[7,12,14] could not be explored. The C=N stretching frequency somewhat coupled with pyridine ring vibration appears as a strong band in oxine at 1580 cm^{-1}, whereas, however, in all the complexes this band shifts to ~1560–1570 cm^{-1}.[16] In all the complexes the presence of a quinoline ring can easily be identified from the appearance of characteristic absorptions such as: (i) a number of bands (more than six) due to ring-breathing vibrations between 1360 and 1625 cm^{-1}, (ii) a sharp band due to the C—O stretching frequency at the >C—O—Sn site (1100 cm^{-1}),[17] and (iii) a number of sharp and strong bands due to the CH deformation modes in the region between 900 and 700 cm^{-1}.[18]



The spectra of the thiocyanate complexes show a very strong band at ~2000–2050 cm^{-1}, in addition to other bands, like the corresponding halide complexes. The ambidentate ligand SCN can coordinate to metal either through the sulphur or the nitrogen, or it can act as a bridge. Though the C—S stretching frequency is more useful in distinguishing these two isomers[19] oxine has many absorptions in this region that they may obscure the C—S stretching band. Hence, on the basis of the C≡N stretching frequency alone, the thiocyanate group may be thought to be linked to tin through the nitrogen as is suggested by Sabatini and Bertini.[19] Hence, a penta-coordinated trigonal bipyramidal structure for the

$$(CH_3CO_2CH_2CH_2)_2Sn(oxine)(SCN)$$

complex[12,20,21] and a hexa-coordinated distorted octahedral geometry (where the *cis*- and *trans*-configurations are less significant) for R_2SnL_2 ($R = CH_3CO_2CH_2CH_2$; L = oxine, 5,7-dichloro oxine or 5,7-dibromo oxine) and $RSnXL_2$ ($R = CH_3CO_2CH_2CH_2$, $C_4H_9CO_2CH_2CH_2$ or $CH_3CO_2CH(CH_3)CH_2$; X = Cl or SCN; L = oxine, 5,7-dichloro oxine or 5,7-dibromo oxine) type of complexes[22–24] may be suggested.

In the IR spectra of all the 5,7-disubstituted oxine complexes, the complete absence of any ν(OH) frequency at the region around 3200 cm^{-1}, the shift of the carbonyl stretching frequency to higher wavenumbers between 1720 and 1735 cm^{-1} and also the presence of some other characteristic bands show the existence of substituted oxines in the complexes. The C=N stretching frequency somewhat coupled with pyridine ring vibration of the substituted oxines at 1580 cm^{-1} shifts to ~1550–1560 cm^{-1} in the complexes.[16] The bands at ~1280, 1190 and 1150 cm^{-1} in the most of these complexes may be attributed to the substituted pyridine ring vibrations.[23] Like oxine complexes these also show a sharp band of C—O stretching frequency (at the >C—O—Sn site) at ~1100 cm^{-1}.[17]

The IR spectrum of the compound $CH_3COCH_2C(CH_3)_2Sn(oxine)_2Cl$ is quite different from all of the other oxinate complexes. The compound showed a strong absorption at 3320 cm^{-1} and the total absence of the ν(C=O) band at ~1720 cm^{-1}. It also showed a new peak at 1630 cm^{-1}, which may possibly be due to the >C=CH group. All these bands may point to an unusual structure of type[3] **VI**:

VI

Without the absence of such an enol form it is rather difficult to explain the IR spectrum of this compound, because it strongly suggests the formation of an oxinate complex in all other aspects.

PMR spectra

From the integration of the curves in PMR spectra, the ratio of different protons have been found to be consistent with the composition of the complexes. In general, on complex formation all types of protons in β-alkoxycarbonyl ethyl groups should exhibit shielding and thereby resonate at a higher magnetic field, which is in agreement with an increased electron density on the tin via ligand donation. In addition, the normal inductive effect of the corresponding ligand and the magnetic influence of the tin atom also combine to govern the alkyl resonance positions. Depending upon the basicity of the donor, the α-methylene protons should be shielded most. Methyl propionate in $CDCl_3$ furnished methoxy signal at 3.66 (ppm) while in β-alkoxycarbonyl ethyl tin chlorides this signal is shifted to downfield due to deshielding of the methyl protons by the lone pair of electrons of methoxy oxygen delocalized because of the coordinated tin.

Due to complex formation, the alkyl protons (H_α, H_β and H_c)* attached to tin in all of the β-alkoxycarbonyl ethyl tin oxinates are shielded compared to the parent organotin chlorides. In β-alkoxycarbonyl ethyl thiocyanato oxinates the amount of shielding is less than the corresponding chloro oxinate complexes due to the less electronegative character of the thiocyanate group. The α-methylene protons in all of the oxinate complexes are mostly shielded, except in

$$CH_3CH(CH_3)CH_2CO_2Sn(oxine)_2Cl,$$

where the methoxy proton is shielded most. When the chlorine atoms are replaced by the ligands, the ester coordination is disrupted, as seen from the IR spectra. Further evidence for the non-chelating nature of the ester carbonyl group in these complexes is obtained from the chemical shift values of β-methylinic and methyl protons. Both the protons in the complexes also suffer shielding and revert to positions characteristic of the free ester group.

The chemical shifts observed for the ring protons in β-alkoxycarbonyl ethyl tin oxinates show that the proton at 2-position of quinoline ring is most affected while the other protons remain practically unaltered or slightly altered. Electron donation to tin has produced a deshielding of the 2-H proton of oxine in

$$(CH_3CO_2CH_2CH_2)_2Sn(oxine)_2(SCN),$$

$$CH_3CO_2CH_2CH_2Sn(oxine)_3$$

and

$$C_4H_9CO_2CH_2CO_2Sn(oxine)_3,$$

and is observed at a lower magnetic field compared to the resonance positions in the free ligand. Shielding of the 2-H proton is observed in all other oxinates, which indicates that

$$(CH_3CO_2CH_2CH_2)_2Sn(oxine)(SCN),$$

$$CH_3CO_2CH_2CH_2Sn(oxine)_3$$

and

$$C_4H_9CO_2CH_2CH_2Sn(oxine)_3$$

possibly appear to involve a greater extent of chelation in solution compared to the other complexes. It is expected that the 2-H proton of oxine will appreciably be affected due to donation of electrons from the neighbouring nitrogen atom and consequently this proton would suffer a considerable downfield shift. But the actual position of such protons may also be influenced by other factors.[25] In certain cases, it may be possible that a ring current effect and other factors can compensate such a downfield shift, and as a result these protons may resonate at a higher magnetic field also. Moreover the presence of the Sn—Cl bond may influence the position of the aromatic proton resonances. Hence, it may not be possible to conclude in a definite manner about the extent of chelation from such a downfield shift of the 2-H proton only. In chloro oxinate complexes H_α, H_β and H_c protons are less shielded compared to bis- or trisoxinate complexes which may be due to Sn—Cl bond and other steric factors.

In $(CH_3CO_2CH_2CH_2)_2Sn$(5,7-dichloro oxine)$_2$ shielding of H_α, H_β and H_c protons is observed and the shielding of the α-methylene proton is maximum. The ring protons at the 3- and 6-positions appear as two separate signals at 7.52 and 7.70 ppm, respectively, while the protons at the 2- and 4-positions are shielded by 9.10 and 8.54 ppm as expected.

In β-alkoxycarbonyl 5,7-dibromo oxinates H_α, H_β and H_c protons are also shielded. Like oxinates, the α-methylene proton is shielded most, except in $CH_3CO_2CH(CH_3)CH_2Sn$ (5,7-dibromo oxine)$_2$Cl, where the methoxy proton is shielded most. In $CH_3CO_2CH_2CH_2Sn$(5,7-dibromo oxine)$_2$Cl and $CH_3CO_2CH(CH_3)CH_2Sn$(5,7-dibromo oxine)$_2$Cl the greater shielding of the H_α, H_β and H_c protons than that of similar oxine complexes may possibly be due to the higher donor capacity of 5,7-dibromo oxine compared to oxine.

The chemical shifts observed for the aromatic ring protons in substituted oxine complexes are consistent with the shifts reported earlier.[26–28] The electron donation to tin on coordination has produced a deshielding of the ligand protons at the 2-position and, in some cases, at the 4-position also, the magnitude of which appears to be influenced by the inductive effect of the alkyl groups. The downfield shift of these protons may be attributed to a strong interaction between tin and nitrogen. The behaviour of the 2-H proton can be explained by the paramagnetic anisotropic effect of the Sn—N bond of substituted oxine ligands and to an intramolecular electric field, and that of the 4-H proton by the latter effect.[29] The deshielding of the 6-H proton of substituted oxine complexes possibly indicates a reduced electron density at C-6. This can arise from electron movement towards the metal through a $d\pi$–

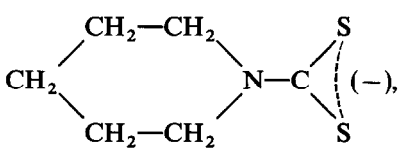
SYNTHESIS AND SPECTROSCOPIC CHARACTERIZATION OF ARSENIC(III), ANTIMONY(III), BISMUTH(III), TIN(II) AND LEAD(II) DITHIOCARBAMATE ADDUCTS



ANTONIO COSTANTINO FABRETTI, ALEARDO GIUSTI, CARLO PRETI, GIUSEPPE TOSI and PAOLO ZANNINI*

(*Received* 27 *June* 1985; *accepted* 18 *September* 1985)

Abstract—The complexes of arsenic(III), antimony(III), bismuth(III), tin(II) and lead(II) with monomethylsubstituted piperidinodithiocarbamates of general formula $M(Rdtc)_3$ and $M(Rdtc)_2$ have been prepared and characterized by spectroscopic methods. The results of the spectroscopic studies indicate that the dithiocarbamate ligands are always bidentate, in both the 1 : 3 and the 1 : 2 complexes. All the complexes are nonconducting in DMF solution. The thermal behaviour of the complexes has been investigated by TG and DTG techniques. The molecular weight determinations indicate that the trisdithiocarbamates of arsenic and antimony are monomeric, while the bismuth trisderivatives tend to dimerize: polymeric structures can be suggested for the tin(II) and lead(II) compounds.

As a contribution to the problem of the coordinating behaviour of the heterocycle-containing dithiocarbamate ligands and on the reactivity of their coordination compounds, we report in this study the preparation and characterization of new complexes of arsenic(III), antimony(III), bismuth(III), tin(II) and lead(II) with monomethylsubstituted piperidine dithiocarbamates:

i.e. 2-, 3- or 4-methylpiperidine dithiocarbamate, hereafter abbreviated as 2-Me-, 3-Me- or 4-MePipdtc.

We have previously described complexes of cyclic dithiocarbamates with many *d*- and *p*-block metals:[1–4] furthermore, the reactivity of the complexes obtained towards bidentate nitrogen donor ligands, the mass spectral investigations and the structural characterization by XPS techniques have been investigated and some preliminary results have already been reported.[5–8]

This paper is an extension of our previous research studies on the dithiocarbamates in which dialkyl groups are replaced by heterocycles and, as a further extension, the heterocycle bears aryl or alkyl groups in different positions on the ring.

RESULTS AND DISCUSSION

The complexes obtained, with their analytical data and other physical properties, are reported in Table 1, Table 2 lists the most important IR bands with their assignments, and Table 3 shows the electronic spectral data.

The complexes are micro-crystalline, soluble in benzene, nitrobenzene, *N*,*N*′-dimethylformamide (DMF), carbon tetrachloride and chloroform. Conductance measurements in DMF solution indicate the absence of ionic species in solution and hence the covalent nature of the complexes.

IR spectra

The most important IR peaks of the free ligand sodium salts and of the complexes are reported in Table 2: the spectra of the complexes show the vibrational modes characteristic of the methyl group at the same wavenumbers as in the free ligands.[3]

The band in the 1442–1420-cm^{-1} range is indicative of a considerable double-bond character

in the carbon–nitrogen bond: this fact could be explained by taking into account the electron-releasing ability of the heterocyclic group bearing a methyl substituent, which forces the electron density towards the sulphur atoms, thus producing a greater double-bond character in the CN bond, which, as a consequence, is shifted to higher energies. In the metal dithiocarbamates here reported the bands assigned to ν(C$\overset{+}{-}$N) in the above reported range lie between the stretching frequencies of ν(CN) and ν(C=N), in the ranges 1350–1250 and 1690–1640 cm^{-1}, respectively. The blue shift of the ν(C$\overset{+}{-}$N) depends on the nature of the central atom and moves to higher frequencies in the orders Sn > Pb and As > Sb > Bi, respectively, for the 1:2 and 1:3 complexes. As regards the influence of the position of the methyl group on the piperidine ring, the ν(C$\overset{+}{-}$N) values increases in the order 2-MePipdtc < 3-MePipdtc < 4-MePipdtc.

The band observed at 950–933 cm^{-1} has been

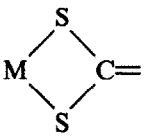
associated with the stretching vibration of the carbon–sulphur bond and indicates that the dithioligands act in a bidentate way: in fact, only one strong or medium-strong band is present, whereas a doublet is expected in the 1000 ± 70 cm^{-1} region in the case of monodentate coordination.[9–11] The analysis of the position of the $\nu(C{=}N)$ mode gives further confirmation of such behaviour: this band, in fact, undergoes blue shifts in all the complexes, while for unidentate coordination the frequency of this stretching would undergo downward shifts or remain unchanged at the same value as for the free sodium dithiocarbamate salt.[12]

By comparing the stretching values of the carbon–nitrogen bond with those of the previously reported complexes with piperidine dithiocarbamate, we observe that the upward shift of $\nu(C{=}N)$ on passing from the sodium salts to their metal complexes is higher in the case of dithiocarbamate ligands bearing a methyl group on the piperidine ring. This behaviour may be explained by taking into account the inductive effect of the methyl group which causes an increase in the carbon–nitrogen bond order. In fact the structure of the dithioligands can be represented by the formalism:



a **b** **c** **d**

and the dithiocarbamate group can behave as a monodentate ligand in the resonance forms **a** and **b**, and as a bidentate S,S′-donor ligand in forms **c** and **d**, giving rise to complexes in which both the sulphur atoms behave as electron donors to the metal ion, thus forming a four-membered chelate ring.

From the above mentioned IR data we can conclude that structure **d** contributes more in the case of the methyl derivatives than in the case of the non-substituted piperidine dithiocarbamates.

The vibrational modes present between 546 and 526 cm^{-1} can be ascribed to the contribution of $\nu(CS) + \delta(SCS)$ and to

ring deformation as previously shown by a detailed IR isotopic study on nickel(II) and copper(II) dithiocarbamates.[2]

In all the hydrated complexes (Table 1) medium-strong bands are present at 3450 cm^{-1} and in the 1640–1630-cm^{-1} range, which are clearly due to $\nu(OH)$ and $\delta(HOH)$, respectively: the absence of the vibrational modes activated by the coordination to the metal (wagging, twisting and rocking) suggests that coordinated water is not present and these results are confirmed by thermogravimetric studies (see below).

In the far-IR region the bands of the ligands are unchanged in the spectra of the complexes: in

addition, new bands, absent in the spectra of the starting materials, are observed in the 361–216-cm^{-1} range. For the 1:3 derivatives the band between 361 and 318 cm^{-1} is due largely to M—S bond stretching, while the two further absorptions in the 309–216-cm^{-1} range could be due to complex normal modes involving both metal–sulphur bond stretching and ring deformation modes. In the 1:2 derivatives the ν(M—S) vibrations are located at 342–331 and 334–318 cm^{-1} for tin(II) and lead(II) complexes, respectively.[13,14]

Electronic spectral studies

The solid-state electronic spectra are given in Table 3: all the complexes show three absorption bands due to the chromophore group NCS_2[15] (these absorptions are indicated as band I, band II and band III).

Band I is assigned to an intramolecular charge transfer in the ligand, i.e. a $\pi^* \leftarrow \pi$ transition located mainly in the N⇢C⇢S group.[16,17] The position of this band is slightly affected by the nature of the central atom, the sequence following the orders As > Sb > Bi and Sn > Pb, in agreement with the electronegativities of the elements.

Band II is also attributed to a $\pi^* \leftarrow \pi$ transition of the S⇢C⇢S group:[18] this band is present as a shoulder and this fact clearly indicates the equivalence of the C⇢S bonds in the complexes. As regards the different metals, the same trend as for the band I is observed.

Band III is a low-intensity band and may be assigned either to a $\pi^* \leftarrow n$ electronic transition located on the sulphur atom or to a charge transfer from ligand to metal.[19–21] The frequency of band III decreases, as already observed for bands I and II, from arsenic to bismuth.

Molecular-weight determinations

The molecular-weight determinations of the complexes show that the arsenic(III) and antimony(III) derivatives are monomeric in nitrobenzene solution, the bismuth complexes show a tendency to dimerize, while polymeric structures could be suggested for the tin(II) and lead(II) dithiocarbamates. By comparing the results obtained for the piperidine dithiocarbamate bismuth complex previously reported, which was monomeric, this tendency of bismuth to dimerize could be explained taking into account the more pronounced π-back donation associated with the lower electron density on the bismuth atom and with the decreased basicity of the amine.

Thermogravimetric studies

The thermogravimetric studies were performed by means of TG and DTG techniques.

The arsenic(III) derivatives were stable up to 200°C, then undergo decomposition and very likely are transformed into As_2O_3 around 350°C. The crucible is completely empty by the time that the temperature reaches 600°C.

The antimony(III) complexes decompose very rapidly in the 200–275°C range: a small loss is observed between 275 and 550°C and the resulting compound, Sb_2O_3 (calc. 23.8%, found 24.1%), is stable up to 950°C. No transformation into Sb_2O_4 is observed.

The bismuth(III) derivatives rapidly decompose in the 200–250°C range, then continuous weight loss is detected up to 950°C: at this temperature yellow Bi_2O_3 is formed (calc. 31.8%, found 31.9%).

As for the tin(II) derivatives, after the loss of two water molecules in the 35–150°C range, the dithiocarbamates are transformed into a polysulphide of type Sn_xS_y, which, above 950°C, gives SnO_2 as the end product.

The lead dithiocarbamates decompose at 300°C rapidly, then slowly up to 440°C. From this temperature gain in weight is observed up to 750°C, probably due to a formation of mixed oxides. Above this temperature a weight loss occurs leading to PbO (calc. 40.2%, found 40.5%).

EXPERIMENTAL

Preparation of the ligands

The sodium salts of the ligands were prepared by reaction of 2-methyl-, 3-methyl- or 4-methylpiperidine (reagent grade) in dry ethyl ether with carbon disulphide and adding NaOH under vigorous stirring over a 5-h period. The molar ratio amine:CS_2:NaOH = 1:1:1: the crude products were recrystallized from isopropyl alcohol.

Analyses. Found for 2-MePipdtcNa·$2.5H_2O$: C, 34.4; H, 7.0; N, 5.8; S, 26.2%; 3-MePipdtcNa·$2.5H_2O$: C, 34.1; H, 7.1; N, 5.7; S, 26.0%; 4-MePipdtcNa·$2.5H_2O$: C, 34.9; H, 7.0; N, 5.9; S, 26.3%. Calc. for $C_7H_{12}NS_2Na \cdot 2.5H_2O$: C, 34.7; H, 7.1; N, 5.8; S, 26.5%.

Preparation of the complexes

Commercial arsenic, antimony and bismuth trichloride, tin dichloride and lead nitrate of high-purity grade were used. For the preparation of the 1:3 derivatives the metal halide in acetone or

dichloromethane and methanol solution was treated with the ligands dissolved in acetone in a 1:3 stoichiometrical ratio. The lead compounds were obtained by reaction of the corresponding dithiocarbamates in the 1:2 molar ratio in aqueous or ethanol solution. The tin(II) derivatives have been prepared by adding dropwise a solution of $SnCl_2$ in absolute ethanol to an ethanolic solution of the dithiocarbamates with continued stirring. The precipitates were filtered, washed with acetone, dry ethyl ether and dried *in vacuo* over P_4O_{10}. Repeated syntheses and elemental analyses gave reproducible results.

IR measurements

The IR spectra were recorded in the 4000–50-cm^{-1} region with a Perkin–Elmer 180 spectrophotometer of the Instruments Centre of Modena University. The spectra in the 4000–400-cm^{-1} region were measured as KBr discs or Nujol mulls. Far-IR spectra were measured on Nujol mulls supported between polyethylene sheets. Atmospheric water was removed from the spectrophotometer housing by flushing with dry nitrogen.

Electronic spectra

The electronic spectra have been recorded with a Shimadzu MPS-50L spectrophotometer in the solid state in the 5000–45,000-cm^{-1} range, the method of Dyer *et al.*[22] being used.

Molecular-weight determinations

The molecular weights were determined in nitrobenzene RP, treated with magnesium sulphate, by the cryoscopic method.

Thermal analyses

Thermogravimetric analyses (TG and DTG) were performed in air on a Mettler TG50 thermobalance equipped with a Mettler TC10TA processor. A scan rate of 10°C min^{-1} was used.

Conductivity measurements

These measurements were carried out with a WTW LBR type conductivity bridge for freshly prepared 10^{-3} M solutions in DMF at 25±0.1°C.

Analyses

Carbon, nitrogen, hydrogen and sulphur were determined using a Carlo Erba 1106 elemental analyzer.

Acknowledgements—We thank Mr G. Pistoni for elemental analyses, the Instruments Centre of Modena University for the availability of the use of the Perkin–Elmer 180 spectrometer and the Consiglio Nazionale delle Ricerche of Italy for financial support.

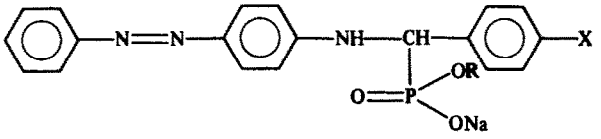
COMPLEXES OF DIBENZO-24-CROWN-8 WITH SOME SODIUM MONOALKYL BENZENEAZOPHOSPHONATES

LJ. TUŠEK-BOŽIĆ* and D. SEVDIĆ

Department of Physical Chemistry, Institute Rudjer Bošković, Zagreb, Yugoslavia

(*Received* 8 *August* 1985; *accepted* 20 *September* 1985)



Abstract—Syntheses and properties of complexes of dibenzo-24-crown-8 with the sodium monoethyl ester and the sodium monobutyl ester of [α-(4-benzeneazoanilino)-*N*-benzyl]phosphonic acid, [α-(4-benzeneazoanilino)-*N*-4-hydroxybenzyl]phosphonic acid and [α-(4-benzeneazoanilino)-*N*-4-methoxybenzyl]phosphonic acid have been studied. The crystalline complexes formed were found to depend not only on the size of the cation and the crown ether cavity but also on the choice of anion and the reaction solvent. It was shown that the molecular structure and electronic configuration of the anion are important factors in a salt–ligand system which influence the ease of solubilization and charge separation in solution. The complexes obtained were characterized on the basis of conductance measurements and UV, IR and ^{1}H NMR spectra.

Crown ethers are of considerable importance because of their ability to form complexes with alkali and other metal cations. This complexation process permits solvation of the ionic salts in non-aqueous solvents, a phenomenon frequently utilized in phase-transfer catalytic systems.[1,2] In addition, crown ethers can also serve as good model systems for biochemical and biological membrane transport agents, such as the macrocyclic antibiotics.[3] The mechanism of these species in complexing ions is similar to that of the crown ethers.[4] The effectiveness of crown ethers as potential phase-transfer reagents and catalysts is determined by the degree of lipophilicity they possess and by the stability of the complexes they form.

The widespread use of crown ethers requires that the details of crown ether complexation be investigated. While a good deal of effort has been directed towards complexes with simple alkali metal salts (i.e. halide, thiocyanate and perchlorate), less attention has been directed towards complexes with the salts of chelating organic anions. The chelating anions mostly used were those derived from 8-hydroxyquinoline, 1-nitroso-2-naphtol, nitrophenols and amino-, hydroxy- or nitrobenzoic acids.[5–9] Salts of organic anions have often been investigated because of their relevance to natural systems.

In our earlier papers we studied some alkali picrate and tetraphenylborate complexes with various crown ethers.[8,10–12] The synthesis and characterization of the crystalline complexes,[8] the association equilibria between the alkali cations and the crown ethers,[10] as well as the ion-pair formation between the crown ether–cation complexes and different anions in nonaqueous media,[11,12] were reported. As an extension of these investigations, the complexes of some sodium monoalkyl benzeneazophosphonates have recently been studied.[13] In this paper we describe the preparation and properties of new complexes between the crown ether dibenzo-24-crown-8 (DB24C8) and sodium salts of monoalkyl esters of some benzeneazophosphonic acids (NaA_1–NaA_6). The influences of the size

of the hole in the crown ether and the diameter of the metal cation, the size and charge density of the anion, as well as the solvent used, on the formation of salt complexes have been investigated and discussed.

EXPERIMENTAL

Starting materials

DB24C8 (systematic name 6,7,9,10,12,13,20,21,23,24,26,27-dodecahydrodibenzo[b,n][1,4,7,10,13,16,19,22]octaoxacyclotetracosin), prepared as previously described,[14] was purified by repeated recrystallization from methanol. Sodium salts of the monoethyl and monobutyl esters of [α-(4-benzeneazoanilino)-*N*-benzyl]phosphonic acid (NaA_1 and NaA_2), [α-(4-benzeneazoanilino)-*N*-4-hydroxybenzyl]phosphonic acid (NaA_3 and NaA_4) and [α-(4-benzeneazoanilino)-*N*-4-methoxybenzyl]phosphonic acid (NaA_5 and NaA_6) were prepared by the methods reported earlier,[15,16] recrystallized twice from absolute ethanol and dried *in vacuo* at approximately 60°C for several hours.

Analytical-grade solvents were used throughout the preparation of the salt complexes. For conductivity measurements, methanol was purified by the method published in Ref. 17.

Preparation of complexes

General procedure. An equimolar amount of crown ether and sodium salt of monoalkyl esters of benzeneazophosphonic acids (NaA_1–NaA_6) was refluxed together in ethanol or acetonitrile to give a clear solution, which was filtered hot and set aside to crystallize at room temperature. Complexes of sodium monoethyl benzeneazophosphonates were gradually formed by removal of solvent. The precipitate was filtered off, washed with a small amount of cold reaction solvent, and dried. The filtrate was again subjected to crystallization or evaporation to dryness to ascertain the presence of any second new product. Complexes of sodium monobutyl benzeneazophosphonates were obtained as syrups after the whole of the solvent was driven off, which solidified slowly on standing. The homogeneity of the crystals was ascertained under the microscope. All complexes obtained were dried under high vacuum at ambient temperature without decomposition, giving stable anhydrous complexes.

We attempted the synthesis of all complexes in methanol, ethanol and acetonitrile solutions. Complexes of sodium salts NaA_1–NaA_4 were isolated from ethanol, while those of sodium salts NaA_5 and NaA_6 precipitated only from acetonitrile solutions. From methanol solutions free crown ether was gradually precipitated, and no complex could be isolated.

Physical measurements and analysis

IR spectra were recorded on KBr pellets and Nujol mulls in the region 4000–200 cm^{-1} using a Perkin–Elmer 580 B spectrophotometer. ^1H NMR spectra were determined on a JEOL FX90Q Fourier Transform NMR spectrometer in $CDCl_3$ solutions with TMS as the internal standard. UV spectra were obtained in methanolic solutions with a Perkin–Elmer 124 model spectrophotometer. Thermogravimetric measurements were performed with a Cahn RG electromicro balance applying a heating rate of 2° min^{-1} in an atmosphere of static air. Melting points were recorded using a hot-stage microscopy and are uncorrected. Conductivity measurements were performed in methanol using a CD 7A Tacussel conductivity bridge. The solutions were thermostated at 25 ± 0.02°C by a double water bath and stirred by means of a magnetic stirrer. The procedure of measuring and calculation of equivalent limiting conductivity and ion-pair association constants of the sodium salt complexes was the same as described elsewhere.[12] The conductance data were analyzed by the Fuoss–Onsager theory in the usual form,[18] through an iterative machine calculation procedure using the expanded form of Fuoss–Hsia conductance equation.

Chemical analyses were performed in the Microanalytical Laboratory of the Rudjer Bošković Institute.

RESULTS AND DISCUSSION

The physical properties and the results of the elemental analysis of the novel complexes, as well as the conductance data, are given in Table 1. The well-defined 1 : 1 (metal : crown) salt complexes are yellow or orange solids. Some of them are hygroscopic compounds, as well as are the free sodium salts, but after drying *in vacuo* they were obtained in an anhydrous form, as was confirmed by elemental and thermogravimetric analyses, and spectral data.

The dimensions of the crown ether hole and the metal ion basically control the stoichiometry of the complex and the lattice position of the metal ion with respect to the crown ether hole. This relationship holds best for the smaller, relatively rigid ligand

Table 1. Analytical results and some physical properties of the novel complexes

molecules. A larger and more flexible crown ether can fold to produce smaller cavities and then bind smaller cations. The formation of complexes between DB24C8 (hole diameter about 4.7 Å) and sodium salts (cationic diameter 1.94 Å) is a good example of this property. A stable complex may be formed if a change in conformation can occur to give one in which the spatial distribution of the oxygen atoms can establish interactions with the cation. Whether this can occur depends largely on the balance between the increase in the free energy on forming ion–dipole bonds with the cation and the energy required by the ligand to achieve an ideal conformation for complexation. Previous studies with DB24C8 have shown that sodium salts may react to give 1:1 and 2:1 complexes, respectively, regardless of the nature of the anion.[5,8,19,20] For example, while the complex with sodium thiocyanate is a bimetallic complex, where the nitrogen atoms of the anions bridge two sodium ions,[5] in sodium picrate and tetraphenylborate complexes it is unlikely that the related anions can take part in this type of bonding, and only 1:1 complexes were obtained.[8,19]

Sodium salts of monoalkyl benzeneazophosphonates produce 1:1 complexes with DB24C8 from a 1:1 as well as a 2:1 reaction mixture, regardless of the anion used. The stoichiometry of the complexes was also conductometrically confirmed. The very low melting points of the complexes obtained, as against the high melting points of the free sodium salts (above 220°C), indicate that the charge of the sodium ion in the complexes is extensively delocalized. Some degree of charge transfer between the sodium ion and anion can take place, increasing the stability of the complex. Although conductance data and some spectral evidences (see later) confirmed that all sodium salts form complexes in alcoholic solutions, they cannot always be isolated in the solid state. Generally, it was shown that the failure to isolate the metal salt complexes can be attributed either to the strong M^+A^- ion association as a consequence of which M^+ fails to cause the necessary polarization of the crown ether molecule (acetonitrile solutions), or to the strong hydrogen bonding between the anion or cation and the media of synthesis (alcoholic solutions). The isolation possibility of a complex is not necessarily related to its solution stability. Differences which were observed in the preparation of complexes of sodium monoalkyl benzeneazophosphonates can be attributed to the different solubilities of sodium salts in the solvent of reaction. The very low solubility of sodium salts NaA_1–NaA_4 in acetonitrile may contribute to our failure to isolate their complexes from acetonitrile solutions.

For a better understanding of the interaction forces which act in solution between the cation–crown complexes formed and the surrounding solvent molecules, a systematic conductometric study of crown ether complexes has been undertaken in methanol at 25°C. The equivalent conductance dependence on the concentration of complexes with sodium salts of monoethyl esters is shown in Fig. 1. which plots equivalent conductance as a function of (concentration)$^{1/2}$. The values of the equivalent conductance at infinite dilution (Λ_o) of the complexes are compared with those obtained for the free sodium

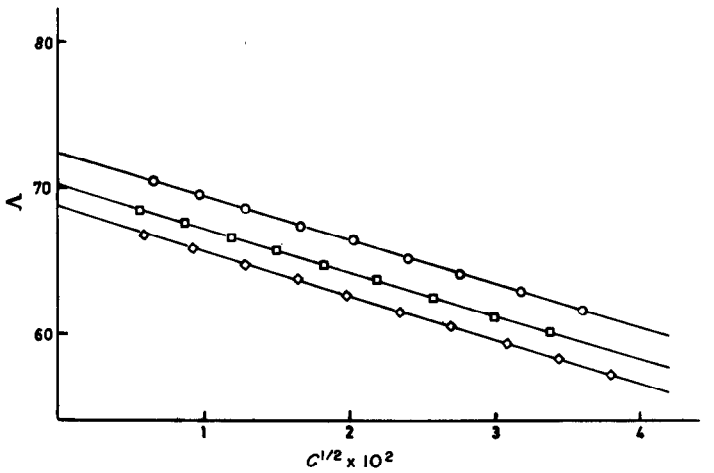

Fig. 1. Equivalent conductance [Λ (Ω^{-1} cm^2 mol^{-1})] vs (concentration)$^{1/2}$ {$C^{1/2}$ [(mol l^{-1})$^{1/2}$]} plots of complexes: (○) Na(DB24C8)A_1, (□) Na(DB24C8)A_3 and (◇) Na(DB24C8)A_5.

salts,[13] and the results obtained are summarized in Table 1. The great differences between the Λ_o values of the free sodium salts and their sodium salt complexes can be explained by assuming that the crown ether complexation considerably increases the size of the cation and that the structure of the complex is such that a few solvent molecules can remain associated with the cation. Undoubtedly, the sodium ion is less strongly bonded to the solvent dipoles than to the negatively charged oxygen of the crown ether, with the consequence that the solvodynamic unit of the sodium cation in pure methanol has a smaller size than the complex cation in the presence of the crown compound. With completely dissociated ion-pairs, where the sodium ion is more exposed to the solvent, some additional interaction of the sodium complex with the solvent molecules causes a further decrease in the complex mobility. The gradation in Λ_o values of the complexes reflects the different final size of the solvodynamic ion–crown units.

The conductivity data obtained show no association with ion-pairs for crown ether complexes in pure methanol. Ion-pair separation is favored when more oxygen atoms are available for co-ordinating with the alkali ion and when the polyether ring is large enough to accommodate the cation. In this case the positive charge of the cation is strongly shifted and there is no appreciable formation of ion-pairs with the anion. This assumption corroborates the results obtained for the conductance of sodium picrate complexes of DB24C8 and some crown ethers with an 18-membered polyether ring.[11,13,21]

Spectral studies

UV spectra. The UV spectra of the complexes dissolved in methanol indicate metal–crown ether interaction. DB24C8 has, in methanol, a characteristic absorption at 276 nm. Upon complex formation distinctive changes in this peak may be noticed if alkali salts themselves do not absorb too strongly in the region of 270–290 nm.[22] In the spectra of complexes of sodium monoalkyl benzeneazophosphonates a slight hypsochromic shift, and the appearance of a new peak in some cases not clearly separated from the main one at about 280 nm, can be attributed to complex formation (see Table 2). It is evident that interactions between crown ether and sodium salts can take place in solution even when it is not possible to isolate the complex in crystalline form.

Sodium salts give an absorption maximum at 397 nm (log ε = 4.45) which corresponds to conjugation of the azo group with aromatic rings (π–π^* transition). It remains unchanged upon complex formation, suggesting that there is no co-ordinated ionic benzeneazophosphonato group.[13]

IR spectra. IR spectra of the crown ether complexes with sodium monoalkyl benzeneazophosphonates are too complex to allow a complete assignment of the absorption bands. However, in every case the spectrum of the solid complex distinctively differed from that of the physical mixture of the constituents. Generally, the greatest changes may be noticed in the region 1260–900 cm^{-1}, where bands arising from various modes of vibration of ether and methylene groups are present. Since all sodium salts alone give a series of complex bands between 1165 and 1240 cm^{-1}, characteristic of asymmetric PO_2^- stretching, and very strong and broad bands between 1070 and 1110 cm^{-1}, characteristic of the symmetric stretching of the ionized PO_2^- group, as well as medium or strong absorption bands around 1150 cm^{-1} due to the C—O—(P) part of the P—O—C bond,[16,23,24] it is

impossible to determine the exact position of the bands assigned to the ether groups. Considerable changes may, however, be noticed in the 1000–900-cm^{-1} region, which contains bands attributed to wagging, twisting and rocking modes of vibration of the methylene groups. While free DB24C8 has two strong bands at 958 and 920 cm^{-1}, and a medium one at 936 cm^{-1} associated with these vibrations, the complexes are characterized by a strong or medium band around 940 cm^{-1} and a medium or weak band around 920 cm^{-1} (Table 2). Less restriction on the coupling of these vibrational modes in the salt complexes is probably due to some bonding between the oxygen atoms of the crown ether ring and the sodium ion.

^{1}H NMR spectra. The proton chemical shifts of DB24C8 and its sodium salt complexes are summarized in Table 2. The resonances of the anion protons are omitted.[13] Free crown ether has three sets of resonant signals at about $\delta = 4.16$ ppm for methylene protons of the polyether ring.[14] The complex spectrum in the ether region can be attributed to the chemically nonequivalent ether fragments (Fig. 2), and the main reason for the separation of the ether resonances is the chemical-shift anisotropy of the benzo groups. Comparison with the spectra of complexes shows chemical-shift differences for all ether protons between complexed and noncomplexed crown ethers. The shift for the aromatic protons remains essentially unchanged on complexation. In the spectra of complexes with sodium salts of nonsubstituted and 4-methoxy-substituted benzeneazophosphonates the so-called "inner" CH_2—O—CH_2 polyether ring protons (H_2 and H_3) are shifted upfield by 7–12 Hz, while the so-called "outer" Ar—O—CH_2 protons (H_1) are shifted upfield only by 3–4 Hz. For the complexes with 4-hydroxy-substituted benzenazophosphonates these chemical shift differences are more visible, so the inner protons are shifted upfield by 26–31 Hz and outer protons by 10–12 Hz, respectively. The close proximity of the crown ether molecule to the aromatic rings of the anion causes a stronger upfield shift of the inner protons and a somewhat lesser one

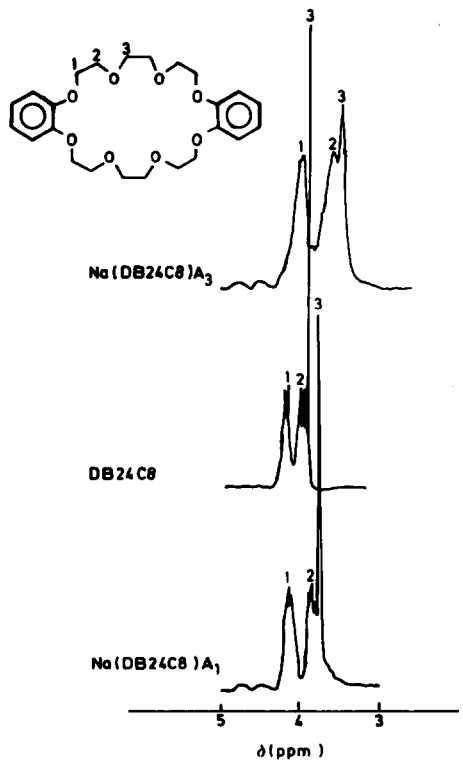

Fig. 2. ^{1}H NMR spectra of the ether region of DB24C8 and two of its complexes in $CDCl_3$. Shifts are relative to TMS.

of the outer protons in spite of the complexation with the sodium cation, which, in itself, would induce a downfield shift due to the increased electronegativity of the oxygen atoms. A similar situation was observed in the spectrum of the sodium tetraphenylborate complex, while the sodium perchlorate and picrate complexes with DB24C8 show a slight upfield shift for the inner protons and a slight downfield shift for the outer protons.[8] Obviously, the anion has an important role in the resulting chemical shift of the polyether ring protons.

In a salt–ligand system the choice of anion is important, as well as the choice of ligand, for the ease of solubilization and the resulting charge separation in solution.

BINUCLEAR SCHIFF BASE COMPLEX OF COBALT(II) LINKED BY *m*-PHTHALOYL AS A BRIDGING GROUP

K. KASUGA,* T. OISHI and Y. YAMAMOTO

Department of Chemistry, Faculty of Science, Shimane University, Matsue 690, Japan

(*Received* 8 *May* 1985; *accepted* 2 *October* 1985)

Abstract—A binuclear cobalt(II) complex with an unsymmetrical quadridentate Schiff base linked by *m*-phthaloyl was prepared and characterized. The complex formed both 1 : 1- and 2 : 1-type oxygenated species in a benzene solution containing 1% of pyridine at room temperature. Although the mononuclear cobalt(II) complex did not significantly catalyze the auto-oxidation of *N*,*N*,*N*′,*N*′-tetramethyl-*p*-phenylenediamine, the reaction was catalyzed by the binuclear cobalt(II) complex.

Binuclear metal complexes have been widely investigated in view of their magnetism and catalytic activities.[1–5] For instance, flexible copper(II) complexes have received considerable attention for their resemblance to Type-III copper proteins.[6–8] Previously, we prepared Schiff base copper(II) complexes linked by dithiol or phthaloyl, and investigated their catalytic activities.[9,10] Binuclear cobalt(II) complexes have also been studied as catalysts for various redox reactions, e.g. tetrakis(bipyridyl)(μ - peroxo)(μ - hydroxo)dicobalt(III) catalyzed the auto-oxidation of 2,5-di-*tert*-butylphenol.[11] Collman *et al.* also studied the catalytic potency of binuclear cobalt(II) cofacial porphyrin complexes for the electroreduction of oxygen to water.[12,13] In this paper, we report the preparation of the binuclear cobalt(II) complex with a Schiff base linked by *m*-phthaloyl (Fig. 1) and its oxygenation, as well as a catalytic activity for the auto-oxidation of *N*,*N*,*N*′,*N*′-tetramethyl-*p*-phenylenediamine (TMPD).

EXPERIMENTAL

Preparation of the mononuclear cobalt(II) complex

A free mononuclear ligand, *N*-(1-methyl-3-oxobutylidene) - *N*′ - salicylideneethylenediamine, was prepared by elimination of copper(II) ion from its complex with hydrogen sulfide.[10] In the present experiment, the ligand was prepared as follows: to 600 cm^3 of a benzene solution containing 50 cm^3 (0.5 mol) of acetylacetone and 56 cm^3 (0.5 mol) of salicylaldehyde, 33 cm^3 (0.5 mol) of ethylenediamine was added dropwise, and the mixture was refluxed for *ca* 3 h. After evaporation of the solvent under a reduced pressure, 300 cm^3 of ethanol was added to the residue, which was stirred for a few minutes. On standing the solution at −7 to −10° C for *ca* 30 min, large amounts of *N*,*N*′-disalicylideneethylenediamine (Salen) were precipitated and were filtered off. After adding adequate amounts of *n*-hexane to the filtrate, the solution was left overnight at 2–4°C. Yellow needles of the ligand then precipitated were washed by *n*-hexane and were dried under a reduced pressure at room temperature. Found: C, 68.3; H, 7.2; N, 11.4%. Calc. for $C_{14}H_{18}N_2O_2$: C, 68.3; H, 7.4; N, 11.4%. ^1H NMR (dimethylsulfoxide-d_6): δ 2.05 (3H, s, CH_3), 2.18 (3H, s, CH_3), 3.96–4.29 (4H, m, CH_2CH_2), 5.54 (H,

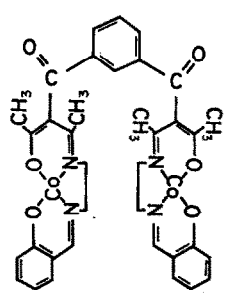

Fig. 1. Binuclear Schiff base complex of cobalt(II) linked by *m*-phthaloyl.

* Author to whom correspondence should be addressed.

s, CH), 7.69–8.45 (4H, m, benzene), and 9.67 (H, s, azomethine). Cobalt(II) acetate tetrahydrate (0.52 g, 2.1 mmol) was added to 20 cm^3 of an acetone solution of the free ligand (0.50 g, 2.0 mmol), and the solution was stirred at room temperature for 20–30 min under a nitrogen atmosphere. Orange precipitates were then obtained and were recrystallized from acetone (yield 62%). Found: C, 54.0; H, 5.3; N, 9.0%. Calc. for $C_{14}H_{16}N_2O_2Co \cdot 0.5H_2O$: C, 53.9; H, 5.5; N, 9.0%.

Preparation of the binuclear cobalt(II) complex

A free binuclear ligand was obtained by elimination of copper(II) ion from its complex which was prepared by the method described before:[10] gaseous hydrogen sulfide was bubbled through a chloroform solution of the copper(II) complex at room temperature for 10–20 min. After filtering off copper(II) sulfide, active charcoal was added to the filtrate, and the mixture solution was stirred for several minutes. After filtering off the charcoal, crude precipitates of the free ligand were obtained by concentrating the filtrate to adequate amounts under a reduced pressure. The pale yellow ligand was then obtained by column chromatography on silica gel using dichloromethane as an eluent. Found: C, 66.4; H, 5.5; N, 8.5%. Calc. for $C_{36}H_{38}N_4O_6 \cdot 0.5CH_2Cl_2$: C, 65.9; H, 5.9; N, 8.4%. ^{1}H NMR (dimethylsulfoxide-d_6): 1.88 (6H, s, CH_3), 2.05 (6H, s, CH_3), 4.13–4.22 (8H, m, CH_2CH_2), 7.81–8.56 (8H, m, benzene), and 9.54 (2H, s, azomethine). To 20 cm^3 of the acetone solution containing 0.50 g (0.80 mmol) of the free ligand, 0.42 g (1.7 mmol) cobalt(II) acetate tetrahydrate was added under a nitrogen atmosphere. After stirring the solution at room temperature for 10–20 min, dark brown precipitates were obtained and were recrystallized from acetone under a nitrogen atmosphere (yield 7%). Found: C, 55.0; H, 4.7; N, 6.8%. Calc. for $C_{36}H_{34}N_4O_6Co_2 \cdot 3H_2O$: C, 54.7; H, 5.1; N, 7.1%.

Measurements

The electronic and ^{1}H NMR spectra were obtained by the method described before.[10] The measurements of oxygen affinities of the complexes were also carried out by the method described before.[14]

RESULTS AND DISCUSSION

The free binuclear ligand was obtained by elimination of copper(II) ion from its complex with hydrogen sulfide, and was identified by elemental analysis, ^{1}H NMR and electronic spectra. In the ^{1}H NMR spectrum of the binuclear ligand, the signal for the methine proton of the mononuclear ligand disappeared, and new signals for benzene protons of the phthaloyl group were observed, indicating that the Schiff base ligands are linked by the bridging group. The signals for the methyl groups of the binuclear ligand are somewhat shifted to higher magnetic fields, compared to those of the mononuclear ligand, due to an anisotropic effect of a carbonyl group in the bridging group. The electronic spectrum of the binuclear ligand shows a π–π^* absorption band at 320 nm, and that of the mononuclear species is at 310 nm. Acetone is a suitable solvent for preparation of the mono- and binuclear cobalt(II) complexes. With other solvents such as water, methanol and ethanol, as well as a solvent mixture of acetone and water, the pure complexes could not be obtained. The mono- and binuclear cobalt(II) complexes show *d–d* absorption bands at 490 and 485 nm in a benzene solution, respectively. Both complexes also show charge-transfer bands around 400 nm.

Oxygenation

Spectral changes were recorded for benzene solutions of the mono- and binuclear cobalt(II) complexes containing 1% of pyridine at different partial pressures of oxygen at 20°C. When the mononuclear complex was oxygenated, a new band was observed at 530 nm, as was seen in the oxygenation of other mononuclear cobalt(II) complexes.[15–17] With increasing partial pressure of oxygen, the intensity of the band was monotonously increased. If the mononuclear cobalt(II) complex forms only a 1:1-type oxygenated species, the equilibrium constant for oxygenation (K) is given by the following relation:

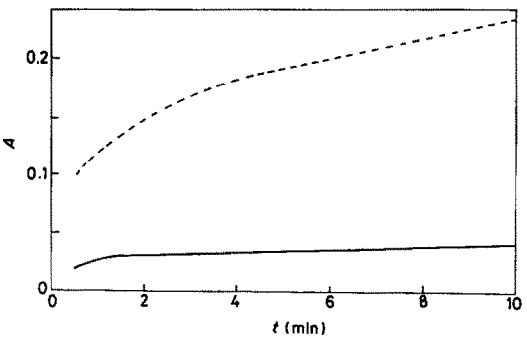
$$P(O_2) = -1/K + (\varepsilon_2 - \varepsilon_1)[\text{Co(II) complex}]_t[P(O_2)]/(A - A_o), \quad (1)$$

where A_o and A are the absorbances at 550 nm in the absence of oxygen and at the proper partial pressure of oxygen, ε_1 and ε_2 are the molar absorption coefficients of the cobalt(II) complex and the oxygenated species, $P(O_2)$ is the partial pressure of oxygen, and $[\text{Co(II) complex}]_t$ is the total concentration of the complex. The plot of $P(O_2)$ against $[P(O_2)]/(A - A_o)$ gave a straight line with a slope nearly equal to 1. This implies that the 1:1-type oxygenated species is predominantly formed in the solution, and the value of log K is -2.95 $torr^{-1}$ (1 torr = 133.322 Pa). This value is in the range of those which were previously reported for the cobalt(II) complexes with *N,N'*-bis(1-methyl-3-oxobutylidene)ethylenediamine, *N,N'*-bis(1-methyl-

3-oxo-3-phenylpropyridene)ethylenediamine and their derivatives.[18,19] It is interesting that the cobalt(II) complex with the unsymmetrical quadridentate Schiff base forms the 1:1-type species, because the cobalt(II) complex with Salen forms a 2:1-type peroxo-bridged species at room temperature.[20]

In the case of the binuclear cobalt(II) complex, the intensity of the band around 500 nm also increased on oxygenation. However, it reached a maximum when the $P(O_2)$ was *ca* 230 torr, and then gradually decreased with an increase in oxygen pressure (Fig. 2).

The same tendency has also been reported for the mononuclear cobalt(II) complexes with a Jäger-type ligand: the species formed under a high partial pressure is the 1:1-type species, and the species under a low oxygen pressure is the 2:1-type peroxo-bridged species.[15] Therefore, the following scheme might represent the oxygenation reaction of the binuclear cobalt(II) complex:



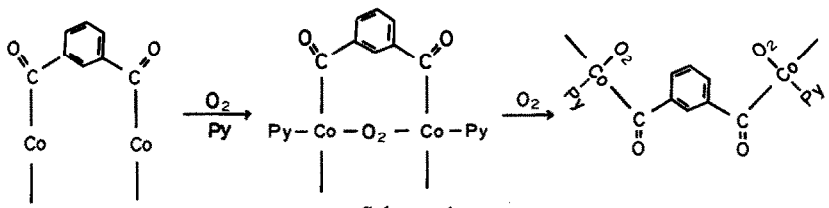


Fig. 3. Time course of the absorbance at 560 nm for the auto-oxidation of TMPD by oxygen in the presence of the cobalt(II) complexes at 20°C; a solvent mixture of methanol and *N*,*N*-dimethylformamide [1:1 (v/v)] was employed: $[TMPD]_t = 5.00 \times 10^{-4}$ mol dm^{-3}: (——) the mononuclear cobalt(II) complex, $[complex]_t = 2.50 \times 10^{-4}$ mol dm^{-3}; (– – –) the binuclear cobalt(II) complex, $[complex]_t = 1.25 \times 10^{-4}$ mol dm^{-3}.

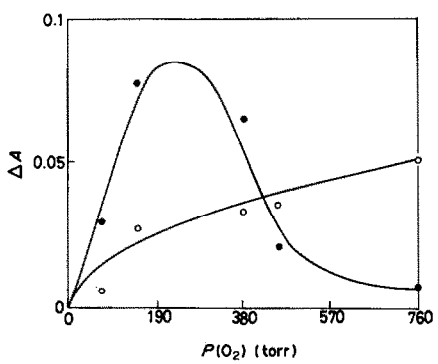
Scheme 1.

At present, both oxygenated species of the mono- and binuclear complexes have not been isolated as a solid.

Catalytic activities

The catalytic activities of the cobalt(II) complexes for the auto-oxidation of TMPD are shown in Fig. 3.



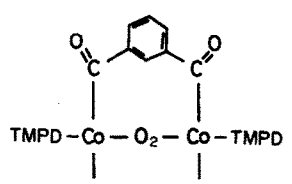


Fig. 2. Plots of absorbance vs partial pressure of oxygen in the benzene solution containing 1% of pyridine at 20°C: (○) the mononuclear cobalt(II) complex, $[complex]_t = 2.00 \times 10^{-4}$ mol dm^{-3}, wavelength used for the measurement = 560 nm; (●) the binuclear cobalt(II) complex, $[complex]_t = 1.00 \times 10^{-4}$ mol dm^{-3}, wavelength = 500 nm. The absorances are shown as differences from that of the nonoxygenated species.

Although the mononuclear cobalt(II) complex did not show an effective catalytic activity, the binuclear complex greatly catalyzed the reaction. It has been reported that the catalytic activity of the binuclear copper(II) complexes for the auto-oxidation of TMPD is closely related to the presence of two adjacent copper(II) ions with the optimum copper(II)–copper(II) distance: e.g. oxygen simultaneously accepts two electrons from the TMPD molecules through the copper(II) ions, resulting in peroxide.[8] The binuclear cobalt(II) complex may form the following intermediate which catalyzes the auto-oxidation of TMPD in a similar manner to the binuclear copper(II) complexes reported by Nishida *et al.*:[5–8]

Scheme 2.

The reaction was not catalyzed by the binuclear copper(II) complex with the ligand used for the present experiment,[10] presumably due to the fact

that the ligand is not flexible enough to form the intermediate. However, the binuclear cobalt(II) complex can form the 2 : 1-type oxygenated species, which indicates that the intermediate must be formed easily, showing the catalytic activity.

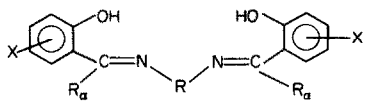
ELECTROCHEMISTRY AND OXYGENATION KINETICS OF TETRADENTATE SCHIFF BASE MANGANESE(II) COMPLEXES



F. C. FREDERICK and L. T. TAYLOR*

Department of Chemistry, Virginia Polytechnic Institute and State University, Blacksburg, VA 24061, U.S.A.

(*Received* 21 *June* 1985; *accepted after revision* 4 *October* 1985)

Abstract—The electrochemistry and oxygenation kinetics of a series of Mn(II) complexes containing ligands derived from substituted salicylaldehyde and linear diamines have been studied. Complexes prepared from ethylenediamine produce cyclic voltammograms with a quasi-reversible Mn(II)–Mn(III) couple and oxygenation reactions which are first-order in both complex and O_2, indicating formation of an Mn(III)–O_2^- species as the slow step in the reaction. The ease of oxidation/oxygenation increases with increasing electron-donating ability of substituents on the salicyladehyde rings. Complexes with from six to 10 methylene groups in the diamine precursor produce highly irreversible voltammograms and oxygenation data which can not be interpreted in terms of a simple mechanism. Polymerization of the complexes is advanced as an explanation for these effects.

Mn(II) complexes containing polydentate ligands are often found to be oxidizable, either by electrochemical anodization or exposure to molecular oxygen.[1,2] We have previously described the electrochemical and oxygenation properties of a series of Mn(II) and Mn(III) complexes containing polydentate Schiff base ligands,[3–8] among them the tetradentate species shown in structure **I**. Redox

I: X = NO_2, CH_3O, Cl, H, or CH_3; R_α = H, Ph; R = *o*-Ph or $(CH_2)_n$

potentials and oxygenation products were found to be dependent on the aryl (X) and imine carbon (R_α) substituents as well as the nature of the bridging (R) group. Oxygen sensitivity was also dependent on the physical state of the complex and, if in solution, the solvent choice in a number of instances. Cationic complexes such as those prepared from pyridine-2-carboxaldehyde instead of salicylaldehyde were oxygen-insensitive and electrochemically inactive.

This paper describes the oxygenation kinetics of some of these Mn(II) complexes [X = 3-CH_3O, 5-Cl or H; R = $(CH_2)_n$ (n = 2, 4, 6, 7, 8 or 10); R_α = H].

The oxygenation products of these complexes have been well characterized, but no firm data on the reaction mechanisms had previously been acquired. Also, comparison of results obtained with the tetradentate chelates with those previously reported for tridentate complexes[3] adds support to a number of theories earlier advanced to explain the tridentate results.

EXPERIMENTAL

Syntheses

The following complexes were prepared according to previously reported literature procedures:[4] Mn($SALC_2$), Mn(3-MeO$SALC_2$), Mn(5-Cl$SALC_2$), Mn($SALC_4$), Mn($SALC_6$), Mn($SALC_7$), Mn($SALC_8$) and Mn($SALC_{10}$).

Electrochemical studies

Voltammetric studies were performed using a combination 551 Potentiostat–Galvanostat and 567 Function Generator from ECO Instruments. The electrodes used were a Beckman platinum disc (working), Fisher saturated calomel (reference) and platinum coil (counter). Solutions were $\sim 10^{-3}$ M complex in degassed dimethylsulfoxide (DMSO) or

* Author to whom correspondence should be addressed.

pyridine, with 0.1 M tetraethylammonium perchlorate as supporting electrolyte.

Kinetic studies

The reaction of complexes with O_2 was studied by following the change in the concentration of either the complex or O_2 as a function of time in an excess ($>10:1$) of the other reactant. The concentration of complex was followed by repetitively scanning the UV spectrum of the solution with an Aminco DW-2 Spectrophotometer. The concentration of O_2 was followed using a 731 Clark-type oxygen electrode from Transidyne General Corp. The order of the reaction with respect to the reactants, specific rate constants, and activation parameters were determined by standard methods.[9]

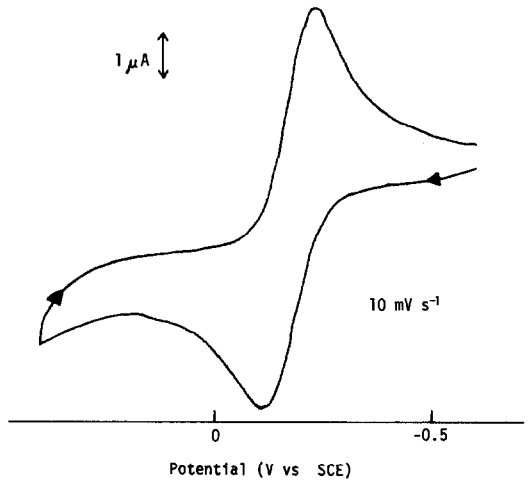


Fig. 1. Cyclic voltammogram of Mn(3-MeOSALC$_2$) in pyridine.

RESULTS AND DISCUSSION

Electrochemical studies

The voltammetric properties of the complexes are a function of the polymethylene chain length. The complexes thus divide themselves into two groups, the substituted Mn(XSALC$_2$) type and the longer chain Mn(SALC$_n$) type. Mn(SALC$_4$) falls into a group by itself, as it was insufficiently soluble in either DMSO or pyridine to give measureable voltammetric signals.

The voltammograms of the Mn(XSALC$_2$) complexes are similar to those previously reported for Mn(SALOPHEN) tetradentate complexes.[5] In both DMSO and pyridine, the complexes exhibit a single pair of coupled peaks, with approximately equal oxidation and reduction currents (Fig. 1), and a constant value for $i_{ox}/n^{1/2}$. The peak separation (Table 1) is greater than 59 mV, and generally increases with increasing scan rate. Comparison of these results with other systems leads to an assignment of the peaks to a quasi-reversible Mn(III)–Mn(II) couple. The solution geometry of both oxidation states is undoubtedly octahedral, with a planar tetradentate ligand and *trans*-coordinated solvent molecules. A cathodic shift in peak potentials is observed on going from pyridine to DMSO. Since the *relative* stabilization of the two manganese oxidation states determines the redox potential, Mn(II) is apparently more favored when coordinated to pyridine than when coordinated to DMSO (Fig. 2).

Voltammograms of the longer-chain complexes could only be obtained in pyridine because of their low solubility in DMSO. A typical voltammogram

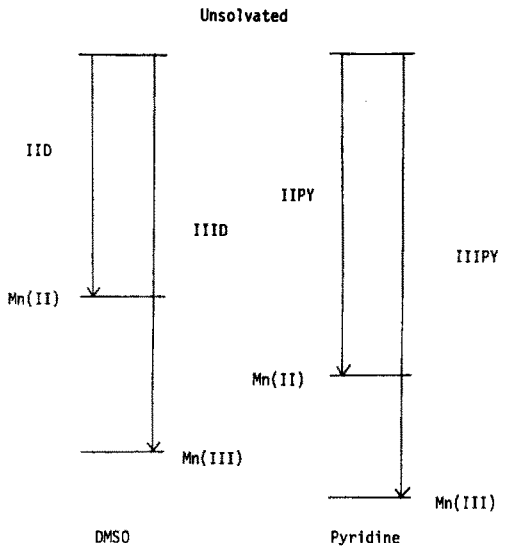

Fig. 2. Coordinated solvent effect on macrocyclic complex redox potentials.

(Fig. 3) contains a large "hump" on or near the solvent oxidation wave on the initial anodic scan, and a smaller, normally shaped cathodic peak on the reverse sweep. The peaks are quasi-reversible in that their separation increases with increasing scan rate, but, unlike the $Mn(XSALC_2)$ complexes, the separation is much greater than 59 mV even at very low scan rates (1 mV s^{-1}). The earlier report of an irreversible reduction for $Mn(SALC_7)(NCS)$[9] is in agreement with this work. A plausible explanation was advanced in this case wherein the monomeric Mn(III) species was suggested to be reduced to a polymeric Mn(II) species. The $Mn(SALC_n)$ species were previously postulated to be polymeric with bridging ligands in the solid state, based on their low solubilities and ESR spectra,[4] and a carry over of this property to a solution phase seems possible. The data therefore imply that the redox scheme is: (1) oxidation of a Mn(II) polymer, (2) slow depolymerization to give an electroactive Mn(III) monomer, and (3) reduction of the monomer with immediate reformation of the Mn(II) polymer.

Voltammograms of $Mn(SALC_{10})$ exhibit further irregularities. At relatively high scan rates, its voltammograms resemble those of the other $Mn(SALC_n)$ complexes. However, as the scan rate is decreased, a second reduction peak grows in at a potential cathodic to the first reduction peak. Such a change is usually indicative of reaction of the initial oxidation product [monomeric Mn(III)] to produce a second electroactive species which is oxidized at a slightly different potential. In this case, the new species has a more negative reduction potential [i.e. it has a more stable Mn(III) center]. Since one way to stabilize Mn(III) is by adding more ligands, one explanation for these time-dependent voltammograms may arise from a slow solvent attack on initially tetrahedral Mn(III) monomers to produce octahedral Mn(III) monomers with two-coordinated solvent molecules. We have found that bi-[10] and tridentate[3] Schiff base complexes of Mn produce time-dependent voltammograms explainable by solvent attack and/or loss. Assignment of tetrahedral geometry to the initial oxidation product seems feasible since it should resemble the Mn(II) starting material, which has been shown to have "pseudo-tetrahedral" geometry in the solid state.[4] A second irregularity occurs when a second anodic scan is performed immediately after a slow cathodic scan. A second oxidation peak is now found anodic to the "hump". Since it is found only after a slow cathodic scan where reduction of a large amount of octahedral Mn(III) is occurring, we

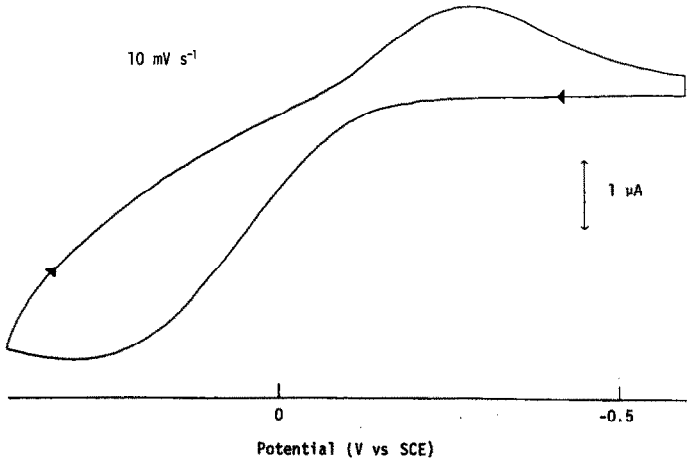

Fig. 3. Cyclic voltammogram of $Mn(SALC_8)$ in pyridine.

believe this peak is due to oxidation of accummulated octahedral Mn(III) which slowly loses solvent before quick collapse to the Mn(II) polymer.

Oxygenation kinetics

Oxygen uptake studies have shown that all of these complexes oxygenate in two distinct steps, first to a μ-oxo-Mn(III) dimer, and second, to a di-μ-oxo-Mn(IV) dimer. However, as in the electrochemical study, the complexes are again separable into short- and long-chain groups. Also, no information could be gained on Mn(SALC$_4$) because its reaction with O_2 was too slow to be conveniently followed via repetitive scanning spectrophotometry. This was also true for Mn(5-ClSALC$_2$), an effect directly attributable to the strong electron-withdrawing effect of the Cl substituent.

A typical repetitive spectrophotometric scan for the oxygenation of Mn(SALC$_2$) in DMSO at low temperature is shown in Fig. 4. Only the first step in the overall reaction (formation of the μ-oxo-dimer) is seen. There is a significant difference between these changes and those of bi-[10] and tridentate[3] complexes in that the tetradentates exhibit a monotonic increase across the spectral range while the other complexes have isobestic points in their spectra. This may be attributed to differences in the changes in ligand geometry and coordination number during oxygenation, and also the fact that the oxidized tetradentate complexes are oxo-bridged dimers, while bi- and tridentate Mn(III) complexes are believed to be monomers with no incorporated reduced form of O_2.

The second step can be observed if the temperature is raised, if the MeO complex is used, or if pyridine is used as the solvent (Fig. 5). Two points should be noted on Fig. 5. First, an isosbestic point occurs at 355 nm. This is fortunate because separation of the spectral changes due to the discrete steps would be difficult without this feature. A different type of spectral change is to be expected for this step since formation of *cis* metal–oxygen bonds requires folding of the ligand from a planar structure. Second, there is no incubation period in the reaction as opposed to that found in the earlier manometric studies.

Numerical analysis of both the UV spectral changes and Clark electrode data for the first oxygenation step show that it is first-order in both complex and O_2. No attempt was made to study the kinetics of the second step. The first step is therefore believed to be:

$$\text{Mn(II)L} + O_2 \rightarrow \text{LMn(III)}\text{–}O_2^-$$

Table 2, however, which gives activation parameters for the first step, shows that there is some complexity in the system. The greater rate constants and lower activation energies for oxygenation of the MeO complex were predictable because of the activating MeO group. Also, if the previously advanced theory of solvent replacement by O_2 in the RDS is correct,[3] then the lower E_a values in DMSO relative to pyridine are no surprise since pyridine is apparently a better ligand for the Mn(II) complexes than DMSO. The difference in E_a values is larger here than observed for the tridentate complexes, however, because there is no competition between a potentially tridentate ligand donor oxygen and solvent for the axial coordination position.

Solvent and substituent effects on activation entropies are not quite as straightforward. The

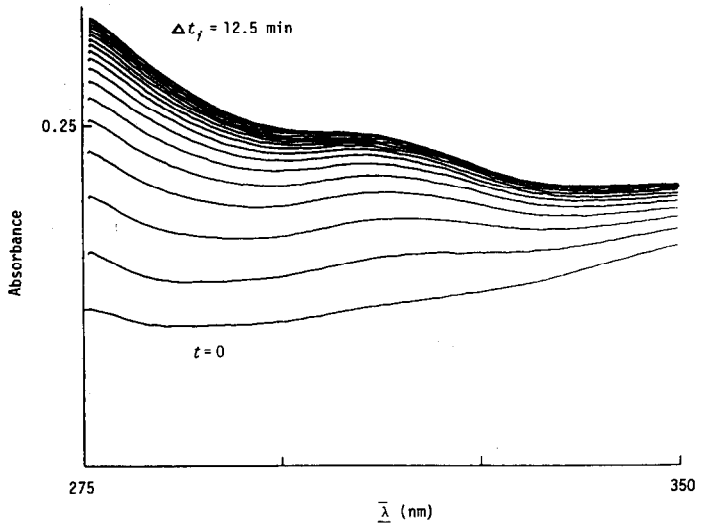

Fig. 4. Repetitive scan of oxygenation of Mn(SALC$_2$) in DMSO.

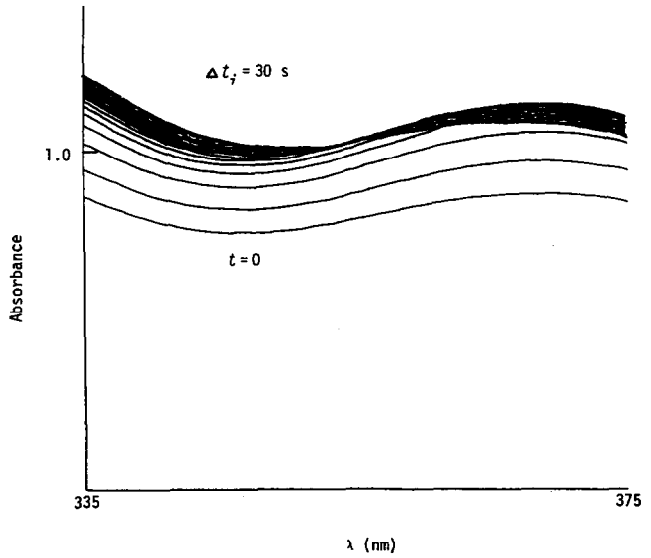

Fig. 5. Repetitive scan of oxygenation of $Mn(SALC_2)$ in pyridine.

addition of the MeO group lowers ΔS by ~ 10 eu in both solvents, and changing from DMSO to pyridine increases ΔS by ~ 40 eu for both $Mn(SALC_2)$ and $Mn(3\text{-}MeOSALC_2)$. Better electron donation by the tetradentate ligand, due to the attached MeO group, should both lessen the degree of solvent coordination in the Mn(II) complex via more complete neutralization of the metal charge, and increase the degree of O_2 coordination in the transition state by increasing the available electron density to transfer and produce $O_2^{\delta-}$. Both of these factors tend to decrease the value of ΔS by decreasing the randomness of the transition state with respect to the ground state. The solvent effect on ΔS may be due to two factors. First, expulsion of a more tightly held pyridine will produce a greater change in randomness than a relatively loosely held DMSO. Second, electrorestriction of DMSO by the transition state will be greater than for pyridine due to its greater dipole moment, further lowering ΔS in DMSO. The remaining steps in the reaction are not accessible via kinetic studies but a reasonable possibility is the Ochiai sequence:[11]

$$\text{LMn(III)–}O_2^- + \text{Mn(II)L} \rightarrow \text{Mn(III)–}O_2^{2-}\text{–Mn(III)L},$$

$$\text{LMn(III)–}O_2^{2-}\text{–Mn(III)L} \rightarrow 2\text{LMn(III)–}O^-,$$

$$\text{LMn(III)–}O^- + \text{Mn(II)L} \rightarrow \text{LMn(III)–}O^{2-}\text{– Mn(III)L}.$$

Table 2. Kinetic parameters for tetradentate oxygenations

		23.7	300 (20)		

[a] Averages with errors in parentheses.

The longer-chain complexes exhibit spectral changes in pyridine similar to those of the $Mn(XSALC_2)$ complexes (i.e. a monotonic increase in absorption across the spectrum). In DMSO, however, the absorbance decreases to a flat line above zero absorbance, typical of a suspension rather than a solution. The Mn(II) complexes are much more soluble in pyridine than in DMSO, and the differences carries over to their μ-oxo-Mn(III) products. $Mn(SALC_{10})$ differs from the other three long-chain complexes in that its Mn(III) product is soluble, possibly due to the longer alkyl chain imparting more "organic" character to the complex, and thus greater compatibility with the solvent. Continuing the scans for a longer period results in a further change to a relatively featureless spectrum similar to that of the Mn(II) complex. This is due to the second step of the reaction, formation of di-μ-oxo-Mn(IV).

Clark electrode data showed that the oxygenation reaction with the long-chain chelates was first order in O_2, but difficulties were encountered when the order of the reaction with respect to the complex was being determined. First-order plots showed marked curvature, as did second- and half-order plots. This immediately eliminates the following reactions from being the RDS:

$$Mn(II)L + O_2 \rightarrow LMn(III)\text{–}O_2^- \quad \text{(first-order)}, \quad (1)$$

$$2Mn(II)L \rightleftharpoons [Mn(II)L]_2,$$

$$[Mn(II)L_2]_2 + O_2 \rightarrow L_2Mn(II)Mn(III)\text{–}O_2^- \quad \text{(second-order)}, \quad (2)$$

$$[Mn(II)L]_2 \rightleftharpoons 2Mn(II)L,$$

$$Mn(II)L + O_2 \rightarrow LMn(III)\text{–}O_2^- \quad \text{(half-order)}. \quad (3)$$

A second-order reaction which could not be immediately eliminated is:

$$Mn(II)L + O_2 \rightleftharpoons LMn(III)\text{–}O_2^-,$$

$$LMn(III)\text{–}O_2^- + Mn(II) \xrightarrow{RDS} LMn(III)\text{–}O_2^{2-}\text{–}Mn(III)L.$$

Steric hindrance by the relatively bulky C_n chains could slow down formation of the μ-peroxo dimer until it was the RDS. However, with a 10:1 excess of O_2, the first step would use up essentially all of the complex, and further reaction would proceed only as Mn(II) was removed by the second step and was replaced by the reverse reaction in the initial equilibrium. This would, of course, not be seen as a second-order reaction. Such a quick reaction with O_2, however, has not previously been seen for any Mn Schiff base complexes, even with electron-donating substituents. Furthermore, since O_2 and Mn(II) are only consumed in the first step, the manometric studies should have shown a virtually instantaneous uptake of O_2, and the spectral studies very quick absorbance changes, if this were the mechanism. They did not, therefore this mechanism may be tentatively ruled out.

Two mechanisms with mixed orders were also investigated. One involved reactive monomeric and dimeric species:

$$Mn(II)L + O_2 \overset{k_1}{\rightarrow} LMn(III)\text{–}O_2^-,$$

$$[Mn(II)L]_2 + O_2 \overset{k_2}{\leftarrow} L_2Mn(II)Mn(III)\text{–}O_2^-.$$

Numerical fits[12] to the data with this assumed mechanism, however, gave very poor results. One assumption in the fit was a dynamic equilibrium between the two complex species, and failure to follow this may explain the bad fit, and, therefore, this mechanism cannot be discarded. A final possibility is the mechanism:

$$Mn(II)L + O_2 \overset{k_1}{\rightarrow} LMn(III)\text{–}O_2^-,$$

$$LMn(III)\text{–}O_2^- + Mn(II)L \overset{k_2}{\rightarrow} LMn(III)\text{–}O_2^{2-}\text{–}Mn(III)L,$$

where the rates are approximately equal. Unfortunately, no general graphical or numerical solution can be derived for this mechanism:[13] therefore, its existence must remain speculation.

In conclusion, we have studied the electrochemistry and oxygenation kinetics of a series of Mn(II) complexes with tetradentate Schiff base ligands. Ligand modifications causing either electronic or steric changes in the ligands have been shown to have a substantial effect on these properties.

THE PREPARATION OF $Ta_2Cl_6(PhN)_2(Me_2S)_2$ BY REACTION OF $Ta_2Cl_6(Me_2S)_3$ WITH PhNNPh: CRYSTAL STRUCTURE OF THE PRODUCT

JO ANN M. CANICH, F. ALBERT COTTON,* STAN A. DURAJ and WIESLAW J. ROTH

Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A&M University, College Station, TX 77843, U.S.A.

(*Received* 24 *July* 1985; *accepted* 5 *September* 1985)

Abstract—The d^0–d^0 ditantalum complex, $(PhN)(Me_2S)Cl_2Ta(\mu\text{-}Cl)_2TaCl_2(Me_2S)(PhN)$, has been prepared from the reaction of $Ta_2Cl_6(Me_2S)_3$ and azobenzene in a benzene–toluene solution. Single-crystal X-ray data show that the dinuclear compound adopts a distorted edge-sharing bioctahedral structure with a Ta–Ta′ distance of 4.096(1) Å. Other crystallographic data are: monoclinic space group $C2/c$, $a = 20.621(4)$ Å, $b = 7.653(2)$ Å, $c = 16.812(5)$ Å, $\beta = 96.66(2)°$, $V = 2635(2)$ Å^3, $Z = 4$. The principal structural dimensions are as follows: Ta=NPh distance of 1.747(8) Å; Ta—SMe_2 distance of 2.627(3) Å; Ta—Cl distances of 2.344(3) and 2.316(3) Å for Ta—$Cl(2)_t$ and Ta—$Cl(3)_t$, and 2.751(3) and 2.454(2) Å for Ta—$Cl(1)_b$ and Ta—$Cl(1)'_b$, respectively. The title compound is isostructural with the previously reported niobium complex, $Nb_2Cl_6(PhN)_2(Me_2S)_2$.

In our earlier report we showed that the N=N bond in PhNNPh reacts with the Nb=Nb bond in $Nb_2Cl_6(Me_2S)_3$ to give a product in which there are two Nb=N bonds, namely,

$$Nb_2Cl_6(PhN)_2(Me_2S)_2.^1$$

It has since been reported that the same product can be obtained from $Nb_2Cl_6(Me_2S)_3$ by reacting it with PhN_3, whereby the required PhN moieties are generated by loss of N_2.[2] We should like to report here that the PhNNPh reagent also reacts smoothly with $Ta_2Cl_6(Me_2S)_3$ to generate the title compound, which is the exact analogue of the previously reported niobium compound and forms isomorphous crystals.

EXPERIMENTAL

All manipulations were carried out under an atmosphere of argon. Standard Schlenk and vacuum line techniques were used. Toluene, benzene and hexane were freshly distilled from benzophenone ketyl prior to use. Solutions were transferred via stainless steel cannulae and/or syringes. Azobenzene was deaerated *in vacuo* at 25°C. $Ta_2Cl_6(Me_2S)_3$[3] was prepared according to the published procedure. The IR spectrum was recorded on a Perkin–Elmer 783 spectrophotometer.

$[TaCl_2(Me_2S)(PhN)]_2(\mu\text{-}Cl)_2$

A solution of $Ta_2Cl_6(Me_2S)_3$ (0.50 g, 0.66 mmol) in 15 cm^3 of benzene–toluene 2:1 (v/v) was filtered and to the filtrate azobenzene (0.40 g, 2.2 mmol) was added. The reaction mixture was stirred for 48 h during which time the color of the solution changed gradually from yellow-brown to red-brown, and in the same time a precipitate was formed. Hexane (20 cm^3) was added to this solution and the solid was filtered off. It was washed 3 times with 10-cm^3 aliquots of freshly distilled hexane, and dried *in vacuo* [yield 55% (0.32 g)]. IR (Nujol) (cm^{-1}): 1320(sh), 1295(w), 1280(sh), 1255(m), 1190(w), 1150(w), 1035(sh), 1025(m), 1000(w), 860(s), 810(w), 740(m), 720(m) and 685(m).

Crystallographic quality single crystals were prepared by a slightly different procedure. The solution of $Ta_2Cl_6(Me_2S)_3$ in benzene–toluene (20 cm^3) [1:1 (v/v)] was carefully covered with a layer of azobenzene in hexane (20 cm^3) in a Schlenk tube, and the reaction mixture was allowed to stand undisturbed for 2–3 weeks. Large, blocklike, red

crystals of $[TaCl_2(Me_2S)(PhN)]_2(\mu\text{-}Cl)_2$ were formed upon mixing of the two solutions [yield 48% (0.28 g)]. The IR spectrum of these crystals is identical with the IR spectrum obtained above.

X-ray crystallography

General procedures have already been described elsewhere.[4] Information about data collection and structure refinement for

$$[TaCl_2(Me_2S)(PhN)]_2(\mu\text{-}Cl)_2$$

is given in Table 1. The intensity data were corrected for Lorentz and polarization effects. The tantalum atoms were found by employing a Patterson function. Full-matrix least-squares refinement and difference Fourier calculations were applied to find the other non-hydrogen atoms. All 14 atoms were refined anisotropically.*

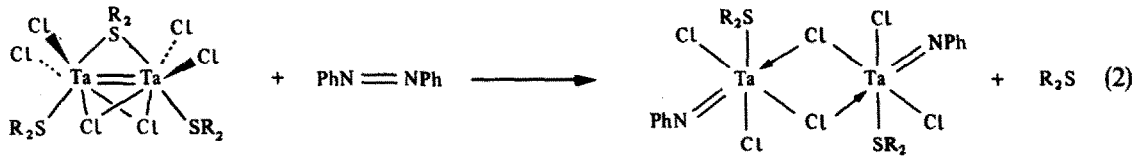
RESULTS AND DISCUSSION

Synthesis

The reaction of

$$(Me_2S)Cl_2Ta(\mu\text{-}Me_2S)(\mu\text{-}Cl)_2TaCl_2(Me_2S)$$

with $C_6H_5NNC_5H_5$ in a benzene–toluene solution yields red crystals, proven by X-ray crystallography to contain



$$(Me_2S)(PhN)Cl_2Ta(\mu\text{-}Cl)_2TaCl_2(PhN)(Me_2S)$$

molecules. This reaction is identical to the reaction previously reported by us of $Nb_2Cl_6(Me_2S)_3$ and

* *Supplementary material available*—Tables of structure factors and anisotropic thermal parameters (11 pages) have been deposited with the Editor at Queen Mary College. Positional parameters and isotropic thermal parameters have been forwarded to the Director, Cambridge Crystallographic Data Centre.

azobenzene. We emphasize this analogy since the chemistry of particular niobium complexes is not always identical to that of their tantalum analogues. As in the case of the niobium compound, $Nb_2Cl_6(Me_2S)_2(PhN)_2$, the new tantalum complex, $Ta_2Cl_6(Me_2S)_2(PhN)_2$, can be regarded as the product of an inorganic double bond metathesis reaction in which Ta=Ta and N=N bonds react to furnish two Ta=N bonds, as represented schematically in eqn (1) and in detail in eqn (2):

$$Ta{=}Ta + N{=}N \longrightarrow 2Ta{=}N, \qquad (1)$$

(2)

This type of reaction has general similarities to some other previously reported cases where starting materials containing metal–metal multiple bonds react with non-metallic reagents that also contain multiple bonds, thereby generating products containing metal to non-metal bonds in a manner that is synthetically useful. Two pertinent examples are provided by reactions (3)[5] and (4):[6]

$$Mo_2(OPr^i)_8 + O_2 \rightarrow 2MoO(OPr^i)_4, \qquad (3)$$

$$W_2(OCMe_3)_6 + RCCR \rightarrow 2W(CR)(OCMe_3)_3. \qquad (4)$$

Molecular structure

The crystal structure of

$$[TaCl_2(Me_2S)(PhN)]_2(\mu\text{-}Cl)_2$$

is comprised of discrete binuclear molecules, which reside on centers of inversion. A view of the molecular structure is shown in Fig. 1, which also defines the numbering scheme. Tables 2 and 3 list interatomic distances and angles.

The molecular structure of

$$[TaCl_2(Me_2S)(PhN)]_2(\mu\text{-}Cl)_2$$

is essentially identical with that previously reported for its isostructual niobium analogue, as is to be expected. It is a dimer consisting of two octahedra sharing a common edge. The octahedra are distorted, however, from that idealization due primarily to a strong *trans*-weakening effect of the Ta=N bonds on two of the tantalum-bridging chlorine bonds. The dimensions of the two octahedral $TaCl_4(Me_2S)(PhN)$ units are very similar to those found in the niobium analogue. Thus, the Ta–Ta′ separation is 4.096(1) Å [cf. 4.096(2) Å in the niobium analogue], which suggests that there is no direct interaction between the two tantalum ions as is to be expected for two such d^0 centers. The Ta—Cl distances in

$$[TaCl_2(Me_2S)(PhN)]_2(\mu\text{-}Cl)_2$$

are as predicted: shorter for the terminal chlorine atoms, Ta—Cl(2) = 2.344(3) Å and Ta—Cl(3) = 2.316(3) Å, and longer for the bridging chlorine

atoms, Ta—Cl(1) = 2.751(3) Å and Ta—Cl(1)′ = 2.454(2) Å.

As in the isostructural niobium complex, the $Ta{=}NC_6H_5$ bonding is of special interest. The Ta=N—C(1) fragment is essentially linear with an angle of 176.4(8)°. The Ta=N bond length of 1.747(8) Å is very short, like that in the niobium analogue, 1.733(7) Å, but this is not unusual since the Ta=N bond lengths in other structurally characterized imido-tantalum complexes are similarly short. For example, in $(THF)_2Cl_3Ta{=}N{-}(CH_3)C{=}C(CH_3){-}N{=}TaCl_3(THF)_2$[7] and $[(CH_3)_2N]_3Ta{=}NC(CH_3)_3$[8] the Ta=N bond lengths are 1.75(1) and 1.77(2) Å, respectively.

DIAMAGNETIC ANISOTROPY OF THE Mo≡Mo BOND IN $Mo_2(O_2CR)_4$ TYPE COMPLEXES

PRADYOT A. AGASKAR and F. ALBERT COTTON*

Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A&M University, College Station, TX 77843, U.S.A.

(*Received* 29 *May* 1985; *accepted* 5 *September* 1985)

Abstract—By using newer structural and NMR data for $Mo_2(O_2CR)_4$ compounds with R = PhCH(OH) and CH_3 the diamagnetic anisotropy of the Mo–Mo quadruple bonds has been estimated as $-(210 \pm 30) \times 10^{-36}$ m^3 per molecule.

The fact that M–M multiple bonds, like those in organic compounds, should be magnetically anisotropic to an extent that should give rise to measurable effects in NMR spectra was first pointed out by San Filippo[1] in 1972. Qualitative use of this concept was made a few years later[2,3] in interpreting the NMR spectra of $M_2(NR_2)_6$ molecules.

More recently McGlinchey[4] pointed out that these anisotropies of M–M multiple bonds should be calculable, at least approximately, by combining quantitative structural data obtained from X-ray crystallography with chemical-shift differences measured in solution NMR spectra. The contribution to the chemical shift of protons in the R groups of complexes of the type $Mo_2(O_2CR)_4$ can be calculated from NMR data by using the general equation derived by McConnell[5] [eqn (1)]:

$$\Delta\sigma_d = \chi \frac{(1 - 3\cos^2\theta)}{3\bar{r}^3} \qquad (1)$$

where $\chi = (\chi_{\parallel} - \chi_{\perp})$, r is the distance from the center of the Mo≡Mo bond and θ is the angle between $\bar{r}$ and the Mo≡Mo bond axis. McGlinchey[4] made such calculations using data obtained by San Filippo.[1,6] For the compound

$$Mo_2Br_2(n\text{-}Bu_3P)_2(O_2CC_6H_5)_2,$$

he compared the chemical shifts of the *ortho*- and *meta*-hydrogen atoms of the benzoate ligands, and his result for χ was in the range -600 to -1000×10^{-36} m^3 per molecule. We believe this is an overestimate.

We have recalculated the value of χ using the crystal structure data[7,8] for the two compounds $Mo_2(O_2CCH(OH)C_6H_5)_4$ (**1**) and $Mo_2(O_2CCH_3)_4$ (**2**) to calculate the geometric factors [i.e. the coefficient of χ in eqn (1)] for the —CH protons in **1** and the —CH_3 protons in two orientations in **2**. The latter were averaged and the two values then are 2.95×10^{27} m^{-3} in **1** and 2.93×10^{27} m^{-3} in **2**.

The NMR spectra of compounds **1** and **2** were measured in DMSO-d_6 solutions at 200 MHz on a Varian XL-200 spectrometer. The choice of reference points for estimating what these shifts would be in the absence of the Mo≡Mo bond but with all other factors the same poses a practical problem. No ideal model compounds are available and we have made the practical choice of using the chemical shift values for the free ligands as standards. This leads to $\Delta\sigma_d$ values of 0.52 for **1** and 0.70 for **2**.

The values of χ calculated by us using the above values of the geometric factors and the appropriate values of $\Delta\sigma_d$ in eqn (1) are then -176×10^{-36} m^3 per molecule for **1** and -239×10^{-36} m^3 per molecule for **2**.

The discrepancy between these values is somewhat larger than we would have liked and presumably shows that the approximations and assumptions made in calculating them are imperfect. Nonetheless, the average value of about $-210 \times$

* Author to whom correspondence should be addressed.

10^{-36} m^3 per molecule seems very reasonable in comparison with the value of -142×10^{-36} m^3 calculated by McGlinchey[4] for the Mo–Mo triple bond in $Mo_2(NMe_2)_6$. The results we have obtained should be more reliable than the higher estimate made earlier by McGlinchey for the Mo≡Mo bond since it is derived from rather large measured values and makes no assumptions other than that specified above concerning the reference points.

Acknowledgements—We thank the National Science Foundation for support and Professor M. J. McGlinchey for correspondence.

SYNTHESIS AND MOLECULAR STRUCTURE OF $(NBu_4)_x[Pt(C_6Cl_5)_2(\mu\text{-}Cl)_2Ag]_x$: A NOVEL CHAIN POLYMERIC COMPOUND

R. USON,* J. FORNIES, M. TOMAS and J. M. CASAS

(*Received* 27 *August* 1985; *accepted* 30 *September* 1985)

Abstract—The reaction of the NBu_4^+ salt of *trans*-$[PtCl_2(C_6Cl_5)_2]^{2-}$ with AgNO in acetone–methanol affords polymeric $[Pt(C_6Cl_5)_2(\mu\text{-}Cl)_2Ag]_x^{x-}$, as the NBu_4^+ salt. The chain anion consists of planar $Pt(C_6Cl_5)_2Cl_2$ units linked by Ag atoms, in which there are Ag—Cl bonds of two types: those which result in $Pt(\mu\text{-}Cl)Ag$ links and those in which *ortho*-Cl atoms of C_6Cl_5 units make close approaches (3.01 and 3.09 Å) to Ag atoms.

We recently have described[1,2] several unusual compounds containing Pt–Ag bonds and C_6F_5 groups attached to the Pt atoms. An unusual feature in these compounds was the interaction of *ortho*-F atoms in the C_6F_5 groups with the Ag atoms in a way that seemed important in the stabilization of the clusters. The first of these novel compounds, the tetrameric $(NBu_4)_2[Pt_2Ag_2Cl_4R_4]$ ($R = C_6F_5$), was prepared[1] by reacting $(NBu_4)_2[trans\text{-}PtCl_2R_2]$ with $AgClO_4$ or $AgNO_3$. We now report that an analogous reaction, starting from the C_6Cl_5 derivative, leads to the polymeric heteronuclear compound $\{(NBu_4)[Pt(C_6Cl_5)_2(\mu\text{-}Cl)_2]Ag\}_x$ (I).

Compound I can easily be prepared (88% yield) from $(NBu_4)_2[trans\text{-}PtCl_2(C_6Cl_5)_2]$[3] in acetone–methanol according to eqn (1):

$$(NBu_4)_2[trans\text{-}PtCl_2(C_6Cl_5)_2] + AgNO_3 \rightarrow NBu_4NO_3 + \frac{1}{x}\{(NBu_4)[Pt(C_6Cl_5)_2(\mu\text{-}Cl)_2Ag]\}_x \quad (1)$$

It is a yellow solid† which is very insoluble in all common solvents, although stable when in contact with them. Crystals suitable for X-ray diffraction studies‡ were obtained by very slow diffusion (*ca* −25°C) of an acetone solution of $AgClO_4$ into a dichloromethane solution of

$$(NBu_4)_2[trans\text{-}PtCl_2(C_6Cl_5)_2]$$

(molar ratio 1 : 1) both separated by an inert layer of 1,2-dichlororoethane.§

†Calc. for $C_{28}H_{36}NCl_{12}PtAg$: C, 30.13; H, 3.22; N, 1.25%. Found: C, 29.80; H, 3.02; N, 1.12%.

‡Space group $C2/c$, $a = 19.300(3)$ Å, $b = 26.523(4)$ Å, $c = 8.450(2)$ Å, $\beta = 103.53(2)°$, $Z = 4$. By using 1487 reflections with $F_o^2 > 3\sigma(F_o^2)$ and 156 parameters, refinement converged at $R = 0.061$.

§Some relevant IR data (in cm^{-1}): (a) for $(NBu_4)_2[trans\text{-}PtCl_2(C_6Cl_5)_2]$, ν(Pt—Cl) = 310(s), X-sensitive mode of the C_6Cl_5 group[3] = 820(m), and ν(Pt—Cl) = 600(m); (b) for $\{(NBu_4)[Pt(C_6Cl_5)_2Cl_2Ag]\}_x$, ν(Pt—Cl) = 310(m), X-sensitive mode = 825(m), and ν(Pt—C) = 598(m).

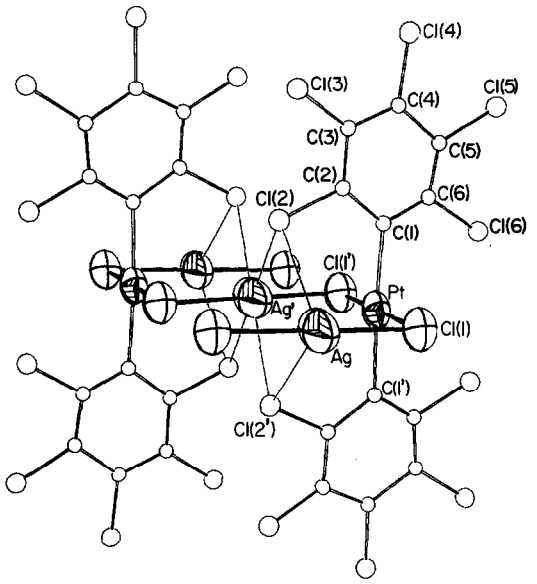

Fig. 1. A portion of the polymeric $[Pt(C_6Cl_5)_2(\mu\text{-}Cl)_2Ag]_x^{x-}$ anion. Some important distances are: Pt—C(1) = 2.08(2) Å, Pt—Cl(1) = 2.324(5) Å, Ag—Cl(1) = 2.477(5) Å, Ag—Cl(2) = 3.010(8) Å or 3.092(8) Å, Ag–Pt = 3.203(1) Å.

The structure consists of $[NBu_4]^+$ cations and polymeric anions. A representative segment of the latter is shown in Fig. 1. The Pt atoms are located on crystallographic two-fold axes and the Ag atoms on inversion centers. Each Pt atom is in a planar *trans*-$PtCl_2(C_6Cl_5)_2$ unit with normal Pt—Cl distances, and each Ag atom is in a linear Cl—Ag—Cl unit, with Ag—Cl distances short enough to imply considerable bonding there as well. There is unlikely to be any significant Pt–Ag or Ag–Ag bonding, in view of the long distances.

An important additional stabilizing factor for this structure is a set of interactions between the Ag atoms and the Cl(2) atoms. The latter are positioned so as to bridge (not quite symmetrically) adjacent Ag atoms, thus completing about each Ag atom a rhombically distorted octahedron of Cl atoms.

The role of the *ortho*-Cl atoms of the C_6Cl_5 groups in this structure is reminiscent of that played by *ortho*-F atoms in previously reported compounds, e.g. $(NBu_4)_2[Pt_2Ag_2Cl_4(C_6F_5)_4]$, but differs in important ways. It seems likely that the greater size of the Cl atom militates against coplanarity of an entire Ag···Pt—C—C—Cl unit, which would be analogous to what occurs with the C_6F_5 groups. The arrangement that has been found is an acceptable alternative. The fact that the Ag atoms receive electron density from six Cl atoms makes Pt → Ag bonding unnecessary as well as sterically infeasible.

Studies in progress on the chemical reactivity of this novel polymeric compound have shown that it is possible to cleave the polymeric anion and at least two different fragments,

$$(NBu_4)[PtAgCl_2(C_6Cl_5)_2L]$$

or $[Pt(C_6Cl_5)_2Cl_2Ag_2L_2]$, can be isolated.

PREPARATION AND STRUCTURAL CHARACTERIZATION OF $Os_2Cl_4(Ph_2Ppy)_2(O_2CCH_3)$: A MIXED-LIGAND COMPOUND WITH AN Os_2^{5+} CORE AND A BOND ORDER OF 2.5

F. ALBERT COTTON,* KIM R. DUNBAR and MAREK MATUSZ

Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A&M University, College Station, TX 77843, U.S.A.

(*Received* 2 *August* 1985; *accepted* 14 *October* 1985)

Abstract—Dichlorotetraacetatodiosmium(III) reacts with 2-(diphenylphosphino)pyridine (abbreviated Ph_2Ppy) in the presence of trimethylsilyl chloride to yield the title compound (**1**) as determined by X-ray crystallography. The molecule contains a cisoid arrangement of two Ph_2Ppy ligands which are distorted from the ideal eclipsed conformation by 30°. A single bridging acetate is also present, and it is twisted about the dimetal unit by 34°. The Os—Os distance of 2.395(1) Å, representing a formal bond order of 2.5, is the longest distance reported for a diosmium multiple bond. An investigation of the electrochemistry of **1** by cyclic voltammetry reveals two processes: a reversible oxidation at $E_{1/2} = +0.95$ V and a quasi-reversible reduction at $E_{1/2} = -0.34$ V vs Ag–AgCl.

Recent work in this laboratory has expanded the chemistry of multiply-bonded diruthenium complexes to include a wide range of Ru(II, III) species, a few of them being mixed-ligand compounds.[1–4] The methods used to prepare many of these new complexes involved either the trimethylsilyl chloride induced substitution of bidentate oxygen donor ligands, or the direct reaction of a ligand with the diruthenium starting material at high temperatures. The syntheses of several interesting diosmium complexes were effected by employing similar conditions, but, in general, the chemistry of the triply-bonded diosmium compounds has been little explored.[5–7]

Presently, we are investigating the substitution chemistry of diosmium tetraacetate. Our preliminary studies indicate that it exhibits an interesting and diverse reactivity. The molecule $Os_2Cl(chp)_4$ (chp = 6-chloro-2-hydroxypyridinato) was prepared from the melt reaction between $Os_2Cl_2(O_2CCH_3)_4$ and Hchp, and the structure was shown to be comprised of four chp ligands in a completely polar arrangement (also called the 4:0 arrangement) and a lone axial chloride.[8] This compound and the present example (**1**) are derivatives of the Os_2^{5+} dinuclear oxidation state. The formation of these neutral Os(II, III) compounds via spontaneous reduction of the triply-bonded Os_2^{6+} parent complex during the course of the substitution, attests to the stability of the Os_2^{5+} core. Furthermore, both $Os_2Cl(chp)_4$ and $Os_2Cl_4(Ph_2Ppy)_2(O_2CCH_3)$ are air-stable in the solid state and in solutuion. The tendency for Os_2^{6+} compounds to undergo a one-electron electrochemical reduction has been documented, and this result was exploited by Walton and co-workers to prepare Os(II, III) complexes by chemical reduction.[7]

Compound **1** was prepared by the reaction of $Os_2Cl_2(O_2CCH_3)_4$ (0.10 g) with 2-(diphenylphosphino)pyridine (0.30 g) in the presence of excess Me_3SiCl in refluxing toluene for 24 h. The red-brown product precipitated from the reaction solution and was separated from the unreacted tetraacetate by extraction with dichloromethane [yield 21 mg (26%)]. About 50 mg of $Os_2Cl_2(O_2CCH_3)_4$ was recovered. Crystals of a quality suitable for an X-ray diffraction study were grown by layering hexane over a solution of **1** in dichloromethane. The compound crystallized as the solvate $Os_2Cl_4(Ph_2Ppy)_2(O_2CCH_3)\cdot CH_2Cl_2$.

The structural identity of **1** has been proven by

* Author to whom correspondence should be addressed.

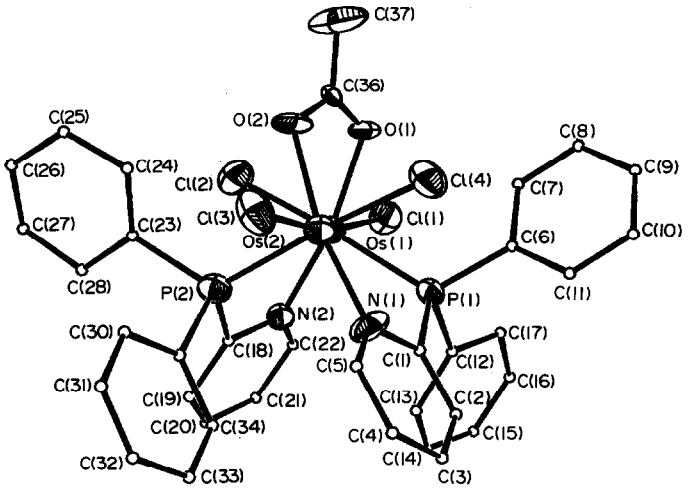

Fig. 1. Molecular structure of **1**. Some important distances (Å) and angles (°) are: Os(1)—Os(2) = 2.395(1), Os(1)—Cl(1) = 2.428(5), Os(1)—Cl(2) = 2.377(5), Os(1)—P(1) = 2.329(5), Os(1)—N(2) = 2.09(2), Os(1)—O(1) = 2.101(13), Os(2)—Cl(3) = 2.421(6), Os(2)—Cl(4) = 2.365(5), Os(2)—P(2) = 2.331(6), Os(2)—N(1) = 2.06(2), Os(2)—O(2) = 2.104(13), Cl(1)—Os(1)—Os(2) = 156.9(1), Cl(3)—Os(2)—Os(1) = 156.3(2), N(2)—Os(1)—Cl(2) = 83.6(4), Cl(2)—Os(1)—O(1) = 83.7(4), O(1)—Os(1)—P(1) = 101.7(4), P(1)—Os(1)—N(2) = 90.8(4), Cl(4)—Os(2)—N(1) = 84.1(5), N(1)—Os(2)—P(2) = 90.2(5), P(2)—Os(2)—O(2) = 102.8(4), O(2)—Os(2)—Cl(4) = 82.9(4).

a single-crystal X-ray study.* An IR spectrum of the complex revealed the presence of both acetate and Ph_2Ppy groups. In addition, electrochemical measurements support the formulation of the complex as a mixed-valence Os(II)Os(III) species. Cyclic voltammetric measurements of $Os_2Cl_4(Ph_2Ppy)_2(O_2CCH_3)$ in dichloromethane revealed an oxidation couple located at $E_{1/2} = +0.95$ V and a reduction at $E_{1/2} = -0.34$ V vs Ag–AgCl. The latter process represents the formation of an Os_2^{4+} species at a reasonably accessible potential. This suggests that it may be feasible to reduce compound **1** chemically. However, it must be noted that the process is "quasi-reversible", i.e. $i_{p,c}/i_{p,a} \neq 1$.

A side view of **1** along the Os—Os bond axis is presented in Fig. 1. This ORTEP diagram depicts clearly the twisting exhibited by the bridging groups to minimize repulsive interactions. The *cis*-Ph_2Ppy ligands are bonded in a "head-to-tail" arrangement (each Os center is bonded to one P and one N atom). The chloride ligands in **1** are of two types: those of one set occupy axial sites [Cl(1) and Cl(3)] and those of a second set [Cl(2) and Cl(4)] are in terminal positions, which are located on opposite sides of the molecule. The axial Os—Cl bonds are not colinear with the Os—Os bond [average Os—Os—Cl(axial) = 156.6]. The existence of such a deviation for dirhodium and diosmium carboxylates which contain axial chloride ligands has been noted in some earlier studies.[6,10] The terminal chlorides are so disposed that the planes defined by atoms Cl(2)—Os(1)—Os(2) and Os(1)—Os(2)—Cl(4) form a dihedral angle of 127°. This is a considerable deviation from the ideal 180° expected for equatorially arranged ligands.

A notable structural feature is the Os—Os distance which is 2.395(1) Å in **1**. As mentioned earlier, this corresponds to a bond order of 2.5, formulated as such because the compound is of the

* Crystal data for

$Os_2Cl_4(Ph_2Ppy)_2(O_2CCH_3)\cdot CH_2Cl_2$:

$Os_2Cl_6P_2O_2N_2C_{37}H_{33}$, $M = 1192.75$, monoclinic, space group $P2_1/n$, $a = 10.496(3)$ Å, $b = 20.688(5)$ Å, $c = 18.440(5)$, $\beta = 91.62(2)°$, $V = 4003(3)$, $Z = 4$, $d_{calc} = 1.826$ g cm^{-3}. A total of 5889 reflections were collected in the range $4 < 2\theta < 45°$ using graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å). The positions of the two Os atoms were obtained from a Patterson map, and the remaining non-hydrogen atoms were located from alternating least-squares refinements and difference Fourier maps. The structure was refined using 2902 reflections having $F_o^2 > 3\sigma(F_o)^2$ to give residuals of $R(F) = 0.0515$ and $R_w = 0.0566$. All non-hydrogen atoms were refined anisotropically with the exception of N(2), C(11), C(18) and C(27). An empirical absorption correction based on psi scans was applied during data reduction, and after the location of all the atoms, the program DIFABS[9] was applied to further eliminate the absorption problems that are common to thin acicular crystals.

d^5–d^6 type with a total of 11 electrons to place in the molecular-orbital scheme. The ground state of these Os_2^{5+} complexes as defined by recent preliminary magnetic measurements consists of contributions from spin states derived from both $\sigma^2\pi^4\delta^2\delta^{*1}\pi^{*2}$ and $\sigma^2\pi^4\delta^2\delta^{*2}\pi^{*1}$ (or $\sigma^2\pi^4\delta^2\pi^{*3}$) configurations.[7,8] The Os—Os distance in the present compound is one of the longest reported Os—Os multiple bonds,† and it is appreciably longer by (0.047 Å) than that found in $Os_2Cl(chp)_4$.[8] This significant difference may perhaps be attributed to the more highly distorted nature of the bridging groups in $Os_2Cl_4(Ph_2Ppy)_2(O_2CCH_3)$, a situation which probably results in less orbital overlap and hence an increase in the Os—Os bond length.

Acknowledgement—We thank the National Science Foundation for financial support.

† The unusual asymmetric complex $Os_2Cl_3(PhNpy)_3$ has an Os—Os distance of 2.392(1) Å which is not statistically different from 2.395(1) Å.

(*Received* 10 *September* 1985; *accepted* 31 *October* 1985)

Abstract—The preparation and structural definition and UV–visible spectrum of the $[W_3(\mu_2\text{-}O)_3(\mu_3\text{-}S)(NCS)_9]^{5-}$ ion are reported. The W—W distances, averaged according to C_{3v} virtual symmetry, are 2.612[6] Å.

There has recently been intense activity in the study of the cuboidal $[Mo_4S_4]^{n+}$ species[1–7] as well as of their important fragment, the $[Mo_3S_4]^{4+}$ unit,[8–12] and the entire series[5,13,14] of mixed oxo–thio species, $[Mo_3S_nO_{4-n}]^{4+}$ of which there are eight, counting isomers and end members. Synthetic routes have been diverse, but it is notable that Sykes and coworkers have demonstrated the existence of a completely general route in which appropriate dinuclear species, with selected O- and S-contents, e.g. $Mo_2O_2(\mu\text{-}S)_2L_n$, are used as building blocks. Similar successful activity is not as yet in evidence for the potential tungsten analogs of these molybdenum compounds. It may also be noted that the Sykes-type synthetic route will in any case not be available because the corresponding tungsten starting materials are unavailable.

Our own routes to Mo_3S_4 and Mo_4S_4 species,[7,11,12] which are different from those of other workers, have the advantage that they should be readily applicable to tungsten analogs as well. An exploration of this possibility has been underway for some time and reports on perthio species will be forthcoming. We wish to report here a more surprising and interesting result, namely, the isolation and structure proof of the first mixed oxo–thio tritungsten species,

$$[W_3(\mu_2\text{-}O)_3(\mu_3\text{-}S)(NCS)_9]^{5-}.$$

Tungsten hexacarbonyl (1 g) and 0.8 g of anhydrous Na_2S were refluxed, under N_2, in 100 cm^3 of acetic anhydride for 12 h. A red precipitate which formed upon cooling of the reaction mixture, was separated by filtration and dissolved in 0.2 M HCl. This solution was passed through a Dowex 50W-X2 cation exchange column, washed with 0.5 M HCl and then eluted with 4 M HCl. This eluate was diluted 10 times and passed again through a cation exchanger. After washing with H_2O the column was soaked with 0.5 M NH_4SCN and left under N_2 for 24 h before it was eluted. To this purple eluate propylenediamine dihydrochloride was added and after 10 days standing in air well-formed purple crystals were obtained. Because of spectral changes that occurred during this period, accompanied by the distinctive smell of H_2S, we are certain that partial hydrolysis of a perthio precursor was occurring during this 10-day period.

The spectrum given by a solution of these purple crystals is shown in Fig. 1. The crystallographic

*Authors to whom correspondence should be addressed.

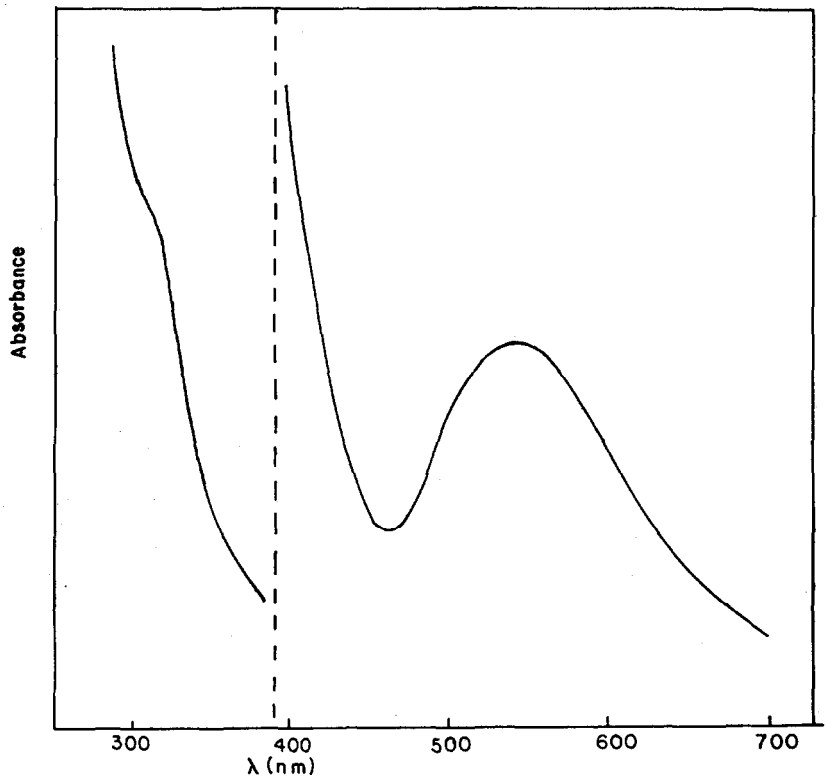

Fig. 1. Electronic absorption spectrum of $[W_3(\mu_3\text{-}S)(\mu_2\text{-}O)_3(NCS)_9]^{5-}$. The absorbance is given on an arbitrary scale.

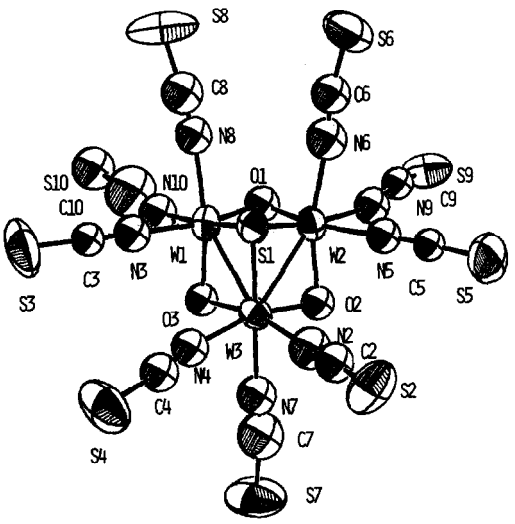

Fig. 2. ORTEP representation of the cluster anion. Thermal ellipsoids are drawn at 50% probability.

* Monoclinic crystals, $P2_1/c$, with $a = 16.616(5)$ Å, $b = 11.744(3)$ Å, $c = 23.780(10)$ Å, $\beta = 109.20(2)°$, $Z = 4$. Refinement is continuing. Current residuals are: $R = 0.051$, and $R_w = 0.066$ for a fit of 253 variables to 1713 data with $F_o^2 > 3\sigma(F_o^2)$. A table of positional parameters has been deposited with the Editor at Queen Mary College and copies are available on request.

work* was not straightforward because the crystals have a pronounced tendency to twinning and scattered X-rays relatively poorly despite their attractive visual appearance.

The $[W_3(\mu_2\text{-}O)_3(\mu_3\text{-}S)(NCS)_9]^{5-}$ anion is shown in Fig. 2. It has effectively C_{3v}-symmetry and the following principal dimensions (averaged accordingly): W—W, 2.612[6] Å; W—S, 2.34[2] Å; W—O, 1.98[2] Å. These may be compared with those previously reported[13] for

$$[Mo_3(\mu_2\text{-}O)_3(\mu_3\text{-}S)(HNTA)_3]^{2-},$$

viz. 2.589, 2.360 and 1.917 Å.

DICHLOROBIS(1,2,5-TRIPHENYLPHOSPHOLE)PALLADIUM(II) IN CARBONYLATION REACTIONS

B. M. CHOUDARY,* N. PRABHAKAR REDDY and M. ZAFAR JAMIL

Regional Research Laboratory, Hyderabad 500007, India

(*Received* 30 *July* 1985; *accepted* 2 *September* 1985)

Abstract—*trans*-Dichlorobis(1,2,5-triphenylphosphole)palladium(II) was synthesised and found to carbonylate organic halides at near atmospheric pressures and gave better yields than its triphenylphosphine analogue.

Stable complexes of 1-substituted-3,4-dimethylphospholes with palladium,[1] platinum[2] and ruthenium[3] have been reported. $Ru(RDMP)Cl_2$ (RDMP = 1-alkyl-3,4-dimethylphosphole) exhibited the ability to catalyse the hydrogenation of 1-heptene to heptane at rates comparable with its phosphine analogue. The complex $RhH(PDBP)_4$ (PDBP = 1-phenyldibenzophosphole) is 7 times more active as a hydrogenation catalyst than the well-known Wilkinson catalyst, $RhCl(PPh_3)_3$.[4] We were interested in comparing the reactivity of palladium complexes of phospholes with that of triphenylphosphine and chose the carbonylation reactions of some organic halides because of their industrial importance.

The present work deals for the first time with the preparation of a new complex of palladium with 1,2,5-triphenylphosphole (TPP) and demonstrates its utility in the carbonylation of some organic halides. The choice of TPP as a ligand is expected to simulate the conditions prevailing in the palladium–triphenylphosphine complex, but with a difference in the free movement of two of the three phenyl groups in the electronic environment around the palladium.

EXPERIMENTAL

Measurements and materials

Spectra were recorded on Perkin–Elmer (IR), V.G. Micromass Ltd (mass) and JEOL FX 90Q (NMR) spectrometers. Standard procedures were used for determining the elements. Carbonylation reactions were carried in a Berghof autoclave (Teflon lined). All solvents were dried by standard procedures. TPP was synthesised from 1,4-diphenyl-1,3-butadiene and phenylphosphonous dichloride.[5]

Preparation of $PdCl_2(TPP)_2$

A solution of TPP (1.97 mmol) in benzene (6 cm^3) was added to a solution of $PdCl_2(PhCH_2CN)_2$ (0.973 mmol) in benzene (8 cm^3) with stirring. The stirring was continued for 5 min and the mixture was allowed to stand at room temperature. The orange crystals formed were filtered off, washed with benzene and dried *in vacuo* at 60°C. Yield 0.748 g (98%).

Carbonylation of aryl, benzyl and phenacyl halides

A mixture of substrate (15 mmol), sodium acetate (20 mmol), and palladium catalyst (0.15 mmol) in 25 cm^3 ethanol was heated in an autoclave pressurized with carbon monoxide (20 psi). After 24 h the reaction mixture was filtered gravimetrically and washed with 50 cm^3 ethanol. The solution was concentrated under reduced pressure and diluted with 100 cm^3 water and extracted with small portions of pentane or dichloromethane. The combined extracts were washed successively with 2 N HCl, saturated aqueous sodium carbonate solution and saturated aqueous sodium chloride solution. The solution was dried over anhydrous sodium sulphate, concentrated and distilled under reduced pressure. The products (Table 1) thus obtained were identified by IR NMR and mass spectra.

Table 1. Carbonylation of aryl, benzyl and phenacyl halides

S. No.	Halide	Temperature (°C)	Product	Yield (%) $PdCl_2(TPP)_2$	Yield (%) $PdCl_2(PPh_3)_2$
1	C_6H_5I	60	$C_6H_5CO_2C_2H_5$	90	70
2	$C_6H_5CH_2Cl$	80	$C_6H_5CH_2CO_2H_5$	65	55
3	$C_6H_5COCH_2Cl$	70	$C_6H_5COCH_2CO_2C_2H_5$	40	25

RESULTS AND DISCUSSION

trans-Dichlorobis(TPP)palladium(II) was obtained in good yield (98%). It is an orange tetracoordinated complex and elemental analysis gave the molecular formula $PdCl_2(TPP)_2$. Found: Pd, 13.3; C, 66.1; H, 4.3; P, 7.2; Cl, 8.8%. Calc. for $PdCl_2(TPP)_2$: Pd, 13.2; C, 65.8; H, 4.3; P, 7.7; Cl, 8.9%.

The IR spectrum shows a single stretching frequency at 360 cm^{-1} for the Pd—Cl bond and 450 cm^{-1} for the Pd—P bond, which indicates a *trans*-configuration for the complex due to its D_{2h}-symmetry.[6] The resultant *trans*-orientation of the complex unlike 1-substituted 3,4-dimethylphosphole which has a *cis*-configuration may be ascribed to the expected larger van der Waals' repulsive forces due to the phenyl moiety. The complex is very stable and gave better yields in carbonylation reactions than the phosphine analogue under identical conditions as reported in Table 1. The results obtained with the phosphole complex at near atmospheric pressures were comparable with those of its phosphine analogue even at 200 psi carbon monoxide pressure.[7] No palladium deposition was observed after completion of the carbonylation reaction. The used catalyst gave almost same yields of carbonylated products.

EFFECTS OF AXIAL LIGAND ON THE OXIDATION OF TRIPHENYLPHOSPHINE CATALYZED BY NITRO(TETRAPHENYLPORPHYRINATO)COBALT COMPLEXES

KENICHI YAMAMOTO

Faculty of Pharmaceutical Sciences, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113, Japan

(*Received* 23 *August* 1985; *accepted* 4 *October* 1985)

Abstract—Nitro(tetraphenylporphyrinato)cobalt complexes catalyze the oxidation of triphenylphosphine to triphenylphosphine oxide by molecular oxygen. The effects of axial ligands in the nitro cobalt complexes on this oxidation reaction were studied. 4-Cyanopyridine gave the best yield. This result suggests that the more unstable is nitro(tetraphenylporphyrinato)cobalt complex the better the yield obtained.

5,10,15,20 - Tetraphenylporphyrinatocobalt(II) ([Co(tpp)]) reacts with nitrogen monoxide and produces five-coordinate nitrosyl(tetraphenylporphyrinato)cobalt(II) ([Co(tpp)(NO)]).[1] In the presence of an axial ligand (L), this nitrosyl cobalt complex reacts with molecular oxygen to give a nitro(tetraphenylporphyrinato)cobalt complex ([Co(tpp)(NO_2)(L)]).[2] This [Co(tpp)(NO_2)(L)] reacts with triphenylphosphine, resulting in triphenylphosphine oxide. So, under an atmosphere of oxygen, [Co(tpp)(NO_2)(L)] catalyzes the oxidation of triphenylphosphine by molecular oxygen [eqns (1) and (2)]:[3]

$$[Co(tpp)(NO)] + L + \tfrac{1}{2}O_2 \rightarrow [Co(tpp)(NO_2)(L)], \quad (1)$$

$$[Co(tpp)(NO_2)(L)] + PPh_3 \rightarrow [Co(tpp)(NO)] + Ph_3PO + L. \quad (2)$$

In this communication we present the effects of axial ligands such as 1-Meim,* 4-Mepy, py and 4-CNpy, which were used in the previous work,[4] on the yield in this oxidation reaction.

5,10,15,20-Tetraphenylporphyrin (H_2tpp) and [Co(tpp)] were synthesized by the literature methods, respectively.[5,6] Nitrosyl(tetraphenylporphyrinato)cobalt(II) was prepared from NO gas and [Co(tpp)] according to the literature method.[1] Nitro cobalt complexes were prepared from [Co(tpp)(NO)] and O_2 gas at a pressure of 1 atm in 1,2-dichloroethane (DCE) solution containing 5% (v/v) axial ligand in a reactor before the oxidation was started. A 5-cm^3 three-necked round bottom flask equipped with a thermometer, a condenser, and a long syringe needle, by which O_2 was passed through the solution during the oxidation reaction, was used as a reactor. After the formation of the nitro cobalt complex, confirmed by monitoring the visible spectrum in the 350–700-nm range—([Co(tpp)(NO)]: λ_{max} (DCE) 413 nm ($\varepsilon = 1.40 \times 10^5$ mol^{-1} dm^3 cm^{-1}), 538 nm (1.68×10^4), 584 nm (sh, 2.81×10^3); [Co(tpp)(NO_2)(py)]: λ_{max} (DCE) 433 nm ($\varepsilon = 3.35 \times 10^5$ mol^{-1} dm^3 cm^{-1}), 512 nm (sh, 5.58×10^3), 549 nm (1.51×10^4), 588 nm (sh, 5.98×10^3)—triphenylphosphine was added to the solution. The oxidation was carried out at 60°C for 16 h with the solution being stirred magnetically on an oil bath. After 16 h, aliquots of the solution were taken by a micro syringe and analyzed by a liquid chromatography {column, 4.3 mm × 15 cm, packed with Partisil-5, ODS-3, Whatman Inc., U.S.A.; eluant CH_3OH and H_2O mixture [75:25 (v/v)]}. As the internal standard, the base involved in the reacted solution was used.

*Abbreviations: py, pyridine; 4-Mepy, 4-methylpyridine; 1-Meim, 1-methylimidazole; pip, piperidine; 4-CNpy, 4-cyanopyridine.

Table 1. Oxidation of triphenylphosphine to triphenylphosphine oxide catalyzed by [Co(tpp)(NO$_2$)(L)]

Experiment	Complex	[Co]^a (mol dm^{-3})	[PPh$_3$]/[Co]^a	Solvent	Ph$_3$PO yield^b (%)

NO$_2^-$ ion	1335	1250	830	11

^{a} KBr disk.
^{b} m stands for "masked" by the ligand absorptions, and the precise absorption frequencies were not clear.
^{c} Solvent is benzene.

Table 1 shows the yields of triphenylphosphine oxide based on the catalyst. The yield depended apparently on the axial ligand (L) and decreased in order as follows:

4-CNpy > py > 4-Mepy > 1-Meim.

In this oxidation reaction, the following factors seem to be responsible for the yield: (a) the ease of formation of the nitro cobalt complex, (b) the ease of reproduction of the nitrosyl cobalt complex, and (c) the coordination geometry or the charge distribution of the nitro group in [Co(tpp)(NO$_2$)(L)]. As is shown by eqns (1) and (2), the stronger the coordination of the axial ligand to the cobalt ion the more stable the nitro cobalt complex formed and reproduction of the nitrosyl cobalt complex becomes more difficult. As the measure of the coordinating ability of the ligand, the values of the equilibrium constants (K^L) (mol^{-1} dm^3) for the reaction shown in eqn (3):[4(c)]

$$[\text{Co(tpp)}] + \text{L} \overset{K^L}{\rightleftharpoons} [\text{Co(tpp)(L)}] \qquad (3)$$

were used. Though the log K^L values were obtained in DCE at room temperature (23°C), the sequence of the values may not be different at 60°C. The coordinating abilities of axial ligand decreased in the following order, 1-Meim (log K^L = 3.22) > 4-Mepy (2.99) > py (2.92) > 4-Cpy (2.57). This sequence is in the reverse order to the yields of triphenylphosphine oxide shown above.

The IR spectra of the isolated nitro cobalt complexes were measured to study the IR spectra of the nitro groups in [Co(tpp)(NO$_2$)(L)].* The frequencies of the asymmetric [ν_{as} (cm^{-1})], symmetric [ν_s (cm^{-1})] and deformation vibrations [δ (cm^{-1})][2,7] are shown in Table 2. It indicates that

* Solid [Co(tpp)(NO$_2$)(L)] complexes were isolated by a modification of the literature method[2] for the IR spectra sample (KBr tablets): L = 1-Meim, 4-Mepy, py and pip. The 4-CNpy complex could not be isolated, though it was formed in the solution.

the nitro groups seem to be nearly nitro anion forms in all the nitro cobalt complexes. The NO_2 group of the analogous

[Co(tpp)(NO_2)(3,5-dimethylpyridine)]

was already shown as the NO_2^- form in the X-ray analysis data.[12] The differences in absorption frequencies among the different axial base complexes are small probably because all the Co–NO_2 bonds are nearly ionic. From the fact that the sequence of the yield is opposite to that of the coordinating ability of axial ligand, factor (b) seems to be the most effective on the yield of this oxidation reaction.

COMMUNICATION

A NOVEL ACCESS TO THE ANIONIC PERMETHYLATED *FAC*-TRIPOD LIGAND $[C_5Me_5Co\{P(O)(OEt)_2\}_3]^-$, AND ITS DERIVED TRINUCLEAR AND BINUCLEAR COMPLEXES

ENRIQUE ROMÁN E.,* FERNANDO TAPIA C. and SERGIO HERNÁNDEZ M.

Facultad de Química, Pontificia Universidad Católica de Chile, Casilla 6177, Santiago, Chile

(*Received* 18 *November* 1985; *accepted* 20 *November* 1985)

Abstract—$[C_5Me_5Co\{P(O)(OEt)_2\}_3]Co(II)$ was obtained in high yield from the reaction of C_5Me_5Li with $Co(acac)_3$ and diethylphosphite in a one-step synthesis. This provides high-yield synthetic routes to several decamethylated triple-decker sandwiches $[C_5Me_5Co\{P(O)(OEt)_2\}_3]M$ [M = Co(III) or Ti(IV)], and pentamethylated binuclear complexes $[C_5Me_5Co\{P(O)(OEt)_2\}_3]M'L_n$, $\{M'L_n = [Re(CO)_3]^+, [VO(acac)]^+$ or $[Ru(\eta\text{-}C_6Me_6)]^{2+}\}$.

We are interested in triple-decker sandwiches in connection with electrochemical studies,[1,2] in particular in their application to multi-step electron transfer reactions that do not imply changes in the molecular configuration of such complexes. Moreover, binuclear compounds having a VO^{2+} active center coordinated with the *fac*-tripod ligand $[C_5H_5Co\{P(O)(OEt)_2\}_3]^-$ have proved to be active in cathecol regio-specific catalysis.[3]

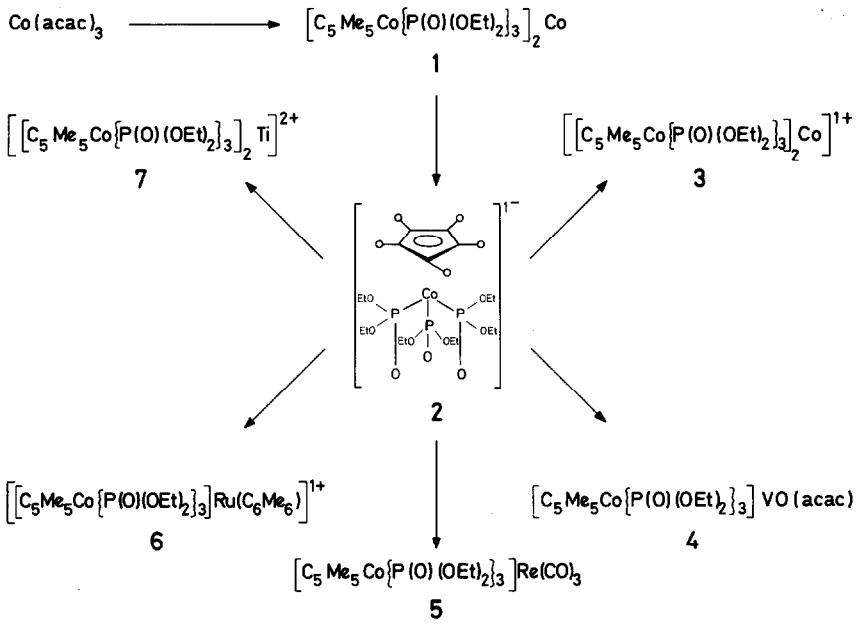
We now report the easy and efficient synthesis of the Co(III) decamethylated triple-decker sandwich **1**, which is the precursor for the preparation of the anionic *fac*-tridentate ligand **2**, isolated as the sodium salt. The addition of C_5Me_5Li in THF to the air-stable complex $Co(acac)_3$ yields an intermediate complex that might correspond to the 16-electron complex $[C_5Me_5Co(acac)]^+$. The latter complex reacts with diethylphosphite at high temperature, affording the trinuclear complex **1** in 90% yield [reaction (2)]. In this reaction no formation of the decamethylated cobalticinium ion was detected unlike what is observed in Wilkinson's reaction[4] [reaction (1)]:

$$2Co(aca)_3 + 4CpMgBr \xrightarrow[\text{benzene}]{} 2[Cp_2Co]Br + MgBr_2 + 3Mg(acac)_2 \quad (1)$$

$$Cp = C_5H_5^- \qquad 65\%$$

$$Co(acac)_3 + Cp^*Li \xrightarrow[\text{(ii) HOP(OEt)}_2]{\text{(i) THF, 273 K}} [Cp^*Co\{P(O)(OEt)_2\}_3]_2Co \quad (2)$$

$$Cp^* = C_5Me_5^- \qquad \mathbf{1}\ (90\%)$$



Oxidative cyanidation of **1** in methanol affords the pentamethylated *fac*-tridentate ligand **2** in high yield (90%). The latter is readily *fac*-coordinated with several acid metallic centers such as Co(III), Ti(IV), $[Re(CO)_3]^+$, $[VO(acac)]^+$ and $[Ru(\eta\text{-}C_6Me_6]^{2+}$, thus leading to new triple-decker sandwich compounds **3** and **7** as well as to new binuclear compounds **4**, **5** and **6** (see Scheme 1). All these were characterized by ^1H NMR, IR spectra, magnetic measurements, and microanalysis (see Table 1).

To conclude, reaction (2) provides a simple and convenient route to the preparation of decamethylated triple-decker sandwich compounds as well as binuclear pentamethylated compounds containing the *fac*-tridentate pentamethylated ligand **2**. This facilitates the comparison of their various physicochemical properties with the series of complexes having non-permethylated Cp rings.[5]

EXPERIMENTAL

All solvents were of reagent grade, dried by standard procedures, and all reactions were conducted using Schlenk standard techniques.

Instruments

IR: Perkin–Elmer 567 grating spectrophotometer; ESR: Brucker ER-420 with ER-400 X-RL cavity; Faraday balance and ^1H NMR: Varian-XL-100 spectrometer (using Evans's method for the determination of magnetic susceptibility). Satisfactory analyses were obtained for all new compounds at the Service Central d'Analyse (CNRS), Vernaison, France. $Co(acac)_3$,[6(a)] $Vo(aca)_2$,[6(b)] $K_2[Re(CO)_3Br_3]$[6(c)] and the dimer $[(C_6Me_6)RuCl_2]_2$[6(d)] were prepared by methods reported in the literature.

Synthesis of $[C_5Me_5Co\{P(O)(OEt)_2\}_3]Co$ (1)

2.58 g (18.192 mmol) of C_5Me_5Li in 20 cm^3 THF were added to a $Co(acac)_3$ suspension [3.24 g (9.096 mmol)], in an equal amount of THF at 273 K with constant stirring for 1 h. To the filtered and vacuum-dried brown solution, 30 cm^3 of diethylphosphite were added. The solution was then heated at 403 K for 24 h. Concentration and cooling of the solution yields **1** (90% yellow crystals recrystallized from MeOH–CH_2Cl_2). Found: C, 41.0; H, 7.0; P, 14.2. Calc. C, 41.5; H, 7.1; P, 14.6%.

Synthesis of $[C_5Me_5Co\{P(O)(OEt)_2\}_3]Na$ (2)

2.89 g (2.28 mmol) of **1** and 1.037 g (15.96 mmol) of NaCN were suspended in methanol, and a homogeneous solution was obtained by bubbling air through it. After solvent elimination in a vacuum system the resulting solid was extracted with diethyl ether, and crystallized by cooling (253 K). Yellow crystals were separated (yield 70%). Found: C, 41.5; H, 7.5; P, 14.4. Calc. C, 42.0; H, 7.2; P, 14.8%.

Synthesis of $[C_5Me_5Co\{P(O)(OEt)_2\}_3]Co(PF_6)$ (3)

1.50 g (2.3087 mmol) of **2** and 0.425 g (1.1945 mmol) of $Co(acac)_3$ were dissolved in 30 cm^3 of CH_2Cl_2. After HPF_6(aq) addition a yellow dichloromethane solution was obtained, which was washed with water, then concentrated, and the complex was precipitated with ether. Recrystallization from an ether–CH_2Cl_2 mixture gives yellow crystals (yield 70%). Found: C, 37.2; H, 6.5; P, 15.2. Calc. C, 37.3; H, 6.4; P, 15.3%.

Synthesis of $[C_5Me_5Co\{P(O)(OEt)_2\}_3]VO(acac)$ (4)

0.50 g (0.796 mmol) of $VO(acac)_2$ and 0.212 g (0.796 mmol) of **2** in 20 cm^3 CH_2Cl_2 were mixed under magnetic stirring at room temperature for 1 h; then, after filtration and crystallization from methanol, green crystals (60% yield) were obtained. Found: C, 41.7; H, 6.9; P, 12.0. Calc. C, 42.0; H, 6.7; P. 12.1%.

Synthesis of $[C_5Me_5Co\{P(O)(OEt)_2\}_3]Re(CO)_3$ (5)

0.253 g (0.430 mmol) of $K_2[Re(CO)_3Br_3]$ and 0.2704 g (0.430 mmol) of **2** in 50 cm^3 THF with a catalytical amount of the *n*-But_4NBr phase transfer agent (0.015 g) were heated at reflux temperature for 12 h. After solvent evaporation the solid was chromatographed on an alumina column. Crystallization from CH_2Cl_2 yields 60% of yellow crystals (**5**). Found: C, 33.8; H, 5.1; P, 10.5. Calc. C, 34.3; H, 5.1; P, 10.6%.

Synthesis of $[C_5Me_5Co\{P(O)(OEt)_2\}_3Ru(\eta\text{-}C_6Me_6)](PF_6)$ (6)

0.1278 g (0.191 mmol) of the dimer $[(C_6Me_6)RuCl_2]_2$ and 0.240 g (0.382 mmol) of **2** in 50 cm^3 of water were heated at reflux temperature for 2 h. Then, 0.0623 g (0.382 mmol) of NH_4PF_6 was added and the solution extracted with CH_2Cl_2 and chromatographed in an alumina column. Crystallization from CH_2Cl_2 yields 65% of orange crystals (**6**). Found: C, 40.0; H, 6.4; P, 12.0. Calc. C, 40.2; H, 6.2; P, 12.2%.

Synthesis of $[C_5Me_5Co\{P(O)(OEt)_2\}_3]_2Ti(PF_6)_2$ (7)

0.0991 g (0.398 mmol) of Cp_2TiCl_2 and 0.50 g (0.796 mmol) of **2** in water were mixed under magnetic stirring for 2 h at room temperature. Then, 0.1298 g (0.796 mmol) of NH_4PF_6 were added. The solid was extracted with CH_2Cl_2 and chromatographed on a silica column (CH_2Cl_2–ether eluant). Recrystallization from CH_2Cl_2–ether yields 75% of yellow crystals (**7**). Found: C, 33.9; H, 6.1; P, 16.1. Calc. C, 34.1; H, 5.8; P, 16.1%.

REPLACEMENT OF TERMINAL AND BRIDGING OXO GROUPS BY PHENYLIMIDO GROUPS IN (η-C_5H_5)OMo(μ-O)$_2$OMo(η-C_5H_5) GIVING (η-C_5H_5)(NPh)Mo(μ-NPh)$_2$Mo(NPh)(η-C_5H_5)

MALCOLM L. H. GREEN* and KELLY J. MOYNIHAN

Inorganic Chemistry Laboratory, South Parks Road, Oxford OX1 3QR, U.K.

(*Received* 22 *November* 1985; *accepted* 27 *November* 1985)

Abstract—The treatment of (η-C_5H_5)OMo(μ-O)$_2$MoO(η-C_5H_5) with excess phenylisocyanate at reflux in tetrahydrofuran yields the arylimido-substituted complex (η-C_5H_5)(NPh)Mo(μ-NPh)$_2$Mo(NPh)(η-C_5H_5), which has been characterized by elemental analysis, and mass, IR and ^{1}H NMR spectra.

Transition-metal–imido complexes have been proposed to be intermediates in industrial processes[1,2] and enzymatic transformations.[3,4] An attractive route to metal–imido complexes proceeds *via* reaction between a metal–oxo group and an organoisocyanate,[5] viz.:

$$[M]{=}O + RNCO \rightarrow [M]{=}NR + CO_2.$$

The versatility of this route is relatively unexplored. Here we describe replacement of the oxygen atoms in the units Mo=O and of Mo—O—Mo, giving M=NPh and Mo—NPh—Mo moieties, respectively.

EXPERIMENTAL

All manipulations were carried out under dry nitrogen or *in vacuo* using standard Schlenk techniques. Solvents were dried, distilled and degassed prior to use. IR spectra were recorded on mulls between CsI plates using a Pye–Unicam SP 2000 spectrophotometer. ^{1}H NMR spectra (300 MHz) were recorded at probe temperature using a Bruker WH300 instrument. Chemical shifts, in ppm relative to Me_4Si, were calibrated using protio impurity peaks of the deuterated solvents as internal standards. C, H and N analyses were performed by the analytical service of this laboratory.

The compound (η-C_5H_5)OMo(μ-O)$_2$MoO(η-C_5H_5) was prepared by the method of Cousins and Green.[6] Phenylisocyanate (PhNCO) (Aldrich Co. Ltd) was used as received.

Synthesis of (η-C_5H_5)(NPh)Mo(μ-NPh)$_2$Mo(NPh)(η-C_5H_5) (1)

A Rotoflo ampoule was charged with (η-C_5H_5)OMo(μ-O)$_2$MoO(η-C_5H_5), tetrahydrofuran (thf) (30 cm^3), (0.34 g, 0.88 mmol) and phenylisocyanate (*ca* 1 cm^3). The mixture was stirred at 70°C for 4 days. On cooling to room temperature a bright orange microcrystalline powder separated. This was collected, washed with ice-cold thf (2 × 3 cm^3) and dried *in vacuo* for 3 h at 60°C. Recrystallization was from dichloromethane–petroleum ether (b.p. 40–60°C). Yield 0.25 g (41%).

Analysis. Found (calc.): C, 59.7 (59.5); H, 4.4 (4.4); N, 8.2 (8.2)%. The mass spectrum (FAB) shows an envelope corresponding to the parent ion, for $^{96}Mo_2$ at $m/z = 686$.

IR data (mull, cm^{-1}): 1577m, 1322ms, 1288m, 1263s, 1164mw (1159sh), 1065mw (1055sh), 1020mw, 1005mw, 994w, 989w, 964m, 907m, 894w, 820w, 809ms, 790ms, 751s (720sh), 695m (660sh), 516vw, 501w, 391w, 360vw, 320w and 273vw. ^{1}H NMR data will be presented and discussed in the text.

* Author to whom correspondence should be addressed.

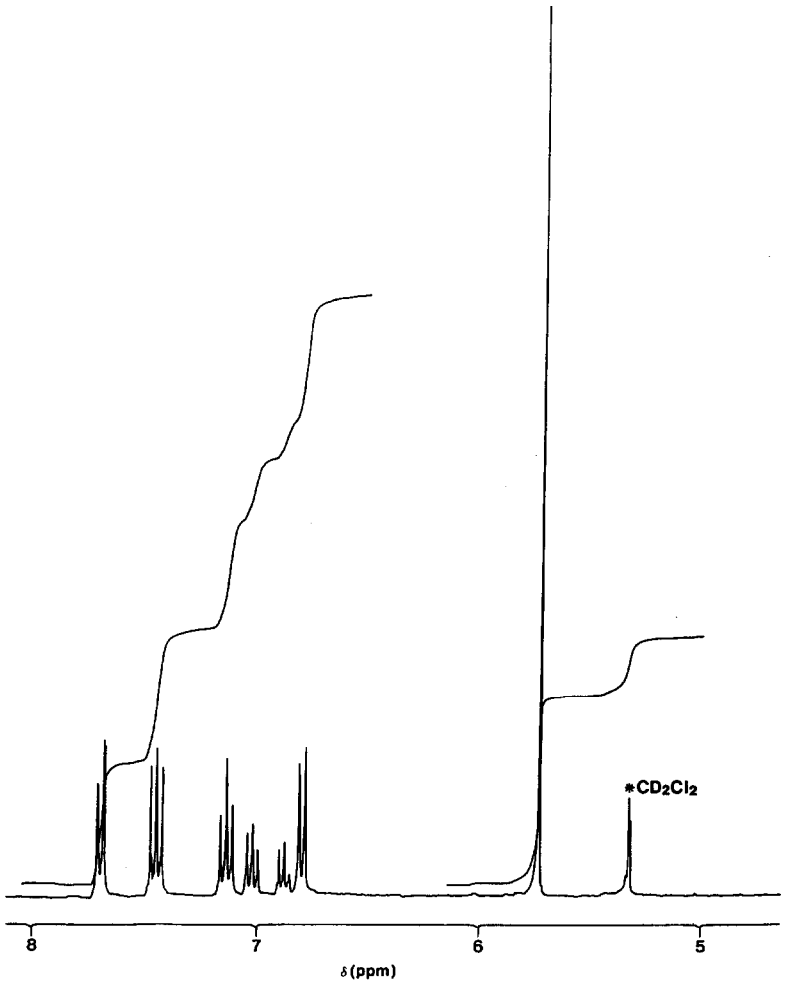

Fig. 1. 300-MHz ^{1}H NMR spectrum of (η-C_5H_5)(NPh)Mo(μ-NPh)$_2$Mo(NPh)(η-C_5H_5) (in CD_2Cl_2).

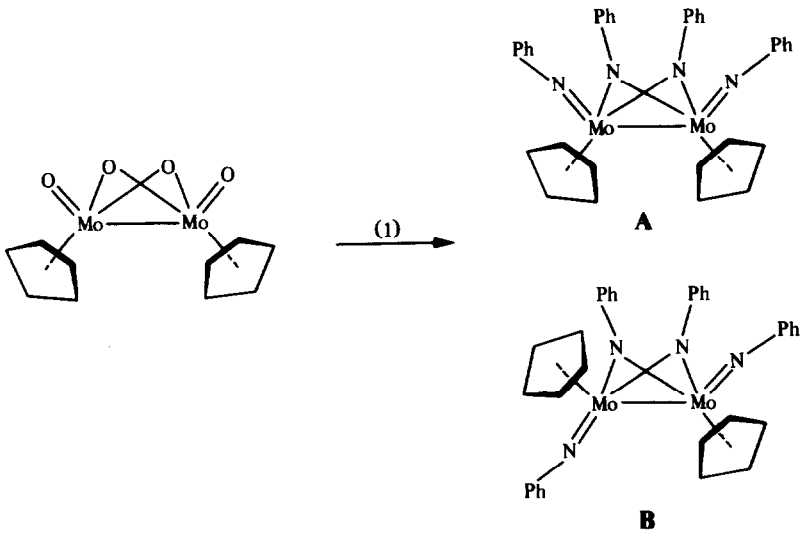
RESULTS AND DISCUSSION



Treatment of [η-$C_5H_5MoO(\mu$-O)]$_2$ with PhNCO gives diamagnetic orange-red crystals of [η-C_5H_5Mo(NPh)(μ-NPh)]$_2$ (**1**) in high yield.

The formulation of **1** is supported by analytical and IR spectroscopic data and especially by its ^{1}H NMR spectrum. The ^{1}H-NMR spectrum of **1** (Fig. 1) shows a sharp singlet at δ 5.73 assignable to magnetically equivalent cyclopentadienyl groups and the pattern of resonances in the aromatic region indicates that two different types of phenylimido groups are associated with each molybdenum centre. The two equally intense pseudo doublets in the spectrum, corresponding to *ortho* protons of NPh moieties, are especially suggestive that both bridging and terminal imido ligands are present in the complex. The more intense pseudo triplets and the less intense pseudo triplets in the spectrum are representative of the *meta* and *para* protons, respectively, belonging to the two distinct types of phenylimido groups in **1**. The data are compatible with two structures for **1** (Scheme 1).

A is the most likely since most dinuclear species of this type exhibit a *cis* geometry.[7,8] Further, the complex (η-C_5H_5)(NR)Cr(μ-NR)Cr(NR)(η-C_5H_5) (R = $SiMe_3$) has structure **A** in the solid state.[9]

The solid complex (**1**) is stable in air, but the orange solutions in (thf or CH_2Cl_2) undergo slow decomposition in air. Compound **1** is unreactive towards ethylene, butadiene, CO_2, H_2 H_2O and pyridine but reacts with HCl gas, giving intractable material.

Acknowledgements—We would like to thank the S.E.R.C. for financial support and the N.S.E.R.C. (Canada) for a postdoctoral fellowship to K.J.M.

NEWSLETTER 1985: IUPAC COMMISSION ON NOMENCLATURE OF INORGANIC CHEMISTRY

INTRODUCTION

The objective of this Newsletter is to inform the readers of this journal about ongoing activities of this commission* and to draw attention to its recently published nomenclature documents. Chemists are invited to write about inorganic chemistry nomenclature problems to the present vice chairman: Professor Daryle H. Busch, Department of Chemistry, The Ohio State University, 140 West 18th Avenue, Columbus, OH 43210, U.S.A., or to any of its members.*

RECENTLY PUBLISHED DOCUMENTS

In addition to the book of nomenclature,[1] the commission has published several documents about topics that have evolved since 1970. The recommendations that have been published from 1982 on deal with isotopically labeled and isotopically substituted compounds,[2] inorganic and coordination polymers[3] (joint activity with the Nomenclature Commission of the Macromolecular Division), and nitrogen hydrides.[4] Short summaries of these recommendations are given below.

ISOTOPICALLY LABELED AND ISOTOPICALLY SUBSTITUTED COMPOUNDS[2]

These rules provide a general system of nomenclature for inorganic compounds whose isotopic nuclide composition deviates from that which occurs in nature. They are also suitable for designating individual isotopic molecular species. An isotopically modified organic residue occurring in an inorganic compound, such as an organic ligand in a coordinated entity, is named according to the rules of the Nomenclature of Organic Chemistry.

There is one other general system in use for describing isotopically modified compounds. It is based on an extension of the principles proposed by Boughton for designating compounds containing hydrogen isotopes, and, although mainly used in the index nomenclature of The Chemical Abstracts Service, it is found in the literature and in some chemical catalogs.

The system of nomenclature for isotopically modified inorganic compounds codified in these rules provides for recognition of various types of isotopic modification, and thus was chosen over the system based on the Boughton principles.

INORGANIC AND COORDINATION POLYMERS[3]

The fundamental principles of polymer nomenclature, which were developed to provide a framework for the unambiguous systematic naming of single-strand organic polymers, are extended to embrace inorganic and coordination polymers. The structures treated are regular single-strand polymers, that is polymers comprising repeating units linked exclusively through single atoms, and regular quasi-single-strand polymers, in which each repeating unit terminates at a single atom on one side but at a plurality of atoms on the other.

The name of the polymer is the name of the constitutional repeating unit (CRU) prefixed by the terms "poly", "catena", or other appropriate structural indicator, the CRU in turn being named by the citing, in order of appearance along the chain, of its constituent subunits, which are the largest structural fragments of the CRU that can be named according to established principles of inorganic and/or coordination nomenclature.

The document contains rules for the identification and orientation of the CRU, and it contains many examples of inorganic/coordination polymer structures together with the recommended names.

NITROGEN HYDRIDES[4]

These rules apply mainly to nitrogen hydrides containing one or two nitrogen atoms. The hydrides are considered as inorganic, although many of their derivatives are organic: the rules compromise between the relevant systems of nomenclature.

The benefit of a systematic nomenclature based on the name "azane" for NH_3 and the atom name "nitrogen" is outlined. However, due to common practice, names from "ammonia" (NH_3), "hydrazine" (N_2H_4), "diazene" (N_2H_2) and "nitrogen" (N) are retained for present use. The cations derived from the nitrogen hydrides by the addition of one or two hydrogen ions are named using the "ium" ending, and the anions derived by the loss of one or more hydrogen ions by the use of the "ide" ending in the established manner. The anions resulting from the loss of all hydrogen as ions from the nitrogen hydrides are named from the atom, e.g. nitride (N^{3-}). The problem of naming ligands N_nH_m attached to transition-metal ions where the actual valence bond structure of the ligand is indeterminate has been explored. The rules recommend that H_nH_m ligands should be named as neutral molecular species where possible, otherwise as anions, zwitterions or cationic ligands in that order of priority, but not as radicals. A table of ligand names is appended.

* Present Titular Members of the Committee are: Y. Jeannin (chairman), D. H. Busch, E. Fluck, P. Fodor-Csanyi, G. J. Leigh, J. Reedijk and E. Samuel.

ONGOING ACTIVITIES

Due to many new fields and to the discovery of many new types of compounds since the publication of the Red Book (1970), it was felt necessary to completely revise the Rules for Nomenclature in Inorganic Chemistry. The commission has agreed to publish a basic manual with the following contents:

(1) Aims, function and methods.
(2) Grammar.
(3) Elements and symbols.
(4) Formulae.
(5) Stoichiometric names.
(6) Solid-state chemistry.
(7) Neutral molecular compounds.
(8) Ions, radicals and salts.
(9) Oxoacids.
(10) Coordination compounds.
(11) Boron compounds.

In addition to this basic material, the commission intends to publish a part II, made up of chapters dealing with more advanced and detailed recommendations covering more specialized fields such as those mentioned above,[2-4] heteropolyanions[5] (almost completed, publication expected in 1985), organometallic compounds, inorganic rings and chains (all in preparation).

Individual chemists are encouraged to write to the commission if they would have ideas or suggestions about these topics or to include other subjects, or if they feel that a particular field is lacking accepted rules of nomenclature.

CORRESPONDENCE, SMALL MATTERS THAT MATTER ETC.

CNIC is a unit of an international public service organization, IUPAC, and we are volunteer chemists from about the world. Since nomenclature is our responsibility, we invite your inquiries and suggestions. We can serve you best if we know your needs and opinions. At worst, we should know someone who can name your cluster—or your ligand! Of course, some people already bring us their questions.

CNIC was formed to eliminate the Tower of Chemical Babel and almost every chemist has both appreciated and despised the tedium of the systematic and proper chemical nomenclature that CNIC is obliged to generate. In this second era of the computer evolution, names, formulae and the like are constrained by the inevitable super-literal reaction of the computer. With sympathy, but because precision and uniformity are increasingly important, we will just point out a few conventions that deserve to be observed.

(1) Representatives from all over the world agreed years ago (1970) to name the coordinated water molecule "aqua". Please do not call it aquo!!

(2) When numerical prefixes are used in naming a *coordination entity*, all vowels remain in the name. In technicalese: "there is no elision of vowels". For example, $[Al(H_2O)_6]^{3+}$ is the hexaaquaaluminium(3+) ion.

(3) This should not seem odd but it seems to cause some problems. The formulae of the common oxoanions are not considered to be *coordination formulae*. Consequently, they are not enclosed in square brackets, but rather in parentheses: $[Ni(H_2O)_6](ClO_4)_2$.

BOOK REVIEWS

Structure and Bonding, Vol. 59/60, Actinides—Chemistry and Physical Properties. Edited by L. Manes, Springer, Berlin, 1985, ix+305 pp., DM164.

The 60 volumes of *Structure and Bonding* have become an indispensable feature of the modern science library. In my experience it is difficult to write too highly of them. The reviews have authority, they are up-to-date, and beautifully produced. The authors, editors and publishers deserve our gratitude.

The title of Vol. 59/60 belies its contents for it is an overview of actinide solid-state physics. As such it is perhaps of greater interest to the physicist, theoretical chemist or chemical physicist than to the person I perceive as the average reader of *Polyhedron*, for the coordination and organometallic chemistries of the actinide elements are not covered. The literature is covered through 1983–1984 and there are some 1985 references.

The book is organized in six chapters and a conclusion on probable developments in the field. The first by Fournier and Manes illustrates the importance of the 5*f* wavefunctions in determining the physical properties of actinide solids, particularly the metals. There is a summary of the main experimental evidence which justifies the theoretical descriptions. In Chapter B (Muller and Spirlet) the preparation of high-purity actinide metals and compounds is described. Compounds in this context refer to the binary halides, oxides, nitrides etc. Chapter C (Manes and Benedict) deals with relationships between structural and thermodynamic properties and Chapter D (Fournier) with the magnetic properties. Chapter E (Naegele, Ghijsen and Manes) is an important review of the photoelectron spectroscopy of actinide metals and oxides in relation to bonding. The results are correlated with the itinerant/localized character of the unsaturated electron shells. The final chapter (Brooks) is a discussion of the most advanced theory of 5*f* bonding in actinide solids.

As is usual in *Structure and Bonding*, the whole is exceptionally well-produced.

Structure and Bonding, Vol. 61, Cation Ordering and Electron Transfer. By C. Gleitzer, J. B. Goodenough, B. G. Hyde, M. O'Keeffe and U. Weser. Springer, Berlin, x+167 pp., DM98.

The present volume of this well-established series is concerned broadly with cation ordering and electron transfer. The first chapter (Gleitzer and Goodenough) considers mixed valency with reference to three model systems: Fe_3O_4 (magnetite), as a representative of the ferrospinels and iron oxides with spinel-related structures; $Fe_{1-\delta}O$ (wüstite), as illustrative of a system with random defects and clustering; and $CaFeO_3$ (a perovskite), as illustrative of a system with strong Fe^4–O–Fe^4 interactions. The second chapter (Keefe and Hyde) concentrates on an alternative approach to non-molecular crystal structures, viz. one of laying emphasis on the arrangements of cations, rather than anions, in determining the packing, and on the attendant advantages of this approach. These two chapters on different aspects of oxide structures comprise the bulk (144 pp.) of Vol. 61: they are erudite, well-written and well-illustrated and important reading for solid-state chemists. The final, short chapter by Weser is on the rather different subject of redox-reactions of sulphur-containing amino-acid residues in proteins and metalloproteins—an XPS study. The link, such as it is, with the earlier chapters is via electron transport reactions. The volume is well-produced and a fitting complement to earlier ones in this series.

NORMAL-COORDINATE ANALYSIS OF THE TiO_5^{6-} ION

E. M. NOUR* and M. ZAKY

Faculty of Science, Zagazig University, Zagazig, Egypt

and

Sh. SALLAM

Faculty of Science, Suez Canal University, Ismalia, Egypt

Abstract—Normal-coordinate analysis for the TiO_5^{6-} ion in M_2TiO_5 (M = rare earths) has been made on the basis of C_{4v}-symmetry and using the Wilson's GF matrix method. The observed frequencies have been quantitatively assigned according to the obtained values of the potential-energy distributions. Force constants for the different bonds and angles have been calculated. The Ti—O′ (axial) and Ti—O (equatorial) stretching force constants were calculated to be 4.15 and 2.48 mdyn $Å^{-1}$, respectively.

The IR and Raman spectra for M_2TiO_5 (M = rare earths) have been reported.[1] Some of the observed frequencies were tentatively assigned on the basis of qualitative analysis and others were left unassigned. Therefore, further detailed investigations seem necessary.

The TiO_5^{6-} ion is of interest because of the way that titanium in this compound is five coordinated, whereas six coordination is more frequently observed. X-ray studies indicate[1] that the isolated ion has C_{4v}-symmetry with a short axial Ti—O′ bond.

In the present study we have made a normal-coordinate analysis for the TiO_5^{6-} ion and have obtained potential-energy distributions in order to assign the observed frequencies. Force constants are reported for the different bonds and angles.

NORMAL-COORDINATE ANALYSIS

An XY_5 molecule[2] may be trigonal bipyramid (D_{3h}) or tetragonal pyramid (C_{4v}). X-ray structural studies indicate[1] that the isolated $TiO'O_4^{6-}$ ion has a square pyramidal structure with C_{4v}-symmetry as shown in Fig. 1. The short Ti—O′ bond occupies the axial position with a bond distance of 1.77 Å, while the equatorial Ti—O has a bond distance of 1.92 Å. All angles are approximately equal to 90°. Group theoretical analysis shows that the $TiO'O_4^{6-}$ ion should display nine fundamental vibrations, three of which are doubly degenerate. These modes of vibration are distributed as follows:

$$\Gamma_{vib.} = 3A_1\,(\text{IR and R}) + 2B_1\,(\text{R}) + B_2\,(\text{R}) + 3E\,(\text{IR and R}),$$

where IR and R refer to IR and Raman activities. From these fundamentals, one, A_1, is related to the axial Ti—O′ bond stretch, while the equatorial Ti—O bond stretch shows three modes, belonging to A_1+B_1+E. The axial angle, bends are related to A_1+B_1+E, while the remaining two modes, B_2+E, are associated with the equatorial angle bends.

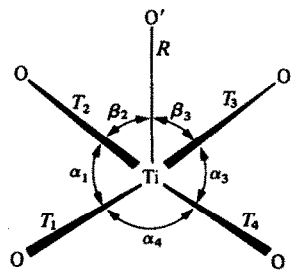

Fig. 1. Definition of the internal coordinates in the TiO_5^{6-} ion.

* Present address: Department of Chemistry, Faculty of Science, Qatar University, Doha, P.O. Box 2713, Qatar. Author to whom correspondence should be addressed.

The internal coordinates for the $TiO'O_4^{6-}$ ion are defined as given in Fig. 1. The symmetry coordinates used in the calculations for the C_{4v}-symmetry are constructed as follows:

A_1: $S_1 = R$, Ti—O′ stretch;
$S_2 = \frac{1}{2}(T_1 + T_2 + T_3 + T_4)$, Ti—O stretch;
$S_3 = \frac{1}{2}(\alpha_1 + \alpha_2 + \alpha_3 + \alpha_4)$, redundant;
$S_4 = \frac{1}{2}(\beta_1 + \beta_2 + \beta_3 + \beta_4)$, O′—Ti—O bend.

B_1: $S_5 = \frac{1}{2}(T_1 + T_3 - T_2 - T_4)$, Ti—O stretch;
$S_6 = \frac{1}{2}(\beta_1 + \beta_3 - \beta_2 - \beta_4)$, O′—Ti—O bend.

B_2: $S_7 = \frac{1}{2}(\alpha_1 + \alpha_3 - \alpha_2 - \alpha_4)$, O—Ti—O bend.

E: $\left.\begin{aligned} S_8 &= \tfrac{1}{2}(T_1 - T_2 - T_3 + T_4) \\ S_9 &= \tfrac{1}{2}(T_1 + T_2 - T_3 - T_4) \end{aligned}\right\}$, Ti—O stretch;

$\left.\begin{aligned} S_{10} &= \tfrac{1}{2}(\beta_1 - \beta_2 - \beta_3 + \beta_4) \\ S_{11} &= \tfrac{1}{2}(\beta_1 + \beta_2 - \beta_3 - \beta_4) \end{aligned}\right\}$, O′—Ti—O bend.

$$\left.\begin{aligned} S_{12} &= \frac{1}{\sqrt{2}}(\alpha_1 - \alpha_3) \\ S_{13} &= \frac{1}{\sqrt{2}}(\alpha_4 - \alpha_2) \end{aligned}\right\}, \text{ O—Ti—O bend.}$$

The normal-coordinate analysis was carried out on the basis of Wilson's GF matrix method.[3] A general quadratic potential-energy function has been used where the potential energy is expressed in terms of harmonic force constants associated with the coordinates of the molecule, i.e. bonded distances and the angle between them. However, the normal vibration can be calculated[3] from the secular equation:

$$(GF - \lambda E) = 0,$$

where E is the diagonal unit matrix and $\lambda = 4\pi^2 C^2 \nu^2$. A version of the Snyder–Schachtschneider programs[4] was used in the computation process.

Table 1. Force constants for $TiO'O_4$ ion

Symbol	Description[a]	Value[b]
F_R	Ti—O′ str.	4.15
F_T	Ti—O str.	2.48
F_α	O—Ti—O bend	0.99
F_β	O′—Ti—O bend	1.28
F_{RT}	Ti—O′, Ti—O	0.32
F_{TT}	Ti—O, Ti—O	0.22
$F_{\alpha\alpha}$	O—Ti—O, O—Ti—O	0.20
$F_{\beta\beta}$	O′—Ti—O, O′—Ti—O	0.31
$F_{R\beta}$	Ti—O′, O′—Ti—O	0.15

[a] str. = stretch.
[b] The units are mdyn Å^{-1} for $F_{str.}$ and $F_{str.str.}$; mdyn rad^{-1} for $F_{str.bend}$; mdyn Å rad^{-2} for F_{bend} and $F_{bend.bend}$.

In the frequency calculations the force constants were introduced and systematically adjusted so as to give the best agreement between the practically observed frequencies reported by Paques-Ledent[1] and the calculated values. The force constants and their values are given in Table 1.

The vibrations of a molecule may be described[5] in terms of normal coordinates, Q_e, which are related to the symmetry coordinates, S_k, by the linear transformation:

$$S_k = \sum_e L_{ke} Q_e,$$

where L_k are the normalized amplitudes of vibration. For a vibration of frequency ν_a associated with the normal coordinate Q_a, the potential energy of the molecule is given by:

$$2V = Q_a \sum_{ij} F_{ij} L_{ia} L_{ja}.$$

Table 2. Observed and calculated frequencies amd assignments for $TiO'O_4^{6-}$ ion

Wavenumber (cm^{-1}) Observed	Calculated	Assignment[a]
787	784	A_1: ν_1, sym. Ti—O′ str.
555	560	ν_2, sym. Ti—O str.
360	356	δ_3, sym. O′—Ti—O bend
486	490	B_1: ν_4, antisym. Ti—O str.
150	161	δ_5, antisym. O′—Ti—O bend
295	297	B_2: δ_6, antisym. O—Ti—O bend
648	652	E: ν_7, antisym. Ti—O str.
324	330	δ_8, antisym. O′—Ti—O bend
235	237	δ_9, antisym. O—Ti—O bend

[a] sym. = symmetric, antisym. = antisymmetric, and str. = stretch.

Table 3. Potential-energy distributions[a] for $TiO'O_4^{6-}$ ion

	F_R	F_T	F_α	F_β
ν_1	97	3	0	0
ν_2	12	88	0	0
ν_3	3	0	0	97
ν_4	0	100	0	0
ν_5	0	0	0	100
ν_6	0	0	100	0
ν_7	0	90	5	5
ν_8	0	4	8	88
ν_9	0	3	89	8

[a] Normalized to total 100 for the diagonal force constant distributions.

Table 4. XY force constants for XY_5 compounds

		F_{XY} (mdyn Å^{-1})		
Compound	Geometry	Axial	Equatorial	Reference
IF_5	C_{4v}	4.68	3.64	6
BrF_5	C_{4v}	4.02	3.19	6
ClF_5	C_{4v}	3.01	2.57	6
TiO_5^{6-}	C_{4v}	4.15	2.48	Present work
PF_5	D_{3h}	3.93	5.47	8
AsF_5	D_{3h}	4.21	5.20	8
VF_5	D_{3h}	3.64	4.28	8

Such terms are large only when $i = j$, where the diagonal force constants, F_{ii}, are much greater than the off-diagonal ones, F_{ij}. Accordingly, the term $\frac{1}{2}F_{ii}L_{ia}^2$ represents the distribution of the potential energy among symmetry coordinates. Therefore, a concrete assignments of the observed frequencies given in Table 2 for the $TiO'O_4^{6-}$ ion may be achieved on the basis of the calculated values of the potential-energy distributions for the different modes as given in Table 3. Descriptions of all the vibrational modes are shown in Fig. 2.

It is of interest to see that the axial Ti—O' stretching force constant is of much higher value than that of the equatorial Ti—O bond. Their values are 4.15 and 2.48 mdyn Å^{-1}, respectively. Using the bond-stretching force constant as an approximate measure of the equilibrum bond strength, it appears that the axial Ti—O' bond is 1.67 times stronger than the equatorial Ti—O bond. This result is in good agreement with the reported force constants for other XY_5 molecules. In the majority of the XY_5 molecules with C_{4v}-symmetry[6,7] (as in TiO_5^{6-}), the

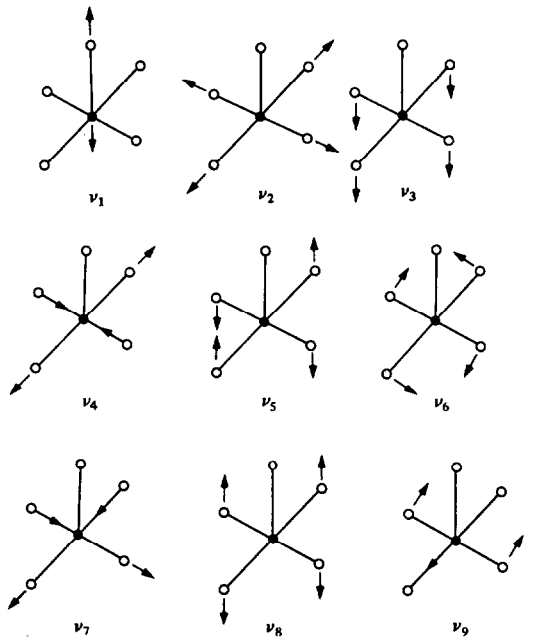

Fig. 2. Vibrational modes for TiO_5^{6-} ion.

axial stretching force constant is higher than the equatorial force constant. This is opposite to the trend found for XY_5 molecules with D_{3h}-symmetry[8] as given in Table 4 for the fluoride compounds. Rossi and Hoffmann[2] have reviewed and discussed the strength of both the axial and equatorial bonds in compounds with a square pyramidal structure with C_{4v}-symmetry. They concluded that the axial bond is the strongest with weaker equatorial bonds in metal complexes with electronic structures d^0 (as in TiO_5^{6-}), d^6 and d^{10}. The situation is reversed, with stronger equatorial and weaker axial bonds, in complexes with d^4- and d^8-configurations.

POLAROGRAPHIC STUDY OF THE COORDINATED Cd(II)–LEUCINATE SYSTEM

G. RUIZ-CABRERA, C. QUINTANA-PERERA, J. C. RODRIGUEZ-PLACERES and A. AREVALO*

Department of Physical Chemistry, University of La Laguna, Tenerife, Canary Islands, Spain

(*Received* 8 *July* 1985; *accepted* 18 *September* 1985)

Abstract—The coordinated Cd(II)–leucinate system has been studied polarographically in an aqueous medium and at constant ionic strength ($\mu = 1.0$) (adjusted with $NaClO_4$). The stabilization of the coordinated species $[CdL_2]$ and $[CdL_3]^-$ has been established, with stability constants $\beta_2 = 3.0 \times 10^7$ l^2 mol^{-2} and $\beta_3 = 8.2 \times 10^{10}$ l^3 mol^{-3}, respectively.

The importance of a knowledge of systems with simple molecules in the study of complex biological macromolecules[1–6] has prompted us to undertake a series of works on metallic ion–amino acid coordination.[7–9]

The polarographic analysis of the coordinated Cd(II)–leucinate system in an aqueous medium is reported here. To the best of our knowledge, this system has only been studied on one previous occasion[10] by the potentiometric method. The mean values obtained under the two conditions assayed were: $\beta_1 = 1 \times 10^4$ l mol^{-1} and $\beta_2 = 2.9 \times 10^7$ l^2 mol^{-2}, and no trace was detected of the presence in the medium of complexes with a greater number of ligands.

EXPERIMENTAL

Each of the i–E curves was plotted with a Metrohm E506 polarograph with an E505 polarographic stand. Pt (EA285) and Ag–AgCl–NaCl, sat. Metrohm EA427 electrodes were used as counter and reference electrodes, respectively, and the working one was a DME. The temperature in the cell was 25 ± 0.05°C. The ionic strength was adjusted to $\mu = 1.0$ with $NaClO_4$. Measurements of pH were carried out with a pHM84 digital potentiometer with a GK2401C radiometer combined electrode. The concentration of metal ion was maintained constant at 2×10^{-5} M in all recordings. Drop-time was controlled at 3.0 s.

The sodium perchlorate and cadmium sulfate were Merck products of p.a. quality, the L-leucine was from Sigma and the sodium hydroxide used for adjusting the pH was also of p.a. quality from May & Baker. The values of pK_1 (2.37) and pK_2 (9.62) were taken from Perrin.[11]

RESULTS

Leucine in aqueous solution gives rise to an equilibrium between its protonated forms, neutral and leucinate ion, governed by the acidity constants. At a sufficiently high pH, the complexes with leucinate will predominate, since its concentration will be significant and the corresponding stability constants are much higher than those of the possible species coordinated with the neutral leucine.

The two studies were carried out, varying the pH of an initial solution, and, therefore the concentrations of the different forms of leucine, between the limits indicated in Table 1.

From plots of log $[(\bar{i}_d - \bar{i})/\bar{i}]$ vs E the reduction was shown to have taken place through a reversible bielectronic process. The half-wave potentials were also obtained from these plots (Table 1).

The analysis of the equilibria was carried out following the method of De Ford and Hume,[12] accepting as the value of β_1 that proposed by Datta *et al.*[10] The good linear dependence found for F_2 vs [leucinate] (Fig. 1) points to the existence in the medium of complexes with two and three leucinate ligands. This is the first experimental evidence of the formation of the species $[CdL_3]^-$.

[a] De Ford and Hume method. Characteristics of the reduction of Cd(II) in 1 M $NaClO_4$: $-E'_{1/2} = 526.8$ mV, $\bar{i}_d = 86.1$ mm.

The values for the stability constants were obtained by the square minima method and are given in Table 2.

Their acceptable general agreement allows us to propose the following constants of the coordinated species $[CdL_2]$ and $[CdL_3]^-$: $\beta_2 = 3 \times 10^7$ l^2 mol^{-2}, and $\beta_3 = 8.2 \times 10^{10}$ l^3 mol^{-3}. The value of β_2 is in perfect agreement with that reported in the literature:[10] $\beta_2 = 2.9 \times 10^7$ l^2 mol^{-2}.

COMPLEXES OF Ag(I) WITH LIGANDS CONTAINING SULPHUR DONOR ATOMS

S. KRZEWSKA* and H. PODSIADŁY

Institute of Chemistry, Wrocław University, Wrocław, Poland

(*Received* 17 *July* 1985; *accepted* 18 *September* 1985)

Abstract—Potentiometric studies of silver complexes with thiourea, thiohydantoin, cysteine and thiobarbituric acid in a perchloric medium are reported. Thiohydantoin, cysteine and thiobarbituric acid form sparingly soluble precipitates with silver ions. Only thiourea forms soluble, colourless complexes with coordination numbers 1–4 and a dinuclear complex $[Ag_2tu_6]^{2+}$. Solubility products and stability constants of those complexes were determined.

Ligands containing sulphur atoms in the −2 oxidation state coordinate easily with many metals, especially with those showing the properties of soft acids, as, for example, Cu(I), Ag(I), Au(I), Hg(II) etc. Those ligands also show reducing properties and often the complexing reaction is accompanied by a redox reaction. An example of such a reaction is the reaction of Cu(II) with thiourea[1–3] or Fe(III) with thiourea.[4–6]

Silver ions, which usually form linear complexes with coordination number 2 with sulphur donors in aqueous solution, form complexes with maximum coordination number $n = 4$. Silver and thiourea complexes were studied both as solids[7–9] and in solution.[10–17]

In solution mononuclear silver–thiourea complexes with coordination number = 1–4[10–16] prevail. Shulman and Saveleva[17] have proved that in solution a stable dinuclear complex, $[Ag_2tu_3]^{2+}$, is also present. Formation of a complex with the same chemical composition was observed by Berthon and Berg[18] for the silver–thiosemicarbazide system.

In this paper we present potentiometric studies of silver complexes with thiourea, thiohydantoin, cysteine and thiobarbituric acid in a perchloric acid medium. For the silver–thiourea system, besides mononuclear complexes, the dinuclear complex $[Ag_2tu_6]^{2+}$ was obtained and its stability determined.

EXPERIMENTAL

Potentiometric measurements were carried out by means of pHM 4 "Radiometer" and OP 208 "Radelkis" pH meters. Indicator electrodes were silver and platinum electrodes in a redox formamidine disulfide–thiourea system. The reference electrode was a silver–silver chloride electrode immersed in a solution of 0.01 M $AgClO_4$ and 0.99 M $HClO_4$. The electrode was joined to the examined solution by a salt bridge of the "Wilhelm" type, filled with a solution of 1.00 M $HClO_4$. Measurements were carried out at a constant temperature (25 ± 0.1°C) and in a constant ionic medium (1 M ClO_4^-).

Silver perchlorate solution was obtained from silver carbonate and perchloric acid. The solution was kept in darkness in order to prevent silver ion reduction. The silver ion concentration was determined by potentiometric titration against sodium chloride using a silver electrode as the indicator electrode.

Thiourea concentration was determined potentiometrically by titrating it with a Ce^{4+} solution using a platinum indicator electrode. Thiobarbituric acid and thiohydantoin concentrations were determined by pH metric titration with sodium hydroxide solution. All solutions were prepared using double distilled water.

RESULTS

Thiohydantoin, cysteine and thiobarbituric acid form sparingly soluble precipitates with silver ions. Solubility products of those complexes were determined potentiometrically. The indicator electrode was a silver electrode, linear over a wide range of concentrations, whose slope was in agreement with the Nernst equation. Figure 1 shows an $AgClO_4$ solution titration with thiohydantoin solution

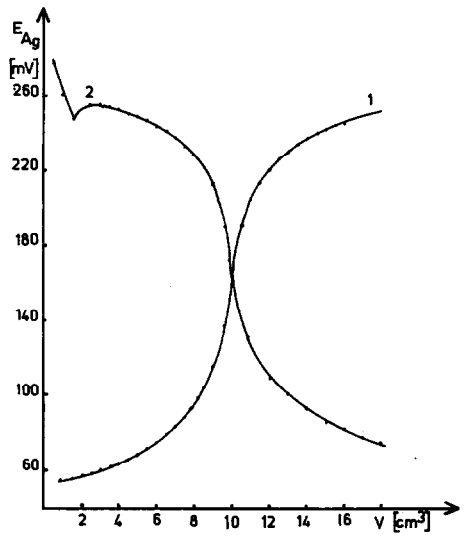

Fig. 1. Dependence of silver–silver chloride electrode potential on Ag^+ : th molar ratio. Curve 1: $V_o = 50$ cm^3, $[Ag^+] = 1.92$ mM, $V = 0$–18 cm^3, [th] = 9.75 mM, $[HClO_4] = 0.5$ M = constant. Curve 2: $V_o = 50$ cm^3, [th] = 1.96 mM, $V = 0$–18 cm^3, $[Ag^+] = 9.65$ mM, $[HClO_4]$ = 0.5 mM = constant.

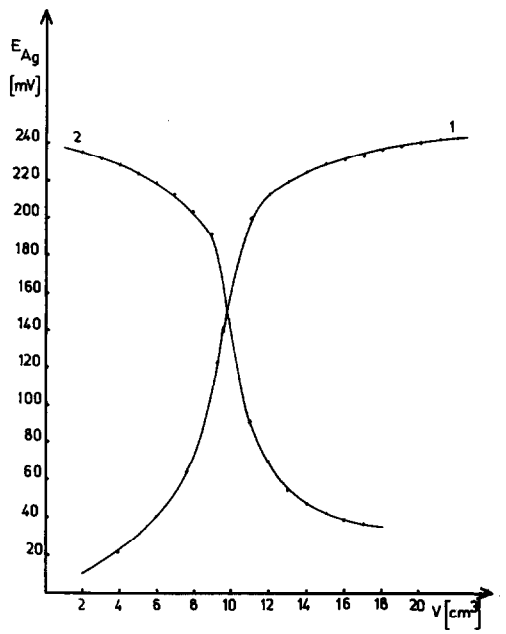

Fig. 2. Silver–silver chloride electrode potential dependence on Ag^+ : cys molar ratio. Curve 1: $V_0 = 50$ cm^3, $[Ag^+] = 1.92$ mM, $V = 0$–18 cm^3, [cys] = 9.84 mM, $[HClO_4] = 0.5$ M = constant. Curve 2: $V_o = 50$ cm^3, [cys] = 1.97 mM, $V = 0$–18 cm^3, $[Ag^+] = 9.65$ mM, $[HClO_4] = 0.5$ M = constant.

(curve 1) and a thiohydantoin solution titration with $AgClO_4$ solution (curve 2) in a 0.5 M $HClO_4$ medium. During titration a sparingly soluble compound of molar ratio Ag : th = 1 : 1 is formed. The solubility product of that compound is 1.78×10^{-9} (m dm^{-3})^2.

Cysteine reacts in a similar way with silver ions. In a 0.5 M $HClO_4$ medium a sparingly soluble complex of molar ratio Ag : cys = 1 : 1 was found. The solubility product of this compound was determined from the equivalence point of the curve of the silver perchlorate solution titration with the cysteine solution (Fig. 2, curve 1) and from the curve of the cysteine solution titration with the silver perchlorate solution (Fig. 2, curve 2). As Fig. 2 shows, those curves are not completely symmetrical and solubility products determined from the equivalence points differ slightly. Thus, the silver cysteinate solubility product determined from the equivalence point of curve 2 (152 mV) is 5.6×10^{-9} (m dm^{-3})^2. The values of the solubility products of silver cysteinate and silver thiohydantoinate are given in Table 1. These values were calculated from potentiometric measurements performed in the presence of cysteine or thiohydantoin excess. Then:

$$[th]_f = [th]_t - [Ag^+]_t \quad (1)$$

and

$$[Ag^+]_f = \frac{E - E^o}{58}. \quad (2)$$

In the system with thiobarbituric acid, formation of sparingly soluble compounds with the following compositions occurred: Ag_2(tba), Ag(tba) and $Ag(tba)_2$. Figure 3 shows the $AgClO_4$ solution titration with the thiobarbituric acid solution in a 0.5 M $HClO_4$ medium. Figure 3 shows clearly that two equivalence points appear on the titration curve: one at a molar ratio (Ag : tba) of 2 : 1, the

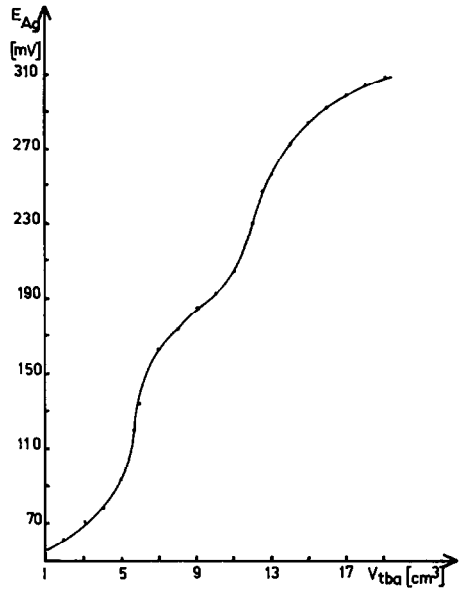

Fig. 3. Potentiometric titration of the solution containing 10 cm^3 9.65 mM $AgClO_4$ in 0.5 M $HClO_4$ with thiobarbituric acid solution (8.61 mM in 0.5 M $HClO_4$).

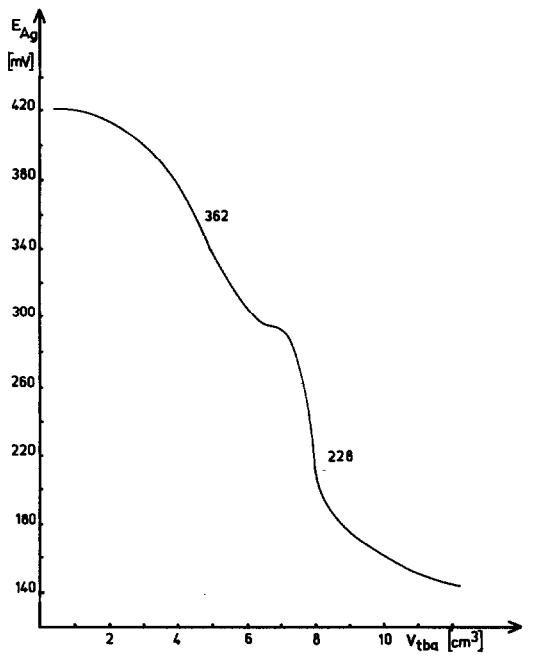

Fig. 4. Potentiometric tiration of the solution containing 5 cm^3 17.2 mM of thiobarbituric acid in 0.5 M $HClO_4$ with silver perchlorate solution (9.65 mM in 0.5 M $HClO_4$).

other at an Ag : tba ratio of 1 : 1. From the titration curve equivalence points free silver ion concentrations were determined and the solubility products of those compounds were calculated. Thus, the solubility product determined for Ag_2(tba) is 1.24×10^{-11} (m dm^{-3})^3 while the K_{so} for the compound with Ag : tba = 1 : 1 is 9.61×10^{-12} (m dm^{-3})^2. Five series of silver ion titrations with thiobarbituric acid were made. Table 2 shows solubility product values calculated from the equivalence points of each titration curve.

Figure 4 shows a thiobarbituric acid solution titration with $AgClO_4$ solution. As can be seen in Fig. 4 two equivalence points appear on the titration curve, which correspond to the formation of $Ag(tba)_2$ and Ag(tba) compounds. The solubility product value for $Ag(tba)_2$ complex is 1.52×10^{-23} (m dm^{-3})^3, while that for Ag(tba) is 12.2×10^{-12} (m dm^{-3})^2. The latter value is in agreement with the values of the corresponding solubility products determined from the silver perchlorate solution titration with thiobarbituric acid solution (Table 2).

In the perchloric acid medium thiourea and silver ions form soluble complexes. Besides mononuclear complexes which are are well known and described in the literature,[10–16] studies were carried out in order to find silver–thiourea polynuclear complexes. Potentiometric measurements were carried out with a large, constant ligand excess. Under such conditions it can be assumed that the free thiourea concentration is the same as the total thiourea concentration. The silver ion reaction with thiourea can be presented by the following equation:

$$qAg^+ + ptu = [Ag_q tu_p]^{q+}. \quad (3)$$

Since, in solution, there is a large ligand excess, the

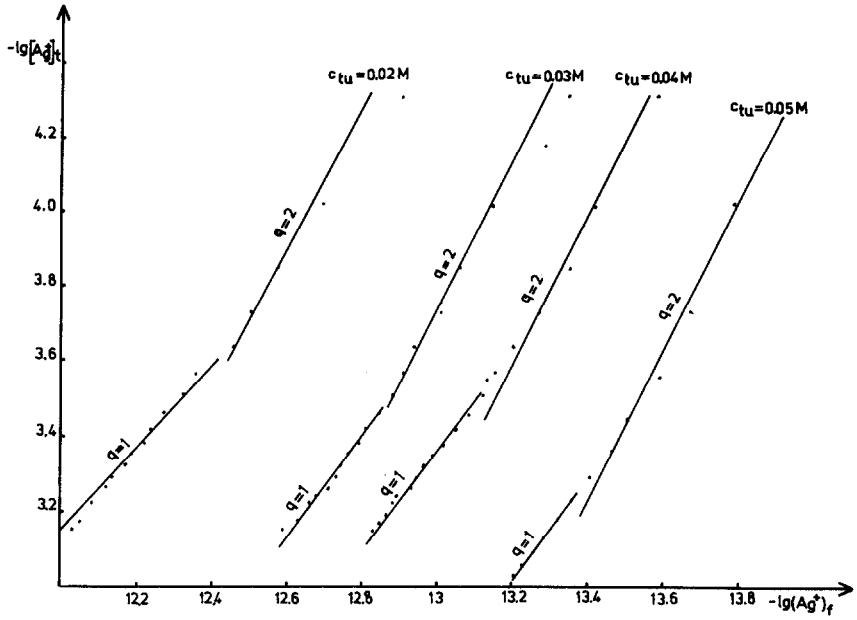

Fig. 5. Determination of the number of nuclei ($\bar{q}$) in a silver–thiourea complex at a constant ligand concentration.

total silver ion concentration is:

$$[Ag^+]_t = \sum_0^q \sum_0^p q[Ag_q tu_p] = \sum_0^q \sum_0^p q\beta_{qp}[Ag^+]^q[tu]^p. \tag{4}$$

Hence:

$$\left(\frac{\partial \log [Ag^+]_t}{\partial \log [Ag^+]}\right)_{[tu]} = \bar{q}. \tag{5}$$

Dependence diagrams of $\log [Ag^+]_t$ on $\log [Ag^+]$ for some thiourea concentrations are presented in Fig. 5. As can be seen, over quite a large concentration range dinuclear silver–thiourea complexes exist in solution.

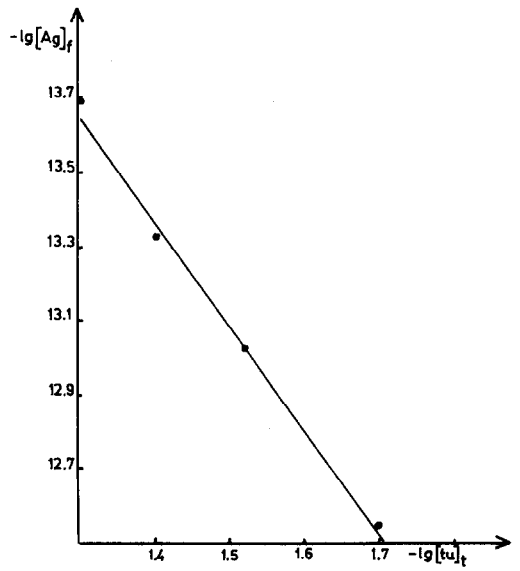

Fig. 6. Determination of the silver–thiourea complex composition at a constant total silver ion concentration.

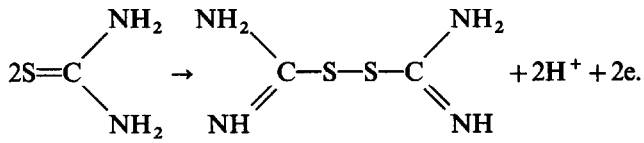
The number of coordinated thiourea molecules can be determined from the following equation:

$$\left(\frac{\partial \log [Ag^+]}{\partial \log [tu]_t}\right)_{[Ag^+]_t} = \frac{\bar{p}}{q}. \tag{6}$$

A graphical presentation of the $\bar{p}/q$ determination is shown in Fig. 6. Taking into account the determined values of p and q, the reaction for silver–thiourea dinuclear complex formation can be presented as follows:

$$2Ag^+ + 6tu = [Ag_2tu_6]^{2+}.$$

The stability constant of this complex is:



$$\beta_{26} = \frac{[Ag_2tu_6^{2+}]}{[Ag^+]^2[tu]^6}. \tag{7}$$

The calculated stability constant values are presented in Table 3.

Table 3. Stability constant values of dinuclear silver–thiourea (tu) complexes in 0.5 M $HClO_4$ medium

Mean value	31.09

For the examination of the stability of mononuclear silver–thiourea complexes the measurements of ligand oxidized and reduced form redox potentials were applied. The result of monoelectronic thiourea oxidation is formamidine disulfide which forms with thiourea a reversible redox system:[19]

The redox potential of formamidine disulfide–thiourea in 1 M perchloric acid solution is:

$$E = E^{o\prime}_{fds} + (RT/F) \ln \frac{[fds]^{1/2}}{[tu]}, \qquad (8)$$

where $E^{o\prime}_{fds}$ = formal redox potential of formamidine disulfide–thiourea system in 1 M $HClO_4$.

Initial measurements have proved that in the concentration range studied formamidine disulfide does not form complexes with silver ions. Silver perchlorate solution titration with formamidine disulfide solution was carried out at a constant silver ion concentration. The silver electrode potential has a constant value during titration, which proves that formamidine disulfide does not react with the silver ions.

Formamidine disulfide was obtained by thiourea coulometric oxidation in 1 M $HClO_4$ solution on the platinum electrode at a potential of 1400 mV vs SCE.

Potentiometric studies of mononuclear silver–thiourea complexes were carried out in the following way: in each series silver ion and formamidine disulfide concentrations were constant. In such a system the redox potential depends only on the thiourea concentration:

$$E = E'_f - (RT/F) \ln [tu],$$
$$E'_f = E^{o\prime}_{fds} + (RT/F) \ln [fds^{2+}]^{1/2} = \text{constant}. \qquad (9)$$

The dependence of the platinum electrode redox potential on the logarithm of the thiourea concentration at a constant concentration of formamidine disulfide is linear over a large concentration range and its slope corresponds to the Nernst equation.

From redox potential measurements the free thiourea concentration can be determined. Knowing the free thiourea concentration, the average ligand number was calculated:

$$\bar{n} = \frac{[tu]_t - [tu]}{[Ag^+]_t}.$$

Figure 7 shows the average ligand number dependence on the logarithm of the free thiourea concentration for various total silver ion concentrations. As can be seen from the formation curve, over the concentration range studied, mononuclear complexes are present.

Stability constants of silver–thiourea complexes were determined graphically by means of Olerup's method[20] (Fig. 8). Table 4 shows stability constant values for each silver ion concentration value.

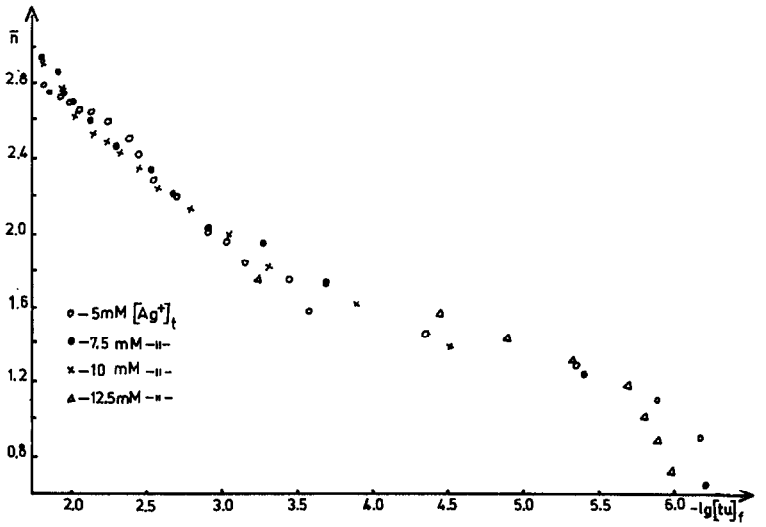

Fig. 7. Average ligand number dependence on log free thiourea concentration.

DISCUSSION

Silver complexes with sulphur-containing ligands studied in this work are sparingly soluble compounds. Only thiourea molecules, which may not form anions, form soluble, colourless complexes with coordination numbers 1–4 and a dinuclear complex, $[Ag_2tu_6]^{2+}$. Thiohydantoin and cysteine form 1:1 complexes, while in the case of

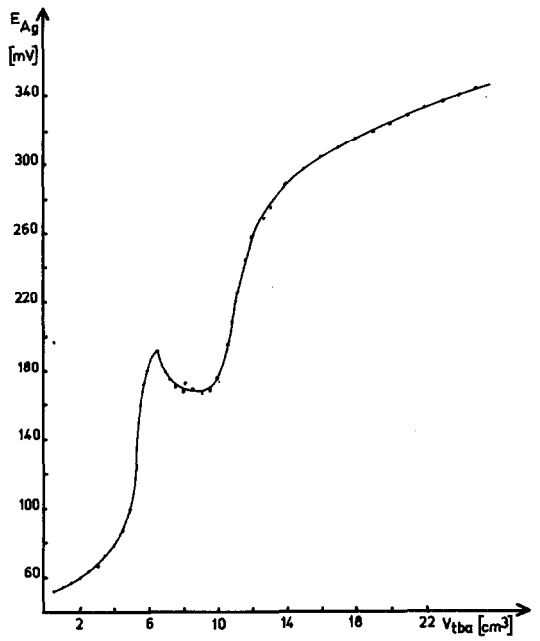

Fig. 10. Silver electrode potential dependence on the thiobarbituric acid volume after full stabilization of the potential value at each titration point.

thiobarbituric acid, sparingly soluble compounds [Ag_2tba, Ag(tba) and $Ag(tba)_2$] were found. Reactions forming scarcely soluble silver compounds with cysteine and thiobarbituric acid are slow reactions. Following the addition of an appropriate ligand amount, the silver–silver chloride electrode potential does not stabilize at once but after a time which depends on the molar ratio of metal to ligand. Figure 9 shows silver electrode potential dependence on the duration of the silver–thiobarbituric acid reaction at different molar ratios of metal ion and ligand.

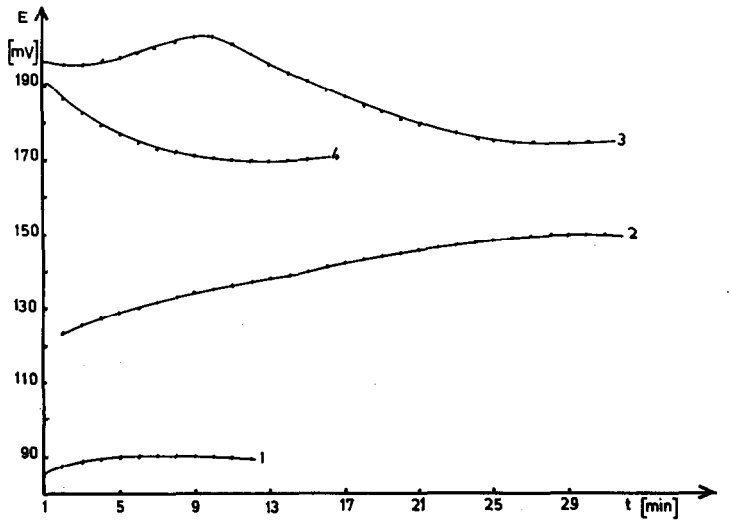

Fig. 9. Silver electrode potential dependence on the reaction time of Ag(I) and thiobarbituric acid for different proportions of metal and ligand.

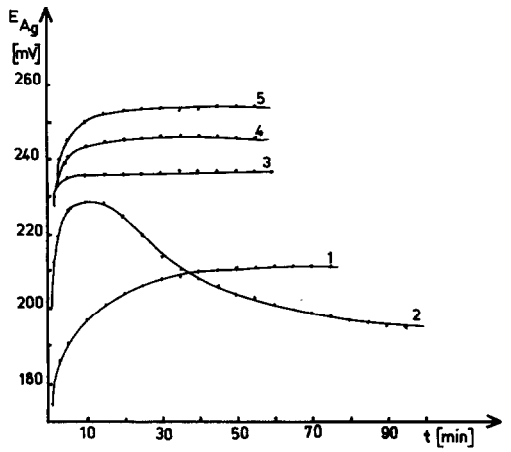

Fig. 11. Silver electrode potential dependence on the reaction time of Ag(I) and cysteine.

Figure 10 shows the $AgClO_4$ solution titration with thiobarbituric acid after a full silver electrode potential stabilization at each titration point. A long time of equilibrium stabilization, as well as a characteristic potential maximum, seen in Fig. 10, are probably connected with the change in the complex structure and transformation of the Ag_2(tba) into the Ag(tba) complex. A similar silver electrode potential dependence on the reaction time was obtained for the silver ion–cysteine reaction

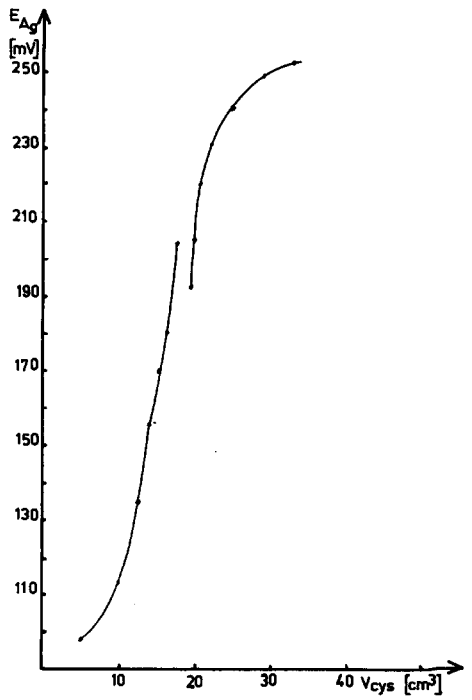

Fig. 12. Silver electrode potential dependence on the cysteine concentration after full stabilization of the silver electrode potential value.

Table 5. Experimental and literature stability constant values of mononuclear silver–thiourea complexes

	This work	Reference 10	Reference 15
$\log \beta_1$	6.05	7.3	7.04
$\log \beta_2$	10.71	10.6	10.61
$\log \beta_3$	12.56	12.68	12.84
$\log \beta_4$	13.95	13.78	13.62

(Fig. 11). At a 1 : 1 molar silver : cysteine ratio there appears to be a maximum on the curve of $E_{Ag} = f(t)$. This result shows that the reaction character is complex. Probably, besides the 1 : 1 complex, a certain amount of another complex is formed, but this could not be proved unequivocally by means of potentiometric measurements. The diagram of silver ion potentiometric titration with cysteine solution after full stabilization of the potential value at each titration point (Fig. 12) shows only a discontinuity at a molar ratio of 1 : 1. We did not manage to find the other equivalence point.

The determined values of silver complex solubility products with the ligands studied are shown in Tables 1 and 2. The silver–thiourea dinuclear complex was isolated in a crystalline state by Udupa and Krebs.[8] The authors presented the structure of this complex on the basis of X-ray measurements.

Stability constant values of mononuclear silver–thiourea complexes were determined using the redox potential measurements of a thiourea–formamidine disulfide system. The stability constants values determined by us are in a good agreement with the stability constants values determined from the silver electrode potential measurements which are presented in Table 5.

REACTIVITY OF ARSENIC SELENIDES AND TELLURIDE: COBALT COMPLEXES CONTAINING THE SELENA- OR TELLURA-DIARSIRENE CYCLIC UNITS *TRIHAPTO*-BONDED TO THE METAL ATOM—CRYSTAL AND MOLECULAR STRUCTURES OF [(TRIPHOS)Co(As_2Se)](BF_4)(C_2H_5OH) AND [(TRIPHOS)Co(As_2Te)](BF_4)(C_6H_6)$_{0.5}$

MASSIMO DI VAIRA, MAURIZIO PERUZZINI and PIERO STOPPIONI*

Dipartimento di Chimica, Università di Firenze and Istituto I.S.S.E.C.C., Via Maragliano, 77, 50144 Firenze, Italy

(*Received* 8 *July* 1985; *accepted* 2 *October* 1985)

Abstract—The reaction of $Co(BF_4)_2(H_2O)_6$ with arsenic selenides and telluride, As_4Se_3, As_2Se_3 and As_2Te_3 in the presence of 1,1,1-tris(diphenylphosphinomethyl)ethane (triphos), yielded the complexes

[(triphos)Co(As_2Se)](BF_4)(C_2H_5OH) (**1**)

and

[(triphos)Co(As_2Te)](BF_4)(C_6H_6)$_{0.5}$ (**2**).

The molecular structures of the complexes have been determined by single-crystal X-ray diffraction methods. The isomorphous compounds crystallize in the monoclinic space group $P2_1/n$ with $Z = 4$ and unit-cell dimensions: (**1**) $a = 17.034(8)$ Å, $b = 20.640(9)$ Å, $c = 13.116(6)$ Å, $\beta = 105.37(6)°$; (**2**) $a = 17.076(7)$ Å, $b = 20.419(9)$ Å, $c = 13.215(7)$ Å, $\beta = 105.15(7)°$. The metal atom in both compounds is in a six-coordinate environment formed by the triphos P atoms and by the atoms of the heterocyclic As_2Se or As_2Te unit.

The E_4X_3 (E = P, X = S or Se; E = As, X = S) cage molecules react with transition-metal–ligand systems to give different products depending on the nature of the metal atom and its oxidation state.[1] In particular, a substantial cleavage of the cage molecules occurs in the reactions with cobalt(II) and nickel(II) tetrafluoroborate in the presence of triphos [triphos = 1,1,1-tris(diphenylphosphinomethyl)ethane], affording stable complexes which contain the heterocyclic E_2X (E = P, X = S or Se;[2] E = As, X = S[3]) or the homocyclic E_3 (E = P[4] or As[5]) units η^3-bonded to the metal atom. Other small molecules formed by atoms of groups V and VI react with transition-metal complexes, affording compounds which contain either "bare" pnicogen[6] or chalcogen[7] atoms, or small groups of such atoms, like S_2,[8] P_2,[9] P_3,[10] As_3[11] or S_5[12] bound to the metal atom. Among such compounds, those containing S or P are much more numerous than the Se, Te or As derivatives. This is probably due to the markedly different chemical behaviour of the latter elements with respect to that of the lighter ones of the same groups.

Here we report the synthesis and characterization of the compounds

[(triphos)Co(As_2Se)](BF_4)(C_2H_5OH) (**1**)

and

[(triphos)Co(As_2Te)](BF_4)(C_6H_6)$_{0.5}$ (**2**)

which contain the new As_2Se and As_2Te cyclic units η^3-bonded to the metal. The comparison between the structures of the present compounds and those of the isomorphous [(triphos)Co(E_2X)](BF_4)(C_6H_6) (E = P, X = S or Se;[2] E = As, X = S[3]) complexes reveals the effects due to the presence of the heavier and larger atoms of groups V and VI in the As_2Se and As_2Te rings.

EXPERIMENTAL

All solvents were reagent grade and were dried by distillation from suitable agents.[13] All reactions and manipulations were carried out under dry nitrogen. Electronic spectra, conductivity and magnetic susceptibilities were measured by procedures already described.[14] ^{31}P NMR spectra were collected (at 32.19 MHz) on a Varian CFT20 spectrometer. ^{31}P positive chemical shifts are downfield relative to H_3PO_4 at 0.0 ppm.

The compound As_2Te_3 was purchased from Ventron GMBH and used without any purification; the ligand triphos[15] and As_4Se_3[16] were prepared according to published procedures. As_2Se_3 was synthesized by reacting in a sealed tube under nitrogen gray As and black Se in a 2:3 ratio for 3 days at 410°C. The solid obtained was finely powdered and stored in an inert atmosphere.

Synthetic procedures

Preparation of **1**. *Procedure A.* Finely powdered As_4Se_3 (3 mmol) was added to a solution of $Co(BF_4)_2(H_2O)_6$ (1 mmol) in ethanol (10 cm^3) and triphos (1 mmol) in tetrahydrofuran–benzene (1:1) (50 cm^3). The resulting mixture was refluxed for 5 days with magnetic stirring and then filtered. The solid was washed with warm dichloromethane (20 cm^3). The combined filtrate and washing solutions were concentrated to dryness *in vacuo*. The solid was extracted with hot dichloromethane (40 cm^3) and ethanol–benzene (2:1) (40 cm^3) was added. Red crystals of the compound were obtained by concentrating the solution. The complex was collected on a sintered-glass frit, in a closed system, and washed with ethanol and then light petroleum (b.p. 40–70°C) before being dried (yield 50–55%). The compound, which crystallizes with one molecule of ethanol, was recrystallized from dichloromethane and ethanol–benzene (1:1).

Procedure B. As_2Se_3 (2 mmol) was added to a solution of $Co(BF_4)_2(H_2O)_6$ (1 mmol) in ethanol (10 cm^3) and triphos (1 mmol) in tetrahydrofuran–benzene (1:1) (50 cm^3). The resulting mixture was refluxed for 4 days with magnetic stirring and then filtered. The compound $[(triphos)Co(As_2Se)](BF_4)$ was isolated as described for procedure A.

Preparation of **2**. As_2Te_3 (2 mmol) was added to a solution of $Co(BF_4)_2(H_2O)_6$ (1 mmol) in ethanol (10 cm^3) and triphos (1 mmol) in tetrahydrofuran–benzene (1:1) (40 cm^3). The mixture was refluxed for 8 days, then filtered while hot and ethanol–benzene (1:1) (30 cm^3) was added. Dark-red crystals of the compound were obtained by concentrating the solution. The complex was collected by the procedure described above for the As_2Se derivative (yield 15–20%). The compound could not be recrystallized due to its tendency to decompose in solution, releasing tellurium.

X-ray crystal structures

Diffraction data for compounds **1** *and* **2**. These were collected at room temperature from crystals of dimensions $0.20 \times 0.20 \times 0.25$ mm (**1**) and $0.15 \times 0.10 \times 0.20$ mm (**2**) using a Philips PW 1100 four-circle diffractometer and graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å). Lattice constants were determined by least-squares refinement of the angular settings of 24 reflections with $22 < 2\theta < 40°$ (**1**) and $18 < 2\theta < 22°$ (**2**).

Crystal data. (**1**) $C_{43}H_{45}As_2BCoF_4OP_3Se$, $M_r = 1045.3$, monoclinic, $a = 17.034(8)$ Å, $b = 20.640(9)$ Å, $c = 13.116(6)$ Å, $\beta = 105.37(6)°$, $U = 4446.4$ Å^3, $Z = 4$, $D_c = 1.56$ g cm^{-3}, $F(000) = 2096$, μ(Mo-K_α) = 28.2 cm^{-1}, space group $P2_1/n$.

(**2**) $C_{44}H_{42}As_2BCoF_4P_3Te$, $M_r = 1086.9$, monoclinic, $a = 17.076(7)$ Å, $b = 20.419(9)$ Å, $c = 13.215(7)$ Å, $\beta = 105.15(7)°$, $U = 4447.6$ Å^3, $Z = 4$, $D_f = 1.66$ g cm^{-3}, $D_c = 1.62$ g cm^{-3}, $F(000) = 2148$, μ(Mo-K_α) = 26.5 cm^{-1}, space group $P2_1/n$.

Crystals of **2** did not provide good material for X-ray diffraction, probably due to larger effects of disorder (see below) in the structure of **2** than in that of **1**. The intensities of all reflections with $k > 0$ and $l > 0$ were measured in the ranges $5 < 2\theta < 44°$ (**1**) and $5 < 2\theta < 40°$ (**2**) in the θ–2θ scan mode with a scan width of $(1.10 + 0.30 \tan\theta)°$ and scan speed of 6° min^{-1}. No crystal decay was observed. Of the total 5912 (**1**) and 4529 (**2**) reflections recorded 2432 (**1**) and 1450 (**2**) having $I > 3\sigma(I)$ were used for structure determination after correction for Lorentz, polarization and X-ray absorption effects. Crystallographic calculations were carried out using SHELX 76.[17]

The structures of the two compounds, which are isomorphous to each other as well as to the $[(triphos)Co(E_2X)](BF_4)(C_6H_6)$ (E = P, X = S or Se;[2] E = As, X = S[3]) complexes previously investigated, were refined assuming as initial values for the atomic coordinates those from the latter structures. All atoms heavier than carbon were assigned anisotropic thermal parameters, whereas the other atoms were refined isotropically. The solvent molecule in each structure was assigned an overall temperature factor. Phenyl groups of the triphos ligand were refined as rigid bodies with idealized geometry. Hydrogen atoms of the triphos ligand were introduced in calculated positions (C—H = 1.00 Å) with an overall temperature factor. The BF_4^- anion was imposed a tetrahedral geometry, the value of the B—F distance being refined. The

scattering factors for the neutral atoms and the anomalous dispersion corrections for Co, Se, As and Te were taken from Ref. 18. It was impossible to identify the As and Se atoms in the triatomic ring of **1**. Therefore, in analogy with the model used for the P_2S derivative,[2] each site of the ring was assigned 0.67 As and 0.33 Se occupancy factors. This led to comparable U_{iso} values for the three sites. The ratio of the C—C and C—O bond lengths in the solvate ethanol molecule of **1** was constrained to an idealized value:[19] the O atom, identified on the basis of peak heights and contact distances, was found from ΔF maps to be distributed with essentially an equal probability between two positions. For **1** no peaks >0.7 *e* Å^{-3} were observed in the final electron-density difference map, and refinement with the weighting scheme $w = [\sigma^2(F_o)+0.0001|F_o|^2]^{-1}$ led to $R = 0.056$ ($R' = 0.062$). For **2** it was evident from the peak heights in ΔF Fourier maps that the Te atom was distributed over at least two sites of the As_2Te ring with different occupancy factors. Refinement of the population parameters of the three sites was performed by the procedure already described for the P_2Se[2] and As_2S[3] isomorphs, i.e. imposing that the U_{iso} values for the three sites should be close to each other. The occupancy factors so obtained [essentially 1.00 As for the site labelled As(1), whereas sites As(2) and Te had 0.80 and, respectively, 0.20 As occupancy factors with complementary Te population parameters] were in reasonable agreement with those previously determined for the P_2Se isomorph,[2] allowing for replacement of As for P and of Te for Se. The solvate benzene molecule was highly disordered, with peak heights <1 *e* Å^{-3} in ΔF Fourier maps. The compromise 0.5 value of its population parameter, lower than indicated by the D_f value, was assigned on the basis of the *R* criterion and in order to avoid an exceedingly high value of the overall temperature factor. Such a benzene ring, without H atoms, was imposed an idealized geometry: the C—C distance was refined to 1.38 Å and the overall *U* value to 0.195(2) Å^2. For **2** no peaks >0.8 *e* Å^{-3} were observed in the final electron-density difference map and refinement with the weighting scheme $w = [\sigma^2(F_o)+0.0005|F_o|^2]^{-1}$ led to $R = 0.068$ ($R' = 0.076$). Final atomic positional and thermal parameters, bond lengths and angles and F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been submitted to the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The reaction of cobalt(II) tetrafluoroborate in the presence of the tripod ligand triphos with As_4Se_3, As_2Se_3 or As_2Te_3 affords complexes of formula [(triphos)Co(As_2X)](BF_4) [X = Se(**1**) or Te(**2**)]. The analytical data (Table 1) for the complexes, which crystallize with solvent molecules in the lattice, are in good agreement with the proposed formula. The complexes behave as 1:1 electrolytes in nitroethane[20] (Table 1). The diamagnetic compounds are moderately air-stable in the solid state. They are slightly soluble in acetone and dichloromethane, whereupon the compound containing the selenadiarsirene unit is stable under nitrogen, whereas the As_2Te derivative decomposes in a short time even in an inert atmosphere by releasing tellurium. A similar behaviour has been found for telluradiphosphirane,[21] which is the only compound containing a Te atom in a three-membered ring so far reported. The low solubility of both compounds here described prevented us from obtaining ^{77}Se and ^{125}Te NMR spectra. The ^{31}P–{^{1}H} NMR spectra of the compounds (Table 2) exhibit a broad resonance at low field (32.56 and 32.39 ppm for compounds **1** and **2**, respectively) affected by the cobalt quadrupole moment, that is assigned to the three atoms of the ligand. The triphos $\delta(^{31}P)$ values are practically identical for complexes **1** and **2** and for all the isostructural [(triphos)Co(E_2X)](BF_4) complexes

Table 1. Analytical and conductivity data for the complexes

	Compound	Λ_M[a] (Ω^{-1} cm^2 M^{-1})	Analysis (%): found (calc.) C	H	Co	P	As	Other

[c] Absorption maxima for CH_2Cl_2 solution at 20°C.

(E = P, X = S or Se[2]; E = As, X = S[3]) having the P_2S, P_2Se or As_2S cyclic unit *trihapto* bonded to the metal. The scarce sensitivity of the triphos chemical shift to replacement of the chalcogen or pnicogen atoms in the triatomic ring might be due to involvement of the triphos P atoms in lower-energy molecular orbitals than the atoms of the cyclic unit. The absorption spectra of the compounds in dichloromethane solution (Table 2) exhibit a shoulder and a band at *ca* 470–500 and 380–390 nm, respectively. In the spectrum of the [(triphos)Co(As_2S)](BF_4) derivative the same transitions occur at 450 and 380 nm, their frequencies decreasing slightly with increasing atomic number of the heteroatom in the As_2X ring. The same trend had been noticed for the P_2X (X = S or Se) derivatives[2] and may be related in part to the accompanying increase, in the mean, of the metal to As_2X or P_2X ring distances, proved by the results of previous [2,3] structural analyses combined with those reported here. The crystal structures of the isomorphous compounds **1** and **2** consist of [(triphos)Co(As_2X)]$^+$ cations (X = Se or Te), BF_4^- anions, and interposed ethanol or benzene molecules from the solvent. Figure 1 shows a perspective view of the cation in compound **1**, the geometry of the cation in **2** being closely similar. Selected values of bond distances and angles in the two structures are listed in Table 3. The metal atom in each cation is in a six-coordinate environment formed by the triphos P atoms and the atoms of the As_2X unit in a staggered arrangement similar to that previously found for the compounds containing the P_3 homocyclic[10] or the E_2X (E = P, X = S or Se;[2] E = As, X = S[3]) heterocyclic inorganic rings. The distances from the metal atom to the P atoms of the triphos ligand in either compound [2.205(4)–2.227(9) Å] are in the range of values already found for the isomorphous derivatives.[2,3] A detailed analysis of the dimensions of the $CoAs_2X$ moieties in the two compounds is prevented

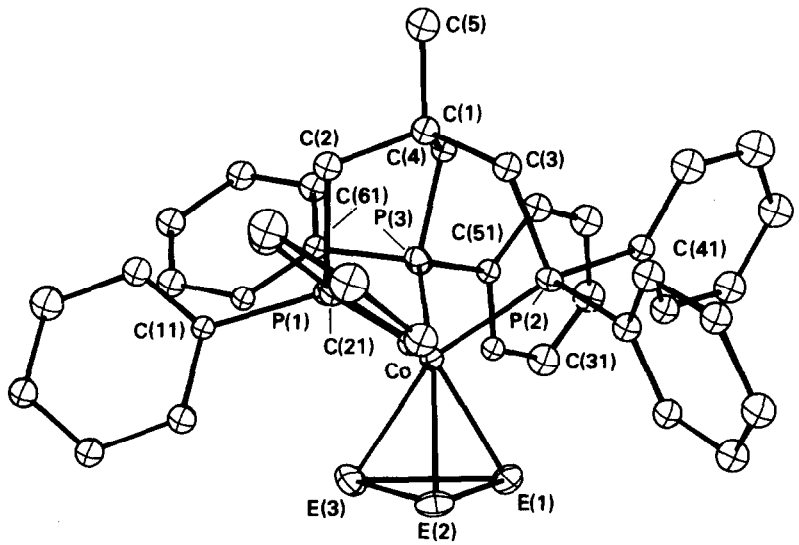

Fig. 1. Perspective view of the [(triphos)Co(As_2Se)]$^+$ cation with 20% probability ellipsoids. The E(1)–E(3) sites have 0.67 As and 0.33 Se occupancy. Only the first carbon atom of each phenyl group is labelled. The [(triphos)Co(As_2Te)]$^+$ cation has substantially the same structure with As_2Te ring site occupancies as specified in Experimental and in footnote [b] to Table 3.

by the disorder affecting the triatomic rings. It should however be noted that the overall geometry of the $CoAs_2Se$ fragment in **1** is approximately tetrahedral (Table 3), with metal to ring-site and intraring distances definitely longer [by *ca* 0.14 and 0.24 Å, respectively] than the corresponding distances in the CoP_2S part of the thiadiphosphirene derivative.[2] The geometry of the $CoAs_2Te$ moiety in **2** is less regular, due to the presence of the large Te atom. The site with the highest Te population is indeed involved in rather long bond distances; in particular, its distance from the metal site, of 2.582(4) Å, is definitely longer than any of the corresponding bond lengths found for compounds of this series.

Although the assignment of the oxidation number of the metal atom in these compounds is not unambiguous, the compounds may be considered to contain cobalt(I), assuming that the As_2X moiety behaves as a neutral four-electron donor, consistently with the electron-counting procedure already used for triphosphirene complexes.[10] Therefore, reduction of the metal atom should occur in the formation of the present or previous[2,3] compounds with the [(triphos)Co(E_2X)](BF_4) stoichiometry as it has been considered[10] to occur in the formation of the [(triphos)M(P_3)]$^{n+}$ complexes [M = Co,[22] Rh[23] or Ir[23]; $n = 0$: M = Ni,[4] Pd[24] or Pt[24]; $n = 1$) or of the triple-decker com-

pounds with P_3 or As_3 internal slices.[10] In such processes, at variance with those where no reduction of the metal atom occurs,[1(a),1(c),1(d)] substantial cleavage of the reacting cage molecule (P_4, As_4, or a molecule of the E_4X_3 class) is invariably involved. An unprecedented feature of the present results is however due to the fact that compounds with the [(triphos)Co(As_2X)](BF_4) stoichiometry have now been obtained not only by reaction of a cobalt(II) salt with the molecular As_4Se_3 compound, but also with polymeric species, such as As_2Se_3[25] or As_2Te_3.[26] While these results are compatible with the view that the disruptive attack of the chalcogenide by the metal–ligand system involves a redox process, they point to the efficiency of the (triphos)Co system in directing the course of the reaction toward the formation of compounds with suitable electron counts, irrespective of the structure of the chalcogenide used as a reactant.

MIXED ALKYL ISOCYANIDE–1,4-DIAZA-1,3-BUTADIENE COMPLEXES OF CHROMIUM: A SERIES OF 17-, 18- AND 19-ELECTRON SPECIES OF THE TYPE $[Cr(CO)_3(CNR)(R'\text{-DAB})]^{1+,0,1-}$

ANDREW BELL and RICHARD A. WALTON*

Department of Chemistry, Purdue University, West Lafayette, IN 47907, U.S.A.

(*Received* 16 *August* 1985; *accepted* 30 *September* 1985)

Abstract—The chromium(0) complexes $Cr(CO)_3(CNR)(R'\text{-DAB})$ (R = Me, $CHMe_2$, CMe_3 or xylyl; R′ = *i*-Pr, *t*-Bu, Cy or *p*-tol) can be prepared by the reaction of $Cr(CO)_3(NCMe)_3$ with equimolar quantities of R′-DAB and RNC. These complexes are oxidized to the paramagnetic 17-electron salts $[Cr(CO)_3(CNR)(R'\text{-DAB})]PF_6$ by $[(\eta^5\text{-}C_5H_5)_2Fe]PF_6$ in ethanol, and can be reduced to the paramagnetic 19-electron radical anions $[Cr(CO)_3(CNR)(R'\text{-DAB})]^-$ using Na–Hg in tetrahydrofuran. The spectroscopic (IR, ^1H NMR, electronic absorption and ESR) and electrochemical properties of the $[Cr(CO)_3(CNR)(R'\text{-DAB})]^{1+,0,1-}$ species (where appropriate) have been recorded. The dark red monocationic species $[Cr(CO)_3(CNR)(R'\text{-DAB})]PF_6$ are subject to disproportionation in solution to give separable mixtures of dark blue $Cr(CO)_3(CNR)(R'\text{-DAB})$ and green $[Cr(CNR)_4(R'\text{-DAB})](PF_6)_2$.

Our discovery of the pairs of six- and seven-coordinate homoleptic chromium(II) isocyanide complexes $[Cr(CNR)_6]^{2+}$ and $[Cr(CNR)_7]^{2+}$ (R = alkyl),[1–3] and subsequent studies of their redox behavior[1,2] and substitution chemistry with nitric oxide[4] and phosphine ligands,[2] have in turn led us to explore other strategies for the synthesis of complexes that contain Cr—CNR bonds. At the outset, our objective had been to prepare mixed isocyanide–1,4-diaza-1,3-butadiene complexes of chromium of the type $[Cr(CNR)_5(R'\text{-DAB})](PF_6)_2$,† in order to compare their chemistry to the molybdenum(II) analogues $[Mo(CNR)_5(R'\text{-DAB})](PF_6)_2$ (R = *i*-Pr or *t*-Bu, R′ = *i*-Pr or C_6H_{11}).[5] While we have not yet been able to prepare these seven-coordinate chromium(II) species and, indeed, have evidence that they might not be stable, we have isolated the chromium(0) complexes $Cr(CO)_3(CNR)(R'\text{-DAB})$. An examination of their redox properties shows that the sets of 17-, 18- and 19-electron species $[Cr(CO)_3(CNR)(R'\text{-DAB})]^{1+,0,1-}$ can be isolated. Details of their chemistry are reported herein.

EXPERIMENTAL

Starting materials

The isocyanides RNC (R = Me, $CHMe_2$ or CMe_3)[6,7] and the 1,4-diaza-1,3-butadiene ligands R′-DAB[8,9] were prepared by standard literature procedures. Ferrocene (Strem Chemicals Inc.) and $Cr(CO)_6$ (Pressure Chemical Co.) were obtained from commercial sources, as were all reagents and solvents. CH_2Cl_2, acetonitrile and tetrahydrofuran (THF) were distilled under N_2 from P_2O_5, CaH_2 and sodium benzophenone ketyl, respectively, before use.

Samples of the oxidizing agent ferricinium hexafluorophosphate ($[(\eta^5\text{-}C_5H_5)_2Fe]PF_6$) were prepared as described in the literature.[10] Chromium hexacarbonyl was converted into the air-sensitive acetonitrile complex $Cr(CO)_3(NCMe)_3$ by heating small quantities of $Cr(CO)_6$ (~10 mmol) with a large excess of acetonitrile (50–75 cm^3).[11] The reaction mixture was cooled and the excess solvent removed at 25°C under reduced pressure. For convenience in handling, this nitrile complex was usually generated *in*

* Author to whom correspondence should be addressed.

† R′-DAB is the abbreviation used for the group of 1,4-diaza-1,3-butadienes of general formula

$$R'N{=}CH{-}CH{=}NR',$$

where R′ = *i*-Pr, *t*-Bu, Cy or *p*-tol.

situ and then reacted further with the R'-DAB and RNC ligands.

Reactions procedures

All reactions were carried out under a dry nitrogen atmosphere, and all reaction solvents were dried and deoxygenated prior to use by purging with N_2 gas for 15 min. In those cases where compounds were prepared by very similar procedures (see Sections A–E), details of representative recipes only will be given. In those instances where microanalytical data are not given, identification of products is based upon their spectroscopic and electrochemical properties.

A. Preparation of $Cr(CO)_3(CNR)(R'\text{-DAB})$ (R = Me, $CHMe_2$, CMe_3 or xylyl; R' = *i*-Pr, *t*-Bu, Cy or *p*-tol). (i) $Cr(CO)_3(CNMe)$(*t*-Bu-DAB). The metal hexacarbonyl, $Cr(CO)_6$ (5.0 g, 22.7 mmol), was heated at reflux for 6 days in 100 cm^3 of freshly distilled acetonitrile. After this time, the murky yellow solution was cooled to ambient temperature. The solution of $Cr(CO)_3(NCMe)_3$, so generated, was treated with *tert*-butyl-DAB (3.82 g, 22.7 mmol) whereupon the reaction mixture quickly changed color to an intense royal blue. The solution was stirred for approximately 11 h. The addition of an equivalent of CH_3NC (1.27 cm^3, 22.7 mmol) at this time turned the mixture a darker blue. After stirring the resulting mixture for a further 15 min, it was filtered to remove a crop of purple-blue crystals. The filtrate was reduced in volume and petroleum ether was added to precipitate a further quantity of purple crystals. The combined crops of crystals was recrystallized from CH_2Cl_2–hexane and acetone–diethyl ether: yield 7.13 g (91%). Found: C, 51.4; H, 6.9; N, 11.9%. Calc. for $C_{15}H_{23}CrN_3O_3$: C, 52.2; H, 6.7; N, 12.2%.

(ii) $Cr(CO)_3(CNCHMe_2)$(*i*-Pr-DAB). Purple-blue crystals of this compound were isolated in 75% yield by an analogous procedure to that described in Section A(i). This complex was identified by its spectroscopic and electrochemical properties which were fully in accord with this formulation.

(iii) $Cr(CO)_3(CNCMe_3)$(*i*-Pr-DAB)·$0.5(CH_3)_2CO$. Yield 88%. Found: C, 54.1; H, 7.6% Calc. for $C_{17.5}H_{28}CrN_3O_{3.5}$: C, 54.1; H, 7.2%. The presence of one half of a mole of acetone as a solvent of crystallization was confirmed by ^1H NMR spectroscopy.

(iv) $Cr(CO)_3(CNCMe_3)$(*t*-Bu-DAB). Yield 81%. Found: C, 56.6; H, 8.2%. Calc. for $C_{18}H_{29}CrN_3O_3$: C, 55.8; H, 7.5%. An alternative method for preparing this compound involved the reaction of $Cr(CO)_4$(*t*-Bu-DAB)[12] with slightly more than one equivalent of *tert*-butyl isocyanide in refluxing toluene for 1 h: yield 32%. This product was identified on the basis of its spectroscopic and electrochemical properties.

(v) $Cr(CO)_3(CNCMe_3)$(Cy-DAB)·H_2O. Yield 90%. Found: C, 57.7; H, 7.6; N, 9.1%. Calc. for $C_{22}H_{35}CrN_3O_4$: C, 57.7; H, 7.6; N, 9.2%. The presence of a molecule of water of crystallization was established by ^1H NMR spectroscopy.

(vi) $Cr(CO)_3$(CNxylyl)(*i*-Pr-DAB). Yield 88%. Found: C, 58.8; H, 6.1%. Calc. for $C_{20}H_{25}CrN_3O_3$: C, 59.0; H, 6.1%.

(vii) $Cr(CO)_3(CNCMe_3)$(*p*-tol-DAB). Yield 54%. This complex was identified on the basis of its spectroscopic properties.

B. Oxidations of $Cr(CO)_3(CNR)(R'\text{-DAB})$. (i) $[Cr(CO)_3(CNCMe_3)$(*t*-Bu-DAB)$]PF_6$. The complex $Cr(CO)_3(CNCMe_3)$(*t*-Bu-DAB) (1.0 g, 2.58 mmol) was dissolved in 10 cm^3 of dry ethanol and a quantity of $[(\eta^5\text{-}C_5H_5)_2Fe]PF_6$ (0.855 g, 2.58 mmol) was added to the solution which was stirred at ambient temperature for 20 min. After this time, the initial blue solutions had turned dark red in color, and the dark red crystals which precipitated were collected by filtration, washed with ethanol and diethyl ether, and dried *in vacuo*: yield 1.17 g (85%). The compound may be recrystallized from acetone–ethanol or CH_2Cl_2–diethyl ether mixtures. Found: C, 41.5; H, 6.0%. Calc. for $C_{18}H_{29}CrF_6N_3O_3P$: C, 40.6; H, 5.4%.

The red crystals are very stable with respect to air oxidation and hydrolysis, but solutions of the product disproportionate at temperatures above −10°C to yield the chromium(0) and chromium(II) species,

$$Cr(CO)_3(CNCMe_3)(t\text{-Bu-DAB})$$

and

$$[Cr(CNCMe_3)_4(t\text{-Bu-DAB})](PF_6)_2,$$

respectively [see Section C(i)].

(ii) $[Cr(CO)_3$(CNMe)(*t*-Bu-DAB)$]PF_6$. Yield 85%. Found: C, 36.4; H, 4.7; N, 8.4%. Calc. for $C_{15}H_{23}N_3CrF_6O_3P$: C, 36.7; H, 4.8; N, 8.6%.

(iii) $[Cr(CO)_3$(CNxylyl)(*i*-Pr-DAB)$]PF_6$ Yield 90%. Found: C, 44.3; H, 5.4%. Calc. for $C_{20}H_{25}CrF_6N_3O_3P$: C, 43.5; H, 5.4%.

(iv) $[Cr(CO)_3(CNCHMe_2)$(*i*-Pr-DAB)$]PF_6$. Yield 57%.

(v) $[Cr(CO)_3(CNCMe_3)$(*i*-Pr-DAB)$]PF_6$. Yield 74%.

C. Disproportionation reactions of $[Cr(CO)_3(CNR)(R'\text{-DAB})]PF_6$. (i) *Thermal disproportionation of* $[Cr(CO)_3(CNCMe_3)$(*t*-Bu-DAB)$]PF_6$. A solution of $[Cr(CO)_3(CNCMe_3)$(*t*-Bu-DAB)$]PF_6$ (0.52 g, 0.97 mmol) in 20 cm^3 of freshly distilled CH_2Cl_2 was stirred at ambient temperature for 24 h. By the end of

this period, the original dark red solution had turned a blue-green in color. The addition of 40 cm^3 of diethyl ether to the reaction mixture precipitated a kelly green solid which was separated from the royal blue solution by filtration, washed with diethyl ether, and vacuum dried. The product, $[Cr(CNCMe_3)_4(t\text{-Bu-DAB})](PF_6)_2$, was recrystallized from CH_2Cl_2–diethyl ether mixtures: yield 0.13 g (16%). Found: C, 42.4; H, 6.4%. Calc. for $C_{30}H_{56}CrF_{12}N_6P_2$: C, 42.7; H, 6.6%. The dark blue filtrate was evaporated to dryness under reduced pressure to yield a blue-purple microcrystalline solid (0.11 g, 20%). This was identified as $Cr(CO)_3(CNCMe_3)(t\text{-Bu-DAB})$ on the basis of its spectroscopic and electrochemical properties [see Section A(iv)].

(ii) *Reaction of* $[Cr(CO)_3(CNCMe_3)(t\text{-Bu-DAB})]PF_6$ *with tert-butyl isocyanide.* A mixture of $[Cr(CO)_3(CNCMe_3)(t\text{-Bu-DAB})]PF_6$ (0.44 g, 0.83 mmol) and six equivalents of *tert*-butyl isocyanide (0.525 cm^3, 4.97 mmol) in 20 cm^3 of CH_2Cl_2 was stirred at room temperature for 24 h. The complexes $[Cr(CNCMe_3)_4(t\text{-Bu-DAB})](PF_6)_2$ (0.29 g, 51%) and $Cr(CO)_3(CNCMe_3)(t\text{-Bu-DAB})$ (0.13 g, 49%) were isolated by using a procedure similar to that described in Section C(i). The spectroscopic and electrochemical properties of these products confirmed their identities.

(iii) *Reaction of* $[Cr(CO)_3(CNCMe_3)(i\text{-Pr-DAB})]PF_6$ *with tert-butyl isocyanide.* The complex, $[Cr(CNCMe_3)_4(i\text{-Pr-DAB})](PF_6)_2$, was prepared in 50% yield using a procedure analogous to that described in Section C(ii). A comparable quantity of the blue-purple complex $Cr(CO)_3(CNCMe_3)(i\text{-Pr-DAB})$ was also isolated. Both complexes were identified on the basis of their spectroscopic and electrochemical properties.

D. Attempted conversion of $[Cr(CNCMe_3)_4(t\text{-Bu-DAB})](PF_6)_2$ *to* $[Cr(CNCMe_3)_5(t\text{-Bu-DAB})](PF_6)_2$. A quantity of the six-coordinate complex $[Cr(CNCMe_3)_4(t\text{-Bu-DAB})](PF_6)_2$ (0.2 g, 0.24 mmol) was placed in a test tube and to it was added sufficient *tert*-butyl isocyanide (~1 cm^3) to form a slurry. This mixture was stirred rapidly at room temperature for 1 h. After this time, the green solid was filtered off and washed with diethyl ether. The green powder so obtained was shown by cyclic voltammetry and its spectroscopic properties to be unreacted starting material.

E. Generation of the reduced complex $Na[Cr(CO)_3(CNCMe_3)(i\text{-Pr-DAB})]$. The title complex, and other chromium-containing radical anions of this type, were generated by the following general procedure. Typically, a solution of $Cr(CO)_3(CNCMe_3)(i\text{-Pr-DAB})$ (0.05 g, 0.14 mmol) in 4 cm^3 of freshly distilled THF was syringed into a flask containing a 1% Na–Hg amalgam (prepared by adding 0.1 g of sodium metal to 10 g of elemental mercury). The reaction mixture was stirred at room temperature for 15 min, after which time the mixture was set aside. The pale yellow supernatant reaction solution which contained the monoanion was carefully transferred (via a syringe) to a nitrogen-flushed EPR tube. Solutions of the paramagnetic complexes were found to be stable for at least several days at room temperature under anerobic conditions.

Physical measurements

IR spectra were recorded as Nujol mulls between KBr plates or as dichloromethane solutions using an IBM Instruments IR/32 Fourier transform (4800–400 cm^{-1}) spectrometer. Electronic absorption spectra were recorded on an IBM Instruments 9420 UV–Visible spectrophotometer. ^1H NMR spectra were recorded at 90 MHz on a Perkin–Elmer R-32 spectrometer. The residual protons of acetone-d_6 ($\delta = 2.05$ ppm vs TMS) were used as reference. Electrochemical measurements were made in CH_2Cl_2 solvent that contained 0.2 M tetra-*n*-butyl ammonium hexafluorophosphate (TBAH) as supporting electrolyte. $E_{1/2}$ values were determined as $(E_{p,a}+E_{p,c})/2$ and are referenced to the Ag–AgCl electrode at room temperature. Voltammetric experiments were performed using a Bioanalytical Systems, Inc., Model CV-1A instrument in conjunction with a Hewlett–Packard Model 7035B x–y recorder. X-band ESR spectra were recorded using a Varian E-109 spectrometer.

Analytical procedures

Elemental microanalyses were performed by Dr H. D. Lee of the Purdue University microanalytical laboratory.

RESULTS AND DISCUSSION

A simple high-yield one-pot synthesis of the blue-purple chromium(0) complexes $Cr(CO)_3(CNR)(R'\text{-DAB})$ (R = Me, $CHMe_2$, CMe_3 or xylyl; R′ = *i*-Pr, *t*-Bu, Cy or *p*-tol) has been developed involving the sequence of reactions shown in eqn (1):

$$Cr(CO)_6 \xrightarrow{MeCN} Cr(CO)_3(NCMe)_3 \xrightarrow{R'\text{-DAB}} Cr(CO)_3(NCMe)(R'\text{-DAB}) \xrightarrow{RNC} Cr(CO)_3(CNR)(R'\text{-DAB}). \quad (1)$$

The IR spectra of these complexes [ν(CN) and ν(CO)

modes] and electronic absorption spectra [λ_{max} *ca* 610 nm, Cr(*d*) → R′-DAB(π^*) charge-transfer band] (see Table 1) resemble the properties of the related derivatives *fac*-M(CO)$_3$(CNR)(R′-DAB) (M = Mo or W).[13]* ^{1}H NMR spectroscopy confirms the stoichiometry of these complexes based upon integration of the RNC and R′-DAB ligand resonances (Table 1).

The electrochemical properties of these isocyanide complexes, as measured by the cyclic voltammetric technique, are given in Table 2 along with related data for the Cr(CO)$_4$(R′-DAB) complexes measured under the same conditions.† The two sets of complexes display qualitatively similar behavior, which is in turn similar to that exhibited by the molybdenum complexes Mo(CO)$_3$(CNR)(R′-DAB),[13] although for the latter species all potentials are shifted by *ca* +0.2 V relative to Cr(CO)$_3$(CNR)(R′-DAB). In the case of Cr(CO)$_3$(CNR)(R′-DAB), a reversible one-electron process occurs at $E_{1/2} \simeq +0.05$ V vs Ag–AgCl and this has been shown by coulometry to correspond to a one-electron oxidation. For sweep rates of 50 to 400 mV s^{-1} this couple is characterized by $i_{p,a}/i_{p,c} \simeq 1$ and the ratio $i_p/v^{1/2}$ was constant in accord with diffusion control. The potential separation between the anodic and cathodic peaks, ΔE_p, is close to 75 mV for a sweep rate of 200 mV s^{-1} and increases slightly with an increase in scan rate. With our cell configuration these properties are consistent with electron transfer processes which are reversible or approach reversibility.[16]‡ The chemical reversibility of the redox process at *ca* +0.05 V is demonstrated by the ease of preparing the crystalline, dark orange-red, 17-electron compounds [Cr(CO)$_3$(CNR)(R′-DAB)]PF$_6$ using ferricinium hexafluorophosphate as the oxidant. The best solvent for these reactions is ethanol since the PF_6^- salts are rather insoluble in this medium and precipitate quite quickly as the oxidation proceeds. The chromium(I) monocations are very stable in the solid state but solutions of these complexes decompose via a disproportionation reaction (*vide infra*).

The electrochemical properties of these complexes (measured in 0.2 M TBAH–CH_2Cl_2) are similar to those of the parent neutral species except that the process at $E_{1/2}$ *ca* +0.05 V now corresponds to a one-electron reduction of the bulk species. The formation of the monocations leads to a sizeable increase in the energies of the C≡N and C≡O stretching modes (Table 1). The shift of ν(CN) and ν(CO) to higher energies is in accord with the expected decrease in metal-to-ligand π-back bonding as the positive charge at the metal center increases. The X-band ESR spectra of dichloromethane solutions of [Cr(CO)$_3$(CNR)(R′-DAB)]PF$_6$ (recorded at −160°C) give broad signals ($g \sim 2.03$–2.10) which display no resolvable hyperfine structure attributable to interaction with the coordinated nitrogen of the R′-DAB ligands [Table 1 and Fig. 1(a)].

Although the reduction process ($E_{p,c}$ in Table 2) which is observed in the cyclic voltammograms of 0.2

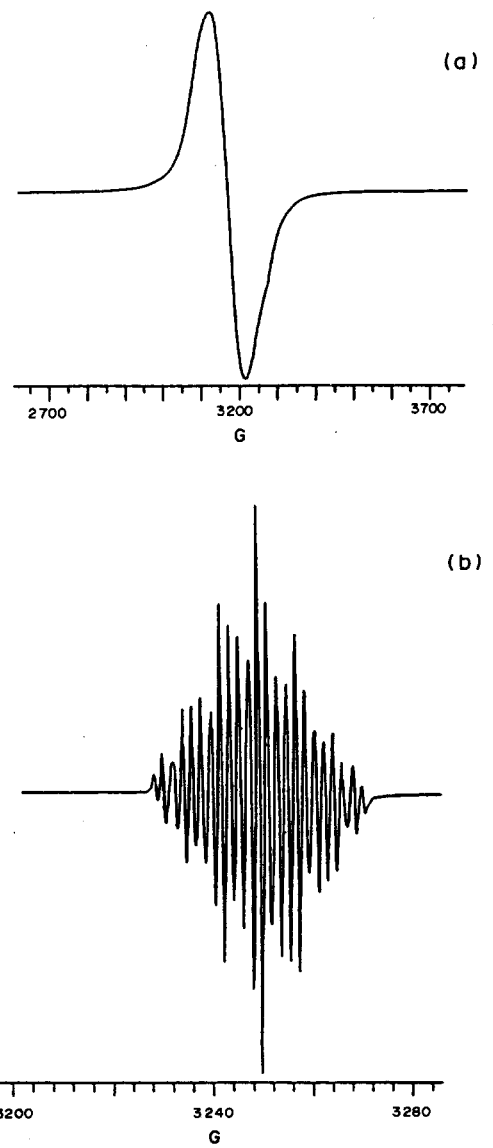

Fig. 1. X-band ESR spectra: (a) [Cr(CO)$_3$(CNCMe$_3$)(*i*-Pr-DAB)]PF$_6$ in CH_2Cl_2 at −160°C and (b) Na[Cr(CO)$_3$(CNCMe$_3$)(*i*-Pr-DAB)] in THF at room temperature.

* The 2,2′-bipyridine (bpy) complexes *fac*-Cr(CO)$_3$(CNR)(bpy) (R = Et or *p*-tol) are also known.[14]

† Our data for the Cr(CO)$_4$(R′-DAB) complexes are in good agreement with results from an earlier study.[15]

‡ Under these same experimental conditions we find that the ferricinium–ferrocene couple has an $E_{1/2}$ value of +0.47 V vs Ag–AgCl.

$Cr(CO)_3$(CNxylyl)(*i*-Pr-DAB)	+1.11	+0.08	−1.77

[a] Potentials are in V vs Ag–AgCl with a Pt-bead electrode. Data recorded at a scan rate of 200 mV s^{-1}.

M TBAH–CH_2Cl_2 solutions of $Cr(CO)_3(CNR)(R'\text{-DAB})$ is irreversible electrochemically, THF solutions that contain the 19-electron radical anions can be generated using sodium amalgam as the reducing agent. The resulting paramagnetic complexes have been characterized by X-band ESR spectroscopy and a typical spectrum is shown in Fig. 1(b). The data distinguish these systems from the previously characterized ligand radicals although the ESR parameters indicate that the unpaired electron is centered mainly on the R'-DAB ligand π-system. In the specific case of the chromium complex $[Cr(CO)_3(CNCMe_3)(i\text{-Pr-DAB})]^-$ [Fig. 1(b)], for which $g = 1.9991$, the hyperfine coupling arises from the interactions with two ^{14}N nuclei ($A_N = 7.05$ G), two protons (C—H; $A_H = 3.60$ G), two *iso*-propyl protons ($CHCMe_2$; $A_{H'} = 1.80$ G) and a single chromium nucleus (^{53}Cr, 9.5%, $I = 3/2$, $A_{Cr} = 3.8$ G).

The dark red monocationic species $[Cr(CO)_3(CNR)(R'\text{-DAB})]PF_6$ (R' = *i*-Pr or *t*-Bu) are unstable in solution and decompose above −10°C to give a mixture of the dark blue chromium(0) complex $Cr(CO)_3(CNR)(R'\text{-DAB})$ and the kelly green chromium(II) complex $[Cr(CNR)_4(R'\text{-DAB})](PF_6)_2$ (*vide infra*). This particular reaction requires that a significant proportion of the chromium complex be "sacrificed" in order to provide the requisite number of RNC ligands to form stable $[Cr(CNR)_4(R'\text{-DAB})](PF_6)_2$. In accord with this, we find that the yields of the isolated chromium(0) and chromium(II) species is no more than *ca* 20% each. However, when an excess of free RNC (six equivalents) is added to the initial solution an essentially quantitative conversion to an equimolar mixture of $Cr(CO)_3(CNR)(R'\text{-DAB})$ and $[Cr(CNR)_4(R'\text{-DAB})](PF_6)_2$ ensues. This disproportionation reaction, which is represented in eqn (2):

$$2[Cr(CO)_3(CNR)(R'\text{-DAB})]PF_6 + 3RNC \rightarrow Cr(CO)_3(CNR)(R'\text{-DAB}) + [Cr(CNR)_4(R'\text{-DAB})](PF_6)_2 + 3CO, \quad (2)$$

was studied in the case of R = CMe_3 and R' = *i*-Pr or *t*-Bu.

The properties of the chromium(II) complexes $[Cr(CNCMe_3)_4(R'\text{-DAB})](PF_6)_2$ (R' = *i*-Pr or *t*-Bu), as prepared in the aforementioned fashion, accord with those of complexes of this type that have been prepared by the reaction of R'-DAB ligands with $[Cr(CNR)_6](PF_6)_2$ in CH_2Cl_2.*† The appropriate data are presented in Table 3, and closely resemble the properties exhibited by other complexes of the type $[Cr(CNR)_4L_2](PF_6)_2$ as has been described elsewhere.[2] As an aside, we note that when the reactions between $[Cr(CNR)_6](PF_6)_2$ (R = CMe_3 or C_6H_{11}) and 2,2'-bipyridine (bpy) were carried out in dichloromethane solution at room temperature (stoichiometric ratios of 1 : 1–1 : 4), they led in all instances to the generation of the tris-bpy

* For further details of the preparation of $[Cr(CNR)_4(R'\text{-DAB})](PF_6)_2$ by this route see A. Bell, Ph.D. Thesis, Purdue University (1985).

† The IR spectra of the mixed ligand complexes $[Cr(CNR)_4(R'\text{-DAB})](PF_6)_2$ exhibit two ν(CN) modes, an observation which is in accord with their possessing a *cis* geometry. The electrochemical properties of the six-coordinate complexes were investigated by the cyclic voltammetric technique. In all instances, the complexes exhibit a one-electron oxidation at *ca* +0.7 V and two one-electron reductions at *ca* −0.5 and *ca* −1.3 V. These data are consistent with values obtained for the species $[Cr(CNR)_6]^{2+}$, $[Cr(CNR)_4(PR_3)_2]^{2+}$ and $[Cr(CNR)_4(dppe)]^{2+}$.[2]

(*Received* 20 *August* 1985; *accepted* 4 *October* 1985)

Abstract—^{119}Sn NMR and Mössbauer spectroscopic data have been recorded for 12 compounds of formula $Ph_3SnO_2CC_6H_4X$ (X = H, Me-2, NH_2-2, NMe_2-2, Cl-2, Cl-3, Cl-4, OH-2, OH-4, SMe-4 or OMe-2) and $Ph_3SnO_2CC_{10}H_7$-1. On the basis of these measurements all the compounds are assigned a coordination number of four at tin in solution, and, with the exception of the Cl-2 and OH-2 derivatives, retain this structure in the solid. Both of these latter compounds exhibit enhanced Mössbauer quadrupole splittings (3.71 and 2.97 mm s^{-1}), which are attributed to carboxylate- and hydroxyl-bridged structures, respectively. The variable-temperature Mössbauer spectra of two compounds (X = OMe-2 or OH-2) are discussed.

In recent years, triphenyltin compounds (Ph_3SnX) have achieved commercialization as toxicants in marine anti-fouling paints.[1–3] Fouling arises from the settlement, attachment and growth of marine animals and plants on submerged structures, and in general, plants are more resistant to this class of organotin biocide than other fouling species.[4–6] As part of an investigation intended to overcome this drawback and hence widen the spectrum of biocidal activity, we have synthesized a series of triphenyltin arylcarboxylates for raft testing.[7] In this report we consider the spectroscopic evidence for the structures of these compounds, determined in the solid state primarily by ^{119}Sn Mössbauer spectroscopy, in non-aqueous solutions by ^{119}Sn NMR, and linked by IR data in both phases.

Triorganotin derivatives of ring-substituted benzoic acids are rich with structural possibilities, centred around the triad of structures **I–III**. In addition to a tetrahedral geometry at tin arising from a monodentate carboxylate ligand, a bidentate ligand can either chelate (**II**) or bridge (**III**) tin atoms to result in variations on a trigonal bipyramidal geometry at the metal. In instances where the ring

* Author to whom correspondence should be addressed.

substituent is non-passive in a coordination sense due to the presence of lone electron pairs or hydrogen bonding possibilities (e.g. X = OCH_3, NH_2 etc.), coordination between X and tin can occur at the expense of (IV), or in addition to (V), the bond from the acyl oxygen. In the solid state available examples are dominated by III,[8] with only one crystallographically authenticated claim being made for structure I, namely tricyclohexylstannyl 3-indolylacetate,[9] while data for $Ph_3SnO_2CC_6H_4X$ (X = NH_2-2, NH_2-4, NMe_2-2, OH-2, OMe-2 or SMe-4) have all been interpreted in terms of the five-coordinate structure II.[10,11] Distinctions between these architectures are important, since chelated structures, e.g. II, have been shown in some cases to lead to a significant decrease in biocidal activity.[12] Moreover, conflicting structural data have recently appeared in the literature relating to these systems,[10,11,13–15] which we now assess in the light of our own studies.

EXPERIMENTAL

Spectroscopic studies

^{119}Sn NMR spectra were recorded under nuclear Overhauser suppressed conditions, in 10-mm tubes on a JEOL FX60Q spectrometer, with field frequency lock to external D_2O. ^{119}Sn chemical shifts (δ ^{119}Sn) are relative to Me_4Sn and are accurate to ± 0.1 ppm.

IR spectra were recorded in the region 4000–200 cm^{-1} on a Perkin–Elmer 1330 spectrometer, either in CCl_4 or toluene solutions [0.2 g (3.0 cm)$^{-3}$], or as KBr discs.

^{119}Sn Mössbauer spectra were obtained using a constant acceleration, microprocessor controlled spectrometer (Cryophysics Ltd, Oxford, U.K.), with a 512 channel data store. A barium stannate source was used at room temperature and samples were packed in perspex discs and cooled to 80 K using a liquid nitrogen cryostat. Isomer shift data are relative to SnO_2 as reference; spectral data obtained at both collaborating institutions were identical within experimental error. Details of the variable-temperature experiment, including the method of data acquisition and manipulation are described elsewhere.[8] Samples containing 1 mg ^{119}Sn cm^{-2} were used to minimize saturation effects and to comply as fully as possible with the criteria of a "thin sample", while maintaining the viability of the experiment, i.e. good-quality spectra accumulated in

ca 12 h. For temperatures above 110 K, samples containing 1.5 mg ^{119}Sn cm^{-2} were required to maintain this condition. However, data from the two parts of each experiment coalesced into a single line which exhibited no systematic curvature, suggesting that vibrational anharmonicity within the lattice is also absent.

Synthesis

Compounds **2**, **3**, **8**, **11** and **13** (Table 1) were prepared by an azeotropic dehydration reaction between stoichiometric amounts of triphenyltin hydroxide and either the appropriate arylcarboxylic acid or 1,3-diphenylpropane-1,3-dione, in refluxing toluene and using a Dean and Stark trap. Reflux times were typically 2 h. The remaining compounds in Table 1 were prepared by refluxing together reagents using acetone as the reaction solvent. Recrystallization solvents, m.ps and analytical data for all the compounds studied are given in Table 1.

DISCUSSION

Solution-state structure

^{119}Sn NMR data for a range of triphenylstannyl esters of substituted benzoic acids (**1–12**) are given in Table 2. The data are measured in non-coordinating solvents, and show no concentration dependence for the chemical shift. This shift is a sensitive indicator of coordination number at tin, shifts moving to low frequency with increasing number of bonds to the metal. The relevant reference data for this discussion are $(Ph_3Sn)_2O$ (−83.6 ppm) and

$Ph_3SnOC(Ph)CHCO(Ph)$ (−221.2 ppm)

which are unambiguously four-[16] and five-coordinate (**II**),[17] respectively, in the solid state and it is unlikely in either case that this situation will alter upon dissolution. The chemical shifts for **1–12** lie in the range −96.2 to −124.5 ppm and can confidently be assigned to a four-coordinate metal atom (**I**). Our data corroborate previous work, which has associated a chemical-shift range of −40 to −120 ppm for Ph_3SnX compounds of coordination number four.[13,14]

These structural inferences can be extrapolated to the solid state, by consideration of $\nu_{asym}(C{=}O)$, as measured in KBr discs or CCl_4 solutions (Table 2). Assignment of these bands cannot however be made with total confidence due to the presence of absorptions associated with stretching vibrations of the benzene ring, which occur in the same region of the spectrum. For **1–11**, the data are essentially independent of phase, and hence imply that the carboxylate moiety is unidentate in the solid state

Table 2. ^{119}Sn NMR (ppm)[a] and IR (cm^{-1})[b] spectroscopic data for Ph_3SnX

			$\nu_{asym}(C{=}O)$

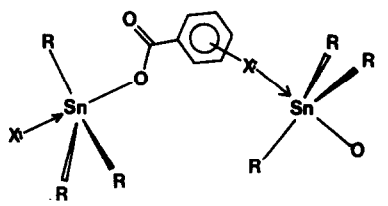
[e] The previously reported value of −82.2 ppm (S. J. Blunden and P. J. Smith, *J. Organomet. Chem.* 1982, **226**, 157) is incorrect and is believed to have been due to either Ph_3SnOH or $(Ph_3Sn)_2O$.

also. This rules out **II**, **III** and **V** as viable structures in this latter phase, and calls into question the interpretation of the X-ray crystallographic data for $Ph_3SnO_2CC_6H_4X$ (X = NH_2-2, NMe_2-2, OH-2, OMe-2 or SMe-4)[10,11] which the authors discuss in terms of a five-coordinate structure (**II**). Structures involving additional coordination via X: → Sn cannot be entirely eliminated. Structures of type **IV** can be discounted since chelation should persist in solution, but an alternative five-coordinate species incorporating intermolecular X: → Sn coordination (**VI**) is still possible.



In contrast, IR data for the Cl-2 derivative (**12**) varies markedly between solution and the solid state, and follows the established pattern for a carboxylate-bridged structure (**III**) in the solid, with breaking of the intermolecular bond upon dissolution. The ^{119}Sn NMR data under the conditions of dilution employed in the study indicate that the tin is, as expected from the IR data, four-coordinate in solution (δ ^{119}Sn −106.3 ppm). In principle, the ^{119}Sn chemical shift of compounds with this structure should show a concentration dependence, with shifts moving to low frequency (more negative values) as concentration (and hence the degree of association) increases. This was not observed in this study, and at the concentration levels used [0.2–0.8 g 3.0 cm)$^{-3}$] the variation in shift was negligible (−106.3 to −107.1 ppm). We conclude that at these concentrations complete dissociation of the polymer into discrete molecules had always occurred.

Solid-state structure

Indirect evidence for the solid-state structure of organotin compounds can be derived from Mössbauer spectroscopy. In this context, the most useful parameter is the quadrupole splitting (QS), for which parameter a given range is associated with a particular coordination number and geometry at tin: 1.00–2.40 mm s^{-1} (**I**), 1.70–2.40 mm s^{-1} (**II**) and 3.00–4.00 mm s^{-1} (**III**).[18] From the foregoing discussion of ^{119}Sn NMR and IR data, two structures are possible for **1**–**11** in the solid state, namely **I** and **VI**. While this latter variation could give rise to a *cis*-$OXSnR_3$ geometry (**VIa**), intermolecular bonding invariably results in the

(VIa)

(VI b)

trans-$OXSnR_3$ structure (**VIb**)[19,20] and should show Mössbauer parameters similar to structure **III**, i.e. QS ~ 3.00–4.00 mm s^{-1}. Mössbauer data for the triphenyltin carboxylates studied are given in Table 3. Compounds **1**–**5** and **7**–**10** all have QS in the range 2.30–2.55 mm s^{-1}, and of the two alternative structures indicated are only consistent with **I**. However, it should be noted that these QS data could also be interpreted in terms of chelated structures **II** and **IV**, *and only with the help of ancillary spectroscopic data (IR and ^{119}Sn NMR) can a valid distinction between these alternatives be made.* Indeed, QS data for five-coordinated **13** (2.25 mm s^{-1}) overlap with the above, and cannot be differentiated on the basis of Mössbauer data alone.

QS data for **6** (2.97 mm s^{-1}) and **12** (3.71 mm s^{-1}) must be considered separately from those above. The solid-state structure for **6** reveals an intramolecular C=O···Sn separation of 3.071(2) Å, and an intermolecular HO···Sn interaction at 3.035(2) Å.[11] Since intermolecular interactions such as the latter will be absent in dilute solutions, ^{119}Sn NMR data indicate that the C=O···Sn intramolecular distance of 3.071(2) Å is fortuitous, and does not represent a bonding interaction (*vide supra*). The enhanced QS value in the solid state relative to other four-coordinated analogues can thus be attributed to the intermolecular HO···Sn bond, which results in coordination expansion at tin to five, and formation of a *trans*-O_2SnR_3 geometry (**VIb**). A parallel bonding situation is evident in the two analogous arylazobenzoates (**16** and **17**).[21] The structure of **16** shows (at best) weak intramolecular C=O···Sn coordination to produce a type **II** structure (QS = 2.36 mm s^{-1}) in which the 2-OH group is involved in intramolecular hydrogen bonding. Intramolecular bonding of this latter type is precluded on steric grounds in the 4-OH derivative (**17**) (QS = 3.06 mm s^{-1}) and thus the hydroxyl group in all likelihood assumes an intermolecular, bridging role akin to **6**.

The 2-chloro derivative (**12**), whose ^{119}Sn NMR and IR data collectively point toward a carboxylate-bridged structure (**III**), shows the highest QS recorded in this study (3.71 mm s^{-1}), and is totally consistent with such a *trans*-O_2SnR_3 environment

Table 3. ^{119}Sn Mössbauer data for Ph_3SnX

	X	IS[a]	QS[a]	Γ_1[b]	Γ_2[b]

[c] Reference 21.

about tin in the solid. From the relative magnitudes of the QS for **6** and **12**, we also conclude that the intermolecular C=O···Sn bond is shorter than 3.0 Å.

Finally, we have attempted to distinguish coordination polymers such as **6** from discrete monomers, e.g. **8**, using variable-temperature ^{119}Sn Mössbauer spectroscopy. Data recorded over the temperature (T) range 78–145 K for compounds **6** and **8** are shown in Fig. 1. We have previously correlated the lattice structure of phenyltin compounds with the temperature coefficient of the natural logarithm of the recoil-free-fraction (a):

$$a = -\frac{\mathrm{d}[\ln f(T)]}{\mathrm{d}T} = -\frac{\mathrm{d}[\ln A(T)]}{\mathrm{d}T},$$

$$a = -\frac{\mathrm{d}[-6E_R T/k\theta M^2]}{\mathrm{d}T},$$

where A is the area under the Mössbauer resonance, E_R the Mössbauer recoil energy and θ_M a characteristic temperature for the lattice, equivalent to the Debye temperature.[22] Under these systematics, in plots of ln A vs T the shallowest slopes are exhibited by linear or zig-zag polymers (10^2a = 0.9–1.5 K^{-1}) while monomeric lattices have 10^2a in excess of 1.20 K^{-1}, except in cases of extremely efficient packing where a more rigid lattice, akin to that of a polymer, results.[23] On the other hand, flexible polymers of an "S" or helical construction afford the tin a vibrational freedom enjoyed in non-associated lattices and steeper slopes ($10^2a \sim 1.70$ K^{-1}) are observed in ln A vs T plots.

The values of 10^2a for compounds **6** (1.36 K^{-1}) and **8** (1.46 K^{-1}) are very similar and consistent with discrete molecules within the lattice. Furthermore, this similarity in behaviour is also in accord with an approximately equal effective vibrating mass for the two cases, in consonance with the near equality in their molecular weights. Comparison can be drawn with Ph_4Sn (10^2a = 1.37 K^{-1})[22] and a series of chelated triphenyltin carboxylates, $Ph_3SnO_2CC_6H_4(N_2R$-$o)$ (10^2a = 1.53–1.71 K^{-1}).[21]

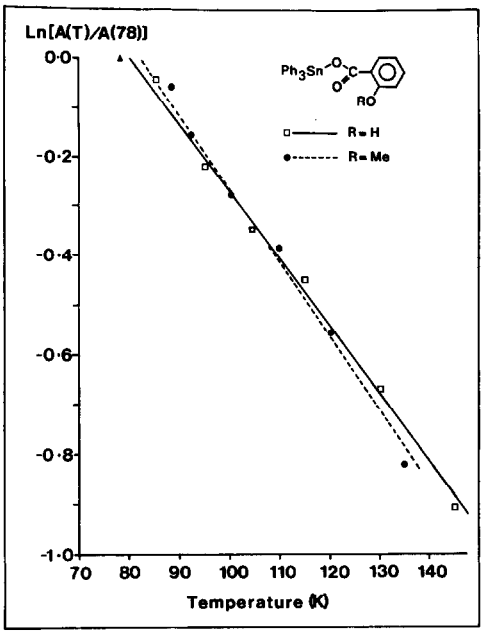

Fig. 1. Plot of $\log_e$ (normalized area) vs temperature for **8** and **6**. The slopes of the lines are 1.46×10^{-2} K^{-1} (r = 0.993, seven points) and 1.36×10^{-2} K^{-1} (r = 0.997, eight points), respectively. The point ▲ (78, 0.00) is common to both plots.

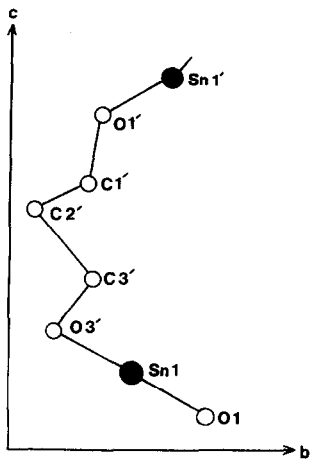

Fig. 2. Polymer propagation in **6**, shown as a projection of part of the cell contents onto the *bc* plane. Only atoms linking metal centres are included for clarity. Data taken from Ref. 11.

In contrast, carboxylate-bridged triorganotins adopt polymers of "stretched-S" construction and are typified by $Ph_3SnO_2CCH_3$ ($10^2a = 1.91\ K^{-1}$).[8]

The variable-temperature Mössbauer experiment is clearly insensitive to the intermolecular Sn···OH interaction in **6**, which weakly associates adjacent molecules. This is, perhaps, not surprising. The Sn···O bond is long (3.035 Å)[11] and hence weak. In addition, and equally importantly, the spatial arrangement of the bridging unit —OC·C_6H_4O— (Fig. 2) lies off the Sn–Sn′ vector, producing a polymer which, like $Ph_3SnO_2CCH_3$, is of flattened helix or "S"-form, and hence plays no role in inhibiting the vibrational motion of the Mössbauer atom. The nature of the Sn···OH interaction in **6** thus manifests itself more clearly in perturbations of the electric field gradient about tin, and hence in the QS, rather than in the lattice dynamics of the metal atom.

CONCLUSIONS

Of the triphenyltin arylcarboxylic acid derivatives studied, most (**1–5** and **7–11**) form four-coordinated structures about tin in both the solid and in solution. Derivatives of 2-OH and 2-Cl benzoic acids are also four-coordinate at tin in dilute solutions, but expand the coordination number to five in the solid, via intermolecular OH···Sn and C=O···Sn linkages, respectively.

These results are in general agreement with other spectroscopic studies on these and related systems[13,14,24] but in the cases of NH_2-2, NMe_2-2, OH-2 and OMe-2 benzoic acid derivatives conflict with the interpretation of X-ray crystallographic data[10,11] in which emphasis is placed upon a weakly bidentate carboxylate group and a five-coordinate geometry about tin. While cases such as these, which are at the interface of two coordination geometries, will always be subjective in their analysis, our work highlights the importance of spectroscopic methods in making these assessments. Moreover, the crystallographic data must be reviewed in terms of both distances and angles about tin *in toto* and not selectively, and our appraisal of the data under these terms reveals a far less clear-cut picture than that presented by the original authors. For example, in the case of $Ph_3SnO_2CC_6H_4NMe_2$-2, while the intramolecular Sn—O bond lengths (2.115 and 2.564 Å) suggest chelation by the carboxylate group, the angular changes are not totally in accord, viz. angles within the "equatorial" plane (which should change from 109°28′ towards 120°) are 122.1, 112.6 and 104.9°, while between the "axial" α-carbon of the phenyl ring and ligating atoms in the "equatorial" girdle about tin (which should change from 109°28′ towards 90°) the angles are 92.9, 108.4, and 114.8°. Many (but in fairness not all!) of these angular variations are simply in accord with the expected rehybridization within a tetrahedral framework, which concentrates *p*-character in the bond to the more electronegative oxygen, hence naturally closing from 109°28′ angles involving oxygen while opening those which only involve carbon. In short, interpretation of this data in terms of a coordination number of five at tin is tenuous, and underlines our recommendations for the need of ancillary spectroscopic data in such circumstances.

We are currently trying to identify those factors which influence the choice of chelated vs bridged structures in systems of this type and will report our findings in a subsequent paper.

O,O-DIALKYL/ALKYLENE DITHIOPHOSPHATE COMPLEXES OF ORGANO-RHODIUM(I)

YASH PAL SINGH and R. C. MEHROTRA*

Chemical Laboratories, University of Rajasthan, Jaipur 302004, India

(*Received* 30 *July* 1985; *accepted* 4 *October* 1985)

Abstract—Reactions of $[(COD)RhCl]_2$ with $MS_2P(OR)_2$ and $H_4NS_2\overline{POGO}$ yield neutral four-coordinate complexes with the general formulae $(COD)Rh[S_2P(OR)_2]$ and $(COD)Rh[S_2\overline{POGO}]$, respectively [where COD = η-cycloocta-1,5-diene; M = Na or NH_4; R = C_2H_5, *i*-C_3H_7 or *n*-C_3H_7; G = $(CH_3)_2C\text{-}C(CH_3)_2$, $CH_2C(CH_3)_2CH_2$ or $(CH_3)CHCH_2C(CH_3)_2$]. These complexes are monomeric in nature and have been characterized by IR, ^1H and ^{31}P NMR spectroscopy, the last technique being specially useful in revealing the bidentate nature of the ligand.

O,O-dialkyl dithiophosphoric acids occupy a unique position amongst the sulphur- and phosphorus-containing ligands due to their various possible (mono- and bidentate, chelating/bridging) modes of bonding.[1–5] In addition, they are receiving extensive potential biocidal,[6] agricultural[7] and industrial applications, (e.g. as pesticides, antioxidants, oil additives and colouring agents for plastics and analytical reagents). Recently, *O,O*-alkylene dithiophosphoric acids and their metal complexes have been reported from these laboratories.[8–11]

An extensive survey of literature revealed that no systematic study of dithiophosphate complexes of organo-platinum metals[12,13] in general and organo-rhodium in particular has been reported. In the present communication, we present the synthesis and characterization of *O,O*-dialkyl/alkylene dithiophosphate derivatives of organo-rhodium(I).

EXPERIMENTAL

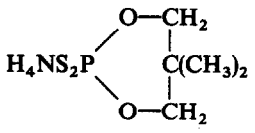
The *O,O*-dialkyl dithiophosphoric acids[14] and *O,O*-alkylene dithiophosphoric acids[8] and their sodium/ammonium salts were prepared by the literature methods. bis[*n*-Cycloocta-1,5-diene rhodium(I) chloride] was prepared by the method of Chatt and Venanzi.[15]

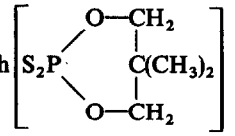
Molecular weights of representative compounds were determined cryoscopically. IR spectra (4000–200 cm^{-1}) were recorded as CsI pallets or Nujol mull. ^1H NMR spectra were recorded in $CDCl_3$ solution using TMS as internal reference. ^{31}P NMR spectra were recorded in benzene–$CDCl_3$ solution using TMP (trimethyl phosphate) as external reference with a JEOL FX-100 spectrometer.

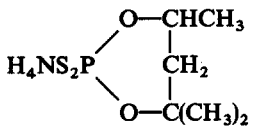
Reaction of bis[η-cycloocta-1,5-diene chloride] with ammonium O,O-diisopropyl dithiophosphate in 1:2 molar ratio

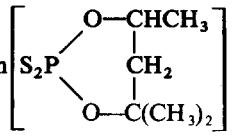
A benzene solution of $[(COD)RhCl]_2$ (0.25 g, 0.51 mmol) was added to the benzene suspension of ammonium salt of *O,O*-diisopropyl dithiophosphoric acid (0.27 g, 1.02 mmol). The reaction mixture was stirred for about 2 h, during which the colour of the solution changed from yellow to wine red. The NH_4Cl was filtered. The excess solvent was distilled from the filtrate. A yellow microcrystalline compound obtained was dried under reduced pressure at the room temperature and recrystallized from benzene–hexane mixture.

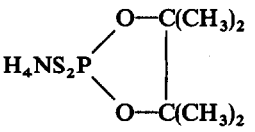
Details of similar syntheses along with analytical data of the products are summarized in Table 1.

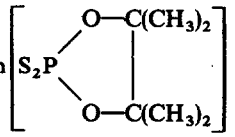


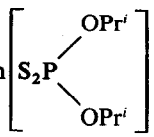


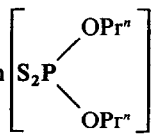


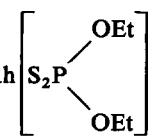












RESULTS AND DISCUSSION

The reactions of cyclooctadiene rhodium chloride dimer with the sodium or ammonium salts of dialkyl/alkylene dithiophosphoric acid were carried out in 1:2 molar ratio in benzene:

$$[(COD)RhCl]_2 + 2MS_2P(OR)_2 \rightarrow 2(COD)Rh[S_2P(OR)_2] + 2MCl, \quad (1)$$

weight determinations of two representative compounds reveal their monomeric nature.

In the IR spectra of these derivatives (Table 2) the bands present in the regions 1000–1050 cm and 800–860 cm^{-1} are assigned to ν(P)—O—C and P—O—(C) vibrations respectively. Two strong bands in the region ~650 and ~540 cm^{-1} which may be assigned to ν(P···S) and ν(P—S) modes, respectively,[16] have also been observed. The bands due to ν(P···S) vibrations show a shift on 20 cm^{-1} as compared to their positions in the spectra of corresponding ligands which is suggestive of their bidentate nature in these complexes. The band present in the region 900–950 cm^{-1} may be due to ring vibrations.[17,18] A sharp band at ~1450 cm^{-1} in the spectra of all these derivatives is due to the cyclooctadiene moiety.[19]

The ^{1}H NMR spectra (Table 3) show the proton resonances characteristic of all the corresponding alkyl/alkylene[8,9] and cyclooctadiene groups.[17] A sharp singlet in the range δ 3.1–3.7 ppm, characteristic of the S—H proton in the free dithiophosphoric acids[8] is absent from the ^{1}H NMR spectra of the organo-rhodium(I) compounds.

^{31}P NMR spectra (proton-decoupled) have been recorded (Table 3) and the high chemical-shift values compared to the parent ligands further confirm the bidentate mode (suggested by their IR spectra) of bonding of these ligand moieties[5] in our rhodium complexes.

On the basis of the evidences discussed so far, the following structure with a four-coordinate rhodium metal atom may be proposed for these dialkyl/alkylene dithiophosphates of organorhodium(I).

COMPLEXES OF HYDROXAMATES—II. MECHANISTIC STUDIES INVOLVED IN THE NICKEL–GLYCINEHYDROXAMATE–PYRIDOXAL SYSTEM

MOHAMED S. EL-EZABY,* HAYAT M. MARAFIE and HUSAM M. ABU-SOUD

Department of Chemistry, Faculty of Science, University of Kuwait, Kuwait

(*Received* 27 *June* 1985; *accepted* 4 *October* 1985)

Abstract—The formation constants of the binary complexes of Ni(II) with glycinehydroxamic acid (GX) were determined by pH-metric titration at 25°C and $I = 0.15$ M NaCl. In addition, the mechanism of complex formation was studied under the same experimental conditions as the equilibrium study using the stopped-flow technique. It has been concluded that Ni^{2+} and $NiOH^{+}$ were the active species in the complex formation reactions. The interaction of GX with pyridoxal (PL) in the absence of metal ions was proved to occur at pH $\geqslant$ 5 by polarographic and spectrophotometric techniques, and was found to be fast enough not to be followed by the stopped-flow technique. The formation constants were also determined by pH-metric titration. However, the reaction of PL with Ni(II)–GX was investigated at pH > 7.0. Ternary-complex formation was proved to exist prior to the possible formation of the Schiff base metal complex. Furthermore, deprotonation of the hydroxamic NH group was found compatible with the proposed reaction mechanism.

Hydroxamic acids exist in nature as trihydroxamic and dihydroxamic acids. They are found to be constituents of antibiotics, growth factors, tumour inhibitors, cell-division factors and pigments. In addition, they also show antituberculous, antifungal and antileukaemic activities.[1–5] Monohydroxamic acids, on the other hand, were used as colorimetric and gravimetric reagents. They have been used recently in attempts to design metal chelates, specially for Fe(III), as suitable oral sources of metals for mammals[6–8] and as a suitable reagent for the treatment of metal-overload and related diseases.[9,10] Glycinehydroxamic acid (GX) (a monohydroxamic acid) forms stable complexes with Ni(II) and Fe(III).[7,11] The complexes of Fe(III) have been proved to react with apotransferrin.[7]

Pyridoxal (PL), a vitamin B_6 compound, forms less stable metal complexes[12,13] than GX. PL and its phosphorylated form are able to undergo trans-amination with amino acids and to serve as catalysts for a variety of other reactions of amino acids in the absence of enzymes.[14] The present work describes the equilibria and reaction kinetics involved in the Ni(II)–GX system. Moreover, the interaction of pyridoxal with GX in the presence and absence of Ni(II) was also investigated.

EXPERIMENTAL

Materials

PL hydrochloride (PL · HCl) (Merck, >99%) and GX (Sigma, >98%) were analytically pure and were used without purification. Stock solutions of PL and GX were 0.10 and 0.05 M, respectively. The GX solution was also ~0.05 M in HCl. They were kept in the dark at 4°C. A stock solution of $NiCl_2$ (~0.1 M) was prepared. The concentration was checked by EDTA complexometric titration as previously described.[15] The ionic strength was kept constant by adding the appropriate amount of an NaCl (2 M) solution at 0.15 M.

Measurements

The pH titration was performed as previously reported,[15] utilizing an Orion Research Ionalyzer type 901 in the pH mode, equipped with a Ross combination pH electrode model 81-02. Kinetic measurements were done using a Durrum stopped-flow apparatus. The optical path length was 20 mm.

* Author to whom correspondence should be addressed.

The mixing syringes and cuvette were thermostatted at 25°C. The kinetic data were acquired and processed by an on-line micro-processor-based system.[16] The observed rate constants were calculated for kinetic data for up to an 85% completed reaction. The absorption spectra were carried out on a Schimadzu model 240 spectrophotometer in the wavelength range 600–200 nm.

Determination of the protonation constants of GX and PL and the formation constants of the binary species in the Ni(II)–GX–PL system were done using the MINIQUAD-75 program.[17] The procedures used to select the correct equilibrium model were similar to those reported previously.[15] In potentiometric measurements, the range of the total Ni(II) concentration (T_{Ni}) was $1.0–2.0 \times 10^{-3}$ M that of GX (T_{GX}) was $1.0–3.0 \times 10^{-3}$ M, and that of PL (T_{PL}) was $1.0–4.0 \times 10^{-3}$ M. In kinetic measurements, T_{Ni} was $0.5–1.0 \times 10^{-4}$ M, T_{GX} was $0.5–5.0 \times 10^{-3}$ M and T_{PL} was $1.0–3.0 \times 10^{-2}$ M.

Polarographic measurements were taken by a Polarocord E506 for solutions of 0.5 M in NaCl, the height of the mercury column was 80 cm, and the drop time was 2.0 s. Deoxygenation of the solution to be polarographed was achieved by passing purified nitrogen through it.

RESULTS AND DISCUSSION

Equilibrium study

Binary complexes of the Ni(II)–GX *system.* The titration of GX (0.002 M) with NaOH (0.1 M) in the presence or absence of Ni(II) did not show signs of precipitation when the concentration of the ligand was twice or more than twice that of the metal ions in the pH range ~5.0–10.0. However, the precipitation of a red crystalline product occurred in the pH range ~7.5–8.5 upon standing overnight. This product was reported previously as $Ni(GX)_2$.[11] The titration data were assessed by the MINIQUAD program where four equilibrium models were found to

[b] The true values should be corrected by the addition of pK_w (13.76) to 13.82, 18.55 and 17.6 for NiGXOH, $NiGX(OH)_2$ and $Ni(GX)_2OH$, respectively.

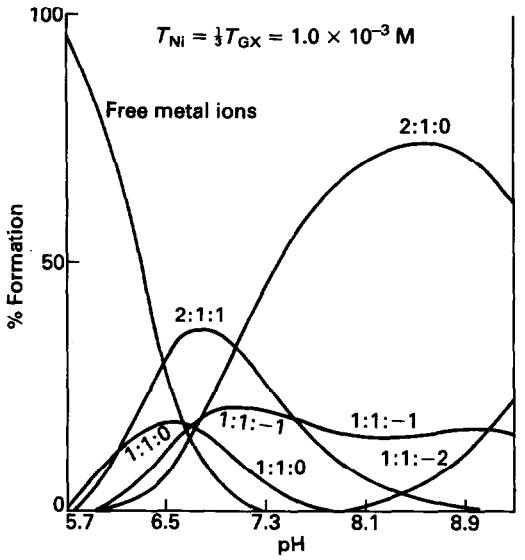

Fig. 1. Distribution diagram of the binary Ni(II)–GX complex system.

describe the Ni(II)–GX system. They are not very different and are depicted in Table 1. The structure of $Ni(GX)_2$ has been elucidated previously and the coordination about the Ni(II) atom is square planar with four nitrogen atoms of the two glycinohydroxamato ligands occupying the four coordination sites.[11] The dihydroxy species may be also similar in geometry to that of the bis(glycinohydroxamato) nickel(II), and it occurs at pH >8.5. Formation constants of the complexes of Ni(II) with glycine are smaller in magnitude than with GX which is attributed to the involvement of the NOH group rather than the —C=O group in the metal ligation.

The presence of 2:1:1 (2GX:Ni:H) species may also describe bis(glycinohydroxamato) nickel(II) species in which the NOH group of one of the ligands is not deprotonated.

The distribution diagram of the percent formation of the complexes as a function of pH is shown in Fig. 1 for one of the successful equilibrium models. It is noticeable that the 2:1:0 species exists predominantly at pH $\geqslant$7.5.

Interaction of GX *with* PL. GX reacted with PL in the pH range 5.0–10.0, as evidenced from the changes in the PL spectra in the wavelength range 220–450 nm upon addition of a 1:1 mole ratio of GX (GX has no spectra at wavelengths greater than 240 nm) (Fig. 2). At lower pH (<7.0), an increase in absorbance was observed in the wavelength range 200–350 nm. At higher pH (>7.0) there was a decrease in absorbance in the wavelength range 340–450 nm, a red shift in the PL wavelength band with the maximum at 300 nm (at pH ~ 10.0), and a blue shift as well as an increase in absorbance of the spectral band of PL in the wavelength range 200–270 nm. After mixing overnight spectra were identical in the presence and absence of a few drops of EDTA solution (to complex any trace metal ions if it happens to exist as impurities). Polarographic evidence of the interaction of PL with GX has been obtained at pH = 7.0 for the equilibrated mixture. The irreversible wave so obtained for PL at $E_{1/2} \approx -1.0$ V, has been replaced by two overlapping irreversible waves at $E_{1/2} = 1.02$ and 1.13 V in the PL–GX system (Fig. 3).

A variation in pH was observed as a function of time when a mixture of GX and PL was titrated with 0.10 M NaOH. The potentiometric data were

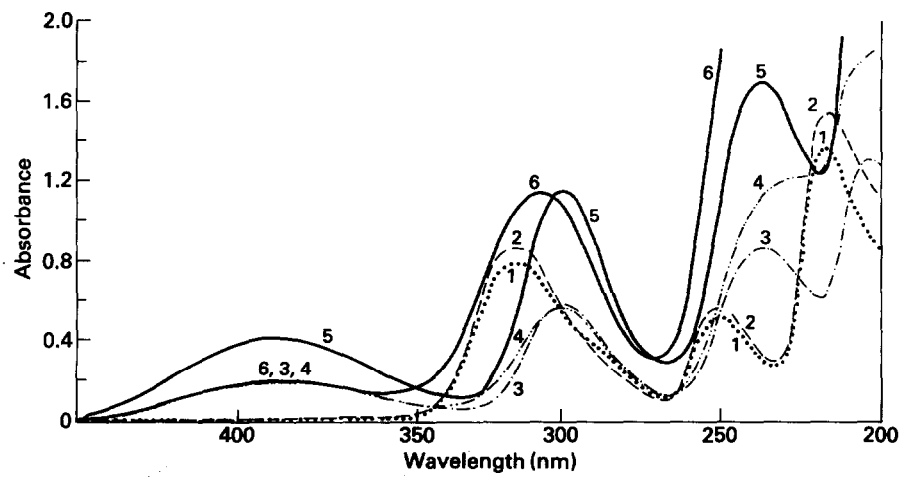

Fig. 2. Absorption spectra of PL, GX and a mixture of PL and GX: (1) PL, pH = 5.18, $T_{PL} = 1 \times 10^{-4}$ M; (2) PL + GX, pH = 5.14, $T_{PL} = T_{GX} = 1 \times 10^{-4}$ M; (3) PL, pH = 10.15, $T_{PL} = 1 \times 10^{-4}$ M; (4) PL + GX, pH = 10.16, $T_{PL} = T_{GX} = 1 \times 10^{-4}$ M; (5) PL, pH = 10.01, $T_{PL} = 2 \times 10^{-4}$ M; and (6) PL + GX, pH = 10.01, $T_{PL} = 2 \times 10^{-4}$ M, $T_{GX} = 1 \times 10^{-3}$ M.

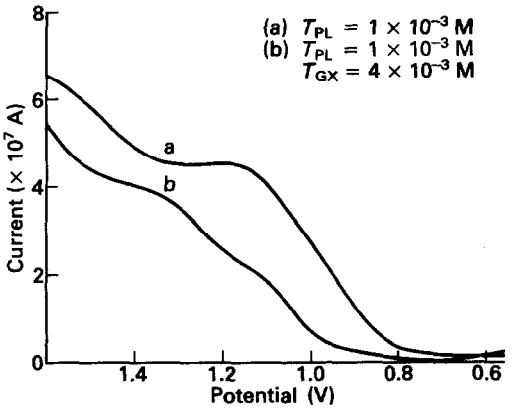

Fig. 3. Polarograms of PL and a mixture of PL and GX.

obtained after equilibration (after 10 min of a small addition of the titrant). Assessment of the data in the pH range 6.7–10.0 for mixtures of GX and PL at different mole ratios (using the MINIQUAD program) indicated the presence of three species. Their stoichiometries, together with their formation constants, are depicted in Table 1. Figure 4 shows the distribution diagram of the condensed species of PL with GX. The fully unprotonated species is predominant at pH > 7.0, while the protonated species are predominant at lower pH values.

Kinetic study

Complexes of Ni(II) *with* GX. An aqueous solution of $Ni(ClO_4)_2$ has been reported to exhibit three main spectral bands at 1149 ($\varepsilon = 2.0$), 690 (shoulder) and 395 ($\varepsilon = 4.6$) nm, which were ascribed to $^3T_{2g}(F) \leftarrow {}^3A_{2g}(F)$, $^3T_{1g}(F) \leftarrow {}^3A_{2g}(F)$ and $^3T_{1g} \leftarrow {}^3A_{2g}(F)$, respectively.[18] Similarly, an aqueous $NiCl_2$ solution showed the same bands, except that they are shifted slightly to shorter wavelengths. However, in the presence of GX, Ni(II) exhibited only one band in the visible region which is similar in pattern to that at ~ 690 nm with the exception that it appears at ~ 446 nm with greater intensity. The band at 395 nm is probably shifted to a shorter wavelength (250 nm). The intensities of these bands are pH-dependent, which indicated that complex formation is enhanced by loss of H^+ from GX. The variation in intensity served as the basis for the evaluation of the formation constants of the existing complexes.[19]

The addition of an Ni(II) solution to GX resulted in the formation of an orange colour at pH ≈ 7.0, which changed to red as the pH increased. Precipitation of red crystals occurred on standing at pH > 7.5. The kinetic data were obtained at wavelength of 250 nm, where the absorbance was mainly due to the complex. Figure 5 shows the observed rate constant (k_{obs}) (under pseudo-first-order conditions) as a function of pH and the analytic concentration of GX ($T_{GX} \gg T_{Ni}$). Figure 6 shows the k_{obs} values as a function of T_{GX} at interpolated values of pH obtained from Fig. 5. The dependence is not linear, with the intercept greater than zero, and it is more or less quadratic. Since the intercept values are usually the result of experimental points which suffer

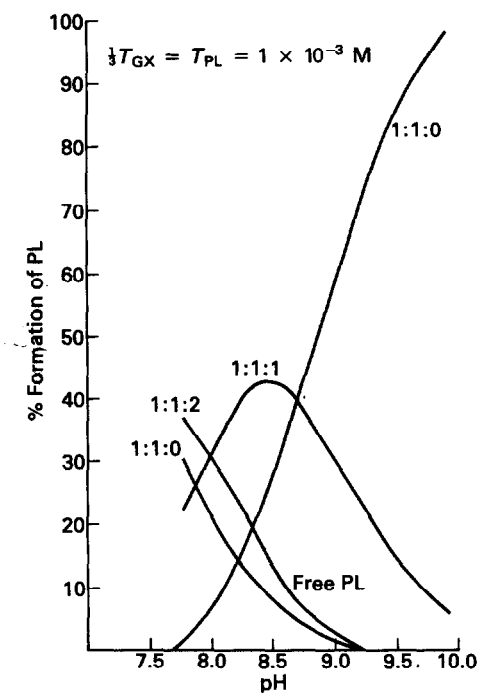

Fig. 4. Distribution diagram of the GX–PL compounds.

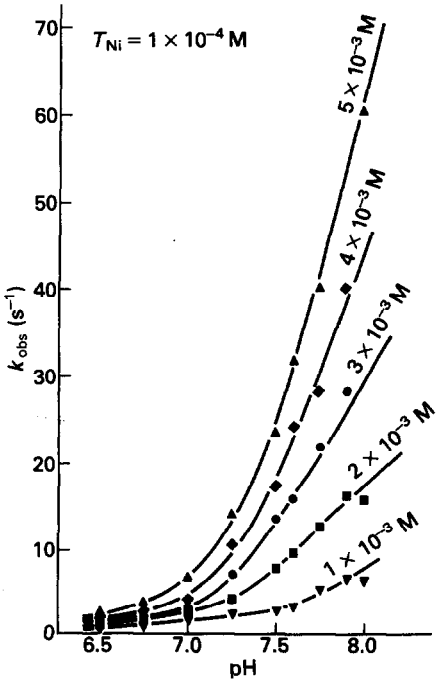

Fig. 5. Dependence of k_{obs} on pH at various T_{GX} and constant T_{Ni}.

from inherited uncertainties, one cannot rely on them for the interpretation of their dependence on pH. If $(k_{obs}-a)/T_{GX}$ (a represents the value of the adjusted intercept at a given pH) is plotted vs T_{GX} linear relationships were obtained (Fig. 7), i.e.:

$$(k_{obs}-a)/T_{GX} = b+cT_{GX}. \quad (1)$$

The ligand and metal species encountered in the pH range used (~6.7–8) are numerous. They are GXH_2^+, GXH and GX^- for the ligand, and Ni^{2+} and $NiOH^+$ for Ni(II). Several reactions may be considered to take place between these species. In order to simplify the mechanism a few reactions are going to be considered in which it has been assumed that the products are mainly $NiGX^+$ and $Ni(GX)_2$. This assumption is reasonable since excess ligand with respect to metal was used throughout the kinetic work. Scheme 1 describes the reactions which probably take place in solution.

Scheme 1.

k_is and k_{-i}s are the forward and backward rate constants.

The above mechanism can be described by the following differential equation:

$$\begin{aligned}
Q_2\frac{dC_2}{dt} = &\left(\frac{T_{Ni}-C_2Q_2}{Q_1}\right)(T_{GX}Q_3+T_{GX}^2Q_4)\\
&+K_{OH}[OH^-]\left(\frac{T_{Ni}-C_2Q_2}{Q_1}\right)\\
&\times(T_{GX}Q_5+T_{GX}^2Q_6)-C_2\\
&\times[(Q_7/K_{1C}\alpha_2T_{GX})+Q_8], \quad (2)
\end{aligned}$$

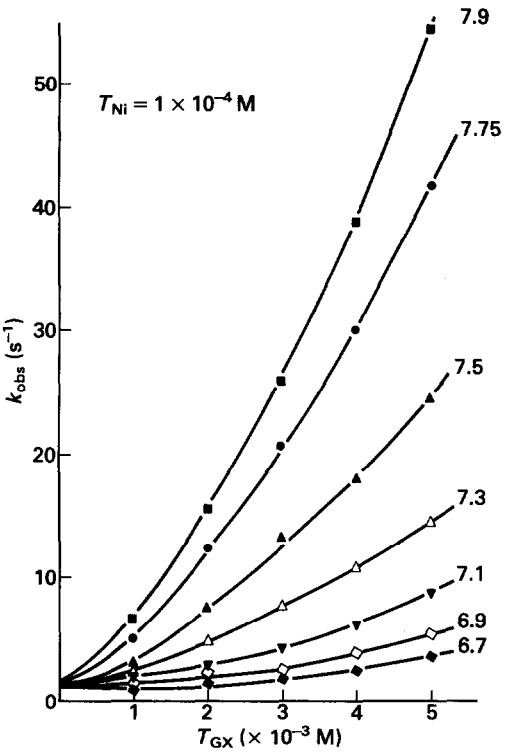

Fig. 6. Dependence of k_{obs} on T_{GX} at various values of pH taken from Fig. 5.

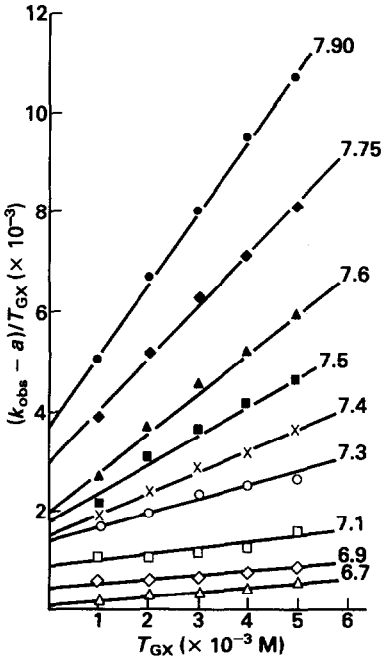

Fig. 7. Plot of $(k_{obs}-a)/T_{GX}$ as a function of T_{GX} at various values of pH.

where:

$$Q_1 = 1 + K_{OH}[OH^-],$$

$$Q_2 = 1 + (K_{1C}\alpha_2 T_{GX})^{-1},$$

$$K_{OH} = [NiOH^+]/[Ni^{2+}][OH^-],$$

$$K_{1C} = C_2/C_1\alpha_2 T_{GX},$$

$$C_1 = [NiGX^+],$$

$$C_2 = [Ni(GX)_2],$$

$$\alpha_0 = [GXH_2^+]T_{GX}^{-1} = [H^+]^2/[H^+]^2 + K_{1h}[H^+] + K_{1h}K_{2h},$$

$$\alpha_1 = [GXH]T_{GX}^{-1} = [H^+]K_{1h}/[H^+]^2 + K_{1h}[H^+] + K_{1h}K_{2h},$$

$$\alpha_2 = [GX^-]T_{GX}^{-1} = K_{1h}K_{2h}/[H^+]^2 + K_{1h}[H^+] + K_{1h}K_{2h},$$

K_{1h} and K_{2h} are the first and second dissociation constants of GXH_2^+,

$$Q_3 = k_1\alpha_0 + k_2\alpha_1 + k_3\alpha_2,$$

$$Q_4 = k_7\alpha_0^2 + k_8\alpha_1^2 + k_9\alpha_2^2,$$

$$Q_5 = k_4\alpha_0 + k_5\alpha_1 + k_6\alpha_2,$$

$$Q_6 = k_{10}\alpha_0^2 + k_{11}\alpha_1^2 + k_{12}\alpha_2^2,$$

$$Q_7 = k_{-1}[H^+]^2 + (k_{-2} + k_{-4})[H^+] + (k_{-3} + k_{-5}) + k_{-6}[OH^-]$$

and

$$Q_8 = k_{-7}[H^+]^4 + k_{-10}[H^+]^3 + k_{-8}[H^+]^2 + k_{-11}[H^+] + k_{-9} + k_{-12}[OH^-].$$

The integrated form of eqn (2) is expressed as follows:

$$\ln \frac{C_\infty}{C_{2,t} - C_{2,\infty}} = k'(GX)t, \quad (3)$$

where $C_{2,\infty}$ and $C_{2,t}$ are the concentration of C_2 at infinity and time t, and k' is the overall rate constant which may be correlated with $k_{obs}(GX)$, i.e.:

$$k_{obs}(GX) = \frac{Q_8}{Q_2} + \left(\frac{Q_3 + Q_5K_{OH}[OH^-]}{Q_1}\right)T_{GX} + \left(\frac{Q_4 + Q_6K_{OH}[OH^-]}{Q_1}\right)T_{GX}^2, \quad (4)$$

where:

$$a = Q_8/Q_2 \approx Q_8, \quad (5)$$

$$b = (Q_3 + Q_5K_{OH}[OH^-])/Q_1 \approx Q_3 + Q_5K_{OH}[OH^-] \quad (6)$$

and

$$c = (Q_4 + Q_6K_{OH}[OH^-])/Q_1 \approx Q_4 + Q_6K_{OH}[OH^-], \quad (7)$$

where $Q_1 \approx Q_8 = 1$ (under the experimental conditions of this work).

It has been found that $a(=Q_8)$ is a linear function of the reciprocal of $[H^+]$ [Fig. 8(a)], with intercept $(=k_{-9})$ and slope $(=k_{-12})$ equal to 0.74 and 1.6×10^{-8}, respectively. If b is multiplied by $([H^+] + K_{1h}[H^+] + K_{1h}K_{2h})$ and plotted vs $[H^+]$ a straight line is obtained [Fig. 8(b)] with intercept $(=k_5K_{OH}K_wK_{1h} + K_{1h}K_{2h}k_3)$ equal to 1.0×10^{-12} and slope $(=k_4K_{OH}K_w + k_2K_{1h})$ equal to 6.4×10^{-5}. The parameter c, if multiplied by

$$\frac{[H^+]^2 + K_{1h}[H^+] + K_{1h}K_{2h})^2}{[H^+]^2},$$

is partly dependent on $[H^+]$ and partly dependent on $[H^+]^{-1}$. Figure 8(c) shows such a dependence: in the case of the reciprocal dependence on $[H^+]$ the intercept $(=k_8K_{1h}^2)$ and slope $(=k_{11}K_{1h}^2K_{OH})$ are equal to 1.6×10^{-9} and 8.8×10^{-18}, respectively, while in the case of the linear dependence on $[H^+]$ the intercept $(=k_8K_{1h}^2)$ and slope $(=k_{10}K_{OH})$ are equal to 1.1×10^{-9} and 7.3×10^{-3}, respectively. With the knowledge of the values of the constants K_w, K_{1h}, K_{2h} and K_{OH} the possible values of the microrate constants k_2, k_3, k_4, k_5, k_8, k_{10}, k_{11}, k_{-9} and k_{-12} may be determined. The values are 2.6×10^2, 1.6×10^5, 3.2×10^5, 2×10^6, 2.5×10^6, $\ll 1$, $\ll 1$, 0.74 and 1.6×10^6, respectively. It seems from these results that the active Ni(II) species in NiGX formation are the Ni^{2+} and $Ni(OH)^{2+}$, but only Ni^{2+} in the case of the formation of the $Ni(GX)_2$ complex.

Complexes of the Schiff base of PL *and* GX *with* Ni(II). Addition of PL in excess to a solution of Ni(II) GX did not show signs of precipitation in the pH range 7.5–10.0. The reaction was slower than that of GX with Ni(II). It was pH-dependent at constant T_{PL} (initial concentration of PL) (Fig. 9). If k_{obs} is plotted as a function of T_{PL} at various interpolated pH values straight lines of significant positive slopes and negative intercepts are obtained. The lines intersected at a fixed concentration of T_{PL} (Fig. 10), i.e.:

$$k'_{obs}(Sch) = d + eT_{PL}. \quad (8)$$

(at constant T_{Ni}, T_{GX} and pH), where $k'_{obs}(Sch)$ is the observed rate constant for the Ni(II)–Schiff base complexation reaction. In the case of $T_{GX} = 5T_{Ni} = 5 \times 10^{-3}$ M, this concentration is equal to 4×10^{-3} M (Fig. 10). Although the negative intercept has no physical meaning, yet it may indicate that Schiff base–Ni(II) complexes are not likely formed when the concentration of PL is less than or equal to $4 \times$

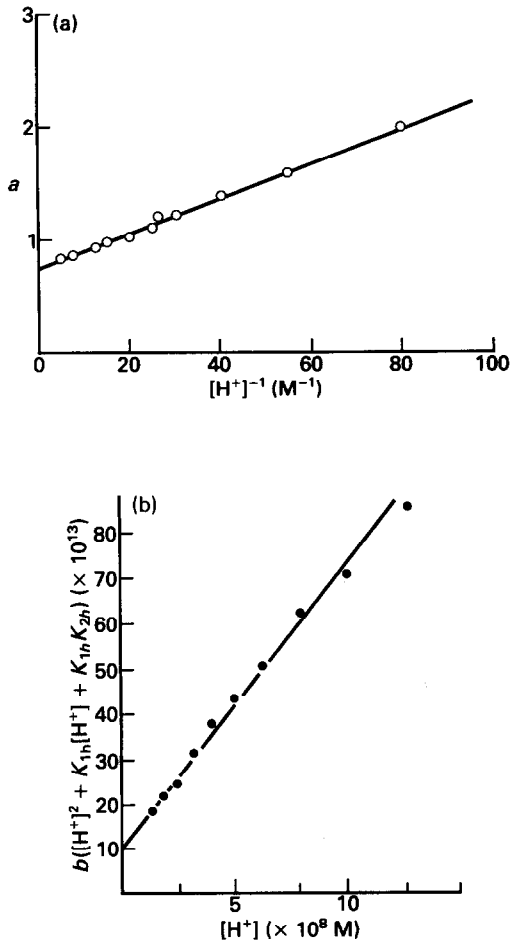

Fig. 8. (a) Plot of a as a function of $[H^+]^{-1}$. (b) Plot of $b([H^+]^2+[H^+]K_{1h}+K_{1h}K_{2h})$ as a function of $[H^+]$. (c) Plot of $c([H^+]^3+[H^+]K_{1h}+K_{1h}K_{2h})^2/[H^+]^{-2}$ as a function of $[H^+]^{-1}$.

10^{-3} M. This type of reaction has been encountered in Schiff base complex formation with Cu(II).[20] It was explained as due to the prior formation of a ternary complex. Similarly, a ternary complex of Ni(II) may also be formed with PL and GX $[Ni(PL)_f(GX)_j(H)_k]$ prior to the Schiff base complex formation. In such a case, eqn (8) can be rewritten as follows:

$$k'_{obs}(Sch) = e(T_{PL} - T'_{PL}), \qquad (9)$$

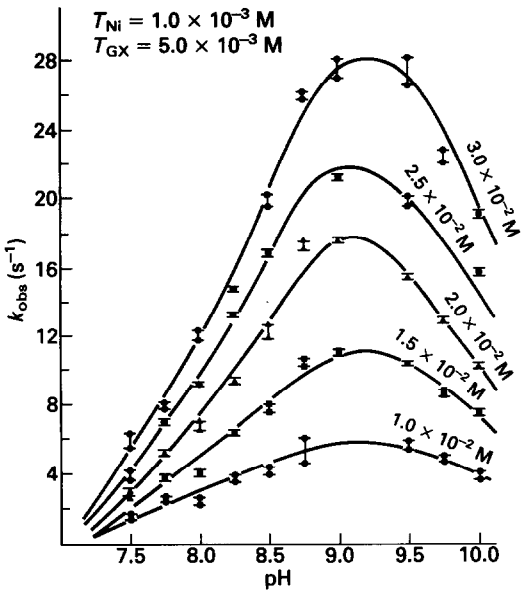

Fig. 9. Dependence of k_{obs} on pH at various T_{PL} and constant T_{Ni} and T_{GX}.

where T'_{PL} is the initial concentration of PL not involved in the Schiff base complex formation with GX ($\leqslant 4\times10^{-3}$ M in this case).

The interacting species of PL and Ni(II)–GX in the pH range of the study are considered to be HPL, PL^-, GX^-, GXH, $NiGX^+$ and $Ni(GX)_2$. Other complex species have been neglected for simplicity. The reaction mechanism which may describe the kinetic data shown in Figs 9 and 10 is visualized in Scheme 2.

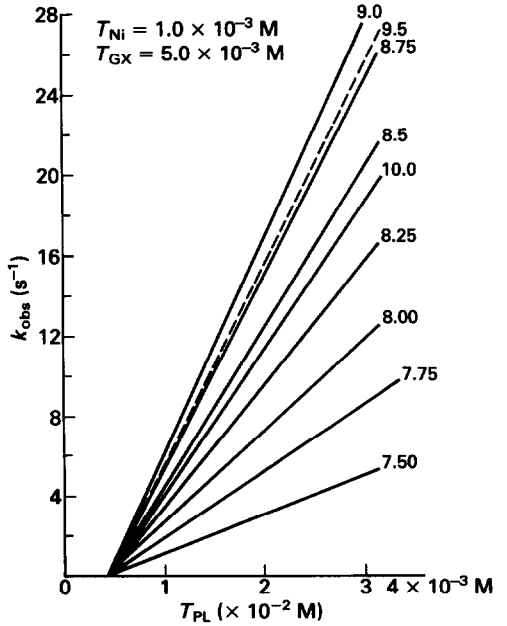

Fig. 10. Dependence of k_{obs} on T_{PL} at various values of pH.

(g) $HPL + GXH \rightarrow Sch\ H_2$, k_{19};

(h) $HPL + GX^- \rightarrow Sch\ H^-$ } k_{20};
or $PL^- + GXH \rightarrow Sch\ H^-$ }

(i) $PL^- + GX^- \rightarrow Sch^{-2}$, k_{21}.

Scheme 2.

Sch is the condensation product (Schiff base) of GX and PL (its formation is a fast process and beyond the ability of the stopped-flow kinetic technique to measure), and Ni Sch H, Ni Sch, Ni Sch H_{-1}, NiGX Sch H, NiGX Sch and NiGX Sch H_{-1} are the various Ni(II) complexes with the condensed product. Here, the reactions were assumed to be irreversible since the intercepts (describing the backward rate constants) of the linear relation described by eqn (9) have been assumed to be equal to zero. The rate equation describing the mechanism shown in Scheme 2 is as follows:

$$-\frac{d[Ni(GX)_2]}{Q_2\,dt} = Ni(GX)_2 Q_{12}, \qquad (10)$$

where:

$$Q_{12} = \frac{k_{13}\alpha'_1 T_{PL}}{K_{1C}\alpha_2 T_{GX}} + \frac{k_{14}\alpha'_2 T_{PL}}{K_{1C}\alpha_2 T_{GX}} + \frac{k_{15}\alpha'_2 T_{PL} K_w}{[H^+]K_{1C}\alpha_2 T_{GX}} + k_{16}\alpha'_1 T_{PL} + k_{17}\alpha'_2 T_{PL} + k_{18}\alpha'_2 T_{PL} K_w/[H^+].$$

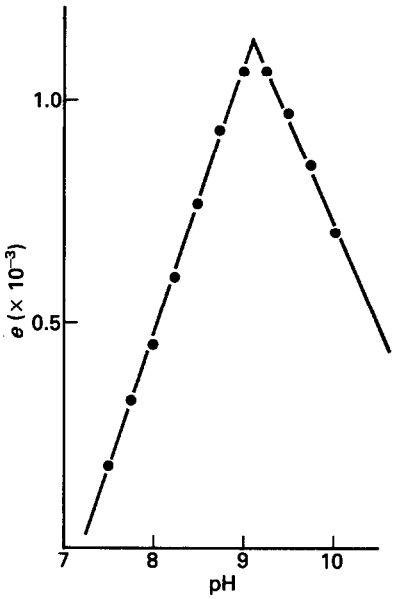
Upon integration of eqn (10), and correlating the result with eqn (9), the following relation is obtained:

$$k_{obs}(Sch) = Q_{12}/Q_2. \qquad (11)$$

Now the slope e in eqn (9) is as follows (if $Q_2 \approx 1$):

$$e = \frac{k_{13}\alpha'_1}{K_{1C}\alpha_2 T_{GX}} + \frac{k_{14}\alpha'_2}{K_{1C}\alpha_2 T_{GX}} + \frac{k_{15}\alpha'_2 K_w}{[H^+]K_{1C}\alpha_2 T_{GX}} + k_{16}\alpha'_1 + k_{17}\alpha'_2 + k_{18}\alpha'_2 K_w/[H^+]. \qquad (12)$$

Equation (12) is non-linear with respect to $[H^+]$ since α_2, α'_1, and α'_2 are also pH-dependent and an approximation should be considered if the curve shown in Fig. 11 could be interpreted. Plotting



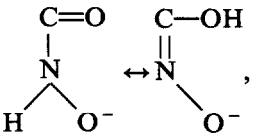


Fig. 11. Dependence of e on pH.

$e[H^+]/\alpha'_2$ vs α_2^{-1} resulted in a linear relationship in the pH range 7.75–10.00 with a very small intercept and a significant slope [Fig. 12(a)]. In such a case, the terms containing k_{13}, k_{14}, k_{16} and k_{17} are ignored in this pH range and $k_{15}K_w/K_{1C}T_{GX} = 3.53 \times 10^{-7}$ and $k_{15} = 5.6 \times 10^{11}$. Since the intercept is very small it should be expected that $k_{18} \leqslant 10^{12}$. On the other hand, the plot of $e[H^+]/\alpha'_2$ vs $[H^+]/\alpha_2$ is only linear in the pH range 9.25–10.00 if all terms in eqn (12) are ignored except for $([H^+]k_{14})/K_{10}\alpha_2 T_{GX}$ and $k_{18}K_w$ [Fig. 12(b)]. In such a case k_{14} is equal to 6.5×10^6 and $k_{18} \approx 2.5 \times 10^6$. If these approximations are correct, the most important reactions in Scheme 2 should be (b), (c) and (f) in which (c) and (f) show a kind of deprotonation of the Ni(II)–Schiff base complex. This may occur through the deprotonation of the tautomeric form of GX coordinating with Ni(II) and PL:

a situation which may account for the presence of the binary species $NiGXH_{-1}$ in aqueous solution at pH > 5.5 (Fig. 1).

In Scheme 2, a substitution reaction between the already fast Schiff base formation and the binary species of Ni(II) with GX was ignored since the rate of the reaction found was not compatible with the general rates of Ni(II) substitution reactions.

Acknowledgements—We would like to thank the University of Kuwait for the provision of Research Grant SCO21.

COMPLEXES OF IRON(III) WITH BENZOYLACETONE 1-NAPHTHOYLHYDRAZONE

VUKADIN M. LEOVAC,* LUKA J. BJELICA, LJILJANA S. JOVANOVIĆ and STEPAN YU. CHUNDAK†

Institute of Chemistry, Faculty of Sciences, V. Vlahovića 2, 21000 Novi Sad, Yugoslavia

(*Received* 17 *July* 1985; *accepted* 4 *October* 1985)

Abstract—One mono(ligand) and three bis(ligand) octahedral complexes (cationic, anionic and non-electrolyte type) of iron(III) and benzoylacetone 1-naphthoylhydrazone have been prepared and characterized by elemental analysis, conductivity measurements, IR and electronic spectra, as well as by linear sweep and cyclic voltammetry. It has been found that formation of these complexes can be explained by the nature of this tridentate (ONO) ligand, taking part in coordination as both a mono- and a dianion.

Due to the diverse properties of carboxylic acid hydrazides and hydrazones and their wide application in many fields (medicine, analytical chemistry etc.), we have witnessed an increased interest in the study of their complexing affinities toward different transition metals.[1–4] There have been described[5,6] the complexes of both 1-naphthoic acid hydrazide and salicylidenehydrazone with some 3*d* elements, showing that coordination had been accomplished via NO and ONO sets of donor atoms, respectively.

Since we could not find in the literature information on iron(III) complexes with benzoylacetone 1-naphthoylhydrazone (H_2L), we have undertaken the task of their preparation and characterization by some physico-chemical methods.

EXPERIMENTAL

Chemicals and methods

Chemicals and some of the methods employed have been already described.[7]

The iron content was determined by a complexometric method[8] after complex decomposition with concentrated nitric and sulphuric acid.

Melting points were determined by Kofler apparatus with no corrections.

Thermogravimetric measurements were carried out on a Paulik–Paulik–Erdey derivatograph in the air atmosphere, employing MgO as a standard. The mass of the sample was 100 mg and the heating rate was 10°C min^{-1}.

Preparation of the ligand and complexes

Ligand. H_2L was synthesized according to the general procedure[9] in the following way. An equimolar mixture of methanolic solutions of 1-naphthoic acid and benzoylacetone was heated with reflux for about 1 h. After cooling to room temperature the white microcrystalline hydrazone precipitate was filtered off and washed with MeOH and Et_2O. Yield 80%. The results of elemental analysis of the ligand recrystallized from MeOH, together with those for the complexes, have been presented in Table 1.

Complexes

$Fe(HL)Cl_2$. To the hot solution of 0.66 g of H_2L in 5 cm^3 of EtOH, a concentrated ethanolic solution of $FeCl_3 \cdot 6H_2O$ (0.54 g) was added (mole ratio 1:1). The solution was left at room temperature for about 12 h. The black crystals (formed in the dark green solution) were filtered off and washed with EtOH and Et_2O. Yield 0.72 g.

[b] MeOH 10.5 (10.0).

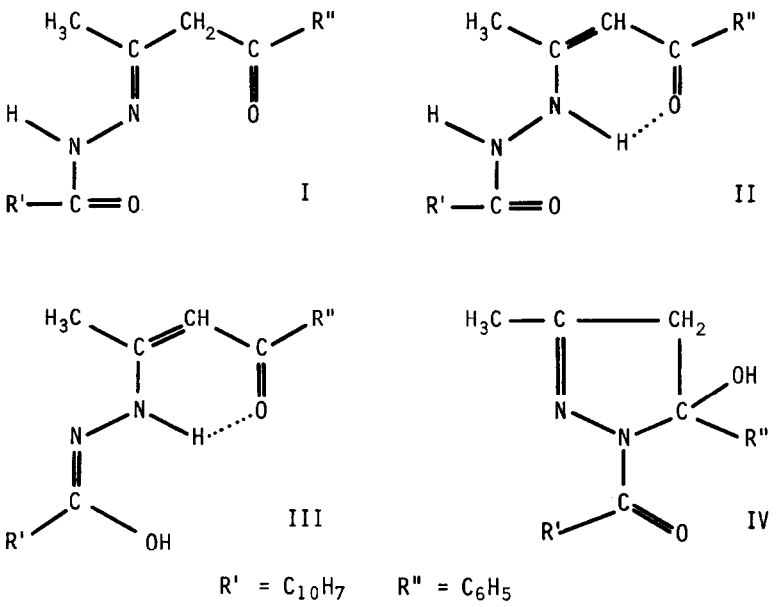
$FeCl_3\cdot 6H_2O$ and 0.40 g (3 mmol) of sodium acetate was dissolved by heating in 5 cm^3 of EtOH. The precipitated NaCl was filtered off and 1.3 g of H_2L (4 mmol), dissolved in 5 cm^3 of EtOH, added to the filtrate. The dark green crystals formed during 48 h of keeping the reaction mixture at room temperature were filtered off and washed with EtOH and Et_2O. Yield 1.20 g.

Fe(HL)L. 0.75 g (1 mmol) of $[Fe(HL)_2]Cl$ was dissolved by heating in 10 cm^3 of MeOH and the obtained solution filtrated out. Then 0.20 g of lithium acetate was added to the filtrate and the mixture heated for 2–3 min. The solution colour changes from dark green into the dark one. After cooling to room temperature, about 2 h later, the dark brown crystals were filtered off and washed with MeOH. Yield 0.54 g.

$Li[FeL_2]\cdot 2.5CH_3OH$. 0.70 g (1 mmol) of Fe(HL)L was dissolved at room temperature in 20 cm^3 of Et_2O (dissolution is not complete). Then 0.080 g (2 mmol) of $LiOH\cdot H_2O$ dissolved in 5 cm^3 of MeOH was added. The obtained solution after stirring was left for about 5 h. The black needle-like crystals were filtered off and washed with EtOH. Yield 0.50 g.

RESULTS AND DISCUSSION

General physico-chemical characteristics of complexes



As seen from Table 1, H_2L forms with Fe(III) one mono(ligand) and three bis(ligand) complexes of cationic, anionic and non-electrolyte type. The complexes are black or dark green crystalline substances, stable in air. They melt (without decomposition) at temperatures considerably higher than the melting point of the ligand itself (Table 2). From the only crystallosolvate, $Li[FeL_2]\cdot 2.5CH_3OH$, the methanol loss is observed at relatively high temperature (120°C). The complexes are insoluble in water, while they are dissolved in MeOH, EtOH, Me_2CO and DMF. Besides, the neutral and anionic complexes are soluble in Et_2O and $CHCl_3$.

Formation of three different types of bis(ligand) complexes can be explained by the fact that the ligand can take part in coordination as both the mono- (HL^-) and the dianion (L^{2-}). It has been shown[9] that the reaction of benzoylacetone with a number of aromatic acids hydrazides yields the

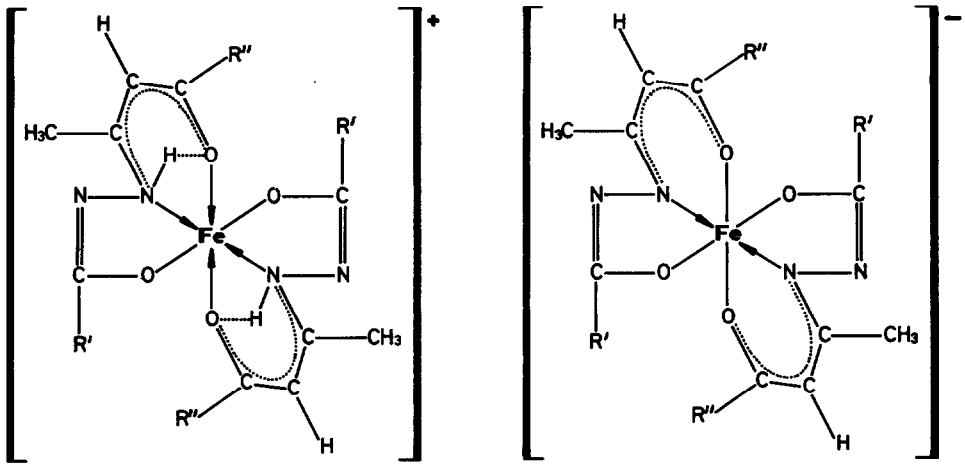
products which can exist in different tautomeric forms. In the case of H_2L four different structures are possible, viz. hydrazonic (I), enhydrazonic (II), enhydrazone-α-oxyazinic (III) and 5-oxypyrazolinic (IV) (Scheme 1).



It has been demonstrated[9,10] that a tautomeric rearrangement can take place in the complexing process of some similar ligands with metal ions. In view of the composition of the synthesized complexes, it can be concluded that our ligand behaves as a tridentate one, and, as mentioned above, is deprotonated in two stages. Because of that it cannot be engaged in the complex in its cyclic form (IV), since in that case it could not behave either as a tridentate ligand (for the stereochemistry reasons), or as a diprotic acid. The hydrazone form (I) is potentially tridentate, but it has only one mobile proton located at the amide nitrogen. On the other hand, enhydrazine form (II) can behave as a tridentate ONO type ligand, having two protons which can be replaced by metal ion. However, it has been recently established that chelate compounds of many ions of transition metals with the aldehyde[11] or ketone[12] hydrazones are formed via an α-oxyazine tautomeric form of the ligand (Scheme 2).

Since form II has an acylhydrazine fragment —NH—NH-COR it can be assumed that the complex formation process is preceded by formation of the enhydrazone-α-oxyazine isomer (III), which satisfies both conditions: it can act as a tridentate ligand and, depending on the reaction conditions, give one or two protons. This supposition is supported by the IR spectral data. An analysis of the IR spectra shows that these are similar for all the complexes, but differ from that of the ligand. Thus, in the region of valence vibrations of multiple bonds the spectrum of free ligand contains a band at 1700 cm^{-1} which can be attributed to the valence C=O group vibration. Also, the bands appearing at 1605 and 1590 cm^{-1} are characteristic of nitrogen derivatives of β-diketones, having a ketoenamine (enhydrazine) structure.[13] In the region of NH valence vibrations, the absorption band at 3290 cm^{-1} can be assigned to the NH bonds taking part in both inter- and intramolecular hydrogen bonds. On the other hand, in the spectra for the complexes ν(C=O) is missing, which indicates that the tautomeric form of the ligand engaged has been changed. In addition, the distinct ν(NH) band is not also observed. Finally, the spectra of both the ligand and complexes contain a band at 1265–1270 cm^{-1} which can be assigned to the C—O group.

Molar conductivity

As seen from Table 2, all complexes, with the exception of Fe(HL)L, behave in MeOH solutions as 1:1 electrolytes (molar conductivity 80–115).[14] In contrast to this, the molar conductivities measured in DMF are significantly lower than the expected ones (65–90).[14] However, these observations are in agreement with those for Fe(III) complexes with the semicarbazone-based ligands,[7] and a similar explanation can be given.

Lower conductivities of $[Fe(HL)_2]Cl$ and $Li[FeL_2]$ in DMF can be attributed to the formation of ion pairs between the weakly solvated Cl^- and the complex cation, and Li^+ with the complex anion,

$[Fe(HL)_2]^+$ $[FeL_2]^-$

R′ = $C_{10}H_7$, R″ = C_6H_5

Scheme 2.

respectively. On the other hand, the conductivity of $Fe(HL)Cl_2$ (monomer) should imply its dissociation into $Fe(HL)Cl^+$ and Cl^-. Since the probability for a tetra- or penta-coordinated Fe(III) with such a planar ligand is low, it seems plausible to assume the existence of a dimer $[Fe(HL)_2][FeCl_4]$ in the solution. However, in contrast to the analogous complexes previously described,[7] the presence of a dimeric structure for Fe(HL)L cannot be proved (apparently, it is only formed under the voltammetric conditions, i.e. in the presence of a supporting electrolyte). Conductivities of $[Fe(HL)_2]Cl$ and $Fe(HL)Cl_2$ show an increase with ageing of the solution (about 20% during 24 h), which suggests that some structural changes take place in their solutions.

Magnetic susceptibility

It is evident from Table 2 that all the complexes have the values for effective magnetic moments characteristic for the high-spin Fe(III) state (d^5-system). Therefore, it can be concluded that H_2L behaves towards Fe(III) as a ligand with a relatively weak ligand field.

Electronic spectra

Similar to some analogous compounds,[15] H_2L and some of its complexes undergo, in solution, certain structural transformations, which is reflected in the appearance of the electronic spectra (Table 3).

The absorption maximum at 30,210 cm^{-1} in the spectrum for a freshly prepared solution of H_2L shows a rapid decrease with time, as illustrated in Fig. 1 (insets). The absorbance after 6 h falls to about one-third of the starting value, remaining approximately the same afterwards. At the same time, two new maxima emerge at 34,250 and 35,460 cm^{-1}, respectively, and they do not exhibit a time effect. The same maxima have been also observed in the spectrum of 1-naphthoic acid hydrazide. Therefore, H_2L in the solution undergoes significant structural changes which can be explained by (a gradual) formation of the cyclic 5-oxypyrazoline form (IV).[9]

Similar changes, though less pronounced, are also observed in the spectra of $Fe(HL)Cl_2$ and $[Fe(HL)_2]Cl$. The emergence of maxima at about 34,000 and 35,000 cm^{-1} might suggest that one ligand from the $[Fe(HL)_2]^+$ entity is replaced by Cl^-; the further process being the same as for free H_2L. Besides, in view of the similarity of the spectra for the two complexes, it should be supposed that the absorption is mainly due to their common constituent, i.e. $[Fe(HL)_2]^+$, which implies a dimeric structure ($[Fe(HL)_2][FeCl_4]$) for $Fe(HL)Cl_2$ in solution.

In contrast to the above, the spectra for Fe(HL)L and $Li[FeL_2]$ exhibit no time effect.

The electronic spectra for all complexes, except for $Li[FeL_2]$, recorded in the presence of an electrolyte (especially of LiCl), employed in voltammetric measurements, differ significantly from those obtained for the pure solutions. The difference is most pronounced in the case of Fe(HL)L; the spectrum in the presence of LiCl appearing as if composed of those for the cationic and anionic complex, which suggests formation of the dimeric $[Fe(HL)_2][FeL_2]$ structure.

On the basis of common characteristics of the

spectra for all complexes and the corresponding values for the absorbance coefficients, it can be concluded that the maxima observed below 30,000 are probably due to the d–π^* interactions and those at higher wavelength are characteristic of the intraligand π–π^* transitions. The absence of maxima belonging to the d–d transitions is not unusual for Fe(III) complexes,[16] especially if it is taken into

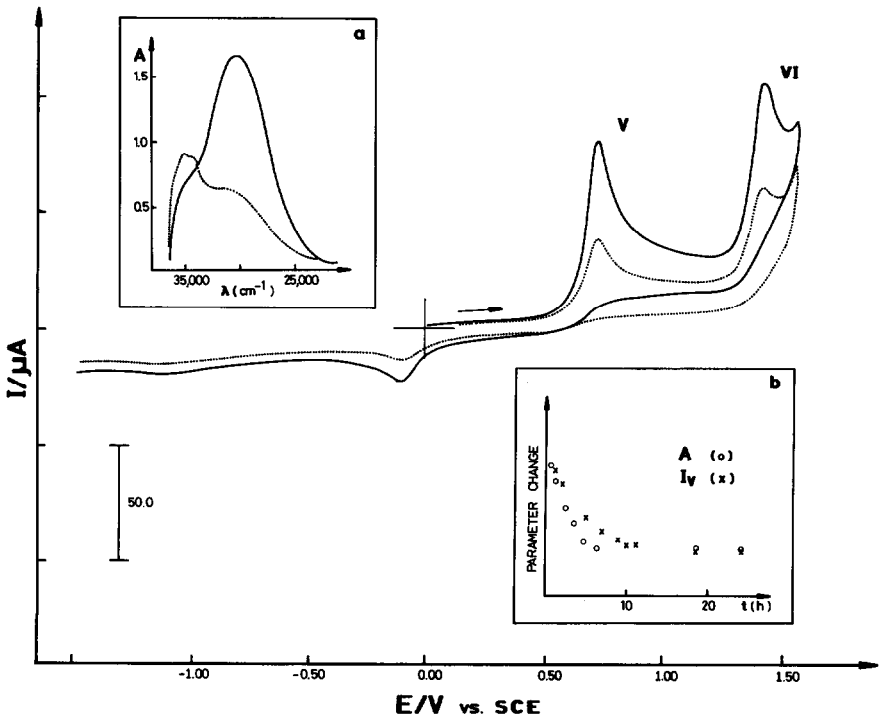

Fig. 1. Cyclic voltammograms for H_2L in 0.1 M $LiClO_4$ recorded at glassy carbon electrode (0.200 V s^{-1}) 1 (——) and 11 h (···) after preparing the solution. account their possible overlapping with the charge-transfer absorptions. Besides, the presence of a number of broad maxima, especially in the region of 27,000–30,000 cm^{-1}, indicate that the levels of electronic transitions in the complexes are not well defined.

Voltammetric studies

Ligand. The above structural changes of the ligand molecule in a DMF solution with time are reflected on the appearance of its cyclic voltammograms (Fig. 1). In the presence of $LiClO_4$ as supporting electrolyte, the oxidation occurs in two steps having the characteristics of the apparently two-electron irreversible process (peaks V and VI); the peak heights falling gradually to about one third of the starting value in about 6 h. Analogously, in the rotating disc experiment for a freshly-made solution the resulting two-electron waves are gradually transformed into those corresponding to the one-electron processes. The controlled potential electrolysis at the potential of peak V results in $n_{app} = 1.0$ and the dimeric product is reduced at -1.17 V ($n_{app} = 0.9$). On the other hand, the electrolysis at peak VI is not possible because of the close potential span limit.

On the cyclic voltammograms for H_2L, as well as for the complexes, recorded in the presence of Cl^-, a cathodic shift of peak V takes place with the slope of about 60 mV for a 10-fold increase in its concentration. This suggests occurrence of ion pairing of the reaction product with one Cl^- ion. It is accompanied by disappearance of the reduction peak at about 0.0 V, while the peak at about -1.30 V becomes more pronounced. The presence of Cl^- causes a significant cathodic shift of the anodic potential limit, so that the second oxidation peak (VI) cannot be recorded.

As for reduction of H_2L, it occurs in three steps at the potentials more cathodic from -2.0 V. The processes are coupled to irreversible chemical reactions whose mechanisms need further investigations.

Complexes. It has been found that the investigated complexes have the voltammetric characteristics similar to those of Fe(III) complexes with semicarbazone-based ligands.[7]

Cyclic voltammograms recorded for the anionic complex (Fig. 2) in the presence of $LiClO_4$ exhibit one reduction peak (II) (anodic counterpart III) corresponding to one-electron quasi-reversible process and three main oxidation peaks (IV–VI). The potentials of peaks II and III depend on the Li^+ concentration which might be attributed to the ion-pair formation. The slope of $+70$ mV indicates the association of one Li^+ with one reduced species ($[FeL_2]^{2-}$); the corresponding K_{ass} being about 6×10^3 mol^{-1} l.

The oxidations at peaks IV and V are followed by irreversible chemical reactions. By controlled-potential electrolysis at the plateau of peak IV ($n_{app} = 1.1$) the anionic bis(ligand) complex is transformed into the mono(ligand) one and the ligand in its oxidized form. A further oxidation at peak V with $n_{app} = 1.7$ results in decomposition of the complex, giving rise to the peaks representing reduction of Fe^{3+} and the oxidized ligand at about $+0.30$ and -1.25 V, respectively.

Cyclic voltammograms for the complexes having $[Fe(HL)_2]^+$ cation recorded in perchlorate medium are less defined. Three peaks (at -0.04, -0.45 and

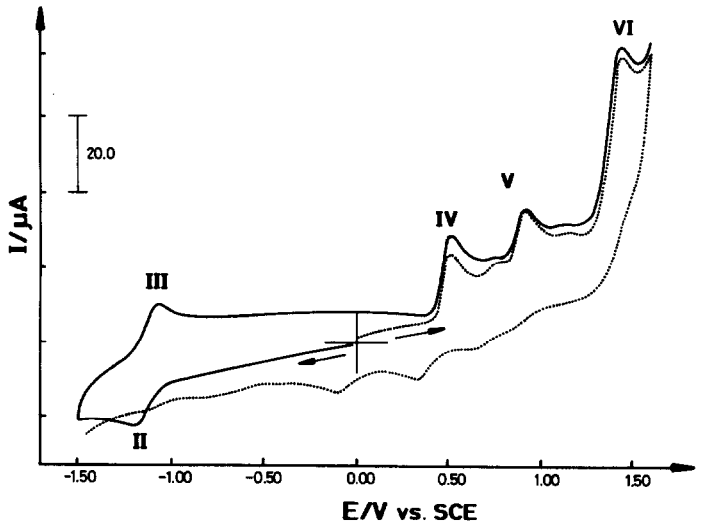

Fig. 2. Cyclic voltammograms of $Li[FeL_2]$ in 0.1 M $LiClO_4$, at glassy carbon electrode (0.200 V s^{-1}).

−1.16 V) representing one-electron reduction of different complex species, together with the more or less pronounced anodic counterparts, are observed. Besides, there appear the ligand oxidation peaks V and VI; the former one being of interest since it is observed in the potential region available in the presence of all supporting electrolytes.

Addition of Cl^- (as LiCl) causes an unequal cathodic potential shift of the two more anodic reduction peaks for the cationic complex and finally they merge into one peak. The slope of $\Delta E/\Delta \log [Cl^-]$ of about −160 mV for the peak at −0.45 V corresponds to the interaction with three Cl^- species. This means that one ligand entity in the bis(ligand) complex had been replaced with three Cl^-, giving thus $[Fe(HL)Cl_3]^-$.

Cyclic voltammograms recorded for cationic and anionic complexes in the presence of LiCl have been presented in Fig. 3. From the voltammetric data collected in Table 4 it is evident that potentials of all peaks depend on the sweep rate, indicating thus the presence of certain kinetic/chemical complications.

An attempt has been made to characterize better the electron transfer occurring at the potential of peak I. The constant potential electrolysis resulted in 0.4 mol of electrons per mole of reactant, giving rise to peak II, which is characteristic of reduction of $[FeL_2]^-$ anion. At the same time, the anodic peak at about 0.0 V, identified as oxidation of $FeCl_2$, showed a proportional enhancement. Therefore, the following reaction scheme (ECC mechanism), confirmed also by the rotating-disc experiment, might be assumed:

$$E \quad [Fe(HL)Cl_3]^- + e \rightarrow [Fe(HL)Cl_3]^{2-},$$

$$C \quad [Fe(HL)Cl_3]^{2-} + [Fe(HL)Cl_3]^- \rightarrow [Fe(HL)_2]^+ + FeCl_2 + 4Cl^-,$$

$$C \quad [Fe(HL)_2]^+ + 2HL^- \rightarrow [FeL_2]^- + 2H_2L.$$

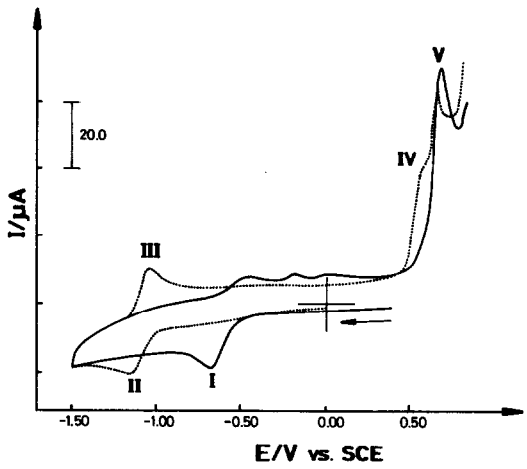

Fig. 3. Cyclic voltammograms of $[Fe(HL)_2]Cl$ (——) and $Li[FeL_2]$ (···) in 0.1 M LiCl at glassy carbon electrode (0.200 V s^{-1}).

Reoxidation of the starting complex (either after reduction at peak I or subsequently at peak II) can be achieved at the potential of $FeCl_2$ oxidation. However, if an oxidation is carried out at the potential of peak V, a complete decomposition of the complex (resulting in $FeCl_4^-$ and the ligand in its oxidized form) is attained. Its regeneration by reduction at cathodic potentials cannot be accomplished.

Cyclic voltammograms for other two complexes, $Fe(HL)Cl_2$ and Fe(HL)L (i.e. $[Fe(HL)_2][FeCl_4]$ and $[Fe(HL)_2][FeL_2]$) reflect their dimeric structure in the solution. They contain peaks representing reduction of the corresponding constituents taken separately with the current functions being approximately the same for each peak. This means that the species involved in the dimers are present in equimolar ratios.

All the complexes can be easily protonated and

thus quantitatively transformed into the corresponding more acidic forms. The course of such a titration of $Li[FeL_2]$ by H^+ ions generated from a Pd–H electrode,[17] monitored via recording the cyclic voltammograms, has been illustrated in Fig. 4. As the final result, the voltammogram is obtained having only the peaks for reduction of $FeCl_4^-$ (VII) and oxidation of the ligand (peak V). This means that a complete decomposition of the complex has been achieved. The same can be concluded on the basis of the corresponding UV spectra.

4-AMINOANTIPYRINE SCHIFF-BASE COMPLEXES OF LANTHANIDE AND URANYL IONS

G. SHANKAR, R. R. PREMKUMAR and S. K. RAMALINGAM*

Department of Inorganic Chemistry, School of Chemistry, Madurai Kamaraj University, Madurai 625021, India

(*Received* 28 *August* 1985; *accepted* 7 *October* 1985)

Abstract—Using a new tridentate ligand, acetylacetone-4-aminoantipyrine (AAP) complexes of lanthanide nitrates having the general formula $[Ln(AAP)_2](NO_3)_3$ (where Ln = Pr, Nd, Sm, Gd, Dy or Y) have been prepared. Uranyl complexes of salicylaldehyde-4-aminoantipyrine (SAAP) of general formulae $[UO_2(SAAP)_2](X)_2$ (where X = NO_3 or I) and $[UO_2(SAAP)_2(OAc)_2]$ have also been prepared. The complexes have been characterized by IR, electronic, NMR, conductivity and analytical techniques. While SAAP acts as bidentate ligand without using its hydroxyl group, AAP acts as tridentate ligand involving hydroxyl coordination. The covalency parameter δ has been calculated for the Pr and Nd complexes.

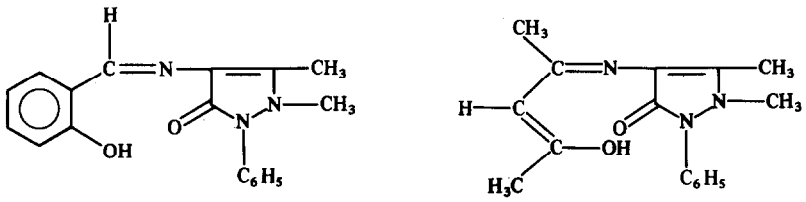
We have synthesized some new Schiff-base metal complexes of heterocyclic amines which are physiologically active and structurally interesting. Previously we reported[1] that in some uranyl Schiff-base complexes the NMR evidence pointed to the —OH group coordinating to the metal in a protonated form. This paper reports the isolation and structure elucidation of the complexes of the Schiff-base ligands salicylaldehyde-4-aminoantipyrine (SAAP) [Fig. 1(a)] and acetylacetone-4-aminoantipyrine (AAP) [Fig. 1(b)] with UO_2^{2+} and Ln^{3+} ions, respectively. The point of interest here is that both AAP and SAAP are capable of acting as bi- or tridentate ligands depending on whether or not the functional group —OH is involved in coordination.[2,3]

EXPERIMENTAL

Uranyl nitrate, uranyl acetate (BDH) and 4-aminoantipyrine (Fluka) were high-purity grade and used as such. An acetone solution of uranyl iodide was prepared metathetically from the nitrate. The lanthanide nitrates were prepared from their respective oxides. SAAP was prepared as reported earlier.[2]

Preparation of AAP

Ethanolic solutions of 4-aminoantipyrine (20.3 g, 0.1 mol) and acetylacetone (10 g, 0.1 mol) were refluxed together for 4 h over a steam bath. The excess solvent was removed by evaporation and the concentrated solution was cooled in an ice bath with stirring. The Schiff base (AAP) which separated out as a cream coloured powder was collected and dried in air (m.p. 136°C).



Preparation of uranyl complexes of SAAP

The uranyl salt (1 mmol and SAAP (2 mmol) were refluxed together in acetone over a steam bath for 1 h. The solution was cooled and the complex obtained was washed with acetone and dried over P_4O_{10} *in vacuo*.

Preparation of lanthanide complexes of AAP

An acetone solution of lanthanide nitrate (2 mmol) was added to an acetone solution of AAP (4 mmol), keeping the mixture stirred. The complex that separated out was allowed to stand for half an hour, filtered, washed with acetone and dried over P_4O_{10} *in vacuo*.

Fig. 1. Ligands used in the preparation of complexes.

Physical methods

Conductivity studies were carried out using a Toshniwal conductivity bridge, type CLO102A using DMF as solvent. The IR spectra of the ligands and complexes were recorded in the range 200–4000 cm^{-1} on a Perkin–Elmer 577 spectrophotometer using KBr disc technique. Electronic spectra of the complexes were recorded on a Bausch & Lomb spectronic 2000 instrument in the range 300–850 nm using DMF as solvent. PMR spectra were recorded on a Perkin–Elmer R32 spectrophotometer operating at 90 MHz using TMS as internal standard and DMSO-d_6 as solvent. C, H, N and metal analyses were performed by the usual methods. The elemental analyses data for the complexes along with molar-conductance values are given in Table 1.

RESULTS AND DISCUSSION

Uranyl complexes

The complexes are stable, non-hygroscopic, orange-yellow coloured solids. They are insoluble in acetone, ethanol, chloroform, benzene etc.; but are soluble in DMF and DMSO.

The IR spectral band assignments for SAAP and its complexes are shown in Table 2. The ligand has bands around 3000 cm^{-1} [ν(OH)], at 1650 cm^{-1} [ν(C=O)] and at 1585 cm^{-1} [ν(C=N)]. In the complexes, the hydroxyl frequency appears at the same region as in the ligand. The carbonyl frequency occurs around 1610 cm^{-1} and the azomethine frequency around 1560 cm^{-1}, indicating that these two groups are involved in bonding. In the acetate

	(41.8)	(4.1)	(13.7)	(17.6)	
$[Y(AAP)_2](NO_3)_3$	45.4	4.5	14.9	14.4	210
	(45.5)	(4.5)	(14.9)	(10.4)	

Table 2. Important IR bands (cm^{-1}) of uranyl complexes[a]

Compound	ν(OH) w	ν(C=O) s	ν(C=N) s	ν_{anion} s
SAAP	2920–3040	1650	1580	—
$[UO_2(SAAP)_2](NO_3)_2$	2920–3040	1610	1560	1380, 1040, 835
$[UO_2(SAAP)_2]I_2$	2920–3040	1600	1560	—
$[UO_2(SAAP)_2(OAc)_2]$	2920–3040	1600	1560	1650

[a] w = weak, s = strong.

complex, a sharp band at 1650 cm^{-1}, which is absent in the nitrate complex, confirms the ν(C=O) of acetate, indicating thereby the unidentate coordination of acetate ion.[4] For the nitrate complex, bands at 1380, 1040 and 835 cm^{-1} correspond to ν_3, ν_1 and ν_2 frequencies of the free nitrate ion.[5]

The conductivity data of the nitrate and iodide complexes show them to be 1:2 electrolytes,[6] while the acetate complex behaves as a non-electrolyte. The elemental analyses are in agreement with a 1:2 stoichiometry between metal and ligand. Judging on these lines, SAAP can be considered to act as a neutral bidentate ligand.

The IR bands due to the uranyl group appear at 920 cm^{-1} [ν_{as}(U—O)], 810 cm^{-1} [ν_s(U—O)] and 250 cm^{-1} (O—U—O bend). These observations indicate that the UO_2 moiety is virtually linear.[7]

The electronic spectra of the nitrate and iodide complexes show absorption bands at 302, 313, 328 (sh) and 433 nm (sh), while that of the acetate complex show bands at 302 and 313 nm, attributable to charge-transfer transitions.[1]

From the foregoing discussion the complexes can be formulated as $[UO_2(SAAP)_2](NO_3)_2$, $[UO_2(SAAP)_2]I_2$ and $[UO_2(SAAP)_2(OAc)_2]$, indicating a probable coordination number of 6, 6 and 8, respectively, for the U(VI) ion in the complexes.

Thus, in contrast to many earlier reports on hydroxyl coordination in Schiff-base complexes of the uranyl ion, the present one appears unique in that the hydroxyl group is not involved in coordination.

Lanthanide complexes

The complexes are stable and non-hygroscopic solids, insoluble in acetone, alcohol, benzene, chloroform etc.; but soluble in DMF and DMSO.

The IR spectral band assignments for the ligand and complexes are shown in Table 3. The ligand exhibits bands at 3180 cm^{-1} [ν(OH)], 1680 cm^{-1} [ν(C=O)] and 1620 cm^{-1} [ν(C=N)]. In the spectra of the complexes, these appear at 3200, 1615–1625 and 1570–1580 cm^{-1}, respectively, indicating thereby that the ligand functions as a neutral tridentate ligand. This is corroborated by PMR spectra wherein the —OH peak appears at 13.45 δ for the ligand and at 13.50 δ for the Y complex.

In the IR spectra of the Pr and Nd complexes, the band at 1710 cm^{-1} is difficult to account for. The slight increase in —OH frequency in the complexes may be due to an increase in the C—O bond order.[8,9] The complexes exhibit bands at 1375–1380 and 805–810 cm^{-1} which are assigned to ν_3 and ν_2 vibrations of ionic nitrate. The conductivity data of the

Table 3. Important IR bands (cm^{-1}) of lanthanide complexes[a]

Compound	ν(OH) m	ν(C=O) m	ν(C=N) m	$\nu_3(NO_3)$ s	$\nu_2(NO_3)$ s
AAP	3180	1680	1620	—	—
$[Pr(AAP)_2](NO_3)_3$	3200	1580	1580	1380	815
$[Nd(AAP)_2](NO_3)_3$	3220	1580	1580	1380	815
$[Sm(AAP)_2](NO_3)_3$	3200	1570	1570	1375	805
$[Gd(AAP)_2](NO_3)_3$	3220	1580	1580	1380	810
$[Dy(AAP)_2](NO_3)_3$	3220	1580	1580	1380	810
$[Y(AAP)_2](NO_3)_3$	3200	1580	1580	1375	805

[a] m = medium, s = strong.

complexes show them to be 1:3 electrolytes. The complexes can be formulated as $[Ln(AAP)_2](NO_3)_3$.

The electronic absorption spectra of the Pr and Nd complexes show characteristic sharp bands. The assignments are as follows:

Pr complex [wavelength (nm)]:
$3H_4 \rightarrow 3P_2$ (443); $3P_1$ (471), $3P_0$ (482); $^1D_2$ (591).

Nd complex [wavelength (nm)]:
$^4I_{9/2} \rightarrow {}^2G_{9/2}$ (512); $^4G_{7/2}$ (526); $^4G_{5/2}$, $^2G_{7/2}$ (582); $^4S_{3/2}$ (738); $^4F_{7/2}$ (747); $^4F_{5/2}$ (800).

Sinha's[10] covalency parameter (δ) values calculated for these two complexes are +0.30 for the Pr complex, and −0.39 for the Nd complex. This leads to the inference that the Pr complex exhibits a certain degree of covalency.

The analytical data of the complexes are in good agreement for 1:2 stoichiometry. The data also indicate water molecules to be absent, which is also evident from PMR spectrum where no peak attributable to water proton is found. Thus the lanthanide ion can be said to have a coordination number of 6 in these complexes.

COMPLEXES OF LANTHANIDE PERCHLORATES WITH 4-*N*-(2′-HYDROXY-1′-NAPHTHYLIDENE)AMINOANTIPYRINE

P. K. RADHAKRISHNAN

Department of Chemistry, University College, Trivandrum 695034, India

(*Received* 18 *July* 1985; *accepted* 7 *October* 1985)

Abstract—Lanthanide perchlorate complexes with 4-*N*-(2′-hydroxy-1′-naphthylidene) aminoantipyrine [HNAAP(HL)] of types $[Ln(L)_2ClO_4]$ (where Ln = La, Pr, Nd or Sm) and $[Ln(HL)_4](ClO_4)_3$ (where Ln = Gd, Tb, Dy, Ho or Y) have been synthesized and characterized. HNAAP acts as a monovalent terdentate ligand in the complexes of the lighter lanthanides and as a neutral bidentate ligand in the complexes of the heavier lanthanides. The perchlorate group is coordinated only in the complexes of the lighter lanthanides.

As part of our studies on lanthanide complexes of pyrazol-5-one type ligands,[1–5] some complexes of lanthanide perchlorates with 4-*N*-(2′-hydroxy-1′-naphthylidene)aminoantipyrine [HNAAP(HL)] were synthesized and characterized. The present complexes include those of La(III), Pr(III), Nd(III), Sm(III), Gd(III), Tb(III), Dy(III), Ho(III) and Y(III). Of these, the perchlorate group and the phenolic oxygen of the ligand are coordinated to the lighter lanthanides, viz. La(III), Pr(III), Nd(III) and Sm(III).

EXPERIMENTAL

Reagents

The perchlorates of La, Pr, Nd, Sm, Gd, Tb, Dy, Ho and Y were prepared from the respective oxides (99.9% pure) as reported earlier.[1] The ligand, HNAAP, was prepared from 4-aminoantipyrine and 2-hydroxy-1-naphthaldehyde by the method reported earlier.[6]

Preparation and analysis of the complexes

La, Pr, Nd *and* Sm *complexes.* Solutions of the perchlorate of La, Pr, Nd or Sm (0.2 mol) and HNAAP (0.4 mol) in hot dry acetone were mixed and the resulting solution was refluxed on a water bath for 1 h. The precipitated complex was filtered, washed several times with hot acetone and dried *in vacuo* over P_4O_{10}.

Gd, Tb, Dy, Ho *and* Y *complexes.* Solutions of the perchlorate of Gd, Tb, Dy, Ho or Y (0.2 mol) and HNAAP (1.2 mol) in hot dry acetone were mixed and the resulting solution was kept under reflux for about 1 h. The black viscous mass obtained on concentrating the solution was washed several times with hot benzene to remove the excess ligand. The separated complex was recrystallized by dissolving it in the minimum amount of dry acetone and stirring vigorously with dry diethylether. It was dried *in vacuo* over P_4O_{10}.

The complexes were analysed for their metal and perchlorate contents by the conventional methods.[7,8]

Physical methods

The physical methods used in the present investigation were the same as described earlier.[2] The solid state electronic spectra of the complexes were recorded in the range 350–850 nm on a Shimadzu UV-200S spectrophotometer by reflectance technique using MgO as the reference material.

RESULTS AND DISCUSSION

All the complexes are non-hygroscopic solids. The complexes of La, Pr, Nd and Sm are insoluble in almost all the common solvents. However, the complexes of Gd, Tb, Dy, Ho and Y are soluble in acetone, acetonitrile, methanol, ethanol and nitrobenzene, and insoluble in benzene, carbon tetrachloride and chloroform. The molar-conductance

values of the complexes of Gd, Tb, Dy, Ho and Y in nitrobenzene (Table 1) indicate 1:3 electrolytic behaviour.[9] Thus the complexes may be formulated (Table 1) as $[Ln(L)_2ClO_4]$ (where Ln = La, Pr, Nd or Sm) and $[Ln(HL)_4](ClO_4)_3$ (where Ln = Gd, Tb, Dy, Ho or Y).

The IR spectra (Table 2) of the complexes of La, Pr, Nd and Sm indicate that HNAAP bind the metal through carbonyl oxygen, azomethine nitrogen and phenolic oxygen (deprotonated): the ν(C=O) and ν(C=N) bands of the complexes are considerably lower than the corresponding ones (around 1635 and 1590 cm^{-1}, respectively) of the free ligand, and the ν(O—H) band of HNAAP (around 3440 cm^{-1}) is absent and the ν_a(C—O) band of HNAAP (around 1310 cm^{-1}) is shifted to higher frequency in the complexes.[10,11] However, in the complexes of Gd, Tb, Dy, Ho and Y, HNAAP is coordinated through the carbonyl oxygen and azomethine nitrogen: the ν(C=O) and ν(C=N) bands are shifted to lower frequency and the ν(O—H) and ν_a(C—O) bands are not appreciably shifted.[10,11] The IR spectra (Table 2) also show the presence of a unidentate perchlorate group in the complexes of La, Pr, Nd and Sm, and an ionic perchlorate group in the complexes of Gd, Tb, Dy, Ho and Y in accordance with the literature.[12]

The electronic spectra of the complexes show that most of the *f–f* bands of the lanthanide ions are obscured in these complexes by the very strong ligand to metal charge-transfer band. However, in the Pr and Nd complexes the following *f–f* bands are observed, the tentative assignments of which are given in brackets:

Pr complex:
16.84 kK ($^3H_4 \rightarrow {}^1D_2$);

Nd complex:
18.94 kK ($^4I_{9/2} \rightarrow {}^4G_{7/2}$); 17.07 kK ($^4I_{9/2} \rightarrow {}^4G_{5/2}, {}^2G_{7/2}$); 14.66 kK ($^4I_{9/2} \rightarrow {}^4F_{9/2}$); 13.41 kK ($^4I_{9/2} \rightarrow {}^4F_{7/2}$); 12.47 kK ($^4I_{9/2} \rightarrow {}^2H_{9/2}$).

An appreciable red shift is observed in these *f–f* bands compared to the position in the aquo ion.[13,14] The Sinha covalency parameters[14] calculated for these two complexes ($\delta = 1.194$ for the Pr complex and 1.133 for the Nd complex) indicate a reasonable covalency for the lanthanide–ligand bond. Further, from the shape of the hypersensitive $^4I_{9/2} \rightarrow {}^4G_{5/2}, {}^2G_{7/2}$ transition of Nd(III), a coordination number of 7[15,16] may be assigned to the complex $[Nd(L)_2ClO_4]$.

The magnetic data (Table 1) indicate that all the complexes, except those of La and Y, are paramagnetic as expected. The observed magnetic moments agree closely with the Van Vleck values[17] in all these complexes which shows that the 4*f* electrons do not participate in bonding.

The thermogravimetric (TG) analysis of the complexes (Table 1) shows that the complexes of La, Pr, Nd and Sm are more stable (up to ~300°C) than the complexes of Gd, Tb, Dy, Ho and Y (up to ~240°C). The La and Pr complexes undergo decomposition in two stages as denoted by the DTG peaks around 350 and 460°C. The Nd and Sm complexes undergo a three-stage decomposition as shown by the DTG peaks around 350, 400 and 480°C. The complexes of Gd, Tb, Dy, Ho and Y undergo decomposition in three stages as represented by the DTG peaks around 295–320, 415–445 and 490–505°C. The decomposition of all the complexes is complete in the range 520–580°C and the respective stable rare-earth oxides are formed.

SYNTHESIS AND STRUCTURAL INVESTIGATIONS OF SOME ALKYLAMINE PENTACYANOFERRATE(II) COMPLEXES

D. V. PARWATE and A. N. GARG*

Department of Chemistry, Nagpur University, Nagpur 440 010, India

(*Received* 25 *April* 1985; *accepted after revision* 9 *October* 1985)

Abstract—A series of alkylamine pentacyanoferrate(II) complexes, $Na_3[Fe(CN)_5L]\cdot(H_2O)_x$, where L = $(CH_3)_2NH$, $(C_2H_5)_2NH$, $(C_3H_7)_2NH$, $(C_4H_9)_2NH$, $(C_6H_5)_2NH$, $(C_2H_5)_3N$, $(C_4H_9)_3N$ or $C_6H_{11}NH_2$, were synthesized and characterized by analysis, magnetic, IR and Mössbauer spectroscopic studies. Characteristic C≡N and Fe—C≡N vibrational frequencies were found to be affected by the nature of the substituent. Mössbauer spectra exhibited a two-line quadrupole doublet with isomer shifts (δ) −0.04 to 0.49 mm s^{-1} (relative to sodium nitroprusside) and quadrupole splitting (ΔE_Q) of 0.73–1.92 mm s^{-1}. A correlation of δ vs ΔE_Q has been attempted and the sign of the electric field gradient predicted. Bonding characteristics seem to change from simple mono- and dialkylamines to bulky di- and trialkylamines in pentacyanoferrate(II) complexes.

Pentacyanoferrate(II) complexes, $[Fe(CN)_5L]^{3-}$, have long been known.[1,2] Recently, several workers have reported the synthesis and structural investigations of such complexes with various substituents (L), such as H_2O, NH_3, CO, NO_2^-, SO_3^{2-}, Py, NO^+, $P(C_6H_5)_3$, POX_3, DMSO, pyrazine, $N_2H_5^+$, N_2, enH^+, RNH_2 etc.[3–18] In most of these complexes, bonding characteristics were investigated with regard to the σ-donor and π-acceptor nature of the ligands.[4–18] The Mössbauer spectrum of $Na_3[Fe(CN)_5NH_3]\cdot H_2O$ was first reported in 1963 by Fluck *et al.*[4] NMR studies have also been carried out on the nature and bonding in pentacyanoferrate(II) complexes.[19,20] Recently, some unusual pentacyanoferrate complexes were reported and metal–ligand charge transfer band positions were correlated with isomer shift (δ) and quadrupole splitting (ΔE_Q) values.[21,22] Rasmussen and Meyers[23] have studied pyrazine-substituted complexes and shown the sensitivity of ΔE_Q to lowered symmetry to be similar to the case of pyrrolidine-substituted complexes.[24] We have synthesized some new pentacyanoferrates(II), $Na_3[Fe(CN)_5L]\cdot(H_2O)_x$, where L = $(CH_3)_2NH$, $(C_2H_5)_2NH$, $(C_3H_7)_2NH$, $(C_4H_9)_2NH$, $(C_6H_5)_2NH$, $(C_2H_5)_3N$, $(C_4H_9)_3N$ or $C_6H_{11}NH_2$, and studied their magnetic, and IR and Mössbauer spectroscopic behaviour. An attempt has also been made to correlate the spectroscopic data with the bonding characteristics of the ligand L *vis-à-vis* CN ligands. The sign of the electric field gradient (EFG) is also predicted from the δ vs ΔE_Q correlation plot.

EXPERIMENTAL

All reagents used were AnalaR (BDH), GR (S. Merck) or of high-purity grade (Koch-Light, U.K., and Fluka, Switzerland) except for the 40% solution of dimethylamine. Solvents were distilled and dried before use. The complexes were prepared following the procedures described in the literature.[2,3,25]

Preparation of the complexes

A solution containing 3 g sodium nitroprusside (SNP) (1 mol) and 2 g sodium acetate was cooled and mixed with an ice-cold solution of the respective amine (20–25 cm^3) in ethanol. The solution was continuously stirred and additional amounts of amine were added until a negative test for nitroprusside was obtained. The mixture was kept in a freezing mixture for varying times (a few hours to a day) during which the complex separated out:

$$Na_2[Fe(CN)_5NO] + CH_3COONa + \text{amine (L)} \rightarrow Na_3[Fe(CN)_5L] + CH_3COOH.$$

* Author to whom correspondence should be addressed.

Complete precipitation of the compound was effected by the addition of cold absolute ethanol. The complexes were filtered and dried *in vacuo* over fused $CaCl_2$. Since the complexes are unstable on prolonged standing, all the measurements were carried out within a week.

The complexes were characterized by C, H and N analysis using a Coleman Analyzer at USIC, Nagpur. The Fe content was estimated by first decomposing the complex and then measuring spectrophotometrically using 1,10-phenanthroline reagent.[26]

Physical measurements

The Mössbauer spectra were recorded at room temperature on a transducer-driven Mössbauer spectrometer (ECIL, Hyderabad) in constant-velocity mode. An ~5 mCi $^{57}Co(Rh)$ source (Amersham International, U.K.) was used. The spectrometer was calibrated using natural iron foil (25 μm).[27] SNP was used as a standard and all the δ values are reported with respect to (wrt) SNP. Spectral lines were assumed to have a Lorentzian line shape.

IR spectra were recorded on a SPECORD 75 IR spectrophotometer in the range 4000–400 cm^{-1} using a Nujol medium. Magnetic moments were calculated using the Gouy balance method and $Hg[Co(SCN)_4]$ as a standard at room temperature.

RESULTS

The complexes are coloured and obtained in low yields. The analytical data of C, H, N and Fe for all the complexes (Table 1) agree well with the proposed molecular formula. Table 2 gives the characteristic IR frequencies. These assignments were made on the basis of the literature where similar types of complexes have been studied.[11,14,28] All of the complexes exhibit a well-resolved quadrupole doublet. Typical Mössbauer spectra of diethyl and dibutylamine substituted complexes are shown in Fig. 1. The Mössbauer parameters δ and ΔE_Q along with linewidths are given in Table 3. Partial isomer shift (pis) and partial quadrupole splitting (pqs) values for the new ligands were calculated on the basis of the point charge formalism, assuming an additivity concept[29] and substituting pis = 0.01 and pqs = −0.84 mm s^{-1} for the CN^- ligands.[8] These are also given in Table 3, along with magnetic moments calculated from magnetic susceptibility measurements.

DISCUSSION

If one of the CN^- ligands in hexacyanoferrate(II), $[Fe(CN)_6]^{4-}$, is substituted by a neutral ligand L to give $[Fe(CN)_5L]^{3-}$, the octahedral geometry remains unaffected but the symmetry is lowered from O_h to approximately C_{4v}. MO calculations of the

nitroprusside anion, $[Fe(CN)_5NO]^{2-}$, have shown that a tetragonal distortion along the axial ligand causes further splitting of t_{2g}-obitals into d_{yz}, d_{zx} and d_{xy} (also called e and b_2).[30] The X-ray crystal structure[31] of sodium nitroprusside shows that the ligands NO and *trans* CN^- are approximately collinear with the central Fe atom slightly displaced in the direction of the NO group from the plane of four pseudo-equivalent CN groups. Braga *et al.*[15] have performed multiple scattering calculations for the isoelectronic iron(II) pentacyanides $[Fe(CN)_5NO]^{2-}$, $[Fe(CN)_5CO]^{3-}$ and $[Fe(CN)_5N_2]^{3-}$, and calculated covalency effects due to 3*d* and 4*p* populations (π-back donation and σ-donation, respectively), electron densities and the EFG at the iron nucleus, which were experimentally verified. In the present study the $[Fe(CN)_5L]^{3-}$ complexes are assumed to be similar to the nitroprusside except that L is a σ-bonding ligand without any possibility of $d_\pi \rightarrow p_\pi$ back donation.

[a] Wrt SNP.

There seems to be a minor change, depending on the nature of the sixth ligand L. Therefore, an asymmetry (or EFG at the Fe nucleus) is generated in all the complexes, primarily due to the ligand contribution with the possibility of a small contribution from asymmetric expansion of the e and b_2 electrons. We have observed small magnetic moments, 0.85–1.30 BM, which may be due to a contribution from the orbital motion of electrons or ligands.

IR spectra

Various vibrational modes were assigned by comparison with those of other monosubstituted pentacyanoferrate(II) complexes[11,14,18] and other literature references.[28,32] At least three ν(CN) stretching modes were observed in the range 2180–2010 cm^{-1} in accordance with the group theoretical prediction (i.e. A_1+E) assuming a C_{4v} point group for the $[Fe(CN)_5L]^{3-}$ moiety. Another very important characteristic mode is due to Fe—C≡N bending, δ(Fe—CN) being observed in the range 550–650 cm^{-1}. A very weak band, observed at ~480 cm^{-1}, has been assigned to ν(Fe—C) stretching vibrations in accordance with the assignments of Fluck *et al.*[14] The stretching mode of Fe—N could not be assigned as this is expected to be observed at ~250 cm^{-1}.

Intense broad peaks in the region 3600–3400 cm^{-1} arose mainly due to weakly bonded water molecules in the lattice. The exact assignments of various bands in this region is not possible, due to several overtones and combinations of bending vibrations. Similarly a sharp to medium intensity band at ~1600 cm^{-1} has been assigned to a bending mode of H_2O molecules occupying interstitial positions.

An interesting feature of the characteristic ν(CN) and δ(Fe—CN) vibrational frequencies is that these could be divided into two well-defined groups, one observed at ~2020 and 550 cm^{-1} for $(CH_3)_2NH$-, $(C_2H_5)_2NH$-, $(C_3H_7)_2NH$- and $C_6H_{11}NH_2$-substituted complexes, and another at ~2140 and 650 cm^{-1} for $(C_2H_5)_3N$-, $(C_4H_9)_2NH$-, $(C_4H_9)_3N$- and $(C_6H_5)_2NH$-substituted complexes. This shifting by ~100 cm^{-1} in both cases may be indicative of a difference in the bonding of the alkylamine group with $[Fe(CN)_5]^{3-}$, dividing them into two groups, group 1 and group 2, respectively. It may be noted that the Fe—C stretching frequencies remain totally unaffected by the substitution. Perhaps the Fe—N stretching frequencies could have correlated well and given some insight about any possible change in bonding characteristics but were not available to us. Earlier, also, several workers[17,18] have correlated the variation in the CN stretching frequency with the nature of the sixth ligand and the change in its bonding characteristics.

Mössbauer parameters

The EFG (V_{zz}) may be represented by:

$$V_{zz} = (1-\gamma_\infty)(V_{zz})_L + (1-R)[(V_{zz})_{CF} + (V_{zz})_{MO}],$$

where $(V_{zz})_{CF}$, the contribution of the aspherical population of the d-orbitals due to crystal field splitting, will be zero for the Fe(II) low-spin (t_{2g}^6) configuration. Thus, any observed ΔE_Q in such compounds is due to $(V_{zz})_L$ and the aspherical electron distribution in the valence molecular orbitals $(V_{zz})_{MO}$. The latter may arise due to anisotropic bond properties,[33] as in the case of $[Fe(CN)_5L]^{3-}$. Here the metal-to-ligand bond is influenced by both a σ- and a π-interaction, and their

relative strengths compared with CN^-. If L is a stronger σ-donor than CN^-, $N(d_{z^2}) > N(d_{x^2-y^2})$ (where N represents the electron population in respective d-orbitals) and a negative contribution to $(V_{zz})_{MO}$ may result along M—L. However, if L is a more effective π-acceptor than CN^-, $N(d_{xy}) > [N(d_{xz}) + N(d_{yz})]/2$, because of a more pronounced charge delocalization from M → L (i.e. $d_\pi \rightarrow p_\pi$) and a positive contribution to $(V_{zz})_{MO}$ is expected. The net effect is to make $(V_{zz})_{MO}$ more negative with increasing $(\sigma - \pi)$.

All the complexes exhibit a well-resolved quadrupole doublet with $\delta = -0.04$ to 0.44 mm s^{-1} (wrt SNP) and $\Delta E_Q = 0.73$–1.92 mm s^{-1}. The δ values are characteristic of low-spin Fe(II) in an octahedral geometry[8,32] and a decrease in the order

$$(CH_3)_2NH > (C_2H_5)_2NH > (C_3H_7)_2NH > (C_6H_5)_2NH > (C_4H_9)_2NH$$

for the dialkylamine-substituted complexes. For the two trialkylamine-substituted complexes studied here, δ values are very low, and for the cyclohexylamine-substituted complex it is almost equal to that for the dialkylamine-substituted complexes. It is known that, on further substitution with bulky alkyl groups in NH_3, its basic character changes (due to hyperconjugation as in trialkylamine), resulting in an increase in electron density and hence decreasing δ values. For mono-, di- and tributylamine-substituted complexes, δ values were found to be 0.28, −0.04 and 0.05 mm s^{-1} (wrt SNP), which supports the assumption that the basic character of amines may affect the σ-donor property of the amine ligands. A cursory look at the δ values in Table 3 also divides the ligands into two groups. Group 1, consisting of $(CH_3)_2NH$-, $(C_2H_5)_2NH$-, $(C_3H_7)_2NH$- and $C_6H_{11}NH_2$-substituted complexes, has higher δ values; and group 2, consisting of $(C_2H_5)_3N$-, $(C_4H_9)_2NH$-, $(C_4H_9)_3N$- and $(C_6H_5)_2NH$-substituted complexes, has lower δ values.

As already described, a strong asymmetry is generated due to the presence of the odd ligand L, resulting in an observable ΔE_Q. Earlier it had been observed in a study of several amine- and monoalkylamine-substituted complexes that ΔE_Q was ~0.80 mm s^{-1}, which is insignificantly affected by alkyl group substitution.[10–17] For the cyclohexylamine-substituted complex, $\Delta E_Q = 0.82 \pm 0.04$ mm s^{-1}. It was expected that, with a flip-flop process (i.e. chair–boat) in the C_6H_{11} group, the distortion would be larger, but that did not seem to happen. It seems that with monalkylamines, irrespective of the nature of the alkyl group, the observed $\Delta E_Q \leqslant 1.0$ mm s^{-1}. In the present study of several di- and trialkylamine (with bulky alkyl groups) substituted complexes, a wide range of ΔE_Q values (0.73–1.92 mm s^{-1}) has been observed. For dialkylamine-substituted complexes, ΔE_Q values increase in the order

$$(CH_3)_2NH < (C_2H_5)_2NH \sim (C_3H_7)_2NH < (C_6H_5)_2NH < (C_4H_9)_2NH.$$

For the dimethylamine-substituted complex, our ΔE_Q value is comparable to that observed by Monaghan and Fanning.[10] The increase in ΔE_Q values, though not very regular, suggests increasing distortion in geometry with substitution of heavier alkyl groups. The two trialkylamine [viz. $(C_2H_5)_3N$ and $(C_4H_9)_3N$] substituted complexes exhibited ΔE_Q values of 1.77 and 1.92 mm s^{-1}, respectively, indicating the largest distortions. Again, the observed ΔE_Q values clearly divide the ligands into two well-defined groups. For group 1 ligands, ΔE_Q is ~0.80 mm s^{-1}, and for group 2 ligands it is ~1.80 mm s^{-1}, which is even higher than that observed for SNP, where strong π-bonding has been suggested. It is further noticed that group 1 ligand complexes exhibit higher δ and low ΔE_Q values while group 2 complexes yield lower δ and high ΔE_Q values.[34] Therefore, it may be quite possible that some sort of change in bonding characteristics may take place from group 1 to group 2 ligands, which may be responsible for more than doubling the ΔE_Q values. It is observed that the distinct ranges of δ and ΔE_Q values for groups 1 and 2, correlating well with C≡N stretching and Fe—C≡N bending vibrational frequencies, may be due to distinct differences between the bonding characteristics of groups 1 and 2. A plausible way of looking at this is that the bonding characteristics of the CN ligands *trans* to alkylamine L may be affected by substitution with heavier alkyl groups. According to Ballhausen and Gray,[35] in all tetragonally distorted complexes of MX_5L type almost all the π-bonding is axially directed and planar π-orbitals remain non-bonded. It is quite possible that d_π-orbitals (d_{yz} and d_{zx}) may be pushed by the bulky alkyl groups, as a result of which the Fe atom may become slightly displaced away from the plane containing the four CN^- towards the axial CN^-, *trans* to L, and the π-bonding character may increase. If π-back donation in *trans* CN is increased with the substitution of a heavier alkyl group then either ν(CN) or δ(Fe—CN) is likely to increase in accordance with our observation. This is similar to increased π-bonding character towards the NO ligand in SNP, where lifting of Fe by 0.183 Å has been confirmed.[31] This slight push of the Fe atom out of the plane can explain the large ΔE_Q values for group 2 ligands quite well.

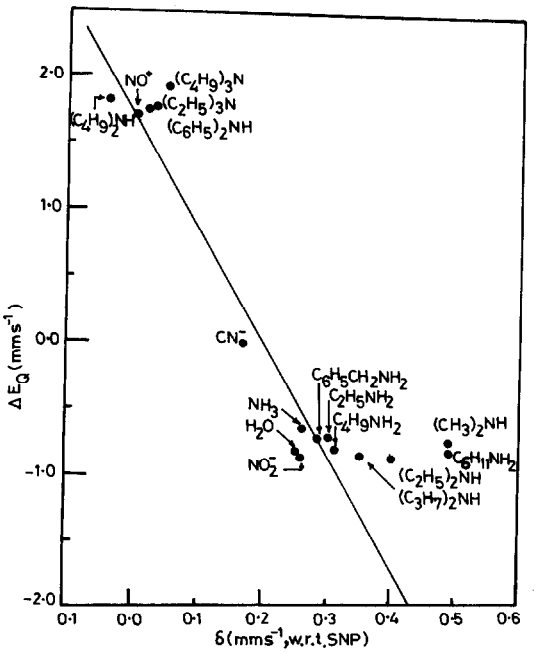

Fig. 2. Correlation of isomer shift (δ) vs quadrupole splitting (ΔE_Q) values in some monosubstituted pentacyanoferrate(II) complexes,

$$Na^+[Fe(CN)_5L^{n-}]^{-3\pm n}\cdot(H_2O)_x.$$

Correlation of δ and ΔE_Q

Such correlations have been extensively used for elucidating structure and bonding characteristics,[8] the sign of the EFG[36,37] and qualitatively separating σ-donor and π-acceptor characteristics.[38] According to this correlation, the sign of the EFG for some isostructural compounds could be predicted provided we know it for some other similar compounds by independent experimental methods.[39] A plot of δ vs ΔE_Q for

$$Na^+[Fe(II)(CN)_5L^n]^{-3+n}\cdot(H_2O)_x,$$

where L = NO^+-, CO-, H_2O-, NH_3-, NO_2^-- or SO_3^{2-}-substituted mono-, di- and trialkylamines, is shown in Fig. 2. It is observed that a linear correlation is obtained only if a positive sign for the EFG is assumed for $(C_2H_5)_3N$-, $(C_4H_9)_2NH$-, $(C_4H_9)_3N$- and $(C_6H_5)_2NH$-, and a negative sign for $(CH_3)_2NH$-, $(C_2H_5)_2NH$-, $(C_3H_7)_2NH$- and $C_6H_{11}NH_2$-substituted complexes. Also, these predictions are in agreement with those obtained from pis and pqs values, which are also indicative of the relative importance of σ- and π-bonding characteristics.[8,34] However, the sign of the EFG needs to be experimentally verified by a crystal orientation or a magnetic perturbation method.

(*Received* 12 *September* 1985; *accepted* 23 *October* 1985)

Abstract—A rigorous procedure to evaluate the solubility product constants of very slightly soluble hydrazinedithiocarboxylate complexes is reported, using the competitive effect of EDTA to dissolve the insoluble chelates. A previous knowledge of the stability constants of the soluble complexes involved as well as an accurate control of the pH and concentration of the competitive ligand is required. The solubility products of 2-methylhydrazinedithiocarboxylate and 3,3-dimethylhydrazinedithiocarboxylate complexes with Ni(II), and 3-methyl-3-phenylhydrazinedithiocarboxylate complexes with Ni(II) and Cu(II), have been determined at 25°C and $I = 0.01$ M from solubility data obtained by atomic absorption measurements. The values determined when the method is applied to the Ni–dimethylglyoxime system are in accordance with those found in the literature, giving confidence on the reliability of the procedure proposed.

An increasing number of papers dealing with methods of synthesis and studies on the structural properties of hydrazinedithiocarboxylates (dithiocarbazates) are coming to light.[1] However, only a few works giving information on the equilibrium of these compounds with hydronium or metal ions are reported. Apart from Izquierdo *et al.* who have recently published the stability constants of several *N*-substituted dithiocarbazate complexes with hydronium ions,[2] and Cu(II) and Ni(II) in aqueous solution,[3] only Byr'ko *et al.*[4] have reported values on the protonation constants of the hydrazinium dithiocarbazate. No information concerning the solubility equilibria of dithiocarbazate complexes has been found.

In previous work[2] it was shown that dithiocarbazates react with many transition-metal ions to give very sparingly soluble complexes. Several methods to determine the solubility product constants could be applied.[5] One of the most important takes advantage of the competition established between the metal ion and the proton to be bound to the ligand: however, it cannot be employed in the present study because of the instability of the dithiocarbazates at low pH values and the small influence of the acidity on the complex formation. The simpler evaluation of ion concentrations in solution coming from the solubilization of the pure solid chelates in a given volume of water is not recommended owing to the small solubility of the dithiocarbazate complexes under study, which would give rise to extremely low concentrations of both free ligand and metal ion in solution.

In the present paper, the determination of the

* Author to whom correspondence should be addressed.

solubility product constants of 2-methyldithiocarbazate and 3,3-dimethyldithiocarbazate complexes with Ni(II), and 3-methyl-3-phenyldithiocarbazate complexes with Ni(II) and Cu(II), is described. The method is based on the competitive effect between EDTA and the ligand under study to bind the metal ion which forms the insoluble chelate initially. In this way, a sufficient amount of the complexes is dissolved and the solubility can be evaluated by measuring the overall concentration of metal ion in solution by atomic absorption spectroscopy (AAS).

The reliability of the method has been assessed by applying it to the Ni–dimethylglyoxime complex, whose solubility product constant has long been reported.[6,7]

EXPERIMENTAL

Reagents

To 50 cm^3 of an 0.1 M aqueous nitrate solution of each metal ion were added, dropwise and with constant stirring, 120 cm^3 of 0.1 M aqueous solutions of the dithiocarbazates. The precipitates were collected in a No. 4 porosity sintered-glass crucible, washed with water and ethanol and dried at 110°C until constant weight. Elemental analyses showed a complete agreement between required and found values, corresponding to a formula $M(DTC)_2$, where DTC stands for the neutral ligand. A standard procedure for the precipitation of the Ni–dimethylglyoxime complex was followed.[8]

Measurements

A Beckman 4260 IR spectrophotometer (KBr disks) was used to record the IR spectra and a Cahn RG Electrobalance TGS-1 (Perkin–Elmer) was used to obtain the thermogravimetric curve. The complexes are stable up to 255°C.

All pH measurements of the filtered solutions were carried out in a water-jacketed vessel maintained at 25 ± 0.1°C with a Radiometer PHM 64 Research pH-meter along with a G-202B glass electrode and a K-401 saturated calomel Radiometer electrode, standardized with buffer solutions of pH 6.865 and 9.180 (25°C) according to the NBS.[9]

The analytical metal ion concentrations in aqueous solution were determined by AAS with an Instrumentation Laboratory Inc. IL 551 spectrophotometer.

Determination of solubility product constants

To similar amounts of the slightly soluble complexes contained in five series (five members each) of 50-cm^3 volumetric flasks were added different known amounts of the standardized EDTA (disodium salt) solutions and the same volume of phosphate buffer solution ($I = 0.01$ M, pH = 7.70) in each series. In another five series (five members each) of 50-cm^3 flasks containing solid complexes were added the same known amount of standardized EDTA (disodium salt) solution and different buffer solutions ($I = 0.01$ M, pH = 6.40–8.90) in each series. Therefore the two available experimental parameters (pH and free competitive ligand concentration) were varied. The flasks were filled with millipore distilled water, placed in a thermostatic bath at 25 ± 0.1°C and smoothly shaken. Once the equilibrium for each complex had been reached (after at least 76 h), the suspensions were filtered off, the pH measured exactly and the total concentration of metal ion determined in the clear solutions by AAS.

Buffer solutions ($I = 0.01$ M) have been prepared as described by Perrin and Dempsey.[10] The pH range was set between 6.40 and 8.90 in order to avoid reagent decomposition in highly acidic media and the appreciable formation of metallic hydroxo-complexes in basic media. Phosphate and Tris were employed to prepare buffer solutions due to the formation of very weak complexes with Ni(II) and Cu(II).[11]

RESULTS AND DISCUSSION

Polyaminocarboxylic acids constitute one of the best groups of complexing agents. Moreover, it has been reported that they do not form mixed complexes with dithiocarbamate ligands:[12] hence, EDTA has been chosen as a competing ligand because, in addition to the previous advantages, its equilibria with both hydronium and metal ions has been extensively studied.

In the presence of an adequate concentration of EDTA, the slightly soluble dithiocarbazate complexes can be partially dissolved, giving rise to a certain amount of soluble EDTA complexes and free ligands in accordance with the equilibrium:

$$M(DTC)_2 + HY^{3-} \leftrightarrows MY^{2-} + 2DTC^- + H_3O^+, \quad (1)$$

where $M(DTC)_2$ stands for the insoluble metal ion dithiocarbazato complexes, DTC^- represents the deprotonated ligand and HY^{3-} the predominant form of EDTA at the working pH. The amount of dissolved complex depends on the free EDTA concentration and the pH: consequently, the careful control of both parameters is compulsory.

The following competing equilibria may exist in solution too:

Protonation of dithiocarbazate:

$$nH_3O^+ + DTC^- \leftrightarrows H_nDTC^{n-1},$$
$$\beta_n^{DTC} = [H_nDTC]/[H_3O^+]^n[DTC]. \quad (2)$$

Protonation of EDTA:

$$nH_3O^+ + Y^{4-} \leftrightarrows H_nY^{n-4},$$
$$\beta_n^Y = [H_nY]/[Y][H_3O^+]^n. \quad (3)$$

Formation of dithiocarbazate soluble complexes:

$$M^{2+} + nDTC \leftrightarrows M(DTC)_n^{n-2},$$
$$\beta_n = [M(DTC)_n]/[M][DTC]^n. \quad (4)$$

Formation of mixed EDTA–DTC–metal ion complexes:

$$M(DTC)_n + qHY^{3-} \leftrightarrows M(DTC)_pY_q + (n-p)DTC^-. \quad (5)$$

Formation of mixed dithiocarbazato-metal ion complexes with hydronium and/or hydroxyl ions and polynuclear complexes.

Prior to the determination of the solubility product constants, the presence of mixed EDTA–DTC–metal ion complexes has been tested spectrophotometrically, with no evidence for significant concentrations of these species. Assuming that the concentration of buffer component–metal ion complexes is expected to be negligible due to the small value of their formation constants and the pH range chosen, and the unlikely existence of polynuclear complexes in this study because of the reduced free metal ion to free dithiocarbazate concentration ratio, it can be assumed that the following equations will hold:

$$S = C_M = \sum_0^2 [M(DTC)_n] + [MY] + [M]\left(\sum_0^2 \beta_n[DTC]^n + K_{MY}[Y]\right), \quad (6)$$

$$2S = C_{DTC} = \sum_0^2 n[M(DTC)_n] + \sum_0^1 [H_nDTC] = [M]\sum_0^2 n\beta_n[DTC]^n + [DTC]\alpha_{DTC(H)}, \quad (7)$$

$$C_Y = \sum_0^4 [H_nY] + [MY] = [Y]\{\alpha_{Y(H)} + K_{MY}[M]\}, \quad (8)$$

where S denotes the molar solubility of metal dithiocarbazato complexes,

$$K_{MY} = [MY]/[M][Y], \quad (9)$$

$$\alpha_{DTC(H)} = \sum_0^1 \beta_n^{DTC}[H]^n \quad (10)$$

and

$$\alpha_{Y(H)} = \sum_0^4 \beta_n^Y[H]^n, \quad (11)$$

since one and four protons could be involved in the acid–base equilibria of dithiocarbazates[2] and EDTA,[13] respectively, in the pH range used. From all parameters involved in the equilibria, the molar solubility S can be known from experimental AAS measurements, pH and C_Y are rigorously checked for each series, and the stability constants have been reported elsewhere.[2,3,13] Hence, the unknowns consist of the free ion concentrations of the dithiocarbazate ([DTC]), metal ion ([M]) and competing ligand ([Y]). From eqn (7):

$$[M] = \frac{2S - [DTC]\alpha_{DTC(H)}}{\beta_1[DTC] + 2\beta_2[DTC]^2}. \quad (12)$$

Substituting eqn (12) into eqn (8) and rearranging gives:

$$[Y] = \frac{C_Y}{\alpha_{Y(H)} + K_{MY}\left\{\dfrac{2S - [DTC]\alpha_{DTC(H)}}{\beta_1[DTC] + 2\beta_2[DTC]^2}\right\}}. \quad (13)$$

Introducing eqns (12) and (10) into eqn (6) results in a single polynomial equation with [DTC] as the sole unknown. The fifth-degree polynomial has been solved rigorously with a desk-computer aid. Only one root is of clear chemical significance. Once [DTC] has been determined for each particular series, [M] can be easily found by solving the equation:

$$(\beta_2[DTC]^2 + \beta_1[DTC] + 1)K_{MY}[M]^2 + \{\beta_2[DTC]^2\alpha_{Y(H)} + K_{MY}C_Y + \beta_1[DTC]\alpha_{Y(H)} + \alpha_{Y(H)} - K_{MY}S\}[M] - \alpha_{Y(H)}S = 0, \quad (14)$$

derived from combining eqns (8) and (6). The solubility product (K_{sp}) is then calculated by means of the expression:

$$K_{sp} = [M][DTC]^2. \quad (15)$$

The EDTA protonation constants (β_n^Y) have a role in the K_{sp} calculation through the auxiliary function $\alpha_{Y(H)}$:

$$\alpha_{Y(H)} = \sum_0^4 \beta_n^Y[H]^n = 1 + K_1^Y[H] + K_1^YK_2^Y[H]^2 + K_1^YK_2^YK_3^Y[H]^3 + K_1^YK_2^YK_3^YK_4^Y[H]^4. \quad (16)$$

The terms including the K_3^Y and K_4^Y protonation constants are negligible with respect to all other terms on the right side of eqn (16) in the pH range

Table 1. Evaluation of the solubility product constants at 25°C

Ligand	Equilibrium	I (M)	$\log [K_{sp} \pm s(K_{sp})]$	$\log K_{sp}$ (lit. value)
2-Methyldithiocarbazate $[NH_2N(CH_3)CS_2]^-$	$Ni + 2L \leftrightarrows NiL_2$	0.01	-19.79 ± 0.17	
3,3-Dimethyldithiocarbazate $[(CH_3)_2NNHCS_2]^-$	$Ni + 2L \leftrightarrows NiL_2$	0.01	-15.88 ± 0.02	
3-Methyl-3-phenyldithiocarbazate $[(C_6H_5)(CH_3)NNHCS_2]^-$	$Ni + 2L \leftrightarrows NiL_2$ $Cu + 2L \leftrightarrows CuL_2$	0.01 0.01	-23.88 ± 0.08 -25.62 ± 0.12	
2,3-Butanedionedioxime (dimethylglyoxime)	$Ni + 2L \leftrightarrows NiL_2$	0.1 Dilute 0.05 (NaCl) 0	-23.06 ± 0.07	-23.66 (6) -23.37 (7) -23.89 (16)

used: therefore, the values given by Carini and Martell[14] (log $K_1^Y = 10.71$ and log $K_2^Y = 6.14$ at 25°C and $I = 0.01$ M) are adequate to calculate K_{sp} under the present conditions.

The values of the formation constants of the Ni(II) and Cu(II) complexes with EDTA [log $K_{NiY} = 19.6$ and log $K_{CuY} = 19.9$ ($I = 0.01$ M and 25°C)] have been calculated from those reported as selected values by Anderegg[13] at $I = 0.1$ M and 25°C and the Davies extension of the Debye–Hückel equation:[15]

$$\log Y_{\pm} = -\frac{0.5 Z_A Z_B I^{1/2}}{1 + I^{1/2}} + 0.1 Z_A Z_B I.$$

The uncertainty associated with the new values found (mean deviation $= \pm 0.25$) do not appreciably influence the precision of the solubility product constants since the error introduced by the experimental solubility values is comparatively much greater. The values of the solubility product obtained are given in Table 1.

The method has been tested by determining the solubility product of the Ni–dimethylglyoxime system at $I = 0.1$ M and 25°C. The following constants have been applied—protonation constant of dimethylglyoxime:[17] log $K_1 = 10.55$; protonation constants of EDTA:[13] log $K_1 = 10.26$, log $K_2 = 6.18$, log $K_3 = 2.78$ and log $K_4 = 2.1$; formation constants of Ni(II) complexes with dimethylglyoxime:[18] log $\beta_1 = 9.0$, log $\beta_2 = 17.62$; and formation constant of Ni(II) complex with EDTA:[13] log $\beta_1 = 18.52$. The value of the solubility product constant found is given in Table 1. The result obtained is in reasonable agreement with those reported in the literature for different ionic strengths: therefore, confidence has been given on the reliability of the procedure used.

The method proposed thus offers a rigorous way to determine solubility product constants of very insoluble complexes. Taking into account the detection limit by flame AAS[19] for Ni (0.005 mg l^{-1}) and Cu (0.003 mg l^{-1}), it can be concluded that the smallest K_{sp}s attainable by this method are *ca* $10^{-33.4}$ and $10^{-33.3}$, respectively. If flameless AAS or even more sensitive techniques (viz. inductively coupled plasma or anodic stripping voltammetry) are employed, the limit of K_{sp} can be lowered down to *ca* $10^{-38.5}$, values that can not be attained by gravimetric, conductimetric or spectrophotometric methods.

IMMOBILIZED LIGANDS ON SILICA: UPTAKE OF COBALT AND OTHER METALS BY 1-NITROSO-2-NAPHTHOL

M. C. GENNARO,* E. MENTASTI and C. SARZANINI

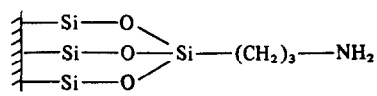
Dipartimento di Chimica Analitica, Università di Torino, Via P. Giuria, 5-10125 Torino, Italy

(*Received* 18 *June* 1985; *accepted* 23 *October* 1985)

Abstract—This paper deals with the preparation and properties of a material formed by 1-nitroso-2-naphthol chemically bound on silica. Its uptake ability towards Co(II), Hg(II), Cu(II), Pb(II), Cd(II), Zn(II) and Al(III) was investigated, as well as the conditions for the release of metals previously fixed.

In metal trace analysis, it is often necessary to determine concentration levels below or near to the detection limits of the available instrumentation. In these conditions, suitable preconcentration methods have to be performed. Among the proposed techniques, in recent years the use of chelating materials able to fix metal traces from great volumes of their diluted solutions was shown to be very effective.

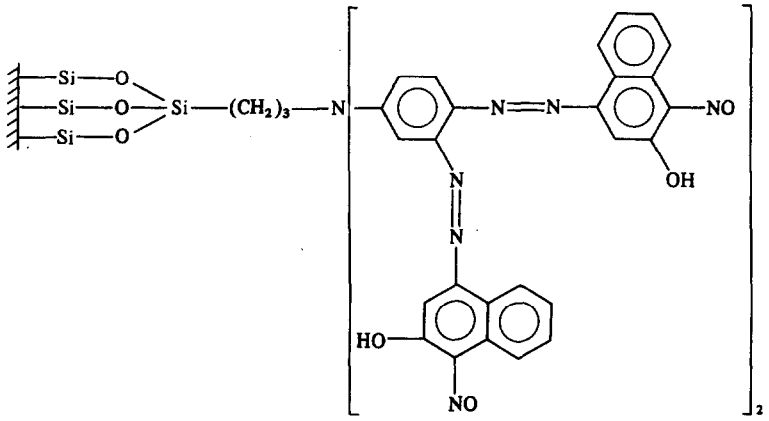
A literature survey shows that ligands of very different structure and properties, as well as substrates of different composition, were throughly employed.[1–6] Although different ligand structures and affinities towards metals are possible, selectivity is hard to achieve. A chelating agent which shows good selectivity is 1-nitroso-2-naphthol.



It was employed after chemical immobilization on a polystyrene–divinylbenzene copolymer,[7] or after support on silica gel.[8] Its use allowed the separation of Pb(II) and Co(II), respectively, from other metal ions.

It seemed, therefore, of interest to study the behaviour of this ligand with respect to preconcentration studies. For this purpose, a material was prepared in which 1-nitroso-2-naphthol was chemically bound on silica gel.

EXPERIMENTAL



The silica–1-nitroso-2-naphthol material was prepared according to procedures described previously.[9,10]

Silica gel BDH 60–120 mesh was activated at 450°C overnight. Twenty grams were then refluxed in the presence of 200 g of toluene and 60 cm^3 of 3-amine-propyl-triethoxy-silane for about 2 h. After cooling, the partially functionalized silica was filtered and repeatedly rinsed with diethyl ether.

The yield of the reaction was evaluated by a back alkalimetric titration. Fifteen grams of product (about 1.2 mmol —NH_2) were mixed with 2.4 mmol of 2,4-dinitrochlorobenzene, dimethylformamide (200 cm^3) and water (50 cm^3) as solvent, in the presence of sodium acetate (10 g). The mixture was refluxed at about 70°C for about 12 h with continuous stirring. After cooling, the nitro-compound was filtered, rinsed with doubly distilled water (DDW) and ethanol [1:1 (v/v)] by using a Soxhlet extractor to ensure complete removal of reagents. In order to reduce the nitro to amino groups, the subsequent reaction was carried on in the presence of 50 cm^3 of 37% HCl, $SnCl_2$ in excess and 300 cm^3 of water. The reaction was continued for about 24 h, by adding diluted HCl, $SnCl_2$ and Zn powder. The product was filtered and repeatedly rinsed. After desiccation (P_4O_{10}) the intermediate product was then diazotized with excess HNO_2 in an acidic medium (HCl) and was treated, through a coupling reaction, with 1-nitroso-2-naphthol (1.7 g in 50 cm^3 of water, pH around 8 with NaOH). The final product was repeatedly washed with DDW and dimethylketone in order to remove unreacted ligand and dried *in vacuo*.

* Author to whom correspondence should be addressed.

0.8 x 4 cm Econo-Column Bio-Rad columns were used in order to support the prepared material.

All reagents were analytical-grade chemicals. DDW from quartz was employed.

A plasma emission spectrograph ("Spectraspan IV", SMI, Andover, MA) was employed for the metal measurement for both solutions, containing, respectively, the metal fraction unretained by the material and the metal fraction fixed and afterwards eluted, when possible, with a proper reagent.

A two-point calibration was used. The most appropriate wavelength for the emission measurement of each metal was chosen. At this wavelength, the accuracy and precision of the measurement were evaluated, as listed in Table 1.

An Orion pH-meter model 811, equipped with a combined glass–calomel electrode, was used for the pH measurement and adjustment.

RESULTS AND DISCUSSION

0.50 g of the functionalized material were packed in a polypropylene Bio-Rad column. After swelling, the chelating ability was tested towards solutions of the following metal ions: Co(II), Hg(II), Cu(II), Pb(II), Cd(II), Zn(II) and Al(III). In order to avoid metal-hydrolyzed insoluble species formation, all the solutions were adjusted to pH 3.0.

Table 1. Spectral and statistical data for plasma emission spectroscopic measurements

Cation	Accuracy	Precision (%)
Co(II)	345.3	100.1 ± 0.9
Hg(II)	253.6	98.5 ± 0.9
Cu(II)	324.7	99.6 ± 0.3
Pb(II)	405.8	99.2 ± 1.0
Cd(II)	214.4	99.6 ± 1.0
Zn(II)	213.8	100.1 ± 1.2
Al(III)	396.1	99.9 ± 0.5

Co(II) was always quantitatively retained from solutions (100.00 cm^3) with a concentration ranging between 1.00 and 25.00 ppm. This result is confirmed by the spectroscopic emission measurement performed on the filtered solutions, which gave no detectable Co(II). To release the fixed Co(II) the following reagents in the indicated amounts were tested: 1.00 N HCl (10.00 cm^3), 1.00 N HCl (20.00 cm^3), 5.00 N HCl (10.00 cm^3), 5.00 N HCl (20.00 cm^3), 1.00 N $HClO_4$ (20.00 cm^3), 1.00 N HNO_3 (20.00 cm^3), and 5.00 N CH_3COOH (20.00 cm^3). None of the indicated reagents was more effective than others; in each experiment the release of about 5% of the residual fixed metal was achieved. This observation agrees with the very low solubility reported for the complex formed by Co(II) with 1-nitroso-2-naphthol, whose exact composition is not known; it is also suggested that a partial oxidation of Co(II) may take place, due to the reagent itself; coprecipitation of the products of reaction may also occur. Literature data furthermore show the formation of a complex species with a ligand: metal molar ratio equal to 3, which shows a very high stability constant (log β around 46), so that the low solubility of the precipitate as well as the high stability of the complex may explain the behaviour of Co(II) in material studied, as observed by other authors for similar materials.[8]

Solutions of high Co(II) concentration were prepared and fluxed. From a solution (100.00 cm^3) at a concentration of 200.00 ppm, a capacity of 0.492 mmol of Co(II) (g of material)$^{-1}$ was obtained.

The uptake on the material of some cations which do not give rise to a precipitate with the ligand was also investigated. Solutions (100.00 cm^3) were prepared at pH = 3.0, containing, respectively,

Cu(II), Pb(II), Hg(II), Cd(II), Zn(II) and Al(III) at 25.00 ppm each.

The solutions were fluxed through the modified silica (0.50 g) in the column and the unretained fraction of the metal in the filtered solution was measured. Differently from Co(II), for the above-mentioned metals the recovery of metal previously fixed on the functionalized material was possible.

For Cd(II), Zn(II), Al(III) and Pb(II), the release was quantitatively gained by employing 10.00 cm^3 of 1.0 N HCl. For the release of Cu(II), 20.00 cm^3 of 1.00 N HCl were necessary, whilst Hg(II) was released by using 1.00 N HNO_3 (10.00 cm^3).

The results obtained are listed in Table 2. It may be noticed that about 90% Cu(II) is retained; this situation agrees with the high stability of the complex which Cu(II) forms with the investigated ligand.

Table 2. Uptake of a series of metals by the investigated material (0.50 g)

	mg			Retained
Metal	Total	Unretained	Released	(%)
Co(II)	0.10	0.0	0.0	100.0
Co(II)	0.50	0.0	0.0	100.0
Co(II)	1.00	0.0	0.0	100.0
Co(II)	2.50	0.0	0.0	100.0
Hg(II)	2.50	0.0	2.40±0.03	100.0
Cu(II)	2.50	0.24±0.01	2.14±0.02	90.4
Pb(II)	2.50	2.17±0.01	0.33±0.01	13.2
Cd(II)	2.50	2.36±0.02	0.13±0.01	5.6
Zn(II)	2.50	2.33±0.01	0.14±0.01	6.8
Al(III)	2.50	2.36±0.02	0.14±0.01	5.6
Co(II)	20.00	5.52±0.01	0.00	72.4

Hg(II), however, shows an unexpected behaviour; although its complex with the ligand is not so stable, it is quantitatively fixed on the functionalized material.

These results indicate the poor selectivity of the prepared material in fixing metals. On the other hand, it offers the advantage of a very high capacity, towards Co(II), of the order of 500 $\mu mol\ g^{-1}$. The impossibility of releasing Co(II) previously fixed, which makes impossible the application to the preconcentration of Co(II), may offer a series of advantages: the separation which is not achieved in the uptake step may be gained, within an error of about 5%, by performing the elution with HCl and HNO_3 in the proper amounts; the release of all metals other than Co(II) is thus achieved.

The material might also be usefully employed when the removal of a great amount of Co(II) from a liquid sample (such as an industrial waste) is desired.

SYNTHESIS AND SPECTRAL STUDIES OF β-DIKETONE AND β-KETOESTER DERIVATIVES OF ALUMINIUM ZIRCONIUM ISOPROPOXIDE

RAMA JAIN, A. K. RAI and R. C. MEHROTRA*

Department of Chemistry, University of Rajasthan, Jaipur 302004, India

(*Received* 5 *August* 1985; *accepted* 10 *October* 1985)

Abstract—The reactions of aluminium zirconium heptaisopropoxide [$AlZr(OPr^i)_7$] with some β-diketones and β-ketoesters, resulting in the formation of derivatives of type $ZrAl(OPr^i)_{(7-x)}L_x$ (where L = acetylacetone, benzoylacetone, methylacetoacetate or ethylacetoacetate; $x = 1$ or 2) have been carried out. These newly synthesized compounds have been characterized by elemental analyses, and IR and NMR (^{27}Al, ^1H and ^{13}C) spectral studies.

The coordination chemistry of β-diketone and β-ketoester derivatives of metals are of particular interest as, in these derivatives, metals have been shown to increase their coordination number up to 8.[1–3] These derivatives also exhibit some interesting structural properties.[4,5] Although some of this class of compounds have been synthesized, characterized and their structural studies investigated,[6] the corresponding derivatives of bimetallic alkoxides have received scanty attention. In the present paper, the synthesis, characterization and structural features of some β-diketone and β-ketoester derivatives of aluminium zirconium heptaisopropoxide [$ZrAl(OPr^i)_7$] are described.

EXPERIMENTAL

Special precautions were taken to prevent hydrolysis.

Benzene (BDH) was dried over a sodium wire. Acetylacetone, methylacetoacetate and ethylacetoacetate were dried by refluxing over aluminium isopropoxide and distillation (b.ps 135–137, 168–170 and 180°C, respectively). Benzoyl acetone was used after distillation under reduced pressure.

Aluminium isopropoxide,[7] zirconium isopropoxide[8] and $ZrAl(OPr^i)_7$,[9] were prepared using literature methods. Zirconium and aluminium were estimated as ZrO_2 and $(C_9H_6NO)_3Al$, respectively.[10] IR spectra were recorded in the range 4000–200 cm^{-1} as Nujol mulls on a Perkin–Elmer 577 grating spectrophotometer. NMR (^1H and ^{13}C) were recorded in $CDCl_3$ on a multinuclear JEOL FX90Q NMR spectrometer using TMS as the internal standard. ^{27}Al NMR spectra were also recorded in $CDCl_3$ and benzene using aluminium isopropoxide as the reference.

Reaction of $ZrAl(OPr^i)_7$ *with acetylacetone in* 1:1 *molar ratio*

Acetylacetone (0.44 g, 4.40 mmol) was added to $ZrAl(OPr^i)_7$ (2.13 g, 4.01 mmol) in benzene (~40 cm^3) and an exothermic reaction occurred. The reaction mixture was refluxed for ~2 h with azeotropic fractionation of isopropanol with benzene. The progress of the reaction was checked by estimating the amount of isopropanol in the azeotrope. After completion of the reaction, the solvent was stripped off, and the product distilled at 110–115°C/0.3 mmHg to give a yellow viscous liquid (72% yield). The azeotrope collected between 72 and 80°C was found to contain 0.23 g isopropanol (calc. for 1 mol 0.24 g).

Found: Zr, 16.1; Al, 4.7%. Calc. for $[ZrAl(OPr^i)_6(acac)]$: Zr, 16.0; Al, 4.7%.

The other β-diketone derivatives were also synthesized similarly. The synthetic and analytical data for these reactions are shown in Table 1.

Reaction of $ZrAl(OPr^i)_7$ *with methylacetoacetate in* 1:1 *molar ratio*

A mixture of $ZrAl(OPr^i)_7$ (1.34 g, 2.52 mmol) and methylacetoacetate (0.30 g, 2.58 mmol) was refluxed in benzene (~40 cm^3) for ~2 h, and, after azeotropic

removal of isopropanol and solvent, gave a highly viscous colourless liquid which was distilled at 122–125°C/0.05 mmHg (87% yield).

Found: Zr, 15.7; Al, 4.4%. Calc. for $[ZrAl(OPr^i)_6(CH_3COCHCOOCH_3)]$: Zr, 15.5; Al, 4.6%.

The other β-ketoester derivatives were also prepared similarly, and the analytical data for the products are summarized in Table 1.

RESULTS AND DISCUSSION

The reactions of $ZrAl(OPr^i)_7$ with β-diketones and β-ketoesters in different molar ratios in refluxing benzene have been carried out. These reactions can be represented by the following general equation:

$$ZrAl(OPr^i)_7 + xL \rightarrow ZrAl(OPr^i)_{7-x}L_x + xPr^iOH\uparrow,$$

where $x = 1$ or 2; L = acetylacetone, benzoylacetone, methylacetoacetate or ethylacetoacetate.

The products obtained were found to be light yellow or colourless viscous liquids or solids, soluble in common organic solvents. Some of the β-diketonate derivatives, like $[ZrAl(OPr^i)_6(acac)]$,

$$[ZrAl(OPr^i)_5(acac)_2]$$

and

$$[ZrAl(OPr^i)_6(C_6H_5COCHCOCH_3)],$$

were found to be distillable under reduced pressure, whereas $[ZrAl(OPr^i)_5(C_6H_5COCHCOCH_3)_2]$ underwent decomposition.

The corresponding β-ketoester derivatives were distilled in quantitative yield without any decomposition.

IR spectra

The characteristic absorption bands observed in the IR spectra of these derivatives in the range 4000–200 cm^{-1} are summarized in Table 2, and tentatively assigned.[12,13] Three sets of stretching vibrations for ν(Al—O) at 710±20, 675±20 and 615±15 cm^{-1}, and two sets of ν(Zr—O) at 570±20 and 470±10 cm^{-1} have been identified. The two bands at 1600±30 and 1530±10 cm^{-1} are assigned to ν(C···O) and ν(C···C) vibrations, respectively. The presence of a ν(C···O) band in these derivatives at a lower frequency in comparison with the corresponding ligands indicates the coordination of the keto group of the ligand moiety to the metal atom.[14] Bands for terminal as well as bridging isopropoxy groups have been identified.

NMR (^1H *and* ^{27}Al)

$ZrAl(OPr^i)_7$. The ^1H NMR spectrum of $ZrAl(OPr^i)_7$ shows three types of methyl proton doublets, indicating the presence of three types of isopropoxy groups: these may be assigned to the bridging groups (δ 1.36–1.44 ppm) and the terminal

groups [δ 1.22–1.29 ppm (bonded to zirconium) and δ 1.10–1.16 ppm (bonded to aluminium)].

The ^{27}Al chemical shift observed at δ 65.14 ppm confirms the tetrahedral nature[15,16] of the aluminium in $ZrAl(OPr^i)_7$.

$[ZrAl(OPr^i)_6(acac)]$. The ^{1}H NMR spectrum of $[ZrAl(OPr^i)_6(acac)]$ also exhibits three types of isopropoxy group, indicating the presence of four terminal (on both zirconium and aluminium) and two bridging isopropoxy groups. A new doublet observed in the δ 1.93–1.99 ppm region may be assigned to the methyl protons of the acetylacetone moiety.[17] The presence of a doublet may be attributed to a *cis* arrangement of the ligand moiety attached to the metal atom.[18–21] (The *cis* form exhibits two resonances due to the non-equivalent environment of the terminal group.)

In $[ZrAl(OPr^i)_6(acac)]$, the acetylacetone moiety may attach either to the zirconium or the aluminium atom of the molecule. In the case of $ZrAl(OPr^i)_7$, the zirconium atom has a coordination number of 5 and it has a greater tendency to attain a coordination number of 6, as indicated by its dimeric nature in refluxing benzene and its monomeric nature in isopropanol, with the formation of $[ZrAl(OPr^i)_7 \cdot Pr^iOH]$.[9] Thus, the incoming acetylacetone moiety, which acts as a bidentate ligand, must replace one of the terminal isopropoxy groups at the zirconium atom in order to acquire a stable coordination number of 6.

In contrast to this prediction, the ^{27}Al chemical shift (δ −0.732 ppm) suggests a penta-coordination for aluminium which is only possible when the incoming group replaces the isopropoxy group on aluminium instead of zirconium.

$[ZrAl(OPr^i)_6(C_6H_5COCHCOCH_3)]$,

$[ZrAl(OPr^i)_6(CH_3COCHCOOCH_3)]$

and $[ZrAl(OPr^i)_6(CH_3COCHCOOC_2H_5)]$. The proton spectra of these compounds also show the types of isopropoxy groups observed in the previous case. Beside the above, signals corresponding to $-CCH_3$ (singlet), $O-CH_3$ (singlet), $O-CH_2$ (quartet), $-C_6H_5$ (multiplet) and O—CH (multiplet) have also been observed and the results are summarized in Table 3.

$[ZrAl(OPr^i)_5(acac)_2]$,

$[ZrAl(OPr^i)_5(CH_3COCHCOOCH_3)_2]$

and $[ZrAl(OPr^i)_5(CH_3COCHCOOC_2H_5)_2]$. The PMR spectra exhibit a multiplet for the methyl protons of the isopropoxy groups. The presence of a doublet for methyl protons (δ 1.88–1.99 ppm) of the ligand moieties indicates that the ligand moieties are attached to zirconium as well as to aluminium, appearing separately but not assignable with certainty on the basis of ^{1}H NMR alone.

However, ^{27}Al NMR shows a single signal at δ 4.557 ppm suggesting hexa-coordination for aluminium.[22,23] Thus, both of the ligand moieties are on the aluminium atom. The presence of both the ligand moieties on aluminium may give rise to different geometrical isomers which may be the reason for the splitting observed in $-CH_3$, $O-CH_3$ and =CH protons in ^{1}H NMR spectra.[24]

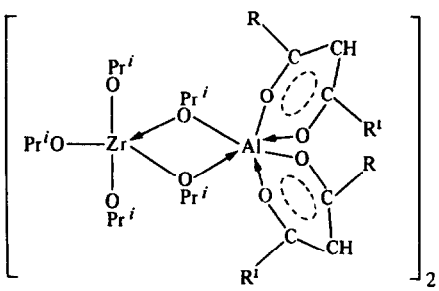
[a] In $CDCl_3$, δ relative to TMS.

^{13}C NMR spectra



^{13}C NMR spectra are recorded only for two compounds in $CDCl_3$.

$[ZrAl(OPr^i)_6(CH_3COCHCOOCH_3)]$ and $[ZrAl(OPr^i)_5(CH_3COCHCOOCH_3)_2]$. ^{13}C NMR spectra of these compounds show the signals due to methyl carbons of isopropoxy groups as well as that of the ligand moieties in the δ 24.18–27.99 ppm region as a complex multiplet. The multiplicity of the signals may be due to different intramolecular stereochemical changes in the molecule due to its complexation. The signals due to $-OCH_3$, $-OCH$ and $=CH$ are $\delta \sim 51.51$, 69.10 and 87.70 ppm, respectively. Two types of signals were observed for C···O and O—C···O at $\delta \sim 185.59$ and 173.64 ppm, respectively, which may be due to the weak chelation of the C=O group to the metal atom.

On the basis of the above studies, the following plausible structures have been suggested for these derivatives.

1 : 1 molar product

1 : 2 molar product

R = CH_3 or C_6H_5, R' = CH_3, OCH_3 or C_2H_5

(*Received* 15 *July* 1985; *accepted* 23 *October* 1985)

Abstract—Various complexes of bivalent transition metals with diamines have been synthesized and studied "*in vitro*" with a diamine oxidase. The inhibition type and K_i value of these compounds have been determined. For the linear-chain diamine complexes the inhibition was competitive and the highest inhibition was for the 1,3-diaminopropane–copper complexes.

Diamine oxidases [amine:oxygen oxidoreductase deaminating (EC 1.4.3.6)] are enzymes evenly distributed among living organisms.[1] They catalyse the oxidation of one primary amino group of a substrate according to the following reaction:

$$R{-}CH_2{-}NH_2 + O_2 + H_2O \rightarrow R{-}CHO + NH_3 + H_2O_2.$$

Despite their broad distribution their physiological role is not fully understood. In plants they are found mainly in seedlings,[2] where cell proliferation requires a fast metabolism of polyamines.[3,4]

An important tool in studying the function of an enzyme is to find specific inhibitors and to follow their effects. Several papers have been published concerning the inhibition of amine oxidase (AO). AO isolated from different sources showed a large variability in specificity toward substrates and sensitivity to inhibitors.[4] Bardsley and Ashford[5] reported the inhibition of pig kidney AO (PKAO) by substrate analogues as a useful tool in probing the structure–function relationship of the enzyme action. Crabbe and Bardsley[6,7] used substrate analogues on the human placental AO to determine if drugs used in pregnancy could modify the activity of the enzyme. Inhibition of PKAO by antihistaminic agents and related drugs on the basis of the chemical relationship of the enzyme substrates has been reported by Finazzi Agró *et al.*[8] and Lorenz *et al.*[9] Joshi and Prakash[10] reported that, during the germination of *Sorghum vulgaris*, two seed inhibitors of pea AO (PSAO) appeared, one, heat-labile, inhibited the enzyme *in vitro*, while the other, heat-stable, inhibited the enzyme synthesis. Macholán and Minář reported the depression of the synthesis of PSAO in growth processes using competitive inhibitors.[11]

Recently AO from lentil seedlings (LSAO) has been purified to homogeneity.[12] This enzyme is similar to other plant AOs. LSAO is inhibited *in vitro* by complexes between bivalent transition metals and some diamines with different metal–ligand ratios: these inhibitors are very similar to the natural substrates of the enzyme. Therefore, it seems of interest to study the influence of the number and nature of the ligands on the inhibitory activity of the complex.

EXPERIMENTAL

Ethylenediamine (en), 1,3-diaminopropane (tn), 1,4-diaminobutane (put) and 1,5-diaminopentane (cad), Fluka purum, were commercially available.

$CuCl_2 \cdot 2H_2O$, $Cu(NO_3)_2 \cdot 3H_2O$, $CuSO_4 \cdot 5H_2O$, $NiCl_2 \cdot 6H_2O$, $CoCl_2 \cdot 6H_2O$, $ZnCl_2$, ZnI_2, $CdCl_2 \cdot 2.5H_2O$, $HgCl_2$, K_2PdCl_4 and K_2PtCl_4 were commercially available, while $CuBr_2$ was prepared by literature methods.

Preparation of the complexes

The complexes were prepared by dissolving appropriate amounts of metal salts and ligands in hot MeOH. After cooling the solution, the precipitated complexes were washed in petroleum ether and dried over P_4O_{10}. The cobalt complexes were prepared in acetone solution. The palladium and platinum complexes were precipitated by a hot aqueous alcoholic solution.

Complexes of general formula $M(L)_nX_2$ (where M = Cu, Ni, Co, Zn, Cd, Hg, Pd or Pt; L = en or tn; n = 1 or 2; X = Cl, Br, I or NO_3), and $Cu_3(put)_2Cl_6$ and $Cu_3(cad)_2Cl_6$ have been obtained.

All the complexes have been characterized by elemental analyses (C, H and N), conductance measurements, IR and diffuse reflectance electronic spectra.

Purification of LSAO

LSAO was purified from *Lens esculenta* seedlings by Floris *et al.*[12] The enzyme activity was measured polarographically with a Gilson GME Oxygraph at 37°C using 10 mM putrescine as substrate. The incubation mixture (1 cm^3) contained 4 μg purified LSAO in 0.1 M K-phosphate buffer (pH 7) or 0.1 M Tris–HCl buffer (pH 8).

The effect of the inhibitors was tested by adding these compounds to the incubation mixture in the presence and in the absence of 100 μg crystalline beef liver catalase (Sigma, St. Louis, MO).

The inhibition constants were determined by Dixon plots.[13]

RESULTS AND DISCUSSION

The structures of the complexes in the solid state are reported in Table 1. The X-ray determinations of some compounds are known: $Cu(en)_2X_2$ (X = Cl, Br or I), square planar pseudooctahedral;[14] $Ni(en)_2Cl_2$, square pyramidal;[15] $M(en)Cl_2$ (M = Pd or Pt), square planar;[16] $Hg(en)Cl_2$, polymeric transoctahedral;[17] and $Cu(tn)_2(NO_3)_2$, octahedral.[18] The $Zn(en)Cl_2$ and $Cd(en)Cl_2$ structures seem equal to that of $Hg(en)Cl_2$ by an IR study.[19] The structure of the other complexes is assigned on the basis of electronic and IR data (Ponticelli *et al.*, unpublished results).

Table 1. Competitive inhibitors of LSAO

Complex	Structure in the solid state	K_i (mM)	Inhibitory activity (%) $C = 3.5 \times 10^{-5}$ M
$Cu(en)_2Cl_2$	Square planar, pseudooctahedral[14]	0.035	50.0
$Cu(en)_2Br_2$	Square planar, pseudooctahedral[14]	0.035	50.0
$Cu(en)_2I_2$	Square planar, pseudooctahedral[14]	0.035	50.0
$Cu(tn)_2Br_2$	Square planar, pseudooctahedral[14]	0.009	100.0
$Cu(tn)_2(NO_3)_2$	Octahedral[18]	0.080	20.0
$Cu_3(put)_2Cl_6$	Polymeric square pyramidal	0.050	27.0
$Cu_3(cad)_2Cl_6$	Polymeric square pyramidal	0.010	94.0
$Co(en)_2Cl_2$	Square planar	0.180	10.0
$Ni(en)_2Cl_2$	Distorted octahedral	0.035	50.0
$Zn(en)_2I_2$	Square pyramidal	0.030	69.0
$Cd(en)_2Cl_2$	Distorted octahedral	0.105	15.0
$Co(en)Cl_2$	Tetrahedral	0.140	12.5
$Ni(en)Cl_2$	Polymeric octahedral	0.052	25.0
$Zn(en)Cl_2$	Polymeric octahedral[19]	0.020	71.0
$Pd(en)Cl_2$	Square planar[16]	0.105	15.0
$Cd(en)Cl_2$	Polymeric octahedral[19]	0.860	3.1
$Pt(en)Cl_2$	Square planar[16]	0.100	15.8
$Hg(en)Cl_2$	Polymeric octahedral[17]	—	—

Table 1 also reports the inihibition types with the K_i values determined by Lineweaver–Burk and Dixon plots.

It is well known that LSAO catalyzes the oxidation of the diamines put to 1,10-diaminodecane.[12] This is the reason why the inhibition caused by $Cu_3(put)_2Cl_6$ and $Cu_3(cad)_2Cl_6$ was expected.

No activity is found with 1,2-diaminoethane and 1,3-tn free ligands.[12] A matter of interest is therefore the competitive inhibition of LSAO by the above-mentioned $M(L)_nX_2$ complexes.

Since in aqueous solution the compounds may show solvolysis in the apical position or in the bridging halides,[20] and a variety of species containing the metal ion may be present and cannot be separated from each other in the experiments described, the inhibitory activity is also expressed in % using a 3.5×10^{-5} M solution of the complexes (Table 1). The same inhibitory activity is found when using 0.1 M K-phosphate (pH 7) or 0.1 M Tris–HCl (pH 8) as the buffer.

The inhibitory activity of the $M(en)_2X_2$ complexes toward the enzyme generally does not change with the anion and decreases in the order Zn, Ni, Cu, Cd and Co. The inhibitory effect of the $M(en)Cl_2$ derivatives decreases in the order Zn, Ni, Pd, Co, Pt, Cd and drops to zero with Hg.

No inhibitory activity is found when the free ligands or the metal salts are used by themselves at the same concentration as in the complexes.

With regard to the inhibitory mechanism it is most probable that the interaction of the complexes occurs with the active site of the enzyme and that the enzyme–inhibitor interaction is very stable.

THE GEOMETRIES AND ELECTRONIC STRUCTURES OF TWO TERMINAL-PHOSPHINIDENE COMPLEXES

JUNG-GOO LEE, JAMES E. BOGGS and ALAN H. COWLEY*

Department of Chemistry, The University of Texas at Austin, Austin, TX 78712, U.S.A.

(*Received* 15 *August* 1985; *accepted* 14 *October* 1985)

Abstract—*Ab initio* MO calculations have been carried out on the terminal-phosphinidene complexes $HPCr(CO)_5$ and $HPNi(CO)_3$.

Terminal-phosphinidene complexes of the type $RPML_n$ (R = Ph or Me; M = Cr, Mo, W)[1] and $RPFe(CO)_4$ [R = 2,4,6-(*t*-Bu)$_3$C$_6$H$_2$][2] have been implicated as short-lived species. However, so far such compounds have eluded isolation. We have therefore undertaken a theoretical study of the prototypical terminal-phosphinidene complexes $HPCr(CO)_5$ (**1**) and $HPNi(CO)_3$ (**2**).

Since the molecules are rather large, it was necessary to employ idealized octahedral and tetrahedral geometries for **1** and **2**, respectively (Fig. 1). The M—C and C—O bond lengths for **1** and **2** are based on those of $H(HO)CCr(CO)_5$[3] and $Ni(CO)_4$,[4] respectively. The P—H bond length was assumed to be 1.42 Å in both complexes. All calculations were carried out with the GUGA program[5] which employs the restricted Hartree–Fock method for both closed- and open-shell systems. The basis sets for Cr (^7S) and Ni (^3F) were of the MINI-2 type[6] supplemented with 4*p* orbitals. Orbital exponents of 0.077 and 0.111 were used for Cr and Ni, respectively. A 3G CGTO minimal basis set was utilized for the C, O, H and P atoms.[7]

Geometry optimization afforded the values R = 2.33 Å, $\alpha = 110°$, and $\theta = 45°$ for **1**, and R = 2.19 Å, $\alpha = 102°$, and $\theta = 30°$ for **2**. For both complexes, the computed metal–phosphorus bond lengths are close to the sums of the respective metal–phosphorus covalent radii. The fact that, in contrast to, for example,

$H(HO)CCr(CO)_5$[3]

and

$H(OH)SiCr(CO)_5$,[8]

both **1** and **2** adopt staggered conformations is presumably a consequence of the phosphorus lone pair. However, the computed rotational barriers for **1** (0.29 kcal mol^{-1}) and **2** (0.25 kcal mol^{-1}) are extremely small. The computed metal–phosphorus bond dissociation energies are 38.1 and 74.9 kcal mol^{-1} for **1** and **2**, respectively. Comparison with $H(HO)SiCr(CO)_5$ (29.6 kcal mol^{-1}), which was investigated with a similar method and basis set,[8] suggests that terminal phosphinidenes are bound to Cr more strongly than terminal silylenes. The computed force constant and frequency for the Cr—P bond of **1** (staggered conformation) are 1.60 mdyn Å^{-1} and 370 cm^{-1}, respectively.

For both **1** and **2**, the metal–phosphorus σ-bond is formed by electron transfer from the HOMO of the phosphinidene [primarily P($3p_z$)] to the LUMO of the $Cr(CO)_5$ or $Ni(CO)_3$ fragment. Back-transfer of electrons stems from interaction of the HOMO of the metal carbonyl fragment to the LUMO ($3p_y$) of the HP moiety. The net result is that, for both **1** and **2**, the HOMO and HOMO-1 are of the π- and σ-symmetry, respectively (Fig. 2). The gap between the π- and σ-MOs is 0.6 and 0.3 eV for **1** and **2**, respectively.

The LUMO of $HPCr(CO)_5$ is very low lying (0.008 eV). Moreover, the LUMO features a large AO coefficient at the phosphorus center [0.82 at P($3p_y$)]. As a consequence, the chromium–phosphinidene complex is anticipated to undergo facile nucleophilic attack at phosphorus. Both the LUMO [0.71 at P($3p_y$)] and the HOMO [0.66 at P($3p_y$)] of **2** feature

* Author to whom correspondence should be addressed.

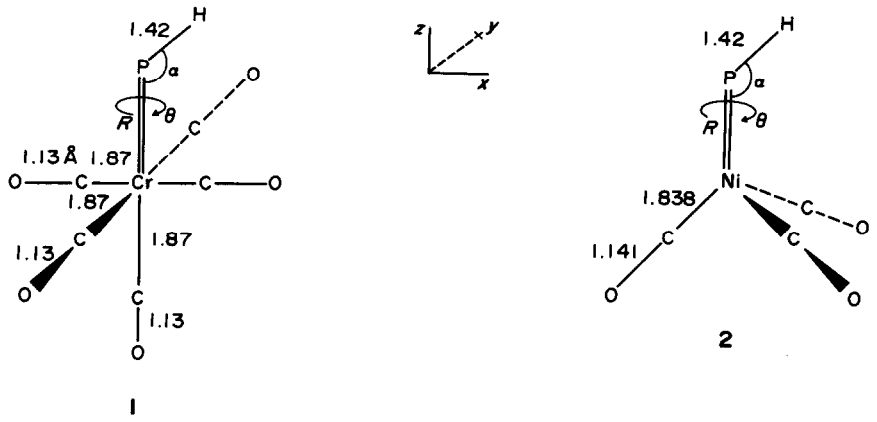

Fig. 1. Geometries of metal–phosphinidene complexes. Both complexes are shown with a rotational angle (θ) of 0°.

large phosphorus AO coefficients: moreover, the LUMO is relatively low-lying (1.3 eV). The nickel–phosphinidene complex is therefore predicted to be reactive toward both nucleophilic and electrophilic reagents.

We have made a preliminary investigation of the triplet state of $HPCr(CO)_5$. For the PH fragment, we compute that the triplet state is more stable than the singlet state by 45 kcal mol^{-1}. Clearly, the method used here overemphasizes the stability of the triplet state, since this figure exceeds the experimental value[9] by 23 kcal mol^{-1}. Like Nakatsuji *et al.*,[3] we calculate that, for the $Cr(CO)_5$ fragment, the singlet state is more stable than the triplet state by 7 kcal mol^{-1}. When the HP and $Cr(CO)_5$ fragments are bonded, the triplet state ($R = 2.67$ Å, $\alpha = 102°$, and $\theta = 45°$) is favored over the singlet state by 27.4 kcal mol^{-1} (at the staggered geometry). However, we anticipate that this gap will be decreased when correlation effects are included. Consequently, we

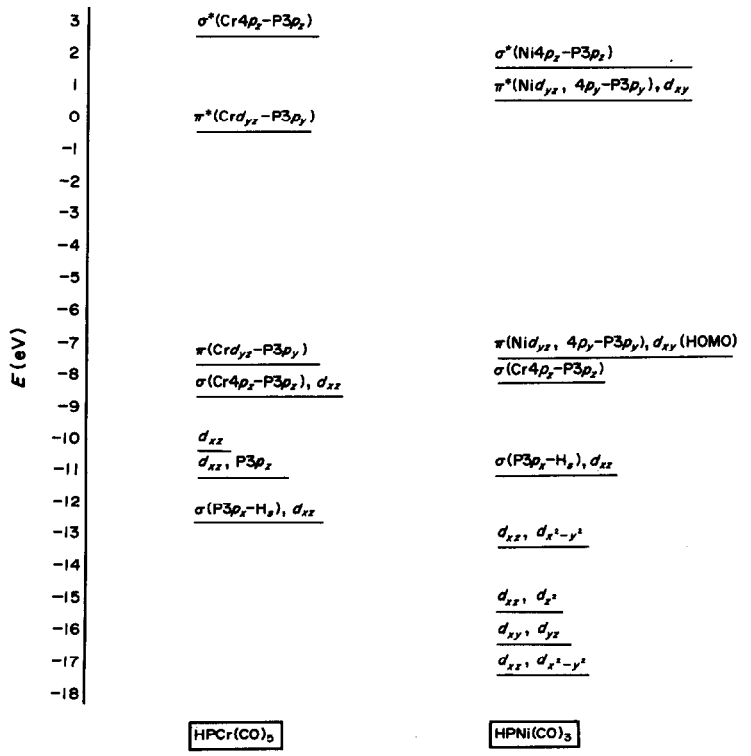

Fig. 2. MOs for $HPCr(CO)_5$ (**1**) and $HPNi(CO)_3$ (**2**) in eclipsed conformations.

predict that the singlet and triplet states of **1** are very close in energy. Further calculations are in progress on **1** and **2** and the related complexes $HPCr(CO)_4$ and $HPNi(CO)_2$.

Acknowledgements—We thank the National Science Foundation and the Robert A. Welch Foundation for financial support. Dr Pfister-Guillouzo and co-workers have performed PSONDO calculations on $HPCr(CO)_5$. We thank Dr Pfister-Guillouzo for her courtesy in sending a preprint of this manuscript.

CATALYSIS BY HETEROPOLYACIDS—VIII. IMMOBILIZATION OF KEGGIN-TYPE HETEROPOLYACIDS ON POLY(4-VINYLPYRIDINE)

KENJI NOMIYA, HIROYUKI MURASAKI and MAKOTO MIWA*

Department of Industrial Chemistry, Faculty of Engineering, Seikei University, Musashino, Tokyo 180, Japan

(*Received* 28 *August* 1985; *accepted* 18 *November* 1985)

Abstract—Anchoring of a Keggin-type heteropolyacid (HPA) to a polymeric support and the effect of heterogenization on the HPA catalysis of the oxidation of a primary diol have been studied. A coloured HPA such as $H_6[Co(II)W_{12}O_{40}]$ (blue green), $H_4[SiMo_{12}O_{40}]$ (yellow) or $H_3[PMo_{12}O_{40}]$ (yellow), as the Keggin-type HPA and poly(4-vinylpyridine) as a polymeric support have been used. The anchoring of $H_6[Co(II)W_{12}O_{40}]$ has led to a markedly increased stability of the oxidation catalyst.

Generally, Keggin-type heterpolyacids (HPAs) $\{H_n[XM_{12}O_{40}]$ (X = heteroatom, M = Mo or W)$\}$ have both a strong Brønsted acidity and are oxidizable.[1] Previously we have reported the polycondensation of benzyl alcohols and the Friedel–Crafts-type reaction of aromatics on the basis of their acid catalysis,[2,3] and the oxidation of cyclohexanol to cyclohexanone and further to adipic acid on the basis of their oxidation catalysis.[4] Recently we have also described the oxidation reactions of primary diols such as 1,4-butane- and 1,5-pentanediols to the corresponding dicarboxylic acids via hydroxy-carbonic acids as intermediates. Such intermediates detected were γ-butyro- and δ-valero lactones resulting from an intramolecular condensation.[5] In the oxidation reactions, the tetrabutylammonium (Y) salt of the HPA as the main catalyst and H_2O_2 as a reoxidizing reagent have been used. In this work, we have tried immobilizing, by anchoring the HPA catalyst to a polymer, in order to further facilitate the recovery of it from the system and recycling in comparison with the case of the Y salt. Since a pyridine is attached to the HPA in the form of the pyridinium counterion, as in Y, we chose poly(4-vinylpyridine) [abbreviated hereinafter to poly(4-VP)] as a polymeric support. Adsorption of the HPA on poly(4-VP) was readily confirmed by using a coloured HPA, such as $H_6[Co(II)W_{12}O_4]$, $H_4[SiMo_{12}O_{40}]$ or $H_3[PMo_{12}O_{40}]$. The immobilized HPA was characterized by analyses and IR spectra, and was used as a catalyst for the reaction of 1,4-butanediol to γ-butyrolactone.

* Author to whom correspondence should be addressed.

EXPERIMENTAL

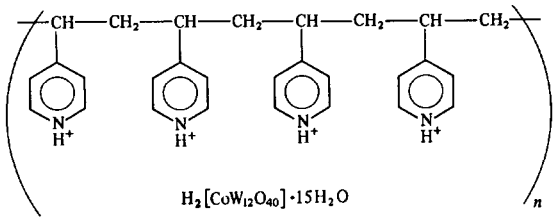
Preparation

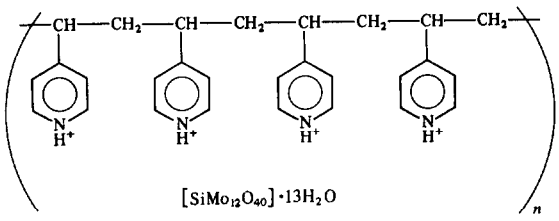
Free HPAs, $H_6[Co(II)W_{12}O_{40}]$ (blue green), $H_4[SiMo_{12}O_{40}]$ (yellow) and $H_3[PMo_{12}O_{40}]$ (yellow), were prepared by the usual methods,[6,7] and are hydrated. They were also converted to the Y salts, $Y_4H_2[CoW_{12}O_{40}]$, $Y_4[SiMo_{12}O_{40}]$ and $Y_3[PMo_{12}O_{40}]$, which contain no solvated molecules. Poly(4-VP), the degree of polymerization of which was *ca* 3000, was obtained by the radical polymerization of 4-vinylpyridine initiated by benzoyl peroxide at 47–50°C under nitrogen.[8]

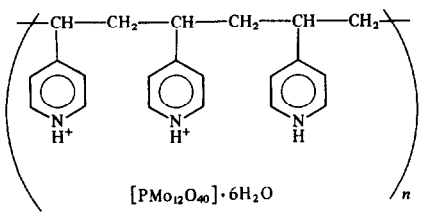
Immobilization of HPAs

To a methanol solution containing 0.1 g of poly(4-VP), which was slightly acidified with nitric acid, the methanol solution containing appropriate amounts of the HPA (X = Co, 3.00 g; X = Si, 1.99 g; and X = P, 1.99 g) was added and stirred for about 30 min

at 30–35°C. The coloured precipitates were filtered, washed thoroughly with methanol and dried *in vacuo*. If the filtrate was still coloured, the methanol solution containing 0.1 g of poly(4-VP) was again added and the coloured precipitates were isolated. This procedure was repeated until the filtrate became colourless. Coloured precipitates were produced by adsorption of the HPA on the polymer, which was characterized by analyses and IR spectra. The stoichiometry of the adsorption of the HPA on the polymer was calculated from the total amounts of poly(4-VP) consumed and the weight of precipitates obtained in each run. The acid catalysis of these immobilized HPAs was tested for polycondensation of benzyl alcohol.[2]







Oxidation of 1,4-*butanediol*

This reaction was performed by refluxing a mixture of the substrate (8 g), the immobilized HPA (170 mg) and 30% aqueous H_2O_2 (15 g) for an appropriate time. After the reaction, the HPA was filtered off, water in the filtrate was evaporated and the residue was extracted with benzene. One of the products, γ-butyrolactone, was obtained by distillation of the extracts under reduced pressure (bp_{22} *ca* 93°C), and identified by ^1H NMR, IR and TCD gas chromatography.

RESULTS AND DISCUSSION

The IR spectra of each immobilized HPA in the 1100–700-cm^{-1} region showed four stretching vibrations [M—terminal oxygen, M—O—M octahedral edge- and corner-sharings, and heteroatom (X)—triply bridged oxygen], characteristic of the Keggin structure.[7] These bands were shifted in the direction observed for the cation exchange from proton to Y, and the magnitudes of the shifts caused by immobilizing were less than half that observed in the Y exchange. The stoichiometry of the adsorption of the HPA on poly(4-VP) indicated that one molecule of HPA interacted with some pyridine groups in the polymer. Since the amount of HPA adsorbed on 0.1 g of the polymer was *ca* 0.51 g for X = Co, *ca* 0.44 g for X = Si, and *ca* 0.46 g for X = P, the number of interacting pyridines was formally estimated to be 5.6, 4 and 3.8, respectively. In these calculations, the contribution from the solvated waters in each HPA was ignored. The

number of interacting pyridines was further explicitly determined by elemental analyses of the immobilized HPA. The analytical data (Table 1) suggest that adjacent pyridines in the polymer are attached to the HPA in the form of the pyridinium counterion, and constitute the new polymeric units, and, moreover, the number of interacting pyridines corresponds to the number of Y groups in the Y salt of the HPA, i.e. $Y_4H_2[Co(II)W_{12}O_{40}]$, $Y_4[SiMo_{12}O_{40}]$ and $Y_3[PMo_{12}O_{40}]$. Since some of the protons of the starting HPA are consumed by protonation to the pyridines in the polymeric unit, acid catalysis of the immobilized HPA could not be expected. In fact, they showed no catalytic activity for the polycondensation of benzyl alcohol to polybenzyl. From this viewpoint, the immobilized HPA is also very close to the Y salts. However, significant differences in the catalysis were observed in the oxidation of 1,4-butanediol.

When the immobilized form of the X = Co HPA was used as the main catalyst, γ-butyrolactone was obtained with a 16% yield after an 18-h refluxing. The number of moles of lactone produced per mole of catalyst per hour was 16.5. In this reaction, the catalyst was very stable and the Keggin structure of the HPA in it was retained after the reaction. The recovery of the catalyst from the system was easy and its reuse was possible several times without a decrease in its activity. On the contrary, the Y salt of the X = Co HPA decomposed after several hours refluxing, and neither recovery nor reuse was possible. In the cases of X = Si and P, both the immobilized forms and the Y salts functioned as good catalysts for the oxidation of the 1,4-diol. However, the reaction time of the immobilized catalyst was markedly shortened. For instance, the time until the H_2O_2 initially used was completely consumed was 3 h for X = Si and 4 h for X = P in the immobilized HPA, whereas it was 11 h for X = Si and 16 h for X = P in the Y salt. For these reaction times, the yields of γ-butyrolactone by both the immobilized catalyst and the Y salt were comparable, 22% for X = Si and 26% for X = P. However, concerning the stability of the catalyst, the Y salt was more excellent than the immobilized catalyst. This is in contrast to the case of X = Co.

COMMUNICATION

THE REACTION OF *o*-XYLYLENE COMPLEXES OF RUTHENIUM WITH ALKYNES UNDER OXIDATIVE CONDITIONS

CHRISTINE L. SKERRATT, S. DAVID CHAPPELL, RICHARD D. BOWEN, RICHARD C. STORR and DAVID J. COLE-HAMILTON*†

School of Chemistry, University of Liverpool, P.O. Box 147, Liverpool L69 3BX, U.K.

(*Received* 23 *September* 1985; *accepted* 25 *November* 1985)

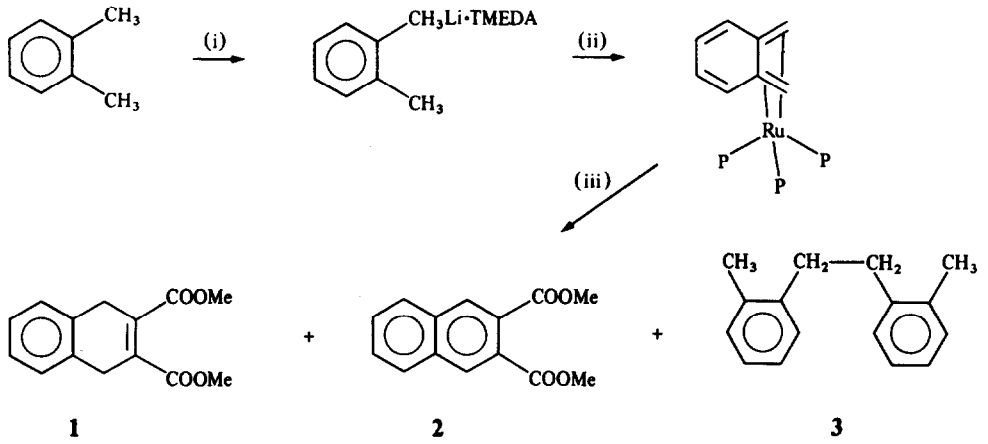
Abstract—Oxidation of *o*-xylylene complexes of ruthenium in the presence of dimethyl(acetylenedicarboxylate) produces the dimethylesters of 1,4-dihydronaphthalene-2,3-dicarboxylic acid and naphthalene-2,3-dicarboxylic acid.

o-Quinodimethanes are important intermediates in a large number of organic transformations, including the synthesis of pharmacologically active compounds such as steroids.[1,2] Although a number of efficient routes to these reactive species has been developed, the precursors tend not to be readily accessible and a new, direct route from a cheap starting material is therefore highly desirable.

In recent years, *o*-quinodimethane (xylylene) complexes of a number of different metals have been synthesized by a variety of routes.[3–9] However, no successful attempts to liberate *o*-quinodimethane from the metal under mild conditions have been reported. Thus, *o*-quinodimethane was not removed from $[C_8H_8Fe(CO)_3]$ by oxidation,[3] although, on thermolysis, benzocyclobutane was formed and reaction with $AlCl_3$ gave benzocyclopentanone.[10]

The only trapping of an *o*-quinodimethane liberated from a metal complex involves the binuclear $[\{CpCo(CO)\}_2C_8H_8]$, from which the bridging xylylidene ligand was displaced with phosphines and intercepted by dienophiles or else dimerized.[11]

We now report the first indication that *o*-quinodimethanes can be liberated from ruthenium complexes $\{[C_8H_8RuP_3]$ ($P = PMe_2Ph$ or $PMePh_2$)$\}$ by oxidation.



Treatment of these complexes in CH_2Cl_2 in the presence of dimethyl(acetylenedicarboxylate) (DMAD) with an excess of aqueous cerium(IV) ammonium nitrate affords the dihydronaphthalene (**1**) and naphthalene (**2**) in yields of 14 and 2%, respectively ($P = PMePh_2$).‡ The other major products are the phosphine oxide and the bibenzyl (**3**). With the less reactive dienophile $Me—C{\equiv}C—CO_2Me$, no adduct was detected and the amount of **3** increased. No reaction occurred between the complex and acetylene in the absence of oxidant and the simplest explanation is therefore that free *o*-quinodimethane is produced.

The yields of **1** and **2** have yet to be optimized by choice of oxidant and reaction conditions. However, the fact that $[C_8H_8RuP_3]$ can be prepared directly from *o*-xylene[5] (Scheme 1) gives the procedure great potential as a route to *o*-quinodimethane-derived products.

8. SPECULATION AND OUTLOOK 1096

1. INTRODUCTION

The organothiolate anion (RS^-) is a fundamental ligand type.* Together with the homologous organoselenolate (RSe^-) and organotellurolate (RTe^-), and alcoxide (RO^-) and aryloxide (ArO^-) anions, the thiolate anion may be classified as a pseudohalide, comparable as a ligand with Cl^-, Br^- and I^-. In metal complexes RS^- can be compared with HS^- and S^{2-}. This comparison highlights the appeal of RS^- to coordination chemists, part of which is that the organothiolate ligand can be regarded as sulfide with a handle, and a further part is that the substituent R can be manipulated powerfully and adjusted delicately to effect steric and electronic control of ligation ability. Consequently, the coordination chemistry of organochalcogenide ligands is potentially more variable than that of the "naked" chalcogenide ions, or of "naked" halide ions.

The categorization of RS^- as a pseudohalide rests in part on the one-electron oxidation [eqn 1]:

$$RS^- \rightleftharpoons \tfrac{1}{2}RSSR + e^-, \tag{1}$$

quantification of which is complicated by chemical irreversibility, and in part on the Bronsted basicity [eqn (2)]:

$$RS^- + H^+ \rightleftharpoons RSH. \tag{2}$$

Thiolates are stronger Bronsted bases than the halides, pK_a^{RSH} values in water ranging from 11.1 (Bu^tSH) through 9.4 ($PhCH_2SH$) to 6.6 (PhSH).[1,2] A third pseudohalide attribute of RS^- is metal complex formation comparable with that of the halides: the better known structural aspect of this characteristic is the subject of this Report.

1.1. *Scope and restrictions*

In order to concentrate on the fundamental chemistry of the thiolate ligand function, this Report emphasizes complexes of monofunctional thiolate ligands. Numerous chelating ligands incorporating a thiolate donor have been concocted and deployed for various purposes,[3,4] but in these cases the intrinsic metal thiolate chemistry is obscured by the geometrical, thermodynamic and electronic influences of the remainder of the ligand. Therefore complexes of the amino acid cysteine functioning as a chelate ligand are excluded, but complexes involving the cysteinate side chains of a polypeptide are included. For the same purpose of focusing on innate ligating characteristics of thiolates, this Report will emphasize complexes which contain only thiolate ligands (homothiolate complexes) or at least a large proportion of thiolate ligands. Comparative descriptions of alcoxide metal complexes (for which there is an extensive secondary literature[5,6]) and selenolate and tellurolate complexes will be included where pertinent.

1.2. *Background*

In this Report the principal emphasis is on the geometrical structures of metal thiolate complexes. Synthetic methods, chemical reactivities and physical properties will be treated in a separate article. The purpose here is to describe and analyse the menagerie of structure types confirmed or probable for metal thiolate compounds, and to elucidate structural principles. Thiolate ligands have a reputation for bridging metal atoms, a reputation engendered by the insolubility and presumed polymeric structures of the familiar metal thiolates $\{[M(SR)_n]_p\}$, frequently formed when thiolate ions and metal ions are

* R represents any non-coordinating function. Other abbreviations used generally in this Report are: Ar, arene substituent; E, chalcogen; X, halogen; t, terminal; b, bridging; ax or a, axial; eq or e, equatorial; i, inner; o, outer.

mixed in protic media. However, the paradigm of bridging thiolate, initiated by Jensen[7] who proposed the structure type **1D-D** below for $[Ni(SR)_2]_\infty$, has been confirmed only in recent years. The first crystal structure of a homothiolate compound [molecular $Hg(SMe)_2$] was reported in 1964,[8] and prior to 1974 there was only one report of the crystal structure of a homothiolate compound with a *non-molecular* structure, namely $[Hg(SBu^t)_2]$.[9]

The structural novelties to be found with other metals were presaged by the report[10] in 1965 of the hexagonal "tiara" structure of $Ni_6(SEt)_{12}$, and the 1969 report[11] of $[Cd_{10}(SCH_2CH_2OH)_{16}]^{4+}$, which is related to the sphalerite structure. Since 1973 there has been sustained effort on the designed syntheses of metal thiolate complexes, supported by structural characterization by diffraction methods, and now almost 70 structure types are known. Almost all of these results have appeared since the early reviews[12,13] which covered the structures of metal thiolates. A limited collection of metal thiolate structures was published in 1984.[14]

1.3. *General characteristics and organization of this Report*

This Report contains descriptive, analytical, evaluative and speculative sections. The descriptive section is subdivided in terms of the structural molecularity of the compounds. Structurally molecular compounds, that is those totally enclosed by non-bonding (van der Waals') boundaries, are treated before one-dimensionally non-molecular (chain) structures, which are followed by two-dimensionally non-molecular (layer) structures. No instances of three-dimensionally non-molecular metal thiolate structures are known (or expected, in view of the spatial requirements of the thiolate substituents). *Structural* molecularity carries no connotations of size or charge.

Molecular structures are subdivided primarily according to increasing number of metal atoms, then according to increasing metal oxidation state, while the finest subdivision is according to metal coordination number. In all cases the first description is of *observed* geometrical structure, followed by more speculative discussion of bonding and electronic structure.

A significant characteristic of most of the structures to be described is actual low symmetry combined with an approach to high symmetry. It is convenient and instructive to symmetrize and idealize the observed structures, and to rationalize deviations from these idealizations. By this means geometrical relationships between apparently diverse structures can be extracted and evaluated. The highest symmetry occurs in the core of M and S atoms, and the structure descriptions are presented with this symmetrization imposed. The substituents R are responsible for the lowered actual symmetry in several different ways: one source of dissymmetry is the pyramidal stereochemistry at the S atom of the doubly-bridging thiolate causing the S—R bonds to be non-radial and allowing *configurational* isomers which cannot adhere to the symmetry of the M, S core. A second originates in repulsions between a small proportion of contiguous substituents, a third is due to various *conformations* of terminal SR ligands, and a fourth is the asymmetry of R alone.

The initial descriptions of the structures in Sections 2 and 3 are made in relatively coarse focus, with a tendency towards idealization, in order to achieve an overview and systematization of the field. Subsequently details of the thiolate substituents and their effects are described in Sections 5.4 and 5.7, and a more finely focussed view of structural dimensions follows in Section 5.8.

In some crystal structures there occurs a disparity of M—S distances and S—M—S angles, referenced to normal symmetrizations. These structures are analysed in terms of primary and secondary metal thiolate coordination, or in terms of weak (secondary) association of molecular units.

1.4. *Incorporation of sulfide and polysulfide ions*

Descriptions of metal thiolates benefit by comparison with compounds containing S^{2-} (the unsubstituted thiolate) and polysulfide ions S_x^{2-} (the "inorganic thiolate").* Mixed sulfide–thiolate–metal complexes $\{[S_wM_x(SR)_y]^z\}$ have been studied in detail since 1973 for M = Fe, and more recently for other metals. Structural relationships exist between binary M–SR compounds, binary M–S compounds (both molecular and non-molecular), and ternary M–S–SR compounds. An emerging theme concerns the structural congruence of different compounds from this set, and in particular the

* Complexes of organopolysulfides (RS_x^-) have not yet been characterized.

occurrence of molecular cages, mainly with thiolate ligands, as fragments of non-molecular structures, mainly metal sulfides.

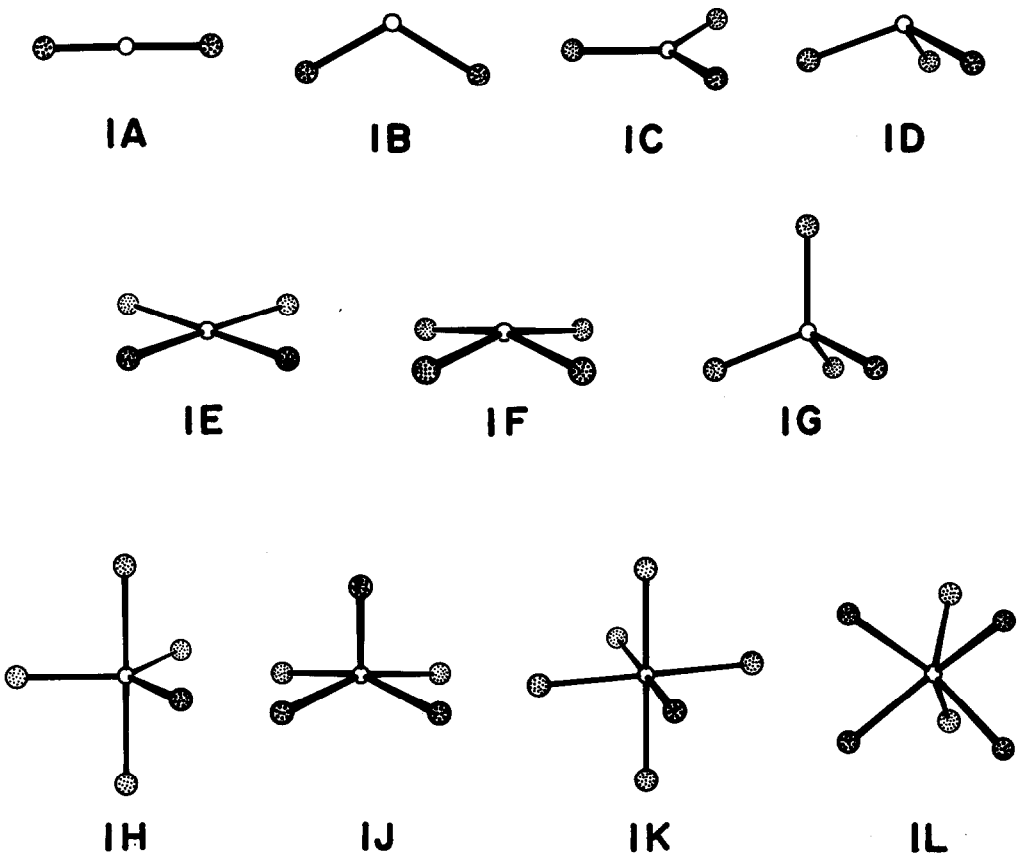
Redox relationships involving thiolate and sulfide ions as ligands are also pertinent.[15] The oxidation products of sulfide, S_x^{2-} (x = 2, 4, 5, 6, 8 or 9), have now been found as ligands in a variety of bonding modes,[16-19] while the immediate oxidation product of thiolate, RSSR, is a distinctly uncompetitive ligand type. Polysulfide ions (S_x^{2-}) function similarly to chelating dithiolate ligands ($^-SRS^-$) in many complexes.

1.5. *Biological metal thiolate coordination*

Metal thiolate coordination occurs naturally, primarily through the thiolate side chain of the amino acid cysteine.[20] Crystal X-ray diffraction analyses[20,21] have clearly defined the metal cysteinate coordination in the following metalloprotein sites: (i) tetrahedral Zn coordination by four cysteinates in alcohol dehydrogenase and aspartate carbamoyl transferase,[22] (ii) tetrahedral Zn coordination by two cysteinates, one histidine and one water or substrate ligand in alcohol dehydrogenase; (iii) Fe with four cysteinates and tetrahedral stereochemistry in rubredoxin; (iv) pseudotetrahedral Cu with one cysteinate, one methionine and two histidine ligands in plastocyanin; (v) $Fe_2S_2(S\text{-cys})_4$ ferredoxins,[21] (vi) $Fe_3S_3(S\text{-cys})_5$ ferredoxins,[21,23] and (vii) $Fe_4S_4(S\text{-cys})_4$ ferredoxins.[20,21] In addition, physicochemical data imply metal cysteinate coordination in: (viii) cytochrome *P*-450 (cysteinate axial to heme Fe), (ix) cytochrome *c* oxidase (cysteinate bridging two Cu atoms[24]), (x) Mn(III) phosphatases,[25,26] (xi) Fe_3 ferredoxins from *Desulfovibrio gigas* and aconitase,[20] and (xii) various Mo-containing oxidoreductase enzymes.[20]

The metallothioneins constitute a unique class of metalloproteins which are polymetallic with *exclusive* coordination by the cysteine thiolate function.[27,28] The best characterized metallothioneins contain seven M atoms (Zn and/or Cd), a singularly high proportion, 20/61, of cysteinate side chains, and are devoid of aromatic amino acids. A determination of crystal structure is expected.[29] All cysteinate groups are metal-bound, some as bridging ligands probably in aggregates with three and four M atoms[30-34] as described in Sections 2.3.6 and 2.4.4. The metals Zn, Cd, Hg, Cu, Ag and Pb induce the formation of metallothioneins, and can be involved in their probable functions of metal storage and metal detoxification by sequestration.

It has been partial knowledge of the structures, properties and functions of metallocysteine proteins which has stimulated much of the recent development of metal thiolate chemistry, particularly the pioneering research by Holm.[35]



2. DESCRIPTION OF MOLECULAR STRUCTURE TYPES

Not all of the following structure types have been confirmed by diffraction methods. Structures indicated by other physical data, and structures which can reasonably be postulated to exist, at least in solution, have been included to maintain completeness. Also included are some structure types which occur in related metal halide/pseudohalide/alkyl systems, and which are discussed as possible structures for metal thiolates.

The diagrams of idealized structure types show M atoms as small open circles, while the SR ligands are usually presented as larger dotted circles at the S positions only, since the substituent configurations and conformations are variable. Where substituents are included the small filled circles represent α-carbon atoms. Stipled circles denote heteroatoms.

2.1. *Monometallic structures*

2.1.1. *Linear* $M(SR)_2$ (**1A**). This structure is established in the mercury thiolates $[Hg(SR)_2]$ {where R = Me,[8] Et,[36] $CH_2CH_2CONHMe$,[37] $[CH_2CH_2NMe_3]^+$,[38] or $[C_5H_9NHMe]^+$ (4-thiolato-*N*-methylpiperidinium)[39]}, in $[HOOCCH(NH_3)CH_2SHgSCH_2CH(NH_3)COO^-]^+$,[40] and in $[Cu(SC_6HMe_4\text{-}2,3,5,6)_2]^-$.[41] It is probable that structure **1A** also occurs in the anions $[M(SC_6F_5)_2]^-$ (M = Cu, Ag or Au[42,43]) and $[ClAuSC_6F_5]^-$.[43] Molecular weight data on $[Cu(SPh)_2]^-$ (Ph_4P^+), and the vibrational spectra of $[Au(SR)_2]^-$ (Ph_4P^+, PPN^+ or Bu_4N^+) (R = Me, Bu^t or Ph),[44] point to the occurrence of the same structure. Related compounds in which the structure is confirmed are $[AuS_9]^-$ (Ph_4As^+)[45] {and possibly $[AgS_9]^-$ (Ph_4P^+)[46]}, in which a linear S–Au–S segment is

contained in a 10-membered ring, Et_3PAuSR (SR = 2,3,4,6-tetra-*O*-acetyl-1-thio-β-D-glucopyranose),[47] $[O_3SSAuSSO_3]^{3-}$,[48] and $PhHgSC_6H_3Me_2$-2,6.[49]

Linear coordination by two bridging alkyl or aryl thiolates is confirmed in other structures (e.g. **5A** and **5B**) for Cu(I) and Ag(I). Therefore, since two bridging ligands, and therefore two terminal thiolate ligands, can provide an electron density sufficient to coordinatively saturate these metals, it can be expected that $[M(SR)_2]^-$ complexes with structure **1A** will occur in solution in equilibria involving these metals and thiolates. These labile equilibria are not readily characterized, and the compositions and structures of crystals from the solutions need not reflect compositions and structures of complexes in solution. For instance, $[Cu(SPh)_3]^{2-}$ with Ph_4P^+ in CH_3CN crystallizes as $[Cu(SPh)_2]^-$, but with Et_4N^+ in CH_3CN–OPr^i_2 it crystallizes as $[Cu(SPh)_3]^{2-}$.[50,51] The properties of many $Hg(SR)_2$ are consistent with digonal coordination.[52,53] In this structure type the M and S atoms are exposed, and the occurrence of secondary M---S interactions is common. These secondary connections usually approach the estimated van der Waals' contact distance of *ca* 3.6 Å. Solid-state aggregation patterns are sometimes regular, with pseudo-octahedral stereochemistry around Hg, while in $[Hg(SCH_2CH_2NMe_3)_2]^{2+}$ (ClO_4^-)[38] there are discrete aggregates of three and six Hg atoms, as in Fig. 1. The alternative one-dimensionally non-molecular structure (**1D-C**) with tetrahedral primary coordination occurs in $Hg(SBu^t)_2$,[9] $Hg(SeMe)_2$[53] and related compounds (see Section 3.1.3).

2.1.2. *Bent* $M(SR)_2$ (**1B**). This structure is known in $Sn(SAr)_2$,[54] where Ar is the hindered substituent 2,4,6-tri-*t*-butylphenyl. The S—Sn—S angle of 85.4° is remarkably small, but not much smaller than the corresponding angles of 88.8° in $Sn(OAr')_2$ (Ar' = 2,6-di-*t*-butyl-4-methylphenyl)[55] or of 104.7° in $Sn[N(SiMe_3)_2]_2$.[56] Structure **1B** could be expected in species $[Tl(SR)_2]^-$.

2.1.3. *Trigonal planar* $M(SR)_3$ (**1C**). This structure is confirmed in $[Cu(SPh)_3]^{2-}$ crystallized with Ph_4P^+,[50] or Et_4N^+,[51] and in $[Hg(TePh)_3]^-$ (Ph_4P^+),[57] each of which is closely planar. There are substantial differences between the CuS_3 cores of the $[Cu(SPh)_3]^{2-}$ ions, that with Et_4N^+ being essentially D_{3h} while that with Ph_4P^+ is distorted towards C_{2v}. The Cu—S distance and S—Cu—S angle disparities, 2.335 vs 2.274 Å and 135.4 vs 111.7 and 113.0°, respectively, are correlated as described in Section 5.8. This distortion towards linear two-coordination in the crystal phase of

$(Ph_4P^+)_2[Cu(SPh)_3]$ can be coupled with the observation of its dissociation [eqn (3)]:

$$[Cu(SPh)_3]^{2-} \rightleftharpoons [Cu(SPh)_2]^- + PhS^- \quad (3)$$

which occurs even in aprotic solvents,[50]* and with the fact that, relative to the Et_4N^+ salt, the Ph_4P^+ salt has a lower-energy electronic absorption in both solid and solution phases.[51] In the presence of Et_4N^+, $[Cu(SPh)_3]^{2-}$ does not dissociate in aprotic solvents. Evidently Ph_4P^+--$[Cu(SPh)_3]^{2-}$ associations (Ph--Ph) influence both the geometrical structure and the dissociative equilibria of $[Cu(SPh)_3]^{2-}$.

Crystalline $(Ph_4P)[Hg(EPh)_3]$ (E = S or Se) are not isomorphous with the Te homolog.[57] The vibrational spectra of $(Ph_4P)[Hg(SPh)_3]$ have been interpreted in terms of trigonal pyramidal HgS_3 coordination:[58(a)] in fact $(Bu_4N)[Hg(SPh)_3]$ has trigonal planar coordination,[58(b)] while the same anion, when crystallized with Me_4N^+, adopts the dimeric structure $[(PhS)_2Hg(\mu\text{-}SPh)_2Hg(SPh)_2]^{2-}$ (**2E**).[58(c)] The IR and Raman spectra of complexes (cat)$[Hg(SR)_3]$ (R = Me in ethanol solution and R = Bu^t)[59] indicate that they are trigonal planar.

A possible member of this structural class is the recently reported tris(isopropylthio)silylenium ion $\{[(Pr^iS)_3Si]^+\}$.[60]

2.1.4. *Pyramidal* $M(SR)_3$ (**1D**). There is IR and Raman spectroscopic evidence[42] that $M(SC_6F_5)_3$ (M = Sb or Bi) are pyramidal in ethanol solution. These two compounds, which are crystallographically isomorphous and monomeric in nitromethane, are soluble in a wide range of organic solvents.[42] The primary coordination in tris(2-pyridinethiolato)antimony(III) is pyramidal SbS_3 (symmetry C_3, Sb—S 2.47 Å, S—Sb—S 90.0° : Sb--N 2.83 Å).[61] Structure **1D**, rather than **1C**, is indicated by the low-frequency vibrational spectra of $[Hg(SPh)_3]^-$ (Ph_4P^+),[58] and may occur also in the monometallic anions $[M(SC_6F_5)_3]^-$ (M = Sn or Pb).[42] Diffraction analysis has confirmed structure **1D** in $[Pb(EPh)_3]^-$ (E = S or Se) (Ph_4As^+),[62] while multinuclear NMR studies reveal the existence of a series of species $[M(SPh)_x(SePh)_{3-x}]^-$ (x = 0–3, M = Sn or Pb) in methanol solution and for which the same structure is presumed.[63] It is probable that structure **1D** also occurs in compounds $M(SPh)_x(SePh)_{3-x}$ (M = As, Sb or Bi, x = 0–3).

2.1.5. *Square planar* $M(SR)_4$ (**1E**). Surprisingly no instance of this simple structure type with monodentate thiolate ligands has been confirmed by diffraction methods, but it probably occurs in the ions $[M(SC_6F_5)_4]^{2-}$ (M = Ni,[64] Pd or Pt[43,65]), $[Pt(SC_6Cl_5)_4]^{2-}$[66] and $[Au(SC_6F_5)_4]^-$. It is significant that $[Ni(SC_6F_5)_4]^{2-}$ (Ph_3MeAs^+) is diamagnetic and presumed to be square planar,[64] while $[Ni(SPh)_4]^{2-}$ (Ph_4P^+) is known[67,68] to be tetrahedral (structure **1G**). Tetrahedral coordination of Ni or Pt (M) by thiolate ligands also occurs in $[(\eta^5\text{-}C_5H_5)_2M'(\mu\text{-}SMe)_2M(\mu\text{-}SMe)_2M'(\eta^5\text{-}C_5H_5]^{2+}$ (PF_6^-) (M′ = Nb or Ta),[69,70] but in these compounds there may be M--M′ bonding, and the electron

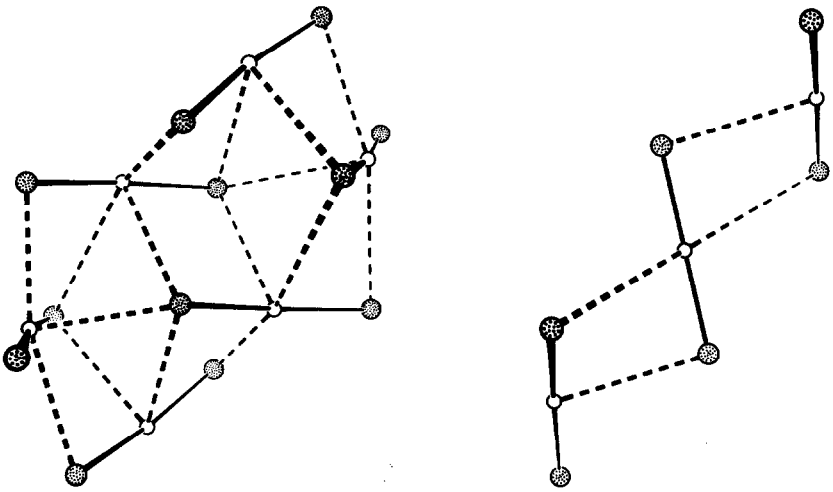


Fig. 1. Aggregates of six and three RSHgSR units in crystalline $[Hg(SCH_2CH_2NMe_3)_3]^{2+}$ $(ClO_4^-)_2$. The broken lines are the elongated secondary bonds.

* In aprotic solvents the thermodynamic activity of the PhS^- product of dissociation (3), relative to the activity of the associated complex, is greater than in protic solvents, and therefore dissociation is least favoured in aprotic solvents.

distribution may be such that the M population is closer to d^{10}, for which tetrahedral stereochemistry is normal.[71] As $(Ph_4P)_2[Ni(SPh)_4]$ is one of a series of isostructural crystals $\{(Ph_4P)_2[M(SPh)_4]\}$ with tetrahedral stereochemistry,[68] it is to be suspected that the coordination stereochemistry is a consequence of a lattice energy dominated by the cation. Chelate complexes with square planar stereochemistry are $[M(SCH_2CH_2S)_2]^{2-}$ [M = Cr[72(a)] or Ni[72(b)]] and the remarkable spin-triplet Co(III) complex $[Co(SCH_2CH_2S)_2]^-$,[72(a)] while $[M(S_4)_2]^{2-}$ (M = Ni or Pd)[18] are square planar, the latter with a slight tetrahedral distortion.

2.1.6. *Pyramidal* $M(SR)_4$ (**1F**). This structure may occur in $[Sb(SC_6F_5)_4]^-$ (and metal-substituted chloro derivatives) and $[Bi(SC_6F_5)_4]^-$.[42]

2.1.7. *Tetrahedral* $M(SR)_4$ (**1G**). This homothiolate structure occurs widely, and has been established crystallographically for the following complexes:

(a) the ions $[M(SPh)_4]^{2-}$ (M = Mn, Fe, Co, Ni, Zn or Cd), which form a series of isomorphous crystals with Ph_4P^+,[68,73–75] and the ions $[M(SPh)_4]^{2-}$ (M = Co, Zn or Cd) in crystals with Me_4N^+;[76]

(b) the ions $[M(SC_6H_4Cl\text{-}4)_4]^{2-}$ (M = Fe, Zn, Cd or Hg) in crystals with Me_4N^+;[76,77]

(c) $[Fe(SEt)_4]^{2-}$ (Et_4N^+);[78]

(d) the Fe(III) species $[Fe(SC_6HMe_4\text{-}2,3,5,6)_4]^-$ (Et_4N^+),[79] $[Fe(SC_6H_2Pr^i_3\text{-}2,4,6)_4]^-$ (Ph_4P^+),[80] $[Fe(SPh)_4]^-$ (Et_4N^+)[81] and $[Fe(SEt)_4]^-$ (Pr_4N^+);[81]

(e) $Mo(SBu^t)_4$;[82]

(f) $Sn(SePh)_4$;[83]

(g) $[Ga(SEt)_4]^-$ (Pr_4N^+);[81,84]

(h) $[M(SCH_2CH_2S)_2]^{2-}$ [M = Mn[85] or Co[72(a)]];

(i) the Fe(II) and Fe(III) complexes $[Fe(S_2\text{-}o\text{-}xyl)_2]^{2-,-}$ of the large-bite chelating dithiolate ligand $1,2\text{-}C_6H_3(CH_2S)_2$;[86]

(j) $[Hg(S_6)_2]^{2-}$ (Et_4N^+),[87] with a slightly distorted tetrahedral HgS_4 coordination from two 1,6-chelating S_6^{2-} ions.

Additional homothiolate compounds for which the tetrahedral monometallic structure is very probable include the ions $[M(SC_6F_5)_4]^{2-}$ (M = Co,[43,64,88,89] Zn,[43,89] Cd[43,89] or Hg[43,89]) and numerous uncharged compounds $[M(SR)_4]$ (M = Ge[90] or Sn[91]) which are monomeric in solution.

Tetrahedral monometallic structures have been established for the following complexes containing heteroligands: $[MeN(CH_2CH_2)_3NZn(SPh)_3]$,[92] $[CH_3CNCo(SC_6HMe_4\text{-}2,3,5,6)_3]^-$ (Pr_4N^+),[93] $[SSi(SPh)_3]^-$ $(HNC_5H_5^+)$,[94] $(piperidine)_2Zn(SPh)_2$,[95] $(1,10\text{-phen})Zn(SC_6H_4Me\text{-}4)_2$,[96] $Cl_2Co(SC_5H_4NHMe)_2$,[97] $(Ph_3P)_3AgSPh$[98] and $HB(3,5\text{-}Me_2Pz)_3CoSC_6F_5$.[99–101] Crystal structures have been determined for many compounds of the type Ar_3MSR (M = Ge, Sn or Pb).[102]

2.1.8. *Proteins containing* $M(S\text{-}cys)_4$ *coordination.* Tetrahedral $M(SR)_4$ coordination by cysteine is known from diffraction studies to occur in three enzymes:[22] (i) rubredoxin (Rd) (M = Fe),[103,104] which has two oxidation states, Rd_{ox} and Rd_{red}; (ii) liver alcohol dehydrogenase (LADH) (M = Zn);[105] and (iii) aspartate carbamoyl transferase (M = Zn[Fe]).[23] The cysteinyl locations in the polypeptide sequences are 3, 6, 39 and 42 for Rd_{ox} from *Clostridium pasteurianum*[104] and *Desulfovibrio vulgaris*,[103] 97, 100, 103 and 111 for horse LADH, and 109, 114, 137 and 140 for aspartate carbamoyl transferase from *E. coli*.[23] A common pattern in these sequences is separation by two residues of cysteinyl residues directly chelating a single M atom.

In LADH the $Zn(S\text{-}cys)_4$ section of the protein appears to have a purely structural function, the active site being another Zn atom coordinated by two cysteines and one histidine, and by water or substrate. Aspartate carbamoyl transferase contains different catalytic (Cat) and regulatory (Reg) subunits. The $Zn(S\text{-}cys)_4$ section is in the Reg chain, establishing an ordered domain which provides for well-defined tight interactions between Reg and Cat. All of the substructures (e.g. loops ending at cysteine residues) determined by the coordination of Zn^{2+} to the four cysteines of the Reg chain participate in the interactions between Reg and Cat chains.

In Rd the $Fe(S\text{-}cys)_4$ region is the site of enzymatic activity, which is electron transfer. Despite early reports to the contrary, the available structural results reveal relatively small variations from tetrahedral stereochemistry. In Rd *ex C. pasteurianum* the Fe—S distances are 2.24(1), 2.29(1), 2.30(1) and 2.33(1) Å, and the S—Fe—S angles range from 103.7(4) to 114.3(5)°.[104]

2.1.9. *Trigonal bipyramidal* $M(SR)_5$ (**1H**). Only one five-coordinate $M(SR)_5$ structure is confirmed,

that of $[Sn(SPh)_5]^-$ (Me_4N^+).[106] The stereochemistry is distorted trigonal bipyramidal, in which the Sn—S^{ax} distances are 2.499(2) and 2.574(2) Å, and the Sn—S^{eq} distances 2.477(1), 2.483(1) and 2.483(1) Å. The S^{ax}—Sn—S^{ax} angle is 172.7°, and the S^{eq}—Sn—S^{eq} angles 111.5, 121.5 and 125.0°. The distortion occurs mostly in the S^{ax}—Sn—S^{eq} angles, which range from 75.8 to 97.9° without evident correlation with the benzenethiolate ligand orientations.

A set of remarkable trigonal bipyramidal complexes $[(CH_3CN)M(SAr)_4]$[107] and $[(CO)M(SAr)_4]$[108] (M = Ru or Os), is formed by the hindered ligands SAr (2,3,5,6-tetramethylbenzenethiolate and 2,4,6-triisopropylbenzenethiolate). An isostructural compound is $[(CH_3CN)Ru(SeAr)_4]$.[109] The heteroligand is in the axial position. Both ruthenium thiolate compounds with acetonitrile have elongated axial bonds in a fairly regular trigonal bipyramid: average dimensions are Ru—S^{eq} 2.108 Å, Ru—S^{ax} 2.378 Å, Ru—N^{ax} 2.102 Å, S^{ax}—Ru—N^{ax} 178.2°, S^{eq}—Ru—S^{eq} range 114–124°. The absence of stereochemical distortion by the bulky 2,6-substituents of the arenethiolate ligands is significant. All four acetonitrile compounds are known to be susceptible to one-electron oxidation and one-electron reduction: it appears[107] that both oxidation and reduction are chemically reversible.

A class of trigonal bibyramidal complexes $[MXY(SR)_3]^z$, with X and Y axial, is emerging. Instances are $[Re(NCCH_3)(PPh_3)(SPh)_3]$ {and probably $[Re(CO)(PPh_3)(SPh)_3]$ by replacement of the CH_3CN},[110] $[Mo(NO)(SAr)_4]^-$,[111] $[W(NO)Cl(SPh)_3]^-$[111] and $[Mo(NO)Cl(SBu^t)_3]^-$.[111] A pattern in the molecular structures is orientation of the aryl substituents of the equatorial thiolate ligands towards (and the S non-bonding electrons away from) the more strongly bound pi-acceptor ligand $NCCH_3$ or NO, and elongation of the other axial bond.

Structural information is not yet available on the monometallic anions $[Sn(SC_6F_5)_5]^-$, $[ClSn(SC_6F_5)_4]^-$ and $[Cl_2Sn(SC_6F_5)_3]^-$,[42] or on the compounds $Nb(\overline{SPh})_5$ and $Ta(\overline{SPh})_5$.[112]

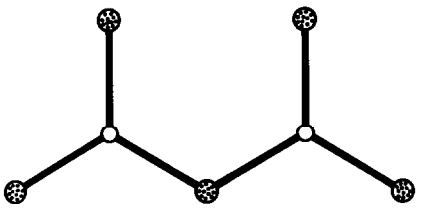
2.1.10. *Square pyramidal* $XM(SR)_4$ (**1J**). This structure type is now established for V, Mo, W, Tc and Re. Crystallographic data are available for: $[OM(SPh)_4]^-$ (Ph_4As^+) (M = Mo[113] or Re[114]), $[OM(SC_6HMe_4\text{-}2,3,5,6)_4]^-$ [M = Mo (Et_4N^+) or W (Pr_4N^+)],[115] $[ORe(SC_6H_2Me_3\text{-}2,4,6)_4]^-$ (Et_3NH^+),[116] $[ORe(SC_6H_3Pr^i_2\text{-}2,6)_4]^-$,[116] $[OV(SCH_2CH_2S)_2]^{2-}$ (Me_4N^+,Na^+),[117] (Na^+),[118] $[(Ph_3PN)Re(SPh)_4]$,[110] $[OTc(SCH_2CH_2S)_2]^-$ (Ph_4As^+),[119] $[SRe(SCH_2CH_2S)_2]^-$ (Me_4N^+),[120] $[SV(SCH_2CH_2S)_2]^{2-}$ (Ph_4P^+),[118] $[OTc(SCH_2CH_2O)_2]^-$ (Ph_4As^+)[121] and $[OTc(SCH_2C(O)S)_2]^-$ (Bu_4N^+).[122] According to similarities of physical properties it is proposed that the following related complexes possess the same molecular structure: $[OM(EPh)_4]^-$ (M = Mo or W, E = S or Se),[123,124] $[ORe(SePh)_4]^-$[114] and $[ORe(SCH_2CH_2S)_2]^-$.[120]

In all cases the stereochemistry is very close to square pyramidal. Basal angles at the metal range from 81 to 87°, and the displacement of the metal from the basal plane ranges from 0.72 to 0.82 Å {in $[OTc(SCH_2CH_2O)_2]^-$ and $[OMo(SPh)_4]^-$, respectively}, except in the complex $[SRe(SCH_2CH_2S)_2]^-$, where the Re atom is 0.4 Å above the basal plane.[120] A comparative compilation of stereochemical data for OMS_4 cores is available.[114] In both $[OMo(SPh)_4]^-$ and $[ORe(SPh)_4]^-$ the benzenethiolate ligands are arrayed approximately as a turbine with C_4-symmetry about the axial bond.

2.1.11. $M(SR)_6$ [*octahedral* (**1K**) *and trigonal prismatic* (**1L**)]. No instances of these structures with monodentate thiolate ligands are known. Re(V) coordinated by six alkyl thiolate functions occurs in the complex $[(CH_3C(CH_2S)_3)_2Re]^-$ (Ph_4P^+).[125] The regular stereochemistry is twisted trigonally by only 6° from a trigonal prism, and, consequently, the eclipsed inter-ligand S—S distances are relatively short (2.80, 2.80 and 2.85 Å), appreciably less than the non-bonded van der Waals' contact distance of 3.6 Å. In the absence of any steric influence on coordination stereochemistry in this complex, it is suggested that direct attractive interactions occur between these S donor atoms, and contribute electronically to the stabilization of the trigonal prismatic stereochemistry.* In $[Ti(SCH_2CH_2S)_3]^{2-}$ with projected twist angles (ϕ) of 35–42°, the stereochemistry is between octahedral (ϕ = 60°) and trigonal prismatic (ϕ = 0°).[72(a)]

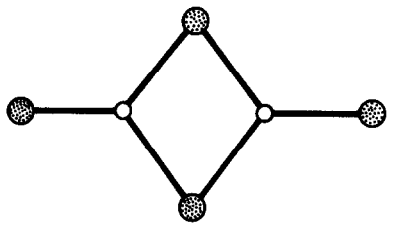
Six-coordinate monometallic thiolate complexes with heteroligands have been characterized structurally: examples are (bipy)$Sn(SPh)_4$[127] and *cis*-$(Bu^tNC)_4Mo(SBu^t)_2$.[128,129]

* Note that these are not the same attractive interactions as those proposed for the triangular edges of trigonal prismatic tris-dithiolene complexes.[126]



2.2. *Bimetallic structures*

Bridging thiolate ligands are now introduced. Although relatively few dimetallic homothiolate structures are confirmed, a large number of closely related heteroligand structures are known and leave little doubt about the feasibility of structures proposed below.

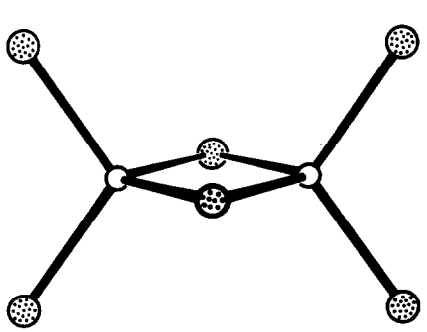


2.2.1. *Two-coordinate* RMS(μ-SR)MSR (**2A**). This structure type has been proposed for Cu(I) species with stoichiometry $[Cu_2(SR)_3]$ (R = $[CH_2CH_2NMe_3]^+$ or $[CH_2CH_2SO_3]^-$) in solution.[130] The same stoichiometry occurs in the confirmed tetrametallic structure type **4C**.

2A

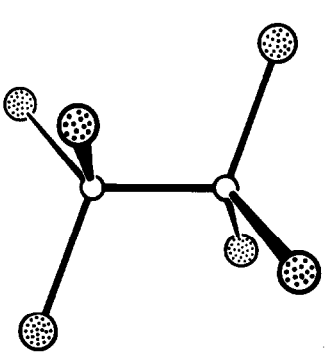
2B

2C



2D

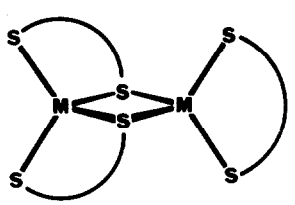
2.2.2. *Three-coordinate metal* (**2B** *and* **2C**). Neither of these structures has been confirmed for thiolate ligands, although precedents exist in comparable chloride complexes such as $[Cl_2Ag(\mu\text{-}Cl)AgCl_2]^{3-}$[131] and $[ClCu(\mu\text{-}Cl)_2CuCl]^{2-}$,[132] and in the polysulfide $[Ag_2(S_6)_2]^{2-}$ (Ph_4P^+)[46] which has structure **2C** with cyclic 1,6-S_6 linkages of the bridging and terminal positions.



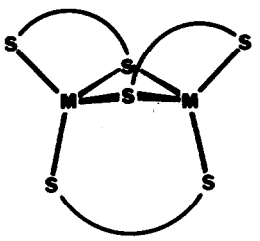
2.2.3. $(RS)_2M(\mu\text{-}SR)_2M(SR)_2$ (*planar four-coordinate metal*) (**2D**). No instance of this structure is confirmed. It probably occurs in the diamagnetic anion $[Ni_2(S_2\text{-}o\text{-}xyl)_3]^{2-}$.[86] Structure **2D** is proposed[42] for the organge-red dianion $[Au_2(SC_6F_5)_6]^{2-}$ which is formally Au(II) and in which alternative structures with an Au—Au bond or mixed oxidation states have been discounted:[42] crystallographic confirmation of the structure is essential for this anion.

Structure **2D** has been established for closely related compounds with heteroligands in terminal positions. Coplanar metal coordination squares occur in $(Ph_3P)(C_6F_5S)Pd(\mu\text{-}SC_6F_5)_2Pd(SC_6F_5)(PPh_3)$, which is centrosymmetric.[133,134] Non-coplanar metal coordination planes occur in $(\mu\text{-}SCH_2Ph)_2[NiS_2CSCH_2Ph]_2$ (dihedral angle 114°),[135] $(\mu\text{-}SBu^t)_2[PdS_2CSBu^t]^2$ (dihedral angle 132°),[135] $(\mu\text{-}SEt)_2[PtCl(PPr_3)]_2$ (dihedral angle 130°),[136] $(\mu\text{-}SEt)_2(AuMe_2)_2$ (dihedral angle 141°),[137] $(\mu\text{-}SPh)_2[Rh(CO)PMe_3]_2$ (dihedral angle 113°),[138] $(\mu\text{-}SBu^t)_2[Ir(CO)P(OMe)_3]_2$ (dihedral angle 123°)[139] and (cyclo-octadiene)$Rh(\mu\text{-}SPh)_2Rh(CO)_2$ (dihedral angle 135°).[140]

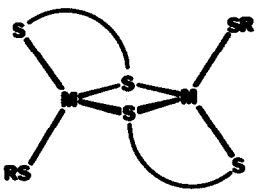
2.2.4. $(RS)_2M(\mu\text{-}SR)_2M(SR)_2$ (*tetrahedral metal coordination*) (**2E**). This structure is confirmed for



2E



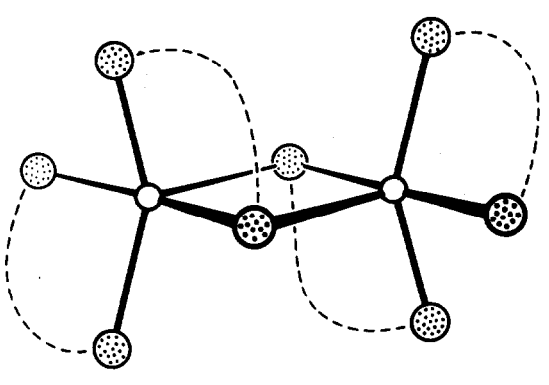
2F



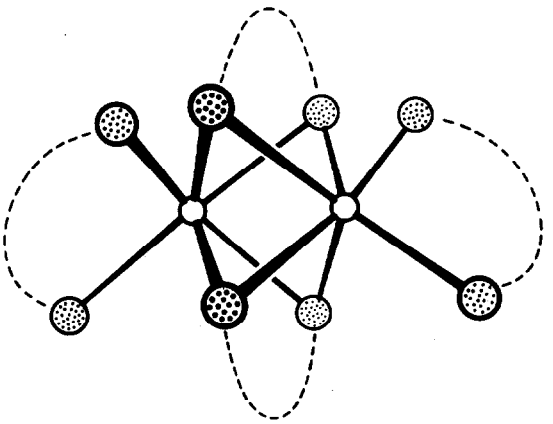
$[Hg_2(SMe)_6]^{2-}$,[59] $[Hg_2(SPh)_6]^{2-}$ (Me_4N^+),[58(c)] $[Fe_2(SEt)_6]^{2-}$ and $[Co_2(SEt)_6]^{2-}$,[141] and is intimated for $[M_2(SEt)_6]^{2-}$ (M = Mn, Zn or Cd).[141] These all occur in a centrosymmetric (or pseudo-centrosymmetric) configuration with *anti* substituents on the bridging ligands, while $[Co_2(SEt)_6]^{2-}$ also crystallizes in the *syn* configuration [**B4** (see Section 5.6.2.3)] (non-planar M_2S_2). NMR data show that these configurational isomers interconvert rapidly in acetone at 200 K, with a slower exchange of terminal and bridging thiolate ligands.[141] Structure **2E** occurs with chelating ligands in $[M_2(S_2\text{-}o\text{-xyl})_3]^{2-}$ (M = Mn, Fe or Co). The Fe compound when crystallized with Et_4N^+ from MeCN has the connectivity **2Ea**, and the Fe and Co compounds when crystallized with Me_4N^+ from MeOH have the connectivity **2Eb**.[141–144] The related complex $[Fe_2(S_2\text{-}o\text{-xyl})_2(SPh)_2]^{2-}$ (Me_4N^+) has a different connectivity (**2Ec**).[142]

2Ea

2Eb



2Ec



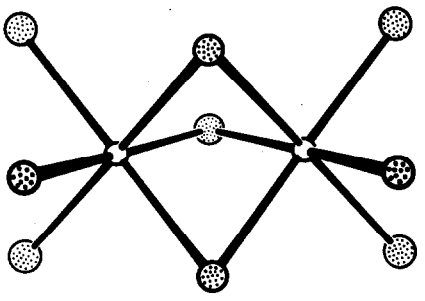
Heteroligand complexes with structure **2E** are known in the series $[(RS)_2FeE_2Fe(SR)_2]^z$ (RS = SPh, SC_6H_4Me or half S_2-*o*-xyl; E = S or Se)[145,146] and $[(E_5)FeE_2Fe(E_5)]^{2-}$ (E = S[147] or Se[148]). Thiolate ligands occur in bridging positions only in $[(Ph_3P)_2Cu(\mu\text{-SPh})_2Cu(PPh_3)_2]$,[149] $(NO)_2Fe(\mu\text{-SEt})_2Fe(NO)_2$[150] and $[Cl_2Zn(\mu\text{-SR})_2ZnCl_2]$ (SR = 4-thiolato-*N*-methylpiperidinium),[151] and in $Me_2Tl(\mu\text{-SPh})_2TlMe_2$,[152] which is distorted severely from a tetrahedral stereochemistry at Tl with C—Tl—C = 164°. $[Mo_2(S_2)_6]^{2-}$ (NH_4^+) also has structure **2E**, but with η^2-S_2 ligands in bridging and terminal positions.[153]

2.2.5. *Metal–metal-bonded* $(RS)_3MM(SR)_3$ (**2F**). This exceptional structure occurs in the centrosymmetric molecule $[Si_2(SPh)_6]$[94] and contravenes the generalization that thiolate bridging prevails over metal–metal bonding in maintaining polymetallic thiolate aggregates. Attempts to prepare compounds $(RS)_3Mo{=}Mo(SR)_3$ by reaction of sterically hindered thiols (unlikely to form bridges) with the analogous compounds $Y_3Mo{=}MoY_3$ (Y = hindered or elimination-stabilized alkyl, NR_2 or OR), have led to $[(Me_2N)_2(Bu^tS)MoMo(SBu^t)(NMe_2)_2]$[154] and compounds $[Y(ArS)_2MoMo(SAr)_2Y]$ (Y = NMe_2 or OR, ArS = 2,4,6-trimethylbenzenethiolate).[155]

2.2.6. *Dimetallic structures with metal coordination numbers greater than* 4. There are to date few structurally confirmed instances of homothiolate complexes in this class, but there are data on numerous related structures which contain and define the pertinent structural units. By construction from these data it is possible to postulate structures of types $(RS)_nM(\mu\text{-SR})_2M(SR)_n$ (n = 3 or 4),

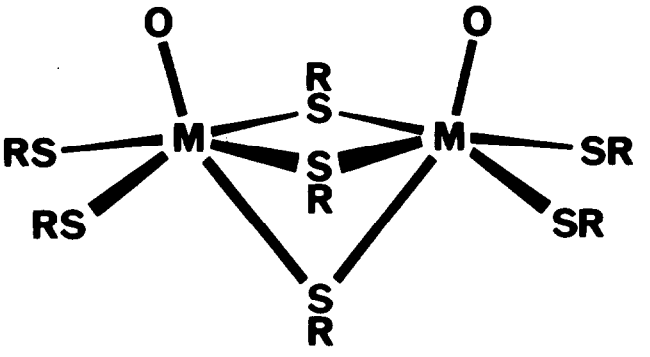
2G

2K



$(RS)_3M(\mu\text{-SR})_3M(SR)_3$ and $(RS)_2M(\mu\text{-SR})_4M(SR)_2$ with two, three or four doubly-bridging thiolates, and it is reasonable to predict that they will be confirmed in crystals after further synthetic enterprise.

2.2.7. $(RS)_3M(\mu\text{-}SR)_2M(SR)_3$ (**2G**). Although not known with monodentate thiolates, this type occurs in the complexes $[M_2(SCH_2CH_2S)_4]^{2-}$, which are essentially isostructural for M = Mn(III)[85,156] and Fe(III).[157] The non-chelated M—S bond in the centrosymmetric ion is 0.27 Å (Fe) or 0.30 Å (Mn) longer than the mean of the other four, and is axial in the distorted trigonal bipyramidal stereochemistry at the metal. Known structures **2G** but with oxide or sulfide heteroligands in the bridging positions, are $[(\mu\text{-}E)_2\{EMo(SPh)_2\}_2]^{2-}$ (E = O[158] or S[159]) $[(\mu\text{-}S)_2\{M(SBu^t)_2(PMe_2Ph)\}_2]$ (M = Mo[128] or W[160]) and $[(\mu\text{-}S)_2\{Mo(SBu^t)_2(NHMe_2)\}_2]$.[161] In the last three instances the bridge is exactly planar. The metal stereochemistry is approximately square pyramidal in the first two structures, while in the last three it is approximately trigonal bipyramidal with a bridging sulfide and a terminal heteroligand in axial positions. Therefore, these last three are presented as two trigonal bipyramids linked along an axial–equatorial edge.



Many complexes possess $L_3M(\mu\text{-}SR)_2ML_3$ structures, with organo, hydride, carbonyl or phosphine ligands (L) in terminal positions. Except as discussed in Section 5.6 for the information they provide about the geometry and stereodynamics of thiolate bridges, these compounds are beyond the scope of this Report.

2.2.8. $(RS)_4M(\mu\text{-}SR)_2M(SR)_4$. Octahedra linked by two bridging thiolate ligands occur in the Mo(III) complexes $[(L\text{–}L)Cl_2Mo(\mu\text{-}SEt)_2MoCl_2(L\text{–}L)]$.[162] The Ti(IV) phenoxide complex $[(PhOH)(PhO)_3Ti(\mu\text{-}OPh)_2Ti(OPh)_3(PhOH)]$ has the same centrosymmetric structure,[163] with three notable stereochemical features: (i) an almost planar stereochemistry occurs at the oxygen atoms of the bridging ligands, (ii) the two terminal phenoxide ligands approximately *trans* to the bridging ligands have Ti—O—C angles of 169 and 175°, and (iii) phenol is coordinated with Ti—O = 2.20 Å (although the H atom was not located crystallographically).

2.2.9. $(RS)_3M(\mu\text{-}SR)_3M(SR)_3$ (**2H**). Although the well-known confacial bioctahedron is not yet

2H

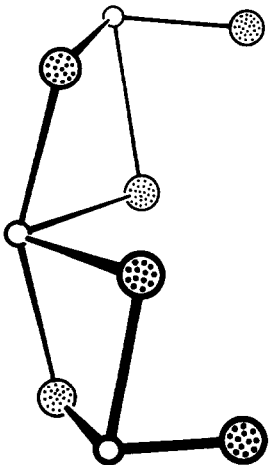
2J

established for a homothiolate molecule, the $M(\mu\text{-}SR)_3M$ bridging section has been characterized in $[Cl_2(Me_2S)W(\mu\text{-}SEt)_3WCl_2(SMe_2)]$,[164] in $[(CO)_3Fe(\mu\text{-}SMe)_3Fe(CO)_3]^+$,[165] and in the thoroughly characterized double-cubane structures (**8G** and **9A**), where triply-bridging sulfide ions take the place of the terminal thiolate ligands on M. Analogous tris double-bridging occurs in $[(\mu\text{-}SH)_3\{Fe(ppp)\}_2]^+$ [ppp = $Ph_2PCH_2CH_2P(Ph)CH_2CH_2PPh_2$].[166] The complex $[L_3Mo(\mu\text{-}SMe)_3MoL_3]^{3+}$ (L = 1-methylimidazole)[167] is relevant, although not crystallographically confirmed.

The complex $[Mo_2O_2(SCH_2Ph)_7]^-$[168] almost certainly has the tri-bridged $[(\mu\text{-}SCH_2Ph)_3\{OMo(SCH_2Ph)_2\}_2]$ structure (**2J**). It is a member of the set $[(\mu\text{-}SR)_2(\mu\text{-}Z)\{OMo(SR)_2\}_2]^-$ [R = Ph, C_6H_4Me-4, $\frac{1}{2}(CH_2CH_2)$ or $\frac{1}{2}(CH_2CH_2CH_2)$], in which alcoxide or amide ligands can occur as the third bridging ligand Z. Structural details for this type are established by the diffraction analyses[168,169] of the four compounds $[Mo_2O_3(SCH_2CH_2O)_3]^{2-}$, $[Mo_2O_2(SCH_2CH_2O)_3(SCH_2OH)]^-$, $[Mo_2O_2(SCH_2CH_2O)_3Cl]^-$ and $[Mo_2O_2(SCH_2CH_2O)_2Cl_3]^-$, and of $[Mo_2O_2(OMe)(SC_6H_4Me)_6]^-$.[170] In all cases the bridging bonds *trans* to both OMo(V) groups are elongated. A compilation of geometrical data for $\{OMo(\mu\text{-}X)_3MoO\}$ bridges involving thiolate is available.[170] Analogous thiolate coordination, but with diazene functions in place of the oxo ligands, occurs in $[Mo_2(NNHPh)(NNPh)(SCH_2CH_2S)_3(SCH_2CH_2SH)]^{2-}$.[171]

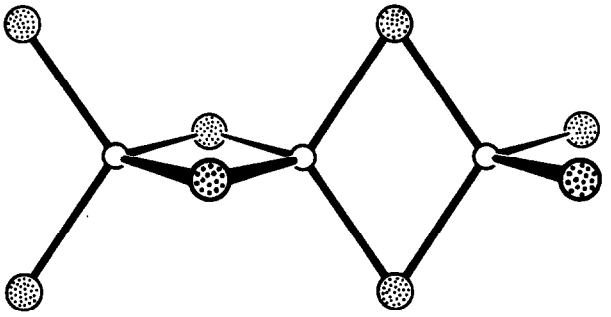
2.2.10. $(RS)_2M(\mu\text{-}SR)_4M(SR)_2$. This type of structure is found in the ion $[V_2(SCH_2CH_2S)_4]^{2-}$

(Ph_4P^+),[117] (Et_4N^+),[172] (Ph_4P^+)[173] with connectivity **2K**, which is distinctly different from the connectivity **2G** for the same formulation. Significant characteristics of **2K** are: (i) the ion has exact[172] or virtual[173] D_2-symmetry; (ii) the bridging V—S distances are in two sets (*ca* 2.39 and *ca* 2.53 Å); (iii) the metal coordination stereochemistry (C_{2v}) is unusual, and can be visualized as a cube without two positions connected by a face diagonal; (iv) the structure can be regarded as two VS_4 square planes, staggered about the V- -V axis, intersecting in the bridging region; (v) the V—V distance is short (*ca* 2.61 Å), indicative of a single bond; and (vi) the complex is diamagnetic, suggesting (but not confirming) electronic coupling through the thiolate bridges.



The tetra double-bridged section of **2K** has been characterized by structure determination for three complexes with pi-arene terminal ligands, namely $[(\mu\text{-SMe})_4\{Mo(\eta^5\text{-}C_5H_5)\}_2]^{0,+}$,[174] in two oxidation states, and $[(\mu\text{-SMe})_4\{Mo(\eta^6\text{-}C_6H_5Me)\}_2]^{2+}$.[167] The M—S—M bridge angles are acute (64–65°).

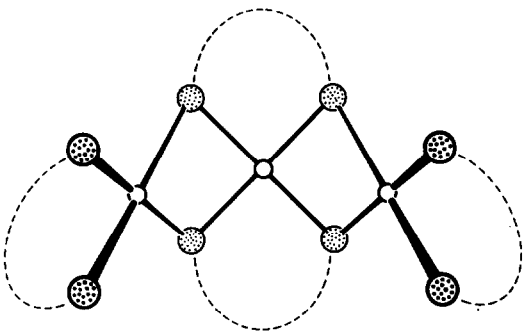
2.2.11. *Miscellaneous structures.* The polysulfide complexes $[(S_6)M(S_8)M(S_6)]^{4-}$ (M = Cu[175] or Ag[176]) each contain two three-coordinate M atoms chelated by the S_6 rings and connected by an elongated central polysulfide (S_8^{2-}).



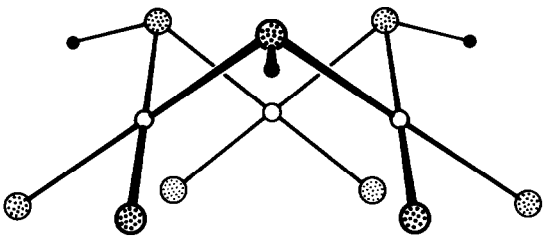
2.3. *Trimetallic structures*

Cyclic and linear trimetallic structures have proliferated since 1980, with recognition of the $Fe_3S_3(S\text{-cys})_5$ ferredoxins, the preparation of diverse complexes with hetereoligands, and the consolidation of knowledge of the $(\mu\text{-}S\text{-cys})_3M_3(S\text{-cys})_6$ aggregate (M = Zn or Cd) in metallothioneins. Although no homothiolate structure has yet been reported, the data on various heteroligand complexes allow the development of principles and the definition of structure types. In view of the report[29] of the crystallization of metallothionein from rat liver it is not unreasonable to expect that diffraction results from a metalloprotein may define a cyclic trimetallic homothiolate aggregate prior to results form any simple coordination complex or synthetic analogue.

2.3.1. $RSM(\mu\text{-}SR)_2M(\mu\text{-}SR)_2MSR$ (**3A**). This structure (symmetry C_2) occurs with R = 2,6-diisopropylphenyl (M = Sn or Pb).[54] The central metal is four-coordinate in a pseudo trigonal bipyramidal stereochemistry $[M(S^{ax})_2(S^{eq})_2$, $M—S^{ax}$ elongated by 0.2 Å, $S^{eq}—M—S^{eq} = 87°$, $S^{ax}—M—S^{ax} = 146°]$ and the terminal metal atoms are three-coordinate pyramidal (S—M—S = 74, 90 and 94°). $[PhSCu(\mu\text{-}S)_2Mo(\mu\text{-}S)_2CuSPh]^{2-}$ (Pr_4N^+, symmetry C_2) contains trigonal planar Cu atoms linked through tetrahedral tetrathiomolybdate.[177]



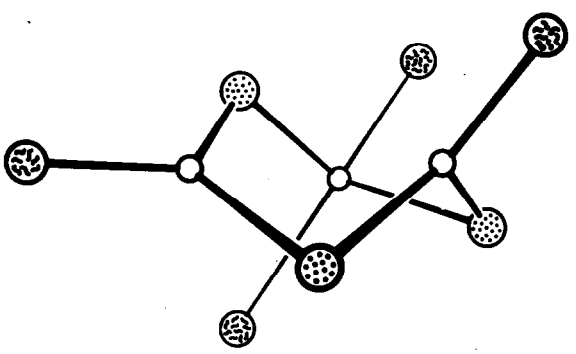
3A



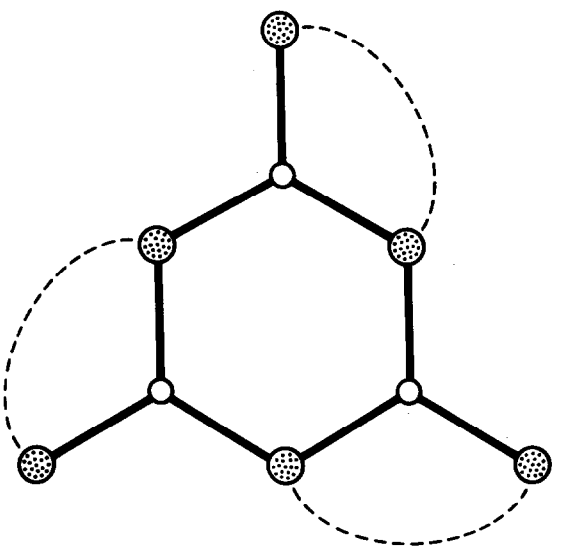
3B

2.3.2. *Linear* $(RS)_2M(\mu\text{-}SR)_2M(\mu\text{-}SR)_2M(SR)_2$ (*tetrahedral coordination*) (**3B**). This type but with bridging sulfide occurs in the complexes $[(RS)_2Fe(\mu\text{-}S)_2Fe(\mu\text{-}S)_2Fe(SR)_2]^{3-}$ (R = Et or Ph).[78,178] The $Fe(III)_3S_8$ core of the complex with R = Ph[78] approaches D_{2d}-symmetry: the Fe—Fe—Fe angle is 172.9°: the two Fe_2S_2 rhombs are planar to within 0.06 Å, and mutually perpendicular to within 0.5°: the internal angles are 102.8° at the central Fe atom, 105.6° at the terminal iron atom, and 75.6° at the sulfide ion. The same structure probably occurs in $[(PhS)_2Fe(\mu\text{-}S)_2V(\mu\text{-}S)_2Fe(SPh)_2]^{3-}$,[179] and is confirmed for $[Cl_2Fe(\mu\text{-}S)_2M(\mu\text{-}S)_2FeCl_2]^{z-}$ (M, $z-$ = Mo; 2–;[180,181] W, 2–;[181] or V, 3–[179]).

2.3.3. $(RS)_2M(\mu\text{-}SR)_2M(\mu\text{-}SR)_2M(SR)_2$ *with planar metal coordination.* The one instance of three edge-linked square planes is $[Ni_3(S_2\text{-}o\text{-}xyl)_4]^{2-}$ (Et_4N^+)[144] which has the chelate connectivity shown as **3C**. The dihedral angle between coordination planes is *ca* 130°. The conformation with coplanar coordination planes has not yet been reported.

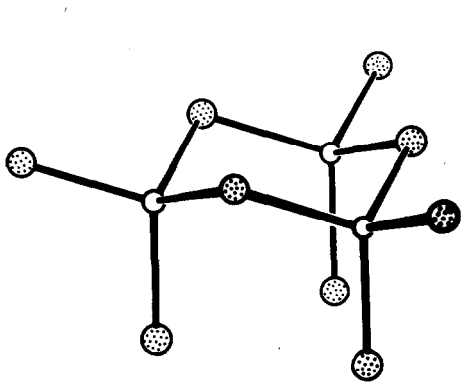


3C

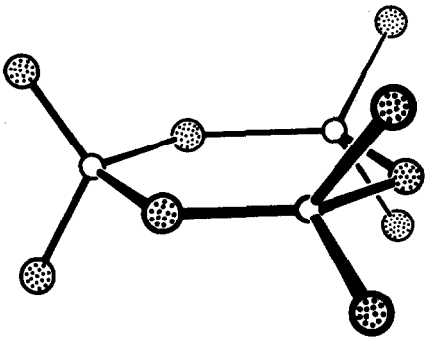


3H

2.3.4. *Linear* $(RS)_3M(\mu\text{-}SR)_3M(\mu\text{-}SR)_3M(SR)_3$ (*octahedral coordination*). Although without confirmed independent existence, this structure constitutes the central region of the centrosymmetric double-cubane structure **9A**.



3D



3E

2.3.5. *Cyclic* $(\mu\text{-}SR)_3(MSR)_3$ (*three-coordinate metal*). The closest approach to this structure type is found in $(\mu\text{-}SAr)_3(CuPPh_3)_2Cu(PPh_3)_2$ (Ar = Ph or C_6H_4Cl-4)[182] where two of the M atoms in the cycle have one terminal phosphine ligand and the third is coordinated by two terminal phosphine ligands (**3D**). The salient stereochemical property of this and other cyclic structures is the ring conformation. Here the conformation is a slightly twisted boat, in which the unique diagonal is not that which posseses the two-fold symmetry of the $S_3Cu_3P_4$ connectivity, but another which permits isoclinical rather than pseudo-axial directions for the two bulky phosphine ligands coordinated to one copper atom. Bond lengths in the cycle are unexceptional, but Cu—S—Cu angles range widely from 87 through 105 to 124°, and are correlated with the inclinations of the S–C vectors at the pyramidal S atoms.[182]

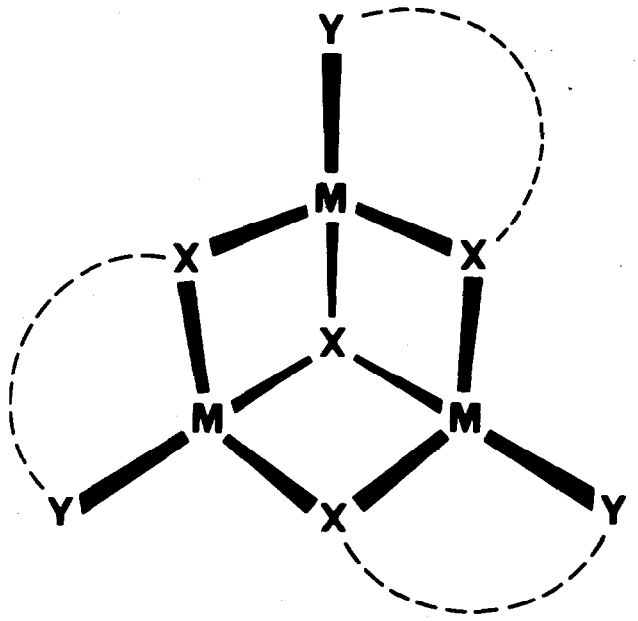
The ions $[Cu_3(S_6)_3]^{3-}$ (Et_4N^+)[19] and $[Cu_3(S_4)_3]^{3-}$ $(NH_4^+$ or $Ph_4P^+)$,[175] prepared from copper(II) acetate and ethanolic polysulfide solution, contain a puckered cyclic core with chelating 1,6-hexasulfide or 1,4-tetrasulfide ions connecting bridging and terminal positions as shown in **3E**.

3F

3G

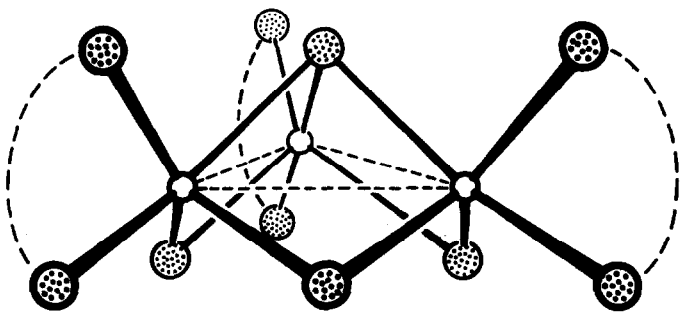
2.3.6. *Cyclic* $(\mu\text{-SR})_3(M(SR)_2)_3$ (*tetrahedral metal coordination*). It is proposed that an $[M_3(S\text{-cys})_9]^{3-}$ aggregate in zinc and cadmium metallothioneins has structure **3F**, which is a fragment of the established adamantanoid $M_4(SR)_{10}$ cage structure **4F**. The removal of one MSR moiety from **4F** to form **3F** in chair conformation generates three parallel, axial, terminal M—S bonds, and therefore it is expected that some conformational modification of the $(\mu\text{-SR})_3M_3$ ring will occur. In this context the planar structure **3G** of the complex $[(\mu\text{-SPh})_3(FeCl_2)_3]^{3-}$ (Et_4N^+) is significant, particularly as it is reported that the three phenyl rings are coplanar with the cycle.[178] Only the six terminal Cl atoms which complete the pseudo-tetrahedral coordination at the Fe atoms deviate from the molecular plane. The Fe—S—Fe angles of 139, 139 and 142° are unusually large.

In this and many other structures with doubly-bridging thiolate (particularly **3D**, **4E** and **4F**) there exists good correlation between the M—S—M angle (θ) and the angle of inclination (ϕ) of the corresponding S–C vector to the M—S—M plane. This relationship extends over a wide range (50° for θ, 60° for ϕ) of stereochemistry at the S atom.[182,183] It may be postulated that, for isolated $(\mu\text{-SR})_3M_3$ cycles, the M—S—M angles, and therefore to some extent the cycle conformation, are quite variable and strongly dependent on the directions of approach of the C—S bonds to the cycle. These latter may be determined by crystal packing effects in small molecules, and by a polypeptide secondary structure in metallocysteine proteins. The cause of the total planarity of the $(\mu\text{-SPh})_3Fe_3$ cycle is not yet revealed.



The compounds $(\mu\text{-SMe})_3(BX_2)_3$ (X = Cl or Br)[184] occur in regular chair conformation with one axial and two equatorial S—C bonds: the S stereochemistry is consistent with the above correlation.

2.3.7. *Cyclic* $(\mu\text{-SR})_3M(SR)_2)_3$ (*planar metal coordination*) (**3H**). In this uncommon structure type three metal coordination planes [*cis*-$(\mu\text{-SR})_2M(SR)_2$] share vertices such that the $(\mu\text{-SR})_3M_3$ cycle has a chair conformation. Close approaches to **3H** occur in the ethyltrithiocarbonate derivative $(\mu\text{-SEt})_3Pd_3(S_2CSEt)_3$[135] and in $Pd_3(SCH_2CH_2SCH_2CH_2S)_3$:[185] in both compounds the bridging thiolate substituents are all equatorial.



2.3.8. *Cyclic* $(\mu_3\text{-S})(\mu\text{-SR})_3(MSR)_3$ (**3J**). In this centred version of **3E**, an apical triply-bridging sulfide ion completes tetrahedral coordination for each of the three M atoms in a triangle. The structure is known only for the flexible, large-bite, chelating *o*-xylyl dithiolates of Fe, Co and Ni.[186–189]

2.3.9. 3-Fe *ferredoxins*. A cyclic structure with bridging sulfide and terminal thiolate ligands occurs in 3-Fe ferredoxins: it has been confirmed in crystals of ferredoxin I from *Azotobacter vinelandii*.[21,23] In *A. vinelandii* one terminal ligand is an O atom which is not part of the polypeptide chain, probably OH or OH_2. The irregular $(\mu\text{-S})_3Fe_3(S\text{-cys})_5O$ structure (at 0.2 Å/5° precision) is shown diagrammatically in Fig. 2. The six-membered Fe_3S_3 ring has a flattened twist conformation in which there is an approximate two-fold axis through Fe3–S1. In the ideal twist structure S2 and S3 would be displaced ±1.4 Å from coplanar Fe3–S1–Fe1–Fe2: in fact that the displacements of the bridging S atoms from the Fe_3 plane are S1 −0.2 Å, S2 −0.5 Å, and S3 +0.5 Å. The four-coordinate stereochemistry around the Fe atoms is quite irregular, with angles at Fe in the ranges 85–153, 78–149 and 74–151° for Fe1, Fe2 and Fe3, respectively. As shown in Fig. 2, four Fe—S(cys) bonds are approximately perpendicular to the ring plane, while the other Fe—S(cys) and the Fe—O bonds are almost parallel to the plane. Angles at bridging sulfide are relatively large, range 113–131°, with the degree of puckering of the $(\mu\text{-S})_3M_3$ cycle intermediate between those of $(\mu\text{-SPh})_3Cu_3(PPh_3)_4$ and $[(\mu\text{-SPh})_3Fe_3Cl_6]^{3-}$.

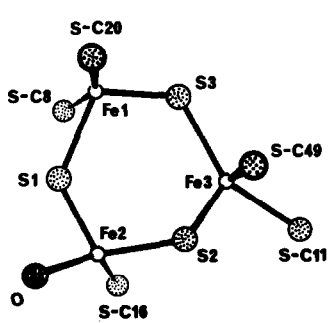
Ferredoxin II from *D. gigas*[190] and inactive beef heart aconitase[191] contain 3-Fe aggregates with

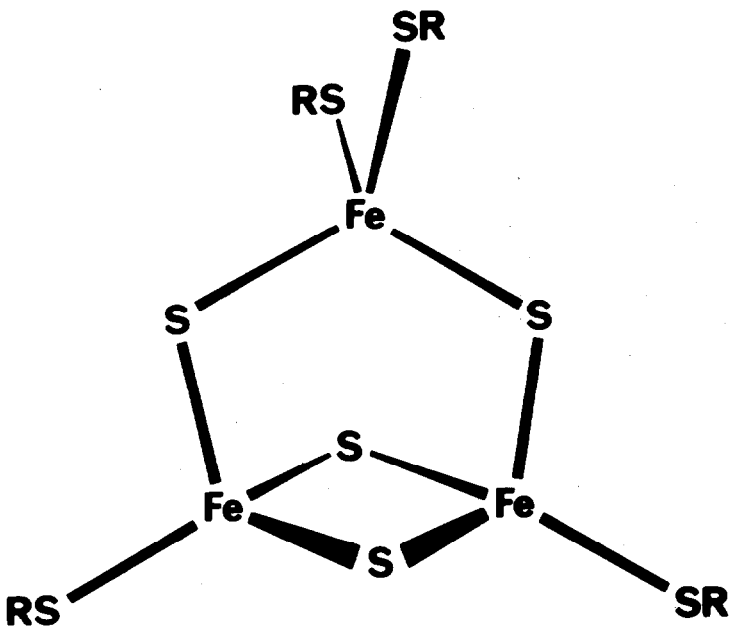
3J

3L

2.7-Å separations (from EXAFS measurements) between Fe atoms, distinctly different from the 4.1-Å separation in *A. vinelandii*. Models proposed for the cores of these two proteins include **3B**, **3J** and **3K**.

2.3.10. *Cyclic* $(\mu_3\text{-S})(\mu\text{-S})_3M_3(SR)_6$ (**3L**). The compound $[Mo_3S_4(SCH_2CH_2S)_3]^{2-}$, obtained by reaction of $[Mo_3S(S_2)_6]^{2-}$ with excess $^-SCH_2CH_2S^-$,[192] has this three-fold structure in which each Mo(IV) atom is five-coordinate (trigonal bipyramidal, μ_3-S axial). The Mo atoms occur sandwiched





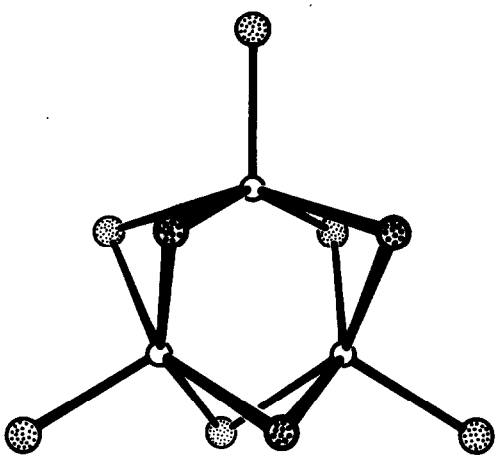


Fig. 2. Coordination structure (at 0.2-Å resolution) of the $(\mu\text{-S})_3Fe_3$(*S*-cysteine)$_3$O core of ferredoxin I from *A. vinelandii*, with the cysteine residues numbered.

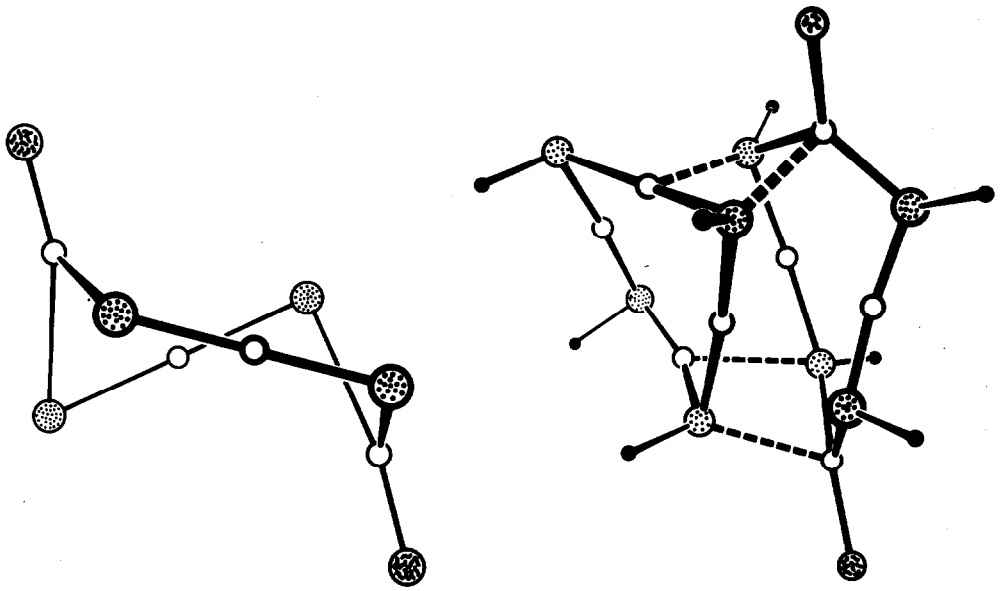
3K

3M

between two triangular layers of S atoms, and in this sense (but not in terms of local metal coordination) there is some resemblance of **3L** with the two-dimensionally non-molecular MoS_2 structure type.

2.3.11. *Cyclic* $(\mu\text{-SR})_6(ML)_3$ (**3M**). Two compounds are derivatives of this D_{3d} structure, in which the triangle of metal atoms is spanned by two doubly-bridging thiolate ligands on each edge. The S atoms constitute a trigonal prism with the M atoms outside the rectangular faces, and the terminal ligands (L) complete the square pyramidal $(\mu\text{-SR})_4ML$ coordination. The structures established are $(\mu\text{-SEt})_5(\mu\text{-CO})(CoCO)_3$[193] and $(S\text{–}S)_3(NiPPh_3)_3$[194] in which (S–S) is the rigid chelating dithiolate ligand hexachloronaphthalene-1,8-dithiolate.

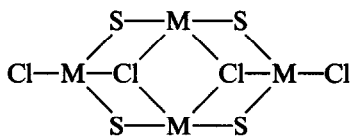
In structure **3M** the configurations of the thiolate substituents may be axial or equatorial relative to the principal axis of the S_6 trigonal prism, but the substituents are subject to steric restrictions due to the relatively short (2.9–3.4 Å) edges of the prism when M is a metal of the first transition series. These S—S distances are much less than half the sum of the van der Waals' radii of even the smallest substituents on contiguous thiolate ligands, and, therefore, it is not possible for substituents connected by an edge normal to the trigonal axis to be both axial, or for substituents connected by an edge parallel to the



trigonal axis to be both equatorial. Neither is it possible to arrange axial–equatorial alternation of substituents around trigonal prismatic $(\mu\text{-SR})_6M_3$, but five bridging thiolates can occur without interference. This argument was used to rationalize the composition of $(\mu\text{-SEt})_5(\mu\text{-CO})Co_3(CO)_3$.[193] The chelate rings of the Ni compound require all S—C bonds to be equatorial.

2.4. *Tetrametallic structures*

No acyclic structures are known. With four bridged M atoms, mono-, bi- and tricyclic structures are possible, and are established.



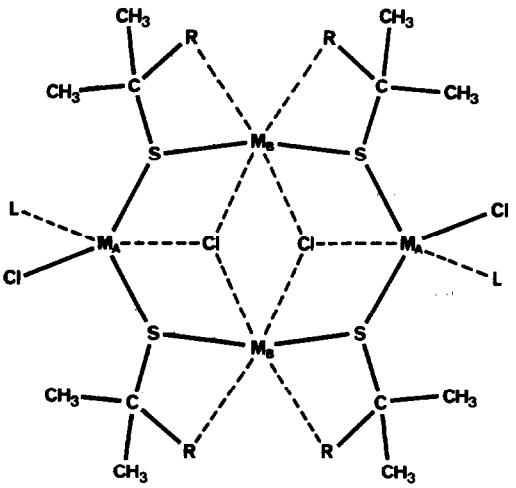
2.4.1. *Monocyclic* $(\mu\text{-SR})_4M_4$. This monocycle occurs 3 times in two guises in the compounds $(Et_2MeCSAg)_8(PPh_3)_2$[195] and $(Bu^tSCu)_4(PPh_3)_2$.[196] The 1,3-diligated cycle **4A** occurs with the *anti* conformation shown in the Cu compound (S—Cu—S angles 176, 173, 119 and 117°), while the Ag aggregate, shown as **4B**, consists of a slightly buckled $(\mu\text{-SR})_4Ag_4$ cycle and a $(\mu\text{-SR})_4Ag_2(AgPPh_3)_2$ cycle, confacially linked by secondary Ag···S interactions, all 0.5 Å longer than the primary Ag–S bonding. Angles at the two-coordinate Ag atoms in the cycle are in the range 166–174°, a consequence of the secondary connections.

Unsubstituted **4A** occurs in the analogous compound $(CuOBu^t)_4$,[197] which is smaller, more tightly bound and symmetrical than the thiolate analogs.

4A **4B**

2.4.2. *Heteroligated* $(\mu\text{-SBu}^t)_4M_4$ *structures.* Attention should be drawn to structural relationships between some derivatives $[M(SR)Cl]_4$ of Zn, Cd and Hg with tertiary thiolates. The compounds are $M_4[SC(CH_3)_2CH_2NH_2]_4Cl_4\cdot 2H_2O$ [M = Zn[198] or Cd[199]] and $Hg_4(SBu^t)_4Cl_4(py)_2$,[200] with structures all based on the framework

(which has the composition and five of the six rhomboidal M_2X_2 structural units of the cubane structure **4H**). The relationships between the structures are expressed in terms of Fig. 3: (i) when M = Zn or Cd the additional heteroligand coordination occurs only at M_B, via R = CH_2NH_2 (L is absent), whereas when M = Hg and R = CH_3 additional heteroligand coordination occurs only via L = pyridine; (ii) as M changes Zn → Cd → Hg the M_A—Cl distance changes from primary bonding (Zn—Cl = 2.27 Å, Cd—Cl = 2.41 Å) to non-bonding (Hg), while the M_B—Cl distance decreases from



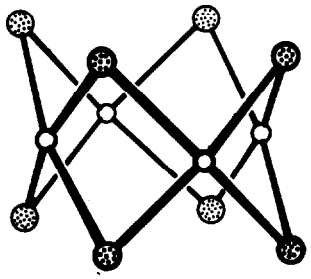


Fig. 3. Framework of variable primary and secondary bonding connections in $[M(SR)Cl]_4$ and derivatives (M = Zn, Cd or Hg).

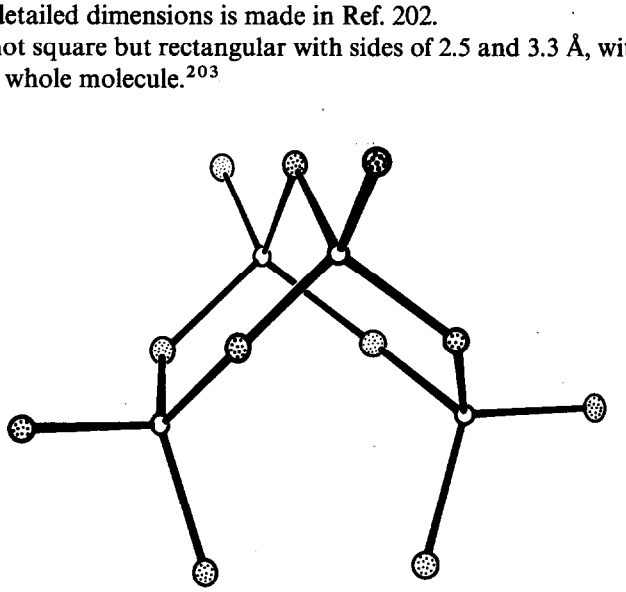

non-bonding (Zn--Cl = 3.4 and 3.5 Å) through weak secondary bonding (Cd--Cl = 2.95 Å) to intermediate bonding (Hg—Cl = 2.70 and 2.81 Å).

2.4.3. *cyclo*-$(\mu\text{-SR})_8M_4$ (**4C**). The Ni complex of 4-mercapto-*N*-methylpiperidine has this square array of Ni atoms, with two double thiolate bridges outside each edge of the square to provide approximately square planar coordination at each Ni atom.[201] The Ni atoms are displaced 0.2 Å outside their coordination planes. The substituents alternate axial and equatorial to the primary axis of the virtual D_{2d} molecule. Analysis of the detailed dimensions is made in Ref. 202.

In $(\mu\text{-SEt})_8(CoCO)_4$ the Co_4 array is not square but rectangular with sides of 2.5 and 3.3 Å, with pseudo-D_{2h}-symmetry maintained for the whole molecule.[203]

4C

4D

2.4.4. *Bicyclic* $(\mu\text{-SR})_5M_4(SR)_6$ (**4D**). This structure, postulated for the $Cd_4(S\text{-cys})_{11}$ aggregate of metallothioneins (Section 1.5), is derived from the well-known adamantanoid $(\mu\text{-SR})_6(MSR)_4$ structure (**4F**) by replacement of a bridging thiolate with additional terminal thiolate ligands on each of the separated M atoms. However this introduces substantial crowding in the vicinity of the inserted ligands, which must be relieved by flattening of the two fused $(\mu\text{-SR})_3M_3$ cycles, or by their adoption of the double-twist conformation. No instance or derivative of this structure has yet been confirmed crystallographically. The homonuclear decoupled ^{113}Cd NMR of metallothioneins supports the metal connectivity of this structure, with ^{113}Cd–^{113}Cd coupling between the two Cd atoms bridged directly across the pseudo two-fold axis being larger than for the other four Cd–Cd couplings.[30]

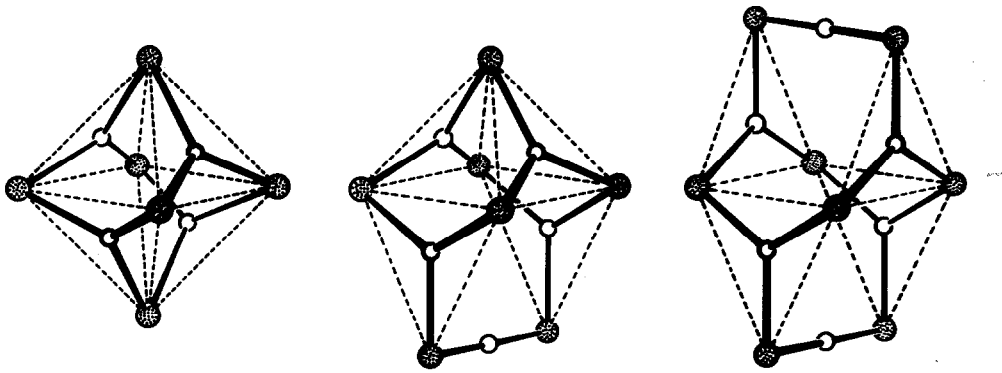

Fig. 4. Structures **4E**, **5A** and **6A**, showing the polyhedral expansion mechanism which relates the three cages.

2.4.5. (μ-SR)$_6$M$_4$ (**4E**). This molecular cage (see Fig. 4) contains a doubly-bridging thiolate ligand across each of the six edges of the M_4 tetrahedron such that each metal has a trigonal planar coordination. The M_4S_6 core can be described as an octahedron of S atoms with M atoms at the midpoints of four faces: in terms of the component polyhedra the structure is *tetrahedro*-M_4-*octahedro*-S_6. The T_d-symmetry of this core is necessarily thwarted by the thiolate substituents, as discussed below. An alternative description[204] of the core recognizes four fused M_3S_3 cycles, each in a severely distorted chair conformation.

This structure is established, but only for Cu(I), in $[Cu_4(SMe)_6]^{2-}$ and $[Cu_4(SPh)_6]^{2-}$[50,204,205]* In all cases (four independent crystal structure determinations of $[Cu_4(SPh)_6]^{2-}$) the Cu atoms lie slightly outside their S_3 coordination planes: the mean displacement is 0.07 Å. This observation, together with the Cu- -Cu distances (range 2.64–2.85 Å, mean 2.74 Å), indicates little direct bonding between the three-coordinate Cu atoms. The aggregate is maintained primarily by the bridging thiolate ligands.

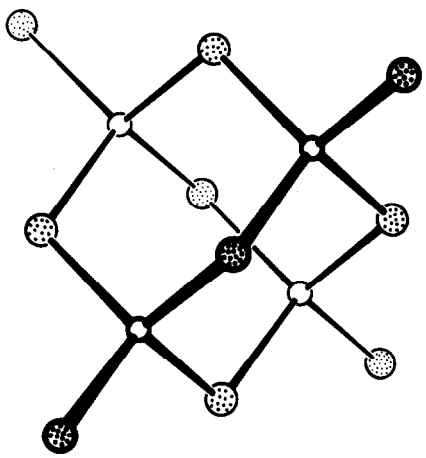
Configurational isomerism of the molecule including the thiolate substituents is due to the pyramidal stereochemistry at the S atoms. Inversion of the doubly-bridging thiolates allows three configurational isomers (each chiral) described in terms of the axial (a)–equatorial (e) distribution of the three S–C vectors in each of the four fused M_3S_3 cycles in the structure.[204] The three isomers are **I** [aaa,aae,aee,eee], **II** [aae,aae,aae,eee] and **III** [aae,aae,aee,aee], **I** and **III** being asymmetric while **II** is C_3. All five instances of $[Cu_4(SR)_6]^{2-}$ occur as isomer **III**, which has the least number (two) of contiguous axial–axial substituents. The asymmetry of the substituent array correlates well with geometrical distortions of the Cu_4S_6 core from its potentially high (T_d) symmetry. Due to intramolecular repulsions between substituents the axial–axial pairs of ligands subtend enlarged S—Cu—S angles, and in all four $[Cu_4(SPh)_6]^{2-}$ cages the following correlation exists between pairwise substituent orientation and S—Cu—S angle:

ax—ax substituents, mean S—Cu—S 138.0 (s† 4.1)°,

ax—eq substituents, mean S—Cu—S 118.3 (s 6.2)°,

eq—eq substituents, mean S—Cu—S 108.1 (s 2.1)°.

Corresponding S—Cu—S values for $[Cu_4(SMe)_6]^{2-}$ with the smaller substituent, 128.0 (0.4†), 118.0 (5.4) and 119.6 (1.1), respectively, deviate less from the 120° ideal. While the susceptibility of the cage to substituent repulsions is more in variation of bond angle than in bond distance, there is a secondary influence on Cu—S distances which are coupled electronically to opposite S—Cu—S angles within each CuS_3 coordination plane (see Section 5.8).



---

* A comparable cage with halide ligands is $[Cu_4I_6]^{2-}$.[206]

† The standard deviation (s) quoted in statistical analyses is that of the sample of n values: $s = [\Sigma(x-\bar{x})^2/(n-1)]^{1/2}$.

The vertices of the S_6 octahedron in **4E** are linked by three α,ω-chelating polysulfide ligands in the cages $[Cu_4(S_4)(S_5)_2]^{2-}$ and $[Cu_4(S_4)_2(S_5)]^{2-}$ which crystallize together.[207]

2.4.6. $(\mu\text{-SR})_6(MSR)_4$ (**4F**). The framework of this molecular cage structure is widely known amongst compounds organic (adamantane), organometallic [e.g. $S_6(SnMe)_4$] and inorganic (e.g. P_4S_{10}),[94] and is ubiquitous amongst the thiolates of metals adopting tetrahedral coordination. Four M atoms, each with one terminal thiolate ligand, are arrayed as a tetrahedron outside the faces of an octahedron formed by the S atoms of the six doubly-bridging thiolate ligands. The metal coordination is $(\mu\text{-SR})_3MSR$. T_d-symmetry is possible for the M_4S_{10} core of this *octahedro*-$(\mu\text{-SR})_6$-*tetrahedro*-M_4-*tetrahedro*-$(SR)_4$ cage, commonly known as the "adamantanoid" cage structure, but the thiolate substituents necessarily break almost all of this high symmetry.

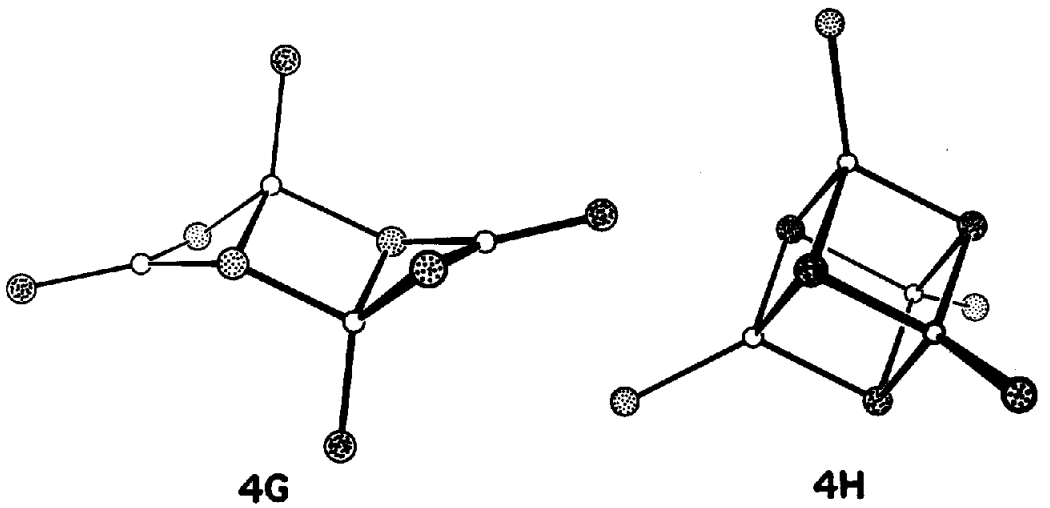
4F

Structure **4F** was first described[208,209] for $[Co_4(SPh)_{10}]^{2-}$ with Me_4N^+. The corresponding isomorphous crystals of $[Mn_4(SPh)_{10}]^{2-}$,[85] $[Fe_4(SPh)_{10}]^{2-}$[210] and $[Zn_4(SPh)_{10}]^{2-}$,[211] have since been subjected to detailed diffraction analysis. Crystal structures have been determined also for $(Et_4N^+)(Et_3NH^+)[Cd_4(SPh)_{10}]^{2-}$[212] and $(Et_3NH^+)_2[Zn_4(SPh)_{10}]^{2-}$,[213] and $(Me_4N)_2[Fe_4(SEt)_{10}]^{2-}$.[141] In addition, structural details are available for related complexes with hetero-ligands in terminal positions, namely $[Zn_4(SPh)_8Cl_2]^{2-}$ {with which $[Co_4(SPh)_8Cl_2]^{2-}$ as the Me_4N^+ salt is isostructural}[214] and $[Fe_4(SPh)_6Cl_4]^{2-}$ (Ph_4P^+).[215] The adamantanoid cage structure is found also in the repeat unit of the one-dimensionally non-molecular crystal structure of *catena*-$(\mu\text{-SPh})[(\mu\text{-SPh})_6Zn_4(CH_3OH)(SPh)]$ where one methanol, one terminal thiolate and two doubly-bridging thiolate ligands complete the coordination of the four Zn atoms (see Section 3.1.6).

An important NMR study has characterized the ligand and metal exchange reactions of $[M_4(SPh)_{10}]^{2-}$ (M = Fe, Co, Zn or Cd), in acetonitrile,[210] while solution equilibria involving $[Co_4(SPh)_{10}]^{2-}$ have been characterized by electronic spectra.[209]

The four fused $(\mu\text{-SR})_3M_3$ cycles approach the ideal chair conformation. Molecular configurational isomerism, arising through inversion at the pyramidal S atoms of the six doubly-bridging thiolates, is analogous to that in **4E** with the same three isomers possible. All of the above-listed instances of the adamantanoid cage structure **4F** occur as the asymmetric isomer **III** [aae,aae,aee,aee] with only two ax–ax ligand pairs, except for the Fe complexes $[Fe_4(SPh)_{10}]^{2-}$, $[Fe_4(SEt)_{10}]^{2-}$ and $[Fe_4(SPh)_6Cl_4]^{2-}$, which are the asymmetric isomer **I** [aaa,aae,aee,eee] with four ax–ax ligand pairs.

The $(\mu\text{-SPh})_6M_4$ core of these structures is angularly floppy, and in all cases the S_6 polyhedron is distorted from a regular octahedron in the manner that increases the S– –S distances between pairs of parallel axial SPh substituents. Thus, in $[Fe_4(SPh)_6Cl_4]^{2-}$ the S_{ax}—Fe—S_{ax} angles average 116.4(2)° while the S_{ax}—Fe—S_{eq} and S_{eq}—Fe—S_{eq} angles average 102.4(3)°. Corresponding average S_{ax}– –S_{ax} and S_{ax}– –S_{eq} plus S_{eq}– –S_{eq} distances are 4.01(4) and 3.68(9) Å, respectively. Similar angular distortions, without significant variation in M—S distances, occur in the other structures.



In all examples of this structure type the metal atoms are displaced slightly outward along the pseudo-three-fold axes such that the mean M—S_b—M and S_b—M—S_t angles are several degrees larger, and the mean S_b—M—S_b angles several degrees smaller than 109.5°. This effect, which need not

break the idealized T_d-symmetry, can be expressed also by the ratio of mean M– –M to mean S_b– –S_b distances, values of which are 1.064, 1.034, 1.035 and 1.051 for $[M_4(SPh)_{10}]^{2-}$ (M = Mn, Fe, Co or Cd), respectively, and 1.040, 1.024 and 1.003 for $[Fe_4(SPh)_6Cl_4]^{2-}$, $[Zn_4(SPh)_8Cl_2]^{2-}$ and $Zn_4(SPh)_8(MeOH)$, respectively. Further comparisons of metrical details of the adamantanoid cage structures are made in Refs 215 and 85.

Antiferromagnetic interaction between M atoms is reported for $[Co_4(SPh)_{10}]^{2-}$[209] and $[Mn_4(SPh)_{10}]^{2-}$.[85] The total interaction energy, $9J \approx 150\,cm^{-1}$ for $[Co_4(SPh)_{10}]^{2-}$, is negligible as a chemical bonding influence, and is consistent with the absence of direct M–M bonding in this structure type. Scalar coupling between Cd nuclei through μ-SPh has been observed in the ^{113}Cd NMR spectra of $[Cd_4(SPh)_{10}]^{2-}$.[216,217]

Although thiourea (tu) is not a thiolate ligand, it supports structure **4F** in $[Cu_4(tu)_{10}]^{4+}$.[218] A heteroligand occurrence of **4F** is $(\mu\text{-SMe})_4(\mu\text{-S})_2(GaI)_4$.[219]

2.4.7. *Tricyclic* $(\mu_3\text{-SR})_2(\mu\text{-SR})_2(ML)_4$ (**4G**). This structure is known only for $Cu_4(SPh)_4(PPh_3)_4$.[220] It is a slightly flattened and twisted version of the "step" structure known for halide-bridged analogues with bulky phosphine ligands.

4G **4H**

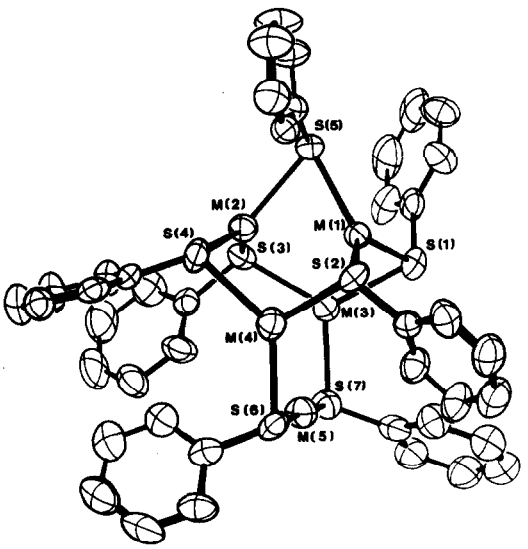
2.4.8. *Derivatives of the* $(\mu_3\text{-SR})_4M_4$ *cubane core.* The homothiolate cubane structure $(\mu_3\text{-SR})_4(MSR)_4$ (**4H**), with triply-bridging and terminal thiolate ligands, has not yet been realized, although it has been proposed, without evidence, for copper metallothionein.[221] Compounds with heteroligands in either the terminal or bridging positions of **4H** are known. The series $[(\mu_3\text{-E})_4Fe_4(SR)_4]^{z-}$ (E = S or Se, z = 2 or 3) has been thoroughly investigated as analogues of the 4-Fe ferredoxins, and structural details, including those of the proteins, have been reviewed.[21,35] These structures are composed of concentric tetrahedra (slightly compressed) of E_4 and Fe_4, with congruent S_4 axes, but the E_4 tetrahedra are substantially larger so that E—Fe—E angles average 104° while Fe—E—Fe angles average 74°.

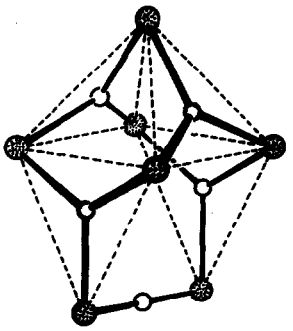
More recently metal-substituted cubanes, $[(RS)_3Fe_3(\mu_3\text{-S})_4M(cat)L]^{z-}$ (M = Mo or W; cat = substituted catecholate; L = RS^-, CN^-, OPh^-, PR_3 or solvent), with six-coordinate heterometals, have been prepared and fully characterized.[222–226] The cluster core is known in two oxidation states $[MFeS_4]^{2+,3+}$ in which the variability of the electron population is accommodated principally at the Fe atoms.[225]

The compound $(\mu_3\text{-SMe})_4[Re(CO)_3]_4$ maintains triply-bridging thiolate ligands in the cubane core,[227] as most probably do the complexes $(\mu_3\text{-SR})_4(PtMe_3)_4$.[228,229]

2.5. *Pentametallic structures*

2.5.1. $(\mu\text{-SR})_7M_5$ (**5A**). This cage occurs in $[M_5(SPh)_7]^{2-}$ (M = Cu or Ag)[205,230] (see Fig. 5). All thiolate ligands are doubly-bridging, providing a trigonal planar coordination for four M atoms and an almost linear digonal coordination for the fifth. Although the overall molecule is asymmetric, the M_5S_7 core is approximately C_{2v}. The polyhedra constituted by the M_5, S_7 or M_5S_7 sets are not regular, and





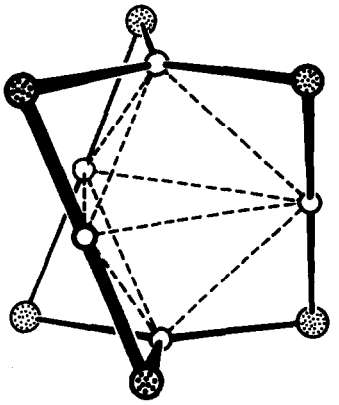


Fig. 5. Structure (**5A**) of $[M_5(SPh)_7]^{2-}$ (M = Cu or Ag).

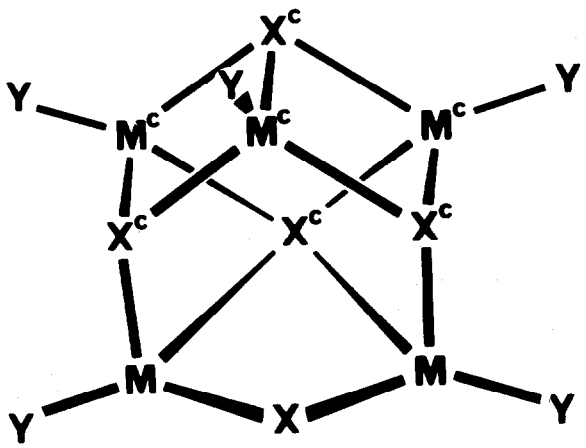
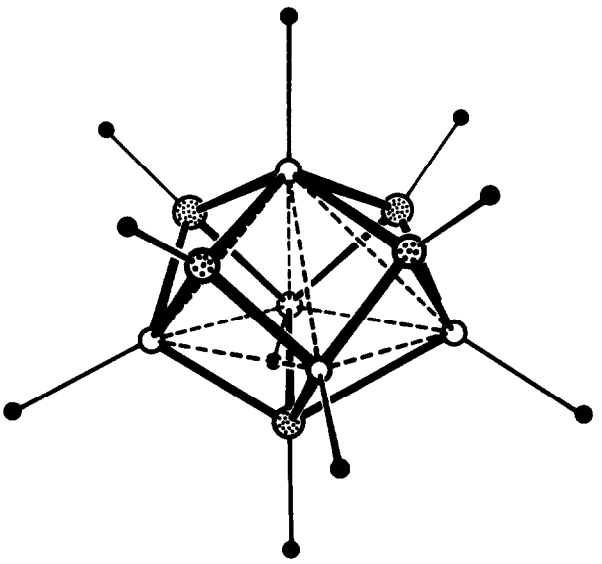
this cage structure is best visualized as an expansion of the $M_4(SR)_6$ cage (**4E**) by an opening of one of the (μ-SR) vertices of the latter and insertion of the digonal (μ-SR)–M–(μ-SR) moiety (see Fig. 4). There is no structural evidence for energetically significant direct bonding between M atoms, and, as a consequence of the relatively low connectivities at the M and S atoms, substantial angular distortions are observed for the cage **5A**.

2.5.2. (μ-SR)$_6$M$_5$ (**5B**). Complexes $[Ag_5(SBu^t)_6]^-$ (Et_4N^+) and $[Cu_5(SBu^t)_6]^-$ (Et_4N^+ or Et_3NH^+) contain this cage.[205,231,232] The six doubly-bridging thiolate ligands provide trigonal planar coordination for two M atoms (M^{trig}) and digonal (almost linear) coordination for three M^{dig} atoms. The M_5 polyhedron is a trigonal bipyramid, and the S_6 polyhedron approximates to a trigonal antiprism. D_3-symmetry is the ideal for the M_5S_6 core, and need not be broken by the substituent array R_6. In the crystals with Et_4N^+ the Bu^t groups maintain a close approximation to D_3 for the whole cage (angle of antiprismatic twist is *ca* 50°), but in the Et_3NH^+ crystal one SBu^t ligand is inverted and as a consequence of increased steric interaction between Bu^t groups the Cu_5S_6 core suffers symmetry reduction, mainly as angular distortions.

5A



5B



In symmetrical $[Cu_5(SBu^t)_6]^-$ the coordination of each Cu^{trig} atom is effectively planar, but the three Cu^{dig} atoms are each displaced *ca* 0.19 Å from the edges of the S_6 antiprism towards the centroid of the cage: the mean S—Cu^{dig}—S is 170°. This implies attractive Cu···Cu interactions, but the mean

dimensions Cu^{dig}--Cu^{dig} = 3.23 Å and Cu^{dig}--Cu^{trig} = 2.72 Å are not consistent with substantial Cu–Cu bonding. The cage is held together essentially by the bridging thiolate ligands.* In **5B** an increased trigonal twist moves the substituents R away from the equatorial region of the molecule and decreases the separations of the M^{dig} atoms.

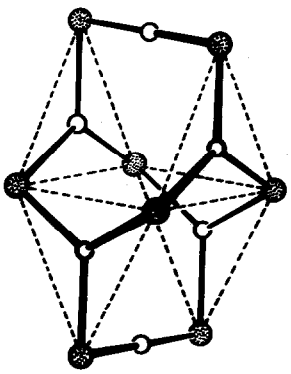
Topological relationships between **5A**, **5B** and other thiolate cages are discussed in Sections 5.5.1, 5.5.2 and 5.5.3.

5C

5D

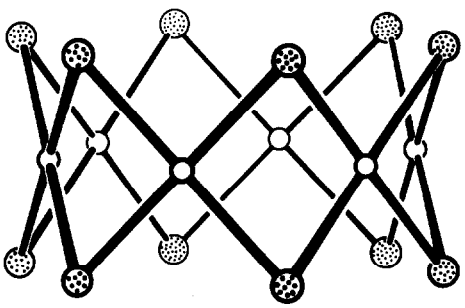
2.5.3. $(R'MSR)_5$. Compounds $RZnSBu^t$ (R = Me or Et), formed by reaction of ZnR_2 with Bu^tSH, are pentameric in benzene solution,[234] and crystals of the methyl derivative contain a pentametallic cage.[235] This partly irregular cage can be conceptualized in two ways: it can be regarded as an expanded cubane where the atoms marked M^c and X^c in diagram **5C** correspond to the seven vertices of the cube, but in place of the last M triconnected to the $(X^c)_3$ tripod there is an M–X–M moiety connected to two pairs of X^c, with the connections to the quadruply-bridging X elongated by 0.2–0.5 Å. An idealization of this structure is **5D** with one five-coordinate Zn atom and one quadruply-bridging thiolate ligand: in fact **5D** is comprised of an M_5 square pyramid and an inverted S_5 square pyramid, which intersect in a staggered conformation.

2.6. *Hexametallic structures*



Variety prevails among actual and potential hexametallic thiolate aggregates. Two structures, **6A** and **6B**, are known for homothiolate complexes: structure **6C** has terminal phosphine ligands: two quite different structures, **6D** and **6E**, involve sulfides in bridging positions: and new sulfide and polysulfide aggregates, **6F** and **6G**, suggest potential arrangements for thiolate structures. One of the two *octahedro*-M_6 structures well known with halide ligands is plausible and one is implausible for metal thiolates.

2.6.1. $(\mu\text{-SR})_8M_6$ (**6A**). The **6A** ideal contains four trigonal and two digonal metal atoms, and can be produced by continuation of the polyhedral expansion that converted **4E** to **5A** (see Fig. 4). Each M^{trig} is linked to two other M^{trig} and one M^{dig} by doubly-bridging thiolate ligands. This ideal has not been observed, and, in view of its anticipated non-rigidity due to a low connectivity at both the M and the S atoms, is not expected. The crystalline compound $(Me_4N)_2[Ag_6(SPh)_8]$[236] has a low-symmetry structure which has been interpreted in terms of distorted **6A**, twisted in order to create two extra intra-cage connections between Ag and S and provide mechanical stability. There are also inter-cage

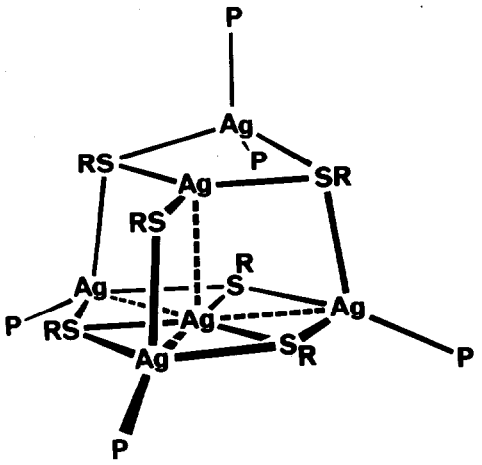


* The unique cluster $[Cu_5Ph_6]^-$ has the same framework as **5B**, but with less twist on the C_6 trigonal prism and shorter Cu^{dig}--Cu^{dig} distances (2.45 Å), indicative of Cu–Cu bonding.[233]

connections at the digonal ends. Consequently, two of the M atoms are four-coordinate, and four of the thiolate ligands become triply-bridging.

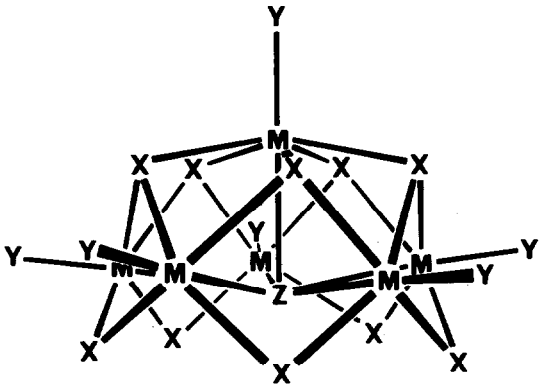
2.6.2. *Hexagono*-$(\mu\text{-SR})_{12}M_6$ (**6B**). This macrocyclic molecule contains a regular hexagon of M atoms, bridged over the edges by pairs of doubly-bridging thiolate ligands such that each metal has a planar coordination (approximately square). The S atoms constitute a larger hexagonal prism, with M atoms at the centres of its rectangular faces. The S–C vectors of the substituents alternate axial and equatorial (relative to the hexagonal axis) around the S_6 hexagons to allow D_{3d} molecular symmetry. The structure is confirmed in $Ni_6(SEt)_{12}$,[10] $Pd_6(SPr^i)_{12}$,[237,238] $M_6(SCH_2CH_2OH)_{12}$ (M = Ni or Pd),[239] $[Ni_6(SCH_2CH_2CH_2NHMe_2)_{12}]^{6+}$ [240] and $Ni_6[SCH_2CH(Me)OH]_{12}$.[241]

6A



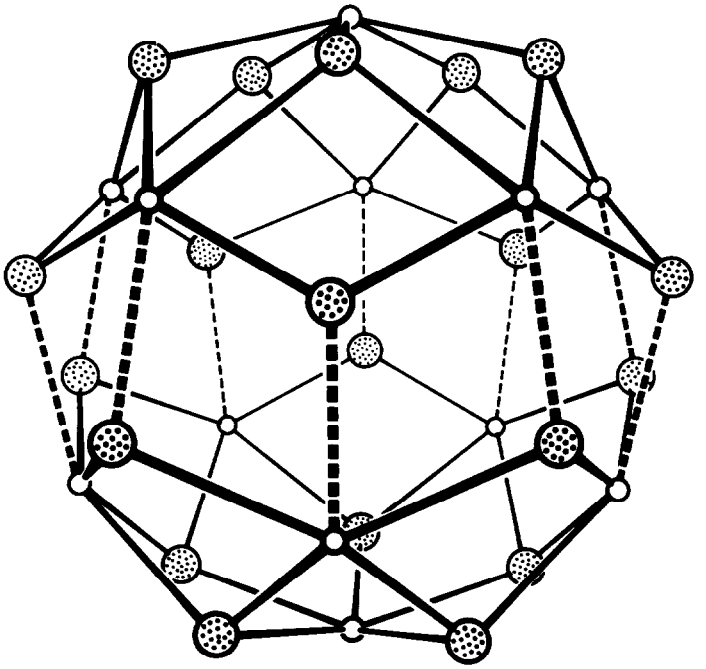
6B

These compounds with branched alkyl substituents are appreciably soluble in indifferent solvents, consistent with their molecular structure, and the solution molecular weights of related homologous compounds also indicate the hexameric structure **6B**.[237,242–244] There are, however, appreciable solubility variations with the identity of R,[237,244] and in some preparations it is found that the one compound can be obtained in soluble and insoluble forms[242,243] with the soluble form less stable. It therefore appears that molecules **6B** can convert to non-molecular solid-state structures, possibly **1D-E**. Investigations by pH titration[241] led to the conclusion that $Ni(SR)_2$ [R = CH_2CH_2OH or $CH_2CH(Me)OH$] are predominantly hexameric in aqueous solution at 25° C. Other species in solution have a lesser degree of oligomerization. At 75°C the solution compositions change, and the titration data have been interpreted in terms of open-chain species $[Ni(Ni(SR)_2)_n]^{2+}$ with a statistical distribution of *n*.



Although topologically different, **6B** has the same composition, metal coordination stereochemistry, and doubly-bridging ligands, as the *cuboctahedro*-$(\mu\text{-X})_{12}$-*octahedro*-M_6 structure (**6L**) adopted by the comparable compounds Pd_6Cl_{12}[245,246] and Pt_6Cl_{12}.[247,248]

2.6.3. $Ag_6(SAr)_6(PPh_3)_5$ (**6C**). This molecular aggregate, reported for Ar = C_6H_4Cl-4,[249] is shown in full in Fig. 6. When simplified as in **6C** it can be described in terms of an $Ag_5(SAr)_6$ central cage, with PPh_3 ligands terminal at three of the Ag atoms, and an $Ag(PPh_3)_2$ appendage inserted between two bridging thiolates. The $Ag_5(SR)_6$ core, when symmetrized, contains a basal unit comprised of an irregular hexagon of alternating Ag and S atoms (Ag_b^{per} and S_b) centered by an Ag_b^{cen} atom with trigonal $(S_b)_3$ coordination. A trigonal planar podal unit, $Ag_{pod}(S_{pod})_3$, is parallel to the basal plane and attached to it by three S_{pod}—Ag_b^{per} bonds. Tetrahedral coordination of each Ag_b^{per} atom is completed by a terminal PPh_3 ligand. The $Ag(PPh_3)_2$ addendum bridges two S_{pod} atoms, and the complete molecule is enclosed within 21 aryl substituents. The connectivity of this aggregate is unique, but it is possible to propose a structural relationship between the $Ag_5(SR)_6$ core of **6C** and the structure **5B** (see Section 5.5.3).



2.6.4. *Pentagonal pyramido*-$[M_6S_{17}]^{4-}$ (**6D**). The sulfide clusters $[M_6S_{17}]^{4-}$ (M = Nb or Ta) [prepared from $M(OEt)_5 + (Me_3Si)_2S$] possess structure **6D** (X = Y = S) which contains a pentagonal pyramid of M atoms, one triply-bridging sulfide over each triangular face, one doubly-bridging sulfide below each edge of the M_5 pentagon, one terminal sulfide (Y) on each metal, and one inner hextuply-bridging sulfide ion (Z) *trans* to each terminal sulfide.[250] The M and bridging sulfide atoms in this cage can be visualized alternatively as half of the array *icosahedro*-M_{12}-*pentagonal dodecahedro*-$(\mu\text{-S})_{20}$, as shown in **6E**, with the intersecting M_{12} and S_{20} polyhedra occurring as reciprocal Platonic polyhedra

6C

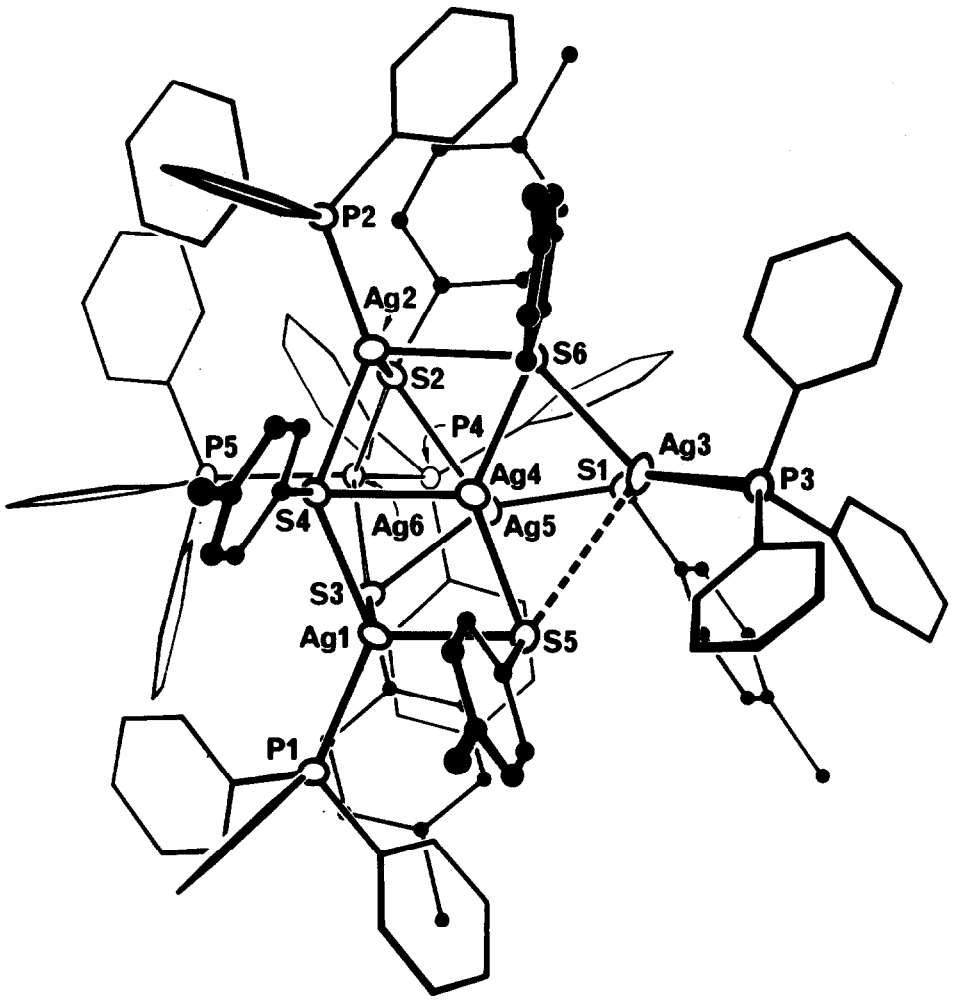
6D

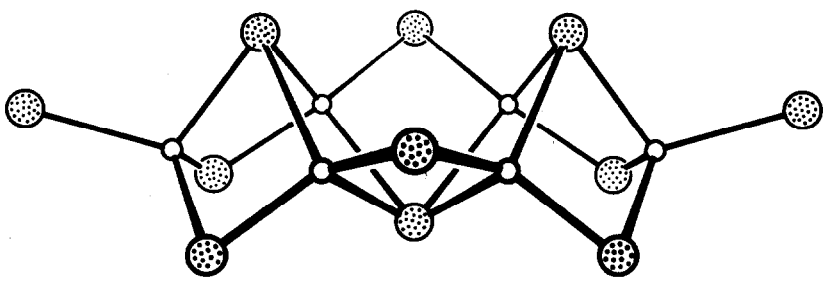
6E

(i.e. they sustain a vertex–face interchange). It is conceivable that the frameworks **6D** and **6E** will be found to occur with thiolate ligands replacing sulfide ligands in terminal positions, and possibly doubly-bridging positions in **6D**, as, for instance, in $(\mu_6\text{-S})(\mu_3\text{-S})_5(\mu\text{-SR})_5(\text{MSR})_6$.

2.6.5. $(\mu_4\text{-S})(\mu_3\text{-S})_2(\mu\text{-S})_6\text{Fe}_6(\text{SR})_2$ (**6F**). Aggregates $[\text{Fe}_6\text{S}_9(\text{SR})_2]^{4-}$ (R = Me,[253] Et,[78] Bu^t,[251,252] CH_2Ph[253,254] or Ph[251,252]) possess structure **6F** (virtually C_{2v}) in which the metal array is a square of four Fe atoms with two (*trans*) coplanar (within 0.2 Å) equilateral triangles. Sulfide ions bridge the six edges of the Fe_6 polygon and cap the M_4 square and the two M_3 triangles. Thiolate ligands occur only at the two terminal positions of **6F**. Each metal has tetrahedral coordination. These complexes are formed in diverse reactions, $\text{Fe(SR)}_3 + \text{Na}_2\text{S}_2$,[253,254] $\text{FeCl}_3 + \text{Li}_2\text{S} + \text{LiSR} + \text{LiOMe}$,[251,252] $[\text{Fe(SR)}_4]^{2-} + \text{S}_8$,[78] and $[\text{Fe}_3\text{S}_4(\text{SEt})_4]^{3-}$ heated,[78] and undergo reversible one-electron oxidation and terminal ligand substitution.

The complex with R = Me has been crystallized as $[\text{Na}_2\{\text{Fe}_6\text{S}_9(\text{SMe})_2\}_2]^{6-}$ (Et_4N^+) in which two clusters (**6F**) are linked by two Na^+ ions, each with an S_6 coordination as shown in **6G**. This larger aggregate contains four fused $\{\text{NaFe}_3\text{S}_4\}$ cubanoid units.[253]





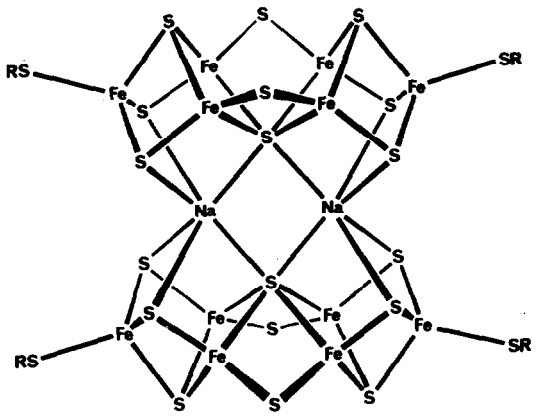


Fig. 6. Structure (**6C**) of $Ag_6(SC_6H_4Cl)_6(PPh_3)_5$, with the thiolate substituent atoms marked as closed circles. The broken line is an elongated bond.

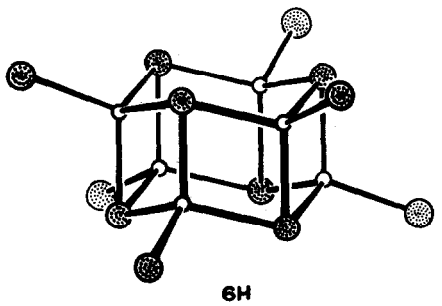
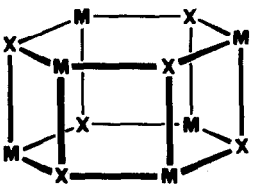
2.6.6. $[(\mu_3\text{-}S)_6M_6X_6]^{z-}$ (**6H**). Structure **6H** has been confirmed in three non-thiolate complexes at two different oxidation levels: $[Fe_6S_6Cl_6]^{3-}$ (prepared from $6FeCl_2+9NaSPh+3Et_4NCl+6S$ in MeCN),[255,257] $[Fe_6S_6Cl_6]^{2-}$ (prepared from $3[Fe_4S_4Cl_4]^{2-}+2[FeCp_2]^+ \rightarrow 2[Fe_6S_6Cl_6]^{2-}+2FeCp_2$)[258] and $[Fe_6S_6I_6]^{2-}$ (prepared from $Fe+S_8+I_2+I^-$).[256] The thiolate complex $[Fe_6S_6(SC_6H_4Me)_6]^{3-}$ can be prepared by substitution of $[Fe_6S_6Cl_6]^{3-}$, and probably has structure **6H**, but is unstable in favour of $[Fe_4S_4(SAr)_4]^{2-}$.[257] Structure **6H** is a logical extension of the cubanoid $S_4M_4X_4$ structure type, with the same coordination stereochemistry at the M and S atoms.

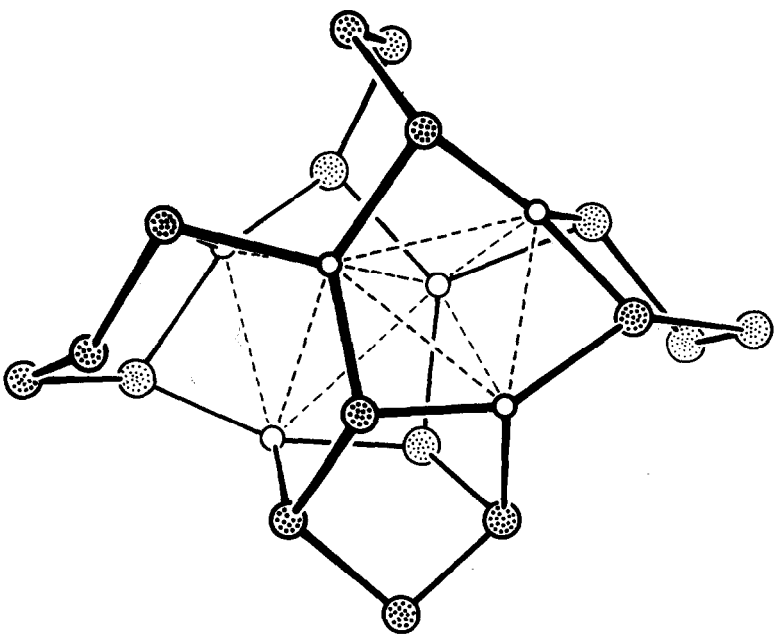


6F



6G

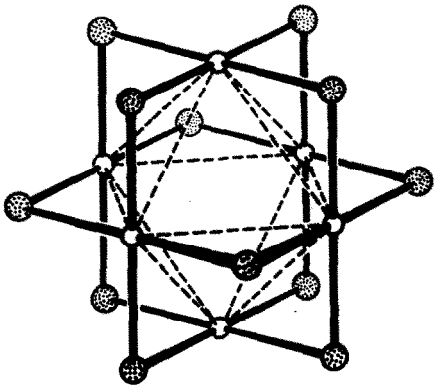
2.6.7. *Hexagono-prismo*-$(\mu_3\text{-SR})_6M_6L_6$ (**6J**). Structure **6J** (X = SR), a variant of the **6H** ion in which only the bond angles at the M and S are affected, has been proposed but not confirmed for the hexamers



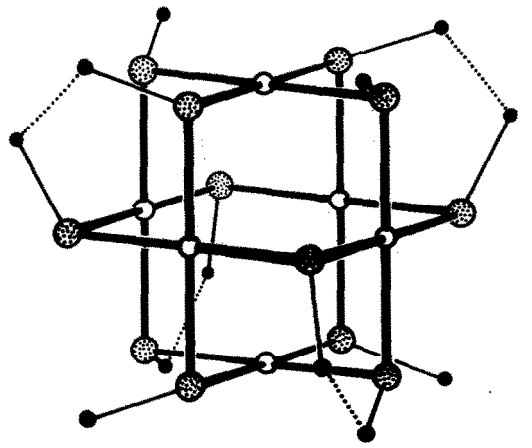
6H

6J

$(MeMSPr^i)_6$ (M = Zn or Cd) which occur in freezing benzene solutions.[259] The Zn compound is octameric, structure **8E**, in crystals.[260]

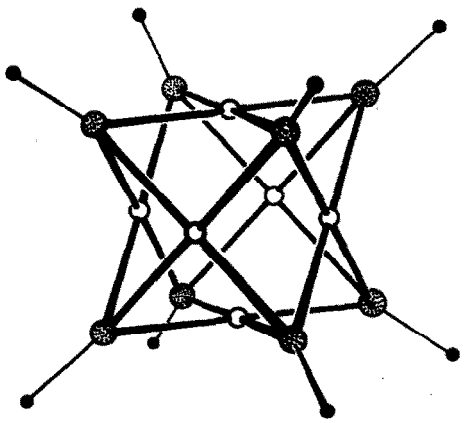


2.6.8. $[M_6(S_5)(S_4)_3]^{2-}$ (**6K**). The intriguing polysulfide aggregate $[Cu_6(S_5)(S_4)_3]^{2-}$ (Ph_4P^+) has

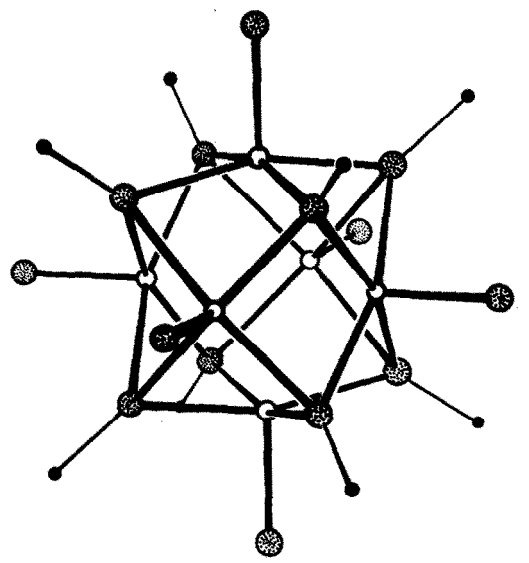


6K

been prepared from the reactions $S_8 + [Cu_4(SPh)_6]^{2-}$,[261] or methanolic S_x^{2-} solution + $Cu(acac)_2$.[262] The structure with symmetry C_2 has the M atoms arranged essentially as an edge-sharing pair of tetrahedra, with terminal S atoms of the S_x^{2-} ligands bridging all but two of the external edges of the tetrahedra, and M–S–S–M bridges on the other two edges. The polysulfide ligands provide eight terminal-S donor atoms in **6K**, and these S atoms could be conceived as thiolate ligands, in which case structure **6K** would be analogous to $[M_6(SR)_8]^{2-}$ (**6A**) with four M atoms trigonal and two digonal. In **6K** it is the non-terminal-S atoms in the S_5^{2-} ligands which complete the trigonal coordination of the last two Cu atoms.



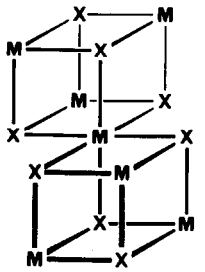
2.6.9. *Cuboctahedro*-(μ-SR)$_{12}$-*octahedro*-M_6 (**6L**). This structure type is well-known in clusters with monatomic ligands, but as shown by diagram **6M** it is not possible to accommodate the substituents of pyramidal doubly-bridging thiolate ligands. The minimum number of conflicts between substituents axial to the rectangular chair $M_3(SR)_3$ cycles is four: these conflicts (C_α–C_α separation *ca* 2 Å) could be removed by chelation with dithiolate ligands, or through some substitution by monatomic (sulfide) ligands. No complexes of this type have been reported.



6L

6M

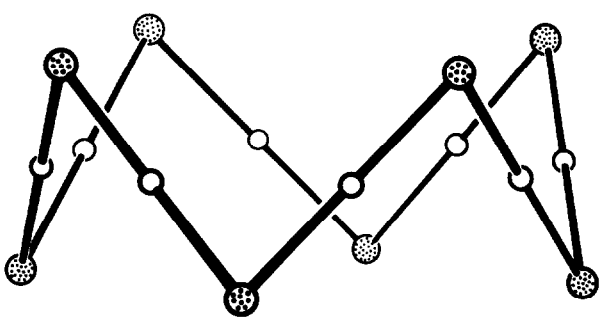
6N



6P

2.6.10. *Hexahedro*-(μ_3-SR)$_8$-*octahedro*-M$_6$ (**6N**). Difficulties due to conflict between ligand substituents do not occur in the **6N** core. No thiolate examples of this otherwise well-known cluster structure type have yet been reported, but a methoxide analogue with terminal methoxide ligands, [(μ_3-OMe)$_8$(MoOMe)$_6$]$^{2-}$ (**6P**), has been fully characterized.[263] Structure **6N** with triply-bridging sulfide and terminal phosphine ligands to create metal five-coordination occurs in the set of clusters [S$_8$M$_6$(PPh$_3$)$_6$]^z (M = Fe or Co; z = 0, + or 2+),[264–267] and in S$_8$Co$_6$(CO)$_6$.[268]

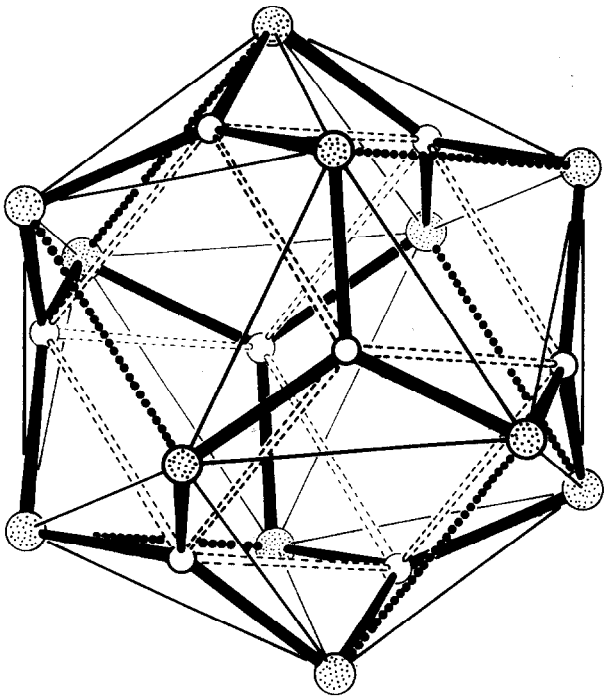
2.7. *Heptametallic structures*



The first heptametallic thiolate complex [Cu$_7$(SCH$_2$CH$_2$S)$_4$(SEt)]$^{2-}$ has been intimated without structural details.[269] A structural precedent is set by the alcoxide-bridged compounds R$_6$Zn$_7$(μ_3-OMe)$_8$ (R = Me[270] or Et[271]), in which a pair of cubanoid cages share a vertex (**7A**).

7A

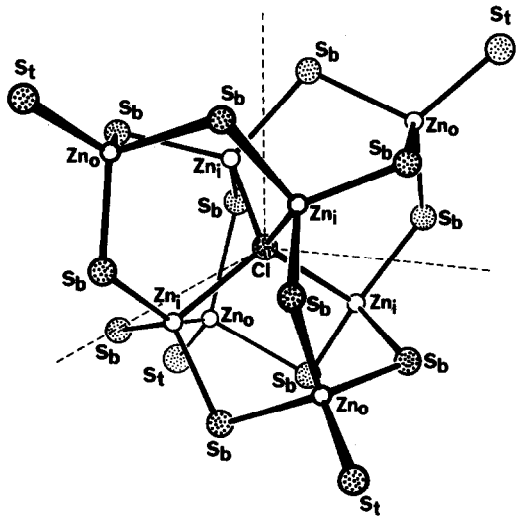
2.8. *Octametallic structures*



2.8.1. *Cyclo*-(MSR)$_8$ (**8A**). Molecular weight measurements[272,273] indicate that silver tertiary-alkane thiolates are octameric [(AgSR^t)$_8$] in solution. A possible structure is the puckered cycle of zig-zag digonal segments (**8A**): this is consistent with the cyclic and zig-zag patterns of other AgSR structures (see Section 3.1.1). **8A** is conceivable as a derivative of the crown S$_8$ structure, with Ag atoms inserted in all S–S bonds.

8A

2.8.2. *Centro*-(μ_8-Z)-*hexahedro*-M$_8$-*icosahedro*-(μ-SR)$_{12}$ (**8B**). Here a cube of M atoms contains a monatomic ligand (Z) at the body centre, with doubly-bridging thiolate ligands over its 12 edges such that the S$_{12}$ array is an icosahedron containing metal atoms in the centres of 8 of its 20 triangular faces. Diagram **8B** shows the structure without the central ligand. T_h-symmetry (T_h is a sub-group of I_h, O_h) is possible for the core, excluding the substituents R. The Z–M bond is abnormally long, and a lesser part of the metal coordination, which is essentially trigonal unless there are additional terminal ligands. The **8B** structural core occurs in [ICd$_8$(SCH$_2$CH$_2$OH)$_{12}$]$^{3+}$, crystallized with 3I$^-$ which provide (with some I bridging) terminal coordination at five of the Cd atoms as shown in Fig. 7.[274] Two other Cd atoms complete similar trigonal bipyramidal coordination through chelating ligand OH functions, while the eighth Cd has three terminal OH donors.



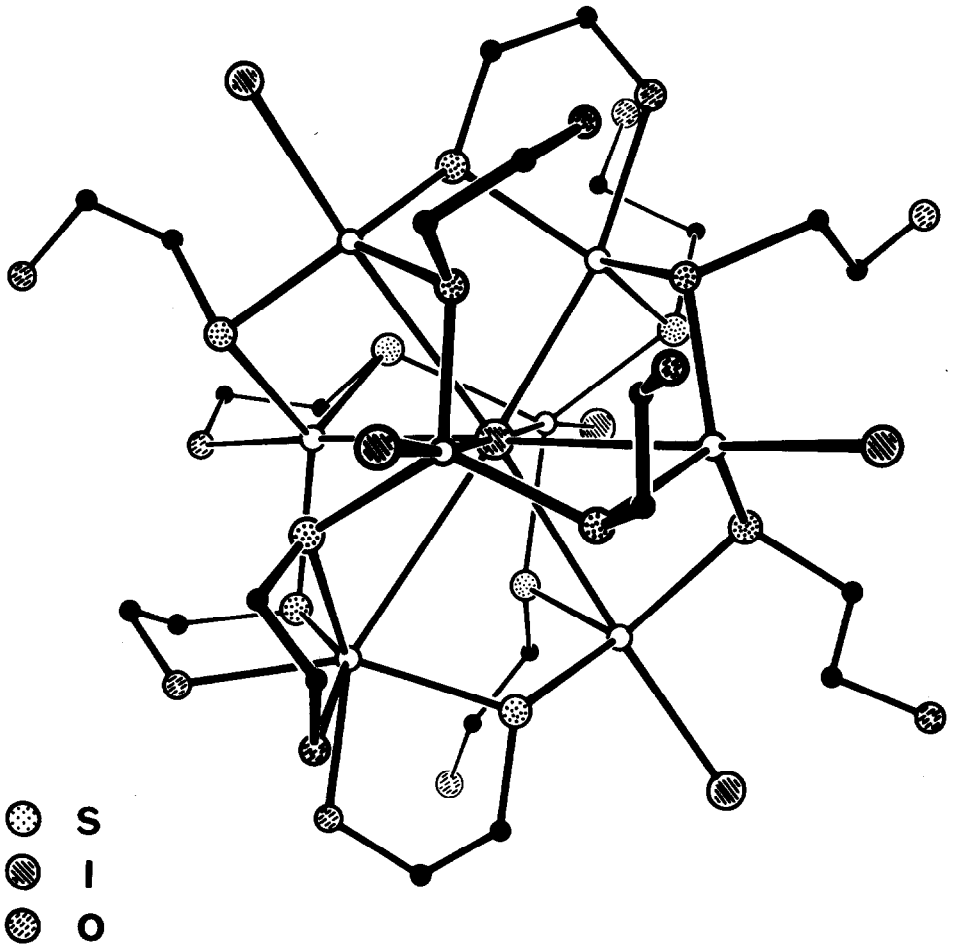
The **8B** core occurs also in the chelated cages [ClM(I)$_8$(SCMe$_2$CQ)$_{12}$M(II)$_6$] [M(I) = Cu or Ag,

8B

M(II) = Cu or Ni], and Q contains a donor function.[275-278] The vertices of the S_{12} icosahedron are linked in pairs (without breaking the T_h-symmetry) by the outer chelate units, as shown by the dotted connections in **8B**, each chelate spanning a face of the inner $M(I)_8$ cube.

2.8.3. *Centro-Z-tetrahedro-*M_4*-icosahedro-*(μ-$SR)_{12}$*-tetrahedro-*$(MSR)_4$ (**8C**). Structure **8C** can be regarded as a derivative of **8B**, in which the metal atoms are displaced alternatively inside and outside the faces of the $(SR)_{12}$ icosahedron: the M_8 polyhedron is a tetracapped tetrahedron, i.e. the concentric bitetrahedron. The inner M atoms (M^i) complete their tetrahedral coordination at the central monatomic ligand, while the outer M atoms (M^o) each have one terminal thiolate ligand for this purpose. One occurrence of **8C** is known, in $[ClZn_8(SPh)_{16}]^-$,[279,280] although reproduceable preparation has not yet been secured. The normal tetrahedral stereochemistry at all atoms in this structure suggests that it should occur with other metals and central monatomic ligands: the preparative difficulty is largely one of solubility.

8C



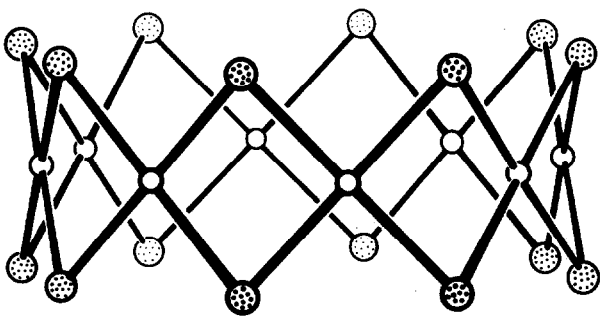


Fig. 7. Structure of $[(\mu_8\text{-I})Cd_8(SCH_2CH_2OH)_{12}]I_3$.

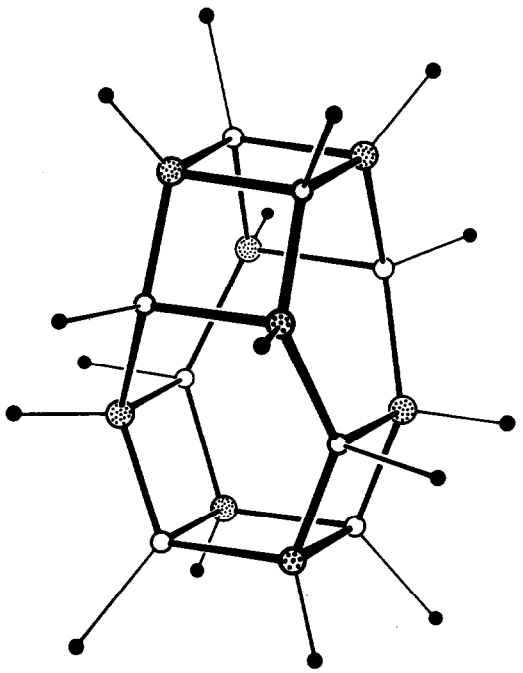
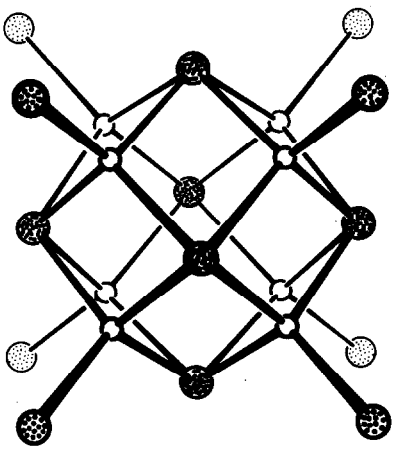
Aggregate **8C** is unique, being composed of expanding, concentric, regular polyhedra, alternating between M and donor atoms as specified in the heading to this section. The structure is distinctive also because the array of bridging substituents also has a high virtual symmetry, that of the rare point group T (the mirror elements of T_h being necessarily broken at the pyramidal S atoms). This occurs because the 12 phenyl substituents, inclined obliquely to the surface of the globular molecule, are packed regularly over its surface.

Structures **8B** and **8C** belong to a set of four, in which an icosahedron or cuboctahedron of doubly-bridging thiolate ligands is associated with a cube or bitetrahedron of M atoms, as described in Section 5.5.5.



2.8.4. *Octagono*-$(\mu\text{-SR})_{16}M_8$ (**8D**). The octagonal toroid **8D** continues the series **4C** (square) and **6B**

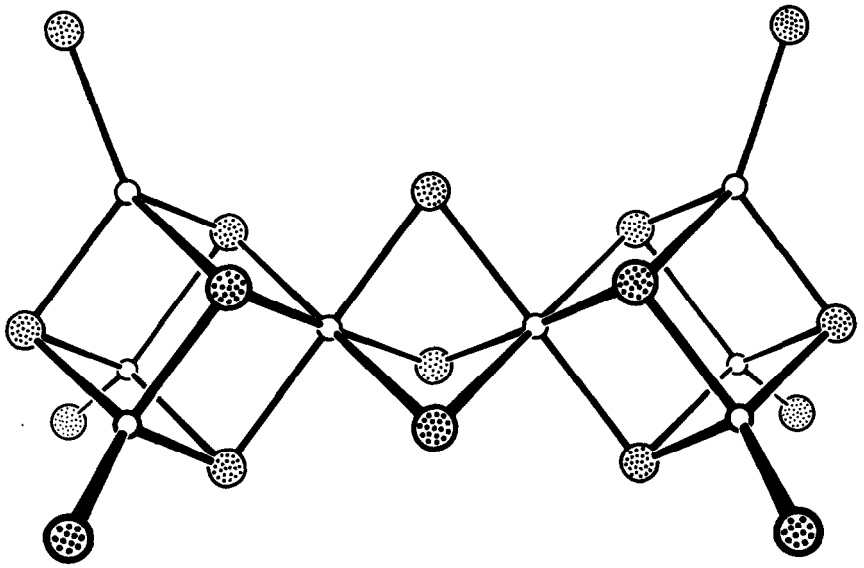


8D

(hexagonal) of toroidal molecules $[M_n(SR)_{2n}]$ which have virtual D_{nd}-symmetry. It is known for the very soluble compound $Ni_8(SCH_2COOEt)_{16}$[202] in which all except one of the ligand substituents are externally pendant. The unique substituent, with axial departure from its bridging S atom, bends around to re-enter the centre of the molecule along the toroid axis, such that the ester oxygen atom is distantly (3.0 Å) located in the axial coordination positions of two Ni atoms. The re-entrant EtO moiety largely fills the van der Waals' cavity of the toroid, and it is this reception by the toroid of its own ligand tail which probably accounts for the abnormal size of **8D** relative to the frequently occurring **6B**. All other geometrical properties of **8D** are normal.

2.8.5. $(R'MSR)_8$ (**8E**). Structure **8E**, comprised of six M_2S_2 cycles and four slightly non-planar M_3S_3 cycles, with symmetry S_4, occurs in crystalline $(MeZnSPr^i)_8$.[260] Tetrahedral stereochemistry exists at all Zn and S atoms, which are subject to positional disorder in the crystal. This compound, like its Cd homolog, is hexameric in cold benzene solution.[234,259]

8E

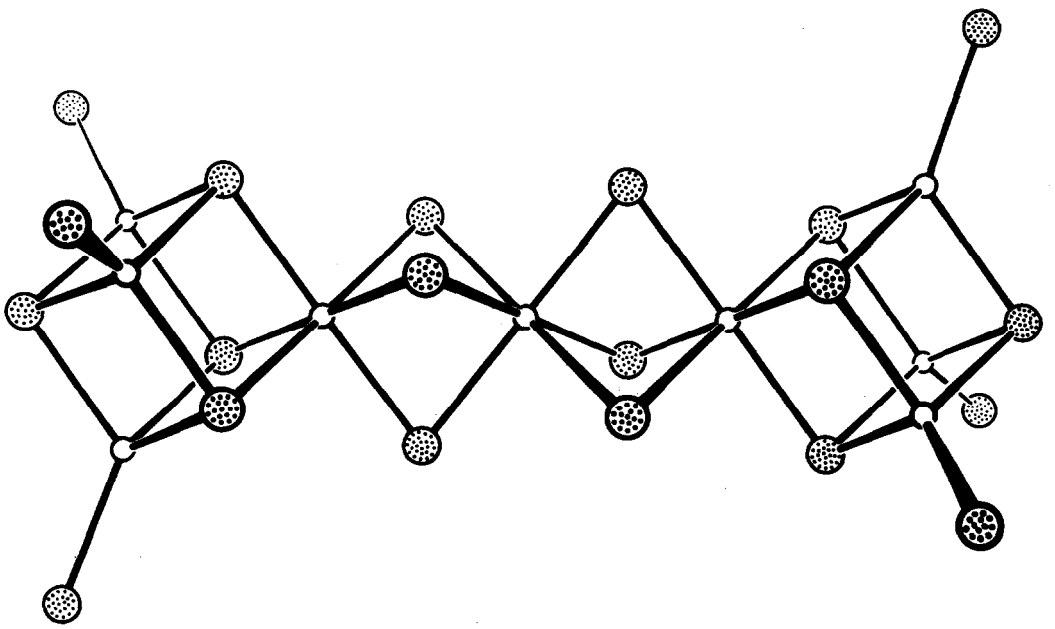


8F

2.8.6. *Octahedro-*$(\mu_4\text{-SR})_6$*-hexahedro-*$(MSR)_8$ (**8F**). Here, in symmetry O_h, a cube of M atoms intersects an octahedron of quadruply-bridging ligands (S^{2-}) to form a rhombic dodecahedron. Terminal thiolate ligands complete tetrahedral coordination at the M atoms. The structure is known so far only for Co (but is expected for other metals such as Mn, Fe, Zn and Cd), with S^{2-} as the quadruply-bridging ligand, and in two cluster oxidation states. $[S_6(CoSPh)_8]^{4-}$ is prepared by the reaction $[Co_4(SPh)_{10}]^{2-} + 3HS^-$,[281] and can be reduced by sodium acenaphthylenide to $[S_6(CoSPh)_8]^{5-}$.[281,282] The structural consequence of reduction is only a very small increase in the length of the terminal Co—SPh bonds. The molecular structure **8F** is part of the non-molecular structure of the mineral pentlandite (M_9S_8), in which the M_8S_{14} units share sulfide vertices and are linked by additional octahedrally coordinated M atoms. However the $[S_6(CoSPh)_8]^{4-,5-}$ cages are not electronically equivalent to the pentlandite aggregate, and have a significantly larger (by *ca* 20%) core volume.

2.8.7. *Bis-cubanoid cages* $[(\mu\text{-Y})_3\{M'(\mu_3\text{-X})_4(ML)_3\}_2]^{z-}$ (**8G**). A series of compounds is known in which three doubly-bridging thiolate or alcoxide ligands (Y) link two cubane clusters (**4H**) such that one M atom (M') in each acquires an octahedral coordination. The identities (M, M', X, Y, L and *z*, respectively) of the compounds characterized are: Fe, Mo, S, SAr, SAr, 3,[283,284] Fe, Mo (or W), S, SEt, SEt, 3,[285,286] Fe, Mo (or W), S, OMe, SPh, 3,[284,287] and Fe, Mo, SPh (or SEt), Cl (or Br), 3.[288]

2.8.8. *Bis-adamantanoid cages* $[M_8(SR)_{19}]$. Here two adamantanoid cages are connected through a shared terminal ligand. Although not yet reported for thiolate ligands, the structure is known for



8G

sulfides in $[Ge_8S_{19}]^{6-}$ (Cs^+).[94] Thiolate bridging between adamantanoid cages is established in the *catena*-polyadamantanoid structure **1D-G** of $Zn_4(SPh)_8(MeOH)$.

2.9. *Nonametallic structures*

2.9.1. *Metal-linked bis-cubanoid cages* $[M''\{(\mu\text{-}SR)_3M'(\mu_3\text{-}S)_4(MSR)_3\}_2]^{z-}$ (**9A**). These elongated bis-cubanes connected by an extra M atom (M″) are obtained in reactions very similar to those yielding the directly linked bis-cubanes (**8G**). All characterized complexes have four-coordinate Fe(M) and six-coordinate Mo or W (M′) in the cubane clusters, Fe as the connecting metal (M″), thiolate as the doubly-bridging and terminal ligands, and overall charge 3− or 4−: $[Mo_2Fe_7S_8(SEt)_{12}]^{3-}$, $[W_2Fe_7S_8(SEt)_{12}]^{4-}$ and $[Mo_2Fe_7S_8(SEt)_{12}]^{4-}$.[289–291] The central Fe atom has slightly twisted trigonal antiprismatic stereochemistry, and undergoes localized electron transfer at a potential less negative than reduction of the cubanoid cage, and therefore the two different oxidation states of the isolated complexes correspond to Fe(II) (high spin) and Fe(III) (low spin) at the central atom.

9A

2.10. *Decametallic structures*

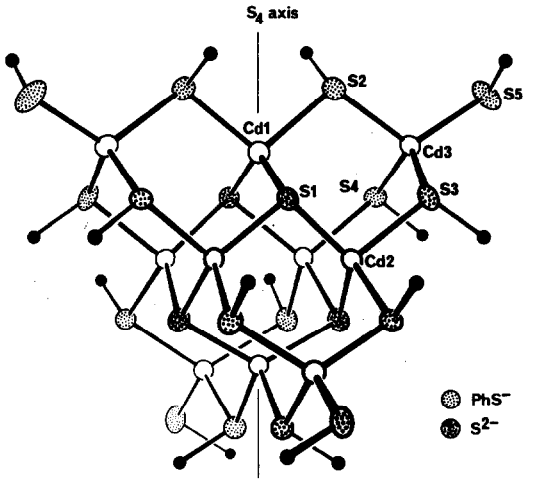
Two closely related M_{10} aggregate structures are known, both based on a tetracapped octahedron of M atoms. The fundamental $M_{10}S_{20}$ framework is conceivable as the fusion of four adamantanoid units (**4F**) creating a super-tetrahedron with symmetry T_d. This array is a 30-atom macro-tetrahedral fragment of the cubic sphalerite lattice.

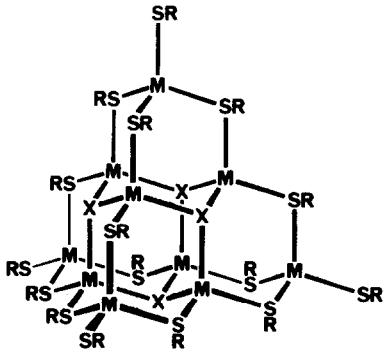
2.10.1. *Tetrahedro*-(μ_3-X)$_4$-*octahedro*-M$_6$-*truncated tetrahedro*-(μ-SR)$_{12}$-*tetrahedro*-(MSR)$_4$ (**10A**). This structure occurs for four complexes $[X_4M_{10}(SPh)_{16}]^{4-}$ (X = S or Se, M = Zn or Cd), prepared by reaction of $[M_4(SPh)_{10}]^{2-}$ with the chalcogen.[292,293] The chalcogenide ions are located at the triply-bridging positions above four faces of the octahedron of inner M atoms, while the other four faces are capped by tripodal (μ-SR)$_3$MSR units. The X_4 set is therefore a tetrahedron, and the 12 doubly-bridging thiolate ligands constitute the tetratruncated tetrahedron shown as **10Ab**. The structure of the cadmium sulfide compound is shown in Fig. 8. As in the adamantanoid structure this framework can have high symmetry (T_d) without requiring local tetrahedral coordination stereochemistry, but in fact each of the 30 metal or chalcogenide atoms has virtual tetrahedral or part-tetrahedral stereochemistry. Direct M–M bonding is absent. Inclusion of the substituents of the 12 doubly-bridging thiolate ligands lowers the maximum symmetry to T, and inversion at these pyramidal S atoms allows 186 molecular configurational isomers. Two different crystal structures with two different configurational isomers, both with molecular symmetry S_4, have been observed to date. At least one of these crystal structures will accommodate cations Me_4N^+ or Et_3NH^+ without change, and the crystalline compounds appear to possess high thermodynamic stability, being formed under a variety of preparative conditions.

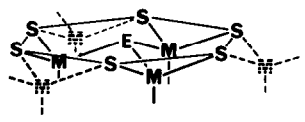
The surface of the super-tetrahedron **10A** is formed by four equivalent hexagonal faces **10Aa**, each equivalent to three fused M_3S_3 rings in chair conformation, with six peripheral substituents R either axial or equatorial to the face. At the face-centre there is one three-coordinate chalcogenide atom, and thus this face represents the smallest portion of the surface of the non-molecular metal chalcogenide, with one accessible reaction site.

^{113}Cd NMR confirms that structure **10A** is maintained in solution, the spectrum revealing isotope ^{113}Cd–E–^{111}Cd coupling within the inner Cd_6 octahedron, and coupling between the inner and outer Cd atoms.[217]

2.10.2. $[Cd_{10}(SCH_2CH_2OH)_{16}]^{4+}$ (**10B**). In this ion (with ClO_4^-[294] or SO_4^{2-}[11,295]) triply-bridging thiolate ligands occur in place of the triply-bridging chalcogenide ions at the centres of the faces of **10A**. The tetrahedral coordination of the outer M atoms by terminal thiolate ligands in **10A** is replaced by *fac*-CdS_3O_3 octahedral coordination using three OH donors from the three doubly-bridging thiolate ligands which now chelate the caps: for reasons of clarity only two of these are shown on diagram **10B**. In addition, the OH groups of the triply-bridging SCH_2CH_2OH ligands coordinate by chelation to four of the six inner Cd atoms, making them pseudo trigonal bipyramidal, as shown in **10B**. With this







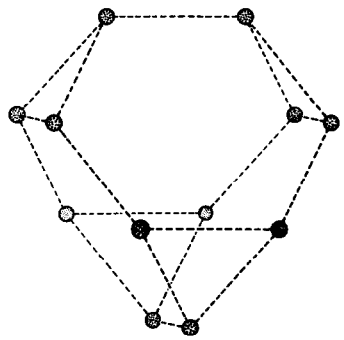


Fig. 8. Structure (**10A**) of $[S_4Cd_{10}(SPh)_{16}]^{4-}$ with S_4 crystallographic symmetry. Phenyl substituents are represented by C_α atoms only.

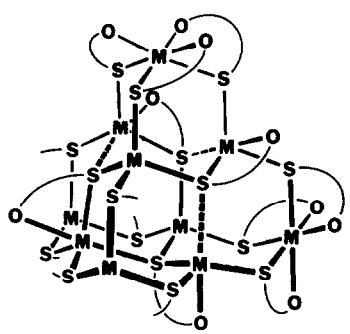
IOA

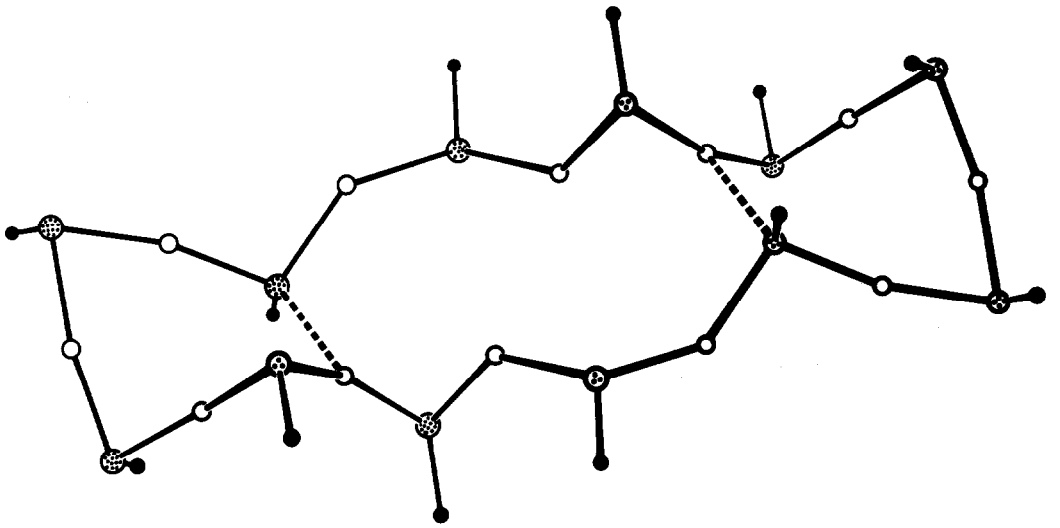


IOAa

IOAb

connectivity, and with the Cd coordination of three types [tetrahedral CdS_4 ($\times 2$), trigonal bipyramidal CdS_4O ($\times 4$) and octahedral CdS_3O_3 ($\times 4$)], the maximum symmetry of **10B** is only S_4, and there is in fact considerable distortion in the crystal structure. At the five-coordinate Cd atoms an axial Cd—(μ_3-S) bond is elongated by *ca* 0.3 Å relative to the equatorial bonds which are two Cd—(μ-S) and one Cd—(μ_3-S).

IOB

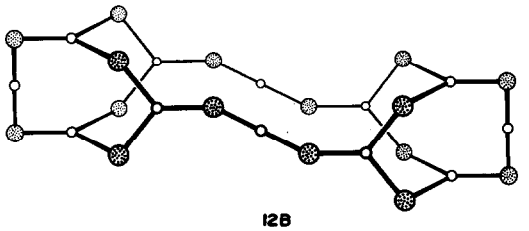


The ^{113}Cd NMR of **10B** has been examined in solution and crystal phases.[294,296,297] In solution the CdS_4 and CdS_4O sites exchange rapidly (*ca* 10^4 s^{-1}[294,297]), probably by a mechanism indicated by the crystal structure in which the triply-bridging ligands rotate, in concert, their chelating OH functions around the three inner Cd atoms of the hexagonal faces (**10Aa**). The solid-state NMR reveals, in addition to the large chemical-shift differences of the three coordination types, appreciable chemical-shift differences of up to 82 ppm due to variations in the crystal environment and hydrogen bonding of the aggregate.[294]

2.10.3. *Molecular* $M_{10}(SR)_{20}$. Geometrical analysis reveals that there is limited steric crowding on the hexagonal faces (**10Aa**) of **10A**, which means that a substituent could radiate from a triply-bridging thiolate (or selenolate) ligand in place of the chalcogenide bridge, yielding uncharged molecules $M_{10}(SR)_{20}$ or $M_{10}(SeR)_4(SR)_{16}$ with the same framework of M and donor atoms as **10A**. It is known

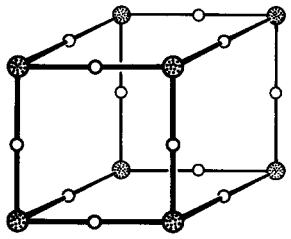
that $[Cd_{10}(SCH_2CH_2OH)_{16}]^{4+}$ (which does have thiolate coordinated at the centre of the face **10Aa**) in solution reacts with excess thiolate,[295] which could generate $Cd_{10}(SCH_2CH_2OH)_{20}$ with structure **10C**.

2.11. M_{12} *structures*



2.11.1. *cyclo*-$(\mu$-$SR)_{12}M_{12}$ (**12A**). This 24-membered ring of alternating Ag and S atoms occurs in crystalline silver cyclohexanethiolate.[298,299] The crystal structure contains these cyclic molecules overlapped, with longer, weaker, secondary Ag--S interactions between molecules. The centrosymmetric cycle **12A**, which also contains two transannular secondary bonds (marked as broken lines), is in an elongated "chaise longue" conformation in the crystal. (Alternatively, it is a complete lounge room, with 12 cyclohexyl "chairs" around the periphery!)

12A



The molecular weights of silver *sec*-alkanethiolates in solution indicate the general formulation $(AgSR^{sec})_{12}$,[272,273] suggesting that structure **12A** occurs generally. Association of these molecules may occur.[299]

2.11.2. $[M_6(SR)_8]_2$ (**12B**). In $(Me_4N)_2[Ag_6(SPh)_8]$ the cages idealized as **6A** are butt-jointed to form hour-glass-shaped aggregates (**12B**). The ideal **12B** is large and open, with an average of only 32/28 Ag—S bonds per Ag, S atom, and thus is subject to crystal and solution forces which produce angular distortions and secondary Ag--S interactions *ca* 0.3 Å longer than the remainder of the Ag—S bonds.[236]

12B

2.11.3. *Cuboctahedro*-M_{12}-*hexahedro*-$(\mu_3$-$SR)_8$ (**12C**). The non-thiolate cage $[(\mu_3\text{-}S)_8Cu_{12}]^{4-}$ (Ph_4P^+), isolated from the reaction of $CuCl_2$, EtS^- and Li_2S in methanol, has structure **12C** in which triply-bridging sulfide ions cap the triangular faces of a cuboctahedron of Cu atoms (edges 2.77–2.95 Å). Each Cu atom is displaced slightly from digonal coordination towards the centre of the cuboctahedron such that S—Cu—S = 167–171°.[300] $[Au_{12}S_8]^{4-}$ (Ph_4As^+), isolated from solutions of gold sulfides in concentrated aqueous sodium sulfide, has the same framework but with almost linear (178–179°) S–Au–S segments.[301] The structural precedent is therefore established for $[(\mu_3\text{-}SR)_8M_{12}]^{4+}$ (M = Cu, Ag or Au), in which thiolate substituent interference is unlikely: a requirement of very strongly electron-releasing thiolate ligands is expected.

12C

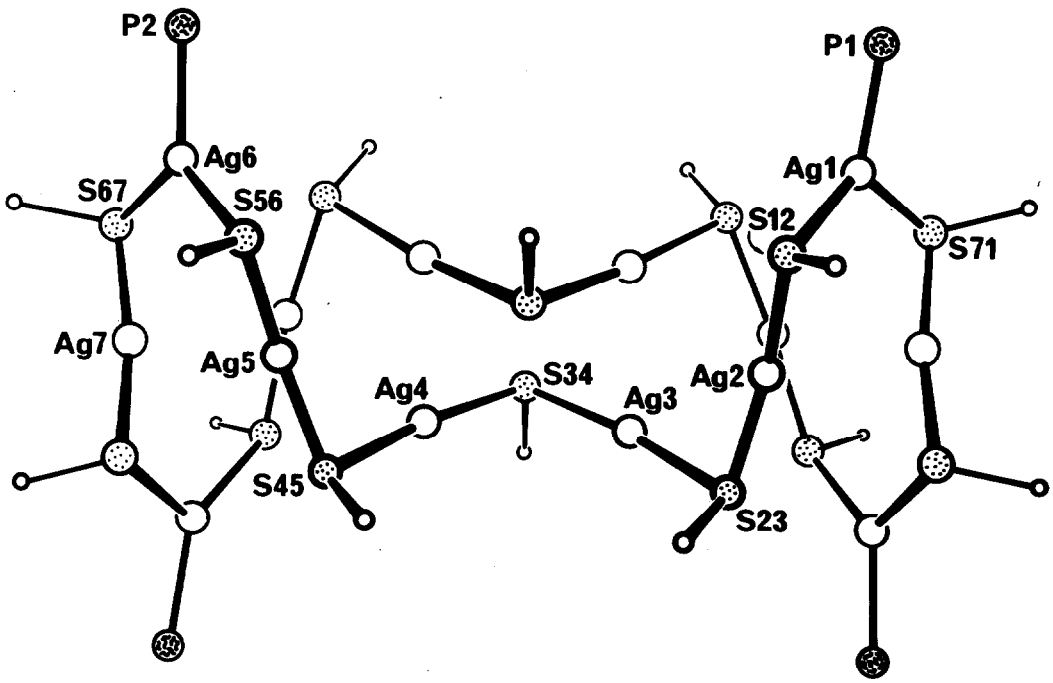
2.12. M_{14} *structures*

A set of M_{14} complexes with an inner cube of metal atoms bridged by thiolate chelate ligands which include also an outer octahedron of M atoms has been mentioned in Section 2.8.2.

2.12.1. *cyclo*-$(\mu\text{-SR})_{14}M_{14}(PPh_3)_4$. The compactly folded monocyclic structure shown in Fig. 9 occurs in crystalline $(\mu\text{-SBu}^t)_{14}Ag_{14}(PPh_3)_4$.[195] The 28-membered centrosymmetric monocycle of alternating Ag and S atoms contains 10 linear S–Ag–S segments, and four bent segments in which PPh_3 ligands are attached to trigonal planar Ag atoms. There is a pseudo-two-fold axis along the length of this molecule, which contains opposed "zig-zag" segments along the central sides, connected by four "crossover" segments to four trigonal "bending" segments, which are linked by two linear "end-connecting" segments. It is significant that there are no secondary Ag–S interactions: the opposing directions of S–Ag–S segments related by the pseudo-two-fold axis allow the closest approach of segments across the molecule to be between Ag atoms at non-bonding distances of *ca* 3.1 Å.

3. DESCRIPTION OF NON-MOLECULAR STRUCTURES

A very large number of metal thiolates, particularly the uncharged $\{M(SR)_n\}_p$ compounds where R is not bulky, are insoluble or sparingly soluble in inert solvents and are therefore presumed to be structurally non-molecular. However confirmation of structural non-molecularity has been achieved in a very small proportion of these compounds because the insolubility makes it difficult to obtain crystals with a quality sufficient for diffraction analysis. Techniques that have been applied successfully to the problem of crystal growth are: (i) addition of non-coordinating solubilizing functions to the



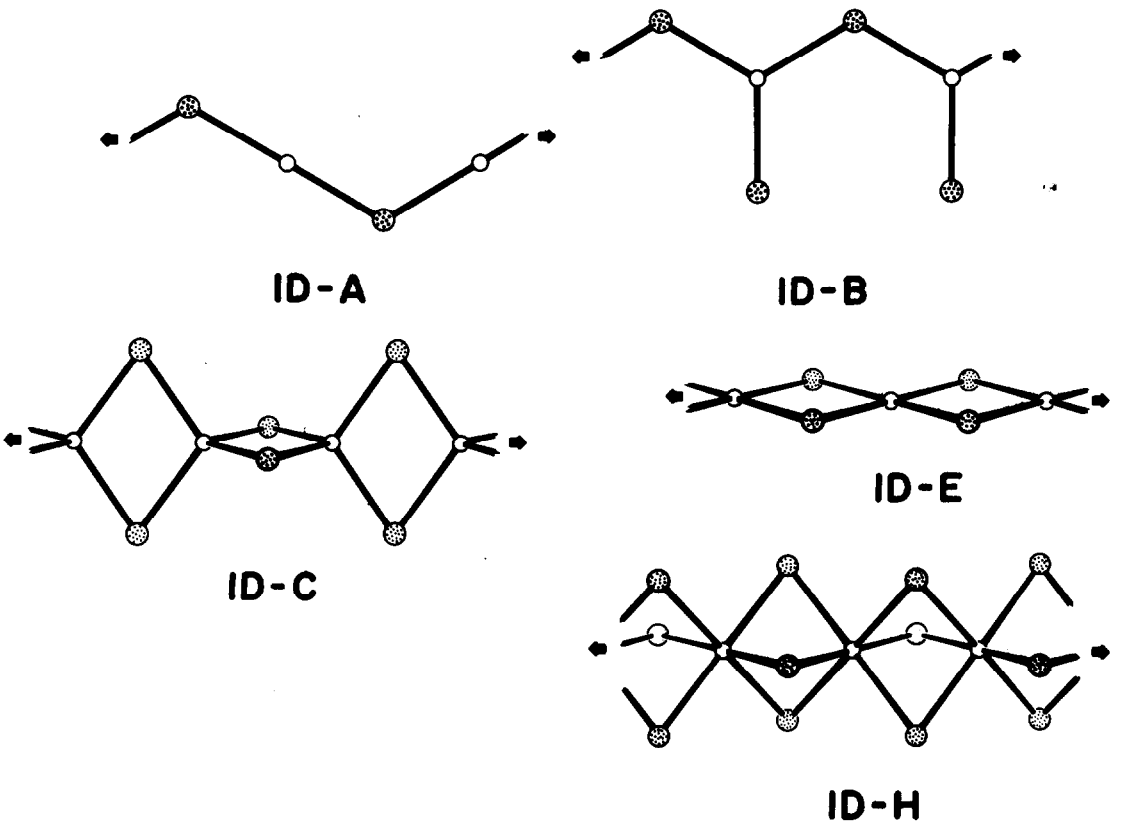


Fig. 9. Centrosymmetric coordination structure of $(\mu\text{-SBu}^t)_{14}Ag_{14}(PPh_3)_4$, with thiolate substituents marked as C_α atoms only.

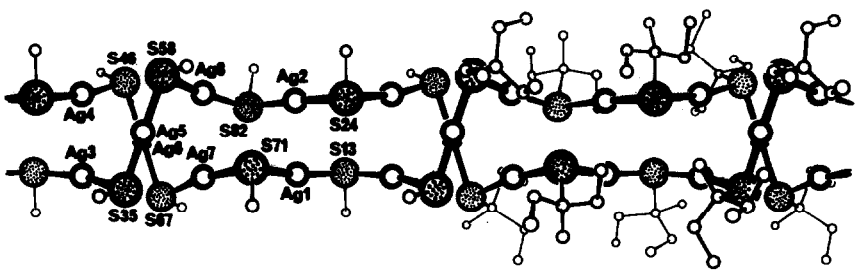
thiolate substituents R,[302] (ii) a controlled slow shift of an equilibrium connecting the insoluble compound and a soluble (further ligated) species in solution, and (iii) a controlled thermal polymerization.[303]

3.1. *One-dimensionally non-molecular structures*

3.1.1. *catena*-$[(\mu\text{-SR})M]_\infty$ (**1D-A**). Crystalline $AgSCMeEt_2$ contains well-separated infinite chains, each *chain* being composed of two intertwined but unconnected *strands* with alternating Ag atoms and doubly-bridging thiolate ligands.[304] Each strand contains approximately planar zig-zag S–Ag–S–Ag–S–Ag–S segments of type **1D-A**, which are connected at their ends by single Ag atoms (also linearly coordinated) linking segments on one side of the chain to parallel segments on the opposite side of the chain. The two strands of the chain thereby wind around each other at every fourth Ag atom without interstrand bonding, as shown in Fig. 10. The shortest distances between the strands are not secondary Ag–S contacts, but non-bonding Ag···Ag at 2.89 Å.

This compound, like other $AgSR^{tert}$ compounds, is octametallic $[(AgSR)_8]$ in benzene solution.[272] The crystal structure allows postulation of a cyclic zig-zag structure **8A** for the molecule (see Section 2.8.1), and of a straightforward mechanism for interconversion of the non-molecular crystal structure and the molecule $(AgSR)_8$ in solution.[304]



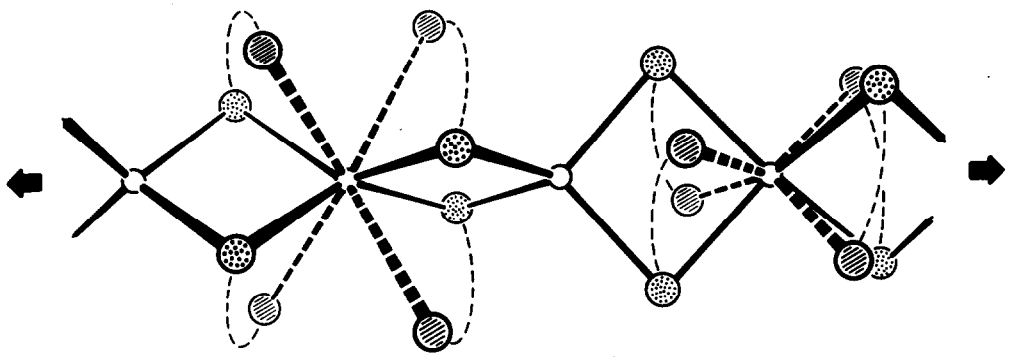


Fig. 10. Crystal structure of *catena*-$AgSCMeEt_2$ showing the two intertwined strands of one chain, viewed almost parallel to the planes which contain the zig-zag segments. Strand crossover occurs at Ag5, Ag6. Two repeat units are shown, with the ligand substituents abbreviated to C_α on the left.

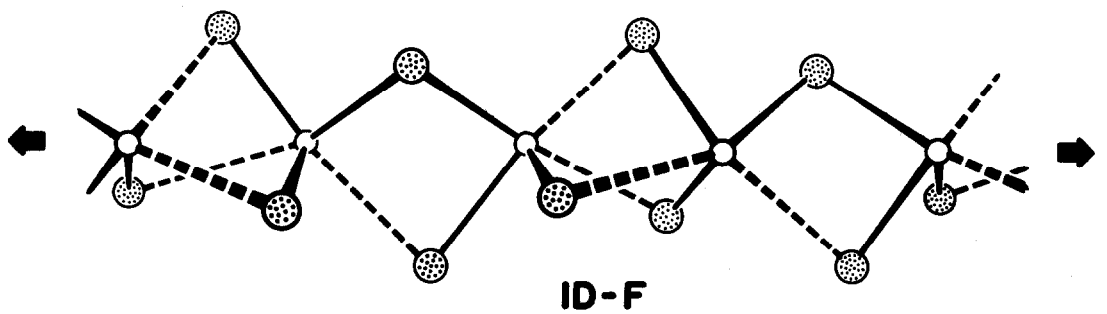
It has been mentioned[298] that $AgSCMe_2Et$ is one dimensionally non-molecular in crystals, but details have not been reported.

3.1.2. *catena*-$[(\mu\text{-SR})MSR]_\infty$ (**1D-B**). This structure with a three-coordinate metal is not known as such (and could be unfavourable relative to a double-bridged structure), but derivatives with heteroligands in the non-bridging positions are known. Several compounds [MeSHgX and their derivatives[200,305]] contain $[(\mu\text{-SMe})Hg]_\infty$ spines, in which the Hg—S bonds (2.41–2.47 Å) are short relative to the remainder of the Hg coordination, and the S—Hg—S angles range from 135 to 163°. A similar interpretation has been given for $Pb[SCH_2CH_2N(CH_2CH_2)_2O](NO_3)$.[306]

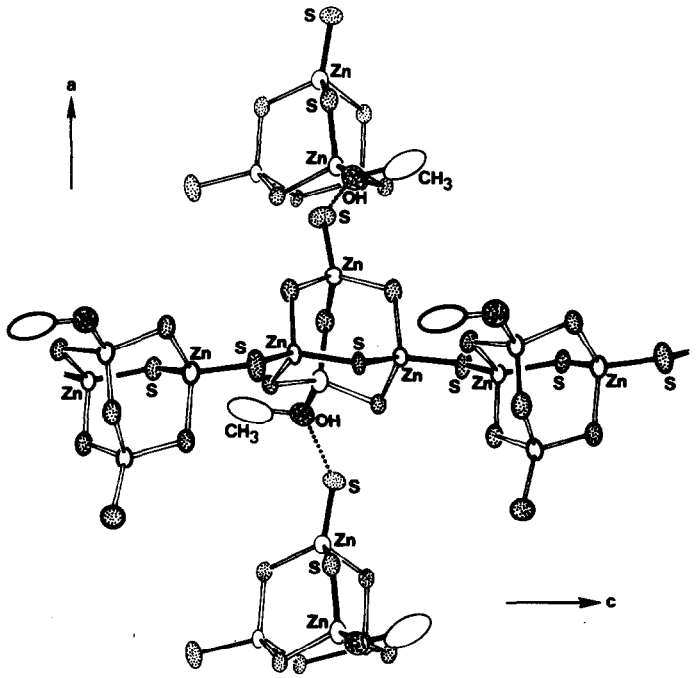
3.1.3. *catena*-$[(\mu\text{-SR})_2M]_\infty$ (*tetrahedral metal coordination*) (**1D-C**). This well-known non-molecular structure type is represented by thiolates and selenolates of Zn, Cd and Hg in the solid state: $Hg(SBu^t)_2$,[9] $Hg(SeBu^t)_2$,[307] $Hg(SeMe)_2$,[308] $[Cd\{SCH(CH_2CH_2)_2NHCH_3\}_2]^{2+}$,[309,310] and $Cd(SCH_2COOEt)_2$.[311] In addition, structure **1D-C** probably occurs in $M(SBu^t)_2$ (M = Zn or Cd), because their low-frequency IR spectra are very similar to that of $Hg(SBu^t)_2$ and different from molecular $Hg(SR)_2$ species.[312] In most instances the M_2E_2 bridge straddles a centre of symmetry (requiring the *anti*-planar configuration), with M—S—M *ca* 82°: an exception is $Hg(SeMe)_2$, where two different bridge cycle geometries alternate along the chain. One cycle is folded, with an *endo–syn*-$(SeR)_2$ configuration, and Hg—Se—Hg = 101°, while the other is centrosymmetric, Hg—Se—Hg = 82°, but with one pair of Hg—Se bonds 0.15 Å longer.



A variation on this type occurs in *catena*-$[Cd(\mu\text{-}SCH_2COOEt)_2]$[311] where there is additional secondary Cd coordination by carbonyl O atoms, to create two coordination stereochemistries: (i) pseudo-dodecahedral CdS_4+O_4, and (ii) tetra-*O*-capped tetrahedral CdS_4, which alternate along the chain as shown in **1D-D**.

1D-D

3.1.4. *catena*-$[(\mu\text{-SR})_2M]_\infty$ (*square planar metal coordination*) (**1D-E**). This structure, proposed[7] for insoluble compounds with M = Ni, Pd or Pt, has not yet been confirmed.



3.1.5. *catena*-$[(\mu\text{-SR})_3M(\mu\text{-SR})_2M]$ (**1D-F**). Here five-coordinate M atoms are connected alternately by two and three double bridges. The structure occurs for M = Pb, and the gross stereochemistry at the M is pseudo-octahedral with one position vacant. In $[Pb_2(SCH_2CH_2NMe_3)_5]^{4+}$ (PF_6^-) there are two crystallographically independent chains of this form in the crystal.[302] In fact the Pb—S distances are in two sets: at each Pb atom there are three mutually orthogonal primary bonds <3.0 Å (in most cases 2.5–2.8 Å) and two secondary interactions of 3.1–3.4 Å which are also *cis*. According to this separation of primary and secondary coordination, the chain consists of secondarily associated $[Pb_2(SR)_5]$ units.

1D-F

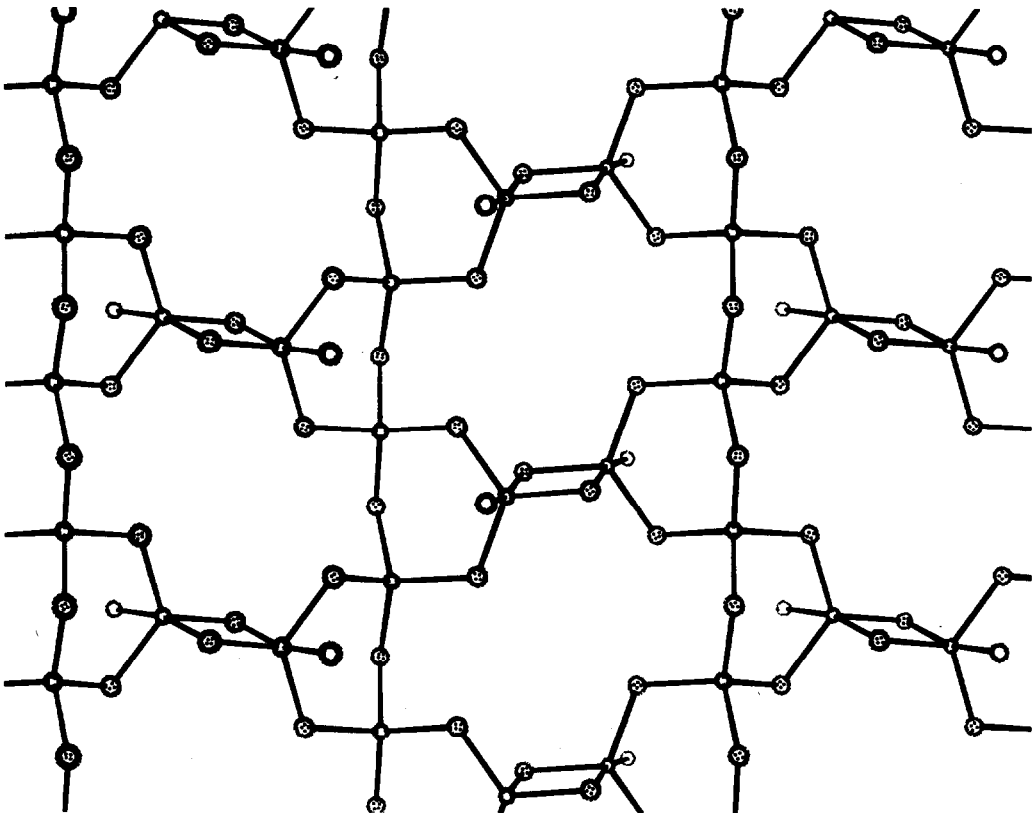
3.1.6. *catena*-(μ-SR)-[(μ-SR)$_6$M$_4$(SR)L] (**1D-G**). This structure, confirmed for the homologous series $Zn_4(SPh)_8(ROH)$ (R = Me, Et, Pr or Bu),[303] consists of adamantanoid cages linked in one dimension by bridging thiolate ligands, with one thiolate and one heteroligand ROH in the two remaining terminal positions. The crystals can be grown by slow thermal polymerization of a solution of $Zn(SPh)_2$ in ROH : depolymerization and repolymerization reactions occur, and it is possible that a similar structure occurs with MeCN as the heteroligand. Two features of the structure are notable, one being the wide (140°) angle at the inter-adamantanoid-bridging thiolate, the other the hydrogen bonding between the alcohol and the terminal thiolate ligand of a different chain. Hydrogen bonding involving a coordinated thiolate is rarely observed in crystal structures.

3.1.7. *catena*-[(μ-SR)$_3$M]$_\infty$ (**1D-H**). This one-dimensional extension of the bridging unit in **9A** may

1D-G

well occur in insoluble M(SR)$_3$ compounds such as Ln(SAr)$_3$[313] and M(SPh)$_3$ (M = Cr or Mo),[314] but has not yet been confirmed crystallographically.

3.2. *Two-dimensionally non-molecular structures*



A two-dimensionally non-molecular (layer) structure has been confirmed by single-crystal diffraction for only one compound, [Cd(SCH$_2$CH$_2$OH)$_2$].[315] There is good evidence from powder diffraction for a layer structure in some (AgSAr)$_\infty$ compounds (Section 3.2.2).

Structural constraints arising from the volume required by the thiolate substituent become more pronounced in two-dimensionally non-molecular structures. Substituents now extend from an approximately planar surface, and consequently the packing density of substituents is greater (for the same surface density of S atoms) than in a more molecular type with a necessarily curved molecular surface.

For steric reasons it is not feasible that many two-dimensionally non-molecular metal sulfide or metal halide structures are adopted by metal thiolates. The lamellar MS_2 structure types cannot be modified by addition of substituents at the S atoms to create six-coordination of M with triply-bridging thiolates because the S atoms are separated by less than double the van der Waals' radius of even the smallest substituent, CH_3.

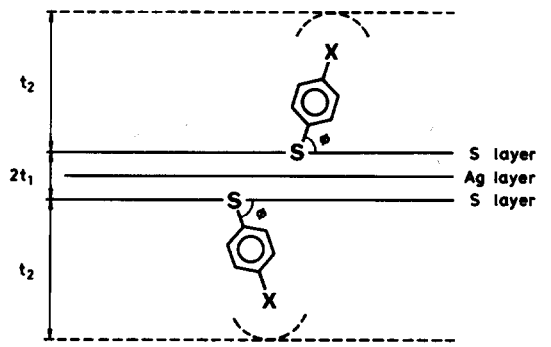
3.2.1. [Cd(SCH$_2$CH$_2$OH)$_2$]$_\infty$ (**2D-A**). Crystals of this compound, grown by a slow neutralization technique, contain buckled layers in which the Cd coordination is primarily Cd(μ-SR)$_4$, with secondary coordination by an alcohol function at one of the two crystallographically distinct Cd atoms.[315] The Cd–S network is shown diagrammatically in **2D-A**, as the Cd primary coordination tetrahedra linked

through vertices and edges, with the secondary coordination at the Cd which shares two vertices and one edge. $Cd_3(\mu\text{-}SR)_3$ and $Cd_2(\mu\text{-}SR)_2$ cycles are present. The structure is open, with hydrogen bonding between OH groups within and between the layers.

2D-A

3.2.2. $[AgSAr]_\infty$ (**2D-B**). The polycrystalline diffraction patterns of $[AgSC_6H_4X\text{-}4]_\infty$ (X = H or Cl) show well-developed progressions of intense axial (00*l*) reflections up to $l = 7$, indicative of a structure containing layers of Ag and S atoms. Other weak non-axial reflections are present, consistent with the occurrence of at least some crystallographic registry of layers. The interlayer spacings are 14.14 and 16.37 Å for X = H and Cl, respectively. The homologous Cu(I) compounds manifest different diffraction patterns, without evidence of layering.[316]

The postulated structure contains a central slab of connected Ag and S atoms, from which the aryl substituents extend, on either side, at a steep inclination (ϕ). This model is supported by its agreement with the observed interlayer spacings. Referring to the cross-sectional parameters of the layer (Fig. 11),



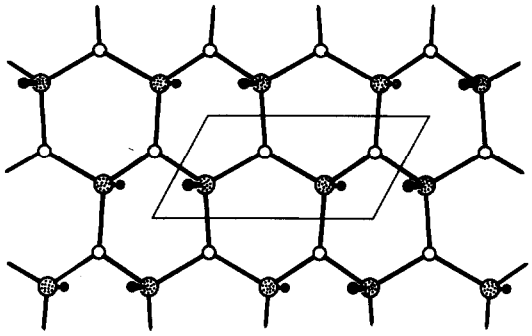


Fig. 11. Postulated layer structure for $[AgSAr]_\infty$ (**2D-B**) with definitions of the thickness of the central Ag–S slab and the thickness of the van der Waals' boundaries (broken lines) formed by aryl substituents inclined to the slab at angle ϕ.

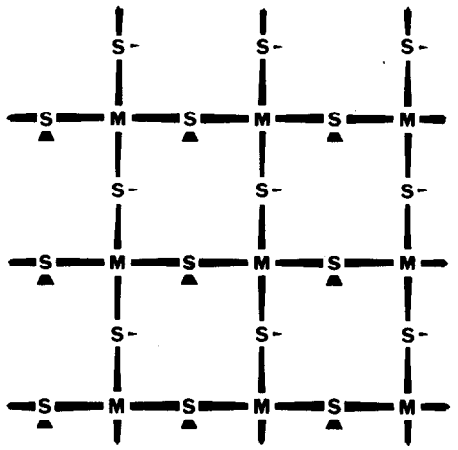
the thickness $(2t_1 + 2t_2)$ of the layer between the planes formed by the van der Waals' boundaries of opposite substituents is calculated as 13.9 and 16.0 Å (X = H and Cl): if $\phi = 90°$, $t_1 = 0$. Assuming that there is no interlayer penetration of substituents, the thickness of the layer represents the axial repeat distance of the crystal structure, and it is clear that excellent agreement between calculated and observed interlayer distances can be achieved for X = both H and Cl with $t_1 = ca$ 0.1 Å ($\phi = 90°$).

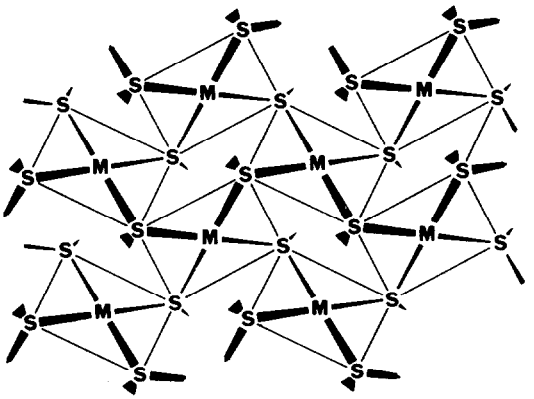
A possible hexagonal network for the central Ag–S slab, shown in **2D-B**, requires a triply-bridging thiolate and allows a normal trigonal planar three-coordinate Ag. With representative dimensions, the thickness $2t_1$ of this slab is *ca* 1 Å, requiring $\phi = ca$ 70° for agreement with the measured layer separations. In this layer structure the smallest separation between S---X axes of parallel aryl substituents is *ca* 4.4 Å, sufficient for the aryl substituents to pack over both surfaces of the slab, but insufficient for mutual penetration of substituents in adjacent layers.



2D-B

Reasonable two-dimensionally non-molecular structures ($[AgSR]_\infty$) with only two-coordinate Ag (and therefore doubly-bridging thiolate) are difficult to postulate, as they would involve a fabric woven with threads like those in structure **1D-A** above.

3.2.3. *Postulated structures with linked* $M(\mu\text{-}SR)_4$ *tetrahedra.* It is unlikely that metal thiolates could occur with layer structures in which coordination tetrahedra share four *edges*, as this would require quadruply-bridging thiolate, $[MSR]_\infty$ stoichiometry, and limit the substituent volume by requiring parallel substituent axes to adhere to a *ca* 4 Å square network. *Vertex* linkage of tetrahedra in two dimensions allows doubly-bridging thiolate with more space for thiolate substituents, and the formulation $[M(SR)_2]_\infty$. The simplest structure type is shown diagrammatically in **2D-C**, which shows a straightforward unhindered pattern for ligand substituent orientations.

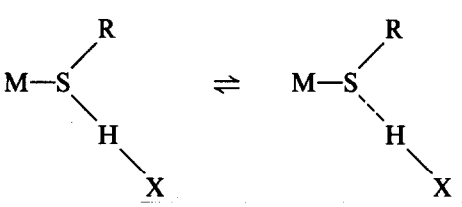


A larger structure type for $[M(SR)_2]_\infty$, with tetrahedral $M(\mu\text{-}SR)_4$ coordination throughout, contains vertex-linked adamantanoid units, $[M_4(\mu\text{-}SR)_6(\mu\text{-}SR)_{4/2}]_\infty$, in the same pattern as **2D-C**.

2D-C

3.2.4. *Postulated structure with linked* $M(\mu\text{-}SR)_4$ *square planes.* A layer structure possible for compounds $M(SR)_2$ (M = Ni, Pd or Pt), with square planar coordination, is shown in **2D-D**. Each

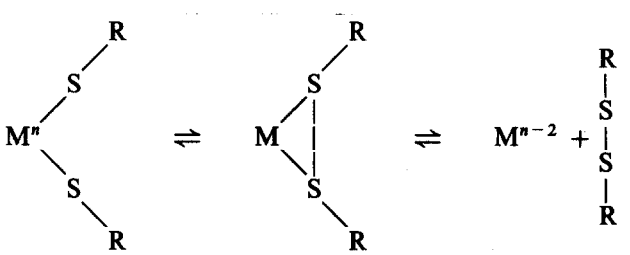
square plane is linked to four others through vertices only, in analogy to the network of **2D-C**. In order to form appropriate angles at the doubly-bridging thiolates the coordination planes are tilted with respect to the plane of the extended layer. By further twisting as shown about axes normal to the layer plane the substituents leaving the pyramidal S atoms can be inclined steeply to the layer plane.



2D-D

3.2.5. *Miscellaneous and heteroligand compounds.* The crystal structure of $Pb(SCH_2CH_2S)$ is pseudo two-dimensionally non-molecular in sandwich form, with Pb atoms between layers of S atoms, and peripheral CH_2 groups.[317] The six Pb–S connections vary in length (2.66, 2.66, 3.03, 3.06, 3.38 and 3.58 Å). MeSHgBr has a two-dimensionally non-molecular structure in which chains resulting from the primary Hg coordination by doubly-bridging SMe (Hg—S = 2.44 Å, S—Hg—S = 163°) are linked secondarily by triply-bridging Br.[305]

Crystalline $\{Pb(SCH_2CH_2OH)(NO_3)\}_\infty$ contains the two-dimensional Pb–S layer network of **2D-B**, with the cycles distorted from hexagonal towards quadrilateral, and with additional out-of-plane coordination of Pb atoms by OH and NO_3 ligands.[318]



4. RELATED COMPOUNDS WITH COORDINATED DISULFIDE OR COORDINATED THIOL

Protonated (RSH) and oxidized (RSSR) thiolate, being uncharged, are uncompetitive ligands. They occur, usually singly, in a small number of compounds. Coordinated RSH may function as a hydrogen bond donor in the Bronsted conjugate of coordinated RS^-, functioning as a hydrogen acceptor [eqn (4)]:

(4)

Coordinated RSSR is one component of the redox addition–elimination process [eqn (5)]:

(5)

A precedent exists for the formation of bridging coordinated RSSR by dimerization of coordinated

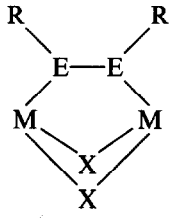
thiolate in the reversible system:[319]

$$2[(\eta^5\text{-Cp})(CO)(PR_3)FeSPh]^+ \rightleftharpoons [(\eta^5\text{-Cp})(CO)(PR_3)Fe(\mu\text{-}SPh)_2Fe(PR_3)(CO)(\eta^5\text{-Cp})]^{2+}. \quad (6)$$

4.1. *Coordinated* RSH

Acid and redox properties of EtSH (and H_2S) coordinated to $(NH_3)_5Ru$(II,III) have been measured.[320]

$Rh_2(OAc)_4$ combines readily with $PhCH_2SH$ to form centrosymmetric $(PhCH_2SH)Rh(\mu\text{-}O_2CCH_3)_4Rh(HSCH_2Ph)$ with an Rh—S distance of 2.55 Å.[321] The presence of the thiol H atom was confirmed by the S—H stretching frequency (2550 cm^{-1}) in the IR, and its position [S—H = 1.21(3) Å] was refined with the X-ray diffraction data.



The compound (PhSH)Fe(TPP)(SPh) (TPP is tetraphenylporphyrin)[322] in its low-spin structure appears to have octahedral Fe(III) coordinated at 2.27 Å to PhS^- and at 2.43 Å to PhSH, but the thiol H atom could not be detected in the diffraction studies. $[IrH(SCH_2CH_2PPh_2)(HSCH_2CH_2PPh_2)CO]^+(Cl^-)$ contains a chelated coordinated thiol, confirmed by diffraction detection and indirect NMR detection of the thiol H atom, which is hydrogen bonded to the lattice Cl^-.[323]

Hydrogen bonding from coordinated MeOH to terminally coordinated PhS^- (S--O = 3.03 Å) occurs in $Zn_4(SPh)_8(MeOH)$ [see **1D-G** (Section 3.1.6)].

4.2. *Coordinated* REER (E = S, Se *or* Te)

Despite many recent reports of investigations of reaction mixtures containing RSSR, particularly with Mo, Fe and Cu, the uncharged disulfide ligands are generally uncompetitive with anionic ligands also present, and complexes containing coordinated RSSR are still relatively rare. Non-molecular compounds of copper(I) halides with dialkyldisulfides have been characterized.[324] The molecules $[Ph_2E_2Ag(\mu\text{-}E_2Ph_2)_2AgE_2Ph_2]^{2+}$ (AsF_6^-) (E = S or Se isostructural[325]) contain terminal monodentate and 1,2-bridging PhEEPh ligands.

A series of carbonyl compounds with REER coordinated symmetrically to two M atoms, with the support of two halide bridges as shown in diagram **A**, have been well characterized for nine compounds with M = Mn or Re, X = Br or I, and E = S, Se or Te.[326–329] The weakness of REER binding in these compounds (S < Se < Te) is revealed by facile displacement of REER by THF and CO, and by REER exchange reactions.[329] The compound $Me_3Pt(\mu\text{-}Br)_2(\mu\text{-}Se_2Me_2)PtMe_3$[330] also has structure **A**.

A

Geometrical results consistent with a bonding interaction between the S atoms of adjacent thiolate ligands, i.e. the first stage of the reductive elimination [eqn (5)], appear in $[(PhS)_2MoO(\mu\text{-}O)_2OMo(SPh)_2]^{2-}$[158] and $[(ArS)_2MoO(\mu\text{-}SAr)_2(\mu\text{-}OMe)MoO(SAr)_2]^-$.[170] The phenyl conformational isomer which allows orbital overlap between the pair of terminal PhS ligands has an S--S distance contracted by 0.25 Å, to 2.94 Å (S—Mo—S 74°). A similar geometrical effect occurs for the terminal ligands of $[(\eta^5\text{-}C_5H_5)_2Mo(SBu^t)_2]$[331] and for two of the doubly-bridging ligands of $[Cl_2(Me_2S)W(\mu\text{-}SEt)_3W(SMe_2)Cl_2]$[164] where the pair of ligands with the *exo–syn* configuration allowing bent overlap of S orbitals are separated by 3.05 Å, 0.55 Å less than the van der Waals'

contact, and the W—S bonds involved are slightly elongated by 0.04 Å. Further diminution of the S---S distance to 2.77 Å (S—Mo—S 70°) occurs in $MoO_2(SCMe_2CH_2NHMe)_2$.[332,333]

Complexes with disulfide coordination enforced by chelation are listed in Ref. 334.

5. STRUCTURAL PATTERNS AND PROPERTIES

5.1. *General characteristics*

The propensity of the thiolate ligand to occur as pyramidal double bridges M—(μ-SR)—M and thereby to form aggregated metal complexes is evident. Thiolate groups also function readily as terminal ligands, less frequently as triple bridges, and rarely in quadruply-bridging positions. It is noted also that there are no instances of aggregates with both triply-bridging and terminal thiolate ligands: for instance the cubane derivative *tetrahedro*-(μ_3-SR)$_4$-*tetrahedro*-(MSR)$_4$ is not known. The polymetallic aggregates are maintained by the thiolate bridges, with direct bonding between M atoms usually negligible or absent.

Amongst the compounds characterized by crystallographic diffraction analysis there is a preponderance of structurally molecular polymetallic complexes. This statistic does not necessarily mean that cages and clusters are more numerous or more stable than monometalic complexes, or that non-molecular compounds are in a minority, but is a practical consequence of the greater solubility of monometallic complexes in equilibria with polymetallic complexes, and of the insolubility and poor crystallinity of non-molecular compounds.

5.2. *Metal oxidation states and coordination numbers*

In thiolate complexes metal oxidation states and coordination numbers tend to occur at the low ends of the ranges for complexes of non-π-acid ligands, as illustrated by the collection of data in Table 1.

It has been pointed out[253] that for the five distinct Fe–S–SR clusters $[Fe_2S_2(SR)_4]^{2-}$ (**2E**), $[Fe_3S(SR)_6]^{2-}$ (**3J**), $[Fe_3S_4(SR)_4]^{3-}$ (**3B**), $[Fe_4S_4(SR)_4]^{2-}$ (**4H**) and $[Fe_6S_9(SR)_2]^{4-}$ (**6F**) there is an approximate correlation between the average Fe oxidation state and the proportions of S^{2-} and RS^- ligands per Fe atom. This proposed stability condition is:

$$\text{mean oxidation state} = 0.54[N_{RS}/N_{Fe} + 2.5(N_S/N_{Fe})] + 0.51, \quad (7)$$

where N_{RS}, N_S and N_{Fe} are the numbers of RS^-, S^{2-} and Fe per cluster. The 2.5 times larger influence of the proportion of sulfide ligands (N_S/N_{Fe}) is considered a reflection of stronger stabilization by S^{2-} (compared to RS^-) of higher oxidation states. Equation (7) can be legitimately extended to postulated clusters *triangulo*-$[Fe(III)_3(\mu\text{-}S)_3(SR)_6]^{3-}$ (**3F** or **3G**) and *hexahedro*-$[Fe(II)_8(\mu_4\text{-}S)_6(SR)_8]^{4-}$ (**8F**). It should be appreciated that M–S–SR clusters undergo change in total oxidation state without change in composition, and that the doubly-, triply- and quadruply-bridging S^{2-} ligands probably have different influences.

5.3. *Structural units*

Structural moieties which can be recognized in many of the polymetallic aggregates described above are cyclic-(μ-SR)$_2$M$_2$, cyclic-(μ-SR)$_3$M$_3$ and cyclic-(μ-SR)$_4$M$_4$. Of these cyclic-(μ-SR)$_3$M$_3$ is most prevalent, and its favourability is emphasized by the ubiquity of the adamantanoid cage **4F** which is composed of four fused (μ-SR)$_3$M$_3$ cycles each in chair conformation.

The smaller cyclic unit (μ-SR)$_2$M$_2$ occurs mainly in *bi*metallic molecules: most *poly*metallic structure types with two or more (μ-SR)$_2$M$_2$ cycles have them connected through the metal atoms ("spiro"-linkage at M) which is necessary to avoid triply-bridging thiolates (**3A, 3B, 3C, 3M, 4C, 6B, 8D, 9A, 1D-C, 1D-D** and **2D-A**). The few instances of polymetallic compounds with (SR)$_2$M$_2$ cycles fused through thiolate are less general: (μ_3-SMe)$_4$Re$_4$(CO)$_{12}$, (μ_3-SR)$_4$Pt$_4$(R′)$_{12}$ (Section 2.4.8), $(SPh)_4Cu_4(PPh_3)_4$ (**4G**), $(SBu^t)_5(ZnMe)_5$ (**5C**), $(SPh)_6Ag_6(PPh_3)_5$ (**6C**) and $(SPr^i)_8(ZnMe)_8$ (**8E**). In this regard the (μ-SR)$_2$M$_2$ structural unit is different from the (μ-SR)$_3$M$_3$ and (μ-SR)$_4$M$_4$ structural units, which can be and are fused without thiolate triple-bridging. All of the many other polymetallic molecules with fused S$_2$M$_2$ cycles involve sulfide or polysulfide as the triply-bridging ligand, with thiolate ligands in terminal positions.

Table 1. Metal oxidation states and coordination numbers in representative metal thiolate complexes[a]

Oxidation No.	Coordination No.	Terminal thiolate ligand only	Bridging thiolate ligand only	Mixed ligand
I	2	$[Cu(SAr)_2]^-$	$[(\mu\text{-}SCMeEt_2)Ag]$ $[M_5(SBu^t)_6]^-$ $[M_5(SPh)_7]^{2-}$ (M = Cu or Ag)	
	3		$[Cu_4(SR)_6]^{2-}$	$(AgSBu^t)_8(PPh_3)_2$
	3		$[M_5(SBu^t)_6]^-$ $[M_5(SPh)_7]^{2-}$	$(CuSBu^t)_4(PPh_3)_2$
II	2	$Hg(SR)_2$		ArHgSr
	3	$[Pb(EPh)_3]^-$ (E = S or Se) $[Hg(TePh)_3]^-$		
	4	$[M(SR)_4]^{2-}$ (M = Mn, Fe, Co, Ni, Zn, Cd or Hg)		$[(RS)_2M(\mu\text{-}SR)_2M(SR)_2]^{2-}$ (M = Fe, Co or Hg)
	6		$[Fe(\mu\text{-}SR)_6\{MoS_4(FeSR)_3\}_2]^{4-}$	
III	4	$[M(SR)_4]^-$ (M = Fe or Ga)		
	6		$[Fe(\mu\text{-}SR)_6\{MoS_4(FeSR)_3\}_2]^{4-}$	
IV	4	$Sn(SePh)_4$		
	5	$[Sn(SPh)_5]^-$		$LM(SAr)_4$ (L = MeCN or CO, M = Ru or Os)
V	5			$[EM(SPh)_4]^-$ (E = O or S, M = Mo or W)
	6	$[Re(SR)_6]^-$ [b]		

[a] R and M indicate series of complexes.
[b] See Section 2.1.11.

The cyclic $(\mu\text{-SR})_4M_4$ moiety occurs in **4A**, **4B**, **4C**, **5A**, **5B**, **6A**, **8B**, **8C** and **12C**.

Smaller structures can be recognized as fragmentary units of larger structures. For instance, **3F** is part **4D**, of **4F**, and of **6H**.

5.4. *Molecular symmetry and molecular distortions*

High symmetry is a characteristic of molecular $[M_x(SR)_y]$ aggregates. In most instances the combined array M_xS_y is less symmetrical as a polyhedron than the separate M_x and S_y polyhedra, which are frequently regular (all vertices identical, and all faces identical) or semi-regular (all vertices identical) and concentric. These M_x and S_y polyhedra may intersect, or be radially distinct in an "onion shell" arrangement of alternating metal and ligand polyhedra. The order of the idealized molecular point group is usually equal to or higher than the number of S atoms. Almost invariably the array R_y of $[M_x(SR)_y]$ cannot maintain the higher symmetry of the M_xS_y array: mirror elements in particular are incommensurate with thiolate bridges. Thus the actual molecular symmetries of these cages, and the observed crystallographic site symmetries are generally very much lower than the potential symmetries of the M_xS_y cores.

The M_xS_y cores of $[M_x(SR)_y]$ aggregates tend to have low connectivities, that is a small number of framework bonds per M, S atom. One consequence of this is a structural non-rigidity which is manifest in distortions of the core polyhedra from idealized symmetry. The distortions are primarily angular (see Section 5.8). The degree of mechanical flexibility and distortion is inversely related to the connectivity, and increases with the size of the $M_n(SR)_n$ cycles which constitute the aggregate, while the direction of distortion can usually be traced to the intramolecular interactions between thiolate substituents.

The smallest deformations which can be clearly defined and which can be unambiguously attributed to intramolecular substituent repulsions occur in structures **4E** and **4F** with the $(\mu\text{-SR})_6M_4$ core [12 bonds per 10 atoms, $M_3(SR)_3$ cycles], and have already been described in Sections 2.4.5 and 2.4.6. The angular floppiness is trapped in the crystal as a flap of the M–(μ-SR)–M plane about the M--M line.

Structure $[M_5(SBu^t)_6]^-$ (**5B**), with 12 bonds between 11 core atoms and $M_4(SR)_4$ cycles only, is also inherently floppy. In the one configurational isomer where the substituents maintain the D_3-symmetry of the core, the angular distortions of the core are minimal, and are opposed by substituent repulsions. Inversion of one doubly-bridging thiolate, as occurs in another crystallographically observed isomer, causes the affected $S—M^{trig}—S$ angles to deviate by up to 27° from the 120° ideal, compared with the $<5°$ deviations in the D_3-isomer.[232]

Drastic deformation occurs in structure **6A** $\{[Ag_6(SR)_8]^{2-}\}$, where the idealized arrangement contains only 16 bonds between 14 polyhedral atoms, with $M_4(SR)_4$ cycles only: this connectivity is unable to support the idealized structure, which is found partially contorted and collapsed, with stabilization provided by intramolecular secondary M–S connections. Similar secondary connections occur in some cyclic $(AgSR)_p$ molecules which would otherwise have only $2p$ cyclic bonds per molecule (see Section 5.6.1).

Another mechanism for provision of mechanical stabilization to low-connected floppy aggregates is incorporation of a central monatomic ligand with normal bonds to M^i atoms (**8C**) or long connections to a larger number of M atoms [**6D**(**6E**) and **8B**].

The molecular cage $(\mu_3\text{-S})_8M_{12}$ (**12C**) is remarkable in this context because it is large and empty, contains only M_4S_4 cycles, and has 24 bonds for 20 atoms. Apparently the S^{2-} ligands engage more rigid triple-bridges than RS^- ligands.

5.5. *Topological relationships: families and progressions of polyhedra*

A considerable number of topological relationships between *idealized* structures of metal thiolates have been recognized, and are outlined here. These relationships involve polyhedral expansion operations and polyhedral capping. Also, some complete structures are fragments of larger complete structures. The following descriptions which are couched in terms of conversion processes are not meant to imply mechanisms: it is very likely that most of these systems are involved in very mobile equilibria, and that factors such as solubility have determined the identity of species isolated.

5.5.1. *Polyhedral expansion* $[M_4(SR)_6$, $M_5(SR)_7$ *and* $M_6(SR)_8]$. The *octahedro*-$(\mu\text{-SR})_6$-*tetrahedro*-M_4 structure **4E** undergoes two stages of polyhedral expansion to form $(\mu\text{-SR})_7M_5$ (**5A**) and then (μ-

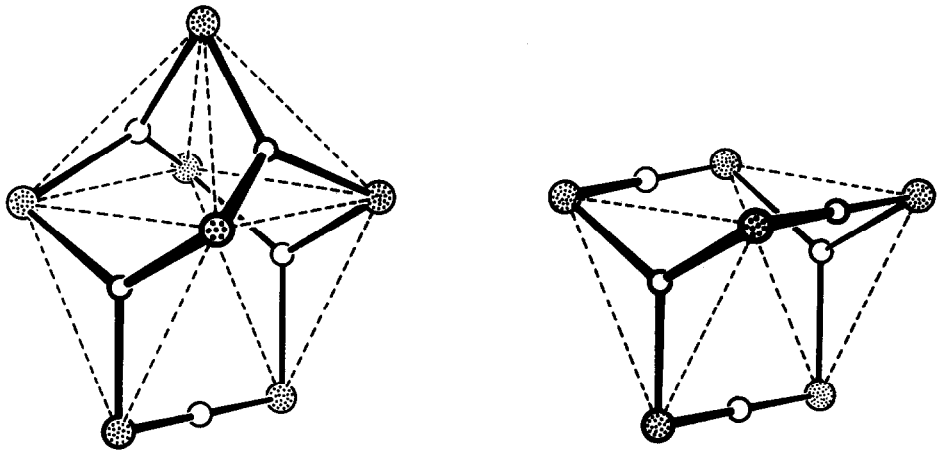


Fig. 12. Relationship between the idealized cage polyhedra of structures **5A** and (trigonal prismatic) **5B**.

$SR)_8M_6$ (**6A**) as shown in Fig. 4. Each stage of the expansion involves replacement of a doubly-bridging thiolate which links two trigonal planar coordination units by a digonal and linear (μ-SR)–M–(μ-SR) function, requiring a separation of the trigonal planes. The second stage occurs at the vertex most distant from that of the first stage. The addition of two-coordinate M atoms decreases cage rigidity, as already mentioned, and hence continued polyhedral expansion by this mechanism is limited by the collapse of the resulting structures.

5.5.2. *Polyhedral contraction* [$M_5(SR)_7$ *and* $M_5(SR)_6$]. Structure **5A** contains a trigonal prism of doubly-bridging thiolate ligands, the basis of **5B**, as shown in Fig. 12. Conversion of **5A** to **5B** is readily envisaged as removal of the unique doubly-bridging thiolate at the vertex opposite the digonal M atom, concomitant with shift of the two-coordinate M atoms so created into digonal stereochemistry, and followed by a trigonal twist about the axis through the two trigonal M atoms.

Monocyclic **4A** (either diligated or unsubstituted) is a component of bicyclic **5A**.

5.5.3. $M_5(SR)_6$ *polyhedra.* The compound $Ag_6(SAr)_6(PPh_3)_5$ (**6C**) contains an $Ag_5(SR)_6$ core which is ideally comprised of a basal unit *centro*-Ag-*hexagono*-$(SR)_3Ag_3$ straddled by a trigonal $Ag(SR)_3$ podal unit (see Section 2.6.3). This idealization contains *octahedro*-$(SR)_6$, which signifies the relationship with other $M_5(SR)_6$ structures shown in Fig. 13.[249] The *trigonal bipyramido*-M_5-*trigonal prismo*-$(SR)_6$ structure [Fig. 13(a)] is partially twisted about the three-fold axis to generate **5B**, and then this twisting is continued by the three digonal M atoms which drop into the lower trigonal plane as shown by the arrows in Fig. 13(b), thereby creating the base-centred hexagonal unit of **6C**. The upper trigonal plane of **5B** becomes the podal trigonal unit of **6C**.

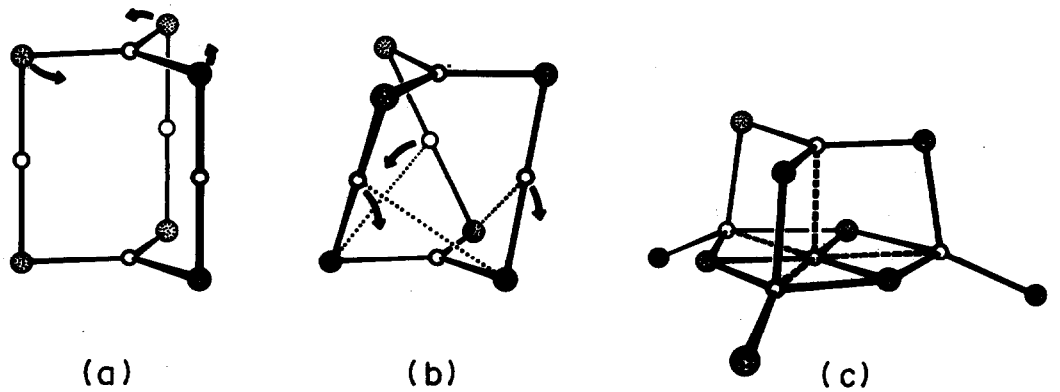

Fig. 13. Relationships between $M_5(SR)_6$ cage polyhedra. (a) *Trigonal-bipyramido*-M_5-*trigonal prismo*-S_6, twisting towards (b) *octahedro*-S_6 (**5B**), collapsing to (c) *base-centred-trigonal-pyramido*-M_5-*octahedro*-S_6 (part of **6C**), with added terminal phosphine ligands.

Structure **5B** which has thiolate ligands bridging the edges of an M_5 trigonal bipyramid is not very different from the face-bridged *trigonal bipyramido*-M_5 structure $(\mu_3\text{-SR})_6M_5$. This alternative has thiolate bridges over all six faces of the M_5 trigonal bipyramid, and can be described also as a trigonal prism of thiolate S atoms with M atoms in the centres of all five faces. Three metals are four-coordinate and two are three-coordinate. This structure is not known for metal thiolates, although it is known with oxide as the triply-bridging ligands in $Cp_5V_5O_6$.[335] The thiolate structure **3M** is a relative without two M atoms.

5.5.4. *Toroidal molecules* $[(\mu\text{-SR})_{2n}M_n]$. Monocyclic structures **3M, 4C, 6B** and **8D** are based on the M_n regular polygon, with two doubly-bridging thiolate ligands between each metal pair, such that there are two slightly larger $(SR)_n$ polygons which sandwich the M_n polygon. Except in the triangular molecule which involves chelating thiolates, the thiolate substituents alternate axial/equatorial around each $(SR)_n$ polygon, and on this basis the odd membered toroids ($n = 5$ or 7) are not expected (see also Section 2.3.11). Toroid size does not appear to be influenced by the M—S—M angles at the folded $(\mu\text{-SR})_2M_2$ bridges, while toroids with $n > 8$ are sufficiently empty to probably require included guest molecules for existence.[202]

Structure **3C**, which also contains chelating ligands, is a semi-circular half of the hexagonal toroid **6B**.

5.5.5. *The ensemble of high-symmetry* $(\mu\text{-SR})_{12}M_8$ *structures.* **8B** and **8C** belong to a set of four structures in which an icosahedron or cuboctahedron of doubly-bridging thiolate ligands is associated with a cube or bitetrahedron of metal atoms.[280] Figures 14 and 15 provide comparative views of the

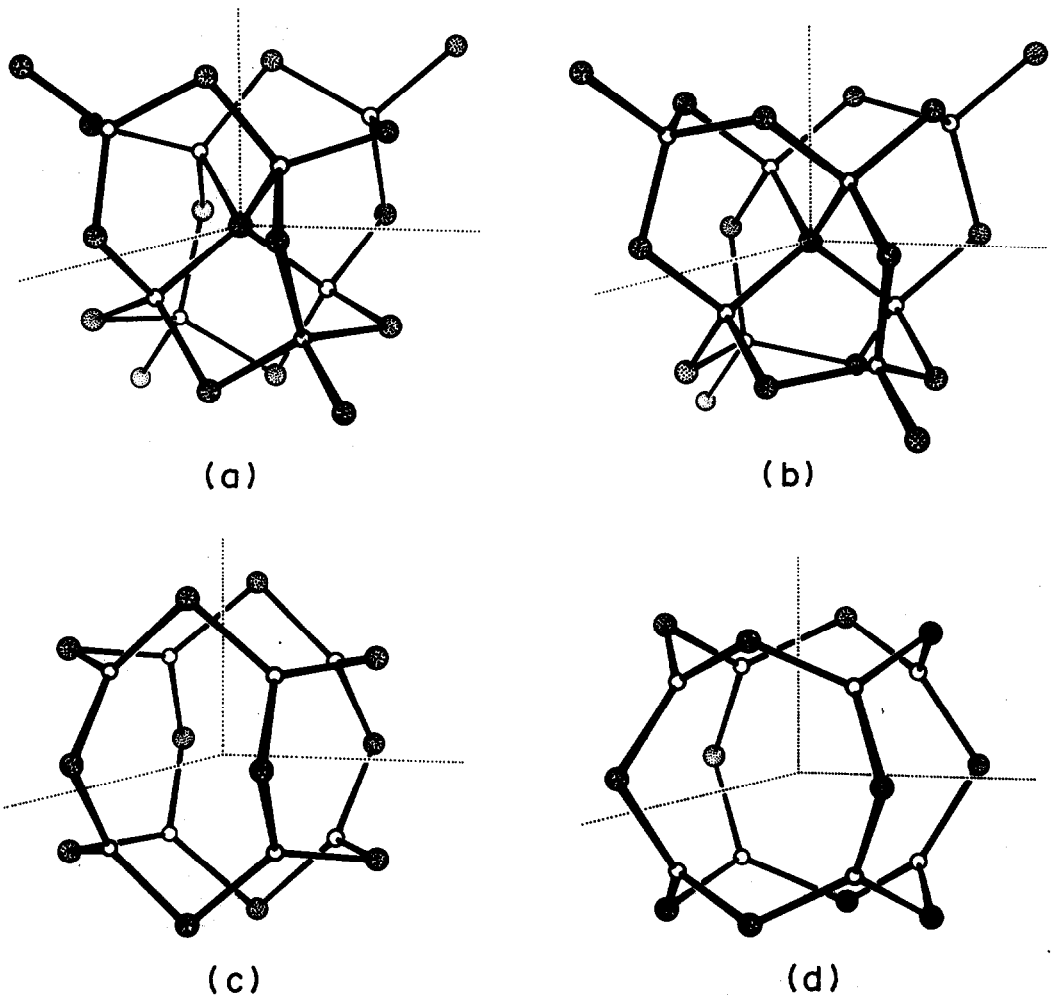

Fig. 14. Comparative views of: (a) *centro-Z-bitetrahedro*-M_8-*icosahedro*-$(SR)_{12}$, (b) *centro-Z-bitetrahedro*-M_8-*cuboctahedro*-$(SR)_{12}$, (c) *hexahedro*-M_8-*icosahedro*-$(SR)_{12}$, and (d) *hexahedro*-M_8-*cuboctahedro*-$(SR)_{12}$.

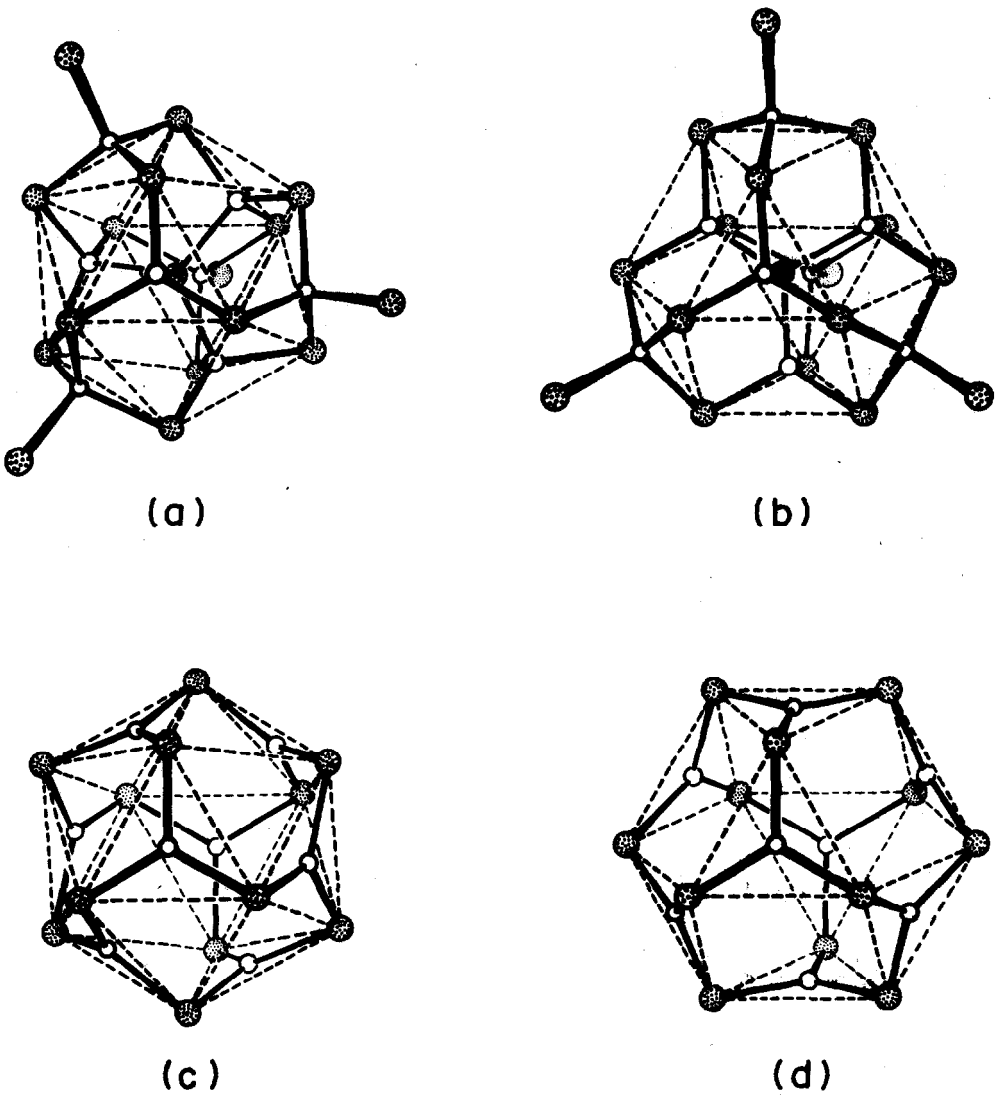

Fig. 15. Comparative views of: (a) *centro-Z-bitetrahedro*-M_8-*icosahedro*-$(SR)_{12}$, (b) *centro-Z-bitetrahedro*-M_8-*cuboctahedro*-$(SR)_{12}$, (c) *hexahedro*-M_8-*icosahedro*-$(SR)_{12}$, and (d) *hexahedro*-M_8-*cuboctahedro*-$(SR)_{12}$.

structures in this set. A central ligand and terminal ligands are required for the *bitetrahedro*-M_8 arrays, and may be present for *hexahedro*-M_8. These four structures are interconvertible without bond-breaking. In each of the four the array of substituents belonging to the bridging thiolate ligands can and probably will have a high symmetry (T or T_h): the array of α-carbon atoms $[(C_\alpha)_{12}]$ is close to a cuboctahedron when S_{12} is an icosahedron, and close to an icosahedron when S_{12} is a cuboctahedron.[280]

5.5.6. *Structural congruence of molecular and non-molecular structures.* The adamantanoid cage **4F** is a fragment of the cubic (sphalerite or zinc blende) MX structure, corresponding to the unit cell of the latter as shown in Fig. 16. Thus there is structural congruence between a *molecular* cage with thiolate ligands and the *non-molecular* structure adopted by metal sulfides (and other chalcogenides). This structural congruence extends to poly-adamantanoid cages, and in particular to the tetra-adamantanoid supertetrahedral cage of **10A** which involves both chalcogenide and thiolate ligands.* The size of these poly-adamantanoid molecules can increase indefinitely without disrupting this

* The hypothetical thiolate cage $M_{10}(SR)_{20}$ described in Section 2.10.3 also adheres to this congruence.

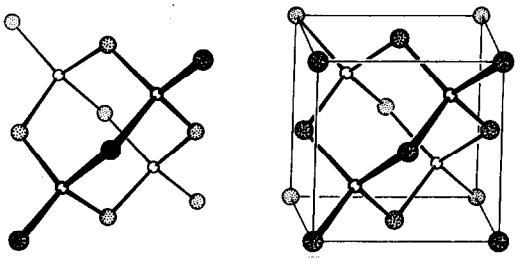

Fig. 16. Correspondence between the adamantanoid molecular structure (**4F**) and the cubic unit cell of sphalerite.

congruence, a fact which leads to speculation about larger molecular structures (Section 8). Analogous molecular fragments of the hexagonal (wurtzite) MX structure, terminated with thiolate ligands, are not as readily conceivable because the unprecedented $(\mu_3\text{-SR})_2M(SR)_2$ units would be required.[293]

The cubic cage $[S_6(CoSR)_8]^{4-}$ (**8F**) is a fragment of the non-molecular structure of the mineral pentlandite (M_9S_8) in which the cages are linked through octahedrally coordinated M atoms.[281] Here it is less feasible to build larger molecules as more extensive fragments of the non-molecular structure.

Structures **10A** and **4F** are both portions of the cubic MX lattice, but their central core polyhedra have an inverse relationship. The core of **4F** (or **4E**) is *tetrahedro*-M_4-*octahedro*-S_6 while the core of **10A** is *octahedro*-M_6-*tetrahedro*-S_4 as shown in Fig. 17. This can occur because the M and X sites in MX are equivalent.

5.5.7. The cubic structure **8F**, known only with sulfide ligands in the quadruply-bridging roles, can be constructed from the adamantanoid cage **4D** by addition of four M–SR caps as shown in Fig. 18. This converts a cage constructed from $M_3(SR)_3$ cycles only to one constructed from $M_2(SR)_2$ cycles only. **8F** can be conceived of also as **6H** plus two M–SR caps, as shown in Fig. 19.

5.5.8. $X_4M_{10}(SR)_{16}$ (**10A**) and $XM_8(SR)_{16}$ (**8C**) both have idealized T_d-symmetry (ignoring substituents) and an outer $(MSR)_4$ tetrahedron connected by four tris-sets of doubly-bridging thiolates to an inner polyhedron of M atoms. The inner section is either an M_6 octahedron with four faces capped by chalcogenide (**10A**) or an M_4 tetrahedron centred with a single atom (**8C**). As a consequence of these differing inner metal polyhedra, the 12 connecting thiolates constitute either a truncated tetrahedron or an icosahedron.

5.6. *Thiolate bridges and bridging stereochemistry*

Classifications of thiolate bridges first separate primary and secondary thiolate bridging. Primary bridges involve M—S bonds of similar (normal) length, while secondary connections to thiolate S are elongated, and provide metal coordination additional to the normal minimum coordination number.

5.6.1. *Secondary* M–S *bridging*. Secondary bridging and variations in bridge bond lengths are most pronounced with the heavier late- and post-transition metals Ag, Hg, Cd and Pb, where the coordination sphere is loose and flexible. Molecules with low-coordinate M atoms and, therefore, a low connectivity are often supported by intramolecular secondary bridges, and where such M atoms are exposed on the surface of the molecule intermolecular secondary bridges are evident in crystal

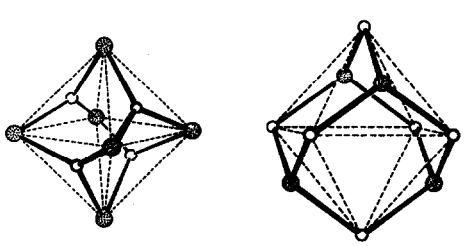

Fig. 17. M–S interchange relationship between the cores of adamantanoid **4F** (or **4E**) and tetra-adamantanoid **10A**.

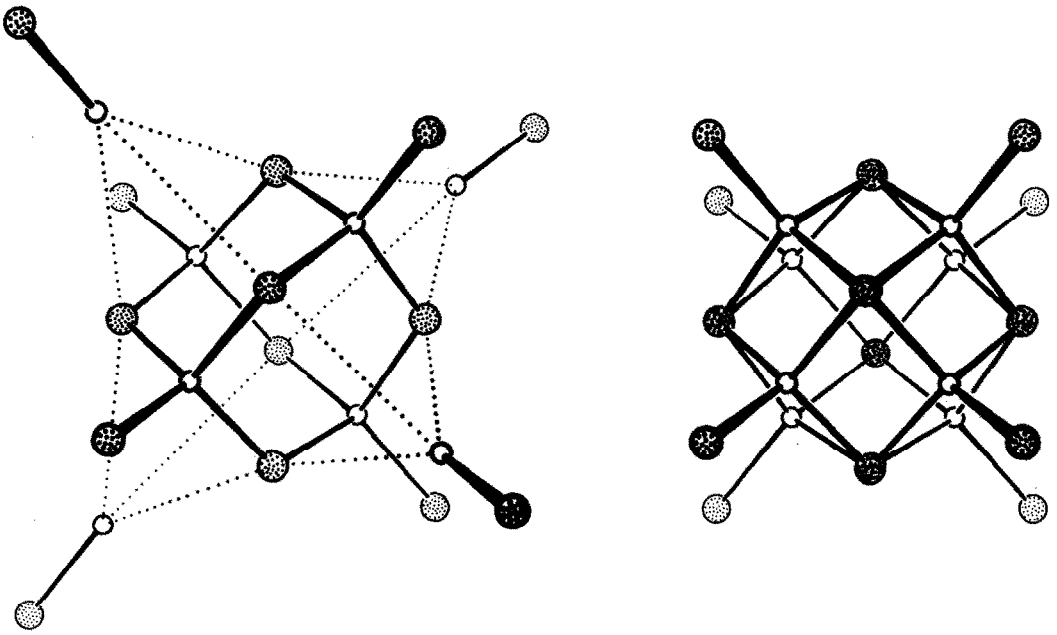

Fig. 18. **8F** as tetra-capped **4F**.

structures. Examples are the molecules $(AgSC_6H_{11})_{12}$ and $[Ag_6(SPh)_8]^{2-}$ which possess both intra- and intermolecular secondary Ag---S bridges, both *ca* 0.3 Å longer than the primary Ag–(SR)–Ag bridges. Two $(\mu\text{-SR})_4Ag_4$ molecular cycles are associated confacially by four secondary Ag---Sr bridges elongated by 0.5 Å relative to the primary bridges in **4B**. Despite the prevalence of intermolecular secondary bridging amongst two-coordinate silver thiolate structures, there is one silver thiolate structure, one-dimensionally non-molecular $\{(\mu\text{-SCMe}_2\text{Et})Ag\}_\infty$, where association of strands occurs with a conspicuous absence of Ag---S secondary bridging (see Section 3.1.1). $Hg(SR)_2$ molecules in the crystal phase associate with Hg---SR secondary bridging ranging in length up to the van der Waals' limit: for example, when R = Et the extra connections are at 3.54 Å (1 Å longer than the primary bonds), and when R = $[CH_2CH_2NMe_3]^+$ they range from 2.95 to 3.80 Å.[38]

5.6.2. *Primary thiolate bridging.* Primary bridges are classified in two stages: first according to the number and arrangement of M–S connections, and secondly in terms of the stereochemistry at S. The M–S connectivity types are organized by the number of M atoms per bridge, the number of bridges per metal pair, and whether the bridge is part of a cyclic (supported) or acyclic (unsupported) structure.

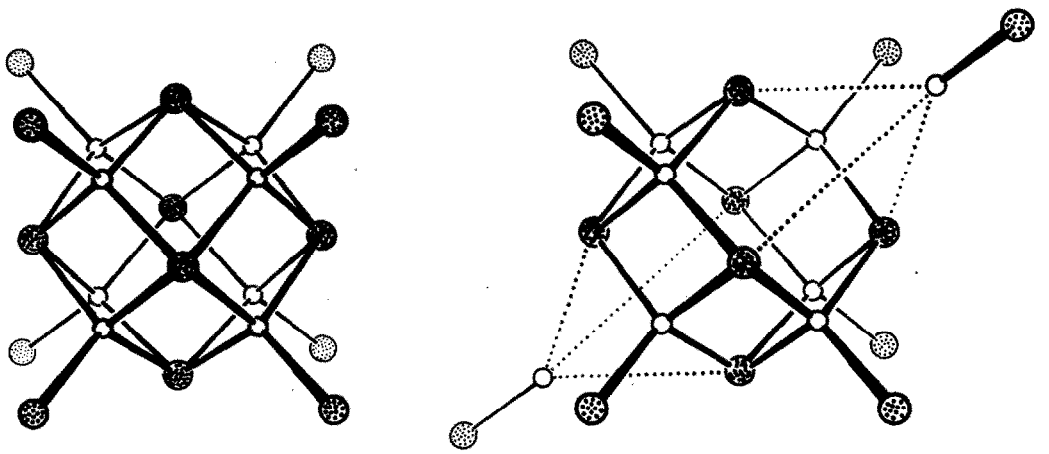

Fig. 19. **8F** as bi-capped **6H**.

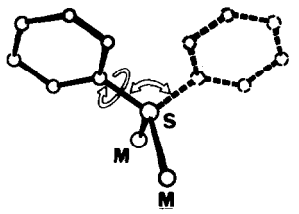

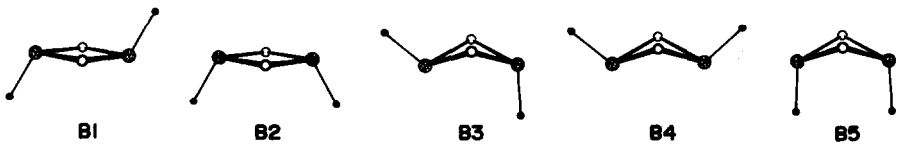

Fig. 20. The configurational (inversion) and conformational (rotation) degrees of freedom at doubly-bridging thiolate.

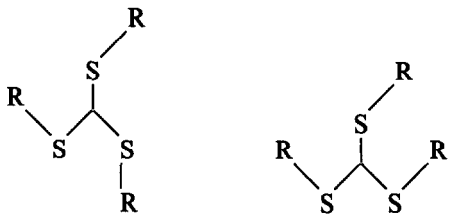
Stereochemical questions of configuration at the bridging S atom and conformation of the substituent, illustrated in Fig. 20, are discussed in Section 5.6.3 below.



5.6.2.1. One unsupported double-bridge (M—S—M) has a rare occurrence in $(CO)_5W(\mu\text{-}SC_6Cl_5)W(CO)_5$ with a W—S—W angle of 132°.[336]

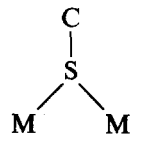
5.6.2.2. One double-bridge (M—S—M), supported only by its occurrence in a larger cyclic structure which indirectly connects the M atoms, appears in the structure types **3D, 3E, 3F, 3G, 3H, 4A, 4B, 4E, 4F, 5A, 5B, 6A, 8A, 8B, 8C, 10A** and **12A**, and also in **1D-A, 1D-G** and **2D-A**. It is evident even from the smallest trimetallic cycles (**3D** and **3G**) that the M—S—M angles can vary widely.

5.6.2.3. The bis double-bridge $[M(\mu\text{-}SR)_2M]$ occurs in modes unsupported (**2C, 2D, 2E, 2G, 3A, 3B, 3C, 4G, 1D-C, 1D-D** and **2D-A**) and supported (**3M, 4C, 6B** and **8D**) by additional cyclic connections. The M_2S_2 quadrilateral may be planar or folded about the S—S diagonal, and the M—S—M angle is variable, ranging from 67 to 100°. With planar M_2S_2 the configurations of R_2 are *anti* (**B1**) and *syn* (**B2**), while with non-planar M_2S_2 the configurations of the two R groups are *anti* (**B3**), *exo–syn* (**B4**) and *endo–syn* (**B5**). Bridge stereochemistry and stereodynamics are discussed further in Section 5.6.3.

5.6.2.4. The tris double-bridge $[M(\mu\text{-}SR)_3M]$ occurs unsupported in **2H, 2J, 8G** and **9A**. Two $(SR)_3$ configurational isomers are possible, *symmetric* (**B6**) {e.g. $[(CO)_3Fe(\mu\text{-}SMe)_3Fe(CO)_3]^{+}$[165]} and *asymmetric* (**B7**) {e.g. $(\eta\text{-}C_7H_7)Mo(\mu\text{-}SBu^t)_3Mo(CO)_2[P(OMe)_3]$[337]}:

5.6.2.5. The tetrakis double-bridge $[M(\mu\text{-}SR)_4M]$ occurs in $[V_2(SCH_2CH_2S)_4]^{2-}$ (**2K**) and $[(\eta\text{-}Cp)Mo(\mu\text{-}SMe)_4Mo(\eta\text{-}Cp)]^{0,+}$ (Section 2.2.10).

5.6.2.6. The unsupported triple-bridge $[(\mu_3\text{-}SR)M_3]$ is unknown.



5.6.2.7. The supported triple-bridge $[(\mu_3\text{-}SR)M_3]$ is relatively rare. Primary bridges where the three M—S bond lengths differ by less than 0.1 Å occur in $(Bu^tS)_5(ZnMe)_5$ (Section 2.5.3, three instances), $Ag_6(SC_6H_4Cl)_6(PPh_3)_5$ (**6C**, three instances), and $(\mu_3\text{-}SMe)_4Re_4(CO)_{12}$[227] (four instances). Geometrical details are unavailable for the eight instances in $(MeZnSPr^i)_8$ (**8E**). $Ag_6(SAr)_6(PPh_3)_5$, $[Cd_{10}(SCH_2CH_2OH)_{16}]^{4+}$ (ClO_4^-) (**10B**) and $[Ag_6(SPh)_8]^{2-}$ contain triple-bridges in which one M—S bond is 0.2–0.4 Å longer than the other two and which, because it increases metal coordination numbers beyond the minima of 2 for Ag and 4 for Cd, can be regarded as secondary bridging.

5.6.2.8. A supported quadruple-bridge $[(\mu_4\text{-}SR)M_4]$ can be claimed for one Bu^tS^- ligand in

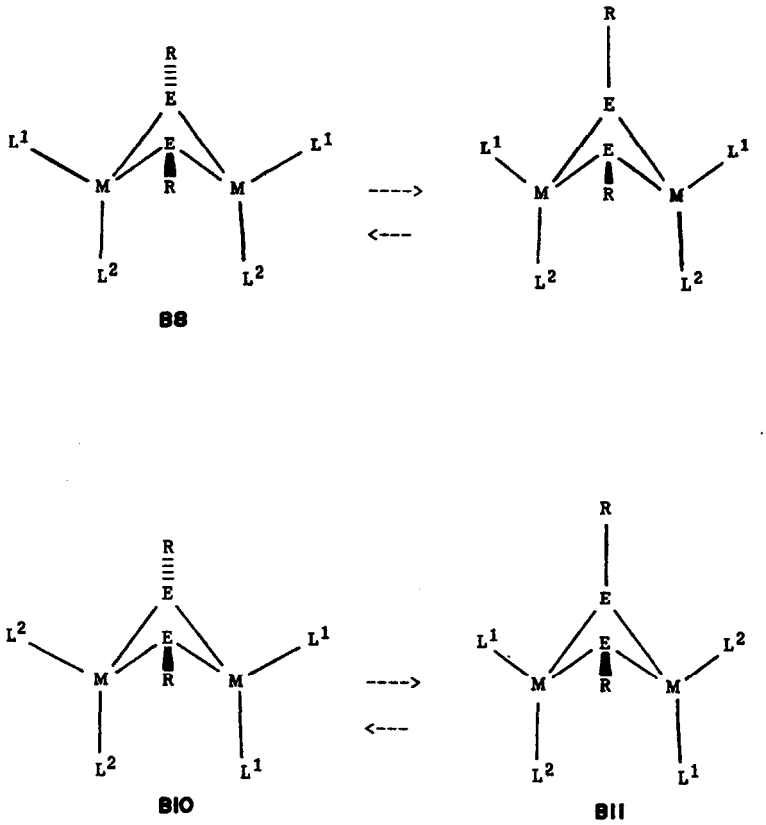
$(Bu^tS)_5(ZnMe)_5$ (Section 2.5.3): the Zn—S distances are disparate (2.51, 2.51, 2.71 and 2.98 Å), but are not secondary bridges because the Zn atoms depend on them to maintain four coordination.

5.6.3. *Stereochemistry at bridging* S.

5.6.3.1. Double-bridges. In all except five of more than 300 instances of doubly-bridging thiolate

in the crystalline state the stereochemistry of the three bonds to the S is pyramidal or pseudo-pyramidal.[183] The exceptional alternative stereochemistry is planar M_2SC.

In the normal pyramidal stereochemistry the M—S—M angles range from 65 to 120°, and the inclination ϕ of the S–C vector to the MSM plane ranges from 45 to 79°, with some evidence of correlation of these two angles.[183] An electronic distinction between alkyl and aryl thiolate is clearly apparent in complexes $[Cu_4(SR)_6]^{2-}$ (Section 2.4.5), where ϕ is 74.9° (s = 3.5°) for R = Me and 63.0° (s = 3.1°) for R = Ph, at an unchanged Cu—S—Cu angle of 73.6° (s = 1.7°) and independent of substituent steric repulsions.[204]



The exceptional planar stereochemistry for a doubly-bridging thiolate occurs at the two bridges of $(Ph_3P)_2Cu(\mu\text{-}SAr)_2Cu(PPh_3)_2$[149] and the three bridges of $[(\mu\text{-}SPh)_3Fe_3Cl_6]^{3-}$.[178] The planarity in the Cu compound can be attributed to crowding of Ph substituents, but the cause in the Fe compound is not yet apparent. Unlike doubly-bridging aryl thiolate, doubly-bridging phenolate adopts a planar or near planar stereochemistry in a large proportion of the complexes with confirmed structures: examples are $(\mu\text{-}OPh)_2Ti_2(OPh)_2Cl_4$,[338] $(\mu\text{-}OPh)_2Ti_2(OPh)_6(PhOH)_2$[163] and $(\mu\text{-}OPh)_2Mo_2(OPh)_4Cl_4$.[339]

The NMR spectra of complexes with doubly-bridging thiolates in solution reveal that the inversion of the configuration at the pyramidal S is in general a relatively rapid (*ca* 10^2 s^{-1}) process. Most information is available for complexes with the unsupported bis double-bridge and terminal heteroligands. Examples of the established processes and their inversion barriers are: (i) **B8** ↔ **B9** (*cis* heteroligands) [L^1L^2M = (η-Cp)(CO)Ru, ER = SePh, ΔG^* = 70 kJ mol^{-1}]; and (ii) **B10** ↔ **B11** (*trans* heteroligands) [L^1L^2M = (η-Cp)(CO)Ru, ER = SePh, ΔG^* = 66 kJ mol^{-1}, and L^1L^2M = (η-Cp)(CO)Ru, ER = SCH_2Ph, ΔG^* = 59 kJ mol^{-1}].[340]

In $[Cl_2OW(\mu\text{-}SBu^t)_2(\mu\text{-}Cl)WOCl_2]^-$, where a bis double-bridge is butressed by an additional (weaker) heterobridge, ΔG^* = 75 kJ mol^{-1} for thiolate inversion.[341] Where the $(\mu\text{-}ER)_2M_2$ cycle of the bis double-bridge is non-planar it may also undergo inversion through a planar E_2M_2 transition state, a process which does *not* require inversion at the S. Such a ring inversion appears to be facile [ΔG^* *ca* 40 kJ mol^{-1} in $(\mu\text{-}SBu^t)_2\{Rh(C_8H_8)\}_2$[140]] only when M–M bonding is clearly absent. At tris double-bridges the free energies of activation for S inversion (**B6** ↔ **B7**) range from 46 to 59 kJ mol^{-1} in $(\eta^7\text{-}C_7H_7)Mo(\mu\text{-}SR)_3Mo(CO)_2(PR_3)$.[342] Abel's review[343] of extensive studies of the stereodynamics of metal complexes of chalcogenide ligands (mainly R_2E) contains data compilations. General patterns extracted from these data are that inversion barriers are decreased substantially by metal coordination, and: (i) decrease with decreased metal electronegativity, (ii) decrease with increased ligand π conjugation, and (iii) increase as E expands from S to Se.

Stereodynamic information for *homo*thiolate complexes is virtually non-existent, largely because systems of interest are subject to rapid exchange by dissociative processes as well as intramolecular configurational isomerism. Paramagnetic shifted ^1H NMR spectra reveal that the inversion of the pyramidal bridging thiolate in $[M_4(SPh)_{10}]^{2-}$ (**4F**) (M = Fe or Co) is fast even at 240 K, whereas SPh ligand exchange is slow (NMR time scale).[210]

5.6.3.2. Triple-bridges. The orthodox stereochemistry for a triply-bridging thiolate has one C and three M atoms subtending pseudo tetrahedral angles at the S atom. However, this stereochemistry is *not* adopted by any of the five triply-bridging thiolates in $Ag_6(SC_6H_4Cl)_6(PPh_3)_5$ (see Fig. 6). At each of two such ligands two S—Ag bonds and the S—C bond are virtually coplanar, while the third S—Ag bond is inclined to this plane at 63 or 67°. At the other three ligands there occurs an unusual stereochemistry, related to the regular tetrahedron by the reflection of two M atoms (M′) as shown in Fig. 21. The S atom lies well outside its coordination polyhedron, and yet all angles at the S are approximately tetrahedral (105–130°), except for the two M—S—M′ (57 and 70°). The unorthodox stereochemistry for triply-bridging thiolate ligands in this compound is possibly dictated by the

crowding of 21 aryl substituents over its surface, and is further evidence of the flatness of the potential surface around the S atoms.

5.7. *Packing of thiolate substituents over aggregate surfaces*

The structures available to metal thiolate aggregates $[M_x(SR)_y]$ {like those with other comparable, bent, non-chelating ligands [XR (where X = O, NH, NH_2, PH, PH_2 or CH_2)]} can be restricted by the requirement that the substituents R be arranged without mutual interference over the surface of the aggregate. This substituent influence arises because the S—C bonds of doubly-bridging thiolate ligands (and sometimes triply-bridging SR) are inclined to the surface of the molecule. Configurational isomerism is due to inversion at pyramidal doubly-bridging S atoms, and where a M–(μ-S)–M plane does not pass through the cluster centroid the two configurational isomers will have different inclinations of the S—C bonds to the molecular surface. These isomers are labelled *radial* and *tangential*[280] (although they will rarely be inclined at angles of 90 or 0°, respectively, to the molecular surface). The *tangential* isomer is the more susceptible to substituent interference. In general terms, the

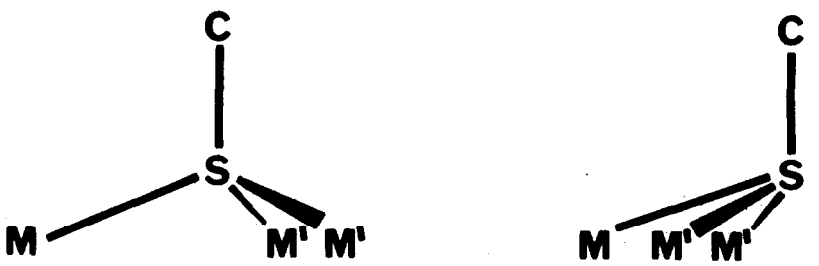


Fig. 21. Orthodox and unorthodox stereochemistry at triply-bridging thiolate, related by reflection of two M′ atoms through the plane containing S—C perpendicular to M—S—C.

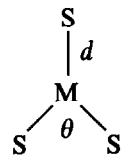
separations of substituents on the aggregate surface are decreased by decreased centroid—S—C angles and by increased centroid—S distances (i.e. decreased surface curvature). In many cases the R_y array must possess less symmetry than the S_y array: for instance the R_6 set of *octahedro*-(μ-SR)$_6$-*tetrahedro*-M_4 (in **4E** and **4F**) can have a maximum symmetry of C_3, much less than the O_h for the S_6M_4 core.

Two levels of influence by the substituents can be recognized. At the lower level, and especially where the R_y-symmetry is necessarily less than the S_y-symmetry, a configurational isomer with a relatively high R_y-symmetry is observed in the crystal and the R--R interactions which remain are relieved by angular displacement of the M–(μ-SR)–M bridges involved. Consequently the S_y polyhedron is distorted according to the R_y-symmetry, and there are angular distortions of metal coordination polyhedra. This effect is evident in structures **4E**, **4F**, **5A**, **5B** and **10A**, and can be expected for structures **3F** and **4D**. The higher level of influence occurs when the substituents can be accommodated only when they are packed in a high-symmetry array. This occurs in structure **8C**.

A structural feature which increases the packing density of substituents over the molecular surface is apparent in some silver thiolates where two-coordinate M atoms are linked in strands {—(μ-SR)—M—(μ-SR)—M—}$_n$. In both a cyclic molecule (Fig. 9) and a one-dimensionally non-molecular structure [**1D-A** (Fig. 10)] two strands are entwined at the shortest non-bonding separation, such that the surface area per strand is effectively halved and the substituents (tertiary alkyl in both cases) can more fully encompass the double-stranded chain.

Metal complexes and aggregates with thiolate (or alcoxide) ligands are distinguished from clusters with tertiary phosphine (amine) ligands, another large class with bulky ligands, by the different inclinations of the ligand volume elements. In the phosphine class the substituent "cones" are usually perpendicular to the molecular surface, while in the thiolate class the ligand "cones" are usually inclined to the surface. Clusters with primary phosphide ligands (RHP^- or RP^{2-}) are relevant sterically to thiolate aggregates.



5.8. *Dimensions*

Disregarding the quite pronounced variations in distance associated with secondary M–SR interactions, primary M—S bond distances in metal thiolates are close to the values of the analogous metal chlorides. In compounds such as $[S_4Fe_4Cl_2(SPh)_2]^{2-}$[215] and $[(\mu\text{-SPh})_6(ZnCl)_2(ZnSPh)_2]^{2-}$,[214] where internal comparisons are possible, and in compound pairs such as $[(\mu\text{-SPh})_6(FeSPh)_4]^{2-}$ and $[(\mu\text{-SPh})_6(FeCl)_4]^{2-}$, the M—SPh bond is 0.02–0.06 Å longer than the M—Cl bond. Differences due to alkyl vs aryl thiolate substituents are negligible: in the "ferromantane" (**4F**) cages $\{[Fe_4(SR)_{10}]^{2-}$ (R = Et[141] or Ph[210])$\}$ the terminal Fe—S distance is 0.013 Å longer for R = Et, but, in contrast, the bridging Fe—S distance is 0.014 Å shorter for R = Et.

Variations in bond length due to a change in the coordination number of the thiolate S atom or the metal are prominent. In general the M–(μ-SR) distance for doubly-bridging thiolate is 0.05–0.1 Å longer than the comparable terminal M–SR distance. Unimpeded evaluations of the extension due to thiolate bridging are available from species such as: $[(\mu\text{-SEt})_2\{M(SEt)_2\}_2]^{2-}$ (**2E**) 0.070 Å for M = Fe and 0.090 Å for M = Co;[141] $[(\mu\text{-SPh})_6(MSPh)_4]^{2-}$ (**4F**) 0.076 Å for M = Fe,[210] and 0.064 Å for Co[209]. The effect of metal coordination number appears in the complexes $[M_5(\mu\text{-SPh})_7]^{2-}$ (**5A**), where the M atoms are all coordinated by doubly-bridging SPh ligands but with coordination numbers of 2 and 3: there are elongations of M—S of 0.11 (Cu) and 0.14 Å (Ag) when the coordination number is increased from 2 to 3.[230] More variety occurs in $(\mu_3\text{-SPh})_2(\mu\text{-SPh})_2Cu_4(PPh_3)_4$ (**4G**), where the dependence is $\{Cu^{tet}\text{–}(\mu_3\text{-SPh})$, 2.417 and 2.484$\}$ > $\{Cu^{tet}\text{–}(\mu\text{-SPh})$, 2.328$\}$ ≈ $\{Cu^{trig}\text{–}(\mu_3\text{-SPh})$, 2.313$\}$ > $\{Cu^{trig}\text{–}(\mu\text{-SPh})$, 2.278 Å$\}$.[220] In $[S_4M_{10}(SPh)_{16}]^{4-}$ (**10A**) there are four distinct M—S bond types which are differentiated only slightly. With reference to the shortest bond length, $\{(\mu\text{-SPh})_3M\}$–SPh, the increases are (for Zn and Cd, respectively) 0.02 and 0.01 Å in $\{(\mu\text{-SPh})_2(\mu_3\text{-S})M\}$—($\mu_3$-S), 0.09 and 0.09 Å in $\{(\mu\text{-SPh})_2(SPh)M\}$—($\mu$-SPh), and 0.12 and 0.13 Å in $\{(\mu\text{-SPh})(\mu_3\text{-S})_2M\}$—($\mu$-SPh).[293]

In metal coordination environments which are symmetrical according to the above criteria, variations are still observed in metal thiolate bond lengths. For instance, differences of up to 0.1 Å occur in M—S distances around one trigonal M–(μ-SR)$_3$ site. A rationale for this variability can be proposed. There is a correlation of the M—S distances with opposite S—M—S bond angles, and the angles are influenced by the interferences between thiolate substituents described in Section 2.4.5. The influence of S—M—S angle on M—S distance is most apparent in trigonal planar stereochemistry,

i.e. d (range 0.1 Å) is correlated with θ (range 40°):

For 36 instances of Cu(μ-SPh)$_3$ coordination in complexes $[Cu_4(SPh)_6]^{2-}$ (**4E**) the correlation is linear, $d = a\theta + b$ [$a = 2.05 \times 10^{-3}$ Å deg^{-1}, $b = 2.044$ Å, correlation coefficient (r) 0.75]. For M(μ-SPh)$_3$ coordination in $[M_5(SPh)_7]^{2-}$ (**5A**), a, b and r are 1.98×10^{-3} Å deg^{-1}, 2.033 Å and 0.79 for M = Cu and 2.74×10^{-3} Å deg^{-1}, 2.176 Å and 0.84 for M = Ag. For 12 instances of Cu(μ-SMe)$_3$ coordination in $[Cu_4(SMe)_6]^{2-}$ $r = 0.84$. These correlations permit extraction of ideal trigonal Cu(μ-SR)$_3$ bond lengths, 2.278 Å for R = Ph and 2.290 Å for R = Me. For the six Cu—SPh bonds in two crystals of $[Cu(SPh)_3]^{2-}$ a, b and r are 2.65×10^{-3} Å deg^{-1}, 1.954 Å and 0.67. The intensity of correlation is less ($a = 1.48 \times 10^{-3}$ Å deg^{-1}) in $[Hg(TePh)_3]^-$.

The linearity of the d–θ correlation is not expected to extend into the secondary bonding domain.

It has been argued[155] that the Mo—S distance of 2.32 Å in $(ArS)_2(Pr^iO)MoMo(OPr^i)(SAr)_2$ (**2F**) (Ar = 2,4,6-trimethylphenyl) with Mo–Mo triple bonding is shortened by *ca* 0.1 Å due to ArS–Mo π-bonding.

In complexes with tetrahedral M(SAr)$_4$ coordination (Section 2.1.7) the S—M—S angles have been observed to deviate from 109.5° by up to 11°, an effect which has been attributed[74] to ligand steric congestion. This interpretation is partly refuted by the absence of stereochemical distortion in more highly coordinated homologues (see Section 2.1.9).

5.9. *Metal–metal interactions*

A large proportion of the known polymetallic aggregates with non-thiolate ligands contain M—M bonds, often as the dominant cohesive force, and it is pertinent to enquire whether M–M interactions, attractive or repulsive, exist in polymetallic thiolate complexes. This assessment is based primarily on M—M distances and stereochemistry: observed antiferromagnetic coupling of paramagnetic sites merely allows characterization of bonding interactions less energetic than 4 kJ mol^{-1}, which is insignificant as an M—M bond.

Evaluation of M—M distances as indicators of M–M bonding must be made with reference to the remainder of the metal coordination and particularly the coordination number: M–M separations in the elemental metals where the coordination number is often 12 are unsuitable as reference distances for isolated M—M single bonds between low-coordinate metal atoms. Illustration of the variability of M—M bond distance with metal coordination capacity, and of the approach to be adopted with polymetallic thiolate complexes, can be made with the structure $\{AgSCMeEt_2\}_\infty$ (**1D-A**).[304] The closest contact between Ag atoms (in different strands of the chain) is 2.89 Å, which is equal to the interatomic separation in Ag metal. These Ag atoms have near linear (μ-SR)–Ag–(μ-SR) coordination, and there are no secondary Ag– –S interactions, indicative of excess bonding capacity at Ag. In fact the slight bending of S—Ag—S is in the sense that the Ag– –Ag distance increases, and therefore the interpretation of this geometry is that it represents the onset of a weak repulsion between coordinatively saturated Ag atoms. The important conclusion is that 12-coordinate Ag with no ligands is *bonding* with Ag at 2.88 Å, while two-coordinate Ag with anionic thiolate ligands is *non-bonding* with Ag at the same distance.

Thus distorted metal stereochemistry is an indicator, with M—M distance, of M–M bonding. Application of these criteria to polymetallic thiolates leads to the conclusion that M–M bonding is uncompetitive with thiolate bridge bonding, and is negligible in all except the compounds described in Section 2.2.5. In some thiolate cages M atoms are displaced slightly from the centroid of their thiolate coordination sphere, towards each other, and it is probable that the reason for this is weak attractive interaction between the M atoms.* This occurs in $[Cu_5(SBu^t)_6]^-$ (**5B**) where the digonal Cu atoms are

* The alternative explanation that the bonding at the S atom of the bridge causes contraction of M—S—M angles is discounted by the wide variability of such angles and the many larger values of M—S—M.

displaced inwards by 0.2 Å, and in $[M_5(SPh)_7]^{2-}$ (**5A**) (M = Cu or Ag) two of the M atoms are located 0.2–0.3 Å from their trigonal coordination planes towards each other.

5.10. *Structural influences of heteroligands*

Metal thiolate complexes with only a minor proportion of heteroligands are evaluated here. These complexes can be divided into two structural classes, depending on the coordination propensities of the heteroligand *relative to thiolate* as reference ligand. Where the heteroligand is monatomic with bridging abilities, as occurs frequently with sulfide, and occasionally with halide, the heteroligand usually plays a structure-expanding role as a central or near-central bridge. At the other extreme are heteroligands which, relative to thiolate, are non-bridging. This class contains oxide, carbonyl, acetonitrile, alkyl, halides, amines and phosphines, which play a structure-terminating role.

Polysulfide ligands (S_x^{2-}) are able to bridge and terminate in polymetallic complexes, and it appears that they have similarities with chelating thiolate ligands. Therefore, when polysulfides are present as heteroligands in metal thiolate complexes it is expected that they could function in either or both of the above structural roles.

The monatomic structure-expanding heteroligands have variable and metal-dependent structural influences. For example, with thiolate ligands only the metals Fe(II), Co(II), Zn(II) and Cd(II) form comparable complexes, $[M(SR)_4]^{2-}$ (**1G**), $[M_2(SR)_6]^{2-}$ (**2E**) and $[M_4(SR)_{10}]^{2-}$ (**4F**), all with a typical tetrahedral coordination. However, in the presence of sulfide or halide ligands these metals form aggregates with distinctly different structures, such as $[S_4Fe_4(SR)_4]^{2-}$ (**4H**), $[S_9Fe_6(SR)_2]^{4-}$ (**6F**), $[S_6Co_8(SR)_8]^{4-}$ (**8F**), $[ClZn_8(SR)_{16}]^{-}$ (**8C**), $[ICd_8(SR)_{12}]^{3+}$ (**8B**) and $[S_4Cd_{10}(SR)_{16}]^{4-}$ (**10A**).

Structure-terminating heteroligands lead to a reduction in the size of metal thiolate aggregates, according to their proportional presence. For instance, in the series of copper and silver thiolates with phosphines, $[(MSR)_x(PR'_3)_y]$, the number of M atoms in the aggregate, x, is inversely related to the proportion y/x of phosphine ligands:

x	y/x	Complex	Structure
1	3	$(Ph_3P)_3AgSPh$	**1G**
2	2	$(Ph_3P)_4(CuSPh)_2$	**2E**
3	1.3	$(Ph_3P)_4(CuSPh)_3$	**3D**
4	1	$(Ph_3P)_4(CuSPh)_4$	**4G**
4	0.5	$(Ph_3P)_2(CuSBu^t)_4$	**4A**
6	0.83	$(Ph_3P)_5(AgSC_6H_4Cl)_6$	**6C**
14	0.28	$(Ph_3P)_4(AgSBu^t)_{14}$	Fig. 9

The structural attributes of the structure-expanding and the structure-terminating types of heteroligands both provoke correlations with non-molecular structure types. The structure-expanding ligands lead to the possibility of molecular structures which are fragments of the non-molecular structures of corresponding binary compounds such as metal sulfides (see Sections 5.5.6 and 8). On the other hand, small proportions of structure-terminating heteroligands in metal thiolates can be conceived of as enclosing fragments of non-molecular metal thiolate structures. This is pertinent in cases such as the copper and silver arenethiolates listed above, where the structures of the parent compounds ($[MSAr]_n$) are unknown, presumed to be non-molecular, and difficult to obtain due to crystallization problems.

6. STRUCTURAL PRINCIPLES FOR METAL THIOLATE COMPOUNDS

From the foregoing data and generalizations a set of principles governing the structures of metal thiolate compounds can be developed, and proposed for evaluation in future research.

(1) Metal coordination numbers are at the low ends of normal ranges. This is attributed to the strongly electron-releasing characteristic and polarizability of thiolate ligands.* M(I) is usually two-

* Corroboration of this view is found in the ν(NO) data: 1675 cm^{-1} for $[Mo(NO)(SPh)_4]^-$ and 1694 cm^{-1} for $[Mo(NO)Cl_4]^-$.[111]

coordinate, M(II) is usually four-coordinate, and M(III) and M(IV) are usually five- and six-coordinate.

(2) Thiolate ligands do not have any prominent influence on metal coordination stereochemistry for the coordination numbers (4–6) where dual stereochemistry can occur.

(3) Thiolate ligands are usually doubly-bridging or terminal. Triple-bridging can be achieved by conventional thiolate ligands, sometimes with a dissymmetry which is similar to a double primary bridging plus a secondary bridging connection. Thiolate bridging can be prevented by incorporation of steric bulk.

(4) Polymetallic cages are maintained by thiolate bridges, not metal–metal bonds, and are normally comprised of fused $M_2(SR)_2$, $M_3(SR)_3$ or $M_4(SR)_4$ cyclic moieties.

(5) Polymetallic cages constructed with two-connected thiolate and two-, three- or four-connected M atoms have insufficient bonds for framework rigidity and are subject to angular distortions from idealized high-symmetry structures. Non-rigidity and distortions increase with cage size and with size (n) of the $M_n(SR)_n$ cycles which comprise the cage.

(6) Polymetal thiolate aggregates can frequently be idealized in terms of highly symmetric cyclic or globular structures containing regular polygons or polyhedra (deltahedra) of M atoms. These idealized structures are related in series by polyhedral expansion or polyhedron-capping operations.

(7) Low connectivities at M and thiolate S atoms, and the consequent cage non-rigidity, allow additional secondary (elongated) M--S connections which increase rigidity: secondary bridging may be intra- or intermolecular.

(8) Cage expansion is limited by the reduction in rigidity which it incurs. A mechanism for mechanical stabilization of globular cages with more than 10–14 M and S atoms is incorporation of an internal (spherical) heteroligand.

(9) Compounds with two-coordinate M atoms and doubly-bridging thiolate ligands are comprised of zig-zag strands of {–(μ-SR)–M–(μ-SR)–M–} segments linear at the M and bent at the S. Although coordinatively saturated these strands can associate in opposed pairs, presumably in order to maximize the coverage by substituents of the remaining molecular surface and to maximize crystal density. A skein-type folding of the strand occurs in cyclic molecules, while two strands are intertwined to form the chain of one-dimensionally non-molecular structures. Recognizable structural functions that: (i) extend a strand (zig-zag segments), (ii) intertwine double strands (crossover segments), and (iii) terminate a chain (bend and end segments) may be combined in the construction of molecules.

(10) Doubly-bridging thiolate normally adopts pyramidal stereochemistry at the S atom, but inversion is fast in solution and in the crystalline phase the inversion barrier (*ca* 40–70 kJ mol^{-1}) can be overcome by steric forces.

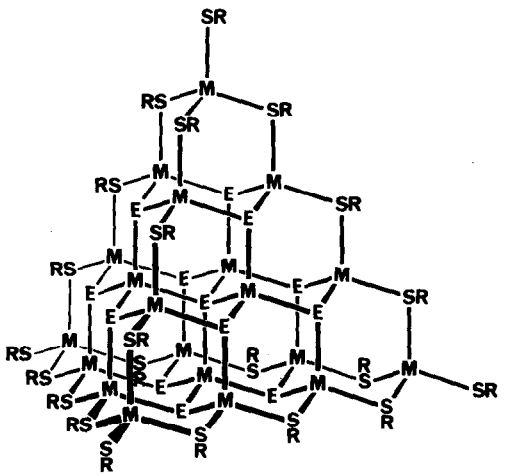
(11) In (μ-SR)$_3$M$_3$ cycles in a chair conformation the three R substituents are usually mixed equatorial and axial in configuration, but three axial substituents are possible, although with some expansion of S—M—S angles as a consequence.

(12) Substituent conflict can occur in folded (μ-SR)$_4$M$_4$ cycles, limiting the configurations available to the cycles and the structures of cages which contain fused cycles of this type.

7. CONCLUSIONS

7.1. *Thiolate as a pseudohalide ligand*

The structural component of the pseudohalide attributes for thiolates, introduced at the outset, can now be assessed. There is no extended similarity between the structures currently known for metal thiolates and for metal halides. Most of the metal thiolate structures reported here, including the paradigmatic thiolate structures which are the polygonal toroids, the adamantanoid structures, and the monocyclic chains, do not have metal halide counterparts. Similarly, there are widespread metal halide structure types that are not yet represented amongst metal thiolate structures: instances are square planar MX_4, octahedral MX_6, planar M_2X_6, *octahedro*-M_6X_{12} and *octahedro*-M_6X_8. On the other hand, structural correspondence between thiolate and halide complexes occurs for the simpler types **1A**, **1C**, **1D**, **1F**, **1G**, **1H**, **1J**, **2D**, **2E**, **2H**, **4E**[206] and **4G**.



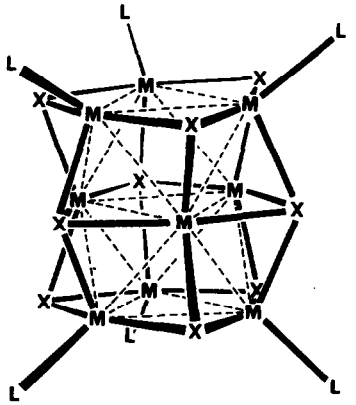
The thiolate substituent is the obvious structural differentiator from halide. Halide can and does play a central spherically coordinated role in aggregation, as for instance in structures **8B** and **8C** (see also Section 2.4.2).

7.2. Comparison with alcoxides

Apart from the results of fruitful recent investigations of the alcoxide chemistry of molybdenum and tungsten in low oxidation states,[344] knowledge of the structures of metal alcoxides and metal phenoxides[345] is still somewhat fragmentary. Nevertheless, there are instances of corresponding or related alcoxide/thiolate structures, some of which have been cited above in Sections 2.1.10, 2.2.9 and 2.8.7. Small alcoxide ligands have a greater propensity to triple-bridging than thiolates.

8. SPECULATION AND OUTLOOK

It is possible to conceive of larger homologues of some established metal thiolate structures. The paradigmatic adamantanoid cage (**4F**) is the basis for an unlimited series of polyadamantanoid aggregates, of which the first member, the supertetrahedral tetra-adamantanoid cage structure (**10A**), is established. Members of this series are molecular fragments of the non-molecular sphalerite lattice. The thiolate ligands in **10A** function as termini at the edges and vertices of the supertetrahedron, without disruption of the molecular lattice structure or modification of the metal coordination stereochemistry, and the thiolate ligands do not affect the faces. Therefore, larger supertetrahedral fragments of sphalerite can also be vertex- and edge-terminated in the same fashion to form hypothetical but legitimate macromolecules.[293] The next member of this series of supertetrahedra would be $[E_{13}M_{20}(SR)_{22}]^{8-}$ (**20**), in which there is only one structural element not present in **10A**, namely the tetrahedrally coordinated central chalcogenide ion, which is the predominant component of the bulk metal chalcogenide. It is also possible that surface (μ_3-E) groups on **20** or larger homologues could be replaced by triply-bridging thiolate ligands, as justified in Section 2.10.3.



20

It has been suggested[253,281] that the structure of the cluster centre of the iron–molybdenum cofactor of nitrogenase could be based on the *octahedro*-$(\mu_4\text{-S})_6$-*hexahedro*-M_8 aggregate of **8F**, specifically $[(\mu_4\text{-S})_6(FeSR)_7MoL_n]$.

In the past few years there has been a spate of discoveries of unprecedented metal thiolates with unpredicted structures, together with unprecedented metal polysulfide complexes. Monosulfide ions have occurred in some of these compounds. In view of the structural relationships between these ligand types, and, in particular, the close correspondence between chelating polysulfide ligands and thiolate ligands, it is not unreasonable to expect that metal thiolate complexes with some similarity to the beautiful (**6D** and **12C**) and the bizarre (**6K**) sulfide and polysulfide species will appear after suitable synthetic enterprise.

Predictions of new thiolate complexes can be made on this basis from structures described in Sections 2.3.2, 2.4.8, 2.6.4, 2.6.6, 2.6.10, 2.7, 2.8.6, 2.8.9, 2.10.3 and 2.11.3. In addition, the ion $[(\mu_4\text{-S})_3(\mu_3\text{-S})_6Ni_9(PEt_3)_6]^{2+}$ (**9B**)[346] provides a precedent for thiolate structures. The metal framework is a confacial bioctahedron, with three quadruply-bridging sulfide ligands (X) in the equatorial plane, and six triply-bridging sulfide ligands (X) located in the upper and lower planes of Ni atoms which carry the six terminal ligands. The S_9 array is also a confacial bioctahedron,

compressed along the three-fold axis and rotated about it by 60° from the Ni_9 bioctahedron. The terminal and triply-bridging ligand positions could be occupied by thiolate ligands, allowing the postulation of analogous structures such as $[(\mu_4\text{-S})_3(\mu_3\text{-S})_6M_9(SR)_6]$ and $[(\mu_4\text{-S})_3(\mu_3\text{-SR})_6M_9(SR)_6]$, with charges 4− and 2+, respectively, if the core electron population is unchanged.

98

The variety of the structural relationships in Section 5.5 supports the expectation that many more varied polymetallic thiolate complexes will be discovered, but it is also expected that they will not contravene the principles proposed in Section 6.

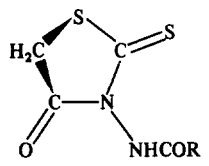
DIOXOURANIUM(VI) COMPLEXES OF 3-BENZAMIDORHODANINE AND ITS SUBSTITUTED DERIVATIVES

KAMAL M. IBRAHIM, ABD EL-HAMMID M. SHALLABY, ASHRAF A. EL-BINDARY and MOHSEN M. MOSTAFA*

Chemistry Department, Faculty of Science, Mansoura University, Egypt



(*Received* 20 *August* 1985; *accepted* 7 *October* 1985)

Abstract—The synthesis and characterization of some dioxouranyl(VI) complexes containing 3-benzamidorhodanine and its substituted derivatives as ligands are reported. The structure of complexes is discussed on the basis of spectral (UV, IR and NMR), elemental analyses, conductivities, molecular weights and thermal analysis (DSC, DTA, TGA and TG) results. IR spectra show that the ligands are bidentate coordinating via the amide nitrogen (NH) and the carbonyl oxygen of rhodanine in the *enol* form with displacement of a proton from the latter group. Also, NMR studies suggest that the enolization and coordination occurs via the carbonyl oxygen of rhodanine and not through the carbonyl of the amide moiety. Finally, the thermal studies suggest the existence of a *cis*-form for the isolated uranyl complexes.

Although the coordination chemistry of the dioxouranyl(VI) ion has been studied extensively, no work including 3-benzamidorhodanine and its substituted derivatives as ligands has been reported. Also, in continuation of our earlier work[1–3] on the uranyl complexes and in view of the importance of these ligands in the inhibition of mycobacterium tuberculosis,[4] we report herein the preparation and characterization of some uranyl(VI) complexes by conventional physical and chemical methods. The possible mode of the complexes is discussed on the basis of IR, UV and NMR spectral data. Both *cis*- and *trans*-structures have been proposed for the isolated solid complexes but all the results are in favour of the former.

EXPERIMENTAL

The ligands (**1**) were synthesized as reported earlier.[4,5]

1

R = C_6H_5 (BR, m.p. 182°C), *o*-OH·C_6H_4 (OHBR, m.p. 96°C), *p*-Cl·C_6H_4 (PCBR, m.p. 176°C), *p*-CH_3O·C_6H_4 (PMEBR, m.p. 162°C), *o*-Cl·C_6H_4 (OCBR, m.p. 173°C), *p*-CH_3-C_6H_4 (PMBR, m.p. 162°C), or C_5H_4N (INR, m.p. 196°C).

Preparation and analysis of the complexes

A methanolic solution of uranyl acetate dihydrate (1 mmol) was added to a solution of the ligands under investigation (2 mmol) in MeOH. The reaction mixture was heated under reflux for 30 min. On cooling and scratching a red and/or orange precipitate (yield 70–85%) was formed. The precipitate was filtered off and washed with cold MeOH followed by Et_2O. The complexes separated from INR and OHBR were brown in colour. The

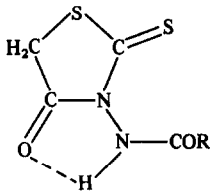
* Author to whom correspondence should be addressed.

elemental analyses were carried out in our laboratory (uranium was determined gravimetrically as U_3O_8).

Physical measurements

All measurements were carried out as reported earlier.[1–3] Thermogravimetric analysis was carried out using a GDTD 16 thermoanalyzer, Setaram, France.

RESULTS AND DISCUSSION



This study indicates that 3-benzamidorhodanine and its substituted derivatives form stable complexes with the formula $[UO_2(HL)_2(MeOH)_2]$ (where H_2L = bidentate monoanionic ligand). The complexes are insoluble in common organic solvents, partially soluble in MeOH and easily soluble in dimethylformamide (DMF) and dimethylsulphoxide (DMSO). The molar conductivities in DMSO at 25°C are in the 16–30 ohm^{-1} cm^2 mol^{-1} range, indicating a non-electrolytic nature.[6] The relatively high value (30 ohm^{-1} cm^2 mol^{-1}) for the complex $[UO_2(OCBR\text{-}H)_2(MeOH)_2]$ may suggest a partial dissociation in DMSO. The magnetic susceptibility measurements at room temperature indicate that the complexes are diamagnetic as expected. Molecular weight determinations suggest a monomeric structure for all complexes (Table 1).

The IR spectra of the free ligands show a broad band centred in the 3330–3220-cm^{-1} region assigned to ν(NH). The strong band in the 1765–1740-cm^{-1} and a shoulder in the 1770–1755-cm^{-1} region are both assigned to the free and hydrogen-bonded carbonyl oxygens of the rhodanine moiety. The strong band in the 1710–1660-cm^{-1} region is attributed to the carbonyl oxygen of the amide moiety. The broadness of the NH band as well as the existence of a shoulder which is characteristic for the carbonyl oxygen of the rhodanine moiety may suggest hydrogen bonding. Moers and coworkers[7] investigated the NMR spectra of rhodanine and its alkyl derivatives with Cu(I) salts and found two signals in the 13.18–13.04- and 4.45–4.32-ppm regions assigned to δ(NH) and $\delta(CH_2)$, respectively. Our ^1H NMR studies for the free ligands under investigation in d_6-DMSO also show two signals at δ 13.2–11.3 and 4.6–4.35 ppm which are similar to those observed by Moers.[7] Those signals are also assigned to the protons of NH and CH_2, respectively, in the spectra of the free ligands under investigation. The existence of the NH signal at high values downfield of TMS suggests strong hydrogen bonding. This bond occurs between NH and the

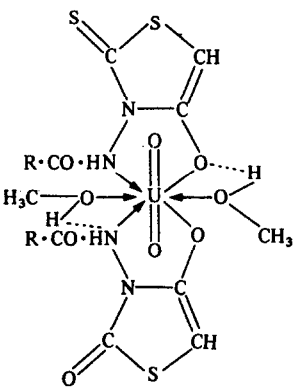
carbonyl oxygen of rhodanine as in **2**.

2

The ligands are more likely coordinated in a bidentate fashion via NH and the enolized carbonyl oxygen of rhodanine with displacement of a proton from the latter group. This is supported by the following evidence.



There is no ν(CO) of rhodanine and new bands at 1590 and 1190 cm^{-1}, assigned to ν(C=C) and ν(C—O),[8] appear. ν(NH) moves to a lower wavenumber. The thioketo-group bands remain more or less at the same positions. New bands in the 580–540- and 460–440-cm^{-1} regions are assigned to ν(UO)[9] and ν(UN),[10] respectively. The spectra of the uranyl(VI) complexes exhibit a strong band at 910 cm^{-1} characteristic of the asymmetric stretching frequency (ν_3) of the dioxouranium ion. The position of this band as well as the colour of the complexes (yellow or orange) indicates the participation of both N and O atoms in the coordination while the S atom is inert toward chelation.

The mode of coordination is also confirmed from the NMR data in which the NH signal is shifted to lower values (8.9–8.15 ppm) upfield of TMS. This indicates the destruction of the hydrogen bond as well as the coordination through the NH group. The disappearance of the CH_2 signal with the simultaneous appearance of a new signal in the 7.5–7.3-ppm region is attributed to the proton of the CH=C group. This signal is too close to the multiplet signals of the phenyl ring but is well-defined.

It is worth mentioning that the carbonyl oxygen of amide moiety is shifted, in the spectra of the ligand, to a higher wavenumber on complexation.[7] Although all the previous studies by others[11] for rhodanine and its related compounds with some divalent metal ions had shown that the carbonyl oxygen of rhodanine is inert in complexation, we are quite confident from the above discussion that this group is the backbone of chelation.

The UV spectra of the free ligands in Nujol mull show bands at 230, 250, 290, 315 and 380 nm assigned, respectively, to Ph → Ph*, $\pi \rightarrow \pi^*$ (phenyl), $n \rightarrow \pi^*$ (CO amide), $n \rightarrow \pi^*$ (CO rhodanine) and $n \rightarrow \pi^*$ (CS). The absence of the band due to $n \rightarrow \pi^*$ (CO rhodanine) on complexation with the simultaneous appearance of a new band in the 410–390-nm region is attributed to $\pi \rightarrow \pi^*$ (CH=C) as a sequence of enolization. Also, it can be taken as evidence for the participation of the carbonyl oxygen of rhodanine in chelation. Moreover, the bands due to $n \rightarrow \pi^*$ (CO amide) and $n \rightarrow \pi^*$ (CS) remain more or less at the same positions. Finally, the band in the 20,200–18,900-cm^{-1} range is assigned to a $^1E_g \rightarrow {}^3\pi_u$ transition.[12]

Differential scanning calorimetry as well as the thermal gravimetric analysis show two exothermic peaks before the melting points for all uranyl(VI) complexes. One peak is in the 80–77°C range and probably corresponds to the loss of one methanol molecule which is attached to NH(O—H...N) group (structure **3**). The second peak is in the 125–117°C range and represents the removal of the second methanol molecule which is linked to the C—O group (O—H...O). This observation indicates that the two coordinated methanol molecules are not identical and their positions within the complex are different. Also, the existence of two different protons for the methyl and hydroxyl resonances in the NMR spectra of the uranyl complexes coincides with the data obtained from the thermal analyses. Moreover, the observation of two signals due to the protons of the free and hydrogen-bonded NH, in the NMR spectra of the complexes, in the 8.85–8.15- and 8.9–8.25-ppm regions, respectively. All these may suggest the existence of the *cis*-form rather than the *trans*-form as shown in **3**.

3

All the results are in favour of our previous studies.[1–3] The pale-colour uranyl(VI) complexes (yellow or orange) contain N and O as donor atoms while those dark in colour (brown and black) must contain an S atom as a potential site in addition to both N and/or O atoms. Also, thermogravimetric

analyses show that the mass loss of the uranyl complexes is in accordance with the *cis*-form and the existence of two different coordinated methanol molecules.

LATTICE ENERGIES OF THE ALKALI METAL BIFLUORIDES: A CORRECTION

JOHN EMSLEY

Department of Chemistry, King's College, Strand, London WC2R 2LS, U.K.

and

DAVID A. JOHNSON*

Department of Chemistry, The Open University, Milton Keynes MK7 6AA, U.K.

(*Received* 5 *August* 1985; *accepted* 9 *October* 1985)

Abstract—Revised auxiliary thermodynamic data allow an improvement in the lattice energies of the alkali metal and ammonium bifluorides which were calculated in a previous paper (*Polyhedron* 1985, **4**, 489). The lattice energies of the bifluorides now exceed those calculated by classical ionic models, but the difference between the lattice energies of the fluorides and bifluorides decreases steadily with increasing cation size.

The results of Ref. 1 have been recalculated with the following modifications:

(i) Apart from $\Delta H_f^\circ(F^-)(g) = -255.1 \pm 2$ kJ mol^{-1} calculated from the electron affinity[2,3] and dissociation energy[4] of fluorine, and the ion cyclotron resonance measurement,[5] all auxiliary data were taken from Ref. 6.

(ii) The lattice energies of MHF_2 and MF, written as $\Delta H_L^\circ(MX)(s)$ and expressed as enthalpies at 298.15 K, were calculated from equations of the type:

$$\Delta H_L^\circ(MX)(s) = \Delta H_f^\circ(M^+)(g) + \Delta H_f^\circ(X^-)(g) - \Delta H_f^\circ(MX)(s). \quad (1)$$

(iii) Values of the thermochemical radius of HF_2^- were calculated from the two-term rather than the one-term Kapustinskii equation.[7(a)]

The results are given in Table 1, together with some of the auxiliary data, and ΔU, the difference between the lattice enthalpies of the fluorides and bifluorides.

The important differences from the figures calculated in Ref. 1 are as follows: firstly, the cycle values of $\Delta H_L^\circ(MHF_2)(s)$ are higher by amounts varying from 28 to 53 kJ mol^{-1}. They now exceed the highest theoretically calculated sums of the coulombic, repulsive and dispersion energies[8] by some 40 kJ mol^{-1}.

Secondly, ΔU now decreases regularly with cation radius in accordance with very crude ionic models.[7(b)] Nevertheless, the decrease is not so severe as to invalidate a major conclusion of Ref. 1: there is no sound basis for the assignment of equal lattice energies to $[N(CH_3)_4]F$ and $[N(CH_3)_4]HF_2$. Consequently the fairly good agreement between the value of ΔH_m° for the process:

$$HF(g) + F^-(g) = HF_2^-(g),$$

which was obtained by making this assumption,[9] and the ion cyclotron resonance value,[5] is probably due to an inaccurate determination of the value of ΔH_m° for the reaction:

$$[N(CH_3)_4]F(s) + HF(g) = [N(CH_3)_4]HF_2(s).$$

Thirdly, the values of $r(HF_2^-)$ in Table 1 span only 5 pm and average 145 pm. If this is combined with $r(NH_4^+) = 146$ pm,[10] and substituted in the two-term Kapustinskii equation, we find $\Delta H_L^\circ(NH_4HF_2)(s) = 735$ kJ mol^{-1}. To obtain a cycle value for comparison, we derive $\Delta H_f^\circ(NH_4^+)(g) = 638 \pm 6$ kJ mol^{-1} from the photo-ionization proton affinity of Ceyer *et al.*[11] This choice lies comfortably within the range spanned by other experimental values,[12,13] and, with the help of eqn (1),

* Author to whom correspondence should be addressed.

Table 1. Thermodynamic properties of the alkali metal bifluorides and fluorides

	Li	Na	K	Rb	Cs
$-\Delta H_f^\circ(MHF_2)(s)$ (kJ mol^{-1})	942.3	920.3	927.7	922.6	923.8
$\Delta H_f^\circ(M^+)(g)$ (kJ mol^{-1})	685.8	609.4	514.3	490.1	458.0
$\Delta H_L^\circ(MHF_2)(s)$ (kJ mol^{-1})	939	841	753	724	693
$r(M^+)$ (pm)	74	102	138	149	170
$r(HF_2^-)$ (pm)	144	147	145	147	142
$-\Delta H_f^\circ(MF)(s)$ (kJ mol^{-1})	616.0	573.6	567.3	557.7	553.5
$\Delta H_L^\circ(MF)(s)$ (kJ mol^{-1})	1047	928	827	793	756
ΔU (kJ mol^{-1})	108	87	74	69	64

it yields $\Delta H_L^\circ(NH_4HF_2)(s) = 752 \pm 9$ kJ mol^{-1}. This exceeds the value estimated from the Kapustinskii equation by nearly 20 kJ mol^{-1}, a discrepancy which is reinforced by noting that, although the ionic radius of NH_4^+ is significantly larger than that of K^+, the cycle lattice energies of KHF_2 and NH_4HF_2 are virtually identical. However, the discrepancy is readily explained as a stabilization of NH_4HF_2 by cation–anion hydrogen-bonding, a phenomenon whose structural consequences have been noted by Pauling.[14]

SPATIAL NOTATION FOR TRANSITION-METAL CLUSTERS

TIEN-YAU LUH* and HENRY N. C. WONG

Department of Chemistry, The Chinese University of Hong Kong, Shatin, N.T., Hong Kong

and

BRIAN F. G. JOHNSON

University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

(*Received* 2 *September* 1985; *accepted* 14 *October* 1985)

Abstract—By the use of a modified Föppl notation and replacement methods, the spatial distribution for metal nuclei and ligands of metal clusters can unequivocally be assigned. For example, the notation for $H_2Os_3(CO)_{10}$ can be written as σ^1_1,σ^1_5-H-[3]-[(2):2:(4):2:(2)].

Metal clusters demonstrate an enormous variety of nuclearity with fascinating structural complexity.[1] Ingenious and practical approaches have been made by several research groups in connection with the systematic classification of clusters concerning their electron numbers and bonding properties.[2–17] These methods are useful in discerning the arrangement of the metal nuclei. However, there is no simple method by which the relative positions of metal nuclei and ligands may be described. Indeed, the description of the spatial distribution of these species in metal clusters is a nontrivial problem.[18] Here, it is our intention to put forth a relatively simple notation system which permits a useful method of describing clusters.[19]

Numerous examples in the literature demonstrates that the ligands in clusters occupy positions that define the vertices of regular and semiregular polyhedra.[1] The Föppl notation[20] has been employed for illustrating the structure and fluxional behaviour of binary metal carbonyls.[21] The basic idea of this approach is to consider a metal polyhedron sitting inside a ligand polyhedron envelope. We felt that this could be applied to the systematic description of cluster structures.

The following rules are hence proposed:

Rule 1

The structures of metal and ligand polyhedra are described by an appropriately modified Föppl notation (*Table* 1) *written in sequence in square brackets with a hyphen between the brackets. The notation therefore has the general form* $[m_1:\ldots:m_p:\ldots:m_n]$-$[l_1:\ldots:l_i:\ldots:l_z]$.

In this paper, the metallic part of a cluster may be constituted by one or more metal atoms. Thus, the term "metal polyhedron" will also designate not only polyhedra in the geometrical sense but also an isolated atom or groups of two or three atoms which, in the geometrical sense, do not constitute polyhedra.

By the use of this rule, the mononuclear metal carbonyls $Ni(CO)_4$ (1), $Fe(CO)_5$ (2) and $Mo(CO)_6$ (3) can be expressed as [1]-[1:3], [1]-[1:3:1], and [1]-[1:4:1], respectively (Fig. 1).

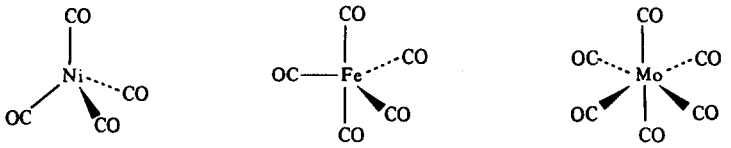

Table 1. Modified Föppl notation[1(d),20]

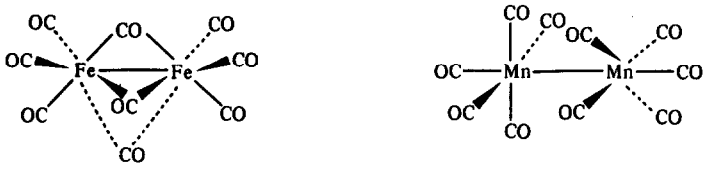
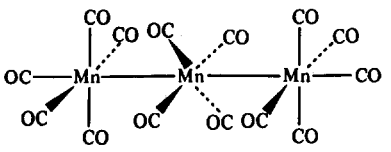
n	Designates planar polygon with *n* vertices
(*n*)	Designates planar polygon with *n* vertices which is in an anti-prismatic configuration to a previously assigned *n*-vertex polygon.[a]
n'	Designates a polygon of *n* vertices which is not strictly planar.[b]

[a] Cf. Rule 3 and Fig. 2.



[b] *n'* must be even. Therefore, an *n'* polygon can also be described as two anti-prismatic *n'*/2 polygons. Hence, for example, the chair-form of a hexagon which constitutes two anti-prismatic triangles is named as 6' rather than 3:(3). Cf. Fig. 1.

* Author to whom correspondence should be addressed.



1 2 3

Fig. 1. Structures of $Ni(CO)_4$(1), $Fe(CO)_5$ (2) and $Mo(CO)_6$ (3).

4 5

6

Fig. 2. Structures of $Fe_2(CO)_9$ (4), $Mn_2(CO)_{10}$ (5) and $[Mn_3(CO)_{14}]^{2-}$ (6).

Rule 2

All metal polyhedra are numbered along the principal rotation axis.[22]

Thus, the notation [1 : 1] rather than [2] is used to define the metal polyhedron in the dinuclear metal complexes $Fe_2(CO)_9$ (4) and $Mn_2(CO)_{10}$ (5). Similarly, [1 : 1 : 1] is employed to demonstrate a linear three metal nuclei, $[Mn_3(CO)_{14}]^{2-}$ (6) (Fig. 2). In a similar manner, tetrahedron, butterfly skeleton and puckered four-membered ring skeletons are distinguished by the notations [1 : 3], [2 : (2)] and [4′], respectively (Fig. 3).

Rule 3

Viewing along the principal rotation axis two eclipsed lines, or one polygon having at least one edge which is parallel to a line, or two polygons having at least one pair of eclipsed edges are considered as prismatic. Otherwise, they are denoted as antiprismatic (*see Table* 1). Some graphic representations of various arrangements are presented in Fig. 4.

Polygons need not necessarily be regular. They can also be puckered, and in this case the projection on the plane perpendicular to the principal rotation axis will be considered.

The use of this rule is particularly useful to identify whether there exist bridging ligands or not. To illustrate, considering a metal triangle inside a ligand hexagon, two commonly seen orientation patterns in metal clusters are shown in Fig. 5. In the first case [Fig. 5(a)], the two polygons are prismatic and can be denoted as [3]-[6]. When clusters have such spatial arrangement, all of these six ligands are terminal. On the other hand, when three of these six ligands are bridging ligands, the two polygons are then antiprismatic as shown in Fig. 5(b), and are represented by the notation [3]-[(6)].

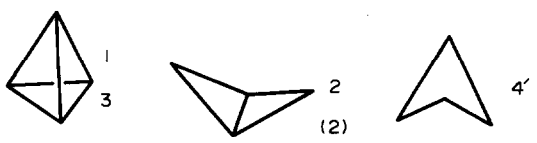


Fig. 3. Föppl notations for tetrahedron, butterfly and puckered four-membered ring skeletons.

Rule 4

A metal polyhedron is considered as a basic set. The orientation of the planes defined by the polygons in the ligand polyhedron is related to this basic set.

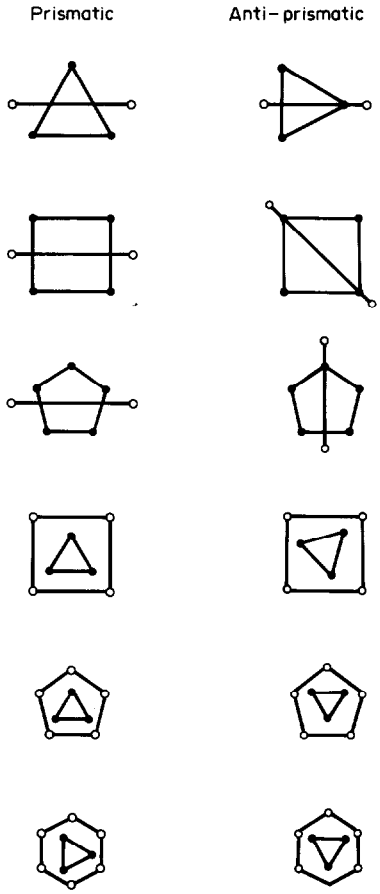

Fig. 4. Graphic representations of prismatic (a) and anti-prismatic (b) arrangements.

Rule 5

The plane of the polygon (or the line) defined by the very first number, l_i, *which is larger than or equal to 2 in the modified Föppl notation of the ligand polyhedron should be parallel to the plane of the polygon (or the line) defined by the first number,* m_i, *which is larger than or equal to 2, of the metal polyhedron. Hence, the polygon* m_i *defines the orientation of the polygon* l_i, *which, in turn, defines the orientation of the rest of the polygons in the ligand polyhedron.*

Considering **4**, the triangle formed by the three bridging COs is anti-prismatic to those defined by other two sets of three terminal CO ligands.

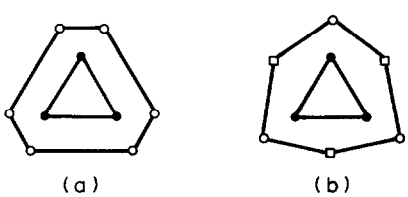

Fig. 5. Two orientation patterns of a triangle inside a hexagon.

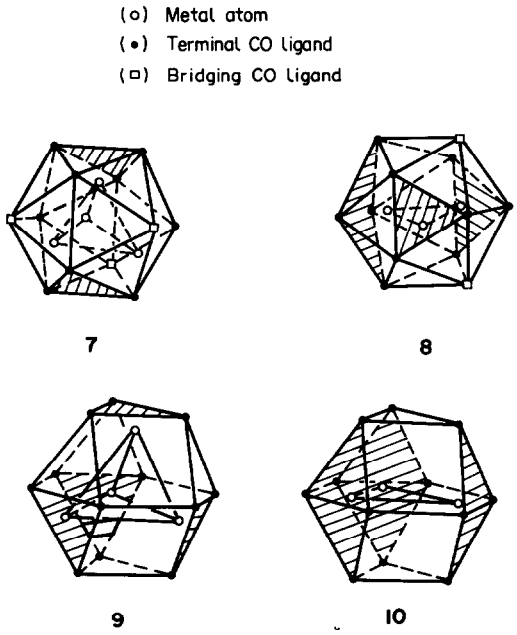

Fig. 6. Structures of $Co_4(CO)_{12}$ (**7**), $Fe_3(CO)_{12}$ (**8**), $Ir_4(CO)_{12}$ (**9**) and $Os_3(CO)_{12}$ (**10**).

Consequently, the ligand polyhedron in **4** is denoted as [3:(3):3] and the notation for **4** is [1:1]-[3:(3):3]. In a similar manner, the notations for **5** and **6** can be written as [1:1]-[1:4:(4):1] and [1:1:1]-[1:4:(4):4:1], respectively.

The CO ligands in either $Co_4(CO)_{12}$ (**7**) or $Fe_3(CO)_{12}$ (**8**) form an eicosahedron (Fig. 6). On the other hand, the 12 COs in $Ir_4(CO)_{12}$ (**9**) or $Os_3(CO)_{12}$ (**10**) occupy the vertices of an anticuboctahedron (Fig. 6). Therefore, $m_i = 3$. The ligand polyhedron is represented by [3:(6′):(3)], where $l_i = 3$ and the triangle defined by the last number, which is (3), is anti-prismatic to that defined by l_i. Moreover, the two triangles formed by m_i and l_i are also anti-prismatic. Consequently, the notation for **7** should be [1:3]-[(3):6′:3]. It is noteworthy that the 6′-polygon in the ligand envelop is also anti-prismatic to the 3-polygon, or triangle, in the metal polyhedron. In other words, three out of six vertices of the ligand 6′-polygon are anti-prismatic to the three vertices of the metal 3-polygon. Therefore, three COs are sitting as bridging ligands. The ligand eicosahedron in **8** can be represented by [2:(2):4:(2):2] and l_i is anti-prismatic to the triangle defined by three metal atoms. Thus, the notation for **8** should be [3]-[(2):2:(4):2:(2)].

Similarly, the notations for **9** and **10** can be expressed by [1:3]-[(3):(6):3] and [3]-[3:6:3], respectively.

The application of these rules to symbolize various binary clusters is given in Table 2.

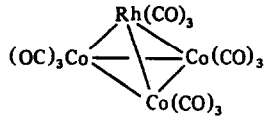

Table 2. Some notations for binary metal clusters

Formula	Notation	Reference
$Ni(CO)_4$	[1]-[1:3]	24
$Fe(CO)_5$	[1]-[1:3:1]	25
$Mo(CO)_6$	[1]-[1:4:1]	26
$Fe_2(CO)_9$	[1:1]-[3:(3):3]	27
$Mn_2(CO)_{10}$	[1:1]-[1:4:(4):1]	28
$[Mn_3(CO)_{14}]^{2-}$	[1:1:1]-[1:4:(4):4:1]	29
$Fe_3(CO)_{12}$	[3]-[(2):2:(4):2:(2)]	30

$Rh_6(CO)_{16}$	[1:4:1]-[2:(2):4:4:2:(2)]	43
$[Os_6(CO)_{18}]^{2-}$	[1:4:1]-[3:6':(6'):3]	44
$[(Nb_6Cl_{12})Cl_6]^{2-}$	[1:4:1]-[1:4:(8):4:1]	45

Rule 6

Clusters containing more than one kind of metal nuclei or ligands are first considered as binary system. When the majority of vertices of a polyhedron is occupied by one kind of metal nuclei (or ligands), this polyhedron is first treated as if all vertices were occupied by these single metal nuclei (or ligands). A replacement method[18] *is employed to treat the other metal nuclei (or ligands), which are henceforth named as heteronuclei (or heteroligands).*

For example, the C_2H_4 ligand in $Fe(CO)_4(C_2H_4)$ is considered to be a replacement of a CO ligand in $Fe(CO)_5$. The rhodium nucleus in $Co_3Rh(CO)_{12}$ (**11**) is similarly regarded as a replacement (Fig. 7).

11

Fig. 7. Structure of $Co_3Rh(CO)_{12}$ (**11**).

* Bidentate and polydentate ligands will be treated in the future.

Rule 7

When clusters contain an equal number of N *nuclei, the one with the highest atomic number is chosen as the basic element for the metal polyhedron. The other metal nuclei are considered as replacement(s) of the metal polyhedron. Monodentate ligands are treated similarly according to the Cahn–Ingold–Prelog sequence rule.*[23]*

To illustrate, the basic element for the metal polyhedron of $Os_2Co_2(CO)_{12}H_2$ is osmium. This polyhedron is hence considered to constitute four osmium atoms and two of which are replaced by cobalt nuclei.

In a similar manner, the basic element for the ligand polyhedron of $Ni(CO)_2(PPh_3)_2$ is PPh_3.

Rule 8

When there are more than one equivalent principal rotation axes in the metal polyhedron containing heteronuclei, the axis is chosen such that the numbering (see Rules 11–13) *for the heteronuclei is minimum. For homonuclear clusters containing heteroligands, the principal rotation axis is similarly selected such that the numbering (see Rules* 11–13) *for the heteroligand becomes the smallest possible number.*

The use of this rule is illustrated in Fig. 8. The

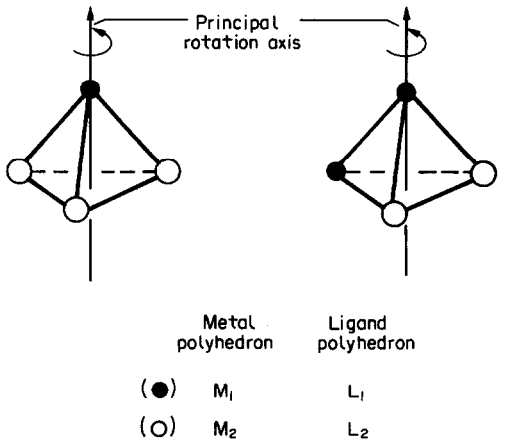

Fig. 8. Diagrammatic expression of the principal rotation axis for heteronucleus- or heteroligand-replaced tetrahedron. M_2s or L_2s in both cases are treated as basic elements.

principal rotation axis is chosen such that the numbering for the heteronuclei M_1 is smallest.

Taking $Ni(CO)_2(PPh_3)_2$ as an example, the principal rotation axis is shown in Fig. 8 where L_1 is CO.

Rule 9

The positions of heteronuclei and heteroligands are represented by $\Delta^{p}_{m_i}$ *and* $\sigma^{q}_{l_i}$,* *respectively.* Δ_{m_i}*s denote the layers defined by the polygons* $m_1, m_2, \ldots m_n$ *occupied by heteronuclei and* σ_l*s denote the layers defined by the polygons* $l_1, l_2, \ldots l_z$ *occupied by the heteroligands. The superscripts* p *and* q *are numerals representing the relative positions of heteronuclei or heteroligands belonging to each layer.*

The definition of Δ_{m_i} or σ_{l_i} can best be represented by the illustration shown in Fig. 9. The four layers of the eicosahedron are defined.

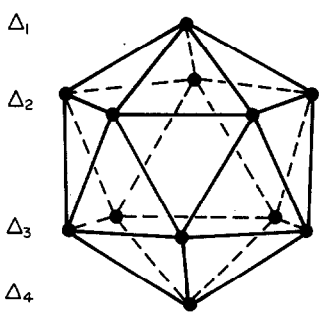

Fig. 9. Spatial notation for layers of eicosahedron.

* The symbol Δ is used because most metal polyhedra in metal clusters are *deltahedra*. The letter σ is employed for ligands from Greek συν- which means together, and from συμπερτλαμβανω which means to include.

12 **13**

Fig. 10. Structures of two isomers of $Fe(CO)_4(PPh_3)$ (**12** and **13**).

Rule 10

The clusters can thus be represented by the general notation $\Delta^{1}_{m_1}\cdots$-M_a-$\Delta^{p}_{m_m}\cdots$-$M_b \ldots \sigma^{q}_{l_i}\cdots$-$L_a$-$\sigma^{z}_{l_j}\cdots$-$L_b \ldots$-$[m_1 : \ldots : m_l : \ldots : m_n]$-$[l_1 : \ldots : l_i : \ldots : l_z]$, *where* M_a, $M_b, \ldots$ *are atomic symbols of heteronuclei, and* L_a *and* L_b *are formulae of heteroligands.*

Rule 11

For clusters having more than one kind of heteronuclei in a polygon layer m_l, *the positions of these heteronuclei are designated as* $\Delta^{1}_{m_1}$-M_a-$\Delta^{p}_{m_1}$-M_b- ... *if* $M_a \neq M_b \ldots$ *or* $\Delta^{1,p\cdots}_{m_1}$-M_a *if* $M_a = M_b \ldots$. *Smallest possible numbers* p ..., *which are counted clockwise, are used. For a polygon layer occupied by only one kind of heteronuclei, superscripts* 1, p, ... *can be omitted. A similar treatment is used for a ligand polyhedron.*

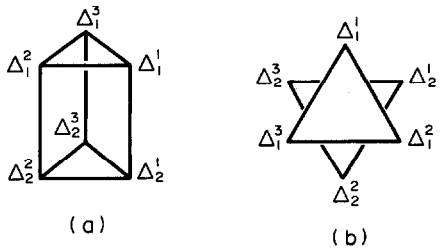
For example, the assignments of the position(s) of heteroligands for the two isomeric structures of $Fe(CO)_4(PPh_3)$ (**12** and **13**) can be denoted as σ_1- and σ^{1}_{2}-PPh_3-[1]-[1 : 3 : 1], respectively (Fig. 10).

Similarly, the notation for **11** is Δ_1-Rh-[1 : 3]-[(3) : 6′ : 3] (Fig. 7).

Rule 12

For clusters having more than one kind of heteronuclei belonging to different polygon layers Δ_{m_1}, $\Delta_{m_m} \ldots$ *with the numbering in the* Δ_{m_1} *layer defined (Rule* 11), *the numbering in* $\Delta_{m_m} \ldots$ *layers is related to that in the* Δ_{m_1} *layer. The vertex of the polygon* m_1 *which is closest to the project point of the* $\Delta^{1}_{m_1}$ *to* Δ_{m_m} *layer, when counting clockwise, is assigned as* $\Delta^{1}_{m_m}$, *and the numbering of the remaining vertices of the polygon in the* Δ_{m_m} *layer is thus defined. The position(s) of heteroligands can be located in a similar manner by using a metal polyhedron as the basis.*

The use of these rules for numbering polyhedra is illustrated in Fig. 11. The positions of the two triangles in the triprism [Fig. 11(a)] can be denoted in a straightforward manner. Nevertheless, for the trigonal antiprism [Fig. 11(b)], Δ^{1}_{2} is thus located by the use of Rule 12. Figure 12 shows that a tetrahedron is sitting inside an anticuboctahedron.



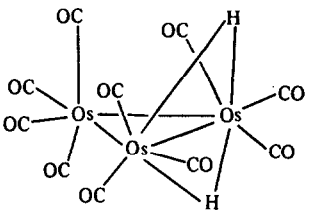


Fig. 11. Numbering for two triangles in prismatic (a) and anti-prismatic (b) orientation.

17

Fig. 14. Structure of $H_2Os_3(CO)_{10}$ (**17**).

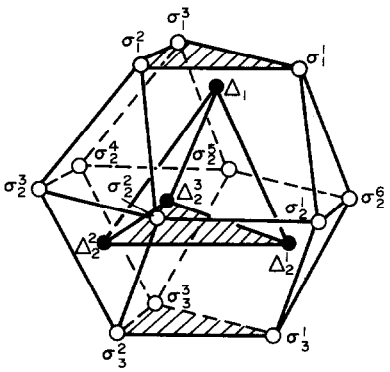

Fig. 12. Numbering for a tetrahedron inside an anti-cuboctahedron.

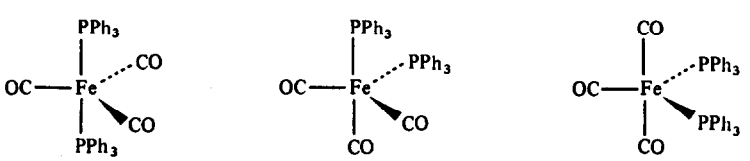
The notation for the binary system having such structure can be written as [1:3]-[3:6:3]. The numberings for the central tetrahedron is trivial. The planes of σ_1 and σ_3 triangles are in a prismatic relation to the plane of the Δ_2 triangle. Accordingly the numbering for these triangles can easily be assigned. The hexagon layer (σ_2), on the other hand, is anti-prismatic to these three-membered rings. Hence, the σ_2^1 position is first designated according to Rules 11 and 12, and the numberings for the remaining vertices of the hexagon can easily be ascribed.

Rule 13

For two or more than two layers, Δ_{m_1,m_m}, . . . , *occupied by only one kind of heteronuclei, the symbol(s) can be simplified and written as* Δ_{m_1,m_m}... . *Heteroligands are treated similarly.*



Considering three isomeric structures of $Fe(CO)_3(PPh_3)_2$ (**14–16**), they can be denoted at $\sigma_{1,3}$-, σ_1,σ_2^1- and $\sigma_2^{1,2}$-PPh_3-[1]-[1:3:1], respectively (Fig. 13).

A bridged hydride is also regarded as a replacement. To illustrate this, the 10 COs and two Hs in $H_2Os_3(CO)_{10}$ (**17**) form an eicosahedron (Fig. 14). Thus, the two Hs can be treated as substituents, and the spatial arrangement for $H_2Os_3(CO)_{12}$ is similar to that for $Fe_3(CO)_{12}$ (**8**). Hence the notation for **17** should be σ_1^1,σ_5^1-H-[3]-[(2):2:(4):2:(2)].

Examples of the use of these rules for denoting metal clusters containing heteronuclear or heteroligands are shown in Table 3.

In order to specify the structure of a metal cluster, we propose to combine its formula with its notation. For example, triiron dodecacarbonyl (**8**) can be written as $Fe_3(CO)_{12}$:[3]-[(2):2:(4):2:(2)]. More precisely, when a formal nomenclature is required, $Fe_3(CO)_{12}$ can also be called triiron[3]-dodecacarbonyl[(2):2:(4):2:(2)]. For a heteronuclear cluster, for instance, $H_3CoRu_3(CO)_{12}$ can be denoted as $H_3CoRu_3(CO)_{12}$: Δ_1-Co-σ_3-H-[1:3]-[3:6:(3):3] or Δ_1-Co-cobalttriruthenium[1:3]-σ_3-H-trihydridododecacarbonyl-[3:6:(3):3].

In summary, we have depicted rules for naming transition-metal clusters. At the present stage, clusters with some kind of symmetry can easily and unequivocally be described. We are currently extending this system in the hope of naming "unsymmetrical" clusters.

SYNTHESIS AND CHARACTERIZATION OF DIOXOOSMIUM(VI) COMPLEXES OF HYDROXYCARBOXYLIC ACIDS

C. C. HINCKLEY* and PIOTR A. KIBALA

Department of Chemistry and Biochemistry, Southern Illinois University, Carbondale, IL 62901, U.S.A.

(*Received* 12 *July* 1985; *accepted after revision* 17 *October* 1985)

Abstract—The synthesis and characterization of stable well-defined osmium(VI)–hydroxycarboxylic acid complexes is reported for the first time. The reaction of dipotassium tetramethylosmate(VI) with hydroxycarboxylic acids [glycolic, 2-hydroxyisobutyric, (*S*)-(+)-mandelic and *o*-salicylic] in the presence of pyridine led to the formation of *trans*-dioxo(oxoacidato)dipyridineosmium(VI) complexes. Elemental analysis, and IR, ^{1}H NMR, ^{13}C NMR and mass spectrometer were used to characterize the new complexes. A structure in which O=Os=O group is perpendicular to the plane produced by the two nitrogen atoms of the pyridine ligands and the two oxygen atoms of the oxoacidato group is proposed for the complexes. In the structure, oxoacidato groups form five- or six-membered rings with the osmium atom.

In this paper, we report the preparation of stable osmyl complexes with hydroxycarboxylic acids. The compounds have been characterized using elemental analyses, and NMR and IR spectroscopy. Mass spectrometry and cyclic voltammetry were used in supporting studies. The structure proposed for the compounds incorporates binding of a carboxylic group to the osmyl similar to that found in osmyl amino acid complexes.[1] In one of the compounds prepared salicylic acid is the ligand. This complex exhibits an unusual six-membered ring structure including the osmium atom.

RESULTS AND DISCUSSION

Preparation

Several α-hydroxycarboxylic acids [glycolic, 2-hydroxyisobutyric and (*S*)-(+)-mandelic] have been reacted with an Os(VI) complex in the presence of pyridine. After several days at −20°C, methano–pyridine solutions of dipotassium tetramethylosmate(VI) (DTMO) with α-hydroxycarboxylic acids yield brown, crystalline materials that can be easily separated via filtration. Magnetic measurements show all of them to be diamagnetic. The results of elemental analysis for the compounds listed in Table 1 are consistent with a formulation in which two pyridine ligands and one α-hydroxycarboxylic acid group are bound to one OsO_2 moiety.

IR spectra

Selected vibrational frequencies for these complexes are listed in Table 2. All complexes display a strong band in the 840–850-cm^{-1} region. This band is assigned to an O=Os=O asymmetric stretch and is characteristic of the osmyl moiety. A strong C=O band around 1700 cm^{-1} in each of the compounds is slightly lower in frequency than the one in the respective free hydroxycarboxylic acid. Only the glycolic acid complex contains an additional carbonyl frequency at 1667 cm^{-1} that is not present in the parent glycolic acid. In the 590–610-cm^{-1} region a medium strength band in each complex is assigned to the CO_2 wagging mode. A strong band at 1610 cm^{-1}, characteristic of C—C stretching vibrations in aromatic rings, is also found for all of these complexes.

NMR spectra

Proton NMR spectra are consistent with the formulation in which bonding of α-hydroxycarboxylic acids to osmium takes place through both carboxylic and hydroxyl groups. Table 3 lists the spectral line positions, along with their multiplicity and the number of protons they represent, of all the complexes. Spectra of the glycolic and 2-hydroxyisobutyric acid complexes are almost identical. Only the positions of the aliphatic protons are different. The 5.17-ppm singlet of the oxoacetato complex is produced by the CH_2 group of the ring, while the 1.64-ppm singlet in the spectrum of the oxoisobutyrato complex is assigned to $C(CH_3)_2$ protons.

The remaining lines are produced by the protons of the two pyridine ligands. With the help of the ^1H NMR spectrum of free pyridine, the necessary line assignments have been made. The ^1H NMR spectrum of pyridine shows three groups of spectral lines: one downfield doublet at 8.60 ppm produced by two *ortho* protons, and two multiplets at 7.00 and 7.60 ppm produced by *meta* and *para* protons, respectively. Based on that information the two downfield doublets in the ^1H NMR of oxoacidato complexes of Os(VI) can be viewed as *ortho* protons of the two pyridine ligands. The two remaining multiplets are produced by the overlap of the spectral lines of *meta* and *para* protons of both pyridines. The downfield multiplet can be associated with the *meta* protons. The other multiplet represents the *para* protons. The respective spectral lines of pyridine protons in the oxoacidato Os(VI) complexes are downfield from those found in free pyridine.

The presence of two doublets for *ortho* protons indicates that both pyridines, though chemically equivalent, are not equivalent magnetically. The molecule is asymmetric.

The proposed structure for the new complexes is:

I

In this structure the O=Os=O group is perpendicular to the plane produced by two nitrogen atoms of the pyridine ligands and two oxygen atoms

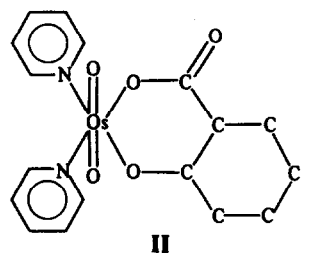
of the oxoacidato group. The ^{1}H NMR spectrum of the (*S*)-(+)-mandelic acid complex, *trans*-dioxo[(*S*)-(+)-oxo(phenyl)acetato]dipyridineosmium(VI), is also in good agreement with the proposed structure. However, its interpretation is not straightforward due to the overlap of the spectral lines of pyridine protons with the spectral lines of the protons from the phenyl group.

Mass spectrometry was used to determine whether the new class of osmyl compounds were monomeric or dimeric species. The mass spectrum of *trans*-dioxo(oxoacidato)dipyridineosmium(VI) was recorded. The interpretation of this spectrum is not simple since osmium has several isotopes with natural abundance higher than 10%. Despite the complexity of the spectrum, the molecular ion can be easily identified. Its molecular weight is 456 as expected for the monomeric species.



The question of the existence of a larger ring size involving the osmium atom has been explored through a synthesis of an *o*-salicylic acid complex.

The preparation devised for the synthesis of oxoacidato complexes of α-hydroxycarboxylic acids did not produce crystalline materials in this case. However, when the reaction mixture was evaporated to dryness, a brown osmium-containing compound could be extracted with CH_2Cl_2. This solid was recrystallized from CH_2Cl_2 through *n*-heptane layering. The brown crystals that were isolated were diamagnetic.

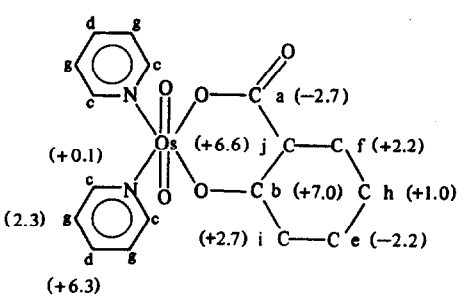
The elemental analysis results for the crystalline material are listed in Table 1. The presence of some chlorine has been detected. This probably comes from CH_2Cl_2 in the crystalline lattice. If one makes the assumption that the salicylate complex is in fact *trans*-dioxo(*o*-oxobenzoato)dipyridineosmium(VI), then the ratio of CH_2Cl_2 to $OsO_2[o\text{-}OC_6H_4COO](py)_2$ can be calculated. It was found to be 2:13. The elemental analysis results are in excellent agreement with the calculated composition based on this ratio. Furthermore, the molecular weight of the crystalline material was determined osmometrically in CH_2Cl_2 and found to be 440. This compares favorably with the value of 459 calculated for the 2:13 ratio of CH_2Cl_2 to *trans*-dioxo(*o*-oxobenzoato)dipyridineosmium(VI). The molecular weight determined for the salicylate complex indicates a monomeric structure for the material.

The structural features of this complex were inferred from its IR spectrum. Selected vibrational frequencies of this complex are listed in Table 2. The IR spectrum of the salicylato complex is similar to those found for other oxoacidato compounds of Os(VI). The strong band at 852.8 cm^{-1} is assigned to an O=Os=O asymmetric stretch. The band at 1643.9 cm^{-1} is probably due to C=O vibrations and is less than the C=O vibration in salicylic acid. Two bands are present at 1610.0 and 1598.6 cm^{-1}. The former is assigned to an aromatic C—C stretching vibration of the pyridine ring. All other oxoacidato complexes have this frequency within ± 2 cm^{-1}. The latter are interpreted as stretching vibrations of aromatic carbon atoms in the phenyl ring of salicylic acid.

Table 3 lists the spectral line positions along with their multiplicity and relative band areas for the ^{1}H NMR spectrum of this compound. The assignments of the spectral lines are consistent with the structure:

II

The assignment of the proton NMR absorptions of the salicylate ring has been made to be consistent with the spectrum of neat salicylic acid.



The positions of ^{13}C spectral lines along with their intensities are listed in Table 4. Assignments are based on the line assignments of the pure starting materials and are presented in the figure accompanying Table 1. The numbers in parentheses represent spectral line shifts of pure starting materials. Two downfield lines have been assigned to the carboxylic carbon of the salicylic group and the carbon atom to which the hydroxyl group is attached. Six spectral lines that can be viewed as three doublets at 126, 141 and 150 ppm are assigned to pyridine carbons: *meta*, *para* and *ortho*, respectively. Three upfield lines are due to the ring carbon bound to the carboxylate group and the two atoms that are at *meta* positions to it. The remaining two atoms of the salicylate ring give rise to the 132.9- and 133.7-ppm lines. The ^{13}C NMR spectrum fully supports the presence of a six-membered ring that includes the osmium atom. This is the first osmyl compound to have this feature.[2]

Cyclic voltammetry

The electrochemical properties of OsO_2(oxoacidato)$(py)_2$ have been explored with the help of cyclic voltammetry. The details of that study are summarized in Table 5. The electrochemical behavior of all of the compounds is very similar. They display one oxidation and two reduction waves. All waves are irreversible. The anodic wave represents oxidation of Os(VI) complexes to OsO_4. Of the two cathodic waves the first one could be interpreted as reduction of OsO_4 to an Os(VI) product, while the second one represents the reduction of that product to an Os(IV) species. This behavior is consistent with the electrochemical properties expected for osmium +6 compounds.

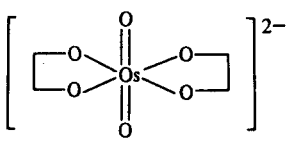


Table 4. ^{13}C NMR spectral line positions of *trans*-dioxo(*o*-oxobenzoato)dipyridineosmium(VI)

Line No.	Intensity	Frequency (Hz)	ppm
1 (a)	402.16	8549.74	169.938

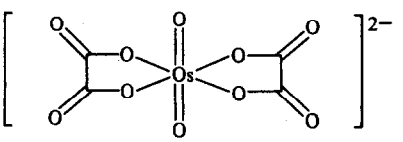
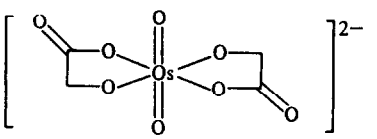
11 (h)	443.74	6049.72	120.247
12 (i)	653.31	6044.15	120.136
13 (j)	413.74	6028.02	119.816



All of these new complexes display a ring structure that involves a central osmium atom. These rings have five or six atoms. Compounds of similar type are represented by Os(VI) monoesters.[3] However, in those complexes oxygen atoms are bound to sp^3 carbons, while in our compounds one of the oxygen atoms forms a bond with an sp^2 carbon atom.

There are several examples of dioxoosmium(IV) complexes with two five-membered rings that include a common osmium center:



III

IV

They are made from other dioxoosmium(VI) materials through exchange of ligands.[4,5] However, we were unable to synthesize an Os(VI) complex that includes two oxoacidato rings:

V

Exchange of $K_2[OsO_2(MeO)_4]$ with glycolic acid leads to a polymeric osmium glycolate with mixed oxidation states of +3 and +4, while the other hydroxacarboxylic acids produce mixtures of oily polymeric materials that are impossible to separate.[6]

Table 5. Electrochemical properties of several *trans*-dioxo(oxoacidato)dipyridineosmium(VI) complexes

Compound	E_a	E_{c1}	E_{c2}
$OsO_2[CH_2(O)COO](py)_2$	2.00	−0.95	−1.68
$OsO_2[(CH_3)_2C(O)COO](py)_2$	2.02	−1.22	−1.88
$OsO_2[d\text{-}C_6H_5CH(O)COO](py)_2$	2.02	−0.93	−1.67
$OsO_2[o\text{-}OC_6H_4COO](py)_2$	1.58	−0.88	−1.54

EXPERIMENTAL

Materials

OsO_4 was purchased from Stevens Metallurgical Co. and was used as received. Hydroxycarboxylic acids were purchased from Aldrich Chemical Co. All other reagents were purchased from different commercial sources and used without additional purification.

Elemental analysis

Determination of all the elements except for osmium was carried out by either Galbraith or MicAnal Laboratories.

Spectroscopy

IR spectra were recorded as KBr pellets containing 1–3 mg of sample per 400 mg of KBr. KBr was dried under high vacuum at 130°C for 24 h and stored in a desiccator filled with nitrogen or divided into 400-mg portions and sealed in vials. A Perkin–Elmer Model 297 or Nicolet Model 20DX FTIR spectrometer was employed.

The ^1H NMR spectra were recorded on a Perkin–Elmer R32 90-MHz spectrometer. ^{13}C FT NMR and ^1H FT NMR spectra were recorded on a Nicolet 200-MHz instrument. The NMR data are reported in the following manner: chemical shift (ppm) with respect to tetramethylsilane as the internal standard, followed by the multiplicity (m = multiplet, q = quartet, t = triplet, d = doublet, s = singlet) and the number of protons represented by the peak(s).

The mass spectrum of *trans*-dioxo(oxoacetato)dipyridineosmium(VI) as recorded at the Midwest Center for Mass Spectrometry at the University of Nebraska-Lincoln. Fast-atom bombardment was used as the ionization method.

Magnetic measurements

Magnetic susceptibilities were determined at ambient temperature using a Faraday balance. $HgCo(CNS)_4$ which has a high magnetic susceptibility of 16.44×10^{-6} cgs units was used as a standard for the calibration of a balance. The Faraday balance was constructed by Cahn Instruments Inc. Five fifteen-milligram samples were used for each determination. Magnetic susceptibilities were corrected for diamagnetism.

Cyclic voltammetry

Electrochemical properties of osmium compounds were investigated by means of cyclic voltammetry. The measurements were done on a locally constructed instrument. A three-electrode system was used to avoid problems associated with solution resistance. Voltammograms were recorded on an X–Y recorder. Electrochemical studies were performed in CH_2Cl_2. $(n\text{-}Bu_4N)PF_6$ was used as a supporting electrolyte, usually as a 0.2 M solution. The concentration of the osmium complex was 10^{-3}–5×10^{-3}. A platinum bead served as a working electrode, platinum wire as a counter electrode and an Ag–0.1 M $AgNO_3$ in CH_3CN electrode was used as a reference. The reference electrode made contact with a solution through a Vycor tip. The typical scan rate was 300 mV s^{-1}. Anodic and cathodic currents were calculated from voltammograms. For comparison with literature data, the potentials measured vs a silver–silver nitrate electrode were converted to an SCE reference electrode. The correction was +0.337 V.

Synthesis of trans-*dioxo(oxoacetato)dipyridineosmium(VI)*

In a typical preparation 0.5 g (2 mmol) of OsO_4 was dissolved in 10 cm^3 of methanol. To this solution 4 cm^3 of 1 N KOH in methanol were added. The initial red color of the solution changed to green in about 5 min. The green solution of DTMO was treated with 40 cm^3 of ethyl ether. The resulting precipitate was removed by centrifugation. The supernatant was discarded and the remaining solid was washed with an additional 40 cm^3 of ethyl ether

and centrifuged again. The sediment was mixed with 20 cm^3 of pyridine to form a very fine suspension. To this suspension 0.9129 g (12 mmol) of glycolic acid in 10 cm^3 of ethanol was added and the reaction mixture was placed in a freezer (−20°C) for a week. After that time the resulting white-brown solid was filtered and washed with water, yielding brown crystals. They were, in turn, washed with ethyl ether and vacuum dried. The yield was 0.56 g (63% with respect to osmium).

Synthesis of trans-*dioxo(oxoisobutyrato)dipyridine-osmium(VI)*

A 0.5-g (2-mmol) sample of OsO_4 was dissolved in 10 cm^3 of methanol. To this solution 4 cm^3 of 1 N KOH methanol were added. The initial red color of the solution changed to green in about 5 min. The green solution of DTMO was treated with 40 cm^3 of ethyl ether. The brown-gray solid that resulted was centrifuged out, washed with 40 cm^3 of ethyl ether and centrifuged again. The sediment was mixed with 20 cm^2 of pyridine to form a very fine suspension to which 1.2547 g (12 mmol) of 2-hydroxy isobutyric acid in 10 cm^3 of ethanol was added. The reaction mixture was placed in a freezer (−20°C) for a week. After that time the resulting brown crystals were filtered, washed with water, ethyl alcohol and ethyl ether, and vacuum dried. Yield 0.58 g (61% with respect to osmium).

Synthesis of trans-*dioxo*[(S)-(+)-*oxo(phenyl)acetato*] *dipyridineosmium(VI)*

A 0.5-g (2-mmol) sample of OsO_4 is dissolved in 10 cm^3 of methanol. To this solution 4 cm^3 of 1 N KOH in methanol were added. The initially red solution changed to green in about 5 min. The green DTMO solution was treated with 40 cm^3 of ethyl ether to produce a brown-gray solid that was centrifuged out, washed with an additional 40 cm^3 of ethyl ether and centrifuged again. The sediment was mixed with 20 cm^3 of pyridine and 1.8305 g (12 mmol) of (*S*)-(+)-mandelic acid in 10 cm^3 of ethyl alcohol to form a very fine suspension that was placed in a freezer (−20°C) for a week. After that time the brown crystalline product was filtered, washed with water, ethanol and ethyl ether, and vacuum dried. Yield 0.47 g (45% with respect to osmium).

Synthesis of trans-*dioxo*(o-*oxobenzoato)dipyridine-osmium(VI)*

A 0.5-g (12-mmol) sample of OsO_4 was dissolved in 10 cm^3 of methanol. To this solution 4 cm^3 of 1 N KOH in methanol were added. The initially red solution turned green in about 5 min. The green DTMO solution was treated with 40 cm^3 of ethyl ether to produce a brown-gray precipitate that was centrifuged, washed with an additional 40 cm^3 of ethyl ether and centrifuged again. The sediment was mixed with 20 cm^3 of pyridine, 1.6766 g (12 mmol) of salicylic acid in 10 cm^3 of ethanol and placed in a freezer for a week. After that time the reaction mixture was evaporated to dryness on a rotavap. The brown solid that resulted was dissolved in CH_2Cl_2 and washed several times with 20-cm^3 portions of water, 5% HCl and 5% NaOH. The organic layer was dried with $MgSO_4$ and evaporated to dryness. The brown product was redissolved in acetone and filtered through a silica gel. The acetone solution was evaporated to dryness and the product was crystallized from CH_2Cl_2 through layering with *n*-heptane. The yield was 0.26 g (25% with respect to osmium).

Abstract—Some new Cr(III) compounds with uracil, uridine and 5′-UMP were obtained by reaction of the starting complexes *cis*-$[Cr(en)_2Cl_2]Cl$ and $[Cr(NH_3)_5Cl]Cl_2$ with the base, nucleoside and nucleotide. The complexes were characterized by their elemental analysis, conductivity, reflectance and IR data. In the case of uracil and uridine compounds, indirect bonding of Cr(III) to the pyrimidine ring seems to occur through the C_4=O and $-NH_3(-NH_2)$ groups of the starting complexes. In the 5′-UMP complex direct bonding is inferred through the phosphate group with additional interactions by hydrogen bonds involving the C_4=O group.

The presence of Cr(III) in biological processes such as glucose metabolism (glucose tolerance factor)[1,2] is well known, as well as its role in the kinetic mechanisms of DNA and RNA polymerases, which catalyse the replication and transcription of DNA.[3] Taking this into account, the study of kinetically inert Cr(III) complexes with nucleotides and their constituents is of interest. This paper is a follow-up of previous studies of the interaction of Cr(III) with nucleotides, nucleosides and bases.[4,5] Until now very few studies of Cr(III) with uracil (URA), uridine (URD) and 5′-UMP in the solid state have been performed.[5,6]

In comparison with other bases and nucleotides the formation of URA and URD complexes proved more difficult because the heterocyclic nitrogens were protonated in a wide range of pH, making coordination by nitrogen possible only under basic conditions different from those found in biological systems.[7,8] By using a suitable dissolving agent, coordination by carbonyl oxygen is possible.[9,10] Recently, the preparation of divalent 3*d* metallic ion complexes of uracil with a bidentate bond through the N(3), C_2=O sites were reported.[11]

In the complexes of 5′-UMP, the phosphate oxygens are the main point for coordination with the metal ion.[12,13]

EXPERIMENTAL

The analyses of carbon, hydrogen and nitrogen were carried out in a Carlo Erba model 1106 microanalyzer in the Institute of Bio-Organic Chemistry in Barcelona and in a Perkin–Elmer 240.B in the Faculty of Chemistry, Tarragona.

The chlorine analysis was determined by the Schoniger method using a 638 Metrohm Titro Processor, by burning the sample in O_2 over sodium bisulphite. Dissolutions were assessed by Volhard.

The sodium content was determined by flame photometry in a Perkin–Elmer 703 spectrophotometer. The working conditions were: λ = 590 nm and 0.2-nm slit with an acetylene–air flame oxidant.

The phosphorus content was determined by using the colorimetric method for phosphomolybdovanadate.[14] The measurements were carried out in a

* Author to whom correspondence should be addressed.

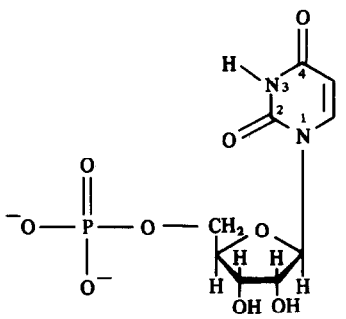

Fig. 1. 5′-UMP.

Perkin–Elmer 552 UV–visible spectrophotometer at 390 nm and 2-nm slit.

Chromium was determined by using the colorimetric method for chromate.[15] The measurements were performed in a Perkin–Elmer 552 UV–visible spectrophotometer at 375 nm and 2-nm slit.

The conductivities were measured with a Crison 525 conductimeter. The cell constant was determined by using a water solution of 10^{-2} N KCl ($k = 1.04\ cm^{-1}$).

The IR spectra were registered in the solid state (KBr pellets) in a Perkin–Elmer 683 IR spectrophotometer with an IR data station.

The reflectance spectra were recorded in the solid state in a Perkin–Elmer 552 UV–visible spectrophotometer with an integrating sphere attachment.

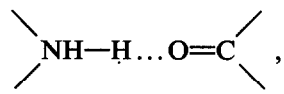
The complexes were prepared using URA (Merck), URD and $Na_2$5′-UMP (Serva) without further purification. The starting complexes *cis*-$[Cr(en)_2Cl_2]Cl$ and $[Cr(NH_3)_5Cl]Cl_2$ were prepared by the methods described in the literature.[16,17]

Synthesis of cis-$[Cr(en)_2Cl_2]Cl \cdot (URA)_2 \cdot \frac{1}{2}AcOEt$, cis-$[Cr(en)_2Cl_2]Cl \cdot (URD)_2$, $[Cr(NH_3)_5Cl]Cl_2$ (URA) *and* $[Cr(NH_3)_5Cl]Cl_2$(URD)

These four complexes were obtained in an ethyl acetate medium in a similar way to that described by Goodgame.[10,18] 0.5 mmol of the *cis*-$[Cr(en)_2Cl_2]Cl \cdot H_2O$ complex {1 mmol of $[Cr(NH_3)_5Cl]Cl_2$} and 1 mmol of finely powdered URA or URD were mixed and about 15 cm^3 ethyl acetate were added. The mixture was then reflux heated by constant stirring for between 5 and 16 h, depending on the case, until the reaction was complete. The product was filtered, washed with ethyl acetate (2.5 cm^3), and dried over P_4O_{10}.

Synthesis of $Na_2[Cr(en)_2(5'\text{-}UMP)_2(5'\text{-}UMPH)] \cdot 7H_2O$

Finely powdered dry samples {0.5 mmol of *cis*-$[Cr(en)_2Cl_2]Cl \cdot H_2O$ and 1 mmol of $Na_2$5′-UMP} were mixed and about 15 cm^3 ethyl acetate were added. The mixture was then reflux heated by constant stirring for 10 h until the reaction was complete. The product was filtered off, washed with ethyl acetate (2.5 cm^3), and dried over P_4O_{10}. Subsequently, this compound was dissolved in 11 cm^3 of water (pH = 6.9) and heated to 55°C for 10 min in a temperature-controlled bath. The complex was precipitated by addition of ethanol, then filtered, washed with ethanol and dried over P_4O_{10}.



The composition of the complexes and the analytical results are shown in Table 1.

RESULTS AND DISCUSSION

Table 2 records the IR data for the compounds obtained with URA and URD. The assignment has been carried out according to the literature.[19–21]

In general, the IR spectra present no noticeable variations in comparison with those of URA, URD and the starting compounds so that one expects the initial environment of the metallic ion to be almost unchanged by the presence of URA or URD.

For the URA compounds, splitting of the bands is observed in the ν(C=O) region. The band corresponding to $\nu(C_4{=}O)$ (1671 cm^{-1}) shifts to lower frequencies (1665 and 1645 cm^{-1}) for the ethylenediamine compound, and to 1669 and 1646 cm^{-1} for the ammonia compound, indicating charge donation by this group probably as a result of a hydrogen bond

direct interaction with Cr(III) being ruled out by the presence of bands in the lower region of the spectrum assignable at δ(NMN) + ν(M—X) with no important shifts or changes in their relative intensity.[22,23]

In the case of the URD compounds, there is no shift in the ν(C=O) region and variations are minimal. The bands belonging to the starting complexes still appear in the lower region, probably coupled to the 357-, 310- and 287-cm^{-1} bands due to ν(ribose),[18] inferring an interaction through hydrogen bonds between URD and the initial system with possible participation of the ribose ring OH.

The remaining bands belonging to the vibrations of the starting complexes remain at approximately the same frequency, except for the 1583–1570-cm^{-1} [$\delta(NH_2)$] and 1608-cm^{-1} [$\delta(NH_3$deg.)] bands which overlap as a shoulder appearing at higher frequencies, which might indicate participation of these groups in the bond.

Table 3 records the IR data for the 5′-UMP complex. For this compound there are changes in

frequency and intensity in the bands appearing mainly in the $\nu(C{=}O)$, ν(ring) and $\nu(PO_3^{2-})$ areas. The 1679-cm^{-1} peak, corresponding to $\nu(C_4{=}O)+\nu(C{=}C)$ shifts at 1632 cm^{-1}, appears as a shoulder, which seems to indicate some kind of interaction through the carbonyl group. The ring-stretching bands also vary in frequency as a consequence of restructuring the ring charge. In the region between 1200 and 900 cm^{-1}, bands appear due to the stretching vibrations of the phosphate group which are also altered. The bands due to $\nu(PO_3$assym.$)+\nu$[C—O(sugar)] settle at two peaks (1114 and 1066 cm^{-1}), and are considerably shifted in frequency, while the band corresponding to $\nu(PO_3$symm.$)$ is shifted slightly at higher frequencies. The 939-cm^{-1} band disappeared. All this infers that the phosphate group of a nucleotide is involved in the metal bond, with additional interaction with the pyrimidine ring, probably through the $C_4{=}O$ group. In this case, it is expected that the other nucleotides not coordinated to the Cr(III) will remain associated with the one coordinated by stacking phenomena or by interaction between the bases through hydrogen bonds.[24] The bands due to "ethylenediamine" and ν(M—N) which overlap with the 5′-UMP bands lose their definition and cannot be observed. The M—Cl bands are not observed either, which is in agreement with the results of the elemental analysis.

The diffuse reflectance spectra of the compounds obtained are consistent with approximately octahedral geometries of Cr(III). The values of $10Dq$ and B' parameters were found using Tanabe and Sugano's diagram[25] (Table 4).

Bands appear on these spectra due to transitions of the URA ring in the 300–240-nm region, which appear modified as a consequence of donation via $C_4{=}O$ and subsequent restructuring of the ring charge. Bands also appear corresponding to ν_1 and ν_2 transitions with practically no change in frequency compared to those of the starting complexes, confirming the permanence of the initial environment of the metallic ion in the case of the URA and URD compounds. The derivative of 5′-UMP presents a considerably lower $10Dq$ value, indicating coordination with —O donor. Probably, the Cl^- has been substituted by the oxygen of the phosphate or $C_4{=}O$ group. The low B' value is consistent with interaction through the $C_4{=}O$ group, permitting back bonding of the electronic density of the chromium to the URA ring carbonyl group. This interpretation is consistent with the reduction in frequency of the $C_4{=}O$ bond, as has been indicated when studying the IR spectrum.

For the "ethylenediamine" derivatives, various peaks are observed in the 465–605-nm area as a result of splitting through loss of symmetry at the $^4T_{2g}$ level, whose average value corresponds to a ν_1 transition. This splitting of the first transition into three peaks is consistent with a C_{2v}-geometry for the geometric environment of Cr(III) for which reason the configuration of the *cis*-$Cr(en)_2Cl_2$ starting

complex has been retained. In the derivative of 5'-UMP four bands appear, some of which must be spin-forbidden.

Λ_M values were obtained for the complexes of URA and URD, confirming the results of the IR and reflectance spectra, as they indicated the presence of types of electrolytes coinciding with those of the starting complexes[26] (Table 1).

The Λ_M value for the 5'-UMP complex indicates a situation corresponding to a 1:2 electrolyte, implying the existence of nucleotides associated by stacking phenomena or hydrogen bonds to the coordination sphere of Cr(III). Taking into account steric hindrance considerations and the IR and UV data, the structure of this compound can be interpreted as a pseudo-octahedral geometry with a C_{2v}-symmetry environment and bonding of Cr(III) to a nucleotide through the C_4=O group or the phosphate group, the other two being joined to the coordinated one. Rearrangement of the complex system in solution with release of the associated nucleotides is a possibility which cannot be ruled out.

POTENTIOMETRIC STUDIES ON COMPLEXES IN Cr(III)–L-ASPARTIC ACID–DL-METHIONINE OR DL-ETHIONINE SYSTEMS

JOANNA MASŁOWSKA* and LONGIN CHRUŚCIŃSKI

Institute of General Food Chemistry, Technical University, 90-924 Łódź, B. Stefanowskiego 4/10, Poland

(*Received* 11 *December* 1984; *accepted after revision* 23 *October* 1985)

Abstract—Simple and mixed-ligand complexes of Cr(III) with L-aspartic acid and DL-methionine or DL-ethionine have been investigated by potentiometric measurements at 25°C and 0.1 M ($NaClO_4$) ionic strength. The stability constants of the complexes and tendency toward mixed-ligand complex formation have been determined.

Cr(III) is an essential metal ion for living organisms. Mertz first described a chromium dependence in rats and later showed that chromium is an essential co-factor for insulin and is required for normal glucose tolerance in rats.[1–3] Studies on the isolation and characterization of biological chromium complexes have shown that various amino acids and nicotinic acid serve as structural components of the active complex.[4–8]

Investigations of the stability of mixed-ligand complexes will help toward understanding the driving forces that lead to the formation of such complexes in biological systems. Stability constants of the binary complexes of Cr(III) with several amino acids were obtained by Tsuchiya *et al.*[9,10] and Khan and Malik,[11] but only one paper[12] was concerned with the determination of stability constants of mixed-ligand complexes of Cr(III) with amino acids.

In previous papers[13–15] we described studies of complexes of Ni(II) and Cr(III) with sulphur-containing amino acids. We now report potentiometric investigation of simple and mixed-ligand complexes in Cr(III)–L-aspartic acid (L-asp)–DL-methionine (DL-met) or DL-ethionine (DL-eth) systems.

EXPERIMENTAL

Materials

L-asp acid (Merck), DL-met (Fluka) and DL-eth (Fluka) were purified by recrystallization from water–ethanol solutions. Their purity was tested by chromatographic and potentiometric methods.

Chromium perchlorate was prepared from chromium hydroxide, perchlorate acid and hydrogen peroxide.[16] The stock solution of chromium perchlorate was standardized by a redoxymetric method.[17] For the pH-metric titration an approximately 1 M NaOH solution, carbonate-free, was used.

Apparatus

All measurements were carried out under nitrogen (freed from oxygen) in a special vessel described previously.[18] A digital OP-208 pH-meter (Radelkis) with OP-0718P glass and OP-0830P calomel reference electrodes was used for the measurements. The pH standards were 0.05 M potassium hydrogen phthalate (pH = 4.008) and 0.025 M KH_2PO_4 and 0.025 M Na_2HPO_4 phosphate buffer (pH = 6.865) at 25°C. To calibrate the glass electrode within the acid range of pH, a standard $HClO_4$ solution with an ionic strength (μ) of 0.1 ($NaClO_4$) was used. An NaOH solution was added from an ABU-11 burette (Radiometer).

Measurement methods

Potentiometric investigations of the simple Cr(III) complexes with amino acids were carried out at metal : ligand ratios of 1 : 1, 1 : 3 and 1 : 6, and those of mixed-ligand complexes at metal : ligand A : ligand B ratios of 1 : 1 : 1, 1 : 3 : 3 and 1 : 6 : 6. The concentration

* Author to whom correspondence should be addressed.

of Cr(III) was 3×10^{-3} or 5×10^{-3} M. The μ of the solutions was maintained constant at 0.1 ($NaClO_4$).

Because of the slow achievement of an equilibrium between Cr(III) ions and ligands we used special techniques, similar to those described in other papers.[9,10,12]

For each measurement series, tens of solution samples were prepared, containing Cr(III) ions, and one or two amino acids of concentration and μ as above: volume = 70 cm^3. Various amounts of NaOH were added to each sample. The samples were heated for 2 h at 80°C, and then they were stored for 1.5 months at a constant temperature of 25 ± 0.1°C.

The equilibrium process was monitored by periodically measuring the pH value of the solution. It was found that equilibrium was achieved within 1 month. Turbid samples with precipitated chromium hydroxide were rejected. The volume of added NaOH was plotted vs pH to obtain a simulated titration curve. The protonation constants of the amino acids were determined on the basis of classical titration curves.[19] Values for dissociation constants and stability constants of Cr(III) complexes were calculated with the aid of the MINIQUAD computer program,[20] using an ODRA 1305 computer.

RESULTS AND DISCUSSION

Based on the potentiometric data obtained for binary systems, values of $\bar{n}$ (average ligand number) and the concentration of free uncomplexed ligand ([L]) were determined. Plots of formation curves are shown in Fig. 1. The formation curves reach a maximum at $\bar{n} = 1.8$ for L-asp, $\bar{n} = 1.2$ for DL-met and $\bar{n} = 1.6$ for DL-eth. The formation curves for various Cr:L ratios do not overlap, which shows that the formation curve depends on the Cr(III) concentration. This indicates the formation of complexes different from mononuclear 1:1 and 1:2 complexes. The pH range (1.8–4.3) and the protonated forms of ligands occurring within this pH range suggest the possibility of the formation of protonated species. The appearance of such complexes meant that it was impossible to use graphic methods for the determination of stability constants. Among several possible models for complexes appearing in the binary systems, the best fit to the experimental data was obtained for the Cr(III)–L-asp system with ML, ML_2 and MHL complexes, and for the Cr(III)–DL-met and Cr(III)–DL-eth systems with ML, ML_2 and MHL complexes.

The values of the stability constants for binary Cr(III) complexes are given in Table 1. Table 1 also contains the protonation constants of the ligands investigated.

The formation of mixed-ligand complexes in the Cr(III)–L-asp (A)–DL-met (B) or DL-eth (B) systems was confirmed by the composition curve which was found using the assumption that mixed-ligand complexes were not formed. The composition and titration curves for the systems containing the Cr(III) ion and two ligands do not overlap. The possibility of the formation of the following complexes was considered: MAB, MHAB, MH_2AB, MA_2B and

Table 1. Stability constants (log β_{pqr}) of $M_pH_qL_r$ complexes formed in the Cr(III)–L–H_2O systems and protonation constants (log β_n) of H_nL ligand, where L = L-asp, DL-met or DL-eth: 25°C, μ = 0.1 ($NaClO_4$)[a]

	L-asp	DL-met	DL-eth
log β_1	9.918(3)	9.150(3)	9.190(4)
log β_2	13.882(5)	11.471(4)	11.400(4)
log β_3	15.814(5)		
log β_{101}	12.46(7)	8.35(6)	8.46(4)
log β_{111}		11.41(8)	11.50(6)
log β_{102}	21.86(5)	15.52(7)	15.67(7)
log β_{112}	24.30(10)		

[a] Standard deviation values in parentheses.

MAB_2. The best fit to the experimental data was obtained for the MAB and MHAB complexes. The stability constants for the mixed-ligand complexes are given in Table 2. The values are also given for the parameters determining the tendency toward mixed-ligand complex formation: Δ log K_{MAB}, showing the difference between the stability of the binary and ternary complexes, the disproportionation constant (log χ_{MAB}) and Δ_{MAB} [the stabilization constant (difference between the measured and statistically calculated stability constants) for the MAB complex].

It is clear from a comparison of the stability constants that L-asp forms considerably more stable complexes with Cr(III) than does DL-met or DL-eth. This results from the possible formation of five- and six-member chelate rings for L-asp complexes. The values of the stability constants for the binary complexes determined by us are consistent with the literature data. Tsuchiya *et al.*[10] obtained log β_{101} = 10.1 and log β_{102} = 19.6 at 25°C and μ = 0.1 for L-asp, and Santappa *et al.*[12] for the same ligand obtained log β_{101} = 12.15, log β_{102} = 21.13 and log β_{112} = 24.07 at 50°C. Khan and Malik[11] reported values for log β_{101}, log β_{102} and log β_{103} of 8.3, 14.5 and 19.8, respectively, for methionine. There is no value for ethionine in the literature.

The values of the stability constants for mixed Cr(III) complexes (Table 2) show that DL-met and DL-eth as well as L-asp from complexes with similar stabilities, the somewhat higher stability of DL-eth complexes resulting from the higher basicity of this amino acid. For statistical reasons,[21] if Δ log K_{MAB} > −0.4, log χ_{MAB} > 0.6 and Δ_{MAB} is positive then there is an increase in the stability of mixed complexes compared to the binary ones. Negative values of log K_{MAB} for DL-met and DL-eth suggest a shift in the equilibrium of eqn (1) (Table 2) to the left. The values of log χ_{MAB} in Table 2 are higher than 0.6, which suggests stabilization of the mixed complexes compared to the binary ones, and the positive value of Δ_{MAB} points to an increase in the stability of mixed-ligand complexes compared to the statistical case.

The concentration distribution of particular forms of complexes (Figs 2 and 3) shows that the binary MA and MA_2 complexes and the mixed-ligand MHAB complex are predominant within the given pH range and that the mixed-ligand MAB complex is insignificant, which is confirmed by the negative value of Δ log K_{MAB}.

Table 2. Stability constant (log β_{pqrs}) of $M_pH_qA_rB_s$ complexes formed in the Cr(III)–A–B–H_2O systems where A = L-asp, and B = DL-met or DL-eth: 25°C, μ = 0.1 ($NaClO_4$)[a]

POTENTIOMETRIC STUDIES ON MIXED-LIGAND COMPLEXES OF Cr(III) WITH DL-METHIONINE, DL-ETHIONINE AND OTHER AMINO ACIDS

JOANNA MASŁOWSKA* and LONGIN CHRUŚCIŃSKI

Institute of General Food Chemistry, Technical University, 90-924 Łódź, B. Stefanowskiego 4/10, Poland

(*Received* 4 *September* 1985; *accepted* 4 *October* 1985)

Abstract—Binary and ternary complexes of Cr(III) with amino acids have been investigated by the potentiometric method using a glass electrode in the Cr(III)–A–B–H_2O systems, where A = DL-methionine or DL-ethionine, and B = L-glutamic acid, DL-α-amino-*n*-butyric acid, L-serine or L-threonine. The stability constants of the complexes and a tendency toward mixed-ligand complex formation have been determined.

The biological significance and function of the Cr(III) ion as an essential microelement have been described in papers by Mertz[1–5] and other authors,[6–8] as partly summarized in our previous paper.[9]

Doubtless the participation of mixed Cr(III) complexes with amino acids in the formation of biologically active forms in living organisms has encouraged us to start our studies on the interactions between Cr(III) ion and amino acids in aqueous solutions. As mentioned previously,[9] the literature concerning the determination of stability constants of Cr(III) complexes with amino acids by the potentiometric method, particularly of mixed complexes, is extremely scarce.[10–13]

Carrying on our investigations of the thermodynamic equilibrium between Ni(II) and Cr(III) ions with amino acids,[9,14–17] in the present paper we report the results of examinations of simple and mixed Cr(III) complexes formed in Cr(III)–amino acid (A)–amino acid (B) systems where A = DL-methionine (DL-met) or DL-ethionine (DL-eth), and B = L-glutamic acid (L-glu), DL-α-amino-*n*-butyric acid (DL-ambut), L-serine (L-ser) or L-threonine (L-tre).

EXPERIMENTAL

Reagents

The following were used as ligands after being additionally purified by crystallization from water–ethanol solutions: DL-met (Reanal), DL-eth (Fluka), L-glu (Merck), DL-ambut (Reanal), L-ser (Merck) and L-tre (Merck). Their purity was tested by a chromatographic method. Chromium perchlorate was prepared and standardized as described previously.[9] For the pH-metric titration, a 1.0415 M solution, carbonate-free, was used.

Apparatus

Potentiometric measurements were carried out by means of a digital OP-208 pH-meter (Radelkis) with OP-0718P glass and OP-0830P calomel electrodes.

The measurement vessel and calibration procedure were as described previously.[9] The NaOH solution used for titration was added from an ABU-11 burette (Radiometer). The ionic strength (μ) of the solutions was 0.1 ($NaClO_4$) at 25°C.

Measurement methods

To determine the composition and stability constants of the complexes, samples of their solutions with variable initial composition were titrated with NaOH solution.

Because of the very slow achievement of an equilibrium between Cr(III) ions and amino acid molecules we used a titration technique typical for Cr(III) complexes, as described elsewhere.[9,11,13] Titration curves were prepared from pH-measurements of tens of samples with constant ratios of the concentrations of Cr(III) ions and amino acids within the given measurement series, and with various amounts of added NaOH. Before measure-

ments, the samples were maintained at 25°C for a period to reach equilibrium. For binary systems the initial metal:ligand ratios were 1:1, 1:3 and 1:6, while for the ternary systems the metal:ligand A:ligand B initial ratios were 1:1:1, 1:3:3 and 1:6:6. The concentration of Cr(III) ions was 3×10^{-3} or 5×10^{-3} M. The stability constants of the complexes were found by means of the MINIQUAD program,[18] using an ODRA 1305 computer.

RESULTS AND DISCUSSION

Analysis of the Bjerrum formation curves, $n = f(-\log [L])$ (Fig. 1), determined from potentiometric measurements shows that, in the systems under investigation, besides mononuclear complexes of compositions 1:1 and 1:2, other complexes may also appear. The formation curves found for various initial Cr(III):L ratios do not overlap. The low pH range (1.8–4.3) and the existence of protonated ligand forms within this range suggest the possible formation of complexes with a protonated ligand. The formation curves for systems containing DL-ambut, L-ser and L-tre (Fig. 1), and DL-met and DL-eth (see also Ref. 9), show similar courses, which suggests the same model for the formation and appearance of the complexes. The course of the formation curve for L-glu is different. Calculations made for the binary systems showed that the best fit to the experimental data was obtained when the formation of the following types of complexes was taken into consideration: ML, ML_2 and MHL for DL-met, DL-eth, DL-ambut, L-ser and L-tre, and ML, ML_2, MHL and MHL_2 for L-glu.

The values of the stability constants of the Cr(III) complexes formed in the systems investigated are given in Table 1, which also includes the protonation constants of the ligands.

Table 1. Stability constants (log β_{pqr}) of $M_pH_qL_r$ complexes formed in the Cr(III)–L–H_2O system and protonation constants (log β_n) of H_nL ligand, where L = L-glu, DL-met, DL-eth, DL-ambut, L-ser or L-tre: 25°C, $\mu = 0.1$ ($NaClO_4$)[a]

	L-glu	DL-ambut	DL-met	DL-eth	L-ser	L-tre
$\log \beta_1$	9.974(4)	9.622(3)	9.150(3)	9.190(4)	9.171(6)	9.103(7)

$\log \beta_{112}$	24.19(11)					

[a] Standard deviation values in parentheses.

The titration curves for the mixed systems did not agree with the composition curves theoretically calculated using the assumption that mixed complexes are not formed in the given systems. This would suggest that mixed complexes can appear in the ternary systems investigated. As in Ref. 9, the possibility exists of the formation of mixed complexes of various types as simple, protonated and polynuclear complexes. The best fit to the experimental data was obtained when it was assumed that complexes are formed of types MAB and MHAB. This is supported by the fact that the stability constants for these complexes (Table 2) have small standard deviations. Table 2 also includes values of other parameters describing the stability and tendency to form mixed complexes in the given systems. Below Table 2 are the equations used to calculate the values of these parameters.

The values of the stability constants shown in Table 1 prove that Cr(III) forms complexes of high stability with the amino acids investigated. A characteristic increase in the stability constant $\log \beta_{101}$ is seen with increasing ligand basicity, expressed by the pK of the amino group of the amino acid. The increasing order of $\log \beta_{101}$ is as follows: L-tre < L-ser < DL-met < DL-eth < DL-ambut < L-glu. The values of the stability constants of Cr(III) with L-tre and L-ser show that it is doubtful that the hydroxyl group of these amino acids takes part in the coordination. Similarly, participation of the thioether group of DL-met and DL-eth in the coordination can be excluded since the values of the stability constants of all the complexes are much the same, which suggests a classical type of coordination of amino acids through amino and carboxyl groups. Only the higher values of the stability constants of the L-glu complexes [similar to L-aspartic acid (L-asp[9,13])] point to a tridentate coordination of this amino acid and the possibility of the atom of five- and seven-member chelate rings. The values of the stability constants of simple Cr(III) complexes with the amino acids investigated are similar to those found potentiometrically by other authors. Khan and Malik[10] found that the stability constants of Cr(III) complexes with methionine and serine were: $\log K_1 = 8.3$, $\log K_2 = 6.2$ and $\log K_3 = 5.3$; and $\log K_1 = 8.0$ and $\log K_2 = 5.2$, respectively, at 25°C and $\mu = 0.1$.

Venkatachalapathi *et al.*[13] found the following values of the constants: $\log \beta_{101} = 11.39$, $\log \beta_{111} = 14.04$, $\log \beta_{102} = 18.96$, and $\log \beta_{112} = 23.91$ for L-glu at 50°C and $\mu = 0.1$.

There are no data for ethionine, threonine and α-aminobutyric acid in the literature.

Based on the stability constants of the mixed complexes, it can be stated that, in the ternary systems investigated, mixed complexes of comparable stabilities are formed; somewhat higher values were obtained for complexes containing DL-eth compared to DL-met complexes.

According to Sigel,[19] if $\Delta \log K_{MAB} > -0.4$ and $\log \chi_{MAB}$ is > 0.6, at positive values of Δ_{MAB} there is an increase in the stability of mixed-ligand complexes compared to the simple ones. From the analysis of these parameters for the systems investigated it follows that the values of $\Delta \log K_{MAB}$ decrease in the following order for ligand B (also using data from our previous paper[9]): DL-ambut ≈ L-ser > L-tre > L-

Table 2. Stability constants ($\log \beta_{pqrs}$) of $M_pH_qA_rB_s$ complexes formed in the Cr(III)–A–B–H_2O systems, where A = DL-met or DL-eth; B = L-glu, DL-ambut, L-ser or L-tre: 25°C, $\mu = 0.1$ ($NaClO_4$)[a]

[b] $MA + MB \rightleftharpoons MAB + M$, $\Delta \log K_{MAB} = \log \beta_{MAB} - (\log \beta_{MA} + \log \beta_{MB})$.
[c] $MA_2 + MB_2 \rightleftharpoons 2MAB$, $\log \chi_{MAB} = 2 \log \beta_{MAB} - (\log \beta_{MA_2} + \log \beta_{MB_2})$.
[d] $\Delta_{MAB} = \log \beta_{calc.} - \log \beta_{stat.}$.

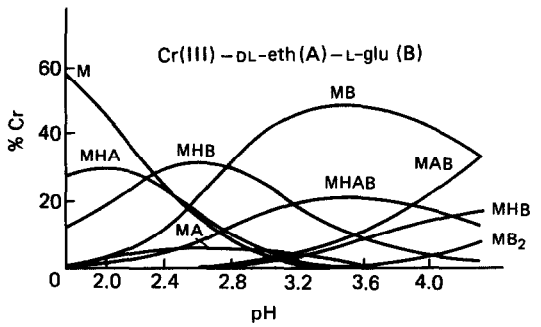

Fig. 2. Concentration distribution of complexes in the Cr(III)–DL-eth (A)–L-glu (B) system.

asp > L-glu. The tendency to form mixed complexes also decreases in the same order. Values of log $\chi_{MAB} > 0.6$ and $\Delta_{MAB} > 0$ are for all the mixed complexes except for those containing L-ser and L-tre. The values of log χ_{MAB} show that there is a greater tendency to form 1 : 2 mixed complexes from the simple complex than 1 : 1 ones. Thus, it can be stated that the tendency to form mixed complexes is a moderate one in all the systems except those which contain L-ser and L-tre. As is also seen from Table 2, the tendency to form mixed protonated complexes is greater than that to form mixed non-protonated complexes.

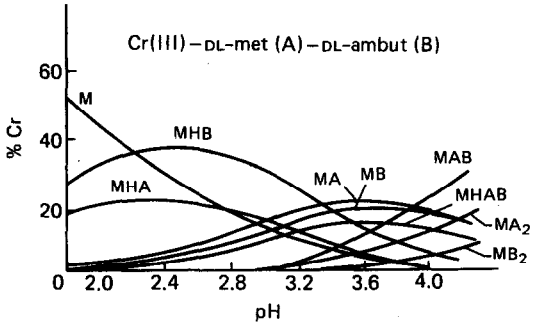

Fig. 3. Concentration distribution of complexes in the Cr(III)–DL-met (A)–DL-ambut (B) system.

These conclusions are supported by the curves of percent share of particular complex vs pH. The plots shown in Figs 2–4 are typical for the systems investigated. In the Cr(III)–DL-met or DL-eth–L-glu systems (Fig. 2), the highest shares are for MHA and MHB complexes at pH 1.8–2.8. Within the pH range 2.8–4.3 there is about 50% of MB (at pH 3.6) and about 20% of MHAB (at pH 3.3). At pH 4.3 the share of MAB was about 30%.

In the Cr(III)–DL-met or DL-eth–DL-ambut system (Fig. 3), MHA and MHB complexes prevail up to pH 3.3. The share of MHAB (about 17% at pH 3.6) is lower than that of MA and MB, and, above pH 3.9, the MAB complex predominates.

In the Cr(III)–DL-met or DL-eth–L-ser or L-tre system the highest shares are for MHA and MHB for pH 1.8–2.9, while for pH 2.9–4.2 MA, MB and MHAB complexes are predominant. At pH 4.2, the share of the MAB complex is about 25%.

AZIDE LIGAND SUBSTITUTION REACTION IN ZINC BIS(DIETHYLDITHIOCARBAMATE)

M. T. KOSTANSKI*† and W. MENDYK

Department of Chemistry, Poznan Technical University, 60-965 Poznan, Poland

(*Received* 27 *June* 1985; *accepted* 7 *October* 1985)

Abstract—The azide ligand substitution reaction in tetrahedral zinc bis(diethyldithiocarbamate) has been studied by extraction. The reaction has been shown to proceed by both solvent and azide ion interactions, with $k_0 = 5.0 \times 10^{-4}$ s^{-1} and $k_1 = 1.9 \times 10^{-3}$ M^{-1} s^{-1}. A general discussion of the reaction mechanism is provided.

The reaction of sodium azide with iodine is induced by organic compounds of sulphur-containing thiolic or thionic groups. Among other compounds several dithiocarbamates were analyzed with very favourable detection limits.[1–6] The so-called "iodo-azide" reaction was also applied to the determination of traces of several metals. This method is based on the assumption of the inertness of some of chelate complexes formed with the sulphur-containing ligands. Diethyldithiocarbamate (dedtc) was also successfully applied in this analytical method.[7,8]

Our investigations of the ligand exchange reactions in the diethyldithiocarbamato complexes using the radio tracer method indicated the inertness of Co(III) and Cr(III) chelates.[9,10] Complexes of Ni(II), Cu(II), Zn(II) and Fe(III) were labile. It was found that both $Cr(dedtc)_3$ and $Co(dedtc)_3$ undergo in DMF a very slow ligand exchange via a dissociative mechanism, with an activation energy of 15.9 and 21.1 kcal mol^{-1}, respectively. These results are in agreement with those obtained by Palazzotto *et al.*,[11] Moriyasu and Hashimoto,[12] Duffy,[13] Duffy *et al.*,[14] Beinrohr and Garaj,[15] and Liska *et al.*[16] However, all the above mentioned studies were performed in non-aqueous solutions. Due to the specific experimental conditions in the iodo-azide reaction (i.e. aqueous solution and very high azide ion concentration) it was interesting to investigate the ligand substitution in detc complexes in these conditions. In this work we examine the reaction of $Zn(dedtc)_2$ with the azide ion in aqueous medium. It has been demonstrated that the solvent extraction is a very useful technique for the examination of the ligand substitution reactions of water-insoluble chelates. This technique was therefore applied throughout the experimental part of this work.

EXPERIMENTAL

Reagents

$Zn(dedtc)_2$ labelled with ^{65}Zn was prepared similarly to a method described in Ref. 17 using radioactive $^{65}ZnSO_4$ (OPiDI, Swierk, Poland). All other reagents were of analytical grade. Chloroform was purified by shaking with sodium bicarbonate, washing with water and finally distilling. A stock solution of 1×10^{-3} M $Zn(dedtc)_2$ in $CHCl_3$ was prepared by weighing: working solutions were obtained by appropriate dilution of the stock solution. Investigations were conducted in the pH range 5.8–6.9: the pH of the aqueous phase was adjusted with $HClO_4$ and did not change during the kinetic run due to the formation of the N_3^-–HN_3 buffer. Because of the very high concentration of azide ion applied (1.5–4.0 M), the ionic strength was not kept constant and varied with the NaN_3 concentration. The concentration of $Zn(dedtc)_2$ in the $CHCl_3$ phase varied from 1×10^{-5} to 1×10^{-4} M.

Extraction procedure

Experiments were performed in a specially designed glass extraction vessel which allowed the measurements of the radioactivity of both phases

* Author to whom correspondence should be addressed.
† Present address: Department of Chemistry, University of Arizona, Tucson, AZ 85721, U.S.A.

without having to withdraw aliquots of either phase. The vessel was agitated with a magnetic stirrer, whose stirring speed was adjusted by an autotransformer. In order to assure that the mass transport across the phase boundary was not the rate-determining process preliminary experiments on the influence of the stirring speed on the reaction's kinctics were undertaken. Further experiments were carried out in the "plateau" region where there was no influence of the stirring conditions and the whole process was controlled by the rate of reaction. Thirty cubic centimetres of the organic phase containing $Zn(dedtc)_2$ was introduced into the extraction vessel and its radioactivity was measured with an NaI well-type scintillation counter. The aqueous phase containing azide ions was then carefully added and the phases stirred for determined time intervals. After phase separation the radioactivities of both phases were measured and their sum agreed within 1% with the initial activity of the organic phase. Finally, the pH of the aqueous phase was measured with a pH-meter. Experiments which were duplicated agreed within 10%.

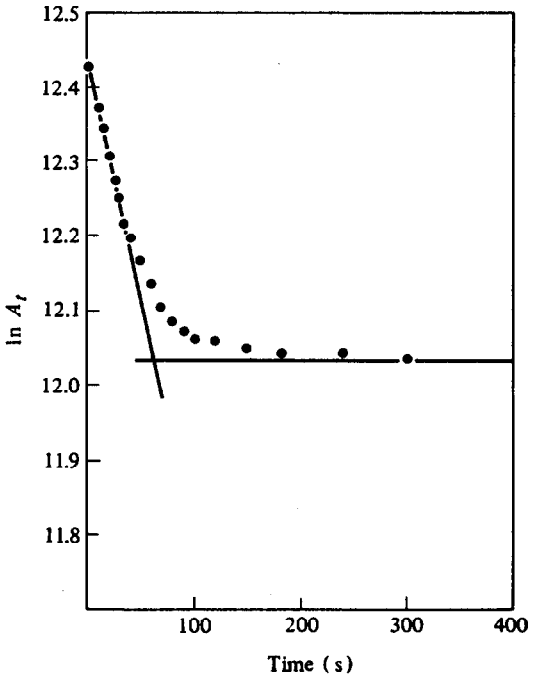

Fig. 1. Plot of $\ln A_t = f(t)$ for the experimental conditions: $[N_3^-] = 3$ M, $[Zn(dedtc)_2] = 3 \times 10^{-5}$ M, pH = 6.12.

Kinetic experiments

Kinetic runs were carried out under pseudo-first-order conditions with azide ions in the aqueous phase being in large excess over $Zn(dedtc)_2$ in the organic phase. All experiments were made at ambient temperature (21 ± 1°C). The pseudo-first-order rate constants (k_{absd}) were determined from the equation:

$$\ln \frac{[Zn]_t - [Zn]_\infty}{[Zn]_0 - [Zn]_\infty} = \ln \frac{A_t - A_\infty}{A_0 - A_\infty} = kt,$$

where $[Zn]_0$, $[Zn]_t$, $[Zn]_\infty$, A_0, A_t and A_∞ are total concentrations of Zn in the aqueous phase and their respective radioactivities at reaction times zero, t, and after completion of the reaction. Since the value of A_0 was zero and A_∞ was constant, plots of $\ln A_t = f(t)$ were used to calculate the rate constants.

RESULTS AND DISCUSSION

A typical plot of $\ln A_t$ against time (t) is presented in Fig. 1. None of these plots was linear, which indicates complex reaction kinetics. Moreover, the value of $A_{aq,t=\infty}/A_{o,t=\infty}$ depends on the concentrations of $Zn(dedtc)_2$ and the azide ion.

Both facts suggest that reversible, consecutive reactions operate in the system and that one of the reaction's products accumulates in the aqueous phase. This, in turn, influences the position of the attained equilibrium. The concentration of Zn in the aqueous phase in the equilibrium can be calculated from the following equations:

$$\beta_{Zn(dedtc)_2} = \frac{[Zn(dedtc)_2]}{[Zn] \cdot [dedtc)]^2}, \quad (1)$$

$$P = \frac{[Zn(dedtc)_2]_o}{[Zn(dedtc)_2]}, \quad (2)$$

$$[Zn]_t = [Zn](1 + \beta_1[N_3] + \beta_2[N_3]^2 + \beta_3[N_3]^3 + \beta_4[N_3]^4), \quad (3)$$

$$[Zn]_t = 2[dedtc^-], \quad (4)$$

where P is the distribution constant of $Zn(dedtc)_2$, β_1–β_4 are consecutive stability constants for the zinc azide complexes, $\beta_{Zn(dedtc)_2}$ is the stability constant of the zinc dedtc complex and $[Zn]_t$ is the total concentration of zinc in the aqueous phase. For the pH applied in this study (5.8–6.9) the protonation of the $dedtc^-$ ion and further extraction of the Hdedtc formed ($K_{HA} = 4.17 \times 10^{-4}$ [18]) as well as the protonation of the azide ion ($K_{HA} = 3.61 \times 10^{-5}$ [19]) can be neglected. Since the high azide ion concentrations were applied, the first two terms in the parentheses in eqn (3) can also be omitted. Solving eqns (1)–(4) with $P = 1.9 \times 10^5$,[20] $\beta_{Zn(dedtc)_2}$

$= 3.98 \times 10^{10}$,[20,21] $\beta_2 = 22$, $\beta_3 = 220$ and $\beta_4 = 780$,[22] and known initial concentration of $Zn(dedtc)_2$ and the azide ion, the position of the equilibrium was calculated. These values along with the experimental data are presented in Table 1. It is seen from Table 1 that there is a fairly good agreement between calculated and experimental values describing the position of the equilibrium. Small differences are probably caused by the change in the ionic strength.

The values of k_{obsd} in Table 1 were calculated from the linear part of the plot of $\ln A_t = f(t)$. The dependence of k_{obsd} on the azide ion concentration is presented in Fig. 2. From the plot of $k_{obsd} = f([N_3])$ a value for k_1 of 1.9×10^{-3} M^{-1} s^{-1} was obtained. The Y-intercept gave a value for k_0 of 5×10^{-4} s^{-1}. Assuming that the distribution of $Zn(dedtc)_2$ between both phases is very fast, the rate constants obtained can be replaced by $k'_1 = k_1 P = 3.6 \times 10^2$ and $k'_0 = k_0 P = 9.5 \times 10^1$.

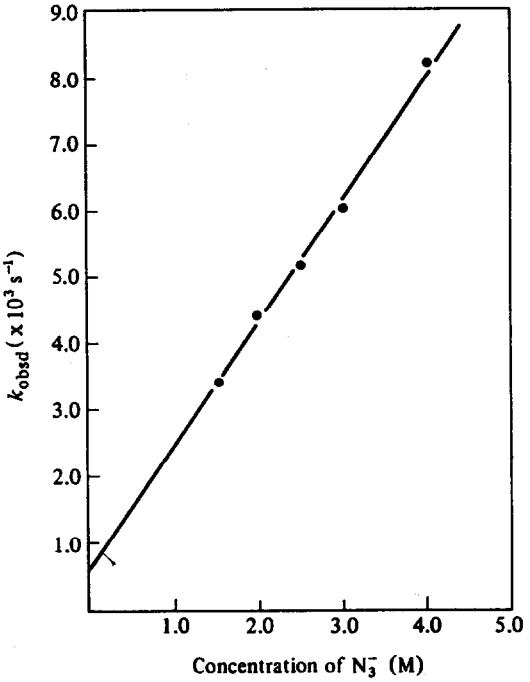
No influence of pH on the reaction rate was found in the pH region 5.8–6.9. The value for k_0 of 5.0×10^{-4} obtained agrees with that reported by Wyttenbach[23] for metal isotopic exchange in $Zn(dedtc)_2$ ($k_0 = 4.6 \times 10^{-4}$). It is apparent from the above data that the value of k_0 reported by Wyttenbach[23] is in fact the rate constant for the solvent path. Since the azide ion is not a very good nucleophile and water is always in much higher concentration than the azide ion, the value of k_1 obtained being only moderately higher than k_0 seems reasonable. The probable reaction mechanism for the substitution reaction with the azide ion is shown in Scheme 1.

Applying the steady-state approximation for **B**, **C** and **D**, and assuming that $k_{-1} \gg k_2[N_3]$, $k_{-2} \gg k_3$ and $k_{-3} \gg k_3$, eqn (5) is obtained:

$$k_{obsd} = k_a \frac{[N_3]^2}{k_{-3}[S{-}S] + k_4[N_3]}, \qquad (5)$$

where:

$$k_a = \frac{k_1 k_2 k_3}{k_{-1} k_{-2}} = K_1 K_2 k_3.$$



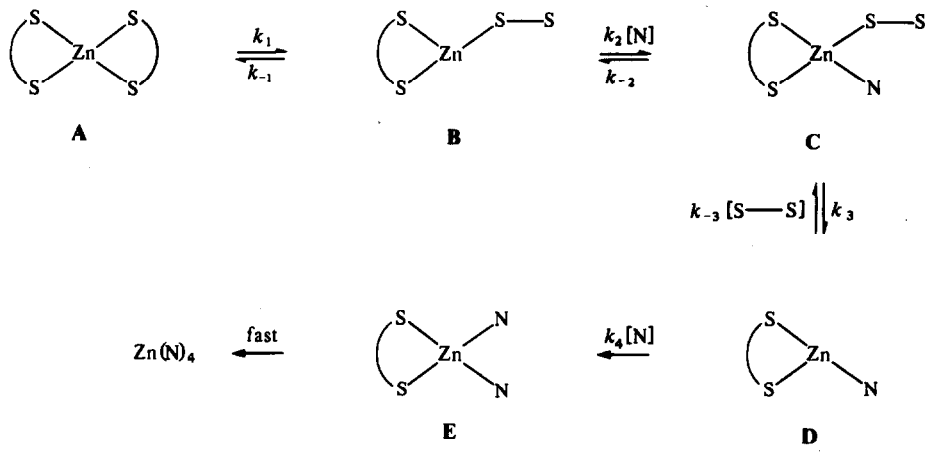


Fig. 2. Dependence of k_{obsd} on the azide ion concentration. Experimental conditions: $[Zn(dedtc)_2] = 3 \times 10^{-5}$ M, pH = 6.12.

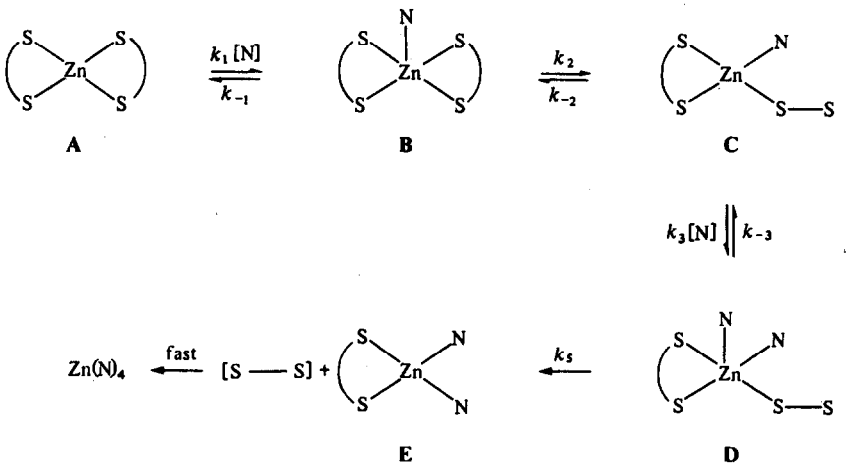
Table 1. Calculated and experimental data for azide ligand substitution in $Zn(dedtc)_2$ at pH = 6.12

Initial concentration		Calculated value		Experimental data	
$[N_3^-]$ (M)	$[Zn(dedtc)_2]$ (M)	$[Zn]_t$ ($\times 10^6$M)	$\frac{[Zn]_t}{[Zn(dedtc)_2]_i}$	$\frac{A_t}{A_i}$	k_{obsd} ($\times 10^3$ M^{-1} s^{-1})
2.5	1×10^{-4}	11.7	0.117	0.13	5.34
2.5	5×10^{-5}	9.1	0.181	0.19	4.87
2.5	3×10^{-5}	7.4	0.248	0.25	5.18
2.5	1×10^{-5}	4.6	0.461	0.48	5.23
4.0	3×10^{-5}	12.6	0.420	0.47	8.24
3.0	3×10^{-5}	9.2	0.306	0.34	6.05
2.0	3×10^{-5}	5.7	0.190	0.19	4.41
1.5	3×10^{-5}	4.2	0.138	0.15	3.40

Scheme 1.

It is apparent from eqn (5) that, depending on the relative magnitudes of k_{-3}[S—S] and $k_4[N_3]$, the k_{obsd} may have various values and show different dependences on the azide ion concentration. For the initial period of the reaction the dedtc$^-$ concentration is very low and we can assume that $k_4[N_3] \gg k_{-3}$[S—S], which leads to eqn (6):



$$k_{obsd} = k_b[N_3], \tag{6}$$

where $k_b = K_1K_2k_3/k_4$. With the progress of the reaction the concentration of the dedtc$^-$ ion increases and can no longer by neglected. This is visualized in the deviation from linearity in the ln $A_t = f(t)$ plot shown in Fig. 1. Addition of a small (0.1 cm^3) volume of Nadedtc solution to the aqueous phase to a final concentration of 1×10^{-5} M greatly influenced the reaction and totally deviated the plot of ln $A_t = f(t)$ from linearity. Zn(dedtc)$_2$ in the solid state is a dimer with Zn atoms having a coordination number of 5.[24] Similar properties were found for zinc bis(dimethyldithiocarbamate).[25] Both complexes are monomeric in benzene and chloroform solutions.[25,26] These facts indicate the relative ease of the formation of five-coordinate Zn complexes. It was therefore interesting to check the possibility of the associative mechanism for the azide ligand substitution in tetrahedral Zn(dedtc)$_2$ with the five-coordinate intermediate. The alternative mechanism is presented in Scheme 2.

Applying the steady-state approximation for **C** and **D**, and assuming that $1 \gg (k_5/k_{-2})[N_3]$, eqn (7) is obtained:

$$k_{obsd} = \frac{k_aK_1[N_3]^2}{1+K_1[N_3]}, \tag{7}$$

where $K_1 = k_1/k_{-1}$ and $k_a = k_1k_5/k_{-2}$.

Scheme 2.

From eqn (7) it is seen that the overall reaction order may be second-, intermediate second–first- or first-order. Assuming reversibility of the reaction between **D** and **E** the concentration of the dedtc$^-$ ion will also influence the kinetics, decreasing the rate with progress of the reaction. Although the relative ease of formation of pentacoordinated Zn complexes[27] may suggest that an associative mechanism operates, on the basis of the data presented it is difficult to make definite conclusions. Since the value of k_0 obtained may be regarded as the rate constant for the solvent path, the associative mechanism seems more plausible. Such an associative mechanism was also proposed for the substitution reactions in planar dithiolato complexes of Ni, Pd and Pt with such a strong nucleophile as the CN^- ion.[28–31]

PROTONATION AND COMPLEX FORMATION OF THE *CIS* AND *TRANS* ISOMERS OF ALICYCLIC β-AMINO ACIDS

F. GAIZER*

(*Received* 8 *August* 1985; *accepted* 7 *October* 1985)

Abstract—The protonation constants of β-alanine and the *cis* and *trans* isomers of aliphatic 2-amino-1-carboxylic acids containing a cyclohexane, cyclopentane or cyclohexene(4) ring were determined pH-metrically, as were the formation constants of their complexes with Ni^{2+}, Cu^{2+}, Hg^{2+} and Cd^{2+} ions. The analysis of about 70 formation constants revealed significant differences between the behaviours of the different ligands, each of which has a fixed β-alanine conformation. It is concluded that complex formation is primarily determined by the nature of the fixed β-alanine conformation and in some cases by the type of aliphatic ring.

In its protonation and complex formation processes, β-alanine is presumed to take part in a number of conformeric forms, to each of which micro constants can be assigned. The measured protonation and complex stability constants[1–3] are actually average values, therefore. To substantiate this assumption and to elucidate the differences in behaviour between the individual conformers, we have determined the protonation and complex stability constants of compounds with a fixed β-alanine conformation.

Some alicyclic 2-amino-1-carboxylic acids were chosen as model compounds. In cyclohexane and cyclopentane compounds of this type, the substituents can occupy axial or equatorial positions. We have also investigated the analogous cyclohexene(4)-β-amino acid in which, as a consequence of the double bond, the ring is more planar, whereby the valence directions are slightly modified and the substituents occupy quasi-axial or quasi-equatorial positions. In all three ring systems the carboxylic group can only be situated equatorially. Thus, depending on the position of the amino group, two isomers can be formed: in the *cis* isomers the positions of the two groups are opposite (e.g. equatorial–axial), while in the *trans* isomers they are identical (e.g. diequatorial).

The pH-metric studies reported in this paper were made not only on the above six amino-carboxylic acids but also on β-alanine.

EXPERIMENTAL

Chemicals

The amino-carboxylic acids were prepared as previously described.[4,5] All other chemicals used were of analytical grade.

The pH-metric measurements were performed in sodium perchlorate solution of 0.5 mol dm^{-3} ionic strength at 25±0.1°C by using an ORION digital potentiometer (with an accuracy of 0.1 mV). The measuring electrode was a RADELKIS OP 718 P glass electrode, and the reference electrode was a RADELKIS OP 820 Ag–AgCl electrode. In the electrode the separating electrolyte solution was 0.5 mol dm^{-3} sodium perchlorate. During the experiments 50.0 cm^3 0.01 mol dm^{-3} solutions of the compounds, containing 0.01 mol dm^{-3} perchloric acid, were titrated under a nitrogen atmosphere with

* Author to whom correspondence should be addressed.

0.1 mol dm^{-3} sodium hydroxide also containing 0.4 mol dm^{-3} sodium perchlorate. For the compounds available in larger amount the pH-metric measurements in the presence of metal ions were carried out at two metal : ligand ratios.

The results were evaluated by the least-squares computer program described earlier.[6] The refinements were carried out for the sum of the squares of the residuals of the electromotive forces $[\sum(\Delta E^2)]$. As a characterization of the extent of the fit, the standard deviations (σ) of the electromotive forces are given in the tables: σ (mV) = $\sqrt{\sum(\Delta E^2)/\mathrm{NMP}-\mathrm{NP}-1}$, where NMP denotes the number of measured points and NP the number of parameters to be refined.

For calculation of the protonation and stability constants, the values of $E^{\ominus}$, j_H, j_{OH} and K_W obtained from the blank titration curves were used.[6] Optimization of only the $E^{\ominus}$ values was considered necessary. The parallel measurements and those made at two metal : ligand ratios were evaluated simultaneously by using the individual $E^{\ominus}$ values.

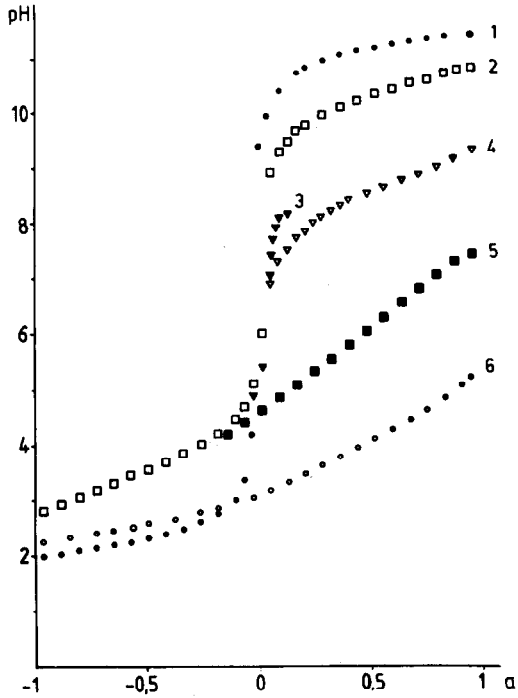

Fig. 1. pH-metric titration of 0.02 mol dm^{-3} *cis*-cyclohexane-β-amino acid in the absence of metal (2), and in the presence of 0.01 mol dm^{-3} Cd^{2+} (3), Ni^{2+} (4), Cu^{2+} (5) and Hg^{2+} (6). 1 is the blank curve.

RESULTS

As typical pH-metric measurements, the titration curves of the cyclohexane *cis* derivative are shown in Fig. 1. The protonation constants of the compounds studied are listed in Table 1. It can be seen that, in some cases, the differences, for both the amino and the carboxyl groups, exceed the experimental errors. The protonation constants of the amino groups (and also the experimental errors) are almost the same as or larger than that for β-alanine (cyclopentane derivatives). With one exception, the protonation constants of the carboxyl groups are lower than that for β-alanine.

The stability constants of the *nickel(II) complexes* are shown in Table 2. In the saturated derivatives, only the formation of two complexes could be

substantiated. Inclusion of a third species definitely made the fit worse. The two unsaturated ligands appear to be slightly better complex-forming agents than β-alanine. Formation of the NiL_2 species can be substantiated unambiguously in these systems, as in the case of β-alanine (Fig. 2B).

The *cis*-cyclohexane derivative and the two unsaturated ligands are evidently better complex-forming agents than β-alanine with the *copper(II)* ion (Table 3). Formation of the CuL_2 species with these ligands and with β-alanine is particularly intensive (Fig. 3). Occasionally, in other systems too, but without exception in the case of copper(II), the distribution curves reveal that the HL species displays two, more or less sharp, maxima[13,14] as a function of pH.

Of the investigated metal ions, *mercury(II)* forms the most stable complexes (Table 4). Except for the *cis*-cyclopentane derivative, all four types of complexes could be substantiated. The distribution curves in Fig. 4 show that hydroxo complex formation is also very important in these systems.

For the *cadmium(II) complexes*, only the stability

constant of the CdL species can be determined. The data in Table 5 reveal that these equilibrium studies do not provide reliable information about he compositions and stability constants of other species formed. Complex formation with *cobalt(II)* and *zinc(II)* ions is very weak too.

DISCUSSION

Protonation constants

Amino group protonation constants larger than that for β-alanine can probably be explained by the fact that, in these compounds, those β-alanine conformations are fixed which favour protonation of the amino nitrogen. The protonation constants of the *cis* derivative of cyclohexane is significantly larger than those of all the other compounds in Table 1. This is certainly a consequence of the repulsive effect of the 4,6-diaxial hydrogens of the ring, which leads to fixing of the amino group in a position such that the non-bonding electron pair on the nitrogen is directed away from the ring, which makes proton bonding much easier. However, the possibility can not be excluded that a hydrogen bond in another position is formed between the protonated amino group and the carboxyl group, resulting in an increase in the protonation constant. The protonation constant of the amino group of the *trans*-cyclohexane derivative, however, is considerably smaller than that of the *cis* isomer, which can be attributed to the screening effect of the neighbouring carboxyl group.

In the cyclopentane and cyclohexene derivatives, the protonation constants of the amino groups are not significantly influenced by whether the functional groups are in the *cis* or the *trans* position. In the cyclohexene derivatives, the slightly larger protonation constants may be due to the molecules being sterically less crowded.

With regard to the protonation constants of the carboxyl groups, that of the *trans*-cyclopentane derivative is the largest, in accordance with expectations. This compound corresponds to the staggered conformation of β-alanine. Due to the free rotation about the C—C bonds, β-alanine exists in many other conformations which are less favourable for proton uptake; the protonation constant of this ligand is almost the average for these processes. The explanation why the stability constants for the other compounds are lower than that of the carboxyl group of β-alanine may be that, in these derivatives, the skew conformation of β-alanine is fixed, which is less favourable for protonation. The equally more inhibited uptake of protons in the cyclohexene derivatives can certainly be attributed to the fact that, due to the flattening of the ring, the difference between the positions of axial and equatorial groups decreases and the configuration formed is even less optimum.

Nickel(II), copper(II) and mercury(II) complexes

Of the examined metal ions, only nickel(II), copper(II) and mercury(II) undergo complex formation to such an extent that the compositions and stability constants of the resulting species can be determined sufficiently accurately to allow reliable conclusions on the complex-forming characteristics of the different β-alanine conformers.

As concerns the stability constants of these metal complexes, primarily coordination of the amino groups occurs; if the position of the carboxyl group and the directions of its non-bonding electron pairs are favourable, stable chelate formation can be assumed. However, the compositions and stabilities of the complexes differ from metal to metal: the complexes of nickel(II) are octahedral, those of copper(II) are square planar, and those of mercury(II) are, in all probability, octahedral.

The σ and the errors in the stability constants presented in Tables 2–4 suggest that there is no need to suppose the formation of more than four complexes to describe any of the examined systems. For β-alanine, with the exception of CuL(OH),[9] only the stability constants of the (1,1,0)* and (1,2,0) complexes have so far been determined.[1–3] Our experiments indicate that, for all three metal ions, the formation of both (1,1,−1) and (1,2,−1) species can be assumed. The tris-β-alanino complexes, however, could not be substantiated in any of the systems.

In general, it is true for the complexes of the investigated ligands [except for the mercury(II) complexes of the two unsaturated ligands] that the *cis*-cyclohexane derivative forms the most stable complexes. This seems somewhat surprising. However, models reveal that the free rotation of the carboxyl group and the positions of the neighbouring hydrogens of the functional groups bring about conditions favourable for chelate formation. In the *trans*-cyclopentane derivative, the substituents are somewhat farther from each other, which results in weaker chelate formation.

Among the examined ligands, the *trans*-cyclohexane derivative appears to be the weakest complex-forming agent. We assume that the reason for this is that the two functional groups are too close,

* The complexes $M_qL_pH_r$ are denoted by (q,p,r).

which is unfavourable for chelate formation. For similar reasons, the analogous cyclopentane derivative also seems a weaker complex-forming agent.

With the two unsaturated ligands, there is no substantial or inexplicable difference between either the two nickel(II) complexes or the two copper(II) complexes. This seems reasonable on the basis of models for, as a consequence of the respective quasi-axial–quasi-equatorial and quasi-diequatorial directions of the valences of the carbon atoms containing functional groups and of the free rotation of the carboxyl group, the ligands can assume configurations in which the distances between the donor atoms are practically the same. Naturally, the orientation of the planes of the cyclohexene rings and those formed by the coordination sphere differ considerably. The difference between the stabilities of the two $(1,1,-1)$ complexes of copper(II) can probably be explained by this. In the *cis*-cyclohexene derivative, one of the ring hydrogens is situated above the z-axis, thereby impeding the formation of the hydroxo complex. The same explanation may be given for the fact that no hydroxo complex formation could be detected for the *trans*-cyclopentane derivative.

The mercury(II) complexes of the two unsaturated ligands differ significantly in behaviour from the other compounds. The fairly large stability constants suggest practically quantitative complex formation, but, since ligand deprotonation during complex formation is also practically quantitative, the difference in stability of the two derivatives can be attributed to the uncertainty in the experimental errors of the pH-metric measurements. The present equilibrium studies do not allow reliable conclusions, but the formation of polynuclear complexes is not considered improbable.

Our equilibrium data alone, of course, are not enough to substantiate all the factors and the extents of their effects in the protonation and complex formation of the examined compounds. The present experiments, however, unambiguously demonstrate that there are well-detectable differences between the protonation constants of the individual β-alanine conformers. It seems that, in the determination of the compositions and stabilities of the nickel(II), copper(II) and mercury(II) complexes, the principal factor is what kind of β-alanine conformer is fixed in each ligand and thus how distant the donor atoms are from each other. The influence of the rings on complex formation seems somewhat less appreciable.

Acknowledgement—We wish to express our gratitude to Mrs Mária Palotai for her valuable help in carrying out the experiments.

Abstract—Chlorogallium(III) porphyrins [Ga(Por)Cl] were obtained in good yield by treating the corresponding free bases with gallium trichloride. The action of the hydrogen halides HX (X = F or I) on chloro derivatives Ga(Por)Cl led to the corresponding halogeno complexes Ga(Por)X. These derivatives were characterized on the basis of mass spectrometry, ^{1}H NMR, and UV–visible data. The crystal structure of the title compound has been determined by X-ray diffraction methods. $C_{44}N_4H_{28}GaCl$ [Ga(TPP)Cl], F_w = 717.9 g, tetragonal, *I*4/*m*, a = 13.508(2) Å, c = 9.846(2) Å, V = 1797(3) Å^3, Z = 2, D_x = 1.326, μ = 11.1 cm^{-1}, $F(000)$ = 736 $\bar{e}$, room temperature, $R(F)$ = 0.044, $R_w(F)$ = 0.049 for 1237 unique reflections. Ga(TPP)Cl is isomorphic to Fe(TPP)Cl: both gallium and chloride atoms are statistically averaged by the crystallographic mirror plane. The gallium–chlorine distance is 2.196(2) Å, whereas the gallium atom lies 0.317(1) Å from the perfect porphyrin plane.

Recently, Wynne[1,2] and Marks[3–6] described the synthesis and characterization of inorganic–organic polymers in which a metallic or pseudometallic element alternates in a linear chain with an atom such as oxygen or dicoordinate fluorine. The metallic or pseudometallic element is always the central atom of a phthalocyanine system and the bridge-stacked polymeric structure is rigid. These derivatives are electrical conductors after iodine oxidation.[7–13] In a preliminary paper,[14] we pointed out a series of similar systems, the large phthalocyanine ring being replaced by a porphyrin ligand. Difference Fourier analysis of EXAFS spectra of the hydroxo and fluorogallium(III)-2,3,7,8,12,13,17,18-octamethylporphyrins [Ga(OMP)OH† and Ga(OMP)F] afforded some evidence for the polymeric structure of the latter complex.[14]

In this paper we report the synthesis and complete description of the Ga(Por)F complexes, and the detailed preparation of the Ga(Por)Cl precursors. The effort below focuses also on the characterization of the Ga(Por)I complexes and on the description of the crystal structure of Ga(TPP)Cl which is, as far as we know, the first X-ray study of a gallium(III) porphyrin.

EXPERIMENTAL

Preparation of complexes

The chloro, fluoro, and iodo complexes were synthesized following a general procedure described below.

* Author to whom correspondence should be addressed.

‡ Abbreviations: Por, unspecified porphyrinate(2−); OEP, 2,3,7,8,12,13,17,18-octaethylporphyrinate(2−); TPP, 5,10,15,20-tetraphenylporphyrinate(2−); OMP, 2,3,7,8,12,13,17,18-octamethylporphyrinate(2−).

Chloro-(porphyrinato) gallium(III). To a solution of porphyrin (9.35 mmol) and $GaCl_3$ (13.7 mmol) in acetic acid (400 cm^3) sodium acetate (61 mmol) was added in acetic acid (25 cm^3). The mixture was refluxed for 12 h, then the resulting solution was cooled down to 0°C and the precipitate obtained was recrystallized. The reaction mixture also contains small amounts of acetato-(porphyrinato) gallium(III).

Fluoro-(porphyrinato) gallium(III). Chloro-(porphyrinato) gallium(III) (80 mmol) was dissolved in 200 cm^3 of methanol. After the addition of 10 cm^3 of an aqueous solution of hydrofluoric acid (40%) the mixture was stirred for 16 h. The excess hydrofluoric acid was removed by vacuum distillation (at 240°C and 2.5×10^{-3} mmHg). The residual precipitate was washed with heptane and cooled methanol, and recrystallized.

Iodo-(porphyrinato) gallium(III). Chloro-(porphyrinato) gallium(III) (80 mmol) was dissolved in 200 cm^3 of toluene and a gentle stream of hydroiodic acid was bubbled through the toluene solution (4 h). After reaction, the solvent was removed under reduced pressure and the residual precipitate was dried at 80°C under 15 mmHg, and recrystallized.

The reaction conditions, yields and elemental analyses for all the complexes are summarized in Table 1.

[a] A = methanol, B = toluene, C = chloroform, D = heptane.
[b] Calculated values are given in parentheses.
[c] X = F, Cl or I.
[d] About 3.5% of the free base is transformed to the corresponding acetato derivative Ga(Por)AcO.

Physical measurements

Elemental analyses were performed by the "Service de Microanalyses du C.N.R.S.". Mass spectra were obtained in the electron-impact mode with a Finnigan 3300 spectrometer; ionizing energy 30–70 eV, ionizing current 0.4 mA, source temperature 250–400°C. ^1H NMR spectra were recorded on a JEOL FX 100 or Bruker WM 400 of the CEREMA ("Centre de Résonance Magnétique" of University of Dijon). Spectra were measured for complex (5 mg) solutions in 0.6 cm^3 of DMSO or $CDCl_3$ with tetramethylsilane as internal reference. IR spectra were recorded on a Perkin–Elmer 580 B apparatus. Samples were prepared as 1% dispersions in CsI pellets or Nujol mulls. Electronic absorption spectra were recorded on a Perkin–Elmer spectrophotometer using 5×10^{-3} mol l^{-1} methanolic solutions.

Crystal and molecular structure determination

A suitable crystal of Ga(TPP)Cl was obtained from recrystallization of the complex in a solution of toluene. Preliminary Weissenberg photographs along the $\vec{c}$ axis revealed a four-fold symmetry and systematic extinction of the type $h+k+l = 2n+1$,

leading to the centrosymmetric space group $I4/m$ and to the non-centrosymmetric $I4$ or $I\bar{4}$ space groups. Experimental conditions and details of the calculations are given in Table 2. The crystal structure was solved by the heavy-atom method, assuming the space group $I4/m$. As observed for Fe(TPP)Cl,[15] the gallium and chlorine atoms are statistically disordered up and below the mirror plane m. The good convergence of the least-squares process confirmed the choice of the space group; furthermore refinements in the $I4$ and $I\bar{4}$ space groups did not improve the convergence results. All the hydrogen atoms were found in difference Fourier maps and added as fixed contributors to the least-squares calculations. The scattering factors were taken from Refs 16 and 17; all non-hydrogen atoms were refined anisotropically. A summary of the least-squares results is given in Table 2. Fractional atomic coordinates, anisotropic thermal parameters and a list of structure factors has been deposited as supplementary data with the Editor, from whom copies are available on request.*

RESULTS AND DISCUSSION

During the last decade gallium(III) porphyrin complexes possessing the axial ligands Cl^-,[18,19] RO^-[20,21] and RCO_2^-[22] have been reported. Two general methods have been used to synthesize the gallium(III) porphyrins: the first one used $Ga(Acac)_2$ for metallation in phenol,[20] and the second $NH_4Ga(SO_4)_2\cdot12H_2O$ in acetic acid.[19] We have prepared the chloro-gallium(III) porphyrins (**1**) by the action of $GaCl_3$ on porphyrins in acetic acid. The complexes **1** were obtained with very satisfactory yields varying from 70 to 90%. Treatment of Ga(Por)Cl (**1**) with HF in methanol and HI in toluene led, respectively, to the fluoro-Ga(Por)F (**2**) and iodo-Ga(Por)I (**3**) derivatives. The yield of the reaction depends on the nature of the axial and equatorial ligands (57–80%).

In most of the mass spectra of complexes **1** and **2**, the molecular peak appears.† Its intensity is very

*Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

† The relative intensity of the peaks $M^{+\cdot}$, $[M+1]^+$ and $[M+2]^+$ is attributable to the abundance of the natural isotopes ^{69}Ga and ^{71}Ga (see Table 3).

high for the chloro and fluoro derivatives and corresponds in a few cases to the parent peak. However for Ga(OMP)F the fragment ion $[M-F+1]^+$ is higher. The same ion $[M-X]^+$ is the most abundant for the iodo complexes **3** while the intensity of the molecular peak is very low (0.32–2.50%) and does not appear for Ga(TPP)I. These data are in good agreement with the more labile character of the metal–iodine bond compared to the metal–fluorine or metal–chlorine bonds. Moreover the typical morphology of the mass spectrum of Ga(OMP)F may be due to a particular coordination scheme when the gallium atom is bound to a planar macrocycle.

Ga(Por)X exhibit electronic absorption spectra belonging to "normal" class[23] (Table 4). They show an intense band in the 395–415-nm region and two bands between 500 and 600 nm (α- and β-bands). One

extra band [$Q(2, 0)$] is observed in the visible region and another one appears blue shifted compared to the Soret band. As previously reported by Gouterman *et al.*[24,25] in tin octaethylporphyrin dihalides (with halide = F, Cl, Br or I), the shifts in the transition energies and relative intensities of the α- and β-bands depend on the charge and polarizability of the axial ligand and correlate with changes in the electron density in the porphyrin ring.

The IR spectra of the whole isolated chloro complexes show one band in the region 330–370 cm^{-1}, assigned to the Ga—Cl stretching (Table 3). This characteristic band is found between 550 and 590 cm^{-1} for the fluoro derivatives, and between 210 and 261 cm^{-1} for the iodo compounds.

^1H NMR characteristics of the Ga(Por)X complexes at ambient temperatures are listed in Table 5. The spectra of Ga(OMP)X give poor structural information since the resonance lines corresponding to the *meso* and methylic protons are two singlets which appear in the same region whatever the nature of X. The bridge-stacked polymeric structure of Ga(OMP)F being demonstrated on the basis of EXAFS spectroscopy,[14] the same arrangement could be postulated for Ga(OMP)Cl and Ga(OMP)I in the solid state. We have also studied NMR characteristics of the gallio-octaethylporphyrin systems. At the same concentration we observe an ABR_3 multiplet for the ethyl groups of Ga(OEP)Cl and Ga(OEP)I which can be explained only by the presence of a non-octahedral monomeric structure.[26,27] In contrast the resonance signal of the methylenic protons of Ga(OEP)F is a quadruplet and these protons have very similar chemical shifts (see Fig. 1). These observations may be consistent with a polymeric structure for Ga(OEP)F similar to that of Ga(OMP)F, the two other complexes 'being pentacoordinate.

At room temperature the resonances of the *ortho* phenyl protons are broad for Ga(TPP)Cl and Ga(TPP)I, and split in a doublet for Ga(TPP)F. This reflects the well-known phenomenon of the restricted rotation of phenyl rings.[18,19,28–31] If the effect of axial ligands on the rate of phenyl ring rotation is not very well established, it is clear that the

chemical-shift difference is higher when the axial ligand is the more electronegative halide (X = F). It thus appears that the coordination polyhedron of the metal does not possess planar symmetry with respect to the porphyrinic plane and the metal should be out of this plane. The above assumptions are confirmed by the X-ray crystal structure of Ga(TPP)Cl.

Figure 2 is an ORTEP view of the molecule and Table 6 gives the bond lengths and angles. The crystal structure is isomorphic to that of Fe(TPP)Cl[15] and Ti(TPP)Br_2.[32] The statistically averaged molecule of *I4/m* symmetry is centered at the origin and at every other lattice point of the unit cell. Hence the coordination polyhedron of the metallic atom is a square pyramid [Ga—N = 2.021(1) Å, Ga—Cl = 2.196(2) Å]. Eaton *et al.*[19] postulated an in-plane position of the gallium atom and a highly distorted macrocycle for the chloro substituted tetraphenylporphyrinate gallium(III). In contrast for Ga(TPP)Cl the metal atom lies 0.317(1) Å from the crystallographically required perfect porphyrin plane. The bond distances and angles in the porphyrinic group are statistically equal to those usually found.

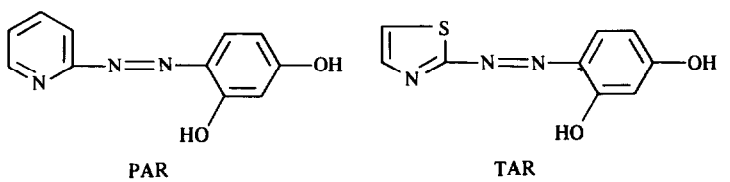
RELATIVE STABILITIES OF METAL COMPLEXES OF 4-(2-PYRIDYLAZO)RESORCINOL AND 4-(2-THIAZOLYLAZO)RESORCINOL

EMIKO OHYOSHI



Yatsushiro National College of Technology, Hirayamashinmachi 2627, Yatsushiro, Kumamoto 866, Japan

(*Received* 10 *September* 1985; *accepted* 23 *October* 1985)

Abstract—The stability constants of 1 : 1 complexes of 4-(2-pyridylazo)resorcinol (PAR) and 4-(2-thiazolylazo)resorcinol (TAR) with Mn(II), Ni(II), Cu(II) and Zn(II) have been determined spectrophotometrically at $\mu = 0.1$ and 25°C. The method is based on indirect estimation of the protonated and normal complexes by measuring the ligand absorption peak. Both protonated and normal complexes of these metals with PAR are more stable than those with TAR. The reverse order was previously observed for the pronated complexes of the lanthanides(III). The different behaviour of the 3*d* transition metals(II) compared to the lanthanides(III) is discussed. The proton dissociation constants of the protonated complexes of PAR or TAR with various metals are also discussed.

The two reagents 4-(2-pyridylazo)resorcinol (PAR) and 4-(2-thiazolylazo)resorcinol (TAR) have the same reactive group (a heterocyclic nitrogen, azo group, and *o*-hydroxyl group as shown in Fig. 1) available for possible coordination to metal ions, and appear to be very similar in character. According to Irving and Rossotti,[1] a linear relation should be obtained between the logarithms of the stability constants for complexes of such a pair of ligands with a series of metal ions. However, no attempt has been made to correlate the stability constants for complexes of PAR with TAR. Both reagents are a dibasic acid and simultaneously form the protonated and the normal type of complexes with most metal ions. Therefore, it is necessary to study such a correlation for complexes of the same type. In general, TAR forms less stable complexes with metal ions than PAR because of the lower basicity of the thiazole rings. From the results previously obtained for the lanthanide complexes of PAR[2] and TAR,[3] this was valid for the normal complexes but the reverse order was observed for the protonated complexes. It is of interest to study the relative stabilities of these complexes with some 3*d* transition-metal ions whose coordination properties are different from those of lanthanide ions. Also of interest is the effect of the complexed metal ions on the acidity of the protonated complexes of PAR or TAR. Corsini *et al.*,[4] who studied the 1 : 2 PAR complexes of some 3*d* transition metals by potentiometry, reported that the order of acidity follows the stability order of the protonated complexes. However, the acidity should be proportional to the relative stability of the normal and the protonated complexes.

In this study, we made a comparison of the

PAR TAR

Fig. 1. Structures of PAR and TAR.

stability of complexes, first of the same type (the normal or the protonated type), formed by PAR and TAR, and, second, of different types, formed by PAR or TAR with some 3*d* transition metals(II) and lanthanides(III).

EXPERIMENTAL

Materials

All chemicals used were of reagent grade. PAR and TAR were obtained from Dojindo Chemical Co., and their purities were checked by using thin-layer chromatography.[5] A weight quantity of PAR or TAR was dissolved in a small volume of 1.0 M NaOH and the solutions were diluted with distilled water to prepare the stock solutions of 2.0×10^{-3} M. Standard metal salt solutions with concentrations of about 0.02 M [Cu(II), Ni(II) or Zn(II)] and 0.1 M [Mn(II)] were prepared from nitrates. The metal solutions were standardized by EDTA titrations using TAR (Cu and Ni), xylenol orange + methylthymol blue (Mn), and xylenol orange (Zn) as indicators. The solutions of various pH values used were mixtures of 0.1 M HNO_3 and 0.1 M $NaNO_3$ at various ratios (pH < 1.5), and 0.1 M $NaNO_3$ buffered with chloroacetate (pH 1.5–3), acetate (pH 4–5), and hexamine (pH 5–7). Complexation between the metal and the buffer ions was neglected under the conditions used.

Procedure

The metal solution was added in small steps, 20–50×10^{-3} cm^3 each, using a microliter pipet, to 10 cm^3 of PAR or TAR solution ($1.5–3.0 \times 10^{-5}$ M) of constant pH, to give concentrations of 10^{-4}–10^{-2} M. Before and after addition of the metal for each $20–50 \times 10^{-3}$ cm^3, the absorbance around the peak of the ligand, which depends on the pH (385–413 nm for PAR and 420–440 nm for TAR), was measured by using a Shimadzu UV 200s spectrophotometer. Each spectrum had a well-defined isosbestic point which varied according to the metal ions used and the pH. No precipitation occurred under these experimental conditions.

RESULTS AND DISCUSSION

Determination of the stability constants

When the ligand, H_2L, such as PAR or TAR, itself has an intense absorption peak, the stability constants of the metal complexes, MHL and ML, can indirectly be estimated by utilizing the ligand absorption peak.[6] The absorbance at the free ligand peak measured in the absence (A_o) and the presence (A) of the metal under conditions where $C_M \gg C_L$ (C_M and C_L are the total concentrations of the metal and the ligand), i.e. formation of the 1 : 1 complexes, MHL and ML, is assumed, can be related to their stability constants, K_{MHL} and K_{ML}, as follows (the charges are omitted for simplicity):

$$C_L = [MHL] + [ML] + [L'], \quad (1)$$

$$A = \varepsilon_{MHL}[MHL] + \varepsilon_{ML}[ML] + \varepsilon_{L'}[L'], \quad (2)$$

where L′ is the free ligand not combined with metal, and ε_{MHL}, ε_{ML} and $\varepsilon_{L'}$ are the molar extinction coefficients of MHL, ML and L′, respectively, at the free ligand peak. With the stability constants, $K_{MHL} = [MHL]/([M][HL])$ and $K_{ML} = [ML]/([M][L])$, the acid dissociation constants of H_2L, $K_1 = [H][HL]/[H_2L]$ and $K_2 = [H][L']/[HL]$, and α-coefficient,[7] $\alpha_L = [L']/[L]$, eqns (1) and (2) can be transformed into the following expressions:

$$[M](K_{MHL}K_1[H] + K_{ML}K_1K_2)/(\alpha_L K_1 K_2) = C_L/[L'] - 1, \quad (3)$$

$$A/\varepsilon_{L'} = [L']\{1 + (\varepsilon_{MHL}K_{MHL}K_1[H] + \varepsilon_{ML}K_{ML}K_1K_2)[M]/(\varepsilon_{L'}\alpha_L K_1 K_2)\}. \quad (4)$$

Combining eqns (3) and (4), and substituting C_M for [M] (since $C_M \gg C_L$) and A_o for $C_L\varepsilon_{L'}$, we obtain:

$$\frac{K_{MHL}K_1[H] + K_{ML}K_1K_2}{\alpha_L K_1 K_2} - \frac{\varepsilon_{MHL}K_{MHL}K_1[H] + \varepsilon_{ML}K_{ML}K_1K_2}{\varepsilon_{L'}\alpha_L K_1 K_2} \times \frac{A_o}{A} = (A_o/A - 1)/C_M. \quad (5)$$

From eqn (5), a linear relation between $(A_o/A - 1)/C_M$ and A_o/A should be obtained at a constant pH where $\varepsilon_{L'}$ remains constant. The product of the intercept of the *y*-axis [$y = (A_o/A - 1)/C_M$], y_o, at a fixed pH and $\alpha_L K_1 K_2$ is given as a function of [H]:

$$y_o \times \alpha_L K_1 K_2 = K_{MHL}K_1[H] + K_{ML}K_1K_2. \quad (6)$$

If a protonated ligand species, H_3L, is formed at low pH values, eqn (6) can be written as:

$$\alpha_L K_o K_1 K_2 y_o = K_{MHL}K_o K_1[H] + K_{ML}K_o K_1 K_2, \quad (7)$$

where $K_o = [H][H_2L]/[H_3L]$. According to eqn (6) or (7), a linear plot of the left-hand side of eqn (6) or (7) vs [H] should be obtained in a pH range where no hydrolysis of the metal ion occurs. From the slope and the intercept of the line, both

K_{MHL} and K_{ML} values can be determined. In this experiment, we used PAR (H_2P) or TAR (H_2T) as the ligand, H_2L, and Mn(II), Ni(II), Cu(II) or Zn(II) as the metal.

Under conditions where $C_M \gg C_L$, the pH ranges had to be greatly varied from metal to metal to give an observable decrease in the absorbance of the ligand peak with increasing C_M. The pH values were 5.5–6.4 (Mn), 4.2–5.5 (Zn),[6] 2.1–2.5 (Ni) and 1.2–1.7 (Cu) for the PAR complexes, and 6.5–7.1 (Mn), 5.3–6.0 (Zn), 4.2–4.7 (Ni) and 1.5–2.2 (Cu) for the TAR complexes. The results of the plots according to eqn (5) for the Cu(II)–TAR and the Mn(II)–PAR system are shown in Fig. 2. Similar linear plots with a negative slope were obtained for all the other systems studied. To confirm the value of the intercept (y_o) we tried to plot the data at another wavelength around the ligand peak and obtained a line having the same intercept (the slope is different).

To determine the stability constants of MHL and ML complexes we plotted the relationship expressed by eqn (6) or (7). The values, $pK_o = 2.69$, $pK_1 = 5.50$ and $pK_2 = 12.30$[8] for PAR, and $pK_o = 0.98$, $pK_1 = 6.23$ and $pK_2 = 9.44$[9] for TAR, were used for calculation of $\alpha_L K_o K_1 K_2$ or $\alpha_L K_1 K_2$. All the plots exhibited straight lines, some of which had intercepts but others passed through the origin. This indicates that both MHL and ML complexes exist in the former group, including the Mn–PAR, the Mn–TAR and the Zn–TAR system, but there is only the MHL complex in the latter, including the Ni–PAR, the Ni–TAR, the Cu–PAR and the Cu–TAR system. By use of the least-squares method, the stability constants, both K_{MHL} (slope) and K_{ML} (intercept) for the former group, but only K_{MHL} (slope) for the latter group, were determined.

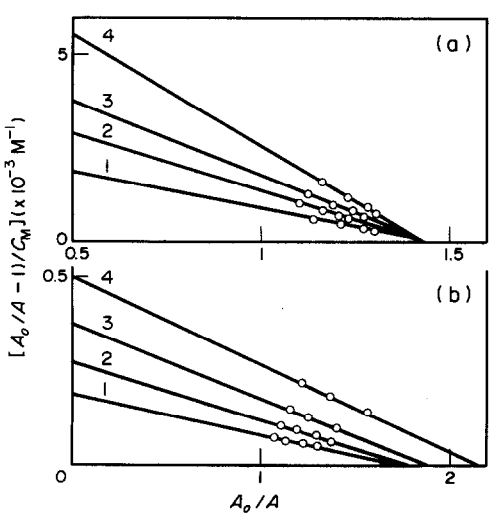


Fig. 2. Plots according to eqn (5) at different pH values for the Cu–TAR (a) and Mn–PAR (b) systems: (a) pH 1.56 (1), 1.70 (2), 1.83 (3), and 1.94 (4); (b) pH 5.73 (1), 5.89 (2), 6.16 (3), and 6.37 (4).

To obtain K_{ML} for the latter group, we studied the acid–base equilibrium: MHL = ML+H. The solution involving only the MHL complex was used for this study. The spectral changes of the solution with increasing pH showed a well-defined isosbestic point in each system. The analysis of the data gave the proton dissociation constant of MHL, K^H_{MHL}, from which K_{ML} could be calculated by eqn (8):

$$K_{ML} = K_{MHL} K^H_{MHL} / K_2. \quad (8)$$

This equation is also used to obtain K^H_{MHL} for the former group. The values of K_{MHL}, K_{ML} and K^H_{MHL} are listed together with those previously obtained for the PAR–Zn complexes,[6] and the PAR[2,6]– and TAR[3]–lanthanide complexes in Table 1. The values for the PAR–Cu complexes and the TAR–Cu and TAR–Ni complexes obtained here are in good agreement with those reported in the literature.[9–11]

Relationship between stabilities of PAR (H_2P) and TAR (H_2T) complexes

The stabilities of complexes of the same type (ML or MHL), formed by a similar pair of ligands, H_2P and H_2T, with two different series of metal ions are compared by plotting log K_{MP} vs log K_{MT} or log K_{MHP} vs log K_{MHT} (Figs 3 and 4). For both types of complexes, the plots yield two separate lines, respectively, one for the transition metals and the other for the lanthanides. This suggests that there would be a clear difference in the coordination mode of these ligands toward the two series of metal complexes.

Irving and Rossotti[1] derived the theoretical relationship between the logarithms of the stability constants for metal complexes of a similar pair of ligands, A and B, as follows:

$$\log K_{MA} = \log K_{MB} + (\log K_{HA} - \log K_{HB}). \quad (9)$$

This equation is based on the assumption that the term including the partial molar free energy of each species S, denoted $\bar{G}^o_S$, $1/RT\{(\bar{G}^o_{MB} - \bar{G}^o_{MA}) - (\bar{G}^o_{HB} - \bar{G}^o_{HA})\}$, and the term including the activity coefficient can be neglected when ligands A and B are similar in character. For PAR and TAR in this study, there are two possible forms of the proton ligand complexes, H_3L^+ and H_2L. Thus, the following equations corresponding to eqn (9) will be given for the normal [eqn (10) or (11)] and the protonated [eqn (12) or (13)] complexes:

$$\log K_{MP} = \log K_{MT} + (\log K_{H_3P} K_{H_2P} K_{HP} - \log K_{H_3T} K_{H_2T} K_{HT}), \quad (10)$$

Table 1. Stability constants, K_{MHL} and K_{ML}, and proton dissociation constants of MHL, K^{H}_{MHL}, for metal complexes of 4-(2-pyridylazo)resorcinol (PAR) and 4-(2-thiazolylazo) resorcinol (TAR) ($\mu = 0.1$, 25°C)[a]

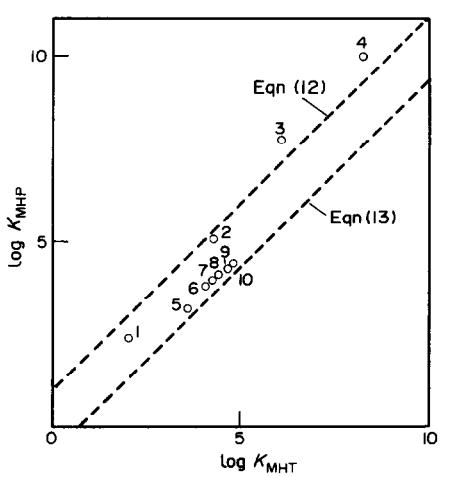

Fig. 4. Relationship between the stability constants for the protonated type of metal complexes with PAR (K_{MHP}) and TAR (K_{MHT}). (1) Mn, (2) Zn, (3) Ni, (4) Cu, (5) La, (6) Ce, (7) Pr, (8) Nd, (9) Sm–Tm, and (10) Yb, Lu.

$$\log K_{MP} = \log K_{MT} + (\log K_{H_2P}K_{HP} - \log K_{H_2T}K_{HT}), \quad (11)$$

and

$$\log K_{MHP} = \log K_{MHT} + (\log K_{H_3P}K_{H_2P} - \log K_{H_3T}K_{H_2T}), \quad (12)$$

$$\log K_{MHP} = \log K_{MHT} + (\log K_{H_2P} - \log K_{H_2T}), \quad (13)$$

where K_{H_3P}, K_{H_2P} and K_{HP} are the protonation constants of H_2P, HP and P, and K_{H_3T}, K_{H_2T} and K_{HT} are those of H_2T, HT and T. These equations are based on the following assumptions:

$$1/RT\{\bar{G}^o_{MT} - \bar{G}^o_{MP} - (\bar{G}^o_{H_3T} - \bar{G}^o_{H_3P})\} \simeq 0 \text{ [eqn (10)]},$$

$$1/RT\{\bar{G}^o_{MT} - \bar{G}^o_{MP} - (\bar{G}^o_{H_2T} - \bar{G}^o_{H_2P})\} \simeq 0 \text{ [eqn (11)]},$$

$$1/RT\{\bar{G}^o_{MHT} - \bar{G}^o_{MHP} - (\bar{G}^o_{H_3T} - \bar{G}^o_{H_3P})\} \simeq 0 \text{ [eqn (12)]},$$

$$1/RT\{\bar{G}^o_{MHT} - \bar{G}^o_{MHP} - (\bar{G}^o_{H_2T} - \bar{G}^o_{H_2P})\} \simeq 0 \text{ [eqn (13)]},$$

and the term including the activity coefficients $\simeq 0$. The theoretical relationships between log K_{MP} and log K_{MT} given by eqn (10) or (11), and those between log K_{MHP} and log K_{MHT} given by eqn (12) or (13) are shown by dotted lines in Figs 3 and 4, respectively.

For the normal complexes, as is seen in Fig. 3, the experimental points for the transition metals and the lanthanides fall closely on the theoretical lines of eqns (10) and (11), respectively. Although the data points somewhat deviated from the theoretical lines (Fig. 4), eqns (12) and (13) can be applied to the protonated complexes of the transition metals and lanthanides, respectively. From these facts, the stabilities of the two series of metal complexes are found to be related to the stabilities of each of the two forms of proton–ligand complexes (H_3L^+ and H_2L), i.e. the heterocyclic nitrogens of the ligands are coordinated to the transition metals but not to the lanthanides. Thus, both PAR and TAR act as a tridentate ligand (a heterocyclic nitrogen, azo nitrogen, and *o*-hydroxyl oxygen) for the transitions metals as indicated by Geary *et al.*,[8] but as a bidentate ligand for the lanthanides.

Relationship between stabilities of normal and protonated complexes of PAR (H_2P) or TAR (H_2T)

A comparison was made of complexes of a pair of ligands, P and HP, or T and HT, with various metal ions. Although the individual complexes of both pairs of ligands differ in stability from metal to metal the values of K_{MP}/K_{MHP} or K_{MT}/K_{MHT} are relatively close together. This indicates a linear relationship between log K_{MP} and log K_{MHP}, or log K_{MT} and log K_{MHT}. If we can assume that:

$$1/RT\{\bar{G}^o_{MHP} - \bar{G}^o_{MP} - (\bar{G}^o_{H_2P} - \bar{G}^o_{HP})\} \simeq 0,$$

$$1/RT\{\bar{G}^o_{MHT} - \bar{G}^o_{MT} - (\bar{G}^o_{H_2T} - \bar{G}^o_{HT})\} \simeq 0,$$

and the term including the activity coefficients $\simeq 0$, the theoretical relationships for both systems are given by eqns (14) and (15):

$$\log K_{MP} = \log K_{MHP} + \log K_{HP} - \log K_{H_2P}, \quad (14)$$

$$\log K_{MT} = \log K_{MHT} + \log K_{HT} - \log K_{H_2T}. \quad (15)$$

Plots of log K_{MP} vs log K_{MHP} or of log K_{MT} vs log K_{MHT} are shown in Fig. 5 together with the theoretical (dotted) lines. The experimental points, with the exception of the Cu(II)–TAR system, lie near the theoretical lines, although most of them for the PAR complexes are in positions somewhat lower than the lines. There is a small but significant effect of the complexed metal ion on the acidity of the protonated complexes (the K^H_{MHL} value in Table 1 which is proportional to the K_{ML}/K_{MHL} value), i.e. the effect increases with increasing the π-bonding tendencies for the transition metals or increasing the charge densities for the lanthanides. The largest effect is observed for Cu(II) which is able to form a stable π-bond with an aromatic nitrogen.[12,13]

In conclusion, the theoretical relationship between the stabilities for complexes of a similar pair of ligands, PAR and TAR, can generally be applied to understand the coordination mode of the ligands toward different series of metal ions.

SEMI-EMPIRICAL EVALUATION OF MOLECULAR-ORBITAL PARAMETERS, AND SPIN–ORBIT, DIPOLAR AND FERMI-CONTACT TERMS OF VO^{2+} ION IN LATTICES

M. SALAGRAM,*† N. SATYANARAYANA and S. RADHAKRISHNA

Department of Physics, Indian Institute of Technology, Madras 6000036, India

(*Received* 13 *May* 1985; *accepted* 31 *October* 1985)

Abstract—The ESR spectra of the VO^{2+} ion doped in oxalate, tartrate and cadmium crystals taken in the polycrystalline form are analysed. The transition energies ΔE_1 and ΔE_2 obtained from the electronic absorption spectra of the VO^{2+}-doped single crystals in conjunction with the spin-Hamiltonian parameters obtained from ESR data are used to evaluate the spin–orbit coupling constant, the dipolar term and the Fermi-contact term. The bonding coefficient β_2^2 is evaluated from the available molecular-orbital theories and the experimental data. The various terms evaluated are correlated and the general behaviour of the VO^{2+} ion in various ligand fields of different symmetries is discussed.

When paramagnetic radicals or ions are fixed but randomly oriented in a powder sample, the ESR spectrum will consist of an envelope of the absorptions at all possible orientations of the species.[1] Thus, ESR studies on polycrystalline samples are expected to provide valuable information, such as the nature of the g- and A-tensors of the paramagnetic ion in a given environment. The quantitative data obtainable from the ESR spectra of polycrystalline samples together with the electronic absorption data is generally sufficient to calculate important molecular-orbital (MO) parameters which, besides the single-crystal data, throw further light on the ligand environment and its effect on the electronic structure of the paramagnetic ion embedded in a crystal.

The method of evaluation of the spin–orbit coupling constant (λ), the Fermi-contact term (K), the bonding (β_1^2 and β_2^2) and other parameters for the vanadyl (VO^{2+}) ion using a semi-empirical MO approach is reported in the present paper. The approach itself is based on the crystal field[2,3] and MO theories[4,5] proposed so far to explain the electronic structure of the VO^{2+} ion.

The lattices chosen for the study were: potassium oxalate monohydrate (POMH), $K_2C_2O_4 \cdot H_2O$; ammonium oxalate monohydrate (AOMH), $(NH_4)_2C_2O_4 \cdot H_2O$; potassium hydrogen oxalate (PHO), KHC_2O_4; $3CdSO_4 \cdot 8H_2O$; cadmium ammonium sulphate hexahydrate (CdASH), $Cd(NH_4)_2(SO_4)_2 \cdot 6H_2O$; cadmium potassium sulphate hexahydrate (CdKSH), $CdK_2(SO_4)_2 \cdot 6H_2O$; and strontium tartrate tetrahydrate (SrTrTH), $SrC_4H_4O_6 \cdot 4H_2O$. The electronic (optical) absorption and ESR studies on the VO^{2+} ion doped in all the above single crystals were carried out by the authors and either have already been published[6–8] or are in the process [9–12] of publication.

The discussion of the parameters for the VO^{2+} ion calculated from such a variety of crystalline matrices is not only expected to correlate the optical absorption and ESR data on single crystals but also expected to lead to many important conclusions about covalency effects, hydrogen bonding effects and ligand field effects on the VO^{2+} ion. The magnitudes of the parameters and the corresponding conclusions reported in this paper would serve as a cross-check on the consistency of single-crystal data while establishing the general characteristic pattern of the electronic and paramagnetic behaviour of the VO^{2+} ion in various host environments.

EXPERIMENTAL

Crystals of POMH, AOMH, $3CdSO_4 \cdot 8H_2O$, CdASH and CdKSH doped with VO^{2+} were grown

* Author to whom correspondence should be addressed.

† Present address: Department of Physics, P. G. College of Science, Saifabad, Osmania University, Hyderabad 500004 (A.P.), India.

by a slow-evaporation method from their respective saturated solutions consisting of 1–2% by weight of $VOSO_4 \cdot 5H_2O$. PHO crystals were grown similarly from a solution containing equivalent amounts of potassium oxalate and oxalic acid and 1% by weight of $VOSO_4 \cdot 5H_2O$. SrTrTH crystals doped with VO^{2+} ions (2% by weight) were grown by a "gel" method.[12]

The crystals were crushed and ground into fine powder and separately taken in thin quartz tubes. The ESR spectra of each of the above polycrystalline samples were recorded at 300 or 77 K on a Varian E-4 X-band spectrometer. The optical absorption spectra were recorded using a Cary-14 spectrophotometer.

RESULTS AND DISCUSSION

ESR spectra

The ESR spectra of VO^{2+}-doped AOMH, PHO, CdASH, CdKSH and SrTrTH polycrystalline samples exhibit the expected 16 lines corresponding to the usual parallel and perpendicular components of g- and hyperfine (hf) A-tensors. As a typical representative, the ESR spectra of VO^{2+}-doped CdASH polycrystalline samples is shown in Fig. 1. It can be seen that the parallel and perpendicular components are well-resolved.

All these spectra suggest the characteristic behaviour of the VO^{2+} ion. The ion exhibits only one 16-line pattern in any polycrystalline sample irrespective of the number of substitutional or interstitial[6–12] sites that it actually occupies in the single crystal, provided all the sites are chemically equivalent. The pattern suggests that g and A are axially symmetric in nature. Despite the general resemblance in the ESR spectra, the small variations in the magnitudes of the principal components of g and A (Table 1) are indicative of a sensitive behaviour of VO^{2+} in different ligand field environments. In Table 1, VO^{2+} data for $Zn(NH_4)_2(SO_4)_2 \cdot 6H_2O$ (ZASH)[13] and $NH_4Al(SO_4)_2 \cdot 12H_2O$ (alum)[14] crystals are included as typical examples for comparison[15] with the present data.

Figure 2 shows the first derivative ESR spectrum of VO^{2+}-doped POMH polycrystalline samples recorded at 77 K. In contrast to the typical spectra observed in other lattices, the spectrum does not give a simple picture of $g_\parallel$ and $g_\perp$, and $A_\parallel$ and $A_\perp$, but exhibits the rhombic nature of g- and A-tensors in conformity with the results obtained from single-crystal studies.[6]

Similarly, the ESR spectrum of VO^{2+}-doped

$3CdSO_4 \cdot 8H_2O$ polycrystalline samples shown in Fig. 3 is again different not only from the typical spectra but also from that of POMH : VO^{2+} shown in Fig. 2. Although, the usual 16-line pattern is obvious, the distinct resolution in the extreme lines (Fig. 3) shows that two chemically inequivalent sites for VO^{2+} are present in the lattice and each of them exhibit axially symmetric g- and A-tensors in conformity with single-crystal data. The spin-Hamiltonian parameters derived from all the spectra are given in Table 1. A further justification of the observed $\tilde{g}$ and $\tilde{A}$ can be given in terms of bonding coefficients and other MO parameters computed from these experimental data.

Electronic absorption spectra

The electronic absorption spectra of VO^{2+} in all the present lattices have been reported.[6–12] They reveal a variety of behaviour for the VO^{2+} ion in the lattices. A typical representative spectrum observed in PHO : VO^{2+} is shown in Fig. 4. The spectra in the cases of AOMH, PHO, CdASH,

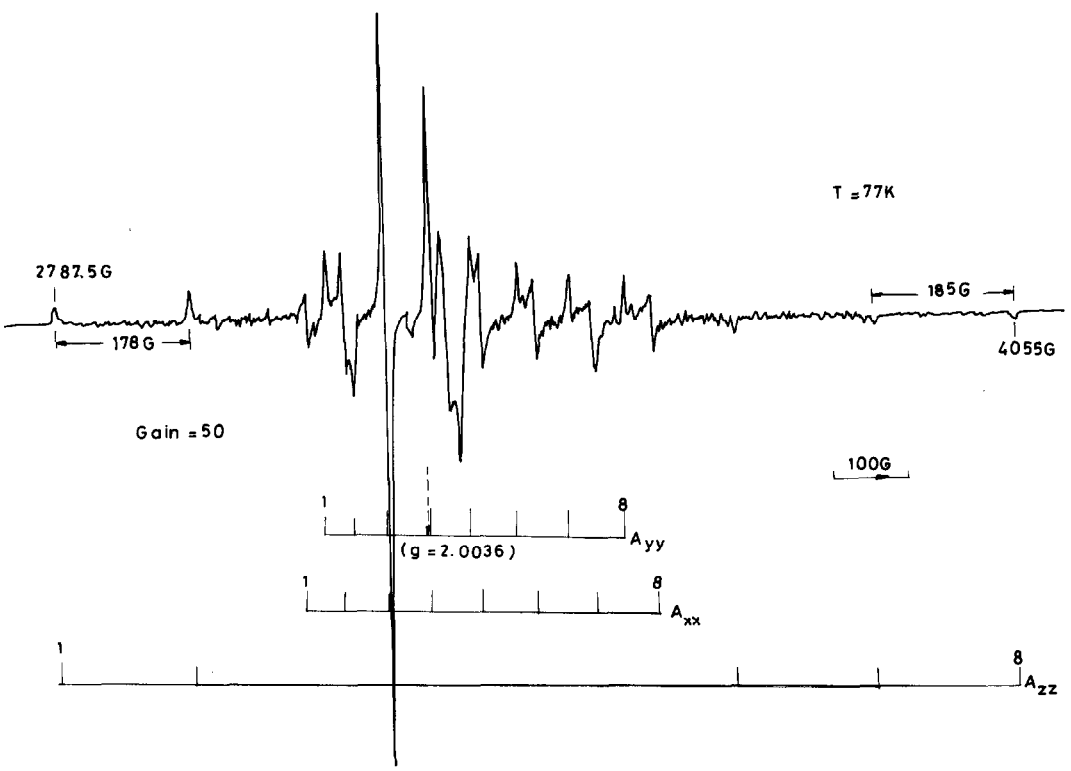

Fig. 2. EPR spectrum of VO^{2+}-doped $K_2C_2O_4 \cdot H_2O$ polycrystalline sample recorded at 77 K.

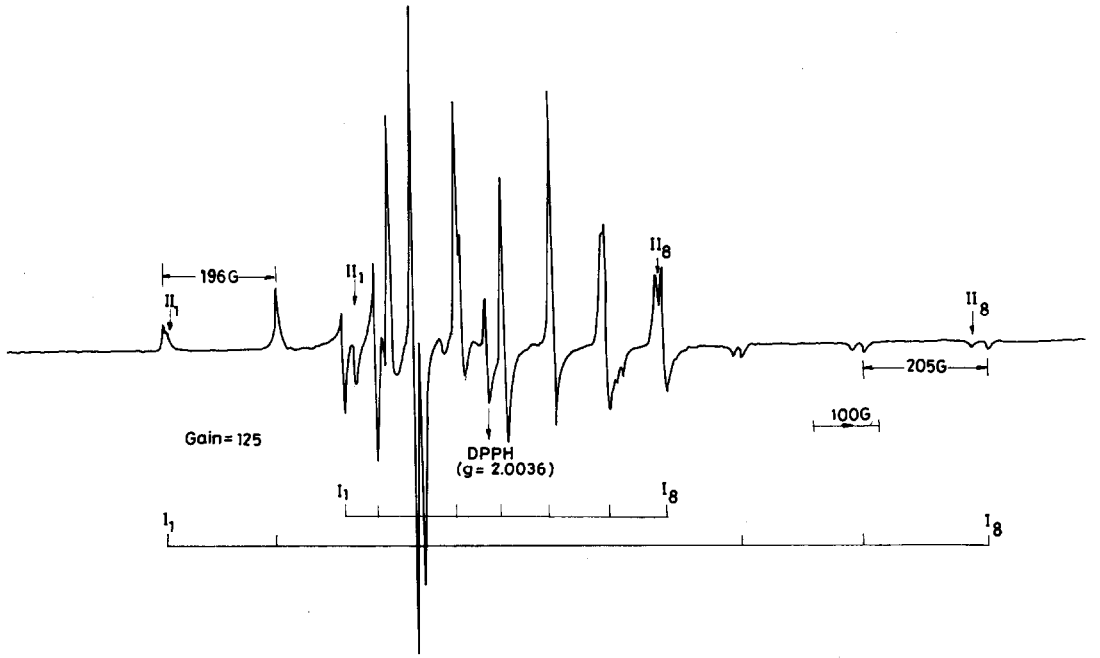

Fig. 3. EPR spectrum of VO^{2+}-doped $3CdSO_4 \cdot 8H_2O$ polycrystalline sample recorded at 300 K.

CdKSH and SrTrTH are generally similar, however, with individual variations in the band positions and their intensities. The variations cause differences in the magnitudes of the transition energies (given in Table 2) which, in turn, affect the bonding and MO parameters computed from these data.

Interestingly, the optical absorption spectrum[6] of POMH : VO^{2+} is entirely different from the spectra of the above samples and suggests a low-symmetry (C_2) site for VO^{2+}. Similarly, the site symmetry of VO^{2+} in $3CdSO_4 \cdot 8H_2O$ as determined by polarization studies[9] is also C_2, although the actual band positions are different.

Calculation of λ

The VO^{2+} ion consists of a single unpaired electron (d^1-system) in a non-degenerate ground state d_{xy}, and it is expected[16] for the ion that $g_\parallel < g_\perp$. The principal parameters evaluated from single-crystal and polycrystal (ESR) spectra of all the present lattices show (Table 1) that $(g_{zz})g_\parallel < g_\perp(g_{xx}, g_{yy})$. Assuming pure d-orbitals and using first- and second-order perturbation theory, the spin-Hamiltonian parameters can be related to the transition energies:

$$\Delta E_1(d_{xy} \rightarrow d_{x^2-y^2} \quad \text{or} \quad b_2 \rightarrow b_1^*)$$

and

$$\Delta E_2(d_{xy} \rightarrow d_{xz}, d_{yz} \quad \text{or} \quad b_2 \rightarrow e_\pi^*)$$

by the expressions:

$$g_\parallel = g_e - \frac{8\lambda}{\Delta E_1} \quad \text{and} \quad g_\perp = g_e - \frac{2\lambda}{\Delta E_2}, \qquad (1)$$

where g_e is the free-electron "g" value, i.e. 2.0023. Using the values of ΔE_1 and ΔE_2 (Table 2) derived from the optical absorption spectra, and g parameters from Table 1, λ values have been evaluated and are included in Table 2.

A value for λ of 250 cm^{-1} is reported[17] for the free V^{4+} ion. The reduction in the magnitude of λ for the double bonded oxovanadium (molecular) complex $(V{=}O)^{2+}$ is attributed to substantial π-bonding. Kivelson and Lee[18] have theoretically predicted a value of 170 cm^{-1} for λ for C_{4v}-symmetry. While the λ values in most lattices of the present work (Table 2) are within reasonable limits of predicted value, the reduction in λ for the VO^{2+} ion in some lattices has to be accounted for in terms of the individual structural natures of the compounds.

In POMH, where $\lambda = 86.3$ cm^{-1}, the VO^{2+} ion is at a very low symmetry site. In CdASH, where $\lambda = 85$ cm^{-1}, the VO^{2+} ion replaces a large-size Cd^{2+} ion relative to the Zn^{2+} ion in ZASH and the ligand oxygens of water molecules about the Cd^{2+} ion are in a different arrangement from those of other tutton salts.[19] In SrTrTH, where $\lambda = 86$ cm^{-1}, the oxygen ligands forming a distorted octahedron are bonded to either water hydrogens or carbon atoms.[20] In all such cases of low-symmetry ligand fields and covalency effects arising from hydrogen bonding, eqn (1) cannot be applied rigorously, hence the reduction in the λ value. These effects are also reflected in the magnitudes of the g- and A-parameters with a bearing on the MO coefficients and bonding parameters which are calculated in the following sections.

Sign of hf coupling constant and calculation of P

The expressions for the hf interaction constant are given[21] by:

$$A_\parallel = -P\left(\frac{4}{7} + K + \frac{3}{7}\frac{\lambda}{\Delta E_1}\right), \qquad (2a)$$

$$A_\perp = P\left(\frac{2}{7} - K - \frac{3}{14}\frac{\lambda}{\Delta E_1}\right), \qquad (2b)$$

where $P = 2\gamma\beta\beta_N\langle r^{-3}\rangle$.

In eqn (2), P is the direct dipolar term which takes into account the dipole–dipole interaction of the electron moment with the nuclear moment, and K is the Fermi-contact term representing the unpaired electron density at the vanadium nucleus. Watson[22] has calculated the $\langle r^{-3}\rangle$ value to be 3.67 Å U for the d^1-electron in V^{4+} and this gives a value for P of 171.2 G.

Solving eqn (2a) and (2b), the expression for P is

given by:

$$P = \frac{7(A_\parallel - A_\perp)}{2 + \frac{3}{2}\frac{\lambda}{\Delta E_1}}. \quad (3)$$

Neglecting the second-order effects and taking negative values for $A_\parallel$ (or A_{zz}) and $A_\perp$ [or $(A_{xx}+A_{yy})/2$], the P values are calculated from eqn (3) for the data in the present work and are given in Table 3. If $A_\parallel$ is taken to be negative and $A_\perp$ positive, the P value will be more than 270 G, which is far from the expected value. Thus, the signs of both $A_\parallel$ and $A_\perp$ are taken as negative and are indicated in Table 2 in the form of the isotropic hf constant (A_o) (*vide infra*). The value of P was theoretically calculated to be +136 G by McGarvey for vanadyl complexes.[23] The calculated P values (Table 3) do not deviate much from this expected value and the values for ΔE_1 seem to be justifiable in this case.

Calculation of MO coefficients and bonding parameters

ΔE_1 is dependent on the σ- and π-donor strength of the in-plane ligands while ΔE_2 reflects the difference between the in-plane and the axial ligand π-bonding to vanadium in a vanadyl complex.[24] The deviations in ΔE_1 and ΔE_2 values are accountable in terms of MO bonding coefficients for the VO^{2+} ion and such an analysis was made by Ballhausen and Gray[4] (BG) using the LCAO–MO method. The method of description of the magnetic properties of the complexes such as $VO(H_2O)_5^{2+}$ involves the evaluation of the matrix elements between the ground state of symmetry $^2B_2$ and antibonding orbitals of symmetry $^2B_1$ and ^2E. The LCAO–MO wave functions for these orbitals are:[4,25]

$$|^2B_2\rangle = \beta_2|d_{xy}\rangle - \beta_2'\langle\theta_{b_2}\rangle, \quad \text{ground state}$$

$$|^2B_1\rangle = \beta_1|d_{x^2-y^2}\rangle - \beta_1'\langle\theta_{b_1}\rangle, \quad (4)$$

$$|^2E\rangle = e_\pi|d_{xz}\rangle - e_\pi'\langle\theta_x\rangle \quad \text{and} \quad e_\pi|d_{yz}\rangle - e_\pi'\langle\theta_y\rangle,$$

where d-functions represent the metal orbitals and the group orbitals are given by ligand θ-functions of appropriate symmetry.

The g values observed so far for most vanadyl complexes are generally lower than 2.0023 and the ESR data in the present work (Table 1) also support this observation. This lowering is related to the spin–orbit interaction of the ground-state d_{xy}-level with low-lying excited states. The interaction is given by[26] the following first-order expressions:

$$g_e - g_\parallel = 8\beta_1^2\beta_2^2\lambda/\Delta E_1, \quad (5a)$$

$$g_e - g_\perp = 2\beta_2^2 e_\pi^2\lambda/\Delta E_2. \quad (5b)$$

The isotropic and anisotropic g and A parameters are related by the equations:

$$A_o = (A_\parallel + 2A_\perp)/3 \quad \text{or} \quad (A_{zz}+A_{xx}+A_{yy})/3, \quad (6)$$

$$g_o = (g_\parallel + 2g_\perp)/3 \quad \text{or} \quad (g_{zz}+g_{xx}+g_{yy})/3. \quad (7)$$

The hf coupling constants are related to P and to an indirect dipolar interaction caused by the anisotropy in g values. Neglecting small corrections, the expressions are:

$$A_\parallel = -PK - \frac{4}{7}\beta_2^2 P - (g_e - g_\parallel)P - \frac{3}{7}(g_e - g_\perp)P, \quad (8)$$

$$A_\perp = -PK + \frac{2}{7}\beta_2^2 P - \frac{11}{14}(g_e - g_\perp)P. \quad (9)$$

Combining eqns (8) and (9) with (6) and (7) gives

Table 3. Calculated values of the dipolar term (P), Fermi-contact term (K) and molecular-orbital coefficient (β_2^2) for the VO^{2+} ion in various lattices

Host lattice	Ligands	P (G)	K	β_2^2	Reference

$NH_4Al(SO_4)_2 \cdot 12H_2O$	H_2O	135.7	0.77	0.945	14

the expression:

$$A_o = -PK-(g_e-g_o)P. \quad (10)$$

Because of the various approximations made in all these equations, highly accurate values for bonding coefficients are not expected. Only the relative values and the order of the molecular parameters are important and the results reported here are more qualitative than quantitative in nature. Combining eqns (8) and (9), and eliminating K, one arrives at the following expression for β_2^2:

$$\beta_2^2 = (A_\perp - A_\parallel)\frac{7}{6P} - \frac{3}{4}g_e + \frac{7}{6}g_\parallel - \frac{5}{12}g_\perp. \quad (11)$$

Thus, β_2^2 can be computed in terms of the empirical data, taking $A_\parallel$ and $A_\perp$ to be negative (from Table 1). The expression for K, from eqn (10), is:

$$K = -\frac{A_o}{P} - (g_e - g_o), \quad (12)$$

and thus K can be evaluated from the data given in Tables 1 and 4. The calculated values of β_2^2 and K for the present data are given in Table 3 along with the ligands of the VO^{2+} ion.

McGarvey[23] also evaluated the β_2^2 using slightly different spin-Hamiltonian parameters for vanadyl-doped crystals and the values are close to the values obtained in the present work. The β_2^2 value is nearly constant and close to unity. This suggests that the ground-state b_2-orbital is non-bonding, as predicted by BG theory.[4]

Correlation between the evaluated parameters

Since the ligands in all the matrices chosen for the present work are only oxygens either non-bonded or bonded to water-hydrogen or carbon atoms, the properties like electronegativity, π-bonding ability, crystal field strength etc. are nearly the same for all the ligands. Precisely for this reason the variation in the g-parameter in various lattices (Table 1) is really insignificant. However, the variation in the hf parameter. A is significant establishing that the electron–nuclear hf interaction is influenced much more by any slight change in the ligand environment (like in the POMH:VO^{2+} system[6]) than the electron–Zeeman or fine-structure interaction.

Relation between K *and hf interaction term* A_o. The isotropic contact term K is a parameter representing the isotropic Fermi-type interaction between electronic and nuclear spins. K is an independent property of the central ion and it serves as a check on the experimental results.[26]

From eqn (12) we find that K is proportional to A_o. Consistent with this fact, it is found that K is lowest for POMH, for which A_o is also the lowest (Tables 1 and 3). For other lattices, A_o and K are proportionately higher. Figure 5 gives a plot of K vs A_o which is a straight line in agreement with eqn (12).

The relation between K and hf interactions of paramagnetic ions has been the subject of many studies.[15,26] If the unpaired electron is not confined to the vanadium nucleus, contact with the metal nucleus is reduced and this causes a smaller hf interaction. Then, the origin of K should be an indirect process. It was first postulated by Abragam *et al.*[27] and later by others[23,26] that the unpaired electrons in the d-orbitals polarize the inner s-shell electrons. McGarvey[23] has shown that the single electron in the d_{xy}-orbital of the d^1 (VO^{2+}) system polarizes the electrons in the filled $2s$ and $3s$ orbitals, thereby creating a finite spin-density at the vanadium nucleus.

Relation between K *and* β_2^2. The value of K is directly proportional to the d-orbital population for

the unpaired electron according to the equation:

$$K = (\beta_2^2)K_o, \tag{13}$$

where K_o is the free-ion polarization. A plot of β_2^2 vs K is shown in Fig. 6, and is almost a straight line passing through the origin, conforming to eqn (13). Some of the points do not lie exactly on the line and the scatter indicates the possible deviations due to

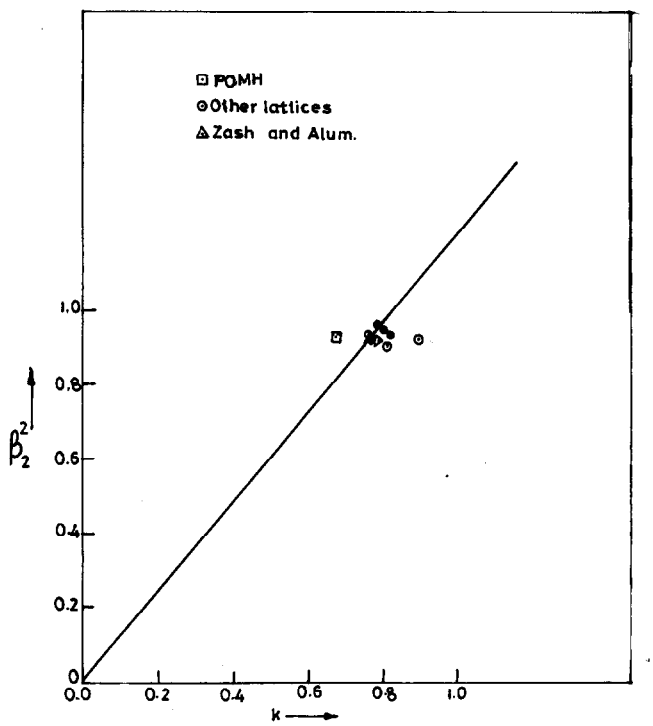

Fig. 6. Plot of bonding coefficient (β_2^2) vs Fermi-contact term (K).

the second-order contributions to K together with probable inadequacies in the existing theories (*vide infra*).

While K is lowest for POMH, the β_2^2 values are nearly the same for all the lattices (Table 3) and close to unity, indicating that the delocalization of electrons is not great and, hence, the π-bonding ability of the oxygen ligands is poor. Thus VO^{2+} in POMH is less covalently bonded than the overestimated covalency predicted by the BG theory.[4] In that case, the major change in K must be due to either the $4s$ σ-bonding effect or d_{xy}, $4s$ mixing. In low-symmetry vanadyl complexes, it is believed[23] that the d_{xy}, $4s$ mixing mechanism is responsible for the observed low value of A_o (and also K). In POMH, and to some extent in SrTrTH also, this mechanism must be operative. Since this should lead to a higher ΔE_1 value than 15,384 cm^{-1}, it is probable that inversion of the levels occurs,[28] in which case[6] $\Delta E_1 = 17{,}543$ cm^{-1} as required. Accordingly, P will be highest (Table 3), leading to the lowest β_2^2 in proportion to the lowest K.

Further, in POMH only the sixth ligand is O_W (water oxygen) which, though weak, increases the ligand field along the z-axis alone. As a result ΔE_2 is lowered in energy by the decrease in V=O π-bonding. This explains why ΔE_2 is lowered in POMH (11,530 cm^{-1}) and is smaller than in many other vanadyl complexes.[28] Besides the low-symmetry ligand field effects, hydrogen-bonding effects also give the same results.[24,29] Such hydrogen-bonding effects may be offered as the reason for the reduction in ΔE_2 and K for the VO^{2+} ion not only in POMH but also in SrTrTH and ammonium alum.

Relation between K, β_1^2 *and* e_π^2. The order of other evaluated bonding coefficients, β_1^2 and e_π^2, in relation to K does not seem to be in reasonable agreement with that expected from eqn (5) together with eqn (12). Since none of the available theories[2-5] for electronic absorption spectra of the VO^{2+} ion observed in the various lattices of the present work is uniquely applicable,[7] there is an element of uncertainty in the transitions assigned and, hence, in the values of ΔE_1 and ΔE_2. Even the optical-polarization technique does not yield accurate transition energies because in any of the lattices chosen VO^{2+} does not have a single unique orientation. As mentioned earlier, the discrepancies in the relation between K and bonding coefficients clearly bring out the inadequacy of crystal field and MO theories for the VO^{2+} ion.

Relation between g *anisotropy and ligand field strength.* The anisotropy in g is measured by the difference (Δg) in the $g_\perp$ and $g_\parallel$ components, i.e. $\Delta g = g_\perp - g_\parallel$, and it is related to the ligand field strength. Assuming that the axial field experienced by the VO^{2+} ion in a lattice is due to the double

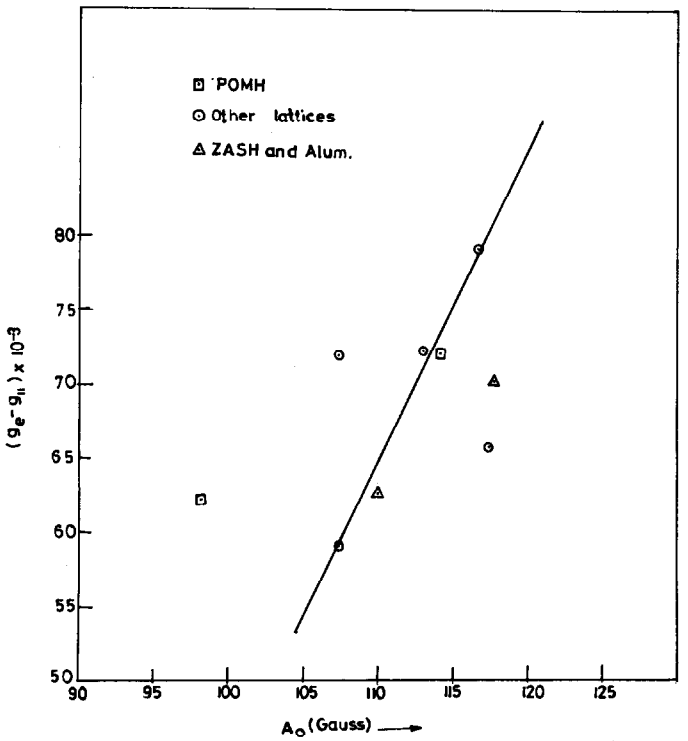

Fig. 7. Graph giving the linear relationship between $g_e - g_\parallel$ and the isotropic hyperfine coupling constant (A_o) (assumed to be negative).

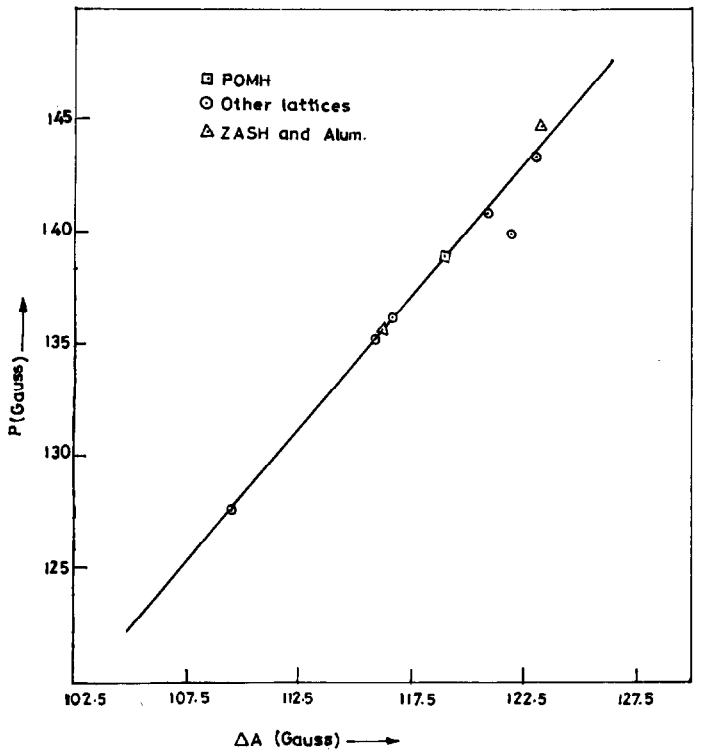

Fig. 8. Plot giving the linear increase in the dipolar term (P) with increase in anisotropy (ΔA) of the hyperfine coupling constant.

bonded oxygen and the in-plane field is due to the ligands, Δg is smaller for strong field ligands. From the Δg values given in Table 4, we find that Δg is smallest for alums and highest for $3CdSO_4 \cdot 8H_2O$. Thus, oxygens directly bonded to hydrogen are probably stronger than pure or indirectly-hydrogen-bonded oxygen ligands. Interestingly, a low-symmetry field such as seen in POMH need not be due to strong ligands.

Relation between $g_e - g_\parallel$ *and* A_o. It has been shown from eqns (5), (11) and (12) that K is proportional to β_2^2, β_1^2 and $1/\Delta E_1$. Since K and A_o are directly related, A_o is proportional to the quantity $\beta_1^2\beta_2^2/\Delta E_1$. Combining eqn (5a) with this, we infer that the relation between $g_e - g_\parallel$ and A_o must be linear. The plot of $g_e - g_\parallel$ against A_o (from Tables 1 and 4) is shown in Fig. 7 and the general behaviour seems to be in agreement with the theoretical predictions.

Relation between hf anisotropy (ΔA) *and* P. The anisotropy in A is measured by the difference (ΔA) in $A_\parallel$ and $A_\perp$, i.e. $\Delta A = A_\parallel - A_\perp$. The ΔA values are given in Table 4.

The anisotropy arises because of a direction-dependent interaction of electron-spin with nuclear spin. However, the direct dipolar term P accounts for the dipole interaction of the electron magnetic moment with the nuclear magnetic moment [see eqn (2)]. Thus, P and ΔA are related by eqn (3), which shows that, as the anisotropy in the hf coupling constant increases, P should increase provided ΔE_1 is nearly constant. A plot of P vs ΔA is given in Fig. 8. The graph is almost a straight line with little scatter.

Thus, the relationship between various parameters of the VO^{2+} ion discussed so far is exact and unambiguous when ESR theory is predominantly involved. An inexact, ambiguous relationship arises mostly due to uncertainties in the theories of electronic absorption spectra.

Abstract—The Pd(II) and Rh(I) complexes of tetra-acetylethane [H_2dahd (3,4-diacetyl-2,4-hexadiene-2,5-diol)] with O,O'-bonded chelates, represented as $[M_2(O_2,O'_2\text{-dahd})(L_2)_2][X]_m$ {M = Pd, $L_2 = (PPh_3)_2$ or bdpe [1,2-bis(diphenylphosphino)ethane], X = BF_4 or PF_6, $m = 2$; M = Rh, L = Co, $m = 0$}, have recently been prepared. $[Pd_2(O_2,O'_2\text{-dahd})(PPh_3)_4][PF_6]_2$ reacts with the potentially bidentate 1,10-phenanthroline (phen) to give the five-coordinate complex $[Pd(PPh_3)(phen)_2][PF_6]_2$ and $[Pd(O_1,O'_1\text{-dahd})(phen)]_n$, the latter of which is rather insoluble in organic solvents. $[Pd(O_1, O'_1\text{-dahd})(phen)]_n$ in CH_2Cl_2 readily transforms to a monomer complex $[Pd(C^3,O'\text{-dahd})phen)]$. These anomalous Pd(II) and Rh(I) complexes of the tetra-acetylethane dianion have been characterized from elemental analyses, conductance, IR, ^1H and ^{13}C NMR spectroscopy, magnetic susceptibility and ESR spectroscopy.

Despite a number of studies being directed to β-diketonate Pd(II) and Pt(II) complexes with a variety of coordination modes,[1–9] tetra-acetylethane [H_2dahd (3,4-diacetyl-2,4-hexadiene-2,5-diol)] complexes with second- or third-row transition metals

have been strangely elusive. It is well known that the first-row transition metals easily form insoluble coordination polymers of dahd,[10,11] whose characterization has thus been restricted. However, the ligand is attractive because it may form bifunctional O_2-chelates with a metal. The crystal structure of H_2dahd has been established by X-ray and neutron diffraction studies to have the di-enolic form of γ,γ′-bis(acetylacetone),[12] in which the position of the enolic hydrogen is asymmetric.[13] This solid structure of H_2dahd is also consistent with that in solution (experimental), while acetylacetone is well known to undergo keto–enol tautomerization. This gives rise to a preliminary question concerning chelate coordination of the dahd anion to the metal as to which is stabilized more, the six- or the seven-membered ring. The latter case, in which each 2,5-diketonate group might be in the conjugated form by coordination through oxygen atoms, seems improbable from a first glance at a molecular model: for electronic reasons the dahd ligand may be expected to form one ligand plane which would inappropriately mean two oxygen atoms of the 2,5-diketonate group approaching so close as to be at an unlikely bond distance.

With these in mind, a dahd–Pd(II) complex, $[Pd(dahd)_{1/2}(PPh_3)_2][PF_6]$, has been prepared by an analogous procedure to that of [Pd(*o*-acac)$(PPh_3)_2][PF_6]$.[14] A corresponding bdpe [1,2-bis(diphenylphosphino)ethane] complex $[Pd(dahd)_{1/2}$(bdpe)$][BF_4]$ has been obtained, by treating $PdCl_2$(bdpe) with $AgBF_4$ and H_2dahd, in a moderate yield. Some physical properties of these new complexes resemble those of the acac complex, as expected. No spectral evidence to confirm that these complexes have the dahd ligand chelating with a seven-membered ring has been obtained, and firm evidence should solely depend on X-ray diffraction studies. The data suggest that the γ,γ′-bis(diketonate) groups of the dahd are highly conjugated.

Accordingly, these complexes may be denoted as $[Pd_2(O_2,O'_2\text{-dahd})(L_2)_2][X_2]$ [$L_2 = (PPh_3)_2$ or bdpe, $X = BF_4$ or PF_6].

$Rh_2(O_2,O'_2\text{-dahd})(CO)_4$ has also been prepared by reacting $Rh_2Cl_2(CO)_4$ with Na_2dahd.

By reacting $[Pd_2(O_2,O'_2\text{-dahd})(PPh_3)_4][PF_6]_2$ with the potentially bidentate 1,10-phenanthroline (phen), a polymeric $[Pd(dahd)(phen)]_n$, always concomitant with a trace amount of the paramagnetic species, and a monomeric $Pd(C^3,O'\text{-dahd})(phen)$ have successively been isolated. From IR, ^1H and ^{13}C NMR, and ESR spectroscopy, these unusual complexes have been characterized, in which polymeric $[Pd(dahd)(phen)]_n$ is rather insoluble in organic solvents and is supposed to contain six-membered chelates of dahd with Pd(II) and dahd is newly bound to the Pd(II) as an *O_1-uni,O'_1-unidentate* bridging ligand. Small amounts of paramagnetic species included in this complex are also discussed in the light of the novel linkage isomerization of dahd bound to Pd(II).

EXPERIMENTAL

The solvents acetone and CH_2Cl_2 were distilled over $CaCl_2$, and diethylether over Na before use. Elemental analyses were performed by the Microanalytical Centre, Department of Pharmaceutical Sciences, Kyoto University. IR spectra were recorded on an Hitachi 260-10 IR spectrometer. Spectrometers used for NMR studies were: ^1H NMR, JEOL 100; ^{13}C NMR, JEOL FX-90Q (22.49 MHz) operating in the Fourier transform mode with a flip angle of 30° and a pulse repetition time of 3 s to observe the relative integral ratio. Mass spectral measurement was carried out using a Hitachi RMU-6 by a direct-beam method at under 90°C and 50 eV. Molecular weights were obtained by using a Corona Molecular Weight Apparatus M-117 (vapor pressure osmometer) at 30°C in CH_2Cl_2 based on its calibration by benzil. Electroconductivity was measured using a DKK AO-6 instrument in a dried acetone solution (*ca* 3.3×10^{-4} M). ESR spectra of the solid were recorded on a Varian E line Century Series EPR spectrometer using a quartz tube with a field of 3400 ± 400 G, microwave frequency of 9.483–9.488 GHz, and the cavity with the empty sample tube was checked *in situ*. Magnetic susceptibility was obtained by the Faraday method using a Cho-Keiryo Magnetic Balance MSB-10 at 300 K.

H_2dahd

H_2dahd was prepared by the literature procedure.[15] *m/z*: [M^+], 198; [$M-H_2O$], 180, ^1H NMR ($CDCl_3$): δ(Me) 2.00 (6-H), δ(OH), 16.65 (1-H) ppm. IR (Nujol mull): ν(C—C) + ν(C—O) + δ(O—H), 1600 (vs, br) cm^{-1}.

Na_2dahd–$(CH_3OH)_x$

H_2dahd (2 g) was suspended in CH_3OH and a CH_3OH solution of NaOH (~0.9 g) was added to the former solution, when the suspension became a homogeneous solution. The solution was then reduced to ~5 cm^3 and addition of diethylether to the residual solution gave a pale brown solid, which was recrystallized from CH_3OH–diethyl ether (3 g, 100%). ^1H NMR [$CDCl_3$–$(CD_3)_2CO$]: δ(Me)(dahd), 1.87 (s, br) ppm: δ(Me) (CH_3OH of solvation), 3.18 ppm.

$[Pd_2(dahd)(PPh_3)_4][PF_6]_2$

$[Pd(PPh_3)_4][PF_6]_2$[14] (1.7 g) was suspended in acetone (50 cm^3), and an acetone solution containing H_2dahd (0.23 g) was added to the solution. The suspension gradually became a canary yellow homogeneous solution. After 24 h, the solution was reduced in volume to 15 cm^3 under reduced pressure and addition of diethylether to the solution gave canary yellow crystals, which were recrystallized from acetone–CH_2Cl_2 and ethylether to give yellow needles (1.1 g, 100%). Found: C, 56.7; H, 4.3; P, 10.0%. Calc. for the molecular formula with two acetones of solvation: C, 56.7; H, 4.5; P, 10.0%. IR (Nujol mull); ν(CO) (acetone of solvation), 1704 (vs) cm^{-1}. Conductance (acetone): Λ_M, 258 $\Omega^{-1} \cdot cm^2 \cdot mol^{-1}$.

$[Pd_2(dahd)(bdpe)_2][BF_4]_2$

$PdCl_2$(bdpe) (2.2 g), prepared *in situ* by reacting $PdCl_2(PhCN)_2$ with an equimolar quantity of bdpe, was suspended in acetone containing H_2dahd (0.8 g). An acetone solution of $AgBF_4$ (1.6 g) was added to the solution. The suspension gradually became a transparent yellow solution, while white AgCl was precipitated. After 2 h, the precipitate of AgCl was filtered (1 g. 200% per Pd atom). The solution was reduced in volume to 10 cm^3 and addition of diethylether to the residual solution gave yellow crystals, which were recrystallized from CH_2Cl_2–diethylether (2 g, 66%). Found: C, 52.3; H, 4.3%. Calc. for the molecular formulae with $(CH_2Cl_2)_{2/3}$ of solvation: C, 52.4; H, 4.3%. ^1H NMR [$(CD_3)_2CO$–$(CD_3)_2SO$]: $\delta(CH_2)$ (CH_2Cl_2 of solvation) 5.60 ppm.

Rh_2(dahd)$(CO)_4$

$Rh_2Cl_2(CO)_4$ (0.6 g) was dissolved in CH_2Cl_2 and Na_2dahd–$(CH_3OH)_x$ (0.4 g) was added to the solution. The solution gradually gave a yellow solid. After 2 h, the solid product was filtered and washed with water, CH_3OH and diethylether (0.6 g, 63%). Found: C, 32.4; H, 2.2%, $M = 475$. Calc. for the molecular formulae: C, 32.7; H, 2.3%, $M = 514$.

Catena-[Ph(dahd)(phen)]$_n$

$[Pd_2$(dahd)$(PPh_3)_4][PF_6]_2$–$[(CH_3)_2CO]_2$ (0.5 g) was dissolved in acetone (25 cm^3), and the solution was charged with dried nitrogen for 1 h. Then, an acetone solution containing phen monohydrate (0.2 g) was added to the former solution. The yellow solution gradually turned orange while a yellow crystalline solid precipitated. After 3 h, the yellow solid was filtered and washed with a few cm^3 of acetone, then instantly dried *in vacuo* and preserved (for its EPR spectrum *vide infra*). The product relatively sensitive in air was washed furthermore with diethylether (the diethylether phase was coloured yellow, but species included in it were uncharacterized) to yield 0.08 g (34%). Found: C, 54.0; H, 4.1; N, 5.8%. Calc. for the molecular formulae: C, 54.7; H, 4.1; N, 5.8%. Magnetic susceptibility: $\chi_g = -0.50 \times 10^{-6}$ cgs emu.

The filtrate separated from [Pd(dahd)(phen)]$_n$ (acetone phase) was reduced in volume to $\sim$10 cm^3 and addition of diethylether to the residual solution gave orange crystals of $[Pd(PPh_3)(phen)_2][PF_6]_2$–$(CH_3)_2CO$[14] (0.24 g, 48%).

Pd(C^3,O′-dahd)(phen)

Catena-[Ph(dahd)(phen)]$_n$ ($\sim$0.5 g) was dissolved in CH_2Cl_2 ($\sim$20 cm^3), and the solvent was removed by natural vaporization at room temperature to give pale orange crystals. Found: C, 54.7; H, 4.2; N, 5.8%. M (osmometry in CH_2Cl_2) = 469. Calc. for the molecular formulae: C, 54.7; H, 4.2; N, 5.80%, $M = 483$. Magnetic susceptibility: $\chi_g = -0.66 \times 10^{-6}$ cgs emu.

Rh_2(dahd)$(CO)_2(PPh_3)_2$

Rh_2(dahd)$(CO)_4$ (0.27 g) was suspended in CH_2Cl_2, and PPh_3 (0.29 g) was added to the solution, when the solution turned yellow and was homogeneous, and CO was evolved. Then the solution was reduced in volume under reduced pressure by warming to $\sim$10 cm^3, when the yellow solution turned orange. Addition of diethylether to the residual solution gave a mixture of yellow and orange solids. To the suspension solution, more CH_2Cl_2 was added. By warming the solution for a few minutes, a homogeneous canary yellow solid, which is insoluble in organic solvents, could be obtained. Found: C, 58.2; H, 4.3%. Calc. for the molecular formulae: C, 58.7; H, 4.3%.

RESULTS AND DISCUSSION

IR, and ^{1}H and ^{13}C NMR, data of $[Pd_2$(dahd)$(PPh_3)_4][PF_6]_2$, $[Pd_2$(dahd)$(bdpe)_2][BF_4]_2$ and Rh_2(dahd)$(CO)_4$, as given in Tables 1 and 2, show that dahd coordinates to the metal with symmetrical *O*-bonding bi-functional chelation.

These spectral data are quite comparable with those of $[Pd(acac)(PPh_3)_2][PF_6]$[14] and $Rh(acac)(CO)_2$.[16] The IR spectra of all the dahd complexes also show a single and strong absorption band due to $\nu(C{=}O)+\nu(C{=}C)$, which may indicate that the diketonates of dahd are highly conjugated by its chelation with metal compared to the acac complexes [two bands for the Pd(II) complex and three bands for the Rh(I) complex]. One should notice that *O*,*O*′-bonding dahd improbably chelates with metal forming a seven-membered ring. Accordingly, it is concluded that in these Pd(II) and Rh(I) complexes the dahd dianion bridges two metal nuclei with *O*,*O*′-bonded six-membered chelates.

Some carbonyls in Rh_2(dahd)$(CO)_4$ are readily displaced by PPh_3, forming $[Rh_2$(dahd)$(CO)_2(PPh_3)_2]_n$, which is rather insoluble in organic solvents. For both complexes, IR absorption bands for the carbonyl stretching vibration are also comparable with those of the corresponding acac complexes, $Rh(acac)(CO)_2$ and $Rh(acac)(CO)(PPh_3)$ (Table 1).[16]

Unexpectedly, $[Pd_2$(dahd)$(PPh_3)_4][PF_6]_2$ reacts with phen in acetone to give a rather insoluble complex {[Pd(dahd)(phen)]$_n$} and the five-coordinate complex $[Pd(PPh_3)(phen)_2][PF_6]_2$.[14] [Pd(dahd)(phen)]$_n$ in CH_2Cl_2 transforms to a monomer complex [Pd(C^3,*O*′-dahd)(phen)].

^{1}H NMR of the monomer complex Pd(dahd)(phen) and its ^{13}C–{^{1}H} NMR (carried out with a flip angle of 30° to observe the relative integral ratio of four carbonyl and Me carbons on the dahd ligand) show dahd with two equivalent Me groups, while the other two are non-equivalent. They also exhibit a non-equivalency of the two nitrogen atoms of the phen. A ^{1}H NMR resonance at 2.33 due to two equivalent acetyl groups and that at 2.51 due to another group of dahd are both in a comparatively lower field region close to those of γ-carbon-bonded β-diketonate complexes of Pd(II) and Pt(II),[6] while the third resonance at 2.07 cor-

[a] Measured in $CDCl_3$.

[b] $|J_{RhC}|$ (CO) = 73.24, $|J_{RhC^{3,4}}|$ (dahd) = 3.06, $|J_{RhC}|$ (Me of dahd) = 1.22 Hz.

[c] Measured with flip angle of 30° to observe the relative intensities of the groups which are given in parentheses.

[d] Any signal due to C^3 could not be discerned.

[e] The signals due to $C^{11,12}$ were observed with very weak intensities.

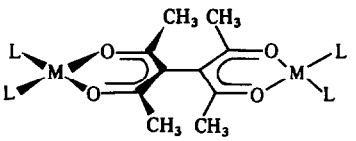

Fig. 1. Proposed structure of $[M_2(dahd)(L_2)_2][X]_n$ (M = Pd, L = PPh_3, X = PF_6^-, $n = 2$; M = Pd, L_2 = bdpe, X = BF_4^-, $n = 2$; M = Rh, L = CO, $n = 0$).

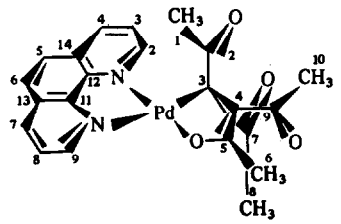

Fig. 2. Proposed structure of monomeric Pd(dahd)(phen).

responding to the fourth Me group of dahd is close to the free H_2dahd ligand. These indicate that the complex has a low symmetry with one carbonyl of dahd bound to the metal through its enolic oxygen, while the other three, in the keto form, are liberated from the metal. Characteristic IR absorption bands of the complex evidently show those in which two absorption bands in the region 1600–1700 cm^{-1} are due to ν(C═O), 1535 cm^{-1} to ν(C—O), and 1595 cm^{-1} due to ν(C═C), respectively, of the dianionic dahd ligand. Another coordination site of the dianionic dahd ligand to Pd(II) would be shown by the ^{13}C NMR spectrum, particularly for its 3-carbon nucleus. However, the ^{13}C NMR signal due to the 3-carbon of the dahd could not, unfortunately, de discerned owing to broad resonances that might be caused from an interaction with its *trans* ^{14}N quadrupole nucleus.[8,17]

Other conceivable structures for this complex are also depicted in Fig. 3. Structure **B** is improbable because the presumed dienol 2,5-diketonate group with a seven-membered chelate ring with Pd(II) may mean dahd forming a ligand plane that may improbably cause its two oxygen atoms to approach so close as to be at an unlikely bond distance. Another extreme structure (**C**) with allylic formation through carbonyl oxygen and 3-carbon atoms has also been excluded because the NMR spectra for the structure should show four unequivalent Me and carbonyl groups for the dahd. Any dynamic structure of **C** averaging two carbonyl or Me groups, in total equivalent to four groups, is still unlikely. For electronic reasons, the assumed allylic formation through the 2(5)-carbonyl and 3(4)-carbon of the dianionic dahd should require atoms lying on the same plane as one occupied by the 5(2)-carbonyl and 4(3)-carbon, while the stereochemistry of an assumed configuration would impose enough distortion to prevent allylic formation. In addition, even in the β-diketonate Pd(II) complexes, such an example has not been found except in the case of allylic formation through a terminal carbon.

Structure **D** for a protonated species, as found in $K[Pt(acac)_2Cl]$,[18] has been precluded because no ^1H NMR resonance due to O—H has been observed.

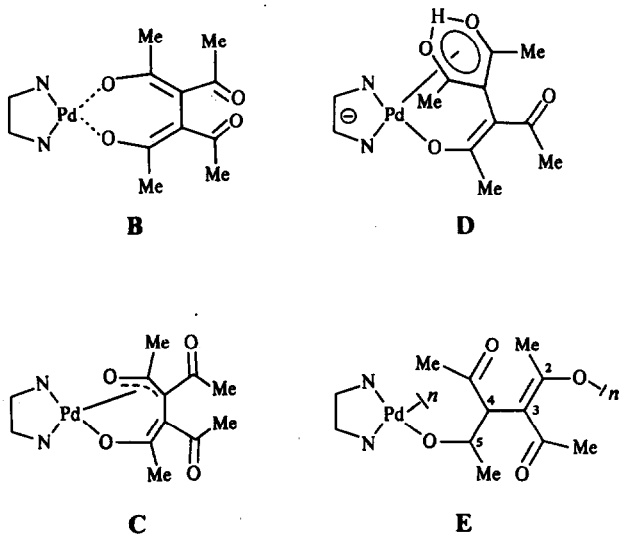

Fig. 3. Four conceivable structures of monomeric Pd(dahd)(phen) which are unlikely.

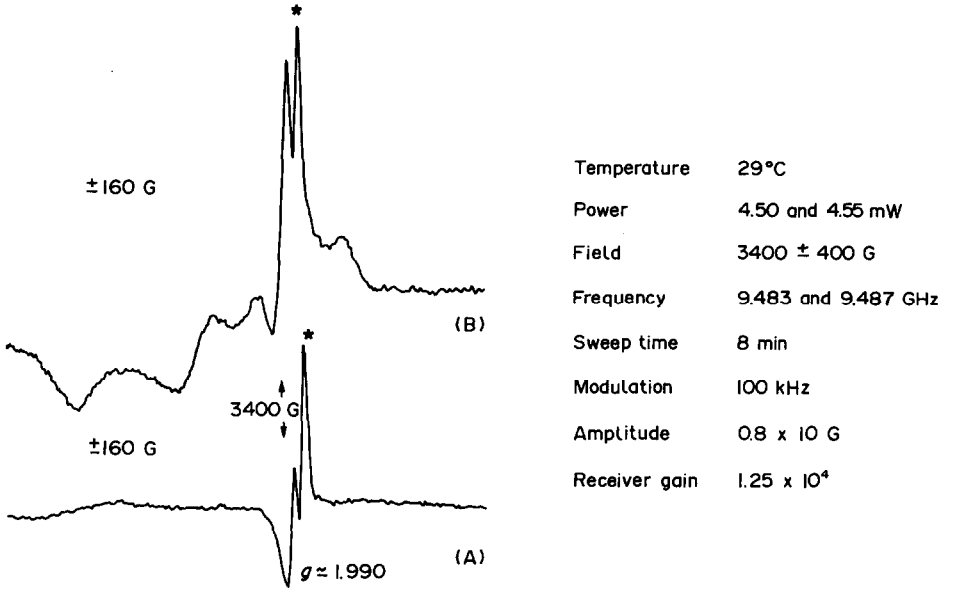

Fig. 4. ESR spectra of [Pd(dahd)(phen)]$_n$, showing paramagnetic species included: (A) after washing with diethylether, and (B) before washing with diethylether. The g values are directly estimated from the field resonances without using any references. * Due to impure quartz tube.

These conditions only fit **A** of Pd(C^3,O'-dahd)(phen), consistent with the spectral data.

The other complex Pd(dahd)(phen) was rather insoluble in organic solvents, except in CH_2Cl_2 or $CHCl_3$ (transformation to the monomer complex with an M—C bond), and its spectral evidences have been restricted. This complex may be a polymeric [Pd(dahd)(phen)]$_n$. Characteristic IR absorption bands of this complex (Table 1) show that the 2,5- or 2,7-diketonate group of dahd no longer chelates the metal in such a conjugated form as observed in [Pd(O_2,O'_2-dahd)(PPh_3)$_4$][PF_6]$_2$. Three strong absorptions in the region 1600–1700 cm^{-1} apparently correspond to ν(C═O) and ν(C═C), and at 1508 cm^{-1} to ν(C—O) of the dahd. In this case also, any corresponding absorptions due to ν(O—H)[18] or ν(C∴O) have not been observed at greater than 3100 or in the region 1510–1600 cm^{-1}.

A probable configuration of this complex is accordingly one in which the coordination of the dahd to Pd(II) is as an O_1-uni,O_1-unidentate bridging ligand, that is [Pd(μ-O_1,O'_1-dahd)(phen)]$_n$. The

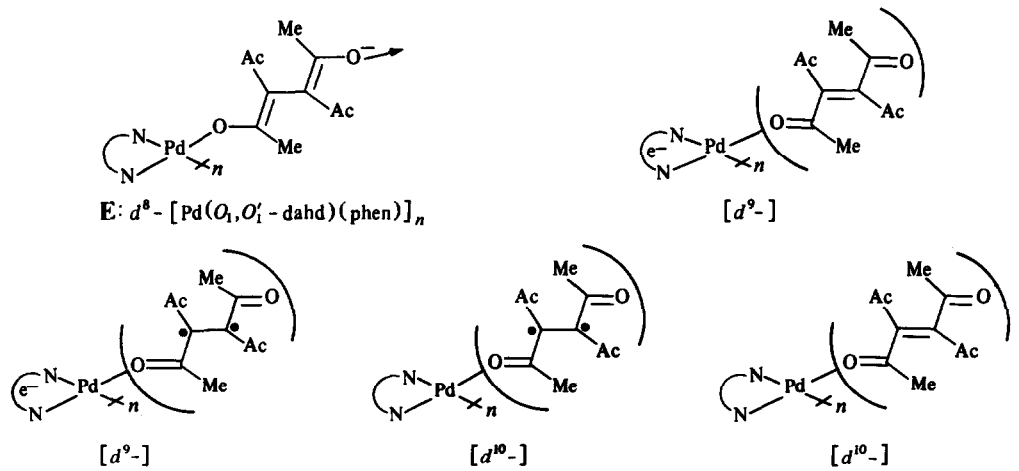

Fig. 5. Assumed paramagnetic intermediates of Pd(C^3,O'_2-dahd)(phen), given by two-electron transfer from d^8-[Pd(O_1,O'_1-dahd)(phen)]$_n$.

result of magnetic-susceptibility measurements was diamagnetism, corresponding to a Pd(II) complex. However, unexpectedly, this complex was always contaminated with a paramagnetic species in only a trace amount. Its ESR spectrum (Fig. 4) show these and two other resonances could be obtained, one of which is in the background with a very wide resonance. Nevertheless, the diamagnetism of the species can conceivably be enough to be caused by compensation of the relatively large diamagnetic contribution from the predominant d^8-complex $[Pd(O_1,O'_1\text{-dahd})(phen)]_n$. Noticeably, $[Pd(O_1,O'_2\text{-dahd})(phen)]_n$ precipitated from the reaction solution was contaminated with species soluble in diethylether and its ESR spectrum shows six resonances with no hyperfine structures. No definite evidence for these concomitant species has been obtained. However, it may be tempting to speculate that these paramagnetic species, despite only minute amounts, because $[Pd(O_1,O'_1\text{-dahd})(phen)]_n$ is an isomer of $Pd(C^3,O'\text{-dahd})(phen)$ whose transformation may proceed via any species of dahd with its 3- or 4-carbon atom activated as a methylene structure or a carbocation radical. The configuration of the dahd linkage mode as an O_1-uni-O'_1-unidentate bridging ligand to Pd(II) may allow a likely conjugated system through its two–five carbon atoms which may presumably facilitate electron transfer from dahd to the metal or the phen ligand.[19] Such an assumption may give four idealized species in which the dahd is oxidized to form a tetra-acetylethylene (Fig. 5). Nevertheless, any details of the concomitant species with $[Pd(O_1,O'_1\text{-dahd})(phen)]_n$ are uncertain at present.

Acknowledgements—I am grateful to Dr K. Hata (JEOL Ltd) for obtaining ^{13}C–$\{^1H\}$ FT-NMR spectral data, and to Dr W. Mori (Osaka University) for obtaining magnetic-susceptibility data.

(*Received* 9 *September* 1985; *accepted* 31 *October* 1985)

Abstract—The homoleptic benzyl $Mo_2(CH_2Ph)_6$ has been obtained by reaction of either $MoCl_4(thf)_2$ or $Mo_2(OPr^i)_6$ with $Mg(CH_2Ph)_2$. The dark-red, sparingly soluble complex has been characterized by ^1H and ^{13}C NMR as well as by a solid-state structure analysis. Pertinent bond distances (Å) and angles (°) for the unbridged, ethane-like molecule which contains crystallographic S_6-symmetry are: Mo—Mo = 2.175(1), Mo—C = 2.162(2), Mo—Mo—C = 97.61(6), and Mo—C—C(Ph) = 98.9(1).

Following our recent studies on the structure and reactivity of benzyl complexes of Gp 4 metals (Ti and Zr)[1,2] we have begun an investigation into the analogous compounds of the heavier Gp 6 elements Mo and W. During attempts to prepare the tetrabenzyl $Mo(CH_2Ph)_4$ for comparison with the known Ti, Zr and Hf analogues[3] we have isolated crystals of the dinuclear benzyl compound $Mo_2(CH_2Ph)_6$. Although briefly referred to in the literature,[4,5] details concerning the spectroscopic and structural characteristics of this molecule have not been reported. We wish to report here both a fortuitous as well as rational synthesis of this complex together with details of its molecular structure.

RESULTS AND DISCUSSION

Synthesis

Attempts to obtain tetrabenzyl-molybdenum by reaction of $MoCl_4(thf)_2$ with $Mg(CH_2Ph)_2$ (>2 equivalents) in thf to a brown-red solution from which deep-red crystals of a compound identified as $Mo_2(CH_2Ph)_6$ could be isolated on suitable workup. The compound is only very sparingly soluble in hydrocarbon solvents (hexane, benzene or toluene) and is stable in air for a number of hours in the solid state. The molecular structure of the complex was confirmed by a single crystal X-ray diffraction study (*vide infra*). Higher yields of the compound can be achieved by alkylation of the dimolybdenum alkoxide $Mo_2(OPr^i)_6$ as shown in eqn (1):

$$Mo_2(OPr^i)_6 + 3Mg(CH_2Ph)_2 \rightarrow Mo_2(CH_2Ph)_6 + 3Mg(OPr^i)_2. \quad (1)$$

It has previously been shown that the analogous alkyl, $Mo_2(CH_2SiMe_3)_6$, can also be obtained via this dinuclear alkoxide.[6]

The product is obtained as a deep-red crystalline precipitate from toluene. Although only sparingly soluble, both ^1H and ^{13}C NMR spectra were obtained in toluene-d_8. The methylene resonance, δ 3.70 ppm, is significantly downfield of the position normally found for diamagnetic benzyl complexes such as $M(CH_2Ph)_4$ (M = Zr or Hf)[1,3] and we ascribe this low-field shift to the deshielding caused by the diamagnetic anisotropy associated with the Mo–Mo triple bond. The Mo—$\underline{C}H_2Ph$ carbon resonates at δ 64.6 ppm. Attempts to obtain a more soluble derivative by use of the alkylating agent $Mg(CH_2Ph\text{-}p\text{-}Me)_2$ (CH_2Ph-*p*-Me = *p*-tolyl) allowed the isolation of $Mo_2(CH_2Ph\text{-}p\text{-}Me)_6$ as red

cubes, but again the complex was only sparingly soluble.

Solid-state molecular structure of $Mo_2(CH_2Ph)_6$

An ORTEP view of the $Mo_2(CH_2Ph)_6$ molecule is shown in Fig. 1 along with the numbering scheme. Selected bond distances and angles are given in Table 1 while Table 2 contains the crystallographic data. The complex can be seen to adopt the unbridged, staggered, ethane-like geometry typical of M_2X_6 (M = Mo or W) type complexes[5,7] with the molecule containing crystallographic S_6-symmetry making all benzyl ligands equivalent (Fig. 2). The Mo—Mo distance of 2.175(1) Å is comparable to that of the only other reported Mo_2R_6 complex, $Mo_2(CH_2SiMe_3)_6$, 2.167(?) Å.[4] Both of these distances are considerably shorter than found in the molecules $Mo_2(NMe_2)_6$, 2.211(2) and 2.217(2) Å,[8] and $Mo_2(OCH_2CMe_3)_6$, 2.222(2) Å,[9] and possible electronic reasons for the shorter Mo≡Mo distance in the alkyl complexes have been discussed.[5]

Table 1. Selected bond distances (Å) and angles (°) for $Mo_2(CH_2Ph)_6$

Mo(1)—Mo(1)′	2.175(1)
Mo(1)—C(2)	2.162(2)
C(2)—C(3)	1.482(3)
C(3)—C(4)	1.400(3)
C(3)—C(8)	1.401(3)
C(4)—C(5)	1.381(3)
C(5)—C(6)	1.382(3)
C(6)—C(7)	1.381(4)
C(7)—C(8)	1.390(3)
Mo(1)—Mo(1)′—C(2)	97.61(6)
C(2)—Mo(1)—C(2)′	118.28(3)
Mo(1)—C(2)—C(3)	98.9(1)

The size of the Mo—C—Ph angle is worthy of note. An important characteristic of high-valent early-transition-metal and actinide benzyl compounds is the interaction of the π-cloud of the aromatic ring with the electron-deficient metal center.[1] This is indicated in structural studies by small M—C—Ph angles as well as short M—C (*ortho* and *ipso*) distances. An η^3 bonding mode somewhat analogous to that found in 18-electron systems is sometimes used to describe the situation, but in the actinide case a more extensive multisite bonding mode has been proposed.[10,11] Although the Lewis acidity of the Mo_2^{6+} core in Mo_2X_6 compounds has been well documented,[12] the Mo—C—Ph angle of 98.9(1)° found in $Mo_2(CH_2Ph)_6$ is too large to indicate any significant electron donation from the aryl ring to the metal. However, this angle is significantly smaller than that reported for $Mo_2(CH_2SiMe_3)_6$, 121.1(?)°,[4] although steric effects clearly cannot be ignored. The Mo—C distance of 2.162(2) Å in $Mo_2(CH_2Ph)_6$ is only slightly shorter than the corresponding bond distances in $Mo_2(CH_2Ph)_2(NMe_2)_4$,[13] 2.182(5) and 2.0201(5) Å, and $Mo_2(OPr^i)_4(CH_2Ph)_2(PMe_3)$,[14] 2.22(1) Å.

EXPERIMENTAL

All reactions were carried out under an atmosphere of dry, oxygen-free nitrogen using standard

Schlenck and glove box techniques. Solvents were distilled under nitrogen from sodium benzophenone and stored under nitrogen. $MoCl_4(thf)_2$,[15] $Mo_2(OPr^i)_6$[9] and $Mg(CH_2Ph)_2$[16] were obtained by literature methods. ^1H NMR and ^{13}C spectra were recorded on a Varian Associates XL-200 spectrometer.

Preparations

$Mo_2(CH_2Ph)_6$. (a) *From* $MoCl_4(thf)_2$: to a suspension of $MoCl_4(thf)_2$ (2.7 g, 7.0 mmol) in thf (50 cm^3) cooled to 0°C was slowly added solid $Mg(CH_2Ph)_2$ (3.2 g, 15 mmol) through a solid addition funnel. The reaction mixture was allowed to warm up to room temperature and stirred overnight. Filtration followed by cooling the resulting red filtrate gave large, deep-red cubes of product. Yield ~50 mg. ^1H NMR (toluene-d_8): δ 3.70 (s, CH_2Ph), 6.8–7.3 (m, C_6H_5). $\{^1H\}$–^{13}C NMR (toluene-d_8): 64.6 ($\underline{C}H_2Ph$).

(b) *From* $Mo_2(OPr^i)_6$: to a solution of $Mo_2(OPr^i)_6$ (0.5 g, 0.92 mmol) in toluene (25 cm^3) was added $Mg(CH_2Ph)_2$ (0.63 g, 3.0 mmol). The resulting deep-red mixture was stirred overnight. Filtration afforded a powdery sample of $Mo_2(CH_2Ph)_6$ while cooling the filtrate yielded large red cubes of product. Yield = ~200 mg.

$Mo_2(CH_2Ph\text{-}p\text{-}Me)_6$. Using a similar procedure to that in (b) above, $Mo_2(CH_2Ph\text{-}p\text{-}Me)_6$ was obtained as deep-red crystals. Found: C, 70.1; H, 6.9%. Calc. for $Mo_2C_{48}H_{54}$: C, 70.1; H, 6.6%. ^1H NMR (toluene-d_8): δ 3.72 (s, $\underline{CH_2}Ph$), 2.15 (s, $CH_2Ph\text{-}\underline{CH_3}$), 6.8–7.2 (m, $CH_2C_6\underline{H_4}CH_3$).

Crystallographic studies

General operating procedures and a listing of programs have been published previously.[17] Crystal data are summarized in Table 2.

A small well-formed crystal was selected and transferred to the goniostat using standard inert-atmosphere handling techniques. The crystal was cooled to −154°C for characterization and data collection. A search of a limited hemisphere of reciprocal space yielded a set of reflections which exhibited three-fold symmetry and could be indexed using a rhombohedrally centered hexagonal lattice. The diffraction symmetry was determined to be $\bar{3}$, requiring the space group to be either $R\bar{3}$ or $R\bar{3}$. The structure was solved and refined in the space group $R3$.

The only sensible calculated density required six $Mo(CH_2C_6H_5)_3$ units in the unit cell. A trial structure based on three dimers placed at $R3$ sites in the unit cell proved to be correct. Initially the Mo atoms were placed with a separation of 2.3 Å. A difference map phased on the Mo atom revealed the atoms in the benzyl group. The structure was refined using full-matrix least squares. All hydrogen atoms were located in a subsequent difference map and were included in the refinement with isotropic thermal parameters. All non-hydrogen atoms were refined using anisotropic thermal parameters. The final R was 0.019, using 862 reflections with $F > 3.0\sigma(F)$.

A final difference Fourier was essentially featureless, the largest peak being 0.27 e Å^{-1}.*

PREPARATION AND ^{31}P NMR SPECTRA OF *N*-THIOCYANATO DERIVATIVES OF SOME ORGANOPHOSPHORUS(III) HALIDES

RUSMIDAH ALI and KEITH B. DILLON*

Chemistry Department, University of Durham, South Road, Durham DH1 3LE, U.K.

(*Received* 27 *September* 1985; *accepted* 6 *November* 1985)

Abstract—The compounds $RP(NCS)_2$ (R = Ph, Me, Et or C_6F_5) have been prepared, and ^{31}P NMR data have been recorded both for them and for their precursors RPX(NCS) (X = Cl or Br). They are all thermally unstable, particularly the alkylphosphorus compounds, thus accounting for some discrepancies with literature NMR data. The NCS group has been shown to be *N*-bonded in each instance by means of IR spectroscopy.

Various methods have been described in the literature for preparing thiocyanato derivatives of organophosphorus(III) halides, usually involving either reaction of RPX_2 (X = Cl or Br) with a metal thiocyanate such as AgSCN,[1–4] $Hg(SCN)_2$,[2] $Pb(SCN)_2$[2] or NH_4NCS,[2] or exchange with a thiocyanato compound of silicon[5,6] or germanium.[5] ^{31}P NMR shifts of 37.9 ppm for $MeP(NCS)_2$,[2] 33.0 ppm for $PhP(NCS)_2$[6] and 62.2 ppm for $C_6F_5P(NCS)_2$[4] have also been reported, but these values do not appear to be self-consistent when compared with the shifts of the starting materials (Table 2). Furthermore the preparative procedures required heating in each case, usually under reflux in a suitable solvent,[1–6] and thiocyanato compounds of phosphorus are often thermally unstable.[4,7,8] Fild[4] found that further heating of freshly-distilled $C_6F_5P(NCS)_2$ led to complete transformation to a mixture of two substances, which could not be separated by distillation. From NMR and other evidence he deduced that these were pentavalent phosphorus thiocyanato and cyano compounds[4] [eqn (1)]:

$$2C_6F_5P(NCS)_2 \rightarrow C_6F_5P(S)(NCS)_2 + C_6F_5P(S)(CN)_2. \quad (1)$$

No NMR data have been reported for the intermediate halogenothiocyanato compounds RPX(NCS) (X = Cl or Br). We have therefore prepared the compounds $RP(NCS)_2$ (R = Ph, Me, Et or C_6F_5) under mild conditions from $RPCl_2$, and monitored the NMR spectra during the reactions, enabling shift values to be derived for RPCl(NCS) and $RP(NCS)_2$. The pentafluorophenyl compound has been similarly prepared from $C_6F_5PBr_2$. The compounds have been isolated and further characterized by elemental analysis, carried out as soon as possible to minimize the risk of decomposition. The thiocyanato group has been shown to be *N*-bonded in each case by means of IR spectroscopy.

EXPERIMENTAL

All manipulations including NMR sample preparation were carried out either under an inert atmosphere of dry nitrogen or *in vacuo*. Chemicals of the best available commercial grade were used, in general without further purification. $C_6F_5PBr_2$ was prepared by reaction of the Grignard reagent C_6F_5MgBr with PBr_3,[9] and $C_6F_5PCl_2$ was either prepared similarly from C_6F_5MgCl and PCl_3,[9] or by reaction of $C_6F_5PBr_2$ with Et_4NCl (2 equivalents) in CH_2Cl_2. The ^{31}P NMR spectrum showed when reaction was complete. The CH_2Cl_2 was removed *in vacuo*, the product was extracted into low-boiling (303–313 K) petroleum ether, the Et_4NBr was filtered off, and the solvent was removed *in vacuo* to leave $C_6F_5PCl_2$.

Dithiocyanatophenylphosphine [$PhP(NCS)_2$]

Dichlorophenylphospine (0.99 g, 5.53 mmol) was dissolved in CH_2Cl_2 and an excess of AgSCN (2.40 g, 14.46 mmol) was added, with constant stirring. The reaction mixture was allowed to stir for 1–2 h,

Table 1. Elemental analyses for dithiocyanato-organophosphines

	Analysis (%)									
	Found					Calculated				
Compound	C	H	N	P	S	C	H	N	P	S
$PhP(NCS)_2$	41.2	2.2	8.1	13.8	27.5	42.9	2.2	12.5	13.8	28.6
$MeP(NCS)_2$	23.2	1.7	15.9	19.3	40.0	22.2	1.9	17.3	19.1	39.5
$EtP(NCS)_2$	28.5	3.0	15.3	16.9	35.7	27.3	2.9	15.9	17.6	36.4
$C_6F_5P(NCS)_2$	30.6	—	7.2	10.5	19.4	30.6	—	8.9	9.9	20.4

and the excess AgSCN and AgCl were then removed by filtration. The solvent was removed *in vacuo* to yield a yellow liquid.[1] Elemental analyses for this and the other compounds prepared are given in Table 1. In each case analysis was carried out as quickly as possible after preparation of the compound, in view of their thermal instability (Results and Discussion).

Dithiocyanatomethylphosphine [$MeP(NCS)_2$]

The above reaction was repeated using $MePCl_2$ (0.73 g, 6.24 mmol) and AgSCN (2.32 g, 13.98 mmol), with stirring for 1 h. A yellow liquid was isolated, and was analysed immediately.

Dithiocyanatoethylphosphine [$EtP(NCS)_2$]

This compound had not been previously reported in the literature, but was similarly prepared from $EtPCl_2$ (0.66 g, 5.04 mmol) and AgSCN (1.87 g, 11.27 mmol). It was isolated as a yellow liquid.

Dithiocyanatopentafluorophenylphosphine [$C_6F_5P(NCS)_2$]

A similar reaction between $C_6F_5PBr_2$ (4.50 g, 12.58 mmol) and AgSCN (5.02 g, 30.25 mmol), with stirring for 2–3 h, led to isolation of the compound as a yellow liquid.[4]

^{31}P NMR spectra were recorded at 307.2 K as described previously;[7] chemical shifts were measured relative to external 85% H_3PO_4, and are quoted with the downfield (higher frequency) direction taken as positive. IR spectra were also recorded as indicated in earlier papers, as were microanalyses for C, H, N and P.[7,10] Sulphur was determined by titration with $Ba(ClO_4)_2$ following an oxygen flask combustion, with sulphonazo III as the indicator.

RESULTS AND DISCUSSION

The reactions were initially monitored by adding a smaller amount of AgSCN than required for complete substitution to a solution of RPX_2 in CH_2Cl_2, with stirring, and recording the ^{31}P NMR spectrum of the mixture. Two signals upfield from that of the starting material were observed in each instance (Table 2), assigned to RPX(NCS) and $RP(NCS)_2$. The value of 61.2 ppm for $C_6F_5P(NCS)_2$ is in good agreement with the result of Fild[4] for the freshly-distilled compound. The shift separation between $RPCl_2$ and $RP(NCS)_2$ is slightly larger for aliphatic than for aromatic R groups, but is quite similar for R = Me or Et, and for R = Ph or C_6F_5. There is a striking discrepancy, however, between our results and literature data for $PhP(NCS)_2$ (δ 33.0 ppm[6]) and $MeP(NCS)_2$ (δ 37.9 ppm[2]). This is discussed below.

The compounds were isolated as yellow liquids

Table 2. $\delta(^{31}P)$ (ppm) for *N*-thiocyanato derivatives of RPX_2

		$\delta(^{31}P)$ (ppm) for		
R	X	RPX_2	RPX(NCS)	$RP(NCS)_2$
CH_3	Cl	192.6	141.8	103.3
C_2H_5	Cl	199.8	150.0	112.9
C_6H_5	Cl	161.3	117.7	88.7
C_6F_5	Cl	135.6	90.4	61.2
C_6F_5	Br	111.3	79.1	61.2

(Experimental), and all proved to be thermally unstable at room temperature, so analyses were carried out as soon as possible after preparation. $PhP(NCS)_2$ readily turned to a dark brown viscous liquid giving low C, N and S analyses, while the methyl and ethyl compounds were even more unstable, quickly becoming reddish-brown and viscous even within the entry port of the inert atmosphere box. The most stable material was $C_6F_5P(NCS)_2$; this compound had been isolated by Fild[4] by distillation, but further heating led to a mixture of two substances which could not be separated by distillation, and gave higher-field ^{31}P signals at 7 and −40 ppm. These were deduced to arise from $C_6F_5P(S)(NCS)_2$ and $C_6F_5P(S)(CN)_2$, respectively. In support of this hypothesis a chemical shift of 6.8 ppm was measured for $C_6F_5P(S)(NCS)_2$, but the cyano compound could not be isolated pure.[4] It therefore seems probable that the signals reported previously for $MeP(NCS)_2$[2] and $PhP(NCS)_2$[6] may be due to one of the corresponding decomposition products, possibly $RP(S)(NCS)_2$ (R = Me or Ph), although it is not then apparent why two signals were not detected in the earlier work.

The IR spectra of the phenyl, methyl and ethyl compounds all showed strong, broad absorptions between 2150 and 1850 cm^{-1} for the asymmetric stretch of the NCS moiety, as expected for thiocyanato groups bonded to phosphorus via the nitrogen atom.[11,12] The same mode of coordination has been deduced from vibrational spectroscopic studies of $C_6F_5P(NCS)_2$[3] and $P(NCS)_3$,[11,12] as well as in the phosphorus(V) compounds $PO(NCS)_3$,[11,12] $PhPO(NCS)_2$,[11] $PS(NCS)_3$[11] and $PhPS(NCS)_2$.[11]

We therefore conclude that thiocyanato derivatives of organophosphorus(III) halides may be prepared and isolated, but that their thermal stability is low, particularly for alkyl-substituted compounds. The NCS groups are coordinated through nitrogen in all of the compounds prepared, and reliable ^{31}P shift data have now been obtained for RPCl(NCS), $RP(NCS)_2$ (R = Ph, Me, Et or C_6F_5) and $C_6F_5PBr(NCS)$.

(*Received* 15 *May* 1985; *accepted after revision* 25 *November* 1985)

Abstract—The reactions of $[\pi\text{-}C_3H_5Fe(CO)_3X]$ [where X = Cl (**1**), Br (**2**) or I (**3**)] with different chemical species are described. Thus, **2** and **3** react with $Ph_2C{=}NLi$ in Et_2O to yield $[(\pi\text{-}C_3H_5)(CO)_3Fe(N{=}CPh_2)]$, while the reaction of **1** with PhC(=S)N(Me)Li in THF yielded a novel σ-allylironcarbonyl compound. Ethynyl magnesium bromide, $HC{\equiv}CMgBr$, reacts with **3** in THF to give a π-allyltricarbonyl ethynyliron complex, which undergoes a dipolar cycloaddition reaction with $PhC{\equiv}N{-}O$ in Et_2O, yielding a novel organoiron complex, [(μ-CO)bis{5(σ-allyltricarbonyliron)(3-phenylisoxazole)}]. The reaction of $[\pi\text{-}C_3H_5(CO)_3FeNa]$ with $ClCH_2CH_2NMe_2$ is also described. Data on molar conductances, molecular weights, and IR and ^1H NMR spectra, were used to assign structures.

The study of the reactivity of π- and σ-allyl transition metal complexes is significant for various reasons, one being their involvement in many catalytic processes. In many such reactions formation of cationic allyl metal complexes as intermediates have been proposed. As not much work is available on the synthesis and reactivity of cationic allyliron carbonyl complexes,[1,2] we have synthesized and studied the reactivity of such cationic iron complexes. Very recently we have described[3] the reactions of $[\pi\text{-}C_3H_5(CO_3)X]$ [where X = Br (**2**) or I (**3**)] leading to the successful isolation of cationic and neutral π- and σ-allyliron carbonyl complexes. We have further studied the reactions of $\pi\text{-}C_3H_5(CO_3)Cl$ (**1**), **2** and **3** leading to the novel synthesis of organoiron compounds, and the present paper describes these results.

EXPERIMENTAL

Elemental analyses, spectroscopic measurements and measurement of conductances were done as described previously.[4–6] All manipulations were carried out under nitrogen and solvents were dried and purified by usual procedures.

Preparation of the starting materials

$Ph_2C{=}NLi$[7] (**4**), PhC(=S)N(Me)Li[8] (**5**) and $HC{\equiv}CMgBr$[9] (**6**) were synthesized as described in the literature. The π-allyltricarbonyliron halide complexes were prepared by a previously published method.[1] The compound $ClCH_2CH_2NMe_2$ (Sigma Chemical Co.) was used as obtained without further purification, while $PhC{\equiv}N{-}O$ (**7**) was synthesized by the literature methods[10] and used immediately. Molecular weights were determined osmometrically in benzene, cyclohexane or chloroform.

Physical methods

IR spectra (KBr discs and Nujol mulls) were recorded on a Perkin–Elmer 781 spectrophotometer; ^1H (60-MHz) NMR spectra for the complexes in d_6-acetone or $CDCl_3$ solutions, with TMS as internal reference, were recorded at room

temperature in a Varian T 60 instrument. Molecular weights were determined osmometrically in benzene, cyclohexane or chloroform solution using a vapour pressure Macrolab Osmometer (Model 301A).

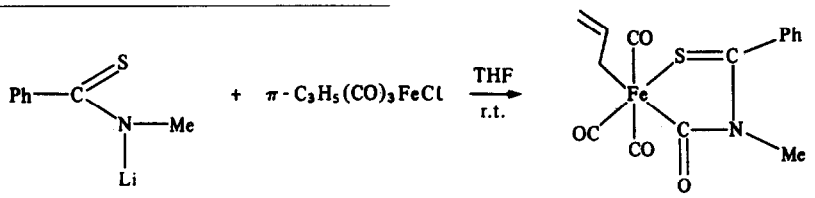
Reactions of **1**, **2** *and* **3**

Reactions of **2** *and* **3** *with* **4**. Ether solution (25 cm^3) of **4** (0.9 g, 0.005 mol) was added dropwise to a magnetically stirred ether solution (30 cm^3) of **2** (1.3 g, 0.005 mol) or **3** (1.53 g, 0.005 mol) at 0°C. After about 1 h the mixture was filtered and the coloured filtrate, on concentration and cooling to −20°C, yielded a brown mass, which on fractional crystallization from a pentane–ether mixture [50 : 50 (v/v)] at −10°C gave [(π-C_3H_5)$(CO)_3$Fe(N=CPh_2)] (**8**) in 60% yield, m.p. 63–65°C (d).

Reaction of **1** *with* **5**. To a magnetically stirred solution of **5** (0.78 g, 0.005 mol) in THF (25 cm^3) was added a solution of **1** (1.1 g, 0.005 mol) in THF (25 cm^3) at about −40°C and the stirring was continued for 1 h and then raised to room temperature and filtered. The filtrate was chromatographed through SiO_2 and the major brown band was eluted with a benzene–ether [50 : 50 (v/v)] mixture, which yielded orange–red crystals of **9** in 52% yield, m.p. 88–91°C (d). From the other two minor bands (dark red and red) no definite compounds could be isolated in the pure state.

Reaction of **3** *with* **6**. A solution of **6** (1.26 g, 0.01 mol) in THF (150 cm^3) was added slowly to a stirred solution of **3** (3.0 g, 0.01 mol) in THF (50 cm^3) at −10°C and stirred for 30 min more, followed by work up (hydrolysis with saturated aqueous NH_4Cl solution) and extraction with a pentane–hexane [50 : 50 (v/v)] mixture, dried with anhydrous Na_2SO_4 and concentrated and cooled to −20°C to yield a red powder, [(π-C_3H_5)$(CO)_3$Fe(C≡CH)] (**10**) in 55% yield.

Reaction of **10** *with benzonitrile oxide* (**7**). A solution of **10** (1.0 g, 0.005 mol) in an ether–THF mixture (50 cm^3) [50 : 50 (v/v)] was added to a solution of **7** (0.6 g, 0.005 mol) in a benzene–THF mixture (100 cm^3) [50 : 50 (v/v)] at −10°C and stirred at that temperature for 2 h to yield a coloured solution, which on concentration and cooling gave reddish-brown [(μ-CO)bis{5(σ-allyltricarbonyliron)3-phenylisoxazole}] (**11**) in about 50% yield, m.p. 110–112°C (d). The brown filtrate on evaporation and titration with Et_2O gave a light brown powder, which has not been identified yet.



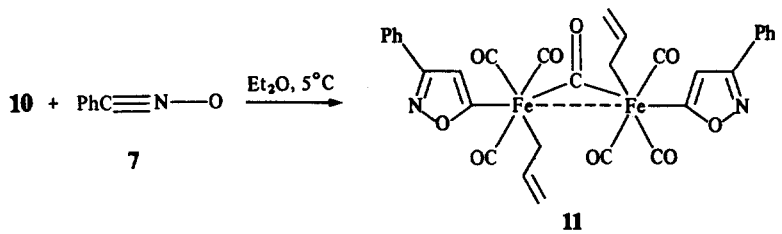
Reaction of [(π-C_3H_5)$(CO)_3$FeNa] (**12**) *with* 2-*chloroethyldimethylamine* ($ClCH_2CH_2NMe_2$) (**13**). Complex **3** (0.6 g, 0.002 mol) in 50 cm^3 of THF was treated with elemental sodium (0.095 g, 0.004 g atom) and stirred for 2 h and then filtered directly into a solution of **13** (0.3 g, 0.002 mol) in THF (50 cm^3) at about 35°C. The mixture was stirred for 3 h and filtered. The filtrate was evaporated to dryness and then extracted with a benzene–hexane [50 : 50 (v/v)] mixture, which gave an orange-red π-allyliron complex, [(π-C_3H_5)$(CO)_2$Fe(C=O)$CH_2CH_2NMe_2$] (**14**), in 42% yield, m.p. 79–82°C (d). No pure compound was isolated from the benzene–hexane-insoluble dark solid.

RESULTS AND DISCUSSION

The reaction [eqn (1)] of **2** or **3** with **4** (1 : 1 molar ratio) in Et_2O, subsequent removal of the precipitated LiX, and vacuum concentration of the filtrate yielded brown **8**. The complex was stable under an inert atmosphere, but unstable in air and sensitive to light. Irradiation with UV light gave an unidentified deep red powder:

$$\underset{\textbf{2 or 3}}{\pi\text{-}C_3H_5(CO)_3FeX} + \underset{\textbf{4}}{Ph_2C{=}NLi} \xrightarrow{Et_2O,\,0^\circ C} \underset{\textbf{8}}{\pi\text{-}C_3H_5(CO)_3Fe\cdot N{=}CPh_2}. \quad (1)$$

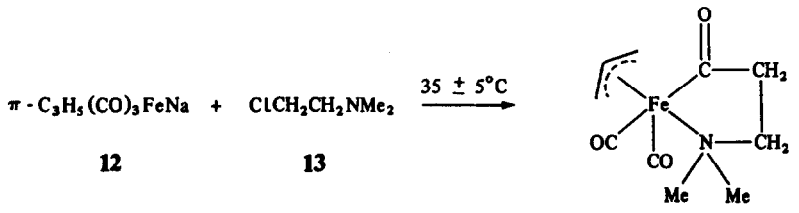
The reaction of **1** with a stoichiometric amount of **5** in THF leads, according to eqn (2), to the novel σ-allyl complex **9** in about 52% yield. This was also stable only under an inert atmosphere and sensitive to light. Treatment of solutions of **3** with **6** in THF



5 **1** **9** (2)

at −10°C yielded the π-allyltricarbonylethynyliron(II) complex (**10**) [eqn (3)]:

$$\underset{\textbf{6}}{3 + HC{\equiv}CMgBr} \xrightarrow{THF,\,-10^\circ C} \underset{\textbf{10}}{\pi\text{-}C_3H_5(CO)_3Fe\cdot C{\equiv}CH}. \quad (3)$$



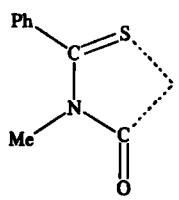
Complex **10** was found to be a good 1,3-dipolarophile. Reaction of **10** with **7** in Et_2O at 5°C proceeded to give **11**, in the form of a carbonyl-bridged dimer, possibly with a linkage between two iron centres, as shown in eqn (4):

(4)

In the absence of X-ray crystal structural data, the present proposed structure for complex **11** must be considered as tentative.

Treatment of **3** with Na in THF produced the sodium salt (**12**), which, in turn, reacted with **13** to give **14** [eqn (5)]:

(5)



All of these complexes are coloured, stable in an inert atmosphere, unstable in air and soluble in suitable organic solvents, and the solutions are stable for 1–3 h. Complexes **8–11** and **14** are non-conducting in nitromethane. Elemental analyses (Table 1) support their formulations. Molecular weights are also in agreement with these formulae.

In the IR spectra of **8**, **10** and **14** the expected π-

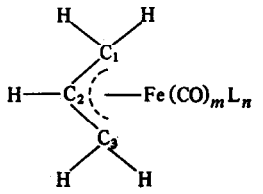
allylic, C---C---C, bands are observed around 1515–1525 cm^{-1}. Two or three very strong bands were observed around 1930–2080 cm^{-1} in complexes **8–11** and **14**, which may be assigned to ν(C≡O) absorption.[11,12] In addition a medium intense band was observed around 1858 cm^{-1} in complex **11** supporting the presence of a bridging CO group. The same compound (**11**) also showed three IR absorption bands around 1610, 1475 and 1385 cm^{-1}, supporting thereby the presence of a substituted isoxazole moiety in that complex.[13] The absorption at 1610 cm^{-1} appears as a very strong band with a shoulder at ~1600 cm^{-1}. This shoulder may be considered as a ring ν(C=N) absorption.[14] However, the presence of a σ-allylic group in this complex complicates this interpretation (see later discussion). The ν(C≡C) for **10** also absorbs in the ν(C≡O) region. Complexes, **9** and **14** show additional bands [for ν(C=O)] around 1631 and 1625 cm^{-1}, respectively. These relatively low energy absorptions suggest the presence of a carbamoyl function in these complexes,[15–19] which is formed by the insertion of a CO group between iron and nitrogen in complex **9a**, the possible intermediate species that might be formed in the synthesis of complex **9** [see eqn (2) above]. The tricarbonyl nature of the complex is retained, the additional CO being derived from the decomposed carbonyl complex. This may account for the low yield of complex **9**. The low yield of the carbonyl-bridged dimeric complex **11** may be accounted for similarly. The nucleophilic attack of metal-bound N to the C of CO may give rise to complex **9** with a five-membered ring:[20]



9a

9

The presence of the σ-allylic group in complexes **9** and **11** is demonstrated by the appearance of IR bands for ν(C=C) (allylic) in the 1610–1600 cm^{-1} region.[21] Two strong bands, one at about 685 cm^{-1} and another at about 500 cm^{-1} (slightly broad), were observed in complex **14** and may tentatively be assigned to the Fe—N stretching mode, which might be coupled with the N—CH_3 stretching mode.[20–22] Other important chromophoric groups (e.g. C=S, C=N, C=O etc.) present in these complexes could easily be identified from the IR spectral bands.[22]

These structural features of the present iron complexes have also been substantiated by the ^1H NMR spectral data (Table 2):

8 $m = 3$, $L_n = N{=}CPh_2$
10 $m = 3$, $L_n = C{\equiv}CH$
14 $m = 2$, $L_n = Me_2NCH_2CH_2C{=}O$

In complexes **8**, **10** and **14** (see Fig. 1) absorption of the proton at C_2 appears as complex bands around δ 4.7–5.1 ppm. A pair of doublets (broad) centred at around δ 2.7 and 1.8 ppm, which may be *syn* and *anti* protons at the C_1 and C_3 carbon atoms, respectively, are also observed for these complexes. These bands cannot be further resolved at room temperature. However, the integration is approximately correct for these formulations. These proton NMR data support the presence of π-allyl ligands[21,23–26] in complexes **8**, **10** and **14**. Complex **10** shows an additional band at δ 3.25 (singlet) ppm, showing the presence of acetylinic proton.

The synthesis, proton NMR spectral studies and X-ray crystal structure determination of σ-allyl-palladium(II) and σ-allyl-platinum(II) complexes have received much attention in the last few years,[26–31] in view of the role of these species as intermediates in the catalytic reactions of π-allyl metal complexes. Surprisingly, very few σ-allyliron complexes are known,[1,19] and in this sense the present complexes **9** and **11** are significant in representing some stable types of σ-allyliron complexes in solutions. The chelated (S, C and N, C) bonded ligands in complexes **9** and **14**, formed *in situ*, by the insertion of a CO molecule between Fe—N and Fe—C bonds, respectively, appear to be very strongly bound to iron so that the proton NMR spectra of complexes **9** and **14** at room temperature can be satisfactorily

interpreted in terms of rigid σ-allyliron bonding. In complex **9** the absorption of N—CH_3 and C_6H_5 protons appear as singlet and multiplets at δ 2.5 and 6.77 ppm, respectively. On the other hand, the presence of a σ-allylic ligand is demonstrated by the appearance of bands[1] at δ 2.80 ppm (broad, doublets) for Fe—CH_2, at δ 4.60 ppm (complex) for =CH_2 and at δ 6.00 ppm (complex) for —CH= species. Integrations of these bands are correct for these formulations. Similarly, the presence of the π-allyl ligand has been confirmed for complex **14**. The most interesting feature of the ^{1}H NMR spectrum of compound **14** is the low-field shift of the N—Me absorption in the complex (N—Me, δ 2.86 ppm) compared to the free-ligand absorption (N—Me, δ 2.23 ppm), the reason for which may be ascribed to the donation of electrons from N to Fe.

BOND LENGTH BASED BOND ORDERS FOR BORANE CLUSTER COMPOUNDS

NOEL W. THOMAS

H. H. Wills Physics Laboratory, University of Bristol, Royal Fort, Tyndall Avenue, Bristol BS8 1TL, U.K.*

(*Received* 5 *September* 1985; *accepted* 25 *November* 1985)

Abstract—The known molecular structures of several *closo* borane cluster compounds, together with established electron-counting rules, are used to derive a relationship between bond length and bond order for boron–boron two-centre bonds. This relationship is useful in deducing the distribution of electronic charge, and the approach can be extended to other homonuclear clusters.

The relationship between the structures of *closo* boron hydrides and their total enthalpies of atomization has been studied by two sets of workers. Wade *et al.*[1,2] have used a simple power law to relate the enthalpy of a boron–boron bond to its length. The total enthalpies of atomization of the clusters are then regarded as the sum of the enthalpies of all the bonds in the polyhedral cage. By contrast, Fuller and Kepert[3] have considered the total enthalpy of atomization of a cluster as made up of all boron–boron interactions, both bonded and non-bonded. To this end they use a bireciprocal relationship between the enthalpy of interaction of two boron atoms and their internuclear separation.

In this paper, a procedure analogous to that of Wade *et al.* is carried out, to relate the number of electrons in a given B—B bond to its corresponding length. The relationship is expressed as a polynomial, and the resulting order–length curve has a form similar to that for carbon–carbon bonds derived in the 1950s.[4] The method assumes, as a starting point, that the total number of skeletal electrons in a borane or carborane cluster, $(CH)_a(BH)_pH_q^{c-}$, is given by $3a+2p+q+c$, according to the electron-counting rules developed by Wade.[5] These rules have been proved to be very effective in rationalizing the chemistry of these compounds.

EXPERIMENTAL

Derivation of the order–length relationship for B—B *bonds*

The crystal structures of five *closo* boron hydrides, $B_nH_n^{2-}$, have been determined, where $n = 6$, 8, 9, 10 or 12[6–10] (Fig. 1). Knowledge of five independent structures allows us to express the number of electrons in a B—B bond as a polynomial of order four with respect to the bond length, i.e.:

$$p_i = A_{BB}+B_{BB}d+C_{BB}d_i^3+D_{BB}d_i^3+E_{BB}d_i^4. \quad (1)$$

In this equation, p_i is the number of electrons in the bond i, and d_i is its length. A_{BB}, B_{BB}, C_{BB}, D_{BB} and E_{BB} are variable parameters to be determined. For a given compound, $B_nH_n^{2-}$, the total number of skeletal electrons in the cluster is given by $\Sigma_{i=1,N}p_i$, where N is the total number of bonds in the cluster. By considering electron-counting rules,[5] it is known that the n atoms in the cluster are held together by $2(n+1)$ skeletal electrons, distributed over the B—B bonds. So, for each compound:

$$\sum_{i=1,N} p_i = 2(n+1). \quad (2)$$

Substituting for p from eqn (1):

$$2(n+1) = A_{BB}N+B_{BB}\sum_{i=1,N} d_i+C_{BB}\sum_{i=1,N} d_i^2 + D_{BB}\sum_{i=1,N} d_i^3+E_{BB}\sum_{i=1,N} d_i^4. \quad (3)$$

n is the number of atoms in the cluster, N the number of bonds in the cluster, and d_i is the length

* Present address: Department of Ceramics, Houldsworth School of Applied Science, The University of Leeds, Leeds LS2 9JT, U.K.

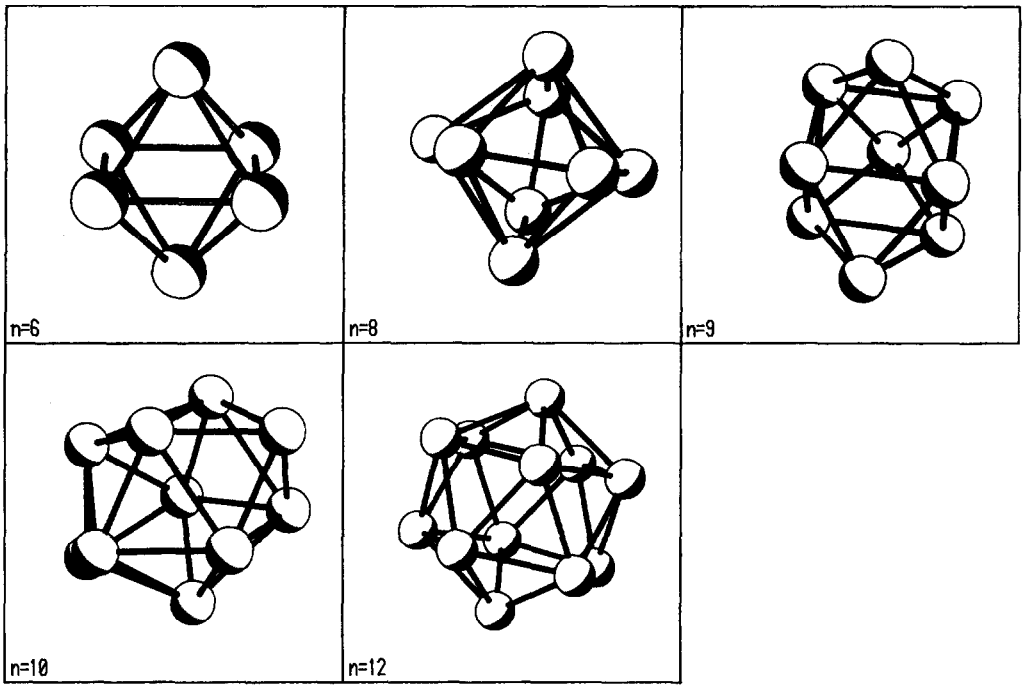

Fig. 1. Shapes of the polyhedral skeletons for *closo* clusters $B_nH_n^{2-}$: $n = 6$, 8, 9, 10 or 12.

of the ith bond. The summations in eqn (3) are evaluated for each cluster (Table 1), so that eqn (3) reduces to five simultaneous linear equations in the unknowns A_{BB}, B_{BB}, C_{BB}, D_{BB} and E_{BB}. For example, the equation for the $B_6H_6^{2-}$ cluster is:

$$14 = 12A_{BB} + 20.23B_{BB} + 34.12C_{BB} + 57.53D_{BB} + 97.00E_{BB}. \quad (4)$$

The simultaneous equations were solved numerically,[11] to yield the following parameters for boron–boron bonds:

$$A_{BB} = 0.92905 \times 10^3 \text{ electrons},$$

$$B_{BB} = -0.22361 \times 10^4 \text{ electrons Å}^{-1},$$

$$C_{BB} = 0.20238 \times 10^4 \text{ electrons Å}^{-2},$$

$$D_{BB} = -0.81409 \times 10^3 \text{ electrons Å}^{-3},$$

$$E_{BB} = 0.12263 \times 10^3 \text{ electrons Å}^{-4}.$$

The order of a given B—B bond is simply the number of electron pairs it contains, and the curve of bond order vs bond length obtained with these parameters is plotted in Fig. 2(a). This curve is reasonable apart from a minimum at a bond length of 1.87 Å. There is no physical basis for such a minimum, however. Assuming that this method is sound, its presence is a result of incorrect electron counts in some of the compounds and/or unreliable structural data. To establish which of the five clusters is causing this minimum, the above procedure was applied to sets of four structures and sets of three structures at a time. The most satisfactory curve was obtained from the structures of $B_6H_6^{2-}$, $B_{10}H_{10}^{2-}$ and $B_{12}H_{12}^{2-}$, as shown in Fig. 2(b). As only three structures are being considered, coefficients D_{BB} and E_{BB} in eqn (1) are set to zero. The values obtained for the other coefficients are as follows:

$$A_{BB} = 0.21781 \times 10^2 \text{ electrons},$$

$$B_{BB} = -0.20620 \times 10^2 \text{ electrons Å}^{-1},$$

$$C_{BB} = 0.49785 \times 10^1 \text{ electrons Å}^{-2}.$$

Note that these coefficients define the order–length relationship only within the range of bond lengths from 1.56 to 1.94 Å; bonds with lengths outside this range are not found in these *closo* clusters.

In deriving the order–length curve shown in Fig. 2(b), the structural data of compounds $B_8H_8^{2-}$ and $B_9H_9^{2-}$ have been omitted from the analysis. The above coefficients can be used, however, to calculate the total number of electrons involved in boron–boron bonding in these two clusters. The $B_8H_8^{2-}$ cluster is found to have 17.16 bonding electrons, and the $B_9H_9^{2-}$ cluster has 18.58; electron-counting rules, by comparison, ascribe 18 electrons to the former compound, and 20 electrons to the latter.

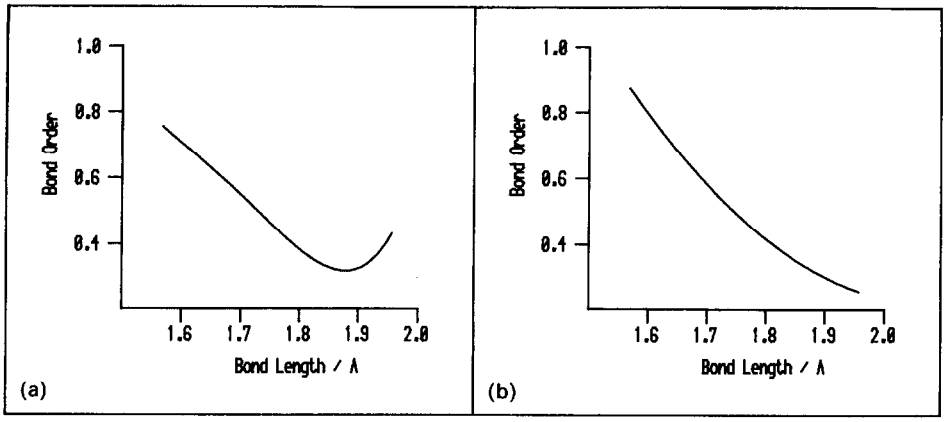

Fig. 2. (a) Curve of bond order vs bond length obtained from all five *closo* compounds. (b) Curve of bond order vs bond length obtained from compounds $B_6H_6^{2-}$, $B_{10}H_{10}^{2-}$ and $B_{12}H_{12}^{2-}$ only.

Several points can be made about this apparent discrepancy. First, the total number of bonding electrons contained in the skeletal cages may be less than $2(n+1)$ because of incomplete charge transfer from the relevant cations. Secondly, this method calculates the number of electrons involved in bonding: it is possible that the overlap of boron atoms in the $B_8H_8^{2-}$ and $B_9H_9^{2-}$ polyhedral cages is inadequate for use of all the $2(n+1)$ valence electrons in bonding. There is also experimental evidence that $B_8H_8^{2-}$ and $B_9H_9^{2-}$ species use their skeletal electrons less effectively than the $B_6H_6^{2-}$, $B_{10}H_{10}^{2-}$ and $B_{12}H_{12}^{2-}$ compounds.[2,12-14] It appears, therefore, that the order–length curve derived above is applicable to all *closo* borane clusters, to a good approximation.

Application to nido *and* arachno *boranes*

The validity of this approach may be assessed by calculating distributions of electronic charge in *nido* and *arachno* boranes. These systems can be regarded as clusters made up of B—B two-centre bonds and B—H—B bridge bonds. Table 2 summarizes the results obtained for three *nido* and two *arachno* boranes whose structures are known. The total number of bonding electrons in a *nido* cluster, B_nH_{n+4}, is $2n+4$; and the total number in an *arachno* cluster, B_nH_{n+6}, is $2n+6$, according to electron-counting rules.[5] Coefficients A_{BB}, B_{BB} and C_{BB} are used to calculate the total electronic charge distributed over boron–boron two-centre bonds in these compounds. The remaining charge is assumed to be distributed over the B—H—B bonds, of which there are four in *nido* clusters. The six *endo* hydrogen atoms in *arachno* boranes may be either bridging or terminal in character. In the case of B_4H_{10}, there are four bridging and two extra terminal hydrogen atoms; and in B_5H_{11} there are three bridging and three terminal atoms among its *endo* hydrogen atoms. It is seen in Table 2 that the average charge per B—H—B bridge bond varies between 1.34 and 1.64 electrons for the three *nido* compounds, B_5H_9, B_6H_{10} and $B_{10}H_{14}$; these values are of the correct order of magnitude: the hydrogen atoms can be considered to contribute one electron to the bridge bonds; and the contributions of the boron atoms will vary according to the different geometries adopted by the B—H—B bonds.

For the *arachno* clusters, however, the average charge per B—H—B bond is 2.58 electrons for the B_4H_{10} species, and 3.20 electrons for the B_5H_{11} compound. These values are erroneously large: either the method is inappropriate for *arachno* clusters, or the assumed role of the terminal *endo* hydrogen atoms must be brought into question. If it happens that these *endo* atoms do not *donate* an electron to the framework, but, rather, behave similarly to the *exo* hydrogen atoms in withdrawing charge from the boron atoms in forming B—H bonds, then the total number of electrons in the cage will be significantly less than $2n+6$. There is structural evidence that similar bonds do link both *endo* and *exo* terminal hydrogen atoms in both these *arachno* clusters. In B_4H_{10}, there are four *exo* B—H terminal bonds of length 1.190 Å, and two *endo* B—H terminal bonds of length 1.191 Å, and in B_5H_{11}, both *exo* and *endo* terminal bonds have lengths within the narrow range from 1.190 to 1.213 Å. The $2n+6$ electron-counting rule assumes that *endo* hydrogen atoms donate an electron to the cage-bonding. However, it is instructive to examine the different distributions of charge that would result if this rule were violated; Table 3 summarizes the alternative distributions.

It is seen that reasonable results are obtained for

Table 2. *Nido* and *arachno* boranes: distributions of bonding electrons over B—B two-centre and B—H—B three-centre bonds calculated with the use of electron-counting rules

Compound	Total charge[5] (electrons)	Charge distributed over B—B bonds (electrons)	Charge distributed over B—H—B bridge bonds (electrons)	Number of B—H—B bridge bonds	Average charge per B—H—B bridge bonds (electrons)
B_5H_9[15]	14	8.63	5.37	4	1.34
B_6H_{10}[16]	16	9.44	6.56	4	1.64
$B_{10}H_{14}$[17]	24	18.18	5.82	4	1.46
B_4H_{10}[15]	14	3.68	10.32	4	2.58
B_5H_{11}[15]	16	6.39	9.61	3	3.20

the charge distributed over the B—H—B bonds in these two compounds, provided that the $2n+6$ electron-counting rule is not applied.

DISCUSSION

This order–length relationship is a useful method of rationalizing the known structures of borane clusters, and in particular the variations in B—B bond lengths. It could be used to test the feasibility of alternative polyhedral arrangements which are consistent with known total electronic charges. And it has applications also in understanding patterns of reactivity, which are known to be dependent upon electronic charge distributions. Its self-consistency implies that the electron density in these compounds is, indeed, concentrated within the polyhedral surfaces.

A notable weakness of the approach is that it fails to take account of the partitioning of charge between atomic centres and interatomic bonds; so a formal calculation of residual atomic charges cannot be made. This is not a serious defect for the homonuclear clusters considered in this paper, but

Table 3. *Arachno* boranes B_4H_{10} and B_5H_{11}: variation of charge distributions with behaviour of *exo* terminal hydrogen atoms

	Compound					
	B_4H_{10}			B_5H_{11}		
Type of behaviour of *endo* terminal hydrogen atoms[a]	A	B	C	A	B	C
Total charge in cage (electrons)	14	12	10	16	13	10
Charge distributed over B—B bonds	3.68	3.68	3.68	6.39	6.39	6.39
Charge distributed over B—H—B bridge bonds	10.32	8.32	6.32	9.61	6.61	3.61
Number of B—H—B bridge bonds	4	4	4	3	3	3
Average charge per B—H—B bridge bond	2.58	2.08	1.58	3.20	2.20	1.20

[a] The total charge in the cage varies according to the behaviour of the *endo* terminal hydrogen atoms: for type A behaviour, *endo* H atoms donate an electron to the cage, giving rise to total charge of $(2n+6)$ electrons; for type B behaviour, *endo* H atoms do not add or remove any electrons from the cage; for type C behaviour, *endo* H atoms withdraw an electron from the cage. These three types of behaviour are limiting cases which indicate how the average charge per B—H—B bridge bond is affected.

problems are likely to arise for heteronuclear clusters, e.g. carboranes. In these compounds, the electronic charge distribution is influenced strongly by differences in electronegativity between atoms in the clusters. There is no reason, however, why a similar treatment should not be applied to other homonuclear *closo* clusters, such as metal carbonyl compounds.

This method does show, however, that the electron-counting rules for *closo* and *nido* boranes, coupled merely with an analysis of geometrical structures, provide a sensible and applicable picture of boron hydride chemistry.

All calculations have been carried out on a DEC VAX 11/750 computer, using software written by the author.

Acknowledgement—I thank Professor K. Wade for stimulating my interest in this field during my sojourn at the Department of Chemistry, University of Durham.

COMPLEXES OF PALLADIUM(II) AND PLATINUM(II) WITH 2-HYDRAZINOPYRIDINE AND 8-HYDRAZINOQUINOLINE

D. A. EDWARDS* and S. J. LARTER

School of Chemistry, University of Bath, Bath BA2 7AY, U.K.

(*Received* 23 *August* 1985: *accepted* 25 *November* 1985)

Abstract—The square planar complexes *cis*-$[MCl_2(hypy)]$, *cis*-$[MCl_2(hyqu)]$, $[Pt(hypy)_2][PtCl_4]$, $[Pd(hypy)_2][ClO_4]_2$ and $[Pd(hyqu)_2][ClO_4]_2$ (M = Pd or Pt, hypy = 2-hydrazinopyridine, hyqu = 8-hydrazinoquinoline), in which hypy and hyqu act as bidentate chelating ligands, have been prepared and characterized. Complexes containing hyqu do not appear to have been isolated previously.

Schiff bases have been used as multidentate ligands in coordination chemistry for many years. Many have been prepared simply by reacting 2-hydrazinopyridine (hypy) with suitable aldehydes and ketones. Typical examples are the terdentate ligand paphy[1] produced by condensation of hypy with pyridine-2-aldehyde and the quadridentate ligand arising from the reaction of two equivalents of hypy with one of diacetyl.[2] However, it is surprising to find that hypy itself has been neglected as a potential ligand. It would be expected to act in a bidentate manner, bonding via the pyridyl-nitrogen and the terminal hydrazino-nitrogen donor atoms. The only known complexes are $[Fe(hypy)_3]Cl_n$ ($n = 2$ or 3), reported[3] as early as 1933, and $[M(hypy)_3][ClO_4]_2$ (M = Fe, Co or Ni) and $[Co(hypy)_3][ClO_4]_3$ briefly documented[4] in 1969 without preparative, spectroscopic or magnetic data. In view of this sketchy knowledge of hypy as a ligand, we report here the isolation and characterization of some palladium(II) and platinum(II) complexes.

This study has also been extended to include the related ligand 8-hydrazinoquinoline (hyqu) which would also be expected to act as a chelating ligand but with the formation of six-membered, rather than five-membered, rings. As far as we have been able to ascertain, the only previous mention[5] of the use of hyqu as a ligand is a brief indication that it has been tested for complex formation with nickel chloride, the stability of the resulting, uncharacterized, complex being less than that of a related 8-aminoquinoline (amqu) complex. Amqu has found more use as a ligand, the complexes *cis*-$[MCl_2(amqu)]$ (M = Pd or Pt)[6] being most closely related to those reported here.

EXPERIMENTAL

Hypy[7] [yield 70%, m.p. 48°C (lit. 46–48°C)] and hyqu[8] [yield 65%, m.p. 65°C (lit. 64°C)] were prepared according to literature procedures. Apart from the ^1H NMR spectrum of hypy,[9] no other NMR data have been reported for these compounds. The ^1H and ^{13}C NMR spectra of the free ligands were therefore recorded using $CDCl_3$ solutions (hypy: ^{13}C: 107.1, d, C^3; 114.3, d, C^5; 137.4, d, C^4; 147.6, d, C^6; 161.4, s, C^2; hyqu: ^1H: 8.7, d, 1, H^2; 8.0, d, 1, H^4; 6.8–7.6, m, 4, H^3, H^5, H^6 and H^7; 3.0–4.2, br, 3, $NHNH_2$; ^{13}C: 105.8, d, C^7; 115.9, d, C^5; 121.5, d, C^3; 127.5, d, C^6; 128.5, s, C^{10}; 135.9, d, C^4; 137.6, s, C^9; 147.2, s, C^8; 147.3, d, C^2). A 70 eV EI mass spectrum of hyqu showed major ions (*m/z*, relative intensity, assignment) at: 159, 100, $[hyqu]^+$; 142, 67, $[hyqu-NH_3]^+$; 129, 57, $[hyqu-N_2H_2]^+$, i.e. $[quinoline]^+$; 102, 17, $[quinoline-HCN]^+$.

Preparations

Dichloro(2-hydrazinopyridine)palladium(II). A concentrated aqueous solution of K_2PdCl_4 (0.50 g, 1.53 mmol) was added to an ethanolic solution of hypy (0.18 g, 1.65 mmol). A precipitate immediately appeared. The reaction mixture was thoroughly stirred, allowed to stand for a few minutes and then filtered. The pale brown product was washed with ethanol and ether, and dried in air. Yield 0.28 g

(64%). Found: C, 21.2; H, 2.52; N, 14.7%. Calc. for $C_5H_7Cl_2N_3Pd$: C, 21.0; H, 2.46; N, 14.7%.

Bis(2-hydrazinopyridine)platinum(II) tetrachloroplatinate(II). The addition of a concentrated aqueous solution of K_2PtCl_4 (0.50 g, 1.20 mmol) to an ethanolic solution of hypy (0.14 g, 1.28 mmol) gave a green solution which slowly deposited a dark green precipitate on standing at room temperature. After 1 h this product was filtered off, washed with ethanol and ether, and dried in air. It slowly turned brown on prolonged exposure to moist air. Yield 0.14 g (31%). Found: C, 16.2; H, 1.91; N, 11.5%. Calc. for $C_5H_7Cl_2N_3Pt$: C, 16.0; H, 1.88; N, 11.2%.

Dichloro(2-hydrazinopyridine)platinum(II). Aqueous solutions of K_2PtCl_4 (0.50 g, 1.20 mmol) and hypy (0.14 g, 1.28 mmol) were mixed to give a green solution which was heated to boiling. As the temperature increased the green colour was replaced by a brown colour and, just before the solution reached its boiling point, a pale brown precipitate appeared. After cooling, this product was filtered off, washed with water and ethanol, and dried in air. Yield 0.28 g (60%). Found: C, 16.2; H, 1.82; N, 11.2%. Calc. for $C_5H_7Cl_2N_3Pt$: C, 16.0; H, 1.88; N, 11.2%.

Bis(2-hydrazinopyridine)palladium(II) perchlorate. An aqueous solution of K_2PdCl_4 (0.50 g, 1.53 mmol) was added to a mixed aqueous solution of hypy (0.35 g, 3.30 mmol) and $NaClO_4 \cdot H_2O$ (3.30 g, 23.5 mmol). A sandy-yellow precipitate formed immediately. The reaction mixture was heated to boiling, allowed to cool and the product filtered off, washed with water, then ethanol, and dried in air. Yield 0.51 g (63%). Found: C, 23.0; H, 2.69; N, 16.6%. Calc. for $C_{10}H_{14}Cl_2N_6O_8Pd$: C, 22.9; H, 2.69; N, 16.1%.

Dichloro(8 - hydrazinoquinoline)palladium(II). A concentrated aqueous solution of K_2PdCl_4 (0.56 g, 1.71 mmol) was added to an ethanolic solution of hyqu (0.30 g, 1.89 mmol). A brown precipitate formed immediately. The reaction mixture was heated to boiling, allowed to cool and the product filtered off, washed with ethanol, then ether, and dried in air. Yield 0.39 g (68%). Found: C, 31.6; H, 2.50; N, 12.6%. Calc. for $C_9H_9Cl_2N_3Pd$: C, 32.1; H, 2.70; N, 12.5%.

Dichloro(8 - hydrazinoquinoline)platinum(II). A concentrated aqueous solution of K_2PtCl_4 (0.50 g, 1.20 mmol) was added to an ethanolic solution of hyqu (0.21 g, 1.32 mmol). On boiling the reaction mixture the colour darkened and a brown precipitate formed. After cooling this was filtered off, washed with ethanol, then ether, and dried in air. Yield 0.22 g (42%). Found: C, 25.3; H, 2.10; N, 9.90%. Calc. for $C_9H_9Cl_2N_3Pt$: C, 25.4; H, 2.13; N, 9.88%.

Bis(8-hydrazinoquinoline)palladium(II) perchlorate. Mixing an aqueous solution of K_2PdCl_4 (0.50 g, 1.53 mmol) and an ethanolic solution of hyqu (0.52 g, 3.26 mmol) and $NaClO_4 \cdot H_2O$ (1.80 g, 12.8 mmol) gave an immediate sandy-brown precipitate. The reaction mixture was boiled, allowed to cool and the product filtered off, washed with ethanol, then ether, and dried in air. Yield 0.49 g (51%). Found: C, 34.1; H, 3.03; N, 13.6%. Calc. for $C_{18}H_{18}Cl_2N_6O_8Pd$: C, 34.7; H, 2.91; N, 13.5%.

Physical measurements

IR spectra of Nujol and hexachlorobutadiene mulls were recorded using a Perkin–Elmer 599B spectrometer. Conductivity measurements were carried out at 25°C on 10^{-3} M acetonitrile solutions using a Wayne–Kerr Autobalance bridge and a dip-type cell with platinum electrodes. Magnetic measurements were carried out at room temperature by the Gouy method. Electronic spectra were recorded using a Cecil Instruments CE 595 spectrophotometer. Proton and ^{13}C NMR spectra were recorded using JEOL PS 100 and FX-90Q spectrometers, respectively. Mass spectra were obtained using a VG 7070E spectrometer.

RESULTS AND DISCUSSION

The ^{13}C NMR spectrum of hypy, and the ^1H and ^{13}C NMR spectra of hyqu, do not appear to have been reported previously, so chemical-shift values, multiplicities and assignments are given in Experimental. The hydrazino protons appear as a broad singlet in the ^1H NMR spectra. The assignment of the ^{13}C NMR spectrum of hypy follows simply from that suggested for 2-aminopyridine.[10] In the decoupled ^{13}C NMR spectrum of hyqu the weak quaternary C^8 signal is virtually coincident with that associated with C^2, so only six intense and two weak resonances are observed as well-separated signals. In an off-resonance spectrum the C^8 signal is easily detected almost exactly midway between the two components of the C^2 doublet. The assignments proposed then follow those suggested[11] for 8-aminoquinoline.

The bidentate chelating behaviour of hypy and hyqu has been demonstrated by the preparation of the four *cis*-$[MCl_2(ligand)]$ (M = Pd or Pt, ligand = hypy or hyqu) complexes from K_2MCl_4. The reactions employing K_2PdCl_4 may be carried out at room temperature, but boiling solutions are required for the preparation of the platinum analogues, room-temperature reactions leading to alternative dark green products, discussed below.

Table 1. IR bands (cm^{-1})

Complex	ν(MCl)	ν(M–pyridyl nitrogen)	ν(ClO)	δ(OClO)
$PdCl_2$(hypy)	330s, 323s	255w		
$PtCl_2$(hypy)	325s, 315s	240w		
$PdCl_2$(hyqu)	325s, 315s	255w		
$PtCl_2$(hyqu)	320s, 310s	240w		
$[Pd(hypy)_2][ClO_4]_2$		255w	~1100vs,vbr	620vs
$[Pd(hyqu)_2][ClO_4]_2$		260w	~1100vs,vbr	620vs

The *cis*-[MCl_2(ligand)] complexes are, as expected, diamagnetic and are sufficiently soluble in acetonitrile to produce 10^{-3} M solutions which are essentially non-conducting at 25°C (Λ_M below 10 Ω^{-1} cm^2 mol^{-1}) (1:1 electrolytes have Λ_M in the range 120—160 Ω^{-1} cm^2 mol^{-1}). Thus the complexes are formulated as *cis*-square planar monomers with hypy and hyqu bonding through the pyridyl-nitrogen and hydrazino-NH_2 lone pairs. IR spectral evidence (Table 1) supports this proposal, two ν(MCl) bands being detected for each complex at similar frequencies to those of the related *cis*-[MCl_2(amqu)] (M = Pd or Pt) complexes.[6] A further band at *ca* 250 cm^{-1} can be assigned to a mode containing considerable metal–pyridyl-nitrogen stretching character, such a band being found at 227 cm^{-1} for *cis*-[$PtCl_2L$] (L = 2-aminomethylpyridine).[12] We are unable to suggest assignments for metal–hydrazino-nitrogen stretching frequencies, because both the free ligands and the complexes have a multiplicity of bands in the 400–500-cm^{-1} region of the IR spectra. As expected, the ν(NH) frequencies are lowered on coordination, e.g. uncoordinated hypy has ν(NH) at 3295, 3230 and 3150 cm^{-1}, whereas *cis*-[$PtCl_2$(hypy)] has ν(NH) at 3220, 3120 and 3040 cm^{-1}.

When aqueous K_2PtCl_4 and ethanolic hypy solutions are mixed at room temperature and the reaction mixture not warmed, a dark green, rather than a pale brown, product can be isolated which also has an analysis in agreement with the formulation $PtCl_2$(hypy). The intense green colour is reminiscent of a group of complexes that possess columnar structures with alternating, and strongly interacting, planar $[PtL_4]^{2+}$ and $[PtCl_4]^{2-}$ ions.[13] The prototype is Magnus' green salt $[Pr(NH_3)_4][PtCl_4]$ and several $[Pt(L_2)_2][PtCl_4]$ examples are known (L_2 = bidentate nitrogen donor chelating ligand, e.g. 2,2′-bipyrimidine[14]). The colour should not, however, be regarded as necessarily indicative of this structural type. Thus, for example, *cis*-$[PtCl_2(ampy)_2]\cdot H_2O$ (ampy = 2-aminopyridine bonded via the pyridyl-nitrogen only) is also green but suggested to be a square-planar monomer.[15] Nevertheless, we formulate our product as [Pt hypy)$_2$][$PtCl_4$] since: (i) only one IR band, at 315 cm^{-1}, is clearly assignable to υ(PtCl) as predicted for $[PtCl_4]^{2-}$, (ii) the complex has an absorption band with a maximum at 670 nm, a similar wavelength to the absorption peak maximum (690 nm) of $[Pt(bipym)_2][PtCl_4]$, (bipym = 2,2′-bipyrimidine),[14] and (iii) a 10^{-3} M solution in acetonitrile has a Λ_M of 154 Ω^{-1} cm^2 mol^{-1} per empirical formula unit. No attempts were made to find conditions which may have led to the hyqu analogue.

Reactions of K_2PdCl_4 with an excess of either hypy or hyqu in the presence of sodium perchlorate lead to the immediate formation of diamagnetic $[Pd(hypy)_2][ClO_4]_2$ and $[Pt(hyqu)_2][ClO_4]_2$ products. These complexes show the expected bi-univalent electrolyte behaviour as 10^{-3} M solutions in acetonitrile with Λ_M values of 280 and 286 Ω^{-1} cm^2 mol^{-1}, respectively. The normal Λ_M range for 10^{-3} M solutions of bi-univalent electrolytes in this solvent is 220–300 Ω^{-1} cm^2 mol^{-1}. The IR spectra of these two complexes show very strong bands (Table 1) associated with the ν(ClO) and δ(OClO) vibrations of the tetrahedral anions, a single band at *ca* 250 cm^{-1} assigned to ν(Pd–pyridyl nitrogen) but no bands in the ν(PdCl) region. These complexes are similar in type to $[Pd(phen)_2][ClO_4]_2$, which is known to contain square planar cations,[16] but in the hypy and hyqu complexes the bidentate ligands are unsymmetrical. As a result, the pyridyl-nitrogen donor atoms (and, of course, the hydrazino-nitrogen donor atoms) can be disposed in either *cis* or *trans* positions. The observation of only one ν(Pd–pyridyl nitrogen) band for each complex suggests that the *trans* isomers are favoured.

PREPARATIVE CHEMISTRY WITH $[Ru(\eta^6\text{-ARENE})(H_2O)_3]^{2+}$: BIS-ARENE AND MONOBENZENE COMPLEXES WITH O, N AND S DONORS

MONIKA STEBLER-RÖTHLISBERGER and ANDREAS LUDI*

Institut für Anorganische Chemie, Universität Bern, CH-3000 Bern 9, Switzerland

(*Received* 14 *November* 1985; *accepted* 18 *November* 1985)

Abstract—The preparation, and electronic, ^1H and ^{13}C NMR spectra of the complex ions $[Ru(\eta^6\text{-}C_6H_6)L_3]^{2+}$ (L = acetonitrile, dimethylsulphoxide, dimethylsulphide or tetrahydrothiophene) from $[Ru(\eta^6\text{-}C_6H_6)(H_2O)_3]^{2+}$ are reported. The NMR data of coordinated benzene are discussed in terms of the π-backbonding capacity of the monodentate ligand.

Half-sandwich complexes of general stoichiometry $[Ru(\eta^6\text{-arene})L_1L_2L_3]^{2+}$ have been conventionally prepared using $[Ru(\eta^6\text{-arene})Cl_2]_2$ as the starting reagent, affording monomeric species still retaining one or two chloro ligands.[1] The chloro-bridged dimeric precursor itself is obtained by the reaction of "$RuCl_3 \cdot xH_2O$" with cyclohexadiene.[2] Hydrolysis of the dimer produces the ion $[Ru(\eta^6\text{-arene})(H_2O)_3]^{2+}$, which shows a very high tendency to dimerize and tetramerize.[3] We became interested in the monomeric ruthenium–arene–triaqua cation because it is a remarkable link between the classical hexaaqua ions and the organometallic $Ru(\eta^6\text{-arene})_2^{2+}$ sandwich compounds. A solution study of a variety of $Os(benzene)^{2+}$ complexes and some of their ruthenium analogs led to the conclusion that these Os(II)– and Ru(II)–arene moieties are perfectly stable in an aqueous environment, at least in the dark.[4] Our investigation of the $Ru(H_2O)_6^{2+/3+}$ couple[5] and of the formation, the molecular structure, and the substitution kinetics of $[Ru(\eta^6\text{-}C_6H_6)(H_2O)_3]^{2+}$[6] initiated a more general study of these "piano-stool" complexes, including the variation of the arene ligand and, more importantly, of the three monodentate ligands. Owing to its rather high substitution lability the ion $[Ru(\eta^6\text{-}C_6H_6)(H_2O)_3]^{2+}$ is a very convenient precursor in preparative ruthenium chemistry, as in a recent report dealing with the specific case of phosphine ligands.[7]

EXPERIMENTAL

Two different procedures have been used for the synthesis of the $[Ru(\eta^6\text{-arene})(H_2O)_3]^{2+}$ complex ion:

(A) An aqueous acidic (0.1 M) solution of the dimeric $[Ru(\eta^6\text{-arene})Cl_2]_2$[2] (2 mmol) is stirred for 3 h with the stoichiometric amount of an appropriate silver salt [SO_4^{2-}, tos^- (*p*-toluenesulphonate) or $tmms^-$ (2,4,6-trimethylbenzenesulphonate)]. Solid AgCl is removed by filtration.

(B) $Ru(H_2O)_6^{2+}$ salts[5] smoothly react under argon in tetrahydrofuran or ethanol with cyclohexadiene to produce $[Ru(\eta^6\text{-}C_6H_6)(H_2O)_3]^{2+}$ in very good yield.[6] 1,3- as well as 1,4-cyclohexadiene may be used as the reagent. ^1H NMR monitoring of the reaction reveals the conversion of the 1,4- into the 1,3-isomer prior to substitution and further rearrangement. The complex disproportionation reaction produces the arene complex together with cyclohexene and cyclohexane.[6]

Subsequent concentration of the solutions obtained by procedures A or B under reduced pressure at 40°C and cooling to 5°C affords crystalline salts of the $[Ru(\eta^6\text{-arene})(H_2O)_3]^{2+}$ ion.

Substitution of the three water molecules by other monodentate ligands (L) is carried out under quite mild conditions:

L	Solvent	*T* (°C)	Yield (%)	Color
Acetonitrile (AN)	AN	40	63	Yellow-white
Dimethylsulphoxide (DMSO)	H_2O	50	50	Orange
Dimethylsulphide (DMS)	MeOH	25	85	Yellow
Tetrahydrothiophene (THTP)	MeOH	50	90	Yellow

Microcrystalline solids of the resulting $[Ru(\eta^6\text{-}C_6H_6)L_3]^{2+}$ ions are isolated as PF_6^- salts.

$[Ru(\eta^6\text{-}C_6H_6)(H_2O)_3]^{2+}$ is also a convenient precursor for simple and efficient syntheses of the known mixed bis-arene complexes $[Ru(\eta^6\text{-}C_6H_6)(\eta^6\text{-arene})]^{2+}$ (arene = benzene, mesitylene, hexamethylbenzene, *p*-cymene or anisole), originally prepared from $[Ru(\eta^6\text{-arene})Cl_2]_2$.[8] $Ru(\eta^6\text{-}C_6H_6)(H_2O)_3(tos)_2$ (0.87 mmol) dissolved in trifluoroacetic acid (20 cm^3) is heated for 1 h under reflux with 20 cm^3 of the appropriate arene. The resulting reaction mixture is evaporated to dryness under reduced pressure and the residue is dissolved in MeOH. Colorless solids are precipitated as tos^- or BF_4^- salts with yields in the 80–98% range.

Ruthenium was determined spectrophotochemically;[9] elemental analyses were carried out by Ciba-Geigy, Basel. Analytical results are collected in Table 1. ^1H NMR spectra were measured with a Bruker WP 80 or a Varian EM 360 instrument, and ^{13}C NMR spectra with a Varian XL 100. UV–VIS spectra were recorded on a Cary 17 DX.

RESULTS

Whereas complete removal of the chloro ligands is rather difficult for the conversion of $[Ru(\eta^6\text{-arene})Cl_2]_2$ into monomeric $[Ru(\eta^6\text{-arene})L_3]^{2+}$ species,[2,4] the precursor $[Ru(\eta^6\text{-arene})(H_2O)_3]^{2+}$ offers a very facile and efficient route for the synthesis of these half-sandwich complexes for a variety of monodentate ligands (L). As a byproduct of this study $[Ru(\eta^6\text{-arene})(H_2O)_3]^{2+}$ is also shown to be a very good starting reagent for high-yield preparations of mixed bis-arene compounds, $[Ru(\eta^6\text{-arene})(\eta^6\text{-arene})]^{2+}$.

The isolated solid salts of $[Ru(\eta^6\text{-arene})L_3]^{2+}$ are perfectly stable in air. Their solutions in aqueous and non-aqueous solvents do not show any feature in the cyclic voltammetry that could be assigned to a reversible redox process. In other words, the compounds described in this study are neither oxidized nor reduced in the potential interval −0.25 to +1 V (vs NHE). This considerably enhanced stability of the oxidation state II of ruthenium is generally attributed to the π-backbonding behavior of the arene ligands (cf. next section).

Solution spectra of the various half-sandwich complex ions exhibit absorption bands in the short visible and the UV region (Table 2). The lowest-energy band generally is observed around 400 nm. Considering the intensity of these absorptions we assign them to charge-transfer transitions which are significantly red-shifted with respect to the corresponding bis-arene compounds.[1,2] The very similar spectra for $[Ru(\eta^6\text{-}C_6H_6)(H_2O)_3]^{2+}$ and $[Ru(\eta^6\text{-}C_6H_6)(DMSO)_3]^{2+}$ are accepted as supporting evidence for oxygen-coordinated DMSO in line with the NMR data.

^1H and ^{13}C NMR spectroscopic results of the various complex ions are collected in Tables 3 and 4. We observe an overall upfield shift for the signals

of the carbon and hydrogen atoms within the ring of the arene ligands compared to the free aromatic molecule. The uncoordinated hydrocarbons show ^1H signals for the ring protons between 6.73 ppm (mesithylene) and 7.27 ppm (benzene) and ^{13}C resonances between 126 and 136 ppm. Significantly smaller shifts, upfield as well as downfield, are recorded for the C and H atoms of the ring substituents.

DISCUSSION

The most important general feature of the NMR data for the arene ligands, the high-field shift of the ring carbon and hydrogen signals (Table 3), is attributed to π-backbonding within the ruthenium–arene moiety.[10] Accordingly, electron density is removed from the metal atom to the arene molecule, thus leading to an enhanced shielding of the ring atoms. This effect is opposed by the positive charge of the metal center. We do not attempt, however, to assess a closer or quantitative relation between these or other effects on the chemical shifts.

A somewhat more informative picture is presented by the NMR data for $[Ru(\eta^6\text{-}C_6H_6)L_3]^{2+}$ (Table 4). ^1H and ^{13}C NMR signals of coordinated benzene show a strong dependence on the bonding properties of the ligand L, in particular, whether L itself is a π-acceptor or not. Spectroscopic data of η^6-benzene can thus be used to probe selected properties of the remaining monodentate ligands. The ordering of ligands according to measured ^1H and ^{13}C shift differences (Table 5) matches a ligand series of π-acidity observed for ruthenium(II) pentaammine complexes.[11] The selection of ligands employed in our study ranges from virtually pure σ-donors, such as H_2O, to the typical π-acceptors AN and dialkyl sulfide. The observed NMR behavior is thus qualitatively attributed to the influence of the monodentate ligand competing in the bonding scheme of the $[Ru(\eta^6\text{-arene})L_3]^{2+}$ ions with the aromatic molecule. π-Acidity is also strongly reflected in thermodynamic and kinetic properties of related hexacoordinated complex ions such as $[Ru(H_2O)_6]^{2+}$ and $Ru(AN)_6^{2+}$. The reduction potential of the $[Ru(H_2O)_6]^{3+/2+}$ couple is 0.21 V, whereas $Ru(AN)_6^{2+}$ cannot be oxidized up to 1.9 V.[12] Similarly, the rates for ligand exchange are $2 \times 10^{-2}\,s^{-1}$ for water[13] and $10^{-9}\,s^{-1}$ for AN.[14] Current studies in our laboratory dealing with a variety of ligands within the series $[Ru(\eta^6\text{-arene})_2]^{2+} \rightarrow [Ru(\eta^6\text{-arene})L_3]^{2+} \rightarrow RuL_6^{2+}$ are expected to provide further insight into this relationship between electronic structure and chemical reactivity.

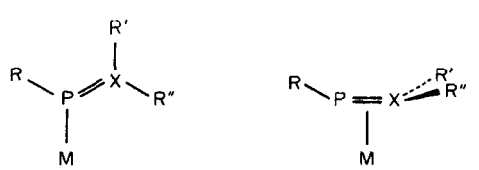
ON THE *E–Z* ISOMERIZATION IN PHOSPHAALKENE METAL COMPLEXES



MINH THO NGUYEN, M. A. McGINN and A. F. HEGARTY*

Department of Chemistry, University College, Belfield, Dublin 4, Ireland

(*Received* 8 *October* 1985; *accepted* 9 *December* 1985)

Abstract—Extended Hückel calculations of the model $(MeP{=}CMe_2)Cr(CO)_5$ showed that η^1-complexation of phosphaethene with the transition-metal fragment reduces the rotation barrier about the P=C bond. This is due to stabilization of the non-planar transition state by an additional π-interaction. Because the P—M bond in the planar complex is of σ character, the angle of rotation around this bond is determined by the non-bonding repulsions between the substituents on the phosphaalkene and $M(CO)_5$ groups.

The ability of phosphaalkenes RRC=PR [and also diphosphenes (RP=PR′) and iminophosphanes (RP=NR′)] to form transition-metal complexes has been recognized for several years, and a number of such compounds have now been characterized both structurally and spectroscopically.[1–12] These have shown that the phosphaethene system has a choice of two co-ordination modes—η^1 via the phosphorus lone pair (**I**) or η^2 via the P=C double bond (**II**). The majority of known compounds adopt the η^1-mode, but a few examples of η^2-co-ordination have been characterized recently—$(\eta^2$-(mesityl)P=C$(Ph)_2)Pt(PPh_3)_2$,[2] $(\eta^2$-(xylyl)P=C$(Ph)_2)Ni(bipy)$[4] and $(\eta^2$-$((Me_3Si)_2CH)$P=C$(SiMe_3)_2)Ni(PMe_3)_2$.[6]

I **II**

Preference for the η^2-mode over η^1 seems to depend on the nature of the metal atom (for example, no η^2-bonded chromium complex has yet been observed). However, a recent HFS-LCAO-X_α study of η^1- and η^2-binding in $(\eta^2$-(mesityl)P=C$(Ph)_2)Pt(PPh_3)_2$[2] revealed only a small energy difference between the two structures, suggesting that the incorporation of very bulky groups into the phosphaethene might be sufficient to tip the balance in favour of the η^1-geometry.

An interesting feature of these molecules has recently been noted by Yoshifuji and co-workers, who have reported the structure and properties of the η^1-pentacarbonylchromium complexes of *cis*-(mesityl - 2,4,6 - tri - *tert* - butylphenyldiphosphene)[1] and *cis*-(P-2,4,6-tri-*tert*-butylphenyl)phenylphosphaethene.[11] They found that *trans* → *cis* isomerization can occur easily in the complex, but not in the isolated species, and inferred that the energy barrier to rotation about the P=P or P=C bond is lowered by co-ordination.

A preliminary self-consistent charge and configuration extended Hückel[13] study of a model pentacarbonylchromium η^1-phosphaethene complex was carried out (the η^2-bonding mode was not considered because no such structure has been experimentally observed). The objectives were to: (a) establish the main conformational features of the structures, (b) assess the relative importance of the σ and π contributions to the M—P bond, and (c) explain the decrease in the energy barrier to rotation about the P=C bond.

The geometries of the model complexes (η^1-$MeP{=}CMe_2)Cr(CO)_5$ (**III**), based on available structural data[10] are shown in Fig. 1. Methyl groups were used as substituents on the phosphaethene ligands to simulate as far as possible the bulky groups which are a common feature of all the experimentally known molecules. These were disposed so as to minimize non-bonded repulsions between the hydrogen atoms.

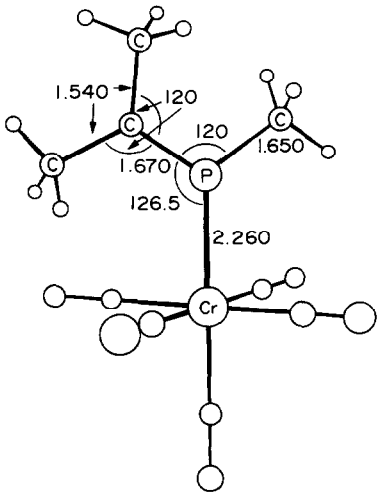

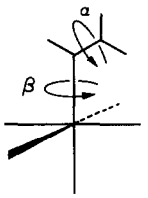

Fig. 1. Model geometries for (η^1-$H_3CP{=}C(CH_3)_2$)Cr$(CO)_5$ (**III**).

Calculations on the isolated ligands [Fig. 2(a)] show that for $MeP{=}CMe_2$, where there are no *cis* and *trans* isomers for the model, the barrier to internal rotation is 2.12 eV (compared to a value of 3.2 eV calculated for $HP{=}CH_2$ with the same method and basis).

Optimization of the P=C and P—Cr rotation angles, α and β (**IV**), of the complex, shows that the lowest-energy pathway for isomerization by rotation occurs at $\beta = 45°$ (i.e. when the Cr—P—C plane bisects an edge of the octahedron). The energy profiles for the variation in α at this angle are shown in Fig. 2(b).

IV

The barrier to P=C rotation in **III** is 1.1 eV, approximately half of that calculated for unco-ordinated phosphaethene, and also comparable with the experimental findings.[11] The origin of the decrease in barrier height was examined in detail for **III**, because in this case only "planar" and "non-planar" (rotation transition state) geometries must be considered. An energy level diagram showing the isolated and complexed planar and non-planar geometries is depicted in Fig. 3. The fragment orbitals of $M(CO)_5$ have been analysed by several groups.[14] The LUMO is a σ-symmetry hybrid consisting of d_{z^2} contributions, related to the e_g-set of

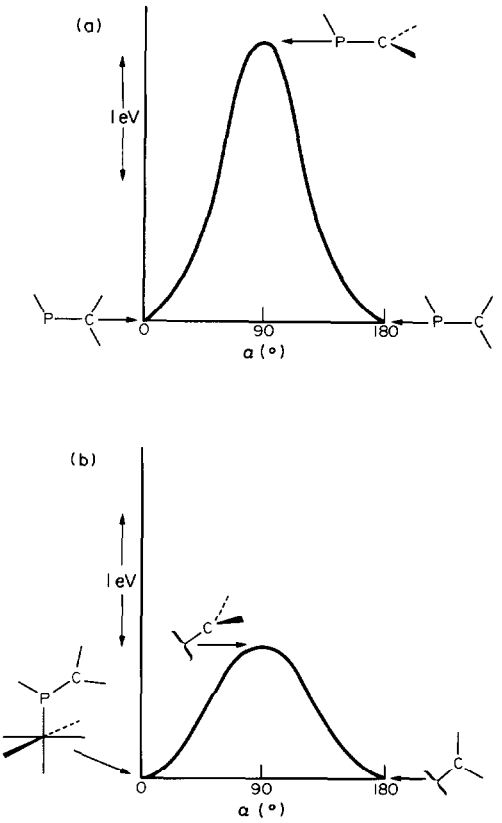

Fig. 2. Energy barriers to rotation in isolated (a) and co-ordinated (b) $H_3CP{=}C(CH_3)_2$.

an octahedron. Similarly, the HOMOs are derived from the t_{2g} octahedral set and comprise a d_{xz} and d_{yz} π-symmetry degenerate pair and a lower-lying δ-symmetry d_{xy}-orbital.

In the case of the "planar" co-ordinate phosphaethene complex, the major bonding interaction is of σ-type between the d_{z^2} LUMO of $M(CO)_5$ and the phosphorus-lone-pair-character HOMO of phosphaethene. The π-character $M(CO)_5$ HOMOs are destabilized slightly by interaction with the low-lying π phosphaethene-bonding MO, but interaction is weak. The π^*-orbital lies too high in energy to interact. Hence the Cr—P bond is almost purely σ in nature and its strength should not be affected by rotation. The presence for the $\beta = 45°$ geometry thus arises solely from steric repulsion between the $M(CO)_5$ and methyl groups. This is confirmed by calculations on the $HP{=}CH_2$ complex which indicate an almost zero rotational barrier.

For the complexed non-planar (rotation transition state) phosphaethene, the picture is quite different. The destabilization of the HOMOs of the unco-ordinated ligand relative to the planar structure accounts almost entirely for the energy barrier to P=C rotation in the isolated ligand. The LUMO

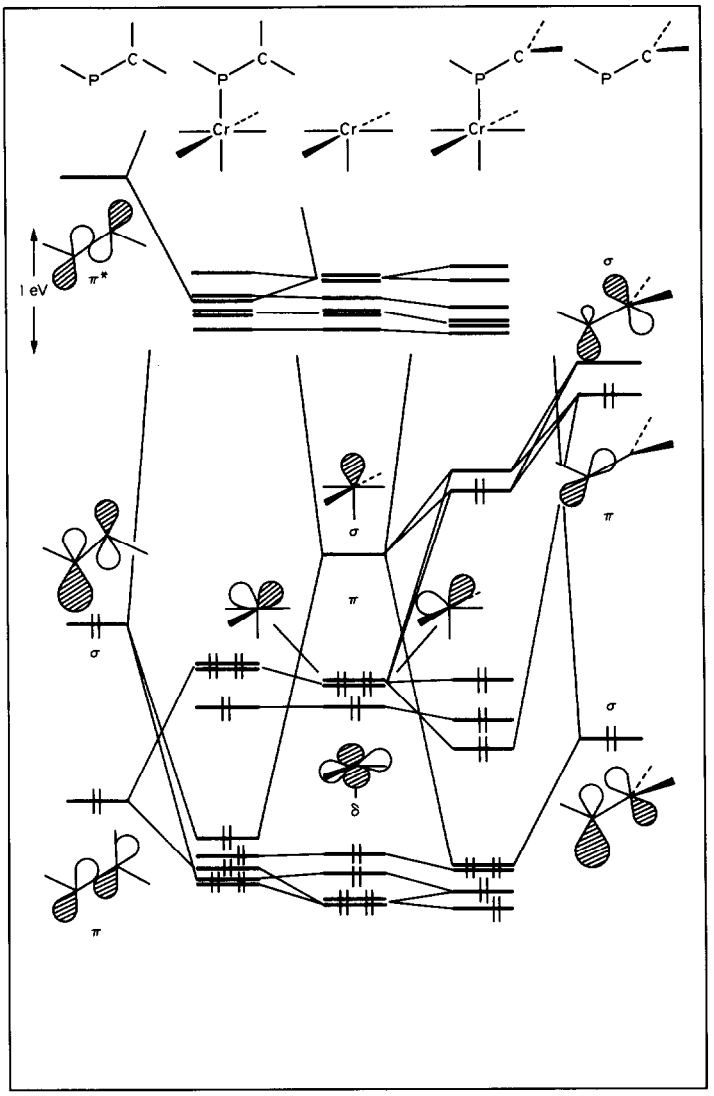

Fig. 3. Energy level diagram for (η^1-$H_3CP{=}C(CH_3)_2$)$Cr(CO)_5$ in "planar" (left) and "non-planar" (right) conformations.

lies much lower than that in the planar conformer, resulting in a very small HOMO–LUMO separation. The σ-interaction is smaller in this case than in the "planar" complex, because the energy separation between orbitals of suitable symmetry is bigger. This, combined with the destabilization of the HOMO levels largely accounts for the rotational barrier in the complex. The reason that this barrier is lower is an additional stabilizing interaction which occurs between the π $M(CO)_5$ HOMOs and the HOMO of phosphaethene. (The latter orbital is almost exclusively phosphorus p_π.) The antibonding interaction between these orbitals gives rise to the HOMO of the complex.

In summary, the SCCC calculations on the model ($MeP{=}CMe_2$)$Cr(CO)_5$ complex show that η^1-complexation of phosphaethene with the transition-metal fragment reduces the energy barrier to isomerization via rotation about the P=C bond. This is due to stabilization of the non-planar transition structure by an additional π-interaction. In the planar complex, the P—M bond is almost exclusively of σ character, and thus the angle of rotation around the P—M bond is determined by the non-bonding repulsions between the substituents on the phosphaethene and $M(CO)_5$ group.

SYNTHESIS AND SPECTROSCOPIC INVESTIGATION OF ADDUCTS OF DIORGANO TIN(IV) DICHLORIDE

J. C. TREHAN, R. K. SHARMA and C. P. SHARMA*

National Physical Laboratory, Hillside Road, New Delhi 110012, India

(*Received* 12 *July* 1985; *accepted after revision* 12 *December* 1985)

Abstract—Adducts of bis-*p*-biphenyl tin(IV) dichloride of types $(p\text{-}C_6H_5\text{-}C_6H_4)_2SnCl_2 \cdot 2L$ and $(p\text{-}C_6H_5\text{-}C_6H_4)_2SnCl_2 \cdot L_1$ (where 2L = pyridine, piperidine, α-, β- or γ-picolines, isoquinoline or morpholine and L_1 = 2,2′-bipyridine or 1,10 phenanthroline) have been prepared by the reaction of bis-*p*-biphenyl tin(IV) dichloride with the corresponding ligand in 1:2 and 1:1 molar ratios in acetone. IR, ^1H NMR and Mössbauer studies indicate that the biphenyl group occupies the *trans* position, except in morpholine, where it is in the *cis* position.

Organotin halides, like the tetrahalides of tin, react with certain electron pair donors to form addition compounds.[1–6] From a review on organotin compounds[1] it is clear that the majority of adducts are of type $R_xSnX_{4-x} \cdot 2L$ (where R = organic radical, X = halogen, and L = electron pair donor). Studies have been done on both types of adducts, i.e. adducts with symmetric diorgano tin dichlorides as well as adducts with asymmetric diorgano tin dichloride.[1–10] Jaura *et al.*[3,7,9,10] have carried out stereochemical investigations on asymmetric diorgano tin dichloride adducts and with the help of IR and Mössbauer spectroscopy have concluded that organic R groups occupy positions *trans* and *cis* to the halogens. Similar types of arrangement of the organo and halogen groups have also been supported by different workers[1–19] on the basis of spectral studies, e.g. IR, NMR and Mössbauer, and also by crystal structures.

The present paper describes the synthesis and spectroscopic investigation of some new adducts of bis-*p*-biphenyl tin dichloride of type $(p\text{-}C_6H_5\text{-}C_6H_4)_2SnCl_2 \cdot 2L$ (where L = pyridine, α-, β- or γ-picoline, morpholine, piperidine or isoquinoline) and $(p\text{-}C_6H_5\text{-}C_6H_4)_2SnCl_2 \cdot L_1$ where (L_1 = 2,2′-bipyridyl or 1,10-phenanthroline.

EXPERIMENTAL

(a) All the required organic solvents, e.g. benzene, petroleum, ether (60–80°C), acetone, dichloromethane etc., were purified and dried before use by standard methods.

(b) Nitrobenzene for conductance measurements was purified as described by Fay and Lowry.[20]

(c) Pyridine, α-, β- and γ-picoline, piperidine, morpholine, isoquinoline, 2,2′-bipyridyl and 1,10-phenanthroline (A.R.B.D.H.) were used.

(d) Bis-*p*-biphenyl tin dichloride was prepared as described in the literature.[21]

Bis-p-*biphenyl tin(IV) dichloride* · 2*pyridine*

A solution of dichloro bis-*p*-biphenyl tin (0.4957 g, 1 mmol) in acetone (50 cm^3) was added dropwise to a solution of pyridine (0.1582 g, 2 mmol) in acetone (50 cm^3). The solvent was concentrated to 10 cm^3 under reduced pressure and then precipitated by adding petroleum ether dropwise with constant shaking. The complex was filtered and dried *in vacuo*. Recrystallization from benzene gave a white solid (70% yield).

Complexes with α-, β- and γ-picoline, morpholine, piperidine and isoquinoline were prepared by the same method. Bis-*p*-biphenyl tin(IV) dichloro 2,2′-bipyridyl and 1,10-phenanthroline were also

prepared by the same method using (p-C_6H_5-$C_6H_4)_2SnCl_2$ (0.495 g, 1 mmol) and 2,2′-bipyridyl (0.1562 g, 1 mmol).

Analytical data of these complexes are reported in Table 1.

IR spectra

IR spectra were recorded with a Perkin–Elmer 621 grating spectrometer, with the main emphasis in the 600–250-cm^{-1} region.

^{1}H *NMR*

Proton magnetic resonance spectra were recorded at ambient temperature (28°C) at a sweep width of 900 Hz with a Perkin–Elmer R-32 spectrometer. Spectra were recorded in triplicate. The magnetic field sweep was calibrated with a standard sample of chloroform and tetramethyl silane (1%) in deuterated chloroform.

Mössbauer spectroscopy

Mössbauer spectra were recorded as reported earlier.[22]

RESULTS AND DISCUSSION

The new bis-p-biphenyl tin(IV) dichloride adducts of types (p-C_6H_5-$C_6H_4)_2SnCl_2 \cdot 2L$ (where L = pyridine, α-, β- or γ-picoline, morpholine, isoquinoline or piperidine) and (p-C_6H_5-$C_6H_4)_2SnCl_2 \cdot L_1$ (where L_1 = 2,2′-bipyridine or 1,10-phenanthroline) have been prepared from bis-p-biphenyl tin(IV) dichloride and the corresponding ligand in acetone in 1:2 and 1:1 molar ratios according to the following equations:

$$(p\text{-}C_6H_5\text{-}C_6H_4)_2SnCl_2 + 2L \rightarrow (p\text{-}C_6H_5\text{-}C_6H_4)_2SnCl_2 \cdot 2L,$$

$$(p\text{-}C_6H_5\text{-}C_6H_4)_2SnCl_2 + L_1 \rightarrow (p\text{-}C_6H_5\text{-}C_6H_4)_2SnCl_2 \cdot L.$$

The isolated products were of high purity as indicated by their satisfactory elemental analysis and ^{1}H NMR spectroscopy. The complexes are white crystalline solids, fairly stable in a dry and inert atmosphere, and are soluble in most of the common organic solvents like acetone, chloroform and benzene, but insoluble in petroleum ether.

IR spectra

In the IR studies reported in Table 2 the main emphasis is on the 650–200-cm^{-1} region where there are Sn—C and Sn—Cl stretching frequencies.

In all the adducts of bis-p-biphenyl tin(IV) dichloride reported here we get one strong band (~550–600 cm^{-1}) which may be assigned to a

Sn—C stretching vibration, which suggests that the phenyl group occupies the *trans* position.[11,23,24]

Each complex reported here, except for the morpholine complex, shows two bands corresponding to symmetric and asymmetric Sn—Cl stretching (~245 and 290 cm^{-1}, respectively). This suggests that chlorine atoms occupy the *cis* position. In the case of the morpholine adducts, only one Sn—Cl stretching frequency appears to be IR-active. The chlorines are thus likely to occupy a linear position.[19] N—H stretching frequencies in the cases of the piperidine and morpholine complexes decrease, as is evident from Table 2. This is also due to the donation of electrons by nitrogen on coordination.[25]

^{1}H *NMR spectra*

The ^{1}H NMR spectra of the bis-*p*-biphenyl tin(IV) dichloride adducts are given in Table 3 and correlations of the resonance signals with various groups present in the molecules have been made.

[a] Mössbauer measurements were carried out at 88 K. All the IS values are with respect to $BaSnO_3$ absorbent at room temperature.
[b] Values are correct within ± 0.05 mm s^{-1}.

Mössbauer spectra

The Mössbauer data, including the isomer shift (IS) and quadrupole splitting (QS), of bip-*p*-biphenyl tin dichloride adducts are summarized in Table 4. The IS values are well within the range characteristic of Sn(IV) species.

It is evident from Table 4 that the IS values of the picoline adducts lie in the range 1.25–1.30 mm s^{-1}, which shows that the values are almost constant within experimental error. This reveals that the *s*-electron density on the tin atom remains almost unchanged even on co-ordination with picolines. In the case of the isoquinoline adduct the IS is $\sim$1.31 mm s^{-1}, which is higher than in the case of the picoline adducts. This indicates an increased *s*-electron density on the tin nucleus on complexation with isoquinoline in contrast to the picoline adducts. This is probably due to the greater p_π–d_π bonding effect of isoquinoline than of picolines.

In the case of the adduct with morpholine, there is a variation in the IS, which is $\sim$1.15 mm s^{-1}, which indicates a decrease in the *s*-electron density around the tin atom. This is probably due to the hydrogen bonding between morpholine and the chlorine atom of the organo tin chloride which is expected to reduce the electron density on the central tin atom. This suggests that the chlorine atom and the morpholine adduct lie close to each other.

QS values for all the adducts reported here, except for the morpholine adduct, are in the range 3.7–4.0 mm s^{-1}. This value of about 4 mm s^{-1} suggests a *trans* arrangement of the organic groups in these adducts.[15,26–28] However, for the morpholine adduct the situation is different. The QS value is 2.32 mm s^{-1}, not far away from 2 mm s^{-1}, suggesting that the organic groups around the tin atom occupy *cis* positions. Earlier Hendrichar[8] reported a *trans* alkyl configuration on the basis of NMR data for the symmetrical dialkyl tin dichloride γ-picoline adduct.

Thus, on the basis of elemental analysis, and IR, ^{1}H NMR and Mössbauer studies, all the adducts reported here, except for the morpholine adduct, can be assigned the structure in Fig. 1(a). The morpholine adduct can be assigned the structure in Fig. 1(b).

COMMUNICATION

SYNTHESIS, SPECTRAL PROPERTIES AND REACTIONS OF THE NOVEL DINUCLEAR ALKYNE COMPLEXES $[M(\mu\text{-}I)I(CO)(NCMe)(\eta^2\text{-}PhC_2R)]_2$ (M = Mo OR W, R = Ph OR Me)

PAUL K. BAKER* and ELAINE M. KEYS

(*Received* 6 *December* 1985; *accepted* 19 *December* 1985)

Abstract—$[MI_2(CO)_3(NCMe)_2]$ (M = Mo or W) and PhC_2R (R = Ph or Me) react in CH_2Cl_2 to initially afford the "four-electron" alkyne complexes $[MI_2(CO)(NCMe)_2(\eta^2\text{-}PhC_2R)]$, which subsequently dimerize to the novel iodide-bridged compounds $[M(\mu\text{-}I)I(CO)(NCMe)(\eta^2\text{-}PhC_2R)]_2$, with loss of acetonitrile. These complexes react *via* symmetrical cleavage of the iodide bridges.

Alkynes are becoming increasingly important as ligands in organometallic chemistry, mainly due to their unique ability to utilize the filled alkyne perpendicular π-bonding orbitals, which permits the possibility of variable electron donor interactions which can formally be two, three or four electrons. This depends on the electronic configuration of the metal and the bonding properties of the other ligands in the coordination sphere.[1] Although a large number of six-coordinate d^4 mononuclear alkyne complexes have been reported for molybdenum(II) and tungsten(II)—$[MX(CO)(\eta^2\text{-}PhC_2Ph)(\eta^5\text{-}C_5H_5)]$ (M = Mo or W; X = Cl, Br or I);[2] $[Mo(CO)(S_2CNR_2)_2(\eta^2\text{-}RC_2R)]$ (R = alkyl or aryl);[3] $[M(SR)(CO)(\eta^2\text{-}R^1C_2R^1)(\eta^5\text{-}C_5H_5)]$ (R = CF_3 or C_6F_5; R^1 = Me, CF_3 or Ph);[4] $[WMe(CO)(\eta^2\text{-}RC_2R)(\eta^5\text{-}C_5H_5)]$ (R = alkyl or aryl);[5] $[MoLL^1(\eta^2\text{-}RC_2R^1)(\eta^5\text{-}C_5H_5)][BF_4]$ {L,L^1 = CO or PR_3; L = L^1 = $P(OMe_3)$; R, R^1 = Me, Ph etc.};[6] $[Mo(^tBuS)_2(^tBuNC)_2(RC_2R^1)]$ (R,R^1 = H or Ph);[7] $[MoX_2(CO)L_2(\eta^2\text{-}PhC_2R)]$ (X = Cl or Br, L = phosphine, R = H or Ph);[8] $[Mo(SR)\{P(OMe)_3\}(\eta^2\text{-}MeC_2Me)(\eta^5\text{-}C_5H_5)]$ (R = Me, *p*-$NH_2C_6H_4$, *p*-$MeOC_6H_4$, *p*-MeC_6H_4, C_6H_5 or *p*-$NO_2C_6H_4$)[9]—hitherto very few dinuclear compounds of this type have been reported. In this communication we describe the synthesis of the novel iodide-bridged dimers $[M(\mu\text{-}I)I(CO)(NCMe)(\eta^2\text{-}PhC_2R)]_2$ (M = Mo or W, R = Ph or Me), and preliminary studies of their reactivity.

Equimolar quantities of PhC_2R (R = Ph or Me) and $[MI_2(CO)_3(NCMe)_2]$[10] react in CH_2Cl_2 to give the crystalline complexes $[M(\mu\text{-}I)I(CO)(NCMe)(\eta^2\text{-}PhC_2R)]_2$. These complexes are stable in the solid state when stored under argon at 0°C, and have been fully characterized by elemental analysis (C, H and N) and by IR and ^1H NMR spectroscopy (Table 1). The complexes are thermally unstable, i.e. similar to the well-known halide-bridged dimers[11] $[M(\mu\text{-}X)X(CO)_4]_2$ (M = Mo or W; X = Cl, Br and I), and their thermal instability is reflected by their high reactivity. They react via symmetrical cleavage of the iodide bridges (Scheme 1). The ^{13}C NMR spectrum of **4** shows resonances at δ (ppm) = 207.7 and 206.9 (s, CO), 199.7 (s, PhC≡), 196.9 (s, MeC≡), 136.7 (s, ≡C—C), 130.6 (s, *o*-Ph), 129.2 (s, *m*-Ph), 128.7 (s, *p*-Ph), 117.48 (s, N≡CMe), 23.52 (s, ≡CMe) and 4.55 (s, NCMe). The low-field resonances due to the "acetylenic" carbon atoms are typical of terminally bonded "four-electron" alkynes coordinated to molybdenum(II) or tungsten(II).[6-9]

It is proposed that these reactions proceed via the mononuclear intermediates $[MI_2(CO)(NCMe)_2(\eta^2\text{-}PhC_2R)]$. For example, reaction of $[MoI_2(CO)_3$

4	W	Me	2050(s), 1990(s)	2315(w), 2285(w)	1610(w)	2.72 (s, 6H, NCMe) 3.21 (s, 6H, ≡CMe) 7.62 (m, 10H, ≡CPh)

[a] Spectra recorded in $CHCl_3$: s, strong; w, weak.
[b] Spectra recorded in $CDCl_3$ (+25°C) and referenced to $SiMe_4$.

$(NCMe)_2]$ with PhC_2Ph in CH_2Cl_2 at room temperature proceeds rapidly with effervescence of CO which ceases after 15 min. An IR spectrum of this solution shows not only carbonyl bands due to the dimer at ν = 2050 and 2005 cm^{-1}, but also a very intense carbonyl band at 1978 cm^{-1}. This band is due to $[MoI_2(CO)(NCMe)_2(\eta^2\text{-}PhC_2Ph)]$ (**5**) and decreases with time until after 12 h only the bands due to the dimer **1** are observed. **5** can be prepared by reacting $[MoI_2(CO)_3(NCMe)_2]$ with PhC_2Ph in acetonitrile at 40°C for 2 h, when removal of solvent affords very air-sensitive red crystals of **5** which has been fully characterized by elemental analysis (C, H and N), and IR and ^{1}H NMR spectroscopy. The room-temperature ^{1}H NMR spectrum of **5** in $CDCl_3$ showed a methyl resonance at δ = 2.45 ppm which after 12 h shows two MeCN resonances at δ = 2.40 (dimer **1**) and 2.12 ppm (uncoordinated MeCN). Hence the proposed mechanism for the formation of the dimer is given in Scheme 2.

The preparation of a wide variety of these dinuclear complexes of molybdenum(II) and tungsten(II) with different alkynes, RC_2R^1 (R, R^1 = Me and Me, CH_2Cl and CH_2Cl, Me and SPh, Me and *p*-tolS etc.) has been carried out and a wide range of different rates of dimerization has been observed. It appears that the larger and more electron-deficient alkynes dimerize more slowly (probably due to there being less electron density on the metal,

BOOK REVIEW

Gmelin Handbook of Inorganic Chemistry. Sn—Organotin Compounds, Part 12, Tripropyltin– and Tributyltin–Oxygen Compounds. H. Schumann and I. Schumann, Springer, Berlin, 1985. ISBN 3-540-93521-5, x+266 pp., DM997.

This is the twelfth Gmelin volume on organotin compounds, and covers only tripropyltin– and tributyltin–oxygen compounds, but it is a key volume as the tri-*n*-butyltin derivatives are the most familiar in both the laboratory and industry.

The unstable hydroxides are included but surprisingly not the much more familiar bistrialkyltin oxides; perhaps they are to appear in a future volume. The alkoxides, ketonates and acylates follow, then the derivatives of the carbonic and carbamic acids, the peroxides, and the derivatives of the oxyacids of the halogens, nitrogen, phosphorus etc., and there is a separate section on free radicals containing R_3SnO groups.

For example, 18 pp. are devoted to tributyltin methoxide. Its preparations and physical properties are critically presented, and then its reactions with 168 reagents are tabulated, with footnotes on particular reactions. This section contains 125 references.

The many applications of the compounds in industry and agriculture are included, and there is a formula index.

The presentation, now wholly in English, is of the familiar very high standard of these volumes, and the errors are very few. The literature is covered up to the end of 1982.

Again, all chemists handling organotin compounds are indebted to Herbert and Ingeborg Schumann for presenting this important section of organotin chemistry in such a convenient and lucid format.

WHOLE EQUILIBRIUM ANALYSIS OF THE INNER- AND OUTER-SPHERE CHROMIUM(III)–PHOSPHINATE COMPLEX SYSTEM

HIROHIKO WAKI,* QI FENG, KAZUHISA TSURUTA and SHIGERU OHASHI

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka, Japan

(*Received* 18 *September* 1985; *accepted* 6 *November* 1985)

Abstract—The stability constants of the inner- and outer-sphere chromium(III)–phosphinate complexes have been evaluated by two ion-exchange methods: one is the Donnan exclusion chromatography and the other is the cation-exchange equilibrium method: $\log K_{1,0} = 2.7$, $\log K_{2,0} = 1.8$, $\log K_{3,0} = 1.3$, $\log K_{4,0} = 1.6$, $\log K_{5,0} = 0.71$, and $\log K_{6,0} = 0.079$ for inner-sphere complexes; $\log K_{0,1} = 0.90$, and $\log K_{0,2} = 0.079$ for outer-sphere complexes; and $\log K_{1,1} = 0.56$ for the inner–outer mixed-sphere complex—all these being values at 50°C (20°C for $K_{1,1}$) and ionic strength of 0.2. Donnan exclusion chromatography has been proved as an effective method for such a system involving inert species. A total scheme has been clarified for this complex system under the conditions studied and the characteristic absorption spectrum of each chromium–phosphinate complex has also been established.

Although a large number of studies on inert chromium(III) complexes have been made,[1,2] there have only been a few reports with qualitative work[3,4] concerning the complexation between chromium(III) and phosphinate. A complete analysis on a whole chromium(III)–phosphinate complex system has not yet been made.

When chromium(III) reacts with phosphinate under appropriate conditions, it may be expected that inert inner-sphere complexes $\{[Cr(PH_2O_2)_m(H_2O)_n)]^{(m-3)-}\}$ [ligand number $(n+m) = 6$], outer-sphere complexes $\{[Cr(H_2O)_6 \cdot (PH_2O_2)_m]^{(3-m)+}\}$ $(m = 0–3)$ and mixed inner–outer-sphere complexes such as $[Cr(PH_2O_2)(H_2O)_5 \cdot (PH_2O_2)]^+$ or $[Cr(PH_2O_2)(H_2O)_5 \cdot (PH_2O_2)_2]$ are formed simultaneously. Inner-sphere complexes may be distinguished and separated from outer-sphere complexes by different reaction rates for complexation. Since the mutual separation of labile outer-sphere complexes is impossible, the analyses can only be done by means of the equilibrium technique.

In this work the analysis of a whole inner- and outer-sphere equilibrium system was attempted by combining the recently developed Donnan exclusion chromatography[5–7] and the cation-exchange equilibrium method.

EXPERIMENTAL

Reagents and ion-exchangers

Chromium(III) perchlorate, sodium phosphinate, sodium perchlorate and tetramethylammonium chloride were of commercially available reagent grade. Chromium(III) phosphinate solution was prepared by passing chromium(III) perchlorate solution through a column of the phosphinate form Dowex 1-X4 (100–200-mesh). A cross-linked dextran gel-type cation exchanger, SP-Sephadex C-25 (Pharmacia Fine Chemicals), was used for the chromatographic separations and well-conditioned Dowex 50W-X4 (100–200-mesh) of sodium form for batch equilibrium analyses.

Time dependence measurement of the absorption spectrum of the chromium(III)–phosphinate complexes

The chromium(III) perchlorate solution was mixed with sodium phosphinate solution resulting

* Author to whom correspondence should be addressed.

in a 0.00509 M chromium(III) perchlorate–0.305 M sodium phosphinate solution. Absorption spectrum of this solution was measured at appropriate time intervals with a Hitachi Recording Spectrophotometer EPS-3T and a 5-cm cell at $20 \pm 1°C$. The absorption spectrum of a 0.00509 M chromium(III) perchlorate solution was used as the spectrum at zero time.

Preparation of the equilibrium mixture of the chromium(III)–phosphinate complexes

Since it is impossible to prepare an equilibrium mixture containing all chromium(III)–phosphinate complex species in balanced abundance in just a single solution, three solutions were separately prepared by mixing chromium(III) phosphinate or chromium(III) perchlorate with sodium phosphinate at different ratios. The ionic strengths of the solution mixtures were adjusted to about 0.2 with sodium perchlorate and perchloric acid, if necessary. The chromium(III) and phosphinate concentrations, and the pH of the resulting solutions, are shown in Table 1. The solutions were kept at 50°C for about 2 weeks to reach equilibrium.

Separation of the inner-sphere complexes by Donnan exclusion chromatography

A gradient elution technique was employed. A mixing chamber initially containing 200 cm^3 of water and a reservoir containing a 3 M tetramethylammonium chloride solution were connected to a column packed with SP-Sephadex C-25 of tetramethylammonium form swollen with water to make a bed of 1.5 cm $\phi \times 90$ cm. After passing 65 cm^3 of eluant through the column (at that moment the concentration of the eluant flowing into the column top was about 1 M) 1 cm^3 of the sample solution of chromium–phosphinate complexes prepared as described in the foregoing section was added to the ion-exchanger bed. The gradient elution continued at a flow rate of 70 $cm^3 h^{-1}$ until all the components were eluted. The chromium complex species in the effluent were automatically detected at 420 nm with an Atto variable-wavelength spectrophotometer LDC Model Spectromonitor III, which was connected to the end of the separating column, to make an elution curve. For the determination of the inner-sphere stability constants, a quantitative analysis of chromium was made spectrophotometrically by a diphenylcarbazide method for each part of the effluent. When necessary phosphinate ions combined with chromium were spectrophotometrically determined with a molybdenum(V)–molybdenum(VI) reagent after liberation from the complexes using EDTA.

Cation-exchange equilibrium anlyses for the outer-sphere complex formation

Stability constants of the outer-sphere complexes were determined by a cation-exchange equilibrium

analysis proposed by Schubert.[8] A series of solutions containing chromium perchlorate and excess sodium phosphinate of different concentrations were prepared. Sodium perchlorate was added to each solution to maintain the sodium ion concentration and the ionic strength constant. 50 cm³ of this solution was equilibrated with 0.5 g of Dowex 50W-X4, sodium form for 10 min at 50°C. The distribution ratio of chromium was calculated from the absorbance measurement of the equilibrated supernatant by the following equation:

$$D = \frac{A^o - A}{A} \cdot \frac{V}{m},$$

where A^o and A are the absorbances at the same wavelength (preferably at the absorption maximum) of the initial solution and the solution at equilibrium, respectively, V is the volume of the solution in cm³ and m is the gravity of the ion-exchanger in g. The amounts of chromium taken were adjusted so that its sorbed amount was maintained approximately constant in all batches, because a constant loading of chromium should fulfil the requirement of a constant sodium concentration and an unvaried activity coefficient in using equations for the ion-exchange method. It was confirmed that equilibration for 10 min does not give any inner-sphere complex formation. The same batch equilibration was made on the solution without phosphinate ligand to obtain the D^o value.

The stability constant of the mixed inner–outer-sphere complex was determined by a similar cation-exchange equilibrium analysis. The sample solution of $[Cr(PH_2O_2)(H_2O)_5]^{2+}$ was obtained from the effluent (containing 1 M sodium perchlorate as eluant) in the Donnan exclusion chromatography. This species was mixed with excess sodium phosphinate and sodium perchlorate of different concentrations and the 50 cm³ solution was shaken with 2 g of the same resin at 20°C for 20 min. The chromium sorbed on the resin was analysed using a diphenylcarbazide method after stripping and the distribution ratio was calculated as:

$$D = \frac{\bar{m}_{Cr}}{m^o_{Cr} - \bar{m}_{Cr}} \cdot \frac{V}{m},$$

where m^o_{Cr} and $\bar{m}_{Cr}$ are the total amount of chromium initially given and in the resin at equilibrium, respectively.

Construction of characteristic absorption spectra on individual inner-sphere complexes

The absorption spectrum of the effluent containing the individual chromium–phosphinate complex species isolated by Donnan exclusion chromatography was measured with a Hitachi Recording Spectrophotometer EPS-3T and a 5-cm cell. In combination with the elemental analysis of chromium, each characteristic absorption spectrum was obtained.

RESULTS AND DISCUSSION

A general behavior of absorption spectra of chromium(III)–phosphinate complexes with time

The time dependence of the absorption spectra of the solution containing chromium(III) perchlorate and sodium phosphinate at 20°C is shown in Fig. 1. The chromium(III) aqua ions have two characteristic peaks at wavelengths 410 and 580 nm in the visible-light region. The absorption peak at 410 nm first shifted instantaneously after the addition of

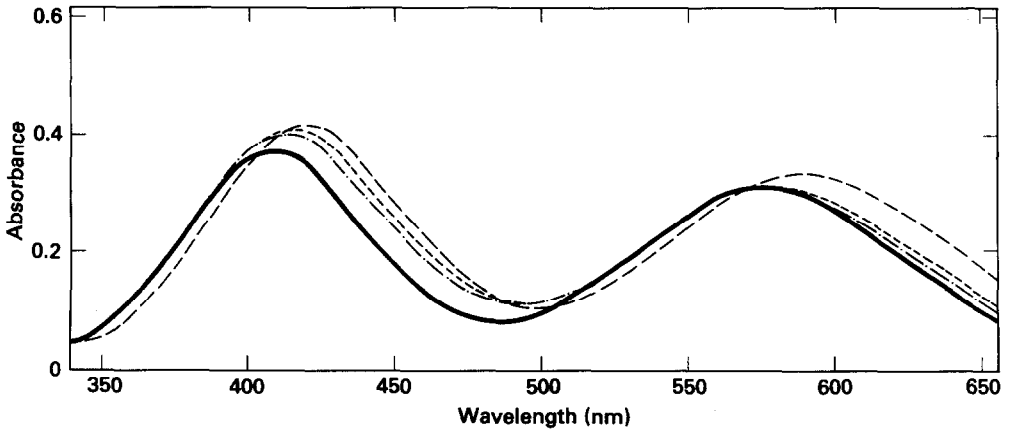

Fig. 1. Time dependence of absorption spectra of chromium(III) complexes: (———) 5.09×10^{-3} M $Cr(ClO_4)_3$ solution; and (– – –) 2.5 min, (– – –) 2.3 h, and (———) 30 h after mixing of 5.09×10^{-3} M $Cr(ClO_4)_3$ and 0.305 M $NaPH_2O_2$.

phosphinate and thereafter both peaks changed only very slowly with time, always shifting to longer wavelengths. Clearly the former phenomenon reflects the outer-sphere complex and the latter the inner-sphere complex formation with phosphinate ions. This fact indicates that the presence of both types of complex should be taken into account when a considerable time has elapsed after mixing. Consequently, the equilibrium analysis for outer-sphere complexes or the separation of inner-sphere complexes must be carried out as rapidly as possible, while the equilibrium analyses for inner-sphere types have to be made after the establishment of equilibrium with a very long time even at an elevated temperature.

Donnan exclusion chromatogram for chromium(III)–phosphinate complexes with a cation-exchanger column

In order to know the whole formation equilibrium on inner and outer complexes, the mutual separation of inner-sphere complexes is crucial since its chromatogram can give some of the stability constants directly and shows a general picture of species distribution. The Donnan exclusion chromatography[5,6] seems to be the most convenient for such a separation, because all successive anionic and cationic inner-sphere complexes $[Cr(PH_2O_2)_m(H_2O)_{6-m}]^{(m-3)-}$ could be separated from each other rapidly with a single cation-exchanger column. A typical elution curve for a synthesized sample, a mixture of solutions prepared separately, on an SP-Sephadex column is shown in Fig. 2, from which it is seen that each component could be almost quantitatively isolated in a rather short time.

According to the theory of Donnan exclusion chromatography, the elution position (retention time) for an excluded component depends only on its ionic charge, and the higher the anionic charge the earlier the ion elutes. Thus the elution peaks within one column volume revealed in the chromatogram of Fig. 2 could be assigned to $[Cr(PH_2O_2)_6]^{3-}$, $[Cr(PH_2O_2)_5(H_2O)]^{2-}$, $[Cr(PH_2O_2)_4(H_2O)_2]^{-}$ and $[Cr(PH_2O_2)_3(H_2O)_3]$ in that order. The unreacted phosphinate ions come out together with $[Cr(PH_2O_2)_4(H_2O)_2]^{-}$. The succeeding peaks are $[Cr(PH_2O_2)_2(H_2O)_4]^{+}$, $[Cr(PH_2O_2)(H_2O)_5]^{2+}$ and $[Cr(H_2O)_6]^{3+}$ (the last), respectively, which were confirmed by a direct analysis of the effluent for chromium and phosphorus.

For the sample solution with a real equilibrium, the analysis of chromium in the first four peaks of the chromatogram and the free phosphinate ion concentration may directly give the stepwise stability constants of the inner-sphere complexes, $K_{4,0}$, $K_{5,0}$ and $K_{6,0}$. On the other hand, the same analyses for subsequent peaks do not always give the stability constants $K_{1,0}$, $K_{2,0}$ and $K_{3,0}$, since these peaks correspond not only to pure inner-sphere complexes but also to outer-sphere or mixed inner–outer-sphere complexes which were present, if any, in the original solution. For example, $[Cr(H_2O)_6 \cdot (PH_2O_2)]^{2+}$ or $[Cr(H_2O)_6 \cdot (PH_2O_2)_2]^{+}$ should be eluted only as $[Cr(H_2O)_6]^{3+}$ by the release of phosphinate ions which were bound in the outer coordination sphere during the elution with an eluant containing no phosphinate ions. The true distribution among all species could be determined only by combining the chromatographic results with batch equilibrium data obtained separately.

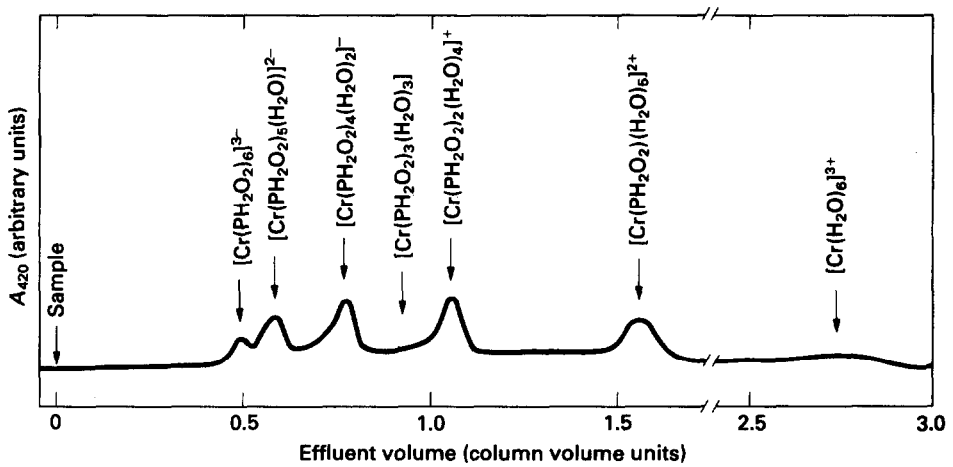

Fig. 2. A typical Donnan exclusion chromatogram for inner-sphere complexes of chromium(III) and phosphinate. Column: SP-Sephadex C-25, $N(CH_3)_4^+$ form, 1.5 cm $\phi \times 90$ cm; sample: mixture of $Cr(PH_2O_2)_3$ and $NaPH_2O_2$ not in equilibrium; eluant: 1–3 M $N(CH_3)_4Cl$ gradient; flow rate: 70 $cm^3 h^{-1}$.

These treatments are described in the following section.

General equations for stability constants in a chromium(III)–phosphinate complex system

A general equation for the overall stability constant of a chromium(III)–phosphinate complex is given by:

$$\beta_{n,m} \equiv \frac{[Cr(PH_2O_2)_n(H_2O)_{6-n}\cdot(PH_2O_2)_m^{(3-n-m)+,(n+m-3)-}]}{[Cr(H_2O)_6^{3+}][PH_2O_2^-]^{n+m}}, \quad (1)$$

where n and m are the ligand numbers bound in the inner and outer sphere, respectively.

The corresponding stepwise stability constant is defined as:

$$K_{n,m}^{in} \equiv \frac{[Cr(PH_2O_2)_n(H_2O)_{6-n}\cdot(PH_2O_2)_m^{(3-n-m)+,(n+m-3)-}]}{[Cr(PH_2O_2)_{n-1}(H_2O)_{7-n}\cdot(PH_2O_2)_m^{(4-n-m)+,(n+m-4)-}][PH_2O_2^-]} \quad (2)$$

for inner-sphere coordination of the ligand, or:

$$K_{n,m}^{out} \equiv \frac{[Cr(PH_2O_2)_n(H_2O)_{6-n}\cdot(PH_2O_2)_m^{(3-n-m)+,(n+m-3)-}]}{[Cr(PH_2O_2)_n(H_2O)_{6-n}\cdot(PH_2O_2)_{m-1}^{(4-n-m)+,(n+m-4)-}][PH_2O_2^-]} \quad (3)$$

for outer-sphere binding. Here the assumption $1 \leqslant n \leqslant 6$ [eqn (2)] or $0 \leqslant n \leqslant 6$ [eqn (3)], and $0 \leqslant m \leqslant 3-n$ may be reasonable, since chromium(III) has a coordination number of 6 and outer-sphere binding takes place only by a weak electrostatic attraction between the hydrated cation (complex) and phosphinate anion.

Determination of the outer-sphere stability constants $K_{0,1}$ *and* $K_{0,2}$

$K_{0,1}$ and $K_{0,2}$ were determined by Schubert's cation-exchange equilibrium analysis[8] at 50°C using the following relation:

$$\frac{D_{Cr}^o}{D_{Cr}} = 1 + K_{0,1}[PH_2O_2^-] + K_{0,1}K_{0,2}[PH_2O_2^-]^2 + \cdots, \quad (4)$$

where D_{Cr} and D_{Cr}^o are the distribution ratios of chromium when the phosphinate ligand is present and absent, respectively. The D_{Cr}^o/D_{Cr} vs $[PH_2O_2^-]$ plot showed a parabola, indicating only the presence of the first and second outer-sphere complexes $[Cr(H_2O)_6\cdot(PH_2O_2)]^{2+}$ and $[Cr(H_2O)_6\cdot(PH_2O_2)_2]^+$ (Fig. 3). The best fit of the experimental data to a parabola with a least-squares treatment resulted in $\log K_{0,1} = 0.90$ and $\log K_{0,2} = 0.0079$, and the negligible presence of the third outer-sphere complex $[Cr(H_2O)_6\cdot(PH_2O_2)_3]$.

Determination of the outer-sphere stability constant $K_{1,1}$

$K_{1,1}$ was determined by the same method as described above:

$$\frac{D_{Cr}^o}{D_{Cr}} = 1 + K_{1,1}[PH_2O_2^-] + \cdots. \quad (5)$$

In this the chromium sample was taken from the effluent for the $[Cr(PH_2O_2)(H_2O)_5]^{2+}$ peak in the Donnan exclusion chromatographic separation. A temperature of 20°C was used in the experiment to avoid an inner-sphere reaction. The D_{Cr}^o/D_{Cr} vs $[PH_2O_2^-]$ plot showed an approximately linear relation (Fig. 3), indicating only the outer-sphere formation of the singly-charged cationic complex $[Cr(PH_2O_2)(H_2O)_5\cdot(PH_2O_2)]^+$, which may correspond to the result in the foregoing section.

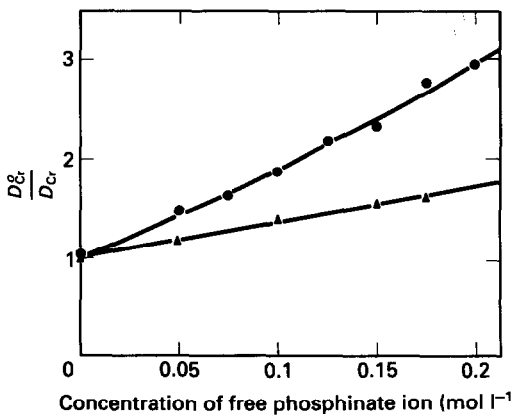

Fig. 3. Determination of stability constants of outer-sphere and inner–outer-sphere complexes by the cation-exchange equilibrium method: (●) outer-sphere complex, (▲) inner–outer-sphere complex.

Determination of the inner-sphere stability constants $K_{1,0}$–$K_{6,0}$

The analyses of $[Cr(H_2O)_6]^{3+}$, $[Cr(PH_2O_2)(H_2O)_5]^{2+}$ and $[Cr(PH_2O_2)_2(H_2O)_4]^{+}$ for the corresponding peaks in a chromatogram of the type in Fig. 2 do not give a direct calculation on the inner-sphere complex formation in the original sample solution. Instead, the following relationships hold:

$$\frac{m_{CrL}}{m_{Cr}} = \frac{[Cr(PH_2O_2)(H_2O)_5^{2+}] + [Cr(PH_2O_2)(H_2O)_5 \cdot (PH_2O_2)^{+}]}{[Cr(H_2O)_6^{3+}] + [Cr(H_2O)_6 \cdot (PH_2O_2)^{2+}] + [Cr(H_2O)_6 \cdot (PH_2O_2)_2^{+}]}$$

$$= \frac{K_{0,1}(1 + K_{1,1}[PH_2O_2^-])[PH_2O_2^-]}{1 + K_{0,1}[PH_2O_2^-] + K_{0,1}K_{0,2}[PH_2O_2^-]^2} \quad (6)$$

and

$$\frac{m_{CrL_2}}{m_{CrL}} = \frac{[Cr(PH_2O_2)_2(H_2O)_4^{+}]}{[Cr(PH_2O_2)(H_2O)_5^{2+}] + [Cr(PH_2O_2)(H_2O)_5 \cdot (PH_2O_2)^{+}]} = \frac{K_{2,0}[PH_2O_2^-]}{1 + K_{1,1}[PH_2O_2^-]}, \quad (7)$$

where L refers to the $[PH_2O_2]^-$ ligand and m is the total amount of chromium contained in each elution peak for the subscribed complex in the chromatogram. It may be reasonable to assume that the neutral complex $[Cr(PH_2O_2)_2(H_2O)_4 \cdot (PH_2O_2)]$ is negligible. Thus the inner-sphere constants $K_{1,0}$ and $K_{2,0}$ can be determined by:

$$K_{1,0} = \frac{m_{CrL}}{m_{Cr}} \cdot \frac{1 + K_{0,1}[PH_2O_2^-] + K_{0,1}K_{0,2}[PH_2O_2^-]^2}{(1 + K_{1,1}[PH_2O_2^-])[PH_2O_2^-]}, \quad (8)$$

$$K_{2,0} = \frac{m_{CrL_2}}{m_{CrL}} \cdot \frac{1 + K_{1,1}[PH_2O_2^-]}{[PH_2O_2^-]}, \quad (9)$$

when $K_{0,1}$, $K_{0,2}$, $K_{1,1}$ and $[PH_2O_2^-]$ are known.

The inner-sphere stability constants $K_{3,0}$, $K_{4,0}$, $K_{5,0}$ and $K_{6,0}$ for the higher complexes can be expressed in a simpler form, since no complexes involve outer-sphere binding with phosphinate anions:

$$K_{3,0} = \frac{m_{CrL_3}}{m_{CrL_2}[PH_2O_2^-]}, \quad (10)$$

$$K_{4,0} = \frac{m_{CrL_4}}{m_{CrL_3}[PH_2O_2^-]}, \quad (11)$$

$$K_{5,0} = \frac{m_{CrL_5}}{m_{CrL_4}[PH_2O_2^-]}, \quad (12)$$

$$K_{6,0} = \frac{m_{CrL_6}}{m_{CrL_5}[PH_2O_2^-]}. \quad (13)$$

The free phosphinate concentration, $[PH_2O_2^-]$, in the original sample solution containing the complex mixture can be expressed as:

$$[PH_2O_2^-]V_s = m_{\Sigma L} - 6m_{CrL_6} - 5m_{CrL_5} - 4m_{CrL_4} - 3m_{CrL_3} - 2m_{CrL_2} - m_{CrL} \times \left(1 + \frac{K_{1,1}[PH_2O_2^-]}{1 + K_{1,1}[PH_2O_2^-]}\right) - m_{Cr}K_{0,1}[PH_2O_2^-] \times \left(\frac{1 + 2K_{0,2}[PH_2O_2^-]}{1 + K_{0,1}[PH_2O_2^-] + K_{0,1}K_{0,2}[PH_2O_2^-]^2}\right), \quad (14)$$

where V_s is the sample solution volume injected into the column and $m_{\Sigma L}$ is the total amount of phosphinate injected.

Accordingly, all unknown six inner-sphere constants can be evaluated from all m values analyzed and the total ligand concentration using eqns (8)–(14). The experimental condition and analytical data are shown in Table 1. Three chromatographic runs were made with different compositions of chromium and phosphinate in order to obtain each complex component in reasonable abundance for analysis. A difference in the stability constant between different runs was not serious for such a complicated system (for instance, $\log K_{5,0} = 0.68$ and 0.74).

All the constants evaluated are shown in the whole complexation scheme (Fig. 4) with some additional constants calculated merely by numerical balancing (not experimentally determined). A general view concerning both the inner- and outer-

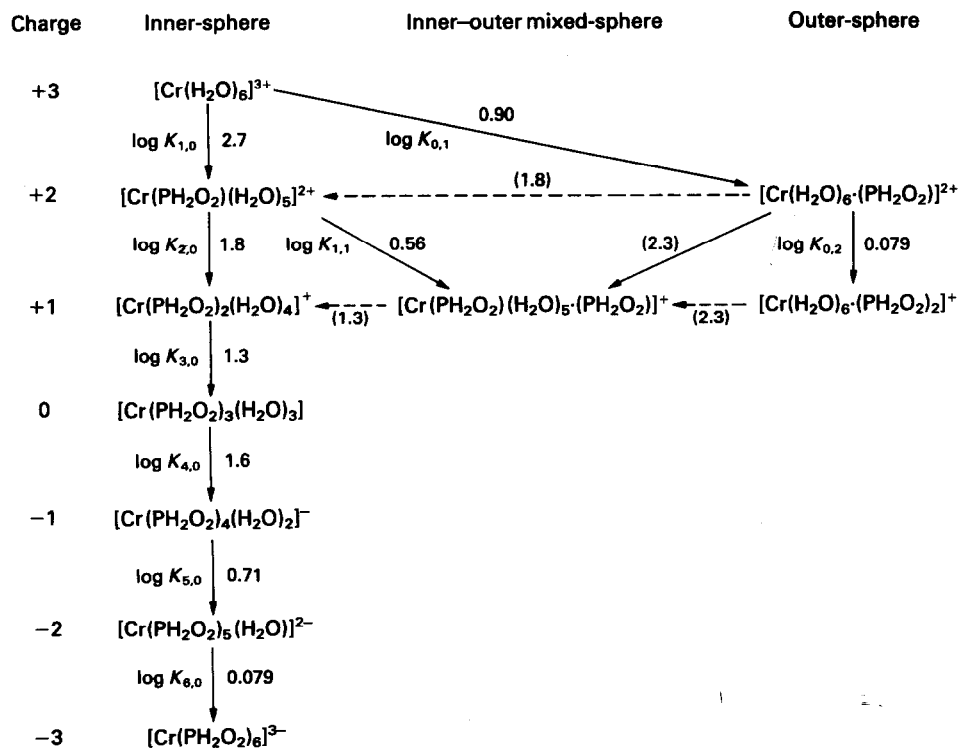

Fig. 4. Stability constants of chromium(III)–phosphinate complexes at 50°C and ionic strength 0.2.

sphere distribution of chromium(III)–phosphinate complexes has been reached, at least for the mononuclear system. The inner-sphere constants were mostly in the decreasing order: $K_{1,0} > K_{2,0} > K_{3,0} < K_{4,0} > K_{5,0} > K_{6,0}$, showing a normal behavior for the complexation reaction with the exception between $K_{3,0}$ and $K_{4,0}$. The irregularity $K_{3,0} < K_{4,0}$ might be ascribed to an easier displacement of H_2O molecules from the uncharged complex $[Cr(PH_2O_2)_3(H_2O)_3]$ in comparison with other charged complexes which can strongly attract H_2O dipoles by an electrostatic force.

Also, it was found that the outer-sphere constants are considerably lower than those for the corresponding inner-sphere ones, though this is a matter of course.

Characteristic absorption spectra for the inner-sphere chromium–phosphinate complexes

From the success of the isolation of each inner-sphere complex species, an absorption spectrum characteristic of the complex of each ligand number was obtained by measuring the absorbance of the effluent solution at each elution peak in the chromatogram, combined with the elemental analysis of chromium. Table 2 gives the wavelengths of the absorption maximum and the maximal molar

Table 2. Absorption spectrum characteristics of chromium(III)–phosphinate complexes

Complex	Maximal absorption wavelength (nm)		Molar absorption coefficient ($M^{-1}cm^{-1}$)	
	I	II	I	II
$[Cr(H_2O)_6]^{3+}$	410	580	15.3	12.8
$[Cr(PH_2O_2)(H_2O)_5]^{2+}$	419	594		
$[Cr(PH_2O_2)_2(H_2O)_4]^{+}$	430	614	19.2	15.7
$[Cr(PH_2O_2)_3(H_2O)_3]$	435	620		
$[Cr(PH_2O_2)_4(H_2O)_2]^{-}$	440	626	21.5	18.0
$[Cr(PH_2O_2)_5(H_2O)]^{2-}$	444	630		
$[Cr(PH_2O_2)_6]^{3-}$	447	634	25.2	23.0

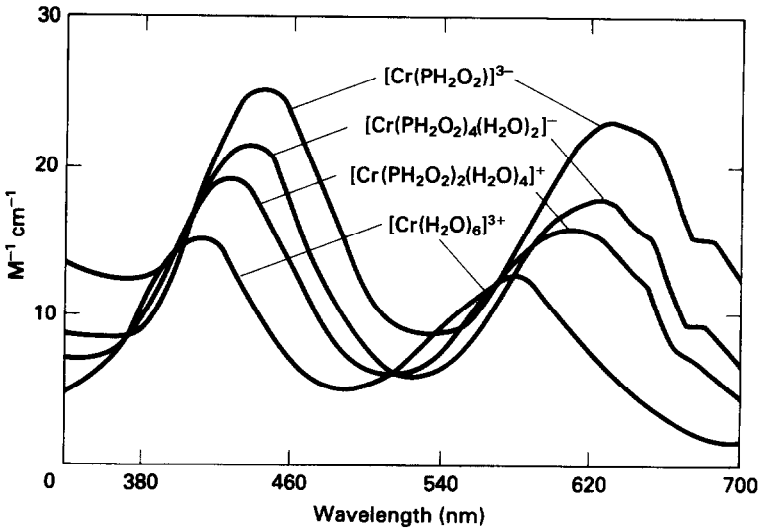

Fig. 5. Absorption spectra of chromium(III)–phosphinate complexes.

absorption coefficients and Fig. 5 shows four absorption spectra as examples. It was found that the wavelength shifts to longer wavelengths continuously and the molar absorption coefficient increases with increase in the ligand number, though this behavior can also be observed in most other systems of complex formation.

(*Received* 23 *September* 1985; *accepted* 6 *November* 1985)

Abstract—The complex species formed in aqueous solution between Fe(II) and *N*-methyliminodiacetic acid (MIDA), *N*-ethyliminodiacetic acid (EIDA) and *N*-propyliminodiacetic acid (PIDA) were studied at 25°C and ionic strength 0.1 M in KCl. The experimental potentiometric data were analysed with the least-squares computer program LETAGROP, taking into account hydrolysis of the Fe(II) ion. The ionization constants of MIDA, EIDA and PIDA acids are determined for the corresponding ionic strength and temperature. The following complex species were found (ligands, H_2C): MIDA, $[FeHC]^+$, FeC and $[FeC_2]^{2-}$; EIDA, FeC and $[FeC_2]^{2-}$; PIDA, FeC, $[FeC_2]^{2-}$ and $[Fe(OH)C]^-$. The corresponding stability constants were determined.

Studies of the coordinating capacity in aqueous solution of Fe(II) with aminoacids or polyamicarboxylic derivatives have not been undertaken as frequently as those of other bivalent first-row transition-metal cations,[1–3] perhaps because of the precautions needed to avoid oxidation of Fe(II) to Fe(III).[4] The studies are of biological interest.[5] In the specific case of iminodiacetic acid (IDA) and its derivatives, *N*-methyliminodiacetic acid (MIDA), *N*-ethyliminodiacetic acid (EIDA) and *N*-propyliminodiacetic acid (PIDA), investigations have only been carried out with Fe(II) for IDA[6] at 25°C and ionic strength 0.5 M in $NaClO_4$ and for MIDA[7] at 20°C and ionic strength 0.1 M in KCl. The species FeY and $[FeY_2]^{2-}$ (H_2Y acids) were identified for both ligands. No studies have been reported on the ligands EIDA and PIDA. In the present work the coordinating capacity in aqueous solution of Fe(II) with the ligands MIDA, EIDA and PIDA at 25°C and ionic strength 0.1 M in KCl is studied. An example of the biological interest of IDA and ligand derivatives is the recent proposal[8] of the complex $VOL_2 \cdot 2H_2O$ (H_2L = IDA) as a model for Amavadina, a natural product of vanadium from the fungus *Amanita muscaria*.

EXPERIMENTAL

Reagents

The acids MIDA, EIDA and PIDA were synthesized by reacting methylamine, ethylamine and *n*-propylamine (Merck, products for synthesis), respectively with previously neutralized chloracetic acid, following the procedure described by Souchay *et al.*[9] The previously obtained barium salts gave the corresponding acid on adding conc. H_2SO_4. The acids were purified by recrystallization in water–isopropanol mixtures, and were identified by their potentiometric equivalents, NMR, mass spectra and IR.

* Author to whom correspondence should be addressed.

The Fe(II) solutions were freshly prepared using $FeSO_4 \cdot 7H_2O$ (Merck, analytical grade). The ferrous solution was stored out of contact with the air, in a vessel with an atmosphere of hydrogen. Possible traces of Fe(III) were reduced by means of a current of hydrogen and using palladium carbon, as indicated in an earlier work.[10] Before adding the solution of Fe(II) to the titration cell, Fe(II) concentration was determined by dichromatic titration,[11] and the absence of Fe(III) checked by means of thiocyanate. Carbonate-free sodium hydroxide solution was prepared according to the school of Sillén[12] and standardized against potassium hydrogen phthalate. The solution of HCl was prepared from hydrochloric acid (Merck, analytical grade). Potassium chloride was prepared by recrystallization of KCl (Merck, analytical grade).

Apparatus and titration procedures

The potentiometric titrations were carried out in argon inert atmosphere, at 25 ± 0.05°C, ionic strength 0.1 M in KCl, using a Radiometer Type PHM-64 potentiometer, a Radiometer G 202 B glass electrode and a K 401 calomel electrode. The free hydrogen ion concentration, $[H^+]$, was determined by measuring the e.m.f. of the cell Hg/Hg_2Cl_2, KCl sat//Fe^{2+}, ligand, KCl 0.1 M/glass electrode.

The cell constants were determined according to the method of Biedermann and Sillén,[13] the liquid junction potentials were found to be negligible within the margins of $[H^+]$ studied. It was found that $pK_w = 13.77$, in good agreement with reported data.[14]

The ligands were measured alone at the following concentrations: MIDA ($C_L = 3.00 \times 10^{-3}$); EIDA ($C_L = 3.94 \times 10^{-3}$), and PIDA ($C_L = 5.70 \times 10^{-3}$); the Fe(II) alone ($C_M = 5.00 \times 10^{-3}$ and 2.50×10^{-3}) in order to study hydrolysis by dilution of the solution of initial concentration at 25°C and ionic strength 0.1 M in KCl; and the ligands in the presence of Fe(II) at the following concentrations and ligand : metal ratios: MIDA 1 : 1 ($C_L = 3$ mM), 3 : 1 ($C_L = 3$ mM), 1 : 15 ($C_L = 1$ mM); EIDA 1 : 1 ($C_L = 4$ mM), 2.54 : 1 ($C_L = 3.74$ mM), 1 : 15 ($C_L = 1$ mM); and PIDA 1 : 1, 3 : 1, 5 : 1 ($C_L = 3$ mM), 1 : 15 ($C_L = 1$ mM).

Data treatment

The experimental potentiometric data were analysed by means of the NERNST/LETA/GRAFICA version[15] of the LETAGROP programme,[16] based on a generalized form of the least-squares method, that establishes the best model and best values of the β_{pqr} constants, minimizing the function $U = \Sigma (Z_{exp} - Z_{calc})^2$, Z being the average number of dissociated protons for the total concentration of ligand (Z_c) or for the total concentration of metal (Z_B). The LETAGROP calculations also give standard deviations $\sigma(Z)$ and $\sigma(\log \beta_{pqr})$.[17] The computations were performed on a Burroughs 6700 computer (Facultad de Ciencias, Universidad Central de Venezuela, Caracas).

RESULTS AND DISCUSSION

Hydrolysis of Fe(II)

Twenty-five experimental points of the two potentiometric titrations carried out were used for the calculations. For the equilibrium

$$qFe^{2+} + pH_2O \rightleftharpoons [Fe_q(OH)_p]^{(2q-p)+} + pH^+, \quad \beta_{-pq}$$

it is found that $\log \beta_{-11} = -7.301 \pm 0.185$, with a standard deviation $\sigma(Z) = 0.003$ (25°C and $I = 0.1$ M in KCl), that corresponds to the formation of the species $[Fe(OH)]^+$. The value found is in good agreement with that obtained by Gayer and Woontner at 25°C and $I = 0.5$ M in KCl, $\log \beta_{-11} = -7.17$.[18]

Ionization constants of the acids

Potentiometric titrations were carried out of each of the acids with NaOH 0.1 M and HCl 0.1 M, respectively. From the values obtained for the constants β_{pr}, corresponding to the equilibria

$$pH^+ + rH_2C \rightleftharpoons H_p(H_2C)_r,$$

the ionization constants of the acids, K_i, given in Table 1, could readily be determined.

For comparison purposes, values from the literature for other acids, at the same ionic strength and temperature, are also included, as well as those of acid IDA.[2] It is observed that the order of basicity of the N atom (equilibrium HC^-/C^{2-}) is IDA < MIDA < EIDA ≤ PIDA, which corresponds to the electrodonor effect of the corresponding alkyl radical.

The validity of the values found for the constants β_{pr} is proven in Fig. 1 by the excellent agreement between the experimental curves $Z(-\log[H^+])$ and those calculated from the β_{pr} values given in Table 1.

Stability constants of the complexes formed

The analysis of the experimental data of each of the three ligand–metal systems by the

NERNST/LETA/GRAFICA version[15] of the LETAGROP programme[16] allowed us to calculate the β_{pqr} constants for the complex species formed for each ligand, defined by means of the equilibrium

$$pH^+ + qFe^{2+} + rH_2C \rightleftharpoons [H_pFe_q(H_2C)_r]^{(p+2q)+}, \quad \beta_{pqr}.$$

Taking into account the species resulting from the massive ionizations of the ligand (H_2C, HC^- and C^{2-}) and the species $[Fe(OH)]^+$ obtained from the hydrolysis of Fe(II), the results that best fit the experimental results are those given in Table 2, the validity of which is proven in Figs 2–4, where an

excellent fit can be observed between the experimental curves $Z(-\log [H^+])$ and those calculated from the β_{pqr} values given in Table 2.

From the β_{pqr} constants and taking into account the β_{pr} constants of the acids given in Table 1, the stability constants of the complex species formed can readily be calculated, according to the following equilibria:

$$Fe^{2+} + HC^- \rightleftharpoons [FeHC]^+, \qquad K';$$

$$Fe^{2+} + C^{2-} \rightleftharpoons FeC, \qquad K_1;$$

$$FeC + C^{2-} \rightleftharpoons [FeC_2]^{2-}, \qquad K_2;$$

$$Fe^{2+} + C^{2-} + OH^- \rightleftharpoons [Fe(OH)C]^-, \qquad K''.$$

The value of K_w at the same ionic strength and temperature must also be taken into account in order to calculate K''.

The results are also given in Table 2 and are compared with data for MIDA from the literature; for comparison purposes, in this series of ligands, they are also contrasted with data for IDA.

The complex $[FeHC]^+$ only appears in significant amounts for MIDA acid, and even here it is not well defined, as can be deduced from the data found for $-\log \beta_{-111}$ in Table 2. The value calculated for the pK corresponding to ionization of the complex ($[FeHC]^+ \rightleftharpoons FeC + H^+$) is 5.60, indicating that this

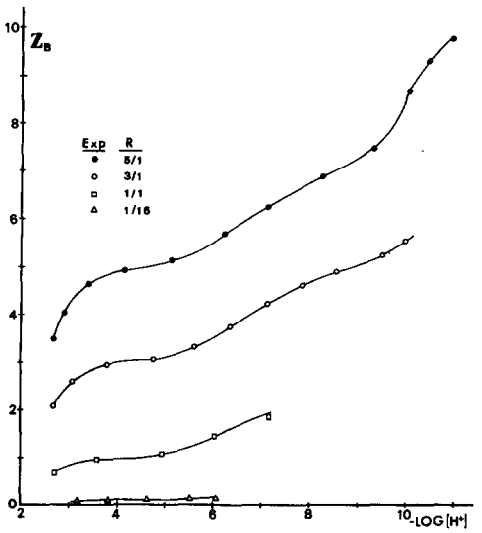

Fig. 4. $Z_B(-\log [H^+])$ curves of the system PIDA–Fe(II). Full curves have been calculated using the constants β_{pqr} in Table 2.

species has the proton over the N atom and that only the carboxylate groups will coordinate with the metal. The value of 5.60 also indicated that the proton is subjected to repulsion of the metallic cation, that tends to displace it in order to form the stable complex FeC. The species $[MHC]^+$ is of weak stability and for the acids EIDA and PIDA has only been found for divalent cations forming complexes more stable than Fe(II), such as Co(II), Ni(II), Zn(II) and Pb(II).[21]

The monohydroxycomplex $[Fe(OH)C]^-$ only appeared well defined for PIDA, probably resulting from the hydrolysis of the neutral complex, i.e. $FeC(H_2O) \rightleftharpoons [Fe(OH)C]^- + H^+$. The intervals referred to are, of course, those of $-\log [H^+]$ studied, which in the case of PIDA attained 11. The formation of this species was hindered, especially with excess of ligand, by the tendency to form the 2:1 complex, $FeC + C^2 \rightleftharpoons [FeC_2]^{2-}$. The species $[FeC_2]^{2-}$ was well defined in all the acids, because these ligands are tricoordinating and two ligands saturate the coordination index 6 of the central ion.[22] The neutral complex FeC, that in aqueous solution is really $FeC(H_2O)_3$, in order to fulfil the coordination index 6 of Fe(II),[22] coordinates the N atom and the two O atoms of the two carboxylate groups to the Fe(II). The order of stability found (Table 2), IDA < MIDA $\leqslant$ EIDA > PIDA, no longer corresponds to the expected basicity for the N atom, according to the electrodonor nature of the alkyl radical that became evident with respect to the H^+ (Table 1). Perhaps when the length of the alkyl radical increases, as is manifested in the *n*-propyl radical, steric repulsion effects that counteract the inductive effects are brought to bear on the metallic cation. These effects also become apparent with respect to other divalent transition cations.[21]

If the values of log *K* given in Table 2 for Fe(II) are compared with those found for Mn(II) and Co(II)[21]

	MIDA	EIDA	PIDA
Mn	5.39	5.33	5.32
Co	7.60	7.62	7.58

it is observed that the stability sequence of Irving and Williams is fulfilled.[23]

Abstract—Complex formation between Ni(II), Co(II) and Mn(II) and 3-(2-furyl)-2-mercaptopropenoic and 3-(2-furyl)-2-mercaptopropanoic acids has been studied using glass electrode potentiometry. Ligand–metal ion mixtures in 10% (v/v) ethanol–water containing 0.1 mol dm^{-3} KNO_3 were titrated with potassium hydroxide. The e.m.f. data obtained have been analyzed using the linearization method, and initial estimates of protonation constants for the ligands and complex formation constants have been refined with the MINIQUAD program.

The complexation of metals by 2-mercaptoacids has been widely studied,[1,2] but only a few studies of the complexation of 3-aryl-2-mercaptoacids with metal ions appear in the literature. The 3-aryl-2-mercaptoacids are compounds which act as complexing agents for metal ions. They have many analytical applications and they are also interest in relation to various biological systems. 3-(2-Furyl)-2-mercaptopropenoic acid has been used for the spectrophotometric determination of Ti(IV)[3] and Mo(IV),[4] and 3-(4-methoxyphenyl)-2-mercaptopropenoic acid for Ni(II).[5] Following administration of 3-(2-furyl)-2-mercaptopropenoic acid, blood plasma zinc concentration increases manyfold[6] and evidence for the formation of a ternary complex of plasma albumin, zinc and the furyl derivative has been obtained.[7] Foye and Lo[8] reported stability constant data for complexes of the phenyl derivative with Al(III), Cu(II) and Fe(III), and also found this compound to have antimicrobial activity. Wagner *et al.*[9] studied the inhibition of metaloenzymes by differents 3-aryl-2-mercaptopropenoic acids and the stability constants of metal complexes in 50% (v/v) dioxane–water were reported.

In order to compare the influence of the double bond in the complexing ability of 3-aryl-2-mercaptoacids we have determined potentiometrically the stability constants of 3-(2-furyl)-2-mercaptopropenoic and 3-(2-furyl)-2-mercaptopropanoic acids with the ions Ni(II), Co(II) and Mn(II) in 10% (v/v) ethanol–water.

EXPERIMENTAL

Reagents and solutions

3-(2-Furyl)-2-mercaptopropenoic acid (FMPE) was prepared by alkaline hydrolysis of the rhodanine derivative obtained from the condensation of furylaldehyde with rhodanine, following the procedure of Campaigne and Cline.[10] 3-(2-Furyl)-2-mercaptopropanoic acid (FMPA) was obtained by reduction of FMPE with sodium amalgam and puri-

* Author to whom correspondence should be addressed.

fied as described earlier.[11] Their purity were tested periodically by iodometric titrations.[12] Although FMPE and FMPA were found to be quite stable, freshly prepared solutions were used for each titration.

Standard stock solutions of metals were prepared as its nitrate salts. The Ni(II) (40.3 mmol dm^{-3}) and Co(II) (48.7 mmol dm^{-3}) stock solutions were standardized electrogravimetrically and the Mn(II) (55.4 mmol dm^{-3}) stock solution was standardized gravimetrically as Mn(II) pyrophosphate.[13]

Potassium hydroxide solution (0.05 mol dm^{-3}) was prepared frequently[14] and standardized by titration against standard grade potassium hydrogen phthalate.

Water used to prepare reagent solutions and in all dilutions was double deionized, Culligan Water Ultrapure, 0.08 μohm^{-1} cm^{-1} conductivity. All other reagents used were reagent grade, and all solutions were 10% (v/v) ethanol–water.

Apparatus

A radiometer compensator potentiometer PHM 64 was used. The indicator glass electrode (Radiometer G-202B) was conditioned for several hours in the mixed solvent and saturated calomel reference electrode (Radiometer K-401), with an external salt bridge containing saturated KCl solution. Indicator electrode calibration was performed without buffer solutions by application of Gran's technique.[15] Titration cells, which include pure nitrogen inlet and outlet, were thermostatted at 25 or 30 ± 0.1°C.

Procedure

Complex formation equilibria were studied through e.m.f. measurements along the course of titrations performed in a 10% ethanol–water medium containing 0.1 mol dm^{-3} KNO_3 under a nitrogen atmosphere. Ethanol was used because of the solubility limitations of metal complexes in water. Measurements of e.m.f. were performed according to the following procedure:

50 cm^3 of the test solution (TS) with the initial composition

TS = L_0 mol dm^{-3} FMPE or FMPA,

H_0 mol dm^{-3} HNO_3, M_0 mol dm^{-3} $M(NO_3)_2$,

0.1 mol dm^{-3} KNO_3, 10% ethanol

is titrated with 0.1 mol dm^{-3} KOH solution (T), containing the proper ethanol volume. The free hydrogen concentration was measured from a reading obtained with the glass electrode (GE), against the reference electrode (RE) in the cell:

GE/TS//saturated KCl/RE.

The e.m.f. measurements were taken, after the addition of titrant solution, when equilibrium was reached, i.e. as soon as the readings reached stable values. The stabilization of electrode potentials was achieved in every case within less than 5 min.

The free hydrogen ion concentration [H] is calculated from the expression: $E = E^{\ominus} - g \log [H]$ ($g = 59.16$ mV at 25°C and 60.15 mV at 30°C). Before starting the titration, the initial hydrogen ion concentration (H_0), the standard electrode potential for the glass electrode ($E^{\ominus}$) and the K_w under the experimental conditions were determined according to Gran's method.[15]

Absence of polynuclear species was proved from titrations of several TS solutions with different ligand : metal concentration ratios (see Figs 3–5). A wide range was not used because of solubility limitations of metal complexes.

DATA TREATMENT

The general equilibria studied can be written as

$$pM + qL + rH \rightleftharpoons M_pL_qH_r$$

and the overall formation constants are defined as

$$\beta_{pqr} = [M_pL_qH_r]/[M]^p[L]^q[H]^r,$$

where the square brackets indicate the concentration of free metal, ligand and hydrogen ions (charges are omitted for simplicity).

The experimental values $(V_T, E)_{L_0,M_0}$ obtained from the titrations of TS solutions with potassium hydroxide solution (T) are transformed[16] into pairs $(\bar{n}_L, -\log [L])_{L_0,M_0}$ in order to build the metal complex formation curve which corresponds to each experiment.

Analogously, the experimental values obtained from the titrations of the TS solutions without metal ion ($M_0 = 0$) permit the construction of ligand protonation curves ($\bar{n}_H$, $-\log [H]$). These curves are shown in Figs 1 and 2, and the metal complex formation curves in Figs 3–5.

Data pairs ($\bar{n}_H$, $-\log [H]$) or ($\bar{n}_L$, $-\log [L]$) have been treated graphically by the linearization method,[17] under the assumption that only mononuclear complexes are formed. Figure 6 shows, as an example, the straight line obtained from the application of this method to the data obtained with the Mn(II)–FMPA system. The stability constants β_{120} can be evaluated from the slope and the β_{110} from the intercept of the resulting straight line.

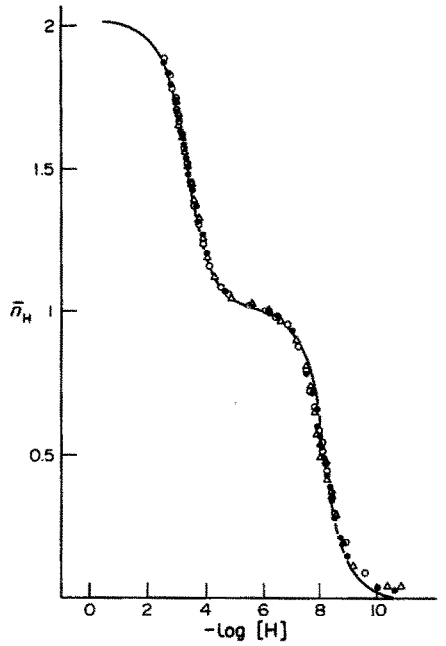

Fig. 1. Protonation curves of FMPE. (●) 3.972 mM, (○) 3.478 mM, (△) 4.419 mM. (—) Theoretical curve.

The experimental values of the ligand protonation constants and the overall formation constants of the metal complexes were refined by the least-squares program MINIQUAD.[18] All calculations were performed on an IBM 3083/XE01 computer.

RESULTS AND DISCUSSION

FMPA and FMPE show two protonation constants that can be assigned to the carboxylate and thiol groups (Table 1). The values found are quite similar to those reported for other 3-aryl-2-mercaptoacids (Table 2). It can be observed that the carboxylic dissociation constants are not greatly influenced by either the nature of the aryl substituent or the presence of the double bond in the α-position, which is in accordance with Wagner *et al.*[6] Besides, this behavior is in agreement with the value obtained for the 2-mercaptopropanoic acid.[1,2]

Conversely, the thiol dissociation constant is strongly influenced because of the presence of the double bond, which allows further conjugation between both thiol and aryl groups. It can be observed that the 3-aryl-2-mercaptopropenoic acids show a higher acidity of the thiol group than the 2-mercaptopropanoic and 3-aryl-2-mercaptoproanoic acids.

In reference to the metal complexes studied, a comparison of their formation constants (Table 1) shows that the propenoic derivatives are more

Mn(II)–FMPA: (▲) $L_0 = 4.564$ mM, $M_0 = 0.554$ mM; (○) $L_0 = 4.036$ mM, $M_0 = 1.108$ mM; (□) $L_0 = 3.130$ mM, $M_0 = 1.108$ mM. (—) Theoretical curves.

stable than propanoic derivatives. This behavior is due in part to the double bond in the α-position and the inductive effect of the aryl substituent, which seems to confer greater stability to the complexes formed. With a given metal ion, but different 3-aryl-2-mercaptoacids, values of the complex formation constants vary with values of the protonation constants, as was to be expected. The results obtained shows that the affinity of complexation follows the Irving–Williams order, Ni(II) > Co(II) > Mn(II).

(*Received* 26 *August* 1985; *accepted* 11 *November* 1985)

Abstract—Slurries of Mg, Ca, Ba and Al, prepared by cocondensation of metal vapour with volatile organic solvents, especially toluene, at −196°C, reacted at ambient temperature with some bis-cyclopentadienyl complexes of Ti, Zr, Hf, V and Cr. $[TiCl_2Cp_2]$ ($Cp = \eta^5$-C_5H_5) with slurries of Al in hexane or toluene, or Mg or Ba, in toluene, formed $[TiClCp_2]_2$ accompanied by side-products. From related reactions with slurries of Mg in tetrahydrofuran (THF), $[TiCl_2Cp(THF)]$ was obtained and with Ca–toluene slurries an unstable paramagnetic dihydrido complex of Ti(III) was observed by using ESR spectroscopy. Reactions of $[TiPh_2Cp_2]$ with slurries of Al or Ba in toluene yielded a form of "titanocene" ($TiC_{10}H_{10}$) and ESR studies of these reactions revealed related paramagnetic species in solution. Reaction of slurries of Al, Mg or Ba with $[TiMe_2Cp_2]$ produced several different paramagnetic products which were studied by ESR spectroscopy, and the reaction of metal slurries with the complexes $[MR_2Cp_2]$ (M = Ti, R = OPh; M = Zr or Hf, R = Cl or Me), $[VRCp_2]$ (R = Cl or Me), and $[CrCp_2]$ are also reported.

In view of the wide application of systems containing Ti, Zr and related metals with Al or Mg as components in Ziegler–Natta catalysts,[1] we have undertaken a study of the products formed in reactions of finely divided slurries of alkaline earth metals or Al, suspended in organic solvents, with compounds of early transition metals. Such products might be expected to show useful catalytic activity in alkene polymerizations and could be interesting reduced oxidation state species, possibly of mixed metal composition.

Active metal slurries have found applications in synthesis in recent years and have been produced either by vaporization techniques[2] or by reduction of metal halides in solution, especially by using K or other alkali metals.[3] Of particular relevance to this work, slurries of Mg[4,5] and Al[6,7] have been previously reported. Such slurries exhibit superior reactivity to bulk metals, undergoing a number of previously unknown or difficult reactions.

Bis-cyclopentadienyl metal complexes of Ti, Zr, Hf, V, Nb and Cr have been shown to undergo reduction reactions with alkali metals, and in some cases metallic Zn, Mg or Al is an effective reducing agent, although products may be mixed bimetallic species.[8] By using finely divided slurries of Mg, Ca, Ba or Al we hoped to observe some variations on reactions of complexes of these early transition metals.

RESULTS AND DISCUSSION

Finely divided slurries of Mg, Ca, Ba or Al were produced by vaporization of the metal and cocondensation with inert organic solvent at −196°C, followed by warming to ambient temperature, using a method similar to that described by Klabunde and coworkers.[2,4,6] Slurries of Al in hexane or toluene[6] and of Mg in toluene or tetrahydrofuran (THF)[4] have been previously formed by this method and we have utilized the same slurries; in the course of this work we also produced slurries of Ca or Ba in toluene which were, respectively, brown or black-brown in colour. The size of particles in these slurries varied with the rate of warm-up of the cold metal–solvent matrix and nature of the organic medium, as noted earlier[9]—e.g. the slurry of Al in hexane was coarser than Al in toluene, and the former showed a lower reactivity.

* Author to whom correspondence should be addressed.

It has been recognized that the particles of metal slurries made by cocondensation include some carbonaceous material derived from the organic medium incorporated either by simple absorption or by chemical reactions to form organometallic species.[9] Microanalysis of vacuum-dried powders from representative slurries in toluene showed that the carbon content increased in the order Mg < Al < Ba < Ca and this must represent an increasing formation of organometallic species between metal atom and toluene during cocondensation, warm-up and/or on standing at ambient temperature. Formation of a benzyl–metal derivative is possible and the brown solid residue from a Ca–toluene slurry did show partial solubility in THF giving a brown-red solution with $\lambda_{max} \sim 330$ nm, similar to that observed for dibenzylcalcium.[10] This observation may explain a greater difference in the course of reactions using Ca slurries when compared to reactions of the other metal slurries.

Reactions with $[MCl_2Cp_2]$ (M = Ti, Zr *or* Hf)

Electrochemical studies on $[TiCl_2Cp_2]$ (Cp = η^5-cyclopentadienyl) in THF support primary reduction to a stable monoanion $[TiCl_2Cp_2]^-$, with an ESR g_{iso} signal of 1.9789, whereas two-electron reduction causes dissociation of Cl^-.[11] Chemical reduction by finely divided Zn in polar solvents gives bimetallic $[Cp_2Ti(\mu\text{-}Cl)_2Zn(\mu\text{-}Cl)_2TiCp_2]$ which can be cleaved by Lewis bases to $[TiClCp_2]_2$.[8] Reduction of $[TiCl_2Cp_2]$ by carefully activated Al foil in THF also yields $[TiClCp_2]_2$,[12] although in the presence of $AlCl_3$ the hydrocarbon soluble $[Cp_2Ti(\mu\text{-}Cl)_2AlCl_2]$ is formed;[13] moreover addition of water to THF causes Al to produce solvated $[TiCl_2Cp]$.[14] Mg metal may reduce $[TiCl_2Cp_2]$ to Ti(II) products[8,15] in a reaction comparable to reduction by Na to "titanocene".

Using metal slurries formed by vaporization, we find that Al suspensions in hexane or toluene form primarily $[TiClCp_2]_2$, identified by analysis and spectroscopy. In hexane, reduction by Al is slow and, even in the presence of added THF to improve solubility, conversion to Ti(III) product was only *ca* 30% after 2 days. In toluene, reduction was complete within a few hours and further stirring at ambient temperature for 3 days gave no reduction beyond oxidation state III; $[TiClCp_2]_2$ was isolated in 66% yield and the remaining product was mainly present as $[Cp_2Ti(\mu\text{-}Cl)_2AlCl_2]$, formed in the stoichiometric reaction:

$$3[TiCl_2Cp_2] + Al \rightarrow [TiClCp_2]_2 + [Cp_2TiCl_2AlCl_2].$$

Toluene slurries of Mg or Ba also produced $[TiClCp_2]_2$ as the main soluble product (isolated yield 26 or 38%, respectively), although much insoluble material was also formed. The insoluble brown solid obtained from the Mg–toluene slurry reaction incorporated toluene and reduced Ti, having a molar composition Ti : Mg : Cl of 2 : 3 : 6; a formulation $2(TiC_{10}H_{10}) \cdot 3(MgCl_2) \cdot 1.5(C_7H_8)$ is consistent with the analytical results but further characterization has not been attempted.

Reduction of $[TiCl_2Cp_2]$ by Mg–THF slurry gave the monocyclopentadienyl product $[TiCl_2Cp(THF)]$ as the only isolable product (deep blue-black crystals, 50%) from a dark-green solution. The THF used in this reaction had been carefully dried and to our knowledge no water had been admitted during handling under dry Ar or *in vacuo*. Thus, removal of either Cp or Cl ligand occurs by Mg in THF or toluene, respectively. ESR spectra of $[TiClCp_2]_2$ or $[TiCl_2Cp(THF)]$ in toluene (or THF) are very similar (Fig. 1a): singlets ($\Delta H_{pp} = 0.4$–0.5 mT) at $g_{iso} = 1.9785$ or 1.979, respectively, with satellites $A_{iso}(^{47/49}Ti) = 1.2$ mT.[13(a)]

Reaction of excess Ca–toluene slurry with $[TiCl_2Cp_2]$ over 16 days gave only a toluene-insoluble product; extraction of this brown product with THF gave a purple solution exhibiting a strong 1 : 2 : 1 triplet ESR signal [$g_{iso} = 1.992$, $A_{iso}(^1H) = 0.88$ mT with satellites $A_{iso}(Ti) = 0.74$ mT] (Fig. 1b). This spectrum is similar to those previously assigned to non-isolated $[Cp_2TiH_2]^-$ with various counter-ions, although coupling to cyclopentadienyl hydrogens was also reported.[16] The product obtained in our work may be $[Cp_2TiH_2]^-$ with a Ca^{2+} counter-ion, formed by hydrogen transfer from toluene (or THF), or a related dihydrido-titanium(III) complex. Attempted isolation of this species yielded a purple solid, itself sparingly soluble in THF, and this solid did not reproduce the former ESR spectrum on redissolution. Analytical data on this solid were inconsistent with a simple species so that some decomposition may have occurred.

Reduction of $[ZrCl_2Cp_2]$ is more difficult than for the Ti analogue, as shown by electrochemical studies.[11,17] Reductions by Na–$C_{10}H_8$ give a form of "zirconocene"[8] and an ESR study of reduction by Mg in THF demonstrates the formation of Zr(III) hydride by H-transfer from a cyclopentadienyl ring.[18] Recently diamagnetic $[ZrClCp_2]_2$ has been synthesized from $[Zr(CO)_2Cp_2]$ and $[ZrCl_2Cp_2]$.[19] We observed that Al–toluene slurries with $[ZrCl_2Cp_2]$ produced a red solution exhibiting a single ESR signal [$g_{iso} = 1.998$ ($\Delta H_{pp} = 1.5$ mT)] but attempted isolation of this product afforded much unreacted starting material and a small amount of uncharacterizable brown solid. It does appear that

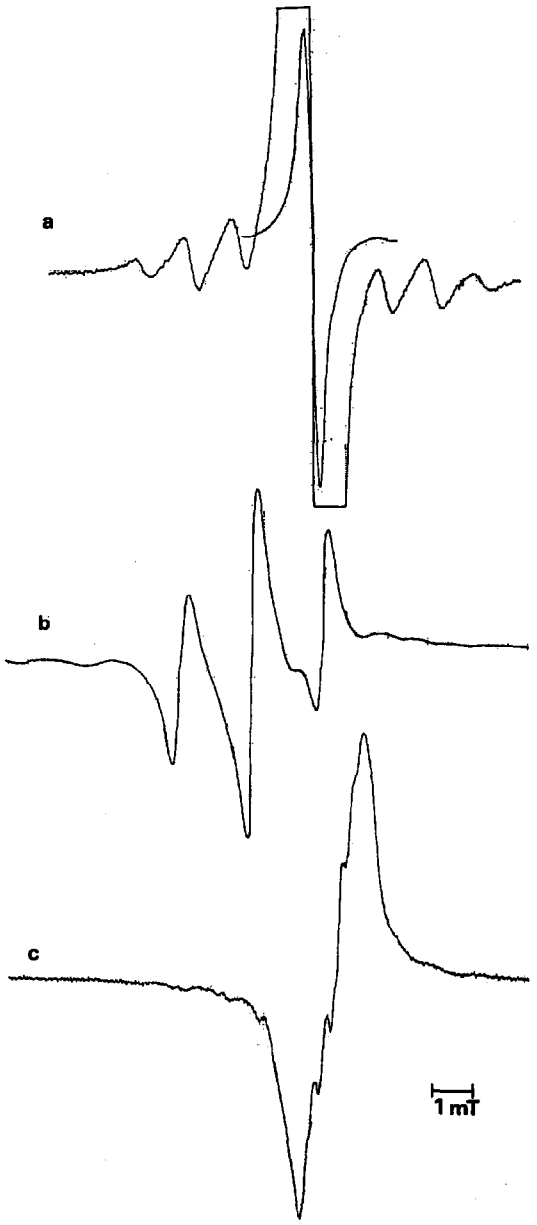

Fig. 1. *X*-band ESR spectra of: (a) $[TiClCp_2]_2$ in THF ($g = 1.979$); (b) product from $[TiCl_2Cp_2]+Ca$, in THF (probably $[TiH_2Cp_2]^- \cdot \frac{1}{2}Ca^{2+}$) ($g = 1.992$); and (c) product from $[Ti(OPh)_2Cp_2]+Al$-toluene ($g = 1.977$).

the Al–toluene slurry will partially reduce $[ZrCl_2Cp_2]$; on the other hand no reactions were observed between Al–toluene slurry and $[HfCl_2Cp_2]$, between Mg–toluene slurry and $[ZrCl_2Cp_2]$ or between Ba–toluene slurry and $[(ZrClCp_2)_2O]$.

Reaction with $[Ti(OPh)_2Cp_2]$

A slurry of Al–toluene readily reacted with $[Ti(OPh)_2Cp_2]$ to give a green solution. The filtered solution showed ESR signals from at least three paramagnetic species: singlets at $g_{iso} = 1.978$ and 1.976 ($\Delta H_{pp} = 0.3$–0.4 mT) and a broader underlying signal [$g_{iso} \sim 1.977$ ($\Delta H_{pp} \sim 1.5$ mT)]. Controlled aerial oxidation of an ESR sample caused the primary disappearance of the two sharper singlets and the broader signal was revealed as a poorly resolved multiplet (Fig. 1c); further oxidation caused the loss of this signal. The multiplet can be analysed as a sextet resulting from coupling to ^{27}Al[20] and may be tentatively assigned to a species $[Cp_2Ti(\mu\text{-}OPh)_2AlR_2]$ with R = OPh, or possibly Cp [$g_{iso} = 1.977$, $A_{iso}(Al) \simeq 0.25$ mT, $A_{iso}(Ti) \simeq 1.0 \pm 0.1$ mT]. Previous studies of electrochemical reductions of complexes $[Ti(OAr)_2Cp_2]$ support the formation of neutral species $[Ti(OAr)_2Cp]$ ($g_{iso} \simeq 1.977$ in THF) by Cp^- dissociation:[21] it thus seems highly likely that the other two ESR species observed in reaction with Al slurry are $[Ti(OPh)_2Cp]$ and $[Ti(OPh)Cp_2]$. Dimeric complexes $[Ti(OR)Cp_2]_2$ with magnetic moments varying with temperature have been studied[22] but ESR studies on these have not been reported.

Reactions with $[TiPh_2Cp_2]$

Both Al– and Ba–toluene slurries react with $[TiPh_2Cp_2]$ to give dark-green, toluene-soluble products, obtainable as dark microcrystalline solids on cooling concentrated solutions. Analysis of the percentage of C, H, Ti and, in the former case, Al established a stoichiometry corresponding reasonably to that of "titanocene", i.e. $TiC_{10}H_x$ ($x \sim 10$) (*ca* 65% yield). IR spectra of these samples showed no significant absorption around 1230 cm^{-1}, which has been assigned to a ν(Ti—H—Ti) vibration in the fulvalene derivative $[Ti_2(\mu\text{-}\eta^5,\eta^5\text{-}C_{10}H_8)(\mu\text{-}H_2)Cp_2]$.[23] The IR spectra were essentially identical to those attributed to metastable "$[TiCp_2]_2$" by Bercaw *et al.*[24] Other physical properties of the products accord with this species: the relation of this species to the black, microcrystalline "titanocene" $[Cp_2Ti(\mu\text{-}\eta^1,\eta^5\text{-}C_5H_4)TiCp]$, described by Pez,[25] is not clear—the published IR spectrum of the latter does show a significant band at 1224 cm^{-1} and, overall, less similarity to that of our dark-green product but, as discussed in previous reviews,[26] these products may basically be structurally the same.

ESR spectra of the products obtained from metal slurry reactions with $[TiPh_2Cp_2]$ have thrown more light on the reaction. Using an Al–toluene slurry, the filtered reaction solution after 7 days exhibited a dominant signal ($g_{iso} = 1.977_5$ with doublet-splitting $A_{iso} = 0.435$ mT), attributable to coupling with a single ^1H, accompanied by other weaker ESR

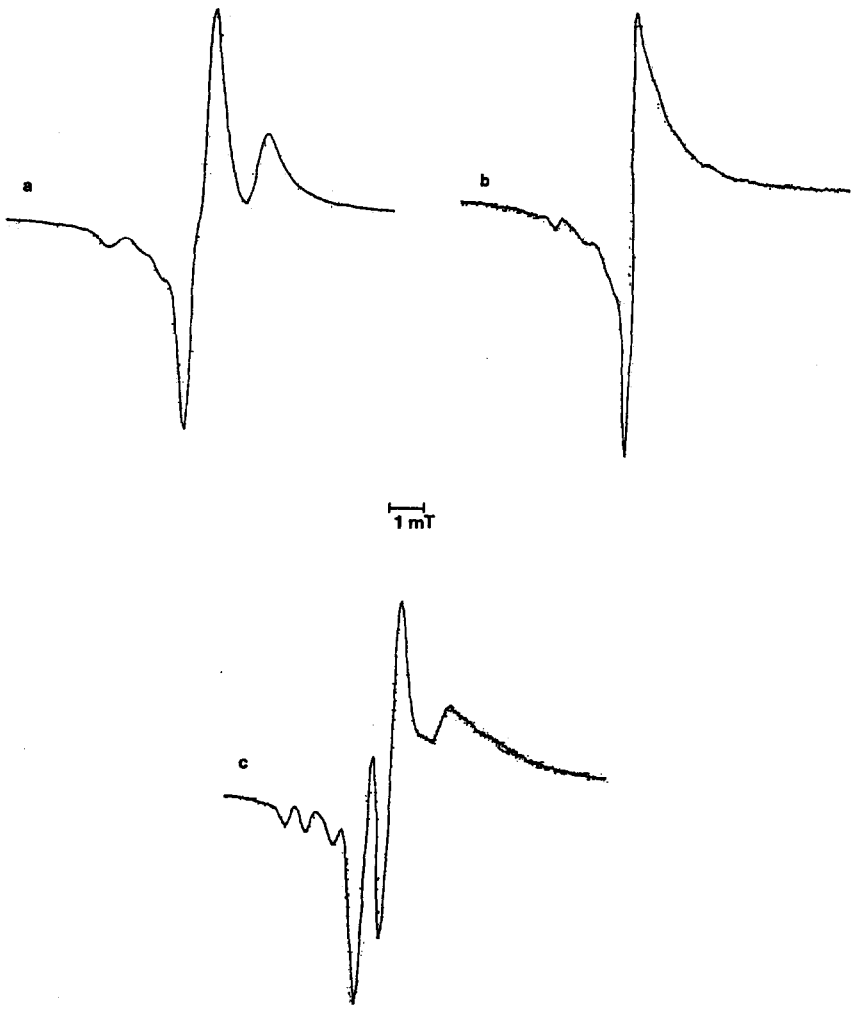

Fig. 2. *X*-band ESR spectra of: (a) reaction mixture of $[TiPh_2Cp_2]$+Al–toluene; (b) product, $TiC_{10}H_{10}$, obtained from $[TiPh_2Cp_2]$+Al reaction, in toluene ($g = 1.979$); and (c) reaction mixture of $[TiMe_2Cp_2]$+Al–toluene.

resonances varying in intensity with different experiments and including one at $g_{iso} = 1.968$ (Fig. 2a). Controlled aerial oxidation of these solutions initially increased the complexity of the ESR spectrum but finally produced a singlet ($g_{iso} = 1.979$) before giving an ESR inactive solution. The green microcrystalline solid obtained by careful addition of hexane under Ar to an unoxidized concentrated solution in toluene showed a broad ESR signal [$g_{iso} = 1.980$ ($\Delta H_{pp} = 6$ mT)]. Redissolution of this solid in toluene gave an apparent singlet [$g_{iso} = 1.979$, $A_{iso}(Ti) = 0.9$ mT] (Fig. 2b), coincidently similar to that produced by oxidation but, we believe, assignable to non-oxidized product. Similar ESR observations were made for reaction of Ba or Ca slurries in toluene, although more ESR active by-products were formed in solutions produced using Ca.

The ESR spectrum of unstable $[TiPhCp_2]$ is reported to show $g_{iso} = 1.95$ in toluene[27] and so is inconsistent with species formed during these slurry reactions. Photolysis of $[TiPh_2Cp_2]$ in benzene is reported to give a singlet ESR resonance ($g_{iso} = 1.979$) at ambient temperature assigned to a monomeric form of metastable "$[TiCp_2]_2$".[18] This latter report is in accord with the proposed nature of our isolated microcrystalline product; the doublet ESR observed in our work may be related to hydrido species such as $[TiHCp_2]_x$[24] or $[Ti_2HCp_4]$[29] (possibly identical—see Ref. 26) which are interconvertible with "titanocene" by loss or gain of hydrogen.

Reactions with $[MMe_2Cp_2]$ (M = Ti, Zr *or* Hf)

Dark-green toluene solutions were obtained by stirring slurries of Al, Mg or Ba with $[TiMe_2Cp_2]$. The products obtained from these reactions (>50% yields), however, appeared to differ and spectroscopic and analytical results suggest that

varying mixtures of two or more reduced organotitanium compounds were formed.

Reaction solutions or solid obtained from Al–toluene slurries gave an ESR spectrum with two equally intense single resonances (Fig. 2c); this spectrum could be assigned to a single species having $g_{iso} = 1.981$ and $A_{iso} = 0.75$ mT with doublet coupling to a single ^1H nucleus or, alternatively, to two species with singlets at $g_{iso} = 1.983$ and 1.979. IR spectra of this solid showed typical Cp bands but no strong band assignable to Ti—H—Ti vibrations apart from a weak absorption at 1155 cm^{-1} and analytical data supported an empirical formula TiC_6H_x ($x \sim 6$).

Filtered reaction solutions obtained from Mg–toluene slurries showed the same two ESR resonances as above superimposed on a strong, broad signal [$g_{iso} = 1.98$ ($\Delta H_{pp} \sim 4.5$ mT)], whereas the green solid isolated from solution showed only an ESR singlet [$g_{iso} = 1.979$ ($\Delta H_{pp} \sim 0.2$ mT)] on redissolution in toluene. This solid did exhibit a broad IR band of medium intensity at 1225 cm^{-1} and had analytical data consistent with the empirical formula $TiC_{6-7}H_x$ ($x \sim 7$).

The green solid isolated from Ba–toluene slurry reaction gave a dominant doublet ESR signal ($g_{iso} = 1.977$, $A_{iso} = 0.4$ mT) and a broad band at 1225 cm^{-1} in its IR spectrum. Analytical data supported an empirical formula TiC_9H_x ($x \sim 10$), i.e. close to $TiC_{10}H_{10}$.

[$TiMeCp_2$] is thermally unstable in ether solution at $> -50°C$,[30] although it may be more stable in toluene, in which solvent an ESR signal ($g_{iso} = 1.980$) has been assigned to this complex.[31] In THF, [$TiMeCp_2$] gives a quartet ESR signal at low temperatures.[30] Electrochemical reduction of [$TiMe_2Cp_2$] in THF may produce [$TiMe_2Cp_2$]$^-$ and/or [$TiMe_2Cp$]:[17,21] at $-20°C$ a septet ($g_{iso} = 1.986$) ([$TiCp_2Me_2$]$^-$) has been reported in one investigation[17] whereas a singlet resonance ($g_{iso} = 1.9789$) at $+20°C$ ([$TiMe_2Cp$]) is quoted in another report.[21] Electrochemical studies, however, do support some cleavage of Cp^- during reduction.[21]

Thus, possible products of our slurry reactions include [$TiMeCp_2$], [$TiMe_2Cp$], a form of "titanocene" and also related hydride species. [$TiMeCp_2$], although a possible intermediate detected in solution, is inconsistent with isolated products which appear to have undergone Cp cleavage by Al or Mg slurries: [$TiMe_2Cp$] or a product involving further transformation of methyl group(s) may be formed. Doublet ESR signals may arise from monohydrido complexes or from interaction of Ti with a C—H group as found in alkyl–metal compounds with agostic hydrogens.[32] The main product from reactions of Ba–toluene slurries more closely corresponds to a form of "titanocene" or a stoichiometrically similar species exhibiting a Ti–H coupling in its ESR spectrum (cf. reactions of [$TiPh_2Cp_2$] discussed above) but has not been isolated in a completely pure state.

It was found that Mg–toluene slurries were unreactive towards [MMe_2Cp_2] (M = Zr or Hf) after stirring for 14 days at ambient temperature. Al–toluene slurries did react to small extent with [MMe_2Cp_2] (M = Zr or Hf), but again much unreacted M(IV) complex was recovered. Thus, [$ZrMe_2Ph_2$] with Al–toluene slurry gave a solution containing ESR active Zr species—a doublet ($g_{iso} = 1.981$, $A_{iso} = 0.7$ mT), superimposed on a broad signal [$g \sim 1.98$ ($\Delta H_{pp} \sim 3$ mT)], and a smaller resonance at $g_{iso} = 2.000$; the brown solid isolated from this reaction (mainly [$ZrMe_2Cp_2$]) contained <0.1% Al and redissolved in THF to give a doublet ($g_{iso} = 1.986$, $A_{iso} \simeq 0.8$ mT) and a broader singlet ($g_{iso} = 1.996$). With an Al–toluene slurry, [$HfMe_2Cp_2$] gave a dark-red coloured solution which was ESR inactive and an attempted separation of this low-yield red product from starting material was unsuccessful. It may be noted that crimson [$ZrMeCp_2]_2$ has been reported[8] and that electrochemical reductions of species [ZrR_2Cp_2] involve Cp^- loss to give [ZrR_2Cp] complexes[17] with $g_{iso} \sim 1.984$–1.987. Photolysis of [$ZrMe_2Cp_2$] and related dialkyl complexes involves primary Me loss and resulting Zr(III) monohydride species have been observed by ESR spectroscopy ($g_{iso} \sim 1.984$–1.987, $A_{iso} \sim 0.65$–0.7 mT).[33]

Reactions with other bis-cyclopentadienyl complexes

Al slurries in toluene reduce [$VXCp_2$] (X = Cl or Me) to vanadocene, isolated in high yield as the only identified vanadium product. However, a Mg–toluene slurry was found to be unreactive towards [$VMeCp_2$] after stirring for 7 days at ambient temperature. Also, no reaction occurred between [$CrCp_2$] and Mg or Ba slurries in toluene; on addition of THF and continued stirring, the solution became dark brown but only small quantities of uncharacterized brown product were isolated and much unreacted [$CrCp_2$] was recovered.

EXPERIMENTAL

All reactions and manipulations were carried out using Schlenk techniques under an atmosphere of dry, dioxygen-free Ar or *in vacuo*. Reagent-grade solvents were subjected to preliminary purifications, followed by refluxing (>2 h) with $Na[OCPh_2]$ (toluene or THF), CaH_2 (hexane or

ether) or P_4O_{10} (dichloromethane) and distillation under dinitrogen. For slurry reactions these solvents were then purged with Ar for 5 min before use. For cocondensation to form slurries, these solvents were treated to at least three freeze–thaw degassing cycles and distilled *in vacuo* ($<10^{-3}$ torr) from appropriate drying reagents before introduction into the evacuated apparatus.

Elemental analyses were determined by Analytische Laboratorien, Engelskirchen, F.R.G., or by Butterworth Laboratories, Teddington, U.K. Aluminium analyses were carried out using a Pye–Unicam AA Spectrophotometer at 309.28 nm. ESR spectra were recorded on samples in evacuated tubes or under Ar at 12 ± 5°C with JEOL PEI-X X band spectrometer using dpph ($g = 2.0036$) as standard and a Bruker ER 035M Gaussmeter for field calibration. IR spectra were obtained from Nujol mulls made up under argon and recorded between CsI plates on a PE 580 spectrometer.

Some starting materials were purchased as follows: $[ZrCl_2Cp_2]$ (Aldrich Chemical Co.); $[HfCl_2Cp_2]$ and Ca, >99.5% (Alfa/Ventron GmbH); Al, >99.9% (BDH); Mg, >99.8% and Ba, >99% (Koch-Light) and VCl_3 (Fluka). Other compounds were prepared according to literature procedures: $[MR_2Cp_2]$ (M = Ti, R = Cl,[34] Ph,[35] Me[36] or OPh;[37] M = Zr or Hf, R = Me[38]), $[MCp_2]$ (M = V[34] or Cr[39]), and $[VRCp_2]$ (R = Cl[40] or Me[40]).

Preparation of metal slurries

The apparatus used comprised a rotating (*ca* 60 rpm) evacuated ($<10^{-3}$ torr) 3-dm^3 flask similar to that described by Timms[41] and used in previous investigations.[42] Mg, Ca or Ba were evaporated from conically wound, electrically heated (45–85-A) Mo wire furnaces and Al was evaporated from a boron nitride crucible wrapped in an alumina-coated, Mo wire heater. Cocondensation of metal (0.4–0.9 g) with solvent (120–200 cm^3) vapour at −196°C gave dark matrices which were then warmed slowly to ambient temperature. Dry Ar was admitted to the vessel during this latter process and the resulting slurry was then siphoned under Ar into a storage Schlenk tube for use in reactions.

Analysis of powders obtained by solvent removal *in vacuo* at 20°C from representative toluene slurries gave the following approximate M:C:H compositions: M = Mg, 10:1:1, M = Ba, 1:1:3; M = Ca, 1:3:3; M = Al, 2:1:2.

Reactions of bis-cyclopentadienyl metal complex with metal slurry

Typical reactions involved stirring the complex with metal slurry (25–70 cm^3; complex:metal ratio = *ca* 1:2, i.e. excess metal) at ambient temperature for several days. Periods of up to 22 days were employed for systems which showed negligible or zero reaction. Normally no additional solvent other than that present in slurry was introduced, except for reactions $[TiCl_2Cp_2]$ + hexane–Al slurry and $[CrCp_2]$ + toluene–Mg or Ba slurry, when THF (35 cm^3) was also added to some reactions. Reaction solutions were then filtered and solid, often crystalline or microcrystalline, product was isolated by

(*Received* 2 *September* 1985; *accepted* 18 *November* 1985)

Abstract—Homogeneous photocatalytic oxidation of isopropyl alcohol by tetrabutylammonium decatungstate $(Bu_4N)_4[W_{10}O_{32}]$ in acetonitrile using O_2 as a reoxidizing reagent has been studied. The photocatalysis is interpreted on the basis of a rapid redox cycle between 2*e*-reduced species and the oxidized species of decatungstate; O_2 as a reoxidizing reagent is converted to water. The catalytic activity and the mechanism of the redox cycle of decatungstate are in contrast to those of Keggin-type heteropolytungstic acids. When the concentration of isopropyl alcohol is lowered by prolonged irradiation, pale yellow precipitates are produced by side reactions due to electron transfer from the counter-ion Bu_4^+ to the decatungstate.

Photosensitivity of heteropoly and isopoly compounds in the presence of organic compounds has been well known. Recently, the photocatalytic oxidations of alcohols using heteropolytungstates such as $[SiW_{12}O_{40}]^{4-}$, $[PW_{12}O_{40}]^{3-}$ and $[P_2W_{18}O_{62}]^{6-}$ have been reported by Papaconstantinou[1] and Darwent.[2] The former used oxygen whereas the latter used colloidal platinum for the reoxidation of the reduced heteropolyacid. In the latter experiment, evolution of H_2 has been confirmed in the reoxidation process. In view of the chemical conversion of solar energy, these experiments are of special interest and have more recently been studied in detail.[3,4] From a similar standpoint, Yamase *et al.*[5] have reported the photocatalytic H_2 evolution from alcohols by $[W_{10}O_{32}]^{4-}$ in the presence of heterogeneous catalysts such as RuO_2, IrO_2 and Pt. They have also shown a quantitative photochemistry of $(Bu_4N)_4[W_{10}O_{32}]$ in acetonitrile under deaerated conditions. On the other hand, Launay *et al.*[6] have investigated the electrochemical and photochemical reductions of $[W_{10}O_{32}]^{4-}$ and characterized one- (1*e*) and two-electron (2*e*) reduced species by optical and ESR spectra. Our attention has been devoted to the catalytic oxidation by hetero- and isopolyanions using O_2 as a reoxidizing reagent and to its application to organic synthesis. In this paper, we report a photocatalytic oxidation of isopropyl alcohol to acetone using $(Bu_4N)_4[W_{10}O_{32}]$ in acetonitrile under O_2, and show that its photocatalysis is more effective than that of the Keggin-type heteropolytungstic acids. The decatungstate is a unique isopolytungstate with color (pale yellow) and there is no isostructural polyanion. The polyhedral model is shown in Fig. 1.

EXPERIMENTAL

Tetrabutylammonium decatungstate was prepared according to a procedure previously described[6] and recrystallized twice from acetonitrile. Found: C, 23.0; H, 4.5; N, 1.8%. Calc. for $[(C_4H_9)_4N]_4[W_{10}O_{32}]$: C, 23.1; 4.4; N, 1.7%. The salt was identified by its characteristic absorption maxima at 324 (ε 14,000), 262 (ε 16,500) and 218 nm (ε 50,000) in acetonitrile, which correspond to oxygen-to-tungsten charge-transfer bands, and by IR bands (cm^{-1}): 990(vw), 954(vs), 941(s), 888(s), 802(vs),

575(vw), 436(m), 420(m) and 405(s). All chemicals used were analytical grade.

A 75-W mercury lamp (SHL-100UV, Toshiba Corporation) in conjunction with a 5-cm cold water IR filter was used as a light source of an external irradiation. The apparatus is shown in Fig. 2. Sample solutions (50 cm^3) were prepared by dissolving decatungstate (5×10^{-3} mol dm^{-3}), isopropyl alcohol as a substrate (0.2–0.8 mol dm^{-3}), and benzene as an internal reference for the gas chromatographic analyses into acetonitrile as a solvent. The Pyrex flask containing the solution was purged with O_2 and irradiated while stirring thoroughly. For the experiment under excess O_2 environment the flask was joined through an inlet tube to a *ca* 5000-cm^3 balloon filled with O_2 before irradiation. Photooxidation of the alcohol was monitored by TCD gas chromatography (Shimadzu GC-8A) on a PEG 20M column. The sampling was performed at time intervals with a microsyringe through a rubber cap of the flask. A blank test of the photoreaction was checked under the system without the decatungstate.

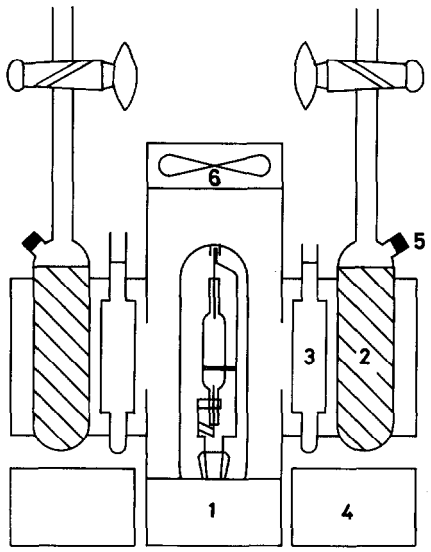

Fig. 2. Apparatus for the photoreaction: (1) light source (75-W mercury lamp); (2) Pyrex flask with a vacuum, stopcock; (3) cold-water IR filter; (4) stirring motor; (5) rubber cap for gas chromatographic sampling; and (6) fan for cooling. For the experiment under excess O_2 environment, a *ca* 5000-cm^3 balloon filled with O_2 is added to the flask.

Absorption spectra of the photoreduced decatungstate observed under N_2 were recorded on a Hitachi-340 spectrophotometer. The decatungstate in the acetonitrile solution was controlled to 1/80 of that in the reaction system described above and the measurements were performed with and without isopropyl alcohol in the region of 1200–300 nm.

RESULTS AND DISCUSSION

When the pale yellow solution of decatungstate (5×10^{-3} mol dm^{-3}) was irradiated under N_2 in the presence of isopropyl alcohol (0.4 mol dm^{-3}), it rapidly became deep blue and reduced decatungstate was formed. If the blue solution was degassed, and O_2 introduced, the initial colour was regenerated within a few minutes. O_2 in the 75-cm^3 Pyrex flask was completely consumed after irradiating for 1 h and the system became a reduced-pressure state—the solution turning deep blue again. O_2 plays an important role in the reoxidation of the reduced form of decatungstate. In conjunction with the redox cycle of decatungstate, isopropyl alcohol was oxidized to acetone. In the presence of O_2, the reaction proceeds with the initial colour being maintained. Under an excess O_2 environment in the Pyrex flask (attached to an oxygen-filled balloon), the gas chromatographic results shown in Fig. 3 were obtained. In each run, the molar amount of acetone produced is equivalent to that of decatungstate used within a few hours of irradiation and thereafter the former continues to increase. This shows that the oxidation of isopropyl alcohol to acetone is truly catalytic with respect to decatungstate. In these reactions, no H_2 evolution was observed; instead H_2O production was observed. Thus, O_2 consumed in the reoxidation of reduced decatungstate was converted into H_2O. The decrease in isopropyl alcohol could be treated as a psuedo-first-order reaction and its rate constant was 2.5×10^{-6} s^{-1}. The catalytic turnover, defined as the molar ratio of the produced acetone to the used catalyst, was 17.6 and the conversion of isopropyl alcohol to acetone was 22% after irradiating for 30 h with 5×10^{-3} mol dm^{-3} $(Bu_4N)_4[W_{10}O_{32}]$, 0.4

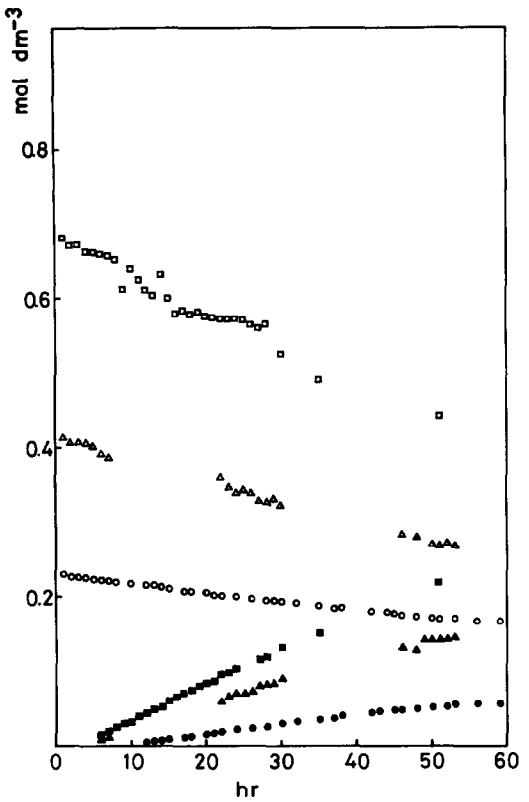

Fig. 3. Plots of decrease in isopropyl alcohol (□, △ and ○) and production of acetone (■, ▲ and ●) by photocatalysis of decatungstate in acetonitrile solutions under excess O_2 environment. Concentrations of isopropyl alcohol used are 0.68 (□), 0.40 (△) and 0.224 (○) mol dm^{-3}, and those of $\{Bu_4N\}_4[W_{10}O_{32}]$ as a catalyst and benzene as an internal reference are 0.5 and 0.256 mol dm^{-3}, respectively. The corresponding open and filled symbols result from the same experimental run.

mol dm^{-3} isopropyl alcohol and 0.287 mol dm^{-3} benzene as an internal reference in a 50-cm^3 acetonitrile solution. These values are larger than those of other polyanions as a photocatalyst; for instance, the turnover and the conversion to acetone were 6 and 7.5%, respectively, after irradiating for 70 h with 5×10^{-3} mol dm^{-3} $H_4[SiW_{12}O_{40}]$, 0.4 mol dm^{-3} isopropyl alcohol and 0.5 mol dm^{-3} H_2SO_4 in a 50-cm^3 aqueous solution. Some advantages of decatungstate as a photocatalyst were confirmed. (1) Both the formation of reduced species under N_2 and its reoxidation by O_2 are very rapid in comparison with other heteropolyanions such as Keggin-type $[PW_{12}O_{40}]^{3-}$ and $[SiW_{12}O_{40}]^{4-}$, and Dawson-type $[P_2W_{18}O_{62}]^{6-}$ under similar conditions. This leads to the high activity of the photocatalysis of decatungstate. (2) The reaction can be carried out under the entirely organic system and no addition of another acid is needed. The latter point is also in marked contrast to the photocatalysis of other heteropolyanions.[1,2,7]

The photoexcitation of the decatungstate is attributed to the absorption at 324 nm, which corresponds to the lowest-energy charge-transfer transition, because the excitations of the higher-energy charge-transfer bands are prevented by the Pyrex tube and the water filter.

The absorption spectra of photoreduced decatungstate in the presence of a large amount of isopropyl alcohol under N_2 are shown in Fig. 4(a). The absorbance increases with the irradiation time and the spectrum saturates after 4 h. Maximum absorptions at 625 and 960 nm are in agreement with those of electrochemically reduced 2*e* species, which have been reported by Launay *et al.*[6] The absorption bands are due to an intervalance charge-transfer (IVCT) transition between W^V—O—W^{VI} and W^{VI}—O—W^V.[8,9] In this experiment, 1*e* species could not be observed, whereas these could be detected in the system without the substrate at the early stage of the irradiation [Fig. 4(b)]. These facts are also consistent with the results reported by Launay's[6] and Yamase's[5] groups. Thus, only when an appropriate amount of substrate remains in the system, does a direct reduction to the 2*e* species presumably occur. The reoxidation of 2*e* species by O_2 was very rapid and could not be monitored by a usual scanning spectrophotometer. A redox cycle between the 2*e* species and the oxidized form is suggested to play a catalytic role for the photo-oxidation of the isopropyl alcohol. The 2*e* species will probably be a diprotonated form ($[H_2W_{10}O_{32}]^{4-}$).[5,6] The schematic diagram is depicted in Fig. 5. Incidentally, the redox cycle is also different from the case of the Keggin-type heteropolyacid. We have examined spectrophotometrically analogous experiments using $H_3[PW_{12}O_{40}]$ in acidic aqueous solution containing isopropyl alcohol. The spectral bands of electrochemically reduced 1*e* and 2*e* species of $[PW_{12}O_{40}]^{3-}$ have been previously reported by Pope *et al.*:[10] 490 (ε 1200), 750 (ε 2000) and 1250 nm (ε 1600) for the 1*e* species; and 490 (ε 3300), 654 (ε 4400) and 1110 nm (ε 3000) for the 2*e* species. It has been shown that there are two processes of reduced-species formation under N_2: the relatively rapid step due to 1*e* species formation and the following slow step due to 2*e*-species formation. Exposure to O_2 gave spectra comprising a rapid decrease in the 2*e* species followed by a gradual decrease in the 1*e* species. This suggests that the 1*e* species of $[PW_{12}O_{40}]^{3-}$ plays an important role in the photo-oxidation of isopropyl alcohol under O_2.

In the photo-oxidation by decatungstate, prolonged irradiation (more than 35 h) gave pale yellow

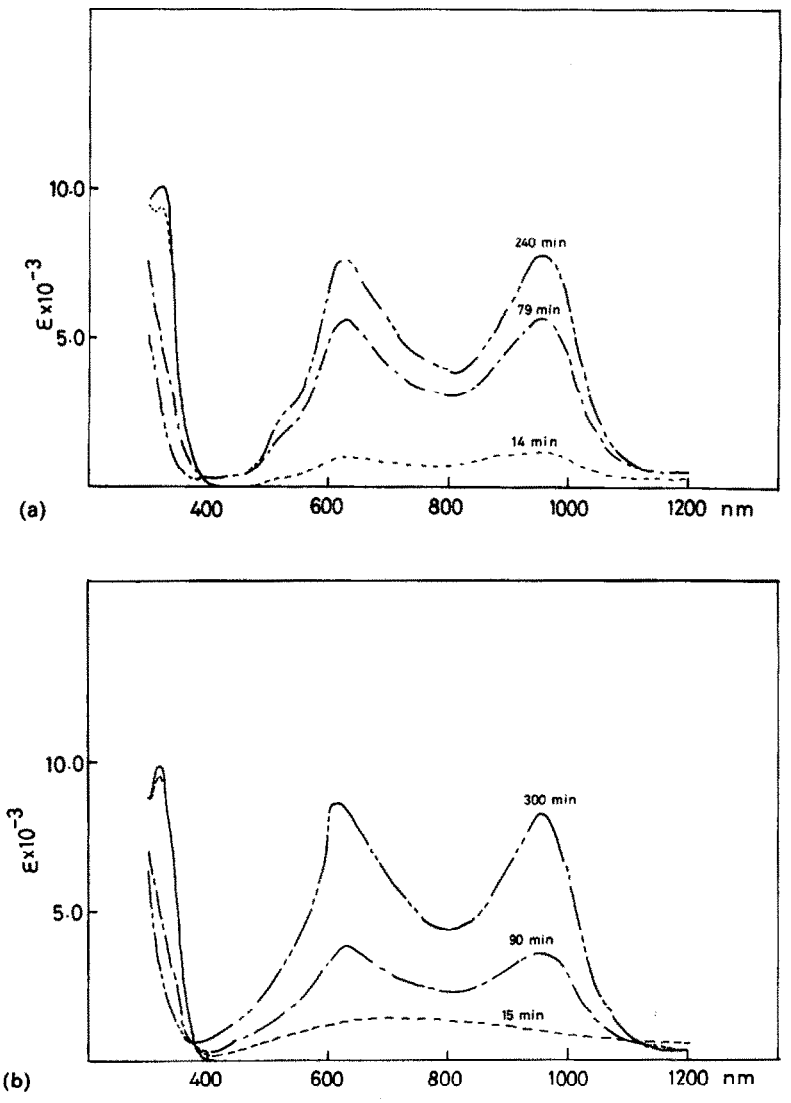

Fig. 4. Absorption spectra of photoreduced decatungstate under N_2 in acetonitrile solutions with (a) and without (b) isopropyl alcohol. Conditions are 4.37×10^{-5} (a) and 4.11×10^{-5} (b) mol dm^{-3} of $(Bu_4N)_4[W_{10}O_{32}]$ and 3.08×10^{-3} mol dm^{-3} (a) of isopropyl alcohol. The figures on the curves are times after irradiation. Full lines show the spectra before irradiation.

precipitates and the system became heterogeneous, even if enough O_2 was present. The IR and electronic absorption spectra showed the presence of the $[W_{10}O_{32}]$ structure and of the carbonyl group. The elemental analysis (found: C, 21.3; H, 3.5; N, 1.8%) indicated that some tetrabutylammonium counter-ions were converted to tributyl- and dibutylammoniums. Such precipitates were also obtained by irradiation both in the absence of any substrates and in the presence of other substrates such as cyclohexanol and ethyl lactate. Furthermore, an aldehyde was detected in the filtrate. These facts suggest that the formula of the precipitate obtained is $(Bu_4N)_2(Bu_3NH)(Bu_2NH_2)[W_{10}O_{32}] \cdot PrCHO$ (calc. C, 20.9; H, 4.0; N, 1.7%)

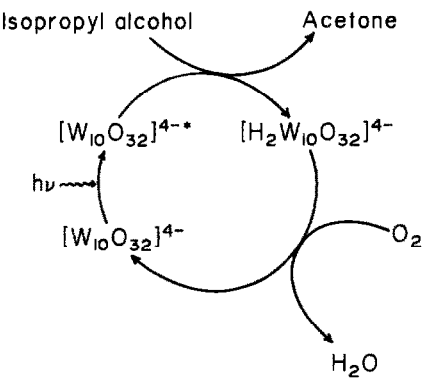

Fig. 5. Schematic diagram of photo-oxidation of isopropyl alcohol by decatungstate.

or $(Bu_3NH)_2(Bu_2NH_2)_2[W_{10}O_{32}]\cdot 5PrCHO$ (calc. C, 21.5; H, 4.1; N, 1.7%). This shows that decatungstate also promotes the photo-oxidation of the tetrabutylammonium counter-ion when the concentration of substrate is lowered. This leads necessarily to a decrease in the photocatalysis for isopropyl alcohol, because of interrupting the homogeneity. The photo-oxidation of tetrabutylammonium by decatungstate in acetonitrile has recently been investigated by Yamase *et al.* and a mechanism for the production of Bu_3N, Bu_2NH and PrCHO has been proposed.[5] The composition of the pale yellow precipitates obtained supports such a mechanism. Yamase *et al.*[5] have also revealed the production of 1*e* species by electron transfer from Bu_4N^+ to $[W_{10}O_{32}]^{4-}$ within the lifetime of the photoflash ($t_{1/2} = 50\,\mu s$), the protonation of $[W_{10}O_{32}]^{5-}$ and its disproportionation to diprotonated species of the 2*e* form $[H_2W_{10}O_{32}]^{4-}$. They have applied the same mechanism to the oxidation of BuOH in acetonitrile by decatungstate, which is based on the absorption kinetics at 780 and 630 nm for the flash photolysis. However, since the observation of 1*e* oxidation by decatungstate should be dependent upon the composition of the acetonitrile–alcohol system and the sort of alcohol, we prefer rather to adopt a different mechanism for decatungstate—namely direct 2*e* oxidation for the isopropyl alcohol and 1*e* oxidation for the ammonium.

STABILITY CONSTANTS AND PROTONATION CONSTANTS OF TETRACYANO BIS(PHENANTHROLINE) MOLYBDATE(IV) AND TETRACYANO BIS(BIPYRIDYL) MOLYBDATE(IV)

S. I. ALI* and ZAKIR MURTAZA

Department of Chemistry, Jamia Millia Islamia, New Delhi 110025, India

(*Received* 13 *September* 1985; *accepted* 18 *November* 1985)

Abstract—1,10-Phenanthroline (phen) and 2,2′-bipyridyl (bipy) form 2:1 complexes with the dioxotetracyanomolybdate(IV) ion by substitution reactions. The stepwise stability constants and the protonation constants of the substituted products $Mo(CN)_4(phen)_2$ and $Mo(CN)_4(bipy)_2$ have been calculated using spectrophotometric and potentiometric methods. Two successive protonation steps have been found for these systems. Concentration protonation constants have been determined at different ionic strengths and the thermodynamic protonation constants were evaluated by extrapolation to infinite dilution. The dependence of log K_n^p (where $n = 1.5$ or 3.0) on ionic strength is given by the equation $\log K_n^p = \log {}^TK_n^p + B\sqrt{I}/(1+\sqrt{I})$. Thermodynamic parameters for the complex formation have been calculated and the results have been discussed. The protonated products have been isolated and analysed.

Numerous studies have been made on the dioxotetracyano complexes of rhenium(V),[1–5] molybdenum(IV)[6–11] and tungsten(IV),[8–10] regarding their structure and reactivity. Previously, the reported hydrolysis constants[12] calculated for tungsten(IV) and molybdenum(IV) complexes were based on limited data and were not suitable for quantitative treatment, but the mixed tetracyano complexes need more knowledge of proton transfer equilibria in solution. Extensive investigations have been carried out in order to assess quantitatively the importance of various proton transfer equilibria governing the behaviour of these mixed tetracyano complexes. The protonation constants have been recalculated[13] for these complexes and the $[MO_2(CN)_4]^{4-}$ ion (where M = Mo or W) has been treated as a Bronstead base. The corresponding base strength has been expressed conveniently in terms of the successive protonation constants:

$$[MO_2(CN)_4]^{4-} \underset{K_1^p}{\overset{H^+}{\rightleftharpoons}} [MO(OH)(CN)_4]^{3-} \underset{K_2^p}{\overset{H^+}{\rightleftharpoons}} [M(OH)_2(CN)_4]^{2-}.$$

In this study the complexes $Mo(CN)_4(phen)_2$ (phen = 1,10-phenanthroline) and $Mo(CN)_4(bipy)_2$ (bipy = 2,2′-bipyridyl) were investigated by physical methods. The stepwise stability constants (K_1 and K_2) for the reaction of dioxotetracyanomolybdate(IV) with AA ligands (where AA = phen or bipy), the concentration protonation constants (K_n^p) and the thermodynamic protonation constants ($^TK_n^p$) have been calculated. The thermodynamic parameters $\Delta G^\ominus$, $\Delta H^\ominus$ and $\Delta S^\ominus$ have also been evaluated. The protonated products were isolated and their composition determined by analysis.

EXPERIMENTAL

Materials

$K_4MoO_2(CN)_4 \cdot 6H_2O$ was prepared by the method of Samotus *et al.*[14] and its solution strength was determined potentiometrically against $K_3Fe(CN)_6$.[15] The ligands phen, bipy and potassium chloride were of A.R. grade.

Apparatus

The absorbance was recorded on the Spectromom 361 using quartz cells. The pH of the solutions was

* Author to whom correspondence should be addressed.

recorded on Toshniwal's digital pH meter (Cat. CL 46) using a combined glass electrode (Toshniwal's Moeller).

Preparation of compounds

The stoichiometry of the substitution reactions of dioxotetracyanomolybdate(IV) with AA ligands was determined spectrophotometrically by the method of continuous variation and the mole ratio method.

Tetracyano bis(phenanthroline) molybdate(IV) was prepared in solution by mixing a 0.01 M $K_4MoO_2(CN)_4 \cdot 6H_2O$ solution with a 0.02 M phen solution. The colour of the solution changed from blue to green and the mixture was kept for 30 min for completion of the reaction. Tetracyano bis(bipyridyl) molybdate(IV) was prepared in solution similarly.

For the extraction of the protonated product, a solution of HCl was added to a $Mo(CN)_4(AA)_2$ solution so that the pH is lowered to 4 or below, the brown precipitates were extracted by filtration and washed with water and alcohol, and then dried in a desiccator over calcium chloride. The dried complexes were analysed by standard gravimetric methods.[16] Water of crystallization was determined by heating the sample at 110°C. From the analysis the following results were obtained.

Found: Mo, 17.4; N, 13.6; C, 53.2; H_2O, 4.2%. Calc. for $Mo(OH)_3(CN)(phen)_2(H_2O)_2$: Mo, 17.5; N, 12.9; C, 54.8; H_2O, 3.3%. Found: Mo, 17.6; N, 13.7; C, 40.9; H_2O, 4.9%. Calc. for $Mo(OH)_3(CN)(bipy)_2(H_2O)_2$: Mo, 17.8; N, 13.0; C, 46.7; H_2O, 4.3%.

Determination of protonation constants

The protonation constants were determined by the method of Bjerrum.[17] Dilute aqueous solutions of known concentrations of tetracyano bis(phenanthroline) or (bipyridyl) molybdate(IV) were titrated with standard HCl and the pH values recorded. The ionic strength was maintained at levels of 0.0785, 0.125, 0.250 and 0.4 M for the phen system and at 0.039, 0.075, 0.15 and 0.25 M for the bipy system by adding the right amounts of KCl. The pH changes from 11 to 1.5. The glass electrode was standardized with the help of buffer solutions of pH 4.01 and 9.2. All the measurements were carried out at 30°C. Volume changes occuring during the titration were taken into account in calculating the protonation constants. The titration curves show sharp changes in pH of the solution at 1.5 and 3.0 mol of acid per mol of $Mo(CN)_4(phen)_2$ or $Mo(CN)_4(bipy)_2$.

RESULTS AND DISCUSSION

The stepwise stability constants were determined[18] by using spectroscopic techniques monitoring changes at 450 nm for both the systems. The stepwise equilibrium reactions for the 1:2 complex of $K_4MoO_2(CN)_4$ and AA ligands are represented by the following equations.

$$[MoO_2(CN)_4]^{4-} + 2H_2O \rightleftharpoons [Mo(OH)_4(CN)_4]^{4-},$$

$$[Mo(OH)_4(CN)_4]^{4-} + AA \overset{K_1}{\rightleftharpoons} [Mo(OH)_2(CN)_4(AA)]^{2-} + 2OH^-,$$

$$[Mo(OH)_2(CN)_4(AA)]^{2-} + AA \overset{K_2}{\rightleftharpoons} Mo(CN)_4(AA)_2 + 2OH^-.$$

The concentration protonation constants $K^p_{1.5}$ and K^p_3 of the complex $Mo(CN)_4(AA)_2$ were calculated[18] from the equations:

$$K^p_{1.5} = \left(\frac{\bar{n}-0.5}{1.5-\bar{n}}\right)\frac{1}{[H^+]} \quad \text{for} \quad 0 < \bar{n} < 1.5,$$

$$K^p_3 = \left(\frac{\bar{n}-2}{3-\bar{n}}\right)\frac{1}{[H^+]} \quad \text{for} \quad 3 > \bar{n} > 1.5,$$

where $\bar{n}$ = ratio of the concentration of proton bound, H_b, to complex C:

$$\bar{n} = \frac{[H_b]}{C} = \frac{[HCl]+[OH^-]-[H^+]}{C},$$

where C = concentration of the protonated complex and [HCl] = concentration of acid added at any stage of titration. The equilibrium concentrations of H^+ and OH^- ions were obtained from the pH at any stage of titration. The thermodynamic protonation constants ${}^TK^p_{1.5}$ and ${}^TK^p_3$ were calculated by using equation $\log K^p_n = \log {}^TK^p_n + B\sqrt{I}/(1+\sqrt{I})$. On plotting $\log K^p_n$ against $\sqrt{I}/(1+\sqrt{I})$ a straight line was obtained and values of B and $\log {}^TK^p_n$ were obtained from the slope and intercept, respectively.

The values of the changes in free energy ($\Delta G^\ominus$), enthalpy ($\Delta H^\ominus$) and entropy ($\Delta S^\ominus$) accompanying the complex formation have been calculated using the standard equations[19] at 31°C. The enthalpy change ($\Delta H^\ominus$) has been calculated by carrying out experiments at different temperatures (31–40°C). On plotting $\log \beta$ against $1/T$ a straight line was obtained. $\Delta H^\ominus$ was obtained from the slope of the curve. The values of these parameters are given in Table 1.

The AA ligands react with $[Mo(OH)_4(CN)_4]^{4-}$ to form the complexes $[Mo(OH)_2(CN)_4AA]^{2-}$ and $Mo(CN)_4(AA)_2$ with formation constants K_1 and

Table 1. Successive stability constants and thermodynamic parameters at 31°C and $I = 0.04$ M[a]

Complex	Temperature (°C)	log K_1	Mean log K_2	Mean log B	$\Delta G^\ominus$	$\Delta H^\ominus$	$\Delta S^\ominus \times 10^2$
$Mo(CN)_4(phen)_2$	31	3.56	4.00±0.01	7.56±0.05	−44.1±0.2	98	46.7±0.1
	35	3.57	4.13±0.20	7.70±0.13

	35	3.50	3.70±0.16	7.20±0.12			
	40	3.53	3.92±0.10	7.45±0.21			

[a] $\Delta G^\ominus$, $\Delta H^\ominus$ and $\Delta S^\ominus$ are in kJ mol^{-1} K^{-1}.

K_2, respectively. Two species have been assumed in solution so the absorbance of the solution could be expressed as:

$$A = e_o[Mo(OH)_4(OH)_4^{4-}] + e_1[Mo(OH)_2(CN)_4AA^{2-}] + e_2[Mo(CN)_4(AA)_2],$$

where brackets represent the equilibrium concentrations and the e values are the molar absorptivities. The method of continuous variation and the mole ratio method give a 1:2 stoichiometry between dioxotetracyanomolybdate(IV) and the AA ligands. The reaction can be represented by the following equation:

$$[Mo(OH)_4(CN)_4]^{4-} + 2AA \rightarrow Mo(AA)_2(CN)_4 + 4OH^-.$$

The stepwise stability constants of the above reaction have been calculated and are given in Table 1. The small difference between log K_1 and log K_2 suggests the simultaneous formation of both 1:1 and 1:2 complexes in solution. The stability of the complex depends on the basicity of the ligand.[20] The lower stability of the bipy complex than that of phen may be attributed to the less basic character of bipy.

The typical pH titration curve can readily be interpreted in terms of the formation of $Mo(CN)_3(AA)_2OH$, $Mo(CN)_2(AA)_2(OH)_2$ and $Mo(CN)(AA)_2(OH)_3$, which can be represented by the following equation:

$$Mo(CN)_4(AA)_2 \underset{K_1^p}{\overset{H^+}{\rightleftharpoons}} Mo(CN)_3(AA)_2OH \underset{K_2^p}{\overset{H^+}{\rightleftharpoons}} Mo(CN)_2(AA)_2(OH)_2 \underset{K_3^p}{\overset{H^+}{\rightleftharpoons}} Mo(CN)(AA)_2(OH)_3. \quad (1)$$

After adding 1, 2 or 3 equivalents of acid per mol of the complex only two widely separated end points are observed, one at 1.5 (pH range 7–9) and the other at 3.0 (pH range 3–4). The value of $n = 1.5$ reveals the formation of a 1:1 as well as a 1:2 complex, and $n = 3.0$ shows the formation of a 1:3 complex. The above results show the replacement of three cyanide ions from $Mo(CN)_4(AA)_2$. Protonation curves ($\bar{n}$ vs pH) at various ionic strengths are plotted. The concentration protonation constants calculated from experimental data are given in Table 2. The protonation constants $K_{1.5}^p$ and K_3^p were calculated for a suitable range of pH and $\bar{n}$ values. A straight line was obtained on plotting log K_3^p vs $\sqrt{I}/(1+\sqrt{I})$. The intercept is equal to log K_3^p and the slope is equal to B. The dependence of K_3^p on the ionic strength can be expressed by the equation $\log K_n^p = \log {}^TK_n^p + B\sqrt{I}/(1+\sqrt{I})$, where $B = -1.0$ for the $K_{1.5}$ plot and -0.5 for the K_3^p plot for both the systems.

The values of the thermodynamic protonation constants are given in Table 3. The values of the protonation constants decrease with increasing ionic strength. This is in accordance with the earlier conclusions since in media of higher ionic strength the metal ions are shielded from the ligands by the other ions present.[21] The $\Delta G^\ominus$ values were found to be negative in the above case, showing the substitution reactions to be spontaneous processes. $\Delta G^\ominus$ values are higher for the phen complex than for the bipy complex. The $\Delta S^\ominus$ values are all positive, indicating that the change in entropy favours complex formation. The positive values of $\Delta H^\ominus$ predict the endothermic nature of the reaction. The plots of log β against T^{-1} in all the systems are linear and indicate that the values of $\Delta C_p^\ominus$ are equal to zero.[22] The colour of the $Mo(CN)_4(AA)_2$ solution changes from green to brown on acidification, and precipitates are obtained at pH < 4. The change of pH to <2 is very slow, which may be attributed to

Table 2. Comparison of the experimentally determined protonation constants (log $K^{p}_{1.5}$ and log K^{p}_{3}) at various ionic strengths (I) for $Mo(CN)_4(phen)_2$ and $Mo(CN)_4(bipy)_2$ at 30°C

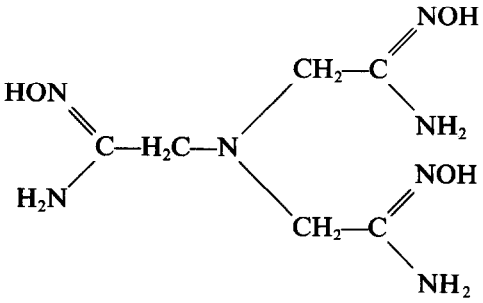
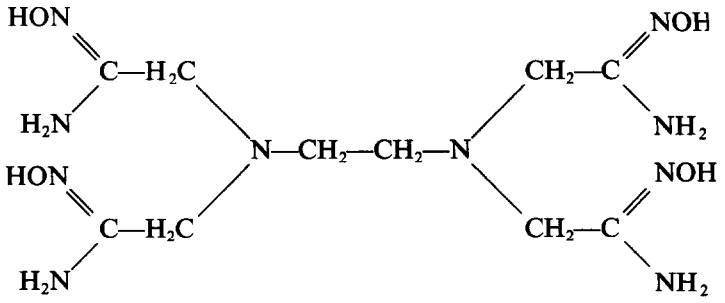
Abstract—The spectrophotometric behaviour of a number of amidoxime–metal complexes is studied, mainly those formed by Cu(II). The influence of several variables (pH, time etc . . .) on complex formation is determined, together with the performance of Beer's law and the precision according to Ringbom. For the Cu(II) complexes of several polyamidoximes the conditional stability constants are calculated and refined by means of the MINISPEF program. These constants, after correction using the appropriate side-reaction coefficients, are used to draw the corresponding distribution diagrams.

In previous papers, the physico-chemical properties of several amidoximes, including their acid–base dissociation equilibria, were studied.[1–5] Some of these amidoximes have been proposed as analytical reagents,[6–9] on the basis either of their ability to form metal complexes or of their redox properties. The physico-chemical properties of the metal complexes of the amidoximes, however, have scarcely been studied.



As a part of a research project directed towards the study of the analytical behaviour of the amidoxime group, some spectrophotometric properties were determined for the complexes formed in solution between several metal ions [Cu(II), Co(II), Ni(II), Fe(II), Fe(III), Pd(II), Mo(VI) and U(VI)] and the following polyamidoximes: 3,3′-imino-, 3,3′-oxy- and 3,3′-thiodipropioamidoxime (IDPA, ODPA and TDPA, respectively), α,α′-azobis(isobutyroamidoxime) (AIBA), nitrilotriacetoamidoxime (NTAA) and ethylenediaminotetraacetoamidoxime (EDTAA):



X = NH (IDPA)
X = O (ODPA)
X = S (TDPA)

NTAA

EDTAA

Although the tests for most of metal ions with these amidoximes do not show very low limits of detection and, as a consequence, these reagents are not, in principle, suitable for metal-ion determination at trace levels, the spectrophotometric study was performed in order to explore all possibilities and to correlate its results with data resulting from previous thermometric experiments. Among the several metal complexes reviewed, those of the Cu(II) ion, which give well-defined absorption bands with all the selected amidoximes, were selected for a more thorough study, which included the determination of their pH and time stability, and their stoichiometry, as well as the evaluation of their formation constants.

EXPERIMENTAL

Apparatus

A double-beam UV–VIS spectrophotometer, Beckman 5260, with 1.0-cm quartz cells was used for measurements.

A microcomputer, HP-85, with 32 kilobytes of RAM memory was used for computation of the results.

Chemicals and solutions

Amidoximes, obtained as described[2,10] and purified, were used to prepare stock 1% aqueous solutions. Test solutions were prepared from the stock solutions by appropriate dilution, as needed.

All metal-ion solutions were prepared from metal salts of analytical-reagent grade, at a concentration of 1000 ppm. These solutions were standardized by the usual recommended methods.[11]

Other chemicals (e.g. for buffer preparation) were also analytical-reagent grade. The buffer solution used was an universal buffer of a constant 0.1 mol l^{-1} ionic strength.[12]

Procedure

Absorption spectra. 1 cm^3 of the metal-ion solution and 1 cm^3 of the buffer of the appropriate pH were introduced into a 10-cm^3 volumetric flask, the amidoxime solution was then added in excess in order to ensure quantitative complex formation, and then water was added up to the mark. The spectra of these solutions were recorded from 300 to 900 nm against a reference blank containing the same metal ion and buffer components. Spectra of the pure amidoximes at the same concentration and in the same buffer were also recorded (against the buffer solution as a blank). Wavelengths of maximum absorption and molar absorptivity for the complexes at these wavelengths were measured in all cases where their absorption bands did not overlap with those of the amidoximes. For each metal ion and amidoxime, optimum pH conditions to record the spectra were found in a previous qualitative study performed by the usual procedures.[10]

The pH and time dependence of the spectra of the Cu(II) complexes, the Beer's law range of linearity and the Ringbom's maximum-precision range were determined according to the standard procedures.

Stoichiometry. The stoichiometry of the Cu(II) complexes in aqueous solution was determined by the Yoe–Jones method in the presence of a selected buffer.[13]

Conditional formation constants. Approximate values of the conditional stability constants of the Cu(II)–amidoxime complexes were evaluated directly from the absorbance and concentration data obtained in the experiments done for the stoichiometry determination. These constants were then refined by means of the MINISPEF program,[14] as described later.

RESULTS AND DISCUSSION

Absorption spectra

Table 1 gives the results of the qualitative tests yielding coloured solutions, given by each of the

selected amidoximes with various metal ions, including the reaction medium, observed colour, and limit of detection (expressed as the dilution limit). The absorption spectra of each one of the coloured solutions, supposed to contain a soluble metal ion–amidoxime complex, together with the spectrum of the respective amidoxime, are shown in Figs 1–6.

All Cu(II)–amidoxime complexes gave well-defined absorption bands. The wavelength of their maxima clearly showed that the heteroatom in the amidoximes enters into the co-ordination sphere of the Cu(II) ion: for the ODPA complex (O, heteroatom), λ_{max} = 740 nm; for the IDPA and AIBA complexes (N, heteroatom), λ_{max} = 610 and 605 nm, respectively; for the TDPA complex (S, heteroatom), λ_{max} = 500 nm. The polyaminopolyamidoximes ligands, NTAA and EDTAA, gave, respectively, λ_{max} = 710 nm (absorbance grows towards the 850–900 nm end of the recorded spectrum) and λ_{max} = 690 nm.

Ni(II) complexes showed well-defined absorption bands with ligands containing an O heteroatom (with ODPA, λ_{max} = 645 nm, shoulder at 750 nm) or an S heteroatom (with TDPA, λ_{max} = 615 nm, shoulder at 770 nm), but not with those ligands containing an N heteroatom. The complexes with NTAA and EDTAA showed maxima at about 380 and 580 nm, both with a rather low absorptivity.

In the spectra of the Co(II) complexes with NTAA an absorption band was observed at 520 nm; for the Co(II) complex of EDTAA the band shifted to 505 nm. The spectra of the AIBA complex showed two shoulders, at about 500 and 650 nm, but not any well-defined band.

Only the ligands NTAA, EDTAA and TDPA yielded complexes with Fe(III) which showed well-defined absorption bands at 425, 435 and 575 nm,

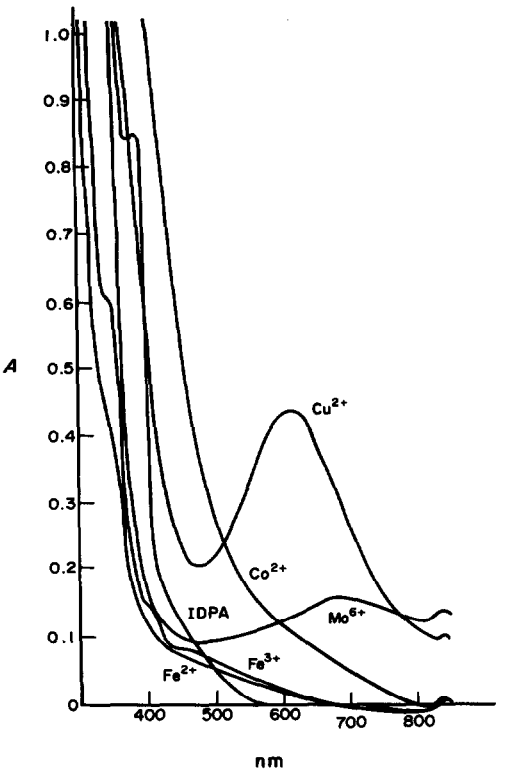

Fig. 1. IDPA–metal complexes

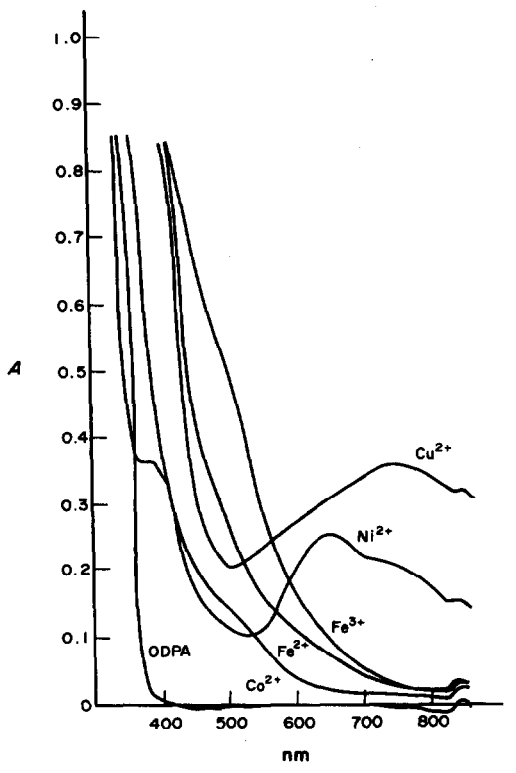

Fig. 2. ODPA–metal complexes

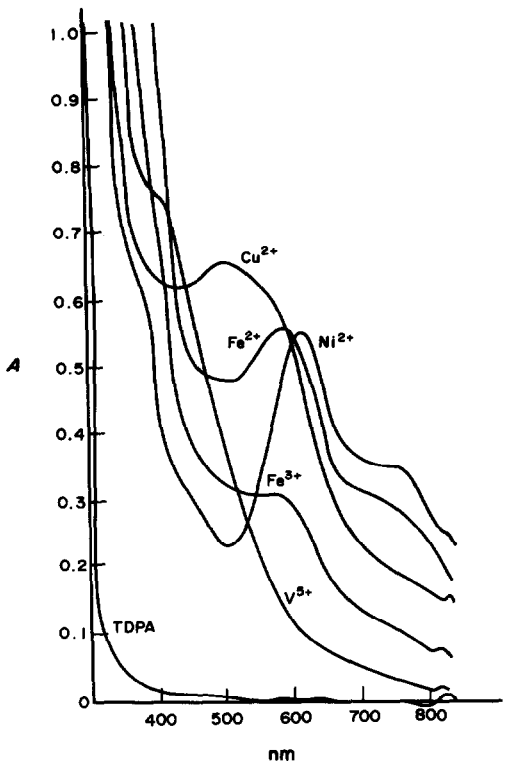

Fig. 3. TDPA–metal complexes.

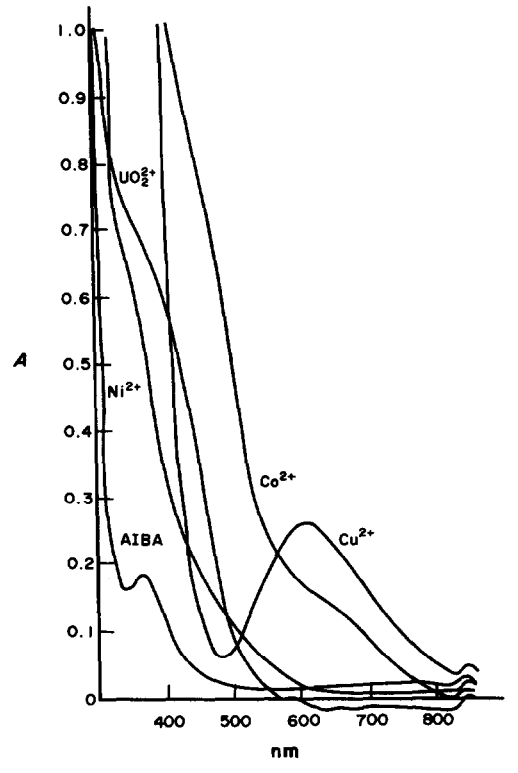

Fig. 4. AIBA–metal complexes.

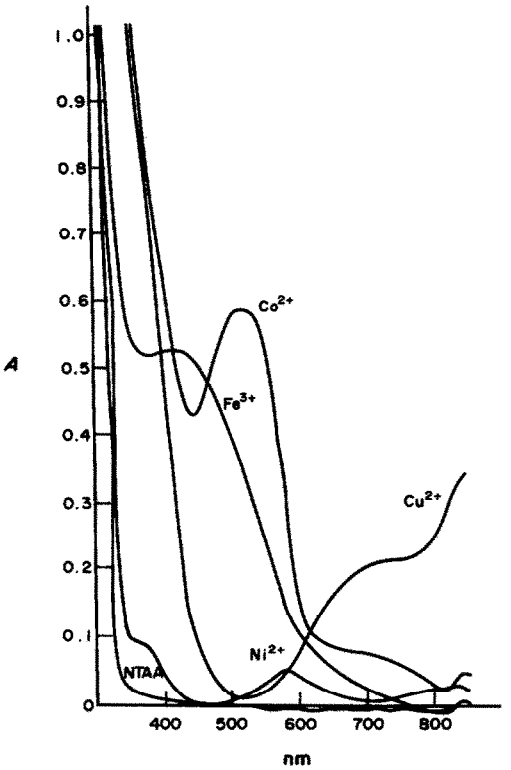

Fig. 5. NTAA–metal complexes.

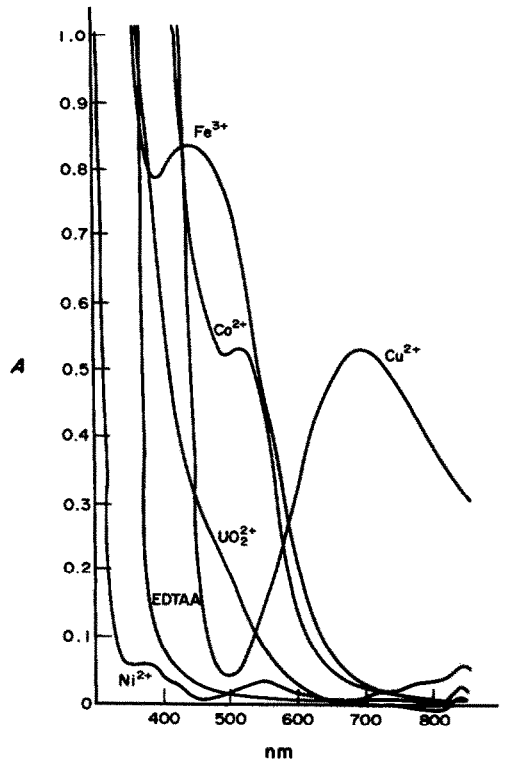

Fig. 6. EDTAA–metal complexes.

respectively. The absorption band of the Fe(III)–TDPA complex was a charge-transfer band which clearly results from a strong S–Fe interaction. For the Fe(II)–TDPA complex, this band appears at 585 nm.

The Mo(VI)–IDPA complex showed a band with $\lambda_{max} = 680$ nm.

All other complexes studied yielded spectra which strongly overlap with those of the respective amidoxime.

Cu(II) *complexes*

The formation equilibria of the Cu(II) complexes of amidoximes were quantitatively studied after the data in Table 2 were collected. Absorbance of each Cu(II) complex is pH-independent within the pH ranges given in Table 2. In these pH ranges, Beer's law is obeyed within a large Cu(II) ion concentration range, as shown by the empirical linear equation given in Table 2, together with their correlation coefficients. As is shown by these equations, none of the amixodimes studied can be adopted as a reagent for a new absorptiometric method for Cu(II) ion determination, since the molar absorptivity of the Cu(II) complexes formed is too low for a good limit of detection to be reached (Ringbom intervals of maximum precision of these potential methods, also given in Table 2, would have lower limits of about 40–50 ppm in the optimum cases).

The stoichiometry of the Cu(II)–amidoxime complexes was determined by use of the well-known Yoe–Jones method.[13] The results obtained yield a stoichiometric Cu(II) : amidoxime ratio equal to 1 : 1 for the complexes of the ligands which contain N heteroatoms, IDPA, AIBA, NTAA and EDTAA, and to 1 : 2 for the complexes of the ligands containing O or S heteroatoms, ODPA and TDPA.

Formation constants of the Cu(II) *complexes*

From the experimental data [absorbance, Cu(II) ion concentration, and ligand concentration] obtained in the course of the study of the stoichiometry, approximate values of the conditional stability constants were obtained as shown in Table 3(A) for the Cu(II)–IDPA complex. Results for log β_{11} for the 1 : 1 complexes are as follows: IDPA complex (at pH 4.1, buffer components : acetic acid and NaOH), 4.42; AIBA complex (at pH 4.1, buffer components : acetic acid and NaOH), 5.40; NTAA complex (at pH 5.8, buffer components : KH_2PO_4 and Na_2HPO_4), 4.87; EDTAA complex (at pH 3.9, buffer components : acetic acid and NaOH), 5.07; and for log β_{11} and log β_{12}, for the cases where the 1 : 2 complex is the dominant complex formed, are

Table 2. Absorptiometric behaviour of the Cu(II)–amidoxime complexes

Compound	pH range	Beer's law equation C (mol l^{-1})	r	Concentration range (ppm)	Linear Ringbom range (ppm)
IDPA	3.9–5.0	$A = 1.61 \times 10^{-3}C - 5.99 \times 10^{-3}$	1.0000	0–1000	100–800
ODPA	—	$A = 3.15 \times 10^{-3}C - 9.20 \times 10^{-4}$	0.9999	0–500	50–220
AIBA	4.2–5.6	$A = 2.40 \times 10^{-3}C - 9.99 \times 10^{-3}$	0.9999	0–500	40–300
NTAA	3.5–9.2	$A = 1.53 \times 10^{-3}C - 5.63 \times 10^{-3}$	0.9995	0–700	250–500
EDTAA	3.0–5.8	$A = 2.40 \times 10^{-3}C - 2.71 \times 10^{-3}$	1.0000	0–500	150–500

as follows: ODPA complexes [pH 6.5, water solution ($I = 0.1$ mol l^{-1} KNO_3)], 5.40 and 8.00 respectively; TDPA complexes [pH 6.5, water solution ($I = 0.1$ mol l^{-1} KNO_3)], 5.40 and 8.00 respectively.

These values of the constants were then refined by means of the computer program MINISPEF[14] which minimizes the sum of the residuals:

$$U(\log \beta_i, \varepsilon_i, \varepsilon_M, \varepsilon_L) = \sum_i (A_{\text{meas},i} - A_{\text{calc},i})^2 = \sum_i (A_{\text{meas},i} - \varepsilon_M[M] - \varepsilon_L[L] - \sum_j \varepsilon_j \beta_j [M]^{q_j} [L]^{p_j} [H^+]^{r_j})^2.$$

Values of ε_{11}, when only the 1 : 1 complex was formed, and of ε_{12} for the 1 : 2 complexes are experimentally determined by measuring the absorbance of solutions which contained a very large excess of amidoxime. Initial values of ε_{12} when both 1 : 1 and 1 : 2 complexes were simultaneously formed were arbitrarily taken as equal to ε_{12}, since the computer program MINISPEF has the advantage of not needing accurate values of ε_i and $\log \beta_i$ as starting parameters. In all cases, initial values for ε_M and ε_L were considered to be zero, since both metal and ligand are either non-absorbing or very slightly absorbing species in the wavelength range used for measurement. Table 3(B) shows the results obtained from an experiment in the study of the Cu(II)–IDPA complex.

Table 4 gives the conditional constants of the Cu(II) complexes of all the selected amidoximes, together with the molar absorptivities of all the implied species, as refined by use of MINISPEF program. The final values of the minimization function, U, and the standard deviations of the results, S, are also included in Table 4.

Once the conditional formation constants were known, they were corrected using the side-reaction coefficients defined by Ringbom[15] to account for the side-reaction effects produced mainly by the constituents of the buffer systems and by the hydroxide ions. To carry out the correction, the side-reac-

[a] A = log of the refined conditional stability constants by MINISPEF. B = log of the stability constants corrected by means of the side-reaction coefficients defined by Ringbom.

tion coefficients were calculated from the stability constants found in the literature[16] (for hydroxo-complex formation and for complexation with the buffer constituents) or from values previously determined[11] (for protonation of the ligands). Table 4 gives the corrected formation constants of the Cu(II)–amidoxime complexes.

Finally, from these formation constants, the protonation constants of the ligands and all other pertinent constants, the distribution diagrams for all the systems studied were calculated by use of the program COMPLEX, taking into account all possible species present. The resulting distribution diagrams are shown in Figs 7–12.

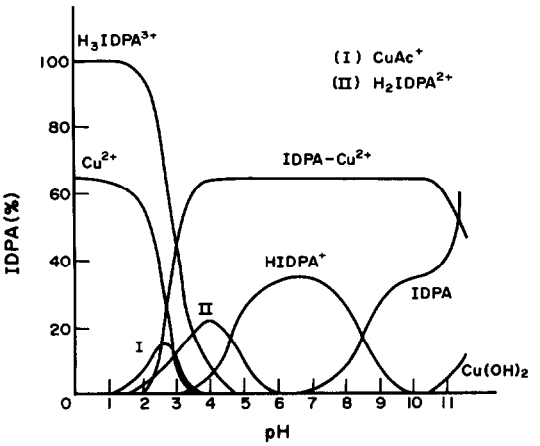

Fig. 7. Distribution diagram corresponding to the Cu–IDPA system. Total concentration ratio [Cu(II)/IDPA] = 0.65. Total acetate (HAc + Ac$^-$) in solution = 7.5×10^{-2} mol l^{-1}.

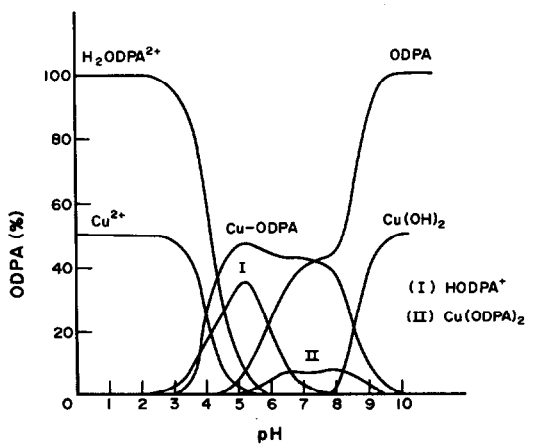

Fig. 8. Distribution diagram corresponding to the Cu(II)–ODPA system. Total concentration ratio [Cu(II)/ODPA] = 0.48.

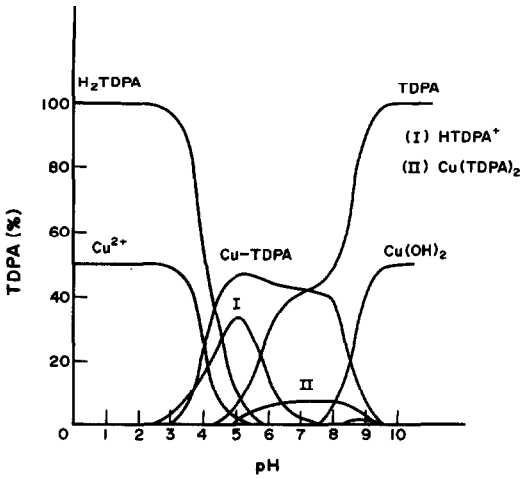

Fig. 9. Distribution diagram corresponding to the Cu(II)–TDPA system. Total concentration ratio [Cu(II)/TDPA] = 0.48.

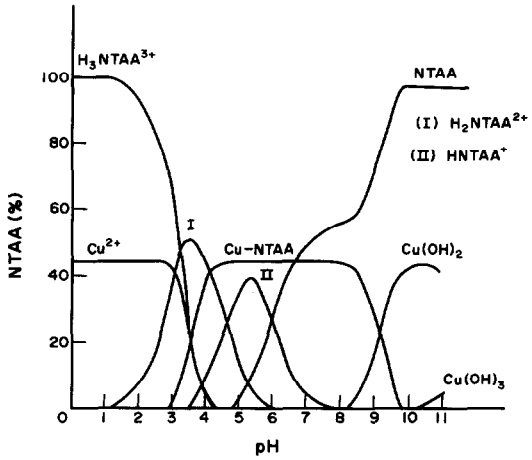

Fig. 11. Distribution diagram corresponding to the Cu(II)–NTAA system. Total concentration ratio [Cu(II)/NTAA] = 0.45.

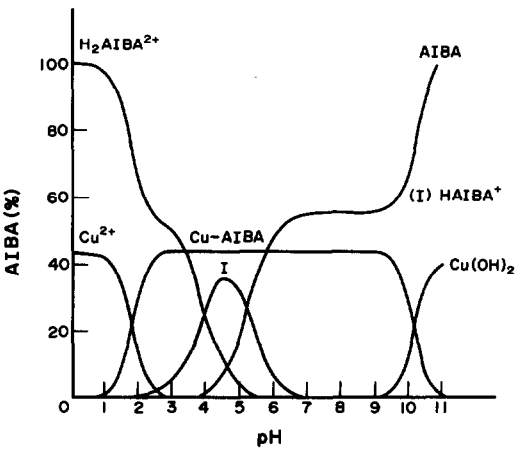

Fig. 10. Distribution diagram corresponding to the Cu(II)–AIBA system. Total concentration ratio [Cu (II)–AIBA] = 0.44. Total acetate ($HAc + Ac^-$) in solution = 3.9×10^{-2} mol l^{-1}.

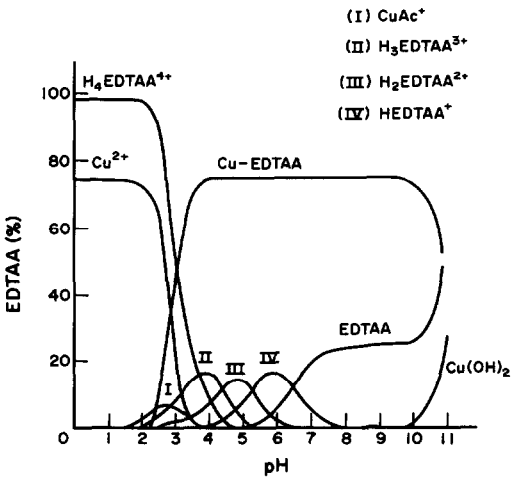

Fig. 12. Distribution diagram corresponding to the Cu(II)–EDTAA system. Total concentration ratio [Cu(II)/EDTAA] = 0.74. Total acetate ($HAc + Ac^-$) in solution = 7.5×10^{-2} mol l^{-1}.

SYNTHESES, CHARACTERIZATION AND ADDUCT FORMATION OF CHLORIDE–2,4,6-TRIMETHYLPHENOXIDE DERIVATIVES OF TITANIUM AND ZIRCONIUM

A. SHAH, A. SINGH and R. C. MEHROTRA*

Chemical Laboratories, University of Rajasthan, Jaipur, India

(*Received* 26 *July* 1985; *accepted after revision* 9 *December* 1985)

Abstract—Chloride phenoxides of type $MCl_{4-n}(OAr')_n$ (where M = Ti or Zr; n = 1, 2 or 3) have been prepared by the interaction of the metal chlorides with 2,4,6-trimethylphenol (Ar'OH). The mixed chloride phenoxides showed considerable reactivity as Lewis acids towards bases, resulting in addition complexes of general formula $MCl_{4-n}(OAr')_nL_2$ (where L = primary or tertiary aromatic amines, or oxygen- or phosphorus-containing bases). These complexes have been characterized by IR and the ^1H NMR studies, conductivity measurements, molecular weight measurements (in the case of soluble products), thermogravimetric and mass spectral studies.

During the last few years, sterically crowded phenoxides have received considerable attention and have exhibited interesting features such as: (i) intramolecular C—H bond activation via metallation of the *t*-Bu group of the phenoxides,[1] (ii) isolation of hydrocarbon-soluble compounds in low coordination states,[2] (iii) accessibility of hydrocarbon-soluble mononuclear complexes,[3] and (iv) possible η^5-phenolate bonding.[4–6]

The interaction of titanium tetrachloride with simple phenol (1:4 equivalents) resulted in the tetrakis derivatives.[7] Similar tetrakis derivatives have also been obtained in the reaction of perfluorophenols with $TiCl_4$.[8] X-ray crystallography has shown the bis derivative of titanium with simple phenol to be dimeric phenoxy-bridged with titanium penta-coordinated in the form of a distorted trigonal bipyramid.[9] Following their observation[4] of the formation of an η^5-bonded phenoxide ion to platinum group metals (Ru or Rh), Wilkinson and coworkers synthesized $TiCl_2(OPh)_2$ to examine any η^5-bonding in the case of this earlier transition metal derivative also. Although no evidence was found for η^5-bonding in the above derivative, yet these workers made a detailed study of its reactions with reducing agents,[10] which aroused considerable interest due to the observation that the reduction of $TiCl_2(OPh)_2$ with sodium naphthalenide or potassium under nitrogen gave appreciable quantities of ammonia.

The tetra-alkoxides (and phenoxides) of titanium and zirconium generally attain higher coordination numbers through oligomerization, and generally do not show Lewis acid character, whereas chloride alkoxides exhibit considerable Lewis acid character, leading to the formation of a large number of adducts.[11–14]

In contrast to the chloride alkoxides, the Lewis acid character of phenoxide derivatives of titanium and zirconium has received scanty attention. Recently reports have appeared in the literature describing the Lewis acidic nature of titanium naphthyloxides.[15,16]

X-ray crystallographic studies of sterically hindered phenoxide derivatives of early transition metals have shown that phenolate ions can also behave as π-donor ligands, M⇐OAr, which would in effect reduce the electrophilicity of the metal atom.

In view of the above interesting findings, it was considered worthwhile to synthesize derivatives of titanium and zirconium with a moderately hindered phenol, i.e. 2,4,6-trimethylphenol, and to study the Lewis acidic behaviour of these phenoxide derivatives.

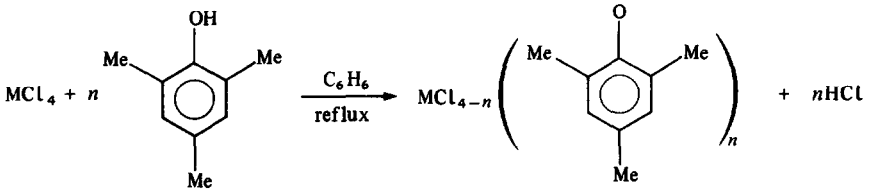
EXPERIMENTAL

Titanium and zirconium tetrachlorides were purified by distillation and sublimation, respectively, under reduced pressure. Solvents and the various bases were made anhydrous before use. Molecular weights were measured either ebullioscopically (Gallenkamp apparatus) or cryoscopically. IR spectra were recorded (4000–200 cm^{-1}) on a Perkin–Elmer grating spectrometer 577. PMR spectra of the compounds were recorded on a 60-MHz Perkin–Elmer instrument. Molar conductances of the addition complexes were measured on a conductivity bridge type 302 Sr No. 471. TGA, DTA and mass spectrum were recorded in air on a thermal balance and under reduced pressure on a mass spectrometer.

Synthetic procedures



$MCl_{4-n}(OAr')_n$ derivatives were synthesized in general by the reaction of the tetrachlorides of titanium and zirconium (M) with 2,4,6-trimethylphenol in different stoichiometric ratios using benzene or toluene as the solvent. Their adducts were synthesized by stirring the benzene solution of $MCl_{4-n}(OAr')_n$ derivatives with various bases. For brevity, details of one reaction each of the above types are given below and the data for these reactions are summarized in Table 1.

Synthesis of titanium bis(2,4,6-trimethylphenoxide)dichloride, $TiCl_2(C_9H_{11}O)_2$. To a solution of titanium tetrachloride (1.92 g, 6.63 mmol) in benzene (~ 40 cm^3) was added 2,4,6-trimethylphenol (2.75 g, 13.27 mmol). The reaction mixture was refluxed for about 15 h till the evolution of HCl gas had ceased. After removal of the solvent under reduced pressure, the product was recrystallized to give a brown-red crystalline solid, $TiCl_2(OAr')_2$.

Synthesis of the bipyridyl adduct of titanium (2,4,6-trimethylphenoxide)trichloride. The addition of bipyridyl (1.03 g, 6.63 mmol) to a benzene (~40 cm^3) solution of $TiCl_3(C_9H_{11}O)$ (1.92 g, 6.63 mmol) resulted in an exothermic reaction with instantaneous precipitation of a red solid. The reaction mixture was stirred for about 8–10 h at room temperature. The product was filtered off, washed with benzene and finally dried under reduced pressure.

RESULTS AND DISCUSSION

The reactions of the tetrachlorides of titanium and zirconium with stoichiometric amounts of 2,4,6-trimethylphenol resulted in the formation of mono-, bis-, tris- and tetrakis derivatives:

The reactions are rather slow and required ~8, ~15, ~22 and ~28 h, respectively, of refluxing in benzene; in a higher boiling solvent such as toluene, the completion time for the tetrakis derivatives could be reduced considerably (20 h).

Although the zirconium derivatives are generally less soluble than their titanium analogues, the solubility of the mixed chloride–phenoxide derivatives of both metals increases with the number of phenoxide groups attached to the metal atom.

The phenoxides of titanium are reddish brown in colour whereas the zirconium analogues are pale-yellow or white in colour. The reddish-brown colour of the substituted phenoxides of titanium is probably due to a charge-transfer transition tailing into the visible region of the spectrum. Measurements (cryoscopic as well as ebullioscopic) of molecular weights of chloride phenoxides which are soluble in organic solvents showed that they were monomeric.

The addition complexes were synthesized by the following reaction:

$$MCl_{4-n}(OAr')_n + 2L \xrightarrow[8\text{–}10\,h]{C_6H_6,\ stir} MCl_{4-n}(OAr')_nL_2,$$

where M = Ti or Zr; OAr′ = 2,4,6-trimethylphenoxy; L = aromatic primary or tertiary nitrogenous bases, tetrahydrofuran (thf) or bis(1,2-diphenylphosphino)ethane.

The reactions with nitrogenous bases were fast and exothermic as they led to the instantaneous precipitation of the adduct, whereas reactions with other bases were comparatively slow. Elemental analysis indicated the addition of 2 mol of various bases to the chloride phenoxides but the tetrakis derivatives formed an adduct with only 1 mol of the base. This may be due either to steric crowding or electronegativity differences. The molecular weight measurements (in the case of soluble complexes)

show them to be monomeric in freezing nitrobenzene or refluxing acetonitrile.

Conductivity measurements

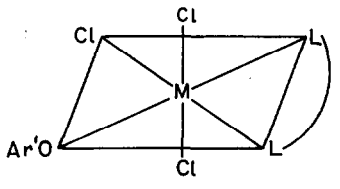
The molar conductance values (in the case of soluble addition complexes) in nitrobenzene were found to lie in the range 1.6–3.5 Ω^{-1} cm^2 mol^{-1}, indicating their non-ionic nature.

IR spectral studies

The chloride phenoxides of titanium, $TiCl_3(OAr')$ and $TiCl_2(OAr')_2$, showed two ν(M—Cl) around 330–365 cm^{-1}, whereas in the zirconium analogues these appear around 320–340 cm^{-1}. As expected, ν(C—O), observed at 1228 cm^{-1} in the free phenol, shifts to lower frequency (by ~75 cm^{-1}) in the metal phenoxides. The alternative η^5-bonding of the phenolic moiety with some later transition metals such as rhodium and iridium has been established by single-crystal X-ray studies,[6] and further corroborated by the appearance of a carbonyl absorption in complexes of type (η^5-2,6-*t*-Bu-4-MeC_6H_2O)$Rh(PPh_3)(CO)$ around 1576 cm^{-1}. However, the absence of absorption around 1580 cm^{-1} and the appearance of ν(M—O) around 440–560 cm^{-1} rules out η^5-bonding and confirms the simple M—O—C bonding in the present titanium and zirconium complexes.

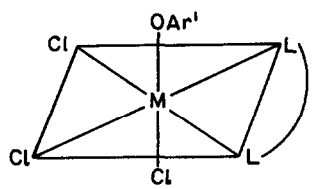
Addition complexes

In the addition complexes $MCl_{4-n}(OAr')_nL_2$ [where L = pyridine or picoline (α, β or γ)], ν(M—Cl) stretching vibrations were observed in the region 320–370 cm^{-1}, which is higher (~10–30 cm^{-1}) than that of the parent chloride–phenoxide derivatives. Although such an increase was considered earlier[17] to be indicative of enhancement of the coordination state of the metal, more recent work[18–20] on early transition metal halide complexes has revealed instances of the shifting of ν(M—Cl) in the reverse direction. However, the latter trend may be reversed by factors such as steric interactions and double bonding.[19]



The bands which emerge around 285 ± 5 cm^{-1} could be assigned to M←N bonds.[20] ν(Ti—O) and ν(Zr—O) bands were observed around 460 ± 20 and 545 ± 10 cm^{-1}, respectively. The ν(C=N) which occurs at 1578 cm^{-1} in the free pyridine molecule exhibits a shift to higher frequency in the addition complexes with phenoxide derivatives. Such a shift towards higher wavenumbers is characteristic of coodination through nitrogen.[21] In a series of pyridine adducts with titanium phenoxide derivatives the values for ν(C=N) (in parentheses) follow the order: $TiCl_3(OAr')L_2$ (1605) > $TiCl_2(OAr')_2L_2$ (1600) > $TiCl(OAr')_3L_2$ (1585) > $Ti(OAr')_4L$ (1582). The above trend in the variation in ν(C=N) can be explained in terms of a decrease in Lewis acidic behaviour of titanium phenoxide derivatives. A similar trend has been observed in the case of the zirconium derivatives also.

The aniline free ligand showed two N—H stretching vibrations at 3400 and 3320 cm^{-1} due to asymmetrical and symmetrical vibrations, respectively.[22] In the complexes $MCl_3(OAr')(ArNH_2)_2$, $MCl_2(OAr')_2(ArNH_2)_2$ and $MCl(OAr')_3(ArNH_2)_2$, the N—H vibrations appeared around 3380 ± 5 and 3300 ± 5 cm^{-1}, indicating a shift of ~20 cm^{-1} to a lower frequency. ν(M—Cl) bands were observed around 345 cm^{-1} and M←N around 285 ± 5 cm^{-1}. The formation of substitution products is ruled out on the basis of the absence of bands for $[ArNH_3]^+Cl^-$ in the region 1520–1600 cm^{-1}.



In the thf adducts $MCl_{4-n}(OAr')_n(thf)_2$ (where n = 1 or 2), ν(M—Cl) appeared around 350 cm^{-1}. The C—O—C vibrational mode which occurred at 1070 cm^{-1} in the free thf molecule was lowered ~70 cm^{-1}, indicating coordination through the oxygen atom of the thf molecule.[23].

Bipyridyl adducts, $MCl_3(OAr')(L–L)$ [where L–L = bipyridyl or bis (1,2-diphenylphosphino) ethane], showed ν(M—Cl) stretching vibrations as a triplet around 320–370 cm^{-1}, ν(M—O) around 445–555 cm^{-1}, and ν(C=N) around 1610 cm^{-1} showed a shift of 30 cm^{-1} to a higher frequency than the ligand bipyridyl [ν(C=N) at 1580 cm^{-1}], indicating coordination through a nitrogen atom. ν(M—P) in diphos adducts were observed around 400 ± 5 cm^{-1}.[24]

The appearance of three bands due to ν(M—Cl) in these complexes is suggestive of an octahedral environment around the central metal atom.[25] Two *cis* chlorine atoms on the metal give rise to a doublet, whereas the *trans* chlorine atoms give rise to a singlet. These octahedral complexes may exist in the meridional (*mer*) and facial (*fac*) forms as illustrated below:

mer

fac

where M = Ti or Zr, OAr′ = 2,4,6-trimethylphenoxide, and L–L = bipyridyl or bis(1,2-diphenylphosphino)ethane.

On the basis of only IR spectra, no conclusive distinction can be made between the *mer* and *fac* configurations.

^1H NMR spectral studies

Free 2,4,6-trimethylphenol exhibits a singlet at δ 2.05 ppm for the methyl protons. However, $TiCl_3(C_9H_{11}O)$ exhibits a doublet [2.2(s), 2.3(s)] centred at δ 2.25 ppm, indicating that the *ortho* and *para* methyl protons are not chemically equivalent (integrating in a 2:1 ratio). The downfield shift is possibly associated with delocalization of electrons from the aromatic nucleus to the titanium atom. In the thf adducts of the titanium and zirconium compounds, the methyl protons on the phenolic ring exhibit a singlet around 2.2 ppm. The CH_2 and OCH_2 protons in the free thf ligand appearing around 1.85 and 3.75 ppm shifted slightly downfield on coordination, and appear around 1.90 and 3.80 ppm, respectively.

Thermogravimetric and mass spectrometric analysis

The TG and DT analyses (in the range 40–990°C) of $[TiCl_3\{2,4,6\text{-}(CH_3)_3C_6H_2O\}(py)_2]$ and $[TiCl_3\{2,4,6\text{-}(CH_3)_3C_6H_2O\}(bipy)]$, indicated an initial decomposition (endothermic) to $TiOCl_2$, which appears to undergo exothermic disproportionation into TiO_2 and $TiCl_4$.

The mass spectral study of $TiCl_3(OAr')(py)_2$ indicated a base peak corresponding to the monoadduct $TiCl_3(OAr')(py)$, suggesting the lower stability of the parent diadduct $[P]^+$. Other metal-containing peaks were observed at m/z 289 $[P-2py]^+$, 238 $[P-2py\text{-}Cl\text{-}CH_3]^+$ and 208 $[P-2py\text{-}Cl\text{-}2CH_3]^+$.

EXTRACTION OF MOLYBDENUM(VI) BY BIS-(DIOCTYLPHOSPHINYL)-ALKANES

YUKO YAMASHOJI,* TAKAYUKI MATSUSHITA and TOSHIYUKI SHONO

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565, Japan

(*Received* 23 *September* 1985; *accepted* 9 *December* 1985)

Abstract—A series of bis-(dioctylphosphinyl)-alkanes [$(DOPO)_2R$], has been prepared and employed as liquid–liquid extractants for molybdenum(VI) from hydrochloric acid solutions [R = p-$CH_2C_6H_4CH_2$ or $—(CH_2)_n—$ (n = 2, 3, 4, 5, 8 or 10)]. These bis-type ligands were found to be much more efficient extractants than trioctylphosphine oxide and benzyldioctylphosphine oxide. The formula of the molybdenum(VI) extracted by $(DOPO)_2(CH_2)_5$ into the organic phase was determined to be $MoO_2[(DOPO)_2(CH_2)_5](Cl)_2$.

Organophosphorus compounds such as alkylphosphonic acid,[1–5] trialkyl phosphates,[6,7] trialkylphosphine oxides[8–10] and bis-(tertiaryphosphine oxide)s[11,12] have been utilized as practical extractants for various metal ions. For example, trioctylphosphine oxide (TOPO) can extract molybdenum(VI) from highly acidic solutions.

In this paper, we describe the preparation of novel bis(dioctylphosphinyl)-alkanes [$(DOPO)_2R$] and their efficiency as extractants for molybdenum(VI). The bis-type ligands were found to extract molybdenum(VI) much more efficiently than TOPO and benzyldioctylphosphine oxide [(Bz)DOPO]. Moreover, among these bis-type ligands, $(DOPO)_2(CH_2)_n$ is a more efficient extractant compared to $(DOPO)_2(p\text{-Xyl})$ (p-Xyl = p-$CH_2C_6H_4CH_2$) (see Fig. 1).

EXPERIMENTAL

Reagents

All reagents were of reagent grade. Chloroform was refluxed over P_4O_{10} and distilled. Water was deionized. An aqueous solution of molybdenum(VI) was prepared by dissolving $Na_2MoO_4 \cdot 2H_2O$ in a hydrochloric acid solution of appropriate concentration.

Preparation of $(DOPO)_2R$

$(DOPO)_2R$ were prepared according to the method described by N'guyen *et al.*[13] as follows. A toluene solution (30 cm^3) of dioctylphosphine oxide (2.0 g, 7.3 mmol) and α,α'-dichloro-p-xylene (1.0 g, 5.7 mmol) was added to a 50% aqueous solution of sodium hydroxide (10 cm^3) containing a phase-transfer catalyst, tetrabutylammonium hydrogensulphate (TBAH) (0.2 g). This heterogeneous mixture was stirred vigorously at 65°C for 10 h under a nitrogen atmosphere. After cooling, the organic phase was separated by a separatory funnel, washed with diluted hydrochloric acid (0.01 M, 50 cm^3) and then water, dried over magnesium sulphate, and evaporated to dryness under reduced pressure. The resulting white precipitate was recrystallized from an acetone–water (1 : 1) mixture. The yield was 80%.

Other $(DOPO)_2R$ were obtained in a similar way to the method described above by using an appropriate alkyl dihalide in place of α,α'-dichloro-

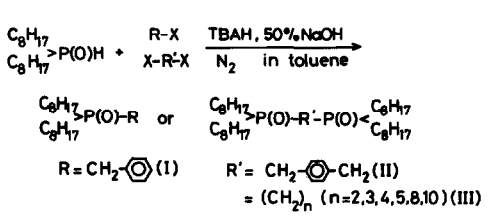

Fig. 1. Preparation scheme for $(DOPO)_2R$ studied.

* Author to whom correspondence should be addressed.

p-xylene. These were recrystallized from acetone and further purified by gel-permeation chromatography. Their yields were 15–20%.

(Bz)DOPO was obtained by the reaction of dioctylphosphine oxide and benzyl chloride in a similar way to that described above. It was recrystallized from an acetone–water (1 : 1) mixture. The yield was 30%.

The preparation scheme for these extractants is shown in Fig. 1.

Extraction and analytical procedures

A chloroform solution (5 cm^3) of a ligand and a molybdenum(VI) solution in hydrochloric acid (5 cm^3) were placed into a 10-cm^3 test-tube with a stopper. This was placed in a water bath thermostatted at 25±0.1°C and shaken for 1 h, and then centrifuged for separation. Preliminary experiments confirmed that a shaking time of 30 min was enough to attain an extraction equilibrium. The concentration of molybdenum(VI) remaining in the aqueous phase was determined by atomic absorption spectrometry. The concentration of molybdenum(VI) in the organic phase was calculated from the mass balance using that determined in the aqueous phase.

Isolation of molybdenum(VI) complexes with TOPO *or* $(DOPO)_2(CH_2)_5$

A chloroform solution (20 cm^3) of TOPO (0.1 M) was mixed with a 6.0 M hydrochloric acid solution (10 cm^3) containing excess amounts of molybdenum(VI) over TOPO. The mixture was stirred vigorously for 2 h at room temperature. The chloroform solution was separated by a separatory funnel, washed with water, and then evaporated to give a yellow oil. This oily product was washed with a methanol–water (1 : 50) mixture (20 cm^3) by decantation and dried *in vacuo* for 48 h. The yield was 80%, based on TOPO. IR (direct): ν(P=O), 1117 cm^{-1}; ν(Mo=O), 938 and 896 cm^{-1}. Found: C, 59.7; H, 10.8; Cl, 6.9%. Calc. for $MoO_2(C_{24}H_{51}PO)_2Cl_2$: C, 59.3; H, 10.5; Cl, 7.3%.

The other molybdenum(VI) complex with $(DOPO)_2(CH_2)_5$ was obtained in a similar way to the above complex as pale-yellow crystals. The yield was 85%, based on the ligand. IR (in KBr disc): ν(P=O), 1106 cm^{-1}, ν(Mo=O), 938 and 896 cm^{-1}. Found: C, 54.7; H, 10.3; Cl, 8.3%. Calc. for $MoO_2(C_{37}H_{78}P_2O_2)Cl_2$: C, 54.5; H, 9.6; Cl, 8.7%.

Physical measurements

UV absorption spectra were recorded on a Hitachi 340 recording spectrophotometer. IR spectra of chloroform solutions were recorded on a JASCO 910 grating spectrophotometer with a 0.1-mm light-pass. Atomic absorption analyses were made with a Nippon Jarrell Ash AA-1 spectrophotometer using a N_2O–C_2H_2 flame. Mass spectra were obtained with a Hitachi RMU-6E mass spectrometer.

RESULTS AND DISCUSSION

Preparation of $(DOPO)_2R$

A series of $(DOPO)_2R$ has been prepared and characterized by melting points, elemental analyses, and mass and IR spectra. These data are summarized in Table 1.

Extraction isotherm

In the present study, we have investigated extractabilities of the $(DOPO)_2R$ for molybdenum(VI) in

Table 1. Elemental analyses, melting points (m.ps), mass spectral data and characteristic IR bands for mono- and bis-type tertiaryphosphine oxides

Compound	Found (%)		Calc. (%)		M.p. (°C)	Mass spectrum [M^+]	ν(P=O) (cm^{-1})
	C	H	C	H			
(Bz)DOPO	75.7	11.4	75.8	11.3	58–59	364	1174
$(DOPO)_2$(*p*-Xyl)	73.3	12.0	73.8	11.7	126–127	650	1172
$(DOPO)_2(CH_2)_2$	70.5	12.7	71.1	12.5	154–155	574	1143
$(DOPO)_2(CH_2)_3$	71.2	13.0	71.1	12.5	90–91	588	1153, 1145
$(DOPO)_2(CH_2)_4$	71.2	13.2	71.8	12.6	88–89	602	1158
$(DOPO)_2(CH_2)_5$	71.8	12.9	72.1	12.7	101–102	616	1151, 1145
$(DOPO)_2(CH_2)_8$	72.6	13.3	72.9	12.8	88–98	658	1146
$(DOPO)_2(CH_2)_{10}$	73.0	13.1	73.5	12.8	64–65	686	1148

comparison with those of the corresponding monophosphine oxides. Figure 2 shows the percentage extractions of molybdenum(VI) by these extractants with various concentrations (1.0–9.3 M) of hydrochloric acid in the aqueous phase. They strongly depend on the concentration of hydrochloric acid for all extractants. The efficiency of extraction increases steeply with increasing concentration of hydrochloric acid, and the maximal values are obtained in the range of 5.0–7.0 M hydrochloric acid. They decreased above 7.0 M hydrochloric acid. It should be noticed that all the bis-type ligands are better extractants than the corresponding monophosphine oxides: the percentage extraction obtained for $(DOPO)_2(CH_2)_5$ (5×10^{-3} M) is 93% under the optimum conditions (5.4 M HCl), whereas that for TOPO (1×10^{-2} M) is 72.5% at 5.4 M HCl.

These results suggest that the bis-type ligands may act as a bidentate ligand to form relatively stable complexes with molybdenum(VI) compared to those of the monodentate ones.

Effect of additional lithium chloride on extraction of molybdenum(VI)

It has been reported that the extraction of molybdenum(VI) by trialkylphosphine oxides depends on the concentration of chloride ion in the aqueous phase. Figure 3 shows the effect of additional chloride ion on the extractions of molybdenum(VI) by $(DOPO)_2(CH_2)_4$ and TOPO when lithium chloride (2.0–6.0 M) was added to aqueous solutions of 1.0 M hydrochloric acid. It can be seen that the concentration of total chloride ions strongly affects the extraction of molybdenum(VI). The percentage extractions of molybdenum(VI) are increased with

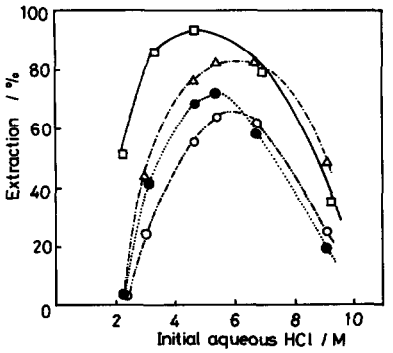

Fig. 2. Effect of hydrochloric acid concentration on extraction of molybdenum(VI) by mono- and bis-type tertiaryphosphine oxides. (●) TOPO (1×10^{-2} M), (○) (Bz)DOPO (1×10^{-2} M), (△) $(DOPO)_2$(*p*-Xyl) (1×10^{-2} M), and (□) $(DOPO)_2(CH_2)_5$ (5×10^{-3} M). Molybdenum(VI) concentration = 5×10^{-4} M.

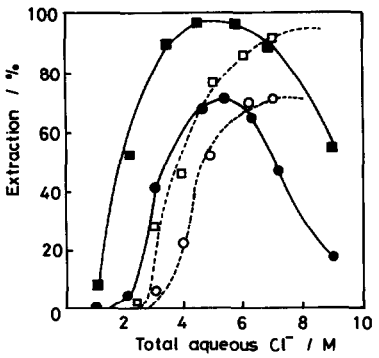

Fig. 3. Additive effect of lithium chloride on extraction of molybdenum(VI). TOPO concentration = 1×10^{-2} M, $(DOPO)_2(CH_2)_4$ concentration = 5×10^{-3} M, and molybdenum(VI) concentration = 5×10^{-4} M. (●) TOPO (hydrochloric acid alone), (○) TOPO (1.0 M hydrochloric acid + lithium chloride), (■) $(DOPO)_2(CH_2)_4$ (hydrochloric acid alone), and (□) $(DOPO)_2(CH_2)_4$ (1.0 M hydrochloric acid + lithium chloride).

increasing concentration of additional lithium chloride: the maximal values are obtained at about 7.0 M of total chloride ion concentration for both extractants. These concentrations of total chloride ions are higher than those observed in hydrochloric acid only systems. This may arise from differences in the activities of the chloride ion between hydrochloric acid and lithium chloride in aqueous phases.

In the present work, the following experiments were conducted in order to identify the species of molybdenum(VI) extracted by the bis-type extractants.

IR spectra

Figure 4 shows the IR spectra of chloroform solutions of TOPO (0.05 M) and $(DOPO)_2(CH_2)_4$ (0.1 M) after extraction of molybdenum(VI) from an aqueous solution of hydrochloric acid (6.0 M) containing molybdenum(VI) (0.2 M). With TOPO, an absorption band due to ν(P═O) observed at 1147 cm^{-1} decreases in intensity after extraction of molybdenum(VI), and a new absorption band appears at 1117 cm^{-1}. Its intensity is greater than that observed for the spectrum of the blank, which was prepared by shaking a chloroform solution of TOPO with 6.0 M hydrochloric acid. Therefore, the new absorption band can be assigned to the ν(P═O) of the TOPO coordinated to molybdenum(VI). Similar spectral changes are observed for the IR spectrum of the chloroform solution of $(DOPO)_2(CH_2)_4$: after extraction of molybdenum(VI), the absorption band due to the ν(P═O) of the free ligand is shifted from 1158 to 1117 cm^{-1}.

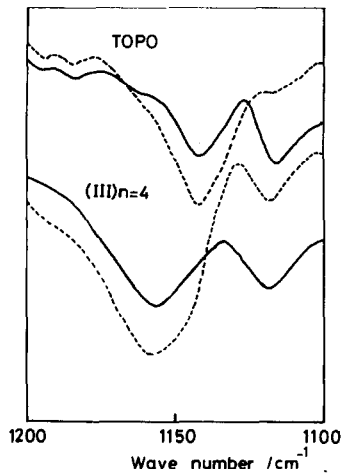

Fig. 4. IR spectra of chloroform solutions of TOPO and $(DOPO)_2(CH_2)_4$ (5×10^{-2} M) before (---) and after (——) extraction of molybdenum(VI) from 6.0 M hydrochloric acid solution.

UV absorption spectra

Figure 5 shows the absorption spectra of the aqueous and chloroform solutions of molybdenum(VI) in the UV region. The spectrum of molybdenum(VI) in water curve (a) shows an absorption maximum at 226 nm with a shoulder band around 240 nm. Its spectrum changes remarkably in 6.0 M hydrochloric acid to the spectrum shown by curve (b) in Fig. 5, which exhibits an absorption maximum at 240 nm and a shoulder band around 260 nm. Previously, Neumann and Cook[14] have reported that all the molybdenum(VI) compounds coordinated with chlorine atoms have an absorption maximum at 226 nm and that the 1 : 2 (molybdenum : chlorine) species particularly can be characterized by the shoulder band observed around 240–250 nm. Moreover, they have pointed out that the amount of the 1 : 2 species formed in aqueous solutions of hydrochloric acid depend on its concentration and is maximum at 6.0 M hydrochloric acid.

On the other hand, the absorption spectra of the chloroform solutions of TOPO (1.0×10^{-2} M) [Fig. 5, curve (c)] and $(DOPO)_2(CH_2)_4$ (1.0×10^{-2} M) [fig. 5, curve (d)] after extraction of molybdenum(VI), at 6.0 M hydrochloric acid, possess shoulder bands around 260 nm. These bands may arise from the same origin as that observed for curve (b) in Fig. 5, because TOPO and $(DOPO)_2(CH_2)_4$ themselves have no absorption bands in this region. Therefore, we have speculated that the complexes of molybdenum(VI) extracted by these ligands from 6.0 M hydrochloric acid may be composed of the 1 : 2 molybdenum : chlorine ratio species.

Relationship between extractant concentration and distribution ratio

Figure 6 shows the log–log plots for extractant concentration vs distribution ratio in the extractions of molybdenum(VI) by the various extractants from 6.0 M hydrochloric acid. With (Bz)DOPO and TOPO, the slopes of their straight lines are 1.6, suggesting that the extractant : molybdenum(VI) ratio in the extracted species is 2 : 1. On the other hand, with $(DOPO)_2(p\text{-Xyl})$ and $(DOPO)(CH_2)_n$ ($n = 2$ or 5), the slopes of the straight lines are nearly unity, suggesting that the extracted species for these systems are in a 1 : 1 extractant : molybdenum(VI) molar ratio.

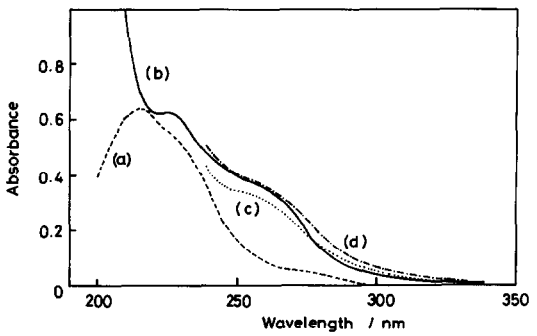

Fig. 5. Absorption spectra of molybdenum(VI) in the UV region. Molybdenum(VI) concentration = 1×10^{-4} M. (a) In water, (b) in 6.0 M HCl, (c) a chloroform solution of TOPO (1×10^{-2} M) after extraction of molybdenum(VI), and (d) a chloroform solution of $(DOPO)_2(CH_2)_4$ (1×10^{-2} M) after extraction of molybdenum(VI). Cell length = 1.0 cm.

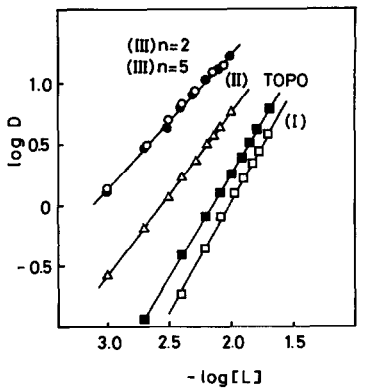

Fig. 6. Log–log plots of distribution ratio vs extractant concentration. Molybdenum(VI) concentration = 5×10^{-4} M, and hydrochloric acid concentration = 6.0 M. (■) TOPO, (□) (BzDOPO), (△) $(DOPO)_2(p\text{-Xyl})$, (○) $(DOPO)_2(CH_2)_2$, and (●) $(DOPO)_2(CH_2)_5$.

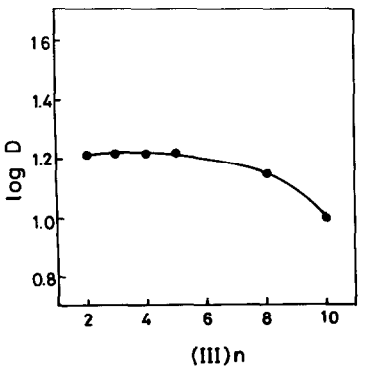

Fig. 7. Effect of the chain length of the methylene group on the distribution ratio of molybdenum(VI). Molybdenum(VI) concentration = 5×10^{-4} M, hydrochloric acid concentration = 6.0 M, and $(DOPO)_2(CH_2)_n$ concentration = 1×10^{-2} M.

Identification of the extracted molybdenum(VI) complexes

We have isolated two molybdenum(VI) complexes with TOPO or $(DOPO)_2(CH_2)_5$ in order to identify the species of molybdenum(VI) extracted by the extractants investigated here. The analytical data for these complexes are fairly in agreement with the calculated values for the formulae $MoO_2(TOPO)_2Cl_2$ and $MoO_2[(DOPO)_2(CH_2)_5]Cl_2$. In their IR spectra, only one absorption band due to ν(P=O) was observed at 1117 and 1106 cm^{-1}, respectively, indicating that all P=O groups of the ligands in these complexes are coordinated to the molybdenum ion. These results are consistent with those obtained from the log–log plots (Fig. 6) and the spectroscopic data (Figs 4 and 5). Thus, it is concluded that the extracted complexes of molybdenum(VI) have the formulae $MoO_2(L^1)_2Cl_2$ and $MoO_2(L^2)Cl_2$, where L^1 and L^2 denote the tertiaryphosphine oxides and $(DOPO)_2R$, respectively.

Effect of the chain length of the methylene group in $(DOPO)_2(CH_2)_n$ on distribution ratio of molybdenum(VI)

Figure 7 shows the effect of the chain length of the methylene group in $(DOPO)_2(CH_2)_n$ on the distribution ratio of molybdenum(VI) in the extraction at 6.0 M hydrochloric acid. The distribution ratios were found to be almost constant for the extractants with $n = 2$, 3, 4 or 5, and to decrease gradually for those with $n = 8$ or 10. These results may reflect the relative stabilities of the extracted species, although the formation constants have not been determined in the present work.

PHOTOREDUCTION OF Fe(III) PROTOPORPHYRIN IX IN ETHANOL–WATER SOLUTIONS CONTAINING BIFUNCTIONAL LIGANDS

CARLO BARTOCCI,* ROSSANO AMADELLI, ANDREA MALDOTTI and VITTORIO CARASSITI

Centro Studio sulla Fotochimica e Reattività degli Stati Eccitati dei Composti di Coordinazione del C.N.R., Dipartimento di Chimica dell'Università di Ferrara, Via L. Borsari 46, I 44100 Ferrara, Italy

(*Received* 30 *October* 1985; *accepted* 19 *December* 1985)

Abstract—The irradiation of Fe(III) protoporphyrin IX [Fe(III)PPIX] in a thoroughly deoxygenated 35% ethanol–water solution containing pyrazine (pyz) leads to changes in the visible spectrum that are indicative of Fe(II)PP species formation. With a large excess of pyz the spectrum is similar to that of the Fe(II) pyridine hemochrome, suggesting that the monomer Fe(II)PP(pyz)$_2$ is formed. With a lower pyz content, the photochemically formed bis-pyz complex converts to a polymeric Fe(II)PP species. A similar photochemical behaviour is observed when piperazine or 4,4′-bipyridine are used as bridge ligands instead of pyz. The origin of the absorptions characteristic of the photoreaction products is discussed on the basis of the dependence of the spectra on the nature of the bridge ligands.

The photochemical reduction of chlorohemin {Fe(III)protoporphyrin IX chloride [Fe(III)PP Cl]} in pyridine–ethanol–water mixtures has been the object of previous investigations.[1] The results have shown that the primary act is an electron transfer from an ethanolate axial ligand to Fe(III). An ethoxy radical and a co-ordinatively unsaturated Fe(II)PP species were the primary photoproducts from which a bis-pyridine Fe(II)PP complex and acetaldehyde were formed.

Pyrazine (pyz), piperazine (pip) and 4,4′-bipyridine (bipy) were known to function as bridging ligands in a number of polynuclear transition-metal complexes.[2] Since they, like pyridine, are good ligands for Fe(II) porphyrin complexes, it was of interest to check the possibility of photochemically obtaining ligand-bridged Fe(II) protoporphyrin species.

The formation of square planar Fe(II) macrocyclic complexes bisaxially linked through bifunctional ligands have been prepared recently.[3] In particular, ligand-bridged phtalocyaninate Fe(II) polymeric complexes have been studied in detail.[3,4] Although these polymers are studied especially in view of their properties as monodimensional electrical conductors, they could be of some utility in studies aiming at elucidating the photosynthesis mechanism. In fact, it has been reported[5] that chlorophyll is able to form, with bifunctional ligands, bridged oligomeric adducts which give rise to substantial red shifts in the visible absorption spectrum. The spectral behavior of these models was found to be useful for clarifying the nature of the chlorophyll red absorptions, which seem to result from interactions between several chlorophyll molecules in an assembly where the macrocyclic planes are close to each other.

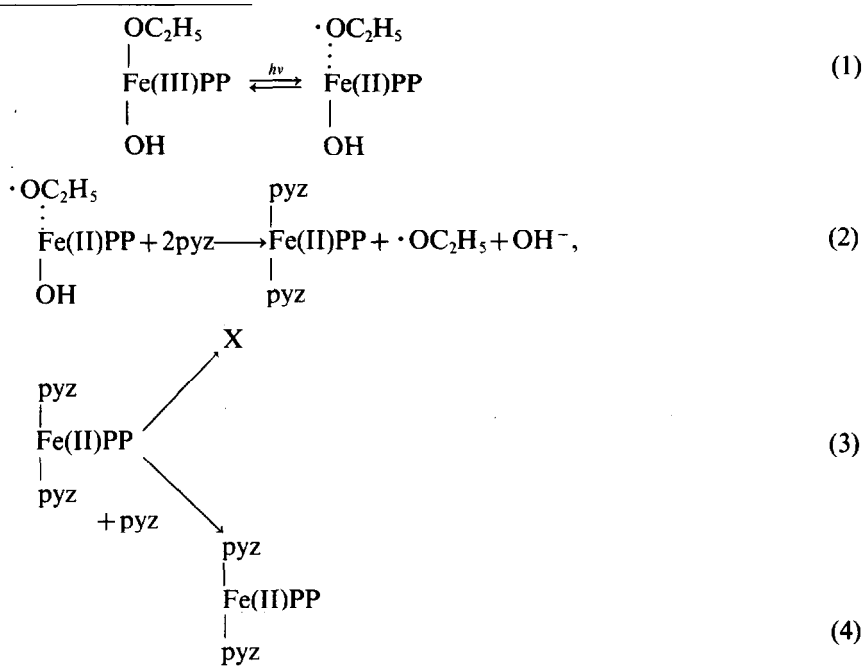
In the present paper we report evidence for the photochemical formation of ligand-bridged polymeric Fe(II)PP species from Fe(III)PP Cl in a water–ethanol solvent containing bifunctional ligands. The photoreaction mechanism and the differences in the electronic spectrum between the monomeric and the polymeric species are also discussed.

EXPERIMENTAL

Chlorohemin was obtained from Fluka and recrystallized following the reported glacial acetic acid method.[6] All the other chemicals were reagent

* Author to whom correspondence should be addressed.

grade commercial products. UV–VIS spectra were recorded with a Jasco Uvidec 650 spectrophotometer. Irradiations were carried out at room temperature with a Hanau Q 400 mercury vapor lamp. Light of wavelength below 360 nm was cut off with suitable glass filters. Solutions of 2×10^{-5} mol dm^{-3} Fe(III)PP Cl in 35% (v/v) ethanol–water at pH 11 were employed. All solutions were deaerated by means of at least four vacuum line freeze–thaw pump cycles ($> 10^{-6}$ torr) prior to irradiation.



RESULTS AND DISCUSSION

Reaction mechanism

The electronic spectrum obtained following the irradiation of a Fe(III)PP Cl solution (see Experimental) containing a 5000-fold excess of pyz* shows a Soret band (415 nm) and Q-bands (520 and 550 nm) at the same wavelengths as the bis-pyridine Fe(II)PP complex, indicating that the photoproduct in the above conditions is $(pyz)_2$Fe(II)PP. This compound is stable in the absence of oxygen, but is rapidly reoxidized to the initial Fe(III)PP complex when air is let into the reaction vessel.

When the pyz:Fe concentration ratio is decreased, the electronic spectrum obtained after irradiation shows, in addition to the bands characteristic of $(pyz)_2$Fe(II)PP, absorptions at 455, 530, 575 and 805 nm, which are indicative of the formation of another Fe(II)PP product. With the aim of verifying if the two photoproducts were formed through parallel or consecutive processes, an experiment was carried out in which Fe(III)PP Cl was irradiated for a long enough time to obtain spectral evidence of $(pyz)_2$Fe(II)PP, but not sufficient to allow an eventual additional product to build up in a detectable amount. Spectral changes in time were then followed in the dark at constant temperature (22°C). The result (Fig. 1) was that the bands at 415, 520 and 550 nm decreased while, at the same time, new bands at 455, 530, 575 and 805 nm increased. This behavior is a clear evidence that the photochemical formation of $(pyz)_2$Fe(II)PP is followed by a thermal process which converts the bis-pyz complex to a new Fe(II)PP species. The rate of the secondary thermal reaction increases with decreasing pyz concentration and the process becomes spectrophotometrically undetectable at a pyz:Fe concentration ratio less than 10:1.

On the basis of the above results we propose the following reaction scheme:

Scheme 1.

When the pyz:Fe concentration ratio is decreased, the electronic spectrum obtained after irradiation shows, in addition to the bands characteristic of $(pyz)_2$Fe(II)PP, absorptions at 455, 530, 575 and 805 nm, which are indicative of the formation of another Fe(II)PP product. With the aim of verifying if the two photoproducts were formed through parallel or consecutive processes, an experiment was carried out in which Fe(III)PP Cl was irradiated for a long enough time to obtain spectral evidence of $(pyz)_2$Fe(II)PP, but not sufficient to allow an eventual additional product to build up in a detectable amount. Spectral changes in time were then followed in the dark at constant temperature (22°C). The result (Fig. 1) was that the bands at 415, 520 and 550 nm decreased while, at the same time, new bands at 455, 530, 575 and 805 nm increased. This behavior is a clear evidence that the photochemical formation of $(pyz)_2$Fe(II)PP is followed by a thermal process which converts the bis-pyz complex to a new Fe(II)PP species. The rate of the secondary thermal reaction increases with decreasing pyz concentration and the process becomes spectrophotometrically undetectable at a pyz:Fe concentration ratio less than 10:1.

On the basis of the above results we propose the following reaction scheme:

$$\text{Fe(III)PP(OH)} \overset{h\nu}{\rightleftharpoons} \text{Fe(II)PP(OH)}\cdot OC_2H_5 \qquad (1)$$

$$\text{Fe(II)PP(OH)}\cdot OC_2H_5 + 2\text{pyz} \longrightarrow \text{Fe(II)PP(pyz)}_2 + \cdot OC_2H_5 + OH^-, \qquad (2)$$

$$\text{Fe(II)PP(pyz)}_2 \longrightarrow \text{X} \qquad (3)$$

$$\text{Fe(II)PP(pyz)}_2 + \text{pyz} \longrightarrow \text{Fe(II)PP(pyz)}_3 \qquad (4)$$

Scheme 1.

$(pyz)_2$Fe(II)PP is formed through the same mechanism [eqns (1) and (2)] previously proposed for the photochemical formation of $(py)_2$Fe(II)PP.[1] The formation of X from the bis-pyz complex [eqn (3)] occurs in competition with a pyz exchange process [eqn(4)], thus accounting for the dependence

* The addition of this excess of ligand does not appreciably change the spectrum of the Fe(III)PP Cl solution.

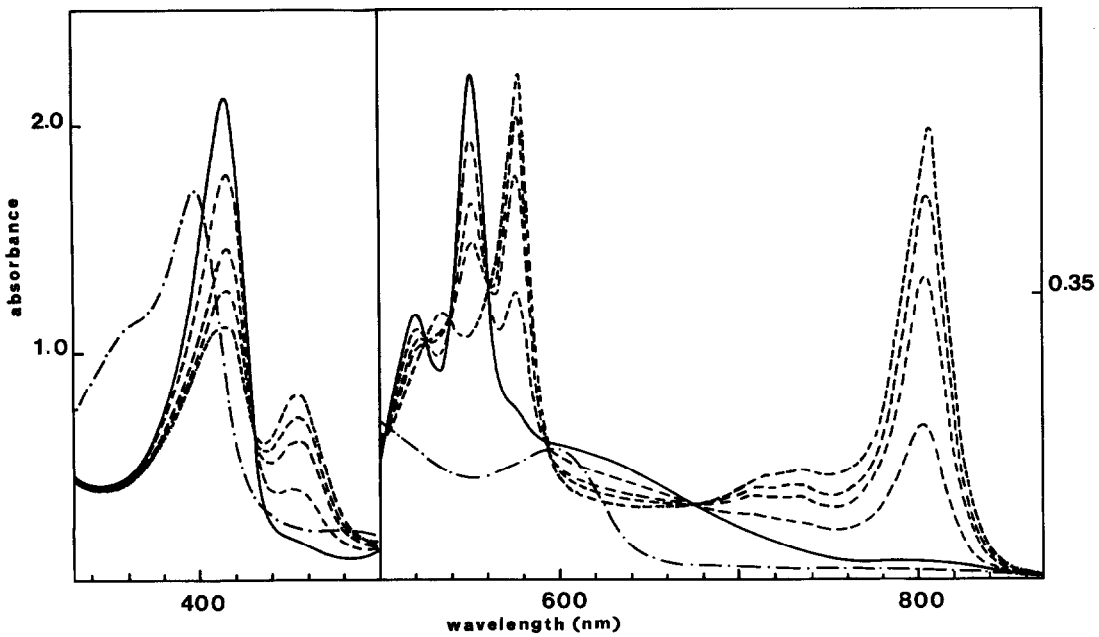


Fig. 1. Electronic spectra obtained from deaerated solutions (see Experimental) of Fe(III)PP Cl, containing a100-fold excess of pyrazine: (–·–·–) before irradiation; (——) immediately after 90 s of irradiation with $\lambda > 360$ nm; and (– – –) 15, 30, 45 and 120 min in the dark at 22°C, after irradiation.

of the rate of process (3) on the pyz:Fe concentration ratio.

As far as the nature of species X is concerned, the bifunctional character of the pyz ligand is in favour of a binuclear or polynuclear pyz-bridged Fe(II)PP species. The formation of mixed-valence [Fe(II)–Fe(III)] polynuclear species can be ruled out by the fact that the absorption spectrum of the irradiated solution does not undergo appreciable changes when dithionite is added.

An electronic spectrum quite similar to that of species X has been obtained by Furhop *et al.*[7] by reducing chlorohemin with an excess of dithionite in a pyz-containing alkaline aqueous solution. The authors suggested that a pyz-bridged Fe(II)PP dimer was the reduction product. Following the method used by Furhop *et al.*,[7] we have titrated with pyz a 35% ethanol–water solution of Fe(II)PP Cl at pH 11, which had been previously reduced with an excess of dithionite. We observed that the maximum intensity of the 805-nm band corresponds to a pyz:Fe concentration ratio of 1:1 rather than 1:2 obtained by the above-cited authors. On the basis of this result, we expect that in an eventual dimer compound the axial positions *trans* to the bridge are also occupied by pyz. The known enhancement in the basicity of the non-coordinated terminal nitrogen in this complex would favor the lengthening of the chain to form a polymeric species. This is supported by the isolation and characterization of bridged phthalocyaninate Fe(II) polynuclear compounds.[3,4]

Any attempt to isolate and then characterize the porphyrin polymeric compound was unsuccessful due to the extremely high sensitivity of the product towards the oxygen.

Electronic spectra

The electronic spectrum of the $(pyz)_2$Fe(II)PP monomer is similar to that of $(py)_2$Fe(II)PP, as far as the position and the intensity of the Soret and Q-bands are concerned (Fig. 1). The bis-pyridine complex, however, presents a band at 480 nm which has been attributed to an Fe(II) → pyridine charge-transfer (CT) transition.[8] This 480-nm absorption disappears in the bis-pyz complex which, in turn, exhibits a band at about 650 nm (Fig. 1). It seems plausible that this absorption corresponds to an Fe(II) → pyz CT transition, shifted to longer wavelengths with respect to the Fe(II) → pyridine transition, because pyz has π^*-orbitals at a lower energy than pyridine.[9]

Besides the presence of a sharp and intense absorption band at 805 nm, other features distinguish the spectrum attributed to the polymer from that of the monomer; that is, a less intense Soret band shifted from 415 to 455 nm, and a shift in the Q-bands from 520 to 530 and from 550 to 575 nm, respectively.

In order to investigate the role played by the bridge ligand in determining the observed spectral behavior, the above-described photochemical experiments were repeated in the same experimental conditions except that pip was used instead of pyz. The results indicate that: (i) in strong excess (5000-fold) of pip† the spectrum shows the Soret and Q-bands in the same positions as observed for $(pyz)_2Fe(II)PP$, indicating that $(pip)_2Fe(II)PP$ was the photoproduct; on the other hand, no evidence of bands attributable to CT transitions are observed in the visible region of the spectrum, in accordance with the lack of low-energy π^*-orbitals in the pip molecule; (ii) with a pip : Fe of 100 : 1, the spectrum changes in the dark after irradiation. The spectral variations are the same as those observed for the pyz complex as far as the Soret and Q-bands are concerned, but differ from them in that no absorptions are observed to increase in the red spectral region.

The fact that the same shift of the Soret and Q-bands is observed with pyz and pip can be taken as an indication of the formation also of polymeric species with the latter ligand.

The intense band observed at 805 nm in the case of the pyz Fe(II)PP polymer is likely to be due to a Fe(II) → pyz CT transition which, as a consequence of the polymerization, appears at longer wavelengths (805 nm) with respect to the monomeric species (650 nm) (Fig. 1). Similar shifts of d–π^* bands have been previously reported for ruthenium and iron ligand-bridged polynuclear complexes.[10] On the other hand, the shifts in the bands for these complexes are generally less dramatic, and the bands tend to be broader than in the present case.

Another potential explanation may be that of Fuhrop *et al.*[7] who ascribe the 805-nm band to a direct electron transfer involving two porphyrin chromophores, which should be favored in some way by the aromaticity of the bridge ligand.

As far as the Soret and Q-bands are concerned, the shift caused by the polymerization appears to be quite similar in both the pyz and pip complexes. Since these bands are π–π^* in origin, the shift is likely to be caused by a perturbation of the π-system of the porphyrin macrocycle, due to the face-to-face approach of the tetrapyrrolic rings. This statement is confirmed by the results obtained from photochemical runs carried out with bipy as the bifunctional ligand, in entirely identical conditions as those described above for pyz and pip. The absorption spectrum obtained after irradiation of Fe(III) PP Cl solutions (see Experimental) containing a 10-fold excess of bipy‡ is reported in Fig. 2 (spectrum a). Spectrum b in Fig. 2 represents the monomeric $(bipy)_2Fe(II)PP$ species, obtained by chemical (dithionite) reduction of Fe(III)PP Cl in an ethanol–water solution containing a 5000-fold excess of bipy. The red shifts of the Q-bands, which are attributable to polymer formation, are smaller than

† See footnote * on p. 1298.

‡ Spectral evidence of axial coordination of bipy is observed with a higher excess of ligand.

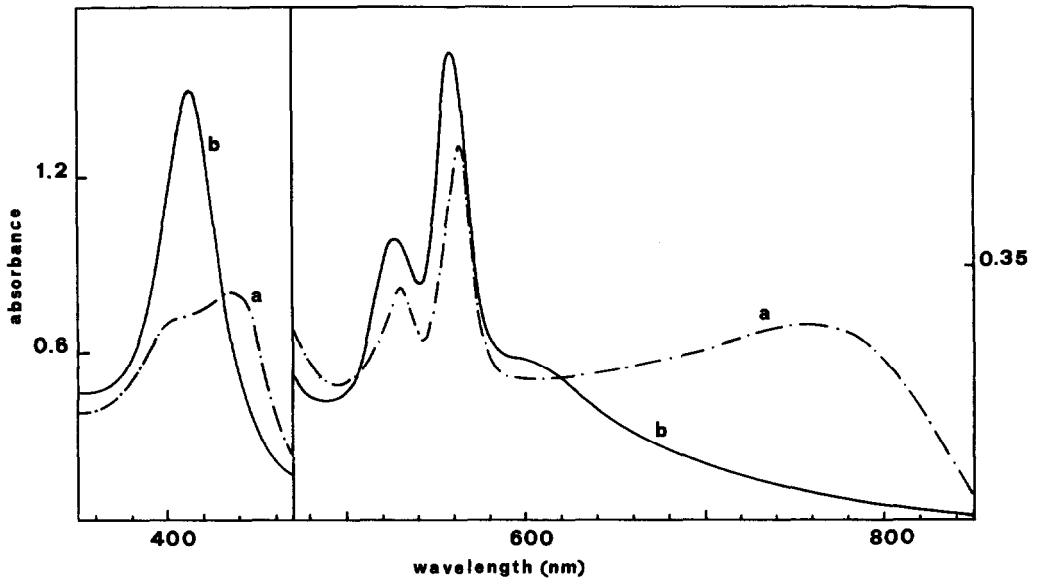

Fig. 2. (——) Electronic spectrum of $(bipy)_2Fe(II)PP$ obtained by addition of an excess of sodium dithionite to a Fe(III)PP Cl solution (see Experimental) in the presence of a 5000-fold excess of bipy, and (–·–·–) electronic spectrum obtained after irradiation with light of $\lambda > 360$ nm of Fe(III)PP Cl solution (see Experimental) containing a 10-fold excess of bipy.

those observed for pyz and pip polymers. This may be explained by a minor perturbation effect on the transitions due to an increased length of the bridge.

Owing to the aromaticity of the bridge molecule, the bipy Fe(II)PP polymer presents, as expected, an absorption in the red region of the spectrum, as observed for the analogous pyz compound. The shape of this band, however, appears to be strongly dependent on the nature of the bridge ligand.

SUBSTITUTION OF *ARACHNO*-4,6-$C_2B_7H_{13}$ CARBORANE

TOMÁŠ JELINEK, STANISLAV HEŘMÁNEK, BOHUMIL ŠTIBR* and JAROMIR PLEŠEK

Institute of Inorganic Chemistry, Czechoslovak Academy of Sciences, 250, 68 Řež near Prague, Czechoslavakia

(*Received* 25 *November* 1985; *accepted* 19 *December* 1985)

Abstract—Substitution of the 4,6-$C_2B_7H_{13}$ cluster yields a series of 3-X-4,6-$C_2B_7H_{12}$ (X = Cl, Br, I or HS), 5-X-4,6-$C_2B_7H_{12}$ (X = Br, I, HS or Bu), and 3,5-X_2-4,6-$C_2B_7H_{11}$ (X = D, Cl, Br or I) derivatives whose ^1H and ^{11}B NMR spectra are reported and discussed.

The 4,6-dicarba-*arachno*-nonaborane(13), 4,6-$C_2B_7H_{13}$ (Fig. 1), and its *C*-alkylderivatives have been used for the synthesis of a relatively large number of metallacarboranes and *closo*-boranes. The parent compound is available in high yields either by the oxidation of the *nido*-[7,9-$C_2B_9H_{12}$]$^-$ anion[1] or by acid hydrolysis of the *nido*-[6,9-$C_2B_8H_{10}$]$^{2-}$ dianion.[2] Surprisingly, no attention has so far been paid to boron substitution of the 4,6-$C_2B_7H_{13}$ cluster. We wish to report in this paper our preliminary results obtained in studying its electrophilic and, in part, nucleophilic substitution reactions.

Direct $AlCl_3$-catalyzed halogenation and/or sulphydrylation of 4,6-$C_2B_7H_{13}$ with CCl_4 (25°C, 4 h), Br_2 (CS_2, 25°C), I_2 (benzene, reflux, 6 h), and elemental sulphur (130°C, melt, 3 h) gives rise to mixtures of monosubstituted 3-X-4,6-$C_2B_7H_{12}$ (X = Cl, Br, I or HS), 5-X-4,6-$C_2B_7H_{12}$ (X = Br, I or HS), and disubstituted 3,5-X_2-4,6-$C_2B_7H_{11}$ (X = Cl or Br) derivatives. Uncatalyzed iodination (sealed tube, 100°C, 4 h) produced a mixture of 3-I, 5-I and 3,5-I_2 derivatives in which the disubstituted derivatives prevails. The mixtures were separated by column chromatography on silica gel in benzene–hexane (1 : 2). Prolonged deuteration of 4,6-$C_2B_7H_{13}$ in a DCl–$AlCl_3$–CS_2 system is ambient temperature afforded the 3,5-dideuterioderivative.

Of some interest is the observed 3-X-4,6-$C_2B_7H_{12}$: 5-X-4,6-$C_2B_7H_{12}$ ratio in the $AlCl_3$-catalyzed reactions varying with the substitution agent used and sharply descending in the series Cl (only 3-isomer is formed) > Br ~ HS (3 : 2) > I (1 : 10), while a reverse (10 : 1) ratio of 3-I and 5-I derivatives was observed in the uncatalyzed iodination. Quantum chemical calculations on 4,6-$C_2B_7H_{13}$ suggest a preference for electrophilic substitution at the B(3) and B(8) sites.[3] The observed substitution of the relatively positive B(5) vertex, however, contrasts with the calculated data, which is indicative of an alternative substitution mechanism.

In fairly good agreement with the quantum chemical results is the reaction of 4,6-$C_2B_7H_{13}$ with butyllithium in ether–hexane (3 : 2) to produce 5-Bu-4,6-$C_2B_7H_{12}$ on decomposing the reaction mixture with anhydrous HCl. The result is consistent with a nucleophilic addition of the [C_4H_9]$^-$ anion at the B(5) atom to form an intermediate [5-Bu-4,6-$C_2B_7H_{13}$]$^-$ anion which loses H_2 on proton attack and generates 5-Bu-4,6-$C_2B_7H_{12}$.

Substitution of the B(3) and B(5) vertices in 4,6-$C_2B_7H_{13}$ does not bring any symmetry change and therefore the number and intensity of individual ^1H and ^{11}B NMR signals are the same as in the parent

[d] Relevant data for the parent compound for comparison.

[e] Three additional signals at δ 2.17 (t, CH_3), 1.13 and 1.41 (m, CH_2 groups) ppm.

compound. Assignments of signals (Tables 1 and 2) are based on previous works[3,4] and the recent[5] two-dimensional $\{^{11}B\text{–}^{11}B\}$ NMR study of $4,6\text{-}C_2B_7H_{13}$.

For monohalogenated compounds, inspection of Table 2 immediately reveals a trend of decreasing shielding of the substituted atoms in the order $\sigma(I) > \sigma(HS) > \sigma(Br) > \sigma(Cl)$. There is a fairly good linear correlation of relevant $\Delta\delta$ values (δ_i^s for substituted $-\delta_i^p$ for parent compound) for 3- and 5-substituted compounds with the electronegativity of the substituent, the low-field shift being more pronounced in the 3-substituted series due to a higher electron density at B(3).

Taking into account the mean effect of halogen

[c] Singlets of substituted atoms.

substituents on the shielding of adjacent and *meta*-atoms, a general trend for a decrease in shielding in the order $\sigma(Cl) > \sigma(Br) > \sigma(I)$, i.e. in the order of decreasing ability of the substituent nonbonding electron pairs to share their electron density with the cluster, is readily seen from Table 2. Due to a lower electron density at the B(5) site, both effects are more pronounced in the 5-substituted series in which a remarkable antipodal shielding[6] of the B(8) atom, decreasing in the same order, is observed. The same trends caused by combined effects of the two substituents are clearly seen in the 3,5-dihalogenated series.

To draw more general conclusions on the effect of substituents on the NMR shielding in the 4,6-$C_2B_7H_{13}$ framework, we are presently engaged in developing methods for obtaining derivatives substituted on other cluster atoms.

SPECTROPHOTOMETRIC INVESTIGATIONS OF BINARY AND TERNARY COMPLEXES OF Cd(II), METHYLTHIOUREA AND HALIDE IONS IN AQUEOUS SOLUTION

JOANNA MASŁOWSKA* and ELŻBIETA CHRUŚCIŃSKA

Institute of General Food Chemistry, Technical University of Łódź, 90-924 Łódź, Stefanowskiego 4/10, Poland

(*Received* 20 *September* 1985; *accepted* 6 *November* 1985)

Abstract—The results of spectrophotometric investigations of mixed-complex formation equilibria of Cd(II), methylthiourea (MeTU) and halide ions (Cl^-, Br^- and I^-) in aqueous solution have been reported. The formation of binary and ternary complexes has been found. The values of the equilibrium constants (log units) for the reaction $MA_2+MB_2 \rightleftharpoons 2MAB$, are 1.03 ± 0.10, 1.17 ± 0.12 and 1.34 ± 0.08 for $[CdMeTUCl]^+$, $[CdMeTUBr]^+$ and $[CdMeTUI]^+$, respectively. It was found that the stability of ternary complexes depends on the values of the normal redox potential of halide ions.

The spectrophotometric method was used to determine the equilibrium constants of the mixed complexes of mercuric halides[1] and the mixed complexes of Cu(II) with pyrophosphate and ethylenediamine,[2] ethylenediamine and iminodiacetate[3] and ethylenediamine and oxalate.[4] Because of lack of data for the mixed complexes of Cd(II) with methylthiourea (MeTU) and halide ions, we undertook the studies in this field. In our previous papers[5,6] we proved the formation of the mixed complexes of Cd(II) with derivatives of thiourea and halide ions using electrochemical methods: potentiometry and polarography. Thus it seemed to be appropriate to use the spectrophotometric method to study the equilibrium reaction of the formation of mixed complexes in similar systems, in order to find new experimental data and extend the information about these little known complexes.

EXPERIMENTAL

Reagents

Triply distilled water was used. *N*-methylthiourea was recrystallized from water–ethanol mixtures and dried *in vacuo* over P_4O_{10}. Cadmium perchlorate was prepared by treating cadmium oxide with perchloric acid. $Cd(ClO_4)_2$ solution was standardized by a complexometric method.[7] Sodium chloride, bromide and iodide were purified by crystallization from aqueous solution. NaCl, NaBr and NaI solutions were standardized by argentometric methods. All stock solutions were acidified with $HClO_4$ to pH = 2.0 to prevent any hydrolysis of the complexes. The concentrations used were selected according to Spiro and Hume's data.[1] The concentration of Cd(II) was kept constant, 5×10^{-5} M; total concentration of NaCl (NaBr, NaI) and that of MeTU was about 0.01 M. The ionic strength of solutions was $\mu = 0.02$.

Apparatus

The measurements were recorded on a Specord UV–Vis (Carl Zeiss, Jena) spectrophotometer in the range of λ = 200–300 nm with 1-cm quartz cells.

Measurement method and calculation procedure

Spiro and Hume[1] described a spectrophotometric method for the determination of the equilibrium constant, K, for the reaction of the mixed-complex formation [(1)]:

$$MA_2+MB_2 \rightleftharpoons 2MAB. \quad (1)$$

The equilibrium constant K for the reaction (1) is

* Author to whom correspondence should be addressed.

given by eqn (2):

$$K = \frac{4\alpha_{11}^2}{(1-\alpha_{11})^2-(1-R/1+R)^2}, \quad (2)$$

hence:

$$\alpha_{11} = \frac{1}{1-4K^{-1}}\left(1 \pm \sqrt{1-\frac{4R}{(1+R)^2}(1-4K^{-1})}\right), \quad (2')$$

where

$R = c_{MB_2}/c_{MA_2}$,
$\alpha_{11} = [MAB]/c_M$ (the mole fraction of metal ion present as the complex MAB),
c_M = the total concentration of metal,
c_{MA_2} and c_{MB_2} = the total concentrations of binary complexes, MA_2 or MB_2.

The equilibrium constant K can be calculated for each value of R, if the value of α_{11} is known. The value of α_{11} can be determined from the spectrophotometric data. The total absorbance of solution of three species MA_2, MB_2 and MAB is given by eqn (3):

$$A = \varepsilon_{20}[MA_2]+\varepsilon_{11}[MAB]+\varepsilon_{02}[MB_2], \quad (3)$$

where ε_{20}, ε_{11} and ε_{02} are the molar absorptivities of MA_2, MAB and MB_2, respectively. From the stoichiometry of the reaction (1) and eqn (3), the result is:

$$\varepsilon = \varepsilon_{11} - \frac{\varepsilon_{20}+\varepsilon_{02}}{2}, \quad (4)$$

$$\Delta A = A-(\varepsilon_{20}c_{MA_2}+\varepsilon_{02}c_{MB_2}), \quad (5)$$

$$\alpha_{11} = \frac{\Delta A}{\Delta\varepsilon c_M}. \quad (6)$$

If the absorptivity of the mixed complex is the same as the absorptivity of the binary complexes, $\Delta\varepsilon = 0$, then there is no spectrophotometric evidence of mixed-complex formation. On the other hand, the greater the value of $\Delta\varepsilon$ which can be obtained relative to the total molar absorbance, the greater will be the sensitivity of the measurements. Therefore, the calculations should be carried out at those wavelengths where $\Delta\varepsilon$ is greatest. In eqn (5), c_{MA_2} and c_{MB_2} are known and values of ε_{20} and ε_{02} can be measured, while values of ε_{11} can be determined at low or high values of R. For those values of R one of the binary complexes is present in excess, and the other is converted to the mixed complex. The result is a two-component mixture, for which the single unknown α_{11} can be easily determined. Equations (7) and (8) can be obtained for these conditions:

(for low R)

$$A-\varepsilon_{20}c_{MA_2} = (2\varepsilon_{11}-\varepsilon_{20})c_{MB_2}, \quad (7)$$

(for high R)

$$A-\varepsilon_{02}c_{MB_2} = (2\varepsilon_{11}-\varepsilon_{02})c_{MA_2}. \quad (8)$$

The plots of the left-hand side of eqns (7) and (8) against c_{MB_2} or c_{MA_2}, respectively, should be straight lines passing through the origin. From their slopes ε_{11} can be calculated. As R approaches unity, the solutions change from two- to three-component systems, and the above plots then deviate from linearity (provided $\Delta\varepsilon \lesssim 0$). The statement of this deviation is very important because it is the evidence for mixed-complex formation. If no deviation occurs, the solutions always contain two components, and the plots are linear over the entire concentration range. In the present paper, absorptivities of the mixed complexes were calculated from linear plots of $A-\varepsilon_{20}c_{MB_2}$ vs c_{MB_2} at low R and of $A-\varepsilon_{02}c_{MA_2}$ against c_{MA_2} at high R. The resulting spectra are shown in Figs 1–3. For each system, the absorptivities were determined at maximal values of $\Delta\varepsilon$. Values of ε_{20} and ε_{02} were calculated as the slopes of absorbance vs concentration plots for the binary complexes, while ε_{11} was determined from linear plots at low and high R. The results are shown in Table 1.

RESULTS AND DISCUSSION

For formation of mixed complexes, of type $[CdMeTUX]^+$, where X = Cl, Br or I, has been

found. Values of α_{11} were calculated for each point in the vicinity of R equal to unity and plotted vs log R (Fig. 4). The equilibrium constant was calculated for each point and log K was averaged for all points in each researched system (Table 2).

An analysis of the plots, presented on Fig. 4, indicates a scatter in the points resulting from different wavelengths of the research solutions. This is a reflection of inaccuracies in the spectrophotometric measurements. There are two principal sources of error in the above spectrophotometric method. One is the uncertainty in the determination of α_{11}, which depends on the experimental technique used and which is increased in the subsequent calculation of K. Differentiation of eqn (2′) with respect to α_{11} at $R = 1$ (where the highest accuracy in determining K is to be expected) provides eqn (9):

$$\frac{dK}{K} = (K^{1/2}+2)\frac{d\alpha_{11}}{\alpha_{11}}, \qquad (9)$$

which means that a small relative error in the determination of α_{11} is magnified by a factor of $(K^{1/2}+2)$ in calculating K even at the point of greatest accuracy. Clearly, the determination of large constants involves a considerable uncertainty on theoretical considerations alone.

The other possible and serious source of error is the assumption that the equilibrium reaction of the formation of the mixed complex is mainly fixed and

$[CdMeTUI]^+$	1.34±0.08

that both the dissociation and disproportionation of the binary complexes are not being considered. This means that the accepted concentrations of species can differ considerably from those existing in the researched solutions.

We conclude that the present method is less precise than the potentiometric and polarographic methods described in our previous papers.[5,6] In order to explain the relations existing between changes of mixed complex stability and redox properties of halide ions, the plot of log K vs the normal redox potential of halide ions has been drawn (Fig. 5). The above relation shows the mixed-complex stability increases after the addition of halide ion with the greater reducing action, in the following order:

$$[CdMeTUCl]^+ < [CdMeTUBr]^+ < [CdMeTUI]^+.$$

This indicates that Cd(II) forms mixed complexes in which a significant contribution of the covalent bond between Cd(II) and halide ions occurs with a small E_x°.[8]

SPECTROSCOPIC AND STRUCTURAL PROPERTIES OF HOMONUCLEAR Fe(II) POLYMERIC COMPOUNDS—II. THERMAL DECOMPOSITION PRODUCTS OF $[Fe(PYRAZINE)_2X_2]_n$

K. RACHLEWICZ*, J. PIETRZYK and K. DRABENT

Institute of Chemistry, University of Wrocław, 50-383 Wrocław, F. Joliot-Curie 14, Poland

(*Received* 22 *July* 1985; *accepted* 6 *November* 1985)

Abstract—The thermal decomposition of $[Fe(pyz)_2X_2]_n$ (where pyz = pyrazine and X = Cl, Br or I) was investigated. For the chloride and bromide complexes the decomposition proceeds in two stages in which two pyrazine molecules dissociate successively, whereas in the iodide complex both pyrazine molecules dissociate in a single stage. Spectroscopic measurements (UV, Vis, Raman and Mössbauer spectra) indicate that intramolecular rearrangement resulting from dissociation of one pyrazine molecule leads to a change in coordination from FeN_4X_2 characteristic of initial compounds, $[Fe(pyz)_2X_2]_n$, to FeX_4N_2 characteristic of $[Fe(pyz)X_2]_n$ which is accomplished through both pyrazine and halide bridges. Thus, polymers are being formed in which the $(FeX_2)_n$ chains are being bridged by the pyrazine molecules. The magnetic moments of monopyrazine intermediate compounds are independent of temperature and low-temperature magnetic measurements do not indicate any magnetic ordering above 4.2 K.

The FeL_4X_2 compounds (where L = pyridine and its derivatives),[1,2] and FeL_2X_2 compounds (where L = 2,2′-bipyridyl, 1,10-phenanthroline and its derivatives, and X = Cl, Br, I, NCS or NCO),[3–6] undergo thermal decomposition at temperatures above 100°C. In the first stage of thermal dissociation two coordination positions are liberated and—as a result of intramolecular rearrangement—polymeric compounds with the halide or pseudohalide bridges of the FeL_2X_2 and $FeLX_2$ formulae, respectively, are formed. The FeL_2X_2 compounds (L = ligands coordinating through nitrogen and sulphur) with the polymeric pseudo-octahedral and monomeric pseudotetrahedral structures may also be prepared by wet synthesis. This group of compounds attracts attention because of the existence of metamagnetic transitions and a structural-phase transition in certain of these complexes.

The compounds with pyrazine of formula $[Fe(pyz)_2X_2]_n$ (X = Cl, Br or I) were prepared by direct synthesis.[7] The structure of these compounds was defined as pseudo-octahedral polymeric with pyrazine bridges. Thermal decomposition of $[Fe(pyz)_2Cl_2]_n$ was investigated by Beech *et al.*[8] The authors found this compound to decompose in two stages in which the pyrazine molecules are being released successively:

$$Fe(pyz)_2Cl_2 \rightarrow Fe(pyz)Cl_2 \rightarrow FeCl_2.$$

The authors have incorrectly determined the structure of the initial compound and did not attempt to determine the structure of the monopyrazine intermediate compound.

The present paper deals with spectroscopic (UV, Vis, IR, FIR, Raman and Mössbauer) and magnetochemical studies of intramolecular rearrangement resulting from dissociation of the ligand molecule and with determination of the product structure.

EXPERIMENTAL

The products of the first stage of thermal decomposition of $Fe(pyz)_2X_2$ (where X = Cl or Br) were analysed as $Fe(pyz)X_2$.

$Fe(pyz)Cl_2$. Found: Fe, 27.0; C, 23.3; H, 2.0; N, 13.5; Cl, 34.3%. Calc. for $Fe(pyz)Cl_2$: Fe, 27.0; C, 23.2; H, 1.9; N, 13.5; Cl, 34.3%.

$Fe(pyz)Br_2$. Found: Fe, 18.8; C, 16.3; H, 1.4; N, 9.5; Br, 54.1%. Calc. for $Fe(pyz)Br_2$: Fe, 18.9; C, 16.2; H, 1.4; N, 9.5; Br, 54.0%.

Physical measurements

Diffuse-reflectance electronic spectra in magnesium oxide were recorded on a Beckman 5240.

The IR spectra in the region 4000–20 cm^{-1} were obtained on a Perkin–Elmer 180 spectrometer in both KBr pressed pellets and Nujol mulls.

The Raman spectra were measured by means of a JEOL IRS-S1 spectrophotometer using the 488- and 514.5-nm exciting lines of an Ar-ion laser. The magnetic measurements were made on either a Gouy or a Faraday balance calibrated with $HgCo(NCS)_4$. The diamagnetic corrections were applied using Pascal's constants. The Mössbauer effect measurements of powders were done on a Mössbauer 2330 spectrometer (Polon, Poland). Measurements were made at 80 and 295 K. The isomer shift (IS) values was related to a sodium nitroprusside (SNP) standard. ^{57}Co in a chromium matrix of 20-mCi activity was used as the source. The source and SNP during all measurements were stored at room temperature. The spectra were processed numerically by distribution into Lorentz curves.

Carbon, hydrogen, nitrogen and halide analyses were performed by the Analytical Laboratory of the Institute of Chemistry, University of Wrocław.

Iron was determined by using dichromate titrimetry.

RESULTS AND DISCUSSION

The $[Fe(pyz)_2X_2]_n$ complexes (X = Cl or Br) undergo thermal decomposition according to the scheme suggested by Beech *et al.*,[8] whereas the iodide compound decomposes in a single stage with simultaneous detachment of both pyrazine molecules. The TG and DTG curves are shown in Fig. 1. Depending on process conditions up to 1000°C the final product is FeX_2 or Fe_2O_3.

Elementary analysis and physicochemical studies of intermediate monopyrazine compounds indicate that they are sufficiently pure for spectroscopic and magnetic studies.

The magnetic susceptibility was examined as a function of temperature over the 4.2–293 K range. Over this temperature range the monopyrazine chloride and bromide complexes obey the Curie–Weiss law. The magnetic moment is independent of temperature and characteristic of the pseudo-octahedral, high-spin iron(II) complexes.

The electronic spectra of the compounds investigated exhibit two well-resolved bands in the NIR region and a CT band at 20,800 cm^{-1} whose energy is independent of the X substituent. The bands found in the NIR region should be assigned to intraconfigurational *d–d* transitions which are typical of Fe(II) with the high-spin d^6 structure in the distorted octahedral field.[9,10] These are transitions from the ground state $^5T_{2g}$ to the excited state E_g which becomes split in the low-symmetry field into $^5B_{1g}$ and $^5A_{1g}$. The parameters of the *d–d* bands are presented in Table 1. The $\nu_1 - \nu_2$ parameter deter-

$Fe(pyz)Br_2$	9500	6000	3500	7750

[a] All data in cm^{-1}.

mines the value of splitting for the ^5E_g state, whereas ν_{av} is the arithmetic mean of the energy values for both bands. A considerable increase in $\nu_1-\nu_2$ and a decrease in ν_{av} with respect to those found for the initial $[Fe(pyz)_2X_2]_n$ complexes[7] indicates a molecular rearrangement resulting from thermolysis and leading to a change in the coordination type from FeN_4X_2 to FeX_4N_2. This type of chromophore is characteristic of the polymeric compounds containing halide bridges, for instance $[Fe(py)_2X_2]_n$.[1] In comparison with the pyridine compounds the monopyrazine compounds with the same type of FeX_4N_2 chromophore exhibit lower values of $\nu_1-\nu_2$ splitting, an increase in the value of that parameter on changing from the chloride compounds to bromide compounds being comparable in both types of compounds. On the other hand, higher values of the ν_{av} parameter (which is equivalent to the $10Dq$ parameter in the crystal field approximation) are observed. The differences found may be explained as due to stronger π-acceptor properties of pyrazine as compared to pyridine. According to the Jørgensen's principle[11] of mean environment the effect of π-acceptor properties of pyrazine is weaker for $[Fe(pyz)X_2]_n$ than that observed for the $[Fe(pyz)_2X_2]_n$ compounds.

The IR and Raman spectra of the compounds investigated over the medium IR range exhibit bands of pyrazine which become slightly shifted with respect to those found for the parent complexes.[12-14,7] As in the case of the initial $[Fe(pyz)_2X_2]_n$ compounds, also in their thermal decomposition products no band coincidence in the IR and Raman spectra occurs.[7] This is evidence for the presence of the symmetry centre in the coordinated pyrazine molecule[16,17] and indicates that the pyrazine bridges appear in the compounds under investigation. A decrease in the ν(Fe—X) frequency found in the FIR spectra in comparison to those found for $[Fe(pyz)_2X_2]_n$[7] by 20 cm^{-1} for the chloride compound and 30 cm^{-1} for the bromide compound suggests that halide bridges occur also in the monopyrazine complexes.

The results obtained indicate that the FeX_4N_2-type coordination in the compounds under investigation is accomplished through both the halide and pyrazine bridges.

Mössbauer spectroscopy is considered to be particularly useful for investigation of intramolecular rearrangement in the solid phase.[18] Mössbauer spectra of the monopyrazine compounds that result from thermal decomposition of the $[Fe(pyz)_2X_2]_n$ compounds consist of well-formed quadrupole doublets with narrow lines; their quadrupole splitting parameters (QS) and IS parameters are presented in Table 2. The values of IS are characteristic of the suggested structure containing hexacoordinated, high-spin Fe(II). The values of IS are about 1.3 mm s^{-1} and are almost identical to those for the polymeric compounds $Fe(py)_2X_2$,[1] $Fe(phen)X_2$[6] and $Fe(bipy)X_2$[3-5] investigated earlier which contain iron surrounded by FeX_4N_2. A comparison of this parameter for the initial compounds and thermolysis products shows that the parameter decreases in the series:

$$FeX_2 > Fe(pyz)X_2 > Fe(pyz)_2X_2.$$

A decrease in the IS parameter results from an increase in electron density on the iron nucleus as a result of electron descreening by the *d*-electrons whose density on the iron atom decreases because of the π-acceptor effect of pyrazine. This interaction is most effective for $Fe(pyz)_2X_2$ and is confirmed

by the conclusions resulting from interpretation of the electronic spectra.

The values of QS are characteristic of the compounds with the FeX_4N_2 type of coordination.[1-6] This confirms the conclusion that—as a result of thermal dissociation of one pyrazine molecule—intramolecular rearrangement takes place leading to the formation of a spatial polymer in which the $(FeX_2)_n$ chains are bridged by the pyrazine molecules (Fig. 2).

In comparison with the initial compounds, the products of their thermal decomposition exhibit a considerable difference in the value of QS on changing from the chloride compound to the bromide compound. This might also be explained by the reduced effect of the π-acceptor interactions of pyrazine in the monopyrazine complexes.

The temperature dependence of the QS observed results from the Boltzman population effect; magnetic studies over the temperature range 4.2–298 K are not indicative of any phase transitions in the complexes under investigation as is the case for $[Fe(py)_2Cl_2]_n$.[1] This transition is related to the transformation of a symmetric chloride bridge into an asymmetric one, something that cannot occur in the monopyrazine compounds because of the increased stiffness of the molecule that is afforded by the additional pyrazine bridges.

(*Received* 24 *June* 1985; *accepted after revision* 11 *November* 1985)

Abstract—The synthesis and physicochemical characterization of Co(II) and Cu(II) complexes of the title ligands are reported. Effective magnetic moment values and electronic diffuse-reflectance and solution spectral features along with ligand field parameters classify the Co(II) and Cu(II) complexes as six-coordinated. Vibrational spectral data furnish meaningful information regarding the bonding sites of the title ligands.

In view of the significant importance of pyridimidine derivatives in many bio-systems, we report herein, in continuation of our recent publication,[1] the synthesis and characterization of Co(II) and Cu(II) complexes of the title ligands.

EXPERIMENTAL

[GPym = 6 - guanidino - 2,4 - dimethyl - 1,3 - diazine (pyrimidine), and PGPym = 6 - phenylguanidino - 2,4 - dimethyl - 1,3 - diazine (pyrimidine)] $M(GPym/PGPym)_2X_2 \cdot (H_2O)_n$[M = Co(II); X = Cl, Br, I, ClO_4 or BF_4; $n = 0$ or 2: M = Cu(II), X = CH_3COO, $n = 0$]. The general preparative method consisted of refluxing an ethanolic solution of a mixture of the ligand and the corresponding hydrated M(II) salt in 1:2 ratio at water-bath temperatures for 30 min. The resultant solution was concentrated to half its original volume by heating on a steam bath and then kept at room temperature in a desiccator over fused $CaCl_2$. The coloured microcrystalline solid which separated out was filtered off, washed with cold ethanol and dried over silica gel. The complex species on recrystallization from methanol did not afford crystals large enough for X-ray diffraction work.

The complexes of Cu(II), namely $Cu(GPym/PGPym)_2X_2$ (X = Cl, Br or SCN) were prepared by refluxing an ethanolic solution of $Cu(GPym/PGPym)(CH_3COO)_2$ with a saturated solution of the ammonium salt of the corresponding anion for 30 min. The deep-brown solution was, in each case, concentrated to a smaller bulk by heating on a steam bath. On cooling to room temperature (31°C) the brown compounds separated out and were filtered off. Upon recrystallization from water–ethanol mixtures the complexes were obtained in a brownish, microcrystalline state, but no single crystals could be isolated. Co(II) thiocyanate complexes of both the ligands were obtained by metathesis reactions of the corresponding chloro complex with potassium thiocyanate in dry ethanolic medium for 15 min at water bath temperatures; in each case a reddish-violet product was isolated. The metals were analysed by standard analytical procedures. Carbon and nitrogen were estimated by the departmental microanalytical laboratory. Different physicochemical measurements were carried out as described earlier.[1]

RESULTS AND DISCUSSION

The characterization of both ligands has been reported in a previous paper[1] from mass spectral and PMR data. All the metal complexes of Co(II) and Cu(II) give satisfactory C, N and metal analysis (Table 1). The room-temperature magnetic-moment values (Table 1) of Co(II) are above the spin-only value of 3.89 BM for high-spin, octahedral complexes due to a high orbital contribution.[2] The observed magnetic moments, in the

[a] M—N (pyrimidine).
[b] M—N (guanidine).
[c] Including nitrogen present in thiocyanate.

range 1.70–1.80 BM at room temperature for Cu(II) complexes, are consistent with the presence of a single unpaired electron and furnish no other stereochemical information unlike other first-row divalent transition metal complexes. Molar-conductance values[3] (Table 1) suggest that these complexes are either 1 : 1 or 1 : 2 in nature, depending on the counter-ion (X), and the data may be reconciled in terms of equilibria of the following types:

$$M(GPym/PGPym)_2X_2 + DMF \rightleftharpoons [M(GPym/PGPym)_2 \cdot X \cdot DMF]^+ + X^-, \quad (1)$$

where M = Co(II) or Cu(II); X = Cl, Br, I or SCN.

$$M(GPym/PGPym)_2X_2 + 2DMF \rightleftharpoons [M(GPym/PGPym)_2(DMF)_2]^{2+} + 2X^-, \quad (2)$$

where M = Co(II), X = ClO_4 or BF_4.

In the diffuse-reflectance spectra of Co(II) complexes, two principal bands are observed in the range 8000–9600 and 18,400–21,000 cm^{-1}, respectively, and these are assigned to ν_1 and ν_3 transitions for an octahedral ligand environment around the Co(II) ion. There are two other weak bands in the region of 17,800 and 20,400 cm^{-1} (on both the low- and the high-energy side of ν_3) and they may be the result of splitting the $^4T_{1g}(P)$ state due to spin–orbit coupling or tetragonal distortion.[4] Hence, the pink variety of Co(II) complexes may have a pseudo-octahedral configuration. This proposition is further substantiated by calculated values of Dq, B and β from standard relationships and low values of molar extinction coefficients (ε_{molar} 1.01–13.65) of the main spectral bands in DMF solutions of the species. Additional shoulders around 14,200 cm^{-1} in the cases of $Co(PGPym)_2X_2$ (X = Cl or Br) are likely to be of symmetry-split–spin-allowed transitions[5] in a lower symmetry field.

Six-coordinate Cu(II) complexes might exist in either D_{4h}- or C_{4v}-symmetry, and the d_γ- and d_ε-levels of the ^2D free ion term will further split into B_{1g}, A_{1g} and B_{2g}, E_g levels, respectively. Thus, three spin-allowed transitions [ν_1 ($^2B_1 \rightarrow {}^2A_1$), ν_2 ($^2B_1 \rightarrow {}^2B_2$) and ν_3 ($^2B_1 \rightarrow {}^2E$)], predicted for Cu(II) complexes of D_{4h}-symmetry,[6] are observed in the examined Cu(II) complexes as a broad maxima in the range around 14,700–17,000 cm^{-1} with poorly resolved shoulders on the low-frequency side in the diffuse-reflectance spectra of the Cu(II) complexes. In DMF, absorption peaks are shifted to lower-frequency regions as compared to the solid-state spectrum—suggesting a considerable degree of solvation. In the absence of single-crystal polarized spectra[7] or magnetic circular dichroism studies[8] no definite conclusion regarding spectral assignments can be made.

In the IR spectra of all these metal complexes, the bands in the 3μ region arising due to ν_{asy}(N—H) (3300–3390 cm^{-1}) and ν_{sy}(N—H) (3100–3140 cm^{-1}) modes of vibration of the guanyl group[9] remain practically unaltered as compared to those of the uncomplexed ligands, with only slight decreases in intensities, suggesting participation of the ligands

Table 2. Anion frequencies with probable assignments[a]

Compound	Anion band (cm^{-1})	Assignment

[a] vs = very strong, s = strong, m = medium, w = weak.

in complex formation without deprotonation. The most probable involvement of the imino nitrogen (>NH) of the guanidine moiety of the title ligands in complex formation with Co(II) and Cu(II) is substantiated by a negative shift of the order of 10 ± 5 cm^{-1} of the ν(C≡N) stretching band of the guanidine part of both the ligands appearing around 1650 cm^{-1} in the free ligands.[10] IR bands due to the 1:3 diazine (pyrimidine) system have been found to experience shifts in the higher-energy side ($\Delta\nu \sim 10\pm5$ cm^{-1}) in the metal complexes, indicating expected involvement of the pyrimidyl ring nitrogen in complexation;[11] this is in agreement with our earlier observations.[12] The above proposition has been further substantiated by far-IR data (down to 200 cm^{-1}) of some of the metal complexes (Table 1) through appearance of new bands (absent in the free ligands) in the ranges 238–265 cm^{-1} and 530–542 cm^{-1} which may safely be assigned to ν(M—N)(Pym)[13] and ν(M—N)(guanidine),[14] respectively. The diagnostic band frequencies of the polyatomic counterions with probable assignments (Table 2) indicate their monodentate nature.

The IR bands appearing around 340–295 cm^{-1} assigned to ν(M—Cl) and around 280–265 cm^{-1} due to ν(M—Br) [M = Co(II) and Cu(II)] indicate the coordinated nature of the chloro and bromo groups,[15] respectively. The absence of any recognizable bands for rocking and wagging modes of vibrations due to water molecules indicates their non-coordinating nature. The lattice nature of water molecules is further substantiated by the appearance of a broad diffuse band around 3500 cm^{-1} in the IR spectra of those complexes. Mass-loss data on heating samples with attached water molecules at 120°C may be considered as additional evidence for the lattice water molecules.

Acknowledgements—We are thankful to Sri Subhas Maikup, R.S.I.C., Eastern Zone, India, for providing diffuse-reflectance and solution spectra of the metal complexes.

MIXED ALKYL ISOCYANIDE–1,4-DIAZA-1,3-BUTADIENE COMPLEXES OF CHROMIUM—II.* SECONDARY-ION, ELECTRON IMPACT AND CHEMICAL-IONIZATION MASS SPECTROMETRY OF THE 18-ELECTRON SPECIES $Cr(CO)_3(CNR)(R'\text{-DAB})$

LISA D. DETTER and RICHARD A. WALTON†

Department of Chemistry, Purdue University, West Lafayette, IN 47907, U.S.A.

(*Received* 11 *October* 1985; *accepted* 14 *November* 1985)

Abstract—Mass analysis of the 18-electron mixed isocyanide–1,4-diaza-1,3-butadiene complexes $[Cr(CO)_3(CNR)(R'\text{-DAB})]$ (R = Me, $CHMe_2$, CMe_3 or xylyl; R′ = *i*-Pr, *t*-Bu or Cy) was undertaken using secondary-ion mass spectrometry (SIMS), electron impact (EI) mass spectrometry and both positive- and negative-ion chemical-ionization (CI) (PICI and NICI) mass spectrometry. With the exception of the PICI spectra, abundant molecular ions were not present. In all instances, well-defined, structurally informative fragment ions were identified which arise by loss of CO and/or the intact RNC and R′-DAB ligands. Cleavage of the RNC ligands (dealkylation) occurs in the SIMS and EI spectra to give fragment ions containing $[Cr(CNH)]^+$, whereas only in NICI are fragments observed in which the cyano moiety $[Cr(CN)]^+$ is present. High-abundance carbonyl-containing fragments are seen only in the case of the CI spectra and are most common in the NICI measurements. These trends are discussed in the light of the Cr–ligand bonding.

Fast atom bombardment (FAB), secondary-ion mass spectrometry (SIMS) and allied techniques are being increasingly applied to the characterization of non-volatile and/or thermally labile coordination complexes and organometallics.[2] While other groups have focused their attention upon the use of the FAB–MS technique using liquid matrices,[3] we have employed SIMS with solid-phase samples. Previous studies have involved a general survey of organometallic and coordination complexes,[4] β-diketone complexes of the transition metals,[5] phosphine complexes and phosphonium salts,[6] nickel(II) complexes on oxide supports,[7] Ag(I) complexes,[8,9] and various isocyanide complexes of Cu,[10] Ag,[8,10] Cr[11,12] and Mo.[11]

In the SIMS experiment the secondary ions ejected upon surface bombardment are mass analyzed using conventional methods. Although it is formally a surface-sensitive technique, SIMS can clearly be used for the bulk analysis of inorganic complexes. With our understanding of the general types of processes which can lead to the formation of secondary ions now well-established,[4] we have increasingly turned our attention to a comparison of results obtained by this technique with those emanating from related types of mass spectrometry. Our previous study of the SIMS and laser desorption mass spectra of β-diketonate complexes[5] is a case in point. We now report the results of a comparative SIMS, electron impact (EI) mass spectrometry, and chemical-ionization (CI) (both positive and negative ions) study of a series of mixed alkyl isocyanide–1,4-diaza-1,3-butadiene complexes of chromium of stoichiometry $Cr(CO)_3(CNR)(R'\text{-DAB})$ [R = Me, $CHMe_2$, CMe_3 or xylyl; R′-DAB = R′N=CH—CH=NR′, where R′ = *i*-Pr, *t*-Bu or Cy (cyclohexyl)]. These complexes were available from an earlier study[1] in which we had examined the preparation and characterization of the series of 17-, 18- and 19-electron species of type $[Cr(CO)_3(CNR)(R'\text{-DAB})]^{+,0,-}$.

* For Part I, see Ref. 1.

EXPERIMENTAL

Materials

All the Cr compounds used in this study were provided by Dr Andrew Bell.

Instrumentation

SIMS spectra were obtained on a Riber Instrument (Model SQ 156L) in the positive ion mode by using an energy selector, a quadrupole mass filter, a channeltron electron multiplier and pulse-counting electronics. An argon ion beam was used at 4 keV with a primary-ion (PI) current of 5.0×10^{-9} A cm^{-2} or less and was focused to a beam size of 0.1 cm^{-2}. Under these conditions, the static SIMS condition can be assumed.[13] The main-chamber pressure during analysis was 1.0×10^{-8} torr or less. In most cases the SIMS samples were admixed 1 : 10 with excess ammonium chloride[14] and were burnished directly onto an abrasively cleaned 1-cm^2 graphite foil. No charge compensation was used in any of the experiments.

The EI and CI experiments were performed utilizing a Finnigan model 4000 mass spectrometer with an INCOS data system. The source was maintained at 250°C, the average probe temperature was 120°C and the primary-ion beam for EI and CI was 70 eV. The reagent gas for positive- and negative-ion CI (PICI and NICI) was isobutane.

The FAB spectrum of $Cr(CO)_3(CNCMe_3)$(*t*-Bu-DAB) was recorded in a dithiothreitol matrix using a Kratos MS-50 spectrometer.

RESULTS AND DISCUSSION

Mass spectral measurements were carried out on the complexes $[Cr(CO)_3(CNR)$(R′-DAB)]. Key spectral data are summarized in Tables 1–3. Measurements of the FAB spectrum of $Cr(CO)_3(CNCMe_3)$(*t*-Bu-DAB) showed that it resembled very closely the related SIMS spectrum, with the single important exception that the molecular ion (M^+, *m/z* 388) was present in higher relative abundance in the FAB spectrum. In view of the similarity between the SIMS and FAB spectral results, we decided to concentrate our attention upon the SIMS measurements to the exclusion of FAB. Additionally, the striking similarity that we found existed between the SIMS spectrum

[a] Numbers in the table refer to the relative abundances of the identified positive ions in the SIMS spectrum, where 100 represents the maximum relative abundance.

[b] Peaks at *m/z* 175 and 176 (see Fig. 1) may arise from loss of CH_4 from $[Cr(i\text{-Pr-DAB})]^+$ to give $[Cr(i\text{-PrNCH-CHNCMe})]^+$ (*m/z* 176) followed, subsequently, by loss of $H^\cdot$. There is ample precedence in the literature for this (see, for example, M. L. Sigsby, R. J. Day and R. G. Cooks, *Org. Mass Spectrom.* 1979, **14**, 556).

[c] Peaks at *m/z* 205 and 189 may be due to sequential loss of $CH_3^\cdot$ and CH_4 from $[Cr(t\text{-Bu-DAB})]^+$ (*m/z* 220).

[b] Clusters corresponding to $[Cr_2(CO)_2(CNCHMe_2)(i\text{-Pr-DAB})_2]^-$ (*m/z* 509), $[Cr_2(CO)_3(i\text{-Pr-DAB})_2]^-$ (*m/z* 468), and $[Cr_2(CNCHMe_2)(i\text{-Pr-DAB})_2]^-$ (*m/z* 453) were observed in low abundance.

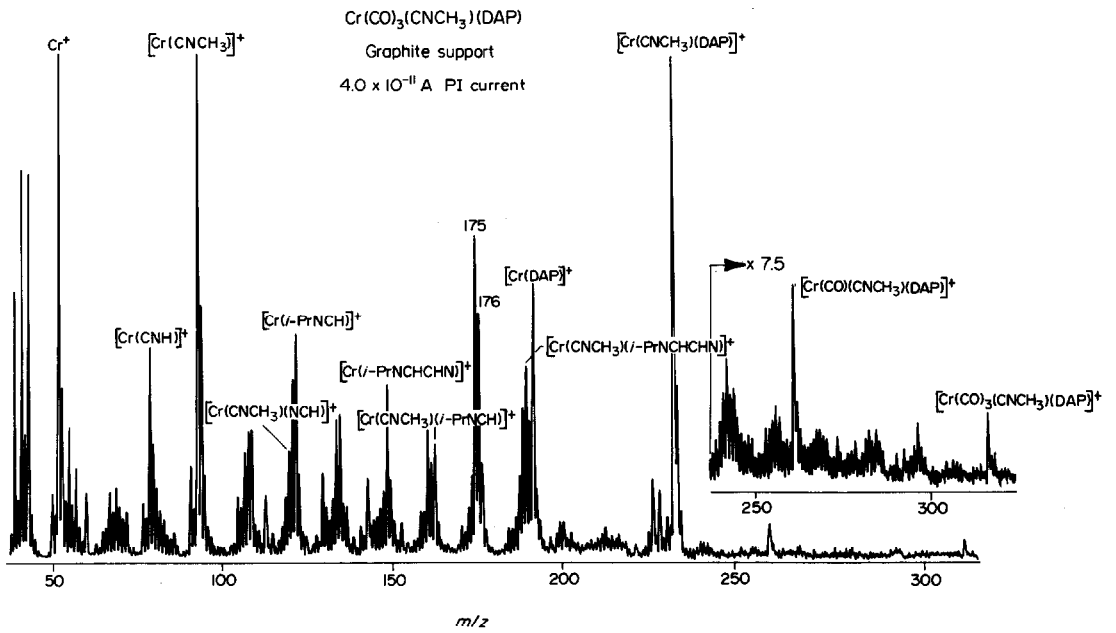

Fig. 1. SIMS spectrum of $Cr(CO)_3(CNMe)(DAP)$ admixed with NH_4Cl on graphite foil showing the molecular cation and additional fragmentation. DAP is used as an abbreviation for *i*-Pr-DAB. Inset shows region from *m/z* 240 to 320 recorded with 7.5-fold increase in PI current.

abundant ions in the SIMS. Powdered samples of the complexes were admixed with an excess of NH_4Cl as has been our usual practice[4,14] and recorded using a graphite support. A representative SIMS spectrum, that of $Cr(CO)_3(CNMe)$(*i*-Pr-DAB), is shown in Fig. 1. In one instance, difficulty was experienced in causing samples of the complex $Cr(CO)_3(CNCHMe_2)$(*i*-Pr-DAB) to adhere to the graphite support. Although this problem was eventually overcome, we found that a satisfactory alternative was a copper support (see Fig. 2); under these conditions the spectrum was very similar to that recorded from graphite foil.

Molecular cations (M^+) were obtained in very low abundance at best (Table 1). This result accords with our previous results for the SIMS of neutral β-diketonate complexes of the transition metals[5] where only in the case of the vanadyl complex $VO(CH_3COCHCOCH_3)_2$ did we see evidence for the molecular ion (albeit of low intensity). Note that for the β-diketonate complexes the intact molecular complex is only encountered under conditions

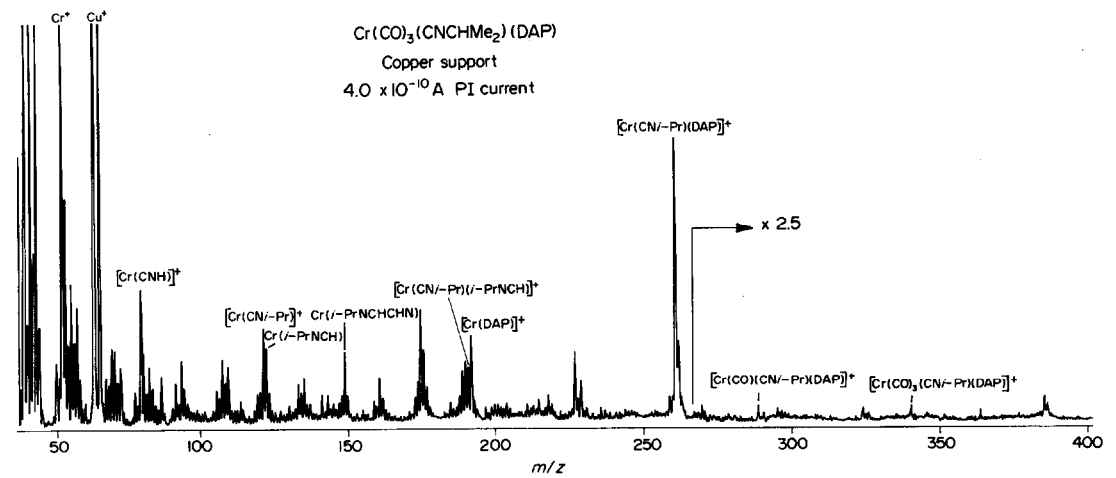

Fig. 2. SIMS spectrum of $Cr(CO)_3(CNCHMe_2)(DAP)$ admixed with NH_4Cl on copper. This spectrum is very similar to that obtained using a graphite foil support. The molecular cation and additional fragmentation are shown. DAP is used as an abbreviation for *i*-Pr-DAB. For *m/z* above 270 spectrum recorded using a 2.5-fold increase in PI current.

where cationization can occur, i.e. to give CM^+, where C^+ represents a suitable cationizing agent (e.g. Ag^+ or Na^+) and M is the molecular complex. We found no evidence for significant levels of "self-cationization", to give $[Cr_2(CO)_3(CNR)(R'\text{-DAB})]^+$, as has been encountered in other systems.[5] The samples apparently do not form higher mass polymetallic ions, which can subsequently fragment to give such bimetallic fragment ions, or undergo $Cr^+ + Cr(CO)_3(CNR)(R'\text{-DAB})$ combination reactions in the selvedge region. These results contrast with those for β-diketonate complexes in which bimetallic and higher cluster ions have been observed using a silver support (in conjunction with an NH_4Cl matrix).[5]

Several characteristic fragmentation sequences were observed in the SIMS spectra for all the complexes. Fragmentation is seen to occur by the loss of the three carbonyl ligands, to give in most instances $[Cr(CNR)(R'\text{-DAB})]^+$ as a very abundant species. This loss of carbonyls from the molecular cations $[Cr(CO)_3(CNMe)(i\text{-Pr-DAB})]^+$ and $[Cr(CO)_3(CNCMe_2)(i\text{-Pr-DAB})]^+$ yields the base peak in these two instances (see Fig. 1). Further fragmentation of $[Cr(CNR)(R'\text{-DAB})]^+$ occurs by loss of the isocyanide ligand to give the $[Cr(R'\text{-DAB})]^+$ ion. Likewise, species were present due to loss of the intact R′-DAB ligand thereby yielding the chromium isocyanide cations, $[Cr(CNR)]^+$. The ions $[Cr(CNR)]^+$ and $[Cr(R'\text{-DAB})]^+$ are seen in comparable abundance (Table 1 and Figs 1 and 2) thereby affirming the similar stabilities of these species. Subsequent loss of RNC and R′-DAB from $[Cr(CNR)]^+$ and $[Cr(R'\text{-DAB})]^+$ yields the intense Cr^+ ion.

These fragmentation patterns accord in a general way with those reported previously[15] in the EI mass spectra of mixed carbonyl–isocyanide complexes of type $M(CO)_{3+n}(CNR)_{3-n}$ (M = Cr or Mo; R = Me, Et, $CHMe_2$, CMe_3, p-MeC_6H_4 or p-ClC_6H_4; n = 0, 1 or 2). In these systems, carbonyl ligands are lost in preference to RNC and the homoleptic isocyanide cations $[M(CNR)_n]^+$ (n = 2 and/or 1) were abundant species. The preferential loss of CO indicates that the $[Cr(CNR)(R'\text{-DAB})]^+$ ions which are formed after fragmentation are more stable than the fragment ions $[Cr(CO)_{3-x}(CNR)(R'\text{-DAB})]^+$. While relative bond strengths are certainly important in determining initial ligand loss from large molecular cations,[11] the subsequent fragmentation of the smaller cations is governed by their ability to delocalize charge. Thus, these observations seem to reflect the greater ability of the RNC and R′-DAB ligands to delocalize the positive charge compared to CO. However, note that in SIMS studies on mixed nitrosyl–isocyanide complexes of type $[Cr(NO)(CNR)_4L]^+$ (L = RNC or an amine or tertiary phosphine ligand) and some closely related species[11,12] loss of NO is competitive with loss of RNC.

Fragmentation of the bound R′-DAB ligand is seen to give rise to ions in which dealkylation (loss of R′) and/or cleavage (C—C bond breaking) has formally occurred (see Table 1 and Figs 1 and 2). These results, which appear to be consistent with prior mass spectral results on R′-DAB ligands,[16] are of little direct structural interest to us. However, a much more significant and interesting process is encountered in the dealkylation of the isocyanide ligands. In all instances, dealkylation occurs to give $[Cr(CNH)]^+$ in quite high abundance and, in a couple of instances, also fragment ions with m/z values corresponding to $[Cr(CNH)(R'\text{-DAB})]^+$. Note that while we write the ion as $[Cr(CNH)]^+$ we cannot distinguish between this formulation as the isocyanic acid complex and the alternative hydrocyanic acid form $[Cr(NCH)]^+$. We found no evidence for the formation of the corresponding cyano species $[Cr(CN)]^+$ and $[Cr(CN)(R'\text{-DAB})]^+$. The latter type of process (to give cyanide) has been encountered in the field desorption (FD) mass spectrometry of $[M(CNCMe_3)_6X](PF_6)_2$ and $[M(CNCMe_3)_5(CN)X]PF_6$ (M = Tc or Re, X = Cl or Br) where dealkylation of the Me_3CNC ligands occurs quite easily.[17] While dealkylation has been found to give the fragment ion $[Cr(CN)]^+$ (and in some instances $[Cr(CN)(CNR)_2]^+$ as well) in the EI mass spectra of the series of complexes $Cr(CO)_{3+n}(CNR)_{3-n}$ (n = 0, 1, or 2), the ion $[Cr(CNH)]^+$ is also encountered in the EI spectra of $Cr(CO)_5(CNR)$[15] and is present in high relative abundance in the case of the t-butyl isocyanide complex. The generality of our own observations suggests that the loss of olefin (formally speaking at least) from MCNR to give MCNH (+alkene) may be a favored pathway in SIMS over that observed with the more energetic EI and, possibly, FD mass spectroscopic techniques. Thus, the loss of butene and propene from some mixed nitrosyl–isocyanide complexes of chromium and molybdenum which contain the $CNCMe_3$ and $CNCHMe_2$ ligands, respectively, has been well documented.[11] Such is the case also for Cu(I) and Ag(I) complexes that contain methyl, cyclohexyl and t-butyl isocyanide ligands.[8,10,11] While the formation of an MCNH moiety can arise through an intramolecular mechanism by loss of olefin, other pathways include: (1) the loss of carbonium ion from MCNR (clearly favored in the case of Me_3C^+) to generate MCN^-, and (2) homolytic bond cleavage to give M—CN$^\cdot$ and R$^\cdot$. The latter two processes then require sub-

sequent protonation, or abstraction of H$^{\bullet}$ (perhaps involving an adventitious source of hydrogen), respectively, in order to form MCNH. While we are uncertain of the mechanistic details in the case of the Cr complexes listed in Table 1, such studies are currently underway in the case of the homoleptic isocyanide complexes of Cu(I) and Ag(I).[10]

(b) EI mass spectra

These spectra, which were not especially informative, were dominated by intense peaks due to organic cations ($C_3H_5^+$, $C_3H_7^+$ or $C_4H_9^+$). Molecular cations were very weak (< 5% relative abundance) and other carbonyl-containing fragments, if present, also exhibited very low relative abundances (< 3%). Fragmentation to give [Cr(CNR)(R′-DAB)]$^+$, [Cr(CNH)(R′-DAB)]$^+$, [Cr(R′-DAB)]$^+$, [Cr(CNR)]$^+$, [Cr(CNH)]$^+$ and Cr$^+$ was observed, thereby revealing a basic similarity to the SIMS results, although with much lower abundance. Thus, the most intense [Cr(CNR)(R′-DAB)]$^+$ ion in the EI spectra was [Cr(CNCHMe$_2$)(*i*-Pr-DAB)]$^+$ (26% abundance relative to $C_3H_7^+$ as 100%) whereas in the SIMS spectrum it was the base peak. These observations seem reasonable since EI mass spectrometry is a more energetic process relative to the SIMS methodology.[13] As in the SIMS experiment, the N—C bonds of the RNC and R′-DAB ligands were easily cleaved and deakylation occurred from both the isocyanide and the diimine moieties. No fragments formally containing CN$^-$ were detected.

The most noteworthy differences between the SIMS and EI spectral results were seen in the presence of low-abundance peaks corresponding to [Cr(*i*-Pr-DAB)$_2$]$^+$ (*m/z* 332) and [Cr(*t*-Bu-DAB)$_2$]$^+$ (*m/z* 388) in the EI mass spectra of Cr(CO)$_3$(CNR)(R′-DAB) in the cases of R = CHMe$_2$, CMe$_3$ or xylyl when R′ = *i*-Pr, and R = Me or CMe$_3$ when R′ = *t*-Bu. These ions may result from fragmentation of higher clusters, such as [Cr$_3$(*i*-Pr-DAB)$_3$]$^+$ (*m/z* 576) and [Cr$_2$(*i*-Pr-DAB)$_2$]$^+$ (*m/z* 384), which are seen (< 10% relative abundance) in the spectra of the *i*-Pr-DAB complexes.

(c) CI mass spectra

In the CI measurements, ionization was effected by chemical reaction with *iso*-butane. The internal energy content of the pseudomolecular ion, e.g. MH$^+$ produced by isobutane CI, is generally much less if compared to the excess energy imparted to M$^+$ via EI. Therefore, the MH$^+$ ions, formed in PICI, are usually more stable towards dissociation than are the odd-electron ions, generated by EI.[18] A smaller degree of fragmentation relative to EI and SIMS is therefore expected and, indeed, observed (see Table 2). This is especially noticeable in the occurrence of fragments (many of high abundance) which contain CO ligands. Most noteworthy are the molecular cations [Cr(CO)$_3$(CNMe)(*i*-Pr-DAB)]$^+$ and [Cr(CO)$_3$(CNCMe$_3$)(*i*-Pr-DAB)]$^+$ which are present in 100% abundance or close to it. Only in the case of Cr(CO)$_3$(CNMe)(*t*-Bu-DAB) and Cr(CO)$_3$(CNCHMe$_2$)(*i*-Pr-DAB) were the relative abundances of Cr-containing ions uniformly low. We have no simple explanation for this observation.

In addition to the occurrence of some of the same fragments as found in the SIMS studies, the protonated forms of many species were observable in PICI, e.g. [Cr(CO)$_3$(CNR)(R′-DAB)+H]$^+$, [Cr(CO)$_3$(R′-DAB)+H]$^+$ and [Cr(CNR)(R′-DAB)+H]$^+$ (Table 2). Unlike the SIMS and EI mass spectra, a total of six carbonyl-containing ions were identified. However, that loss of the carbonyl ligands is still a favorable process is seen by the rather high relative abundance of the [Cr(CNR)(R′-DAB)]$^+$ ion in some of the spectra. The resistance of this ion to further fragmentation is reflected by the absence of [Cr(CNR)]$^+$ and Cr$^+$. The base peaks in the PICI mass spectra are generally due to the protonated isocyanide ligand and the intact protonated α-diimine ligand. The only exception was in the case of Cr(CO)$_3$(CNMe)(*i*-Pr-DAB), where the molecular cation was the base peak (Table 2).

A resemblance to the EI mass spectral results is seen in the presence of [Cr(R′-DAB)$_2$]$^+$ ions (Table 2). In the case of Cr(CO)$_3$(CNCHMe$_2$)(*i*-Pr-DAB), this is accompanied by the presence of higher clusters (see footnote *b* in Table 2) which may be the parents of [Cr(R′-DAB)$_2$]$^+$.

In the case of the NICI spectral results, the majority of fragments contain CO ligands (Table 3). Although the 19-electron molecular anion [Cr(CO)$_3$(CNR)(R′-DAB)]$^-$ was observed only in the case of [Cr(CO)$_3$(CNCMe$_3$)(*t*-Bu-DAB)]$^-$ (2% relative abundance), other structurally informative ions were present, many in high abundance, in these spectra. Of special note is the presence of carbonyl-containing fragment ions in high abundance. Thus, the loss of RNC from [Cr(CO)$_3$(CNR)(R′-DAB)]$^-$ gives [Cr(CO)$_3$(R′-DAB)]$^-$ as a highly abundant anion in the majority of the spectra (Table 3). A competitive loss of one CO vs the intact isocyanide ligand from the parent molecule yields high relative abundances of the following ions:

[Cr(CO)$_2$(CNCMe$_3$)(*t*-Bu-DAB)]$^-$ (36%),
[Cr(CO)$_2$(CNCMe$_3$)(*i*-Pr-DAB)]$^-$ (48%),

$[Cr(CO)_2(CNCMe_3)(Cy\text{-}DAB)]^-$ (71%),
$[Cr(CO)_2(CNCHMe_2)(i\text{-}Pr\text{-}DAB)]^-$ (71%)

and

$[Cr(CO)_2(CNxylyl)(i\text{-}Pr\text{-}DAB)]^-$ (100%).

Dealkylation occurs from $[Cr(CO)_2(CNCMe_3)(i\text{-}Pr\text{-}DAB)]^-$ and $[Cr(CO)_2(CNCMe_3)(Cy\text{-}DAB)]^-$ to yield the cyano-containing anions $[Cr(CO)_2(CN)(R'\text{-}DAB)]^-$ in 100% abundance. This result is very important since it reveals the first instances where dealkylation of these chromium complexes gives the $[Cr(CN)]^+$ moiety rather than $[Cr(CNH)]^+$ as we have seen in the SIMS and EI mass spectra. The restriction of this process to complexes which contain Me_2CHNC and Me_3CNC ligands supports the notion that simple cleavage is favored in those instances where the more stable radicals ($Me_2CH^\cdot$ and $Me_3C^\cdot$) are eliminated.[15] Further loss of two CO ligands can give rise subsequently to $[Cr(CN)(R'\text{-}DAB)]^-$, as seen in the case of $[Cr(CO)_2(CN)(R'\text{-}DAB)]^-$ for $R' = i$-Pr or Cy (Table 3).

The loss of a CO from $[Cr(CO)_3(R'\text{-}DAB)]^-$, where $R' = i$-Pr or t-Bu, gives $[Cr(CO)_2(t\text{-}Bu\text{-}DAB)]^-$ (33% abundance) and $[Cr(CO)_2(i\text{-}Pr\text{-}DAB)]^-$ (60% abundance). The high abundance of $[Cr(R'\text{-}DAB)_2]^-$ fragments in certain of the spectra again argues for the formation of putative cluster species (see, for example, footnote *b* in Table 3) which can fragment further. While the intensities of the $[Cr(R'\text{-}DAB)_2]^-$ anions are surprisingly high in some instances, it is reasonable that they exceed those of the analogous electron-deficient cations $[Cr(R'\text{-}DAB)_2]^+$ which are seen in the PICI spectra (see Table 2).

The fact that isocyanide is lost competitively with the carbonyl in the NICI spectra indicates that $[Cr(CO)_3(R'\text{-}DAB)]^-$ is of comparable stability to the corresponding $[Cr(CO)_2(CNR)(R'\text{-}DAB)]^-$ ions. This would appear reasonable since CO ligands can be very effective at delocalizing negative charge of the molecule through Cr-to-CO π-backbonding.

CONCLUSIONS

This work represents the first comparative study of the SIMS, EI and CI mass spectra of a group of inorganic or organometallic complexes. The absence of intense 17-electron molecular cations $[Cr(CO)_3(CNR)(R'\text{-}DAB)]^+$ in the SIMS and EI spectra is perhaps surprising in view of the stability of such species in solution and the solid state.[1] On the other hand, abundant molecular cations are seen in the PICI spectra. This difference presumably reflects the low internal energy content of these ions as produced by CI. In addition to the parent ions, well-defined fragment species are formed by loss of the carbonyl groups, by loss of the intact RNC and R′-DAB ligands, and by fragmentation of the latter. Similar fragmentation patterns were observed in the SIMS, and the EI and PICI spectra. Of greatest interest in the case of ligand fragmentation are the cleavage reactions of the bound RNC ligands which give rise to fragment ions that contain the $[Cr(CN)]^+$ or $[Cr(CNH)]^+$ moieties. The formation of fragment ions containing $[Cr(CNH)]^+$ is favored in the case of the SIMS and EL spectra, whereas the cyano species (i.e. $[Cr(CN)]^+$ are observed in the fragmentation patterns encountered in the NICI spectra. Another important and interesting difference which is seen in the NICI spectra (and to a certain extent in PICI) is the high relative abundance of carbonyl-containing fragments. This feature makes the CI spectra the most structurally diagnostic of the methods we have investigated. The paucity of CO fragments in the SIMS and EI spectra reflects the higher internal energies encountered with these techniques, and the enhanced ability of the RNC and R′-DAB ligands (compared to CO) to delocalize the positive charge in the cations. However, CO is lost competitively with RNC from the anions that are produced in the NICI measurements. This difference arises because the CO ligands are now very effective in delocalizing the negative charge (through Cr-to-CO π-backbonding) and, as a consequence, CO-containing fragments are much more stable.

^{133}Cs NMR STUDY OF Cs^+ ION COMPLEXES WITH DIBENZO-21-CROWN-7 AND DIBENZO-24-CROWN-8 IN SOME MIXED SOLVENTS

GHOLAMHOSSEIN ROUNAGHI and ALEXANDER I. POPOV*

Department of Chemistry, Michigan State University, East Lansing, MI 48824, U.S.A.

(*Received* 23 *September* 1985; *accepted* 18 *November* 1985)

Abstract—Complexation of the cesium ion with macrocyclic ligands, dibenzo-21-crown-7 and dibenzo-24-crown-8, was studied in binary solvent mixtures of dimethylsulfoxide with acetone, acetonitrile, propylene carbonate, pyridine and hexamethylphosphoramide (HMPA) as well as in pyridine–methanol mixtures. In the first four binary mixtures the complexation constants increased with decreasing amounts of dimethylsulfoxide (DMSO), the trend is reversed in the DMSO–HMPA system. In all of the above cases, the variation of the stability constant with composition was monotonic and showed good correlation with the inherent solvating ability of the neat solvents which form the mixture. In the pyridine–methanol system, however, for both complexes, the log K_f vs composition plots show several changes in direction. This behavior is probably due to a change in the structure of this binary solvent as the composition of the medium is varied.

While macrocyclic complexes of the alkali and alkaline earth cations have been extensively investigated in aqueous solutions and in a wide variety of neat nonaqueous solvents,[1,2] complexation reactions in mixed solvent systems have been investigated only to a very limited extent and seem to have been essentially restricted to water–methanol (MeOH) mixtures.[2,3] Yet it is well known that the selectivity of complexations strongly depends on the solvating ability of the solvent not only with respect to the cation but also with respect to the ligand.[4] It was of interest to us to investigate the dependence of complex stabilities on the composition of several binary solvent mixtures in order to see how this variation in solvent composition affects the selectivity of complexation.

For our initial studies we selected the Cs^+ ion as the probe cation and used ^{133}Cs NMR measurements to determine stability constants of the cesium complexes with the crown ethers dibenzo-21-crown-7 (DB21C7) and dibenzo-24-crown-8 (DB24C8). The cavities of these ligands are sufficiently large to accommodate the cesium ion, and, in contrast to 18-crown-6 and smaller crown ethers, only 1 : 1 complexes are formed.

EXPERIMENTAL

Reagents and solvents

The complexing agents, DB24C8 and DB21C7 (Parish), were recrystallized from normal heptane and then dried in a vacuum oven for 3 days at room temperature. Cesium thiocyanate (Pfaltz & Bauer) was recrystallized in absolute MeOH and dried in a vacuum oven at 50°C for 4 days.

Hexamethylphosphoramide (HMPA), dimethylsulfoxide (DMSO), acetonitrile (AN), propylene carbonate (PC), acetone (AC) and pyridine (Py) were refluxed for several days over dehydrating agents (calcium hydride for the first four, anhydrous calcium sulfate and barium oxide for AC and Py, respectively) and then fractionally distilled. MeOH was refluxed over magnesium turnings and iodine, and then fractionally distilled. CCl_4 was dried over activated molecular sieves. All of these solvents were transferred into a dry box under a nitrogen atmosphere and further dried over activated molecular sieves (Lind type 4 A). Water contents of the solvents were tested either by Karl Fischer titration using an automatic Karl Fischer Aquatest (Photovolt Corp.) titrator, or by using a Varian Aerograph Model 490 gas chromatograph with a propak Q column. In all cases the water content of the purified solvents was below 100 ppm.

Instrumental measurements

Most of the ^{133}Cs NMR measurements were performed on a Bruker WH-180 spectrometer in the Fourier transform mode, operating at a field of 42.3 kG and a frequency of 23.62 MHz. Spinning 10-mm-o.d. NMR tubes (Wilmad) were used for samples. A 5-mm coaxially insert NMR tube, containing a solution of 0.5 M CsBr in D_2O (lock) was used as an external standard. The chemical shifts, obtained at $22 \pm 1°C$ (probe temperature), were referenced to a 0.5 M solution of cesium bromide in deuterium oxide.

Some of the ^{133}Cs data were obtained with a Varian DA-60 spectrometer operating at a field of 14.09 kG and a frequency of 7.87 MHz in the pulsed Fourier transform mode. This spectrometer was equipped with a wide-band probe capable of multinuclear operation and with a homebuilt lock which used the DA-60 console to lock the magnetic field on an external proton resonance. Measurements were made in nonspinning 10-mm NMR tubes at $30 \pm 1°C$. A 0.5 M aqueous solution of CsBr was used as the reference.

All of the chemical-shift values obtained with both instruments were subsequently referenced to the infinitely dilute aqueous solution of cesium ions, and they were corrected for the difference in the bulk diamagnetic susceptibility of the pure or mixed nonaqueous solvents and the aqueous reference solution. The paramagnetic (downfield) shifts are designated as *positive*.

Proton NMR measurements were carried out on a Bruker WM-250 spectrometer, operating at a field of 58.7 kG and at 250 MHz. Spinning 5-mm-o.d. NMR tubes were used for the samples. A 2-mm coaxially insert NMR tube, containing a solution of a 0.28-mol fraction of TMS (Aldrich) in acetone-d_6 (Aldrich, gold label) was used as an external standard. All of the proton chemical shifts were referenced to the external Me_4Si resonance in acetone-d_6 and they were corrected for the difference in the bulk diamagnetic susceptiblity of the pure or mixed solvents. The probe temperature was $22 \pm 1°C$.

Data handling

Analysis of the data and calculations of the complexation constants were carried out by previously described procedures.[5]

RESULTS AND DISCUSSION

The $Cs^+ \cdot$ DB21C7 complex was studied in AC–DMSO and Py–MeOH systems, while its DB24C8 analog was studied in binary DMSO mixtures with AC, AN, PC and HMPA, as well as in the Py–MeOH system. In all cases the exchange was fast and only one, population-averaged, signal was observed at the probe temperature. An example of the variation of the ^{133}Cs chemical shift for the different DMSO–AN mixtures, as a function of the [DB24C8]/[Cs^+] mole ratio, is illustrated in Fig. 1. It is seen that the curvature of the plots increases with increasing concentrations of AN giving a qualitative indication that the stability of the complex increases with increasing concentration of AN. Similar plots were obtained for the DMSO mixtures with AC, PC and Py. In the case of the DMSO–HMPA mixtures, however, the curvature of the plots decreased with increasing concentration of HMPA.

The formation constants of the two macrocyclic complexes in different solvent mixtures and in neat solvents are listed in Table 1. The observed trends are not particularly surprising and, with the exception of Py (Table 2), show that the donor abilities of the solvents, as expressed by the Gutmann donor number,[6] play a very important role in determining the stabilities of the complexes. We have previously observed similar, seemingly exceptional, behavior of Py[7] and ascribed it to the fact that, although it

has a high donor number, it is a "softer" base than the other solvents and does not solvate strongly the cesium ion ("hard" acid). Consequently its solvation shell is easily replaced by the ether oxygens of the crown ethers. On the other hand, it reacts strongly with a "soft" acid, $SbCl_5$, thus giving a high donor number on the Gutmann scale.

The variation of the stability constants with solvent composition is illustrated in Fig. 2. Several reversals of stability can be observed, e.g. the complex is more stable in a 75–25 mol % DMSO–AN mixture than in the 75–25 mol % DMSO–PC system; however, with a 10–90 mol % composition of the two mixtures, the stabilities are reversed. The above and the other reversals of stabilities shown in Fig. 2 are not large, but they do indicate the possibility that more substantial changes in stabilities and reversals of cation selectivities may be obtained in more optimally selected mixed solvent systems.

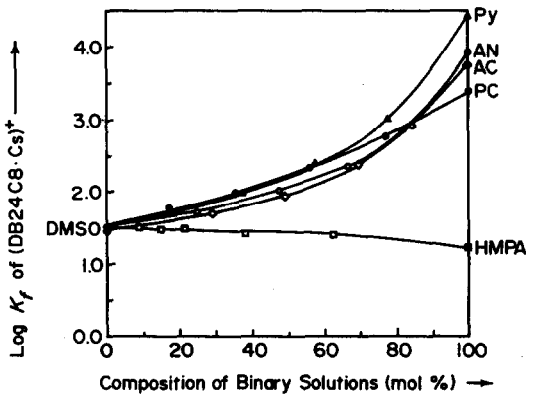

Fig. 2. Variation of the stability constant of the $Cs^+ \cdot$ DB24C8 complex with the solvent composition in binary solvent mixtures.

A very different behavior was observed in the MeOH–Py system. As shown in Fig. 3, the change in the formation constant is certainly not mono-

tonic. As the concentration of Py increases, the complex stability first goes down, then increases to a maximum value at about 20 mol % Py, then decreases only to rise again very gradually after 40 mol % Py. Somewhat similar results were obtained with the $Cs^+ \cdot$ DB21C7 complex in the same solvent mixtures (Fig. 4). The data are given in Table 3.

Proton NMR measurements on the Py moiety in the binary mixtures (Fig. 5) show that the variation of the chemical shift of the *ortho-* proton is not monotonic and in fact, strongly resembles the behavior of the complexity constants (Figs 3 and 4) in the same solvent mixture. On the other hand, the resonances of the *meta-* and *para*-protons show only a minor monotonic variation with the change in the composition of the medium. Similar monotonic variation for *all three protons* was observed in Py–CCl_4 mixtures. Of course, in the first case we have two associated dipolar solvents both with substantial dipole moments (2.87 D for methanol and 2.23 D for pyridine). In addition neat MeOH is strongly hydrogen-bonded. There is little doubt that as the two solvents are mixed the homo-dimers (and/or higher aggregates) are broken up with the formation of hetero-aggregates. We have previously observed such behavior in DMSO–Py mixtures, where the solvating abilities of DMSO are considerably enhanced as compared to the neat solvent.[8,9] Our knowledge of the structure and properties of solvent mixtures is still very rudimentary and a more detailed study is needed (in this case) of the Py–MeOH system to elucidate the details of the intermolecular interactions in these systems.

COMPLEX FORMATION OF Ni(II) AND Fe(III) WITH THE NITRITE ANION

EFRAIM AVSAR* and F. BEDIA ERIM

Department of Chemistry, Technical University of Istanbul, Istanbul, Turkey

(*Received* 3 *July* 1985; *accepted* 6 *November* 1985)

Abstract—The stepwise stabilities of the complexes formed by Ni(II) and Fe(III) with the nitrite anion have been determined potentiometrically in an aqueous sodium perchlorate medium of unit ionic strength at 25.0°C. Two fairly weak mononuclear complexes are formed in the Ni(II)–nitrite system with the overall formation constants as $\beta_1 = 5.9 \pm 0.9$ M^{-1} and $\beta_2 = 12 \pm 2$ M^{-2}, while for the Fe(III)–nitrite system three mononuclear complexes of moderate strengths, namely $\beta_1 = (3.9 \pm 0.7) \times 10^2$ M^{-1}, $\beta_2 = (5 \pm 2) \times 10^3$ M^{-2} and $\beta_3 = (2.8 \pm 0.6) \times 10^5$ M^{-3}, are found. No evidence has been found for the formation of polynuclear or acid complexes in the concentration range studied.

Much of the interest in transition-metal–nitrite complexes in solution concerns the fact that the nitrite ligand can be bonded to a metal ion via either the nitrogen or the oxygen atom. The electronic structure of the metal ion has a dominant influence on this bonding.

Studies on the formation of metal–nitrite complexes in aqueous solution have been carried out by different techniques. Data pertaining to the equilibrium measurements on the nitrite complexes are, however, scarce.[1] The nitrite system of Fe(III) has already been studied spectrophotometrically at 25°C in a 0.01 M perchloric acid medium.[2] However, only the first formation constant was evaluated. For the Ni(II)–nitrite system, on the other hand, no such measurements seem to have been made so far.

The potentiometric measurements have been carried out by means of a glass electrode. Thus, the free ligand concentration ([L]), has been determined via pH measurements in metal ion solutions containing nitrite–nitrous acid buffers.[3] This method can, generally, be applied for the numerous ligands which are anions of weak acids. To do this, the acidity constant of nitrous acid has to be known under the same conditions. This has therefore been determined in separate measurements with solutions which are free from the metal ion.

All measurements have been performed at 25.0°C and in an aqueous medium of unit ionic strength with sodium perchlorate as inert salt.

EXPERIMENTAL

Chemicals

Ni(II) perchlorate was prepared by dissolving $NiCO_3 \cdot 2Ni(OH)_2 \cdot 4H_2O$ (Merck, p.a.) in perchloric acid (Merck, p.a.) and recrystallized once from an acidic aqueous solution. The concentration of Ni(II) was determined gravimetrically by dimethylglyoxime. Fe(III) perchlorate solutions were prepared as before.[4] The free-acid concentrations in the stock solutions were determined both potentiometrically and by passing aliquots through a column containing Dowex 50 W cation exchange resin in the hydrogen form and titrating the eluate with standard sodium hydroxide. The perchloric acid (Merck, p.a.) solutions were standardized against borax. Sodium perchlorate was prepared and analyzed as described before.[5] Sodium nitrite solution was made from $NaNO_2$ (Merck, p.a.) without further purification. Analysis for $NaNO_2$ was made volumetrically by standard $KMnO_4$.[6] The Ag–AgCl electrodes were prepared according to Brown.[7]

Apparatus and procedure

A Metrohm E500 Digital pH meter equipped with a Metrohm EA 109 glass electrode has been

* Author to whom correspondence should be addressed.

used for the potentiometric measurements. The glass electrode has been checked, before and after each titration series, and gave a slope of 59.2 ± 0.2 mV. A magnetic stirrer was used for mixing. Stable e.m.fs were reached in a few minutes. The reproducibility was generally within ± 0.4 mV and even better for the Fe(III)–nitrite system. The e.m.fs of the following cell were measured:

$$-\mathrm{RE}//C_M\mathrm{M\ Me(ClO_4)_v}, C_H\mathrm{M\ HClO_4},$$
$$C_L\mathrm{M\ NaNO_2, NaClO_4\ to}\ I = 1\ \mathrm{M/GE}+,$$

where

$$\mathrm{RE}// = \mathrm{Ag,AgCl/0.025\ M\ NaCl},$$
$$0.975\ \mathrm{M\ NaClO_4/1.00\ M\ NaClO_4/}.$$

Here, Me denotes Ni or Fe, and v is the valency.

The measurements have been performed as titrations at constant metal ion and constant acid concentrations, C_M and C_H, respectively. Equal volumes of solutions T_1 and T_2 were added from piston burettes to V_0 ml of solution S. These solutions had the following compositions:

S: C_M M $Ni(ClO_4)_2$, C_H M $HClO_4$, $(1.0–3C_M)$ M $NaClO_4$,

T_1: 1.00 M $NaNO_2$,

T_2: $2C_M$ M $Ni(ClO_4)_2$, $2C_H$ M $HClO_4$, $(1.0–6C_M)$ M $NaClO_4$,

for the Ni(II)–nitrite system. In the case of Fe(III), the compositions were:

S: C_M M $Fe(ClO_4)_3$, C_H M $HClO_4$, $(1.0–6C_M)$ M $NaClO_4$,

T_1: 1.00 M $NaNO_2$,

T_2: $2C_M$ M $Fe(ClO_4)_3$, $2C_H$ M $HClO_4$, $(1.0–12C_M)$ M $NaClO_4$.

Thus, up to $C_L = C_H$ the ionic strength is higher than 1 M. But when $C_L = C_H$, which is reached soon in the titrations, practically all the free acid will be converted into HNO_2. The ionic strength of the resulting solution will then be 1 M.

Calculation of constants from measurements

The e.m.f. of the above cell is given, in mV, at 25.0°C by:

$$E_H = E_H^\circ + E_j + 59.16 \log h \qquad (1)$$

where E_H° is the cell constant, E_j the liquid junction potential, and h the free hydrogen ion concentration. E_j depends almost only on h and can therefore be determined separately.[8]

By measuring the values of h, the free ligand concentration ([L]) and the average ligand number ($\bar{n}$) can be calculated from:

$$[L] = K_a(C_H - h)/h \qquad (2)$$

and

$$\bar{n} = (C_L - C_H + h - |L|)/C_M, \qquad (3)$$

respectively.

Once corresponding values of $\bar{n}$ and [L] are known the function

$$X = 1 + \sum_{j=1}^{N} \beta_j [L]^j$$

can be evaluated from a graphical integration of an $\bar{n}/[L]$ vs [L] plot. The constants are then obtained graphically[9] by plotting the functions $X_j = (X_{j-1} - \beta_{j-1})/[L]$ vs [L], where $1 \leqslant j \leqslant N$; $X_0 = X$; $\beta_0 = 1$.

RESULTS AND DISCUSSION

Proton–nitrite system

The measurements were carried out as a series of titrations of a solution $C_H = 100$ mM ($I = 1.0$ M) into a solution containing sodium nitrite in different concentrations, i.e. 10, 20 and 40 mM. In another series, titrations were performed where a solution of nitrite–nitrous buffer was added to various perchloric acid solutions of the same ionic strength of 1.0 M. From these measurements the acidity constant of nitrous acid can be calculated by the relation:

$$K_a = \frac{h(C_L - C_H + h)}{C_H - h}, \qquad (4)$$

where C_L is the ligand concentration, C_H the total acid concentration and h is found according to eqn (1).

The value of $K_a = (1.03 \pm 0.06) \times 10^{-3}$ M obtained from these measurements agrees excellently with that reported in literature under the same conditions.[1]

Ni(II)–*nitrite system*

The potentiometric titrations were performed with three different values of C_M, i.e. 40, 60 and 80 mM. The acid concentrations, constant during the titrations, were 40 mM for $C_M = 40$, 30, 60 and 120 mM for $C_M = 60$, 80 and 40 mM for $C_M = 80$ mM. Thus, various ratios of C_M/C_H have been used for

The full-drawn curve has been calculated from the values of β_j listed in Table 1. Only half of the experimental points, chosen at random, have been plotted.

each series. A free ligand ion concentration up to $\simeq 300$ mM could be reached in the measurements. In spite of the fairly large variation of both C_M and C_H during the measurements, no systematic deviations can be observed between the various titrations series, which proves that neither polynuclear nor acid complexes are formed (Figs 1 and 2).

The formation constants of the complexes formed in the concentration range studied were evaluated both graphically[9] and numerically by a high-speed computer using a program written for this purpose.[10] Both the methods gave the same results: $\beta_1 = 5.9 \pm 0.9\ M^{-1}$, $\beta_2 = 12 \pm 2\ M^{-2}$.

The errors given correspond to confidence limits on the 99.9% level of significance.

(○) $C_M = 5$ mM, $C_H = 60.35$ mM; (□) $C_M = 10$ mM, $C_H = 114.70$ mM; (△) $C_M = 15$ mM, $C_H = 156.97$ mM; (◇) $C_M = 20$ mM, $C_H = 214.32$ mM. The full-drawn curve has been calculated from the values of β_j listed in Table 1. Only half of the experimental points, chosen at random, have been plotted.

Fe(III)–*nitrite system*

For this system four different values of C_M, namely 5, 10, 15 and 20 mM, were used. In order to prevent the initial hydrolysis of the Fe(III) ion, the concentration of perchloric acid was kept high for each series, i.e. 60, 115, 157 and 214 mM, respectively. Once the formation of nitrite complexes proceeds the hydrolysis is virtually suppressed even in buffers containing a fairly high proportion of the ligand.

The $\bar{n}/[L]$ vs [L] plot is shown in Fig. 3 and the complex formation function is presented in Fig. 4.

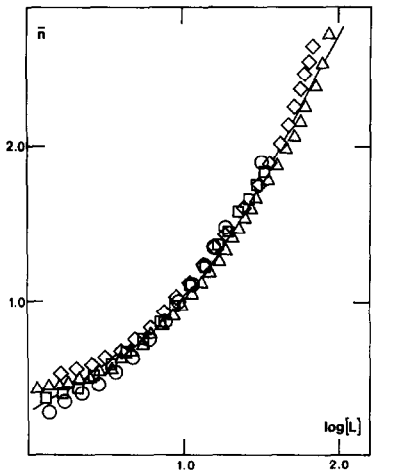

Fig. 4. Complex formation function of the Fe(III)–nitrite system. For symbols refer to Fig. 3. [L] in mM.

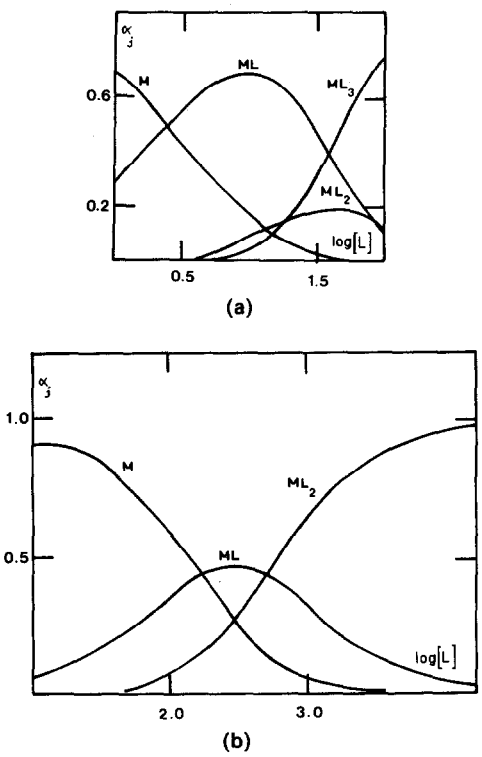

Fig. 5. Distribution of nickel(II) (a) and iron(III) (b) between the different ML_j complexes with varying nitrite ion concentration ([L] in mM).

The complex formation function is independent of both C_M and C_H, which indicates that no polynuclear and acid complexes exist.

In the graphical determination of the constants, the plot of the function $X_3([L])$ against [L] shows a slight positive curvature. This may, of course, be interpreted in terms of the formation of a fourth complex. It is more likely, however, that this slight deviation from linearity is due to the changes in the activity coefficients at high ligand concentrations. In the numerical calculations models including three and four, as well as two, mononuclear complexes have been tried. For a model containing four mononuclear complexes a value of $(1 \pm 1) \times 10^5\ M^{-3}$ is found for β_3. The value of β_4 becomes $(1.3 \pm 0.6) \times 10^6\ M^{-4}$ in this case. Thus, introducing the fourth complex in the evaluation increases the uncertainty in β_3. For a model including only three mononuclear complexes a good fit of experimental data is obtained with estimates, $\beta_1 = (3.9 \pm 0.7) \times 10^2\ M^{-1}$, $\beta_2 = (5 \pm 2) \times 10^3\ M^{-2}$ and $\beta_3 = (2.8 \pm 0.6) \times 10^5\ M^{-3}$. A model with only two mononuclear complexes, on the other hand, should be discarded since only a very poor fit to the potentiometric data can be obtained.

The results of this study are collected in Table 1. Considering the different media and techniques used in the determination of β_1 for $[FeNO_2]^{2+}$, the agreement with the value found by Zhuravleva and Berdnikov is fairly good.[2] Nitrogen- and oxygen-containing ligands form complexes in aqueous solution with most acceptors. Nitrogen should be classified as a considerably softer donor atom than oxygen. The nitrite ion, as both an oxygen and a nitrogen donor, shows linkage isomerism in its complexes. The best known complexes of this kind are those formed by Co(III), Rh(III), Ir(III) and Pt(IV).[11] In fact, the nitrite anion acts as a strong σ-donor when bonded through the nitrogen atom compared to oxygen bonding. In agreement with this, metal complexes involving only nitrogen donors are more stable than those involving oxygen donors as well.[4,12] When π-interactions are involved, however, the non-bonding orbital is mainly localized on the two oxygen atoms. As a result of that, the nitrite ligand acts as a π-donor when bonding takes place over oxygen.[11]

Acknowledgement—We are most grateful to Dr Arvid Sandell of the University of Lund, Lund, Sweden, for good advice on discussions of the results and for invaluable help with computer calculations.

Abstract—We report the synthesis and study of bis(8-quinolinol) oxovanadium(IV) adducts with pyridine and substituted pyridines. These complexes were identified by IR and electronic spectra, magnetic susceptibility measurements and analytical data. The relation between the basicity of the pyridines and the V=O stretching frequency has also been studied. The effects of steric hindrance and the inductive effects exercised by the functional groups, amino and methyl of the pyridine, in the formation of the adducts are discussed.

Henry *et al.*[1] reported the synthesis of the adducts of bis(8-quinolinol) oxovanadium(IV) with several organic bases whose formulae correspond to VOQ_2B and $BH^+[VOQ_3]^-$, in which Q = 8-quinolinol and B = organic base, by means of the reactions:

$$VO^{2+} + HQ + B \rightarrow VOQ_2B + 2H^+,$$

$$VO^{2+} + 3HQ + B \rightarrow [VOQ_3]^- + BH^+ + 2H^+.$$

These authors also reported the impossibility of obtaining these adducts by the direct reaction between the complex VOQ_2 and the organic base B, because the complex presents a trigonal bipyramid structure.

In this paper we describe the synthesis of the bis(8-quinolinol) oxovanadium(IV) adducts with substituted pyridines (3-methyl-, 4-methyl-, 3,5-dimethyl-, 3-amino- and 4-aminopyridine) by the direct reaction between the complexes and the pyridines. The study of these complexes by IR and electronic spectroscopy, magnetic susceptibilities and analytical data, shows that stoichiometry of the complex is 2:1 (ligand:metal) and 1:1 (base:complex) for these adducts.

From IR and electronic spectral data, we assign a square pyramidal structure for the complex and a distorted octahedral structure for the adducts. We have also obtained a relationship between the pyridine's basicity (pK_b values), and V=O stretching mode and the $^2B_2 \rightarrow {}^2B_1$, $^2B_2 \rightarrow {}^2E(I)$ transition frequencies.

EXPERIMENTAL

Materials

8-Quinolinol, vanadyl-oxosulphate and the organic bases were Merck commercial products. The solvents used to prepare the complexes were Carlo Erba or Merck.

Analytical procedures

Elemental analyses were performed with a Perkin–Elmer model 240B. Vanadium was determined by atomic absorption with a Perkin–Elmer 430 atomic absorption spectrophotometer after decomposing the compounds with a concentrated HNO_3 and H_2SO_4 mixture (1:1).

The analytical data for the compounds are shown in Table 1.

Methods

Magnetic susceptibilities were measured by the Gouy[2] method at room temperature on a

[a] Py, pyridine; 3MP, 3-methylpyridine; 4MP 4-methylpyridine; 3,5DMP, 3,5-dimethylpyridine; 3AP, 3-aminopyridine; 4AP, 4-aminopyridine.

Mettler H-51 A.R. balance and a type C-Oxford electromagnet. Molar susceptibilities have been corrected for the diamagnetism of the constituent molecules.[3,4] The magnetic moments were calculated according to the formula $\mu = 2.84(\chi'_M T)^{0.5}$ BM, where χ'_M is the corrected molar susceptibility. The values of the magnetic moments are given in Table 1.

The IR spectra were taken on a Perkin–Elmer 283 recording spectrophotometer. The samples were run as KBr pellets. The IR absorption peaks for the compounds prepared in this study are listed in Table 2.

The visible–near-UV spectra of the compounds were carried out in the range 220–1000 nm on a Beckman 5240 recording spectrophotometer using solutions of the complexes in dichloromethane. The results obtained are given in Table 3.

Preparation

$VO(C_9H_4NO)_2$: 1.27 g (5 mmol) of $VOSO_4 \cdot 5H_2O$ was dissolved in 5 cm^3 of water. Another solution of 1.45 g (10 mmol) of 8-quinolinol in 10 cm^3 of absolute ethanol was prepared. This solution was added to the previous one stirring continuously and a greenish-black precipitate was formed. The precipitate was separated by filtration *in vacuo*, washed repeatedly with a boiling water–ethanol mixture and dried over P_4O_{10} in a nitrogen atmosphere to avoid oxidation. Yield 80%.

$VO(C_9H_4NO)_2 \cdot B$: The complex previously obtained was dissolved in the organic base (3-methyl-, 4-methyl- and 3,5-dimethylpyridine, and pyridine) or in an ethanolic solution of 3-amino- and 4-aminopyridine with continuous stirring. After cooling for 2 days, the adducts—obtained as green crystals—were separated by filtration *in vacuo* and dried over P_4O_{10} in a nitrogen atmosphere. Yield 42%.

DISCUSSION

The complexes obtained in this study gave analytical results which are concordant with the formulas assigned: $VO(ox)_2$ and $VO(ox)_2 \cdot B$ (ox = 8-quinolinol; B = pyridine, 3-methyl-, 4-methyl-, 3,5-dimethyl-, 3-amino- and 4-aminopyridine).

The complex $VO(ox)_2$ is less stable to vanadium(V) oxidation than the new adducts.

[a] Abbreviations as in Table 1.

All these compounds are paramagnetic with values of magnetic moments between 1.65 and 1.72 BM. These results show the existence of monomeric species of vanadium(IV) (ion d^1).

IR spectra exhibit a very strong band at 920–970 cm^{-1}, which is attributed to the stretching vibration of the terminal V=O bond. If we compare the complex $VO(ox)_2$ with the adducts $VO(ox)_2 \cdot B$, one observes that the adducts show the V=O band displaced to lower frequencies (920–965 cm^{-1}) than the complex (970 cm^{-1}). This displacement can be attributed to the different basicity of the pyridine or substituted pyridine employed. The pK_b value reflects the basicity of the ligand towards the proton. It may be assumed that the pK_b of the ligand provides a measure of the ability of the ligand to form σ-bonds to metal ions. In general (see Table 2), the greater the basicity the lower the frequency of the V=O vibration. The outstanding exceptions are the 3,5-dimethyl- and 4-methylpyridine adducts. The explanation of this behaviour may be due to the existence of resonance forms to the complex with 4-methylpyridine and to the steric effects to the complex with 3,5-dimethylpyridine as has been reported previously.[5–7]

The IR spectra of the adducts exhhibit a band at 330–350 cm^{-1}, which is assigned to the stretching vibration of the V—N(base)[8] bond. The frequencies of this band listed in decreasing order are:

$$VO(ox)_2(4AP) > VO(ox)_2(3AP) > VO(ox)_2(3MP) > VO(ox)_2(Py),$$
$$VO(ox)_2(4MP) > VO(ox)_2(3,5DMP).$$

These differences can be attributed to the electronic donation of the pyridine or substituted pyridine to the vanadium (N → V) which increases the electron density on the metal *d*-orbitals and consequently the $p_\pi \rightarrow d_\pi$ donation from the oxygen atom to vanadium is expected to be reduced to an extent which depends upon the donor ability of the base. As a result there will be a lowering of the V=O bond [hence ν(V=O)] and a greater frequency of the V—N bond.

The IR spectra of all the compounds obtained in this work show two bands at 550–573 and 365–379 cm^{-1}, which are assigned to the antisymmetrical and symmetrical vibration, respectively, of the stretching V—O ligand. Both bands are displaced to greater frequencies in the adducts than in the complex $VO(ox)_2$ (see Table 2).[8]

All the compounds exhibit a very strong band in the 1100-cm^{-1} region and another band of lower intensity in the 350-cm^{-1} region. We attribute the first band to C—O—V vibration and this indicates the formation of a vanadium chelate, while the second band corresponds to the stretching of the V—N bond as also happens in other complexes that were studied previously. These bands appear at higher frequencies in the adducts than in the complex $VO(ox)_2$.[9,10]

The electronic spectra of the compounds obtained here is in accordance with the Ballhausen–Gray scheme for a square pyramidal structure for the complex and a distorted octahedral structure for the adducts.[11]

The electronic spectra of the compounds obtained here exhibit three bands in the visible zone at 13,793–13,986, 18,018–19,379 and 20,242–21,276 cm^{-1}. The first band can be attributed to a $^2B_2 \rightarrow {}^2E(I)$ transition and it is displaced to lower frequencies in the adducts. This displacement is greater for lower values of the pK_b value of the pyridine or substituted pyridine, which is indicative that the $^2B_2 \rightarrow {}^2E(I)$ transition is very sensitive to the electronic donation V → O (see Table 3).

The second band can be assigned to a $^2B_2 \rightarrow {}^2B_1$ transition. This band shows the greater or lesser bonding force from the vanadium to the ligands. Therefore the band is displaced to higher frequencies in the adducts, because the introduction of the base in the six-coordination position and the "*trans*" effect strengthen the

8-quinolinol–vanadium σ-bond, as we have observed in the IR spectra.

The last band (20,242–21,276 cm^{-1}) corresponds to a ligand-to-metal charge transfer and generally is displaced to higher frequencies in the adducts.

In the UV region one observed an intense band between 37,037 and 38,314 cm^{-1}, which is attributed to an intraligand transition.

Institute of Materials Science, University of Tsukuba, Niihari, Ibaraki 305, Japan

(*Received* 28 *August* 1985; *accepted after revision* 18 *November* 1985)

Abstract—The substitution reaction with ethylenediamine of the coordinated glycinate ligand of bis(ethylenediamine)glycinatocobalt(III) complex has been studied at 60–70°C in a weakly alkaline aqueous solution (buffered around pH 12) of 1.0 mol dm^{-3} chloride concentration. The reaction was studied under the pseudo-first-order kinetic condition with respect to ethylenediamine and followed by means of electronic absorption spectra for the racemate and by circular dichroism spectra for the optically active isomers. The reaction proceeds stepwise with three rate-determining steps: the first step is dependent neither on ethylenediamine nor on hydroxide ion concentration but is accompanied by loss of optical activity, while the second one is dependent both on ethylenediamine and on hydroxide ion concentrations. Mechanisms of the ligand substitution reaction are discussed.

Elucidation of the substitution reaction mechanism of a coordinated multidentate ligand in a chelated cobalt(III) complex of octahedral or pseudo-octahedral coordination with another multidentate ligand is of fundamental importance, not only in stereochemistry but also in synthetic chemistry of the substitution-inert metal complexes. There have been vast numbers of studies concerning kinetics and mechanisms of the cobalt(III) complexes; however these studies are largely centered around aquation, acid or base hydrolysis, anation etc.[1] It has been reported[2] that the ligand substitution reaction with ethylenediamine of the carbonatobis(ethylenediamine)cobalt(III) complex $\{[Co(CO_3)(en)_2]^+$ (en = ethylenediamine)$\}$ proceeds with two successive rate-determining steps, where the first rate-determining step corresponds to the parallel aquation and base-catalyzed hydrolysis pathways and accompanies loss of optical activity and the second one corresponds to the ethylenediamine coordination pathway. In order to get further information on this sort of ligand substitution reaction, we investigated the substitution with ethylenediamine of coordinated glycinate ligand in the racemate and the optically active isomers of the bis(ethylenediamine)glycinatocobalt(III) complex $\{[Co(gly)(en)_2]^{2+}$ (gly = glycinate)$\}$ at 60–70°C in weakly alkaline aqueous solution (buffered around pH 12) of 1.0 mol dm^{-3} chloride concentration.

* Author to whom correspondence should be addressed.

EXPERIMENTAL

$[Co(gly)(en)_2]Cl_2$ was prepared from *trans*-$[CoCl_2(en)_2]Cl$ and glycine.[3,4] Its optical resolution was carried out by using $K_2[Sb_2(d\text{-}(+)\text{-tart})_2]\cdot H_2O$ (tart = tartrate) according to the literature procedure.[4] The complex and its optically active isomers were characterized by elemental analysis and electronic absorption and circular dichroism (CD) spectra. Ethylenediamine of analytical reagent grade was used. All the other reagents used were also of analytical grade.

The absorption and CD spectra were recorded

on JASCO spectrophotometers, models UVIDEC-1 and 610 C, and on JASCO spectropolarimeters, models J-20 and 500 C, respectively. The pH of the solution was measured with a Horiba glass electrode pH meter, model F7-SS. The pH meter reading was converted to the hydroxide ion concentration by defining $-\log [OH^-]$ of a solution containing 0.0100 mol dm^{-3} sodium hydroxide and 0.9900 mol dm^{-3} sodium chloride to be 2.00.

Kinetic runs were made in a weakly alkaline aqueous solution of 1.0 mol dm^{-3} chloride concentration under the pseudo-first-order reaction condition with respect to ethylenediamine (at a temperature between 60 and 70°C) by following absorbance changes with time (at 515 nm) for the racemate and CD intensity changes with time (at 510 nm) for the optically active isomers. The sample solution was highly buffered for $[OH^-]$ owing to the large concentration of ethylenediamine; no other buffer systems were necessary for its control. The temperature was regulated at a specified value within ±0.1°C. The observed rate constant, k_{obsd}, was calculated from the net absorbance and from CD intensity changes with time—as will be described in the following section.

RESULTS

The ligand substitution reaction of $[Co(gly)(en)_2]^{2+}$ with ethylenediamine does not proceed noticeably at room temperature (25°C) but does proceed at an elevated temperature of 60–70°C. A typical example of absorbance change at a fixed wavelength with time of the reaction system at 70°C is shown in Fig. 1. The absorbance vs time plots consist of three exponential parts. Absorption spectral measurements of the reaction system in the *d–d* transition $[^1T_{1g}(O_h) \leftarrow {}^1A_{1g}(O_h)]$ region on the time course revealed that the starting complex with an absorption maximum at 487 nm changed successively—via two intermediate states—to the final complex with an absorption maximum at 469 nm, which corresponds to $[Co(en)_3]^{3+}$. Liquid column chromatography on the reaction product with a column of SP Sephadex C-25 (Na^+ form) and elution with 0.1–0.5 mol dm^{-3} aqueous sodium chloride solution (programmed concentration) showed quantitative formation of $[Co(en)_3]^{3+}$. Hence, it is concluded that the ligand substitution reaction proceeds through three rate-determining steps to give $[Co(en)_3]^{3+}$.

The rate equation of the consecutive system $S \xrightarrow{k_1} I_1 \xrightarrow{k_2} I_2 \xrightarrow{k_3} P$ can be given as follows:

$$A_t = B_1 \exp(-k_1 t) + B_2 \exp(-k_2 t) + B_3 \exp(-k_3 t) + A_\infty,$$

$$B_1 \equiv [S]_0\{\varepsilon_S(k_2-k_1)+\varepsilon_{I_1}k_1-\varepsilon_P k_2\}/(k_2-k_1), \quad (1)$$

$$B_2 \equiv [S]_0\{\varepsilon_{I_1}k_1(k_2-k_3)-\varepsilon_{I_2}k_1k_2+\varepsilon_P k_1k_3\}/(k_3-k_2)(k_2-k_1),$$

$$B_3 \equiv [S]_0\{(\varepsilon_{I_2}-\varepsilon_P)k_1k_2\}/(k_3-k_2)(k_2-k_1).$$

Here, k_1, k_2 and k_3 are the rate constants for the first, the second and the third rate-determining steps; S, I_1, I_2 and P are the starting, the first and second intermediate and the final complexes; $[S]_0$ is the initial concentration of the starting complex; ε_S, ε_{I_1}, ε_{I_2} and ε_P are the molar absorption coefficients of S, I_1, I_2 and P; and A_t and A_∞ are the absorbances at the fixed wavelength at time t and at equilibrium, respectively. When the magnitudes of these rate constants differ sufficiently to give three linear portions in the logarithmic net absorbance changes vs time plots, these rate constants can be estimated

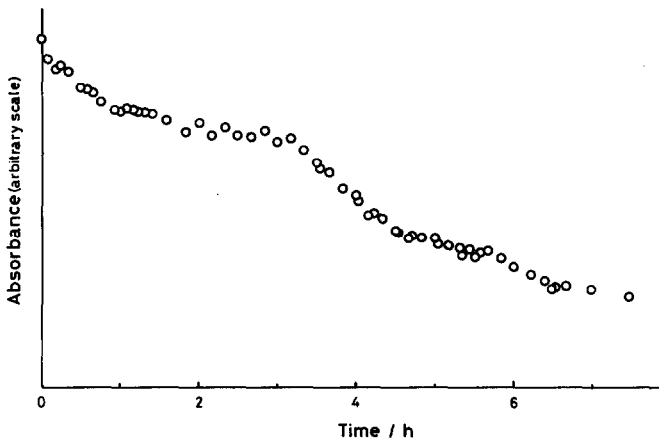

Fig. 1. Absorbance change with time of $[Co(gly)(en)_2]^{2+}$. $[[Co(gly)(en)_2]^{2+}] = 1.00 \times 10^{-2}$ mol dm^{-3}. [en] = 2.00 mol dm^{-3}. $[OH^-] = 1.58 \times 10^{-2}$ mol dm^{-3} (buffered). $[Cl^-] = 1.0$ mol dm^{-3}. 70°C. Wavelength = 515 nm.

from the slope of the corresponding linear portions and refined by simulation of the experimental absorbance vs time plots by using the estimated rate constants. In the $[Co(gly)(en)_2]^{2+}$ complex, k_3 was considerably smaller than k_2 with small net absorbance changes and much scattered experimental data on the plots; this is because fluctuations in the preceding two kinetic processes were superimposed directly on the third kinetic process. Hence, no reliable estimation of k_3 was possible; but it may not exceed the order of 10^{-7} s^{-1} based on the simulation. The constant k_2 was calculated from the linear portion of $\ln\{A_t - B_3\exp(-k_3t) - A_\infty\}$ vs t plots by assuming the contribution of the second term in the logarithm to be constant and small and by estimating B_3 from the absorbance change after the second kinetic step and A_∞ from the molar absorption coefficient of $[Co(en)_3]^{3+}$. The validity of this treatment was checked by determining k_2 from the Guggenheim plots[5] on a $\ln\{A_t - A_\infty\}$ vs t curve. The constant k_1 can be determined in the same way as k_2 from the linear portion of $\ln\{A_t - B_2\exp(-k_2t) - B_3\exp(-k_3t) - A_\infty\}$ vs t plots by assuming that the contribution of the second and the third terms in the logarithm to be constant and by estimating B_2 from the absorbance change during the second kinetic step. The values thus obtained were less reliable than k_2 because the time interval giving linearity was rather narrow as compared with the second rate-determining step, where linearity was found for more than two half-lives. Therefore, the magnitude of k_1 was calculated to only one significant figure.

Figures 2 and 3 show the hydroxide ion and ethylenediamine concentration dependencies on the observed rate constant in the second rate-determining step, k^2_{obsd}. The first step (k^1_{obsd}) was dependent neither on the hydroxide ion nor on the ethylenediamine concentration. It should be emphasized that the second step depends both on the hydroxide ion and on the ethylenediamine concentration. Hence, the following relations can be deduced from Figs 2 and 3:

$$k^1_{obsd} = k^1_{H_2O},$$
$$k^2_{obsd} = (k^2_{en} + k^2_{OH,en}[OH^-])[en]. \quad (2)$$

Here, $k^1_{H_2O}$, k^2_{en} and $k^2_{OH,en}$ denote the rate constants for the aquation, the ethylenediamine coordination and the hydroxide-assisted ethylenediamine coordination pathways, respectively.

These spectrochemical and kinetic results indicate that, in the first step, $[Co(gly)(en)_2]^{2+}$ undergoes the aquation uniquely to give the first intermediate species having a unidentate glycinate ligand, and that the first intermediate species then—in the second step—undergoes ligand substitution by ethylenediamine and hydroxide-assisted ethylenediamine coordination in a parallel way to give the second intermediate species. This then changes in the third step to give $[Co(en)_3]^{3+}$ with liberation of the unidentate glycinate ligand followed by the ethylenediamine chelate ring closure. Kinetic par-

ameters of these reaction pathways are summarized in Table 1.

The kinetic study was made on the optically active isomer, Λ-(+)$_{589}$-[Co(gly)(en)$_2$]$^{2+}$,[4] under otherwise the same experimental conditions as those adopted for the racemate. Figure 4 shows CD spectral change with time of the Λ-(+)$_{589}$ isomer in the *d–d* transition region. The CD intensity decreased with time without any changes in the spectral pattern. The CD spectral changes with time of the Δ-(−)$_{589}$ isomer were antipodal to those of the Λ-(+)$_{589}$ isomer. The half-life of this stereochemical step was of the same magnitude as that of the first rate-determining step of the racemate. These CD spectral features imply that the first rate-determining step in the reaction of [Co(gly)(en)$_2$]$^{2+}$ with ethylenediamine accompanies the racemization into the first intermediate species.

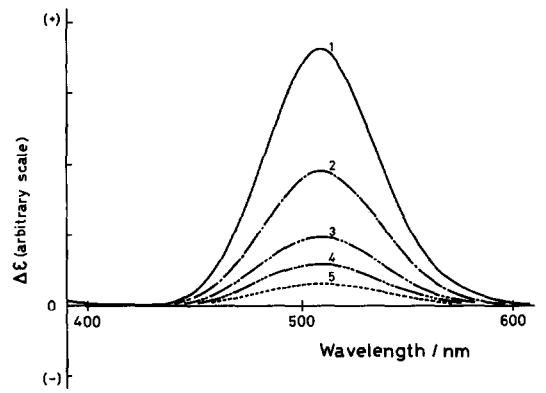

Fig. 4. CD spectral change with time of Λ-(+)$_{589}$-[Co(gly)(en)$_2$]$^{2+}$. $[[Co(gly)(en)_2]^{2+}] = 1.00\times10^{-2}$ mol dm^{-3}. [en] = 2.00 mol dm^{-3}. $[OH^-] = 1.58\times10^{-2}$ mol dm^{-3}. $[Cl^-] = 1.0$ mol dm^{-3}. 70°C. Time: 1, 0; 2, 120; 3, 240; 4, 360; and 5, 480 min.

In the case where the starting optically active isomer, $S_{\Lambda(or\Delta)}$, changes to enantiomers of the first intermediate complex, $I_{1\Lambda}$ and $I_{1\Delta}$, $S_{\Lambda(or\Delta)} \xrightarrow{k_{1\Lambda(or\Delta)}} I_{1\Lambda} + I_{1\Delta}$ the rate equation can be given in logarithmic form as follows:

$$\ln\{(\Delta\varepsilon_0-\Delta\varepsilon_\infty)/(\Delta\varepsilon_t-\Delta\varepsilon_\infty)\} = k_{1\Lambda(or\Delta)}t. \quad (3)$$

Here, $k_{1\Lambda(or\Delta)}$ is the rate constant of the starting Λ (or Δ) isomer and $\Delta\varepsilon_0$, $\Delta\varepsilon_t$ and $\Delta\varepsilon_\infty$ are total CD intensities in the initial state, at time t and at equilibrium, respectively. A linear relation was obtained on the $-\ln(\Delta\varepsilon_t-\Delta\varepsilon_\infty)$ vs t plots, from which the observed rate constant, $k^1_{obsd,\Lambda}$, was estimated for the Λ-(+)$_{589}$ isomer.

It was found that, in the concentration range $(0.20\text{–}1.58)\times10^{-2}$ mol dm^{-3} for the hydroxide ion and 1.00–2.00 mol dm^{-3} for the ethylenediamine concentration, $k^1_{obsd,\Lambda}$, was dependent on neither of them and it was the same magnitude as $k^1_{H_2O}$ for the racemate

$$k^1_{obsd,\Lambda} = k^1_{H_2O,\Lambda}. \quad (4)$$

Hence, it is concluded that the stereochemical change is accompanied solely in the aquation pathway. Kinetic parameters of the reaction pathway is given in Table 1.

DISCUSSION

The ligand substitution reaction of [Co(gly)(en)$_2$]$^{2+}$ with ethylenediamine proceeds with three rate-determining steps. This evidence rules

out a ligand substitution reaction mechanism in which the coordinated glycinate ligand dissociates from the starting complex to form an intermediate complex species such as di(aqua or hydroxo)bis(ethylenediamine)cobalt(III) or a related complex followed by coordination of ethylenediamine because this mechanism necessitates two rate-determining steps.

Presence of the third rate-determining step implies that slow liberation of unidentately coordinated ligand before the rapid ethylenediamine chelate ring closure[2] is expected as a mechanistic rate-determining step; the ligand may be glycinate coordinated through the oxygen donor atom (*vide infra*).

The reaction mechanism with three rate-determining steps can be modelled either by $S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} I_1 \underset{k_{-1}}{\overset{k_2}{\rightleftharpoons}} I_2 \xrightarrow{k_3} P$ or by $S \xrightarrow{k_1} I_1 \xrightarrow{k_2} I_2 \xrightarrow{k_3} P$, where the ks are the rate constants for the corresponding kinetic steps. Of these two model expressions, the former was rejected because we could not obtain any absorption and CD spectral evidence supporting backward processes ($I_2 \rightarrow I_1$ and $I_1 \rightarrow S$) and because no attempts to determine equilibrium constants for the processes $S \rightleftharpoons I_1$ and $I_1 \rightleftharpoons I_2$ were successful for the substitution-inert cobalt(III) complex species in the present system. Hence, the latter was adopted for the analysis of experimental data.

The first rate-determining step, which depends neither on the hydroxide ion nor on the ethylenediamine concentration and which accompanies the loss of optical activity when the optically active isomer is used as the starting complex, corresponds to the aquation with dissociative chelate ring opening[2] of the coordinated glycinate ligand. The first intermediate complex species thus formed is expected to have a glycinate ligand coordinated through the *O* donor atom and an aqua ligand *cis* to each other. This configuration occurs because glycinate tends to coordinate more easily through the *O* than through the *N* donor atom[6]* and because the intermediate species gave no splitting pattern in the first *d–d* transition band [$^1T_{1g}(O_h) \leftarrow {}^1A_{1g}(O_h)$].[7] Among three possible geometrical configurations[2] in the glycinate ring-opened, five-coordinate, transitional species are: a square planar configuration with a $(N)_3(O)$ basal plane (**I**); a trigonal bipyramidal configuration with a $(N)_3$ trigonal basal plane (**II**); and a trigonal bipyramidal one with a $(N)_2(O)$ basal plane (**III**); the species **II** is expected for the present kinetic step because the starting optically active isomer changes into racemic first intermediate complex species. Species **I** requires complete configurational retention and **III** configurational retention and conversion to *trans*-(O) isomer; hence, optical activity after the first kinetic step is anticipated for these two species. The first intermediate monoaqua complex with unidentate glycinate ligand may be subjected—before the second kinetic step—to rapid deprotonation of the coordinated water molecule in a weakly alkaline solution to give *cis*-(*O*)-[Co(gly-*O*)(OH)$(en)_2]^+$ (racemates in the case of the optically active isomer as the starting complex), where gly-*O* denotes glycinate ligand coordinated through the *O* donor atom.

The second rate-determining step corresponds to reaction of *cis*-(*O*)-[Co(gly-*O*)(OH)$(en)_2]^+$ with ethylenediamine because k^2_{obsd} is directly proportional to the ethylenediamine concentration with zero intercept (cf. Fig. 3). This step proceeds via two parallel pathways: one is independent of and the other is dependent on the hydroxide ion concentration (cf. Fig. 2). The second intermediate complex may be of a form of *cis*-(*O*,*N*)-[Co(gly-*O*)(en-*N*)$(en)_2]^{2+}$ with two unidentate ligands at the *cis* position each other, where en-*N* denotes ethylenediamine ligand unidentately coordinated. A large positive value of the activation entropy in the ethylenediamine coordination pathway of $[Co(gly)(en)_2]^{2+}$, which can be compared with that of the related pathway in the reaction of $[Co(CO_3)(en)_2]^+$,[2] implies that the mechanistic ligand substitution reaction process of the former is intrinsically analogous to that of the latter. The hydroxide-assisted ethylenediamine coordination pathway can be explained as follows; deprotonation of amino group of bidentately coordinated ethylenediamine *trans* to the hydroxide ligand in *cis*-(*O*)-[Co(gly-*O*)(OH)$(en)_2]^+$ takes place rapidly to give *cis*-(*O*)-[Co(gly-*O*)(OH)(en(−H))(en)]$^+$, where en(−H) denotes ethylenediamine in the conjugate base form, then the ligand substitution of coordinated hydroxide ligand with ethylenediamine takes place as a mechanistic rate-determining step to give *cis*-(*O*,*N*)-[Co(gly-*O*)(en-*N*)(en(−H))(en)]$^+$, to which protonation occurs rapidly to give *cis*-(*O*,*N*)-[Co(gly-*O*)(en-*N*)$(en)_2]^{2+}$.

On the basis of the discussion given above, the second rate-determining step can be expressed as eqn (5):

$$k^2_{obsd} = \{k^2_{en} + k^{2\prime}_{OH,en}(K_a/K_w)[OH^-]\}[en]/\{1+(K_a/K_w)[OH^-]\}, \quad (5)$$

* Boreham *et al.*[10] reported on base hydrolysis of *cis*-$[CoX(gly\text{-}N)(en)_2]^+$ (X = Cl and Br) to form *cis*-[Co(gly-*N*)(OH)$(en)_2]^+$ with glycinate coordinated through the *N* donor atom (gly-*N*), but the starting complex was prepared specifically from *cis*-$[CoX(gly\text{-}CH_3)(en)_2]^{2+}$,[11,12] where gly-$CH_3$ denotes methyl ester of glycine.

where K_a and K_w are the deprotonation constant of coordinated ethylenediamine to its conjugate base and the ionic product of water, respectively, and $k^{2'}_{OH,en}$ is the rate constant for the hydroxide-assisted ethylenediamine coordination pathway in its intrinsic sense. Figures 2 and 3 indicate that $(K_a/K_w)[OH^-]$ does not contribute to the denominator in eqn (5); and eqn (6) holds for the present second rate-determining step:

$$k^2_{obsd} \doteqdot \{k^2_{en} + k^{2'}_{OH,en}(K_a/K_w)[OH^-]\}[en]. \quad (6)$$

$k^2_{OH,en}$ in Table 1 may be a composite constant in which K_a and K_w are incorporated. If the tentative assumption is made that $(K_a/K_w)[OH^-] \leqslant 0.1$, then $k^{2'}_{OH,en}$ should be larger than 10^{-5} mol^{-1} dm^3 s^{-1} and K_a should not exceed 10^{-12} because K_w is of the order of 10^{-13} at 65°C[9] and $[OH^-]$ is of the order of 10^{-2} mol dm^{-3} under the experimental conditions. This estimated K_a is very small; it implies high basicity of the conjugate base because deprotonation constant of coordinated water molecule has been reported to be *ca* 10^{-8} at 25°C {*cis*-(*O*)-$[Co(OH)(H_2O)(en)_2]^{2+}$}.[10]

We could not estimate the rate constant for the third rate-determining step owing to large experimental errors accumulated from the previous two kinetic steps. However, we can safely state {from the results of $[Co(CO_3)(en)_2]^+$}[2] that the third rate-determining step corresponds to liberation of the unidentately coordinated glycinate ligand as a mechanistic rate-determining step followed by rapid chelate ring closure to give $[Co(en)_3]^{3+}$.

In conclusion, the ligand substitution reaction of $[Co(gly)(en)_2]^{2+}$ with ethylenediamine proceeds according to the following mechanism: $[Co(gly)(en)_2]^{2+}$ becomes in the first kinetic step with stereochemical structural change followed by rapid deprotonation in alkaline medium to the first intermediate *cis*-(*O*)-$[Co(gly\text{-}O)(OH)(en)_2]^+$ complex, which then reacts in the second kinetic step by hydroxide-dependent and independent parallel pathways to give the second intermediate *cis*-(*O*,*N*)-$[Co(gly\text{-}O)(en\text{-}N)(en)_2]^{2+}$ complex. This second intermediate complex finally changes in the third kinetic step to the $[Co(en)_3]^{3+}$ complex with liberation of the unidentately coordinated glycinate ligand followed by ethylenediamine chelate ring closure.

A PROTON MAGNETIC RESONANCE STUDY OF LIGAND EXCHANGE ON HEXAKIS(1,1,3,3-TETRAMETHYLUREA)THULIUM(III)

STEPHEN F. LINCOLN* and ALEX WHITE

Department of Physical and Inorganic Chemistry, University of Adelaide, South Australia 5001, Australia

(*Received* 9 *October* 1985; *accepted* 25 *November* 1985)

Abstract—A ^1H NMR study of the rate of exchange of 1,1,3,3-tetramethylurea (tmu) on $[Tm(tmu)_6]^{3+}$ is found to be independent of [tmu] over a five-fold variation in CD_3CN solution, and to be characterized by $k(298.2\ K) = 145 \pm 1\ s^{-1}$, $\Delta H^{\#} = 29.3 \pm 0.3\ kJ\ mol^{-1}$, and $\Delta S^{\#} = 105 \pm 1\ J\ K^{-1}\ mol^{-1}$. These data are discussed in conjunction with data from related lanthanide and pseudo-lanthanide systems and the mechanistic implications are considered.

The trivalent lanthanide $[Ln(solvent)_n]^{3+}$ species are characterized by $n = 9$ for water,[1] $n = 8$ for dimethylformamide (dmf),[2,3] and $n = 6$ for trimethylphosphate (tmp)[3] and 1,1,3,3-tetramethylurea (tmu).[4,5] This decrease in coordination number also appears to be characterized by a decrease in the lability of $[Ln(solvent)_n]^{3+}$ towards solvent exchange as exemplified by $[Gd(OH_2)_9]^{3+}$ and $[Lu(tmu)_6]^{3+}$ for which the exchange rate constants [k(298.2 K)] for one solvent molecule $= 1.06 \times 10^9$ and 41.9 s^{-1}, respectively.[4,6] Such variations indicate the opportunity offered by the trivalent lanthanides for the study of the factors controlling the lability and mechanism of ligand substitution processes on metal ions in the absence of significant ligand field and directional bonding effects.[7] However, at present there are no reported studies of solvent exchange or ligand substitution on a given trivalent lanthanide exhibiting different coordination numbers. Accordingly we have undertaken a study of tmu exchange on six-coordinate $[Tm(tmu)_6]^{3+}$ in order to make a comparison of the lability of this species with that of eight-coordinate $[Tm(dmf)_8]^{3+}$ and other lanthanide and pseudo-lanthanide (Sc^{3+} and Y^{3+}) species.

EXPERIMENTAL

Materials

$[Tm(tmu)_6](ClO_4)_3$ was prepared by literature methods.[8,9] Found: C, 30.7; H, 6.3; N, 14.7; Tm, 14.5%. Calc. for $[Tm(tmu)_6](ClO_4)_3$: C, 30.9; H, 6.2; N, 14.4; Tm, 14.5%. Tm(III) was determined as a trivalent cation using an ion-exchange technique,[10] and other elemental analyses were carried out by the Australian Microanalytical Service, Melbourne. (*Caution—perchlorate salts of metal complexes may be explosive under some conditions and should be handled with care. No explosion hazard was encountered during the course of this study.*) The IR spectrum of the complex in a Nujol mull exhibited no absorptions attributable to coordinated perchlorate or the presence of trace amounts of water. Hydrated thulium perchlorate was obtained through the reaction of Tm(III) oxide (Spex) with the stoichiometric amount of concentrated perchloric acid. Tmu (Fluka) and CD_3CN (99% deuterated, Aldrich) were distilled and stored over Linde 4A molecular sieves prior to use. Solutions of $[Tm(tmu)_6](ClO_4)_3$ and tmu in CD_3CN were prepared in a dry nitrogen flushed glove box, and were sealed *in vacuo* in 5-mm NMR tubes.

NMR spectroscopy

Variable-temperature 90-MHz ^1H NMR studies were carried out on a Bruker HX-90E spectrometer.

* Author to whom correspondence should be addressed.

Depending on the concentration and temperature of the sample up to 1200 transients were collected and stored as 8192 datum point blocks prior to Fourier transformation and lineshape analysis[11] on a Nicolet BNC-12 computer. Probe temperature control was ±0.03 K and the Bruker B-VT 1000 temperature controller was calibrated with a copper–constantan thermocouple.

RESULTS AND DISCUSSION

Stoichiometry of the complex in solution

The compositions of the four solutions studied are shown in Table 1. In the temperature range 235–260 K well-resolved singlet ^1H resonances were observed for coordinated and free (upfield) tmu, and comparisons of the integrated resonance areas showed that Tm(III) retains a coordination number of 6.0 ± 0.1 in solution consistent with $[Tm(tmu)_6]^{3+}$ being the greatly predominant Tm(III) species in solution. (Under the conditions of this study rotation about the C—N bonds in both coordinated and free tmu is rapid on the NMR time scale and in consequence singlet resonances are observed.[12]) Similar observations have been made for $[Lu(tmu)_6]^{3+}$ and $[Y(tmu)_6]^{3+}$ in CD_3CN solution, which indicates that CD_3CN does not compete significantly with tmu for coordination sites, and that the larger size of tmu restricts the coordination number of these metal ions to 6 in contrast to the smaller H_2O and dmf molecules, which allow coordination numbers of 9 and 8, respectively, to be attained.[1-3,7]

NMR kinetic measurements

The ^1H singlets arising from coordinated and free tmu coalesce to an environmentally averaged singlet as the temperature is increased and tmu exchange between these two environments becomes increasingly rapid (Fig. 1). The mean site lifetime of a single coordinated tmu, τ, is readily derived through lineshape analysis,[11] and some examples of the calculated lineshapes and the corresponding τ values are shown in Fig. 1. For each of the four solutions

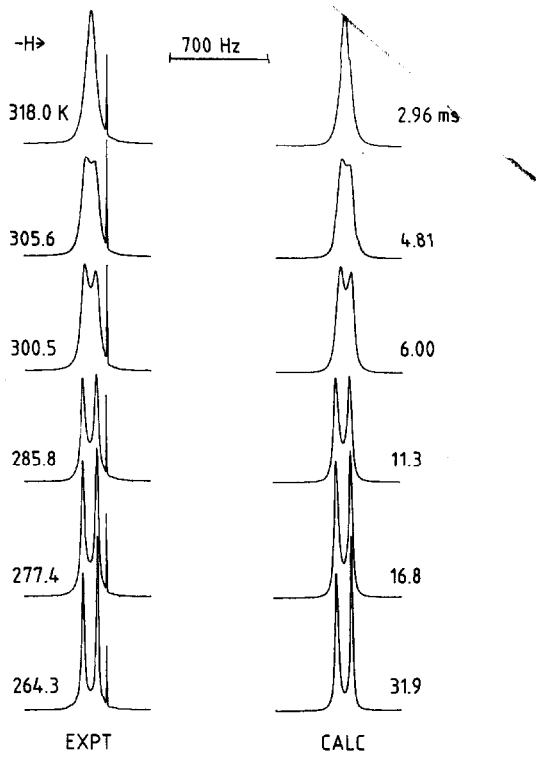

Fig. 1. ^1H NMR (90-MHz) spectra of a CD_3CN solution of $[Tm(tmu)_6](ClO_4)_3$ (0.09220 mol dm^{-3}) and tmu (0.5167 mol dm^{-3}). The downfield resonance arises from $[Tm(tmu)_6]^{3+}$. The experimental spectra and temperatures (K) are shown on the left, and the best-fit calculated lineshapes and τ (ms) values derived through complete lineshape analyses are shown on the right. The narrow multiplet appearing at high field arises from the CD_3CN proton impurity.

[a] Quoted errors represent standard deviations obtained from a linear regression fit of the experimental data to the Eyring equation.

τ values were determined for at least 10 temperatures in the range 260–315 K. The relationship between τ and the rate of tmu exchange is given by eqn (1) in which k is the first-order exchange rate constant and all other symbols have their usual meaning.

$$1/\tau = k = \text{exchange rate}/6[\text{Tm(tmu)}_6^{3+}] = k_B T/h \exp(-\Delta H^{\#}/RT + \Delta S^{\#}/R). \quad (1)$$

The derived k, $\Delta H^{\#}$ and $\Delta S^{\#}$ values for the four solutions appear in Table 1 from which it is seen that they exhibit no significant variation over the approximately five-fold variation in [tmu]. This independence of k of [tmu] is consistent with the operation of either a dissociative (D) mechanism for tmu exchange in which the rate-determining step is the formation of the reactive five-coordinate intermediate $[Tm(tmu)_5]^{3+}$ as shown in eqn (2):

$$[Tm(tmu)_6]^{3+} \xrightarrow{k} [Tm(tmu)_5]^{3+} + tmu$$
$$[Tm(tmu)_5]^{3+} + *tmu \xrightarrow{\text{fast}} [Tm(tmu)_5(*tmu)]^{3+}. \quad (2)$$

Alternatively these observations are consistent with the operation of an interchange (I) mechanism [eqn (3)] in the limit in which all of the $[Tm(tmu)_6]^{3+}$ exists in the encounter complex form, $[Tm(tmu)_6]^{3+} \ldots tmu$, in which one tmu resides in the second coordination sphere, such that $k = k_i$.

$$[Tm(tmu)_6]^{3+} + *tmu \underset{\text{fast}}{\overset{K_0}{\rightleftharpoons}} [Tm(tmu)_6]^{3+} \ldots *tmu \quad (3)$$
$$[Tm(tmu)_6]^{3+} \ldots *tmu \xrightarrow{k_i} [Tm(tmu)_5(*tmu)]^{3+} \ldots tmu.$$

For the latter mechanism to operate the encounter complex would need to be characterized by an apparent stability constant (K_0) of ~ 100 dm^3 mol^{-1}, which is approximately 100 times greater than that determined for the formation of the $[Tb(dmf)_8]^{3+} \ldots$ dmf encounter complex in CD_3NO_2 solution[3] and also that calculated through the Fuoss equation.[13] (The concentration of CD_3CN ranges from 15.474 to 17.839 mol dm^{-3} in solutions 1–4 in Table 1, and hence on a statistical basis the expectation of finding one tmu in the second coordination sphere of $[Tm(tmu)_6]^{3+}$ ranges from 95 to 20% for solutions 1–4, assuming 15–20 solvent molecules in the second coordination sphere.) Hence it appears that tmu exchange on $[Tm(tmu)_6]^{3+}$ proceeds through a D-mechanism, but the further ramifications of this conclusion are considered later.

It is now appropriate to consider the 2×10^5-fold difference in lability between $[Tm(tmu)_6]^{3+}$ and $[Tm(dmf)_8]^{3+}$ (Table 2). Tmu and dmf are both oxygen donor ligands of similar electron-donating ability, as judged from their respective Gutmann donor numbers[14] of 29.6 and 26.6, and accordingly the greater lability of $[Tm(dmf)_8]^{3+}$ must be largely attributable to its higher coordination number. The coordination of eight oxygens to Tm(III) should result in greater steric crowding close to the metal centre and therefore longer and weaker Tm—O bonds in $[Tm(dmf)_8]^{3+}$ by comparison with those in $[Tm(tmu)_6]^{3+}$. (Evidence for an increase in bond length may be adduced from the observation that in the solid state Er—O bond distances in tricapped trigonal prismatic $[Er(OH_2)_9]^{3+}$ are 2.52 and 2.37 Å for the capping and prismatic waters, respectively,[15] which compare with Er—O distances of 2.25(2) and 2.185(9)–2.198(8) Å observed in octahedral $[Er(OH_2)_6]^{3+}$ and $[Er(tmu)_6]^{3+}$, respectively.[4,16]) Thus for a dissociatively (d) activated solvent exchange process it is anticipated that for similarly bonding ligands the lability of a given metal ion should increase with increase in coordination number as is seen here for $[Tm(tmu)_6]^{3+}$ and $[Tm(dmf)_8]^{3+}$, which is seemingly the first such observation for a single metal ion.

The data in Table 2 show that as the effective ionic radius[17] of M^{3+}, r, decreases from Sc^{3+} to Y^{3+} the following systematic variations occur in the parameters characterizing tmu exchange on $[M(tmu)_6]^{3+}$: k(298.2 K) increases, $\Delta H^{\#}$ decreases and $\Delta S^{\#}$ becomes more negative. (On the basis of the observed first-order rate law all four of these exchange processes are considered to proceed through a D-mechanism.[5,8,18] As a consequence of the smaller chemical shifts exhibited by the $[Y(tmu)_6]^{3+}$ and $[Lu(tmu)_6]^{3+}$ systems[8,5] it was possible to study the tmu exchange at 270 MHz and the consequently increased sensitivity permitted the establishment of the first-order exchange rate law over [tmu] ranges of 15.3 and 19.6, respectively, and at lower [tmu] values than was possible for $[Tm(tmu)_6]^{3+}$.) A major cause of the decrease in $\Delta H^{\#}$ is probably the increase in r and the consequent decrease in the electrostatic interaction between tmu and M^{3+}, and the resultant decrease in bond strength in the ground state. The large negative $\Delta S^{\#}$ values observed for $[Tm(tmu)_6]^{3+}$ and its Lu^{3+} and Y^{3+} analogues are unexpected for a d-activated exchange process unless there is a substantial contribution to $\Delta S^{\#}$ arising from interactions outside the first coordination sphere. In the case of these species such interactions seem particularly feasible. The tricapped trigonal prismatic structure[1] in which the three capping waters are up to 9% more distant from M^{3+} than the six prismatic waters is well established for the $[Y(OH_2)_9]^{3+}$ and

$[Ln(OH_2)_9]^{3+}$ species, and it is considered that these waters may rapidly interchange between the two types of coordination sites through a capped square antiprism intermediate in solution.[7] In view of this propensity of the trivalent lanthanides for high coordination numbers it seems probable that this may be reflected in the six-coordinate $[Ln(tmu)_6]^{3+}$ exchange mechanism. Taking the tricapped trigonal prism as the reference geometry it may be envisaged that as one Ln—tmu bond lengthens (and thereby assumes some of the character of a capping ligand) to form the dissociative transition state or intermediate, there will also be a change in the bond distances and angles of the remaining five tmu ligands towards a trigonal prismatic geometry simultaneously with the positioning of the incoming tmu to take up the incipient vacancy in the sixth prismatic position. The two remaining capping positions will be occupied by acetonitrile. Because of the bulkiness of tmu it is unlikely that acetonitrile in the two capping positions could approach the metal centre as closely as water in $[Ln(OH_2)_9]^{3+}$, and in consequence the interaction between these two acetonitriles and Tm(III) will be weak at best. Nevertheless such a mechanism would produce considerable ordering into the second coordination sphere and a substantial negative entropy contribution leading to a negative $\Delta S^{\#}$ whilst retaining the dissociative character of the tmu exchange process. This proposal is highly idealized but it does suggest that the mechanistic schemes which seem to work well for the lighter six-coordinate metal ions may need modification to incorporate a more active role of the second coordination sphere in the ligand exchange processes of six-coordinate trivalent lanthanides. In the case of the smaller Sc(III) ion there appears to be no reported case of a coordination number >6 observed in the presence of monodentate ligands, and it seems unlikely that the involvement of the second coordination sphere in the $[Sc(tmu)_6]^{3+}$ exchange process will be as significant as that for its heavier analogues in Table 2.

For dmf exchange on $[Ln(dmf)_8]^{3+}$ it has also been reported that $\Delta H^{\#}$ decreases and $\Delta S^{\#}$ changes from positive to negative as r increases (Table 2). The positive $\Delta V^{\#}$ values and the rate laws for dmf exchange are consistent with the operation of D and I_d dmf exchange mechanisms for $[Tm(dmf)_8]^{3+}$ and $[Tb(dmf)_8]^{3+}$, respectively, with the negative $\Delta S^{\#}$ for the latter species being largely attributed to the involvement of a ninth dmf in the transition state.[3]

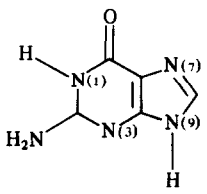
Cu(II) HALIDE AND PRIMARY AMINE COMPLEXES OF GUANINE AND XANTHINE

W. J. BIRDSALL,* B. W. PFENNIG and J. L. TOTO

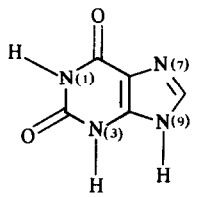
Department of Chemistry, Albright College, Reading, PA 19604, U.S.A.

(*Received* 28 *September* 1985; *accepted* 26 *November* 1985)



Abstract—Guanine (Gua) and xanthine (Xan) complexes of copper halides of types Cu(Gua)Cl_2, Cu(Gua)Br_2, Cu(Xan)$_2Cl_2 \cdot 2H_2O$ and Cu(Xan)$_2Br_2$ were synthesized by the interaction of the ligand and respective metal halide in methanol. In addition, Cu(Gua)$(CH_3NH_2)_2 \cdot 2H_2O$ and Cu(Xan)$(CH_3CH_2NH_2)_2 \cdot 2H_2O$ were prepared by reacting $CuSO_4 \cdot 5H_2O$ with the respective purine in the indicated primary amine. IR spectra of the halide complexes suggest that their stereochemistry is distorted tetrahedral, in keeping with previously reported complexes of this type. The amine compounds exhibit significant carbonyl IR shifts, indicating hydrogen bonding is present between purine carbonyl and the primary amine. Room-temperature magnetic susceptibilities are normal for related Cu(II) complexes. Comparison of these compounds with known complexes suggests the possibility of N(7)–N(9) purine bridging between copper atoms leading to polymer formation.

The interaction of metal ions with nucleic acids and nucleic acid constituents has been actively studied in recent years.[1,2] Research has provided information as to how certain metal ions bind to and influence DNA and RNA, as well as the mode of action of anti-cancer drugs containing metal ions such as *cis*-$PtCl_2(NH_3)_2$.[3,4] We have prepared a number of complexes with theophylline, a purine derivative with structural similarities to guanine and xanthine.[5] We report now the synthesis and structural study of halide adducts of Cu(II) with guanine and xanthine, with the general formulae Cu(Gua)X_2 (Gua = guanine) and Cu(Xan)$_2X_2$ (Xan = xanthine), where X = Cl and Br. We have also synthesized Cu(II) complexes of xanthine and guanine with primary amines, namely Cu(Xan)$(CH_3CH_2NH_2)_2 \cdot 2H_2O$ and Cu(Gua)$(CH_3NH_2)_2 \cdot 2H_2O$.



Cu(Gua)Cl_2 and Cu(Xan)$_2Cl_2 \cdot 2H_2O$ have been prepared previously but not structurally characterized.[6] X-ray structural determinations have been performed on Zn(Gua)Cl_3,[7] a monomer with Zn–N(9) bonding, and on Cu(Gua)$Cl_3 \cdot 2H_2O$,[8] a dimer with Cu–N(9) bonding and copper bridging by chlorine atoms. Structures of Cu(II) complexes with xanthine and hypoxanthine have been reported with metal coordination to the ligand N(9) nitrogen, as well as N(3) nitrogen in bidentate complexes.[9,10] Related Cu(II) complexes of xanthine and guanine have been reported,[11] as well as 3*d* metal perchlorate complexes of guanine,[12,13] guanine metal chloride adducts,[14–17] and xanthine 3*d* metal complexes.[18] The syntheses of guanine adducts with Co(II), Cu(II) and Zn(II) of general formula M(Gua)Cl_2 have recently been reported,[19] and a linear polymeric structural type with metal centers of tetrahedral symmetry bridged by guanine ligands has been proposed for these complexes.

Vestues and Sletten have reported the X-ray structure of the copper–purine complex, [Cu(Pur)$(H_2O)_4$]$SO_4 \cdot 2H_2O$ (Pur = purine), to be a polymeric chain with copper atoms in an octahedral coordination binding to N(7) and N(9) of two purine rings, a mode of bonding known for imidazole and benzimidazole complexes.[20] Many other purine metal complexes do not exhibit this N(7)–N(9) purine bridging, however; the dimeric nature of Cu(Gua)$Cl_3 \cdot 2H_2O$ and the monomeric Cu(Tp)$_2Cl_2$ (Tp = theophylline)[21] illustrate that a wide variety of bonding is present in compounds of

Purine

this type. We have used IR (4000–200 cm^{-1}) and room-temperature magnetic susceptibility measurements to study the presently reported guanine and xanthine complexes, in an attempt to better understand their structures.

EXPERIMENTAL

Preparation of $Cu(Gua)Cl_2$, $Cu(Gua)Br_2$, $Cu(Xan)_2Cl_2 \cdot 2H_2O$ *and* $Cu(Xan)_2Br_2$

The synthetic procedure was similar to that used in the preparation of theophylline–copper halide complexes reported previously.[5] 5.0 mmol of the purine and 5.0 mmol of either $CuCl_2 \cdot 2H_2O$ or $CuBr_2$ were refluxed in methanol for 24 h, and allowed to cool to room temperature before filtration of the solid product. A 4:1 molar ratio of $CuBr_2$–xanthine was employed to form $Cu(Xan)_2Br_2$; this eliminated the need to separate unreacted xanthine at the conclusion of the reflux period. Found: C, 16.2; H, 1.5; N, 18.9; Cu, 16.7%. Calc for $Cu(C_5H_4N_5O)Br_2$ (dark brown): C, 16.1; H, 1.1; N, 18.7; Cu, 17.0%. Found: C, 23.1; H, 1.1; N, 21.5; Cu, 11.9%. Calc. for $Cu(C_5H_3N_4O_2)_2Br_2$ (orange–yellow): C, 22.8; H, 1.1; N, 21.2; Cu, 12.0%. $Cu(Gua)Cl_2$ (dark brown) and $Cu(Xan)_2Cl_2 \cdot 2H_2O$ (green) have been prepared previously by another method,[6] but the present synthetic procedure produced identical compounds, as evidenced by identical IR spectra and Cu analyses.

Preparation of $Cu(Xan)(CH_3CH_2NH_2)_2 \cdot 2H_2O$ *and* $Cu(Gua)(CH_3NH_2)_2 \cdot 2H_2O$

These compounds were synthesized in a similar fashion to previously reported copper–theophylline adducts with primary amines.[22,23] Because of the low solubility of guanine in methylamine, 5.0 mmol $CuSO_4 \cdot 5H_2O$ and 5.0 mmol guanine were stirred for 24 h in 25% methylamine–H_2O to produce a blue powder. Found: C, 31.9; H, 5.8; N, 24.5; Cu, 18.6%. Calc. for $(C_5H_3N_4O_2)Cu(C_2H_7N)_2 \cdot 2H_2O$ (blue): C, 31.7; H, 6.2; N, 24.7; Cu, 18.6%. Found: C, 26.9; H, 5.5; N, 31.5; Cu, 20.1%. Calc. for $(C_5H_4N_5O)Cu(CH_5N)_2 \cdot 2H_2O$ (blue): C, 27.0; H, 5.8; N, 31.5; Cu, 20.4%.

IR spectra were obtained as Nujol mulls between high-density polyethylene windows (600–200 cm^{-1}) and as KBr pellets (4000–500 cm^{-1}) on a Perkin–Elmer 1430 spectrophotometer. Room-temperature magnetic susceptibility measurements were made on a Gouy balance of standard design. Elemental analyses (C, H and N) were performed by Galbraith Laboratories.

RESULTS AND DISCUSSION

The crystal structure of $Cu(Tp)_2Cl_2$ has recently been reported.[21] Copper is coordinated to two imidazole N(7) atoms from theophylline ligands and two chlorine atoms. The stereochemistry about copper is a flattened tetrahedron, intermediate between tetrahedral and *cis*-square-planar. Monomeric $Cu(Tp)_2Cl_2$ units are hydrogen bonded to one another through N(9) hydrogen donor atom from one complex and the O(6) exocyclic oxygen atom from another complex. A distorted tetrahedral stereochemistry was also reported for this complex as well as for $Cu(Tp)_2Br_2 \cdot H_2O$ on the basis of low-frequency IR analysis.[5] Prominent doublets could be assigned to Cu—Cl and Cu—Br stretching, suggesting a tetrahedral or *cis*-square-planar symmetry about the copper atom.

Table 1 lists selected IR frequencies for the guanine and xanthine complexes. Prominent doublets are observed for $Cu(Gua)Cl_2$ and $Cu(Gua)Br_2$ at 285 and 258, and 245 and 220 cm^{-1}, respectively. The Cu—Br/Cu—Cl frequency ratio is 0.86, in keeping with ratios of other reported complexes of this sort, and confirming their assignments. This was the only region of the 4000–200-cm^{-1} IR spectra where significant differences were observed in these two compounds. Two low-frequency guanine bands at 345 and 398 cm^{-1} are slightly shifted to higher frequencies upon complexation, similar to but not to the same extent as low-frequency bands of compounds of theophylline and pyridine.[5,24] Guanine exhibits strong absorbances at 1698 and 1672 cm^{-1}, primarily due to $\nu(C{=}O)$ and $\delta(NH_2)$, respectively;[25] the carbonyl frequency at 1698 cm^{-1} does not change appreciably in the halide complexes, but two intense absorbances replace the peak at 1672 cm^{-1} [1698, 1645 and 1605 cm^{-1} in

Table 1. Selected IR frequencies (cm^{-1}) of Cu(II) halide and Cu(II) primary amine complexes of guanine and xanthine

$\delta(NH_2)$ and δ(OH) also present in guanine and xanthine, respectively.

$Cu(Gua)Cl_2$; and 1695, 1642 and 1600 cm^{-1} in $Cu(Gua)Br_2$]. Methylmercury(II) complexes of 9-methylguanine with metal coordination to N(7) exhibit similar changes in this spectral region, but X-ray analysis demonstrates that the C(6) carbonyl of 9-methylguanine is not involved in chelate formation with the metal and hydrogen bonding does not occur between guanine molecules.[26]

The binuclear $Cu(Gua)Cl_3 \cdot 2H_2O$ complex is a dimer consisting of chlorine-bridged copper atoms, each having a trigonal-bipyrimidal environment.[8] Copper is bonded to the N(9) of guanine and to one of the bridge chlorines in the axial direction. The trigonal plane consists of three Cu—Cl bonds. Other halogen-bridged Cu(II) guanine dimers include $Cu(Gua)Cl_3$, $Cu(Gua)Br_3$ and $Cu(Gua)F_3 \cdot 2H_2O$.[27] The C(6) carbonyl IR frequency for these compounds does not change upon coordination, suggesting that carbonyl is not involved in bonding.

Mikulski *et al.* have recently reported the synthesis of $Cu(Gua)Cl_2$, a green solid obtained by refluxing a 2:1 molar ratio of guanine and $CuCl_2$ for 2–3 days in a 7:3 (v/v) mixture of ethanol–triethylorthoformate.[19] This complex is physically different from the presently reported dark brown $Cu(Gua)Cl_2$, which is identical to that reported by Weiss and Venner.[6] However, the structure of the green $Cu(Gua)Cl_2$ is proposed to be a linear chain-like polymer with copper atoms of tetrahedral symmetry bridged by bidentate guanine molecules, a structure which is also possible for the present compound. Cu—Cl and Cu—N doublets are assigned at 329 and 313 and 292 and 253 cm^{-1}, respectively, and C(6) carbonyl frequencies do not shift appreciably upon complexation, suggesting that the C(6) carbonyl does not participate in coordination. However, this complex is not identical to the presently discussed $Cu(Gua)Cl_2$;[6] its color and IR spectrum are significantly different.

Vestues and Sletten have obtained the crystal structure of the purine complex $[Cu(Pur)(H_2O)_4]SO_4 \cdot 2H_2O$, and report that the copper ion is octahedrally surrounded, binding equatorially to N(7) and N(9) in two symmetry-related purine rings, producing a polymeric chain.[20] This bonding is known for imidazole– and benzimidazole–metal complexes, and Vestues and Sletten suggest that this mode of bonding is probably also present in other metal halide complexes of purine.[28] In fact, the authors assign a Cu—Cl stretching frequency in $Cu(Pur)Cl_2 \cdot H_2O$ at 298 and 284 cm^{-1},[28] an assignment which could suggest distorted tetrahedral coordination about the copper atoms linking purine molecules through N(7)–N(9) bridges. N(7)–N(9) bridging in platinum complexes of theophylline has also been reported;[29] theophylline anions are reported to form a trimeric complex with trimethylplatinum(IV) containing Pt–N(7)–N(9)–Pt bridges and O(6)–Pt bonds.

Table 1 lists several IR frequencies for $Cu(Gua)(CH_3NH_2)_2 \cdot 2H_2O$. Guanine carbonyl frequencies at 1698 and 1672 cm^{-1} are shifted to 1638 and 1588 cm^{-1} in this complex, demonstrating significant hydrogen bonding between methylamine and the C(6) carbonyl. The magnitude and direction of this shift is similar to those noticed in copper amine complexes of theophylline.[30] Intramolecular hydrogen bonding between the C(6) carbonyl and other metal-coordinated ligands has been documented through several X-ray structural determinations of theophylline–metal complexes.[1,2,31] Cu–N absorbances can be tentatively assigned at 280 and 227 cm^{-1}, which is consistent with those reported for other guanine–copper complexes;[11] these weak absorbances, however, could arise from either copper–methylamine or copper–guanine nitrogen stretching. Metal halide bands obscure this region in $Cu(Gua)Cl_2$ and $Cu(Gua)Br_2$. Low-frequency ligand bands in Cu(Gua)

$(CH_3NH_2)_2 \cdot 2H_2O$ are similar to those of the guanine halide complexes.

Room-temperature magnetic susceptibility measurements for the guanine and xanthine complexes are normal for Cu(II) compounds, with the bromide and amine derivatives of both xanthine and guanine slightly subnormal. X-ray structure determinations of adenine and hypoxanthine Cu(II) compounds with room-temperature magnetic susceptibilities between 1.38–1.74 BM[6,32] show that they consist of quadruple bridges of bidentate purine connecting two Cu(II) centers through N(3) and N(9) ring nitrogen atoms.[9,33–35] Mikulski *et al.*[11] have prepared $Cu(Xan)_2 \cdot 2C_2H_5OH$ (μ_{eff} 1.60 BM) and $Cu(Gua)_2 \cdot H_2O$ (μ_{eff} 1.57 BM), and propose that they are binuclear complexes with copper atoms bridged by purine nitrogen atoms.

Selected IR frequencies for the isomorphous xanthine–copper halide complexes (Table 1) exhibit a low-frequency doublet for the copper compound in keeping with that observed for the above guanine derivatives, but a single peak for the bromide compound. The bromide absorption, 234 cm^{-1}, may be the high-frequency peak of a doublet extending below 200 cm^{-1}, or it may suggest a different stereochemistry in this complex. Tentative assignments can be made for Cu—N stretching at 258 cm^{-1} for $Cu(Xan)_2Cl_2 \cdot 2H_2O$ and at 250 cm^{-1} for $Cu(Xan)_2Br_2$; these absorbances are not observed for the above guanine halide complexes. A low-frequency xanthine band at 353 cm^{-1} shifts slightly to higher frequency upon complexation. Broad absorbances in xanthine at 1700 and 1660 cm^{-1}[11] sharpen and shift slightly to higher energy in $Cu(Xan)_2Cl_2 \cdot 2H_2O$ (1720 cm^{-1}) and $Cu(Xan)_2Br_2$ (1728 and 1700 cm^{-1}); this suggests that carbonyl is not involved in extensive hydrogen bonding in these complexes, perhaps even less than in free xanthine. Carbonyl frequencies shift considerably in $Cu(Xan)(CH_3CH_2NH_2)_2 \cdot 2H_2O$, however, from 1700 and 1660 to 1651 and 1600 cm^{-1}; this indicates that xanthine carbonyl is involved in hydrogen bonding with ethylamine in this complex, similar to the situation in the above $Cu(Gua)(CH_3NH_2)_2 \cdot 2H_2O$ and also in theophylline–copper(II) amine adducts.[30] Cu—N absorbances can be tentatively assigned at 283 and 250 cm^{-1}.

Copper halide complexes of guanine and xanthine exhibit low-frequency IR spectra which suggest that their stereochemistry is tetrahedrally distorted, similar to that observed in $Cu(Tp)_2Cl_2$.[5,21] Tetrahedral coordination about the metal center cannot be assigned with certainty to the primary amine complexes of guanine and xanthine; significant carbonyl hydrogen bonding with the primary amines is noticed in these adducts, however. Normal to slightly low room-temperature magnetic moments are present, suggesting bridged polymeric structures may occur in at least some of the complexes. These observations are similar to those of Cu(II) halide and amine complexes of theophylline.[5,30]

Crystal structure determinations of metal complexes of guanine reveal metal ion–N(9) coordination,[7,8] and N(9)–metal coordination is also observed in xanthine–metal complexes whose structures have been determined.[9,10] If N(9) coordination is assumed for the present compounds on the basis of previous structures, copper bonding may also occur to N(7) [or possibly N(1)] in $Cu(Gua)(CH_2NH_2)_2 \cdot 2H_2O$ and $Cu(Xan)(CH_3CH_2NH_2)_2 \cdot 2H_2O$, as evidenced by purine carbonyl hydrogen bonding to coordinated amines. On the basis of the known structure of polymeric $[Cu(Pur)(H_2O)_4]SO_4 \cdot 2H_2O$, where copper centers are bridged by purine N(7) and N(9) atoms,[20] N(7)–Cu–N(9) bridging for polymer formation may occur as well in the present complexes.

MONO-η-ARENEBIS(TRIMETHYLPHOSPHINE)RHENIUM CHEMISTRY: ALKYL, HYDRIDO, HALOGENO AND OLEFIN DERIVATIVES

MALCOLM L. H. GREEN,* DERMOT O'HARE and JULIAN M. WALLIS

Inorganic Chemistry Laboratory, South Parks Road, Oxford OX1 3QR, U.K.

(*Received* 22 *November* 1985; *accepted* 27 *November* 1985)

Abstract—Co-condensation of rhenium atoms with a benzene–trimethylphosphine mixture gives the dimer $[Re(\eta\text{-}C_6H_6)(PMe_3)_2]_2$ which is a precursor to the new compounds $Re(\eta\text{-}C_6H_6)(PMe_3)_2R$ (R = H, Cl, I, Me, Et, CH=CH$_2$ or Ph), $[Re(\eta\text{-}C_6H_6)(PMe_3)_2X_2]BF_4$ ($X_2 = H_2$ or HI), $[Re(\eta\text{-}C_6H_6)(PMe_3)_2H_2][BF_4]_2$, and $[Re(\eta\text{-}C_6H_6)(PMe_3)_2L]BF_4$ (L = $\eta\text{-}C_2H_4$ or CO). Co-condensation of manganese atoms with benzene–trimethylphosphine gives $Mn(\eta\text{-}C_6H_6)(PMe_3)_2H$.

There are relatively few mono-η-arene rhenium complexes known, with the majority of these being members of the class of cations $[(\eta\text{-arene})Re(CO)_3]^+$.[1] Recently, the η-arene complex $(\eta\text{-}C_6H_6)Re(PPh_3)_2H$, synthesized from $Re(PPh_3)_2H_7$, has been described.[2] Co-condensation of rhenium atoms with a mixture of benzene and alkanes, or with alkyl-substituted benzenes gives binuclear compounds in the class $(\eta\text{-arene})Re(\mu\text{-}H)_2(\mu\text{-alkylidene})Re(\eta\text{-arene})$.[3,4] The compounds $Re(\eta\text{-}C_6H_6)(\eta\text{-}C_6H_8)H$ and $(\eta\text{-}C_6H_6)Re(\mu\text{-}H)_2Re(\eta\text{-}C_6H_8)_2$ have also been synthesised via rhenium atom reactions.[5,6] In a further development of η-arene rhenium chemistry we explored the reaction between rhenium atoms and a mixture of benzene and trimethylphosphine and found that the dimer $[Re(\eta\text{-}C_6H_6)(PMe_3)_2]_2$ could be prepared on a 1–2-g scale. Here we describe the chemistry of the $Re(\eta\text{-}C_6H_6)(PMe_3)_2$ system. A brief report of part of this work has been communicated previously.[7]

RESULTS

Co-condensation of rhenium atoms with a benzene–trimethylphosphine mixture (5:1) gives a red oil. Chromatography on alumina separated three rhenium compounds. Elution with toluene separated a small yellow band from which the compound $Re(\eta\text{-}C_6H_6)(PMe_3)_2Ph$ (**1**) was isolated. Further elution with diethyl ether separated a second band from which orange crystals of the dimer $[Re(\eta\text{-}C_6H_6)(PMe_3)_2]_2$ (**2**) were obtained. Finally, elution with acetone–water followed by addition of sodium tetrafluoroborate to the eluate gave the dihydride $[Re(\eta\text{-}C_6H_6)(PMe_3)_2H_2]BF_4$ (**3**).

Elemental analysis, NMR spectroscopic data and other characterizing data for compounds **1**–**3**, and for all the other new compounds described below, are given in Table 1 and, except where interpretation is not straightforward, the data are not further discussed.

The $^{13}C\text{-}\{^1H\}$ NMR spectrum of **1** shows a virtual triplet at δ 23.5 assigned to two trimethylphosphine ligands, and a triplet η-benzene resonance at δ 72.9 ($J = 2.08$ Hz). Resonances at δ 120.0, 126.1 and 144.2 are, respectively, assigned to the *para*-, *meta*- and *ortho*-carbons of the phenyl group: the *ipso*-carbon was not observed. The ^1H NMR spectrum of **3** showed the two Re-hydrogens to be equivalent and the data are consistent with either a *trans*- or a fluxional *cis*-structure. Compound **3** is presumed to be formed from the protonation on the chromatography column of the neutral hydride $Re(\eta\text{-}C_6H_6)(PMe_3)_2H$, which is described below. Evidence for this comes from the fact that the ^1H NMR spectrum of the sublimate from a crude sample of the co-condensation mixture showed a triplet hydride at δ 8.70, assignable to $Re(\eta\text{-}C_6H_6)(PMe_3)_2H$.

Treatment of **2** with iodine gave no tractable product, neither did **2** react with sodium amalgam (2%). However, stirring a tetrahydrofuran (thf) solution of **2** in the presence of a K film caused the

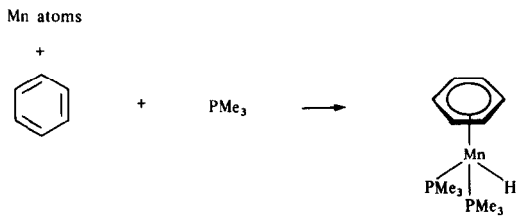
[h] ν(C=O) = 1912 cm^{-1}.

[i] ν(Mn–H) = 1722 cm^{-1}.

initial orange solution to darken gradually to deep red; this reaction could be facilitated by addition of a catalytic amount of naphthalene. The red thf solution was very air- and water-sensitive, and this intermediate species, which we presume to be the K salt of the 18-electron anion $[Re(\eta\text{-}C_6H_6)(PMe_3)_2]^-$ (**4**), was not characterized. Indirect evidence for the nature of **4** comes from its reaction with water; dropwise addition of the red thf solution into wet Et_2O causes an immediate decolorization to give a bright yellow solution. Chromatography of the solution gave **3** as the only isolated complex.



Treatment of the red solution (**4**) with MeI gave orange crystals of $Re(\eta\text{-}C_6H_6)(PMe_3)_2I$ (**5**). Addition of HBF_4 in Et_2O to **2** gives orange-pink crystalline $[Re(\eta\text{-}C_6H_6)(PMe_3)_2H]_2[BF_4]_2$ (**6**). The protonation may be reversed by treatment of **6** with $NaOH_{aq.}$ or potassium hydride (KH).

The iodo compound **5** is a useful synthetic intermediate for development of the chemistry of the $Re(\eta\text{-}C_6H_6)(PMe_3)_2$ radical. Thus, treatment of **5** with Grignard reagents (RMgX) (RX = MeI, EtI or $CH_2{=}CHBr$) or PhLi gives the compounds $Re(\eta\text{-}C_6H_6)(PMe_3)_2Me$ (**7**), $Re(\eta\text{-}C_6H_6)(PMe_3)_2Et$ (**8**), $Re(\eta\text{-}C_6H_6)(PMe_3)_2(CH{=}CH_2)$ (**9** and **1**), respectively. Treatment of **5** with lithium tetrahydridoaluminate(III) gives the hydrido derivative $Re(\eta\text{-}C_6H_6)(PMe_3)_2H$ (**10**).

Treatment of the iodo compound **5** with HBF_4 in Et_2O gives the iodohydride $[Re(\eta\text{-}C_6H_6)(PMe_3)_2HI]BF_4$ (**11**). The η-ethylene compound $[Re(\eta\text{-}C_6H_6)(PMe_3)_2(\eta\text{-}C_2H_4)]BF_4$ (**12**), is formed by treatment of **5** with $TlBF_4$ in the presence of 1 atm ethylene; by abstraction of a hydride ion from the β-hydrogen of **8** using trityl tetrafluoroborate and also by protonation of **9** with HBF_4in Et_2O. The ^1H and ^{13}C NMR spectra of **12** show the hydrogen and carbon atoms to be equivalent and coupled to two ^{31}P nuclei. This suggests that the ethylene hydrogens are made equivalent by rotation of the ethylene ligand about the Re–ethylene bond.

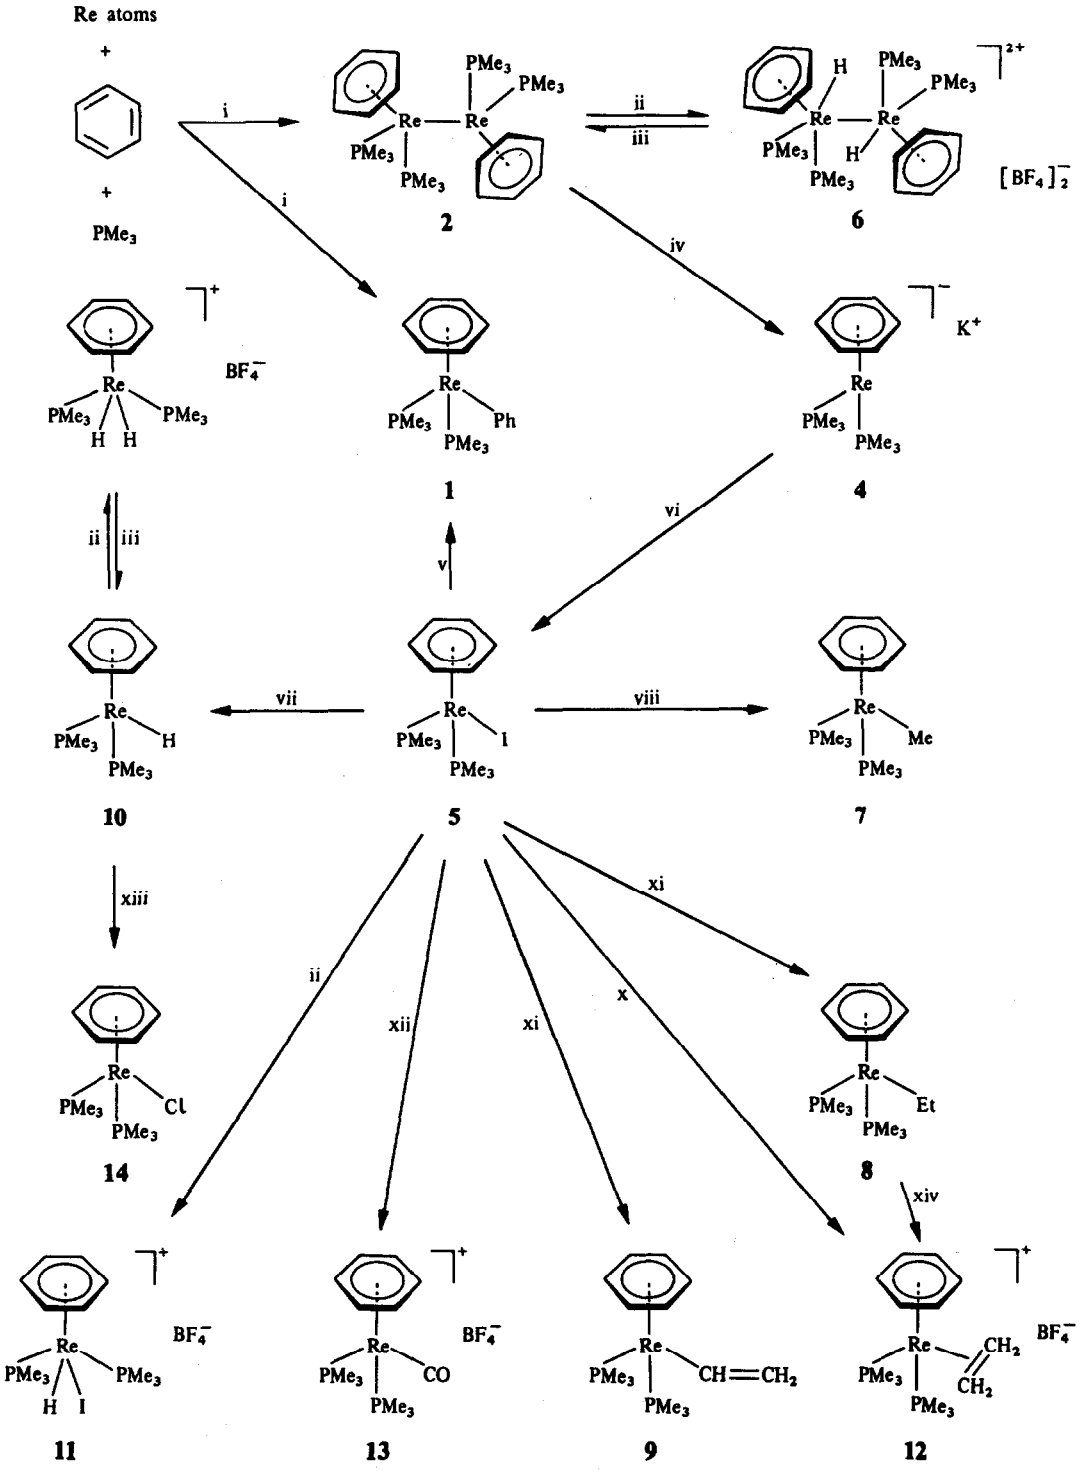
Treatment of **5** with $TlBF_4$ in the presence of CO gives colourless crystals of the monocarbonyl $[Re(\eta\text{-}C_6H_6)(PMe_3)_2CO]BF_4$ (**13**), for which the IR spectrum shows a strong band assignable to $\nu(C{=}O)$ at 1912 cm^{-1}.

The hydride **10** is highly reactive towards CH_2Cl_2, giving the chloro compound $Re(\eta\text{-}C_6H_6)(PMe_3)_2Cl$ (**14**), in excellent yields. Treatment of **10** with triethyloxonium tetrafluoroborate gives the dihydride $[Re(\eta\text{-}C_6H_6)(PMe_3)_2H_2]BF_4$ (**3**); it is possible that protonation resulted from adventitious water. Compound **3** is stable in aqueous base but may be deprotonated using potassium hydride.

15

Scheme 1.

Co-condensation of manganese atoms with benzene–trimethylphosphine (5 : 1) affords, on work-up, volatile, orange-red, petroleum ether soluble crystals of $Mn(\eta\text{-}C_6H_6)(PMe_3)_2H$ (**15**). The ^1H NMR spectrum of **15** shows three resonances; a singlet at δ 4.36 may be assigned to a coordinated η-benzene ring, a virtual triplet at δ 1.04 is assignable to the two trimethylphosphine ligands, and a high-field triplet at δ 10.39 ($J = 82.8$ Hz) is attributable to a single metal hydride ligand (see Scheme 1).



The photoelectron spectra of **2**, **5**, **10** and **15** show the first ionization potentials to be 6.18, 6.40, 6.21 and 6.06 eV, respectively.[8]

DISCUSSION

The structures proposed for compounds **1–14** are shown in Scheme 2. The low ionization energies for the compounds **2**, **5** and **10** show them to be classifiable as high-energy (electron-rich) compounds. This is supported by the basicity of these compounds as exemplified by their ease of protonation. Unlike the well-known dimer $[Fe(\eta\text{-}C_5H_5)(CO)_2]_2$, the dimer **2** is not cleaved by sodium amalgam but requires more vigorous conditions, namely a K film. The formation of the iodo compound from the reaction between the anion $[Re(\eta\text{-}C_6H_6)(PMe_3)_2]^-$ and iodomethane may be presumed to proceed via a radical process and contrast with the reaction between methyl iodide and the anion $[Fe(\eta\text{-}C_5H_5)(CO)_2]^-$, in which the methyl derivative $Fe(\eta\text{-}C_5H_5)(CO)_2Me$ is formed. In other respects the chemistry of the radical $Re(\eta\text{-}C_6H_6)(PMe_3)_2$ follows expected patterns.

EXPERIMENTAL

All preparations and reactions described were carried out under an atmosphere of dinitrogen using standard Schlenk vessel and vacuum line techniques. Solvents were pre-dried over molecular sieves and then distilled from K (toluene, benzene, cyclohexane or thf), Na–K alloy [pentane, petroleum ether (40–60°C) or Et_2O] or phosphorus pentoxide (CH_2Cl_2), under dinitrogen.

Scheme 2. (i) Rhenium atoms with benzene–trimethylphosphine, 2% for **1**, 20% for **2**, (ii) HBF_4 in Et_2O (90%), (iii) $NaOH_{aq.}$ (> 90%), (iv) K metal film in thf (> 90%), (v) PhLi in Et_2O at rt (> 70%), (vi) MeI in thf at rt for 30 min (62%), (vii) $LiAlH_4$ in thf at rt for 3 h (85%), (viii) MeMgBr in thf at 50°C for 2 h (70%), (ix) EtMgBr in Et_2O at rt for 1 h (49%), (x) $TlBF_4$ and ethylene (2 atm) in thf for 2 days (30%), (xi) vinylmagnesium bromide in thf at rt (49%), (xii) $TlBF_4$ and CO (2 atm) in thf at rt for 16 h (20%), (xiii) CH_2Cl_2 at rt for 2 h (93%), (xiv) $[Ph_3C][BF_4]$ in CH_2Cl_2 at rt (21%).

Elemental analyses were performed by the Analysis Department in this laboratory, or, in the case of very air-sensitive materials, by the Analytische Laboratorien, 5270 Gummersbach 1 Elbach, F.R.G.

IR spectra were recorded on a Pye–Unicam SP2000 double-beam grating spectrophotometer, or on a Perkin–Elmer 457 double-beam grating spectrophotometer. NMR spectra were recorded on a JEOL PMX60 (^{1}H NMR 60 MHz, c.w.), a Bruker WH300 (^{1}H NMR, 300 MHz) or a Bruker AM250 (heteronuclear NMR, 250 MHz). ^{13}C NMR and ^{31}P NMR spectra were run at frequencies of 62.9 and 101.2 MHz, respectively. Low-resolution mass spectra were recorded on an AEI MS902 mass spectrometer. Photoelectron spectra were recorded on a PES Laboratories 0078 spectrometer using a heated inlet system. The spectrometer was calibrated using He, Xe and N_2 ionization potentials. Syntheses with metal atoms were carried out using the apparatus described elsewhere,[9] metals were vaporized from a positive-hearth, electron-gun furnace, based on designs provided by G. V. Planer Co. Ltd.

Reaction of rhenium atoms with benzene–trimethylphosphine: *η-benzenebis(trimethylphosphine)phenylrhenium* (**1**), *bis[η-benzene-bis(trimethylphosphine)rhenium* (**2**) *and η-benzenebis(trimethylphosphine)dihydridorhenium tetrafluoroborate* (**3**)

A sample of rhenium powder (*ca* 12 g) was melted in an electron-gun furnace giving a rhenium ingot free of volatiles. This sample was then heated to *ca* 2600°C at which temperature rhenium vaporizes steadily. The vacuum in the reaction chamber, measured at a point below the furnace was *ca* 10^{-4} torr. The input power to the electron-gun furnace was maintained at 6 kV and 450 mA throughout. Rhenium atoms (4.1 g, 22 mmol) were co-condensed with a 5:1 molar mixture of benzene and trimethylphosphine (100 cm^3) for 4 h. After warming to room temperature (rt) the red-brown mixture was washed out of the machine with toluene (750 cm^3), filtered through a bed of Celite and reduced to a brown oil under reduced pressure at 50°C. The oil was extracted with petroleum ether (40–60°C, 5 × 300 cm^3), filtered through Celite and reduced in volume to 50 cm^3, giving a deep red solution. The red solution was adsorbed onto a chromatography column (neutral alumina, 6% water by weight, 50 × 4 cm).

Elution with toluene gave an orange band, which upon concentration of the eluate gave a deep red oil. Extraction with petroleum ether (40–60°C, 50 cm^3) gave an orange solution, which, on cooling to −80°C, yielded yellow crystals of **1**. Yield 0.2 g (2%).

Further elution with Et_2O produced a yellow band, which upon reduction in volume of the eluate and cooling to −20°C gave orange crystals of **2**. Yield 1.8 g (20%), based on rhenium evaporated from the furnace.

Further elution with aqueous acetone (1 : 1) gave a quickly moving brown band. Removal of the acetone under reduced pressure, followed by the addition of excess aqueous ammonium tetrafluoroborate produced an orange precipitate, which was collected and dried. Recrystallization from acetone (20 cm^3) gave yellow microcrystals of **3**. Yield 0.2 g (2%).

10 (50 mg, 0.12 mmol) was dissolved in Et_2O (30 cm^3), and three drops of ethereal HBF_4 were added. An immediate orange precipitate formed, which was washed with Et_2O (3 × 20 cm^3), and dried *in vacuo*. Recrystallization from acetone–water afforded orange crystals of (η-benzene) bis(trimethylphosphine)dihydridorhenium tetrafluoroborate. Yield 58 mg (95%).

Reaction beween **2** *and* K *metal*: *synthesis of* **4**

2 (1.0 g, 1.2 mmol) in thf (70 cm^3) was transferred on to a freshly prepared K film. One crystal of naphthalene was added to the orange solution. The solution was stirred and turned to deep red after 10 min. The colour deepened markedly over 8 h. The resulting solution was filtered and used immediately in subsequent reactions.

η-Benzenebis(trimethylphosphine)iodorhenium (**5**)

2 (1.0 g, 1.2 mmol) was used to prepare a red solution, as described above. Freshly distilled MeI (0.5 cm^3, 8.0 mmol) was added dropwise to the deep red solution with stirring. A white precipitate immediately developed and the solution changed from deep red to orange. The mixture was stirred for 30 min and then reduced to an oily solid under reduced pressure. Extraction with toluene (3 × 20 cm^3), followed by filtration and concentration produced a red oil. Extraction with petroleum ether (40–60°C, 3 × 20 cm^3) yielded, on concentration and cooling to −20°C, orange crystals of Re(η-C_6H_6)$(PMe_3)_2$I. Yield 0.8 g (62%).

Bis[(η - benzenebis(trimethylphosphine)hydridorhenium] bis-tetrafluoroborate (**6**)

The (η-benzene)bis(trimethylphosphine)rhenium dimer (70 mg, 0.08 mmol) was dissolved in Et_2O (30 cm^3), and excess of HBF_4 in Et_2O was added dropwise. An immediate orange-pink precipitate

formed, leaving a colourless solution. After washing with ether (3×20 cm^3), the solid was collected and dried *in vacuo*. Recrystallization from acetone–water gave orange crystals of **6**. Yield 76 mg (90%).

Reaction of **6** *with* $NaOH_{aq.}$

6 (50 mg, 0.05 mmol) in thf (10 cm^3) was treated wih $NaOH_{aq.}$ solution (5 cm^3). The mixture was stirred at rt for 3 h and the organic layer developed a yellow colour. Addition of pentane (30 cm^3), followed by separation of the organic layer, and partial removal of solvent under reduced pressure gave yellow crystals of **2** (^{1}H NMR). Yield > 80%.

5 (50 mg, 0.09 mmol) in petroleum ether (40–60°C, 30 cm^3) was treated with an excess of PhLi (3 cm^3, 1 M solution in Et_2O) at −78°C. After warming to rt the solvent was removed under reduced pressure. The residue was extracted with petroleum ether (40–60°C, 50 cm^3), the extract was filtered and the orange filtrate was cooled to −80°C giving yellow crystals which were collected, washed and dried *in vacuo*. Yield > 70%.

η-Benzenebis(trimethylphosphine)methylrhenium (**7**)

A solution of **14** (*vide infra*) (20 mg, 0.044 mmol) in thf (20 cm^3) was stirred while a saturated solution of MeMgBr in thf (1 cm^3) was added dropwise. No colour change was observed in the yellow-orange solution. Warming to 50°C for 2 h, followed by removal of solvent, gave a white powder and a yellow solid. Extraction with petroleum ether (40–60°C, 2×20 cm^3) and removal of the solvent under reduced pressure gave a yellow solid. This was recrystallized from light petroleum ether yielding yellow microcrystals of $Re(\eta\text{-}C_6H_6)(PMe_3)_2Me$. Yield 13 mg (70%).

η-Benzenebis(trimethylphosphine)ethylrhenium (**8**)

5 (50 mg, 0.09 mmol) in petroleum ether (40–60°C, 30 cm^3) was treated with an excess of EtMgBr (4 cm^3, 1 M solution in Et_2O) at −78°C. On warming to rt an off-white precipitate developed in a yellow solution. The solution was filtered, and the remaining solid was washed with petroleum ether (40–60°C, 2×20 cm^3). The combined extracts were reduced to a yellow oil under reduced pressure. Sublimation at 90°C (2×10^{-2} mmHg) gave yellow microcrystals of **8**. Yield 20 mg (49%).

η-Benzenebis(trimethylphosphine)vinylrhenium (**9**)

5 (50 mg, 0.09 mmol) was dissolved in petroleum ether (40–60°C, 30 cm^3) and cooled to −78°C. Dropwise addition of vinylmagnesium bromide (3 cm^3, 1.3 M solution in thf), followed by warming to rt, gave an orange solution and a white precipitate. Petroleum ether (40–60°C, 40 cm^3) was added, and the solution was filtered. Degassed water (30 cm^3) was added to the orange petroleum ether solution, and the two phases were shaken vigorously. The organic layer was decanted off, and upon removal of the solvent an orange oil remained. Repeated extraction with petroleum ether (40–60°C) yielded orange crystals of **9**. Yield 20 mg (49%).

η - Benzenebis(trimethylphosphine)hydridorhenium (**10**)

5 (70 mg, 0.13 mmol) was dissolved in thf (40 cm^3) and transferred on to excess $LiAlH_4$ (150 mg, 4.0 mmol). After stirring for 3 h at rt, the mixture was reduced to an oily yellow solid *in vacuo*. Extraction with toluene (2×20 cm^3), followed by removal of solvent gave an oily solid. Extraction with pentane (2×20 cm^3), and concentration (to 10 cm^3) and cooling to −20°C gave yellow crystals of **10**. Yield 46 mg (85%).

Reaction of **3** *with potassium hydride*

3 (40 mg, 0.08 mmol) was suspended in thf (30 cm^3), and a suspension of potassium hydride (excess, 1.2 g) in petroleum ether (60–80°C) was added with stirring. Over 4 h the orange solid dissolved, forming a yellow solution. Removal of solvent, followed by extraction with petroleum ether (40–60°C, 2×20 cm^3) gave a bright yellow solution. Concentration to low volume gave a high yield of yellow crystals. Comparison of the ^{1}H NMR data with that of an authentic sample of **10** showed them to be identical.

η - Benzenebis(trimethylphosphine)hydridoiodorhenium tetrafluoroborate (**11**)

5 (40 mg, 0.07 mmol) was dissolved in Et_2O (30 cm^3), giving an orange solution. Dropwise addition of ethereal HBF_4 produced an immediate orange precipitate, and the colour of the solution was completely discharged. The solution was decanted, and the residual solid was washed with Et_2O (3×20 cm^3). Recrystallization from acetone–water afforded orange-red microcrystals of **11**. Yield 40 mg (86%).

Reaction of **5** *with silver tetrafluoroborate*

Dropwise addition of silver tetrafluoroborate (10 mg, 0.05 mmol) in thf (10 cm^3) to an orange solution

of **5** (20 mg, 0.04 mmol) in thf (20 cm^3) at −78°C, followed by slow warming to rt produced a black precipitate and a bright red solution. Filtration of the solution followed by careful removal of the solvent under reduced pressure gave red crystals, which were shown to be **11** by ^1H NMR spectroscopy. Yield *ca* 30%.

η - Benzenebis(trimethylphosphine)(η - ethylene) rhenium tetrafluoroborate (**12**)

Method A. **5** (70 mg, 0.13 mmol) was dissolved in thf (30 cm^3) and $TlBF_4$ (200 mg, 0.69 mmol) was added with stirring. The solution was saturated with ethylene, and the Schlenk vessel was pressurized to 2 atm with ethylene. The orange solution containing a suspension of $TlBF_4$ was stirred at rt for 2 days. After that time a white solid remained suspended in a yellow-green solution. The solution was filtered, and the solvent was removed from the filtrate under reduced pressure, giving a yellow solid, which was washed with petroleum ether (40–60°C, 2 × 20 cm^3). Recrystallization from aetone–water afforded yellow microcrystals of **12**. Yield 20 mg (30%).

Method B. A solution of trityl hexafluorophosphate in CH_2Cl_2 was added dropwise to a stirred solution of **8** (20 mg, 0.045 mmol) in CH_2Cl_2 (20 cm^3). An immediate fine purple precipitate formed, and the solution became completely decolorized. The solvent was removed under reduced pressure, and the resulting pink solid was washed with petroleum ether (40–60°C, 2 × 20 cm^3). The solid was redissolved in thf (2 × 20 cm^3), filtered, and concentrated to *ca* 10 cm^3. Addition of petroleum ether (40–60°C, 30 cm^3) caused the pink solution to decolorize, and deposit a pale pink powder, which was collected and dried *in vacuo*. A ^1H NMR spectrum of the pink solid showed it to be identical to that of an authentic sample of the $[Re(\eta\text{-}C_6H_6)(PMe_3)_2(\eta\text{-}CH_2{=}CH_2)]^+$ cation. Yield 5 mg (21%).

Method C. Two drops of ethereal HBF_4 were added to an orange solution of **9** (15 mg, 0.03 mmol) in petroleum ether (40–60°C, 10 cm^3). An immediate pale orange precipitate formed. The orange solid was washed with Et_2O (3 × 20 cm^3), collected, and dried *in vacuo*. Yield 5 mg (28%). The ^1H NMR spectrum showed the product to be the $[Re(\eta\text{-}C_6H_6)(PMe_3)_2(CH_2{=}CH_2)]^+$ cation, by comparison with that of a known sample.

η - Benzenebis(trimethylphosphine)carbonylrhenium tetrafluoroborate (**13**)

5 (50 mg, 0.09 mmol) was dissolved in thf (30 cm^3) and a suspension of $TlBF_4$ (150 mg, 0.52 mmol) in thf (20 cm^3) was added. The atmosphere and solution were charged with CO to 2-atm pressure. The orange solution and white suspension was stirred at rt for 16 h, and then the atmosphere was repressurized to 2 atm, and stirred for a further 16 h. After this time the solution had become almost colourless, and was filtered off the white insoluble material. The solution was reduced to a white solid *in vacuo*. This solid was re-extracted with thf (2 × 20 cm^3), filtered, and concentrated; on cooling to −20°C a white powder precipitated. This was collected and dried. Yield 10 mg (20%).

η-Benzenebis(trimethylphosphine)chlororhenium (**14**)

8 (30 mg, 0.07 mmol) was dissolved in dry, distilled CH_2Cl_2 (20 cm^3) giving a yellow solution, which on extraction with petroleum ether (40–60°C, 2 × 20 cm^3) and filtration yielded a bright yellow solution. Concentration and cooling to −20°C afforded yellow microcrystals (30 mg, 93%) of $(\eta\text{-}C_6H_6)Re(PMe_3)_2Cl$.

(*Received* 14 *October* 1985; *accepted* 19 *December* 1985)

Abstract—Lanthanide(III) complexes of general composition $Ln(p\text{-}TSO)_8(ClO_4)_3$ (where Ln = Tb–Lu or Y and *p*-TSO = di-*p*-methylphenyl sulfoxide) were synthesized and characterized by chemical and thermal analysis, magnetic moments and IR spectra in the solid phase, and by molar conductance and molecular weights in solution studies. The thermal decomposition, in an air stream, of these complexes leads to the formation of pure lanthanide oxysulfates at 900°C. The formation of these species requires the transformation of part of the ligand sulfoxide and this process is discussed in terms of the identification of the solid and gaseous products obtained after heating to different temperatures by X-ray diffraction, IR spectroscopy and mass spectrometry.

The coordination chemistry of the transition metals with sulfoxides was developed in the 1960s and began with the use of dimethylsulfoxide (DMSO) as an appropriate ligand for all the transition metals in view of its ambidentate nature.[1]

More recently, the coordination chemistry of DMSO and of the higher sulfoxides has been reviewed, the main advances in the field being due to the application of such complexes in extraction processes, in preparative chemistry, in homogeneous catalysis and even in bioinorganic chemistry.[2]

Later work[3] examined the thermochemistry of the sulfoxide complexes of the transition metals and the application of thermoanalytical methods in the area of coordination chemistry, and underlined the impossibility of using thermal analysis in such complexes if they contain oxidizing anions, mainly the perchlorate ion, due to the explosive nature of the labile complexes formed after losing one or several ligand molecules of the original complex following a rise in temperature. Even then, the available information is scanty and only in one case has an attempt been made to represent the decomposition mechanism.[4]

Regarding the halo-complexes, thermal degradation takes place with the more or less gradual loss of the ligands at temperatures close to that of the boiling point of the complex-forming sulfoxide, the solid products found being those expected in the decomposition in air of anhydrous halides; oxohalides or oxides. Only in the case of copper(II) complexes does a so-called catalytic combustion yield Cu_2S, which is later oxidized to copper(II) sulfate.[5]

The aim of the present work was to prepare a series of complexes where the nature of the sulfoxide ligand itself minimizes the explosive nature of the perchlorate complexes with sulfoxide ligands in order to establish the reaction by which their decomposition takes place.

EXPERIMENTAL

The perchlorates of the hydrated lanthanides were prepared from the corresponding oxides supplied by BDH (U.K.). They were obtained by dissolving the oxide in 30% warm perchloric acid, and then evaporating to dryness. Following this, the product was dissolved in 10 cm^3 of dry methanol.

Di-*p*-methylphenyl sulfoxide (*p*-TSO), melting point 94°C, was supplied by Aldrich-Europe.

Synthesis

The $Ln(ClO_4)_3 \cdot 8p$-TSO complexes, where Ln = Tb–Lu or Y, were prepared by dropwise addition at 0°C of a solution of 5 g of *p*-TSO in 20 cm^3 of methanol onto a solution of the corresponding lanthanide perchlorate in this medium, with continuous shaking. The precipitates obtained were washed with dry, cold methanol and with carbon tetrachloride, and then dried *in vacuo* over P_4O_{10} at room temperature.

Methods

The conductivity measurements were carried out in 10^{-3} M solutions of DMSO and nitrobenzene, using a Radiometer CDM 2E conductimeter with a CDC 104 immersion cell.

Magnetic susceptibilities were obtained at room temperature using a Stanton MC-5 microbalance, according to the Gouy method.

IR spectra were recorded with a Beckman Acculab 10 spectrophotometer in the 4000–400-cm^{-1} range in KBr discs.

Differential thermal analysis was carried out with a Perkin–Elmer DTA 1700 high-temperature differential thermal analyzer with a model 3600 data station.

Thermogravimetry was conducted with a Perkin–Elmer mod. TGS-2 thermobalance.

X-ray debyegrams were recorded with a Siemens Kristalloflex 810 apparatus with Cu-K_α radiation (λ = 154.050 pm) with a nickel filter.

Mass spectra were registered on a Hewlett–Packard mod. 5930-A spectrometer. In each case, samples were introduced in the chromatograph of the apparatus on an empty column, using He as the support gas at a rate of 60 cm^3 min^{-1}. The ion source temperature was 170°C and the ionization energy was 60 eV.

RESULTS AND DISCUSSION

According to the quantitative determinations of the contents of ligand, perchlorate and lanthanide ions and from the results deduced from the study of molar conductivity, molecular weights (Table 1), IR and thermogravimetric analysis, the general formula of $Ln(p\text{-TSO})_8(ClO_4)_3$ has been assigned to all the complexes.

The complexes are stable at room temperature, they melt without decomposing (Table 1) and are very insoluble in non-polar solvents. They decompose rapidly in water with precipitation of the ligand, though the increase in temperature favours their complete decomposition. They are soluble in DMSO, nitrobenzene, acetone, acetonitrile and nitromethane, among other polar solvents. Their colours are similar to those of the hydrated lanthanide perchlorates, though there is an appreciable decrease in intensity.

Quantitative analyses were carried after decomposing the complexes in water at 80°C. The white precipitate obtained, characterized by its IR spectrum as *p*-TSO, was dried to constant weight in an oven at 85°C. Using aqueous solutions, the lanthanide elements were determined by complexiметric evaluation with EDTA and using xylenol orange as indicator. The perchlorate anion was determined by precipitation with nitron and weighing the $C_{20}H_{17}N_4ClO_4$ compound.

The molar conductivities of the solutions of the complexes in DMSO and nitrobenzene at a concentration of 10^{-3} M revealed 3:1 and 2:1 electrolyte behaviour, respectively.[6]

Determination of molecular weights by studying the cryoscopic decreases of the complexes in DMSO and nitrobenzene revealed the presence of 12 and three particles in solution, respectively, per molecule of complex.

The IR spectra of all the complexes are very similar. A comparison of their spectra with that of free *p*-TSO (Table 2) reveals that the complexing affects the bands assigned to the stretching vibration of the S—O bond (1040 cm^{-1}) and those of the CH bending vibrations outside the plane (820 and 805 cm^{-1}).[7] The former undergoes a shift towards lower wavenumbers by a magnitude of 60 cm^{-1}, which shows that the coordination of the ligand takes place through the oxygen atom and that the bonding strength in all the complexes is the same.[8] The out-of-plane CH bending vibration appears as a doublet with the two bands separated by about 20 cm^{-1} in those compounds having two phenyl groups bound to a common atom which, in turn, is multiple bonded to another adjacent one. This is due to a mode coupling, originated by the great proximity of the *o*-hydrogen atoms and the aforementioned common atom.[9] In the spectrum of the complexes, this vibration appears as a single band at 810 cm^{-1} which, taking into account the nature of the bond of the sulfoxide group, confirms the coordination of the *p*-TSO through the oxygen atom, since it implies a decrease in the p_π–d_π bond strength and, in turn, a decrease in the order of such a bond. The T_d-symmetry of the perchlorate ion is conserved since only two bands appear in the spectrum, showing that this ion is not coordinated to tripositive lanthanides.[10]

The differential thermal analysis shows that heat decomposition in air of these complexes is identical in energy terms. In all the diagrams a first peak was

[a] Abbreviations: s, strong; m, medium; w, weak.

obtained, which was endothermic, whose minimum appears within a temperature range of 220–225°C and is attributed to the melting of the complexes. A second, exothermic peak is located between 280 and 400°C, with a maximum in the 340–350°C range, and corresponds to the rapid decomposition of the complexes. The third peak, also exothermic, has a maximum in the 530–545°C range (Fig. 1).

The thermogravimetric curves of all the complexes are similar and show that the complexes are stable, in air, until temperatures in the region of their melting points. Thereafter their decomposition abruptly begins to take place accompanied by a huge loss of weight up to a temperature close to 360°C where the mass of the residues ranges between 32 and 35% of the initial amount of the complex.

From this temperature onwards and up to 560°C the loss of mass is very slow and gradual; in an interval of 200°C, the variation in mass is only 7–8% of the initial amount of the complex.

Between 560 and 750°C, an important decrease

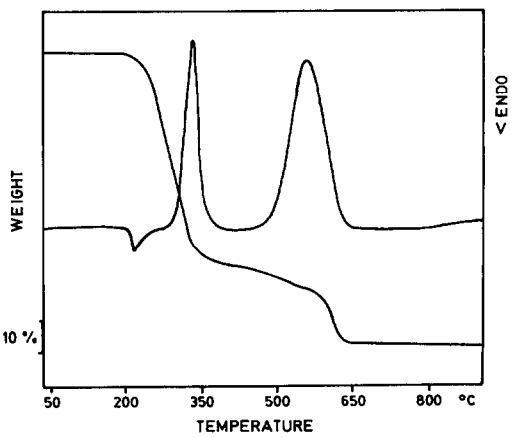

Fig. 1. TG–DTA curves of $Yb(p\text{-}TSO)_8(ClO_4)_3$.

in mass takes place in the residues (16–18%) after which their mass remains stable until the maximum heating temperature of 900°C (Fig. 1).

The residues of the calcination of the complexes at 750°C are white solids which are insoluble in water but will dissolve in dilute hydrochloric acid. Their IR spectrum exhibits active absorptions in the IR range, corresponding to a point group C_{2v}. The frequencies of the absorption maxima are in good agreement with those assigned for the sulfate ion in the oxysulfates of the lanthanides.[11] Likewise, the interlayer spaces deduced from the measurement of the X-ray diffraction diagrams are in accordance with those calculated from the reticular parameters published in the literature for the lanthanide oxysulfates.[12] Finally, the percentages of the residuals found at the end of the thermal decomposition ($Ln_2O_2SO_4$) are those corresponding to an initial complex composition identical to the formulation proposed and hence confirm the results obtained from the quantitative analyses and those of the molecular weight.

The IR spectra of the calcination residues of the complexes up to 560°C show a strong band with a maximum close to 1130 cm^{-1} and a sharp band at 610 cm^{-1} which are the active bands in the IR range of a T_d point group to which the undistorted sulfate belongs. The X-ray diffraction diagrams display interlayer spaces in agreement with those published in the literature for the anhydrous sulfates of lanthanum, cerium, gadolinium and lutetium.[13] The residue is black.

The gaseous products of the thermal decomposition of the complexes up to 360°C have been identified in two fractions; in the first, using mass spectrometry, are included those which remain in the gaseous state at room temperature. The second fraction, by IR spectroscopy, includes those gases which condense on the collecting flask on cooling. These latter residues are insoluble in water but soluble in dry methanol and their IR spectrum contains all the bands assigned to the uncoordinated *p*-TSO. Besides these bands, the spectrum also shows another with a medium intensity at 1700 cm^{-1} together with a further three bands at 1320, 1150 and 550 cm^{-1}. These latter three bands can be assigned, respectively, to $\nu(SO_2)$(asym), $\nu(SO_2)$ (sym) and scissoring modes active in IR of the aromatic sulfones.[7] The band at 1700 cm^{-1} must be the result of the combination of those taking place at 1150 and 550 cm^{-1}.

The mass spectra of the gases, the product of the thermal decomposition of the complexes up to temperatures of about 360°C, show peaks with the following mass/charge ratios [m/z (%)]: 44 (28) attributable to carbon dioxide, 48 (31) assignable to SO^+, 64 (100) due to sulfur dioxide, and 79 (30), 91 (15) and 92 (9), all ionization fragments of methylbenzene, together with the peaks which permit the identification of the presence of chlorine molecules in the gaseous mixture.

The solid residues of the pyrolysis of the complexes up to a temperature of 360°C are black in colour and it is not possible to identify them by X-ray diffraction owing to the poor resolution of the lines present in the diagrams. The IR spectra of these residues display the absorptions assigned to the ν(OH) stretching vibration (3400 cm^{-1}) and the δ(HOH) bending vibration (1600 cm^{-1}) of the water, together with a very wide band with two well-defined maxima at 1150 and 1100 cm^{-1}, and an another maximum of lower intensity at 1000 cm^{-1}, two strong bands at 630 and 605 cm^{-1}, and a band of medium intensity at 435 cm^{-1}. All of them correspond to active absorptions in the IR of a point group C_{3v} generated by a decrease in the T_d-symmetry of the sulfate ion due to an effect of the crystallization water. From this it is deduced that the weight loss observed between 360 and 560°C (7–8%) is due to the loss of the water present in the residues and the consequent stabilization of the corresponding anhydrous lanthanide sulfates.

Accordingly, the study of the thermal decomposition in air of the complexes examined here shows that, contrary to what has been reported by other authors, the loss of the sulfoxide ligand in them is not total; rather, part of the ligand is present in the residues in a number of sulfate ions sufficient to neutralize the existing lanthanide ions. Likewise, the oxidation of this sulfoxide to sulfate ion also gives rise to amorphous carbon which is only eliminated from the residues, as carbon dioxide, at temperatures greater than 560°C. The presence of this carbon accounts for the colouring of the solids and for the lack of resolution in the X-ray diagrams. In turn the combustion of this carbon induces the transformation of the anhydrous lanthanides sulfates into oxysulfates at temperatures substantially lower than that normally considered as their normal decomposition temperature in air.

UNEXPECTED PRODUCTS FORMED BY THE ADDITION OF HALOGENS [X_2 (= I_2 OR Br_2)] TO $W_2(O_2CBu^t)_4$ (M≡M): THE X-RAY CRYSTAL STRUCTURES OF $[W_2(O_2CBu^t)_5 \cdot 2Bu^tCONMe_2]^+[W_2I_4(O_2CBu^t)_2]^-$ AND $W_2Br_2(O_2CBu^t)_3 \cdot 2THF$

(*Received* 17 *September* 1985; *accepted* 7 *January* 1986)

Abstract—Addition of halogens, X_2 (X = I or Br), to hydrocarbon solutions of $W_2(O_2CBu^t)_4 \cdot 2L$, where L = THF or Bu^tCONMe_2, does not lead to simple oxidative-addition products of formula $W_2X_2(O_2CBu^t)_4$ having axially aligned halogen–tungsten bonds [cf. $W_2R_2(O_2CR')_4$ compounds, where R = CH_2CMe_3 or CH_2Ph, and R' = Me, Et, Bu^t or Ph] but rather leads to facile carboxylate group exchange. The overall reactions are thus complex and two crystalline products isolated in *ca* 20% crystalline yield have been characterized by X-ray studies. Addition of I_2 has allowed isolation of the salt $[W_2(O_2CBu^t)_5 \cdot 2L]^+[W_2I_4(O_2CBu^t)_2]^-$, where L = Bu^tCONMe_2, while addition of Br_2 gave $W_2Br_2(O_2CBu^t)_3 \cdot 2L$, where L = THF.

It is now a well-recognized aspect of the reactivity of multiple bonds between metal atoms that the bonds between elements of the 3rd transition series are more easily oxidized than those involving the 2nd transition series.[1,2] Our discovery of the axially bound (R') d^3–d^3 compounds $W_2(O_2CR)_4R'_2$ (**I**), where R = Me, Et, Bu^t or Ph, and R' = CH_2Ph or CH_2CMe_3,[3,4] prompted us to see whether or not the quadruply bonded compounds $W_2(O_2CR)_4$[5,6] or their lightly ligated adducts $W_2(O_2CR)_4L_2$ (e.g. L = THF or Me_2NCOR[7]) might react with halogens to give by oxidative-addition axially bound (X) compounds $W_2(O_2CR)_4X_2$ (**II**).

I

II

It should be noted that earlier work by Katovicc and McCarley[8] had shown that the addition of ½ equivalent of I_2 to $MoW(O_2CBu^t)_4$ (M ≡ M) in CH_3CN gave the mixed-valence compound of formal bond order 3.5, $MoW(O_2CBu^t)_4(I)(MeCn)$, where the iodo ligand was bound to W and the MeCN molecule ligated to Mo. Also recently Santure *et al.*[9] reported the preparation of $W_2(O_2CBu^t)_4I$ in a similar oxidative-addition reaction, though little was reported on this compound. We show here that compounds of type **II** are not readily prepared by the addition of halogens to $W_2(O_2CBu^t)_4$ because of facile carboxylate ligand scrambling.

In typical experiments $W_2(O_2CBu^t)_4 \cdot 2L$, *ca* 0.4 mmol, where L = Bu^tCONMe_2 or THF, was allowed to react with 1 equivalent of I_2 or Br_2 in toluene/hexane solutions at room temperature. Note the use of dry and oxygen-free atmospheres

(N_2) and solvents. Crystals formed and were separated from the solution by filtration. In both instances the isolated yield based on tungsten was *ca* 20%. From the formula established by X-ray analyses* and elemental analyses it is evident that other species must also be formed.

$W_2(O_2CBu^t)_5 \cdot 2Bu^tCONMe_2]^+[W_2I_4(O_2CBu^t)_2]^-$ is formulated as a salt because: (i) the overall sample is paramagnetic (detailed magnetic studies have yet to be performed), and (ii) ^1H NMR spectroscopy reveals a spectrum entirely consistent with expectations for the d^3–d^3 (M≡M) cation based on the solid structure which contains two independent but essentially equivalent cations. Similarly there are are two independent $W_2I_4(O_2CBu^t)_2$ anions in the unit cell. The structure of $[W_2(O_2CBu^t)_5 \cdot 2Bu^tCONMe_2]^+$ is shown in Fig. 1, and can be seen to be related to the previously characterized d^3–d^3 triple bonded compounds $W_2(O_2CNMe_2)_6$[10] and $W_2(O_2CBu^t)_6$.[11] Specifically there are five relatively short W—O bonds in a pentagonal plane at each tungsten center and one long axial W---O bond involving here the Bu^tCONMe_2 molecules. The W–W distance, 2.28 Å (averaged), for the two cations is also essentially identical to that seen for the other d^3–d^3 compounds mentioned above. The anion $[W_2I_4(O_2CBu^t)_2]^-$ is NMR-silent and has a slightly shorter W–W distance, 2.24 Å (averaged), consistent with its formal bond order 3.5 and M–M bonding configuration $\sigma^2\pi^4\delta^1$. The gross structural features are similar to those seen in $[Ph_4As]_2[Mo_2(O_2CMe)_2Cl_4] \cdot 2MeOH$[12] and $Re_2(O_2CPh)_2I_4$[13] (see Fig. 2).

*(i) Crystal data for $[W_2(O_2CBu^t)_5 \cdot 2Bu^tCONMe_2]^+[W_2I_4(O_2CBu^t)_2]^-$ at −161°C: $a = 33.275(9)$ Å, $b = 24.600(11)$ Å, $c = 17.474(5)$ Å, $Z = 8$, $d_{calc} = 2.06$ g cm^{-3}, and space group $P2_12_12_1$. Of the 10,199 unique intensities collected (Mo-K_α, $6° \leq 2\theta \leq 45°$) the 6151 having $F > 2.33\sigma(F)$ were used in the refinement. Patterson techniques indicated that there were up to four W–W vectors and further indicated that there were numerous heavy atoms. Several direct approaches were used to obtain trial positions for the metal atoms. It was finally possible to get a MULTAN solution which agreed with the Patterson solution, and subsequent refinement of six W atoms thus revealed not only the remaining W atoms but also the eight I atoms. Subsequent difference Fourier synthesis were used to locate all 150 non-hydrogen atoms in the cell. Refinement was by block with each ion representing a block. No attempt was made to include the 206 H atoms in the least-squares refinement and no absorption correction was made. Final residuals are $R(F) = 0.071$ and $R_w(F) = 0.069$.

(ii) Crystal data for $W_2Br_2(O_2CBu^t)_3 \cdot 2THF$ at −160°C: $a = 18.694(7)$ Å, $b = 17.106(6)$ Å, $c = 9.437(3)$ Å, $\beta = 95.55(2)°$, $Z = 4$, $d_{calc} = 2.16$ g cm^{-3}, and space group $P2_1/a$. Of the 3943 unique intensities collected (Mo-K_α, $6° < 2\theta < 45°$) the 3218 having $F > 3\sigma(F)$ were used in the refinement.

The crystal used in the study was cleaved from a larger crystal. ψ scans indicated a severe absorption and the data were corrected accordingly. Due to the irregular shape of the faces (resulting from crystal cleavage), the absorption correction is not as precise as one might wish. The agreement between "equivalent" reflections for a subshell of 485 reflections decreased from 0.145 to 0.048 after correction. Because of the imperfect nature of the absorption coefficient, no attempt to refine the model anisotropically (except for Br and W atoms) was made. The structure was solved using a combination of direct methods (MULTAN 78) and Fourier techniques, and refined by full-matrix least squares. H atoms were located in fixed idealized positions. Final residuals are $R(F) = 0.070$ and $R_w(F) = 0.069$.

Supplementary materials available. Tables of fractional coordinates and thermal parameters have been deposited with the Cambridge Crystallographic Data Centre. Complete structural information is available from the Editor at Queen Mary College and, in microfiche form only, from the Indiana University Library, Bloomington, IN 47405, U.S.A. at a cost of $2.50 per copy. For $[W_2(O_2CBu^t)_5 \cdot 2Bu^tCONMe_2]^+[W_2I_4(O_2CBu^t)_2]^-$ request MSC Report No. 84024 and for $W_2Br_2(O_2CBu^t)_3 \cdot 2THF$ request MSC Report No. 84082.

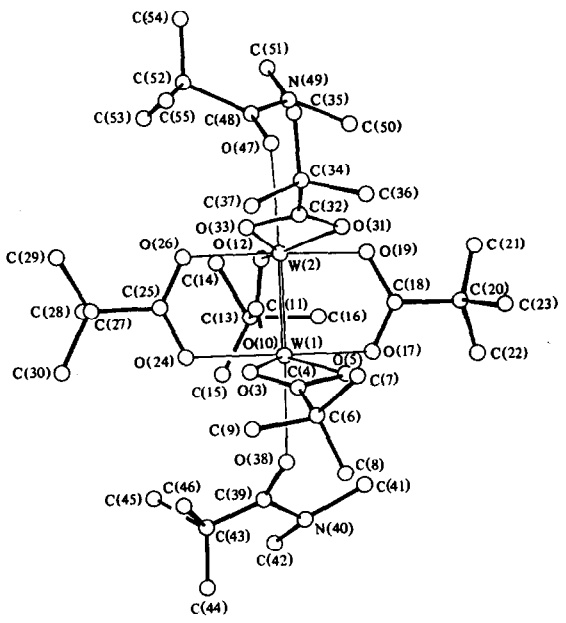

Fig. 1. A view of one of the $[W_2(O_2CBu^t)_5 \cdot 2Bu^tCONMe_2]^+$ cations showing the atom-numbering scheme. The central portion of the cation, $W_2(O_2CBu^t)_5$ has virtual C_{2v}-symmetry with three bridging carboxylate ligands and two bidentate ligands. The W–W distance is 2.29 Å (averaged) and the W—O bond distances in the pentagonal plane to the carboxylate oxygen atoms fall in the range 2.04–2.15 Å while the axially aligned W---O bonds involving the Bu^tCONMe_2 ligands are in the range 2.36–2.46 Å.

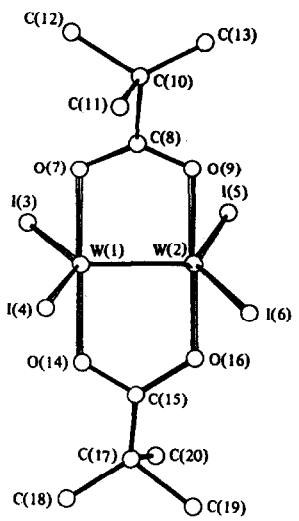

Fig. 2. A view of one of the $[W_2I_4(O_2CBu^t)_2]^-$ anions giving the atom-numbering scheme. The anion has virtual D_{2h}-symmetry. Pertinent distances (Å) and angles (°) (averaged) are W–W = 2.237, W—I = 2.68, and W—O ranges from 2.00 to 2.12; W–W—I = 109, and W–W—O = 90.

$W_2Br_2(O_2CBu^t)_3 \cdot 2THF$ forms dark brown crystals from hexane solutions and in toluene-d_8 shows only broadened ^1H NMR signals centered at *ca* 7 ppm for the Bu^t protons. We believe that this is also indicative of the paramagnetic nature of the species which contains a central W_2^{5+} center. An ORTEP view of the molecule is shown in Fig. 3 which reveals the virtual C_{2v}-symmetry. Again the axial W---O (THF) bonds are long, 2.45 Å (averaged), and the W–W distance, 2.31 Å, is in the range typically found for W≡W bonds of configuration $\sigma^2\pi^4$, though in this instance the W–W bond is formally of order 3.5 and of configuration $\sigma^2\pi^4\delta^1$. Ignoring the THF molecules the structure is somewhat related to that seen for $Re_2(O_2CBu^t)_3Cl_3$.[14]

Clearly more work is needed to characterize these paramagnetic W_2-containing centers. What is clear from this work is that compounds of type **II** are not readily accessible by oxidative-additions of halogens to $W_2(O_2CR)_4$ compounds because of facile carboxylate exchange reactions. To our knowledge this communication reports the first example of a cationic $(W{\equiv}W)^{6+}$-containing compound. Further studies are in progress.

COMMUNICATION

SYNTHESIS, SPECTRAL PROPERTIES AND REACTIONS OF THE NOVEL ACETONITRILE DIIODOTRICARBONYLTRIPHENYL PHOSPHINE, ARSINE AND ANTIMONY COMPLEXES OF MOLYBDENUM(II) AND TUNGSTEN(II)

PAUL K. BAKER* and STUART G. FRASER

Department of Chemistry, University College of North Wales, Bangor, Gwynedd LL57 2UW, U.K.

(*Received* 24 *January* 1986; *accepted* 10 *February* 1986)

Abstract—The bisacetonitrile complexes $[MI_2(CO)_3(NCMe)_2]$ (M = Mo or W) react with L (L = PPh_3, $AsPh_3$ or $SbPh_3$) to give the novel compounds $[MI_2(CO)_3(NCMe)L]$, which undergo acetonitrile displacement reactions to afford a variety of new mixed complexes.

The complexes $[MX_2(CO)_3L_2]$ (M = Mo or W, L = PPh_3 or $AsPh_3$, X = Cl or Br) are currently under investigation as catalysts for the ring-opening polymerization of norbornene,[1,2] and it is proposed that it is the ease of phosphine or arsine dissociation in these complexes which is the rate-determining step in the mechanism. Although a wide variety of bisphosphine complexes of the type $[MX_2(CO)_3L_2]$ (L = phosphine) have been prepared,[3] until now no mixed seven-coordinate complexes of this type have been reported with a labile ligand such as acetonitrile attached to the metal which should enhance the catalytic activity of these complexes in view of the work of Bencze *et al.*[1,2] In this communication the synthesis of the new mixed compounds $[MI_2(CO)_3(NCMe)L]$ (M = Mo or W; L = PPh_3, $AsPh_3$ or $SbPh_3$) and preliminary studies of their reactivity are reported.

Equimolar quantities of $[MI_2(CO)_3(NCMe)_2]$,[4] and L (L = PPh_3, $AsPh_3$ or $SbPh_3$) react in CH_2Cl_2 to afford high yields of the crystalline compounds $[MI_2(CO)_3(NCMe)L]$, which have been fully characterized by elemental analysis (C, H and N) and IR spectroscopy (Table 1) and ^1H NMR spectroscopy.† All the complexes are stable in the solid state when stored under argon, but decompose rapidly in solution when exposed to air. Several X-ray crystal structures of the known seven-coordinate bisphosphine compounds $[MX_2(CO)_3L_2]$ have been carried out,[5–16] all having capped octahedral geometry. Since the spectral properties of $[MI_2(CO)_3(NCMe)L]$ closely resemble those of the analogous bisphosphine compounds it is likely that they will have a similar geometry.

It is interesting to note that $[MoI_2(CO)_3(NCMe)_2]$ reacts with $SbPh_3$ to initially afford $[MoI_2(CO)_3(NCMe)(SbPh_3)]$, which rapidly loses acetonitrile to afford the iodide-bridged dimer $[Mo(\mu\text{-}I)I(CO)_3(SbPh_3)]_2$, whereas the other complexes $[MI_2(CO)_3(NCMe)L]$ are fairly stable to loss of acetonitrile. We are currently investigating the electronic and steric effects of different phosphine and phosphite ligands on the rate of dimerization of the complexes $[MI_2(CO)_3(NCMe)L]$ (L = phosphine or phosphite). The chemistry of these complexes is dominated by acetonitrile displacement (Scheme 1).

DIFFERENTIAL-PULSE VOLTAMMETRIC STUDIES ON SOME BINARY AND TERNARY COPPER(II) AMINO ACID COMPLEXES

P. S. ZACHARIAS,* T. SREENIVAS and J. MARY ELIZABATHE

School of Chemistry, University of Hyderabad, Hyderabad 500134, India

(*Received* 20 *August* 1985; *accepted* 6 *November* 1985)

Abstract—Some selected binary and ternary copper(II) amino acid complexes are investigated by differential-pulse voltammetry and the results are discussed. These results are compared with cyclic voltammetric results of the same systems.

The electrochemical behaviour of several binary and ternary copper(II) amino acid complexes in aqueous media has been investigated recently by cyclic voltammetry and an electrode reaction mechanism has been proposed.[1,2] An important step in this mechanism is the electrochemical generation of a copper(I) intermediate species by a one-electron reduction of the starting amino acid complex. Since the eletrochemical identification of such an intermediate for the amino acid complexes had been reported for the first time, further evidence to show the generation of this species seemed desirable. Hence differential-pulse voltammetry (DPV), another sensitive electrochemical technique,[3,4] is used in the investigation of the electrochemical behaviour of some selected binary and ternary copper(II) amino acid complexes. For a reversible electrochemical process, the number of electrons (n) involved is related to the width (in mV) at the half-height of the DPV peak.[5] Since the first step in the electrode mechanism of the binary and ternary system is nearly reversible, this relationship is employed to find out the value of n for this step.

The binary copper(II) complexes are of general composition $Cu(AA)_2$ and ternary systems of composition Cu(BPY)(AA), where AA represents an amino acid ligand and BPY is the 2,2′-bipyridyl ligand. The interest in the study of copper(II) amino acid complexes is due to their reported participation in the catalysis of superoxide dismutation[6,7] and to the observation that the type 2 copper centres of copper enzymes undergo a one-electron reduction.[8] Ternary complexes containing an amino acid and another ligand system are similar to biologically important copper(II) mixed amino acid complexes.[9] Hence these binary and ternary copper(II) amino acid systems are selected for the investigation. The DPV data on these systems are presented and discussed.

EXPERIMENTAL

The binary and ternary complexes were prepared by reported methods.[1,10] The ternary systems were purified by preparative TLC on silica gel with an n-butanol–water–methanol (20 : 40 : 40) solvent system. Differential-pulse voltammograms were recorded with a three-electrode system consisting of an HMDE working electrode, PAR model 9331 SCE reference electrode and a platinum wire auxiliary electrode on a PAR 370 electrochemistry system. Aqueous solutions of 10^{-3} M concentration range with TEAP as the supporting electrolyte were used. Solution pH was changed by the addition of μl quantities of pure perchloric acid and determining the pH value by a sensitive pH meter.

RESULTS AND DISCUSSION

The DPV data on the binary and ternary complexes are presented in Tables 1 and 2, respectively. The n values calculated for the C, D Peaks are also given in Tables 1 and 2. Figure 1 represents the differential-pulse voltammograms from a repetitive scan for a representative binary compound at neutral pH conditions (neutral pH is taken to be the pH of the solution on dissolving the compound).

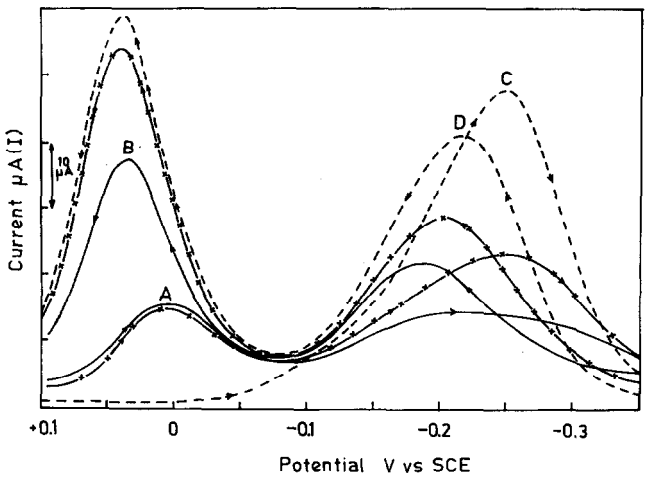

Fig. 1. Multiscan differential-pulse voltammograms of $Cu(Ser)_2$: (----) first scan, (—×—) second scan, (——) third scan.

The DPV profiles of the ternary systems at neutral pH conditions for slow scan rates are similar to the binary systems and hence will be discussed in relation to Fig. 1.

Before discussing the DPV results, the cyclic voltammetric results of the binary and ternary systems will be briefly mentioned here. The CV results can be summarized on the basis of a three-step electrode reaction mechanism. The first step involves a one-electron reduction (peak C) of the starting copper(II) complex to give an intermediate copper(I) species. Reoxidation of this to the starting complex gives peak D. The second step is the chemical reaction involving a fraction of the intermediate copper(I) species, eventually generating copper(0) species. The third step involves a two-electron oxidation of the Cu^0 to Cu^{2+} ions and its subsequent reduction, and is responsible for the B–A couple. These steps have been discussed in detail.[1,2]

The differential-pulse voltammograms (Fig. 1) show four peaks (C,D and A,B) and the potentials are listed in Tables 1 and 2. The n value of approximately 1 for the peaks C and D suggests that the redox process for this step involves a single electron. This suggests that the intermediate generated is the copper(I) species. Thus the peak C results from a single electron reduction of the starting complex while D results from the reoxidation of the generated copper(I) species. In a reversible electron transfer process, the DPV peak should be traced back in the reverse scan. The slight separation observed in peaks C and D implies that the electron transfer is only close to reversibility. A,B forms the other redox couple and involves a two-electron process between Cu^0 and Cu^{2+} species. It is clear that peak A is absent in the first scan but increases in magnitude as the scan number increases with the simultaneous decrease of C and D. This is expected as more and more Cu^{2+} is generated at the electrode on repetitive scan and this is compatible with the reaction mechanism discussed earlier. The DPV features mentioned here are observed for all the binary systems and for the ternary systems at slow scan rates. However, for the ternary systems at faster scan rates ($v > 0.01$ V s^{-1}), the A,B, couple is absent. This suggests that the chemical reactions of the intermediate species are not fast enough to generate Cu^0 species. In other words, intermediate Cu(I)(BPY)(AA) has a longer lifetime than the corresponding copper(I) binary amino acid complexes.

Protonation

The differential-pulse voltammetric characteristics of binary and ternary systems have been investigated in low pH (acidic) conditions. It is known that the binary amino acid complexes get protonated as the pH is lowered and the protonated species disproportionate to give free Cu^{2+} ions.[11] When this happens, the peaks C and D should decrease while A and B should increase in magnitude—if the earlier proposed mechanism is correct. Figure 2 shows these features clearly. However, the ternary systems behave differently. Figure 3 shows the pH-dependent DPV profiles of a representative ternary system. Peaks C and D start decreasing as pH is decreased. Simultaneously a new peak C′ starts appearing and peak A is absent. The position of peak C′ is in between that of C and A indicating that the origin of C′ is different from that of C and A. C′ does not correspond to the reduction peak of free copper ions. It is known that monobipyridyl copper(II) complex is stable at low pH conditions[12] and hence it can be believed that the

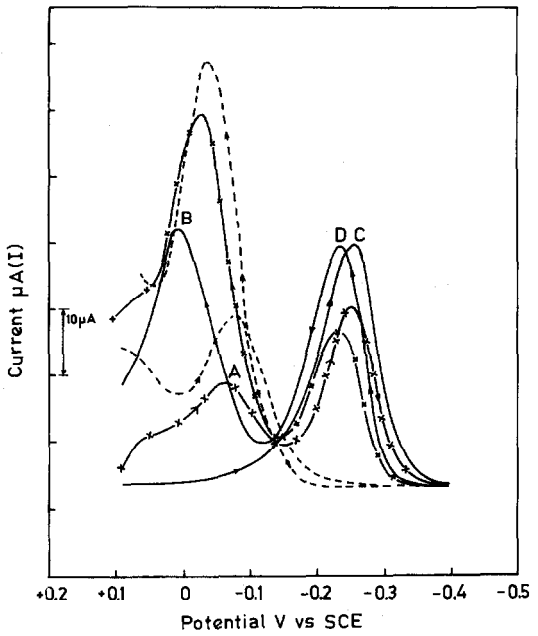

Fig. 2. Differential-pulse voltammograms at different pH values of $Cu(Ser)_2$ compound: (——) 7.86, (—×—) 4.77, (– – – –) 3.83.

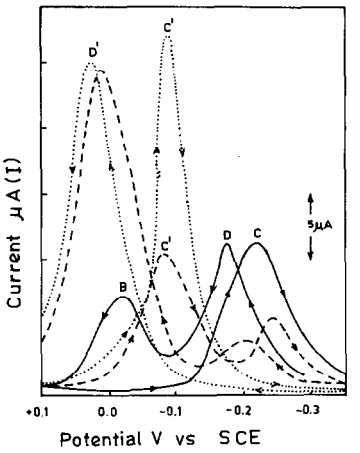

Fig. 3. Differential-pulse voltammograms at different pH values of Cu(BPY)(Val) compound: (——) 7.80, (– – – –) 4.60, (· · · ·) 3.20.

end product of protonation of the ternary systems is this species and not Cu^{2+} ions. Then peak C′ should be related to the reduction of this species. This explains the shift in the potential of C′ compared to peak A.

Thus the differential-pulse voltammetric experiments clearly support the cyclic voltammetric results on the binary and ternary systems. These experiments give additional proof to the one-electron reduction of the starting copper(II) complex, thereby confirming the electrochemical generation of the copper(I) intermediate.

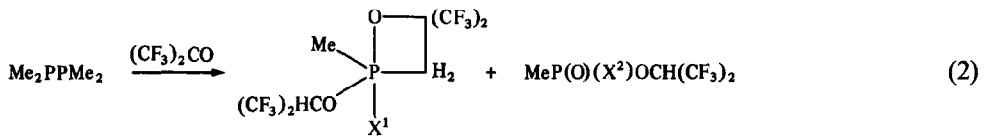
(*Received* 4 *September* 1985; *accepted* 18 *November* 1985)

Abstract—The diphosphorus compounds $R^1R^2PPR^1R^2$ ($R^1 = R^2 = Me$ or Et; $R^1 = Me$, $R^2 = Bu^t$) and $Me_2P(:O)PMe_2$ were found to react with hexafluoroacetone (HFA) to give 1,2-λ^5-oxaphosphetanes, phosphonates and phosphinates. For $R^1 = R^2 = Et$ and $R^1 = Me$, $R^2 = Bu^t$ 1,3,2-λ^5-dioxaphospholanes were obtained. For $R^1 = R^2 = Et$, in addition, a 1,3,4-λ^5-dioxaphospholane was found. With tetramethyldiphosphine a thermally stable compound was formed containing a P(III)$C(CF_3)_2$OP(V) moiety which could be bound to a $(OC)_4Mo$ fragment. No reaction has been observed between HFA and $Bu^t_2PPBu^t_2$ and Ph_2PPPh_2.

The reactions of trimethylphosphine and triethylphosphine with hexafluoroacetone (HFA) give indications of the presence of two centres of reactivity in the molecules—the lone pair and the methyl or methylene group at phosphorus—furnishing 1,3,2-λ^5-dioxaphospholanes[1] (**A**) and 1,2-λ^5-oxaphosphetanes[1] (**B**), respectively. From the thermal decomposition of the products phosphinates (**C**) and bis(trifluoromethyl)ethene are obtained [eqn (1)]:



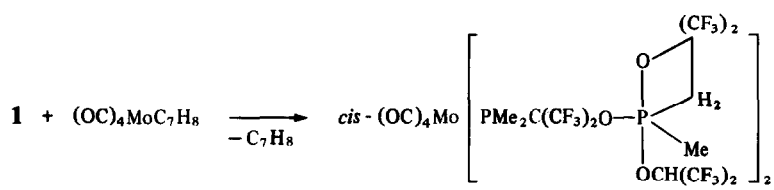
(1)

The P—P bond in tetraalkyldiphosphines may be considered a third centre of reactivity; tetrafluorodiphosphine and tetraethyldiphosphite[3]

* Dedicated to Professor Hans-Herloff Inhoffen on the occasion of his 80th birthday.

† Author to whom correspondence should be addressed.

are known to react with HFA to form a P(III)C$(CF_3)_2$OP(III) system. In the case of tetramethyldiphosphine apparently all three centres of reactivity are active [eqn (2)]:



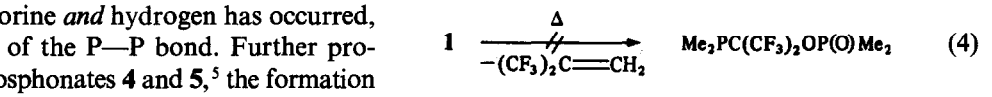
(2)

1 $X^1 = OC(CF_3)_2PMe_2$
2 $X^1 = OCH(CF_3)_2$
3 $X^1 = F$
4 $X^2 = OCH(CF_3)_2$
5 $X^2 = F$

In addition to the phosphinophosphorane (**1**), involving a P(III)C$(CF_3)_2$OP(V) bridge, phosphetanes **2** and **3** are found,[4] proving that abstraction of fluorine *and* hydrogen has occurred, as well as fission of the P—P bond. Further products were the phosphonates **4** and **5**,[5] the formation of which may be rationalized by assuming a formal loss of bis(trifluoromethyl)ethene[6] from **2** and **3**. Here we describe some properties of compound **1** and products of the reaction of diphosphines, $R^1R^2PPR^1R^2$ ($R^1 = R^2 =$ Et, Bu^t or Ph; $R^1 =$ Me, $R^2 =$ Bu^t) with HFA. The change in substituent size should provide some insight into the reaction pathway.

RESULTS AND DISCUSSION

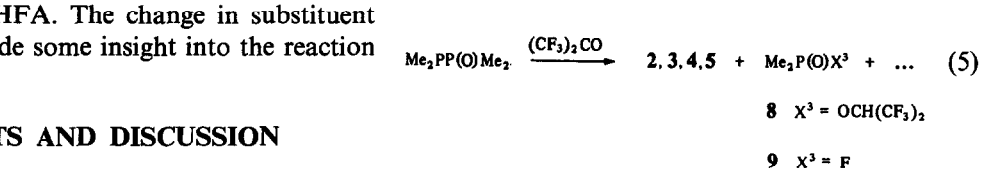
Compound **1**[2] with its phosphine portion is able to function[1] as a ligand in a carbonyl complex [eqn (3)]:



(3)

6

In norbornadiene tetracarbonyl molybdenum the olefin was readily displaced by **1** with formation of the *cis* complex (**6**), a yellow, air-sensitive solid. The IR spectrum of **6** in the CO region showed three absorptions. For a C_{2v} arrangement four ν(CO) bands are expected, two of which are apparently overlapping. HFA did not oxidize the phosphine part of the molecule of **1** with formation of a $C(CF_3)_2O$-bridged diphosphorane.



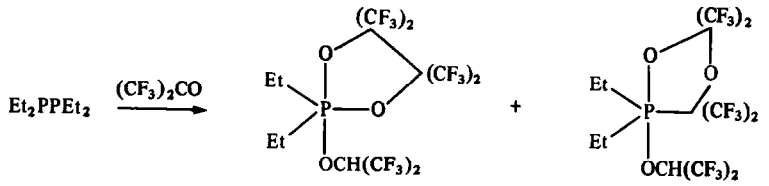
The thermal decomposition of **1** with the expected formation of **7** was not straightforward.*

In order to obtain the product of oxidation of **1**, involving the $Me_2P(O)C(CF_3)_2O$ moiety tetramethyldiphosphine monoxide[7] was allowed to react with HFA but compounds **2**, **3**, **4** and **5**, and the phosphinates **8**[1] and **9**[8] were formed [eqn (5)]:

(4)

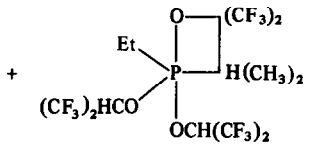
7

(5)



8 $X^3 = OCH(CF_3)_2$
9 $X^3 = F$

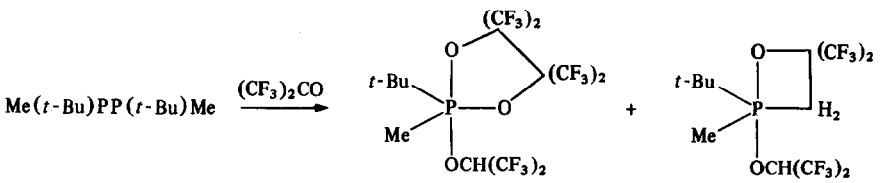
A small amount of bis(trifluoromethyl)ethene was also detected.



The products of the reaction of tetraethyldiphosphine[9] with HFA [eqn (6)] were three isomeric phosphoranes,[10] the 1,3,2-λ^5- and 1,3,4-λ^5-dioxaphospholanes (**10** and **11**), the 1,2-λ^5-oxaphosphetane (**12**), and the phosphinate **13**,[1] respectively, in the ratio 1:4:28:57. From the monochlorophosphines, R_2PCl (R = Me or Et), and HFA 1,3,4-λ^5-dioxaphospholanes were also obtained.[11,12]

In the case of Me(Bu^t)PP(Bu^t)Me[13] the 1,3,2-λ^5-dioxaphospholane (**14**), the 1,2-λ^5-oxaphosphetane (**15**),[14] the phosphonate **4**, and the phosphinate **16**

*A non-separable mixture of **2** (10%), **3** (10%), **4** (15%), **5** (10%), **8** (20%) and **9** (7%), and other, unidentified, products was observed.

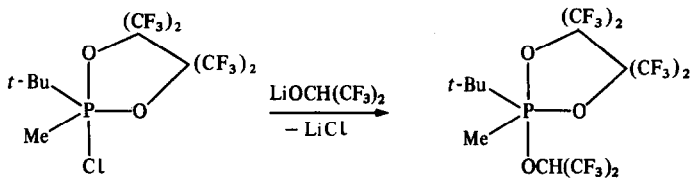


10 11

12 13

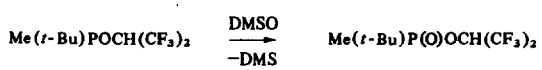
(6)

were observed in the reaction mixture in a ratio 1:35:36:22 [eqn (7)]:



14 15

16

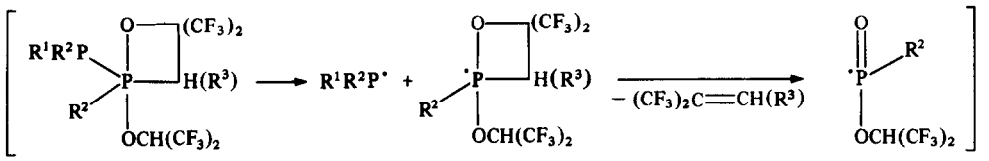


(7)

Formation of the 1,3,4-λ^5-dioxaphospholane system was not observed, presumably for steric reasons. Compound **15** could be separated from **14**, **4** and **16** by means of preparative thin-layer chromatography while **14**, **4** and **16** could not be isolated in a pure state. **14** was prepared via a different route [eqn (8)]:

17 14

Starting from **17**[11] chlorine was substituted by lithium - [2,2,2 - trifluoro - 1 - (trifluoromethyl)]-ethylate to furnish **14** in good yield. **16** was obtained by oxidation of the phosphinate $Me(Bu^t)POCH(CF_3)_2$[15] with dimethylsulfoxide [eqn (9)]:



16

Tetra-*tert*-butyldiphosphine[16] and tetraphenyldiphosphine did not react with HFA under the conditions employed. In the reaction of the diphosphine monoxide, $Me_2P(O)PMe_2$, and of the diphosphine, $Me(Bu^t)PP(Bu^t)Me$, with HFA small amounts of $(CF_3)_2C{=}CH_2$, in the case of Et_2PPEt_2 traces of $(CF_3)_2C{=}CHCH_3$,[1] were formed and were characterized by IR and NMR spectroscopy. As a result of the formation of phosphonates and phosphinates the observation of the corresponding olefins was to be expected if the Wittig-type products, the oxaphosphetanes are the precursors. On the other hand the phosphoryl group may also be created by oxygen transfer from HFA which is not observed in the case of Me_3P or Et_3P but is with $(Me_2N)_3P$.[17] When Et_2PPEt_2 and $(CF_3)_2C{=}CH_2$ are allowed to react a red, viscous oil is formed. A red, non-distillable liquid was found to be left as a residue in all cases, after the more volatile products

had been removed by distillation. It was *not* formed during the separation process.

The reaction mechanism operative here is not clear. There is the possibility of the formation of a phosphinophosphorane (**D**), which may serve as a source of radicals [eqn (10)]:

(10)

D $R^3 = H$ or CH_3

yielding further products. It also seems likely that an insertion of HFA into the P—P bond is taking place giving species **E** which is decomposed in a fashion similar to that of $Ph_2PC(CF_3)_2OH$ to yield the products observed [eqn (11)]:

(11)

E

The mass spectrum of **6** showed ions formed due to a successive loss of CO: M^+, M^+-CO, M^+-2CO, M^+-4CO and M^+-CO-L, $M^+-2CO-L$, $M^+-3CO-L$ and $M^+-4CO-L$. The fragment of highest abundance is CF_3^+. The mass spectrum of **14** did not exhibit a molecular ion but fragments due to M^+-F, M^+-Bu^t, M^+-CF_3, $M^+-OCH(CF_3)_2$, CF_3^+ and Bu^t (100%) were observed.

The ^1H and ^{19}F NMR data for the ligand in **6** were found not to differ significantly from those of the non-coordinated species.[4] The ^{19}F NMR spectrum of **14** proves clearly that the phosphorane structure is rigid, relative to the NMR time scale. Four multiplets for the ring–CF_3 groups and two doublets of quartets for the $OCH(CF_3)_2$ grouping are observed, due to the presence of chiral phosphorus (five different groups are bonded to λ^5-phosphorus). The phosphorus atom in **16** is also chiral and induces magnetic inequivalence on the CF_3 groups.

EXPERIMENTAL

All manipulations were carried out in an atmosphere of dry nitrogen using standard techniques. Literature procedures were employed for the preparation of the phosphorane **1**,[4] norbornadiene molybdenum tetracarbonyl,[18] tetramethyldiphosphine monoxide,[7] tetraethyldiphosphine,[9] 1,2-dimethyl-1,2-di-*t*-butyldiphosphine,[13] tetra-*t*-butyldiphosphine,[16] and hexafluoroisopropyl methyl-*t*-butylphosphinate.[4]

NMR spectra were recorded on a Bruker WH-360 instrument. Chemical shifts are referenced to internal TMS for ^1H, external CCl_3F for ^{19}F, and external 85% H_3PO_4 for ^{31}P. High-field chemical shifts are listed with a negative sign. IR spectra were obtained on solutions using a Perkin–Elmer 577 instrument. Mass spectra (at 70 eV) were recorded on a Varian MAT-CH 7 spectrometer. Elemental analyses were performed by Mikroanalytisches Laboratorium Beller, Göttingen.

Preparation of bis-{2 - [2,2,2 - trifluoro - 1 - (trifluoromethyl)ethoxy - 2 -]2,2,2 - trifluoro - 1 - (trifluoromethyl) - 1 - (dimethylphosphino)ethoxy - 2 - methyl - 4,4 - bis(trifluoromethyl) - 1,2 - λ^5 - oxaphosphetan}tetracarbonylmolybdenum (**6**)

A mixture of **1** (12.40 g; 0.02 mol) in 50 cm^3 of methylcyclohexane and 3.00 g (0.01 mol) of norbornadiene tetracarbonylmolybdenum was stirred at room temperature for 6 days. After solvent and norbornadiene were distilled off a residue of 14.00 g (95%) of **6** (m.p. 114°C) remained.

IR spectrum (*n*-hexane): 2040(m), 1985(s), 1950(s) [ν(CO)].

Mass spectrum [proposed fragment and relative abundance (^{98}Mo) in parentheses]: *m/z* 1450 (M^+, 11%); 1422 (M^+-CO, 2); 1394 (M^+-2CO, 1); 1338 (M^+-4CO, 2); 930 (M^+-L, 23); 802 (M^+-CO-L, 30); 774 ($M^+-2CO-L$, 15); 744 ($M^+-3CO-L$, 35); 716 ($M^+-4CO-L$, 41); 620 (L^+, 71); 69 (CF_3^+, 100).

Analysis. $C_{30}H_{24}F_{36}MoO_{10}P_4$ (1448.30): Calc. C, 24.9; H, 1.7; F, 47.2%. Found C, 24.9; H, 1.6; F, 47.1%.

Attempted reaction of **1** *with HFA*

A mixture of **1** (12.40 g, 0.02 mol) and HFA (6.60 g, 0.04 mol) was sealed in a heavy-wall glass tube. After 1 week the two compounds were recovered unreacted.

Reaction of tetramethyldiphosphine monoxide with HFA

A mixture of 1.38 g (0.01 mol) of tetramethyldiphosphine monoxide and 3.32 g (0.02 mol) of HFA was allowed to react for 1 day at room temperature. The olefin, $(CF_3)_2C{=}CH_2$ (0.10 g), was recovered from the reaction mixture which was found to contain compounds **2**,[4] **3**,[4] **4**,[5] **7**[1] and **8**[8] in the ratio 3:2:1:1:2. All compounds could be removed from the red oily residue by distillation at 100°C (0.001 mm).

Reaction of tetraethyldiphosphine with HFA

A mixture of 2.70 g (0.015 mol) of tetraethyldiphosphine and 10.00 g (0.06 mol) of HFA was allowed to react at −50°C for 2 days and was subsequently warmed up to room temperature over 1 day. The attempted separation of the reaction mixture into its components by distillation was unsuccessful. ^{31}P NMR spectroscopy revealed the presence of **9**,[10] **10**,[10] **11**,[10] and **12**[1] in a ratio of 1:4:28:57. All compounds were found to be distillable from the viscous, red reaction mixture at 100°C (0.001 mm). The olefin $(CF_3)_2C{=}CHCH_3$ could be separated and was characterized by its IR and NMR spectra.

Reaction of 1,2 - *dimethyl* - 1,2 - *di* - tert - *butyldiphosphine with HFA*

1,2 - Dimethyl - 1,2 - di - *tert* - butyldiphosphine (4.00 g, 0.02 mol) and 13.30 g (0.08 mol) of HFA were allowed to react for 3 h at −50°C. Over a period of 5 h the mixture was allowed to warm up to room temperature. Compound **14** could be separated by preparative thin-layer chromatography (Al_2O_3, 150*F*; benzene; R_f 1.0). The ^{31}P NMR investigation of the reaction mixture revealed the presence of **13**, **14**,[4] **15** and **5**[5] in a ratio of 1:35:36:22. All compounds could be removed by distillation from the reaction mixture—a red, viscous oil—at 100°C (0.001 mm) but their separation was not possible.

Preparation of 2 - [2,2,2 - *trifluoro* - 1 - (*trifluoromethyl*)*ethyl*] - 2 - *methyl* - 2 - tert - *butyl* - 4,4,5,5 - *tetrakis*(*trifluoromethyl*) - 1,3,2 - λ^5 - *dioxaphospholane* (**13**)

2 - Chloro - 2 - methyl - 2 - *tert* - butyl - 4,4,5,5 - tetrakis(trifluoromethyl) - 1,3,2 - λ^5 - dioxaphospholane (**16**)[15] (2.00 g, 0.004 mol) was added to 1.10 g (0.06 mol) of lithium - 2,2,2 - trifluoro - 1 - (trifluoromethyl)ethylate. After the mixture had been warmed up to 40°C for 30 min, 10 cm^3 of pentane were added. in order to separate the lithium chloride formed. The solvent was removed and the remaining liquid was distilled at 128°C (2 mm). Compound **14** was obtained in a yield of 1.10 g (43%).

IR spectrum: 2998(m), 2948(s), 2930(m), 2900(m), 2862(m) [ν(CH)], 1475(m), 1460(m), 1415(w), 1398(m), 1362(s), 1350(s), 1300(vs), 1260(vs), 1180(vs), 1100(vs) [ν(CF)], 1017(m), 990(m), 954(s), 936(s), 878(s), 816(s), 755(s), 740(s), 705(s), 680(s).

Mass spectrum: *m/z* 583 (M^+-F, 2%); 545 (M^+-Bu^t, 48); 533 (M^+-CF_3, 12); 435 [$M^+-OCH(CF_3)_2$, 20]; 69 (CF_3^+, 57); 57 (Bu^t, 100).

NMR spectra—^1H: δ 2.05 [9H, Bu^t; ^3J(PH) 25.00]; 2.60 [3H, Me; ^2J(PH) 12.40]; 5.10 [1H, $CH(CF_3)_2$; ^3J(HF) 5.80]. ^{19}F: δ −66.98 (3F, multiplet); −67.47 (3F, multiplet); −69.00 (3F, multiplet); −70.09 (3F, multiplet); −74.27 (3F, multiplet); −74.82 (3F, multiplet). ^{31}P: δ +12.30.

Analysis. $C_{14}H_{13}F_{18}O_3P$ (602.21). Calc. C, 27.9; H, 2.2; F, 56.8%. Found C, 28.0; H, 2.3; F, 56.5%.

Preparation of methyl - tert - *butyl* - [2,2,2 - *trifluoro* - 1 - (*trifluoromethyl*)*ethyl*]*phosphinate* (**16**)

Dimethylsulfoxide (1.50 g, 0.02 mol) in 20 cm^3 of diethylether was added to 5.30 g (0.02 mol) of methyl - *tert* - butyl[2,2,2 - trifluoro - 1 - (trifluoromethyl)ethyl]phosphinate,[16] and the mixture was stirred for three days at 70°C. The solvent was removed and the remaining liquid (dimethylsulfoxide) was distilled at 50°C (0.3 mm); m.p. 28°C. **16** [4.20 g (77%)] remained as a residue.

IR spectrum: 2970(m), 2932(m), 2868(m) [ν(CH)], 1460(m), 1372(s), 1290(s), 1260(s), 1255(vs), 1200(vs), 1105(vs) [ν(CF)], 1011(m), 940(w), 890(s), 868(m), 820(m), 755(m), 723, 682(m).

NMR spectra—^1H: δ 1.04 [9H, Bu^t; ^3J(PH) 16.00]; 1.40 [3H, Me; ^2J(PH) 13.00]; 5.10 [1H,

$CH(CF_3)_2$; ^3J(HF) 5.80]. ^{19}F: δ −73.50 (3F, multiplet); −74.36 (3F, multiplet). ^{31}P: δ +49.30.

Analysis. $C_8H_{13}F_6O_2P$ (286.15). Calc. C, 33.6; H, 4.6; F, 39.8%. Found C, 33.5; H, 4.6; F, 40.1%.

*Attempted reaction of tetra-*tert*-butyldiphosphine and tetraphenyldiphosphine with HFA*

A mixture of the diphosphine (0.01 mol) and HFA (6.64 g, 0.04 mol) was heated for 3 days at 100°C in a steel cylinder. The starting compounds were recovered unreacted.

Reaction of tetraethyldiphosphine with 3,3,3 - trifluoro - 2 - (trifluoromethyl)propene (2)

Tetraethyldiphosphine (1.80 g, 0.01 mol) and 1.60 g (0.01 mol) of 3,3,3 - trifluoro - 2 - (trifluoromethyl)propene were sealed together into a heavy-wall glass tube. After 2 days at room temperature a red, viscous oil was obtained after removal of the unreacted tetraethyldiphosphine. The ^{19}F and ^1H NMR spectra showed very broad signals at δ_F −67.0 and δ_H 5.3.

(*Received* 30 *September* 1985; *accepted* 25 *November* 1985)

Abstract—Raman spectra of vapor mixtures $ZrCl_4$–$POCl_3$, $HfCl_4$–$POCl_3$, $ZrCl_4$–$AlCl_3$ and $HfCl_4$–$AlCl_3$ are obtained in the temperature range 300–500°C. The spectra consist of superposition of bands due to the component gases plus a few new bands which were attributed to vapor complexation. A comparison of the spectra features in the systems MCl_4–$POCl_3$ (M = Zr or Hf) with the spectra of the 1:1 liquid and glass $MCl_4 \cdot POCl_3$ (M = Zr or Hf) with the spectra of the 1:1 liquid and glass $MCl_4 \cdot POCl_3$ indicate that the vapor complexes also have a 1:1 stoichiometry and that complexing occurs through oxygen bridging. The strongest Raman bands for the Zr–O–P and the Hf–O–P complex are at 508 and 512 cm^{-1}, respectively. For the MCl_4–$AlCl_3$ systems two possible vapor complexes, MAl_2Cl_{10} and $MAlCl_7$, are considered. Temperature dependence measurements of the Raman spectra of the $ZrCl_4$–$AlCl_3$ systems indicate that the predominant vapor complex is probably 1:1 and permit the estimation of the enthalpy of the reaction: $ZrCl_4(g) + \frac{1}{2}Al_2Cl_6(g) = ZrAlCl_7(g)$; $\Delta H^0 = -34.9 \pm 2.5$ kJ mol^{-1}. The strongest Raman bands for the Zr–Cl–Al and the Hf–Cl–Al complex are at 401 and 391 cm^{-1}, respectively, and is assigned to M—Cl (terminal) stretching.

It has been established that inorganic salt vapors at elevated temperatures (typically above 150°C) react with condensed-phase compounds or other vapors to form vapor complexes.[1–3] Vapor complexation appears to be a general phenomenon for many metal-halide salts as well as oxides and sulfides and is important in determining the vapor pressures, rates of vaporization and apparent volatilities of materials. A large number of vapor complexes involving mainly metal halides have been reported and extensive reviews on their structural[4–7] and thermodynamic[8–10] properties are available. The most important of the complex-forming agents are the chlorides and bromides of tervalent Al, Ga, In and Fe. Reactions of these trihalides with many monovalent, divalent and tervalent metal halides have been reported and the structural properties of the vapor complexes have been studied by means of electronic and vibrational (mainly Raman) spectroscopy.[4,5] Raman spectroscopy has also been used for investigating the vapor complexes of $AlCl_3$ with $ZrCl_4$[11] and $NbCl_5$,[12] and for studying the structures of the "adduct"-type molecules $AlX_3 \cdot NH_3$ (X = F, Cl or Br).[13]

Like Al, Ga, In and Fe trihalides the $POCl_3$ has

*Author to whom correspondence should be addressed.

"acid"-like properties and is known to react with metal halides to form complexes (adducts) in the liquid, solid and vapor phase.[14-16] The formation of vapor complexes of $POCl_3$ with $ZrCl_4$ and $HfCl_4$ has been carefully investigated due to the potential use of these systems for separation by distillation of Zr from Hf in nuclear reactor materials.[17]

The present work is concerned with the characterization of the vibrational spectra of equilibrium vapor complexes of the tetravalent chlorides of Zr and Hf with $POCl_3$ and $AlCl_3$. Raman spectroscopy is used to study the vapors over the liquid $POCl_3$–MCl_4 and $AlCl_3$–MCl_4 mixtures (M = Zr or Hf). Certain vibrational band wavenumbers of the vapor complexes in these systems are determined and, for the $ZrCl_4$–$AlCl_3$ system, the enthalpy of complex formation is measured from the spectral data. Finally, the vibrational band wavenumbers in the 1:1 "adduct molecules" $MCl_4 \cdot POCl_3$ in the liquid and glass state are determined by Raman spectroscopy.

EXPERIMENTAL

High-purity $AlCl_3$, $ZrCl_4$ and $HfCl_4$ were prepared from "Cerac Pure" reagents by repeated slow sublimations in fused silica tubes sealed *in vacuo*. Liquid $POCl_3$ was purchashed from Cerac Pure and used without further purification.

The Raman (optical) cells containing the salt vapors were made of 20-mm o.d. fused silica tubing.[18] All cells were approximately of the same dimensions with a volume of ~ 5 cm^3. Before use all cells were carefully cleaned, rinsed well, flamed to red-heat with a propane–oxygen torch and degassed by evacuating while hot.

The cells for recording the vapor-phase Raman spectra of MCl_4–$POCl_3$ (M = Zr or Hf) were loaded using dry-box techniques as follows. Preweighed amounts of MCl_4 were transferred into a cell of known volume which was then attached to a vacuum line. The desired amounts of $POCl_3$ were fed into the evacuated cell by connecting it with a spherical flask containing known quantities of $POCl_3$. The bottom of the Raman cell was then cooled with liquid nitrogen to condense all the $POCl_3$ from the flask, and the neck of the cell was sealed *in vacuo*.

The amount of $POCl_3$ added was more than 50 mol %. By heating up a cell, low-melting glass-forming liquids, $MCl_4 \cdot 2POCl_3$ and $MCl_4 \cdot POCl_3$, were formed.[14] At temperatures above 150°C a stable liquid, presumably the 1:1 adduct, was always present in the cell in equilibrium with the vapor phase. Raman spectra of the vapors over this liquid are presented here.

Raman spectra of the 1:1 adduct liquid at 200°C and its glass at 25°C were also measured by fast cooling of the cell and by condensing and isolating the vapors away from the liquid glass. Additional cells containing pure $POCl_3$, $ZrCl_4$ and $HfCl_4$ were also prepared for recording the vapor-phase Raman spectra of the pure compounds. Detailed spectra for all three compounds have been measured and reported previously[19,20] but it was necessary to repeat these measurements so to compare the relative intensities of the vapor mixtures with those of the pure compounds.

The cells for measuring the Raman spectra of the MCl_4–$AlCl_3$ (M = Zr or Hf) vapors were prepared by adding preweighed amounts of MCl_4 and $AlCl_3$ into the neck of the cell then subliming the chemicals into the cell *in vacuo*. Several cells were also made having largely varying molar ratios of $AlCl_3$ and MCl_4 to be able to obtain the spectra of vapor in equilibrium with the liquid mixture.

For the $POCl_3$–MCl_4 systems the spectra were measured in cells where the vapors were in equilibrium with the liquid phase. For the $AlCl_3$–MCl_4 systems measurements from two cells (I and II) containing vapor mixtures and no condensed phases, as well as gas over liquid spectra concerning the $ZrCl_4$–$AlCl_3$ (cell III) will be presented here. Other gas–liquid-containing cells for both sets of systems, $POCl_3$–MCl_4 and $AlCl_3$–MCl_4, gave similar results and do not contribute much to the discussion.

Cell I had 171 mg $AlCl_3$ plus 36 mg $ZrCl_4$. Cell II had 116 mg $AlCl_3$ plus 20 mg $HfCl_4$. Cell III had 110 mg $AlCl_3$ plus 170 mg $ZrCl_4$ but its total volume was less than 1 cm^3. At temperatures above 220°C, all the $AlCl_3$ contained in cells I and II was in the vapor phase (mainly as Al_2Cl_6) giving rise to "ideal-gas" Al_2Cl_6 pressures of ~ 3.5 and ~ 2 atm, respectively. At the same temperature the partial pressures of $ZrCl_4$ (cell I) and $HfCl_4$ (cell II) should be ~ 0.5 and ~ 2 atm, respectively (values calculated assuming that all $ZrCl_4$ or $HfCl_4$ should be in an "ideal gas" gas phase). At 220°C or higher temperatures no formation of solid compounds could be observed.

The procedures and techniques for obtaining the Raman spectra at elevated temperatures have been described before.[18] By stabilizing the laser power and frequency, the same optical geometry and the same size cells, the relative Raman intensities could be reproduced to within less than 5%. Relative Raman intensities of gases obtained from the same cell at different temperatures could be also obtained within the same error.[18]

RESULTS AND DISCUSSION

MCl_4–$POCl_3$ (M = Zr *or* Hf) *systems*

A series of Raman spectra of vapors over the MCl_4–$POCl_3$ liquid mixtures were obtained. Representative spectra for the $ZrCl_4$–$POCl_3$ and $HfCl_4$–$POCl_3$ systems are shown in Figs. 1 and 2, respectively. A comparison with the spectra of the pure gases, $POCl_3$(g) and MCl_4(g) (see, for example, Fig. 2), shows that the vapor spectra over the liquid mixtures are mainly a superposition of bands due to the component gases plus certain new bands which are attributed to vapor complexation. The wavenumbers of these new bands are given in Table 1 which shows all the measurements including the wavenumbers of the 1 : 1 liquids and glasses, as well as the wavenumbers of the pure component gases. The glass–liquid spectra are shown in Fig. 1 for the $ZrCl_4$–$POCl_3$ mixture. Spectra of similar quality were also obtained for the $HfCl_4$–$POCl_3$ glass–liquid mixture and the Raman wavenumbers are

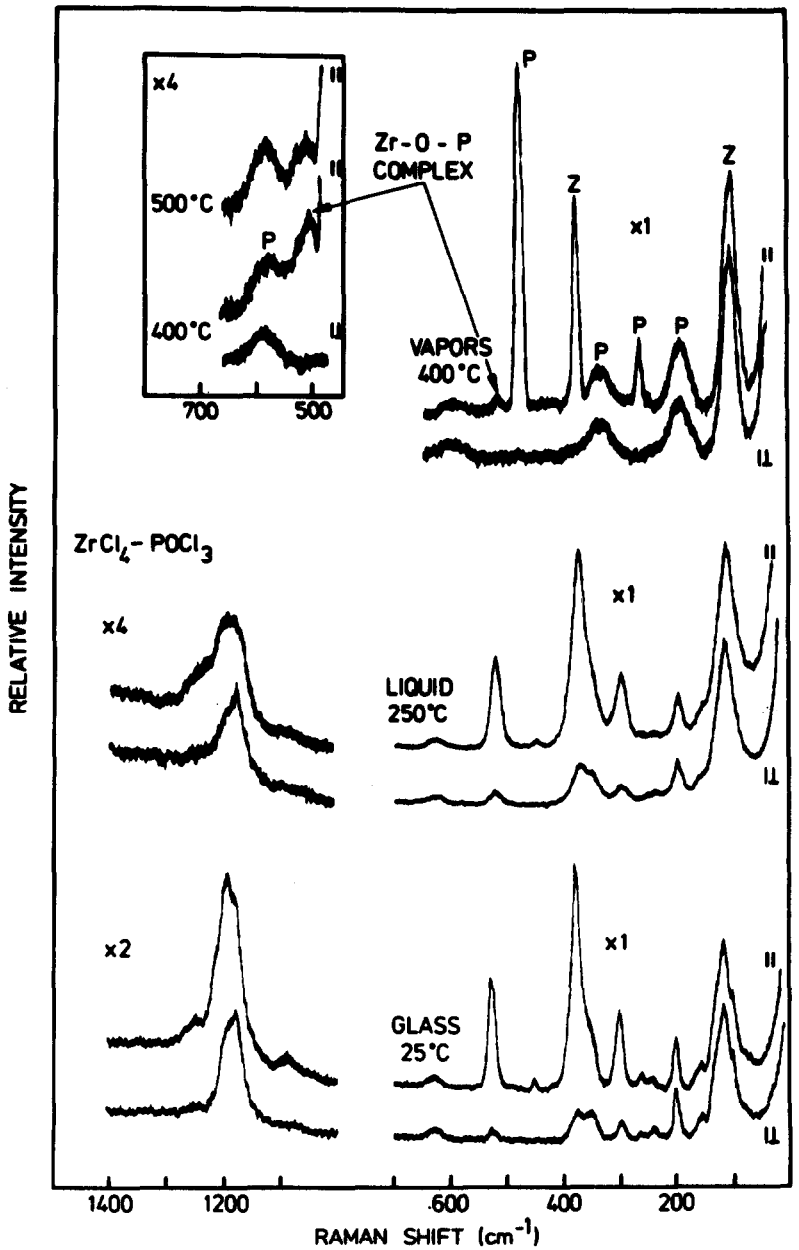

Fig. 1. Raman spectra of $ZrCl_4$–$POCl_3$ system. $\lambda_0 = 514.5$ nm, laser power = 1 W for the upper part (vapors); $\lambda_0 = 488.0$ nm, laser power 220 mW for the liquid and glass. Spectral slit width: 8 cm^{-1} for vapors and liquid, 2 cm^{-1} for glass.

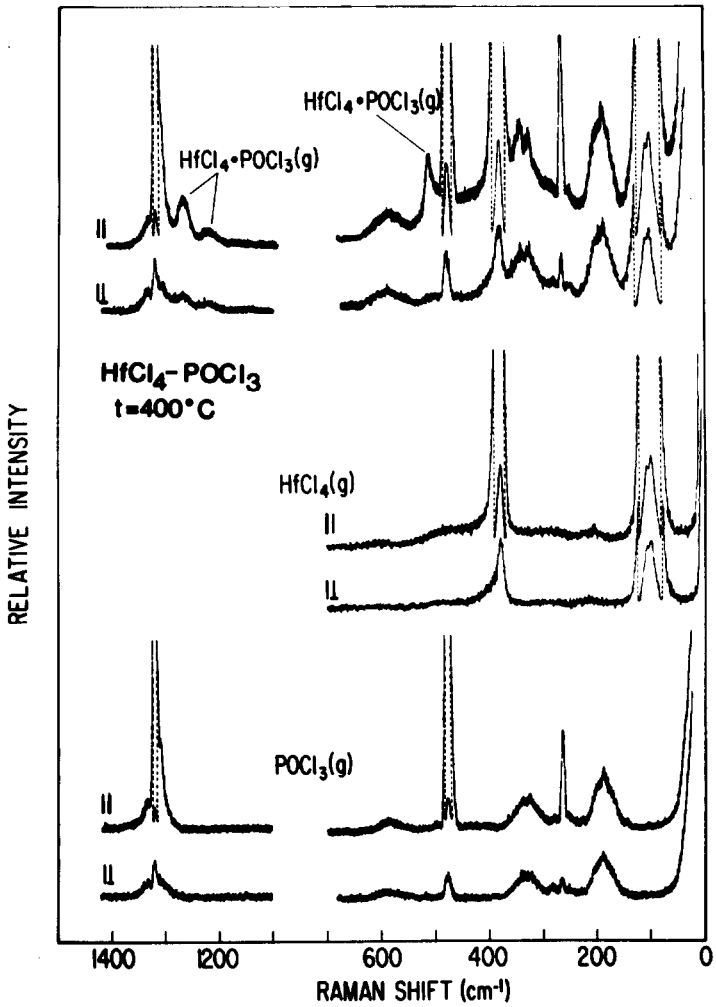

Fig. 2. Raman spectra of $POCl_3$ and $HfCl_4$ vapors, and vapors over $POCl_3$–$HfCl_4$ liquid mixtures at 400°C. $\lambda_0 = 514.5$ nm, laser power = 1 W. Spectral slit width = 4 cm^{-1}.

reported in Table 1. Presumably the spectra of the 1 : 1 liquid or glass mixture are due to the formation of the $MCl_4 \cdot POCl_3$ "adduct" molecules.[14,17]

In the $ZrCl_4$–$POCl_3$ system the data in Table 1 and Fig. 1 show a vapor complex band at 508 cm^{-1}. Three bands at 512, 1221 and 1263 cm^{-1} are seen for the complex in the $HfCl_4$–$POCl_3$ system (Table 1, Fig. 2). In the wavenumber region 1110–1500 cm^{-1} the vapor Raman cells with $ZrCl_4$–$POCl_3$ gave a strong fluorescence background and the probable bands due to the complex in that range were not seen, presumably due to the low signal : noise ratio. It should be noticed that most of the strong bands due to $MCl_4(g)$ and $POCl_3(g)$ are also present as strong bands in the spectra of the adduct liquid or glass with wavenumbers shifted to higher or lower energies. Thus, it is expected that in the vapor-phase spectra only those bands of the complex with strong intensities and with wavenumbers far away from those of the component gases will be seen.

With increasing temperature the intensities of the Raman bands due to the vapor complexes decreased relative to the bands of the component gases, indicating decomposition of the complex. An example of the temperature effect on the vapor spectra is shown in the insert of Fig. 1. The most probable equilibrium established in the gas phase[15,17] and also compatible with the spectral behavior here is:

$$MCl_4(g) + POCl_3(g) = MCl_4 \cdot POCl_3(g). \quad (1)$$

The formation of $(MCl_4 \cdot POCl_3)_2$ dimers[21(a)] as well as $MCl_4 \cdot 2POCl_3$ molecules[14] can be excluded from the previously reported vapor density measurements.[14,17]

The bonding in the "adduct" vapor complex $MCl_4 \cdot POCl_3$ (I) presumably occurs[14] by bridging the oxygen of $POCl_3$ (C_{3v} molecular symmetry)[19] to the metal atom through the face of the MCl_4 tetrahedron (T_d molecular symmetry in the gas[20,21(b)] phase).

[b] Due to high partial pressures of MCl_4 and $POCl_3$, the Raman bands of the vapor complex are contained in the strong bands of the component gases.

[c] Vibrational–rotational contour.

I

The molecular symmetry of the vapor-complex is C_{3v}. Rotation of the component molecules around the P–O–M axis does not alter this symmetry. The distribution of the 24 vibrational degrees of freedom of the complex can be classified by group theory into 16 modes as follows:

$$\Gamma_{\text{complex}} = 7A_1(\text{R, IR}) + 8E(\text{R, IR}) + A_2(\text{IR}).$$

An assignment of the observed bands is given in Table 1.

It is noteworthy that the ν(P—Cl) stretching frequency in the vapor complex is blue-shifted relative to the corresponding band of the free $POCl_3$(g). On the other hand, the ν(P—O) stretching frequency of the complex is red-shifted. These shifts are compatible with the above-proposed structure, indicating that the formation of the P—O—M bridging bond weakens the P—O and M—Cl bonds and strengthens the P—Cl bonds.

MCl_4–$AlCl_3$ (M = Zr *or* Hf) *systems*

Typical vapor Raman spectra from cells containing $ZrCl_4$–$AlCl_3$ and $HfCl_4$–$AlCl_3$ are presented in Figs 3 and 4. In Figs 3 and 4 the spectra of $ZrCl_4$, $HfCl_4$ and Al_2Cl_6 are included for comparison and are in agreement with the previously reported spectra of Clark *et al.*[20] and Tomita *et al.*[22]

It is evident that the spectra of $ZrCl_4$–$AlCl_3$ (Fig. 3C) consist mainly of a superposition of bands due

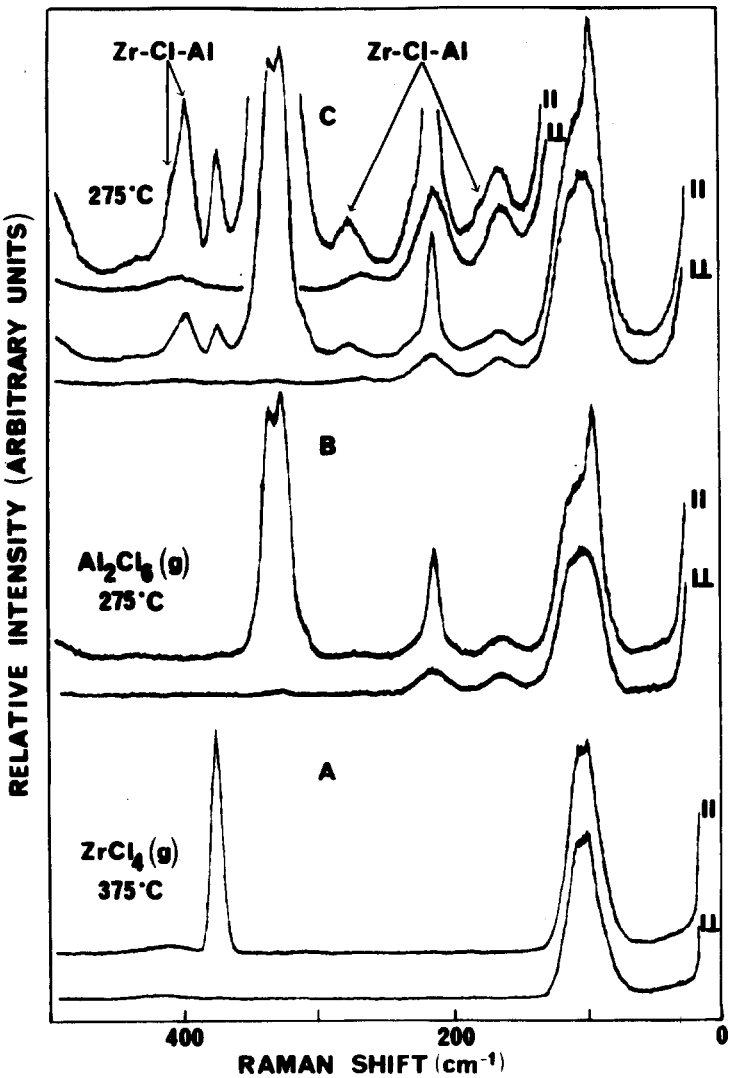

Fig. 3. Vapor Raman spectra of: (A) $ZrCl_4$ at 375°C, (B) Al_2Cl_6 at 275°C, and (C) mixtures of $ZrCl_4$–$AlCl_3$ from cell I at 275°C; λ_0 = 514.5 nm, laser power = 700 mW. Spectral slit width = 6 cm^{-1}.

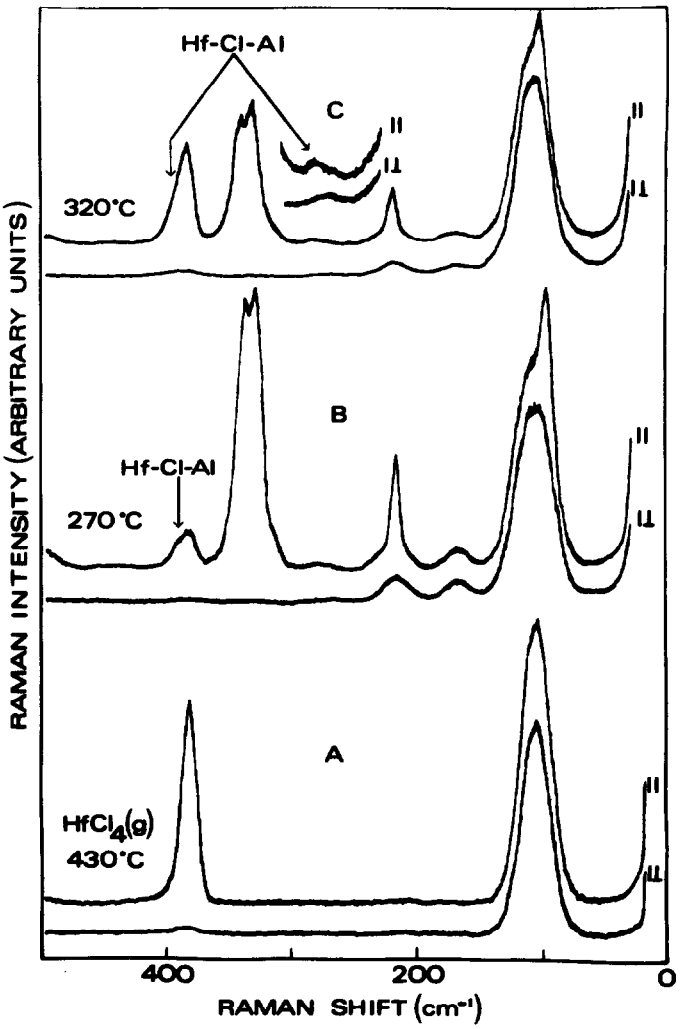

Fig. 4. Vapor Raman spectra of: (A) $HfCl_4$ at 430°C, (B) mixtures of $HfCl_4$ and Al_2Cl_6 from cell II at 270°C, and (C) mixtures of $HfCl_4$ and Al_2Cl_6 from cell II at 320°C. $\lambda_0 = 514.5$ nm; laser power = 700 mW. Spectral slit width = 6 cm^{-1}.

to $ZrCl_4$(g) and Al_2Cl_6(g). At 375°C, zirconium tetrachloride has its strongest ν_1 band at 377 cm^{-1} and a doublet (ν_2, ν_4) at ~100 cm^{-1}. At temperatures below 550°C and pressures near 1 atm the $AlCl_3$ vapors consist primarily of Al_2Cl_6 dimers,[18(a),22] having the strongest characteristic bands at ~335 (doublet), ~218 and ~100 cm^{-1}. In the spectra of the vapor mixture a new "strong" band at 401 cm^{-1} can be recognized which has also been observed by Taylor and Larsen[11] and is attributed to Zr–Cl–Al vapor complex(es). Careful examination of the polarization characteristics of the Raman bands established the presence of two additional bands at 281 and 188 cm^{-1} and a shoulder band with wavenumber near 412 cm^{-1}. The latter bands were best observed in the spectra of cell III (investigation of vapors over the liquid mixture) and are shown in Fig. 5. The wavenumbers and polarizations of the Raman bands measured for the Zr–Cl–Al complex(es) are listed in Table 2.

A comparison of the spectra of the $HfCl_4$–Al_2Cl_6 vapor mixtures (Fig. 4B and C) with the spectra of $HfCl_4$ (Fig. 4A) and Al_2Cl_6 (Fig. 3B) vapors shows that vapor complex bands are difficult to recognize. Gaseous $HfCl_4$ has a strong polarized band (ν_1) at 380.7 cm^{-1} and a very weak band (ν_2) at ~392 cm^{-1}. In the vapor mixture, however, a shoulder band appears at ~391 cm^{-1}, whose intensity at temperatures near 270°C is comparable with that of the ν_1 of $HfCl_4$(g). This band and the weak polarized band at 281 cm^{-1} are attributed to the Hf–Cl–Al vapor complex. The correspondence of the bands for the two complexes of Zr and Hf, and a tentative assignment is given in Table 2.

Vapor complexation of bivalent or tervalent metal chlorides with aluminum chloride usually

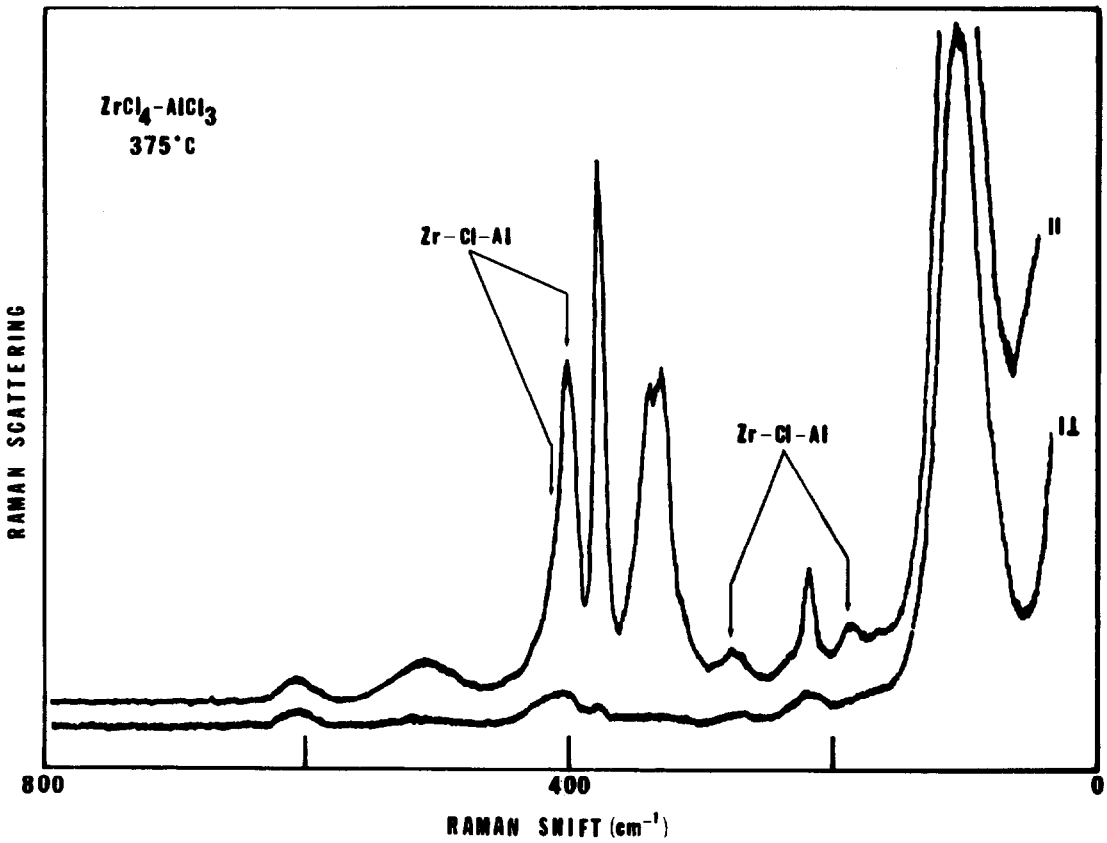

Fig. 5. Raman spectra of vapors over molten $ZrCl_4$–$AlCl_3$ mixtures (cell III) at 375°C. $\lambda_0 = 514.5$ nm; laser power = 700 mW. Spectral slit width = 6 cm^{-1}.

involves one molecule of the metal chloride and one, two, three or more molecules of $AlCl_3$.[5,23] Thus, it is more likely that the vapor complexation of tetravalent chlorides occurs with the general reaction:

$$MCl_4(g) + nAl_2Cl_6(g) = MAl_{2n}Cl_{6n+4}(g). \quad (2)$$

In the case of $ZrCl_4$, Taylor and Larsen[11] suggested that the vapor complex is $ZrAl_2Cl_{10}$, while the mass spectrometric measurements of Schäfer and Flörke[24] indicated that both $ZrAlCl_7$ and $ZrAl_2Cl_{10}$ are present in the gas-phase equilibrium. The thermodynamic functions of reaction (2) involving the $n = \frac{1}{2}$ and $n = 1$ Zr complexes are listed in Table 3.[24]

An average value of the enthalpies of reaction (2) can also be calculated from measurements of the relative Raman intensities of the gaseous species participating in the equilibrium [i.e. $ZrCl_4(g)$, $Al_4Cl_6(g)$ and the complexes]. The basic assumption

Table 2. Vibrational band wavenumbers (cm^{-1}) of vapor complexes in the $ZrCl_4$–Al_2Cl_6 and $HfCl_4$–Al_2Cl_6 systems[a]

Table 3. Thermodynamic functions of reactions in the temperature range 300–500°C

n	Reaction	ΔS^0 (J K^{-1} mol^{-1}) (Ref. 24)	ΔH^0 (kJ mol^{-1}) (Ref. 24)	ΔH^0 (kJ mol^{-1}) (this work)
$\frac{1}{2}$	$ZrCl_4(g)+0.5Al_2Cl_6(g) = ZrAlCl_7(g)$	−75.4	−36.0	−34.9±2.5
1	$ZrCl_4(g)+Al_2Cl_6(g) = ZrAl_2Cl_{10}(g)$	−140.7	−65.3	−35.6±3.1

made is that the partial pressures (P_i) of the species are proportional to the Raman intensity (I_i). Thus, for each cell at temperature T, the equilibrium constant of reaction (2) is:

$$k_p = \frac{P_C}{P_A^n P_M} = \lambda \frac{I_C}{I_A^n I_M} \quad (3)$$

where C, A and M are subscripts indicating the vapor complex, Al_2Cl_6 and MCl_4, respectively, and λ is a proportionality constant. The relation leads to:

$$\ln\left(\frac{I_C}{I_A^n \cdot I_M}\right) = -\frac{\Delta H}{R}\left(\frac{1}{T}\right) + [\Delta S - \ln \lambda], \quad (4)$$

and $\Delta H/R$ is determined as the slope of the logarithmic function vs $1/T$.

Measurements of the relative Raman intensities I_C, I_A and I_M for the $ZrCl_4$–$AlCl_3$ system were obtained at different temperatures from four cells. Variable amounts of $ZrCl_4$ and $AlCl_3$ were added into the cell and the measurements were obtained for each cell in the temperature range where all species (i.e. $ZrCl_4$, Al_2Cl_6 and complex) were in the gas phase. Figure 6 shows the temperature dependence of the relative intensities from 275 to 525°C. At temperatures above 450°C, small amounts of $AlCl_3(g)$ monomers are also present, giving rise to a Raman band at ~370 cm^{-1} [22] which overlaps with the $ZrCl_4(g)$ ν_1-band. However, based on previous work[22] the expected intensity of $\nu_1[AlCl_3(g)]$ could be estimated relative to the $\nu_2[Al_2Cl_6(g)]$ intensity and subtracted from the total intensity of the band observed at ~370 cm^{-1}. Thus, an intensity solely due to $\nu_1(ZrCl_4)$ could be measured.

Plots of the logarithmic function [eqn (4)] vs $1/T$ for each Raman cell gave straight lines with $n = \frac{1}{2}$ (Fig. 7) and values of ΔH very close to each other with a mean value of −34.9±2.5 kJ mol^{-1}. Similar plots were obtained with $n = 1$ and the mean enthalpy is −35.6±3.1 kJ mol^{-1}. The proximity of the ΔH^0 values of the $n = \frac{1}{2}$ reaction (1) (Table 3) relative to those of the $n = 1$ reaction measured by mass spectrometry[24] and by Raman experiments suggests that $ZrAlCl_7$ is the predominant vapor complex in the $ZrCl_4$–$AlCl_3$ system. On the other hand the accuracy of the data and the method used cannot completely exclude any possible formation of $ZrAl_2Cl_{10}$. Finally, it should be noticed that the

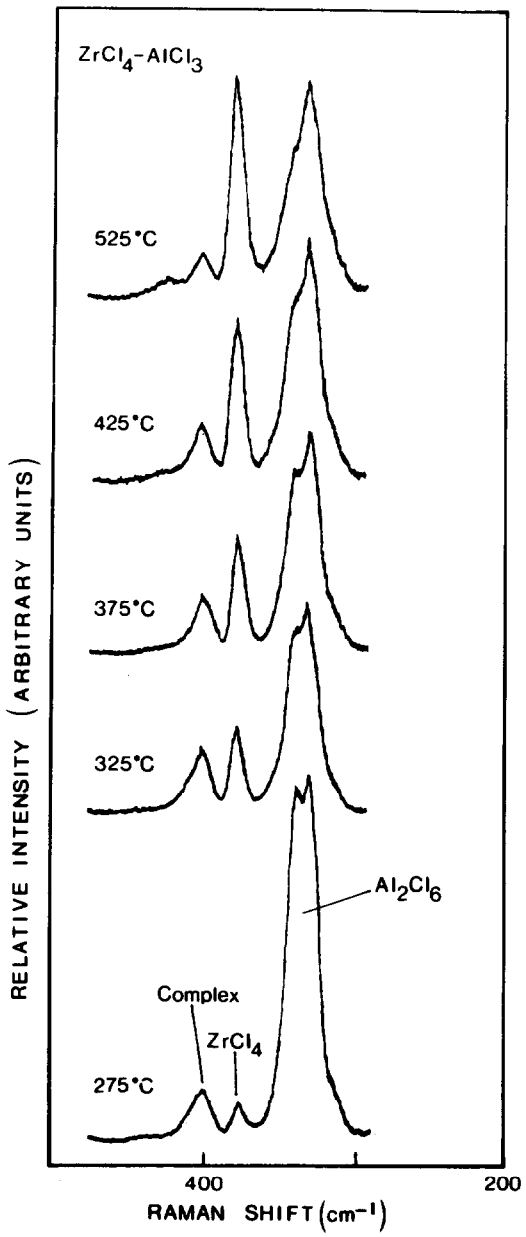

Fig. 6. Temperature dependence of vapor Raman spectra from cell I. λ_0 = 514.5 nm; laser power = 700 mW. Spectral slit width = 6 cm^{-1}.

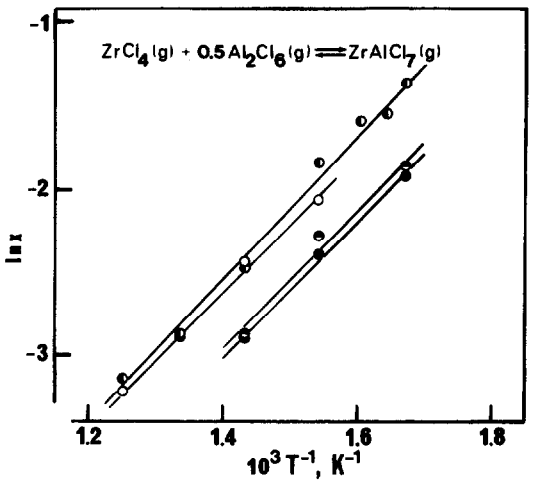

Fig. 7. Plots of

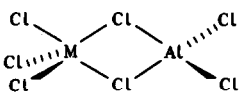
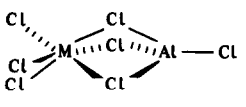


$$\ln x\left(x = \frac{I_C}{I_Z I_A^{0.5}}\right) \text{ vs } 1/T.$$

Points indicate molar ratios of Al_2Cl_6 to $ZrCl_4$: cell A (◑) $Al_2Cl_6/ZrCl_4 = 7$, cell B (○) $Al_2Cl_6/ZrCl_4 = 1$, cell C (◓) $Al_2Cl_6/ZrCl_4 = 4$, cell D (●) $Al_2Cl_6/ZrCl_4 = 4$.



intensity of the shoulder band at 412 cm^{-1} relative to that at 401 cm^{-1} remained unchanged with temperature and total pressure. This is an indication that both bands are due to the same species (i.e. $ZrAlCl_7$) and not due to species with different structural conformations or stoichiometries.

From a structural point of view the MAl_2Cl_{10} complex is more likely to have a D_{2h} molecular symmetry with M as the central atom in a six-fold coordination and two bidentate $AlCl_4$ tetrahedra.[11,5] From the 33 vibrational modes, six are expected[5] with A_1-symmetry and are Raman-active only.

There are two possible structures concerning the

II

III

molecule $MAlCl_7$: Structure **II** has C_s-symmetry and a five-fold coordination [as in the case of the $M_2Cl_8(g)$ dimer] while structure **III** has C_{3v}-symmetry with triple chloride bridging and a six-fold coordination for M. The distribution of vibrational modes for these molecules are:

$$\Gamma_{C_s} = 13A'(R, IR) + 8A''(R, IR),$$

$$\Gamma_{C_{3v}} = 5A_1(R, IR) + 8E(R, IR).$$

The small number (four) of polarized bands seen for the Zr–Cl–Al complex points to a C_{3v} rather than a C_s-symmetry, but no definite conclusion can be made on this basis.

CHARACTERIZATION OF COPPER(II) COORDINATION COMPOUNDS OF 5,7-DIMETHYL[1,2,4]TRIAZOLO[1,5-*a*]PYRIMIDINE: THE CRYSTAL STRUCTURE OF DIAQUATETRAKIS(5,7-DIMETHYL[1,2,4]TRIAZOLO[1,5-*a*]PYRIMIDINE-N^3)-COPPER(II) HEXAFLUOROPHOSPHATE*

T. L. F. FAVRE, J. G. HAASNOOT† and J. REEDIJK

Department of Chemistry, Gorlaeus Laboratories, State University Leiden, P.O. Box 9502, 2300 RA Leiden, The Netherlands

(*Received* 17 *October* 1985; *accepted* 25 *November* 1985)

Abstract—Copper(II) coordination compounds of several CuA_2 salts (A = PF_6, BF_4, ClO_4, CF_3SO_3 or NO_3) with 5,7-dimethyl[1,2,4]triazolo[1,5-*a*]pyrimidine (dmtp) as a ligand have been studied. The crystal structure of $[Cu(dmtp)_4(H_2O)_2](PF_6)_2$ is described. This compound is monoclinic, space group $P2_1/c$, $a = 11.826(2)$ Å, $b = 9.463(2)$ Å, $c = 17.673(3)$ Å, $\beta = 97.50(1)°$, $Z = 2$, $d_{calc.} = 1.66$ Mg m^{-3}, and has been refined to a final discrepancy factor (R) of 0.0382 based on 2316 reflections. The structure consists of PF_6^- anions and centrosymmetric mononuclear $[Cu(dmtp)_4(H_2O)_2]^{2+}$ cations, Cu^{2+} being coordinated by four equatorial N(3)-bonded dmtp molecules with Cu—N = 2.019 and 2.050 Å, and by two axial water molecules with Cu—O = 2.650 Å. The water molecules form intramolecular hydrogen bonds with the dmtp N(4) atoms.

The coordination chemistry of purines, pyrimidines and imidazole-type ligands has recently been subjected to intensive studies, because of the importance of the interactions between such ligands and metal ions in many biological systems.[1]

With a few exceptions these purines appear to have either a monodentate coordination via the N(9) or a bidentate bridging coordination via the N(3) and N(9) nitrogen atoms.[2–7] If the N(9) nitrogen atom has been blocked, as, for example, in 9-methyladenine, the respective coordination sites are N(7) in the case of monodentate coordination or N(1) and N(7) in the case of bidentate bridging coordination.[8]

In the present study the ligand 5,7-dimethyl-[1,2,4]triazolo[1,5-*a*]pyrimidine, hereafter abbreviated as dmtp, is considered as a model for the naturally-occurring purines. In this paper the IUPAC ring numbering[9] has been used, which is shown in Fig. 1.

The main structural modifications of [1,2,4]triazolo[1,5-*a*]pyrimidines with respect to the purines are as follows. Firstly, none of the nitrogen atoms in these triazolopyrimidines are protonated in neutral or even weakly acidic solvents, which is in contrast with the purines.[6–8] Secondly, coordination via the purine N(1) nitrogen atom is ruled out due to the N(8) bridge-head position in [1,2,4]triazolo[1,5-*a*]pyrimidine, leaving three possible coordination sites at pH > 4, viz. N(1), N(3) and N(4). The coordination properties of [1,2,4]triazolo[1,5-*a*]pyrimidines can further be modified by steric or electronic effects due to the presence of substituents, as the two methyl groups in dmtp. This ligand was selected for a first study.

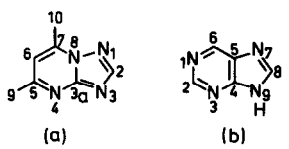

Fig. 1. IUPAC ring numbering of dmtp (a) and purine molecules (b).

* Dedicated to the memory of Dr Gerrit C. Verschoor, who died on 29 September 1985.

† Author to whom correspondence should be addressed.

Earlier work from this laboratory has shown that interesting coordination compounds can be obtained with dmtp and metal(II) thiocyanates.[10–12] We now extend this to the use of "non-coordinating" anions, like PF_6^-, ClO_4^- and BF_4^-, to see whether or not more than two dmtp ligands can be coordinated to Cu^{2+}. Results of coordination compounds with dmtp and copper(II) salts with relatively strong coordinating anions, like halides, will be published later.[13]

In addition, the present paper contains the description of the crystal structure determined by X-ray analysis of $[Cu(dmtp)_4(H_2O)_2](PF_6)_2$ to demonstrate how the ligand is coordinated.

EXPERIMENTAL

Preparations

Triazolopyrimidines can be obtained by reaction of two out of three possible tautomers of 3-amino-1,2,4-triazole, viz. the 2H and 4H tautomers, resulting in the [1,5-*a*] and [4,3-*a*] isomers, respectively.[14,15] The ligand dmtp was prepared according to the method of Bülow and Haas[16] from 3-amino-1,2,4-triazole and pentanedion-2,4. Melting point (136–137°C) and ^1H NMR [2.64(s), 2.78(s), 6.85(s), 8.44(s)] confirm that the [1,5-*a*] isomer was obtained.

$Cu(dmtp)_4(H_2O)_2(PF_6)_2$ was prepared by adding ammonium hexafluorophosphate (4.0 mmol) in water (5 cm^3) to a mixture of copper(II) perchlorate (2.0 mmol) and dmtp (3.0 mmol) in water (20 cm^3). The precipitate was separated by filtration and recrystallized from hot water, yielding blue crystals (m.p. = 158–159°C). Found: C, 34.1; Cu, 6.9; H, 3.8; N, 22.5%. Calc. for $C_{28}CuF_{12}H_{36}N_{16}O_2P_2$: C, 34.2; Cu, 6.5; N, 22.8%.

$Cu(dmtp)_4(C_2H_5OH)_2(BF_4)_2$ was obtained by adding dmtp (4.0 mmol) in ethanol (25 cm^3) to a filtered solution of copper(II) tetrafluoroborate (2.0 mmol) in ethanol (20 cm^3). After adding triethylorthoformate (teof) blue crystals could be isolated (m.p. = 155–117°C). Found: C, 41.1; Cu, 6.8; H, 4.8; N, 24.0%. Calc. for $B_2C_{32}CuF_8H_{44}N_{16}O_2$: C, 41.6; Cu, 6.9; H, 4.8; N, 24.3%.

$Cu(dmtp)_4(ClO_4)_2(H_2O)_1(C_2H_5OH)_{1.5}$ was prepared from copper(II) perchlorate and dmtp (1 : 1.5) in ethanol. After adding some diethylether and standing for one night, dark blue crystals were isolated by filtration (m.p. = 111–113°C). Found: C, 40.1; Cu, 6.8; H, 4.6; N, 23.5%. Calc. for $C_{31}Cl_2CuH_{43}N_{16}O_{10.5}$: C, 39.5; Cu, 6.7; H, 4.6; N, 23.8%.

$Cu(dmtp)_{3.67}(ClO_4)_2(H_2O)_{2.67}$ was prepared by reacting copper(II) perchlorate with dmtp (1 : 1.5) in water. Bluish purple crystals were isolated by filtration (m.p. = 133–134°C). Found: C, 35.8; Cu, 7.6; H, 4.1; N, 24.0%. Calc. for $C_{77}Cl_6Cu_3H_{104}N_{44}O_{32}$: C, 35.8; Cu, 7.5; H, 4.1; N, 23.9%.

$Cu(dmtp)_3(CF_3SO_3)_2(C_2H_5OH)_1$ was prepared from copper(II) triflate and dmtp (1 : 1.5) in ethanol–teof (1.5 : 1). After addition of some diethylether and standing at −20°C dark and light blue crystals formed. After dissolving the light-coloured product at room temperature, the dark blue crystals were obtained by filtration (m.p. = 153–155°C). Found: C, 34.8; Cu, 7.6; H, 3.4; N, 19.9%. Calc. for $C_{25}CuF_6H_{30}N_{12}O_7S_2$: C, 35.2; Cu, 7.5; H, 3.6; N, 19.7%.

$Cu(dmtp)_2(NO_3)_2$ was prepared from copper(II) nitrate and dmtp (1 : 1.5) in ethanol. The precipitate was isolated by filtration and recrystallized from hot ethanol, yielding blue crystals (m.p. = 180–181°C). Found: C, 34.9; Cu, 13.1; H, 3.6; N, 28.5%. Calc. for $C_{14}CuH_{16}N_{10}O_6$: C, 34.8; Cu, 13.1; H, 3.3; N, 28.9%.

Measurements

IR spectra were recorded on a Perkin–Elmer model 580B IR spectrophotometer as Nujol mulls between KRS-5 (4000–400 cm^{-1}) and polyethene (400–180 cm^{-1}) windows and as KBr, CsCl or CsI disks (concentration about 2%). Ligand field spectra (Table 1) were recorded in the solid state on a Beckman DK2A UV–vis–NIR spectrophotometer, by means of the diffuse reflectance technique using MgO as a reference. ^1H NMR spectra were taken on a JEOL PS 100 spectrometer using $Si(CH_3)_4$ as an internal standard. ESR spectra of powdered samples were measured on a Varian E3 instrument (X-band) or on a Varian V4500 instrument (Q-band) at either 77 K or ambient temperature. Magnetic measurements were obtained on a model 150A PAR instrument (2–80 K) and on a automated Faraday balance (80–300 K), using $Hg[Co(NCS)_4]$ as a calibration agent. Magnetic susceptibilities per copper(II) ion were corrected for diamagnetism using Pascal's constants[17] and for temperature-independent paramagnetism, equal to 60×10^{-6} $cm^3\ mol^{-1}$.

C, H and N analyses were performed by the Microanalytical Laboratory of Pascher (Bonn) and University College of Dublin. Copper was determined by indirect titrations with EDTA and zinc acetate using xylenol orange as an indicator. Experimental densities were determined by flotation in a mixture of 1,2-dibromoethane and trichloromethane.

[a] L = dmtp.
[b] Not recorded.
[c] The molecular formula of this compound can be written as $[CuL_4(H_2O)_2][CuL_4(H_2O)_1][CuL_3(H_2O)_2](ClO_4)_6(H_2O)_3$.
[d] Complicated pattern.

X-ray structure determination

X-ray analysis on a blue monocrystal of $[(Cu(dmtp)_4(H_2O)_2](PF_6)_2$ of dimensions $0.25 \times 0.20 \times 0.15$ mm was done on an Enraf–Nonius CAD-4 diffractometer. Intensities were collected at room temperature using Mo-K_α radiation ($\lambda = 0.71073$ Å) monochromated by graphite. No absorption or extinction corrections were applied. Relevant crystallographic and experimental data are tabulated in Table 2. All 2316 measured independent reflections with $I > 2\sigma(I)$ in the range of $2° < 2\theta < 24°$ were used in the analysis. The structure was solved by standard Patterson and Fourier methods. Calculations were carried out on an Amdahl V7B computer. Refinements were carried out by least-squares full-matrix cycles using unit weights, first with isotropic and later with anisotropic thermal parameters for all non-hydrogen atoms.Two positions of PF_6 with occupation ratios of 1.0 and 0.90, respectively, were introduced, because of disorder in the anion, treating all P—F bond distances and F—P—F valence angles with constraints.[18]

Most hydrogen atoms were directly located from a difference synthesis, except for a few hydrogen atoms of the dmtp methyl groups, which were placed in the geometrically calculated positions and included in the final structure factor calculations with fixed isotropic thermal parameters and fractional atomic coordinates. No significant peaks were present in the final difference map. The final residual indices are defined as $R = \Sigma(\|F_c| - |F_o\|)/\Sigma|F_o|$ and $R_w = \{\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|_2\}^{1/2}$.

Lists of structure factors, fractional coordinates and anisotropic thermal parameters have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.[19]

RESULTS AND DISCUSSION

Description of the structure of $[Cu(dmtp)_4(H_2O)_2](PF_6)_2$

The compound consists of centrosymmetric mononuclear $[Cu(dmtp)_4(H_2O)_2]^{2+}$ units, as depicted in Fig. 2, and PF_6^- anions. The copper(II) ion, which is situated on an inversion centre, has an elongated tetragonally-distorted octahedral configuration, being coordinated by four equatorial dmtp molecules and two axial water molecules. The ligand dmtp is monodentately coordinated via the N(3) nitrogen atom to copper, the Cu—N(3) bond lengths of 2.019 and 2.050 Å being in agreement with the values of 2.000 and 2.019 Å in α-$Cu(dmtp)_2(NCS)_2]_2$,[11] with 1.995 and 2.058 in β-$[Cu(dmtp)_2(NCS)_2]_2$,[12] and with 1.962 and 2.016 Å in copper(II) compounds with 5-methyl-[1,2,4]triazolo[1,5-*a*]pyrimidine-7-ol as a ligand.[21]

The ligand dmtp has a planar geometry, as deduced from the maximum distances from the ring atoms to the least square planes, which are 0.03 and 0.02 Å for the odd and even numbered dmtp molecules, respectively. The Cu—O bond length of 2.456 Å is shorter than in most compounds with similarly axially coordinated water molecules, e.g. the value of 2.638 Å in $[Cu(Him)_4(H_2O)_2]F_2$ (Him = imidazole).[22]

Both hydrogen atoms of the water molecule

appear to form intramolecular hydrogen bonds to the N(4) nitrogen atoms of dmtp: H---N(4) = 1.909 and 2.113 Å, O---N(4) = 2.787 and 2.902 Å, OW—H---N(4) = 163.2 and 148.0°. The constrained octahedral PF_6^- ions are neither bonded to the metal ions nor hydrogen-bonded to the water molecules, which explains the disorder in the anions. The P—F bond lengths are in the range of 1.559–1.570 Å and the F—P—F valence angles in the range of 88.6–91.0°.

Bond distances and relevant valence angles are listed in Table 3.

General

Table 1 lists the results of ligand field and ESR spectra of the coordination compounds. The IR absorptions of dmtp appeared to be similar in all the copper(II) compounds described here, indicating similar coordination of this ligand.

$[Cu(dmtp)_4L_2]A_2$ ($A = PF_6$, BF_4 *or* ClO_4; $L = H_2O$ *or* C_2H_5OH)

The presence of water and/or ethanol in these compounds with four dmtp ligands and two solvent molecules per copper(II) ion is confirmed by the IR O—H absorption bands at 3200–3300 cm^{-1}. The anions will be non-coordinated, as can be seen from the broad but single band at 1060 cm^{-1} of BF_4^- and the sharp single band at 1100 cm^{-1} of ClO_4^-.[23,26] The very similar ligand field spectra of the three compounds show a broad band at about 16,200 cm^{-1} which is indicative of an elongated tetragonally-distorted octahedral geometry.[24,25] This conclusion is supported by the axial ESR spectra, of which the results are summarized in Table 1. The clear hyperfine splitting of about 15.0 mT ($A_\parallel$) points to the absence of significant magnetic interactions between the Cu^{2+} ions, confirming the presence of mononuclear copper(II).[25]

From comparison of the spectral results it can be concluded that these three compounds will have a very similar coordination geometry, copper(II) being coordinated by four equatorial dmtp ligands and two axial solvent molecules, which has been confirmed by X-ray analysis on $[Cu(dmtp)_4(H_2O)_2](PF_6)_2$ (*vide supra*).

$Cu(dmtp)_{3.67}(ClO_4)_2(H_2O)_{2.67}$

The broad and unsplit IR absorption band at 1100 cm^{-1} is indicative of non-coordination of perchlorate.[23,26] The presence of water is confirmed by a broad band at 3380 cm^{-1}. The broad band at 16,800 cm^{-1} in the ligand field spectrum points to an elongated tetragonally-distorted octahedral or square pyramidal geometry of copper(II).

Both the X- and Q-band ESR spectra were complicated and could not be interpreted as just a rhombic distorted Cu^{2+} species and suggest the presence of more than one species containing Cu^{2+}. Therefore X-ray analysis on a monocrystal of this compound was attempted, of which the first results indicate that this compound does not consist of trimers as might be expected from the molecular formula, but of different monomeric units. One third of the copper ions appears to be six-coordinated by four dmtp ligands and two water molecules, having the same coordination geometry as $[Cu(dmtp)_4(H_2O)_2](PF_6)_2$, whereas two-thirds of the copper ions are five-coordinated, one third being surrounded by four equatorial dmtp ligands and one axial water molecule, and one third by three dmtp ligands and two water molecules.

The non-coordinated perchlorate anions and water molecules appear to be partly in disorder. This very complicated structure will be described elsewhere in detail.[27]

$Cu(dmtp)_3(CF_3SO_3)_2(C_2H_5OH)_1$

The IR $\nu_{as}(E)$ SO_3 band at triflate is split into two peaks at 1263 and 1292 cm^{-1}, which is clearly indicative of a monodentate coordination of the anions.[28–30] The presence of ethanol is confirmed by the absorption at 3250 cm^{-1}. The broad band at 15,600 cm^{-1} in the ligand field spectrum points to a tetragonally-distorted octahedral geometry.[24,25] This conclusion is supported by the axial ESR spectrum.

The absence of significant interactions between the Cu^{2+} ions has been demonstrated by magnetic measurements at 4–80 K. Extrapolation of the inverse susceptibility $1/\chi$ against the temperature resulted in a straight line with intercept (θ) of 0 K. So, $Cu(dmtp)_3(CF_3SO_3)_2(C_2H_5OH)_1$ appears to be a mononuclear compound, Cu^{2+} having a tetragonally-distorted octahedral configuration with three dmtp $N(3)$ ligands, two monodentately coordinated trifluoromethanesulfonate ions and one ethanol molecule. It is not clear from the spectral data whether or not $[CF_3SO_3]^-$ or EtOH forms the fourth equatorial ligand.

$Cu(dmtp)_2(NO_3)_2$

The absorption bands of the nitrate group in the IR spectrum clearly indicate the presence of both bidentately (1484 and 1293 cm^{-1}) and monodentately (1433 and 1306 cm^{-1}) coordinated nitrate.[23,31,32] From this result combined with the results from the ligand field spectrum and Q-band ESR spectrum (see Table 1) it can be concluded that Cu^{2+} has a rhombic geometry, and is coordinated by two dmtp $N(3)$ ligands and one monodentate and one bidentate nitrate group, resulting in a five-coordinated species.

CONCLUSIONS

The nature of coordination compounds with dmtp appears to be strongly influenced by the coordination properties of the used anions. It has been demonstrated that four dmtp ligands in the equatorial positions can be coordinated to copper(II) in the presence of non-coordinating anions, like PF_6, BF_4 and ClO_4. The axial positions can be occupied by solvent molecules, resulting in an elongated tetragonally-distorted octahedral or square pyramidal copper(II) configuration.

The number of dmtp ligands coordinated to copper(II) becomes less, when anions with an increasing tendency for coordination are used, as appears from the compounds with weak coordinating triflate and stronger coordinating nitrate. From the IR spectra it can be concluded, that the coordination mode of dmtp will be similar in all copper(II) compounds described here, being monodentate via the N(3) nitrogen atom, which has been proven by the crystal structure of $[Cu(dmtp)_4(H_2O)_2](PF_6)_2$.

Coordination via the N(4) nitrogen atom of dmtp will be hindered (but not excluded) by the presence of the methyl group at the C(5) position. In order to favour coordination via N(4), coordination compounds with unsubstituted [1,2,4]triazolo[1,5-*a*]pyrimidine and 6-methyl[1,2,4]-triazolo[1,5-2]pyrimidine will be studied.

From the hydrogen bonding of the N(4) nitrogen atom in $[Cu(dmtp)_4(H_2O)_2](PF_6)_2$ it can be concluded that coordination via this atom is negatively influenced by the presence of protic molecules like

water and ethanol. The use of aprotic solvents will presumably favour coordination via the atom.

The coordination properties of dmtp can be summarized as:

(1) coordination via N(3) is obviously preferred, since dmtp coordinates via this nitrogen atom in all coordination compounds known so far;

(2) coordination via N(4) will be probably favoured by using triazolopyrimidines unsubstituted at C(5) and/or by using aprotic solvents;

(3) no indications for coordination via N(1) have been found.

CHEMISTRY OF 3,4-DIMETHYLPHOSPHOLYL ANION IN THE COORDINATION SPHERE OF TUNGSTEN: SYNTHESIS AND X-RAY CRYSTAL STRUCTURE ANALYSIS OF (η^5-3,4-DIMETHYLPHOSPHOLYL)TRICARBONYL-IODOTUNGSTEN

(*Received* 9 *September* 1985; *accepted* 25 *November* 1985)

Abstract—The reaction of the 3,4-dimethylphospholyl anion with $W(CO)_6$ and $W(CO)_5THF$ yields, according to the experimental conditions and stoichiometries, the η^1-P complex $(Me_2C_4H_2\bar{P})W(CO)_5$ or the μ^2-P complex $(Me_2C_4H_2\bar{P})[W(CO)_5]_2$. We have compared the reactivities of the free phospholyl anion and its P–$W(CO)_5$ and P–$[W(CO)_5]_2$ complexes toward H^+, $ClSnR_3$, S_8 and iodine. The most spectacular result has been observed when allowing iodine to react with the P–$[W(CO)_5]_2$ complex. The new η^5-$(Me_2C_4H_2P)W(CO)_3I$ complex has been obtained and characterized by X-ray crystal structure analysis. A typical nucleophile such as hydroxide ion attacks this η^5-complex not at the W—I bond as expected, but at the P atom with breaking of the P—W bond and formation of a η^4-diene complex. The lone pair at P remains able to coordinate with another metallic centre.

In a series of preceding papers, we have shown that complexation of the phosphorus lone pair by a pentacarbonyltungsten unit drastically alters the chemistry of tervalent phosphorus compounds. For example, strained phosphorus heterocycles gain additional stability[1–3] and decomposition of RP(H)X species through reductive elimination at phosphorus is quenched in many cases.[4–6] From another standpoint, if η^5-phospholyl complexes have been described with transition metals of the titanium (Zr[7]), manganese (Mn[8,9] or Re[9]), iron[10,11] and cobalt[12] families, no such complex has been reported till now with a metal of the chromium subgroup. These two kinds of considerations prompted us to study the chemistry of the well-known phospholyl anions[13] in the coordination sphere of tungsten.

EXPERIMENTAL

NMR spectra (chemical shifts in ppm from internal Me_4Si for ^1H and ^{13}C, and from external H_3PO_4 for ^{31}P; δ positive for downfield shifts in all cases) were recorded on a Bruker WP 80 instrument respectively at 80.13, 20.15, and 32.44 MHz. Mass spectra [electronic impact desorption (EID) or chemical ionization desorption (CID)] were recorded on a Nermag R10-10 spetrometer by Mr Charré (SNPE). All reactions were carried out under argon. Chromatographic separations were performed on deoxygenated silical gel columns (70–230-mesh, Riedel de Haën).

Preparation of phospholyllithium–tungsten complexes

[η^1 - P - 3,4 - *dimethylphospholyllithium*]*pentacarbonyltungsten* (**3**). Solid tungsten hexacarbonyl (3.5 g, 10 mmol) was added to 10 mmol of 3,4-dimethylphospholyllithium (**2**) (see Ref. 14) in THF (80 cm^3). After stirring at room temperature for 8 h, the ^{31}P NMR spectrum of the reaction mixture showed a single signal at −54.8 ppm corresponding to the monotungsten complex. To a sample of the solution in a NMR tube was added an excess of methyl iodide. After 10 min at room temperature, the ^{31}P NMR spectrum showed a single signal corresponding to the known [1,3,4-trimethylphosphole]pentacarbonyltungsten complex (**4**) at −8.4 ppm [$^1J(^{31}P–^{183}W)$ 207.5 Hz].

[μ^2 - P - 3,4 - *dimethylphospholyllithium*]*decacarbonylditungsten* (**5**). To the preceding solution of phospholyllithium complex **3** (10 mmol) was added one equivalent of tungsten hexacarbonyl (3.5 g). After 5 h of reflux, the ^{31}P NMR spectrum showed a single signal at −99.5 ppm [$^1J(^{31}P–^{183}W)$ 141.5 Hz, intensities 1:6:1]. The same result was obtained by refluxing one equivalent of phospholyllithium (**2**) for 8 h with two equivalents of $W(CO)_6$, or by reaction of anion **2** with $W(CO)_5THF$.[5]

Preparation of [η^1-P-3,4-*dimethylphosphole*]*pentacarbonyltungsten* (**6**)

Methane sulfonic acid (1.9 g, 20 mmol) in 20 cm^3 of CH_2Cl_2 was treated at room temperature by a solution of 10 mmol of the phospholyllithium complex **3**. After vacuum distillation of the THF, the residue was chromatographed with toluene leading to a mixture which was dissolved in 1 cm^3 of CH_2Cl_2 and 50 cm^3 of hexane. Filtration over diatomaceous silica and distillation of the solvents gave a partially crystallized oil. Yield 2.5 g (ca 47%). The ^{31}P NMR spectrum in CH_2Cl_2 showed a major signal at −46.1 ppm [$^1J(^{31}P–^{183}W)$ 232 Hz, ^1J(P–H) 322 Hz] and a minor signal at 20.2 ppm [$^1J(^{31}P–^{183}W)$ 224.5 Hz]. A recrystallized sample at EtOH (pale yellow solid) gave the same spectrum.

[η^1 - P,η^1 - P′ - 3,3′,4,4′ - *tetramethyl* - 2,5 - *dihydro* - 1,1′ - *biphospholyl*]*decacarbonylditungsten* (**7**)

To a solution of **3** (10 mmol in THF), cooled at about −40°C, was added 3.4 g (20 mmol) of 4-toluene sulfonic acid monohydrate. The solvent was vacuum distilled and the residue chromatographed with CH_2Cl_2 leading to 7.4 g of a solid; m.p. 190°C (yield 85%). An analytical sample was recrystallized in acetone; pale yellow crystals; m.p. 195°C; ^{1}H NMR ($CDCl_3$) phosphole ring: δ 2.20 [pseudo t, ^4J(H–P) ~ 1 Hz, 6H, CH_3], 6.20 [d, ^2J(H–P) 37.4 Hz, 2H, =CH]; phospholene ring: δ 1.7 (s, 6H, CH_3), 2.53 and 2.96 [AB system, $^2J(H_A–H_B)$ 17.6 Hz, 4H, CH_2]; ^{13}C–{^{1}H} NMR ($CDCl_3$) phosphole ring: δ 17.7 [d, ^3J(C–P) 11 Hz, CH_3], 128.8 [pseudo q, ^1J(C–P) 30.5 Hz, ^2J(C–P) 2.5 Hz, =CH], 154.0 [pseudo q, ^2J(C–P) 6.1 Hz, ^3J(C–P) 3.7 Hz, =C<]; phospholene ring: δ 16.2 [d, ^3J(C–P) 6 Hz, CH_3], 43.3 [pseudo q, ^2J(C–P) 18.3 Hz, ^3J(C–P) 4.9 Hz, CH_2], 131.9 (s, =C<) and δ 196.1 (d, CO), 197.0 (d, CO); IR ($CHCl_3$) ν(CO) 2080, 2070, 1950, 1930 cm^{-1}; mass spectrum (EID, 70 eV, ^{184}W) m/z (relative intensity): 872 [M (50%)], 437 [M − phosphole ring (50%)], 435 [M − phospholene ring (40%)]. Found: C, 30.4; H, 2.1; P, 7.0; W, 42.1%. Calc. for $C_{22}H_{18}O_{10}P_2W_2$: C, 30.3; H, 2.1; P, 7.1; W, 42.2%.

[η^1 - P - 3,4 - *dimethyl* - 1 - *triphenylstannyl phosphole*]*pentacarbonyltungsten* (**9**)

To the phospholyllithium complex (**3**) (10 mmol in 80 cm^3 of THF) was added at room temperature triphenyltin chloride (4.25 g, 11 mmol) in 20 cm^3 of THF. After 30 min of stirring, the solvent was vacuum distilled and the residue chromatographed in toluene on silica gel dried at ca 150°C under 10^{-2} mmHg. Evaporation of the solvent led to 5.4 g (yield 68.5%) of an orange oil. ^{1}H NMR ($CDCl_3$): δ 1.82 (poorly resolved d, 6H, CH_3), 6.60 [d, ^2J(H–P) 41.2 Hz, 2H, CH], 7.4 (m, 15H, Ph); ^{13}C–{^{1}H} NMR: δ 17.8 [d, ^3J(C–P) 9.7 Hz, CH_3], 129.7 [d, ^1J(C–P) 40.3 Hz, =CH], 128.5–132.2 (m, aromatic CH), 135.8–138.9 (m, arom. =C<), 152.9 [d, ^2J(C–P) 4.9 Hz, =C<], 196.5 [d, ^2J(C–P) 6.1 Hz, CO], 200.1 [d, ^2J(C–P) 20.7 Hz, CO], ^{119}Sn–{^{1}H} NMR (C_6D_6): δ Me_4Sn (neat) −88.4 [d, $^1J(^{119}Sn–^{31}P)$ 92.8 Hz]; IR (hexane): ν(CO) 2068, 1985, 1950 cm^{-1}.

[η^1 - P - 3,4 - *dimethyl* - 1 - *methylthiophosphole*]*pentacarbonyltungsten* (**10**)

Solid sulphur (0.35 g, 11 mmol) was added to the THF solution of complexed phospholyllithium (10 mmol) at room temperature. After 30 min of stirring the thioanion formation was checked by ^{31}P NMR (resonance at 14.9 ppm in THF). Methyl iodide (1.56 g, 11 mmol) was then added. The reaction

mixture was stirred 30 min more and the THF was distilled under vacuum. Chromatography of the residue with toluene followed by solvent distillation led to 3.25 g (yield ca 70%) of complex **10**; m.p. 105°C (orange yellow crystals). ^{1}H NMR ($CDCl_3$): δ 1.77 [d, ^3J(H–P) 9.0 Hz, 3H, SCH_3], 2.2 [d, ^4J(H–P) 1.0 Hz, 6H, CH_3], 6.13 [dd, ^2J(H–P) 38.8 Hz, ^4J(H–H) 1.0 Hz, 2H, =CH]; ^{13}C–{^{1}H} NMR ($CDCl_3$): δ 13.65 [d, ^2J(C–P) 2.4 Hz, SMe], 16.75 [d, ^3J(C–P) 12.2 Hz, C–Me], 127.6 [d, ^1J(C–P) 37.6 Hz, =CH], 151.45 [d, ^2J(C–P) 9.7 Hz, =C<], 195.4 [d, ^2J(C–P) 7.3 Hz, CO]; IR (hexane): ν(CO) 2073, 1947 cm^{-1}. Found: C, 30.0; H, 2.0; P, 6.3; S, 6.4%. Calc. for $C_{12}H_{11}O_5PSW$: C, 29.9; H, 2.3; P, 6.4; S, 6.6%.

3,4-*Dimethyl*-1-*methylthiophosphole* P-*sulphide* (13)

To a solution of 10 mmol of **2** in THF, was added 2.2 equivalents of solid sulphur. After 10 min, the formation of the intermediate thioanion **13a** was controlled by ^{31}P NMR [δ(^{31}P) 63.9, t, ^2J(P–H) 29.3 Hz] and then 1.7 g (ca 12 mmol) of methyl iodide in 5 cm^3 of THF was added. The reaction mixture was vacuum concentrated and the residue chromatographed with hexane–CH_2Cl_2 (80 : 20) leading to 1.3 g (yield 65.5%) of **13**; m.p. 85°C (pale yellow crystals); ^{1}H NMR ($CDCl_3$): δ 2.1 [q, ^4J(H–P) 2 Hz, ^4J(H–H) 1 Hz, 6H, C—CH_3], 2.3 [d, ^3J(H–P) 14.5 Hz, 3H, SCH_3], 6.0 [dd, ^2J(H–P) 33.0 Hz, 2H, =CH]; ^{13}C–{^{1}H} NMR ($CDCl_3$): δ 12.7 [d, ^3J(C–P) 2.9 Hz, C–CH_3], 16.8 [d, ^2J(C–P) 19.5 Hz, S–CH_3], 123.2 [d, ^1J(C–P) 82.0 Hz, =CH], 151.7 [d, ^2J(C–P) 20.5 Hz, =C<]; mass spectrum (EID) m/z (relative intensity): 190 [M (26%)], 143 [M – SMe (100%)]. Found: C, 44.3; H, 5.8; P, 16.3%. Calc. for $C_7H_{11}PS_2$: C, 44.2; H, 5.8; P, 16.3%.

[η^1 - P,η^1 - P′ - 3,3′,4,4′ - *tetramethyl* - 1,1′-*biphospholyl*]*decarbonylditungsten* (14)

A solution of iodine (1.27 g, 5 mmol) in 10 cm^3 of THF was slowly added at room temperature to **3** (10 mmol in THF). The reaction mixture was vacuum contentrated and the residue chromatographed with first CH_2Cl_2 and then ethyl acetate. Distillation of the solvents led to 2.4 g (yield 55%) of yellow orange crystals; m.p. (dec.) 230°C. An analytical sample was recrystallized in THF; m.p. (dec.) 233–236°C; ^{1}H NMR (THF-d_8): δ 2.24 (pseudo t, 12H, CH_3), 6.63 [m, ^2J(H–P) 39.5 Hz, 4H, CH]; ^{13}C–{^{1}H} NMR (THF-d_8): δ 17.45 (pseudo t, CH_3), 130.9 (pseudo t, =CH), 156.2 (pseudo t, =C<), 195.5 (d, CO); IR ($CHCl_3$), ν(CO) 2065, 1980, 1950 cm^{-1}; mass spectrum (EID, ^{184}W) m/z (relative intensity): 870 [M (50%)], 590 [M – 10CO (20%)], 435 [M/2 (100%)]. Found: C, 30.4; H, 1.8; W, 42.5%. Calc. for $C_{22}H_{16}O_{10}P_2W_2$: C, 30.4; H, 1.8; W, 42.3%.

Complex **14** was also obtained by reaction of 3,3′,4,4′-tetramethyl-1,1′-biphospholyl[4] with two equivalents of $W(CO)_5$THF in THF.

[η^5 - 3,4 - *Dimethylphospholyl*]*tricarbonyliodotungsten* (15) *and* [η^1 - P - (η^5 - 3,4 - *dimethylphospholyl*) *tricarbonyliodotungsten*]*pentacarbonyltungsten* (17)

To a solution of 10 mmol of the ditungsten complex **5** was added iodine (11 mmol in 10 cm^3 of THF) at room temperature. After 2 h of stirring, the reaction mixture gave a single or major ^{31}P NMR signal at –31.5 ppm. The solvent was vacuum distilled and the residue dissolved in a small amount of CH_2Cl_2. In this solution, the ^{31}P NMR resonance at –31.5 decreased to the benefit of a new signal at –11.2 ppm. A large amount of hexane was then added and the mixture was filtered through a column of diatomaceous silica. The solvent was removed and the residue chromatographed on acidic silica gel giving first, by elution with hexane + 20% of CH_2Cl_2, complex **15**, then, with CH_2Cl_2, complex **17**.

Complex **15**: 1.9–2.7 g (yield 37.5–53.5%), dark purple crystals; m.p. 112°C; ^{1}H NMR ($CDCl_3$): δ 2.48 (s, 6H, CH_3), 5.16 [d, ^2J(H–P) 35.2 Hz, 2H, =CH]; ^{13}C–{^{1}H} NMR ($CDCl_3$): δ 16.6 (s, CH_3), 100.1 [d, ^1J(C–P) 67.1 Hz, =CH], 126.8 [d, ^2J(C–P) 8.5 Hz, =C<], 207.7 and 221.5 (CO); IR (hexane) ν(CO) 2037, 1968, 1957, 1945 cm^{-1}; mass spectrum (EID, ^{184}W) m/z (relative intensity): 506 [M (15%)], 478 [M – CO (50%)], 450 [M – 2CO (30%)], 422 [M – 3CO (75%). Found: C, 21.6; H, 1.5; I, 25.0; P, 6.1%. Calc. for $C_9H_8IO_3PW$: C, 21.4; H, 1.6; I, 25.1; P, 6.1%.

Complex **17**: in addition to the chromatographed product, another fraction of complex **17** was recovered by washing the celite column with CH_2Cl_2. Recrystallization of the two fractions gave 1–3 g (yield 12–36%) of orange crystals; m.p. (dec.) 185–187°C; ^{1}H NMR ($CDCl_3$): δ 2.60 (s, 6H, Me), 5.10 [d, ^2J(H–P) 32.0 Hz, 2H, =CH]; ^{13}C–{^{1}H} NMR (CD_3COCD_3): δ 15.75 [d, ^3J(C–P) 3.6 Hz, CH_3], 94.4 [d, ^1J(C–P) 7.3 Hz, =CH], 124.8 (s, =C<), 193.4 [d, ^2J(C–P) 7.3 Hz, W(CO)$_5$]; IR ($CHCl_3$): ν(CO) 2085, 2040, 2000 (sh), 1975, 1957 cm^{-1}; mass spectrum (CID, iso-C_4H_{10}, ^{184}W) m/z (relative intensity): 830 [M (90%)], 703 [M – I (40%)], 506

[M – $W(CO)_5$ (100%)]. Found: C, 20.4; H, 0.9; I, 15.2; P, 3.7; W, 44.4%. Calc. for $C_{14}H_8IO_8PW_2$: C, 20.3; H, 1.0; I, 15.3; P, 3.7; W. 44.3%.

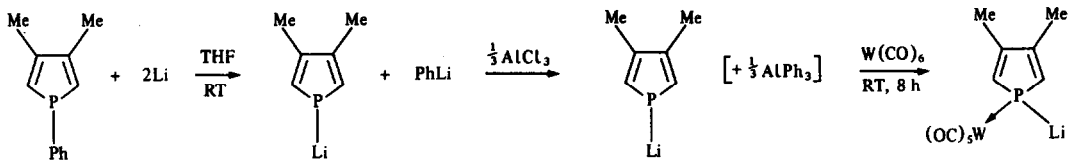
The ditungsten complex **17** was also obtained by allowing the η^5-phospholyltungsten complex **15** to react with $W(CO)_5$THF in THF.

Tetramethylammonium [η^4 - C_4 - 3,4 - *dimethyl* - 1 - *oxophosphole*]*tricarbonyliodotungstate* (**16**)

To the η^5-phospholyl complex **15** (1.02 g, 2 mmol) in 30 cm^3 of CH_2Cl_2 was added 1.03 cm^3 (2 mmol) of a 20% methanolic solution of tetramethylammonium hydroxide. The reaction mixture turned from dark red to orange. Filtration on diatomaceous silica followed by vacuum concentration of the filtrate led to an orange oil which crystallized. The solid was sucked dry on sintered glass after washing with a mixture of hexane and CH_2Cl_2 (50:50). Yield 0.9 g (75%) orange crystals; m.p. 188°C; ^{1}H NMR (CD_3COCD_3): δ 2.26 (s, 6H, CH_3), 3.01 [dd, ^2J(H–P) 14.1 Hz, ^3J(H–H) 0.95 Hz, 2H, =CH], 3.43 [t, $^1J(^1H-^{14}N)$ 0.6 Hz, 12H, NCH_3], 7.36 [dt, ^1J(H–P) 530.2 Hz, 1H, PH]; ^{13}C–{^{1}H} NMR (CD_3COCD_3): δ 16.7 [d, ^3J(C–P) 3.6 Hz, CH_3], 52.4 [d, ^1J(C–P) 78.1 Hz, =CH], 56.0 [t, $^1J(^{13}C-^{14}N)$ 3.6 Hz, NCH_3], 90.1 [d, ^2J(C–P) 14.6, =C<], 218.2 and 228.6 (CO); IR (KBr): ν(PH) 2380 cm^{-1}; ν(PO) 1177 cm^{-1}; ν(CO) 1990, 1915, 1880 cm^{-1}. Found: C, 26.7; H, 3.9; N, 2.3; P, 5.0%. Calc. for $C_{13}H_{21}INO_4PW$: C, 26.1; H, 3.5; N, 2.3; P, 5.2%.

X-ray data collection and processing

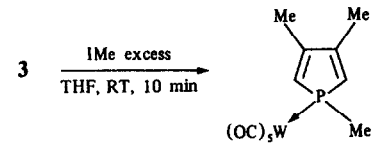
Suitable single crystals of **15** were obtained by slow evaporation of CH_2Cl_2–hexane solutions at room temperature under argon. A systematic search in reciprocal space using a Philips PW 1100/16 automatic diffractometer showed that crystals of **15** belong to the monoclinic system. The unit-cell dimensions and their standard deviations were obtained and refined at –100°C with Mo-K_α radiation (λ = 0.71073 Å) by using 25 carefully selected reflections and the standard Philips software. Crystal data: $C_9H_8O_3PIW$, M = 506, a = 7.325(3) Å, b = 14.545(6) Å, c = 12.169(5) Å, β = 103.46(2), V = 1261 Å^3, Z = 4, d_c = 2.665 g cm^{-3}, d_o = 2.63 ± 0.02 g cm^{-3}, μ = 118.93 cm^{-1}, F(000) = 912, space group $P2_1/n$.



A parallelepipedic crystal of dimensions 0.15 × 0.22 × 0.26 mm was glued at the end of a glass fibre and mounted on a rotation free goniometer head. All quantitative data were obtained using the same diffractometer, graphite-monochromated radiation and standard software in a cold nitrogen gas stream (–100°C). The vertical and horizontal apertures in front of the scintillation counter were adjusted so as to minimize the background counts without loss of net peak intensity at the 2σ level. The total scan width in the θ–2θ flying step-scan used was $\Delta\theta = 1.0 + 0.343\ \mathrm{tg}(\theta)°$, with a step width of 0.05° and a scan speed of 0.02° s^{-1}. 7631 *hkl*, $\bar{h}kl$, $h\bar{k}l$ and $\bar{h}\bar{k}l$ reflections were recorded ($3° < \theta < 30°$). Three standard reflections measured every hour during the entire data-collection period showed no significant trend. The resulting data-set was transferred to a PDP 11/60 computer, and for all subsequent computations, the Enraf–Nonius SDP/V18 package was used,[16] with the exception of a local data-reduction program.

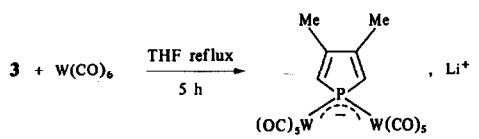
The raw step-scan data were converted to intensities using the Lehmann–Larson method[17] and then corrected for Lorentz, polarization and absorption factors, the latter computed by the empirical method of Walker and Stuart[18] (transmission factors between 1.00 and 0.81). Averaging of equivalent reflections (R_i = 0.019) led to a unique data set of 2942 reflections having $I > 3\sigma(I)$ used for determining and refining the structure.

The structure was solved using the heavy-atom method. After refinement of the heavy atoms, a difference-Fourier map revealed maxima of residual electronic density close to the positions expected for hydrogen atoms; they were introduced in structure factor calculations with computed coordinates (C—H = 0.95 Å) and isotropic temperature factors [B_{eqv}(C)] of +1 Å^2 but not refined. Full least-squares refinement converged to $R(F)$ = 0.029 and $R_w(F)$ = 0.060 $\{\alpha(F^2) = [\sigma^2(\mathrm{count}) + p(I)^2]^{1/2}\}$. The unit-weight observation was 1.32 for p = 0.08. A final difference map revealed no significant maxima. The scattering factors coefficients and anomalous dispersion coefficients come, respectively, from Refs 19 and 20.



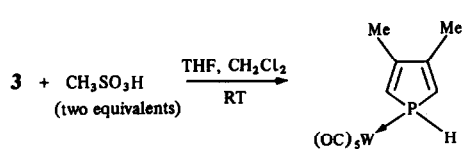
RESULTS AND DISCUSSION

Throughout this study, our starting product has been the readily available 1-phenyl-3,4-dimethylphosphole (**1**).[21] The cleavage of the P–phenyl bond of **1** is achieved by reaction with lithium in THF as usual. Then, phenyllithium is selectively destroyed by adding a stoichiometric amount of anhydrous aluminium trichloride (see Ref. 14). The solution of 3,4-dimethylphospholyllithium (**2**) thus obtained is then allowed to react at room temperature with one equivalent of hexacarbonyltungsten:



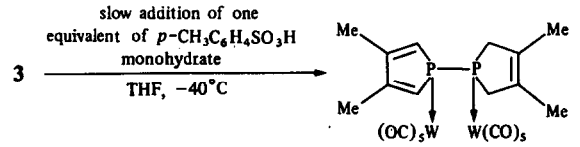
1 2 3

The ^{31}P NMR resonance of **2** at ca +55 ppm (vs external 85% H_3PO_4) slowly disappears and is replaced by a new resonance at −54.8 ppm corresponding to the complexed anion (**3**). The structure of **3** is established by methylation with methyl iodide which gives the already known 1,3,4-trimethylphosphole complex (**4**) [$\delta(^{31}P)$(**4**) −8.4 ppm in THF, $^1J(^{31}P-^{183}W)$ 207.5 Hz].



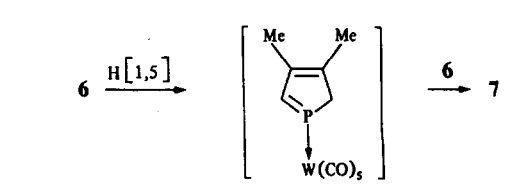
4

At room temperature, the reaction of **2** with $W(CO)_6$ stops at the level of the monocomplexed anion (**3**) but in refluxing THF, **3** is in turn able to react with another equivalent of $W(CO)_6$ to afford the already described[15] and almost unreactive dicomplexed anion (**5**) which has been previously obtained by allowing **2** to react directly with two equivalents of $W(CO)_5THF$ [$\delta(^{31}P)$(**5**) −99.5 ppm in THF].



5

The protonation of **3** is very interesting. When pouring a THF solution of **3** into a CH_2Cl_2 solution of a strong acid such as methanesulfonic acid at room temperature, the sole product is the P–H phosphole complex (**6**) [$\delta(^{31}P)$(**6**) −46 ppm, $^1J(^{31}P-^{183}W)$ 232 Hz, ^1J(P–H) ≃ 322 Hz].

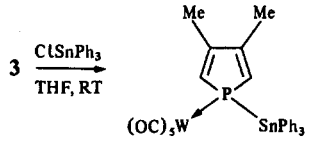


6

Complex **6** has only a limited stability in THF at room temperature and decomposes completely in ca 4 h to give two dimers (**6a** and **6b**) [$\delta(^{31}P)$ (**6a**) +25.6 ppm, $^1J(^{31}P-^{183}W)$ 237 Hz; and +15.6 ppm, $^1J(^{31}P-^{183}W)$ 229.5 Hz, J(P–P) 14.6 Hz, ^1J(P–H) 285.5 Hz. $\delta(^{31}P)$ (**6b**) −1.8 ppm, $^1J(^{31}P-^{183}W)$ 239.5 Hz; and −29.8 ppm, $^1J(^{31}P-^{183}W)$ 229.5 Hz, J(P–P) 7.3 Hz, ^1J(P–H) 325 Hz]. Both dimers contain one P—H bond and no P—P bond. We suspect that they are formed through addition of the P—H bond of one molecule of **6** to the dienic system of another molecule of **6**. Such dimerizations have been encountered during a study of the protonation of **1** (Quin *et al.*, to be published). Complex **6** can be also prepared by acidic cleavage of the P–$SnPh_3$ complex (**9**) by HCl in methanol (*vide infra*). If the protonation of **6** is either carried out with a weak acid (acetic acid, silica gel) or at low temperature, then the course of the reaction changes and the main product becomes the phospholenophosphole complex (**7**) [$\delta(^{31}P)$ (**7**) +6.0 ppm in THF, $^1J(^{31}P-^{183}W)$ 202 Hz (phosphole cycle); −8.65 ppm, $^1J(^{31}P-^{183}W)$ 220 Hz, ^1J(P–P) 178 Hz (phospholene cycle)] which is sufficiently stable to be isolated in the pure state and completely characterized contrary to **6**, **6a** and **6b**.

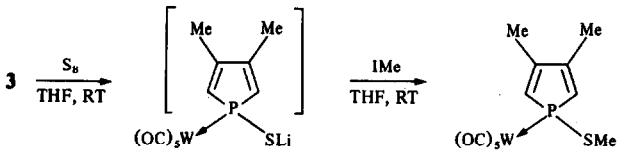
7

The formation of **7** deserves some comments. We have shown previously[17] that P–H phospholes tend to rearrange through hydrogen [1, 5] sigmatropic shifts to give the very reactive 2H-phospholes. This tendency still exists when P–H phospholes are complexed at phosphorus. Thus the mechanism through which **7** is formed simply involves the addition of the P—H bond of **6** onto the P=C double bond of the corresponding 2H-phosphole complex (**8**).



8

Such a dimerization has already been described in the case of the uncomplexed 2,3,4,5-tetraphenylphosphole.[22]

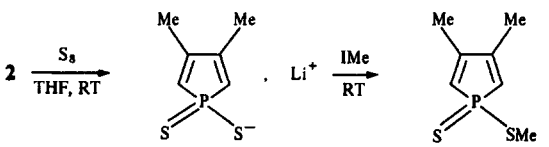


As mentioned earlier, it is possible to prepare

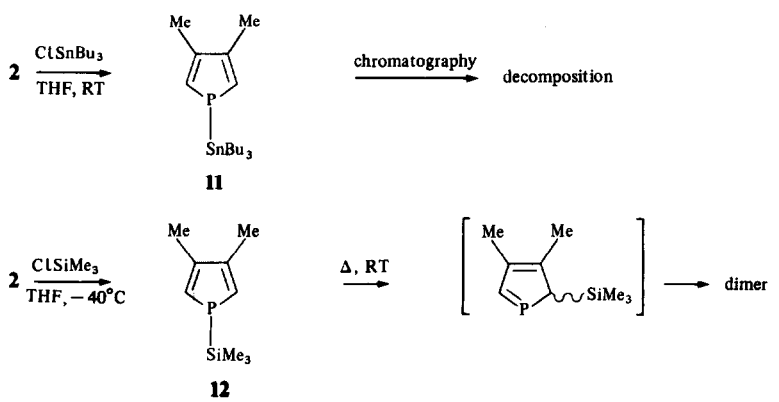
the P–$SnPh_3$ complex (**9**) [$\delta(^{31}P)$ (**9**) −66 ppm in THF, $^1J(^{31}P–^{183}W)$ 190 Hz, $^1J(^{31}P–^{119}Sn)$ 88 Hz] by reaction of the appropriate tin chloro derivative with **3**.

9

Complex **9** can be purified by chromatography and is obtained in ca 68% yield. Complex **3** is also able to react cleanly with sulphur at room temperature. The P–SLi complex thus obtained can be alkylated at sulphur by methyl iodide to give the P–SMe complex (**10**) in 70% yield [$\delta(^{31}P)$ (**10**) 19.6 ppm in THF, $^1J(^{31}P–^{183}W)$ 222 Hz].



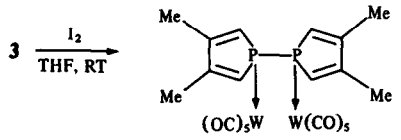
10



It is interesting to compare what occurs during the syntheses of **9** and **10** with what is observed when attempting similar reactions with the uncomplexed anion **2**. The reaction of **2** with *n*-Bu_3SnCl in THF gives the expected P–$SnBu_3$ phosphole (**11**) [$\delta(^{31}P)$ (**11**) −62.7 ppm in THF] but an attempted purification by chromatography led to decomposition. This decomposition probably occurs through hydrolysis and (or) oxidation of the P—Sn bond of **11** but can also involve a [1,5] migration of the $SnBu_3$ group similar to what happens when **6** is converted into **7** by chromatography on silica gel. Indeed, such a migration has been observed in a related case when attempting to prepare silylphosphole (**12**).

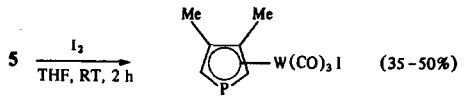
This silylphosphole [$\delta(^{31}P)$ (**12**) −50 ppm in THF] immediately rearranges to give a P—P bonded dimer [$\delta(^{31}P)$ +0.8 and −21.0 ppm in THF, ^1J(P–P) 195 Hz]. Even though we are unable to assign a precise formula to this dimer because it is very sensitive toward oxidation and hydrolysis and cannot be purified, the formation of a P—P bond necessarily involves a migration of the silyl group. Thus, the reasonable stabilities of both complexes **6** and **9** clearly demonstrate that P–$W(CO)_5$ complexation not only stabilizes phospholes toward oxidation and hydrolysis but also toward [1,5] sigmatropic shifts. It may be noted here that we[23] and Jutzi[24] have already demonstrated that P-complexation by $W(CO)_5$ or $Cr(CO)_5$ quenches the fluxionality of some selected cyclopentadienylphosphines which occurs through H and PR_2 [1,5] shifts. The freezing of these various types of migrations probably involves a common mechanism.

P-complexation also alters the course of the reaction of phospholyl anion with sulphur. Indeed, monosulphurization of **2** proved to be impossible. The reaction goes directly to the dithiophosphinic anion which can be easily alkylated by methyl iodide to give **13** [$\delta(^{31}P)$ (**13**) +62.9 ppm in THF].



13a **13**

11



12

Finally, we have also studied the reaction of **3** with iodine. Here, the behaviour of **3** appears to be exactly similar to that of **2** (see Ref. 14): in both cases, a P—P bond is created. Complex **14** [$\delta(^{31}P)$ (**14**) +5.9 ppm in THF] is thus obtained in 55% yield.

14

The study of the reactivity of the dicomplexed anion (**5**) has been much less complete. In fact **5** is far less reactive than **3**. The protonation of **5** is difficult and requires a strong acid. It gives an interesting stable 2H-phosphole complex which has been described previously.[15] Quite unexpectedly, the reaction of **5** with iodine also affords a very interesting result: the first known η^5-phospholyltungsten complex (**15**) [$\delta(^{31}P)$ (**15**) −31.5 ppm in THF] is thus obtained.

15

The crystal structure of **15** was established by X-ray diffraction and consists of discrete molecules only linked by van der Waals' contacts; there are no non-usual intermolecular contacts.* Figure 1 displays one molecule of **15**. Table 1 gives selected bond lengths and angles with their estimated standard deviations. The tungsten atoms are nine-coordinated: three carbonyl and the iodine atom lie on one side whereas the η^5-phospholyl ring occupies the opposite side of the coordination polyhedron. C7, C8, C9 and I form a roof: I is outside the plane containing C7, C8 and C9 by 0.421(1) Å on the same side as W; the dihedral angle between the planes C7–C8–C9 and I–C8–C9 is 9.5°. The W—I bond length of 2.8331(5) Å is not significantly different from that reported for $WI_2(OCMe_3)_6$, 2.8293(8).[25] The three W—C (carbonyl) bond lengths range from 1.982(8) to 2.017(6) Å and the W—C≡O bond angles have values near to 180°. The W atom is not equidistant from the four

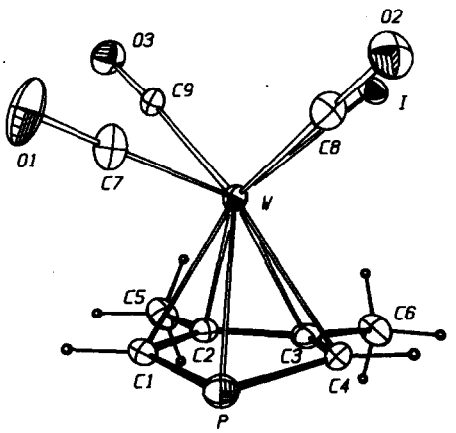


Fig. 1. Structure of complex **15**. The heavy-atom ellipsoids are scaled to enclose 50% of the electron density, hydrogen atoms have arbitrary radii.

C atoms of the phospholyl core: the W—C1 bond length is shorter than the three other bond lengths, thus the projection of W on the C1 → C4 plane is out of the line joining the P atom to the middle of the C2—C3 bond in the direction of C1.

The carbon atoms C1–C4 are coplanar within experimental error; the phosphorus atom is outside from this mean plane by 0.150(3) Å and the tungsten atom by 1.963(0) Å. As expected, the W—P bond length of 2.516(2) Å is greater than those found in pure W—P σ-bonds[2,15] but less than those in complexes having some π character in their W—P bond.[15] The dihedral angle between the mean planes of these four carbon atoms and P–C1–C4 is equal to 6.8°, a value greater than those found in η^5-phosphacymantrenes[8] or diphosphaferro-

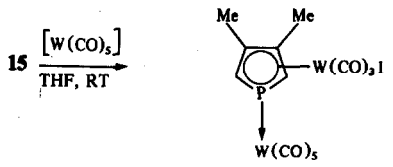
cenes,[11] suggesting some loss of aromaticity of the phospholyl ring in complex **15**. The bond lengths and angles in the phospholyl ring are not significantly different from those found in η^5-phosphacymantrenes.[8]

From a spectroscopic point of view, we have noted one very peculiar characteristic of this π-complex. No NMR coupling is visible between ^{31}P and ^{183}W nuclei, whereas the P—W bond length lies close to the normal value. This property seems to be characteristic of tungsten π-complexes involving P=C delocalized multiple bonds. Indeed, a similar situation has been encountered in the case of $\eta^2[CH_2{=}PCl]W(CO)_5$.[26]

Theoretical studies[27–29] have shown that the main difference between corresponding η^5-cyclopentadienyl and η^5-phospholyl complexes lies in the presence of a low-lying LUMO highly localized at phosphorus in the latter case. Since complex **15** is the first known η^5-phospholyl complex in which the P ring shares the coordination sphere of a metal with an halogen, it offered us the opportunity to compare the reactivities of P–metal and metal–halogen bonds toward nucleophiles. Two types of attacks could be envisaged: (a) the "normal" attack at the metal with loss of an halide ion; (b) the "abnormal" attack at phosphorus with cleavage of the phosphorus–metal bond.



Apparently the "abnormal" attack is preferred at least in the case of the hydroxide ion.

16

Complex **16** [$\delta(^{31}P)$ (**16**) +38.8 ppm in acetone, ^1J(P–H) 532 Hz] is thus obtained in 75% yield. Finally, it is also interesting to note that, during the synthesis of **15**, a P → $W(CO)_5$ complex of **15** (**17**) is formed as a by-product [$\delta(^{31}P)$ (**17**) −14 ppm in $CDCl_3$, $^1J(^{31}P–^{183}W)$ 274 Hz].

17

Here of course, a normal ^1J coupling is observed between P and the $W(CO)_5$ tungsten. The formation of **17** from **15** is exactly similar to the various P-complexations observed with phosphamantrenes,[30] phosphaferrocenes[26] and diphosphaferrocenes.[32]

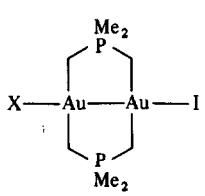
BINUCLEAR PLATINUM(I) COMPLEXES WITH BIS(DIMETHYLPHOSPHINO)METHANE LIGANDS: EVIDENCE FOR BOTH SHORT- AND LONG-RANGE NMR *TRANS*-INFLUENCES

SAMSON S. M. LING and RICHARD J. PUDDEPHATT*



Department of Chemistry, University of Western Ontario, London, Ontario, Canada N6A 5B7

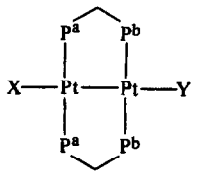
(*Received* 9 *August* 1985; *accepted* 26 *November* 1985)

Abstract—The diplatinum(I) complexes or complex ions $[Pt_2X_2(\mu\text{-dmpm})_2]$ (X = Cl or I), $[Pt_2X(PPh_3)(\mu\text{-dmpm})_2]^+$ (X = I, Br or Me), and $[Pt_2(PPh_3)_2(\mu\text{-dmpm})_2]^{2+}$, where dmpm = $Me_2PCH_2PMe_2$, have been prepared and characterized by ^1H and ^{31}P NMR spectroscopy. In the linear X–Pt–Pt–Y unit the *trans*-influence of X is felt primarily at the Pt–Pt bond, but groups X having a very high *trans*-influence (X = H or Me) can also exert a weaker long-range *trans*-influence on the Pt–Y bond.

Diplatinum(I) complexes with bridging bis(diphenylphosphino)methane (dppm) ligands are now well-known and have been important in investigations of the reactivity of the Pt–Pt bond.[1,2] The bulky phenyl substituents limit the reactivity of such complexes since only small molecules can approach the Pt–Pt bond.[3] We were therefore interested in preparing similar complexes with the small bis(dimethylphosphino)methane (dmpm) ligand in order to compare the reactivities with those of the known dppm analogues.

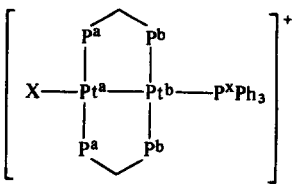
A feature of diplatinum(I) complexes is the transmission of electronic effects through the linear X–Pt–Pt–Y framework.[4–6] Fackler has described this effect in terms of a long-range *trans*-influence based on bond length determinations in gold–gold-bonded complexes[7] (1) in which gold(II) may be considered isoelectronic with platinum(I).

1a X = I
1b X = Me



The Au–Au distances were similar in the two complexes (2.660 Å for **1a**, 2.695 Å for **1b**) but the Au–I distance was much longer in **1b** (2.699 Å for **1a**, 2.894 Å for **1b**). It was noted that the *trans*-influence[8] of the methyl group was not attenuated by the Au–Au bond, and the result was rationalized in terms of a qualitative MO diagram.[9] In contrast, both bond distances and $^1J(PtX)$ or $^1J(PtY)$ coupling constants indicate that increasing the *trans*-influence of X in the linear X–Pt–Pt–Y system (e.g. X and Y = H, Me, Ph_3P or Cl) significantly weakens both the Pt–Pt bond and the Pt–Y bond.[3–6] It is difficult to distinguish between these electronic effects and bond weakening due to steric effects in $[Pt_2XY(\mu\text{-dppm})_2]^{n+}$ complexes since, for example when X or Y = PPh_3, very large steric effects between phenyl substituents on the PPh_3 and μ-dppm ligands are observed.[6,10,11] It was expected that this complicating factor would be less severe in the analogous dmpm derivatives. A preliminary account of part of this work has been published.[12]

RESULTS



The first successful synthesis of a dmpm complex of platinum(I) involved reaction of $[\{PtCl_2(dmpm)\}_n]$[13] with $Na[BH_4]$ to give $[Pt_2Cl_2(\mu\text{-dmpm})_2]$ (**2a**). However, the yield of **2a** was low and so alternative synthetic methods were sought.

The most general route found involved oxidative addition to the diplatinum(0) complex $[Pt_2(\mu\text{-dmpm})_3(PPh_3)]$, which could be isolated or prepared *in situ* by reaction of dmpm with

2a X = Y = Cl
2b X = Y = I
2c X = Me, Y = I

3a X = I
3b X = Br
3c X = Me

4a P^P = dmpm
4b P^P = dppm

$[Pt(PPh_3)_3]$.[14] Reaction with iodine gave **2b** in high yield and **2b** with triphenylphosphine gave the ionic **3a** and **4a** which were isolated as the hexafluorophosphate salts. Reaction with methyl iodide gave **2c** and **3c** as a mixture. It was not possible to isolate **2c** in pure form, and it was characterized spectroscopically in the mixture, but **3c** could be isolated as the hexafluorophosphate salt. Other alkyl halides failed to give alkyldiplatinum(I) derivatives. For example, $I(CH_2)_nI$, where $n = 3$, 4 or 5, gave only the iodo derivatives **2b** or **3a** and $1,2\text{-}C_6H_4(CH_2Br)_2$ gave the bromo derivative **3b**, isolated as the $[PF_6]^-$ salt.

The above oxidative additions and ligand substitutions are, in general, very similar to those of the analogous dppm complexes.[4,5,10] However, we note that in these oxidative addition reactions one of the three dmpm ligands is always lost whereas, in the corresponding dppm chemistry, the third dppm is retained as a monodentate ligand in place of the triphenylphosphine in **3** and **4**.[4,5] This difference is probably a result of the lower steric requirement of the $Pt_2(\mu\text{-dmpm})_2$ unit which allows the bulky triphenylphosphine to coordinate without undue strain (see later).

Structural characterization of these complexes was by ^1H, $^1H\text{-}\{^{31}P\}$ and $^{31}P\text{-}\{^1H\}$ NMR spectroscopy, and full details of spectra are given in Experimental. The spectra were complex but very characteristic as discussed in detail for the μ-dppm analogues, whose spectra are similar and have been discussed in detail elsewhere.[4,5,10,15,16]

DISCUSSION

In these complexes $[Pt_2XY(\mu\text{-LL})_2]^{n+}$, μ-LL = dmpm or dppm, the *trans*-influence of the terminal ligand X affects both the Pt–Pt and Pt–Y bonds, but the major effect is on the Pt–Pt bond. This is illustrated by bond length data given in Table 1 for monocationic complexes. For example, substituting PPh_3 for CO in $[Pt_2Cl(CO)(\mu\text{-dppm})_2]^+$ increases the Pt–Cl distance by 0.02 Å but the Pt–Pt distance by 0.045 Å.

Confirmation of this effect can be obtained by consideration of PtP and PtH coupling constants (Tables 2 and 3) bearing in mind that, at least within closely related families of complexes, there is an approximately linear correlation of $^1J(PtP)$ with the Pt–P bond distance.[8,17] In the complexes $[Pt_2X(PPh_3)(\mu\text{-dmpm})_2]^+$, there is a correlation of $J(PtPPh_3)$ with the *trans*-influence of X but the range is relatively small, from 2336 Hz for X = I to 2048 Hz for X = Me. Differences are much greater in mononuclear complexes with the phosphine directly *trans* to X as, for example, in *cis*-$[PtMeBr(PEt_3)_2]$ which has $^1J(PtP)$ values of 4178 and 1743 Hz for the phosphines *trans* to halogen and methyl, respectively. On the other hand, the long-range couplings $^2J(PtPtPPh_3)$ cover a very wide range (Table 2), from 1152 Hz for X = I to 416 Hz for X = Me. This coupling operates through the Pt–Pt bond, which is greatly weakened by the *trans*-influence of the terminal methyl group, and so the trend in coupling constants is greatly amplified.

A number of complexes of formula $[Pt_2HL(\mu\text{-dppm})_2]^+$ have been prepared recently and some coupling constants $[^1J(PtH)]$ are given in Table 3.[5,18,19] The magnitude of $^1J(PtH)$ is only slightly affected by the *trans*-influence of L and the coupling constant actually increases slightly as the *trans*-influence of L increases. Compare, for example, the values of $^1J(PtH)$ in Table 3 for L = PPh_3, CO and

Table 3. Coupling constants $^1J(PtH)$ and $^2J(PtH)$ (Hz) in hydrido $[Pt_2HL(\mu\text{-dppm})_2]^+$ complexes

	L					
	PPh_3	PMe_2Ph	CO	η^1-dppm	C_5H_5N	CD_3CN
$^1J(PtH)$	1005	999	990	980	975	963
$^2J(PtH)$	—	66	61	—	73	76

C_5H_5N of 1005, 990 and 975 Hz with the corresponding values in *trans*-$[PtHL(PMe_2Ph)_2]^+$ of 890, 967 and 1106 Hz, respectively.[8] A weak inverse long-range *trans*-influence is observed for the platinum(I) compounds.

Together, these bond length and coupling constant data provide strong evidence that, in these diplatinum(I) complexes with linear X–Pt–Pt–Y groups, the *trans*-influence of X and Y has its primary effect on the Pt–Pt bond, in contrast to the effect observed in digold(II) complexes.[7] In these platinum complexes the *trans*-influence of X on the Pt–Y bond is attenuated by the Pt–Pt bond and the usual *trans*-influence series may even be reversed in some situations (e.g. when Y = H).

The coupling constant $^1J(Pt\text{–}PPh_3) = 2125$ Hz in $[Pt_2(PPh_3)_2(\mu\text{-dmpm})_2]^{2+}$ (**4a**) is in the region expected from the *trans*-influence of PPh_3,[8] and can be compared to the anomalously low value for $^1J(Pt\text{–}PPh_3)$ of 1680 Hz in the corresponding μ-dppm complex **4b**.[10] The latter value is now clearly due to steric effects in $[Pt_2(PPh_3)_2(\mu\text{-dppm})_2]^+$ leading to anomalously weak $Pt\text{–}PPh_3$ bonds, and illustrates the advantages of using the smaller dmpm ligand in studies of this kind.

EXPERIMENTAL

General techniques have been described elsewhere, as have the syntheses of $[\{PtCl_2(dmpm)\}_n]$ and $[Pt_2(\mu\text{-dmpm})_3(PPh_3)]$.[12–14]

$[Pt_2Cl_2(\mu\text{-dmpm})_2]$ (2a)

To a suspension of $[\{PtCl_2(dmpm)\}_n]$ (0.25 g) in MeOH (8 cm^3) was added a solution of $NaBH_4$ (0.15 g) in MeOH (4 cm^3). After 30 min, the mixture was filtered, the solvent was evaporated from the

filtrate and the residue was extracted with CH_2Cl_2 (20 cm^3). Evaporation of the solvent gave the product. Yield 0.02 g, m.p. 252°C (decomp.). NMR (CD_2Cl_2): ^1H; 1.70 [m, $^2J+^4J(PH) = 7$ Hz, $^3J(PtH) = 28.5$ Hz, *Me*P]; 2.80 [m, $^2J(PH) = 7$ Hz, $^3J(PtH) = 43$ Hz]; ^{31}P; −43.4 [s, $^1J(PtP) = 2674$ Hz, $^3J(PtP) = 148$ Hz, $J(PP) = 50$ and 29 Hz, Pt*P*]. Found: C, 16.2; H, 3.8%. Calc. for $C_{10}H_{28}Cl_2P_4Pt_2$: C, 16.4; H, 3.8%.

$[Pt_2I_2(\mu\text{-dmpm})_2]$ (**2b**)

A solution of I_2 (0.053 g) in benzene (4 cm^3) was added to a solution of $[Pt_2(\mu\text{-dmpm})_3(PPh_3)]$ (0.21 mmol) in benzene (4 cm^3). The product precipitated as a brown solid and was purified by precipitation from CH_2Cl_2 solution using pentane. Yield 0.23 g, m.p. 232°C. NMR ($CDCl_3$): ^1H; 1.88 [m, $^3J(PtH) = 29$ Hz, *Me*P]; 2.88 [quintet, $^2J(PH) = 4$ Hz, $^3J(PtH) = 40$ Hz, CH_2P_2]; ^{31}P; −32.5 [s, $^1J(PtP) = 2630$ Hz, $^2J(PtP) = -150$ Hz, $J(PP) = 44$ and 27 Hz, Pt*P*]. Found: C, 12.8; H, 3.0%. Calc. for $C_{10}H_{28}I_2P_4Pt_2$: C, 13.1; H, 3.1%.

Reaction with excess I_2 gave the known *trans,trans*-$[Pt_2I_4(\mu\text{-dmpm})_2]$.[13]

$[Pt_2(PPh_3)_2(\mu\text{-dmpm})_2][PF_6]_2$ (**4a**)

PPh_3 (0.07 g) was added to a stirred solution of $[Pt_2I_2(\mu\text{-dmpm})_2]$ (0.04 g) in MeOH (120 cm^3), followed by addition of $NH_4[PF_6]$ (0.075 g). The solvent was evaporated *in vacuo*, the residue was washed with water and then recrystallized from acetone–pentane. Yield 0.022 g; m.p. 265°C (decomp.); NMR [$(CD_3)_2CO$]: ^1H: 1.3 (broad, *Me*P); 3.32 [m, $^2J(P^aH) = 8.0$ Hz, $^4J(P^xH) = 8.8$ Hz, $^3J(PtH) = 56$ Hz, CH_2P_2]; 7.32–7.50 (complex, *Ph*); ^{31}P: −33.3 [t, $^1J(PtP) = 2460$ Hz, $^2J(PtP) = 90$ Hz, $J(PP) = 27$ Hz, PtP^a]; 17.3 [quintet, $^1J(PtP) = 2125$ Hz, $^2J(PtP) = 696$ Hz, $J(P^xP^x) = 175$ Hz, PtP^x]. Found: C, 37.7; H, 4.1%. Calc. for $C_{46}H_{58}F_{12}P_8Pt_2$: C, 37.4; H, 3.9%.

$[Pt_2MeI(\mu\text{-dmpm})_2]$ (**2c**) *and* $[Pt_2Me(PPh_3)(\mu\text{-dmpm})_2][PF_6]$ (**3c**)

To a solution of $[Pt_2(\mu\text{-dmpm})_3(PPh_3)]$ (0.16 mmol) in toluene (8 cm^3) was added a solution of MeI in benzene (0.12 cm^3, 1.46 M). The yellow precipitate (0.11 g) was identified as a mixture containing **2c** and $[\mathbf{3c}]^+I^-$ in approximately equal amounts by ^{31}P and ^{31}H NMR spectroscopy. This precipitate was dissolved in CH_2Cl_2 (10 cm^3) and converted to $[\mathbf{3c}]^+[PF_6]^-$ by addition of $NH_4[PF_6]$ and PPh_3. Yield 0.144 g. NMR of **2c** (acetone-d_6): ^1H: 0.58 [t, $^2J(PtH) = 76$ Hz, $^3J(PH) = 7$ Hz, *Me*Pt]; 1.24–1.78 (m, *Me*P); 3.35 [m, $^2J(PH) = 9$ Hz, $^3J(PtH) = 30$ and 44 Hz, CH_2P_2]; ^{31}P: −6.5 [m, $^1J(PtP) = 2592$ Hz, $J(P^aP^b) = 65$ Hz, P^a]; −11.6 [m, $^1J(PtP) = 2208$ Hz, P^b]. NMR of **3c** (acetone-d_6): ^1H: 0.44 [m, $^2J(PtH) = 67$ Hz, $J(P^aH) = 3$ Hz, $J(P^xH) = 6$ Hz, *Me*Pt]; 1.53–1.98 (m, CH_3P); 2.94 [m, $J(PH) = 7$ Hz, $J(PtH) = 33$ Hz, CH_2P_2]. Reaction of **3c** with excess MeI gave the known $[Pt_2Me_2(\mu\text{-I})(\mu\text{-dmpm})_2][PF_6]$.

$[Pt_2I(PPh_3)(\mu\text{-dmpm})_2]I$

To a solution of $[Pt_2(\mu\text{-dmpm})_3(PPh_3)]$ (0.08 mmol) in benzene (4 cm^3) was added a solution of CH_2I_2 in benzene (0.136 cm^3, 1.13 M). An intense red coloration developed and a yellow precipitate formed. The precipitate of the product was filtered off and washed with hexane. Yield 0.088 g. NMR (acetone-d_6); ^1H: 1.86–1.98 (m, CH_3P); 3.14 [m, $^3J(PtH) = 37$ Hz, CH_2P_2]; ^{31}P: −31.2 [m, $^1J(PtP) = 2568$ Hz, $^3J(P^aP^x) = 5$ Hz, $J(P^aP^b) = 64$ Hz, P^a]; −34.8 [m, $^1J(PtP) = 2528$ Hz, $^2J(PtP) = 176$ Hz, $^2J(P^bP^x) = 24$ Hz, P^b]; 10.7 [m, $^1J(PtP) = 2336$ Hz, $^2J(PtP) = 1152$ Hz, P^x].

A similar reaction between $[Pt_2(\mu\text{-dmpm})_3(PPh_3)]$ and $C_6H_4(CH_2Br)_2$ gave $[Pt_2Br(PPh_3)(\mu\text{-dmpm})_2]Br$. NMR ($CD_2Cl_2$): ^1H: 1.76–2.30 (m, CH_3P); 3.14 [m, $^2J(PH) = 8.5$ Hz, $^3J(PtH) = 38$ and 80 Hz, CH_2P_2]; ^{31}P: −26.1 [m, $^1J(PtP) = 2576$ Hz, $J(P^aP^x)] = 8$ Hz $J(P^aP^b) = 64$ Hz, P^a]; −33.6 [m, $^1J(PtP) = 2528$ Hz, $^2J(PtP) = 160$ Hz, $^2J(P^bP^x) = 23$ Hz, P^b]; 27.7 [m, $^1J(PtP) = 2240$ Hz, $^2J(PtP) = 1120$ Hz, P^x].

(*Received* 1 *October* 1985; *accepted* 26 *November* 1985)

Abstract—A comparative study of the catalyzed decomposition of hydrogen peroxide using the following copper(II) complex salts, Cu(bipy)(*S*-threo)Cl·$3H_2O$, Cu(phen)(*S*-threo)Cl·$2H_2O$, Cu(bipy)(*S*-prol)Cl·$2H_2O$ and Cu(phen)(*S*-prol)Cl·$2H_2O$ has been made. Kinetic parameters were experimentally determined by the polarographic method at 25°C, pH 7.7 and constant ionic strength (μ = 0.1 M $NaNO_3$). The catalytic behavior of the chelate with 2,2′-bipyridine and *S*-prolinate was also studied at pH 6.5 and 8.5. The reactivity follows the sequence: [Cu(bipy)*S*-prol] > [Cu(phen)*S*-prol] > [Cu(bipy)*S*-threo] > [Cu(phen)*S*-threo]. Activation energies are very similar to each other. The pH-dependent exchange of the amino acid ligand with hydrogen peroxide seems to be a critical factor in the reaction pathway. Several reaction mechanisms are proposed.

The catalytic activity of copper(II), iron(III) and cobalt(III) binary metal complexes on the disproportionation of hydrogen peroxide in aqueous solution has already been well studied.[1–3] Sigel *et al.*[1,4] investigated the catalase-like activity of copper(II) promoted by the coordination of 2,2′-bipyridine and showed that increasing concentrations of chelating agent inhibit the catalytic activity of the Cu(II)–bipy (1:1) system on account of an increase in the concentration of the *cis*-diaquobis(2,2′-bipyridine)copper(II) complex. This species behaves as less active a catalyst than the 1:1 species owing to the higher degree of saturation of its coordination sphere, which becomes less accessible for hydrogen peroxide.[1,4] In this respect a study of the catalytic properties of ternary complexes of copper(II) with aromatic heterocyclic bases and optically active α-amino acid in aqueous solution appeared to be interesting for comparative purposes since these complexes would consist essentially of *trans*-diaqua tetragonally distorted octahedral species[5–7] and, hence, they would present accessible coordination positions somewhat different from those of the 1:2 Cu(II)–2,2′-bipyridine *cis*-diaqua species. Moreover, the accessible apical coordination positions of the above ternary complexes are not strictly equivalent as the presence of an α-carbon substituent would provide some degree of "out-of-plane" hydrophobic environment close to the coordination sphere. On the other hand the presence of a chiral center in these potential catalysts could constitute an advantage in further studies of a system containing, for instance, chiral organic peroxides. This work includes data on the catalytic activity of this kind of ternary complex in the decomposition of hydrogen peroxide in aqueous solution as well as a study of the influence upon the reaction rate of the dissociation equilibria involving the secondary ligand, i.e. the chiral amino acid. The kinetic parameters of the reaction are comparatively studied by using the complex ions [Cu(bipy)*S*-prol$(H_2O)_2]^+$, [Cu(phen)*S*-prol$(H_2O)_2]^+$, [Cu(bipy)*S*-threo$(H_2O)_2]^+$ and [Cu(phen)*S*-threo$(H_2O)_2]^+$ as catalysts since preliminary work indicated that they exhibit fairly different catalytic behavior. For convenience, coordinated water molecules will be hereafter omitted in all of the complex species formulae. However, a distorted octahedral structure will be reasonably assumed for all the explicit mononuclear species involved in the proposed reaction mechanisms.

EXPERIMENTAL

The mixed-ligand copper(II) complexes used in this work were synthesized in our laboratory

according to Dutta and Dé's technique[8] with some modifications. The analytical data of the resulting compounds agreed with a 1:1:1 stoichiometry. Found: C, 44.3; N, 10.3; H, 4.5; Cu, 15.5%. Calc. for Cu(bipy)(*S*-prol)Cl·$2H_2O$: C, 44.6; N, 10.4; H, 5.0; Cu, 15.7%. The other analytical data have a similar agreement. The kinetic experiments were done by using different concentration ranges for each reactant. The complex salt concentration was varied from 10^{-3} to 10^{-5} M according to the degree of catalytic activity exhibited by each of the mixed-ligand complexes. The hydrogen peroxide concentration was varied from 10^{-1} to 10^{-2} M and was periodically checked against a standard solution of $TiOSO_4$ on a Carl Zeiss DMR 21 spectrophotometer (the resulting compound exhibits an absorption maximum at 410 nm[9]). In the determination of the order of reaction with respect to hydronium ion concentration the pH was varied from 6 to 9. However, both for the determinations of the orders of reaction of the other reacting species as for the activation energy measurements the initial pH was adjusted to 7.7 Moreover, since the concentrations of the catalytically active species depend upon the hydronium ion concentration, further kinetic experiments were performed at pH 6.5 and 8.5 by employing [Cu(bipy)*S*-prol]$^+$ as a catalyst. The solutions were freshly prepared. In all the determinations the system was deoxygenated by flushing pure N_2, before addition of the hydrogen peroxide solution. In all the cases the pH was adjusted with diluted NaOH or HCl, since the use of the appropriate buffers (phosphate, borate or Tris buffer) strongly inhibits the catalytic activity of these ternary complexes.[4] In the activation energy determinations the temperature was varied from 15 to 45°C. On the other hand, in the determinations of the orders of reaction the temperature was kept constant at 25°C. In all the cases the ionic strength was kept constant by using 0.1 M $NaNO_3$. The kinetics of the disproportionation of hydrogen peroxide were followed by measuring the oxygen concentration in the reaction solution, using a Fieldlab Oxygen Analyzer Model 123309 coupled with a Servogor recorder.

RESULTS AND DISCUSSION

The results obtained in the different kinetic determinations are illustrated in Figs 1–5 and are collected in Tables 1 and 2. The four complex salts under study exhibit reaction orders with respect to the complex ion less than 1, the *S*-threoninates compounds showing the lowest values. This would be attributed to the fact that the first dissociation equilibrium of the catalyst strongly influences the reaction pathway, as will be shown subsequently in the proposed reaction mechanisms. The reaction orders with respect to hydrogen peroxide, slightly greater than 1, do no differ too much from those obtained by other authors under conditions of rela-

tively high concentration of substrate.[4,10] The reaction orders with respect to hydronium ion concentration are less negative than the ones found in the catalase-like activity of binary copper(II) complexes.[1,4] This behaviour would be ascribed to the presence of the *S*-amino acid ligand, since the tendency of this species to adopt the zwitterionic form renders the first dissociation equilibrium of the ternary complex strongly pH-dependent. Furthermore, additional experiments showed that increasing concentrations of free amino acid inhibit the

catalytic activity of the complex [Cu(bipy)*S*-prol]$^+$. These data gave for the log V_o vs log [*S*-prolH] plot a straight line with a slope of about -1.3. They also showed that the amino acid behaves as a competitive inhibitor.

The specific constants of reaction rate, k, were calculated by using the reaction orders obtained from experimental data by regression analysis (Table 2). The resulting activation energy values are very similar to each other, suggesting that at pH 7.7 the four complexes are involved in similar reaction mechanisms (Table 2). The ternary complexes having *S*-prolinate as a secondary ligand exhibit higher catalytic activity than the ones having *S*-threoninate. This result would be accounted for by a more easy exchange of the *S*-prolinate ligand with hydrogen peroxide. Indeed the peculiar kinetic behavior of these ternary complexes would be precisely ascribed to their lack of accessible coordination positions appropriate for catalytic activity, these being generated only by dissociation. This fact

(○) $[[Cu(bipy)S\text{-prol}]^+]_{tot} = 3.13 \times 10^{-5}$ M, $[H_2O_2]_{tot(t=0)} = 0.064$ M, pH 7.7; (◒) $[[(Cu(phen)S\text{-prol}]^+]_{tot} = 2.5 \times 10^{-4}$ M, $[H_2O_2]_{tot(t=0)} = 0.064$ M, pH 7.7; (●) $[[Cu(bipy)S\text{-threo}]^+]_{tot} = 2.5 \times 10^{-4}$ M, $[H_2O_2]_{tot(t=0)} = 0.06$ M, pH 7.7; (◐) $[[Cu(phen)S\text{-threo}]^+]_{tot} = 2.5 \times 10^{-4}$ M, $[H_2O_2]_{tot(t=0)} = 0.0567$ M, pH 7.7; k values calc. with partial reaction orders of Table 1.

agrees with the inhibitory properties of the free amino acid previously mentioned. However, the apical accessible coordination positions of these complexes should be considered inadequate for catalysis only in the sense of the scarce possibility of formation of quaternary peroxo complexes, since it is not indispensable a *cis* bicoordination for a fast electron transfer through the metal ion.[11] On the other hand, if the assumption that such a ligand exchange greatly influences the reaction rate were relevant, [Cu(phen)*S*-threo]$^+$ should be the most stable of the mixed-ligand complexes under study. This inference does not agree with the relative stability of the binary species [Cu*S*-threo]$^+$ and [Cu*S*-prol]$^+$ whose formation constants, K_{Cu}^{CuA}, are 1.02×10^8 and 6.8×10^8, respectively.[12] Nevertheless, at the pH conditions of our experiments the free chiral ligand must be mainly in the form of a zwitterion. Hence, at pH 7.7 $[CuA^+]/[Cu^{2+}][HA]$ has values of 5.6×10^6 and 1.4×10^6 for *S*-threoninate and *S*-prolinate, respectively, i.e. the prolinate complex turns out to be of lower stability. Furthermore, the formation constants of ternary complexes of copper(II) with 2,2′-bipyridine or 1,10-phenanthroline and *S*-amino acid, K_{CuB}^{CuBA}, are very similar for a series of *S* amino acids, the small differences observed being independent upon pK_{HA}^{A}.[13] If the value for log $K_{Cu,bipy}^{Cu,bipy,prol} - \log K_{Cu,bipy}^{Cu,bipy,threo}$ were assumed to be similar to the greater difference of log K_{CuB}^{CuBA} values found in Malik's work,[13] i.e. about 0.5, the ratio $[S$ - prolH)[Cu(bipy)*S* - threo]$^+]/[S$ - threo] [(Cu(bipy)*S* - prol]$^+$] should be approximately 8.1, that is, the ternary complex of *S*-threoninate should be of higher stability.

The kinetic parameters for the reaction in the presence of [Cu(bipy)*S*-prol]$^+$ at pH 6.5 and 8.5 are found in Figs 6–8 and arranged in Table 3. According to these data both the reaction order with respect to the ternary complex and hydrogen peroxide appear to be pH-dependent. This would be accounted for by the presence of two or more reaction mechanisms occurring simultaneously, whose contribution to the reaction rate depends

[Cu(phen)*S*-threo]$^+$	2.5×10^{-7}	0.2	—	—

upon the pH conditions. The activation energy turned out to be also pH-dependent, probably on account of the same reasons.

At pH 7.7 the kinetic behavior of the four complexes studied fit acceptably with the rate expression:

$$V_o = \frac{k'_1[\mathrm{CuBA}^+]^{0.5}[\mathrm{H_2O_2}]}{[\mathrm{H}^+]^{0.5}} + k'_2[\mathrm{CuBA}^+][\mathrm{H_2O_2}]^2, \quad (1)$$

where B and A stand for the heterocyclic base and the amino acid ligand, respectively. An appropriate set of rate constants, k'_1 and k'_2, is listed in Table 4. These figures were obtained by averaging k'_1 and k'_2 values calculated from the regression equations of the different experimental determinations of reaction orders. Theoretical log V_o vs log [CuBA$^+$], log V_o vs log [H_2O_2] and log V_o vs log [H^+] plots, calculated from eqn (1), are included in Figs 1–4. As can be seen, the agreement between the theoretical plots and the experimental points is somewhat smaller for [Cu(bipy)*S*-prol]$^+$. Indeed the data of this complex fit better with the rate equation:

$$V_o = \frac{k''_1[\mathrm{CuBA}^+]^{0.5}[\mathrm{H_2O_2}]^2}{[\mathrm{H}^+]^{0.5}} + k''_2[\mathrm{CuBA}^+][\mathrm{H_2O_2}], \quad (2)$$

whereas [Cu(phen)*S*-prol]$^+$ fits both eqn (1) and eqn (2) well. The values of k''_1 and k''_2 for the *S*-prolinate complexes were calculated in the same way as k'_1 and k'_2, and are also included in Table 4. The log V_o values for [Cu(bipy)*S*-prol]$^+$ calculated from eqn (2) are included in Figs 1–3. The quantities k'_1, k'_2, k''_1 and k''_2 depend upon the equilibrium reactant concentrations and hence upon pH. Therefore it should not be expected that they are valid for wide ranges of concentration. These "constants" correspond rather to $k'_1 = k_{11}(1-\alpha_c)^{0.5}(1-\alpha_s)$, $k'_2 = k_{21}(1-\alpha_c)(1-\alpha_s)^2$, $k''_1 = k_{12}(1-\alpha_c)^{0.5}(1-\alpha_s)^2$ and $k''_2 = k_{22}(1-\alpha_c)(1-\alpha_s)$, where α_c and α_s are the degree of dissociation of the ternary complexes and the hydrogen peroxide, respectively. If it was assumed that the ternary complex dissociation mainly occurs according to the fast equilibrium:

$$[\mathrm{CuBA}]^+ + \mathrm{H}^+ \overset{K_1}{\rightleftharpoons} [\mathrm{CuB}]^{2+} + \mathrm{HA},$$

at t = 0 α_c should be given approximately by:

$$\alpha_c^2 + \frac{K_1[\mathrm{H}^+]\alpha_c}{[\mathrm{CuBA}^+]_{tot}} - \frac{K_1[\mathrm{H}^+]}{[\mathrm{CuBA}^+]_{tot}} = 0.$$

In order to verify the validity of rate expressions (1) and (2), the experimental data obtained from the determination of the reaction order with respect

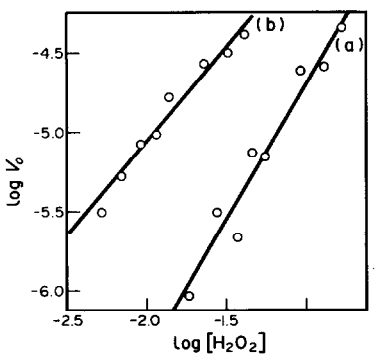

Fig. 7. Catalytic activity of [Cu(bipy)*S*-prol]$^+$ as a function of the total initial concentration of hydrogen peroxide at different initial concentrations of hydrogen ion and $\mu = 0.1$ M $NaNO_3$; (a) pH 6.5, $[[\mathrm{Cu(bipy)}S\text{-prol}]^+]_{tot} = 2.5\times10^{-4}$ M; (b) pH 8.5, $[[\mathrm{Cu(bipy)}S\text{-prol}]^+]_{tot} = 2.5\times10^{-4}$ M. Temperature 25°C.

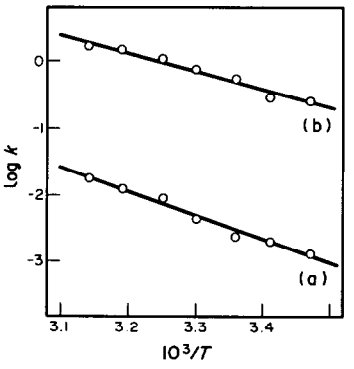

Fig. 8. Catalytic activity of [Cu(bipy)*S*-prol]$^+$ at different temperatures and concentrations of hydrogen ion. $\mu = 0.1$ M $NaNO_3$. (a) pH 6.5, $[[\mathrm{Cu(bipy)}S\text{-prol}]^+]_{tot} = 5\times10^{-4}$ M, $[\mathrm{H_2O_2}]_{tot(t=0)} = 9.23\times10^{-3}$ M; (b) pH 8.5, $[[\mathrm{Cu(bipy)}S\text{-prol}]^+]_{tot} = 1.25\times10^{-4}$ M, $[\mathrm{H_2O_2}]_{tot(t=0)} = 9.23\times10^{-3}$ M.

to hydrogen ion concentration for [Cu(bipy)*S*-prol]$^+$ and [Cu(phen)*S*-threo]$^+$ as catalyst were further analyzed. The above k' and k'' expressions were, respectively, substituted in eqns (1) and (2). The corresponding values of k' and k'' listed in Table 4 were used as a starting point for the calculation of the pH-independent rate constants by assuming an appropriate value for K_1. Reasonable K_1 values were successively iterated until an acceptable fitting with experimental data was reached. For H_2O_2 pK_a = 11.62 was employed. The results obtained from these calculations are shown in Figs 9 and 10. In the case of *S*-prolinate complex results from the application of eqn (1) are also included. According to this analysis the kinetics summarized by eqn (2) agrees with the experimental data of [Cu(bipy)*S*-prol]$^+$ over almost all the pH range studied, whereas eqn (1) agrees only up to pH 7.7. However, the log K_{CuB}^{CuBA} value resulting from the fitting with eqn (1) seems to be somewhat more realistic than the one obtained from eqn (2), i.e. log K_{CuB}^{CuBA} = log $K_A^{HA} - K_1$ = 8.30 from eqn (1) and 7.54 from eqn (2).[13] The application of eqn (2) to the data of [Cu(phen)*S*-threo]$^+$ was not attempted since previous calculations of k_1'' and k_2'' for the reaction in the presence of this species showed a rather poor accordance between the different reaction order experiments. On the contrary, eqn (1) showed a moderate agreement between the different kinetic determinations (Figs 1, 2 and 4). Since the starting point of these calculations were the average values of k_1' and k_2', an improvement of the fitting between the theoretical curve and the experimental data of Fig. 10 by decreasing k_{11} and k_{21} impairs the agreement with the experiments at variable concentrations of complex ion and hydrogen peroxide. A somewhat low value for the log K_{CuB}^{CuBA} of

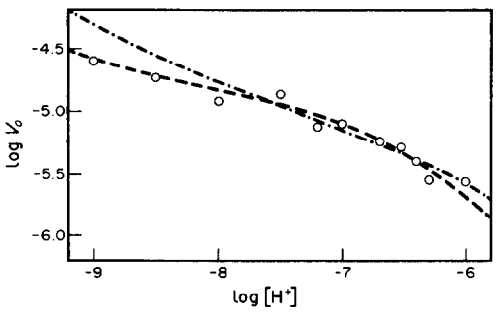

Fig. 9. Theoretical rate equations for catalytic activity of [Cu(bipy)*S*-prol]$^+$. $[[Cu(bipy)S\text{-prol}]^+]_{tot} = 1.25 \times 10^{-4}$ M, $[H_2O_2]_{tot(t=0)} = 0.0415$ M, $\mu = 0.1$ M $NaNO_3$, 25°C; (○) experimental values; (–·–·–·–) eqn (1) with $k_{11} = 3.02 \times 10^{-6}$ s^{-1}, $k_{21} = 20.37$ M^{-2} s^{-1} and $K_1 = 120$; (––––––) eqn (2) with $k_{12} = 2.13 \times 10^{-5}$ M^{-1} s^{-1}, $k_{22} = 2.792$ M^{-1} s^{-1} and $K_1 = 700$.

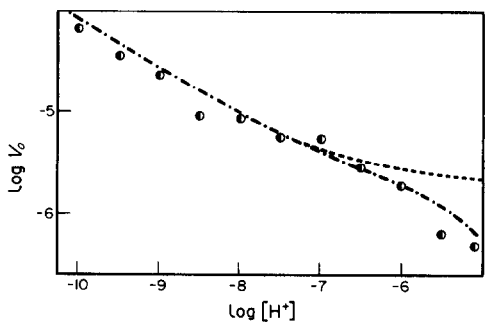

Fig. 10. Theoretical rate equations for catalytic activity of [Cu(phen)*S*-threo]$^+$. $[[Cu(phen)S\text{-threo}]^+]_{tot} = 2.5 \times 10^{-4}$ M, $[H_2O_2]_{tot(t=0)} = 0.1983$ M, $\mu = 0.1$ M $NaNO_3$, 25°C; (●) experimental values; (–·–·–·–) eqn (1) with $k_{11} = 2.56 \times 10^{-7}$ s^{-1}, $k_{12} = 0.21$ M^{-2} s^{-1} and $K_1 = 40$; (·····) eqn (1) with $k_1' = 2.5 \times 10^{-7}$ (pH 7.8), $k_2' = 0.2$ (pH 7.8) and $K_1 = 0$.

[Cu(phen)*S*-threo]$^+$ was obtained from the calculations summarized in Fig. 10. This value is, however, of the same order as the ones found for similar ternary complexes,[13] i.e. log K_A^{HA} – log K_1 = 7.37 (μ = 0.1).

From the above considerations it seems that kinetics of eqn (1) is predominant at lower values of K_1, i.e. at lower degrees of dissociation of the ternary complex; the one of eqn (2) being seemingly predominant at higher degrees of dissociation. Moreover, it is possible that the four mechanisms involved in eqns (1) and (2) were occurring simultaneously in these systems but with different degrees of importance, according to the concentration of the catalytically active species,[4] which in the present case depends upon both the tendency of the chiral ligand to adopt the zwitterionic form and the stability of the ternary complex, i.e. upon K_1. The following simultaneous fast equilibria would be considered as a starting point for the different possible mechanisms:

$$[CuBA]^+ + H^+ \overset{K_1}{\rightleftharpoons} [CuB]^{2+} + HA, \quad (3)$$

$$[CuB]^{2+} + H_2O_2 \overset{K_2}{\rightleftharpoons} [CuB(H_2O_2)]^{2+}, \quad (4)$$

$$[CuB(H_2O_2)]^{2+} \overset{K_3}{\rightleftharpoons} [CuB(HO_2)]^+ + H^+. \quad (5)$$

Equilibria (4) and (5) have been previously proposed by Sigel *et al.*[4] in order to account for the catalase-like activity of [Cu(bipy)]$^{2+}$. Starting from eqn (5), the reaction course would go on through different simultaneous pathways.

Mechanism (I-1)

$$[CuB(HO_2)]^+ \xrightarrow{k_4} \text{intermediate products}, \quad (6)$$

$$\text{Intermediate products} + H_2O_2 \xrightarrow{\text{fast}} [CuB]^{2+} + OH^- + H_2O + O_2.$$

Since at t = 0 $[CuB^{2+}] \cong [HA]$:

$$[CuB^{2+}] \cong K_1^{0.5}[CuBA^+]^{0.5}[H^+]^{0.5}. \quad (7)$$

Hence:

$$V_o = \frac{k'_1[CuBA^+]^{0.5}[H_2O_2]}{[H^+]^{0.5}},$$

where $k'_1 = K_1^{0.5}K_2K_3k_4$.

Mechanism (I-2)

$$[CuB(HO_2)]^+ + [CuB(H_2O_2)]^{2+} \rightleftharpoons^{K_4} [(CuB)_2(HO_2)(H_2O_2)]^{3+}, \quad (8)$$

$$[(CuB)_2(HO_2)(H_2O_2)]^{3+} \xrightarrow{k_5} 2[CuB]^{2+} + OH^- + H_2O + O_2. \quad (9)$$

From eqns (4), (5), (7), (8) and (9):

$$V_o = k'_2[CuBA^+][H_2O_2]^2,$$

where $k'_2 = K_1K_2^2K_3K_4k_5$. This mechanism is similar to the one proposed by Nishida *et al.*[14,15] with respect to the binuclear nature of the intermediate species. Although eqn (8) is not the only possible route of formation of such an intermediate, other suitable pathways originate the same rate equation, unless it were supposed that the amino acidate ligand plays some bridging role in the binuclear species.

Mechanism (II-1)

$$[CuB(HO_2)]^+ + H_2O_2 \rightleftharpoons^{K_5} [CuB(HO_2)(H_2O_2)]^+, \quad (10)$$

$$[CuB(HO_2)(H_2O_2)]^+ \xrightarrow{k_6} [CuB]^{2+} + OH^- + H_2O + O_2. \quad (11)$$

From eqns (4), (5), (7), (10) and (11) it can be deduced that:

$$V_o = \frac{k''_1[CuBA^+]^{0.5}[H_2O_2]^2}{[H^+]^{0.5}},$$

where $k''_1 = K_1^{0.5}K_2K_3K_5k_6$. This mechanism is essentially the same one proposed by Sigel *et al.*[4] for the catalase-like activity of $[Cu(bipy)]^{2+}$.

Mechanism (II-2)

$$[CuB(HO_2)]^+ + [CuB]^{2+} \rightleftharpoons^{K_7} [(CuB)_2(HO_2)]^{3+}, \quad (12)$$

$$[(CuB)_2(HO_2)]^{3+} + H_2O_2 \xrightarrow{k_8} \text{intermediate products}, \quad (13)$$

$$\text{Intermediate products} \xrightarrow{\text{fast}} 2[CuB]^{2+} OH^- + H_2O + O_2.$$

From eqns (4), (5), (7), (12) and (13):

$$V_o = k''_2[CuBA^+][H_2O_2],$$

where $k''_2 = K_1K_2K_3K_7k_8$.

Discussion on the possible nature of the intermediate species involved in the above proposed mechanisms has been already provided by other authors on similar systems.[1,2,14] However in mechanism (II-2) a mixed-valence intermediate, i.e. Cu(I) and Cu(II), might be also proposed.

The pH dependence of the reaction orders (Table 3) seems to be agreeing with the simultaneous occurrence of these kinetic pathways, since at low pH values the experimental rate law tends to be similar to the equation obtained from mechanism (II-1), which should predominate at relatively higher concentration $[Cu(bipy)]^{2+}$. On the other hand, at higher pH values the experimental rate equation tends to adopt the form of the equation obtained from mechanism (I-2), which was previously assigned to the catalysis by threoninate complexes. Again, this seems to agree with the increasing stability of the prolinate complexes on increasing pH, which lowers the concentration of $[Cu(bipy)]^{2+}$.

The second term of eqns (1) and (2) would be also accounted for by reaction pathways involving the ternary complex itself acting as a catalyst; for instance:

$$[CuBA]^+ + H_2O_2 \rightleftharpoons^{K'} [CuBA(H_2O_2)]^+,$$

$$[CuBA(H_2O_2)]^+ + H_2O_2 \rightleftharpoons^{K''} [CuBA(H_2O_2)_2]^+,$$

$$[CuBA(H_2O_2)_2]^+ \xrightarrow{k'} [CuBA]^+ + 2H_2O + O_2,$$

$$V_o = k[CuBA^+][H_2O_2]^2, \quad k = K'K''k',$$
