Although the iridathiabenzene portion of **2** is best represented by a combination of resonance forms **A** and **B** in which the iridium is a $16e^-$- or $18e^-$-centre, respectively, complex **2** reacts very much like a $16e^-$-system by adding $2e^-$-donor ligands such as phosphines and CO and by undergoing oxidative-addition with H_2. The other

isomer, **1**, undergoes the same reactions as **2** but generally they are slower; there is evidence to suggest that these reactions proceed by initial isomerization of **1** to **2**; then **2** combines with the $2e^-$-donor ligands or H_2 to form the final products.

SYNTHESIS AND CRYSTAL STRUCTURES OF TWO DIRUTHENIUM POLYSULPHIDE COMPLEXES*

PAUL M. TREICHEL,† RICHARD A. CRANE and K. J. HALLER

Department of Chemistry, University of Wisconsin-Madison, Madison, WI 53706, U.S.A.

Abstract—The reaction between $Ru(SPh)(PPh_3)\{P(OMe)_3\}(\eta\text{-}C_5H_5)$ and sulphur, in acetonitrile, affords two diruthenium polysulphide complexes, $Ru_2\{P(OMe)_3\}_2(\eta\text{-}C_5H_5)_2S_4$ (**I**) and $Ru_2\{P(OMe)_3\}_2(\eta\text{-}C_5H_5)_2S_6$ (**II**). The latter could be converted to the former by reaction with PPh_3. Structures of both blue–black, crystalline species were determined by single crystal X-ray diffraction methods. The former contained a six-membered, non-planar ring (cyclohexane chair structure) consisting of the two metal atoms and four sulphurs with the metals in the 1- and 4-positions, while the latter contained a Ru_2S_6 eight-membered ring, with metal atoms in the 1- and 5-positions and a long bond between two sulphurs across this ring, a structure not unlike that of $[S_8]^{2+}$. Comments are presented on the unusual bonding in the Ru_2S_n rings in these two species.

The synergism between synthesis and theory has been much in evidence over the last two decades. In our laboratories, perhaps the most notable example of this arose with the collaboration that grew up between our group and the Fenske group involving studies on oxidative electrochemistry of metal complexes with isonitrile ligands. Theory established[1] that a linear relationship exists between ease of oxidation, as measured by an $E_{1/2}$ value, and the energy of the HOMO, the latter calculated by Fenske–Hall[2] methods. This work was later extended to rationalize the different $E_{1/2}$ values for isomeric species.[3] This research has taken on larger proportions as further experimental and theoretical studies were completed.[4,5]

A similar recent story is related here. Work in our group, part of a larger programme on organosulphur complexes of metals, resulted in the synthesis and characterization of the two compounds that are the subject of this paper; in turn, this led to investigations into the theory needed to understand these species.

Frequently, a well conceived reaction produces unexpected results and opens up a new area of even greater proportions than had been contemplated in the original study. We carried out a reaction between $Ru(SPh)(PPh_3)\{P(OMe)_3\}(\eta\text{-}C_5H_5)$ and sulphur; our expectation was that PPh_3 would dissociate and then be captured by reaction with sulphur. In this compound, as in a number of other ruthenium complexes, triphenylphosphine is quite easily displaced.[6] Sulphur had been used successfully as an agent to capture this phosphine in other situations.[7] Our initial goal was to prepare a dinuclear complex, $Ru_2(\mu\text{-}SPh)_2\{P(OMe)_3\}_2(\eta\text{-}C_5H_5)_2$, which we predicted would have striking oxidative chemistry by analogy to the behaviour of similar iron complexes.[8]

Instead, this reaction produced two diruthenium polysulphide complexes. We have characterized both by single crystal X-ray diffraction studies and found that they have unexpected molecular structures. To rationalize these structures and to explain the bonding in these species, a collaboration was set up with David Kanis, at the time a student in the Fenske group. The theoretical study that followed became a major part of Kanis' PhD thesis; two papers, one for each compound, describing the theoretical calculations and their interpretations have since been written.[9]

During the course of our work a communication was published by Rauchfuss and co-workers[10] describing the synthesis and structures of two similar compounds. These species, differing from ours by the nature of the phosphorus ligand, were obtained by a different route.

RESULTS AND DISCUSSION

The ruthenium complex that is the precursor in this synthesis was obtained in a two-step sequence

* Dedicated to our faculty colleague and friend, Professor Richard F. Fenske, upon his retirement.

portrayed by the equations below:

$$RuCl(PPh_3)_2(\eta\text{-}C_5H_5) + P(OMe)_3 \longrightarrow RuCl(PPh_3)\{P(OMe)_3\}(\eta\text{-}C_5H_5) + PPh_3$$

$$RuCl(PPh_3)\{P(OMe)_3\}(\eta\text{-}C_5H_5) + n\text{-}Bu_3SnSPh \longrightarrow Ru(SPh)(PPh_3)\{P(OMe)_3\}(\eta\text{-}C_5H_5) + n\text{-}Bu_3SnCl.$$

There are analogous procedures in the literature for both the replacement of triphenylphosphine[6] and the use of tributyltin thiolate as a source of PhS^-.[11]

The reaction between $Ru(SPh)(PPh_3)\{P(OMe)_3\}(\eta\text{-}C_5H_5)$ and elemental sulphur (in small excess) was carried out in refluxing acetonitrile and resulted in formation of the two compounds, $Ru_2\{P(OMe)_3\}_2(\eta\text{-}C_5H_5)_2S_4$ (**I**) and $Ru_2\{P(OMe)_3\}_2(\eta\text{-}C_5H_5)_2S_6$ (**II**). As anticipated, the PPh_3 turned up as $S{=}PPh_3$. The disulphide, PhSSPh, was also found among the products of this reaction, making known the fate of the thiolate group and strongly suggesting that this group was not the source of sulphur in these two species.

Product **I** was most easily separated based on its much lower solubility in CH_2Cl_2 and it also crystallized well from $CHCl_3$. The second product, **II**, was then separated from small amounts of **I** using column chromatography.

It is possible to convert **II** to **I** by reaction with PPh_3. This type of desulphurization reaction has been used previously.[12] The reaction appears to be clean and specific, according to data obtained when the reaction was monitored by NMR. No intermediate products were seen and there was no indication that **I** will lose further sulphur.

$$\underset{(\mathbf{II})}{Ru_2\{P(OMe)_3\}_2(\eta\text{-}C_5H_5)_2S_6} + 2PPh_3 \longrightarrow \underset{(\mathbf{I})}{Ru_2\{P(OMe)_3\}_2(\eta\text{-}C_5H_5)_2S_4} + 2S{=}PPh_3.$$

The relatively mild conditions are noteworthy. The reaction occurs at reflux temperature of acetonitrile (80°C); no starting material remained after a reaction time of 50 min. A reaction between the rather similar complex $Ru(SH)(PPh_3)_2(\eta\text{-}C_5H_4Me)$ and sulphur, in refluxing toluene (b.p. 110°C) is reported to yield only a single species, the cubane-like tetramer, $Ru_4S_4(\eta\text{-}C_5H_4Me)_4$;[13] the fact that there is only a single product may be related to the lengthy reaction time, 18 h. In preliminary studies, we had also used toluene as a solvent and found a more complicated mixture of products which did, however, include both **I** and **II**.

Similar compounds, $Ru_2(PPh_3)_2(\eta\text{-}C_5H_5)_2S_x$ ($x = 4$, 6), were reported via a communication in the course of our work.[10] They were made by a different procedure that involved coupling of S_6^{2-} and the dication, $[(\eta\text{-}C_5H_5)Ru(PPh_3)_2\text{-}\mu\text{-}S_2\text{-}Ru(PPh_3)_2(\eta\text{-}C_5H_5)]^{2+}$, the latter having been made first from $RuCl(PPh_3)_2(\eta\text{-}C_5H_5)$, $AgSbF_6$ and S_8. Also, there is a recent reference to $Ru_2(CO)_2(\eta\text{-}C_5H_5)_2S_6$, a compound formed from photolysis of sulphur and $Ru_2(CO)_4(\eta\text{-}C_5H_5)_2$. This compound is possibly a carbonyl analogue of **II**, although confirming structural information was not presented.[14]

The structures of **I** and **II** were determined by single crystal X-ray diffraction and are shown in Figs 1 and 2. Selected bond lengths and angles for these compounds are given in Tables 1 and 2. In **I**, the two metals and four sulphurs form a six-membered non-planar ring (the chain form, as in cyclohexane). The metal atoms in the 1- and 4-positions contain the phosphite and cyclopentadienyl with axial and equatorial orientation, respectively. Sulphur–sulphur bond lengths in the ring are 2.04 Å, comparable with the single bond length value in S_8 of 2.05 Å. The ruthenium–sulphur bond lengths are 2.29 Å, shorter than a single bond between these elements which is generally assumed to be around 2.38 Å.[15] The structure of **II** may be viewed as an eight-membered ring with metal atoms in the 1- and 5-positions and a *trans*-ring interaction (bond) between the sulphur atoms in positions 4 and 8. [In the ORTEP drawing in Fig. 2, these atoms are labelled as S(1) and S(4).] There is a long distance between these sulphurs across the ring,

Table 1. Selected bond lengths and bond angles in **I**

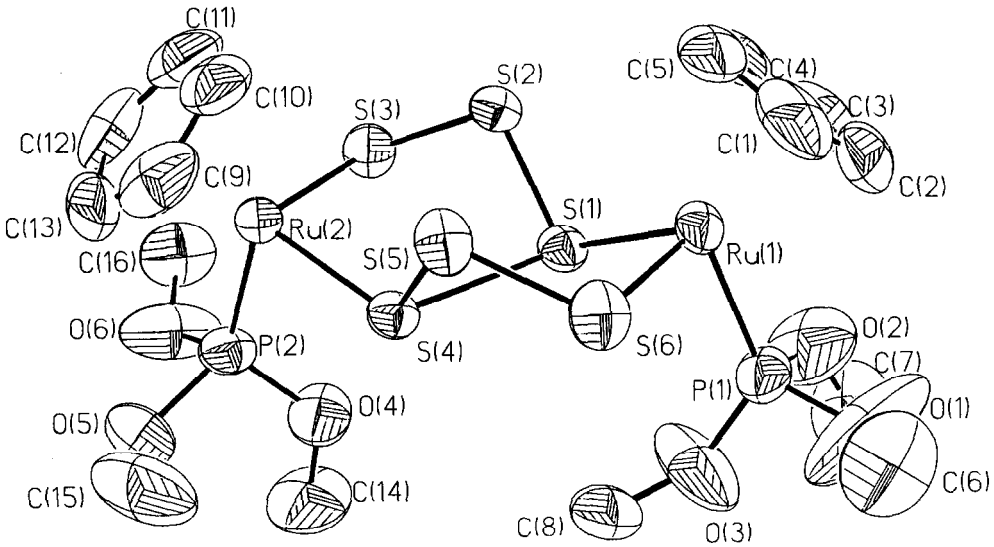

Fig. 2. ORTEP drawing of one of the two independent molecules of $Ru_2\{P(OMe)_3\}_2(\eta\text{-}C_5H_5)_2S_6$ (**II**); hydrogen atoms are omitted for clarity.

2.609(2) Å; this is shorter than the 2.77 Å measured for this bond in the triphenylphosphine analogue. Folding of the ring across this bond is consequent to these sulphurs being pyramidal; a further small distortion from planarity for each of the two halves of this molecule is seen to simply allow the atoms to bond with normal bond angles. Other sulphur–sulphur bond lengths in **II** are close to the single bond value. The two ruthenium–sulphur bonds are approximately 2.36 and 2.26 Å; the former is a typical single bond length[15] while the latter is like the ruthenium–sulphur bond length in **I**, the shortening presumed to be due to partial multiple bond character (*vide infra*).

A notable structural difference between **I** and its analogue is that the phosphorus and cyclo-

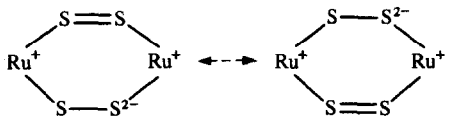
pentadienyl groups have the opposite axial–equatorial orientation. This seems most likely to be a result of the sizes of these groups, with the largest group in each compound taking the least sterically-hindered equatorial site. Other than the difference in the *trans*-ring distance, noted above, bond lengths are similar to those reported for the analogous compounds.[10] Bond angles for **I** and **II** are also similar to the bond angles in the triphenylphosphine compound.

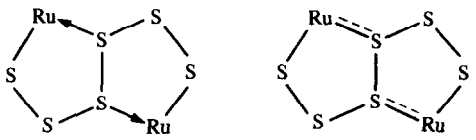
Our initial approach to rationalize these structures was based on simple valence bond representations. Noting that **I** is diamagnetic, we conceived a valence bond model with two resonance forms, shown below, to account for the fact that structural parameters showed equivalence of the two disulphur ligands:



Formally, this picture portrays one of the bridging disulphur units as a neutral species (S_2) while the other unit is a dianion (S_2^{2-}). Each can donate a pair of electrons; in conjunction with the other ligands an 18-electron configuration is conveyed to each metal.

Given that a rather interesting and unusual type of delocalization is postulated, this compound seemed a logical candidate for a more detailed theoretical study.

In **II**, a rather more simple valence bond picture is possible, with a chain of sulphur atoms wrapped in a way that permits bidentate coordination of the sulphurs to the two metals.



The problem with this representation of the structure is, of course, that the long bond across the ring between the two sulphurs is not explained. It is possible to overcome this obstacle by postulating delocalization, as shown, which involves hypervalent sulphur atoms. This bonding representation makes **II** also a likely candidate for further theoretical study. The fact that the structure is actually more like that for S_8^{2+}, with similarities including the long sulphur–sulphur bond, makes a theoretical study even more attractive.

Thus, as noted above, we set about interesting the experts in this problem. The detailed molecular orbital calculations (**I**) showed alignment of the energies of the metal orbitals and the π-symmetry orbitals of the S_4 unit to favour delocalization between these groups. A significant σ-bonding interaction between sulphurs on opposite sides of the ring was indicated by theory, even though the bond distance was long. Theory also points to multiple ruthenium–sulphur bonding, as postulated from bond length data. In the case of **II**, it was apparent from calculations that there is delocalization of charge in the molecular LUMO which involves multiple metal–sulphur bonding and antibonding character between sulphurs in the ring. The details of the calculations and the relationship of these species to analogous species like S_8^{2+} and S_6^{2+} may be found in the literature.[9]

EXPERIMENTAL

All experiments were carried out under nitrogen; this was largely a precautionary measure since reactants and products are not noticeably air-sensitive. Solvents were dried before use, following standard methodology (acetonitrile distilled from CaH_2; acetone distilled from K_2CO_3; CH_2Cl_2 distilled from P_4O_{10}; toluene distilled from Na; hexane distilled from $CaSO_4$). Alumina, weakly acidic, was purchased from Aldrich Chemical Co. and was used without pretreatment. Samples of n-Bu_3SnSPh[11] and $RuCl(PPh_3)_2(\eta\text{-}C_5H_5)$[16] were prepared by literature methods.

The precursor to the synthesis of the diruthenium polysulphide compounds, $Ru(SPh)(PPh_3)\{P(OMe)_3\}(\eta\text{-}C_5H_5)$, was prepared in a two-step process as described below.

Synthesis of $RuCl(PPh_3)\{P(OMe)_3\}(\eta\text{-}C_5H_5)$

A solution of $RuCl(PPh_3)_2(\eta\text{-}C_5H_5)$ (0.999 g, 1.38 mmol) and $P(OMe)_3$ (0.18 cm^3, 1.5 mmol) in 50 cm^3 of toluene was heated at reflux for 12 h. The resulting red–orange solution was allowed to cool and then concentrated to a volume of about 2 cm^3 on a rotary evaporator. Chromatography of the red oily substance was performed on an alumina column packed with CH_2Cl_2; a single orange band eluted with this solvent. After evaporation of solvent the material was dissolved in about 3 cm^3 of CH_2Cl_2; addition of 20 cm^3 of hexane caused the product to precipitate as orange crystals, m.p. 180–181°C (0.44 g, 55%).

Found: C, 52.69; H, 5.02. $C_{26}H_{29}ClO_3P_2Ru$ requires: C, 53.1; H, 4.97%. ^1H NMR ($CDCl_3$): 3.45 d, J(P—H) = 11 Hz, $P(OMe)_3$; 4.46 s, C_5H_5; 7.30 m, 9H and 7.57 m, 6H, PPh_3.

Synthesis of $Ru(SPh)(PPh_3)\{P(OMe)_3\}(\eta\text{-}C_5H_5)$

A solution of n-Bu_3SnSPh (0.15 cm^3, 0.42 mmol) and $RuCl(PPh_3)\{P(OMe)_3\}(\eta\text{-}C_5H_5)$ (0.192 g, 0.327 mmol) in 15 cm^3 of methanol was heated at reflux for 4 h. After being allowed to cool, the solvent was removed *in vacuo* to give an oily residue. This was chromatographed on an alumina column packed with acetone; acetone eluted a small colourless fraction containing the tin compound followed by a second orange fraction. The latter was concentrated to about 2 cm^3 and 20 cm^3 of hexane was layered on the top of this concentrated solution. On cooling the solution overnight at −25°C, the product precipitated as orange crystals, m.p. 161–163°C (0.134 g, 62%).

Found: C, 57.39; H, 5.34. $C_{32}H_{34}O_3P_2RuS$ requires: C, 58.1; H, 5.20%. ^1H NMR ($CDCl_3$): 3.34 d, J = 10 Hz, $P(OMe)_3$; 4.59 s, C_5H_5; 6.71 t, 1H, 6.90 t, 2H, 7.31 m, 9H, and 7.49 m, 8H, SPh and PPh_3.

Synthesis of $Ru_2\{P(OMe)_3\}_2(\eta\text{-}C_5H_5)_2S_x$ (x = 4, 6)

A three-necked flask with a water cooled condenser and magnetic stirring was charged with $Ru(SPh)(PPh_3)\{P(OMe)_3\}(\eta\text{-}C_5H_5)$ (0.436 g, 0.659 mmol), S_8 (0.51 g, 0.20 mmol) and 25 cm^3 of CH_3CN. The mixture was heated at reflux for 50 min, changing from red to blue during this time. After being allowed to cool, the solution was evaporated to dryness using a rotary evaporator. The black residue was extracted with CH_2Cl_2 until the extraction no longer gave blue solutions. The residue was dissolved in $CHCl_3$ and this solution was filtered. Slow evaporation of the solvent gave crystals of $Ru_2\{P(OMe)_3\}_2(\eta\text{-}C_5H_5)_2S_4$ as black platelets that did not melt up to 300°C (0.071 g, 31%).

^1H NMR ($CDCl_3$): 3.65 d, J = 11.8 Hz, $P(OMe)_3$; 4.40 s, C_5H_5. UV–vis ($CDCl_3$): λ(max) = 525 nm, ε = 6600.

The CH_2Cl_2 extracts from above were concentrated and then placed on an alumina chromatographic column packed with CH_2Cl_2. Elution with this solvent gave a colourless solution which on evaporation yielded a mixture of PhSSPh and S=PPh_3. Further elution using 5% acetone/95% CH_2Cl_2 eluted a blue band followed closely by a smaller purple band. The second band was shown to contain $Ru_2\{P(OMe)_3\}_2(\eta\text{-}C_5H_5)_2S_4$, isolated earlier. The blue band was collected and the solvent removed by evaporation *in vacuo*. The sticky residue was dissolved in a minimal quantity of CH_2Cl_2 and hexane was added. On standing, the second product, $Ru_2\{P(OMe)_3\}_2(\eta\text{-}C_5H_5)_2S_6$, crystallized as a black powder that did not melt up to 300°C (0.020 g, 8%).

^1H NMR ($CDCl_3$): 3.50 d, J = 11.9 Hz, $P(OMe)_3$; 4.95 s, C_5H_5. UV–vis ($CHCl_3$): λ(max) = 587 nm, ε = 4700.

Various other procedures for synthesis and separation were attempted; the procedure described here seemed to work the best.

Reaction of $Ru_2\{P(OMe)_3\}_2(\eta\text{-}C_5H_5)_2S_6$ *and* PPh_3

Equimolar samples of these reagents were placed in an NMR tube and C_6D_6 was distilled into the tube under vacuum. After the solution had warmed to room temperature and the solids were dissolved, the NMR tube was maintained at room temperature while ^1H NMR spectra were run period-

ically. Over several hours, new resonances associated with $Ru_2\{P(OMe)_3\}_2(\eta\text{-}C_5H_5)_2S_4$ were seen to grow into the spectrum while resonances for the starting material diminished accordingly. No cyclopentadienyl resonances indicating possible intermediates were seen and the product appeared to undergo no further reaction; this latter fact was confirmed by a similar study with a known sample of that species.

It was quite easy to obtain a clean sample of **I** from reaction mixtures by making use of this reaction to convert crude mixtures of **I** and **II** to this species.

X-ray diffraction study of $Ru_2\{P(OMe)_3\}_2(\eta\text{-}C_5H_5)_2S_6$ **(II)**

A dark blue crystal suitable for X-ray diffraction was grown by vapour diffusion of hexane into a 1 : 1 CH_2Cl_2–acetone solution of this compound at ambient temperature. Two crystal morphologies, feathery needles and parallelepipeds, were observed, a crystal of the latter being used for this study. Data (12,493 reflections, with 11,355 having $F_o > 3\sigma F_o$) were collected with a Syntex P3/F diffractometer and corrected for Lorentz and polarization factors.

Crystal data. $C_{16}H_{28}O_6P_2Ru_2S_6$, $M = 773$, triclinic, $a = 13.923(3)$, $b = 17.488(3)$, $c = 12.779(2)$ Å; $\alpha = 107.62(1)$, $\beta = 93.27(2)$, $\gamma = 93.27(1)°$, $U = 2719.1(2)$ Å^3, $Z = 4$, $D_c = 1.89$ g cm^{-3}, space group $P\bar{1}$, Mo-K X-radiation 0.71069 Å, graphite monochromator, $\mu = 16.80$ cm^{-1}.

The solution of the structure and subsequent refinement were carried out by heavy atom and differential Fourier methods. Interestingly, there were two independent molecules with opposite chirality in the unit cell; except for small differences in the orientation of the phosphite ligand these were mirror images (Fig. 2 shows only one of these molecules.) Anisotropic thermal parameters were used for all non-hydrogen atoms and hydrogen atoms were inserted in standard positions. Final refinement was by least-squares methods minimizing $w(F_o - F_c)^2$ in cascaded large blocks using appropriate atomic scattering factors* [17] to a final R value of 0.0633 ($R_w = 0.0867$).

X-ray diffraction study of $Ru_2\{P(OMe)_3\}_2(\eta\text{-}C_5H_5)_2S_4$ **(I)**

Dark blue crystals suitable for X-ray diffraction were grown by vapour diffusion of hexane into a chloroform solution of this compound. Data collection at −167°C yielded 3558 reflections with 3396 having $F_o > 3\sigma F_o$. Data collection and the solution and refinement of the structure were carried out with procedures described above.* Since the molecule was centrosymmetric, only half of the molecule was refined and the other half was generated by projection through the centre of symmetry. In the figure, these atoms are denoted by the symbol (+).

Crystal data. $C_{16}H_{28}O_6P_2Ru_2S_4$, $M = 708.7$, triclinic, $a = 7.636(2)$, $b = 7.644(1)$, $c = 11.001(1)$ Å, $\alpha = 84.37(1)$, $\beta = 77.20(1)$, $\gamma = 73.38(1)°$, $U = 599.6$ Å^3, $Z = 1$, $D_c = 1.96$ g cm^{-3}, space group $P\bar{1}$, Mo-K X-radiation, 0.71069 Å, graphite monochromator, $\mu = 17.33$ cm^{-1}.

Refinement of the structure was carried out to a final R value of 0.0227 ($R_w = 0.0371$).

*Atomic positional parameters, complete tables of bond lengths and angles, and structure factor tables have been deposited as supplementary material with the Editor. Atomic coordinates have also been submitted to the Cambridge Crystallographic Data Centre.

THE KAGOMÉ NET: BAND THEORETICAL AND TOPOLOGICAL ASPECTS*

ROY L. JOHNSTON† and ROALD HOFFMANN‡

Department of Chemistry and Materials Science Center, Cornell University, Ithaca, NY 14853, U.S.A.

Abstract—The Kagomé net (a two-dimensional hexagonal network comprising triangles and hexagons) is a building block of a number of intermetallic compounds. In order to understand the electronic characteristics of such an array of atoms, extended Hückel tight binding calculations have been performed on a Kagomé net of boron atoms. Comparisons have been drawn with other hexagonal nets, namely the graphite net and the close packed triangular net, and topological relationships between these nets are used to explain similarities in their band spectra. It is shown that simple Hückel theory can be used to obtain a rough estimate for the energies of the bands at specific high symmetry *k*-points, and a way of representing and evaluating energies of crystal orbitals with complex coefficients is discussed. A moments-based analysis of the relative energies of the three nets as a function of electron count is also presented. The effect on its band structure of trigonally distorting the Kagomé net is investigated. Finally, substituted ABC and AB_2 derivatives of the Kagomé net are discussed.

A particularly useful way of describing complex solids is via a conceptual decomposition of the structure into layers and nets.[1] This paper deals with a planar net (the so-called Kagomé net)[1a] which is found in a number of complex intermetallic compounds, most notably the Laves phases ($MgCu_2$, $MgZn_2$ and $MgNi_2$ types).[2] The Laves phases, which possess interesting electronic and magnetic properties[3] as well as being of great interest from a structural point of view,[2a,4] are the subject of a separate publication.[5]

The Kagomé net (**1**) is four-connected (each vertex has four neighbours) and is described by the indices (3636), meaning that if we start counting the rings around any vertex from one of the triangles we encounter in order (independent of the direction of motion) a triangle followed by a hexagon, then another triangle and finally another hexagon.[1a] It is a hexagonal net, belonging to the plane group *p6mm*.[6] The dashed line in **1** denotes the primitive unit cell of the net.

More familiar two-dimensional hexagonal nets are the graphitic (6^3) net (**2**), and the triangular or close packed (3^6) net (**3**).

3

In the following sections we shall investigate the electronic band spectrum characteristic of a Kagomé net of main group atoms (boron), making comparisons with alternative graphitic and close packed layer structures. Calculations of the extended Hückel[7a] tight binding [7b,c] type were performed. Standard parameters for boron were chosen ($H_{ii}(2s) = -15.2$ eV, $H_{ii}(2p) = -8.5$ eV, $\zeta(2s) = \zeta(2p) = 1.30$).[7d] Average properties were

4

calculated using the irreducible wedge of the Brillouin zone shown in **4** (hashed area), with *k*-points chosen according to the geometrical method of Ramirez and Böhm.[7e]

While there are hundreds of Laves phases, only one of them contains boron. Many more do contain aluminium. And there is no phase in which the Kagomé net forms a separate bonded entity (we are using here the words of a perceptive reviewer of this paper). Why then study this net, for a main group element that does not form it?

The reason is that the net is simple and symmetrical. Stackings of it are plausible. It deserves to be studied; the question, one which will be approached in this paper, is why does it not occur, or, optimistically, what electron counts might favour its materialization.

COMPARISON OF THE BAND STRUCTURES OF KAGOMÉ, GRAPHITIC AND CLOSE PACKED NETS OF BORON ATOMS

In the solid state, boron is known to form icosahedral clusters which are bonded together in a three-dimensional lattice.[8] The connectivity of the boron atoms is six. This should be contrasted with the three-dimensional allotropes of carbon (e.g. diamond) where the carbon atoms are four-connected. It is also well known that boron forms molecular clusters with atom connectivities of five or more,[9] while carbon maintains an approximately tetrahedral local environment.[10] Electron-deficient atoms such as boron (with fewer electrons than valence orbitals) adopt highly-connected structures (with more nearest neighbours than valence orbitals) because such structures are known to stabilize the small number of occupied orbitals to a greater extent.[11] If this idea of increasing connectivity in order to mitigate electron deficiency is carried over into two-dimensions (think of three-connected layers of carbon atoms in graphite) then a layer structure based on Kagomé or close packed nets of boron atoms becomes an interesting possibility. We do not imply that two-dimensional elemental boron nets are likely—boron clearly likes icosahedra. But perhaps formally charged boron sheets of this type might occur in binary AB_x structures.

If we assume constant distances between connected vertices (bearing in mind that for nets of atoms the bond lengths generally increase with connectivity) then the relative densities of the three hexagonal nets (**1–3**) discussed above increase in the order graphite (1.0) < Kagomé (1.125) < close packed (1.5). Figure 1 depicts the partial band structures for nets of boron atoms (with B—B bonds of 1.8 Å) with these structures. Unit cells were chosen with one (close packed), two (graphite) and three (Kagomé) atoms (see **1–3**).

The Brillouin zone (BZ) has the same symmetry for all three nets (see **4**). Rather than using the plane group *p6mm*, it is convenient to assign these structures to the three-dimensional space group *P6mmm* (D^1_{6h}),[6] since the horizontal mirror plane is a good

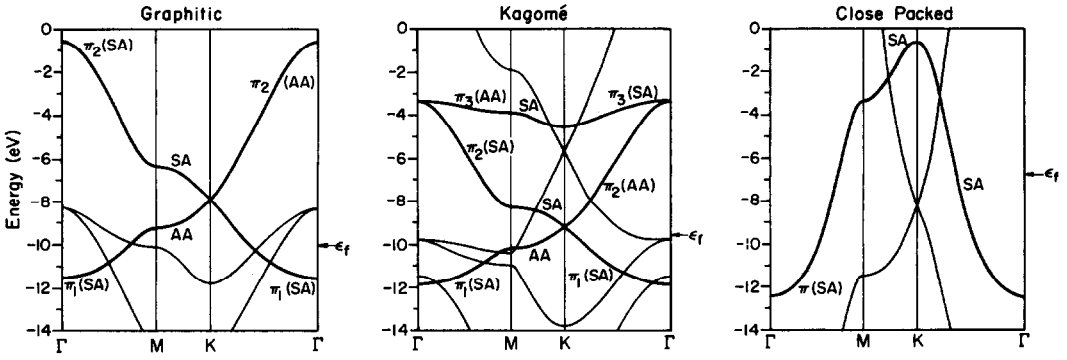

Fig. 1. Band structures of boron with the graphite, Kagomé and close packed (2-d) structures. The π-bands are highlighted and their symmetries with respect to vertical and horizontal mirror planes are indicated.

symmetry element, distinguishing between σ- and π-bands. The symmetries of the special points in the BZ (**4**) (i.e. the "group of k", G_k) for the space group *P6mmm* are as follows: $G_\Gamma = D_{6h}$; $G_M = D_{2h}$; $G_K = D_{3h}$, while the symmetries of the symmetry lines in the BZ are: $G_\Sigma = G_T = G_\Lambda = C_{2v}$.[12] We expect, therefore, to observe degeneracies at Γ and K, but not M. This is indeed the case, as can be seen in Fig. 1. We are only here interested in the π-bands. The labels of the bands (SA and AA) refer to the symmetries of the π bands (S = symmetric, A = antisymmetric) with respect to the two mirror planes containing each of the specified symmetry lines (where the first refers to the vertical plane and the second to the horizontal plane).

From the Figure, it is evident that, for boron, with three valence electrons per atom, all three structures are metallic due to overlap of the σ- and π-bands (the latter have been highlighted). Other interesting features of Fig. 1 include, for Kagomé boron [Fig. 1(b)], the small dispersion of the top π-band (π_3), the non-bonding nature of the middle π-band (π_2) at M (the energy of the atomic boron $2p$ orbitals is -8.5 eV) and the non-bonding nature of the degenerate π-bands at K in the graphite structure [Fig. 1(a)]. We shall endeavour to explain these features in the following paragraphs.

Each of these three planar sheet geometries presents interesting features, which are more or less familiar. The graphite network is best known, the Kagomé net least known. So we will concentrate on the latter.

The π-symmetry crystal orbitals of Kagomé boron (at the high symmetry points Γ, M and K) are sketched in Fig. 2, where the constituent atomic p-orbitals are shown in projection). To understand the figure, however, it will first be necessary to talk a little about the shading conventions used and the problem of the phase angle.

COMPLEX CRYSTAL ORBITALS: PHASE ANGLES AND OVERLAP

We are used to discussing bonding in terms of linear combinations of real atomic orbital functions. In the case of a simple diatomic, such as H_2, the orbital overlap (as a function of internuclear separation, r) is equal to $\pm S(r)$. The overlap is positive (stabilizing) when the orbitals are "in-phase" (**5a**) and negative (destabilizing) when the

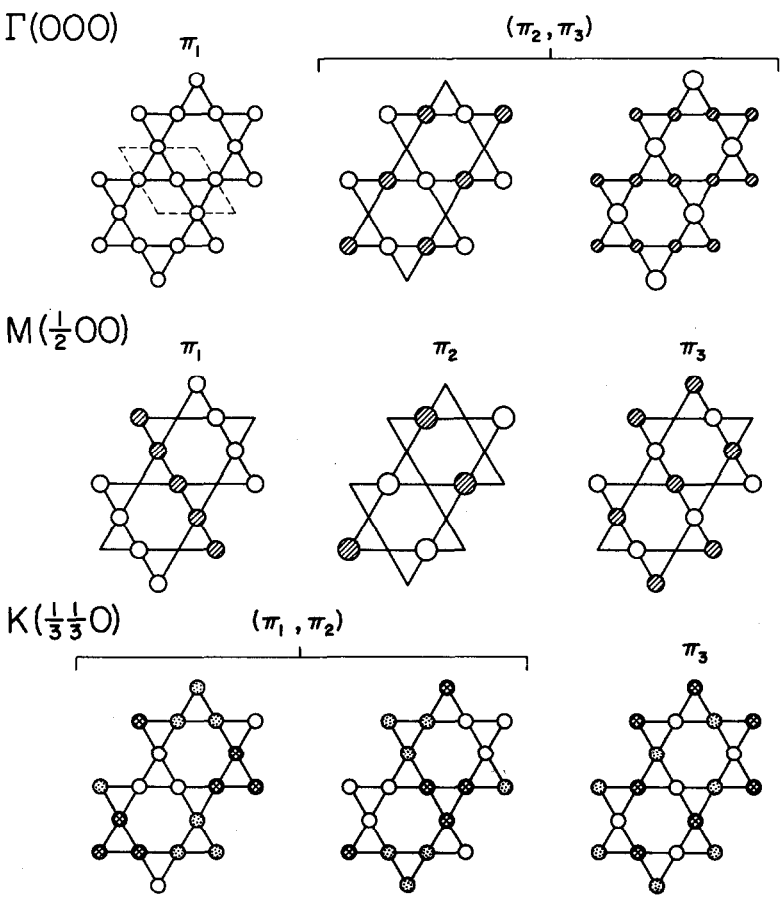

Fig. 2. Representation of the crystal orbitals of Kagomé boron at points Γ, M and K in the BZ.

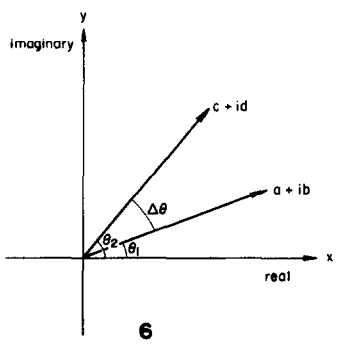
5a 5b

orbitals are "out-of-phase" (**5b**). In the solid state, however, in most regions of the BZ (including some high symmetry points, such as K in the space group $P6mmm$) the crystal orbitals have coefficients which are complex (of the form $a+ib$, where $i=\sqrt{-1}$) rather than real. By depicting the coefficients of orbitals on neighbouring atoms as vectors on an Argand diagram we can calculate the angles made between these vectors and the (real) positive x-axis. These angles are the absolute "phase angles" (θ) of the orbital. However, in order to determine the size and sign of the overlap between neighbouring orbitals, it is the difference in "phase angle" ($\Delta\theta$) which is important. These concepts are illustrated in **6**, for an example where the coefficients have the same magnitude (i.e. the vectors have the same length, $a^2+b^2=c^2+d^2$).



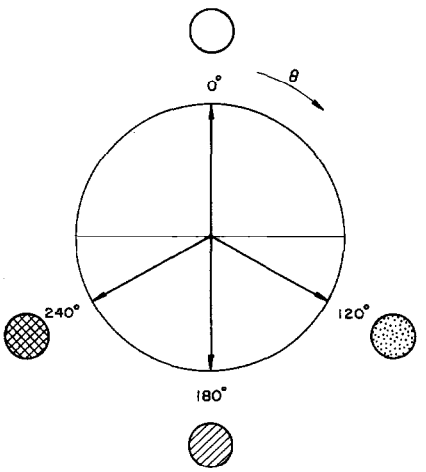
6

As a convention, we generally make one of the coefficients arbitrarily positive and real (i.e. lying along the positive x-axis of the Argand diagram), since only the relative phase angles (i.e. the differences) are important. Classical "in-phase" and "out-of-phase" combinations have phase angle differences ($\Delta\theta$) of 0 and 180°, respectively. The general expression for overlap between a pair of orbitals at separation r, with a phase angle difference of $\Delta\theta°$ between them, is:

$$S_{\Delta\theta}(r) = S_0(r)\cdot\cos(\Delta\theta),$$

where $S_0(r)$ is the overlap integral for $\Delta\theta = 0°$. From this formula, it can readily be seen that, when a pair of complex orbitals are orthogonal ($\Delta\theta = \pm 90°$) the overlap between them is zero.

The crystal orbitals in Fig. 2 have atomic orbital contributions related by factors $e^{2\pi i/3}$, $e^{\pi i}$, $e^{4\pi i/3}$, $e^{2\pi i}$, i.e. relative phase angles of 120, 180, 240 and 360° (≡0°). The shading conventions used to represent these phase angles are shown in **7**. The $\Delta\theta$



7

values which are present in the crystal orbitals shown in Fig. 2 are: 0 and 180° at Γ and M; and 0, 120 and 240° (−120°) at K. The corresponding overlaps are as follows:

S_0 ("in-phase") at a constant (arbitrary) separation

$S_{180} = -S_0$ ("out-of-phase")

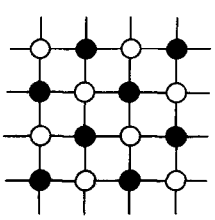
$S_{120} = S_{240} = -0.5S_0$ ("half-out-of-phase").

The ideas developed above can be extended from the calculations of the overlap between complex orbitals to an estimation of their energies by means of simple Hückel theory.[13] Thus, the Hückel resonance energy (β) can be given a phase angle (difference) dependence:

$$\beta_{\Delta\theta} = \beta_0\cdot\cos(\Delta\theta)$$

while the Coulomb energy (α) is independent of phase angle.

It should be noted that the three orbital shadings shown in the representations of the crystal orbitals at K are equally out-of-phase (or in-phase) with respect to each other. This has an important effect which is related to the theory of alternancy.[14] An alternant (two- or three-dimensional) network or graph is one in which all rings or cycles (connected subgraphs) are even-membered. These networks (such as the square lattice shown in **8**) have the

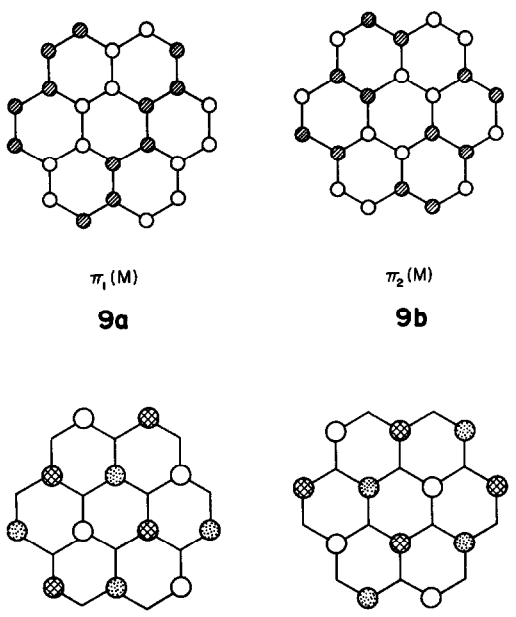


8

property that the vertices can be coloured in one of two ways such that no two adjacent vertices are coloured the same. In terms of atomic lattices, this means that there is always one crystal orbital in which all of the nearest-neighbour interactions are antibonding ($\Delta\theta = 180°$).[15] If we have three different colours (or types of shading) we can extend this principle to (some) systems containing odd-membered rings, such as the Kagomé net, which we shall describe as three-alternant. In three-alternant atomic lattices there will always be a crystal orbital (e.g. π_3 at K in the Kagomé net) in which all nearest-neighbour interactions are equally antibonding, though the phase angle difference ($\Delta\theta$) is now $\pm 120°$.

The small dispersion of the π_3-band in Kagomé boron [Fig. 1(b)] can be explained by examining the crystal orbitals in Fig. 2. At M the π_3-orbital is antibonding along chains of connected boron atoms. In a simple Hückel sense,[13] the energy of this band would be $\alpha-2\beta$. At Γ the π_3-orbital is one of a degenerate pair, one component of which can also be represented as antibonding chains of borons, with a Hückel energy of $\alpha-2\beta$. The energies of the bands in our extended Hückel calculation (and in reality) depart from the simple Hückel model through the inclusion of small non-nearest-neighbour interactions. The next-nearest-neighbour interactions at M are overall bonding while those at Γ are net antibonding, so the π_3-band lies at lower energy at M than the π_2/π_3 pair at Γ [see Fig. 1(b)]. At point K in the BZ, as mentioned above, the π_3-band describes a three-alternant pattern. In simple Hückel terms the energy of this crystal orbital would be $\alpha+4(-0.5\beta) = \alpha-2\beta$, once more. This time the next-nearest-neighbour interactions are more bonding (each atomic orbital has four next-nearest-neighbour orbitals which are in-phase) than at Γ or M, so the π_3-band shows a minimum at K. Thus, the bonding character of the π_3-band changes very little throughout the BZ. In the density of states (DOS) diagram for this net (not shown here), the flat π_3-band leads to a sharp spike. Because this band is so high above any realistic Fermi level, it is unlikely to have any consequence.

The π_2-band in the Kagomé structure is interesting in that it is antibonding at Γ (where it is degenerate with π_3), non-bonding at M (Hückel energy $= \alpha$), as there are no non-zero coefficients on adjacent sites and bonding at K, where it is degenerate with π_1 (Hückel energy $= \alpha+2\beta+2(-0.5\beta) = \alpha+\beta$). From Fig. 1 it can be seen that the π_1-band of graphite at M lies at almost exactly the same energy as the Kagomé π_2-band at K. Indeed the Hückel energy of this orbital (**9a**) is also $\alpha+\beta$. Incidentally, the upper π-band (π_2) of graphite at M (**9b**) is antibonding by the same amount (Hückel energy $= \alpha-\beta$) as π_1 is bonding.[16] As for the Kagomé π_2-band at M, the non-bonding nature of the two degenerate π-bands at K for the graphite structure [Fig. 1(c)] can also be rationalized in terms of complex linear combinations which have nodes at every second atom (**9c**).



9a **9b** **9c**

From Fig. 1 (a and b), it is apparent that the π_1- and π_2-bands of the Kagomé net exhibit the same pattern as the two π-bands of the graphite net. Figure 3 shows the spectra of crystal orbitals at Γ, M and K for the two structures, with simple Hückel energies given, together with the spectrum of π-MO's obtained for the unit cell contents. It can be seen that at all the high symmetry points of the BZ the Kagomé π_1- and π_2-orbitals are stabilized with respect to those of graphite by β. The reason for this similarity can be traced to the topological relationship which exists between the two nets. Thus, the loci of the centroids of the triangles in the Kagomé net define the graphite net (similarly the centroids of the Kagomé hexagons define the close packed triangular net). The degenerate π-bands of graphite at K (**9c**) can be generated from those of the Kagomé net (Fig. 2) by replacing a triangle (in which all the atomic orbital contributions are in-phase) by a single atomic orbital, with the same phase. Triangles where there are three out-of-phase ($\Delta\theta = 120°$) coefficients are replaced by single atoms with zero atomic orbital coefficients (i.e. nodes).

The single π-band in the close packed structure [Fig. 1(c)] is highly dispersed, due to the high connectivity (six) of the lattice. The minimum energy

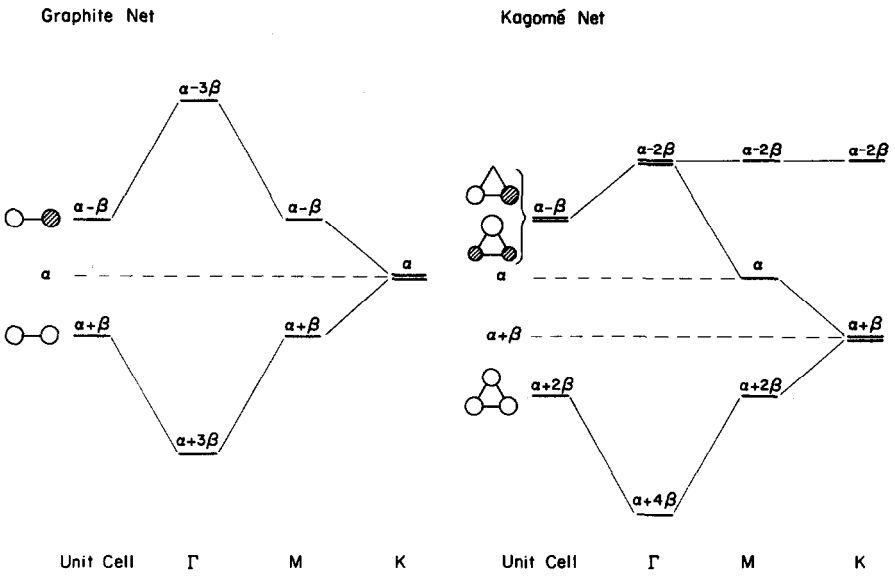


Fig. 3. Comparison of the spectra of crystal orbitals at the high symmetry BZ points for the graphite and Kagomé structures.

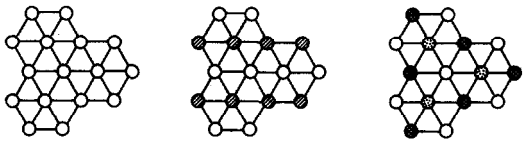
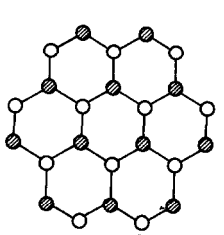


10a **10b** **10c**

occurs at Γ, where each atom experiences a bonding interaction with its six nearest neighbours (**10a**). At *M*, the π-band (**10b**) has a simple Hückel energy of $\alpha-2\beta$ and, indeed from Fig. 1 it can be seen that the energy of the π-band at *M* is close to that of the π_3-band of the Kagomé structure. At *K*, the π-band of the close packed structure has complex coefficients, again with phase angle differences of 0 and $\pm 120°$, and the crystal orbital may once more be represented by a three-alternant colouring (**10c**). The simple Hückel energy of the crystal orbital depicted in **10c** is $\alpha+6(-0.5\beta)=\alpha-3\beta$, which is the same energy as that of the π_2-band of graphite at Γ (**11**), where the connectivity is only three but the neighbouring orbitals are completely (180°) out-of-phase (since graphite is an alternant net).



11

Of the two-dimensional structures studied for boron, the graphitic structure is calculated to be the most stable (by 0.47 eV/atom over Kagomé boron and by 1.46 eV/atom over the close packed layer structure). This order of relative stability is also reflected in the Fermi energies: −9.89 eV (graphitic); −9.53 eV (Kagomé); −6.73 eV (close packed), as well as in the B—B Mulliken reduced overlap populations,[17] which decrease with increasing connectivity: 0.84 (graphitic, three-connected); 0.67 (Kagomé, four-connected); 0.48 (close packed, six-connected).

As they have odd numbers of electrons in their unit cells, the Kagomé and close packed boron structures would be paramagnetic. In the case of Kagomé boron, a more likely structure would be composed of anionic $(B_3^-)_n$ sheets with intercalated alkali metal cations, leading to metallic solids with the composition MB_3.

COMPARISON OF THE RELATIVE STABILITIES OF THE GRAPHITE, KAGOMÉ AND CLOSE PACKED STRUCTURES BY THE MOMENTS METHOD

The moments method[18] has been applied to Hückel-based tight binding theory very successfully by Burdett and Lee, to establish relationships between geometric and electronic structures in a variety of solids.[19] The application of the moments method to the construction of the DOS of a given structure and to the calculation of the difference in

energy between two topologically distinct structures has proved particularly useful.

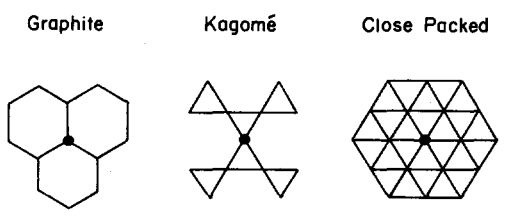
In mathematical terms, the nth moment is defined as the trace of the Hückel hamiltonian matrix (**H**) to the nth power:[18]

$$Tr(\mathbf{H})^n = \Sigma_i E_i^n$$

where the summation is over all the eigenvalues (E_i) generated by **H**. In geometric terms, the nth moment (μ_n) is equivalent to the weighted sum over all closed paths of length n amongst all the orbitals of the system.[19] Moments can also be split into σ and π components if the topology of the solid permits such separation, as in, for example planar nets.

Clusters containing all walks of length 2, 3 and 4 for the graphite, Kagomé and close packed nets are depicted in Fig. 4, together with the calculated π-only 2nd, 3rd and 4th moments. Burdett and Lee have stated that the same qualitative trends are seen for $\sigma+\pi$ occupation as for π alone, except at very low and very high orbital occupations where σ-orbitals alone are being filled. A moments-based comparison of the energies of these three nets as a function of electron count is complicated by the fact that the connectivities are different. This leads directly to the calculated differences in μ_2. One-electron models can lead to wrong conclusions by overestimating the μ_2's, thereby leading to the (incorrect) prediction that the highest-coordinate net is the most stable at all electron counts.

In the cases of the Kagomé and close packed nets, there are a large number of three-rings and the inherent instability of the three-rings at high electron counts (due to the nature of μ_3) can overcome the discrepancy in μ_2 and thus give a qualitatively correct difference curve. The large difference in μ_3 for all three structures leads to the prediction of a



μ_2^π	$3\beta^2$	$4\beta^2$	$6\beta^2$
μ_3^π	0	$4\beta^3$	$12\beta^3$
μ_4^π	$15\beta^4$	$28\beta^4$	$90\beta^4$

Fig. 4. Clusters used to evaluate the 2nd, 3rd and 4th moments of the graphite, Kagomé and closed packed structures.

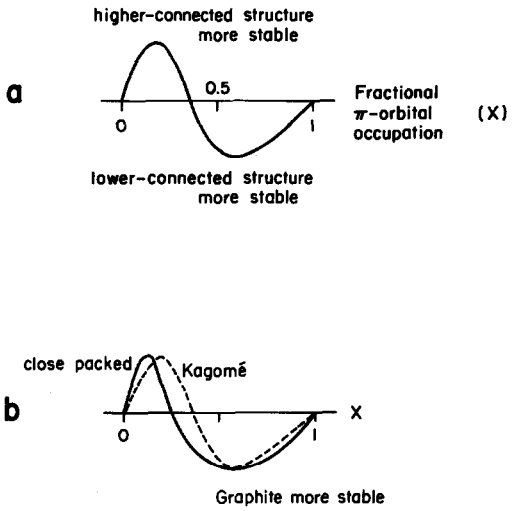


Fig. 5. Qualitative difference in energy curves as a function of the fractional occupation of the π-orbitals: (a) comparing any two of the three planar structures; (b) comparing all three structures together.

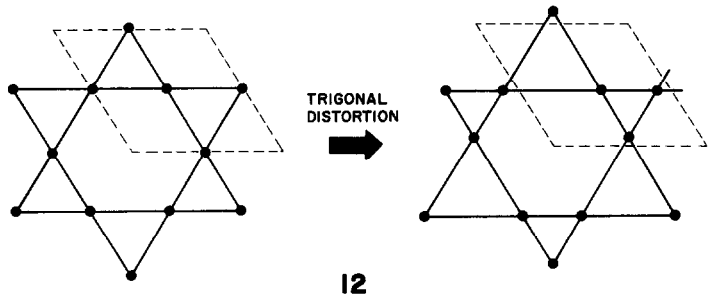
double peaked ΔE curve [see Fig. 5(a)] for graphite/Kagomé, Kagomé/close packed and close packed/graphite comparisons, with the more highly connected structure more stable until a certain band filling below the half-filled mark after which the less highly connected structure is more stable. Taken together, the close packed structure will be the most stable at very low counts, followed by the Kagomé structure and finally the graphite net is most stable, as shown schematically in Fig. 5(b). The stability of graphite for the half-filled shell is not surprising, since this is the situation for carbon. The large differences in μ_4 for the three structures may lead to extra nodes in the ΔE curves or may just create ripples on the μ_3 curve. As mentioned above, the differences in μ_2 will extend the range of stability of the more highly connected Kagomé and (especially) close packed structures to somewhat higher electron counts.

ELECTRONIC STRUCTURE OF A TRIGONALLY DISTORTED KAGOMÉ NET

In the hexagonal Laves phases ($MgZn_2$ type) the Kagomé nets of atoms (e.g. Zn) are often distorted such that the triangles alternate in size, as shown in **12**.[20] Such distortions are due to the capping of every second triangle above and below the Kagomé plane by zinc atoms, so that the capped triangles expand and the uncapped ones contract. It was decided to establish the effect of such a distortion on the π-bands of the boron Kagomé net.



12

The B—B distances in the distorted Kagomé net are 1.70 and 1.90 Å, respectively. Since the average is 1.80 Å, the unit cell is the same size as in the undistorted case. The partial (π-only) band diagram for distorted Kagomé boron is shown in Fig. 6. The distorted Kagomé net possesses the same Bravais lattice as the undistorted net so the BZ has the same shape (**4**), though, as will be discussed below the symmetries of the special k points are different.

Comparing Fig. 6 with Fig. 1(b) reveals one very noticeable feature, namely that the lowest π-bands at $K(\pi_1/\pi_2)$ are no longer degenerate in the distorted structure (the splitting is approximately 1 eV for the distortion indicated above). In the following paragraphs, this loss of degeneracy will be rationalized using two different, though related explanations. The first makes use of symmetry arguments while the second, more empirical but more apparent explanation, uses simple ideas related to the changing of bonding and antibonding interactions as the structure is distorted.

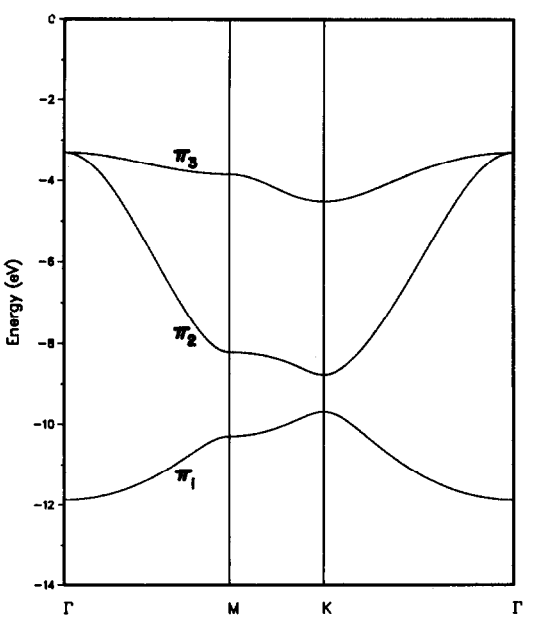


Fig. 6. π-Band diagram for boron with the trigonally distorted Kagomé structure.

The distorted Kagomé structure no longer has a six-fold axis and belongs to the plane group $p3m1$. If we include the horizontal mirror plane the distorted Kagomé net belongs to the three-dimensional space group $P\bar{6}m2$ (D^1_{3h}).[6] The symmetries of the special points in the BZ are as follows: $G_\Gamma = D_{3h}$; $G_M = C_{2v}$; $G_K = C_{3h}$ (the symmetries of the symmetry lines are: $G_\Sigma = C_{2v}$; $G_T = G_\Lambda = C_s$).[12] Thus, we expect to see some degenerate bands at Γ, but not at M. The point K is less straightforward, however. Although the point group C_{3h} does have degenerate representations (e' and e''), these representations are complex. The effect of this is that there are no degeneracies at K, but rather those bands of e' or e'' symmetry at K have their degenerate counterparts at $-K$. The character of the two components of the e (i.e. e' or e'') representations with respect to the three-fold rotation axis are ε and ε^*, where $\varepsilon = \exp(2\pi i/3)$ and, therefore $\varepsilon^* = \exp(-2\pi i/3)$. These represent phase angle changes upon C_3 rotation of 120 and 240° (−120°), respectively. Such a reversal does in fact occur as a consequence of time inversion (which is what interrelates $\pm K$).

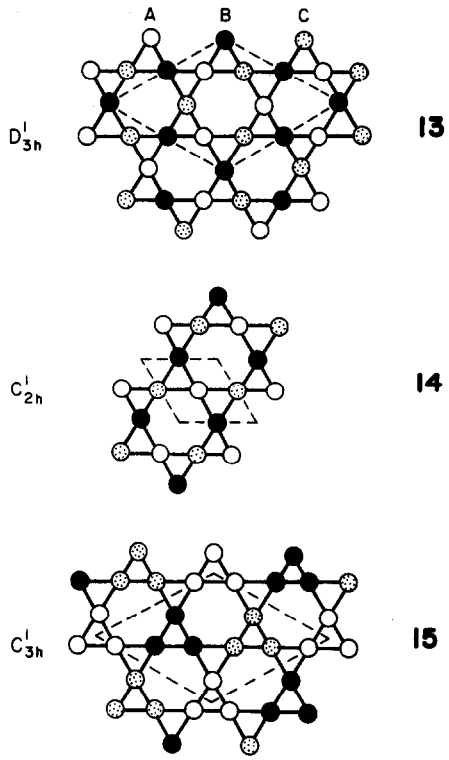
The same lowering of symmetry and consequent loss of degeneracy at K is observed on going from graphite ($P6mmm$) to the boron nitride net ($P\bar{6}m2$) by replacing alternating carbons in the graphite structure by boron and nitrogen atoms.[21] As mentioned earlier, the Kagomé lattice is topologically related to that of graphite by the fact that the centroids of the triangles in the Kagomé net define the vertices of the graphite net. Thus the distorted Kagomé net, where alternate triangles are distinguishable, is topologically (and symmetry) related to the boron nitride structure. The loss of degeneracy between π_1 and π_2 at K on going from graphite to boron nitride can simply be explained by looking at the functional form of the crystal orbitals at this point. As shown in **9c**, π_1 and π_2 can be expressed as crystal orbitals with non-zero coefficients on either the starred or the unstarred (but not both) sets of atoms of the alternant graphite net. (The terms starred and unstarred refer to the convention of labelling every second atom of an alternant hydro-

carbon with a star, so that no two starred atoms are bonded.)[14] Upon substituting the carbon atoms by borons at the starred positions and by nitrogens at the unstarred positions the Hückel energies of the π-orbitals are simply α(B) and α(N). There is a loss of degeneracy simply because nitrogen is more electronegative than boron [i.e. α(N) is more negative than α(B)].

A similar analysis can be applied to the distortion of the Kagomé net. The π-symmetry crystal orbitals of the undistorted net, at the point K, are shown in Fig. 7. In this case the lowering in symmetry does not come about due to atom substitution (i.e. the loss of degeneracy is not due to changing α's) but rather arises out of the fact that the bond lengths are no longer constant. The Hückel β's are smaller for the longer bonds. If the central triangles of the crystal orbitals shown in Fig. 7 are contracted and the outer ones expanded, one component (labelled π_a in the figure) rises in energy because the antibonding interactions increase and the bonding ones decrease. The reverse is true for the second component (π_b) which, therefore descends in energy. Thus, the degeneracy is lifted. The π_3 crystal orbital is, however, essentially unaffected by the trigonal distortion because the increased antibonding interactions within the smaller triangles are approximately compensated by the decreased antibonding interactions within the larger triangles. To determine which of these two changes wins out it is necessary to know the change in interaction energy (whether as a Hückel β or some complex function of the overlap integral S) as a function of internuclear separation.

STRUCTURES OBTAINED BY MAKING SUBSTITUTIONS IN THE KAGOMÉ NET

As in the case of the graphite to BN "transformation", the symmetry of the Kagomé net can be lowered by substituting some of the sites.



(i) *ABC substitutions*

In **13–15** are shown three derivatives of the Kagomé net, all with the stoichiometry ABC. The substitution patterns shown in **13** and **14** are three-alternant. The pattern in **13** has D^1_{3h} symmetry (as in BN) as half of the mirror planes of the Kagomé net have been lost, as well as the C_3 axes at the centre of the triangles. In contrast to the graphite/BN case, however, the substitution results in a unit cell which is three times as large as the original (i.e. nine atoms). This means that the loss of degeneracy due to lowering space group symmetry is countered by increased degeneracies due to band folding.[7c] It should be noted that this pattern is that observed for crystal orbital π_3 at K (see Fig. 2).

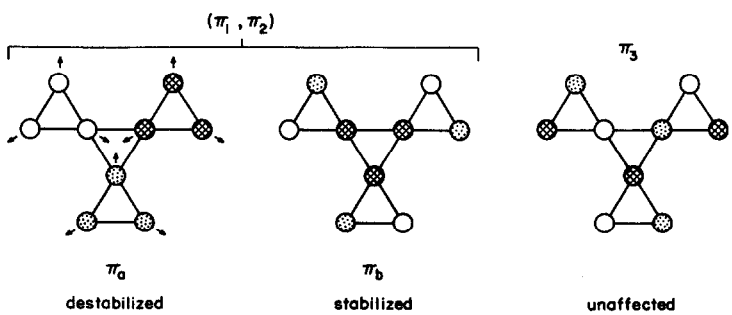


Fig. 7. Representation of the π-bands at K for the Kagomé structure, including the effect of the trigonal distortion (indicated by arrows at left) on their energies.

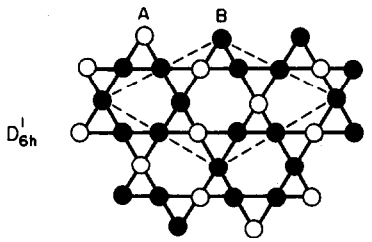
The substitution pattern shown in **14**, while also being three-alternant, is distinct from the first as going along straight lines of atoms in the structure the pattern is –A–B–A–B–A–; –B–C–B–C–B– and –A–C–A–C–A–, rather than –A–B–C–A–B–C– etc. This second pattern has much lower symmetry (C^1_{2h}), possessing C_2 axes (perpendicular to the net) at the atom sites and at the centres of the hexagons, with three atoms in the non-hexagonal unit cell (assuming all bond lengths are unequal). In terms of crystal orbitals, the shading of **14** is equivalent to a complex representation of one of the π_2, π_3 pair at Γ.

The substitution pattern shown in **15** is non-alternant, consisting of A_3, B_3 and C_3 triangles. Even with unequal bond lengths, three-fold symmetry is maintained at the centres of the hexagons and half of the triangles, though all vertical mirror planes and the C_6 axis have been lost. As for the first shading, the unit cell is three times the size of the Kagomé cell. This shading has the same symmetry (C^1_{3h}) as the complex representations of π_1 and π_2 at K (see Fig. 2).

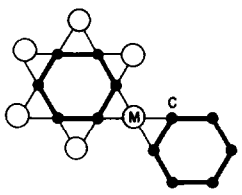
(ii) *AB_2 substitutions*

Replacing atom type C by B in the pattern shown in **13** yields the AB_2 structure shown in **16**. The



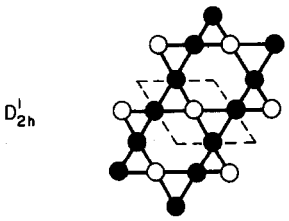
16

symmetry is D^1_{6h} once more, but with a nine-atom (A_3B_6) unit cell. It is intriguing to think of this pattern as representing a possible MC_2 solid, with planar C_6 rings having each edge coordinated to a metal atom (see **17**). The possibility of metal–metal bonding also exists.

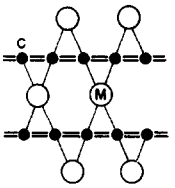


17

A similar substitution in the ABC net of **14** leads to an AB_2 net with parallel chains of B atoms coordinated to A atoms, as shown in **18**. A possible realization of this pattern is the metal–poly-



18



19

cumulene MC_2 structure shown in **19**. The symmetry is once again increased on going from ABC to AB_2, with the generation of vertical mirror planes leading to D^1_{2h} symmetry.

SUMMARY

The electronic band structure characteristic of a Kagomé net of boron atoms has been determined and compared with topologically related graphite and close packed (triangular) nets. The dispersion of the bands in these structures has been rationalized from a simple Hückel viewpoint and a method for determining the interaction between atomic orbitals with complex coefficients has been developed. This, together with an analysis of the topological relationships between the three nets has facilitated their comparison and enabled explanations to be constructed. The application of a moments analysis has shown how the relative stabilities of the three structures may vary with electron count. The symmetry reasons for the loss of band degeneracy at K upon trigonally distorting the Kagomé net, have also been rationalized. Finally, ABC and AB_2 substitution patterns have been presented and the effect of substitution on the symmetries of the net discussed.

THE COORDINATION OF MONO- AND DIPHOSPHINES TO THE SURFACE OF CADMIUM SELENIDE*

CATHERINE J. MURPHY and ARTHUR B. ELLIS†

Department of Chemistry, University of Wisconsin-Madison, Madison, WI 53706, U.S.A.

Abstract—Band edge photoluminescence (PL) of single-crystal *n*-CdSe provides evidence for adduct formation between the solid's surface and various mono- and diphosphines present in toluene solution. Relative to a toluene ambient, solutions of triphenylphosphine (PPh_3), ethyldiphenylphosphine ($PEtPh_2$), bis(diphenylphosphino)methane (dppm) and bis(diphenylphosphino)ethane (dppe) in toluene enhance the semiconductor's PL intensity. For all of the phosphines, the increases in PL intensity can be fit to a dead-layer model, allowing the estimation of the reduction in depletion width resulting from phosphine exposure; reductions in dead-layer widths are about 300–400 Å for all phosphines except $PEtPh_2$, which yields a reduction roughly twice as large. Fits of the PL changes to the Langmuir adsorption isotherm model yield formation constants for the phosphine/CdSe adducts of $30 \pm 7\ M^{-1}$ for PPh_3 and $220 \pm 30\ M^{-1}$ for $PEtPh_2$; the diphosphines, which do not fit this simple model as well, give adsorption equilibrium constants of ~ 100–$200\ M^{-1}$. The results suggest that the diphosphines do not coordinate to the surface in a chelating fashion, but in some combination of bridging and monodentate bonding modes at lower effective surface coverages than the monophosphines.

Semiconductor-derived interfaces continue to be of fundamental and technological significance.[1] We have shown by PL measurements that the surfaces of the II–VI semiconductors CdS and CdSe [CdS(e)] can engage in adduct formation with a variety of Lewis acids and bases.[2–6] These studies have identified a "luminescent litmus test": relative to a reference nitrogen or solvent ambient for gas- and liquid-phase studies, respectively, Lewis bases increase the PL intensity of CdS(e), and Lewis acids decrease it. For Lewis bases, our working hypothesis has been that coordinatively unsaturated surface Cd^{2+} sites serve as the principal binding sites. In the systems studied to date, the surface-bound base (a monoamine, for example) has had a single functionality, making it a simple monodentate ligand.

In principle, other surface coordination modes should be achievable by use of multifunctional Lewis bases. Diphosphines are particularly attractive candidates for study: they are soft bases that should be capable of interacting with soft, acidic Cd^{2+} surface sites, based on the existence of molecular phosphine/Cd^{2+} complexes;[7] they are sterically and electronically tunable; and, based on molecular chemistry, they could exhibit monodentate, bidentate chelate, and bidentate bridging bonding modes, as illustrated for the 0001 face of CdSe in Scheme 1.[8,9]

In this paper, we demonstrate that the mono- and diphosphines whose structures are shown below, viz. PPh_3, $PEtPh_2$, dppm and dppe, form adducts from toluene solution with single-crystal *n*-CdSe surfaces, as revealed by changes in PL intensity. The PL changes can be used to estimate adduct-induced reductions in depletion width as well as equilibrium constants for adduct formation. These results are interpreted in terms of the steric and electronic properties of the phosphines, and suggest that the particular diphosphines of this study function as monodentate or bridging ligands with lower effective surface coverages than the monophosphines.

The smaller circles represent Cd^{2+} sites; the larger circles, Se^{2-} sites. Orientation of the crystallographic *c*-axis is indicated.

EXPERIMENTAL

Materials and methods

Triphenylphosphine (M & T) and bis(diphenylphosphino)ethane (Aldrich) were recrystallized from ether before use. Ethyldiphenylphosphine and bis(diphenylphosphino)methane were obtained from Strem Chemicals and used as received. Toluene was distilled over Na/benzophenone in an inert atmosphere. Stock 0.1 M solutions of each phosphine in toluene were prepared in oven-dried glassware in a dry, N_2-filled glovebag. Single-crystal, vapour-grown *c*-plates ($10 \times 10 \times 1$ mm) of *n*-CdSe with resistivity of $\sim 2\ \Omega$ cm were obtained from Cleveland Crystals, Inc., Cleveland, Ohio. Samples, scored and broken to $\sim 4 \times 4 \times 1$ mm, were etched in 1:30 (v/v) Br_2/MeOH for 5 s (or until the 0001, Cd-rich face was observed), sonicated and rinsed with methanol, and soaked in toluene at least 1 h prior to use. Samples were mounted with Duco cement and black epoxy as previously described.[3]

Apparatus

An all-glass cell was constructed for exposing *n*-CdSe to various solutions under a N_2 atmosphere and static conditions. The mounted crystal was placed in a Teflon adapter that served as a stopper for a 20-mm diameter tube that surrounded the sample. The bottom of the tube was equipped with a Teflon stopcock to drain the cell; during experiments involving repeated drainings, some air may enter the cell. Aliquots of N_2-saturated stock solutions were introduced via syringe through a sidearm equipped with a rubber septum. The entire cell was stored under N_2 when not in use.

Optical measurements

Irradiation sources included a Coherent Innova 90-5 Ar^+ laser (457.9 and 514.5 nm) and a Melles-Griot Model 80 He–Ne laser (632.8 nm). Laser plasma lines were eliminated by passing the beam through Oriel interference filters (fwhm of 10 nm, centred at the laser line). The beams from both lasers were passed through a $10\times$ beam expander and masked to illuminate only the semiconductor surface. Uncorrected, low resolution ($\sim$ 3 nm) PL spectra were obtained with a McPherson Model 270, 0.35-m monochromator, equipped with a grating blazed at 500 nm, and an R928 PMT. Laser excitation was filtered by placing a Corning 2-58 filter at the entrance slit to the emission monochromator. The PL signal was brought to the spectrometer by a 3-mm diameter optical fiber. Spectra were displayed on a Houston Model 2000 *X–Y* recorder. Typically, PL intensity was monitored by setting at the band maximum ($\sim$ 720 nm), with the recorder operated in time-base mode as the solution was varied. The detection optics were positioned between the incident and the reflected light beams.

RESULTS AND DISCUSSION

Upon irradiation with ultra-bandgap light, single-crystal *c*-plates of *n*-CdSe emit red band edge light ($E_g \sim 1.7$ eV; $\lambda_{max} \sim 720$ nm). For this study, the crystal was exposed to toluene solutions of several mono- and diphosphines, viz. PPh_3, $PEtPh_2$, dppm and dppe. The phosphines cause a reversible

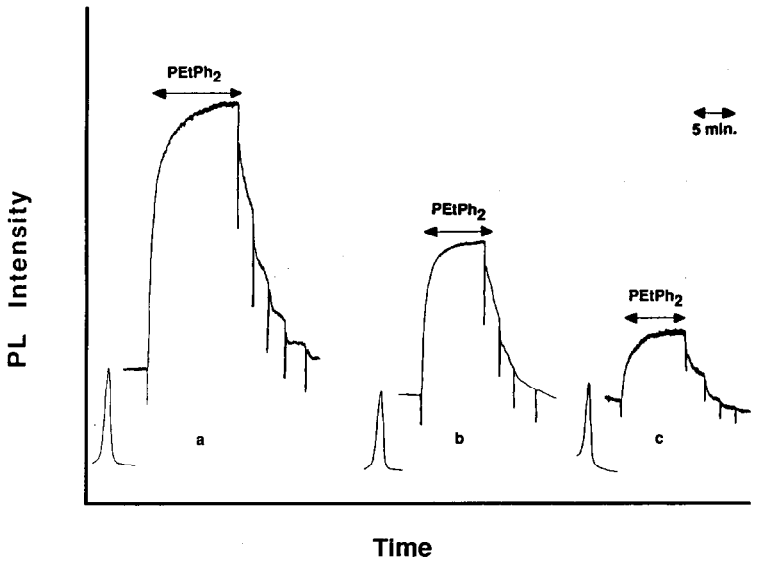

Fig. 1. Temporal changes in PL intensity at 720 nm for a single, etched CdSe crystal, in alternate contact with toluene and 0.1 M $PEtPh_2$ in toluene. Arrows indicate the duration of exposure to $PEtPh_2$. Downward spikes in the intensity are caused by the draining of the cell. Excitation wavelengths were (a) 457.9 nm, (b) 514.5 nm and (c) 632.8 nm. Superimposed on each plot is the initial PL spectrum in toluene.

increase in PL intensity relative to a pure toluene ambient. Because the spectral distribution of the emission does not change, we simply monitor PL intensity at the band maximum as a function of time. Figure 1 illustrates the modulation in intensity found with $PEtPh_2$ and the increase in this effect with shorter wavelength.

Electronic interactions

To quantify these changes in PL intensity, we have used a dead-layer model.[10] This model assumes that electron-hole pairs formed within a distance of the order of the depletion width do not contribute to PL. Ignoring changes in surface recombination velocity,[1]

$$PL_1/PL_2 = \exp(-\alpha'\Delta D), \qquad (1)$$

where PL_1 is the PL intensity in toluene; PL_2 is the PL intensity in phosphine solution; $\alpha' = (\alpha+\beta)$ is the sum of the CdSe absorptivities for the exciting and emitted light;[11] and ΔD is the contraction in dead-layer width that occurs upon passing from toluene to phosphine solution. The derivation of eq. (1) is illustrated in Fig. 2. An operational test of the dead-layer model involves excitation with several different interrogating wavelengths: α' and the corresponding PL ratios will vary (Fig. 1), but calculated values of ΔD should remain constant.

Figure 3 displays results for the phosphines employed. All of the phosphines gave excellent

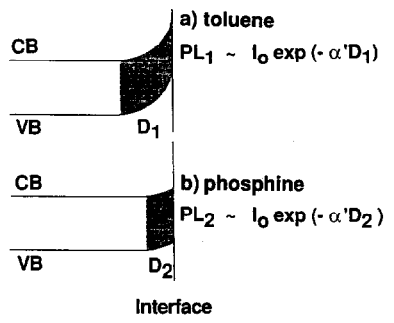

Fig. 2. The dead-layer model for analysing changes in PL intensity for two states, (a) and (b). As indicated in the figure, state (a) corresponds to the PL intensity in a toluene ambient, and state (b) corresponds to the PL intensity in the presence of toluene solutions of phosphines. CB and VB represent the solid's conduction and valence band edges, respectively. For each state, the PL intensity is proportional to the amount of incident light (intensity I_0; absorptivity α') absorbed beyond the non-emissive layer whose thickness is D. The ratio of the two PL intensities leads to eq. (1).

agreement with the dead-layer model. Looking first at the monophosphines, ΔD values of ~ 400 and 700 Å are found for PPh_3 and $PEtPh_2$, respectively. Qualitatively, we expect (and have found with amines and butenes[3,4]) that stronger bases provide

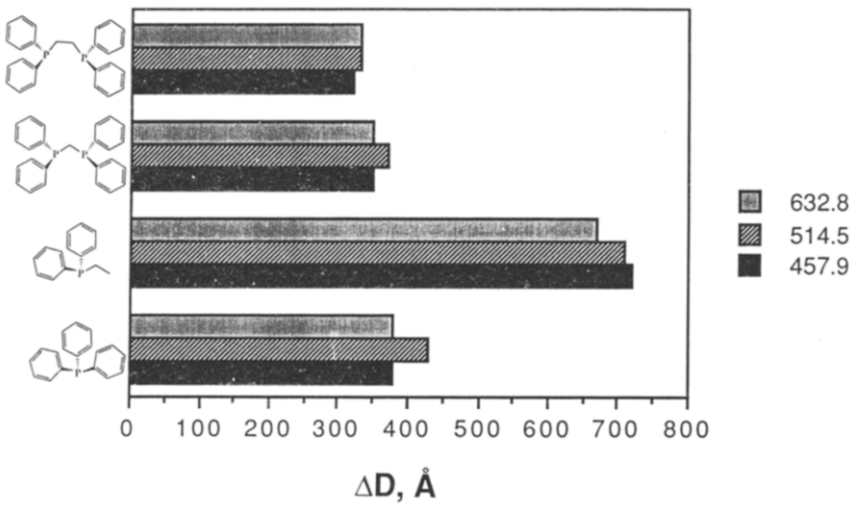

Fig. 3. Calculated values of ΔD ($\pm 20\%$) for each of the phosphines examined, using eq. (1) of the text. Excitation wavelengths (in nm) are shown in the legend.

larger dead-layer width reductions.[12] The substitution of an alkyl group for an aryl group of a tertiary phosphine is known to increase basicity in solution studies, implying that $PEtPh_2$ should yield a larger ΔD value, as observed.[13] The larger ΔD value for $PEtPh_2$ may also reflect its more compact dimensions (cone angle of 140° for $PEtPh_2$ vs 145° for PPh_3), permitting it to occupy more surface sites.[14]

Although the basicity of the diphosphines should be comparable and similar to $PEtPh_2$, their ΔD values, while being nearly equivalent within experimental error, more closely match the low value found for PPh_3 (Fig. 3). The diphosphine ΔD results by themselves are consistent with any of the bonding modes of Scheme 1: for monodentate binding, lower coverage by diphosphines relative to $PEtPh_2$ could occur because of steric bulk, thereby reducing ΔD; bidentate chelation could diminish ΔD if the different electronic structure that characterizes the individual Cd^{2+} sites yields a smaller electronic effect, or if relatively few sites of double coordinative unsaturation exist; and bidentate bridging could reduce ΔD through low coverage, resulting from ligand blockage of some fraction of the Cd^{2+} sites that are utilized in monodentate binding. In the last case we note that the smaller dppm can span metal centres approximately 6.5 Å apart.[15a] This distance would permit adjacent Cd^{2+} lattice sites ($\sim$ 4.3 Å separation on the idealized 0001 face of CdSe), or even next-nearest-neighbour Cd^{2+} lattice sites (separation distance of $\sim$ 6.1 Å) to be bridged.[15,16] We should note two other simplifications in our analysis: we are assuming a single binding mode when, in fact, a mixture of Cd^{2+} surface sites could result in the use of several binding modes simultaneously; and water, oxygen or species derived therefrom that are likely present on these ambiently-prepared surfaces could influence our results. We also cannot rule out phosphorus–selenium coordination.[17]

Adduct formation constants

The strength of the bonding interaction between the CdSe surface and the phosphines may be treated with the Langmuir adsorption isotherm model.[18] Experimentally, PL changes as a function of phosphine concentration, C_p, are determined. For either exclusively monodentate coordination or exclusively bidentate chelate coordination, the quantitative form of the model is

$$(1-\theta)/\theta = 1/(KC_p). \quad (2)$$

Here θ represents the fractional surface coverage, assumed equal to the fractional PL change, and K is the adsorption equilibrium constant. A plot of $(1-\theta)/\theta$ vs $1/C_p$ should be linear with a slope of $1/K$ and an intercept of zero. For simple bidentate bridging coordination, we would expect the multisite adsorption isotherm expression of eq. (3) to apply:[19]

$$(1-\theta)^2/\theta = 1/(2KC_p). \quad (3)$$

In this case, a plot of $(1-\theta)^2/\theta$ vs $1/C_p$ should give a straight line with a slope of $1/(2K)$ and an intercept of zero.

We have attempted to fit our data to both of these models and find that the one-site model of eq. (2) gives excellent fits for PPh_3[6] and $PEtPh_2$ (Fig. 4). Consistent with its greater basicity, $PEtPh_2$ exhibits a larger formation constant (220 ± 30 M^{-1})

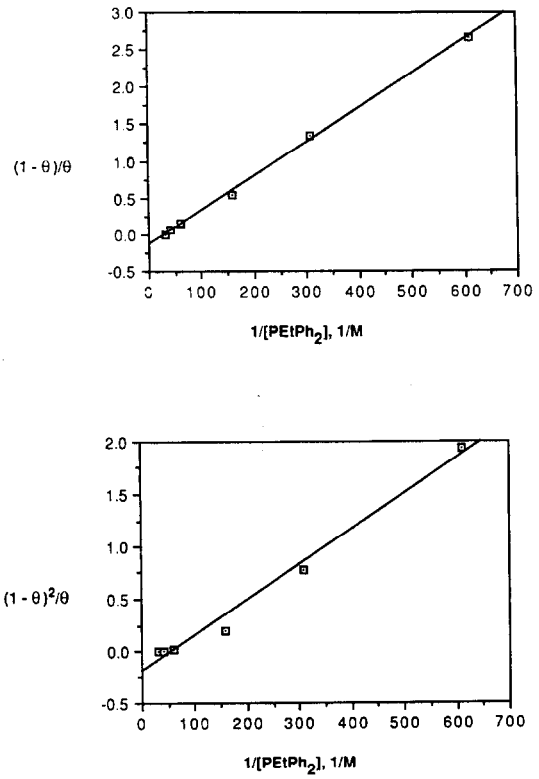

Fig. 4. Upper panel: Plot of $(1-\theta)/\theta$, where θ is the fractional surface coverage (equated to fractional PL change) vs $1/[PEtPh_2]$, using eq. (2) of the text. Lower panel: Plot of $(1-\theta)^2/\theta$ vs $1/[PEtPh_2]$, using eq. (3) of the text.

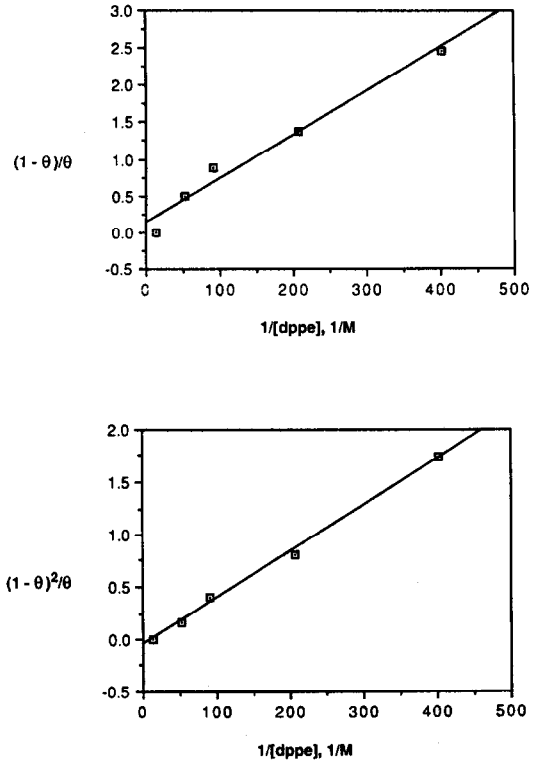

Fig. 5. Upper panel: Plot of $(1-\theta)/\theta$ vs 1/[dppe], using eq. (2) of the text. Lower panel: Plot of $(1-\theta)^2/\theta$ vs 1/[dppe], using eq. (3) of the text.

than PPh_3 (30 ± 7 M^{-1}). The diphosphine data are more ambiguous. For dppe, the two-site model of eq. (3) gives a better fit than the one-site case (Fig. 5). For dppm, neither model fits particularly well (Fig. 6). Despite the poorer fits, it is still possible to extract estimates of K from these plots for comparative purposes; the results are displayed in Table 1. In general, values of K for the diphosphines are intermediate between those of PPh_3 and $PEtPh_2$.

Table 1. Comparison of equilibrium constants for diphosphine/CdSe adducts[a]

Diphosphine	One-site[b] K (M^{-1})	Two-site[c] K (M^{-1})
dppm	140	80
dppe	170	110

[a] Equilibrium constants (±25%) for the indicated diphosphine/CdSe adducts in toluene solution.

[b] Calculated with eq. (2), using the data shown in Figs 5 and 6.

[c] Calculated with eq. (3), using the data shown in Figs 5 and 6.

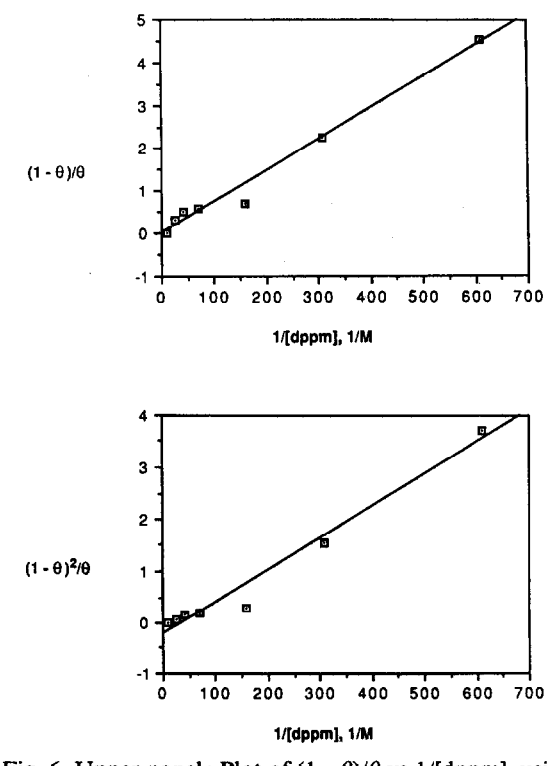

Fig. 6. Upper panel: Plot of $(1-\theta)/\theta$ vs 1/[dppm], using eq. (2) of the text. Lower panel: Plot of $(1-\theta)^2/\theta$ vs 1/[dppm], using eq. (3) of the text.

One explanation for the ambiguity of our results is that multiple binding modes exist simultaneously for the diphosphines, and the preponderance of one mode over another may be a function of concentration. For example, at low coverages the bridging mode may dominate, but at higher coverages monodentate binding is preferred. Another possibility is that assumptions inherent in eqs (2) and (3) are no longer valid for the diphosphines: we are assuming that there are no adsorbate–adsorbate interactions. Moreover, we are treating the two phosphine moieties of a bridging ligand as independent units, which may not be a good assumption given the short chain lengths involved.

In assessing the possibility of bidentate chelation, we note that chelating ligands generally impart greater stability to complexes than analogous monodentate ones and that five-membered chelate rings are generally more stable than four-membered rings.[8] Therefore, we would have anticipated clearly superior fits to eq. (2) and much larger values of K for the diphosphines, compared to $PEtPh_2$, as well as a significant difference between dppm and dppe, were chelation occurring. Based on our data, we feel that the primary mode of binding of the diphosphines to the CdSe surface does not involve chelation. Moreover, the lower ΔD values for the diphosphines compared to $PEtPh_2$ suggest that less effective coverage is present (*vide supra*), consistent with the more sterically demanding bridging or monodentate binding modes. Other diphosphines may, of course, employ different coordination modes and are being investigated.

Abstract—We have completed Hartree–Fock–Slater theoretical studies on the title molecules. The minimum energy configuration corresponds to a linear geometry for MgF_2, whereas the remainder of the molecules are bent with a bond angle in the range 120–132°. These results are in agreement with experimental evidence where it exists. The bent geometries are more stable than the linear by only 1–3 kcal mol^{-1}. The simplest rationalization for the (anomalous) bent geometries is that the central metal $(n-1)d$ orbitals are more important to the bonding than are the *np* orbitals. In valence bond language we can summarize this as *sd* (bent) vs *sp* (linear) hybridization. The 4*f* orbitals of cerium and ytterbium also do not contribute enough for the molecules to become linear as a result of *f* orbital involvement. This analysis is borne out by close scrutiny of the eigenvalues and changes in Mulliken atomic populations for the linear and bent structures. There is no need to invoke a "reverse" polarization argument to rationalize the geometry of the bent molecules, as has been done in the classical multipole expansion model. We show that this model is very sensitive to the polarizability value chosen for the metal. Furthermore, in the multipole expansion the dipole–dipole term is of equal importance to the charge–dipole term, although in qualitative discussions only the latter is emphasized.

Early in 1989 Beattie and co-workers[1] published a short communication with the provocative title "Do Any AB_n Molecules Have Anomalous Shapes?". The paper predominantly dealt with a careful look at the experimental evidence relating to TiF_2, but called into question the gamut of evidence related to AB_n molecules. According to Beattie *et al.*, TiF_2 and CaF_2 are "key molecules" in the answer to their question. It is not our purpose here to review their discussion. Rather, this question sets the tone for the present manuscript.[2]

The molecular geometry of the gas-phase alkaline earth dihalides has been of interest ever since Skinner examined the comparative valence-state excitation energies of the alkaline earth metals.[3] In the closing paragraph of his paper he discusses the (then) unknown geometrical structures of the MX_2 molecules. He did not outright predict that they would be bent, but the possibility is definitely brought up for consideration. Some 8 years later Klemperer and co-workers reported electric deflection experiments on these molecules.[4] If the molecules deflected in the electric field it was assumed that they must possess a permanent dipole moment and hence be bent. Other experimental methods that have been applied to the determination of molecular structure for these species are gas-phase electron diffraction, matrix isolation IR spectroscopy and matrix isolation Raman spectroscopy.

There is extensive literature on the molecular

* Dedicated to Professor Richard F. Fenske upon the occasion of his retirement, with many thanks for introducing R.D.K. to the world of electronic structure and chemical bonding.

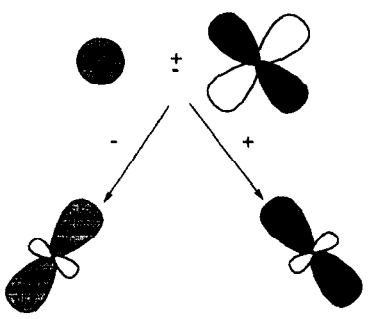
structure of these compounds; we refer to review articles only.[5] A brief summary of these results is given in Table 1, as found in ref. 5b. Where more than one bond angle is reported, from different experimental methods, we have arbitrarily presented the bond angle from the latest reference only. Although estimated uncertainties are not given for many of these numbers, those that are reported are in the order of $\pm 10°$. A recent matrix isolation IR spectrum[6] of CaF_2 reported results for both $^{40}CaF_2$ and $^{44}CaF_2$, and the bond angle was calculated to be $142 \pm 1°$.† The lightest dihalide of any alkaline-earth metal to be bent is CaF_2. The heavy-metal fluorides are all bent, but the tendency again returns to linear for heavier halides. For example, all of the di-iodides are linear except BaI_2. Turning to the title molecules other than those of Group 2, there are a number of references on CeO_2;[7] the bond angle is stated to be $146 \pm 2°$.[7c] A matrix isolation IR spectrum of $YbCl_2$ has been interpreted to give a bond angle of $126 \pm 5°$.[8] Among the title molecules, there are no experimental reports for CaH_2. It is included in our study to provide a model compound with a simple ligand.

It is not only the alkaline-earth dihalides, CeO_2 and $YbCl_2$, that provide examples of anomalous shapes for AB_2 type molecules. There are a number of Cp_2M molecules that are bent about the angle formed by the metal atom and the two ring centroids ("centroid" angle). For example, Andersen *et al.*[9] completed electron diffraction studies on Cp^*_2M where M = Mg, Ca and Yb and Cp* refers to the pentamethylcyclopentadienyl ligand. The rings were found to be parallel for M = Mg, but the centroid angle was 154° for the Ca compound and 158° for the Yb compound. Evans *et al.*[10] observed an angle of 140.1° in an X-ray structure of Cp^*_2Sm, and 140.1° for Cp^*_2Eu. Since the Cp ligand is isolobal[11] with F and Cl, these results are pertinent to the present study.

To round out this introduction on the matter of anomalous shapes of AB_2 molecules we note that ThO_2 has an angle of 122.5°,[7a,c] this molecule is isovalent with CeO_2. Also, ScH_2^+, which is isoelectronic with CaH_2, has a theoretical bond angle near 107°.[12]

A glance at the periodic table reveals that all of the title molecules have, in the ionic formulation, a metal valence configuration that is $s^0p^0d^0$, f^0 for Ce^{4+}, and f^{14} for Yb^{2+}. That is, all these molecules will be closed-shell with four valence σ electrons around the central metal atom in a covalent bond formulation. Hence, the bent molecules represent exceptions to the valence-shall-electron-pair-repulsion model (VSEPR), simple hybrid orbital, simple Walsh digram,[13] or simple second-order Jahn–Teller models.[13] The word "simple" in this context means that the metal atom employs predominantly its *s* and *p* orbitals in chemical bonding to the ligands. If we utilize *d* orbitals then all of the models just mentioned are capable of rationalizing the bent structures, except for the VSEPR model. The contention that the *d* orbitals do provide an Occam's razor understanding of the bent structures forms a major part of this paper.

We now introduce both the orbital model and the classical multipole expansion model that can be used to rationalize the bent structures. The orbital model may be cast either in valence bond language with the attendant use of localized (hybrid) orbitals, or in molecular orbital language with emphasis on the delocalized molecular orbitals. In valence bond language, the fact that many of the experimental structures are bent suggests that *sp* hybrid orbitals are incorrect and that one should instead invoke an *sd* set of hybrid orbitals.[14] We will not make more use of valence bond language, but refer to Scheme 1 in passing.



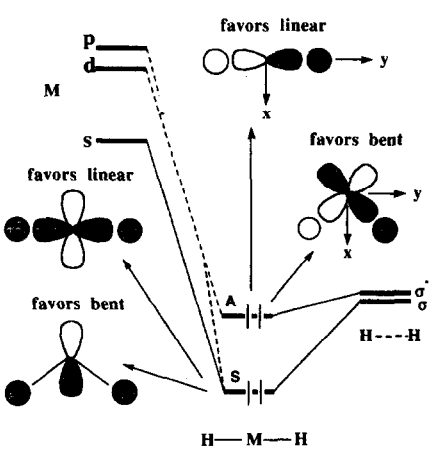
1

Scheme 1.

† Such reported uncertainties are within the framework of the assumptions used to calculate the bond angle. For example, most such calculations assume a harmonic force field. Interaction between stretching and bending frequencies are often neglected. If these effects are factored in, the reported uncertainty should be much larger.

We now turn to a qualitative molecular orbital scheme. Skinner[3] and later Hayes[15] introduced the idea that the $(n-1)d$ orbitals might be more important than the np orbitals in bonding to the ligands. This idea is introduced in Scheme 2 where the MOs that hold the four valence electrons of CaH_2 are depicted. This scheme summarizes the countering effects that the d and p valence orbitals exert regarding structure. In the HOMO the d orbital favours a bent structure and the p orbital a linear structure. In the penultimate MO it is just reversed. The sizeable energy splitting of the HOMO and the penultimate MO is caused mainly by the strong contribution of the metal s orbital to the penultimate MO (symmetric, S). This energy splitting results in a lesser interaction of either the d or the p metal orbitals in the penultimate MO as compared to the HOMO. Furthermore, these high-lying metal orbitals must compete with the metal s orbital for per cent character in the penultimate MO. Both of these effects serve to make mixing of d and/or p character into the HOMO more important than into the penultimate MO. Hence, the HOMO controls the geometry of these systems. (It is interesting to observe that it is the valence s orbital on the metal atom that indirectly exerts stereochemical activity.[16]) As seen in Scheme 2, the result is a linear geometry if p orbitals are important but a bent geometry if the d orbitals are involved. An example of the former might be BeH_2 and of the latter ScH_2^+. (We have purposely chosen the z axis to be perpendicular to the plane of the bent molecule. This will facilitate the population analysis and the angular overlap analysis to be presented later.)

But this is all by way of qualitative introduction. If life were as simple as presented in Scheme 2 there would be no need for this manuscript. Hence we present a brief review of the quantum chemical history of CaF_2. Hayes not only examined the neutral atom valence-state excitation energies but also those of the cation.[15] In a later paper Gole *et al.* completed an *ab initio* theoretical study and found indeed that if a basis set without d orbitals was employed the molecule was linear, but with d orbitals it was bent.[17] This would have been the end of the matter except that in the same year Yarkony *et al.*[18] also completed an *ab initio* study on the same molecule with a much larger d basis set and found the molecule to be linear! Other calculations of CaF_2 have appeared;[19] they predict a linear geometry or obtain a bent geometry only by choosing a d orbital exponent to provide the desired answer.



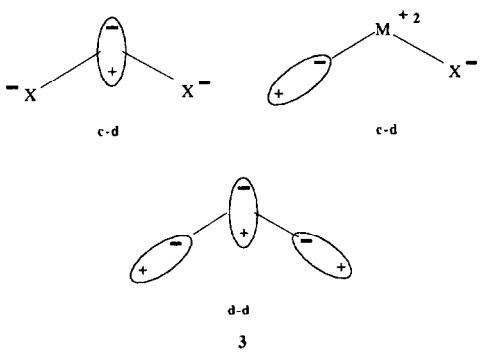
2

Scheme 2.

One of us has completed further *ab initio* theoretical studies[20] on both CaF_2 and CaH_2 using a larger basis set than used heretofore. Even though correlation effects were included at the CISD level the results still predicted a linear structure for both of these molecules. After our work was completed we learned that Marsden[21] had also carried out an *ab initio* study on CaF_2 in which the d basis set was enlarged even further and attention was paid to choosing "optimum" d exponents; he finds the most stable configuration to be bent at the SCF level.

We turn now to the multipole expansion model that was mentioned before. This model suggests that one should forget about orbital arguments and employ a classical multipole expansion, starting from the completely ionic formulation. This method was first used quantitatively by Rittner[22] to rationalize the vibration frequencies, dipole moments and dissociation energies of the alkali halides. It has subsequently been used extensively for the alkali halides, for which we provide a pair of more recent references.[23] In the multipole expansion the first-order term is the Coulombic interaction of the ions (charge–charge interaction). Higher-order terms involve the charge on one ion inducing a dipole on another, and the interaction of the induced dipoles with each other. We refer to these as simply charge–dipole (c–d) and dipole–dipole (d–d) interactions. See Scheme 3 for a pictorial introduction. The magnitude of these higher order interactions depends directly upon the (dipole) polarizability of the ion; in order to apply the model these values must be chosen from empirical data for both the cation and the anion.

The multipole expansion method also has been applied to the alkaline-earth dihalides. The most rigorous application has been that of Guido and Gigli.[24] Hildenbrand[25] employed a truncated version (charge–charge and charge–dipole terms only)



3

Scheme 3.

which he used to rationalize the bond dissociation energies but not to predict the molecular structure. There also are two papers[5a,26] which review the structures of the dihalides and qualitatively rationalize them in terms of polarizability arguments. In the inorganic chemistry literature this model is sometimes referred to as "reverse" polarizability, because it is stated that the term in which the anions polarize the cation is most important for causing the molecule to bend. The feature of this model which is difficult to accept is that the "core" electrons of the metal cation must be distorted in order to bring about this stabilization. For Ca^{2+} this means that the 3*s* and 3*p* electrons must be distorted. On the face of it this model sounds implausible, but because it has gained such widespread use in the literature we scrutinize it. The same model has been used to rationalize the structures of the bent Cp_2M molecules that were introduced above.[9,10]

The present study was undertaken with the desire to employ a single theoretical method to study the diverse molecules listed in the title. We have employed the Hartree–Fock–Slater (HFS) theoretical method;[27] once we had ascertained that the model reproduced the experimental results we set out to determine if we could trace the origin of the bending within an SCF (orbital-based) model. This method has been employed for a number of geometrical studies on small molecules[28] and on transition metal molecules.[29] We include relativistic effects for CeO_2 and $YbCl_2$ as described below.

THEORETICAL METHOD

Important background papers for the theoretical method have been referenced above. The basis set consists of uncontracted Slater-type atomic orbitals.[30] The method utilizes the frozen core approximation; valence orbitals are orthogonalized onto the core by employing a single ζ exponent in the valence set for each core type orbital. The following orbitals were kept in the core: O, F and Mg (1*s*); Cl and Ca (1*s*, 2*s*, 2*p*); Ce and Yb (1*s*, 2*s*, 2*p*, 3*s*, 3*p*, 3*d*, 4*s*, 4*p*, 4*d*). Notice that eight electrons more than "necessary" have been kept in the valence shell, except for O, F and Mg.

We used a flexible valence basis set which is briefly described as follows: H (double ζ, 1*s*; single ζ, 2*p*); O and F (double ζ, 2*s*; double ζ, 2*p*; single ζ, 3*d*); Mg (double ζ, 2*s*; double ζ, 2*p*; double ζ, 3*s*; double ζ, 3*p*; triple ζ, 3*d*); Ca (double ζ, 3*s*; double ζ, 3*p*; double ζ, 4*s*; double ζ, 4*p*; triple ζ, 3*d*); Ce and Yb (double ζ, 5*s*; double ζ, 5*p*; double ζ, 6*s*; double ζ, 6*p*; triple ζ, 5*d*; triple ζ, 4*f*).* Atomic calculations were performed and these eigenvectors were used as fragments for the molecular calculations. This feature facilitates the interpretation of the Mulliken population analysis for an uncontracted basis set.

The bond lengths and angles of the magnesium and calcium compounds were optimized using the recently developed analytical gradient method for the HFS model.[28] Since we knew that the difference in energy between the linear and bent structures would be small, we chose to employ a new, more accurate method for numerical integration in this work.[31] For the cerium and ytterbium molecules a manual procedure involving parabolic fits was employed to optimize the structure.

The atomization energies have been calculated for each of the compounds,[32] including Becke's non-local exchange correction.[33,34] For the purpose of incorporating relativistic effects, the quasi-relativistic theoretical method has recently gained attention.[35] With this approach bond dissociation energies can be calculated accurately for any element in the periodic table. Briefly, the quasi-relativistic method incorporates the major effects of relativity on the kinetic (mass–velocity term) and potential (Darwin term) energies of the electrons, but effects due to spin–orbit coupling are neglected. Since the ground states of the title molecules are closed-shell, the spin–orbit effects are of no consequence to us.

* We employed the neutral atom wave function in the molecular calculation and used the experimental atomic electron configuration in all cases, except for Yb where the configuration [core] $4f^{13}\ 5d^{1}\ 6s^{2}$ was used rather than the experimental configuration [core] $4f^{14}\ 5d^{0}\ 6s^{2}$. Since the population analysis for $YbCl_2$ showed that there was about one 5*d* electron, the basis set we have chosen is appropriate for the molecular study. We have corrected this reference state to that of the ground state Yb atom in reporting the theoretical atomization energy of $YbCl_2$.

RESULTS AND DISCUSSION

We divide the results and discussion into six sections. In the first we present an overview. In the second and third we examine the general population analysis and the *d* orbital population analysis. In the fourth section we look at the angular overlap model. The fifth section exhibits a decomposition of the bonding in CaH_2 in terms of Ca and H_2 fragments for both the linear and bent geometries. The last section examines the electrostatic multipole expansion method.

Overview

In Table 2 we present the theoretical geometries, a summary of the atomic charges as obtained from the Mulliken population analysis, energy differences between bent and linear structures, dipole moments, and the theoretical atomization energies.

The ground state of each molecule is bent, except for MgF_2. These results are in agreement with the electric deflection and IR spectral experiments, as was outlined in the introduction. The bond angle is calculated to be near 130° for CaH_2, CaF_2 and CeO_2, whereas it is 120° for $YbCl_2$. The bent structure is only about 1–3 kcal mol^{-1} more stable than the linear structure. This is indicative of a small bending potential, as is also evident from the small bending force constants that have been derived from the IR stretching frequencies. In contrast to the bent geometry of the Ca, Ce and Yb compounds, the MgF_2 molecule is predicted to be linear and strongly so. The difference in energy between the linear geometry and one at 120° is 13.4 kcal mol^{-1}. We will return to a detailed analysis of the linear vs bent structure later in the discussion.

Our theoretical bond lengths are about 0.05 Å shorter than the Hartree–Fock lengths for (linear) CaH_2 (2.10 Å) and CaF_2 (2.05 Å).[20] The Ce—O bond length of CeO_2 (1.82 Å) is close to the experimental bond length of the diatomic molecule CeO (1.84 Å).[36] The MgF_2 bond length is nearly identical to that reported from electron diffraction studies (1.77 Å).[5b,37] The optimized Yb—Cl bond distance of 2.40 Å is identical to that used by Culberson *et al.*[38] in their INDO study on this molecule. All in all, the bond lengths that we obtained are very reasonable.

In each case the difference in optimized bond length between the linear and the bent molecule is only a few hundredths of an Å. This also is an indication of the flatness of the potential energy surface for bending these molecules. This result is in contrast to the work of Baird[39] on simple molecules such as H_2O; he found large variations in bond length with angle, but he was looking at the range 90–120° where the energy varies strongly with angle. It is interesting to note that for CaH_2, CaF_2 and $YbCl_2$ there is a bond length *shortening* as the molecule is bent, whereas for MgF_2 there is a slight *lengthening* (Table 2). This is exactly what one would predict based upon the most stable geometry in each case. The minor variation in bond length with angle is in agreement with our *ab initio* results for CaF_2.[20]

Table 2. Theoretical results for the title molecules

Molecule	r (Å)	ϕ (degrees)	q (M)	ΔE^a (kcal mol^{-1})	Dipole moment[b]	Atomization energy[c]
MgF_2	1.75	180	1.32	0.0	—	243
MgF_2	1.76	120[d]	1.30	−13.4	—	—
CaH_2	2.06	180	0.90	—	—	—
CaH_2	2.01	127	1.00	2.0	4.77	76
CaF_2	1.99	180	1.38	—	—	—
CaF_2	1.96	130	1.35	1.5	5.23	265
CeO_2	1.82	180	1.39	—	—	—
CeO_2	1.82	132	1.37	3.1	4.59	346
$YbCl_2$	2.49	180	1.01	—	—	—
$YbCl_2$	2.40	120	0.89	1.8	5.86	154

[a] Difference in energy, linear minus bent. A positive number indicates that the bent form is more stable.

[b] In Debye units.

[c] In kcal mol^{-1}, for $MX_2 \rightarrow M + 2X$.

[d] This is an arbitrary point on the energy surface. No bent structures for MgF_2 were found to be stable.

The charge polarization is quite large based upon the Mulliken population analysis; the positive charge on the metal atom is in the range 0.9–1.4. The charge polarization in CeO_2 is no greater than in CaF_2; in the ionic formulation the charge on the cerium atom is two units larger than that on calcium. This is an example of Pauling's electroneutrality principle at work. The theoretical dipole moments also indicate significant charge polarization, although as Rittner warned us 40 years ago we should be careful about deducing partial charges from dipole moments.[22]

The atomization energies ($D_0°$) have been reported for MgF_2,[40] CaF_2[40] and CeO_2;[41] the values are 246, 266 and 344 kcal mol^{-1}, respectively. The theoretical results that we report in Table 2 are very close to these values. The theoretical value for CaH_2 is only 76 kcal mol^{-1}. Since the bond dissociation energy of H_2 is over 100 kcal mol^{-1},[42] it is evident that CaH_2 could exist only as a metastable molecule. However, this is not unusual for MH_2 molecules.[43]

The bond dissociation energy of CeO is reported as 192 kcal mol^{-1}.[44] With this value and the experimental atomization energy of CeO_2, we have enough information to obtain the stepwise bond dissociations of CeO_2:

$CeO_2 \rightarrow CeO + O$	152 kcal mol^{-1}
$CeO \rightarrow Ce + O$	192 kcal mol^{-1}
$CeO_2 \rightarrow Ce + 2O$	344 kcal mol^{-1}.

This contrasts with the corresponding values[45] for CO_2 which has the same valence electron count:

$CO_2 \rightarrow CO + O$	127 kcal mol^{-1}
$CO \rightarrow C + O$	257 kcal mol^{-1}
$CO_2 \rightarrow C + 2O$	384 kcal mol^{-1}.

Notice that the carbon atom in CO_2 is able to take "advantage" of the loss of the first O atom so as to considerably strengthen the bond with the remaining O atom. In classical Lewis electron dot structures (or more precisely GVB structures) we can see that there is a net loss of one σ bond for the first bond dissociation of CO_2, whereas the loss of the second O atom requires breaking one σ bond and two π bonds.

For CeO_2 the increase in bond dissociation for the loss of the second oxygen is not nearly so large as for CO_2. The most likely explanation for this difference is that the bonding is controlled more by electrostatic effects for CeO_2 than it is for CO_2. Hildenbrand[25,40] has tabulated the bond dissociation energies of MX and the atomization energies for MX_2, where M is an alkaline earth metal atom. The first bond dissociation energy is about 50% of the atomization energy for the alkaline earth dihalides, for CeO_2 it is 44%, and for CO_2 33%. From these values it is clear that CeO_2 behaves more like MX_2 than like CO_2.

We briefly examine the behaviour of the HOMO as a function of bond angle. For MgF_2 the HOMO is a degenerate π^* orbital which is destabilized by 0.7 eV as the molecule is bent to 120°. The σ_u orbital lies slightly lower in energy; it is destabilized by 0.4 eV upon bending the molecule. For each of the other title molecules the HOMO in the linear molecule is σ_u. As the molecule is bent this HOMO is *stabilized*, exactly as would be expected if the *xy* orbital on the metal takes an active role in the bonding (Scheme 2). The amount of stabilization (in eV) experienced by the HOMO is 0.05 (CaH_2), 0.19 (CaF_2), 0.66 (CeO_2) and 0.43 ($YbCl_2$). The idea that one can correlate molecular shape with the behaviour of the HOMO as a function of angular variation is well documented.[46] We turn to the population analysis in order to examine further the conjecture that the *xy* orbital is involved in causing the molecule to bend. First we look at the general population analysis and later focus explicitly on the *d* orbitals.

Angular geometry—General population analysis

In Table 3 we present the Mulliken population analysis for these molecules. First, we notice that the metal atom $(n-1)s$ and $(n-1)p$ orbitals that were included in the valence basis set have full occupation in all cases except for CeO_2. Even in that case the population of these orbitals changes little upon going from the linear to the bent geometry. Second, the populations of the ligand orbitals also change very little upon going from the linear to the bent configuration. The largest change is 0.05 electrons for the σ bonding (p_z) orbital of the Cl atom in $YbCl_2$. Third, the situation for the valence orbitals of the metal atom is quite different. In Table 2 we saw that the overall charge on the metal atom was relatively unchanged upon bending. Table 3 shows, however, that except for MgF_2 there is a dramatic rearrangement of electrons on the metal as bending occurs. We now look at the orbital occupancies in more detail.

The occupancy of the halogen p_π type orbitals is roughly 1.9 electrons, whereas there are only about 1.6 electrons in the corresponding orbitals on the oxygen atoms in CeO_2. This is evidence of π bonding in CeO_2. Turning to the metals, the population of the $(n-1)d$ orbitals shows a significant increase in each case, ranging from 0.06 electrons for CaF_2 to 0.26 for CeO_2. Meanwhile, the *np* population suffers a decrease ranging from 0.03 to 0.28 elec-

Table 3. Mulliken population analysis for the title molecules[a]

[a] There are some minor differences between this table and the charges reported in Table 2. Some of this is due to round-off, and some is due to that fact that we do not tabulate the (small) d orbital populations on the ligands.

[b] The coordinate system on the ligands has the p_z orbital pointing at the metal. The p_y orbital is perpendicular to the plane of the bent molecule.

trons. For CeO_2 and $YbCl_2$, there is a decrease in the $4f$ population of 0.22 and 0.14 electrons, respectively.

What do we conclude from these variations? The simplest conclusion is that the $(n-1)d$ orbitals provide the driving force for bending these molecules (except MgF_2). In other words we come to the same conclusion that Hayes came to more than 20 years ago.[15] In hybrid orbital language the sd hybridization (Scheme 1) which favours a bent molecule is more important than either sp or sf hybridization which favour the linear geometry.[47] The implication of the valence d orbitals is in agreement with the interpretation of the bonding in ScH_2^+,[12,*] and the conclusion that Wadt[48] and Pyykkö *et al.*[49] reached in their theoretical studies on ThO_2. (We do not agree with Culberson *et al.*[38] who ascribe the bent geometry of $YbCl_2$ to "a small amount of p orbital hybridization".) The use of "outer" d orbitals in chemical bonding has been a topic of ongoing discussion for many years. We provide but a few references to that literature here.[50]

Why do the d orbitals attain an importance that surpasses that of the p and f orbitals for the title molecules? Consider calcium; the relative energy of the $3d$ and $4p$ orbitals undergoes a dramatic change upon going from Ca to Ca^+.[15] The s–p promotion energy[51] of Ca is roughly 1.9 eV, whereas the s–d is 2.5 eV. The situation is more or less reversed for the cation, 3.2 and only 1.7 eV, respectively. The ordering of our theoretical excitation energies is the same as that found experimentally.† Hence the most accessible valence orbital (beyond $4s$) is the $3d$ orbital for Ca^+; see Scheme 2. This effect is seen for all of the Group 2 elements except for Be and Mg, the very elements that invariably exhibit a linear MX_2 geometry. The formation of the anions of Group 2 also shows how Mg is decidedly different from Ca, Sr and Ba; the states with an occupied d orbital are relatively high in energy for Mg.[52]

The $5d$ orbital also has a preferential position in the lanthanoid elements Ce and Yb.[53,54] For example the ground state of Ce is [core] $4f^15d^16s^2$, so that the d orbital already is occupied. The ground state of Yb is [core] $4f^{14}6s^2$, but there are low-lying states with the $5d$ orbital occupied. The latter statement applies also to cations of Ce and Yb.

But what about the $4f$ orbitals? If they were sufficiently involved in the bonding, the molecules would be linear. The $4f$ orbitals of Ce have a total population of 1.3 electrons in CeO_2, and those of Yb have 13.8 electrons in $YbCl_2$. The latter indicates that a full occupancy of 14 electrons is very nearly achieved for Yb, which would render the stereochemical activity of the $4f$ orbitals nil. But what about the 1.3 electrons of Ce? Might they tend to make the CeO_2 molecule linear? We believe that the answer is a decided no. The reason is that

* As part of the present study we also have determined the optimized geometrical structure of ScH_2^+; we find the bond length to be 1.74 Å and the bond angle to be 107°. These results are in excellent agreement with those reported in ref. 12.

† Energies are reported here for unrestricted calculations in "spherical" symmetry. That is, fractional electron occupancies are employed as needed. The four values, reported in the same order as the experimental numbers given in the text are: 1.4, 3.1, 3.0 and 2.4 eV.

although in energy terms the $4f$ orbitals function as valence orbitals, in terms of radial extent they behave as core orbitals.[54-56] In fact, this is true to such a large extent that electronic structure studies have been successful on atomic and molecular lanthanoids with partially occupied $4f$ orbitals treated as part of the core via pseudo-potentials.[54,57] The compact nature of the $4f$ orbitals compared to the $5d$ is borne out by the overlap integrals with the symmetry adapted linear combination of p_z orbitals on the ligands with the $f(z^3)$ and $d(z^2)$ orbitals for linear CeO_2 and $YbCl_2$.* Ortiz and Hoffmann have affirmed the lack of stereochemical activity of f orbitals in their Extended Hückel study of Cp_2Sm.[58]

Before leaving the CeO_2 and $YbCl_2$ molecules we point out that our theoretical study has employed the quasirelativistic method; we have not done the corresponding non-relativistic study. Results in the literature[59] suggest that relativity affects the lanthanoids much less than the actinoids, and that the effect is to stabilize s and p orbitals on the metal atom and to destabilize d and f orbitals. Such being the case, we expected that a non-relativistic study also will produce bent molecules since the $6p$ orbital will be destabilized and the $5d$ will be stabilized in relation to the relativistic results.

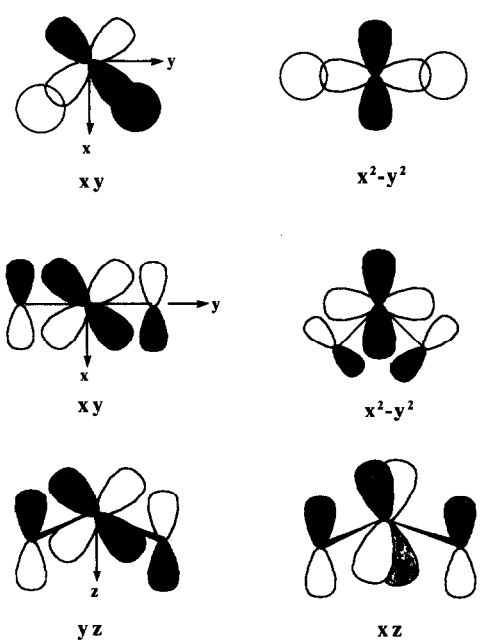
*Angular geometry—*d *orbital population analysis*

In the previous section we pointed out that the theoretical results implicate d orbital involvement as the important feature which causes the molecules to bend. In this section we examine the population of each of the five d orbitals in both the linear and bent geometries.

We employ a coordinate system in which the local z axis on the metal atom is perpendicular to the plane of the molecule. The local x axis is chosen to bisect the molecular bond (Scheme 2). This coordinate system has the advantage of producing a z^2 orbital which is isotropic to changes in bond angle with ligand σ bonding orbitals, and is unable to π bond with ligand orbitals either in-plane (π_{ip}) or out-of-plane ($\pi_\perp$). The metal x^2-y^2 orbital is purely σ bonding for the linear molecule and σ non-bonding at a bond angle of 90°; it is purely in-plane π bonding at 90°. The situation for the xy orbital is just the reverse of that for the x^2-y^2 orbital. The xz and yz orbitals are either non-bonding or purely π bonding, depending upon whether the molecule is linear or bent. This coordinate system has many advantages for understanding changes in population of the d orbitals as a function of angle. For example, other things being equal we expect no change in the z^2 orbital population as the angle is varied. In Scheme 4 we show some interactions of d orbitals with ligand orbitals. Some of the orbital interactions are shown for the linear configuration and others for the bent. The reader easily can envision the interactions that are not shown.

The results in Table 4 show that the z^2 orbital population changes only slightly as the molecule is bent.† This was expected in our coordinate system. The x^2-y^2 and xy orbitals are involved in σ and π_{ip} bonding. For both Ca molecules the former orbital loses population, while for the Ce and Yb molecules it gains population. The xy orbital gains in population in all cases, as expected, since the ligand σ bonding orbitals come into better alignment with it as the molecule is bent (see Scheme 2 or 4). Among the xz and yz orbitals ($\pi_\perp$), the changes also are as expected. For example, the former cannot participate in the bonding in the linear molecule since it is of δ symmetry. Upon bending the molecule it gains in $\pi_\perp$ bonding whereas yz loses because of less effective overlap with the ligand orbitals.

The really intriguing thing about these results can be garnered already by looking at the populations



4

Scheme 4.

* For these overlap integrals we take the z axis as the molecular axis. The overlap integrals with the appropriate symmetry adapted linear combination [$p_z = (1/\sqrt{2})(z_1 \pm z_2)$] are as follows: CeO_2, $S(z^2,p_z) = 0.131$ and $S(z^3,p_z) = 0.080$; $YbCl_2$, $S(z^2,p_z) = 0.215$ and $S(z^3,p_z) = 0.026$.

† We do not present results for MgF_2 since the d orbitals were of no consequence for this molecule.

Table 4. Mulliken population analysis of the *d* orbitals[a]

[a] Molecule lies in the *xy* plane; the *x* axis is the two-fold axis for the bent molecule.

of the x^2-y^2 and xy orbitals of CaH_2. In the linear molecule the former is σ bonding and the latter nonbonding. If the molecule were bent to 90° their roles would just be reversed. Why then already at 127° do we find that the xy orbital gains in population more than the x^2-y^2 loses? The answer is easily seen in Scheme 2 and it was alluded to already in the introduction: the former is energetically closer in energy to the ligand bonding combination than is the latter. This effect is brought about by the metal *s* orbital involvement with the penultimate MO. We can quantify this idea by relating changes in population to changes in $S^2/\Delta e^0$, where S is the overlap integral of the ligand function with the designated *d* orbital and Δe^0 is the energy difference between the metal and ligand orbitals of the same symmetry. In the section on the angular overlap model presented next, we develop more fully the reason for choosing the function $S^2/\Delta e^0$. It should be clear to the reader that this function comes from second-order perturbation theory.

In Table 5 we present changes in *d* orbital population for the valence atomic orbital of our triple ζd basis set. For example, for Ca we tabulate the 3*d*

values and neglect the higher energy 4*d*-like and 5*d*-like orbitals. (The population changes in Table 5 cannot be gleaned directly from Table 4 since the latter included populations in all three *d* orbitals of the triple ζd basis set). It is clear that there is a rough correlation between change in population of a metal *d* orbital and $\Delta[S^2/\Delta e^0]$ but not with $\Delta[S^2]$. For example, in the case of CaH_2 the $\Delta[S^2]$ value decreases for the x^2-y^2 orbital by about the same amount that the xy increases. Yet the latter gains in population almost twice what the former loses. The inability of $\Delta[S^2]$ to track such trends in population changes is immediately obvious when one recalls the sum rule that is familiar in the angular overlap model (see below). For our situation, this sum rule states that the sum of $\Delta[S^2]$ must add to zero for the set of *d* orbitals. The reason they do not sum to exactly zero in Table 5 is that the Ca—H bond length is slightly different in the two geometries.

We next examine the xz and yz orbital changes, those orbitals that are $\pi_\perp$. (Here there can be no metal *s* orbital participation in either the linear or bent geometry and so there is no competitition between different types of metal orbitals.) These changes also are readily interpreted in terms of the function $\Delta[S^2/\Delta e^0]$. There is one exception (CeO_2) in that $\Delta[S^2/\Delta e^0]$ predicts the xz orbital should gain less than the yz loses, whereas the opposite occurs. We already knew that something was drastically amiss for CeO_2 in that the z^2 orbital experienced a large change in population contrary to what we would expect based upon its isotropic nature.

The correlation of population changes for the x^2-y^2 and xy orbitals is not so straightforward as it was for CaH_2. Perhaps the gain in population for the x^2-y^2 orbital of CeO_2 and $YbCl_2$ is due to a π_{ip} bonding interaction for these molecules. The population changes in the x^2-y^2 and xy orbitals of CaF_2 compared to CaH_2 are readily comprehended based on the contribution of π_{ip}.

In summary, the results of Table 5 indicate that the function $\Delta[S^2/\Delta e^0]$ provides a ready understanding of the population changes in the *d* orbitals on the metal atoms, except for CeO_2 where only about one-half of the changes can be understood in this fashion.

Angular overlap model

Under the assumption that the ligand levels are considerably more stable than the metal levels and/or the overlap between the metal and ligand orbitals is small, one can introduce perturbation approaches to determine if they provide an understanding of the angular geometry. There are two approaches. One is to use a perturbational molecular orbital (PMO) theory and the second is to use the angular overlap model (AOM).

Albright *et al.* show how PMO theory can be used to rationalize Walsh's rules.[60] We do not have available the necessary perturbation matrices which would allow us to employ this method. The first order terms involve changes in overlap and since the HOMO has a nodal plane (Scheme 2) it is clear[60] that the first-order perturbation terms would predict it to be *destabilized* upon bending. But our theoretical results show that the HOMO is stabilized (*vide supra*). Hence, we turn to the second-order terms which essentially leads us to AOM.[61]

Within AOM the energy of stabilization as a result of interaction between two orbitals is βS^2, where S is the overlap integral and β is given by $(e_M{}^0)^2/(e_X{}^0-e_M{}^0) = (e_M{}^0)^2/\Delta e^0$. This term for stabilization energy is very familiar in that it also appears in a second-order perturbation treatment within Extended Hückel Theory.[62] For purposes of our discussion, $e_X{}^0$ is the diagonal element of the **H** matrix for the symmetry adapted linear combination of ligand orbitals and $e_M{}^0$ is the corresponding term for a metal *d* orbital. The angular overlap model generally ignores changes that might occur in β and concentrates on changes in the values of the overlap integrals. (If our computational method is non-iterative EHT, there will be no change in β.) It is interesting to note that the electron population (Mulliken method) of the metal orbital in EHT is proportional to $[(e_M{}^0)S^2/\Delta e^0 + (e_M{}^0)^2S^4/(\Delta e^0)^2]$.[63] The leading term in this expression is closely related to the angular overlap term. In the application of AOM, if changes in S^2 do not distinguish one geometry over another the method is sometimes extended[62] to include the next higher power term in the expansion, namely $(-)\gamma S^4$, where γ is given by $(e_M{}^0)^4/(e_X{}^0-e_M{}^0)^3 = (e_M{}^0)^4/(\Delta e^0)^3$.

At the quadratic level there is a sum rule that can be invoked in AOM.[62,64] Consider CaH_2; the ligand combinations s_1+s_2 and s_1-s_2 are both occupied in this four-valence electron system, so that the sum of the squares of the overlap integrals between the metal and ligand orbitals will be constant with variation in bond angle. Hence, we cannot use "constant β" AOM to explain why CaH_2 is bent. This is the approach which Burdett used in his application of AOM.[61,62,65] We need to delve deeper into the problem in order to understand why the *d* orbitals gain in population as the molecule is bent; AOM predicts that there would be no change in population and no tendency to bend. (We neglect any contribution from the metal *s* orbital to the

bonding in the symmetric orbital in the previous statement.) Consideration of the fourth-order terms would provide a rationale for the bent structures. What we showed in the previous section is that there is no need to invoke a fourth-order perturbation approach, but that a detailed analysis of changes in metal orbital populations is provided by the function $S^2/\Delta e^0$.*

In summary, our work shows that AOM treatments which ignore changes in Δe^0 may be flawed. Treatments which pursue a fourth-order perturbation may be unnecessary if second-order terms are covered properly. Explanations that involve only overlap arguments to explain geometry also may be flawed if there is no cognizance of the sum rule. For example, Myers *et al.*[66] claim that the lanthanoid trihalides are pyramidal based on an overlap argument. The sum rule shows clearly that, while the square of one particular overlap is increasing, others are decreasing by a like amount. Jolly and Marynick[2d] have rationalized the pyramidal structure of ScH_3 with statements such as "all five *d* orbitals are of the correct symmetry" for bonding to the ligand orbitals in the pyramidal structure but not in the trigonal planar structure. Once again, such arguments essentially boil down to overlap considerations which do not take account of the sum rule mentioned above. Explanations might rather be sought that involve a function such as we have used: $\Delta[S^2/\Delta e^0]$. On the other hand, one could argue that the interactions between metal and ligand orbitals are so large for these molecules that an AOM approach should never be attempted. Then there is no validity to the sum rule, since one needs to solve the secular equations, and a back-of-the-envelope interpretation is not possible. In that case, the above authors cannot be criticized for their approach. The "rule of thumb" that a central atom seeks to use as many orbitals as possible in bonding to the ligands[62] cannot be rationalized at the quadratic level of AOM treatment.

Bond energy analysis of CaH_2 *from* Ca *and* H_2 *fragments*

The bond energy analysis of the wavefunction can be referenced to molecular fragments rather than to atomic fragments (atomization energies).[32,67] It can be broken down further into *steric* and *electronic* components; the latter can be subdivided into components due to each irreducible representation of the molecular point group. For CaH_2 we have completed such a fragment study in C_{2v} symmetry for both the linear and the bent molecule. The fragments that we have employed are the ground state Ca atom and the H_2 fragment in its "prepared" state. The latter is at the bond length appropriate for "insertion" of the Ca and with electron occupation $(\sigma_u)^2$. This choice of electron occupation for the two fragments ensures that we will not have an avoided crossing of energy states as the two fragments come together. That is, the reaction is symmetry allowed for the Ca atom approaching the "prepared" H_2 in a side-on fashion.

We are interested only in the relative values of the terms mentioned in the previous paragraph; that is, the bent geometry relative to the linear geometry. In Table 6 we present these values. Notice that the relative preparation energy is destabilizing for the bent geometry. This is as expected since we are forming the H_2 fragment with the electrons in the antibonding orbital. In the bent molecule the two protons are nearer each other so that this geometry is less stable than it is in the linear molecule. The steric term favours the bent geometry slightly. The major relative energy changes are in the electronic terms. As expected, the term involving the representation that includes the z^2 and x^2-y^2 orbitals shows a destabilization due to the decrease in effective overlap with the latter orbital. However, this destabilization is more than compensated by the stabilization afforded by the representation that contains the xy orbital. These energy numbers demonstrate very clearly effects that are used often in Walsh-rule explanations. For example, the importance of the antisymmetric representation to the bond (xy) which results in the molecule becoming bent. The sum of all these effects is the 2 kcal mol^{-1} stabilization for the bent

* As seen in the discussion, the leading term in the expression for population of metal orbital is $(e_M{}^0)S^2/\Delta e^0$. We ignore the $e_M{}^0$ term. The resultant term in $(-)S^2/\Delta e^0$ is familiar in second-order perturbation theory. Now, the eigenvalues in HFS take on a different meaning than in the Hartree–Fock theory. (L. Noodleman, D. Post and E. J. Baerends, *Chem. Phys.* 1982, **64**, 159.) This has little effect upon Δe^0 but it has a drastic effect upon $e_M{}^0$. The latter should be stabilized by several electron volts if it is going to take on the values found in the Hartree–Fock theory. Our values of $e_M{}^0$ are near zero for the metal *d* orbitals. Hence, shifts of only a few tenths of an electron volt can have a dramatic effect upon the expression $(e_M{}^0)S^2/\Delta e^0$. On the other hand, if $e_M{}^0$ values were at about -5 eV, shifts of a few tenths of an electron volt would have little influence upon $(e_M{}^0)S^2/\Delta e^0$. In principle, since $e_M{}^0$ values do not shift much for a given molecular system as the geometry is changed, we should be able to ignore it and garner trends from $(-)S^2/\Delta e^0$. Finally, we point out that the values of Δe^0 that we have available are not from the original **H** matrix, but rather from the transition state matrix.[32]

Table 6. Relative energetics for insertion of a ground-state calcium atom into "prepared" H_2

Term	Relative energy[a] (kcal mol^{-1})
Preparation of H_2 fragment	−3.4
Steric effect	0.5
Electronic effect	
symmetric representation (e.g. s, z^2, x^2-y^2)	−8.2
antisymmetric representation (e.g. xy)	13.0
Total	1.9

[a] A positive number indicates that the bent geometry is favoured.

geometry that we mentioned at the outset of our discussion on relative energies.

Angular geometry—Electric multipole expansion model

As mentioned in the introduction, the electric multipole expansion method[68] was first applied by Rittner[22] to the alkali halides and later by Guido and Gigli,[24] and Hildenbrand[25] to the alkaline earth dihalides. Guido and Gigli used the method to interpret both the geometry and the atomization energies. Hildenbrand used a truncated version (charge–charge and charge–dipole terms only) to rationalize the atomization energies. Both methods gave good results in comparison to experiment. Since we already have discussed the theoretical and experimental atomization energies, and since the published literature has established that the atomization energies can be understood well within the framework of the multipole expansion method, we focus our attention in this section on the ability of the multipole expansion to rationalize the *angular* geometry of the alkaline earth dihalides.

Following the approach of Hildenbrand, the variation in energy as a function of angle θ is given by the following expression for a metal cation (+2) and ligand anions (−1):

$$E(\theta) = -\frac{e^2}{r}\left(4-\frac{1}{2\cos\theta}\right) \quad \text{c–c}$$

$$-\frac{e^2}{r^4}\left[(2\sin^2\theta)\alpha_M+\left(4+\frac{1}{16\cos^4\theta}-\frac{1}{\cos\theta}\right)\alpha_X\right] \quad \text{c–d}$$

$$-\frac{6\alpha_M\alpha_X e^2}{r^7}\left[\sin^2\theta\left(2+\cos^2\theta-\frac{1}{2\cos\theta}\right)\right] \quad \text{d–d.}$$

The angle θ is related to the X—M—X bond angle, ϕ, by the relation $\theta = 90° - (1/2)\phi$. The M—X bond length is r, the dipole polarizability of the metal cation is α_M and that of the ligand anion is α_X. The first, second and third lines refer to the charge–charge, charge–dipole and dipole–dipole terms, respectively. The sign of the equation is such as to provide the energy *lowering* that results upon bringing the ions together to form the neutral molecule. We have not included dipole–dipole terms between the two ligands as this term is negligible for non-bonded atoms.[24] We also have neglected the (Born–Mayer) repulsive and (London) attractive terms that arise between the non-bonded ligands, since for the bond angles that we are interested in the distance between these two atoms is so large as to again make these terms unimportant.[23,24] Our expression is the same[69] as that given by Hildenbrand[25] except we have added the third term (d–d) in the multipole expansion. As we shall see this term is important if we are to make sense of the angular geometry of these molecules. In Scheme 3 we presented typical pictures that can be associated with the c–d and d–d terms. The first c–d picture on the left is associated with the "reverse" polarizability effect that was mentioned in the introduction. It is related to the $(2\sin^2\theta)\alpha_M$ term in the equation for $E(\theta)$.

Figure 1 shows the variation of each of the three terms as a function of angle for CaF_2, scaled

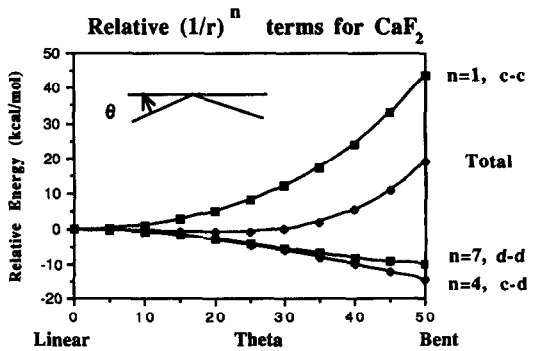

Fig. 1. Multipole expansion for CaF_2. See text for details.

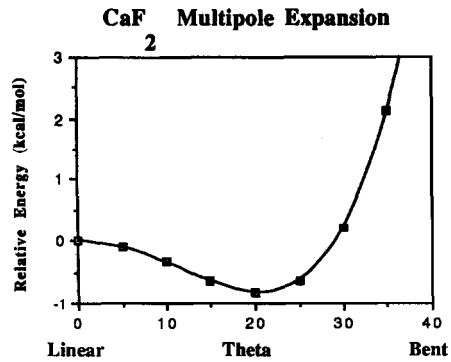

Fig. 2. Blow-up of the "total" energy term for the multipole expansion results of Fig. 1, for CaF_2.

relative to the value of the term for the linear molecule. The sum of these three terms is given also. The parameters that we have employed for this plot are: $r = 2.10$ Å, $\alpha_M = 0.95$ Å^3 and $\alpha_X = 1.0$ Å^3. The bond length is the same as that assumed by Hildenbrand and by Guido and Gigli. The α_M value corresponds to that chosen by Guido and Gigli and α_X to that used by Hildenbrand. (At this stage we take these values as representative. Other values could have been chosen for any of the three parameters but they would be close to these three. For example, Hildenbrand assumed a value for α_M of 0.70 Å^3; Guido and Gigli assumed a value of 1.05 Å^3 for α_X.)

Notice that the c–c term becomes *less* negative as the molecule is bent, exactly as expected due to the ligand–ligand repulsion. Meanwhile each of the higher order terms becomes *more* negative and are of about equal importance. The sum of the three gives the total energy $E(\theta)$, which on the scale of Fig. 1 seems not to show any energy lowering as a function of bond angle. However, a detailed blow-up as shown in Fig. 2 reveals that the energy drops by about 1 kcal mol^{-1} and reaches a minimum at a bond angle of about 140° before again increasing. This result is about the same as that provided by our quantum chemical results both for the depth of the well and the angle.

But how worthwhile is such a result for explanation of the bond angle? We contend that it is not worth much. For example, if we decrease the value of α_M from 0.95 to 0.70 Å^3 we find that no potential well is exhibited whatsoever! Guido and Gigli have argued that the model is fairly robust with respect to its ability to predict bond angles for different values of α_M. They used as their examples BaF_2 and $BaCl_2$. These are molecules that have a relatively deep potential well and so the effect of variation in one of the parameters is less important. For the case of CaF_2 we find that a slight variation in α_M is very important. Our point in presenting Figs 1 and 2 is simply to show the competing effects of the various terms in the multipole expansion, and to comment upon how sensitive the method is to changes in the parameters that are employed. We do not claim to have carried out a complete multipole expansion, but the terms that we have neglected are an order of magnitude less important than the ones we have included, as far as their angular dependence is concerned.*

We attempted to apply the multipole expansion method also to CeO_2.† The value of α_M was taken from Pauling (0.73 Å^3);[70] two values of α_X were employed: 2.75 and 3.88 Å^3.[49] A small value of α_X (1.93 Å^3) is suggested by the work of Duffy.[71] We also used a value of α_M that was 1.46 Å^3; in none of the six combinations of these parameters could we obtain an energy lowering upon bending the molecule.

In summary, we do not put much faith in the multipole expansion method as a reliable model to rationalize the angular geometry of the title molecules. This conclusion agrees with that of Coulson.[72] Furthermore, while it is true that the reverse polarization term $[(2\sin^2\theta)\alpha_M]$ is important in lowering the energy, the d–d effect is equally important as seen from Fig. 1. This also is clear from the detailed work of Guido and Gigli as shown in Fig. 4 of their paper.

Before leaving the electric multipole expansion model we note that the method is by no means outdated. Two areas in which it seems to be useful are in understanding the nature of weak *intermolecular* interactions[73a] and the bonding in singly charged metal clusters.[73b]

SUMMARY AND CONCLUSIONS

This work has shown that the simplest way to interpret the bent geometry of the title molecules is through *sd* hybridization (Scheme 1). The electric multipole expansion method is shown to be suspect for all the molecules, and unable to obtain the correct answer for CeO_2. Our results are in agreement

* Not only are the terms that we have neglected small, but they also tend to cancel one another. The Born–Mayer and negative dipole–negative dipole terms become more repulsive as the molecule is bent. The London term becomes more attractive.

† The form of the equations for the multipole expansion is exactly the same for CeO_2 as it is for MX_2, except that a factor of four is introduced into each term. Since we are interested only in change in energy with angle this has no effect in our treatment. The bond length that we used was 1.82 Å.

with the work of Schilling *et al.*[74] who obtain for CaH^+ a metal contribution to the bond which is 60.0% 4*s*, 16.3% 4*p* and 23.7% 3*d*. Their work further shows that, for CaH^+, the *intrinsic* bond strength of the 3*d* orbital is very high compared to that of the 4*s*, so that the 3*d* contribution to the bond strength is greater than indicated simply by the per cent composition of the orbital.

It is of interest to relate the present work to that of Group 12 divalent metal molecules such as $ZnCl_2$ or $Hg(CH_3)_2$ which are always linear about the metal atom.[5b,75] Our work[76] on such molecules emphasized that neither the unoccupied valence *p* orbital nor the fully occupied valence *d* orbital contribute much to the bonding, and so these molecules are best thought of in terms of three-centre four-electron bonds involving the metal *ns* orbital. A combination of *sp* hybridization and ligand–ligand repulsion effects work together to bring about the linear geometry for these molecules. The effect of the valence *d* orbitals on the bonding is minimal because these orbitals are fully occupied in the free atom. This conclusion is consistent with the work of Schilling *et al.*[74] who obtain for ZnH^+ a metal contribution to the bond which is 90.7% 4*s*, 8.9% 4*p* and 0.4% 3*d*. Finally, we point out that the "rule of thumb" that a central atom seeks to use as many orbitals as possible in bonding to the ligands cannot be rationalized on AOM grounds.

Acknowledgements—The authors thank Calvin College for a Calvin Research Fellowship to R.D.K. Financial support for this work also was provided by the Petroleum Research Fund, administered by the American Chemical Society, and by NATO through a Collaborative Research Grant. Appreciation also is expressed to A. J. Krominga and to D. L. Hildenbrand for assistance with the multipole expansion work. Thanks are also due to C. J. Marsden for communicating his results on CaF_2.

ATOM SITE PREFERENCE IN S_4N_4*

KIMBERLY A. SCHUGART

Department of Chemistry and Biochemistry, California State University, Long Beach, CA 90840, U.S.A.

Abstract—The question of atom site preference as it pertains to the observed and inverse (not observed) structures of S_4N_4 is investigated from the standpoint of electronic structure theory. An analysis is made through an understanding of geometric constraints in simplified systems and extrapolation to the larger question of factors controlling structure is discussed.

The most fundamental issue of structural inorganic chemistry is the question of atom site preference. For a given structural framework of a molecule, polymer or solid, different arrangements of different types of atoms or atomic groupings can be imagined. In the case of S_4N_4 two sites exist. One is two-fold (a two-coordinate site) while the other is three-fold (a three-coordinate site). This experimentally observed form of the structure is shown in Fig. 1(a). In observed S_4N_4, sulphur occupies the three-fold positions while nitrogen occupies the two-fold sites. However, there is no obvious reason why the inverse structure (nitrogen in the three-fold position and sulphur in the two-fold position) could not exist, though its existence has not been detected. This inverse arrangement is shown in Fig. 1(b). In one sense the inverse structure is more plausible as the ground state of nitrogen is ^4S, making it a likely candidate for the three-fold position, and the ground state of sulphur is ^3P, placing it as a likely possibility for the two-fold site.

THEORETICAL APPROACH

The Gaussian 88[1] electronic structure methodology run on a Multiflow Trace 14 supercomputer generated the wavefunctions used in this study from a 6-31G basis set. All species considered were geometry optimized at the single determinant level. Constraints to maintain D_{2d} symmetry for observed and inverse structures of S_4N_4 and mirror plane symmetry in the fragment systems were the only restrictions to the optimizations.

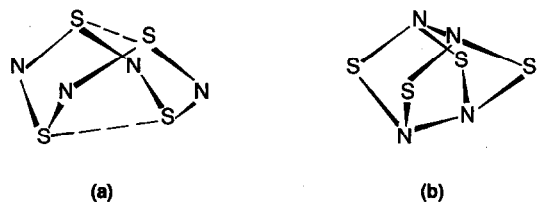

Fig. 1. Observed (a) and inverse (b) structures of S_4N_4.

RESULTS AND DISCUSSION

The atom site preference question has been treated through semi-empirical[2] and non-rigorous *ab initio*[3] approaches, as well as through topological[4] and group theoretical[5] methods. (Traditionally, the terms "delocalized bond" and "free electron model" categorize the computational and mathematical approaches, respectively.[6]) Here, the question is examined through a rigorous *ab initio* approach.

Table 1 compares the experimental structure with a geometry optimized single determinant wavefunction structure. The angles about nitrogen and sulphur are in close agreement with the theoretical

Table 1. Data for observed (experimentally determined) and inverse (theoretically determined) S_4N_4

	Experimental	Theoretical
Angles (in deg)		
S—N—S	115[8] and 113[9]	113.8
N—S—N	102[8] and 105[9]	104.3
Distances (in Å)		
N—S	1.62[8,9]	1.60
S—S	2.58[8,9]	2.58

* Dedicated to Professor Richard F. Fenske in appreciation of his fundamental contributions to molecular orbital theory and his inspiration as my PhD advisor.

results (roughly 114° for S—N—S and 104° for N—S—N) lie between the two sets of experimentally determined results (113 and 115° for S—N—S and 105 and 102° for N—S—N). Likewise, the results for the intramolecular distances show a good match between experimental (1.62 Å for N—S and 2.58 Å for S—S) and theoretical (1.60 Å for N—S and 2.58 Å for S—S) data. Table 2 lists the calculated results for the hypothetical inverse structure, the structure that is not observed experimentally. The S—N distance is lengthened considerably and the angles about sulphur and nitrogen are much smaller than in the observed structure. Both of these structural changes are expected.

The structural results of the calculations can be deduced from a comparison of Lewis dot structures for S_4N_4 and its inverse. The dot structures are shown in Figs 2 and 3. The extensive electron delocalization and concomitant N—S multiple bond character in the observed structure is clear through the type and number of resonance structures that must be used to describe the bonding as shown in Fig. 2. The observed and calculated angles in the observed structure correspond to the hybridization that is expected as well. While four structures are shown, many more might be drawn as well. Contrastingly, the inverse structure, with single S—N bonds is adequately represented by one diagram, shown in Fig. 3. The angles about sulphur and nitrogen in the inverse arrangement point to the 90.0° arrangements that characterize angles about atoms which bond to other atoms primarily through *p* orbitals. Interestingly, the total energy of the inverse, unobserved structure, −1807.1691 hartrees, is lower than the total energy of the observed structure, −1807.0737 hartrees. The 95 millihartree difference between these two values can be understood as the inadequacy of the single determinant wavefunction to truly represent the many resonance structures that are involved in a complete description of the molecule's electronic structure. As the data for both the observed and inverse structures appear reasonable in terms of molecular geometries, and the energies of the two are close in the limit of the single determinant wavefunction, the question of atom site preference must be addressed by breaking the compound into smaller fragments, to assess more simply the forces involved in the larger structure.

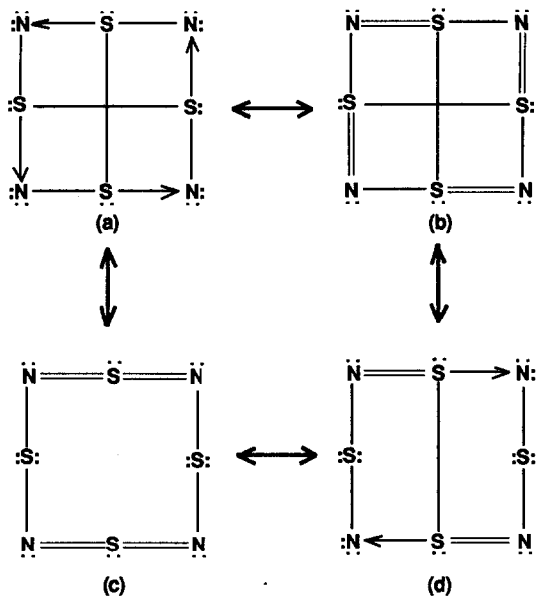

Fig. 2. Lewis dot representations of electronic structure of observed S_4N_4.

A pivotal difference that can be analysed easily lies in the bonding at the two-fold sites in the observed and inverse structures. The two-fold position is occupied by nitrogen in the observed structure and by sulphur in the inverse one. The angle at nitrogen in the observed structure is stretched somewhat with respect to a tetrahedral angle (113.8 vs 109.5°), while the angle at sulphur in the inverse structure of S_4N_4 is compressed to 83° relative to the 90° angles for *p* orbital bonding orientations. Two artificial fragment structures can be constructed to mimic the environments of the sulphur and nitrogen in the two-fold positions they occupy in the inverse and observed structures respectively, and these are shown in Fig. 4. Figure 4(a) shows the fragment used to analyse the two-fold position for the nitrogen in the observed structure and Fig. 4(b) shows the one used to mimic the two-fold position for sulphur in the inverse structure. Both frag-

ments are described as ground-state singlet wavefunctions with hydrogen atoms tying-off electrons that would otherwise serve to connect the fragment to the rest of the structure. By optimizing the angles for these two systems and then comparing the energies of the optimized angle wavefunctions to the energies for the angles as they are constrained for these two systems in the larger parent molecules, an assessment of the energetic costs to form the entire molecule is derived.

The data for the angle optimization and cost to achieve the geometry of the actual molecular structure is presented in Table 3. For the observed structure, the optimum angle about the two-fold nitrogen site is 105.2°. Stretching this angle to the 113.8° of the observed molecule costs 0.002 hartree. The potential for the angle opening is soft and little energy is required to achieve it. For the inverse structure, the optimum angle about the two-fold sulphur site is 106.1°. A difference of 23° exists between it and the 83° angle of the optimized structure. The energetic costs to compress the fragment angle is substantial; it requires 33 millihartrees to do so. All told then, while virtually no energy input is required to alter the two-fold site fragment for the observed structure to its parent molecular geometry, more than 30 millihartrees is required to alter the two-fold site fragment for the inverse structure to its parent molecular geometry. By this analysis, although the total energies of the observed and inverse strucures are close, the actual energetic cost to building the molecule in the inverse structure will be substantially higher. The conclusion that can be drawn is not that the inverse structure will never be observed, but rather that a markedly different set of conditions is required to synthesize it.

Table 3. Data for optimized angles of fragment structures and costs to achieve geometry of parent structures

Species	Optimum angle (deg)	Parent structure angle (deg)	Difference (hartrees)
Fragment of observed	105.2	113.8	+0.002
Fragment of inverse	106.1	83.0	+0.033

CONCLUSION

Based upon the analysis of the two-fold sites in S_4N_4 and its inverse, the reason for the site preference of the observed over the inverse structure is the much greater energetic cost encountered in meeting the geometric requirements of the inverse structure. This argument, in its most abstract sense suggesting that an investiture of energy to overcome a barrier will yield an alternative result, can be seen as reducing the question of atom site preference to one of kinetic control. It is important to recognize, though, that kinetic control is not exclusive of thermodynamic control and only through further study of S_4N_4 can a more complete determination of the reasons for site preference in this molecule be made.

THE ELECTRONIC STRUCTURE OF SOME RUTHENIUM(II) COMPLEXES RELATED TO $[Ru(bipy)_3]^{2+}$: AN INVESTIGATION OF THE STEPWISE REPLACEMENT OF *N,N*-DONORS BY *C,N*-DONORS*

EDWIN C. CONSTABLE and CATHERINE E. HOUSECROFT

University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

Abstract—An analysis of the electronic structures of members of the series of complexes $[Ru(bipy)_{3-n}(ppy)_n]^{(2-n)+}$ (bipy = 2,2′-bipyridine and Hppy = 2-phenylpyridine) is presented. The cyclometallated complexes (i.e. those in which one or more $[ppy]^-$ replace bipy ligands) exhibit a distinct separation of Ru—C and Ru—N σ-bonding character, and in *cis*-$[Ru(bipy)(ppy)_2]$, further separation of bonding character occurs to give MO's which possess *either* Ru—C, Ru—$N_{[ppy]^-}$, *or* Ru—N_{bipy} components. Comparisons of the *cis*- and *trans*-isomers of $[Ru(bipy)(ppy)_2]$ and of the *fac*- and *mer*-isomers of $[Ru(ppy)_3]^-$ suggest that the observed experimental preference for *cis*- over *trans*- and *fac*- over *mer*-structures may be due to the enhanced σ-donating ability of the carbon atom when it resides *trans* to a nitrogen rather than carbon donor.

The photolysis and photochemical properties of the complex cation $[Ru(bipy)_3]^{2+}$ have been the subject of intensive investigation in the past decade.[1] Particular interest has centred upon the possibilities of using this species as a primary photocatalyst in solar energy photoconversion systems, and numerous chemical modifications involving variation of the metal centre and/or the ligand set have been described. Other transition metal tris(2,2-bipyridine) complexes have been studied, and iridium(III) complexes have proved to possess novel chemical and useful photophysical properties.[2] Complexes nominally formulated as $[Ir(bipy)_3]^{3+}$ have been known since 1959, but have been shown to possess anomalous properties. The anomalies are associated with the formation of cyclometallated complexes in which a bipy ligand is bonded to the metal in a *C,N*-mode. The cyclometallated complex exhibits long luminescence lifetimes in fluid solution and has led us and others to investigate the properties of transition metal complexes incorporating cyclometallated ligands. The ligand Hppy forms cyclometallated complexes in which the $[ppy]^-$ anion may be formally regarded as a *C,N*-donor analogue of bipy (Fig. 1).[3] The introduction of the *C,N*-donor ligand has a dramatic effect upon both the ground- and excited-state redox and electronic properties of the complexes.[4–6] In order to probe the origins of the ground-state effects and to investigate the electronic consequences of the sequential introduction of the cyclometallated ligands we have performed Fenske–Hall quantum chemical calculations upon the series of ruthenium(II) complexes $[Ru(bipy)_{3-n}(ppy)_n]^{(2-n)+}$ (n = 3, 2, 1, 0). A particular interest was to determine whether the spatial arrangement of the cyclometallated ligands in the complexes with n = 2 and 3 greatly perturbed the electronic properties. This is of considerable importance as frequently only one isomer is available from the synthetic routes adopted. The results determined here for the ruthenium(II) complexes (not all of which are known experimentally) are expected to be applicable by analogy to other isoelectronic and isostructural series incorporating $[ppy]^-$ and bipy ligands.

* This paper is dedicated to Professor Dick Fenske on the occasion of his retirement.

EXPERIMENTAL

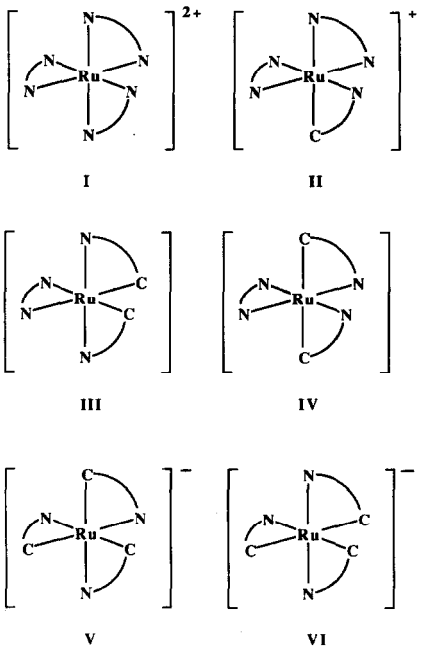
The Fenske–Hall[7,8] quantum chemical technique was used to examine the bonding in $[Ru(bipy)_3]^{2+}$ (**I**), $[Ru(bipy)_2(ppy)]^+$ (**II**), *cis*-$[Ru(bipy)(ppy)_2]$* (**III**), *trans*-$[Ru(bipy)(ppy)_2]$ (**IV**), *fac*-$[Ru(ppy)_3]^-$ (**V**) and *mer*-$[Ru(ppy)_3]^-$ (**VI**). In each case, a four fragment transformed orbital basis set was generated such that the interaction of each ligand with the metal ion could be examined. Positional coordinates for the complexes were taken from those previously reported in structural determinations of salts of the $[Ru(bipy)_3]^{2+}$[9] and isomorphous $[Os(bipy)_3]^{2+}$[10] complex cations. The introduction of the cyclometallated $[ppy]^-$ ligand is known to have no effect upon the overall crystallographic symmetry or individual M—N distances in the $[Rh(bipy)_2(ppy)]^{2+}$ dication[11] which exhibits a six-fold disorder.

The Fenske–Hall calculations employed single-ζ Slater functions for the 1*s* and 2*s* functions of carbon and nitrogen. The exponents were obtained by curve-fitting the double-ζ functions of Clementi[12] while maintaining orthogonal functions; the double-ζ functions were used directly for the 2*p* orbitals. An exponent of 1.16 was used for hydrogen. The ruthenium basis functions were augmented by 5*s* and 5*p* functions with exponents of 2.20;[13] ruthenium functions were chosen for the (+1) oxidation state since these provided a more reasonable charge distribution in line with the Pauling Electroneutrality Principle than results for those using the (+2) oxidation state.

RESULTS AND DISCUSSION

Ligand frontier orbitals

An appreciation of the differences in the bonding capabilities of the bipy and $[ppy]^-$ ligands is fundamental to an investigation of the bonding in compounds **I**–**VI**. Energies and orbital characteristics of the frontier MO's of the two ligands are depicted in Fig. 2. In bipy, MO's 28 and 29 (HOMO) are the in- and out-of-phase combinations of nitrogen atom lone pairs; for each MO, molecular symmetry dictates that there is a 50% contribution from each nitrogen-based orbital. The introduction of carbon in place of nitrogen reduces the symmetry of the ligand, and the effect upon the frontier MO's is quite dramatic. The HOMO of $[ppy]^-$ possesses



> 95% carbon character while the nitrogen lone pair character is localized in MO 28. Figure 2 illustrates that the energy separation of the donor orbitals 28 and 29 is far greater in $[ppy]^-$ than in

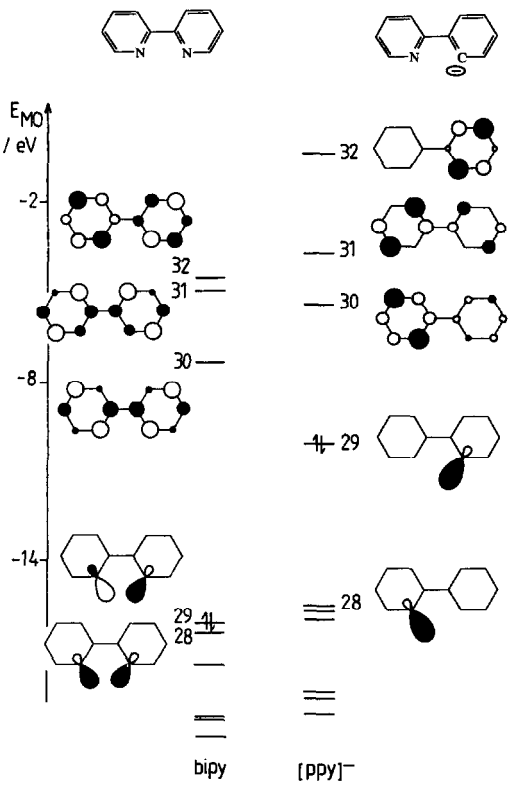


Fig. 2. Comparison of the frontier MO's of bipy and $[ppy]^-$. The MO energies are taken from the Fock matrix of complex **II**.[14] The π-systems of the vacant MO's are represented as a projection down onto the bipy and $[ppy]^-$ rings.

* There are 2 possible isomers of $[Ru(bipy)(ppy)_2]$ in which the C atoms are *cis* with respect to one another, **III** and **VII**. Experimental data are consistent only with structure **III**; see ref. 5.

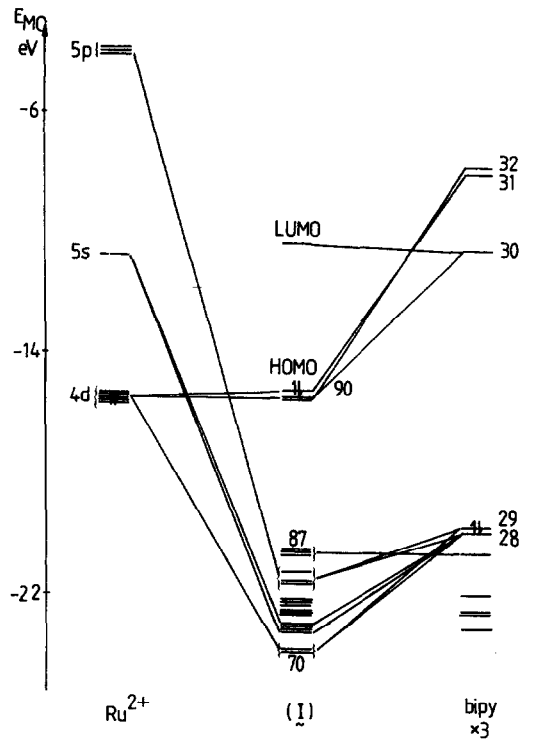

Fig. 3. Orbital correlation diagram for the interaction of three bipy ligands with Ru^{2+} in **I**. Since the three ligands are all chemically equivalent, the MO's of only one bipy is shown. The fragment orbital energies are taken from the Fock matrix of complex **I**.[14] Contributions made by each of MO's 30–32 to MO's 88–90 $\leqslant$ 6%.

bipy and this observation is critical to the discussion which follows. A similar partitioning of orbital character for the nitrogen and carbon donor rings occurs for the unoccupied ligand MO's represented in Fig. 2, where the relative sizes of the 2*p* lobes correspond to atomic orbital coefficients.

The calculated atomic charge distribution for the free ligands results in each nitrogen atom of bipy carrying a charge of −0.295. This remains essentially the same in $[ppy]^-$ (−0.297), leaving the carbon donor site to carry most of the overall negative charge (−0.748).

Bonding in $[Ru(bipy)_3]^{2+}$ (I)

The interaction of the three bipy ligands with the ruthenium centre follows the classical pattern of bonding for an approximately octahedral set of six donor atoms as illustrated in Figs 3 and 4. Linear combinations of bipy MO's 28 and 29 from the three ligands interact with the metal $4d_{x^2-y^2}$, $4d_{z^2}$, 5*s* and 5*p* orbitals to provide the Ru—N σ-bonds; 92% of the total metal–ligand Mulliken overlap population involves these interactions. The molecular symmetry of **I** is D_3 rather than O_h, and hence the interaction of the metal $5p_x$, p_y and p_z orbitals with the bipy frontier orbitals gives rise to a_2 (MO 84) and *e* (MO 82/83) bonding MO's rather

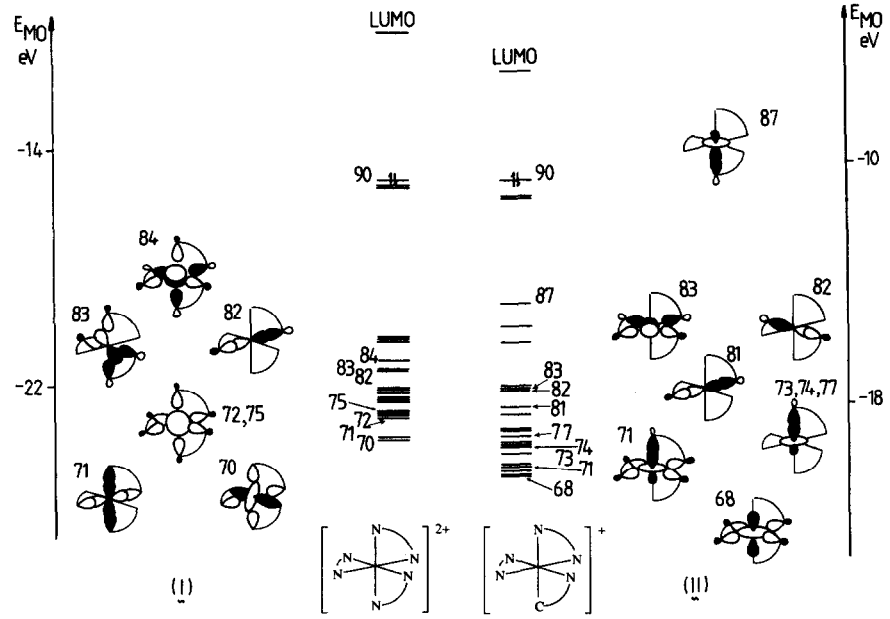

Fig. 4. Perturbation of the MO's of **I** upon substitution of one bipy for the $[ppy]^-$ ligand, i.e. generation of **II**. The energy scales of **I** and **II** have been shifted linearly with respect to each other to facilitate easy comparison of the MO's. MO's 88–90 possess π-backbonding character. Where one diagrammatic representation is assigned to more than one MO, the character is spread through the stated MO's and mixes with the other (Ru—L non-bonding) ligand, L, MO's.

than a t_{1u} set; similarly, MO's 88–90 have a_1 and e symmetries rather than t_{2g}.[15] Within the framework of the Fenske–Hall method, the character of the bonding interaction between the metal 5*s* orbital and in-phase ligand MO's 28 appears both in MO's 72 and 75 of **I** (Fig. 4).

Metal-to-ligand backbonding accounts for 8% of the total Ru–bipy Mulliken overlap population and the lowest unoccupied ligand MO's (30–32) together gain 0.223 electrons per bipy ligand, 67% of this being accepted by the original LUMO.

Comparison of $[Ru(bipy)_2(ppy)]^+$ **(II)** *with* **I**

The degree to which the molecular orbitals of **I** are perturbed upon the substitution of $[ppy]^-$ for one bipy ligand is illustrated in Fig. 4. Firstly, with respect to the HOMO, the lowest unoccupied MO's of **II** tend to be lower in energy than those in **I**. This trend is consistent with the experimental observation that there is a shift to lower energy for transitions in the absorption spectrum in going from **I** to **II**.[16]

The second important feature is that the $Ru—C_{[ppy]^-}$ character is essentially localized in one orbital, MO 87. In **I**, MO's 85–87 comprise a set of ligand based orbitals derived from MO 27 (the highest occupied π-orbital) of each bipy ligand (Fig. 3); this set is identified as MO's 84 through 86 in **II**. Lying above these, but below the Ru—L π-backbonding MO's, is MO 87, the character of which is 90% $Ru—C_{[ppy]^-}$ bonding (Fig. 4). On the other hand, $Ru—N_{[ppy]^-}$ bonding character appears in orbitals which are also $Ru—N_{bipy}$ bonding as shown schematically in Fig. 4. The partitioning of $Ru—C_{[ppy]^-}$ and $Ru—N_{[ppy]^-}$ character in **II** reflects the separation of carbon and nitrogen donor atom character in the free $[ppy]^-$ ligand. The HOMO of $[ppy]^-$, comprising wholly carbon rather than nitrogen σ-donor character and being significantly higher in energy than the nitrogen σ-donor MO 28 (Fig. 2), will interact with the ruthenium AO's to generate $Ru—C_{[ppy]^-}$ bonding orbitals which are higher in energy than the $Ru—N_{[ppy]^-}$ containing MO's.

A third effect resulting from the substitution of one ligand in **I** is, naturally, a change in the σ-donating and π-accepting abilities of the ligands. These trends are shown in Figs 5 and 6, respectively. The occupancies of ligand MO's 28 and 29 after complex formation are a measure of the σ-donating ability of the ligand. Conversely, the occupancies of ligand MO's 30–32 indicate the degree to which ruthenium → ligand π-backbonding occurs. Figure 5 illustrates that the introduction of a $[ppy]^-$ ligand, **I** to **II**, reduces the donor capacity of each remaining bipy ligand. However, the change is slight. Looking now at the right-hand side of Fig. 5, we observe that charge transferred from $[ppy]^-$ MO 29 greatly exceeds that lost by $[ppy]^-$ MO 28. This is expected on the grounds of electronegativities; the carbon

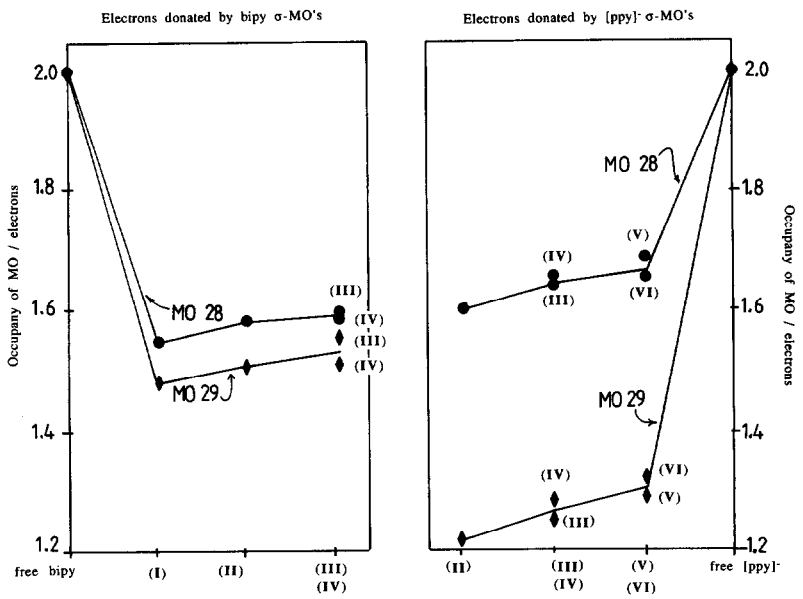

Fig. 5. Donor abilities of bipy and $[ppy]^-$ ligands in complexes **I**–**VI**. Reading from left to right, the diminishing ability of the bipy ligands is observed as increasing substitution occurs. From right to left, the increasing ability of the $[ppy]^-$ ligand to donate σ-electron density as a function of complex composition is seen. Where like donor sites are geometrically distinct, average values are given unless significant variation is seen.

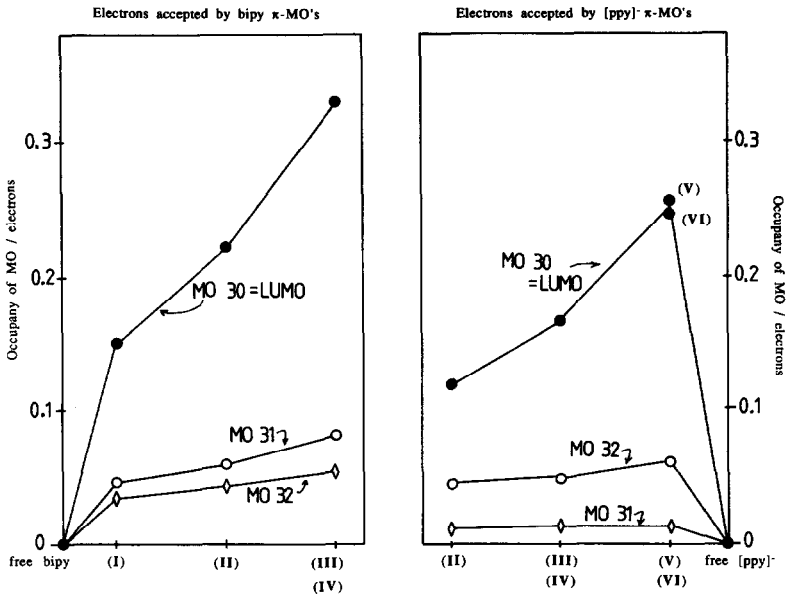

Fig. 6. Acceptor ability of bipy and $[ppy]^-$ ligands as a function of substitution in $[Ru(bipy)_{3-n}(ppy)_n]^{(2-n)+}$ ($n = 0, 1, 2, 3$).

(localized in MO 29) is a better σ-donor than the nitrogen atom (localized in MO 28). The σ-donating ability of $[ppy]^-$ MO 29 greatly exceeds either of bipy MO's 28 and 29. However, the final atomic charge on the ruthenium atom does not change significantly in going from complex **I** to **II** (Table 1).* The reason for this is apparent on inspection of Fig. 6; the π-accepting ability of the bipy ligand is quite dramatically enhanced upon the introduction of the $[ppy]^-$ ligand, and together, the two bipy ligands in **II** remove the excess electron density pumped on to the metal centre by the $[ppy]^-$ ligand.

General trends accompanying stepwise substitution of $[ppy]^-$ *for* bipy *ligands*

The trends in orbital energies, composition and charge distribution discussed above continue

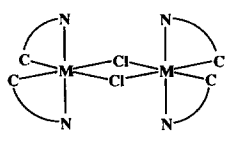
smoothly as bipy ligands are sequentially replaced by $[ppy]^-$ ligands. (A detailed analysis of the bonding in isomers **III** vs **IV** and in **V** vs **VI** is given below.) Consider first the charge distributions. Figure 5 illustrates two important features: (i) the donor ability of the nitrogen atom of the $[ppy]^-$ ligand is always less than that of the nitrogen atoms of bipy, and (ii) the σ-electron donating capacity of the carbon site in $[ppy]^-$ always exceeds that of nitrogen. Corresponding to these differences is a differential in the π-acceptor properties of the two ligands (Fig. 6), controlled largely by the availability of the LUMO. As shown in Fig. 1, the LUMO for $[ppy]^-$ is essentially localized on the nitrogen-containing ring, thus making the nitrogen atom of this ligand a more effective site for π-acceptance than the metal associated carbon atom. The occupancies of MO's 30–32 are represented in Fig. 6 as a function of ligand substitution in $[Ru(bipy)_{3-n}(ppy)_n)]^{(2-n)+}$ ($n = 0, 1, 2, 3$). The π-accepting ability of the bipy ligand (dominated by the rôle of the LUMO) *increases* with the degree of substitution, n, and this increase compensates for the lower π-accepting and for the increased σ-donating capability of the $[ppy]^-$ ligand. Compared to its rôle in the mixed ligand complexes, each $[ppy]^-$ ligand in the tris(2-pyridylphenyl) complex functions more efficiently as a π-acceptor. This state arises from the fact that $[ppy]^-$ ligands *alone* must now satisfy the need of the metal ion to offload residual negative charge and hence satisfy the Electroneutrality Principle.

Trends in orbital energies are influenced by the variation in overall charge of the complexes, and, as expected, the energy of the HOMO becomes less negative as $[ppy]^-$ ligands replace bipy ligands. The observed trend of higher energy HOMO's across the series $[Ru(bipy)_{3-n}(ppy)_n]^{(2-n)+}$ ($n = 0, 1, 2, 3$), is consistent with the increasing ease with which the complexes are oxidized.*

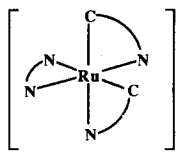
From **I** to **II**, we noted that $Ru—C_{[ppy]^-}$ and $Ru—N_{[ppy]^-}$ bonding character is partitioned, the former being localized in MO 87 of **II** (Fig. 4), while $Ru—N_{[ppy]^-}$ and $Ru—N_{bipy}$ characters mix together. This pattern continues as further ligand substitution occurs. The $Ru—C_{[ppy]^-}$ bonding orbital(s) is(are) always distinct from and lie(s) at higher energy with respect to those containing $Ru—N_{[ppy]^-}$ and $Ru—N_{bipy}$ bonding character. The C/N separation is most noticeable in *fac*-$[Ru(ppy)_3]^-$ (**V**) (see below).

Comparison of cis- *and* trans-$[Ru(bipy)(ppy)_2]$ (**III**) *vs* **IV**

The stereochemistries of $[M(bipy)(ppy)_2]^{n+}$ complexes have not been assigned unambiguously by crystallographic methods. $[M(bipy)(ppy)_2]^{n+}$ complexes are derived from chloro-compounds such as $[M(ppy)_2(\mu\text{-}Cl)_2M(ppy)_2]$ or $[M(ppy)_2Cl_2]^{n-}$, which are known to possess a *cis*-arrangement of the carbon donor atoms, with the chlorine ligands *trans* to carbon (structure **VII**).[17] There are three possible isomers for $[M(bipy)(ppy)_2]^{n+}$ (structures **III**, **IV** and **VIII**), and NMR spectroscopic data are consistent with either **III** and **IV**, each of which possesses C_2 symmetry, although the results of NOE experiments indicate that isomer **III** persists in solution.[5] This structure is also assigned by analogy with the chloro-bridged dimers from which they are prepared. One of the aims of our present study is to attempt to quantify the preference for the *cis*-arrangement of the carbon donor atoms, i.e. the apparent preference for structure **III** over **IV**.



VII



VIII

The diagram in Fig. 7 illustrates the ruthenium–ligand bonding orbitals in complexes **III** and **IV**. As in **II**, we observe partitioning of the $Ru—C_{[ppy]^-}$ and Ru—N σ-bonding character, with $Ru—C_{[ppy]^-}$ lying at the higher energy. One additional feature which is peculiar to the *cis*-isomer of $[Ru(bipy)(ppy)_2]^+$ (**III**) is a separation within the Ru—N σ-manifold into $Ru—N_{bipy}$ and $Ru—N_{[ppy]^-}$ bonding MO's. This may be explained in terms of the *local* symmetry of each N_4-donor set.† Each of isomers **III** and **IV** possesses molecular C_2 symmetry, but the separation of Ru—C and Ru—N character and the fact that the ligand frontier orbitals which are involved in σ-bonding are localized on the donor atoms (see Fig. 2) mean that the interaction of the ruthenium and nitrogen orbitals may be considered in terms of the local symmetry of the set of four nitrogen atoms rather than the molecular symmetry as a whole.‡ The N_4-donor set in **III** possesses C_{2v}

*Although the ruthenium complexes $[Ru(bipy)_{3-n}(ppy)_n]^{(2-n)+}$ are not known for $n = 2$ or 3, the corresponding rhodium and iridium complexes have been characterized. The *trends* within the isostructural series may thus be determined.

† Since atomic positions in **III** and **IV** are based upon the experimental coordinates for **I**, the symmetry is approximate, although deviation from C_{2v} or D_{4h} is not significant.

‡ The Ru—N bonding MO's, although constructed initially under local symmetry will obviously be perturbed by entry into a C_2 regime.

symmetry, and mixing of the two N_4-ligand group orbitals with a_1 symmetry is therefore allowed. Linear combinations of these orbitals provide the observed localization of N_{bipy} and $N_{[ppy]^-}$ character. The b_1 and b_2 orbitals are already localized on either bipy of $[ppy]^-$ nitrogen donors. In contrast, the local D_{4h} symmetry of the N_4-donor set in **IV** produces ligand group orbitals between which mixing is disallowed by symmetry. Hence, each Ru—N bonding MO in **IV** contains contributions from all four nitrogen atoms (i.e. independent of ligand) while in **III**, the Ru—N bonding MO's may be identified as being either Ru—N_{bipy} *or* Ru—$N_{[ppy]^-}$ in nature. Although the present analysis of electronic structure addresses a ground-state species, the localization of Ru—bipy or Ru—$[ppy]^-$ character should be paralleled in the excited state. This offers a possible origin for the differing emitive properties of complexes incorporating cyclometallated ligands as compared to $[M(bipy)_3]^{n+}$.

The separation of Ru—C, Ru—N_{bipy} and Ru—$N_{[ppy]^-}$ character in **III** described above may be consistent with the presence of the *cis*- rather than *trans*-isomer of $[Ru(bipy)(ppy)_2]$, but it does *not* provide a satisfactory explanation for the structural preference of **III** over **IV**. In Fig. 7, on going from **III** to **IV** the highest-lying Ru—C bonding orbital, MO 87, is destabilized by $\approx$ 1 eV. However, concomitant stabilization of other Ru—C bonding MO's appears to more than sufficiently compensate for the change in energy of MO 87. Similarly for the Ru—N bonding MO's, there is no obvious net orbital destabilization on going to **IV**. The HOMO–LUMO separations for the two isomers are similar, and using this energy difference as a means of estimating the relative stabilities of **III** and **IV**, then **IV** appears to be marginally more stable (2.92 vs 3.44 eV). However, this distinction is far from convincing. In terms of the ruthenium–ligand Mulliken overlap populations, there is only a marginal difference between the two isomers, again in favour of **IV**; in each complex, there is negligible difference between the overlap populations for ruthenium interacting with bipy or with $[ppy]^-$. The most significant difference between **III** and **IV** is in the atomic charge distribution (Table 1). We noted in complex **II** that a nitrogen atom *trans* to carbon is a poorer σ-donor than one *trans* to another nitrogen atom. This N—Ru—C *trans*-effect benefits the carbon atom in that it is able to reduce its net atomic charge from -0.748 electrons in free $[ppy]^-$ to -0.264 electrons in **III**. In isomer **IV** where the carbon donors lie *trans* to one another, the charge must be symmetrically distributed across the C—Ru—C bonding interaction and a higher negative charge results on carbon. Electronegativities would suggest that the nitrogen rather than the carbon atom can tolerate the extra negative charge and hence we suggest that the *cis*-isomer (**III**) is favoured on electronic grounds over the *trans*-isomer (**IV**). This result agrees with the related and experimentally based proposal of von Zelewsky and

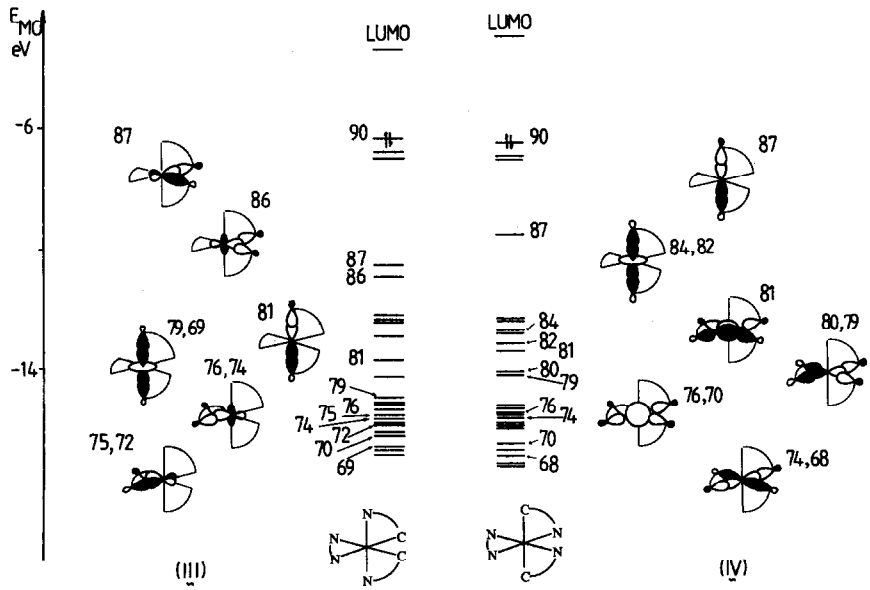


Fig. 7. Comparison of the ruthenium–ligand σ-bonding MO's in **III** and **IV**; MO's 88–90 possess π-backbonding character. Where one diagrammatic representation is assigned to more than one MO, the character is spread through the stated MO's and mixes with other (Ru—L non-bonding) ligand, L, MO's.

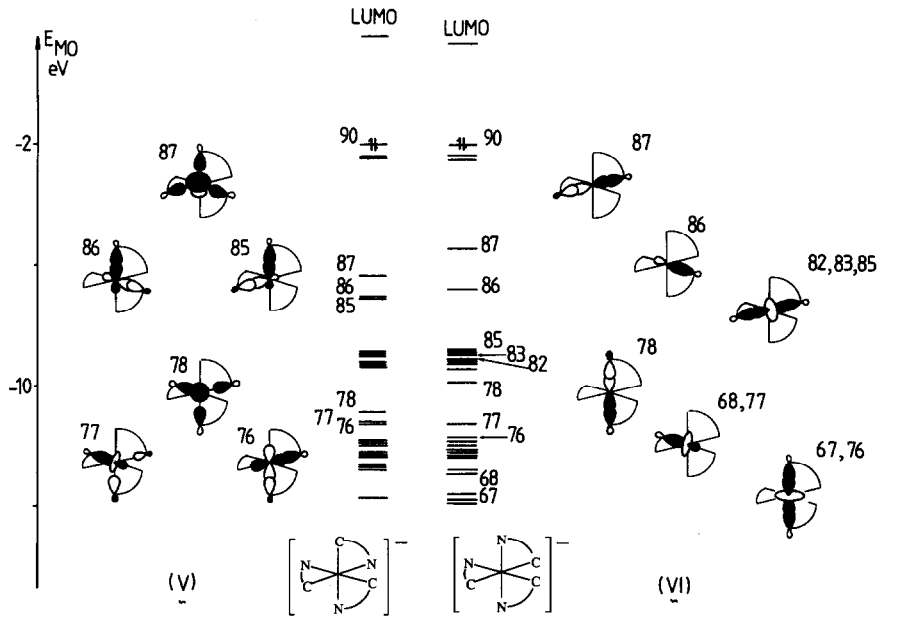

Fig. 8. Comparison of the ruthenium–ligand σ-bonding MO's in V and VI; MO's 88–90 possess π-backbonding character. Where one diagrammatic representation is assigned to more than one MO, the character is spread through the stated MO's and mixes with other (Ru—L non-bonding) ligand, L, MO's.

co-workers.[5] However, our results indicate that the isomer preference dictated by small differences in electronic structure between **III** and **IV** might well be altered if the steric requirements of the ligands are changed.[18]

Comparison of fac- *and* mer-$[Ru(ppy)_3]^-$ (V) *vs* VI

There are two possible isomers of a pseudo-octahedral $[M(ppy)_3]^{n+}$ complex; to date, two such complexes, $[Ir(ppy)_3]$ and $[Rh(ppy)_3]$, have been characterized and only the *fac*-isomer, **V**, has been obtained.[6] By way of rationalizing this observation, the same arguments regarding charge separation across the N—M—C bonds applies to $[M(ppy)_3]^{n+}$ as to $[M(bipy)(ppy)_2]^{m+}$, and atomic charges for isomers **V** and **VI** are listed in Table 1. The carbon donor atoms can reduce their negative charge most effectively when sited *trans* to nitrogen and this, we consider, is the major driving force behind the preference for *fac*- over *mer*-isomer formation.

An analysis of the electronic structures of **V** and **VI** reveals the now familiar separation of Ru—C and Ru—N bonding character (Fig. 8). In **V**, the Ru—C σ-bonding character is localized in MO's 85–87 and a second set of three MO's (76–78) constitute the Ru—N σ-bonding orbitals. On going to **VI**, each three atom donor set, N_3- or C_3-, lowers in local symmetry from C_3 to C_{2v} and, while maintaining their mutual separation, Ru—C and Ru—N σ-bonding character becomes delocalized over a larger number of MO's in **V** than in **VI**, with mixing of the N_3- or C_3-ligand group a_1 orbitals giving rise to MO's containing contributions from only one or two donor atoms rather than from all three. The highest-lying Ru—C σ-bonding MO 87 in **VI** is destabilized with respect to the degenerate set of MO's 85–86 in **V** from which it is derived and rises to a higher energy than the highest-lying Ru—C bonding MO in **V**. However, interpreting this in terms of relative complex stability is ambiguous since significant stabilization of Ru—C σ-bonding character also occurs in going from **V** to **VI**; similarly with the Ru—N σ-bonding character.

EMISSION LIFETIMES OF BINUCLEAR (d^{10}–d^{10}) PALLADIUM AND PLATINUM COMPLEXES*

PIERRE D. HARVEY and HARRY B. GRAY†

Arthur Amos Noyes Laboratory, California Institute of Technology, Pasadena, CA 91125, U.S.A.

Abstract—The emission lifetimes of binuclear (d^{10}–d^{10}) palladium and platinum dibenzylideneacetone complexes and certain derivatives have been measured as a function of emission wavelength and temperature in 2-methyltetrahydrofuran solutions. An unusual wavelength dependence of the emission lifetimes at 77 K is observed. The magnitude of this wavelength dependence is significantly smaller when the substitution occurs at the two-position of the aryl groups of the ligands, suggesting that steric effects play an important role in these excited-state deactivation processes.

Organometallic complexes containing metal–olefin bonds that exhibit luminescence in solution are rare.[1] However, emission from d^{10}–d^{10} $M_2(dba)_3$ complexes (M = Pd, Pt; dba = dibenzylideneacetone) has recently been reported.[2,3] Based on the energy gap between the lowest energy MLCT absorption and emission bands, and on the relatively long lifetime of the excited state, the observed emission has been assigned to a triplet → singlet MLCT transition.[2,3] In the course of our work, we found unusual emission behaviour for the $M_2(dba)_3$ complexes and their substituted derivatives in 77 K glasses. The principal findings of this more detailed investigation are presented here.

EXPERIMENTAL

Materials

The compounds investigated in this work are listed in Table 1; the compounds were synthesized‡ according to standard procedures.[4,5] The complexes were purified by triple recrystallization in dry toluene/hexane or toluene/propanol. There was no change in emission lifetimes when changing the solvent of recrystallization. Purity was checked by elemental analysis and ^{1}H NMR spectroscopy (500 MHz; 1000 scans). The ligands employed in the preparation of complexes were synthesized§ according to Conrad and Dolliver.[6] 2-Methyltetrahydrofuran (2-MeTHF; Aldrich) was purified by a standard procedure.[7] Toluene (B&J) was used without further purification. All spectroscopic measurements were performed immediately after freeze–pump–thaw degassing of the solutions.

Measurements

The UV–vis absorption spectra were recorded on Cary 17 (measurements at 77 K) and Hewlett Packard 8450A Diode Array (measurements at room temperature) spectrophotometers. The emission and excitation spectra were obtained using a Perkin–Elmer MPF-66 spectrofluorometer. The emission lifetime measurements were made on a Quanta Ray Nd–YAG (8 ns FWHM; 532 nm excitation) laser system.[8] Conditions: slit widths, 300 μm, 200 pulses, ~40 mJ/pulse, solute concentrations, 10^{-6}–10^{-3} M.

* Dedicated to Dick Fenske, whose work on the electronic structures of metal complexes has greatly enriched inorganic chemistry.

† Author to whom correspondence should be addressed; this is contribution No. 8038 from the Arthur Amos Noyes Laboratory.

‡ Attempts to synthesize the 2,2′,6,6′-tetrasubstituted binuclear dibenzylideneacetone complexes failed (X = Cl, CH_3, OCH_3).

§ A 2:1 aldehyde–acetone mixture was added dropwise (~1 drop/s) to the 10% NaOH water–ethanol (1:1) solution. For solid aldehyde, a saturated ethanol solution was made prior to addition. After stirring for 2 h, an equivalent portion of water was slowly added to complete precipitation of the yellow product. After filtration, the filtrate was dried *in vacuo* (10^{-6} torr; 24 h) and recrystallized in acetylacetate. The compounds were characterized by ^{1}H NMR, UV, IR and elemental analysis.

Table 1. Binuclear complexes

Compound	Abbreviation
1-Tris(dibenzylideneacetone)dipalladium(0)[a]	$Pd_2(dba)_3$
2-Tris(dibenzylideneacetone)diplatinum(0)[a]	$Pt_2(dba)_3$
3-Tris(4,4′-dimethoxydibenzylideneacetone)dipalladium(0)	$Pd_2(4,4'\text{-dmdba})_3$
4-Tris(2,2′-dimethoxydibenzylideneacetone)dipalladium(0)	$Pd_2(2,2'\text{-dmdba})_3$
5-Tris(2,2′-dimethyldibenzylideneacetone)dipalladium(0)	$Pd_2(2,2'\text{-dMdba})_3$
6-Tris(α-dinaphthalideneacetone)dipalladium(0)	$Pd_2(\alpha\text{-dnapha})_3$
7-Tris(β-dinaphthalideneacetone)dipalladium(0)	$Pd_2(\beta\text{-dnapha})_3$

[a] Isolated solid contains one toluene molecule of crystallization.

RESULTS AND DISCUSSION

Single-crystal X-ray diffraction[9,10] and ^1H NMR spectroscopic studies[11,12] have shown that the molecular structures of the $M_2(dba)_3$ complexes are the same in solution and in the solid state. The two trigonal planar M(olefin)$_3$ units are held face-to-face by the three bridging ligands. For $Pd_2(dba)_3$, r(Pd—Pd) = 3.24 Å. In mono- and binuclear complexes, the dba ligands generally adopt an s-*cis*,*trans* conformation,[10,11,13–15] as shown in Fig. 1. Interestingly, a study of ^1H and ^{13}C NMR spectra of the tris(4,4′ - diisopropyldibenzylideneacetone)dipalladium(0) and -diplatinum(0) complexes (M_2(4,4′-dipba)$_3$) has confirmed[16] that the molecular framework is stereochemically rigid on the NMR time scale over the temperature range −90 to 60°C. The ^1H NMR spectra show that the aryl groups are rotating at 25°C, but are frozen out at low temperature.[16]

At room temperature, the luminescence of $M_2(dba)_3$ is very weak in solution and of medium intensity in a rigid medium such as polymethylmethacrylate. The λ_e(max) values are ~ 755 and 815 nm for M = Pd and Pt at 295 K, respectively; they are ~ 15 nm blue-shifted at 77 K. The τ_e(295K) values show that the exicted states are relatively long-lived ($\tau_e(Pd_2) = 0.22$, $\tau_e(Pt_2) = 0.23$ μs),[3] thereby suggesting that the emissions originate from an MLCT triplet state.[2,3] The finding that d^{10}–d^{10} $Pd_2(dppm)_3$ [dppm = diphenylphosphino(methane)] exhibits a longer τ_e[17,18] and larger emission quantum yield (Φe)[18] than $Pd_2(dba)_3$ in solution at 295 and 77 K is not surprising, because the dppm complex is not as flexible as the binuclear dba species.

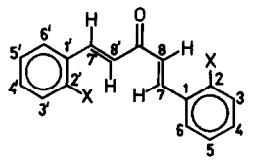

Fig. 1. Structure of s-*cis*,*trans*-2,2′-disubstituted dibenzylideneacetone. With X = H, bridging ligand = dba. (The benzene protons are omitted for the sake of clarity.)

The emission spectra of $M_2(dba)_3$ and the variation of τ_e with λ at 77 K in 2-MeTHF are shown in Fig. 2. Lifetime ranges are $7.5 < \tau_e < 13.5$ (M = Pd) and $0.90 < \tau_e < 1.60$ μs (M = Pt).* The measurements were performed using small slit widths and all decay curves were rigorously monoexponential. The τ_e measurements also were repeated at different solute concentrations (10^{-6}–10^{-3} M) and different toluene–isopentane mixtures at 77 K (1, 3, 5 and 10%).† The τ_e results are

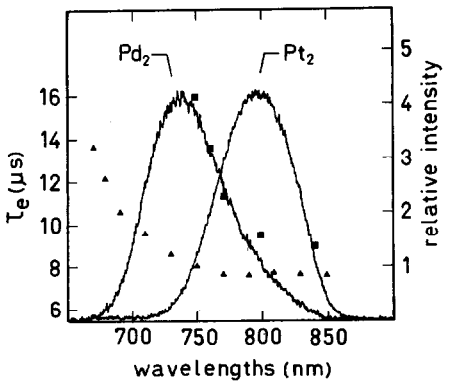

Fig. 2. Emission spectra of $M_2(dba)_3$ complexes in 2-MeTHF at 77 K and λ-dependence of τ_e (M = Pd, ▲; M = Pt, ■). The y-scale has been multiplied by a factor of 10 for M = Pt. Emission intensity has not been corrected for PM tube detection below 750 nm.

* The order $\tau_e(Pd_2) > \tau_e(Pt_2)$ also has been observed[17] for $M_2(dppm)_3$ complexes.

† The $M_2(dba)_3$ complexes are not soluble in saturated hydrocarbons. A mixture of toluene and saturated hydrocarbons at 77 K causes precipitation of the complexes if the quantity of toluene is not sufficient.

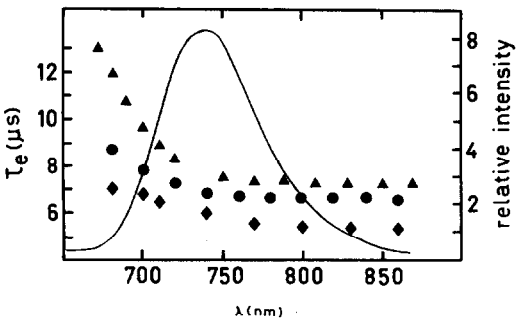

Fig. 3. Emission spectra of Pd_2(4,4′-dmdba)$_3$ in 2-MeTHF at 77 K, and λ-dependence of τ_e for Pd_2(4,4′-dmdba)$_3$ (▲), Pd_2(2,2′-dMdba)$_3$ (◆), and Pd_2(2,2′-dmdba)$_3$ (●). Emission intensity has not been corrected for PM tube detection below 750 nm.

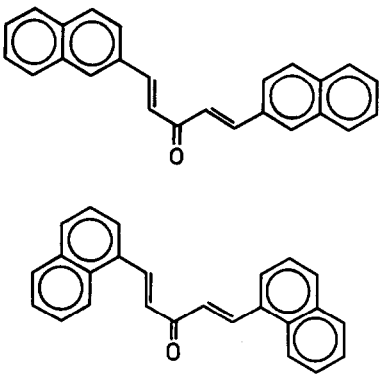

Fig. 4. Structures of β- (top) and α-dinaphthalidine-acetone (bottom) (s-*cis*,*trans*-conformation).

reproducible for both complexes, and the possibility of aggregation as an explanation of this unusual emission behaviour is ruled out.

In attempts to interpret these results, a number of substituted derivatives of Pd_2(dba)$_3$ were investigated. The λ-dependences of τ_e for Pd_2(4,4′-dmdba)$_3$, Pd_2(2,2′dmdba)$_3$ and Pd_2(2,2′-dMdba)$_3$ in 2-MeTHF at 77 K are shown in Fig. 3. There is no spectroscopic difference nor change in τ_e behaviour as a function of λ between Pd_2(4,4′-dmdba)$_3$ and Pd_2(dba)$_3$. On the other hand, substitution at the 2,2′-positions of dba lowers the gap (Δ) significantly between τ_e(min) and τ_e(max); Pd_2(2,2′-dmdba)$_3$, $6.8 < \tau_e < 8.8$ ($\Delta \sim 2.0$); Pd_2(2,2′-dMdba)$_3$, $5.3 < \tau_e < 8.8$ μs ($\Delta \sim 1.6$ μs). Moreover, as for the M_2(dba)$_3$ complexes, τ_e is λ-independent for Pd_2(4,4-dmdba)$_3$ and Pd_2(2,2′-dmdba)$_3$ in 2-MeTHF at room temperature. These results strongly suggest that a dynamic process involving interactions between atom H(8) and substituent X(2) [as well as H(8′) and X(2′)] via rotations of the aryl groups along the C(1)—C(4) axis (see Fig. 1) is the origin of this phenomenon at 77 K.

The postulated role of steric interactions has been tested by investigating complexes with larger aryl groups, such as naphthalene. The two possible structural forms of the dinaphthalideneacetone ligand are the α- and β-isomers (Fig. 4). Figure 5 shows the excitation and emission spectra of these complexes and the τ_e variation with λ. The λ(max) values of the MLCT absorption and emission bands, are, respectively, 585 and 773 (Pd_2(α-dnapha)$_3$) and 570 and 745 nm (Pd_2(β-dnapha)$_3$). The τ_e behaviour with λ at 77 K should be similar for both Pd_2(dba)$_3$ and Pd_2(β-dnapha)$_3$ based on

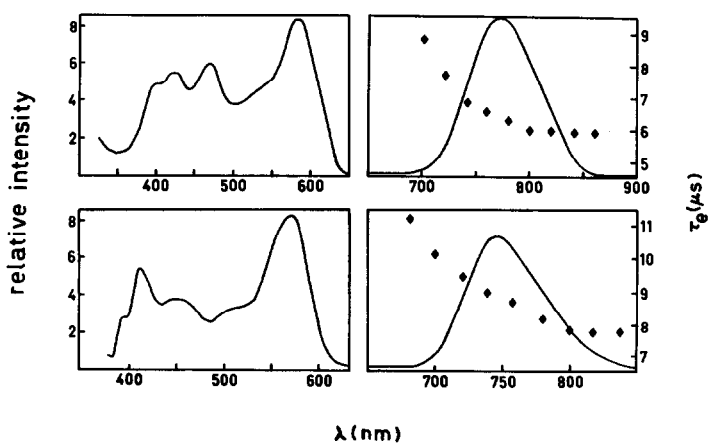

Fig. 5. Emission (right) and excitation (left) spectra of Pd_2(α-dnapha)$_3$ (top) and Pd_2(β-dnapha)$_3$ (bottom) in 2-MeTHF at 77 K, and the λ-dependence of τ_e (◆) in each case. Emission intensity has not been corrected for PM tube detection below 750 nm.

Table 2. Band positions and emission lifetimes

Compound	λ(MLCT) 77 K (nm)	τ_e(295 K) (μs)	λ(max) (nm)	τ_e(77 K) (μs)	λ(max) (nm)	Δ[a] (μs)
$Pd_2(dba)_3$	552	0.22[b]	755	7.5–13.5	740	~ 6.0
$Pt_2(dba)_3$	578	0.23[b]	810	0.9–1.6	800	~ 0.70
$Pd_2(4,4'\text{-dmdba})_3$	556	0.23	760	7.3–13.3	742	~ 6.0
$Pd_2(2,2'\text{-dmdba})_3$	552	—[c]	—	6.8–8.8	748	~ 2.0
$Pd_2(2,2'\text{-dMdba})_3$	566	0.039	765	5.3–6.9	757	~ 1.6
$Pd_2(\alpha\text{-dnapha})_3$	585	—[c]	—	6.0–8.7	773	~ 2.7
$Pd_2(\beta\text{-dnapha})_3$	570	—[c]	—	7.7–11.3	745	~ 3.6

[a] Δ is the difference between the minimum and maximum values for τ_e(77 K).
[b] Data taken from ref. 3.
[c] Due to extensive dissociation of the complexes in fluid solution, room temperature measurements were not made.

H(8)—H(2) steric arguments. Owing to the fact that the barrier to rotation around the C(1)—C(7) bond is larger in the β-dnapha and α-dnapha compounds, the τ_e changes should be smaller, as is the case (Table 2). For $Pd_2(\alpha\text{-dnapha})_3$, the substituent X is a rigid H—C≡ group (Fig. 4), and the steric interactions are larger than that in $Pd_2(\beta\text{-dnapha})_3$. Based on this argument, the Δ values should vary as dba = 4,4′-dmdba > β-dnapha > α-dnapha > 2,2′-dmdba > 2,2′-dMdba, as observed.

The variation of τ_e with temperature for each of the complexes in solution also has been investigated. Figure 6 shows plots of $\ln(k_e)$ ($k_e = 1/\tau_e$) vs $1/T$ for the $M_2(dba)_3$ complexes in 2-MeTHF. At room temperature, the τ_e values for both complexes are the same, and it can be seen from Fig. 6 that this equality is a coincidence. Figure 7 shows the variation of $\ln(k_e)$ with $1/T$ for $Pd_2(4,4'\text{-dmdba})_3$ and $Pd_2(2,2'\text{-dMdba})_3$ in 2-MeTHF. The τ_e behaviour for $Pd_2(4,4'\text{-dmdba})_3$ is virtually the same as that for $Pd_2(dba)_3$, indicating that substitution at the 4,4′-positions of the dba ligand does not influence excited-state deactivation.

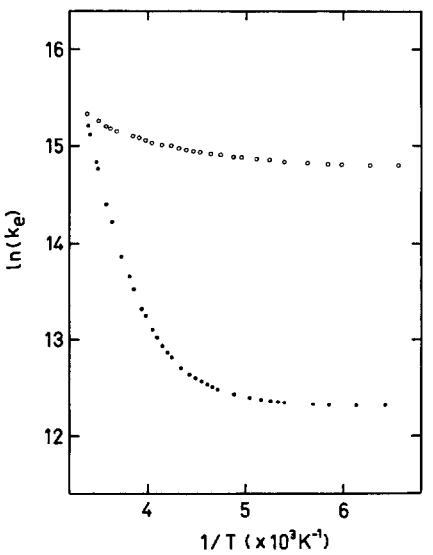

Fig. 6. Plots of $\ln(k_e)$ vs $1/T$ for $M_2(dba)_3$ (M = Pd, ●; M = Pt, O) in 2-MeTHF.

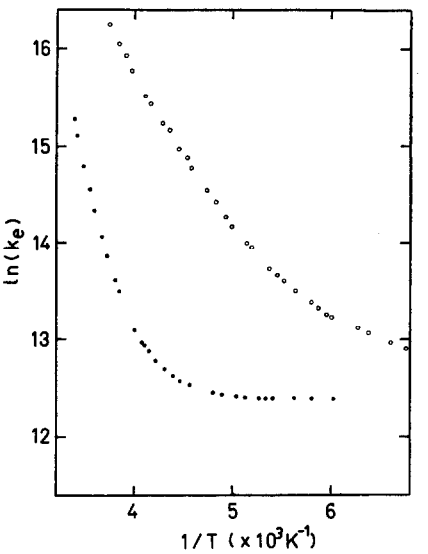

Fig. 7. Plots of $\ln(k_e)$ vs $1/T$ for $Pd_2(4,4'\text{-dmdba})_3$ (●) and $Pd_2(2,2'\text{-dMdba})_3$ (○) in 2-MeTHF.

ON THE ENERGETICS OF THE FORMATION OF E—H—M FROM M—H—M INTERACTIONS ON TRANSITION METAL CLUSTERS

THOMAS P. FEHLNER

Department of Chemistry, University of Notre Dame, Notre Dame, IN 46556, U.S.A.

Abstract—Experimental studies from several laboratories have demonstrated that, when a main group–transition metal atom cluster contains endo-cluster hydrogens, equilibria between tautomers which differ in the placement of one or more endo-hydrogens between M—H—M and E—H—M (E = main group atom, M = transition metal) bridging sites can exist. In this study we show that the preference for E—H—M versus M—H—M sites can be simply described in terms of the difference in electronegativities of the E and M atoms. This model allows a correlation of observed site preferences with calculated enthalpy change and allows predictions of site preference in presently unknown compounds. Further, as the model is independent of exo-cluster structure, it can be used to explain some aspects of the relative reactivity of main group atoms when bound to transition metal atoms at the surface or grain boundaries of a bulk metal.

The body of research created by Richard F. Fenske and his students is distinguished by constant attention to the explanation of inorganic chemistry at the synthetic frontier via approximate, but parameter-free, theory. An essential element of his philosophy has been the development of approaches that not only explain known chemistry but also point to the next logical question to be addressed experimentally. It is an approach that I have admired for many years and one which is difficult to emulate. But it is in this spirit that the following analysis of the placement of endo-cluster hydrogens on transition metal–main group atom clusters is offered. It presents a straightforward way of understanding observed hydrogen site preferences and suggests that characterization of tautomeric equilibria of the type discussed can provide a body of data useful for exploring not only discrete molecules but also solid state systems.

INTRODUCTION

The participation of formally monovalent moieties such as H and CH_3 in bridging interactions constitutes a structural feature that distinguishes inorganic chemistry from classical organic chemistry.[1] Although still occasionally viewed with surprise, examples of the E—H—M interactions, E = main group atom, M = transition metal, for E = C are well established in many mononuclear as well as cluster systems.[2] As this structural feature constitutes a real connection between main group and organic chemistry, the relationship of the natures of atoms and M to the relative stability of the E—H—M interaction deserves to be understood. On metal surfaces, the connection between M—H—M and E—H—M interactions is very important to understanding the hydrogenation and dehydrogenation of main group fragments.[3] In bulk metals the same connection is a crucial part of the explanation of the role of main group species in stabilizing or destabilizing a metal towards hydrogen embrittlement.[4]

The factors important for the formation of C—H—M interactions in mononuclear complexes have been clearly developed.[2] A metal-based empty orbital is a requirement and the CH bond of a ligand acts primarily as a σ donor to the metal, i.e. the σ-CH orbital is depopulated but the σ^* orbital is not significantly populated in forming the C—H—M interaction.[5] This contrasts with C—H—M interactions on metal surfaces[6] or in clusters[7] where no formal metal unsaturation is required and significant population of the σ^* orbital of the organic fragment is important. Even though the various factors important in forming a C—H—M interaction have been discussed, the intimate connection with E—H—M interactions involving other main atoms is often neglected and systematic trends in the formation of E—H—M interactions as a func-

tion of main group atom and transition metal have not been documented previously. A sufficient number of closely related examples of compounds with E—H—M interactions now exist such that a correlation of fundamental significance can be constructed.

Previously, we have compared the properties of isoelectronic clusters containing E—H—M, E = C, B; M = Fe, utilizing Fenske–Hall calculations in an attempt to define factors favouring E—H—M over M—H—M interactions.[7,8] On the basis of these results, we suggested that in these tri- and tetrametal clusters the electronic charge available to an endo-hydrogen at a given site was important. However, geometrical factors associated with the spatial distribution of CO and H ligands were also found to be important, i.e. there is a relationship between the geometric positions of the exo-ligands on the cluster core atoms and the distribution of electron density in the molecular orbital (MO).[9] Hence, steric interactions between exo-cluster ligands can be coupled to the endo-cluster bonding thereby affecting endo-hydrogen site stabilities. The importance of steric repulsion between a substituent on the E atom with the equatorial CO ligands of a capped trimetal cluster in promoting M—H—M over C—H—M interactions was subsequently defined experimentally for $Co_2Fe(CO)_9(HCR)$.[10]

Both the experimental and theoretical studies emphasize the subtlety of the structural problem in that significant electronic structural change is accompanied by small energy changes.[11] Despite this fundamental complexity, the MO calculations on capped trimetal clusters do suggest that the interaction of the orbitals of the capping atom, possessing π symmetry with respect to an axis perpendicular to the trimetal plane, with the appropriate orbitals of the trimetal fragment is particularly crucial in understanding the electronic structure. This suggests that the interaction will be sensitive to the effective nuclear charge of the capping atom as well as the number and location of bridging hydrogens.

Considering the foregoing, one might assume that only with much more sophisticated calculations will the observed structure/energy relationships between tautomers containing E—H—M vs M—H—M interactions be reproduced. Even if such calculations are forthcoming, it is not clear that any more understanding of the fundamental driving forces leading to these kinds of interactions will be produced. On the other hand, the existing experimental characterizations of tautomeric equilibria involving the interconversion of E—H—M and M—H—M interactions in cluster systems provides a set of unambiguous thermodynamic data suitable for exploring general trends. That is, the measured equilibrium constants provide a sensitive measure of E—H—M vs M—H—M preference and, because of the exponential relationship between equilibrium constant and energy, also precisely define energy differences between the two structural forms. The following correlation of observed relative abundances of tautomers with M—H—M vs E—H—M interactions with atom electronegativities verifies earlier observations derived from calculations and allows trends for unknown systems to be easily predicted in a qualitative fashion. Further, selected examples show that because the model is independent of nonlocal structure the conclusions extend beyond discrete cluster chemistry.

RESULTS

The principal data upon which the arguments are based are the observed preferences for reaction (1)

$$[M—H—M] = [E—H—M] \qquad (1)$$

which are given in Table 1, where [M—H—M] refers to a tautomeric cluster structure containing one more M—H—M and one less E—H—M interaction than the tautomer [E—H—M]. These data illustrate trends in the balance of reaction (1) as a function of E and M for tri- and tetranuclear transition meal clusters. Of crucial importance are those systems for which the existence of a tautomeric equilibrium has been established. These systems constitute E,M combinations where the stability of the E—H—M tautomer approaches that of the M—H—M tautomer and define a dividing line of relative stability as E and M are varied. For the trinuclear clusters, note the diagonal relationship (Scheme 1), i.e. the clusters E = B, M = Ru and E = C, M = Fe exhibit tautomeric equilibria, while those for E = B, M = Fe and E = C, M = Ru do not. Further, for the BFe system [E—H—M] is favoured over [M—H—M] while the reverse is true

E = B M = Fe EHM > MHM	E = C M = Fe EHM ≈ MHM
E = B M = Ru EHM ≈ MHM	E = C M = Ru EHM < MHM

Scheme 1.

[e] Calculated using Mullay's electronegativities.

for the CRu system. The experimental evidence shows that the observed trends are due in significant part to enthalpic differences.[10] Thus our approach is based on a consideration of changes in bond energy term values or average bond energies with E and M.

The overall enthalpy change for reaction (1) may be written as:

$$\Delta H = D(\mathrm{MHM}) + D(\mathrm{ME}) - D(\mathrm{EHM}) - D(\mathrm{MM}), \quad (2)$$

where D(X—H—M) and D(XX) refer to average bond energies for three- and two-centre interactions, respectively. The three-centre interaction can be written as a sum of two-centre interactions, i.e. $D(\mathrm{XHM}) = \alpha[D(\mathrm{XH}) + D(\mathrm{MH}) + D(\mathrm{MM})]$ where α is a constant between 0 and 1. Equation (2) then becomes:

$$\Delta H = \alpha[D(\mathrm{MH}) - D(\mathrm{EH})] + (1-\alpha)[D(\mathrm{ME}) - D(\mathrm{MM})]. \quad (3)$$

If the enthalpy is expressed in terms of metal and main group atom electronegativities by using a modified Pauling expression for the two-centre bond energy, i.e. $D(\mathrm{AB}) = 1/2[D(\mathrm{AA}) + D(\mathrm{BB})] + X_{\mathrm{AB}}$, where X_{AB} is a function of the electronegativity difference between atoms A and B,[12] eq. (3) becomes:

$$\Delta H = (\alpha - 1/2)[D(\mathrm{MM}) - D(\mathrm{EE})] + \alpha(X_{\mathrm{MH}} - X_{\mathrm{EH}}) + (1-\alpha)X_{\mathrm{ME}}. \quad (4)$$

The magnitude of α can be obtained from bond energy data, however, thermochemical data on the bond energetics of main group–transition metal compounds is very sparse. Thus the approximate value of α is obtained from data on B—H—B and Fe—H—Fe interactions. D(BHB), D(BH) and D(BB) ae 108, 90 and 74 kcal mol^{-1}, respectively,[13] while D(FeHFe), D(FeH) and D(FeFe) are 83, 55 and 20 kcal mol^{-1}, respectively.[14]. Thus, writing the three-centre interaction as a fraction, α, of the sum of the two-centre interactions leads to values of α of 0.43 and 0.64 for boron and iron, respectively. For convenience in the mixed system we have taken α to be 0.5 and, thus, eq. (4) reduces to:

$$\Delta H \approx 0.5[X_{\mathrm{MH}} - X_{\mathrm{EH}} + X_{\mathrm{ME}}], \quad (5)$$

which expresses the enthalpy of reaction (1) as a function of the electronegativity differences between M, H and E atoms. The electronegativity difference is given by $X_{\mathrm{AB}} = 105\{1 - \exp[-0.219(X_{\mathrm{A}} - X_{\mathrm{B}})^2]\}$ which reduces to $23(X_{\mathrm{A}} - X_{\mathrm{B}})^2$ in the limit of small ΔX.[15]

There are several scales of electronegativity and selected values for the elements of interest here are gathered in Table 2. Clearly, eq. (5) requires electronegativities[16] that reflect the real differences in transition metals and, thus, Pauling's original values[17] are too imprecise to be of use. The Allred/Rochow[18] and the recent scale of Mullay[19] are suitably fine grained. As will be seen below, the qualitative results do not depend on the choice of electronegativity scale and even the Pauling values for different main group atoms and a fixed metal yield the same qualitative conclusions. Pearson's approach utilizing electronegativity and hardness[20] gives essentially the same results as that using electronegativity alone. Thus, the additional complexity of his approach is not justified. It would, or course, be more appropriate to use group electronegativities for the fragments that make up the cluster, i.e. the effective electronegativity of a metal carbonyl fragment can be much higher than that of the metal atom itself. However, until a self-consistent set of such values are available we must be satisfied with atom values. As long as the metal (and main group atom) ligands remain constant, these values should give the correct trends. In addition, if they do so, then the results are not restricted to discrete clusters.

With the electronegativities contained in Table 2, eq. (5) is used to calculate the enthalpies for reaction (1) for a variety of three and four metal cluster systems. The results are given in Table 1 with the

Table 2. Selected electronegativities of the elements

cluster systems ordered according to the magnitude of ΔH. One notes immediately that all the enthalpy values are positive. The free energy change for reaction (1) also includes an entropy term. The overall entropy change for reaction (1) will be generated in large part by the conversion of M—H—M and E—M to M—M and E—H—M interactions. The hydrogen-bridged interactions have relatively high vibrational frequencies (> 1600 cm^{-1}) while the E—M and M—M frequencies are much lower. At room temperature, the latter will be dominant contributors to the entropy and, hence, ignoring any steric interactions which should be small for a hydrogen ligand on E, the overall entropy change should be > 0. Further, for the $Co_2Fe(CO)_9(HCR)$ system[10] we have demonstrated that ΔH is small and < 0 for reaction (1). Thus, the positive values in Table 1 reflect a systematic error in the calculation. This is not surprising as one could hardly hope that such an approximate method would give correct absolute enthalpies. The source of the error may be the neglect of the $(\alpha - 1/2)[D(MM) - D(EE)]$ term in eq. (4), i.e. the choice of $\alpha = 0.5$. As $D(EE)$ is always significantly larger than $D(MM)$ and α does not exactly equal $(1-\alpha)$, this could account for the discrepancy. Likewise the use of atom rather than group electronegativities could be the source of the problem. Thus, we focus discussion on trends as atom type in the cluster framework is varied.

Considering first the ΔHs for the capped trinuclear clusters one notes a crossover from an endo-hydrogen site preference for E—H—M to that for M—H—M at $\Delta H \approx 7$–10 kcal mol^{-1}. The trends in site stability defined by the observed equilibria correlate well with the calculated energetics with the borderline exception of $H_3Os_3(CO)_9BCO$. Most likely the CO ligand when directly bound to boron significantly changes the electronegativity of boron relative to boron in the B—H fragment. But even in this case, the direction of rearrangement of the endo-hydrogens in going from $HFe_3(CO)_{10}(HBH)$ to $H_3Os_3(CO)_9BCO$ is correctly predicted by the ΔH values. Hence, eq. (5) constitutes a quantitative statement of our earlier empirical observation that, for a fixed metal atom type, as the electronegativity of the main group atom increases, M—H—M is favoured over E—H—M and for a constant main group atom, as the electronegativity of the metal is increased, E—H—M is favoured over M—H—M. Thus, with E = B or C going from Fe to Ru promotes the M—H—M interaction while for M = Fe, going from C to B promotes the E—H—M interaction. Note that the difference in ΔHs for E = C and M = Fe, Ru is 4–5 kcal mol^{-1}, which is consistent with the fact that although the C—H—Ru tautomer is not observed directly it is energetically accessible and has been identified as an important intermediate.[21] The situation is similar for osmium.[22] As mentioned above, the modulation of electronegativity by hardness in the manner of Pearson does not change the sign of the enthalpy nor does it particularly improve the correlation with K(eq).[20]

In our approach, the ΔH values are independent of the substituents on metal or main group atoms. However, replacing H with Me on the $Fe_3(CO)_9(H_3CR)$ system leads to a promotion of the M—H—M interaction in that only the tautomer with M—H—M interactions is observed in solution. As the group electronegativity of Me is larger than that of H,[16] the electronegativity of CMe should be larger than that of CH. Hence, ΔH for CMe should be somewhat more positive than that for a CH capping fragment and methyl substitution on the capping carbon leads to promotion of M—H—M site stability over C—H—M.[23] This approach allows one to predict that for the presently unknown compounds $M_3(CO)_9(SiH)_4$, that for M = Fe a form with Si—H—Fe interactions should be prominent ($\Delta H = 4.2$ and 1.4 kcal mol^{-1} using Mullay and Allred/Rochow electronegativities, respectively), while for M = Ru there is a chance to observe an equilibrium between forms containing Si—H—Ru and Ru—H—Ru interactions ($\Delta H = 7.9$ and 4.5 kcal mol^{-1} using Mullay and Allred/Rochow electronegativities, respectively). Although the trimetal capped clusters containing silicon and endo-hydrogens are not known, the Si—H—M interaction has been characterized in mononuclear compounds containing chromium and manganese.[24]

For the $M_4(CO)_{12}CH_2$ cluster system one tautomer is observed for M = Fe (one Fe—H—Fe and one Fe—H—C interaction) but two for M = Ru (a tautomer like the iron analogue and one with two Ru—H—Ru interactions.). In the latter case the tautomer with two M—H—M interactions is seven times more abundant. Again, decreasing the electronegativity of the metal for the same E atom, promotes M—H—M interactions relative to E—H—M. However, one notes that with E = C, M = Fe, tautomeric species are observed in equilibrium in the trinuclear system but with M = Ru only the tautomer with Ru—H—Ru interactions is observed. On the other hand, in the tetranuclear system a similar tautomeric equilibrium is observed for E = C, M = Ru but not for M = Fe. Thus, as might have been anticipated, there is a cluster structural factor in addition to cluster fragment electronegativity involved in determining the absolute tautomer stabilities. The correlation with electronegativity only shows trends and is not sufficient

to predict in an absolute sense when tautomeric equilibria will be observed.

An inspection of the ΔH values in Table 1 shows that this structural dependence is of equal importance to the electronegativity differences. For the clusters with two endo-hydrogens the crossover is at $\Delta H \approx 15$ kcal mol^{-1}, for the homonuclear clusters with one endo-hydrogen the crossover is between 4 and 8 kcal mol^{-1} while for the heteronuclear clusters of Shriver with one endo-hydrogen the crossover is ≈ 10.7 kcal mol^{-1}. Still, even though the electronegativity differences are not as dominating as they appear to be in the trinuclear cluster systems, the trends in the magnitudes of the calculated ΔH values clearly identify one factor of importance in determining endo-hydrogen site stability.

The final two compounds in Table 1 involve a comparison of the first experimentally characterized example of an E—H—M, M—H—M equilibrium, with E = C, with a more recently described tin compound. The $Os_3(CO)_{10}(CH_4)$ cluster in solution exists as an equilibrium mixture of a form with two Os—H—Os bridges plus a bridging CH_2 and a form with one Os—H—Os bridge plus a bridging CH_3 with a single Os—H—C interaction. The tin analogue, $Os_3(CO)_{10}(SnH_2R_2)$, is found as a single species with one Os—H—Os bridge and a bridging $SnHR_2$ fragment with an Os—H—Sn interaction. As predicted by the ΔH calculation, the tin compound is observed exclusively as the Sn—H—Os tautomer. Again the fact that the tautomeric equilibrium is observed for a $\Delta H \approx 19$ rather than ≈ 10 kcal mol^{-1} shows that there is a structure factor differentiating the capped versus uncapped trimetal clusters.

The data in Table 1 constitute a closely related set of equilibrium constants but there are other individual observations of equilibria equivalent to (1) that allow further testing and, ultimately, justification of the correlation with electronegativity. The cluster of composition $Co_2Fe(CO)_9(CHR)$ has a C—H—M/M—H—M ratio greater than one. The calculated ΔHs for all possible hydrogen edge-bridging combinations in reaction (1) are given in Table 3. Note that eq. (5) cannot be applied directly but taking into account the different metals leads to eq. (6) which is applicable to the first entry in Table 3. Two of the four calculated ΔH are in the 7–10 kcal mol^{-1} range for which a tautomeric equilibrium is observed in the homonuclear cases in Table 1. Based on an analysis of the IR spectra of a mixture of the two tautomers, we have suggested[10] that reaction (1) involves Fe—H—Co and C—H—Fe sites and, indeed, this combination is one of the two with low calculated ΔH values.

Table 3. Calculated ΔH for the various possible sites of the $Fe_2Co(CO)_9HCCH_3$ mixed metal cluster

Reaction (1)	ΔH (M)[a]	ΔH (A/R)[b]
Co—H—Co → Co—H—C	8.4	6.8
Fe—H—Co → Fe—H—C	9.5	7.8
Fe—H—Co → Co—H—C	11.4	9.4
Co—H—Co → Fe—H—C	12.6	10.0

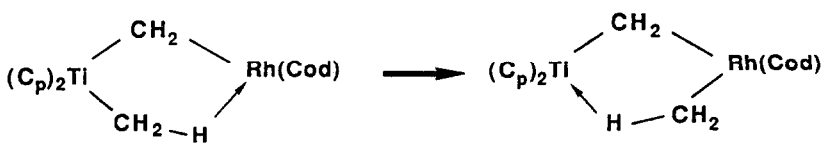
[a] Mullay's electronegativities.
[b] Allred/Rochow's electronegativities.

$$\Delta H \approx 0.5[X_{M'H} - X_{EH} + X_{M'E} - X_{MM'}] \quad (6)$$

Finally, the two compounds shown in Scheme 2 provide a more stringent test of the model. The bridging methyl group can form a C—H—M bridge with either titanium or rhodium. Experimentally only the C—H—Ti bridge has been observed.[25] For the change as shown in Scheme 2, the model gives $\Delta H = 0.9$ and 0.6 kcal mol^{-1} using the Mullay and Allred/Rochow electronegativities, respectively. If we assume the crossover is 7–10 kcal mol^{-1}, as it is in the trinuclear cluster systems, then the C—H—Ti bridge is favoured by 6–10 kcal mol^{-1}. In any case, the qualitative result is the same, i.e. bridging to the metal with the lower electronegativity is favoured.

DISCUSSION

The formation and rupture of E—H—M interactions are of fundamental importance to understanding the ease of oxidation and reduction of main group fragments by the action of transition metals. The source and sink of hydrogen is M—H



Scheme 2.

bonds of some type and M—H—M bridges can certainly play a role. If terminal M—H bonds are solely involved, the value of the enthalpy of the equivalent of reaction (1) will be changed but the relative direction of the "driving" force will remain the same. This view of metal versus main group interactions with hydrogen can be applied to significant chemical problems outside of discrete cluster chemistry *per se*. Two relevant examples follow.

The hydrogenation of carbon monoxide in the presence of heterogeneous catalysts involves the rupture of C—O bonds and the formation of C—H and C—C bonds.[26] This chemistry, known as the Fischer–Tropsch process, is very complex and the products observed are a complex function of catalyst and condition. The model developed here has some relevance to understanding the distribution of hydrocarbon products formed. A crucial point in the Fischer–Tropsch mechanism for hydrocarbon production is the partitioning of the products between CH_4 and those containing C—C bonds.[27] That is, chain growth by C—C bond formation at a metal site competes with chain termination via hydrogenation. If hydrogenation is very fast then chain growth is not competitive and CH_4 will be the primary product of CO reduction. It is reasonable to assume that hydrogenation of a CR_n fragment proceeds via a R_nC—H—M interaction by movement of a hydrogen atom from a M—H—M site on the catalyst surface. If barriers are low such that equilibria determine branching ratios then the greater the stability of the C—H—M site relative to the M—H—M site the more predominant will be the methanation reaction and the shorter will be the C—C chain products. Equation (5) allows one to estimate the effect of metal on the stabilization of C—H—M over M—H—M interactions in reaction (1) and in Table 4 ΔHs for M_3CH systems are calculated as a function of metal atom. One sees that on going from iron to cobalt to nickel the C—H—M interaction becomes more favoured relative to the M—H—M interaction. It is a well known fact that nickel is exclusively a methanation catalyst while iron yields both methane as well as higher hydrocarbons.[28] Going from iron to ruthenium favours the M—H—M interaction and should result in longer chain products. Indeed at high pressures with a ruthenium catalyst, linear polymethylene is the principal product.[29] Further, potassium promotes an increase in average chain length in the Fischer–Tropsch process. We expect potassium to donate electron density to the metal thereby reducing its effective electronegativity, promoting the M—H—M interaction and increasing the C—C chain length of the products. Of course by focusing entirely on the hydrogen transfer process we ignore other important factors, e.g. heats of adsorption of hydrogen, that change with the metal. Our point is not to explain the mechanism in any complete sense but merely to demonstrate that the model developed here can be effectively incorporated into an overall description of the Fischer–Tropsch process.

Table 4. Variation in preferences for E—H—M versus M—H—M interactions on main group atom capped trimetal sites

	Metal	ΔH_R[a]
E = C	Fe	10.3
	Co	8.4
	Ni	6.3
	Ru	15.3
E = B	Fe	3.6
E = P	Fe	5.2

[a] Calculated using Mullay's electronegativities.

The embrittlement of steel by hydrogen is an important practical problem.[30] It is known that hydrogen embrittlement of steel is inhibited by the presence of boron,[31] that carbides and nitrides are inert and that phosphorus and arsenic promote brittle failure in iron-based materials.[32] Again in Table 4 we compare Fe_3E clusters for E = B, C and P. Based on the ΔH values, the tendency for E—H—Fe interactions to form decreases in the order B > P > C. The main group atom tends to be segregated at grain boundaries and we have suggested previously that the size of the E—H fragment relative to the metal is important.[4] Hence, when boron is located at grain boundaries, there will be a tendency for it to sequester hydrogen in the form of B—H—Fe interactions which, because of the small size of boron, does not result in decohesion. Phosphorus also will have a significant tendency to form P—H—Fe interactions at grain boundaries but now the large size leads to destabilization at the grain boundary. Carbon has less tendency to form C—H—M interactions and, further, has a small size. Hence, carbon neither promotes nor inhibits hydrogen embrittelement. Again our point here is that the understanding of the distribution of hydrogen atoms between E—M and M—M sites provided

by our model can be readily applied to aspects of complex problems.

Although the overall picture is clear, this approach suffers from its simplicity and the fact that electronegativities are not well enough defined to give precise answers. Still, there is sufficient correlation with observed chemistry to show that conclusions based on an analysis of discrete cluster systems do carry over to reactions on surfaces. This suggests that more precise predictions would be both useful and enlightening. The use of electronegativities could be avoided if more equilibria were known. This would allow one to sort out the effects of structure as well as number and types of ligands on the metal and main cluster atoms. Hence, the characterization of more cluster systems with observable tauromeric equilibria, particularly those involving different main group atoms and metals, would constitute a valuable addition to our understanding of hydrogen transfer between main group and transition metal atoms. When combined with an appropriately more sophisticated model than the one presented here, these data will provide predictive insight on the distribution of hydrogen atoms between metal and main group atoms in a variety of structural environments.

He I VALENCE PHOTOELECTRON SPECTRA OF OXOMOLYBDENUM(V) COMPLEXES CONTAINING DIOLATO OR ALKOXIDE LIGANDS*

C. S. J. CHANG, A. RAI-CHAUDHURI, D. L. LICHTENBERGER and J. H. ENEMARK†

Department of Chemistry, University of Arizona, Tucson, AZ 85721, U.S.A.

Abstract—The He I valence photoelectron spectra (PES) are reported for several monooxomolybdenum(V) compounds with the general formula of $LMoO[O—(CH_2)_n—O]$ and $LMoO(OR)_2$ (L = hydrotris(3,5-dimethyl-1-pyrazolyl)borate; $n = 2$–4; R = Me, Et, ^{n}Pr). The spectra show that the size of the metal–chelate ring in these diolato complexes has a substantial effect on the HOMO ionization. As the chelate ring size in the diolato complexes increases, the HOMO shifts (*ca* 0.21–0.24 eV) to lower ionization energy. The diolato complexes have their HOMO's at a higher ionization energy than analogous open chain bis-alkoxide complexes possessing the same number of carbon atoms. The unconstrained bis-alkoxide complexes show much smaller shifts ($\leqslant 0.11$ eV) in the ionization potential associated with the HOMO upon the addition of a CH_2 unit to each alkoxide group. These gas-phase results are similar to the results observed by electrochemistry in acetonitrile solution, where both the diolato and bis-alkoxide complexes become easier to oxidize upon increasing the number of CH_2 groups, as indicated by their half-wave potentials. The $p\pi$ orbital ionizations of the oxygen atoms in the alkoxide functions are also shifted (*ca* 0.12 eV) to lower ionization energy upon adding CH_2 residues to the alkoxide chain.

The study of models for the molybdenum cofactor (Mo-co) remains an intriguing topic.[1–5] Previous studies of model compounds for Mo-co of "oxo-type" molybdoenzymes[6] have mainly focused on mimicking the enzyme's catalytic reactions,[7,8] or duplicating parameters of the EPR (electron paramagnetic resonance) spectra,[9] the EXAFS (Extended X-Ray Absorption Fine Structure) spectra,[5,10] and electrochemical behaviour.[9d,11,12] To date, however, little attention has been given to the role of the backbone and side chain of the metal–chelate ring and how it can affect the electrochemical and spectroscopic properties of the molybdenum centre. Some systematic investigations of the effect of the backbone of the metal–chelate ring on the spectroscopic properties of a metal centre have been reported,[13] but only a few studies of the spectroscopic properties of monooxo–metal complexes with chelated ligands have been published.[14]

We have recently reported solution electrochemical and spectroscopic measurements of a series of diolato and bis-alkoxide oxomolybdenum(V) complexes with the general structure shown below in **1**–**6**,[15] where compounds **1**–**3**, and **4**–**6** are diolato and bis-alkoxide complexes, respectively.

The reduction potentials of both the Mo^{VI}/Mo^{V} and the Mo^{V}/Mo^{IV} pairs and the lowest energy electronic absorption bands (λ_{max}) for these complexes are a function of the backbone of the diolato or alkoxide ligands. The shifts of the half-wave potentials of the Mo^{VI}/Mo^{V} pair for compounds **2** and **3**, **4** and **5**, and **5** and **6** are 0.217, 0.030 and 0.019 V, respectively. Clearly, the shifts are significant in the diolato compound series, but not in the bis-alkoxide compound series. A similar situation is also observed for the half-wave potentials of the Mo^{V}/Mo^{IV} pair, where the shift is 0.168 and 0.218 V between compounds **1** and **2**, **2** and **3**, individually, and the shift for compounds **4** and **5**, and **5** and **6** is 0.066 and 0.042 V, respectively. We have

(4) R = Me
(5) R = Et
(6) R = ^{n}Pr

suggested that a steric effect, especially ring strain, could be primarily responsible for this observed pattern of electrochemical behaviour because unconstrained bis-alkoxide complexes show no significant changes in their electrochemical properties.

Photoelectron spectroscopy provides primary information about the orbital ionization energies of electrons and about electron distribution in the complexes. In addition, comparison of results obtained from PES of a series of related families of compounds is considered to be highly useful for obtaining secondary information relating to the geometries of compounds.[16] The relative shifts of the valence ionizations in a series of similar compounds are not only sensitive to charge distributions and relaxation energies, but also to the orbital overlap interactions. The result of the He I valence photoelectron spectroscopy measurements and their significance for these complexes form the basis of this report.

EXPERIMENTAL

Preparation

Compounds **1–7** were prepared by previously reported methods,[3,15] and characterized by elemental analysis, mass spectrometry, cyclic voltammetry, IR, UV–vis spectroscopy and EPR. The neutral ligand, tris(3,5-dimethylpyrazolyl)methane [compound (**8**)] was prepared by a modification of the method of Trofimenko[17] and showed a satisfactory C, H, and N analysis.

Photoelectron spectra

All PES were measured with use of a spectrometer which features a 36-cm radius hemispherical analyser (10-cm gap), and customized sample cells, excitation sources, detection and control electronics, and data collection methods that have been described previously.[18] The Ar $^{2}P_{3/2}$ ionization at 15.759 eV was used as an internal spectral lock for the energy scale. The spectrum of each compound was taken at least twice with no discernable differences between replicate spectra; no decomposition was observed either before or after the compound sublimed. Data were collected at different sample cell temperatures for different compounds (130°C for **1**, 141°C for **2**, 158°C for **3**, 130°C for **4**, 121°C for **5**, 120°C for **6**, 173°C for **7** and 45°C for **8**). The mass spectra recorded at temperatures used in the collection of the spectra indicated that the samples do not decompose. The collected data are represented analytically with the best fit of asymmetric Gaussian peaks by using the program GFIT.[19] The asymmetric Gaussian peaks are defined with the position, the amplitude, the half-width indicated by the high binding energy side of the peak (W_h), and the half-width indicated by the low binding energy side of the peak (W_l). The confidence limits of the peak positions and deviation for widths are generally ± 0.02 eV. The confidence limit of the area of a band envelope is about $\pm 5\%$, with uncertainties introduced in the baseline subtraction and fitting in the tails of the peaks. The parameters of overlapping peaks are not independent and therefore are more uncertain.

RESULTS AND DISCUSSION

Photoelectron spectra

The He I valence PES of the complexes studied in this work are recorded over the range 5.5–15.5 eV, as shown in Fig. 1. The ionization energy region above 11.0 eV displays broad and unresolved overlapping ionizations which mainly result from ionization of σ-bonding electrons in ligand moieties, C—C, C—H etc., and will not be discussed further.

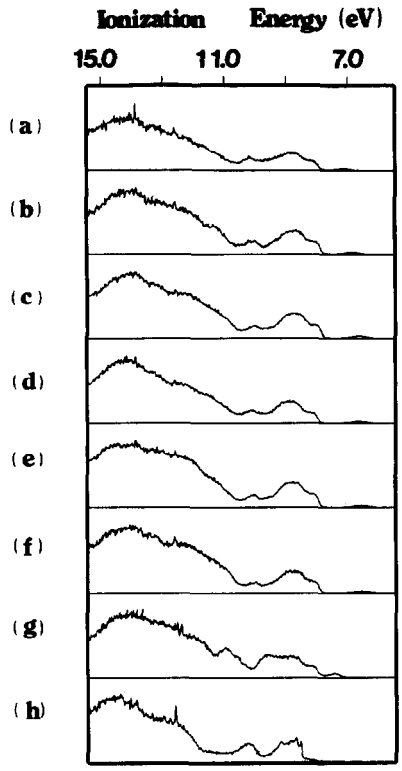

Fig. 1. Photoelectron spectra from 5.5 to 15.5 eV of compounds (a) LMoO[O—$(CH_2)_2$—O]; (b) LMoO[O—$(CH_2)_3$—O]; (c) LMoO[O—$(CH_2)_4$—O]; (d) $LMoO(OMe)_2$; (e) $LMoO(OEt)_2$; (f) $LMoO(^nPr)_2$; (g) $LMoOCl_2$; (h) $HC\{(3,5\text{-}Me)_2Pz\}_3$.

The close-up PES are shown in Figs 2–4. For Figs 2 and 4, the region of 5.5–11.0 eV was analytically represented with six and seven asymmetric Gaussian peaks (labelled 1–6 and 1–7), respectively, whereas only three peaks (labelled 1–3) were used to fit Fig. 3 which is the PES of compound **8**. The overall band shapes for the metal and ring π-ionization bands of compounds **1–6** remain the same throughout the series and are obviously different from those of $LMoOCl_2$ [compound (**7**)], which is the starting material.

In Figs 2 and 4, three distinct regions of ionizations can be observed in the close-up spectra of the diolato and bis-alkoxide compounds. The first region comprises the lowest ionization energy band (band 1), which is always broad and well isolated from other ionizations, except for that of the ethanediolato compound (**1**). The second region is a broad, unshifted set of bands (*ca* 7.75–9.5 eV) with one distinct shoulder on the low ionization energy side (band 2) and one partially resolved shoulder on the high ionization energy side (band 4 in Fig. 2 and bands 4 and 5 in Fig. 4). The last region (band 5 in Fig. 2 and band 6 in Fig. 4) is a broad band with similar position as observed in compound **8** (band 3 in Fig. 3). The vertical ionization energies of the bands are given in Table 1.

Diolato complexes **1–3**

From Fig. 2 and Table 1, it is very clear that band 1 shifts toward lower ionization energy with the increase in the size of the metal–chelate ring. Band 1 (HOMO) represents the contribution from the unpaired electron in the 4*d* orbital of the molybdenum atom. This assumption is based on the fact that this ionization is not observed in the PES of diols,[20] alcohols[20,21] and tris(3,5-dimethylpyrazolyl)methane [compound (**8**)]. The ranges of W_h and W_l for this ionization envelope are 0.62–0.70 eV and 0.37–0.51 eV, respectively. Such a broad feature reflects the bonding property for this band, and shows that the electron is not absolutely localized in the molybdenum *d* orbital.

Band 2 (SHOMO) in Fig. 2 also has a pronounced asymmetric feature not observed in the spectrum of compound **8**. Band 2 is primarily comprised of the $2p_x$ and $2p_y$ orbital ionizations of the terminal oxo ligand, which are oriented to interact with the empty $4d_{xz}$ and $4d_{yz}$ orbitals of the mol-

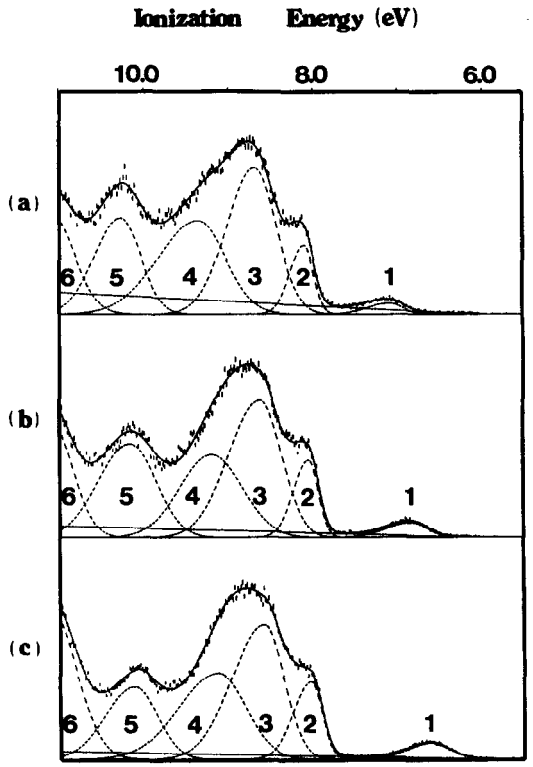

Fig. 2. Close-up PES in the range of 5.5–11.0 eV of (a) LMoO[O—$(CH_2)_2$—O]; (b) LMoO[O—$(CH_2)_3$—O]; (c) LMoO[O—$(CH_2)_4$—O].

[a] For the first ionization, the error bar in the fit analysis is ± 0.02 eV for peak position, 0.05–0.2 eV in half-widths, 5–10% in relative amplitudes.

ybdenum atom. This ionization envelope is also observed in compound **7** [Fig. 1(g)], with a similar position to that shown in the spectra of compounds **1–3** [Fig. 1(a)–(c)]. Since the only oxygen atom involved in compound **7** is the terminal oxo ligand, we assign band 2 to ionizations from this oxygen atom. In addition, the lone-pair electrons of chlorine ligands in compound **7** should be well separated from the ionization envelope of lone-pair electrons of the oxygen atom. The Fenske–Hall molecular orbital calculations on compound **7** showed that the ionization energies of the lone-pair electrons of chlorine differ by at least 0.6 eV from those of the oxygen atom. The experimental result shows that the lone-pair electrons on the chlorine atoms in compound **7** have much higher ionization energy (IP $\approx$ 11 eV) compared with the lone-pair electrons of the terminal oxygen atom. Similar behaviour is found for many organic compounds[20] containing both a chlorine atom and carbonyl oxygen atom

and which exhibit ionization energies for the lone-pair electrons of the oxygen atom that are lower than the lone-pair electrons of the chlorine atom. Band 2 shows almost no shift with change of the number of methylene units in diolato or alkoxide groups (8.04–8.11 eV and 8.09–8.11 eV for diolato and bis-alkoxide compounds, respectively). The small range of ionization energies is also consistent with the narrow range of molybdenum–oxygen bond lengths in most monooxo complexes.[22] Thus, the bonding between the molybdenum atom and the terminal oxo ligand is quite insensitive to the nature of the ligands which occupy the remaining coordination sites.

Comparison of the spectra obtained from 1H-pyrazole,[23] 1H-3,5-dimethylpyrazole[24] and tris(3,5-dimethylpyrazolyl)methane (Figs 1(h) and 3) indicate that bands 3 and 4 are probably derived from the $p\pi$ orbital electron ionizations of the pyrazole rings. The energies of these orbitals will not be significantly affected by a change of the local environment around the metal centre of the complexes. However, comparison of the band widths of the $p\pi$ ionizations (bands 1 and 2) of compound **8** with bands 3 and 4 of the complexes shows that the band 4 is significantly more broadened than band 3. This result indicates that either the bonding character has increased or that overlapping with other ionizations occurs (as is observed in bands 4 and 5 of compounds **4–6**, *vide infra*). These $p\pi$ orbitals do not interact with the *d* orbitals of molybdenum and show no disturbance of their electronic environment by other ligands around the metal centre, and the first possibility can be ruled out. The broadening of band 4 is assigned to overlapping $p\pi$ ionizations from oxygen atoms in the diolato ligands that might be buried under band 4.

The last band (band 5) for compounds **1–3**, is assigned to the lone-pair electrons of nitrogen atoms in the pyrazole rings and has a similar feature to band 3 in compound **8**. Ionizations of the oxygen

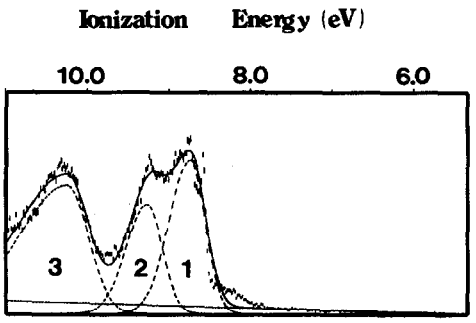

Fig. 3. Close-up PES in the range of 5.5–11.0 eV of compound **8**, $HC\{(3,5\text{-}CH_3)Pz\}_3$.

$p\pi$ electrons might also have some overlap with this band; however, it is very difficult to confirm this. The ionization energy of this band shifts from 10.27 to 10.12 eV from compound **1** to **3**, suggesting that the ionization energy of band 5 is still quite close to that of compound **8**, probably also indicating that the interaction with the *d* orbitals of the metal centre is not as important as that between $p\pi$ electrons of the diolato oxygen atoms and $d\pi$ electrons of the molybdenum atom mentioned above. The symmetry of these molecules is no higher than C_s, and these compounds contain at least four kinds of chemically different nitrogen atoms. Nevertheless, no splitting of this ionization is observed, in contrast to the case of $[Ir(\mu\text{-dimethylpyrazolyl})(CO)_2]_2$.[24]

For the ionization energies within the range of 9–10 eV, compounds **1–3** can be represented by one asymmetric Gaussian peak (band 5), whereas compounds **4–6** are represented by two asymmetric Gaussian peaks (bands 5 and 6). In complexes **4–6**, the ionizations of $p\pi$ electrons of the alkoxide oxygen atoms are observed separately as band 5 which is at lower IP than band 6 which is the nitrogen lone pair ionization. The oxygen $p\pi$ ionizations are not resolved in complexes **1–3** because they are shifted due to the stabilization of the diolato oxygen $p\pi$ ionizations in these complexes as a result of $O(p\pi)$–$Mo(d\pi)$ bonding interactions.

Bis-alkoxide complexes **4–6**

The vertical ionization energies of each band for these complexes are listed in Table 1 (spectra in Fig. 4). Bands 2, 3, 4 and 6 for all these compounds maintain similar positions throughout the entire compound series and they are also located in similar positions to those in the diolato complexes. Therefore, they probably arise from those orbitals mentioned in the case of the diolato complexes. The only difference is that the ionizations from $p\pi$ electrons of the orbitals of the oxygen atoms (band 5) of the alkoxide ligands are resolved in these compounds, whereas the ionizations from $p\pi$ electrons of the diolato oxygen atoms are not.

The PES of alkyl alcohol, ROH (R = Me, Et and ^{n}Pr), have been published.[21] The leading vertical ionization potentials decrease from 10.94 to 10.49 eV from R = Me to R = ^{n}Pr due to association with the inductive effect of alkyl groups and reduced oxygen 2*p* character in the HOMO. The ionization energies of the oxygen $p\pi$ electrons are initially lowered by forming the alkoxide anion (RO^-) from the alcohol molecule due to increase of the electron density of the oxygen atom in the alkoxide ligand.

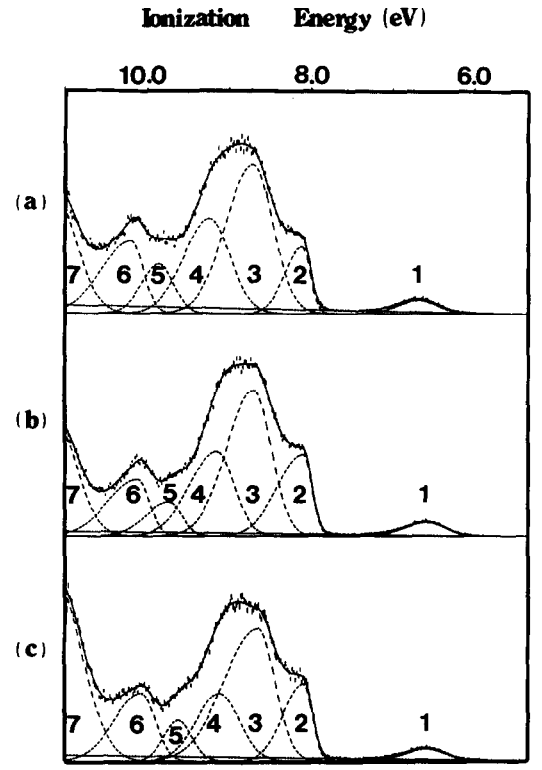

Fig. 4. Close-up PES in the range of 5.5–11.0 eV of (a) $LMoO(OMe)_2$; (b) $LMoO(OEt)_2$; (c) $LMoO(O^nPr)_2$.

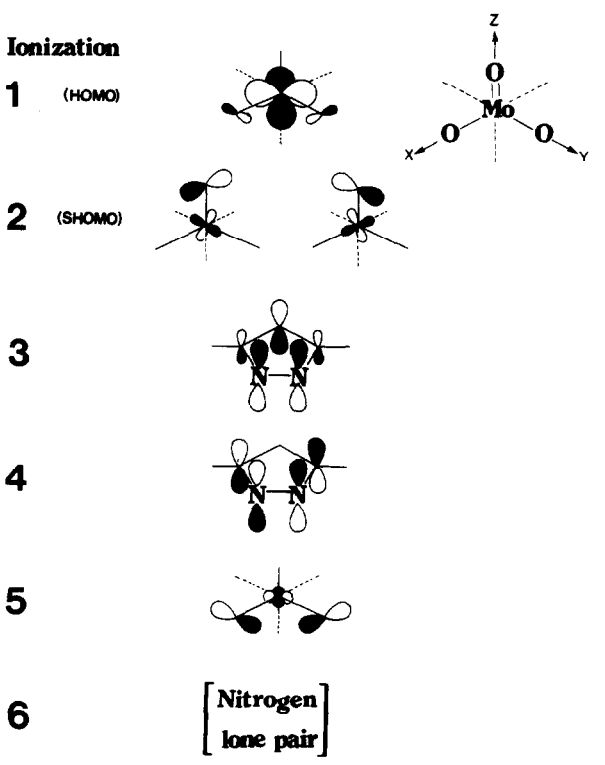


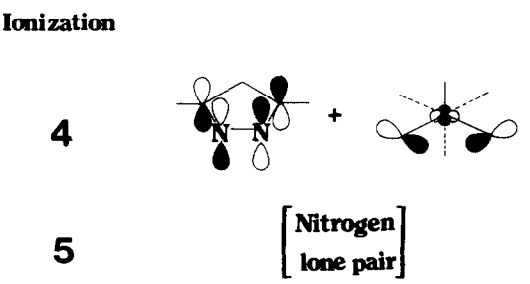
Scheme 1.

The σ-bonding between the oxygen atom in the alkoxide ligand and the molybdenum atom slightly stabilizes this $p\pi$ ionization, but there is no additional stabilization from π-bonding interactions between the alkoxide oxygen atoms and the molybdenum d electron, as occurs in the diolato complexes (*vide supra*).

In bis-alkoxide complexes, both bands 1 and 5 exhibit shifts to lower ionization energy with the introduction of more methylene units to the linear alkyl groups. For band 1, the maximum shift is only 0.11 eV. The error in the fit analysis is ± 0.02 eV for peak position, so the shift in band 1 among the bis-alkoxide compound series is barely significant. Briefly, according to these two facts, in the bis-alkoxide complexes, the interaction between $p\pi$ electrons of the oxygen atoms, in the alkoxide groups and the $d\pi$ electron of the molybdenum atom is a purely electrostatic repulsion. Consequently, the HOMO is only destabilized by a small degree upon increasing the number of methylene units in the alkyl moieties. This is different from the case in the diolato complex series. Since the HOMO in the diolato complexes is destablized by an overlap interaction between $p\pi$ electrons of the diolato oxygen atoms and the $d\pi$ electron of the molybdenum atom, a significant variation of the ionization energy of the HOMO is observed upon changing the number of methylene units in the ring (*vide ante*).

Summary of PES spectra

Both the diolato and bis-alkoxide compound series exhibit similar He I PES. Consequently, comparing with the PES of 1H-3,5-dimethylpyrazole and tris(3,5-dimethylpyrazolyl)methane, a purely qualitative molecular orbital diagram can be used to assign each band discussed in compounds **1**–**6**, as shown in Scheme 1 (for compounds **4**–**6**) and Scheme 2 (for compounds **1**–**3**).



Scheme 2.

Correlation with electrochemistry

The detailed results of solution electrochemistry have been reported earlier.[15] Within the diolato compound series, the complexes become easier to oxidize with increasing chelate ring size. In the bis-alkoxide compound series, complexes become easier to oxidize with extension of alkyl chains in alkoxide ligands.

The oxidation potential recorded from solution electrochemistry is the energy difference between the positively charged molecular ion (oxidized species) in its electronic ground state and the neutral molecule and some other energy terms, like solvation energy. The ionization potential for the HOMO is the energy necessary to generate the positive ion in its electronic ground state in the gas phase and can be thought of as a difference of the heat of formation between the molecule and its molecular ion, neglecting vibrational energy. Nevertheless, since we measure a series of similar complexes under similar experimental conditions, the $E_{1/2}$ value from solution electrochemistry should be directly proportional to the HOMO energy from gas-phase PES, as suggested by Bursten:[25]

$$E_{1/2} = k_1(-\varepsilon_{\mathrm{HOMO}}) + k_2.$$

The equation for the least-squares line of compounds **2**–**6** is shown in Fig. 5, where IP(eV) = $0.685(E_{1/2},\mathrm{V}) + 6.25$ with a correlation coefficient of 0.919.

The half-wave potentials ($E_{1/2}$) for oxidation obtained from solution phase by electrochemical methods can be thought of as a "solution ionization potential" of the highest occupied orbital.[25] Studies on the linear correlation between the HOMO energy and $E_{1/2}$ for oxidation have been reported for many systems.[25,26] In the present oxidation–reduction reactions, the participating orbital is mainly the Mo($4d_{xy}$) orbital, which has the lowest ionization energy. Consequently, the less stable the HOMO of a complex, the easier it is to oxidize, as shown in Fig. 5. The oxidation potentials from solution electrochemistry follow the order **6** < **5** < **4** < **3** < **2**; however, this trend is altered somewhat in the gas phase, **6** ≃ **5** < **3** < **4** < **2** < **1**. In the solution electrochemistry measurement, the redox process is not a Frank–Condon type instantaneous electronic excitation. However, the photoionization of a molecule in the gas phase obeys the Frank–Condon principle. Consequently, the difference between these trends from two different phases might reflect a contribution from the solvation energy of various molecular ions.

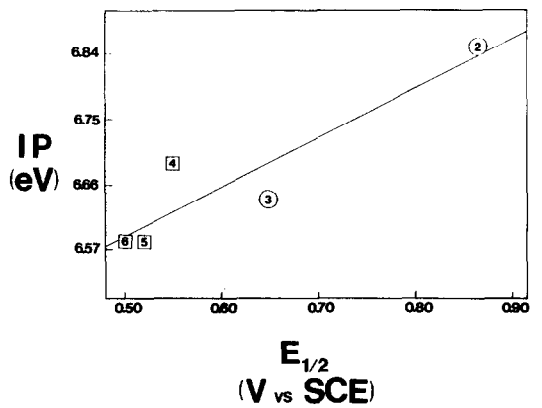


Fig. 5. Correlation of half-wave oxidation potential ($E_{1/2}$), in V vs SCE, with lowest energy ionization potential (IP), in eV, for compounds **2**–**6**.

On the basis of arguments mentioned earlier, the ionizations 1, 2, 4 (for compounds **1**–**3**), or 5 (for compounds **4**–**6**) contain some *p* character from oxygen atoms in the diolato and alkoxide ligands. Therefore, the *strength* of the interaction between $d\pi$ electron of the molybdenum atom and $p\pi$ electrons of the ligand group orbitals of diolato or alkoxide moieties primarily determines whether or not the HOMO will be destabilized. The larger the interaction between the half-filled $d\pi$ and filled oxygen $p\pi$ orbitals, the more the HOMO will be destabilized, and the easier it is to oxidize the complex. In the diolato compound series, this interaction becomes significant in a compound with larger ring size because better overlap is possible between $4d_{xy}$(Mo) and $p\pi$(O) with such a flexible ring conformation. This phenomenon is reflected by increasing the ionization energy difference between band 4 and band 1 from 2.27 to 2.50 eV for compounds **1** to **3**. The seven-membered ring diolato compound (**3**) has the lowest ionization energy for a HOMO in a diolato series, and it also exhibits the lowest half-wave potential and becomes the easiest to oxidize in that series. The unconstrained bis-alkoxide compounds show only minor or no shift of the HOMO to lower ionization energy with longer chain alkyl groups, suggesting that the interaction between $4d_{xy}$(Mo) and the alkoxide $p\pi$(O) orbitals is quite similar in all bis-alkoxide compounds because of similar electronic and steric effects among those alkoxide ligands. However, for the diolato complex series, the steric constraints of the chelate ring will alter the $4d_{xy}$(Mo) and $p\pi$(O) interaction for different complexes.

CONCLUSION

This work has shown that a series of structurally similar diolato and bis-alkoxide complexes exhibit

similar PES. However, there are three differences between these two complex series. (1) The ionization energies of the HOMO of the diolato complexes show significant shifts, but those for the bis-alkoxide complexes do not. (2) The ionization from the $p\pi$ electrons of the alkoxide oxygen atoms is resolved as band 5 in the bis-alkoxide complexes, but that from analogous diolato oxygen atoms in the diolato complexes is not. (3) The main source of the shifts of the ionization energies of the HOMO of the diolato complexes is the bonding interaction between the $p\pi$(O) and $d\pi$(Mo) orbitals which depends on the steric constraints of the metal–chelate ring. Such steric constraints are absent in the bis-alkoxide complexes and the slight destabilization of the HOMO is mainly due to electrostatic repulsion between the $p\pi$(O) and $d\pi$(Mo) electrons which varies little among the compounds.

The electronic effect for diolato and alkoxide ligands having the same number of carbon atoms in their backbones should be similar to one another (as ethanediolato and butanediolato are similar to that of bis-methoxide and bis-ethoxide, respectively), but their steric effects can be considerably different. This work shows that the diolato compound series exhibits a significant shift of the ionization energy of the HOMO, but only a small shift is found among the bis-alkoxide compounds. This result implies that the steric effect resulting from the strain in the diolato chelated ring is primarily responsible for the strength of the interaction between $4d_{xy}$(Mo) and $2p\pi$(O).

STERIC EFFECTS ON THE SELECTIVITY OF PROTEIN LABELLING WITH CHELATE COMPLEXES OF PLATINUM(II)*

XIA YING ZHOU and NENAD M. KOSTIĆ†

Department of Chemistry, Iowa State University, Ames, IA 50011, U.S.A.

Abstract—The Cl^- ligand in complexes of the type [Pt(tridentate)Cl] can be displaced by amino-acid side chains in proteins so that the Pt(tridentate) tag becomes covalently attached to the protein. The selectivity in this displacement can be controlled by adjusting the steric properties of the tridentate ligand. In the complex $[Pt(dipic)Cl]^-$, in which dipic represents 2,6-pyridinedicarboxylate, the Cl^- ligand is accessible. This complex reacts with methionine and histidine and their derivatives and with the side chain of methionine 65 in cytochrome *c*. The reactivity of amino-acid side chains toward $[Pt(trpy)Cl]^-$ depends mainly on their nucleophilicity; the soft thio-ether ligand in methionine is more reactive than the hard imidazole ligand in histidine. In the complex $[Pt(dpes)Cl]^+$, in which dpes represents di(2-pyridyl-β-ethyl)sulphide, the Cl^- ligand is partially shielded. This complex reacts with N-acetylmethionine, N-acetylhistidine, and the side chains of both methionine 65 and histidine 33 in cytochrome *c*. The reactivity of amino-acid side chains toward $[Pt(dpes)Cl]^+$ depends on their steric bulk as well as on their nucleophilicity; the thio-ether ligand in methionine is less reactive than the imidazole ligand in histidine. Principles of stereochemistry can be used in designing metal complexes for selective covalent modification of proteins.

Covalent modification of proteins is an important and frequent procedure in biochemical work. As many organic reagents have been used for this purpose,[1] the potential of inorganic reagents is becoming recognized. The amino-acid side chains contain heteroatoms that can bind metal atoms. Because substitution reactions of transition-metal complexes can be controlled by the choice of the metal and the ligands, and because these complexes have convenient spectroscopic and other properties, they are well-suited for selective labelling of proteins.[2] The complex chloro(2,2′:6′,2″-terpyridine)platinum(II) or $[Pt(trpy)Cl]^+$, designated **1**, contains a tridentate trpy ligand, so that only the chloride ion is displaced under ordinary conditions. Because complexes of platinum(II) are kinetically inert, the $Pt(trpy)^{2+}$ tag is stable on the protein. Because the tag is a UV–vis chromophore, it is easily detected and quantitated. Our studies with various cytochromes *c*,[2–4] α-chymotrypsin,[2,5] α-lytic protease,[5] papain,[6] peptides[2–4] and amino acids[2–4] showed that $[Pt(trpy)Cl]^+$ reacts mainly with cysteine and histidine side chains, i.e. with thiolate and imidazole (Im) functional groups. Arginine side chain (the guanidine group) can also react if its basicity, i.e. the pK_a value of the guanidinium ion, is lower than usual.[7,8]

The unreactivity of methionine and reactivity of histidine toward $[Pt(trpy)Cl]^+$ was surprising since a thio-ether should be much more nucleophilic than imidazole toward the soft platinum(II) atom. Our molecular orbital calculations on $[Pt(trpy)SMe_2]^{2+}$ and on $[Pt(trpy)Im]^{2+}$ showed that this unusual reactivity is caused by the ancillary terpyridine ligand.[3] The *ortho*-H atoms repel the thio-ether, but not the imidazole.[3] The strain in the N—Pt—N bond angles,[9–11] and perhaps also the aromatic character of terpyridine,[12] facilitate the displacement of the chloride ligand by the imidazole. A comparison between the complexes $[Pt(trpy)Cl]^+$ and $[PtCl_4]^{2-}$ shows the decisive effect of the ancillary ligands on the selectivity of protein labelling. Although both of them are platinum(II) chloro complexes, the former does not react with methionine even under forcing conditions,[3] whereas the latter is used as a methion-

* Dedicated to Professor Richard F. Fenske on the occasion of his retirement.

† Author to whom correspondence should be addressed.

ine-specific heavy-atom tag in protein crystallography.[13] Indeed, our molecular orbital calculations revealed no steric crowding in $[PtCl_3(SMe_2)]^-$ and $[PtCl_3Im]^-$ because the chloride ligands are small.[14] In the absence of steric effects, evidently, the displacement reactivity depends on the nucleophilicity of the competing functional groups in the protein that act as entering ligands.

In this study we show how the selectivity of platinum(II) toward the protein can be controlled by adjusting the steric properties of ancillary ligands attached to the metal. These ligands are 2,6-pyridinedicarboxylate (dipicolinate) in the complex designated **2** and di(2-pyridyl-β-ethyl)sulphide in the complex designated **3**.

EXPERIMENTAL

Materials and methods

Amino acids, horse-heart cytochrome *c* (of type VI), tuna-heart cytochrome *c* (of type XI), and cation exchanger CM 52 were obtained from Sigma. The horse protein was purified chromatographically,[15] and the tuna protein was used as received. Piperidine was obtained from Fisher; 2-vinylpyridine, $K_2[PtCl_4]$ and D_2O, from Aldrich; and CD_3OD, from Cambridge Isotope Laboratories. Water was distilled and demineralized. Ultrafiltration was carried out with Amicon YM 5 membranes under nitrogen at 4°C.

The UV–vis spectra were recorded with an IBM 9430 spectrophotometer. The difference spectra of the labels were obtained by subtracting the spectrum of the native cytochrome *c* from the spectra of the different labelled derivatives. The IR spectra were recorded with an IBM IR 98 spectrophotometer. The ^1H NMR spectra were recorded at 300 MHz with a Nicolet NT 300 spectrometer, with DSS as an internal reference. The proteins for NMR measurements were ultrafiltered into D_2O and lyophilized repeatedly with it. The ^{195}Pt NMR spectra were recorded with a Bruker WM 200 spectrometer; the chemical shifts are expressed with respect to $K_2[PtCl_4]$. Differential-pulse voltammograms were obtained with an IBM EC 225 analyser in the standard way.

Synthetic procedures

Horse-heart cytochrome *c* was carboxymethylated by the published procedure.[16,17] Potassium (2,6 - pyridinedicarboxylato)chloroplatinate(II), K[Pt(dipic)Cl], was prepared by our published procedure.[18] The aromatic protons, H^3 and H^4, are in *meta* and *para* positions with respect to the nitrogen atom.

Di(2-pyridyl-β-ethyl)sulphide was prepared by the published method.[19] The aromatic protons are designated H^3, H^4, H^5 and H^6, with H^6 being the *ortho*-H highlighted in the complex **3**; the CH_2 protons adjacent to the ring and those adjacent to the sulphur atom are designated H^7 and H^8, respectively. ^1H NMR (δ values) in CD_3OD: 8.47 d (H^6, 2H), 7.77 t of d (H^4, 2H), 7.35 d (H^3, 2H), 7.27 t of d (H^5, 2H), $^3J(H—H) = 6.3$ Hz, $^4J(H—H) = 1.5$ Hz; 3.07 t of d (H^7, 4H), 2.92 t of d (H^8, 4H), $^3J(H—H) = 7.8$ Hz, $^2J(H—H) = 1.4$ Hz.

Di(2-pyridyl-β-ethyl)sulphidochloroplatinum(II) chloride, [Pt(dpes)Cl]Cl, was prepared by the published method.[20] M.p.: 205°C. ^1H NMR (δ values) in D_2O: 9.02 d, 8.03 t of d, 7.60 d, 7.45 t of d, $^3J(Pt—H^6) = 30$ Hz, $^3J(H—H) = 7.2$ Hz, $^4J(H—H) = 1.5$ Hz; 3.94 t of d, 3.55 d of t, 3.26 d of t, 3.11 t of d, $^3J(Pt—H^8) = 42$ Hz, $^2J(H—H) = 14.6$ and 2.9 Hz, $^3J(H—H) = 13.7$ and 3.4 Hz. IR in Nujol: 358, 326 and 243 cm^{-1}. UV–vis in water: $\lambda = 265$ nm, $\varepsilon = 12{,}000$ M^{-1} cm^{-1}.

Reactions with amino acids

The following amino acids and their N-acetyl derivatives were incubated, one at a time, with K[Pt(dipic)Cl] and with [Pt(dpes)Cl]Cl: Met, Cys, His, Trp, Tyr, Asp, Asn, Glu, Gln, Lys, Arg, Pro, Thr and Gly. The reaction mixture was 5–10 mM in each reactant, the solvent was either 85 mM phosphate buffer at pH 7.0 or D_2O adjusted to the desired pH value with NaOD or DCl. The incubation lasted for several days at room temperature,

and the reaction mixtures were examined periodically by UV–vis and ^{1}H NMR spectroscopy. When the substitution reactions took place they were complete or nearly complete, except that substitution of AcMet for Cl^- in $[Pt(dpes)Cl]^+$ was only partial. The reactivity of His, Trp, Tyr and Arg was compared with the reactivity of imidazole, indole, phenol and guanidine, respectively. Salts for the IR spectroscopic measurements were prepared by precipitation with common counterions.

Labelling of cytochrome c *with* $[Pt(dipic)Cl]^-$

An equimolar mixture (2 mM each) of ferricytochrome *c* and K[Pt(dipic)Cl] in 85 mM phosphate buffer at pH 7.0 or in 100 mM acetate buffer at pH 5.0 was left for 24 h at room temperature. The reaction was ended by ultrafiltration into the phosphate buffer. The reaction mixture was oxidized by $[Co(phen)_3](ClO_4)_3$, and the excess of the oxidizing agent was removed by ultrafiltration into the phosphate buffer. The chromatographic separation on a CM 52 column was achieved easily by elution with 60 mM phosphate buffer at pH 7.0. The horse cytochrome *c* yielded 16% of the labelled protein and 84% of the native protein, in this elution order. The incubation of ferrocytochrome *c* with an excess of K[Pt(dipic)Cl], up to the molar ratio of 1:4, followed by oxidation and chromatography as before, gave a greater yield of the modified protein, up to 56%. The two fractions were identified by comparison of their mobilities with the mobility of the native protein on a parallel column, and by spiking each fraction with the known amount of the native protein. The mixture of the first fraction and the native protein gave two bands, whereas the mixture of the second fraction and the native protein gave only one band on the CM 52 column. The tuna protein reacted like the horse protein and gave similar chromatographic results.

Labelling of cytochrome c *with* $[Pt(dpes)Cl]^+$

Ferricytochrome *c* (2 mM) was incubated with [Pt(dpes)Cl]Cl (6 mM) in 85 mM phosphate buffer at pH 7.0 or in 100 mM acetate buffer at pH 4.0 for 4 days at 25°C. The reaction was ended, and the reaction mixture chromatographed, as described above. The horse cytochrome *c* at pH 7.0 yielded 18% of the native protein (N) and the following derivatives: 16% of the singly-labelled (S1), 49% of the singly-labelled (S2), 10% of the singly-labelled (S3), 3% of the doubly-labelled (D1), 3% of the doubly-labelled (D2) and 1% of the triply-labelled (T), in this elution order. The horse protein at pH 4.0 yielded only the derivative S3. The tuna protein at pH 7.0 yielded the derivatives S1 and S3, but at pH 4.0 it yielded only S3. The number of the platinum labels was determined by subtracting the spectrum of the native protein from the spectra of the protein derivatives. The band of the $Pt(dpes)^{2+}$ chromophore at *ca* 261 nm was seen clearly in the spectra of the protein derivatives and in the difference spectra. The number of the chromophores was estimated using the assumption that the $Pt(dpes)^{2+}$ chromophore has the same extinction coefficient when attached to an amino acid and to such an amino-acid residue in cytochrome *c*.

RESULTS AND DISCUSSION

Properties of the complexes $[Pt(dipic)Cl]^-$ *and* $[Pt(dpes)Cl]^+$

The chemical and physical properties of the various $[Pt(dipic)Cl]^-$ salts were described in our previous publication.[18] The presence of the ^{195}Pt satellites around both the aromatic and aliphatic ^{1}H resonances in the NMR spectrum of [Pt(dpes)Cl]Cl proves the tridentate coordination of the dpes ligand. The ^3J(Pt—H) values are consistent with the analogous coupling constants in bipyridyl[21] and thio-ether[22,23] complexes of platinum(II). The aromatic ^{1}H resonances of the free dpes ligand are not significantly affected by coordination, but the aliphatic resonances are. In particular, the geminal methylene protons in the complex are inequivalent. Even without a detailed analysis it is evident that the two chelate rings in the tridentate complex $[Pt(dpes)Cl]^+$ are puckered. The IR bands at 358, 326 and 243 cm^{-1} can be assigned to the Pt—S,[24] Pt—Cl[25] and Pt—N[26] stretching vibrations. The UV band at 265 nm can be assigned to the pyridine $\pi \rightarrow \pi^*$ transition.

Reactions of $[Pt(dipic)Cl]^-$ *with amino acids*

Every amino acid containing heteroatoms in the side chain was tested, and glycine was tested in order to check the (un)reactivity of the α-NH_2 and α-COO^- groups. The compounds (e.g. imidazole) that are contained in the side chains of important amino acids (e.g. His) were tested separately. Only the side chains of Cys, Met and His proved reactive under the general conditions of protein labelling. Since the horse and tuna cytochromes *c* do not contain free Cys, the reactions of this amino acid were not investigated further. In order to make the model reactions more relevant to the protein reactions, N-acetyl derivatives, esters and amides

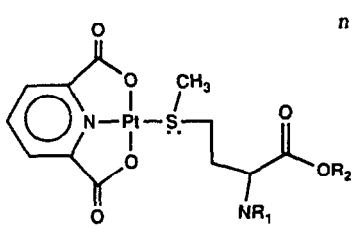
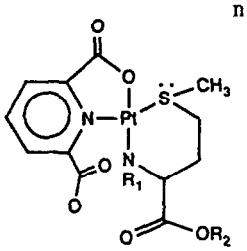
were used instead of the free amino acids in most of the experiments.

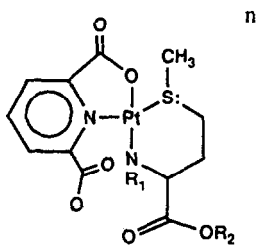
Immediately upon addition of Met or its derivatives to the yellow complex $[Pt(dipic)Cl]^-$, the solution becomes pale yellow or colourless, and the UV absorption band at 328 nm disappears. The reactions are best followed by ^{1}H NMR spectroscopy because the aromatic resonances due to dipic and the aliphatic ones due to the incoming ligand do not overlap; see Table 1. The downfield shift of the CH_3S resonance is characteristic of thioether coordination to platinum(II). The products, designated **4**–**7**, are shown below. In neutral and weakly-acidic solutions the amino group is pro-



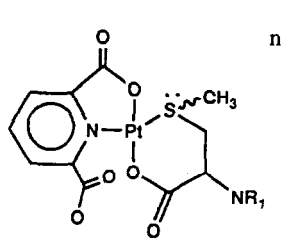
4



5



6



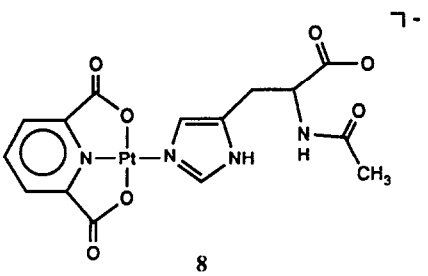
7

Ligand	Met	AcMet	$AcMetNH_2$	$MetCH_3$
R_1	H_3	CH_3CO	CH_3CO	H_3
R_2	None	None	NH_2	CH_3
n in **4**	0	–	0	+
n in **5**	–	2–	–	0
n in **6**	–	2–	–	0
n in **7**	0	–	None	None

tonated, and the carboxylate group is deprotonated. The ligands $AcMetNH_2$ and $MetCH_3$ cannot form the chelate complex **7**. The complexes **4** show only one doublet in the aromatic region, evidence of tridentate (symmetrical) coordination of the dipicolinate ligand. The complexes **5**, **6** and **7** show two such doublets, evidence of bidentate (unsymmetrical) coordination of this ligand. The easy displacement of one of the two carboxylate groups from the platinum(II) atom is probably a consequence of the steric strain in the tridentate Pt(dipic) unit.[18] The yields of the products **4**–**7** after 1 day are as follows: with Met, 0, 52, 26 and 13%; with AcMet, 31, 36, 9 and 9%; with $AcMetNH_2$, 35, 56, 3 and 0%; and with $MetCH_3$, 0, 56, 44 and 0%. The total yields are less than 100% because small amounts of the reactants remain. The ligands Met and $MetCH_3$ form the product **4** initially, but this product is no longer evident after 1 day. The products **4** and **7** convert into the products **5** and **6** with time. The ligands $AcMetNH_2$ and $MetCH_3$ cannot form the product **7** because the carboxylate group in them is blocked. The coordination of methionine as an S-unidentate and an S,O-bidentate ligand has been observed in other platinum(II) complexes as well.[27] The products **5** and **6** are diastereomers, having different configurations at the chiral sulphur atom. The S,N-bidentate coordination of Met (as in the complexes **5** and **6**) and coordination of the peptide nitrogen atom in such chelates also are known.[28–30]

The reaction between $[Pt(dipic)Cl]^-$ and AcMet was followed by ^{195}Pt NMR spectroscopy at 21°C. The resonance at 43 ppm is assigned to the tridentate $[Pt(dipic)AcMet]^-$ complex, **4**. The resonances at −574 and −580 ppm differ little in chemical shift, as is expected of the diastereomeric platinum(II) thio-ether complexes;[22,23] they are assigned to the complexes **5** and **6**. Indeed, these two resonances coalesce at *ca* 80°, as expected of the diastereomers.[22,23]

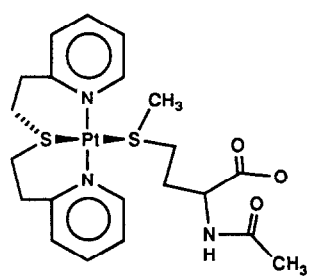
When His and $[Pt(dipic)Cl]^-$ are mixed at pH 7.0 an orange precipitate forms immediately, but when they are mixed at pH 5.0 the precipitate appears only after some time. Imidazole behaves exactly like His. Evidently the amino acid coordinates via the pyridine-like nitrogen atom (N^3), whose pK_a value is *ca* 6.2.[31] The Pt—Cl stretching band disappears when $[Pt(dipic)Cl]^-$ is converted into [Pt(dipic)Im]. The conversion of $[Pt(dipic)Cl]^-$ into [Pt(dipic)AcHis]$^-$ does not affect the UV–vis spectrum significantly, but the reaction is easily followed by ^1H NMR spectroscopy. Only one product, designated **8**, is formed. ^1H NMR (δ values) in D_2O: 8.44 t dipic H^4, 7.88 d dipic $H^{3,5}$, 7.63 s Im H^2, 7.07 s Im H^4, 4.70 t CH, 2.90 d CH_2 and 1.98 s CH_3CO.



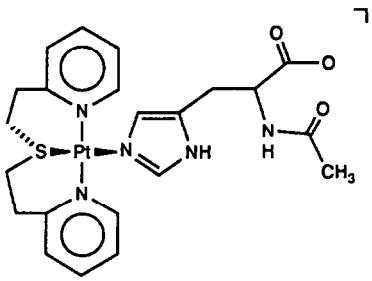
8

Reactions of $[Pt(dpes)Cl]^+$ *with amino acids*

Only the side chains of His and Met react with this complex under the general conditions of protein modification. The reactions were studied with the N-acetyl derivatives of these amino acids, and the ^1H NMR properties of the products, designated **9** and **10**, are summarized in Table 2. The resonances



9



10

of the pyridine protons move downfield by 0.15–0.19 ppm upon the displacement of the Cl^- ligand by AcMet, except the resonance of H^6, which moves upfield by 0.03 ppm. Both this anomaly and the small downfield movement (by 0.09 ppm) of the CH_3S resonance upon coordination may be due to the spatial proximity of the CH_3S and H^6 protons and to the anisotropic effects of the Pt—S bond on H^6.[9] The upfield movement by 0.10 ppm of the CH_3CO resonance may be an indication of non-covalent, probably hydrophobic, interactions between the AcMet and dpes ligands.[32,33] A band at 317 cm^{-1} in the IR spectrum of [Pt(dpes)AcMet]PF_6 can be assigned to the Pt—S stretching vibration.

[a] See the text for formulae.
[b] The protons designated only by numbers belong to the dpes ligand.

The reaction between [Pt(dpes)Cl]$^+$ and AcHis gives two products in a ratio of 1 : 0.6. Since only the Cl^- ligand in [Pt(dpes)Cl]$^+$ is displaced by AcHis, the two products probably are stereoisomers of [Pt(dpes)AcHis]$^+$, designated **10**, with different configurations of the non-planar dpes chelate, the AcHis ligand, or both. The UV–vis spectrum of [Pt(dpes)Cl]$^+$ does not change significantly as the Cl^- ligand is replaced by AcMet or AcHis.

Binding sites in cytochrome c

Cytochrome *c* is an electron-transporting haem protein. In the schematic representations **11**, **12** and **13**, the haem group and the polypeptide backbone are shown in a simplified way, and only the binding amino-acid residues are shown in detail. Since the cytochrome *c* from neither horse nor tuna contains free Cys residues, the possible binding sites for the platinum(II) reagents are Met and His residues. They are His 18, His 26, His 33, Met 65 and Met 80 in the horse protein and His 18, His 26, Met 65 and Met 80 in the tuna protein. The position 33 in the tuna protein is occupied by Trp, an amino acid unreactive toward the platinum(II) complexes. In the identification of the binding sites we benefitted from our thorough previous studies, including peptide-mapping experiments, of labelling of different proteins with the [Pt(trpy) Cl]$^+$ complex.[2–7]

Protein derivatives having the same number of identical, charged labels in different locations are separated efficiently by cation-exchange chromatography.[3,4] Since [Pt(dipic)Cl]$^-$ yields only one protein derivative, this complex probably binds to a single site. Binding to His 18 and Met 80, which are axial ligands to the iron atom, can be ruled out. As Table 3 shows, labelling does not perturb the UV–vis spectrum and the reduction potential of the protein. These properties, especially the band at 695 nm, are very sensitive to the changes in the axial ligation of the iron atom. The ^{1}H NMR hyperfine chemical shifts are sensitive to the tertiary structure of the protein in the vicinity of the haem.[34,35] Since these shifts in the labelled protein [Pt(dipic)cyt] are not perturbed appreciably, the protein structure is probably not significantly altered. Histidine 26 is barely accessible,[36] and even the highly reactive [Pt(trpy)Cl]$^+$ labels it with a very low yield.[3] The labelling yields of 16–56%, achieved with [Pt(dipic)Cl]$^-$, are inconsistent with His 26 as the binding site. Carboxymethylation, which blocks only His 33 and Met 65,[16,17] practically suppresses the reaction of the protein with [Pt(dipic)Cl]$^-$. Histidine 33 is ruled out by two different experiments. Firstly, the labelling yield is the same at pH 5.0 and 7.0; because the pK_a value of His 33 is 6.4,[36] its imidazole group should be almost fully protonated and thus unreactive at pH 5.0. Secondly, the tuna protein, although it lacks His 33, reacts with [Pt(dipic)Cl]$^-$ like the horse protein.

Since the yield is independent of pH, the binding site must be Met 65, which has a thio-ether in its side

Table 3. Spectroscopic and electrochemical properties of native and Pt(dipic)-labelled horse cytochrome *c*

Property		Cyt	[Pt(dipic)cyt]
UV–vis abs. max. (nm)		410 530 695	410 530 695

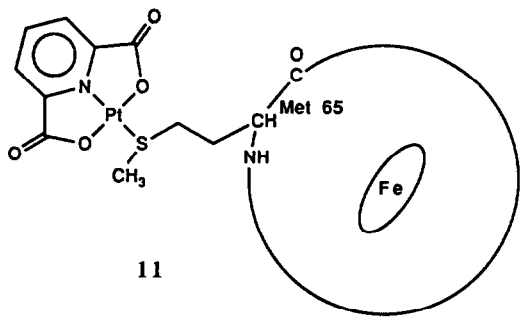
chain. Indeed, this residue is exposed on the protein surface.[37,38] Because the [Pt(dipic)AcMet]$^-$ complex has a featureless absorption band (a sloping tail) in the UV region, in which the protein absorbs strongly, the label is not evident in the UV–vis difference spectrum.

The number of the Pt(dpes)$^{2+}$ chromophores in the protein derivatives—one, two or three—was determined on the basis of the UV–vis difference spectra, all of which contain the characteristic absorption band in the region 260–263 nm. The lack of significant perturbations of the protein derivatives, evident in Table 4, rules out the labelling of His 18 and Met 85. The binding sites are deduced by comparing the yields of the horse-protein derivatives obtained at pH 7.0 and at pH 4.0 and by comparing the derivatives of the two proteins obtained at the same pH (4.0 and 7.0), keeping in mind that His 33 (in the horse protein) and Met 65 (in both proteins) are exposed on the surface, whereas His 26 (in both proteins) is unexposed. Derivatives designated S1, S2, S3, D1, D2 and T contain the Pt(dpes)$^{2+}$ labels at His 26, at His 33, at Met 65, at His 26 and His 33, at His 33 and Met 65, and at His 26, His 33, and Met 65, respectively. The most abundant derivative, S2, was also examined by ^{1}H NMR spectroscopy. The labelling of His 33 causes a movement upfield of the imidazole H^2 and H^4 resonances by 0.33 and 0.06 ppm, respectively. The corresponding movements in the minor form of the model complex [Pt(dpes)AcHis]$^-$ are 0.33 and 0.01 ppm.

Selectivity in protein labelling

Because platinum(II) is a soft metal, it has a greater affinity, in both a kinetic and a thermodynamic sense, for the soft thio-ether ligand (the Met side chain) than for the hard imidazole ligand (the His side chain). The trpy ligand, however, sterically shields the Cl$^-$ ligand in [Pt(trpy)Cl]$^+$ and prevents its displacement by the Met side chain, which is rather bulky. Displacement by the His side chain, which is less bulky, occurs readily.[3–5]

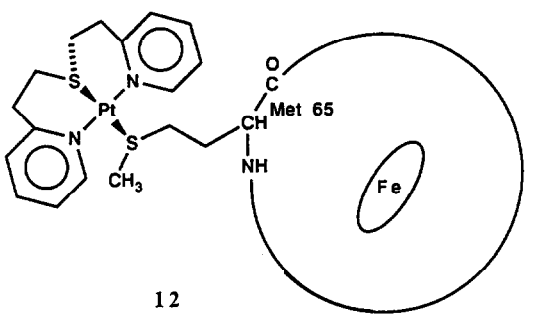
Because the dipic ligand does not shield the Cl$^-$ ligand, the complex [Pt(dipic)Cl]$^-$ reacts with both Met and His (and their derivatives), but faster with the former than with the latter. In cytochrome *c*, however, only Met 65 is labelled (as shown schematically in **11**), whereas His 33 is not. Perhaps His 33 is unreactive toward this anionic complex because the environment of this residue is negatively charged, whereas the environment of Met 65 is approximately electroneutral. Indeed, His 33 reacts only slightly with the anionic reagent [Pt(sbpaphy)Cl]$^-$.[39]



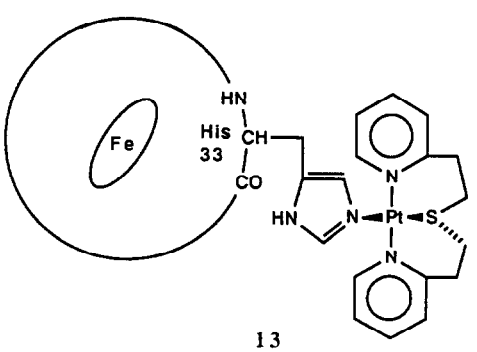
11

The steric properties of [Pt(dpes)Cl]$^+$ (**3**) are intermediate between those of [Pt(trpy)Cl]$^+$ (**1**) and of [Pt(dipic)Cl]$^-$ (**2**). Molecular models of **3** show that the puckering of the chelate rings tilts the S—Pt—Cl axis away from the pyridine planes and that the Cl$^-$ ligand therefore is incompletely shielded by the *ortho*-H atoms of the pyridine rings. Moreover, the Cl$^-$ ligand is labilized owing to the pronounced *trans* effect of the thio-ether ligand.

The reactivity of the complex **3** likewise is intermediate between those of the complexes **1** and **2**. It reacts with both Met and His (and their derivatives) and with both Met 65 and His 33 in cytochrome *c*, as shown schematically in **12** and **13**. But the Cl$^-$ atoms must still be considerably shielded because the yield of the His 33 derivative is greater than the yield of the Met 65 derivative.



12



13

CONCLUSION

Principles of coordination chemistry and stereochemistry can be used in designing inorganic reagents for selective covalent modification of proteins.

COUNTING ELECTRONS AND RATIONALIZING STRUCTURES OF CLUSTERS AND CLUSTERS OF CLUSTERS*

BOON K. TEO† and HONG ZHANG

Department of Chemistry, University of Illinois at Chicago, Chicago, IL 60680, U.S.A.

Abstract—The investigation of the electronic structures of high nuclearity metal clusters constitutes an important prerequisite for the basic understanding of the relationship between discrete metal clusters and the extended bulk metal. Simple electron counting principles are particularly useful in this regard. It not only allows a systematization or rationalization of the observed structures of these clusters, but also can lead to prediction of clusters of yet unknown molecular architectures and/or formulations. In this review, electron counting principles for the metal clusters of varying nuclearity (magic numbers), size, shape and packing arrangements will be discussed. Emphasis will be focused upon: (1) the topological electron counting (*TEC*) rule; (2) the C^2 model for clusters of clusters; (3) the *Shell* model for v_n polytopal close-packed metal clusters; and (4) the *Extended Hume–Rothery* rule for metal clusters of close-packed arrangements.

A cluster is an aggregate of atoms or molecules. Current interest in clusters stems from the fact that the collective behaviour of a cluster often differs significantly from that of its constituents.

Chemists have been able to prepare and/or observe a wide variety of clusters in gas, liquid, solution or solid phases. Some clusters are *naked* (for example, Bi_8^{2+} [1a] and Ge_9^{2-} [1b]) while others are *ligated* with ligands such as phosphines {e.g. $[Au_{13}Cl_2(PMe_2Ph)_{10}]^{2+}$ [2]} and carbonyls {e.g. $[Pt_{19}(CO)_{22}]^{4-}$ [3]}. They can either be discrete clusters in solution or extended clusters in solid states. Finally, atoms (or molecules) within a cluster can be held together by ionic, covalent, metallic or hydrogen bonding, as well as weak van der Waals' interactions.

A metal cluster, as defined by Cotton and Wilkinson,[4] is "a group of two or more metal atoms in which there are substantial and direct *bonds* between the metal atoms". Large metal clusters[5,6] (containing, say, dozens of metal atoms) are of particular interest in that they lie in the region of aggregation between individual atoms and bulk metal. Investigations of the chemical and physical properties of these clusters will therefore shed light on how, where and when metallic behaviour begins or ends. In other words, how many metal atoms must a cluster have before it begins to behave as a metal? Conversely, how small must metal particles become before they lose their metallic character? In the region between one and a large number of associated atoms, there is, evidently, some intermediate number or numbers that determine the presence or absence of metallic or other bulk properties.

A crucial first step toward such a goal is the understanding of the structure and bonding of large, structurally well-defined metal clusters with discrete *size* and *shape* approaching that of small metal particles. Recent developments in cluster synthesis[7–9] have produced high nuclearity metal clusters with metal arrangements resembling (or related to) fragments of the bulk metal.

The investigation of the electronic structures of these high nuclearity metal clusters constitutes an important prerequisite for the basic understanding of the relationship between discrete metal clusters and the extended bulk metal. Simple electron counting principles[10–17] are particularly useful in this regard. It not only allows a systematization or rationalization of the observed structures of these clusters, but also can lead to predictions of clusters of yet unknown molecular architectures and/or formulations.

In this review, we shall give a brief account of the electron counting principles we helped develop over the years for metal cluster systems.

We shall categorize metal clusters into three broad classes. The *primary* clusters are the simplest *polytopal* clusters such as a triangular or a tetra-

hedral cluster. Mathematically, a *polytope*[18] is the general term for point, line, polygon and polyhedron in 0-, 1-, 2- and 3-dimensions, respectively. A polytopal cluster therefore constitutes a cluster framework which comprises isolated, chain-like, polygonal or polyhedral atomic arrangements in the respective dimensions. These clusters, generally of low nuclearity, are of prime importance in that they can be used as "*building blocks*" or "*nucleation core*" for the *secondary* clusters which may be categorized into two broad classes: the "*clusters of clusters*"[19]; and the "v_n *polytopal clusters*",[5-9] respectively, as depicted schematically in Chart 1. We shall first briefly describe electron counting principles for the primary clusters, followed by similar discussions on the two categories of secondary clusters. Emphasis will be placed upon: (1) the topological electron counting (*TEC*) rule;[13,14] (2) the C^2 model for clusters of clusters;[16] (3) the *Shell* model[15] for v_n polytopal close-packed metal clusters; and (4) the *Extended Hume–Rothery* role[17] for metal clusters of close-packed arrangements. Readers are referred to the literature[10-12] for other elegant alternative electron counting schemes which may or may not be equivalent to those discussed in this review.

TOPOLOGICAL ELECTRON COUNTING (TEC) RULE

Basic assumptions

The TEC scheme assumes that (1) each vertex atom contributes three orbitals for cluster interaction of which only the bonding contributions (B) are filled; and (2) the remaining valence orbitals (one for main-group and six for transition metal vertex atoms) are "filled" as a result of ligand bondings or as lone pairs, as represented schematically in Chart 2. For a cluster with V_n main-group and V_m transition metal vertices, there will therefore be $3V$ orbitals for cluster interaction (where $V = V_n + V_m$). [These orbitals can be visualized as hybrid orbitals based on the three valence p orbitals. The remaining valence orbitals (one s for main-group elements; five d and one s for transition metals) as "atomic" orbitals are used for ligand bonding or lone pairs. In reality, of course, extensive mixing of s and p orbitals and of d, s and p orbitals can occur for main-group elements and transition metals, respectively.]

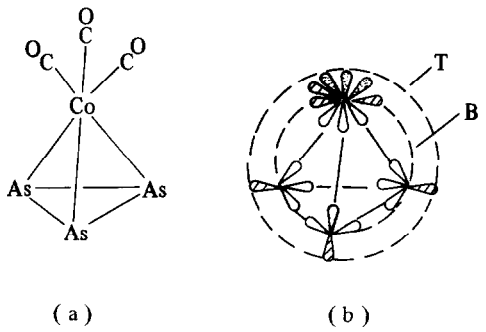
If B is the number of (filled) *bonding* orbitals formed by the 3V *cluster orbitals*, the total number of topological electron pairs is given by[14]

$$T = V_n + 6V_m + B. \quad (1)$$

Equation (1) in effect separates the total number of electron pairs into two parts: viz. those occupying the energetically low-lying valence orbitals (V_n s orbitals for main-group elements, $5V_m$ d orbitals and V_m s orbitals for transition metals) and those (B) primarily responsible for "holding the cluster together".

Physical significance of B *and* T

We shall illustrate the utility of the TEC[14a] theory with an example, $As_3Co(CO)_3$, shown in Chart 3(a). Here we have $V_n = 3$, $V_m = 1$. The observed electron count is $N = 3 \times 5(As) + 1 \times 9(Co) + 3 \times 2(CO) = 30$, or a total of $T = N/2 = 15$ electron pairs. Note that the Co atom contributes nine atomic orbitals and nine electrons while each As atom contributes four atomic orbitals and five electrons to cluster bonding. The disposition of 15 topological electron pairs, T (outer circle), is shown pictorially in Chart 3(b): three bonding electron pairs donated by the three carbonyls (dotted), six lone pairs (crossed), three on the Co atom and one



(a) (b)

Chart 3. (a) Structure of $As_3Co(CO)_3$, a tetrahedral cluster. (b) Pictorial representation of the topological electron pairs, T (outer circle), and the skeletal electron pairs, B (inner circle).

on each of the three As atoms, and six bonding electron pairs ($B = 6$) that occupy the bonding combinations of the 12 cluster orbitals (open), three from each vertex atom.

If the electron pairs "exo" to the cluster [cf. dotted or crossed orbitals in Chart 3(b)] are removed, one obtains a quantity B [cf. inner circle, Chart 3(b)]:

$$B = T-(V_n+6V_m) = 15-(3+6\times 1) = 6. \quad (2)$$

For this particular cluster, the value of $B = 6$ corresponds exactly to the number of the edges of a tetrahedron (this is not always the case as we shall see). Hence, the parameter B can be interpreted as the number of *bonding cluster orbitals/electron pairs*. As we shall see later, for primary clusters, parameter B also corresponds to the number of *skeletal electron pairs* in the context of the skeletal electron pairs (SEP) theory.[10c] It is interesting to note that B depends on the total number of vertices, V, regardless of its make-up (V_n or V_m).†

COUNTING ELECTRONS AND RATIONALIZING STRUCTURES OF PRIMARY CLUSTERS

Three-dimensional polyhedral clusters

Two types of polyhedra are of particular importance in cluster chemistry: three-connected polyhedra and deltahedra, which we shall discuss next.

Three-connected polyhedral clusters. It is of interest to consider a particular type of polyhedra in which each vertex is connected to three other vertices. Some examples of three-connected polyhedra are shown in Chart 4. Polyhedral C_nH_n belongs to this class of clusters. Other examples of main-group or metal clusters are listed in refs 13 and 14. Since each vertex is connected to three other vertices via three cluster orbitals, these clusters (with a total of V vertices) can be considered as electron precise in that one half of the $3V$ orbitals will be bonding:

$$B = 3V/2 \text{ for three-connected polyhedral clusters.} \quad (3)$$

The other half, of course, will be antibonding ($A = 3V/2$) as tabulated in Table 1. As it turns out (Euler's theorem), for three-connected polyhedra, the number of edges, E, is also given by $3V/2$. Hence, the B value for a three-connected polyhedron is equal to the number of edges ($B = E$). The B values for other important three-connected polyhedral clusters are given in Chart 4.

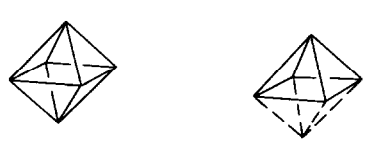
Deltahedral clusters. A deltahedron is a polyhedron with triangular faces only. Important examples are also shown in Chart 4. Boron hydrides of general formula $B_nH_n^{2-}$ are prime examples of this class of clusters. Other representative main-group or transition metal clusters can be found in refs 13 and 14.

SEP theory[10c] predicts that the number of skeletal electron pairs, $B = V+1$ for this class of clusters (except tetrahedron). The B values for the common deltahedra are given in Chart 4. For example, an icosahedron has $V = 12$ vertices and a B value of 13, thereby satisfying the

$$B = V+1 \quad \text{for deltahedral clusters} \quad (4)$$

rule of the SEP theory.

It turns out that the SEP theory applies not only to deltahedral clusters (excluding tetrahedron) but also to polyhedra which can be visualized as derivable from a deltahedron with one, two or three missing vertices. Equation (4) is appropriately modified to $B = V+2$, $V+3$, $V+4$ for these latter polyhedra, commonly called *nido-*, *arachno-* or *hypho*-clusters. For example, a square pyramid ($V = 5$) can be considered as an octahedron ($V = 6$) with a missing vertex (a *nido*-cluster) as shown below, hence $B = V+2 = 5+2 = 7$. We may call this the *debor* principle.



† It is apparent that eq. (1) allows a direct comparison between TEC and the SEP rules. As pointed out in ref. 14(a), both theories can be derived from molecular orbital calculations.

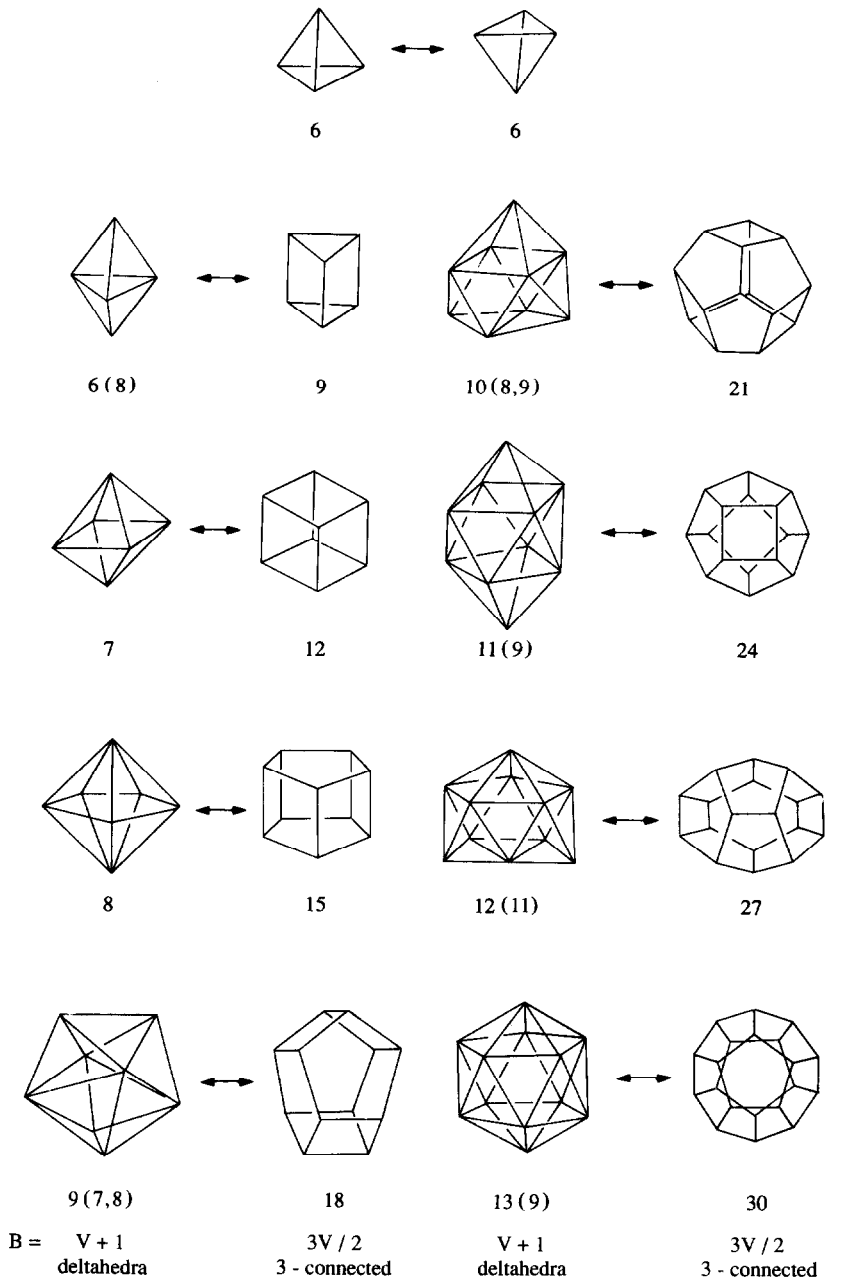


Chart 4. The B values for some 3-D polyhedral clusters and their duality: the three-connected (left) and the deltahedra (right).

Table 1. Numbers of antibonding (A) and bonding (B) cluster orbitals for a cluster with V vertices (Sum: $A+B=3V$)

Dimensions	3-D 3-Connected	3-D Deltahedron	2-D Ring	1-D Chain	0-D Isolated
A (empty)	$3V/2$	$2V-1$	V	$V-1$	0
B (filled)	$3V/2$	$V+1$	$2V$	$2V+1$	$3V$

The opposite of the *debor* principle is the *capping* principle,[20] which states that capping does not alter the number of skeletal electron pairs of the parent polyhedron. For example, tetracapped tetrahedron is a deltahedron with eight vertices, yet there are only six skeletal electron pairs ($B = 6$) within the central tetrahedron.

One important feature of the pairs of polyhedra shown in Chart 4 is their *duality* or *conjugation*. The dual of a polyhedron is defined as the polyhedron formed by interchanging the vertices and the faces. *Dual polyhedra have exactly the same number of edges.* (Note that tetrahedron is self-dual.)

Zero-, one- and two-dimensional clusters

Since the TEC rule assumes that each vertex atom contributes three orbitals for cluster bonding, the B value for zero-, one- or two-dimensional (D) clusters can be given by[14b]

$$B = 3V - E \quad \text{for 0-, 1-, 2-D clusters,} \qquad (5)$$

where E is the number of edges (or bonds). The B values for some representative zero-, one- and two-dimensional clusters are given in Chart 5. For example, the n-membered ring clusters will have n sides (bonds) and therefore $B = 3n - n = 2n$ via eq. (5). Other more complex polyhedral two-dimensional clusters can likewise be determined.

We can now summarize the number of anti-bonding (A) and bonding (B) cluster orbitals for clusters of various dimensions in Table 1. Since each vertex atom contributes three orbitals for cluster orbitals, we have $A + B = 3V$. The utility of Table 1 will be illustrated later in this review.

Counting electrons and rationalizing structures

Two ways of selecting cluster framework. For a metal cluster with bridging ligands, electron counting principles can be applied to either the metal framework or the metal-(bridging ligand) cluster framework. For example, the framework of the $Ni_8(\mu_4\text{-}PPh)_6(CO)_8$ cluster[21] can either be considered as a cube (Ni_8) [Chart 6(a)] or a hexa-capped cube (Ni_8P_6) [Chart 6(b)].

From formula to structure. For the $Ni_8(\mu_4\text{-}PPh)_6(CO)_8$ cluster, we may consider

(a) (b)

Chart 6. The (a) Ni_8 and (b) Ni_8P_6 core of $Ni_8(\mu_4\text{-}PPh)_6(CO)_8$.

(a) Ni_8 as cluster framework, then from the formula, we obtain,

$$N_{obs} = 8 \times 10(Ni) + 6 \times 4(\mu_4\text{-}PPh) + 8 \times 2(CO) = 120$$

$$T = N/2 = 120/2 = 60$$

$$B = T - 6V_m = 60 - 6 \times 8 = 12$$

via eq. (1). We therefore conclude that Ni_8 has a cubic structure ($B = 12$) which is a three-connected polyhedron (cf. Chart 4).

(b) Ni_8P_6 as cluster framework, again, from formula,

$$N_{obs} = 8 \times 10(Ni) + 6 \times 5(P) + 6 \times 1(Ph) + 8 \times 2(CO) = 132$$

$$T = N/2 = 132/2 = 66$$

$$B = T - V_n - 6V_m = 66 - 6 - 6 \times 8 = 12$$

via eq. (1). We conclude, in this case, that Ni_8P_6 is a hexa-capped cube ($B = 12$ since capping does not change the B value of the parent polyhedron).

From structure to formula. Given a particular cluster geometry, electron counting allows reasonable predictions to be made concerning the electronic requirements of the cluster. This is highly valuable in the design and synthesis of clusters. It may also be helpful in cases where the exact formulation (e.g. the number of disordered ligands, the interstitial hydrides or the overall charges) is difficult to ascertain.

For example, suppose one wishes to synthesize an octahedral and bicapped tetrahedral cluster of the general formula $[Os_6(CO)_{18}]^{q-}$, what should the charge q be? From Chart 4, an octahedral cluster has a B value of 7, eq. (1) gives

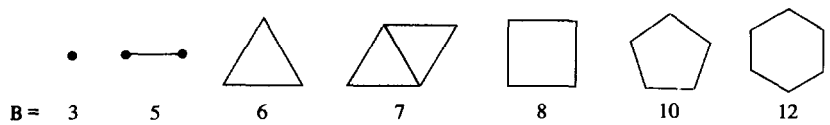

Chart 5. The B values for some 0-, 1- and 2-D cluster systems.

$T = 6V_m + B = 6 \times 6 + 7 = 43$ or $N = 2T = 86$. The overall charge can be calculated as follows: $q = 86 - (6 \times 8 + 18 \times 2) = 2$. So the formula for the octahedral cluster should be $[Os_6(CO)_{18}]^{2-}$. Similarly, for the bicapped tetrahedral cluster, $B = 6$ (since the capping does not change the B value), $T = 6 \times 6 + 6 = 42$, $N = 84$, $q = 84 - (6 \times 8 + 18 \times 2) = 0$, and hence the formula $Os_6(CO)_{18}$. These formulae are indeed observed by Lewis, Johnson and co-workers.[22]

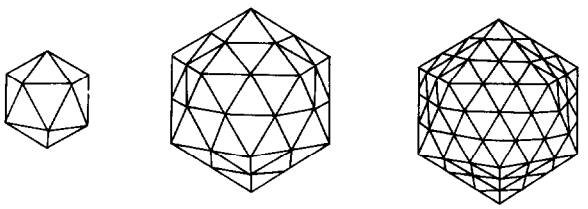

Chart 8. The v_n polyhedral clusters.

COUNTING ELECTRONS AND RATIONALIZING STRUCTURES OF HIGH NUCLEARITY CLUSTERS

As discussed earlier, the *primary* clusters can either be used as building blocks to form cluster of clusters, or, act as nucleation/core for further layer-by-layer (LBL) growth. Here we shall distinguish between two broad categories of highly symmetrical high-nuclearity metal clusters: the s_n supraclusters and the v_n polyhedral clusters.

A s_n supracluster is defined as a cluster of n smaller cluster units fused together via vertex-, edge- or face-sharing.[16] Chart 7 illustrates the early members of supraclusters based on vertex-sharing centred icosahedral cluster units of 13 atoms. Since these supraclusters, s_n, are made up of smaller cluster units, they are also referred to as clusters of clusters (COC).[19] One common characteristic of cluster of clusters is that the interactions of the metal atoms within the cluster units are stronger than those between the units.

A v_n polyhedral cluster[15] is defined as a cluster with $(n+1)$ atoms on each edge of the polyhedron and built by LBL growth on a cluster surface.[5-9] Chart 8 portrays the early members of the v_n icosahedral clusters (Mackay[23] Sequence). The magic numbers, defined as the nuclearity (number of atoms) of a cluster, are given in parentheses. These magic numbers represent structurally stable, often closed-shell, configurations of atoms in a cluster and can be observed experimentally. For example, adiabatic jet expansion of inert gas (e.g. Xe)[24] produces van der Waals' clusters following the sequence of magic numbers: 1, 13, 55, 147, ...

The C^2 *model for cluster of clusters*

According to the C^2 model,[16] for a supracluster which can be regarded as a cluster formed by n polyhedral clusters fused together, the B value is given by the sum of the B_j values (j = 1–n) of the n individual cluster *units* (building blocks) minus the sum of the B_k values (k = 1–s) of the s *shared* vertice(s), edge(s) or face(s). The B values for the commonly observed cluster units and shared moieties can be found in Chart 5. In other words, in order to obtain the overall number of skeletal electron pairs (B) of a supracluster, we simply sum up the skeletal electron pairs (B_j) of the individual cluster units (building blocks) followed by subtracting the overcounting of the skeletal electron pairs (B_k) of the shared vertices, edges or faces. Some interesting examples of vertex-, edge- and face-sharing supraclusters in 2-D, 3-D, or mixed 2-D and 3-D systems can be found in ref. 16. The total number of electron pairs (T) can be calculated from eq. (1) and the total electron counts is given by $N = 2T$.

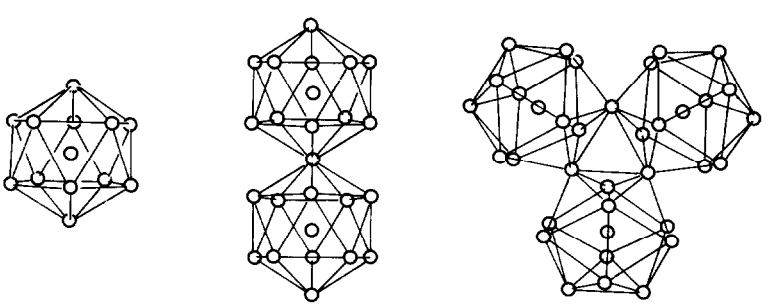

Chart 7. The s_n supraclusters: (a) s_1 (13); (b) s_2 (25); (c) s_3 (36).

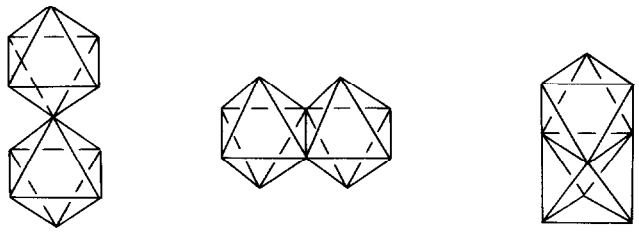


B = 2 x 7 − 3 = 11 2 x 7 − 5 = 9 2 x 7 − 6 = 8

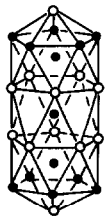
Chart 9. Two octahedra sharing a vertex (left), an edge (middle) and a face (right).

Take, for example, two octahedra sharing a vertex, an edge, or a face as depicted in Chart 9. Since each octahedron (O_h) contributes a B value of 7 [cf. eq. (4)], two octahedra sharing a vertex (Chart 9, left), an edge (middle) and a face (right) will give rise to the predicted B values of $B = 2\times7(O_h)-3(\text{atom}) = 11$, $2\times7(O_h)-5(\text{edge}) = 9$, and $2\times7(O_h)-6(\Delta) = 8$, respectively (cf. Chart 5). The latter two structures are exemplified by clusters $Ru_{10}C_2(CO)_{24}^{2-}$[5f] and $Rh_9(CO)_{19}^{3-}$[25] with $N_{obs} = 10\times8+2\times4+24\times2+2 = 138$ and $9\times9+19\times2+3 = 122$, which agree reasonably well with the predicted electron counts of $N = 2T = 2(6V_m+B) = 2\times(6\times10+9) = 2\times69 = 138$, $2\times(6\times9+8) = 124$, respectively.

For the 25-atom cluster formed by two centred-icosahedra sharing one vertex [cf. Fig. 1 and Chart 7(b)], the C^2 model predicts that $B = 2\times13$ (icosahedron) $-(1\times3)$(sharing one vertex) $= 23$, and the TEC rule [eq. (1)] predicts $T = 6V_m+B = 6\times(25-2)+23 = 161$ skeletal electron pairs or a total valence electron count of $N = 2\times161 = 322$. One known example is the structurally characterized $[(p\text{-Tol}_3P)_{10}Au_{13}Ag_{12}Br_2(\mu\text{-Br})_2(\mu_3\text{-Br})_4]^+$ cluster[26] for which the N_{obs} of $(10\times2+25\times11+2\times1+2\times3+4\times5-1) = 322$ electrons is in accordance with the calculated value. Likewise, three 13-atom centred-icosahedra [Chart 7(c)] sharing three vertices in a cyclic manner result in $B = (3\times13)-(3\times3) = 30$. For such a 36-atom cluster, $T = 6V_m+B = 6\times(36-3)+30 = 228$ and $N = 2\times228 = 456$. This cluster is presently unknown. However, the closely related structurally characterized 38-atom cluster $[(p\text{-Tol}_3P)_{12}Au_{18}Ag_{20}Cl_2(\mu\text{-Cl})_6(\mu_3\text{-Cl})_6]$[19b,27] depicted in Fig. 2, is predicted to have $456+2\times18 = 492$ valence electrons, since the two exopolyhedral Ag atoms do not form metal–metal bonds with the 36-atom polyhedral framework, as is indeed observed: $N_{obs} = 12\times2+38\times11+2\times1+6\times3+6\times5 = 492$. [If six metal–metal bonds (three on each side) are formed between the two exopolyhedral Ag atoms and the 36-atom polyhedral framework, the electron count would reduce to $492-12 = 480$.]

Other highly symmetrical higher members of this series of vertex-sharing centred-icosahedral clusters are shown in Fig. 1 of ref 16(a), in analogy to $B_nH_n^{2-}$ clusters. The electron counting principles based on the C^2 model had also been discussed. We shall discuss here one member of this series, $s_4(46)$, and its capped derivatives.

The superpolyhedron of $s_4(46)$ is a supertetrahedron based on four vertex-sharing centred-icosahedra. The capped derivatives (designated by the asterisk), s_5, s_6*, s_7* and s_8*, correspond to the mono-, bi-, tri- and tetracapped supertetrahedra as shown in Fig. 3. Here each sphere represents a 13-atom centred icosahedron. The corresponding



$Au_{13}Ag_{12}$

Fig. 1. The metal framework of the 25-atom cluster: $[Au_{13}Ag_{12}Br_8(p\text{-Tol}_3P)_{10}]^+$.

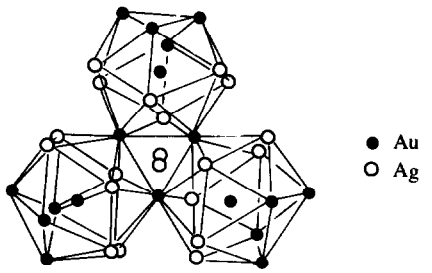


Fig. 2. The metal framework of the 38-atom cluster: $[Au_{18}Ag_{20}Cl_{14}(p\text{-Tol}_3P)_{12}]$.

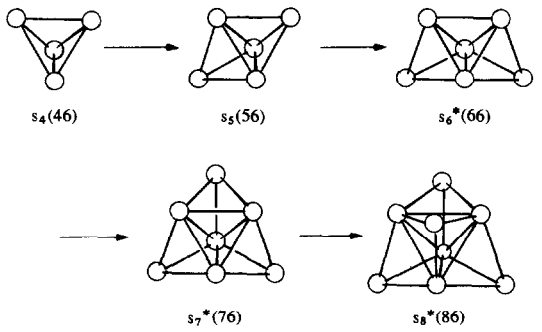

Fig. 3. Successive cappings of the super-tetrahedron to form mono-, bi-, tri- and tetracapped supertetrahedra, corresponding to the vertex-sharing icosahedral supraclusters $s_4(46)$, $s_5(56)$, s_6*(66), s_7*(76), and s_8*(86), respectively. The nuclearities are in parentheses. Here each sphere represents a 13-atom centred icosahedron.

nuclearities are 56, 66, 76 and 86, respectively, which follow the $(10n+6)$ rule. In fact, the general formulae given by us in ref. 16(a) for super-deltahedral supraclusters also apply here. In other words, since each cap of the superpolyhedron implies the addition of one icosahedron to the parent cluster via sharing of three vertices, the C^2 model predicts that the B value should increment by 13(icosahedron) -3×3(sharing three vertices) $= 4$. The general formula for B would still be†

$$B = 4n+18 \qquad (6)$$

for $n \geqslant 3$ [see eq. (8) of ref. 16(a)]. Similarly, since the addition of each icosahedron increases the number of "surface" atoms by 9 [13 − 3(shared vertices) − 1(central atom of icosahedron)] and B by 4, the general formula for T remains as‡

$$T_n = 58n+54 \qquad (7)$$

[see eq. (9) of ref. 16(a)]. The total electron count should be

$$N_n = 2T_n = 116n+108. \qquad (8)$$

We can use eqs (6) and (7) to predict the electron counts for the *stellated* supraclusters s_n*$(10n+6)$, where $N = 4$–8 as depicted in Fig. 3. For example, one possible formulation for $s_5(56)$ may be $(Ph_3P)_{12}M_{56}(\mu\text{-X})_6(\mu_3\text{X})_6$ [$N = 12\times2+56\times11+6\times3+6\times5 = 688$ which agrees with $116\times5+108 = 688$ via eq. (8)] and that for s_6*(66) may be $[(Ph_3P)_{12}M_{66}(\mu\text{-X})_7(\mu_3\text{-X})_6(\mu_4\text{-X})]^{2+}$ [$N = 12\times2+66\times11+7\times3+6\times5+1\times5-2 = 804$ which agrees with $116\times6+108 = 804$ via eq. (8)], where M = Au, Ag; X = Cl, Br.

† Note that $B_{n+1} = B_n + B_{cap} = (4n+18)+4 = 4(n+1)+18$.

‡ Note that $T_{n+1} = T_n + T_{cap} = (58n+54)+(6\times9+4) = 58(n+1)+54$.

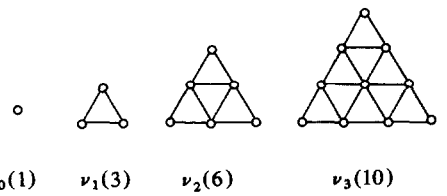

Chart 10. ν_n Triangular clusters of frequency (n) 0, 1, 2 and 3.

The Shell model for ν_n polytopal metal clusters

A ν_n polytopal cluster is a polygonal or a polyhedral cluster in two- or three-dimensions, respectively, as exemplified by ν_n triangles (Chart 10), ν_n tetrahedra (Chart 11), and ν_n octahedra (Chart 12).

Concepts of "peeling onion" and "slicing cheese" for atom counting. In order to understand the packing of spheres (or atoms) in a ν_n polyhedron, Teo and Sloane[15a] introduced the concepts of "peeling an onion" and "slicing a cheese".

"Peeling an onion" refers to the removal of the S_n surface atoms (the "skin") to reveal the I_n interior atoms (the "core") of a ν_n polyhedral cluster. There are, in fact, three classes of ν_n polyhedral clusters. In the *first* class, exemplified by the icosahedron, the cuboctahedron and twinned cuboctahedron, the removal of the surface atoms produces a ν_{n-1} polyhedron of the same shape. In this case the whole "onion" can be built up from layers of the same shape. The *second* class is exemplified by a ν_n octahedron which has the property that removal of the outer shell produces a ν_{n-2}, not a ν_{n-1} octahedron. The "onion" is now composed of layers of the same shape, but the size of the layers decreases by two each time, viz. step size of $s = 2$. Similarly, for a ν_n

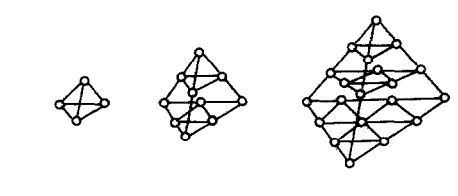

Chart 11. ν_n Tetrahedral clusters of frequency (n) 0, 1, 2 and 3.

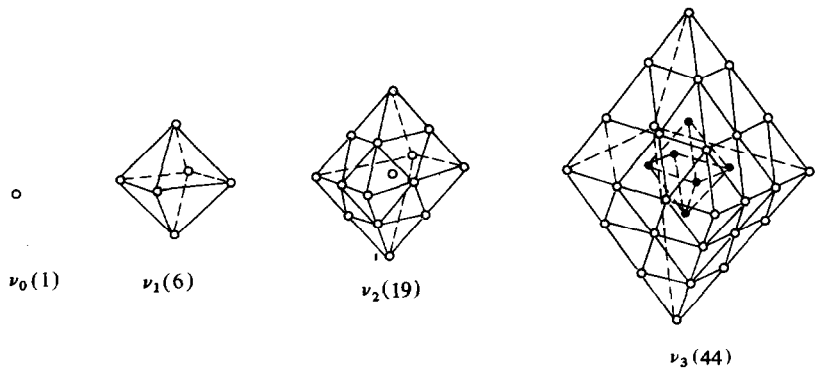

Chart 12. ν_n Octahedral clusters of frequency (n) 0, 1, 2 and 3.

tetrahedron the interior is a ν_{n-4} tetrahedron, in steps (s) of 4. A *third* class comprises those in which the interior polyhedron has a shape different from the original. For example, removing the outer shell from a truncated ν_3 octahedron does not produce a similar polyhedron of a smaller size. The core of a truncated ν_3 octahedron [cf. Chart 13(a)], in fact, is a ν_1 octahedron.

The concept of "slicing a cheese" involves removing the atoms layer by layer, i.e. in planar layers, each layer being parallel to the next, as illustrated in Chart 13 for the truncated ν_3 octahedron along the three-fold [13(b)] and the four-fold [13(c)] symmetry axes. Here we assume close-packing arrangements between adjacent layers of metal atoms. The most common types of close packing are; icosahedral (icp), face-centred cubic (fcc), hexagonal close packing (hcp), cubic, and body-centred cubic (bcc) as we shall discuss in the next section.

Electron counting of close-packed ν_n *polytopal metal clusters.* From eq. (1), a ν_n polytopal (polygonal or polyhedral) metal cluster is required to have a total of T_n topological electron pairs (TEC rule):[14]

$$T_n = 6S_n + B_n, \tag{9}$$

where S_n is the number of "surface" atoms and B_n is the number of *shell electron pairs*.† For a *close-packed* high nuclearity metal cluster, T_n can be rewritten (Shell model)[15a] as

$$T_n = 6G_n + K, \tag{10}$$

where G_n is the total number of atoms (nuclearity) and K is related to the B value of the centre of the cluster. One of two possibilities arises. First, if the cluster is centred at a *primary* cluster such as a triangle, a tetrahedron or an octahedron, $K = B_1$, where B_1 corresponds to the primary cluster (or hole) at the centre. The commonly observed polytopes/holes and the corresponding B_1 values are tabulated in Table 2. Second, if the cluster is centred at an atom, then the $K = B_0$ which depends on the coordination sphere (geometry and symmetry) of the central atom. For example, $K = B_0 = 7$ if the central atom is surrounded by 12 neighbouring atoms in a cuboctahedral arrangement of fcc packing. Note that in this case $T_0 = 6 \times 1 + 7 = 13$ which is exactly equal to the B_1 value of the 13-atom centred cuboctahedral cluster. Other commonly observed coordinations can be found in Table 2. Note the similarities between Table 2 and Charts 4 and 5.

We can now use eq. (10) and the K values listed in Table 2 to predict the electron counts of ν_n polygonal or polyhedral close-packed metal clusters. We shall consider three series: (a) ν_n triangular clusters (Chart 10); (b) ν_n tetrahedral clusters (Chart 11); and (c) ν_n octahedral clusters. The K, B and T values for the first few members of the series are

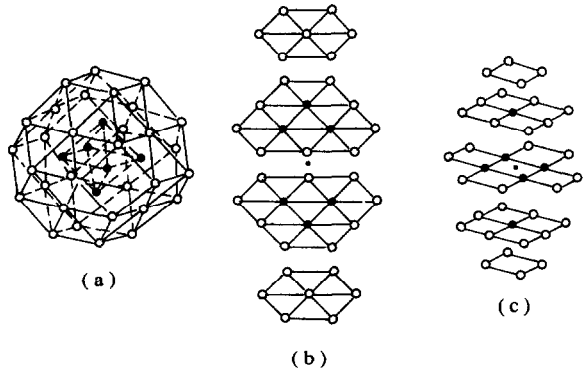

Chart 13. Three views of the truncated ν_3 octahedral cluster: Peeling onion (a); slicing cheese along the three-fold (b) and the four-fold (c) axes.

† As pointed out in ref. 15(a), T_n, B_n and S_n correspond to T, B and V_m, in eq. (1) only for the primary clusters. For large clusters of close-packed metal atoms, this connection is lost.

Table 2. The K, B and T values for various cluster centres[a]

Number	Centre	$K = B_0$ (Atom)	$K = B_1$ (Hole)	T_1
1	Monomer (see below)		3	7
2	Dimer		5	17
3	Trimer		7	25
4	Triangle		6	24
5	Butterfly		7	31
6	Square		8	32
7	Pentagon		10	40
8	Tetrahedron (T_d)		6	30
9	Trigonal bipyramid (tbp)		6	36
10	Octahedron (O_h)		7	43
11	Icosahedron (I_h)	3	9	81
12	Icosahedron (I_h)	7	13	85
13	Bicapped pentagonal prism (bpp)	9	15	87
14	Cuboctahedron (fcc)	7	13	85
15	Twinned cuboctahedron (hcp)	7	13	85
16	Cubic	6	12	60
17	Body-centred cubic (bcc)	6	12	96
18	Rhombic dodecahedron (rdd)	9	15	99

[a] $K = B_0$ or B_1 for metal clusters centred at an atom or a hole, respectively. $T_1 = 6S_1 + B_1$ and $T_0 = 6 \times 1 + B_0$ (since $S_0 = 1$) follow directly from the TEC rule [cf. eq. (9)]. $B_1 = T_0$ for polyhedra 11–18 follows from inclusion principle (see text).

tabulated in Tables 3–5, respectively. General formulae for atom and electron countings are also given in the Tables. Some known clusters are discussed below.

v_n *Triangular metal clusters.* An examination of Chart 10 revealed that a v_n triangle repeats itself in steps of three. In other words, removal of the peripheral atoms of a v_n triangle produces a v_{n-3} triangle. Hence we have the following three situations: (1) for v_0, v_3, v_6, ..., v_{3n} triangles centring at an atom, $K = 7$; (2) for v_1, v_4, v_7, ..., v_{3n+1} triangles centring at a triangle, $K = 6$; and (3) for v_2, v_5, v_8, ..., v_{3n+2} triangles centring at a triangle, $K = 6$. Only the first two structures are known in metal clusters:

(i) The v_1 triangular metal cluster (cf. Chart 10 and Table 2):

Table 3. Electron counting of the v_n triangular metal clusters via the Shell model[a]

	v_0	v_1	v_2	v_3	v_4	v_5	...	v_{10}
S_n	1	3	6	9	12	15		30
I_n	0	0	0	1	3	6		36
G_n	1	3	6	10	15	21		66
K	7	6	6	7	6	6		6
B	7	6	6	13	24	42		222
T	13	24	42	67	96	132		402

[a] The general formulae[15a] are: $S_n = 3n$; $I_n = n^2/2 - 3n/2 + 1$; $G_n = n^2/2 + 3n/2 + 1$; $K = 7$ for v_{3n}; $K = 6$ for v_{3n+1} or v_{3n+2}; $B_n = T_n - 6S_n$ or $B_n = 6I_n + K$; $T_n = 6G_n + K$.

Table 4. Electron counting of the v_n tetrahedral metal clusters via the Shell model[a]

	v_0	v_1	v_2	v_3	v_4	v_5	...	v_{10}
S_n	1	4	10	20	34	52		202
I_n	0	0	0	0	1	4		84
G_n	1	4	10	20	35	56		286
K	7	6	7	6	7	6		7
B	7	6	7	6	13	30		511
T	13	30	67	126	217	342		1723

[a] General formulae[15a] are: $S_n = 2n^2 + 2$; $I_n = (n-1)(n-2)(n-3)/6$; $G_n = (n+1)(n+2)(n+3)/6$; $K = 7$ for v_{4n} (atom) or v_{4n+2} (O_h); $K = 6$ for v_{4n+1} (T_d) or v_{4n+3} (T_d); $B_n = 6I_n + K$; $T_n = 6G_n + K$.

Table 5. Electron counting of the v_n octahedral metal clusters via the Shell model[a]

	v_0	v_1	v_2	v_3	v_4	v_5	...	v_{10}
S_n	1	6	18	38	66	102		402
I_n	0	0	1	6	19	44		489
G_n	1	6	19	44	85	146		891
K	7	7	7	7	7	7		7
B	7	7	13	43	121	271		2941
T	13	43	121	271	517	883		5353

[a] General formulae are: $S_n = 4n^2+2$; $I_n = (n-1)(2n^2-4n+3)/3$; $G_n = (n+1)(2n^2+4n+3)/3$; $K = 7$; $B_n = 6I_n+K$; $T_n = 6G_n+K$.

$K = 6$

$T_1 = 6G_1+K = 6\times3+6 = 24$

$N_1 = 2T_1 = 48$

e.g. $N_{obs} = 3\times8+12\times2 = 48$ in $Os_3(CO)_{12}$.[28]

(ii) The v_2 triangular metal cluster centring at a triangle structure (cf. Chart 10 and Table 2):

$K = 6$

$T_2 = 6G_2+K = 6\times6+6 = 42$

$N_2 = 2T_2 = 84$

e.g. $N_{obs} = 3\times11+3\times8+12\times2+3 = 84$ in $[Cu_3Fe_3(CO)_{12}]^{3-}$.[29]

v_n *Tetrahedral metal clusters.* As mentioned earlier, a v_n tetrahedron repeats itself in steps of four (cf. Chart 11). We have the following four situations: (1) since v_1, v_5, v_9, ... tetrahedra all centre at a tetrahedral hole, $K = 6$; (2) since v_2, v_6, v_{10}, ... tetrahedra all centre at an octahedral hole, $K = 7$; (3) since v_3, v_7, v_{11}, ... tetrahedra all centre at a tetrahedral hole, $K = 6$; (4) since v_4, v_8, v_{12}, ... tetrahedra all centre at an atom, $K = 7$. Only the first two structures are characterized in metal clusters:

(i) The v_1 tetrahedral metal cluster (cf. Chart 11 and Table 2):

$K = 6$

$T_1 = 6G_1+K = 6\times4+6 = 30$

$N_1 = 2T_1 = 60$

e.g. $N_{obs} = 4\times9+12\times2 = 60$ in $Co_4(CO)_{12}$.[30a]

(ii) The v_2 tetrahedral metal cluster centred on an octahedron hole framework (cf. Chart 11 and Table 2):

$K = 7$

$T_2 = 6G_2+K = 6\times10+7 = 67$

$N_2 = 2T_2 = 134$

e.g. $N_{obs} = 10\times8+4+24\times2+2 = 134$ in $[Os_{10}C(CO)_{24}]^{2-}$.[5e]

v_n *Octahedral metal clusters.* As discussed earlier, a v_n octahedron repeats itself in steps of two (cf. Chart 12). For v_0. v_2, v_4, ..., v_{2n} octahedra centring at an atom with a cuboctahedral coordination, $K = 7$ (cf. Table 2). For v_1, v_3, v_5, ..., v_{2n+1} octahedra centring at an atom with octahedral hole, $K = 7$ (cf. Table 2). Hence, $K = 7$ for all v_n octahedral metal clusters. Only the following examples are known:

(i) The v_1 octahedral metal cluster (cf. Chart 12 and Table 2):

$K = 7$

$T_1 = 6G_1+K = 6\times6+7 = 43$

$N_1 = 2T_1 = 86$

e.g. $N_{obs} = 6\times9+16\times2 = 86$ in $Rh_6(CO)_{16}$.[30b]

(ii) The v_3 octahedral metal cluster (cf. Chart 12 and Table 2):

$K = 7$

$T_3 = 6G_3+K = 6\times44+7 = 271$

$N_3 = 2T_3 = 542$

e.g. $N_{obs} = 38\times10+6\times10+48\times2+1+5$

$= 542$ $[Ni_{38}Pt_6(CO)_{48}H]^{5-}$.[6a]

If we now apply the TEC rule [eq. (9)] to the v_3 octahedral metal cluster we just discussed, we obtain $B_3 = T_3-6S_3 = 271-6\times38 = 43$. This turns out to be exactly equal to the T_1 value of the v_1 octahedral metal cluster described previously. Since a v_3 octahedron can completely encapsulate a v_1 octahedron (cf. Chart 12), this electron counting characteristic (viz. $B_3 = T_1$) signifies a sort of *inclusion principle* which deserves further comments in the next section.

The electron counting results, via the Shell model, of other representative examples of close-packed metal clusters are tabulated in Table 6.

Inclusion principle. A natural consequence of the Shell model in the electron counting of high nuclearity close-packed metal clusters is the *inclusion principle.* This follows directly from the "peeling onion" concept (atom counting) we described in a previous section. As is evident from Charts 10–13 and Tables 3–5, for close-packed v_n polygonal or polyhedral

Table 6. Electron counting of close-packed metal clusters via the Shell model

[c] The total number of atoms.
[d] From Table 2.
[e] $T = 6G+K$.
[f] $N_{Shell} = 2T$.

metal clusters, $B_n = T_{n-s}$. For example, for v_n octahedral metal clusters, $T_0 = B_2$, $T_1 = B_3$, $T_2 = B_4$, ..., $B_n = T_{n-2}$ (Table 5). In other words, the number of shell electron pairs of a v_n polytopal cluster is exactly equal to the number of topological electron pairs of a (smaller) polytopal v_{n-s} cluster. This is actually not too surprising because in previous sections we have shown that the clusters can be built up in step size of s. In other words, a v_{n-s} polyhedral can be completely encapsulated within a v_n polyhedral cluster of the same shape (the "onion" concept). In fact, we can generalize this principle by combining eqs (9) and (10) to give

$$B_n = 6I_n + K, \tag{11}$$

since $G_n = S_n + I_n$, where I_n is the number of "interior" atoms. Now if there is a smaller cluster (denoted by n') containing $G_{n'} = I_n$ atoms, we have [via eq. (10)]

$$B_n = 6G_{n'} + K = T_{n'}. \tag{12}$$

Again, using the v_3 octahedron ($n = 3$) as an example, we have a total of $G_3 = 44$ atoms, of which $S_3 = 38$ are surface atoms and $I_3 = 6$ are interior atoms (cf. Chart 12). The latter constitutes a v_1 octahedron ($n' = 1$) with $G_1 = I_3 = 6$. Equation (12) therefore predicts that $B_3 = T_1$. In other words, in order for a cluster (denoted by n) to completely encapsulate a smaller cluster (denoted by n'), $B_n = T_{n'}$. This is the essence of the *inclusion principle*. (Incomplete encapsulation can occur if $T_{n'} > B_{n'}$.) For example, a v_3 octahedron and truncated v_3 octahedron both have $B = 43$ shell electron pairs, which satisfy the $T = 43$ total electron pairs of a v_1 octahedron. Indeed, both $[Ni_{38}Pt_6(CO)_{48}H]^{5-}$ [6a] and $[Pt_{38}(CO)_{44}]^{2-}$ [5a] (Chart 13) contain a completely encapsulated Pt_6 octahedron. The electron counting procedures for these two clusters, highlighting the inclusion principle, are given in Chart 14.

In fact, this inclusion principle holds for any *close-packed metal cluster* with encapsulants which may be an atom, a primary cluster, or a smaller close-packed cluster. Some representative examples are listed in Table 7. The inclusion principle, in combination with the TEC rule, allows electron counting of these high nuclearity metal clusters without the assignment of the "degrees of radial vs tangential bonding contributions".[31]

For example, the cluster $[Pt_{19}(CO)_{22}]^{4-}$ (**1**)[3] has a dimer as its core. Applying the Shell model [eq. (10)], we obtain $T = 6G+K = 6\times 19+5 = 119$, since $K = 5$ for a dimer (cf. Chart 5 or Table 2). The predicted electron count of $N = 2T = 2\times 119 = 238$ agrees with the observed value of $N_{obs} = 19\times 10+22\times 2+4 = 238$. On the other hand, the inclusion principle is also operative in cluster **1**. Here the TEC rule gives $B = 5$ (Chart 5) and

(a) $[Ni_{38}Pt_6(CO)_{48}H_{6-n}]^{n-}$

For the v_1 octahedral core:

$B_1 = 7$ (v_1 O_h core)

$T_1 = 6S_1 + B_1 = 6\times6+7 = 43.$ (TEC on v_1 O_h core)

For the v_3 octahedron:

$B_3 = T_1$ (inclusion principle)

$T_3 = 6S_3 + B_3 = 6\times(44-6)+43 = 271$ (TEC on v_3 O_h)

$N = 2T = 542$

$N_{obs} = 38\times10+6\times10+48\times2+6 = 542.$

(b) $[Pt_{38}(CO)_{44}]^{2-}$

For the v_1 octahedral core:

$B_1 = 7$ (v_1 O_h core)

$T_1 = 6S_1 + B_1 = 6\times6+7 = 43.$ (TEC on v_1 O_h core)

For the truncated v_3 octahedron:

$B_3 = T_1$ (inclusion principle)

$T_3 = 6S_3 + B_3 = 6\times(38-6)+43 = 235$ (TEC on truncated v_3 O_h)

$N = 2T = 470$

$N_{obs} = 38\times10+44\times2+2 = 470.$

Chart 14. Inclusion principle for clusters $[Ni_{38}Pt_6(CO)_{48}H_{6-n}]^{n-}$ and $[Pt_{38}(CO)_{44}]^{2-}$.

$T_i = 6\times S_i + B_i = 6\times2+5 = 17$ for the encapsulated dimer (designed by the subscript i). The inclusion principle then predicts $B = T_i = 17$ and $T = 6S+B = 6\times(19-2)+17 = 6\times17+17 = 119$ or $N = 238$.

Other close-packed metal clusters listed in Table 6 can likewise be treated; the results are tabulated in Table 7.

A detailed examination of Tables 6 and 7 shows that the Shell model and the inclusion principle, in combination with the TEC rule, give essentially the same results, as expected from the earlier discussions. However, for a very large metal cluster, it is more convenient to apply the *one-step* Shell model [cf. eq. (10)] than to invoke the *multi-step* inclusion principle [eq. (12)]. For example, a v_5 octahedral metal cluster is predicted to have $T_5 = 6G_5+K = 6\times146+7 = 883$ by the Shell model [eq. (10)]. The same result can also be obtained by applying the inclusion principle successively to v_5, v_3, v_1 octahedral clusters (via the "peeling onion" concept) as follows (cf. Table 5)

Table 7. Electron counting of close-packed metal clusters via the inclusion principle and extended Hume–Rothery rule

Hume–Rothery rule—the bulk connection

A simple electron counting rule based on the extended Hume–Rothery rule has been suggested in ref. 17 for correlating and/or predicting the metal packing arrangements in high nuclearity metal clusters. For a metal cluster with m_b "*bulk*" atoms and m_s "*surface*" atoms (the nuclearity is $m = m_b+m_s$), the total number of electrons N (including valence electrons from the metals and electrons donated by the ligands) is given by $N = m_bn_b+m_sn_s = (m_b+rm_s)n_b$, where n_b and n_s are the numbers of electrons per bulk and surface atoms, respectively, and $r = n_s/n_b$, which is basically an empirical constant given by $18/16 = 1.125$. Including the d electrons, the n_b values for the commonly observed close-packed structures are: 11.17 for pentagonal close-packing; 11.24 for fcc; 11.50 for bcc; 11.62 for γ-phase; and 11.75 for hcp.† The electron counts predicted by the extended Hume–Rothery rule are also given in Table 7. They compare favourably with the observed values.

It is striking to find that the electronic requirements predicted by the Hume–Rothery rule or band structure theory for bulk metals or metallic alloys, which are characterized by long-range order, can be extended to discrete metal clusters where only short-range order is important. Nevertheless, the electron counting rule proposed here is consistent with the recent theoretical results that the density of states of a metal cluster rapidly converges to that of the bulk metal even at the aggregation of 13 (fcc) to 15 (bcc) atoms.[33] As the cluster size increases, this approximation should improve. This is, in essence, the *bulk connection* of large metal clusters.

† The Hume–Rothery rule (see ref. 32) states that certain alloy structures occur at a definite electron/atom ratio (viz., sum of valence electrons/sum of ionic atoms). For example, the β (body-centred cubic, bcc), γ (complicated cubic structure) and ε (hexagonal close packed, hcp) phases inevitably occur at ratios 21/14, 21/13 and 21/12, as exemplified by CuZn, Cu_5Zn_8 and $CuZn_3$, respectively. Also observed is the α (face-centred cubic, fcc) phase of Cu_3Zn at the ratio of 5/4. If we include d shell electrons, the number of valence electrons per bulk atom can be approximated by $n = 10+21/18 = 11.17$ for pentagonal; $10+21/17 = 11.24$ for fcc; $10+21/14 = 11.50$ for bcc; $10+21/13 = 11.62$ for γ phase; and $10+21/12 = 11.75$ for hcp structures.

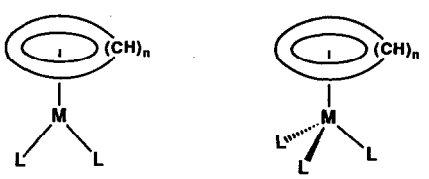
Abstract—The stability of 18-electron two-legged piano-stool complexes of the type (η^n-C_nH_n)ML_2 (n = 4, 5 or 6; L = CO or NO; M = first-row transition metal) is correlated to the energetic separation of the HOMO from both the LUMO and the SHOMO (second-highest occupied molecular orbital) of the complexes calculated by using the Fenske–Hall molecular orbital method. Complex stability is observed to increase with increasing HOMO/LUMO and decreasing HOMO/SHOMO separations. This correlation is reflected in an examination of known stable complexes and unsuccessful synthetic attempts at others. On the basis of these findings, predictions are made as to the stability of a number of unknown 18-electron two-legged piano-stool complexes for which syntheses have not yet been attempted.

The synthesis of 18e two-legged piano-stool organometallic complexes containing carbonyl and/or nitrosyl ligands (**1**) appears to have lagged behind that of their three-legged analogues (**2**); in contrast to the dozens of known three-legged species, only a



1 2

very limited number of two-legged complexes have been isolated. We believe that the relative dearth of compounds **1** likely results from electronic differences between the coordination environments **1** and **2**. In the course of our earlier investigations of the comparative orbital energetics of two- and three-legged piano-stool complexes resulting from deprotonation of three- and four-legged piano-stool hydride species, we observed that the HOMO of 18e two-legged piano-stools is metal-localized and non-bonding, whereas the HOMO in three-legged complexes is involved in extensive metal-to-ligand π-backbonding.[1,2] Furthermore, the stability of the two-legged piano-stool complexes was noted to depend upon two energetic differences, viz. the HOMO/LUMO separation (HOMO = highest occupied molecular orbital; LUMO = lowest unoccupied molecular orbital) and the HOMO/SHOMO separation (SHOMO = second-highest occupied molecular orbital).

In this paper we report the use of these two orbital energetic quantities as a means of predicting the stability of various systems **1**. It will be demonstrated that, kinetic arguments notwithstanding, the isolability of two-legged piano-stool complexes is highly dependent on the *relative* orbital energies, even for an isoelectronic series. Inasmuch as all the compounds studied obey the effective atomic number rule, we propose that there are electronic

† Author to whom correspondence should be addressed.

constraints beyond the 18e rule that govern the successful synthesis of these systems. Finally, we will use these arguments to predict some new complexes that should be electronically stable.

COMPUTATIONAL SECTION

Molecular orbital calculations were carried out on an Amdahl 470/V8 computer system or an IBM 3081D computer system using the Fenske–Hall approximate MO method.[3]

In all of the calculations, the cyclobutadiene, cyclopentadienyl and benzene rings are assumed to have local D_{4h}, D_{5h} and D_{6h} symmetry with C—C bond lengths of 1.46, 1.38 and 1.42 Å, respectively. All C—H bond lengths were chosen to be 1.08 Å. The geometry assumed for all of the $(\eta^n\text{-}C_nH_n)ML_2$ piano-stool complexes has the ML_2 plane orthogonal to the plane of the C_nH_n ring, with the L—M—L angle equal to 90°; this geometry is adopted by the structurally characterized species $(\eta^5\text{-}C_5Me_5)Co(CO)_2$,[4] $(\eta^5\text{-}C_5Me_5)Rh(CO)_2$[5] and $[(\eta^5\text{-}C_5H_5)Fe(CO)_2][Bu_4N]$,[6] and our previous calculations indicate that it is the optimum geometry for two-legged piano-stool complexes.[1] All C—O and N—O bond lengths were set equal to 1.13 Å, and the assumed metal–ligand distances are listed in Table 1.

The atomic orbital basis was generated by a least-squares fit of Slater-type orbitals to the atomic orbitals from neutral (C, N, O) or +1 (transition metal atoms) Herman–Skillman atomic calculations.[7] Contracted double-ζ minimal basis representations were used for the metal 3*d* AOs and for the C, N and O 2*p* AOs; single-ζ representations were used for the remainder of the AOs. The 4*s* exponent was fixed at 2.0 for Cr, Mn, Fe and Co, with the 4*p* exponents for these being set to 1.6, 1.8, 2.0 and 2.2, respectively. The 4*s* and 4*p* exponents for Ni were both fixed at 2.2. An exponent of 1.16 was used for the H 1*s* AO.[8] In all calculations, the 3σ and the 6σ MOs of CO and NO, and the first three occupied and all virtual orbitals above the LUMO of the C_nH_n ligands, were deleted from the basis transformation set.[9]

Table 1. Bond lengths used in the $(\eta^n\text{-}C_nH_n)ML_2$ calculations

M—L bond lengths (Å)		Metal-to-ring[a] centroid distance (Å)	
Cr—C	1.90	Cr—Cp	1.85
Cr—N	1.72	Cr—Bz	1.65
Mn—C	1.72	Mn—Cp	1.80
Mn—N	1.72	Mn—Bz	1.65
Fe—C	1.76	Fe—Cb	1.79
Fe—N	1.76	Fe—Cp	1.72
		Fe—Bz	1.54
Co—C	1.73	Co—Cp	1.70
Co—N	1.73	Co—Bz	1.53
Ni—C	1.80	Ni—Cb	1.75
		Ni—Cp	1.74

[a] Cb denotes $\eta^4\text{-}C_4H_4$; Cp denotes $\eta^5\text{-}C_5H_5$; Bz denotes $\eta^6\text{-}C_6H_6$.

RESULTS AND DISCUSSION

The molecular orbitals of the ML_2 fragment and (polyene)ML_2 complexes have been discussed previously by several authors.[10] We will briefly reiterate these so that the effects of changing ML_2 fragments upon the electronic structure of two-legged piano-stool molecules will be more apparent.

The frontier orbitals of a typical C_{2v} d^8 ML_2 fragment, $Co(CO)_2^+$, are shown in Fig. 1. The results are very similar to those of Lichtenberger, *et al.*[10a] We consider the ML_2 fragment to lie in the *xy* plane. At lowest energy, we find an orbital of a_1 symmetry, which can roughly be described as a $d_{x^2-y^2}$ orbital on the metal that is stabilized by interaction with the in-plane π^* orbitals of the ligands L. At slightly higher energy are orbitals of b_1 and a_2 symmetries, corresponding to the metal d_{yz} and d_{xz} orbitals, respectively. Each of these can be stabilized by donation to the out-of-plane L π^* orbitals. The HOMO of the fragment is another orbital of a_1 symmetry, which is best described as a d_{z^2} orbital on M. This orbital is non-bonding with respect to the ligands L and is essentially localized on the metal atom, a fact that has been used by us to explain the seemingly anomalous differences in carbonyl stretching frequencies in 16- and 18e $CpM(CO)_2$ complexes.[11] The LUMO of the frag-

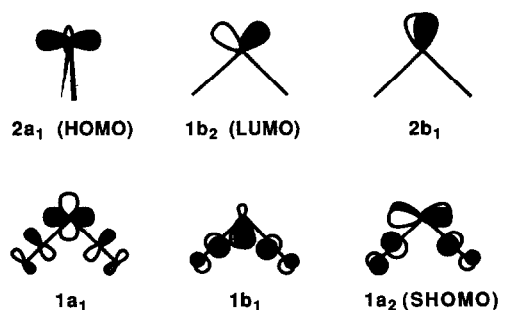

Fig. 1. Metal-based frontier orbitals of a d^8 ML_2 fragment.

ment is an orbital of b_2 symmetry corresponding to the M d_{xy} orbital. This orbital is at higher energy as it is the antibonding counterpart of one of the M—L σ bonding orbitals.

The interaction of a Cp^- ligand with the d^8 ML_2 fragment is shown in Fig. 2. The important frontier orbitals of the Cp ligand to consider are the doubly-degenerate, occupied e_1'' orbitals; the occupied a_2'' and unoccupied e_2'' are too low and too high in energy, respectively, to perturb the ML_2 orbitals significantly. The two e_1'' orbitals are of appropriate symmetry to interact with the ML_2 b_1 and b_2 orbitals. For a d^8 ML_2 fragment, the b_2 frontier orbital is empty and hence the corresponding Cp e_1'' orbital is stabilized while the LUMO is raised in energy. The other e_1'' interacts with the filled orbital of b_1 symmetry on the ML_2 fragment. This "filled–filled" interaction results in two occupied orbitals of b_1 symmetry, the lower one bonding and the higher one antibonding between the ML_2 fragment and the Cp ring. In the case of $CpCo(CO)_2$, the higher of these two is pushed above the non-bonding a_1 orbital and becomes the HOMO of the complex, an ordering that has been determined unequivocally from photoelectron spectroscopic studies.[10a]

The energies of the $1a_1$, $1b_1$, $1a_2$ and $1b_2$ orbitals of the ML_2 fragment are substantially dependent on both the nature of M and the relative energies of the interacting orbitals on M and L. The $2a_1$ orbital, by comparison, is non-bonding with respect to L and will be comparatively unaffected by the choice of L. The right-side of Fig. 2 shows the effect of replacing the $Co(CO)_2^+$ fragment with the isoelectronic $Mn(NO)_2^+$ fragment. In making this change, M has become more electropositive and L has become a stronger π-acid. The $1a_1$, $1a_2$ and $1b_1$ orbitals of $Mn(NO)_2^+$ are at nearly the same energy as those of $Co(CO)_2^+$. This is a result of the compromise between the higher energy 3*d* orbitals of the manganese compared to cobalt and the greater stabilization conferred by the nitrosyl ligands as compared to the carbonyl ligands. However, because the $2a_1$ orbital of $Mn(NO)_2^+$ is not affected by the change in L, it is significantly higher in energy than that of $Co(CO)_2^+$.

As can be seen in Fig. 2, the influence of these changes on the electronic structure of the resulting $CpML_2$ molecule is quite profound. The energetic separation of the $2a_1$ and $1b_1$ orbitals of $Mn(NO)_2^+$ is now great enough that the former comprises the HOMO of $CpMn(NO)_2$, and the HOMO is at a higher energy than the HOMO in $CpCo(CO)_2$. In addition, because NO^+ is a weaker σ donor than CO, the $1b_2$ orbital of $Mn(NO)_2^+$ is less polarized toward the Cp ligand than that of $Co(CO)_2^+$; hence the antibonding b_2 interaction is weaker in $CpMn(NO)_2$ than in $CpCo(CO)_2$. This results in a lower-lying LUMO in $CpMn(NO)_2$ than in $CpCo(CO)_2$. The combination of these two effects leads to a much smaller HOMO/LUMO gap in $CpMn(NO)_2$ than in $CpCo(CO)_2$. It is also noted that the HOMO is energetically quite separated from the SHOMO in $CpMn(NO)_2$, whereas the HOMO and SHOMO are nearly degenerate in $CpCo(CO)_2$. We believe that the small HOMO/

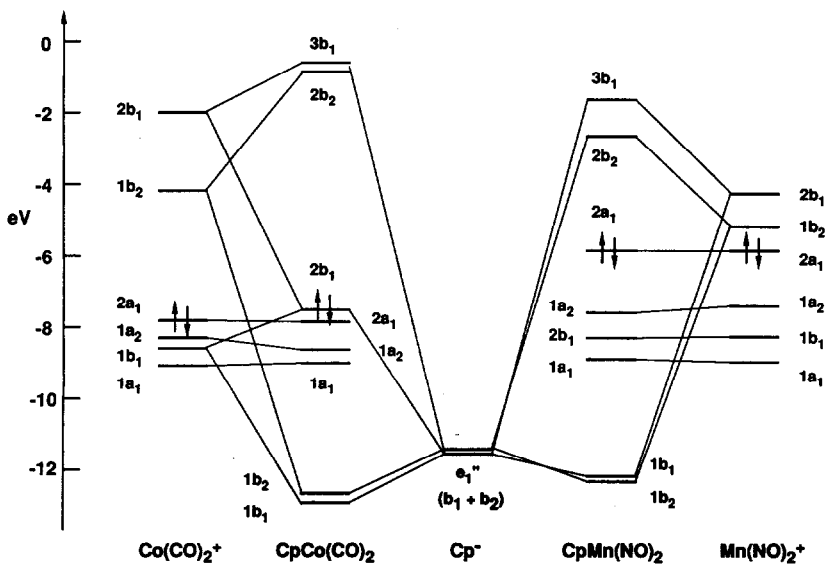

Fig. 2. Molecular orbital interaction diagram comparing the orbitals of $CpCo(CO)_2$ and $CpMn(NO)_2$.

LUMO and large HOMO/SHOMO gap in $CpMn(NO)_2$ contribute to its electronic instability relative to $CpCo(CO)_2$, as will be discussed below.

The effect on the molecular orbitals of changing the ligand L in $CpML_2$ is evident in Table 2, in which the Mulliken per cent characters of the valence orbitals of $CpCo(CO)_2$ and $CpMn(NO)_2$ are compared. It is seen that the stronger π-acidity of nitrosyl relative to carbonyl manifests itself in greater π^* L contributions in the $1a_1$, $2b_1$ and $1a_2$ orbitals of $CpMn(NO)_2$ than in $CpCo(CO)_2$. It is also seen that the character of the $2a_1$ MO is virtually invariant to the changes in M and L.

On comparing $CpCo(CO)_2$ and $CpMn(CO)_2$, we can see several trends that govern the comparative orbital energetics of these isoelectronic d^8 two-legged piano-stool complexes. First, a more electropositive metal atom (i.e. earlier or in a lower formal oxidation state) will lead to an overall rise in the energies of the metal-based MOs. Second, as the π-accepting ability of the ligand L increases, the stabilization of the $1a_1$, $1b_1$ and $1a_2$ orbitals of the ML_2 fragment increases. By contrast, the nonbonding $2a_1$ orbital of ML_2 is unaffected by the π-acidity of the ligand. Third, as the σ-donating ability of L decreases, the HOMO/LUMO separation in the ML_2 fragment decreases, and the $1b_2$ LUMO of ML_2 becomes less polarized toward the cyclic hydrocarbon "bench" of the piano stool. Because the relative π-acidity and σ-basicity of isoelectronic ligands are usually inversely related (as they are for CO and NO^+), the HOMO/LUMO separation in the ML_2 fragments generally will decrease and the HOMO/SHOMO separation will increase as the ligand becomes a stronger π-acid. Finally, we note that the HOMO/LUMO separation in the $CpML_2$ complexes is proportional to the HOMO/LUMO separation in the ML_2 fragments; the Cp cap serves to "amplify" the HOMO/LUMO gap in the fragment.

What influence will the HOMO/LUMO and HOMO/SHOMO separations have on the stability of the two-legged piano-stool complexes? A difficult aspect of any such discussion is to define what is meant by *stable*, and whether this stability is thermodynamic or kinetic. Inasmuch as we are interested in addressing the synthesis of the complexes by standard synthetic organometallic methods, we must consider the means by which such complexes demonstrate their instability. As we will see, most failed attempts to synthesize two-legged piano-stool complexes lead to (a) coordination of a third leg to

[a] Highest occupied molecular orbital (HOMO).

the piano stool, (b) oxidation of the metal atom, (c) both increased coordination and oxidation, or (d) ill-defined products. The ease with which an additional ligand can be coordinated depends in some way on the σ-acidity of the complex, i.e. the energy of its LUMO in a molecular orbital picture. Likewise, the ease of oxidation of a complex depends on the energy of its HOMO. These are, of course, not new notions. As a complement to Mulliken electronegativities,[12] Pearson has recently advanced the concept of "formal hardness", a parameter that, in an orbital picture, is equal to one-half the HOMO/LUMO separation.[13] Pearson ties his definition to the long-accepted but poorly-understood correlation between HOMO/LUMO separation and molecular stability: "There seems to be a rule of nature that molecules arrange themselves so as to be as hard as possible. A large HOMO/LUMO gap increases stability".[14]

With regard to the HOMO/SHOMO gap, we believe this to be tied to the ease with which the two-electron oxidation of a two-legged piano stool can be accomplished. Within the constraints of Koopmans' theorem,[15] the HOMO/SHOMO gap of an 18e $(\eta^n\text{-}C_nH_n)ML_2$ complex will be related to the HOMO/LUMO gap of the 16e doubly-oxidized complex $(\eta^n\text{-}C_nH_n)ML_2^{2+}$. Because the two electrons in the HOMO of most two-legged piano stools are non-bonding, their removal should not significantly perturb the metal–ligand bonding. Thus, the HOMO/SHOMO gap could be related to the stability of a hypothetical electronically-unsaturated decomposition product, which presumably could react further to form an 18e three-legged piano stool. While the above rationalization may strike the reader as specious, the main reason for including the HOMO/SHOMO gap is a pragmatic one: the correlation between stability and orbital energetics that we will describe shortly does not exist unless we include the HOMO/SHOMO separation.

The HOMO/LUMO separation, ΔE^{HL}, and HOMO/SHOMO separation, ΔE^{HS}, for the two-legged piano-stool complexes are defined in Fig. 3.* If the relative stability of a complex depends on both ΔE^{HL} and ΔE^{HS}, it is convenient to define a single energetic quantity that incorporates both of these energetic differences. The simplest means of combining these in proper functional relationship is to define a new quantity, $\Delta\Delta E$, as

$$\Delta\Delta E = \Delta E^{HL} - \Delta E^{HS}.$$

It is seen that a complex with a large ΔE^{HL} and a small ΔE^{HS} will lead to a large positive value for $\Delta\Delta E$, whereas a small ΔE^{HL} and a large ΔE^{HS} can lead to a negative value for $\Delta\Delta E$. It is proposed, therefore, that electronic stability should increase as $\Delta\Delta E$ increases.

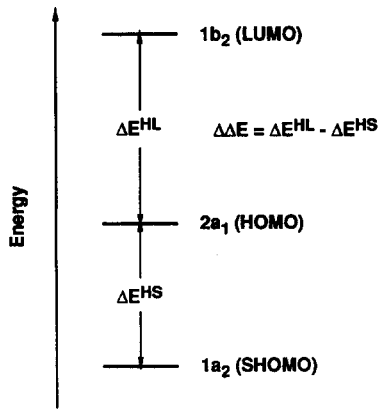

Fig. 3. Definitions of the HOMO/LUMO separation, ΔE^{HL}, the HOMO/SHOMO separation, ΔE^{HS}, and $\Delta\Delta E$ for most d^8 two-legged piano-stool complexes.

Fenske–Hall molecular orbital calculations have been used to calculate $\Delta\Delta E$ for a variety of known and unknown $(\eta^n\text{-}C_nH_n)ML_2$ complexes. Qualitatively, the orbital energetics of all such d^8 complexes with $n = 5$ or 6 are described by the bonding schemes discussed above for $CpCo(CO)_2$ and $CpMn(NO)_2$. However, as we have seen for these two isoelectronic Cp derivatives, there are quantitative differences in the compositions of the frontier orbitals, and hence in ΔE^{HL} and ΔE^{HS}, and, ultimately, in the value of $\Delta\Delta E$. In Table 3, we report the $\Delta\Delta E$ values for a large number of 18e $(\eta^n\text{-}C_nH_n)ML_2$ piano-stools. In the discussion to follow, we will examine the correlation of experimentally observed stability with $\Delta\Delta E$ values. To understand better the electronic effects influencing the stability of two-legged piano-stool systems, we examine both the isolability of known compounds as well as the results of reactions that might be expected to lead to as yet unknown derivatives.

Dicarbonyl complexes

Given the number of such compounds that are known, the dicarbonyl derivatives appear to be the

* In most d^8 two-legged piano stools, the non-bonding $2a_1$ orbital is the HOMO of the complex, as shown in Fig. 3. In rare instances, such as $CpCo(CO)_2$ (Fig. 2), the $2a_1$ orbital is the SHOMO of the complex. While in principle this would change the significance of ΔE^{HL} and ΔE^{HS}, in practice the HOMO and SHOMO of such systems are very close in energy,[10a] and the conclusions drawn here will be unaffected.

Table 3. ΔE^{HL}, ΔE^{HS} and $\Delta\Delta E$ values and predicted stabilities of some known and unknown $(\eta^n\text{-}C_nH_n)ML_2$ complexes

Complex	ΔE^{HL} (eV)	ΔE^{HS} (eV)	$\Delta\Delta E$ (eV)	Predicted stability[a]	Reference

[a] Predicted stabilities are from the criteria discussed in the text.

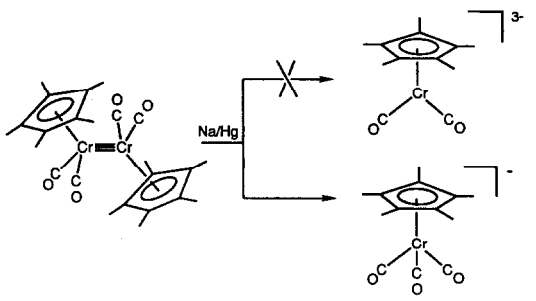
most stable $(\eta^n\text{-}C_nH_n)ML_2$ piano-stool complexes. This is also the conclusion reached by examination of the calculated $\Delta\Delta E$ values in Table 3. Three complexes in the table, $CpFe(CO)_2^-$, $CpCo(CO)_2$ and $(\eta^6\text{-}C_6Me_6)Fe(CO)_2$[16] (modelled with an unsubstituted benzene ring) are among the small group of known two-legged piano-stool complexes. All three are considered quite stable and reasonably straightforward to synthesize. These complexes all have large $\Delta\Delta E$ values, greater than 4 eV, resulting from large HOMO/LUMO gaps and small HOMO/SHOMO gaps.

The synthesis of other two-legged piano-stool complexes has not been as simple as for those above. For example, consider $CpMn(CO)_2^{2-}$, which is isoelectronic to $CpCo(CO)_2$ and $CpFe(CO)_2^-$. Ellis *et al.* attempted the synthesis of this dianion[17] by a reductive route similar to the one Fischer used to prepare $CpV(CO)_3^{2-}$ from $CpV(CO)_4$.[18] Quite unexpectedly, sodium reduction of $CpMn(CO)_3$ led to the formation of the trianion $Mn(CO)_4^{3-}$, which is isoelectronic to $Ni(CO)_4$. Similarly, the attempted synthesis of $CpRe(CO)_2^{2-}$ by the double deprotonation of $CpRe(CO)_2H_2$ was unsuccessful; the parent dihydride could only be singly deprotonated, yielding the three-legged piano-stool hydride anion, $CpRe(CO)_2H^-$.[19] Leong and Cooper have recently synthesized $CpMn(CO)_2^{2-}$ via the sodium naphthalenide reduction of $CpMn(CO)_2(py)$,[20] a synthetic route that is arguably less obvious than the previous ones attempted.

In addition to $CpMn(CO)_2^{2-}$, there are many other $(\eta^n\text{-}C_nH_n)M(CO)_2$ complexes that have been reported as having marginal stability; for some of these, only partial characterization has been obtained. These include $BzCr(CO)_2^{2-}$ $(Bz = \eta^6\text{-}C_6H_6)$,[21] $BzMn(CO)_2^-$,[22] and $Bz^*Mn(CO)_2^-$ $(Bz^* = \eta^6\text{-}C_6Me_6)$,[23] all of which have $\Delta\Delta E$ values between 2.5 and 4 eV. While these complexes can be generated in synthetically useful quantities, they are generally harder to make, far more reactive, and less stable than the cobalt and iron complexes. We believe this inherent reactivity is reflected in the smaller values of $\Delta\Delta E$ relative to the more stable complexes such as $CpCo(CO)_2$.

The trianion $CpCr(CO)_2^{3-}$, while isoelectronic

with $CpCo(CO)_2$, is as yet unknown. MO calculations on this trianion give a $\Delta\Delta E$ value of 1.39 eV. We believe this small value is indicative of an inherent electronic instability and will prevent even detection of such a species. As shown below, the synthesis of $Cp^*Cr(CO)_2^{3-}$ ($Cp^* = \eta^5$-C_5Me_5) has been attempted by Na/Hg reduction of the Cr—Cr triply-bonded dimer $[Cp^*Cr(CO)_2]_2$:[24]

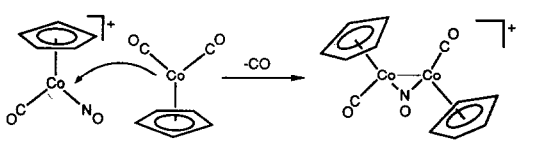


(1)

This reaction might have been expected to proceed in an analogous fashion to the facile reductive cleavage of $[CpCr(CO)_3]_2$ to $CpCr(CO)_3^-$.[25] Rather, $[Cp^*Cr(CO)_2]_2$ undergoes reductive disproportionation to yield the d^6 three-legged piano-stool anion $CpCr(CO)_3^-$, a remarkable example of the desire of the chromium atom to avoid a two-legged, d^8 configuration. The d^6 three-legged piano-stool $CpCr(CO)_3^-$ complex enjoys stabilized filled orbitals very similar to those of d^6 octahedral complexes, whereas the d^8 two-legged piano-stool trianion is burdened with a destabilized HOMO.

Mononitrosylmonocarbonyl complexes

To our knowledge, the only reasonably well-characterized examples of a $(\eta^n$-$C_nH_n)M(CO)(NO)$ derivative are $CpCo(CO)(NO)^+$ and $(\eta^5$-$C_5Me_5)Co(CO)(NO)^+$, isolated as PF_6^- salts in 33 and 80% yields, respectively, from the reaction of the dicarbonyl with $[NO][PF_6]$.[26] Care must be taken to add the dicarbonyl slowly to a well-stirred $[NO][PF_6]$ suspension as the dicarbonyl can add in a nucleophilic fashion to the carbonylnitrosyl product (possibly through a bent NO) to give the μ-NO dicarbonyl dimer:



(2)

It should be noted that although these $(\eta^5$-$C_5R_5)Co(CO)(NO)^+$ derivatives are described as reactive and highly air- and water-sensitive, they were prepared and isolated at room temperature. Our MO calculations indicate that $CpCo(CO)(NO)^+$ has a $\Delta\Delta E$ value of 5.01 eV. On the basis of this high value we would predict this complex to be electronically stable. This is in agreement with the experimental results as the reactivity described can probably be attributed to low kinetic barriers for nucleophilic reaction.

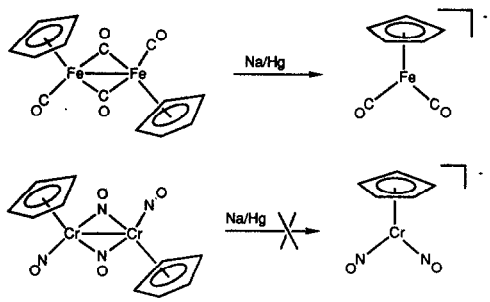
The synthesis of CpFe(NO)(CO) has been attempted with indeterminate success.[27] We note that the $\Delta\Delta E$ value of this complex is smaller than that of the cobalt cation, but is larger than some other $(\eta^n$-$C_nH_n)ML_2$ species that have been detected. Other mononitrosyl complexes with considerably smaller $\Delta\Delta E$ values have not yet been isolated, even though reactions have been attempted that could reasonably be expected to lead to their synthesis. For example, the attempted synthesis of $CpMn(CO)(NO)^-$ via Na/Hg reduction of $[CpMn(CO)(NO)]_2$ leads to intractable products;[28] likewise, a study of the electrochemistry of $[CpMn(CO)(NO)]_2$ indicates a very complicated series of reduction steps.[29] Synthesis of the third-row analogue, $CpRe(CO)(NO)^-$, has been attempted by the treatment of CpRe(CO)(NO)H with base.[30] Even with extremely strong bases such as $NaN(SiMe_3)_2$ or KO(*t*-Bu), the hydride complex cannot be deprotonated to give the two-legged anion.

Dinitrosyl complexes

Although isoelectronic to various CO derivatives, there are no known examples of $(\eta^n$-$C_nH_n)M(NO)_2$ piano-stool complexes. Our MO calculations indicate that most of these dinitrosyl complexes suffer from small $\Delta\Delta E$ values. This unfavourable orbital energetic arrangement as compared to carbonyl piano-stool complexes results from the electronic differences between CO and NO, as discussed earlier in the comparison of $CpCo(CO)_2$ and $CpMn(NO)_2$.

Many reactions, however, have been carried out that might have been expected to lead to dinitrosyl complexes, and it is instructive to examine the results of these reactions. Early attempts to prepare $CpCr(NO)_2^-$, involved the reduction of $[CpCr(NO)_2]_2$ by sodium amalgam.[31] In contrast to the reduction of $[CpFe(CO)_2]_2$, which readily leads to quantitative yields of the stable $CpFe(CO)_2^-$ anion,[32] the attempted reduction of $[CpCr(NO)_2]_2$ under identical conditions resulted in only the rapid and complete decomposition of

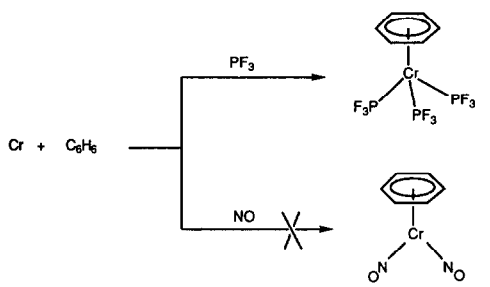
the chromium dimer:



(3)

Subsequent attempts to prepare the tungsten analogue of $CpCr(NO)_2^-$ by deprotonation of $CpW(NO)_2H$ have also failed.[33] The electrochemical reduction of $[CpCr(NO)_2]_2$ was reported to form the dinuclear radical anion $[CpCr(NO)_2]_2^-$ rather than $CpCr(NO)_2^-$, unlike the electrochemical reduction of $[CpFe(CO)_2]_2$, which yields $CpFe(CO)_2^-$.[34] As we saw for $CpMn(NO)_2$, the inherent instability of $CpCr(NO)_2^-$ vis-à-vis the stability of $CpFe(CO)_2^-$ reflects the greater ability of the nitrosyl ligands to stabilize the LUMO and the orbitals below the HOMO, leading to a small HOMO/LUMO gap and a large HOMO/SHOMO gap. Similarly, $BzCr(NO)_2$ ($\Delta\Delta E = 0.62$ eV) does not exist, whereas the carbonyl analogue, $Bz^*Fe(CO)_2$ ($\Delta\Delta E = 5.20$ eV for the Bz analogue) is known.

The proposed inherent instability of some of the nitrosyl complexes appears to be supported experimentally. For example, in contrast to the successful metal atom synthesis of $BzCr(PF_3)_3$, an attempt to prepare $BzCr(NO)_2$ from chromium, benzene and nitric oxide in a metal atom reactor resulted instead in a violent explosion:[35]

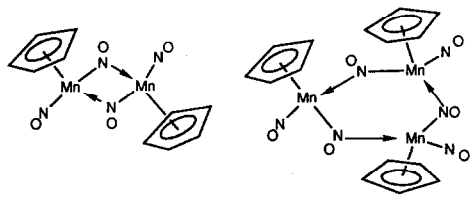


(4)

It is not surprising that $BzCr(PF_3)_3$ could be isolated while $BzCr(NO)_2$ could not; the former is a d^6 three-legged piano-stool complex with stabilized filled orbitals very similar to those of d^6 octahedral complexes, whereas the latter is a d^8 two-legged piano-stool complex with a destabilized HOMO.

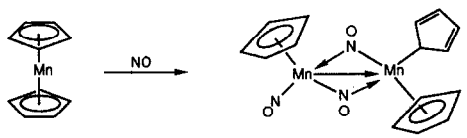
* It has been suggested to us that a one-legged piano stool would be better referred to as a barstool.

An attempted synthesis of $CpMn(NO)_2$ by treatment of $CpMn(NO)(CO)_2^-$ with nitrite ion yielded instead polymeric $[CpMn(NO)_2]_n$ ($n \geqslant 2$).[18] The structures proposed for the dimer (**3**) and the trimer (**4**) both allow the manganese atom to adopt a three-legged piano-stool configuration via bridging NO groups. In essence, the coordination sphere about each manganese atom consists of the Cp ligand, one linear nitrosyl (usually formulated as NO^+) and two bent nitrosyls (usually formulated as NO^-), allowing the metal to achieve a d^6 configuration. Thus, the oligomerization of $CpMn(NO)_2$ appears to be one further example of how the unfavourable orbital energetics imposed by a two-legged structure can be avoided through the formation of a d^6 three-legged piano-stool complex.



3 4

Another reaction that might have been expected to yield $CpMn(NO)_2$ is the addition of nitric oxide to manganocene.[36] Whereas the reaction of Cp_2Ni with NO leads to the monomeric one-legged piano-stool $CpNiNO$,[37]* treatment of Cp_2Mn with NO yields the dimeric product $Cp_3Mn_2(NO)_3$, another compound that contains local three-legged piano-stool fragments (excluding the dative metal–metal bond):[32,38,39]

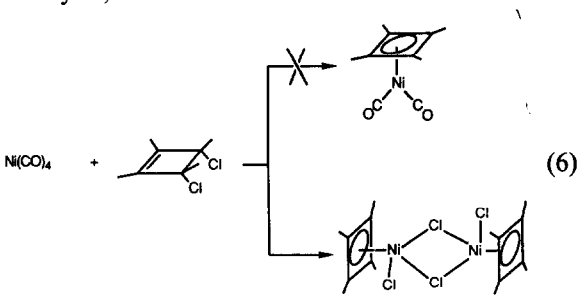


(5)

Cyclobutadiene complexes

We consider cyclobutadiene piano-stool complexes, such as $CbNi(CO)_2$ ($Cb = \eta^4$-C_4H_4), separately as these species are formally d^{10} and their electronic structure does not strictly parallel that of the d^8 complexes discussed above. We have previously advanced a rationale for the inherent instability of $CbNi(CO)_2$,[40] an explanation that depended on the large HOMO/SHOMO gap of the complex. This separation was offered as an explanation of the preferential formation of the d^8 dimeric complex $[Cb^*NiCl_2]_2$ ($Cb^* = \eta^4$-C_4Me_4) from the reaction of $Ni(CO)_4$ with 1,2,3,4-tetra-

methyl-3,4-dichlorobutene:[41]



(6)

As was the case for the $[CpMn(NO)_2]_n$ derivatives, the nickel atoms in this dimer achieve a local three-legged geometry.[42] In view of our finding large $\Delta\Delta E$ values for the stable d^8 three-legged cyclobutadiene complexes $(\eta^4\text{-}C_4Ph_4)Mn(CO)_2NO$[43] ($\Delta\Delta E = 5.10$ eV), $CbFe(CO)_2(NO)^+$[44] ($\Delta\Delta E = 7.33$ eV), and $CbFe(CO)_3$[45] ($\Delta\Delta E = 5.10$ eV), we are encouraged that the $\Delta\Delta E$ values seem to be applicable to systems other than the aforementioned d^6 three-legged and d^8 two-legged piano-stool complexes. It is also clear, however, that the relationships between d^8 three-legged and d^{10} two-legged complexes will depend strongly on the nature of the ligands. Thus, although $CbNi(CO)_2$ is still unknown despite numerous attempts at its synthesis, Eisch *et al.* have successfully made and structurally characterized $(\eta^4\text{-}C_4Ph_4)Ni(PEt_3)_2$.[46] We find it rather surprising that the electron-rich nickel centre apparently prefers alkyl phosphine ligands to carbonyl ligands.

Predictions using $\Delta\Delta E$

After examining the data in Table 3, it appears that we can use the value of $\Delta\Delta E$ as a stability criterion for two-legged piano-stool complexes. Stable and isolable complexes such as $CpCo(CO)_2$, $CpFe(CO)_2^-$, $BzFe(CO)_2$ and $CpCo(CO)(NO)^+$ all have $\Delta\Delta E$ values greater than 4 eV. In contrast, those complexes with $\Delta\Delta E$ values less than 2.5 eV appear to be intrinsically unstable, escaping isolation or even detection. In the middle range of $\Delta\Delta E$ values between 2.5 and 4 eV, we observe "reactive" complexes, such as $CpMn(CO)_2^{2-}$. These are complexes that exist but are likely to be extremely reactive and difficult to isolate.

It should thus be possible to use these $\Delta\Delta E$ values to predict the electronic stability or instability of two-legged piano-stool complexes that are not as yet known. We have therefore performed Fenske–Hall MO calculations and found $\Delta\Delta E$ values for various $CpML_2$ and $BzML_2$ complexes, the syntheses of which, to our knowledge, have not yet been attempted. The ΔE^{HL}, ΔE^{HS} and $\Delta\Delta E$ values can be found in Table 3, along with predictions of their stabilities according to the criteria noted above. Thus, we expect the cationic complexes, $BzCo(CO)_2^+$ and $BzFe(CO)(NO)^+$ to be stable, isolable complexes, while two other cationic species $CpNi(CO)_2^+$ and $CpFe(NO)_2^+$ and the neutral $BzMn(CO)(NO)$ fall into the "reactive" range. $BzMn(NO)_2^+$, $BzCr(CO)(NO)^-$ and $BzV(NO)_2^-$ are predicted to be so unstable as to escape detection. In light of our above discussions, it is not surprising that the cationic complexes of this group should be the most stable, and that stability should decrease within an isoelectronic series as CO is replaced by NO.

It is interesting to note that different trends seem to hold for d^{10} cyclobutadiene two-legged piano-stool complexes. As mentioned earlier, $CbNi(CO)_2$ is not a known molecule; not surprisingly, it has a small $\Delta\Delta E$ value (1.67 eV). We do not yet know whether the quantitative values of $\Delta\Delta E$ for d^{10} systems follow the same stability scale as those for the d^8 systems. Nevertheless, the isoelectronic molecule $CbFe(NO)_2$, which is also unknown, has a significantly higher $\Delta\Delta E$ value (3.09 eV). We would therefore expect $CbFe(NO)_2$ to be less unstable than $CbNi(CO)_2$. By analogy to the synthesis of $(\eta^4\text{-}C_4H_4)Mn(NO)(CO)_2$,[43] we have attempted the synthesis of the tetraphenyl derivative of $CbFe(NO)_2$ via the direct reaction of PhC≡CPh and $Fe(CO)_2(NO)_2$:

$$Fe(CO)_2(NO)_2 + 2PhC{\equiv}CPh \longrightarrow (\eta^4\text{-}C_4H_4)Fe(NO)_2.$$

Although the IR and ^{13}C NMR spectra of the product of this reaction are consistent with its formulation as the cyclobutadiene derivative, we have been unable to isolate it as a pure compound.[47]

CONCLUSIONS

It is nearly certain that the scarcity of d^8 two-legged piano-stool complexes as compared to d^6 three-legged ones is due to the electronic demands of each geometry. As has been pointed out previously, d^6 three-legged piano-stool complexes of π-acid ligands achieve an electronic structure quite similar to that of d^6 octahedral complexes with π-acid ligands.[48] On the other hand, the two-legged piano-stool geometry in consort with the 18e rule dictates that the HOMO of such complexes cannot be stabilized by the π-acid ligands, and it is the relative energy of this HOMO in relation to both the LUMO and the SHOMO that will govern the existence of the complexes.

The empirical observation that a large HOMO/LUMO gap is an indication of stability has traditionally been accepted. Rationalizations for this

observation include the notion that promotion to excited electronic states as well as the ease of reduction of the complex have an inverse dependence on the magnitude of the energy difference between the HOMO and the LUMO. That the stability of a complex should be related to the value of ΔE^{HS} is also an empirical observation and also can be rationalized. If a complex possesses a large HOMO/SHOMO difference and the HOMO is non-bonding, oxidation should have a significant stabilizing effect. Thus, just as a small HOMO/LUMO gap might be an indication that a complex is prone to reduction, a large HOMO/SHOMO gap may be a sign that a complex is likely to undergo oxidation easily.

The use of orbital energy differences to predict the stability or instability of piano-stool complexes appears to be quite promising. There are some unresolved questions with regard to the utilization of $\Delta\Delta E$ values, most notably: (1) Although we can rationalize the observations of stability with increasing ΔE^{HL} and decreasing ΔE^{HS}, a theoretical basis for this analysis is still lacking. (2) The definition of $\Delta\Delta E$ was chosen empirically and is the simplest means of combining ΔE^{HL} and ΔE^{HS} into a single parameter. Lacking a firm theoretical understanding of the significance of ΔE^{HL} and ΔE^{HS} separately, it is not clear that they should be weighted equally in arriving at $\Delta\Delta E$. (3) The electronic stability predicted by $\Delta\Delta E$ is entirely thermodynamic; there is no consideration made for kinetic stability or instability. It does not seem likely, however, that kinetic arguments could explain the correlations found. (4) The values of ΔE^{HL} and ΔE^{HS} are highly dependent on the choice of atomic orbital basis sets, and, it seems likely, computational method. The use of $\Delta\Delta E$ as a stability criterion in the future will thus require both a systematic method of basis set choice (such as that used here) and suitable benchmark calculations to establish the ranges for $\Delta\Delta E$ values.

In spite of the above questions, we believe that orbital energetics will prove to be important in the prediction of new molecules that should be amenable to synthesis. However, we emphasize that our observations are empirical in nature and to generalize these ideas, we are directing further efforts toward a firmer theoretical understanding of the significance of ΔE^{HL} and ΔE^{HS}.

SQUARE PLANAR AND SQUARE PYRAMIDAL COMPLEXES OF RHODIUM(II)

KRISHNA K. PANDEY,† DELEEP T. NEHETE and RAM B. SHARMA

Department of Chemistry, Devi Ahilya University of Indore, Khandwa Road, Indore 452001, India

(*Received* 16 *May* 1989; *accepted after revision* 21 *March* 1990)

Abstract—The rhodium nitrosyl complex $Rh(NO)Cl_2(PPh_3)_2$ reacts with $Na(S_2CNR_2)$ (R = Et or Me), in benzene under reflux, to give the square planar complexes $Rh(S_2CNR_2)_2$. A similar reaction, on stirring the reaction mixture affords the square pyramidal complexes $Rh(S_2CNR_2)_2(PPh_3)$. The products have been characterized by elemental analysis, IR, UV–vis, magnetic measurements, ESR and ^1H NMR studies.

Coordination compounds of platinum metal d^7 ions have as yet attracted less attention than those of d^5 and d^6 metal ions of ruthenium and osmium, and d^6 and d^8 metal ions of rhodium, iridium, palladium and platinum. There is a very marked contrast in the coordination compounds of d^7 metal ions between iron, cobalt and nickel on the one hand and platinum metals on the other. Only a few substantiated examples of mononuclear complexes of ruthenium(I),[1–7] osmium(I),[8,9] rhodium(II),[10–30] iridium(II),[31–36] palladium(III)[37–39] and platinum(III),[40–42] have been reported in the literature.

We have previously described the synthesis of ruthenium(I) and osmium(I) complexes,[7,9] and in this paper we wish to report the synthesis of mononuclear square planar and square pyramidal complexes of rhodium(II). So far there is no report of the penta-coordinated monomeric rhodium(II) complex.

EXPERIMENTAL

All the reagents used were AnalaR or of chemically pure grade. All the solvents were dried by standard procedures and were freshly distilled before use. Dichloronitrosylbis(triphenylphosphine)rhodium(I) was prepared by a literature method.[43] Dithiocarbamate ligands were used as purchased from Fluka.

Sulphur estimation in the complexes was carried out by the standard method.[44] Carbon, hydrogen and nitrogen analyses were performed by the Microanalytical Section of the Central Drug Research Institute, Lucknow. For the estimation of phosphorus, samples were decomposed with sodium peroxide, sugar and sodium nitrate in the ratio 20 : 1 : 3 in a Parr bomb crucible and extracted with water. The solution was then neutralized with dil. H_2SO_4 and an excess of conc. H_2SO_4 (0.5 cm^3) added. This was heated until the evolution of SO_3 fumes ceased, then cooled and diluted with water. From the filtrate of the solution, phosphorus was estimated as phosphoammonium molybdate. The IR spectra of the samples were recorded with a Perkin–Elmer Model 580 spectrophotometer in the range 4000–300 cm^{-1}. The electronic spectra were recorded in benzene solution on a Simadzu 160 spectrophotometer. ESR spectra of the powdered samples were recorded on a Varian Associates E-line ESRCentury Series Model E-104 A spectrometer at X-band frequencies. The spectra were calibrated by using a sample of DPPH ($g = 2.0036 \pm 0.0003$). The magnetic measurements were made on a Gouy balance at room temperature (25°C) and mercury tetrathiocyanatocobaltate(II) was used as calibrant. A varian CFT-20 spectrometer was used to obtain ^1H NMR spectra. All the results are given in Tables 1–4.

(a) *Preparation of* $Rh(S_2CNEt_2)_2$

$Rh(NO)Cl_2(PPh_3)_2$ (0.2 g) and $Na(S_2CNEt_2)\cdot 3H_2O$ (0.4 g) were refluxed in benzene (30 cm^3) for 4 h. The resulting orange solution was filtered and reduced in vacuum to *ca* 5 cm^3, and on addition

of *n*-hexane, orange crystals of $Rh(S_2CNEt_2)_2$ separated. These were centrifuged, then washed with water and cold ethanol, and dried *in vacuo* (yield 90 mg, 83%); m.p. 237°C.

(b) *Preparation of* $Rh(S_2CNMe_2)_2$

$Rh(NO)Cl_2(PPh_3)_2$ (0.2 g) and $Na(S_2CNMe_2)\cdot 2H_2O$ (0.3 g) were refluxed in benzene (30 cm^3) for 4 h. The yellowish-orange crystals of $Rh(S_2CNMe_2)_2$ were isolated by a procedure similar to that given in part (a) (yield 70 mg, 74%); m.p. 210°C.

(c) *Preparation of* $Rh(S_2CNEt_2)_2(PPh_3)$

$Rh(NO)Cl_2(PPh_3)_2$ (0.2 g) and $Na(S_2CNEt_2)\cdot 3H_2O$ (0.1 g) were stirred in benzene (30 cm^3) for 6 h. The resulting solution was filtered and reduced *in vacuo* to *ca* 5 cm^3. Addition of *n*-hexane precipitated the yellow complex $Rh(S_2CNEt_2)_2(PPh_3)$, which was filtered off, washed with water and dried *in vacuo* (yield 124 mg, 75%); m.p. 120°C.

(d) *Preparation of* $Rh(S_2CNMe_2)_2(PPh_3)$

$Rh(NO)Cl_2(PPh_3)_2$ (0.2 g) and $Na(S_2CNMe_2)\cdot 2H_2O$ (0.1 g) were stirred in benzene (30 cm^3) for 6 h. The yellow complex $Rh(S_2CNMe_2)_2(PPh_3)$ was isolated by a procedure similar to that given in part (c) (yield 141 mg, 78%); m.p. 110°C.

RESULTS AND DISCUSSION

Reaction of the rhodium nitrosyl complex, $Rh(NO)Cl_2(PPh_3)_2$, with $Na(S_2CNR_2)$ (R = Et or Me), in benzene under reflux, gives the square planar complexes $Rh(S_2CNR_2)_2$. A similar reaction, on stirring the reaction mixture for 6 h without reflux, affords square pyramidal complexes, $Rh(S_2CNR_2)_2(PPh_3)$. The IR spectra of these complexes show no bands due to ν(NO), indicating the absence of the NO group in the complexes. The IR spectra exhibit bands due to the S_2CNR_2 ligands in $Rh(S_2CNR_2)_2$ complexes and due to S_2CNR_2 and PPh_3 ligands in $Rh(S_2CNR_2)_2(PPh_3)$. The ν(CN) frequency of these complexes at *ca* 1540 cm^{-1} is nearly independent of the substituent. It is shifted to higher energy compared with the free ligand as a result of increased double bond character upon coordination to the metal centre.[45,46]

The electronic spectra of $Rh(S_2CNR_2)_2$ and $Rh(S_2CNR_2)_2(PPh_3)$ complexes (Table 2) show intense absorption bands in the UV region in the vicinity of 315–280 nm ($\varepsilon = 10^4$ mol^{-1} dm^3 cm^{-1}). A very weak absorption band was also seen in the 425 nm region (Fig. 1). A study of dithiolic acids assigned the high energy absorption to π–π^* transitions.[47] The ground state of low-spin rhodium(II) complexes in square planar and square pyramidal environments is probably $^2A_{1g}$ with the configuration $e_g^4 b_{2g}^2 a_{1g}^1$. The band in the region 425 nm is probably a transition from the lower filled orbitals $e_g(d_{xz},d_{yz})$ to the empty $b_{1g}(d_{x^2-y^2})$ antibonding orbital. The four coordinated complexes are more intensely coloured. The shoulders at *ca* 425 nm in the visible region were stronger for the four coordinated complexes.

The ^{1}H NMR spectrum of $Rh(S_2CNEt_2)_2$ produced a triplet and quartet due to the $-CH_3$ and $-CH_2$ groups, respectively (Table 3). A singlet was observed for $Rh(S_2CNMe_2)_2$, indicating the equivalence of the methyl group. The complex $Rh(S_2CNEt_2)_2(PPh_3)$ showed a triplet, quartet and a complex multiplet due to the $-CH_3$, $-CH_2$ and $-C_6H_5$ groups, respectively. The spectrum of $Rh(S_2CNMe_2)_2(PPh_3)$ produced a sharp singlet and

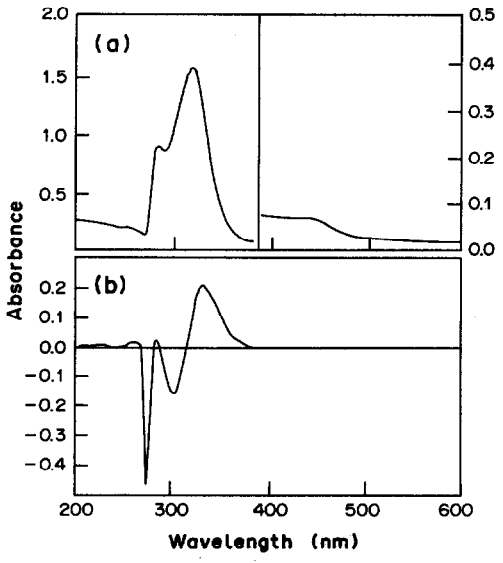

Fig. 1. Absorption spectrum of $Rh(S_2CNEt_2)_2$: (a) absorption curve; (b) first derivative curve.

a complex multiplet due to the $-CH_3$ and $-C_6H_5$ groups. The ^1H NMR spectra indicate that the chemical shifts are the same for $Rh(S_2CNR_2)_2$ and $Rh(S_2CNR_2)_2(PPh_3)$ despite the differences in coordination number and symmetry. This constancy suggests that the total rhodium–sulphur π-bonding in these complexes is invariant.

The complexes $Rh(S_2CNR_2)_2$ and $Rh(S_2CNR_2)_2(PPh_3)$ are paramagnetic with magnetic moment $\mu = 2.0$–2.1 at 298 K. The first derivative X-band ESR powder spectra of the undiluted rhodium(II) complexes (Fig. 2) show three g values ($g_1 > g_2 > g_3$) near two (Table 4). The ESR spectra are similar to the previously reported ESR spectrum for rhodium(II) complexes with sulphur ligands.[11,30] The following g values have been reported for $[Rh(S_2C_2(CN)_2)_2]^{2-}$, $g = 2.447$, 2.019 and 1.936, and for $[Rh(o\text{-Me-Cys}^-)_2]$, $g = 2.035$, 2.020 and 1.955. Hyperfine splitting could not be observed on the broad lines. To interpret the EPR data, we use the theory described by various authors[48–51] to determine the sign of g_1 components and the correspondence between the experimental g values and g_x, g_y and g_z components of the g tensor. The g_1, g_2 and g_3 values are derived as g_x, g_y and g_z, respectively. If the axis of the square planar molecules $Rh(S_2CNR_2)_2$ are as defined in Fig. 3, one would expect energy level ordering as in Fig. 4. The ground state electronic configuration is then $(e_g)^4(b_{2g})^2(a_{1g})^1$, leading to a $^2A_{1g}$ ground term for which the g values, $g_\parallel$ (approximately equal to g_3) and $g_\perp$ (approximately equal to g_1) are

$$g_\parallel = 2.0023$$

$$g_\perp = 2.0023 - \frac{6K^2\lambda}{\Delta E(E_{d_{xz,yz}} - E_{d_{z^2}})},$$

where K is the orbital angular momentum reduction factor[52,53] and λ is the spin–orbit coupling constant, equal to -1235. The $g_\parallel$ value which is smaller than two may be justified by higher order perturbation terms. Using the values of ΔE from the electronic spectra of the complexes, K is found from $g_\perp$ to be approximately 0.4. For the penta-coordinated d^7 system, the unpaired electron could be either in d_{z^2} in the case of square pyramidal geometry, the normal g value pattern being $g_\perp > g_\parallel = 2.00$, or the

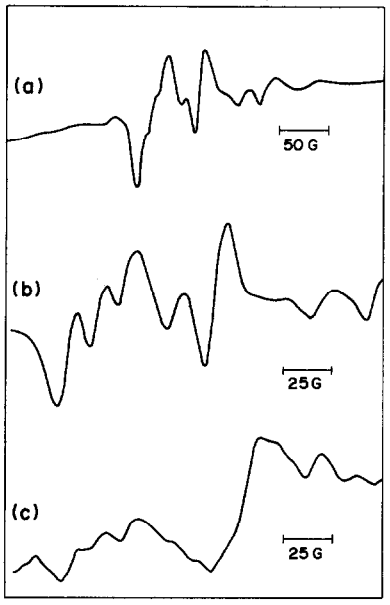

Fig. 2. ESR spectrum of (a, b) $Rh(S_2CNEt_2)_2$ and (c) $Rh(S_2CNEt_2)_2(PPh_3)$ at 295 K.

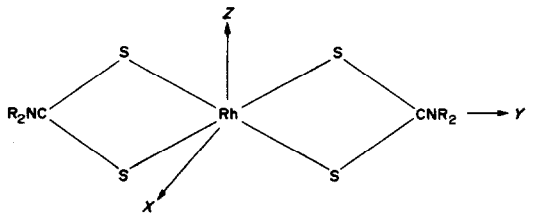

Fig. 3. Stereochemistry of $Rh(S_2CNR_2)_2$.

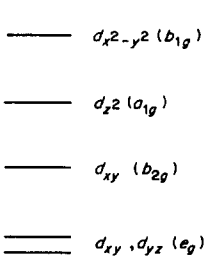

Fig. 4. Energy level ordering of a square planar complex.

unpaired electron may be in a $d_{(x^2-y^2)}$ or $d_{(xy)}$ orbital in the case of trigonal bipyramidal geometry, yielding $g_\parallel > g_\perp > 2.00$.[53,54] The g value patterns for the complexes $Rh(S_2CNR_2)_2(PPh_3)$ (R = Et or Me) are those of a square pyramidal structure.

COMPLEXES OF LANTHANIDE NITRATES WITH A SCHIFF BASE DERIVED FROM *o*-VANILLIN AND *p*-TOLUIDINE

LIU GUOFA,* NA CHONGWU, LI BIN and MAO KUNYUAN

Institute of Material Science, Jilin University, Changchun, China

(*Received* 27 *July* 1989; *accepted* 21 *March* 1990)

Abstract—New complexes of lanthanide nitrates with a Schiff base derived from *o*-vanillin (2-hydroxy-3-methoxy-benzaldehyde) and *p*-toluidine having the general formula $[LnL_2(NO_3)_2]NO_3$ (where Ln = Pr–Lu except Pm, L = Schiff base) have been prepared and characterized. Molar conductance studies indicate 1 : 1 electrolyte behaviour for these complexes. The IR spectra show that two Schiff base ligands and two nitrate groups are bound to the lanthanide ion in a bidentate fashion. Another nitrate group is in the outer coordination sphere. TG and DTA studies indicate that these complexes are stable up to 235°C and do not contain water or alcohol molecules.

There have been a number of reports about lanthanide ion complexes with Schiff bases derived from acetylacetone and ethylenediamine,[1] bis-acetylacetone and ethylenediamine,[2] bis-acetylacetone and benzidine,[3] salicylaldehyde and anthranilic acid,[4] bis-salicylaldehyde and ethylenediamine,[5] bis-salicylaldehyde and *o*-phenylenediamine,[5] *p*-dimethylaminobenzaldehyde and benzidine,[6] 2,6-pyridinedicarboxaldehyde and *o*-aminophenol,[7] vanillin and triethylenetetraamine,[8] bis-vanillin and *o*-phenylenediamine,[9] bis-vanillin and benzidine,[10] 2-hydroxybenzaldehyde and 4-aminoantipyrine.[11] In this paper the lanthanide complexes of a Schiff base derived from *o*-vanillin (2-hydroxy-3-methoxy-benzaldehyde) and *p*-toluidine, $[LnL_2(NO_3)_2]NO_3$ (where Ln = Pr–Lu except Pm, L = Schiff base), have been prepared and characterized.

EXPERIMENTAL

Preparation of the Schiff base

The Schiff base was prepared by reaction of *o*-vanillin (3.04 g) with an equimolar amount of *p*-toluidine (2.14 g) in absolute alcohol (50 cm^3). The reaction solution was heated and brought to reflux for 1 h. The precipitate was filtered, washed with absolute alcohol, and recrystallized from absolute alcohol. Yield 4.34 g, 90%.

Preparation of Schiff base complexes

The absolute alcohol solution (10 cm^3) of lanthanide nitrate $Ln(NO_3)_3 \cdot 6H_2O$ (1.0×10^{-3} mol, 0.31–0.35 g, Pr–Lu) was added in drops to the absolute alcohol solution (10 cm^3) of Schiff base (2.0×10^{-3} mol, 0.48 g) for 5 min with vigorous stirring. The solution was then allowed to stand for 1 week at room temperature. The precipitate was filtered, washed with absolute alcohol and dried *in vacuo*. The crude product was recrystallized from absolute methanol. Yields 0.63–0.69 g, 75–85% (Table 1).

Measurements

Elemental analyses were obtained with a 240C auto elmentary analyser. IR spectra were recorded on a 5DX-FT spectrometer in the region 400–4000 cm^{-1} using KBr pellets. Molar conductances of 10^{-3} mol dm^{-3} methanol solutions at 25°C were measured on a DDX-111A conductometer. TG and DTA were carried out using a 4.1 mode thermobalance (sample: 20 mg, heating rate: 10°C min^{-1}, atmosphere: static air).

RESULTS AND DISCUSSION

Composition of the complexes

Analytical results (Table 1) show that the composition of all these complexes is $LnC_{30}H_{30}N_5O_{13}$

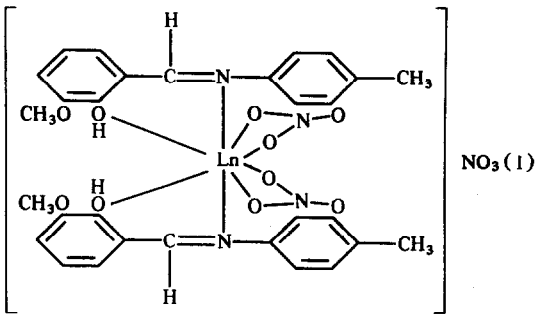
s: strong, m: medium, w: weak.

and they have the general formula $[LnL_2(NO_3)_2]NO_3$.



IR spectra

The important IR frequencies of the Schiff base ligand and the complexes are presented in Table 2. The IR spectrum of the Schiff base shows a strong band at 1618 cm^{-1} attributable to the C=N stretching vibration. On complexation this band shifts to the region 1635–1652 cm^{-1} showing that nitrogen of the azomethine group is coordinated to the lanthanide ions.[12,13] A broad band at 3452 cm^{-1} is due to the phenolic OH stretching vibration in the Schiff base. On complexation this band shifts to the region 3402–3409 cm^{-1}. A medium intensity band at 1420 cm^{-1} is due to the phenolic C—O stretching vibration in the Schiff base. In complexes this band shifts to the region 1380–1385 cm^{-1}. Since the phenolic OH and C—O stretching vibrations shift to lower wavenumbers, this indicates that the oxygen of the phenolic OH is also coordinated to the lanthanide ion.[12,13]

The complexes show six absorption bands near 1501, 1295, 1025, 817, 749 and 702 cm^{-1} which are assigned, respectively, to ν_4, ν_1, ν_2, ν_6 ν_3 and ν_5 vibrations of the coordinated (C_{2v}) nitrate group.[14,15] The magnitudes of ν_4–ν_1 and ν_3–ν_5 are in the range 201–210 and 43–47 cm^{-1}, respectively, indicating that the nitrate groups are coordinated in bidentate fashion.

Molar conductance

The molar conductance data of the complexes are presented in Table 1. From these data it is clear that all the complexes show 1 : 1 electrolytic behaviour in absolute methanol.[16]

Thermal behaviour

The thermal analytical results of some complexes (Table 3 and Fig. 1) show that the complexes are stable up to 235°C. The TG and DTA curves do not have stages or peaks up to 235°C, therefore the complexes do not contain small molecules (water or alcohol). The complexes undergo complete decomposition in the region 660–690°C.

Table 3. Thermal analysis data for some of the complexes

Complexes	Decomposition ranges in TG (°C)	Peaks in DTA (°C)
Pr	262–684	283, 366, 482, 654
Sm	258–680	276, 353, 418, 641
Gd	249–682	277, 327, 476, 653
Ho	247–660	268, 347, 477, 621
Lu	235–690	260, 350, 496, 672

On the basis of elemental analysis, IR spectra, molar conductance and thermal analysis, it is concluded that two Schiff base ligands and two nitrate groups are bound to the lanthanide ion, and another nitrate group is in the outer coordination sphere. Hence the present complexes may be formulated as $[LnL_2(NO_3)_2]NO_3$ (I). The lanthanide ions in the complexes exhibit eight coordination numbers.

(*Received* 1 *August* 1989; *accepted* 21 *March* 1990)

Abstract—The structure of guanidinium hexamolybdobis(*o*-nitrophenylarsonate)monohydrate was determined by single-crystal X-ray diffraction analysis. Each molecule contains one $[(o\text{-}NO_2C_6H_4As)_2Mo_6O_{25}H]^{5-}$ anion, five $CN_3H_6^+$ cations and one water molecule. The structure of the anion is similar to $[(C_6H_5As)_2Mo_6O_{25}H]^{5-}$, $[(C_6H_5As)_2W_6O_{25}H]^{5-}$ and $[(p\text{-}NH_3C_6H_4As)_2W_6O_{25}]^{4-}$ except for one molybdenum atom which is considered as five-coordinated. Five MoO_6 octahedra and one MoO_5 square-pyramid are connected with edge- or corner-sharings to form a ring. Two *o*-nitrophenylarsenic groups join the ring above and below. Although the two arsenic atoms are not equivalent in their bonding manner, both dihedral angles between the phenyl plane and the corresponding nitro plane are 28.8°. It may be noted that the two phenyl planes are almost perpendicular to each other. It is indicated that a special oxygen atom may be bonded to a proton.

The organo-phosphorus and organo-arsenic polymolybdates have been synthesized by Pope and co-workers.[1,2] The compounds consist of a ring of linked MoO_6 octahedra with two organic handles above and below the molybdenum ring.[3] It was stated by Pope and co-workers that only one type of organo-arsenic polymolybdate $[(RAs)_2Mo_6O_{24}]^{4-}$ is formed at pH = 3–5 independent of whether R is an alkyl or aryl group.[2] They only reported the crystal structural data for a double salt of the methyl derivative $[(CH_3)_4N]_2Na_2[(CH_3As)_2Mo_6O_{24}]\cdot 6H_2O$[2] and took it for granted that all alkyl- or aryl-arsenic polymolybdates are of the same type. Matsumoto reported, however, the crystal and molecular structure of a guanidinium salt of the phenyl derivative $(CN_3H_6)_4[(C_6H_5As)_2Mo_6O_{25}H_2]\cdot 4H_2O$.[4]

When *n*-propylarsenic polymolybdates were prepared in our laboratory, we found a unique phenomenon that two types of crystal, containing different numbers of ring molybdenum atoms, are formed under the same pH conditions from the same solution.[5] The six-molybdenum compound $(CN_3H_6)_4[(n\text{-}C_3H_7As)_2Mo_6O_{24}]$[6] is consistent with Pope's prediction, whereas the five-molybdenum compound $(CN_3H_6)_4[(n\text{-}C_3H_7As)_2Mo_5O_{21}]\cdot 2H_2O$[7] is isostructural with organo-phosphorus polymolybdates.[8] In the case of allyl arsonic acid, however, only a five-molybdenum compound $(CN_3H_6)_4[(n\text{-}C_3H_5As)_2Mo_5O_{21}]\cdot 2H_2O$ can be isolated.[9] When phenylarsenic polymolybdates were prepared in our laboratory, only $(CN_3H_6)_5[(C_6H_5As)_2Mo_6O_{25}H]\cdot H_2O$ was isolated from the solution at pH = 3–5.[10] Single-crystal X-ray diffraction studies and elemental analyses show that this compound is different from that reported by Matsumoto, but is isostructural with its tungsten

* Author to whom correspondence should be addressed.

congener $(CN_3H_6)_5[(C_6H_5As)_2W_6O_{25}H]\cdot 2H_2O$ reported by Wasfi *et al.*[11] In order to investigate the types of compound of arylarsenic polymolybdates, we have prepared *ortho*-, *meta*- and *para*-nitrophenylarsonic acid and tested the reactions of these acids with sodium molybdate at pH = 3–5. Five new salts of arylarsenic polymolybdates have been synthesized and characterized.[12] Here we wish to report the X-ray crystal structure of one of these five new salts: the *o*-nitrophenyl derivative. It is demonstrated that the $[(RAs)_2Mo_6O_{25}H]^{5-}$ type of complex and not the $[(RAs)_2Mo_6O_{24}]^{4-}$ type as stated by Pope and co-workers, is formed.

EXPERIMENTAL

The starting material, *o*-nitrophenylarsonic acid, was prepared by the improved Bart reaction.[13] The title compound was prepared by mixing an aqueous solution of sodium molybdate with a hot aqueous solution of *o*-nitrophenylarsonic acid in the molar ratio Mo/As = 3, adjusting the pH value to 3–5 with hydrochloric acid, followed by adding guanidinium hydrochloride solution. The light yellow crystals can be obtained by recrystallization from water. A selected single crystal with $0.1\times0.1\times0.2$ mm approximate dimensions was mounted on a glass fibre. All the intensity data were collected on an Enraf–Nonius CAD4 diffractometer using graphite-monochromated Mo-K_α radiation ($\lambda = 0.7107$ Å). The scan mode was ω–2θ. 4973 independent reflections were collected in the range $2° < 2\theta < 50°$, and 4612 independent reflections with $I > 3\sigma(I)$ were used for further computation.

The title compound is orthorhombic, space group $P2_12_12_1$, mol. wt 1689.09, cell dimensions $a = 12.826(1)$, $b = 18.386(1)$, $c = 21.701(3)$ Å, $V = 5117.3$ Å^3, $Z = 4$, $D_{calc} = 2.192$ g cm^{-3}, $F(000) = 3280$, $\mu = 27.725$ cm^{-1}.

The structure analysis was performed on a PDP11/44 computer with the SDP program. The positions of all the molybdenum and arsenic atoms were determined by direct methods. The positions of the other non-hydrogen atoms were revealed by difference Fourier synthesis. The structure was refined by full-matrix least-squares to a final $R = 0.044$.

DESCRIPTION OF THE STRUCTURE AND DISCUSSION

The selected bond distances and bond angles are listed in Tables 1 and 2, respectively. The final atomic coordinates and the thermal parameters, together with bond distances and bond angles relating to the aromatic rings and the cations, have been deposited as Supplementary Material with the Editor, from whom copies are available on request. The structure of the anion $[(o\text{-}NO_2C_6H_4As)_2Mo_6O_{25}H]^{5-}$ and its atomic numbering is shown in Fig. 1, while Fig. 2 shows the crystal structure. It can be seen that each molecule has one $[(o\text{-}NO_2C_6H_4As)_2Mo_6O_{25}H]^{5-}$ anion, five $CN_3H_6^+$ cations and one water molecule. In the anion, each molybdenum atom is bonded to six oxygen atoms and is located in the centre of a distorted octahedron, except for the Mo(5) atom which is bonded to only five oxygen atoms and is located in the centre of a distorted square-pyramid. Four MoO_6 octahedra are connected by edge-sharing [Mo(1) and Mo(2) by O(3)O(5) edge-sharing, Mo(2) and Mo(3) by O(9)O(10), Mo(3) and Mo(4) by O(12)O(14), respectively], while the other Mo(6) octahedron is connected to Mo(1) by corner-sharing [O(4)]. The Mo(5) square-pyramid is connected to Mo(4) and Mo(6) by corner-sharing [O(18)] and edge-sharing [O(21)O(22)], respectively. All of these molybdenum polyhedra are connected to form a ring. Each arsenic atom is tetrahedrally coordinated by three oxygen atoms from these molybdenum polyhedra and an *o*-nitrophenyl group, and each joins the ring by sharing the three oxygen atoms with the molybdenum atoms. It is notable that these

two arsenic atoms are not equivalent in their bonding manner. As(1) is bonded to one molybdenum-unshared oxygen atom and two edge-shared oxygen atoms, and so it is connected to five MoO_6 octahedra. As(2) is bonded to one edge-shared oxygen atom and two molybdenum-unshared oxygen atoms, and so it is connected to four MoO_6 octahedra. It is interesting to note that each *o*-nitro group is not co-planar with its corresponding phenyl group, see Table 3. Although the two arsenic atoms are not equivalent in their bonding manner, both dihedral angles between the phenyl plane and the corresponding *o*-nitro plane are 28.8°. It is also noticed that the two phenyl planes are almost perpendicular to each other, the dihedral angle between them is 86°.

Each molybdenum atom has two terminal oxygen atoms, which are connected to neither the other molybdenum atom nor to the arsenic atom. This type of Mo—O_t bond length is the shortest one. As shown in Table 2, the 12 Mo—O_t bond lengths range from 1.683 to 1.738 Å, and the average is 1.717 Å. There are four Mo—O_c bond lengths between the corner-shared polyhedra. They range from 1.871 to 1.915 Å, and the average is 1.888 Å. In the case of edge-shared polyhedra, the 10 Mo—O_e bond lengths range from 1.877 to 2.175 Å, and the average is 1.978 Å, if the oxygen atoms are doubly shared by two molybdenum atoms; whereas the six Mo—O_{ea} bond lengths range from 2.228 to 2.408 Å, and the average is 2.299 Å, if the oxygen atoms are triply shared by two molybdenum atoms and one arsenic atom. The Mo—O_{ea} bond length is the longest one. When the oxygen atom is only shared by one molybdenum atom and one arsenic atom, the Mo—O_{ma} bond lengths range from 2.175 to 2.234 Å, and the average is 2.205 Å. The average Mo—O bond lengths of the various types follow

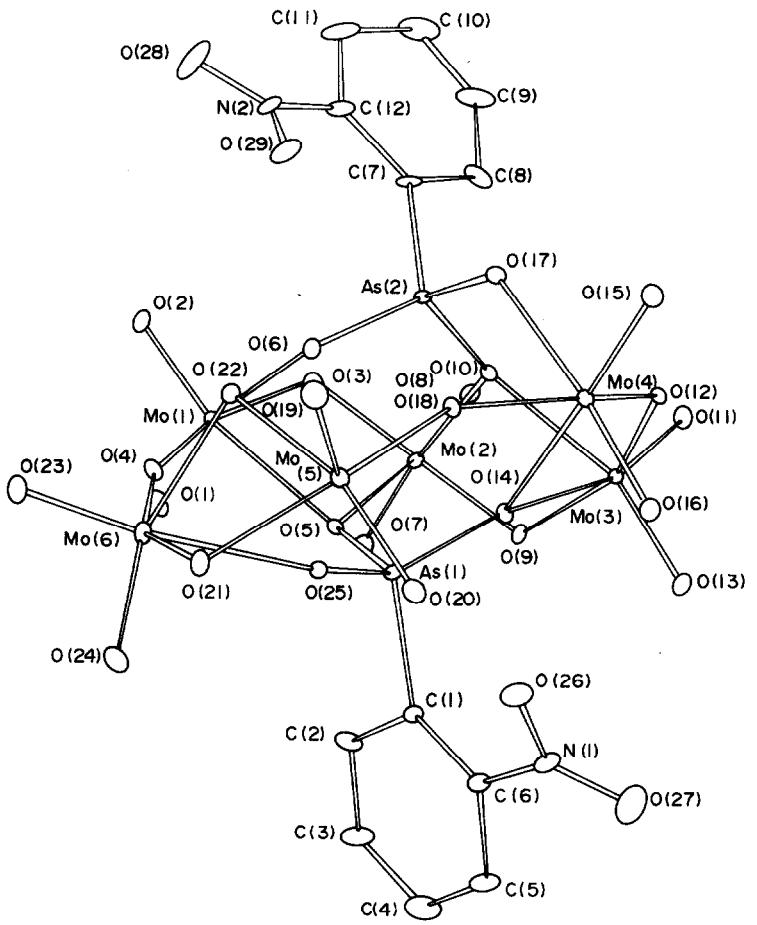

Fig. 1. Structure of the anion $[(o\text{-}NO_2C_6H_4As)_2Mo_6O_{25}H]^{5-}$.

Table 3. Equations of some planes and distance from atom to plane

Equation of plane 1:	$0.5425x-0.8255y-0.1559z = 2.1152$									
Atoms in plane and others atoms:	O(18)	O(20)	O(21)	O(22)	Mo(5)	O(19)				
Distance from atom to plane:	−0.053	0.055	−0.062	0.061	0.381	2.091				
Equation of plane 2:	$0.8595x+0.0346y-0.5100z = -6.2547$									
Atoms in plane and other atoms:	C(1)	C(2)	C(3)	C(4)	C(5)	C(6)	As(1)	N(1)	O(26)	O(27)
Distance from atom to plane:	−0.004	0.002	−0.004	0.009	−0.011	0.009	0.034	0.117	0.624	−0.367
Equation of plane 3:	$-0.2804x+0.7816y-0.5572z = -14.9638$									
Atoms in plane and other atoms:	C(7)	C(8)	C(9)	C(10)	C(11)	C(12)	As(2)	N(2)	O(28)	O(29)
Distance from atom to plane:	−0.014	0.002	0.024	−0.035	0.022	0.001	−0.096	−0.128	0.310	−0.637

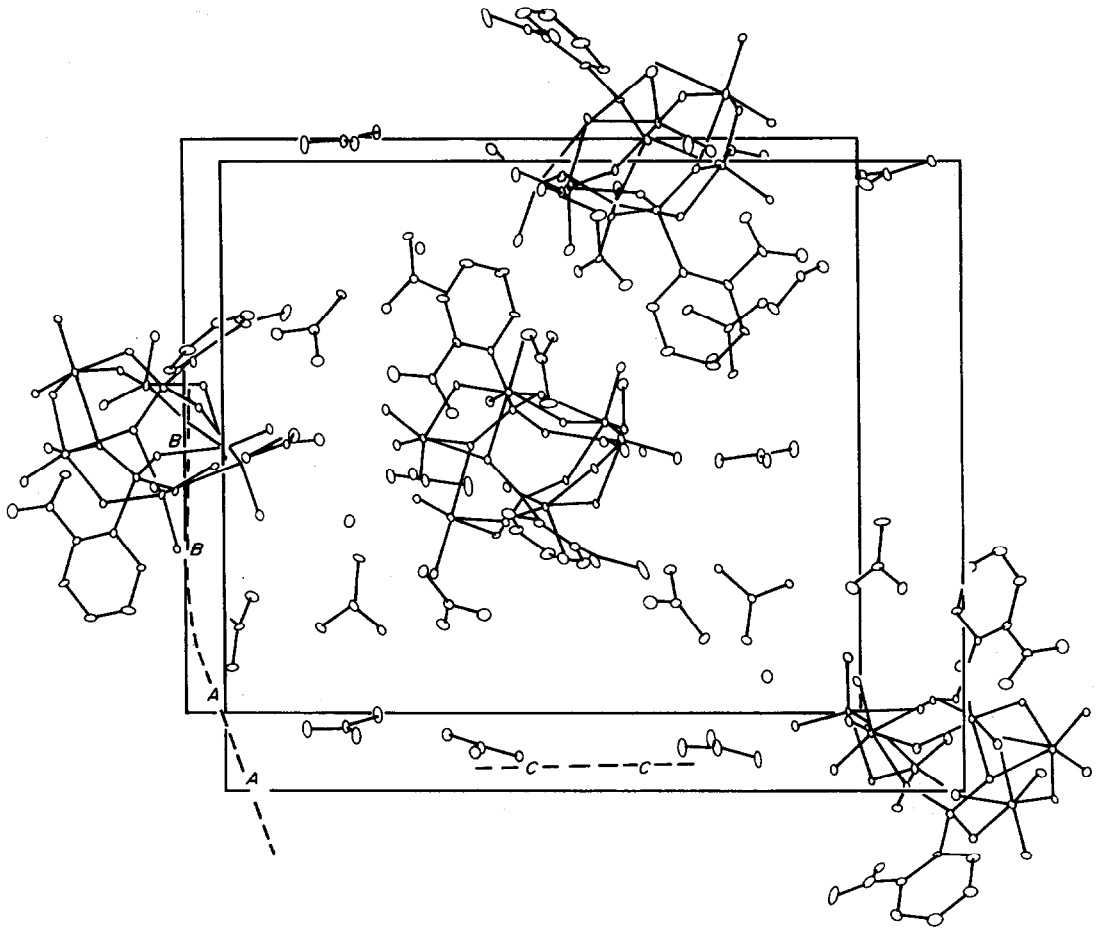

Fig. 2. A view of the unit cell.

the sequence:

$$\underset{1.717}{Mo—O_t} < \underset{1.888}{Mo—O_c} < \underset{1.978}{Mo—O_e} < \underset{2.205}{Mo—O_{ma}} < \underset{2.299}{Mo—O_{ea}}$$

It is obvious that the Mo—O_{ma} bond lengths are much longer than Mo—O_c and Mo—O_e bond lengths. This phenomenon is due to the large electronegativity of the arsenic atom.

The As—O bond lengths range from 1.660 to 1.721 Å, and the average is 1.683 Å. The bonding environments of the oxygen atoms have little influence on the As—O bond lengths. The average As—C bond length is 1.935 Å. In the *o*-nitrophenyl group, the 12 C—C bond lengths range from 1.338 to 1.53 Å, and the average is 1.393 Å, the average C—N bond length is 1.444 Å, the four N—O bond lengths range from 1.177 to 1.225 Å, and the average is 1.201 Å.

From Table 2 it can be seen that the angles O—Mo—O vary regularly with the coordination properties of the oxygen atoms. The O—Mo—O angles are larger than 145.7° if two oxygen atoms are in the *trans* position. When the Mo—O bond lengths increase, the O—Mo—O angles decrease, so that the distances of neighbouring oxygen atoms in the same polyhedron are staying in the similar level. The O—As—O angles range from 106.9 to 112.9°, and the average is 110.5°; while the O—As—C angles range from 102.1 to 113.5°, and the average is 108.4°.

The structure of the anion is similar to that of the known anions $[(C_6H_5As)_2Mo_6O_{25}H]^{5-}$,[10] $[(C_6H_5As)_2W_6O_{25}H]^{5-}$[11] and $[(p\text{-}NH_3C_6H_4As)_2W_6O_{25}]^{4-}$.[14] In all these known anions, all molybdenum atoms are six-coordinated. This Mo(5) is five-coordinated. As shown in Table 3, the oxygen atoms O(18), O(20), O(21) and O(22) are almost co-planar, they constitute the bottom of a square pyramid. The distance from the Mo(5) atom to the plane is 0.381 Å. The calculated distance between Mo(5) and O(25), 2.497(5) Å, is so large that these atoms cannot be considered as bonding to each other. It is emphasized that the O(25) atom is a special one. The bond length Mo(6)O(25), 2.298 Å,

is much longer than the average Mo—O_{ma} bond length of 2.205 Å where the oxygen atom is doubly shared, and almost equal to the average Mo—O_{ea} bond length of 2.299 Å where the oxygen atom is triply shared. From the fact that the Mo(6)O(25) bond length is unusually large, it may be deduced that the O(25) atom should be bonded to an X-ray-undetected hydrogen atom.

In five $CN_3H_6^+$ cations, the C—N bond lengths range from 1.279 to 1.402 Å. The average, 1.337 Å, is between single and double bonds. The angles N—C—N are all close to 120°. Each $CN_3H_6^+$ cation adopts a planar structure, and the multiple-electron delocalized π bond Π_4^6 is thus formed. From the fact that each molecule contains five $CN_3H_6^+$ cations, not four, it may be concluded that the $[(RAs)_2Mo_6O_{25}H]^{5-}$ type of compounds is formed and there must be a proton attached somewhere in the anion to balance the electrical charge.

There is one water molecule in the lattice. Together with the five $CN_3H_6^+$ cations, they provide many hydrogen atoms to form a large number of hydrogen bonds with oxygen atoms in the large anion. These hydrogen bonds between the cations and anions throughout the whole crystal play an important role in stabilizing the crystal. As a matter of fact, the crystals of the title compound remain transparent for a long time.

SPECTRAL, MAGNETIC AND ELECTRICAL PROPERTIES OF 1-SUCCINYL BIS(4-PHENYLTHIOSEMICARBAZIDE) COMPLEXES

A. A. EL-ASMY,* T. Y. AL-ANSI, R. R. AMIN and M. MOUNIR†

Chemistry Department, Faculty of Science, Sana'a University, Sana'a, P.O. Box 11503, Yemen AR

(*Received* 20 *October* 1989; *accepted* 21 *March* 1990)

Abstract—The preparation and properties of a series of transition metal complexes $M(SPTS)\cdot nH_2O$ [where SPTS is the deprotonated form of 1-succinyl bis(4-phenylthiosemicarbazide), H_2SPTS; M = Co^{II}, Ni^{II}, Cu^{II}, Zn^{II} and Cd^{II} and $n = 0$–2] are described. Analytical, spectral (IR, ^1H NMR), conductometric, magnetic and electronic spectral data show that the cobalt(II) and copper(II) complexes have tetrahedral and octahedral structures, respectively, while the nickel(II) complex shows a mixed stereochemistry of tetrahedral and square-planar isomers. In its complexes, the ligand behaves as a dibasic quadridentate (NSSN) donor. The stoichiometry and stability constants of cobalt(II), nickel(II) and copper(II) complexes have been determined spectrophotometrically. Also, the electrical properties of H_2SPTS and its cobalt(II), nickel(II), copper(II) and zinc(II) complexes were investigated and their activation energies calculated. The values obtained for the nickel(II), cobalt(II) and copper(II) complexes are similar to narrow band semiconductor materials.

Metal ion interaction with ligands containing the thiosemicarbazide moiety plays a vital role in a vast number of widely differing biological processes. They are well known for their anticarcinogenic,[1,2] antibacterial[3] and antifungal[4] properties, as well as certain types of tumour.[5] In our previous work, the antimicrobial activities of some thiosemicarbazides were investigated.[6] In addition, transition metal complexes of these compounds have assumed new importance due to their medicinal properties.[7] In the last three decades, complexes of many thiosemicarbazides have been prepared and characterized.[8–11] In view of the biological significance and diverse coordinating behaviour of these compounds, it was considered worthwhile to study the interaction of some thiosemicarbazide and bis(thiosemicarbazide) derivatives with transition metal ions. In the present investigation, complexes of cobalt(II), nickel(II), copper(II), zinc(II) and cadmium(II) with 1-succinyl bis(4-phenylthiosemicarbazide) are discussed with the aim of investigating the possibility of applying these compounds as semiconductors.

EXPERIMENTAL

All the chemicals used are BDH quality.

Preparation of H_2SPTS

Phenylisothiocyanate (13.5 cm^3, 0.1 mol) was added dropwise with constant stirring to a solution of succinic acid hydrazide (7.8 g, 0.05 mol) in absolute ethanol in a 2 : 1 ratio. The mixture was refluxed for 1/2 h. A white precipitate appeared after cooling in a refrigerator and on scratching the mixture with a glass rod in the presence of diethyl ether. The precipitate was removed by filtration, washed with EtOH and recrystallized, dried and preserved *in vacuo* over anhydrous $CaCl_2$.

Preparation of the metal complexes

A hot, ethanolic solution of metal chloride (0.01 mol) was mixed with an aqueous–ethanol solution

* Author to whom correspondence should be addressed.
† Physics Department, Faculty of Science, Sana'a University, Sana'a, P.O. Box 11503, Yemen AR.

of H_2SPTS (0.01 mol). The mixture was refluxed on a water bath for 3–5 h depending on the metal salt and concentrated to half volume. The product thus formed was filtered, washed with ethanol and dried in an electric oven at ~ 60°C and preserved in a desiccator over anhydrous $CaCl_2$.

Physical measurements

Magnetic measurements were carried out by the Gouy method using mercury tetrathiocyanatocobaltate(II) ($\chi_g = 16.44 \times 10^{-6}$ cgs unit) as a calibrating agent. Electronic and spectral studies in solution were carried out on a Pye Unicam SP 8800 spectrophotometer. IR spectra were recorded on a Perkin–Elmer 1430 model with samples in KBr pellets. The ^1H NMR spectrum of H_2SPTS was recorded on a EM-390 (90 μHz) NMR spectrometer using d_6-DMSO. The molar conductance values were measured with a Leitfahigkeitsme PHYWE bridge. Elemental analyses were carried out in Egypt at the Microanalytical Unit of Cairo University. The analyses of sulphur and the metal ions were carried out according to standard methods.[12] For electrical conductivity measurements in the solid state, compressed pellets, 1 cm^2 area and 0.3–0.5 cm thickness, were moulded at a pressure of 8 tons cm^{-2}. Two thin copper wires of 0.2 mm diameter were attached to the major surface of the pellet after carefully painting them with conducting silver paste. The conduction current was measured using a Keithly 610 C electrometer. The minimum current which can be measured by this method is 10^{-4} A with an accuracy of 2–4%. All measurements were carried out in the 20–180°C temperature range; an electric oven was used to control the ambient temperature. The cell used in the measurements was as described previously.[13]

RESULTS AND DISCUSSION

The reaction of H_2SPTS with the chloride and/or the sulphate salts of cobalt(II), nickel(II), copper(II) or zinc(II) and $CdCl_2$ gives only one type of complex having the formula $M(SPTS)\cdot nH_2O$; the reaction with $CdSO_4$ affords $Cd(H_2SPTS)SO_4\cdot 2H_2O$. The first type is isolated in the presence of CH_3COONa and accompanied by the replacement of two hydrogen atoms, the reaction being exothermic. All the complexes have melting points $\geqslant$ 244°C and are insoluble in most available organic solvents. The cadmium(II) complexes are readily soluble in dimethylsulphoxide (DMSO) and their molar conductivity values (Table 1) lie in the range of non-electrolyte complexes.[14] The presence of the sulphate group in the $CdSO_4$ complex was confirmed quantitatively and supported by IR spectra.

The ligand IR spectrum exhibits three intense bands at 3080, 3230 and 3310 cm^{-1} assigned to $\nu(N^1H)$, $\nu(N^2H)$ and $\nu(N^4H)$ vibrations,[15] respectively, while the band at 1000 cm^{-1} is due to the ν(N—N) vibration.[16] The ν(C=C) vibration of the benzene ring is observed as a strong band at 1595 cm^{-1}. The two bands at 1720 (strong) and 1690 (weak) cm^{-1} are assigned to the stretching vibrations of free and bonded carbonyl groups. The other amide bands (II–IV) are observed at 1510, 1210 and 720 cm^{-1} as reported earlier.[17] The existence of these bands at lower wavenumbers proves hydrogen bonding (Structure I). The ligand spectrum also shows two bands at 770 and 1270 cm^{-1} assignable to ν(C=S) (IV) and a combination of ν(C=S)+ν(N—C—N) (II) vibrations. The other thioamide bands, [δ(C—H)+δ(N—H)] (I) and [ν(C—N)+ν(C=S)] (III), are observed at 1540 and 930 cm^{-1}, respectively. The keto : thioketo form (**I**) is one of the four tautomeric forms of H_2SPTS and

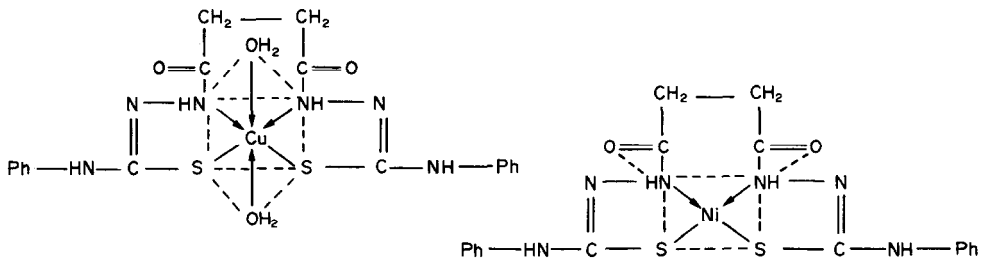
is supported by the absence of ν(SH) in the 2600–2400 cm^{-1} region. There is also a broad band centred at 3500 cm^{-1} which may be due to the ν(O···H—N) vibration of the intramolecular hydrogen bond.[18]

Two strong signals are observed at 9.5 and 10.1 ppm in the ^{1}H NMR spectrum of H_2SPTS which are attributed to N^4H and N^2H protons, while the weak signal at 9.7 ppm is due to the N^1H proton. The weakness is due to hydrogen bonding.

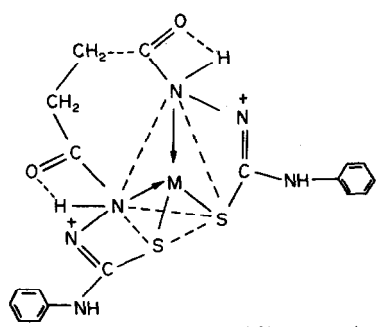
In the complexes, M(SPTS)·nH_2O, the ligand acts as a quadridentate dibasic (NSSN) donor forming two five-membered rings, as well as a seven-membered ring as shown in structure **II** for the copper(II) complex and **III** for the cobalt(II), zinc(II) and Cd(SPTS)·$2H_2O$ complexes. In their IR spectra, the $\nu(N^2H)$ vibration completely disappears, $\nu(N^1H)$ shifts to lower wavenumbers, the ν(N—N) vibration is slightly shifted to higher wavenumbers and two new bands at ~ 1570 and ~ 430 cm^{-1} due to ν(C=N) and ν(M←N)[19] appear. This evidence suggests nitrogen coordination. Also, the thioamide band I suffers a negative shift upon coordination of nitrogen. Strong evidence for enethiolization is the disappearance of thioamide II and IV bands; this indicates that the —NH—C(S)— moiety converts to —N=C(SH)— by enethiolization. Also, the appearance of a new band at ~ 580 cm^{-1}, due to ν(C—S),[20] is strong evidence for the enethiolization process as well as the coordination through sulphur; this phenomenon is also confirmed by the appearance of the ν(M—S) vibration[21] at ~ 495 cm^{-1}. Finally, the existence of amide bands, which are more or less invariant, indicates that the C=O group is not taking part in coordination.

The reflectance spectrum of Co(SPTS)·$2H_2O$, in Nujol mull, shows a band centred at 16,400 cm^{-1} due to a *d–d* transition; the absence of any bands at ~ 20,000 and ~ 12,000 cm^{-1}, which are characteristic for the square-planar geometry, excludes this structure. The observed broad band is due to the ν_3 [$^4A_2 \rightarrow {}^4T_1$(P)] transition in a tetrahedral structure.[22] Unfortunately, the other bands for the suggested structure are not observed when using our instrument due to its limited range (up to 850 nm). The anomalous moment (1.54 BM) determined for this complex may be due to lower symmetry; the only evidence for this phenomenon is the broadening of the ν_3 transition. Knowing the magnetic moment of the complex, $10Dq$ is generally calculated by the equation: $\mu_{eff} = 3.87(1 - 4\lambda/10Dq)$. Moreover, the anomalous moment of our complex precluded the calculation of $10Dq$ and also B and β values.

The magnetic and spectroscopic studies of Ni(SPTS) suggest a structure with nickel atoms in two different stereochemistries. Its magnetic value is 2.25 BM which is lower than that reported for both tetrahedral and octahedral values; the lowering may be due to mixed geometries of tetrahedral and planar isomers (structure **IV**). The calculation may suggest equal proportions. The reflectance spectrum shows two bands at 14,184 and 23,258 cm^{-1} which are due to the $^3T_1 \rightarrow {}^3A_2$ and $^3T_1 \rightarrow {}^3T_1(F)$ transitions in tetrahedral geometry. Also, the spectrum shows a band at 18,518 cm^{-1} assigned

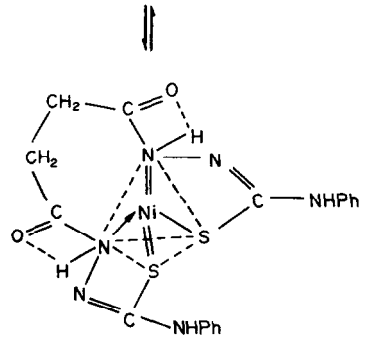


(II)



M = Co(II), Zn(II) or Cd(II)

(III)



(IV)

to the $^1A_{1g} \rightarrow {}^1A_{2g}$ transition in the square-planar environment. It is concluded that the position and assignments of the reflectance spectral bands reveal the existence of mixed stereochemistries for the nickel(II) complex.

The magnetic moment value (2.11 BM) for the copper(II) complex lies within the permissible range recorded for one unpaired electron. This value excludes the copper–copper interaction and is measured only for compounds with strong covalent bonds. The reflectance spectrum shows one broad band centred at 20,408 cm^{-1} which is characteristic for the existence of the copper(II) ion in an octahedral configuration.[23] The broadening may be due to a lower symmetry resulting from the Jahn–Teller effect. The water molecules complete the octahedral configuration (**II**) and its characteristic bands are observed in the IR spectra at 3460 [ν(OH)], 1630 [$\delta(H_2O)$], 915 [$\rho_r(H_2O)$] and 715 [$\rho_w(H_2O)$] cm^{-1}.

Spectral studies in solution

The spectrum of H_2SPTS was recorded in EtOH and buffer solutions with pHs ranging from 3.15 to 11.86. The UV spectrum recorded in EtOH shows three bands at 202, 228 and 266 nm due to π–π^* and n–π^* transitions. The absorption spectra measured in a series of aqueous Thiel–Coch buffer solutions exhibit two bands at 220 and 248 nm in solutions of the pH range 3.15–8.0 with a slight increase in absorbance. These bands are mainly due to absorption of the non-ionic form of H_2SPTS (**I**). On increasing the pH, a blue shift is observed in the band at 220 nm while its absorbance decreases; this shift reaches a maximum at pH > 10. However, the band at 248 nm is still present at higher pH but its absorbance decreases. The ligand pK values are calculated using the method of half-height of the absorbance–pH curve and are found to be 9.5 and 10.5.

By comparing the metal–ligand spectrum with that of the ligand it has been shown that a new band is formed, indicating the formation of a new species in solution. The new band is found at 290, 306 and 300 nm for the cobalt(II), nickel(II) and copper(II) complexes, respectively.

The widely used Job's method of continuous variation[24] was applied to determine the composition of the complexes formed in EtOH and/or buffer media. The results indicate that the overall ratios of M–L are 1 : 1 and 1 : 2. The stoichiometry of the complexes was also confirmed by the molar ratio method.[25] The apparent formation constant (K_f) for the investigated complexes is calculated using the results obtained from the continuous variation method. The $\log\beta$ values for the cobalt(II), nickel(II) and copper(II) species are listed in Table 2.

Table 2. Apparent formation constants for H_2SPTS complexes

Metal chloride	Cobalt(II)	Nickel(II)	Copper(II)
Type of complex	1 : 1 1 : 2	1 : 1 1 : 2	1 : 1 —
Concentration	4.15×10^{-5} 6.25×10^{-5}	7.7×10^{-6} 1.4×10^{-5}	4.6×10^{-5} —
A/Am	0.9625 0.9478	0.9416 0.9645	0.9714 —
λ_{max} (nm)	290	300	300
K_f	1.65×10^{7} 4.34×10^{11}	3.5×10^{7} 2.77×10^{13}	2.16×10^{7} —
$\log\beta$	7.22 11.64	7.55 13.44	7.33 —

Beer's law is not valid for these systems, so the ligand could not be used in the microdetermination of these metal ions.

Electrical conductivity measurements

The conductivity (σ) and the activation energy (ΔE) of the studied compounds were calculated by applying the Arrhenius equation:

$$\sigma = \sigma_0 \exp -\Delta E/KT.$$

Since this equation is obeyed by inorganic semiconductors, it may also be used to describe the electrical properties of organic and complex compounds.

Figure 1 shows the temperature dependence of the dc electrical conductivity of H_2SPTS and of its cobalt(II), nickel(II) and zinc(II) complexes. The plot of $\ln\sigma$ vs $1/T$ is nearly linear for the cobalt(II) complex but an inflection is observed in the case of H_2SPTS and its nickel(II) complex; this may be attributed to a change in conduction mechanism. The activation energies of cobalt(II) and nickel(II) complexes are calculated to be 0.54 and 0.71 eV, respectively. The conductivity of H_2SPTS and its zinc(II) complex decreases slightly with temperature, i.e. $d\sigma/dT$ is negative. This decrease may be due to the rearrangement of molecules or to the accidental impurities on the surface.

Figure 2 shows the relationship between the electrical conductivity of the copper(II) complex and the applied electric field measured at 50 and 100°C. It is clear that the conductivity sharply increases; the increase becomes more pronounced at $T =$

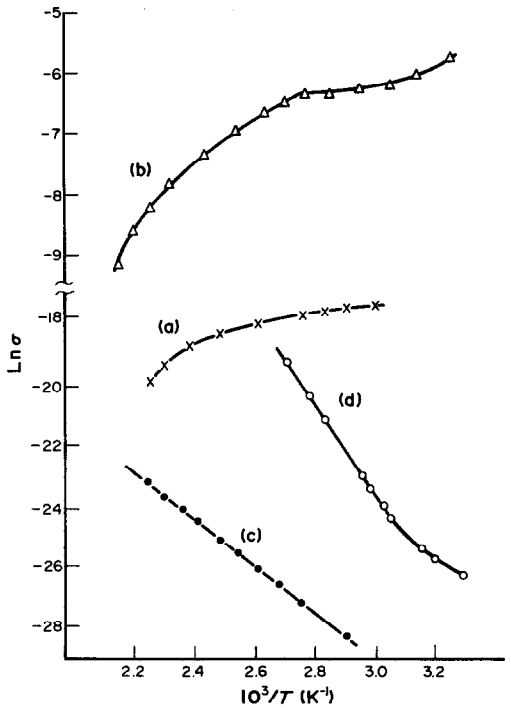


Fig. 1. Plot of ln σ vs $1/T$ for: (a) ligand; (b) Zn^{II} complex; (c) Co^{II} complex; (d) Ni^{II} complex.

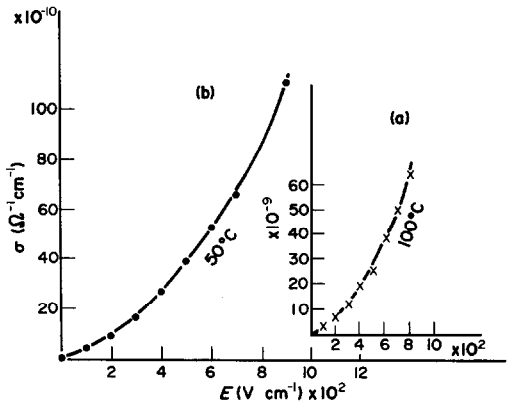

Fig. 2. Dependence of the electrical conductivity (σ) of the copper(II) complex on the applied electric field (E) at (a) 100°C and (b) 50°C.

100°C (see inset a). At room temperature ($\sim$ 22°C), the current is independent of the applied voltage.

The temperature dependence of the electrical conductivity for the annealed and unannealed copper(II) complex is shown in Fig. 3. The error in the measurements, due to the dependence of conductivity on time, is very small. The conductivity of annealed and unannealed samples increases with temperature, i.e. $d\sigma/dT$ is positive and the activation energy is 0.72 eV. This increase may be due to the loss of water molecules at 120°C which are

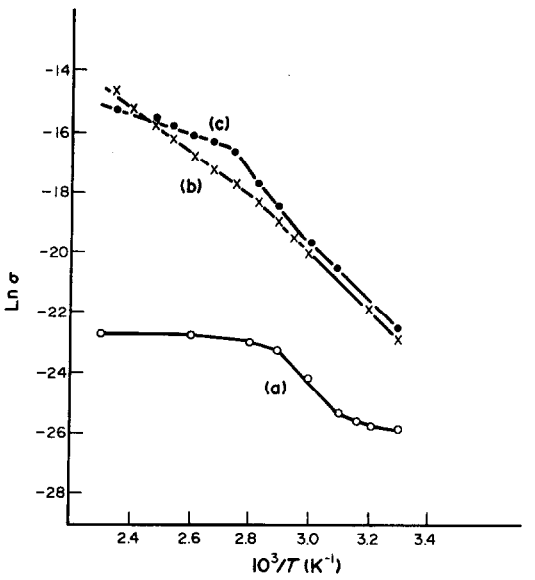

Fig. 3. Plot of ln σ vs $1/T$ for the copper(II) complex: (a) unannealed sample; (b) annealed at 120°C for 1 h; (c) annealed at 120°C for 2 h.

present in the unannealed sample (Table 1). The annealed sample has a large value of conductivity which increases with increasing annealing time.

In conclusion, the activation energy values for the cobalt(II), nickel(II) and copper(II) complexes are similar to those reported for narrow band semiconductor materials.[26]

(*Received* 1 *December* 1989; *accepted* 21 *March* 1990)

Abstract—Complexes of copper(II) acetate, oxalate and sulphate and 1-(2-carbamylethyl)-2-alkylimidazoles (alkyl = H, CIm; = CH_3, CMIm; = CH_2CH_3, CEIm) have been studied. The following compounds have been prepared and characterized by spectral (IR, UV–vis and EPR) and variable temperature magnetic susceptibility determinations: $Cu(CH_3COO)_2L_n$ (L = CIm, $n = 2$ and 4; L = CMIm or CEIm, $n = 2$), $Cu(C_2O_4)(CIm)_2 \cdot H_2O$, $Cu(SO_4)L_n \cdot xH_2O$ (L = CIm, $n = 1.5$, 3 and 4, $x = 1$ or 3; L = CMIm, $n = 1$ and 2, $x = 2$). Only for $Cu(SO_4)(CIm)_{1.5} \cdot H_2O$ and $Cu(SO_4)(CMIm)_n \cdot 2H_2O$ ($n = 1$ and 2) has evidence of magnetic interactions been found.

Complexes of imidazole and its derivatives have been thoroughly studied and are very important due to their application as analytical, industrial and biochemical reagents[1,2] (and see refs in ref. 3). For instance, the complex bis(acetato)bis(imidazole) copper(II) was recently found to have antitumour activity.[2]

There has also been great interest in dimeric copper(II) carboxylate complexes with bridged structures of the copper(II) acetate monohydrate or similar types, many of which have nitrogen-donor ligands in the terminal positions.[4–6] Oxalate and similar ligands have also been found to form bridges between copper atoms.[7,8] Sulphate can also act as a bridge between metal ions forming, for example, copper(II) compounds with sulphate-bridged chain polymeric structures[9,10] and magnetic interactions have been found in compounds where sulphate bridges alone[9] or with other bridges are present.[11]

In 1-(2-carbamylethyl)-2-alkylimidazoles another biologically important coordinating moiety, the amide group, co-exists with the imidazole group. We have been investigating the coordinating properties of these ligands[3,12] and recently reported halide or pseudo-halide copper(II) complexes with three ligands of this type (alkyl = H, CIm; = CH_3, CMIm; = CH_2CH_3, CEIm).[3] Considering the interest in copper(II) complexes with oxyanions in which polyatomic bridges support magnetic interaction between paramagnetic metal centres, it was decided to extend the study to compounds with acetate, oxalate and sulphate, which is reported in this paper.

EXPERIMENTAL

Chemicals

All the reagents used were commercially available and were used without further purification. 1-(2-Carbamylethyl)imidazole was prepared according to a reported procedure[13] and the other two ligands by a similar procedure, using 2-methylimidazole or 2-ethylimidazole instead of imidazole.[3]

Synthesis and analysis of the complexes

Metal complexes were obtained by the following general procedure. A solution of the organic ligand in methanol (*ca* 1 M) was mixed with 0.25 M copper(II) sulphate or 0.08 M copper(II) acetate solution in methanol previously dehydrated with 2,2′-dimethoxypropane. Acetate complexes were

* Author to whom correspondence should be addressed.

obtained using stoichiometric amounts of metal salt and organic ligand, except for $Cu(CH_3COO)_2(CIm)_4$ which was obtained from a 1 : 6 molar ratio mixture. $Cu(SO_4)(CIm)_n \cdot xH_2O$ (n = 1.5, 3 and 4) compounds were isolated, respectively, from mixtures with 1 : 2, 1 : 4 and 1 : 5 molar ratios. Very often, no solid separated immediately and to obtain a precipitate, the solution was concentrated by slow evaporation (IR lamp) and left standing overnight at room temperature. The solids were filtered off, washed with acetone and dried *in vacuo* (over P_4O_{10}). The following two compounds were prepared by different procedures:

$Cu(SO_4)(CMIm)_2 \cdot 2H_2O$. By adding a 0.25 M solution of the metal salt to a 0.5 M solution of the organic ligand, both in methanol (1 : 2 molar ratio), a light green product was formed (this solid decomposes on standing). After filtering off this powder, acetone was added to the solution and a light blue compound precipitated. This was filtered, washed with methanol and dried over P_4O_{10}.

$Cu(C_2O_4)(CIm)_2 \cdot H_2O$. By heating a mixture of aqueous solutions (all *ca* 1 M) of copper(II) nitrate, potassium oxalate and the organic ligand (1 : 1 : 2), a light blue product precipitated. After cooling, the solid was filtered off and discarded. Acetone and propanol were added to the filtrate, the resulting solution was allowed to stand for a few days, and eventually a flocculent product suspended in the solution and a blue crystalline precipitate formed. The latter was separated by decantation, washed with acetone and dried as before.

The compounds are hygroscopic and were handled under nitrogen atmosphere.

Carbon, nitrogen and hydrogen microanalyses were performed by the Microanalytical Laboratory of the University of Manchester or by the Laboratório Nacional de Engenharia e Tecnologia Industrial (Queluz, Portugal). The copper contents of the complexes were determined by titration with EDTA.

Physical measurements

The following equipment was used: Varian–Cary 17DX spectrophotometer for electronic spectra (Nujol mulls and solutions, 30–8.0 × 10^3 cm^{-1}); Perkin–Elmer 457 spectrophotometer for IR spectra (KBr pellets or Nujol mulls, 4000–250 cm^{-1}); Varian E-109 spectrometer for X-band EPR spectra (operated at ~ 9 GHz and 100 kHz field modulation); Metrohm E518 conductivity meter for measurements on *ca* 10^{-3} M methanolic solutions of the complexes (at 25°C). Magnetic susceptibilities were measured as before.[3]

RESULTS AND DISCUSSION

Synthesis

Yields, analytical and some physical data for the compounds are presented in Table 1.

Tetrakis-complexes were obtained only with 1-(2-carbamylethyl)imidazole. For the other ligands, in contrast with what was found for copper(II) halides, where tetrakis-complexes were also obtained with 1-(2-carbamylethyl)-2-methylimidazole,[3] we were unable to prepare compounds with a ligand-to-metal molar ratio higher than 2 : 1.

Attempts to prepare copper(II) acetate complexes with the metal ion and organic ligands in a 1 : 1 molar ratio were unsuccessful. In attempts to synthesize oxalate compounds of the type $Cu(C_2O_4)L_2$ (where L = CMIm or CEIm), impure products were always obtained.

All the sulphate compounds contain water molecules. These were probably absorbed from the atmosphere during handling of the solutions from which they were isolated.

Copper(II) acetate complexes

The electronic spectra (Table 2) of the compounds with acetate are of the general type found for square- or tetragonally-distorted octahedral copper(II) complexes. They show a broad *d–d* band in the visible region (15–19 × 10^3 cm^{-1}), with a shoulder on the lower energy side [except for $Cu(CH_3COO)_2(CMIm)_2$]. The molar conductivity values (Table 1) for methanolic solutions of the compounds (*ca* 10^{-3} M) indicate a non-electrolyte type of behaviour,[14] but electronic spectra show that the compounds undergo some structural changes in solution.

It seems reasonable to assign to $Cu(CH_3COO)_2(CIm)_4$ a structure with the four coordinating atoms of the organic ligands in the equatorial plane and very weak axially-coordinated or even uncoordinated acetate anions. The IR spectrum of the compound exhibits a multiple and very broad band in the region 1600–1500 cm^{-1} and another band at about 1400 cm^{-1}. These involve bands assignable to acetate vibrations, and suggest that this anion may be ionic or semi-coordinated.[15,16] Assuming D_{4h} symmetry, the observed broad band in the electronic spectrum is assigned to the $^2B_{1g} \rightarrow {}^2B_{2g}, {}^2E_g$ transition. The EPR data (Table 2) for this compound also support tetragonal symmetry and nitrogen coordination of 1-(2-carbamylethyl)imidazole. The EPR spectrum of the powdered compound is of the axial type with $g_\parallel > g_\perp$ ($d_{x^2-y^2}$ ground state). Observed g values are

[b] EPR spectrum of this compound shows a very weak feature at half-field region.
[c] g value obtained from the magnetic field value corresponding to the interception point of the high-field derivative line with the horizontal base line.

in the ranges usually found for tetragonally-distorted copper(II) compounds with four monodentate nitrogen donor ligands.[17] Unlike what was observed for $CuX_2(CIm)_4$ compounds, with $X = Cl^-$, Br^-, ClO_4^-,[3] no hyperfine structure due to copper is observed in the parallel signal (probably due to an increase in dipole–dipole or exchange interactions). Although the compound undergoes structural changes in methanol, its axial EPR spectrum in frozen solution shows, beyond copper hyperfine structure in the $g_\parallel$ signal, superhyperfine structure in the $g_\perp$ region due to nitrogen coordinated atoms of the imidazolic group of the ligand (the amide group nitrogen only coordinates when the amide group is deprotonated[18]).

The complexes $Cu(CH_3COO)_2L_2$ (L = CIm, CMIm or CEIm) exhibit IR spectra that confirm the presence of acetate groups. However, in the region of 1400 cm^{-1} (where the $\nu_s(CO_2)$ band, sensitive to the acetate coordination mode, is expected), the organic ligands also absorb and therefore no conclusions about the coordination mode of the anion are possible (anyway, limitations to the usefulness of IR spectroscopy for the diagnosis of carboxylate coordination have been noted[19]).

Spectral data for $Cu(CH_3COO)_2(CIm)_2$ show that its structure is either monomeric square-distorted involving a CuN_2O_2 chromophore or tetragonally-distorted octahedral, depending whether the terminal acetate oxygen atoms are or are not weakly bonded in (or close to) the axial positions. The compound of the same type with imidazole has an almost *trans*-square planar arrangement of CuN_2O_2, with the second oxygen atoms of the two carboxylate groups interacting weakly with the copper atom, and forming a distorted octahedron.[20] However, steric requirements and different hydrogen bonding possibilities due to the replacement of the hydrogen atom at the N(1) atom of the imidazole ring in 1-(2-carbamylethyl)imidazole by the carbamylethyl group, may provoke a different spacial distribution of atoms in the inner coordination sphere of $Cu(CH_3COO)_2(CIm)_2$. The observation of axial EPR spectra (Table 2) agree with the above proposed geometries.

EPR spectra for powdered $Cu(CH_3COO)_2L_2$ (L = CMIm or CEIm) compounds exhibit an unsymmetrical signal (Fig. 1) and a very weak intensity feature at the half-field region, but are not typical of dimeric copper(II) compounds. The axial spectrum of $Cu(CH_3COO)_2(CMIm)_2$ in frozen solution exhibits poorly resolved superhyperfine structure in the $g_\perp$ region, due to nitrogen coordinated atoms of the organic ligand.

Room temperature magnetic moments (Table 2) for powdered samples of the $Cu(CH_3COO)_2L_2$ compounds are all above the spin-only value expected for a copper(II) ion. The molar magnetic susceptibilities at different temperatures follow the Curie–Weiss law (Table 3) and, since θ values are small and only very slight variations of magnetic moments with temperature are observed, provide no evidence of significant magnetic interactions between copper atoms.

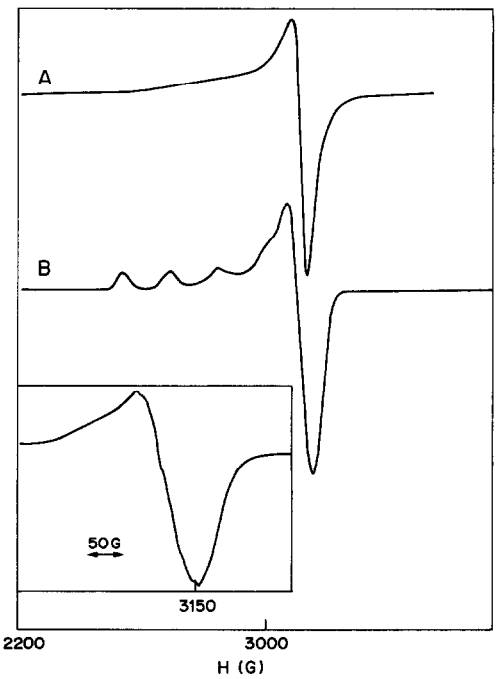

Fig. 1. EPR spectra of: (A) $Cu(CH_3COO)_2(CMIm)_2$, powder, at 133 K; (B) $Cu(CH_3COO)_2(CMIm)_2$ in methanol, at 103 K; insert: *ibidem*, in the $g_\perp$ region.

Copper(II) *oxalate complexes*

The electronic spectrum (Table 2) of the compound $Cu(C_2O_4)(CIm)_2 \cdot H_2O$ consists of an unsymmetrical broad band whose maximum position is consistent with a pentacoordinated copper(II) complex or a rhombic octahedral stereochemistry. An EPR spectrum with three g values is observed, which agrees with low symmetry for the compound. Magnetic data for this complex (Table 3) provide no clear evidence for the existence of significant magnetic interaction. In conclusion, these results do not rule out a monomeric structure for the compound but, as for bis(2-methylimidazole)(oxalato)copper(II),[8] which exhibits weak ferromagnetic coupling, it may have a chain structure.

Table 3. Magnetic data for some of the compounds

Compound	μ (BM)							Curie–Weiss law[a]	
	T (K) 298.4	250.2	206.2	175.7	155.9	126.5	97.0	$10^5 C$ (m^3 mol^{-1} K)	θ
$Cu(CH_3COO)_2(CIm)_2$	1.84	1.85	1.85	1.84	1.85	1.87	1.86	0.5273	4
$Cu(CH_3COO)_2(CMIm)_2$	1.91	1.90	1.91	1.90	1.90	1.90	1.89	0.5800	−3
$Cu(CH_3COO)_2(CEIm)_2$	1.88	1.88	1.90	1.91	1.92	1.92	1.92	0.5447	7
$Cu(C_2O_4)(CIm)_2 \cdot H_2O$	1.87	1.89	1.90	1.90	1.91	1.92	1.97	0.5330	10
$Cu(SO_4)(CIm)_{1.5} \cdot H_2O$	1.82	1.80	1.80	1.76	1.74	1.72	1.67	0.5705	−29
$Cu(SO_4)(CMIm)_2 \cdot 2H_2O$	1.86	1.86	1.85	1.80	1.78	1.77	1.73	0.5896	−24
$Cu(SO_4)(CMIm) \cdot 2H_2O$	1.86	1.83	1.77	1.74	1.72	1.64	1.54	0.6896	−81

[a] Values of C and θ were obtained by least-squares adjustment of magnetic susceptibility data to the Curie–Weiss law, $\chi = C/(T-\theta)$. Values of the correlation coefficients were always greater than 0.999.

Copper(II) sulphate complexes

The organic ligands exhibit bands in the IR regions where sulphate groups are expected to absorb and therefore the IR spectra provide no useful information about coordination modes of sulphate in the compounds.

Electric conductance data in methanol (*ca* 10^{-3} M) (Table 1) indicate that the compounds behave as non-electrolytes in solution, but their electronic spectra in the same solvent (Table 2) show that they undergo structural changes, especially the 1-(2-carbamylethyl)imidazole compounds (the EPR spectrum for $Cu(SO_4)(CIm)_{1.5} \cdot H_2O$ seems to indicate the presence of more than one species in solution). The electronic spectra of all the compounds in Nujol mulls exhibit one broad unsymmetrical *d–d* band, although this occurs in different regions (Table 2). For the compounds $Cu(SO_4)(CIm)_n \cdot 3H_2O$ ($n = 3$, 4) the band appears at higher energy and the spectra are consistent with a tetragonal arrangement of coordinated atoms around copper. In $Cu(SO_4)(imidazole)_4$, distorted octahedral coordination occurs, with the four nitrogen atoms from the imidazoles in the equatorial plane and the two oxygens from the two shared sulphate groups completing the octahedron.[21] On the other hand, $Cu(NH_3)_4(H_2O)(SO_4)$ shows square-based pyramidal symmetry with non-coordinated sulphate.[22] The observed high energy for the *d–d* band in the spectrum of $Cu(SO_4)(CIm)_4 \cdot 3H_2O$ is consistent with very weak coordination of the sulphate group in the axial position. The axial EPR spectrum of this compound (Fig. 2) is characterized by the resolution of copper ion hyperfine structure in the $g_\parallel$ region. In the spectrum in frozen solution, superhyperfine structure is observed in the $g_\perp$ region, due to coordinated nitrogen atoms.

The EPR spectrum of $Cu(SO_4)(CIm)_3 \cdot 3H_2O$ consists of a broad unsymmetrical signal in the high field region, and provides no information about the stereochemistry of the compound.

Solution and Nujol mull spectra (Table 2) for $Cu(SO_4)L_n \cdot xH_2O$ ($n = 1$, 1.5 or 2 and L = CIm or CMIm) are similar, with the maxima positions in the solution spectra slightly shifted to higher energies, which could be due to substitution of coordinated species by methanol molecules or even to structural change.

The EPR spectrum for $Cu(SO_4)(CIm)_{1.5} \cdot H_2O$ shows an apparently axial signal with a perpendicular component at $g = 2.12$ and a shoulder derivative around $g = 2.45$. In addition to this large signal, the spectrum exhibits a very weak feature in the half-field region which corresponds to the $\Delta M_s = 2$ forbidden transition in a dimeric copper(II) compound.

With respect to the 1-(2-carbamylethyl)-2-methylimidazole compounds, the EPR spectrum of $Cu(SO_4)(CMIm) \cdot 2H_2O$ is of the axial type and exhibits copper hyperfine structure resolution in the parallel signal (three of the four lines are clearly seen). $Cu(SO_4)(CMIm)_2 \cdot 2H_2O$ exhibits a broad spectrum (Fig. 2) with apparently only partially resolved hyperfine structure in the parallel signal (no data can be extracted from this spectrum but the g value measured at the point with a derivative value of zero).

Magnetic moments for the sulphate compounds, at room temperature, are all above the spin-only value for single copper(II) ions. Magnetic susceptibility data in the range 90–300 K for $Cu(SO_4)(CMIm)_n \cdot 2H_2O$ ($n = 1$ or 2) and $Cu(SO_4)(CIm)_{1.5} \cdot H_2O$ show that their magnetic moments decrease with decreasing temperature (Table 3). When molar magnetic susceptibilities are fitted to $1/\chi = f(T)$, negative values of θ are obtained (Table

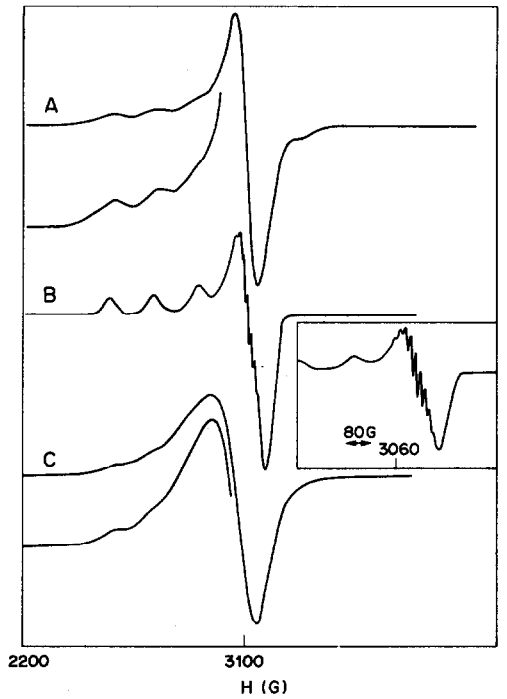

Fig. 2. EPR spectra of: (A) $Cu(SO_4)(CIm)_4 \cdot 3H_2O$, powder, at 113 K; (B) $Cu(SO_4)(CIm)_4 \cdot 3H_2O$ in methanol, at 113 K; insert: *ibidem*, in the $g_\perp$ region; (C) $Cu(SO_4)(CMIm)_2 \cdot 2H_2O$, powder, at 113 K.

3). These results indicate that antiferromagnetic interactions may operate between copper(II) atoms in these compounds. Nevertheless, the EPR spectra of $Cu(SO_4)(CMIm)_n \cdot 2H_2O$ ($n = 1$ or 2) exhibit hyperfine structure which is usually absent for magnetically concentrated compounds.[23] However, signals due to small amounts of impurities not detected by elemental analysis may be responsible for these features in the spectra.

The stoichiometry of the compound $Cu(SO_4)(CIm)_{1.5} \cdot H_2O$ would be consistent with a dimeric structure with a bridged 1-(2-carbamylethyl) imidazole molecule. If this is the case, as magnetic properties for the compound indicate magnetic exchange interaction, and this molecule is not effective to transmit intramolecular exchange, this exchange may be also of the intermolecular type.

CONCLUSIONS

In view of the measured properties, it is not possible to assign unequivocal structures to some of the synthesized complexes.

With reference to magnetic interactions, these were not clearly detected in the $Cu(CH_3COO)_2L_2$ compounds, which leads to the exclusion of acetate bridges in these complexes. For some sulphate compounds, variable temperature magnetic susceptibility results show evidence of magnetic interactions. The results for $Cu(SO_4)CMIm)_n \cdot 2H_2O$ compounds do not rule out polymeric structures with bridged sulphate groups but the magnetic exchange pathway may also involve the water molecules.

SYNTHESIS AND X-RAY CRYSTAL STRUCTURE OF A MERCURY(II)–TELLUROAMINE COMPLEX. MONODENTATE BEHAVIOUR BY A POTENTIALLY BIDENTATE HYBRID TELLURIDE LIGAND, 1-(NMe_2)-2-(TeC_6H_4-4-OEt)-4-MeC_6H_3

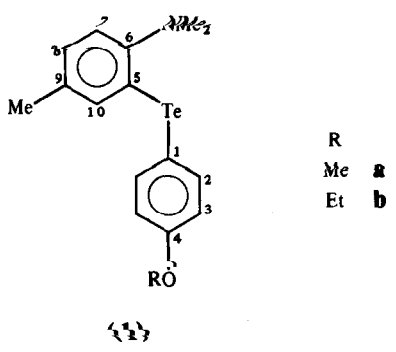
(*Received* 22 *January* 1990; *accepted* 22 *March* 1990)

Abstract—The telluroamines 1-(NMe_2)-2-(TeAr)-4-MeC_6H_3 (**1**) (Ar = 4-$MeOC_6H_4$ or 4-$EtOC_6H_4$) react with mercury(II) halides forming adducts of composition $HgX_2 \cdot$ **1** (X = Cl or Br). The IR, far-IR (up to 50 cm^{-1}), ^1H and ^{13}C NMR spectra of the mercury(II) complexes indicate that the ligands (**1**) behave as monodentate donors, coordinating through tellurium only. The complexes seem to be dimers of the composition [**1** · $XHg(\mu\text{-}X)_2HgX \cdot$ **1**]. The crystal structure of the adduct obtained from mercury(II) bromide has been determined. It reveals that the NMe_2 group does not coordinate with mercury(II) and the complex is a dimer in which two somewhat asymmetrical bromine bridges are present between the mercury atoms. The coordination environment of each mercury is almost tetrahedral [91.25(3)–118.40(4)°]. The Hg—Br bridging bond lengths are 2.755(1) and 2.710(1) Å.

Considerable interest has been devoted to the ligand chemistry of tellurium during the last 15 years,[1–4] but very few hybrid bidentate or polydentate ligands containing the element are known.[5–7] We are interested in the synthesis of potentially polydentate ligands containing "hard" donor atoms, viz. nitrogen and oxygen along with tellurium, and we have recently synthesized telluroamines, 1-(NMe_2)-2-(TeAr)-4-MeC_6H_3[8] and $RN(CH_2CH_2TeAr)_2$[9] (where Ar = C_6H_5, 4-$MeOC_6H_4$ or 4-$EtOC_6H_4$ and R = Me or H) and investigated their complexation behaviour with palladium(II) and platinum(II). They ligate as bi- and tridentate donors, respectively. The potentially bidentate (Te, N) donors 1-(NMe_2)-2-(TeAr)-4-MeC_6H_3 (**1**), however, coordinate with mercury(II) through tellurium only, resulting in a halo-bridged dimer of composition $[Hg_2X_4(\mathbf{1})_2]$ (X = Cl or Br). The monodentate behaviour of a potentially bidentate ligand,



(**1**)

1b, has been demonstrated by the crystal structure of $[Hg_2Br_4(\mathbf{1b})_2]$. The synthesis of mercury complexes of **1**, their IR, far-IR and ^1H and ^{13}C NMR spectra and X-ray crystal structure of one such derivative mentioned above are the subject of the present paper. The complexes described here are the first examples in which a potentially bidentate hybrid organotellurium ligand has been shown to behave as a monodentate donor.

EXPERIMENTAL

The ligands, 1-(NMe_2)-2-(TeAr)-4-MeC_6H_3 (Ar = 4-$MeOC_6H_4$ or 4-$EtOC_6H_4$), were synthesized by the method reported earlier.[8] Chloride, bromide, mercury and tellurium were estimated by standard methods.[10] Carbon, hydrogen and nitrogen analyses were carried out with a Perkin–Elmer elemental analyser 240C. ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded in $CDCl_3$ on a JEOL FX-100 FT–NMR spectrometer at 99.55 and 25 MHz, respectively. IR spectra (of Nujol mulls between CsI windows or KBr/CsI discs) in the range 4000–200 cm^{-1} were recorded on a Nicolet 5DX FT–IR spectrometer. Far-IR spectra (400–50 cm^{-1}) were recorded on a Perkin–Elmer Far-FT–IR spectrometer model 1700X on the sample between polyethylene films. The conductance measurements were made on *ca* 1 mM solutions in acetonitrile with a Pye conductivity bridge. Molecular weights (5–20 mM solutions) in chloroform were determined using a Knauer vapour pressure osmometer.

Synthesis of $HgX_2 \cdot$ **1** (X = Br *or* Cl)

$HgCl_2$ or $HgBr_2$ (1 mmol) was dissolved in methanol (~ 5 cm^3). The solution of the ligand **1a** or **1b** (1 mmol in ~ 5 cm^3 benzene) was added dropwise with stirring at room temperature to a solution of the mercuric halide. The white to pale yellow crystalline solid which precipitated instantaneously, was filtered and then successively washed with methanol (~ 10 cm^3) and benzene (~ 5 cm^3). The mercury complexes were recrystallized from a chloroform–benzene mixture (80 : 20 and 60 : 40 for the adducts of $HgCl_2$ and $HgBr_2$, respectively). The yield, melting point, results of elemental analyses, ^1H and $^{13}C\{^1H\}$ (25°C) spectral data are recorded below.

$HgCl_2 \cdot$ **1a**. Yield 82%; m.p. ~ 150°C (dec.). Found: C, 29.5; H, 2.9; N, 2.5; Te, 19.4; Hg, 30.9; Cl, 10.5. Calc. for $C_{16}H_{19}NOCl_2TeHg$: C, 30.0; H, 3.0; N, 2.2; Te, 19.9; Hg, 31.3; Cl, 11.1%. NMR [^1H]: δ, 2.20 (s, 3H, Me); 2.74 (s, 6H, NMe_2); 3.82 (s, 3H, OMe); 6.90–7.89 (m, 7H, aryl); [$^{13}C\{^1H\}$]: δ 20.8 (Me); 47.5 (NMe_2); 55.4 (OMe); 105.0 (C_1); 116.6 (C_3); 121.0 (C_{10}); 132.0 (C_7); 135.0 (C_8); 137.0 (C_5); 140.0 (C_2); 151.0 (C_6); 161.0 (C_4). The signal for C_9 was not observed.

$HgCl_2 \cdot$ **1b**. Yield 85%; m.p. ~ 160°C (dec.). Found: C, 30.9; H, 3.2; N, 2.4; Te, 18.8; Hg, 30.0; Cl, 10.2. Calc. for $C_{17}H_{21}NOCl_2TeHg$: C, 31.2; H, 3.2; N, 2.1; Te, 19.5; Hg, 30.7; Cl, 10.8%. NMR [^1H]: δ, 1.35–1.48 (t, 3H, CH_3 of OEt); 2.19 (s, 3H, Me); 2.74 (s, 6H, NMe_2); 3.94–4.15 (q, 2H, CH_2 of OEt); 6.88–7.87 (m, 7H, aryl); [$^{13}C\{^1H\}$]: δ, 14.7 (CH_3 of OEt); 20.8 (Me); 47.4 (NMe_2); 63.8 (CH_2 of OEt); 105.1 (C_1); 117.1 (C_3); 121.1 (C_{10}); 121.3 (C_9); 132.1 (C_7); 135.3 (C_8); 137.6 (C_5); 140.5 (C_2); 152.1 (C_6); 161.6 (C_4).

$HgBr_2 \cdot$ **1a**. Yield 62%; m.p. ~ 155°C (dec.). Found: C, 25.9; H, 2.7; N, 1.6; Te, 16.2; Hg, 26.7; Br, 20.6. Calc. for $C_{16}H_{19}NOBr_2TeHg$: C, 26.3; H, 2.6; N, 1.9; Te, 17.5; Hg, 27.5; Br, 21.9%. NMR [^1H]: δ 2.19 (s, 3H, Me); 2.74 (s, 6H, NMe_2); 3.82 (s, 3H, OMe); 6.90–7.87 (m, 7H, aryl).

$HgBr_2 \cdot$ **1b**. Yield 68%; m.p. ~ 165°C (dec.). Found: C, 26.9; H, 2.7; N, 1.7; Te, 16.1; Hg, 25.2; Br, 20.1. Calc. for $C_{17}H_{21}NOBr_2TeHg$: C, 27.4; H, 2.8; N, 1.9; Te, 17.2; Hg, 27.0; Br, 21.5%. NMR [^1H]: δ, 1.34–1.48 (t, 3H, CH_3 of OEt); 2.18 (s, 3H, Me); 2.74 (s, 6H, NMe_2); 3.93–4.14 (q, 2H, CH_2 of OEt); 6.88–7.86 (m, 7H, aryl).

Determination of crystal structure

Crystals of $HgBr_2 \cdot$ **1b** suitable for X-ray analysis were grown from a chloroform–benzene (60 : 40) solvent as pale yellow prisms.

Crystal data. $C_{17}H_{21}NOBr_2HgTe$, $M = 743.37$, monoclinic, $a = 15.417(2)$, $b = 14.693(3)$, $c = 19.252(4)$ Å, $\beta = 104.96(2)°$, $U = 4213.2$ Å^3, space group C_2/c, $Z = 8$, $D_c = 2.344$ g cm^{-3}, $F(000) = 2720$, μ(Mo-K_α) = 124.3 cm^{-1}.

Data collection and processing. Intensity data from a crystal of dimensions $0.3 \times 0.4 \times 0.3$ mm were collected on an Enraf–Nonius CAD4 diffractometer in the ω–2θ scan mode with scan width = $0.7 + 0.35 \tan\theta$ (scan speed 3.33° min^{-1} to a maximum of 90 s for weak reflections) using graphite-monochromated Mo-K_α radiation. 4462 reflections were measured (h, k, $\pm l$; $l \leqslant \theta \leqslant 26.0°$) yielding 4120 unique reflections after averaging and rejection of systematic absences. During the course of the data collection (89 h) a standard reflection monitored hourly showed a 3% decay for which a correction was applied. The unfavourable orientation of the crystal did not enable a set of ψ-reflections to be collected and hence, no empirical absorption correction could be applied.

Structure analysis and refinement. The structure was solved by the heavy atom method, the coordinates of both the mercury and tellurium atoms being derived. Subsequent Fourier maps determined the positions of all the remaining non-hydrogen atoms. Full-matrix anisotropic refinement of the metal and bromine atoms, isotropic refinement of the remaining atoms converged at $R = 0.102$. An absorption correction using "DIFABS",[11] followed by subsequent full-matrix anisotropic refinement of all non-hydrogen atoms converged at $R = 0.036$, $R_w = 0.042$. Hydrogen atoms positions were deter-

mined from geometric criteria and were included but not refined. The weighting scheme $\omega = 1/[\sigma(F^2)+(0.02F)^2+2.0]$ gave a satisfactory agreement analysis with the ESD of an observation of unit weight = 1.1. All calculations were performed on a DEC Microvax II computer using the SDP Plus V. 3.0 system of crystallographic programs.[12]

Table 1. Selected bond distances (Å)[a]

Hg—Te	2.728(1)	O—C(24)	1.406(12)
Hg—Br(1)	2.755(1)	O—C(27)	1.360(14)
Hg—Br(2)	2.710(1)	N—C(16)	1.411(13)
Hg—Br(3)	2.500(1)	N—C(17)	1.457(13)
C(11)—Te	2.097(9)	N—C(18)	1.468(15)
C(21)—Te	2.100(9)	C(27)—C(28)	1.55(2)
		C(13)—C(19)	1.52(2)

[a] Detailed bond lengths for the phenyl rings have been deposited as supplementary data. [C—C(phenyl) distances range from 1.348(14) to 1.398(14) Å.]

Important bond lengths and angles are given in Tables 1 and 2, respectively. Atomic coordinates, anisotropic thermal parameters, observed and calculated structure factors and a full list of bond lengths and angles have been deposited as supplementary data with the Editor.

RESULTS AND DISCUSSION

The telluroamines, **1a** and **1b**, synthesized by us recently by mercuration of 1-(NMe_2)-4-MeC_6H_4, followed by transmetallation with a suitable aryltellurium(IV) chloride in good yield (Scheme 1), have been shown to behave as bidentate ligands[8] with palladium(II) and platinum(II). The mercury(II) halides, HgX_2 (X = Cl or Br), react with **1a** and **1b** resulting in adducts of composition $HgX_2 \cdot$ **1a**/**1b**, which behave as non-electrolytes in acetonitrile at millimolar concentration levels. In the ^1H NMR spectra of the mercury complexes the NMe_2 protons appear as a singlet, marginally

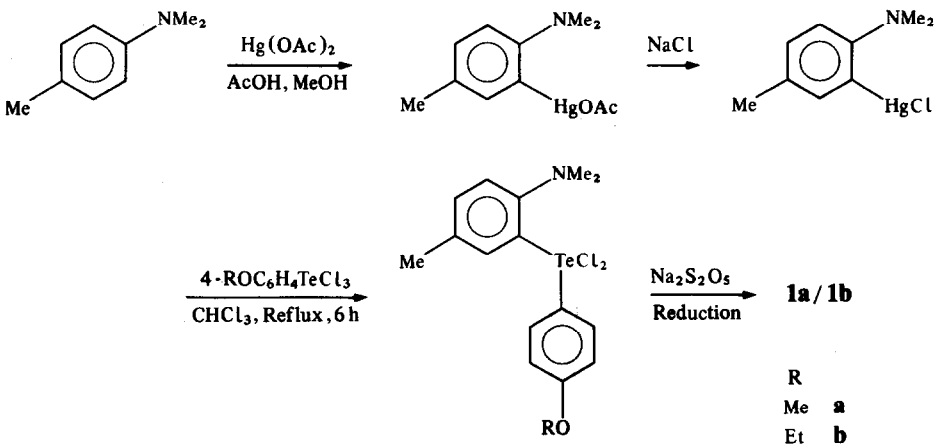
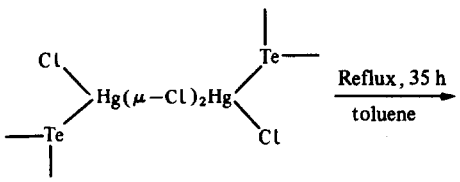
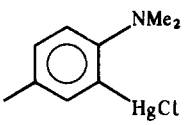


Scheme 1.

deshielded ($\sim$ 0.06 ppm) in comparison to similar protons of the ligands. This suggests that these ligands (**1a/1b**), in solution, probably do not coordinate with mercury through nitrogen, otherwise a doublet for these protons would have appeared. The small deshielding of these protons may arise due to the effect of the Te---Hg interaction on the ring current. The two ν(C—N) bands undergo a blue shift (10–15 cm^{-1}) on the formation of mercury complexes in comparison to their positions around 1280 cm^{-1} (Ar—N) and 1200–1250 cm^{-1} (NMe_2) in the spectra of ligands **1a** or **1b**. There probably exists a Te$\cdots$N interaction[6] in the ligands and its breakdown results in the observed blue shift. The $^{13}C\{^1H\}$ NMR spectra of $HgCl_2\cdot$**1a** and $HgCl_2\cdot$**1b** are consistent with the conclusion drawn above about the dormant NMe_2 group, as the signal of C_6 remains unaffected on complexation of **1a/1b** with mercury(II). The C_1 signal of **1a/1b**, appearing around 103.4 ppm, has been found to be deshielded by $\sim$ 2 ppm on the formation of mercury(II) complexes. Similarly, the C_5 signals appearing around 136.3 ppm for the ligands, undergo a downfield shift ($\sim$ 0.6–1.0 ppm) on complexation with mercury(II). The deshielding of the signals of carbon atoms linked to tellurium is not very high but favours the coordination of mercury(II) through tellurium. The small magnitude of the deshielding of these carbon signals is consistent with the fact that the mercury–tellurium bond strength, particularly in the complexes of the neutral Te-donors, is considered somewhat weak. Thus ligands **1a** and **1b** probably behave as a monodentate Te-donor in the mercury complexes. Mercury(II) generally adopts a tetrahedral geometry in its complexes, therefore the moiety $HgX_2\cdot$**1a/b** having a three-coordinate mercury(II) may be expected to dimerize and result in [**1a/b**$\cdot XHg(\mu\text{-}X)_2HgX\cdot$**1a/1b**], which has the usual four-coordinate mercury. Such a speculation has been substantiated by the far-IR spectrum of $HgBr_2\cdot$**1a** and the crystal structure of $HgBr_2\cdot$**1b**. The far-IR spectrum of $HgBr_2\cdot$**1a** contains bands at 119(s), 156(w) and 189(s) cm^{-1} which may be assigned to ν(Te—Hg), ν(Hg—Br_b) and ν(Hg—Br_t), respectively. The occurrence of a band in the region of the Hg—Br(bridging) vibration supports the possibility of dimerization. The bands appearing at 256, 272, 286 and 300 cm^{-1} in the far-IR spectrum of this complex may be attributed to various Te—Ph vibrations, whereas ν'(phenyl)[13] appears at 232 cm^{-1}.

The mercury complex ($HgCl_2\cdot$**1a/1b**) on refluxing for 35 h in toluene results in the mercurated aniline derivatives [eq. (1)] and a yellow-coloured polymeric material almost insoluble in all organic solvents. The ratio of mercury and tellurium suggests that it has composition **2** shown in eq. (1). The molecular weights of the mercury complexes have been found in chloroform to be almost half of the dimer. Therefore, either the reaction shown in eq. (1) or dissociation of one ligand molecule (or both) due to heating of the solution in the course of osmometric molecular weight measurements seem to be responsible for obtaining the lower values for molecular weights.





$+ \quad [ArTeHg(TeArAr')Cl]_n \qquad (1)$

(2)

Crystal structure of [**1b**$\cdot BrHg(\mu\text{-}Br)_2HgBr\cdot$**1b**]

The structure in the solid state consists of discrete dimeric molecules. The molecular structure and numbering scheme are shown in Fig. 1, while important bond lengths and bond angles are given in Tables 1 and 2. The geometries of the phenyl rings appear normal and their bond information has been deposited as supplementary material. The dimer has a two-fold rotation axis. Each mercury atom is situated in a roughly tetrahedral coordination environment [91.25(3)–118.40(4)°], bonding to two bridging bromine atoms at distances of 2.710(1) and 2.755(1) Å, one terminal bromine at 2.500(1) Å and one terminal tellurium at 2.728(1) Å. The Hg—Te bond length is consistent with the earlier report.[14] The asymmetry in the bromine bridges is of the order reported for the chloro-bridge in $(PPh_3)ClHg(\mu\text{-}Cl)_2HgClPPh_3$[15] ($\sim$ 0.04 Å). On adding the difference between the covalent radii of bromine and chlorine to the Hg—Cl(bridge) bond lengths,[15] the expected values for the present Hg—Br(bridge) bond lengths are calculated as 2.77 and 2.81 Å, which are of the order of the observed Hg—Br(bridge) bond lengths and consequently support our results. The distance between the nitrogen of the NMe_2 group and mercury is 3.56 Å, which rules out any interaction between them. Thus the potentially bidentate telluroamines ligate with mercury(II) only through tellurium behaving as a monodentate ligand. The distance between two mercury atoms is 3.82 Å, ruling out the possibility of any interaction between them.

KINETICS AND MECHANISM OF LIGAND EXCHANGE REACTIONS OF THE METHYLBIS(DIMETHYLGLYOXIMATO)RHODIUM(III) COMPLEX IN NON-COORDINATING SOLVENT

R. DREOS GARLATTI* and G. TAUZHER

Dipartimento di Scienze Chimiche, Università degli Studi di Trieste, P. le Europa 1, 34127 Trieste, Italy

(*Received* 17 *January* 1990; *accepted* 22 *March* 1990)

Abstract—Axial ligand exchange reactions of the methylbis(dimethylglyoximato) rhodium(III) complex were studied in dichloromethane. When exchanging ligands have similar dissociation rate constants, reactions do not go to completion in the presence of an excess of added leaving ligand. Kinetic results for the examined reactions are fully consistent with a *D* mechanism, where the five-coordinate intermediate reacts at approximately the same rate with all the incoming ligands.

We have previously studied both the anation and the hydrolysis reactions of alkylbis(dimethylglyoximato)rhodium(III) complexes (organorhodoximes) in aqueous solution.[1–3]

A first indication that a dissociative activation process is operative for these reactions comes from the relative independence of the anation rate constants of the nature of the entering ligand.[1] This suggestion is further supported by the parallel lability trend in the anation reactions of organorhodoximes and organocobaloximes,[3] the latter being known to undergo substitution through a dissociative mechanism.[4] As no kinetic evidence has been found for a five-coordinate intermediate, the mechanism was classified as I_d.[3]

On the other hand, it has been recognized for some time that establishing the stoichiometric mechanism of substitution reactions of octahedral complexes in aqueous solution, or more generally in coordinating solvents, is very difficult owing to the competition of the coordinating solvent itself.[5,6] In non-coordinating solvents this difficulty is removed, but some ambiguities still persist. If reactions proceed to completion both a *D* mechanism and an outer-sphere complexation mechanism, including pre-association with both entering and leaving ligand, lead to equivalent expressions of k_{obs}.[7–9]

In spite of this ambiguity, Marzilli *et al.* were able to prove that the axial substitution reactions of organocobaloximes in CH_2Cl_2 occur through a *D* mechanism[4,9]

$$\text{X—M—L} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{X—M} + \text{L} \qquad \text{Step 1}$$

$$\text{X—M} + \text{L}' \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \text{X—M—L}' \qquad \text{Step 2}$$

Scheme 1.

where M represents the central metal ion with the equatorial ligands and X is the non-labile axial group.

The steady-state treatment for X—M leads to the relationship

$$k_{obs} = \frac{k_1 + k_{-2}k_{-1}[L]/k_2[L']}{1 + k_{-1}[L]/k_2[L']}, \qquad (1)$$

which reduces to

$$k_{obs} = \frac{k_1}{1 + k_{-1}[L]/k_2[L']} \qquad (2)$$

if the reaction proceeds to completion, that is if the reverse reaction of Step 2 is neglected.

In the present work we report a kinetic study

of the substitution reactions of the methyl-bis(dimethylglyoximato)rhodium(III) complex in dichloromethane and show that a *D* mechanism is fully consistent with the kinetic results.

EXPERIMENTAL

Preparation of complexes

The $CH_3Rh(DH)_2L$ complexes, where L = pyridine (py), tetramethylthiourea (tmtu), triphenylphosphine (PPh_3), N-methylimidazole (NCH_3im), were prepared from $CH_3Rh(DH)(DH_2)I$, whose synthesis has been previously described.[3] 0.2 g of this complex were dissolved in the least volume of methanol and a stoichiometric amount of $AgNO_3$ was added. The resulting precipitate of AgI was filtered off and a slight excess of the appropriate ligand or of its methanolic solution, if solid, was added to the clear solution. The volume was reduced in a rotary evaporator until precipitation began. Crystals of the desired products were obtained by allowing the solution to stand. $CH_3Rh(DH)_2py$: Found: C, 38.1; H, 5.0; N, 16.2. Calc. for $C_{14}H_{22}N_5O_4Rh$: C, 39.3; H, 5.2; N, 16.4%. $CH_3Rh(DH)_2tmtu$: Found: C, 36.5; H, 6.5; N, 18.2. Calc. for $C_{14}H_{19}N_5O_4RhS$: C, 34.9; H, 6.1; N, 17.5%. $CH_3Rh(DH)_2PPh_3$: Found: C, 50.3; H, 4.6; N, 9.1. Calc. for $C_{27}H_{32}N_4O_4PRh$: C, 53.1; H, 5.3; N, 9.2%. $CH_3Rh(DH)_2NCH_3im$: Found: C, 36.1; H, 5.4; N, 19.6. Calc. for $C_{15}H_{23}N_6O_4Rh$: C, 36.2; H, 5.6; N, 19.5%.

If ligand L was added directly to a methanolic solution of $CH_3Rh(DH)(DH_2)I$, without previous treatment with $AgNO_3$, compounds were obtained whose analytical composition corresponds to $CH_3Rh(DH)(DH_2)L^+I^-$. $CH_3Rh(DH)(DH_2)py^+I^-$: Found: C, 29.0; H, 4.2; N, 12.4. Calc. for $C_{14}H_{23}N_5O_4IRh$: C, 30.3; H, 4.2; N, 12.6%. $CH_3Rh(DH)(DH_2)tmtu^+I^-$: Found: C, 26.0; H, 4.6; N, 13.2. Calc. for $C_{14}H_{20}N_6O_4IRhS$: C, 27.6; H, 5.0; N, 13.8%. $CH_3Rh(DH)(DH_2)PPh_3^+I^-$: Found: C, 41.8; H, 4.4; N, 7.3. Calc. for $C_{27}H_{33}N_4O_4IPRh$: C, 43.9; H, 4.5; N, 7.6%.

As the yields of the above reported syntheses were rather poor and the products very soluble, no recrystallization has been attempted. The discrepancies between the calculated and found elemental analyses are likely to be due to the presence of absorbed impurities.

Reagents

Triphenylphosphine was recrystallized from diethyl ether. All other materials were reagent grade and used without further purification.

Kinetic measurements

Ligand substitution reactions were followed spectrophotometrically in the range 350–450 nm using a Perkin–Elmer Lambda 5 spectrophotometer for the slower reactions and a Hi Tech SF3 series stopped-flow apparatus for the faster reactions.

Kinetic runs were carried out under a pseudo-first-order excess of entering ligand, with L′ concentrations ranging from 4×10^{-3} to 5×10^{-1} M. Generally, $2\text{–}4\times10^{-4}$ M solutions of complex were used.

The same concentration range was used in competition experiments, where a pseudo-first-order excess of both incoming and leaving ligand was present. The highest accessible [L]/[L′] ratio was determined by the requirement that reactions remain within a conveniently observable range of velocities and that spectral variation, which decreases at high [L]/[L′] for equilibrium reactions, does not become too small.

Data analysis

The computer program used for the non-linear least-squares analysis was the Statistical Package for Social Sciences, Version 9.0 (Vogelback Computing Center, Northwestern University, U.S.A.).

RESULTS

The axial ligand exchange reactions

$$CH_3Rh(DH)_2L+L' \rightleftharpoons CH_3Rh(DH)_2L'+L \quad (3)$$

were studied at 25°C, in a non-coordinating solvent (CH_2Cl_2) under a pseudo-first-order excess of entering ligand (L′). The observed rate constants were obtained from the linear plots of $\log(A_t-A_\infty)$ vs time.

In a first series of experiments, carried out without added leaving ligand, the k_{obs} values were independent of the concentration of the incoming ligand

$$k_{obs} = a. \quad (4)$$

The values of a so obtained are reported in Table 1. It can be noted that the k_{obs} values for the dissociation of py in reactions with PPh_3 and NCH_3im are very similar.

In a second series of experiments, performed in the presence of an excess of both entering and leaving ligand, at various [L]/[L′] ratios, different results were obtained depending on the chemical identity of the exchanging ligands.

Table 1. Kinetic parameters for exchange reactions of $CH_3Rh(DH)_2L$ with L′ in CH_2Cl_2 at 25°C

L	L′	$a = k_1$ (s^{-1})	$b = k_{-1}k_{-2}/k_2$ (s^{-1})	$c = k_{-1}/k_2$	$b/c = k_{-2}$ (s^{-1})
tmtu	PPh_3	$(4.6\pm0.2)\ 10^{-1}$ [a] $4.7\ 10^{-1}$ [b]		0.9 ± 0.1	
py	PPh_3	$(3.3\pm0.1)\ 10^{-2}$ [a] $2.9\ 10^{-2}$ [b]		1.1 ± 0.1	
py	NCH_3im	$(3.10\pm0.05)\ 10^{-2}$ [a] $3.07\ 10^{-2}$ [b]		0.8 ± 0.1	
NCH_3im	PPh_3	$(3.07\pm0.05)\ 10^{-3}$ [a] $3.07\ 10^{-3}$ [b]	$(1.5\pm0.4)\ 10^{-3}$	1.8 ± 0.3	$(8\pm3)\ 10^{-4}$ [c]
PPh_3	NCH_3im	$(6.34\pm0.05)\ 10^{-4}$ [a] $6.7\ 10^{-4}$ [b]	$(2.1\pm0.6)\ 10^{-3}$	0.6 ± 0.3	$(3.5\pm2.0)\ 10^{-3}$ [c]

[a] Extrapolated from plot of k_{obs} vs [L]/[L′].

[b] Measured in experiments without added leaving ligand. The values reported are the mean of at least three independent determinations performed at various concentrations of entering ligand.

[c] The relatively high uncertainty of this value arises from propagation of errors of b and c, which are inherently large.

(i) For L = py or tmtu and L′ = Ph_3P, and for L = py and L′ = NCH_3im an inverse dependence of k_{obs} on [L]/[L′] is observed (Fig. 1), which is consistent with the expression

$$k_{obs} = \frac{a}{1+c[L]/[L']}. \qquad (5)$$

A plot of $1/k_{obs}$ vs [L]/[L′] is linear and allows calculation of a and c. The values reported in Table 1 have been calculated by a non-linear least-squares analysis on the basis of these preliminary estimates.

(ii) For L = NCH_3im and L′ = PPh_3, k_{obs} still decreases with [L]/[L′]. The kinetic data are consistent with a rate law for which k_{obs} can be expressed as

$$k_{obs} = \frac{a+b[L]/[L']}{1+c[L]/[L']}. \qquad (6)$$

A linear relationship was found between $1/(a-k_{obs})$ and [L′]/[L] from which a, b and c can be calculated. These values were used as preliminary estimates in the calculation of a, b and c performed by a non-linear least-squares analysis.

(iii) For L = PPh_3 and L′ = NCH_3im, k_{obs} increases almost linearly over the range of examined [L]/[L′], but some deviations are evident at the highest [L]/[L′] ratios (Fig. 2). The kinetic data are still in accord with eq. (6). Preliminary estimates of a, b and c were obtained from the linear plots of $1/(k_{obs}-a)$ vs [L′]/[L].

Values of a, b and c are summarized in Table 1.

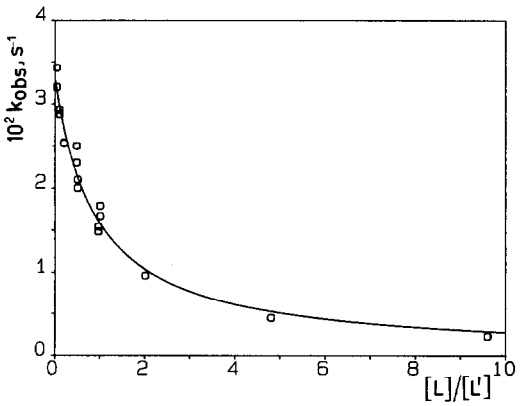

Fig. 1. Dependence of k_{obs} on [L]/[L′] for the reaction between $CH_3Rh(DH)_2py$ and PPh_3. The solid line is calculated from eq. (1) and the parameters contained in Table 1.

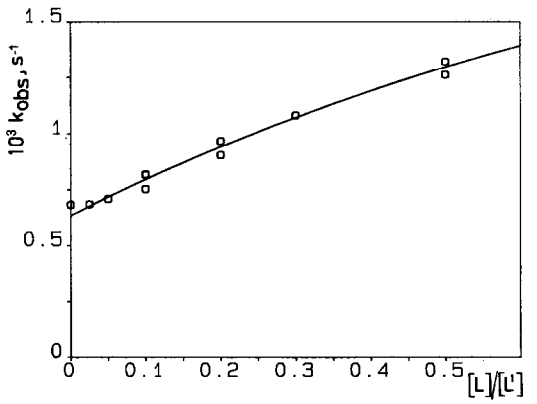

Fig. 2. Dependence of k_{obs} on [L]/[L′] for the reaction between $CH_3Rh(DH)_2PPh_3$ and NCH_3im. The solid line is calculated from eq. (4) and the parameters contained in Table 1.

DISCUSSION

In the present case, Scheme 1 and the related expression of k_{obs} [eq. (1)] are consistent with all the above kinetic results, with $a = k_1$, $b = k_{-2}k_{-1}/k_2$ and $c = k_{-1}/k_2$.

When the experiments are performed without addition of leaving ligand, [L]/[L'] is about zero, so that kinetics follow a pseudo-first-order rate law until near completion, when the release of L by the complex could cause deviations. In these conditions k_{obs} reduces to k_1, according to the experimentally found expression (4).

When the reactions are carried out in the presence of an excess of both entering and leaving ligand, the reverse reaction of Step 2 may become relevant. It can be predicted that the term $k_{-2}k_{-1}$[L]/k_2[L'] in the numerator of eq. (1) will not be negligible at high [L]/[L'] values or, even at relatively low [L]/[L'], when the exchanging ligands are of comparable strength ($k_{-1}k_{-2}/k_1k_2$ is not very different from 1). For the ligands reported in Table 1 k_{-1}/k_2 is never far from 1, which implies that the five-coordinate intermediate reacts at approximately the same rate with all the examined incoming ligands. As the reactions were performed at relatively low [L]/[L'] ratios the reverse reaction will not be negligible only when k_1 and k_{-2}, that is the dissociation rates of L and L' from the complex have comparable values. It appears from the data of Table 1 that NCH_3im dissociates from the complex only about five times faster than PPh_3, so that the reverse reaction should become relevant even at low [L]/[L']. Actually, for the exchange reaction between L = NCH_3im and L' = PPh_3 the experimental expression of k_{obs} [eq. (6)] agrees completely with the expression of k_{obs} calculated by taking into account the reverse reaction of Step 2 [eq. (1)].

It should be noted that, if the reaction does not proceed to completion, addition of an excess of leaving ligand may cause either a deceleration or an acceleration in the substitution rate. More quantitatively, eq. (1) indicates that if k_{-2}/k_1 is less than 1, as in the exchange between L = NCH_3im and L' = PPh_3, a rate retardation will be observed when an excess of leaving ligand is present in solution. When k_{-2}/k_1 is greater than 1 an acceleration will be observed if an excess of leaving ligand is present in solution. This actually occurs in the reaction between $CH_3Rh(DH)_2PPh_3$ and NCH_3im. The almost linear dependence of k_{obs} on [L]/[L'] (Fig. 2) is in accord with the fact that at a sufficiently low [L]/[L'] ratio the term k_{-1}[L]/k_2[L'] in the denominator of eq. (1) becomes negligible.

If the reverse reaction of Step 2 can be neglected, as occurs if $k_1 \gg k_{-2}$, k_{obs} reduces to eq. (2), which is in complete agreement with the empirical rate expression found for L = py or tmtu and L' = PPh_3, and for L = py and L' = NCH_3im [eq. (5)]. For these ligands the dissociation rate constant of L is at least ten times that of L' (Table 1).

The consistency of the proposed scheme can be verified in several ways by the agreement between the values of kinetic constants relative to the same process calculated from data obtained in different exchange reactions.

First of all, the dissociation rate constants experimentally measured in the reactions carried out without added leaving ligand agree very well with those extrapolated from the plots of k_{obs} vs [L]/[L'] (Table 1).

Furthermore, when the reactions do not go to completion, the dissociation rate constant of L' can be calculated as $k_{-2} = b/c$ and compared with that directly measured. For the examined complexes, the dissociation rate constant of PPh_3 may be calculated as k_{-2} from data relative to the reaction between $CH_3Rh(DH)_2NCH_3im$ and PPh_3 and that of NCH_3im from data relative to the reaction between $CH_3Rh(DH)_2PPh_3$ and NCH_3im. The calculated values are in reasonable accord with the k_1 values measured in the dissociation reactions of $CH_3Rh(DH)_2PPh_3$ and $CH_3Rh(DH)_2NCH_3im$, respectively (Table 1).

Internal checks are also possible for the k_{-1}/k_2 values, as the value for the reaction between $CH_3Rh(DH)_2L$ and L' should be the inverse of that for the reaction between $CH_3Rh(DH)_2L'$ and L. This relationship is satisfactorily verified when the exchanging ligands are NCH_3im and PPh_3.

Finally, a sufficient agreement, in the limits of experimental errors, is obtained between the k_{-1}/k_2 value directly obtained from the reaction between $CH_3Rh(DH)_2py$ and NCH_3im (1.8 ± 0.3) and that calculated as the ratio of the k_{-1}/k_2 values obtained for the exchange reactions between L = py and L' = PPh_3 and between L = NCH_3im and L' = PPh_3 (1.4 ± 0.2).

On the basis of the above considerations it seems quite reasonable to assume that ligand exchange reactions of $CH_3Rh(DH)_2L$ in non-coordinating solvent occur via a *D* mechanism. The independence of k_1 of both concentration and nature of the entering ligand, indicating that dissociation of L is the rate-determining step, and the k_{-1}/k_2 ratios being very close to 1, suggesting the formation of a five-coordinate intermediate, are both in accordance with a *D* process.

An interchange mechanism including pre-association with both entering and leaving ligand has been ruled out because the related k_{obs} expression[7-9] becomes independent of entering

ligand only when virtually all the substrate or the product are present in the associated form, and no evidence has been found for such extensive aggregation.

Previous extensive studies on the analogous $RCo(DH)_2L$ complexes led to the conclusion that the ligand exchange process in non-coordinating solvents is dissociative.[4,9] Furthermore, for these complexes it was evidenced that the dissociation rate increases with decreasing basicity and with increasing steric bulk of the leaving ligand.[4] The relatively small number of data in Table 1 does not allow us to draw similar conclusions for $CH_3Rh(DH)_2L$; however, the low dissociation rate of PPh_3 appears somewhat surprising, as in the analogous cobalt complexes PPh_3 dissociates about five times faster than py,[4] due to its lower basicity and greater steric bulk. The remarkable inertness of the phosphorus ligand in the rhodium complex could suggest that the electronic and steric properties of L may affect the dissociation rate in cobalt and rhodium complexes in different ways. Further studies are in progress to elucidate this point.

(*Received* 8 *November* 1989; *accepted* 26 *March* 1990)

Abstract—The synthesis and characterization of the salts of $[M(S_2C_2(CN)_2)_2]^{2-}$ (where M = Ni, Pd and Pt) with small counter cations is described. The solid-state electronic spectra of the salts indicate some degree of interaction which is cation dependent. The crystal structure of $Rb_2[Ni(S_2C_2(CN)_2)_2]\cdot H_2O$ shows the anions to be well separated with no S···S contacts of less than 4 Å.

Recent studies on the structures and properties of metal dithiolene monoanions have revealed important differences between compounds containing bulky cations such as Et_4N^+ and those containing the relatively small Group 1 cations.[1] In the latter compounds extensive cooperative phenomena may be observed but in the former compounds the presence of the bulky counter ions prevents long range interactions between the anions and only intradimer interactions are observed. Previous structural studies on $[M(S_2C_2(CN)_2)_2]^{2-}$ (where M = Ni, Pd or Pt) dianion salts have been restricted to the salts of the bulky cations $[N(CH_3)_4]^+$ and $[N(C_4H_9)_4]^+$.[2,3] We now report an extensive series of studies of the dianion salts of $[M(S_2C_2(CN)_2)_2]$ (where M = Ni, Pd or Pt) containing the relatively small cations of Group I and Group II.

EXPERIMENTAL

Preparation of the bis(1,2-dicyanoethylene-1,2-dithiolato)nickelate(2−) dianion salts

Preparation of $(NH_4)_2[Ni(S_2C_2(CN)_2)_2]\cdot 2H_2O$. An aqueous solution of $NiCl_2\cdot 6H_2O$ (2.40 g, 20 cm^3) was added to an aqueous solution of $Na_2S_2C_2(CN)_2$ (3.72 g, 20 cm^3). The solution was stirred for 5 min and filtered. To the filtrate was added NH_4Cl (4.0 g) to yield, on agitation, a red crystalline product (4.14 g, 100%).[4] The product was filtered off, washed with distilled water (1–2 cm^3) and dried *in vacuo* at 30°C. ^1H NMR (acetone

* Author to whom correspondence should be addressed.

d_6): 8.02 (N—*H*, very broad) also a shoulder ≈ 5 (O—*H*). Found: C, 23.2; H, 3.2; N, 20.0. Calc. for $C_8H_{12}N_6NiO_2S_4$: C, 23.4; H, 2.9; N, 20.4%.

Preparation of $Rb_2[Ni(S_2C_2(CN)_2)_2]\cdot 1.5H_2O$. An aqueous solution of $(NH_4)_2[Ni(S_2C_2(CN)_2)_2]\cdot 2H_2O$ (1.0 g, 15 cm^3) was filtered and to the filtrate was added a saturated solution of RbCl (0.96 g, 5 cm^3). The red precipitate which formed immediately was filtered off, washed with distilled water (1 cm^3) and dried *in vacuo* at 42°C. The product was collected and recrystallized from hot water to yield large red single crystals of $Rb_2[Ni(S_2C_2(CN)_2)_2]\cdot 1.5H_2O$, one of which was selected for a crystal structure determination. Found: C, 17.8; H, 0.49; N, 10.7. Calc. for $C_8H_3N_4NiO_{1.5}Rb_2S_4$: C, 17.9; H, 0.56; N, 10.4%.

Preparation of $Mg[Ni(S_2C_2(CN)_2)_2]\cdot 6H_2O$. A solution of $[N(C_2H_5)_4]_2[Ni(S_2C_2(CN)_2)_2]$ (1.0 g, 250 cm^3) in 70% acetone–water was eluted through a cationic exchange column Dowex 50W-X8 in the acid form. The elutant was passed into a suspension of MgO (0.11 g) under a nitrogen atmosphere. The mixture was filtered and the filtrate rotary evaporated to dryness. The product was dried *in vacuo* overnight at 52°C to give the red product $Mg(Ni(S_2C_2(CN)_2)_2]\cdot 6H_2O$. Found: C, 20.5; H, 2.1; N, 10.6. Calc. for $C_8H_{12}MgN_4NiO_6S_4$: C, 20.4; H, 2.6; N, 11.9%.

Preparation of $K_2[Ni(S_2C_2(CN)_2)_2]\cdot 2.5H_2O$. $K_2[Ni(S_2C_2(CN)_2)_2]\cdot 2.5H_2O$ was prepared using KCl in a similar manner to that used to prepare $Rb_2[Ni(S_2C_2(CN)_2)_2]\cdot 1.5H_2O$. Found: C, 21.0; H, 1.1; N, 11.9. Calc. for $C_8H_5K_2N_4NiO_{2.5}S_4$: C, 20.8; H, 1.2; N, 12.1%.

Preparation of $Cs_2[Ni(S_2C_2(CN)_2)_2]\cdot 2H_2O$. $Cs_2[Ni(S_2C_2(CN)_2)_2]\cdot 2H_2O$ was prepared using CsCl in a similar manner to that used to prepare $Rb_2[Ni(S_2C_2(CN)_2)_2]\cdot 1.5H_2O$. Found: C, 14.7; H, 0.30; N, 8.6. Calc. for $C_8H_4Cs_2N_4NiO_2S_4$: C, 15.0; H, 0.63; N, 8.7%.

Preparation of the bis(1,2-*dicyanoethylene*-1,2-*dithiolato*)*palladate*(2−) *dianion salts*

Preparation of $(NH_4)_2[Pd(S_2C_2(CN)_2)_2]\cdot 0.5H_2O$. An aqueous suspension of $PdCl_2$ (0.59 g, 50 cm^3) in deaerated water was stirred under nitrogen for 72 h. To this suspension was added $Na_2S_2C_2(CN)_2$ (1.86 g) under nitrogen and the solution was stirred for a further period of 24 h. The solution was filtered and a deaerated aqueous solution of NH_4Cl (2.0 g, 20 cm^3) was added to the filtrate. After stirring for 5–10 min the product was filtered off and washed with chilled water (5 cm^3). The product was obtained in high yields and purity after drying *in vacuo* overnight at 42°C. The yields can be increased to near 100% by stirring for longer periods prior to the addition of $Na_2S_2C_2(CN)_2$. ^1H NMR (acetone d_6): s, 7.31 and 3.76, N—*H* and O—*H*, respectively. Found: C, 23.1; H, 2.5; N, 20.1. Calc. for $C_8H_9N_6O_{0.5}PdS_4$: C, 22.2; H, 2.1; N, 19.5%.

Preparation of $Li_2[Pd(S_2C_2(CN)_2)_2]\cdot 3H_2O$. A deaerated aqueous solution of $(NH_4)_2[Pd(S_2C_2(CN)_2)_2]\cdot 0.5H_2O$ (0.70 g, 100 cm^3) was passed down a column of Dowex 50W-X8 cationic exchange resin (in acid form) under nitrogen. The acid, $H_2[Pd(S_2C_2(CN)_2)_2]$, was neutralized with an aqueous solution of $LiOH\cdot H_2O$ (0.14 g, 5 cm^3), filtered and evaporated to dryness, to yield a dark green product after drying *in vacuo* for 24 h. Found: C, 21.0; H, 1.4; N, 11.9. Calc. for $C_8H_6Li_2N_4O_3PdS_4$: C, 21.0; H, 1.3; N, 12.3%.

Preparation of $Na_2[Pd(S_2C_2(CN)_2)_2]\cdot 2H_2O$. $Na_2[Pd(S_2C_2(CN)_2)_2]\cdot 2H_2O$ was prepared according to the following procedure of Haller.[5] $PdCl_2$ (1.0 g) was added to an aqueous solution of $Na_2S_2C_2(CN)_2$ (2.15 g, 100 cm^3) in deaerated water under nitrogen. The product was obtained in high purity by rotary evaporation at 35°C and drying *in vacuo* at 46°C for 48 h. Found: C, 20.6; H, 0.70; N, 12.2. Calc. for $C_8H_4N_4Na_2O_2PdS_4$: C, 20.5; H, 0.86; N, 11.9%.

Preparation of $K_2[Pd(S_2C_2(CN)_2)_2]\cdot H_2O$. KCl (1.0 g) was added to a filtered aqueous solution of $(NH_4)_2[Pd(S_2C_2(CN)_2)_2]\cdot 0.5H_2O$ (1.0 g, 45 cm^3) producing a light green precipitate of $K_2[Pd(S_2C_2(CN)_2)_2]\cdot H_2O$. The product was collected by filtration and washed with chilled water (5 cm^3) and dried *in vacuo* for 24 h. Found: C, 20.0; H, 0.64; N, 12.3. Calc. for $C_8H_2K_2N_4O_2PdS_4$: C, 19.9; H, 0.42; N, 11.6%.

Preparation of $Rb_2[Pd(S_2C_2(CN)_2)_2]\cdot 2H_2O$. $Rb_2[Pd(S_2C_2(CN)_2)_2]\cdot 2H_2O$ was prepared using RbCl in a similar manner to that used to prepare $K_2[Pd(S_2C_2(CN)_2)_2]\cdot H_2O$. Found: C, 15.9; H, 0.74; N, 8.7. Calc. for $C_8H_4N_4O_2PdRb_2S_4$: C, 16.2; H, 0.68; N, 9.4%.

Preparation of $Cs_2[Pd(S_2C_2(CN)_2)_2]\cdot H_2O$. $Cs_2[Pd(S_2C_2(CN)_2)_2]\cdot H_2O$ was prepared using CsCl in a similar manner to that used to prepare $K_2[Pd(S_2C_2(CN)_2)_2]\cdot H_2O$. Found: C, 14.6; H, 0.20; N, 8.4. Calc. for $C_8H_2Cs_2N_4OPdS_4$: C, 14.3; H, 0.30; N, 8.3%.

Preparation of the bis(1,2-*dicyanoethylene*-1,2-*dithiolato*)*palladate*(2−) *dianion salts with the alkaline earth counter cations* $M = Ca^{2+}$, Sr^{2+} *and* Ba^{2+}

The Ca^{2+}, Sr^{2+} and Ba^{2+} dianion salts were prepared in a similar manner to that used to prepare

$Li_2[Pd(S_2C_2(CN)_2)_2]\cdot 3H_2O$ by neutralizing the acid $H_2[Pd(S_2C_2(CN)_2)_2]$ with either the appropriate metal hydroxide or carbonate.

M = Ca^{2+}; Found: C, 21.7; H, 1.2; N, 12.0. Calc. for $C_8H_2CaN_4OPdS_4$: C, 21.6; H, 0.45; N, 12.6%.

M = Sr^{2+}; Found: C, 18.4; H, 1.7; N, 10.8. Calc. for $C_8H_6N_4O_3PdS_4Sr$: C, 18.4; H, 1.1; N, 10.6%.

M = Ba^{2+}; Found: C, 18.1; H, 0.37; N, 10.6. Calc. for $C_8H_2BaN_4OPdS_4$: C, 17.7; H, 0.37; N, 10.3%.

Preparation of the bis(1,2-dicyanoethylene-1,2-dithiolato)platinate(2−) dianion salts

Preparation of $(NH_4)_2[Pt(S_2C_2(CN)_2)_2]\cdot 2H_2O$. A filtered, aqueous solution of $K_2[PtCl_4]$ (4.15 g, 40 cm^3) was added dropwise to an aqueous solution of $Na_2S_2C_2(CN)_2$ (3.72 g, 20 cm^3) and the solution stirred for 5 min and then filtered. To the filtrate was added NH_4Cl (4.0 g) and the $(NH_4)_2[Pt(S_2C_2(CN)_2)_2]\cdot 2H_2O$ precipitated as dark red crystals which were filtered off and washed with a little chilled water (3 cm^3). The product was dried *in vacuo* at 40°C (yield 85%). ^1H NMR (acetone d_6): 7.46 (N—*H*, very broad) and 4.36 (O—*H*, very broad). Found: C, 17.4; H, 2.1; N, 14.4. Calc. for $C_8H_{12}N_6O_2PtS_4$: C, 17.5; H, 2.2; N, 15.3%.

Preparation of $K_2[Pt(S_2C_2(CN)_2)_2]\cdot 2H_2O$ *and* $Rb_2[Pt(S_2C_2(CN)_2)_2]\cdot H_2O$. $K_2[Pt(S_2C_2(CN)_2)_2]\cdot 2H_2O$ and $Rb_2[Pt(S_2C_2(CN)_2)_2]\cdot H_2O$ were prepared using KCl or RbCl, respectively, in a similar manner to that used to prepare $Rb_2[Ni(S_2C_2(CN)_2)_2]\cdot 1.5H_2O$ as described earlier.

M = K^+; Found: C; 16.1; H, 0.90; N, 9.3. Calc. for $C_8H_4K_2N_4O_2PtS_4$: C, 16.3; H, 0.69; N, 9.2%.

M = Rb^+; Found: C, 14.6; H, 0.80; N, 8.1. Calc. for $C_8H_2N_4OPtRb_2S_4$: C, 14.5; H, 0.30; N, 8.4%.

Chemical analyses of the dianion salts suggest that these compounds have a variable degree of water of crystallization. Microanalysis was performed by Mr E. Lewis, using a Carlo Erba Strumentazione elemental analyser, Model 1106.

Reflectance spectra were recorded on powdered samples using a Beckman DK-2A ratio recording spectrophotometer fitted with a standard reflectance attachment. The reference material in all cases was Al_2O_3 and where necessary samples were diluted with Al_2O_3.

The solution spectra of the dianions were recorded on a Beckman DK-2A ratio recording spectrometer.

Electrical conduction measurements of single crystals of the ammonium salts were carried out as previously described.[6] Aquadag (colloidal graphite in water) was used as the contact material between the crystal and the 0.001 in. diameter gold wires. Unfortunately the small crystal size only permitted two probe conduction measurements to be made.

X-ray data collection and analysis of the structure of $Rb_2[Ni(S_2C_2(CN)_2)_2]\cdot H_2O$

A crystal for X-ray structure determination was cut from a large red crystal, $0.15\times 0.2\times 0.25$ mm.

Crystal data

$Rb_2[Ni(S_2C_2(CN)_2)_2]\cdot H_2O$, $M = 528.016$, orthorhombic, space group *Pbcn*, $a = 13.513(2)$, $b = 6.810(1)$, $c = 16.651(2)$ Å, $Z = 4$, $V = 1541.3$ Å^3, density: calc. 2.275 g cm^{-3}, found 2.270 g cm^{-3}.

All the X-ray diffraction intensities were measured on a Rigaku automatic four circle diffractometer, ω–2θ scan mode, using a graphite-monochromator, Mo-K_α radiation.*

RESULTS AND DISCUSSION

(1) *Crystal structure of* $Rb_2[Ni(S_2C_2(CN)_2)_2]\cdot H_2O$

The $[Ni(S_2C_2(CN)_2)_2]^{2-}$ anion is almost planar with average bond lengths of Ni—S 2.175 Å, S—C 1.738 Å and C—C 1.380 Å. The bond lengths and angles are in good agreement with those found for the dianion in the $[N(C_4H_9)_4]^+$ salt.[3] Selected intramolecular bond lengths and angles for $Rb_2[Ni(S_2C_2(CN)_2)_2]\cdot H_2O$ are given in Table 1.

The projection of the crystal structure down the *b*-axis is given in Fig. 1. It can be seen that the anions are arranged in columns along the *b*-direction of the unit cell. The equidistant intramolecular separation of ≈ 6.8 Å is almost twice the intra-stack separation found in the monoanion salt $NH_4[Ni$

* The total number of measured reflections was 3059 and independent reflections ($|F_o| > 3\sigma|F_o|$) 1183. The structure was solved by the usual heavy-atom method and refined by a block-diagonal least-squares method. Anisotropic thermal parameters were applied to all the atoms. Atomic scattering factors and anomalous scattering corrections were taken from *International Tables for X-ray Crystallography*.[7] The final *R* value was 0.077 and *R*w was 0.091. The weighting formula was $w = 1/(\sigma^2+0.01|F_o|)$, $|F_o| \geq 15.0$, $w = 1/(1.0+0.01|F_o|^2)$, $|F_o| < 15.0$. The absorption correction was not made due to the crystal's irregular shape. The fractional atomic coordinates are deposited. Calculations were carried out on a HITAC M680H computer at the Computer Centre of the University of Tokyo with a local version of UNICS.[8]

Table 1. Selected intramolecular bond lengths (Å) and angles (°)

Lengths		Angles	
Ni—S(1)	2.172(2)	S(1)—Ni—S(2)	92.19(10)

		S(2)—C(2)—C(4)	119.0(8)

$(S_2C_2(CN)_2)_2]\cdot H_2O$.[9] The dianion centred at $(\frac{1}{2}\,\frac{1}{2}\,0)$ penetrates between the anions forming these columns. Clearly there can be no interaction between the anions at these distances.

In a number of metal dithiolene complexes the columns of anions have been shown to pack together in an arrangement similar to that shown along *c* in Fig. 1 and this results in S—S contacts slightly shorter than the sum of the van der Waals' radii, thus allowing interactions between the columns of anions. Hoffmann and co-workers have discussed this arrangement in terms of minimizing the steric interaction of the lone pair of electrons on the sulphur atoms.[10] However, the separation of the columns in the *c*-direction in $Rb_2[Ni(S_2C_2(CN)_2)_2]\cdot H_2O$, is 8.4 Å, which is much greater than that commonly found in compounds of this type ($\approx$ 6.7 Å).[9]

In $Rb_2[Ni(S_2C_2(CN)_2)_2]\cdot H_2O$, therefore, there are no short S···S contacts and all intra-anion S···S contacts are greater than 4 Å. Thus clearly in the $Rb_2[Ni(S_2C_2(CN)_2)_2]\cdot H_2O$ salt the anions are completely isolated from one another. It was observed that the presence of small Group I cations in the monoanion series of salts of $[Ni(S_2C_2(CN)_2)_2]^-$ facilitated inter-anion interactions. The absence of any interaction between anions in the $[Ni(S_2C_2(CN)_2)_2]^{2-}$ salts is therefore not dependent upon the size of the cation but probably results from the absence of free spins in the HOMO in contrast to the one unpaired electron in the HOMO of the monoanion.

(2) *The reflectance spectra of the dianion salts*

The reflectance spectra of the bis(1,2-dicyanoethylene-1,2-dithiolato)nickelate(2−), palladate(2−) and platinate(2−) dianion salts were

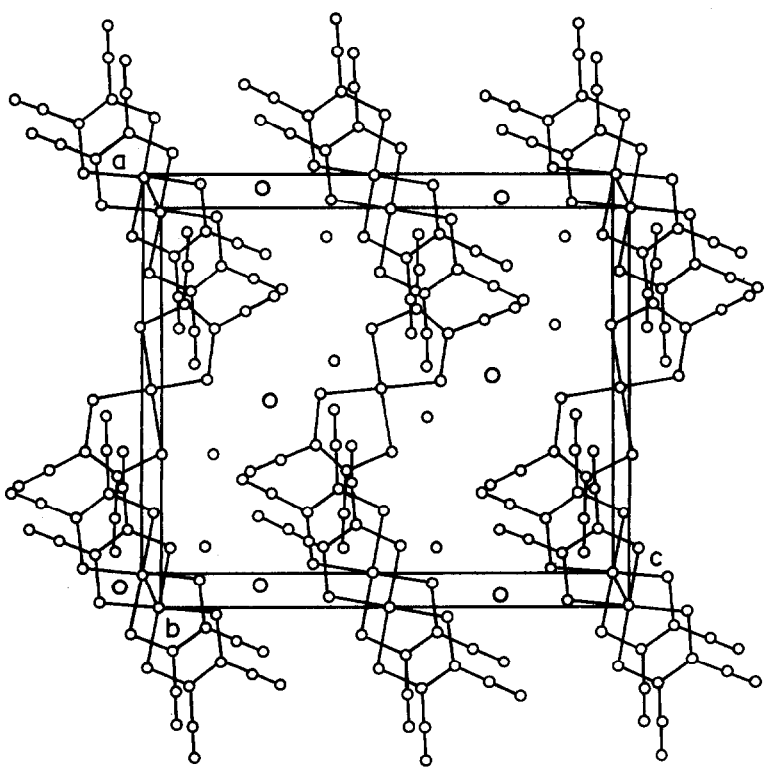

Fig. 1. The *b*-axis projection of $Rb_2[Ni(S_2C_2(CN)_2)_2]\cdot H_2O$.

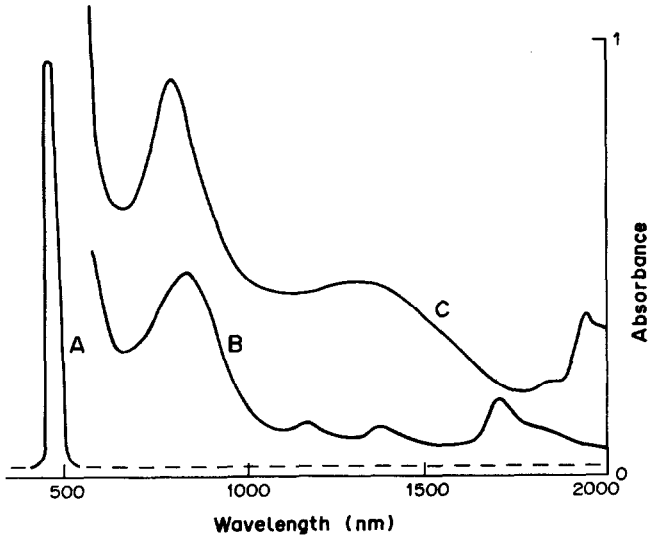

Fig. 2. (A) The UV–vis spectra in acetone of $(NH_4)_2[Ni(S_2C_2(CN)_2)_2]\cdot 2H_2O$ and reflectance spectra of (B) $[N(C_4H_9)_2]_2[Ni(S_2C_2(CN)_2)_2]$ and (C) $(NH_4)_2[Ni(S_2C_2(CN)_2)_2]\cdot 2H_2O$.

determined in order to establish whether or not the salts show evidence of interactions between the dianions in the solid state.

The UV–vis spectrum of an acetone solution of $(NH_4)_2[Ni(S_2C_2(CN)_2)_2]\cdot 2H_2O$ (A) is given together with the reflectance spectra $[N(C_4H_9)_4]_2[Ni(S_2C_2(CN)_2)_2]$ (B) and $(NH_4)_2[Ni(S_2C_2(CN)_2)_2]\cdot 2H_2O$ (C) in Fig. 2. The observed solution spectrum (λ_{max} 478 nm) is similar to that observed for an acetonitrile solution of $[N(C_2H_5)_4]_2[Ni(S_2C_2(CN)_2)_2]$ (λ_{max} 476 nm).[11] The solution spectrum of $[N(C_4H_9)_4]_2[Pd(S_2C_2(CN)_2)_2]$ (A) is compared with the reflectance spectra of $[N(C_4H_9)_4]_2[Pd(S_2C_2(CN)_2)_2]$ (B) and $(NH_4)_2[Pd(S_2C_2(CN)_2)_2]\cdot 0.5H_2O$ (C) in Fig. 3. Finally, the solution spectrum of $(NH_4)_2[Pt(S_2C_2(CN)_2)_2]\cdot 2H_2O$ (A) is compared with the reflectance spectra of $[N(C_2H_5)_4]_2[Pt(S_2C_2(CN)_2)_2]$ (B) and $Mg[Pt(S_2C_2(CN)_2)_2]\cdot xH_2O$ (C) in Fig. 4.

The overall intensity of the reflectance spectra of the dianion salts decreases in the approximate order $NH_4^+ > Rb^+ > K^+ > Cs^+ > [N(C_4H_9)_4]^+$ for

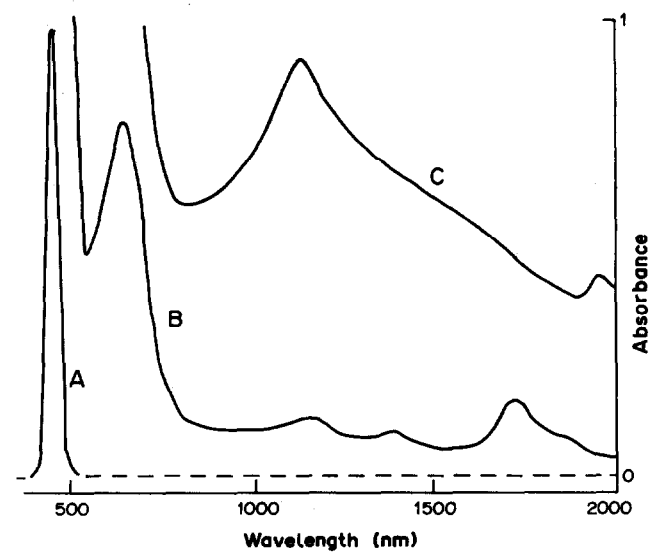

Fig. 3. The solution spectra of $[Pd(S_2C_2(CN)_2)_2]^{2-}$ (A) is compared with the reflectance spectra of $[N(C_4H_9)_4]_2[Pd(S_2C_2(CN)_2)_2]$ (B) and $(NH_4)_2[Pd(S_2C_2(CN)_2)_2]\cdot 0.5\ H_2O$ (C).

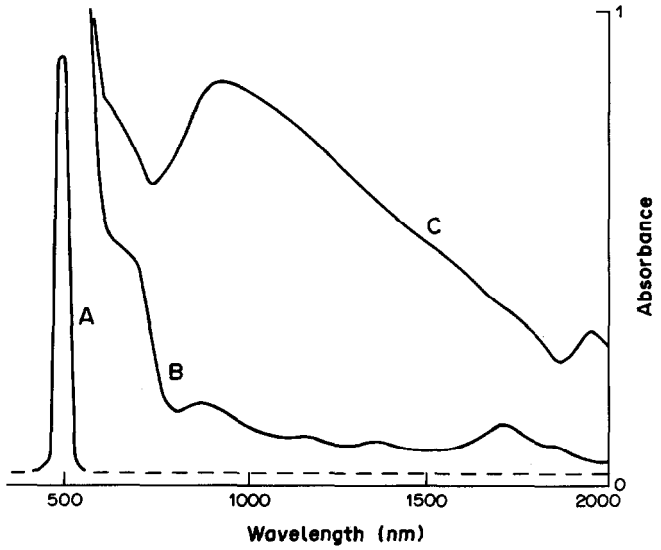

Fig. 4. The acetone solution spectra (A) and reflectance spectra of the $[Pt(S_2C_2(CN)_2)_2]^{2-}$ salts (B) = $[N(C_2H_5)_4]_2[Pt(S_2C_2(CN)_2)_2]$ and (C) = $Mg[Pt(S_2C_2(CN)_2)_2]\cdot xH_2O$.

the nickelate(2−) salts, $NH_4^+ > Ca^{2+} > Rb^+ > Cs^+ > [N(C_4H_9)_4]^+$ for the palladate(2−) salts and $Mg^{2+} > NH_4^+ > K^+ > Rb^+ > [N(C_2H_5)_4]^+$ for the platinate(2−) salts. The increased intensity of the reflectance spectra compared to the solution spectrum indicates that there is some degree of solid-state interactions in many of the dianion salts and that the extent of this effect is dependent on the cation. The salts of the large cation $[NR_4]^+$ always exhibit much lower intensities than those of the smaller cations with the NH_4^+ salts often being the most intense. It has been shown that $[Ni(S_2C_2(CN)_2)_2]^{2-}$ salts exhibit adsorptions at higher energies than most square-planar nickel complexes.[12] More recently Vogler and Kunkely[13] reported the reflectance spectra of $[Ni(tim)]^{2+}[M(S_2C_2(CN)_2)_2]^{2-}$ (tim = 2,3,9,10-tetramethyl-1,4,8,11-tetraazocyclotetradeca-1,3,8,10-tetracene, M = Ni^{2+}, Pd^{2+} and Pt^{2+}) and considered that the intense absorption band at 840 nm for the nickel complex was due to an outer-sphere ligand-to-ligand charge-transfer transition from the anion to the cation. However, the reflectance spectra of all the $[Ni(S_2C_2(CN)_2)_2]^{2-}$ dianion salts of small cations discussed here exhibit an intense broad band around 820–860 nm. The $[Pd(S_2C_2(CN)_2)_2]^{2-}$ and $[Pt(S_2C_2(CN)_2)_2]^{2-}$ salts exhibit a similar band from around 900 to 1500 nm. Since anion-to-cation charge-transfer would not be expected in this region for the cations present in these compounds it seems that the absorption must arise from some other source.

The electrical conductivity of single crystals of $(NH_4)_2[Pd(S_2C_2(CN)_2)_2]\cdot 0.5H_2O$ and $(NH_4)_2[Pt(S_2C_2(CN)_2)_2]\cdot 2H_2O$ salts at room temperature (see Table 2) are higher than those observed previously for compressed pellets of the dianion salts $[N(C_2H_5)_4]_2[Ni(S_2C_2(CN)_2)_2]$ ($< 10^{-12}\ \Omega^{-1}\ cm^{-1}$) and $[N(C_2H_5)_4]_2[Pt(S_2C_2(CN)_2)_2]$ ($< 10^{-10}\ \Omega^{-1}\ cm^{-1}$).[14] This observation is consistent, however, with the increased intensity of the reflectance spectra for the dianion salts with small counter cations,

Table 2. Electrical conductivity of single crystals

	σ_{RT} ($\Omega^{-1}\ cm^{-1}$)	Activation energy of the semiconductor (meV)
$(NH_4)_2[Pd(S_2C_2(CN)_2)_2]\cdot 0.5H_2O$	8×10^{-6}	280 (310–210 K)
$(NH_4)_2[Pt(S_2C_2(CN)_2)_2]\cdot 2H_2O$	7×10^{-8}	360 (310–210 K)

when compared to salts containing bulky counter cations.

(*Received* 29 *January* 1990; *accepted* 26 *March* 1990)

Abstract—Four novel copper(II) complexes of 4-hydroxy-6-methyl-3-[dimethylamino-acryloyl]-2H-pyran-2-one (Hacrp) have been isolated: $Cu(acrp)_2 \cdot 1/2KCl$, $Cu(acrp)_2(py) \cdot H_2O$, $Cu(acrp)(bipy)Cl \cdot H_2O$ and $Cu(acrp)(phen)Cl \cdot 2H_2O$ (acrp = monodeprotonated form of Hacrp; py = pyridine; bipy = 2,2′-bipyridine; phen = 1,10-phenanthroline). The crystal structures of Hacrp and $Cu(acrp)_2(py) \cdot H_2O$ have been determined. Hacrp is clearly a pyran-2-one molecule. The copper(II) ion is pentacoordinated, in a square-pyramidal stereochemistry, with py in the apical position; the acrp ligand is intermediate between the pyran-2-one form and the pyran-2,4-dione one. Both Hacrp and $Cu(acrp)_2(py) \cdot H_2O$ react with hydroxylamine hydrochloride in ethanol to give the novel molecule 8-hydroxy-5-oxo-7-methyl-5,8-dihydro-4H-pyrano[2,3-b]pyridin-4-one. Hacrp, in aqueous hydrochloric acid, transforms into 2,4-dihydroxyacetophenone. The same product has been obtained by reacting Hacrp and $CuCl_2 \cdot 2H_2O$ in water. Mechanisms for these reactions are proposed.

In the course of our studies on the structure and reactivity of pyrone derivatives and their complexes with metal ions,[1] we turned our attention to the 4-hydroxy-6-methyl-3-[3-dimethylaminoacryloyl]-2H-pyran-2-one (referred to as Hacrp). This molecule appears to be very promising because it presents a complicated set of tautomeric equilibria (see Scheme 1) and a presumably high reactivity (as well as most enamines) both of which could be influenced by interaction with metal ions.

Among the metal ions we choose copper(II) because many naturally occurring pyrone derivatives (i.e. flavonoids) are known to interact strongly, although in a still unknown way, with Cu^{2+} in several biological systems;[2] the study of the complexes between Cu^{2+} and pyrone derivatives could therefore provide useful information for understanding the biological interaction between flavonoids and copper ions. In the present paper we describe the synthesis and characterization of four novel copper(II) complexes of Hacrp: $Cu(acrp)_2 \cdot 1/2KCl$, $Cu(acrp)_2(py) \cdot H_2O$, $Cu(acrp)(bipy)Cl \cdot H_2O$ and $Cu(acrp)(phen)Cl \cdot 2H_2O$ (acrp = monodeprotonated form of Hacrp; py = pyridine; bipy = 2,2′-bipyridine; phen = 1,10-phenanthroline). The molecular structures of Hacrp and of $Cu(acrp)_2(py) \cdot H_2O$ have been determined in order to examine the effects of copper coordination to the ligand. Moreover, the hydrolysis of Hacrp

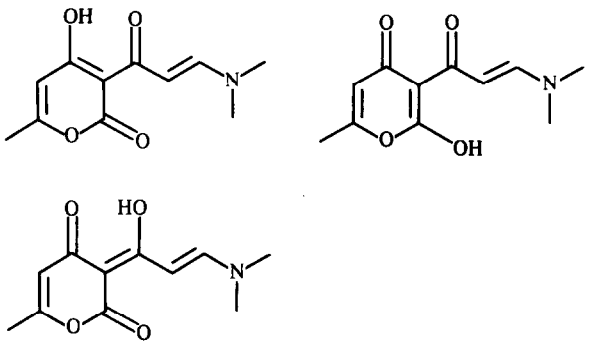

Scheme 1.

and its reaction with hydroxylamine, both in the absence and in the presence of copper(II), have been studied. The 2,4-dihydroxyacetophenone has been recovered by hydrolysing Hacrp in the presence of hydrochloric acid or $CuCl_2 \cdot 2H_2O$. A novel molecule, 8-hydroxy-5-oxo-7-methyl-5,8-dihydro-4H-pyrano[2,3-b]pyridin-4-one, has been obtained by reacting Hacrp or $Cu(acrp)_2(py) \cdot H_2O$ with hydroxylamine.

EXPERIMENTAL

Physicochemical measurements

IR spectra were recorded with a 1130 Perkin–Elmer spectrophotometer; electronic absorption spectra were obtained with a Varian Cary spectrophotometer; NMR spectra were recorded on a Bruker WP80SY spectrometer; and mass spectra were obtained with a Finnigan-MAT 8222 spectrometer. The deprotonation constant of Hacrp was determined using the Calvin–Wilson pH-titration technique,[3] in ethanol–water (1 : 1 v/v). An E366 Metrohm pH-meter equipped with a Metrohm glass electrode was used for pH measurements; the concentration of Hacrp was 1×10^{-4} M, temperature 25 ± 0.1°C and $I = 0.1$ M $NaClO_4$. The deprotonation constant of Hacrp in its first singlet excited state was calculated using the appropriate equation,[4] by observing that in ethanol–water (1 : 1 v/v) λ_{0-0} is 433 nm (in $HClO_4$ 0.1 M) and 480 nm (in KOH 0.05 M).

Synthesis of Hacrp

Hacrp was synthesized by literature methods.[5]

Synthesis of $Cu(acrp)_2 \cdot 1/2KCl$

$CuCl_2 \cdot 2H_2O$ (0.1 g) in 6 cm^3 of ethanol was added to an aqueous boiling solution of Hacrp (0.26 g) and KOH (0.065 g), and the mixture was refluxed for about 1 h. The dark green solid which separated at room temperature was filtered off, washed with ethanol and dried for 3 h at room temperature and 0.5 mm Hg. M.p. 260°C. Found: C, 48.7; H, 4.5; N, 5.1. Calc. for $C_{22}H_{24}Cl_{0.5}CuK_{0.5}N_2O_8$: C, 48.5; H, 4.4; N, 5.1%.

Synthesis of $Cu(acrp)_2(py) \cdot H_2O$

$Cu(acrp)_2 \cdot 1/2KCl$ (0.2 g) in 60 cm^3 of a mixture of pyridine and ethanol (1 : 1 v/v) were refluxed for about 1 h. By slowly concentrating the obtained solution, small dark green crystals precipitated in a few days. They were filtered, washed with ethanol, and dried for 3 h at room temperature and 0.5 mm Hg. M.p. 135–140°C. Found: C, 55.0; H, 5.1; N, 7.1. Calc. for $C_{27}H_{29}CuN_3O_8$: C, 55.2; H, 5.0; N, 7.2%.

Synthesis of $Cu(acrp)(bipy)Cl \cdot H_2O$

2,2′-Bipyridine (0.06 g) in 5 cm^3 of ethanol were added to a suspension of $Cu(acrp)_2 \cdot 1/2KCl$ (0.2 g) in 40 cm^3 of ethanol and refluxed for about 2 h, thus obtaining the dissolution of all the solid residue. By slowly evaporating the solvent, a green product was precipitated, filtered off and washed with ethanol and dried for 3 h at room temperature and 0.5 mm Hg. M.p. 240–250°C. Found: C, 51.2; H, 4.3; N, 8.5. Calc. for $C_{21}H_{22}ClCuN_3O_5$: C, 50.9; H, 4.5; N, 8.5%.

Synthesis of $Cu(acrp)(phen)Cl \cdot 2H_2O$

In the synthesis of $Cu(acrp)(phen)Cl \cdot 2H_2O$, the same procedure as described for Cu(acrp)(bipy) $Cl \cdot H_2O$ was used, using 1,10-phenanthroline instead of 2,2′-bipyridine. M.p. 190°C. Found: C, 51.3; H, 4.4; N, 7.6. Calc. for $C_{23}H_{24}ClCuN_3O_6$: C, 51.4; H, 4.5; N, 7.8%.

Synthesis of 8-*hydroxy*-5-*oxo*-7-*methyl*-5,8-*dihydro*-4H-*pyrano*[2,3-b]*pyridin*-4-*one*

(a) Hydroxylamine hydrochloride (0.03 g) and Hacrp (0.10 g) were dissolved in 50 cm^3 of ethanol, stirred at room temperature for 12 h. By slowly concentrating this solution, a yellow solid precipitated which was filtered off and dried at room temperature and 0.5 mm Hg for 3 h. Dec. point 245–248°C. Found: C, 55.8; H, 3.6; N, 7.2. Calc. for $C_9H_7NO_4$: C, 55.9; H, 3.6; N, 7.2%. Mass spectrum: M^+ 193. ^1H NMR (^6D-DMSO): 2.25 (d, 3H, $J = 0.5$ Hz, CH_3), 6.20 (d, 1H, $J = 0.5$ Hz,

6-H), 6.75 (d, 1H, $J = 5$ Hz) and 8.50 ppm (d, 1H, $J = 5$ Hz, CH=CH).

(b) By adding hydroxylamine hydrochloride (0.076 g) to a boiling suspension of $Cu(acrp)_2 \cdot 1/2KCl$ (0.15 g) in 30 cm^3 of ethanol, a clear solution was obtained and refluxed for about 1 h. By slowly evaporating the solvent, a yellow solid precipitated. This was collected and dried as described above and identified as 8-hydroxy-5-oxo-7-methyl-5,8-dihydro-4H-pyrano[2,3-b]pyridin-4-one.

Synthesis of (2,4-dihydroxyacetophenonato) copper(II)

$CuCl_2 \cdot 2H_2O$ (0.075 g) in 6 cm^3 of water was added to a boiling solution of Hacrp (0.20 g) in 20 cm^3 of water. The mixture was refluxed for 1 h and the green product obtained was filtered and dried at room temperature and 0.5 mm Hg for 3 h. Dec. point 240–250°C. Found: C, 44.7; H, 2.8. Calc. for $C_8H_6CuO_3$: C, 44.8; H, 2.8%.

Synthesis of 2,4-*dihydroxyacetophenone*

(a) Hacrp (0.5 g) in 20 cm^3 of water and 1 cm^3 of hydrochloric acid (37%), was refluxed for 1 h. The resulting solution was chromatographed on silica gel (70–230 mesh) with cyclohexane–ethyl acetate (7 : 3 v/v). 2,4-Dihydroxyacetophenone was obtained as a first fraction.

(b) A suspension of (2,4-dihydroxyacetophenonato)copper(II) (0.2 g) and KCN (0.14 g) in 40 cm^3 of ethanol was refluxed for 5 h and then filtered. By slowly concentrating the so obtained solution, crude 2,4-dihydroxyacetophenone was obtained, which was purified by chromatography as described above.

X-ray analysis of Hacrp

The specimen size was $0.10 \times 0.15 \times 0.25$ mm. All measurements were made at 18 ± 2°C with Cu-K_α radiation (1.5418 Å) using a CAD 4 diffractometer equipped with a graphite monochromator. All the calculations were performed with SDP software.[6]

Crystal data: $C_{11}H_{13}NO_4$; $M_r = 223.23$; orthorhombic; space group *Pnma*; $a = 12.652(1)$, $b = 6.775(1)$, $c = 12.907(1)$ Å; $U = 1106.3$ Å^3; $Z = 4$; $D_c = 1.340$ g cm^{-3}; $F(000) = 118$; μ(Cu-K_α) = 8.2 cm^{-1}.

The cell was determined by refining the angular parameters of 25 reflections with $50 < \theta < 55°$ automatically centred. The space group was determined from systematic absences and intensity statistics, and confirmed by the structure analysis. 1252 *hkl* reflections were measured for $2 < \theta < 70°$, with scan mode 3ω–2θ, scan speed 4.12° min^{-1} and scan width $(1.05 + 0.142 \operatorname{tg}\theta)°$; their intensities were corrected for Lorentz–polarization, decay (three standard reflections, maximum correction 17.8%) and absorption effects[7] (transmission minimum 90.28%; maximum 99.59%).

The structure was solved with MULTAN, by considering 1048 unique reflections (systematic absences rejected), and Fourier methods, by considering only 704 reflections [$I > 3\sigma(I)$]. The positions of the hydrogen atoms were calculated (C—H = 1.0 Å; the methylic ones were considered disordered), and their thermal parameters were taken proportionally ($\times 1.3$) to those of the bonded non-hydrogen atoms. All the non-hydrogen atoms were refined anisotropically with full-matrix least-squares, minimizing the function $[\Sigma w(F_o - F_c)^2 / \Sigma F_o^2]^{1/2}$, with $w = 959/F_o$ (for $F_o < 959$) and $w = F_o/959$ (for $F_o > 959$) being 959 one third of the largest F_o. The structure converged to a final $R = 7.6\%$ ($R_w = 8.2\%$).

An ORTEP view of the structure of Hacrp is reported in Fig. 1; bond distances and angles are reported in Tables 1 and 2.

X-ray analysis of $Cu(acrp)_2(py) \cdot H_2O$

The procedure was analogous to that above described for the X-ray analysis of Hacrp, with the following differences.

The specimen size was $0.06 \times 0.06 \times 0.08$ mm.

Crystal data: $C_{27}H_{29}CuN_3O_8$; $M_r = 587.09$; orthorhombic; space group *Pnna*; $a = 14.275(2)$, $b = 13.095(2)$, $c = 14.904(2)$ Å; $U = 2786.1$ Å^3; $Z = 4$; $D_c = 1.400$ g cm^{-3}; $F(000) = 305$; μ(Cu-K_α) = 15.2 cm^{-1}.

The cell was determined by refining the angular parameters of 22 reflections with $39 < \theta < 40°$. 2954 *hkl* reflections were measured for $2 < \theta < 70°$, with scan mode 3ω–4θ, scan speed 2.75° min^{-1}, scan width $(1.10 + 0.142 \operatorname{tg}\theta)°$. Maximum decay correction 3.5%. Transmission minimum 93.02%; maximum 99.97%

The structure was solved with MULTAN, by

using 2112 unique reflections [$I > 0.01\sigma(I)$], and Fourier methods, by using 1324 reflections [$I > 3\sigma(I)$]. Form factors with anomalous dispersion components were used.[8] The function minimized in full-matrix least-squares was $[\Sigma w(F_o - F_c)^2/\Sigma w F_o^2]^{1/2}$, with $w = \sigma^2 + 0.01F_o + 1.0$. The structure converged to a final $R = 6.5\%$ ($R_w = 7.5\%$).

An ORTEP view of the structure of the $Cu(acrp)_2(py)$ complex is reported in Fig. 2; bond distances and angles are reported in Tables 1 and 2.

RESULTS AND DISCUSSION

The aim of the present work was to study the influence of the complexation to copper(II) on the structure and the reactivity of Hacrp. The preliminary step was the synthesis of copper(II) complexes of Hacrp. By reacting this ligand and $CuCl_2\cdot 2H_2O$ in the presence of KOH, the complex $Cu(acrp)_2\cdot 1/2KCl$ was obtained, but it was impossible to grow crystals suitable for crystallographic studies. In order to overcome this problem, we reacted $Cu(acrp)_2\cdot 1/2KCl$ with some nitrogen heterocyclic bases [pyridine (py), 2,2′-bipyridine (bipy) and 1,10-phenanthroline (phen)], and three new complexes, formulated as $Cu(acrp)_2(py)\cdot H_2O$, $Cu(acrp)(bipy)Cl\cdot H_2O$ and $Cu(acrp)(phen)Cl\cdot 2H_2O$ on the basis of the analytical data, were obtained. A crystallographic study was possible only on the first complex (see below); in it, the pyridine ligand, although present in large excess during the synthesis (i.e. as solvent), does not replace any of the pyrone ligands. On the contrary, 2,2′-bypyridine and 1,10-phenanthroline, although used in stoichiometric amounts, replace one of the two pyrone ligands bonded to the metal.

In the IR spectra of the molecules here described the stretching of the pyrone carbonyl is the only band of sound diagnostic value. In the case of Hacrp, this band is found at 1705 cm^{-1}, indicating

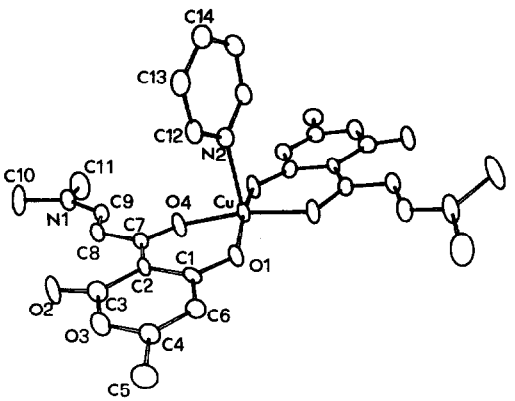

Fig. 2. ORTEP view of the $Cu(acrp)_2(py)$ complex.

that the heterocyclic ring is probably a pyran-2-one.[9] In the complexes $Cu(acrp)_2 \cdot 1/2KCl$ and $Cu(acrp)_2(py) \cdot H_2O$, the ν(C=O, pyrone) is slightly shifted to lower energy (1695 cm^{-1}) with respect to the free ligand. Such a small shift could easily depend on packing effects, and it agrees with the crystallographic data (see below) which show a lengthening of the pyrone carbonyl bond on passing from Hacrp [1.179(16) Å] to $Cu(acrp)_2(py) \cdot H_2O$ [1.209(8) Å]. In the complexes $Cu(acrp)(bipy)Cl \cdot H_2O$ and $Cu(acrp)(phen)Cl \cdot 2H_2O$, the ν(C=O, pyrone) is found at 1675 and 1670 cm^{-1}, respectively, thus quite greatly shifted to lower energy. A shift as large as 30–35 cm^{-1} could be justified by coordination of the pyrone carbonyl oxygen to the metal, or by isomerization of the heterocyclic ring from pyran-2-one to pyran-4-one; in fact, in pyran-4-ones, the carbonyl stretching is generally found at 1665–1670 cm^{-1}, and it is not greatly affected by the substituents on the ring.[9]

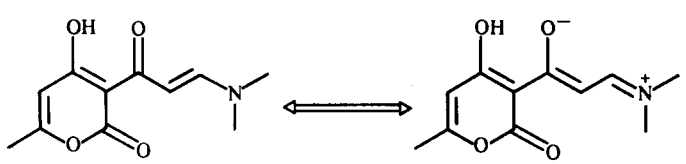
Also, the electronic absorption spectra show a significant difference between $Cu(acrp)_2 \cdot 1/2KCl$ and $Cu(acrp)_2(py) \cdot H_2O$ on one side, and $Cu(acrp)(bipy)Cl \cdot H_2O$ and $Cu(acrp)(phen)Cl \cdot 2H_2O$ on the other side. All the spectra are dominated by the intense bands of the ligands, whose tail probably hides the *d–d* copper(II) transitions at lower energy (the lower energy band of Hacrp in ethanol shows two maxima at 368.5 and 380.5 nm, with $\log \varepsilon$ 4.68 and 4.69, respectively). The spectra of the adducts $Cu(acrp)_2 \cdot 1/2KCl$ and $Cu(acrp)_2(py) \cdot H_2O$ are different in the solid state (λ_{max}: 242, 314, 375, and 270, 318, 396 nm, respectively), but almost superimposable in ethanol solution (λ_{max}: 228, 258, 298, 366 nm). This indicates their instability in solution, where they probably decompose to give a molecule with the formula $Cu(acrp)_2$. This behaviour is frequently observed in hexa- and pentacoordinated adducts of neutral copper(II) bis-chelated.[10] However, no attempt to isolate a complex of formula $Cu(acrp)_2$ was successful. The spectra of the complexes $Cu(acrp)(bipy)Cl \cdot H_2O$ and $Cu(acrp)(phen)Cl \cdot 2H_2O$ are different both in the solid state (λ_{max}: 246, 314, 376, 398, and 205, 280, 400 nm respectively) and in ethanol solution (λ_{max}: 231, 308, 370, 380, and 223, 260, 292, 370 nm, respectively); they also differ significantly from the spectra of $Cu(acrp)_2 \cdot 1/2KCl$ and $Cu(acrp)_2(py) \cdot H_2O$.

However, in the absence of crystallographic data, it is impossible to infer any conclusion about the actual structures of the 2,2′-bipyridine and 1,10-phenanthroline adducts, thus it is not clear what the influence of bipy and phen is on the molecular structure and the coordinative properties of Hacrp.

Structural studies

The Hacrp molecule is planar and located on the crystallographic plane at $y_0 = 1/4$. The ring is clearly a pyran-2-one and not a 4-one nor a 2,4-dione (see Scheme 1). In fact, the distance C(3)—O(2) [1.179(16) Å] is shorter than C(1)—O(1) [1.281(16) Å], and the carbon–carbon bonds of the ring are alternatively short and long as expected for such a structure. This diagnosis is supported also by an analysis of the ring aromaticity, which considers all the bond distances in the whole ring. For Hacrp we obtain an HOMAS of −0.593,[11] and an I_6 of 32.9,[12] which are closer to the values of pyran-2-one (HOMAS = −0.341 and I_6 = 32.9) than to those of pyran-4-one (HOMAS = −0.146 and I_6 = 37.2).[11]

Another interesting feature arising from the structural data of Hacrp is the charge separation existing in the acryloyl chain, which can be represented as reported in Scheme 2. In fact the dis-



Scheme 2.

tance C(9)—N(1) [1.327(17) Å] is considerably shorter than the expected one for a carbon–nitrogen single bond [1.474 Å];[11] moreover, the bond distances C(7)—C(8) [1.400(19) Å] and C(8)—C(9) [1.391(19) Å] are not significantly different; eventually the bond distance C(7)—O(4) [1.318(14) Å] is longer than the enolic one C(1)—O(1) [1.281(16) Å]. The negative charge localized on the O(4) atom could be stabilized by strong hydrogen bonding to the hydroxyl group on the 4-position of the pyrone ring; the hydrogen atom of this OH group was not found even in the last difference-Fourier map; thus with no evidence for its actual position in the molecule, we do not know if it is nearer to O(1) than to O(4). The existence of a charge separation in the acryloyl chain is also supported by the following observations. (i) The projection of the packing of the Hacrp crystal structure down axis *a* (Fig. 3) shows that the molecules are packed in layers; each enaminic nitrogen atom of a molecule is surrounded by the O(1) atoms of two other molecules belonging to different layers (related to N(1) by the symmetry transformations $1/2-x$, $-y$, $1/2+z$ and $1/2-x$, $1-y$, $1/2+z$), and the O(1) atom of each molecule is surrounded by the N(1) atoms of two other molecules belonging to different layers (related to O(1) by the symmetry transformations $1/2-x$, $-y$, $-1/2+z$ and $1/2-x$, $1-y$, $-1/2+z$); the intramolecular distance O(1)—N(1) [3.426(2) Å] is not much higher than the sum of the van der Waals' radii (2.9 Å),[13] indicating a certain ionic interaction. (ii) The deprotonation constant of Hacrp in its electronic ground state ($\log K_a = -9.37 \pm 0.01$) is very low (see for comparison the value of dehydroacetic acid: $\log K_a = -5.12$[14]), consistently with an excess of negative charge on the atoms O(1) and/or O(4). By means of appropriate relations,[4] it is possible to estimate the acidity of Hacrp in its first singlet excited state as $\log K_a = -4.63$; therefore, it is probable that the lowest energy electronic absorption band of Hacrp is an intramolecular charge-transfer one, that undergoes the charge separation between O(1)/O(4) and N(1); this interpretation agrees with the high intensity of this band ($\log \varepsilon = 4.69$) and with the red-shift of its maxima induced by increasing the solvent polarity (from 368.5 and 380.5 nm in ethanol, to 370.5 and 383.0 nm in 70% aqueous ethanol).

In the complex $Cu(acrp)_2(py)\cdot H_2O$, the copper(II) chromophore is clearly a square-pyramid, with the two pyrone ligands bonded to the metal through the oxygen atoms O(1) and O(4) at the vertices of the square base, and the pyridine nitrogen atom N(2) in the apical position. The Zemann *R* factor is only 0.037, quite a low value for pentacoordinated copper(II) complexes, which are normally very distorted.[15] The four basal oxygen atoms are in a plane of equation $x-1.8870=0$, with the copper(II) atom shifted by 0.212(2) Å out of this plane towards the pyridine nitrogen atom. The mean Cu—O basal distance [1.909(5) Å] is 0.397 Å shorter than the Cu—N(2) distance [2.306(8) Å], agreeing with the axial distortions generally observed in square-pyramidal copper(II) complexes.[16] The plane of the pyridine forms dihedral angles of 62.3° with the plane containing the atoms O(4), Cu and N(2), and of 26.5° with the plane containing the atoms O(1), Cu and N(2). As a consequence of this asymmetric orientation of the pyridine plane with respect to the direction of the basal coordinative bonds, a strong π-interaction between the copper(II) atom and the pyridine seems unlikely, in agreement with the observations of Menabue *et al.*[17] The copper(II) centre, the nitrogen atom N(2) and the carbon atom C(14) are situated along the two-fold axis at $x_0 = y_0 = 1/4$. Thus, the whole complex results from two asymmetric units related by the symmetry transformation x, $1/2-y$, $1/2-z$. Also the oxygen atom of the water molecule, O(5), is in a special position, on the two-fold axis

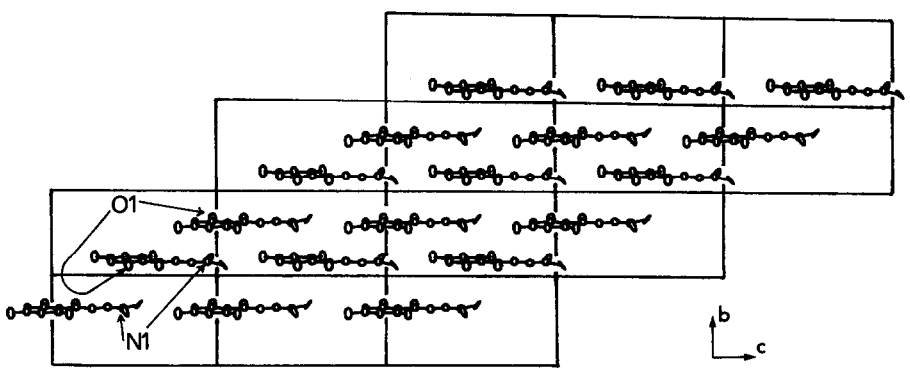


Fig. 3. Projection down the *a* axis of the crystal structure of Hacrp.

at $x_0 = 1/4$ and $y_0 = 0$, and it is at the centre of a cluster of hydrogen bonds. In fact it is bonded to four other oxygen atoms, O(1) (with symmetry transformation x, y, z), O(4)^{i} (with symmetry transformation $x, 1/2-y, 1/2-z$), O(4)^{ii} (with symmetry transformation $1/2-x, -1/2+y, 1/2-z$) and O(1)^{iii} (with symmetry transformation $1/2-x, -y, z$), at distances O(5)—O(1) = 2.999(8) Å, O(5)—O(4)^{i} = 3.290(5) Å, O(5)—O(4)^{ii} = 3.290(5) Å and O(5)—O(1)^{iii} = 2.999(8) Å. The two hydrogen atoms of the water molecule are considered disordered with occupancy 0.5 (for obvious symmetry reasons); they are considered located in the direction of O(1) and O(1)^{iii}, because the contacts O(5)—O(1) and O(5)—O(1)^{iii} are the shortest ones and the angle O(1)—O(5)—O(1)^{iii} [94.1(3)°] is not far from the theoretical H—O—H bond angle.

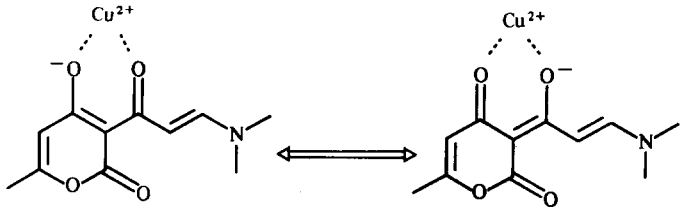
The ligand acrp coordinated to the copper(II) atom is intermediate between the two limit formulae depicted in Scheme 3. In fact, the C(3)—O(2) bond distance [1.209(8) Å] is still shorter than the C(1)—O(1) one [1.293(7) Å] and the HOMAS aromaticity index (−0.334)[11] is nearer to that of pyran-2-one (−0.341) than to that of pyran-4-one (−0.146). However, the I_6 aromaticity index (35.5)[12] is intermediate between that of pyran-2-one (32.9) and that of pyran-4-one (37.2) and the alternance between short and long carbon–carbon bonds within the heterocyclic ring is not as pronounced as expected. In particular, the C(1)—C(2) bond distance [1.414(8) Å] is greater than the corresponding one in the free ligand [1.382(18) Å]. Moreover, the Cu—O(1) and Cu—O(4) bond distances [1.911(5) and 1.907(4) Å] are not significantly different, indicating that the two oxygen atoms O(1) and O(4) are electronically similar. As a consequence of the resonance shown in Scheme 3, the charge separation in the acryloyl chain, clearly present in the free ligand, is inhibited in the ligand coordinated to the metal. In fact, although the enaminic group is still planar and the C(9)—N(1) bond distance is short [1.322(9) Å], the bond distances C(7)—C(8) and C(8)—C(9) [1.429(9) and 1.370(10) Å] are significantly different, contrary to the corresponding ones in the free ligand [1.400(19) and 1.392(19) Å].

Study of the reactivity

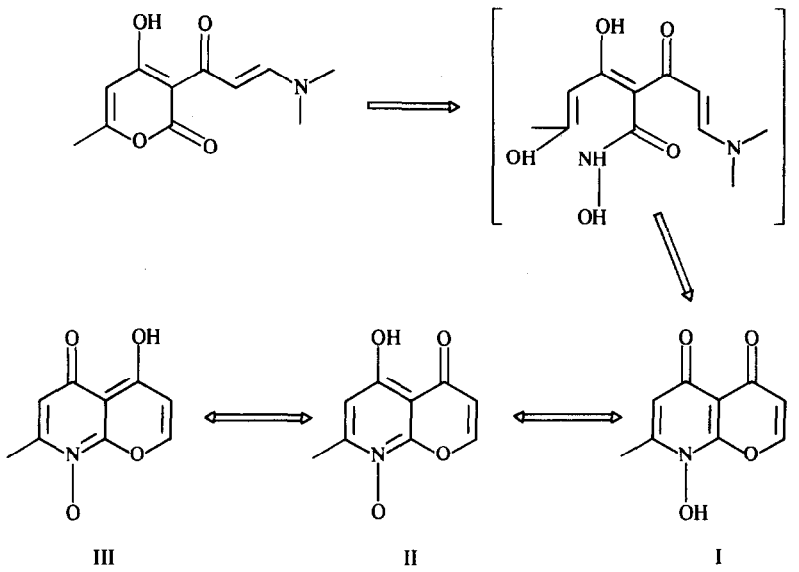
We studied the reaction of Hacrp with hydroxylamine and hydrolysis in acid medium, in order to compare its reactivity in the presence and in the absence of copper(II).

It is well known that Hacrp reacts with an excess of hydroxylamine in alkaline aqueous solution to give 8-hydroxy-5-oximino-7-methyl-5,8-dihydro-4H-pyrano[2,3-b]pyridin-4-one (referred to as Hppyox).[5] The same procedure cannot be followed with the Hacrp copper(II) complexes, because of the hydrolysis of the metal cation. Thus, this reaction was performed in ethanol using hydroxylamine hydrochloride (molar ratio Hacrp–hydroxylamine in the range from 1:1 to 1:4). Under these conditions, both Hacrp and Cu(acrp)$_2$·1/2KCl reacted to give the novel molecule 8-hydroxy-5-oxo-7-methyl-5,8-dihydro-4H-pyrano[2,3-b]pyridin-4-one (referred to as Hppy). By analogy with the mechanism proposed for Hppyox formation, we suppose that Hppy is formed as shown in Scheme 4. Hydroxylamine opens the pyran-2-one ring, by interacting with the carbon in the 2-position; then, in acid medium, two new rings are formed with elimination of dimethylamine. The novel molecule Hppy has been characterized by its analytical, mass and ^{1}H NMR spectral data. From these data it is not clear which is the isolated tautomer but some more information is obtained from its IR spectrum. In the latter one, three significant absorption bands are present at 1660, 1705 and 3200 cm^{-1}. They can be assigned to a pyran-4-one carbonyl stretching,[9] to a pyridone carbonyl stretching, and to a ν(OH), respectively; therefore, the most probable Hppy structure seems to be the tautomer I (see Scheme 4).

It is noteworthy that the formation of Hppy instead of Hppyox is merely determined by the acidity of the reaction medium. A possible explanation of this behaviour may be the protonation of the acryloyl carbonyl which stabilizes the charge separation in the acryloyl chain, thus inhibiting the acquisition of double bond character by the C(1)—O(1) bond and its consequent oximation. This interpretation apparently diagrees with the fact



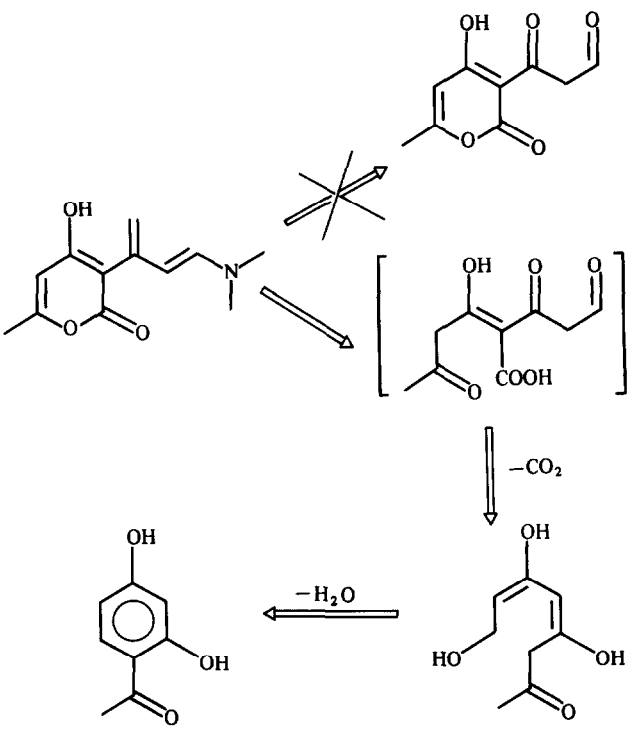
Scheme 3.



Scheme 4.

that Hppy is also obtained by reacting hydroxylamine hydrochloride with $Cu(acrp)_2 \cdot 1/2KCl$; in fact, it seems probable that in this complex the C(1)—O(1) bond acquires double bond character (as observed in the adduct $Cu(acrp)_2(py) \cdot H_2O$), thus becoming more easily oximable. However, it is possible that in the case of $Cu(acrp)_2 \cdot 1/2KCl$, the reaction proceeds only after the dissociation of the copper(II) complex and the subsequent protonation of acrp.

By reacting Hacrp with aqueous hydrochloric acid, 2,4-dihydroxoacetophenone was obtained instead of the expected β-diketone. A mechanism for this reaction is proposed in Scheme 5. The



Scheme 5.

β-diketone is perhaps an intermediate of the reaction, but the pyrone ring opens, eventually giving the 2,4-dihydroxoacetophenone by elimination of carbon dioxide and water. In fact, carbon dioxide has been evidenced by stripping in a $Ba(OH)_2$ solution. 2,4-Dihydroxyacetophenone has been identified by comparing its IR, ^1H NMR and mass spectra and melting point with those of an authentic sample. By reacting the copper(II) complexes of Hacrp described here, with aqueous hydrochloric acid, only ill-defined products were isolated. However, the 2,4-dihydroxyacetophenone was also formed by reacting Hacrp with an aqueous solution of $CuCl_2 \cdot 2H_2O$. In this case the (2,4-dihydroxyacetophenonato)copper(II) was isolated at first, and then the 2,4-dihydroxyacetophenone was recovered by precipitating the metal as cyanide, thus proving considerable hard Lewis acid character of the copper(II) ion.

Abstract—The interaction of methyllithium and the tetrahydrothiophen (THT) complexes, $MCl_3(THT)_3$ (M = Ru, Rh and Ir), in diethyl ether in the presence of tetramethylethylenediamine (TMED) gives the air- and thermally-sensitive compounds $[Li(TMED)]_3[MMe_6]$. The rhodium compound is the starting material for the synthesis of the *fac*-trimethyl compounds, $RhMe_3(THT)(TMED)$, $RhMe_3(CO)(TMED)$ and $RhMe_3(PMe_3)_3$; the iridium compound *fac*-$IrMe_3(CO)(TMED)$ is also described. Interaction of neopentyllithium or neopentylmagnesium bromide with $RhCl_3(THT)_3$ in the presence of a source of oxygen atoms (O_2 or Me_3NO) gives the diamagnetic compound, $[(Me_3CCH_2)_3Rh]_2\mu$-O, which contains rhodium in the IV oxidation state and a linear Rh—O—Rh bond. X-ray structures of the compounds listed in the title have been determined.

As noted in a preliminary communication,[1] the first homoleptic compounds of the platinum group metals to be described were the anionic species $[PtMe_6]^{2-}$ and $[PtMe_4]^{2-}$, that were characterized in solution by spectroscopic methods.[2] Subsequently, pentahalogeno anions for both palladium and platinum in oxidation states II and III have been characterized;[3] during the course of this work, the compound $[Ph_3P(CH_2Ph)][Rh(C_6F_5)_5]$, where the anion had a square-pyramidal structure according to X-ray study, was reported.[4] Neutral homoleptic alkyls[5,6] such as $Ru_2(CH_2SiMe_3)_6$ and $Ru(C_6H_{11})_4$ and aryls[6,7] such as $Ru(2\text{-}MeC_6H_4)_4$ and $Os(C_6H_5)_4$ have been described and some of the reactions of $Os(o\text{-}tol_4)$[8] and the electrochemistry[9] of the tetra-*o*-tolyls of Mo, Re, Ru and Os studied; the X-ray structure of the osmium(V) cation in the salt $[Os(2\text{-}MeC_6H_4)_4]CF_3SO_3$ was also determined by X-ray diffraction.[10]

This paper gives details of the synthesis and reactions of the compounds $[Li(TMED)]_3[MMe_6]$ (M = Ru, Rh and Ir); the X-ray structures of the rhodium and iridium compounds are described.[1] We describe also the synthesis and structure of the neopentyl compound $[(Me_3CCH_2)_3Rh]_2\mu$-O, which

* Authors to whom correspondence should be addressed.

contains rhodium, formally in the IV oxidation state.

RESULTS AND DISCUSSION

(1) *Lithium hexamethylmetallates of rhodium*(III), *iridium*(III) *and ruthenium*(III)

The compounds $[Li(TMED)]_3[MMe_6]$ (M = Rh, Ir, Ru) were made by interaction of the tetrahydrothiophen compounds, $MCl_3(THT)_3$, with six equivalents of methyllithium in diethyl ether at −78°C, with subsequent addition of TMED and crystallization from ether at *ca* −30°C.

All three compounds are very air-sensitive and thermally unstable; the rhodium and iridium compounds are stable to about 20°C but the ruthenium analogue decomposes above about 0°C. Although X-ray studies on the rhodium and iridium compounds were successful,[1] we have been able to show only that $[Li(TMED)]_3[RuMe_6]$ is isomorphous with the other two since decomposition under X-radiation occurs quite rapidly even at low temperature.

The hexamethylruthenate compound and $RuCl_3(THT)_3$ gave good X-band EPR spectra. For the latter in toluene at 77 K there are three distinct g values (2.61, 2.31 and 1.73); this is consistent with the *mer* structure of C_{2v} symmetry found in various ruthenium(III) tertiary phosphine and dialkyl and aryl sulphide complexes.[11] The EPR spectrum of $[Li(TMED)]_3[RuMe_6]$ in THF at 77 K indicated that it was consistent with that of an octahedral species of higher symmetry, with $g = 2.53$ and 1.56. A small band in the spectrum at $g = 2.08$ was shown to be a decomposition product as it increased in size at the expense of the other bands on re-recording the spectrum after storage at −30°C. The interaction of the $MCl_3(THT)_3$ compounds with a variety of lithium alkyls and aryls, e.g. $LiCH_2SiMe_3$, $Li(2\text{-}MeC_6H_5)$ and $LiCH_2CMePh_2$, gave solutions from which no clearly defined products could be isolated. However, the use of neopentyllithium or neopentyl Grignard reagent in the presence of an oxygen source led to the compound $[(Me_3CCH_2)_3Rh]_2O$ discussed below.

Reactions of the hexamethylmetallates. The rhodium compound has been most studied since it is easier to obtain than its iridium analogue and is somewhat more reactive. No clean reactions of the ruthenium compound have been discovered.

$[Li(TMED)]_3[RhMe_6]$ is stable for long periods in solution in petroleum, diethyl ether and aromatic hydrocarbons at −30°C. When the C_6D_6 solution stands at room temperature, decomposition occurs giving a black deposit and a colourless solution; successive ^1H NMR spectra showed that there is an unstable, unisolable intermediate containing equivalent methyl groups different from those in the hexamethyl with δ −0.36 ppm, $J_{Rh-H} = 1.0$ Hz, while the TMED resonances collapsed to a broad singlet at 2.06 ppm. When a concentrated diethyl ether solution of the initial reaction products from $RhCl_3(THT)_3$ and MeLi, containing $[Li(TMED)]_3[RhMe_6]$ and tetrahydrothiophen, is allowed to stand for a long period (*ca* 7 days at −30°C) a different product, namely $RhMe_3(TMED)(THT)$, can be isolated; the crystal structure is described later. An alternative, faster route to this compound is the interaction of ethylene with the filtered initial solution from the reaction of $RhCl_3(THT)_3$ and MeLi to which TMED was added. The hexamethyliridate is more stable in solution at −30°C but no isolable product has been obtained after decomposition. Interaction of $[Li(TMED)]_3[RhMe_6]$ with many reagents causes only decomposition and formation of rhodium metal or rhodium-containing solutions from which no clean products could be isolated. Molecular hydrogen with all three hexamethylates rapidly gives metal and methane.

Interaction of the rhodium and iridium compounds with carbon monoxide at atmospheric pressure gives the compounds *fac*-$MMe_3(CO)(TMED)$. The reaction presumably removes MeLi as an intermediate acylate,[12] for example

$$[LiTMED]_3[RhMe_6] \xrightarrow{CO} RhMe_3(CO)(TMED) + 3\text{ "Li(MeCO)"} + 2TMED.$$

The rhodium compound can also be made by action of carbon monoxide on $RhMe_3(TMED)(THT)$. Trimethylphosphine with the ruthenium compound gives only a black insoluble material; the iridium compound is unreactive up to the point where decomposition occurs but the rhodium compound and $RhMe_3(THT)(TMED)$ give *fac*-$RhMe_3(PMe_3)_3$ [m.p. (decomp.) 135°C]. A compound of this stoichiometry (m.p. 106–108°C) was made previously[13] by interaction of $Rh_2(CO_2Me)_4$, PMe_3 and $MgMe_2$, and was formulated as the *fac*-compound; however, in view of the X-ray structure of the present compound (below), its NMR spectra and difference in melting points, we now consider the earlier product to be the *mer*-isomer.

Cyclic voltammetric studies on the three lithium compounds in THF gave only irreversible waves for ruthenium, no oxidation or reduction waves for iridium, and only an irreversible oxidation wave for rhodium.

X-ray structures of the fac-*trimethyl compounds.* Diagrams of the three trimethylrhodium complexes are given in Figs 1 $RhMe_3(CO)(TMED)$, 2 $RhMe_3(THT)(TMED)$ and 3 $RhMe_3(PMe_3)_3$. Bond lengths and angles are given in Tables 1–3, respectively. For the carbonyl complex, the Rh—C(methyl) bond *trans* to the CO ligand is slightly longer than those *trans* to the nitrogen atoms, as expected. The ethylene bridge carbons of TMED are disordered, but this does not seem to have affected the positioning of the TMED methyl groups, which are probably locked into position via the rhodium-bonded methyl groups. Similarly, for the THT complex, the longest Rh—C bond is *trans* to the THT ligand.

For the phosphine complex the three Rh—C and the three Rh—P bonds are very similar, with the Rh—C(methyl) bonds longer than any of those in the first two complexes, indicating perhaps both greater steric crowding and *trans* influence from the trimethylphosphine ligands.

(2) *The compound* $[(Me_3CCH_2)_3Rh]_2\mu$-O

On one occasion, the interaction of neopentyllithium with $RhCl_3(THT)_3$ in diethyl ether gave a solution from which, after evaporation and extraction of the residue with hexane, green black crystals were obtained. This compound, as discussed below, has been shown to be the oxo-bridged rhodium(IV) species. It has turned out that, as in the discovery of hexamethyltungsten,[14] fortuitous interaction with oxygen dissolved in hexane was involved. The solubility of dioxygen in *n*-hexane at ambient temperature and pressure is *ca* 0.015 mol dm^3;[15] dioxygen reacts with alkyllithiums [ref. 11(a) p. 129 and (b) p. 192] to yield *ca* 36% of a peroxo species which could be the source of oxygen in the rhodium complex. Thus, for *ca* 0.3 g $RhCl_3(THT)_3$ used, a six-fold excess of neopentyllithium in degassed hexane needed to be treated with 28.4 cm^3 of dioxygen. In the absence of oxygen no compound could be isolated. Instead of dioxygen, we have found trimethylamine-N-oxide can be used. The addition of Li_2O, to thoroughly de-oxygenated reaction systems did not give the oxo complex. Even in the presence of oxygen sources, other lithium or magnesium alkylating agents, such as $LiCH_2SiMe_3$, $LiCH_2CMePh_2$, etc. do not give isolable products. The only exceptions are the aryls (mesityl and 2,6-xylyl) that will be described separately. Similar reactions using the ruthenium and iridium tetrahydrothiophen complexes gave no evidence for similar compounds.

As discussed below, the X-ray structural data on the compound initially suggested that it was a

lithium salt, so that it was necessary therefore to rigorously exclude this possibility:

(a) No lithium was found by flame test or by direct analysis.
(b) The identical compound, as shown by X-ray powder diffraction study and by NMR spectra, was obtained using neopentylmagnesium bromide again in the presence of dioxygen.
(c) Since X-ray photoelectron spectroscopic data is available for rhodium compounds in different oxidation states[16] we compared, under identical conditions, $Rh_2^{II}(O_2CMe)_4$, $Rh^{III}Cl_3(THT)_3$ and the μ-oxo compound. The observed binding energy for Rh $3d_{5/2}$ in each was 315.25, 316.3 and 317.0 eV (vs C1*s* of 291.3 eV), respectively, confirming the oxo species as having Rh^{IV}.

The molecular structure of $[(Me_3CCH_2)_3Rh]_2\mu$-O found by the X-ray study is shown in Fig. 4; diagrams of the crystal packing are shown in Figs 5 and 6. Selected bond lengths and angles are given in Table 4. The Rh—O—Rh bridge is linear by symmetry and the two Rh—O distances are equal within experimental error. Similarly, the Rh—C distances at the two independent rhodium atoms are equal within error, indicating equivalence of the

two rhodium atoms, which are thus assigned as rhodium(IV). This is significant since the complex could be formulated as a mixed-valence species $R_3Rh^V{=}O \rightarrow Rh^{III}R_3$ with donor oxygen, but this seems less satisfactory. On the basis of the Dunitz and Orgel model for the linear M—O—M bonding[17] ion, the Rh—O—Rh bonding could be represented as $(e^6)^4[(b_{2g})^2(b_{1u})^2(e_g)^4](e_4{*})^2$, and the length of the Rh—O bonds at *ca* 1.90 Å perhaps reflect the occupancy of the antibonding orbitals.

The diamagnetism of the compound is thus associated with electron pairing of rhodium(IV) and Rh d_π–O p_π bonding. Other species[18a,b] with linear MOM groups include ions such as $[M_2(\mu\text{-O})X_{10}]^{4-}$ (M = Ru, Os, X = halogen) and $[Mo_2(\mu\text{-O})(MeCN)_{10}]^{4+}$.[18c]

The ^1H and ^{13}C NMR spectra of the compound show only neopentyl group resonances while IR spectra show neopentyl bands plus a band at 802 cm^{-1} that is assigned to the Rh—O—Rh stretch. We were unable to detect a RhORh band in the Raman spectrum, probably due to the intense

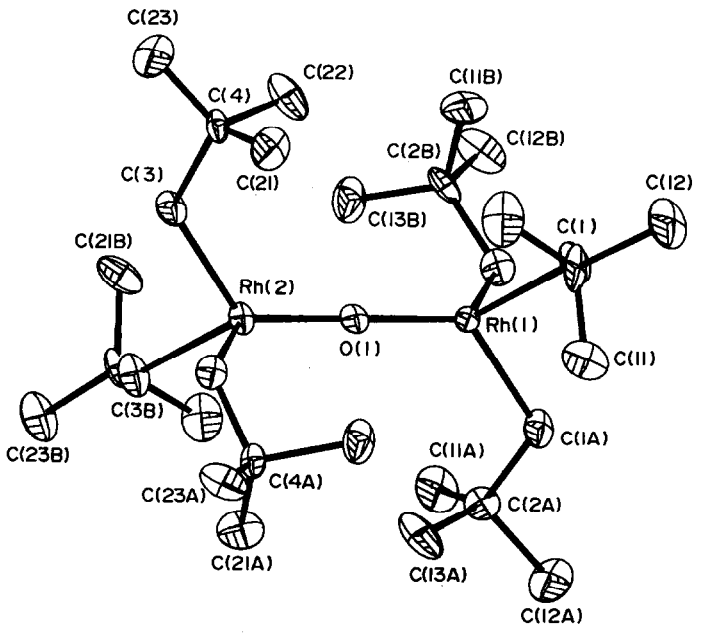

Fig. 4. The structure of $[(Me_3CCH_2)_3Rh]_2\mu$-O.

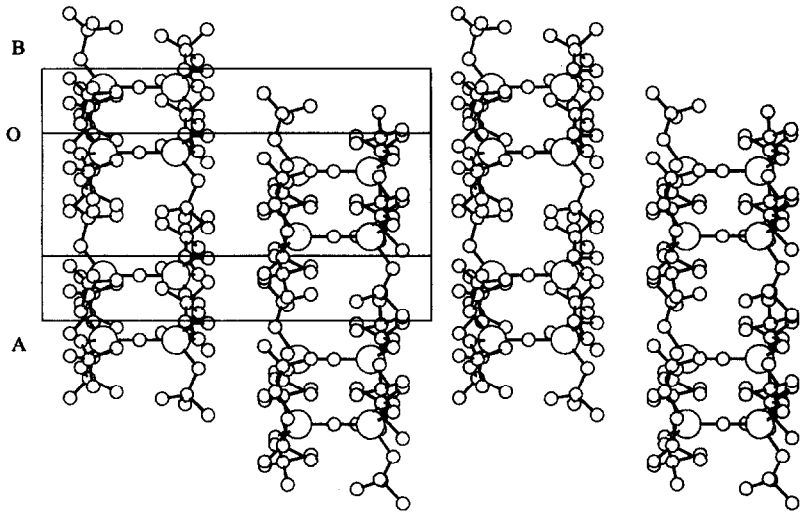

Fig. 5. Crystal packing in $[(Me_3CCH_2)_3Rh]_2\mu$-O.

colour of the solution. No oxo species of this type have been described for rhodium; μ_3-oxo groups in compounds of the type $[Rh_3(\mu_3O)(CO_2R)_6L_3]^+$ (L = neutral ligand) are known [18a,19] and an oxo-bridged species $[ONpORh^{III}(H_2O)_5]^{4+}$ has been characterized in solution.[20a] Well-characterized rhodium(IV) species are also rare.[20b,c] The only known organometallic compounds of rhodium in oxidation states IV and V are those having η^5-pentamethylcyclopentadienyl groups such as $[*CpRh^{IV}Me(\mu\text{-}CH_2)]_2$.[21]

The compound reacts with CO and Bu^{t}NC but several products are formed in both cases and we have not succeeded in isolating well-defined compounds. There was no reaction with O_2 nor with PhNCO at room temperature.

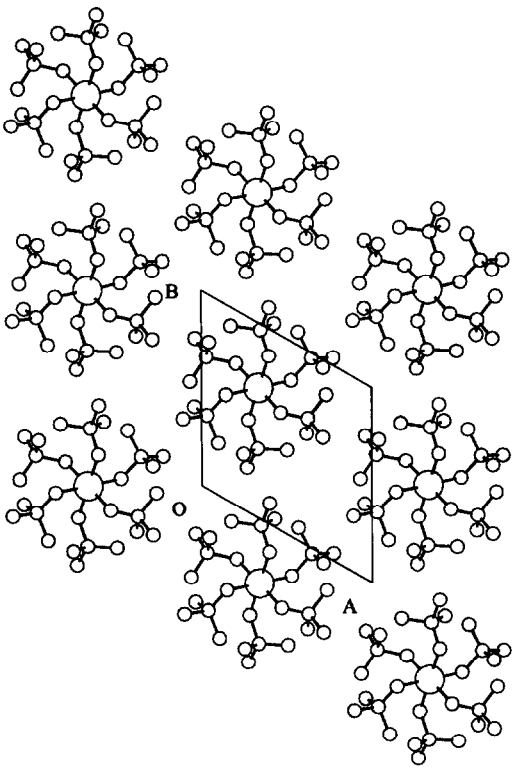

Fig. 6. Crystal packing along the *C* axis.

EXPERIMENTAL

Microanalyses were carried out by Imperial College Laboratories and Pascher, F.R.G. Spectrometers used were, IR, Perkin–Elmer 1720 (spectra in Nujol mulls in cm^{-1}); NMR, Bruker AM-500 and Bruker W-M 250 (data in ppm relative to $SiMe_4$ for ^1H in C_6D_6 unless otherwise stated and relative to external 85% H_3PO_4 for ^{31}P); EPR, X-band, Varian E-12.

X-ray powder spectra were recorded on a Siemens D-500 diffractometer with Cu-K_α, 40 kV, 30 mA source, using the following conditions: slit, 1°–1°–1°–0.15 mm; stepwidth, 0.02°; time, 0.5 s, and scan range, 2–60° (2θ). The rhodium compounds were finely ground and sealed in plastic bags, 25 × 10 mm, under argon.

X-ray photoelectron spectroscopic studies used a VG ESCALAB Mark II spectrometer with Al-K_α X-ray radiation. The analyser was set at 0.4 eV and the base pressure in the analysis chamber was 5×10^{-11} torr. The sample discs were prepared under argon with a layer of firmly ground compound pressed onto the surface of KBr.

Melting points were determined in sealed capillaries and are uncorrected. Solvents were purified by standard methods and all manipulations were carried out *in vacuo* or under purified argon or nitrogen. Methyllithium was prepared by standard methods from lithium metal and CH_3Cl in diethyl ether, while neopentyllithium was prepared by sonication as described previously.[22] Me_3NO was dried using literature methods.[23]

(1) *Tris(tetramethylethylenediaminelithium)hexamethylmetallates of rhodium, iridium and ruthenium*(III)

Rhodium. To a stirred solution of $RhCl_3(C_4H_8S)_3$[24] (0.6 g, 1.3 mmol) in diethyl ether (*ca* 50 cm^3), at −78°C, was added a cooled six-fold excess of methyllithium (29.2 cm^3 of 0.26 M solution in Et_2O), and the solution allowed to warm to 0°C with vigorous stirring. After disappearance of $RhCl_3(THT)_3$ (*ca* 1 h) the colourless solution was filtered and $Me_2NCH_2CH_2NMe_2$ (4 cm^3) added. After 5 min the solution was reduced to about a third of its volume at 0°C under vacuum, then cooling to −30°C gave the hexamethylrhodate salt as colourless crystals. Yield: *ca* 92%. Recrystallization from Et_2O gave crystals of X-ray quality. The compound is very air-sensitive and decomposes above *ca* 20°C turning black.

^{1}H NMR: −0.52, 18H, d (J_{Rh-H} = 1.1 Hz), Rh—CH_3; 2.0, 12H, s, CH_2 (TMED); 2.04, 36H, s, NCH_3(TMED).

Iridium. The preparation was similar to that above but using $IrCl_3(THT)_3$[24] and allowing the reaction mixture to stir for a longer time (2–3 h) to completion. Yield: *ca* 90%. X-ray quality crystals were obtained from Et_2O at −30°C.

^{1}H NMR: 2.14, 54H, br, s, IrCH_3 plus N—CH_3(TMED); 2.18, 12H, br, s, CH_2(TMED). In concentrated solutions only a broad singlet at *ca* 2.0 ppm is observed and lowering the temperature gives no improved resolution.

Ruthenium. The previously unreported $RuCl_3(THT)_3$ was obtained as follows. To "$RuCl_3$(aq.)" (4.0 g, 19.3 mmol) in ethanol (300 cm^3) was added tetrahydrothiophen (10 cm^3) and the solution refluxed for 30 min. After filtering hot, the solution was cooled (−10°C) and the red crystalline product collected and dried *in vacuo*. Yield: 55%; m.p. 161–163°C. (Found: C, 30.6; H, 5.1. $C_{12}H_{24}Cl_3RuS_3$ requires: C, 30.6; H, 5.1%.)

The synthesis of [Li(TMED)]$_3$[RuMe$_6$] followed that for the rhodium compound. The yield is high, *ca* 90%, but the compound is very difficult to handle due to its low thermal stability and high air-sensitivity, but crystals can be obtained from ether and mounted in a capillary provided the temperature is kept at as low temperature as feasible.

(2) fac-*Trimethylrhodium and -iridium compounds*

fac - *Trimethyl(tetrahydrothiophen)(tetramethylethylenediamine)rhodium*(III). As noted in the discussion, this compound was first isolated from aged solutions of the reaction solution of $RhCl_3(THT)_3$ and MeLi in Et_2O. It is best obtained as follows. Through a diethyl ether solution of $RhCl_3(THT)_3$ (0.4 g, 0.8 mmol) and six equivalents of MeLi in Et_2O, to which TMED had been added at −78°C as above, was bubbled ethylene while the solution was allowed to warm to 0°C. After removal of volatiles *in vacuo*, the residue was extracted with hexane (*ca* 50 cm^3), which on cooling at −30°C gave the product. Yield: *ca* 75%; m.p. 83–84°C decomp. X-ray quality crystals were obtained from hexane. (Found: C, 45.0; H, 9.5; N, 8.1. $C_{13}H_{33}N_2RhS$ requires: C, 44.3; H, 9.4; N, 7.95%.)

^{1}H NMR: 0.5, 9H, d (J_{Rh-H} = 2.5 Hz), Rh—CH_3; 1.5, 4H, m, CH_2CH_2CH_2CH_2S; 1.87, 4H, s, CH_2(TMED); 2.01, 12H, s, CH_3(TMED); 2.61, 4H, br, s, CH_2CH$_2$CH$_2$CH_2S. ^{13}C-{^{1}H} NMR: −2.08, d (J_{Rh-C} = 36 Hz), Rh—CH_3; 30.65, $CH_2CH_2CH_2CH_2S$; 31.33, br, CH_2CH_2

CH_2CH_2S; 48.33, CH_3(TMED); 59.6, CH_2 (TMED).

fac - *Trimethyl(carbonyl)(tetramethylethylenediamine)rhodium*(III). Through a tetrahydrofuran solution of $[Li(TMED)]_3[RhMe_6]$ (0.7 g 1.25 mmol) and TMED (0.19 cm^3, 1.26 mmol) at −78°C was slowly bubbled CO for 0.75 h; after warming to room temperature and removing volatiles *in vacuo* the residue was extracted with hexane (50 cm^3), which was filtered, reduced in volume (15 cm^3) and cooled at −30° to give cream crystals. Yield: 0.12 g, 50%; m.p. 104–106°C decomp. X-ray quality crystals were obtained from hexane at −30°C. (Found: C, 40.2; H, 8.6; N, 8.9. $C_{10}H_{25}N_2ORh$ requires: C, 41.1; H, 8.6; N, 9.6%.)

IR (Nujol): 1978 [ν(CO)]. ^{1}H NMR: 0.32, 3H, d (J_{Rh-H} = 1.8 Hz), Rh—CH_3; 0.71, 6H, d (J_{Rh-H} = 2.4 Hz), Rh(CH_3)$_2$; 1.64, 4H approx. AB system ($J_{a-b/2}$ = 2.1 Hz), CH_2 (TMED); 1.8, 6H, s, NCH_3; 2.1, 6H, s, NCH_3. ^{13}C-{^{1}H} NMR: −4.6, d (J_{Rh-C} = 28.8 Hz), Rh(CH_3)$_2$; 25.7, d (J_{Rh-C} = 25.2 Hz), Rh—CH_3; 47.0, NCH_3; 54.1, NCH_3 60.0 CH_2(TMED); 190.75, d (J_{Rh-C} = 50.2 Hz), Rh—CO.

There was no further reaction of the compound with CO at 100°C and no reaction with Me_3NO, but Bu^{t}NC (at low temperature) gave a cream-coloured crystalline material which rapidly turned black–red at room temperature; no clean product could be isolated.

fac - *Trimethyltris(trimethylphosphine)rhodium*(III). Although this compound can be made from $[Li(TMED)]_3[RhMe_6]$ it is more convenient to use $RhMe_3$(THT)(TMED) (*ca* 1g) in Et_2O at 0°C and excess PMe_3. After *ca* 15 min the solution was evaporated, and the residue extracted with hexane (*ca* 10 cm^3); cooling at −30°C gave yellow crystals. Yield; *ca* 95%; dec. >135°C. (Found: C, 38.0; H, 9.7. $C_{12}H_{36}P_3Rh$ requires: C, 38.3; H, 9.6%.)

^{1}H NMR: 0.94, 27H, m (J = 5.6 Hz) P—CH_3; this resonance has a broad central line flanked by the 1:1 doublet; the J value corresponds to the separation of the outer peaks; 0.20, 9H, complex m, Rh—CH_3. ^{13}C-{^{1}H} NMR: 6.5 d, d, d, d, ($J_{P_{ax}-C}$ = 114 Hz, J_{Rh-C} = 22.5 Hz, J_{P-C} = 13.8 Hz, J_{P-C} = 9 Hz) Rh—CH_3; 17.9, complex m, P—CH_3. ^{31}P-{^{1}H} NMR: −32.4, *d* (J_{Rh-P} = 83.5 Hz).

fac - *Trimethyl(carbonyl)tetramethylethylenediamine)iridium*(III). A THF solution of $[Li(TMED)]_3$ $[IrMe_6]$ (*ca* 0.5 g) was treated with CO as for the rhodium analogue above to give a cream solid. Yield: *ca* 40%.

IR (Nujol): 1962 [ν(CO)]. ^{1}H NMR: 0.24, 3H, s, Ir—CH_3; 1.02, 6H, s, Ir—CH_3; 1.69, 4H, complex m, CH_2 (TMED); 1.87, 6H, s, NCH_3; 2.38, 6H, s, NCH_3. The complex multiplet for the CH_2 groups in $Me_2NCH_2CH_2NMe_2$ showed increased inequivalence of these CH_2 ring protons compared to those in the rhodium analogue.[25]

(3) *Bis[tris(neopentyl)rhodium*(IV)]μ-oxo

To a six-fold excess of neopentyllithium (7.8 cm^3 of a 0.49 M solution in Et_2O) in Et_2O (30 cm^3) at −78°C was added, via syringe, 28.4 cm^3 of dry dioxygen. The solution was allowed to warm slowly to room temperature, then re-cooled to −78°C when it was added to a suspension of $RhCl_3(THT)_3$ (0.3 g, 0.6 mmol) in Et_2O (30 cm^3) at −78°C. The vigorously stirred solution was allowed to warm to room temperature and after *ca* 1 h, the volatiles were removed *in vacuo* and the residue extracted with hexane (3 × 30 cm^3). Reduction in volume of the filtered solution to 40 cm^3 and cooling at −30°C gave dark green–black crystals. Yield: *ca* 30%; m.p. 167–168°C decomp. Crystals of X-ray quality were obtained by repeated crystallization from hexane. (Found: C, 55.5; H, 10.2; O, 2.5; Li, 0.0. $C_{30}H_{66}ORh_2$ requires: C, 55.5; H, 10.3; O, 2.5; Li 0.0%.)

IR: 802, Rh—O—Rh, and neopentyl bands. ^{1}H NMR: 1.29, 54H, s, CCH_3; 2.9, 12H, s, CH_2. Pulse studies gave no evidence of ^{103}Rh coupling with the CH_2 groups bound to Rh. ^{13}C-{^{1}H} NMR: 32.9 (CH_3)$_3$C; 34.8 Me_3C; 52.8 d (J_{Rh-C} = 39 Hz), RhCH_2.

The compound is also obtained in similar yield by addition to $RhCl_3(THT)_3$, as above, of a four-fold excess of neopentyllithium plus a two-fold excess of trimethylamineoxide in Et_2O. An alternative procedure uses the Grignard reagent: a mixture of a four-fold excess of neopentylmagnesium bromide (0.25 M) and Me_3NO (0.064 g, 0.85 mmol) in Et_2O (27 cm^3) was added to $RhCl_3(THT)_3$ (0.8 g, 1.69 mmol) in Et_2O (60 cm^3) at −78°C. After warming to room temperature the mixture was stirred for *ca* 12 h after which it was evaporated *in vacuo*. Extraction of the residue with hexane and work-up gave the compound in *ca* 36% yield.

X-ray crystallography

Crystals of the three trimethylrhodium compounds were sealed under argon in thin-walled glass capillaries. Following preliminary photography, orientation matrices and associated cell dimensions were obtained using standard procedures on a CAD4 diffractometer with graphite monochromated Mo-K_α radiation (λ = 0.71069 Å). In the case of the oxo-bridged dimer, many crystals had to be tried before an acceptable one was found.

Intensity data were recorded using the ω–2θ scan mode and empirical absorption corrections were applied. The structures were solved and developed via the Patterson and heavy atom method, and refined by full-matrix least-squares. Non-hydrogen atoms were assigned anisotropic displacement factor coefficients and hydrogens were included in idealized positions, with individual U_{iso} values only in the carbonyl structure and then not on the TMED CH_2 groups which were disordered over two sites (occupancies 0.56 and 0.44).

For the oxo-bridged compound, a difference map computed after all atoms in the [(Me$_3$CCH$_2$)$_3$Rh]$_2$O unit had been included showed four residual peaks of significant density, all on three-fold axes. At first these were believed to be lithium ions with the occupancies summing to give an overall complex formula $Li_2\{[(Me_3CCH_2)_3Rh]_2O\}$, and thus a rhodium(III) complex, moreover, the lithium ions were co-ordinated, albeit with a very distorted geometry, to neopentylmethyl groups. After comprehensive chemical and spectroscopic studies (see above) showed quite clearly that there was no lithium present, we realized that the four peaks, which occurred in two pairs were images of the Rh—Rh pair—the interatomic distances were closely similar. The origin of this "ghosting" we believe to be stacking faults. Examination of the molecular packing shows that the dimers, aligned along the C axis, occur on sheets—see Fig. 6—and it is easy to see how slippage could occur in the stacking of the layers. Although the occupancy of the ghost sites corresponds to only *ca* 0.07 Rh, inclusion in the structure factor calculation made a very significant difference to the R value—0.041 vs 0.064 and led to stable refinement. The geometry parameters for the dimer molecule were essentially unaffected. Accordingly, these fractional rhodium atoms have been retained in the atom list and for the final R value calculation. Details of the crystal data, data collection and structure refinements are given in Table 5. Tables of atom parameters and F_o/F_c values have been deposited as supplementary material with the Editor. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

Abstract—The interaction of $Re(NBu^t)_2Cl_3$ with 2,6-xylyl magnesium bromide gives rise to the paramagnetic rhenium(VI) compound, $Re(NBu^t)_2(xyl)_2$, which is readily oxidized to the cation $[Re(NBu^t)_2(xyl)_2]^+$, isolated as its PF_6^- salt; the latter with Bu^tNC gives the iminoacyl cation $[Re(NBu^t)_2(xyl)(Bu^tN{=}Cxyl)]^+$. An unstable rhenium(V) anion, $[Re(NBu^t)_2(xyl)_2]^-$, has been characterized. Interaction of $Re(NBu^t)_2Cl_3$ with excess mesityl Grignard gives a compound of stoichiometry $Re(NBu^t)(mes)(C_{27}H_{32})$ in which three aromatic rings are coupled, the central one comprising a η^5-cyclohexadienyl ring bearing an *exo*-mesityl group in the 1-position and in the 3-position linked by a CH_2 group to an aryl group σ-bonded to the metal, which is formally in the V oxidation state. The compound $Re(NBu^t)_2Cl(o\text{-}tol)_2$ has been synthesized; treatment with $AgPF_6$ produces the salt $[Re(NBu^t)_2(o\text{-}tol)_2]PF_6$. Hydrolysis of $Re(NBu^t)_2ReCl_3$ with LiOH gives $Re(NBu^t)_2Cl(OH)_2$, which on arylation, gives the oxo imido species $Re(NBu^t)_2(O)mes$ and $[(Bu^tN)Br(mes)Re(\mu\text{-}NBu^t)(\mu\text{-}O)Re(OC_6H_2Me_2CH_2)(NBu^t)_2]$. Interaction of excess NO with $Re(NBu^t)_2Ar_2$, Ar = 2,6-xylyl and mesityl, gives the compounds $[Re(NBu^t)(O)(\mu\text{-}O)Ar]_2$; the reaction involves a unique N—N bond formation to give $Bu^tN{=}NAr$. Stoichiometric reactions of $Re(NBu^t)_2(xyl)_2$ and NO lead to the complexes $Re(NBu^t)_2(xyl)_2NO$ and $Re(NBu^t)_2(O)(xyl)$. Mechanisms for the NO reactions are proposed. X-ray structures of the compounds listed in the title have been determined; the compounds $[Re(NBu^t)(O)(\mu\text{-}O)Ar]_2$ have asymmetric oxo bridges.

In previous papers we have described the synthesis and X-ray crystal structures of a number of oxo[1,2] and *t*-butylimido[2,3] aryls of rhenium(V), (VI) and (VII). Extensions of these studies are now reported; Table 1 summarizes present knowledge of the aryl compounds. Table 2 gives analytical and physical data for the new compounds described in this paper.

RESULTS AND DISCUSSION

produced the rhenium(VI) compound, $Re(NBu^t)_2(mes)_2$, which was paramagnetic with one unpaired electron and which was readily oxidized to the rhenium(VII) cation $[Re(NBu^t)_2(mes)_2]^+$. The latter gave an iminoacyl cation with Bu^tNC.

The 2,6-dimethylphenyl analogue has now been made in a similar way; it is also oxidized by Ag^+ salts to give the cation $[Re(NBu^t)_2(xyl)_2]^+$ which was isolated as orange PF_6^- or $CF_3SO_3^-$ salts. The ^1H NMR spectrum of the salts in solution shows equivalent *t*-butyl and xylyl groups. This cation, like the mesityl analogue, undergoes insertion with *t*-butylisocyanide to give the iminoacyl cation which was isolated as a white, air-stable PF_6^- salt.

Although a cyclic voltammetry study showed[3] that $Re(NBu^t)_2(mes)_2$ underwent a reversible one-electron reduction, the rhenium(V) anion could not be isolated. Reduction of the xylyl by Na/Hg or Mg in THF gives purple solutions of a very air-sensitive diamagnetic species that is evidently $[Re^V(NBu^t)_2(xyl)_2]^-$. Dark purple, crystalline solids can be isolated from the solution but they are difficult to handle being very readily re-oxidized to the rhenium(VI) precursor. The ^1H NMR spectrum of the anion has signals at 7.24–7.06 (*m*, *p*-$C_6H_3Me_2$), 2.41 (*o*-Me) and 1.49 (Bu^t) ppm that are shifted relative to those in the cation (cf. 7.42–7.21, 2.46, 1.80 ppm); this shift is consistent with the anionic formulation.

The X-ray crystal structure of $Re(NBu^t)_2(xyl)_2$ has been determined and a diagram of the structure is shown in Fig. 1; bond lengths and angles are given in Table 3. The coordination geometry of rhenium is, as expected, very similar to that found for the analogous dioxo complex.[2] The Re—C (xylyl) distances in the imido complex are just slightly larger [*ca* 0.03(1) Å] than those in the oxo complex. The C—Re—C angles are equal within experimental error. The Re=NBu^t distances are *ca* 0.05(1) Å longer than the Re=O distances, consistent with the large covalent radius of N, but the N—Re—N angle at 121.7(6)° is equal, within error, to the O—Re—O angle of 121.3(4)°.

$Re(NBu^t)_2(xyl)_2$ in solution at 295 K has an electron paramagnetic resonance spectrum similar to that for the mesityl analogue;[3] there is again

Table 2. Analytical[a] and physical data for rhenium compounds

[a] For mass spectra see Experimental.
[b] Required in parentheses.
[c] Melting point, 134°C, is probably that of $Re(NBu^t)_2Cl(O)$ formed on loss of H_2O.

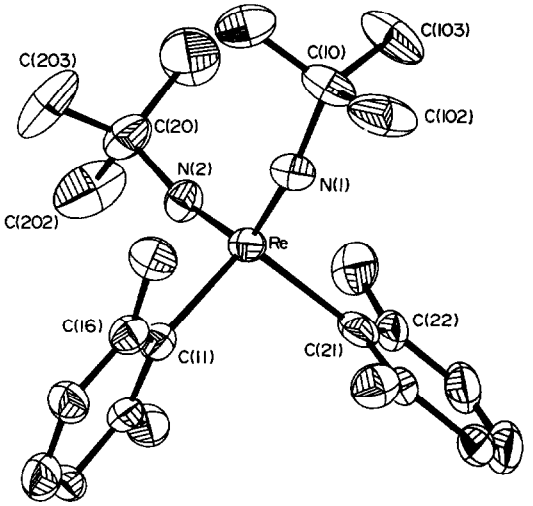

Fig. 1. The structure of $Re(NBu^t)_2(xyl)_2$.

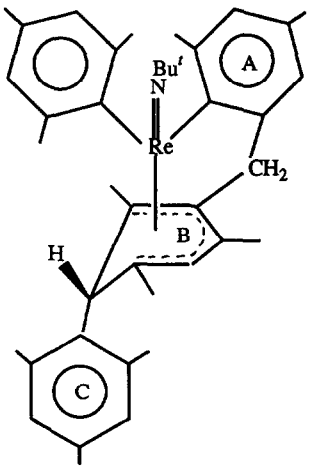
a six-line hyperfine structure with $g_{iso} = 1.934$, $A = 0.0141\ cm^{-1}$. On lowering the temperature the spectrum changes giving a complicated pattern comprising three sets of six rhenium hyperfine lines with uneven spacing. Similar patterns for the mesityl[3] and the related oxo aryls, $Re(O)_2(Ar)_2$,[1,2] were attributed to restriction of rotation of the aryl groups about the Re—C bonds and the same explanation probably holds in the present case.

(b) *The compound* $Re(NBu^t)(mes)(C_{27}H_{32})$. As noted above, interaction of $Re(NBu^t)_3Cl_3$ with mesityl Grignard, in diethyl ether gave $Re(NBu^t)_2(mes)_2$.[3] When this reaction is carried out in THF using a large excess of Grignard reagent (1:5 or more), about 15% of the rhenium can be recovered as a new complex with the structure shown in structure **1** together with $Re(NBu^t)_2(mes)_2$



(1)

and small amounts of bimesityl. The structure was determined by X-ray diffraction and a diagram of the molecule is shown in Fig. 2; selected bond lengths and angles are given in Table 4.

The formulation shown above as **1** was confirmed by experimental location and successful refinement of one hydrogen on each of C(31) and C(33). The bonding of the rhenium atom to the cyclohexadienyl ring is unsymmetrical with the Re—C(31) and Re—C(32) distances of 2.19 and 2.25(1) Å being considerably shorter than Re—C(34), Re—C(35) and Re—C(36) distances, 2.45, 2.44 and 2.39(1) Å, respectively. The shortest C—C distances in the ring are C(34)—C(35) and C(35)—C(36), each at 1.40(1) Å. The five-atom fragment C(31), C(32), C(34), C(35) and C(36) is planar to within 0.05 Å and the envelope fold up to C(33) is 36.7°. The two Re—C(aryl) distances are slightly different with Re—C(21) being the shortest at 2.159(7)°. Interestingly, the Re—C(11) distance, 2.191(8) Å, is very similar to the shortest Re—(dienyl) distance Re—C(31), 2.194(7) Å. The Re≡N distance to the *t*-butylimido ligand lies in the range found for the same interaction in other complexes. The compound is diamagnetic having rhenium formally in the V oxidation state. The ^{1}H NMR spectrum shows numerous bands for CH_3, CH_2 and aryl hydrogens and we have not attempted detailed assignment.

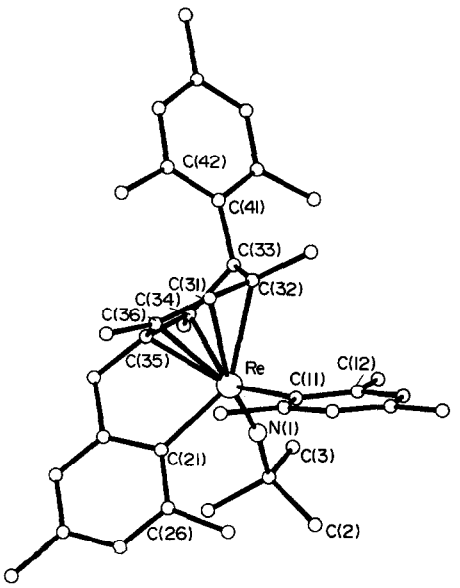


Fig. 2. The structure of the compound Re(Bu^{t}N)(mes) ($C_{27}H_{32}$).

The formation of the main product in the reaction, $Re(NBu^t)_2(mes)_2$, is presumably an independent reaction involving one-electron reduction by the Grignard of unisolated $Re(NBu^t)_2(mes)_2Cl$ or of $[Re(NBu^t)_2(mes)_2]^+$.

The generation of the moiety with rhenium bound to rings **A**, **B** and **C** in structure **1** may be accounted for by the established reactions of cyclometallation[4a] and reductive coupling,[4b,5] followed by nucleophilic attack[4c] by mesitylmagnesium bromide (i.e. by mes$^-$) on a cationic species.

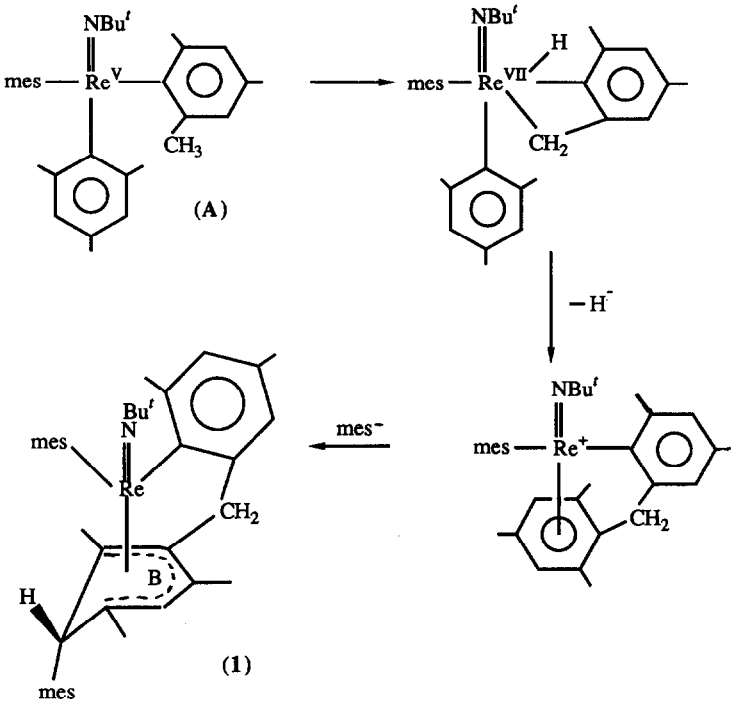
Thus, assuming an initial rhenium(V) species (**A**), a reasonable sequence for the synthesis of the compound can be envisaged as in Scheme 1. A problem arises in the formation of species **A** from the reaction of $Re(NBu^t)_2Cl_3$ with the Grignard reagent and in the loss of the NBu^t group, as well as in the fate of the hydride ion removed in Scheme 1. In the reaction products we have not been able to identify Bu^tNH_2 or Bu^t(mes)NH, which should arise from attack on the imido group by mes^-. There are precedents for removal of imido groups, e.g. by the attack of H^- on Re≡NPh in reductions of $Re(NPh)Cl_3(PR_3)_2$ by Na in THF.[6a] Interaction of this rhenium compound with excess $Mg(CH_2SiMe_3)_2$ also led to removal of the phenylimido group.[6b] The interaction of $Cr(OR)_2(NBu^t)_2$ with $ZnPh_2$ gave rise to Bu^tNHPh, biphenyl and other products,[7] while another elimination of an NBu^t



Scheme 1. Possible route for linking of mesityl groups with starting compound **A**.

group is that from $Cr(NBu^t)_2(COmes)_2$ to give *t*-butylmesitylamide, probably via acyl transfer to the imido nitrogen atom followed by another hydride transfer, probably from a mesityl group.[8]

(c) *Other aryl compounds.* The interaction of one equivalent of (*o*-tol)MgBr with $Re(NBu^t)_2Cl_3$ gave $Re(NBu^t)_2Cl_2(o\text{-tol})$[2] and three equivalents of $Re(NBu^t)_2(o\text{-tol})_3$.[3] Using two equivalents we obtained $Re(NBu^t)_2Cl(o\text{-tol})_2$ whose NMR spectrum suggests a *tbp* structure with equatorial imido and chlorine ligands (cf. refs 2 and 3). The IR spectrum has a band at 322 cm^{-1} assignable as ν(Re—Cl). The compound reacts with $AgPF_6$ in THF and the salt $[Re(NBu^t)_2(o\text{-tol})_2]PF_6$, which is a 1 : 1 electrolyte in MeCN, can be isolated. The ^1H NMR spectrum of the cation is similar to that of $Mo(NBu^t)_2(xyl)_2$[8] and of the mesityl and xylyl analogues discussed above.

For the molecule $Re(NBu^t)_3mes$, the crystals that could be obtained were not of good quality and this has reduced the precision of the structural determination. A diagram of the molecule is given in Fig. 3, selected bond lengths and angles in Table 5. The geometry is distorted tetrahedral with angles ranging from 95 to 123(1)°. The Re—N—C angles in the imido ligands vary from 142 to

161(1)° and the large deviations from 180° are consistent with the metal electron count exceeding 18 if all three imido groups were to act as 4e ligands.

(2) t-*Butylimido oxo compounds*

A number of compounds having both Bu^tN and oxo groups were obtained either from the hydrolysis product of $(Bu^tN)_2ReCl_3$ or by interaction of nitric oxide with the aryls $(Bu^tN)_2Re(Ar)_2$, Ar = xyl and mes. A bis-imido oxo compound, $ReO[N(2,6\text{-}C_6H_3{}^iPr_2)]_2CH_2Bu^t$, was made[9] by interaction of $Re(NAr)_2(CHBu^t)Cl$ with Me_4NOH in MeOH and characterized spectroscopically; the reaction was proposed to proceed via a hydroxo intermediate; an osmium(VI) compound, $Os(NBu^t)(O)(mes)_2$, has been structurally characterized by X-ray diffraction.[10]

(a) *From hydroxo species.* In a reaction of mesMgBr with a sample of $Re(NBu^t)_2Cl_3$ that had been inadvertently exposed to air for several weeks, work-up gave the two imido oxo aryls described below. In order to obtain a more rational synthesis, the hydroxo compound $Re(NBu^t)_2Cl(OH)_2$ was made by interaction of the trichloride with two equivalents of LiOH. The NMR and IR spectra are consistent with this formula; on heating, loss of water occurs to give $Re(NBu^t)_2Cl(O)$ as shown by the disappearance of OH bands and the appearance of an Re=O band in the IR spectrum. Interaction of the hydroxide in THF with mesMgBr gave products similar to the ones obtained from the aged sample of $Re(NBu^t)_2Cl_3$. These were separated by fractional crystallization and identified as $Re(NBu^t)_2(O)(mes)$, $[(Bu^tN)Br(mes)Re(\mu\text{-}NBu^t)(\mu\text{-}O)\overline{Re(OC_6H_2Me_2CH_2)(NBu^t)}]$, Bu^tNH_3Cl and a magnesium-containing solid. The compound $Re(NBu^t)_2(O)(mes)$ has also been obtained as the sole rhenium-containing product by the reaction

$$Re(NBu^t)_2ReCl_2(mes) \xrightarrow{Ag_2O,\ Et_2O} Re(NBu^t)_2(O)(mes) + 2AgCl.$$

This monomeric compound has a Re=O stretch at 908 cm^{-1} in the IR spectrum, while the mass spectrum shows the parent ion and peaks due to loss of oxygen and NBu^t groups.

The more complicated bridged dimer has been characterized by X-ray diffraction and the structure is shown in Fig. 4; selected bond lengths and angles are given in Table 6.

Neglecting the proposed metal–metal interaction, the coordination geometry at each metal is very distorted trigonal bipyramidal. Thus, for Re(1), O(1) and O(2) define the axis [angle = 149.9(4)°] and for Re(2), N(1) and Br(1) [angle = 158.0(3)°]. The Re—O(1)—Re bridge is close to symmetrical, whereas the two Re—N distances

C(20)—N(2)—Re(1)	161.9(13)		

in the Re—N(1)—Re bridge differ by *ca* 0.07 Å, with Re(2)—N(1) being the longer. This may be a reflection of N(1) occupying an axial site in the Re(2) coordination. The two imino functions show some bending [Re(1)—$\widehat{N(2)}$—C(20) = 162(1)°, Re(2)—$\widehat{N(3)}$—C(30) = 158(1)°] but both can be considered to act as normal 4e ligands, Re≡N—R.

The rhenium atoms that are bridged by μ-O and μ-NBu^t have formal oxidation state VI; since the compound is diamagnetic there is probably a metal–metal bond as in the homoleptic rhenium(VI) dimer,[3] $Re_2(NBu^t)_4(\mu\text{-}NBu^t)_2$, and the bond distances in the two compounds are 2.61 and 2.70 Å, respectively.

The ^{1}H NMR and IR spectra of the compound can be interpreted in terms of the above structure; the ^{1}H resonance of the *t*-butyl group of μ-NBu^t is at lower field than the terminal ones and the latter appear equivalent.

There must be a complex series of reactions leading to this product probably comprising condensation of Re(OH) groups to give ReORe, and hydrolysis of one imido group, probably via an amido intermediate; the phenolic moiety could arise by a cyclometallation reaction of an *o*-CH_3 group on a mesityl followed by an oxygen atom "insertion" into the Re—C bond.

(b) *From nitric oxide.* When NO is bubbled rapidly through hexane solutions of $Re(NBu^t)_2(Ar)_2$, Ar = xylyl or mesityl, the colour changes almost instantaneously and from the solutions yellow (xyl) or orange (mes) crystals of the dioxoimido compounds, $[Re(NBu^t)(O)_2Ar]_2$, can be isolated in high yield.

The X-ray crystallographic structure determinations of these two complexes have showed them to be dimeric with two oxo bridges. Diagrams of the structures are given in Figs 5 and 6, with selected bond lengths and angles in Table 7. In both cases the geometry about the metal is trigonal bipyramidal with the terminal imido group and a bridging oxygen atom occupying the axial sites. The bridging thus involves one axial and one equatorial site and both dimers are centrosymmetric.

In the mesityl the bridges are quite unsymmetrical, with equatorial and axial Re—O distances of 1.791(7) and 2.364(7) Å, respectively. This is not unexpected and can be ascribed to lengthening of the axial Re—O bond through the *trans* influence of the imido group. It was, therefore, surprising to

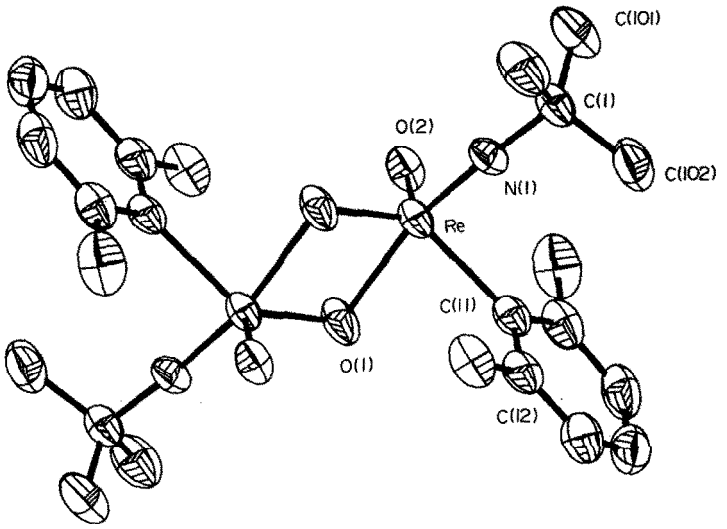

Fig. 5. The structure of $[Re(NBu^t)(O)(\mu\text{-}O)(xyl)]_2$.

find that in the xylyl, the bridge is more symmetrical, with equatorial and axial Re—O distances of 1.867(8) and 2.081(8) Å—a difference of only 0.21 Å compared to 0.57 Å in the mesityl. In all other respects, the geometries of the two compounds are very similar. We find it difficult to explain this major difference. The two compounds differ only in the presence of the extra methyl group in the mesityl complex, and this is most unlikely to affect the geometry of ligands around the metal. It does, however, affect the packing of the molecules in the unit cell, as evidenced by the choice of two quite different unit cells and crystal systems.

Asymmetric M_2O_2 rings have also been found in $Ru_2(\mu\text{-}O)_2(CH_2SiMe_3)_6$,[10a] which has a metal–metal bond and Ru—O distances of 2.208 and 1.733 Å, while $[OsO(o\text{-}OC_6H_{10}O)(quin)]_2$,[10b] quin = quinuclidene, has Os—O distances of 2.22 and 1.78 Å. An unsymmetrical single bridge has been found in a tungsten compound.[10c] For general information on MO and MOM distances see ref. 7(b) Table 5.2, p. 159 and West;[10d] in other compounds with Re_2O_2 rings such as $Re_2O_2(\mu\text{-}O)_2(CH_2CMe_3)_4$,[10e] the Re($\mu$-O) distances are essentially the same (1.967, 1.946 Å) but there is also a Re—Re bond (2.606 Å).

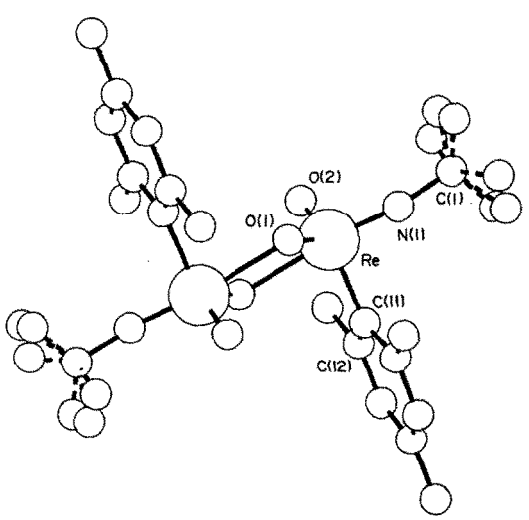

Fig. 6. The structure $[Re(NBu^t)(O)(\mu\text{-}O)(mes)]_2$.

The mass spectra do not show peaks of mass greater than the monomeric parent ions, $Re(NBu^t)_2(O)_2Ar^+$, so that the dimers must dissociate in the gas phase; there are other peaks to lower mass indicating loss of oxo and NBu^t groups.

The IR spectra of these and similar aryls (see Table 1 and ref. 11) show strong aromatic bands in the region associated with metal–oxygen stretching frequencies, and consequently it is not always easy to identify the Re=O or Re—O—Re stretch, and indeed some of these could be obscured. The IR of the xylyl compound shows two Re=O stretches at 952 and 925 cm^{-1} both in the solid state and in hexane solution. The mesityl differs in that only bands at 939 and 830 cm^{-1} in the solid-state spectrum can be identified, while in solution in hexane there are, as in the xylyl, two bands at 956 and 932 cm^{-1}. Oxygen exchange with $^{18}OH_2$ which would have helped identification of ReO bands cannot be done due to hydrolysis of the imido groups. For discussion of IR spectra of MO compounds see refs 7(b) and 10(d) and for compounds with Re_2O_2 (μ-O)$_2$ groups, ref. 10(e).

The other products of the NO reactions were identified as N_2O (by MS) and the unsymmetrical

Key to symmetry operations relating designated atoms to reference atoms at (x, y, z); (a) $-x, 1.0-y, 2.0-z$.

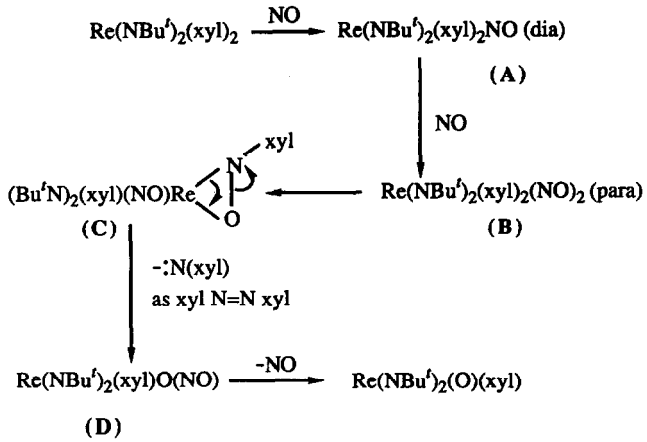
azo compounds, Bu^{t}N=NAr, so that the stoichiometry is that of eq. (1):

$$Re(NBu^t)_2(Ar)_2 + 3\,NO \longrightarrow Re(NBu^t)(O)_2Ar + N_2O + Bu^tN{=}NAr. \quad (1)$$

The reaction of $Re(NBu^t)_2(xyl)_2$ with one equivalent of NO was much slower than when excess NO was bubbled through the solution (*ca* 1 h vs a few seconds) and from the solution the nitrosyl compound, $Re(NBu^t)_2(xyl)_2(NO)$, could be isolated. This compound, formally having rhenium(V), is diamagnetic and the ^{1}H NMR spectrum shows that the NBu^t and aryl groups have a 1:1 ratio and that the equivalence is maintained to 223 K as there is no broadening or splitting of the peaks. The IR spectrum has a new band at 1639 cm^{-1} assignable as ν(ReNO). The spectra are thus consistent with a *tbp* structure with equatorial NBu^t and axial aryl groups. The mass spectrum shows the parent ion at $m/z = 569$ (Re^{187}) with other peaks due to loss of NO, O, Bu^t, N(xyl) and xylyl. Crystals suitable for X-ray study could not be obtained. The only similar nitrosyl derived by addition to a rhenium(VI) compound is the diamagnetic $ReMe_6(NO)$ which has ν(NO) at 1710 cm^{-1}.[12] The low NO stretches suggest that both species have bent MNO groups.

Treatment of the nitrosyl with slightly less than one equivalent of NO gives, as the final product, the complex $Re(NBu^t)_2(O)(xyl)$, which is the analogue of the tetrahedral $Re(NBu^t)_2(O)(mes)$ obtained by arylation of $Re(NBu^t)_2Cl(OH)_2$ as described above. Hence, there appears to be a substantial difference, presumably due to kinetic factors, between the reactions of the diaryls with stoichiometric amounts of NO and the very rapid reaction found when NO is bubbled through the solution. The final product in both cases has rhenium(VII) and does not react further with NO.

Considering first the stoichiometric reaction, this can be accounted for by well established chemistry as in Scheme 2. The five-coordinate diamagnetic nitrosyl **A** reacts with more NO to give a six-coordinate, paramagnetic dinitrosyl **B**, which would then undergo the well established aryl (or alkyl) transfer reaction[13] (also ref. 4, p. 1210) via an η^2-RNO intermediate leading to an M=O group and RN=NR as found for other paramagnetic compounds[12,13] such as $ReOMe_4$[13c] and

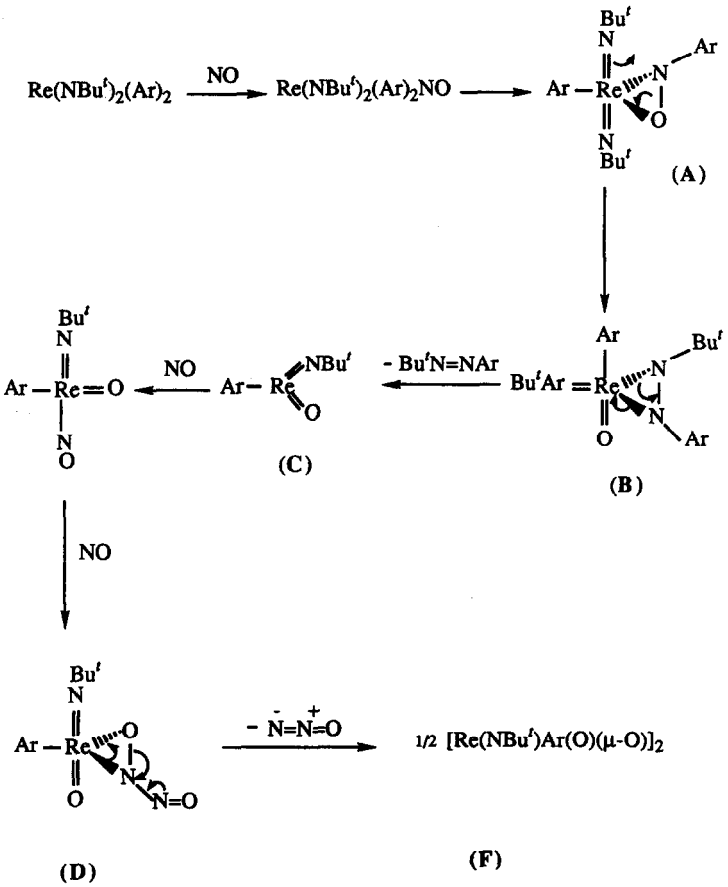


Scheme 2. Stoichiometric reaction of $Re(NBu^t)_2(xyl)_2$ with NO leading to $Re(NBu^t)_2(O)(xyl)_2$ and xylN=Nxyl.

$(C_5H_5)_2NbMe_2$.[13d] The oxo species **D** would doubtless readily lose NO to give the final stable product; the overall reaction is that of eq. (2):

$$Re(NBu^t)_2(xyl)_2 + NO \longrightarrow Re(NBu^t)_2(O)(xyl) + \tfrac{1}{2}(xyl)N{=}N(xyl). \quad (2)$$

The fast reaction presents a different problem since the mixed azo compounds, $Bu^tN{=}NAr$, were isolated. Although mixed azo compounds have been prepared by other methods,[14] these particular ones appear to be new. In Scheme 3 we propose that the ArNO species first formed by aryl migration to



Scheme 3. Interaction of $Re(NBu^t)_2(Ar)_2$, Ar = xyl, mes, with excess NO.

NO (either η^2 as in **A** of Scheme 2, or η^1), instead of giving ArN=NAr, either in an intermolecular reaction or by dimerization of eliminated :NAr, undergoes N—N bond formation to give species **B**. This intermediate could be regarded as an η^2-azo compound of rhenium(V) or more likely as a rhenium(VII) compound with a hydrazido (2−) ligand as drawn in Scheme 3. Examples of metal azo and hydrazido (2−) complexes are well established;[15] the distinction between azo and hydrazido (2−) is a somewhat formal one (cf. alkene and alkyne complexes, ref. 4, p. 71). This species, **B**, then undergoes a cheletropic[16] elimination of the azo compound leaving the coordinately unsaturated species **C** to react successively with two molecules of NO, probably via a dinitrosyl,[17a] to form the hyponitrite **D** which finally eliminates N_2O giving the isolated products **F**. The initial formation of a dinitrosyl as in **B** (Scheme 2) and elimination of N_2O at this point can be ruled out as this would give $Re(NBu^t)_2(Ar)_2O$ with rhenium in the impossible oxidation state of VIII.

While hyponitrites such as **D** have been proposed as intermediates and some examples characterized spectroscopically,[12a,b,17] recent calculations[17b] comparing $Re(NS)_2$ coupling with $Re(NO)_2$ coupling suggest[17b] that the latter "is disfavoured but might occur via N—N bonding". It can be noted regarding the formation of the azo compound that no examples of coupling of $M(NR)_2$ appear to be known (see ref. 7b, p. 273).

Finally, a question arises why in its reactions with NO, $Re(NBu^t)_2(mes)_2$ differs from $Re(O)_2(mes)_2$ which reacts quantitatively[10] as in eq. (3) to give dimesitylamido trioxorhenium(VII) via an η^2-ON(mes) intermediate,

$$Re(O)_2(mes)_2 + NO \longrightarrow O_3Re{=}N(mes)_2. \quad (3)$$

There would seem to be no reason *a priori* why the present reaction should not give $Re(NBu^t)_2O(Nmes_2)$ by the same route, but in order for a second aryl transfer to NAr to occur, the second aryl group would have to be in a position *cis* to the N atom of the η^2-ONAr group. Species **A** hence presumably has a NBu^t group in this position as shown in Scheme 3; *cis* geometry would be preserved even if the molecule is fluxional.

EXPERIMENTAL

Microanalyses were carried out by Imperial College and Pascher, Remagen, Laboratories. The spectrometers and general techniques used have been described.[3] The compounds $Re(NBu^t)_2Cl_3$[18] and $Re(NBu^t)_3Cl$[3] were prepared as described. Nitrogen oxide (British Oxygen Company) was passed through a tube of solid KOH and a copper spiral cooled at −78°C. In mass spectra, the rhenium compounds showed the correct $Re^{185,187}$ patterns for parent ions and fragments. NMR spectra were referenced to Me_4Si and are in ppm; IR spectra in cm^{-1} are in Nujol mulls unless otherwise specified.

(1) *Di*(t-*butylimido*)*di*(2,6-*dimethylphenyl*)*rhenium* (VI)

To $Re(NBu^t)_2Cl_3$ (0.43 g, 1 mmol) in Et_2O (20 cm^3) at −20°C was added 13 cm^3 of a 0.38 M solution of xylylmagnesium bromide in Et_2O. The resulting red solution was then stirred for 15 h at room temperature. After filtration and evaporation of the solution, the residue was extracted with hexane (3×15 cm^3) and the solution filtered through celite; concentration to 20 cm^3 and cooling at −20°C gave large red crystals. Yield: 0.45 g (83%). MS(FAB): 539 (100%), $^{187}M^+$; 537 (58%), $^{185}M^+$; 483 (8%), $M^+ - Bu^t$; 434 (10%), $M^+ - xylyl$; 427 (7%), $M^+ - 2Bu^t$. IR: 3047m, 2969s, 2926s, 1594m, 1456s, 1360s, 1261s, 1210m, 1091w, 1022m, 911vs, 801s, 766s, 716m, 525w. EPR: see text.

(2) *Di*(t-*butylimido*)*di*(2,6-*dimethylphenyl*)*rhenium* (VII) *hexafluorophosphate*

The solids $Re(Bu^tN)_2(xyl)_2$ (0.54 g, 1 mmol) and $AgPF_6$ (0.25 g, 1 mmol) were mixed under nitrogen and 25 cm^3 of THF added. On vigorous stirring the solution became bright orange and a grey precipitate of Ag appeared. After 2 h the solution was filtered and Et_2O (15 cm^3) added; cooling at −20°C gave crystals of the salt. Yield: 0.6 g (88%). MS(FAB): 539 (100%), $^{187}M^+$; 483 (5%), $M^+ - Bu^t$; 434 (6%), $M^+ - xyl$; 427 (5%), $M^+ - 2Bu^t$. IR: 1572w, 1365s, 1302w, 1261m, 1227m, 1173m, 1140w, 1099w, 1026w, 914s, 876w, 840vs, 786m, 739m, 704w, 557s, 471w. NMR: ^1H ($CDCl_3$): 7.42 (1H, m, *p*-$C_6H_3Me_2$); 7.21 (2H, d, *m*-$C_6H_3Me_2$); 2.46 (6H, s, *o*-$C_6H_3Me_2$); 1.80 (9H, s, NBu^t).

The *trifluoromethanesulphonate* was obtained similarly using AgO_3SCF_3 (0.26 g, 1 mmol). Yield: 0.55 g (81%); m.p. 131°C dec. The IR spectrum is the same as for PF_6^- except for anion bands.

(3) *Interaction of* $[Re(NBu^t)_2(xyl)_2]PF_6$ *and* Bu^tNC

To the PF_6^- salt (0.2 g, 0.3 mmol) in THF (15 cm^3) was added Bu^tNC (0.04 cm^3, 0.35 mmol). The solution became pale yellow and after stirring for 1 h, hexane (10 cm^3) was added to precipitate a white solid. Recrystallization from THF gave crystals of

$[Re(NBu^t)_2(xyl)(\eta^2\text{-}Bu^tNC{=}Cxyl)]PF_6$. MS(EI): 513 (1%), $^{187}M^+$, and a variety of peaks from 435 to 131. IR: 2981s, 2935s, 1713s, 1639w, 1459s, 1365m, 1246m, 1215m, 1188s, 1173s, 1093w, 1030w, 911m, 816w, 842vs, 785m, 737w, 710w, 558s, 472w, 360w. NMR: ^1H ($CDCl_3$): 7.34 (2H, m, *p*-$C_6H_3Me_2$); 7.21 (4H, m, *m*-$C_6H_3Me_2$); 2.44 (6H, s, *o*-$C_6H_3Me_2$); 2.32 (6H, s, *o*-$C_6H_3Me_2C{=}NBu^t$); 1.61 (18H, s, NBu^t); 1.14 (9H, s, $C{=}NBu^t$).

(4) $(Bu^tN)(2,4,6\text{-}Me_3C_6H_2)(C_{27}H_{32})Re^V$

To $(Bu^tN)_2ReCl_3$ (0.7 g, 1.6 mmol) in THF at −40°C was added mesMgBr (8 cm^3 of a 1 M solution in THF) and the red solution stirred for 12 h, while warming to room temperature. The solvent was removed, the residue extracted with Et_2O and this solution evaporated and the residue extracted with hexane. The filtered solution on cooling at −20°C yields $Re(NBu^t)_2(mes)_2$[1] in *ca* 65% yield. Dissolution of the residue from the hexane extraction in THF–hexane (2 : 1) and cooling the solution at −20°C gave red crystals. Yield: *ca* 13%. The compound was recrystallized from THF–hexane to give X-ray quality crystals. IR: 2973s, 1638s, 1618, 1505w, 1456w, 1403w, 1385w, 1372w, 1357s, 1256s, 1211s, 1134s, 1010m, 949w, 922w, 844s, 805w, 710m, 669m, 602w, 554w, 511w, 464w. NMR: ^1H (C_6D_6): 6.94 (2H, s, *m*-H); 6.71 (2H, s, *m*-H); 3.98 (1H, s, cyclohexadienyl-H); 2.80 (1H, s, *endo*cyclic H); 2.27 (3H, s, Me); 2.18 (2H, s, CH_2); 2.15 (3H, s, Me); 2.11 (3H, s, Me); 2.06 (3H, s, Me); 2.04 (9H, s, 3Me); 1.98 (12H, s, 4Me); 1.26 (9H, s, Bu^t). Some bimesityl[19] was also isolated from the solution after removal of $Re(NBu^t)_2(mes)_2$.

(5) *Bis*(t-*butylimido*)*chlorobis*(2-*methylphenyl*)*rhenium*(VII)

To $Re(NBu^t)_2Cl_3$ (1.0 g, 2.3 mmol) in Et_2O (10 cm^3) at −25°C was added *o*-tolMgBr (1.5 cm^3 of a 3.3 M solution in Et_2O) and the mixture slowly warmed to room temperature and stirred for 5 h. Removal of solvent, extraction of the residue with hexane (*ca* 10 cm^3) and cooling (−20°C, 3 days) gave crystals. Yield: 0.86 g (68%). MS(FAB): 511 (100%), $^{187}M^+ - Cl$; 437 (53%), $^{187}Re(NBu^t)(o\text{-tol})_2^+$; 420 (16%), $^{187}Re(NBu^t)_2(o\text{-tol})^+$.

(6) *Bis*(t-*butylimido*)(2-*methylphenyl*)*rhenium*(VII) *hexafluorophosphate*

The interaction of equimolar quantities of $Re(NBu^t)_2(o\text{-tol})_2Cl$ (0.464 g) and $AgPF_6$ (0.225 g), each in THF (*ca* 5 cm^3), at room temperature gives a precipitate of AgCl and a yellow solution. After 2 h stirring, the solution was filtered, concentrated (5 cm^3) and hexane (*ca* 3 cm^3) added; cooling at −20°C gave crystals. Yield: 0.43 g (78%). MS(FAB): 511 (85%), $^{187}Re(NBu^t)_2(o\text{-tol})_2^+$; 420 (19%), $^{187}Re(NBu^t)_2(o\text{-tol})^+$; 57 (100%), Bu^{t+}.

(7) *Bis*-t-*butylimido*(*chloro*)(*dihydroxo*)*rhenium*(VII)

To a mixture of $(Bu^tN)_2ReCl_3$ (0.435 g, 1 mmol) and LiOH (0.06 g, 1.5 mmol) was added THF (50 cm^3). The dark red solution slowly turns yellow with a white precipitate (LiCl). After stirring for 1 h the solution was filtered, concentrated (3 cm^3) and hexane (5 cm^3) added to precipitate the yellow solid which was washed with Et_2O (3 × 10 cm^3). Yield: 81%. MS(FAB): 399, (35%) $^{187}M^+$; 74 (100%), $Bu^tNH_3^+$; 57 (100%), Bu^{t+}. MS(EI): 310 (1%), $^{187}Re(NBu^t)OH^{35}Cl^+$; 270 (2%), $^{187}Re(N)(OH)_2{}^{35}Cl^+$; 58 (100%), Bu^tH^+. IR: 3417s(OH), 2966m, 2925w, 1634m, 1455w, 1359w, 1261s, 1219w, 1093s, 1019s, 914s, 879w, 858m, 800m, 454m, 397m, 321m. NMR: ^1H ($CDCl_3$): 5.62 (2H, br, OH); 1.32 (18H, s, Bu^t).

(8) *Reaction of* $Re(NBu^t)_2Cl(OH)_2$ *with mesityl magnesium bromide*

(a) *Bis*(t-*butylimido*)*oxomesitylrhenium*(VII). *Method A*: To $Re(NBu^t)_2Cl(OH)_2$ (0.6 g) in THF (10 cm^3) at −20°C was added mesMgBr (6 cm^3, 1 M solution in Et_2O) and the solution stirred for 12 h at room temperature. Removal of solvent, extraction of the residue into hexane (3 × 15 cm^3), filtration and concentration (5 cm^3) of the dark yellow solution followed by cooling at −20°C gave yellow crystals of $Re(NBu^t)_2(O)(mes)$. Yield: 0.48 g (68%). MS(EI): 464 (29%), $^{187}M^+$; 448 (25%), $^{187}M^+ - O$; 393 (80%), $^{187}M^+ - NBu^t$; 336 (24%), $^{187}Re(N)(O)(mes)^+$; 329 (3%), $^{187}Re(NBu^t)_2^+$; 306 (9%), $^{187}Re(mes)^+$; 58 (100%), Bu^tH^+. IR: 2970s, 2924s, 1597w, 1453m, 1376w, 1359m, 1261s, 1209s, 1094s, 1025s, 908s, 849m, 805s, 706w, 596w, 511w, 462w, 387m.

Method B: A solution of $Re(Bu^tN)_2Cl_2(mes)$[1] (0.26 g) in THF (10 cm^3) was stirred with 0.15 g of moist Ag_2O for 2 h. After filtration the solution was evaporated and the residue extracted into hexane (15 cm^3); concentration (to 3 cm^3), followed by cooling at −20°C gave yellow crystals of $Re(NBu^t)_2(O)mes$. Yield: 0.18 g (73%).

(b) *The bridge species* $(Bu^tN)(Br)(mes)Re(\mu\text{-}NBu^t)(\mu\text{-}O)\overline{ReOC_6H_2Me_2CH_2}(NBu^t)$. The mother liquor from above in method A after removal of $Re(NB^t)_2(O)(mes)$ was evaporated and the residual dark yellow oil allowed to stand at −20°C for *ca* 3

days. The red crystals were collected, washed with Et_2O and dried. Yield: 0.25 g (19%). IR: 2974s, 2924s, 2856m, 1456s, 1385s, 1357s, 1259s, 1200s, 1133m, 1099m, 1018s, 912w, 844s, 805s, 710s, 669s, 513m. NMR: $^1H(C_6D_6)$: 6.87 (1H, s, *m*-H); 6.83 (1H, s, *m*-H); 6.49 (2H, s, *m*-H); 3.01 (3H, s, Me); 1.68 (6H, s, 2Me); 1.07 (9H, s, μ-NBu^t); 0.88 (18H, s, NBu^t).

(9) *Reactions with nitrogen monoxide*

(a) t-*Butylimido(dioxo)(2,6-dimethylphenyl)rhenium*(VII). Nitrogen monoxide was bubbled through a hexane solution of $Re(NBu^t)_2(xyl)_2$ (0.54 g, 1 mmol) until the colour changed to light orange. The solvent was removed and the residue was dissolved in hexamethyldisiloxane (5 cm^3); the solution was filtered, concentrated to 2 cm^3 and cooled to -20°C to give yellow crystals. Yield 0.35 g (90%). MS(EI): 395 (35%), $^{187}M^+$; 393 (21%), $^{185}M^+$; 379 (71%), M^+-O; 339 (85%), M^+-Bu^t; 323 (62%), $^{187}Re(NH)(O)(xyl)^+$; 105 (100%), xyl. IR: 2966s, 1652w, 1575w, 1447m, 1404w, 1379m, 1362m, 1261s, 1130w, 1023m, 952s, 925s, 829s, 805m, 770m, 752w, 707w, 558m, 483w, 391m. NMR: ^1H ($CDCl_3$): 7.31–7.19 (3H, m, *m*, *p*-$C_6H_3Me_2$); 2.55 (6H, s, *o*-$C_6H_3Me_2$) 1.58 (9H, s, Bu^{t}N).

(b) t-*Butylimido(dioxo)(2,4,6-trimethylphenyl) rhenium*(VII). Nitrogen monoxide was bubbled through $(Bu^tN)_2Re(mes)_2$ (0.283 g) in hexane (10 cm^3) at room temperature until the dark red solution became light orange with the appearance of a faint precipitate. The solution was filtered, evaporated and the residue extracted into hexamethyldisiloxane (*ca* 8 cm^3). After concentration (3 cm^3) and cooling (-20°C) the orange crystals were collected. Yield: 0.29 (84%). MS(EI): 409 (40%), $^{187}M^+$; 393 (71%), $^{187}M^+-O$; 377 (4%), M^+-O_2; 353 (73%), $^{187}M^+-Bu^t$; 306 (13%), $^{187}Re(mes)^+$; 119 (90%), $C_9H_{11}^+$. IR: 3016w, 2975s, 2920m, 1589s, 1541w, 1467w, 1448s, 1398w, 1379m, 1362m, 1286m, 1230s, 1033m, 984w, 939s, 857m, 830s, 803m, 706w, 599m, 582m, 565w, 541w, 387w, 329m. NMR: ^1H ($CDCl_3$): 7.14 (2H, s, *m*-H); 2.52 (6H, s, *o*-Me), 2.32 (3H, s, *p*-Me); 1.58 (9H, s, Bu^t).

The hexamethyldisiloxane mother liquor from above was evaporated, the residue dissolved in Et_2O (5 cm^3), the solution filtered, concentrated to 2 cm^3 and cooled at -20°C to give orange crystals of the azo compound Bu^{t}N=Nmes, which were recrystallized from Et_2O. Yield: 0.05 g (70%), m.p. 116°C. [Found (required): C, 74.2 (74.5); H, 9.5 (9.8); N, 13.9 (13.7)%.] NMR: ^1H ($CDCl_3$): 6.98 (2H, s, *m*-$C_6H_2Me_3$); 2.80 (6H, s, *o*-$C_6H_2Me_3$); 2.18 (3H, s, *p*-$C_6H_2Me_3$); 1.60 (9H, s, N*Bu^t*). IR: 2966s, 2921m, 2861m, 1652w, 1610w, 1597w, 1550w, 1465s, 1376w, 1360m, 1261m, 1208w, 910w, 882w, 853m, 801s, 709w.

(c) *Di*(t-*butylimido)di*(2,6-*dimethylphenyl)nitrosylrhenium*(V). To a solution of $Re(NBu^t)_2(xyl)_2$ (0.3 g, 0.55 mmol) in hexane (10 cm^3) at -78°C, in a small flask with septum, was injected via a gas syringe NO (11 cm^3, 0.5 mmol). The solution was allowed to warm and was stirred at room temperature until the initial deep red colour changed to light yellow (*ca* 1 h). Evaporation in vacuum, extraction of the residue into $(Me_3Si)_2O$ (2×3 cm^3) and cooling of the solution (-30°C) gave orange crystals. Yield: 0.14 g (45%). MS(EI): 569 (44%), $^{187}M^+$; 567 (26%), $^{185}M^+$; 553 (14%), M^+-O; 539 (10%), M^+-NO; 513 (8%), M^+-Bu^t; 450 (30%), $Re(NBu^t)_2(xyl)O^+$; 434 (51%), $Re(NBu^t)_2(xyl)^+$; 379 (72%), $Re(NBu^t)NH(xyl)^+$; 322 (33%), $Re(NH)_2(xyl)^+$; 105 (100%), xyl^+. IR: 1639m, 1616m, 1575w, 1564w, 1533m, 1439s, 1384w, 1360s, 1286w, 1250m, 1230s. NMR: $^1H(CDCl_3)$: 7.21–7.11 (3H, m, *m*, *p*-$C_6H_3Me_2$); 2.85 (6H, s, *o*-$C_6H_3Me_2$); 1.61 (9H, *s*, NBu^t).

(d) *Interaction of nitrosyl compound with* NO. To a solution of $Re(NBu^t)_2(xyl)_2NO$ (0.1 g, 0.17 mmol) in Et_2O (15 cm^3) was injected slightly less than one equivalent of NO and the solution stirred for *ca* 12 h. No change in colour takes place. Evaporation of the solution, extraction of the residue with $(Me_3Si)_2O$ (5 cm^3) and cooling of the filtered solution (-30°C) affords dark yellow crystals of $Re(NBu^t)_2(O)(xyl)$. Yield: 0.06 g (68%). MS(EI): 450 (30%), $^{187}M^+$; 448 (18%), $^{185}M^+$; other peaks due to M^+-Bu^t and M^+-NBu^t; 338 (21%), $Re(NH)_2(O)(xyl)^+$; 323 (17%), $ReNH(O)(xyl)^+$; 105 (61%), xyl^+; 58 (100%), $C_4H_{10}^+$. IR: Re=O, 912 cm^{-1} and other Bu^{t}N and xylyl bands. NMR: ^1H ($CDCl_3$): 7.37–7.15 (3H, m, *m*, *p*-$C_6H_3Me_2$); 2.78 (6H, s, *o*-$C_6H_3Me_2$); 1.62 (18H, s, *Bu^t*N).

X-ray crystallography

Crystals of all six compounds were sealed under argon in thin-walled glass capillaries for X-ray work. Following preliminary photography, orientation matrices and associated cell dimensions were obtained using a CAD4 diffractometer and standard procedures. Intensity data were recorded[20] using ω–2θ scans and graphite monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å), and corrected for Lp effects and for absorption using psi-scan information. Further corrections for absorption were made during the refinement process, using the DIFABS method.[21]

The structures were solved and developed via the heavy atom method and refined by full-matrix least-squares. The usual difficulties were encountered with disorder of *t*-butyl groups generally, and the crystal quality for $Re(NBu^t)_3(xyl)$ was poor. Otherwise all atoms were refined in the anisotropic displacement mode and no hydrogens were included except for $Re(NBu^t)(mes)(C_{27}H_{32})$.

Details of the crystal data, intensity measurements and refinement are given in Table 8.

Tables of final atomic positional parameters and displacement factor coefficients, bond lengths and angles and F_o/F_c values have been deposited with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

Abstract—The oxidation of the titanium(III) ketimido complex, $Cp^*_2Ti{-}N{=}CPh_2$ ($Cp^* = C_5Me_5$), with $AgBPh_4$ in the presence of traces of moisture gives the cationic ketimine complex $[Cp^*_2Ti(OH)(HNCPh_2)]BPh_4 \cdot Et_2O$ (**1**). The structure of the complex has been determined by X-ray diffraction. The cation has a pseudo-tetrahedral structure. The Ti—OH distance is short [1.853(7) Å], indicating Ti—O double bond character, while the diphenylketimine ligand acts as an N-donor, with a bent Ti—N—C arrangement [145.1(5)°].

Cationic titanium complexes of the type $[Cp_2Ti{-}X]^+$ are highly reactive, coordinately unsaturated organometallic Lewis acids. If X = alkyl they readily undergo insertion reactions with unsaturated organic substrates,[1,2] including the polymerization of alkenes.[3] As we have shown recently,[4] the one-electron oxidation of titanium(III) complexes by $AgBPh_4$ provides a convenient synthetic route to such complexes under very mild conditions. We have explored the usefulness of this method for the synthesis of a number of compounds with different ligands X and report here the synthesis and crystal structure of a complex obtained by the oxidation of a titanium(III) ketimido complex.

EXPERIMENTAL

All operations were carried out under dry argon using standard vacuum-line techniques. Solvents were distilled under nitrogen from sodium benzophenone (THF, diethyl ether, petrol), sodium (toluene) or calcium hydride (dichloromethane). Perkin–Elmer 684 and 1720X (IR) and Jeol PMX-60 spectrometers were used. Cp^*_2TiCl[5] and $AgBPh_4$[4] were prepared as described. $LiN{=}CPh_2$ was prepared from PhCN and LiPh in diethyl ether.[6]

Preparation of $[Cp^*_2Ti(OH)(HNCPh_2)]BPh_4 \cdot Et_2O$ (1)

To a solution of Cp^*_2TiCl (0.5 g, 1.4 mmol) in 30 cm^3 of diethyl ether at −70°C were added dropwise 6 cm^3 of a 0.25 M solution in $LiNCPh_2$ in Et_2O–THF 10:1 (1.5 mmol). The mixture was allowed to warm to room temperature, during which time the colour changed from blue to brown. The solvent was removed *in vacuo*, the residue was extracted with petrol and filtered. Removal of the solvent left $Cp^*_2Ti{-}NCPh_2$ as an air-sensitive brown oil. IR (neat film, cm^{-1}): 1630 [ν(C=N)]. The product was not characterized further but was immediately used for the subsequent reaction.

The crude product was taken up in 20 cm^3 of THF and the solution cooled to −78°C. After addition of solid $AgBPh_4$ (0.5 g, 1.1 mmol) in small portions the solution turned orange and was allowed to warm to room temperature. Removal of the solvent gave a deep orange oil which solidified

† Author to whom correspondence should be addressed.

on treatment with diethyl ether. The product was recrystallized from THF–Et_2O to give **1** as orange plates (0.3 g, 0.34 mmol, 31%). IR (Nujol mull, cm^{-1}): 3630 [m, sharp, ν(OH)], 3275 [m, sharp, ν(NH)], 1648 [m, ν(C=N)]. Found: C, 80.5; H, 8.3; N, 1.5. Calc. for $C_{61}H_{70}BNTiO$: C, 82.1; H, 7.9; N, 1.6.

X-ray crystallography

All measurements were made on a crystal sealed under argon in a glass capillary, using a CAD4 diffractometer and graphite monochromated Mo-K_α radiation (λ = 0.071069 Å). Unit cell and intensity data were obtained following standard procedures previously described.[7]

The structure was solved using the heavy-atom procedure and refined via full-matrix least-squares methods. Non-hydrogen atoms were refined anisotropically, hydrogen atoms with idealized positions and group U_{iso} values. The ketimine hydrogen was located on a difference map and included, but the hydroxyl hydrogen was not. A molecule of diethyl ether of solvation was identified towards the end of the structure determination.

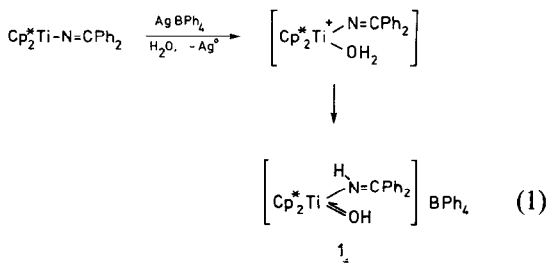
Crystal data. $C_{61}H_{72}BNO_2Ti$, M_r = 1066.44, triclinic, a = 10.321(5), b = 14.774(2), c = 17.151(3) Å, α = 86.01(1), β = 85.63(3), γ = 89.55(3)°, V = 2601.36 Å^3, Z = 2, D_{calc} = 1.36 g cm^{-3}, $F(000)$ = 977, μ(Mo-K_α) = 1.62 cm^{-1}, space group $P\bar{1}$. 5715 intensities measured ($1.5 \leqslant \theta \leqslant 25.0°$), 5571 unique, 3348 observed [$F_o > 3\sigma(F_o)$], corrected for absorption via azimuthal scan data. 241 parameters in least squares, R = 0.070, R_w = 0.070, g = 0.001188.

Atomic coordinates, displacement factor coefficients, full lists of bond lengths and angles and F_o/F_c lists have been deposited with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

While there is evidence for 16-electron cationic titanium azavinylidene complexes as intermediates of nitrile insertion reactions of $[Cp_2TiMe(L)]^+$, such compounds could not be isolated.[2] By contrast, analogous isoelectronic (and presumably isostructural) neutral compounds of scandium exist.[8] Work was therefore aimed at exploiting increased steric hindrance as a means of stabilizing coordinately unsaturated azavinylidene complexes of titanium(IV).

Treatment of the blue titanium(III) complex Cp^*_2TiCl with $LiC{=}NPh_2$ gives brown solutions of a petrol-soluble oily product, assumed to be $Cp^*_2TiNCPh_2$, which could not be crystallized. Oxidation of this compound with $AgBPh_4$ in THF is facile, producing metallic silver and an orange product, **1**, which is obtained as orange plates on recrystallization from THF–diethyl ether. The IR spectrum of **1** indicates the presence of C=N double bonds and also exhibits two sharp bands at 3630 and 3275 cm^{-1}. While the first of these is the typical stretching frequency of an OH ligand free of hydrogen bonding,[4] the second is reminiscent of ν(N—H) in ketimine complexes; in the Lewis adduct $(4\text{-}MeC_6H_4)_2C{=}NH \cdot BF_3$, for example, this band appears at 3280 cm^{-1}.[6] Apparently, traces of moisture† were present during the oxidation reaction, leading to the formation of a titanium hydroxo complex and the protonation of the azavinylidene ligand [eq. (1)]:



(1)

1

The structure of **1** has been determined by X-ray crystallography. A diagram of the cation is shown in Fig. 1, selected bond lengths and angles are given in Table 1. The coordination geometry of the titanium centre in the cation is pseudo tetrahedral. The Ti—OH distance is remarkably short [1.853(7) Å], suggesting double bond character via d_π–p_π interactions for the Ti—O bond. The neutral diphenylketimine ligand forms a Ti—N single bond of 2.170(9) Å, similar to the Ti—nitrile bond in $[(Indenyl)_2Ti(N{=}CMePh)(NCPh)]^+$ [2.175(7) Å][2] but significantly less than the Ti—pyridine distance in the sterically crowded complex $Ti(OC_6H_3Bu^tCMe_2CH_2)(OC_6H_3Bu^t_2)(CH_2SiMe_3)(py)$ [2.293(5) Å].[9] Comparison with the pyridine complex points to an absence of significant steric hindrance in the case of **1**. The Ti—N—C(21) linkage forms an angle of 145.1(5)°, rather wider than required for sp^2-hybridized nitrogen, and is tilted 18.1° out of the O—Ti—N plane. The two phenyl substituents of C(21) are twisted out of the

† Examination of the $AgBPh_4$ used by FT-IR suggested minute traces of coordinated water [ν(OH) 3670, 3610 cm^{-1}] which could not be removed by vacuum drying at 60°C for 6–8 h. Complete removal of water is hampered by the temperature sensitivity of the silver salt.

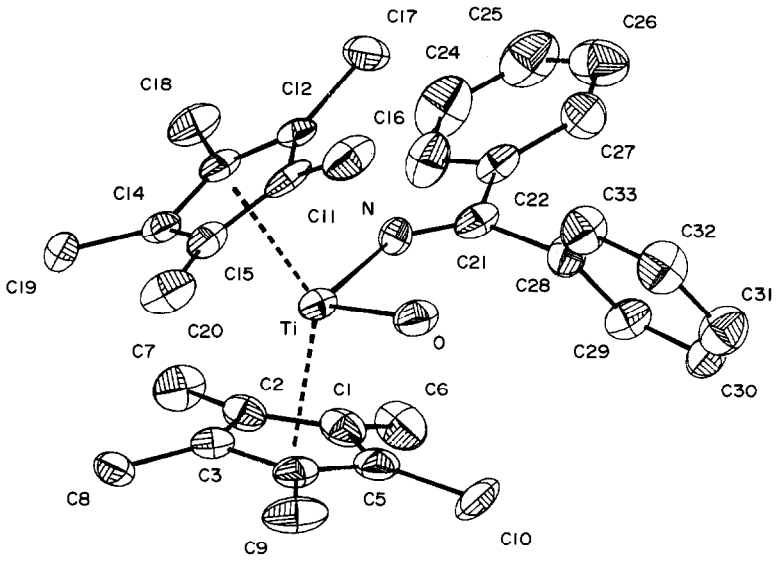

Fig. 1.

Ti—N—C(21) plane by 25.9 and 120.1°, respectively.

The coordination geometry of **1** and the bond lengths distribution resembles a pattern previously observed for $[Cp^*_2Ti(OH)(OH_2)]^+$, with a tightly bonded OH ligand free of hydrogen bonds, and a more loosely coordinated neutral donor ligand.[4] The formation of the hydroxo-ketimine complex **1** in preference to the isomeric azavinylidene-aquo complex $[Cp^*_2Ti(N{=}CPh_2)(OH_2)]^+$ reflects the different acidities of the two ligands and is evidence for the more effective Ti—O d_π–p_π interaction compared to Ti—N.

(*Received* 24 *January* 1990; *accepted* 3 *April* 1990)

Abstract—The aqueous equilibria in the systems L-cysteine or D-penicillamine + VO^{2+} have been studied by a combination of pH-potentiometric and spectroscopic methods [electron paramagnetic resonance (EPR), visible absorption and circular dichroism (CD)] in the pH range 1.8–13.5. For pH > 4, high ligand-to-metal ratios were used. The results of the various methods are made self-consistent, then rationalized assuming an equilibrium model including species ML_2H_2, ML_2H_4, ML_2H_3, ML_2H_2, ML_2H, ML_2, ML_2H_{-1} and M_2L_2 (where H_2L denotes either L-cysteine or D-penicillamine) and several hydrolysis products; their formation constants and individual electronic spectra (isotropic and CD) are given. Isomeric structures are discussed for each stoichiometry.

The first part of this series[1] introduced our work and gave detailed results for the system L-AlaH + VO^{2+} in the pH range 2–12. Part II concerned complexing of oxovanadium(IV) by L-serine or L-threonine,[2] and Part III the L-aspartic acid + VO^{2+} system.[3] The present paper describes our potentiometric and spectroscopic study of the complexation of oxovanadium(IV) by the sulphur-containing amino acids L-cysteine and D-penicillamine. Part of this work has been presented in a preliminary form.[4]

The inherent interest of such vanadium sulphur systems exemplified by studies of their localization in blood components from cells of ascidians (e.g. *A. mentula* and *A. aspersa*)[5] is reinforced by the discovery that the vanadium nitrogenase of *Azotobacter* is apparently a vanadium–sulphur–iron complex.[6] Further, the well-known vanadium impurities in some crude oils, arising from vanadyl porphyrins and elsewhere, are converted under hydrorefining to sulphido–vanadium complexes. These deactivate hydrotreating catalysts, rendering the treatment of Western crudes problematic.[7]

Some work has been published on systems involving cysteine and its derivatives.[8–17] Johnson and Shepherd[8] recorded EPR spectra at room temperature of solutions at pH = 7 with total oxovanadium(IV) and L-cysteine concentrations of 6.8×10^{-3} and 1.0 M, respectively, and calculated $A_0 = 85$ gauss. The corresponding visible spectra show maxima at 535 and 730 nm. Comparing these results with those for several other systems, Johnson and Shepherd concluded that, under their conditions, coordination of cysteine to VO^{2+} involves in-plane binding of sulphhydryl S and glycinate N.[8]

Cysteine reduces vanadate(V) to oxovanadium(IV): kinetics and products depend on the pH

† For Parts I–III, see refs 1–3.

‡ Author to whom correspondence should be addressed.

and on the concentrations of cysteine and vanadium.[9] With excess of cysteine, cystine is produced.[9,11-13]

In solutions containing an excess of cysteine at pH ~ 7, a stable, purple complex forms with a structure probably similar to that of the complex of cysteine methyl ester (CysOMe) prepared and characterized by X-ray diffraction by Sakurai and co-workers.[13-15] This contained S_2N_2 coordination in the equatorial plane.

The EPR spectra of the CysOMe–VO^{2+} complex in borate buffer (pH 10.5) at 77 K show the presence of two species, the more important having $g_\parallel = 1.964$, $g_\perp = 2.003$, $A_\parallel = 143.6$ and $A_\perp = 47.0 \times 10^{-4}$ cm^{-1}.[14] The minor component was detected not only in the EPR but in the IR and Raman spectra and Sakurai and co-workers concluded that *cis*- and *trans*-isomers were present.[13,14] Sifri and Riechel studied the electrochemistry in DMSO of 2:1 complexes of cysteine, CysOMe and CysOEt.[16]

A Chinese publication mentions the preparation of $K[VO(CysH)(H_2O)_2]SO_4$ and *cis*- and *trans*-$K_2[VO(Cys)_2]$ ($CysH_2$ = cysteine).[17] Further, for $VOSO_4$ and cysteine in 1:1 ethylene glycol–water, when increasing the pH from 1 to 14, the EPR spectra were said to suggest stepwise formation of $[VO(OH_2)_5]^{2+}$, $[VO(H_2O)_3(CysH_2)]^{2+}$, $[VO(H_2O)_2(CysH)]^{+}$, *cis*- and *trans*-$[VO(Cys)_2]^{2-}$ and $[VO(OCH_2CH_2O)_2]^{2-}$.

The results of our work with L-$CysH_2$ and D-$PenH_2$ differ from those for the L-AlaH,[1] L-SerH, L-ThrH,[2] L-aspartic acid[3] and L-glutamic acid[18] systems for much of the pH range studied (1.8–13.5). This difference stems from coordination of the thiol group at quite low pH (~ 4).

Experimental difficulties in work involving oxovanadium(IV) and amino acids were discussed in Part I.[1] Between pH 4 and 8, relatively high ligand-to-metal ratios (L/M) must be used to avoid extensive hydrolysis and eventual precipitation of $VO(OH)_2$. However, such precipitation and/or the presence of a soluble product of oxovanadium(IV) hydrolysis for pH $\gtrsim$ 5 is clearly less important for L-$CysH_2$ and especially for D-$PenH_2$ as compared to L-AlaH, L-SerH and L-ThrH systems, and lower L/M ratios may be used.

Both ligands contain three dissociable protons, with macroscopic dissociation constants: $pK_{a1} \sim 2$, $pK_{a2} \sim 8$ and $pK_{a3} \sim 10.5$. The value of pK_{a1} can be ascribed unambiguously to deprotonation of the carboxyl group, but the values of pK_{a2} and pK_{a3} arise from a combination of microprocesses corresponding to (i) dissociation of the thiol group followed by the amino group, or (ii) dissociation of the amino group followed by the thiol group. For the present study of formation constants the microconstants are not required, so we have not measured them.

Since pK_{a1}, pK_{a2} and pK_{a3} can easily be determined, the calculated formation constants correspond to the general reaction:

$$xM^{2+} + yL^{2-} + zH^{+} \rightleftharpoons M_xL_yH_z. \qquad (1)$$

We abbreviate L-cysteine as H_2C and the cysteinate dianion is then C^{2-}. D-Penicillamine is abbreviated as H_2P and the penicillaminate dianion as P^{2-}. For the formulations $(VO)_x(Cys)_y(H)_z$ and $(VO)_x(Pen)_y(H)_z$ we normally use the abbreviations $M_xC_yH_z$ and $M_xP_yH_z$, respectively, or $M_xL_yH_z$ to denote both. When needed, we abbreviate L-alanine and L-serine as HA and HS, and alaninate and serinate as A^- and S^-, respectively.

For each $M_xL_yH_z$ in our final equilibrium model, the isotropic visible absorption spectrum (ε_{xyz}) and CD spectrum ($\Delta\varepsilon_{xyz}$) are calculated and possible structures are discussed.

EXPERIMENTAL

Materials and methods

The MINIQUAD,[19] SUPERQUAD[20] and the SQUAD[21] programs were used to refine formation constants and calculate spectra of individual species.

All solutions were prepared in an inert atmosphere (high purity dinitrogen passed through soda-lime and glass wool). All measurements were performed at 25°C with solutions containing 2.25 M $NaNO_3$.

The instruments used and the calibration procedure for pH measurements were described in Part I.[1] The maximum pH value for the titration curves of solutions containing L-$CysH_2$ or D-$PenH_2 + VO^{2+}$ was ~ 6.7.

D-Penicillamine (Sigma) for stock solutions was dried for 2 days (in a vacuum desiccator over silica gel). For the more concentrated solutions, HNO_3 (2.00 M) was added. For cysteine stock solutions, L-$CysH_2 \cdot HCl \cdot xH_2O$ ($x \sim 1$) (Merck) was always used. The value of x was determined by thermogravimetry. Such stock solutions were used within a maximum of ~ 36 h and exact concentrations were checked by titration with strong base (graphic representation and the Gran procedure[22] were used). Refinement of total H^+ and/or amino acid, in the calculations with SUPERQUAD, always gave final values for these "dangerous parameters" very close to the initial values supplied.

Several titration curves with $0.04 \lesssim C_{Cys}$ or

$C_{Pen} \lesssim 0.07$ M (C_{Cys}, C_{Pen}—total cysteine and penicillamine concentrations, respectively) were obtained to determine the protonation constants in 2.25 M $NaNO_3$; NaOH (2.2 M) was used. As $J_H \sim 20$ [eq. (2)], the corrections in the acid range are significant only for pH < 2.0.

$$E = E^{\ominus} + S \times \log[H^+] + J_H \times [H^+] + J_{OH} \times [OH^-]. \quad (2)$$

As for previous systems,[1-3] two types of titration curves were obtained: those involving measurements in the range $2.2 \lesssim pH \lesssim 4.3$ (with $1 \lesssim L/M \lesssim 4$ and $0.005 \lesssim C_{VO} \lesssim 0.017$ M) and those involving pH measurements in the range $4.0 \lesssim pH \lesssim 6.7$ ($20 \lesssim L/M \lesssim 79$ and $0.0025 \lesssim C_{VO} \lesssim 0.0063$ M).

Unusually, for D-$PenH_2$, in the titration with L/M = 4 ($C_{VO} = 0.016$ M), no precipitation or unstable EMF readings were found in the pH range 4–7. This notwithstanding, EMF readings for pH > 4.3 were not used in the calculations with MINIQUAD and SUPERQUAD, because the properties of the soluble hydrolysed vanadium species which forms in this pH range (presumably $[(VO)_2(OH)_5^-]_n$) are not accurately known.[23,24]

Totals of 75 and 100 CD spectra were recorded for the L-cysteine and the D-penicillamine systems, respectively; a total of about 50 isotropic visible absorption spectra was recorded for each system. Calculations with the SQUAD program were made only for D-Pen: 40 visible spectra and 95 CD spectra (visible region) were used for the calculation of spectra of individual species, with total concentrations in the range $0.0017 \lesssim C_{VO} \lesssim 0.03$ M and $0.036 \lesssim C_{Pen} \lesssim 0.26$ M, respectively. Ligand-to-metal ratios were in the range 1.9–73.

Several spectra were recorded with solutions containing S-methyl-L-cysteine (Sigma) or L-cysteine ethyl ester (Aldrich). For these, a solution of pH = 2.0 and $C_{VO} = 0.0088$ M was prepared and its CD spectrum recorded. NaOH (4 M) was added and CD was measured for each ~0.6 pH increment. At pH ~ 4.2, vanadyl hydroxide precipitated. An excess of base was then added to pH ~ 9.2, and the CD spectrum taken of the resulting clear greenish-blue solution. HNO_3 (2 M) was added and CD spectra were recorded for each decrement of ~0.6 pH units. For pH < 5.0, vanadyl hydroxide again precipitated.

For $pH \gtrsim 10$, the pH reading of solutions containing L-CysOEt: VO^{2+} = 45.1 slowly decreased. For $pH \gtrsim 11.3$, this decrease was fairly rapid (the $|\Delta\varepsilon_m|$ values simultaneously increased). This is probably due to hydrolysis of the ester group, producing L-cysteine. This may also be the origin of the slight pH modifications in solutions containing L-CysOEt + VO^{2+} at pH < 3.0.

For $pH \lesssim 10$, L-CysOEt hydrolyses slowly: the production of any appreciable concentration of L-Cys would have prevented precipitation of vanadyl hydroxide at pH 4–5. However, this was in fact observed both on addition of base to solutions with pH < 4, or of acid to solutions with pH > 8. Consequently, the measured spectra involve L-CysOEt as ligand.

RESULTS

(1) *Preliminary comments*

The spectroscopic results permit, on cursory inspection, some deductions useful in defining the detailed method of treating the potentiometric results. We therefore present our results in two sections, viz. these preliminary deductions from spectra followed by the calculations of speciation.

EPR spectra

The EPR spectra for frozen "solutions" containing L-cysteine or D-penicillamine and VO^{2+} at 77 K are typical VO^{2+} axial spectra. The field region that corresponds to $A_\parallel$ and $M_I = 5/2$ and 7/2 gives more information about the type and number of species present.

Figure 1 includes the high-field region of the spectra of frozen "solutions" containing D-penicillamine with L/M 18.5 at several values of pH. Results for L-cysteine are similar. PI to PVII (CI to CVII for the L-cysteine system) represent distinct components. Each corresponds to a set of g and A values ($\parallel$ and $\perp$): there may of course be more than one vanadium complex with these approximately the same, so there is not necessarily a 1:1 correlation of observed component with a single chemical species.

Analysing Fig. 1, and comparing it with results for L-cysteine and other systems, we make the general observations:

(i) Components PIII, PIV and PV are detected at values of pH lower by 0.3–0.8, than are CIII–CV.

(ii) For $pH \lesssim 4.7$ (for L-Cys) or $\lesssim 3.9$ (for D-Pen) one can distinguish at least two components, PI (or CI) and PII (or CII). Their g and A parameters indicate that the species responsible are of the same type as those we earlier associated with components LI and LII in the L-AlaH, L-SerH and L-ThrH + VO^{2+} systems.

(iii) The g and A parameters for CIII and PIII

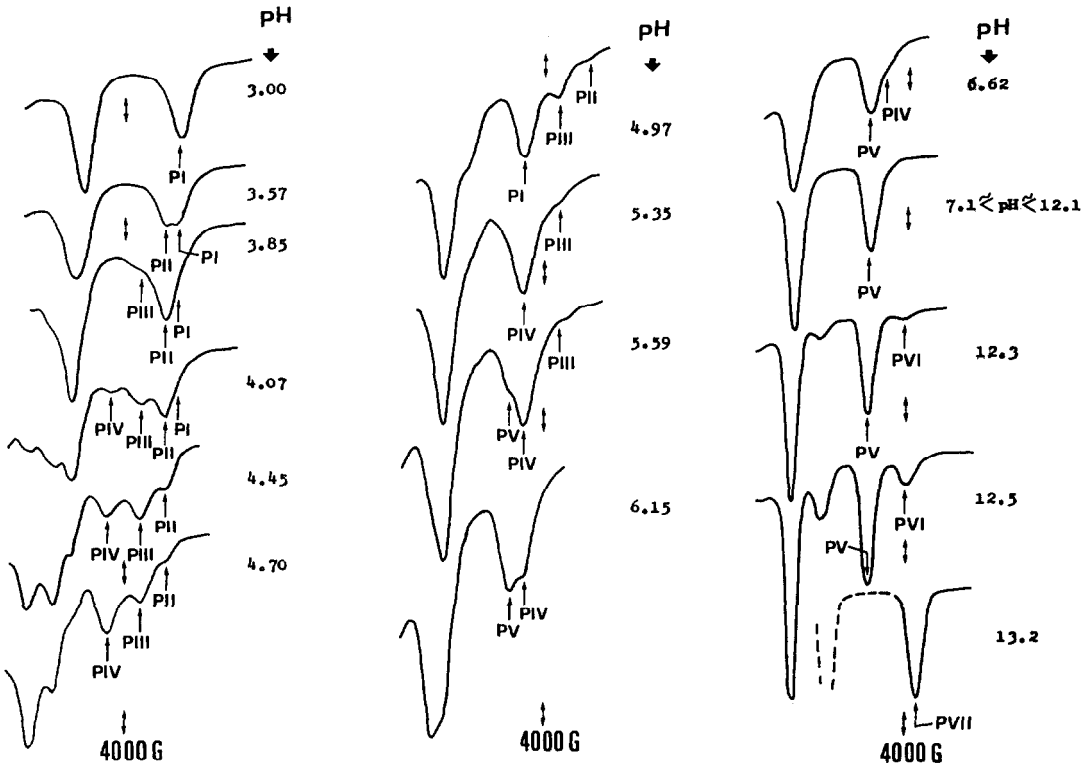

Fig. 1. High-field range (3600–4200 gauss) of the first derivative EPR spectra at 77 K of frozen "solutions" containing D-Pen and VO^{2+} with L/M = 18.5. The total vanadium concentration is ~ 0.004 M. pH values are indicated.

correspond to those for LIII in the L-AlaH, L-SerH and L-ThrH + VO^{2+} systems.[1,2] However, while in those systems, LIII is the sole component detected at pH ~ 6, CIII and PIII are always detected simultaneously with other signals, and they predominate at lower pH values (~ 4.1–7 for CIII and ~ 3.8–5.7 for PIII). Further, the stepwise spectral changes CIII → CIV → CV and PIII → PIV → PV occur in a much narrower range of pH than for the "same type" of components in the L-serine or L-threonine systems.

(iv) While the transformations SIV → SIV′ (L-serine system) and TIV → TIV′ (L-threonine system) occur with no detectable differences in the g and A parameters,[2] in the "corresponding" transformations CIV → CV and PIV → PV, $A_{\parallel}$(CIV,PIV) > $A_{\parallel}$(CV,PV).

(v) The range of pH where CIV + CV or PIV + PV can be detected, ~ 5–12.2 and 4–13, respectively, is much broader than for SIV + SIV′ or TIV + TIV′.

(vi) In the L-Cys and D-Pen systems, PV, PVI and PVII (or CV, CVI and CVII) are clearly distinct. This was not the case for the "corresponding" components in the L-SerH and L-ThrH + VO^{2+} systems.[2]

(vii) Hydrolysis at high pH of the cysteinate and penicillaminate complexes ($[VO(OH)_3]^-$ being formed?) occurs at slightly lower pH than for the "corresponding" serinate and threoninate complexes.

Components CV and PV correspond to $g_{\perp} = 1.976$, $g_{\parallel} = 1.962$, $A_{\perp} = 45$ and $A_{\parallel} = 143 \times 10^{-4}$ cm^{-1}; the following approximate values are estimated from spectra with two or more components:[25]

PIII and CIII → $g_{\parallel} \sim 1.945$ and $A_{\parallel} \sim 164 \times 10^{-4}\,cm^{-1}$

PIV and CIV → $g_{\parallel} \sim 1.956$ and $A_{\parallel} \sim 151 \times 10^{-4}\,cm^{-1}$

PVI and CVI → $g_{\parallel} \sim 1.942$ and $A_{\parallel} \sim 156 \times 10^{-4}\,cm^{-1}$.

The EPR parameters estimated for PVII (and CVII) approximately correspond to those reported for $[VO(OH)_3]^-$.[26]

CD and visible absorption spectra

As for EPR, these electronic absorption spectra and their changes with pH are similar for the present systems. We ascribe minor differences to the fact that the stepwise transformations as pH increases: PI, PII → PIII → PIV → PV occur in a narrower pH range than for the L-cysteine case. We shall, in the main, present results (and calculations) for D-penicillamine. L-Cysteine is, *mutatis mutandis*, similar.

(a) *Fixed* L/M, *variable pH*. Figures 2 and 3 include visible spectra of D-PenH_2 solutions with L/M 23.7 (ε_m and $\Delta\varepsilon_m$ are measured ε and $\Delta\varepsilon$ per mole of vanadium). The changes in the pH range 2–4.5 resemble those for L-serine and L-threonine[2] in the pH range 2–6. In the pH range 4.5–7.4, bands I and II shift further to lower wavelengths, but while band II weakens, band I increases.

In the pH range 8.3–10.3, the visible spectra are invariant with maxima at 526 and 729 nm and $\varepsilon_m = 18.3$ and 42.1. This and the EPR spectra suggest that in these conditions only one species exists: its visible spectrum is therefore known. For pH $\gtrsim$ 12.6, as in the other systems studied, the general increase in ε_m (especially for 450–600 nm) suggests extensive hydrolysis of VO^{2+}; the characteristic bands I and II are no longer distinct.

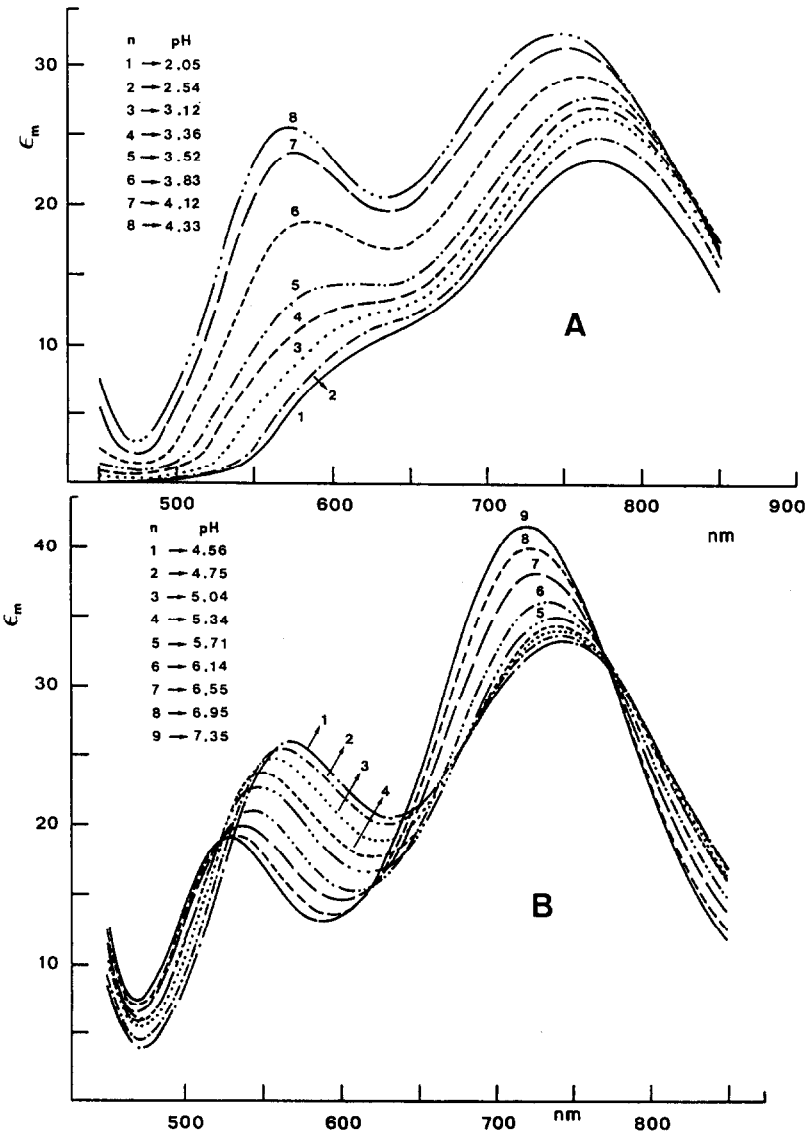

Fig. 2. Visible spectra of solutions containing D-Pen+VO^{2+} with L/M = 23.7 and $C_{VO} = 9.8$–10.6×10^{-3} M. The pH corresponding to each spectrum is indicated. The CD spectra of some of these solutions are given in Figs 4 and 5.

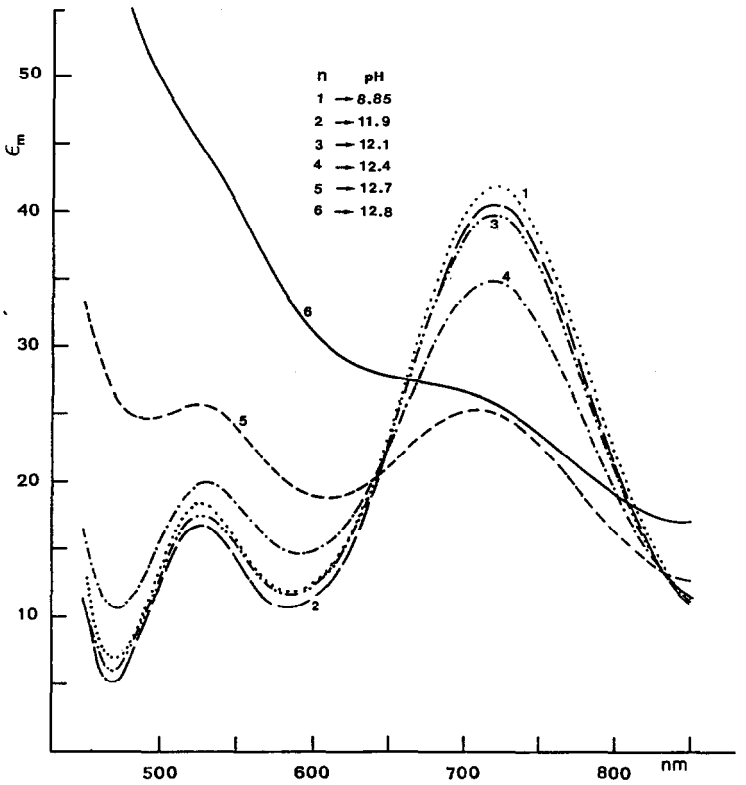

Fig. 3. Visible spectra of solutions containing D-Pen+VO^{2+} for pH > 8.8 with L/M = 23.7 and $C_{VO} = 8.9–9.8 \times 10^{-3}$ M. The pH corresponding to each spectrum is indicated and the CD spectra for the same solutions are given in Fig. 6.

As for other systems,[1-3,18] the visible CD spectra for D-penicillamine or L-cysteine+VO^{2+} vary enormously in the pH range 1–14. For them, this occurs especially for $2 \lesssim pH \lesssim 7.5$ and $10.5 \lesssim pH \lesssim 13.5$. Figures 4–6 include CD spectra for D-penicillamine with L/M = 23.7, all inverted [$\Delta\varepsilon_m \times (-1)$] to facilitate comparison with other L-amino acids. The CD spectra and their changes with pH have some similarities with those in the L-serine and L-threonine systems.[2]

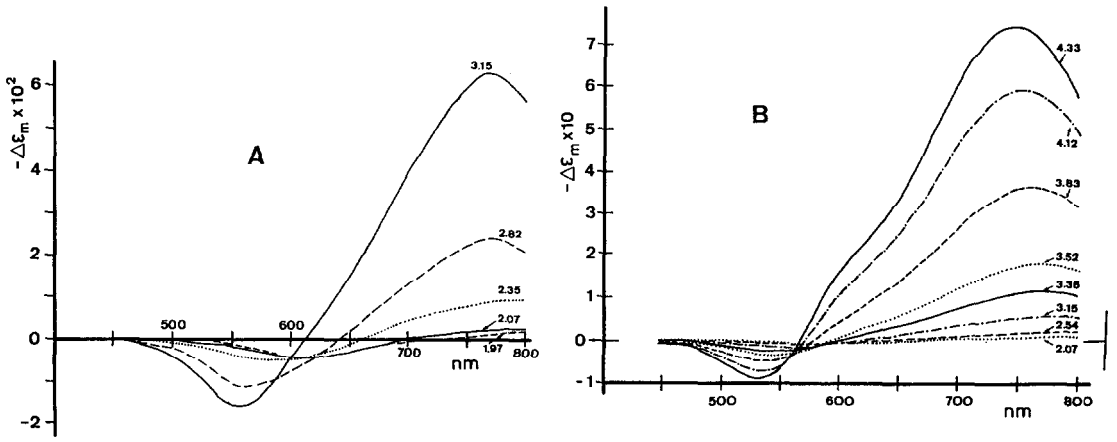

Fig. 4. CD spectra of solutions containing D-Pen+VO^{2+} with L/M = 23.7 and $C_{VO} \sim 0.01$ M. The pH corresponding to each spectrum is indicated. The visible spectra of some of these solutions are given in Fig. 2.

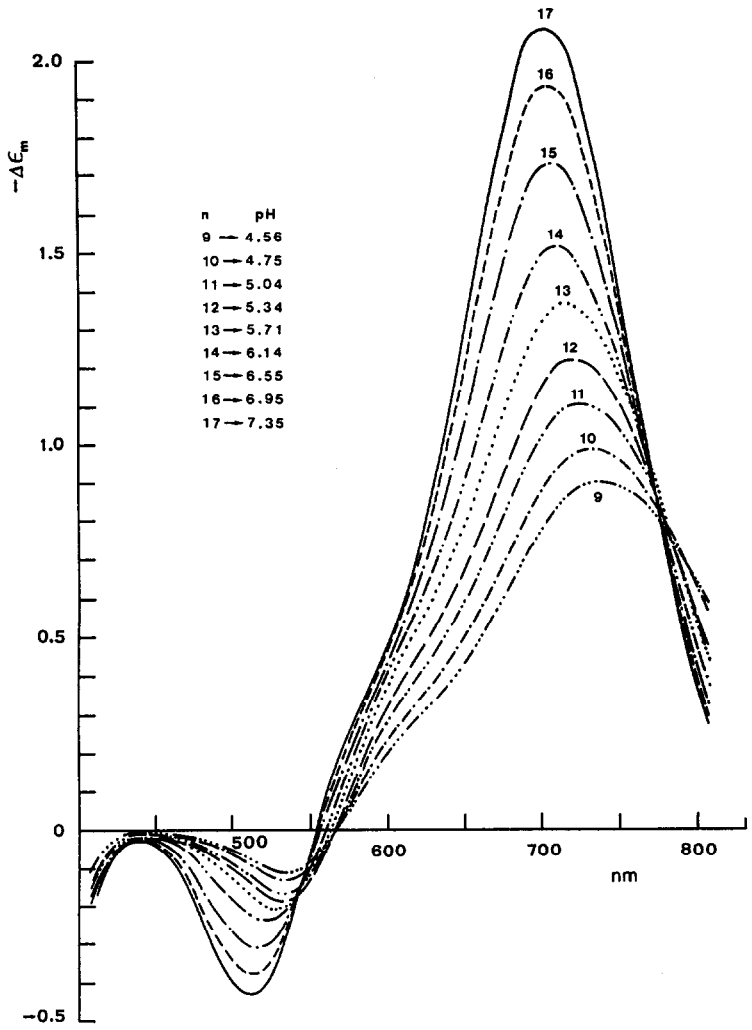

Fig. 5. CD spectra of solutions containing D-Pen+VO^{2+} with L/M = 23.7 and $C_{VO} \sim 0.01$ M. The isotropic absorption spectra of these solutions are given in Fig. 2.

Analysing Figs 2–6, and comparing them with L-cysteine and other systems, we can make the general observations:

(i) The CD spectra of Fig. 4 show that—for very low pH—$\Delta\varepsilon_m$ for $\lambda > 600$ nm are approximately zero. Depending on C_{VO} and C_{Pen}, $\Delta\varepsilon_m$ are always very small but may be of either sign. This, clearer in the glutamic acid system,[18] suggests the existence of two (or more) complexes with differing signs of $\Delta\varepsilon$ for $\lambda > 600$ nm. Their relative importance may differ slightly in the L-cysteine system. This (L/M = 35.0 and $C_{VO} = 0.01$ M, pH $\sim$ 1.2 and 1.8) manifests two CD bands at $\sim$ 680 and 780 nm and $\Delta\varepsilon_m > 0$, as for L-Ala at low pH.[1]

(ii) For pH < 3.5, $|\Delta\varepsilon_m|^{Pen}$, and—to an extent—$|\Delta\varepsilon_m|^{Cys}$ ($400 < \lambda < 800$ nm), are much greater than $|\Delta\varepsilon_m|^{Ser,Thr}$, notably for $\lambda > 600$ nm. The species are akin (as concluded from the EPR spectra), but complexes with high $|\Delta\varepsilon_{xyz}|$ values form at lower pHs with L-cysteine or D-penicillamine.

(iii) As pH increases, the differences between $|\Delta\varepsilon_m|^{Pen,Cys}$ and $|\Delta\varepsilon_m|^{Ser,Thr}$ diminish and $|\Delta\varepsilon_m|^{Pen,Cys}$ of band I increase much more than those of band II.

(iv) As for the visible spectra, CD spectra of solutions containing D-penicillamine with L/M = 23.7 coincide in the range $8.3 \lesssim$ pH $\lesssim 10.3$. Spectra in the same range with L/M = 72.7 still coincide.

(v) For L-cysteine/VO^{2+} = 35.0, the visible and CD spectra in the pH range 8.8–10.3 do not quite coincide. This means that—besides

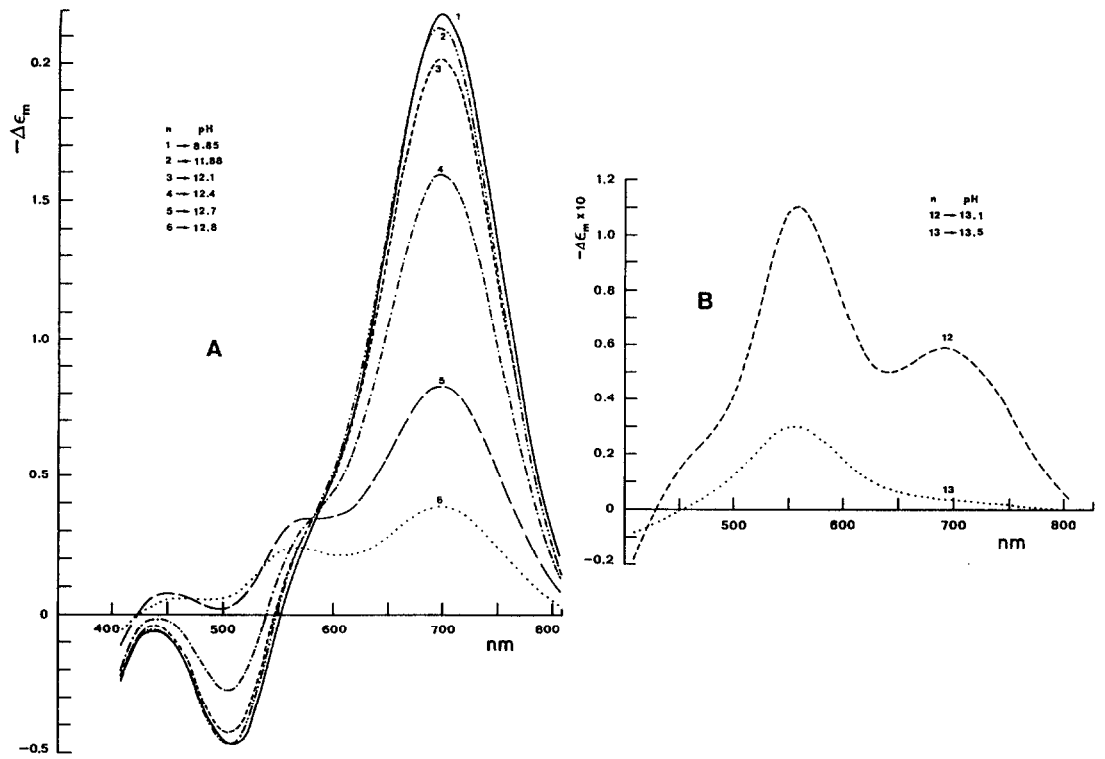

Fig. 6. CD spectra of solutions containing D-Pen + VO^{2+} with L/M = 23.7 and $C_{VO} = 8.4–9.6 \times 10^{-3}$ M. The isotropic absorption spectra of the solutions with pH < 12.8 are given in Fig. 3. Note the different scales for (A) and (B).

species CIII, CIV and CV forming at pH higher than the corresponding PIII, PIV and PV—CV never (unlike PV) gets to ~ 100%.

(vi) For pH > 10.3, $|\Delta\varepsilon_m|$ for $600 < \lambda < 800$ nm decrease [Fig. 6(A)] and for pH ~ 12.7 a band at ~ 500 ($\Delta\varepsilon < 0$) is clear. The complex responsible probably gives component PVI in the EPR (Fig. 1). At pH ~ 13.5, the CD spectrum [13 in Fig. 6(B)] of D-Pen : VO^{2+} = 23.7 gives only one band for $\lambda > 500$ nm. For L-Cys with L/M = 35.0, the spectra at pH ~ 12.8 and 13.2 (C1 and C2 in Fig. 15) clearly show this band ($\lambda \sim 550$ nm; $\Delta\varepsilon_m > 0$) and another ($\lambda \sim 660$ nm; $\Delta\varepsilon_m < 0$). The species responsible (CVI?) is probably a product from hydrolysis of CV. A similar CD spectrum is *not* seen for pH ~ 13.5 for D-penicillamine, probably because PV hydrolyses at significantly higher pH than CV does.

(b) *Fixed pH, variable* L/M. Figures 7–9 show CD spectra for D-penicillamine (Fig. 9(A) is for L-cysteine) at fixed pH and variable L/M. Analysing and comparing them with L-cysteine, we can make the following general observations:

(i) At pH = 4.04 [Fig. 7(A)], the CD spectra show only minor changes for L/M in the range 72.7–38.8. For L/M $\lesssim$ 30 the $|\Delta\varepsilon_m|$ decrease substantially.

(ii) At pH = 4.54 [Fig. 7(B)], as L/M decreases from 72.7 to 14.5, $|\Delta\varepsilon_m|$ (600–800 nm) clearly increase and band I shifts hypsochromically. For L/M < 14, all $|\Delta\varepsilon_m|$ (400–600 nm) decrease.

(iii) At pH = 5.54 [Fig. 8(A)], the CD spectra show no important changes, but as L/M decreases from 72.8 to 4.8, $|\Delta\varepsilon_m|$ (600–800 nm) clearly fall and band I shifts to higher wavelengths. To a lesser extent, the same happens at pH 5.74 (spectra not shown).

(iv) At pH ~ 7.2, for both L-cysteine and D-penicillamine, the CD spectra show minor changes as L/M decreases (spectra not shown). For L-cysteine, $\Delta\varepsilon_m$ ($\lambda \sim 710$ nm) decreases only by 10% as L/M varies from 97.0 to 9.7.

(v) At pH ~ 12.8 [Fig. 8(B)], the visible $|\Delta\varepsilon_m|$ substantially decrease as L/M varies from 23.7 to 7.8; an isodichroic point is observed ($\lambda \sim 420$ nm, $\Delta\varepsilon_m \sim 0$). For L-cysteine at pH ~ 12.8 with L/M between 35 and 13, the CD spectra all resemble C1 (Fig. 15) and the $|\Delta\varepsilon_m|$ values decrease with L/M. For pH ~ 12.5 and

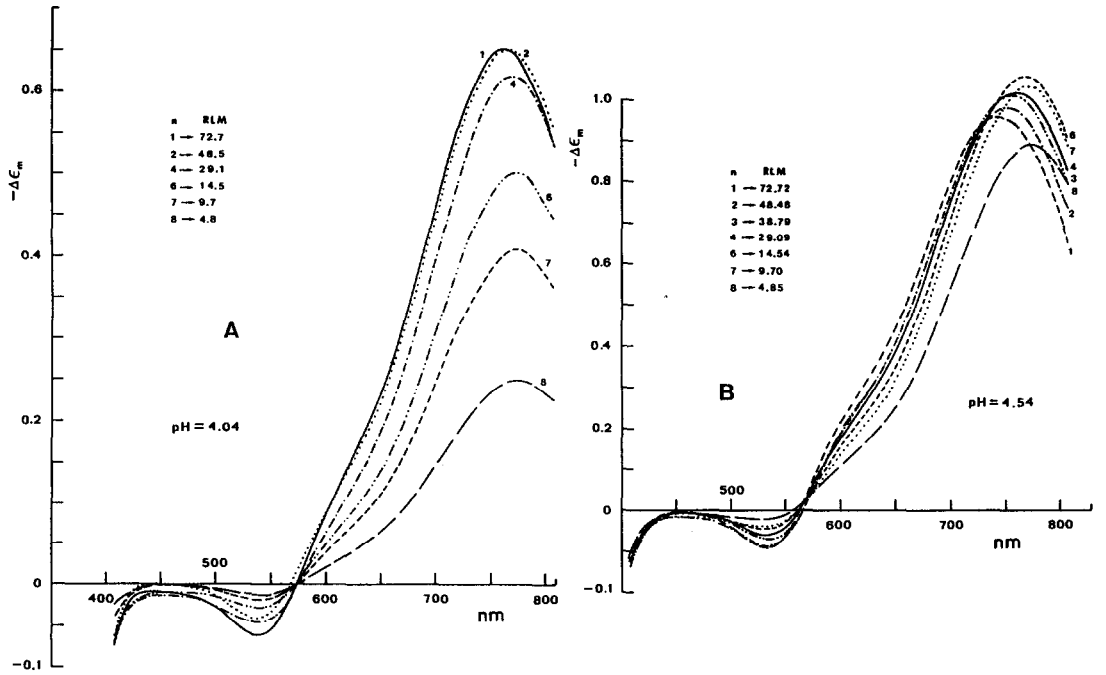

Fig. 7. CD spectra of solutions containing D-Pen and oxovanadium(IV) with varying L/M (denoted by RLM) at fixed pH.

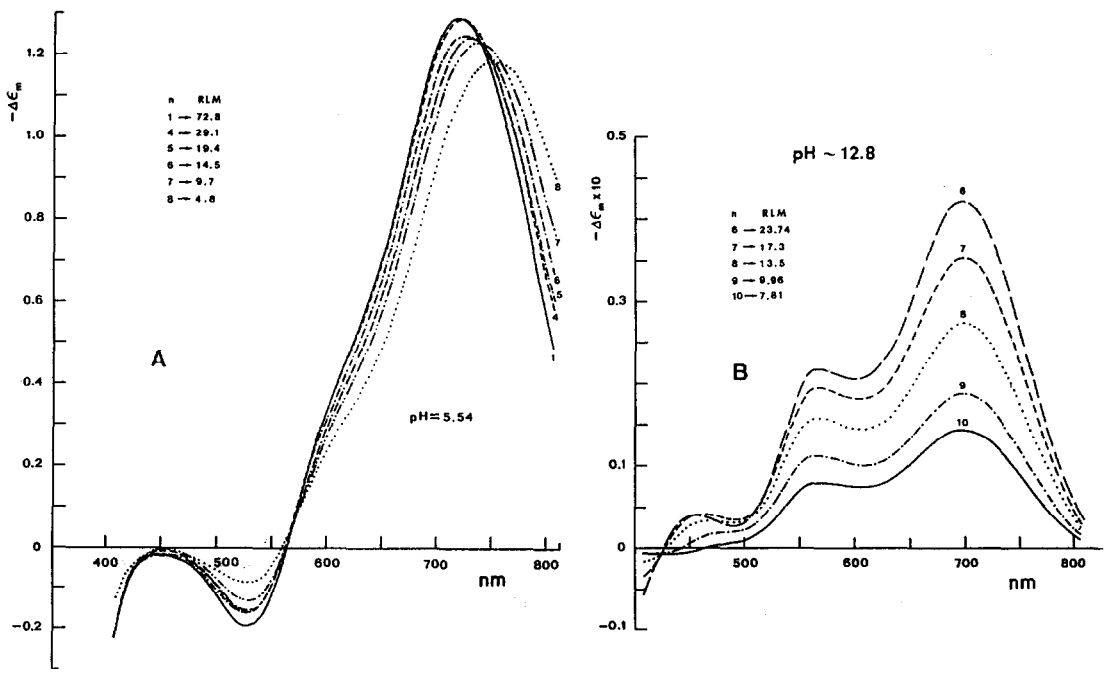

Fig. 8. CD spectra of solutions containing D-Pen and oxovanadium(IV) with varying L/M (denoted by RLM) at fixed pH.

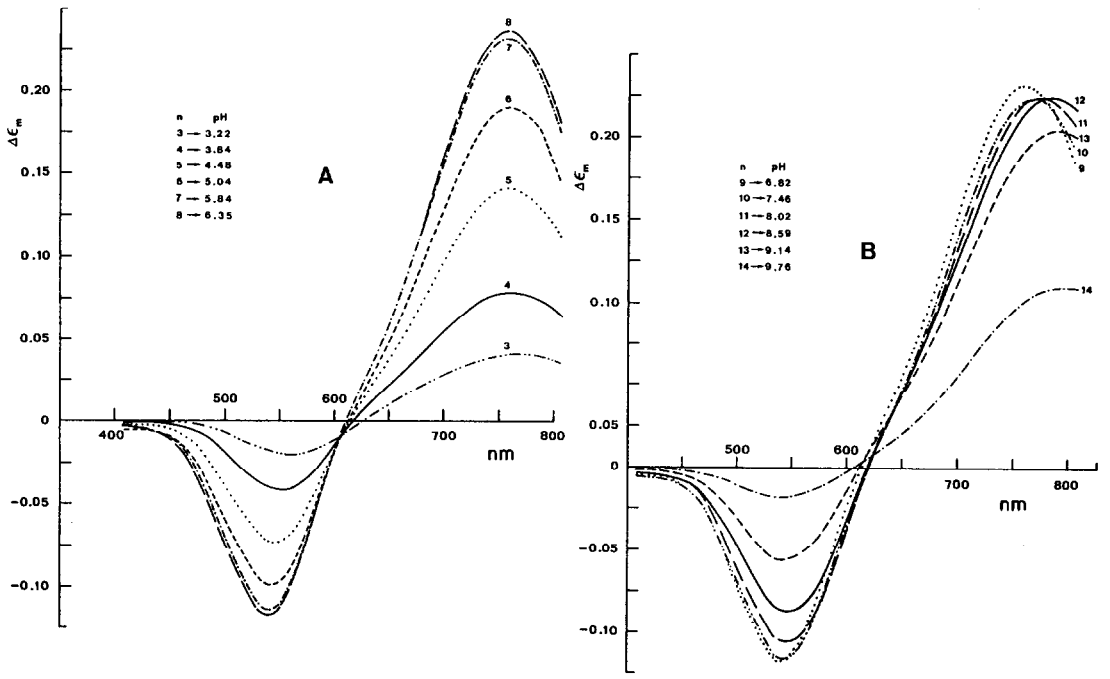

Fig. 9. CD spectra of solutions containing S-methyl-L-cysteine+VO^{2+} with L/M = 41.0 and $C_{VO} \sim 0.01$ M. The pH corresponding to each spectrum is indicated.

L/M = 35, the CD spectra of L-Cys solutions are like those in Fig. 8(B).

The spectroscopic results show that, for pH < 12, polymeric species are relatively much more important with L-alanine[1] than for L-cysteine or D-penicillamine. Here polymers are more important for $3.3 \lesssim$ pH $\lesssim 6.0$ and for pH $\gtrsim 12$. For L/M $\gtrsim 20$, hydrolysis {of $[(VO)_2(OH)_5^-]_n$} hardly happens (at least for pH < 12). Potentiometric results confirm this.

(c) *Substituted derivatives of* L-*cysteine*. The CD spectra (Fig. 9) of solutions containing S-methyl-L-cysteine (S—Me—Cys) with L/M = 41.0 resemble those for L-alanine[1] showing that sulphur is not coordinated. They differ completely from those for cysteine and penicillamine, confirming that, for them, sulphur does coordinate to vanadium for pH $\gtrsim 4$.

Figure 10 includes CD spectra for L-cysteine ethyl ester (L-CysOEt) with L/M = 45.1. These practically coincide in the pH range 8.9–9.2 (see spectrum 7 in Fig. 10).

One can make the following comments:

(i) In the pH range 2–3.5, the spectra resemble those for L-cysteine (or D-penicillamine), but the $\Delta\varepsilon_m$ values are much lower.

(ii) For pH > 3.5, CD spectra for L-CysOEt do not differ much from the L-cysteine (and D-penicillamine) systems. The main difference is for 400–580 nm, where $|\Delta\varepsilon_m|$ are much lower than for $\lambda > 580$ nm as compared to L-cysteine (or D-penicillamine).

(iii) The $|\Delta\varepsilon_m|$ values for 550–800 nm in the pH range 8.3–9.2 are $\sim 20\%$ lower than for the corresponding L-cysteine solutions with L/M = 35.0.

From these differences, the carboxylate group of at least one L-cysteine is coordinated to vanadium in the pH range 4–10 (at least).

The CD spectra for L-CysOEt (Fig. 10) are relatively similar to those for L-cysteine in similar conditions, suggesting that CV and PV involve equatorial coordination of N_2S_2.

(2) *Calculations of speciation from observations*

Potentiometry

Protonation constants calculated by the MINIQUAD[19] and SUPERQUAD[20] programs almost coincide. From SUPERQUAD, for L-cysteine in solutions containing 2.25 M $NaNO_3$ (at 25°C): $pK_{a1} = 2.092 \pm 0.006$, $pK_{a2} = 8.367 \pm 0.003$ and $pK_{a3} = 10.358 \pm 0.007$, and for D-penicillamine: $pK_{a1} = 2.128 \pm 0.005$, $pK_{a2} = 8.151 \pm 0.003$ and $pK_{a3} = 10.637 \pm 0.008$.

As we had found for L-alanine,[1] L-serine and L-

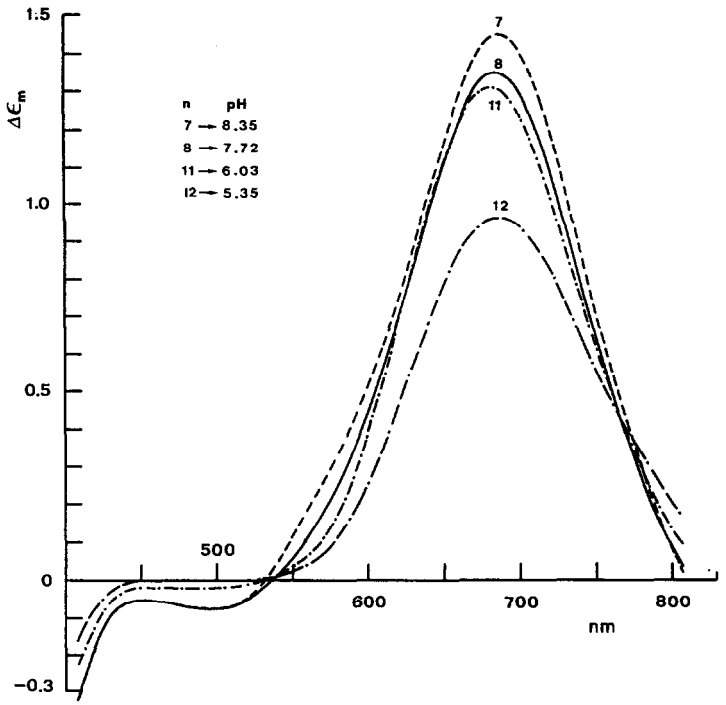

Fig. 10. CD spectra of solutions containing L-cysteine ethyl ester and VO^{2+} with L/M = 45.1 and $C_{VO} = 5.5–6.7 \times 10^{-3}$ M. The pH corresponding to each spectrum is indicated. Spectra of similar solutions at pH 4.5 and 5.9 were recorded every 10 min. At least till 60 min after the preparation of the solutions the CD spectra showed no evolution with time.

threonine,[2] the titration curves with high L/M show a progressive increase of pH as base is added in the pH range 3.5–7. The formation curves calculated for these conditions have $\bar{n} \sim 1.5$ in the pH range 5.8–6.7, so ML_2H complexes make an important contribution.

As in previous cases,[1-3] refinements of β_{xyz} values for all possible species (i.e. $M_xL_yH_z$ with x, y, z quite general) were meaningless. For L-alanine,[1] L-serine and L-threonine,[2] our strategy determined formation constants of species predominant at low pH using selected "titration points" from curves with low L/M. This was impossible for the present systems, because MLH_2, ML_2H_4, MLH and/or ML_2H_3 and ML_2H_2 become important at quite low pH. Therefore β_{122} and β_{124} were determined after a critical examination of results: (i) from titration curves of solutions of "low" L/M, (ii) from all titration curves and (iii) from visible and CD spectra recorded for pH < 5.

Taking β_{122} and β_{124} as known, the programs MINIQUAD and SUPERQUAD were used to calculate the β_{xyz} of the other species, including the full set of the "complete" titration curves.

Our best model (model I) from this procedure is in Table 1. For each value $\log \beta_{xyz}$, plausible ranges are also given, established by a critical examination of all calculations, including those based on the spectroscopic results (model II).

Using SUPERQUAD, attempts to refine both β_{111} and β_{123}, simultaneously, failed; normally β_{111} was rejected. If a fixed value for either constant was included, eventually the other would refine but with unacceptable statistical parameters.

For some of the earlier models tested for Ala, Ser and Thr, we also had some similar difficulties in refining the corresponding pair of constants β_{110} and β_{121},[1,2] but in our final models their simultaneous refinement was possible (and necessary). Here for the pair β_{111} and β_{123}, this never happened.

A major problem in all calculations for L-alanine[1] was hydrolysis in the pH range 5–8.[2,3] Hydrolysis is much less important in the L-serine and L-threonine systems[2] and scarcely exists in the L-aspartic acid system[3] for pH < 8 and relatively high L/M ratios. The same occurs in the present study; consequently, the calculations are more reliable and the χ^2 values (10–30) of the models contributing to Table 1 are reasonable, considering the complexity of the systems, the many titration curves included, the several NaOH concentrations used and the two pH ranges included (2.2–4.3 and 4.0–6.7).

Table 1. Composition and formation constants of the species in the system L-cysteine or D-penicillamine + VO^{2+} assuming various equilibrium models. Values for $\log \beta_{xyz}$ of eq. (1) are given[a,b]

[a] Some constants here differ slightly from the preliminary results presented in Table 1 of ref. 4(c).

[b] The products of hydrolysis of vanadium(IV) considered with their formation constants are given in Table 1 of ref. 1.

[c] In the calculations performed with MINIQUAD, SUPERQUAD and SQUAD, it was possible to refine formation "constants" for such stoichiometries as M_2L_2H and $M_2L_2H_{-1}$. However, the values differed substantially depending on the other formation constants included; further, at least for $M_2L_2H_{-1}$, the β values obtained were such that it was impossible to rationalize them with the experimental visible and CD spectra.

[d] MLH and MLH_{-2} are not needed to explain the potentiometric and spectroscopic results for solutions with high L/M. If they exist, their formation constants will have the indicated order of magnitude.

[e] Model IIA resulted from calculations with SQUAD but these were not performed for solutions containing L-Cys + VO^{2+} for pH > 7.

Spectrometry

In solutions of VO^{2+} and L-cysteine or D-penicillamine, only the species containing vanadium contribute to ε_m or $\Delta\varepsilon_m$ in the visible. This by-passes the limitation of potentiometry to those regions of pH where the ligand has no significant buffer effect. Consequently, calculations of formation constants based on visible or CD spectra do better for species like MLH_2 and ML_2H_4, which predominate in the pH range 1.5–4.0. Further, solutions with pH > 7 may be used.

As in previous work,[1-3] the SQUAD program was used to check that the visible and CD measurements were consistent with the potentiometric results in the pH range 2–7. Calculations were performed on results for 450–830 nm (visible) and 445–800 nm (CD), respectively. ε (or $\Delta\varepsilon$) corresponding to the stoichiometries MPH_2, MPH, MP_2H_4, MP_2H_3, MP_2H_2, MP_2H, MP_2 and M_2P_2 are considered as parameters to be refined: β_{xyz} were calculated either individually or in sets (2, 3, 4 or even 5 $\log \beta_{xyz}$ values).

Either MLH or ML_2H_3 must be excluded from the equilibrium model, because no meaningful calculations using both could be achieved, for either spectrophotometric or potentiometric results. Since results were better when ML_2H_3 is included, we exclude MLH.

The β_{xyz} values calculated are within the range obtained with MINIQUAD and SUPERQUAD, so those given in model IA may be accepted as correct. Taking these as known, the visible and CD spectra of the corresponding species were calculated

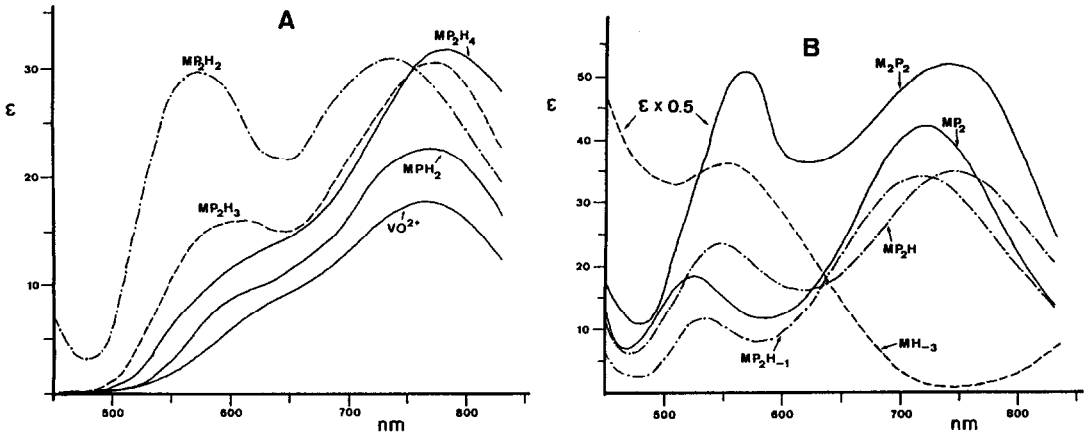

Fig. 11. Visible absorption spectra of the species in solutions containing D-Pen and oxovanadium(IV) with high L/M, calculated using the SQUAD[18] program (see text for details). (A) Species that predominate for pH < 5. (B) Species that predominate for pH > 5 (except M_2P_2).

using SQUAD based on experimental spectra in the pH range 2–8.3. As for previous systems,[1,2] we went step-by-step, but now following the order:

Visible spectra:

(i) MP_2H and MP_2,

(ii) MPH_2 and MP_2H_4,

(iii) MP_2H_3, MP_2H_2 and M_2P_2.

CD spectra:

(i) MP_2H and MP_2,

(ii) MPH_2, MP_2H_4, MP_2H_3, MP_2H_2 and M_2P_2.

The calculated spectra are included in Figs 11 and 12.

Once spectra of the species important for pH < 8 are known, calculations may be performed for the high pH range. In solutions containing D-penicillamine with high L/M, between pH 8.3 and 10.3, almost 100% of vanadium(IV) exists as MP_2. For calculations involving solutions with pH > 10, only the spectrum of MP_2 needs to be included in SQUAD. Tables 2 and 3 summarize the results.

Besides the inherent uncertainties of pH measurements in alkaline solutions containing high Na^+ concentrations, the unknown nature of hydrolysis products at high pH introduces several inaccuracies.[23] For the models tested in Tables 2 and 3, the sole hydrolysed species important for pH > 10–11 is $[(VO)_2(OH)_5^-]$ ($\log\beta = -22.22$).[1,23] Species of the type $[(VO)_2(OH)_6^{2-}]_n$ (or with other stoichiometries) are not included.

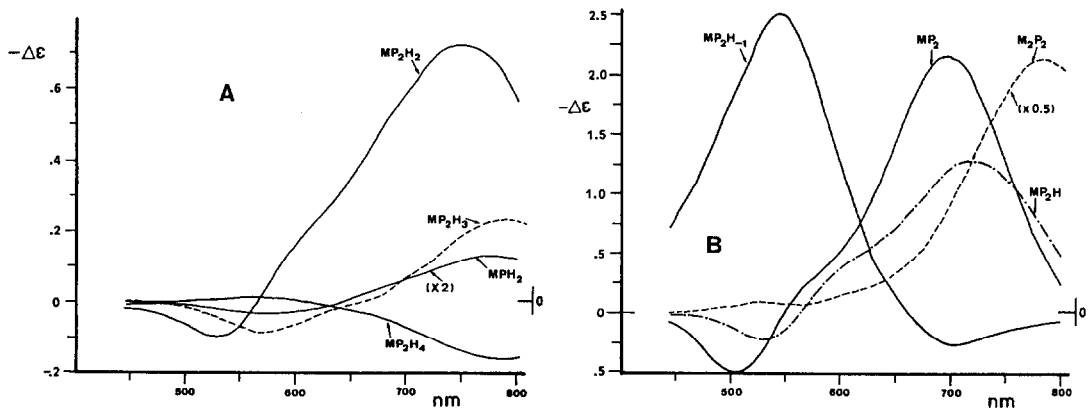

Fig. 12. CD spectra of the species in solutions containing D-Pen and oxovanadium(IV) with high L/M, calculated using the SQUAD[18] program (see text for details). (A) Species that predominate for pH < 5. (B) Species that predominate for pH > 5 (except M_2P_2). The spectra for MPH_2 and MP_2H_4 have opposite signs in the range 600–800 nm. This explains why $\Delta\varepsilon_m \sim 0$ values were found in some of the experimental CD spectra at low pH.

Table 2. Calculations of visible spectra and/or formation constants using the SQUAD program,[18] based on experimental visible spectra (450–830 nm) of D-Pen + VO^{2+} solutions (high L/M) in the pH range 8.3–12.4[a,b,c]

Calculation number	Refinement of		
	$\log\beta_{12-1}$	$\log\beta_{11-2}$	$\log\beta_{10-3}$

VIS2	8.7±0.1	—	−18.1±0.1
VIS3	8.16±0.04	—	−18.7 (Fixed)
VIS4	—	−4.5±0.1	−18.7 (Fixed)
VIS5	8.4±0.1	−5.3±0.15	−18.7 (Fixed

[a] In all calculations the ε_{xyz} of the complexes included are also refined. Where β_{10-3} is assumed to have a fixed value, the ε_{10-3} values are considered as parameters to be refined.

[b] According to the order of magnitude obtained for the formation constants of MP_2H_{-1}, MPH_{-2} and MH_{-3}, the concentration of M_2H_{-5} is significant only for pH $\gtrsim$ 12.5.

[c] All calculations involving MPH_{-3} diverged.

[d] The visible spectrum calculated for this species makes no sense.

Despite these problems, the results using SQUAD based on experimental visible and CD spectra are self-consistent and satisfactory. For both spectroscopic techniques, β_{12-1} and β_{10-3} are consistently refined, but while for CD spectra, their log values are ~ 7.8±0.3 and ~ −18.6±0.2, respectively, from visible spectra, they are ~ 8.4±0.3 and ~ −18.2±0.2.

For basic solutions containing D-Pen + VO^{2+}, the spectrophotometric results are consistent with the

Table 3. Calculations of CD spectra and/or formation constants using the SQUAD program,[18] based on experimental CD spectra (445–800 nm) of D-Pen and VO^{2+} solutions (high L/M) in the pH range 8.3–13.5[a,b]

[e] The calculation diverged; main problem in β_{11-2}.

existence of MH_{-3} with $\log\beta_{10-3}$ being -18 to -19 (as for the L-Ser+VO^{2+} system[2]), and of MP_2H_{-1} with $\log\beta_{12-1}$ in the range 7.5–8.7.

DISCUSSION

The equilibrium model—the set of species (with values for their formation constants) proposed to explain all the experimental potentiometric and spectroscopic results—is shown in Table 1 (model II). For low L/M, other complex species might be important.

Figure 13 gives the concentration distribution of components in the EPR spectra (Fig. 1 and spectra obtained for the L-cysteine system). Comparing Fig. 13(B) with the concentration distribution of species presented in Fig. 14, calculated using the program COMICS[27] for $C_{Pen}/C_{VO} = 23.7$ and with the total vanadyl concentration close to those corresponding to the EPR, visible and CD spectra of Figs 1–6, one may remark that:

(i) Signals PI+PII correspond to several stoichiometries: M, MPH_2, MP_2H_4 and MP_2H_3 (and MPH). The L-Ala, L-Ser and L-Thr+VO^{2+} systems[1,2] presented a similar situation. The EPR peaks show only gradual (but clear) changes in positions as H_2O in $[VO(OH_2)_5]^{2+}$ is substituted by the first and second R—COO^- group or by a R—NH_2 group.

(ii) Component PIII corresponds to the species of stoichiometry MP_2H_2 (M_2P_2 is probably EPR silent). Its crossing point with EPR signals PI+PII at pH 4.2 in Fig. 13(B) approximately coincides with the crossing point of $\{MP_2H_4+MPH_2+MP_2H_3\}$ and MP_2H in Fig. 14.

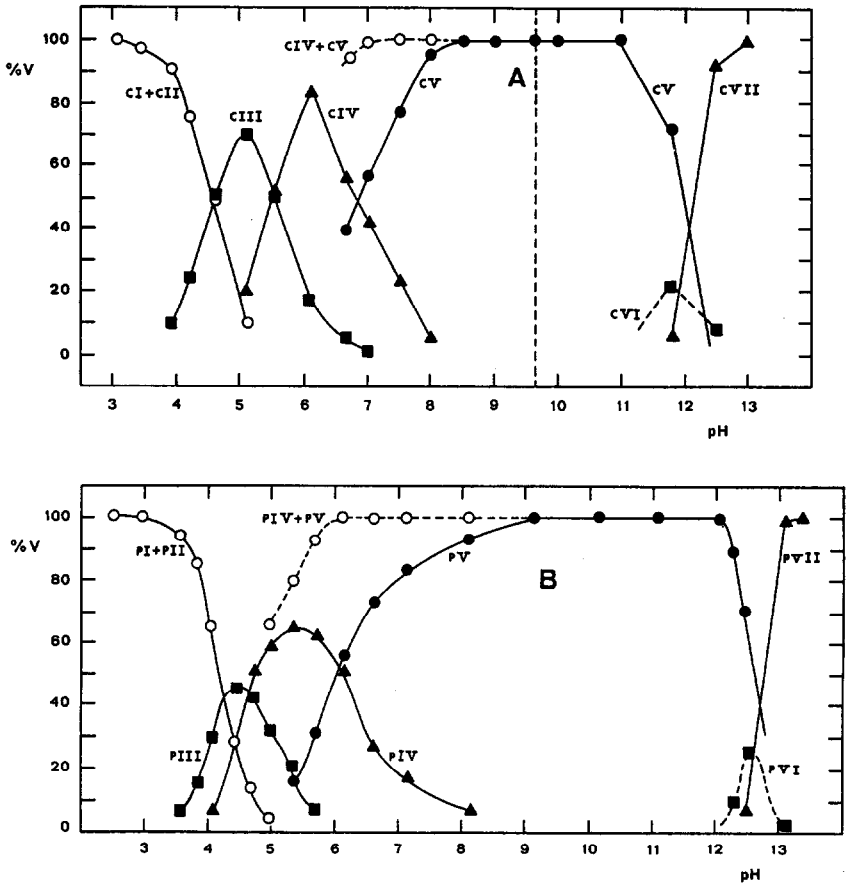

Fig. 13. Concentration distribution of the components CI–CVII (A) and PI–PVII (B), detected in the EPR spectra. These distributions should be considered approximate. EPR silent species are obviously not included. (A) L-Cysteine+VO^{2+} system: pH < 9.8, concentrations were estimated from EPR spectra with L/M = 26.2 and $C_{VO} \sim 0.01$ M; for pH > 9.8, from spectra with L/M = 20.0 and $C_{VO} \sim 0.004$ M. (B) D-Penicillamine+VO^{2+} system: the species concentrations were estimated from EPR spectra with L/M = 18.5 and $C_{VO} \sim 0.004$ M (Fig. 1).

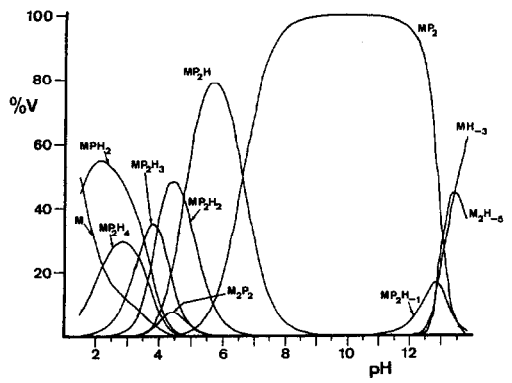

Fig. 14. Concentration distribution of the complexes formed in the D-Pen+VO^{2+} system with $C_{VO} = 0.01$ M and L/M = 23.7, calculated using the β_{xyz} of model IIA in Table 1 (MPH not included), $\log\beta_{20-5} = -22.22$ and $\log\beta_{10-3} = -18.7$. Because no other hydrolysed species was included in the equilibrium model, the only polymeric species indicated for pH > 12 is M_2H_{-5}. If the formation constant of any species with such a stoichiometry as $[VO(OH)_3^-]_n$ ($n > 2$) were included in the model, the calculated concentration for M_2H_{-5} would become small. This speciation is on a molar basis, while the concentration distribution of Fig. 11 in Part I[1] was calculated on an atomic basis. On recalculating this concentration distribution but now including MPH with $\log\beta = 16.3$, the ratio of the concentrations: $MP_2H_3/MPH \sim 2$.

(iii) Signals PIV and PV correspond to species of stoichiometry MP_2H and MP_2, respectively.
(iv) Components PVI and PVII arise from species with stoichiometry MP_2H_{-1} and MH_{-3}, respectively.

Our model differs from an earlier proposal:[17] it has more species but no evidence for *cis*- and *trans*-isomers of $[VO(L)_2]^{2-}$ complexes.

Under the conditions used by Johnson and Shepherd for EPR spectra ($C_{VO} = 6.8 \times 10^{-3}$ M, $C_{Cys} = 1.0$ M and pH = 7),[8] our model would predict approximately 60% of MC_2 and 40% of MC_2H. One component only is detected (although in Fig. 1 of ref. 1 the higher field EPR signal is rather broad). The g and A parameters corresponding to MC_2H and MC_2 are similar (see PIV and PV in Fig. 1). The visible spectra (maxima at 535 and 730 nm) presented by Johnson and Shepherd also suggest that MC_2 is not the only species present[8] (compare with results for MP_2H and MP_2 in Table 4).

According to Fig. 14, the sole polymer of importance in the pH range 2–12 is M_2P_2, which is significant in the pH range 3.8–5.3. In solutions with high L/M at fixed pH no great change should occur in the experimental $\Delta\varepsilon_m$ as C_{VO} varies, if (at that pH) there is no equilibrium between species with different degrees of polymerization.[1,2] In fact, such $\Delta\varepsilon_m$ change significantly at pH 4.04 and 4.54 (Fig. 7), and much less at pH 5.54 [Fig. 8(A)], 5.74 and 7.1 (not shown). In Fig. 7(B) (pH 4.54), as L/M decreases to ~ 10, λ and $\Delta\varepsilon_m$ of band I both clearly increase. This can be easily understood from the spectra for MP_2H_2, MP_2H and M_2P_2 and the equilibrium:

$$\begin{bmatrix} MP_2H_2 \\ \text{and} \\ MP_2H \end{bmatrix} \underset{\text{L/M increases}}{\overset{\text{L/M decreases}}{\rightleftharpoons}} M_2P_2.$$

Correlation of formation constants

Representation of $\log\beta^{Pen}$ vs $\log\beta^{Cys}$ does not obey a single linear correlation.

To compare the present β_{xyz} values with those for the L-alanine, L-serine and L-threonine+VO^{2+} systems,[1,2] it is convenient to consider constants β^*_{xyz} defined according to eq. (3) instead of eq. (1).

$$xM^{2+} + yHL^- + zH^+ \overset{\beta^*_{xyz}}{\rightleftharpoons} M_xL_yH_z \qquad (3)$$

$$\beta^*_{xyz} = \beta_{xyz}/(\beta_{013})^y. \qquad (4)$$

A linear correlation of $\log\beta^{*Pen}$ (or $\log\beta^{*Cys}$) vs $\log\beta^{Ser}$, is observed only for pK_{a1}, MLH_2, MLH, ML_2H_4 and ML_2H_3 (L = P, C) against the corresponding stoichiometries in the L-serine system. Therefore, for other stoichiometries, the structure and/or the donor atoms of the complexes containing D-penicillamine (or L-cysteine) and VO^{2+} differ from those in the L-serine system.

The formation constants calculated for MP_2H_2, MP_2H, MP_2 and M_2P_2 are substantially greater than for corresponding stoichiometries in the L-Cys+VO^{2+} system. The differences seem too large to be explained solely by the slightly higher basicity of D-penicillamine than L-cysteine.

No major differences were detected between the CD spectra of the L-cysteine and D-penicillamine systems, which indicates that the donor atoms and their coordination positions are the same in both systems.

Formation constants for complexes of vanadyl often correlate well with those of nickel,[28] at least for ligands containing nitrogen and oxygen donor atoms. Indeed, as we find for vanadyl, the β(NiL) and $\beta(NiL_2)$ formation constants for penicillamine are substantially greater than for cysteine, in both the distinct equilibrium models which have been assumed for Pen or Cys and nickel(II). Lenz and Martell,[29] assuming that only NiL and

$M_2S_2H_{-2}^2$	585	51.9	—	0.96	778	59.3	—	1.2
	542	—	0.5		730	—	−0.736[b]	

[a] The ε and $\Delta\varepsilon$ are the extinction coefficients—at λ—of the visible and CD spectra, respectively, calculated for each of the $M_xL_yH_z$ species included in model IIa (Table 1). $|\Delta\varepsilon/\varepsilon|$ is the asymmetry factor (so called g-factor) for each band, according to: [$|\Delta\varepsilon|$ (at its λ)]/[ε (at its λ)]: values of $10^2 g$ greater than one prove that the transition is magnetic-dipole in character.

[b] The CD spectra for $M_2A_2H_{-2}^1$ and $M_2S_2H_{-2}^2$ are rather similar, but differ completely from the one obtained for the corresponding stoichiometry M_2P_2, where band I at ~ 775 nm is extremely intense.

NiL_2^{2-} are present, obtained: $\log\beta(NiC) = 9.6$, $\log\beta(NiC_2) = 19.0$, $\log\beta(NiP) = 11.1$ and $\log\beta(NiP_2) = 21.8$. Perrin and Sayce[30] later obtained: $\log\beta(NiP) = 10.75$ and $\log\beta(NiP_2) = 22.89$ (no other complexes in solution), and $\log\beta(NiC) = 8.98$ and $\log\beta(NiC_2) = 20.16$ (other complexes in solution).

While it is often considered that the methyl groups in penicillamine might sterically hinder, or even prevent, the bridging of metal ions by sulphur atoms, inhibiting formation of polynuclear species, the observed preference of vanadyl and nickel for penicillamine may also reflect geometric differences in the coordination sphere of VO^{2+} in order to accommodate the steric demands of the $—(Me)_2S^-$ donor unit, some sort of interligand interaction (e.g. hydrophobic interaction involving the β,β-dimethyl substituents) or an entropic origin.

Structures

Because the vanadyl ion is lop-sided, many of its chelates may form more isomers than do apparently analogous monoatomic metal centres; refs 1 and 23 briefly discuss this. Even in the absence of this extra isomerism, i.e. for monodentate ligands, such as amino acid bonded via carboxylate, the common geometric isomers may both be present.

Table 5 includes structures for each stoichiometry of Table 1. Estimated values of EPR parameters $g_\parallel$ and $A_\parallel$ for each structure using those contributions of $R—COO^-$, $R—NH_2$, RS^-, OH^- and H_2O to $g_\parallel$ and $A_\parallel$ proposed by Chasteen are also included.[25] Such estimates consider only groups coordinated equatorially. They imply that the axial ligand is H_2O: when this is not the case, no safe estimates can be made for $g_\parallel$ and $A_\parallel$.

Table 5. Schematic representations of possible structures for complexes in solutions containing L-Cys or D-Pen and oxovanadium(IV). The corresponding estimated $g_{\|}$ and $A_{\|}$ EPR parameters[25] are also included (see text for details)

[a] In the schematic representation of the structures, when no group is included in any of the coordination positions, it is assumed that H_2O is coordinated. When (...) is included opposite to the V=O bond, this means that coordination in the axial position may occur (or not).

[b] $M_xL_yH_z \rightarrow$ stoichiometries according to eq. (1). $M_xL^*_yH_z \rightarrow$ stoichiometries according to eq. (3).

MLH_2 *stoichiometry*

This corresponds to complexes with the R—COO^- group equatorial, as in (I)—Table 5. Writing their formation as ($n = 1$):

$$VO^{2+} + nH_2L \overset{K_n}{\rightleftharpoons} [VO(H_2L)_n]^{2+}, \qquad (5)$$

K_1(D-Pen) = 20.0 and K_1(L-Cys) = 15.0, to be compared with K_1(L-Ala) = 15.6,[1] K_1(Gly) = 14.8[30] (in a different medium, 1 M $NaClO_4$), K_1(L-Ser) = 12.5, K_1(L-Thr) = 12.9[2] and K_1(L-Asp) = 78.[3]

The visible spectrum for MPH_2 is, as expected, similar to those for the corresponding stoichiometries: MAH, MSH and MDH_2 (L-alanine, L-serine and L-aspartic acid systems, respectively), with amino acids monodentate via carboxylate.

ML_2H_4 *stoichiometry*

This probably corresponds to complexes with two monodentate carboxylate groups coordinated equatorially, as in (II)—Table 5. From Table 1, K_1K_2(D-Pen) ~ 70 and K_1K_2(L-Cys) ~ 45. The corresponding values for L-Ser and L-Ala are ~ 24[1] and ~ 30,[2] respectively.

At this point, we re-emphasize that the particular stoichiometry for each "species" $M_xL_yH_z$ corresponds to more than one isomer. Relative isomeric concentrations are independent of concentrations of metal, ligand and H^+, so our experimental techniques do not discriminate (in some cases, detailed study of the EPR spectra may ultimately help do this). Therefore not only each formation constant, but also the visible and CD spectra reflect the features of each isomer in proportion to its relative importance. For example, for stoichiometry ML_2H_4, the value for β_{124} is the weighted sum of $\beta_{124}(cis)+\beta_{124}(trans)$ and the visible and CD spectra may involve contributions from both geometric isomers.

The visible spectrum calculated for MP_2H_4 is very similar to that for MS_2H_2.[2] However, the CD spectra calculated for MP_2H_4 and MS_2H_2 differ. In particular, $|\Delta\varepsilon_{124}$(D-Pen)$| \gg |\Delta\varepsilon_{122}$(L-Ser)$|$, $|\Delta\varepsilon_{122}$(LAla)$|$ [Fig. 12(A)].

This striking difference in the size of CD spectra for the corresponding stoichiometries: MP_2H_4 as against MS_2H_2 (or MA_2H_2) is real. The spectra of Fig. 12(A) are based on many experimental CD spectra, with a very broad range of amino acid and vanadyl concentrations and the results of several types of calculation were always consistent. However, despite this difference in magnitude, the signs for the CD absorptions at *ca* 750 nm are positive both for M(L—S)$_2H_2$ and for M(D—P)$_2H_4$. (Note that in Fig. 12, the ordinate, $\Delta\varepsilon$, has been inverted, by -1.) The configurational shorthand attached to penicillamine, based upon the same rules as those for serine and the like, shows that D-penicillamine is a derivative of D-cysteine. As an α-amino acid (i.e. unidentate via carboxylate, or chelated bidentate via O and N) D-penicillamine is opposite to L-serine or L-alanine in the chirality it induces at the metal centre.

In general, for complex molecules $[(VO)L_n(OH_2)_m(OH)_y]^{2\pm}$ of related structures, differing only in the nature of the amino acid (say for L-alaninate as against L-serinate), we expect and find related CD spectra. Similarly, where the overall structures of two such species differ only in the hand of the ligated amino acids, we expected similar but essentially enantiomeric CD spectra, as, for example, found for MP_2H_2 [Fig. 12(A)] and MS_2 (Fig. 12 of ref 2) or for the pair MP_2H_3 [Fig. 12(A)] and MS_2H [Fig. 10(b) of ref. 2].

Conversely, the similarity of sign, in this one case, between the CD of stoichiometric analogues containing D-Pen and L-Ser speaks strongly for the D-Pen species, MP_2H_4 (containing two coordinated unidentate α-amino acids) having a structure different from these of MS_2H_2.

It may be that the ratio of *cis*- to *trans*-isomers present in MP_2H_4 differs from that for MS_2H_2 and that this would help to account for the much greater $\Delta\varepsilon$ at longer wavelengths in the D-Pen case. This could also underlie two other differences between MS_2H_2 (or MA_2H_2) and MP_2H_4, namely the presence of two obvious positive CD components for the former, at ~ 640 and 780 nm (640 and 740 nm for L-alaninate) as opposed to the single Cotton effect (at 780 nm) for the penicillamine complex, and the anomaly in stepwise formation constants. Values of K_1 and K_1K_2 of eq. (5) are comparable between L-serine (12.5 and 24) and L-alanine (15.6 and 30) but are distinct for D-penicillamine (K_1 = 20.0 but K_1K_2 = 70) and L-cysteine (K_1 = 15.0, but K_1K_2 = 45).

ML_2H_3 *stoichiometry*

This corresponds to complexes with one amino acid bidentate (probably equatorial) and the other coordinated by the carboxylate group (probably also equatorial), as shown for V and VI in Table 5.

The visible spectrum for MP_2H_3 is quite similar to those for the "corresponding" stoichiometries MA_2H[1] and MS_2H;[2] bands I and II are slightly less separated (by ~ 20 nm) in MP_2H_3. The CD spectra for MP_2H_3, MA_2H and MS_2H are likewise similar except that:

(i) in MP_2H_3, bands I and II are slightly more separated (by 10 nm);
(ii) $|\Delta\varepsilon(MP_2H_3)| \sim 2.5 \times |\Delta\varepsilon(MA_2H$ or $MS_2H)|$.

As MP_2H_3 (and MPH) is important only for pH $\lesssim$ 4.5, it corresponds approximately to the component PII in Figs 1 and 13(B). The values of $g_\parallel$ and $A_\parallel$ are inconsistent with RS^- being coordinated, but structures like V (Table 5) seem adequate.

Therefore, EPR, visible and CD spectra all suggest that the geometries of the species corresponding to MP_2H_3, MS_2H and MA_2H are very alike. For each, more than one isomer may be important and their relative concentrations may differ. This, the different nature of the ligands and the possibility that the visible and CD spectra calculated for MP_2H_3 may incorporate part of the spectra of MPH, may account for the differences in their spectra.

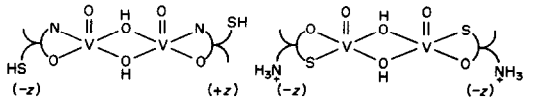
ML_2H_2 *stoichiometry*

Several structures (e.g. VII–IX in Table 5) can be envisaged for this stoichiometry. Despite minor differences in band II, the visible spectrum for MP_2H_2 is similar to those of the corresponding stoichiometries MA_2[1] and MS_2.[2] Further, the CD spectrum calculated for MP_2H_2 is also quite similar to those of MA_2 and MS_2.

The stoichiometry corresponds to PIII (or CIII) in Fig. 1. Their estimated $g_\parallel$ and $A_\parallel$ parameters suggest, as do the two electronic spectra, that both ligands are coordinated through their carboxylate and amino groups. Only two *d–d* bands are found for MA_2, MS_2 and MP_2H_2 rather than the three for many complexes with *trans*-geometries.[23] Assuming equatorial coodination of N_2O_2, this suggests that the *cis*-isomeric geometry predominates: $\beta_{122}(\text{Pen}) \sim \{\beta_{122}(\text{Pen})\}^{cis}$.

M_2L_2 *stoichiometry*

Here, several structures are plausible (e.g. XLII and XLIII, where the $-z$ means that the corresponding non-coordinated group of the ligand is antiparallel to the V=O group). These representations are merely schematic: both ligands are, of course, the same enantiomer.



(XLII) (XLIII)

The electronic spectra of M_2P_2 differ (Table 4) from those of $M_2A_2H_{-2}$ and $M_2S_2H_{-2}$, therefore the structures differ. Further, $\log\beta_{220}$ is higher—the corresponding $\log\beta^*$ [from eq. (3)] does not correlate with $\log\beta_{22-2}$(L-Ser). The differences could arise from the same isomers being present but in different proportions, though this alone would not suffice to explain the different properties for M_2P_2 and $M_2A_2H_{-2}$ (or $M_2S_2H_{-2}$). More likely, the range of isomers (geometric and/or linkage —RS^-) differs from M_2P_2 to $M_2A_2H_{-2}$.

ML_2H *stoichiometry*

This, the most important stoichiometry in the pH range 5–7, corresponds to PIV (and CIV) in the EPR spectra (Figs 1 and 13). Many structures can be envisaged (e.g. XIV–XXII in Table 5).

The visible and CD spectra for MP_2H, and the order of magnitude of the corresponding $\log\beta^*$ are quite different from those of the corresponding MA_2H_{-1}[1] and MS_2H_{-1}.[2] Therefore the structures are not alike here. As $A_\parallel(ML_2H) \sim 151 \times 10^{-4}$ cm^{-1}, at least one RS^- group is coordinated equatorial (Table 5). Only two *d–d* bands are present in the electronic spectrum of MP_2H, so structure XVIII (Table 5) is reasonable and consistent with the high value of β_{121}.

ML_2 *stoichiometry*

This, the most important in the pH range 7–13, corresponds to PV (and CV) EPR (Figs 1 and 13). Structures XXVI–XXXIV in Table 5 may be envisaged. As mentioned above, the calculated $A_\parallel = 143 \times 10^{-4}$ cm^{-1} and the CD spectra for L-cysteine+VO^{2+} (pH range 8–12) and L-Cys OEt+VO^{2+} (pH range 6–9.5), are consistent with the coordination of the thiol and amino groups. Further, the results suggested that a carboxylate group is coordinated: g and A parameters and λ (bands I and II) for MP_2 agree with a much stronger ligand-field strength than in MP_2H.

In the L-cysteine methyl ester–vanadyl complex, (from X-ray diffraction[15]) the nitrogen and sulphur atoms are *trans*. Sakurai *et al.*[14] detected two EPR components in solutions at pH 10.5 containing L-CysOMe (10 mM) and VO^{2+} (2 mM). One had g and A parameters corresponding to the present PV and CV (only $g_\perp$ differs): a minor component corresponded to higher $A_\parallel$. The conclusion was that the two components correspond to *cis*- and *trans*-isomers. The EPR spectra of *cis*- and *trans*-VO(Cys OMe)$_2$ differ much and more likely correspond to VO(CysOMe)$_2$ and its hydrolysis product. In the EPR spectra for L-cysteine+VO^{2+} solutions (with higher L/M ratios), we detect only one component.

For the present cases of MP_2 and MC_2 only two *d–d* bands are detected, suggesting *cis*-geometry.

ML_2H_{-1} *stoichiometry*

This (MP_2H_{-1} is never an important species) probably corresponds to PVI (and CVI) in the EPR spectra (Figs 1 and 13). Some of the many possible structures are in Table 5 (XXXV–XXXVII).

Comments on the equilibria at high pH

As found in the L-Ser and L-Thr+VO^{2+} systems, when increasing the pH equilibration is reversible and very fast, except when the complexes hydrolyse extensively and the solutions become brown.

The pH at which solutions become brown depends at least on the nature of the amino acid, on L/M, and on C_{VO}. When adding acid to the "very basic" brown solutions to pH 10–11, they remain brown for some time, then become green and finally the original colour at the corresponding pH is

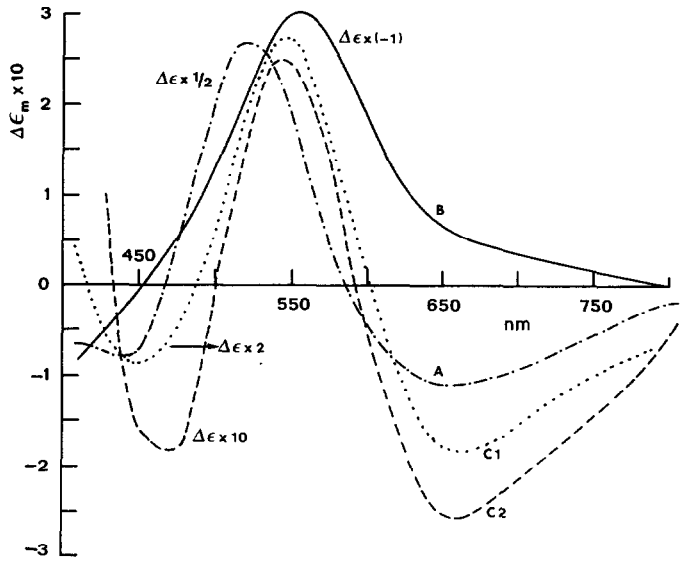


Fig. 15. CD spectra of solutions containing VO^{2+} and amino acids at high pH: (A) L-Ser+VO^{2+} solution with L/M = 38 and C_{VO} = 0.0068 M at pH ~ 13.6. (B) D-Pen+VO^{2+} solution with L/M = 23.7 and C_{VO} = 0.0084 M at pH ~ 13.5. (C) L-Cys+VO^{2+} solutions with L/M = 35 and C_{VO} = 0.0078 M at pH ~ 12.8 (C1) and ~ 13.2 (C2). The similarity between (A) the L-Ser+VO^{2+} and (C) L-Cys+VO^{2+} is quite clear. For (B) D-Pen+VO^{2+} at pH 13.6, MP_2 is still important: its spectrum masks that of the species that forms at high pH. This species would have the same −, +, − pattern (×(−1) as it involves a D-amino acid), as for L-Cys: MC_2 hydrolyses at approximately one unit lower in pH. In the calculations with SQUAD, the stoichiometry MP_2H_{-1} alone of those tested gave such a −, +, − pattern, a main reason for including it in the final equilibrium.

recovered. At pH 8–10 the equilibrium is established much faster and for pH < 8 fast equilibration occurs.

Figure 8(B) includes spectra of D-penicillamine +VO^{2+} solutions with variable total vanadium concentration at pH ~ 12.8. Similar experiments were performed for L-cysteine+VO^{2+} solutions at pH ~ 12.9 with L/M varying from 35.0 to 13.9. The type of spectra differ (in passing, the latter are similar to spectra C1 in Fig. 15) and the $|\Delta\varepsilon_m|$ also decrease as C_{VO} is increased.

For both sets of spectra, as C_{VO} is increased, $|\Delta A|$ decreases. The opposite was observed for L-serine and L-threonine+VO^{2+} solutions (Fig. 17(a) in ref. 2). This indicates that VO^{2+} complexes of amino acids containing ROH as side groups are more "resistant" to hydrolysis than those of penicillamine and cysteine. As in the systems involving L-serine and L-threonine, a fair description at high pH is of optically active monomeric complexes in equilibrium with dimeric (or oligomeric) non-optically active hydrolysis products of vanadium(IV).

ADDUCTS OF COORDINATION COMPOUNDS—XV.* THE STRUCTURE OF *TRANS*-$[Rh(py)_4Cl_2][Ag(ONO_2)_2]$, A SALT OF THE DINITRATO-ARGENTATE(I) ION, $[Ag(ONO_2)_2]^-$

(*Received* 23 *February* 1990; *accepted* 2 *April* 1990)

Abstract—The compound originally reported by Poulenc in 1935 as *trans*-$[Rh(py)_4Cl_2]NO_3 \cdot AgNO_3$ is the salt *trans*-$[Rh(py)_4Cl_2][Ag(ONO_2)_2]$ (py = pyridine). Its crystal structure consists of discrete silver dinitrate anions $[Ag(ONO_2)_2]^-$ and the complex cation $[Rh(py)_4Cl_2]^+$, each with C_2 symmetry. The silver atom is disordered between two neighbouring sites [0.30(2); 0.20(2)]. There are two pairs of Ag—O distances (given in pm); Ag(1): 224.8(3) (almost linear on silver) and 259.7(5), Ag(2): 231.3(7) and 241.3(10).

There are many solid adducts of coordination (and other) salts, formula A, with silver salts, AgX, B, of formula A_xB_y. These include[2] AB and AB_2 with B = silver perchlorate, for A = $[M(acac)_n]$, where $n = 3$ and M = Cr, Co, etc., and where $n = 2$ and M = Ni, Pd (acac indicating the monoanion of pentane-2,4-dione). Similarly, adducts of the silver salt $Ag[Ni(acac)_3]$ are known with 1 and 2 moles of "extra" silver nitrate.

Such adducts ($A \cdot nAgNO_3$, where A is a known compound capable of independent existence) formally involving silver nitrate are occasionally described. Their structures, whether they involve one ($n = 1$) or more ($n > 1$) moles of silver nitrate, have not yet been found to contain discrete anions $[E(NO_3)_2]^-$, with $E = Ag^+$. Rather, silver is variously coordinated by four to six atoms or molecules giving an irregular geometry and forming chains or sheets in the lattice. Silver nitrate itself has a peculiar structure.

Poulenc's compound[3] (an adduct of silver bromide) was recently characterized[1] as *trans*-$[Rh(py)_4Br_2][AgBr_2]$ and we synthesized[4] a number of new adducts AB_n, where A was *trans*-$[ML_4X_2](NO_3)$ (M = Rh, Ir; L is a pyridine; X = Cl or Br) and B was $AgNO_3$. For the 1:1 adducts, *trans*-$[M(L)_4X_2](NO_3) \cdot ENO_3$ (with $E = Ag^+$), the properties suggested[4] a close analogy to the hydrogen dinitrates ($E = H^+$), and consequently formulation as salts of the silver dinitrate ion $[Ag(ONO_2)_2]^-$. The structure of the hydrogen dinitrate is well known[5] from X-ray and neutron diffraction.

We now report the crystal and molecular structure, determined by X-ray diffraction, of *trans*-$[Rh(py)_4Cl_2]NO_3 \cdot AgNO_3$. This confirms our earlier deductions.[4] The compound is indeed a salt of the novel dinitrato(O-)argentate(I) ion, remarkably similar to the $[H(ONO_2)_2]^-$ salt, in that the silver ion is linearly coordinated by two oxygen atoms from the two nitrate groups. Other features of the present structure are described, including the propeller conformation of the N-heterocyclic ligand blades about the Cl—Rh—Cl spindle.

* For Part XIV, see ref. 1.

EXPERIMENTAL

Crystals were grown in methanol (2–3 cm^3) in the dark by allowing dissolved material to diffuse together from silver nitrate (excess) and *trans*-$[Rh(py)_4Cl_2]NO_3 \cdot 5H_2O$ (*ca* 30 mg) solids separated in a vial. Suitably large crystals grew over 7–10 days.

Cell: $C_{20}H_{20}AgCl_2N_6O_6Rh$, $M = 722.09$; orthorhombic $a = 7.658(2)$, $b = 21.486(3)$, $c = 14.953(3)$ Å; $U = 2460.36(88)$ $Å^3$, space group *Pbcn* (no. 60), $Z = 4$, $D_c = 1.95$, $D_m = 1.91$ g cm^{-3} (by flotation in $ZnBr_2$ solution). A crystal, $0.16 \times 0.16 \times 0.70$ mm, was used. Results were collected at low temperature (boil-off gas from liquid N_2) using an ω-scan method and Mo-K_α radiation. This acquisition of results was carried out by Dr W. T. Robinson at the University of Canterbury, Christchurch, New Zealand. An empirical absorption correction was applied to the reflection results. There were originally 4480 unique reflections, 391 of which were rejected from the analysis ($F_o > 3\sigma F_o$).

SHELX programs[6] were used for the structure determination. Atomic scattering factors for rhodium and silver were taken from the *International Tables for X-ray Crystallography*.[7]

All non-hydrogen atoms were located from Patterson and difference Fourier maps; hydrogen atoms were introduced by calculation of their positions (C—H bond length 108 pm, coordinates riding with the appropriate carbon atom). The structure was refined using the full-matrix least-squares method, with the weighting scheme $w = 1/sF_o$.

A good R factor ($R = 0.057$, $R_w = 0.0438$) was obtained from a structure containing all the necessary atoms. However, difference Fourier maps showed residual electron density on a C_2 site close to the silver, but too close to be part of the "existing" anion.

Alternative models (2) and (3) were investigated in which the residual electron density is explained by the presence of an alternative silver position/site. Model (2) has two distinct but disordered anions. In (3), the silver atom alone is disordered between two sites.

Model (2): the site occupancy of both silver atoms was refined, with the already known nitrate atoms assigned to the major silver atom. The result of refining this structure was that the major silver gained strength while the minor silver moved away along the C_2 axis, leaving the original electron density by the major silver.

Model (3): from the same starting point, the occupancy of the silver atoms was refined. This refinement progressed satisfactorily and gave $R = 0.0434$, $R_w = 0.0327$ and occupancies of 0.299(19) [Ag(1)] and 0.201(19) [Ag(2)].

The program PARST[8] was used to calculate structural dimensions, with ESDs where appropriate.

RESULTS AND DISCUSSION

The crystal structure consists of discrete silver dinitrate anions and *trans*-$[Rh(py)_4Cl_2]^+$ cations, each with C_2 symmetry. The general features of the entire structure are shown in Fig. 1. The structure

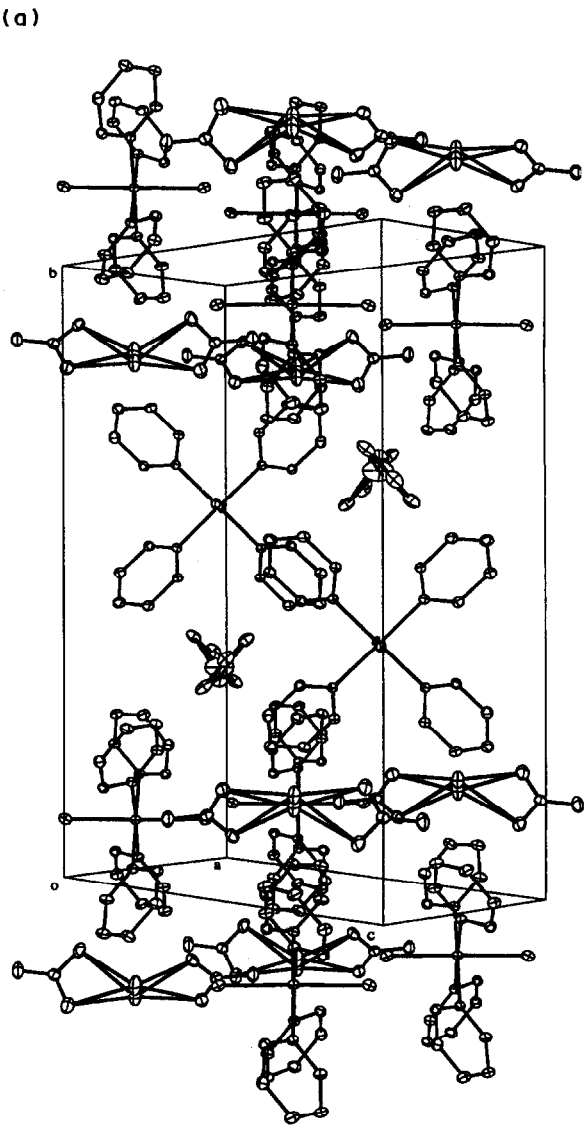

Fig. 1. ORTEP views of the cell of *trans*-$[Rh(C_5H_5N)_4Cl_2][Ag(ONO_2)_2]$: (a) down *a*-axis; (b) down *c*-axis; (c) down *b*-axis; (d) Perspective view. Ellipsoids of probability 50% for *a*, *b* and *c*, but 30% for *d*.

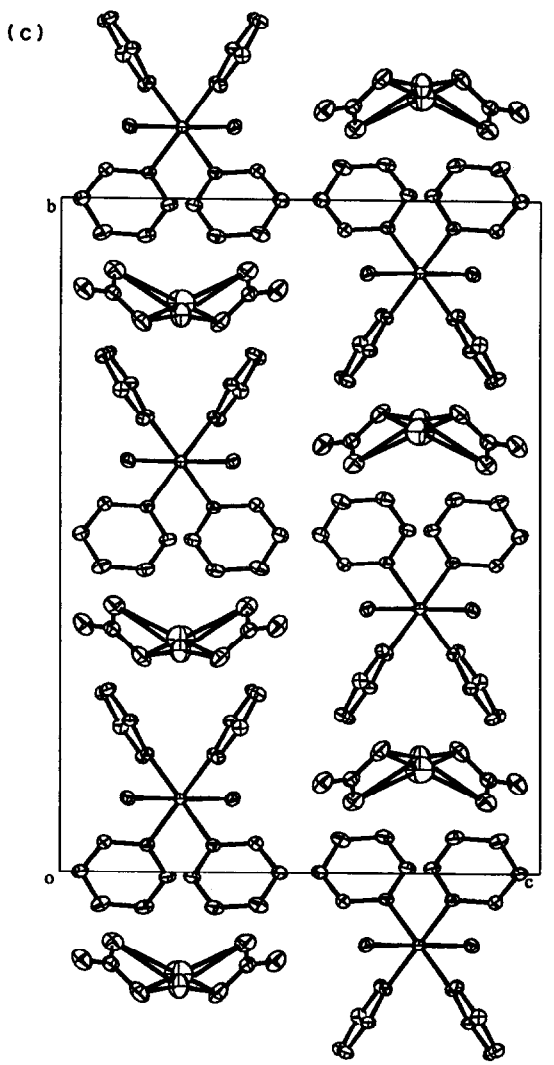

Fig. 1(c).

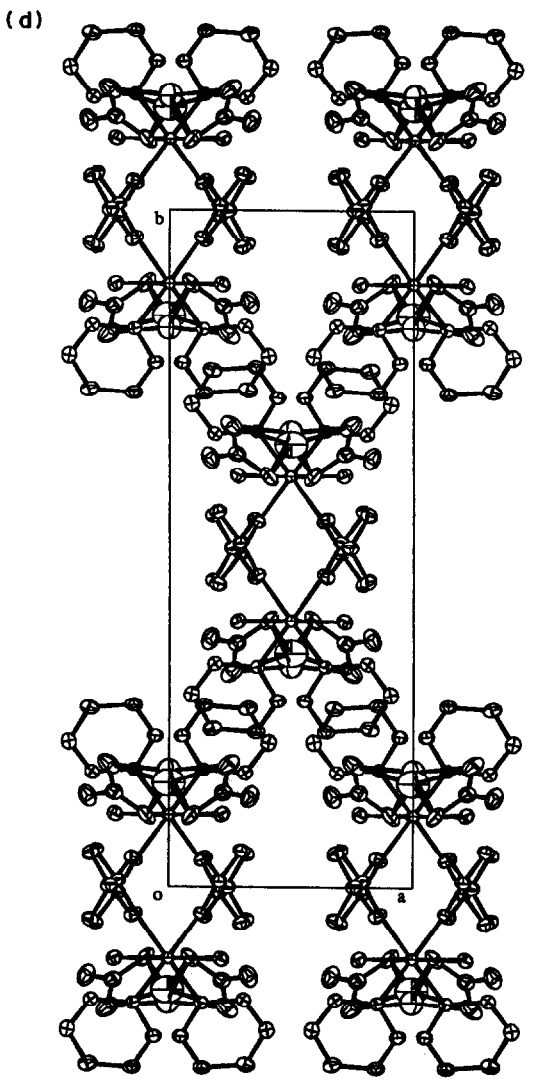

Fig. 1(d).

of the anions is shown in Fig. 2, and relevant dimensions and angles are given in Tables 1 and 2.

The anion containing Ag(1) has an O(1)—Ag—O(1) sequence that approaches linearity. The Ag—O distances around this silver ion are very different. The Ag(1)—O(2) bond is longer by 34.9 pm than the Ag(1)—O(1) bond, while the silver in the other site is less linear and its Ag—O bonds differ only by 10.0 pm. The nitrate–nitrate interplanar angle is 81.8(1)°.

Comparison with the hydrogen dinitrate analogue studied by Roziere and others[9] confirms our earlier conclusion[4] that the two structures are isomorphous.

The complex cations in both structures have similar coordinates and geometry (see Table 1).

The main distinction is for the anions. It results largely from the differing H—O and Ag—O bond lengths. Apart from this difference and the con-

sequential effect on angles O(1)—Ag—O(2), Ag—O(2)—N and inter-nitrate separations, the anions are remarkably similar (see Table 3).

The present salt increases the already significant number of known structures involving species with four flat moieties disposed around a spindle, such as *trans*-$[ML_4X_2]^{n+}$, where M = a metal ion of charge m^+ like platinum(II), rhodium(III) or iridium(III), L = an N-heterocycle—such as pyridine—attached to the metal via N, X is a unidentate ligand, charge x^-, and $n = (m-2x)$. L is not restricted to uncharged N-heterocycles, and may for example be a positively-charged species, like S-nicotine in[10] *trans*-$[Rh(S\text{-}nicH)_4Cl_2](PF_6)_5$ or indeed any planar unit, like NO_2 in Erdmann's salt[11] K-{*trans*-Co$(NH_3)_2(NO_2)_4$]}.

The possible conformations for essentially tetra-

[a] Bond lengths and angles from this study.

[b] These values are recalculated, using PARST, from earlier results.[4,9]

We transformed the *z*-coordinates (by $0.5-z$) to compare directly.

gonal arrangements of four such planar units around a common central point are many, but the four-bladed propeller is quite common and is again found here.

The present observation of two forms of the anion may result from the low temperature of this diffraction study. All our previous measurements[4] were made at room temperature and hence may refer to one form of dinitrato-argentate only. The IR spectrum is consistent with (though it does not prove) one structure only for the anion.

We analysed[4] the IR spectrum in terms of the bands of free monomeric NO_3^- becoming split on bonding in pairs to the silver ion. One band only (ν(NO) at 1281 cm^{-1}) showed fine structure, attributed to coupling. A number of bands remained unobserved.

Coordination of the nitrate

Nitrate groups serving as essentially unidentate ligands are not yet particularly common. The few isoleptic examples include (a) $K_2[Pt(ONO_2)_4]H_2O$ (with a strange lop-sided structure[12] for the complex anion, all four nitrate groups lying to one side of the PtO_4 ligand plane); (b) $K[Au(ONO_2)_4]$;[13] and (c) $K_2[Pd(ONO_2)_4]H_2O$, rather similar[14] to its platinous analogue. Unidentate nitrate groups on silver(I) seem uncommon:[15] typically, in $[Ag(Pcy_3)_2]NO_3$, where cy denotes cyclohexyl, the nitrate ligand is bidentate,[16] though the Ag—O distances differ (245 and 273 pm). In (μ-1-methyluracilato-N^3,O^4) (μ-1-methylcytosine-N^3,O^2)-*cis*-diammineplatinum(II)·silver dinitrate·silver nitrate·$2\frac{1}{2}$ water, some nitrate ions (others are ionic) bridge four-coordinated silver ions, some of which also carry unidentate nitrate ions.[17]

Among oxo-anion environments, a number (like the present) have two stronger bonds (or, at least, shorter distances) almost linear, from oxygen to silver and between one and four rather longer interactions, the $2+n$ arrangement, here in Ag(2) 2+2. This is found in $[Co(PO_4)(NH_3)_5]3AgNO_3 \cdot H_2O$, where two of the crystallographically-independent silver ions have the properties: O—Ag(1)—O, 157.7°; Ag(1)—O, 219.0, 216.5 and 267.5, 270.1 pm; O—Ag(3)—O, 163.3°; Ag(3)—O, 214.6, 216.0 and 271.1, 280.6 pm.[18]

One virtue of the present cation is that it is relatively non-polar and—in its unsolvated salts— complications from hydrogen-bonding to or from it are unlikely. The properties of the two silver ions here possibly reflect this. In substances involving stoi-

[a] Atoms denoted by (a) are related to the corresponding atom in the asymmetric unit by symmetry operation $1-x$, y, $0.5-z$.

[b] Bond lengths (O—Ag(1)—O, etc.) are compared in Table 1.

chiometric dinitrato-argentate(I) ions, the only examples so far known of homoleptic monomeric silver–nitrate systems, $MAg(NO_3)_2$—for $M = K^+$, NH_4^+ or Rb^+—contain $[Ag_2(NO_3)_4]^{2-}$ chains:[19] the resulting structure seems to represent a compromise between the small bite of the nitrate acting as a bidentate ligand and the range of silver–oxygen bond lengths for varied coordination numbers of the silver ion. Approximately speaking, the four-membered chelate ring is strained, and the compromise situation is adopted.

Coordination numbers at silver(I)

The description of coordination numbers and bonding in these Ag—O systems depends on the prediction of Gagnon and Beauchamp[20] that a silver–oxygen distance shorter than 300 pm indicates an interaction between a silver ion and an oxygen. A strong (or covalent) interaction is (based on the Pauling sum of covalent radii[21]) around 210 pm. The close similarity between the $[H(ONO_2)_2]^-$ ion and the $[Ag(ONO_2)_2]^-$ ion here may raise some question as to the nature of (secondary) Ag—O interactions larger than about 260 pm.

We would describe the hydrogen dinitrate ions in Table 3 as containing two coordinated protons, essentially linear, and it seems illogical to alter that description when we refer to the equally linear silver ions of $[Ag(ONO_2)_2]^-$. Indeed, the angle at the silver(I) ion is actually closer to linearity than at H^+.

As a further encouragement to reconsider the meaning of the secondary Ag—O contacts, we may take the known isoleptic complexes of unidentate nitrate. These are three, the tetrakis-nitrato-metallates of palladium(II), platinum(II) and gold(III). The former pair are eutropic, the latter isoelectronic. In each case, we accept the description as of four unidentate nitrates, all disposed to the same side of the M—O_4 plane. However, the distance to the secondary oxygens for Pt is 299 pm, and to the primary oxygens is 201 pm. The platinum ion is slightly above its PtO_4 plane.

The silver dinitrate ion studied here (certainly that containing Ag(1), with bond angle 169.7°) could reasonably be described in the same vein as a linear complex with two unidentate nitrate groups on silver, with both nitrate ligands situated on the same side of the line through silver, parallel to the O—O direction.

Such non-linear, two-coordinated silver ions are known elsewhere. For example, in silver thiocyanate, AgSCN, in proustite (Ag_3AsS_3) and in pyrargyrite (Ag_3SbS_3), the angles S—Ag—S are also about 165°.

The salts $[M(py)_4Cl_2]E(ONO_2)_2$ are all isomorphous,[4] with $M = Rh^{III}$, Ir^{III}; $E = H^+$, Ag^+. The member with $M = Rh^{III}$, $E = Ag^+$ is the subject of the present paper so—*mutatis mutandis*—the present findings apply equally to the other members.

The importance of the complex anion

Aqueous solutions of silver nitrate have great practical importance as analytical reagents, as oxidants often in syntheses, and as progenitors of controlled values of *p*Ag in producing photographic emulsions. This lends particular interest to observations of new species in them. The aqueous equilibria (1)

$$Ag(OH_2)_n^+ + RXO_2^- \rightleftharpoons [Ag(RXO_2)]^0 + (y-1)RXO_2^- \rightleftharpoons [Ag(RXO_2)_y]^{(y-1)-} \quad (1)$$

are known[22] for carboxylates (X = C, R = alkyl, $y > 1$) but seem not to have been previously observed for nitrate, X = N, R = O, $y = 2$. Clearly, from the existence of solid salts of the anion $[Ag(ONO_2)_2]^-$, it has a finite concentration in solution. Ethanoate (acetate: $R = CH_3$) is a 24-electronic system, isoelectronic with nitrate. For equilibrium (1), with $y = 2$, Vartak and Shetiya recorded[22a] (for $\mu = 1.0$, $T = 30°C$) a value of $\log K$ of 0.62 for the benzoate ion as the carboxylate, while MacDougall and Topol had earlier helped[22b] to explain the lack of precipitation of silver ion at neutral pH in the presence of ethanoate by measuring the stability constant for

$$Ag^+ + 2CH_3COO^- \rightleftharpoons Ag(CH_3COO)_2^-$$

as $\log K = 0.64$.

Quantitative values for the equilibria in (2)

$$Ag^+ + 2ONO_2^- \rightleftharpoons [Ag(ONO_2)_2] + (n-2)NO_3^- \rightleftharpoons [Ag(ONO_2)_n]^{(n-1)-} \quad (2)$$

and in particular for β_{120} are not yet known. In concentrated aqueous silver nitrate, the Raman spectrum shows[23] no identified Ag—O bands, though the nitrato-argentates of (2) were described as "inner-sphere complex".

Monomeric complex anions $[AgY_2]^-$, where Y is itself a singly-charged anionic ligand, are not so common as would be expected. In adducts, environments for silver are extremely varied, but rarely include the quasi-linear. Thus, in the adduct of bis-1,2-benzenequinonedioximatoplatinum(II) with silver perchlorate $Pt(C_6N_2O_2H_5)_2 \cdot 0.5AgClO_4$, the $Ag^+ClO_4^-$ ion pairs are intact as such within the parent lattice.[24] In a similar way, crystalline $NH_4Ag(SCN)_2$ was made up of intact AgSCN mol-

ecules and of thiocyanate and ammonium ions.[25] Coordination numbers in the related systems of stoichiometry HgX_2 and $[CuX_2]^-$ are discussed by Sandström and Persson;[26] here too, deviation from two is common.

Among the complex anions of silver(I), a cation of the type *trans*-$[M(py)_4X_2]^+$ ($X = Br^-$ or Cl^-; M = Rh or Ir) has again served to crystallize an unusual ion.

The following supplementary material has been deposited with the editor: (a) Table A. Observed and calculated structure factors. (b) Table B, list of atomic coordinates. (c) Table C, thermal parameters. (d) PARST output (for silver compound only: A similar one is available for the hydrogen dinitrate if that should be required).

THE SYNTHESIS AND BRIDGE-CLEAVAGE REACTIONS OF THE NOVEL DICATIONIC IODO-BRIDGED DIMER $[\{W(\mu\text{-}I)(CO)\{Ph_2P(CH_2)PPh_2\}(\eta^2\text{-}MeC_2Me)\}_2][BF_4]_2$

PAUL K. BAKER* and KEVIN R. FLOWER

Department of Chemistry, University of Wales, Bangor, Gwynedd LL57 2UW, U.K.

(*Received* 21 *December* 1989; *accepted* 2 *April* 1990)

Abstract—The monobut-2-yne tungsten complex $[WI_2(CO)(dppm)(\eta^2\text{-}MeC_2Me)]$ [dppm = $Ph_2P(CH_2)PPh_2$] reacts in CH_2Cl_2 at room temperature with $Ag[BF_4]$ to slowly afford the iodo-bridged dimer $[\{W(\mu\text{-}I)(CO)(dppm)(\eta^2\text{-}MeC_2Me)\}_2][BF_4]_2$ (**1**) in good yield. ^{13}C NMR spectroscopy suggests that each but-2-yne ligand is donating four electrons to each tungsten centre in **1**. Compound **1** reacts with two equivalents of L [L = CN^tBu, $P(O^iPr)_3$ and $SC(NH_2)_2$] in CH_2Cl_2 to give the iodo-bridge cleaved products $[WI(CO)L(dppm)(\eta^2\text{-}MeC_2Me)][BF_4]$ (**2–4**) in high yield. ^{13}C NMR spectroscopy of **2–4** indicates that the but-2-yne ligand is donating four electrons to the tungsten in these compounds.

Cationic alkyne complexes of molybdenum(II) and tungsten(II) have received considerable attention in recent years. In particular, the cationic cyclopentadienyl or indenyl bis-alkyne complexes of the type $[Mo(CO)(\eta^2\text{-}RC_2R')_2(\eta^5\text{-}C_5H_5$ or $C_9H_7)][BF_4]$[1] have been found to be extremely useful precursors for a wide range of novel chemistry.[2–8] However, very few cationic halo-alkyne complexes of molybdenum(II) and tungsten(II) have been reported. Some examples include the cationic isonitrile complexes of the type $[MI(CNR)_4(\eta^2\text{-}RC_2R')]I$ and closely related derivatives reported by Lippard and co-workers.[9–14]

Recently we have reported the synthesis of the cationic alkyne complexes $[WI(CO)(NCMe)\{Ph_2P(CH_2)_nPPh_2\}(\eta^2\text{-}RC_2R)][BF_4]$ (n = 1–6; R = Me or Ph).[15] These complexes are prepared by reaction of the neutral complexes $[WI_2(CO)\{Ph_2P(CH_2)_nPPh_2\}(\eta^2\text{-}RC_2R)]$ (n = 1–6; R = Me or Ph) with one equivalent of $Ag[BF_4]$ in acetonitrile to give $[WI(CO)(NCMe)\{Ph_2P(CH_2)_nPPh_2\}(\eta^2\text{-}RC_2R)][BF_4]$. In this paper we describe the reaction of $[WI_2(CO)(dppm)(\eta^2\text{-}MeC_2Me)]$ [dppm = $Ph_2P(CH_2)PPh_2$] with an equimolar quantity of $Ag[BF_4]$ in CH_2Cl_2 to give the novel dicationic dimeric complex $[\{W(\mu\text{-}I)(CO)(dppm)(\eta^2\text{-}MeC_2Me)\}_2][BF_4]_2$ (**1**), and several bridge-cleavage reactions of this complex.

* Author to whom correspondence should be addressed.

EXPERIMENTAL

The complex $[WI_2(CO)(dppm)(\eta^2\text{-}MeC_2Me)]$ was prepared according to the published method.[16] All chemicals were purchased from commercial sources except for dppm which was prepared according to the literature method.[17]

Elemental analyses for carbon, hydrogen and nitrogen were determined using a Carlo Erba elemental analyser MOD 1106 (using helium as a carrier gas). IR spectra were recorded on a Perkin–Elmer 1430 ratio recording IR spectrophotometer in $CHCl_3$ as thin films between NaCl plates. ^1H and ^{13}C NMR spectra were recorded on a Bruker AC 250 CP/MAS NMR spectrometer (all spectra were calibrated against tetramethylsilane).

$[\{W(\mu\text{-}I)(CO)(dppm)(\eta^2\text{-}MeC_2Me)\}_2][BF_4]_2$ (1)

To $[WI_2(CO)(dppm)(\eta^2\text{-}MeC_2Me)]$ (1 g, 1.106 mmol) dissolved in CH_2Cl_2 (25 cm^3), with continuous stirring under a stream of dry nitrogen, was added $Ag[BF_4]$ (0.2153 g, 1.106 mmol). After 72 h the solution was filtered and the solvent volume reduced to 4 cm^3. Dropwise addition of Et_2O precipitated the brown cationic complex $[\{W(\mu\text{-}I)(CO)(dppm)(\eta^2\text{-}MeC_2Me)\}_2][BF_4]_2$ (**1**). The supernatant was then syringed off and the crude product washed with Et_2O (15 cm^3) twice and dried *in vacuo*. The product was then recrystallized from CH_2Cl_2–Et_2O

to afford brown crystals of **1**, yield of pure product = 0.54 g, 57%.

[WI(CO)(CN^{t}Bu)(dppm)(η^2-MeC$_2$Me)][BF$_4$] (**2**)

To **1** (0.5 g, 0.29 mmol) dissolved in CH_2Cl_2 (10 cm^3) was added ^{t}BuNC (0.0488 g, 0.58 mmol). After stirring for 2 h the solution was filtered and the solvent volume reduced to 3 cm^3. Dropwise addition of Et_2O precipitated the brown cationic complex [WI(CO)(CN^{t}Bu)(dppm)(η^2-MeC$_2$Me)][BF$_4$] (**2**), which was washed with Et_2O (15 cm^3) twice and dried *in vacuo*. Recrystallization of **2** from CH_2Cl_2–Et_2O afforded brown crystals of **2**, yield of pure product = 0.3 g, 54%.

Similar reactions of **1** with two equivalents of L [L = P(O^{i}Pr)$_3$ and SC(NH$_2$)$_2$] in CH_2Cl_2 at room temperature for 2 h gave the bridge-cleaved products [WI(CO)L(dppm)(η^2-MeC$_2$Me)][BF$_4$] (**3** and **4**) (see Table 1 for physical and analytical data).

Table 2. IR data[a] for the compounds [{W(μ-I)(CO)(dppm)(η^2-MeC$_2$Me)}$_2$][BF$_4$]$_2$ and [WI(CO)L(dppm)(η^2-MeC$_2$Me)][BF$_4$]

Compound	ν(C≡O) cm^{-1}	ν(C≡N) cm^{-1}	ν(C≡C) cm^{-1}
1[b]	1940 (b,s)	—	—[c]
2[b]	1995 (s)	2200 (m) 2150 (m)	—[c]
3[b]	1965 (s)	—	1640 (vw)
4[b]	1925 (s)	—	—[c]

s, strong; m, medium; vw, very weak; b, broad.

[a] Spectra recorded in $CHCl_3$ as thin films between NaCl plates.

[b] A broad strong band at ~1020 cm^{-1} [ν(BF)] is observed for all the complexes **1**–**4**.

[c] ν(C≡C) was not observed for these complexes.

RESULTS AND DISCUSSION

Equimolar quantities of the complex [WI$_2$(CO)(dppm)(η^2-MeC$_2$Me)] and Ag[BF$_4$] react in CH_2Cl_2 at room temperature to afford eventually a good yield of the novel dicationic iodo-bridged dimer **1**. Compound **1** reacts with two equivalents of L [L = CN^{t}Bu, P(O^{i}Pr)$_3$ and SC(NH$_2$)$_2$] in CH_2Cl_2 at room temperature to give the bridge-cleaved products **2**–**4** in high yield. Complexes **1**–**4** have been fully characterized by elemental analysis (C, H and N) (Table 1), IR (Table 2), ^{1}H and ^{13}C NMR spectroscopy (Tables 3 and 4). Complexes **1**–**4** are stable when stored under nitrogen, however they are air-sensitive when exposed to air, particularly in solution. The dinuclear complex, **1**, is only slightly soluble in CH_2Cl_2 and $CHCl_3$ and insoluble in diethyl ether and hydrocarbon solvents, whereas the mononuclear compounds, **2**–**4**, are much more soluble in CH_2Cl_2 and $CHCl_3$, but as expected since they are salts they are insoluble in diethyl ether and hydrocarbon solvents.

Reaction of [WI$_2$(CO)(dppm)(η^2-MeC$_2$Me)] and an equimolar quantity of Ag[BF$_4$] in CH_2Cl_2 must initially involve iodide abstraction by Ag^+ to give AgI leaving a vacant coordination site. Two equivalents of [WI(CO)(dppm)(η^2-MeC$_2$Me)]$^+$ combine by forming two dative bonds with the lone

pairs on the iodide ions to give **1**. The structure of **1** is likely to have but-2-yne ligands *trans*- to iodide which has often been observed for other halo-alkyne complexes of molybdenum(II) and tungsten(II),[15,18-21] which leaves the bidentate phosphine and carbon monoxide ligands to occupy the other sites, as shown in Fig. 1. Unfortunately we were unable to grow suitable single crystals of **1** for X-ray crystallography, however the IR and NMR data conforms with the proposed structure shown in Fig. 1. The IR spectrum of **1** shows a broad, single carbonyl band at 1940 cm^{-1} which suggests the *trans*-arrangement of carbonyl ligands, and the ^{1}H NMR shows a single resonance for the but-2-yne ligands which indicates rapid rotation of the but-2-yne ligands (faster than the NMR time scale) at room temperature. This rapid rotation of a but-2-yne ligand attached to molybdenum(II) and tungsten(II) has been observed previously.[2,15,16,18,20-22] The ^{13}C NMR spectrum of **1** shows a single alkyne contact carbon resonance at δ = 222.62 ppm and a single carbonyl resonance at δ = 207.6 ppm, which again agrees with the structure shown in Fig. 1. The alkyne contact carbon resonance at δ = 222.62 ppm indicates[23] that each but-2-yne ligand on **1** is donating four electrons to each tungsten atom in **1**.

The dicationic iodo-bridged dimer [{W(μ-I)(CO)(dppm)(η^2-MeC_2Me)}$_2$][BF_4]$_2$ (**1**) reacts with two equivalents of L [L = CN^tBu, $P(O^iPr)_3$ and $SC(NH_2)_2$] in CH_2Cl_2 at room temperature to afford the bridge-cleaved products [WI(CO)L(dppm)(η^2-MeC_2Me)][BF_4] (**2–4**). These complexes have been previously prepared from reaction of the mono-acetonitrile complex [WI(CO)(NCMe)(dppm)(η^2-MeC_2Me)][BF_4] with an equimolar quantity of L in CH_2Cl_2.[15,21,24] The X-ray crystal structures of the cations [WI(CO)L(dppm)(η^2-MeC_2Me)]$^+$ [L = $P(O^iPr)_3$[15] and $SC(NH_2)_2$[21]] have been determined and the disposition of ligands around the tungsten is the same for both complexes and is shown in Fig. 2. Reaction of **1** (shown in Fig. 1) with two equivalents of L afford, after symmetric cleavage of the iodo-bridges, the structure shown in Fig. 2 with iodide *trans*- to

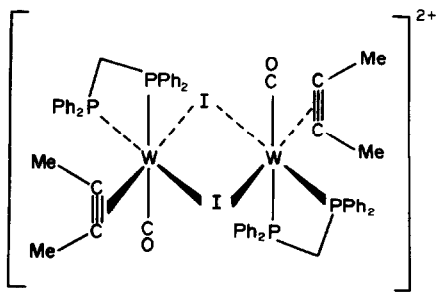

Fig. 1. Proposed structure of [{W(μ-I)(CO)(dppm)(η^2-MeC_2Me)}$_2$][BF_4]$_2$

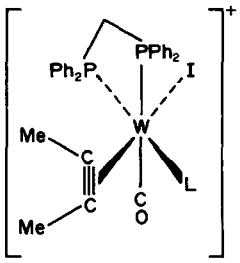

Fig. 2. Proposed structure of [WI(CO)L(dppm)(η^2-Me C_2Me)][BF_4].

but-2-yne, which also helps to confirm the structure of **1** shown in Fig. 1. ^{13}C NMR studies again show[23] the but-2-yne ligand in **2**–**4** is utilizing both of its filled $p\pi$-orbitals to donate four electrons to the metal in **2**–**4**. Refluxing the dicationic iodo-bridged dimer **1** in acetonitrile or acetone for 24 h did not afford mononuclear complexes of the type [WI(CO)L(dppm)(η^2-MeC_2Me)][BF_4] (L = NCMe or $OCMe_2$); only starting material **1** was recovered from these reactions. Also no reaction occurred when carbon monoxide was bubbled through a CH_2Cl_2 solution of **1** for 24 h.

SYNTHESIS AND STRUCTURE OF DICHLORODI-[1,2-BIS(DIMETHYLPHOSPHINO)ETHANE]IRON(III) TETRACHLOROFERRATE(III), $[Fe(DMPE)_2Cl_2]^+[FeCl_4]^-$

(*Received* 19 *February* 1990; *accepted* 2 *April* 1990)

Abstract—$[Fe(DMPE)_2Cl_2]^+[FeCl_4]^-$ was formed in high yield by the photochemical oxidation of $Fe(DMPE)_2Cl_2$ with chlorinated organic solvents CH_2Cl_2, $CHCl_3$ or CCl_4. Crystals of $[Fe(DMPE)_2Cl_2]^+[FeCl_4]^-$ are orthorhombic, space group *Pcab*, $a = 16.250(3)$, $b = 19.392(3)$, $c = 34.451(7)$ Å, $Z = 16$, $R = 0.058$ (3597 F). This represents the first structural characterization of an iron(III) complex with a P_4Cl_2 donor set and saturated phosphine ligands.

Iron(II) bis(diphosphine)dihalide complexes of the type $[Fe(PP)_2X_2]$ [PP = 1,2-bis(dialkyl- or diarylphosphino)ethane, X = halide] have been intensively studied and the crystal structures of a number of such compounds have been determined.[1] By contrast, little work on the iron(III) analogues has been reported, although the *ortho*-phenylenebis(dimethyl)arsine complexes of iron(III) halides were synthesized and characterized in the 1950s.[2] $[Fe(DMPE)_2Cl_2]^+$ [DMPE = 1,2-bis(dimethylphosphino)ethane] has been employed in metal exchange experiments to produce $[^{99}Tc(DMPE)_2Cl_2]^+$, used as a myocardial imaging agent.[3,4] Exposure of methanol solutions of $Fe(DMPE)_2Cl_2$ or $Fe(DEPE)_2Cl_2$ [DEPE = 1,2-bis(diethylphosphino)ethane] to oxygen results in the formation of red iron(III) cationic complexes[5] and the redox chemistry of the iron(II)–iron(III)–iron(IV) dihalide complexes with bisphosphine and bisarsine ligands has been investigated in some depth.[6,7] Iron(III) complexes containing neutral ligands have been employed as precursors for reactive iron(IV) species.[7]

We report here, the facile photochemical synthesis of $[Fe(DMPE)_2Cl_2]^+[FeCl_4]^-$ (**1**), and the crystal structure of this iron(III) complex. Previously reported syntheses of $[Fe(DMPE)_2Cl_2]^+$ include the ferric chloride oxidation of the iron(II) complex, $Fe(DMPE)_2Cl_2$,[5] and a direct route involving the reaction of ferric chloride and DMPE in refluxing anhydrous methanol.[3]

EXPERIMENTAL

NMR spectra were recorded on a Bruker WM400 NMR spectrometer operating at 400.1 MHz for ^1H observation and 162.0 MHz for ^{31}P observation. ^1H NMR spectra were referenced to residual solvent resonances; ^{31}P NMR spectra were referenced to external neat trimethyl phosphite (taken to be 140.85 ppm at the temperature quoted).

Synthesis of $[Fe(DMPE)_2Cl_2]^+[FeCl_4]^-$ (1)

Dichloromethane, chloroform and carbon tetrachloride were of reagent grade and were degassed before use. Dichloromethane was shaken with concentrated H_2SO_4, washed with water, aqueous

* Author to whom correspondence should be addressed.

Na_2CO_3, water, then dried over $CaCl_2$ and distilled from P_4O_{10}.[8] $Fe(DMPE)_2Cl_2$ was prepared using the method of Chatt and Hayter.[9]

A stirred solution of $Fe(DMPE)_2Cl_2$ in dichloromethane (Pyrex flask) was irradiated with a 125 W mercury vapour lamp at 30°C. The initially green solution darkened and after 3 h the solution had attained a magenta colour and the irradiation was stopped. The solvent was removed under reduced pressure and the crude solid recrystallized from chloroform/carbon tetrachloride to yield $[Fe(DMPE)_2Cl_2]^+[FeCl_4]^-$ (**1**) as a magenta crystalline solid in 68% isolated yield, m.p. >160°C (dec.). The complex is insoluble in carbon tetrachloride, toluene and pentane, but soluble in dichloromethane, chloroform, acetone and isopropanol. ^{31}P NMR (CH_2Cl_2, 220 K) δ59 (very broad singlet $W_{1/2}$ 153 Hz at 200 K; 723 Hz at 220 K; 2900 Hz at 250 K); ^1H NMR (acetone-d_6, 220 K) δ2.1 (very broad singlet, 8H, 4× —CH_2—), 1.4 (very broad singlet, 24H, 8× —CH_3). λ_{max} (CH_3CN, log ε) 556 (3.35), 360 (3.72), 283 (4.29), 237 (4.35), 207 (3.28) nm.

X-ray crystallography

Cell constants were determined by a least-squares fit to the θ values of 25 independent reflections, measured and refined on an Enraf–Nonius CAD4-F diffractometer with a graphite monochromator. Data were reduced and Lorentz, polarization, absorption and decomposition corrections were applied using the Enraf–Nonius Structure Determination Package.[10] The structure was solved by direct methods and was refined by full-matrix least-squares analysis with SHELX-76.[11] Hydrogen atoms were included at sites calculated assuming tetrahedral geometry (C—H, 0.97 Å) with group isotropic thermal parameters, all other atoms were refined anisotropically. Conformational disorder in one of the chelate rings is evidenced by very high thermal parameters. Attempts to locate alternative sites for C(9) and C(10) were unsuccessful and the electron density appears as a smear, particularly for the former atom. Scattering factors and anomalous dispersion corrections for iron were taken from the *International Tables for X-ray Crystallography*,[12] and for all others the values supplied in SHELX-76 were used. The atomic nomenclature is defined in Fig. 1.[13]

Crystal data. $C_{12}H_{32}Cl_6Fe_2P_4$, $M = 624.70$, orthorhombic, space group *Pcab*, $a = 16.250(3)$, $b = 19.392(3)$, $c = 34.451(7)$ Å, $U = 10856(3)$ Å^3, D_c ($Z = 16$) = 1.529 g cm^{-3}, $F(000) = 5088$, μ(Mo-K_α) = 18.33 cm^{-1}. Specimen: magenta prisms, 0.12 × 0.26 × 0.15 mm. $N = 7733$, $N_o = 3597$, range of *hkl*: 0 → 17, 0 → 21, 0 → 37, $R = 0.058$, $R_w = 0.058$, residual extrema ±0.50 eÅ^{-3}.

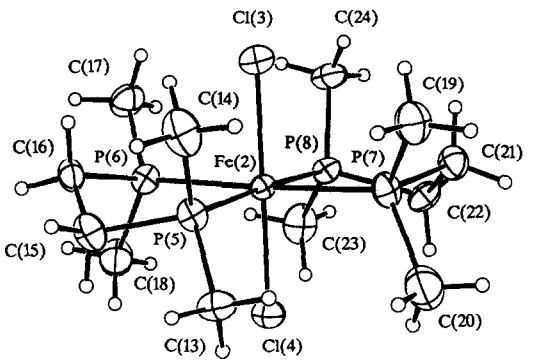

Fig. 1. ORTEP plot of cation 2 of $[Fe(DMPE)_2Cl_2]^+$ $[FeCl_4]^-$ (**1**).

RESULTS AND DISCUSSION

Photolysis of $Fe(DMPE)_2Cl_2$ in a halogenated solvent in a Pyrex vessel, under an atmosphere of argon, resulted in the effectively quantitative production of a magenta-coloured complex, identified by X-ray crystallography as the tetrachloroferrate salt of $[Fe^{III}(DMPE)_2Cl_2]^+$ (**1**) (Fig. 1).

The complex, **1**, is formed equally well if dichloromethane or chloroform is used as the reaction solvent; in carbon tetrachloride, the complex precipitates directly from solution. The reaction probably involves a light-stimulated electron transfer from iron(II) to the alkyl halide, resulting in a chain reaction which exhaustively oxidizes iron(II) to iron(III) and forms organic radicals. After the irradiation is complete, the reaction solution contains a mixture of various condensed chloroalkanes whose formation can be rationalized by reductive radical coupling.

The electronic spectrum of the complex is in accord with that reported previously for $[Fe(DMPE)_2Cl_2]^+[BF_4]^-$.[7] The complex is paramagnetic and the ^{31}P NMR spectrum is observable as a single broad resonance only at low temperatures.

Description of the structure

The asymmetric unit is made up of two $[Fe(DMPE)_2Cl_2]^+$ cations and two $[FeCl_4]^-$ anions, packed with no unusual contacts between them. The cations have geometries which are close to octahedral with the Cl^- ligands *trans* to one another. The largest deviations from octahedral geometry are the chelate ring bite angles of 83.9(1)–84.8(1)°. The average Fe—Cl and Fe—P bond lengths are 2.240 and 2.304 Å, similar to, but marginally longer

Table 1. Comparison of average Fe—Cl and Fe—P bond lengths (Å) in $[Fe(diphosphine)_2Cl_2]^{x+}$ and $[FeCl_4]^-$ complexes

Complex	Fe—Cl	Fe—P	Reference
$[Fe(DMPE)_2Cl_2]^+$	2.240	2.304	This work
$[Fe\{o\text{-}C_6F_4(PMe_2)_2\}_2Cl_2]^+$	2.234	2.294	6(c), 7
$Fe(DMPE)_2Cl_2$	2.352	2.235	1(e)
$Fe(DEPE)_2Cl_2$	2.344	2.260	1(a)
$Fe(DPrPE)_2Cl_2$	2.345	2.268	1(a)
$[FeCl_4]^-$	2.179		This work
$[FeCl_4]^-$	2.182		7, 15

than those in the only other structurally characterized iron(III) complex with four phosphine and two chloride ligands, $[Fe\{o\text{-}C_6F_4(PMe_2)_2\}_2Cl_2]^+[BF_4]^-$ (2.234(1) and 2.292–2.295(1) Å).[14] The similarity of the Fe—P bond lengths in these structures shows that they are not significantly affected by the steric or electronic properties of the diphosphine ligands. The Fe—Cl bonds are shorter than those in comparable iron(II) complexes $[Fe(PP)_2Cl_2$, PP = DMPE, DPPE, DPrPE; DPrPE = 1,2-bis (di-*n*-propylphosphino)ethane] which range from 2.344(1) to 2.352(1) Å, but the Fe—P bonds are significantly longer than those in the iron(II) complexes (2.230(1)–2.275(2) Å, Table 1).[1a,e]

The anions have nearly tetrahedral geometries with the Cl—Fe—Cl angles ranging from 107.0(2) to 114.2(3)°. The Fe—Cl bond lengths range from 2.165(7) to 2.199(5) Å and average 2.179 Å, which is indistinguishable from that found in $[As(C_6H_5)_4]^+[FeCl_4]^-$ (2.182(1) Å).[15] A tetragonal distortion was observed in that structure which is similar to that in one of the anions in the present structure. However, since the distortion of the other anions in the present structure is significantly lower (108.4(2)–112.1(2)°) we suggest that these distortions are the result of crystal packing forces.

(*Received* 21 *December* 1989; *accepted* 2 *April* 1990)

Abstract—Eight new mixed-ligand lanthanide complexes of the general formula CpLnLL′ [Ln = Sm, Dy, Ho, Yb; Cp = C_5H_5; L = CF_3COOO; L′ = 8-OC_6H_3N:CHCH:CH, OC_6H_4(*o*-NH_2)] have been synthesized. All the complexes were characterized by elemental analysis, IR, XPS and MS spectra, showing that they are dimers with carboxylate ions as bridging groups, and the donor atom nitrogen in each complex coordinates with the metal. Their thermal stability has been studied and discussed. All these complexes are thermally unstable, and at moderately high temperatures they tend to disproportionate into a mixture of Cp_2LnL, Cp_2LnL', LnL_3 and LnL'_3.

Recently, we have reported studies on the thermal stability of some mixed-ligand lanthanide (Nd, Yb) complexes involving both cyclopentadienyl (Cp) and classical chelate ligands (8-quinolinolato, *o*-aminophenolato, *o*-aldehydophenolato, furfuralcoholato ligand), and found that they are susceptible to heat and tend to disproportionate at moderately high temperatures.[1,2] However, the mixed-ligand lanthanide complexes involving both Cp and two different classical chelate ligands have not hitherto been reported and studied. In continuation of our previous work,[1,2] we have now carried out the synthesis and studies on the thermal stability of eight new mixed-ligand lanthanide (Sm, Dy, Ho, Yb) complexes involving three ligands including the Cp ligand and two different classical chelate ligands—trifluoroacetato and either 8-quinolinolato or *o*-aminophenolato ligands, and the results are reported in this paper.

RESULTS AND DISCUSSION

By the reaction of Cp_2LnCl (Ln = Sm, Dy, Ho, Yb) first with sodium trifluoroacetate and then with 8-hydroxyquinoline or *o*-aminophenol (mole ratio, 1:1:1) in THF (tetrahydrofuran) at room temperature, eight new mixed-ligand lanthanide complexes involving the Cp ligand and two classical chelate ligands—trifluoroacetato and either 8-quinolinolato or *o*-aminophenolato ligands have been synthesized, as shown in the following equation:

$$Cp_2LnCl + NaL + HL' \xrightarrow[RT]{THF} CpLnLL' + C_5H_6 + NaCl$$

Ln = Sm, Dy, Ho, Yb; L = CF_3COO;

L′ = 8-OC_6H_3N:CHCH:CH, OC_6H_4(*o*-NH_2).

All these complexes were characterized by elemental analysis, IR, XPS and MS spectra.

The elemental analyses (Table 1) for all the complexes are in compliance with the general formula CpLnLL′. All the complexes are soluble in THF, but only partially soluble in benzene and toluene. All of them are insoluble in pentane and n-hexane. They have no melting points; decomposition is observed in a sealed capillary above 200°C.

The IR spectra (Table 2) of all the complexes show absorptions at about 250, 780, 1010, 1400 and 3080 cm^{-1}, characteristic of the η^5-Cp ligand.[3] All

four 8-quinolinolato complexes exhibit two bands characteristic of the 8-quinolinolato ligand at about 1495 and 1570 cm^{-1}.[4] Moreover, a band appearing in the 390 cm^{-1} region may be assigned to the chelate ring deformation vibration of 8-quinolinolato complexes.[5] The IR spectra of four *o*-aminophenolato complexes show the bands of the 1,2-disubstituted benzene ring at about 750, 1500, 1600 and 3030 cm^{-1}.[6] In addition, two ν(OH) bands for the free ligand *o*-aminophenol at 3527 and 3628

$CpYb(CF_3COO)[OC_6H_4(o\text{-}NH_2)]$ (**8**)	3335m, 3225m, 3075w, 3040w, 1667s, 1603m, 1492s, 1455s, 1432m, 1206s, 1116m, 1106m, 1013m, 775m, 752s, 490w, 271w, 252w.

cm^{-1} are absent in the complexes, and the two $\nu(NH_2)$ bands for the free ligand at about 3390 and 3478 cm^{-1} are shifted to lower frequencies, about 3230 and 3360 cm^{-1}, on complexation. This indicates coordination of the nitrogen atoms of the NH_2 groups.[7] All the complexes also exhibit two bands in the IR spectra in the regions 270 and 1115 cm^{-1}. We tentatively attribute the first one to a Ln—N vibration mode and the second one to Ln—O—C bond stretching.[5,8,9] A band appearing near 490 cm^{-1} may be assigned to the ν(Ln—O) mode.[8]

In the IR spectra of all the complexes, the absorptions associated with the antisymmetric and symmetric stretches of carboxylate ions appear near 1455 and 1660 cm^{-1}, respectively. Deacon pointed out that three useful correlations between $\nu(CO_2)$ frequencies and carboxylate coordination can be justified for trifluoroacetato complexes, viz. (a) separations between $\nu(CO_2)$ frequencies (Δ) substantially greater than ionic are indicative of unidentate carboxylate coordination; (b) separations significantly less than ionic values are indicative of chelating and/or bridging carboxylate groups; (c) very low separations generally indicate chelation or a combination of chelation and bridging.[10] The $\nu(CO_2)$ separations of the eight new complexes are lower than the ionic values (Table 3). Therefore, we assume that all these complexes may be dimers with carboxylate ions as bridging groups.

These complexes were also verified by X-ray photoelectron spectroscopy. From the XPS data (Table 4), it was revealed that in each complex the binding energy of the nitrogen atom of the 8-quinolinolato or *o*-aminophenolato ligand was increased, as compared with corresponding reference substances. This further proves coordination through the nitrogen atom of the 8-quinolinolato or *o*-aminophenolato ligand.

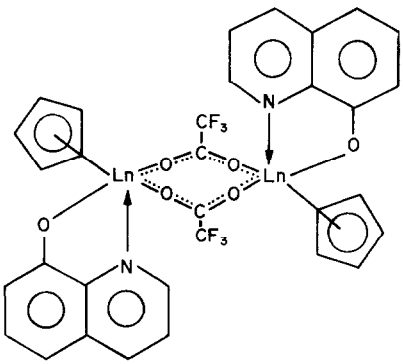

Fig. 1.

The molecular ions and main fragments of these complexes are clearly observed in their mass spectra (Table 5). All the molecular ions are characterized by the ready loss of the Cp group with the $(M—Cp)^+$ ion as base peak in the mass spectra, but the peaks corresponding to the fragments of dimers of greater mass than the molecular ions are observed as well. So, on the basis of elemental and spectral analyses, it can be concluded that all the complexes are dimers with carboxylate ions as bridging groups and the intramolecular five-membered chelating ring, produced by chelation coordination of the 8-quinolinolato or *o*-aminophenolato ligand, in each complex. Thus, the structures shown in Figs 1 and 2 for the complexes may be proposed.

For the purpose of studying the thermal stability of these complexes, their mass spectra were recorded at different evaporation temperatures. It is interesting to note that when the evaporation temperature of a sample reaches a certain value for each complex, not only are the molecular ion $CpLnLL'^+$

[b] ΔE is the binding energy difference.

peaks observed in the spectra, but the peaks corresponding to Cp_2LnL^+, $Cp_2LnL'^+$, LnL_3^+ and their fragments are observed also. Furthermore, with increasing evaporation temperature, the molecular ion $CpLnLL'^+$ peaks gradually disappear and the ion peaks of Cp_2LnL^+, $Cp_2LnL'^+$, LnL_3^+ and their fragments are enhanced. According to the results reported in our previous reports,[1,2] we predict that the following disproportionation reaction may take place:

$$4CpLnLL' \rightarrow Cp_2LnL + Cp_2LnL' + LnL_3 + LnL'_3.$$

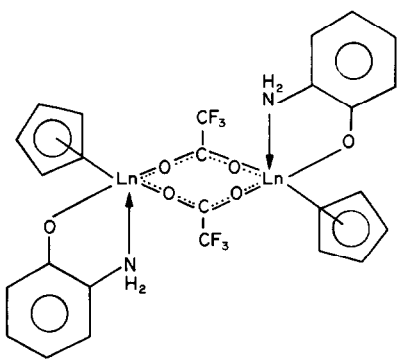

Fig. 2.

The ion peaks of the disproportionation product LnL'_3 were not observed in the mass spectra.

As the η^5-Cp ligands in both lanthanide and actinide complexes are quite labile,[11] it may be assumed that the lability of Cp ligands causes the above disproportionation reaction. It is also possible that the disproportionation reaction takes place via an intermediate bimolecular complex in which the Cp ligands are bonded in an η^5-fashion to one molecule, and in an η^1-fashion to the second molecule of the complex. The transfer of one Cp ligand from one molecule to another may initiate the disproportionation reaction.

Since no $CpLnL_2^+$ and $CpLnL'^+_2$ ion peaks were observed in the mass spectra recorded at different evaporation temperatures, we predict that all the complexes do not undergo the following rearrangement reaction:

$$2CpLnLL' \rightarrow CpLnL_2 + CpLnL'_2$$

but directly disproportionate into a mixture of Cp_2LnL, Cp_2LnL', LnL_3 and LnL'_3 during the course of raising the temperature.

In view of decomposition temperatures and MS data, we also found that the order of relative thermal stability of the complexes is CpYbLL' > CpHoLL' > CpDyLL' > CpSmLL', which may be due to the lanthanide contraction. The attraction of the Ln–ligand bond formed by

[a] MS data are given for the isotopes ^{152}Sm, ^{164}Dy, ^{165}Ho, ^{174}Yb, ^{14}N, ^{16}O and ^{19}F, the peak patterns correspon to theoretical values based on the natural abundance of isotopes.

Ln^{3+} and an anionic ligand increases with decreasing Ln^{3+} radius. According to the concept of correlation of stability with steric saturation,[12,13] the above order also may be a consequence of the greater steric saturation present around the smaller metal centre. In addition, the four 8-quinolinolato complexes have relatively higher decomposition and disproportionation temperatures than the corresponding *o*-aminophenolato complexes. This can be attributed to the following. Firstly, probably due to the stronger complexing ability of the 8-quinolinolato ligand compared with the *o*-aminophenolato ligand. The Ln–ligand bond formed by Ln^{3+} and the 8-quinolinolato ligand is stronger than that of the *o*-aminophenolato ligand. Secondly, the large steric volume of the 8-quinolinolato ligand relative to the *o*-aminophenolato ligand is favourable for the stabilization of the coordinated unsaturated organolanthanide complexes.

EXPERIMENTAL

All operations were carried out in an atmosphere of dry oxygen-free argon using standard Schlenk techniques or in a glovebox. All the reagents are of analytical or chemically pure grade. All solvents were dried over sodium, refluxed over sodium benzophenone or finely divided $LiAlH_4$ and distilled immediately before use. Cp_2LnCl (Ln = Sm, Dy, Ho, Yb) were prepared by literature methods.[14]

The analyses for C, H and N were performed using a Yanaco MT- 2 CHN analyser. Metal analyses for lanthanides were accomplished by a literature method.[15] The IR spectra were recorded in the range 4000–200 cm^{-1} with a Perkin–Elmer 983G spectrometer. Samples were prepared as Nujol and Fluorolube mulls between CsI plates. The X-ray photoelectron spectra were obtained on a VG ESCALAB MKII spectrometer with Mg-K_α exciting irradiation. All the mass spectrometric measurements were performed on a VG ZAB-HS spectrometer operating in EI mode at a resolving power of 1000 (electron energy, 70 eV; emission current, 1 mA; ion acceleration, 3 kV). The samples were protected under argon and introduced by direct inlet techniques with a source temperature of 110°C and sample evaporation temperature in the range of 50–300°C.

General procedure for the synthesis of complexes

The appropriate CF_3COONa (2 mmol) was added to a 50 cm^3 THF solution of Cp_2LnCl (Ln = Sm, Dy, Ho, Yb) (2 mmol). The reaction mixture was allowed to stir for 24 h at room temperature. Then, equimolor 8-hydroxyquinoline or *o*-aminophenol was added to the reaction mixture. After the resulting mixture was stirred for 24 h at room temperature, the volume was reduced *in vacuo* to about 20 cm^3. The NaCl precipitate was removed from the reaction mixture by centrifugation. By the addition of 40 cm^3 of n-hexane to the resulting solution, a solid precipitated out which was recrystallized twice from THF–n-hexane and dried *in vacuo* to afford the product. Yields, analyses and physical properties of all the complexes are given in Table 1.

(*Received* 5 *February* 1990; *accepted* 2 *April* 1990)

Abstract—In the crystal structure of Δ-*cis*(NO_2),*trans*(NH_2)-silver(I)–dinitrobis(*S*-valinato) cobaltate(III) the *S*-valinato ligand is found to form the chelate ring of a strained envelope conformation with one methyl group of the ring side chain completely axially oriented and in the proximity of the cobalt atom. The conformation supports the basic idea that an axial positioning of an aminocarboxylato chelate ring side chain induces a large contribution to the optical activity of a complex.

In the investigation of the optical activity of *cis*(NO_2),*trans*(NH_2)-bis(*S*-aminocarboxylato)dinitrocobaltate(III) diastereomers we have observed the effect of the conformation of the aminocarboxylato chelate ligand on the optical activity.[1] On the basis of the crystal structures of two complexes [Δ-*cis*(NO_2),*trans*(NH_2)-silver(I)–bis(*S*-alaninato)dinitrocobaltate(III)[2] and Λ-*cis*(NO_2),*trans*(NH_2)-bis(*S*-arginine)dinitrocobalt(III) nitrate[3]] and the solution NMR data for the aminocarboxylato ligands in all complexes from the series, it has been inferred that a more axially oriented ring side chain of an *S*-aminocarboxylato ligand induces a larger negative contribution to the circular dichroism of a complex.[1] The largest contribution has been observed for the Δ-diastereomers of the investigated complexes containing *S*-valinato and *S*-isoleucinato ligands. Hence, the ligand conformation in these complexes is of special importance for the explanation of the effect.

Therefore, we undertook a crystal structure analysis of Δ-*cis*(NO_2),*trans*(NH_2)-silver(I)–dinitrobis(*S*-valinato)cobaltate(III) and the investigation of the ligand conformation in relation to the solution optical activity of the complex.

EXPERIMENTAL

Crystal preparation

About 0.5 g of the optically pure Δ-*cis*(NO_2), *trans*(NH_2)-potassium–dinitrobis(*S*-valinato)cobaltate(III)[1] was dissolved in 10 cm^3 of water and 1.2 cm^3 of silver nitrate solution (1 mol dm^{-3}) added. The solution was kept overnight in a refrigerator and dark brown prismatic crystals of the corresponding silver salt were obtained.

X-ray analysis

Crystal data: $Ag[Co(C_5H_{10}NO_2)_2(NO_2)_2]$; M_r = 496.8, monoclinic, space group $C2$, a = 18.851(2), b = 7.019(1), c = 6.2788(7) Å, β = 102.01(4)°, V = 812.6(1) Å^3, Z = 2, D_o = 2.070 g cm^{-3}, D_x = 2.088 g cm^{-3}, μ(Mo-K_α) = 22.5 cm^{-1}.

The dark brown prismatic crystal having the dimensions 0.48 × 0.20 × 0.34 mm was mounted with the b axis approximately parallel to the ϕ axis of an ENRAF–NONIUS CAD 4 automatic diffractometer equipped with a graphite monochromator. Unit cell dimensions were determined from a least-squares fit of the setting angles of 25 reflections with $15 < \theta < 18°$. Intensity data were collected with graphite monochromatized Mo-K_α, radiation (λ = 0.71069 Å) at room temperature (20°C). The θ–2θ scanning mode was used with $\Delta\theta = 0.80 + 0.35 \tan\theta$, and the background was estimated by extending the scans of both ends by 25%. The scan speeds were adjusted to give $\delta I/I > 0.03$ subject to a time limit of 90 s. Of the 1310 independent intensities measured with $2 < \theta < 36°$, 976 were considered to be observed [$I > 3\sigma(I)$]. Two standard reflections measured every 120 min showed no sign of decay over the period of data collection. The data were corrected for Lorentz and polarization effects, but not for absorption.

The structure was solved by heavy-atom and difference Fourier methods and refined by full-matrix least-squares, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where $w = 1/\sigma^2(F_o)$. At a later stage of isotropic refinement of non-hydrogen atoms, the absolute configuration was established by carrying out the refinement with the two alternative configurations for values of polarity factor, η, 1 and −1 giving R factors of 0.076 and 0.072, respectively. The model of the lower R value which was in accordance with the configuration deducted from the configuration of *S*-valine, was further anisotropically refined. All hydrogen atoms were included in the structural model at calculated positions at C—H and N—H distances of 0.95 Å and were allowed to ride on the atom to which they are bonded with $U(H) = 1.2 \times U$ of the corresponding atom. The final least-squares refinement of the accepted enantiomorph included an extinction coefficient, g (defined by Stout and Jensen[4]), converged at R = 0.025 and R_w = 0.031. Scattering factors for neutral atoms and anomalous dispersion terms were taken from ref. 5. All calculations were performed on a PDP 11/73 computer using the SDP program,[6] version 4.2.

RESULTS AND DISCUSSION

Crystal structure

The crystal structure of Δ-*cis*(NO_2),*trans*(NH_2)-silver(I)–dinitrobis(*S*-valinato)cobaltate(III) consists of the complex molecule anions and silver cations joined by Coulombic forces. An ORTEP drawing of the complex molecule with the numbering scheme of the atoms is given in Fig. 1. The cobalt atoms lie on two-fold axes and are six-coordinated

by two carboxylato oxygen atoms and two amino nitrogen atoms belonging to different valinato ligands and two nitro nitrogen atoms, respectively.

Bond lengths and angles in the anion are listed in Table 1. The Co—O and Co—N bond distances and angles are in agreement with values previously observed in the cobalt(III) amino acidato complexes. The largest deviation from octahedral geometry occurs for the O(1)—Co—N(1) angle of the five-membered aminocarboxylato chelate ring. The bond distances and angles in the valinato ligand are unexceptional; the same holds for the nitro group.

The conformation of the five-membered chelates and the positions of the ring side chain methyl groups are expressed by the relevant parameters, as given in Table 2. The chelate rings adopt the strained λ-envelope conformation, with one of the side chain methyl groups in the axial position relative to the mean least-square plane defined by the five-membered ring. In addition, the side chain methyl groups are in positions which correspond to almost ideal staggered conformations relative to the amino and carboxylato groups of the ligand.

The cation resides on a crystallographic two-fold axis. Each Ag^+ ion is surrounded in an irregular arrangement by the eight oxygen atoms belonging to the four complex anions. The independent $Ag\cdots O$ distances are 2.529 and 2.616 Å for the carboxylato groups and 2.456 and 2.999 Å for the nitro groups.

Ligand conformation in relation to optical activity

It has been suggested by us that the λ-twist conformation of an *S*-aminocarboxylato chelate ring is typical for the Δ-*cis*(NO_2),*trans*(NH_2)-bis(aminocarboxylato)dinitrocobaltate(III) diastereomers.[1] However, in the present case, the strained envelope conformation of the *S*-valinato ligand is established in the solid complex. This seems to be caused mainly by a mutual repulsion of the ring side chains of two *S*-valinato ligands in the complex molecule. If so, *S*-valinato ligand conformations could be considered fixed by intramolecular interactions. Indeed, the proton NMR spectrum of the complex in solution shows that the *S*-valinato chelate ring side chains do not rotate. Furthermore, in the H_α proton signal, observed as a quartet of lines in the spectrum, the spin–spin coupling constant with H_β proton ($J_{\alpha\beta} = 3.6$ Hz) corresponds very well[7] with the conformation of the *S*-valinato ligand observed in the solid complex. On this bases the ligand conformation observed in

the solid complex may be considered relevant for the solution optical activity of the complex. This gives an opportunity of checking whether the proposed explanation of the aminocarboxylato ligand conformation influence on the optical activity is supported by the experimentally observed ligand conformation.

The effect of the *S*-valinato ligand conformation on the optical activity of the complex, according to the Quadrant rule for ligand contribution to the optical activity of the octahedral complexes,[8] is presented in Fig. 2. It is seen that there is a strong negative contribution to the optical activity, in accordance with the experimental result.[1] Since a completely axial positioning of one CH_3-group of the ring side chain is displayed, the basic idea that an axial positioning of a side chain atom induces a large contribution to the optical activity is fully supported. Moreover, it is evident that early branching of the ring side chain is important for the axial positioning of a CH_3-group in the proximity of the cobalt atom. This then explains the largest contribution of the *S*-valinato and *S*-isoleucinato ligands to the optical activity of Δ-*cis*(NO_2), *trans*(NH_2)-bis(aminocarboxylato)dinitrocobaltate(III) complexes.

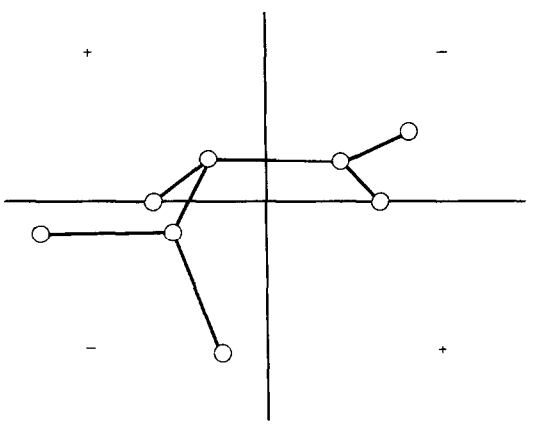

Fig. 2. The *S*-valinato ligand skeletal atom projection according to the Quadrant rule for ligand contribution to the optical activity of a complex.

(*Received* 5 *February* 1990; *accepted* 2 *April* 1990)

Abstract—Reactions of [RuH(CO)Cl(EPh$_3$)$_3$] (E = P, As) with 4-cyanopyridine, 1,4-dicyanobenzene, 1,4-dicyanobutene and of [Ru(η^5-C$_5$H$_5$)ClL$_2$] [L$_2$ = (PPh$_3$)$_2$, (AsPh$_3$)$_2$, dppe, dppm] with 1,4-dicyanobenzene in the presence of anions like BF$_4^-$, PF$_6^-$, BPh$_4^-$, ClO$_4^-$, have been carried out. Cyanopyridine containing hydridocarbonyl complexes showed a marked tendency to react with halogenated solvents yielding complexes containing no hydride ions. The cationic mononuclear, binuclear and neutral complexes have been characterized by elemental analyses and spectral (IR, UV–vis, ^{1}H and ^{13}C NMR) studies.

We describe and discuss herein the structural properties of the complexes resulting from the reactions of [RuH(CO)Cl(EPh$_3$)$_3$] (E = P, As) with 4-cyanopyridine (4-CNPy), 1,4-dicyanobenzene (DCB) and 1,4-dicyanobutene (DCBT). Although the ligational behaviour of 4-CNPy has been the subject of several previous publications[1] those of DCB and DCBT have little studied.[2] Our interest in these ligands stems from the presence of two donor sites which raises the possibility of formation of mononuclear and bi/or polynuclear complexes. The latter systems are of interest in various fields, for example, in understanding the mechanism of biological redox processes, and in the conversion of solar to chemical energy. An additional feature of this study was to investigate the effect on the bonding properties of a second functional group, remote from the coordinated site in the mononuclear complexes (if formed). In addition to this, we have been concerned for the past few years with the coordination properties of organonitriles, which prompted us to extend our studies in a similar direction.

EXPERIMENTAL

The chemicals used for reactions were Analar or chemically pure grade. Solvents were dried prior to use. [RuH(CO)Cl(EPh$_3$)$_3$] (E = P or As) and [Ru(η^5-C$_5$H$_5$)ClL$_2$] (L = PPh$_3$, AsPh$_3$ or SbPh$_3$; L$_2$ = dppe, dppm) were prepared by the literature procedures.[3–5] 4-Cyanopyridine (Aldrich), 1,4-dicyanobenzene (Aldrich) and *trans*-1,4-dicyanobutene (Fluka) were used as received. Physicochemical measurements were made as described elsewhere.[6] The results are given in Table 1.

(A) *Reactions of* [RuH(CO)Cl(EPh$_3$)$_3$] (E = P, As) *with* 4-CNPy *in the presence of a suitable anion* (BF$_4^-$, BPh$_4^-$, PF$_6^-$, ClO$_4^-$)

A solution of 4-CNPy (0.3 mmol) and [RuH(Co)Cl(EPh$_3$)$_3$] (0.16 mmol) in benzene (30 cm^3) was heated under reflux for 4.5 h. After cooling the resultant solution to room temperature it was filtered to remove any solid impurity and the filtrate was concentrated to about 5 cm^3 under reduced pressure. A solution of the suitable anion (NaBF$_4$, NaBPh$_4$, NH$_4$PF$_6$ or LiClO$_4$) in methanol (30 cm^3) was added and it was then left for slow crystallization. After about 10 h, a brown microcrystalline complex separated out, which was centrifuged, washed with methanol, water, methanol, diethyl ether and dried *in vacuo*. Its analyses corresponded to [RuH(CO)(NCpy)$_2$(EPh$_3$)$_2$]X (X = BF$_4^-$, PF$_6^-$, BPh$_4^-$, ClO$_4^-$) (hereafter referred to as **I**; yield, *ca* 55%).

Reactions of [RuH(CO)Cl(EPh$_3$)$_3$] with DCB and *trans*-DCBT in the presence of anions were

RB = red–brown; YB = yellowish-brown; B = brown; OB = orange–brown; CNPy = 4-cyanopyridine; DCB = 1,4-dicyanobenzene; DCBT = 1,4-dicyanobutene.

carried out using a similar procedure to that described in (A) except that DCB or DCBT was used in place of 4-CNPy. Their analyses corresponded to a dinuclear formula $[RuH(CO)(EPh_3)_2\text{-}\mu\text{-}\{DCB \text{ or } DCBT\}_2,\mu\text{-}RuH(CO)(EOh_3)_2]X_2$ (hereafter referred to as **II** (DCB) and **III** (DCBT); yield, *ca* 55%).

(B) *Reactions of* $[Ru(\eta^5\text{-}C_5H_5)Cl(E'Ph_3)_2]$ (E' = P, As) *with* $[RuH(CO)(NCPy)_2(PPh_3)_2]X$ *in the presence of a suitable anion* (BF_4^-, PF_6^-, BPh_4^-, ClO_4^-)

A suspension of $[RuH(CO)(NCPy)_2(EPh_3)_2]X$ (0.15 mmol) and $[Ru(\eta^5\text{-}C_5H_5)Cl(E'Ph_3)_2]$ (0.21 mmol) in methanol (30 cm^3) was heated under reflux for *ca* 5 h, whereupon the suspended material went into a reddish-brown solution. This was cooled to room temperature and filtered to remove any solid residue. The filtrate was concentrated to about 5 cm^3 under reduced pressure and a solution of the suitable anion (BF_4^-, PF_6^-, BPh_4^-, ClO_4^-) in methanol (25 cm^3) was added. This was then left for slow crystallization whereby a red–brown microcrystalline compound was obtained, which was separated by filtration, washed with methanol, water, methanol, diethyl ether and dried *in vacuo*. The analyses corresponded to a dinuclear complex, $[H(CO)(PPh_3)_2(NCPy)Ru\text{-}\mu\text{-}NCPy\text{-}Ru(\eta^5\text{-}C_5H_5)(E'Ph_3)_2]X_2$ (hereafter referred to as **IV**; yield, *ca* 50%).

(C) *Reactions of* 1,4-*dicyanobenzene with* $[Ru(\eta^5\text{-}C_5H_5)ClL_2]$ (L = PPh_3, $AsPh_3$, $SbPh_3$; L_2 = dppe or dppm) *in the presence of a suitable anion* (BF_4^-, PF_6^-)

The complex $[Ru(\eta^5\text{-}C_5H_5)ClL_2]$ (0.13 mmol) was suspended in dry methanol (25 cm^3) containing a salt of a suitable anion ($NaBF_4$, NH_4PF_6) (0.25 mmol) and DCB (0.31 mmol). The contents were refluxed for *ca* 2 h, whereupon $[Ru(\eta^5\text{-}C_5H_5)ClL_2]$ slowly dissolved and bright yellow shiny crystals appeared. These were separated by filtration, washed with methanol, diethyl ether, light petroleum ether and dried *in vacuo*. In the cases of the complexes of dppe or dppm, crystals did not separate out. In those cases the bright yellow filtrate was evaporated to dryness and the residue was extracted with 5 cm^3 of CH_2Cl_2. Addition of about 40 cm^3 of petroleum ether to the extract precipitated a bright yellow compound which was filtered, washed several times with petroleum ether and dried *in vacuo* (yield, *ca* 40%). Analyses corresponded to a dinuclear formula $[Ru_2(\eta^5\text{-}C_5H_5)_2(L_2)_2(\mu\text{-}C_8H_4N_2)]X_2$ (L = PPh_3, $AsPh_3$, $SbPh_3$; L_2 = dppe or dppm; X = BF_4^-, PF_6^-) (hereafter referred to as **V**; yield, 50%).

(D) *Reactions of* $[RuH(CO)(EPh_3)_2(NCPy)_2]X$ (E = P, As) *with* CH_2Cl_2 *or* $CHCl_3$

$[RuH(CO)(EPh_3)_2(NCPy)_2]X$ (0.2 mmol) was refluxed in 30 cm^3 of $CHCl_3$–CH_2Cl_2 for *ca* 4 h, which resulted in an orange–brown solution. After cooling to room temperature it was filtered to remove any remaining solid and evaporated to dryness under reduced pressure. The residue thus obtained was dissolved in CH_2Cl_2 (5 cm^3) and filtered. To the filtrate, light petroleum ether (*ca* 40 cm^3) was added, whereupon a yellowish-brown precipitate formed. This was separated by filtration, washed with methanol, light petroleum ether and dried *in vacuo*.

Reactions of $[RuH(CO)Cl(EPh_3)_3]$ with 4-CNPy in a 1 : 2 molar ratio in CH_2Cl_2–$CHCl_3$ yielded the same product as in reaction (D)

Purification of the reaction products of reaction (D)

The product obtained in reaction (D) was dissolved in the minimum volume of CH_2Cl_2 and passed through a neutral alumina column (25 × 1.5 cm). It was eluted by CH_2Cl_2. The first major yellow band was collected and evaporated to dryness. The residue was extracted with CH_2Cl_2 and precipitated with light petroleum ether. This was washed several times with petroleum ether and dried *in vacuo*; it was analysed for $[Ru(CO)Cl_2(EPh_3)NCPy]_2$ (hereafter referred to as **VI**; yield, 25%).

The second brownish band was eluted with methanol and the complex was obtained by evaporating the eluent to dryness, extracting it with dichloromethane and precipitating it using light petroleum ether. This was separated by filtration, washed several times with light petroleum ether and dried *in vacuo*. It was analysed for $[Ru(CO)_2Cl_2(EPh_3)MeOH]$ (hereafter referred to as **VI**; yield 25%).

RESULTS AND DISCUSSION

The reddish-brown to yellow cationic complexes (Table 1) resulting from the reactions of $[RuH(CO)Cl(EPh_3)_3]$ (E = P, As) with CNPy, DCB or DCBT were found to be non-hygroscopic, air-stable, high melting, crystalline solids. The reactions with CNPy yielded the mononuclear cationic species (**I**), while those with DCB and DCBT yielded dinuclear complexes (**II** DCB, **III** DCBT). Mononuclear complexes did not react any further with the $[RuH(CO)Cl(EPh_3)_3]$. These were then allowed to react with

$[Ru(\eta^5\text{-}C_5H_5)Cl(EPh_3)_2]$, whereupon dinuclear cyano-bridged complexes (**IV**) (Table 1) were formed. These were slightly soluble in methanol, benzene; soluble in chloroform, dichloromethane, DMF, DMSO; and insoluble in light petroleum ether and diethyl ether. The solutions of cyanopyridine complexes in halogenated solvents CH_3CN, DMSO, or in other coordinating solvents changed their colours slowly, from which yellowish-brown complexes (**VI** and **VII**), having different melting points, were obtained. Presumably complexes **I** reacted with the solvents, and because of this their NMR and electronic spectra in these solvents could not be obtained. In other solvents the complexes were practically insoluble.

The products **VI** and **VII** obtained from the solutions of cyanopyridine complexes in halogenated solvents were found to be neutral, highly soluble in most of the common solvents except hydrocarbons or ether. Neither there IR or NMR spectra exhibited any band characteristic of the Ru—H bond. Their analytical data and the fact that the Ru—H bond is absent in both the products suggested their formulae as $[Ru(CO)Cl_2(PPh_3)(NCPy)]_2$ (**VI**) and $[Ru(CO)_2Cl_2(PPh_3)MeOH]$ (**VII**). Attempts are being made to identify other products. It is interesting that a dicarbonyl complex (**VII**) is one of the products in the latter reactions but it is not unexpected because a number of ruthenium(II) hydride monocarbonyl complexes on reacting with $CHCl_3$ yield dicarbonyl products.[7]

The bonding modes in the complexes and their tentative structures have been deduced following the spectral studies.

IR spectra

The IR spectra of mononuclear cyanopyridine complexes (**I**) exhibited a fairly strong broad band for the cyanide stretching vibration around 2240 cm^{-1} compared to 2243 cm^{-1} in the corresponding free ligand. The broadness of the band indicated the presence of two CN groups in *cis* positions. The position of ν(CN) is essentially unaffected, implying the non-involvement of the CN group in coordination. A slight change ($+3$ cm^{-1}) in the ν(C≡N) position may be due to the resonance and the electronic effects arising from coordination with the metal ion. It is therefore presumed that the ligand binds the metal ion through its pyridine nitrogen atom. The bonding through the pyridine nitrogen is also evidenced from the blue shifts of the band arising from those having contributions from ν(C=C) and ν(C=N) of the pyridine molecule in the 1400–1600 cm^{-1} region.

Since our attempts to bind another molecule of $[RuH(CO)Cl(EPh_3)_3]$ with mononuclear complexes (**I**) through uncoordinated nitrogen of the nitrile failed, presumably because of the low basicity of the bonded 4-CNPy groups, these complexes were allowed to react with $[Ru(\eta^5\text{-}C_5H_5)Cl(EPh_3)_2]$. The purpose of doing this was to investigate the basicity of the nitrile nitrogen towards the cationic species $[Ru(\eta^5\text{-}C_5H_5)(EPh_3)_2]^+$ formed in their methanol solutions. These reactions yielded the dinuclear complexes $[(EPh_3)_2H(CO)CNPy\text{-}Ru\text{-}\mu\text{-}NCPy\text{-}Ru(\eta^5\text{-}C_5H_5)(EPh_3)_2]X_2$ ($X = BF_4^-$, PF_6^-, BPh_4^-) (**IV**). Their IR spectra exhibited a weak and a broad band corresponding to ν(C≡N) around 2230 cm^{-1} ($\nu_{1/2} = 15$ cm^{-1}). The broadness and shape of the band suggested the overlap of two ν(C≡N) bands of coordinated and uncoordinated CN groups. The analysis of the broad band indicated that it is composed of two bands, one having a maximum around 2240 cm^{-1} and the other at around 2230 cm^{-1}. This suggests that the reactions lead to binding of one of the two free C≡N groups of bonded cyanopyridine molecules in the mononuclear species (**I**) to the $[Ru(\eta^5\text{-}C_5H_5)(EPh_3)_2]^+$ ion, yielding dinuclear species (**IV**). The red shift of ν(C≡N) of the bridged 4-CNPy (2230 cm^{-1}) may be attributed to metal-to-ligand back-bonding. This is due to the drift of *d* π-electron density from the metal to the π^*-orbitals of the CN group, thus leading to a reduction in the CN bond order. The position of ν(CN) of the unbonded CN group in **IV** remained unchanged (2240 cm^{-1}). The band structure in the 1450–1600 cm^{-1} region is a little too complicated to make any definite assignments. It, however, suggests the presence of two non-equivalent pyridine rings.

The IR spectra of the free 4-dicyanobenzene molecule displayed one intense, sharp band around 2232 cm^{-1} assigned to ν(C≡N). In the spectra of the binuclear products resulting from the reactions of $[RuH(CO)Cl(EPh_3)_3]$ with DCB (**II** DCB), the band moved to 2225 cm^{-1}, while in those of the products obtained from the reactions with $[Ru(\eta^5\text{-}C_5H_5)L_2X]$ (**V**), it appeared around 2230 cm^{-1} [ν(C≡N)]. The presence of a single sharp band in the spectra of these complexes suggested the coordination of both nitrile groups to two separate ruthenium(II) centres forming a symmetrical bridge between them and the absence of any inter–intramolecular interactions.

The IR spectrum of the free 1,4-dicyanobutene displayed an intense, sharp band at 2280 cm^{-1} [ν(C≡N)]. The spectra of the binuclear cationic complexes obtained from the reactions between $[RuH(CO)Cl(EPh_3)_3]$ with DCBT (**II** DCBT) showed a shift of the sharp band which appeared around 2260 cm^{-1}. The ν(C≡N) bands of the com-

plexes of both ligands (**II** DCB, **III** DCBT) occurred at lower frequency compared with in the free ligands, indicating π-back donation from ruthenium to the π^*-orbitals of the CN group.

Interestingly, the order of the negative shift of the 1,4-dicyanobenzene, 4-cyanopyridine and 1,4-dicyanobutene complexes is DCBT > CNPy > DCB. This is consistent with the literature cited order of back-bonding ability of these ligands (DCBT > CNPy > DCB).[8] Attempts to prepare mononuclear complexes of DCB and DCBT failed and the reactions under various conditions yielded only binuclear complexes.

The positions of $\nu(C{\equiv}O)$ and $\nu(Ru{-}H)$ in the spectra of all the complexes were also shifted towards higher and lower frequency, respectively, leading to a decrease in the metal-to-carbon interaction and a decrease in the Ru—H bond order. All the bands of the "spectator" ligands and the anions, in addition to the bands assigned to $\nu(C{\equiv}N)$, $\nu(C{\equiv}O)$ and $\nu(Ru{-}H)$, were present in the spectra of these complexes at their characteristic positions.

The IR spectra [Fig. 1(a)] of the product, $[Ru(CO)Cl_2(PPh_3)(NCPy)]_2$ (**VI**), resulting from the reactions of mononuclear complexes of $[RuH(CO)(PPh_3)_2(NCPy)_2]$ with halogenated solvents showed a band due to $\nu(C{\equiv}N)$ at 2250 cm^{-1} and bands at 1592, 1541, 1495 and 1414 cm^{-1} due to the pyridine moiety of 4-CNPy. The bands of CNPy and PPh_3 appeared at the same positions as they did in the mononuclear complexes. The band due to $\nu(Ru{-}H)$ was absent in the spectrum and that due to $\nu(C{\equiv}O)$ became relatively sharper and appeared at 1960 cm^{-1}. The slight shift of the $\nu(C{\equiv}N)$ band towards higher wavenumbers suggested linkage of the CN group to the metal atom with practically no π-bonding from the metal centre. This observation seems to indicate that the CNPy molecule forms a bridge between two ruthenium centres. Thus in the spectrum of the complex, two CN bands will appear at the same position because of the equivalence of the two CN groups. In addition, the two ruthenium atoms compete to donate their electron densities from the *d*-orbitals to the π^*-orbitals of CNPy. This will result in a relatively small shift of the $\nu(CN)$ band.

In the spectrum [Fig. 1(b)] of the second product $[Ru(CO)_2Cl_2(EPh_3)MeOH]$ (**VII**) bands characteristic of (1) two *cis* (CO) stretching bands and (2) EPh_3 appeared at 2070, 1965 cm^{-1} and 1485, 1440, 1088, 840, 747, 698 cm^{-1}, respectively. The presence of two $\nu(C{\equiv}O)$ bands characteristic of the *cis* positions supports the evidence for the formation of the *cis*-dicarbonyl complex in the reactions with the halogenated hydrocarbons. In addition, the presence of CH_3OH bands in the spectrum suggested that one molecule of CH_3OH is either coordinated or is present as a lattice molecule in the complex. We prefer it to be acting as a lattice CH_3OH rather than a coordinated one. We further assume that the $[Ru(CO)_2Cl_2EPh_3]$ moiety is dimerizing via chloro-bridges, due to the broadness of the OH band indicating hydrogen bonding.

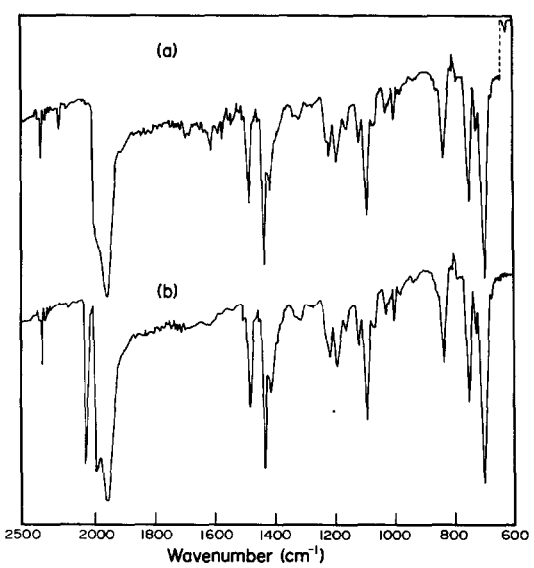

Fig. 1.

^1H *NMR spectra*

Because of poor solubility in some solvents or their tendency to react with halogenated solvents, we could not obtain good ^1H or ^{13}C NMR spectra of hydridocarbonyl complexes of cyanopyridine (**I**).

^1H NMR spectra of DCB complexes with $[Ru(\eta^5\text{-}C_5H_5)X(EPh_3)_2]$ (E = P, As, Sb; X = Cl) (**V**) displayed signals around δ 4.58–4.68 (η^5-C_5H_5); δ 7.1–7.8 (multiplets EPh_3 and DCB). In the spectra of the dppe and dppm complexes, the η^5-C_5H_5 protons were shifted downfield (δ 4.90) compared to that in the parent complexes $[Ru(\eta^5\text{-}C_5H_5)(EPh_3)_2Cl]$. These positions are comparable with those of $[Ru(\eta^5\text{-}C_5H_5)(EPh_3)_2(CN)]$. This suggests that the CN moiety in DCB affects the environment of the (η^5-C_5H_5) protons in a similar way to the NC group. The phenyl carbon atoms attached to the CN groups of DCB do not have much effect on the (η^5-C_5H_5) protons through their other contributing resonance structures like $N^+{\equiv}C\langle$ which are rather insignificant.

The signals of the phenyl protons of DCB should appear around δ7.8 ppm in the complexes (**V**).

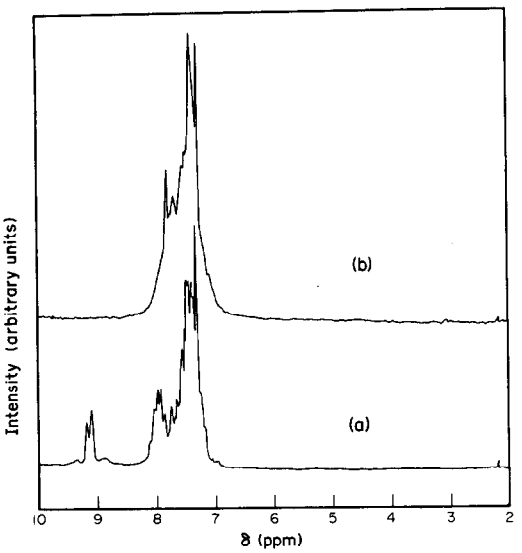

Fig. 2.

Although it was difficult for us to distinguish these from those of EPh_3, dppe or dppm protons, in a few of their PF_6 salts a single, sharp band appeared at δ7.8 which could be assigned to the phenyl protons of DCB. It appears that in these cases the interaction between $d\pi$-orbitals of the two ruthenium(II) centres with the lowest unoccupied π^*-orbitals of DCB seems to be simultaneously producing shielding and deshielding effects on the benzene protons of DCB, resulting in a very small net effect with the protons of DCB resonating at the same positions (δ7.2–7.81) as in the free ligand.

The ^{1}H NMR spectra [Fig. 2(b)] of the complex $[Ru(CO)Cl_2(PPh_3)CNPy]_2$ (**VI**) contained signals at δ9.1–9.3 (br multiplet; CNPy, protons); δ7.8–8.1 (br multiplet; CNPy, protons) and δ7.2–7.65 (EPh_3). The positions of the bands at δ9.1–9.3 and δ8.1 support the presence of cyanopyridine in the complex. The proton ratio of CNPy and PPh_3 (1 : 4) further suggested the presence of equal numbers of CNPy and PPh_3 molecules.

The ^{1}H NMR spectra [Fig. 2(a)] of the second product $[Ru(CO)_2Cl_2(EPh_3)MeOH]$ (**VII**) exhibited peaks around δ7.2–7.5 (EPh_3), δ2.2 (OH of CH_3OH) and δ 3.5 (CH_3). No signals appeared downfield of δ7.5 indicating the absence of CNPy.

^{13}C *NMR spectra*

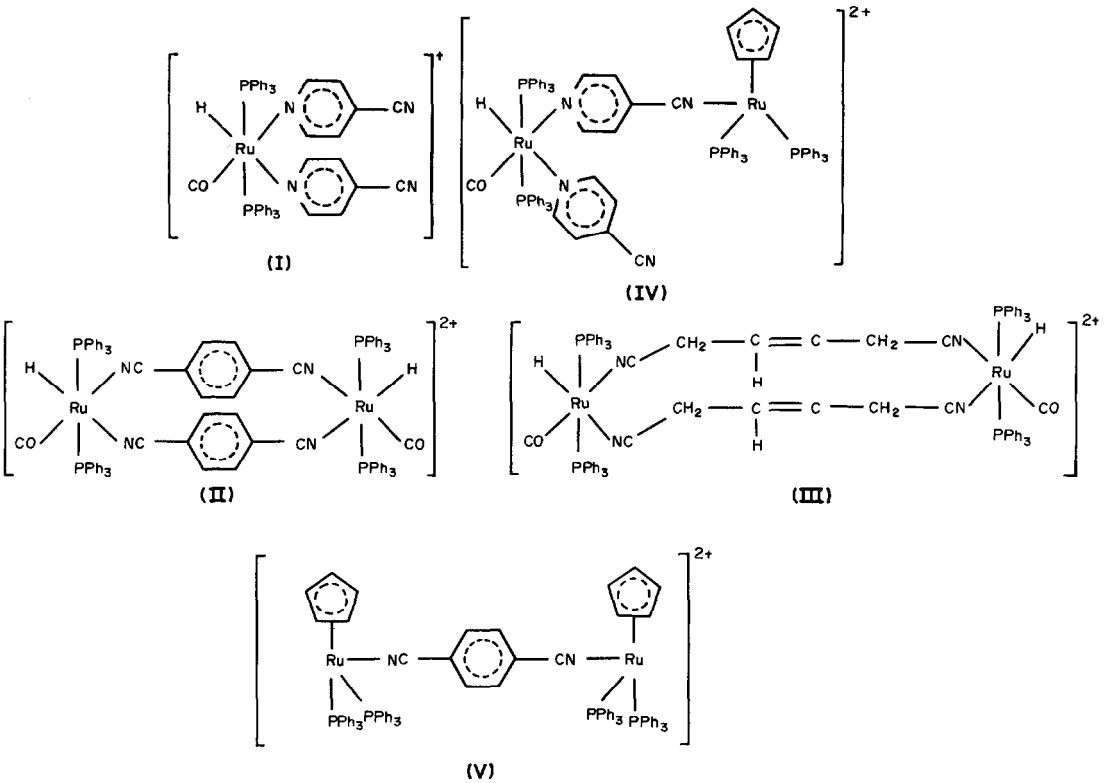
The (η^5-C_5H_5) carbons of 1,4-dicyanobenzene complexes of $[Ru(\eta^5\text{-}C_5H_5)Cl(EPh_3)_2]$ (**II** DCB) in their ^{13}C NMR spectra appeared as a single band around δ84.6, while in dppe or dppm complexes the band appeared around δ80.2. In a few hexafluorophosphate salts of EPh_3 complexes the (η^5-C_5H_5) ^{13}C signal appeared as a doublet at δ83.3 and 84.3, indicating two different environments of the ring carbon. This may possibly be due to the interaction of the (η^5-C_5H_5) carbons with the other co-ligands or with phosphorus of PF_6^- anion.

The nitrile (C≡N) carbon in **II** DCB resonates at δ116.6 and shows a slight shift upfield (0.52 ppm) compared to that in the free ligand (*ca* δ117.1). Although the shift is not very large, it may be that on complexation of ruthenium with nitrile nitrogens, the electron density on the carbon atom of the C≡N group is polarized towards the nitrogen, resulting in the deshielding of the carbon atom through the σ-bond, but the back-donation of the electron density from the ruthenium to the π^*-orbitals of CN more than compensates the deshielding effect, so that only a small amount of net shielding of the carbon nucleus occurs. This supports the back-donation of π-electrons from ruthenium to the π^*-orbitals of DCB (cf. IR spectra). The carbon atoms of the benzene ring of DCB underwent deshielding due to the strong electron attracting inductive effect of the CN groups. This occurred at around δ122.9 in the complexes compared to the value reported for the free ligand. The *ortho-* and *meta*-carbon atoms of the benzene ring appeared in the region characteristic for phenyl carbon resonances of other co-ligands present in the complexes (δ128.0–136.0) as multiplets.

Electronic absorption spectra

The electronic spectra of DCB complexes with $[Ru(\eta^5\text{-}C_5H_5)XL_2]$ (**IV**) (Table 1) exhibited bands in the visible and UV region (420 and 348–360 nm). The broad, medium intensity band centred at 420 nm has been assigned to an MLCT transition arising due to transfer of charge density from the filled $d\pi(t_{2g})$ orbitals of ruthenium(II) to low-lying unoccupied π^*-orbitals of the CN group of DCB. The position of this band is comparable to those obtained in other organonitrile complexes. It also exhibited a negative solvatochromic effect which is strong evidence in support of the charge-transfer assignment. A metal-to-ligand charge-transfer leads to the separation of charge in the excited state. The energy required for this type of transition is generally sensitive to the environment of the complex ion. The band around 350 nm has been assigned to an MLCT transition [$Ru^{II} \rightarrow$ antibonding orbitals on (η^5-C_5H_5)]. It was also found to overlap with the broad band observed in this region in the UV spectra of these complexes. We have not made any assignments to the band. It could, however, be an intraligand transition.

In $[RuH(CO)(EPh_3)_2(CNPy)_2]$ complexes, two



EPh_3 molecules have been shown to be *trans* to each other. This is based on the crystal structures of similar molecules determined previously.[9] On reacting these complexes with halogenated solvents like $CHCl_3$ or CH_2Cl_2 it appears that in the first product, viz. $[Ru(CO)Cl(EPh_3)(CNPy)]_2$, one of the two EPh_3 molecules and the hydride ion are substituted by Cl^- ions, and the two CNPy molecules form bridges with the two $[Ru(CO)Cl_2(EPh_3)]$ moieties. EPh_3, being strongly *trans* directing,[10] prefers to coordinate to the metal ion *trans* to a ligand having the weakest *trans* effect. Therefore in the presence of excess Cl^- ions (from $CHCl_3$ or CH_2Cl_2) one of the EPh_3 molecules (strong *trans*-directing) is labilized and is substituted by the chloride ion. In addition, it is generally observed that the hydride ion in many ruthenium hydride complexes is easily substituted by the chloride ion.[11] Thus the $[Ru(CO)Cl_2EPh_3]$ moiety could possibly be formed in the solution of the halogenated solvents, but we do not speculate any further on the mechanism of the reaction.

Based on the above spectral and analytical data it appears that the metal is coordinated in cyanopyridine mononuclear complexes (**I**) through the pyridine nitrogen, while in other complexes the coordination takes place through the CN groups. The above structures are therefore tentatively proposed for the reaction products.

(*Received* 6 *March* 1990; *accepted* 2 *April* 1990)

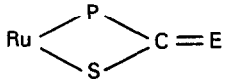
Abstract—The phosphinothioformate ligands, $Ph_2PCS_2^-$ and $Ph_2PCSNPh^-$, react with $Ru(\eta^5\text{-}CH_3C_5H_4)ClL_2$ (L = PPh_3, dppe/2) and involve substitution of chlorine and bidentate coordination of the P,S-donor ligand to the metal in the triphenylphosphine complex. In the reaction of the dppe derivative only monodentate coordination has been observed. The crystal structure of $Ru(\eta^5\text{-}CH_3C_5H_4)(Ph_2PCSNPh)(PPh_3)$ has been determined.

In previous work[1,2] we have studied the interactions of 1,1-dithiolato ligands with the complexes $Ru(RCp)Cl(L)_2$‡ (R = H, CH_3, CH_3CO; L = PPh_3, dppe/2, CO). These reactions were characterized by the easy substitution of the chloride ligand, due to a labile Ru—Cl bond as has previously been reported.[3] In those reactions we found a competition between the donor character of the dithiolate, leading to bidentate S,S-complexes, and that of the phosphine that gives monodentate dithiolate complexes. We now report the reactions of $Ru(RCp)Cl(L)_2$ (L = PPh_3, dppe/2) with phosphinothiolate ligands that could be seen as intermediates between phosphines and dithiolates; in fact the ligands employed, $Ph_2PCS_2^-$ and $Ph_2PCSNPh^-$, usually have been found to be bonded bidentately to a metal via P and S in Ni[4] and Ir[5] complexes, respectively. The latter ligand, when neutral, i.e. $Ph_2PC(S)NHPh$, can also act as a typical phosphine, as in the complex $[Mo(Cp)Cl(CO)_2(Ph_2PCSNHPh)]$, with chelation by addition of base to form $[Mo(Cp)(Ph_2PCSNPh)(CO)_2]$.[6]

RESULTS AND DISCUSSION

The reaction of $Ru(RCp)Cl(PPh_3)_2$ (R = H, Me) with KPh_2PCS_2 or with $Ph_2PCSNHPh$ in the presence of excess NEt_3, affords the complexes $Ru(RCp)(P—S)(PPh_3)$ (**I–III**).

The IR spectra of these compounds show strong bands at 1130–1180 cm^{-1} for the $Ph_2PCS_2^-$ complexes and at 1585 cm^{-1} for the $Ph_2PCSNPh^-$ complex, attributed to the exocyclic $\nu(C{=}E)$, which indicates coordination via P—S to the metal[4] and formation of the cycle



This coordination mode was confirmed by the ^{31}P NMR spectrum of **III**, which shows two doublets with a coupling constant of 36.5 Hz, indicating

* For Part II, see ref. 2.
† Author to whom correspondence should be addressed.
‡ RCp = $\eta^5\text{-}RC_5H_4$.

coordination by the phosphorus of the phosphinothioformamide ligand. The crystal structure of this complex (Fig. 1) also confirms this coordination.

The ^{1}H NMR spectrum of **I** shows one single resonance for the equivalent cyclopentadienyl protons, while that of **II** shows two resonances shifted to higher field, protons 2 and 5,[1] and lower field, protons 3 and 4, relative to **I**. On the other hand, complex **III** shows a set of four resonances for the non-equivalent cyclopentadienyl protons, as is expected for a chiral molecule.[7,8] The assignment of these resonances is not straightforward, but has been achieved in carbonylmethylcyclopentadienyliron complexes using NOE experiments,[7] determining protons 2 and 5, the *ortho* protons, as being responsible for the signals at the lowest and higher fields, with the peaks of 3 and 4 lying between them. This assignment is not a general one and there are many exceptions, even found by the same authors,[8,9] mainly with H(4) being more shielded than H(5); nevertheless it has always been observed that the separation between H(2) and H(5) is greater than that between H(3) and H(4), and the average of H(2) and H(5) lies at lower field than that of H(3) and H(4), as is observed in the M(RCp)(A)$_2$(B) type of complexes.[10]

We have not been able to obtain any conclusive data from the NOE spectra of compound **III**, where only small and inconclusive differences were observed, probably by consequence of the very small coupling between the protons which makes the signals appear as pseudo singlets. However, the ^{13}C NMR spectrum shows different signals for carbons 2–5. The first and the third resonances appear as doublets, probably by coupling with phosphorus. These two resonances can be assigned to C(2) and C(5), respectively, which lie over the two phosphorus atoms of the molecule, Fig. 2, and thus the other singlets correspond to C(3) and C(4). Assuming the same order for the proton resonances, the signals should correspond to H(2), 4.49 ppm; H(3), 4.14 ppm, H(5), 3.86 ppm; and H(4), 3.52 ppm. A similar pattern of signals for carbon and proton resonances has been found for Fe(MeCp)I(CO)(PR$_3$) using the same method of assignment as ours.[11]

The Ru(MeCp)Cl(dppe) complex reacts with $Ph_2PCS_2^-$ leading to unstable compounds which

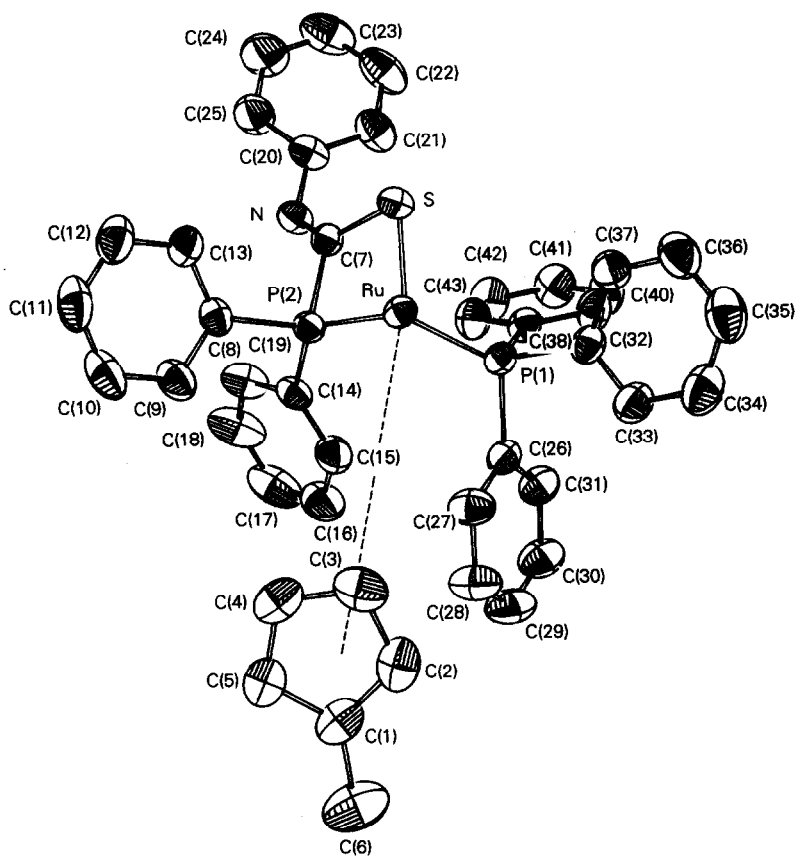


Fig. 1. ORTEP view of the structure of **III**.

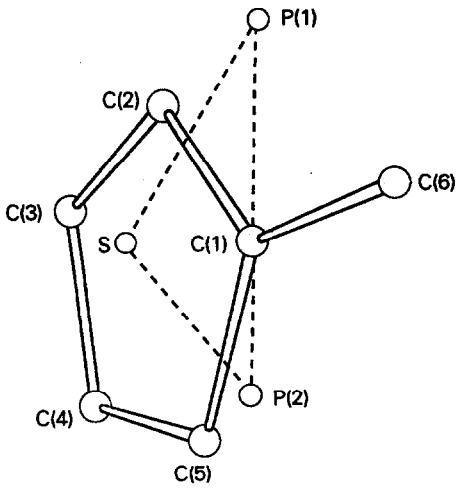

Fig. 2. Projection of the ring and the P(1)—P(2)—S planes of the molecule of **III**.

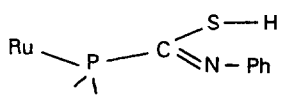
decompose before they can be isolated. However, the reaction with $Ph_2PCSNPh^-$ gives Ru(MeCp)($Ph_2PCSNPh$)(dppe) (**IV**) as an air-stable yellow solid, whose IR spectrum shows a ν(C=N) band shifted 60 cm^{-1} towards lower frequencies relative to that of complex **III**. There is also an additional band at 1185 cm^{-1}, which may be attributed to ν(C=S) for a phosphinothioformamide only bonded through the phosphorus and with a partial double C=S bond. This coordination mode is similar to that found for xanthates in their reaction with Ru(MeCp)Cl(dppe).[2] The ^{31}P NMR spectrum at 208 K seems to confirm the proposed coordination with a broad doublet at 92.2 ppm for the bidentate dppe and a triplet at 21.3 ppm (J = 76 Hz) for the coordinated phosphorus of $Ph_2PCSNPh^-$. The spectrum at room temperature shows only broad bands suggesting a kind of interchange in the molecule.

When the reaction between Ru(MeCp)Cl(PPh_3)$_2$ and $Ph_2PCSNHPh$ is carried out in toluene in the absence of base, the neutral ligand acts as a phosphine giving the complex Ru(MeCp)Cl(PPh_3)($Ph_2PCSHNPh$) (**V**), whose IR spectrum shows the ν(C=N) stretch at 1587 cm^{-1} and ν(C—S) at 934 cm^{-1}, with values similar to those found for the anionic bidentate phosphinothioformate, e.g. complex **III**. In addition to these bands which indicate a double C=N and a single C—S bond, also ν(Ru—Cl) = 286 cm^{-1} and a strong band at 2320 cm^{-1}, which should be attributed to a ν(S—H) stretch, appear, suggesting the displacement of the proton from the amido nitrogen to the sulphur:



The proton bonded to the sulphur appears as a peak at 4.35 ppm in the ^1H NMR spectrum. This signal also diminishes in intensity when the sample is shaken with deuterated methanol, by interchange of the acidic thiol proton. As a chiral molecule, complex **V** also shows four signals for the cyclopentadienyl protons.

The ^{31}P NMR spectrum shows two doublets at 46.95 and 39.27 ppm (J = 46.4 Hz) for the two phosphorus atoms bonded to the metal. Physical data for all of these compounds are given in Table 1.

Crystal structure

Bond lengths and angles are given in Table 2; a view of the molecule is shown in Fig. 1.

The ruthenium atom is bonded to one sulphur atom, two phosphorus atoms and the cyclopentadienyl ring in the typical piano tool disposition. The five Ru—C bond lengths fall within the range found for individual Ru—C distances (2.16–2.26 Å)[12,13] in cyclopentadienyl ruthenium complexes. The five C—C distances in the ring are approximately equal, suggesting symmetrical coordination of the cyclopentadienyl ring. Both Ru—P distances are equal and fall in the usual range (2.2–2.4 Å).[14] The plane formed by P(1), P(2) and S is parallel to the cyclopentadienyl ring within an error of ±3°,[15] the phosphorus atom lying, respectively, below C(2) and C(5) (Fig. 2) and this fact may be responsible for the coupling observed in the ^{13}C NMR.

The phosphinothioformate ligand is coordinated to the ruthenium via P and S. Similar coordination has been observed for the closely related ligand (cyclo-C_6H_{11})$_2PCS_2$ in Ni(P—S)$_2$.[4]

The C—S distance is slightly shorter (0.05 Å) than that found for a single C—S bond[16] and the C—N distance is 0.15 Å shorter than N—Ph, reflecting a considerable double bond character in the C=N bond, partially delocalized over the C—S bond.

EXPERIMENTAL

All reactions were carried out under oxygen-free nitrogen. KPh_2PCS_2,[4] $Ph_2PCSNPh$,[17] Ru(Cp)Cl(PPh_3)$_2$,[18] Ru(MeCp)Cl(PPh_3)$_2$[1] and Ru(MeCp)Cl(dppe)[2] were prepared according to the published methods. Analyses were carried out by Elemental Microanalysis Ltd, Devon. IR spectra were taken on KBr pellets using a Perkin–Elmer 1330 spectrophotometer. ^1H, ^{13}C and ^{31}P NMR spectra were recorded on a Bruker WP80SY instru-

ment in $CDCl_3$ solutions using TMS and 85% H_3PO_4 as standards.

Preparation of Ru(Cp)(Ph_2PCS_2)(PPh_3) (**I**)

To a refluxed suspension of Ru(Cp)Cl(PPh_3)$_2$ (0.74 g, 1 mmol) in 25 cm^3 of methanol, KPh_2PCS_2 (0.36 g) was added and the mixture was refluxed for 20 min. The solution was filtered and the solvent reduced to 5 cm^3 by concentration *in vacuo*. Addition of 2 cm^3 of Et_2O and cooling to $-20°C$ afforded a brown solid, recrystallized from chloroform–hexane. Yield 54%. Found: C, 62.4; H, 4.2. Required: C, 62.7; H, 4.4%.

Preparation of Ru(MeCp)(Ph_2PCS_2)(PPh_3) (**II**)

This complex was obtained using the same method as for **I**. Yield 68%. Found: C, 63.2; H, 4.5. Required: C, 63.1; H, 4.6%.

Preparation of Ru(MeCp)($Ph_2PCSNPh$)(PPh_3) (**III**)

A suspension of Ru(MeCp)Cl(PPh_3)$_2$ (0.75 g), $Ph_2PCSNHPh$ (0.38 g) and NEt_3 (0.1 cm^3) in 25 cm^3 of methanol was refluxed for 15 min. After cooling to room temperature, the solvent was removed *in vacuo* and the solid was recrystallized from chloroform–hexane to give orange crystals of **III**. Yield 84%. Found: C, 68.0; H, 4.9; N, 2.0. Required: C, 67.7; H, 4.9; N, 1.8%.

Preparation of Ru(MeCp)($Ph_2PCSNPh$)(dppe) (**IV**)

A suspension of Ru(MeCp)Cl(PPh_3)$_2$ (0.62 g), $Ph_2PCSNPh$ (0.38 g) and NEt_3 (0.1 cm^3) in 30 cm^3 of methanol was refluxed for 5 h. The resulting solution was concentrated *in vacuo* to 10 cm^3 and 5 cm^3 of Et_2O were added. The white precipitate that appears was filtered off and the solution was concentrated to 5 cm^3 and 2 cm^3 of degassed water were added. The yellow solid was recrystallized from dichloromethane–hexane. Yield 64%. Found: C, 68.2; H, 5.3; N, 1.7. Required: C, 68.1; H, 5.2; N, 1.6%.

Preparation of Ru(MeCp)Cl($Ph_2PCSHNPh$)(PPh_3) (**V**)

A solution of Ru(MeCp)Cl(PPh_3)$_2$ (0.74 g) and $Ph_2PCSNHPh$ (0.76 g) in 30 cm^3 of toluene was refluxed for 2 h. The solution was then concentrated *in vacuo* to one third of the volume and 10 cm^3 of Et_2O were added. The solid that appeared was filtered off and the clear solution was evaporated to dryness. Extraction with dichloromethane (10 cm^3)

and addition of 15 cm^3 of Et_2O–hexane (1:2 in volume) afforded orange microcrystals of **V**. Yield 71%. Found: C, 63.7; H, 4.7; N, 1.8. Required: C, 64.6; H, 4.7; N, 1.7%.

X-ray crystal structure

The crystal data and the parameters used during the collection and refinement of the diffraction data are summarized in Table 3. A red crystal was mounted on the diffractometer and the cell dimensions were refined by a least-squares fit of the θ values of 25 reflections. The intensities were corrected for Lorentz and polarization dispersion.

Scattering factors for neutral atoms and anomalous dispersion corrections for ruthenium and phosphorus were taken from the *International Tables for X-ray Crystallography*.[19]

The structure was solved by Patterson and Fourier methods, and an empirical absorption correction[20] was applied at the end of the isotropic refinement.

The final refinement was made with anisotropic thermal motion for the non-hydrogen atoms and

A STUDY OF THE INTERACTION OF DI-μ-PHENOXOBIS(DICHLOROPHENOXO)MOLYBDENUM(V) WITH ALIPHATIC AMINES

K. C. MALHOTRA, S. C. CHAUDHRY, A. V. S. RAJA RAO and NEERAJ SHARMA*

Department of Chemistry, Himachal Pradesh University, Summer Hill, Shimla-171005, India

(*Received* 4 *October* 1989; *accepted* 2 *April* 1990)

Abstract—The compound $[MoCl_2(OC_6H_5)_3]_2$ reacts with various aliphatic amines such as *n*-propylamine, *n*-butylamine, *sec*-butylamine, *t*-butylamine, diethylamine, di-isopropylamine and triethylamine under different experimental conditions to give complexes of 1 : 1 stoichiometry. The complexes have been characterized by elemental analysis, conductance measurements, molecular weight determinations and IR spectral studies. An octahedral configuration is proposed for all the complexes.

Transition metal halides are known to react with amines giving solvolytic, aminolysed or simple addition compounds depending upon experimental conditions such as temperature, concentration and the nature of the solvent used.[1-3] Edwards and Fowles[4] have reported the aminolysis of the Mo—Cl bond in the reactions of $MoCl_5$ with primary and secondary amines, while simple addition compounds are formed with tertiary amines. It was therefore of interest to investigate the reactions of $[MoCl_2(OC_6H_5)_3]_2$ (**I**) with amines under different experimental conditions.

EXPERIMENTAL

Compound **I** was prepared by the reported method.[5] The molybdenum content in the complexes was determined as bis(8-hydroxyquinolinol)dioxomolybdenum(VI). Chloride was estimated by Volhard's method and amines by steam distillation with alkali and titration of the distillate with sulphuric acid using Bromophenol blue.

IR spectra were recorded as KBr discs as well as in Nujol mulls on Perkin–Elmer 337 and 621 spectrophotometers. Molecular weights were determined cryoscopically in benzene.

The different conditions under which compound **I** was reacted with amines are:

(i) Compound **I** suspended in CCl_4 was reacted with amines in a 1 : 2 molar ratio with continuous stirring at room temperature for about 8 h. The compounds were isolated by the addition of petroleum ether.
(ii) An excess of amine was added to **I** suspended in CCl_4 and a clear solution was immediately obtained at room temperature. After about 8 h stirring, excess base was distilled off and the residue was extracted with petroleum ether.
(iii) Compound **I** in CCl_4 was refluxed with amine in a 1 : 2 molar ratio for about 8 h. Solvent was distilled off and the residue was extracted with petroleum ether.
(iv) Lastly, compound **I** was reacted directly with excess amine without using any solvent and refluxed. Excess base was distilled off, followed by addition of petroleum ether to obtain the product.

RESULTS AND DISCUSSION

The complexes of **I** isolated with different amines are given in Table 1. They are hygroscopic in character, non-electrolytes and monomers in nitrobenzene as is evident from the data in Table 1, which shows that an increase in amine concentration causes no base-catalysed elimination of

$MoCl_2(OC_6H_5)_3 \cdot$triethylamine	17.4 (17.5)	12.8 (12.9)	3.1	525 (548)	3385	1035	505	325	315

hydrogen chloride and forms only 1:1 addition compounds. Even heating the reactants in the presence or absence of any solvent under reflux did not change the nature of the product formed. These observations are in contrast to those of Edwards and Fowles[4] and others, but in agreement with those of Colclough and co-workers[6,7] who have prepared a variety of addition compounds of aryloxides of boron(III) with different amines.

In the IR spectra of the complexes, sharp bands at *ca* 510–520 cm^{-1} have been assigned to terminal ν(Mo—O) modes. No band that could be assigned to bridging Mo<O>Mo modes has been observed in the IR spectra which suggests a breakdown of the dimeric structure of the title compound (**I**) on adduct formation. Splitting of the bands in the region 340–350 cm^{-1} assigned to the ν(Mo—Cl) modes[8] suggests that chlorine atoms in the adducts are in the *cis*-position in an octahedral environment. Coordination of amines to the metal has been further confirmed by the appearance of new bands around 300–310 cm^{-1} assigned to ν(Mo ← N) modes.[9] All the important bands are given in Table 1.

The most significant changes which have been observed in the IR spectra of the different amines on adduct formation with **I** concern the ν(N—H), ν(C—N) and H—N—C deformation modes. The trends in shifts of these bands on coordination with metal are in agreement with those earlier reported.[10–13] A significant positive shift of the H—N—C deformation mode in primary and secondary amines has been attributed to additional hydrogen bonds between the hydrogen of the N—H group and the chlorine of **I**. Similar observations have been made in the complexes of diaryl tin dihalides with diethylamine.[14] Thus, based upon limited analytical and spectroscopic data, it is proposed that the complexes of **I** with amines are mononuclear 1:1 adducts with an octahedral arrangement around molybdenum and no evidence for aminolysis has been obtained.

PREPARATION OF URANIUM TRIBROMIDE BY THERMAL VACUUM DECOMPOSITION OF $NH_4UBr_4 \cdot 1.5CH_3CN \cdot 6H_2O$

E. ZYCH and J. DROŻDŻYŃSKI*

Institute of Chemistry, University of Wrocław, 50-383 Wrocław, Poland

(*Received* 29 *March* 1990; *accepted* 26 *April* 1990)

Abstract—Pure uranium tribromide may be prepared by applying an effective non-static high vacuum of 10^{-5}–10^{-6} hPa over the temperature range 20 to 350°C to $NH_4UBr_4 \cdot 1.5CH_3CN \cdot 6H_2O$.

The most frequently recommended procedure for the preparation of UBr_3 involves the action of gaseous hydrogen bromide on finely powdered uranium or uranium hydride at 300°C.[1,2] This method is suitable also for large scale preparation but requires a somewhat complex apparatus. Other convenient methods are based on reduction of UBr_4 with metallic zinc or finally divided uranium at *ca* 600°C.[2] Since uranium tribromide is very sensitive to oxidation and hydrolysis and at higher temperatures reacts with silica, the preparative procedures need to be performed in tantalum or molybdenum installations under strict moisture- and oxygen-free conditions. All methods also involve very pure starting materials.

This paper describes a convenient method for the preparation of uranium tribromide by thermal vacuum decomposition of $NH_4UBr_4 \cdot 1.5CH_3CN \cdot 6H_2O$. The procedure does not require pure preparative materials and seems to be very suitable in cases where only gram amounts of the compound are needed.

For the preparation of the complex bromide uranium tetrabromide (4–4.4 g) was added on shaking to a mixture of 100 cm^3 of methyl cyanide with an excess of ammonium bromide and left standing for 10–15 h. Subsequently, 0.5 cm^3 of propionic acid, 0.4 cm^3 of water and after 0.5 h 15 cm^3 of freshly distilled ether, were added. Next, the filtered solution was reduced in an inert atmosphere by gently shaking with liquid zinc amalgam. The reduction resulted in a colour change of the solution from green to dark brown followed by the immediate formation of a fine, crystalline, greyish-green precipitate of the formula $NH_4UBr_4 \cdot 1.5CH_3CN \cdot 6H_2O$. The precipitate was filtered off, washed under an inert atmosphere with a deoxygenated 7:1:0.05 mixture of acetonitrile, ether and propionic acid, and afterwards, with ethyl ether. Finally, the compound was dried under reduced pressure for about 5 min and stored in sealed tubes at temperatures below 15°C. As for most uranium(III) compounds it must be handled under anhydrous and oxygen-free conditions.

The synthesis was performed in a relatively simple all-glass apparatus with provisions for precipitation, filtration and drying in an inert atmosphere.[3] The inert atmosphere was obtained by vacuum evaporation of the solution and wash-liquids for 1–2 min. The synthesis may also be performed in an inert atmosphere glove-box as well as by using a set of Schlenk tubes.

The preparation of uranium tetrabromide was based on the procedure given in ref. 4. Since the required compound could be of technical grade the method was significantly simplified. The product was obtained by passing bromine vapour in dry, oxygen-free nitrogen over a carbon–uranium oxide mixture placed in a quartz tube, at 700–800°C. Other reagents were of analytical grade. The physical and chemical properties of $NH_4UBr_4 \cdot 1.5CH_3CN \cdot 6H_2O$ will be given elsewhere.[5]

The complex bromide obtained in the above

* Author to whom correspondence should be addressed.

manner was converted into UBr_3 by a thermal high vacuum decomposition. For this purpose $NH_4UBr_4 \cdot 1.5CH_3CN \cdot 6H_2O$ (1–4 g) was placed in the bottom of the sealed-off end of a quartz tube, 40 cm long and 2 cm in diameter. The other end of the tube was fitted with a stopcock and connected to a high vacuum system. A small furnace was slipped over the tube and the system was pumped off to *ca* 10^{-6} hPa. The decomposition was first accomplished between 25 and 80°C for at least 2–3 h and then, the temperature was slowly raised to *ca* 350°C. The pressure should never be higher than *ca* 5×10^{-4} hPa. Samples of UBr_3 prepared in this manner are pale brown in colour. In order to obtain larger crystals, the section of the tube containing the product was sealed off and heated at 400°C for a couple of days. The pycnometrically determined density of the compound approaches 6.20 g cm^{-3} and is somewhat better than those reported in the literature.[2] From X-ray data[2] a value of 6.4 g cm^{-3} was obtained. Found: U, 50.1; Br, 50.3. Calc. for UBr_3: U, 49.8; Br, 50.2%.

ALKALINE HYDROLYSIS OF LINEAR TETRA-, HEXA- AND OCTAPHOSPHATE

GENICHIRO KURA

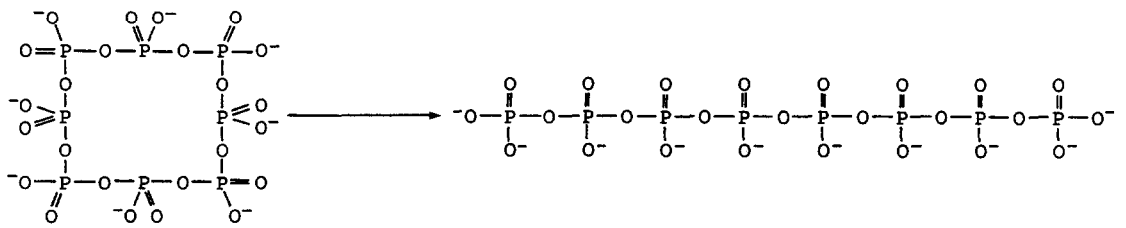
Department of Chemistry, Fukuoka University of Education, Akama, Munakata, Fukuoka 811-41, Japan

(*Received* 5 *April* 1990; *accepted* 7 *June* 1990)

Abstract—The hydrolysis rates for the linear tetra-, hexa- and octaphosphate in several alkaline solutions have been determined. The hydrolysis reaction takes place most rapidly in LiOH solution. Activation energies of the linear polyphosphates in 1 M $(CH_3)_4NOH$ were higher than those for the cyclic oligomers with a similar polymerization degree.

Inorganic condensed phosphate polymers are one of the most commonly used materials in solution and solid-state chemistry.[1] These polymers consist mainly of the linear and cyclic phosphates. The structures of cyclo-octaphosphate and linear octaphosphate are shown in Fig. 1. We have studied the chemistry of oligomers with a polymerization degree smaller than about eight.[2–4] In this paper, the hydrolysis reaction of linear tetra-, hexa- and octaphosphates in alkaline solutions were investigated. These linear oligomers are very interesting materials for solution chemistry and their stability in aqueous solutions against hydrolysis must be known.

Since the preparative methods of the hexa- and octaphosphate in macro quantity have not been reported, the sample solutions to be hydrolysed were prepared by the partial hydrolysis of cyclo-hexa- and cyclo-octaphosphate. To prepare sample solutions which contain adequate quantities of linear hexamer or octamer, cyclo-hexa- or cyclo-octaphosphate were hydrolysed in 0.5 M LiOH at 40°C for about 7–9 h and the reactions were stopped by neutralization with HCl. The Li^+ ions contained in the sample solutions in the quantities prepared by the above procedure have been known to affect strongly the hydrolysis rates.[5] Thus, the Li^+ ions in the hydrolysis samples were converted to $(CH_3)_4N^+$ ions by the use of ion-exchange resins. The linear tetraphosphate was prepared as the ammonium salt by the method of Griffith.[6] Analyses of the parent phosphates and the hydrolysis products were performed using automated liquid chromatography.[7] In the analysis of the hydrolysis rates of hexa- and octaphosphates, the concentration of the corresponding cyclo-polyphosphates and the linear



$P_8O_{24}^{8-}$ (P_{8m}) $P_8O_{25}^{10-}$ (P_8)

Fig. 1. The structures of cyclo-octaphosphate and linear octaphosphate.

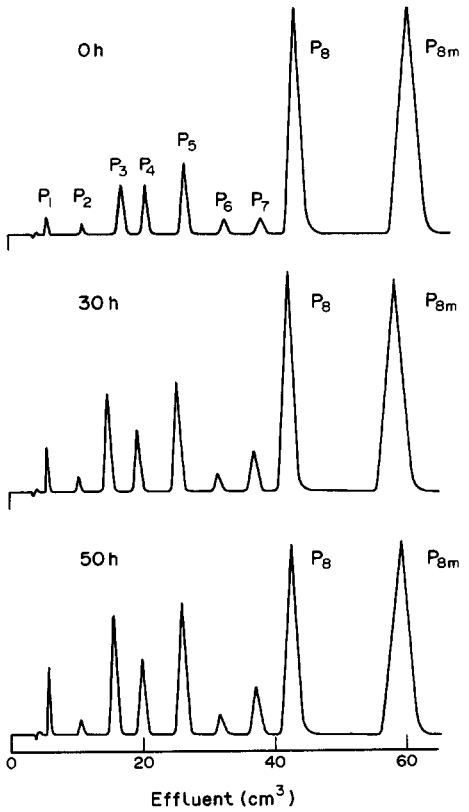


Fig. 2. Chromatograms of the hydrolysis samples in 0.5 M KOH at 50°C.

polyphosphates as the first hydrolysis product at time t are defined as x and y, respectively, and also their first-order rate constants are designated as k_m and k_n, respectively. The hydrolysis rate constant of hexa- or octaphosphates, k_n, can be obtained by solving the following differential equations:[7]

$$-dx/dt = k_m x \quad (1)$$

$$-dy/dt = k_n y - k_m x. \quad (2)$$

The chromatograms of the hydrolysis samples of octaphosphate in 0.5 M KOH at 50°C are shown in Fig. 2. In this paper, cyclic and linear oligomers are abbreviated as P_n and P_{nm}, in which n is the polymerization degree. The rate constant, k_n, was estimated by successive approximation involving substitution of the initial value of x and y, and k_m which had been already determined by the separate experiments in eq. (2). In Fig. 3, the time dependence of the concentration of octaphosphate is shown, where the curved line was drawn by substituting k_m and k_n into eq. (2) and the experimental points are indicated by black circles. The coincidence of both values is satisfactory. The hydrolysis rates in alkaline solutions have been known to be markedly affected not only by OH^- concentration

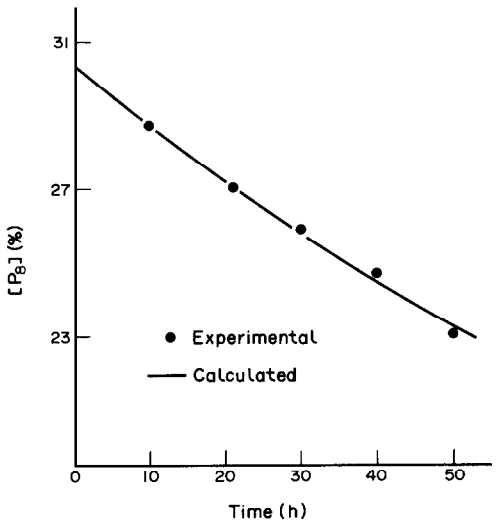

Fig. 3. Variation of the concentration of octaphosphate with time in 0.5 M KOH at 50°C.

but by the counter ion of OH^-.[8] The effect of the counter ions, Li^+, Na^+ and K^+, on the hydrolysis rates of linear tetra-, hexa- and octaphosphates at $[OH^-] = 0.5$ M were also examined. In Table 1, rate constants in each alkaline solution at 50°C are shown. For every linear phosphate, the hydrolysis reaction takes place most rapidly in 0.5 M LiOH and the reaction rate decreases in the order, LiOH > NaOH > KOH. In every alkaline solution, the hydrolysis rate decreases with decreasing polymerization degree, i.e. $P_8 > P_6 > P_4$. The Li^+ ions accelerate the hydrolysis rates the most and thus interact most strongly with linear phosphate anions. Next, the hydrolysis rates in $(CH_3)_4NOH$ were measured, where the $(CH_3)_4N^+$ ion is known to be an inert cation which does not interact with many anions. In this solution, the hydrolysis reactions of linear oligomers were very slow, thus the rates in 1.00 M $(CH_3)_4NOH$ and at relatively higher temperatures, i.e. 70, 80 and 90°C were determined. However, since the rates for tetraphosphate were very slow, taking into account the experimental error, only the rate at 90°C was measured. The rate constants obtained are shown in Table 2. Tetra-

Table 1. Hydrolysis rate constants of linear phosphates at 50°C

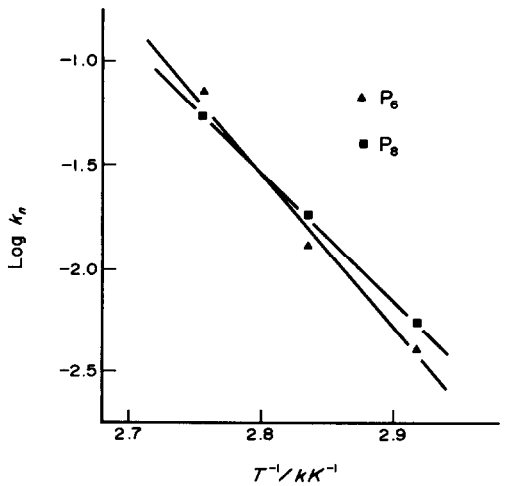

Fig. 4. Arrhenius plots of hexa- and octaphosphate in 1 M $(CH_3)_4NOH$.

phosphate is most stable and the half-life even at 90°C is 52 h. The large difference between the rates of hexa- and octaphosphates was not observed. The Arrhenius plots for hexa- and octaphosphates are shown in Fig. 4; linear relations were obtained. The rate constants of hexa- and octaphosphates at 50°C were estimated by the linear extrapolation of the Arrhenius plots as 1.64×10^{-4} and 4.04×10^{-4}, respectively. Although the concentration of OH^- is twice that of other alkalis, the hydrolysis reaction is very slow. The hydrolysis rates of linear phosphates in alkaline solution are markedly influenced by the cations present. Arrhenius activation energy of cyclo-hexa- and cyclo-octaphosphate in 1.00 M $(CH_3)_4NOH$ solution were 19.4 and 21.7 kcal mol^{-1}, respectively. The activation energies of linear hexa- and octaphosphates in Table 2 are about 10–15 kcal mol^{-1} larger. For the cleavage of the P—O—P bond due to the attack of OH^- ion on the P atoms, the electrostatic repulsion between OH^- and the anionic atmosphere near the P atoms is enhanced for the linear oligomer structure, and thus the activation energies are larger for the hydrolysis of the linear oligomers. When the hydrolysis rates, at 50°C, of the cyclic and linear oligomers are compared with each other, linear tetraphosphate is extremely stable relative to cyclo-tetraphosphate but the rate constants for the hexamer or octamer are comparable.

SYNTHESIS AND X-RAY CRYSTAL STRUCTURE OF $[Pd(C_6F_5)(\eta^2\text{-}\{(Ph_2P)_3C\})(PPh_3)]$, A MONONUCLEAR COMPOUND CONTAINING η^2-TRIS(DIPHENYLPHOSPHINE)METHANIDE

(*Received* 18 *May* 1990; *accepted* 20 *June* 1990)

Abstract—The reaction between $[Pd(C_6F_5)(acac)(PPh_3)]$ and $(Ph_2P)_3CH$ in CH_2Cl_2 affords $[Pd(C_6F_5)(\eta^2\text{-}\{(Ph_2P)_3C\})(PPh_3)]$ (**1**) which can be protonated by HBF_4 to yield $[Pd(C_6F_5)(\eta^2\text{-}\{(Ph_2P)_3CH\})(PPh_3)](BF_4)$ (**2**). The X-ray structure determination of complex **1** reveals a distorted square-planar environment for the metal centre with an η^2-coordination of the tris(diphenylphosphino)methanide, the skeletal P_3C group of this ligand is moderately distorted from a $C(sp^2)$ arrangement.

1,1,1-Tris(diphenylphosphino)methane, $(Ph_2P)_3CH$ (tdppm),[1] has received considerable attention because of its variety of coordination modes. Complexes in which $(Ph_2P)_3CH$ acts as an η^1-monodentate,[2] η^2- or η^3-chelating,[2,3] η^2-μ_2-bridging,[2] η^3-μ_2-bridging–chelating[2,3b,4] and η^3-μ_3-bridging ligand[3a,5] have been characterized. By contrast, as far as we know, no complexes containing the anionic methanide $[(Ph_2P)_3C^-]$ group have been described and only a few derivatives of main group elements with the similar $[(Me_2P)_3C^-]$ group have been characterized: $[Sn\{(Me_2P)_3C\}_2]$,[6] $[Al\{(Me_2P)_3C\}_3]$[7] and $[Ge\{(Me_2P)_3C\}_2]$.[8]

Here we present a preliminary report on the synthesis and structural characterization of $[Pd(C_6F_5)\{(Ph_2P)_3C\}(PPh_3)]$ (**1**) which contains an η^2-$[(Ph_2P)_3C^-]$ chelating group. The reaction of **1** with HBF_4 results in the protonation of the methanide ligand and formation of $[Pd(C_6F_5)\{(Ph_2P)_3CH\}(PPh_3)]^+$ (**2**), a cationic complex containing an η^2-$[(Ph_2P)_3CH]$ as neutral ligand.

Addition of tris(diphenylphosphino)methane, $(Ph_2P)_3CH$, to a colourless dichloromethane solution of $[Pd(C_6F_5)(acac)(PPh_3)]$[9] (1:1 molar ratio, room temperature) gives a yellow solution from which, after evaporation almost to dryness and addition of n-hexane, $[Pd(C_6F_5)\{(Ph_2P)_3C\}(PPh_3)]$ (**1**) is obtained, the triphosphine being deprotonated by $acac^-$ [eq. (1)]:

$$[Pd(C_6F_5)(acac)(PPh_3)]+(Ph_2P)_3CH \longrightarrow [Pd(C_6F_5)\{(Ph_2P)_3C\}(PPh_3)]+acacH. \quad (1)$$

On the other hand, the methanide $[(Ph_2P)_3C^-]$ ligand in **1** can be protonated by HBF_4, so that addition of HBF_4 (HBF_4/Et_2O, 54%) to a diethyl ether solution of **1** (molar ratio 1:1, room temperature) renders $[Pd(C_6F_5)\{(Ph_2P)_3CH\}(PPh_3)](BF_4)$ (**2**) (57% yield), which reacts with NaH in Et_2O yielding **1** (45% yield) [eq. (2)]:

$$[Pd(C_6F_5)\{(Ph_2P)_3C\}(PPh_3)] \underset{+NaH,\,-NaBF_4,\,-H_2}{\overset{+HBF_4}{\rightleftharpoons}} [Pd(C_6F_5)\{(Ph_2P)_3CH\}(PPh_3)](BF_4). \quad (2)$$

The cationic species $[Pd(C_6F_5)\{(Ph_2P)_3CH\}(PPh_3)]^+$ can also be obtained by reacting $[Pd(C_6F_5)(OClO_3)(PPh_3)_2]$ with $(Ph_2P)_3CH$ (molar ratio 1:1) in benzene [eq. (3)], although $[Pd(C_6F_5)(PPh_3)_3](ClO_4)$ is also formed:

$$[Pd(C_6F_5)(OClO_3)(PPh_3)_2]+(Ph_2P)_3CH \longrightarrow [Pd(C_6F_5)\{(Ph_2P)_3CH\}(PPh_3)](ClO_4) + [Pd(C_6F_5)(PPh_3)_3](ClO_4). \quad (3)$$

Complexes **1** and **2** give microanalytical data and IR, ^{19}F and $^{31}P\{^1H\}$ spectroscopic data which are in

The palladium atom has a distorted square-planar environment formed by the C_6F_5 group, the P atom of the PPh_3 and two P atoms of the $[(Ph_2P)_3C^-]$ anion, which is acting as a chelating ligand. The four-membered chelate ring shows considerable distortion as evidenced by a P(3)—Pd—P(1) chelate bite angle of 69.9(1)° (90° for a regular square-planar coordination) and a P(3)—C(1)—P(1) angle of 99.3(5)° (120° for a C(1) sp^2 hybridization). The P(3)—Pd—P(1) angle is similar to those reported previously in bis(diphenylphosphino)methanide complexes, η^2-$[(Ph_2P)_2CH^-]$,[10] and larger than the ones reported in the complexes $[M\{(Me_2P)_3C\}_2]$[6,7] [M = Ge, 68.0(1) and 63.8(1)°; M = Sn, 62.9(1) and 62.8(1)°].

The four-membered ring Pd—P(3)—C(1)—P(1) is basically planar, the dihedral angle between the P(1)—Pd—P(3) and P(3)—C(1)—P(1) planes is 3.37°.[11]

The P—C(1)—P angles of the η^2-$[(Ph_2P)_3C^-]$ ligand average 119.3°, close to 120°, although the three P—C(1)—P angles are very different.

This situation is similar to the corresponding complexes $[M\{(Me_2P)_3C\}_2]$[6,7] (the P—C—P angles average: 119.9 and 120.0°, M = Sn and Ge, respectively), and logically different to the corresponding $(Ph_2P)_3CH$ derivatives; for instance in the case of $[Pt\{\eta^2\text{-}(Ph_2P)_3CH\}_2]^{2+}$ the P—C(1)—P angles average 110.7°, close to the tetrahedral value of 109.5°.[3c] The P—C—P angle of the chelate ring is smaller than the other two P—C—P angles, which involve the non-coordinated P atom. However, the P_3C skeleton is moderately distorted from planarity, the dihedral angles between the planes P(1)—C(1)—P(4) and P(4)—C(1)—P(3), P(1)—C(1)—P(4) and P(1)—C(1)—P(3), P(1)—C(1)—P(3) and P(3)—C(1)—P(4) are 19.88, 17.36 and 13.13°, respectively, and the distance from C(1) to the P(1)—P(3)—P(4) plane is 0.137 Å.

Deprotonation of the neutral group $(Ph_2P)_3CH$ leads to a delocalized system as shown in Fig. 2; the P—C(1) bond lengths (1.738(11), 1.751(10) and 1.786(11) Å) indicate some component of a double bond and are shorter than the single P—C(phenyl) distances (1.818(7)–1.850(7) Å) in complex **1**, and also shorter than the single P—CH distances in the $[Pt\{\eta^2\text{-}(Ph_2P)_3CH\}_2]^{2+}$ derivative (1.830(12), 1.878(10) and 1.891(11) Å).[3c]

CYCLOPENTADIENYL REPLACEMENT BY TRISPYRAZOLYLBORATE AND THE SYNTHESES OF $M(\eta^5\text{-}C_5H_5)\{HB(C_3H_3N_2)_3\}X_2$ (M = Hf, X = Cl; M = Zr, X = Cl, OPh, OC_6H_4-4-NO_2, OC_6H_4-4-OMe, OC_6H_4-2-Ph)

ROMAN A. KRESINSKI, CHRISTOPHER J. JONES* and JON A. McCLEVERTY*

School of Chemistry, University of Birmingham, PO Box 363, Birmingham B15 2TT, U.K.

(*Received* 5 *June* 1990; *accepted* 25 *June* 1990)

Abstract—The reactions between $M\{C_5H_5\}_2Cl_2$ (M = Zr, Hf) and $HB(C_3H_3N_2)_3H$ afford $M(\eta^5\text{-}C_5H_5)\{HB(C_3H_3N_2)_3\}Cl_2$. These compounds undergo halide substitution reactions with phenols and the new complexes $Zr(\eta^5\text{-}C_5H_5)\{HB(C_3H_3N_2)_3\}X_2$ (X = Cl, OC_6H_4Z; Z = H, 4-NO_2, 4-OMe, 2-Ph) have been isolated and characterized.

An extensive chemistry has been developed[1] for the $\{Zr(\eta^5\text{-}C_5H_5)_2\}^{2+}$ moiety, much of which has been stimulated by the prospect of potential applications in homogeneous catalysis. In view of the parallel chemistries which may be developed for complexes containing the $C_5H_5^-$ and $HB(C_3H_3N_2)_3^-$ (L^-) ligands,[2,3] others[4] and ourselves have been interested in developing the chemistry of the $\{ZrL_2\}^{2+}$ moiety. Furthermore, although there are several reports describing polypyrazolylborate complexes of zirconium, to our knowledge there are no reports of such complexes containing hafnium. Zirconium complexes containing the hydrotris(pyrazol-1-yl) borate (L^-),[3,5] hydrotris(3,5-dimethylpyrazolyl) borate,[6] tetrakis(pyrazolyl)borate[7] and *i*-propyltris(pyrazolyl)borate[8] ligands have been reported. There is only one report of a zirconium complex containing two polyprazolylborate ligands.[7] This describes the synthesis of $\{B(C_3H_3N_2)_4\}_2ZrCl_2$ and $\{B(C_3H_3N_2)_4\}_2ZrBr_2$ by the reaction of the appropriate zirconium tetrahalide with $K^+B(C_3H_3N_2)_4^-$. Since this report, attempts to repeat the synthesis of the former complex in our laboratory, and that of others,[8] have failed. Similarly, our attempts to prepare ZrL_2Cl_2 directly from the reaction of $ZrCl_4$ with KL resulted only in the formation of insoluble intractable precipitates. As an alternative approach the reaction between $M(\eta^5\text{-}C_5H_5)_2Cl_2$ (M = Ti, Zr, Hf) and the free acid of the hydrotris(pyrazolyl)borate anion (HL)[9] was investigated in the hope that proton exchange between HL and $C_5H_5^-$ would provide a means of replacing C_5H_5 with L to give ML_2Cl_2.

The formation of HL was first reported[9] by Trofimenko, who found that the acidification of aqueous solutions containing L^- gave a precipitate which is tentatively formulated herein as $HB(C_3H_3N_2)_2(C_3H_4N_2)$ or HL. This material is unstable in solution, and also decomposes at its melting point of *ca* 95°C liberating pyrazole. In view of the instability of HL in solution it was considered best to melt an intimate mixture of solid $Zr(\eta^5\text{-}C_5H_5)_2Cl_2$ and HL together. Cyclopentadiene is evolved during this reaction but, irrespective of the amount of HL present in excess, only one of the two cyclopentadienyl ligands can be replaced affording the known[5] complex $Zr(\eta^5\text{-}C_5H_5)LCl_2$. Similar results were obtained using HL with $Hf(\eta^5\text{-}C_5H_5)_2Cl_2$ and the new compound $Hf(\eta^5\text{-}C_5H_5)LCl_2$ was isolated from the reaction mixture.† However, the reaction of $Ti(\eta^5\text{-}C_5H_5)_2Cl_2$ with HL did not afford any tractable products.

The reactions of HL with $Zr(\eta^5\text{-}C_5H_5)_2ClH$ and

* Authors to whom correspondence should be addressed.

† All of the new compounds have been characterized by IR, ^1H NMR and mass spectroscopy and all give satisfactory elemental analyses.

$ZrCl_4$ were also investigated but the only identifiable products were the two isomers of 1,4-dipyrazolylpyrazabole.[10] The stereochemistries of these two isomers were not determined and they are simply described here as isomers **A** and **B**. Whilst HL is known[10] to produce 1,4-dipyrazolylpyrazabole under certain conditions, the possibility exists that 1,4-dipyrazolylpyrazabole formation is stimulated by the association of two L ligands bound to a zirconium atom. If the $\{ZrL_2\}$ moiety were unstable with respect to decomposition to 1,4-dipyrazolylpyrazabole, this would account for our inability to obtain derivatives of $\{ZrL_2\}^{2+}$. The observation of decomposition products of tris(pyrazolyl)borate ligands is not unprecedented. Quite apart from examples of "complex dissociations" documented in the literature and resulting in the liberation of pyrazole,[11,12] the compounds $HB(C_3HN_2\text{-}3,5\text{-}Me_2)_3BH^+TaCl_6^-$ and $(C_3HN_2\text{-}3,5\text{-}Me_2)_3B(C_3H_2N_2\text{-}3,5\text{-}Me_2)$ have been isolated from the reaction of $K^+HB(C_3HN_2\text{-}3,5\text{-}Me_2)_3^-$ and $TaCl_5$.[13] The formation of both these products requires the cleavage of B—N bonds, as would the formation of 1,4-dipyrazolylpyrazabole.

Although the melting of HL alone afforded 1,4-dipyrazolylpyrazabole the reproducibility of this reaction was poor. However, it is clear that the behaviour of zirconium toward HL is not always totally passive. When HL was combined with $ZrO(NO_3)_2$ and heated, the zirconium salt acted purely as a diluent, reducing the yield of 1,4-dipyrazolylpyrazabole. When the procedure was repeated using $Zr(\eta^5\text{-}C_5H_5)_2ClH$ or $ZrCl_4$ in place of $ZrO(NO_3)_2$ a different isomer of 1,4-dipyrazolylpyrazabole was favoured depending upon the zirconium complex used. ^1H NMR studies[14] have shown that the reaction between HL and $Zr(\eta^5\text{-}C_5H_5)_2ClH$ gives a varying ratio of isomer **A** to isomer **B**. This ratio is strongly dependent on the concentration of $Zr(\eta^5\text{-}C_5H_5)_2ClH$, falling from 4.5:1 for 1:1 HL to $Zr(\eta_5\text{-}C_5H_5)_2ClH$ stoichiometry, to 2.5:1 for an 8.6:1 HL to $Zr(\eta^5\text{-}C_5H_5)_2ClH$ stoichiometry. Furthermore, the fractional yield of 1,4-dipyrazolylpyrazabole based on HL rises with the concentration of $Zr(\eta^5\text{-}C_5H_5)_2ClH$. The reaction between HL and $ZrCl_4$ afforded almost exclusively isomer **B**. Thus it seems possible that two L ligands may simultaneously associate with a zirconium centre, ultimately giving pyrazaboles as some of the products. The lack of reproducibility in the behaviour of HL has precluded any quantitative investigation of this system. However, the results obtained do indicate that the zirconium centre can play a role in the pyrazabole formation process.

The chloride substitution reactions of $Zr(\eta^5\text{-}C_5H_5)LCl_2$ have been investigated using phenols. The reactions of $Zr(\eta^5\text{-}C_5H_5)LCl_2$ with two molar equivalents of HOC_6H_4Z (Z = H, 4-OMe, 4-NO_2 and 2-Ph) in solutions containing triethylamine afforded the corresponding bis-phenoxides in yields of approximately 70%. In the case of $Zr(\eta^5\text{-}C_5H_5)_2(OC_6H_4\text{-}2\text{-}Ph)_2$ this formulation has been confirmed by an X-ray crystal structure[14,15] which shows the presence of an η^5-cyclopentadienyl ligand and a κ^3 hydrotrispyrazolylborate ligand as illustrated schematically in Fig. 1. ^1H NMR evidence indicates that similar reactions take place with $Hf(\eta^5\text{-}C_5H_5)_2Cl^2$ when using HOC_6H_4-4-OMe or HOC_6H_5-4-F, but the products could not be isolated in a sufficiently pure state to give satisfactory elemental analyses.

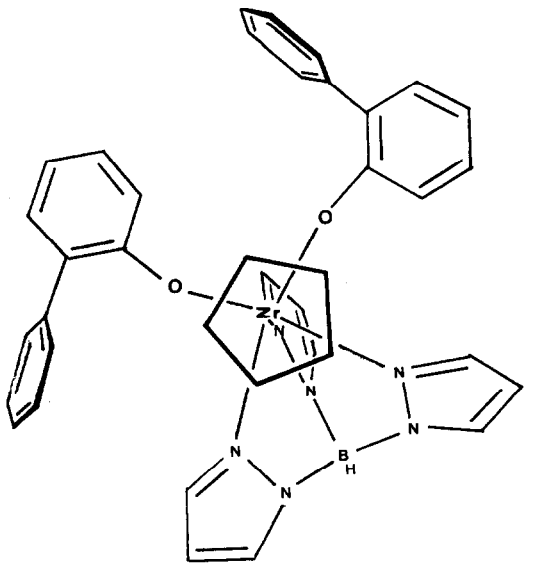

Fig. 1. A schematic view of the structure of $Zr(\eta^5\text{-}C_5H_5)_2(OC_6H_4\text{-}2\text{-}Ph)_2$ viewed along the Zr–C_5H_5 (ring centriod) vector. The third pyrazolyl ring of the ligand L is seen edge-on and lies behind, and is partly obscured by, the zirconium atom.

COMMUNICATION

SYNTHESIS AND PROPERTIES OF POLYFLUOROALKOXYGERMANES

H. G. ANG* and C. H. KOH

Chemistry Department, National University of Singapore, Kent Ridge Road, Singapore 0511, Republic of Singapore

(*Received* 24 *May* 1990; *accepted* 28 *June* 1990)

Abstract—Two new polyfluoroalkoxygermanes, $(CF_3)_2C(H)OGeH_3$ (**A**) and $[(CF_3)_2C(H)O]_2GeH_2$ (**B**), were synthesized from the reactions of $(CF_3)_2C{=}O$ and GeH_4. The Ge—O bond in **A** was cleaved by HCl to give $(CF_3)_2C(H)OH$ and GeH_3Cl. Pyrolysis of both the alkoxygermanes also resulted in the formation of the alcohol, with concomitant deposition of germanium metal.

Hexafluoroacetone has been known to add to hydrides of Group 14 elements to give polyfluoroalkoxide derivatives. A variety of hexafluoroisopropoxysilanes have been produced from the reactions of hexafluoroacetone with various substituted silanes.[1–3] However, the addition of hexafluoroacetone to germane has not received much attention. Until now, only one hexafluoroacetone derivative of germanium, namely, hexafluoroisopropoxytrimethylgermane, has been prepared from the reaction of hexafluoroacetone with trimethylgermane;[4] but its properties have not been investigated. We now report the isolation of two new alkoxygermanes from the reactions of hexafluoroacetone with germane, and also their properties.

When an equimolar mixture of hexafluoroacetone and germane was heated at 120°C for $2\frac{1}{2}$ days in an evacuated glass ampoule, hexafluoroisopropoxygermane and bis(hexafluoroisopropoxy)germane were obtained:

$$3(CF_3)_2C{=}O + 2GeH_4 \longrightarrow (CF_3)_2C(H)OGeH_3 + [(CF_3)_2C(H)O]_2GeH_2.$$
(**A**) (**B**)

The products were not formed at temperatures below 120°C. On the other hand, reactions at higher temperatures afforded decomposition products. Both products **A** and **B** are stable at room temperature.

Hexafluoroisopropoxygermane (**A**) was trapped as a white solid at −86°C under vacuum fractionation, and melted to a colourless liquid on warming to room temperature. Its IR spectrum showed the following absorptions: 2905 cm^{-1}, ν(C—H); 1376 cm^{-1}, δ(C—H); 2134, 2099 cm^{-1}, ν(Ge—H); 902, 859 cm^{-1}, δ(Ge—H); 1303, 1276, 1224, 1155, 1111 cm^{-1}, ν(C—F); 691 cm^{-1}, δ(C—F); 768 cm^{-1}, ν(Ge—O). Molecular weight determination by Regnault's method gave 242 g mol^{-1} ($C_3H_4F_6OGe$ requires 243 g mol^{-1}). Found: C, 15.1; H, 1.5; F, 47.9. $C_3H_4F_6OGe$ requires: C, 14.8; H, 1.6; F, 47.0%.

The EI–MS of **A** did not exhibit the parent ion. However, clusters of peaks due to the following fragmentation ions were observed: 241 $\{[C_3F_6{}^{72}GeH_3O]^{+\cdot}, [C_3F_6{}^{74}GeHO]^{+\cdot}\}$, 239 $\{[C_3F_6{}^{70}GeH_3O]^{+\cdot}, [C_3F_6{}^{72}GeHO]^{+\cdot}\}$, 237 $\{[C_3F_6{}^{70}GeHO]^{+\cdot}\}$, 175 $\{[C_2F_3{}^{74}GeH_4O]^{+\cdot}\}$, 173 $\{[C_2F_3{}^{72}GeH_4O]^{+\cdot}, [C_2F_3{}^{74}GeH_2O]^{+\cdot}\}$, 171 $\{[C_2F_3{}^{70}GeH_4O]^{+\cdot}, [C_2F_3{}^{72}GeH_2O]^{+\cdot}, [C_2F_3{}^{74}GeO]^{+\cdot}\}$, 93 $\{[{}^{74}GeH_3O]^{+\cdot}\}$, 91 $\{[{}^{72}GeH_3O]^{+\cdot}, [{}^{74}GeHO]^{+\cdot}\}$, 89 $\{[{}^{70}GeH_3O]^{+\cdot}, [{}^{72}GeHO]^{+\cdot}\}$, 77 $\{[{}^{74}GeH_3]^{+\cdot}\}$, 75 $\{[{}^{72}GeH_3]^{+\cdot}, [{}^{74}GeH]^{+\cdot}\}$, 73 $\{[{}^{70}GeH_3]^{+\cdot}, [{}^{72}GeH]^{+\cdot}\}$. Fragmentation ions of the hexafluoroisopropoxyl group were also found in the mass spectrum.

Bis(hexafluoroisopropoxy)germane (**B**) was isolated as a colourless liquid at a −30°C trap under fractionation. It remained as a colourless liquid at

* Author to whom correspondence should be addressed.

room temperature. The following peaks were observed in its IR spectrum: 2916 cm^{-1}, ν(C—H); 1377 cm^{-1}, δ(C—H); 2175 cm^{-1}, ν(Ge—H); 904, 866 cm^{-1}, δ(Ge—H); 1304, 1276, 1228, 1135, 1111 cm^{-1}, ν(C—F); 690 cm^{-1}, δ(C—F); 807, 763 cm^{-1}, ν(Ge—O). Found: C, 17.7; H, 0.98; F, 55.9. $C_6H_4F_{12}GeO_2$ requires: C, 17.6; H, 0.98; F, 55.8%.

The mass spectrum of **B** was very similar to that of **A**. Again, the parent ion was not observed, but clusters of peaks due to the isotopes of germanium were obtained. The highest *m/z* observed was 241, which was assigned to the fragmentation ions $[C_3F_6{}^{72}GeH_3O]^{+\cdot}$ and $[C_3F_6{}^{74}GeHO]^{+\cdot}$. An additional cluster of peaks with *m/z* 193 $\{[C_2F_4{}^{74}GeH_3O]^{+\cdot}\}$, 191 $\{[C_2F_4{}^{72}GeH_3O]^{+\cdot}, [C_2F_4{}^{74}GeHO]^{+\cdot}\}$, 189 $\{[C_2F_4{}^{70}GeH_3O]^{+\cdot}, [C_2F_4{}^{72}GeHO]^{+\cdot}\}$ was observed as compared to the mass spectrum of **A**.

The Ge—O bond in **A** was found to be completely cleaved by an equimolar quantity of anhydrous hydrogen chloride at 80°C to afford 2H-hexafluoro-2-propanol (**C**) and chlorogermane:

$$(CF_3)_2C(H)OGeH_3 + HCl \longrightarrow (CF_3)_2C(H)OH + GeH_3Cl.$$
(**C**)

Metal deposition was obtained upon pyrolysis of both alkoxygermanes, **A** and **B**. When **A** was pyrolysed at 180°C for 7 days, it underwent about 70% decomposition to give the alcohol (**C**), germanium metal and hydrogen gas. A trace of germane was also isolated:

$$(CF_3)_2C(H)OGeH_3 \longrightarrow (CF_3)_2C(H)OH + GeH_4 + H_2 + Ge.$$

However, pyrolysis of **B** at 150°C for 2 days afforded a quantitative yield of **C** and germanium metal, with the elimination of hydrogen, as shown below:

$$[(CF_3)_2C(H)O]_2GeH_2 \longrightarrow 2(CF_3)_2C(H)OH + H_2 + Ge.$$

In both cases germanium, confirmed by chemical analysis, was formed as a uniform mirror on the wall of the reaction ampoule.

BOOK REVIEW

Gmelin Handbook of Inorganic Chemistry. Sn—Organotin Compounds, Part 17. By H. Schumann and I. Schumann. Organotin–Oxygen Compounds of the Types $RSn(OR')_3$ and $RSn(OR')_2OR''$; $R_2Sn(X)OR'$, $RSnX(OR')_2$ and $RSnX_2(OR')$. Published by Gmelin Institute for Inorganic Chemistry of the Max Planck Society for the Advancement of Science, 8th edn. Springer, Berlin, 1989, ISBN 3-540-93596-7, XIV + 245 pp., DM 1133.

This is the 17th volume on organotin compounds to be written by Herbert and Ingeborg Schumann (Berlin Technical University), and covers compounds of the type $RSn(OR')_3$, $RSn(OR')_2OR''$, $R_2Sn(X)OR'$, $RSnX(OR')_2$ and $RSnX_2(OR')$, where X = hydrogen, halogen or pseudohalogen. The principal examples are the alkoxides, phenoxides and carboxylates, and compounds such as the oxinates, β-diketones and triethanolamine (stannatrane) derivatives are included. The literature closing date is 1987.

The monoorganotin compounds have a significant patent literature relating to p.v.c. stabilization, pesticides and bactericides, transesterification catalysts, waterproofing and flame-proofing, and vulcanizing agents for polysiloxane elastomers, but they have not found the extensive and varied applications that the tri- and di-alkyltin compounds have.

In the usual Gmelin style, the compounds are collected in 175 pages of tables which list structure, preparative methods, properties and remarks, and references. Further information on special compounds is given in extensive footnotes. The book includes 55 pages of indexes of empirical formulae and ligand formulae.

The presentation of the information and the printing are of the usual high standard of this series. The publishers and authors are providing a valuable service to chemistry in making this information available.

STEPWISE CONVERSION OF A FIVE- INTO A NINE-MEMBERED PHOSPHAMETALLACYCLE VIA TWO INSERTIONS OF ALKYNE INTO A CHROMIUM–CARBON DOUBLE BOND

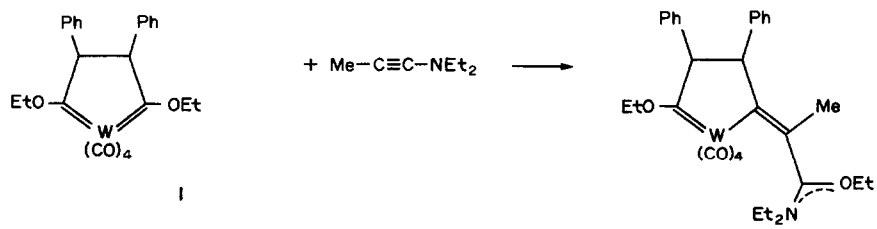
NGOC HOA TRAN HUY, LOUIS RICARD and FRANÇOIS MATHEY*

Laboratoire de Chimie du Phosphore et des Métaux de Transition, DCPH, Ecole Polytechnique, 91128 Palaiseau Cedex, France

(*Received* 16 *February* 1990; *accepted* 2 *April* 1990)

Abstract—The reaction of a five-membered (η^1-P,η^1-C-phosphinocarbene)tetracarbonylchromium chelate with several electron-rich triple bonds including an ynamine, a cyanamide and an ethoxyacetylene gives stable seven-membered phosphametallacycles via the insertion of the triple bond into the chromium–carbene bond. With an excess of ethoxyacetylene, a double insertion also takes place leading to a nine-membered phosphametallacycle whose structure has been established by X-ray analysis. A C=C double bond of this cycle is loosely coordinated to the $Cr(CO)_3$ group: C—Cr = 2.384(4) and 2.619(4) Å. This first example of a stable double insertion product of a C≡C triple bond into a metal–carbene bond probably owes its stability to its phosphinocarbene chelate structure.

The insertion of triple bonds into metal–carbene bonds is a well documented process.[1] In many cases, a complicated series of events takes place which ultimately leads to carbocycles after extrusion of the transition metals. In some other cases the initial insertion products can be isolated. In such a way, aminovinylcarbene,[2,3] methyleneaminocarbene[4] and alkoxyvinylcarbene[5] complexes have been obtained, respectively, by insertion of ynamines,[2,3] cyanamides[4] and ethoxyacetylene[5] into carbene complexes. The reactivity of electrophilic carbene complexes toward these electron-rich triple bonds is highly dependent on the structural features of the carbene unit. For example, as far as we know, no ring expansion has been observed upon reaction of cyclic carbene complexes with these alkynes. In particular, the formation of the expected seven- or nine-membered rings does not occur during the reaction of the cyclic carbene, **1**, with ynamines; An insertion into the carbon–oxygen bond takes place instead[6] [eq. (1)]:



I (1)

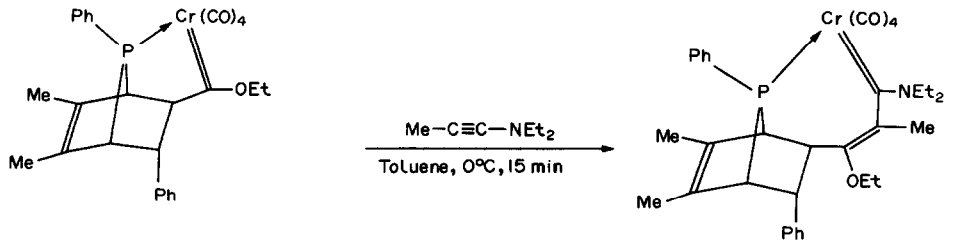
In such a context, it was tempting to investigate the reaction of electron-rich triple bonds with a recently discovered phosphinocarbene chelate, **2**.[7] In so doing, we discovered an unprecedented double insertion of ethoxyacetylene converting a five- into a nine-membered phosphametallacycle.

RESULTS AND DISCUSSION

The reaction of **2** with a slight excess of 1-diethylaminopropyne leads cleanly and rapidly to the

* Author to whom correspondence should be addressed.

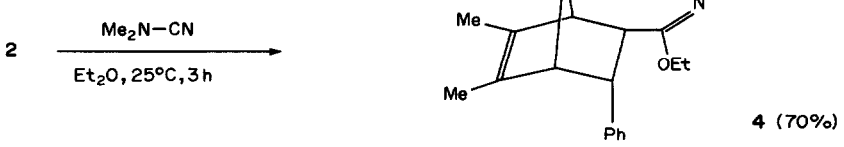
mono-insertion product **3** [eq. (2)]:



2 **3** (65%) (2)

The experimental formula of **3** was established by carbon and hydrogen elemental analyses and mass spectrometry (EI, 70 eV): *m/z* 595 ($M^+ - CO$, 27%), 511 ($M^+ - 4CO$, 100%). Its IR spectrum indicated a tetracarbonylchromium structure. The corresponding bands are shifted to lower frequencies by comparison with those of **2**, in agreement with the good σ-donor/weak π-acceptor properties of aminocarbene ligands.[8] Its ^1H, ^{13}C and ^{31}P spectra confirmed the proposed structure. The carbenic carbon resonates at 285.4 ppm, i.e. at much higher fields than in the starting product (356.4 ppm), supporting the aminocarbene formulation, and the ^{31}P resonance at low field (+161.4) is characteristic of the 7-phosphanorbornene skeleton.

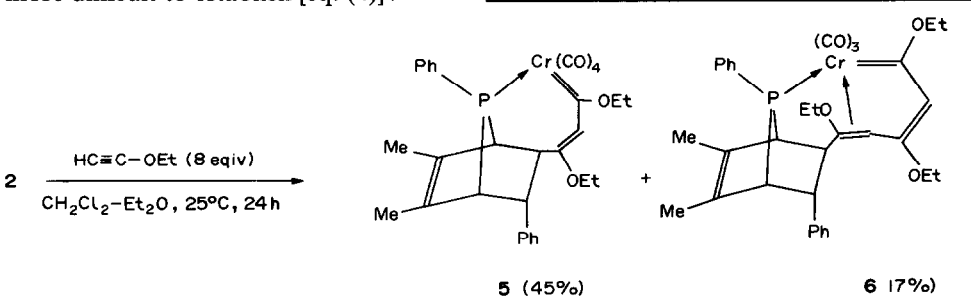
A similar reaction takes place between complex **2** and dimethylcyanamide [eq. (3)]:



4 (70%) (3)

The presence of the amino–imino–carbene functionality and of the 7-phosphanorbornene skeleton was established as for compound **3**: δ (Cr=*C*) +245 ppm; $\delta^{31}P$ +162.1 ppm.

The case of ethoxyacetylene is more interesting. The reaction of a huge excess (8 equiv.) of this alkyne with complex **2** affords the mono-insertion product **5** and another complex **6**, the structure of which was more difficult to establish [eq. (4)]:



5 (45%) **6** 17%) (4)

The mass spectrum of **6** indicated that two molecules of ethoxyacetylene had reacted with **2**: *m/z* 624 (*M*(**2**)+2 EtO—C≡CH −CO, 100%). The IR spectrum clearly showed the disappearance of the $Cr(CO)_4$ complexing group, **5**: ν(CO), 2005 (s), 1900 (vs) cm^{-1} (in CH_2Cl_2); **6**: ν(CO), 1925 (vs), 1850 (s), 1815 (s) cm^{-1} (in CH_2Cl_2).

We thus decided to perform the X-ray crystal structure analysis of **6** (Fig. 1). A double insertion of ethoxyacetylene into the chromium–carbene bond of **2** had occurred to give a new nine-membered phosphametallacycle. Rather unexpectedly, one carbonyl has been lost in the process and one of the double bonds of the heterocycle is now coordinated to chromium. The coordination appears to be loose as indicated by the very long Cr—C(4) and Cr—C(5) bonds, respectively, 2.384(4) and 2.619(4) Å. The easy formation of chromium carbene–alkene chelates from the corresponding open-chain alkenylcarbene–chromium complexes has recently been described by Rudler and co-workers.[9] In the cases of both Rudler and ours, a six-membered cyclic structure is thus obtained. However, in our

case, the strain which results from the distortion of the initial nine-membered metallacycle destabilizes the chromium–alkene bond.

From another standpoint, the stepwise insertion of two alkyne units into a chromium–carbene bond is already known.[10] However, the products resulting from this double insertion are always unstable and extrude chromium to give cyclohexadienones or phenols in low yields.[10] In our case, the double insertion product **6** probably owes its stability to its chelated phosphino carbene structure.

EXPERIMENTAL

All the reactions were performed under argon. NMR spectra were recorded on Multinuclear WP 80 and AC 200 SY Bruker spectrometers operating at 80.13 and 200.13 (^{1}H), 20.15 and 50.32 (^{13}C), and 32.44 (^{31}P) MHz. Chemical shifts are in ppm downfield from internal TMS (^{1}H and ^{13}C) and external 85% H_3PO_4 (^{31}P). Mass spectra were recorded on a Shimadzu GC-MS QP 1000 instrument at 70 eV under electronic impact. Elemental analyses were performed by the Service Central de Microanalyse du CNRS, France. Silica gel (70–230 mesh) was used for the chromatographic separations. All commercially available reagents were used as received from the suppliers.

Complex **3**

The ynamine, Me—C≡C—NEt_2 (0.3 cm^3, 2.6×10^{-3} mol, 5 equiv.), was added at 0°C to a solution of **2** (0.25 g, 5×10^{-4} mol) in toluene (5 cm^3). The reaction was monitored by TLC. After stirring for 15 min, the solvent was evaporated and the residual oil was chromatographed with pentane–CH_2Cl_2 (3:7) as the eluent. Complex **3** was obtained as yellow crystals in 65% yield (0.2 g).

^{31}P NMR ($CDCl_3$): δ+161.4; ^{1}H NMR

($CDCl_3$): δ 1.03 (s, 3H, CH_3—C), 1.19 (t, 3H, CH_3—CH_2), 1.29 (t, 3H, CH_3—CH_2), 1.57 (t, 3H, CH_3—CH_2), 1.62 (s, 3H, CH_3—C), 1.78 (s, 3H, CH_3—C=), 3.0 (m, 2H, CH—P), 3.4 (m, 1H, CH_2), 3.78 (m, 4H, CH_2+CH junction), 4.15 (m, 1H, CH_2), 4.75 (m, 1H, CH_2), 7.07–7.30 (m, 10H, Ph); ^{13}C NMR ($CDCl_3$): δ 13.76 (d, CH_3), 14.24 (d, CH_3), 15.96 (s, CH_3), 16.28 (d, CH_3), 22.74 (s, CH_3), 31.68 (s, CH_3, 46.81 (s, NCH_2), 47.91 (d, J(C—P) = 7.5 Hz, CH), 48.31 (s, CH), 51.43 (s, NCH_2), 52.27 (d, J(C—P) = 17.6 Hz, CH), 56.35 (d, J(C—P) = 17.1 Hz, CH), 65.43 (s, OCH_2), 219.46 (d, J(C—P) = 17.8 Hz, CO), 222.59 (d, J(C—P) = 16 Hz, CO), 228.14 (d, J(C—P) = 7.9 Hz, CO), 228.79 (s, CO), 285.38 (d, ^2J(C—P) = 12.07 Hz, *C*=Cr); IR (CH_2Cl_2): ν(CO) 1990 (s), 1900 (s), 1870 (vs) cm^{-1}; Found: C, 65.7; H, 6.9. Calc. for $C_{34}H_{38}NO_5PCr$: C, 65.5; H, 6.1%.

Complex **4**

An excess of Me_2N—CN (1 cm^3) was added to a solution of **2** (0.5 g) in ether (20 cm^3). After stirring for 3 h, the solution became yellow. The solvent was evaporated and the residual oil was chromatographed with pentane–CH_2Cl_2 (7:3) as the eluent. Yield of **4**: 0.4 g (70%) of yellow crystals; m.p. 158°C (dec.).

^{31}P NMR (Et_2O): δ +162.1; ^{1}H NMR ($CDCl_3$): δ 1.16 (s, 3H, CH_3), 1.34 (t, 3H, CH_3—CH_2), 1.69 (s, 3H, CH_3), 3.02 (s, 3H, CH_3—N), 3.07 (m, 3H, 3C*H*), 3.82 (s, 3H, CH_3N), 4.0 (m, 1H, C*H*), 4.16 (q, 2H, OCH_2), 7.0–7.3 (m, 10H, Ph); ^{13}C NMR ($CDCl_3$): δ 14.36 (s, Me), 14.59 (s, Me), 16.68 (s, Me), 40.54 (s, NMe), 47.05 (s, NMe), 47.18 (d, J(C—P) = 24.3 Hz, CH), 51.75 (d, J(C—P) = 13.1 Hz, CH), 53.57 (d, J(C—P) = 14.6 Hz, CH), 56.85 (d, J(C—P) = 16.8 Hz, CH), 62.96 (s, OCH_2), 150.67 (s, N=*C*—OEt), 220.72 (d, ^2J(C—P) = 17.1 Hz, CO), 222.61 (d, ^2J(C—P) = 16.8 Hz, CO), 226.46 (d, ^2J(C—P) = 8.8 Hz, CO); 229.48 (s, CO), 244.99 (d, ^2J(C—P) = 11.2 Hz, *C*=Cr); IR (CH_2Cl_2): ν(CO) 1995 (s), 1900 (shoulder), 1875 (vs) cm^{-1}; mass spectrum (EI, 70 eV): m/z 582 (M^+, 6%), 470 (M^+ −4CO, 100%).

Complex **5**

An excess of ethoxyacetylene (2 cm^3, 60% in Et_2O) was added to a solution of **2** (0.75 g) in dichloromethane (10 cm^3). The reaction was monitored by TLC. After stirring for 24 h, the solvent was evaporated and the residual oil was chromatographed with pentane–CH_2Cl_2 (4:1) as the eluent. Complex **5** was obtained in 45% yield (0.38 g) as red crystals; m.p. 103°C (dec.).

^{31}P NMR ($CDCl_3$): δ +163.8; ^{1}H NMR ($CDCl_3$): δ 1.16 (s, 3H, CH_3), 1.32 (t, 3H, CH_3—CH_2), 1.59 (t, 3H, CH_3—CH_2), 1.68 (s, 3H, CH_3), 3.0 (m, 2H, CH—P), 3.46 (m, 1H, CH), 3.79 (q, 2H, OCH_2); 3.97 (m, 1H, CH); 5.86 (s, 1H, =CH); 7.0–7.3 (m, 10H, Ph); ^{13}C NMR ($CDCl_3$): δ 14.36 (d, Me), 15.47 (s, Me), 16.55 (s, Me), 17.37 (s, Me); 51.53 (d, J(C—P) = 26.1 Hz, CH), 52.48 (d, J(C—P) = 7.2 Hz, CH), 56.32 (d, J(C—P) = 18.9 Hz, CH), 59.78 (d, J(C—P) = 20.7 Hz, CH), 64.42 (s, OCH_2), 72.30 (s, OCH_2), 119.69 (s, =CH), 164.42 (s, *C*—OEt), 342.95 (d, ^2J(C—P) = 10.6 Hz, *C*=Cr); IR (CH_2Cl_2): ν(CO) 2005 (s), 1900 (vs) cm^{-1}; mass spectrum (EI, 70 eV): m/z 554 (M^+ −CO, 7%), 470 (M^+ −4CO, 66%), 428 (100%).

Complex **6**

Complex **6** was eluted after complex **5** and isolated as black–red crystals in 17% yield (0.1 g); m.p. 158°C (dec).

^{31}P NMR ($CDCl_3$): +166.4; ^{1}H NMR ($CDCl_3$): δ 1.02 (s, 3H, CH_3); 1.14 (t, 3H, CH_3—CH_2), 1.42 (t, 3H, CH_3—CH_2), 1.50 (t, 3H, CH_3—CH_2), 1.68 (s, 3H, CH_3), 2.87 (m, 1H, CH—P?), 3.40 (dm, ^3J(H—P) = 40 Hz, HC_6 endo), 3.70–3.98 (m, 4H, OCH_2), 4.25 (s broad, 1H, CH—P?), 4.47–4.56 (m, 1H, OCH), 4.61 (d, 1H, HC_{11} *exo*), 4.73–4.62 (m, 1H, OCH), 4.96 (s, 1H, HC(4)=), 6.06 (s, 1H, HC(2)=, 6.79–7.48 (m, 10H, Ph); ^{13}C NMR ($CDCl_3$): δ 14.03, 14.33, 14.94, 15.61, 16.46 (5s, CH_3), 40.50 (d, J(C—P) = 11.1 Hz, CH), 50.77 (d, J(C—P) = 26.2 Hz, CH), 61.80 (d, J(C—P) = 13.1 Hz, CH), 62.88 (s, =C_4H), 67.62, 71.99, 74.62 (3s, OCH_2), 76.08 (s, =*C*(5)—OEt), 231.6 (s, CO), 233.15 (d, ^2J(C—P) = 13.4 Hz, CO), 236.92 (d, ^2J(C—P) = 13 Hz, CO), 327.94 (d, ^2J(C—P) = 14.8 Hz, *C*=Cr).

X-ray structure determination for **6**. Crystals of **6**, $C_{34}H_{36}CrO_6P \cdot CH_2Cl_2$, were grown at −18°C from a CH_2Cl_2–pentane solution of the compound. Data were collected at 18 ± 1° on an Enraf–Nonius CAD4 diffractometer. The crystal structure was solved and refined using the Enraf–Nonius supplied SDP package. The compound crystallizes in space group $P2_1/N$, a = 12.849(1), b = 19.226(2), c = 15.250(1) Å, β = 110.77(1)°; V = 3522.5(1.1) Å^3; Z = 4; d_{calc} = 1.336 g cm^{-3}; Mo-K_α radiation (l = 0.71073 Å) graphite monochromator; μ = 5.5 cm^{-1}; $F(000)$ = 1476. A total of 3277 unique reflections were recorded in the range 2° ≤ 2θ ≤ 40.0° of which 738 were considered as unobserved [$F^2 < 3.0\ \sigma(F^2)$], leaving 2539 for solution and refinement. The structure was solved by Patterson methods, yielding a solution for the chromium and

phosphorus atoms. The hydrogen atoms were included as fixed contributions in the final stages of least-squares refinement, while using anisotropic temperature factors for all other atoms. A non-poisson weighting scheme was applied with a p factor equal to 0.08. The final R factors were $R = 0.045$, $R\omega = 0.065$, G.O.F. = 1.46.

(*Received* 16 *February* 1990; *accepted* 2 *April* 1990)

Abstract—Co-crystallization of $Na[AuCl_4]$ with 1-methyluracil, $C_5H_6N_2O_2$ (1-MeUH), and 1-methylthymine, $C_6H_8N_2O_2$ (1-MeTH), at pH 0.8 yields predominently salts of composition $[Na(1\text{-MeUH})_4][AuCl_4]$ (**1**) and $[Na(1\text{-MeTH})(H_2O)_4][AuCl_4]\cdot 1\text{-MeTH}\cdot 2H_2O$ (**2**). Both **1** and **2** crystallize in space group $P\bar{1}$ with cell dimensions $a = 10.531(3)$, **1**, 8.436(5), **2**; $b = 9.194(3)$, **1**, 10.521(7), **2**; $c = 7.924(2)$, **1**, 15.917(11) Å, **2**; $\alpha = 96.68(3)$, **1**, 102.61(5), **2**; $\beta = 85.09(3)$, **1**, 90.45(5), **2**; $\gamma = 103.88(3)$, **1**, 108.10(5)°, **2**; $U = 738.4$, **1**, 1306(2) Å^3, **2**; $Z = 1$, **1**, 2, **2**. Na^+ binding to 1-MeUH is through O(4) in **1** and O(2) in **2**. The packing of cations and anions in **1** is special in that infinite stacks of alternating $[Na(1\text{-MeUH})_4]^+$ and $[AuCl_4]^-$ are formed with the metals 3.962(1) Å apart.

The neutralization of the negative charges of the nucleotides in nucleic acids is mainly accomplished by alkali cations.[1] With DNA, the cations appear to form a highly mobile cylinder of positive charges around the polynucleotide strands.[2] Interactions are thought to take place preferentially though the phosphate oxygens,[3] but it is feasible that donor atoms of the bases in the grooves are involved as well. In several X-ray structures of mono- and dinucleotides containing uracil or thymine bases, alkali cations are found to directly interact with O(2) oxygen atoms.[4] The O(4) sites usually are involved in hydrogen bonding. Theoretical calculations of charge density distributions in nucleobases,[5] as well as electrostatic potentials[6] in the unsubstituted bases, have suggested O(2) and O(4) of these bases to be intrinsic metal binding sites. According to an *ab initio* computation, Na^+ binding to neutral uracil is expected to take place via both O(2) and O(4).[7]

Reports on metal binding to the exocyclic oxygens of neutral uracil and thymine nucleobases are relatively scarce.[8–11] To our knowledge, only four X-ray structures of such compounds are available, including that of a potassium complex: $HgCl_2$(uracil-O^4)$_2$,[9] $HgCl_2$(dihydrouracil-O^4)$_2$,[9] $CuCl_2$(1,3-dimethyluracil-O^4)$_2$,[10] and $[K_2$(1-propylthymine-O^2,O^4)$_4][Pd_2Cl_6]$.[11] Na^+ binding to O(2) and O(4) of 1-methylthymine has also been observed in CH_3Hg(1-methylthyminate) $0.5NaNO_3$,[12] but the situation is different in that mercury binding to the deprotonated N(3) position increases the basicity of the exocyclic oxygens, generating a situation intermediate between an anionic and a neutral ligand. A similar situation also applies to the $NaNO_3$ adducts of *cis*-$(NH_3)_2$Pt(1-methyluracilate)$_2$.[13] Finally, K^+ binding to O(2) in potassium thyminate[14] is not unexpected and not to be compared with the situation described in this paper.

EXPERIMENTAL

Preparation

$[Na(C_5H_6N_2O_2)_4][AuCl_4]$ (**1**) and $[Na(C_6H_8N_2O_2)(H_2O_4)][AuCl_4]\cdot C_6H_8N_2O_2\cdot 2H_2O$ (**2**) were isolated from aqueous, HCl acidic solutions (pH ~ 0.8)

* Author to whom correspondence should be addressed.

containing 1-methyluracil (1-MeUH, $C_5H_6N_2O_2$) (**1**), 1-methylthymine (1-MeTH, $C_6H_8N_2O_2$) and $NaAuCl_4$ in a 1 : 1 ratio upon slow evaporation at 3°C. Yields were 65% (**1**) and 58% (**2**). Compound **1** crystallizes as yellow cubes while **2** forms orange–yellow needles. Found (**1**): C, 27.3; H, 2.6; N, 12.4. Calc. for $C_{20}H_{24}N_8O_8Cl_4AuNa$: C, 27.7; H, 2.7; N, 12.9%. Found (**2**): C, 19.2; H, 3.1; N, 7.4; O, 19.7; Cl, 18.8, Au, 26.3; Na, 3.1. Calc. for $C_{12}H_{28}N_4O_{10}Cl_4AuNa$: C, 19.2; H, 3.8; N, 7.5; O, 21.3; Cl, 18.9; Au, 26.2; Na, 3.0%. The poor analysis of H and O in **2** is probably due to partial loss of H_2O, as confirmed by thermogravimetry.

Spectroscopy

IR spectra were recorded as KBr pellets on a Perkin–Elmer 580 B spectrometer. No reliable spectra were obtained with Nujol mulls and CsI windows due to reaction of $[AuCl_4]^-$ with CsI, leading to Au^0 formation. Raman spectra (solid state) were obtained on a Coderg T 800 instrument with 647.1 nm excitation, ^1H NMR spectra on Bruker AM 300 and AC 200 spectrometers in D_2O. pD values were determined by use of a glass electrode and addition of 0.4 units to the meter reading.

Crystal data for **1** *and* **2**

$C_{20}H_{24}N_8O_8Cl_4AuNa$ (**1**), $M = 866.23$, triclinic, $a = 10.531(3)$, $b = 9.194(3)$, $c = 7.924(2)$ Å, $\alpha = 96.68(3)$, $\beta = 85.09(3)$, $\gamma = 103.88(3)°$, $U = 738.4$ Å^3, $F(000) = 422$, space group $P\bar{1}$, $Z = 1$, $D_c = 1.948$ g cm^{-3}, Mo-K_α radiation ($\lambda = 0.71069$ Å), μ(Mo-K_α) = 51.8 cm^{-1}.

$C_{12}H_{28}N_4O_{10}Cl_4AuNa$ (**2**), $M = 750.14$, triclinic, $a = 8.436(5)$, $b = 10.521(17)$, $c = 15.917(11)$ Å, $\alpha = 102.61(5)$, $\beta = 90.45(5)$, $\gamma = 108.10(5)°$, $U = 1306(2)$ Å^3, $F(000) = 732$, space group $P\bar{1}$, $Z = 2$, $D_c = 1.908$ g cm^{-3}, Mo-K_α radiation ($\lambda = 0.71073$ Å), μ(Mo-K_α) = 61.0 cm^{-1}, $T = 291(1)$ K.

Data collection and processing

Phillips PW-1100 (**1**) and Nicolet R3m/V diffractometer (**2**); θ–2θ technique ($\theta_{max} = 25°$) for **1**, ω—2θ scan, scan speed 2.00–14.65° min^{-1} in θ, scan width (1.2 + dispersion)° for **2**, graphite-monochromated Mo-K_α radiation; 2609 (**1**), 7083 (**2**) reflections measured, 2558 (**1**), 3104 (**2**) used [$F_o > 2F_o$ (**1**), $F_o > 3F_o$ (**2**)]; correction for Lorentz and polarization factors, empirical absorption correction.

Structure analysis and refinement

The structures were solved by the heavy-atom method. All non-hydrogen atoms were refined anisotropically. With **2**, hydrogen atoms were placed in geometrically calculated positions (C—H, N—H 0.96 Å). Refinement was by full-matrix least-squares method for **1** to $R = 0.064$, $R_w = 0.065$ ($w^{-1} = \sigma^2(F) + 0.0026\ F^2$) and for **2** to $R = 0.047$, $R_w = 0.046$ ($w^{-1} = \sigma^2(F) + 0.001157\ F^2$). Calculations were performed using SHELX 76 (**1**) and PARST, SHELXTL PLUS; PCK83, PLATON and MISSYM (**2**).*

RESULTS AND DISCUSSION

1-MeUH and $Na[AuCl_4]$ interact in moderately acidic solution (pH 1–2, HCl) mainly with formation of **1**. In the ^1H NMR spectra, resonances due to four minor products are observed in addition to the signals due to averaging between 1-MeUH and **1**. Only one of these, 5-chloro-1-methyluracil [δ(ppm) H(δ), 7.94, s], has unambiguously been identified. A second one, which amounts to *ca* 20% of **1** at 1-MeUH : $[AuCl_4]^- = 1$, is probably a species containing coordinated 1-MeU [δ(ppm) H6, 7.55, d, 7.7 Hz; H5, 5.80, d; CH_3, 3.41 s]. There is no indication of addition of HOCl to the 5,6-double bond of 1-MeUH after several days at 22°C, analogous to reactions of $[AuBr_4]^-$ with uridine[15] and uracil.[16] As the pH of the mixture of 1-MeUH and $Na[AuCl_4]$ is raised, reactions become very complex, leading to reduction to Au(1-MeU), elemental gold and other unidentified products.

Figure 1 provides a view of $[Na(1\text{-MeUH})_4][AuCl_4]$ (**1**) with the atom numbering as indicated. Selected bond lengths and angles are listed in Table 1. The compound consists of discrete $[Na(1\text{-MeUH})_4]^+$ cations and $[AuCl_4]^-$ anions. Within the centrosymmetric cation, the four 1-MeUH rings are bound via their exocyclic O(4) oxygens to a single Na^+, distances being 2.336(7) Å (rings *a*) and 2.301(8) Å (rings *b*). Rings *a* and *b* are almost coplanar (dihedral angle 5.3°). The geometry of the 1-MeUH rings do not display significant differences as compared to 1-MeUH in the absence of Na^+.[17] The geometry of the $[AuCl_4]^-$ is also normal.[18] Anions and cations are arranged in a co-linear fashion with gold and sodium lined up like pearls on a string (Fig. 2). Cations are parallel to each

* Additional details of the X-ray work, atomic coordinates, displacement factors coefficients, lists of bond lengths and angles and F_o, F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

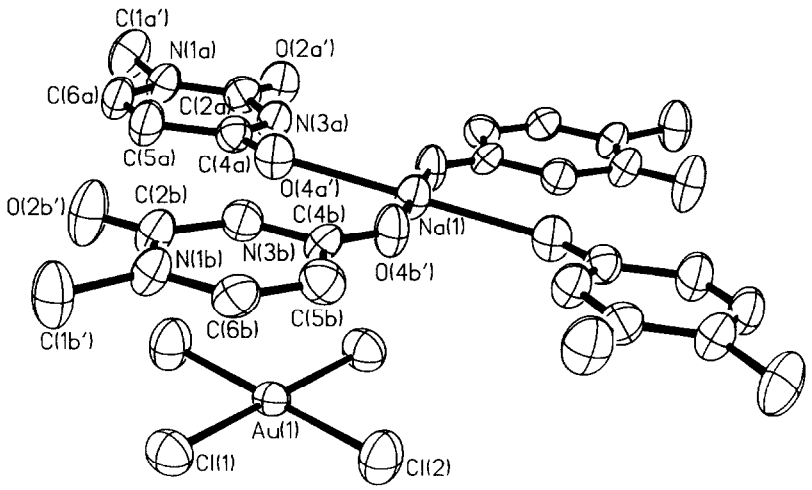

Fig. 1. Presentation of $[Na(1\text{-MeUH})_4]^+$ and $[AuCl_4]^-$ ions of **1** with the atom numbering scheme.

other and in an eclipsed arrangement, as are the anions, but there is a 14.6° angle between the $NaO(4)_4$ and $AuCl_4$ planes. Since the Au—Na separations of 3.962 Å are much too long for any significant interaction, the Na^+ may be regarded as being present in a square-planar coordination sphere. This situation appears to be unusual for sodium.

Figure 3 gives a view of the contents of the unit cell of $[Na(C_6H_8N_2O_2)(H_2O)_4][AuCl_4]\cdot C_6H_8N_2O_2 \cdot 2H_2O$ (**2**). Selected interatomic distances and angles are summarized in Table 2. The compound consists of a centrosymmetric $[Na_2(1\text{-MeTH})_2(H_2O)_8]^{2+}$ entity, two discrete $[AuCl_4]^-$ anions, two extra 1-MeTH rings and four molecules of water of crystallization. Binding of Na^+ to the 1-MeTH rings is through the exocyclic O(2) oxygens, designated O(12) and O(12a) in the figure. Refinement with O(4) as the assumed binding site [O(14), O(14a) in Fig. 3] gave somewhat poorer R values. The Na—O(12) distance [2.286(8) Å] in **2** is slightly shorter than Na—O(4a) in **1**. The octahedrally distorted coordination sphere of Na^+ is completed by three terminal and two bridging water molecules. The coordination pattern of the two Na^+ ions with two bridging aqua groups thus has similarities with those observed in alkali salt hydrates.[19] Geometries

of the anion and of both types of 1-MeTH rings[20] are normal. Free and coordinated 1-MeTH stack along the *Y* axis (dihedral angle 2.9°). The $[AuCl_4]^-$ anion is virtually parallel with the two 1-MeTH rings (dihedral angles with bound and free ligand 2.0 and 2.1°, respectively) but does not participate in stacking with the two 1-methylthymines. Both N(3)H protons of the two rings are hydrogen bonded to water molecules [N(13)···O(2), 2.88(1) Å; N(23)···O(4) intermol., 2.90(1) Å].

Vibrational spectra of **1** and **2** differ from their respective starting components, 1-MeUH and 1-MeTH, in a number of details which refer, for example, to the CO stretching region of the IR (split into two intense components at 1705 and 1655 cm^{-1} in **1**, structured single band at 1660 cm^{-1} in 1-MeUH), to positions of the most intense ring modes[21] in the Raman [ring-stretch 1235 cm^{-1} (**1**), 1225 cm^{-1} (1-MeUH); ring-breathing 760 cm^{-1} (**1**), 770 cm^{-1} (1-MeUH)] or to the position of the δ_{oop} NH in the IR (860 cm^{-1} in **2**, 900 cm^{-1} in MeTH). It is not possible to attribute these difference exclusively to Na^+ binding, since the hydrogen bonding patterns are completely different in the free bases[17,20] and the Na^+ adducts **1** and **2**. It actually appears that the effects of Na^+ binding and hydrogen bonding are comparable since the Raman spectrum of **2** (solid state), albeit different from that of 1-MeTH, does not permit a differentation of modes due to 1-MeTH bound to Na^+ and free 1-MeTH. In both compounds **1** and **2**, the three Raman active Au—Cl vibrations are clearly identified at *ca* 350 (vs), 327 (s) and 169 (s) cm^{-1}.

Abstract—The crystalline product $[Al(CH_3)_2]_2[C_{12}H_{32}N_2Si_4]$ (**I**), obtained from reaction of 2,2,5,5-tetramethyl-2,5-disila-1-azacyclopentane with trimethylaluminium in a heptane–chlorobenzene mixture, crystallizes in the orthorhombic space group *Pbca* (No. 61) with unit-cell parameters $a = 15.393(3)$, $b = 12.987(2)$, $c = 13.189(4)$ Å, $V = 2637.4(2)$ Å^3 and $D_c = 1.06$ g cm^{-3} for $Z = 4$. Full-matrix least-squares refinement based on 1549 observed reflections with intensities in the range $4.00 < 2\theta < 50.0°$ converged at $R = 0.048$ ($R_w = 0.064$). Compound **I** resides about a crystallographic centre of symmetry and contains a planar Al_2N_2 four-membered ring with an Al···Al contact of 2.790(3) Å. Reaction of trimethylaluminium with 1,1,3,3-tetramethyldisilazane in heptane affords the crystalline product $[Al(CH_3)_2]_2[C_8H_{28}N_2Si_4]$ (**II**). Compound **II** crystallizes in the triclinic space group $P\bar{1}$ (No. 2) with unit-cell parameters $a = 9.354(2)$, $b = 14.670(3)$, $c = 17.536(4)$ Å, $\alpha = 91.24(2)$, $\beta = 90.63(2)$, $\gamma = 99.46(2)°$, $V = 2372.7(9)$ Å^3 and $D_c = 1.06$ g cm^{-3} for $Z = 4$. Full-matrix least-squares refinement based upon 5033 observed reflections with intensities in the range $3.50 < 2\theta < 45.0°$ converged at $R = 0.035$ ($R_w = 0.048$). The mean Al···Al contact across the Al_2N_2 four-membered ring in **II** is 2.813(1) Å. The mean Al—N bond distance in **I** is 2.005(3) Å while the mean Al—N bond distance in **II** is 1.992(3) Å.

The interaction of aluminium species with amine moieties, particularly primary and secondary amines, has been extensively investigated. Seminal investigations may be traced to the condensation reactions involving aluminium alkyls and monodentate amines reported by Smith and coworkers.[1,2] These systems, demonstrated to eliminate alkane, were shown to result in interesting oligomeric reaction products possessing extensive Al—N association. The voluminous number of studies on the organoaluminium chemistry of primary and secondary amines notwithstanding, it is particularly interesting to note that the literature reveals a paucity of studies concerning the corresponding chemistry of silazanes. Silazanes represent a particularly intriguing class of compounds in this regard. Herein, we report the synthesis and molecular structure of $[Al(CH_3)_2]_2[C_{12}H_{32}N_2Si_4]$ (**I**) and $[Al(CH_3)_2]_2[C_8H_{28}N_2Si_4]$ (**II**). Compounds **I** and **II**, isolated from reactions of trimethylaluminium with 2,2,5,5-tetramethyl-2,5-disila-1-azacyclopentane and 1,1,3,3-tetramethyldisilazane, respectively, represent the first silazalanes characterized by single-crystal X-ray diffraction techniques.

EXPERIMENTAL

General comments

Standard Schlenk techniques were employed in conjunction with an inert-atmosphere glove-box (Vacuum Atmospheres HE-43 Dri-Lab). Heptane and chlorobenzene were distilled under prepurified argon prior to use. 1,1,3,3-Tetramethyldisilazane and 2,2,5,5-tetramethyl-2,5-disila-1-azacyclopentane were purchased from Petrarch Systems, Inc. Both silazanes were used as received. Single-crystal X-ray diffraction data for **I** were collected on an Enraf–Nonius CAD-4 diffractometer, while single crystal data for **II** were collected on a Nicolet R3m/V diffractometer. NMR data were recorded on an IBM 200 MHz NMR spectrometer. IR spectra were recorded on a Nicolet DX5 FT–IR spectrometer.

Synthesis of $[Al(CH_3)_2]_2[C_{12}H_{32}N_2Si_4]$ (I)

A reaction vessel was charged with a heptane–chlorobenzene mixture (20 and 5 cm^3, respectively) and 2,2,5,5-tetramethyl-2,5-disila-1-azacyclopentane (5.3 mmol) in the dry-box. Trimethylaluminium (5.2 mmol) was slowly added via syringe. Reaction was immediate and vigorous. The reaction vessel was removed from the dry-box and heated (120°C) in a sand bath for 24 h. The reaction vessel was vented periodically over the course of the reaction. The reaction system was allowed to slowly cool to room temperature at which point the solution was filtered via cannula and concentrated *in vacuo*. Colourless, extremely water-sensitive, X-ray quality crystals were isolated: 80% yield; m.p. 129–132°C. ^{1}H NMR ($CDCl_3$): δ −0.59 (s, 12H, $AlCH_3$), 0.41 (s, 24H, $SiCH_3$), 0.78 (s, 8H, $SiCH_2$). ^{29}Si NMR ($CDCl_3$): δ −0.44 (s). IR (Nujol): cm^{-1} 1255 (m, Si—CH_3).

Synthesis of $[Al(CH_3)_2]_2[C_8H_{28}N_2Si_4]$ (II)

A reaction vessel was charged with heptane (20 cm^3) and 1,1,3,3-tetramethyldisilazane (5.2 mmol) in the dry-box. Trimethylaluminium (5.2 mmol) was slowly added via syringe. Reaction was immediate and vigorous. The reaction vessel was removed from the dry-box and heated (90°C) in an oil bath for 24 h. The reaction vessel was vented periodically. After heating, the system was allowed to stand undisturbed for several hours at room temperature. A multitude of colourless, X-ray quality crystals were isolated: 75% yield; m.p. 163–66°C. ^{1}H NMR ($CDCl_3$): δ −0.45 (s, 12H, $AlCH_3$), 0.36–0.31 (m, 24H, $SiCH_3$), 4.80 (m, 4H, Si*H*). ^{29}Si NMR ($CDCl_3$): δ −2.25 (d). IR (Nujol): cm^{-1} 1270 (s, Si—CH_3), 2180 (m, Si—H).

Structural solution and refinement of I

A colourless parallelepiped crystal of **I** was mounted in a thin-walled glass capillary under an inert atmosphere of argon. Cell parameters and an orientation matrix for data collection, obtained from least-squares refinement using the setting angles of 25 reflections measured by the computer controlled diagonal slit method of centering, corresponded to an orthorhombic cell. The space group was determined to be *Pbca* (No. 61). The structure was solved by direct methods. The scan rate varied from 5 to 20° min^{-1} in omega. Hydrogen atoms were located from difference maps. The positional parameters of the hydrogen atoms were refined for several cycles and then fixed for the remainder of the refinement. The data were collected using the ω–2θ scan technique. Refinement based on 1549 observed reflections converged at $R = 0.048$, $R_w = 0.064$. Relevant crystallographic data for **I** are provided in Table 1, while selected bond distances and angles are given in Table 2.

Structural solution and refinement of II

A colourless parallelepiped crystal of **II** was mounted in a thin-walled glass capillary under an inert atmosphere of argon. Cell parameters and an orientation matrix for data collection, obtained from a least-squares refinement of the setting angles of 32 carefully centred reflections, corresponded to a triclinic cell. The space group was determined to be $P\bar{1}$ (No. 2). The structure was solved by direct methods and refined using SHELXTL PLUS.[3] Non-hydrogen atoms were refined by using anisotropic thermal parameters. Hydrogen atoms were located by standard difference Fourier techniques. Hydrogen atoms bound to silicon atoms were refined using isotropic thermal parameters. An isotropic group thermal parameter [$U_{iso} = 0.135(2)$] and positional parameters were refined for the methyl hydrogen atoms. The final cycle of full-matrix least-squares refinement, based on 5033 observed reflections, converged at $R = 0.035$, $R_w = 0.048$. Compound **II** crystallized with four molecules per unit cell.[4] Relevant crystallographic data are given in Table 1 while selected bond distances and angles are given in Table 3.

RESULTS AND DISCUSSION

Wiberg reported the reaction of trimethylaluminium with ammonia in 1948.[5] Smith and co-workers later studied the reactions of aluminium alkyls with primary and secondary amines

and reported that these systems would readily eliminate alkane and result in reaction products possessing Al_2N_2 fragments.[6] This laboratory has recently investigated the reaction of aluminium species with macrocyclic and multidentate open-chain amines and found that the coordination of core aluminium atoms could be extended beyond four-coordinate tetrahedral to five- and six-coordinate environments.[7,8] As silazalanes are relatively rare we endeavoured to examine the organo-aluminium chemistry of silazanes.

As shown in Fig. 1, **I** contains two tetramethyldisilaazacyclopentane moieties bridged by a pair of dimethylaluminium units. Compound **I** resides about a crystallographic centre of symmetry. The core of the dimer contains a four-membered Al_2N_2 ring. The independent Al—N bond distance of 2.005(3) Å may be considered rather long and may be regarded as a consequence of the crowding about the bridgehead nitrogen atom of the silazane imposed by the two bulky tetramethyldisila units. The Al—N—Al bond angle in the Al_2N_2 ring is 89.5(3)° while the N—Al—N bond angle is 90.5(2)°. The Al···Al contact in **I** is 2.790(1) Å. The preparation of **I** prompted us to consider the reaction of trimethylaluminium with silazanes possessing Si—H bonds. 1,1,3,3-Tetramethyldisilazane was examined in this regard.

The X-ray crystal structure of **II** is provided in Fig. 2. Several points are worthy of note regarding structure and bonding. Similar to **I**, compound **II** is a dimer as two tetramethyldisilazane units are bridged by a pair of dimethylaluminium units, thereby constituting an Al_2N_2 four-membered ring. The bond angles of the Al_2N_2 ring are determined to be 89.7(1) and 90.3(1)° for Al—N—Al and N—Al—N, respectively. The mean Al—N bond distance in **II** of 1.992(3) Å is certainly a

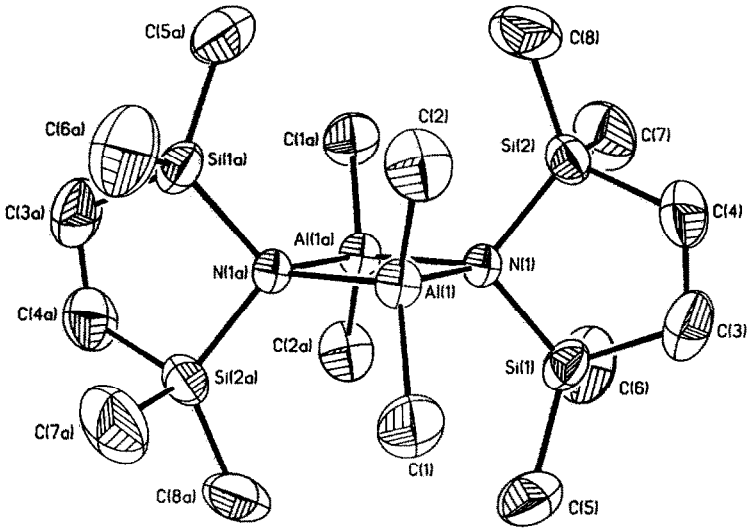

Fig. 1. A view of the $[Al(CH_3)_2]_2[C_{12}H_{32}N_2Si_4]$ (I) molecule showing the atom labelling scheme. Thermal ellipsoids show 50% probability levels; hydrogen atoms have been omitted.

result of less severe steric constraints than those found in **I**. The mean Al···Al contact of 2.813(1) Å in **II** is noticeably longer than the corresponding contact of 2.790(3) Å observed for **I**. It is also interesting that, regardless of the severity of the reaction conditions or the molar ratio of trimethylaluminium, the sila-hydrogen atoms remained inert with regard to reaction with the aluminium alkyl.

The literature reveals only a few studies concerning silazalanes. Based on cryoscopic molecular weight determinations, IR and NMR, Schmidbaur and Schmidt[9] reported the synthesis of $[(CH_3)_3SiNHAlCl_2]_2$ (**III**) and $[(CH_3)_3SiNHAl(CH_3)_2]_2$ (**IV**). These workers reported that **III** could be alkylated by methyllithium in a facile manner to provide **IV**. Both **III** and **IV** were predicted to contain Al_2N_2 four-membered rings. Even though **IV** has one remaining hydrogen atom on each nitrogen atom, condensation did not take place. More recently Sonnek *et al.*[10] reported the synthesis of some interesting Si—N—Al compounds.

The organoaluminium chemistry of silazalanes represents a potentially intriguing, and largely

unexplored, region of study. Future studies will continue to address the hydridic reactivity of the Si—H bond relative to organoaluminium moieties.

MULTIPLE BONDS BETWEEN MAIN GROUP ELEMENTS AND TRANSITION METALS—LXXXI.* CONDENSATION REACTIONS OF HIGH-VALENT PENTAMETHYLCYCLOPENTADIENYL RHENIUM COMPLEXES WITH THIOPHENOL AND DERIVATIVES: SYNTHETIC AND STRUCTURAL ASPECTS

JANOS TAKACS,† PAUL KIPROF and WOLFGANG A. HERRMANN‡

Anorganisch-chemisches Institut der Technischen Universität München, Lichtenbergstraße 4, D-8046 Garching (Germany)

(*Received* 12 *March* 1990; *accepted* 26 *April* 1990)

Abstract—The half-sandwich rhenium(VII) complex $(\eta^5\text{-}C_5Me_5)ReO_3$ (**1**; Me = CH_3) undergoes reduction with thiophenol giving the rhenium(V) condensation product $(\eta^5\text{-}C_5Me_5)Re(O)(SC_6H_5)_2$ (**2a**) in high yield. However, toluene-3,4-dithiol reacts only slowly with **1**, with traces of the fully substituted rhenium(V) species $(\eta^5\text{-}C_5Me_5)Re(1,2\text{-}S_2C_6H_3\text{-}4\text{-}CH_3)_2$ (**3a**) being formed. The related *N,S*-chelating ligand 2-aminothiophenol forms the amido derivative $(\eta^5\text{-}C_5Me_5)Re[1,2\text{-}S(HN)C_6H_4]_2$ (**3b**) in good yield. Compounds **3a** and **3b** are also accessible by two alternative routes: (i) from $(\eta^5\text{-}C_5Me_5)Re(O)Cl_2$ (**4**) and the corresponding thiols in the course of two-step substitution/condensation reactions via the intermediates $(\eta^5\text{-}C_5Me_5)Re(O)(1,2\text{-}S_2C_6H_3\text{-}4\text{-}CH_3)$ (**2b**) and $(\eta^5\text{-}C_5Me_5)Re(O)[1,2\text{-}S(HN)C_6H_4]$ (**2c**), respectively; (ii) from the tetrachloro complex $(\eta^5\text{-}C_5Me_5)ReCl_4$ (**5**) and two equivalents of the respective ligands. Employing a 1:1 stoichiometry, reaction of $(\eta^5\text{-}C_5Me_4Et)ReCl_4$ (**5′**; Et = C_2H_5) with 2-aminothiophenol yields the amidothiophenolato(*N,S*) complex of formula $(\eta^5\text{-}C_5Me_4Et)Re[1,2\text{-}S(HN)C_6H_4]Cl_2$ (**6′**). The solid-state structure of the bis(dithiolato)rhenium(V) complex **3a** was determined by means of X-ray diffraction techniques. The core geometry around the rhenium is almost perfectly square pyramidal, with the five-membered ring ligand occupying the apical position (centroid π-coordination), while the four sulphur atoms define the basal plane. The relatively short distances between the interligand sulphur atoms (297–301 pm) are compatible with possible bonding interactions, e.g. partial disulphide character.

High oxidation state half-sandwich organometallic compounds have received considerable attention in recent years. Thiolato transition metal complexes in medium to high oxidation states are also the focus of interest, not least because of their special relationship to biochemically relevant systems.[1,2] Finally, some emphasis on rhenium stems from the properties of the ^{186}Re and ^{188}Re isotopes that are candidates for certain radiopharmaceuticals for therapeutic applications.[3]

It was recently determined in our laboratory that condensation reactions of methyltrioxorhenium(VII), CH_3ReO_3, with catechols and similar *aromatic* bifunctional ligands of type HX···Y (X = O, S, Y = N, NH_2, OH) provide a convenient route to novel hexacoordinate *cis*-dioxo(methyl) rhenium derivatives of d^0 configuration.[4,5] In order to find out as to whether replacement of the σ-bonded methyl group in CH_3ReO_3 by the much bulkier pentamethylcyclopentadienyl π-ligand in $(\eta^5\text{-}C_5Me_5)ReO_3$ would entail a different reactivity pattern, $(\eta^5\text{-}C_5Me_5)ReO_3$ (**1**), $(\eta^5\text{-}C_5Me_5)Re(O)Cl_2$

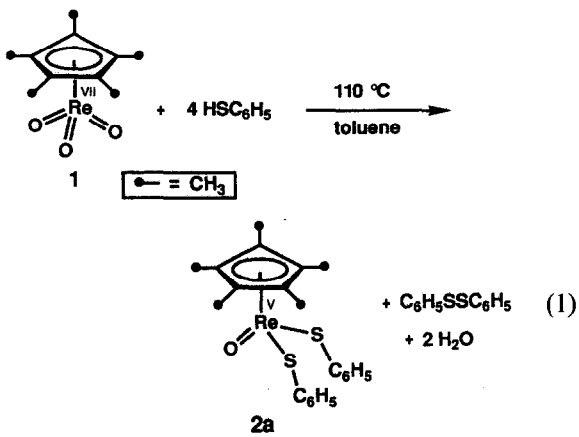
(**4**), $(\eta^5\text{-}C_5Me_5)ReCl_4$ (**5**) and $(\eta^5\text{-}C_5Me_4Et)ReCl_4$ (**5′**) were investigated in their reactions with mono- and bifunctional thiophenols. The synthetic results as well as the crystal structure of the bis (dithiolato) complex $(\eta^5\text{-}C_5Me_5)Re(1,2\text{-}S_2C_6H_3\text{-}4\text{-}CH_3)_2$ (**3a**) are reported in the present publication.

RESULTS AND DISCUSSION

(1) *Rhenium*(V) *complexes derived from aromatic thiols*

The reaction of $(\eta^5\text{-}C_5Me_5)ReO_3$ (**1**) with thiophenol is slow at room temperature as compared to the fast condensation reaction of this ligand with CH_3ReO_3.[6] Addition of mineral acids (that promote the protonation of the oxo ligand, presumed to be the first step in the condensation) or of 2,2-dimethoxypropane (as water scavenger) somewhat increase the rate but not sufficiently. However, temperatures around 110°C (boiling toluene) effect high-yield formation of the half-sandwich oxo complex of formula $(\eta^5\text{-}C_5Me_5)Re(O)(SC_6H_5)_2$ (**2a**) according to eq. (1). This compound is also formed from $(\eta^5\text{-}C_5Me_5)Re(O)Cl_2$ and thiophenolate,[7] but the new route reported here is more straightforward.

The process involves both *condensation* and *reduction* reactions as the heptavalent rhenium is reduced to oxidation state +V, with the thiol serving as reductant. Diphenyl disulphide [eq. (1)] was isolated and identified. Formation of the hypothetical rhenium(VII) condensation products such as $(\eta^5\text{-}C_5Me_5)Re(O)(SC_6H_5)_4$ (in analogy to the stable $CH_3Re(O)(SC_6H_5)_4$[6] formed from CH_3ReO_3) or $(\eta^5\text{-}C_5Me_5)Re(O)_2(SC_6H_5)_2$ does not occur. Due to the bulk of the pentamethylcyclopentadienyl and thiophenolate ligands, these complexes would sterically be more crowded than **2a**. Further condensation of **2a** to $(\eta^5\text{-}C_5Me_5)Re(SC_6H_5)_4$ was not observed even upon prolonged reflux with thiophenol.



(1)

(2) *Rhenium*(V) *complexes of toluene*-3,4-*dithiol*

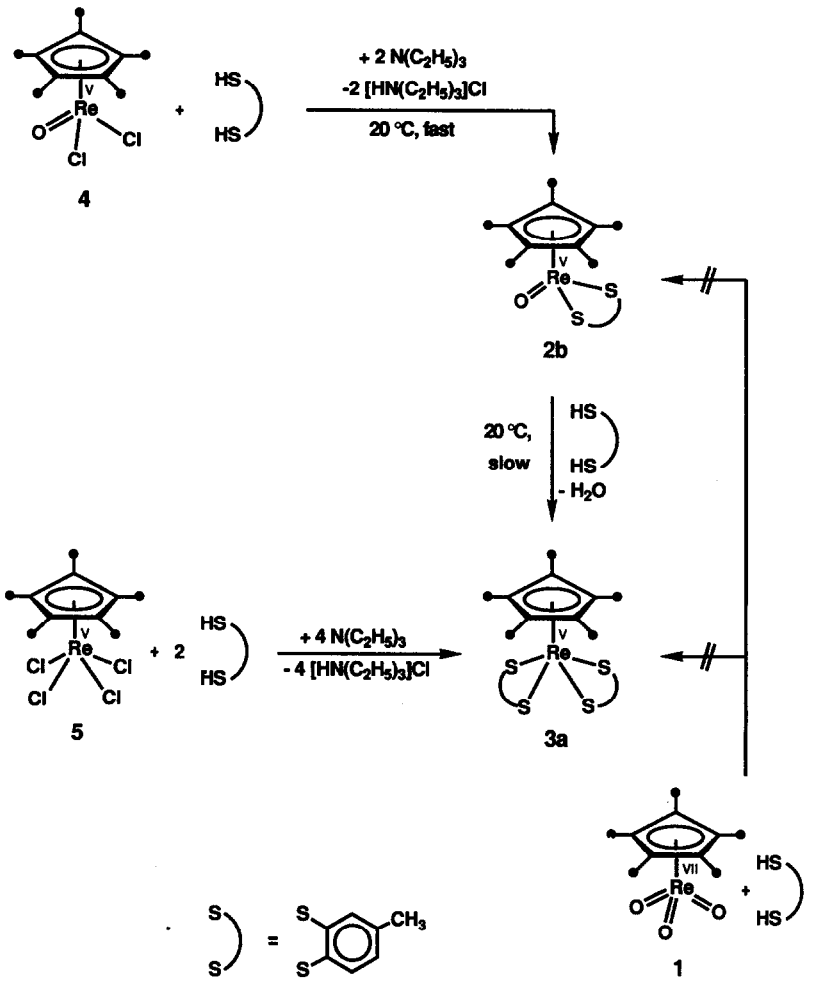
By way of contrast, reaction between **1** and toluene-3,4-dithiol under similar conditions is very slow. The starting compound **1** is recovered almost quantitatively after 2 h in refluxing toluene. This is surprising since both aromatic *mono-* and 1,2-*di*thiols react with CH_3ReO_3 cleanly with condensation.[6] This different reactivity is also puzzling, considering that the expected products $(\eta^5\text{-}C_5Me_5)Re(O)(1,2\text{-}S_2C_6H_3\text{-}4\text{-}CH_3)$ (**2b**) or $(\eta^5\text{-}C_5Me_5)Re(1,2\text{-}S_2C_6H_3\text{-}4\text{-}CH_3)_2$ (**3a**) are thermodynamically stable (*vide infra*). The difference in acidity of the dithiol does not impose a barrier on the condensation reaction (*vide infra*), and aromatic 1,2-dithiols are known to be stronger reductants than thiophenol.[8] On the other hand, they do not form simple disulphides but rather eight-membered $(C_2S_2S_2C_2)$ ring systems.

The above-mentioned monosubstituted rhenium (V) compound **2b** was synthesized from **4** and stoichiometric amounts of thiolate generated from thiol/triethylamine (Scheme 1). *Aliphatic* congeners of **2b,c** with *O,O*-, *O,S*-, *S,S*-, and *O,N*-chelating ligands have been reported from analogous reactions.[9] The substitution reaction shown in Scheme 1 is fast. If one employs an *excess* of dithiol, however, a subsequent slow condensation with high-yield formation of the reddish bis(dithiolato) derivative **3a** takes place.

(3) *Rhenium*(V) *complexes of* 2-*aminothiophenol*

Counting the oxo ligand as a two- or a four-electron donor, the half-sandwich rhenium(V) derivatives **2a,b** are formally *16e-* or *18e-*species, respectively. Although they did not form adducts with Lewis base amine ligands, it seemed interesting to study the reaction of **1** and **4** with the bifunctional ligand 2-aminophenol, since formation of a five-membered chelate ring with a N → Re dative bond or, more common in high oxidation state oxo complexes,[5,10] deprotonation of the amino group could not be excluded. If a toluene solution of **1** in the presence of an *excess* of 2-aminothiophenol is boiled under reflux, the colour quickly turns green. A dark green compound was isolated and characterized as the novel rhenium(V) complex **3b** of formula $(\eta^5\text{-}C_5Me_5)Re[1,2\text{-}S(HN)C_6H_4]_2$ (Scheme 2).

The same condensation product **3b** can be obtained in good yields at room temperature starting from **4** and *two equivalents* of 2-aminothiophenol in the presence of a base such as triethylamine to deprotonate the aminothiol (Scheme 2). Consecutive colour changes in this particular case

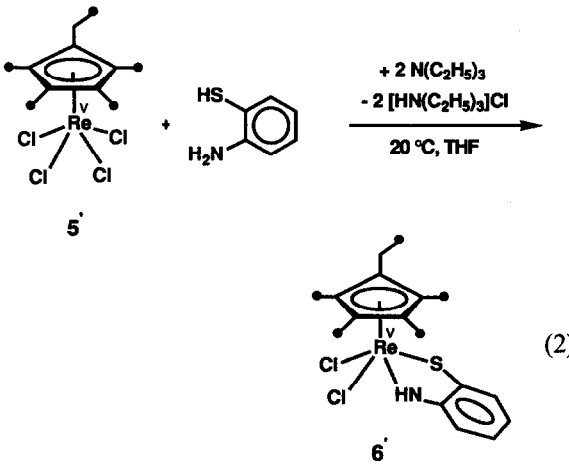


Scheme 1.

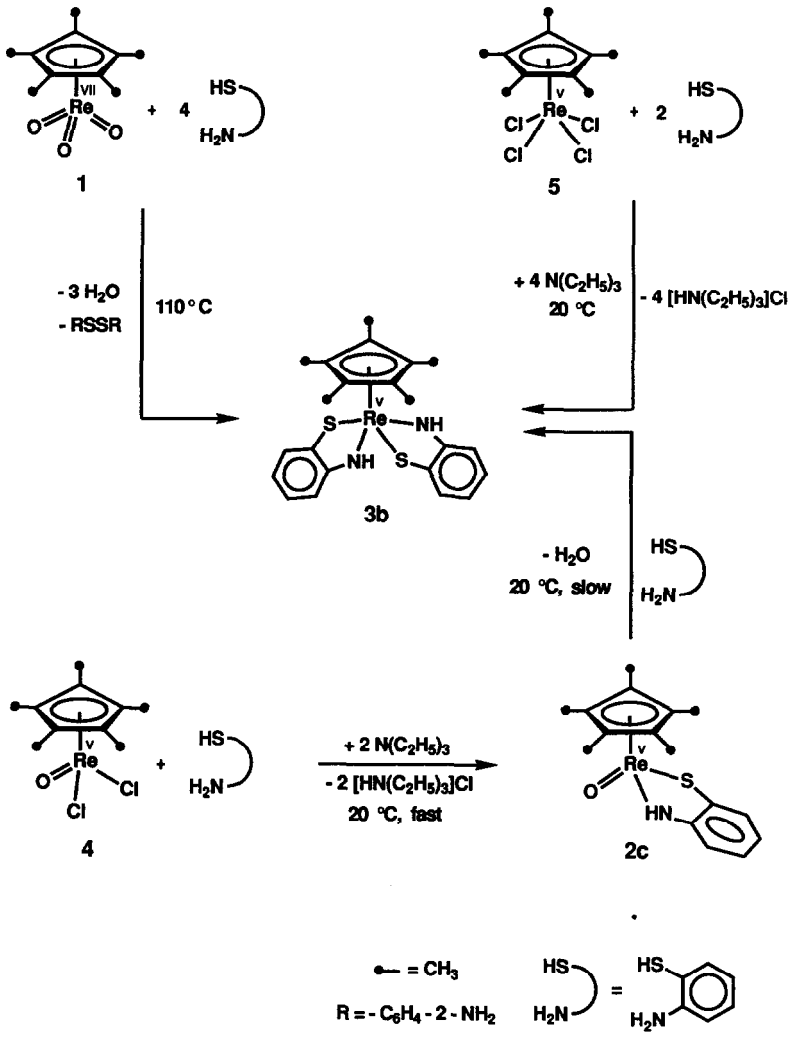
indicated that the formation of the fully substituted product **3b** proceeds in two steps: the first step is fast (HCl elimination), while the second step (condensation) is slow. The yellow intermediate **2c** of formula $(\eta^5\text{-}C_5Me_5)Re(O)[1,2\text{-}S(HN)C_6H_4]$ was isolated in high yields (Scheme 2).

Another convenient route to the bis(dithiolato-*S*,*S*) and bis(amidothiophenolato-*S*,*N*) compounds **3a** and **3b**, respectively, commences from the tetrachloro complex $(\eta^5\text{-}C_5Me_5)ReCl_4$ (**5**): treatment with two equivalents of toluene-3,4-dithiol and 2-aminothiophenol in the presence of a base according to Schemes 1 and 2, respectively, gives **3a** and **3b** in greater than 85% isolated yield.

A yellow complex, **6**, is formed when **5** and 2-aminothiophenol react in equimolar amounts. The formula $(\eta^5\text{-}C_5Me_5)ReCl_2[1,2\text{-}S(HN)C_6H_4]$ is tentatively assigned on the basis of the spectroscopic data. Complex **6** was also obtained by treatment of compound **2c** with chlorotrimethylsilane, a reagent widely used to replace an oxo ligand by two chloro ligands. However, the isolation of analytically pure **6** was rendered impossible due to its low solubility in organic solvents. In order to gain increased solubility, $(\eta^5\text{-}C_5Me_4Et)ReCl_4$ (**5'**) was used in a similar reaction, and the yellow dichloro complex of formula $(\eta^5\text{-}C_5Me_4Et)ReCl_2[1,2\text{-}S(HN)C_6H_4]$ (**6'**) was in fact isolated in high yields and analytically pure [eq. (2)].



(2)



Scheme 2.

Attempted synthesis of $(\eta^5\text{-}C_5Me_5)Re(SC_6H_5)_4$ starting from **5** and an excess of thiophenolate lead to an intractable, moisture-sensitive oil which yielded **2a** upon hydrolysis.

(4) *Spectroscopic data*

All new compounds are thermally stable, and the condensation products **2a**, **3a** and **3b** are stable against water. The ^{1}H NMR spectra of compounds **2c** and **3b** show that the amido protons resonate at 8.89 and 9.23 ppm, respectively. The chemical shifts of the NH protons in compounds **6** and **6′**, are 12.67 and 12.68 ppm, respectively. As an explanation of this strong low-field shift, one is tempted to invoke an interaction (hydrogen bridge) between the NH proton and the chloride ligands.

CRYSTAL AND MOLECULAR STRUCTURE OF THE BIS(DITHIOLATE) RHENIUM(V) COMPLEX (3a)

Due to the asymmetry in the ligand toluene-3,4-dithiol, the synthesis of **3a** (Scheme 1) gives rise to formation of *cis*- and *trans*-isomers. Crystallographic investigations of **3a** have shown that the crystal chosen for this study contained both isomers (Fig. 1). As a result, disorder of one methyl group in the 4-position [(C(57) and C(57′)] occurs. The disorder at only one side of the molecule may arise from packing effects. Both methyl groups [C(57) and C(57′)] were nevertheless refined with anisotropic displacement parameters and a site occupation factor of 0.5.

The core geometry around the rhenium atom can

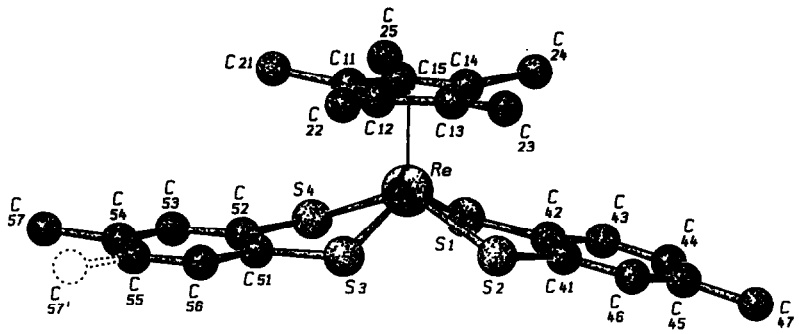


Fig. 1. SCHAKAL drawing of compound **3a**. Hydrogen atoms are omitted for clarity. The disordered methyl group C(57)′ is shown by dotted lines.

be described as square pyramidal, with the centre of the aromatic π-ligand located in the apical position and the four sulphur atoms forming the basal plane (Fig. 1). The rhenium atom lies 92 pm above this plane. All rhenium-to-sulphur distances are almost equal [231.8(1)–234.6(1) pm; Table 1] and are in the normal range for single bonds found in rhenium(V) thiolato complexes such as $[Re(O)(SR)_4]^-$ [11] and $[Re\{(SCH_2)_3CCH_3\}_2]^-$.[12] The angles S—Re—S′ are *all* close to 80°, and the sulphur–sulphur distances are almost the same within the ligands and between the two ligands, respectively. These distances cover the range between 298.5(3) and 307.4(3) pm (Table 1) so they hardly deviate from the data of the previously published bis(μ-sulphido) dinuclear compound $[(\eta^5\text{-}C_5Me_5)Re(O)(\mu\text{-}S)]_2$.[13] It is also remarkable that the sulphur contacts between two different ligands are significantly smaller [298.5(3) and 300.5(3) pm] as compared to the contacts of two sulphur atoms of the same ligand [305.4(3) and 307.4(3) pm]. For comparison, the sum of the van der Waals' radii is 360 pm; the S—S distance in the (monoclinic) elemental sulphur is 204 pm.[14] The relatively short interligand sulphur distances, e.g. the partial disulphide character of the toluene-3,4-dithiolate ligand is in our opinion due to both a repulsion effect of the sterically demanding C_5Me_5 ligand and an electronic effect originating from the oxidation state of the metal. Disulphide complexes M(RSSR) of transition metals are relatively rare as compared to the large number of thiolate compounds $M(SR)_2$.[15] Complexes with thiolate ligands showing *partial* disulphide character are usually found for the high metal oxidation states, examples being $[Re\{(SCH_2)_3CCH_3\}_2]^-$ [*d*(S—S): 283 pm[12]], $MoO_2[(R)_2NC(R)_2C(R)_2S]_2$ [*d*(S—S): 273–282 pm[16]], and/or have a sterically crowded environment around the metal atom such as in $(\eta^5\text{-}C_5H_5)_2Mo(SR)_2$.[17] *It is obvious that these two factors play an important role in the reductive elimination of organic disulphides from transition metal thiolato*

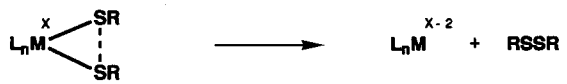
complexes according to eq. (3).



(3)

An interesting feature of the structure is the *folding* of the toluene-3,4-dithiolate ligands along the S—S axis by 22.6(2) and 36.5(1)° off planarity yielding the envelope form of the five-membered ring Re—S—C—C—S. The related rhenium(V) complex (η^5-C_5Me_5)Re(1,2-$O_2C_6Cl_4$)$_2$ contains practically *planar* catecholate ligands.[23] This difference may be attributed to the stronger π-donor properties of the oxygen atoms (catecholates have been shown to be good π-donor ligands) as compared to sulphur atoms, although packing effects as well as the inter-ligand sulphur–sulphur interaction may also effect the observed ligand folding. It seems likely that the difference in the folding angles of the two toluene-3,4-dithiolate ligands is the result of packing effects (Fig. 2).

CONCLUSIONS

Condensation reactions of the half-sandwich oxo rhenium(VII) complex (η^5-C_5Me_5)ReO_3 (**1**) with thiophenols proceed in a different manner than the analogous reactions of CH_3ReO_3. Reduction of the heptavalent rhenium to oxidation state V prevales, in spite of the fact that the electron-rich pentamethylcyclopentadienyl ligand is expected to make the rhenium less susceptible towards reduction as compared with CH_3ReO_3.* We believe that reduction is facilitated by the bulkiness of the pentamethylcyclopentadienyl ligand which prevents the accomodation of the same number of thiolate and oxo ligands at rhenium as in the case of $CH_3Re(O)(SR)_4$. This steric requirement could also induce the observed reductive elimination of disulphides [eq. (3)]. 1,2-Aminothiophenol leads to a similar deprotonation of the amine function as in the case of CH_3ReO_3; an amido group attached to rhenium thus forms. The crystal structure of the half-sandwich compound (η^5-C_5Me_5)Re(1,2-$S_2C_6H_3$-4-CH_3)$_2$ (**3a**) shows interaction between sulphur atoms of different toluene-3,4-dithiolate ligands, indicating some disulphide contribution to the overall structure. The chelate effect of the *S,S*-ligand is likely to prevent disulphide elimination in this particular case.

* Studies on the electrochemistry of CH_3ReO_3 and (η^5-C_5Me_5)ReO_3 support this view (W. A. Herrmann and R. Albach, unpublished results).

EXPERIMENTAL

All reactions were carried out in a dry nitrogen atmosphere employing conventional Schlenk techniques. The starting compounds **1**, **5**, **5′** and **4** were synthesized as described in the literature.[22] The thiols and 2-aminothiophenol were used as received from Aldrich Chemicals. The ^{1}H NMR spectra were recorded at 25°C and 400 MHz (JEOL JNM GX-400), electron-impact mass spectra at 70 eV (Finnigan MAT 311-A). The mass spectra are based on the ^{187}Re and ^{35}Cl isotopes (*m/z* values).

(1) *Synthesis of oxo(η^5-pentamethylcyclopentadienyl)bis(thiophenolato)rhenium*(V) (**2a**)

To **1** (73.8 mg, 0.2 mmol) in 10 cm^3 of toluene, thiophenol (81×10^{-3} cm^3, 0.8 mmol) was added.

The solution was refluxed for 2–3 h, then cooled down to room temperature. After filtration and concentration of the solution to 2–3 cm^3 *in vacuo*, n-hexane was added to precipitate the product as a yellowish-brown solid. Recrystallization from toluene–n-hexane at −30°C yielded analytically pure **2a**. Yield 79 mg (71%). Found (Calc.): C, 47.1 (47.5); H, 4.9 (4.5); Re, 33.3 (33.5); S, 11.3 (11.5)%.

IR (KBr; cm^{-1}): 923 vs [ν(Re═O)], 2962 m, 2915 m, 1577 s, 1465 s, 1381 s. ^1H NMR ($CDCl_3$; ppm): δ(C_5Me_5) 1.64 (s, 15H), δ(C_6H_5) 7.15–7.72 (m, 10H). EI–MS (*m/z*; rel. int. %): 556 ($[M]^+$), 447 ($[M-SC_6H_5]^+$, 65%), 370 ($[C_5Me_5ReOS]^+$, 100%).

(2) *Synthesis of oxo(η⁵-pentamethylcyclopentadienyl)(toluene-3,4-dithiolato-S,S′)rhenium*(V) (**2b**)

To **4** (81.6 mg, 0.2 mmol) dissolved in 10 cm^3 of toluene and 4 cm^3 of n-hexane, toluene-3,4-dithiol (26×10^{-3} cm^3, 0.2 mmol), and triethylamine (56×10^{-3} cm^3, 0.44 mmol) were added under vigorous stirring. The green solution turned yellow and triethylammonium chloride precipitated. After 3–4 min the solution was filtered through 2 cm of silylated silica (Merck No. 7719, 70–230 mesh), then the volume was reduced to 2–3 cm, and finally n-hexane was added. A yellowish-brown microcrystalline solid precipitated. The mother liquor was decanted and the product was washed twice with n-hexane and dried *in vacuo*. Recrystallization from toluene–n-hexane at −30°C afforded analytically pure **2b**. Yield 89 mg (90%). Found (Calc.): C, 41.8 (41.5); H, 4.1 (4.3)%.

IR (KBr; cm^{-1}): 920 sh, 912 s [ν(Re═O)], 2917 w, 1456 m, 1376 m, 1026 w, 808 s, 548 m. ^1H NMR ($CDCl_3$; ppm): δ(C_5Me_5) 2.04 (s, 15H); δ(1,2-$S_2C_6H_3$-4-CH_3) 2.35 (s, 3H); δ(5-$S_2C_6H_3CH_3$) 6.77 (d, 1H, $^3J = 7.7$ Hz); δ(3-$S_2C_6H_3CH_3$) 7.63 (s, 1H); δ(6-$S_2C_6H_3CH_3$) 7.70 (d, 1H, $^3J = 7.7$ Hz). EI–MS (*m/z*; rel. int. %): 492 ($[M]^+$, 100); 135 ($[C_{10}H_{15}]^+$, 10).

(3) *Synthesis of oxo(η⁵-pentamethylcyclopentadienyl)(1,2-amidothiophenolato-S,N)rhenium*(V) (**2c**)

A procedure similar to the synthesis of **2b** was used starting from **4** (81.6 mg, 0.2 mmol), 2-aminothiophenol (24×10^{-3} cm^3, 0.22 mmol) and triethylamine (61×10^{-3} cm^3, 0.44 mmol). Yield 72 mg (78%). Found (Calc.): C, 41.8 (41.7); H, 4.7 (4.4); N, 3.0 (3.0)%.

IR (KBr; cm^{-1}): 3321 m [ν(N—H)], 906 s [ν(Re═O)], 3055 w, 2920 w, 1467 m, 1444 m, 1376 m, 1297 m, 1022 w, 851 m, 754 s, 709 m. ^1H NMR ($CDCl_3$; ppm): δ(C_5Me_5) 1.98 (s, 15H); δ(HNC_6H_4S) 6.63–7.57 (m, 4H); δ(HNC_6H_4S) 8.89 (br, 1H). EI–MS (*m/z*; rel. int. %): 461 ($[M]^+$, 100).

(4) *Synthesis of (η⁵-pentamethylcyclopentadienyl) bis(toluene-3,4-dithiolato-S,S′)rhenium* (V) (**3a**)

Method (a), *from* **4**. To **4** (81.6 mg, 0.2 mmol) dissolved in toluene (8 cm^3), toluene-3,4-dithiol (58×10^{-3} cm^3, 0.44 mmol) and triethylamine (56×10^{-3} cm^3, 0.4 mmol) in 2 cm^3 methanol were added. The stirring was continued for 48 h at room temperature, then the dark brown–red precipitate was filtered, washed with small amounts of water and then cold methanol and finally dried *in vacuo*. Recrystallization from CH_2Cl_2–n-hexane at −30°C yielded 97 mg (89%) of **3a**.

Method (b), *from* **5**. A similar procedure as above starting from **5** (93 mg, 0.2 mmol) in toluene (5 cm^3), and toluene-3,4-dithiol (58×10^{-3} cm^3, 0.44 mmol) as well as triethylamine (122×10^{-3} cm^3, 0.88 mmol) in methanol (5 cm^3) yielded **3a** in 86% yield. Found (Calc.): C, 45.9 (45.8); H, 4.3 (4.3); Re, 29.9 (29.6)%.

IR (KBr; cm^{-1}): 2912 w, 1578 m, 1373 s, 1285 m, 1206 m, 1094 m, 1022 m, 813 sh, 798 s, 692 s, 545 m, 436 m. ^1H NMR ($CDCl_3$; ppm): δ(C_5Me_5) 1.71 (s, 15H), δ(1,2-$S_2C_6H_3$-4-CH_3) 2.34 (s, 6H), δ(5-$S_2C_6H_3CH_3$) 6.79 (d, 2H, $^3J = 7.9$ Hz), δ(3-$S_2C_6H_3CH_3$) 7.51 (S, 2H); δ(6-$S_2C_6H_3CH_3$) 7.57 (d, 2H, $^3J = 7.9$ Hz). EI–MS (*m/z*; rel. int. %): 630 ($[M]^+$, 100), 135 ($[C_{10}H_{15}]^+$, 33).

(5) *Synthesis of (η⁵-pentamethylcyclopentadienyl) bis(1,2-amidothiophenolato-S,N)rhenium* (**3b**)

Method (a), *from* **1**. To **1** (73.8 mg, 0.2 mmol) dissolved in toluene (10 cm^3), 2-aminothiophenol (86×10^{-3} cm^3, 0.8 mmol) was added and the mixture was refluxed for 1.5 h. After cooling to 25°C, the solution was filtered and concentrated to 3 cm^3 *in vacuo*. Upon addition of n-hexane (15 cm^3), an olive-green precipitate formed which was filtered and dried *in vacuo*. The product was recrystallized from THF–n-hexane at −30°C. The dark olive-green crystals contain 0.5 mol of the solvent THF per mol of **3b**. Yielded 91 mg (75%).

Method (**b**), *from* **4**. To **4** (81.6 mg, 0.2 mmol) dissolved in 10 cm^3 of toluene, 2-aminothiophenol (47×10^{-3} cm^3, 0.44 mmol) and triethylamine (70×10^{-3} cm^3, 0.5 mmol) were added under stirring. The colour turned yellow, while triethyl-

ammonium chloride precipitated. After *ca* 5–10 min, the colour slowly started to turn green. The stirring was continued for 3 days. The volatiles were then removed *in vacuo*. The residue was extracted with toluene, the green solution was filtered and concentrated to *ca* 2–3 cm^3. Upon addition of n-hexane, a green precipitate of **3b** formed which was recrystallized from THF–n-hexane at −30°C. Yield 96 mg (87%).

Method (**c**), *from* **5**. A procedure similar to (b) starting from **5** (93 mg, 0.2 mmol), 2-aminothiophenol (47×10^{-3} cm^3, 0.44 mmol) and triethylamine (140×10^{-3} cm^3, 1.0 mmol) yielded **3b** in 87% yielded. Found (Calc. for **3b** · 0.5 THF): C, 47.6 (47.7); H, 4.7 (4.8); N, 4.7 (4.6); Re, 30.6 (30.8)%.

IR (KBr; cm^{-1}): 3294 m [ν(N—H)], 3053 w, 2908 w, 1569 m, 1442 m, 1375 m, 1301 s, 1023 m, 746 s, 726 m, 704 m, 459 m, 436 m. ^1H NMR ($CDCl_3$; ppm): $\delta(C_5Me_5)$ 1.66 (s, 15H), $\delta(HNC_6H_4S)$ 6.64–7.47 (m, 8H); $\delta(HNC_6H_4S)$ 9.23 (br, 2H). EI–MS (*m/z*; rel. int. %): 568 ($[M]^+$, 90): 135 ($[C_5Me_5]^+$, 10); 124 ($[SC_6H_4NH_2]^+$, 100).

(6) *Synthesis of dichloro*(η^5-*tetramethylethylcyclopentadienyl*)(1,2-*amidothiophenolato*-S,N)*rhenium* (V) (**6′**)

To **5′** (119.2 mg, 0.25 mmol) dissolved in 20 cm^3 of THF, 2-aminothiophenol (27.0×10^{-3} cm^3, 0.25 mmol) and anhydrous sodium carbonate (1–2 g powder) were added under vigorous stirring. The colour immediately turned to intense yellow. After 5 min, the solution was filtered, and the Na_2CO_3 was washed with THF. The combined THF fractions were evaporated to dryness. The residue was taken up in methylenechloride and was filtered through silylated silica (*ca* 3 cm). The filtrate was then concentrated *in vacuo*. Upon addition of n-hexane, a bright yellow microcrystalline solid separated, which was filtered and washed with n-hexane. Recrystallization from methylenechloride–n-hexane yielded 104 mg (79%) of analytically pure **6′**. Found (Calc.): C, 38.0 (38.5); H, 4.2 (4.2); N, 2.6 (2.6); Re, 35.0 (35.2)%.

IR (KBr; cm^{-1}): 3224 s [ν(N—H)], 2965 m, 2927 m, 1477 m, 1454 m, 1376 m, 1263 w, 1031 m, 1019 m, 821 w, 761 s. ^1H NMR ($CDCl_3$; ppm): $\delta(C_5Me_4CH_2CH_3)$ 0.96 (t, 3H, $^3J = 7.4$ Hz); $\delta(C_5Me_4CH_2CH_3)$ 1.62 (q, 2H, $^3J = 7.4$ Hz); $\delta(C_5[CH_3]_4CH_2CH_3)$ 1.71, 1.74, 1.77, 1.81 (4S, 12H); δ(1,2-S(NH)C_6H_4) 7.14–7.93 (m, 4H); δ(1,2-S(N*H*)C_6H_4) 12.68 (br, 1H). EI–MS (*m/z*; rel. int. %): 529 ($[M]^+$, 2); 493 ($[M - HCl]^+$, 3); 125 ($[H_2NC_6H_4S]^+$, 100).

(7) *X-ray diffraction study of* (η^5-*pentamethylcyclopentadienyl*)*bis*(*toluene* - 3,4 - *dithiolato* - S,S′) *rhenium*(V) (**3a**)[18–21]

Details of the data collection and structure refinement are listed in Table 2. The data were collected on a CAD4 (Enraf–Nonius). All computations were carried out on VAX 8200 and VAX 11/730 computers with the computer programs SDP[18] and SCHAKAL,[19] in the STRUX-II[21] system. Scattering factors were taken from ref. 20.

(*Received* 27 *February* 1990; *accepted* 26 *April* 1990)

Abstract—A new scheme, which considers the sequential edge cleavage of ligand polyhedra, has been employed to explain the phenomenon of pseudorotation in simple homoleptic coordination complexes.

The stereochemical changes—fluxionality and isomerization—that many coordination compounds exhibit have become amongst the most widely studied phenomena in inorganic chemistry and although the mechanisms of some, for example, five- and six-coordination, may be simply explained, apart from simple ideas of diamond–square–diamond rearrangements no simple, coherent approach applicable to *all* examples appears to have evolved. In this paper we wish to discuss such an approach which we believe offers a unified view of these fascinating phenomena.

It is reasonable to claim that reactions in this category have become one of the most fascinating areas of study during the past decade. Although the phenomenon had been appreciated for some time the detailed examination of pseudorotation had to wait until the advent of a suitable analytical tool, and NMR proved ideal for this purpose. There were also early indications that X-ray analysis would provide support and complementary data for molecular rearrangements along well-defined pathways. In this case evidence derived for one molecular state (the solid) was initially employed to explain a phenomenon in another (solution). More recently magic-angle spinning (MAS) NMR spectrometry has been used to make detailed studies of molecular motions in the solid, and in an earlier communication, we commented[1] on the way in which information derived by this method could be used in conjunction with information from the X-ray experiment to explain motion in the solid. In this paper we shall examine possible complementary geometries for mononuclear coordination compounds ML_n and offer a new, more convenient method of understanding these phenomena.

MOLECULAR POLYHEDRA

Before we consider some of the problems associated with coordination geometry it is essential that we recall some of the more important aspects of polyhedral geometries. The most symmetric of all polyhedra are the regular polyhedra of Plato. These are the tetrahedron (a), the octahedron (b), the hexahedron (or cube) (c), the icosahedron (d), and the dodecahedron (e) which are illustrated in Fig. 1. These are the only convex polyhedra that are bound by identical regular polygonal faces in which all vertices are equivalent. Of these polyhedra only three, viz. the tetrahedron, the octahedron and the icosahedron, are fully triangulated and therefore stable. In contrast, the cube which has all square faces and 12 edges is unstable and will collapse (or contract) to the stable fully triangulated dodecahedron with 18 edges. Similarly, the dodecahedron

* Author to whom correspondence should be addressed.

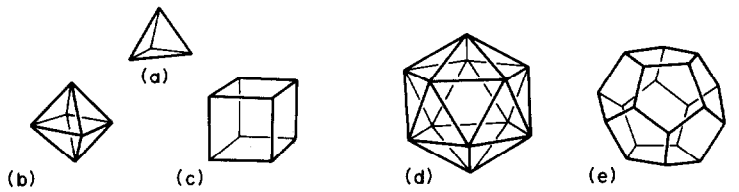

Fig. 1. The platonic solids.

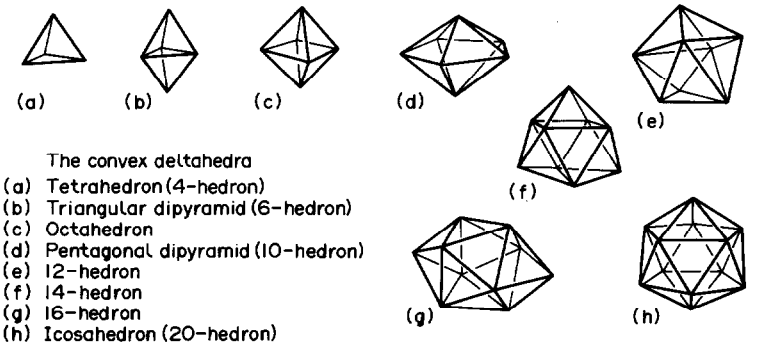

Fig. 2. Stable triangulated polyhedra.

with all pentagonal faces and 30 edges is also unstable and will collapse to the stable fully triangulated 36-hedron with 54 edges. Polyhedral stability does not therefore necessarily correlate with high symmetry. Rather, stability is associated with triangulation; the most stable polyhedra being those with all triangular faces. According to this view the most stable polyhedra for four- to 12-hedra are those given in Fig. 2. These are the polyhedra often observed in coordination chemistry and in the boranes and carboranes. We shall refer to them by their number of vertices, e.g. {4}, {5}, {6}, etc.

These polyhedra provide us with a prototypical array of geometric structures that reveals a useful and fascinating insight into chemical polyhedra. However, it is useful for our purposes to examine the relationship these polyhedra bear one to another. Consider the tetrahedron, {4}. Breakage of any one edge leads to a butterfly arrangement which, provided the extension is sufficiently large, corresponds to a trigonal bipyramid with one equatorial vertex removed—we shall therefore refer to this as {5−1}. Hence, if we cap this butterfly we produce the trigonal bipyramid {5} (see Fig. 3). Similarly, removal of one edge from the octahedron leads to the {7−1} polyhedron, and if we cap this polyhedral form the bicapped pentagonal bipyramid {7} (Fig. 4) will result. In the same vein we may progress from {7} through {8−1} to {8}, from {8} to {9−1} to {9}, and so on until we reach {10} (see Figs 3–5). If we consider these polyhedra to be

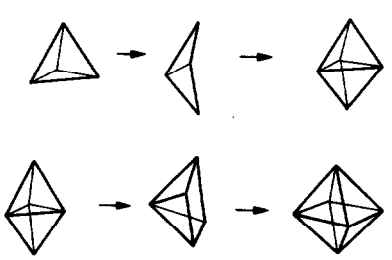

Fig. 3. Polyhedral growth sequence 1.

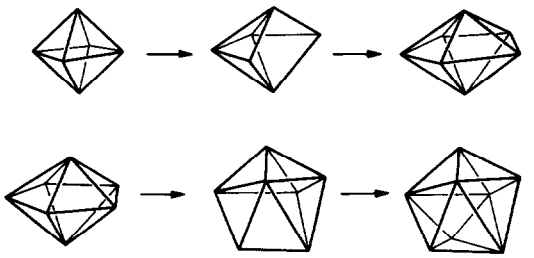

Fig. 4. Polyhedral growth sequence 2.

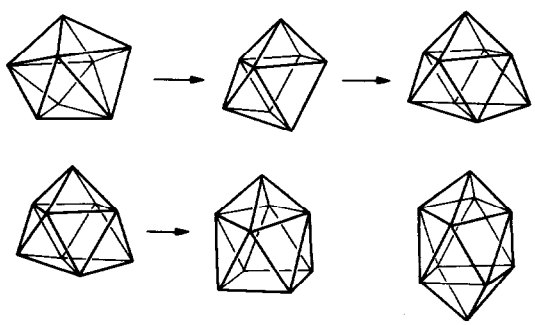

Fig. 5. Polyhedral growth sequence 3.

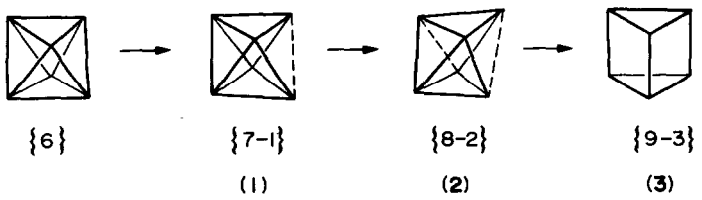

Fig. 6. Multi-edge cleavage for six-coordination.

constructed of equal spheres (or ligands) then progress from say {4} to {5−1} to {5} corresponds to an increase in size of the interstitial site. The site in the square-based pyramid, {6−1}, is larger than that in the trigonal bipyramid, {5}. For coordination polyhedra the same progression would require a steady and systematic increase in the metal–ligand bond lengths.

It is important to recognize that of the polyhedra given in Fig. 2 only the tetrahedron, the octahedron and the icosahedron are such that their vertices are constrained to lie on the surface of a sphere. Putting this in chemical terms, in coordination polyhedra all M—L bond lengths are equal only in these three arrangements in Fig. 2; all other polyhedra produce unequal bond lengths. For this reason alternative polyhedra for {5}, {7}, {8}, {9} and {10} in which all M—L bond lengths are equivalent have been sought. We shall not consider this aspect in detail but it is worth noting that a complete range of polyhedral forms in which the vertices lie on the surface of a sphere have been derived. Thus, if we consider eight-coordination the square antiprism {10−2} is an example of a polyhedron in which all M—L bonds are equal but which is not the most stable form. In coordination geometry we are frequently presented with the question of whether or not the coordination geometry approximates to one in which all L—L contacts are equal but the M—L bonds are not, or an alternative in which all M—L contacts are equal but longer. There is apparently no hard and fast answer to this question and examples of both occur.

It should also be noted that there is a discontinuity in this polyhedral growth sequence (Figs 3–5) at 11 and 12. According to the sequence developed above the polyhedron with 12 vertices corresponds to the omni-capped cuneane arrangement and not the icosahedron, although the two polyhedra are related by a simple edge transfer. The sequence of polyhedra for higher vertex numbers will be discussed in a subsequent paper.[2]

We shall consider now the effect of breaking two or more edges. Edge cleavage with retention of the maximum number of edges, will lead to the results shown in Fig. 6 for the octahedron, and in Fig. 7 for the triangulated dodecahedron. For {6}, the successive cleavage of appropriate edges leads first to {7−1}, then to {8−2}, and finally to {9−3}—the trigonal prism:

$$\{6\} \rightarrow \{7-1\} \rightarrow \{8-2\} \rightarrow \{9-3\}.$$

The corresponding treatment of {8} (Fig. 7) leads to the sequence:

$$\{8\} \rightarrow \{9-1\} \rightarrow \{10-2\} \rightarrow \{11-3\} \rightarrow \{12-4\} \rightarrow \{13-5\} \rightarrow \{14-6\}.$$

In this sequence, {9−1} is the bicapped trigonal prism, {10−2} the square antiprism and {14−6} the cube. There are no such simple names for the other members of this series.

For {9} we find:

$$\{9\} \rightarrow \{10-1\} \rightarrow \{11-2\} \rightarrow \{12-3\} \rightarrow \{13-4\} \rightarrow \{14-5\}$$

and for {10}:

$$\{10\} \rightarrow \{11-1\} \rightarrow \{12-2\} \rightarrow \{13-3\} \rightarrow \{14-4\}.$$

In each case the systematic and steady progression across the series leads to increasingly open polyhedra (i.e. with some square rather than all triangular faces) and a controlled increase in the M—L bond length. A decrease in stability will also follow the same progression. This will be important to our consideration of pseudorotation of coordination compounds.

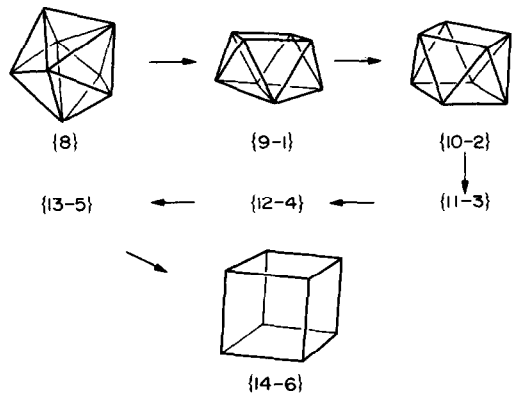

Fig. 7. Multi-edge cleavage for eight-coordination.

PSEUDOROTATION

The act of pseudorotation as it relates to simple coordination compounds ML_n requires that certain bond angles and bond distances in the parent compound change until the coordination shell of ligands, L, assumes its complementary geometry in what would constitute either the transition state or the intermediate. The ease with which these processes can occur will depend upon the energy difference between the complementary geometries (the ground state or the transition state) which constitutes the barrier to the process. These in turn depend on the relative movements of atoms or groups of atoms within the parent. When the complementary geometries are energetically close, either because of the nature of the ligands or because of the inherent properties of certain coordination numbers, the barrier to pseudorotation will be small. In many cases the barrier will be increased by the need of the system to traverse an intermediate in which the ligand distribution or unfavourable bond angles and/or unfavourable bond distances lead to instability. The best examples of pseudorotation and stereochemical non-rigidity will be found for those complexes in which the barrier between complementary geometries is significantly smaller than the free energy of activation for bond fission. The problem usually is on deciding upon the appropriate, accessible, complementary geometry.

For five-coordination the complementary geometries—the trigonal bipyramid, $\{5\}$, and the square pyramid, $\{6-1\}$, are energetically close to one another. Their relationship is clear to see. Expansion of one of the three *equatorial* edges of the trigonal bipyramid leads directly to the square pyramidal complementary geometry, and on further expansion along the same vector to the new trigonal bipyramid, $\{5\}'$ (Fig. 8). This expansion corresponds to a low energy or soft vibrational mode of the trigonal bipyramid and does not depend on excessive extension of the M—L bonds. As a consequence, the tendency to undergo pseudorotation via the Berry Twist Mechanism is quite considerable as is observed for $Fe(CO)_5$. This mechanism also provides an example of the simple, single diamond–square–diamond rearrangement process.

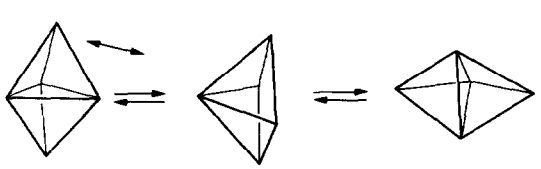

Fig. 8. Berry Pseudorotation Mechanism for five-coordination.

In contrast, the octahedron is stereochemically extremely rigid. According to the Bailar Twist Mechanism the most likely complementary geometry for pseudorotation is the trigonal prism and a trigonal twist of 60° about one of the octahedral three-fold axes will convert an octahedron into a trigonal prism and vice versa. The barrier to this pseudorotation is generally regarded as being similar to or greater than the activation energy for bond fission. The high barrier to pseudorotation in octahedral systems is thus easy to understand. First, it requires a considerable movement of ligands L, second, there is a significant decrease in the number of L—L contacts, finally, and most importantly, the conversion to the trigonal prismatic intermediate requires a substantial increase in the M—L bond lengths.

In the trigonal bipyramidal case we have an example of a relatively small movement of atoms or ligands leading to pseudorotation, and in the octahedron an example of a large movement leading to a relatively major reorganization of the molecular geometry. Clearly, the extent of these motions is dependent on the magnitude of the M—L bond strength (and to a much less extent on the L—L interactions), but most importantly on the physical state of the sample. First and foremost the complementary geometry must, obviously, be available by a low-energy procss corresponding to a soft normal mode of the molecule. Secondly, and very importantly, the route to the proposed complementary geometry must not involve any unreasonable extension of the M—L bond length. Finally, the process should sustain as many L—L contacts as possible. It is important to recognize that although two polyhedra may be easily converted one to another, the need to maintain reasonable M—L bond distances throughout the process is of paramount importance. It is also clear that, given the different constraints imposed on the molecule in either the solid or solution, barriers will vary widely from phase to phase.

In the past it has proved to be relatively more difficult to derive satisfactory complementary geometries for coordination numbers other than four, five and six. For larger coordination numbers, e.g. seven or eight, the availability of several closely related polyhedral forms has usually been taken as sufficient to explain the generally observed low barriers to fluxionality and no general scheme appears to exist. In this paper we wish to present such a general scheme which we believe offers a convenient approach to these fascinating phenomena and permits a simple view of suitable complementary geometries.

As we described above for five-coordination the

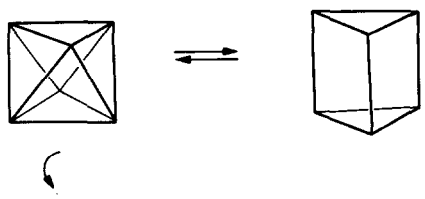

Fig. 9. Bailar Twist Mechanism.

complementary geometries—the trigonal bipyramid, {5}, and the square pyramid, {6−1}, are energetically close to one another, and so the essential, low-energy pseudorotation process may be viewed as involving two steps:

$$\{5\} \rightarrow \{6-1\} \rightarrow \{5\}'.$$

Of course we must not forget that there are three, equivalent, equatorial edges within the trigonal bipyramid and that the soft mode under consideration will lead to cleavage of any one of them. Hence, at any given moment three "different" {6−1} polyhedra may be produced from a given sample of ML_5 in the ground state, although of course for a homoleptic ML_5 complex they are indistinguishable.

For the octahedron which is stereochemically extremely rigid, the Bailar Twist is usually considered to occur in a one-step process as outlined in Fig. 9. However, here we will choose, for convenience, to consider the process as occurring in three distinct steps according to Fig. 6. Cleavage of one octahedral edge, which corresponds to a soft vibrational mode, generates intermediate (1), of two edges intermediate (2) and of three edges intermediate (3). Examination of these three species (1), (2) and (3) reveals that (1) corresponds to a *nido*-pentadonal bipyramid, {7−1}; that (2) corresponds to an *arachno*-dodecahedron, {8−2}; and finally (3) to a *hypho*-tricapped trigonal prism, {9−3}. Thus, the Bailar Twist Mechanism *could be viewed* as a six-step process:

$$\{6\} \rightarrow \{7-1\} \rightarrow \{8-2\} \rightarrow \{9-3\} \rightarrow \{8-2\}' \rightarrow \{7-1\}' \rightarrow \{6\}'.$$

The high barrier to pseudorotation in octahedral systems is thus more easily understood. It is interesting to observe that the formation of {7−1} from {6} corresponds to an opening of one polyhedral edge and is closely related to the process {5} → {6−1}. Hence, the energies for the two processes might be expected to be similar. However, the intermediate {7−1} does not collapse to a new {6} and ligand exchange does occur. It is also worth noting that any compound possessing a {7−1} geometry might be expected to show a lower barrier to interconversion since it has only two steps to the {9−3} complementary geometry. This is found to be the case for XeF_6. In this case rearrangement presumably occurs via the reaction sequence:

$$\{7-1\} \rightarrow \{8-2\} \rightarrow \{9\} \rightarrow \{8-2\}' \rightarrow \{7-1\}'.$$

This illustrates what we believe to be a general phenomenon, viz. pseudorotation always proceeds via polyhedral expansion, i.e. M—L stretching. Thus, for a compound with a square pyramidal, {6−1}, ground state, pseudorotation is expected to take place via a {7−2} intermediate and for a compound with a {9−1} ground state through a {10−2} intermediate, etc.

For seven-coordination there is no single-step suitable, complementary geometry available. Single edge cleavage, as illustrated in Fig. 4, will lead to a *nido*-dodecahedron {7−1} which cannot serve as a complementary geometry since operation of the diamond–square–diamond process in this instance will not return us to the parent polyhedral form {7}. Instead the capped-octahedron will be produced. This may be regarded as unfavourable for a homoleptic ML_7 complex since one M—L bond (viz. that involving a bond to the capping ligand) is required to undergo a relatively large extension. A further edge cleavage is required to give the more favourable *arachno*-tricapped trigonal prism, {9−2}, which can serve as an appropriate complementary geometry. Hence, ligand rearrangement in this case may be viewed as the five-step process:

$$\{7\} \rightarrow \{8-1\} \rightarrow \{9-2\} \rightarrow \{8-1\}' \rightarrow \{7\}'.$$

Again the edge cleavage corresponds to a soft vibrational mode, and it is important to remember that although we are *choosing* to consider the process as occurring in two independent steps it will in reality occur in one concerted motion. This may be visualized as taking place via the simultaneous opening of two edges (joining two vertices of connectivity four and five, and there are 10 such edges).

For eight-coordination we have a situation similar to that found for coordination number five. The parent polyhedron is the dodecahedron {8}. Single edge cleavage takes us to the bicapped trigonal prism or {9−1} which can clearly serve as a suitable complementary geometry since further extension along the same vector leads to a new dodecahedron {8}'. In this case, therefore, the rearrangement process may be viewed as:

$$\{8\} \rightarrow \{9-1\} \rightarrow \{8\}'.$$

Coordination number nine is somewhat similar. Here again single edge cleavage leads us directly to a suitable complementary geometry, in this instance

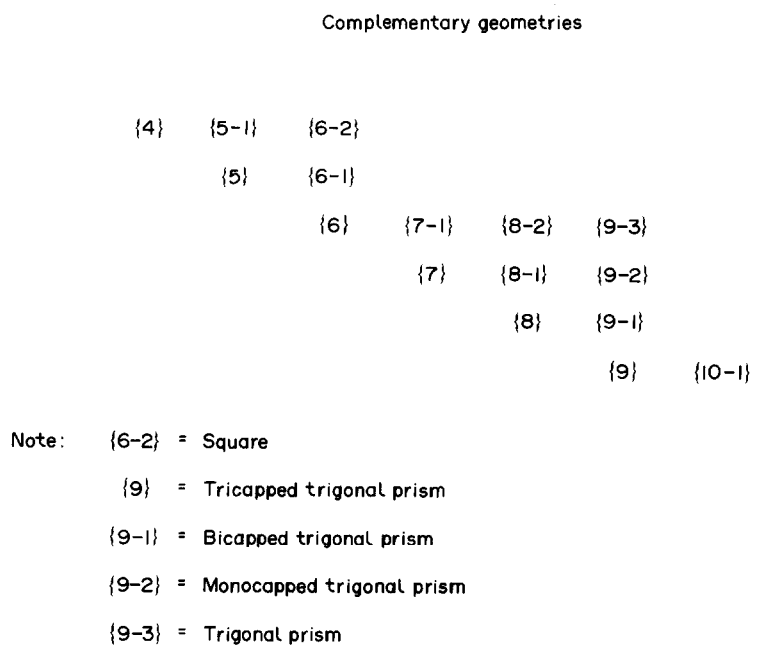

Fig. 10. General scheme for pseudorotation.

a *nido*-bicapped square antiprism—{10−1} (Fig. 5) and pseudorotation may occur via the process:

$$\{9\} \rightarrow \{10-1\} \rightarrow \{9\}'.$$

The general scheme shown in Fig. 10 for pseudorotation in coordination compounds thus emerges. It may be extended to higher (> 9) or lower (< 5) coordination numbers although care must be exercised when dealing with numbers > 11. This aspect will be the subject of a further publication.[2]

CONCLUSIONS

We have shown that the observed or postulated pseudorotation in simple coordination compounds may be understood in terms of a simple, polyhedral edge cleavage mechanism. The main advantage of this mechanism is the ease with which the complementary geometries for a range of coordination numbers may be derived and the wide range of energy barriers to rearrangement processes understood. Of particular importance is the need to limit the extent of M—L bond extension and sustain as many as possible L—L contacts.

(*Received* 14 *March* 1990; *accepted* 26 *April* 1990)

Abstract—Reaction of (4,7-diazadecane-1,10-diamine)copper(II) or (3,6-diazaoctane-1,8-diamine)nickel(II) ions in alcoholic base with formaldehyde and a variety of carbon acids with nitro-substituents has been studied. The R—CH_2—NO_2 carbon acids 1-nitrododecane, 12-nitrododecanoic acid, 3-nitropropanoic acid, tetrahydro-2-(2′-nitroethoxy)-2H-pyran and nitromethane undergo facile Mannich-type reactions to yield new pendant-arm macrocycles with a —NH—CH_2—C(R)NO_2—CH_2—NH— link built between the two primary amines of the precursor compound. In the case of nitromethane, R in the major product is —CH_2—OH rather than —H, due to further condensation of the residual acidic proton with formaldehyde; otherwise, R is the expected substituent carried through from reaction of the R—CH_2—NO_2 unit. Zinc/acid reduction of the copper(II) complex of the long-chain pendant macrocycle formed by condensation involving 12-nitrododecanoic acid permitted isolation of 1,4,8,12-cyclopentadecane-10-amine-10-undecanoic acid as the hydrochloride salt.

Reaction of copper(II) or nickel(II) complexes of polyamines which contain *cis*-disposed primary amines with formaldehyde and the carbon acid nitroethane have been shown to produce new substituted macrocycles in a facile reaction, eq. (1).[1–4] The generality of this type of reaction for nitro-carbon acids has not been investigated, with only nitropropane employed in addition to nitroethane previously.[4] We are aware that other types of carbon acids except nitro-carbon acids may be employed; for example, diethyl malonate reacts to yield a carboxylate-substituted macrocycle, but often with substantially lower yield.[5] Factors which influence the Mannich-type condensation reaction with formaldehyde and a carbon acid around the metal template are not fully understood, hence it was of interest to see how reaction with a range of nitro-substituted molecules which are strong carbon acids would proceed. The synthesis and characterization of a number of new pendant-arm macrocycles as the copper(II) or nickel(II) complexes are reported herein.

EXPERIMENTAL

Syntheses

Commercial samples of all precursor organic compounds were employed generally, as supplied. Analytical reagent grade metal salts were used as supplied, as well as laboratory reagent grade organic solvents.

(10-(Ethanoic acid)-10-nitro-1,4,8,12-tetraazacyclopentadecane)copper(II) perchlorate hydrate, [Cu(1)]$(ClO_4)_2 \cdot H_2O$

To a solution of copper(II) nitrate trihydrate (3.65 g) in methanol (200 cm^3) was added 4,7-diaz-

* Author to whom correspondence should be addressed.

adecane-1,10-diamine (2.75 g) in methanol (40 cm^3) and triethylamine (6 cm^3), and the solution was warmed. To the warm solution was added 3-nitropropionic acid (2.1 g) and formaldehyde (6 cm^3, 36% aq.), and the solution was heated and stirred at *ca* 60°C for 2 h, then stirred at room temperature overnight. The reaction was quenched with acetic acid and allowed to stand for 2 days. A blue solid formed and was collected, redissolved in water, treated with *ca* 10 cm^3 of 5 M $HClO_4$ and set aside to crystallize. Slow evaporation produced crystals, which were collected, washed with ethanol and then diethyl ether, and air dried (3.5 g).

Chromatography of the initial filtrate on SP-Sephadex C-25 resin using 0.2 M $NaClO_4$ as eluate separated a blue–purple band of the required product from small amounts of precursor complex and other products; however, only a small additional amount of the required product was isolated from this procedure, and minor bands did not contain sufficient compound to yield solid products for identification. Found: C, 25.9; H, 5.05; N, 11.5. Calc. for $C_{13}H_{27}Cl_2CuN_5O_{12}\cdot H_2O$: C, 26.1; H, 4.9; N, 11.7%. Electronic spectrum (water): λ_{max} 569 nm (ε 93 M^{-1} cm^{-1}). IR spectrum (KBr disc): 1588 cm^{-1} (—COO^-), 1545, 1350 cm^{-1} (—NO_2).

(12-(*Ethanoic acid*)-12-*nitro*-1,4,7,10-*tetraazacyclotridecane*)*nickel*(II) *perchlorate dihydrate ethanolate*, [Ni(**1A**)]$(ClO_4)_2\cdot 2H_2O\cdot C_2H_5OH$

To a warm solution of nickel(II) perchlorate hexahydrate (3.05 g, 8.3 mmol) in methanol (70 cm^3) was added dropwise a solution of 3,6-diazaoctane-1,8-diamine (1.2 g, 8.2 mmol) in methanol (*ca* 5 cm^3). The initial flocculent precipitate redissolved to give a deep green solution and a purple gum. Formaldehyde (3 cm^3, 36% aq., 36 mmol), 2-nitropropanoic acid (1.1 g, 9 mmol) and triethylamine (0.5 cm^3) were added and the mixture was heated and stirred for 4 h. Filtration gave a green fluffy solid (5 g). This was treated with conc. HCl and the green soluble material discarded. The residual yellow gum was again washed with HCl, then ethanol and diethyl ether, to give a yellow granular solid (3.5 g). This could be purified if required by chromatography on SP-Sephadex C-25 resin as above, and crystallized from water–ethanol. Found: C, 24.5; H, 5.2; N, 10.8. Calc. for $C_{11}H_{23}Cl_2CuN_5O_{12}\cdot 2H_2O\cdot C_2H_5OH$: C, 24.8; H, 5.3; N, 11.1%. Electronic spectrum (water): λ_{max} 365 nm (sh, ε 45 M^{-1} cm^{-1}). IR spectrum (KBr disc): 1730 cm^{-1} (—COOH), 1560, 1355 cm^{-1} (—NO_2). ^{13}C NMR spectrum (D_2O): δ 20.0 (CH_3CH_2OH), 38.0 (—CH_2—COOH), 46.1, 46.3, 47.5, 52.0 (—CH_2—NH), 60.0 (CH_3CH_2OH), 93.0, (C—NO_2), 174.0 (—COOH).

(10-*Nitro*-10-*undecyl*-1,4,8,12-*tetraazacyclopentadecane*)*copper*(II) *perchlorate ethanolate*, [Cu(**2**)]$(ClO_4)_2\cdot C_2H_5OH$

To a solution of copper(II) nitrate (3.7 g, 15.3 mmol) in methanol (80 cm^3) was added 4,7-diazadecane-1,10-diamine (2.7 g, 15.5 mmol), triethylamine (1 cm^3), 1-nitrododecane (3 g, 14 mmol) and aqueous formaldehyde (3 cm^3, 36 mmol). The mixture was stirred and warmed for 3 h, then filtered through Celite and sorbed onto a column of SP-Sephadex C-25 resin (6 × 3.5 cm). Elution with 0.2 M aqueous $NaClO_4$ removed some unreacted precursor complex, then elution with 0.2 M $NaClO_4$ as a 50% propanol solution removed an intense blue band. This separated into two layers on concentration on a rotary evaporator. The blue oil was washed well with water then taken up in methanol and evaporated to dryness. The residual gum (4 g) solidified on standing in the refrigerator. Trituration with ethanol–ether gave the product as a fine pearly blue solid. Found: C, 40.1; H, 7.3; N, 9.7. Calc. for $C_{22}H_{47}Cl_2CuN_5O_{10}\cdot C_2H_5OH$: C, 39.9; H, 7.4; N, 9.7%. Electronic spectrum (1:1 ethanol–water): λ_{max} 572 nm (ε 148 M^{-1} cm^{-1}), 268 (ε 9600). IR spectrum (KBr disc): 1550, 1350 cm^{-1} (—NO_2), 1470 cm^{-1} (—CH_2—).

Reduction of the nitro group to a pendant amino group can be achieved conveniently, and recomplexation to copper(II) performed. Dissolution of the above complex (*ca* 1 g) in aqueous methanol (75%, 200 cm^3) and addition of a half-volume of 1 M HCl and zinc powder (*ca* 4 g) afford reduction of the nitro group and the metal ion. The warmed solution was reacted until a colourless solution was obtained, then it was filtered through cellulose to remove excess zinc and copper, and excess copper(II) nitrate trihydrate was added, and the pH adjusted to *ca* 7 with 1 M NaOH. Filtration removed metal hydroxides, after which the filtrate was diluted with 1:1 EtOH–H_2O to *ca* 600 cm^3 and sorbed onto a column (25 × 3.5 cm) of SP-Sephadex C-25 resin, and the complex eluted with 0.2 M $NaClO_4$. Following reduction by rotary evaporation, a blue powder precipitated on standing, and was collected, washed with acetone, then diethyl ether, and air dried (0.3 g, 30%). Addition of ethanol and diethyl ether produced a second crop. The product analysed as the ethanol solvate of the protonated pendant amine complex. Found: C, 31.8; H, 5.8; N, 7.8. Calc. for $C_{24}H_{55}Cl_4CuN_5NaO_{17}$: C, 31.55; H, 6.05; N, 7.65%. Electronic

spectrum (MeOH): λ_{max} 585 nm (ε 112 M^{-1} cm^{-1}), 271 (2800). IR Spectrum (KBr disc): 2923 , 1465 cm^{-1} (—CH_2—), 1635 cm^{-1} (—NH_3^+).

(10-*Nitro*-10-(11′-*undecanoic acid*)-1,4,8,12-*tetraazacyclopentadecane*)*copper*(II) *perchlorate*, [Cu(**3**)]$(ClO_4)_2$

A methanolic solution (40 cm^3) of copper(II) nitrate trihydrate (0.4 g) and 4,7-diazadecane-1,10-diamine (0.3 g) was stirred, warmed (*ca* 40°C) and triethylamine (0.3 g), 1-nitrododecanoic acid (1.0 g) added, followed by aqueous formaldehyde (37%; 1 cm^3) added dropwise. After stirring for 1 h, the solution was stirred at room temperature overnight. The solution was made just acid with 1 M HCl, filtered, diluted with 1 : 1 ethanol–water (400 cm^3), and sorbed onto a column of SP-Sephadex C-25 resin. Following washing with 1 : 1 ethanol–water (200 cm^3), elution was performed with 0.2 M $NaClO_4$ in 1 : 1 ethanol–water, yielding a single purple band. Following concentration on a rotary evaporator, blue crystals formed on standing. These were collected, washed with ethanol, then diethyl ether, and dried (0.45 g, 35%). Further crops formed on extended standing. Found: C, 36.5; H, 6.5; N, 9.7. Calc. for $C_{22}H_{47}Cl_2CuN_5O_{13}$: C, 36.5; H, 6.5; N, 9.7%. Electronic spectrum (1 : 1 EtOH–H_2O): λ_{max} 572 nm (ε 110 M^{-1} cm^{-1}), 268 (ε 7800). IR spectrum (KBr disc): 2930, 2855 cm^{-1} (—CH_2—), 1720 cm^{-1} (—COOH), 1547, 1350 cm^{-1} (—NO_2).

(12-*Nitro*-12(11′-*undecanoic acid*)-1,4,7,10-*tetraazacyclotridecane*)*nickel*(II) *chloride dihydrate diethanolate*, [Ni(**3A**)]$Cl_2 \cdot 2H_2O \cdot 2C_2H_5OH$

A methanolic solution (*ca* 10 cm^3) of 3,6-diazaoctane-1,8-diamine (1.2 g, 8.2 mmol) was added dropwise to a warm solution of nickel(II) perchlorate hexahydrate (3.0 g, 8.2 mmol) in methanol (70 cm^3), to give a green solution and purple gum. Aqueous formaldehyde (3 cm^3, 36%, 39 mmol), 12-nitrododecanoic acid (1.8 g, 7.3 mmol) and triethylamine (1 cm^3) were then added. The mixture was warmed and stirred for 3 h, then filtered to give a pale green powder. This material was triturated with 1 M HCl to give a yellow gum. The gum was ground under ethanol–diethyl ether and dried to give a hygroscopic yellow granular powder (2.2 g, 50%). Found: C, 43.2; H, 9.0; N, 10.6. Calc. for $C_{20}H_{41}Cl_2N_5NiO_4 \cdot 2H_2O \cdot 2C_2H_5OH$: C, 42.8; H, 8.5; N, 10.4%. Electronic spectrum (water): λ_{max} 345 nm (sh, ε 750). ^{13}C NMR (D_2O–dioxan): δ 25.4, 29.7, 34.7, 36.2 (acid side-chain; cf. free acid), 44.1, 45.2 (—*C*—NH—), 73.3 (*C*—NO_2), 165.4 (—COOH); 14.5, 61.3 (EtOH). IR spectrum (KBr disc): 1738 cm^{-1} (—COOH), 1553, 1368 cm^{-1} (—NO_2), 1470 cm^{-1} (—CH_2—).

(10-*Nitro*-10-(2″-*tetrahydropyranyl*-2′-*oxaethyl*)-1,4,8,12-*tetraazacyclopentadecane*)*copper*(II) *perchlorate hydrate*, [Cu(**4**)]$(ClO_4)_2 \cdot H_2O$

A methanolic solution (70 cm^3) of copper(II) nitrate trihydrate (1.4 g, 5.8 mmol), 4,7-diazadecane-1,10-diamine (1.0 g, 5.7 mmol), formaldehyde (2 cm^3 of 36% aq., 25 mmol), triethylamine (1 cm^3) and tetrahydro-2-(2′-nitroethoxy)-2H-pyran (1.0 g, 5.7 mmol) was stirred at room temperature overnight, then heated for 2 h. The solution was diluted with water and adsorbed on to a column of SP-Sephadex C-25 resin. Elution with 0.2 M $NaClO_4$ gave one blue band which was acid stable and hence macrocyclic. On standing, this deposited blue crystals of the product (0.4 g, 10%). Found: C, 31.3; H, 5.6; N, 10.8. Calc. for $C_{17}H_{35}Cl_2CuN_5O_{12} \cdot H_2O$: C, 31.2; H, 5.7; N, 10.7%. Electronic spectrum (water): λ_{max} 568 nm (ε 116 M^{-1} cm^{-1}), 380 (sh, ε 120), 267 (ε 7900). IR spectrum (KBr disc): 1555, 1355 cm^{-1} (—NO_2).

(10-*Nitro*-10-(*hydroxymethyl*)-1,4,8,12-*tetraazacyclopentadecane*)*copper*(II) *perchlorate*, [Cu(**5**)]$(ClO_4)_2$

A solution of 4,7-diazadecane-1,10-diamine (1.0 g) and copper(II) nitrate trihydrate (1.3 g) in methanol (70 cm^3) was warmed and triethylamine (0.64 g), nitromethane (0.86 g) and aqueous formaldehyde (37%; 3 cm^3) were added. The mixture was warmed at *ca* 50°C for 1 h, and then allowed to cool to room temperature. Following dilution with water (500 cm^3) and acidification to pH 5, the mixture was sorbed onto a column of SP-Sephadex C-25 resin (20 × 3.5 cm) and eluted with aqueous $NaClO_4$ (0.2–0.4 M). Following removal of unreacted complexed tetraamine, the major band containing a macrocyclic species was removed, followed by two other minor bands whose identity was not elucidated fully. The major macrocyclic product was concentrated on a rotary evaporator and yielded fine purple crystals on standing. These were collected, washed with ethanol and air dried; they analysed with a molecule of $NaClO_4$ present. Found: C, 21.5; H, 4.1; N, 10.4. Calc. for $C_{12}H_{27}Cl_3CuN_5NaO_{15}$: C, 21.4; H, 4.05; N, 10.4%. Electronic spectrum (water): λ_{max} 572 nm (ε 96 M^{-1} cm^{-1}), 265 (ε 8000). IR Spectrum (KBr

disc): 3415 cm^{-1} (—OH), 1560, 1355 cm^{-1} ($—NO_2$).

1,4,8,12-*Tetraazacyclopentadecane*-10-*amine*-10-(11′-*undecanoic acid*) *pentahydrochloride hydrate ethanolate*, (**6**)·5HCl·H_2O·C_2H_5OH

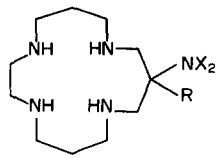
To a solution of [Cu(**3**)]$(ClO_4)_2$ (1 g) in 1 : 1 ethanol–water (100 cm^3) was added Zn(Hg) prepared from 4 g of zinc shavings. The mixture was heated and stirred for 40 min, then filtered through Kieselguhr to give a clear, colourless solution. This was concentrated to a small volume on a rotary evaporator, diluted with ethanol (*ca* 200 cm^3) and treated with concentrated HCl (*ca* 10 cm^3) to produce a white precipitate which was collected, washed with ethanol and diethyl ether, and dried (0.4 g). Found: C, 43.4; H, 9.2; N, 10.5. Calc. for $C_{22}H_{47}N_5O_2$·5HCl·H_2O·C_2H_5OH: C, 43.7; H, 9.2; N, 10.6%. IR spectrum (KBr disc): 1724 cm^{-1} (—COOH), 1602 cm^{-1} (br, amine). ^{13}C NMR (D_2O): δ 25.0, 26.1, 27.1 (—N—C—*C*—C—N—, —*C*—C—COOH, —C(NH_2)—C—*C*—), 31.3–31.3 (overlapping peaks, side chain —C—*C*—C), 36.7, 38.9 (—*C*—COOH, —C(NH_2)—*C*—C—), 42.2, 45.6, 47.6 (—*C*—NH—), 177.6 (—COOH), (tert. C not observed); 17.0, 57.0 (EtOH). Addition of ether to the filtrate from the above isolation yielded a further precipitate (0.34 g), with microanalysis and spectroscopy consistent with formulation as a lipophilic macrocycle.

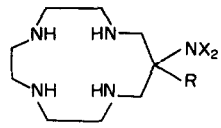
Further reactions

The strong nitro-carbon acid *p*-nitrobenzyl nitrite was prepared by reaction of silver nitrite with *p*-nitrobenzyl bromide;[6] separation of nitrito and nitro isomers from the reaction product was achieved via the carbanion.[7] Reaction with either copper(II) or nickel(II) tetraamines and formaldehyde in ethanol, in the presence or absence of base, produced coloured precipitates immediately, but these did not prove to contain macrocyclic species.

Physical methods

Electronic spectra were recorded with an Hitachi 150-20 spectrophotometer and IR spectra for complexes dispersed in KBr discs were recorded on Nicolet MX-1 FT–IR or Hitachi spectrometers. Nuclear magnetic resonance spectra were recorded using a Jeol FX-90Q spectrometer, with chemical shifts cited vs tetramethylsilane. Microanalyses were performed by the Australian National University microanalysis service.





1	X=O	R=CH_2-COOH	1A
2	X=O	R=$(CH_2)_{10}$-CH_3	
3	X=O	R=$(CH_2)_{10}$-COOH	3A
4	X=O	R=CH_2-O-	
5	X=O	R=CH_2-OH	
6	X=H	R=$(CH_2)_{10}$-COOH	

RESULTS AND DISCUSSION

Of the range of nitro-substituted molecules investigated, each containing acidic hydrogens as a result of the electronic propoerties of the nitro substituent, all aliphatic molecules led to macrocyclization reactions. With the aromatic-substituted molecule *p*-nitrobenzyl nitrite, reaction to an isolable macrocyclic complex was not achieved; organic products and insoluble precipitates formed preferentially. At least with the aliphatic molecules, the chemistry which is well established with nitroethane earlier[1-4] persists, and would appear generally applicable.

A range of new pendant-arm macrocycles were identified in this study, employing copper(II) or nickel(II) as templating metal ion, and two different tetraamines as the precursor ligand. The macrocycles **1** and **1A** exhibit both a pendant nitro group and a pendant carboxylic acid group. The macrocycles **3** and **3A** also contain both pendant nitro and carboxylate groups, although in these cases the carboxylate is the terminal group of a long aliphatic, hydrophobic chain, —$(CH_2)_{10}$COOH. Both groups exhibit characteristic strong absorbances in the IR spectrum. These occur near 1545 and 1350 cm^{-1} for nitro groups. The acid side chains of the copper complex of **1** evidently exists in the carboxylate anion form, based on the strong absorbance at 1588 cm^{-1}. The complex of **3** has been isolated as both the acid (band at 1720 cm^{-1}) and carboxylate anion (band at 1550 cm^{-1}) species in different syntheses. The nickel analogues **1A** and **3A** have strong absorbances at 1730 and 1738 cm^{-1}, respectively, indicating that in these cases the free acid is present. The NMR spectrum of the diamagnetic nickel(II) complex of **1A** identifies the macrocycle clearly; resonances from the acid carbon (174 ppm), the tertiary carbon adjacent to the nitro group (93.0 ppm), the methylene adjacent to the acid group (38.0 ppm) and the ring methylenes all adjacent to secondary amines (46–52 ppm) were observed in

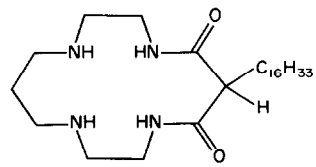
the ^{13}C NMR spectrum. Again, synthesis of the diamagnetic nickel(II) complex **3A** permitted characterization by NMR spectroscopy. The long-chain analogue **2**, with R = $(CH_2)_{10}CH_3$, was also prepared as the copper(II) complex. Macrocyclization (in all cases studied) is also indicated by stability in aqueous acid for extended periods. The presence of the long aliphatic chain in complexes of **2**, **3** and **3A** influences solubility properties, with complexes appreciably more soluble in polar organic solvents and less soluble in water, yet metal-based spectroscopic properties (such as electronic maxima) differ little from short-chain analogues. For example, the electronic maximum for the copper(II) complex with R = $(CH_2)_{10}CH_3$ (572 nm) is the same as that reported for the complex with R = CH_3.[2]

The complex with the protected alcohol, **4**, was isolated without hydrolysis of the protecting group to form a —CH_2—OH pendant, as indicated by microanalysis and IR spectroscopy. The —CH_2—OH pendant is present in the major macrocyclic product isolated from reaction with nitromethane, however. It was hoped that reaction with nitromethane would produce a complex with an R = H pendant, thus providing a macrocycle with an acidic hydrogen in the ring, available for further reaction. However, the acidity of this site initiated immediate reaction, since condensation with another molecule of formaldehyde has occurred, producing a —CH_2—OH pendant in **5**. The reaction between nitromethane and formaldehyde,

$$CH_3NO_2 + CH_2O \longleftrightarrow CH_2(CH_2OH)NO_2$$

is known to occur independently in solution,[8] so that the alcohol pendant may be introduced directly from this process. All three hydrogens in nitromethane are replaced by new C—C bonds in reaction with formaldehyde and $[M(H_2NCH_2CH_2NH_2)_3]^{n+}$ complexes, forming macrobicyclic species;[9] in the present case, macromonocycle formation requires only two of the three available acidic hydrogens, permitting other additional chemistry in this specific case.

The ligands **2**, **3** and **3A** represent new macrocycles with long hydrophobic "tails", somewhat related to ligand **7** reported previously.[10] Robustness is enhanced by reduction of the nitro group to a primary amine. Simple zinc/acid reduction in aqueous solution of both **2** and **3** has been performed; concomitant reduction of the copper ion occurs. In the former case, recomplexation to copper(II) has been performed as described in the Experimental. In the latter case, isolation of the free ligand **6** as a hydrochloride salt has been achieved. Characterization of the salt by microanalysis and NMR spectroscopy has indicated that reduction has been achieved without cleavage of the macrocycle. The properties of this new lipophilic polyamino acid will be pursued.



7

The general applicability of the formaldehyde/nitro-carbon acid condensation reaction with polyamines, where two primary amines are constrained in *cis*-disposed positions by a labile metal ion, has been demonstrated. A range of new macrocycles with various types of pendant groups have been prepared, and the facility of the chemistry suggests that this synthetic strategy offers a convenient route to a range of pendant-arm macrocycles.

Abstract—The monobut-2-yne complex $[WI(CO)(NCMe)\{Ph_2P(CH_2)PPh_2\}(\eta^2\text{-}MeC_2Me)][BF_4]$ reacts with an equimolar quantity of phosphines, L {L = PMe_3, PMe_2Ph, $PMePh_2$, PPh_3, $PEtPh_2$, PEt_2Ph, PEt_3, P^nPr_3, P^nBu_3, $P(CH_2CH{=}CH_2)Ph_2$ and $[Fe(\eta^5\text{-}C_5H_5)(\eta^5\text{-}C_5H_4PPh_2)]$} in CH_2Cl_2 at room temperature to give the highly coloured acetonitrile displaced products $[WI(CO)L\{Ph_2P(CH_2)PPh_2\}(\eta^2\text{-}MeC_2Me)][BF_4]$ (**1–11**) in good yield. The barriers to but-2-yne rotation of a number of these complexes have been determined using variable temperature ^1H NMR spectroscopy. The but-2-yne ligands in **1–11** show ^{13}C NMR resonances above 200 ppm for the alkyne contact carbon chemical shifts, which suggests that the but-2-yne ligand is donating four electrons to the tungsten in these compounds.

The barrier to alkyne rotation of alkyne complexes of molybdenum(II) and tungsten(II) have received considerable attention in recent years. For example, the barriers to but-2-yne rotation of the monobut-2-yne complexes $[MoLL'(\eta^2\text{-}MeC_2Me)X][BF_4]$ (X = $\eta^5\text{-}C_5H_5$, L—L = $Me_2P(CH_2)_2PMe_2$, $Ph_2P(CH_2)_2PPh_2$ or $Ph_2P(CH{=}CH)PPh_2$; L = L′ = $PMePh_2$; L = CO, L′ = PEt_3, PPh_3 or PCy_3 for X = $\eta^5\text{-}C_9H_7$, L = CO, L′ = PEt_3 or PPh_3),[1,2] $[W(CO)(S_2CNEt_2)_2(\eta^2\text{-}MeC_2Me)]$,[3] $[Mo(\sigma\text{-}MeC{=}CMe_2)(CO)(\eta^2\text{-}MeC_2Me)(\eta^5\text{-}C_5H_5)]$,[4] $[Mo(SR)\{P(OMe)_3\}_2(\eta^2\text{-}MeC_2Me)(\eta^5\text{-}C_5H_5)][BF_4]$ (R = C_6H_5, $C_6H_4NO_2$, C_6H_4Me, C_6H_4OMe or $C_6H_4NH_2$),[5] $[Mo(SePh)\{P(OMe)_3\}_2(\eta^2\text{-}MeC_2Me)(\eta^5\text{-}C_5H_5)]$,[5] *cis*-$[WBr_2(CO)(CN^tBu)_2(\eta^2\text{-}MeC_2Me)]$,[6] *trans*-$[WBr_2(CO)(PPh_3)_2(\eta^2\text{-}MeC_2Me)]$,[6] $[WMe(CO)(\eta^2\text{-}MeC_2Me)(\eta^5\text{-}C_5H_4R)]$ (R = Me or Ph)[7] and $[MX_2(CO)L_2(\eta^2\text{-}MeC_2Me)]$ (for M = Mo, X = Cl, L = py, PEt_3 or PPh_3; X = Br, L = PEt_3; for M = W, X = Cl, L = PPh_3).[8] More recently we have reported the preparation and calculated the barriers to but-2-yne rotation of the tungsten diiodide complexes $[WI_2(CO)L_2(\eta^2\text{-}MeC_2Me)]$ {L = PMe_3, PMe_2Ph, $PMePh_2$, PPh_3, $PEtPh_2$, PEt_2Ph, PEt_3, P^nBu_3 or PPh_2Cy; L_2 = $Ph_2P(CH_2)PPh_2$}.[9] The complexes $[WI_2(CO)\{Ph_2P(CH_2)_nPPh_2\}(\eta^2\text{-}RC_2R)]$ (*n* = 1–6; R = Me or Ph) react with one equivalent of $Ag[BF_4]$ in acetonitrile at room temperature to give the cationic monoacetonitrile compounds $[WI(CO)(NCMe)\{Ph_2P(CH_2)_nPPh_2\}(\eta^2\text{-}RC_2R)][BF_4]$.[10]

In this paper we describe the preparation of the cationic monobut-2-yne complexes $[WI(CO)L\{Ph_2P(CH_2)PPh_2\}(\eta^2\text{-}MeC_2Me)][BF_4]$ {L = PMe_3, PMe_2Ph, $PMePh_2$, PPh_3, $PEtPh_2$, PEt_2Ph, PEt_3, P^nPr_3, P^nBu_3, $P(CH_2CH{=}CH_2)Ph_2$ and $[Fe(\eta^5\text{-}C_5H_5)(\eta^5\text{-}C_5H_4PPh_2)]$}, and the barrier to but-2-yne rotation of several of these complexes which have been determined using variable temperature ^1H NMR spectroscopy.

EXPERIMENTAL

Syntheses were carried out under an atmosphere of nitrogen using standard Schlenk-line techniques. CH_2Cl_2 was dried and distilled before use. The compound $[WI(CO)(NCMe)\{Ph_2P(CH_2)PPh_2\}(\eta^2\text{-}$

* Author to whom correspondence should be addressed.

$MeC_2Me)][BF_4]$ was prepared by the published method.[10] All chemicals were purchased from commercial sources, except $Ph_2P(CH_2)PPh_2$ which was synthesized by a literature method.[11]

Elemental analyses for carbon, hydrogen and nitrogen were determined on a Carlo Erba elemental analyser MOD 1106 (using helium as a carrier gas). IR spectra were recorded on a Perkin–Elmer 1430 ratio recording IR spectrophotometer. All ^1H and ^{13}C NMR spectra were recorded on a Bruker AC 250 CP/MAS NMR spectrometer (all spectra were calibrated against tetramethylsilane).

$[WI(CO)(PMe_3)\{Ph_2P(CH_2)PPh_2\}(\eta^2$ - $MeC_2Me)][BF_4]$ (1)

A solution of $[WI(CO)(NCMe)\{Ph_2P(CH_2)PPh_2\}(\eta^2$-$MeC_2Me)][BF_4]$ (0.5 g, 0.552 mmol) in CH_2Cl_2 (15 cm^3) in a Schlenk tube was frozen in liquid nitrogen. PMe_3 (0.0420 g, 0.552 mmol) was distilled into the Schlenk tube by direct pyrolysis of $[\{AgI(PMe_3)\}_4]$ (0.1680 g, 0.138 mmol) at 200°C *in vacuo*. After completion of pyrolysis the reaction Schlenk was opened to nitrogen and allowed to warm up to room temperature. After the reaction mixture had been stirring for 5 h, the solution was filtered and the solvent volume reduced to 1 cm^3 *in vacuo*. Dropwise addition of diethyl ether precipitated the red cationic complex $[WI(CO)(PMe_3)\{Ph_2P(CH_2)PPh_2\}(\eta^2$ - $MeC_2Me)][BF_4]$ (**1**), which on recrystallization from CH_2Cl_2/Et_2O yielded 0.28 g, 54% of pure product.

$[WI(CO)(PMe_2Ph)\{Ph_2P(CH_2)PPh_2\}(\eta^2$-$MeC_2Me)][BF_4]$ (2)

To $[WI(CO)(NCMe)\{Ph_2P(CH_2)PPh_2\}(\eta^2$-$MeC_2Me)][BF_4]$ (0.5 g, 0.552 mmol) dissolved in CH_2Cl_2 (15 cm^3), with continuous stirring under a stream of dry nitrogen, was added PMe_2Ph (0.079 cm^3, 0.552 mmol). After stirring the solution for 4 h, the solution was filtered and the solvent volume reduced to 2 cm^3 *in vacuo*. Dropwise addition of diethyl ether precipitated the red cationic complex $[WI(CO)(PMe_2Ph)\{Ph_2P(CH_2)PPh_2\}(\eta^2$-$MeC_2Me)][BF_4]$ (**2**), which on recrystallization from CH_2Cl_2/Et_2O yielded 0.29 g, 52% of pure product.

Similar reactions of $[WI(CO)(NCMe)\{Ph_2P(CH_2)PPh_2\}(\eta^2$-$MeC_2Me)][BF_4]$ with L {L = $PMePh_2$, PPh_3, $PEtPh_2$, PEt_2Ph, PEt_3, P^nPr_3, P^nBu_3, $P(CH_2CH{=}CH_2)Ph_2$ and $[Fe(\eta^5$-$C_5H_5)(\eta^5$-$C_5H_4PPh_2)]$} in CH_2Cl_2 at room temperature afforded the analogous cationic monodentate phosphine compounds $[WI(CO)L\{Ph_2P(CH_2)PPh_2\}(\eta^2$-$MeC_2Me)][BF_4]$ (**3–11**) (see Table 1 for colours and yields).

RESULTS AND DISCUSSION

Equimolar amounts of the cationic monoacetonitrile complex $[WI(CO)(NCMe)\{Ph_2P(CH_2)PPh_2\}(\eta^2$-$MeC_2Me)][BF_4]$ and L {L = PMe_3, PMe_2Ph, $PMePh_2$, PPh_3, $PEtPh_2$, PEt_2Ph, PEt_3, P^nPr_3, P^nBu_3, $P(CH_2CH{=}CH_2)Ph_2$ and $[Fe(\eta^5$-$C_5H_5)(\eta^5$-$C_5H_4PPh_2)]$} react in CH_2Cl_2 at room temperature to afford the substituted products **1–11** in good yield. The complexes **1–11** have been fully characterized by elemental analysis (C, H and N) (Table 1), IR (Table 2) and ^1H, and in selected cases ^{13}C, NMR spectroscopy (Tables 3 and 4). The complexes with L = PPh_3 (**4**) and $[Fe(\eta^5$-$C_5H_5)(\eta^5$-$C_5H_4PPh_2)]$ (**11**) were confirmed as CH_2Cl_2 solvates by repeated elemental analyses and ^1H and ^{13}C NMR spectroscopy (Tables 3 and 4). The compounds **1–11** are stable in the solid state when stored under nitrogen, however, they decompose in solution when exposed to air. Compounds **1–11** are soluble in polar solvents such as CH_2Cl_2, $CHCl_3$, acetone, etc., however, they are insoluble in hydrocarbon solvents and diethyl ether.

The structures of complexes **1–11** are highly likely to have the but-2-yne ligand *trans* to the iodide ligand, with the bidentate phosphine $Ph_2P(CH_2)PPh_2$, carbon monoxide and the monodentate phosphine, L, occupying the equatorial sites, since the X-ray crystal structures of the related cations $[WI(CO)L\{Ph_2P(CH_2)PPh_2\}(\eta^2$-$MeC_2Me)]^+$ [for L = $P(O^iPr)_3$[10] and $SC(NH_2)_2$[12]] have been determined and have this geometry. The spectroscopic properties of **1–11** are similar to these complexes and hence the proposed structure for **1–11** is shown in Fig. 1.

The IR spectra of **1–11** all show a single carbonyl resonance at $\sim$ 1955 cm^{-1}, and in selected cases very weak alkyne (C≡C) stretching bands at $\sim$ 1635 cm^{-1}, i.e. at a lower wavenumber compared to free but-2-yne due to donation of electron density from filled metal *d*-orbitals to empty π^*-orbitals on the coordinated but-2-yne ligand. Complexes **1–11** also show strong bands in the IR spectra at 1016 cm^{-1} and a strong sharp band at 529 cm^{-1} due to the ν(BF) of the tetrafluoroborate counter anion.[13]

The ^1H NMR spectra show the expected features for the structure shown in Fig. 1. The barrier to but-2-yne rotation of the complexes $[WI(CO)L\{Ph_2P(CH_2)PPh_2\}(\eta^2$-$MeC_2Me)][BF_4]$ (where L = PMe_3, PMe_2Ph, PPh_3, $PEtPh_2$, PEt_2Ph, PEt_3, P^nPr_3 and P^nBu_3) have been determined by variable temperature ^1H NMR spectroscopy. From a knowledge of the coalescence temperature, T_c, and the separation of the two methyl groups of the but-2-yne ligand ($\Delta\nu$), calculations using the equation $\Delta G^{\ddagger}_{T_c} = -RT_c \ln(\pi\Delta\nu h/\sqrt{2}K_BT_c)$[14,15] allows the

barrier to but-2-yne rotation to be calculated. The barriers to but-2-yne rotation for complexes **1**, **2**, **4**, **5**, **6**, **7**, **8** and **9** are given in Table 5. The data in Table 5 show that from the highest barrier to but-2-yne rotation for L = PMe_3, $\Delta G^{\ddagger}_{T_c}$ = 55 kJ mol^{-1}, to the lowest barrier i.e. for L = PEt_2Ph, $\Delta G^{\ddagger}_{T_c}$ = 49 kJ mol^{-1}, there is only a difference of 6 kJ mol^{-1}. Since the accuracy of this method for calculating the barriers to but-2-yne rotation is ± 1 kJ mol^{-1} at best, it appears that the different steric and electronic effects of the phosphines in these complexes is having little effect on the barrier to but-2-yne rotation. These results are in contrast to the series of complexes [$WI_2(CO)L_2(\eta^2$-$MeC_2Me)$] where the electronic and steric effects of the phosphine ligands had a marked effect on the barrier to but-2-yne rotation.[9] For example, across the series L = PEt_3, PEt_2Ph, $PEtPh_2$ and PPh_3 for [WI_2(CO)$L_2(\eta^2$-$MeC_2Me)$] the values for $\Delta G^{\ddagger}_{T_c}$ are 58,

Me)][BF_4] have only one monodentate phosphine different in the series, whereas for the previously reported complexes [$WI_2(CO)L_2(\eta^2$-$MeC_2Me)$][9] there are two monodentate or one bidentate phosphine which significantly affect the barrier to but-2-yne rotation in these neutral monobut-2-yne complexes. It is useful to note that the related triisopropylphosphite-containing complex [WI(CO){$P(O^iPr)_3$}{$Ph_2P(CH_2)PPh_2$}(η^2-MeC_2Me)]$^+$ [10] has a barrier to but-2-yne rotation, $\Delta G^{\ddagger}_{T_c}$ = 57 kJ mol^{-1}, i.e. similar to the compounds described in this paper.

The ^{13}C NMR spectra for selected complexes (Table 4) show alkyne contact carbon resonances above 200 ppm, which indicates[16] that the but-2-yne ligand is donating four electrons to the tungsten in these compounds. This is supported by the fact that the complexes [WI(CO)L{$Ph_2P(CH_2)PPh_2$}(η^2-MeC_2Me)][BF_4] obey the effective atomic number rule if the alkyne is donating four electrons to the metal in these compounds.

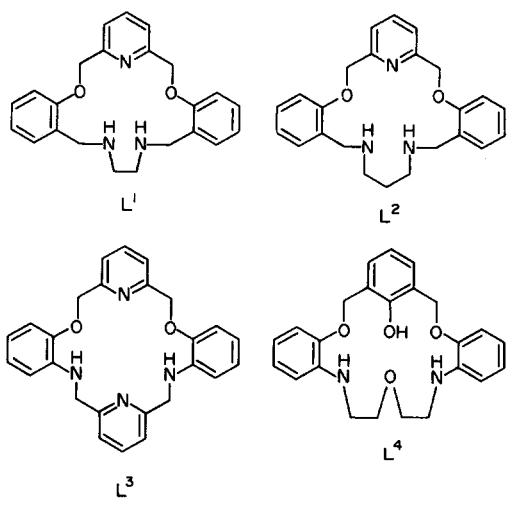
Abstract—The formation constants of the binary complexes [CuL] and the ternary complexes [CuAL], where A refers to 2,2′-bipyridyl and L refers to oxaazamacrocyclic ligands, have been determined potentiometrically in 50% water–dioxan at 25°C (ionic strength 0.2 M $NaClO_4$). The constants have been correlated with the proposed structures of the binary and ternary complexes.

Tetraazamacrocyclic ligands are known to form very stable coordination complexes,[1–3] the stability of which is attributed to favourable enthalpy and entropy changes.[4–7] Interesting correlations between the metal ion size, the ligand hole size and the stability have been made;[8–10] the formation of such complexes is a slow process, however, and so study of the formation constants has mainly been confined to labile copper(II) species. The introduction of ethereal oxygen donor atoms into the macrocyclic rings results in faster reaction and the coordinating properties of the oxygen atoms may be assumed to be destabilizing.[11] Numerous transition, and non-transition, metal complexes with oxaazamacrocyclic ligands have now been synthesized[12–16] and the formation constants of a number of transition metal complexes have been determined.[17] For nickel(II) complexes of a series of O_2N_2 donor macrocycles it has been shown that the thermodynamic stability is dependent upon the macrocyclic ring size and is at a maximum for a 16-membered ring.[18,19] In contrast, for the copper(II) complexes no ring size dependence has been observed and this may be related to the ease with which copper(II) is able to accommodate different coordination geometries.[20]

In the present study the formation constants of the 1:1 copper(II) complexes of ligands (L^1–L^4) have been determined in 50% (v/v) water–dioxan together with those of the ternary complexes [Cu–bipy–L] (bipy = 2,2′-bipyridyl).



EXPERIMENTAL

Synthesis

The ligands L^1–L^4 were synthesized by the methods detailed in ref. 14. The complexes

* Author to whom correspondence should be addressed.

$Cu(L^1)(NO_3)_2$, $Cu(L^1)(ClO_4)_2$ and $Cu(L^2)(ClO_4)_2$ were prepared by reaction of the ligand and the appropriate hydrated metal salt in methanolic solutions.[15]

The ternary complexes were prepared by reaction of equimolar amounts of the macrocyclic complexes with stoichiometric amounts of either 1,10-phenanthroline (phen) or 2,2′-bipyridyl (bipy) in ethanol. The macrocyclic complex was first dissolved in warm ethanol and a solution of the ligand in ethanol added. The reactions proceeded as follows.

(i) $Cu(L^1)(ClO_4)_2$ *with* phen *or* bipy. The solution darkened slowly and a purple precipitate settled out. This was filtered off and dried. Found: C, 49.9; H, 4.0; N, 8.5. $Cu(L^1)(ClO_4)_2$, bipy ($C_{33}Cl_2CuH_{35}N_5O_{10}$) requires: C, 49.9; H, 4.2; N, 8.8%.

(ii) $Cu(L^1)(NO_3)_2$ *with* phen. A clear blue solution was obtained. This was reduced by rotary evaporation until a blue solid began to separate. The solid was filtered off and dried. Found: C, 54.3; H, 4.7; N, 12.3. $Cu(L^1)(NO_3)_2$,phen,$2H_2O$ ($C_{35}Cl_2CuH_{37}N_5O_{10}$) requires: C, 54.0; H, 4.7; N, 12.6%.

(iii) $Cu(L^2)(ClO_4)_2$ *with* phen. A green precipitate slowly settled out. This was filtered off and dried to give a green product of indeterminate composition.

Formation constants

All reagents used were of AR grade. Potentiometric titrations were carried out in 50% (v/v) water–dioxan using a GP electronics pH meter (No. 8021, accuracy ±0.01 pH units), at 25°C, using 0.2 M NaOH. For determination of ligand protonation constants the ligands (1.00×10^{-3}, 2.00×10^{-3} and 3.00×10^{-3} M) in 50 cm^3 of a 2.00×10^{-2} M $HClO_4$ solution ($I = 0.2$ M $NaClO_4$) were titrated with 0.2 M NaOH. The pH electrode was calibrated in aqueous solution using buffer solutions of pH 4, 7, and 9. Solvent corrections for pH were carried out as detailed earlier.[21]

The formation constants of the binary copper(II) complexes were determined under the same experimental conditions. For this the solution containing the metal ion and the ligands in the ratios 1:1, 1:2 and 1:3 (Cu^{2+}:L) in 50 cm^3 water–dioxan were titrated against standard alkali. The values were refined using SCOGS.[22] The species considered for the calculation of the protonation constants are L, $[LH]^+$ and $[LH_2]^+$, and for the binary constants are L, $[LH]^+$, $[LH_2]^+$, M and ML. These values were used as constants in calculating the formation constants of the ternary complexes. The formation constants of the ternary complexes were determined by titration of 50% (v/v) water–dioxan solutions (50 cm^3) of the reagents with concentrations of 2.00×10^{-3} and 1.00×10^{-3} M in the ratios M^{2+}:A:L = 1:1:1 and M^{2+}:A:L = 1:2:2 against carbonate-free standard NaOH. Titration of each set was carried out twice to check the reproducibility of the data. As macrocyclization is a slow process, sufficient time (2–3 min) was allowed between successive additions of NaOH solution to permit equilibrium to be reached, indicated by the system attaining constant pH. The experimental values of pH and volume of alkali used were fed into the computer and calculations were carried out using the computer program SCOGS.[22] The species considered were L, $[LH]^+$, $[LH_2]^+$, A, $[AH]^+$, M, [ML], [MA], $[MA_2]$ and MAL. The values of the protonation constants of the ligands and the formation constants of the binary complexes are presented in Table 1, and the values of the formation constants for the ternary complexes are presented in Table 2.

Mass spectra (FAB) of the ternary complexes

Fast atom bombardment mass spectra of the ternary complexes were recorded using a Kratos MS80RF mass spectrometer (accelerating voltage 4 kV, resolution 1500) coupled to a DS55 data system. The atom gun was an adapted saddle-field source (ION Tech Ltd) operated at *ca* 6 eV and a

Table 1. Proton–ligand formation constants ($\log K^H$ values) of the ligands and formation constants ($\log K$ values) of binary complexes of copper(II) with the ligands in 50% (v/v) water–dioxan and $\mu = 0.2$ M ($NaClO_4$) at 25°C (Standard deviation $\sigma\beta$ in parentheses)

Ligand	K_1^H	K_2^H	K_1	K_2

tube current of *ca* 2 mA. Xenon was used to provide the primary beam of atoms and the samples were mixed with a small amount of 3-nitrobenzyl alcohol matrix on a stainless steel probe. Spectra were recorded in the positive-ion mode at a scan speed of 30 s per decade.

RESULTS AND DISCUSSION

Only two protonation constants could be determined for each ligand; these correspond to those for the —NH protons. The protonation of the pyridinyl nitrogen is very much reduced because of the two protonated NH_3^+ sites in the ring.[23] The values for the protonation constants of the ligands L^1 and L^2 are higher than those for L^3 and L^4, and are comparable to those of 1,2-diaminoethane and 1,3-diaminopropane; this is because the nitrogen atoms are removed from the aromatic rings and so subjected to a reduced electron-withdrawing effect. The ligands L^3 and L^4, in which the nitrogen is linked directly to the aromatic ring, have lower protonation constants, which are comparable to those of the anilino-NH_2 group.

The complex formation can be shown by the following equilibrium.

$$M + L \rightleftharpoons ML$$

$$K^{M}_{ML} = \frac{[ML]}{[M][L]}.$$

It is observed that for complexes CuL^1 and CuL^2 the formation constants (10.10 and 9.17, respectively) are comparable to those for 1,2-diaminoethane and 1,3-diaminopropane complexes of copper(II).[24] For the CuL^3 and CuL^4 complexes the formation constants are lower in value because of coordination with the less basic nitrogen atoms.[14] The formation constant for CuL^1 is greater than that of CuL^2 and similarly that of CuL^3 is higher than that of CuL^4. This may be related to the increased ring sizes found in L^2 and L^4 as compared with L^1 and L^3 and also with the difference in the functional groups of L^3 and L^4.

The comparability of the formation complexes of CuL^1 and CuL^2 with those for complexes of aliphatic diamines suggests that coordination from the ethereal oxygens and the pyridinyl nitrogen might be weak. The crystal structure of $[Cu(L^1)H_2O](ClO_4)_2$ has been solved and shows that the copper is in a tetragonally elongated octahedral environment provided by the five ligand donor atoms and the water molecules.[25] The Cu—N distances are all within the standard range (2.02, 1.99 and 2.03 Å),[26] together with the Cu—O(water) at 2.02 Å. The axial Cu—O(ether) distances are long, 2.30 and 2.67 Å. In solution (dioxan–water) it is likely that the water is retained. The availability of 1(metal) : 2(ligand) complexes of L^1 both in solution and in the solid state[26] further suggests that it is also possible to release the pyridinyl-nitrogen in these complexes.

The formation of the ternary complexes takes place as follows:

$$Cu + A + L \rightleftharpoons CuAL$$

$$K^{Cu}_{CuAL} = \frac{[CuL]}{[Cu][A][L]}$$

$$CuA + L \rightleftharpoons CuAL$$

$$K^{CuA}_{CuAL} = \frac{[CuAL]}{[CuA][L]}$$

$$CuL + A \rightleftharpoons CuAL$$

$$K^{CuL}_{CuAL} = \frac{[CuAL]}{[CuL][A]}.$$

The difference in stability between the binary and ternary complexes is a way to characterize the tendency for ternary complex formation. Since more coordination positions are available for binding the first ligand than for binding the second ligand, the formation constant of the 1 : 1 complex is generally higher than that for the 1 : 2 complex.[27]

Table 3. Mass spectra of the ternary complexes

	X = ClO_4		X = NO_3
	L = phen	L = bipy	L = phen
$[Cu(L^1)(L)X]^+$	717	693	680
$[Cu(L^1)X]^+$	537	537	500
$[Cu(L_1)]^+$	438	438	438
$[(L^1)H]^+$	376	376	376
$[Cu(L)_2]^+$	423	—	423
$[Cu(L)]^+$	243	219	243

From a statistical consideration $K^{CuA}_{CuAL} < K^{Cu}_{CuL}$ or $K^{CuL}_{CuAL} < K^{Cu}_{CuA}$, therefore, $\Delta \log K$ ($= \log K^{CuA}_{CuAL} - \log K^{Cu}_{CuL}$ or $\log K^{CuL}_{CuAL} - \log K^{Cu}_{CuA}$) should be negative. In the ternary complexes studied here $\Delta \log K$ is small and negative and is comparable to the magnitude of $\Delta \log K$ in [Cu–bipy–neutral bidentate] ternary complexes.[28]

If the ternary complexes derived from bipy are octahedrally derived, the bipy can coordinate via two equatorial positions or by one equatorial and one axial position. The macrocycle would then have to become distorted in order to occupy the remaining coordination positions. The maximum expected coordination would then be seven (probably pentagonal bipyramidal) for L^1 and L^2 if all the donor atoms were involved. If the apparently weaker oxygen donors were not involved then five-coordination is likely. The $\Delta \log K$ values are comparable with those for [Cu–bipy–neutral bidentate] complexes and this suggests that the macrocycles are effectively coordinating via the two —NH donor sites only and so acting as bidentate ligands.

Studies on the speciation of L^1 have shown that binding through the diamino-nitrogen atoms of the macrocycle can occur and this is validated through the crystal structure of $[Ni(L^1)_2(NO_3)](NO_3)$, 2MeOH.[25] In this complex, which may be regarded as being similar to a ternary species due to the presence of the two ligand molecules, the nickel(II) is octahedrally coordinated by a bidentate nitrate anion and by two bidentate macrocycles in an exocyclic mode. The observation that the 1 : 2 species is retained in DMSO leads to the proposal that in the ternary complexes derived from L^1 or L^2 and bipy, a similar binding mode occurs for the macrocycle and so the macrocyclic nitrogen donors and the bipy provide a square-planar environment around the metal with accompanying axial molecules of solvation. The similarity of the $\Delta \log K$ values for these complexes and those derived from L^3 or L^4 and bipy suggests that the latter complexes also involve a bidentate binding mode for the macrocycle, probably through the nitrogen donors.

It was possible to isolate species from solution for complexes derived from the macrocycles L^1 and L^2 together with the ligands phen and bipy. The FAB mass spectra of the complexes isolated from solution indicated the presence of ternary complexes for $Cu(L^1)(L)(ClO_4)_2$, where L = phen or bipy, and for $Cu(L^1)(L)(NO_3)_2$, where L = phen, with the breakdown pattern for these species giving peaks corresponding to $[Cu(L^1)(L)X]^+$, $[Cu(L^1)X]^+$, $[Cu(L^1)]^+$, $[(L^1)H]^+$ and $[Cu(L)]^+$ (X = anion). The presence of the peaks such as $[Cu(L^1)]^+$ and $[Cu(L)]^+$ suggests that some reduction of either the metal or the ligand has occurred. No such spectrum was obtained for the product involving L^2 for which the breakdown pattern gave peaks corresponding to $[Cu(phen)_2ClO_4]^+$, $[Cu(phen)_2]^+$ and $[Cu(phen)]^+$, with very small peaks corresponding to $[Cu(L^2)]^+$ and $[(L^1)H]^+$. In the absence of crystals suitable for X-ray analysis it is only possible to speculate on the structures of the complexes, but it would seem likely that the complexes $Cu(L^1)(L)(ClO_4)_2$, where L = phen or bipy, would have a structure in which the macrocycle is bidentate as discussed above, with the second organic ligand and one perchlorate anion also coordinated to the metal. The presence of ligand bands in the same regions of the IR spectrum as the perchlorate band prevents an unambiguous assignment of the anion binding mode. The different colour of the $Cu(L^1)(L)(NO_3)_2,2H_2O$ complex would suggest a different arrangement, probably with the waters coordinated to the metal and with non-coordinated anions. The absence of a ternary complex in the reaction using L^2 may be related to the presence of a 1,3-trimethylene bridge in the macrocycle, leading to a less stronger bidentate chelating mode for L^2.

MIXED-LIGAND COMPLEXES—II.* (METHIONINATO)ETHYLENEDIBIGUANIDE COBALT(III) SALTS

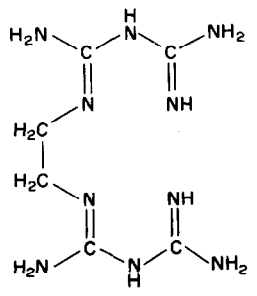
R. K. RAY

Department of Chemistry, Rama Krishna Mission Vivekananda Centenary College, Rahara-743186, West Bengal, India

(*Received* 30 *January* 1989; *accepted after revision* 1 *May* 1990)

Abstract—A series of new cobalt(III) complexes of the formulation $[Co(meth\text{-}O^-)(EBG)]^{2+}$ (where meth-OH = DL-methionine, L-methionine; EBG = ethylenedibiguanide) has been prepared, and characterized using elemental analyses, conductivity measurements, visible and IR spectral data. The electronic absorption spectra reveal two ligand-field bands representing the transitions $^1A_{1g} \rightarrow {}^1T_{1g}$ and $^1A_{1g} \rightarrow {}^1T_{2g}$. The ligands obey their expected position in the spectrochemical series. The visible spectra of all the $[Co(meth\text{-}O^-)(EBG)]^{2+}$ salts are very similar, which reveals that coordination of methionine is through the amino and carboxylated groups. The mercaptide group of methionine remains uncoordinated in the mixed chelate $[Co(meth\text{-}O^-)(EBG)]^{2+}$.

The preparation and properties of the mixed chelate $[Co(meth\text{-}O^-)(EBG)]^{2+}$ (meth-OH = methionine; EBG = ethylenedibiguanide, **I**) were undertaken in order to examine the donor behaviour (SNO, SN or NO)[1–4] of methionine. Several other mixed chelates $[Co(AB)(EBG)]^{2+}$ containing one bidentate amino acid (ABH = glycine, DL-alanine, α-alanine, L-leucine, DL-valine, L-histidine) (donor set NO) and one ethylenedibiguanide (donor set NNNN) have been synthesized and characterized[5–7] in order to aid the elucidation of the structure of $[Co(meth\text{-}O^-)(EBG)]^{2+}$. The mode of chelation of methionine, a potentially flexidentate ligand, is discussed.



I

* For Part I, see ref. 6.

EXPERIMENTAL

Ethylenedibiguanide sulphate and diamine ethylenedibiguanide cobalt(III) hydroxide sulphate were prepared by published procedures.[8,9]

Analyses

Cobalt and nitrogen were determined as $CoSO_4$ and by the combustion method, respectively. Carbon and hydrogen were analysed by CDRI, Lucknow, India. Halides were determined as the silver salts and sulphate as barium sulphate. Electrical conductances were measured with a Philips PR 9500 conductivity bridge. IR spectra were recorded at CDRI, Lucknow. Solution spectra were obtained with a Hilger Uvispec spectrophotometer over the range 320–600 mm. Relevant data are given in Tables 1 and 2.

DL-(*Methioninato*)*ethylenedibiguanide cobalt*(III) *sulphate*

Diamine ethylenedibiguanide cobalt(III) hydroxide sulphate 4-hydrate (1 g) in water (20 cm^3) was allowed to react with heated DL-methionine (0.35 g in 20 cm^3 of water) on a steam bath for 1 h. After ammonia evolution had ceased, the solution was filtered, cooled and neutralized with cold, dilute H_2SO_4 (1:4) and filtered. After concentration and cooling, the filtrate deposited red–violet crystals,

[a] This study.

α-alan-OH = α-alanine; bigH = biguanide; gly-OH = glycine; HCYOH = cysteine; SMCYOH = S-methyl-L-cysteine.

which were further purified from hot water and dried over $CaCl_2$ (yield, 0.8 g).

DL-(*Methioninato*)*ethylenedibiguanide cobalt*(III) *chloride*

This was obtained by metathesis of the complex sulphate (1 g) with barium chloride. After the removal of $BaSO_4$ the filtrate was concentrated to a small volume, cooled and filtered, when reddish-violet crystals separated. These were purified from hot water (yield, 0.8 g).

DL-(*Methioninanto*)*ethylenedibiguanide cobalt*(III) *idodide*

The reddish-violet iodide crystal salt was obtained by the addition of KI to a concentrated aqueous solution of the chloride (1 g). These were purified by two recrystallizations from hot water (yield, 0.8 g).

L-(*Methioninato*)*ethylenedibiguanide cobalt*(III) *sulphate*

L-Methionine (0.36 g in 20 cm^3 of water) and diamine ethylenedibiguanide cobalt(III) hydroxide base (1 g in 20 cm^3 of water) were reacted as described above and the solution was neutralized with dil. H_2SO_4. The red–violet crystalline salt was recrystallized from hot water (yield, 0.75 g).

L-(*Methioninato*)*ethylenedibiguanide cobalt*(III) *chloride*

This compound was obtained by metathesis of the complex sulphate (1 g) with $BaCl_2$. The filtrate after separation of $BaSO_4$ was concentrated to a small volume, cooled and filtered. The product was recrystallized from hot water (yield, 0.7 g).

L-(*Methioninato*)*ethylenedibiguanide cobalt*(III) *iodide*

The red–violet compound was obtained by a metathetic reaction using the above chloride salt (1 g) and KI, and was recrystallized from warm water (yield, 0.75 g).

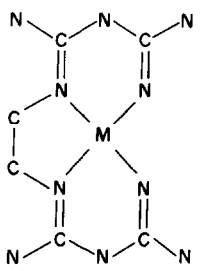
RESULTS AND DISCUSSION

Busch, Dutta, Ray, Kauffman and others[3–7,10–13] have reported the isolation and detailed study of $[Co(AB)(bigH)_2]^{2+}$ (bigH = biguanide; ABH = amino acids), $[Co(AB)(EBG)]^{2+}$ (EBG = ethylenedibiguanide), $[Co(AB)(en)_2]^{2+}$ etc., in which the amino acids such as glycine (gly-OH) act as bidentate chelating ligands (NO donor) coordinating through the amino and carboxylate groups. Relatively little has been done with similar derivatives of tridentate ligands (histidine, cysteine, methionine, etc.) even though they offer the additional interesting question of which functional groups are utilized in chelation. Methionine is of particular interest in compounds of this composition because of the presence in its structure of three functional groups, only two of which can bind to the cobalt(III) in a given derivative.

Like other amino acids, methionine reacts with diamine ethylenedibiguanide cobalt(III) hydroxide sulphate liberating ammonia and a reddish solution resulted. On concentrating the solution to a small volume and neutralizing with acid the cations could be isolated. The salts are highly crystalline, appear homogeneous under the microscope and are very stable both in the solid state and in aqueous solution. The molar conductance measurements are indicative of the bi–univalent nature of the cations.[14,15] The high conductance value for $[Co(HCY\text{-}O^-)(en)_2]ICl$ ($pK_a = 3.7$)[16] indicates a highly dissociated form of the complex—the majority of the conductance value is due to ionization of the carboxyl group and release of the proton into solution (Table 2).[3]

Strong IR spectral bands around 3450–3100 cm^{-1} have been assigned to ν_{asy}(N—H) (3300–3380 cm^{-1}) and ν_{asy}(N—H) (3100–3150 cm^{-1}) modes of vibration of the guanyl group[6,17] and are observed almost in the same positions as those in the original ligand (EBG) but with a slight decrease in the intensities. This supports participation of EBG without deprotonation. The two bands at 3100–3200 cm^{-1} (NH_2 stretching region) indicate that the amino groups in these complexes are coordinated. Bands around 1650 cm^{-1} have been assigned to the ν(C=N) stretch, ν(N—H) deformation and ν(O—H) deformation vibrations. In ethylenedibiguanide sulphate ($EBG \cdot H_2SO_4$) the ν(C=N) stretch occurs at 1696 cm^{-1} and the ν(N—C—N) stretch at 1585 cm^{-1}.[18–20] A similar ν(N—C—N) stretching frequency for the other cobalt(III) biguanide complexes was noted at 1580 cm^{-1}.[19] Lowering of the ν(C=N) stretch (1655 cm^{-1}) and the ν(N—C—N) stretch (1545 cm^{-1}) in metal complexes is due to coordination with the nitrogen atoms of the =NH groups. The ν(C—N) stretch of the C—NH_2 group in both EBG and the corresponding cobalt(III) complexes is assigned at *ca* 1345–1375 cm^{-1}. Antisymmetrical COO^- stretching frequencies for other cobalt(III) complexes, viz. $[Co(CY^-\text{-}O^-)(en)_2]I$, $[Co(HCY\text{-}O^-)(en)_2]ICl$ and $[Co(SMCY\text{-}O^-)(en)_2]I_2$, are observed at 1616,

1721 and 1656 cm^{-1}, which represent $—CO_2^-$, —COOH and —OOCCo groups, respectively. No band at 1616 cm^{-1} has been observed, and therefore it can be concluded that the free carboxylate ion is not present.[3] An intense C=O stretching band for $[Co(CY^-\text{-}O^-)(en)_2]I$ occurs at 1616 cm^{-1}; the value being consistent with the presence of free carboxylate ion. For $[Co(SMCY\text{-}O^-)(en)_2]I_2$, the C=O stretching occurs at 1656 cm^{-1}, which is typical for coordinated carboxylate groups. The higher frequency noted for coordinated carboxylated groups is well established. The ν(C—N) stretch of the $C—NH_2$ group was located at *ca* 1345–1375 cm^{-1},[19] and chelate ring formation was confirmed when a new strong band appeared at 1200–1300 cm^{-1}.[20] This new band is not found in the studied ligand (EBG). In all metal chelates another new prominent band around 1200–1260 cm^{-1} appeared.[20,21] This is assigned to the following fragment of the molecular structure.



II

The electronic spectra of all the salts show two *d–d* absorption bands and their positions are consistent with assignments based on the C_{4v} symmetry approximated by the donor atoms (five nitrogens and one oxygen positioned octahedrally) rather than the true O_h symmetry.[22,23] The band at longer wavelength is assigned to the transition $^1A_{1g} \rightarrow {}^1T_{1g}$ and the one at shorter wavelength to $^1A_{1g} \rightarrow {}^1T_{2g}$. The visible spectra of all $[Co(meth\text{-}O^-)(EBG)]^{2+}$ salts are very similar to the spectra of $[Co(AB)(bigH)_2]^{2+}$ (ABH = amino acid), where the amino acids are chelated through the amino and carboxylated groups. In the visible spectra of $[Co(SMCY\text{-}O^-)(en)_2]I_2$ the two bands are observed at 483 and 345 nm. The bands are comparatively higher in frequency than the bands in the visible spectra of *cis*-$[Co(gly\text{-}O^-)(Cl)(en)_2]Cl$, $[Co(HCY\text{-}O^-)(en)_2]ICl$ and $[Co(CY^-\text{-}O^-)(en)_2]I_2$ (Table 2). This reflects the relative position of the groups in the spectrochemical series: $S^- < Cl^- < CO_2^-$.[24] From the nature of the spectral profile and their ε_{max} values, it appears that all of the studied complexes have CoN_5O chromophores instead of CoN_5S chromophores. This assumption is verified by comparing the spectra of several other cobalt(III) complexes containing CoN_5O and CoN_5S chromophores. Thus whereas the complexes containing the CoN_5O chromophore show a lower energy band at 490 nm and a higher energy band at 355–360 nm, the CoN_5S chromophore complexes exhibit these two bands at 590–600 nm and at 490 nm, respectively[3–7] (Table 2).

NEW, STABLE, CHELATED, TETRACOORDINATED SILVER(I) COMPLEXES OF THE 2-(ARYLAZO)PYRIDINE LIGAND SYSTEM: SYNTHESIS, CHARACTERIZATION AND ASSESSMENT OF BONDING AND STRUCTURE

ALOK K. DEB, SUBRATA CHOUDHURY and SREEBRATA GOSWAMI*

Department of Chemistry, North-Eastern Hill University, Shillong 793 003, India

(*Received* 6 *December* 1989; *accepted* 1 *May* 1990)

Abstract—The 2-(arylazo)pyridines (L, **1**) in methanol gave bis-chelated silver complexes, $[AgL_2]^+$ (**2**), as the crystalline perchlorate salts which were characterized by elemental analyses. The complexes are 1:1 electrolytes in methanol. In contrast to the copper analogue, there is only a small shift of ν(N=N) to low energy in the IR spectrum of $[AgL_2]^+$ as compared to that of uncoordinated L, indicating a negligible $d\pi$–π^*(L) interaction. The high resolution ^{1}H NMR spectra of silver complexes with different substituted ligands (L^1–L^3) are reported. The complexes are quite stable and solutions in methanol and chloroform obey Beer's law.

This work stems from our continued interest in the transition metal chemistry of the azoimine ligand system (L, **1**) which is well-known as a versatile ligand capable of chelating[1–8] a wide range of metal ions. Recently, Datta and Chakravorty have reported[1] the 2-(phenylazo)pyridine chemistry of copper. The richness of this chemistry encouraged us to initiate research on the chemistry of the neighbouring element silver involving L.

Although silver(I) forms a great variety of complexes with N-donors, it is evident from a survey of the literature that the reports on stable, monomeric compounds of silver(I) with chelated ligands are scanty.[9,10] It is also well-documented that the metal ion has a pronounced tendency[11–13] to exhibit a linear two-coordination. The chemistry of monomeric silver(I) complexes of bidentate ligands with N,N-donors has grown primarily around 2,2′-bipyridine (bpy) and related ligands.[14,15] They are usually isolated in low yields and mostly used as intermediates for the preparation of the corresponding silver(II) complexes.[15] Many compounds of silver(I) are now known with soft donors like P, As, S, Se, etc., but they are mostly obtained as dimers or polymers.[16–19]

In this report we describe the high yield synthesis of stable, monomeric tetracoordinated silver(I) complexes of L. Assessment of structure and the stability of the complexes in solutions have been made on the basis of spectral data. Comparisons, where relevant, with the corresponding copper(I) complexes are also made. The four ligands used for the present work are abbreviated as L^1–L^4.

RESULTS AND DISCUSSION

(A) *Synthesis and formulation*

$AgNO_3$ reacts smoothly with L (**1**) in boiling methanol in the ratio of 1:2 to yield cationic $[AgL_2]^+$ (**2**), which have been isolated as perchlorate salts from the reaction mixture in high

yields (> 80%). The silver(I) complexes of L, obtained as dark brown needles, are stable and can be stored for a long time. They were characterized by elemental analyses which confirmed that the number of ligands (L) per silver is two. Magnetic susceptibility measurements showed that the compounds are diamagnetic (d^{10}) in nature, as expected. They are soluble in common polar organic solvents and are insoluble in non-polar benzene, hexane, etc. The molar conductance of $[AgL_2]ClO_4$ in methanol lies between 105 and 110 Ω^{-1} cm^2 mol^{-1} (Table 1), suggesting a 1 : 1 type of electrolytic nature of the compounds.[20] These results collectively conform to the formulation of the compounds as $[AgL_2]ClO_4$. We have also synthesized the corresponding $[CuL_2]ClO_4$ (L = L^1–L^4). These compounds have been synthesized by following the procedure described by Datta and Chakravorty.[1] Out of these four complexes, three with ligands L^2–L^4 are new. The IR data of the copper compounds have been compared with those of the silver complexes.

(B) *Bonding and assessment of structure*

(i) *IR spectra.* IR data were collected in the range 4000–300 cm^{-1} using KBr discs. Characteristic group frequencies are collected in Table 1. Some of these are found to be useful in identifying the geometry and bonding of the complexes and are considered here. The very broad structureless band, $\nu(ClO_4)$, at *ca* 1100 cm^{-1} suggests the lack of significant perchlorate coordination[21] in the solid state. Our main objective in studying the IR spectra of silver(arylazo)pyridines was to locate the ν(N=N) mode. The position of this band in our complexes was identified by comparison of the IR spectra of $[AgL_2]^+$ with those of $[CuL_2]^+$ and free L (Table 1). Since the N=N stretching frequency in free L appears[2] at *ca* 1425 cm^{-1}, we anticipated ν(N=N) in $[AgL_2]^+$ below this region. The IR spectra of $[AgL_2]^+$ systematically show a strong absorption at *ca* 1420 cm^{-1} (Table 1). Interestingly, the vibrational spectra of $[AgL_2]^+$ and the corresponding $[CuL_2]^+$ are nearly superimposable except for a single frequency shift from 1420 to 1380 cm^{-1} (Table 1). The band at 1380 cm^{-1} in $[CuL_2]^+$ has been assigned[1] to ν(N=N). Evidently, the band at *ca* 1420 cm^{-1} in $[AgL_2]^+$ is also due to ν(N=N). The ability of L to act as a strong π-acceptor towards electron-rich metal centres are well documented and the diagnostic test[1-7] for this interaction is the shift of ν(N=N) to lower frequencies in moving from free L to its complex. The small shift of ν(N=N) in $[AgL_2]^+$ suggests that the $d\pi$–π^*(L) interaction in the present silver(I) complexes is weak. This is similar to the bonding pattern in other silver(I) complexes with π-acid ligands having phosphorus and sulphur donors.[11] Near superimposability of the IR spectra of $[AgL_2]^+$ on those of $[CuL_2]^+$ suggests that like $[CuL_2]^+$, the gross stereochemistry of $[AgL_2]^+$ is tetrahedral.

(ii) *Electronic spectra.* The electronic spectra of the solutions of silver complexes were studied to assess their stabilities in solutions. 2-(Arylazo)-pyridines (**1**) and their silver complexes (**2**) show one absorption band of moderate intensity (ε, *ca* 1000 dm^3 mol^{-1} cm^{-1}) in the visible region, which has been assigned[22] to an n–π^* transition, centred primarily on the azo group. The small bathochromic shift of the absorption maximum in the silver complexes compared to that of free L indicates a weak interaction between N^2 and Ag^+. This observation is consistent with the IR data (*vide supra*). The silver complexes obey Beer's law in both $CHCl_3$ and MeOH. The intensity of the band at *ca* 460 nm does not change with dilution. Hence, the $[AgL_2]^+$ ion is stable in these solvents.

(iii) ^{1}H *NMR spectra.* The ^{1}H NMR data in $CDCl_3$ of the complexes are summarized in Table 2. Different protons are numbered as shown in Structure **1**. All the complexes display well-resolved spectra. The compounds with methyl substituted ligands, $[Ag(L^2)_2]^+$ and $[Ag(L^3)_2]^+$, systematically show a sharp and single methyl signal at δ_{Me} *ca* 2.3 ppm (Table 2).

The assignments of individual pyridyl ring proton signals were made[7,23-25] on the basis of their chemi-

[b] Solubility of $[Ag(L^4)_2](ClO_4)$ in $CDCl_3$ is low, a well-resolved spectrum could not be obtained.

cal shifts and also by examining the spin–spin splitting patterns of the signals. Thus, the signal due to 6-H and 3-H appear as doublets, whereas 5-H and 4-H are triplets. The chemical shifts of the pyridyl protons of $[AgL_2]^+$ complexes are in the order: $\delta_{6\text{-H}} > \delta_{3\text{-H}} > \delta_{4\text{-H}} > \delta_{5\text{-H}}$. Large downfield shifts of the 5-H and 6-H protons in moving from free L to the coordinated L also have been observed. In fact, this is a common feature of the ^1H NMR spectra of the transition metal complexes of L.[25] The signals due to individual aryl protons were assigned mainly by the use of the relative intensities of the signals and also by examining the substitution induced effect on the splitting patterns. For example, 8-H and 12-H signals appear as coincident doublets in the complexes of L^1 and L^3, as expected. The 8-H signal of the corresponding L^2 complex should appear as a separate singlet. Unfortunately, the assignment of the 8-H proton in $[Ag(L^2)_2]^+$ has not been achieved so far because of serious overlap with other signals. It is also to be noted here that like the methyl protons, all of the aromatic protons exhibited only one signal for each proton. From this data it is very likely that both the chelate rings in $[AgL_2]^+$ are magnetically equivalent at least on the NMR time scale and the complexes contain an effective C_2-axis, which is also in agreement with the proposed tetrahedral structure of the complexes.

CONCLUSION

It is demonstrated that 2-(arylazo)pyridine ligands display high affinity towards silver(I). Stable, tetracoordinated, bis-chelated complexes of the type $[AgL_2]^+$ are isolated and throroughly characterized with the help of spectroscopic data. We wish to note here that the examples of stable, monomeric, tetra-coordinated silver(I) complexes are rare. The ease with which L reacts with silver(I) and the stability of the resultant bis complexes, even in solutions, are uncommon in silver(I) chemistry.

EXPERIMENTAL

Materials

The ligands were synthesized as previously.[26] The purification/preparation of solvents and supporting electrolytes was carried out as previously.[2] Reagents were used as received. The $AgNO_3$ salt was obtained from Glaxo Laboratories, Bombay. All other chemicals and solvents used for preparative work were of reagent grade and were used without further purification.

Physical measurements

Spectroscopic data were obtained with the use of the following instruments: Electronic spectra, Beckman 26 spectrophotometer; IR spectra (KBr disc, 4000–300 cm^{-1}), Perkin–Elmer IR-983 spectrophotometer; ^1H NMR spectra ($CDCl_3$), Varian EM 390. Solution electrical conductivity was measured using a Elico CM 82 T conductivity bridge with a solution concentration of *ca* 10^{-3} mol dm^{-3}. Magnetic susceptibilities were measured with a PAR vibrating sample magnetometer (Model 155) fitted with a Walker scientific magnet (Model L 75 FBAL).

Beer's Law verification of the solutions of $[Ag(L^1)_2](ClO_4)$ have been made spectrophotometrically using the following concentrations: (i) MeOH: 2.6678×10^{-4}, 4.0017×10^{-4}, 5.3357×10^{-4}, 6.2694×10^{-4}, 6.6696×10^{-4} M. (ii) $CHCl_3$: 2.7027×10^{-4}, 4.0541×10^{-4}, 4.8649×10^{-4}, 5.4054×10^{-4}, 6.7568×10^{-4} M.

Synthesis of bis[2-(phenylazo)pyridine]silver(I) perchlorate, $[Ag(L^1)_2](ClO_4)$

A sample of $AgNO_3$ (0.170 g, 1 mmol) in methanol (10 cm^3) was heated to reflux for 15 min, and to it a solution of L^1 (0.365 g, 2 mmol) in methanol (10 cm^3) was added. The mixture was further heated

to reflux for 3 h. The reddish-brown solution was then cooled and filtered through a G4 sintered glass funnel. To the cold filtrate a solution of aqueous $NaClO_4$ (*ca* 2 g in 10 cm^3 of water) was added with constant stirring. A dark coloured compound precipitated and was collected by filtration and washed thoroughly with water. Recrystallization of the compound from methanol–water (1 : 1) yielded a highly crystalline, dark brown product which was dried *in vacuo* over P_4O_{10}. Yield 0.46 g (80%). Found: C, 45.5; H, 3.0; Ag, 18.9; N, 14.2. Calc. for $C_{22}H_{18}ClN_6O_4Ag$: C, 46.0; H, 3.1; Ag, 18.8; N, 14.6%. λ_{max} ($CHCl_3$): 448 nm (ε, 935 dm^3 mol^{-1} cm^{-1} and λ_{max} (CH_3OH): 462 nm (ε, 990 dm^3 mol^{-1} cm^{-1}).

Syntheses of bis[2-(m-*tolylazo*)*pyridine*]*silver*(I) *perchlorate*, $[Ag(L^2)_2](ClO_4)$; *bis*[2-(p-*tolylazo*)*pyridine*]*silver*(I) *perchlorate*, $[Ag(L^3)_2](ClO_4)$; *and bis*[2-(p-*chlorophenylazo*)*pyridine*]*silver*(I) *perchlorate*, $[Ag(L^4)_2](ClO_4)$

These were prepared similarly using the appropriate ligand. $[Ag(L^2)_2](ClO_4)$: Yield, 95%. Found: C, 47.6; H, 3.5; Ag, 18.2; N, 13.8. Calc. for $C_{24}H_{22}ClN_6O_4Ag$: C, 47.9; H, 3.7; Ag, 17.9; N, 14.0%. λ_{max} ($CHCl_3$): 457 nm (ε, 720 dm^3 mol^{-1} cm^{-1}) and λ_{max} (CH_3OH): 462 nm (ε, 825 dm^3 mol^{-1} cm^{-1}). $[Ag(L^3)_2](ClO_4)$: Yield, 80%. Found: C, 47.7; H, 3.6; Ag, 18.0; N, 13.8. Calc. for $C_{24}H_{22}ClN_6O_4Ag$: C, 47.9; H, 3.7; Ag, 17.9; N, 14.0%. λ_{max} ($CHCl_3$): 450 nm (ε, 875 dm^3 mol^{-1} cm^{-1}) and λ_{max} (CH_3OH): 455 nm (ε, 1010 dm^3 mol^{-1} cm^{-1}). $[Ag(L^4)_2](ClO_4)$: Yield, 80%. Found: C, 40.9; H, 2.3; Ag, 16.6; N, 12.9. Calc. for $C_{22}H_{16}Cl_3N_6O_4Ag$: C, 41.1; H, 2.5; Ag, 16.8; N, 13.1%. λ_{max} ($CHCl_3$): 455 nm (ε, 765 dm^3 mol^{-1} cm^{-1}) and λ_{max} (CH_3OH): 458 nm (ε, 830 dm^3 mol^{-1} cm^{-1}).

Syntheses of bis[2-(*arylazo*)*pyridine*]*copper*(I) *perchlorate*, $[CuL_2](ClO_4)$ (L = L^2–L^4)

These were prepared from $Cu(ClO_4)_2 \cdot 6H_2O$ and appropriate L by following the method described by Datta and Chakravorty.[1] The analytical and spectral data are as follows: $[Cu(L^2)_2](ClO_4)$: Yield, 60%. Found: C, 51.5; H, 3.8; Cu, 11.2; N, 15.0. Calc. for $C_{24}H_{22}ClN_6O_4Cu$: C, 51.7; H, 3.9; Cu, 11.4; N, 15.1%. λ_{max} (CH_3OH): 700 and 560 nm (ε, 1570 and 5625 dm^3 mol^{-1} cm^{-1}). $[Cu(L^3)_2](ClO_4)$: Yield, 55%. Found: C, 51.6; H, 3.7; Cu, 11.2; N, 14.9. Calc. for $C_{24}H_{22}ClN_6O_4Cu$: C, 51.7; H, 3.9; Cu, 11.4; N, 15.1%. λ_{max} (CH_3OH): 700 and 560 nm (ε, 1480 and 5530 dm^3 mol^{-1} cm^{-1}). $[Cu(L^4)_2](ClO_4)$: Yield, 60%. Found: C, 44.0; H, 2.4; Cu, 10.3; N, 13.9. Calc. for $C_{22}H_{16}Cl_3N_6O_4Cu$: C, 44.1; H, 2.77; Cu, 10.6; N, 14.0%. λ_{max} (CH_3OH): 700 and 560 nm (ε, 1415 and 5262 dm^3 mol^{-1} cm^{-1}).

Acknowledgement—We thank RSIC, North-Eastern Hill University, Shillong, for the spectral data.

VARIATION IN STABILITY OF MONOHALIDE COMPLEXES AND SOME PROPERTIES OF THE SOLVATED CATIONS WITHIN THE Mn^{2+}–Zn^{2+} SERIES

WACŁAW GRZYBKOWSKI

Department of Chemistry, Technical University of Gdańsk, 80-952 Gdańsk, Poland

(*Received* 18 *December* 1989; *accepted* 1 *May* 1990)

Abstract—The stability of the monohalide complexes of the divalent first-row transition metal cations in water as well as in other donor solvents follows the sequence: $MnX^+ > FeX^+ > CoX^+ > NiX^+ < CuX^+ > ZnX^+$. Moreover, some of the properties of the $M(solvent)_6^{2+}$ solvo-cations may be rationalized in terms of the same series. The observed sequence is opposite to that known as the Irving–Williams series.

The stability of the metal complexes in solution often is discussed in terms of hard and soft interactions of the metal cations and the respective ligands. This approach explains satisfactorily some of the observed variations and/or differences. More quantitative discussion is based upon the Gutmann's donor number (DN). Further and more profound analysis makes use of splitting the free-energy change into the enthalpy and entropy contributions.

However, these common and useful tools seem to be useless when the stability constants of similar but weak complexes are compared, and relatively small differences are discussed.

It seems to be well established that the stability constants of the monohalide complexes of the divalent first-row transition metal cations in water, as well as in most non-aqueous solvents, follow the sequence

$$MnX^+ > FeX^+ > CoX^+ > NiX^+ < CuX^+ > ZnX^+.$$

This series has been reported for both the MCl^+ and MBr^+ type complexes in water,[1,2] and for the MCl^+ complexes in dimethyl sulphoxide solutions.[3–5] The same trend was observed for the MF^+ complexes in water and methanol,[6] and for MCl^+ in methanolic solutions.[7] More recently, this series was reported for MCl^+ complexes in N,N-dimethylformamide (DMF) solution.[8] A similar sequence was obtained for MBr^+ type complexes in N,N-dimethylacetamide (DMA).[9,10]

The values of logarithms of the stability constants for most of the above mentioned systems are presented in Table 1. It was impossible to find data for the monohalide complexes of all the transition metal cations belonging to the Mn^{2+}–Zn^{2+} series, in the same solvent and obtained using the same method. This is due to the known sensitivity of iron(II) towards oxidation, and the high stability of di-, tri- and tetrahalide complexes of zinc(II), both responsible for most of the gaps existing in the table. Inspection of the collected data shows that the values for a given solvent vary within relatively narrow limits, while the copper(II) complexes are the most stable species within the series studied. Moreover, the lowest stabilities are displayed by the monohalide complexes in aqueous systems. Despite the gaps and experimental uncertainties, unavoidably present in the values of the similar data, the above sequence seems to be well established.

The same variation within the Mn^{2+}–Zn^{2+} series was observed for the first-step ionic association with the perchlorate anion in methanolic solution.[11]

The presented trend is distinctly opposite to the regularity

$$Mn^{2+} < Fe^{2+} < Co^{2+} < Ni^{2+} < Cu^{2+} > Zn^{2+}$$

well known as the Irving–Williams series[12] and obeyed by a large number of complexes in aqueous solution, especially when ligands have an N- or O-donor atom.

It has been shown by different authors that the stabilities of the monohalide complexes of the tran-

[d] Thermodynamic stability constants (variation of activity coefficients assumed to follow D–H equations).

sition metal cations are entropy controlled, i.e. the entropy term in free energy predominates over the enthalpy term, and although their enthalpies of formation are positive, the complexes have negative free energies of formation.[5,6] The results reported by Doe *et al.* clearly show that the ionic association of the transition metal perchlorates in methanol is also the consequence of unfavourable enthalpy and favourable entropy changes.[11]

The exceptions to the Irving–Williams series were considered as rather atypical behaviour. However, in the existing experimental data, the same trends and the same orders of magnitude, observed for non-aqueous systems, are an indication of the existence of a factor common for the complexes under consideration, and the sequence

$$Mn^{2+} > Fe^{2+} > Co^{2+} > Ni^{2+} < Cu^{2+} > Zn^{2+}$$

seems to be characteristic for the complexes whose stabilities are entropy controlled. The opposite situation, i.e. the enthalpy control of the complex formation, is related to reactions following the Irving–Williams series.

In Table 2 the available values of entropies of complex formation are listed along with the data for the ionic association of the perchlorates in methanol. Inspection of the collected data shows that for each of the solvents the entropy of formation of the CuX^+ complex is distinctly higher than that of the MnX^+, FeX^+, CoX^+, NiX^+ and ZnX^+ complexes or associates. Furthermore, the values for the latter species in DMSO and methanol may be considered as practically independent of the nature of the cation. The scatter of the data obtained for the aqueous systems seems to result from large experimental uncertainties in the very small stability constants of the monofluoride complexes.[6]

The divalent first-row transition metal ions are known to form well-defined coordination clusters in solution, and in the absence of coordinatively active anions exist as the $M(solvent)_6^{2+}$ type species in water as well as in most non-aqueous solvents.[13,14]

The equilibrium between the hexakis- and tetrakis-(solvent) species seems to be one of the factors controlling the solvation processes in DMA solution. The steric crowding caused by the acetyl groups stabilizes the $M(solvent)_4^{2+}$ solvates. However, at room temperature the tetrakis-(solvent) species exist as less than 5% of the total metal concentration, and $Co(DMA)_6^{2+}$ and $Ni(DMA)_6^{2+}$ are predominant species present in solutions of the respective perchlorates.[15,16] The

Table 2. Entropy of formation of MX^+ type complexes at 25°C

Units: $J\,K^{-1}\,mol^{-1}$.

tetrakis-(solvent) species of the transition metal cations exist in N,N,N-hexamethylphosphortriamide (HMPA) solutions.[17]

Thermodynamical aspects of complex formation and the properties of the solvates cannot be discussed separately. It is obvious that the high entropy gain is related to the release of the solvent molecules during the inner-sphere complex formation, in accordance with

$$MS_6^{2+} + X^- \rightleftharpoons MXS_5^+ + S,$$

where S denotes a solvent molecule. The entropy gain on desolvation is increased on account of the loss of order in the bulk solvent. Substitution of the X^- anion for a solvent molecule in the first coordination sphere of a metal cation results in a substantial decrease in charge density. Thus, the total entropy change may be independent of the nature of the central metal ion with the same electrical charge. Distinctly higher entropy of formation of the $CuCl^+$ complex in DMSO was interpreted by Libuś and Pastewski in terms of formation of the pentacoordinated $CuCl(DMSO)_4^+$ complex, resulting in the liberation of two solvent molecules.[5] An analogous explanation was suggested by Doe *et al.* for the relatively high enthalpy and entropy values of the Cu^{2+}–ClO_4^- ion-pair in methanol.[11] The ClO_4^- anion which forms the ion-pair with the Cu^{2+} cation may be substituted for a methanol molecule in the primary solvation shell, while the ClO_4^- ions are outside this shell for other transition metal cations.

It is well known that the Jahn–Teller distorted octahedrons are observed for the structure of the primary solvation sphere of the Cu^{2+} cation. Two of the six solvent molecules are bound weakly to the Cu^{2+} ion with a long Cu^{2+}–donor atom of a solvent molecule distance, and they are more susceptible to ligand substitution as well as solvent exchange. Thus the reactivity of the Cu^{2+}–solvates and their position within the Mn^{2+}–Zn^{2+} series are a consequence of the $3d^9$ electronic structure.

The exchange of solvent molecules between the primary solvation shell of a cation and bulk solvent is a fundamental reaction for metal ions in solution. The kinetic parameters obtained from NMR studies of the first-row divalent transition metal cations indicate that the mechanism for solvent exchange varies from an associative activation mode for the early elements to a dissociative activation mode for the latter ones.[18] However, it has been reported by Merbach that the sequence of reactivity is independent of the exchange mechanism and the solvent following the series.

$$Cu^{2+} > Mn^{2+} > Fe^{2+} > Co^{2+} > Ni^{2+} > V^{2+},$$

which agrees well with the predictions based on the crystal-field theory.

The solvent-exchange rate constants for Mn^{2+}–Zn^{2+} are listed in Table 3 which includes data collected by Merbach,[19] Funahashi,[20] and Hewkin[21] plus that reported by other authors.[22-24]

Inspection of the data shows that Merbach's series can be presented by the sequence

$$Mn^{2+} > Fe^{2+} > Co^{2+} > Ni^{2+} < Cu^{2+} > Zn^{2+}$$

which reflects exactly the above variation of the respective stability constants within the Mn^{2+}–Zn^{2+} series.

The logarithms of the stability constants of the monohalide complexes in aqueous solution and the water-exchange rate constants are presented in Fig.

Table 3. Logarithms of first-order rate constants (s^{-1}, 25°C) for solvent exchange in the Mn^{2+}–Zn^{2+} cations

	Solvent

1. In order to observe the dependence of the studied properties on the nature of the central metal ion, the data are plotted against the position of the metal cation within the Mn^{2+}–Zn^{2+} series, i.e. as a correlation with the number of 3*d* electrons. Moreover, the electrostriction partial molar volumes of the hydrated cations[25] are presented in this figure. The partial molar volume of the ion can be split into two major components. One of them, the intrinsic partial molar volume, is related to the size of an ion, while the second, the electrostriction partial molar volume, is determined by ion–solvent interactions. The correlation of the electrostriction volume with the rate constant of solvent exchange was reported earlier.[14]

It thus appears that the volume properties of the hydrates show a variation which may be interpreted in terms of ligand-field effects. According to the theory the highest LFSE is expected for the octahedral high-spin complexes of nickel(II). Thus, it is not surprising that the largest electrostriction is observed for $Ni(H_2O)_6^{2+}$. The position of $Cu(H_2O)_6^{2+}$ within the series is obviously due to the tetragonal elongation of two metal–ligand bonds arising from the Jahn–Teller effect. Otherwise, the evident parallel between the electrostriction volume of the cations and their lability appears to be easily understood. The faster the water-exchange mechanism the more distinct is the looseness of the structure of the nearest environment of the cation, irrespective of the mechanism for solvent exchange.

The striking parallel between the stability of the monohalide complexes and the rate of the water-exchange mechanism seems to be a distinct representation of the relationship between the thermodynamic and kinetic parameters. The greater the lability of the hydrates the higher the frequency of appearance and disappearance of the intermediate species. Their generation precedes entry of the X^- anion into the coordination sphere of the cation and MX^+ complex formation. The discussed analogy in the variation within the Mn^{2+}–Zn^{2+} series may be considered as a simple relationship between the probability of complex formation and its stability. Thus, it may be referred to the entropy change as a factor controlling stability of the monohalide complexes.

Analogous correlations for the methanol and DMF solutions are presented in Figs 2 and 3. Unfortunately, there are some gaps in the data and a full comparison cannot be completed. However, in accordance with the crystal-field theory, high lability of the $Cu(DMF)_6^{2+}$ may be expected, and the assumption that the Cu^{2+}–solvate is much more reactive than the Zn^{2+}–solvate does not need any additional support.

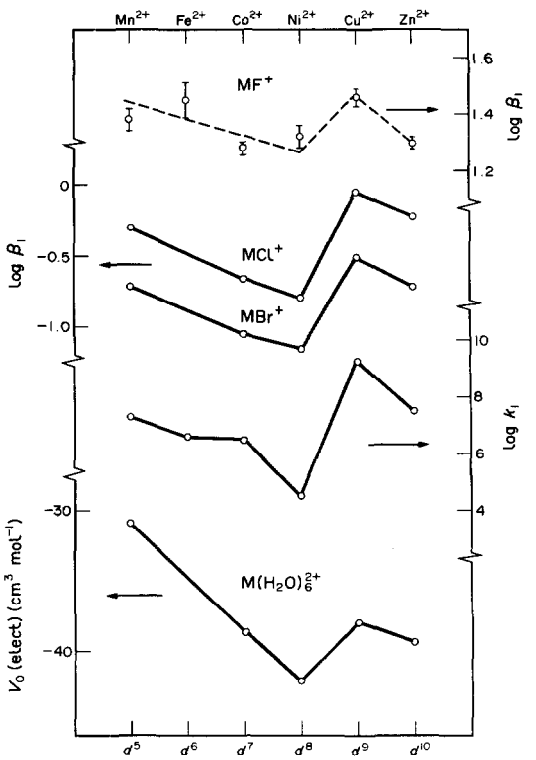

Fig. 1. Plots of logarithms of the stability constants of the monohalide complexes ($\log \beta_1$), logarithms of the rate constant for the water-exchange mechanism ($\log k_1$), and the electrostriction volumes $\bar{V}^0$(elect) against the position within the Mn^{2+}–Zn^{2+} series for the divalent cations in water.

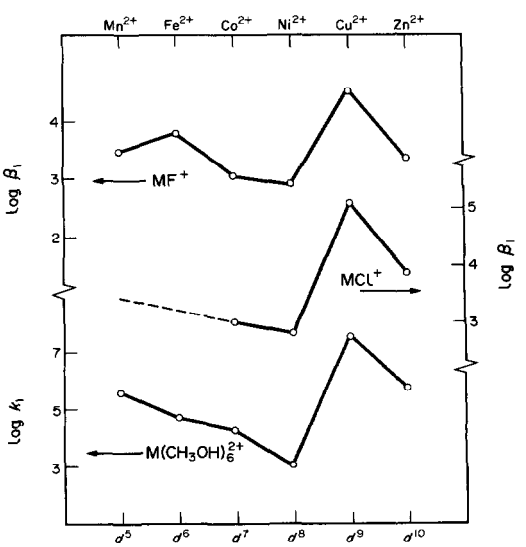

Fig. 2. Plots of logarithms of the stability constants ($\log \beta_1$) and logarithms of the rate constant ($\log k_1$) for the solvent exchange of the divalent cations in methanol.

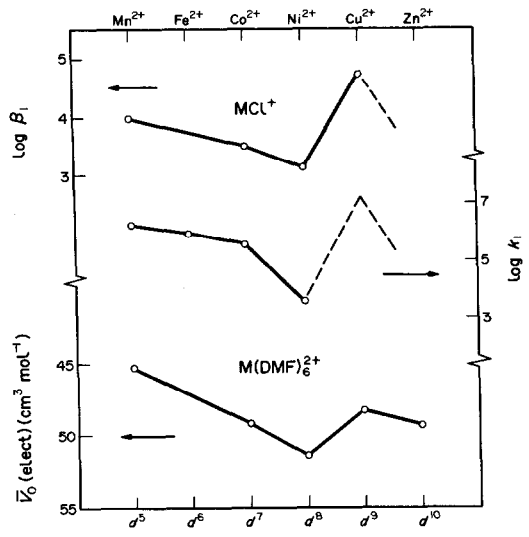

Fig. 3. Plots of logarithms of the stability constants of the MCl^+ type complexes, logarithms of the rate constant for solvent exchange, and the electrostriction volumes for the divalent cations in DMF.

Exceptional behaviour was observed for the monobromide complexes in DMA. The $MnBr^+$ complex exhibits significantly lower stability, its stability constant is lower than the value obtained for $CoBr^+$.[9,10] This difference exceeds the differences observed for MnF^+ and FeF^+ complexes in water and methanol, and is probably due to the sensitivity of iron(II) towards oxidation. The peculiarity of the DMA solutions may be related to the steric effects resulting in a lowering of the stability of the hexakis-(solvent) species.

Thus, the sequence

$$Mn^{2+} > Fe^{2+} > Co^{2+} > Ni^{2+} < Cu^{2+} > Zn^{2+}$$

seems to be valid for the cations forming the stable octahedral solvates. Moreover, it is independent of solvent and is related to the progressive filling of the 3*d* orbitals. The exchange of solvent molecules between the first coordination sphere of a metal cation and bulk solvent may be considered as the fundamental process for understanding the solvocation properties as well as complex formation and stability.

The relationships between the probability of complex formation and the stability constants were used in the mathematical models concerned with the formation of a stepwise series of mononuclear complexes. The pioneering and classical work was due to J. Bjerrum, while a more recent model was described by Mihailov.[26] However, the problem seems to be more complex and too difficult to be solved in terms of these oversimplified mathematical models.

(*Received* 23 *January* 1990; *accepted* 1 *May* 1990)

Abstract—Several (trialkylgermyl)alkali metals (M = Li, Na, K) were investigated by UV, ^{1}H and ^{13}C NMR spectroscopic methods to clarify the nature of a germanium–(alkali metal) bond. On conversion of a trialkylgermane to the corresponding germylalkali metals, the bathochromic shift of UV absorption maxima, upfield shift of the ^{1}H NMR signals and downfield shift of the ^{13}C NMR signal are observed.

Group 4B element-centred anions, homologues of carbanions, especially silyl and germyl anions have recently been recognized as useful synthetic reagents, and are effective for the introduction of the silyl and germyl groups into some types of organic compounds.[1] Although UV and NMR spectroscopic studies on properties of carbanions pertaining to their reactivities have been extensively carried out,[2] there have been relatively few reports on those of other group 4B element-centred anions.[3–15] Particularly on organogermyl anions, there have been no reports except one for phenyl-substituted germylalkali metals.[16] We describe herein the first information on UV and NMR spectroscopic characteristics of several (trialkylgermyl) alkali metal compounds and endeavour to clarify their spectroscopic properties.[1,17,18]

EXPERIMENTAL

^{1}H and ^{13}C NMR spectra were recorded on a JEOL FX 90Q instrument with HMPA–THF-d_8 solutions, and chemical shifts are referred to internal HMPA (δ 2.54 ppm for ^{1}H NMR) and THF-d_8 (δ 68.40 ppm for ^{13}C NMR). UV and visible spectra were recorded on a Shimazu UV-180 spectrometer.

Solvent

HMPA was distilled from CaH_2 under argon. THF-d_8 was distilled from sodium/benzophenone under argon.

Materials

Me_3GeCl, b.p. 115°C;[19] Me_3GeH, b.p. 26°C;[20] $(Me_3Ge)_2$, b.p. 137°C;[21] Et_3GeCl, b.p. 92°C/30 mmHg;[22] Et_3GeH, b.p. 123°C;[23] and $(Et_3Ge)_2$, b.p. 73°C/0.7 mmHg[24] were prepared by established methods.

Preparation of trialkylgermyl anions

(Trialkylgermyl)alkali metals were prepared from the reaction of the corresponding chlorides with alkali metals in HMPA–THF using the method described by Bulten and Noltes.[24]

UV absorption spectra of trialkylgermyl anions

The alkyl-substituted germyl anions are extremely sensitive to oxygen and moisture. A

* Author to whom correspondence should be addressed.

closed absorption cell was used to observe the UV absorption spectra of these anions.[26] The absorption cell apparatus used in this study consists of a 1 cm quartz absorption cell sealed to the side arm of a round-bottomed flask. The apparatus was connected to a high-vacuum system for alternate degassing and flushing with argon. Access to the flask was through a second side arm closed by a rubber syringe cap. The anions were prepared by contact of alkali metal with alkylgermyl chlorides in highly degassed HMPA–THF solvent in the round-bottomed flask.

NMR studies of trialkylgermyl anions

Alkyl-substituted germyl anions in HMPA–THF were prepared as described above. Approximately 1 cm^3 of the anion solution was transferred by means of a syringe into an argon-flushed NMR tube. The NMR tube containing the anion was degassed and sealed.

RESULTS AND DISCUSSION

Absorption spectra of trialkylgermyl anions

Electronic spectra of anions provide a good insight into the nature of their electronic structures. (Trialkylgermyl)alkali metal compounds have been generated from the corresponding chlorogermanes and alkali metals in HMPA–THF at room temperature quantitatively[24] and their formation can be rationalized by the dissociative electron-transfer attachment processes as shown below[16]

$$2\,R_3GeCl + 2\,M \longrightarrow (R_3Ge)_2 + 2\,MCl \quad (1)$$

$$(R_3Ge)_2 + 2\,M \longrightarrow 2\,R_3GeM \quad (2)$$

R = Me, Et, n-Pr, n-Bu; M = Li, Na, K.

All of the (trialkylgermyl)alkali metal compounds are yellow in HMPA–THF. As typical examples, the absorption spectra of Me_3GeM (M = Li, Na and K) are shown in Fig. 1. All show absorption maxima at 270–300 nm. The absorption maxima of starting trimethylchlorogermane and the intermediate, hexamethyldigermane, are known to be located below 220 nm.[25] Since measurements of these absorption spectra arising from germylalkali metals are possible only by the use of sealed UV cells in an inert gas atmosphere, the molar extinction coefficient could not be determined. The wavelength data for the absorption maxima (λ_{max}) of the (trialkylgermyl)alkali metal compounds in HMPA–THF are summarized in Table 1. Judging from the data in Table 1, the nature of the counterion has only a slight influence on λ_{max} which increases in the order Li ≃ Na < K. This implies that the germyl metal has highly ionic character, and hence in a qualitative way the absorption band observed may be stated to arise from the transition from the non-bonding orbital of the germyl anions (HOMO) to the lowest antibonding orbital of germanium–carbon bonds (LUMO). Similar small red shifts have been reported for the spectra of some organoalkali metals[26] and phenyl-substituted group 4B element-centred anions.[16]

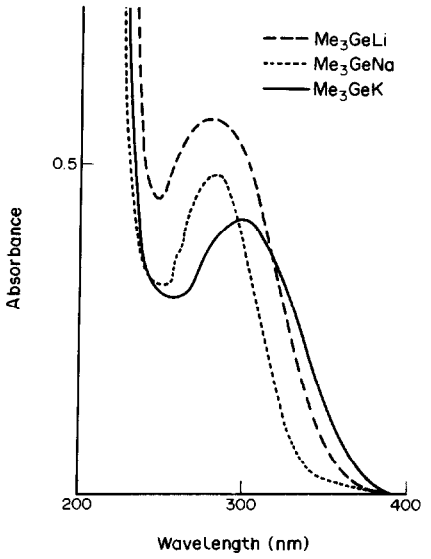

Fig. 1. UV spectra of (trimethylgermyl)alkali metals.

Table 1. Absorption data of UV spectra for alkyl-substituted germylalkali metals in HMPA–THF

Compound	λ_{max} (nm) for M = Li	Na	K
Me_3Ge	280	280	300
Et_3Ge	< 280	~ 280	290
n-Pr_3Ge	< 280	~ 280	290
n-Bu_3Ge	< 280	~ 280	290

A small but distinct substituent effect on absorption maxima is noted, namely, the (trimethylgermyl)alkali metal compounds exhibits it at longer wavelengths than the other (trialkylgermyl) alkali metal compounds (see Table 1).

^1H and ^{13}C NMR studies

The ^1H NMR chemical shifts of (trimethylgermyl)alkali metals and (triethylgermyl)alkali metals, and their related compounds are summarized in Table 2. As shown in Table 2, the

Et_3GeH	5.09	11.45
$(Et_3Ge)_2$	7.18	11.55

methyl proton signal of trimethylgermane is located at +0.21 ppm, whereas trimethylgermyllithium gives the corresponding signal slightly further upfield, −0.35 ppm. On the other hand, trimethylgermylsodium affords the signal at small but further upfield than those of trimethylgermyllithium and -potassium, this may be attributed to the difference in their degree of aggregation. The ethyl protons of triethylgermane appear as rather complex multiplets around +1.2 ppm. Metallation of the hydrogen atom of triethylgermane with lithium causes a considerable upfield shift of the signal due to the α-hydrogen (CH_2Ge) which appears as a quartet at +0.13 ppm. The influence of metallation on the chemical shift of the β-hydrogen (CH_3—C—Ge) is small, the signals appear at +0.97 ppm as a triplet. The ^{1}H NMR signals due to triethylgermylsodium and -potassium have very similar chemical shifts and patterns.

The ^{13}C NMR data of trimethyl- and triethylgermyl metals and their related compounds are summarized in Table 3. On metallation of trimethylgermane to trimethylgermyllithium, the ^{13}C NMR methyl signal moves to lower field, namely, from δ −2.15 to δ 12.59. Similarly, in the case of the ethyl derivatives, the ^{13}C NMR signal due to the α-carbon of the ethyl group shifts to lower field from δ 5.09 to δ 17.49. Similar trends in ^{13}C NMR data of triethylgermylsodium and -potassium are observed as shown in Table 3. The paramagnetic shift on metallation may be attributed to the decrease in transition energy which may cause a red shift of the UV absorption maxima described above. On metallation of a hydrocarbon with lithium, the ^{13}C NMR signal due to the α-carbon to lithium is reported to show an upfield shift in contrast to the germane mentioned above, whereas that of the β-carbon is shifted downfield from the corresponding hydrocarbons.[27]

Acknowledgements—The authors thank Professor Yoshito Takeuchi and Dr Toshie Hanazono of Tokyo University for recording the ^{13}C NMR spectra of some of the germyl anions.

ELECTRON DISTRIBUTION WITHIN BIS(QUINONE)RUTHENIUM COMPLEXES. STRUCTURAL CHARACTERIZATION ON DELOCALIZED (BIPYRIDINE)BIS(QUINONE)RUTHENIUM AND ON THE LOCALIZED *TRANS*-BIS(3-CHLOROPYRIDINE)BIS(3,5-DI-TERT-BUTYL-1,2-SEMIQUINONE)RUTHENIUM(III) CATION

STEVEN R. BOONE and CORTLANDT G. PIERPONT*

(*Received* 19 *January* 1990; *accepted* 9 *May* 1990)

Abstract—Structural information obtained on complexes containing semiquinone and catecholate ligands has provided insights on charge distribution. Ligand C—O lengths found for *trans*-Ru(4-t-Bupy)$_2$(DBQ)$_2$ averaged 1.321(5) Å, midway between values of 1.34 and 1.29 Å expected for localized catecholate and semiquinone ligands. This value may arise from crystallographic disorder of a localized Ru^{III}(SQ)(Cat) species or it may result from charge delocalization over both quinone ligands. Crystallographic characterization of Ru(bpy)(Q)$_2$, where Q is the unsubstituted *o*-quinone ligand, has shown that the complex molecule crystallizes without imposed symmetry on the molecule, in a crystal structure that places both quinone ligands in different solid-state environments. The four independent C—O lengths average 1.321(5) Å, without significant variation, strongly suggesting charge delocalization over both quinone ligands. Characterization on the *trans*-Ru(3-Clpy)$_2$(DBQ)$_2^+$ cation, formed by one-electron oxidation of a neutral species that would be expected to show ligand charge delocalization, has shown ligand C—O lengths of 1.293(4) Å, exactly the value expected for semiquinone ligands. Oxidation of the neutral complex appears to occur at a ligand delocalized electronic level to give a ligand localized bis(semiquinone) product, Ru^{III}(SQ)$_2^+$.

Internal transfer of charge between electroactive transition metal ions and chelated *o*-quinone ligands sometimes complicates the assignment of formal charge within the chelate ring of complexes containing semiquinone and catecholate ligands.[1] Spectroscopic or magnetic properties may provide information on the oxidation state of the metal. Mössbauer spectra and variable-temperature magnetic susceptibility measurements have provided specific information on the charge distribution within the tris(semiquinone)iron(III) complexes, compounds that were among the first homoleptic semiquinone metal complexes.[2,3] Crystallographic molecular structure determinations have provided structural criteria for assigning charge distributions for complexes containing semiquinone and catecholate ligands.[1] Bond lengths to the metal are sometimes sensitive to both oxidation and spin state, but the structural features of the quinone ligand are nearly invariant. In particular, carbon–oxygen bond lengths of 1.34, 1.29 and 1.23 Å have been found from a large number of structure determinations to be characteristic of coordinated catecholate, semiquinone and *o*-benzoquinone electronic forms of the quinone ligands. Since localized charge assignments appear to be appropriate for the ligands of quinone complexes, charge delocalization between ligand and metal is thought to be less important for this class of compounds than for the oxidized 1,2-dithiolene or reduced 1,2-diimine complexes.[4]

Recent structural characterization on ruthenium quinone complexes seemed to show a break in this pattern of well-defined metal and quinone ligand

* Author to whom correspondence should be addressed.

charge assignments.[5] Spectroscopic characterization on the Ru(bpy)$(Q)_2$ and *trans*-Ru(py)$_2(Q)_2$ series failed to provide definitive information on charge distribution, and appeared to indicate electronic delocalization.[6] Structural characterization on *trans*-Ru(4-t-Bupy)$_2$(DBQ)$_2$, containing the 3,5-di-tert-butylquinone ligand, supported the idea of delocalization by showing that both quinone ligands were structurally equivalent with C—O lengths of 1.321(5) Å.[5] This value is midway between the semiquinone and catecholate values observed in other structures, and could potentially arise from disorder of semiquinone and catecholate ligands coordinated to ruthenium(III) in a complex molecule of localized charge distribution, Ru^{III}(4-t-Bupy)$_2$(DBSQ)(DBCat). Species with mixed-charge quinone ligands are known for the M^{III}(bpy)(DBSQ)(DBCat) (M = Cr, Fe, Co) series,[7–9] and the difference in charge between the two quinone ligands of Co(bpy)(DBSQ)(DBCat) appeared in the structural features of the molecule.[9] We now report the results of structural studies on two bis(quinone)ruthenium complexes with the hope that metrical features of the molecules will provide information on charge distribution and electronic structure. The first complex is Ru(bpy)$(Q)_2$, where the unsubstituted quinone ligands are not directly related by crystallographic symmetry and are contained in different solid-state environments in the crystal lattice. The second complex is the Ru(3-Clpy)$_2$(DBQ)$_2^+$ cation, which was obtained by oxidation of the neutral complex, and may provide information on the nature of the electronic level involved in the oxidation of the neutral parent complex.

RESULTS

Description of Ru(bpy)$(Q)_2$

The Ru(bpy)$(Q)_2$ molecule is isoelectronic with *trans*-Ru(4-t-Bupy)$_2$(DBQ)$_2$ and may be expected to have a similar charge distribution. Reasonable options for localized charge distribution for the Ru$(Q)_2$ regions of both complexes include $Ru^{II}(SQ)_2$, Ru^{III}(SQ)(Cat) and $Ru^{IV}(Cat)_2$. Ruthenium–nitrogen and ruthenium–oxygen bond lengths are more sensitive to the donor properties of the ligand than to electronic differences in the ruthenium ion, and are not reliable indicators of metal ion charge.[10] Carbon–oxygen lengths of the quinone ligands have been generally found to reflect ligand charge, and the formal charge of the quinone ligands can be used to determine the oxidation state of the metal. The two independent C—O lengths of *trans*-Ru(4-t-Bupy)$_2$(DBQ)$_2$ were 1.320(5) and 1.322(5) Å, indicating a charge for the ligand that was midway between SQ and Cat, with delocalization contributing to the similarity between the two ligands. A second possibility is that the charge distribution is localized as Ru^{III}(SQ)(Cat), but that the two different quinone ligands are disordered with the crystallographically-imposed inversion symmetry on the molecule.[5] The crystal structure of Ru(bpy)$(Q)_2$ consists of complex molecules with no imposed symmetry. A view of the molecule is shown in Fig. 1 and bond distances and angles are given in Table 1. Closest intermolecular contacts result from a weak stacking interaction between bipyridine ligands of adjacent molecules, shown in Fig. 2, through the inversion centre at [1/2,0,0]. Weaker pairing interactions occur between quinone ligands through inversion centres at [0,0,0] and [1/2,1/2,0], and the intermolecular interactions in the solid-state place the two quinone ligands in symmetrically different environments. If a localized Ru^{III}(SQ)(Cat) charge distribution is appropriate for the complex, the asymmetry in its solid-state environment may result in a structural difference between the two ligands. Effects of this type sometimes result in valence-trapped electronic structures for otherwise delocalized mixed-valence metal complexes,[11] and the structure of Co(bpy)(DBSQ)(DBCat) showed structurally dissimilar quinone ligands.[9] All four C—O lengths of the structure, given in Table 1, are within error of being identical, and the average value of 1.321(5) Å is identical to the average value found for *trans*-Ru(4-t-Bupy)$_2$(DBQ)$_2$.

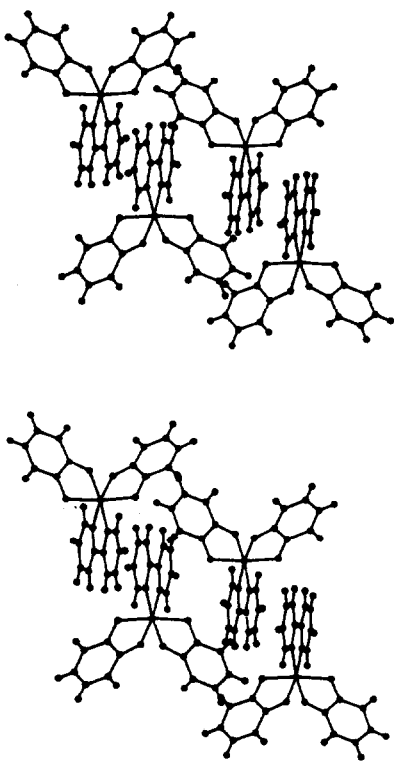

Fig. 2. Stereoview showing the bipyridine stacking interactions between adjacent Ru(bpy)$(Q)_2$ molecules.

shorter than Ru—O lengths to the oxygens *trans* to the bipyridine nitrogens. All four Ru—O lengths are relatively short due, presumably, to strong σ- and π-bonding interactions. Ruthenium–nitrogen lengths of 2.042(3) and 2.055(4) Å agree well with values of 2.045(5) and 2.054(5) Å found at sites *trans* to chloro ligands of *cis*-Ru(bpy)$_2Cl_2^+$.[10] Synergistic stabilization of *trans*-quinone Ru—O bonds also appears as a feature in Ru$(DBQ)_3$, where the average length is 1.972 Å and the bonds are among the shortest reported for all but lengths to oxo ligands.[12]

Bond angles about the ruthenium show that the complex has a regular octahedral structure with allowance for angular constraints of five-membered chelate rings. Bite angles of the quinone ligands are slightly larger [81.9(1)°] than the bipyridine bite angle of 78.2(2)°.

Description of trans-Ru(3-Clpy)$_2(DBSQ)_2^+$

The *trans*-Ru(3-Clpy)$_2(DBQ)_2^+$ cation is located about a crystallographic inversion centre which results in *trans* dispositions for the chloro substituents of the pyridine ligands and for the t-butyl substituents of the quinone ligands in the solid-state. A view of the cation is shown in Fig. 2, bond distances and angles are given in Table 2. Quinone C—O lengths of the cation are clearly indicative of charge distribution in this case. With values of 1.289(4) and 1.296(4) Å, they are both in the 1.29 Å range associated with semiquinone ligands.[1,3] Carbon–carbon bond lengths within the ring conform to the pattern noted for semiquinone ligands of other complexes[3] with a length for C(1)—C(2) which is slightly longer than the aromatic value, and shorter values for C(3)—C(4) and C(5)—C(6). Charge distribution for the cation is therefore $Ru^{III}(SQ)_2^+$, and a direct comparison can be made with

O(2)—Ru—N(1)	88.9(1)		

neutral *trans*-Ru(4-t-Bupy)(DBQ)$_2$. Ruthenium–nitrogen lengths for the two structures are essentially the same with values of 2.085(3) Å for the cation and 2.079(3) Å for the neutral molecule. The average Ru—O length of the cation is 2.010(2) Å, slightly longer than the value of 1.994(3) Å for the neutral complex molecule. This may result from weaker donation to the metal by the partially reduced semiquinone ligands. The bite angle of the semiquinone ligand of *trans*-Ru(3-Clpy)$_2$(DBSQ)$_2^+$ is 79.8(1)°, slightly more contracted than the 80.5(1)° value of *trans*-Ru(4-t-Bupy)(DBQ$_2$).

DISCUSSION

Structural characterization on the neutral bis (quinone) complexes, *trans*-Ru(4-t-Bupy)$_2$(DBQ)$_2$ and Ru(bpy)(Q)$_2$, has provided results that indicate that the charge distributions for the two complexes are essentially the same. Carbon–oxygen lengths of the quinone ligands are intermediate between values expected for semiquinone and catecholate ligands. The localized charge form Ru^{III}(SQ)(Cat) with resonant delocalization over both ligands, eq. (1), is, perhaps, the most appropriate description for the electronic structure.

$$(SQ)Ru^{III}(Cat) \rightleftharpoons (Cat)Ru^{III}(SQ). \quad (1)$$

The electronic ground states of the oxidized 1,2-dithiolene and reduced 1,2-diimine complexes are ligand delocalized levels with little or no metal orbital contributions.[4] Electron pairing between the ruthenium(III) centre and the semiquinone radical ligand may occur by strong antiferromagnetic coupling or within the set of electronic levels that arise from strong molecular orbital interactions. The sharp NMR signals that the neutral complexes show seem to point most strongly to a delocalized MO electronic structure.

Reversible oxidation of the ligand delocalized level would result in an electronic form for the complex which is ostensibly a bis(semiquinone)species, eq. (2).

$$Ru^{III}(SQ)(Cat) \rightleftharpoons Ru^{III}(SQ)_2^+ + e^-. \quad (2)$$

This is in accord with the structural features of *trans*-Ru(3-Clpy)$_2$(DBSQ)$_2^+$. It also agrees with the EPR spectra recorded on the $S = 1/2$ cationic com-

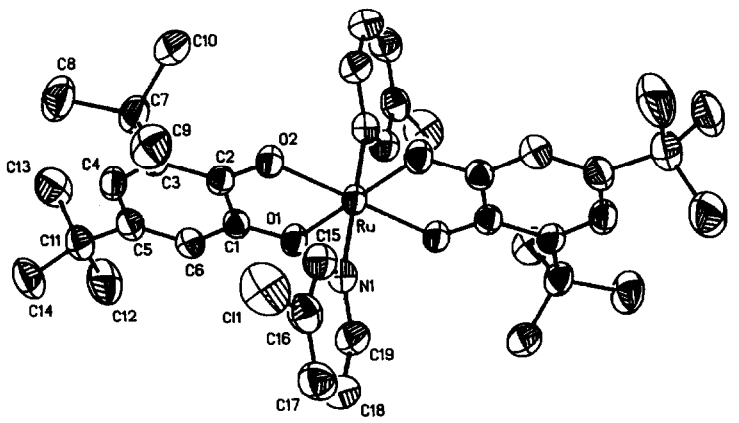

Fig. 3. View of the Ru(3-Clpy)$_2$(DBSQ)$_2^+$ cation.

plexes.[6] Resonances of the one-electron oxidation products are centred close to the free-electron g value, show no ligand proton hyperfine, and split to give weakly axial or rhombic signals at 77 K, with a difference between $g_{\parallel}$ and $g_{\perp}$ of 0.04. A slight metal orbital contribution to the ground state together with the large spin–orbit coupling constant of ruthenium(III) may be responsible for the anisotropy of the low-temperature glass spectrum.

Neutral quinone complexes have been prepared with metals on either side of ruthenium and osmium. With technetium and rhenium, charge-localized catecholate complexes, $M(Cat)_3$, are formed.[13] Palladium and platinum form bis(semiquinone) complexes, $M(SQ)_2$, with divalent metal ions.[14] Quinone complexes of rhodium and iridium await detailed characterization, but there is a marked tendency toward localized charge distributions for quinone complexes of metals other than ruthenium. Even the osmium analogues of the ruthenium complexes appear to show properties characteristic of charge-localized catecholate species.[12,15] Currently, the neutral bis and tris (quinone) complexes of ruthenium stand as the unique examples of delocalized quinone bonding with transition metals.

EXPERIMENTAL

Crystals used in this investigation were provided by Professor A. B. P. Lever of York University, Ontario, Canada.

Structure determination on $Ru(bpy)(C_6H_4O_2)_2$

A dark blue crystal of $Ru(bpy)(Q)_2$ suitable for crystallographic analysis was mounted and aligned on a Nicolet P3/F automated diffractometer. Crystal quality was examined by using rotational and axial photographs and was judged satisfactory for data collection. Information regarding data collection and structure determination is given in Table 3 and in the supplementary material. The location of the ruthenium atom was determined from a Patterson map; the locations of other atoms were determined from phases generated by using the ruthenium atom position. Fixed contributions for hydrogen atoms were included in final cycles of refinement. All non-hydrogen atoms of the molecule were refined with anisotropic thermal parameters. Final atomic coordinates for $Ru(bpy)(Q)_2$ and tables containing anisotropic thermal parameters and structure factors are available as supplementary material.

Structure determination on $[Ru(3\text{-}Clpy)_2(DBSQ)_2](PF_6)\cdot Et_2O$

A dark blue crystal of $[Ru(3\text{-}Clpy)_2(DBSQ)_2](PF_6)$, grown from a diethyl ether solution, was mounted and aligned on the diffractometer. Crystallographic information for the complex is given in Table 3 and in the supplementary material. The complex crystallizes in the centrosymmetric triclinic space group $P\bar{1}$ with one formula unit per unit cell.

Phases obtained from a structure factor calculation with the ruthenium atom at the origin [0,0,0] gave other non-hydrogen atoms of the complex cation and revealed the PF_6^- anion with the phosphorus atom located at the inversion centre [1/2,1/2,1/2]. Fluorine atoms of the anion were disordered about four sets of factional-atom locations. Final cycles of refinement revealed a cluster of peaks on the difference Fourier map located near the inversion centre at [0,0,1/2]. These peaks were judged to be a disordered diethyl ether solvate molecule, and were refined accordingly. Fixed contributions for the hydrogen atoms of the cation were included in the final cycles of refinement. Tables containing atomic coordinates, anisotropic thermal parameters and structure factors are available as supplementary material.

Acknowledgements—Our thanks to Professor A. B. P. Lever for providing crystalline samples of the complexes used in this investigation and to the National Science Foundation for providing support for this research under grant CHE 88–09923.

THE FORMATION OF COBALT AND NICKEL COMPLEXES ON CLAY SURFACES

NIGEL DAVISON and WILLIAM R. McWHINNIE*

Department of Chemical Engineering and Applied Chemistry, Aston University, Aston Triangle, Birmingham B4 7ET, U.K.

(*Received* 9 *November* 1989; *accepted* 9 *May* 1990)

Abstract—Treatment of hectorite exchanged with cobalt or nickel with various ligands is investigated. Basic ligands such as 2,2′-bipyridyl,1,2-diaminoethane (ethylenediamine, en) and ammonia readily afford complexes of nickel(II) and cobalt(III). In the case of ammonia, evidence is obtained for the isolation of an oxidation intermediate on the clay. More quantitative studies including some typical groundwater ligands such as pentanoic and butanoic acids reveal that the weak acid ligands are effective in displacing significant quantities of exchanged cobalt and nickel to solution; by contrast, some basic ligands can "stabilize" the more labile ion pair sorbed fractions of the metal on the clay surface. Although $[Ni(en)_3]^{2+}$ is much more strongly sorbed than Na^+ or Ca^{2+}, copper(II) ions release large quantities of nickel(II) to solution when aqueous $[Cu(H_2O)_6]^{2+}$ contacts $[Ni(en)_3]^{2+}$–hectorite. Tracer studies using ^{60}Co show that similar behaviour pertains at microscopic concentration levels to that observed with macroscopic concentrations.

The presence of organic material in groundwaters is well established,[1] but the possible influence of such materials on the sorption properties of metal ions on clay minerals is not well documented. Organic material, which has sites of Lewis basicity, may affect transition metal–sorbent interactions in three significant ways.

(1) Transport properties of the ion in the groundwater may be modified by complexation, indeed even precipitation could occur.
(2) Complex formation may promote desorption and hence alter the lability of the sorbed ion.
(3) The organic ligand may itself become sorbed onto the clay.

The direct sorption of ammonia from aqueous solution onto soils was first reported in 1852,[2] more recent work has covered such complex organic molecules as pesticides and other compounds of biological importance, e.g. amino acids and peptides.[3] The majority of transition metal sorption studies involving organic ligands have been concerned with the uptake of simple complexes onto the clay, e.g. tris(1,3-diaminopropane)cobalt(III) onto laponite,[4] and their characterization by a variety of spectroscopic methods.[5,6]

The fact that the presence of ligands could alter the lability of a metal ion sorbed onto a clay has obvious importance in the environmental context, particularly if the ions concerned were toxic or radioactive. We have recently been interested in factors affecting the lability of nickel(II) and cobalt(II) ions in clay environments and decided to explore the effect of ligands on this property. We have therefore carried out an initial qualitative study involving the addition of simple ligands to previously prepared Ni(Co) clay samples, and followed this with a more quantitative survey of the influence of typical groundwater organics. The work was carried out with hectorite which, due to the low iron content, is virtually colourless and thus facilitates the use of techniques such as visible adsorption spectroscopy.

EXPERIMENTAL AND RESULTS

Solution concentrations of cobalt and nickel were measured by atomic adsorption. It was established that the excess ligand in the solutions did not interfere with the metal analysis under the conditions used in this work.

(A) *Qualitative study of the effect of ligands on cobalt- and nickel-saturated hectorite*

Samples of hectorite (sodium form; from Hector California) (15 g) were shaken with 0.1 M solutions of $NiCl_2$ or $CoCl_2$ (150 cm^3) for 3 days, filtered and left to air-dry. The clays were then resuspended in distilled water (150 cm^3) and shaken for a further 3 days, filtered and air-dried. The washing procedure was repeated and the air-dried clays were crushed to a fine powder prior to use in the following experiments.

Nickel(II) hectorite: 46 meq Ni^{2+} 100 g^{-1}; UV–vis: 395 nm, 660 nm; $d(001)$ = 15.1 Å (FWHM = 2.6 Å, where FWHM = full width at half maximum). Cobalt(II) hectorite: 50 meq Co^{2+} 100 g^{-1}; UV–vis; 459 nm, 512 nm; $d(001)$ = 15.3 Å (FWHM = 3.0 Å).

Treatment of Ni(Co) *clay with ligands.* Samples (2 g/0.5 mmol Ni^{2+}; 3 g/0.75 mmol Co^{2+}) of the above treated clays were contacted with a 0.03 M solution of NH_3 (50 cm^3, 1.5 mmol, i.e. Ni/NH_3 = 1:3, Co/NH_3 = 1:2). The mixture was stirred for 4 h, in the cobalt case ammonia-saturated air was passed through the solution during the period of the reaction. The solids were filtered, air-dried and subjected to XRD and diffuse reflectance analysis. In the nickel case no colour change was seen during the reaction, the clay retaining the green colour. By contrast the cobalt suspension turned brown within 3–4 min, the colour darkening after a further 20 min. In both cases the filtrates were colourless.

Similar experiments were then carried out with other ligands: ammonia (various ratios), 1,2-diaminoethane ("ethylenediamine", en), dimethylglyoxime (DMG) and 2,2′-bipyridyl (bipy). The reaction of the cobalt clay with en was carried out with the passage of en-saturated air. The ratios of reactants, XRD data and diffuse reflectance data for the ligand treated clays are given in Tables 1 and 2 (nickel), and Tables 3 and 4 (cobalt). Neither the 10:1 nor the 25:1 ammonia/cobalt clays gave a detectable ESR signal at room temperature.

Table 1. $d(001)$ Values obtained from Ni–hectorite treated with model organic ligands

Organic ligand added	Organic/Ni ratio	Colour of solid product	$d(001)$ (Å)	FWHM[a] (Å)
NH_3	3:1	Green	14.0	5.7
NH_3	10:1	Green[b]	12.8	3.6
NH_3	25:1	Green[b]	12.8	3.2
en	9:1	Violet–pink	14.7	3.6
DMG	6:1	Orange	14.3	2.8
bipy	5:1	Red–brown	18.2	3.0

[a] Full width of peak at half maximum peak height.

[b] The blue colour exhibited by both samples initially was lost on air-drying.

(B) *Typical groundwater ligands with nickel and cobalt hectorite*

A more quantitative approach was adopted for this section of the investigation, thus initially the following procedure was used to prepare clay samples: a sample of hectorite (15 g) was shaken with 0.1 M nickel chloride (cobalt chloride) solution (150 cm^3) for 3 days, filtered, then redispersed in a 1 M solution of $NiCl_2$ ($CoCl_2$) (150 cm^3) and shaken for a further 3 days prior to filtration. The clay was rinsed twice with distilled water, and a portion (5 g) was retained for further experiments [Ni(Co)–hectorite/rinse]. The remaining clay was dispersed in distilled water (100 cm^3), shaken for 2 h, then separated by ultracentrifugation. This procedure was repeated a further four times, after which the clay was left to air-dry [Ni(Co)–hectorite/wash].

Table 2. Peaks derived from diffuse reflectance spectra of Ni–hectorite treated with model organic ligands

Organic ligand added	Organic/Ni ratio	Absorption peaks (nm)			
NH_3	3:1	391(m-s)			669(w)
NH_3	10:1	392(m-s)			684(w)
NH_3	25:1	392(m-s)			686(w)
en	9:1	356(s)	456(w)	542(m-w)	
DMG	6:1	369(m-w)	422(m-w)	534(m-w)	
bipy	5:1	367(m-s)	422(w)	536(m-s)	

Peak intensities: s—strong, m—medium, w—weak, v—very.

Table 3. *d*(001) Values from Co–hectorite treated with model organic ligands

Weight of Co–hectorite used (g)	Organic ligand added	Organic/Co ratio	Colour of solid product	*d*(001) (Å)	FWHM (Å)
3.00	NH_3	2:1	Red–brown	13.1	3.2
2.00	NH_3	10:1	Yellow–brown	12.7	3.2
2.00	NH_3	25:1	Red–brown	13.5	3.0
1.75	en	1:1	Yellow–brown	14.9	4.0
1.75	en	9:1	Light brown	15.2	3.3

Table 4. Peaks derived from diffuse reflectance spectra of Co–hectorite treated with model organic ligands

Organic ligand added	Organic/Co ratio	Absorption peaks (nm)				
NH_3	2:1		385(m-w)		531(w)	
NH_3	10:1		384(m-w)		527(m-w)	
NH_3	25:1		399(m-w)	454(vw)		
en	1:1	348(w)		465(w)	518(m)	570(w)
en	9:1	349(s)		466(s)		573(w)

The metal contents of the clay were deduced from AA analysis of the contacting solutions, thus:

Ni–hectorite/rinse 64 meq 100 g^{-1}, *d*(001) 15.0 Å (FWHM 2.7 Å);
Ni–hectorite/wash 56 meq 100 g^{-1}, *d*(001) 15.1 Å (FWHM 2.5 Å);
Co–hectorite/rinse 69 meq 100 g^{-1}, *d*(001) 15.1 Å (FWHM 3.3 Å);
Co–hectorite/wash 64 meq 100 g^{-1}, *d*(001) 15.3 Å (FWHM 2.7 Å).

Reaction with ligands. Portions of the four clay types (0.2 g) were covered separately with solutions (10 cm^3) of ammonia (0.08 M), en (0.08 M), butanoic acid (BA, 0.08 M), pentanoic acid (PA, 0.08 M), and with distilled water. (n-Butanoic acid and n-pentanoic acid have been identified in "run off" from domestic waste disposal sites and may well be groundwater constituents. Also, they constitute useful, even if simplistic, models for humic and fulvic acids.) The mixtures were stirred for 3 days and the suspensions separated by ultracentrifugation. The solids were air-dried at room temperature and the supernatant liquids were retained for analysis. The appropriate ligand/metal reaction ratios were: Ni–hectorite/rinse, 12.5:1; Ni–hectorite/wash, 14.3:1; Co–hectorite/rinse, 11.6:1; Co–hectorite/wash, 12.5:1. Only in the cases of ammonia and en were rapid colour changes noted. Each clay specimen was examined by diffuse reflectance, XRD and IR. Results are given in Tables 5 and 6 (nickel), and in Tables 7 and 8 (cobalt).

The effect of differing metal/ligand ratios was then explored, thus Ni–clay specimens (0.2 g) were added separately to solutions of ammonia (12, 1.2 and 0.12 mM) and of butanoic acid (8.0, 0.8 and 0.08 mM) and treated as above. In parallel experiments, samples of the Co–hectorites (0.2 g) were treated with solutions of en (10 cm^3) (8.0, 0.8 and 0.08 mM) and butanoic acid (concentrations as for nickel). The visible absorption spectra and pH data for the supernatant solutions are shown in Tables 9 and 10, and data for the solids are in Tables 11 and 12.

Lability of complexed nickel(II) *on hectorite.* Ni–hectorite/wash (2.2 g) was added to an en solution (100 cm^3, 9.2 mmol) and stirred for 24 h. The suspension was then filtered and washed with three aliquots of distilled water (25 cm^3). The air-dried solid was a pale violet colour and gave *d*(001) 14.9 Å (FWHM 2.1 Å) and characteristic peaks at 550, 465 and 342 nm in the diffuse reflectance spectrum. The clay contained 56 meq Ni 100 g^{-1}.

Portions (0.2 g) of this $[Ni(en)_3]^{2+}$ clay were then added separately to solutions (10 cm^3) of NaCl (30, 6.0 and 1.2 mM); $CaCl_2$ (30, 6.0 and 1.2 mM); and

centrations of the ions in contact with a clay and the surrounding groundwaters would be very low, hence the conclusions that may be drawn from the macroscopic studies above may not extrapolate to the microscopic concentration levels that pertain in practice. We therefore decided to explore the microscopic regime by carrying out some experiments using ^{60}Co.

The work involved spiking a hectorite sample with a low concentration of ^{60}Co and treating the clay with various solutions of ligands. Analysis of the equilibrium solutions for cobalt content was then carried out.

Preparation of ^{60}Co*–hectorite.* Na–hectorite (2.92 g) was added to a 1.87 ppm solution of $^{60}CoCl_2$ (265.2 cm^3, 0.0084 mmol Co^{2+}) and shaken for 3 days. The suspension was then filtered and redispersed twice in distilled water prior to ultracentrifugation. The clay was air-dried for 3 days, and ground to a fine powder prior to use in subsequent experiments. γ-Spectrometric analysis of the contacting solutions indicated a cobalt content for the clay (i.e. ^{60}Co–hectorite) of 0.35 meq 100 g^{-1}.

Influence of ligands on ^{60}Co*–hectorite.* Portions of ^{60}Co–hectorite (0.204 g, 0.35 μmol Co^{2+}) were added separately to solutions (10.2 cm^3) of ammonia (0.44, 0.11 and 0.008 mM giving NH_3/Co ratios of 12.5 : 1, 3 : 1 and 1 : 5) and of butanoic acid (0.44, 0.044 and 0.0044 mM giving BA/Co ratios of 12.5 : 1, 1.25 : 1 and 1 : 8). Blank experiments in which the clay (0.204 g) was contacted with demineralized water were also carried out. All suspensions were stirred for 8 days and then ultracentrifuged, the solution phase being analysed for cobalt by γ-spectrometry. In the case of the 0.44 mM ammonia solution, ultacentrifugation did not remove all suspended material, hence the suspension was filtered through a 0.22 μ filter, all surfaces being subsequently washed with aqueous $CoCl_2$ to remove adhered ^{60}Co. The resulting clear solution was then analysed for radiocobalt. Relevant data are summarized in Table 14.

Physical measurements. X-ray diffraction (XRD) data were obtained with a Philips X-ray diffractometer using Co-K_α radiation with an iron filter. Traces were recorded at 1° 2θ min^{-1} in the range 1–4 $\times 10^3$ counts s^{-1} and could be observed from 3° 2θ upwards. UV–vis spectra were recorded, using a diffuse reflectance attachment for solids, on a Pye–Unicam SP 800 B spectrophotometer (300–800 nm). IR spectra were recorded with a Perkin–Elmer 599 B instrument; discs were pressed from 0.5 mg clay with 170 mg KBr. Some specimens were examined on a JEOL PE-IX type ESR spectrometer.

dw	—	1.5	4.3

[a] After re-analysis.
BA—butanoic acid; dw—demineralized water.

Atomic absorption measurements were made with a Perkin–Elmer Model 460 AA spectrometer. Pre-analysed AnalaR samples of nickel and cobalt chloride hexahydrates were used as standards and 0.1% CsCl was added to all solutions prior to AA analysis to suppress ionization effects.

DISCUSSION

(A) *Preliminary survey*

It has previously been demonstrated that transition metal complex exchanged clays may be generated by contacting the clay with a solution of the chosen complex.[4,7,8] Little work has been carried out on the synthesis of complexes on clays *in situ* by allowing a transition metal ion exchanged clay to contact a solution of the appropriate ligand. The latter approach is of more interest if attempts are made to evaluate the influence of ligands on the lability of sorbed metal ions; the influence of groundwater organics on the lability of clay sorbed metal ions which may be toxic or radioactive, for example. We have been interested recently in gaining more information on the nature of exchange sites on hectorite and montmorillonite for iron exchanged clays (via Mössbauer spectroscopy[9]) and for cobalt and nickel exchanged clays (via XPS[10]). Since a major objective of this work was to obtain information on the environmental role of clays with respect to cobalt on nickel which might have been released to groundwaters, we restrict our attention in this paper to Co^{2+} and Ni^{2+} exchanged hectorite.

The clay samples used in the preliminary study were not totally saturated w.r.t. Ni^{2+} or Co^{2+}, they were, however, very rigorously washed and we

believe that the concentration of sorbed ion pairs on the clay surface is small,[11] i.e. the Co^{2+} and Ni^{2+} is mostly *exchanged* at interlayer and external sites. The samples gave values of $d(001)$ typical of a clay exchanged with dipositive ions (Tables 1 and 3);[12] further, diffuse reflectance spectra (Co^{2+}: 459 and 512 nm, Ni^{2+}: 395 and 660 nm) were consistent with $[M(H_2O)_6]^{2+}$ (M = Co, Ni) as the exchanged species.[13] We suggest at this juncture that a useful parameter in the following discussion may be the FWHM of the peak relating to the basal spacing [$d(001)$] of the clay, since the presence of different complex species in the interlayers will give rise to an inhomogeneity which will be reflected in a larger FWHM.

The addition of bipy to Ni–hectorite gave a clay with a diffuse reflectance spectrum characteristic of $[Ni(bipy)_3]^{2+}$, also the increase in $d(001)$ to 18.2 Å is indicative of the presence of a large complex ion.[14,15] The complex formed on addition of en to the Co–hectorite depends on the ratios, Co/en. A 1:1 ratio generated both $[Co^{III}(en)_3]^{3+}$ and $[Co^{II}(H_2O)_6]^{2+}$ (all experiments were carried out in air) as judged from the diffuse reflectance spectra and enhanced FWHM for $d(001)$ (4.0 Å); however a nine-fold excess of the ligand gave only $[Co^{III}(en)_3]^{3+}$ as evidenced from the diffuse reflectance spectrum[16] (note also FWHM for $d(001)$ is now 3.3 Å). We found no evidence for the presence of bis or tris complexes of cobalt(II) on the clay; we note that Schoonheydt *et al.*[5] have prepared a $[Co^{II}(en)_2]^{2+}$/hectorite. A 9:1 en/Ni ratio only was used, and this produced a clay containing both $[Ni(en)_2]^{2+}$ and $[Ni(en)_3]^{2+}$. Schoonheydt *et al.*[5] were able to generate $[Ni(en)_2]^{2+}$ on the surface of a montmorillonite clay and the band observed at 465 nm for this species agrees with the one noted here (456 nm, Table 2).

Although the dimethylglyoxime treated Ni–hectorite gave a spectrum typical of that expected for the square-planar bis(dimethylglyoximato) nickel(II)[17] complex, the value of $d(001)$ at 14.3 Å (Table 1) was larger than that normally expected for the presence of square-planar complexes (12.5–13.0 Å). It is suggested that the complex may in fact not be oriented parallel to the silicate sheets.

Treatment of the clays with ammonia produced some interesting results. In the case of Ni–hectorite all three ratios of Ni/NH_3 used (Table 1) gave a final clay that was green, however, whilst in contact with the ammonia solutions the 10:1 and 25:1 specimens exhibited a blue colour which we take to be evidence for the formation of $[Ni(NH_3)_6]^{2+}$. During the drying process ammonia is lost giving partially dehydrated clays. The 3:1 ratio clay (Tables 1 and 2) gives a spectrum suggesting that some $[Ni(H_2O)_6]^{2+}$ is present, however, both the value of $d(001)$ and more particularly the large FWHM indicate that the specimen is inhomogeneous. The 10:1 and 25:1 ratio treated clays are much more homogeneous and, whilst the diffuse reflectance spectra are consistent with a "NiO_6" environment, it appears that the ligand-field strength is lower than in $[Ni(H_2O)_6]^{2+}$. Also the value of $d(001)$ is inconsistent with the presence of the hexa-aquo-ion. We suggest therefore that, on loss of ammonia, at least two coordination sites are occupied by lattice silicate oxygen atoms giving $[Ni(O_{lat})_x(H_2O)_y]^{2+}$, where $x+y=6$ and $x \geqslant 2$; O_{lat} represents a silicate oxygen. We note that Tarasevich and Sivalov[18] observed bands at 403 and 694 nm for a partially dehydrated Co–montmorillonite and invoked a similar explanation.

Herman[19] also studied partially dehydrated Ni–montmorillonite, but no bands observed in that study correspond to those determined from the diffuse reflectance spectra of ammonia treated Co–hectorite (Table 4). Indeed it is clear from our results that coordinated ammonia is retained in the dry clay. Evidence for the presence of $[Co^{III}(NH_3)_6]^{3+}$ is obtained from the diffuse reflectance spectra of the 25:1 treated clay (454 nm) (Table 4). However, bands appear at 390 and 530 nm and we believe these arise from the formation of a species such as $[(NH_3)_5Co(O_2)(NH_3)_5]^{4+}$, which is an intermediate in the oxidation of cobalt(II) by molecular oxygen.[13] Such species are characteristically red or brown (as observed here). The $d(001)$ values (Table 3) are in the range 12.7–13.5 Å, rather low for the presence of species such as $[Co(NH_3)_6]^{3+}$ in any concentration. The cobalt/ammonia–hectorite specimens are ESR silent, a fact we take to eliminate the presence of superoxo-bridged species.

(B) *Groundwater ligands* (*Tables* 5–8)

Small quantities of longer chain carboxylic acids may be present in some groundwaters and pentanoic (PA) and butanoic acids (BA) were selected as being representative. The clay samples used in this work were prepared to achieve saturation of exchange sites with Ni^{2+} (Co^{2+}) but differed in the treatment given subsequently. Thus the samples labelled "rinse" were briefly rinsed with distilled water after exchange, whereas those labelled "wash" were rigorously washed with distilled water to remove, as far as possible, the "labile" ions sorbed as ion pairs.[11]

Treatment of the clays with PA and BA (see Experimental) resulted in an increase of initial solution pH and the release of > 70% of the exchanged nickel and cobalt to solution as the hexa-aquo-ions

(Tables 6 and 8); by contrast ammonia or en at the same concentration released less than 4% of the metal ion to solution—too little to give a detectable solution spectrum. Diffuse reflectance spectra of the acid treated clays [together with values of $d(001)$] (Tables 5–8) all indicate that the $[M(H_2O)_6]^{2+}$ ions are still present, but in much reduced concentration.

Although K_a for PA and BA is approximately 10^{-5} mol dm^{-3}, and the solution concentration of protons is low, in the presence of the clay we observed enhanced ionization of the acid and the displacement of M^{2+} (M = Ni, Co) by H^+. IR studies of the treated clays reveal that some acid was sorbed onto the clay. A band at 1690 cm^{-1} [ν(CO)] is significantly shifted from 1770 cm^{-1} of the hydrogen-bonded dimer[19] and that of the monomer, 1712 cm^{-1}. Yariv *et al.*[20] have investigated the sorption of benzoic acid into montmorillonite with differing exchanged ions (Ca^{2+}, Mg^{2+}, Cu^{2+}, Al^{3+}) but ν(CO) was invariant; however, when the montmorillonite was dehydrated, ν(CO) correlated with the Lewis acidity of the exchanged ion. It was proposed that the initial interaction was with a coordinated water molecule, but that direct metal–carboxylate interaction occurred on dehydration. We believe that the acid in our case interacts with coordinated water of the unreleased hexa-aquo-ions.

Treatment of the "rinse" and "wash" clays with distilled water induces, as anticipated, a greater loss of metal ion from the "rinse" specimen (but even the loss from the rigorously washed specimens is non-zero) (Tables 6 and 8). However, when the clays were treated with 0.08 M en or ammonia no differentiation between "wash" and "rinse" is seen and *less* metal is released to solution than with distilled water, with the exception of Co–hectorite/0.08 M en (Tables 6 and 8). This suggests that some metal complex ion pairs may be more tenaciously held on the clay surface than the corresponding $[M(H_2O)_6]^{n+}$–anion pairs and that they may be present even in rigorously washed clays. It is of interest to note that Pinnavaia and co-workers[21] believe that such species are responsible for the electroactivity of clay-modified electrodes.

Physical investigation of the ammonia and en treated clays (Tables 5 and 7) gave results which could be interpreted along the lines of section (A). Thus evidence for a degree of hydration was seen for the NH_3–Ni–hectorite on drying, and good evidence for the presence of both $[Ni(en)_2]^{2+}$ and $[Ni(en)_3]^{2+}$ was obtained from diffuse reflectance and IR data of the en–Ni–hectorites. The NH_3–Co–hectorite data seem to parallel those in Table 4, thus evidence for some $[Co^{III}(NH_3)_6]^{3+}$ is available ($\sim$ 460 and 590 nm); other peaks at $\sim$ 385 and $\sim$ 525 nm can be assigned, as previously, to a peroxocobalt(III) species. Careful examination of the IR spectrum reveals a significant peak at 1400 cm^{-1} attributed[22] to NH_4^+; indeed Mortland *et al.*[23] have shown that treatment of montmorillonite saturated by mono- or divalent ions was completely converted to NH_4^+. It is clear that conversion to NH_4^+ is less than complete in our case, but the observation of some NH_4^+ means that we must also consider the possibility of the presence of complementary mixed cobalt hydroxoammine species.

Addition of en to Co–hectorite generated $[Co^{III}(en)_3]^{3+}$ and, in this case, no evidence of redox intermediates was observed.

Tables 9–12 give data for the "wash" clay, which investigate the influence of varying ligand/metal ratios. Figure 1 presents a log–log plot of the per cent Ni(Co) desorbed as a function of initial ligand concentration. The per cent desorption by PA and BA is virtually a linear function of the ligand solution concentration. The significant dip in the en/NH_3 curves is attributed to the precipitation of metal hydroxide at ligand/metal ratios insufficient to involve complex formation, but where the hydroxide ion concentration is sufficient to exceed the solubility product of the metal hydroxide. Since we are dealing essentially with the lability of surface sorbed ion pairs from the "wash" clay, it seems likely that the hydroxide formation will be at the surface. As the ligand/metal ratio increases, complex formation proceeds, indeed if the third data point were ignored on the NH_3/Ni and en/Co plots (Fig. 1), the other data points also lie on a reasonable straight line. Not surprisingly, at very low ligand/metal ratios, the quantity of metal released tends to the value of distilled water alone. However, when, with basic ligands, the ratio is in the regime

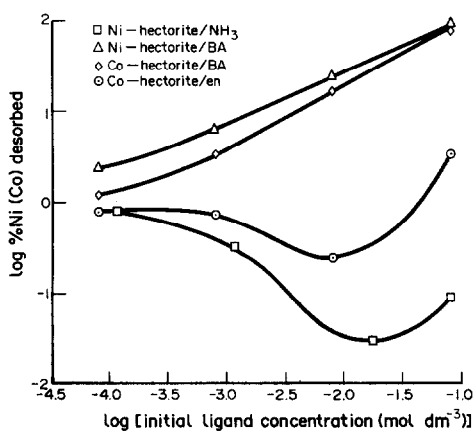

Fig. 1. Per cent Ni(Co) desorbed from Ni/Co–hectorite by various organic "ligands" at a number of initial solution concentrations.

of complex formation, in some cases *less* metal is released than from the distilled water treated as noted previously (e.g. see Co/en curve in Fig. 1). A variety of factors are involved, in the specific case of $[Co(en)_3]^{3+}$ a combination of a relatively low solvation energy for the large complex cation, together with a greater attraction of the tripositive ion, compared to $[Co(H_2O)_6]^{2+}$ for negative sites on the clay may be dominant. Others have noted the strong affinity of laponite, montmorillonite and bentonite for tripositive cobalt complexes $[Co(NH_3)_6]^{3+}$,[24] $[CoL_3]^{2+}$ (L = en, pn).[4,25,26] Indeed, even when the interlamellar ion is $[Ce(H_2O)_6]^{3+}$, Fripiat and Helsen[27] noted that $[Co(NH_3)_6]^{3+}$ was very strongly sorbed by montmorillonite.

Groundwaters will contain some inorganic cations, including possibly some transition metal ions, e.g. samples of pore water squeezed from Oxford clay contained 0.54–45 ppm amounts of iron, nickel and copper.[28] We undertook some experiments in which a $[Ni(en)_3]^{2+}$–hectorite was treated with various concentrations of NaCl, $CaCl_2$ and $CuCl_2$ (Table 13). The results are self explanatory. Not surprisingly Na^+ and Ca^{2+} have little success in mobilizing Ni^{2+} to the solution phase. By contrast Cu^{2+} is extremely effective at releasing nickel from the clay. Not only is the stability constant for the copper(II) complex greater, but the copper complex which in this instance is $[Cu(en)_2]^{2+}$ [$d(001)$ = 13.0 Å, a value typical for an intercalated square planar complex] has a greater affinity for the clay surface, an observation in agreement with the study of the thermodynamics of sorption of polyamine complexes on montmorillonite surfaces in which $[Cu(en)_2]^{2+}$ showed a greater affinity than $[Ni(en)_3]^{2+}$. Thus the relative affinities for the clay surface of two ions which form kinetically labile complexes may be strongly perturbed in the presence of some ligand species.

(C) *Microscopic effects*

The environmental concentrations of Co^{2+} and Ni^{2+} are likely to be low, hence it may not be appropriate to extrapolate from the data in sections (A) and (B) to situations in which the metal ion concentration may be in the ppb–ppm range. A sample of hectorite was spiked with ^{60}Co and treated as described in the Experimental (Table 14). The results are usefully summarized in Fig. 2. Again, as in the macroscopic studies, evidence for the stabilization of cobalt on the clay surface is seen for the basic ligand. With BA, at higher ligand/metal ratios cobalt is released to solution, but at this concentration level, a BA/Co ratio of 1 : 8 actually stabilized the cobalt relative to a simple distilled water treatment. At low absolute ligand/metal concentration ratios, a different mechanism seems operative, possibly explaining the non-linearity of this log–log plot in contrast to Fig. 1.

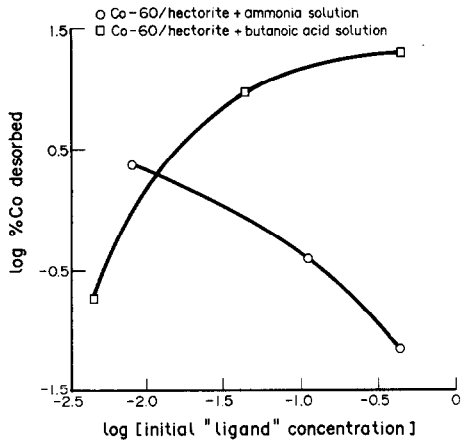

Fig. 2. Desorption of cobalt from a ^{60}Co–hectorite by organic "ligand" solutions.

The conclusion is then that groundwaters which are relatively rich in acidic ligands may labilize sorbed metal ions from clay minerals, but, by contrast, the presence of some basic ligands might actually increase the affinity of the ion for the clay surface.

(*Received* 19 *September* 1989; *accepted* 9 *May* 1990)

Abstract—The synthesis of 14 mixed-ligand solid complexes of lanthanide ions with 1,4-bis-(1′-phenyl-3′-methyl-5′-pyrazolone-4′)-1,4-butanedione (BPMPBD) and 1,10-phenanthroline (PHEN) in an alcohol–water solution is presented. The comosition of the complexes is determined as $Ln_2L_3P_2 \cdot nH_2O$ (Ln = Y, La, Pr, Sm–Lu; L = BPMPBD; P = PHEN; n = 4,5) by chemical and elemental analyses. The complexes are regarded as binuclear and characterized by IR, UV, ^{1}H NMR, fluorescence spectra, thermoanalysis and conductance methods.

1,4-Bis-(1′-phenyl-3′-methyl-5′-pyrazolone-4′)-1,4-butanedione (BPMPBD) is a 4-acyl-bis-pyrazolone in which two acylated pyrazolones are present as end groups of the diketone. The first 4-acyl-bis-pyrazolone was synthesized by Dong *et al.* in 1983[1] and later some derivatives and their complexes with lanthanide ions were reported.[2,3]

4-Acyl-bis-pyrazolones, in which there are four oxygen atoms available for complexation, are ideal chelating agents for lanthanides and actinides and are able to form mononuclear, polynuclear or heteronuclear complexes under differing conditions. These complexes are of interest because they provide the opportunity to study catalytic activity, energy transfer, electron transitions and the interaction between the metal ion and complexing agents. Some lanthanide ions when combined with 4-acyl-bis-pyrazolone exhibit excellent fluoresence[4] which provides an opportunity for studying their applications in analysis and optic materials.

In the present work the preparation and characterization of complex compounds formed by lanthanide elements (except for Ce, Sc and Pm) with BPMPBD (noted H_2L)—a tetradentate ligand and PHEN (noted P)—a bidentate ligand are reported first.

EXPERIMENTAL

Reagents

BPMPBD (m.p. 222–222.5°C) was prepared by literature methods.[5] Found: C, 66.8; H, 5.0; N, 12.9. Calc. for BPMPBD ($C_{24}H_{21}N_4O_4$): C, 67.0; H, 5.1; N, 13.0%. Solutions of lanthanide nitrate were obtained by dissolving Ln_2O_3 (99.95%) in concentrated HNO_3 and evaporating the excess acid, followed by dilution to a certain concentration with distilled water. PHEN and other reagents were analysis grade.

Preparation of complex compounds

H_2L (0.220 g, 0.50 mmol) was dissolved in 30 cm^3 of alcohol solvent (95%) by adding an aqueous ammonia solution (2 N) and then the pH of this solution was adjusted to 5–6 with dilute HNO_3 solution. The PHEN (0.059 g, 0.33 mmol) ethanol solution and lanthanide nitrate (0.35 mmol) ethanol solution in the molar ratio $[H_2L]:[PHEN]:[Ln^{3+}] = 1.5:1:1.05$ were added successively to the H_2L ethanol solution and a precipitate appeared immediately. The precipitate was centrifugally separated after being stirred for 2 h and washed with dilute aqueous HNO_3 solution (pH = 3–4) until no Ln^{3+} and NH_4^+ could be detected in the washings.

Then the precipitate was washed with distilled water until the washings were neutral and did not contain NO_3^-. Finally the products were dried to constant weight at 40°C in a vacuum dryer after being washed 2 or 3 times with warm $CHCl_3$. The yields of the products were generally more than 75%.

Physical measurements and analyses

IR spectra, which were obtained as KBr discs and the dispersion media were free of water, were recorded with a Model FT-170SX IR spectrophotometer (U.S.A.). ^1H NMR spectra were obtained on a Model FA-80A spectrometer (U.S.A.). Fluorescence and UV spectra were recorded with a Model 850 fluorescence spectrophotometer (Japan) and a Model UV-730 spectrophotometer (China), respectively. A Model PCT-2 precision thermal analyser and Model DDS-11A conductometer were used, respectively, to determine the thermostability and conductivity of the complexes.

C, H and N analyses were performed with a Model 1106 elemental analyser (Italy). Water in the complexes was determined by thermoanalyses.

Lanthanide ions in the complexes were determined by the following method: A certain quantity of complex was decomposed by heating in a small amount of HNO_3–$HClO_4$ (1 : 1) solution and the excess acid was evaporated. This was diluted with distilled water and finally the Ln^{3+} was titrated with a standard solution of EDTA in a hexamethylenamine buffer solution.

RESULTS AND DISCUSSION

Composition and properties of the complexes

Table 1 contains the elemental analyses of the complexes. It is known from Table 1 that the composition of the complexes is $Ln_2L_3P_2 \cdot nH_2O$ ($n = 4$, 5) and the complexes are neutral, which also has been proved by their molar conductivity (3–8 Ω^{-1} cm^2 mol^{-1}) in DMSO solvent.[6]

All the complexes are insoluble in water, slightly soluble in ethanol, methanol, chloroform and benzene, and soluble in DMSO and DMF solvents. The complexes absorb moisture when they are exposed to the air.

IR spectra

All 14 complexes have similar IR spectra, which indicates that these complexes have similar structures.

The main changes found after complexing are:

(1) The C=O stretching frequency shifts from 1554 cm^{-1} in BPMPBD by about 22 cm^{-1} to a lower frequency (at 1532 cm^{-1}) in the complexes, and the strength of the vibration decreases, which is attributed to the interaction between the Ln^{3+} and carbonyl group in BPMPBD.
(2) The weak and broad band at 2600–3000 cm^{-1} in the IR spectrum of the free ligand BPMPBD, due to the intramolecular hydrogen bond formed between the carbonyl and hydroxyl group,

L = BPMPBD ($C_{24}H_{20}N_4O_4$-); P = PHEN ($C_{12}H_8N_2$).

disappears after chelation. The reason is that the intramolecular hydrogen bond is broken after chelation with lanthanide ions.

(3) The out-of-plane bending frequencies (δ_{C-H}) shift from 855 and 737 cm^{-1} in PHEN to 845 and 731 cm^{-1} in the complexes and the 1642 cm^{-1} band due to the stretching vibration of C=N of free PHEN is absent in these complexes, whereas a new band is observed around 1619 cm^{-1}, which is attributed to the fact that $\nu_{C=N}$ of chelated PHEN is overlapping with $\nu_{C=O}$ of BPMPBD at 1618 cm^{-1}, and increasing with the vibration strength. All these points can be taken as evidence of PHEN being bonded to lanthanide ions.

(4) The absorption peaks of ν_{Ln-O} and ν_{Ln-N} in the far-IR spectra appear, respectively, at about 415–436 cm^{-1} and 270–316 cm^{-1} which is similar to all other lanthanide complexes. This conforms to the result reported in the literature.[7]

(5) The presence of the broad absorption peak at 3450 cm^{-1} indicates the existence of water molecules in the complexes.

From the changes in the IR spectra, the analysis of the complex composition and the electroneutrality of the complexes above, it can be inferred that the complexes have a binuclear structure in which each of two Ln^{3+} ions combines with two complexing nitrogen atoms in each PHEN, and three BPMPBDs as tetradental ligands chelate two Ln^{3+} ions in two ways. One way is that the three BPMPBs bridge two Ln^{3+} ions side by side by means of the enolic form [see Fig. 1(a)]. The other method involves one of the three BPMPBDs bridging two Ln^{3+} ions and the other two chelating, respectively, one of the two Ln^{3+} ions [see Fig. 1(b)]. Which one of the two structures above is correct remains to be proved by studying the structure of the single crystal which is being grown in our laboratory.

UV spectra

The important UV absorption bands of the ligands and the complexes in CH_3OH solvent are listed in Table 2. No absorptions were observed in the visible for any of the compounds. It is clear that the spectra of the complexes are similar in character to that of ligands. The absorption maxima of the ligands remain either unchanged or suffer slight shifts in the complexes. This is because the spectra of the complexes are attributed mainly to that of the ligands and it appears reasonable to assign the absorption bands to π–π^* transitions.

Two weak absorption peaks of PHEN at 310 and 323 nm that are due to the n–π^* transition do not appear in the spectra of the complexes. The reason is that the solubility of the complexes in CH_3OH is so low that we cannot observe the n–π^* transition in the spectra.

^{1}H *NMR*

Table 3 contains the ^{1}H NMR spectral data for BPMPBD, PHEN and some complexes in DMSO.

The methyl proton signal of the free ligand BPMPBD is observed as a singlet at 2.56 ppm and the methylidyne proton signal as a singlet at 3.23 ppm, while the benzene ring proton signals are observed as a multiplet at around 7.35–7.88 ppm. In our experiment, the hydroxyl proton signal of the enolic form of the BPMPBD ligand is not observed. Similar phenomena were observed in the literature.[5]

The proton signals of the free neutral ligand PHEN are found at 7.98, 8.12, 8.80 and 9.19 ppm.

In the complexes, the ^{1}H NMR spectra contain greater shifts and changes in comparison with the ^{1}H NMR of the free ligands. Meanwhile, the ^{1}H NMR spectra of the lanthanide ion complexes are obviously different due to the different number of unpaired $4f$ electrons and the different magnetism of lanthanide ions. The lanthanum ($4f^0$) complex exhibits a sharp ^{1}H NMR spectrum in which all protons suffer upfield shifts. The methyl and methylidyne signals have shifted from 2.56 to 2.05 ppm and from 3.23 to 2.75 ppm, respectively, while the phenyl multiplet has now shifted to 6.95–7.75 ppm. The proton signal of PHEN in the complex which has also shifted upfield appears at 7.82, 7.93, 8.45 and 9.10 ppm. This indicates that the deshielding effect of the electron atmosphere in the phenanthrene ring decreases after complexation of the nitrogen atoms in PHEN with the La^{3+} ion. The hydrogen proton signal of the waters in the complex is at 3.25 ppm, which should disappear when H_2O is exchanged by D_2O. In the samarium ($4f^5$) complex the proton signals become much weaker and broader than those in the lanthanum complex. The methyl and methylidyne signals have shifted to

[a] The ^{1}H NMR data were obtained at 80 MHz frequency.

2.32 and 2.75 ppm. The proton signals of phenyl and the phenanthrene ring become a broad multiplet appearing at 7.2–8.7 ppm. With the gadolinium ($4f^7$) complex no signal was observed at all. This may be due to a combination of large shifts and extensive broadening of the signals,[8] since the gadolinium ion has the maximum number of unpaired electrons and is therefore strongly paramagnetic. Hence this change from sharp and strong to broad and weak proton signals for the lanthanum, samarium and gadolinium ion complexes is obviously the result of an increase in paramagnetism in going from the lanthanum, samarium to gadolinium ions. In addition, the integrated intensity of the methyl protons is in the ratio 2 : 1; the ratio shows that the structure of complexes have non-equivalent ligands, with possibly structure type (b) (see Fig. 1).

Fluorescence

The terbium and samarium complexes exhibited excellent green and orange fluorescence, respectively, when the solid lanthanide complex samples were irradiated with UV light ($\lambda = 254$ nm). Fluorescence was not observed in the rest of the lanthanide complexes. The fluorescence spectral data of the ligands and complexes, measured in DMSO solvent, are displayed in Table 4. It can be seen from Table 4 that the terbium complex shows a high emission intensity when the samarium complex exhibits a weak emission intensity in DMSO, although it shows excellent fluorescence in the solid state. This may be due to the solvent effect. In addition to the terbium and samarium complexes, the dysprosium complex has a line emission that indicates the lowest triplet state energy level of the complexes lies above the resonance energy level of the lanthanide ions and efficient energy transfer from the triplet state. The neodymium and gadolinium complexes exhibit band emission attributable to L*–L luminescence. The praseodymium, europium, holmium, erbium and ytterbium complexes do not fluoresce or fluoresce very weakly due to internal quenching through strong coupling of the ions with the crystal forces.[9,10]

Thermal analysis

The thermal analysis for BPMPBD [see Fig. 2(a)] shows that the compound initially melts at 231°C and then begins to decompose from 260 to 565°C when it is heated in air. TG and DTA measurements of PHEN·H_2O indicate loss of water at 104°C, melting at 123°C and explosive decomposition from 217 to 318°C [see Fig. 2(b)].

Since all 14 complexes exhibit similar thermal analysis diagrams due to their similar structures, here we discuss thermostability of $Tb_2L_3P_2 \cdot 4H_2O$

Table 4. The fluorescence spectral data for the ligands and complexes in DMSO (1×10^{-3} M)

$Lu_2L_3P_2$	—	—	—	

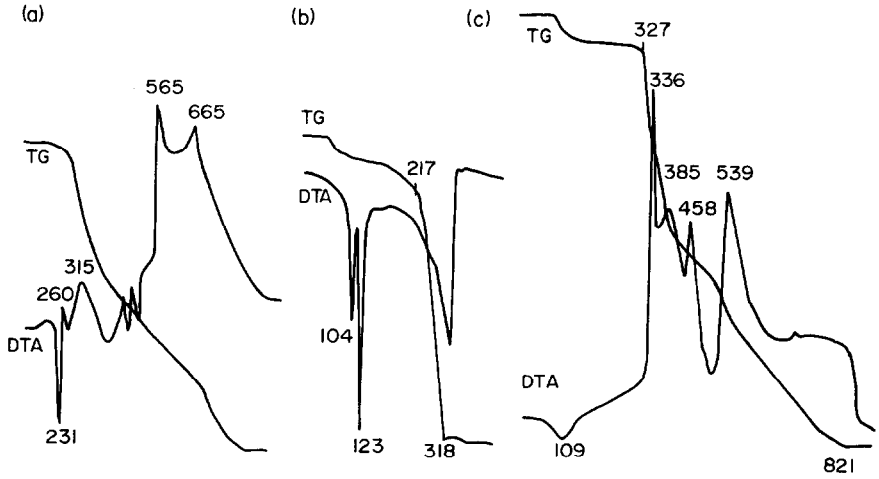

Fig. 2. The thermostability of the ligands and complexes: (a) H_2L(BPMPBD); (b) PHEN; (c) $Tb_2L_3P_2 \cdot 4H_2O$.

as an example [see Fig. 2(c)]. The compound loses water molecules at 109°C with a weight loss of about 3.41% (calc. 3.54%). These types of complexes have no melting point, so after losing water molecules the compound begins to decompose in the temperature range 327–821°C, in which four exothermic peaks appear successively on the DTA curve and obvious weight loss occurs on the TG curve. The total weight loss of the compound when heated was found to be 81.12%, which is nearly equal to the calculated 81.63% (considering the product of decomposition for $Tb_2L_3P_2 \cdot 4H_2O$ to be Tb_4O_7).

It is found from the discussion above that the complex is more thermostable than either BPMPBD and PHEN. In addition, the initial temperature of decomposition and the thermostability of the 14 complexes generally increase with decreasing ionic radii of the lanthanide ions (see Table 5). The "tetrad effect" phenomenon is found from the diagram of the relationship between the atomic numbers of lanthanide with the temperatures of the third

Table 5. The values of the thermal peaks of the complexes (°C)

(*Received* 8 *January* 1990; *accepted* 11 *May* 1990)

Abstract—Convenient procedures for the preparation of molybdenum and tungsten oxo- and thiohalides are described which exploit reactions between transition metal halides and bis(silyl)ether and -thioether reagents, according to the general equation:

$$MCl_x + (Me_3Si)_2Y\ (Y = O,S) \longrightarrow M(Y)Cl_{x-2} + 2\,Me_3SiCl.$$

$W(O)Cl_4$ (**1**) and $Mo(O)Cl_3$ (**5**) are formed in high yield by room temperature treatment of WCl_6 and $MoCl_5$ with $(Me_3Si)_2O$ in CH_2Cl_2 solvent. $Mo(O)_2Cl_2$ (**6**) may be obtained from $Mo(O)Cl_4$ by an analogous room temperature procedure; efficient generation of $W(O)_2Cl_2$ (**2**) requires warming of $W(O)Cl_4$ with $(Me_3Si)_2O$ at 80°C in octane. In acetonitrile solvent, $W(O)Cl_4$ reacts with one equivalent of $(Me_3Si)_2O$ to give $W(O)_2Cl_2(CH_3CN)_2$ (**3**) in 70% yield. Treatment of $W(O)Cl_4$ with two equivalents of $(Me_3Si)_2O$ in CH_2Cl_2 leads to blue crystalline $W(O)_2Cl(OSiMe_3)$ (**4**), which is stable to elimination of Me_3SiCl to 100°C. $W(S)Cl_4$ (**7**), $W(S)_2Cl_2$ (**8**) and $Mo(S)Cl_3$ (**9**) are obtained by low temperature treatment of WCl_6, $W(S)Cl_4$ and $MoCl_5$, respectively, with one equivalent of $(Me_3Si)_2S$ in CH_2Cl_2 solvent. The mixed oxothiohalide compounds $W(O)(S)Cl_2$ (**10**) and $Mo(O)(S)Cl_2$ (**11**) may be isolated in good yield through the reaction of $W(O)Cl_4$ or $Mo(O)Cl_4$ with $(Me_3Si)_2S$ in CH_2Cl_2 at low temperature.

There is considerable interest in the chemistry of high oxidation state molybdenum and tungsten compounds containing oxo or sulphido ligands due to their importance in industrial and biological catalysis. The oxo- and thiohalides represent convenient starting materials for the study of these systems, and the oxo derivatives also allow access to analogous imido compounds by "NR" for "O" exchange. Although a variety of different routes to these materials has been developed over many years,[1] with few exceptions,[2] the vast majority of molybdenum and tungsten oxohalide syntheses require elevated temperatures, many involving hot tube/furnace procedures and further purification of the products (e.g. by sublimation) is often necessary. Thiohalide materials have generally proved more accessible under mild conditions.[1d,e,3]

In this paper, we describe straightforward procedures for the synthesis of oxo- and thiohalide compounds of molybdenum and tungsten which exploit reactions of transition metal halides with bis(silyl)ethers and bis(silyl)thioethers, respectively, according to the general equation (1):

$$MCl_x + (Me_3Si)_2Y\ (Y = O,S) \longrightarrow M(Y)Cl_{x-2} + 2Me_3SiCl. \quad (1)$$

The reactions are generally rapid, proceed at low temperature and give good yields of high purity materials. Base-free compounds may be obtained from either hydrocarbon or chlorocarbon solvents; the majority of these materials are insoluble in common solvents and therefore are not readily amenable to purification by solution procedures. However, since many metal halides and the $(Me_3Si)_2E$ (E = O,S) reagents may be readily purified by sublimation or distillation, materials of high purity may be obtained (provided moisture and oxygen are excluded during the preparations) and

* Author to whom correspondence should be addressed.

significantly, thiohalides free of oxide contaminants are accessible. Base adducts, which are formed in certain cases when the reaction is carried out in acetonitrile, can be readily purified by crystallization from the reaction solvent. This low temperature methodology is also suited to the synthesis of mixed oxythiohalide compounds such as $W(O)(S)Cl_2$ and $Mo(O)(S)Cl_2$ which have not proved conveniently accessible; indeed, to our knowledge, $Mo(O)(S)Cl_2$ has not been reported previously. Optimization of reaction conditions have led to some minor modifications of the procedures outlined in our earlier reports[4] of this synthetic approach.

RESULTS AND DISCUSSION

The treatment of WCl_6 with an equimolar amount of $(Me_3Si)_2O$ in CH_2Cl_2 at room temperature leads to deposition of $W(O)Cl_4$ (**1**) in the form of red crystals. If the reaction is carried out in hydrocarbon solvent, e.g. octane, the product is of similar purity but is obtained in the form of an amorphous orange powder. In contrast with other procedures, this method requires no further purification of the $W(O)Cl_4$ product once formed. $W(O)_2Cl_2$ (**2**) is best prepared by warming $W(O)Cl_4$ with an equimolar amount of $(Me_3Si)_2O$ in octane at 80°C for 4 h. The product is deposited as a finely-divided pale yellow amorphous powder. The solid gradually darkens if left to stand in the reaction mixture for a prolonged period, and its IR spectrum then shows contamination with siloxide groups, which suggests that a back reaction may occur with the liberated Me_3SiCl. Nevertheless, good quality $W(O)_2Cl_2$ may be obtained if the reaction is stopped as soon as the $W(O)Cl_4$ has been consumed (the end-point of the reaction can be judged when the orange colouration due to $W(O)Cl_4$ is discharged from the octane solution—typically *ca* 4 h). It did not prove possible to prepare **2** by treating **1** or WCl_6 with one or two equivalents, respectively, of $(Me_3Si)_2O$ in dichloromethane solvent at room temperature. Under these conditions, an amorphous off-white solid is obtained which gives strong bands at 1250 and 1000 cm^{-1} in the IR spectrum attributable to metal–siloxide species.[5] An additional broad absorption in the range 800–850 cm^{-1} is indicative of bridging oxo groups suggesting a heavily bridged oxo–siloxide lattice which we have found to be insoluble in all common solvents. The acetonitrile adduct $W(O)_2Cl_2(CH_3CN)_2$ (**3**), obtained previously by prolonged heating of **2** at 90°C in CH_3CN[6] (in a sealed tube), may be prepared in 70% yield by room temperature treatment of **1** with $(Me_3Si)_2O$ in acetonitrile solvent [eq. (2)]. Compound **1** is consumed to give a pale blue solution which upon concentration and cooling affords colourless crystals of **3**. It is not possible to replace all of the chloride groups on tungsten using $(Me_3Si)_2O$ since treatment of **1** with two equivalents of $(Me_3Si)_2O$ in CH_2Cl_2 gives $W(O)_2Cl(OSiMe_3)$ (**4**) [eq. (3)], which may be isolated as a pale blue microcrystalline solid in 70% yield.

$$\underset{(\mathbf{1})}{W(O)Cl_4} + (Me_3Si)_2O \xrightarrow{CH_3CN(S)} \underset{(\mathbf{3})}{W(O)_2Cl_2(CH_3CN)_2} + 2Me_3SiCl \quad (2)$$

$$\underset{(\mathbf{1})}{W(O)Cl_4} + 2(Me_3Si)_2O \xrightarrow{CH_2Cl_2} \underset{(\mathbf{4})}{W(O)_2Cl(OSiMe_3)} + 3Me_3SiCl. \quad (3)$$

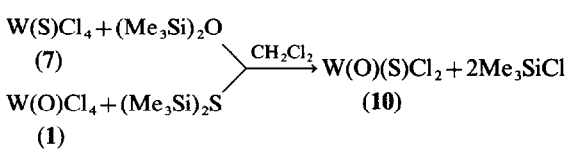
Sharp absorptions at 1255 and 1000 cm^{-1}, and a broad absorption over the range 700–900 cm^{-1} in the IR spectrum are indicative of the siloxide ligand and bridging oxo groups, respectively. The methyls of the siloxide groups are also also seen as a singlet resonance at δ 0.42 ppm in the ^1H NMR spectrum ($CDCl_3$). Compound **4** does not eliminate Me_3SiCl to give WO_3 even upon prolonged warming at 100°C.

$MoCl_5$ reacts smoothly with an equimolar amount of $(Me_3Si)_2O$ to give a dark brown solid in high yield whose IR spectrum displays the terminal Mo=O stretch at 1007 cm^{-1}, characteristic of $Mo(O)Cl_3$ (**5**).[1c] $Mo(O)_2Cl_2$ (**6**) may be isolated in similar yield via the reaction of $Mo(O)Cl_4$ with $(Me_3Si)_2O$ under essentially analogous conditions; these are notably more mild than for the preparation of the tungsten analogue, **2**.

The reactions of metal halides with hexamethyldisilthiane, $(Me_3Si)_2S$, are generally exothermic and are therefore carried out at low temperature. Dropwise addition of a chilled (−30°C) dichloromethane solution of $(Me_3Si)_2S$ to a suspension of WCl_6 in CH_2Cl_2 at −78°C gives an immediate reaction which results in a red solution of $W(S)Cl_4$ (**7**). Two extractions with CH_2Cl_2 and a low temperature crystallization allows the thiohalide to be isolated in 80% yield. $W(S)_2Cl_2$ (**8**) may be isolated in similar yield as an insoluble blue–black amorphous solid upon treatment of $W(S)Cl_4$ with a molar equivalent of $(Me_3Si)_2S$. The synthesis of **8** has been reported on two previous occasions.[3b,7] However, in both cases full characterizing data were not given. An IR spectrum of **8** produced via the route described here reveals a strong terminal W=S

stretch at 538 cm^{-1} and bands at 365, 321 and 287 cm^{-1} due to ν(W—Cl). The mass spectrum also gives an envelope at m/z 318 due to the parent ion, with daughter fragments at m/z 286, 251 and 216 which correspond to $[M-S]^+$, $[M-S-Cl]^+$ and $[M-S-2Cl]^+$, respectively. $Mo(S)Cl_3$ (**9**) may be prepared by the reaction of $MoCl_5$ with $(Me_3Si)_2S$ in CH_2Cl_2 at −78°C. The data for **9** is found to be similar in all respects to those previously reported for $Mo(S)Cl_3$.[3b]

The relatively mild conditions under which $(Me_3Si)_2Y$ (Y = O,S) reagents react with molybdenum and tungsten halides suggested that it might prove possible to prepare mixed oxothiohalide materials such as $W(O)(S)Cl_2$ and $Mo(O)(S)Cl_2$. The molybdenum compound represents a potentially useful starting material for investigations of mixed oxo/thio molybdenum compounds of relevance to bio-inorganic systems. Although there have been reports of $W(O)(S)Cl_2$,[3b,8] routes to it are not entirely satisfactory and there is a paucity of characterizing data. To our knowledge, $Mo(O)(S)Cl_2$ is hitherto unknown. It was envisaged that $W(O)(S)Cl_2$ would prove more readily accessible by treatment of $W(S)Cl_4$ with $(Me_3Si)_2O$ rather than by the reaction of $W(O)Cl_4$ with $(Me_3Si)_2S$ (Scheme 1) since the thiane has been used on previous occasions to exchange an oxo ligand for a thio group.[9] However, these concerns were unfounded since $W(O)(S)Cl_2$ may be prepared by either permutation, presumably due to the very mild conditions and the swift reaction time (oxide for sulphide exchange often requires prolonged treatment of the oxide with the thiane reagent at ambient temperature[9]). Thus, CH_2Cl_2 solutions of either **1** or **7** react with equimolar amounts of $(Me_3Si)_2S$ or $(Me_3Si)_2O$, respectively, to give colourless supernatant solutions and in both cases an identical pale brown amorphous solid, which has been characterized as $W(O)(S)Cl_2$ (**10**) by elemental analysis, IR spectroscopy and mass spectrometry. The IR spectrum shows a characteristic terminal ν(W=S) stretch at 540 cm^{-1} and a strong broad absorption at 815 cm^{-1} is attributable to bridging oxo groups. The preference for terminal sulphide and bridging oxo ligands is also seen in the solid-state structures of **1** and **7**. The former is a linear oxo-bridged polymer[10] while **7** is a dimer with weak chlorine bridges



Scheme 1.

and a terminal sulphide ligand.[11] These features are also reproduced in the structure of $WCl_4 \cdot W(O)(S)Cl_2(dme)_2$ (dme = dimethoxyethane) reported by Rice and co-workers.[3b] The mass spectrum of **10** shows envelopes at m/z 604 and 302 attributable to dimeric and monomeric fragments, respectively.

$$Mo(O)Cl_4 + (Me_3Si)_2S \xrightarrow{CS_2} Mo(O)(S)Cl_2 + 2Me_3SiCl \quad (4)$$
$$(11)$$

$Mo(O)(S)Cl_2$ (**11**) is best prepared by treatment of $Mo(O)Cl_4$ with $(Me_3Si)_2S$ in CS_2 solvent [eq. (4)]. The pale brown solid formed in this reaction is found to be analytically pure. Its IR spectrum shows a terminal oxo stretch at 982 cm^{-1} and the absence of bands in the region 500–600 cm^{-1} suggests that the sulphide groups preferentially adopt bridging sites. The mass spectrum provides evidence for at least a dimeric structure; fragments are observed at m/z 361 and 342 corresponding to $[M_2-S-Cl]^+$ and $[M_2—O—2Cl]^+$, respectively, while an envelope at m/z 214 is due to $[M]^+$ with additional daughter fragments corresponding to further loss of oxygen, sulphur and chlorine groups.

In summary, reactions of molybdenum and tungsten halides with bis(silyl)ether and -thioether reagents provide straightforward syntheses of a range of molybdenum and tungsten oxo- and thiohalides which provide alternatives to the well-established hot tube/furnace methods.

EXPERIMENTAL

General

All manipulations of air- and/or moisture-sensitive materials were performed on a conventional vacuum/inert atmosphere (nitrogen or argon) line using standard Schlenk and cannula techniques, or in an inert atmosphere (nitrogen or argon) filled glove box.

The following solvents were dried by prolonged reflux over a suitable drying agent, being freshly distilled and deoxygenated prior to use (drying agent in parentheses): petroleum ether, b.p. 40–60°C (lithium aluminium hydride), b.p. 100–120°C (sodium), octane (sodium), acetonitrile (calcium hydride), dichloromethane (calcium hydride), carbon disulphide (4 Å molecular sieves) and diethyl ether (lithium aluminium hydride). NMR solvent: d-chloroform (phosphorus(V) oxide).

Elemental analyses were performed by the microanalytical services of this department. IR spectra were recorded on Perkin–Elmer 577 and 457 grating

spectrophotometers using either KBr or CsI windows. Absorptions abbreviated as: s (strong), m (medium), w (weak), br (broad), sp (sharp), sh (shoulder). Mass spectra were recorded on a VG 7070E mass spectrometer. ^{1}H NMR spectra were recorded on a Bruker AC 250 spectrometer at 250.13 MHz. $Mo(O)Cl_4$ was obtained by a literature procedure.[12] The following chemicals were obtained commercially and used as received unless stated otherwise: WCl_6 (Aldrich), $MoCl_5$ (Aldrich), hexamethyldisiloxane (Aldrich, distilled and stored over 4 Å molecular sieves), hexamethyldisilthiane (Fluka, distilled and stored over 4 Å molecular sieves).

Synthesis of $W(O)Cl_4$ **(1)**

A dichloromethane solution of $(Me_3Si)_2O$ (2.05 g, 12.6 mmol in 15 cm^3 of CH_2Cl_2) was added dropwise at room temperature to a stirred suspension of WCl_6 (5.0 g, 12.6 mmol) in dichloromethane (20 cm^3) over a period of 15 min. An immediate reaction ensued leading to deposition of $W(O)Cl_4$ in the form of red crystals. The mixture was stirred at room temperature for a further 60 min. The supernatant liquor was then decanted from the solid which was collected, washed with petroleum ether (2 × 10 cm^3, b.p. 40–60°C) and dried *in vacuo*. Yield, 4.28 g (99%). Elemental analysis for Cl_4OW: Found (Required): W, 53.9 (53.8); Cl, 41.2 (41.5)%; IR data (Nujol, CsI, cm^{-1}): 880–900(s,br), 387(s,br), 368(m,sh), 355(m,sh), 334(s,sp), 329(m,sh), 320(m,sh), 308(w,sh), 285(w).

Synthesis of $W(O)_2Cl_2$ **(2)**

An octane solution of $(Me_3Si)_2O$ (2.38 g, 14.7 mmol in 15 cm^3 of octane) was added to a stirred suspension of $W(O)Cl_4$ (5.0 g, 14.6 mmol) in octane (40 cm^3). The mixture was rapidly warmed to 80°C and stirred until the orange coloration of the octane solution was discharged to leave a yellow solid and a colourless solution. After cooling to room temperature, the supernatant solution was decanted from the solid, which was collected, washed with petroleum ether (2 × 20 cm^3; b.p. 40–60°C) and dried *in vacuo*. Yield, 3.99 g (95%). Elemental analysis for Cl_2O_2W: Found (Required): W, 63.7, (64.1); Cl, 24.4, (24.7)%; IR data (Nujol, CsI, cm^{-1}): 800–830(s,br).

Synthesis of $W(O)_2Cl_2(CH_3CN)_2$ **(3)**

An acetonitrile solution of $(Me_3Si)_2O$ (2.38 g, 14.7 mmol in 15 cm^3 of CH_3CN) was added dropwise at room temperature to a stirred suspension of $W(O)Cl_4$ (5 g, 14.6 mmol) in acetonitrile (40 cm^3) over a period of 15 min. The $W(O)Cl_4$ was consumed to give a pale blue solution which was stirred for a further 2 h. Filtration of this solution followed by concentration to half volume and cooling to −45°C gave white moisture-sensitive crystals of $W(O)_2Cl_2(CH_3CN)_2$. The remaining dark blue supernatant solution was decanted from the solid which was collected, washed with petroleum ether (2 × 10 cm^3, b.p. 40–60°C) and dried *in vacuo*. Yield, 3.77 g (70%). Elemental analysis for $C_4H_6Cl_2N_2O_2W$: Found (Required): W, 50.12, (49.84); Cl, 19.25, (19.22); H, 1.65, (1.64); C, 13.02, (13.03); N, 7.64, (7.59)%; IR data (Nujol, CsI, cm^{-1}): 2320(s,sp), 2300(s,sp), 1409(m), 1367(s,sp), 1040(m,sp), 1031(m,sh), 980(s,sp), 971(m,sh), 946(s,sh), 932(s,sh), 927(s,sp), 920(s,sh), 379(s,sp), 394(s,br), 380(m,sh).

Synthesis of $W(O)_2Cl(OSiMe_3)$ **(4)**

A dichloromethane solution of $(Me_3Si)_2O$ (0.96 g, 5.86 mmol in 15 cm^3 of CH_2Cl_2) was added dropwise to a stirred suspension of $W(O)Cl_4$ (1.0 g, 2.93 mmol) in dichloromethane (20 cm^3) at room temperature over a period of 15 min. The $W(O)Cl_4$ suspension reacted during stirring over 2 h to give a blue solution. Filtration, followed by concentration to half volume and cooling to −78°C, afforded blue crystals of $W(O)_2Cl(OSiMe_3)$. Yield, 0.7 g (70%). Elemental analysis for $C_3H_9ClO_3SiW$: Found (Required): W, 55.9 (56.7); Cl, 10.1 (10.9); C, 10.2 (11.1); H, 2.5 (2.8)%; IR data (Nujol, CsI, cm^{-1}): 1255(s,sp), 1002(s,br), 700–900(s,br), 280–360(s,br); ^{1}H NMR data (250 MHz, d-chloroform, 298 K): 0.42 (s, Si*Me*$_3$).

Synthesis of $Mo(O)Cl_3$ **(5)**

A dichloromethane solution of $(Me_3Si)_2O$ (2.97 g, 18.3 mmol in 15 cm^3 of CH_2Cl_2) was added dropwise at room temperature to a solution of $MoCl_5$ (5.0 g, 18.3 mmol) in dichloromethane (20 cm^3). The mixture was stirred at room temperature for 2 h to give a dark brown solid and a colourless solution. The supernatant solution was decanted from the solid, which was collected, washed with petroleum ether (2 × 20 cm^3, b.p. 40–60°C) and dried *in vacuo*. Yield 3.90 g (97.5%). Elemental analysis for Cl_3OMo: Found (Required): Cl, 48.69 (48.72)%; IR data (Nujol, CsI, cm^{-1}): 1007(s,sp), 398(s), 352(s), 309(m), 295(m,sh).

Synthesis of $Mo(O)_2Cl_2$ (**6**)

A dichloromethane solution of $(Me_3Si)_2O$ (3.2 g, 19.7 mmol in 15 cm^3 of CH_2Cl_2) was added dropwise at room temperature to a stirred suspension of freshly prepared $Mo(O)Cl_4$ (5.0 g, 19.7 mmol) in dichloromethane (20 cm^3). The mixture was stirred at room temperature for 4 h to give a pale brown solid suspended in a brown solution. The solid was isolated by cannula filtration, washed with light petroleum ether (2×20 cm^3, b.p. 40–60°C) and dried *in vacuo*. Yield 3.78 g (97%). Elemental analysis for Cl_2O_2Mo: Found (Required): Cl, 35.7 (35.7)%; IR data (Nujol, CsI, cm^{-1}): 800–830(s,br), 443(s,sp), 425(m,sh), 409(m,sh), 385(s,sp), 354(s,sp), 291(m,sp).

Synthesis of $W(S)Cl_4$ (**7**)

A suspension of WCl_6 (5.0 g, 12.6 mmol) in dichloromethane (20 cm^3) was cooled in a dry-ice/acetone slush bath and treated dropwise over a period of 15 min with a solution of $(Me_3Si)_2S$ (2.25 g, 12.6 mmol in 15 cm^3 of CH_2Cl_2) chilled to *ca* −30°C. An immediate reaction ensued leading to a red solution and precipitation of a brown, amorphous solid. The mixture was allowed to warm to room temperature and stirred for a further 30 min. Filtration of the supernatant solution followed by concentration and cooling to −78°C afforded red, moisture-sensitive crystals of $W(S)Cl_4$ (2.95 g, 65%). A second extraction of the residue with CH_2Cl_2 (20 cm^3) followed by crystallization resulted in a combined yield of 80% of analytically pure $W(S)Cl_4$. Elemental analysis for Cl_4SW: Found (Required): W, 51.5, (51.4); Cl, 39.5, (39.6); S, 9.0 (9.0)%; IR data (Nujol, CsI, cm^{-1}): 560(s,sp), 392(m,sh), 355(s), 306(m,sh), 285(w); mass spectral data, *m/z* (EI, 70 eV, W^{184}, S^{32}; Cl^{35}): 356 $[WSCl_4]^+$, 321 $[WSCl_3]^+$, 286 $[WSCl_2]^+$, 251 $[WSCl]^+$, 216 $[WS]^+$, 324 $[WCl_4]^+$, 289 $[WCl_3]^+$, 254 $[WCl_2]^+$, 219 $[WCl]^+$.

Synthesis of $W(S)_2Cl_2$ (**8**)

A solution of $WSCl_4$ (1.0 g, 2.8 mmol) in dichloromethane (20 cm^3) was cooled in a dry-ice/acetone slush bath and treated dropwise over a period of 15 min with a dichloromethane solution of $(Me_3Si)_2S$ (0.50 g, 2.8 mmol in 15 cm^3 of CH_2Cl_2) chilled to *ca* −30°C. An immediate reaction ensued, which after 30 min resulted in a colourless solution and a black, amorphous solid. The mixture was allowed to warm to room temperature and stirred for a further 2 h. The supernatant solution was decanted from the black solid, which was collected, washed with petroleum ether (2×10 cm^3, b.p. 40–60°C) and dried *in vacuo*. Yield, 0.72 g (81%). Elemental analysis for Cl_2S_2W: Found (Required): W, 57.64 (57.66); Cl, 21.69 (22.24); S, 19.90 (20.11)%; IR data (Nujol, CsI, cm^{-1}): 538(s,sp), 365(m,sh), 321(m,sh); mass spectral data, *m/z* (EI, 70 eV, W^{184}, S^{32}, Cl^{35}) 318 $[WS_2Cl_2]^+$, 286 $[WSCl_2]^+$, 251 $[WSCl]^+$, 216 $[WS]^+$.

Synthesis of $Mo(S)Cl_3$ (**9**)

A solution of $MoCl_5$ (1.0 g, 3.66 mmol) in dichloromethane (20 cm^3) was cooled in a dry-ice/acetone slush bath and treated dropwise over a period of 15 min with a dichloromethane solution of $(Me_3Si)_2S$ (0.65 g, 3.66 mmol in 15 cm^3 of CH_2Cl_2) chilled to *ca* −30°C. An immediate reaction ensued, which after 30 min had afforded a colourless solution and an olive green, amorphous solid. The mixture was allowed to warm to room temperature and stirred for 2 h. The supernatant solution was decanted from the solid which was collected, washed with petroleum ether (2×20 cm^3, b.p. 40–60°C) and dried *in vacuo*. Yield 0.75 g (87%). Elemental analysis for Cl_3SMo: Found (Required): S, 14.40 (13.68); Cl, 45.25 (45.38)%; IR data (Nujol, CsI, cm^{-1}): 398(s,br), 375(m,sh), 354(m), 346(w,sh), 290(m,br); mass spectral data *m/z* (EI, 70 eV, Mo^{96}; S^{32}, Cl^{35}, O^{16}): 326 $[Mo_2S_2Cl_2]^+$, 291 $[Mo_2S_2Cl]^+$, 259 $[Mo_2SCl]^+$, 233 $[MoSCl_3]^+$, 198 $[MoSCl_2]^+$, 163 $[MoSCl]^+$, 128 $[MoS]^+$.

Synthesis of $W(O)(S)Cl_2$ (**10**)

A chilled (*ca* −30°C) dichloromethane solution of $(Me_3Si)_2S$ (0.52 g, 2.93 mmol in 15 cm^3 of CH_2Cl_2) was added dropwise over a period of 15 min to a stirred suspension of $W(O)Cl_4$ (1.0 g, 2.93 mmol) in dichloromethane (20 cm^3) cooled in a dry-ice/acetone slush bath. An immediate reaction ensued, which after 30 min resulted in a colourless solution and a light brown, amorphous solid. The mixture was allowed to warm to room temperature and stirred for a further 2 h. The supernatant solution was decanted from the light brown solid, which was collected, washed with petroleum ether (2×10 cm^3, b.p. 40–60°C) and dried *in vacuo*. Yield, 0.73 g (82%). Elemental analysis for Cl_2SOW: Found (Required): W, 60.09, (60.71); S, 9.75, (10.59); Cl, 22.83, (23.42)%; IR data (Nujol, CsI, cm^{-1}): 815(s,br), 540(s,sp), 410(s), 372(m,br), 343(s,sp); mass spectral data *m/z* (EI, 70 eV, W^{184}, S^{32}, Cl^{35}) 604 $[W_2O_2S_2Cl_4]^+$, 585 $[W_2S_2O_3Cl_3]^+$, 566 $[W_2S_4Cl_2]^+$, 318 $[WS_2Cl_2]^+$, 302 $[WOSCl_2]^+$.

Synthesis of $Mo(O)(S)Cl_2$ (**11**)

A chilled (*ca* −30°C) carbon disulphide solution of $(Me_3Si)_2S$ (0.70 g, 3.92 mmol in 15 cm^3 of CS_2) was added dropwise over a period of 15 min to a stirred solution of $Mo(O)Cl_4$ (1.0 g, 3.92 mmol) in carbon disulphide (20 cm^3) cooled in a dry-ice/acetone slush bath. An immediate reaction ensued, which after 30 min resulted in a colourless solution and a light brown, amorphous solid. The mixture was allowed to warm to room temperature and stirred for 2 h. The supernatant solution was decanted from the solid, which was collected, washed with petroleum ether (2 × 20 cm^3, b.p. 40–60°C) and dried *in vacuo*. Yield 0.73 g (86%). Elemental analysis for Cl_2OSMo: Found (Required): S, 15.14 (14.92); Cl, 32.75 (32.99)%; IR data (Nujol, CsI, cm^{-1}): 982(s,sp), 851(w), 720(m), 473(s,sp), 378(s), 369(m,sh), 325(s,sp), 298(s,sh), 255(m); mass spectral data *m/z* (EI, 70 eV, Mo^{96}, S^{32}, Cl^{35}, O^{16}): 361 $[Mo_2O_2SCl_3]^+$, 342 $[Mo_2OS_2Cl_2]^+$, 326 $[Mo_2S_2Cl_2]^+$, 310 $[Mo_2OSCl_2]^+$, 214 $[MoOSCl_2]^+$, 198 $[MoSCl_2]^+$, 179 $[MoOSCl]^+$, 163 $[MoSCl]^+$, 147 $[MoOCl]^+$, 128 $[MoS]^+$, 112 $[MoO]^+$.

SUBSTITUENT EFFECTS ON THE OXIDATION OF BENZOINS BY THE OCTACYANOMOLYBDATE(V) ION

H. A. HODALI* and R. A. EL-ZARU

Department of Chemistry, Faculty of Science, University of Jordan, Amman, Jordan

(*Received* 18 *December* 1989; *accepted* 11 *May* 1990)

Abstract—The kinetics of the oxidation of a series of benzoins (BH_2) by octacyanomolybdate(V) (OX^{3-}), in a buffered alkaline aqueous methanolic medium, have been studied spectrophotometrically. The experimental results are in agreement with the following rate law:

$$-1/2\,d[OX^{3-}]/dt = k[OX^{3-}][BH_2][OH^-],$$

and the following order of reactivity was observed: *o,o'*-dichloro- > *p,p'*-dichloro- > *m,m'*-dimethoxybenzoin > benzoin > *p,p'*-dimethoxy- > *o,o'*-dimethoxybenzoin. The rate measurements were used to calculate the thermodynamic activation parameters $\Delta G^{\ddagger}$, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$. The relative rates correlate very well with the Hammett substituent constants and support a negatively-charged intermediate. The effect of substituents correlated with a ρ-value of 1.36.

Octacyanomolybdate(V) has been employed in the oxidation of many classes of compounds, in both basic and acidic media. Examples are, the oxidation of hydrazine and substituted hydrazines,[1] iodide ions,[2] ascorbic acid[3,4] and benzenediols.[5] Acyloins (1,2-enediols), on the other hand, are readily oxidized by several oxidizing agents.[6,7] The kinetics of oxidation of benzoins (BH_2)[8] and aliphatic acyloins[9] by $[Fe(CN)_6]^{3-}$ in basic medium have been investigated. The oxidation reaction was found to be first-order with respect to each of the acyloin, the hexacyanoferrate(III) and the hydroxide ion. These findings prompted us to investigate the oxidation of benzoin and substituted benzoins by another oxidizing agent in order to compare its kinetic data with that obtained for $[Fe(CN)_6]^{3-}$, and also to study the effect of substituents on the rates of benzoin oxidation.

Herein, the kinetics of oxidation of a series of benzoins (**I–VI**) by $[Mo(CN)_8]^{3-}$ in alkaline medium are investigated. The results are used to calculate the reaction rates and thermodynamic parameters. The relative rate values were used along with the substituent constants (σ_m, σ_p) to find the value of the reaction constant (ρ).

EXPERIMENTAL

Materials

The benzoin used in this investigation was B.D.H. Analar grade, and was used without further purification. The substituted benzoins, *o,o'*-dichloro-,[10] *p,p'*-dichloro-,[10] *m,m'*-dimethoxy-,[11] *p,p'*-dimethoxy-,[11] *o,o'*-dimethoxybenzoin[11] and the cyano complexes, $K_4[Mo(CN)_8]\cdot 2H_2O$[12] and $Cs_3[Mo(CN)_8]\cdot 2H_2O$[13] were prepared by literature methods. The oxidizing agent, $Cs_3[Mo(CN)_8]\cdot 2H_2O$, was purified by recrystallization from water and was used as a primary standard. Analytical grade reagents and doubly-distilled water

* Author to whom correspondence should be addressed.

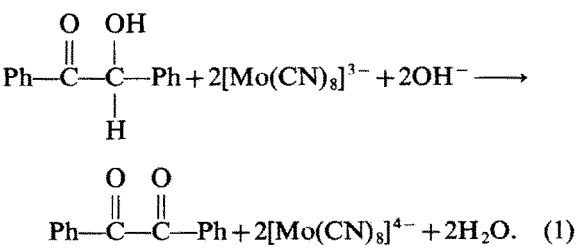
were used throughout the measurements. The desired buffer solutions for varying the pH of the reaction medium were prepared by mixing suitable volumes of 0.025 M borax and 0.10 M NaOH (pH = 9.0–10.0) or 0.05 M disodium hydrogen phosphate and 0.10 M NaOH (pH = 11.0–12.0). The pH was measured with a Metrohm 632 pH meter. The measured pHs were corrected for 50% v/v aqueous methanol using the relationship:[14] $pH_{corr} = pH_{meas} + 0.08$.

Kinetic measurements

The oxidation reactions were carried out in buffered alkaline aqueous methanol (50% v/v) using a thermostated bath to regulate the temperature to ±0.2°C. The ionic strength was adjusted to a constant value of 0.10 M by the addition of NaCl. Kinetic data were obtained by monitoring the decrease in the concentration of $[Mo(CN)_8]^{3-}$ at 390 nm with a thermostated Unicam SP8-500 spectrophotometer. Solutions of the benzoins and the octacyanomolybdate(V) were protected from light during the preparation and kinetic measurements.

Stoichiometry

The oxidation of benzoin was found to proceed by a 1:2 stoichiometry represented in eq. (1):[15]



(1)

The formation of the 1,2-diketone (benzil), in high yield, was confirmed by a preparative scale reaction.[15]

RESULTS AND DISCUSSION

Effect of benzoin

Absorption measurements carried out at constant concentration of the oxidant, $[Mo(CN)_8]^{3-}$, the hydroxide ion and at constant ionic strength, but with varying concentrations of the benzoins (**I–VI**), showed a first-order dependence on the concentration of the benzoin (Table 1). The plot of $\ln(A_0/A_t)$ vs time for *m,m'*-dimethoxybenzoin (**IV**) is linear for about 75% of the reaction (Fig. 1). Similar plots were obtained for the other benzoins.

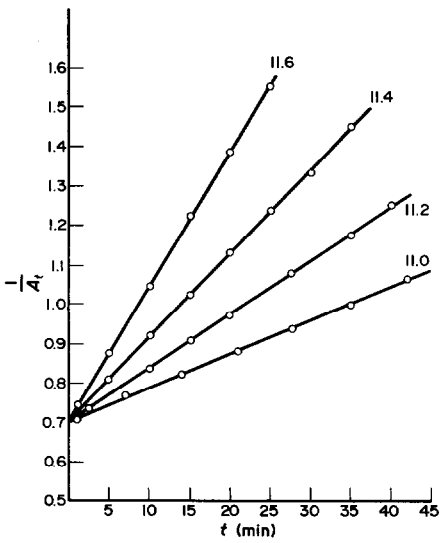

Fig. 2. Plots of $(1/A_t)$ vs time for the oxidation of **IV** by $[Mo(CN)_8]^{3-}$ at different pH values.

Effect of $[Mo(CN)_8]^{3-}$

Absorption measurements carried out at stoichiometric molar ratios of the reactants (benzoin (**I–IV**): oxidant ratio, 1:2) and at different pH values are shown in Table 2. The plots of $1/A_t$ vs t are linear, indicating a first-order dependence on both the benzoin and $[Mo(CN)_8]^{3-}$. The plot for *m,m'*-dimethoxybenzoin (**IV**) is shown in Fig. 2. Accordingly, the rate can be expressed as shown in eq. (2):

$$-d/dt[[Mo(CN)_8]^{3-}] = k[[Mo(CN)_8]^{3-}][\text{benzoin}]. \quad (2)$$

Effect of pH

The above kinetic measurements were used to obtain the plots of log k vs pH (Fig. 3). The slopes of these linear plots indicate first-order rate dependence on the hydroxide ion concentration. This is consistent with an overall rate defined by eq. (3). These kinetic measurements are also used to obtain the plots of k vs $1/[H^+]$ (Fig. 4). With the pH range available, the slopes of the straight lines obtained are used to evaluate approximate values of K_a for benzoins **I–IV** (Table 2).

$$-d/dt[[Mo(CN)_8]^{3-}] = k_{obs}[\text{benzoin}][Mo(CN)_8]^{3-}][OH^-]. \quad (3)$$

In view of the above data, the following simple

[a] $[BH_2] = 4.0 \times 10^{-3}$ M, $[[Mo(CN)_8]^{3-}] = [[Fe(CN)_6]^{3-}] = 1.0 \times 10^{-3}$ M, $T = 25.0$°C, pH = 11.0, $I = 0.10$ M.
[b] Rate constants for the benzoins (I–IV) were obtained from ref. 8.

mechanism is proposed:[9]

$$BH_2 + OH^- \underset{}{\overset{K}{\rightleftharpoons}} BH^- + H_2O \quad (4)$$

$$BH^- + [Mo(CN)_8]^{3-} \xrightarrow{k_2} BH^{\cdot} + [Mo(CN)_8]^{4-} \quad (5)$$

$$BH^{\cdot} + [Mo(CN)_8]^{3-} + OH^- \xrightarrow{\text{Fast}} B + [Mo(CN)_8]^{4-} + H_2O. \quad (6)$$

On the assumption that step (6) proceeds by a fast one-electron oxidation, and step (5) is the rate-determining step, then the following third-order rate law can be easily derived [eq. (7)]:

$$-d[[Mo(CN)_8]^{3-}]/dt = k_2K[BH_2][[Mo(CN)_8]^{3-}][OH^-], \quad (7)$$

where $k_2K = k_{obs}$.

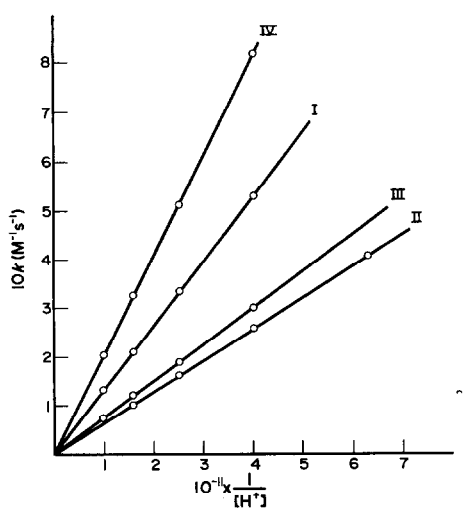

Fig. 4. Plots of k vs $1/[H^+]$ for the oxidation of benzoins (I–IV).

Relative reactivities

The relative reactivities of the benzoins studied are found in the following order (Table 3): **I** (1.00), **II** (0.300), **III** (0.487), **IV** (1.55), **V** (2.43), **VI** (9.17). The exceptionally high reactivity of *o,o'*-dichlorobenzoin (**VI**) and the relatively low reactivity of *o,o'*-dimethoxybenzoin (**II**) are attributed to the strong electron-withdrawing effect of the *o*-chloro substituents as compared with the electron-releasing effect of the *o*-methoxy groups. The electron-withdrawing groups are of importance in stabilizing the benzoin anion and thus enhancing its rate of oxidation. Similar trends were also observed for *p,p'*-dichlorobenzoin (**V**) and *p,p'*-dimethoxybenzoin (**III**). However, the higher reactivity of *m,m'*-dimethoxybenzoin (**IV**) compared with benzoin (**I**) is due to the stabilization of the intermediate benzoin anion through the mesomeric inductive effect of the *m*-methoxy group.

The values of $\log k_{rel}$ ($k_{rel} = k_{substituted}/k_{benzoin}$ under similar conditions) were plotted vs the substituent constants σ_m, σ_p. The substituent constants utilized here (Table 4) were derived from the ionization constant of the substituted benzoic acids[16,17] due

Compound	$10^4 k$ (s^{-1})	k_{rel}	$\log k_{rel}$	σ
I	7.95	1.00	0.00	0.00
III	3.87	0.484	−0.315	−0.268
IV	12.3	1.54	0.187	0.115
V	19.3	2.43	0.385	0.240

[a] $[BH_2] = 4.0 \times 10^{-3}$ M, $[[Mo(CN)_8]^{3-}] = 1.0 \times 10^{-3}$ M, $T = 25$°C, pH = 11.0, $I = 0.10$ M.

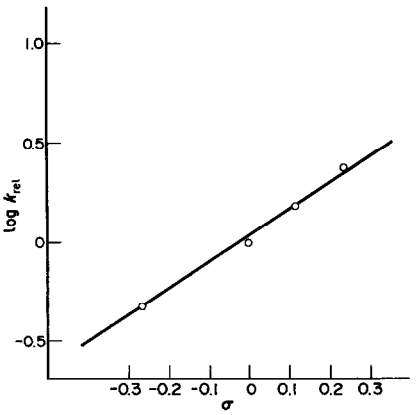

Fig. 5. Plots of $\log k_{rel}$ vs σ for the oxidation of benzoins **I, III, IV** and **V** (See Table 4).

to structural similarities. The slope of the linear plot obtained (Fig. 5) gives a Hammet ρ of +1.36. The sign and magnitude of ρ for this series of substituted benzoins are in good agreement with reported values for the cupric oxidation of acyloins[18] and *o*-hydroxyacetophenone.[19]

Thermodynamic parameters

The enthalpies of activation were evaluated by variation of the reaction temperature between 15 and 30°C under pseudo-first-order conditions ($[BH_2] = 4.0 \times 10^{-3}$ M, $[OX^{3-}] = 1.0 \times 10^{-3}$ M), at constant pH (11.0) and constant ionic strength (0.10 M). Plots of $-\log(k/T)$ vs $1/T$ gave straight lines for all the benzoins studied (**I–VI**). The values of $\Delta H^{\ddagger}$ were obtained from the slopes and the values of $\Delta S^{\ddagger}$, $\Delta G^{\ddagger}$ and k_{rel} were calculated at 25°C (Table 3, Fig. 6).

From the data accumulated in Table 3, a direct relationship between the benzoin reactivity and $\Delta S^{\ddagger}$ values could be easily formulated. The benzoin with the highest reactivity (**VI**) has the highest positive $\Delta S^{\ddagger}$ (+62.0) for the activated complex, while the least reactive (**II**) has the largest negative value of $\Delta S^{\ddagger}$ (−105). This can be explained in view of the closest approach through the formation of the activated complex, and thus, the value of $\Delta S^{\ddagger}$ is a function of the electron-transfer distance. For the high negative values of $\Delta S^{\ddagger}$, the electron transfer takes place at relatively short distances, which accordingly may be hindered by several factors such as, solvation, ion-pairing, hydrogen-bonding and substituent steric effects. The observed relationship between reactivity and electron-transfer distance was in full agreement with conclusions of other researchers[20] in this field.

For the purpose of comparison, the thermodynamic parameters, $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$ and $\Delta G^{\ddagger}$, for the oxidation of the benzoins (**I–IV**)[8] and **VI** with $[Fe(CN)_6]^{3-}$ were calculated under conditions similar to those employed for $[Mo(CN)_8]^{3-}$. The thermodyamic parameters for $[Fe(CN)_6]^{3-}$ are also found to be consistent and in perfect agreement with the above derived relationship between reactivity and electron-transfer distance (Table 3). However, the higher reactvity of $[Mo(CN)_8]^{3-}$ in comparison with $[Fe(CN)_6]^{3-}$ is mainly due to its higher reduction potential.[3]

SUBSTITUTED METAL CARBONYLS—XIV. POLYNUCLEAR HETEROMETALLIC COMPLEXES OF Cr, Mo, W AND Mn SUPPORTED BY SINGLY-BRIDGING 1,1′-BIS(DIPHENYLPHOSPHINO)FERROCENE

T. S. A. HOR* and L.-T. PHANG

Department of Chemistry, Faculty of Science, National University of Singapore, Kent Ridge 0511, Singapore

(*Received* 7 *March* 1990; *accepted* 11 *May* 1990)

Abstract—A series of polynuclear heterometallic complexes $(OC)_5M(\mu\text{-dppf})M'(CO)_5$ (M, M′ = Cr, Mo, W; M ≠ M′) and $(OC)_5M(\mu\text{-dppf})Mn_2(CO)_9$ (dppf = 1,1′-bis(diphenylphosphino)ferrocene) has been synthesized at room temperature based on the metalloligand $M(CO)_5(\eta^1\text{-dppf})$. The use of amine oxide as a decarbonylant preserves the integrity of the Mn—Mn bond. The mixed metals are linked by a singly-bridging diphosphine group which does not perturb the two metal spheres.

Carbonyl complexes of the Group 6 metals which contain 1,1′-bis(diphenylphosphino)ferrocene (dppf) as a bridging, chelating and unidentate ligand are well represented in the literature.[1] Relatively rare are those in which dppf serves as a bridging ligand between atoms of two different metals. We recently reported the use of the unidentate-diphosphine complex $Fe(CO)_4(\eta^1\text{-dppf})$ as a metalloligand in the systematic synthesis of a series of novel mixed-metal carbonyls.[2] In view of the emerging importance of these functionalized metalloligands[3] and the chemistry of dinuclear complexes which are of relevance in solid-state and catalytic studies,[4] we herein report an extension of this avenue to the syntheses of the heterometallic Group 6 carbonyls and the hitherto unknown $(CO)_5M(\mu\text{-dppf})Mn_2(CO)_9$ (M = Cr, Mo, W) clusters.

RESULTS AND DISCUSSION

Trimethylamine *N*-oxide (TMNO)-induced decarbonylation of the binary carbonyls $M'(CO)_6$, followed by nucleophilic attack by $M(CO)_5(\eta^1\text{-dppf})$ (M, M′ = Cr, Mo, W; M ≠ M′) at ambient temperature (25°C), affords the desired heterometallics $(OC)_5M(\mu\text{-dppf})M'(CO)_5$ (Fig. 1). The basicity of the dangling phosphine and the generality of this route are exemplified by the ease of the conversion either with $M(CO)_5(dppf)$ or $M'(CO)_5(dppf)$ as the substrates, the only exception being the Mo—W complex which is best synthesized from $W(CO)_5(dppf)$. The carbonyl region

[a] $CHCl_3$.
[b] $CDCl_3$.
[c] H_a and H_b refer to the external and internal cyclopentadienyl protons, respectively. H^M denotes the protons of the M- (M = Cr, Mn, Mo, W) coordinated phosphinocyclopentadienyl ring.

in the IR spectra of these complexes (Table 1) exhibit bands additive of their respective homonuclear analogues.[1e] This is best indicated by the resolutions of the high energy A_1 modes which have been discussed by Keiter *et al.*[5] Such an additive effect is also evident in the overlapping signals of the cyclopentadienyl ring protons in the ^1H spectrum, as well as the presence of two resonances with shift values comparable to those of the respective $M_2(CO)_{10}(\mu$-dppf) in the ^{31}P spectrum (Table 1). These spectral characteristics are consistent with two linked, yet essentially unperturbed coordination spheres. The present synthetic route requires the isolation of the pentacarbonyl metalloligand. This in many cases is found to be thermodynamically less stable compared to the chelate or bridged dimer,[6] as exemplified in the hitherto non-existence of complexes such as $M(CO)_5(\eta^1$-L—L) [L—L = $Ph_2P(CH_2)_nPPh_2$, $n > 3$; $Ph_2As(CH_2)_nAsPh_2$, $n > 1$; $Fe(C_5H_4AsPh_2)_2$]. Our earlier study on $M(CO)_5$(dppm)[7] also suggested that the nucleophilicity of the pendant phosphine can be significantly suppressed by the presumably steric crowding and hence is unsuitable as a precursor for mixed-metal syntheses. The good stability of $M(CO)_5$(dppf) and yet their ready conversion to the dimers are attributed to a delicate balance between the chelate bite, torsion angle and cone angle of dppf as a ligand. Though there are insufficient data to date to probe further into these parameters for different complexation modes of dppf, there is emerging evidence that dppf is not only a chelate ligand, as previously known, but a bridging ligand that can support metal–metal interaction should the situation dictate.[8]

With $Mn_2(CO)_{10}$, the metalloligand attaches itself axially,[9] as evident from IR data (Table 1), to one end of the molecule resulting in the novel $(OC)_5M(\mu$-dppf$)Mn_2(CO)_9$ complexes (Fig. 1) in reasonable yields. The negative mass susceptibility supports the diamagnetic nature of the complex, and together with molecular weight and microanalytical data preclude the possibility of a monomeric 17-electron manganese fragment. Heterometallic complexes of manganese with other metals are abundant and well-documented,[10] but, most of these reported are either dinuclear in nature or larger clusters but based on a single manganese sphere. It is thus envisaged that such an engagement of a $M(CO)_5$ unit onto the dimanganese framework,

as in the title complexes, without inducing metal–metal support between manganese and the metal, and without disrupting the Mn_2 entity, is partly owing to the characteristically low-energy requirement facilitated by the oxidative decarbonylation.[11] There is conflicting evidence in the literature on the stability of Mn—Mn bonds with respect to homolytic scission,[12] but the arguments tend to favour the bond being photosensitive but thermally resistant. Nucleophilic attack leading to the rupture of the metal–metal bond is, however, undisputed in many dinuclear species.[13] The absence of serious side-reactions arising from the fission of the Mn—Mn bond in the present complexes lends further support to the notion that nucleophilic attack of TMNO occurs on the carbonyl carbon instead of the metal centre.[14] This, together with our recent isolation of the other polynuclear Mn_2-based $(OC)_4Fe(\mu\text{-dppf})Mn_2(CO)_9$ and $(OC)_9Mn_2(\mu\text{-dppf})Mn_2(CO)_9$,[2b] affirms our prediction that there is a rich but largely unexplored low-energy substitution chemistry of dimanganese carbonyls.

Unlike many metal–metal bonded dimers, these singly ligand-bridged complexes are more open and flexible in their structures. The bridging dppf juxtaposes the two metals without significantly altering the reactivity pattern at each site. These characteristics, which contrast distinctly with the metal–metal bonded species and the dppm-bridged complexes[15] which emphasize the cooperative effect of the metals, provide the necessary impetus for our future directives.

EXPERIMENTAL

General procedures

All the preparations and reactions were carried out under a dry nitrogen atmosphere using standard Schlenk techniques. The general procedures and instruments used followed those described in our earlier reports.[1c,2] $M(CO)_5(\eta^1\text{-dppf})$ was prepared as previously described.[1e]

Preparations

$MM'(CO)_{10}(\mu\text{-dppf})$ (M,M′ = Cr, Mo, W; M ≠ M′). Solid $Mo(CO)_5(dppf)$ (0.201 g, 0.23 mmol) was added to a yellow mixture of $Cr(CO)_6$ (0.078 g, 0.35 mmol) and TMNO (0.037 g, 0.33 mmol) which had been stirring in THF (40 cm^3) for 15 min at 25°C. The resultant orange–yellow solution was further stirred for 3 h, after which the reaction mixture was filtered and the solvent removed *in vacuo*. Preparative TLC was used to separate the products, which were eluted with 15% CH_2Cl_2 in hexane solution. Further recrystallization from a CH_2Cl_2–hexane mixture yielded the required orange, heterometallic complex $(OC)_5Cr(dppf)Mo(CO)_5$ (0.082 g, 33%, Found: C, 53.7; H, 2.8. Calc. for $C_{44}H_{28}CrFeMoO_{10}P_2$: C, 53.8; H, 2.9%), together with an unidentified orange side product (0.033 g).

$(OC)_5Cr(dppf)W(CO)_5$ (0.054 g, 13%) was similarly prepared from $Cr(CO)_5(dppf)$ (0.313 g, 0.42 mmol), TMNO (0.060 g, 0.54 mmol) and $W(CO)_6$ (0.198 g, 0.56 mmol) with a reaction time of 4 h. (Found: C, 49.0; H, 2.5. Calc. for $C_{44}H_{28}CrFeO_{10}P_2W$: C, 49.4; H, 2.6%.)

$(OC)_5Mo(dppf)W(CO)_5$ was similarly obtained from $W(CO)_5(dppf)$ (0.201 g, 0.23 mmol), TMNO (0.032 g, 0.30 mmol) and $Mo(CO)_6$ (0.084 g, 0.32 mmol) with a reaction time of 2 h 15 min (Yield = 0.067 g (26%), Found: C, 47.7; H, 2.5. Calc. for $C_{44}H_{28}FeMoO_{10}P_2W$: C, 47.4; H, 2.5%.)

$MMn_2(CO)_{14}(\mu\text{-dppf})$ (M = Cr, Mo, W). A typical procedure of the synthesis involved the addition of solid $M(CO)_5(dppf)$ (0.3–0.4 g) to a stirred orange mixture of TMNO and $Mn_2(CO)_{10}$ in a stoichiometric ratio of 1:1.3:1.4 in THF for 3 h. Separation by preparative TLC (eluted with 15% CH_2Cl_2 in hexane), followed by recrystallization with hexane led to the isolation of the analytically pure orange–yellow complex.

$(OC)_5Cr(dppf)Mn_2(CO)_9 \cdot 1/3C_6H_{14}$: Yield = 56%; mass susceptibility, $\chi_g = -0.324 \times 10^{-6}$ c.g.s.; Found: C, 52.9; H, 3.0. Calc. for $C_{50}H_{33}CrFeMn_2O_{14}P_2$: C, 52.8; H, 2.9%. Mol. wt (benzene), Found: 1110. Calc.: 1108.

$(OC)_5Mo(dppf)Mn_2(CO)_9 \cdot 1/4C_6H_{14}$: Yield = 61%; mass susceptibility, $\chi_g = -0.312 \times 10^{-6}$ c.g.s.; Found: C, 50.6; H, 2.5. Calc. for $C_{50}H_{32}FeMn_2MoO_{14}P_2$: C, 50.6; H, 2.7%. Mol. wt (benzene), Found: 1150. Calc.: 1152.

$(OC)_5W(dppf)Mn_2(CO)_9$: Yield = 61%; mass susceptibility, $\chi_g = -0.223 \times 10^{-6}$ c.g.s.; Found: C, 46.3; H, 2.2. Calc. for $C_{48}H_{28}FeMn_2O_{14}P_2W$: C, 46.5; H, 2.3%.

COMPLEXES OF OSMIUM(III) DERIVED FROM O,O-DONOR LIGANDS

AHMED M. EL-HENDAWY

Chemistry Department, Faculty of Science, Damietta, Egypt

(*Received* 16 *March* 1990; *accepted* 11 *May* 1990)

Abstract—The complex $[Os^{III}Cl_3(PPh_3)_2MeOH]$ has been prepared and found to be a precursor for the synthesis of $[Os^{III}Cl_2(PPh_3)_2L]$ (L = monoanions of maltol, tropolone, acetylacetone, trifluoroacetylacetone, hexafluoroacetylacetone, benzoylacetone and dibenzoylmethane). These new complexes were characterized by spectroscopic measurements and exhibited a rich redox chemistry as demonstrated by cyclic voltammetry. The catalytic oxidation of alcohols in the presence of excess N-methylmorpholine-N-oxide by $[Os^{III}Cl_2(PPh_3)_2(acac)]$ has been studied and compared with that of the related ruthenium(III) complexes.

Mixed complexes of ruthenium(II) with triphenylphosphine and β-diketones, $[Ru(\beta\text{-diket})_2(PPh_3)_2]$, have been reported.[1] The low-spin ruthenium(III) complexes, $[RuX_2(\beta\text{-diket})(EPh_3)_2]$ (X = Cl, Br; E = P, As), have also been noted.[2,3] Recently,[4] we have prepared and characterized the complexes $[Ru^{III}Cl_2(PPh_3)_2L]$ (L = monoanions of maltol, kojic acid, tropolone and acetylacetone), but no work has so far been reported on similar complexes of osmium(III).

We now report the preparation of the new complexes $[Os^{III}Cl_2(PPh_3)_2L]$ [L = monoanions of maltol (malt), 3-hydroxy-2-methyl-4-pyrone; tropolone (trop), 2-hydroxy-2,4,6-cycloheptatrienone; acetylacetone (acac); trifluoroacetylacetone (tfacac); hexafluoroacetylacetone (hfacac); benzoylacetone (bac); and dibenzoylmethane (dbm)], starting with $[OsCl_3(PPh_3)_2MeOH]$. We also report their spectroscopic and electrochemical behaviour, together with the application of $[Os^{III}Cl_2(PPh_3)_2(acac)]$ to the catalytic oxidation of alcohols in the presence of N-methylmorpholine-N-oxide (NMO) as co-oxidant, since the analogous ruthenium(III) complex[4] and also the $Ru^{II}Cl_2(PPh_3)_3$/NMO system have been studied in this way.[5,6]

RESULTS AND DISCUSSION

On attempting to prepare *fac*-$[OsCl_3(PPh)_3]$ by the method of Taqui Khan *et al.*[7] using $Na_2[OsCl_6]$ instead of $(NH_4)_2[OsCl_6]$, a yellow solid was isolated and shown to be $[OsCl_3(PPh_3)_2MeOH]$ after recrystallization from methanol. Its IR spectrum has a strong broad band at 3473 cm^{-1} likely to have arisen from the ν(O—H) vibration, medium intensity bands at 2984 and 2911 cm^{-1} probably due to ν(C—H), and strong ones at 906 and 889 cm^{-1} which are attributed to the ν(C—O) of coordinated MeOH in the complex. These bands are absent both in $[RuCl_2(PPh_3)_3]$ and our present complexes $[OsCl_2(PPh_3)_2L]$ (L = O,O-donor ligand). We have also prepared $[RuCl_3(PPh_3)_2MeOH]$[8] and observed similar IR bands at 3505, 2941, 2836 and 1012 cm^{-1}, compared with those reported for $[RuCl_3(AsPh_3)_2MeOH]$[9] at 3480 and 1010 cm^{-1}.

Reaction of $[OsCl_3(PPh_3)_2MeOH]$ (**I**) with the O,O-donor ligands (HL) by refluxing for 0.5–2.5 h in methanol affords nice microcrystals with yields of 20–65%. Analytical data indicate that complexes have the formula $[OsCl_2(PPh_3)_2L]$ (L = malt, trop, acac, tfacac, hfacac, bac or dbm). These complexes are only soluble in CH_2Cl_2 and their molar conductivities are very low. Refluxing complex **I** alone in CH_3CN for a few hours gave a red solution from which red crystals were isolated. Analytical data were consistent with this being $[OsCl_3(PPh_3)_2CH_3CN]$, which was previously[10] prepared by long reflux of *trans*-$[OsCl_4(PPh_3)_2]$ in CH_3CN. Dissolution of **I** in CH_2Cl_2 and concentration of the solution by heating yields $[OsCl_3(PPh_3)_2CH_2Cl_2]$ as brown crystals.

The IR spectra of the complexes showed all the

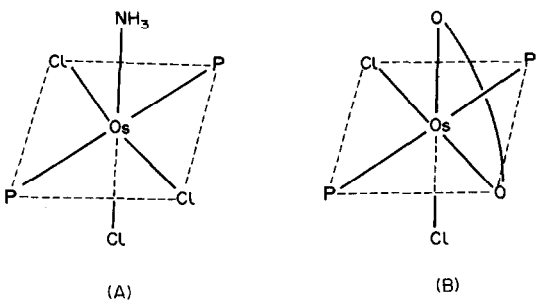
bands due to triphenylphosphine and coordinated L. The general features are similar to those observed for analogous ruthenium complexes.[2-4] Characteristic bands of L are slightly shifted to lower wavenumbers; e.g. the band in the region 1555–1510 cm^{-1} for $[MCl_2(PPh_3)_2L]$ (M = Ru,[4] L = malt, trop, acac) was found at 1549–1510 cm^{-1} (M = Os). This band is tentatively assigned to ν(C═O), where a bathochromic shift (75–105 cm^{-1}) for the carbonyl groups upon coordination is expected.[11,12] A strong band attributed to ν(C—O) was found around 1350 cm^{-1} for $[OsCl_2(PPh_3)_2L]$ (L = trop, acac, bac, dbm), similar to those observed for analogous ruthenium complexes[4] and for $W_2O_5(trop)_2$.[13] The trifluoro- and hexafluoroacetylacetonato complexes show strong bands at 1296 and 1257 cm^{-1}, respectively, also arising from ν(C—O) vibrations. Only one band around 315 cm^{-1} has appeared in the $[OsCl_2(PPh_3)_2L]$ complexes, this is likely to be due to ν(Os—Cl).[14,15] This band is shifted to lower wavenumber in the osmium complexes compared with that observed near 335 cm^{-1} for ruthenium complexes.[4] The most important IR bands are listed in Table 1; the deep colours of the complexes make them unsuitable for Raman studies.

Magnetic susceptibility measurements for $[OsCl_3(PPh_3)_2MeOH]$ at room temperature showed a magnetic moment, μ_{eff}, of 1.48 BM corresponding to one unpaired electron. The other complexes $[OsCl_2(PPh_3)_2L]$, however, have μ_{eff} close to the spin-only value of one unpaired electron lying in the range 1.7–2.0 BM (Table 2), similar to those of *mer-* and *fac*-$[OsL'_3X_3]$ (L' = PBu^n_2Ph, PPr^n_2Ph, PPr^n_3; X = Cl, Br).[16] This suggests the low-spin d^5 $(t_2g)^5$ configuration for the osmium(III) ion in an octahedral environment, which is also the case for the analogous ruthenium(III) complexes.[4]

Electronic spectra and electron spin resonance

The UV–vis spectra of complexes in CH_2Cl_2 solution (Table 1) showed a broad band around 550 nm of low molar absorptivity (ε = 500 M^{-1} cm^{-1}) compared with those for analogous ruthenium(III) complexes[4,17,18] which have been observed at 600 nm. This band may owe its origin to a *d–d* transition. In $[OsCl_2(PPh_3)_2L]$ complexes (L = malt, trop), the band at 550 nm is replaced by high intensity bands in the region 700–500 nm which are tentatively assigned to the π(O,O donor) → $t_2(Os^{III})$ transition, while the weaker ligand-field bands may be obscured by such transitions. Similar bands also were found for $[Os(bipy)_2(acac)]^{2+}$ and $[RuCl_2(bipy)(acac)]$ at 530 nm (ε = 1500).[19] The strong bands in the 400 nm region or below could arise from Cl → t_2 transitions.[14,19]

The ESR spectra in CH_2Cl_2 frozen glasses of the complexes (concentration 5×10^{-3} M) were carried out at −170°C. Cooling was by means of cold nitrogen gas passed over the sample tube. The most significant spectra are those of $[OsCl_2(PPh_3)_2L]$ (L = acac, hfacac). The acetylacetone complex [Fig. 1(a)] shows only two peaks, $g_x = 2.96$ and $g_y = 1.59$, while the third component, g_z, is presumably very low (< 0.46) and lies beyond the maximum field obtainable (B_z > 1400 G). This is typically in accordance with the ESR spectrum of polycrystalline *mer*-$[OsCl_3(PBu^n_2Ph)_3]$ which has g values of 3.3, 1.65 and 0.36 in C_{2v} symmetry.[20] The hexafluoroacetylacetonate complex has another type of ESR spectrum [see Fig. 1(b)] with g_x = 3.00, $g_y = 1.63$ and $g_z = 1.53$, similar to that of $[RuCl_3(PBu^n_2Ph_3)_2]$[20] but with closer peaks (g_y and g_z). The X-ray crystal structure of $[OsCl_3(NH_3)(PPh_3)_2]$ (**A**)[21] has a distorted octahedral configuration with the movement of Cl atoms *cis* to N towards the nitrogen atom. A similar structure (**B**) for our compounds of C_2 symmetry is expected as shown below.



(A) (B)

(P = PPh_3, O–O = acac, hfacac)

Redox properties

The electrochemical properties of the complexes were investigated by cyclic voltammetric techniques. Voltammetric half-potential vs the Ag electrode for 0.1 M $Bu^n_4NPF_6$–CH_2Cl_2 solutions are presented in Table 2. The voltammogram reveals a pair of cathodic and anodic peaks in each case which correspond to Os^{III}/Os^{II} reduction and Os^{III}/Os^{IV} oxidation, respectively, and the peak separation (ΔE) for each complex is close to that anticipated for a Nernstian one-electron process (59 mV).[22] For $[OsCl_2(PPh_3)_2(acac)]$, a representative example (Fig. 2) compared with that of ferrocene [$E_{1/2}$ = 0.21 V, ΔE = 50 mV) under the same conditions, shows a quasi-reversible one-electron oxidation wave, $E_{1/2}$ = 0.78 V, ΔE = 70 mV, and of another wave reduction of $E_{1/2}$ = −0.56 V and ΔE = 80 mV.

[a] Corresponding anodic peak of oxidation.

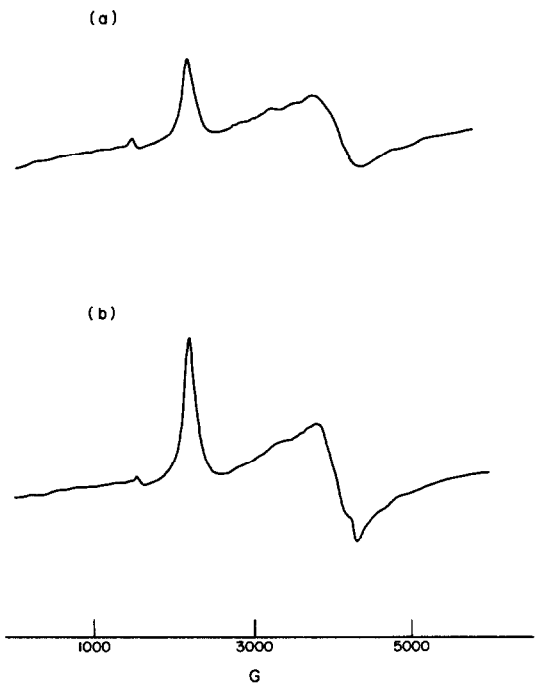

Fig. 1. (a) ESR spectra of *trans*-$[OsCl_2(PPh_3)_2(acac)]$; (b) ESR spectra of *trans*-$[OsCl_2(PPh_3)_2(hfacac)]$.

For scan rates (SR) between 10 and 100 mV s^{-1}, the ratio $i_p/(SR)^{1/2}$ (i_p = peak current) was constant and the ratio of the anodic to cathodic peak current is one, the peak separation being independent of the scan rate. This indicates that electron transfer is reversible or approaches reversibility and the mass transfer is limited. In tropolonato and maltolato complexes, the peak separation of the oxidation wave is 240–250 mV, indicating irreversible behaviour. The presence of such oxidation and reduction waves seems to be typical of osmium(III) halide complexes, e.g. $[OsCl_3(PPh_3)_2(CH_3CN)]$, $[OsCl_3(py)_2(PPh_3)]$[10] and $[Os^{III}X_2(PPh_3)_2L]$[23] (X = Cl, Br; HL = 2-hydroxypyridine, 2-hydroxy-6-methylpyridine and picolinic acid). From Table 2 which includes the cyclic voltammetric data, we conclude that $E_{1/2}$ of the reduction wave is shifted to lower or more negative values relative to $[OsCl_2(PPh_3)_2(acac)]$, reflecting an increase of basicity with more negative values of $E_{1/2}$ as the O,O-donor ligand changes in the order

hfacac < tfacac ≃ trop

< acac ≃ malt < dbm ≃ bac.

There is thus an anticipated increase in the ease of oxidization and decrease in the ease of reduction for the complexes containing benzoylacetone or dibenzoylmethane ligands. The stabilities of the Os^{IV}, Os^{III} and Os^{II} oxidation states in these complexes is reflected by the reversibility of these processes:

$$[OsCl_2(PPh_3)_2L]^+ \underset{-e^-}{\overset{+e^-}{\rightleftharpoons}} [OsCl_2(PPh_3)_2L]$$

$$\underset{-e^-}{\overset{+e^-}{\rightleftharpoons}} [OsCl_2(PPh_3)_2L]^-.$$

Catalytic oxidations

Since $[RuCl_2(PPh_3)_2(acac)]$[4] has been used in the presence of excess NMO for the catalytic oxidation of primary alcohols to aldehydes and secondary alcohols to ketones we tried to use $[OsCl_2(PPh_3)_2(acac)]$ (**II**) as an oxidation catalyst. Although it did catalytically oxidize *p*-methoxybenzyl alcohol to the aldehyde and α-tetralol to α-tetralone over 15 and 36 h, respectively, the yields were low (12 and 18%, respectively, with catalytic turnovers of 50) while piperonyl alcohol and benzohydrol were not oxidized at all. The low reactivity of the osmium

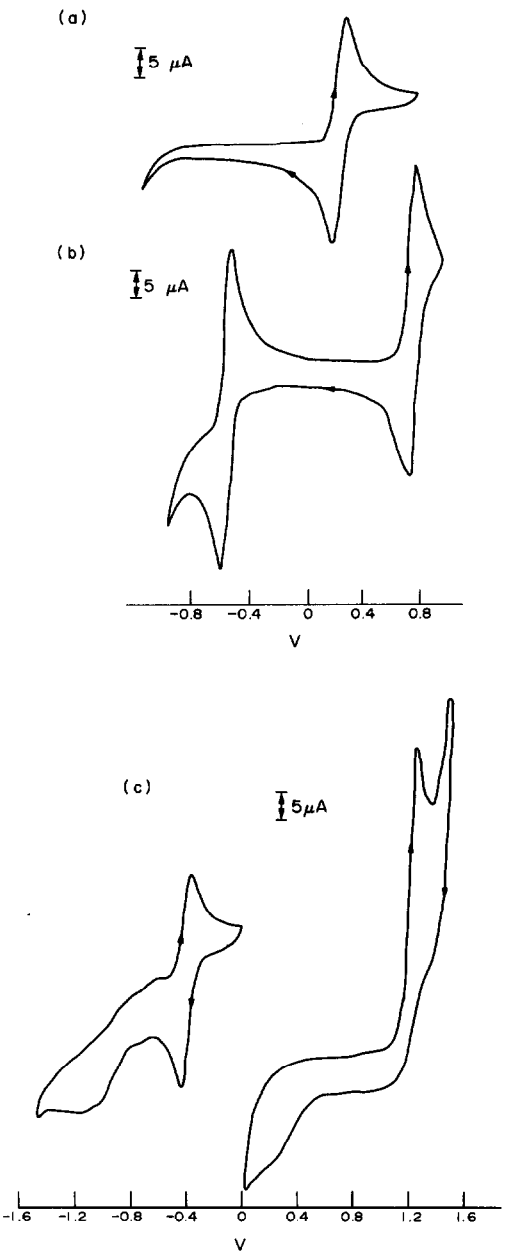

Fig. 2. Cyclic voltammogram, in CH_2Cl_2 with 0.1 M $(Bu^n{}_4N)PF_6$ as supporting electrolyte; volts vs Ag electrode, scan rate 100 mV s^{-1}: (a) Ferrocene; (b) *trans*-$[OsCl_2(PPh_3)_2(acac)]$ ($\sim 10^{-3}$ M), scan rate 50 mV s^{-1}; (c) *trans*-$[RuCl_2(PPh_3)_2(acac)]$ ($\sim 10^{-3}$ M).

complex in comparison with its ruthenium analogue is perhaps not surprising, thus $[RuO_4]^-$ is a much better oxidant than $[OsO_4]^-$.[24] In connection with the effectiveness of $[RuCl_2(PPh_3)(acac)]$ as an oxidant it is of interest to note that an extension of our earlier[4] cyclic voltammetric work on $[RuCl_2(PPh_3)_2(acac)]$ (**III**) to more positive potentials shows a further irreversible oxidation peak ($E = +1.26$ V) of height three times greater than the reduction wave at $E_{1/2} = -0.41$ V ($\Delta E = 70$ mV) vs Ag electrode. The latter wave is due to the Ru^{III}/Ru^{II} reduction,[4] so that the oxidation peak at 1.26 V probably arises from oxidation of Ru^{III} to Ru^{VI}; such an oxidation peak is not found for $[OsCl_2(PPh_3)_2(acac)]$, which gives only Os^{III}/Os^{IV} oxidation. This supports our earlier suggestion[4] that oxidations effected by **III** are likely to occur via higher oxidation states of ruthenium. It is also relevant that $[Ru(acac)_3]$, which has a similar cyclic voltammogram[4,25] to that of **II**, does not effect oxidations of alcohols in the presence of NMO.

EXPERIMENTAL

Preparation of complexes

All preparations use $[OsCl_3(PPh_3)_2MeOH]$ as starting material. This was prepared as follows; a solution of $Na_2[OsCl_6]\cdot 3H_2O$ (0.45 g, 0.9 mmol) in 2-methoxyethanol (60 cm^3) was degassed by passing N_2 through, then conc. HCl (30 cm^3) was added. The mixture was refluxed for 30 min. To the hot solution was added a solution of triphenylphosphine (1.0 g, 3.8 mmol) in 2-methoxyethanol (10 cm^3) and refluxing was continued for 3–4 h under nitrogen. The volume was reduced by 75% and the remaining solution was stored in a refrigerator overnight. After addition of methanol (50 cm^3) the solution was heated and cooled again, when a yellow solid appeared, which was washed thoroughly with water, methanol and ether. The product was recrystallized from methanol and dried *in vacuo*.

Preparation of $[OsCl_2(PPh_3)_2(acac)]$. The complex $[OsCl_3(PPh_3)_2MeOH]$ (0.42 g, 0.5 mmol) was dissolved in methanol (80 cm^3) and refluxed for 30 min on a steam bath until the solution became slightly dark yellow. Distilled acetylacetone (1 cm^3) was then added. A reddish-brown solution was obtained and after continuing reflux for another 30 min, nice brown crystals precipitated which were filtered off, washed with methanol and ether, and dried *in vacuo*.

Preparation of $[OsCl_2(PPh_3)_2L]$ (L = malt, trop, tfacac, hfacac, bac, dbm). A solution of $[OsCl_3(PPh_3)_2MeOH]$ (0.42 g, 0.5 mmol) in methanol (80 cm^3) was refluxed for 30 min, followed by the addition of the ligand (HL) (0.9 mmol). The mixture was refluxed for an appropriate time (as in Table 1). Nice microcrystals formed, which were filtered off, washed with a little methanol and ether and finally dried *in vacuo*. Analytical data are given in Table 1.

Catalytic oxidation by $[OsCl_2(PPh_3)_2(acac)]$ **(II)**

The oxidation of *p*-methoxybenzyl alcohol is typical. To a solution of *p*-methoxybenzyl alcohol (1 mmol) was added NMO (3 mmol) in CH_2Cl_2 (20 cm^3) and 2×10^{-2} mmol of compound **II**. The solution was stirred for 15 h in the presence of 4 Å molecular sieves (0.5 g). The mixture was evaporated to dryness and extracted with ether (2×25 cm^3). The combined ethereal extracts were filtered and evaporated to give *p*-methoxybenzaldehyde which was characterized and quantified as its 2,4-dinitrophenylhydrazone derivative.

The same experiment was carried out using $[Ru(acac)_3]$ (prepared by the literature method[26]) in place of **II** above. The red solution of the reaction mixture does not change and there was no oxidation.

IR spectra were measured on a Perkin–Elmer FT 1720 instrument as liquid paraffin mulls between CsI plates and as KBr discs. The electronic spectra were measured on a Philips PU 8740 UV–vis spectrophotometer or Varian 634 model. ESR spectra were recorded with a Varian E-12 spectrometer. Cyclic voltammetric studies were carried out on a potentiostat/generator (Oxford Electrodes) using a platinum working electrode and silver reference electrode in conjunction with a Philips PM 8043 X–Y recorder. Magnetic measurements were made on a Johnson Matthey magnetic susceptibility balance.

Acknowledgements—We thank the British Council for support, Dr W. P. Griffith for helpful advice, Dr J. F. Gibson for helpful discussion of ESR spectra and also Johnson Matthey Ltd for the loan of precious metals.

(*Received* 4 *June* 1990; *accepted* 20 *July* 1990)

Abstract—An X-ray determination of the crystal structure of the cobalt chloride pyridine-N-oxide complex $CoCl_2(pyo)(H_2O)$ shows it to have a polymeric chain structure with mixed bridging by pyo and one chlorine atom. Octahedral coordination of cobalt is completed by the second chlorine atom and the water molecule. These latter two ligands show interchange of positions.

The cobalt chloride pyridine-N-oxide (pyo) complex of composition $CoCl_2(pyo)(H_2O)$ was identified in 1961.[1] Despite the low pyo:Co ratio, the pale red–violet colour of the compound is indicative of six-coordinate cobalt, presumably through ligand bridging. However, the nature of the bridging has remained unanswered.[2–4] The considerable structural information on copper halide–pyo complexes with low pyo:Cu ratios, including $CuCl_2(pyo)(H_2O)$,[5] affords no useful guide; copper develops five-coordination only, with the ligands in varying roles. Through crystal structure determination we have now established the chain polymeric nature of the compound. It represents a type quite apart from other cobalt halide–pyo complexes, which contain the $[Co(pyo)_6]^{2+}$ cation.[6]

EXPERIMENTAL

Preparation

Acicular crystals slowly separated from a violet methanol solution (4.0 cm^3) containing $CoCl_2 \cdot 6H_2O$ (0.30 g) and pyo (0.12 g). Conditions for formation of crystals suitable for diffraction (rather than microcrystalline material) were found rather critical and may depend upon water content. (Found: C, 24.9; H, 2.8; N, 5.8. Calc. for $C_5H_7Cl_2CoNO_2$: C, 24.7; H, 2.9; N, 5.8%.) The corresponding bromide obtained in the microcrystalline form gave: C, 18.6; H, 2.0; N, 4.2. Calc. for $C_5H_7Br_2CoNO_2$: C, 18.1; H, 2.1; N, 4.2%.

X-ray structure determination

Crystal size $0.06 \times 0.1 \times 0.4$ mm; monoclinic, space group $P2_1$, $Z = 2$; $a = 6.835(2)$, $b = 6.706(1)$, $c = 9.217(2)$ Å, $\beta = 102.96(0.02)°$, $U = 411.7(2)$ Å^3, $D_c = 1.96$, $D_m = 1.91$ (room temp.); $F(000) = 242$, $\mu = 26.82$ cm^{-1} (Mo-K_α). Data collection at 160 K, scan rate 2.44° min^{-1}, 2θ range 4–52° with $h = 0$–9, $k = 0$–9, $l = -12$ to 12; 974 unique reflections, 880 [$I > 2\sigma(I)$] used; transmission range 0.816–0.756, absorption correction applied.

Atoms were located from Patterson and difference Fourier syntheses. Refinement indicated the probability of disordering interchange of Cl(2) and O(2) to positions Cl(2′) and O(2′)—see Fig. 1. Partial occupancy was therefore introduced, but with tying between the Cl(2), Cl(2′) and O(2), O(2′) pairs. Excepting these pairs, all other non-hydrogen atoms were refined anisotropically with the weighting factor g fixed at 0.00025. Hydrogen atoms of pyo were located and their positions refined, giving convergence at $R = 0.0246$ and $R' = 0.0313$. Chirality was tested.

Bond lengths and bond angles are given in Table 1. Full data are deposited.

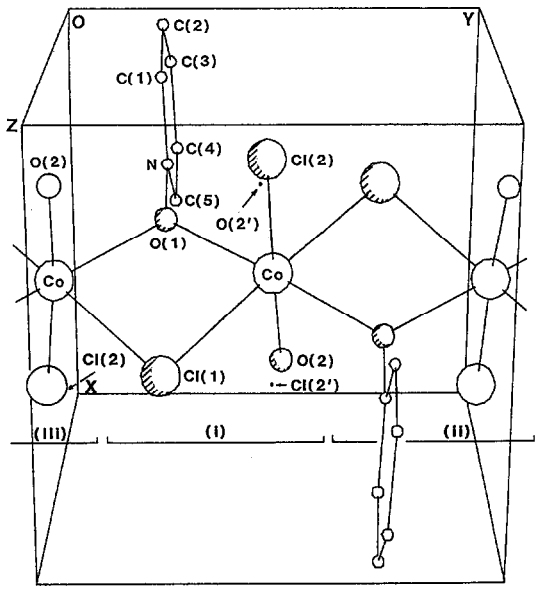

Fig. 1. The cell, containing its asymmetric units (i) x, y, z, (ii) $1-x$, $\frac{1}{2}+y$, $1-z$. The additional atoms Co, Cl(2) and O(2) to the left are from unit (iii) $1-x$, $y-\frac{1}{2}$, $1-z$. Inter-chain approaches to Cl(2) (i) are by O(2) (iv), C(1) (v), C(3) (vi) and C(4) (vi). Approaches to Cl(1) (i) are by C(2) (vii), C(3) (vii) and C(4) (vi). The symmetry codes are: (iv) $x-1$, y, z; (v) $-x$, $y+\frac{1}{2}$, $1-z$; (vi) x, y, $z+1$; (vii) $x+1$, y, $z+1$.

DISCUSSION OF STRUCTURE

The structure comprises a polymer chain developed through mixed bridging by Cl(1) and O(1) of pyo. The atoms Cl(2) and O(2) of the water molecule complete the octahedral coordination around cobalt (see Fig. 1). Refinement gave Cl(2) and O(2) as having 74.6(1.0)% site occupancy with Cl(2′) and O(2′) in the alternative interchanged directions (but at modified distances) contributing the balance. The polymer chains lie parallel to the Y axis, with the asymmetric units in a screw-axis relationship, but with the Co(i) coordinates 0.4915(2), 0.5000, 0.5008(1) there is a slight zigzag of the cobalt atoms. The mean plane through the chain ring atoms CoCl(1)CoO(1) is inclined 67.6° to the YZ face of the cell. The pyo ring is almost perpendicular (92.5°) to this mean plane, with all its carbon atoms involved in (inter- or intra-chain) C···Cl approaches of 3.5–3.8 Å. Atom deviations from ring planarity are small, with maximum 0.022 Å in the chain ring and 0.004 Å in the pyo ring. The atoms O(1) and C(1) lie, respectively, 0.020 and 0.086 Å from the pyo plane. The Co—Cl(1)—Co bridge shows definite asymmetry, with $l = 2.471(2)$, 2.494(2) Å, but asymmetry of Co—O(1)—Co is not certain [$l = 2.038(5)$, 2.047(5) Å]. The screw-axis, rather than mirror plane, relationship of successive units avoids compressed (3.35 Å) distances between pyo ring-planes and at the same time enables intra-chain Cl(1)···C(1)/C(5) approaches. Within the crystal as a whole, cohesion between the chains is provided by the inter-chain C/CH approaches to Cl(1) and Cl(2), and by inferred hydrogen-bonding between O(2) and Cl(2), or between O(2′) and Cl(2′). These O(2)···Cl(2) and O(2′)···Cl(2′) distances are 3.23 and 3.16 Å, respectively.

The structure, though of unusual type, can be considered in relation to that of $CoCl_2(H_2O)_2$ in which there is a chlorine-bridged chain of edge-sharing octahedra.[7] Interestingly, this chain structure also occurs, almost unmodified, as a component of the $[(CH_3)_3NH]CoCl_3 \cdot 2H_2O$ lattice.[8] In the present case, one of the two chlorine bridges between each successive cobalt pair is broken in favour of a pyo oxo-bridge; and in consequence only one water molecule is required to complete the cobalt octahedral coordination. From a comparison of bond lengths and angles (Table 2), it is

3.030(21)	3.016(19)	3.091(12), 3.012(21)
2.527(14)	2.520(16)	2.724(16)
2.389(15)	2.372(7)	2.437(25)
2.019(15)	2.025(12), 2.010(12)	

Other reflections are: $CoCl_2(pyo)(H_2O)$, 1.602(10); $NiCl_2(pyo)(H_2O)$, 3.387(13); $CoBr_2(pyo)(H_2O)$, 4.077(12), 3.612(14), 2.837(16).

seen that the shorter Co—O—Co bridge provided by pyo causes reduction in the Co—Cl—Co bridge angle. Formation of a crystalline compound of this present structure can thus be seen as the outcome of several factors, including the ability of the chlorine bridging angle (normally in the range 85–95°) to vary, a favourable chain packing which accommodates the pyo rings within surrounding chlorine atoms, and the retention of inter-chain hydrogen-bonding of the kind in $CoCl_2(H_2O)_2$.[7]

The same structure evidently extends to $NiCl_2(pyo)(H_2O)$,[1] because its X-ray powder diffraction pattern is so closely similar to that of $CoCl_2(pyo)(H_2O)$, Table 3, as to indicate an isostructural relationship. The $CoBr_2(pyo)(H_2O)$ pattern is comparable, but differs in detail. We have found no evidence for the formation of cobalt complexes of composition $CoX_2(pyo)_2$, either monomeric—as known for $ZnCl_2(pyo)_2$[9]—or polymeric through halogen- or ligand-bridging. In the absence of water, cobalt chloride gives only $[Co(pyo)_6][CoCl_4]$.[10]

1. INTRODUCTION

The element copper is very widely distributed as salts and complexes in plants, invertebrates, animals and common minerals. The known oxidation states are I, II, III and IV.[1]

Of these, the copper(II) or cupric form is by far the most common. Copper(II) displays a wide variety of coordination geometries in its many salts and complexes. Its most common coordination numbers are four, five and six.[2-6]

The next most common oxidation state is copper(I) or cuprous, which also forms a variety of complexes with common ligands. Aquocopper(I) readily disproportionates to elemental copper and aquocopper(II) but copper(I) may be stabilized against disproportionation under aprotic conditions in the presence of a variety of ligands, including amines. The most common coordination numbers for copper(I) are two, three and four.[7-12]

Most copper(I) salts and complexes are air-sensitive. Rates and products of oxidation by dioxygen very much depend on the coordinated ligands, the physical state (solid or in solution) and the presence of water. Copper(I) is stabilized by soft, π-acid ligands like iodides, phosphines,[7] arsines[7,8] and carbon monoxide,[9] while copper(II) has a strong preference for O-donors like water and hydroxide and hard N-donors like ammonia, pyridines and aliphatic polyamines.[2-6] This means that amine–copper(I) complexes are almost invariably air-sensitive, while at the same time implying that the rates and products of their oxidation can be modified or controlled with π-acids coordinated to copper(I).

Air-sensitivity and previous lack of success in growing single crystals of simple amine–copper(I) complexes were, until recently, the major reasons why the structural chemistry of copper(I) is much less well developed[10-12] than that of copper(II).[2-6] Availability of structural information is all the more important when we recall that copper(I), d^{10}, is transparent to common techniques like electronic and ESR spectroscopy and magnetic measurements that are so useful for copper(II) characterization.[2-6,13]

If we are to understand the mechanisms of oxidation of copper(I) complexes and of the many natural and synthetic oxidative reactions that are initiated and catalysed by the copper(I)/(II) couple,[11,14-17] then it is necessary to gather and classify as much information as possible on the underlying copper-based structures.

The aim of this Report is to update previous reviews[10-12] of the structural chemistry of simple halo(amine)copper(I) complexes. This information will be used to discuss recent progress in relating

structure to physical and chemical properties and to explain reactivity in stoichiometric and catalytic systems involving the copper(I)/copper(II) couple. Particular attention will be paid to reactions of halo(amine)copper(I) complexes with carbon monoxide and dioxygen that are so characteristic of copper(I). We also discuss aspects of copper(I)–dioxygen reactions that are the basis of many useful catalytic systems.[11,14-17]

2. SYNTHESIS OF HALO(AMINE)COPPER(I) COMPLEXES

Although copper(I) fluoride is unknown, the other copper(I) halides are common laboratory solids that are only slowly air-oxidized. Purified or freshly-made[18] copper(I) chloride, bromide and iodide thus serve as convenient starting materials for the synthesis of a wide variety of copper(I) complexes. Copper(I) complexes can be made under aprotic or protic conditions.

2.1. *Aprotic conditions*

Many halo(amine)copper(I) complexes may be made simply by adding the appropriate copper(I) halide to the liquid amine, either neat or dissolved in a solvent at a known concentration. However, stoichiometry is not necessarily always controllable by this method.

The preparation of halo(amine)copper(I) complexes in solution requires consideration of solubility as well as attention to maintenance of the copper(I) state. Copper(I) halides are soluble in acetonitrile and to some extent in acetone, methanol, ethanol, tetrahydrofuran, methylene chloride, nitrobenzene and di- and triglyme. The solubility of copper(I) halides in acetonitrile is due to solvent coordination. This and other solvents (and even excess free amine) may co-crystallize in the solid product. Copper(I) may be preserved by maintenance of an argon or dinitrogen atmosphere or by the addition of small amounts of ascorbic acid or hydrazine at any sign of green coloration.[19]

The slow extraction of CuX from a Soxhlet thimble by the distillate from a solvent–ligand[20] mixture has led to complex formation when CuX solubility in the solvent is low. Under these conditions, iodides normally form crystals of greater resistance to decomposition.

Crystallization may also be achieved by solvent diffusion techniques, evaporation of solvent at atmospheric conditions or under vacuum. The addition of a nitrobenzene solution of halo(amine)copper(I) complexes to deoxygenated hexane frequently leads to a solid product.[21] Crystallization from different solvents and at different temperatures has been shown to lead, on occasion, to complexes which differ in stoichiometry and/or structure.[22]

2.2. *Protic conditions*

CuI may be preserved in the cuprous state in saturated solutions of aqueous KI. Reactions under these conditions may lead to KCu_yI_z complexes without amine coordination.[23]

2.3. *Amines employed*

Copper(I) complexes of high stability are obtained with aromatic amines. Thus, many copper(I) halide–amine complexes are known with derivatives of pyridine. However, complexes with tertiary amines (N,N,N',N'-$Me_2NC_2H_4NMe_2$,[24] $Et_2NC_2H_4NEt_2$,[25] triethylamine[26]) and with secondary amines (morpholine,[27] piperidine,[28] N,N'-diisopropylethylenediamine[29] and aniline derivatives[30]) have also been isolated.

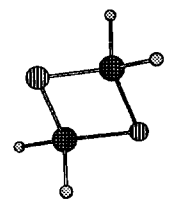
Complexes of formula CuXL, L = amine, have been the focus of research over a long period of time. Research groups such as that of Hardt *et al.*[31] focused on the wide variety of stoichiometries and emission properties evinced by these complexes in the solid state. Synthesis has frequently been carried out in neat liquid amine, resulting in an array of different materials. Characterization has too often been limited to an indication of the stoichiometry of reactants and the colour of the solid product. X-ray powder diffraction patterns are sometimes reported. Copper(I) iodide complexes are normally more stable with respect to air and moisture than the chlorides or bromides. Copper(I) fluoride–amine complexes are unreported. Complexes of stoichiometry Cu : X : L (L = ligand) of 1 : 1 : 0.5, 1 : 1 : 1, 1 : 1 : 1.5, 1 : 1 : 2, 1 : 1 : 2.5 and 1 : 1 : 3 have been noted. Many of these are aggregates and include bridging halides. Those of non-integral stoichiometry usually involve bidentate amines.

3. MOLECULAR STRUCTURES AND PROPERTIES OF MONO- AND POLYMERIC HALO(AMINE)COPPER(I) COMPLEXES

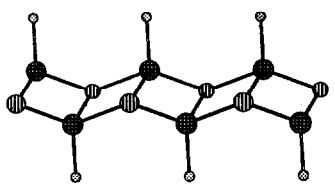
3.1. *General structural types*

In the drawings which follow, copper is cross (i.e. double) hatched, halogens are (singly) hatched, nitrogen and carbon are shaded, and oxygen is white.

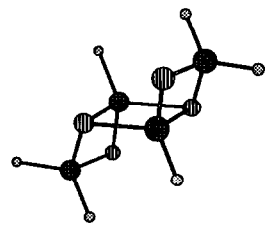
3.1.1. *General considerations.* Single crystal X-ray diffraction reveals much of the structural chemistry of copper(I) halide complexes with amines to be based on the Cu_2X_2 rhombohedron which may be found in isolation, **I** ($Cu_2X_2L_4$), extended by the sharing of edges to form polymeric pleated sheets **II** [$(CuXL)_x$] or chairs **III** ($Cu_4I_4L_6$), and combined by face sharing to give cubes **IV** ($Cu_4X_4L_4$). Other motifs such as —Cu(L_2)—X—Cu(L_2)—X— chains **V**, $CuXL_3$ monomers **VI** and the $Cu_4X_4L_4$ distorted rectangle **VII** have also been observed. Copper normally achieves tetrahedral coordination by further binding to one or more amine molecules.



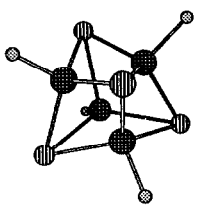
I



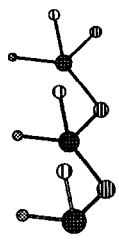
II



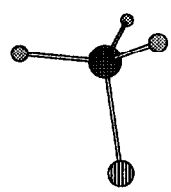
III



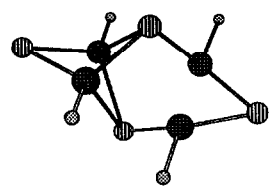
IV



V

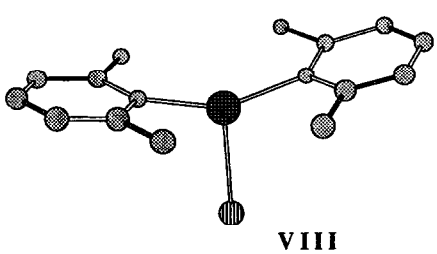


VI

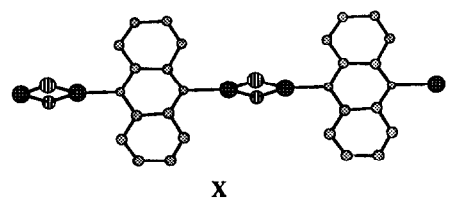


VII

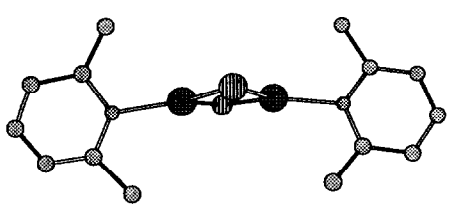
3.1.2. *Coordination number three.* Bulky ligands such as *ortho*-disubstituted pyridine molecules may lead to three coordinate copper(I) atoms which are normally trigonal planar. The $Cu_2X_2L_2$ rhombohedron, $CuXL_2$ monomers, **VIII**,[32] $Cu_2X_2L_2$ rhombohedra (bent **IX**[33] or flat **X**[34]), Cu(L)—X—Cu(L)—X— chains [$(CuXL)_x$], **XI**,[33] and the $Cu_4I_4L_4$ distorted rectangle **VII**[22] are examples of complexes containing three-coordinate copper.



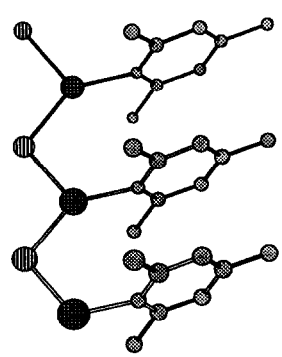
VIII



X

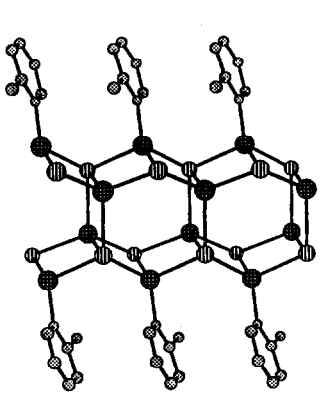


IX

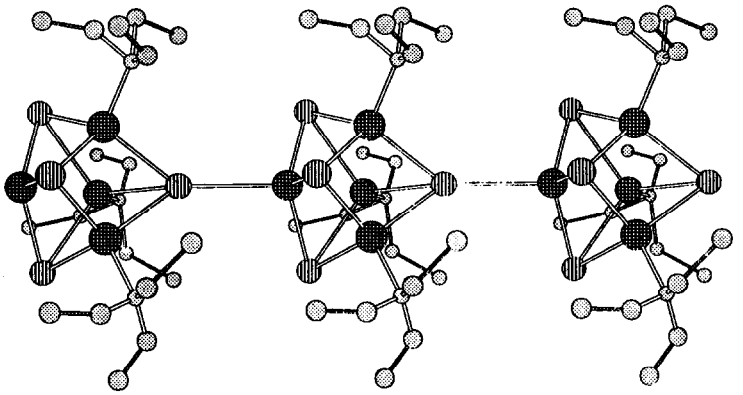


XI

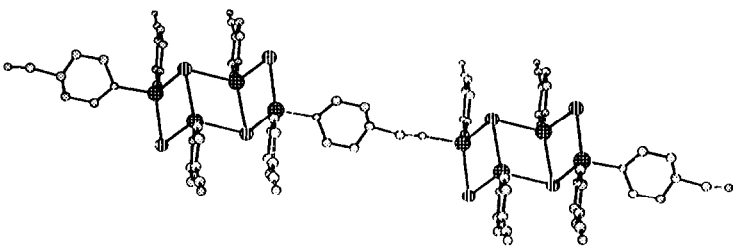
3.1.3. *Crosslinked motifs.* There are examples of motifs (chairs and cubes) substituting intermotif Cu—X bonds for Cu—L binding. Thus, in addition to the Cu_4I_2(2-methylpyridine)$_6$ chair,[26] a Cu_4I_4(2-methylpyridine)$_2$ chair **XII**[35] has been isolated with Cu—I bonds linking adjacent chairs. Similarly, a linked (Cu—I), $Cu_4I_4(Et_3N)_3$ cube **XIII** has been observed.[26] Other types of crosslinking of motifs occur when ligands possess a second potentially coordinating group **XIV**. Thus, pyrazine, quinazoline, phenazine[34] and 3-cyanopyridine[19] lead to motifs of low ligand stoichiometry **XV** with full or partial utilization of additional donor sites on the organic ligand.



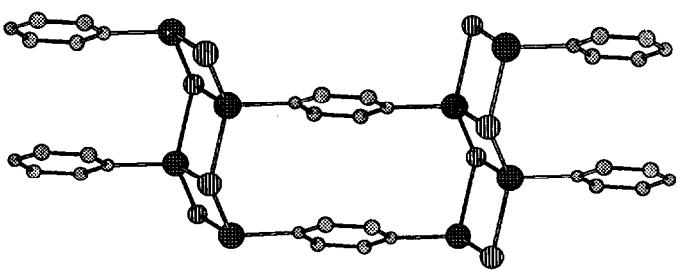
XII



XIII



XIV



XV

It must be emphasized that there are authenticated cases where a single stoichiometry exists in more than one crystal and molecular structure: "CuI(pyridine)" is found as both a tetramer (cube)[47] and a pleated sheet polymer.[35]

3.2. *Bond lengths and angles*

The Cu_2X_2 rhombohedra, when not extended by edge or face sharing, display considerable variation in Cu—Cu separation (2.5–3.3 Å) which is achieved by distortion of angles within the rhomb. The Cu—Cu separation is normally shorter [2.535(9)–2.586(5) Å] in the ($Cu_2X_2L_2$) rhombohedron than in the corresponding $Cu_2X_2L_4$ complexes. The origins of this flexibility are unclear and may be due simply to crystal packing. In a series of rhombohedral Cu_2I_2 complexes with quinoline, the identity of the organic molecule co-crystallized in the unit cell appears to influence the rhomb

geometry without direct bonding to the metal. Thus, the Cu—Cu separation in Cu_2I_2(quinoline)$_4$ without a lattice guest is 3.364(5) Å,[22] with included CH_3CN is 3.137(2) Å[36] and with co-crystallized quinoline is 2.866(3) Å.[32] Cu_2X_2 rhombohedra are normally planar; however, there are examples of rhombohedra bent about the $X\cdots X$ axis, in one case by as much as 28°.[37]

While the length of the Cu—N bond appears to be a relatively constant, 2.01 Å, the length of the copper(I)–halide bond appears to be influenced by a number of factors: the coordination number of copper, the μ_2, μ_3 or terminal bonding nature of the halide, and the ratio of halide to amine bound to copper. Copper–halide distances also increase with an increase in the overall number of atoms bound to copper. Cu—I bond lengths average 2.55 Å in rhombohedra in which copper is three-coordinate, and elongate to 2.65–2.70 Å in rhombohedra in which copper is four-coordinate. There is less comparative data available for chloro and bromo complexes. Cu—I bonds lengthen as iodide is bound to successively more copper atoms; thus, Cu—X distances increase in the order: terminal $< \mu_2 < \mu_3$.[34] Cu—I distances at four-coordinate copper increase with decreasing numbers of Cu—I bonds (and a corresponding increase in the number of Cu—N bonds). For three complexes of CuI with 3-methylpyridine the distances vary as follows: ($NCuI_3$—cube) 2.649(2) Å,[38] (N_2CuI_2—rhombohedron) 2.655(3) Å,[39] (N_3CuI—monomer) 2.710(3) Å.[40]

Polymeric pleated sheet structures may show successive Cu—X bonds along the polymeric repeat direction to be equivalent or to alternate between long and short distances. For example, sheet polymer CuI(2-methylpyridine) crystallizes with alternating Cu—I bond lengths of 2.646(4) and 2.806(4) Å. This non-equivalence of Cu—X distance has also been observed in molecular species. Thus, in the Cu_2I_2 rhombohedron with N,N′-diisopropylethylenediamine, successive Cu—I distances are 2.661(1), 2.579(1), 2.666(1) and 2.581(1) Å,[29] while in the Cu_2Br_2 rhombohedron with 2,4-dimethyl-1,10-phenanthroline, alternating Cu—Br distances are 2.400(1) and 2.559(1) Å.[37]

3.3. *Caution*

Listed in Table 1 are the copper halo amine compounds which have been structurally characterized.

It is evident that this field has advanced considerably based on intensive utilization of X-ray diffraction. It is equally evident from the multiplicity of complexes isolated with a single ligand under slightly different conditions of solvent, temperature and stoichiometry that a bulk sample may not duplicate the structure or composition of one single crystal. Similarly, these solid-state structures may correlate poorly (or even not at all!) with solution composition or structure. For example, a 2:1 mixture of CuI and quinoline refluxed in acetone/aqueous KI and crystallized at 55°C yielded $Cu_4I_4(quinoline)_4$ of stoichiometry 1:1.[22] $Cu_2I_2(quinoline)_4$ was crystallized at room temperature from a 1:2 mixture of CuI and quinoline refluxed in a similar manner in acetone and aqueous KI. $Cu_2I_2(quinoline)_4 \cdot quinoline$ was prepared from a solution of CuI in 2-methylpyridine to which quinoline was added (various complexes of CuI and 2-methylpyridine are known to arise from other synthetic procedures).[32] $Cu_2X_2(quinoline)_4 \cdot quinoline$ (X = Br or Cl) were prepared by crystallization of the parent halide from a solution of hot quinoline.[41] These $Cu_2I_2(quinoline)_4$ complexes display a rhombohedral motif with an additional quinoline molecule included in the unit cell. Thus, solvent and temperature of crystallization play a role in determining the structure of the product and the product does not necessarily display the stoichiometry of the reactants as combined. The crystalline materials on which our structural knowledge is based do not necessarily represent the stoichiometries or structures of the complexes formed in solution. Nor is it common practice to establish that the structure of the bulk solid material is the same as that of the single crystal selected for study. Routine comparison of an X-ray powder pattern calculated from the single crystal data with the pattern measured on the bulk solid is highly recommended.

A number of the polymeric pleated sheet and linear chain structures portrayed here exemplify the tendency of aromatic ligands to form planar ("graphitic") stacked arrays, both in molecules and especially in polymeric arrays. Since the coordination sphere of copper(I) appears to be easily deformable, it may be that such inter-ring stacking actually *controls* solid-state aggregation and geometry. Similarly, it is in this way that an included (lattice) aromatic molecule could be more than a passive bystander in the matter of solid-state structure. It has been reported that face-to-face

stacking of aromatic ligands influences luminescence behaviour,[22] when the interaromatic plane distance approaches 3.1 Å.

4. CARBONYL COMPLEXES

4.1. *Scope*

Although the scope of this review is nominally *halo amine* copper complexes, the full impact of the halide ligand upon bonding of the carbonyl only becomes clear by considering halide-free situations. As will be seen, it is the bridging ability of halide ligands which can cause these to competitively inhibit binding of carbon monoxide. We therefore temporarily expand the scope of the review in this section, in order to better understand the general phenomenon of CO binding by copper.

4.2. *General principles*

4.2.1. *Redox trends.* As mentioned in Section 1, a general characteristic of soluble copper(I) in an oxygen (e.g. acetylacetonate) or amine ligand environment is the occurrence of disproportionation [eq. (1)]:[10a]

$$2\,CuX \longrightarrow Cu^0 + CuX_2. \tag{1}$$

Such disproportionation of monovalent copper has been halted in several reports by stabilization via "soft" ligands (e.g. tertiary phosphines, CO, etc.). Binding of CO has been used to stabilize otherwise unstable copper(I)/ligand combinations.[51] Thus, while CuCl + NaOPh soon deposits Cu^0 in methanol or THF solvent, under one atm CO a carbonyl phenoxide complex is formed. Because of the ready reversibility of CO binding, addition of a second ligand (sometimes with replacement of CO gas by N_2) leads smoothly to complexes otherwise unobtainable.

A constructive application of the *reversible* redox reaction in eq. (1) occurs when CuX itself is not available. Then, the comproportionation of copper metal with CuX_2 (e.g. X = β-diketonate) in the presence of a soft ligand has furnished the corresponding monovalent copper complex, Cu(X)L.[52]

Floriani and co-workers have emphasized the tendency of copper(I) aryloxides to decompose to copper metal and have claimed that this represents disproportionation [eq. (2)]:[51]

$$2\,CuOAr \longrightarrow Cu^0 + Cu(OAr)_2. \tag{2}$$

While it is true that deposition of copper metal is accompanied by the appearance of a blue colour, we find[53] that this blue material (hydrocarbon soluble) when Ar = 2,4,6-^{t}Bu$_3$H$_2$C$_6$ is not a copper(II) complex. It can be sublimed at 30–50°C. Elemental analysis of the sublimed blue crystals show it to be the known[54] stable phenoxy radical. Thus, the blue colour of the stable radical can be mistaken as indicating copper(II), and the decomposition reaction is not disproportionation [eq. (2)], but rather homolysis [eq. (3)]:

$$CuOAr \longrightarrow Cu^0 + ArO^0. \tag{3}$$

4.2.2. *Principles of* CO *binding.* Another general observation is that copper(I) and CO are relatively poorly matched reaction partners. Carbon monoxide relies heavily on back-bonding for the strength of the M/C bond: witness the rarity of carbonyl compounds of oxidation number +3 and higher, as well as the rarity of carbonyl adducts of the non-transition metals. Copper(I), on the other hand, is reluctant to back-bond strongly: the high values of ν(CO) in copper carbonyls is the best indication of this. This is perhaps due to the increased metal nuclear charge of the late transition metals. In summary, CO binding to copper(I) is generally weak (yet there *are* exceptions!) and efforts are required (e.g. working under a CO atmosphere) to maintain them intact.

4.2.3. *Characterization of solution behaviour.* It remains true that progress in copper(I) carbonyl chemistry [and indeed much of the chemistry of copper(I)!] has been severely inhibited by excessive focus on that data which can be reliably gathered: solid-state structure by X-ray diffraction. While such work is both objective (i.e. unbiased by literature precedent and the chemists' preconceived thinking) and definitive, it provides no reliable guide to solution behaviour. Since most studies of chemical reactivity will take place in solution, and since copper(I) is kinetically labile, thus reaching

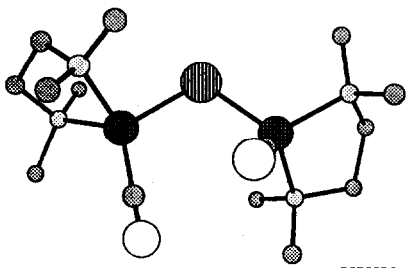
chemical equilibrium "immediately" (i.e. time of mixing) on change of phase (i.e. dissolving) we make a plea here for more systematic characterization of solution behaviour of newly isolated compounds. Such studies must employ spectral techniques which are diagnostic and definitive (e.g. the d^{10} configuration of copper(I) makes electronic spectra rather insensitive to the environment at the metal), and not obscured by time averaging (as is NMR at 25°C). The closed shell d^{10} configuration also makes NMR chemical shift changes small for ligands upon coordination. Finally, bridging the solid/solution phase change with measurements in both phases by the same spectral method promises to be exceptionally useful (e.g. solid-state NMR). It is unfortunate, in this regard, that copper NMR suffers from large quadrupolar signal broadening in all but close-to-T_d symmetry. Extending available methods for definitive characterization of species present in solution is an objective which warrants the attention of everyone who would subsequently explore the reactivity of copper(I) complexes in solution.

4.3. *Bidentate amines*

CuCl suspended in MeOH, THF or diglymes absorbs[55] CO, but only reversibly; attempts at isolation of the species giving CO absorption at 2070–2085 cm^{-1} result in partial loss of CO. CuBr and CuI absorb CO poorly, if at all. Addition of chelating diamines makes possible the isolation of copper(I) carbonyls, *when* $NaBPh_4$ *is added* (eq. (4), X = Cl, Br, I; TMEDA = N,N,N′,N′-tetramethylethylenediamine):

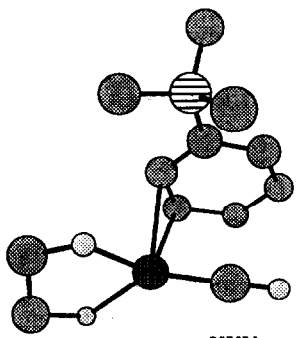
$$2\,CuX + 2\,TMEDA + 2\,CO + NaBPh_4 \longrightarrow NaX + [Cu_2(TMEDA)_2(CO)_2X]BPh_4. \qquad (4)$$

The structures, **XXIV**, for X = Cl, Br and I, all have two approximately tetrahedral coppers linked only by a bent and symmetrical halide bridge; each TMEDA is bidentate to a single metal. The identity of X has no influence on the Cu—C distances or on the Cu—X—Cu angle, but the TMEDA ligand bends further away from the halide as the halide becomes larger.[55]

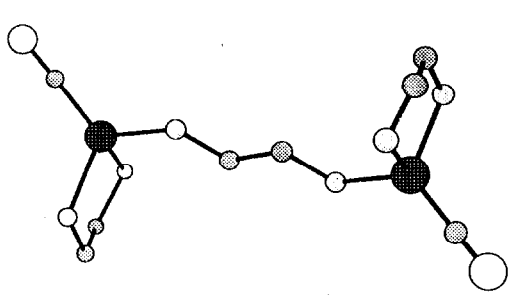


XXIV

Working in methanol, the situation is markedly different when $H_2NC_2H_4NH_2$ (en) is the amine. Then, depending on the en/Cu ratio, either (en)Cu(CO)(η^2-BPh_4) (**XXV**) or $[Cu_2(en)_3(CO)_2](BPh_4)_2$ (**XXVI**) is isolated.[56] The difference has been attributed to the fact that bulkier TMEDA cannot bridge, and does not permit approach of the bulky BPh_4^- unit for η^2-coordination. The interaction of copper with one *ortho* and one *meta* ring carbon is very weak (2.7–2.9 Å; cf. Cu—CO of 1.81



XXV



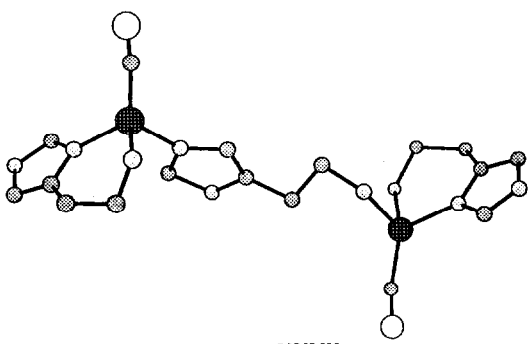
XXVI

Å), and it is suggested, based upon IR observations, that **XXV** transforms to $Cu(en)(CO)S^+$ on dissolving in methanol.

We suggest that there are additional possible factors at work. The presence or absence of halide as a reactive partner will depend in part on the solubility of NaX in the solvent employed. Moreover, the tertiary amine (TMEDA) is unique in precluding the hydrogen bonding available to secondary and primary (i.e. en) amines. Thus, $[Cu(^tBu)(H)NC_2H_4N(H)(^tBu)](OPh)]_2$ is a dimer by virtue of hydrogen bonding from one amine proton to the oxygen of the phenoxide on a second copper.[57] As an extension of this point, protic solvents can alter thermodynamics by hydrogen bonding to halide ligands. Ligands attached to late transition metals are expected to be particularly electron rich (i.e. good hydrogen bond participants) because π-donation from such ligands to the metal is minimal.[58]

Neither $[Cu_2(en)_3(CO)_2](BPh_4)_2$ nor $Cu(en)(CO)BPh_4$ loses CO in the solid state. Curiously, reaction of $Cu(en)(CO)BPh_4$ with $P(OEt)_3$, in methanol, displaces CO essentially quantitatively (rather than the η^2-BPh_4^-). In spite of this *displacement* of CO by added Lewis base, carbonylation of CuI in the presence of a large excess of en *does* give a carbonyl, $[Cu(en)_2(CO)]I$. Whether this contains five-coordinate CO or monodentate en is unknown. Another indication of the importance of competing nucleophiles is the observation that, with CuCl (rather than CuI), some of the above carbonylations are reversible. In summary, the authors note that the two crystallographically-characterized compounds may both arise from the common unit $Cu(en)(CO)^+$ or from $Cu(en)(CO)(MeOH)^+$, which can then bind BPh_4^- in the solid, or two of which can be linked by additional $H_2NC_2H_4NH_2$.

The reactivity of the labile coordination site in $Cu(bidentate)CO(solvent)^+$ is also evident in the composition and structure of $Cu_2(histamine)_3(CO)_2^+$ (**XXVII**) as its BPh_4^- salt.[59] Here, two of the

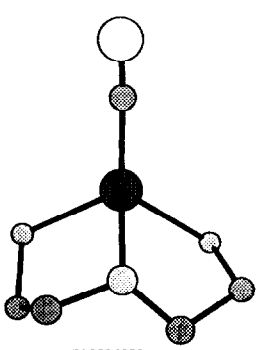


XXVII

histamines are each bidentate on a different metal, and the third links the two metals, thus making the two metal centres inequivalent. Two ν(CO) absorptions are evident in the solid state, at 2055 and 2066 cm^{-1}. The structure of the compound $Cu(histamine)(CO)BPh_4$, from a reaction with a lower histamine/Cu ratio, remains uncertain.

4.4. *Tridentate amines*

The "chelate effect" has been successfully utilized to enhance the stability of copper(I) amine/carbonyl complexes.[60] Thus, while ammonia/copper/carbonyls have eluded isolation,



XXVIII

$Cu(NH_2C_2H_4NHC_2H_4NH_2)(CO)^+$ (**XXVIII**) is isolable and does not lose CO at 100°C in the solid state. The synthetic route, eq. (5):

$$CuI + dien + CO + NaBPh_4 \longrightarrow [Cu(dien)CO]BPh_4 + NaI \quad (5)$$

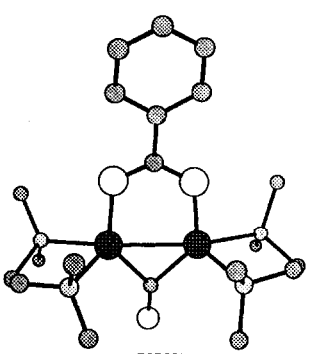
is noteworthy for its utilization of $NaBPh_4$ to not only provide a bulky counter ion for the cationic copper carbonyl, but also to remove I^- (in the form of poorly soluble NaI) as a potential nucleophile competing with CO. This compound exhibits a rather low ν(CO) value (2080 cm^{-1}).

Threefold-symmetric amines have also been employed[60–62] (e.g. $HBpz_3^-$, pz = pyrazolyl) to give a thermally stable molecular carbonyl, $Cu(CO)(HBpz_3)$, with ν(CO) = 2083 cm^{-1}. While resistant to decarbonylation in solution, it does lose CO during vacuum removal of solvent and thus provide access to an interesting composition, "$Cu(HBpz_3)$", which is in fact[63] a dimer containing *four*-coordinate copper (one-third of the pyrazole nitrogens bridge copper pairs). The more sterically "protecting" $HB(3,5\text{-}Me_2pz)_3^-$ ligand gives $CuCO[(HB(3,5\text{-}Me_2pz)_3]$ (ν(CO) = 2066 cm^{-1}). This requires pumping for 1 week at 65°C to effect decarbonylation, with formation of a dimer of structure wholly distinct from that of $[CuHBpz_3]_2$; each copper is in an approximately trigonal planar CuN_3 coordination environment.[63] This theme has been extended with $HB(3,5\text{-}R_2pz)_3^-$, where R = ^{i}Pr and Ph, to generate the corresponding monocarbonyls, as well as acetone and PMe_3 adducts.[64]

It thus appears clear that the tridentate ligands $HBpz_3^-$ and diethylenetriamine simplify the chemistry by closing off the additional equilibria which exist at the open coordination site of Cu(bidentate)CO^+. While this is advantageous for characterizing compounds involving a labile metal centre, it may be counterproductive in effecting catalysis of carbonylation reactions. Cu(en)(CO)(η^2-BPh_4) serves as an example of this point. Note also, in this regard, that copper(I) *di*carbonyl compounds are exceedingly rare.

4.5. *The influence of oxyacid anion co-ligands*

Tetrameric copper(I) benzoate reacts with CO in the presence of TMEDA to give a carbonyl complex (ν(CO) = 2080 cm^{-1}).[65] Upon addition of $NaBPh_4$ and work-up, some CO is lost to give the only example of a symmetrically *bridging* CO. The structures of the two cations $Cu_2(diamine)_2(\mu\text{-}O_2CPh)(\mu\text{-}CO)^+$ (**XXIX**), where diamine = $Me_2N(CH_2)_nNMe_2$ (n = 2, 3), are very similar. The



XXIX

bridging benzoate is thought to assist in stabilizing a *di*metal carbonyl (indeed it was selected for that purpose), and the Cu—C distances in the bridging carbonyl moiety (1.87 Å) are consistently short. The carbonyl carbon symmetrically bridges a short (2.41 Å) Cu—Cu distance, and the ν(CO) values ($\sim$ 1925 cm^{-1}) are the lowest reported for a copper carbonyl, yet the highest reported for a μ-CO. The μ-CO moiety becomes terminal in THF solution. This underscores the limited utility of solid-state structural information for solution behaviour.

Attempts to generalize this chemistry to acetate (replacing benzoate) reveals acetate loss in solution. In the presence of excess acetate, an acetato/terminal carbonyl complex could be isolated, which underwent *partial* conversion to a μ-carbonyl only at 60°C in the solid state.

The kinetic lability of copper(I) is thus seen to make impossible the observation and characterization of metastable (kinetically trapped) solution species. Only under unpredictable circumstances does low solubility (e.g. the benzoate complex above) permit isolation of unusual and

interesting species in the *solid* state. It bears mention that ethylenediamine[65] furnishes different steric and basicity properties, but also perhaps because of the considerable hydrogen bonding capability of the amine hydrogens. In the search for non-coordinating counterions which will not be competitive inhibitors of CO binding to copper(I), the group of Floriani has frequently employed BPh_4^-. While this is one of the best available "inert" counterions, we have already seen that a phenyl ring will sometimes function as a π-olefin donor.[56]

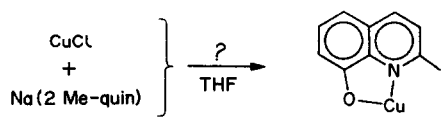
Doyle noted the dominance of (poly)amines as co-ligands among copper carbonyl complexes studied.[66] At the same time, it was known that $CuCl/AlCl_3$ (presumably $CuAlCl_4$) forms a benzene-soluble species which reversibly absorbs CO. Motivated by a desire to develop commercially-viable systems for the separation of CO as a component of gas mixtures, Doyle investigated[52,66] sulphonate (RSO_3^-) as a (weak) co-ligand for copper.

Doyle's synthesis is remarkably simple [eq. (6)]:

$$Cu_2O + 2\,CF_3SO_3H + 2\,CO \longrightarrow 2\,Cu(CO)O_3SCF_3 + H_2O \qquad (6)$$

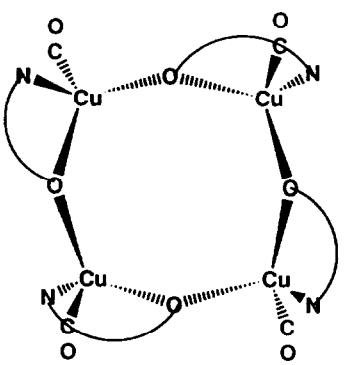
with the evolved water being removed by added molecular seive. Under nitrogen, certain of the compounds (various R) lose CO. All lose CO in air due to oxidation to copper(II). Since the sulphonate vibrational bands were not diagnostic of structure, a single-crystal X-ray diffraction structure determination was carried out on $Cu(CO)O_3SEt$. As is often the case in species of stoichiometry LCuX, the solid is an infinite polymer with bridging X group. In $Cu(CO)O_3SEt$, all sulphonate oxygens are bound to copper, but each oxygen is terminal on a *different* copper, leading to a zigzag, one-dimensional chain of copper(I). These sulphonate carbonyl complexes react with diamines (e.g bipy, *o*-phen or TMEDA) to give $Cu(CO)(diamine)O_3SR$ compounds, but phosphines displace CO instead of sulphonate, to yield $CuL(O_3SR)$. The important conclusion is that there is some thermodynamic bias against a "soft/soft" $Cu(L)(CO)^+$ species. Significantly, mono-olefins, dienes and alkynes also displace CO rather than giving $CuL(CO)^+$ species.[66]

Floriani[67] has attempted to increase CO binding by offering it a particularly reactive metal/ligand fragment possessing an unstable (i.e. reactive) geometry: bent, two-coordinate copper(I) [eq. (7)]:



(7)

In fact, disproportionation takes place to give $Cu^{II}(2Me\text{-}quin)_2$. However, if eq. (7) is carried out under 1 atm CO, the thermodynamics of the disproportionation are reversed and $[Cu(2Me\text{-}quin)CO]_4$ may be isolated. This *air-stable* solid dissolves without decarbonylation in THF. An X-ray structure determination shows $[Cu(2Me\text{-}quin)CO]_4$ to have a non-planar eight-membered $(CuO)_4$ ring molecular structure, **XXX**, with the phenoxide oxygens functioning as μ_2-bridges. Four-



XXX

coordination at each copper is then achieved by terminal binding of CO and the pyridine nitrogen. There is no direct Cu—Cu interaction (they are 3.6 Å apart). *Para*-tolyl isocyanide does not rupture the phenoxide bridges, but instead displaces CO to give $[Cu(2Me\text{-}quin)(CNR)]_n$.

Under vigorous conditions (6–100 atm CO, 80–110°C) $[Cu(2Me\text{-}quin)CO]_4$ reacts to deoxygenate

a number of N/O functionalities [eqs (8)–(11)]:

$$PhNO \longrightarrow PhN(O){=}NPh \tag{8}$$

$$C_6H_5NO \longrightarrow C_6H_5N \tag{9}$$

$$RCH_2NO_2 \longrightarrow (RCN + H_2O) + RC(O)NH_2 + RCO_2H \quad (R = Et, {}^nPn, {}^nBu) \tag{10}$$

$$Me_2CHNO_2 \longrightarrow Me_2C{=}NOH \tag{11}$$

with evolution of CO_2. In certain cases the reaction was catalytic in copper, and, after eq. (8), 40% of the $[Cu(2Me\text{-}quin)CO]_4$ could be recovered.

4.6. *General conclusions*

Both thermodynamic and kinetic factors conspire to limit the number of copper carbonyls. The kinetics of both copper(I) and copper(II) are rapid enough that metastable species will only be detected with substantial effort and even then will only rarely be isolated. Copper in oxidation state II (and above) will probably strongly activate any coordinated CO to nucleophilic attack. Thus, in the presence of traces of water, rapid reduction [eq. (12)]:

$$Cu^{II}(CO)^{2+} + OH^- \longrightarrow Cu^{II}[C(O)OH]^+ \longrightarrow \begin{matrix} Cu^{II}{-}H^+ + CO_2 \\ \downarrow \\ Cu^I + \tfrac{1}{2}H_2 \end{matrix} \tag{12}$$

will occur. The thermodynamics of CO binding to copper(I) can be deduced from the observed high ν(CO) stretching frequencies; back-bonding is very weak, and thus the Cu—C bond is primarily a dative bond, with negligible multiple bond character. One might compare[68] the ν(CO) value of 2044 cm^{-1} in the d^0 complex $Cp^*_2Zr(H)_2CO$. Consider also that there are *no* known carbonyl compounds of the neighbouring metal zinc.

With the Cu^I—CO bond established as weak, it follows that other competitor ligands, even ones as weak as alcohol solvent or bridging halide, represent effective competitors, or even inhibitors of CO binding. While removal of halide from the system has been one effective strategy for halide binding, it is also possible to remove a maximum number of ligands (i.e. use simply unligated CuX), minimize the nucleophilicity of X^- (e.g. $AlCl_4^-$ or HSO_4^-) and choose the solvent to be nearly non-nucleophilic (e.g. benzene). In this way,[69] $CuAlCl_4/C_6H_6$, Cu supported on polystyrene, or CuCl in fuming sulphuric acid have been demonstrated to bind one CO (and even more!) per copper(I). Even here, however, the CO binding is reversible upon swings of pressure, and this property has been put to use for "scrubbing" CO impurities from industrial gases.

5. OXIDATION OF HALO(AMINE)COPPER(I) COMPLEXES BY DIOXYGEN

5.1. *General observations*

As pointed out in the Introduction and emphasized throughout this Report, one of the most characteristic reactions of halo(amine)copper(I) complexes is aerobic oxidation, often referred to as "autoxidation".[16,17] There has been continuous interest in copper(I) autoxidation since the catalytic properties of the products were first recognized.[70]

To work with the most air-sensitive halo(amine)copper(I) complexes is an object lesson in careful experimental technique. Very air-sensitive copper(I) systems are among the most effective known initiators and catalysts for metal-catalysed dioxygen reactions with protic substrates.[16,17,71]

The impetus for study of the reactions of copper(I) with air and dioxygen is the well known fact that pre-oxidation of copper(I) with dioxygen is required for initiation and catalysis of the most effective copper-catalysed oxidation systems.[16,17,71–73] In support of this principle, it is observed that halocopper(I) complexes made with 2,9-dimethyl-1,10-phenanthroline, N,N,N′,N′-tetrabenzylethylenediamine, 1,2-bis(diphenylphosphino)ethane and 2-(2-(dimethylamino)ethyl)pyridine

ligands are air-stable as solids; these solids are either insoluble or air-stable in solvents like methylene chloride and, as a consequence, are not the basis of useful catalytic systems.[74]

As might be expected from its π-acid character, iodide nearly always stabilizes copper(I) to oxidation and so most practical catalytic systems employ either copper(I) chloride or copper(I) bromide. Aprotic solvents are much preferred in such applications.[11,14,16,73]

We do not wish to disparage work on the autoxidation of copper(I) complexes in protic environments,[16,17,71] but would like to express the following opinion. The most straightforward method of studying the reactions of dioxygen with an air-sensitive metal complex is to work, if possible, in an inert, non-coordinating solvent like benzene,[75] toluene or methylene chloride.[21] The reason for this is that all aprotic reduced forms of dioxygen (that is, superoxide, peroxide, O^- and oxide) are protic bases and hence will be involved in acid–base reactions with any protic or aqueous environment. This acid–base behaviour makes study of the mechanisms of copper(I)-promoted reactions in alcohols or water extremely complicated and the results are not always easy to interpret.[16,17,71]

Most metal–dioxygen reactions are studied with the metal complex in excess, which calls for reasonable ($> ca$ 5 mM) ambient copper(I) solubility. Nitrobenzene and methylene chloride are effective, inert, aprotic solvents for most halo(amine)copper(I) complexes and offer a good range of dielectric properties (the dielectric constants are 34.8 and 8.9, respectively, at 25°C). This solvent dielectric difference is a useful probe of oxidation mechanisms (Section 5.5). Methylene chloride is a particularly convenient inert solvent for synthetic work because it is easily purified and evaporated (b.p. 40°C at 1 atm) and can also be used for gel permeation chromatographic product separations (Section 6.5).

Cryoscopic measurements in nitrobenzene (K_f 7.00°C m^{-1}) are appropriate for establishment of the molecularity of halo(amine)copper complexes in aprotic solution. The reason for this is that halides are good ligands for copper(I) and copper(II), especially in the presence of simple mono-, di- or triamines.[76] As a result, such halo(amine)copper complexes commonly exist either as neutral monomers or as polynuclear molecules in nitrobenzene and methylene chloride, depending on the experimental conditions.[11,14,21] This characteristic neutrality simplifies cryoscopy and at the same time eliminates uncertainty connected with the effects of ion-pairing[77,78] on the kinetics of copper(I) oxidation or copper(II) reduction. However, their neutrality often makes halo(amine)copper complexes difficult to crystallize from aprotic solvents (Section 2).

The driving force[11] for aprotic oxidation of a copper(I) complex by dioxygen is the formation of strong bonds between copper(II) and reduced dioxygen species.[14,16,21] The products might be superoxo-, peroxo- or oxocopper(II) complexes.[14,16,79–84] The stoichiometry of oxidation can be measured manometrically at ambient[21] or low[15,16,79] temperatures to determine the extent of dioxygen reduction.

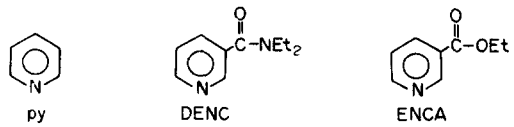
Manometric measurements also establish whether or not the ligands attached to the copper(II) product(s) of oxidation are themselves oxidatively stable. If not, we often see two distinct stages of dioxygen consumption. The first stage is for copper(I) oxidation and the second is for ligand oxidation.[82] This behaviour is observed, for example, with N,N,N′,N′-tetraethylethylenediamine (TEED)[79–81] and 2-methylpyridine[82,83] ligands, both of which suffer alkyl substituent oxidation in the presence of excess dioxygen.

Quite a lot of effort has been expended on finding soluble halo(amine)copper(I) complexes whose ligands are oxidatively stable[82] and a list of desirable ligand characteristics has been drawn up.[14] The number of common, acceptable ligands is small because simple, dissolved halo(amine)copper(I) complexes have a great tendency to reduce dioxygen completely to oxide and the resulting oxocopper(II) products are strongly basic oxidants.[82,83] This means that oxocopper(II) complexes are very sensitive to water and will react with or oxidize most other protic substances.

Among the few common oxidatively stable ligands that form well-characterized, soluble, air-sensitive complexes with copper(I) halides in aprotic solvents are monodentate pyridine (py), ethylnicotinate (ENCA) and N,N-diethylnicotinamide (DENC). The ligand py has long been of interest because of its ability to promote a wide variety of copper-catalysed reactions of dioxygen (see below).[11,16,72,73]

Solubility of copper(I) halides is always greater with ENCA and DENC ligands than with py, which is an important synthetic consideration.[21,75,84] Bidentate ligands from the N,N,N′,N′-tetraalkyldiamine family also form useful dimeric halo(amine)copper(I) reductants for dioxygen[12,79–81]

but the dimeric oxocopper(II) products must be stabilized, for example by reaction with carbon dioxide (see below).[74,78,84]



py DENC ENCA

We will now discuss the solution properties of halo(pyridine)– and halo(amine)–copper(I) complexes in more detail.

5.2. *Monodentate pyridine ligand systems*

The solubility of halo(pyridine)copper(I) complexes is usually greatest for the chloride but is also dependent on the pyridine ligand, molar ratio R = [pyridine]/[copper(I)], solvent and temperature. Solubility in ambient methylene chloride increases with DENC $\simeq$ ENCA $\gg$ py at $R = 1.0$. We will deal with the simplest molecular copper(I) systems first.

Cryoscopic determinations in nitrobenzene and measurements of the kinetics of copper(I) oxidation by dioxygen in an aprotic solvent can be used to establish the copper species present in a given aprotic system.[21,79–81] We find that N = DENC readily forms tetranuclear species $N_4Cu_4X_4$ that are "cubanes"[7,21,75] containing monodentate DENC, as indicated by an X-ray crystallographic study of the iodide,[75] PMR data and a characteristic, single sharp IR band at 1635 cm^{-1} for ν(C=O) in DENC.[7,21,75,85] These cubane tetramers have very little tendency to add DENC.[21] The common ligand DENC is therefore particularly attractive for generating simple tetrameric copper(I) reductant systems.[21,74]

Changing the amine ligand from N = DENC to N = ENCA has two very interesting effects. First, we now find that each copper(I) centre can coordinate up to *two* ENCA molecules in tetrameric molecules $N_4Cu_4X_4$ and $N_8Cu_4X_4$. Cryoscopic and kinetic measurements indicate that these species are both symmetrical, halo-bridged "cubanes"[7] with terminal N ligands.[21,75] This means that each copper(I) centre in $N_8Cu_4X_4$ is five-coodinate. Use of R between 1 and 2 presumably gives mixtures of $N_{8-x}Cu_4X_4$ species (x = 1–4). An ability to change the coordination number of copper(I) in a common tetrameric core structure is very important in establishing oxidation mechanisms (Section 5.6).[11,21]

Formation of $N_8Cu_4X_4$ is particularly favoured with N = ENCA and X = Br in nitrobenzene at $R = 2.0$. However, changing R from 1.0 to 2.0 in methylene chloride gives a system whose constituents very much depend on the total copper(I) concentration, especially when X = Cl. In fact, the predominant species in methylene chloride at low copper(I) concentrations is monomeric N_2CuCl, which dimerizes to $N_4Cu_2Cl_2$ with increasing [CuCl] but does not further dimerize to $N_4Cu_4Cl_4$ or $N_8Cu_4Cl_4$ species except at the highest practical copper(I) concentration in this solvent.[21]

As already noted, py gives less soluble complexes with copper(I) halides than do most *m*- or *p*-substituted monodentate pyridines. Although useful concentrations of $py_4Cu_4Cl_4$ can be obtained in nitrobenzene, this is not a practical proposition in methylene chloride.[11,21,86,87] The solubility is much higher at $R = 2.0$, but we now find a complicated mixture of soluble species py_2CuCl, $py_4Cu_2Cl_2$ and $py_8Cu_4Cl_4$, with the latter most favoured by high copper(I) concentrations (as found with ligand ENCA).[21] Marked sensitivity to the pyridine concentration [py] greatly complicates the kinetics of the well-known[73] oxidative coupling of phenols catalysed by oxo(pyridine)–copper(II) species in methylene chloride (Scheme 1).[14,16,79,81,82,86–88]

The most important recommendation of this Section is to establish the molecular forms of copper(I) halides in any particular amine/solvent system by cryoscopy or other suitable means before reactivity studies are made. This is, of course, absolutely essential in kinetic studies.[11,14,17,21,79–81,84,88] We note that the simplest known aprotic halocopper(I) systems with monodentate pyridine ligands in aprotic solvents are those made from DENC/CuX, which give tetrameric $(DENC)_4Cu_4X_4$ species over a wide range of copper(I) concentrations.[11,21,75,87]

5.3. *Other amine ligand systems*

Except for some examples of systems mentioned earlier,[74] most aliphatic mono- and polyamines L form very air-sensitive, soluble complexes with copper(I) halides.[14,16,17,73,79-81] These complexes characteristically exist as halo-bridged dimers both in the solid state (Section 2)[12,80] and in aprotic solvents.[79-81] They are excellent initiators for a wide variety of useful dioxygen reactions, most of which involve protic substrates.[12,14,16,73,79-81,88] The persistently short, 2.5–2.7 Å, Cu—Cu distances in LCu(X,X)CuL molecules (Section 2)[12,25] are important in determining the products and mechanisms of their oxidation by dioxygen[14,29-31] (Section 5.6). Dimeric halocopper(I) complexes with diamine ligands L show little tendency to add L or to break down to monomers in methylene chloride or nitrobenzene, but osmotic molecular weight measurements show that dimer breakdown is more likely to occur in acetonitrile (AN).[12] We note that $Cu(AN)_4Y$ salts, where Y is a variety of monoanions, are common starting materials for the synthesis of many amine–copper(I) complexes;[16] AN is a good ligand for copper(I) and for this reason greatly complicates measurements of the kinetics of copper(I) reactions with dioxygen in aqueous AN.[89] We should therefore avoid AN as an additive or solvent if the desired copper(I) products are polynuclear and contain only mono- or diamine ligands.

It has been accepted for some time that ligands containing N—H groups are not stable ligands for oxidized copper(I) halides.[11,16,73,82] The simplest solution to this problem is alkylation of all ligand N—H groups and the use of poly-N-(alkyl)polyamines as ligands in studies of copper(I) oxidation by dioxygen.[76,79-82]

5.4. *Stoichiometries, products and kinetics of oxidation of halo(amine)copper(I) complexes by dioxygen. General observations*

There have been many studies of copper(I) "autoxidation" reactions[16,17] which can be considered under four main headings.

5.4.1. *Solid or slurry oxidations.* Solid or slurry copper(I) oxidation systems are qualitative in the sense that the ultimate products often are unidentified solids, catalytic solutions or mixtures.[16,72,73,83] Studies of the stoichiometries and rates of such reactions by dioxygen uptake measurements may or may not give useful information, depending on whether the product is non-stoichiometric, the ligand is oxidatively unstable or the solvent is protic. Even in favourable circumstances, kinetic measurements of dioxygen uptake by solids or slurries often are irreproducible and are of questionable value in understanding oxidation and catalytic mechanisms.[90]

5.4.2. *Oxidation in protic solvents.*[16,17,71,89] Data obtained for oxidation of copper(I) complexes by dioxygen in protic solvents are a source of useful rate information. However, such systems often are not completely understandable in mechanistic terms because of the basic character of reduced forms of dioxygen and the inevitable presence of many different copper(I) reductant species and copper(II) oxidation products (see comments in Section 5.1).

5.4.3. *Biomimetic studies.* These are intended to duplicate the physical and chemical properties of the active sites of copper-containing proteins.[15,16] A careful choice of polyamine ligands has led to considerable success in this area, particularly with respect to the characterization of dimeric peroxocopper(II) cations at low temperatures and the discovery of stoichiometric oxygenase activity.[15,16,91-93] The use of aprotic solvents is appropriate because the active sites of copper-containing proteins probably are hydrophobic.[15,16,93] The stage is now set for kinetic and mechanistic studies of these interesting biomimetic systems. Success is likely because of the availability of X-ray structural information on the dimeric copper(I) reactants.[16,94] Information gained from studies of the kinetics of simple halo(amine)copper(I)–dioxygen systems should be useful in interpreting the data.[14]

5.4.4. *Aprotic halo(amine)copper(I) systems.* As already emphasized, halo(amine)copper(I) complexes are the basis of many practical catalytic systems that employ dioxygen as the formal oxidant.[11,14,16,73] Pre-oxidation of copper(I) with dioxygen is necessary for catalytic activity[11,14,72,73] and particular ligands survive the oxidation process in aprotic solvents.[11,14,74,82] For this reason we focus attention on the stoichiometries, products and kinetics of specific aprotic copper(I)–dioxygen systems in the following sections.

5.5. Stoichiometries of aprotic oxidation by dioxygen at ambient temperatures

The primary stoichiometries of ambient, aprotic oxidation of halo(amine)copper(I) complexes with coordinated ligands py, N and L by dioxygen are given in eqs (13)-(21):[11,14,21,79-84]

$$3py + 4CuX(s) + O_2 \longrightarrow py_3Cu_4X_4O_2 \textbf{(XXXIa)} \quad (13)$$

$$py_4Cu_4X_4 + O_2 \longrightarrow py_4Cu_4X_4O_2 \textbf{(XXXIb)} \quad (14)$$

$$4py_2CuX + O_2 \longrightarrow py_4Cu_4X_4O_2 + 4py \quad (15)$$

$$2py_4Cu_2X_2 + O_2 \longrightarrow py_4Cu_4X_4O_2 + 4py \quad (16)$$

$$py_8Cu_4X_4 + O_2 \longrightarrow py_4Cu_4X_4O_2 + 4py \quad (17)$$

$$N_4Cu_4X_4 + O_2 \longrightarrow N_4Cu_4X_4O_2 \textbf{(XXXII)} \quad (18)$$

$$N_8Cu_4X_4 + O_2 \longrightarrow N_4Cu_4X_4O_2 + 4N \quad (19)$$

$$2N_4Cu_2X_2 + O_2 \longrightarrow N_4Cu_4X_4O_2 + 4N \quad (20)$$

$$2L_2Cu_2X_2 + O_2 \longrightarrow 2L_2Cu_2X_2O \textbf{(XXXIII)} \quad (21)$$

$$2L_2Cu_2X_2O \rightleftharpoons L_4Cu_4X_4O_2. \quad (22)$$

These reactions invariably are studied in the presence of excess copper(I). It is understood here that the data refer to copper(I) oxidation in an inert, aprotic solvent, that py, N and X are oxidatively stable and that L are N,N,N′,N′-tetraalkyldiamines that only suffer slow oxidation in the presence of *excess* dioxygen.[11,14,21,79-82]

The most important features of these reactions are as follows.

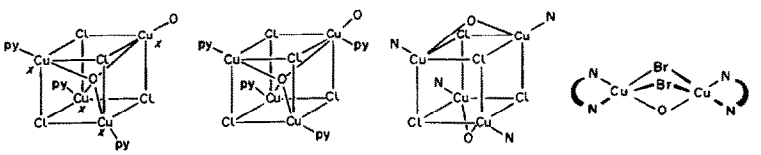
(1) Every reaction results in complete dioxygen reduction to give oxocopper(II) products. The stoichiometries $\Delta[CuX]/\Delta[O_2] = 4.0$ distinguish these systems from those that give peroxocopper(II) products (Section 5.6).[14,16,92,93]

(2) Oxidation of monomeric, dimeric and tetrameric halo(pyridine)copper(I) complexes with dioxygen {eqs (13)–(17); the copper(I) halide actually is slurried in eq. (13)[21,87] and reactions (13)–(20) are written in order of increasing R and [CuX]} gives soluble tetrameric oxocopper(II) products that contain either three (in tetrameric product **XXXIa**) or four (in **XXXIb**) py ligands. Distinguishable[87] products **XXXIa** and **XXXIb** are catalytically active in a variety of useful dioxygen systems[16,73] but they cannot be isolated as intact solids.[11,21,83,87]

(3) The products **XXXII** of eqs (18)–(20) also are soluble tetrameric oxocopper(II) complexes that with monodentate N = DENC or ENCA are isolatable as intact solids.[21,75] These products are catalytically inactive in dioxygen reactions, which distinguishes them from products **XXXI**. However, they can be made catalytically active by addition of excesses of aliphatic alkylamines, which substitute for N.[11,21,87]

(4) By contrast, the products **XXXIII** of eqs (21) are oxocopper(II) dimers.[81] Reaction (22) evidently is prevented by (a) high affinity of copper(II) for bidentate L; (b) reluctance of copper(II) to be six-coordinate (it is five-coordinate in tetrameric pyridine-containing products $N_4Cu_4X_4O_2$);[21] and (c) the bulky alkyl substituents of the diamine ligands.[79-82]

(5) A variety of physical and chemical evidence indicates the following core structures for products **XXXI–XXXIII**.[11,14,21,81,87] One piece of chemical evidence comes from eqs (23) and (24):



XXXIa **XXXIb** **XXXII** **XXXIII**

$$N_4Cu_4X_4O_2 + 2CO_2 \longrightarrow N_4Cu_4X_4(CO_3)_2 \textbf{(XXXIV)} \quad (23)$$

$$L_2Cu_2X_2O + CO_2 \longrightarrow L_2Cu_2X_2(CO_3) \textbf{(XXXV)} \quad (24)$$

Reaction (23) is not characteristic of products **XXXI**.[11,21,87] Reaction (24) is an important means of stabilizing products **XXXIII** against polymerization[80–82] and the monocarbonate products **XXXV** are useful "off-the-shelf" oxidative coupling initiators.[73,75]

(6) Most neutral oxo(halo)aminecopper(II) complexes disproportionate (with py and N ligands)[21,86,87] or polymerize (L ligands)[81] on attempted crystallization and only products **XXXV** have been crystallized intact. X-ray structural studies on examples of **XXXV** reveal symmetrical (with L = N,N,N′,N′-tetramethyl-1,3-propanediamine, TMPD) and asymmetrical (with L = TEED) μ-carbonato bridging systems that have *trans*- and *cis*-halide configurations in the respective dimers.[74,84] These different dimer configurations can also be *chemically* distinguished from the different products and kinetics of their reactions with 2,4,6-trichlorophenol.[78]

5.6. *Oxidation kinetics*

The kinetics of irreversible, aprotic oxidation of well-characterized excess monomeric, dimeric and tetrameric halo(amine)copper(I) complexes by dioxygen have been measured in benzene, methylene chloride and nitrobenzene.[11,21,75,79–81,88] Ambient oxidation of halo(amine)copper(I) complexes by dioxygen is driven by the formation of strong bonds between copper(II) and oxide. However, oxidation of copper(I) can be strongly inhibited by water and the oxocopper(II) products are very water sensitive.[82,88] For these reasons it is absolutely essential to use pure, anhydrous aprotic ligands and solvents in kinetic studies. The major results of this work are as follows.

(1) The characteristic rate laws for oxidation of monomeric, dimeric and tetrameric halo(amine) copper(I) complexes by dioxygen at ambient temperatures are given by eqs (25)–(27):

$$\text{Rate} = k_m[\text{monomer}]^3[O_2] \tag{25}$$

$$\text{Rate} = k_d[\text{dimer}]^2[O_2] \tag{26}$$

$$\text{Rate} = k_t[\text{tetramer}][O_2] \tag{27}$$

respectively. These rate laws apply to halocopper(I) complexes with py, N or L ligands because dioxygen is completely reduced by copper(I) under non-coordinating ambient aprotic solvent conditions to give oxocopper(II) products.[11,14,21,75,79–81] As a result, the rate laws directly reflect the copper(I) reductant molecularity.[21]

(2) Rate laws (13) demonstrate[21,90] that transfer of the third electron from copper(I) to the dioxygen molecule is required for irreversible dioxygen reduction.[11,14] The reason for this statement is that three monomeric copper(I) species are present in the activated complex associated with irreversible rate law (25). These three electrons are required to break the O—O bond in O_2. Two copper(I) dimers or one copper(I) tetramer contain the four electrons that reduce O_2 to two mols of oxide and so these are the stoichiometric constituents of the activated complexes for irreversible rate laws (26) and (27), respectively. Thus, a very important factor in reactions (13)–(19) is that the tetrameric halo(amine)copper(I) reductants contain the four electrons required to completely reduce a dioxygen molecule to two mols of oxide in a complementary reaction. This results in simple rate law (27)[21] (see also Section 6.4).

(3) Tetranuclear $py_8Cu_4Cl_4$ is oxidized about seven times more rapidly than $py_4Cu_4Cl_4$ by dioxygen in nitrobenzene at 25°C.[21,88] The corresponding second-order rate constant ratio for $(ENCA)_8Cu_4Cl_4$ and $(ENCA)_4Cu_4Cl_4$ is about four.[21] These observations indicate that dioxygen is not coordinated to copper(I) in the rate-determining oxidation step.[21,88]

(4) The oxidation rates are not very sensitive to the solvent dielectric constant and there is no spectral or kinetic evidence for reaction precursors or intermediates. This argues against a rate-determining step involving polar intermediates created by electron transfer from copper(I) to dioxygen.[11,21]

(5) Rate laws (27) with py and N ligands have very small experimental activation enthalpies (the range is 2.1–5.9 kcal mol^{-1}) and very negative activation entropies in the range $-(35–48)$ cal deg^{-1} mol^{-1} at 25°C. The activation enthalpies increase by about 2 kcal mol^{-1} on changing from X = Cl to X = Br in $(py,N)_4Cu_4X_4$ molecules. Very negative activation entropies indicate an associative rate-determining step. The activation parameters actually are quite well correlated by a plot of $\Delta H_t^{\ddagger}$ vs $\Delta S_t^{\ddagger}$, Fig. 1, which is further support for a common slow reaction step. The activation enthalpy for oxidation of $py_8Cu_4Cl_4$ is about 3 kcal mol^{-1}, lower than expected from the other activation

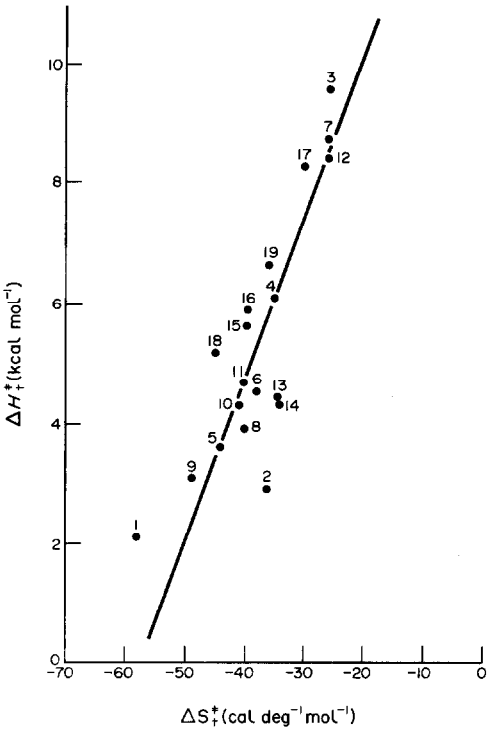


Fig. 1. Correlation of $\Delta H_t^{\ddagger}$ and $\Delta S_t^{\ddagger}$ (at 25°C) for oxidation of tetrameric copper(I)-containing molecules $N_mCu_{4-x}M_x(NS)_yX_4$[a] and L_4Cu_4[b] with dioxygen via rate laws (27) and (48) in nitrobenzene. Each point in the figure is identified in the following key. We conclude from this and other evidence (see text) that electron transfer from copper(I) to dioxygen is not rate-determining in any of the cited systems since correlation of the data is apparent for a wide range of redox driving forces and copper(I) reactants. The major factors that appear to influence $\Delta H_t^{\ddagger}$ and $\Delta S_t^{\ddagger}$ are the stiffness or electron density of the reductant molecular core, the effective nuclear charge of M and possible obstruction of O_2 insertion by NS ligands.[101,102]

KEY

[a] X = Cl unless noted otherwise; [b] L is 6-methyl-2-oxopyridinate (ref. 108); [c] M. A. El-Sayed, G. Davies, A. Abu-Raqabah and A. El-Toukhy, to be published; [d] X = Br.

parameters in Fig. 1 (see Section 7). This evidently is due to the presence of *five*-coordinate py_2CuCl_3 centres in this particular reductant.

The accumulated cryoscopic, spectral and kinetic evidence indicates that dioxygen *insertion* into the tetranuclear cores X_4[7,21,75] of $(py,N)_nCu_4X_4$ molecules is the rate-determining oxidation step. Insertion in this context means that the leading O atom of O_2 has to penetrate one of the six faces of $(py,N)_4Cu_4X_4$ before any electron transfer from copper(I) to dioxygen can take place. The X_4 core evidently is "stiffer" and dioxygen insertion is more obstructed with X = Br. However, the core evidently is "loosened" by an increase in the coordination number of copper(I) on addition of

py and ENCA ligands.[21,88] Dioxygen insertion seems to be obstructed in the same slow step of the corresponding oxidations of transmetallated halo(pyridine)copper(I) species $N_3Cu_3M(NS)_yX_4$ (Section 6.4).

Different product core structures **XXXI** and **XXXII** arise from different relative rates of (a) penetration of the X_4 core by the leading atom of O_2 and (b) concomitant dioxygen reduction by copper(I).[21,87,88] Electron transfer from copper(I) to O_2 is fastest in $py_8Cu_4Cl_4$ tetramers and partial insertion before complete electron transfer required to break the O—O bond results in asymmetrical core structures **XXXI** with ligand py.[21,87,88] Slower electron transfer in $N_mCu_4X_4$ systems results in symmetrical structures **XXXII**.[21]

The third-order rate constants, k_d, of eq. (26) and their activation parameters are very sensitive to the identity of py or N and to the alkyl substituents of ligands L in dimers $[(py,N)_4,L_2]Cu_2X_2$. Particular N-alkyl diamine substituents cause large differences of rate in methylene chloride and nitrobenzene.[81] It is very likely that activated complex assembly (not electron transfer) is the rate-determining step in halo(amine)copper(I) monomer and dimer oxidation by dioxygen.[21,79,81]

5.7. *Low temperature aprotic oxidation*

A great deal of effort has been expended on trying to limit the extent of dioxygen reduction by copper(I) and on characterization of the copper(II) products.[11,14,16,80,92,93] We have seen that there is a marked tendency for complete dioxygen reduction by low molecular weight halo(amine)copper(I) complexes. The physically isolated active sites of the high molecular weight copper-containing proteins called haemocyanins and tyrosinases contain only two copper centres.[16,93] It is known that the copper(I) forms of these metalloproteins reduce dioxygen under ambient conditions to give peroxocopper(II) species.[15,16,92,93] This information has stimulated great interest in making peroxocopper(II) models. Success has been achieved with carefully chosen binucleating tridentate amine ligands.[16,91–93] However, the peroxocopper(II) products are stable only at low temperatures ($< ca$ 240 K), which means that *temperature* is a very important means of controlling the extent of dioxygen reduction by copper(I).[14,16,79] This control could have kinetic or thermodynamic origins.[14,16]

Reducing the temperature simply reduces the rates of reactions (14) and (17)–(19) because each of these redox reactions is complementary. However, reactions (15), (16), (20) and (21) have the potential to generate superoxo- and peroxocopper(II) products because they involve monomeric and dimeric copper(I) complexes. In these cases the anticipated stoichiometries are given by eqs (28)–(30):[16,79]

$$M + O_2 \longrightarrow MO_2 \tag{28}$$

$$2M + O_2 \longrightarrow M_2O_2 \tag{29}$$

$$D + O_2 \longrightarrow DO_2, \tag{30}$$

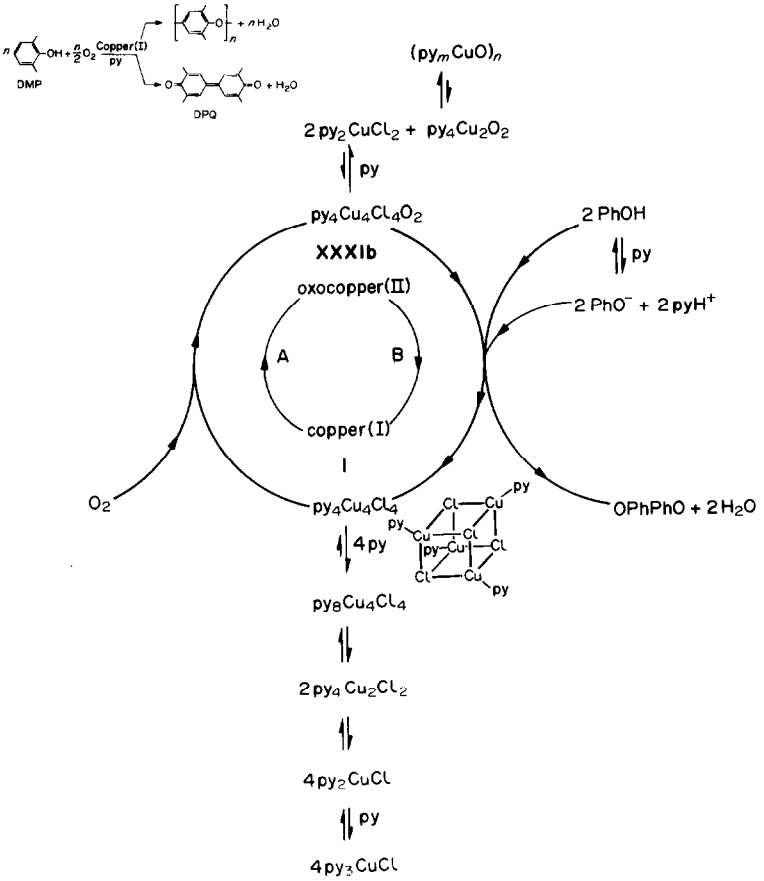
where M and D represent copper(I) monomers and dimers, respectively. These stoichiometries can be determined manometrically.[15,16,79,91–93] We know of no evidence for the occurrence of reaction (28) in copper(I)–dioxygen systems.[14,79]

A recent study shows that the complete reduction of dioxygen by simple dimers $L_2Cu_2X_2$, eq. (18), can indeed be intercepted at low temperatures in methylene chloride to give peroxocopper products with L = TEED.[79] The products of eqs (18) and (31):

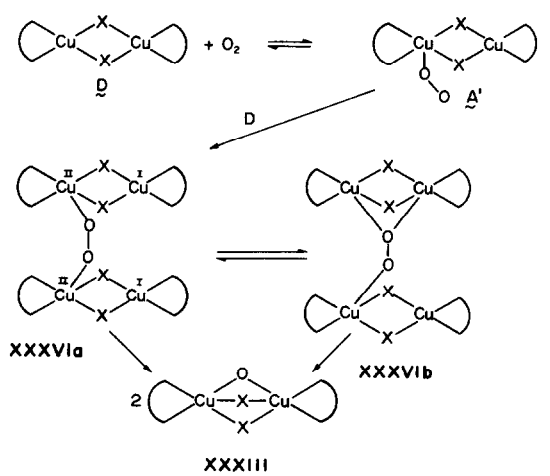
$$2L_2Cu_2Cl_2 + O_2 \longrightarrow (L_2Cu_2Cl_2)_2O_2\ (\mathbf{XXXVI}) \tag{31}$$

are green and blue, respectively. Low temperature blue products **XXXVI** actually are an equilibrium mixture of two, mixed-valence tetrameric peroxocopper species of stoichiometry $(L_2Cu_2X_2)_2O_2$ (Scheme 2).[79] This stoichiometry seems to be imposed by the 2.60 Å separation of the copper centres in $L_2Cu_2Cl_2$ (see refs 12, 25 and Section 2). Irreversible reaction (32) takes place over a very narrow temperature range (−40 to −30°C) because the activation enthalpy and entropy of reaction (32) are estimated to be 25 kcal mol^{-1} and 40 cal deg^{-1} mol^{-1} at 25°C, respectively, in methylene chloride.[79]

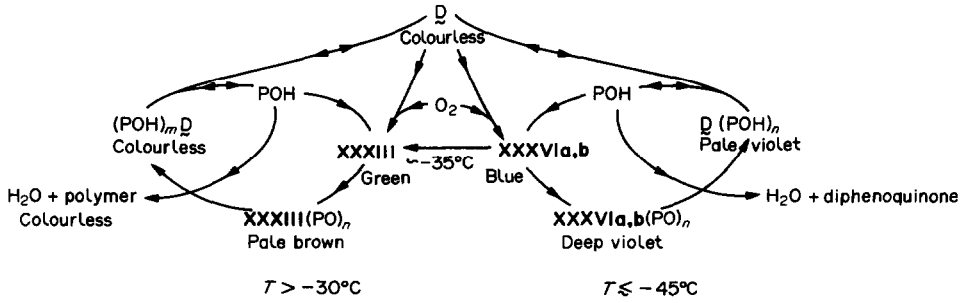
The chemistry summarized in Scheme 2 demonstrates that temperature is indeed a very important factor in controlling the extent of reduction of dioxygen by simple monomeric and dimeric copper(I)



Scheme 1. Equilibria and the proposed[88] central catalytic components **A** and **B** of the py/CuCl/O_2/2,6-dimethylphenol (DMP) system that gives the oxidatively-coupled diphenoquinone product (inset) in methylene chloride and nitrobenzene.[11,73,86b] The catalytic intermediate in the cycle apparently has formal stoichiometry $py_3Cu_4Cl_4O(DMP)_2$.[88] The predominant product at higher pyridine concentrations is poly(2,6-dimethylphenylene oxide) (see inset).[73,88]



Scheme 2. Equilibria and irreversible reactions in the low temperature oxidation of $(TEED)_2Cu_2Cl_2$ (**D**) by O_2 in methylene chloride.[79] There is no firm evidence for the existence of significant concentrations of species **A′**. Peroxocopper complexes **XXXVIa** and **XXXVIb** [eq. (31)] are irreversibly converted to oxocopper(II) complex **III** in eq. (32) at $T \geq ca.\ -35°C$ (see text).[79]



Scheme 3. Schematic catalytic cycles for the low and ambient temperature oxidative coupling of 2,6-dimethylphenol by the $L_2Cu_2Cl_2/O_2$ system of Scheme 2.[79]

complexes.[14,79] This control clearly is kinetic[14,79] because known reactions (29) and (30) have large equilibrium constants.[14–16]

After establishment of the underlying copper chemistry in Scheme 2 it was possible to show that the oxocopper(II) complex $(TEED)_2Cu_2Cl_2O$ from eq. (21) or (32):

$$(L_2Cu_2Cl_2)_2O_2 \longrightarrow 2L_2Cu_2Cl_2O \tag{32}$$

is the initiator and catalyst for the oxidative coupling of 2,6-dimethylphenol (DMP) to poly(2,6-dimethylphenylene oxide) by dioxygen (Scheme 3; also see inset of Scheme 1).[79] A similar approach shows that the catalytic intermediate in the corresponding system with $py_4Cu_4Cl_4$ as initiator in nitrobenzene is a formal oxocopper(II) complex of stoichiometry $py_3Cu_4Cl_4O(DMP)_2$.[88] The phenolic oxidation product in this case is the diphenoquinone (Scheme 1).[88]

The benefits of employing simple, well-characterized halo(amine)copper(I) complexes as reductants and non-coordinating, aprotic solvents as media in studies of copper(I) oxidation are obvious from the results of this Section. Neutrality of the copper(I) reactants considerably simplifies the interpretation of kinetic data for oxidation of copper(I).[14,21,79–81,88] We trust that the same systematic approach will be used in future studies of copper(I) "autoxidation" and copper-based catalysis.[16,73]

6. TRANSMETALLATION OF POLYNUCLEAR HALO(AMINE)COPPER(I) COMPLEXES WITH M(NS)$_n$ TRANSMETALLATORS AND OXIDATION OF THE PRODUCTS BY DIOXYGEN

Simple halo(amine)copper(I) complexes and the products of their aprotic reactions with dioxygen have a remarkable ability to serve as targets in aprotic reactions in which the copper centres are stoichiometrically replaced with other metals. These reactions are called transmetallation.[95]

6.1. *The discovery of transmetallation*[95]

Neutral oxocopper(II) complexes **XXXI–XXXIII** have not been crystallized intact.[11,21,87,88] Attempted crystallization of products **I** and **II** often gives crystalline products $(\mu_4\text{-O})(py,N)_4Cu_4X_6$ in a little understood series of disproportionation reactions.[21,86a,87] Products **XXXIII** must be freshly prepared because they polymerize in aprotic solvents, as indicated by cryoscopic measurements.[81]

The two important properties of products **XXXI–XXXIII** are that they are oxidants and strong protic bases. The need to distinguish as clearly as possible between the different basic oxo groups in their proposed core structures led us to examine their reactions with aprotic Lewis acids $M(NS)_2$, where NS is a monoanionic hydrazinecarbodithioate Schiff base ligand in structures **A–F** (Fig. 2).[95,96] We instead observed ambient, stoichiometric exchange of M for Cu, as exemplified by the reaction series summarized in eq. (33):[97]

$$(\mu_4\text{-O})(py,N)_4Cu_4X_6 + xC \longrightarrow (\mu_4\text{-O})(py,N)_4Cu_{4-x}Ni_xX_6 + xCu(NS)_2. \tag{33}$$

This new transmetallation chemistry has subsequently been shown to apply to a wide range of polynuclear copper targets.[98] However, we emphasize that it is *not* restricted to copper replacement.[98,99]

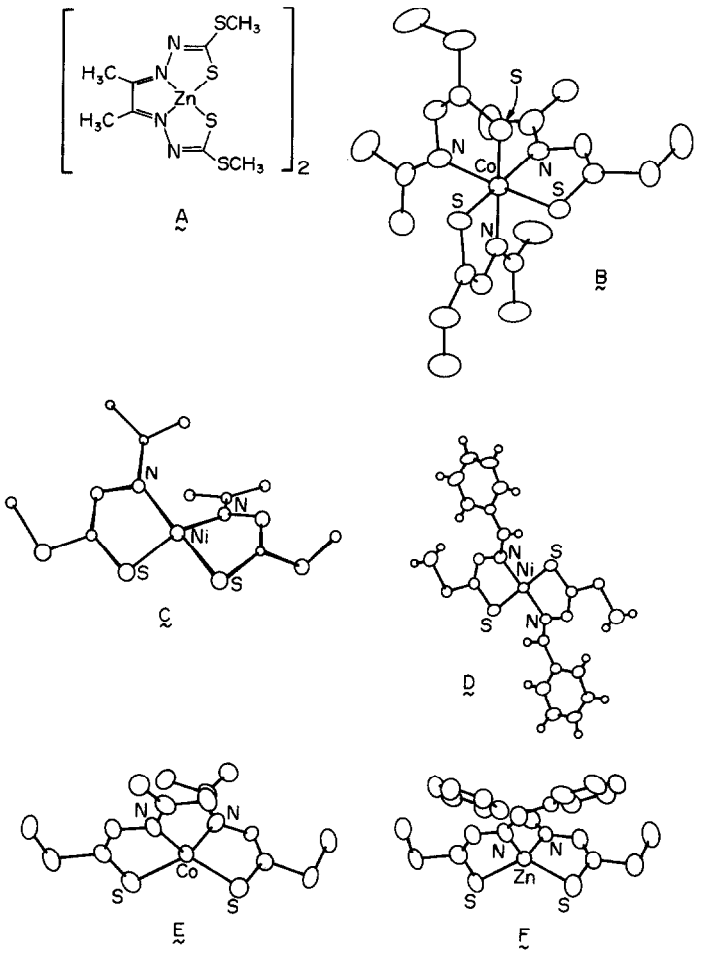


Fig. 2. Structures of S-methylhydrazinecarbodithioate transmetallators **A–F**.[96]

Transmetallation chemistry can be used to obtain literally hundreds of entirely new heteropolymetallic molecules that cannot be made by other means.[98]

The transmetallation phenomenon has been reviewed in detail[98] but the application of transmetallation still is in its infancy. Therefore, the remainder of this Report will highlight the most important aspects of halo(amine)copper(I) transmetallation with $M(NS)_n$ transmetallators and of oxidation of the transmetallated products with dioxygen.

6.2. *Transmetallation of halo(amine)copper(I) complexes with* $M(NS)_n$ *transmetallators*

Equations (34)–(40):

$$(py,N)_4Cu_4X_4 + M(NS)_2 \longrightarrow (py,N)_3Cu_3M(NS)X_4\,(\mathbf{XXXVII}) + (py,N) + Cu(NS)\,(s) \quad (34)$$

$$(py,N)_4Cu_4X_4 + 2M(NS)_2 \longrightarrow (py,N)_4M_2X_4 + 4Cu(NS)\,(s) \quad (35)$$

$$(py,N)_4Cu_4X_4 + Co(NS)_3 \longrightarrow (py,N)_3Cu_3Co(NS)_2X_4\,(\mathbf{XXXVIII}) + (py,N) + Cu(NS)\,(s) \quad (36)$$

$$(py,N)_4Cu_4X_4 + 2Co(NS)_3 \longrightarrow (py,N)_4Co_2X_4 + 2Cu(NS)_2 + 2Cu(NS)\,(s) \quad (37)$$

$$L_2Cu_2X_2 + M(NS)_2 \longrightarrow LCuM(NS)X_2 + L + Cu(NS)\,(s) \quad (38)$$

$$LCuM(NS)X_2 \longrightarrow LMX_2 + Cu(NS)\,(s) \quad (39)$$

$$LCuM(NS)X_2 + M(NS)_2 \longrightarrow (M(NS))_2X_2 + L + Cu(NS)\,(s) \quad (40)$$

summarize the stoichiometries of transmetallation of dimeric and tetrameric halo(amine)copper(I)

complexes with $M(NS)_n$ reagents **B**, **C** and **E** (Fig. 2) in methylene chloride and nitrobenzene under dinitrogen.

The advantage of using the S-methyl isopropylidenehydrazinecarbodithioate NS ligand system of these particular transmetallators is the precipitation of insoluble, pale yellow co-product Cu(NS) (s), which can be filtered, dried and weighed to establish transmetallation stoichiometries. The polymeric transmetallation products are identified by elemental analysis and by cryoscopic measurements in nitrobenzene.[98-104]

Reactions (34)–(40) have many interesting features, including the following.

(1) Reactions (34) and (36) are *direct* transmetallations.[86a] The word *direct* in this context means that the target and ultimate transmetallation product have the same molecularity. This is the most useful kind of transmetallation reaction because it allows the option of replacing all the copper in a given target with other metals and thus generates large transmetallation product families.[87,89,100]

(2) Reaction (34) proceeds even with M = copper(II) because Cu(NS) (s) is more stable than dissolved $Cu(NS)_2$. The product **XXXVII** in this case is a *mixed-valence* copper species.[101]

(3) Cryoscopic and spectroscopic measurements indicate that the first products of eqs (34) and (36) are tetrameric species containing only three ligands py or N.[88,99,101,102] This is evidently because each molecule contains three, four-coordinate (py,N)Cu centres, which means that M is five-coordinate in products **XXXVII** (that is, the NS ligand is bidentate, as indicated by a strong IR band at 1000 cm^{-1}).[96,101]

(4) Reactions (36) and (37) are preceded by rapid electron transfer from copper(I) to cobalt(III) in **B**.[99,102] This means that products **VIII** are mixed-valence species that formally contain two copper(I), one copper(II) and one cobalt(II) centres, as indicated by their electronic spectra.[99,102] Spectroscopic (electronic, IR) data also indicate that cobalt(II) in **XXXVIII** is five-coordinate and hence contains monodentate NS ligands (Scheme 4).[99,102]

(5) Reactions (35) and (37) are not direct because intramolecular NS ligand transfer (INLT) from M or cobalt to copper occurs on replacement of a second copper(I) centre of **XXXVII** or **XXXVIII** with **B**, **C** or **E**. INLT and intermolecular transmetallation thus are competitive processes in progressive copper(I) transmetallation.[99,102] This situation could be changed by altering the NS ligand or by employing M(NS) transmetallators.[98] However, systems based on reactions (35) and (37) are valuable new sources of heterometallic dimers because we can use equimolar $M(NS)_2$ and $M'(NS)_2$, where M and M′ are different metals, instead of two mols of $M(NS)_2$.[98-102]

(6) Reactions of species **XXXVIII** with mixtures of transmetallators $M(NS)_2$, $M'(NS)_2$ and **B** actually are quite selective.[99] This is partly because of decreasing thermodynamic transmetallator stability in the order $Cu(NS)_2 > Ni(NS)_2 > Co(NS)_2 > \mathbf{B} > Zn(NS)_2$[99] and partly because of differences in transmetallation rate laws for different M and NS.[98,105-107]

(7) Reactions (39) are a quantitative new source of LMX_2 complexes.[103] Faster reactions (40) give new dimers $[M(NS)]_2X_2$ whose stability depends on M.[103]

6.3. *Transmetallation kinetics and mechanisms*

The rate laws of transmetallation reactions that result in the replacement of a single metal centre in a polymetallic target can be determined by maintaining the target in large excess over the transmetallator.[97] The rate laws for these *mono*-transmetallation reactions, eqs (41)–(45):

$$\text{Rate} = k_{29}[\text{TM}][\text{T}]^2 \tag{41}$$

$$\text{Rate} = k_{30}[\text{TM}][\text{T}] \tag{42}$$

$$\text{Rate} = k_{31}[\text{TM}] \tag{43}$$

$$\text{Rate} = k_{32}[\text{TM}][\text{T}] + k_{-32} \tag{44}$$

$$\text{Rate} = k_{33}K_{33}[\text{TM}][\text{T}]/(1 + K_{33}[\text{T}]) \tag{45}$$

depend on the properties of the target R and transmetallator TM.[97,104-107]

Rate laws (41), (43) and (45) are indications of very weak, very strong and moderately strong transmetallation reaction precursors, respectively.[106,107] These precursors are proposed to be constructed via four-membered Cu—X—M—S rings between the reactants.[97,104-107] Excellent support

for this conclusion is that transmetallations of L_4Cu_4 (L is 6-methyl-2-oxopyridinate), which contains no halo ligands, are very much slower than those of halocopper targets under the same experimental conditions.[108] Reversible rate law (44) is only observed for the earliest events of transmetallation of particular copper(I) dimers $L_2Cu_2Cl_2$ in (polar) nitrobenzene. It does not actually refer to transmetallation, which is much slower in these cases than is discrete copper(II) replacement.[103,104]

The reader is referred to the original papers[97,104–107] for a detailed analysis of the information derived from different transmetallation rate laws. The most important factor for efficient known transmetallation systems involving halocopper targets and $M(NS)_n$ transmetallators seems to be the availability of nucleophilic X and S atoms in the respective labile reactants. These atoms are used to construct Cu—X—M—S precursor rings.[106,107] Other important attributes of halocopper species as transmetallation targets and $M(NS)_n$ reagents as transmetallators have been discussed in detail.[98,105–108]

6.4. *Oxidation of the products of halo(amine)copper*(I) *transmetallation by dioxygen*

Replacement of the redox-active metal centres of a catalyst with other metals is a powerful means of investigating catalytic mechanisms.[86a,109]

Products **XXXVII** and **XXXVIII** of eqs (34) and (36), respectively, react with dioxygen via eqs (46) and (47):

$$(py,N)_3Cu_3M(NS)X_4 + O_2 \longrightarrow \underset{\textbf{XXXIX}}{(\mu_4\text{-O},\mu\text{-O})N_3Cu_3M(H_2O)X_4} + 1/2N_2S_2 \qquad (46)$$

$$(py,N)_3Cu_3Co(NS)_2X_4 + O_2 \longrightarrow \underset{\textbf{XXXIXa}}{(\mu_4\text{-O},\mu\text{-O})N_3Cu_3Co(H_2O)X_4} + N_2S_2. \qquad (47)$$

The respective rate laws are eq. (48):[102,103]

$$d[\textbf{IX}]/dt = k_t[\textbf{XXXVII}, \textbf{XXXVIII}][O_2] \qquad (48)$$

Correlation of the activation parameters for common second-order rate laws (27) and (48) (Fig. 1)[21,88,101,102] indicates the same rate-determining dioxygen insertion mechanism (see Section 5.6). This very important observation shows that rapid oxidation of the coordinated NS ligands in **XXXVII** and **XXXVIII** to the disulphide N_2S_2 results from prior reduction of dioxygen by copper(I).[101,102] The impressive correlation of activation parameter data for oxidation of $(N,py)_mCu_{4-x}M_x(NS)_yX_4$[101,102] *and* L_4Cu_4[108a] complexes (L is 6-methyl-2-oxopyridinate) in Fig. 1 suggests contribution of some inherent property of the dioxygen molecule to $\Delta H_t^{\ddagger}$ and $\Delta S_t^{\ddagger}$ because L_4Cu_4 (point 19 in Fig. 1) has no halo core.

6.5. *Transmetallation of oxocopper*(II) *complexes*

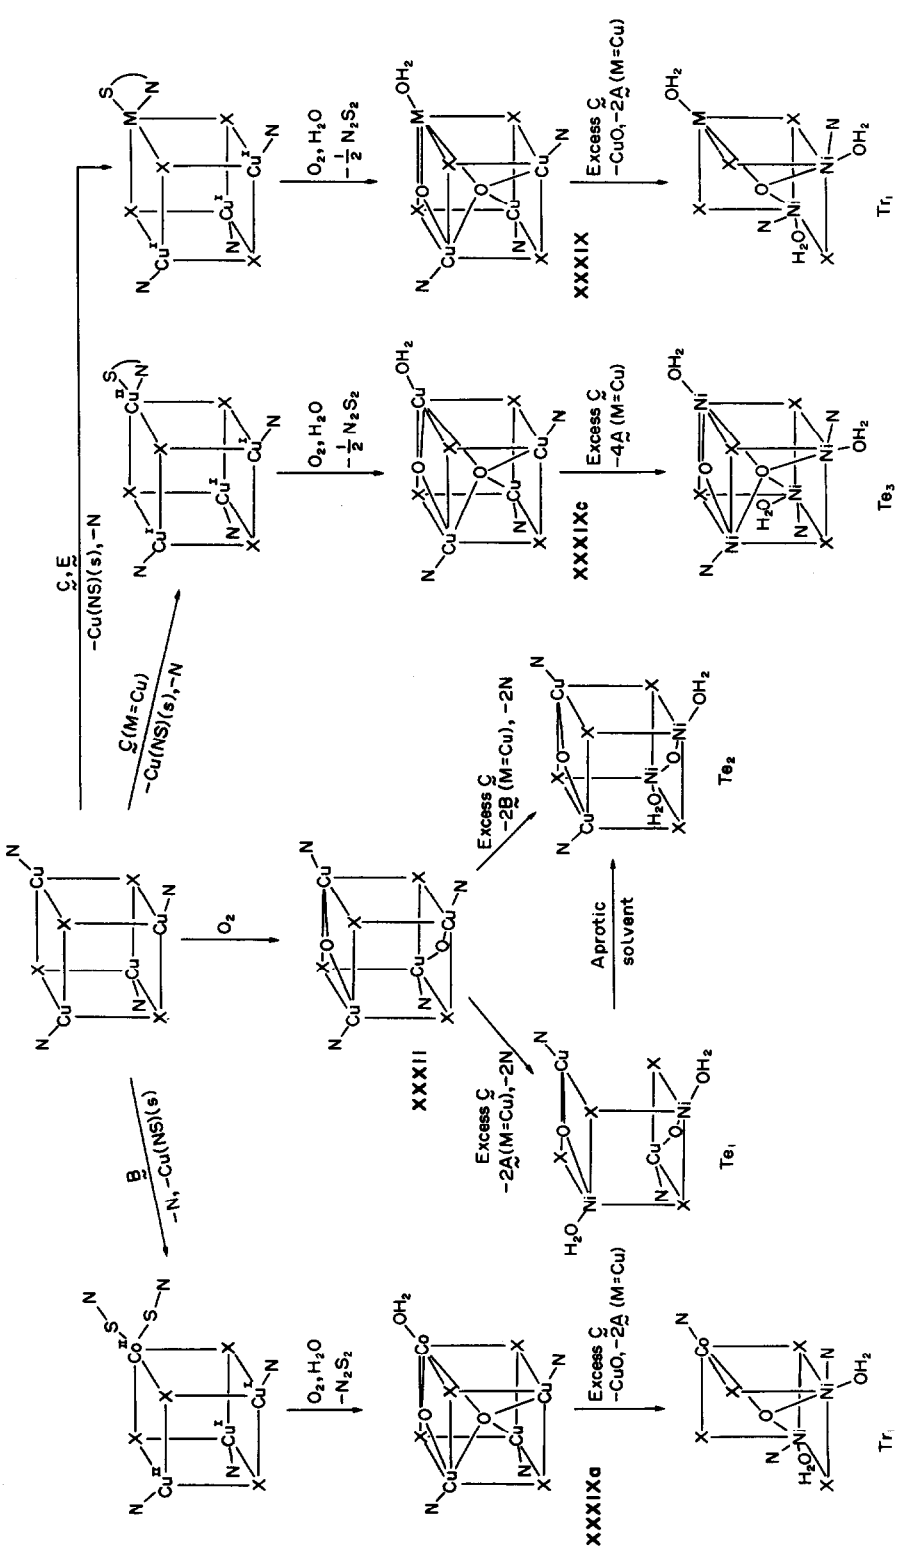
Tetrameric oxocopper(II) products **XXXIX** and those from other copper(II) transmetallation systems[98] can easily be isolated by gel permeation chromatography with divinylbenzene/styrene copolymer resins under a positive dinitrogen pressure with methylene chloride as eluant.[86a]

Scheme 4 shows the proposed core structures of products **XXXIX**.[87,101,102] Evidence for these core structures comes from a variety of sources, including their behaviour on transmetallation with $M(NS)_n$ reagents, where characteristic CuO fragmentation is observed, eq. (49):[99,110]

$$\textbf{XXXIX} + xM'(NS)_2 \longrightarrow N_3M_{3-x}M'_xX_4O + CuO + 2Cu(NS)_2. \qquad (49)$$

The products $N_3M_{3-x}M'_xX_4O$ can be μ-oxo or μ_3-oxotrimers, Tr_1, because the CuO fragmentation patterns depend on the target and transmetallator.[110] The exception is with M = Cu in **XXXIX** and M′ = Ni in eq. (49), which gives no CuO fragmentation and leads to a complete, six-membered family of copper–nickel tetramers (μ_4-O, μ-O)$N_4Cu_{4-x}Ni_xCl_4$ (x = 0–4) through a sequence of site-selective transmetallation steps.[87] Scheme 4[110] illustrates the effects of reversing the oxidation/transmetallation sequence with halo(amine)copper(I) starting materials.

The patterns of transmetallation of copper(II) targets thus primarily depend on the target core structure and the transmetallator.[98] A very special kind of *trans*-effect operates specifically across the unrestrained[101] μ-oxo groups of species like **XXXII** in Scheme 4.[86a,108b,110] This means that one metal



Scheme 4. Effects of changing the oxidation/transmetallation sequence in the reactions of copper(I) complexes $(DENC)_4Cu_4X_4$ with $M(NS)_n$ transmetallators **B**, **C** and **E** of Fig. 2.[102]

can either facilitate or retard the replacement by transmetallation of another metal that shares the same μ-oxo group. The *trans*-effect phenomenon results, for example, in selective replacement of metals *trans*- to cobalt(II) in $L_4Cu_{4-x}(Co,M)_xO_2$ molecules, where L is 6-methyl-2-oxopyridinate. The result is the generation of specific product isomers.[108b] The complete *trans*-effect order for Co, Ni, Cu and Zn centres has been worked out[108b] and appears to be general.[110] The *trans*-effect was only discovered because trimeric[110] and tetrameric[86a,108b,110] μ-oxocopper(II) targets were available for study.

6.6. *Prospects for the development and use of transmetallation chemistry*

All this remarkable transmetallation and oxidation chemistry was discovered as a result of a longstanding interest in copper-catalysed reactions of dioxygen.[11,82,83] It has already been demonstrated that transmetallation with redox-inactive metals like nickel(II) can be used to shut down active catalytic copper–dioxygen systems.[86a,88,109] Replacement of one metal in a polymeric catalyst with other redox-active or -inactive metals could have substantial effects on the efficiency and specificity of many metal-catalysed dioxygen reactions.[98]

There is substantial interest in the synthesis and use of heteropolymetallic molecules,[111,112] catalysts[112] and materials.[113] The objective is to modify the properties of existing materials in a beneficial manner. It is apparent that transmetallation chemistry has considerable potential in the synthesis of entirely new heteropolymetallic molecules, families of catalysts with closely similar structures but easily variable redox properties,[98] new alloys under very mild conditions[113] and large families of heterogeneous catalysts with systematically controllable properties.[98,113]

7. CONCLUDING REMARKS

Halo(amine)copper(I) complexes display a wide variety of molecular structures and physical properties. Carbonylcopper(I) complexes are relatively rare but there is sufficient structural information to illustrate their interesting structural variations. Chloro- and bromocopper(I) complexes with pyridine and alkylpolyamine ligands are very suitable for establishing the basic characteristics of aprotic copper(I) autoxidation and the mechanisms of catalysis by copper(I)–dioxygen systems. Polymeric halo(amine)copper(I) complexes and the products of their oxidation by dioxygen are excellent targets for the generation of many new heteropolymetallic molecules through transmetallation. Availability of these products should be of considerable value in the synthesis of new materials and in determining the mechanisms of metal-catalysed reactions.

Acknowledgements—This work was supported by Grant CHE-8717556 from the National Science Foundation and Grant 20022-AC3 from the Donors of the Petroleum Research Fund, administered by the American Chemical Society (to G.D.). G.D. particularly wishes to thank Professors Mohamed A. El-Sayed and Ahmed El-Toukhy for their many contributions to work on copper–dioxygen and transmetallation chemistry. All the drawings in this Report were prepared with the Chem 3D Molecular Modelling System supplied by Cambridge Scientific Computing, Inc.

(*Received* 22 *January* 1990; *accepted* 23 *March* 1990)

Abstract—1,4,8,11-Tetraazacyclotetradecane (cyclam) condensed with 2-chloro-methylquinoline-1-oxide yields the tetrasubstituted title compound, a ligand for copper(II). The redox properties of the copper(II) complex were characterized by voltammetric methods. Contrary to the complex with unsubstituted cyclam, the electroreduction proceeds stepwise with the generation of a copper(I) complex in the first step. The electron is transferred in a quasi-reversible process and the formal potential, $E^{\ominus}$, of the $Cu^{II}L/Cu^{I}L$ system was found to be −0.137 V in propylene carbonate and −0.113 V in N,N′-dimethylformamide.

Possible relationships to copper biochemistry have stimulated studies of the copper complexes with tetraaza macrocycles. Electroanalytical methods are used to determine the influence of structure on the reactivity of the copper complexes in the electron-transfer processes.[1] In biological systems copper compounds such as azurin or plastocyanin containing a single copper atom undergo rapid electron exchange which is assumed to be due to nearly identical geometries in the reduced and oxidized states.[2,3] The hydrophobic environment of the copper atom should minimize the solvent reorganization contributions. It is, therefore, believed that a properly tailored model ligand should provide a similar constrained environment for the copper atom and eliminate the large inner-coordination sphere changes observed for simple copper complexes during the electron-transfer reactions. In the case of the N_4-type ligands these attempts were, however, usually unsuccessful. The copper(I) complexes formed upon electroreduction of copper(II) were found to decompose or disproportionate to copper(II) and metallic copper. Stabilization of copper(I) was sometimes achieved with unsaturated N_4-type ligands or substituted cyclams.[4,5] Stable copper(I) complexes were observed for five-coordinate environments with a tetradentate ligand enforcing a nearly square-pyramidal geometry.[6–11] Direct electroreduction of $Cu^{II}N_4$ to the metal was reported by Fabrizzi and co-workers.[6,12] Air- and moisture-sensitive complexes of formally zero-valent copper were described by Bond and Khalifa.[11] On the other hand, electrochemical oxidation of the copper(II) complexes with some tetraazacyclotetradecane macrocycles was shown to yield copper(III) complexes[6,13] similarly to deprotonated peptide complexes.[14,15] In the present work, the cyclam substituted with heterocyclic N-oxide (Fig. 1) was used to complex the copper(II) ions. The complex was characterized by vol-

tammetry on glassy carbon and mercury electrodes with the aim of determining the accessibility of various oxidation states of copper.

EXPERIMENTAL

Chemicals

The solvents used: dichloromethane (CH_2Cl_2), acetonitrile (AN), N,N'-dimethyloformamide (DMF) and propylene carbonate (PC) were purified by distillation, dried and stored over 4 Å molecular sieves. Et_4NClO_4 (TEAP) was recrystallized from methanol and used in 0.1 mol dm^{-3} concentration as the supporting electrolyte. The ligand dissolved readily only in halogenated organic solvents, therefore CH_2Cl_2 was used to prepare the stock solution of the ligand.

Preparation of the complex

The title ligand was prepared as described previously.[16] The ligand (414 mg, 0.5 mmol) was stirred in ethanol (10 cm^3) with $Cu(NO_3)_2 \cdot 3H_2O$ (187.6 mg, 0.5 mmol) at 70°C for 1 h. Upon cooling the complex was crystallized slowly by vapour diffusion with ethyl ether to form deep green crystals. Yield: 386 mg, 76%. Found: C, 53.4; H, 4.6; N, 12.3. Calc. for $C_{50}H_{52}N_8O_4+Cu(NO_3)_2$: C, 53.5; H, 4.6; N, 12.5%.

Instrumentation

Voltammetry experiments were carried out in a three-electrode arrangement with a saturated calomel reference electrode and platinum foil counter electrode, both separated from the cell solution by a glass frit. The working electrode was either a static mercury drop electrode, SMDE 1 (Laboratorni Pristroje) of 0.014 cm^2 drop area, used in the dropping (sampled d.c. voltammetry) or hanging (cyclic voltammetry) mode, or a glassy carbon electrode, GCE (Bioanalytical Systems, Inc.) of 0.07 cm^2 area. The surface of the GCE was polished with a polishing microcloth using alumina powder (1 μm) and electrochemically treated by holding the potential at -1.5 V for 60 s and at $+0.3$ V for 60 s in the solution studied. All experiments including controlled-potential electrolysis with a mercury macrocathode were carried out using a BAS-100 Electrochemical Analyser (Bioanalytical Systems Inc.) with a KX-P1091 Printer (Panasonic) and HIPLOT DMP-40 Plotter (Houston Instrument).

The reference electrode potential was calibrated by using the ferrocene, $Fe(C_2H_5)_2$, oxidation process in the appropriate solvent so that the junction potential effects could be estimated. The cell resistance was externally compensated for by BAS-100.

RESULTS

Stoichiometry of the complex

In contrast to the behaviour of the ligand itself, the copper(II) complex dissolves readily in potentially coordinating solvents such as AN, DMF and PC. The stoichiometry of the complex was established by adding aliquots of the copper(II) solution to a sample containing a known amount of the macrocycle. On complexation the macrocycle dissolved and voltammograms were recorded 1 h after each aliquot addition. Two couples of peaks were formed, c_1/a_1 and c_2/a_2 (Fig. 2), increasing upon addition of copper(II). At concentration ratios, $C_{Cu^{II}}/C_L$, larger than one the peaks attained constant height and an additional peak corresponding to free copper(II) reduction to metallic copper was observed at potentials positive to that of peak c_1. This suggests that the macrocycle is able to accommodate a single copper ion. The same stoichiometry was found when aliquots of cyclam in CH_2Cl_2 were added to the copper(II) solution in DMF or PC. In AN the copper(II) complex is unstable and upon standing undergoes chemical reduction to the Cu^I–AN complex. The voltammogram exhibits a reduction peak at -0.36 V vs SCE on the GCE corresponding to the reduction of the Cu^I–AN complex to metallic copper. A similar potential for the Cu^I/Cu^0 couple in AN was reported by Farka and Iwamoto.[17] In AN solutions the anodic peak increases upon maintaining the electrode at -0.5 V prior to recording the anodic half-cycle. This confirms that copper(0) is formed during reduction and stripped off from the electrode surface during oxidation. Therefore, further experiments were carried out in DMF or PC. The low solubility of the complex in acetone or CH_2Cl_2 made it impossible to study the electrode processes in these non-coordinating solvents.

Voltammetry in PC

Voltammograms similar to those presented in Fig. 2 are obtained when the $Cu^{II}L$ complex is prepared externally and dissolved in 0.1 mol dm^{-3} TEAP solution in PC. For the c_1/a_1 couple of peaks the current ratio given by eq. (1):[18]

$$i_{pa}/i_{pc} = (i_{pa}/i_{pc})_0 + 0.485i/(i_{pc})_0 + 0.086, \quad (1)$$

where i is the current at the switching potential and the 0-index denotes that current is measured from

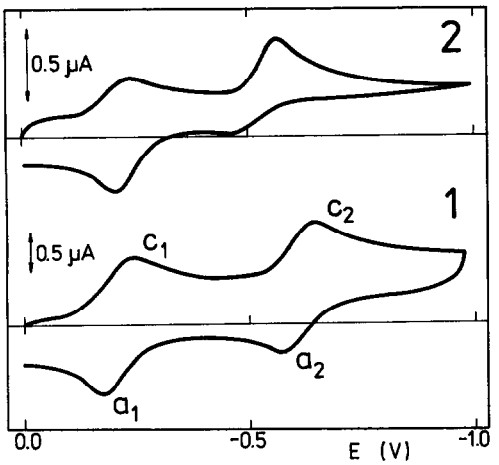

Fig. 2. Cyclic voltammograms for 2.32×10^{-4} mol dm^{-3} Cu^{II} after addition of 6.2 mg of the ligand recorded on (1) GCE and (2) SMDE in 0.1 mol dm^{-3} TEAP/PC solution. Scan rate: 20 mV s^{-1}.

the base line in the supporting electrolyte alone, was found to be unity (Table 1). The $E_{pc_1} - E_{pc_1/2}$ value close to 60 mV and the value of $E_{pa_1} - E_{pc_1}$ close to 60 mV at low scan rates and increasing with the increase of scan rate reveal quasi-reversibility of the system. The shifts of the cathodic and anodic peaks are symmetrical with respect to the midpoint potential, $(E_{pc} + E_{pa})/2$. The formal potential, $E^{\ominus}$, approximated by the midpoint potential value is given in Table 2. Figure 3 shows the c_1/a_1 couple of peaks recorded from 0 V towards negative potentials (curve 1) and a voltammogram recorded in the opposite direction—from −0.5 V, where the electrode is maintained for 1 min before initiating the anodic scan (curve 2). The curves appear identical which indicates the absence of complicating reactions and accumulation at the electrode. The heterogeneous rate constant, k^0, estimated from the anodic–cathodic peak separation by the method of Nicholson[19] was found to be $(8.3 \pm 0.2) \times 10^{-3}$ cm s^{-1} at the GCE.

[b] GCE.
[c] SMDE.

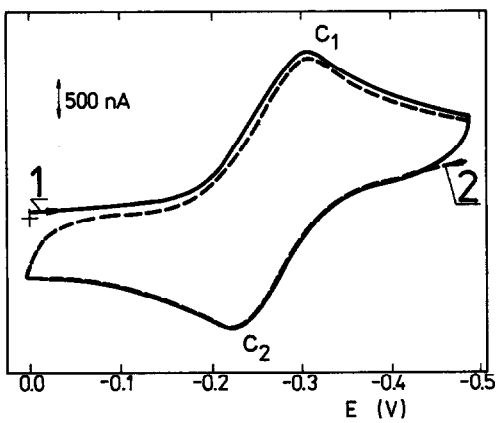

Fig. 3. Cyclic voltammograms of 4×10^{-4} mol dm^{-3} $Cu^{II}L$ on GCE in 0.1 mol dm^{-3} TEAP/PC solution. Scan rate: 50 mV s^{-1}. (——) Started from 0 V in the direction of negative potentials; (– – –) started from −0.5 V towards positive potentials.

Sampled d.c. voltammetry at the SMDE in the dropping mode gave a wave corresponding to peak c_1 with $E_{1/2}$ almost identical to the $E^{\ominus}$ value obtained from the cyclic voltammograms. The limiting currents increased linearly with the complex concentration and the $i_{lim}\sqrt{t_{drop}}$ was constant with increasing drop time, t_{drop}. The value $n\sqrt{D}$ was similar to that obtained from cyclic voltammetry, 2.3×10^{-3}. The slope of the wave $dE/d \log (i/i_d - i)$ was 59.16 mV.

The second reduction process was found to be chemically irreversible and largely dependent on the presence of traces of water, thus exhibiting that the product of this reduction step undergoes decomposition. Since no special effort was made to obtain solutions without traces of water this process was not studied more carefully.

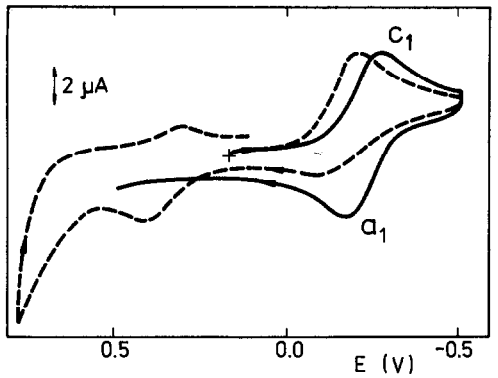

Fig. 4. The influence of (– – –) 5×10^{-3} mol dm^{-3} TEACl on the cyclic voltammograms of 5.6×10^{-4} mol dm^{-3} $Cu^{II}L$ in 0.1 mol dm^{-3} TEAP/DMF at the GCE. Scan rate: 50 mV s^{-1}.

Coulometry

To evaluate the number of electrons used in the first reduction step exhaustive electrolysis on a mercury pool electrode was carried out at −0.5 V, in solutions containing different concentrations of $Cu^{II}L$. The $i-q$ plots obtained were linear and extrapolation gave 0.98 F mol^{-1} at $i = 0$ as the mean value. The colour of the solution turned from green to yellow. The results confirmed consumption of 1e in the first step of reduction. The diffusion coefficients of $Cu^{II}L$ obtained in DMF and PC are depicted in Table 2.

Influence of chlorides

Addition of TEACl to the solution leads to a positive shift of the E_{pc_1} and a decrease of the a_1 peak. An additional anodic peak is formed at +0.460 V (Fig. 4). This points to chemical reaction following electron transfer, leading to the incorporation of Cl^- into the copper(I) complex. The new complex formed is more stable than Cu^IL.

Relative stabilities of the copper(II) and copper(I) complexes

Assuming that in the absence of chlorides the $E^{\ominus}$ value obtained from cyclic voltammetry approximates the thermodynamic formal potential of the $Cu^{II}L/Cu^IL$ pair, the ratio of stability constants of the complexes was calculated from eq. (2):[20]

$$(E^{\ominus}_{Cu^{II}/Cu^{I}})_{complex} = (E^{\ominus}_{Cu^{II}/Cu^{I}})_{uncomplexed} - 0.059 \log (K_{Cu^{II}L}/K_{Cu^{I}L}).$$

Using the value $(E^{\ominus}_{Cu^{II}/Cu^{I}})_{uncomplexed}$ equal to 0.0160 V vs NHE the ratio $K_{Cu^{II}L}/K_{Cu^{I}L}$ is 1×10^5, reflecting the higher stability of the copper(II) complex.

Conclusions

In most 14-membered saturated macrocycles the cavity is inappropriate for the larger copper(I) ion and the ability of these ligands to distort to tetrahedral geometry stabilizing copper(I) is reduced. Therefore, the copper(I) complex dissociates and disproportionates rapidly. The tetrasubstituted tetraazamacrocycle presented in this work was found to possess ligating properties both toward copper(II) and copper(I) ions. In contrast to the cyclam complex, substitution of the ligand with quinoline oxide groups renders the complexes insoluble in water and leads to enhancement of the stability of the copper(I) state. The reduction of the copper(II) complex is shifted 400 mV towards positive potentials, compared to the unsubstituted cyclam complex. Good ligands for copper(I), however, such as Cl^- or AN have to be avoided, since in their presence the Cu^IL complex undergoes fast chemical reactions leading to more stable copper(I) compounds.

(*Received* 4 *December* 1989; *accepted* 1 *May* 1990)

Abstract—The dependence of bridging hydrogen atoms on terminal hydrogen positions in *nido*-metalloboranes has been studied using the model compounds B_4H_8X (**6**, X = BH) and $B_4H_8Fe(CO)_3$ (**1d**). Calculations on B_5H_9 at both MNDO and extended Huckel levels have shown that the bridging hydrogen positions are controlled by the terminal hydrogen positions. Bridging hydrogen atoms might be observed above the B_n plane (towards the cap), if the caps have sufficiently diffuse orbitals. Model studies at both MNDO and extended Huckel levels of B_4H_8X [X = BeH^-, Li^- and $Fe(CO)_3$] supported these results. The effects of increasing ring size from B_4H_8 to B_5H_{10} are also studied. Suitable metal fragments for polyhedral borane ligands (rings) having five, six, seven, 11 and 13 vertex boron atoms can be selected using the ring–cap overlap match. Calculations have shown that $B_6H_6^{4-}$ (**13**) has more diffuse orbitals compared to $B_{11}H_{11}^{4-}$ (**14**) and $B_{13}H_{13}^{4-}$ (**15**). Compounds **14** and **15** preferred caps with less diffuse orbitals because of the rigidity of the ligands. The metal–ring boron distances in metalloboranes are controlled by this ring–cap compatibility. The concept of topological charge stabilization is also used in predicting the stabilities of various isomers of metalloboranes.

Boranes constitute one of the most studied polyhedral molecules with a variety of structural arrangements which are well understood using various electron-counting rules.[1] Two basically different types of hydrogen atoms, viz. terminal (H_t) and bridging (H_b) as in **1**, are present in many boranes. The bridging hydrogen atoms provide additional electrons required for a given structural type. B_5H_9 (**1a**) is a well-studied example of **1**, having both terminal and bridging hydrogen atoms.[2] The terminal hydrogen atoms here are bent towards the apical BH (X, cap)† and the bridging hydrogen atoms are bent away from it, lying below the B_4H_8 ring.[3] It is well documented in the literature that when there are only terminal hydrogens in the ring the diffuseness of the cap and the size of the ring control the position of terminal hydrogens.[4] In metal complexes of C_nH_n ring systems, the hydrogen atoms are bent away from the metal for smaller rings and towards the metal for larger rings to optimize the ring metal overlap match.[4a] Similarly, bending of ring substituents in pyramidal carbocyclic and polyhedral borane ring systems is also an attempt to optimize the ring–cap overlap.[4b,c,d] Based on this, a cap with more diffuse orbitals than appropriate for the ring orbitals should push the ring substituents away from it. When the cap orbitals are less diffuse than the ring orbitals, the ring substituents will be pushed towards the cap. The ideal situation involves optimum ring–cap overlap with no bending of ring-substituents, as excessive bending (in either way) weakens the ring-substituent σ bonds.

The situation is further complicated in polyhedral boranes because these contain bridging hydrogen atoms in addition to the terminal hydrogen atoms. Since the BH cap (X) orbitals are less diffuse than appropriate for the orbitals of the B_4H_8 ring, the terminal hydrogen atoms bend towards it as in **1a** and the bridging hydrogens are observed below the

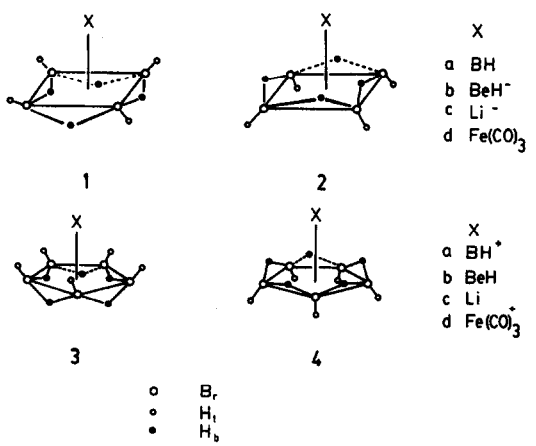
† Throughout this paper apical or cap represents the unique vertex.

B_4 ring. Is it the only structure possible for bridged boranes? Can we think of a second minimum involving the bridging hydrogen atoms moved towards the cap (X)? Replacement of the BH cap by metal fragments with more diffuse orbitals should push the terminal hydrogen atoms below the B_4H_8 ring.[4] Does this affect the bridging hydrogen positions? If the terminal hydrogen positions can influence the bridging hydrogen positions, it should be possible to design compounds where the bridging hydrogen atoms attach themselves to the same side as that of the cap (X). This type of bonding has not been obtained for bridged boranes so far. In the first part of this paper the interdependence of bridging and terminal hydrogen positions is probed. The effects of ring size and differing capping groups on the positions of bridging hydrogen atoms are also analysed. Previous theoretical studies on these molecules did not address this problem.[5] We have selected B_4H_8X [X = BH, BeH^-, Li^- and $Fe(CO)_3$] (**1**, **2**) and $B_5H_{10}X$ [X = BH^+, BeH, Li and $Fe(CO)_3^+$] (**3**, **4**) for the theoretical study. Calculations are carried out using semi-empirical MNDO[6] [except for X = $Fe(CO)_3$] and the extended Huckel methods.[7] The MNDO calculations on **1a** and **3a** are already reported.[5e,c]



Apart from B_4H_8 and B_5H_{10}, many boranes and carbonates such as $C_2B_9H_{11}^{2-}$, $C_2B_3H_5^{4-}$ and $C_2B_4H_6^{2-}$ are available as ligands to the metal fragments. An extension of the ring–cap overlap analysis[4] helps us to find out suitable metal caps for given borane ligands. The above carborane anions are six-electron ligands similar to $C_5H_5^-$ but with a variety of orbital extensions. $C_2B_9H_{11}^{2-}$, the fragment of the icosahedral $C_2B_{10}H_{12}$ has a set of π-type MOs with totally different directional character in comparison to the pentagonal pyramidal $C_2B_4H_6^{2-}$ ligand. A survey of the available literature showed that 11 vertex boranes and carboranes are the most commonly found borane ligands to various metal fragments. To discover the stability order of a given borane ligand for different metal fragments as caps, we have selected ligands with five, six, seven, 11 and 13 vertex boron atoms for the theoretical study (second part of the paper). $Fe(CO)_3$ is taken as the model metal fragment. The metal–boron distances in the structurally-characterized complexes are examined to support the differences in the pentahapto and hexahapto borane ligands. A relationship is also sought between the topological charge stabilization rule[8] and the diffuse nature of the cap orbitals in metalloboranes. The qualitative arguments are supported by extended Huckel calculations with geometries and atomic parameters specified in the Appendix.[7]

RESULTS AND DISCUSSION

Initially a qualitative MO reasoning is presented to show why we expect two minima in bridged boranes. The electronic structure of **1** is similar to that of C_5H_5X (X = BH^+, CH^{2+}, etc.) molecules with three three-dimensionally delocalized MOs occupied by six electrons.[4] In **1** the square pyramidal B_4H_4X [X = BH, $Fe(CO)_3$, etc.] has two delocalized electrons. Four more are added by the four bridging hydrogen atoms. An alternative way of looking at **1** is to treat it as $B_4H_4X^{4-}$ with four protons attached at the sites of maximum electron density. With the terminal ring B_r—H_t (B_r corresponds to the ring boron atom as shown in **1**–**4**) bonds bent towards the cap (X) as in B_5H_9, the greater electron density should be found at the opposite side of the cap (X), i.e. below the ring (**5**). The same argument also leads to the expectation that the position of electron density should shift towards the cap, X (above the ring), if the terminal ring B_r—H_t bonds are bent away from the cap. From a localized picture of bonding we could anticipate the following. Both σ- and π-type MOs of the ring are involved in bonding with bridging hydrogen atoms. While the ring σ-bonding orbitals may prefer to interact with the "1*s*" orbitals of the bridging hydrogen atoms in the plane, the π-orbitals would have the node near the ring plane. The preferred positions for bridging hydrogen atoms to interact with them will be either below or above the ring. *This leads to the possibility of two minima for bridging hydrogens atoms.* The qualitative MO reasoning is supported by quantitative results on **1**–**4** using the semi-empirical MNDO method.

Various structures for B_4H_8X are optimized first by keeping the terminal hydrogen atoms towards the cap (X) and the bridging hydrogen atoms away from it (**1**) within C_{4v} symmetry. In **2** the positions

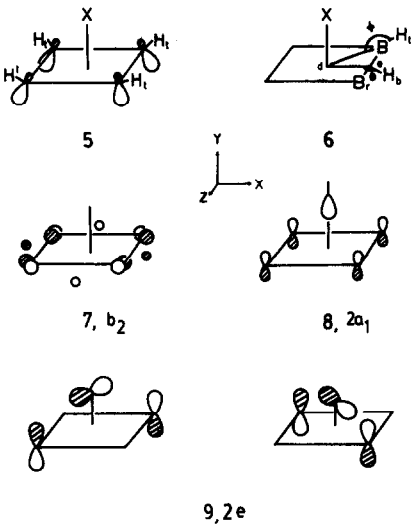
ible. But in all the examples, structures with terminal hydrogen atoms towards the cap (X) and bridging hydrogen atoms away from it (X) are more stable. Our results on **1a** and **3a** in C_{4v} and C_{5v} symmetry are in agreement with the reported MNDO values.[5e,c] The relative energy differences ($\Delta\Delta H_f$) between the two isomers (**1** and **2**, and **3** and **4**) show that it is lowest for X = Li compared with BH or BeH (Table 1). The $\Delta\Delta H_f$ for a given cap is less for a four-membered ring compared to the corresponding five-membered ring. For example, with Li $\Delta\Delta H_f$ is 17.3 and 34.7 kcal mol^{-1} for the four- and five-membered rings, respectively (Table 1). This is because Li, being a very diffuse cap for a four-membered ring, pushes the terminal hydrogen atoms away from it in B_4H_8. This pushes the bridging hydrogen atoms towards the cap (X). Since the differences in the positions of the bridging and terminal hydrogen atoms are not very large, the energy difference between the two isomers **1** and **2** is lower for X = Li over B_5H_9. When the bridging hydrogen atoms are towards the cap (**2** or **4**), the B_r—B_r distance is found to be short compared to that in **1** or **3**, indicating that the electrons which bind the ring boron atoms are less delocalized to the bridging hydrogen atoms in this geometry. The B_r—H_b distance increases to large values as the H_b atoms are pushed towards the cap (X). At the same time the bridging hydrogen atoms developed some bonding interactions with the cap (Table 2). The variation in the terminal hydrogen positions (DBH_t in Table 2) in the two isomers is small for four-membered rings, with a maximum value of 8° for **1a** and **2a**. In the five-membered rings this increases to a maximum of 29° for **3c** and **4c**.

The above results using the MNDO method imply the possibility of two minima, one where the bridging hydrogen atoms are away from the cap (X) and the other where they are towards it. If the MNDO values are any indication for two minima in bridged boranes, caps with higher diffuse orbitals like metal fragments should show this trend more strongly. Our computational facilities do not permit quantitative studies with metalloboranes. We use the extended Huckel method to explain the possibility of two minima in bridged metalloboranes.

For the qualitative analysis we have selected B_5H_9 and $B_4H_8Fe(CO)_3$.[9] The possibility of a second minimum with bridging hydrogen atoms towards the cap on the B_4H_8X [X = BH and $Fe(CO)_3$] energy surface is studied in the following way. In the model B_5H_9 (**6**), ϕ is the angle made by d (middle of the ring), B_r and H_t. The angle made by d, e (middle of the B_r—Br bond) and H_b is θ. Energy curves are generated for the variation of bridging hydrogen atoms for fixed terminal hydrogen positions. In the calculations ϕ is kept at 120, 160° (terminal hydrogen atoms towards the cap, X), 180, 200 and 230° (terminal hydrogen atoms away from the cap, X) and θ is varied from 100 to 260° in 10° intervals for each value of ϕ. The total energy plots are given in Fig. 1. As anticipated above, for each value of ϕ the energy curve has two minima in θ (θ_1 and θ_2, as in Table 3). When ϕ is increased there is a lateral shift in the two minima. For example, when ϕ is 160°, the two minima are at 120 and 255° of θ and when it is changed to 200° they appear at 115 and 240°. The reasons for this are discussed below.



The Walsh diagram (Fig. 2, ϕ = 180°) shows the important MOs responsible for the change in total energy curves (**7**–**10**). The curve for MO b_2 (**7**), with no contribution from the terminal hydrogen atoms and the cap BH, is symmetric because the overlap between the bridging hydrogen atoms and the ring

Table 3. Comparison of the minimum in θ (θ_1 and θ_2) as a function of ϕ (**6**) for various caps of B_4H_8X (X = BH, BeH^-, Li^- and $Fe(CO)_3$). All values in degrees (obtained at the extended Huckel level)

Cap X	θ	ϕ 120	160	180	200	230
BH	θ_1	135	120	115	115	105
	θ_2	275	255	245	240	185
BeH^-	θ_1	135	120	120	110	100
	θ_2	265	250	245	240	230
Li^-	θ_1	135	120	110	110	100
	θ_2	270	255	250	245	235
$Fe(CO)_3$	θ_1	135	125	120	115	110
	θ_2	280	270	260	205	195

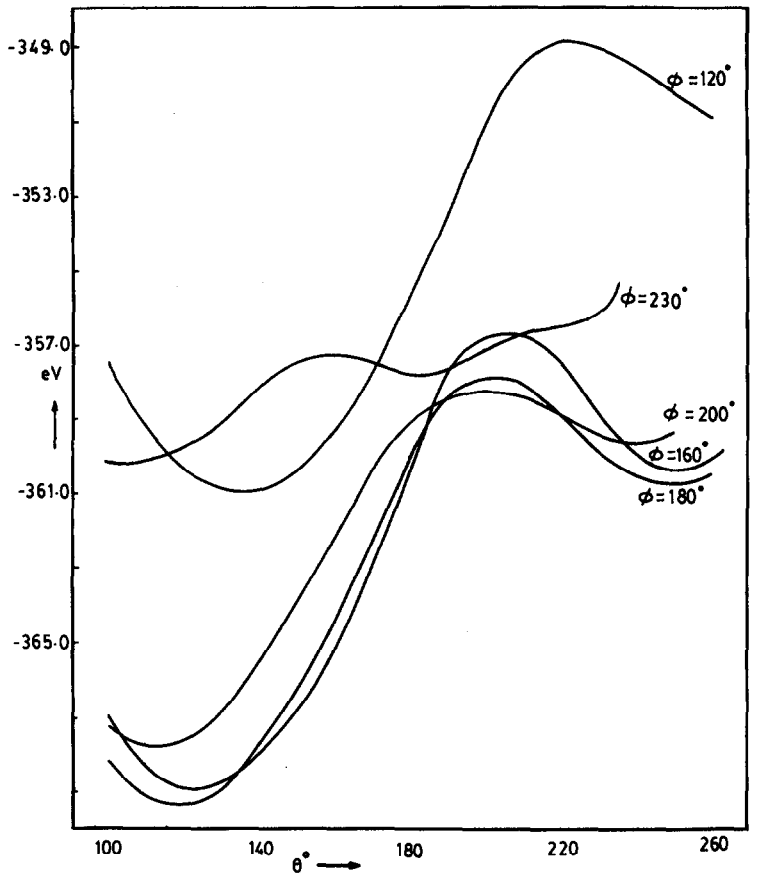


Fig. 1. Total energy plots for the variation of bridging hydrogen positions (θ) for a fixed terminal hydrogen position (ϕ) in B_5H_9 (**6**). ϕ is kept at 120, 160, 180, 200 and 230° and θ is varied from 100 to 260° in 10° intervals.

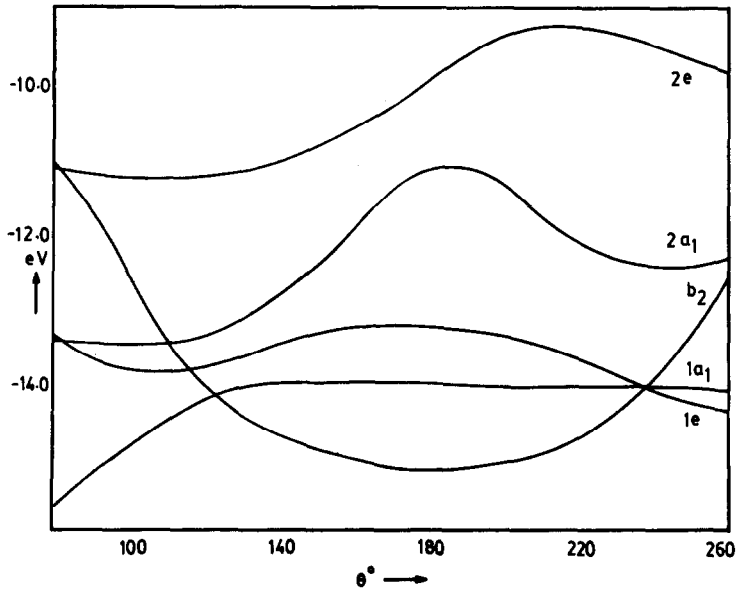

Fig. 2. Walsh diagram for the variation of the bridging hydrogen positions (θ) for a fixed terminal hydrogen position (ϕ) in B_5H_9 (**6**). ϕ is kept at 180°. Only the top five occupied MOs are shown.

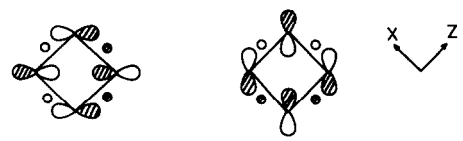
boron atoms increases until θ becomes 180° and then starts decreasing with further increase of θ. Since there is no contribution from the terminal hydrogen atoms in b_2, similar curves are obtained with other values of ϕ. $2a_1$ reproduces the total energy plot closely (**8**). In **8** the bridging hydrogens can interact effectively with the ring p_y orbitals on either side of the node. A shift in the minimum value of θ is brought about by the change in the terminal hydrogen position. When the terminal hydrogen atoms are away from the cap (ϕ = 230°), the bridging hydrogen atoms are calculated to go towards it (X), as judged by the small barrier between the two minima in Fig. 1. This gives an indication that given a cap, which can push the terminal hydrogen atoms sufficiently below the B_4 ring, such as metal fragments, the bridging hydrogen atoms may be observed towards the cap. However, all the known metalloboranes had the terminal B_tH_t bonds bent towards the cap (X) so that the bridging hydrogens were away from the cap (X).[9c]

Calculations were carried out on the model metalloborane $B_4H_8Fe(CO)_3$ (**1d**) for the θ and ϕ values used in B_5H_9. Two minima in θ are found for each value of ϕ (Fig. 3). The minima shifted laterally with increasing values of ϕ (Table 3). An interesting point from the total energy plot is that when ϕ is at 230° [terminal hydrogen atoms away



10, 1e

from the cap $Fe(CO)_3$] the energy minimum corresponded to a θ value (= 195°) where the bridging hydrogen atoms were bent towards the cap. Though such extreme values of ϕ may not be practical, these results along with the MNDO results discussed earlier indicate that the bridging hydrogen positions can be controlled by the terminal hydrogen positions.

Apart from $Fe(CO)_3$, caps from the main group

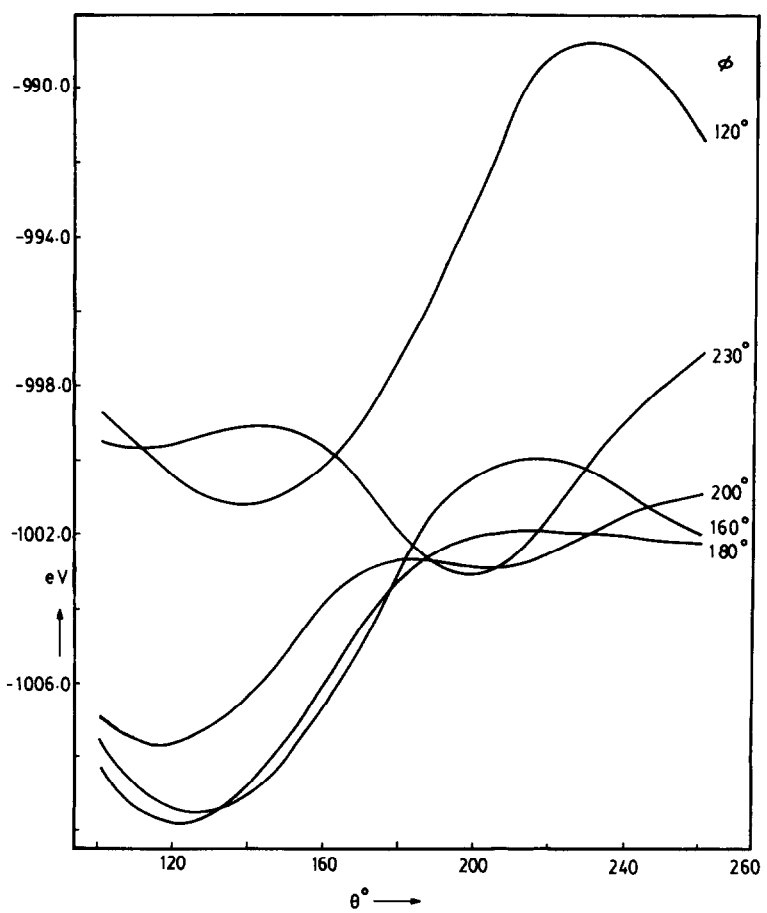


Fig. 3. Total energy plots for the variation of bridging hydrogen positions (θ) for a fixed terminal hydrogen position (ϕ) in $B_4H_8Fe(CO)_3$ (**1d**). ϕ is kept at 120, 160, 180, 200 and 230° and θ is varied from 100 to 260° in 10° intervals.

metals with diffuse orbitals are also tried to see the dependence of bridging hydrogen atoms on the terminal hydrogen positions. Table 3 indicates that two minima are obtained for both $B_4H_8BeH^-$ and $B_4H_8Li^-$. Therefore a smaller ring such as B_3H_6 should show the trend of bridging hydrogen atoms towards the cap (X) more strongly and caps like Li, BeH, $V(CO)_4$ and $Cr(CO)_4$ should also show this trend effectively.

Table 1 also gives the energy difference between the two θ minimum values (θ_1 and θ_2) for B_5H_9, $B_4H_8BeH^-$, $B_4H_8Li^-$ and $B_6H_{11}^+$ obtained from the extended Huckel method. A comparison of this to the $\Delta\Delta H_f$ of MNDO shows that even though the numbers from the extended Huckel method are always high, they follow the trends of MNDO results.

The role of ring size on the interdependence of terminal and bridging hydrogen positions is studied

X BH $Fe(CO)_3$

by changing the B_4 ring to a B_5 ring, $B_6H_{11}^+$ (**11a**), which is known to be a stable species with five bridging hydrogens.[10,5c] The variation of θ for each value of ϕ (160, 170, 180, 190 and 200°) in $B_6H_{11}^+$ (**11a**) gave again two minima. A comparison of the two θ minimum values (θ_1 and θ_2) for B_5H_9 and $B_6H_{11}^+$ showed that the bridging hydrogen atoms tend to occupy lower positions in $B_6H_{11}^+$ in relation to those of B_5H_9 (Table 4). The same trend is shown by the MNDO values (Table 2). This happens only when the terminal hydrogen atoms (H_t) are bent away from the cap. The difference in energy between the two θ minimum values for **11a** is 190.6 kcal mol^{-1} using the extended Huckel method. The corresponding value is found to be 199.1 kcal mol^{-1} with MNDO.

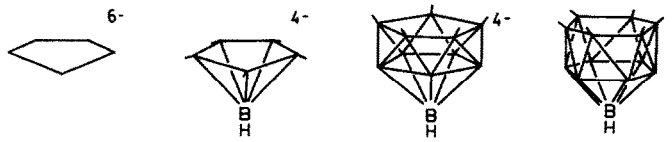
Similarly, calculations were carried out on $B_5H_{10}Fe(CO)_3^+$ (**11b**), obtained by replacing the BH cap in **11a** by $Fe(CO)_3$. Although **11b** is not known experimentally, the neutral derivative $B_5H_9Fe(CO)_3$ is known.[11] Related to this is $B_5H_{10}X$, where X = FeCp. Two isomers are known with this composition where FeCp occupies either the apical (cap) position or a site in the ring.[12] The bridging hydrogen atoms in **11b** are optimized for three values of ϕ (160, 180 and 200°). Again the energy curves show two minima (Table 4).

Table 4. Comparison of the minimum in θ (θ_1 and θ_2) as a function of ϕ (**6**) for the rings B_5H_9 (**6**) and $B_6H_{11}^+$ (**11a**) and $B_4H_8Fe(CO)_3$ (**1d**) and $B_5H_{10}Fe(CO)_3^+$ (**11b**). All values in degrees (obtained at the extended Huckel level)

Molecule	θ	ϕ 160	180	200
B_5H_9 (**6**)	θ_1	120	115	115
	θ_2	255	245	240
$B_6H_{11}^+$ (**11a**)	θ_1	120	110	100
	θ_2	250	240	235
$B_4H_8Fe(CO)_3$ (**1d**)	θ_1	125	120	115
	θ_2	270	260	205
$B_5H_{10}Fe(CO)_3^+$ (**11b**)	θ_1	120	115	105
	θ_2	275	250	240

We now use the above concept for compatibility of orbitals in overlap to find suitable caps for given borane ligands. Since most of the known metalloboranes and carboranes contain five, six, 11 and 13 BR and CR groups, borane ligands in planar (**12**, D_{5h}), pentagonal pyramidal (**13**, C_{5v}), icosahedral (**14**, C_{5v}), the hexagonal antiprismatic (**15**, C_{6v}) forms are chosen for the theoretical study. This involves the optimization of the ring terminal B—H bonds using the extended Huckel method. Since metal fragments (ML_ns) with varying cap orbitals are known, caps with a differing diffuse nature are simulated by changing the CFeC angle, α (**16**), in $Fe(CO)_3$.

The electronic structure of all these anionic ligands shows that the open face of the ligand has five (six in **15**) orbitals with varying hybridization. These are similar to the orbitals of the cyclo-



$B_5H_5^{6-}$ $B_6H_6^{4-}$ $B_{11}H_{11}^{4-}$ $B_{13}H_{13}^{4-}$

12 13 14 15

pentadienyl anion (Cp^-).[13] Their interaction with a metal fragment (ML_n) is also similar to that observed in the metallocenes. The strength of the interaction between the ring and ML_n depends on the extent to which the ring orbitals are hybridized and the size of the ring. For a given ring system, the out-of-plane bending value changes from positive (towards the cap) to negative (away from the cap) with decreasing diffuse nature of the cap. Thus the orbitals of $B_6H_6^{4-}$ (**13**) are splayed out, while those of the icosahedral fragments, $B_{11}H_{11}^{4-}$ (**14**) and $B_{13}H_{13}^{4-}$ (**15**), are bent in. The ring out-of-plane bendings in these ligands (**13–15**) are calculated to be 16.0, −22.6 and −25.0°, respectively, using the extended Huckel method. The value of 22.6° observed for $B_{11}H_{11}^{4-}$ (**14**), which is equal to that found in the icosahedral $B_{12}H_{12}^{2-}$, shows the rigidity of the ligand.

The interaction of these ligands (**12–15**) with the model transition metal fragment $Fe(CO)_3$ is studied while maintaining the CFeC angle α (**16**) at 90°. Combination of the planar $B_5H_5^{6-}$ and $Fe(Co)_3^{2+}$ gives $B_5H_5Fe(CO)_3^{4-}$ (**17**). The calculations gave a B—H bending angle of 13° towards the $Fe(CO)_3$ cap. When a BH^{2+} cap is attached from the second side of **17**, $B_6H_6Fe(CO)_3^{2-}$ (**18**) is obtained. This ion resembles $B_7H_7^{2-}$ (D_{5h}), where the ring hydrogen atoms are in the B_5 plane. In $B_6H_6Fe(CO)_3^{2-}$ (**18**), the ring hydrogen atoms are bent towards the metal cap by a small value, 3°. These two values are different to the optimum B—H bending angle (16°) found for $B_6H_6^{4-}$ (**13**).

$B_{11}H_{11}Fe(CO)_3^{2-}$ (**19**), obtained by the addition of $Fe(CO)_3^{2+}$ to $B_{11}H_{11}^{4-}$ (**14**), provides the opposite extreme to $B_6H_6Fe(CO)_3^{2-}$ (**18**). Calculations on **19** gave a B—H bending angle of 24° towards the $Fe(CO)_3$ cap. This is because with the B_5H_5 ring, $Fe(CO)_3$ preferred the B—H bonds to be bent towards the cap as in $B_5H_5Fe(CO)_3^{4-}$ (**17**). Since the ring hydrogen atoms in $B_{11}H_{11}^{4-}$ (**14**) are bent towards the vacant site by 22.6°, **14** provides it naturally for the incoming cap, $Fe(CO)_3$.

We consider three structures with a six-membered boron ring, $B_7H_7^{4-}$, $B_6H_6Fe(CO)_3^{4-}$ and $B_7H_7Fe(CO)_3^{2-}$, obtained from **13**, **17** and **18** by replacing the five-membered B_5H_5 ring with a B_6H_6 ring. The apical boron–ring boron distance in $B_6H_6^{4-}$ is 1.815 Å (MNDO). This is considerably longer (1.929 Å) in $B_7H_7^{4-}$ at the same level. The trends are similar to those reported using the PRDDO calculations, where the distances are 1.770 and 1.840 Å, respectively, for six- and seven-coordinate boron.[14a] The ring out-of-plane bending is calculated to be 25° (towards the BH cap) at the extended Huckel level. When the apical BH in $B_7H_7^{4-}$ is replaced by $Fe(CO)_3$, the ring out-of-plane angle is found to be 17°, towards the $Fe(CO)_3$ cap. Addition of another BH group from the oppposite side to $B_6H_6Fe(CO)_3^{4-}$ leads to $B_7H_7Fe(CO)_3^{2-}$. Here the ring out-of-plane value is 9° towards the $Fe(CO)_3$ cap at the extended Huckel level. $Fe(CO)_3$ orbitals find a natural match in the $B_{13}H_{13}$ ligand (**15**) as well, which has the BH bonds bent towards the missing apex by 26° as in $B_{13}H_{13}Fe(CO)_3^{2-}$ (**20**). The values indicate the more diffuse nature of the $Fe(CO)_3$ orbitals compared with those of BH. This is reflected in the energies of the following reactions (eqs (1)–(12), $ML_n = Fe(CO)_3$, numbers in parentheses correspond to values obtained with optimized CFeC angles). All the numbers being obtained at the extended Huckel level:

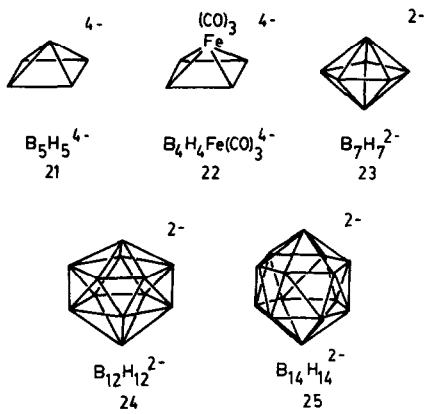
Since $B_{11}H_{11}^{4-}$ and $B_{13}H_{13}^{4-}$ have less diffuse orbitals compared to the $B_6H_6^{4-}$ ligand, they prefer to interact with the group having less diffuse orbitals [BH rather than $Fe(CO)_3$] to form the more stable **24** and **25** [eqs (7)–(12)].[14] Obviously these numbers



which are obtained from the sum of one-electron energies are only approximate. It is possible to change the metal and ligands in the transition metal fragment to give contracted or diffuse frontier orbitals so that the thermodynamics of the above reactions may be shifted in either direction. This is carried out as follows.

Initially the CFeC angle in $Fe(CO)_3$ is kept at 90°. To generate the required diffuse nature of the various metal fragments, the calculations are repeated on **12**–**15** by varying α in **16** but keeping the ring hydrogen atoms at the optimal positions found previously for $\alpha = 90°$. This shows that **12** prefers a metal cap with $\alpha = 99°$, whereas **13** prefers a cap with $\alpha = 103°$. This shows again that **13** prefers a cap with more diffuse orbitals. As anticipated, both **14** and **15** prefer caps with lower α, optimum values being 91 and 80°, respectively. The optimum α value for $B_7H_7Fe(CO)_3^{2-}$ is calculated to be 102° when the ring hydrogen atoms are kept in the boron plane. This indicates that $B_7H_7^{4-}$ in the C_{6v} geometry requires a diffuse metal cap if the ring hydrogen atoms are kept in the plane. The total energy corresponding to this structure is lower than that obtained when the ring hydrogen atoms are 9° towards the $Fe(CO)_3$ cap, even though all the interatomic distances between bonded atoms are kept constant. The numbers in parentheses refer to the values obtained for optimized CFeC angles.

Structural dependence

The differing diffuse nature of the above borane ligands (**13**–**15**) is also reflected in the experimentally observed M–B_r distances in the corresponding metalloboranes. Table 5 compares the

Table 5. M—B_r distances (Å) in metalloboranes and carboranes (**17–20**) available from X-ray data

Molecule	Fe—B	Reference
Five-atom ligand.		
$(CO)_3FeC_2B_3H_7$ (**17**)	2.125	15
Six-atom ligand,

Thirteen-atom ligand,		
$Cp_2Fe_2C_4B_8H_8Me_4$ (**20**)	2.106	18

M—B_r distances obtained from the X-ray diffraction data available in the literature for a given metal (Fe) with varying ligand sizes. The M—B_r distances are 2.125 Å in $(CO)_3FeC_2B_3H_7$,[15] 2.145 Å in $(CO)_3FeC_2B_4H_4Me_2$,[16] 2.090 Å in $CpFeC_2B_9H_{11}$[17] and 2.106 Å in $Cp_2Fe_2C_4B_8H_8Me_4$.[18] The longest distance (2.145 Å) is found with the $C_2B_4H_4Me_2$ ligand, which is the equivalent of **13**. The shorter values are found in $CpFeC_2B_9H_{11}$ (2.090 Å) and $Cp_2Fe_2C_4B_8H_8Me_4$ (2.106 Å), which are, respectively, equivalent to $B_{11}H_{11}^{4-}$ and $B_{13}H_{13}^{4-}$ ligands. The above analysis shows that ligand **13** prefers more diffuse caps, whereas both ligands **14** and **15** prefer caps with less diffuse orbitals. Since the ring *p*-orbitals are bent away from the vacant site in the B_5 ring of $B_6H_6^{4-}$, the distance between the ring and the cap will become longer in $(CO)_3FeC_2B_4H_4Me_2$. The reverse will be true with $B_{11}H_{11}^{4-}$ and $B_{13}H_{13}^{4-}$ ligands, which makes the ring to cap distance smaller in $CpFeC_2B_9H_{11}$ and $Cp_2Fe_2C_4B_8H_8Me_4$, which are in accordance with the predictions. Since structural data for all the borane ligands (**12–15**) with the same metal are not available, a comparison of the above mentioned could not be made for other metals. The basic idea that the bond distances between atoms would be short for optimal ring–cap interactions holds good in the examples known exprimentally.

Topological charge stabilization

According to the concept of topological charge stabilization,[8] when a more electronegative heteroatom is to be placed in a homoatomic ring system, it prefers the site of larger electron density. For example, $C_2B_5H_7$ can have four possible isomers in the pentagonal bipyramidal form, viz. 1,2-, 1,7-, 2,3- and 2,4-derivatives. Based on the charges in the isoelectronic reference C_6N^-, it is found that 2,4-positions carried more electron density. These two positions are occupied by the contracted CH groups in the most stable 2,4-isomer. BH groups with more diffuse orbitals than CH occupy the less negative 1,7-positions. This shows that diffuse nature and electropositive character go together. Since $Fe(CO)_3$ has more diffuse orbitals than BH, it would prefer to occupy more positive sites rather than BH.

To find out the relative positions of BH and $Fe(CO)_3$ caps in metalloboranes, the charges in various positions of the ligands $B_6H_6^{4-}$ (**13**), $B_6H_6Fe(CO)_3^{2-}$ (**18**), $B_{11}H_{11}Fe(CO)_3^{2-}$ (**19**) and $B_{13}H_{13}Fe(CO)_3^{2-}$ (**20**) are compared. In $B_6H_6^{4-}$ (**13**) the apical BH carries less negative charge (−0.14) than the remaining centres in the ring (−0.77). Therefore in pyramidal metalloboranes of the composition $B_5H_5ML_n$ the metal fragment (ML_n) would occupy the apical (cap) position, which is in agreement with experimental observations. In $B_6H_6Fe(CO)_3^{2-}$ (**18**) the apical BH position opposite to $Fe(CO)_3$ carries more positive charge (0.09) than the remaining centres in the ring (−0.24). A second metal fragment (ML_n) therefore may occupy that site. This explains the observation of 1,7-$Cp_2Co_2C_2B_3H_4Me$[19] and 1,7-$Cp_2Co_2C_2B_3H_3(\mu\text{-}C_3H_4)$.[20] Even though the apical BH position in $B_{11}H_{11}Fe(CO)_3^{2-}$ (**19**) carries less negative charge (−0.10) than the five BHs which are above it (−0.12, −0.13), it carries more charge than the top five BHs (−0.08, −0.11). However, the differences in the charges are much smaller than that discussed earlier with **13** and **18**. Therefore for the second metal fragment (ML_n) to occupy a site in **19**, we anticipate the various isomers not to differ in energy by large amounts. Again the apical BH position in $B_{13}H_{13}Fe(CO)_3^{2-}$ (**20**) carries less negative charge (−0.005) than the remaining centres (−0.14). Thus we can explain the formation of the complex $Cp_2Fe_2C_4B_8H_8Me_4$ with two CpFe caps in the apical positions.[18]

CONCLUSIONS

Metalloboranes with terminal (H_t) and bridging hydrogen atoms (H_b), as shown in **1–4**, are studied theoretically to understand the dependence of the positions of the bridging hydrogen atoms on those of the terminal hydrogen atoms. Model studies on B_5H_9 (**6**) showed that terminal hydrogen atoms do control the bridging hydrogen positions and predicted that bridging hydrogen atoms might be observed above the B_n plane (towards the cap) for caps with diffuse orbitals. Calculations on $B_4H_8Fe(CO)_3$ (**1d**), $B_4H_8BeH^-$ (**1b**) and $B_4H_8Li^-$ (**1c**) supported these ideas. The bridging hydrogen atoms in $B_4H_8Fe(CO)_3$ (**1d**) are found to be bent towards the cap atom when the terminal hydrogen atoms are below the B_4 ring.

Ring–cap overlap criterion is used to find suitable metal fragments for borane ligands with five, six, 11 and 13 vertex boron atoms. Hapto-five ligands such as $B_6H_6^{4-}$ (**13**) and $B_{11}H_{11}^{4-}$ (**14**) have very different orbitals arising from the varying terminal BH bond directions. This leads to the preference of $B_6H_6^{4-}$ (**13**) for metal caps with diffuse orbitals. Both $B_{11}H_{11}^{4-}$ (**14**) and $B_{13}H_{13}^{4-}$ (**15**) preferred caps with less diffuse orbitals because of the rigidity of the ligands. This results in longer M—B_r with $B_6H_6Fe(CO)_3^{2-}$ (**18**) and shorter M—B_r with $B_{11}H_{11}Fe(CO)_3^{2-}$ (**19**) and $B_{13}H_{13}Fe(CO)_3^{2-}$ (**20**). The experimentally known M—B_r distances varied accordingly. The variations of the metal–boron (M—B_r) distances in polyhedral metalloboranes can be understood from the directionality of the orbitals of the polyhedral ligand. Using the concept of topological charge stabilization we found that metal fragments (ML_n) occupy positions of less negative charge in metalloboranes. Accordingly a second ML_n should occupy the apical position (opposite to the first ML_n) in **18** and **20**, whereas in **19** the preference is not clear cut.

APPENDIX

The parameters for all the atoms used in the extended Huckel calculations are taken from previous studies: C, H, O, B, Be, Li[7] and Fe[21]. In B_5H_9 (**6**), B_r—B_r, B_r—X, B_r—H_t and B_r—H_b distances are kept at 1.800, 1.700, 1.230 and 1.360 Å, respectively. In $B_4H_8Fe(CO)_3$ (**1d**), the B_r—Fe distance is kept at 2.000 Å. Other distances involving the $Fe(CO)_3$ ligand are Fe—C = 2.000 Å and C—O = 1.150 Å. Fixed B_r—B_r and B_r—B_a (apical boron) of 1.770 Å and B—H = 1.150 Å are used in **12–15**. In **15**, B_r—B_a is kept at 1.86 Å. B_r—Fe is kept at 2.160 Å in **17–20**. The CFeC angle, α, in **16** is varied to simulate orbitals of different diffuse nature. The B_r—Li and B_r—Be distances are kept at 2.200 and 1.860 Å, respectively, in $B_4H_8Li^-$ and $B_4H_8BeH^-$.

STUDIES ON RARE EARTH COMPLEXES WITH CROWN ETHERS—XIX. SYNTHESIS AND CHARACTERIZATION OF THE COMPLEXES OF LANTHANIDE THIOCYANATES WITH DIBENZO-24-CROWN-8

LU TONGBU, GAN XINMIN, TANG NING and TAN MINYU*

Department of Chemistry, Lanzhou University, Lanzhou 730000, P.R.C.

(*Received* 20 *March* 1990; *accepted* 11 *May* 1990)

Abstract—The lanthanide thiocyanate complexes with DB24C8 have been prepared in acetonitrile medium. These new complexes with the general formula $[Ln(SCN)_3 \cdot DB24C8 \cdot 2H_2O \cdot CH_3CN]$ (Ln = La–Nd, Sm–Lu) have been characterized by elemental analysis, IR spectra, conductivity measurements and TG–DTA techniques. In the complexes, the ligand DB24C8, the thiocyanate groups and the water molecules are all coordinated to the metal ions.

Many rare earth–crown ether complexes have been investigated in recent years.[1–8] The previous research work was concentrated on some crown ethers with a relatively small cavity such as 12-crown-4, 15-crown-5 and 18-crown-6 as well as their derivatives,[2–7] while the rare earth complexes with larger cavity crown ethers were little reported.[8] In order to investigate the coordinating power of a large cavity crown ether with rare earth ions, we have recently synthesized the solid complexes of lanthanide thiocyanates with DB24C8, and investigated the composition and properties of these new complexes.

EXPERIMENTAL

Reagents

Hydrated lanthanide thiocyanates were prepared by the literature method.[9] DB24C8 was obtained from Shanghai Reagent Company and purified by recrystallization from ethanol before using, m.p. = 101.5–102.0°C.

Chemical and physical measurements

The metal ion was determined by EDTA titration using Xylenol-orange as an indicator. Carbon, nitrogen and hydrogen were determined using a Carlo Erba 1106 elemental analyser. The IR spectra were recorded in the 4000–200 cm^{-1} region using KBr pellets and a 170 SX FTIR spectrometer. Thermal analyses (TG and DTA) were performed on a Beijing PcT-2 thermobalance. The heating rate was 10°C min^{-1}. Conductivity measurements were carried out with a DDS-11A type conductivity bridge for freshly prepared solutions in acetone at 25°C.

Preparation of the complexes

A solution of 0.2 mmol $Ln(SCN)_3 \cdot xH_2O$ in 3 cm^3 of acetonitrile was added dropwise to a solution of 0.2 mmol DB24C8 in 4 cm^3 of acetonitrile. The mixture was stirred at room temperature for 24 h. The precipitated solid complex was filtered, washed with acetonitrile and diethyl ether, respectively, and dried in a desiccator (0.1 mmHg) over P_4O_{10} for 48 h. All the complexes are powdered solids with the characteristic colour of the corresponding lanthanide thiocyanates.

RESULTS AND DISCUSSION

The composition of the complexes

The analytical data for the newly synthesized complexes, listed in Table 1, indicate that all of the 14 complexes conform to a 1:1 stoichiometry of metal ion and crown ether.

[a] L = DB24C8.

IR spectra

The most important IR peaks of the ligand and the complexes are reported in Table 2.

Compared with the free ligand, the absorptions of ν(Ar—O—R) and ν(R—O—R) of the complexes showed shifts towards lower wavenumbers. This provides evidence for the coordination of the crown ether with the metal ions. In addition, new bands, absent in the IR spectrum of the free ligand, are present in the 388–399 cm^{-1} region, which may be assigned to the ν(M—O_{crown}) stretching frequency.[8]

The IR absorptions of ν(CN), ν(CS) and δ(NCS) of the thiocyanate groups are present in the 2044–2058, 794–810 and 477–490 cm^{-1} regions, respectively, which suggests that the thiocyanate groups in the complexes are coordinated to the metal ions through the nitrogen atoms,[10] while the absence of absorptions near 2100, 700 and 420 cm^{-1} indicates that the sulphur atoms in the thiocyanate groups are not bonded to the metal ions.

In all the IR spectra of the complexes, strong bands which appear near 3400 and 1650 cm^{-1} are clearly due to ν(OH) and δ(HOH), respectively. Additionally, weak bands assigned to ρ_r(HOH) are found near 604 cm^{-1}, providing evidence that the water molecules in the complexes are also coordinated to the metal ions.[10] The presence of weak bands in the range 2250–2280 cm^{-1} due to ν[CN(CH_3CN)] suggests that the acetonitrile molecules in the complexes are not coordinated with the metal ions.[5]

Thermal analyses

The thermal analysis studies were performed by means of TG and DTA techniques. The thermal analytical data for some of the complexes are summarized in Table 3.

[a] The ν(CN) of the thiocyanate groups.
[b] The ν(CN) of the acetonitrile molecules.

Table 3. Thermal analytical data of some of the complexes

Compound	Endothermic peaks (°C)	Exothermic peaks (°C)	Total weight loss (%) Found	Calc.[a]
$La(SCN)_3 \cdot L \cdot 2H_2O \cdot CH_3CN$	126, 222	302, 494, 564	74.60	75.81
$Gd(SCN)_3 \cdot L \cdot 2H_2O \cdot CH_3CN$	121, 203	293, 478, 547	76.32	74.18
$Lu(SCN)_3 \cdot L \cdot 2H_2O \cdot CH_3CN$	104, 189	296, 466, 544	72.22	72.68

[a] Calculated weight loss for the change from the complexes to $Ln_2O_2SO_4$.
Ln = La, Gd, Lu.

The complexes of lanthanum, gadolinium and lutetium lose one acetonitrile molecule and two water molecules when heated to 126, 121 and 104°C, respectively. The weight losses found in this process are 8.82, 8.95 and 8.77%, respectively (Calc. 8.70, 8.82 and 8.34%, respectively).

After the loss of one acetonitrile molecule and two water molecules the three complexes melted when heated to 222, 203 and 189°C, respectively. In this process a small endothermic peak appeared in the DTA curve but no weight loss occurred in the TG curve of each complex. On raising the temperature further, the three complexes decomposed exothermically at 302, 293 and 296°C, respectively. After this other exothermic peaks and continuous weight loss were detected up to 850°C. At this temperature $Ln_2O_2SO_4$ (Ln = La, Gd and Lu) is formed.[11] The total weight loss found was approximately consistent with that calculated (Table 3). The DTA–TG curves of the other complexes are similar to those of the three complexes discussed above.

Solubility and molar conductance

All the complexes are sparingly soluble in benzene, chloroform and nitromethane, slightly soluble in water, methanol, ethanol and acetonitrile, and much more soluble in acetone, ethylacetate and tetrahydrofuran. The molar conductance values of the complexes measured in acetone at 25°C lie in the range 8.2–18.6 Ω^{-1} cm^2 mol^{-1} (Table 1), indicating that all the complexes are non-electrolytes.[12] This indicates that all the thiocyanate groups in the complexes are held in the coordination sphere.

From the data discussed above, it can be concluded that the large cavity crown ether DB24C8 can react with lanthanide thiocyanates in acetonitrile medium to form stable solid complexes, in which the ligand DB24C8, thiocyanate groups

and water molecules are coordinated to the metal ions, and therefore the correct molecular formula of the new prepared complexes should be $[Ln(DB24C8)(H_2O)_2(SCN)_3]\cdot CH_3CN$.

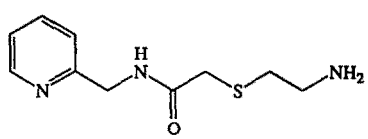
(*Received* 29 *March* 1990; *accepted* 16 *May* 1990)

Abstract—The preparations of complexes of type [Cu(pyge)X] and [Cu(pyge)(OH_2)]BF_4, where pygeH is *N*-[(2-pyridyl)methyl]-2-[(2-aminoethyl)thio]acetamide and X is Br, N_3, NCO, NCS, $OC_6H_4NO_2$-*p*, and NO_2, are described. The new complexes have been characterized by elemental analysis, IR and electronic spectroscopy, magnetic moment, and in two cases (X = Br and $OC_6H_4NO_2$-*p*), EPR spectroscopy. The available data suggest that the complexes are of tetragonal, probably square pyramidal geometry in solution. X-ray structural analyses of [Cu(pyge)Br] (**1**) and [Cu(pyge)N_3] (**2**) were undertaken. Complex **1** crystallized in the monoclinic space group $P2_1/n$, $a = 9.676(2)$, $b = 9.147(2)$, $c = 15.171(3)$ Å, $\beta = 106.73(2)°$, $V = 1286.0(5)$ Å^3, $Z = 4$. Refinement was based on 1594 reflections and converged at $R = 0.059$, $R_w = 0.058$. Complex **2** crystallized in the monoclinic space group $P2_1/c$, $a = 9.925(2)$, $b = 9.354(3)$, $c = 15.141(4)$ Å, $\beta = 106.96(2)°$, $V = 1344.3(6)$ Å^3, $Z = 4$. Refinement was based on 1196 reflections and converged at $R = 0.065$, $R_w = 0.065$. The geometry of the complexes is best described as very slightly distorted square pyramidal, with the terminal amino group of the tetradentate ligand occupying the apical site. Origins of the observed stereospecificity and structural comparisons to octahedral [Co(pyge)$(NO_2)_2$] are discussed.

The study of the factors affecting the stereochemistry of copper(II) coordination compounds has been an area of intense research.[1–3] Part of this interest stems from attempts to model the copper-containing active sites in metalloproteins.[2–5] The copper(II) ion can accommodate a large range of coordination geometries.[1–3] This pliant ability of copper(II) has been likened to a kind of "plasticity" which is apparently overcome by the rigid tertiary structures of proteins to bind this ion in a specific geometry for a particular biological function.[1]

Recently, we have been investigating octahedral cobalt(III) coordination complexes containing stereospecific, linear NSNN tetradentate ligands, such as *N*-[(2-pyridyl)methyl]-2-[(2-aminoethyl) thio]acetamide (pygeH).[6–8] The ligand pygeH,



pygeH

after deprotonation, is designed to adopt the *cis*-β or unsymmetrical-*cis* geometry in octahedral compounds of type [Co(pyge)X_2].[6,8] The stereochemical control derives from the nature of the internal ligating atoms in the chelating ligand. The thioether atom shows a strong preference for pyramidal coordination when it is at the pivot point of two five-membered chelate rings in which the other donors are nitrogen or oxygen.[9] On the other hand, the deprotonated amide donor maintains planarity about that site.[10] In the course of our studies, it became of interest to apply this versatile ligand to a labile, stereochemically non-rigid situation as

typified by the copper(II) ion. In this contribution, we wish to report upon the preparation and characterization of a series of novel five-coordinate complexes, [Cu(pyge)X], where X is a monodentate uninegative ligand, as well as $[Cu(pyge)(OH_2)]BF_4$. In addition, we have structurally characterized the complexes with X being either Br or N_3 in order to establish the solid-state stereochemistry and to make comparisons to the previously presented structure of octahedral $[Co(pyge)(NO_2)_2]$.[6]

EXPERIMENTAL

Materials and methods

Electronic spectra were determined on dilute *N,N*-dimethylformamide (DMF) or aqueous solutions using a Shimadzu UV-160 spectrophotometer at ambient temperature. Molar absorptivity coefficients are reported in $mol^{-1}\ dm^3\ cm^{-1}$. Room temperature magnetic susceptibilities were measured on a Johnson–Matthey susceptometer. Magnetic moments were calculated using literature diamagnetic corrections.[11] IR spectra were recorded from compressed KBr pellets using a Perkin–Elmer 1600 Series FT–IR spectrometer. Frozen EPR spectra were determined on glassy DMF/CH_2Cl_2 solutions at −196°C utilizing a Varian E-4 spectrometer calibrated with the diphenyl picryl hydrazyl radical. Room temperature EPR spectra in DMF solution were obtained in a special flat cell in order to minimize the dielectric effect of the solvent. Elemental analyses were determined by Atlantic Microlabs Inc. (Atlanta, Georgia).

Preparation of compounds

Unless otherwise noted, all starting materials and solvents were obtained from standard sources and used without further purification.

N-[(2-*Pyridyl*)*methyl*]-2-[(2-*aminoethyl*)*thio*]*acetamide dihydrobromide* (pygeH·2HBr)

The ligand was prepared via the literature method.[6] IR (KBr): 3226 (m), 3164 (m), 2865 (s), 1655 (s), 1612 (s), 1526 (s), 1484 (m), 1461 (s), 1421 (m), 1384 (w), 1372 (w), 1266 (m), 1249 (m), 1162 (w), 1102 (w), 1090 (w), 1078 (w), 1043 (w), 1027 (m), 958 (vw), 907 (vw), 893 (vw), 803 (w), 764 (m), 737 (w), 663 (vw), 558 (vw), 482 (vw).

[Cu(pyge)Br] (1)

Sodium metal (0.144 g, 6.3 mmol) was dissolved carefully in absolute ethanol (60 cm^3). Then pygeH·2HBr (1.20 g, 3.1 mmol) was added. After dissolution of the ligand, copper(II) acetate monohydrate (0.62 g, 3.1 mmol) was added. The suspension was stirred for 2 h and then the green precipitate was collected by filtration. The crude product was taken up in a minimum amount of water (*ca* 18 cm^3) and filtered. The filtrate was set aside for concentration and crystallization, giving 0.79 g (69.3%) of bright green product. Found: C, 32.6; H, 3.8; N, 11.4. Calc. for $C_{10}H_{14}BrCuN_3OS$: C, 32.7; H, 3.8; N, 11.4%. UV–vis (DMF): λ_{max} 673 (ε 170), 356 nm (ε 2300); $\mu_{eff} = 2.1$ BM; IR (KBr): 3324 (m), 3246 (m), 3150 (m), 2950 (m), 2894 (m), 2853 (m), 1605 (br s), 1583 (vs), 1566 (vs), 1484 (m), 1448 (m), 1423 (m), 1406 (m), 1390 (s), 1346 (w), 1285 (m), 1218 (m), 1159 (w), 1097 (w), 1052 (w), 1025 (m), 963 (m), 915 (s), 830 (m), 769 (s), 720 (w), 617 (w), 486 (m).

$[Cu(pyge)N_3]$ (2)

[Cu(pyge)Br] (0.20 g, 0.54 mmol) and sodium azide (0.175 g, 2.7 mmol) were added to water (7 cm^3). The solution was stirred for 2 h. Upon slow evaporation of the solvent, a pure dark green crystalline product was obtained (0.12 g, 67.4%). Found: C, 36.4; H, 4.3; N, 25.4. Calc. for $C_{10}H_{14}CuN_6OS$: C, 36.4; H, 4.3; N, 25.5%. UV–vis (DMF): λ_{max} 643 (ε 270), 389 nm (ε 4300), 360 (sh); $\mu_{eff} = 1.9$ BM; IR (KBr): 3322 (m), 3245 (m), 3155 (m), 2954 (w), 2900 (w), 2858 (w), 2057 (vs), 1609 (s), 1593 (vs), 1584 (vs), 1567 (vs), 1485 (m), 1404 (s), 1388 (s), 1346 (m), 1281 (m), 1217 (m), 1093 (vw), 1051 (w), 1026 (w), 972 (m), 919 (m), 827 (m), 765 (s), 720 (w), 620 (vw), 491 (w).

[Cu(pyge)NCO] (3)

[Cu(pyge)Br] (0.20 g, 0.54 mmol) and potassium cyanate (0.050 g, 0.62 mmol) were added to water (7 cm^3). After stirring the mixture for 2 h, the royal blue microcrystalline product that deposited was collected and dried (0.10 g, 73.9%). Found: C, 40.1; H, 4.3; N, 17.0. Calc. for $C_{11}H_{14}CuN_4O_2S$: C, 40.0; H, 4.3; N, 17.0%. UV–vis (DMF): λ_{max} 663 (ε 200), 354 nm (ε 2400); $\mu_{eff} = 1.9$ BM; IR (KBr): 3346 (m), 3247 (m), 3161 (m), 2950 (w), 2895 (w), 2859 (w), 2230 (vs), 1609 (vs), 1594 (vs), 1584 (vs), 1567 (vs), 1484 (m), 1443 (w), 1421 (m), 1406 (m), 1391 (s), 1346 (w), 1325 (m), 1280 (w), 1216 (w), 1154 (vw), 1093 (vw), 1050 (w), 1025 (w), 974 (w), 919 (m), 832 (m), 762 (s), 720 (w), 608 (w), 494 (w).

[Cu(pyge)NCS] (**4**)

[Cu(pyge)Br] (0.20 g, 0.54 mmol) and sodium thiocyanate (0.051 g, 0.63 mmol) were added to water (7 cm^3). After stirring the mixture for 2 h, the crude blue–green powder was collected. This material was recrystallized by dissolving it in boiling water (30 cm^3) and adding sodium thiocyanate (0.45 g) to the cooled solution. The blue–green microcrystalline product was collected, washed with cold water (5 cm^3), and dried (0.10 g, 70.5%). Found: C, 37.6; H, 4.0; N, 16.1. Calc. for $C_{11}H_{14}CuN_4OS_2$: C, 38.2; H, 4.1; N, 16.2%. UV–vis (DMF): λ_{max} 643 (ε 230), 362 nm (ε 2600); μ_{eff} = 1.9 BM; IR (KBr): 3300 (m), 3270 (m), 3167 (m), 2888 (vw), 2086 (vs), 1609 (vs), 1582 (vs), 1561 (vs), 1483 (m), 1405 (m), 1394 (s), 1342 (w), 1282 (w), 1227 (m), 1212 (w), 1145 (m), 1086 (vw), 1048 (w), 1028 (m), 970 (vw), 930 (vw), 894 (vw), 767 (s), 717 (vw), 637 (vw), 493 (w).

[Cu(pyge)($OC_6H_4NO_2$-*p*)] (**5**)

$AgNO_3$ (0.070 g, 0.41 mmol) was added to a solution of [Cu(pyge)Br] (0.15 g, 0.41 mmol) in H_2O (5 cm^3). The mixture was stirred for 15 min and filtered through Celite filtering aid to give a deep blue filtrate. Sodium *p*-nitrophenoxide (0.066 g, 0.41 mmol) was added to the filtrate. The resulting green solution was stirred for 2 h and allowed to go to dryness overnight. The sticky residue was triturated with methanol (3 cm^3) to give 0.11 g (60.4%) of dark green product which analysed as the monohydrate. Found: C, 43.4; H, 4.5; N, 12.6. Calc. for $C_{16}H_{20}CuN_4O_5S$: C, 43.3; H, 4.5; N, 12.6%. UV–vis (DMF): λ_{max} 673 (ε 220), 431 nm (ε 18,400); μ_{eff} = 1.9 BM; IR (KBr): 3359 (m), 3295 (m), 2870 (vw), 1607 (s), 1582 (vs), 1565 (vs), 1492 (s), 1462 (m), 1428 (w), 1404 (m), 1385 (m), 1351 (w), 1305 (vs), 1289 (vs), 1274 (vs), 1215 (w), 1171 (m), 1110 (s), 1050 (w), 1040 (w), 1023 (w), 1010 (w), 953 (w), 914 (m), 846 (m), 825 (w), 774 (m), 758 (m), 722 (w), 701 (w), 655 (m), 646 (m), 551 (w), 520 (w), 496 (vw), 466 (w).

[Cu(pyge)(NO_2)] (**6**)

A solution containing [Cu(pyge)(OH_2)]NO_3 (0.41 mmol in 5 cm^3 of water) was prepared as above in the synthesis of **5**. To this solution was added sodium nitrite (0.056 g, 0.82 mmol). The solvent was allowed to evaporate overnight and the residue was triturated with methanol (2 cm^3) to give 0.055 g (40%) of the dark green product. Found: C, 35.1; H, 4.1; N, 16.5. Calc. for $C_{10}H_{14}CuN_4O_3S$: C, 36.0; H, 4.2; N, 16.8%. UV–vis (DMF): λ_{max} 632 (ε 170), 354 nm (ε 2800); μ_{eff} = 1.9 BM; IR (KBr): 3298 (m), 3262 (w), 3163 (w), 2963 (vw), 2908 (vw), 2857 (w), 1609 (s), 1588 (vs), 1566 (vs), 1487 (m), 1450 (m), 1393 (s), 1354 (s), 1328 (s), 1290 (m), 1218 (w), 1163 (w), 1100 (vw), 1052 (vw), 1022 (w), 977 (w), 924 (w), 830 (w), 769 (m), 720 (w), 673 (vw), 645 (vw), 620 (vw), 491 (m), 472 (w).

[Cu(pyge)(OH_2)]BF_4 (**7**)

A solution containing [Cu(pyge)(OH_2)]NO_3 (0.41 mmol in 5 cm^3 of water) was prepared as above in the synthesis of **5**. To this solution was added sodium tetrafluoroborate (0.045 g, 0.41 mmol). After filtration, the solvent was allowed to concentrate to small volume to give 0.025 g (16%) of the very water-soluble blue product. Found: C, 30.8; H, 4.1. Calc. for $C_{10}H_{16}BCuF_4N_3O_2S$: C, 30.6; H, 4.1%. UV–vis (DMF): λ_{max} 607 (ε 200), 357 nm (ε 2300); IR (KBr): 3449 (br m), 3378 (m), 3307 (w), 1612 (vs), 1582 (vs), 1560 (vs), 1495 (w), 1415 (s), 1390 (s), 1346 (w), 1336 (w), 1251 (vw), 1213 (w), 1057 (s), 1026 (s), 961 (vw), 834 (vw), 771 (m), 718 (w), 552 (w), 477 (w).

Crystal structure analysis and refinement

Single crystals of compounds **1** and **2** suitable for X-ray diffraction studies were grown by concentration of saturated aqueous solutions at ambient temperature. A Nicolet R3m diffractometer in the θ–2θ mode with variable scan speed (3.0–20.0° min^{-1}) and graphite monochromated Mo-K_α (λ = 0.71073 Å) radiation was used to measure 2282 and 2332 unique reflections with $0 \leqslant 2\theta \leq 50°$, of which 1594 and 1196 reflections with $|F_o| > 6\sigma|F_o|$ were considered to be observed for **1** and **2**, respectively. Data were corrected for background, attenuators, Lorentz and polarization effects in the usual fashion, but not for absorption.[12] The structure of complex **1** was refined (with all non-hydrogen atoms anisotropic) to R = 0.059 and R_w = 0.058. In the case of complex **2**, difference Fourier maps indicated that the coordinated azide ligand was disordered. The disorder was successfully interpreted by assuming a model with two equally populated orientations of the azide group, approximately related by a 180° rotation around an axis passing through the copper atom and the central nitrogen atom of the azide ligand. Refinement of the structure of **2** (with all non-hydrogen atoms anisotropic, except the azide nitrogens) then proceeded to R = 0.065 and R_w = 0.065. Crystal data are summarized in Table 1. Atomic coordinates, full tables of bond lengths and angles, isotropic and aniso-

RESULTS AND DISCUSSION

The reaction of pygeH·2HBr with $Cu(CH_3COO)_2 \cdot H_2O$ in basic ethanol solution, followed by recrystallization of the crude product from aqueous solution, led to the isolation of green air-stable [Cu(pyge)Br] (**1**) in good yield. Previously, it had been reported that pygeH·2HCl and $CuCl_2 \cdot 2H_2O$ in neutral ethanol solution gave square planar [Cu(pygeH)Cl]·2HCl, in which the terminal amino group is protonated and non-coordinating.[13] In the present instance, we have isolated only the neutral five-coordinate complex **1** (*vide infra*).

The bromide ligand of complex **1** can be substituted to give [Cu(pyge)X] either by direct metathesis with a suitable sodium or potassium salt [X = N_3 (**2**), NCO (**3**), NCS (**4**)] or via [Cu(pyge)(OH_2)]NO_3 prepared *in situ* from **1** and $AgNO_3$ [X = $OC_6H_4NO_2$-*p* (**5**) or NO_2 (**6**)]. The very water-soluble [Cu(pyge)(OH_2)]$^+$ cation could be isolated with some difficulty as the BF_4^- salt, **7**.

The IR vibrational spectra of the new series of complexes are essentially as expected. In all cases, moderately intense N—H stretches appear in the 3200–3350 cm^{-1} range. The C—H stretches diminish somewhat in intensity upon coordination and the deprotonated amide carbonyl stretch moves to lower energy. The pseudo-halide complexes **2–4** exhibit strong absorptions in the cumulated and triple bond region of their spectra.[14] The NCO group in **3** is likely N-bound with the symmetric and asymmetric stretches appearing at 2230 and 1325 cm^{-1}, respectively.[14,15] The determination of the coordination mode of the NCS group in **4** is more problematic; we have tentatively assigned the N-bound structure based upon electronic spectral data (*vide infra*). Complexes **5** (1275–1300 cm^{-1}), **6** (1354 and 1328 cm^{-1}) and **7** (3449 and 1025–1060 cm^{-1}) display absorptions in the expected regions for *p*-nitrophenolato, nitro, coordinated water and uncoordinated BF_4^- groups, respectively.[14]

The new copper(II) complexes are relatively soluble in DMF, giving solutions that are similar in colour to the original solid compound. The electronic spectra of [Cu(pyge)X] recorded in this solvent consist of one broad *d–d* band in the 630–675 nm range ($\varepsilon \sim$ 170–270 mol^{-1} dm^3 cm^{-1}) and a charge-transfer band at about 355–360 nm ($\varepsilon \sim$ 2500 mol^{-1} dm^3 cm^{-1}). The latter band, which is relatively invariant as a function of X ligand, can be assigned to $S(\sigma) \rightarrow Cu(d_{x^2-y^2})$ ligand-to-metal charge-transfer (LMCT).[16–18] The energy of the *d–d* band is consistent with a tetragonal,[19,20] probably five-coordinate structure with no apparent "intensity borrowing" from the LMCT band.[16] The energy of the *d–d* transition roughly follows the order expected from the spectrochemical series with $Br^- = p\text{-}NO_2C_6H_4O^- < NCO^- < N_3^- = NCS^- < NO_2^-$.[21] We have assigned the N-bound coordination mode to the NCS^- ligand in complex **4**, since its *d–d* transition occurs at the same energy as that for the azido complex, **2**. Complex **2** has an additional absorption at 389 nm ($\varepsilon \sim$ 4300 mol^{-1} dm^3 cm^{-1}) which is associated with azido-to-copper LMCT.[21] Although complex **5** is isolated as a monohydrate, we believe that the *p*-nitrophenolato group is bound to the copper ion, since the *d–d* transition for **5** in DMF occurs at considerably different energy than that for the aquo complex, **7**. Complex **5** also has a relatively intense absorption at 431 nm ($\varepsilon \sim$ 18,400 mol^{-1} dm^3 cm^{-1}) which can be assigned to phenolato-to-copper LMCT.[22,23]

On the other hand, in *dilute* aqueous solution, complexes **1–6** all form blue solutions that give virtually identical electronic absorptions at about 594 ± 3 nm ($\varepsilon \sim$ 200 mol^{-1} dm^3 cm^{-1}) and 330 nm ($\varepsilon \sim$ 3600 mol^{-1} dm^3 cm^{-1}) that are completely analogous to those of the independently prepared aquo complex **7** [594 nm (ε 160 mol^{-1} dm^3 cm^{-1}) and 329 nm (ε 3500 mol^{-1} dm^3 cm^{-1})]. These results suggest that the X ligand in [Cu(pyge)X] dissociates in aqueous solution to form the [Cu(pyge)(OH_2)]$^+$

cation. Further evidence for this assertion may be derived from the disappearance of the azido-to-copper charge-transfer band for **2** in water. Further, the spectrum of complex **5** in aqueous solution displays an absorption at ~ 400 nm that has essentially the same general shape and molar absorptivity ($\varepsilon \sim 28{,}000$ mol^{-1} dm^3 cm^{-1}) as sodium *p*-nitrophenoxide.

Complexes **2**–**6** were found to have $\mu_{eff} = 1.9 \pm 0.1$ BM at ambient temperature. For complex **1**, however, $\mu_{eff} = 2.1 \pm 0.1$ BM, which is slightly higher than the usual range of 1.80–1.90 BM for five-coordinate copper(II) complexes.[1] Interestingly, [CuLBr$_2$] (where L is MeNH(CH$_2$)$_3$S(CH$_2$)$_3$NHMe) was found to have $\mu_{eff} = 2.5 \pm 0.1$ BM;[24] it is not clear at this time whether the observed higher μ_{eff} for copper(II) bromo complexes of this type is a general phenomenon or an aberration in these two cases.

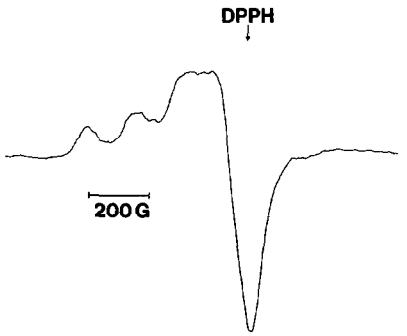

Fig. 1. The EPR spectrum of [Cu(pyge)Br] in frozen (−196°C) DMF–CH$_2$Cl$_2$ glass (*ca* 2.0×10^{-3} mol dm^{-3}). Microwave frequency was 9.25×10^9 Hz at 10 mW power, while the modulation was 0.82 G at 100 kHz.

The X-band EPR spectra of complexes **1** and **5** recorded in DMF–CH$_2$Cl$_2$ glass had similar g and A values. Though of relatively low resolution, they clearly gave the signature spectrum for an axially symmetric complex with a $d_{x^2-y^2}$ ground state ($g_\parallel > g_\perp > 2.0$).[1,25,26] An analysis of the frozen-state spectrum of **1** (see Fig. 1) gives $g_\perp = 2.041$, $g_\parallel = 2.189$, and $A_\parallel$ (Cu) $= 158 \times 10^{-4}$ cm^{-1}. The isotropic spectrum of **1** in DMF solution had $g_{iso} = 2.087$, which is very close to the value calculated from the frozen spectrum [$g_{iso} = 1/3(2g_\perp + g_\parallel) = 2.090$]. On the whole, these observations suggest that a tetragonal, probably square pyramidal, geometry obtains in DMF solution as well as in the solid phase (*vide infra*). In order to unambiguously assign the stereochemistry about the copper ion in the solid-state, the molecular structures of compounds **1** and **2** were determined by single crystal X-ray diffraction techniques.

Selected bond distances and angles for **1** are collected in Table 2. The structure (Fig. 2) is best described as a very slightly distorted square-based pyramid ($\tau = 0.83\%$).[1,27] The coordinating atoms in the basal plane [N(1), N(2), S(1) and Br(1)] are coplanar to within ±0.04 Å and the copper atom is 0.27 Å above this plane. The copper–ligand bond distances within the square plane[24,27–33] and bonding parameters within the ligand[6–8] are all within usual ranges found in related complexes. The Cu(1)—N(2) bond distance is short [1.930(8) Å], reflecting the deprotonation of this site.[34–36] The Cu(1)—N(3) apical bond length [2.218(7) Å] is

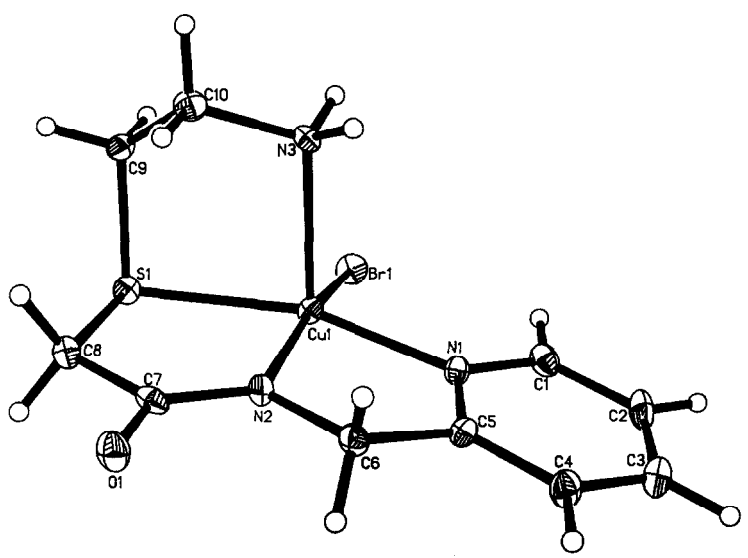

Fig. 2. Perspective view of the structure (20% probability ellipsoids) and atom labelling scheme for the non-hydrogen atoms of **1**; hydrogen atoms have arbitrary radii of 0.1 Å.

longer than typical copper(II)–amine distances[31] by ~ 0.20 Å and is slightly longer than predicted based upon correlations of apical bond lengths with copper out-of-plane distances.[1] This discrepancy likely arises from steric constraints imposed by the neighbouring sulphur ligating atom.

The structure of **2** is depicted in Fig. 3 and selected bond lengths and angles can be found in Table 3. Unfortunately, the azido ligand is disordered approximately about an axis containing the Cu(1)—N(5) vector (see Fig. 4), which necessarily limits discussion of the structure. The gross stereochemistry is best described as slightly distorted

Table 3. Selected bond distances and angles for [Cu(pyge)N_3] (**2**)

[b] Other entries are the angles (°) subtended at the metal by the relevant atoms at the head of the row and column.

[c] N(4) and N(4′) are the two equally populated positions of the coordinating atom of the disordered azide ligand (see text).

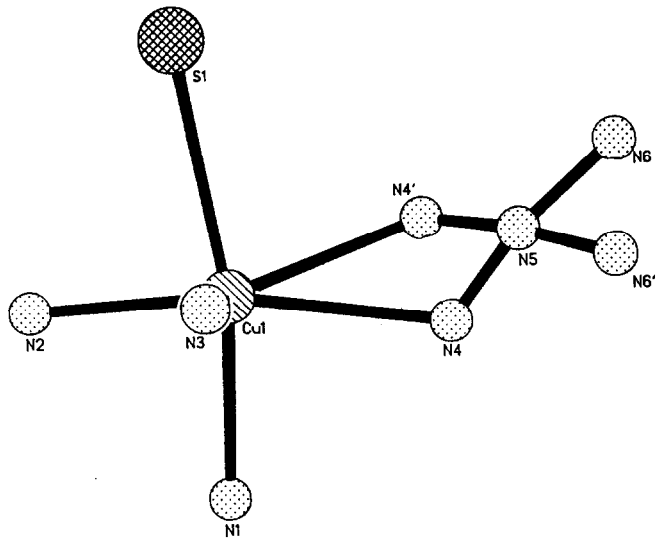

Fig. 4. The coordination sphere about the copper atom in **2** illustrating the disordered azide ligand.

square pyramidal (τ = 2.3% with the copper atom 0.18 Å above the basal plane or 21.5% and 0.32 Å, depending upon which azide orientation is chosen). Bonding parameters within the tetradentate ligand are about as expected and very similar to those found in the structure of **1**. Again, the Cu(1)—N(2) length is short [1.926(7) Å], while the apical Cu(1)—N(3) distance is long [2.189(8) Å]. The azido group is bound in a bent fashion[37-40] to the copper ion in both orientations [Cu(1)—N(4),N(4′)—N(5) = 118.5(17), 128.9(18)°] and is essentially linear [N(4),N(4′)—N(5)—N(6), N(6′) = 168.4(18), 171.4(34)°].

It is of interest to compare the structures of **1** and **2** to that previously determined for octahedral $[Co(pyge)(NO_2)_2]\cdot H_2O$ (**8**).[6] To a first approximation, the five-coordinate square pyramidal copper(II) complexes are derived from the six-coordinate cobalt(III) compound simply by the removal of the ligand *trans* to N(3). Thus, the stereospecific nature of the linear NSNN pyge ligand forces the copper complexes into a relatively undistorted tetragonal five-coordinate geometry.

Despite the structural similarities of **1** and **2** to the cobalt(III) complex (**8**), significant differences become apparent under closer examination. The Cu(1)—N(1) and Cu(1)—N(2) bond lengths are about 0.03–0.06 Å longer than their cobalt counterparts, as might be expected based upon the difference in ionic radii for copper(II) vs cobalt(III).[41] The Cu(1)—S(1) distance, however, is 0.14–0.16 Å longer than for the corresponding Co—S bond; the extra lengthening is likely due in part to the fact that the apical Cu(1)—N(3) distance is ~ 0.20–0.23 Å longer than for the analogous Co—N bond. Also, the copper ion is significantly out of the basal plane of the square pyramid (*ca* 0.25 Å), while the cobalt ion is essentially in the corresponding plane (0.03 Å below). In order to maintain the "bite" angle S(1)—M—N(3) (M = Cu for **1** and **2**; Co for **8**) for the out-of-plane chelate ring at about 87 ± 1°, the M—N(3) bond tilts back relative to the basal plane in the copper complexes. The angle made by the Cu(1)—N(3) bond to this plane is 80.9 and about 80° in **1** and **2**, respectively, as compared to the cobalt complex where this bond is essentially perpendicular to the equatorial plane (89.2°). Considerable strain is evident in this portion of the molecule as reflected in larger ligand torsion angles (Table 4) about S(1) in **1** and **2** as compared with **8**. Also, the S—C—C angles open up slightly but significantly to 115.4(6) and 113.5(6)° in **1** and 116.2(10) and 114.6(8)° in **2** as compared with 112.3(3) and 111.0(3)° in **8**.

Finally, several structures of various geometries for copper(II) complexes containing a flexible, linear NNNN or NSSN tetradentate ligand have been described. These include distorted square pyramidal with all four coordinating atoms of the tetradentate ligand in the basal plane,[30,31,42-45] distorted square pyramidal with an *internal* donating atom of the tetradentate ligand in the apical position,[27,46] trigonal bipyramidal,[30,47-51] distorted octahedral,[30,50-55] and square planar.[56] We note that the five-coordinate copper(II) complexes in the present report appear to constitute the first structurally characterized examples in which one of the *terminal* ligating atoms of the flexible, *linear* tetradentate ligand occupies the apical site in an essentially square pyramidal geometry. Thus in

Table 4. Ligand torsion angles (°)[a]

[b] Reference 7; the atom numbering scheme for **8** was different to that adopted in the present work.

conclusion, the present study reiterates the control of stereochemistry that can be achieved in even conformationally non-rigid systems such as copper(II) via the judicious choice of ligating atoms (NSNN) and chelate ring sizes.[9,32]

CLUSTER SYNTHESIS—XXVII. NEW SULPHIDO OSMIUM CARBONYL CLUSTER COMPLEXES FROM THE PYROLYSIS OF $Os_6(CO)_{16}(\mu_4\text{-}S)(\mu_3\text{-}S)$

RICHARD D. ADAMS,* GONG CHEN, MICHAEL P. POMPEO and SIXIU SUN

Department of Chemistry, University of South Carolina, Columbia, SC 29208, U.S.A.

(*Received* 9 *March* 1990; *accepted* 17 *May* 1990)

Abstract—When $Os_6(CO)_{16}(\mu_4\text{-}S)(\mu_3\text{-}S)$ (**1**) was heated to 125°C for 5 h in octane solvent, two new compounds $Os_6(CO)_{16}(\mu\text{-}S)_2$ (**2**), an isomer of **1**, and $Os_6(CO)_{15}(\mu_3\text{-}S)_3$ (**3**) were obtained in low yields, 10 and 7%, respectively. Both compounds were characterized by single-crystal X-ray diffraction analyses. The cluster of **2** can be described as two edge-fused butterfly tetrahedra that are further connected by an osmium–osmium bond between the wing-tip metal atoms. Compound **3** contains a raft-like cluster of six osmium atoms. Five of the metal atoms lie in an approximate plane. The sixth is folded out of the plane by 1.17 Å. Compound **3** also contains three triply-bridging sulphido ligands. Crystal data for **2**: $Os_6S_2O_{16}C_{16}$, $M = 1653.5$, monoclinic, $P2_1/c$ (No. 14), $a = 8.222(2)$, $b = 16.308(6)$, $c = 19.522(8)$ Å, $\beta = 92.46(3)°$, $V = 2615(3)$ Å^3, $D_c = 4.20$ g cm^{-3}, $Z = 4$, λ(Mo-K_α) = 0.71069 Å (graphite monochromator) $\mu = 293$ cm^{-1}. Methods: MITHRIL, difference Fourier, full-matrix least-squares. Refinement of 2246 reflections [$F^2 \geqslant 3\sigma(F^2)$] gave R and R_w values of 0.030 and 0.032, respectively. For **3**: $Os_6S_3O_{15}C_{15}$, $M = 1699.6$, triclinic, $P\bar{1}$ (No. 2), $a = 11.192(2)$, $b = 18.528(3)$, $c = 7.282(1)$ Å, $\alpha = 95.49(1)$, $\beta = 100.98(1)$, $\gamma = 98.20(2)°$, $V = 1455.5(5)$ Å^3, $D_c = 3.88$ g cm^{-1}, $Z = 2$, λ(Mo-K_α) = 0.71069 Å (graphite monochromator) $\mu = 263.9$ cm^{-1}. Methods: MITHRIL, difference Fourier, full-matrix least-squares. Refinement of 2789 reflections [$F^2 \geqslant 3\sigma(F^2)$] gave R and R_w values of 0.024 and 0.025, respectively.

The controlled pyrolysis of metal carbonyl complexes can be an effective, if not always an efficient, route to the preparation of metal carbonyl cluster complexes.[1] This method has been widely used in the preparation of higher nuclearity metal carbonyl clusters of the element osmium.[2] In the course of our studies of sulphur-containing cluster complexes of osmium,[3] we prepared and characterized the complex $Os_6(CO)_{16}(\mu_4\text{-}S)(\mu_3\text{-}S)$ (**1**).[4] We have now investigated the pyrolytic transformations of **1** and have obtained the two new sulphido osmium carbonyl cluster complexes, $Os_6(CO)_{16}(\mu_3\text{-}S)_2$ (**2**), an isomer of **1**, and $Os_6(CO)_{15}(\mu_3\text{-}S)_3$ (**3**). Both compounds have been characterized crystallographically. The results of this study are described herein.

EXPERIMENTAL

All reactions were carried out under an atmosphere of nitrogen. Octane was dried over sodium/benzophenoneketyl and distilled prior to use. Other reagent grade solvents were stored over 4 Å molecular sieves. All chromatographic separations were performed in air on TLC plates (Whatman 0.25 mm silica gel 60 Å F_{254}). IR spectra were recorded on a Nicolet 5DXB FT–IR spectrophotometer. Mass spectra were obtained on a VG Model 70SQ spectrometer by using electron impact ionization. $Os_6(CO)_{16}(\mu_4\text{-}S)(\mu_3\text{-}S)$ (**1**) was prepared by the previously reported procedure.[4]

Pyrolysis of $Os_6(CO)_{16}(\mu_4\text{-}S)(\mu_3\text{-}S)$ (**1**)

Compound **1** (50 mg) dissolved in 25 cm^3 of octane was heated to reflux for 5 h. The solvent was removed *in vacuo* and the residue was chromatographed by TLC. By using an 85:15, hexane–CH_2Cl_2 solvent mixture, the following compounds were separated in order of elution: grey–green $Os_6(CO)_{15}(\mu_3\text{-}S)_3$ (**3**) (2 mg, 7%), brown **1** (20 mg unreacted) and red–brown $Os_6(CO)_{16}(\mu_3\text{-}S)_2$ (**2**) (3 mg, 10%). Yields were calculated on the basis of the amount of **1** consumed in the reaction, and do not increase with increased reaction periods. For **2**: IR, ν(CO) (cm^{-1}) in hexane: 2080(w,sh), 2074(s),

* Author to whom correspondence should be addressed.

2070(s), 2053(w), 2030(vs). Mass spectral analysis (70 eV, 150°C): m/z for $^{192}Os = 1664-28x$, $x = 0$–16 $\{[M]^+ - x(CO)\}$. For **3**: IR, ν(CO) (cm^{-1}) in hexane: 2083(s), 2079(s), 2032(m), 2026(s), 2020(s), 2008(w). Mass spectral analysis (70 eV, 130°C): m/z for $^{192}Os = 1668-28x$, $x = 0$–15 $\{[M]^+ - x(CO)\}$.

Crystallographic analyses

Crystals of **2** and **3** suitable for diffraction analyses were grown from solutions in CH_2Cl_2–cyclohexane (1 : 1) solvent mixtures at 25°C. The data crystals were mounted in thin-walled glass capillaries. Diffraction measurements were made on a Rigaku AFC6S automatic diffractometer by using graphite-monochromatized Mo-K_α radiation. The unit cells were determined from 15 randomly selected reflections obtained by using the AFC6 automatic search, centre, index and least-squares routines. Crystal data, data collection parameters and results of the analyses are listed in Table 1. All intensity measurements were made by using the standard ω-scan (moving crystal–stationary counter) technique. Background measurements were made by 1/4 additional scan at each end of the scan. All data processing was performed on a Digital Equipment Corp. MICROVAX II computer by using the TEXSAN structure solving program library (Version 2.0) obtained from Molecular Structure Corp., The Woodlands, Texas. Neutral atom scattering factors were calculated by the standard procedures.[5a] Anomalous dispersion corrections were applied to all non-hydrogen atoms.[5b] Full-matrix least-squares refinements minimized the function: $\Sigma w(|F_{obs}| - |F_{calc}|)$, where $w = 1/\sigma(F)^2$, $\sigma(F) = \sigma(F_{obs}^2)/2F_{obs}$, and $\sigma(F_{obs}^2) = [\sigma(I_{raw})^2 + (0.02F_{obs}^2)^2]^{1/2}/Lp$.

Compound **2** crystallized in the monoclinic crystal system. The space group $P2_1/c$ was identified uniquely on the basis of the systematic absences observed during the collection of data. Compound **3** crystallized in the triclinic crystal system. The space group $P\bar{1}$ was assumed and confirmed by the successful solution and refinement of the structure. Both of the structures were solved by a combination of direct methods (MITHRIL) and difference Fourier techniques. For **2** only the osmium and oxygen atoms were refined with anisotropic ther-

mal parameters. All atoms of the molecule of **3** were refined anisotropically. In the final stages of refinement of **3** one half of a molecule of C_6H_{12} disordered about a centre of symmetry was identified. These atoms were refined with isotropic thermal parameters only.*

RESULTS AND DISCUSSION

The two new compounds $Os_6(CO)_{16}(\mu_3\text{-}S)_2$ (**2**) and $Os_6(CO)_{15}(\mu_3\text{-}S)_3$ (**3**) were obtained in low yields, 10 and 7%, respectively, from the thermal treatment of **1** at 125°C for 5 h. Both products were characterized by IR, mass spectrometry and single crystal X-ray diffraction analyses.

Compound **2** is an isomer of **1**. An ORTEP drawing of the molecular structure of **2** is shown in Fig. 1. Selected interatomic bond distances and angles are listed in Tables 2 and 3, respectively. The cluster has an unusual arrangement for the metal atoms. It could be described as a combination of two "butterfly" tetrahedra, Os(1)—Os(2)—Os(4)—Os(3) and Os(1)—Os(3)—Os(5)—Os(6) fused on one edge, Os(1)—Os(3), and joined at the wing-tips, Os(2)—Os(6). The Os—Os bonding distances span a wide range from 2.669(1) Å for the Os(1)—Os(3) bond to 3.033(1) Å for the Os(2)—Os(6) bond. The average Os—Os single bond value in $Os_3(CO)_{12}$ is 2.877(3) Å. A similarly short Os—Os value, 2.686(1) Å, was observed in **1**.[4] Long values, 3.00–3.12 Å, were observed in the 64-electron butterfly cluster complexes $Os_4(CO)_{11}L(\mu_3\text{-}S)_2$, L = CO,[7] PMe_2Ph[8] and $CNBu^t$,[8] but these bonds are believed to be substantially weakened due to the electron-rich character of the clusters.[7] Two contacts, Os(1)···Os(6) = 3.119(1) Å and Os(2)···Os(3) = 3.126(1) Å, are believed to be non-bonding interactions, but based purely on the bond lengths, there could be weak bonding interactions between these atom pairs. The molecule has an approximate two-fold rotation axis that passes through the midpoints of the Os(1)—Os(3) and Os(2)—Os(6) bonds. The triply-bridging sulphido ligands exhibit normal Os—S bond lengths.[9-10] The 16 carbonyl ligands do not deviate significantly from linearity. The mass spectrum of **2** shows the parent ion m/z = 1664 for ^{192}Os and ions corresponding to the loss of each of the 16 carbonyl ligands.

Distances are in Å. Estimated standard deviations in the least significant figure are given in parentheses.

A process that shows the rearrangements of the bonds in the cluster of **1** to yield **2** is shown in Scheme 1. Atom labels in Scheme 1 correspond to those in Fig. 1. In addition, a carbonyl ligand must migrate from Os(1) to Os(6). It is not possible to predict the sequence of the bond rearrangements at this time.

Compound **2** contains a total of 88 cluster valence electrons. 90 electrons would be the count for two butterfly clusters (2 × 64) fused on an edge (minus 34).[11] The deficiency of two electrons accounts for the existence of the additional metal–metal bond between the atoms Os(2) and Os(6).

An ORTEP drawing of the molecular structure

* Complete tables of bond lengths, angles, atomic coordinates, thermal parameters and observed and calculated structure factors have been deposited as supplementary material with the Editor, from whom copies are available upon request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

of 3 is shown in Fig. 2. Selected interatomic distances and angles are listed in Tables 4 and 5. The molecule exhibits a "raft-like" structure[12,13] for the six metal atoms. Five of the six metal atoms Os(1)–Os(5) lie within 0.16 Å of the least-squares plane that they define. Os(6) lies 1.17 Å from this plane.

The cluster can be viewed as a central triangular cluster of three $Os(CO)_2$ groupings, Os(1), Os(2) and Os(3). The three edges of this triangle are bridged by $Os(CO)_3$ groupings which results in the formation of three triangular triosmium groups about the central triangle. Each of the outer three triangular groups contains a triply-bridging sulphido ligand. Two of these ligands, S(1) and S(3), lie on one side of the cluster while the other lies on the other side. All of the metal–metal bonds are shorter than those in the planar raft cluster complex $Os_6(CO)_{17}[P(OMe)_3]_4$ which has no bridging ligands.[12] However, they are very similar to the oxo-bridged Os—Os bonds in the raft cluster $Os_6(CO)_{18}(\mu_3\text{-}CO)(\mu_3\text{-}O)$,[13] and the sulphur-

bridged Os—Os bonds in $Os_3(CO)_9(\mu_3\text{-}CO)(\mu_3\text{-}S)$[10] and $Os_3(CO)_9(\mu_3\text{-}S)_2$.[9] Compound **3** contains 90 valence electrons which is the value expected for an electron-precise raft cluster of six metal atoms.[11,13] Stoichiometrically, the formation of **3** from **2** requires the addition of one sulphido ligand and the elimination of one carbonyl ligand. The mass spectrum of **3** showed the parent ion, $m/z = 1668$, for ^{192}Os and ions corresponding to the loss of each of the 15 carbonyl ligands. While the transformation seems to be simple, we have not yet been able to synthesize this interesting compound by a more direct route.

Abstract—Molybdenum-95 NMR data are presented for the series of ditertiary phosphine-bridged molybdenum dimers $[Mo(CO)_5]_2(\mu\text{-}Ph_2P(CH_2)_nPPh_2)$ (n = 2–6) (**II–VI**) and for the "dangling" phosphine complex $Mo(CO)_5(\eta^1\text{-}Ph_2PCH_2PPh_2)$ (**I**). Values of $\delta(^{95}Mo)$ in the range −1780 to −1788 ppm indicate that there is little effect on net molybdenum metal electron density as the number of bridging methylene groups increases from two to six. Steric effects are deemed as the cause for significantly lower molybdenum metal shielding in **I** [$\delta(^{95}Mo) = -1764$ ppm]. In $[Mo(CO)_5]_2(\mu\text{-}Ph_2PCH_2CH_2CH_2PPh_2)$ (**III**), the $PCH_2CH_2CH_2P$ moiety is maximally extended leading to a Mo---Mo separation of 8.2150(3) Å. The Mo—P distances are 2.545(1) and 2.519(1) Å. This structure, the first featuring a normal ditertiary phosphine bridging two Group 6 metal atoms, is compared with those known for other related molybdenum(0) pentacarbonyl phosphine complexes.

The vast majority of metal complexes incorporating potentially bidentate ditertiary phosphine ligands do so when the ligand acts in a chelating fashion. Ligands such as bis(diphenylphosphino)methane (dppm), 1,2-bis(diphenylphosphino)ethane (dppe) and 1,3-bis(diphenylphosphino)propane (dppp) are well known to form chelate complexes with many metal systems including the ones of Group 6. Carbonyl complexes of the type $M(CO)_4(\eta^2\text{-PP})$ (where M = Cr, Mo or W and PP = bidentate phosphine ligand) are well characterized and studied.[1–3] Considerably less well known are those carbonyl complexes in which the diphosphine acts as a bridging ligand between two metal carbonyl moieties. Studies of complexes of the type $[M(CO)_5]_2(\mu\text{-PP})$ (where M = Cr, Mo or W and PP = bidentate bridging phosphorus donor ligand) are few and most have dealt solely with synthetic techniques and simple characterization of these complexes.[4–9] Recently, however, Hor and his colleagues have begun some thermal stability and decomposition studies of these types of molecules.[8,10–12]

Crystallographically, no Group 6 metal carbonyl-bridged complex has been studied incorporating the ditertiary phosphine ligand type: $Ph_2P(CH_2)_nPPh_2$ (n = 1–6). A few diphosphane-bridged complexes have been characterized[13–15] as well as a dimolybdenum complex utilizing 1,1′-bis(diphenylphosphino)cobaltocene as a bridging ligand $\{[Mo(CO)_5]_2(\mu\text{-}Co(C_5H_4PPh_2)_2\}$.[16]

Since short and long chain ditertiary phosphine complexes of this type are currently of interest,[9–12] we felt that the recently studied $[Mo(CO)_5]_2(\mu\text{-}Ph_2P(CH_2)_nPPh_2)$ (n = 2–6) and $Mo(CO)_5(\eta^1\text{-dppm})$ complexes would be excellent choices to continue our investigation of the effects of various ligand systems on the molybdenum metal nucleus via ^{95}Mo NMR spectroscopy.[17] We also report the first crystal structure of a complex of this series; that of $[Mo(CO)_5]_2(\mu\text{-dppp})$.

EXPERIMENTAL

The complexes studied were synthesized using the literature methods described by Hor.[8,9] Their purity was checked using IR and ^{31}P NMR spectroscopy and in the case of **III**, the thermal decomposition point. IR spectra were recorded using a Nicolet DXC-20 FTIR spectrometer from CH_2Cl_2 solutions in 0.5 cm^3 NaCl solution cells. Phosphorus-31 and molybdenum-95 NMR spectra were recorded from saturated CH_2Cl_2 or CH_3CN solutions at room temperature (22 ± 1°C) on a Bruker WH-400 NMR spectrometer operating at 161.92 and 26.08 MHz, respectively.

Crystals of **III** suitable for X-ray analysis were obtained by slow evaporation of an CH_3CN–MeOH (1:3 v/v) solution of **III** at ambient temperature. The crystal chosen was a colourless prism of approximate dimensions 0.44 × 0.70 × 0.98 mm.

Crystal data for $C_{37}H_{26}Mo_2P_2O_{10}$, $M_r = 884.44$, monoclinic, space group $P2_{1/a}$, $a = 12.555(3)$, $b = 17.652(4)$, $c = 17.381(3)$ Å, $\beta = 99.67(2)°$, $V = 3797(3)$ Å^3, $Z = 4$, $D_c = 1.55$ g cm^{-3}, $\mu = 7.8$ cm^{-1}, $F(000) = 1768$, Mo-K_α radiation ($\lambda = 0.71073$ Å), $T = 21°C$. 8645 reflections were measured on a CAD 4 diffractometer ($2\theta_{max} = 54°$), 8258 were unique and 6782 had $I > 3\sigma(I)$. Lorentz, polarization and empirical absorption corrections were applied. The structure was solved by direct methods (MULTAN). Refinement (with weights derived from counting statistics) by full-matrix least-squares calculations (with all hydrogen atoms allowed for but not refined) converged with $R = 0.030$ and $R_w = 0.046$ for the 6782 observed reflections. The final cycle of refinement had 460 variables and a maximum shift/error ratio of 0.03. A final difference map had no chemically significant features. Full details of the analysis are available from the Cambridge Crystallographic Data Centre or from the authors.

RESULTS AND DISCUSSION

^{95}Mo *NMR spectroscopy*

The ^{95}Mo NMR spectral data for the complexes studied appears in Table 1. Earlier studies by Hor[8,9] had shown similar IR and $\Delta(\delta^{31}P)$* NMR data for complexes **II–VI** indicating a similar overall strain on the bridging group regardless of the chain-length of the diphosphine bridge. We have demonstrated earlier that the net metal electron density, as indicated by $\delta(^{95}Mo)$, is not always related to the measured values of $\nu(C{\equiv}O)$ and $\Delta(\delta^{31}P)$.[17a] In this case, however, we find that $\delta(^{95}Mo)$ is virtually unchanged for complexes **III–VI**. Thus, it appears that $\delta(^{95}Mo)$ is also unaffected by the length of the chain of the bridging group. Steric crowding in complex **I** is likely the major contributing factor in producing the lower overall molybdenum shielding in that species. We observed previously that $\delta(^{95}Mo)$ values could vary over a 150 ppm range for $Mo(CO)_5PR_3$ complexes due to differing steric and electronic effects.[17d] This trend was also noticed in other studies on substituted molybdenum(0) carbonyl complexes.[17,18] In no case were two NMR

* $\Delta(\delta^{31}P) = \delta(^{31}P)$(complex) − $\delta(^{31}P)$(free ligand).

signals seen in the ^{95}Mo NMR spectra. Thus, at least in solution at ambient temperature, both of the metal centres have identical overall shielding; i.e. are magnetically equivalent. These relatively negative $\delta(^{95}Mo)$ values may relate to the great stability of these complexes[8,10–12] and indicate the ability of these ditertiary phosphine bridging ligands to shield the metal nucleus very efficiently. These complexes exhibit very similar metal shielding, in fact, to related monodentate phosphine complexes like $Mo(CO)_5PPh_2Et$ [$\delta(^{95}Mo) = -1789$ ppm].[17d] The one bond Mo—P coupling constants ($^1J_{MoP}$) and peak width at half-height values ($\Delta\nu_{1/2}$) (see Table 1) are also typical of a $Mo(CO)_5$ moiety bound to a triarylphosphine ligand.[17d] This indicates that the electronic field gradient around the metal atom is not greatly distorted and hence symmetry at the metal atom is high, as verified by the X-ray structural determination (*vide infra*).

Attempts to use ^{95}Mo NMR spectroscopy to characterize dimolybdenum species involving other bridging bidentate ligands are currently underway in our laboratory.

Crystal structure of **III**

Relevant bond lengths and bond angles for **III** appear in Table 2. The crystal structure determination of **III** (see Fig. 1) reveals that the two molybdenum centres occupy approximately octahedral geometry, as expected. However, the bulky pentacarbonyl molybdenum moieties have served to extend the bridging dppp ligand, in addition to widening the Mo—P—C angles [115.8(1)° av] from the expected tetrahedral angle of 109.5°. The $Mo(CO)_5$ units are staggered with respect to each other (Mo(1)—P(1)—P(2)—Mo(2) torsion angle 145.9°) and again steric considerations are invoked. Figure 1 clearly shows that one of the two phenyl rings on each phosphorus atom is oriented between two carbonyl ligands of its respective molybdenum. The Mo—P bond lengths [2.519(1) and 2.545(1) Å] are both shorter than those reported for $Mo(CO)_5PPh_3$ (2.560(1) Å)[19] $Mo(CO)_5P(p\text{-tolyl})_3$ (2.562(2) Å)[20] and in the dimer $[Mo(CO)_5]_2(\mu\text{-}Co(C_5H_4PPh_2)_2)$ (2.555(4) Å).[16] The Mo—P bond length in **III** is expectedly longer than in those cases where strong π-acceptor P ligands are incorporated, such as in $Mo(CO)_5P(CH_2CH_2CN)_3$ (2.506(1) Å).[19] In contrast to the "short" Mo—P bond distances in **III**, a longer Mo—P bond length might be expected in **I** due to steric effects. This would explain the failure by us and earlier workers[7,8] to synthesize $[M(CO)_5]_2(\mu\text{-dppm})$ (M = Mo, W). As noted above, the greater bulk of dppm as compared to the other ditertiary phosphine ligands was surmised as the main cause for the lesser shielding of the molybdenum nucleus in **I**. A structural study of **I** would therefore be of interest to address this hypothesis. Interestingly, dppe is even able to form dibridged bimetallic Group 6 $M^1M^2(CO)_{10}(\mu\text{-dppe})_2$ complexes.[21]

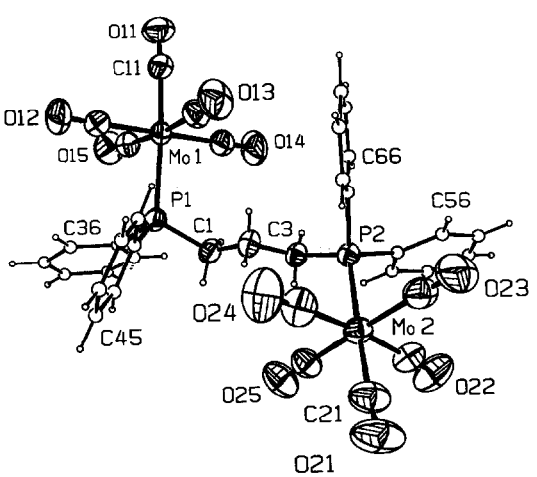

Fig. 1. A view of the $[Mo(CO)_5]_2(\mu\text{-}Ph_2PCH_2CH_2CH_2PPh_2)$ molecule with the crystallographic numbering scheme; ellipsoids are at the 50% level.

The Mo—C—O units are basically linear for Mo(1) and Mo(2) (see Table 2) and differ little from those of $Mo(CO)_5PPh_3$,[19] $Mo(CO)_5P(p\text{-tolyl})_3$[20] or $[Mo(CO)_5]_2(\mu\text{-}Co(C_5H_4PPh_2)_2)$.[16] Similarly, the OC—Mo—CO and OC_{trans}—Mo—P bond angles in **III** also reflect this similarity to the above species except that the OC_{trans}—Mo—P angles for Mo(1) and Mo(2) are significantly different (174.23(9) and 177.83(9)°, respectively).

The stability of the bridged-ligand series of complexes, as demonstrated by Hor and his colleagues,[8,10–12] can be attributed to a similar structural nature of the $Mo(CO)_5$ moieties to the fragment in $Mo(CO)_5PPh_3$[19] but with a considerably shorter, and likely therefore stronger, Mo—P bond. The ability of this series of dimers to withstand stressful thermal conditions[10–12] may make them very useful molecules in the design of larger clusters, metal dopants or in conductive metal polymeric systems.[22–24]

CONCLUSIONS

We have shown by ^{95}Mo NMR spectral studies that the molybdenum(0) nucleus is not greatly affected by the chain length when $n > 2$ in the series $[Mo(CO)_5]_2(\mu\text{-}Ph_2P(CH_2)_nPPh_2)$. Steric effects are likely the cause for deshielding the metal nucleus in $Mo(CO)_5(\eta^1\text{-dppm})$ and the inability to isolate

$[Mo(CO)_5]_2(\mu$-dppm). We have also reported the first crystal structure of any Group 6 metal complex with bridging ditertiary phosphine ligands. The structural differences and similarities of $[Mo(CO)_5]_2(\mu$-dppp) to related species have lent some insight into the stability of these molecules to stressful thermal conditions as noted by earlier work.

(*Received* 7 *February* 1990; *accepted* 7 *June* 1990)

Abstract—The reaction of cysteine with iron(II) sulphate heptahydrate and sodium nitrite, in aqueous solution at 118°C, yields $Na[Fe_4S_3(NO)_7]$; the yield is increased when the reducing agent sodium ascorbate is also present, and for certain reaction stoichiometries when nitrite is limiting the yield is quantitative. Sulphur is similarly captured, to form $Na[Fe_4S_3(NO)_7]$, from a range of other sources including several derivatives of cysteine, homocysteine, sodium thioglycolate, penicillamine and potassium benzylpenicillin, as well as from sodium thiosulphate. Glutathione and cystine both require the presence of sodium ascorbate for formation of $Na[Fe_4S_3(NO)_7]$, while methionine and 2-mercaptopyrimidine are among a number of sulphur compounds which do not provide $Na[Fe_4S_3(NO)_7]$ under these conditions. Both acid-hydrolysed casein and enzyme-hydrolysed casein, which contain low levels of both cystine and iron, react with sodium nitrite in the presence of sodium ascorbate to form $Na[Fe_4S_3(NO)_7]$, as does the synthetic Perigo medium. The $Na[Fe_4S_3(NO)_7]$ was identified by a combination of FTIR and ^{15}N NMR spectroscopy using 99% ^{15}N-labelled material and, in some cases, by isolation.

The mode of action by which nitrite inhibits the development of *Clostridium* species, and other food-spoilage organisms, in preserved foodstuffs has been the subject of investigation for a number of years.[1–6] In a laboratory medium (Perigo medium)[1] which supports the growth of *Clostridium* species, incubation with sodium nitrite not only caused a substantial reduction in the free nitrite concentration, but formed some new component in the medium, presumed[1] to be related to the consumption of nitrite, which was extremely inhibitory to the vegetative growth of a wide range of strains of a number of *Clostridium* species, including *Clostridium botulinum*.[1,2] The formation of an inhibitor associated with disappearance of nitrite has also been demonstrated using pig meat in place of the synthetic laboratory medium,[3] and similarly-formed inhibitors have been shown to be effective against a wide range of micro-organisms other than *Clostridium* species.[4] Earlier chemical studies[4,5] indicated that iron salts and a source of sulphur were required for the formation of the inhibitors.

Treatment[6] of vegetative cells of *C. botulinum* with nitrite in the presence of ascorbate resulted in loss of the ESR signal at $g = 1.94$, characteristic of the reduced form of a {4Fe–4S} iron–sulphur centre, and its replacement by an ESR signal at $g = 2.035$, characteristic of $[Fe(NO)_2X_2]$ complexes, most likely in this case of $[Fe(NO)_2(SR)_2]^-$. We have subsequently shown[7] that treatment with aqueous sodium nitrite of synthetic models for both {2Fe–2S} and {4Fe–4S} centres leads via $[Fe(NO)_2(SH)_2]^-$, identified[9] by ESR spectroscopy, to $[Fe_4S_3(NO)_7]^-$ isolable in yields around 40%.

In earlier work,[4] material with properties similar to those of $[Fe_4S_3(NO)_7]^-$ salts was extracted from a limited range of substrates treated with nitrite, with or without added iron salts, including casein hydrolysate, cysteine and thioglycolate. However, the evidence[4] for the identity of these extracts as a salt of $[Fe_4S_3(NO)_7]^-$ was suggestive only, not definitive. It relied on IR spectroscopy, Mössbauer

* Author to whom correspondence should be addressed.

spectroscopy and elemental analysis. Of these, the IR spectrum measured dispersively in Nujol is not adequately characteristic, while the interpretation of the Mössbauer isomer shifts and quadrupole splitting has proved to be controversial: it is not even clear how many quadrupole doublets characterize the spectra of $[Fe_4S_3(NO)_7]^-$ salts.[10-12] The reported analytical data[4] on the other hand were in excellent agreement with an atomic ratio Fe/S/N of 4:3:6 rather than 4:3:7 expected for the sodium or potassium salts of $[Fe_4S_3(NO)_7]^-$ or 4:3:8 expected for the ammonium salt. The presence of $[Fe_4S_3(NO)_7]^-$ in these extracts[4] is therefore not proven.

We have found that a combination of solution FTIR and ^{15}N NMR on isotopically labelled material provides definitive identification of the $[Fe_4S_3(NO)_7]^-$ anion: at high levels of ^{15}N labelling, the ^{15}N NMR spectrum comprises[13] a singlet of relative intensity one due to the unique apical nitrosyl ligand and a pair of doublets, forming an AX system, each of relative intensity three, due to the basal $Fe(NO)_2$ groups. While the chemical shifts are slightly solvent dependent, the overall spectrum is uniquely characteristic of $[Fe_4S_3(NO)_7]^-$: on the other hand, the ^{15}N NMR spectrum of the related dinuclear anion $[Fe_2S_2(NO)_4]^{2-}$ consists,[14] at any level of ^{15}N labelling, of a singlet, δ +37.8 in aqueous solution.

Here we report on the definitive identification of $[Fe_4S_3(NO)_7]^-$ as a reaction product from the interaction of nitrite and iron salts with a wide range of sulphur-containing substrates, including the capture of sulphur into $[Fe_4S_3(NO)_7]^-$ from a number of sulphur biochemicals including sulphur amino acids and their derivatives, peptides and penicillin derivatives, as well as other sulphur-containing systems.

EXPERIMENTAL

Samples of $[Fe_2(SR)_2(NO)_4]$ were prepared using previously published methods.[15,16] Samples of $Na[Fe_4S_3(NO)_7]$ were prepared by reaction of iron(II) sulphate heptahydrate with sodium sulphide and sodium nitrite in hot aqueous solution.[17] Acid-hydrolysed and enzyme-hydrolysed casein were obtained from Sigma: Perigo medium was prepared, and used, according to the literature.[1] 5,5-Diethylthiobarbituric acid was prepared by base-catalysed condensation of dimethyl diethylmalonate with thiourea.[18] Other organo-sulphur chemicals were the best available commercial grade and were used as received.

Preparation of $Na[Fe_4S_3(^{15}NO)_7]$

$Na^{15}NO_2$ (99% ^{15}N; MSD Isotopes) (0.10 g, 1.43 mmol), $Na_2S \cdot 9H_2O$ (0.35 g, 1.46 mmol) and $FeSO_4 \cdot 7H_2O$ (0.50 g, 1.80 mmol) were dissolved in water (500 cm^3). The solution was heated in an autoclave at 118°C for 20 min. After cooling, the solution was filtered through Hyflo-supercel, and the filtrate extracted with ether (6×50 cm^3). The organic extract was washed with water, dried and evaporated to provide $Na[Fe_4S_3(^{15}NO)_7]$ (80 mg, 70%), identified by IR and ^{15}N NMR spectroscopy.

IR spectra were recorded in tetrahydrofuran (THF) solution using 0.5 mm pathlength cells and a Perkin–Elmer Model 1710 FTIR spectrometer. ^{15}N NMR spectra were recorded in acetone solution, at ambient temperature, relative to 50% CH_3NO_2 in acetone, using a Brüker AM-300 spectrometer at 30.424 MHz. The IR spectra of authentic $Na[Fe_4S_3(NO)_7]$ (Fig. 1) were recorded using 0.002 mol dm^{-3} solutions in THF: $Na[Fe_4S_3(^{14}NO)_7]$, ν(NO) 1795(w), 1742(vs), 1707(m) cm^{-1}; $Na[Fe_4S_3(^{15}NO)_7]$, ν(NO) 1760(w), 1708(vs), 1673(m) cm^{-1}. The ^{15}N NMR spectrum of $Na[Fe_4S_3(^{15}NO)_7]$ was recorded using a saturated solution in acetone: δ_N, 11.8(s), (1N); 39.5 (d, J 3.8 Hz) and 80.6 (d, J 3.8 Hz) (AX, 6N). Electronic spectra were measured using a Pye–Unicam SP8-100 spectrophotometer, and ESR spectra were measured in 1 mm quartz capillaries using a Brüker ER200-D spectrometer.

Reactions of sodium nitrite and iron sulphate with characterized sulphur sources

(i) *Cysteine.* DL-Cysteine (2.0 g, 16.5 mmol), iron(II) sulphate heptahydrate (0.50 g, 1.80 mmol) and sodium nitrite (0.10 g, 1.45 mmol) were dissolved in water (1 dm^3) and the mixture was autoclaved at 118°C for 20 min. The mixture was cooled and filtered, and the filtrate exhaustively extracted with diethyl ether, until the extracts were colourless. The combined ether extracts were washed with water, dried and evaporated to provide $Na[Fe_4S_3(NO)_7]$ (21 mg, 18%) identified by FTIR and by analysis; Found Fe, 40.6; N, 17.5; S, 16.9. $Fe_4N_7NaO_7S_3$ requires Fe, 40.4; N, 17.7; S, 17.4%: derivatives by metathesis (a) $(Ph_4As)[Fe_4S_3(NO)_7]$; Found C, 31.2; H, 2.1; N, 10.6. $C_{24}H_{20}AsFe_4N_7O_7S_3$ requires C, 31.6; H, 2.2; 10.7%: (b) $(Ph_3PNPPh_3)[Fe_4S_3(NO)_7]$; Found C, 40.3; H, 2.7; N, 10.3. $C_{36}H_{30}Fe_4N_8O_7P_2S_3$ requires C, 40.5; H, 2.8; N, 10.5%. An entirely similar experiment using $Na^{15}NO_2$ (99% ^{15}N) provided $Na[Fe_4S_3(^{15}NO)_7]$ in like yield, identified by FTIR and ^{15}N NMR. No other iron–nitrosyl species were

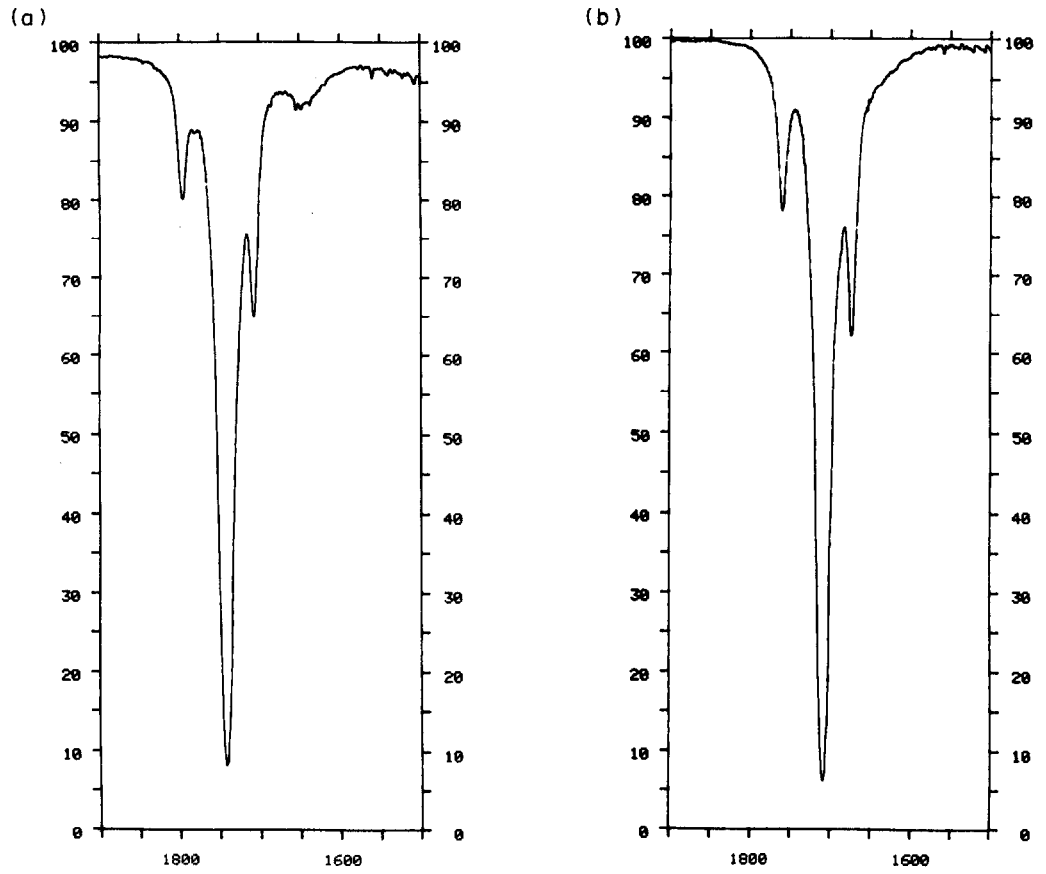

Fig. 1. FTIR spectra of the nitrosyl stretching region for (a) $Na[Fe_4S_3(^{14}NO)_7]$ and (b) $Na[Fe_4S_3(^{15}NO)_7]$: spectra recorded using 2×10^{-3} mol dm^{-3} solutions in THF.

isolated. When the reactions were repeated in the presence of sodium ascorbate (2.0 g, 10.1 mmol) under otherwise identical conditions the yield of $Na[Fe_4S_3(NO)_7]$ rose to 88 mg, 77%. The use of sodium ascorbate in the absence of cysteine or other sulphur sources provided nil $Na[Fe_4S_3(NO)_7]$. When the concentration of sodium nitrite was halved, the yields were little affected: by use of 0.05 g (0.72 mmol) of $NaNO_2$, 1.0 g (3.6 mmol) of $FeSO_4 \cdot 7H_2O$ and 8.0 g (66 mmol) of cysteine,[19] the yield of $Na[Fe_4S_3(NO)_7]$ rose to 39%, while in the presence of sodium ascorbate (13.1 g, 66 mmol) the yield of $Na[Fe_4S_3(NO)_7]$ was quantitative.

(ii) *Sodium thioglycolate.* In a reaction similar to the foregoing, but using sodium thioglycolate ($HSCH_2COO^-Na^+$; 2.0 g, 17.5 mmol) in place of cysteine, the isolated yield of $Na[Fe_4S_3(NO)_7]$, identified by FTIR, was 23.5 mg, 21%. Again proof of identity was reinforced by use of $Na^{15}NO_2$ and identification of $Na[Fe_4S_3(^{15}NO)_7]$ by both FTIR and ^{15}N NMR.

(iii) *Methyl thioglycolate, thioglycolic acid, thioethanol and 2-methyl-2-propanethiol.* The reaction mixture was in each case $NaNO_2$ (0.10 g, 1.45 mmol), $FeSO_4 \cdot 7H_2O$ (0.50 g, 1.80 mmol) and the sulphur source (16.5 mmol) in water (1 dm^3). Duplicate runs were made in the absence and in the presence of sodium ascorbate (3.3 g, 16.7 mmol). After autoclaving at 118°C for 20 min the mixtures were worked-up, as described above, to afford the known[16] complexes $[Fe_2(SR)_2(NO)_4]$, identified by FTIR. The results are summarized in Table 1.

(iv) *Other thiols, thiones and sulphides; elemental sulphur, sodium sulphite and sodium thiosulphate.* The reaction mixture was, in each case $NaNO_2$ (0.10 g, 1.45 mmol), $FeSO_4 \cdot 7H_2O$ (0.50 g, 1.80 mmol) and the sulphur source (16.5 mmol) in water (1 dm^3); where no $Na[Fe_4S_3(NO)_7]$ or $[Fe_2(SR)_2(NO)_4]$ was identifiable in the absence of sodium ascorbate, the run was repeated, as before, with the addition of sodium ascorbate (2.0 g, 10.1 mmol). The results are summarized in Table 1.

Reactions of sodium nitrite with casein hydrolysates

Sodium nitrite (0.10 g, 1.45 mmol) was dissolved in water (1 dm^3) and either acid-hydrolysed casein (150 g) or enzyme-hydrolysed casein (100 g) was

Table 1. Reactions of $FeSO_4 \cdot 7H_2O$ and $NaNO_2$ with sulphur sources

(i) Compounds providing $Na[Fe_4S_3(NO)_7]$ in the absence of sodium ascorbate:[a]

Cysteine;[b,c] *N*-acetylcysteine; cysteine methyl ester hydrochloride (52%); cysteine ethyl ester hydrochloride; homocysteine (6.5%); thioglycolic acid; sodium thioglycolate (21%);[b] penicillamine; potassium benzylpenicillin; 6-aminopenicillanic acid; sodium thiosulphate (20%); *N*-methylthiourea; *N,N'*-dimethylthiourea; *N,N'*-diphenylthiourea; thioacetanilide; thiocarbonyldiimidazole.

(ii) Compounds providing $Na[Fe_4S_3(NO)_7]$ only in the presence of sodium ascorbate:[a]

N-acetylpenicillamine; glutathione; cystine; *S*-methylcysteine; thiodiglycolic acid; thiazolidine-4-carboxylic acid; thiourea (8.9%); thiosemicarbazide; thioacetamide; 2-mercaptopyridine; 2-mercaptobenzothiazole.

(iii) Compounds providing no $Na[Fe_4S_3(NO)_7]$ even in the presence of sodium ascorbate:

Methionine; thiodiethanol; dithiothreitol;[d] 2-mercaptopyrimidine; 2-mercaptothiazoline; 2-mercapto-1-methylimidazole; 2-thiobarbituric acid; 2-thio-5,5-diethylthiobarbituric acid; 2-mercaptobenzimidazole; thiobenzanilide; *S*-(thiobenzyl)thioglycolic acid; thiamine hydrochloride; thioflavin-T; thioxanthen-9-one; 2-thiopheneacetic acid; 3-thiopheneacetic acid; sodium sulphite; octasulphur.

(iv) Compounds providing $Fe_2(SR)_2(NO)_4$:[e]

Methylthioglycolate (52, 72%); thioethanol; 2-methyl-2-propanethiol (0, 26%); thioglycolic acid.[c]

[a] Identification in every case by FTIR on THF solutions; when $Na[Fe_4S_3(NO)_7]$ was cleanly separable, without decomposition, from the reaction mixture, percentage yields are given.

[b] $Na[Fe_4S_3(NO)_7]$ confirmed also by use of $Na^{15}NO_2$ (99% ^{15}N) and ^{15}N NMR spectroscopy (see text).

[c] See text for discussion of yields.

[d] $Na[Fe_4S_3(NO)_7]$ formed in presence of $Na_2S_2O_4$.

[e] Identification and yields (without and with sodium ascorbate: see text) by FTIR on THF solutions.

added: these mixtures were autoclaved and worked-up as described above. Similar reactions were carried out using each of these sodium nitrite/casein hydrolysate mixtures with the following additives:[4]

(a) $FeSO_4 \cdot 7H_2O$ (0.50 g, 1.80 mmol);
(b) sodium ascorbate (2.0 g, 10.1 mmol);
(c) sodium thioglycolate (2.0 g, 17.5 mmol);
(d) $FeSO_4 \cdot 7H_2O$ (0.50 g, 1.80 mmol) and sodium ascorbate (2.0 g, 10.1 mmol);
(e) $FeSO_4 \cdot 7H_2O$ (0.50 g, 1.80 mmol) and sodium thioglycolate (2.0 g, 17.5 mmol).

The reactions under conditions (a) were also repeated using $Na_{15}NO_2$ in place of unlabelled sodium nitrite.

Reactions of sodium nitrite with Perigo medium

Sodium nitrite (0.10 g, 1.45 mmol) was added to 1 dm^3 of Perigo medium:[1] the mixture was autoclaved and worked-up as before. Similar runs were undertaken (a) using $Na^{15}NO_2$ instead of unlabelled sodium nitrite and (b) with the addition of $FeSO_4 \cdot 7H_2O$ (0.50 g, 1.80 mmol).

RESULTS AND DISCUSSION

When sodium nitrite and iron(II) sulphate heptahydrate were autoclaved at 118°C in dilute aqueous solution ($NaNO_2$, 100 ppm; $FeSO_4 \cdot 7H_2O$, 500 ppm) with DL-cysteine, the sodium salt of Roussin's black anion, $Na[Fe_4S_3(NO)_7]$, was isolated in 18% yield. This salt was identified unambiguously by a combination of FTIR, UV–vis, and, most characteristic, ^{15}N NMR spectroscopy: this latter technique, using 99% ^{15}N enrichment, showed that no other diamagnetic iron–nitrosyl complexes were formed. When excess of sodium ascorbate, as reducing agent, was present the isolated yield of $Na[Fe_4S_3(NO)_7]$ rose to 77%, based on sodium nitrite as the limiting component. Similar mixtures,

when held for 24 h at room temperature, gave no trace of $Na[Fe_4S_3(NO)_7]$.

An autoclaved mixture of $FeSO_4 \cdot 7H_2O$, $NaNO_2$ and cysteine in concentrations of 3.6×10^{-3}, 0.72×10^{-3} and 66×10^{-3} mol dm^{-3}, respectively, has been shown[19] to be extremely inhibitory when applied to growing cultures of *Clostridium sporogenes*. Using such mixtures, quantitative FTIR has shown that $Na[Fe_4S_3(NO)_7]$ is formed in 39% yield, based upon nitrite as the limiting component. When sodium ascorbate was also present at the same concentration as the cysteine, the conversion of nitrite to $Na[Fe_4S_3(NO)_7]$ was quantitative. Similar results were obtained using an iron(II) concentration of 1.8×10^{-3} mol dm^{-3}. This result is of interest as it has been found[19] that this autoclaved mixture exhibits the same level of inhibition, based on concentration of NO fragments, as pre-formed, unautoclaved $Na[Fe_4S_3(NO)_7]$, suggesting that this tetranuclear complex, or one of its dissociation products,[9] is the effective inhibitor. However, the observation[19] that the autoclaved mixture shows no ESR spectrum effectively rules out the presence of mononuclear iron–nitrosyl complexes of the types $[Fe(NO)_2(SR)_2]^-$, $[Fe(NO)(SR)_3]$ and $[Fe(NO)(SR)_3]^{3-}$, the common[9] products of $[Fe_4S_3(NO)_7]^-$ cleavage reactions in the presence of anionic sulphur nucleophiles.

The formation of $[Fe_4S_3(NO)_7]^-$ requires cleavage of the carbon–sulphur bonds in cysteine to liberate sulphide and reduction of iron(II) to a mean oxidation state of $-1/2$, followed by spontaneous self-assembly.[20] The role of sodium ascorbate, which causes a significant increase in the yields of $Na[Fe_4S_3(NO)_7]$ appears to be that of keeping the cysteine in the reduced, thiol form $HSCH_2CH(NH_2)COOH$: it is known[21] that the very slow oxidation by molecular oxygen of thiols, such as cysteine and glutathione, to the disulphide forms, cystine and diglutathione, is accelerated by iron salts. Consistent with this interpretation, when cystine was employed as the sulphur source, in the absence of sodium ascorbate, no $Na[Fe_4S_3(NO)_7]$ was formed: only upon addition of the reducing ascorbate was the cluster anion formed. This suggested that a thiol group might be essential for sulphur capture from organosulphur compounds into $[Fe_4S_3(NO)_7]^-$: subsequent investigation showed, however, that this was an over-simple hypothesis.

Although a number of other thiols including *N*-acetylcysteine, cysteine methyl ester hydrochloride, cysteine ethyl ester hydrochloride, homocysteine, sodium thioglycolate and penicillamine all gave $Na[Fe_4S_3(NO)_7]$ in the absence of sodium ascorbate, several thiols including glutathione, *N*-acetylpenicillamine, 2-mercaptopyridine and 2-mercaptobenzothiazole required the addition of sodium ascorbate before any $Na[Fe_4S_3(NO)_7]$ was formed, while the apparently related heterocyclic thiols (2-mercaptopyrimidine, 2-mercaptothiazoline, 2-mercapto-1-methylimidazole, and 2-mercaptobenzimidazole) gave no $Na[Fe_4S_3(NO)_7]$ even in the presence of sodium ascorbate. Dithiothreitol, which is oxidized with extreme ease,[22] provided no $Na[Fe_4S_3(NO)_7]$ even in the presence of sodium ascorbate. However in the presence of 1.50 g (8.6 mmol) of sodium dithionite, $Na[Fe_4S_3(NO)_7]$ was formed in 32% yield: control experiments in the absence of dithiothreitol showed no capture of sulphur from dithionite itself into $Na[Fe_4S_3(NO)_7]$.

In contrast, we have found that several thiones, including *N*-methylthiourea, *N*,*N*′-dimethylurea, *N*,*N*′-diphenylthiourea, thioacetanilide, and thiocarbonyldiimidazole, all provide $Na[Fe_4S_3(NO)_7]$ without added reductant, although sodium ascorbate is necessary for the formation of $Na[Fe_4S_3(NO)_7]$ from the related thiones, thiourea, thiosemicarbazide and thioacetamide, whereas thiobenzanilide and two thiobarbituric acids gave no $Na[Fe_4S_3(NO)_7]$ even in the presence of sodium ascorbate.

A similar spectrum of behaviour was observed with compounds containing sulphur bound in a C—S—C fragment (Table 1). In particular, methionine gave no $Na[Fe_4S_3(NO)_7]$ even in the presence of ascorbate. Hence of the three common sulphur-containing amino acids found in proteins, cysteine provides $Na[Fe_4S_3(NO)_7]$ even in the absence of sodium ascorbate as reductant, although more when the reductant is present; cystine provides $Na[Fe_4S_3(NO)_7]$ only in the presence of sodium ascorbate; and methionine does not yield $Na[Fe_4S_3(NO)_7]$.

In contrast to the reaction of sodium thioglycolate with iron(II) and nitrite which provides $Na[Fe_4S_3(NO)_7]$, in common with most thiols (Table 1), the neutral methyl thioglycolate provides instead the known[23] binuclear complex $[Fe_2(SCH_2COOCH_3)_2(NO)_4]$: the yield was 52%, rising to 72% in the presence of sodium ascorbate. Thioethanol likewise provided the known[23] $[Fe_2(SCH_2CH_2OH)_2(NO)_4]$ in the absence of sodium ascorbate, while 2-methyl-2-propanethiol, Me_3CSH, only gave $[Fe_2(SCMe_3)_2(NO)_4]$[24] (26%) when sodium ascorbate was present. When, in a control experiment, an authentic sample of $[Fe_2(SCH_2COOCH_3)_2(NO)_4]$ was autoclaved alone in aqueous medium at 118°C, it was recovered unchanged. The reaction of thioglycolic acid, $HSCH_2COOH$, with iron(II) and nitrite proved to be more complex: in unbuffered solution, the initial

iron-containing product was a rather labile oil whose IR spectrum, ν(NO) 1783 and 1756 cm^{-1}, ν(CO) 1732 cm^{-1}, was consistent with the presence of the neutral binuclear complex $[Fe_2(SCH_2COOH)_2(NO)_4]$, but attempts to purify this material by chromatography on silica led to its decomposition, to give $Na[Fe_4S_3(NO)_7]$ as the sole isolable iron nitrosyl complex. On the other hand, in buffered solution at pH 4, $Na[Fe_4S_3(NO)_7]$ was formed in 75% yield.

Of the three purely inorganic sulphur sources investigated, sodium thiosulphate, a well-established sulphur transfer agent, readily gave $Na[Fe_4S_3(NO)_7]$ in the absence of any reductant, while neither sodium sulphite nor elemental sulphur gave any evidence of sulphur transfer into the cluster anion. At room temperature, under a dinitrogen atmosphere, sodium thiosulphate reacts with sodium sulphide and iron(II) sulphate to yield[16] the μ-thiosulphato di-iron complex $[Fe_2(S_2O_3)_2(NO)_4]^{2-}$: this upon exposure to air, in solution, is readily transformed to $[Fe_4S_3(NO)_7]^-$, along with nitrate, nitrite and unidentified sulphur-containing, but nitrogen-free, by-products. It is probable that the reaction described here, forming $Na[Fe_4S_3(NO)_7]$ from $Na_2S_2O_3$ at 118°C, in air, proceeds via the di-iron thiosulphato complex, the mechanism of whose conversion to the tetra-iron complex still awaits elucidation.

Acid-hydrolysed casein typically contains *ca* 0.035% by weight of sulphur, incorporated as cystine, and *ca* 0.40% of sulphur, as methionine. Enzyme-hydrolysed casein, on the other hand, typically contains 0.045–0.08% sulphur as cystine and 0.30–0.40% sulphur as methionine. The experiments with single amino acids, described above, show that only cystine sulphur can be captured to form $Na[Fe_4S_3(NO)_7]$, while methionine sulphur remains bound. In our experiments the maximum available sulphur in runs using casein hydrolysates is therefore *ca* 1.6 mmol using acid-hydrolysed casein, and *ca* 1.4–2.5 mmol using enzyme-hydrolysed casein.

Each of the casein hydrolysates employed in this work was found, by AAS, to contain *ca* 20 ppm iron. Hence the maximum available iron in runs using acid-hydrolysed casein was 0.054 mmol, and with enzyme-hydrolysed casein, 0.036 mmol. Iron is thus clearly the limiting component in these experiments, and the maximum quantity of $Na[Fe_4S_3(NO)_7]$ which could be formed in the acid-hydrolysed casein runs was 5 mg.

When acid-hydrolysed casein was autoclaved with sodium nirite alone (see Experimental), no $Na[Fe_4S_3(NO)_7]$ was formed. This was expected since all the sulphur under these conditions is present as either cystine or methionine. However, in the presence of sodium ascorbate, which reduces cystine to cysteine, $Na[Fe_4S_3(NO)_7]$ was indeed detected by FTIR and confirmed by ^{15}N NMR spectroscopy in runs using $Na[^{15}NO_2]$. That the reduction of cystine was the limiting factor, rather than the state of the casein-bound iron, was shown by repeating the experiments in the presence of 500 ppm $FeSO_4 \cdot 7H_2O$. Again no $Na[Fe_4S_3(NO)_7]$ was produced unless sodium ascorbate was present. Use of the other additives suggested in previous work[4] led, as expected from the work on single sulphur sources, to an increase in the yield of $Na[Fe_4S_3(NO)_7]$. Results with enzyme-hydrolysed caseins were essentially identical, with the formation of $Na[Fe_4S_3(NO)_7]$ confirmed by the use of $Na[^{15}NO_2]$ and ^{15}N NMR spectroscopy, as before.

Since Perigo medium contains both sodium thioglycolate and enzyme-hydrolysed casein,[1] the observed formation of $Na[Fe_4S_3(NO)_7]$ was expected: in the absence of added iron, the level of $Na[Fe_4S_3(NO)_7]$ (which could not be satisfactorily separated from the rest of the mixture) was low, but its presence was confirmed by ^{15}N labelling. As expected, much higher yields were obtained in the presence of added iron. In none of the experiments using Perigo medium were any paramagnetic iron nitrosyl complexes detected by ESR spectroscopy, just as with the mixtures involving cysteine.[19]

The results with the casein hydrolysates show that even with very low levels of iron (20 ppm) and sulphur (0.035%) bound in proteins, a simple brief heat treatment with sodium nitrite under reducing conditions readily forms $Na[Fe_4S_3(NO)_7]$. Many canned foodstuffs, particularly meat products, undergo just such a heat treatment with sodium nitrite.

SYNTHESIS AND MOLECULAR STRUCTURE OF [10-*endo*-(Ph_3PAu)-7,8-*nido*-$C_2B_9H_{11}$]$^-$: STRUCTURAL PATTERNS IN [$C_2B_9H_{11}X$]$^-$ ANIONS (X = H^+, $AuPPh_3^+$, $CuPPh_3^+$)

(*Received* 20 *March* 1990; *accepted* 7 *June* 1990)

Abstract—Reaction of equimolar amounts of Tl[$TlC_2B_9H_{11}$], Ph_3PAuCl and [$PhCH_2NMe_3$]Cl affords the compound [$PhCH_2NMe_3$][$Ph_3PAuC_2B_9H_{11}$]. A single crystal X-ray diffraction study of this (as the CH_2Cl_2 solvate) reveals that the {Ph_3PAu} fragment is essentially *endo*-σ-bonded to B(10), in a similar manner to the *endo*-H atom in [7,8-*nido*-$C_2B_9H_{12}$]$^-$. In the title compound the gold atom is slipped towards B(10) by 0.87 Å from a position above the centre of the C_2B_3 carbaborane face. This parameter, together with ⟨B—B_{facial}⟩, ⟨B—C_{facial}⟩ and C—C, is discussed in relation to the corresponding parameters in [7,8-*nido*-$C_2B_9H_{12}$]$^-$ and [3-PPh_3-3,1,2-$CuC_2B_9H_{11}$]$^-$. The structural patterns thus revealed are traced to differing degrees of depopulation of the occupied π-molecular orbitals of [7,8-*nido*-$C_2B_9H_{11}$]$^{2-}$. Crystals of [$PhCH_2NMe_3$][10-*endo*-(Ph_3PAu)-7,8-*nido*-$C_2B_9H_{11}$]·CH_2Cl_2 are monoclinic, space group $P2_1/c$, with a = 9.5509(17), b = 19.232(3), c = 19.813(3) Å, β = 90.741(13)°. Using 4667 observed reflections the structure has been refined to R = 0.0487.

Since their initial syntheses and characterization more than 25 years ago,[1,2] carbametallaboranes have been the subject of intense research activity. The study of their chemistry has contributed significantly to such diverse areas as the development of current bonding theories[3] and homogeneous catalysis;[4] moreover, such compounds have the potential to be of future use, for example, in boron-neutron capture therapy of tumours.[5]

In the vast majority of carbametallaboranes the metal atom is more or less symmetrically disposed with respect to the ligating carbaborane face, although a sub-group, the "slipped" carbametallaboranes, are well known. In these, either the metal atom has access to > 18 valence electrons,[6] or the metal fragment is non-conical,[7] but in both cases (between which there is some degree of overlap) the reasons for the slipping are well understood.[8,9]

One class of slipped species that has received relatively little attention is that in which the metal atom is linearly coordinated, and thus essentially *endo*-σ-bonded to only one boron atom in the (now formally) open polyhedral face. This class is typified by the mercuracarbaborane [10-*endo*-(Ph_3PHg)-7,8-*nido*-$C_2B_9H_{11}$].[10] Recently, we established[11] that in [7,8-*nido*-$C_2B_9H_{12}$]$^-$ the 12th hydrogen atom also occupies an *endo*-terminal position [on B(10)]. Given that the structure of the anion [3-PPh_3-3,1,2-$CuC_2B_9H_{11}$]$^-$ has previously[12] been shown to involve the {Ph_3PCu} moiety reasonably symmetrically bonded to the five facial atoms (C_2B_3) of the carbaborane ligand, we considered it of interest to synthesize and structurally characterize the gold(I) analogue. In terms of the isolobal analogy[13] between H^+ and {Ph_3PAu^+} this species might be expected to show a greater structural similarity to [7,8-*nido*-$C_2B_9H_{12}$]$^-$ than to [3-PPh_3-3,1,2-$CuC_2B_9H_{11}$]$^-$, and thus might represent a further example of an essentially *endo*-σ-bonded $MC_2B_9H_{11}$ species.

EXPERIMENTAL

Synthesis and characterization

The reaction was carried out under dry N_2 using standard Schlenk-line techniques, with some sub-

* Author to whom correspondence should be addressed.

sequent manipulation in air. Solvents were dried and distilled under N_2 prior to use. The IR spectrum was recorded as KBr pellet on a Perkin–Elmer 598 spectrophotometer. NMR spectra were recorded on a Brucker WP200SY spectrometer as CD_2Cl_2 solution at 298 K. Microanalyses were performed by the departmental service. The starting materials, $Tl[TlC_2B_9H_{11}]$[14] and PPh_3AuCl,[15] were prepared by literature methods.

To a stirred mixture of solid $Tl[TlC_2B_9H_{11}]$ (0.2644 g, 0.489 mmol), PPh_3AuCl (0.2422 g, 0.490 mmol) and $[PhCH_2NMe_3]Cl$ {[BTMA]Cl} (0.0908 g, 0.489 mmol), was added CH_2Cl_2 (10 cm^3). The mixture was stirred overnight, filtered and the solvent removed from the pale orange filtrate *in vacuo*. Colourless needles of [BTMA]**1**·CH_2Cl_2 were obtained by diffusion of *n*-hexane into a CH_2Cl_2 solution at −30°C. Yield 0.1789 g, 45%. Found: C, 44.6; H, 5.3; N, 1.8. Calc. for $C_{30}H_{42}B_9NPAu \cdot CH_2Cl_2$: C, 45.0; H, 5.4; N, 1.7%. IR: ν_{max} at 2540 cm^{-1}. NMR: ^1H δ 7.40–7.75 (multiplet, 20H, C_6H_5), 4.41 (s, 2H, CH_2), 3.05 (s, 9H, CH_3) ppm, ^{11}B–{^1H} δ −16.19 (3B), −17.85 (2B), −21.94 (1B), −22.62 (2B), −35.94 (1B) ppm; ^{31}P δ 41.3 ppm.

Crystallographic study

A single crystal (0.1 × 0.1 × 0.5 mm) of [BTMA]**1**·CH_2Cl_2 was mounted on a glass fibre and set on an Enraf–Nonius CAD4 diffractometer equipped with graphite-monochromated Mo-K_α *X*-radiation (λ_{bar} = 0.71069 Å). Unit cell and orientation matrix from the least-squares refinement of the setting angles of 25 centred reflections ($12 < \theta < 13°$).

Crystal data. $C_{30}H_{42}B_9PAu \cdot CH_2Cl_2$, M = 812.83, monoclinic, space group $P2_1/c$, a = 9.5509(17), b = 19.232(3), c = 19.813(3) Å, β = 90.741(13)°, V = 3639.0 $Å^3$, Z = 4, D_{calc} = 1.483 g cm^{-3}, μ(Mo-K_α) = 42.5 cm^{-1}, $F(000)$ = 1612.

Data collected for $1 \leqslant \theta \leqslant 25°$ (h 0 → 11, k 0 → 22, l −23 → 23) by ω–2θ scans (ω scan width = 0.8 + 0.34 tan θ). Over the 194 h of data collection the intensities of two check reflections decayed to *ca* 89% of the original values, and the data were corrected appropriately (CADABS[16]). Of 5307 reflections measured, 4667 [$F \geqslant 2.0\sigma(F)$] were retained.

The structure was solved by Patterson synthesis (Au) and full-matrix least-squares refinement/ΔF syntheses (P, C, B, N, Cl, H_{cage}) using SHELX76.[17] Cage-carbon atoms were identified by internuclear distances and refined (as B) isotropic thermal parameters. Empirical absorption correction (DIFABS[18]) was applied after isotropic convergence. Data were weighted according to $w^{-1} = [\sigma^2(F) + 0.000513F^2]$. All non-hydrogen atoms were refined with anisotropic thermal parameters and phenyl rings were modelled as rigid, planar hexagons (C—C, 1.395 Å). Cage-hydrogen atoms were refined positionally, while all other hydrogen atoms were set in calculated positions (C—H, 1.08 Å). All hydrogen atoms were given a common isotropic thermal parameter, 0.108(5) $Å^2$ at convergence. R = 0.0487, R_w = 0.0482, S = 1.214, for 401 variables. Maximum and minimum residues in the ultimate ΔF synthesis were 0.94 (near Au) and −1.09 $eÅ^{-3}$, respectively. Atomic scattering factors for P, Cl, C, B, N and H inlaid in SHELX76; those for Au were obtained from *International Tables for X-Ray Crystallography*.[19]

Tables of final atomic positional and thermal parameters, a full list of bond angles, and tables of F_o/F_c values have been deposited as supplementary material with the Editor.

Theoretical study

An extended Huckel molecular orbital (EHMO) calculation was performed on [7,8-*nido*-$C_2B_9H_{11}]^{2-}$ with charge iteration [$H_{ii} = H_{ii}^\circ$ + (sense) × (charge)]. The model was derived from the crystallographic coordinates of [7,8-*nido*-$C_2B_9H_{12}]^-$[11] from which the *endo*-H(12) was removed. The calculation was made using the ICON8 program[20] and the weighted H_{ij} formula.[21] H_{ii}'s and Slater exponents for C, B and H were those inlaid in ICON8.

RESULTS AND DISCUSSION

Addition of CH_2Cl_2 to a solid equimolar mixture of $Tl[TlC_2B_9H_{11}]$, PPh_3AuCl and [BTMA]Cl afforded colourless [BTMA]**1** in reasonable yield. The compound was characterized by microanalysis (CH_2Cl_2 solvate) and multinuclear NMR spectroscopy. In particular, the ^{11}B NMR spectrum suggests that the anion has C_s molecular symmetry, subsequently confirmed by an X-ray diffraction study on [BTMA]**1**·CH_2Cl_2. Figure 1 shows a perspective view of the anion and demonstrates the atomic numbering. Table 1 lists internuclear distances and key interbond angles determined.

The anion **1** consists of a *nido*-{7,8-C_2B_9} framework with an *endo*-{PPh_3Au} unit bonded to B(10), Au—B(10) 2.222(9) Å (see Fig. 2 for a view of part of the molecule which emphasizes the orientation of the {AuP} unit relative to the carbaborane cage). Although in solution the molecule clearly displays C_s symmetry, in the solid the {AuP} unit is significantly displaced towards B(11), since Au···B(11) is 2.486(9) Å, cf. Au···B(9) 2.528(9)

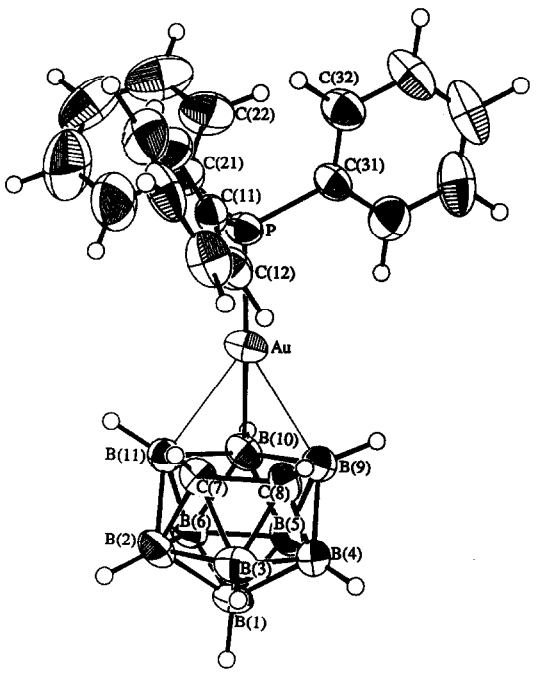

Fig. 1. Perspective view of [10-*endo*-(PPh_3Au)-7,8-*nido*-$C_2B_9H_{11}]^-$. Thermal ellipsoids drawn at the 50% probability level, but the hydrogen atoms are given an artificial radius of 0.1 Å for clarity. Phenyl rings numbered cyclically, C(*ij*) with $i = 1$–3, $j = 1$–6. Hydrogen atoms carry the same number as the boron or carbon to which they are attached.

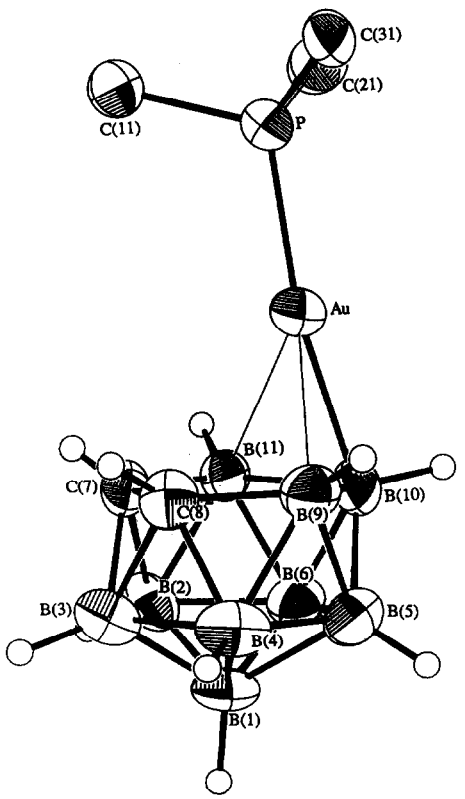

Fig. 2. Alternative view of the central portion of [10-*endo*-(PPh_3Au)-7,8-*nido*-$C_2B_9H_{11}]^-$.

Å, and P—Au···B(11) is 138.08(21)°, cf. P—Au···B(9) 143.53(21)°. The numbering scheme[22] for the carbaborane reflects its *nido* character. The upper C_2B_3 face is non-planar, being folded about the B(9)···B(11) vector with C(7), C(8) and B(10) below the best (least-squares) plane. Fold angles[23] are $\theta = 3.15°$ and $\phi = 3.28°$, and the gold atom, 2.062 Å above the least-squares plane, is slipped by 0.87 Å (= Δ) towards B(10). The lower pentagonal belt [B(2)B(3)B(4)B(5)B(6)] is effectively planar ($\sigma_{\text{lower belt}} = 0.006$ Å vs $\sigma_{\text{upper belt}} = 0.034$ Å).

Compound **1** was expressly synthesized and structurally analysed because of its potential relationship to [10-*endo*-H-7,8-*nido*-$C_2B_9H_{11}]^-$ (**2**)[11] and [3-PPh_3-3,1,2-$CuC_2B_9H_{11}]^-$ (**3**).[12] These three anions can notionally be partitioned into a common $[7,8\text{-}nido\text{-}C_2B_9H_{11}]^{2-}$ ligand and, respectively, $\{Ph_3PAu^+\}$, H^+ and $\{Ph_3PCu^+\}$ fragments, the last three being formally zero electron sources. Table 2 compares Δ, average B—B(facial), average B—C(facial) and C—C for anions **1**–**3** (note that the polyhedral numbering system[22] for *closo*-**3** differs from that for *nido*-**1** and *nido*-**2**). In all four parameters a constant trend is apparent, namely a small change in going from **2** to **1**, and a larger change (in the same direction in every case) in going from **1** to **3**.

To understand the origin of these structural patterns we have considered the form of the occupied π-frontier MO's of $[7,8\text{-}nido\text{-}C_2B_9H_{11}]^{2-}$, as given by a charge-iterated EHMO calculation. These orbitals are sketched in plan view in Fig. 3. The MO's of this species have been reported previously[9a] but the model used was idealized and the calculations were not charge-iterated. Our findings are in broad agreement with this earlier study, except that ψ_2 and ψ_3 are interchanged.

The unoccupied frontier MO's of $\{H_3PAu^+\}$ and $\{H_3PCu^+\}$ comprise[24] a valence (s–p_z) hybrid orbital and a degenerate pair of metal p_x, p_y atomic orbitals. For copper the latter are also valence orbitals, but for gold they are much higher-lying, their relative inaccessibility accounting for the tend-

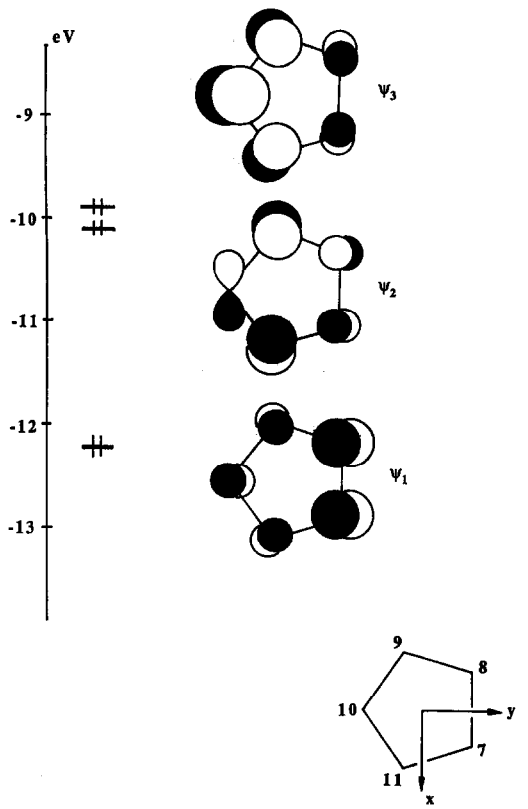

Fig. 3. The occupied π-frontier molecular orbitals of [7,8-*nido*-$C_2B_9H_{11}$]$^{2-}$.

ency of gold(I) to adopt linear coordination vs the tetrahedral coordination typical of copper(I).

The interaction of H^+ with [7,8-*nido*-$C_2B_9H_{11}$]$^{2-}$ to afford **2**, which has an *endo*-H atom bonded to B(10), has been discussed previously.[11] In essence, the key interaction is between H(1*s*) and ψ_3. In moving from H^+ to the formally isolobal {Ph_3PAu^+} some movement of the *endo*-fragment towards the centre of the C_2B_3 face is apparent (Δ from 0.91 to 0.87 Å), and is accompanied by a decrease in $\langle B—B_{facial}\rangle$, an increase in $\langle B—C_{facial}\rangle$ and an increase in C—C. When {Ph_3PAu^+} is replaced by {Ph_3PCu^+} all these structural changes are further magnified. Changing from **2** to **3** we go from a situation in which only ψ_3 is depopulated to one in which the equilibrium geometry results from an attempt to maximize the interaction of all three occupied carbaborane π-orbitals with the appropriate copper acceptor orbitals. The $\langle\psi_2/Cu(4p_x)\rangle$ interaction is maximized when the metal is essentially over the centre of the C_2B_3 face ($\Delta = 0$). Both the $\langle\psi_3/Cu(4p_y)\rangle$ and $\langle\psi_1/Cu(4s–4p_z)\rangle$ interactions would be optimized by a negative slip distortion, and thus the observation of a positive slip in **3** can only be the result of an attempt to maximize the overlap between ψ_3 (carbaborane HOMO) and Cu($4s–4p_z$) (metal LUMO).

Overall, the likely changes in depopulation of the ligand π-MO's as the series **2** → **1** → **3** is progressed are ψ_3 depopulated less, ψ_2 depopulated more and ψ_1 depopulated more. Consequent upon these are the following predicted changes in B—B, B—C and C—C facial distances:

(i) $\langle$B—B$\rangle$ will shorten, the reduced depopulation of ψ_3 outweighing the increased depopulation of ψ_1, since ψ_3 is heavily localized on B(9), B(10) and B(11), whereas ψ_1 lies predominantly on the facial carbon atoms.

(ii) $\langle$B—C$\rangle$ will lengthen, the changes in population of all three carbaborane π-MO's acting in concert.

(iii) C—C will lengthen, the increased depopulation of ψ_1 (localized on carbon) over-riding the effects of changes in the populations of ψ_2 and ψ_3 (both localized on boron).

The structural patterns detailed in Table 2 are fully consistent with these predictions, and indicate that whilst the bonding capabilities of {Ph_3PAu^+} and H^+ are broadly similar, in accord with the isolobal principle, there is firm evidence for some involvement of the high-lying Au($6p_x$,$6p_y$) atomic orbitals.

Finally we note the following:

(i) The mercuracarbaborane [10-*endo*-(Ph_3PHg)-7,8-*nido*-$C_2B_9H_{11}$][10] shows similar structural features to **2** and the isoelectronic **1** (Δ 0.92 Å, $\langle B—B_{facial}\rangle$ 1.86(2) Å, $\langle B—C_{facial}\rangle$ 1.61(2) Å, C—C 1.54(1) Å) consistent with its description as a σ-bonded [Hg—B(10)] species.

(ii) The above results may be contrasted with the effects on ring distances of {Ph_3PCu^+}[25] vs {Ph_3PAu^+}[26] complexation of $[C_5H_5]^-$ or its derivatives. Here, as one moves from {Ph_3PAu} *endo*-bonded to C(1) to {Ph_3PCu} bonded equally to all five carbon atoms, the C(1)—C(2), C(1)—C(5) bonds (≡B—B_{facial}) shorten, C(2)—C(3), C(4)—C(5) bonds (≡B—C_{facial}) lengthen, and the C(3)—C(4) bond (≡C—C) shortens. However, these structural differences are easily traced to the homocyclic nature of the $[C_5H_5]^-$ ligand vs the heterocyclic nature of the open face of [7,8-*nido*-$C_2B_9H_{11}$]$^{2-}$.

(*Received* 3 *April* 1990; *accepted* 8 *June* 1990)

Abstract—Use of the trimethylsilyl protecting function on nitrogen enables the high yield preparation of the potentially tridentate ligands of the type $HN(CH_2CH_2ER_2)_2$ (E = P; R = Me, Et, ^{i}Pr and E = As; R = Me, Et) by nucleophillic substitution of halide in $Me_3SiN(CH_2CH_2Cl)_2$. The di-isopropylphosphino and diethylarsino derivatives have not previously been reported, the other derivatives described are now available in considerably improved yields via this new route. The failure of syntheses or poor yields obtained from unprotected amine precursors is explained by aziridine formation. Deprotonation of the amines provides series of chelating dialkylamido ligands enabling access to new classes of novel complexes.

During the course of a study of the coordination behaviour of the mixed tridentate ligands of the type $L(CH_2)_nX(CH_2)_nL$ (where L = σ-donor/π-acid and X = anionic σ/π base) with early transition metals and actinides, we found access to the compounds $(R_2ECH_2CH_2)_2NH$ (**A**) (R = alkyl, E = P, As) in good yield was not straightforward. These amines are of interest since they are readily deprotonated to give dialkylamides that are likely to form complexes with a range of metals stabilized by five-membered chelate rings, as well as being potentially capable of bridging. Previous studies with the similar diphosphinoamides $[(R_2PCH_2Si(Me)_2)_2N^-$ (R = alkyl or aryl)][1] and studies with $(R_2PCH_2CH_2)_2N^-$ (R = Me, Et)[2] and $(Et_2NCH_2CH_2)_2N^-$[3] demonstrate that new classes of interesting complexes may be obtained. Although the phenyl analogues of **A** are not new,[4] the extension of synthetic methods employed in the past to the preparation of the ligands **A** gives unsatisfactory results. In this paper we describe a general, high yield route to the desired amines, **A**, where R = Me, Et, ^{i}Pr (E = P) and Me, Et (E = As) using the trimethylsilyl protecting function on nitrogen.

EXPERIMENTAL

(1) *Materials and methods*

All manipulations with phosphines, phosphides, arsines and arsenides were performed under nitrogen using standard techniques.[5] NMR spectra were obtained with a Bruker WM 360 spectrometer operating at 360 MHz (^{1}H) or 145 MHz $\{^{31}P[^1H]\}$ and referenced internally to the residual proton impurity in the solvent (C_6D_6, δ 7.27 ppm, ^{1}H) or externally to H_3PO_4 {85%, δ 0 ppm, $^{31}P[^1H]$}. IR spectra were obtained as neat films on a Perkin–Elmer 783 spectrometer and mass spectra were by the SERC Mass Spectroscopy Centre at Swansea on a VG Micromass 7070 by chemical ionization (NH_3), unless otherwise stated.

Solvents were dried by standard methods and distilled under nitrogen prior to use. Et_3N was distilled from sodium under nitrogen. Reagents prepared by literature routes were: Me_2PH,[6] Et_2PH,[7] $^iPr_2PH$,[8] R_2PLi[9] (R = Me, Et, ^{i}Pr), Me_2AsI[10] and Et_2AsI.[11] Other reagents were used as purchased.

(2) *Preparation of bis(2-chloroethyl)trimethylsilylamine* (**I**)

$(ClCH_2CH_2)_2NH \cdot HCl$ (10 g, 0.056 M) was suspended in a mixture of Et_3N (100 cm^3), Me_3SiCl

(40 cm^3) and $(CH_3)_2SO$ (0.25 cm^3) and the mixture was refluxed (16 h) under nitrogen with magnetic stirring. After cooling to room temperature, the off-white suspension was filtered and the excess volatile materials removed *in vacuo*. The yellow–orange oil remaining was $(ClCH_2CH_2)_2NSiMe_3$ (> 98% by NMR). Distillation of this oil was accompanied by decomposition, however, it may be applied directly to the preparations below with good results. Yield, 10.35 g (85% based on amine hydrochloride). Mass spectrum (values are for ions containing ^{35}Cl): 213 (M^+, 0.2%), 178 (M^+-Cl, 0.2%), 106 ($M^++1-SiMe_3-Cl$, 1.0%), 101 ($Me_3SiNCH_2^+$, 1.7%), 86 (Me_3SiN^+, 3.8%), 73 (Me_3Si^+, 93.8%), 56 ($CH_2NCH_2CH_2^+$, 100%).

(3) *Preparation of the bis(2-dialkylphosphinoethyl) amines (alkyl = methyl,* **II**; *ethyl,* **III**; *2-propyl,* **IV**)

The detailed procedure described here is for the ethyl derivative (**III**). To a solution of **I** (10.5 g, 0.049 M) in THF (50 cm^3) was added, at −40°C with stirring, a solution of Et_2PLi (12.5 g, 0.13 M) in THF (50 cm^3) over *ca* 0.5 h. After completion of the addition, the mixture was allowed to warm to room temperature and refluxed for 8 h. The cooled solution was then hydrolysed with water (200 cm^3), completion of hydrolysis of the protecting function being assured by further reflux (1 h) of the two-phase mixture. After cooling and separation of the phases, the aqueous phase was washed (Et_2O, 3 × 50 cm^3) and the combined organic phases dried ($MgSO_4$). This solution was filtered, the volatile solvents were distilled at atmospheric pressure, fractionation of the residue provided **III** as a colourless, viscous oil (b.p. 100–104°C/0.04 mm). Yield based on **I**, 80–92%. IR: 3250 (m, N—H), 1430 (s, CH_2), 1370 (s, CH_3), 1080 (s, CN). Mass spectrum (EI, 70 eV): 221 (M^++1-Et, 43%), 160 (M^+-PEt_2, 22.8%), 146 ($M^+-CH_2PEt_2$, 18.4%), 117 ($CH_2CH_2PEt_2$, 58.2%), 89 (PEt_2^+, 88.2%), 61 ($EtPH^+$, 100%).

Compounds **II** and **IV** are prepared in an analogous manner. Thus from **I** (27.96 g, 0.13 M) and Me_2PLi (18.36 g, 0.27 M) was obtained **II** by low pressure fractionation as a colourless oil (b.p. 78–80°C/0.05 mm). Yield based on **I**, 90–95%. IR: 3260 (m, NH), 1430 (s, CH_2), 1290 (m, CH_3), 1115 (s, CN). Mass spectrum: 194 (M^++1, 4.1%), 192 (M^+-1, 14.0%), 178 (M^+-Me, 89%), 164 ($M^+-1-2Me$, 5.6%), 150 (M^+-43, 8.5%), 132 (M^+-PMe_2, 58.7%), 118 ($M^+-CH_2PMe_2$, 79.9%), 89 ($CH_2CH_2PMe_2$, 95.4%), 61 (PMe_2^+, 100%). Alternatively **IV** may be prepared from **I** (6.5 g, 0.03 M) and $^iPr_2PLi$ (8.5 g, 0.07 M) and isolated as a colourless, viscous oil by vacuum distillation (b.p. 116°C/5 × 10^{-3} mm). Yield based on **I**, 55–60%. IR: 3270 (m), 1460 (s), 1367 (s), 1120 (m). Mass spectrum (CI, NH_3): 306 (M^++1, 0.1%), 263 ($M^+-{}^iPr$), 234 ($^iPr_2PP^iPr_2$, 0.6%), 220 ($M^+-2{}^iPr$, 1.8%), 188 ($M^+-P^iPr_2$), 174 ($M^+-CH_2P^iPr_2$, 29.7%), 160 ($M^+-CH_2CH_2P^iPr_2$, 1.0%), 145 ($M^+-HNCH_2CH_2P^iPr_2$, 90.2%), 117 ($P^iPr_2^+$, 100%).

(4) *Preparation of 2-bis(2-propylphosphino) ethylaziridine* (**V**)

To a cold (−40°C) solution of $^iPr_2PLi$ (5.00 g, 0.04 M) in THF (85 cm^3) was added bis(2-chloroethyl)aminehydrochloride (2.14 g, 0.012 M) in portions over 1 h. The yellow colour of the phosphide dissipated. The mixture was stirred (10 h), followed by hydrolysis with water (40 cm^3). After separation of phases, the aqueous layer was washed (Et_2O, 2 × 50 cm^3) and the combined organic fractions dried ($MgSO_4$). The solution was filtered and the solvents removed by ambient pressure distillation. Low pressure fractionation provided the product **V** (b.p. 50–52°C/0.05 mm). Yield based on aminehydrochloride, 1.68 g, 75%. IR: 3340 (m,br), 3050 (s), 2920 (s,br), 2830 (m), 2800 (m), 2740 (w), 2700 (w), 2660 (w), 1673 (w,br), 1460 (s), 1413 (w), 1385 (s), 1365 (s), 1302 (s), 1270 (m), 1237 (s), 1210 (m), 1185 (m), 1175 (w), 1155 (m), 1142 (m), 1103 (m), 1080 (m), 1055 (m), 1040 (m), 1020 (m), 944 (m), 960 (w), 925 (w), 907 (w), 879 (m), 860 (m), 824 (m), 779 (m), 750 (m), 725 (m), 679 (w), 654 (m), 618 (m), 537 (w), 489 (w), 478 (w), 434 (w), 420 (w). Mass spectrum: 187 (M^+, 1.1%), 186 (M^+-1, 1.2%), 145 ($M^+-NCH_2CH_2$, 10.4%), 144 ($M^+-{}^iPr$, 37.7%), 132 ($M^++1-CH_2NCH_2CH_2$, 8.9%), 118 ($^iPr_2P^++1$, 2.9%), 117 ($^iPr_2P^+$, 13.1%), 102 ($^iPr_2P^+-Me$, 94.1%), 73 ($PCH_2CH_2N^+$, 100%).

(5) *Preparation of the bis(2-dialkylarsinoethyl) amines (alkyl = methyl,* **VI**; *ethyl,* **VII**)

The following procedure is for the ethyl derivative **VII**. To a cooled (−40°C) solution of Et_2AsLi (5.38 g, 0.038 M) in THF (150 cm^3) was added dropwise with stirring a solution of **I** (3.42 g, 0.016 M). The resulting green solution was allowed to warm to room temperature and refluxed (0.5 h). The solution was then cooled (10°C) and hydrolysed with water (20 cm^3) causing the green colour to disappear. The mixture was again refluxed to ensure complete hydrolysis (0.5 h). The cooled mixture was then separated, the aqueous phase washed (Et_2O, 2 × 50 cm^3) and the combined organic phase dried ($MgSO_4$). After filtration and distillation of

the solvents at atmospheric pressure, the product was collected by fractionation at reduced pressure as a colourless liquid (b.p. 121°C/0.05 mm). Yield based on **I**, 4.4 g, 82%. IR: 3270 (w), 2930 (s,br), 2870 (s), 2818 (s), 2740 (m), 2685 (w), 2650 (w), 1455 (s), 1418 (m), 1375 (m), 1365 (w), 1332 (m), 1280 (m), 1265 (w), 1252 (w), 1220 (s), 1140 (m), 1115 (s), 1035 (m), 992 (w), 978 (w), 928 (w), 882 (w), 870 (w), 846 (m), 785 (m), 745 (s,br), 708 (m), 572 (s), 552 (w), 472 (w), 450 (w), 386 (w). Mass spectrum: 309 ($M^+ + 1 - Et$, 4.0%), 308 ($M^+ - Et$, 37.6%), 280 ($M^+ + 1 - 2Et$, 7.0%), 251 ($M^+ + 1 - 3Et$, 4.1%), 222 ($M^+ + 1 - 4Et$, 3.7%), 204 ($M^+ - AsEt_2$, 0.1%), 190 ($M^+ - CH_2AsEt_2$, 1.5%), 176 ($M^+ - CH_2CH_2AsEt_2$ or $M^+ + 1 - AsEt_2 - Et$, 4.8%), 174 ($M^+ - 1 - AsEt_2 - Et$, 6.8%), 133 ($AsEt_2^+$, 65.0%), 105 ($HAsEt^+$, 100%).

The methyl derivative **VI** may be prepared in a similar manner from Me_2AsNa. Thus from Me_2AsNa (19.74 g, 0.154 M) in THF (500 cm^3) and **I** (15.0 g, 0.070 M) was isolated **VI** by fractionation (17.0 g, 86% based on **I**, b.p. 124°C/3 mm). IR: 3250 (w,br), 2960 (m), 2920 (m), 2890 (m), 2790 (m), 2720 (w), 1810 (w,br), 1445 (m), 1410 (m), 1385 (vw), 1276 (w), 1253 (m), 1210 (vw), 1131 (m), 1105 (m), 1040 (w,br), 995 (w), 955 (w), 930 (w), 885 (m), 840 (m,br), 780 (w), 768 (w), 716 (w), 580 (s), 450 (vw), 360 (vw). Mass spectrum: 281 (M^+, 12.1%), 252 ($M^+ - 2Me$, 1.0%), 210 ($Me_2AsAsMe_2$, 0.6%), 176 ($M^+ - AsMe_2$, 25.6%), 162 ($M^+ - CH_2AsMe_2$, 50.5%), 148 ($M^+ - CH_2CH_2AsMe_2$, 7.5%), 122 ($NH_3 \cdot AsMe_2$, 20.5%), 119 ($CH_2AsMe_2^+$, 16.3%), 105 ($AsMe_2^+$, 5.4%), 71 ($M^+ - 2AsMe_2$, 100%).

For both **VI** and **VII**, the arsenide anion may be prepared directly from the dialkyliodoarsine in the reaction flask prior to addition of **I**.

RESULTS

The aminodiphosphines and -arsines (**II**, **III**, **IV**, **VI** and **VII**) have been synthesized according to the reaction sequence outlined in Scheme 1.

In addition, the aziridine (**VII**) has been prepared according to eq. (1). ^1H and $^{31}P[^1H]$ NMR data are presented in Table 1.

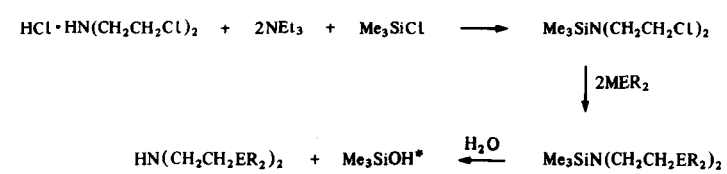
$$HCl \cdot N(CH_2CH_2Cl)_2 + 3LiP^iPr_2 \longrightarrow CH_2CH_2NCH_2CH_2P^iPr_2 + 3LiCl + 2HP^iPr_2. \quad (1)$$

DISCUSSION

(1) *Synthetic methods*

The reaction of $HCl \cdot HN(CH_2CH_2Cl)_2$ or the free amine, $HN(CH_2CH_2Cl)_2$, with dialkyl phosphido or arsenido nucleophiles ($^-ER_2$) in a ratio of 1 : 3 or 1 : 2, respectively, in THF or $NH_3(l)$, gives the desired aminodiphosphines or -arsines (**II**, **III**, **V**, **VI**) in low and variable yields. This procedure completely fails in attempted preparations of **IV**. Indeed, the reaction of the free amine [$HN(CH_2CH_2Cl)_2$] with $^-PPr_2$ leads to the dialkylphosphinoaziridine ($CH_2CH_2NCH_2CH_2PPr^i_2$, **VIII**) in reasonable yields (60%). Similar aziridines are obtained in the preparations of **II** and **III** also, although the proportion of aziridine to diphosphine is greatest for the di-isopropyl and decreases in the order $P^iPr_2 > PEt_2 > PMe_2 > AsEt_2 \approx AsMe_2$. This order parallels that of decreasing basicity and increasing nucleophilicity of the phosphido or arsenido anions. The mechanism we propose for aziridine formation is given in Scheme 2.

The proposed mechanism consists of a strong base-initiated intramolecular nucleophilic cyclization leading to the 2-chloroethylaziridine. Such base-initiated cyclizations of 2-haloalkylamines are well known and are the basis of the Gabriel synthesis of aziridines.[12] Further substitution of chloride results in the phosphinoaziridine. From this it is apparent that increasing the basicity and decreasing the nucleophilicity of the phosphide will decrease the yield of the diphosphinoamine in preference for the aziridine. The use of a protecting function on nitrogen should then suppress the first step and allow intermolecular substitution to predominate. Obviously such a protection must be stable to strong non-aqueous bases and nucleophiles and be readily removed after the substitution. We have



Scheme 1. (M = Li, Na; E = P, As.) *Note that other siloxanes may also be formed.

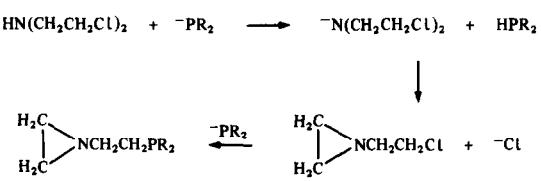
[a] Conditions are as described in the Experimental. All chemical shifts are in ppm.

previously reported[2] on the failure of benzyl since although the diphosphinobenzylamine is readily prepared in high yield, the benzyl function is not readily cleaved in this instance. Ideal for this purpose is the trimethylsilyl group since nitrogen–silicon bonds are readily cleaved by protic reagents (e.g. H_2O or MeOH). The use of trimethylsilyl in this context has been studied.[13] Our preferred method for the synthesis of **I** (Scheme 1) consists of the reaction of the aminehydrochloride with excess triethylamine in the presence of trimethylchlorosilane and a few drops of DMSO. DMSO increases the rate of silylation. This method has advantages over the prior liberation of free amine with either aqueous or non-aqueous bases followed by silylation, as low yields of mixures of unidentified silylamines are obtained from this procedure. Also, other silylating agents such as hexamethyldisilazane give unsatisfactory results. The substitution of chloride in **I** with phosphido or arsenido nucleophiles is suprisingly clean and has high yield; in the case of $^-PMe_2$ and $^-PEt_2$, almost quantitative yields of **II** and **III** are obtained if only a slight excess of phosphide is used. If the reaction is performed at −40 to −30°C, lithium–halogen exchange is minimized and hydrolysis of excess nucleophile and cleavage of the protecting function are conveniently simultaneous.



Scheme 2.

This route is also advantageous for the preparation of the diarsinoamines (**V**,**VI**), since contrary to a previous report,[14] the direct substitution of

chloride in $HCl \cdot N(CH_2CH_2Cl)_2$ or the free amine is not as successful as stated. We have not yet been able to reproduce the quoted yields, indeed total failure of this procedure is common, resulting in the isolation of considerable quantities of white solid after distillation of the more volatile liquid materials. From this white residue, we have isolated the ammonium salt, $HI \cdot HN(CH_2CH_2AsMe_2)_2$, by recrystallization from water. That the ammonium salt is isolated indicates that $^-AsMe_2$ is a better nucleophile than base for bis(2-chloroethyl) ammoniumhalide since substitution of the chlorides does not deprotonate the ammonium nitrogen. The source of iodide is no doubt NaI resulting from the preparation of $NaAsMe_2$ from $IAsMe_2$, presumably metathesis occurs with the hydrochloride due to the insolubility of NaCl under the conditions; we can not say whether this metathesis occurs before or after the substitution. The free ligand may then be reclaimed by treatment with base. We have also shown that on occasions, some mono-substituted amine, $Me_2AsCH_2CH_2N(H)CH_2CH_2Cl$, co-distills with the desired product (NMR) and slowly quaternizes (over several days) producing white crystalline solids.[15] This event seriously depletes the yield of the preparation, but can be minimized by more rigorous drying of the precursors [Me_2AsI and $HN(CH_2CH_2Cl)_2$] and by using a greater excess of arsenide.

(2) *Spectroscopic characterization*

The ^1H NMR spectra of the phosphorus-containing compounds consist of interpretable multiplets in the P–alkyl region (doublet for **II**, doublet of triplets and doublet of quartets for **III**). For **IV** there are two complicated resonances. The 2-propyl methyl protons give rise to an eight-line multiplet that appears as two overlapping doublets of doublets. We presume that this multiplicity of lines arises from the presence of rotamers due to restricted rotation of the adjacent 2-propyl P—C bonds. The unique proton gives rise to a straightforward doublet of septets. The methylene protons of the "backbone" also give rise to two multiplets in each case with the protons on carbons α to nitrogen being relatively deshielded with respect to those on carbons α to phosphorus. The resonance due to the protons on the carbon α to nitrogen appear as a binomial quartet as a result of two overlapping triplets, since homonuclear decoupling of this resonance from the protons on the carbons α to phosphorus gives rise to a doublet for **II**, **III** and **IV**. The magnitude of $^3J_{P-H}$ (*ca* 14 Hz for **II** and **IV**, 7.8 Hz for **II**) is greater than $^2J_{P-H}$ (*ca* 1.5–2 Hz for **II** and **IV**, 2.6 Hz for **II**) presumably due to alternation in the sign of the coupling constants between bonds, as has been reported previously[16] for ethyl phosphines. Resonances assignable to N—H protons were not observed, with the single exception of **VI** (δ 1.33 ppm, width at half height: 17 Hz).

The $^{31}P[^1H]$ NMR are single lines with the order of increasing deshielding $PMe_2 < PEt_2 < PPr^i_2$, a tendency already known for non-chelating analogues.[17] ^{31}P NMR spectra showed broadened lines for which P—H coupling could not be resolved under the conditions employed.

The compounds **II**–**VI** give rise to broad N—H stretches in the IR, in the region 3250–3280 cm^{-1}.

Mass spectroscopic data clearly support the characterizations of compounds **I**–**VII**. All the compounds presented here show a molecular ion with the exception of compounds **III** and **VI** where $M^+ - H - Et$ is observed. There are a number of common features in the fragmentation of **II**, **III**, **IV**, **VI** and **VII**. In each case, loss of one and/or two alkyl groups from the molecular ion is seen. Other fragments arising from E—C (E = P, As) and N—C and C—C cleavage are observed including R_2E, $R_2PCH_2CH_2$, $R_2ECH_2CH_2N$ and $R_2ECH_2CH_2NCH_2$. For the phosphines, the R_2P peaks are intense (100% for R = Me, ^{i}Pr; 88.2% for R = Et).

SIMULATION OF PLASTICITY OF A COPPER(II) COORDINATION POLYHEDRON WITH A FORCE FIELD BASED ON COULOMBIC INTERACTIONS: CONFORMATIONAL ANALYSIS OF COPPER(II) CHELATES WITH α-AMINO ACIDS

J. SABOLOVIČ and N. RAOS*

(*Received* 3 *April* 1990; *accepted* 8 *June* 1990)

Abstract—In order to simulate the plasticity of the copper(II) coordination sphere with the empirical force-field method (molecular mechanics), a square planar complex was defined as an octahedron consisting of four charges situated in the coordination plane, and two charges above and below the plane. Between these point charges only repulsive coulombic interactions take place besides harmonic bond-stretching interactions with the central atom. The model was parametrized on tetrahedrally distorted bis(L-N,N-dimethylvalinato) copper(II) (**1**). The obtained force field reproduced angles around copper in both planar and non-planar copper(II)-aminoacidates with r.m.s.-deviation from 0.15 to 3.4°. The enantioselectivity effect [energy difference between Cu(L-ligand)(L-ligand) and Cu(L-ligand)(D-ligand)] for compound **1** was reproduced within experimental error. The shape of the potential energy surface was analysed using the CuN_2O_2 "complex"; it yielded *cis* and *trans* conformations, but also many "false" minima. The model appears to be reliable for not too great deviations from planarity (15–30° for *trans* valence angles around copper).

There are two basic approaches in molecular-mechanics (or consistent force field) calculations[1,2] to simulate central atom coordination geometry. The first approach (based on "covalent" models) proposes an empirical potential dependent on bond lengths and valence angles around the metal atom, making consequently no basic difference between the "organic" and the "inorganic" parts of a molecule. The second approach assumes that between the central and ligated atoms only non-bonded, usually coulombic interactions take place ("ionic" models). The first approach has been thoroughly employed for conformational analysis of chelates with rigid coordination geometry, e.g. complexes of cobalt[3] and nickel.[4] A purely electrostatic model which treats atoms in the (first) coordination sphere as ionic species (only non-bonded, Lennard–Jones and Coulomb potentials were taken into account) has been applied to complexes of calcium with calcium-binding proteins,[5] e.g. calmodulin. Because calcium lacks any fixed shape of coordination polyhedron, this simple model proved successful.

The problem of simulating the plasticity of the copper(II) coordination sphere (the property of copper complexes that they usually do not form "regular", planar or tetrahedral coordination polyhedra[6,7]) with the molecular-mechanics method calls for modification of these simple models. In our previous papers dealing with tetracoordinated copper(II) bis-aminoacidates and their N-alkylated derivatives[8–15] we proposed two kinds of model. One treated the tetracoordinated (planar) copper(II) atom as being hexacoordinated, with two additional "dummy" atoms placed in the apical position.[10,15] The other was based on the new empirical potential dependent on the distortion coordinate β, defined as an angle between the bisectors of two O—Cu—N angles in opposite chelate rings.[11,12] In general, models with the distortion

* Author to whom correspondence should be addressed.

potential, V_β, proved to be better in reproducing the crystal geometry.

This paper deals with a new type of model, which is based on coulombic repulsion between ligated atoms. The model was inspired by the work of Kepert,[16] who tried to explain the variety of shapes of coordination polyhedra for many metallic and non-metallic elements proposing the repulsive potential between metal–ligand bonds. We adopted his general idea that the planarity of the copper(II) coordination sphere was due to the electron density situated above and below the plane of chelate rings.[16,17] Therefore, we proposed a model without any explicit angle-bending potential for the angles around copper, but with a bond-stretching potential for bonds with ligated and "dummy" atoms (i.e. apically placed charges). The model should, according to our classification, be regarded as "ionic", in contrast to our earlier models which can be described simply as "covalent".

METHODS

The conformational (strain) potential energy was calculated from the basic formula:

$$V = 1/2\sum_i k_{b,i}(b_i - b_{0,i})^2 + 1/2\sum_j k_{\theta,j}(\theta_j - \theta_{0,j})^2 + 1/2\sum_k V_n(1 \pm \cos n\varphi_k) + \sum_l (A_l \exp(-B_l r_l) - C_l r_l^{-6}) + \sum_{m \neq m'} \frac{q_m q_{m'}}{4\pi\varepsilon_0 r_{m'm}} + 1/2\sum_n k_{\chi,n}\chi_n^2, \quad (1)$$

in which b, θ, φ and χ stand for bond lengths, valence, torsional and out-of-plane angles, respectively; r is the non-bonded distance, k_b is an empirical parameter for bond stretching and k_θ for valence angle bending. Torsional interactions were determined with parameters V_n and n (height and multiplicity of the torsional barrier, respectively) and non-bonded interactions were computed from a Buckingham function with parameters A, B and C. The Coulomb potential, dependent on charge parameters ("elementary charges") q, was computed by taking into account only the atoms which define the shape of the coordination polyhedron (see Description of the model). In addition, the out-of-plane deformation potential for the carboxyl groups with a quadratic function dependent on parameter k_χ was also computed.

The parameters were the same as used in our previous research[12,15] with the exception of those developed in this paper (see Results and Discussion). Calculations were performed with Rasmussen's program for conformational analysis,[2] which was further modified to cope with the new model.

Description of the model

The coordination polyhedron is defined with five "real" atoms (M, N, N′, O and O′) situated in the plane of chelate rings, and two "dummy" ligand atoms (denoted as X and X′) placed above and below the plane. Between these atoms only bonding (with the central atom M) and coulombic interactions (between all non-bonded atoms, except between X and X′) were calculated.

The bond-stretching parameters (k_b and b_0) for M—O and M—N bonds [eq. (1)] were the same as used previously.[15] The parameter k_b for the M—X bond was defined so that at the distance b_{MX} from the central atom there was an equilibrium of attractive bonding (between M and X) and the repulsive coulombic forces (between X and ligated atoms). From that condition a simple equation for the calculation of the bond-stretching parameter can be derived ($b_{0,MX} = 0$):

$$k_{M-X} = q_Y q_X k'_b / 4\pi\varepsilon_0, \quad (2)$$

where q_Y is the charge parameter for atom O or N (it is taken to be equal), and q_X is the charge parameter for the "dummy" atom X or X′. K'_b is a sterical parameter dependent on appropriate bond lengths (b_{MX}, b_{MN}, b_{MO}), valence angles (θ_{XMN}, θ_{XMO}), and non-bonded distances between atoms in coordination polyhedron (r_{NX}, r_{OX}):

$$k'_b = \sum_Y r_{XY}^{\ 3} b_{MX}^{\ -1}(b_{MX} - b_{MY}\cos\theta_{XMY}), \quad (3)$$

where Y stands for N or O. The non-bonded distances r_{XY} can be easily calculated from bond lengths and valence angles:

$$r_{XY} = (b_{MX}^{\ 2} + b_{MY}^{\ 2} - 2b_{MX}b_{MY}\cos\theta_{XMY})^{1/2}. \quad (4)$$

Such a formulation [eqs. (2)–(4)] of the problem enabled us to express the M—X bond-stretching parameter as a function of three more basic parameters: (1) "elementary charges" centred on "real" atoms N and O, (2) charge of "electron cloud", i.e. "dummy" atoms X, and (3) distance of the apical charge from the nucleus of the central atom. Moreover, it is possible to choose such a sterical parameter k'_b to obtain a b_{MX} value in the realistic span of M—X distances (Fig. 1), having no reference to charge parameters q_Y and q_X.

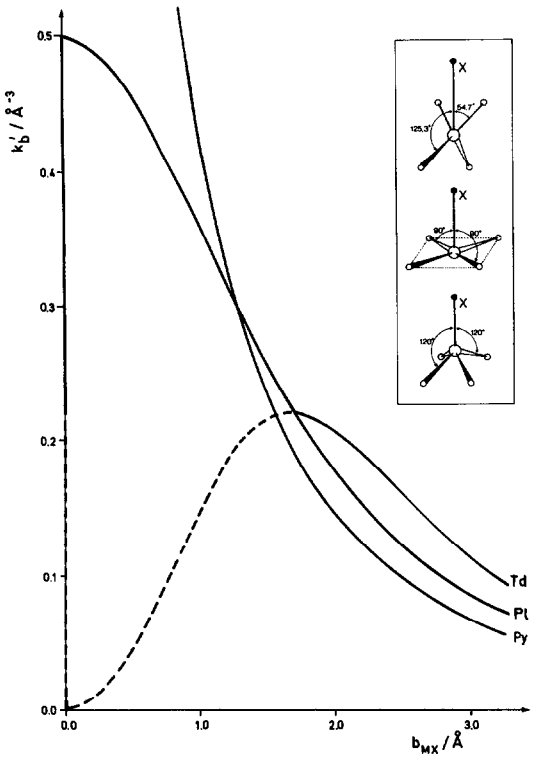

Fig. 1. Plot of the sterical parameter, k_b' [eq. (3)], vs bond length, b_{MX}, when $\partial V/\partial b_{MX} = 0$, "complex" $CuX_2O_2N_2$. Pl, planar (*trans*) configuration; Td, tetrahedral configuration; Py, pyramidal configuration. The points corresponding to the minima of the conformational energy are denoted by the heavy line, and points of maximum value of conformational energy are connected by the broken line. Lengths of the M—O and M—N bonds were taken to be equal (2.0 Å).

Comparison of structures, calculation of average Gibbs energy and construction of conformational energy diagrams

The root-mean-square deviation between crystal and theoretical structures was calculated from:

$$\varepsilon_{r.m.s.}(\Delta X) = \left(1/N \sum_{i=1}^{N} (\Delta X_i)^2\right)^{1/2}, \qquad (5)$$

where X stands for angles around copper (valence angles θ, distortion angle β and "torsional angle" φ_{ONNO}) when comparing the copper coordination geometry, or the interatomic distance, r, when checking the overall similarity. Symbol Δ denotes the difference between the values of the observable X in two structures. For checking of overall similarity, only distances between non-hydrogen atoms were taken into account.

The average Gibbs energy of the diastereomer (MLL or MDL) was calculated from the formula:

$$\langle G \rangle = \sum_i w_i G_i \Big/ \sum_i w_i, \qquad (6)$$

where G_i denotes the Gibbs energy of the ith conformer, and w_i stands for the statistical weight calculated from the Boltzmann formula. Details of calculations were given elsewhere.[13] The potential energy surface for distortion of the copper coordination polyhedron was constructed from the values of potential energy and appropriate values of two internal coordinates obtained after every iteration during the minimization of potential energy (procedure of Rasmussen and co-workers,[18] modified[12]). As the starting points for minimization, arbitrary conformations of the "complex" $CuX_2N_2O_2$ in the whole conformational space were constructed.

RESULTS AND DISCUSSION

The first step in checking the electrostatic model for simulation of the plasticity of the copper(II) coordination polyhedron was to prove how well it reproduced crystal geometry of copper(II) bis-complexes with α-amino acids and their N-alkylated derivatives (Table 1). Both bonding (k_b'), and charge (q_X, q_Y) parameters were systematically varied until the best agreement, in terms of $\varepsilon_{r.m.s.}(\Delta\theta)$ and $\varepsilon_{r.m.s.}(\Delta\theta,\Delta\beta,\Delta\varphi)$, between theoretical and crystal structures[10] of bis(L-N,N-dimethylvalinato) copper(II) has been achieved (Table 1). Although empirical parameters for molecular-mechanics calculation have no strict physical meaning, it has to be noted that obtained parameters (footnote to Table 1) are "realistic", in the sense that they reflect general charge distribution and molecular geometry. The sum of the q_Y charges equals -1.5 e, which is close to -2.0 e, the value to be expected if the complex is purely "ionic". The obtained k_{M-X} yielded M—X distances of about 2.2 Å, which corresponded approximately to the Cu—O (apical) bond length ($\approx$ 2.5 Å).

The obtained force field was checked on all tetracoordinated copper(II) bis-aminoacidates which showed no pronounced intermolecular interactions (Table 1). The new, electrostatic model gave better agreement with the X-ray structures of any model checked so far. The best model with a distortion coordinate potential (Model 5)[12] yielded better agreement with experimental data only in two cases (for the complexes with L-phenylalanine and rac.-N-benzylproline). The "abnormal" behaviour of the former molecule was also observed with other models[12] and was attributed to intramolecular

[a] All values are given in degrees. Standard deviations are given in parentheses.

interactions in the crystal lattice (stacking of phenyl rings, apical ligation of carboxylic oxygens and hydrogen bondings).[23] Both molecules gave higher distortion from ideal planar geometry (N—Cu—O = 90°) with Model 6 than with Model 5, indicating —at least in that case—that the force field was "too loose".

The valence angles around copper were substantially better reproduced with the new model. The linear correlation of measured vs calculated *trans*-angles yielded both the correlation coefficient and slope ($r = 0.68$, $B = 1.08$ for O—Cu—O; $r = 0.88$, $B = 1.19$ for N—Cu—N) acceptable, but the distortion angle ($r = 0.73$, $B = 1.44$) and torsion angle, O′—N′—N—O ($r = 0.58$, $B = 0.44$) were less successfully reproduced. The numbers are close to those achieved with other empirical force-field models.[12] Some improvement was achieved for *cis*-angles (N—Cu—O) which gave upon linear regression a correlation coefficient in the range 0.2–0.4 (< 0.1 for other force fields). Also, the electrostatic model did not yield "too stick" a force field (the force field which gave theoretical values of valence angles too close to their "standard" values, e.g. 90 and 180°) like models with distortion coordinate potential.[12] The mean of the angles in the theoretical structures is in the range of mean angles in the crystal structures (Table 2). Such good agreement was not obtained for the models with a distortion coordinate potential, e.g. Model 5.

The second test for validity of the model is to check its ability to reproduce the diastereoselectivity (or more specifically: enantioselectivity)* effect (Table 3). Contrary to the models with a distortion coordinate potential,[11,12] which gave too high values for the difference between MLL and MDL isomers ($\Delta G = 5.42$–7.43 kJ mol^{-1}), the electrostatic model revealed the value of the enantioselectivity effect in the very limits of experimental error. Comparably good results were obtained only with the "dummy" atom model[9] ($\Delta G = 2.95$ kJ mol^{-1}) but, unfortunately, that model did not give a correct geometry of copper coordination.

The model was further checked on the $CuX_2N_2O_2$ "molecule" in order to study the shape of the potential energy surface in the absence of "additional" sterical influences. Systematically

*The enantioselectivity effect is defined as Gibbs energy difference between MLL and MDL (L and D denote configuration of the ligand) isomers: $\Delta G = -RT \ln (\beta_{MLD}/\beta_{MDL})$; β is the cumulative stability constant of the appropriate complex.

Table 3. Estimation of conformational potential, Gibbs energy and statistical weights of the two isomers of bis-(N,N-dimethylvalinato)copper(II)[a]

Experimental value[9]		2.9...4.0				

[a] All energy values are expressed in kJ mol^{-1}. Statistical weights are given in parentheses. The minima of the conformational energy are denoted as in ref. 8. Zero points: $V = 878.031$ kJ mol^{-1}, $G = 2380.583$ kJ mol^{-1}. The enantioselectivity was calculated from the energy of all 21 conformers; for conformers with high energy (not referred to here) energies were not computed after minimization, but approximative values for both strain and Gibbs energy were taken (approximation $E(n-m) = 1/2[E(n-n)+E(m-m)]$, where n and m were code numbers of the conformers).

minimizing the energy of a great number of starting configurations, only two "real" (*trans*, 1 and *cis* 2; Table 4) minima were obtained. These two minima have virtually the same energy. The slight deviation from planarity ($|\beta| = 180°$) of the *cis* minimum can be explained by the small asymmetry of the system (Cu—O and Cu—N bond lengths are not equal). The tetrahedral minimum has not been possible to achieve, but the tetrahedral configuration appeared only as a transition state at a considerably high energy ($V \approx 930$ kJ mol^{-1}).

Because of the lack of a repulsive potential

Table 4. Some characteristic minima of conformational energy for the "complex" $CuX_2N_2O_2$[a]

[a] All angles are expressed in degrees, M—X bond lengths in Å and conformational potential (V) in kJ mol^{-1}.

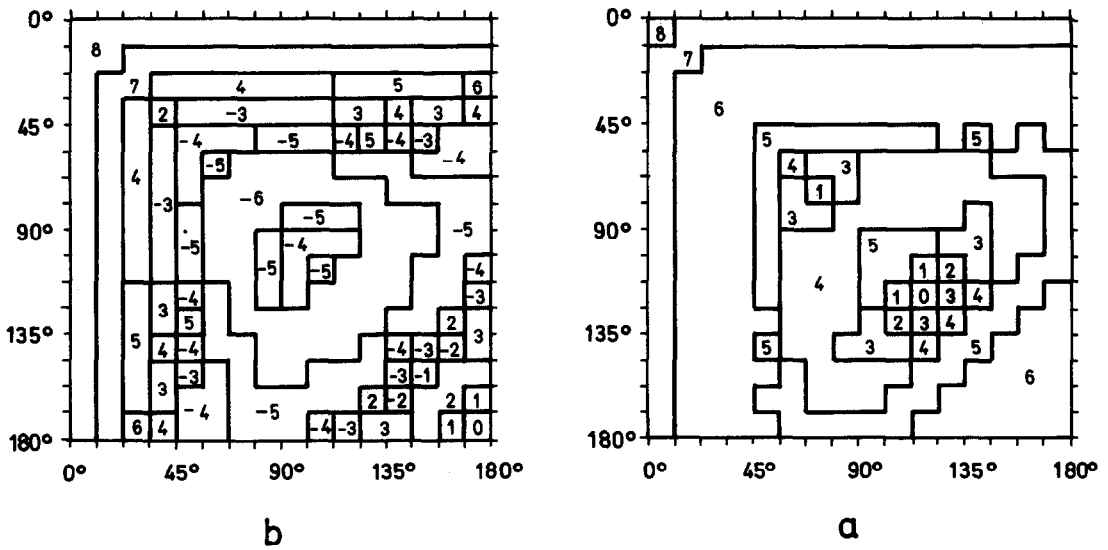

Fig. 3. A diagram of the potential (conformational) energy of the *trans*-$CuX_2N_2O_2$ "complex" in the frame of coordinates N—M—N and O—M—O. The energy ranges (in kcal mol^{-1}) in the appropriate region of the diagram are expressed by the numbers: (a) 0 (< 0.001), 1 (0.001–0.01), 2 (0.01–0.1), 3 (0.1–1), 4 (1–5), 5 (5–10), 6 (10–50), 7 (50–100), 8 (100–1000); (b, absolute values) 0 (< 0.001), 1 (0.001–0.1), 2 (0.1–1), 3 (1–5), 4 (5–10), 5 (10–15), 6 (15–20), 7 (20–50), 8 (50–100). Zero values correspond to $V = 187.420$ kcal mol^{-1} (Min. 3, Table 4) (a) and $V = 204.298$ kcal mol^{-1} (Min. 1, Table 4) (b).

between apically placed charges, the system easily degenerates to the "pentacoordinated complex" $CuXN_2O_2$, i.e. two X "atoms" come atop each other (X—Cu—X′ = 0). As a consequence, a large series of "false" minima was obtained (Table 4), which should be described as (distorted) pyramids (Nos 3, 4), trigonal bipyramids (Nos 6, 7) and even "linear molecules" (Nos 9, 10). Unfortunately, some of these minima (e.g. Nos 3–8) even have a lower conformational energy than the "real" ones.

General properties of the model can be studied by analysing the shape of the potential energy surface (Figs 3 and 4). There is obviously a very flat region around the *trans* minimum (a nearly analogous plot can be drawn for the *cis* minimum, but in the frame of different valence angles). Upon larger distortion

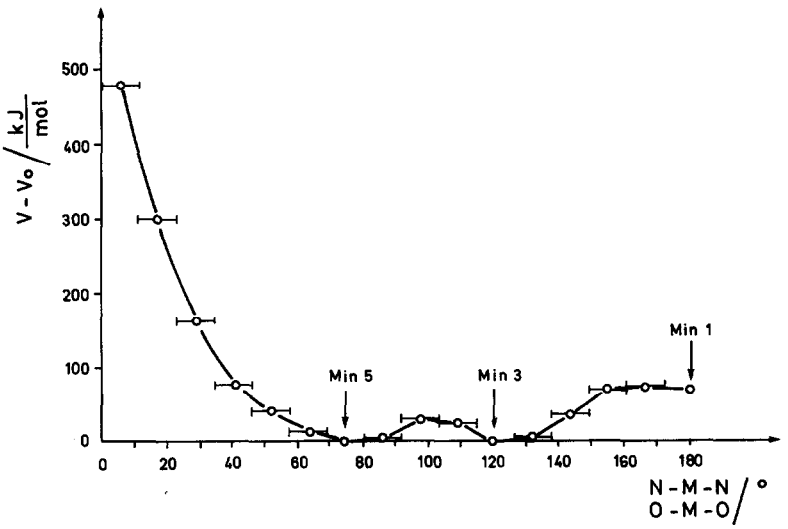

Fig. 4. Plot of the conformational energy of the "complex" $CuX_2N_2O_2$ in the frame of the N—M—N coordinate for the points (obtained from Fig. 3 and Table 4) where N—M—N ≈ O—M—O. The zero point is taken to be equal to 784.165 kJ mol^{-1} (Min. 3, Table 4).

(> 15–30° for N—M—N′ and O—M—O′ angles), the $CuX_2N_2O_2$ "complex" is placed in the lower regions of potential energy surface yielding the "false" minima. In the vicinity of *trans* and *cis* minima the $CuX_2N_2O_2$ "complex" is very flexible, changing its conformational energy by less than 5 kJ mol^{-1} upon distortion.

In conclusion, we can state that the electrostatic model reproduced the geometry of the tetracoordinated copper(II) bis-aminoacidates better than the models checked previously.[10,12] The plasticity of the copper(II) coordination sphere is also evident, because the model generated a very flat potential energy surface for small deviations from planarity (Fig. 3). Unfortunately, for higher deviations it gave a large number of "false" minima (Table 4), and was also incapable of yielding the tetrahedral minimum, which was obtained with the models based on the distortion potential.[12] We tried to solve the problems of false minima by suppressing the "degeneration" of the hexacoordinated to pentacoordinated copper atom through introduction of an additional angle-bending potential for the X—Cu—X′ angle. This attempt did not prove successful, because starting conformations generally did not converge to the minimum even after a very strong potential was applied ($k_{X—M—X} = 1000$ kcal mol^{-1}, $\theta_{X—M—X,0} = 180°$). Fortunately, in our class of compounds the deviation from planarity was not so high as to induce transition of coordination octahedron to any five-top solid. However, the use of the model for conformation analysis of highly distorted structures would call for further development.

STABILITY CONSTANTS FOR THE LEAD(II)–HALIDE SYSTEMS

G. T. HEFTER

School of Mathematical and Physical Sciences, Murdoch University, Murdoch, WA 6150, Australia

(*Received* 12 *December* 1989; *accepted* 15 *June* 1990)

Abstract—The stability constants of the complexes of lead(II) with fluoride, chloride, bromide and iodide in aqueous solution have been measured by potentiometric titrations with a lead amalgam at 25°C and an ionic strength of 1.00 M ($NaClO_4$). The overall stability constants show an interesting "mixed" order with $\log \beta_n$ for $F^- > (Cl^- < Br^- < I^-)$ for $n = 1, 2$, although the fluoride system shows no tendency to form higher order complexes. The stepwise stability constants for each system show variations which may reflect a change in the coordination number of lead(II) from six to four.

Lead(II) is usually considered to be a "borderline" metal ion in Lewis acid terms.[1-3] As such, its stability constants (β_n) with related ligands often show unusual patterns compared with archetypal class A (hard) or class B (soft) metal ions.[1-3] In terms of its halide complexes, lead(II) was thought[1] to exhibit class A behaviour with β_n values having the order $F^- < Cl^- < Br^- < I^-$. However, it was later shown[3,4] that this apparent order was based on an erroneous indirect estimation[5] of $\beta_n[PbF_n^{2-n}(aq)]$. Instead, a mixed order: $F^- > (Cl^- < Br^- < I^-)$ prevails.[3]

Whilst this mixed order was derived[3] from existing literature data, many of the published studies[6-8] disagree markedly as to the relative importance of individual complexes. Thus, it was thought worthwhile to undertake a re-investigation of these systems under comparable conditions. The present paper reports stability constants for the complexes of lead(II) with fluoride, chloride, bromide and iodide in aqueous solution at 25°C and $I = 1$ M ($NaClO_4$) obtained by potentiometric titrations using a lead amalgam electrode.

EXPERIMENTAL

Reagents and apparatus

All chemicals were of analytical reagent grade. A stock solution of lead(II)–perchlorate was prepared by neutralizing (pH 5.0) freshly prepared lead(II)–carbonate[9] with perchloric acid. The concentration was determined polarographically using 5 N purity lead metal as a standard. Ligand solutions were made up by weight from the sodium salts. Sodium fluoride was purified by the method of Lingane.[10] The chloride, bromide, and iodide salts were recrystallized from "conductivity" water then dried at 150°C under vacuum for 24 h. Iodide solutions were prepared and stored under argon to prevent aerial oxidation.

Lead amalgam was prepared by electrolysis of an acidified lead(II)–nitrate solution continually deaerated with argon. The liquid amalgam (about 1% Pb) was transferred to argon-filled storage flasks with a glass syringe. Ionic strength (I) was maintained at 1.00 M with sodium perchlorate and temperature at 25.0 ± 0.1°C. The pH of all the solutions was adjusted to 5.0 ± 0.1 where the presence of HF, HF_2^- and lead(II)–hydroxy species may be ignored.[11,12] All solutions were stored in polyethylene containers.

Measurements were performed under argon on cells which may be represented by:

$$Ag|AgCl, 5\ M\ NaCl \| 5\ M\ NaClO_4 \| x\ M\ Pb^{2+},\ y\ M\ X^-,\ I = 1\ M\ (NaClO_4)|Pb(Hg).$$

No corrections were made for liquid junction potentials but separate measurements[13] and cal-

culations[14] indicated that such corrections were negligible.

The lead amalgam was calibrated using the *in situ* techniques described previously.[11,13] Providing freshly prepared amalgam was used and oxygen was rigorously excluded, calibration slopes were always close to Nernstian (29.6 mV) down to $\sim 10^{-5}$ M Pb^{2+}. In Pb^{2+}-buffered solutions (i.e. in the presence of excess halide) satisfactory response could be obtained down as low as 10^{-7} M in free Pb^{2+}. Care had to be taken to avoid precipitation of PbX_2, a problem which severely limited the range of concentrations which could be studied. All other experimental details are as described previously.[13]

Calculations

Using the usual mass balance relationships, it is readily shown that providing $[Pb^{2+}] \ll [X^-]$ then

$$\frac{1}{[X^-]_T}\left\{\frac{[Pb^{2+}]_T}{[Pb^{2+}]} - 1\right\} = F_0(X) = \sum_1^n \beta_n [X^-]_T^n \quad (1)$$

where $F_0(X)$ represents the experimentally determined left-hand side of the equation, the subscript T refers to the total or analytical concentration and β_n are the overall stability constants (expressed in terms of concentrations) for the reactions

$$Pb^{2+}(aq) + n X^-(aq) \overset{\beta_n}{\rightleftharpoons} PbX_n^{2-n}(aq).$$

The β_n values may be obtained numerically by a least-squares fit of $F_0(X)$ vs $[X^-]_T$ data or graphically, following De Ford and Hume.[15] Both techniques were used and gave identical results within the limits of experimental error.

RESULTS AND DISCUSSION

Typical experimental data for the Pb^{II}/Cl^- system are presented in Table 1; similar data were obtained for the other halide systems. The stability constants obtained are summarized in Table 2. These values are, in general, in good agreement with literature data obtained under comparable conditions,[6,7] although the present data have the advantage of greater self-consistency.

Higher order complexes

The lead(II)–halide systems show interesting variations in their extent of formation of higher order complexes. Thus, even though β_1 and β_2 are greatest for fluoride complexes (Table 2) no higher order complexes ($n > 2$) are formed, consistent with the insolubility of PbF_2 (s) in excess fluoride.[4,8] No evidence was found in the present study for

complexes higher than $n = 3$ for Cl^- or Br^- or $n = 4$ for I^- even at $[X^-]/[Pb^{2+}]$ ratios of up to 70,000.

Relative stabilities

The present results (Table 2) confirm the "mixed" stability order $F^- > (Cl^- < Br^- < I^-)$ previously inferred for the lead(II)–halide complexes, at least for $PbX^+(aq)$ and $PbX_2^0(aq)$. The absence of higher order complexes for Pb^{2+}/F^- implies *complexed* lead(II) shows a classical class B (soft) stability order: $F^- < Cl^- < Br^- < I^-$. Interestingly, in non-aqueous solvents such as DMF[16] and DMSO[17] the lead(II)–halides generally show clear class A (hard) behaviour with stability constants $Cl^- > Br^- > I^-$ (no F^- data are available) although there is some evidence for mixed orderings.

Figure 1 plots the *stepwise* stability constants K_n ($= \beta_n/\beta_{n-1}$) for the lead(II)–halide systems. On statistical grounds, $\log K_n$ is expected to decrease with increasing n since there are fewer available coordination sites for an incoming ligand.[18] Substantial departures are usually due to changes in coordination number.[19] Such changes generally occur abruptly, i.e. in a single step, producing an anomaly in the stability constant order.[19] Figure 1 suggests such anomalies exist for the lead(II)–halide systems with $K_3 > K_2$ for Cl^- and Br^- and $K_4 > K_3$ for I^-. By analogy with zinc(II), cadmium(II) and mercury (II)[19] the coordination change may be envisaged as:

$$PbX_n(H_2O)_{6-n}^{2-n} + X^- \rightleftharpoons PbX_{n+1}(H_2O)_{3-n}^{1-n} + 3H_2O,$$

where the geometry of lead(II) changes from (pseudo) octahedral to (pseudo) tetrahedral.

Such changes are usually more readily apparent in the corresponding enthalpy and entropy changes than in $\log K_n$.[19] Unfortunately, no calorimetric study of these systems has been made[6–8] and the data which can be calculated from the published temperature dependence of the stability constants are dubious. For example, the value of ΔH_1 [$PbF^+(aq)$] which can be calculated from the data of Bond[4,20] is nearly 20 kJ mol^{-1} more negative than any other monofluoride complex.[3] Similarly, independent determinations[21] of ΔH_1 [$PbX^+(aq)$] differ by *ca* 14, 3 and 48 kJ mol^{-1} for X = Cl^-, Br^- and I^-, respectively. Not surprisingly therefore, the available data cannot be used to confirm or refute a possible change in coordination number. A thorough calorimetric investigation of the lead(II)–halide systems would be clearly of considerable interest in understanding the behaviour of these complexes.

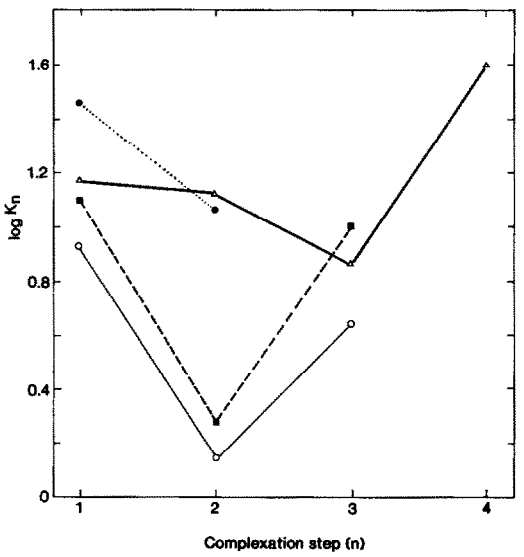

Fig. 1. Plot of stepwise stability constants ($\log K_n$) calculated from Table 2 against the complexation step (n) at 25°C, $I = 1.0$ M ($NaClO_4$): F^- (●); Cl^- (○); Br^- (■); I^- (△).

CYCLIC VOLTAMMETRIC STUDIES OF PENTACYANO(PHOSPHINE)FERRATE(II) COMPLEXES

M. M. MONZYK and R. A. HOLWERDA*

Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, TX 79409, U.S.A.

(*Received* 3 *June* 1990; *accepted* 4 *July* 1990)

Abstract—Half-wave potentials for nine $[Fe(CN)_5L]^{2-/3-}$ couples are reported, where L = P(cyclohexyl)$_3$ (0.321 V), $AsPh_3$ (0.564 V), $SbPh_3$ (0.560 V) and P(Ph-*p*-X)$_3$; X = H (0.522 V), F (0.557 V), Cl (0.585 V), OCH_3 (0.492 V), CH_3 (0.505 V) and CF_3 (0.632 V); $E_{1/2}$ referenced to SHE at 25.0°C, pH 5.0, I = 0.2 M ($NaOAc/NaNO_3$). Linear Hammett plots of $E_{1/2}$ and $\log(K_X/K_H)$ ($\rho = -3.06$) vs σ_p demonstrate that the thermodynamic oxidizability of $[Fe(CN)_5P(Ph\text{-}p\text{-}X)_3]^{3-}$ complexes is moderately sensitive to inductive characteristics of *p*-X groups. The electrochemical reversibility and aqueous solution stability characteristics of $[Fe(CN)_5P(Ph\text{-}p\text{-}X)_3]^{2-/3-}$ couples meet the requirements for biochemical redox mediators in the 0.49–0.63 V vs SHE interval.

Recently completed studies of palladium(II) linkage isomerization processes showed that the rate of carbon-bonded to π-bonded chloranilate (CA^{2-}; 2,5-dioxo-3,6-dichloro-1,4-benzoquinone) rearrangement, induced by incoming PR_3 ligands, depends strongly on triphenylphosphine *para*-substituents.[1,2] Indeed, ^{31}P NMR coordination chemical shifts, phosphine precursor complexation binding constants and intramolecular isomerization rate constants all vary linearly with the Hammett σ_p parameter, suggesting that the polarization of phosphorus 3*p* electron density toward the electrophilic palladium(II) centre strongly destabilizes *trans* Pd–carbanion C bonds.[1] In this way, chloranilate is constrained to function as a weaker σ-donor in the π-CA^{2-} linkage isomer.

Pentacyanoferrate(II) complexes of the form $[Fe(CN)_5L]$ (L = NCS^-, N_3^-, H_2O, NH_3, PPh_3) are useful in probing the dependence of outer-sphere electron transfer rates on thermodynamic driving force.[3–5] Although the IR, electronic, ^{57}Fe Mössbauer and ^{31}P NMR spectral characteristics of $[Fe(CN)_5PR_3]^{3-}$ complexes have been described,[6,7] the dependence of iron(III,II) reduction potentials on phosphine substituents has not been reported. In order to further examine the inductive contributions of phosphine ligands towards bivalent metal centres, we have determined the half-wave potentials of $[Fe(CN)_5P(Ph\text{-}p\text{-}X)_3]^{2-/3-}$ couples (X = H, F, Cl, OCH_3, CH_3, CF_3) by cyclic voltammetry in aqueous solution. For comparison, the $E_{1/2}$ values derived from pentacyanoferrate(II) adducts with P(cyclohexyl)$_3$, $AsPh_3$ and $SbPh_3$ are also reported. In light of these results, the feasibility of $[Fe(CN)_5(Ph\text{-}p\text{-}X)_3]^{3-}$ species as redox mediators will be assessed.

EXPERIMENTAL

Reagent grade chemicals and triply-distilled water were used throughout. Tricyclohexylphosphine, triphenylarsine, triphenylantimony and triphenylphosphines with *p*-H, *p*-F, *p*-Cl, *p*-OCH_3, *p*-CH_3 and *p*-CF_3 substituents were obtained from Strem. Pentacyanoferrate(II) adducts with these ligands were prepared from $Na_3[Fe(CN)_5(NH_3)]\cdot 3H_2O$ by literature procedures,[6,8] vacuum-dried at room temperature and shown to be pure by elemental analyses for C, H and N (Desert Analytics, Tucson, Arizona). All Na_3[Fe

$(CN)_5L]$ complexes subjected to electrochemical study were reported previously,[6,8] except for those where L = $P(C_6H_{11})_3(\cdot 5H_2O)$ and $P(C_6H_4\text{-}p\text{-}CF_3)_3$ $(\cdot 4H_2O)$.

Cyclic voltammograms of nitrogen-purged, 1 mM electroactive solute solutions thermostated to 25.0°C were carried out at a sweep rate of 50 mV s^{-1} with a Bioanalytical Systems CV–1B triangular wave generator and a Hewlett–Packard 7004B *X–Y* recorder. Carbon paste working, gold auxiliary and saturated calomel reference electrodes were employed in $I = 0.2$ M, buffered (HOAc/NaOAc) solutions containing 0.1 M each of sodium acetate and sodium nitrate supporting electrolytes. The carbon paste working electrode was renewed and polished prior to each series of scans on a $Na_3[Fe(CN)_5L]$ complex. Measured potentials were converted to the SHE scale by using hydroxyethylferrocene ($E_{1/2} = 402$ mV vs SHE) as an internal calibrant.[9,10] Reported half-wave potentials were calculated as the average of anodic and cathodic peak potentials ($i_{pa}/i_{pc} = 1.0$) and are the mean of at least three independent trials.

RESULTS AND DISCUSSION

Cyclic voltammograms of $K_4Fe(CN)_6$ and $Na_3[Fe(CN)_5L]$ (L = $P(C_6H_{11})_3$, $AsPh_3$, $SbPh_3$, $P(C_6H_4\text{-}p\text{-}X)_3$; X = H, F, Cl, OCH_3, CH_3, CF_3) in aqueous solution generally exhibit quasi-reversible, one-electron oxidation waves with peak-to-peak separations of 80–120 mV at a sweep rate of 50 mV s^{-1}; substantially larger ΔE_p values were found for $[Fe(CN)_5AsPh_3]^{3-}$ (180 mV) and $Fe(CN)_6^{4-}$ (260 mV), however. In all cases, half-wave potentials calculated as $(E_{pa} + E_{pc})/2$ are independent of sweep rate in the interval 50–300 mV s^{-1}. Table 1 summarizes the $E_{1/2}$ {iron(III,II)} data and represents a comparison with other pentacyanoferrate(III,II) couples of interest. Half-wave potentials of the $[Fe(CN)_5PPh_3]^{2-/3-}$ and $Fe(CN)_6^{3-/4-}$ couples are in reasonable agreement with potentiometrically-measured E^0 values of 0.54 and 0.40 V vs SHE, respectively ($I = 0.05$ M).[3]

As anticipated, $E_{1/2}$ increases substantially with electron-withdrawing capability of the X substituent in $[Fe(CN)_5P(Ph\text{-}p\text{-}X)_3]^{3-}$ complexes. Hammett plots of $E_{1/2}$ or $\log(K_X/K_H)$ ($= \{E_{1/2}(H) - E_{1/2}(X)\}/0.0591$) vs σ_p (Fig. 1) are reasonably linear, with least-squares slopes of 0.181 ± 0.015 and -3.06 ± 0.25, respectively (correlation coefficient = 0.987). In contrast, there is little change or consistent trend in thermodynamic oxidizability when the donor atom is varied from P to As to Sb while holding the phenyl substituent constant. Finally, it should be noted that the entire range in $E_{1/2}$ for triphenylphosphine complexes (0.140

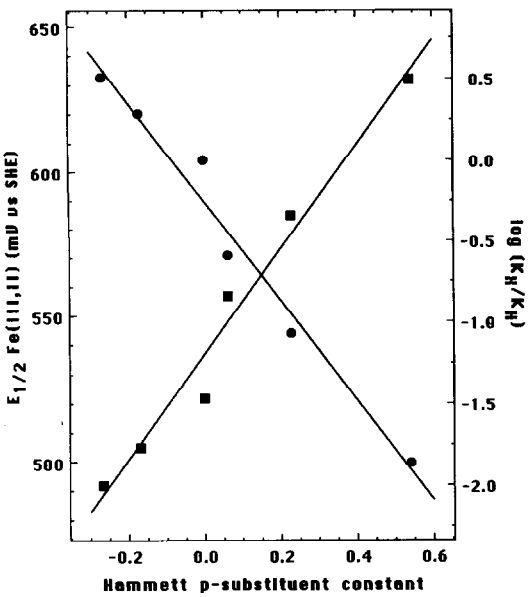

Fig. 1. Linear least-squares correlations of $[Fe(CN)_5P(Ph\text{-}p\text{-}X)_3]^{2-/3-}$ half-wave potentials (■) and $\log(K_X/K_H)$ values (●) with Hammett *p*-substituent constants; 25.0°C, $I = 0.2$ M, pH 5.0.

V) is modest when compared with the difference (0.201 V) between half-wave potentials for the $[Fe(CN)_5PPh_3]^{2-/3-}$ couple and its analogue with a saturated phosphine substituent, $[Fe(CN)_5P(cyclohexyl)_3]^{2-/3-}$. Looked at in perspective, the π-accepting capabilities of triphenylphosphines always exceed those of trialkylphosphines, even when the former contain effective electron-donating functions such as a methoxy group. All of the $Na_3[Fe(CN)_5P(Ph\text{-}p\text{-}X)_3]$ compounds considered here exhibit the electrochemical reversibility and aqueous solution stability characteristics required of biochemical redox mediators. Although the potential range spanned by these reductants is modest, few other suitable mediators are available in the 0.49–0.63 V vs SHE interval.[10]

Triphenylphosphine *p*-substituent effects on the oxidizability of $[Fe(CN)_5P(Ph\text{-}p\text{-}X)_3]^{3-}$ complexes are comparable to those of *p*-substituents on the phenylferricenium/phenylferrocene couple, for which the slope of a $\log(K_X/K_H)$ vs σ_p plot is -2.41.[11] In contrast, a much more negative ρ value of -8.43 pertains in the case of mono- and disubstituted ferrocenes in which substituents are directly bonded to the cyclopentadienyl rings.[12] With regard to phosphine-induced C-bonded to π-bonded chloranilate linkage isomerization with $[Pd(CA)(P\{Ph\text{-}p\text{-}X\}_3)_2]$, the ρ value of -3.12, characteristic of second phosphine ligand pre-equilibrium binding,[1] is surprisingly similar to that of -3.06 which governs $[Fe(CN)_5P(Ph\text{-}p\text{-}X)_3]^{2-}$ reduction, verifying that extensive polarization of the P donor atom accompanies ligation of palladium(II). The sensitivity of the linkage isomerization rate constant to phosphine basicity is considerably smaller ($\rho = -1.32$).[1]

POTENTIOMETRIC INVESTIGATIONS ON THE CADMIUM(II)–AMINO ACID–IMIDAZOLE SYSTEMS (AMINO ACID = GLYCINE, DL-α-ALANINE OR DL-VALINE)

ZUBAIDA KHATOON and KABIR-UD-DIN*

Department of Chemistry, Aligarh Muslim University, Aligarh-202 002, India

(*Received* 6 *June* 1989; *accepted* 15 *January* 1990)

Abstract—The formation constants of mixed-ligand complexes of Cd^{II} with glycine, DL-α-alanine or DL-valine as primary ligands and imidazole as secondary ligand have been determined potentiometrically under physiological like conditions [temp. = 37°C, $\mu = 0.15$ (KNO_3)]. The formation constants for binary systems involving the amino acids and imidazole were also determined under identical conditions. The experimental pH-titration data were analysed using computer program SUPERQUAD. The relative stability of each ternary complex was compared with that of the corresponding binary complexes in terms of $\Delta \log K$ and $\log X$ values.

The ligand imidazole (IM) plays an important role in biochemistry because of its presence in histamine and histidine residues in proteins. The work reported on the interaction of serum albumin with zinc, cadmium and lead ions has demonstrated that the principal sites on the protein molecules responsible for metal binding are the IM group of histidine.[1,2] The effectiveness of the IM group for acting as a metal binding site was attributed to its great flexibility, its availability at physiological pH and its capacity to form both σ and π bonds with metal ions. The neutral IM coordinates via the tertiary nitrogen atom rather than the imino nitrogen of the heterocyclic ring.[4,5]

In the present work we are reporting results of potentiometric investigations on mixed-ligand complexes of Cd^{II} with glycine (GL), DL-α-alanine (AL) or DL-valine (VL) as primary ligands and IM as secondary ligand. Protonation constants of the free ligands, stoichiometry of binary and ternary complexes and their formation constants were computed by analysing the pH-titration data with SUPERQUAD computer program[6] which is an improved version of widely used MINIQUAD program.[7] The values of formation constants for ternary systems containing Cd^{II}–GL–IM were compared with literature values.[8] As no formation constant data on mixed-ligand systems of Cd^{II} with AL, VL and IM are available, the values are being reported for the first time in the present work.

EXPERIMENTAL

The ligands GL (BDH, India), AL, IM (BDH, England) and VL (SDS', India) were used as obtained. Ligand stock solutions were prepared by dissolving calculated amounts in doubly-distilled water. The IM stock solution was standardized by pH-titration with standard nitric acid. Stock solution of nitrate salt of Cd^{II} (S. Merck, India) was prepared in 0.05 M HNO_3. The metal content was determined by complexometric EDTA titration.[9]

Carbonate-free NaOH (the titrant) was prepared and standardized against standard potassium hydrogen phthalate solution.

All the titrations were performed at 37°C (±0.1) in a double-walled glass cell through the outer jacket of which water circulated from a constant temperature bath. Ionic-strength (μ) of all the solutions to be titrated was adjusted to 0.15 by adding requisite amounts of KNO_3. The initial volume of the titration solution in each case was 50 cm^3. Oxygen-free nitrogen gas was passed into the solutions before titrations and then over the solutions during titrations. The titrant was added to the cell

and changes in pH were monitored with a digital pH-meter (ELICO, model LI-120, accuracy: ±0.01 pH unit) using ELICO type EK-62 glass and ELICO type ER-70 calomel electrodes. The pH standard was taken as 4.02 for 0.05 M potassium hydrogen phthalate solution. The electrode system was calibrated by the method of Irving *et al.*[10]

The pK_w of H_2O was taken to be 13.38 at 37°C and $\mu = 0.15$.[11]

Methods

The protonation constants of the free ligands were evaluated as described.[12]

In studying the binary systems, Cd^{II}–AA ratios were 1 : 3 and 1 : 6 while Cd^{II}–IM ratios were 1 : 13.5 and 1 : 22. In the ternary systems, Cd^{II}–AA–IM ratios were 1 : 2 : 4.5 and 1 : 2 : 8.7. The metal ion concentration was *ca.* 2×10^{-3} M. Nitric acid was used to lower the pH of initial solution mixtures in both the binary and ternary systems. The titrations were terminated when either the pH-meter readings became unstable showing a continuous downward drift or visual precipitations occurred.

Titration data analyses, using the SUPERQUAD program, were performed on a VAX-11/780 computer. The procedure used to select the correct equilibrium model was similar to those reported previously.[12,13] The model which gave the best statistical fit to the titration data, as suggested by Gans *et al.*,[6] was assumed to be the true model taking into account the systematic errors in the

experimental data. Finally, the results were assessed on the basis of σ and χ^2 values (for details of χ^2 statistics based on weighted residuals, see Ref. 14). Plots of residuals were also examined to assess the results.[6]

RESULTS AND DISCUSSION

Protonation constants of the free ligands

The protonation constants of ligands GL, AL, VL and IM, evaluated with the aid of the SUPERQUAD program,[12] are given in Table 1.

Binary systems

The formation constants of Cd^{II}–AA and Cd^{II}–IM binary complexes were determined under conditions identical with those of ternary systems, i.e. at 37°C and ionic-strength 0.15 (KNO_3). The values, given in Table 1, show good agreement with the literature values after allowing for changes in experimental conditions as well as in methods of calculation.

With the AAs, Cd^{II} formed $Cd(GL)^+$, $Cd(GL)_2$, $Cd(GL)_3^-$, $Cd(AL)^+$, $Cd(AL)_2$, $Cd(AL)_3^-$, $Cd(VL)^+$ and $Cd(VL)_2$ complexes. In each case, at least one hydroxy species was also detected. El-Ezaby *et al.*[8] have reported formation of a protonated species of Cd^{II} with GL at Cd^{II}–GL ratios of 1 : 1, 1 : 2 and 1 : 3. The stability order in terms of ligands has been found to be GL > AL > VL. The higher stability of GL complexes can be explained due to absence of alkyl chain in GL. Substitution of the methyl group on the α-carbon atom produces a small decrease in $\log\beta$ values but further lengthening of the GL skeleton shows a marked influence on stability.

Under our experimental conditions, formation of only two complexes, *viz.* $Cd(IM)^{2+}$ and $Cd(IM)_2^{2+}$, was observed with IM. Higher species were taken into consideration but were rejected during the refinement.

Distribution curves for various species of Cd^{II} formed in the binary systems with GL, AL, VL or IM as a function of pH at AA = 0.012 M and IM = 0.044 M are shown in Fig. 1.

Ternary systems

The general four-component equilibrium can be written as:

$$pM + q(AA) + r(IM) + sH \rightleftharpoons M_p(AA)_q(IM)_rH_s \quad (1)$$

(p, q, r, s are the stoichiometric coefficients corresponding to Cd^{2+}, AA^-, IM and H^+, respectively; charges are omitted for brevity).

The overall formation constants are defined as:

$$\beta_{pqrs} = \frac{[M_p(AA)_q(IM)_rH_s]}{[M]^p[AA]^q[IM]^r[H]^s}. \quad (2)$$

In the present work results of three mixed-ligand systems, *viz.* Cd^{II}–GL–IM, Cd^{II}–AL–IM and Cd^{II}–VL–IM, are reported. The studies were performed in the pH range 6.0–9.5.

A number of models in sequence were examined with the SUPERQUAD program. Those models were rejected for which value(s) of σ and/or χ^2 were large. Formation constants for the best models examined for the ternary complexes are reported in Table 1. Slight variations in the values of the protonation constants and the formation constants of the binary complexes had no effect on the chosen ternary model; however, the changes observed in the formation constants for the latter were within the experimental error.

For Cd^{II}–GL–IM system, formation of 1 : 1 : 1 : 0, 1 : 2 : 2 : 0 and 1 : 1 : 1 : −1, while for the other systems only 1 : 1 : 1 : 0 complex species have been detected.

The parameters $\Delta\log K_1$, $\Delta\log K_2$, $\log X$ and $\Delta\log\beta$ are generally used to indicate the relative stability of ternary complexes as compared with the binary ones; these are given in Table 2. $\Delta\log K_1$, $\Delta\log K_2$ and $\log X$ represent the formation constants for equilibria (3), (5) and (7) and are calculated from relations (4), (6) and (8), respectively. $\Delta\log\beta$ is the difference between the experimental and the calculated values of β (calculated on the basis of statistical grounds).

$$Cd(AA) + Cd(IM) \rightleftharpoons Cd(AA)(IM) + Cd \quad (3)$$

$$\Delta\log K_1 = \log\beta_{Cd(AA)(IM)} - [\log\beta_{Cd(AA)} + \log\beta_{Cd(IM)}] \quad (4)$$

$$Cd(AA) + Cd(IM)_2 \rightleftharpoons Cd(AA)(IM)_2 + Cd \quad (5)$$

Table 2. The values of $\Delta\log K_1$, $\Delta\log K_2$, $\log X$ and $\Delta\log\beta_{1110}$ for Cd^{II}–AA–IM ternary systems

	AA		
Parameter	GL	AL	VL
$\Delta\log K_1$	0.07	−0.03	−0.05
$\Delta\log K_2$	0.13		
$\log X$	1.29	1.21	1.10
$\Delta\log\beta_{1110}$	0.34	0.30	0.25

Temp. = 37°C; μ = 0.15 (KNO_3).

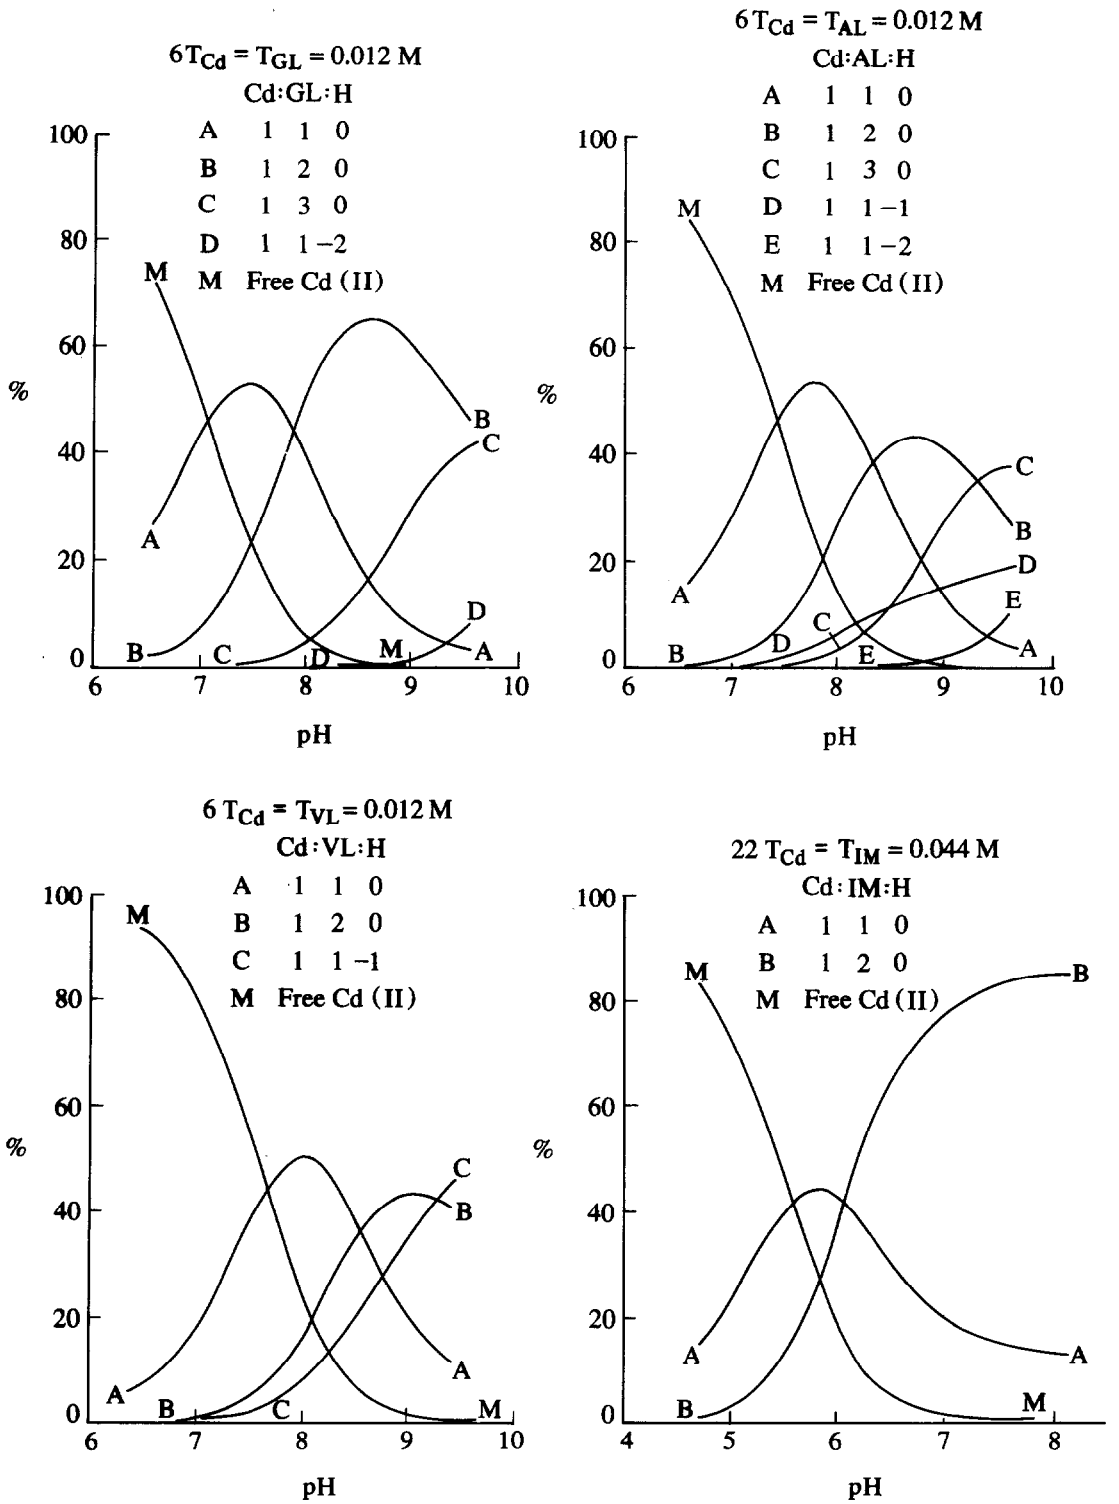

Fig. 1. SUPERQUAD computed species distributions with pH for binary systems of Cd^{II}.

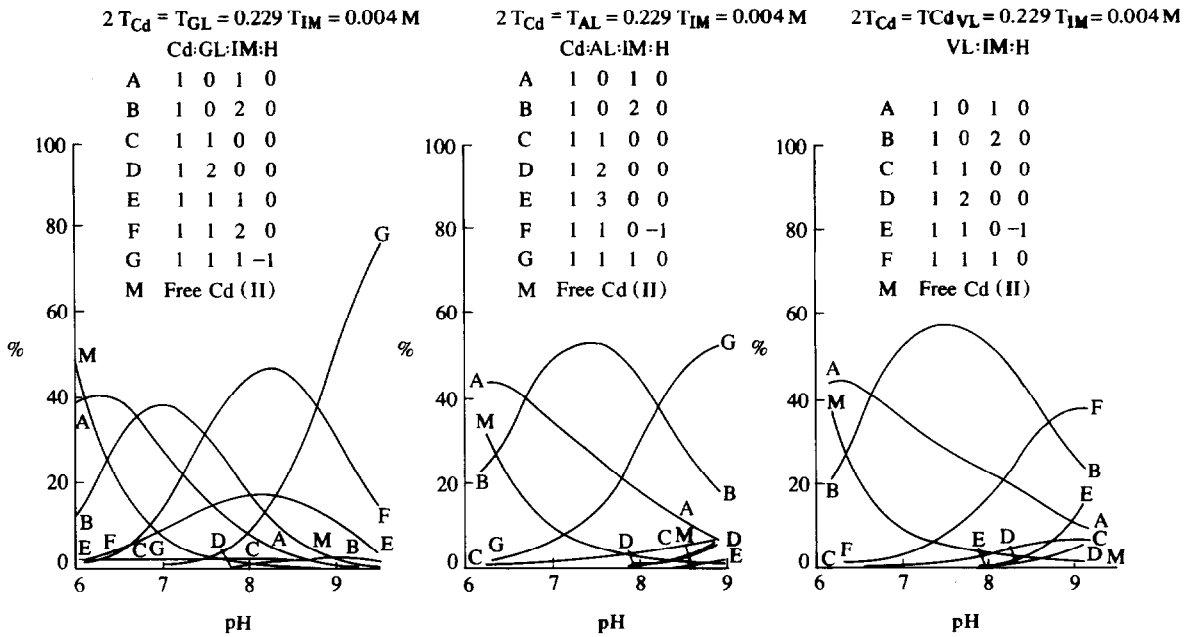

Fig. 2. SUPERQUAD computed species distributions with pH for ternary systems of Cd^{II}.

$$\Delta \log K_2 = \log \beta_{Cd(AA)(IM)_2} - [\log \beta_{Cd(AA)} + \log \beta_{Cd(IM)_2}] \quad (6)$$

$$Cd(AA)_2 + Cd(IM)_2 \rightleftharpoons 2Cd(AA)(IM) \quad (7)$$

$$\log X = 2 \log \beta_{Cd(AA)(IM)} - [\log \beta_{Cd(AA)_2} + \log \beta_{Cd(IM)_2}] \quad (8)$$

$$\Delta \log \beta = \log \beta(\text{exptl}) - \log \beta(\text{calcd}). \quad (9)$$

$\Delta \log K_1$ values which are very close to zero indicate no marked stabilization of the 1:1:1:0 ternary complexes of Cd^{II} formed by equilibrium (3). In other words, imidazole binds better to Cd^{II} than to the binary $Cd(AA)^+$ complexes. This is due to the fact that more coordination positions are available on Cd^{II} than on $Cd(AA)^+$ complexes. However, positive values of $\log X \simeq 1$ (which are greater than the statistical value of 0.6) show that the formation of 1:1:1:0 ternary complexes is favoured by equilibrium (7) or, in other words, 1:2 binary species are less stable than the 1:1:1:0 ternary species. Positive values of $\Delta \log \beta_{1110}$ also show higher stability for the 1:1:1:0 mixed-ligand species compared to binary ones. For the $Cd(GL)(IM)_2^+$ ternary complex, the value of $\Delta \log K_2$ is near to zero showing no marked stabilization over the present binary ones or, in other words, equilibrium (5) is not much favoured in the right direction. Addition of two IM molecules to Cd^{II} and to $Cd(GL)^+$ were equally favoured.

The speciation plots (Fig. 2) of Cd^{II}–AA–IM ternary systems at 1:2:8.7 ratio show that the respective values of maximum concentrations for 1:1:1:0 species were 17.5, 52.5 and 36% respectively with GL, AL and VL while maximum concentration of $Cd(GL)(IM)_2^+$ was 47%. In the case of the Cd^{II}–GL–IM system, formation of the hydroxy species started at *ca.* pH 7 and was *ca.* 76% at pH 9.5.

COMPLEXING ABILITY OF BIS(PHENYL-2-PICOLYLKETONATO)COPPER(II) TOWARDS DIFFERENT METAL(II) AND METAL(III) SALTS

ALI EL-DISSOUKY* and ADEL Z. EL-SONBATI

Chemistry Departments, Faculties of Science, Alexandria and Mansoura Universities, Egypt

(*Received* 4 *October* 1989; *accepted* 3 *April* 1990)

Abstract—A series of binuclear and trinuclear adducts of the bis(phenyl-2-picolylketonato)copper(II), $[Cu(PPK)_2]$, were prepared with Mg^{2+}, Ca^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, La^{3+}, Nd^{3+} and UO_2^{2+} salts. The metal halides gave the binuclear adducts, while the nitrates gave trinuclear adducts. The spectral data show that the planarity of the copper(II) environment in the binuclear adducts is higher, while that in the trinuclear adducts is lower compared to that in the mononuclear complex. Furthermore, the planarity of the adducts was found to be inversely proportional to the ionic radius of the M^{2+} ion in the binuclear adducts. The magnetic susceptibilities of $[Cu(PPK)_2CuX_2]$ and $[\{Cu(PPK)_2\}_2Cu(NO_3)_2]$ complexes were studied over the temperature range of 766–300 K. The magnetic parameters were found to be related to the stereochemistry around the bridging ligand.

In earlier studies,[1–6] the formation and characterization of the complexes of some heterocyclic nitrogen-containing keto-enolates were reported. However, no work has been traced concerning the complexing ability of these complexes. In this paper we report the synthesis and characterization of some binuclear and trinuclear adducts of the bis(phenyl-2-picolylketonato)copper(II) with some metal(II), metal(III) and UO_2^{2+} salts. This work is of interest because of the interesting magnetic and electronic properties of the adducts which are formed. Furthermore, the binuclear and trinuclear copper(II) adducts provide models for metalloenzymes.

EXPERIMENTAL

Physical measurements

Electronic and IR spectra were measured on Pye Unicam SP8-400 and SP3-300 spectrophotometers, respectively. Magnetic susceptibilities were measured on a Faraday magnetic balance and using $HgCo(SCN)_4$ as magnetic susceptibility standard. Molar conductivities were measured on 10^{-3} M solutions of the complexes in nitrobenzene at 20°C using a systronics (303 model) with direct reading conductivity meter. The elemental analyses given in Table 1, were carried out at the Microanalysis Unit at the University of Manchester, U.K. The metal analyses were made using a Chimatzu absorption-flame photometer, Model AA-610S.

Synthesis of the complexes

All chemicals were analar reagent grade and used as supplied. Bis(phenyl-2-picolylketonato) copper(II) was prepared as reported earlier.[1] The binuclear adducts with the general formula $[Cu(PPK)_2MX_2]$ ($M = Mg^{2+}$, Ca^{2+}, Co^{2+}, Ni^{2+} or Cu^{2+} and $X = Cl^-$ or Br^-) were prepared by the general method, *viz.* a suspension of $[Cu(PPK)_2]$ (0.01 mol) in absolute ethanol (30 cm^3) containing MX_2 (0.012 mol). This mixture was stirred at room temperature for 6–8 h and filtered. The filtrate was allowed to stand for 24–36 h at room temperature. The fine crystalline product which was formed in each case was collected by filtration and recrystallized from ethanol. Yield: 82–94%.

* Author to whom correspondence should be addressed. Present address: Chemistry Department, Faculty of Science, Alexandria University, Alexandria, Egypt.

The trinuclear complexes $[\{Cu(PPK)_2\}_2M(NO_3)_n]$ (M = Ca^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Mg^{2+}, La^{3+}, Nd^{3+} or UO_2^{2+} and $n = 2$ or 3) were prepared as follows. Hydrated metal nitrate (0.015 mol) was added to 50 cm^3 of the appropriate solvent (THF, Me_2CO or EtOH) containing $[Cu(PPK)_2]$ (0.03 mol). The reaction mixture was refluxed for 15–20 min, cooled to room temperature and the solid product was collected in each case by filtration and recrystallized from the suitable solvent(s). Yield: 66–79%.

RESULTS AND DISCUSSION

Bis(phenyl-2-picolylketonato)copper(II) reacts with metal(II) and metal(III) halides giving only the binuclear adducts, $[Cu(PPK)_2MX_2]$, while with the metal(II) and metal(III) nitrates, the trinuclear adducts, $[\{Cu(PPK)_2\}_2M(NO_3)_n]$, are formed, Table 1. The adducts are air-stable and decompose above 300°C. They are also soluble in most common organic solvents but can be recovered unchanged from their solution when using non-coordinating solvents. In the solvents such as Py, DMF or DMSO, a drastic change in the colour was observed. This could be due to the dissociation of the adducts and/or formation of new compounds. However, further studies will be performed in the future on the effects of the counter ions and the coordinating solvents on the formation and the behaviour of such adducts.

The molar conductivity of the adducts, Table 1, indicate their non-electrolytic nature.

The IR spectra of PPK and $[Cu(PPK)_2]$ were discussed in previous communications.[1-4] The spectra of the binuclear and trinuclear adducts under investigation exhibit a medium band at 1400–1410 cm^{-1}, due to ν(C—O), compared to that at 1440 cm^{-1} in the complex,[2,3] $[Cu(PPK)_2]$, consistent with the withdrawal of electron density from the oxygen

atom due to polymerization. In addition, the spectra of all the complexes display bands in the region 1580–1586 cm^{-1} compared to those at 1605 cm^{-1} in the spectrum of $[Cu(PPK)_2]$. This band could be assigned to the ν(C=N) of the pyridine moiety. The spectra of all the binuclear adducts contain bonds at 288–296 and 222–218 cm^{-1}, characteristic of coordinated, terminal ν(M—Cl) and ν(M—Br), respectively. The IR spectra of the nitrato complexes (except of uranyl) display absorption bands at 1440–1460 (ν_1), 1026–1030 (ν_2), 742–738 (ν_3), 1340–1378 (ν_4), 712–718 (ν_5) and 810–815 cm^{-1} (ν_6). Such bands are not observed in PPK or $[Cu(PPK)_2]$, and are consistent with the coordinated nitrato group.[7] Moreover, two weak bands are also observed due to the nitrato combination mode at 1700–1800 cm^{-1}. The magnitudes of separation of ν_1 and ν_4 of *ca* 82–100 cm^{-1} indicate the exclusive presence of the monodentate coordinating nitrato group and clearly eliminate the presence of ionic NO_3^-. In the case of the uranyl trinuclear adduct, the spectrum shows a series of bands at 1150 (ν_1), 1285 (ν_4), 1302 (ν_2), 740 (ν_3), 712 (ν_5) and 816 (ν_6), in addition to two weak bands at 1780 and 1736 cm^{-1}. The separation of ν_1 and ν_4 of 265 cm^{-1} and the separation of the combination modes of 44 cm^{-1} indicate the bidentate nature of NO_3^- in the uranyl complex. According to the elemental analyses, conductivity measurements and IR data, structures **Ia**, **Ib** and **Ic** could be assumed for the binuclear and trinuclear adducts. The possibility of the presence of both mono- and bidentate nitrato groups together is ruled out as these would require four bands (two sets corresponding to each type of coordination)[8] in the range 1700–1800 cm^{-1}.

The absorption electronic spectral bands and the extinction coefficients of the *d–d* bands are given in Table 2. The complex, $[Cu(PPK)_2]$, showed a *d–d* band centred at 18,000 cm^{-1}. On the other hand, the binuclear adducts $[Cu(PPK)_2CuX_2]$ (X = Cl^- or Br^-) presented two bands around 18,600–18,700 and 10,600–10,700 cm^{-1}. These are assigned to the *d–d* bands of CuN_2O_2 and CuO_2X_2, respectively. Furthermore, the spectrum of $[\{Cu(PPK)_2\}_2 Cu(NO_3)_2]$ exhibits two asymmetric ligand-field bands at 18,900 and 15,700 cm^{-1}. It is reasonable to assign the high-frequency band to the *d–d* transition for CuN_2O_2 and the low-frequency band to the CuO_6 chromophore. In addition to the *d–d* transition band characteristic of CuN_2O_2 in the binuclear complexes, $[Cu(PPK)_2MX_2]$ (M = Co^{2+} or Ni^{2+} and X = Cl^- or Br^-), the spectra exhibit bands at 15,400 and 14,800 cm^{-1} characteristic of tetrahedral cobalt(II) and at 20,700–20,800 cm^{-1} due to a square-planar nickel(II), as proved by the magnetic data. From the data given in Table 2, one could conclude that the planarity of the CuN_2O_2 chromophore in the binuclear complexes increases

[a] Ethanolic solution.

in the order, $Ni^{2+} > Co^{2+} > Mg^{2+} > Ca^{2+} > La^{3+}$. Thus it is assumed that this effect becomes greater as the size of the second metal ion decreases.

The electronic spectra of the lanthanide(III) and uranyl adducts display one broad band around 17,500–17,600 cm^{-1} and a much weaker one appears in some cases around 10,000 cm^{-1}. The shift of the band characteristic of CuN_2O_2 towards lower energy could be described in terms of the distortion increase of the nearly planar copper(II) environments towards the tetrahedral geometry in these trinuclear adducts. Furthermore, for the alkaline earth and *d*-metal ions, in the trinuclear adducts, this band appears around 17,500–17,700 cm^{-1} indicating a higher distortion decrease towards the tetrahedral geometry relative to the lanthanides. However, in several cases, the appearance of one broad band of relatively low intensity is consistent with rather symmetrical structues. By combining both the well-known tendency of the copper(II) ion to expand its coordination sphere and the existing ambiguity in the assignments of a certain geometry based upon electronic spectra,[9] the spectra of the present adducts may also represent apical expansion through cation–solvent or anion-bridged interactions towards a distorted octahedron.

The magnetic susceptibilities of the formed adducts were measured in the temperature range 76–300 K. The room temperature magnetic moments are given in Table 2. The variable temperature magnetic susceptibilities for trinuclear and binuclear copper(II) adducts are shown in Fig. 1. The room temperature magnetic moments for the

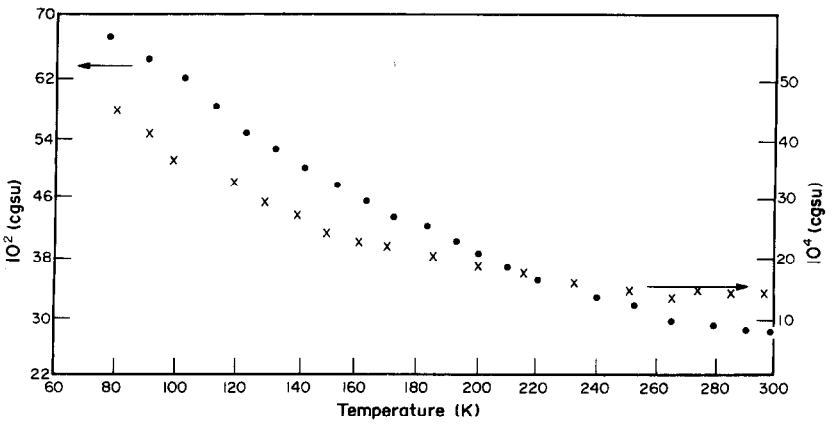

Fig. 1. Magnetic susceptibilities/mol vs temperature curves for: $[Cu(PPK)_2CuCl_2]$ (●) and $[\{Cu(PPK)_2\}_2Cu(NO_3)_2]$ (×).

copper adducts were found to be lower than the expected spin-only value for an unpaired electron on each copper(II). Using the Bleaney–Bowers equation [eq. (1)] for binuclear adducts and eq. (2) for trinuclear adducts,[10] the magnetic parameters were determined by best fit techniques; $g = 2.068$ and $J = -42$ cm^{-1} for $[Cu(PPK)_2CuCl_2]$; $g = 2.066$ and $J = -39$ cm^{-1} for $[Cu(PPK)_2CuBr_2]$; and $g = 2.052$ and $J = -36$ cm^{-1} for $[\{Cu(PPK)_2\}_2Cu(NO_3)_2]$. In all cases N_α was found to be 60×10^{-6} cgs/Cu^{2+}.

$$\chi_A = \left[\frac{N\beta^2 g^2}{3kT}\right][1 + 1/3 \exp^{-2J/kT}]^{-1} + N_\alpha \quad (1)$$

$$\chi_A = \left[\frac{N\beta^2 g^2}{12kT}\right]\left[\frac{e^{2x} + 10e^{3x} + 1}{e^{2x} + 2e^{3x} + 1}\right] + N_\alpha, \quad (2)$$

where $x = -J/kT$ and the other symbols have their usual meanings. The values of J indicate that the spin of the adjacent copper ions are antiferromagnetically coupled. It should be indicated here that the analytical, spectral and the magnetic data support the polynuclear nature of these complexes, with the overall symmetry being low and the g values not being appreciably different from 2.0. The low values of J obtained for the binuclear complexes could be attributed to the distortion and the low symmetry around the bridging oxygen. This distortion (towards planarity) leads to a decrease of the super-exchange integral through the oxygen bridge, resulting in a lower absolute value of J.

CHARACTERIZATION AND ELECTRICAL PROPERTIES OF MoO_2Cl_2 COMPLEXES WITH N-ARYL-N′-(SUBSTITUTED THIAZOLYL) THIOUREAS AND UREAS

K. L. MADHOK* and CHITRA GUPTA

School of Studies in Chemistry, Jiwaji University, Gwalior-474011 (M.P.) India

(*Received* 29 *January* 1990; *accepted* 1 *May* 1990)

Abstract—MoO_2Cl_2 formed six-coordinate complexes with N-(substituted)-N′-(substituted thiazolyl) thioureas and ureas of the general formula $[MoO_2(RNHC{=}SNHR')_2]Cl_2$ and $[MoO_2(RNHC{=}ONHR')_2]Cl_2$, where R = thiazolyl, 4-phenyl and 5-nitrothiazolyl groups and R′ = $-C_2H_5$, $-C_6H_5$, *o*-$C_6H_4(CH_3)$, *p*-$C_6H_4(CH_3)$ and $-C_6H_5CO$. The complexes have been characterized by elemental analysis, molar conductance, magnetic susceptibility, IR, UV–vis and ^1H NMR spectral data. Electrical measurements show that the room temperature conductivities range from 2.3×10^{-8} to 4×10^{-4} Ω^{-1} cm^{-1}. The activation energies (E_a) for conduction have been determined.

The chemistry of oxomolybdenum(VI) complexes involving NS-, SS- and SO-donor ligands has interested coordination chemists in recent years, as evidenced by the flurry of papers published in this area.[1–7] Most simple molybdenum(VI) coordination compounds contain the *cis*-dioxo MoO_2^{2+} cation. Complexes of the type MoO_2L_2 are known,[8–10] where L is a molecule of bidentate Schiff base. Electrical properties of several metal—copper(II), cobalt(II), nickel(II) and platinum(II)—complexes have been investigated.[11–13] Applications of metal complexes as semiconductors[14] and for gas detection[15] have been reported. Earlier communications[16–24] have described the metal chelates of C=S, C=O and C=NH donor ligands, but nothing is reported on the synthesis and physicochemical properties of dioxodichloro-Mo^{VI}-N-aryl-N′-(substituted thioazolyl) thioureas and ureas which was the subject of the present work.

EXPERIMENTAL

All the chemicals used were either BDH "AnalaR" quality or E. Merck "GR" quality. The ligands N-aryl-N′-(substituted thiazolyl) thioureas and N-aryl-N′-(substituted thiazolyl) ureas were prepared[25] by refluxing substituted-2-aminothiazole with respective isothiocyanates, RNCS, and isocyanates, RNCO, where R is alkyl, aryl or substituted aryl groups. The purity of these ligands was checked by melting point, elemental analysis and IR spectral studies.

General method for the preparation of MoO_2Cl_2 *complexes*

All the preparative work of metal complexes was carried out in a dry box. MoO_2Cl_2 was prepared by Zado's method[26] and characterized on the basis of elemental analyses and IR peaks. Molybdenum(VI) dioxydichloride complexes were prepared by the following general method. An ethereal solution of the ligand (50 cm^3, 0.2 M) was added dropwise, with constant stirring, to an ethereal solution of an equal volume (0.1 M) of anhydrous MoO_2Cl_2. During the course of the reaction the temperature was maintained below 10°C. After addition of the ligand was complete, the reaction mixture was allowed to stand for 2 h to attain equilibrium. A coloured complex separated out in most of the cases. In the cases of *o*-T4PTTU, *p*-T4PTTU, *o*-T5TTU and *p*-T5NTTU, the coloured complexes were separated out by distilling off the excess solvent. Complex compounds thus obtained were washed several times with dry ether until free of excess ligand and then dried *in vacuo*. The complexes were characterized on the basis of their melting points and elemental analyses (Table 1). Molyb-

denum was estimated as lead molybdate; sulphur as barium sulphate by fusing the complexes with a 1 : 1 mixture of sodium peroxide and sodium carbonate, extracting the melt with water and then neutralizing with dilute HCl, when $BaSO_4$ precipitated; and chlorine as silver chloride by the method of Piria and Schiff.[27] The analytical data are in good agreement with those calculated for MoO_2Cl_2–ligand (1 : 2) complexes. Melting points were determined in open capillary tubes on a Unimelt temperature instrument and are uncorrected.

Magnetic measurements were carried out on a Gouy balance using a field strength of 5×10^3 gauss and mercury tetrathiocyanatocobaltate(II), Hg[Co(SCN)$_4$], as the standard. Molar conductances were determined in N,N-dimethylformamide using a Digital Conductivity meter CC601, with a cell constant of 1.11 (Century Instruments Pvt. Ltd, Chandigarh, India). The IR spectra of the ligands and their metal complexes were determined using KBr pellets on a Perkin–Elmer Grating IR spectrophotometer, Model 577, in the range 400–300 cm^{-1}. Absorption spectra of MoO_2Cl_2 complexes were measured in CH_2Cl_2 by standard methods using a UV–vis spectrophotometer (Model Shimadzu-UV–vis spectrophotometer-260, Japan).

For electrical measurements the compounds were made into discs of diameter 12 mm and thickness 0.4–0.8 mm. Concentrically, on the flat faces of each disc, electrodes were provided by applying a silver-based conductive paint. The electrical conductivities (σ) of the complexes were measured in the temperature range 30–115°C by employing a conductivity cell and a digital picoammeter (ESA 813 Electronic Corporation of India Ltd).

RESULTS AND DISCUSSION

All the MoO_2Cl_2 complexes are dark yellow–brown, and sparingly soluble in common organic solvents, except N,N-dimethylformamide in which they are more soluble. On heating, all of the complexes decompose or melt with decomposition above 145°C, but are easily decomposed by mineral acids. The analytical results (Table 1) indicate a 1 : 2 ratio of MoO_2Cl_2–ligand which corresponds to the general empirical formula $[MoO_2 \cdot L_2]Cl_2$. The very low solubility of these complexes in suitable solvents precluded molecular weight determinations. The molar conductances of the complexes in DMF and nitrobenzene were in the ranges 144.0–164.2 and 38.0–48.2 Ω^{-1} cm^2 mol^{-1}, respectively. The molar conductance results indicate that the complexes are 1 : 2 electrolytes.[28] The magnetic susceptibilities of the complexes were found to be in the

range -0.48 to -0.90×10^{-6} G, indicating their diamagnetic nature.

The UV spectra of the ligands display bands around 240–265 nm in methylene chloride which are shifted to 275–320 nm in MoO_2Cl_2 complexes. This shift is attributed to the fact that during complex formation, the energy level is lowered due to stabilization of the excited state. All the electronic spectral bands are due to M ← S charge-transfer absorption. Moore and Larsen[29] have observed that S → M charge-transfer in xanthate complexes appears at 6000 cm^{-1} below that of the corresponding dithiocarbamate complexes, and have suggested that xanthates are much greater reducing agents than dithiocarbamates. In our case, it is observed from the spectral data that the present ligands are not reducing agents.

In the IR spectra of thioazolyl-substituted thiocarbamides in KBr, bands appearing at 740–760 cm^{-1} have been assigned to ν(C=S) modes.[30] In MoO_2Cl_2 complexes these bands are reduced in intensity (Table 2). The lowering of C=O frequencies (1715–1730 cm^{-1} in PTU and P5NTU) on complexation (1720 and 1700 cm^{-1}) seems to be a more reliable indication of formation of the M—O bond. Furthermore, a slight increase in the C—N stretching frequency on coordination also supports the view that bonding is through sulphur and oxygen in these complexes. The band appearing at 348–390 cm^{-1} in MoO_2Cl_2 complexes of thiocarbamides is assignable to an Mo—S band. A lowering of the Mo=O stretching vibrations (from 960 cm^{-1} in MoO_2Cl_2 to 904–920 cm^{-1} in complexes) occurs in all the complexes and may be ascribed to chelation. The thiazole nucleus is observed to show the bands in the region 1588, 1480, 1340 and 1025 cm^{-1}, respectively. These bands are observed at lower frequencies and at reduced intensities in the complexes. The bands appearing at 3000–3225 cm^{-1} have been assigned to ν_s(NH) and ν_{as}(NH), the latter being the higher frequency bands. There is a little change in this band on complexation.

The ^1H NMR spectra of PTTU, *o*-TTTU, BzTTU, P4TTU and *p*-T4PTTU indicate four distinct resonances: (i) a sharp singlet (δ 7.4–7.8 ppm) due to the $-C_6H_5$ ring proton; (ii) a broad mul-

tiplet (δ 3.2–3.4 ppm) due to the *o,p*-$CH_3C_5H_4$ ring protons; (iii) a sharp signal (δ 2.2–2.5 ppm) due to the protons of the CH_3 groups; (iv) a doublet at δ 4.38–4.6 ppm due to the NH protons of the —CSNH group. Finally, a singlet at δ 8.4–8.7 ppm is possibly due to the protons of the thiazolyl ring. On account of poor solubility, the NMR spectra of MoO_2Cl_2 complexes with the above ligands were taken in deuterated DMSO. The spectra of molybdenum(VI) complexes show the signal due to the —CNH group does not undergo any shift. The positions of the —C_6H_5 and *o,p*-$CH_3C_5H_4$ ring protons remain unperturbed, ruling out the possibility of coordination of the —NH group of —NHC_6H_5. The lone pair of electrons on the sulphur and nitrogen of the thiazole ring causes paramagnetic shielding of the 4- and 5-protons. Formation of the dative bond using this electron pair of sulphur greatly reduces the paramagnetic shielding, causing a significant upfield shift for the adjacent protons. In other words, we can state that there is a decrease in the electron density of the thiozolyl ring upon adduct formation. This decrease causes a reduction of the paramagnetic anisotropic effect. This will result in an almost uniform upfield shift for all the ring protons. In the molybdenum complexes of PTTU, *o*-TTTU, BzTTU, P4PTTU and *p*-T4PTTU, an upfield sift of heterocyclic ring protons by 2–3.8 ppm is observed, confirming coordination through the thiazolyl sulphur.

In Fig. 1 the logarithm of electrical conductivity (σ) of $MoO_2Cl_2 \cdot 2PTTU$ against the reciprocal of temperature (T) in K is shown. The band gaps E_g for the condution process were calculated using the equation:

$$\sigma = \sigma_0 e^{-E_g/2kT},$$

where σ is the conductivity at T (K), σ_0 is a constant and k is Boltzmann's constant. The slopes of the straight lines of $\log\sigma$ vs $1/T$ were accurately determined by using the least-squares method. The electrical conductivities of the complexes are in the ranges 2.3×10^{-8}–10^{-6} and 4×10^{-7}–10^{-4} Ω^{-1} cm^{-1}. On comparison of these ranges with the electrical conductivity range of the semiconductors (given by Kittel[31]), it is observed that PTTU, *o*-TTTU and *p*-T4PTTU complexes are good semiconductors with band gaps ranging from 1.09 to 1.40 eV. It is also observed that complexes having a substituent in the *para* position in the ligands have greater conductivities than if the substituents are in the *ortho* positions. The Seebeck coefficient (α) measurements in these complexes showed that complexes of PTTU, Et4PTTU and P4PTU are n-type semicondutctors (negative α values) and all other MoO_2Cl_2 complexes are p-type semiconductors (positive α values).

MoO_2Cl_2 has been found to have a tetrahedral structure by Skinner.[32] It seems probable that on complexation with N-aryl-N′-(substituted thiazolyl) thioureas and ureas, the coordination number of molybdenum increases to six and a complex compound with distorted octahedral structure is formed having d^2sp^3 hybridization. Chelation with these bidentate ligands and the displacement of

COMPLEXATION OF EUROPIUM(III) AND AMERICIUM(III) WITH IONIZABLE MACROCYCLIC LIGANDS

V. K. MANCHANDA* and P. K. MOHAPATRA

Radiochemistry Division, B.A.R.C., Bombay-400085, India

(*Received* 14 *March* 1990; *accepted* 11 *May* 1990)

Abstract—The complexation of europium(III) and americium(III) with ionizable macrocyclic ligands, i.e. 1,7-diaza-4,10,13-trioxacyclopentadecane-N,N′-diacetic acid (K21DA) and 1,10-diaza-4,7,13,16-tetraoxacyclooctadecane-N,N′-diacetic acid (K22DA), has been investigated using the solvent extraction technique. Both trivalent cations formed marginally stronger complexes with K22DA than that with K21DA. Apart from the size effect, steric constraints associated with the metal coordination of carboxylate groups attached to the macrocyclic ring appeared to play an important role in complex formation. An attempt was made, wherever possible, to compare the results of macrocyclic ligands with those of ethylene diamine diacetic acid (analogous non-cyclic ligand). The studies carried out on americium(III) up to pH 6.0 in the presence of macrocyclic ligands in the aqueous phase did not reveal any precipitation or adsorption of metal ion. Speciation diagrams in the pH range 3.0–6.0 for the systems Am^{III}–K21DA and Am^{III}–K22DA have been deduced.

During the past two decades, size-selective complexation behaviour of macrocyclic ligands with ions of alkali metals and alkaline earths has been investigated in depth.[1–4] Ion–dipole interaction has been found to be the principal binding force of these metal ions with the macrocyclic ligands.[5] In view of their low-lying partly filled *f*-orbitals, a large number of lanthanide and actinide ions have the electronic configuration (ns^2np^6, where $n = 5$ or 6) analogous to that of monovalent alkali metal ions and divalent alkaline earth ions. In spite of their configurational similarities, the literature on lanthanide macrocyclic complexes and particularly actinide macrocyclic complexes is very scarce.[6,7] Amongst the actinide ions, evaluation of thermodynamic stability data has been carried out only for uranium(VI) complexes.[8,9] Other actinide ions, e.g. Pu^{IV}, Am^{III} and Cm^{III}, were studied for their extraction behaviour using macrocyclic reagents as auxiliary ligands where they acted as neutral oxo-donors.[10–12] No systematic size correlation of the ionic radii of these cations with cavity size of the ligands has been reported so far.

Chang and co-workers[13–15] have investigated the coordination behaviour of ionizable macrocyclic ligands with lanthanide ions and found 1,7-diaza-4,10,13-trioxacyclopentadecane-N,N′-diacetic acid (K21DA) and 1,10-diaza-4,7,13,16-tetraoxacyclooctadecane-N,N′-diacetic acid (K22DA) to possess some selectivity features. Loncin *et al.*[16] found 1,4,7,10-tetraazacyclododecane-N,N′,N″,N‴-tetracetic acid (DOTA) to form the strongest complexes with lanthanides known to date. On the other hand, due to the large increase in the cation solvation energy, interactions of lanthanide and actinide ions (in their high oxidation states) with neutral cyclic polyethers in aqueous solution were found to be too weak to be measured experimentally.[17,18] Ionizable macrocyclic ligands are likely to have strong electrostatic interactions with actinide ions, along with guest–host interactions which are predominantly size selective in nature. These ligands have also gained importance due to their ability to transfer metal ions towards non-aqueous media even in the absence of any other organophilic counter anion.[19]

A typical trivalent actinide ion americium(III) and the analogous lanthanide ion europium(III), along with the 15-membered macrocyclic ligand K21DA and 18-membered macrocyclic ligand K22DA, were chosen for the present investigations. These ligands are reported to offer cavities of a size compatible with the ionic radii of the trivalent ions considered here.[20,21] Due to the presence of oxygen

* Author to whom correspondence should be addressed.

and nitrogen as donor atoms, similar to their behaviour with lanthanides,[22,23] these ligands are expected to interact better with the americium(III) ion compared to the ligands which have only oxygen donor atoms.[24,25] Potentiometric titration techniques were used as previously[13,14] for the determination of complex formation constants of K21DA and K22DA with several lanthanide ions including europium(III). The solvent extraction technique involving tracer concentrations of the metal and milligram amounts of macrocyclic ligand at a constant pH was used in the present work. Apart from overcoming the difficulties encountered in treating the complex equilibria involving polynuclear species as required for potentiometric data, the use of the solvent extraction tracer technique was also helpful in dispensing with the use of elaborate glove-box facilities which is a pre-requisite for handling milligram amounts of americium.

Equilibrium constants obtained in the present work for 1 : 1 complexes revealed that with both macrocyclic ligands americium(III) forms stronger complexes than europium(III). Some observations regarding the prominent equilibria involved and the speciation diagrams have also been included in this paper.

EXPERIMENTAL

Reagents

Proanalysi grade thenoyltrifluoroacetone (TTA) of E. Merck and G.R. grade xylene supplied by Lobo-chemie Indo Austranal. Co. were used. Tetramethylammonium chloride (Fluka Chemie A.G.) and tetramethylammonium hydroxide (Aldrich Chemical Co. Inc.) were used for ionic strength adjustments and for the preparation of buffer solutions, respectively. The ^{241}Am used was obtained by beta decay of ^{241}Pu and was purified by an ion-exchange technique. The ^{152,154}Eu obtained by irradiating spec. pure Eu_2O_3 was used without further purification. Purity of the tracers was confirmed by gamma spectrometry. The syntheses of K21DA and K22DA were carried out by the method reported earlier.[26]

Solvent extraction studies

An aliquot of the radioactive tracer was heated to dryness and then dissolved in a buffer solution of the desired pH and ionic strength (0.1 M). Buffer solutions were prepared using tetramethylammonium hydroxide to avoid possible complexation of the macrocyclic ligand with alkali metal ions. For the same reason the ionic strength adjustment was carried out with tetramethylammonium chloride.

The stock solution of TTA (0.4 M) in xylene was equilibrated with 0.1 M $HClO_4$ overnight to convert it into the ketohydrate form. Subsequently the organic phase was equilibrated with an aqueous solution of desired pH (without radiotracer) to remove traces of $HClO_4$ present.

The concentrated organic extract required for back extraction experiments was prepared by equilibrating 0.4 M TTA in xylene as the organic phase, and radiotracers in the concentration range 10^{-5}–10^{-6} M at pH 3.0 (chloroacetate buffer) as the aqueous phase. The organic phase in the subsequent experiments was obtained by approximately 20 times dilution of this organic concentrate. To study the effect of variation of TTA concentration on distribution coefficient, a varying volume of the radiotracer-loaded organic phase diluted with a suitable volume of xylene was equilibrated with the aqueous phase containing a fixed concentration of K21DA/K22DA at pH 4.6 and i.s. = 0.1 M. To study the effect of the variation of ligand concentration, a varying volume of the freshly prepared K21DA/K22DA solution at pH 4.6 along with a suitable volume of an inert 0.1 M (tetramethylammonium chloride) solution was used as the aqueous phase.

To study the effect of variation of pH, the aqueous phase was pipetted in steps from a ligand solution ($\sim$ 100 cm^3) after adjustment of the pH to the required value by dropwise addition of conc. HCl solution. The equilibrium pH was measured after completion of the experiment.

After equilibration, the two phases were allowed to settle in a waterbath for about 20 min and then were centrifuged for 2 min before assaying. Suitable aliquots of the two phases (20×10^{-3} to 200×10^{-3} cm^3) were pipetted carefully avoiding any cross-contamination. Americium and europium were assayed using a NaI well-type gamma scintillation detector with the appropriate base line voltage and window widths. Distribution coefficients were calculated by dividing the counts per minute per unit volume of the organic phase by the counts per minute per unit volume of the aqueous phase. All experiments were carried out at 25 ± 0.1°C.

Calculations

In the absence and presence of the macrocyclic ligand (H_4L) in the aqueous phase, distribution coefficients D_0 and D are given as

$$D_0 = \frac{[Am(TTA)_3]_0}{[Am^{3+}]_a\left(1+\sum_i \beta_i^{OH}[OH^-]^i+\sum_j \beta_j^{Ac}[Ac^-]^j+\sum_k \beta_k^{Cl}[Cl^-]^k+\sum_l \beta_l^{TTA}[TTA^-]^l\right)} \quad (1)$$

$$D = \frac{[Am(TTA)_3]_0}{[Am^{3+}]_a\left(1+\sum_i \beta_i^{OH}[OH^-]^i+\sum_j \beta_j^{Ac}[Ac^-]^j+\sum_k \beta_k^{Cl}[Cl^-]^k+\sum_l \beta_l^{TTA}[TTA^-]^l+\sum_m \beta_m^{L}[L^{2-}]^m\right)} \quad (2)$$

In the above expression, the concentration of the $AmHL^{2+}$ type species has been neglected in view of the much larger complexation of the L^{2-} ion.[27] By substituting the terms corresponding to hydroxy, acetate, chloride and TTA complexes with I, J, K, and L, respectively, eqs (1) and (2) can be arranged as

$$\frac{1}{D} = \frac{1}{D_0} + \sum_m \beta_m^{L}[L^{2-}]^m \frac{1}{D_0}\cdot\frac{1}{1+C},$$

where $C = I+J+K+L$, or

$$\left(\frac{D_0}{D}-1\right)(1+C) = \beta_1^{L}[L^{2-}]+\beta_2^{L}[L^{2-}]^2+\cdots \quad (3)$$

Depending upon whether the AmL^+ species or a combination of AmL^+ and AmL_2^- species co-exist at equilibrium, we can graphically obtain β_1^{L} alone or both β_1^{L} and β_2^{L} by plotting either

$$\left(\frac{D_0}{D}-1\right)(1+C) \text{ or } \left(\frac{D_0}{D}-1\right)(1+C)/[L^{2-}] \text{ vs } [L^{2-}].$$

The concentration of $[L^{2-}]$ at equilibrium is computed from the total ligand concentration by the following equation:

$$[H_4L^{2+}]_t = [H_4L^{2+}]+[H_3L^+]+[H_2L]+[HL^-]+[L^{2-}]+[AmL^+]+2[AmL_2^-].$$

Since $[Am]_t \ll [H_4L^{2+}]_t$; the last two terms can be neglected.

$$[H_4L^{2+}]_t = [L^{2-}]_e\left(1+\frac{[H^+]}{k_4}+\frac{[H^+]^2}{k_3k_4}+\frac{[H^+]^3}{k_2k_3k_4}+\frac{[H^+]^4}{k_1k_2k_3k_4}\right),$$

where k_1, k_2, k_3 and k_4 denote proton ligand dissociation constants.[13,14] The value of C is obtained from the literature.[28] $[H^+]$ was obtained from the pH using the relation:[29]

$$[H^+] = 10^{-(pH-0.11)} \quad (i.s. = 0.1).$$

RESULTS

Equilibration time

We reported earlier, the variation of the extraction rate constants with variation of lanthanide(III) ion, ligand and pH in the system Ln^{III}–(K21DA/K22DA)–TTA–$CHCl_3$.[30,31] It was observed that the rate of attainment of equilibrium in the forward direction was inversely related to the pH. It was necessary to shake the extraction tube for several hours (> 8) at pH 4.6 to reach equilibrium. On the other hand, the equilibrium was attained in about 20 min at this pH if approached from the reverse direction. This can be explained on the basis of slow dissociation kinetics of the Am–macrocyclic complex in the aqueous phase which governs the forward extraction rate. The reverse extraction rate appeared to be governed by either the rate of transfer of the $Am(TTA)_3$ species from the organic phase to the aqueous phase, or the dissociation rate of this species in the aqueous phase. No attempt was made in the present work to investigate the mechanism of extraction in the forward direction. Results of the studies carried out to investigate the influence of [TTA], $[H_4L^{2+}]$ and $[H^+]$ on equilibrium states (when approached from the reverse direction) for the systems Am^{III}–(K21DA/K22DA)–TTA are given in Table 1.

Effect of variation of TTA *concentration*

Variation of $\log D$ with $\log[TTA]_0$ was investigated at pH 4.6 for Am^{III}–(K21DA/K22DA) systems. Dependency of ~ 3 suggested the presence of the $Am(TTA)_3$ species in the organic phase.

Effect of variation of ligand concentration

Figure 1 shows the variation of $\log D$ vs $\log[H_4L^{2+}]$ at pH 4.6 for americium(III) and europium(III) with both ligands. A linear relationship of $\log D$ vs $\log[H_4L^{2+}]$ with a slope of -1 for the system Am^{III}–K22DA–TTA at pH 4.6 suggested that at this pH and in the ligand concentration range chosen, americium(III) was present predominantly as AmL^+ in the aqueous phase. A slope of ~ 1 was also seen in the straight line plots of $\log(D_0/D-1)(1+C)$ vs $\log[L^{2-}]$. According to eq. (3) given in the section on calculations, this could

be taken as evidence for the presence of 1 : 1 species in the aqueous phase. An attempt was made to compute complex formation constants by assuming that the small variation in slope from unity was experimental error. The D_0 value used was obtained by extrapolation of the plot of $1/D$ vs [L^{2-}] (Fig. 2). This was particularly important since the experimentally observed D_0 referred to the extraction of a different species.[32] Values of log K obtained for the systems studied in the present work are given in Table 2. In a few cases, whenever the graphical method was followed (Fig. 2) for the determination of log K values, an excellent agreement with the values obtained by the simple algebraic method was found.

Complex formation constants were specifically obtained for the systems Eu–K21DA and Eu–K22DA to ascertain the acceptability of the present approach. Agreement of the values obtained by potentiometric methods as well as by the present method, as shown in Table 2, is fairly good. It should be borne in mind that apart from the errors involved in the measurement of pH and distribution data, the values obtained using the present method were also influenced by the literature data on acetate complexation of these ions. On the other hand,

Table 2. Complex formation constants and ionic radii of metal ions with K21DA, K22DA and EDDA

uncertainty in the potentiometric data was only related to the errors of pH measurements.

Variation of pH

Figure 3(a) shows the variation of $\log D$ as a function of pH for the system Am^{III}–K21DA–TTA. The concentration of K21DA was maintained constant at 3.16×10^{-4} M. The slope of the plot was found to change from ~ 2.7 (at pH 3.2) to ~ 1.0 (at pH 4.6). Table 1 shows the $\log D$ dependencies on [TTA], $[H_4L^{2+}]$ and pH in the systems Am^{III}–(K21DA/K22DA)–TTA. On the basis of this data it is possible to write the two-phase equilibria under different pH conditions as follows:

$$Am(TTA)_3(o)+3H^+(a)\rightleftharpoons Am^{3+}(a)+3HTTA(o) \quad \text{(i)}$$
(dominating at pH < 3.0)

$$Am(TTA)_3(o)+H_3L^+(a)\rightleftharpoons AmL^+(a)+3HTTA(o) \quad \text{(ii)}$$

$$Am(TTA)_3(o)+H_2L(a)+H^+(a)\rightleftharpoons AmL^+(a)+3HTTA(o). \quad \text{(iii)}$$
(dominating at pH ~ 4.6).

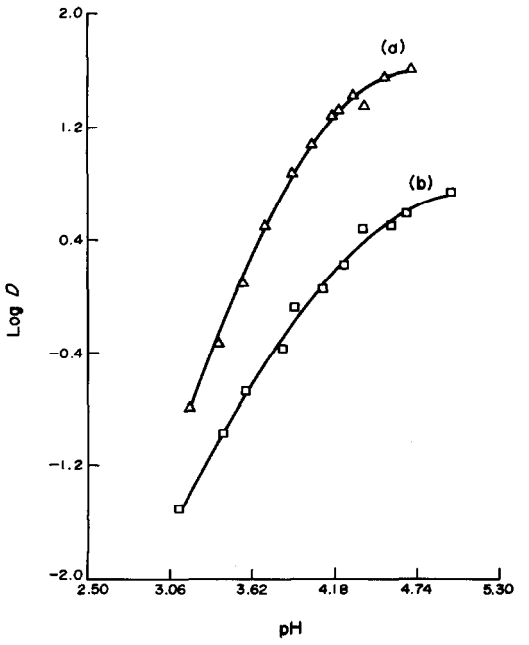

Fig. 3. Variation of $\log D$ vs pH; [TTA] = 1.1×10^{-1} M; i.s. = 0.1 M. (△) Am^{III}–K21DA–TTA; [K21DA] = 3.16×10^{-4} M; (□) Am^{III}–K22DA–TTA, [K22DA] = 2.2×10^{-4} M.

Curve (a) in Fig. 3 also reveals that the dependency of $\log D$ on pH increases with decreasing pH. At pH < 3.0 it appears that there is not much aqueous complexation of americium(III) and the two-phase equilibrium is represented as in (i). The slope of 2.6 in the pH range 3.2–3.8 and 1.6 in the pH range 3.8–4.2 suggests decreasing contribution of equilibrium (i) and increasing contributions of equilibriums (ii) and (iii) with increasing pH.

Experiments carried out substituting K21DA with K22DA under identical conditions resulted in distribution ratios which were too low to be measured reliably. Curve (b) in Fig. 3 refers to [K22DA] = 2.2×10^{-4} M. Throughout the pH range studied (3.1–5.0), in spite of the lower concentration, the K22DA curve was found to be below that of K21DA. This is explained in view of the stronger complexation of americium(III) with K22DA. As expected, even the slope values in a given pH range were lower than those observed for K21DA curve. The slope of ~ 1.0 suggesting predominance of eq. (iii) was observed in the pH range 3.9–4.4 rather than > 4.6 [as seen for curve (a)]. The decrease of the slope below 1.0 in both cases at pH > 4.7 could possibly be attributed to the presence of hydrolysed species of the type Am(K21DA/K22DA)OH in the aqueous phase at equilibrium.

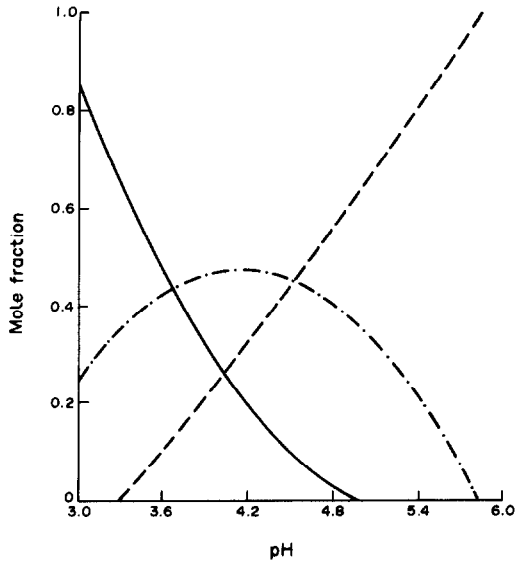

Fig. 4. Speciation diagram of americium(III); [K21DA] = 1.0×10^{-3} M. Am^{3+} (——); $Am(OH)^{2+}$ (—·—·—); $Am(K21DA)^{+}$ (– – –).

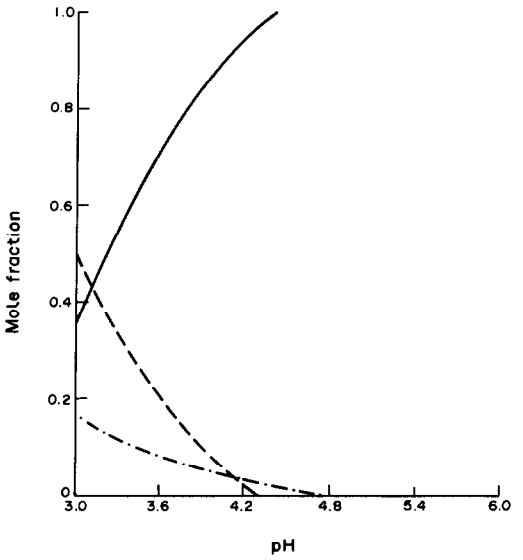

Fig. 5. Speciation diagram of americium(III): [K22DA] = 1.0×10^{-3} M. Am^{3+} (– – –); $Am(OH)^{2+}$ (—·—·—); $Am(K22DA)^{+}$ (——).

Speciation

Figure 4 shows the variation of $[Am^{3+}]$, $[Am(OH)^{2+}]$ and $[AmL^{+}]$ (L = K21DA) as a function of pH. This diagram was constructed using the pK_a data of K21DA,[14] the hydrolysis constant of Am^{3+},[32] the stability constant data obtained in the present work and ligand concentration. At pH 3.0; the major species is Am^{3+} which does not complex K21DA at all. With increasing pH, the Am^{3+} concentration decreases and that of AmL^{+} increases. Am^{3+} is quantitatively converted to AmL^{+} at pH 5.8. The concentration of $Am(OH)^{2+}$ species passes through a maximum at pH 4.0. The speciation diagram for K22DA, constructed similarly, is shown in Fig. 5. In contrast to Fig. 4, there is a significant concentration of the AmL^{+} species even at pH 3.0. This is in agreement with the difference in the nature of the potentiometric titration curves obtained for K21DA and K22DA in the presence of a lanthanide ion like Eu^{3+}.[13,14] Quantitative complexation of Am^{3+} with K22DA occurs even at pH 4.2. Concentration of Am^{3+} as well as $Am(OH)^{2+}$ decreases continuously with increasing pH.

DISCUSSION

The coordination number of lanthanide(III) ions in macrocyclic lanthanide complexes has been reported[6] to vary in the range 8–12 as revealed by their X-ray crystal structure analysis. It is reasonable to assume that the ionic radius of americium(III) in the present case is $\geqslant 1.09$ Å.[21] On the other hand, the cavity size of K21DA appears to be 0.97 ± 0.13 Å (typical of 15-membered ligands) and that of K22DA is 1.45 ± 0.15 Å (typical of 18-membered ligands).[20] In view of the empirical guest–host size correlation arrived at by Christensen *et al.*,[33] it is probable that whereas americium(III) and europium(III) may be loosely held in the K22DA cavity, no such encapsulation is possible in the K21DA cavity. Larger $\log K$ values for americium(III) over europium(III) (Table 2) may be explained on the basis of better availability of f orbitals for participation in the bonding of the actinide ion. Similar results have been reported by several workers on the basis of their studies with macrocyclic[10,24] as well as non-cyclic ligands.[23]

Table 2 also shows the $\log K$ values of the complexes of plutonium(IV) with K21DA, K22DA and EDDA.[34] It may be noted that the larger complex formation constants of plutonium(IV) with K21DA compared to that with K22DA is in sharp contrast to the observed behaviour of americium(III) and trivalent lanthanides. This is explained on the basis of better size compatability of the plutonium(IV) ion (i.r. = 0.96 Å) with K21DA (cavity size = 0.97 ± 0.13 Å). The observed trend in $\log K$ values for trivalent lanthanides[13,14] and of americium(III) for different ligands is EDDA < K21DA < K22DA. This could be rationalized if one considers that steric constraints increase with decrease of the metal ion radius as well as with the increase of ring size.

There has been an attempt to use thorium(IV) and europium(III) as model tetravalent and

trivalent ions for investigating the preferential stabilization of the former using the heteropolytungstate ion.[35] This work has gained in importance due to the increasing interest in the stabilization of the unusual tetravalent state of some *trans*-plutonium elements.[36] In view of the data available in the present work, 15-membered macrocyclic ligands with ionizable pendent groups appear to be promising for the stabilization of americium(IV) [analogous to plutonium(IV)] over americium(III).

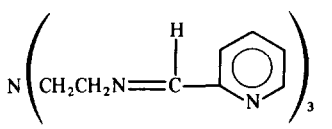
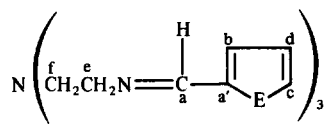
Abstract—Two potentially heptadentate tripodal Schiff base ligands, tris[4-(2-thienyl)-3-aza-3-butenyl]amine (S_3tren) and tris[4-(2-furyl)-3-aza-3-butenyl]amine (O_3tren) have been prepared and characterized by ^1H and ^{13}C NMR spectral data. For the complexes [Cu(E_3tren)]BPh_4 (E = S, O), NMR spectral shifts clearly indicate coordination of all four nitrogen donor atoms. X-ray analysis for [Cu(S_3tren)]BPh_4 shows trigonal pyramidal geometry for the copper(I) cation, with all Co---S distances [average of 3.344(4) Å] being too great for any bonding interaction. IR, ESR and electronic spectral data for the green copper(II) complexes, $CuX_2 \cdot S_3$tren (X = Cl, Br), indicate six-coordination in the solid state and square pyramidal geometry (with halide dissociation) in freshly prepared dimethylformamide solutions.



(1) py_3tren



(2) E = S, S_3tren; (3) E = O, O_3tren

Although seven-coordination is readily achieved by many metal ions,[1,2] the ability of a single ligand to supply all seven donor atoms is rare.[3] The best studied potentially heptadentate ligand, tris[4-(2-pyridyl)-3-aza-3-butenyl]amine, known as py_3tren (**1**), was designed to give transition metal complexes having mono-capped trigonal antiprismatic coordination polyhedra.[4,5] A recent detailed assessment of the bonding properties of py_3tren in a series of $[M(py_3tren)]^{2+}$ (M = Mn, Fe, Co, Ni, Cu and Zn) complexes shows, however, that the seventh bond to the apical or bridgehead nitrogen atom may only be considered as "weakly bonding" in the case of manganese [2.794(2) Å] and cobalt [2.870(2) Å].[5] In order to overcome the domineering influence of the three pendant α-diimine chelating arms on the resultant metal geometry, we have prepared two new analogous ligands that contain thiophene and furan moieties in the pendant arms. These potentially heptadentate tripodal Schiff base ligands, called S_3tren (**2**) amd O_3tren (**3**) are expected to

* Author to whom correspondence should be addressed.

enhance metal interaction with the bridgehead nitrogen atom as compared to py_3tren.[5] The importance of multidentate nitrogen–sulphur ligands in copper model systems for the "blue" copper oxidases and electron transfer proteins[6] led us to explore the coordinating ability of **2** and **3** with both copper(I) and copper(II) ions, which we report in this paper.

The syntheses of the new potentially heptadentate ligands **2** and **3** were readily effected by the Schiff base condensation of tris(2-aminoethyl)amine (tren) with the appropriate aldehyde. S_3tren precipitated from the absolute ethanol solution as a white solid in 93% yield (m.p. 135–137°C) and gave satisfactory elemental analysis; O_3tren was isolated as an easily hydrolysed oil and thus was characterized by spectral methods. ^1H and ^{13}C NMR spectral data (coupled and decoupled) acquired on a Bruker WH-400 spectrometer provided confirmatory evidence for the formation of the expected three azomethine linkages. The assignment of ^1H and ^{13}C resonances according to the above structural formula for **2** and **3** (Table 1) was based on those observed for the precursors. Characteristic mass spectral molecular ion and IR ν(C=N) stretching frequencies occurred at 428 m/z, 1637 cm^{-1} (**2**) and at 380 m/z, 1647 cm^{-1} (**3**). An X-ray crystallographic analysis of S_3tren has confirmed the tripodal geometry of the ligand and revealed the conjugation of the thiophene moieties with the azomethine linkages.[7]

The reactions of **2** with CuX_2 salts gave [CuL]Y and $CuX_2 \cdot L$, where Y = I_3, BPh_4 and X = Cl, Br, N_3, SCN, ClO_4, NO_3. The copper(I) complexes were obtained by the addition of excess NaY to solutions containing $Cu(OAc)_2$ and L; $[Cu(O_3tren)]BPh_4$ was isolated in a similar fashion. Copper(II) is well known to be easily converted to copper(I) by various mild reducing agents or ligands,[8a] for example, the tripodal ligand tris(2-methylthioethyl)amine (NS_3-Me) forms $[Cu(NS_3\text{-Me})]I_3$ due to the instability of the initial copper(II) com-

plex, $[Cu(NS_3\text{-}Me)I]ClO_4$.[8b] The isolation of $[ML](OAc)(BPh_4)$ complexes, where M = Mn, Fe, Co, Ni and L = **2** and **3**, has also been accomplished and spectral and structural characterization is underway.[9] Preliminary ^1H NMR spectral data for $[CuL]BPh_4$, where L = **2** and **3**, and ESR and visible spectra data for $CuX_2 \cdot S_3tren$, where X = Cl and Br, are presented here.

Downfield shifts of proton resonances in the ^1H NMR spectra of $[CuL]BPh_4$ (L = **2** and **3**), compared to those observed for the free ligands, clearly indicate coordination of all four nitrogen donor atoms. The shifts are the most dramatic for the azomethine protons [(H_a) 0.68 (**2**) vs 0.42 (**3**) ppm] and ethylene protons [0.22, 0.31 (**2**) vs 0.18, 0.29 ppm (**3**) for H_e and H_f, respectively]. Resonances due to ring protons are also shifted downfield in the complexes (Table 1), but it is less clear whether this occurs due to E atom complexation. The large shift for H_b (1.07 and 1.03 ppm for **2** and **3**, respectively) could occur simply as a result of increased conjugation with the C=N linkage; the shift of only *ca* 0.2 ppm, which occurs for H_d in both complexes, supports this idea rather than coordination of the E atoms. However, the shift for H_c is much larger for **3** (1.01 vs 0.27 ppm for **2**), implying that the Cu—O interaction is significantly greater than the Cu—S interaction. X-ray investigations are underway to resolve this ambiguity; results for $[CuL]BPh_4$ (L = **2**) confirm the adoption of trigonal pyramidal geometry for the copper(I) ion,* with all Cu---S distances (average of 3.344(4) Å) being too great for any bonding interaction (Fig. 1).* The cation has non-crystallographic three-fold symmetry, with the sulphur atoms being twisted

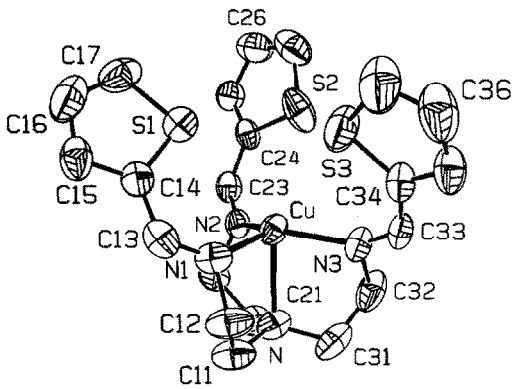

Fig. 1. A view of the $[CuN(CH_2CH_2N{=}CH\text{-}C_4H_3S)_3]^+$ cation with the crystallographic numbering scheme; ellipsoids are at the 50% level.

an average of 40.2° from being eclipsed with the equatorial nitrogen atoms; an angle of 60° corresponds to a trigonal antiprism. The Cu—N distances to the equatorial nitrogens [N(1), N(2), N(3)] are 2.028(5), 2.006(4) and 1.999(4) Å, respectively, while the N(ap)—Cu—N(eq) and N(eq)—Cu—N(eq) angles are 82.1(2) and 118.2(2)° (av.), respectively. The Cu—N(ap) distance is 2.310(5) Å, with the copper atom being 0.275(1) Å above the plane of the equatorial azomethine nitrogen atoms and the apical tertiary amine atom (N) lying 2.035(1) Å below that plane. Other relevant interatomic distances and angles are given in Table 2. Not surprisingly, the coordination geometry is remarkedly similar to that recently described for the cationic copper(I) complex of the related tripodal Schiff base ligand $N[CH_2CH_2N{=}CH(C_6H_5)]_3$ (Ph_3tren).[10] Principal dimensions in that case were Cu—N(ap) 2.232(2) Å, Cu—N(eq) 2.010(2) Å (av) and N(ap)—Cu—N(eq) 84.2(1)° (av), N(eq)—Cu—N(eq) 118.9° (av).

The green complexes of formulation $CuX_2 \cdot S_3tren$ (X = Cl, Br) have similar structures to each other, with spectral evidence indicating six-coordination in the solid state and five-coordination in solution. IR spectra of the solids show coordination of the azomethine nitrogen atoms [ν(C=N) shifts from 1637 to 1616 cm^{-1}], the presence of lattice water in the chloride [ν(O—H) at 3396 cm^{-1}], and ν(Cu—X) bands typical of octahedral geometry (240 and 209 cm^{-1} for Cl and Br, respectively). Three g values are observed in the ESR spectra of powder samples (Table 3) with the minimum g value being less than 2.03, as is typical of distorted *cis*-octahedral geometry.[11] Freshly prepared frozen dimethylformamide solutions gave axial ESR spectra with $g_\parallel > g_\perp$ (Table 2), suggesting a $d_{x^2-y^2}$ electronic ground state of square pyramidal

* Crystal data for $C_{45}H_{44}CuN_4S_3B$, M_r = 811.4, monoclinic, space group $P2_1/c$, a = 11.774(1), b = 17.738(2), c = 22.917(4) Å, β = 121.08(1)°, V = 4099(3) Å^3, Z = 4, Mo-K_α radiation (λ = 0.71069 Å, T = 298 K. A Gaussian absorption was applied (μ = 7.39 cm^{-1}). The structure was solved by a combination of direct methods and difference Fourier synthesis. Successful refinement was by full-matrix least-squares with R = 0.046 and R_w = 0.060 for 3996 reflections with $I > 3\sigma(I)$. Pertinent bond distances and angles can be found in the text and in Table 2. A transformation of the coordinates from $P2_1/c$ using the matrix

$$\begin{bmatrix} -1 & 0 & 0 \\ 0 & 1 & 0 \\ -1 & 0 & -1 \end{bmatrix}$$

will give a $P2_1/n$ monoclinic cell [a = 11.774(1), b = 17.738(2), c = 19.627(4) Å, β = 90.17(1)°] which is isomorphous with $[CuN(CH_2CH_2N{=}CH\text{-}C_6H_5)_3]^+[BPh_4]^-$.[10]

Abstract—The interaction of $C_7H_8Mo(CO)_4$ with 2 equivalents of $Ph_2P(C_5H_5)$ in hexane at −2°C gives two isomers of *cis*-$[Ph_2P(C_5H_5)]_2Mo(CO)_4$ (**II** and **III**) in high yield. In toluene, the coordinated $Ph_2P(C_5H_5)$ ligands of **II** and **III** undergo intramolecular Diels–Alder dimerization at room temperature producing *cis*-[1,3-bis(diphenylphosphino)dicyclopentadiene](tetracarbonyl)molybdenum (**IV**) in quantitative yield. Compound **IV** can also be prepared in high yield by the interaction of *cis*-$Mo(CO)_4(Ph_2PCl)_2$ with 2 equivalents of $(C_5H_5)Tl$ in refluxing toluene. Pyrolysis of **IV** gives a hexane solvate $2[(C_5H_5)Mo]_2(\mu\text{-}PPh_2)_2(CO)(O)\cdot C_6H_{14}$ (**VI**) in low yield, the structure of which was determined by X-ray crystallography.

We recently reported[1] the synthesis of *cis*-[1,3-bis(diphenylphosphino)dicyclopentadiene](tetracarbonyl)molybdenum (**IV**), via the interaction of *cis*-$Mo(CO)_4(Ph_2PCl)_2$ with 2 equivalents of $(C_5H_5)Tl$ and postulated that **IV** was produced via intramolecular Diels–Alder dimerization of the $Ph_2P(C_5H_5)$ ligands of the proposed intermediate *cis*-$[Ph_2P(C_5H_5)]_2Mo(CO)_4$ (**II**). Metal-promoted intramolecular Diels–Alder cycloaddition between coordinated phospholes and coordinated vinylphosphines has also been described recently.[2] Here we report the isolation of **II** and demonstrate that **IV** is indeed formed via intramolecular Diels–Alder dimerization of the coordinated cyclopentadienyldiphenylphosphine of **II**.

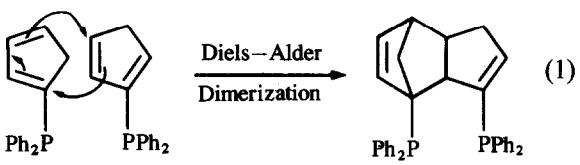
RESULTS AND DISCUSSION

Interaction of $C_7H_8Mo(CO)_4$ *with* $Ph_2P(C_5H_5)$

(i) *At room temperature.* When $C_7H_8Mo(CO)_4$ was treated with 2 equivalents of $Ph_2P(C_5H_5)$ in hexane, light yellow crystals of stoichiometry $(C_{34}H_{30}P_2)Mo(CO)_4$ (**IV**) were obtained in high

yield (85%). The IR spectrum (KBr) of **IV** exhibits three absorptions at 2017s, 1916s and 1880 vs(br) cm^{-1}. The absorption pattern is indicative of a *cis*-configuration for the four terminal carbonyl groups. The mass spectrum shows the highest peak at *m/z* 596, corresponding to the $(M-4CO)^+$ fragment ($C_{34}H_{30}P_2Mo$). The $^{31}P\{^1H\}$ NMR spectrum exhibits two doublets of relative intensity 1 : 1 centred at δ 23.4 (J = 24.4 Hz) and 37.2 ppm (J = 24.4 Hz), respectively. The ^1H NMR spectrum is very complicated. In addition to the phenyl resonances, it exhibits three multiplets of relative intensity 1 : 1 : 1 centred at δ 6.67, 6.19 and 5.19 ppm, respectively, in the olefinic proton region and four multiplets of relative intensity 2 : 1 : 3 : 1 centred at δ 2.94, 2.74, 2.02 and 0.74 ppm, respectively, in the aliphatic proton region. The spectroscopic data suggest that the phosphine ligand is 1,3-bis(diphenylphosphino)dicyclopentadiene (**I**) formed via intramolecular Diels–Alder dimerization of (diphenylphosphino)cyclopentadiene as shown in Eq. (1):

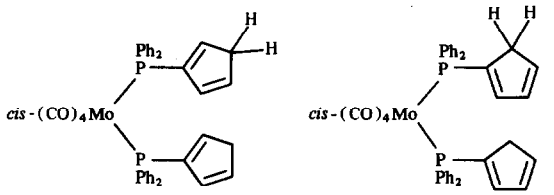


(1)

I

The X-ray diffraction study of **IV** has established a *cis*-configuration for the four terminal carbonyl groups and confirmed that the two $Ph_2P(C_5H_5)$ ligands indeed did undergo dimerization to produce the 1,3-bis(diphenylphosphino)dicyclopentadiene ligands.[1]

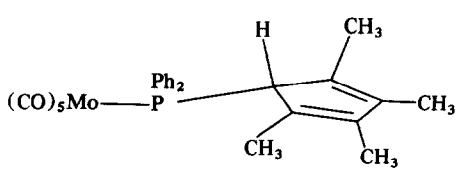
(ii) *At* −2°C. When $C_7H_8Mo(CO)_4$ was treated with 2 equivalents of $Ph_2P(C_5H_5)$ at −2°C in hexane, compounds **II** and **III** were obtained. The major product, **II**, recrystallized from hexane, has a stoichiometry $[Ph_2P(C_5H_5)]_2Mo(CO)_4$. The IR spectrum in KBr exhibits three absorption at 2014s, 1899 vs(br), 1877 vs(br) cm^{-1}, indicative of a *cis*-configuration for the four terminal carbonyls. The $^{31}P\{^1H\}$ NMR spectrum exhibits a singlet at δ 23.2 ppm indicating that the two phosphorus ligands are equivalent. Other than the broad complex multiplets centred at δ 7.18 ppm for the phenyl resonances, the ^1H NMR spectrum shows a broad complex multiplet and a broad singlet of relative intensity 3 : 2 centred at δ 6.50 and 2.81 ppm for the olefinic protons and the aliphatic protons of the C_5H_5 ring, respectively. Based on the above spectroscopic data, two structures are possible for **II**. These are **IIa** and **IIb** as shown below.



IIa **IIb**

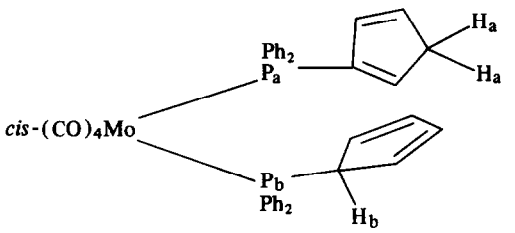
If **II** adopts structure **IIb**, one would then expect that the aliphatic protons of the carbon β to the phosphorus would couple with the phosphorus to give a doublet. The fact that the aliphatic protons resonance shows a singlet suggests that the protons are attached to the carbon γ to the phosphorus atom. In terms of steric hindrance the C_5H_5 ring of **IIa** probably has less steric interaction with the other substituents on the phosphorus than that of **IIb**. Thus, based on the splitting pattern and steric argument, structure **IIa** is assigned to **II**. ^1H and $^{31}P\{^1H\}$ NMR studies show that **II** in C_6D_6 at ambient temperature isomerizes to **IV** quantitatively.

The minor product, **III**, is always contaminated with **II**. However, ^1H and $^{31}P\{^1H\}$ NMR studies show that a mixture of **II** and **III** in C_6D_6 at ambient temperature isomerizes to **IV** quantitatively, and no other products are observed. This suggests that the stoichiometry of **III** is the same as **II** and is $[Ph_2P(C_5H_5)]_2Mo(CO)_4$. The IR spectrum of **III** in KBr exhibits three absorptions at 2014s, 1988 vs(br), 1877 vs(br) cm^{-1}, indicative of a *cis*-configuration for the four terminal carbonyls. The $^{31}P\{^1H\}$ NMR spectrum exhibits two doublets of relative intensity 1 : 1 centred at δ 21.1 (J_{P-P} = 24.4 Hz) and δ 30.8 (J_{P-P} = 24.4 Hz) ppm, suggesting the presence of two non-equivalent phosphorus ligands. Other than the phenyl and olefinic resonances, ^1H NMR shows a doublet (J_{P-H} = 15.0 Hz) and a singlet of relatively intensity 1 : 2 at δ 4.07 and 2.89 ppm, respectively. The chemical shift and coupling constant of the doublet at δ 4.07 ppm is similar to that of the unique proton of the (Me_4C_5H) ring (δ 4.23 ppm; J_{P-H} = 15.3 Hz) of the complex $[(Me_4C_5H)PPh_2]Mo(CO)_5$ (**V**) whose structure has been established by an X-ray diffraction study[3] and is shown below.



V

The chemical shift of the singlet at δ 2.89 ppm is similar to the aliphatic protons of **II**. Based on the above spectroscopic data, the following structure is assigned to **III**.



III

Based on the assigned structures, assignment of ^{31}P NMR data can be made and is shown in Table 1.

Interaction of cis-$Mo(CO)_4(Ph_2PCl)_2$ *with* $(C_5H_5)Tl$

When *cis*-$Mo(CO)_4(Ph_2PCl)_2$ was treated with 2 equivalents of $(C_5H_5)Tl$ in toluene at room temperature, no reaction was observed after 48 h. However, if the reaction was carried out overnight in refluxed toluene, compound **IV** was obtained in high yield (80%). The formation of **IV** probably involves the mechanism shown in Scheme 1. *Cis*-$Mo(CO)_4(Ph_2PCl)_2$ reacts with $(C_5H_5)Tl$ to produce intermediate **II** which then undergoes a series of rearrangements and finally intramolecular Diels–Alder cycloaddition to produce the final product **IV**. The mechanism is further supported by the fact that **II** and **III** isomerize to **IV** quantitatively at room temperature.

Thermolysis of **IV**

Pyrolysis of **IV** in the solid state produces a red crystalline compound **VI** of stoichiometry $C_{35}H_{30}O_2P_2Mo_2$ in low yield. The IR spectrum (KBr) of **VI** exhibits a strong absorption at 1807 cm^{-1} in the terminal carbonyl region. The $^{31}P\{^1H\}$ NMR spectrum exhibits a singlet at δ 167.2 ppm.

IV

Mo = *cis*-Mo(CO)$_4$; P = Ph_2P

Scheme 1.

The low-field chemical shift suggests the presence of phosphido-bridged ligands.[4] The ^{1}H NMR spectrum exhibits a set of three multiplets of total relative intensity 20, centred at δ 8.14, 7.46 and 7.19 ppm for the phenyl protons, a singlet of intensity 5 at δ 4.97 ppm, and a multiplet of relative intensity 5 at δ 4.78 ppm for the C_5H_5 rings.

The structure of **VI** was determined by an X-ray diffraction study of its hexane solvate, 2 **VI** · C_6H_{14}. The crystal data and other parameters for the X-ray structural analysis are listed in Table 2. The hexane molecules centred about a crystallographic inversion centre, exhibits two-fold disorder.

A perspective drawing of **VI** is shown in Fig. 1. Selected bond lengths and bond angles are given in Table 3. The structure is consistent with its spectroscopic data and **VI** can be formulated as $[(C_5H_5)Mo]_2(\mu\text{-}PPh_2)_2(CO)(O)$. The dimer can be considered as a $Mo^{(II)}$—$Mo^{(IV)}$ mixed-valent compound. Mo(1) to which the oxo group is attached is formally in a +4 oxidation state and Mo(2) where the carbonyl is attached is formally in a +2 oxidation state. For the two molybdenum atoms to obey the 18-electron rule, a double bond should exist between them.

This is reflected by the shorter Mo—Mo distance of 2.941(1) Å in comparison with those in the analogous complexes $M_2(CO)_8(\mu\text{-}PEt_2)_2$ (M = Mo, 3.06 Å and M = W, 3.05 Å).[5] The coordination polyhedron around each molybdenum atom can be described as a distorted tetrahedron if the metal–metal bond is neglected, with the cyclopentadienyl group occupying one coordination site, and two bridging phosphorus atoms and the oxo atom [for Mo(1)] or the carbonyl group [for Mo(2)] occupying the other three sites (Fig. 1). The oxo and carbonyl ligands are *trans* to each other as reflected by the torsion angle O(1)—Mo(1)—Mo(2)—C(2) of 178.6°. The planar Mo_2P_2 core (within ±0.036 Å) is similar to that found in $M_2(CO)_8(\mu\text{-}PEt_2)_2$ (M = Mo, W)[5] and $W_2(CO)_8(\mu\text{-}PPh_2)_2$,[6] but different from the butterfly Fe_2P_2 core in $Fe_2(CO)_6(\mu\text{-}PPh_2)_2$.[7] The Mo=O bond distance of 1.687(6) Å falls in the range reported for the other

[a]Cp(1) is the centre of the ring composed of carbon atoms C(3)—C(7), and Cp(2) is the centre of the C(8)—C(12) ring.

molybdenum oxo complexes.[8,9] In accordance with the different oxidation states of the metal atoms, the Mo(1)—P [av. 2.461(2) Å] and Mo(1)—Cp(1) [2.085(8) Å] bonds are significantly longer than Mo(2)—P [av. 2.324(2) Å] and Mo(2)—Cp(2) [2.008(8) Å], respectively. The bond lengths and angles involving the carbon atoms are all normal and there are no unusual intermolecular contacts in the crystal packing.

EXPERIMENTAL

Microanalyses were performed by Butterworth (U.K.). IR spectra were recorded on a Perkin–Elmer 983 spectrometer; data given in cm^{-1} in KBr pellets. NMR spectra were recorded on a JEOL FX90Q spectrometer. Chemical shifts of ^1H NMR spectra were referenced to internal deuterated solvents and then recalculated to TMS = 0.0 ppm. ^{31}P NMR spectra were referenced to external 85% H_3PO_4.

All operations were carried out under nitrogen or *in vacuo*. All chemicals used were of reagent grade. Solvents were dried by standard procedures, distilled and deaerated prior to use. Melting points were taken in sealed capillaries and are uncorrected.

$Ph_2P(C_5H_5)$,[10] $(C_5H_5)Tl$,[10] $C_7H_8Mo(CO)_4$[11] and *cis*-$Mo(CO)_4(Ph_2PCl)_2$[12] were prepared according to literature methods.

Preparation of cis-$[Ph_2P(C_5H_5)]_2Mo(CO)_4$

A solution of $C_7H_8Mo(CO)_4$ (0.5 g, 1.7 mmol) in hexane (50 cm^3) was added dropwise to a freshly prepared solution of $Ph_2P(C_5H_5)$ (0.9 g, 3.6 mmol) in hexane (50 cm^3) at −2°C. After stirring at −2°C for 2 h, the solution was filtered. The filtrate was concentrated to *ca* 60 cm^3 and cooled to −20°C to give white crystalline products which were a mixture of **II** and **III**.

The white crystalline products were then extracted with cold hexane (2 × 20 cm^3) at 0°C. The hexane solution was then concentrated to *ca* 20 cm^3 at 0°C and cooled to −20°C to give pure **II** as a white crystalline solid, which was filtered and dried *in vacuo*. Yield: 0.9 g, 75%; m.p. 202–204°C (decomposed). Found (required): C, 64.5 (64.4); H, 4.0 (4.2); P, 9.0 (8.8)%. IR (KBr), ν(CO): 2014s, 1899 vs(br), 1877 vs(br) cm^{-1}.

Further recrystallization of the filtrate only produced a mixture of **II** and **III**.

Preparation of **IV**

(i) A solution of $C_7H_8Mo(CO)_4$ (0.5 g, 1.7 mmol) in hexane (50 cm^3) was added dropwise to a freshly

prepared solution of $Ph_2P(C_5H_5)$ (0.9 g, 3.6 mmol) in hexane at ambient temperature. After stirring for 3 h at ambient temperature, white precipitates were obtained. The precipitates were filtered and recrystallized from a 1:1 toluene–hexane mixture (20 cm^3) to give light yellow crystals which were dried *in vacuo*. Yield: 1.1 g, 88%; m.p. 198–200°C (decomposed). Found (required): C, 64.4 (64.4); H, 4.1 (4.2); P, 8.9 (8.8)%. IR (KBr), ν(CO): 2017s, 1916s, 1880 vs(br) cm^{-1}.

(ii) A solution of *cis*-$Mo(CO)_4(Ph_2PCl)_2$ (0.9 g, 1.5 mmol) in toluene (50 cm^3) was added dropwise to a suspension of $(C_5H_5)Tl$ (0.9 g, 3.3 mmol) in toluene (50 cm^3) at ambient temperature. The solution was stirred at ambient temperature for 48 h, but no reaction was observed. The solution was then refluxed overnight and allowed to cool to room temperature and filtered. The filtrate was then concentrated under reduced pressure to *ca* 20 cm^3. n-Hexane was then added until the solution turned cloudy. Upon standing at room temperature overnight, light yellow crystals of **IV** were obtained. Yield: 0.9 g, 85%.

Pyrolysis of **IV**

Compound **IV** (0.9 g, 1.2 mmol) was heated at 200°C *in vacuo*. The complex gradually turned black with evolution of gas as the temperature was raised. After heating for 4 h at 200°C, gas evolution ceased. The black residue was cooled down to room temperature, dissolved in a minimum amount of $CHCl_3$, and chromatographed on silica gel using toluene as eluent. A brown band was collected and the solvent was evaporated *in vacuo*. The residue was redissolved in a minimum amount of $CHCl_3$ and chromatographed again on silica gel using a hexane–toluene mixture as eluent. Three bands were obtained. Band A was obtained by eluting with hexane–toluene (2:3), and bands B and C were obtained with hexane–toluene (1:2). Solvents were removed *in vacuo*. Bands A and B yielded only a small amount of solid material and were discarded. Band C gave considerably better yield and recrystallization of the residue, with toluene–hexane, gave dark red prisms which were dried *in vacuo*. Yield: 0.2 g, 22%; m.p. >280°C. Found (required): C, 57.4 (57.1); H, 4.2 (4.1); P, 8.1 (8.4)%. IR (KBr), ν(CO): 1807s cm^{-1}.

$^{31}P\{^1H\}$ *NMR studies*

(i) *Isomerization of* **II**. **II** (20 mg) was dissolved in 0.5 cm^3 of $CDCl_3$ at 10°C. The isomerization process was monitored by $^{31}P\{^1H\}$ NMR spectroscopy at 4-h intervals for 12 h. Within the period,

[a] U_{eq} defined as one third of the trace of the orthogonalized *U* tensor. Atoms C(37)—C(42) belong to the disordered hexane molecule and have site occupancy factors of $\frac{1}{2}$.

II isomerized to **IV** quantitatively. Throughout the course of the reaction, no other resonance signals, other than those of **II** and **IV**, were observed.

(ii) *Isomerization of a mixture of* **II** *and* **III**. **II** and **III** (20 mg) were dissolved in 0.5 cm^3 of $CDCl_3$ at 10°C. The isomerization process was monitored by $^{31}P\{^1H\}$ NMR spectroscopy every 4 h for 12 h. Within the period, both **II** and **III** isomerized to **IV** quantitatively. Throughout the course of the reaction, no other resonances, other than those of **II**, **III** and **IV** were observed.

X-ray diffraction studies

Crystals of **VI** suitable for X-ray diffraction study were grown from toluene–n-hexane as a solvate of stoichiometry 2 **VI** · C_6H_{14}.

Raw intensities collected at 21°C on a Nicolet R3m/V diffractometer were processed with the profile fitting procedure of Diamond[13] and corrected for absorption using ψ-scan data[14] (details in Table 4). Two molybdenum atoms was located by direct phase determination and the coordinates of the other non-hydrogen atoms were derived from successive difference Fourier syntheses. The carbon atoms of the disordered solvent (n-hexane) were found on a subsequent difference Fourier map and interatomic distance constraints of 1.540(2) and 2.52(1) Å were applied to adjacent carbons and alternate carbons. The non-hydrogen atoms were refined anisotropically and the carbon atoms of the solvent molecule isotropically. Hydrogen atoms of the phenyl and cyclopentadienyl groups were generated geometrically (C—H bond fixed at 0.96 Å) and allowed to ride on their respective parent carbon atoms. These hydrogen atoms were assigned appropriate isotropic thermal parameters and included in the structure factor calculation. The hydrogen atoms of the disordered hexane molecule were ignored. Computations were performed using the SHELTXL-PLUS program package[15] on a DEC MicroVAX-II computer. Analytic expressions of atomic scattering factors were employed, and anomalous dispersion corrections were incorporated.[16] The maxima in the last difference map all lie in the neighbourhood of the solvent molecule.

ADDITION OF RHg^+ FRAGMENTS TO P—P BONDS OF HETEROATOMIC CLUSTERS

MASSIMO DI VAIRA, DONELLA ROVAI and PIERO STOPPIONI*

Dipartimento di Chimica, Università di Firenze, Via Maragliano 77, 50144 Firenze, Italy

(*Received* 19 *March* 1990; *accepted* 7 *June* 1990)

Abstract—Treatment of a dichloromethane solution of [(triphos)MP_3] [triphos = 1,1,1-tris(diphenylphosphinomethyl)ethane; M = Co, Rh] with RHgCl (R = CH_3, C_6H_5) in the presence of $TlPF_6$ affords the compounds [(triphos)MP_3HgR]PF_6·solvent (M = Co, Rh; R = CH_3, C_6H_5). An X-ray crystallographic analysis on the [(triphos)CoP_3HgCH_3]PF_6 derivative has shown that the mercury atom of the $HgCH_3$ fragment is bound to two phosphorus atoms of the P_3 unit of [(triphos)CoP_3].

The neutral compounds [(triphos)MP_3] [triphos = 1,1,1-tris(diphenylphosphinomethyl)ethane; M = Co, Rh, Ir] which have a pseudo-tetrahedral core formed by three unsubstituted phosphorus atoms and one cobalt group metal, stabilized by the tripod tridentate ligand triphos, exhibit distinct reactivity. The heteroatomic polarized MP_3 core interacts with electrophilic organic reagents[1] and transition metal–ligand fragments[2] through one P atom or the P_3 triangular face.

We have recently found[3] that the interaction of the $[Au(PR_3)]^+$ (R = CH_3, C_6H_5) cations with the MP_3 core is accompanied by an unusual labilization of the phosphane ligand bound to gold and formation of compounds in which the gold atom bridges two [(triphos)MP_3] units, being linked to a P—P edge of the P_3 group of each unit. It was therefore of interest to examine the reactions of [(triphos)MP_3] with sources of HgY^+ (Y = halide or hydrocarbyl), which are isoelectronic with $[AuPR_3]^+$ and present different bonding abilities according to the nature of Y. Mercury(II) compounds have been found to be capable of binding to transition metals yielding different compounds. The most familiar interactions consist of the linear M—HgY or M—Hg—M arrangements;[4] the HgY fragments in the presence of metal clusters may end over a metal–metal edge[5] or a triangular face of the metal polyhedron.[6] The complexes in which the HgY^+ moiety bridges a metal–metal bond or caps a triangular face of an organometallic cluster, are endowed with good stability and redistribution reactions, analogous to those extensively investigated for organomercurial compounds,[7] have been observed.[8]

EXPERIMENTAL

All reactions and manipulations were performed under an atmosphere of dry oxygen-free nitrogen. Solvents were freshly distilled under nitrogen from the appropriate drying agents immediately before use. The $^{31}P\{^1H\}$ and ^1H NMR spectra were obtained in CD_2Cl_2 using a VARIAN VXR 300 spectrometer operating at 121.4 and 300.1 MHz and are referred to external 85% H_3PO_4 and internal TMS, respectively. Analytical data for carbon, hydrogen and cobalt were obtained in the Microanalytical Laboratory of the Chemistry Department; phosphorus, mercury and rhodium elemental analyses were performed by Mykroanalytisches Labor Pascher, Remagen, F.R.G. [(triphos)MP_3] (M = Co,[9] Rh[10]) were prepared as previously described. CH_3HgCl (Merck), C_6H_5HgCl (Ega Chemie) and $TlPF_6$ (Strem Chemicals) were used as supplied. All the compounds were collected on a sintered-glass frit, in a closed system, and washed with benzene and light petroleum (b.p. 40–70°C) in turn before being dried under a stream of nitrogen.

Synthetic procedures

Synthesis of the compounds. [(triphos)CoP_3HgCH_3]PF_6. CH_3HgCl (0.13 g, 0.5 mmol) dissolved

* Author to whom correspondence should be addressed.

in tetrahydrofuran (30 cm^3) was added to a dichloromethane solution (40 cm^3) of [(triphos)CoP_3] (0.39 g, 0.5 mmol) and solid $TlPF_6$ (0.17 g, 0.5 mmol) was added to the resulting solution. The mixture was stirred at room temperature for 4 h and filtered. Orange crystals of [(triphos)CoP_3HgCH_3]PF_6 were obtained by addition of benzene and slow concentration. The compound crystallizes, as also found from the X-ray work, with dichloromethane solvate molecules whose amount was assigned mainly in accordance with the results of the structural investigation (see below) (yield 85%). Found: C, 43.1; H, 3.9; Co, 4.8; Hg, 16.7; P, 18.1. [(triphos)CoP_3HgCH_3]$PF_6 \cdot 0.7CH_2Cl_2$, $C_{42.7}H_{43.4}Cl_{1.4}CoF_6HgP_7$, requires: C, 42.9; H, 3.7; Co, 4.9; Hg, 16.8; P, 18.1%. NMR ^1H: δ 1.13 (3H, s, $HgCH_3$, ^2J 180 Hz), 1.69 (3H, s, CCH_3), 2.53 (6H, s, PCH_2), 7.04 (30H, m, arom. H). The same procedure was used to obtain [(triphos)$CoP_3HgC_6H_5$]$PF_6 \cdot 0.7CH_2Cl_2$ (yield 80%). Found: C, 45.7; H, 3.7; Co, 4.5; Hg, 15.7; P, 17.1. [(triphos)$CoP_3HgC_6H_5$]$PF_6 \cdot 0.7CH_2Cl_2$, $C_{47.7}H_{45.4}Cl_{1.4}CoF_6HgP_7$, requires: C, 45.5; H, 3.6; Co, 4.7; Hg, 15.9; P, 17.2%. NMR ^1H: δ 1.71 (3H, s, CCH_3), 2.52 (6H, s, PCH_2), 7.05 (30H, m, arom. H). The rhodium derivatives, which also crystallize with dichloromethane, were obtained through the same procedure by reacting [(triphos)RhP_3], RHgCl (R = CH_3, C_6H_5) and $TlPF_6$ in 1 : 3 : 3 stoichiometric ratios. Found: C, 41.9; H, 3.7; Hg, 16.2; P, 17.5; Rh, 8.3. [(triphos)RhP_3HgCH_3]$PF_6 \cdot 0.5CH_2Cl_2$ (yield 75%), $C_{42.5}H_{43}ClF_6HgP_7Rh$, requires: C, 41.7; H, 3.5; Hg, 16.4; P, 17.7; Rh, 8.4%. Found: C, 44.2; H, 3.7; Hg, 15.4; P, 16.6; Rh, 8.0. [(triphos)$RhP_3HgC_6H_5$]$PF_6 \cdot 0.5CH_2Cl_2$ (yield 75%), $C_{47.5}H_{45}ClF_6HgP_7Rh$, requires: C, 44.4; H, 3.5; Hg, 15.6; P, 16.9; Rh, 8.0%.

X-ray crystal structure

Diffraction data for [(triphos)CoP_3HgCH_3]$PF_6 \cdot 0.7CH_2Cl_2$. Crystals of the compound did not provide good material for X-ray diffraction, giving broad reflections. An Enraf–Nonius CAD4 diffractometer and Mo-K_α radiation (λ = 0.71069 Å) were used for all operations, which were performed at room temperature. The crystal used for intensity data collection and determination of lattice constants was an elongated prism with dimensions 0.15 × 0.15 × 0.50 mm. Lattice constants were determined by least-squares refinement of the angular settings of 20 reflections with $18 \leqslant 2\theta \leqslant 28°$.

Crystal data. $C_{42.7}H_{43.4}Cl_{1.4}CoF_6HgP_7$, M_r = 1196.59, triclinic, a = 12.988(3), b = 13.654(3), c = 14.954(5) Å, α = 66.99(5), β = 85.28(8), γ = 70.91(9)°, U = 2304(1) Å, Z = 2, D_c = 1.724 g cm^{-3}, $F(000)$ = 1178.8, μ(Mo-K_α) = 41.5 cm^{-1}, space group $P\bar{1}$.

The intensities of all reflections with $l \geqslant 0$ were measured in the range $5 \leqslant 2\theta \leqslant 44°$ in the ω–2θ scan mode with a scan width of $(1.30 + 0.35 \tan\theta)°$ and variable 4–8° min^{-1} scan speed. No crystal decay was observed. Of the total 5656 reflections recorded, 3211 having $I > 3\sigma(I)$ were used for structure determination. Intensity data were corrected for Lorentz and polarization effects and, at isotropic convergence after the structure was solved, they were also corrected for absorption by an empirical procedure.[11] The principal computer programs used in the crystallographic calculations are listed in refs 11–14.

Crystal structure determination. The structure was solved by a combination of direct methods and heavy-atom procedures. In the least-squares refinement the function $\Sigma w(|F_o| - |F_c|)^2$ was minimized with weights $w = [\sigma^2(F_o) + 0.0015|F_o|^2]^{-1}$. The scattering factors for the neutral atoms and the anomalous dispersion corrections for cobalt and mercury were taken from ref. 15. Atoms heavier than carbon were assigned anisotropic thermal parameters, whereas the other atoms were refined isotropically. The U_c value in the solvate CH_2Cl_2 molecule was assumed to be approximately equal to the mean of the U_{eq} values for the chlorine atoms and not refined. Hydrogen atoms were introduced in calculated positions (C—H = 0.95 Å) with fixed thermal parameters, each *ca* 20% larger than that of the corresponding carbon atom. Phenyl groups of the triphos ligand were refined as rigid bodies with idealized geometry. The triphos and $HgCH_3$ methyl groups were also refined as rigid bodies. The C—Cl distances in the CH_2Cl_2 molecule were constrained to a unique value, which was refined. The 0.7 occupancy factor assigned to the solvent molecule resulted from a compromise choice which was made in view of the results of sets of refinement cycles performed with different, fixed values for the CH_2Cl_2 population parameter. The value finally considered to be satisfactory ensured: (1) a low R value; (2) reasonable chlorine thermal parameters (U_{eq} values close to those of the fluorine atoms in the anion); and (3) acceptable values for the (unique) C—Cl bond length and the Cl—C—Cl angle in the solvate molecule. The highest peaks in the final ΔF map, with heights < 2 $eÅ^{-3}$, were in the region of the mercury atom. The largest shift/error ratios in the final cycles were < 0.06 and the final R values were R = 0.083 and R_w = 0.086. Final atomic positional and thermal parameters, bond lengths and angles and F_o/F_c values have been deposited as supplementary material with the Editor, from whom

copies are available on request. Atomic coordinates have also been submitted to the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Treatment of a dichloromethane solution of [(triphos)MP_3] with RHgCl (R = CH_3, C_6H_5), in a 1:1 stoichiometric ratio for M = Co and two-fold excess for M = Rh, in the presence of $TlPF_6$, affords compounds of formula [(triphos)$MP_3HgR]PF_6$·solvent (M = Co, Rh; R = CH_3, C_6H_5). The compounds are obtained as analytically pure orange crystals in good yield. They are mildly air-sensitive and are soluble in dichloromethane and acetone. The rhodium derivatives decompose quickly in solution yielding the parent [(triphos)RhP_3]; such behaviour prevented any characterization of the rhodium compounds in solution. On the other hand, the reaction of the [(triphos)MP_3] compounds (M = Co, Rh) with HgX_2 (X = Cl, Br) in the presence of $TlPF_6$, the stoichiometric ratios of the reagents being 1:1:1, affords decomposition of the MP_3 core. The cobalt derivative yields the (triphos)Co^{II} species, whose presence was confirmed by the precipitation and characterization of [(triphos)CoI][16] after addition of NaI dissolved in ethanol.

The structure of the [(triphos)CoP_3HgCH_3] PF_6·$0.7CH_2Cl_2$ compound consists of [(triphos)$CoP_3HgCH_3]^+$ dimetal cations, PF_6^- anions and interposed CH_2Cl_2 solvent molecules. Figure 1 shows a perspective view of the cation. Selected values of bond distances and angles in the structure are listed in Table 1. The cobalt atom in the dimetal core is coordinated by the three phosphorus atoms of the triphos ligand and by those of the P_3 unit, as in the parent [(triphos)CoP_3] compound.[9] The mercury atom is linked in a slightly asymmetrical fashion to two phosphorus atoms of the P_3 unit and to the methyl carbon. The Hg—P distances are definitely larger (by 0.18 Å, in the mean) than the Au—P distances found for the $[Au\{(triphos)MP_3\}_2]PF_6$ (M = Co, Rh, Ir) compounds, where the gold atom bridges between two [(triphos)MP_3] units, being linked to one pair of P_{P3} atoms of each unit.[3] They are also larger than the Hg—P distances generally found for mercury phosphine derivatives.[17] The P—P bond into which insertion of the $HgCH_3$ unit occurs lengthens from 2.141(2) Å in the parent compound, where the three P—P bonds are symmetry equivalent, to 2.293(8) Å. The other two P—P bonds of the P_3 unit are substantially unaffected by the insertion. Of the three Co—P_{P3} bonds, which measure 2.301(1) Å in the compound [(triphos)CoP_3], the one lying opposite the $HgCH_3$ group lengthens to 2.349(6) Å whereas the other two shorten to 2.25(1) Å in the mean. The Co—$P_{triphos}$ distances are essentially unchanged. The overall pattern of such deformations is similar to that already found for the gold derivatives mentioned above.[3] The distortions in

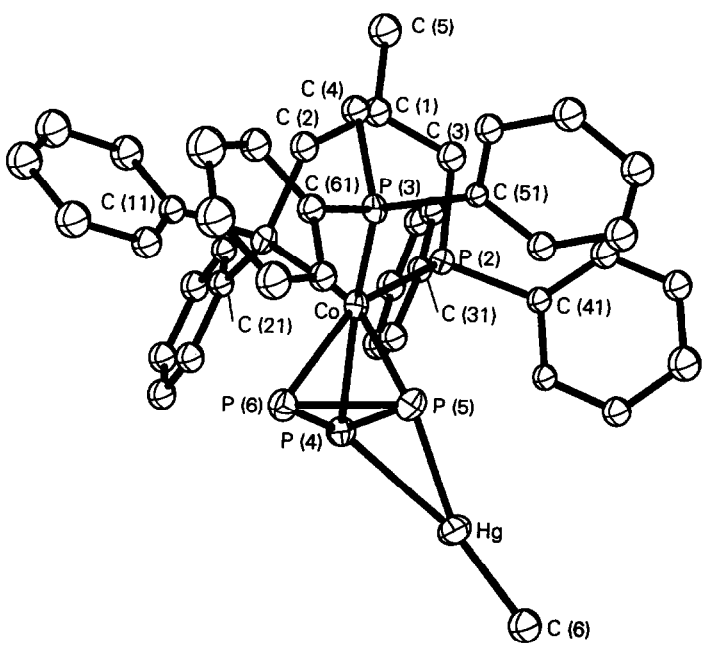

Fig. 1. Perspective view of the cation in the structure of [(triphos)$CoP_3HgCH_3]PF_6$·$0.7CH_2Cl_2$ with 20% probability ellipsoids. Only the first carbon atom of each phenyl group is labelled.

the triangular P_3 group, due to insertion of the present mercury, or of the above gold systems,[3] are notably smaller than those undergone upon insertion of the PtL_2[18] or CPh_2[19] groups. This has to be ascribed to the different electronic requirements of the systems involved. On the other hand, the angle, of 130.4(2)°, between the plane of the P_3 unit and that defined by the atoms Hg, P(4) and P(5) is in the range of values found for the analogous hinge angles in the gold[3] as well as the PtL_2[18] or CPh_2[19] derivatives. The methyl carbon of the $HgCH_3$ group lies strictly in the plane defined by the P(4), P(5) and Hg atoms.

The cobalt compounds exhibit in their ^1H NMR spectra (see the Experimental) the triphos signals with the expected shifts; the methyl mercury derivative presents in addition the CH_3 signal whose chemical shift and coupling constant to mercury are comparable to those reported for other CH_3Hg compounds.[20] The $^{31}P\{^1H\}$ NMR spectra at room temperature exhibit the PF_6^- multiplet with the expected shift (δ −145.4) and two broad, well separated resonances having a 1 : 1 intensity ratio (Table 2). The lower field signal is assigned to the phosphorus atoms of the triphos ligand and the higher field one to the unsubstituted phosphorus atoms, as the corresponding chemical shifts are not significantly different from those found for the parent [(triphos)CoP_3] compound (Table 2).[21] As the equivalence on the NMR time-scale both of the $P_{triphos}$ signals and of the P_{P3} signals is inconsistent with the structure in the solid state, variable temperature $^{31}P\{^1H\}$ spectra were recorded. The two resonances, strongly affected by the cobalt quadrupole moment, become sharper on cooling and their shifts remain substantially unchanged down to −80°C (Table 2). On lowering the temperature further each of the above signals begins to coalesce,

Table 2. $^{31}P\{^1H\}$ NMR data for the complexes

Compound	T (K)	δ (ppm)[a] P(triphos)	δ (ppm)[a] $P(P_3)$

but it was not possible to freeze the fluxional process even at the lowest temperature reached (−94°C). The [(triphos)CoP_3] compound and the isoelectronic [(triphos)CoP_2X]BF_4 (X = S, Se) species[22] undergo dynamic processes in solution, even at low temperatures, which cause the equivalence of the three phosphorus atoms of the triphos ligand as well as of those in the cyclic units (P_3 or P_2X). This is probably due to rotation of the cyclic unit with respect to the triphos–metal fragment. Although such processes are expected to occur also in the present compounds, they are not sufficient to account for the equivalence of the P_3 phosphorus atoms which is only consistent with the HgR fragment undergoing rapid motion over sets of positions in the P_3 rings. The HgR fragment, which in the solid state is bound to a P—P edge, may accomplish such motion in solution through an intermediate state in which the mercury unit is either capping the P_3 face or σ-bonded to one phosphorus atom of the P_3 group. Both arrangements are consistent with the geometrical preferences exhibited by HgR units toward metal polyhedra.[4,6] The difference between the two Hg—P bond lengths in the structure of [(triphos)CoP_3HgCH_3]PF_6 (see above) and the preference of mercury for low coordination numbers, suggest that a possible intermediate may have mercury σ-bound to one phosphorus atom of the P_3 ring.

The above results show that the chemical behaviour of the HgY^+ fragments toward the MP_3 core depends on the nature of Y: when a covalent Hg—Y bond is present (Y = CH_3, C_6H_5) addition of the metal fragment to a P—P edge results, whereas in presence of a predominantly ionic Hg—Y bond (Y = Cl, Br) demolition of the MP_3 core is attained. Such demolition is likely to occur with involvement of the solvent, as found for the bimolecular oxymercuriation reactions of olefin compounds.[23] It has to be observed, in this connection, that the mixed MP_3 core behaves differently from metal clusters, which form stable adducts with HgY moieties irrespectively of the nature of Y.[8]

SYNTHESIS AND CHARACTERIZATION OF SOME β-DIKETONATE DERIVATIVES OF HYDROTRIS(3,5-DIMETHYLPYRAZOLYL)BORATOOXOVANADIUM(IV). THE CRYSTAL AND MOLECULAR STRUCTURE OF HYDROTRIS(3,5-DIMETHYLPYRAZOLYL)BORATO PENTANE-2,4-DIONATO OXOVANADIUM(IV)

(*Received* 30 *March* 1990; *accepted* 8 *June* 1990)

Abstract—A series of compounds of formulation LVOB, where B = pentane-2,4-dionato, 3-chloropentane-2,4-dionato, 1-phenylbutane-1,3-dionato, 1,3-diphenyl-1,3-propanedionato, 4,4,4-trifluoro-1-(2-thenyl)-butane-1,3-dionato and 1,1,1-trifluoro-pentane-2,4-dionato, have been prepared and characterized by elemental analyses, EPR, electronic absorption, IR and mass spectrometry and by cyclic voltammetry. The single crystal X-ray structure of LVO(acac) is also reported. The compound crystallizes in the monoclinic space group $P2_1/c$, $a = 14.943(1)$, $b = 8.127(3)$, $c = 20.894(4)$ Å, $\beta = 113.26(1)°$, $Z = 4$. The unit cell comprises discrete six-coordinate molecules, which have approximate mirror symmetry and exhibit the expected lengthening of the V—N bond *trans* to the terminal oxo group. (V—N(31) = 2.328(2) Å compared with V—N(11) = 2.111(2) and V—N(21) = 2.120(2) Å.) The terminal V=O length is 1.596(2) Å. The atoms within the six-membered ring, comprising vanadium and the pentane-2,4-dionato ligand, are not co-planar with significant tilting (21.5°) about the oxygen–oxygen vector of the ligand.

We have a continuing interest in establishing the relationship between the geometric structures, the reactivity, and the electronic structures of *d*-transition metal compounds. Of particular interest to us are compounds of oxovanadium(IV)[1] and oxomolybdenum(V).[2,3] Not only are these species amenable to study by a wide range of spectroscopic techniques they are also being found in an increasing number of metalloproteins. As part of a substantial continuing programme of study we have already been involved[3] in the synthesis and characterization of a range of LMoO(X)(Y) compounds, where L = the sterically demanding hydrotris(3,5-dimethylpyrazolyl)borato ligand. X and Y are mononegative, unidentate ligands or the mononegative donor atoms of a bidentate ligand, which give electrically neutral complexes. We are currently extending the use of the ligand L to oxovanadium chemistry. The use of mononegative, bidentate ligands, B, to give compounds of formulation LVOB preserves six-coordination and electrical neutrality. These properties enhance the solubilities of the compounds in non-aqueous solvents and also their resistance to hydrolysis. We have already made a preliminary report[4] of the synthesis of LVOB, where B = β-diketonato or N,N-diethyldithiocarbamato, and since then Carrano and co-workers[5] have reported the synthesis of LVO(acac), where acac = pentane-2,4-dionato, as well as the synthesis and X-ray structures of $LVCl_2$dmf, LVOCldmf, where dmf = N,N-dimethylformamide, and $K[LVCl_2(Me_2pz)]$, where Me_2pz = 3,5-dimethylpyrazolide. This present communication extends our preliminary report[4] to include more detailed spectroscopic characterization of the β-diketonato complexes and the X-ray crystal structure of LVO(acac). The detailed single crystal EPR spectroscopy of some of these β-diketonato complexes will be reported elsewhere.

EXPERIMENTAL AND RESULTS

Preparation of the compounds

This is most conveniently accomplished under non-aqueous conditions according to eq. (1):

$$VOB_2 + KL \xrightarrow[\text{Solvent}]{50\text{–}60^\circ C} LVOB + KB. \quad (1)$$

VOB_2

VOB_2, where B = pentane-2,4-dionato (acac), 3-chloro-pentane-2,4-dionato (Clacac), 1-phenyl-butane-1,3-dionato (bzac), 1,3-diphenyl-1,3-propanedionato (dbzac), 4,4,4-trifluoro-1-(2-thenyl)-butane-1,3-dionato (thtf), and 1,1,1-trifluoro-pentane-2,4-dionato (tfa), were each prepared by adding a stoichiometric quantity of the β-diketone in ethanol to a concentrated aqueous solution of oxovanadium(IV) sulphate. The pH of the solution was adjusted with dilute aqueous sodium bicarbonate until the required complex precipitated. The precipitate was filtered off, washed with water, dried in air and used without further purification.

KL

This was prepared according to the literature method.[6]

LVOB

These were all prepared by heating KL (5 mmol) and VOB_2 (5 mmol) in sodium dried toluene (100 cm^3) at 50°C for 15–20 h. The methods of isolation of the desired compounds varied slightly in each case as follows.

LVO(acac). The solution was filtered and the volume was reduced *in vacuo* to 30 cm^3. On cooling this solution a pale blue precipitate was obtained. The precipitate was washed with ice-cold sodium-dried toluene, followed by diethyl ether. Found: C, 51.9; H, 6.4; N, 18.1; B, 2.5; V, 11.0. Calc.: C, 51.8; H, 6.3; N, 18.1; B, 2.3; V, 11.0%.

LVO(Clacac). A dark brown solid was filtered off, washed with toluene followed by diethyl ether. The solid was dissolved in dichloromethane and crystallized by the addition of methanol. Found: C, 48.0; H, 5.6; N, 16.6; V, 10.1. Calc.: C, 48.3; H, 5.7; N, 16.9; V, 10.2%.

LVO(dbzac). The solution was filtered and the filtrate evaporated to dryness *in vacuo*. The resulting olive-green solid was dissolved in dichloromethane and crystallized by the addition of methanol. Found; C, 60.5; H, 5.7; N, 15.2; V, 8.6. Calc.: C, 61.3; H, 5.7; N, 14.3; V, 8.7%.

LVO(bzac)·0.5CH_3CN. The solution was filtered and the filtrate evaporated to dryness *in vacuo*. The resulting green solid was dissolved in dichloromethane and reprecipitated by the addition of methanol. The compound was finally crystallized from methylcyanide. Found: C, 57.5; H, 6.1; N, 16.7; V, 9.3. Calc.: C, 57.2; H, 6.0; N, 16.7; V, 9.3%.

LVO(thtf). The grey precipitate was filtered off and washed with toluene and then with diethyl ether. The compound was crystallized from methylcyanide. Found: C, 46.5; H, 4.4; N, 14.4; V, 8.4. Calc.: C, 47.2; H, 4.5; N, 14.3; V, 8.7%.

LVO(tfa). The green precipitate was filtered off and then crystallized from methylcyanide. Found: C, 46.3; H, 5.1; N, 16.0; V, 9.9. Calc.: C, 46.4; H, 5.1; N, 16.2; V, 9.8%.

The yields in each of these preparations were in the range of 30–40%.

Physical methods

IR spectra. IR spectra of the compounds in KBr discs were recorded using a Perkin–Elmer 1710 IR Fourier transform spectrometer. The B—H and V=O stretching frequencies are summarized in Table 1.

Cyclic voltammograms. Cyclic voltammograms of the compounds in dried methylcyanide were obtained with a Princeton Applied Research Model 173 potentiostat/galvanostat and a Model 175 universal programmer using a glassy carbon working electrode and a saturated calomel reference electrode. The supporting electrolyte was 0.2 M $[Bu^n_4N][BF_4]$ with ferrocene as an internal standard. The results are summarized in Table 1.

Electron paramagnetic resonance (EPR) spectra. EPR spectra of fluid and frozen toluene solutions of LVOB were obtained at both *X*- and *Q*-band frequencies using a Varian E112 spectrometer. Temperature control was achieved as previously described.[7] The spin-Hamiltonian parameters were obtained via spectrum simulation at both frequencies using our previously described simulation methods.[8] The principal g and A values are given in Table 1.

Electronic absorption spectra. Electronic absorption spectra of the compounds in toluene were obtained using a Varian 2390 spectrophotometer over the wavelength range 3000–250 mm. The band maxima of the compounds along with those of other relevant oxovanadium(IV) compounds are given in Table 2.

Mass spectra. Mass spectra of the compounds were obtained using *a Kratos MS25 spectrometer*

[a] The results quoted are for a scan rate of 100 mV s⁻¹. For ferrocene under the same conditions $E = 0.428$ V, $\Delta E = 75$ mV, $I_{pa}/I_{pc} = 1.05$. Errors on g and A values cover the range of values required to fit the spectra at both X- and Q-band frequencies.

with electron impact to effect ionization. The results are summarized in Table 3.

Single crystal X-ray structure determination of LVO(acac). The determination at ambient temperatures was achieved using an Enraf–Nonius CAD4 diffractometer. The crystals were grown from methylcyanide solution by slow evaporation. The data collection parameters are given in Table 4. The solution of the structure was achieved by a combination of Patterson and difference Fourier methods. The least-square refinement minimized $\Sigma w^2(|F_o|-|F_c|)^2$ with the weighting $w^{-1} = (1.307-0.105F+0.00343F^2)^{1/2}$. The positions of all atoms were refined. The atomic numbering scheme is shown in Fig. 1, whilst selected bond lengths and angles are given in Table 5. The non-hydrogen atoms were refined with anisotropic thermal parameters, but for the hydrogen atoms only isotropic temperature factors were refined. Lists of atomic coordinates, bond lengths and angles, thermal parameters, plus the observed and calculated structure factors are deposited as supplementary material.

DISCUSSION

The X-ray crystal structure of LVO(acac) shows it to consist of discrete six-coordinate molecules. The molecular geometry is that of a distorted octahedron (see Fig. 1). There is no crystallographically imposed symmetry in the molecules, but there is an approximate mirror plane containing the atoms O(1)—V(1)— and those of the pyrazolyl ring N(31),

etc. This is illustrated in Fig. 1, which shows a view of the molecule down the edge of this approximate mirror plane. As expected there is a significant lengthening of the V—N bond *trans* to the terminal oxo group (V(1)—N(31) = 2.328(2) Å) compared with those *cis* to this group (V(1)—N(11) = 2.111(2) and V(1)—N(21) = 2.120(2) Å). The V—N bond lengths in LVO(acac) compare favourably with those of equivalent bonds in other five- and six-coordinate $[LVO]^+$ compounds.[5,9] However, the terminal V(1)—O(1) bond length (1.596(2) Å) is significantly shorter than that reported in six-coordinate LVOCl(dmf) (1.649(5) Å), but is similar to those in $LVO(R_2dtc)$,[9] where R = ethyl or n-propyl (1.587(8) and 1.602(6) Å, respectively). No unusual features were observed in the dimensions of the pyrazolyl rings.

The carbon–oxygen and carbon–carbon bond lengths within the pentane-2,4-dionato ligand are comparable to those observed in other oxovanadium(IV) pentane-2,4-dionato compounds.[10] However, the atoms within the six-membered ring comprising the vanadium and the pentane-2,4-dionato ligand are not co-planar. There is a significant tilting about the O(41)–O(42) direction (see Fig. 2). The dihedral angle between the plane formed by V(1), O(41), O(42) and the best plane of the pentane-2,4-dionato ligand is 21.5°. We attribute this distortion to interaction with the methyl group [C(34)] on the pyrazolyl ring which is *trans* to the terminal oxo group. There are some relatively short contacts between the hydrogen atoms of this methyl group and the oxygen and carbon atoms of the

pentane-2,4-dionato ligand (see Table 6). The relatively large tilting of the pentane-2,4-dionate ligand in the present compound is in contrast to a tilt of only 3.6° in six-coordinate VO(acac)$_2$ γ-picoline.[10b]

In view of the similarity of the β-diketonate ligands used in this work, and the small variations in ν(V═O) and ν(B—H) (see Table 1), we assume that all of the compounds have essentially the same distorted octahedral geometry as that formed in LVO(acac). This distorted geometry is reflected in the EPR and electronic absorption spectra of the compounds. The appearance of the frozen solution spectra, at both *X*- and *Q*-band frequencies was indicative of, at most, rhombic EPR symmetry (i.e. $g_1 \neq g_2 \neq g_3$ and $A_1 \neq A_2 \neq A_3$, but with the principal axes of g and A tensors coincident). All of the spectra were satisfactorily simulated on this basis and the mean values of the relevant parameter from both frequencies are shown in Table 1. Although the anisotropies, particularly between g_2 and g_3, and A_2 and A_3, are small they are necessary for satisfactory simulation. The averages of the principal g and A values are in good agreement with the isotropic values obtained from fluid solutions. Not surprisingly, in view of the similarity of the ligand donor atoms, the individual spin-Hamiltonian parameters show little variation over the series of compounds with no effects of the substituents on the β-diketonate being detected.

The electronic absorption spectra also reflect the low symmetry of the compounds in that, for four out of the six compounds studied, we observe four bands which can be attributed to *d–d* transitions based on their absorption coefficients (see Table 2). In the other two compounds the equivalent fourth band would be masked by the intense charge-transfer band from the UV region of the spectrum. Four *d–d* bands have also previously been reported for some low symmetry Schiff-base oxovanadium(IV) compounds.[11] This observation implies the complete removal of degeneracy within the *d*-orbitals of the vanadium. In our initial interpretation of the dilute single crystal EPR data for LVO(Et$_2$dtc), where Et$_2$dtc = N,N-diethyldithiocarbamato, we assumed an electronic structure based on a distortion from D_{3d} point symmetry.[4] However, both the electronic absorption and EPR spectra of the present compounds are also compatible with approximate mirror symmetry (ideally C_s) in the molecules. Further single crystal EPR studies on LVOB and LVO(R$_2$dtc) are in progress to resolve this ambiguity.

The LVOB complexes in methylcyanide solutions all exhibited quasi-reversible one-electron oxidation as assessed by cyclic voltammetry, and by comparison with the simultaneous measurements on ferrocene (see Table 1). The quasi-reversibility was demonstrated by the linear plots of peak current vs the square root of the scan rate, by $\Delta E > 59$ mV which tended towards 59 mV as the scan rate decreased, and by I_{pa}/I_{pc} close to unity. The potentials fall in the narrow range 1.145–1.399 V, suggesting a metal-based process. Those compounds which have electron-withdrawing substituents on the β-diketonate ligand are slightly more difficult to oxidize. Two of the compounds, LVO(bzac) ($E = -1.409$ V, $\Delta E = 83$ mV, $I_{pa}/I_{pc} = 1.00$) and LVO(thtf) ($E = -1.139$ V, $\Delta E = 82$ mV, $I_{pc}/I_{pc} = 1.03$), also, gave quasi-reversible one-electron reductions. The other compounds exhibited ill-defined irreversible reductions. These results, demonstrating the instability of the $[LVOB]^+$ species, are in accordance with our previous observations that the $\{LMoE\}^{2+}$ moiety, where E = O or S, only afford isolable species by achieving six-coordination and overall electrical neutrality.

The LVOB compounds were also examined by mass spectroscopy (see Table 3). The relative molecular masses of each compound are based upon a rounded sum of the relative atomic masses. The mass numbers in Table 3 refer to the peak of maximum intensity within a multiplet. The multiplets arise from the isotopic distribution within the light atoms. For all of the compounds studied we observed the parent ion and the $[LVO]^+$ ion. In addition, all of the compounds except LVO(Clacac) gave a multiplet assignable to the loss of one 3,5-dimethylpyrazolyl ring. These observations are directly comparable with the mass spectroscopy of LMoO(X)(Y) compounds.[3]

PREPARATION OF TEREPHTHALOYL DERIVATIVES OF CYCLIC TRIAMINES AND THEIR SELECTIVITIES TOWARD COPPER(II), NICKEL(II) AND ZINC(II) IONS

MANABU FUJIWARA,* JUN MATSUDA and HISANOBU WAKITA

Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Jonan-ku, Fukuoka 814-01, Japan

(*Received* 3 *January* 1990; *accepted* 8 *June* 1990)

Abstract—Three polymeric ligands containing 9-, 10- and 12-membered cyclic triamines have been prepared by the reaction of cyclic triamine with terephthaloyl chloride. They are insoluble in water and ordinary organic solvents, but under heterogeneous conditions they can adsorb some transition metal ions [copper(II), nickel(II), and zinc(II)] very rapidly. The complexing abilities of the 9- and 10-membered polymeric ligands are stronger in the order zinc(II) < nickel(II) < copper(II), but that of the 12-membered polymeric ligand is nickel(II) < zinc(II) < copper(II).

Selective separation of heavy metal ions is an important subject in the fields of industrial and analytical chemistries. For this purpose, many extractants and chelating resins have been synthesized and some of them have been applied in practice. Tabushi and co-workers[1] reported that the lipophilic cyclams (saturated tetraaza macrocycles) with long alkyl side-chains are able to extract heavy metal ions from aqueous solution to an organic phase. However, the selectivity of these ligands is not very satisfactory. They also reported that the cyclam bound chemically on polystyrene is a good adsorbent for heavy metal ions.[2] Nevertheless, its adsorption rate is very slow and it takes about 3 h for the half-adsorption of the copper(II) ion. Zolotov *et al.*[3] reported that the macrocyclic Schiff base ligand (6,8,15,17 - tetramethyldibenzo - 5,9,14,18 - tetraazacyclotetradecene) exhibits a high selectivity for copper(II) in solvent extraction. Its extraction rate was found to be very slow on account of its rigid structure. In our previous paper,[4] we reported the preparation of polymeric ligands containing the tetraaza macrocycle as an integral part of the polymer backbone, and the complexing ability for copper(II) and nickel(II) under heterogeneous conditions. These polymeric ligands possess a high selectivity for copper(II). In addition, their complexation rates are faster than that of the corresponding monomer ligand, but are not yet satisfactory for practical use. Though many studies on the tetraaza macrocycles and their metal complexes have been reported, a few studies on cyclic triamines and their metal complexes have been carried out.[5] For the complexes with cyclic triamines, the transition metal ion does not incorporate well into the hole of the cyclic triamine, but just sits on the cyclic triamine plane. This means their stability constants may be small but their complexation rates are very high. In this paper, we report the preparation and characterization of the polymeric compounds containing the cyclic triamines and the application to the selective adsorbent for the copper(II) ion.

EXPERIMENTAL

Preparation of the terephthaloyl derivative

To a chloroform solution (300 cm^3) of the free cyclic triamine[6] (1,4,7-triazacyclononane, 1,4,7-triazacyclodecane, or 1,5,9-triazacyclododecane) (0.005 mol) containing pyridine (0.015 mol) as a base, was added dropwise a chloroform solution (200 cm^3) of terephthaloyl chloride (0.006 mol). The mixed solution was refluxed for 24 h. The pale-yellow precipitate formed after the reaction was filtered on a glass filter, washed with dilute sodium hydroxide solution, deionized water and

* Author to whom correspondence should be addressed.

ethanol, and dried *in vacuo*. Three types of polymeric ligands* containing 9-, 10- and 12-membered triamines in the polymer backbone were prepared in about 60% yields.

Preparation of the copper(II) complex with the terephthaloyl derivative

To an aqueous solution (50 cm^3) of copper(II) acetate tetrahydrate (0.030 mol) was added the polymeric ligand (0.003 unit mol). The mixed solution was stirred for 3 h at room temperature, then, the precipitate changed to pale-blue. The bluish precipitate was filtered on a glass filter, washed with water and ethanol, and dried *in vacuo*.

Procedure for the binding of metal(II) ions by the polymeric ligand

The binding of metal(II) ions by the terephthaloyl derivative was carried out using a 10-cm^3 test tube with stopper, in which an aqueous solution (10 cm^3) of metal(II) acetate [copper(II), nickel(II) or zinc(II)] and the uniformly powdered terephthaloyl derivative (10.0 mg) were contained. The test tube was shaken for an appropriate time from 10 to 180 min at room temperature. After shaking, the terephthaloyl derivative was filtered off. The concentration of the metal(II) ion remaining in the filtrate was determined by atomic absorption spectrometry.

RESULTS AND DISCUSSION

The terephthaloyl derivatives are insoluble in water, dilute sodium hydroxide solution and common organic solvents, suggesting that they have rather high molecular weights. The first amine moiety of one cyclic triamine in the terephthaloyl derivative may remain unsubstituted, while its second and third amine moieties react with terephthaloyl chloride to form two amide bonds per one cyclic triamine. The end groups of the polymeric compound are probably carboxyl groups, which are formed by the reaction of one carbonyl chloride in the terephthaloyl chloride by washing with water. The chemical structure of the polymeric compounds estimated from IR spectral data and the results of elemental analyses is shown in Fig. 1. Wieghardt

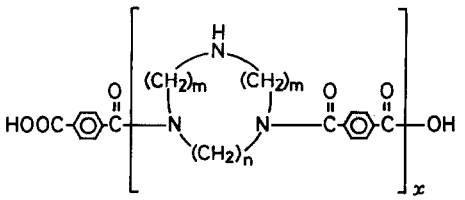

Fig. 1. Structural model of the terephthaloyl derivatives. $m = n = 2$: 9-membered triamine–terephthaloyl derivative; $m = 2, n = 3$: 10-membered triamine–terephthaloyl derivative; $m = n = 3$: 12-membered triamine–terephthaloyl derivative.

et al.[7] reported a similar example where only two nitrogen atoms in a cyclic triamine react with tolylsulphonyl chloride to produce the disubstituted triamine.

Elemental analysis of the terephthaloyl derivative

The elemental analyses of terephthaloyl derivatives are summarized in Table 1. The appropriate x values in Fig. 1, the degree of the polymerization, were estimated from the results of elemental analyses. For the 9-membered triamine–terephthaloyl derivative, the ratio of C:H:N is 16.4:18.7:3.0, where the value of N is fixed at 3.0 because the nitrogen atoms in the polymeric compound belong to only the triamine ring moiety. When the x value is 3.4, the calibrated values of C:H:N are 16.4:18.8:3.0, in good agreement with the found values. In other chemical structures where the end group is one of the cyclic amine moieties, bis(cyclic triamine) connected with terephthaloyl bridge, tris(*p*-carbonylbenzoyl)-cyclic triamine and cross-linked polymer, no x values can be calculated in good agreement with the found values of both C and H.

For the 10-membered triamine–terephthaloyl derivative, the ratio of C:H:N is 15.8:19.6:3.0, and the x value is 10.0. For the 12-membered triamine–terephthaloyl derivative, the ratio of C:H:N is 18.3:24.1:3.0, and the x value is 6.2. These results indicate that the terephthaloyl deriva-

Table 1. Elemental analyses of 9-, 10- and 12-membered triamine–terephthaloyl derivatives

Terephthaloyl derivative	C (%)	H (%)	N (%)
9-Membered	63.92	6.13	13.58
10-Membered	65.46	6.83	14.50
12-Membered	66.90	7.42	12.81

* The IR spectra of the terephthaloyl derivatives have characteristic absorption bands at 3300, 2980, 1730, 1650, 1555, 1480, 1445, 1375, 1290, 1140, 1025, 865, 745 and 730 cm^{-1}. These results indicate that these terephthaloyl derivatives have some unsubstituted amine moieties, amide bonds and disubstituted benzene rings.

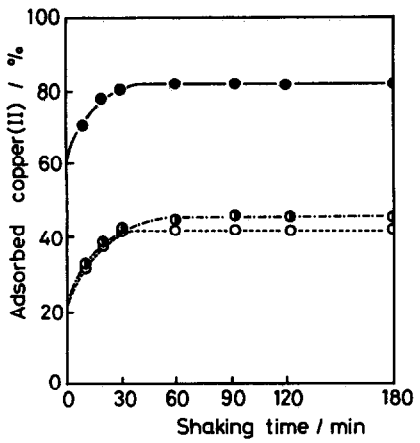

Fig. 2. Effect of shaking time on the adsorption of the copper(II) ion. Adsorbent: (——●——) 9-membered triamine–terephthaloyl derivative (10.0 mg); (-·-◑-·-) 10-membered triamine–terephthaloyl derivative (10.0 mg); (---○---) 12-membered triamine–terephthaloyl derivative (10.0 mg).

tives are polymeric and their molecular weights are probably in the range 1050–2900 depending upon their members of the cyclic triamines.

Binding of metal(II) *ions by the polymeric ligand*

Effect of shaking time. Figure 2 shows the effect of shaking time on the percentage of copper(II) ions bound by the 9-, 10- and 12-membered triamine–terephthaloyl derivatives. For the 9-membered polymeric ligand, the percentage of bound copper(II) ions reached 70% after shaking for only 10 min. This percentage increased with additional shaking for 10 and 20 min. With 30 min shaking, 82% of copper(II) ions were bound by the polymeric ligand. This value implies that 25% of the cyclic triamine moieties in the polymeric ligand were operative for capture of a copper(II) ion and 75% were not. The percentages of other metal(II) ions, nickel(II) and zinc(II), bound by the polymeric ligand were 64 and 55% after shaking for 30 min, respectively. These values are small in comparison with that of copper(II). Within 30 min the reaction between the polymeric ligand and metal(II) ions attained the adsorption equilibria.

For the 10-membered polymeric ligand, the percentage of bound copper(II) ions was 33% after shaking for 10 min. This percentage increased with additional shaking. After 30 min shaking, 45% of copper(II) ions were bound by the polymeric ligand. This value is much smaller than that for the 9-membered polymeric ligand. The percentages of bound nickel(II) and zinc(II) ions were 36 and 28%, respectively, and also much smaller than those of the 9-membered polymeric ligand. However, the complexing ability of the 10-membered polymeric ligand for the metal(II) ions is stronger in the order of zinc(II) < nickel(II) < copper(II), similar to that of the 9-membered polymeric ligand, and the adsorption equilibria between the 10-membered polymeric ligand and metal(II) ions were attained after about 30 min, which is also similar to that of the 9-membered polymeric ligand.

For the 12-membered polymeric ligand, the percentages of bound copper(II), nickel(II) and zinc(II) ions were 42, 15 and 26% after 30 min, respectively. The values for copper(II) and zinc(II) ions are slightly smaller, but that for nickel(II) is much smaller than for the 10-membered polymeric ligand. This leads to the result that the complexing ability of the 12-membered polymeric ligand for metal(II) ions is stronger in the order of nickel(II) < zinc(II) < copper(II), which is different to the order for the 9- and 10-membered polymeric ligands. These results indicate that the structure of the metal(II) complex with the 12-membered polymeric ligand is distinct from those of metal(II) complexes with other polymeric ligands. This may be caused by the differences in the ring size of the cyclic triamines contained within the polymeric ligands. In fact, the ring size of the 12-membered triamine is too large to bind the metal(II) ion at three positions by facial coordination. However, the equilibria between the 12-membered polymeric ligand and metal(II) ions are attained within 30 min, which is similar to the values found for the 9- and 10-membered polymeric ligands. The adsorption rates of metal(II) ions by these polymeric ligands were found to be very fast under such heterogeneous conditions. For other systems containing chelating agents in the solid phase and metal ions in aqueous solutions, the adsorption equilibria were not attained until after more than 48 h.[8]

Effect of pH *on binding capacity.* Figures 3–5 show the effects of the pH of the sample solution on the binding capacity of the polymeric ligands for copper(II), nickel(II) and zinc(II) ions. The pH values were adjusted from 4.0 to 5.5 by using acetate buffer solutions (0.200 mol dm^{-3}) and to above 5.5 by the addition of appropriate amounts of 1.0 mol dm^{-3} sodium hydroxide solution. The shaking time was 1 h.

For the 9-membered polymeric ligand, below pH 4.0 the binding capacity for copper(II) was very small (0.03 mmol g^{-1}) and for nickel(II) and zinc(II) was complete zero. The capacity for copper(II) increased with increasing pH of the sample solution to 6.8. The capacity increased to 0.82 mmol g^{-1}. These behaviours agree well with the result obtained from the pH titration of the corresponding mono-

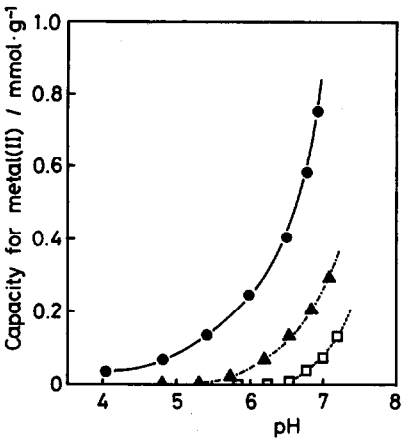

Fig. 3. Effect of pH on the capacity of the 9-membered polymeric ligand for the metal(II) ions. (——●——): copper(II); (-·-▲-·-): nickel(II); (---□---): zinc(II).

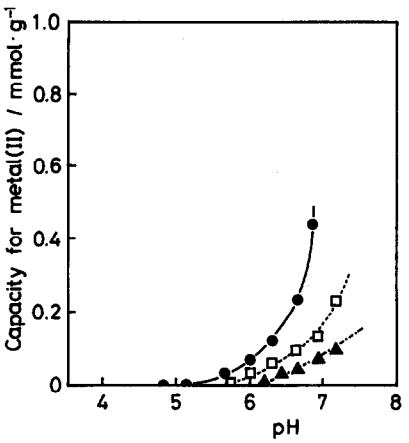

Fig. 4. Effect of pH on the capacity of the 10-membered polymeric ligand for the metal(II) ions. (——●——): copper(II); (-·-▲-·-): nickel(II); (---□---): zinc(II).

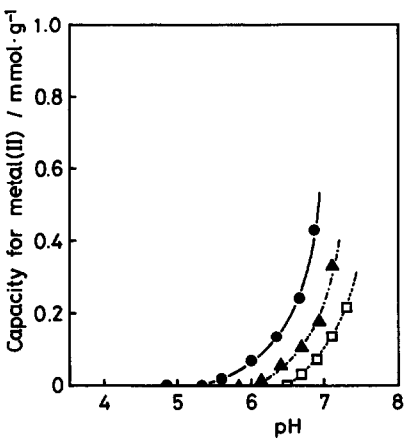

Fig. 5. Effect of pH on the capacity of the 12-membered polymeric ligand for the metal(II) ions. (——●——): copper(II); (-·-▲-·-): nickel(II); (---□---): zinc(II).

meric triamine. In acidic solution, the metal(II) ion and a proton combine with cyclic triamine competitively. In solution around neutral pH, metal(II) ions are coordinated by the cyclic triamine. In alkaline solution, the hydroxyl ion and triamine coordinate to the metal(II) ion competitively. Therefore, the capacity of the triamine–terephthaloyl derivative for the metal(II) ion is probably the highest around neutral acidity of the sample solution. On the other hand, no nickel(II) or zinc(II) was bound by the polymeric ligand below pH 5.3 and 6.5, respectively. The capacity for nickel(II) and zinc(II) ions increased with increasing pH of the sample solution. The values for nickel(II) and zinc(II) increased to 0.21 and 0.04 mmol g^{-1} at pH 6.8, respectively. These are much smaller than the value for copper(II). These results indicate that the 9-membered polymeric ligand binds more strongly in the order of zinc(II) < nickel(II) ≪ copper(II), suggesting that the nature of the triaza ring in the polymeric ligand influences the binding properties of the polymeric ligand towards metal(II) ions.

For the 10-membered polymeric ligand, below pH 5.3 copper(II), nickel(II) and zinc(II) ions were not bound. The binding capacities of this polymeric ligand for copper(II), nickel(II) and zinc(II) increased remarkably with increasing pH of the sample solutions from pH 5.3, 6.1 and 6.6, respectively. At pH 6.8, the binding capacities for copper(II), nickel(II) and zinc(II) were 0.44, 0.19 and 0.07, respectively. The value for copper(II) is much smaller than that of the 9-membered polymeric ligand, but these values for nickel(II) and zinc(II) are slightly smaller and slightly larger than those for the 9-membered polymeric ligand, respectively. These results indicate that the polymeric ligands exert different effects of ionic strength to each other. For the 12-membered polymeric ligand, below pH 5.2 copper(II), nickel(II) and zinc(II) ions were not bound. The binding capacities of this polymeric ligand for copper(II), nickel(II) and zinc(II) increased remarkably with increasing pH of the sample solutions from pH 5.2, 6.2 and 5.7, respectively. The increasing slope for nickel(II) is rather small. At pH 6.8, the capacities for copper(II), nickel(II) and zinc(II) were 0.44, 0.07 and 0.14 mmol g^{-1}, respectively. The capacity for nickel(II) is smaller than that for zinc(II). The complexing ability of the 12-membered polymeric ligand for metal(II) ions is stronger in the order nickel(II) < zinc(II) < copper(II), which is different from those of the 9- and 10-membered polymeric ligands. These results indicate that the structure of the metal(II) complex with the 12-membered polymeric ligand is distinct from those of metal(II) complexes with other polymeric ligands, as mentioned above.

Reflectance spectra of polymeric ligands and their copper(II) complexes

The diffused reflectance spectra of polymeric ligands and their copper(II) complexes were measured. The 9- and 12-membered polymeric ligands have weak absorption bands at 442 and 418 nm, respectively. These bands can be assigned to π–π^* transitions.

The copper(II) complex with the 9-membered polymeric ligand exhibits two absorption bands at 670 and 428 nm. The former can be assigned to ligand-field transitions and the latter may be assigned to charge-transfer transitions. The absorption spectrum of the copper(II) complex with the parent monomeric ligand, CuL^{2+} (L = 1,4,7-triazacyclononane), in H_2O shows an absorption band at 637 nm.[9] This result indicates that the ligand-field strength of the terephthaloyl derivative (9-membered polymeric ligand) is weakened considerably in comparison with that of the parent cyclic triamine. This was caused by the introduction of the terephthaloyl groups, the electron-withdrawing substituents.

The copper(II) complex with the 12-membered triamine–terephthaloyl derivative exhibits absorption bands at 666 and 424 nm. These may be also assigned to ligand-field transitions and charge-transfer transitions, respectively. The absorption spectrum of the copper(II) complex with 1,5,9-triazacyclododecane in H_2O shows an absorption band at 689 nm.[9] The absorption band of the copper(II) complex with the terephthaloyl derivative was shifted not to longer wavelengths, but to shorter wavelengths by about 20 nm in comparison with that of the unsubstituted 12-membered triamine. As mentioned above, the structure of the copper(II) complex with the 12-membered polymeric ligand may be different from that of the corresponding parent triamine. This difference influences the adsorption character of the 12-membered polymeric ligand, where the polymeric ligand binds to the zinc(II) ion more strongly than to the nickel(II) ion.

(*Received* 3 *April* 1990 ; *accepted* 8 *June* 1990)

Abstract—The speciation of Pb^{II} and Cd^{II} complexes of 1,10-phenanthroline has been studied in varying concentrations (0–29.64% w/w) of urea solutions maintaining an ionic strength of 0.16 mol dm^{-3} (NaCl) at 30°C. The strength of the acid and the base was checked using the Gran plot method. Titrations were performed with a wide range of metal to ligand ratios (1 : 2–1 : 6). The primary alkalimetric data are pruned either with SCPHD (2.0) or by a new graphical procedure. The approximate equilibrium constants thus obtained were refined with MINIQUAD 75. The selection of best chemical models was based on statistical parameters and residual analysis. Since the active form of the ligand is LH^+, the species detected are ML, ML_2 and ML_3 only. Global stability constants were evaluated using ANOVA. The solvent effects have been analysed in terms of macroscopic properties of the solvent mixture with ESOCE. The trend in β values of the proton–ligand and the metal–ligand complexes with the dielectric constant is explained on the basis of electrostatic and non-electrostatic forces.

The role of urea is significant in the metabolism, though it acts as denaturant of DNA,[1] proteins,[2] insulin[3] and other macromolecules.[4] Acinus (micro-circulatory unit of the liver) contains periportal and perivenous cells which convert the ammonia in the blood into non-toxic urea.[5] The synthesis of urea is maximal[6] at physiological pH (7.4) and markedly decreased at pH 7.05. The release of the urea thus produced is regulated[7] by sympathetic and para-sympathetic nerves. The patients with urea toxicity (ureamia) exhibit the symptoms as pneumonitis, pericardiatis, gastrointestinal disorders and peripheral neuropathy. The lethal dose of urea to fish[8] (*Channa punctatus*) is 27 000 ppm. This is significant with respect to water pollution by fertilizers containing urea; feeding experimental animals resulted[9] in reduced venous concentrations of plasma amino acids. Urea from urea-based fertilizer is degraded to ammonia in soil by urease (Ni-containing enzyme), the activity of which is essential for plant growth. In addition urea can be used as a drug in the treatment of syndrome of inappropriate antidiuretic hormone secretion (SIADH).[10]

The globular structure of protein in aqueous solution may be due to the hydrophobic interactions. The contact between non-polar side chains of proteins and water requires an unfavourable arrangement of water molecules. There are many such contacts in an unfolded conformation but relatively few in a globular one, which is stabilized in spite of its own low conformational entropy.[11] Two alternative mechanisms are proposed for the denaturing effect of urea on proteins: (1) Direct interaction of urea molecules with amide and peptide groups which destroys intermolecular hydrogen bond and hydrophobic interactions[12] that are involved in the maintenance of ternary structure of DNA, macromolecules, etc. (2) Urea exerts its influence through changes in the water structure.[13] The negative heat capacities of transfer of certain amino acids[14] from water to aqueous urea solution and the increments in the critical micelle concentration[15] of certain micelles, suggest that urea may reduce the co-operative structure of water. Hence it is proposed to

* Author to whom correspondence should be addressed.

study the urea–water interactions in order to understand the denaturing property of urea.

Toxicity of metals occurs when an organism is unable to cope with the additional metal concentration by direct usage, storage or excretion. The toxicity effects of heavy metal ions may also be the result of their strong bonding with reactive groups of enzymes. Hence studies of the interaction of toxic metal ions with bioligands in the presence of urea throw light on: (1) the understanding of the mechanism of the adverse effect of these cations on metabolic processes, (2) in suggesting antidotes and (3) on the effect of denaturant on the speciation.

In the present study the complexation of Pb^{II} and Cd^{II} with 1,10-phenanthroline (phen) is studied electrometrically in urea–water mixtures.

EXPERIMENTAL

Solutions of phen (E. Merck), Pb^{II} and Cd^{II} were prepared in doubly distilled water. All other solutions were of A.R. grade and were prepared in doubly distilled water. Urea was recrystallized twice from ethanol[16] and was dried at 60°C for 2 h. Stock urea solutions were prepared and stored frozen. The solution was never allowed to stand at room temperature for more than 24 h before its usage. The strength of the alkali was determined using the Gran plot method.[17] The errors in the concentrations of ligand, metal ions and alkali were subjected to analysis of variance (ANOVA) by the computer program COSWT (concentration of solution by weight method).[18]

The titrations were carried out in the medium containing varying amounts of urea maintaining an ionic strength of 0.16 mol dm^{-3} with NaCl at 30 ± 0.05°C. The measurements were recorded with a Systronic (model 335) pH meter of 0.01 readability in conjunction with a glass and calomel electrode. The glass electrode was equilibrated in a well-stirred urea–water mixture containing inert electrolyte. Titration of strong acid with alkali was carried out at regular intervals to check whether complete equilibration was achieved or not. The calomel electrode was refilled with urea–water mixture of equivalent composition as that of the titrand. In each of the titrations, the titrand consists of mineral acid of approximately 1 mmol in a total volume of 50 cm^3. Titrations with different ratios (1 : 2–1 : 6) of metal–ligand are carried out with 0.3 mol dm^{-3} NaOH (Table 1). The details of experimental procedure and titration assembly are given elsewhere.[19]

Modelling strategy

The approximate stability constants of protonation or complexation of phen were calculated either with the computer program SCPHD (2.0)[20] or by a graphical method developed[21] in our laboratory (Fig. 1). The best fit chemical model for each system investigated was arrived at using non-linear least squares analysis using MINIQUAD 75,[22] which exploits the advantage of constrained least squares method in the initial refinement and reliable convergence of undamped, unconstrained Marquardt algorithm. The variation of stepwise equilibrium constants of proton–ligand as well as metal–ligand species was analysed on electrostatic grounds using ESOCE and on the basis of solute–solute and solute–solvent interactions.

RESULTS AND DISCUSSION

Mathematical models for proton–ligand equilibria

Although phen is a bifunctional base, its behaviour in aqueous solutions involves the addition of

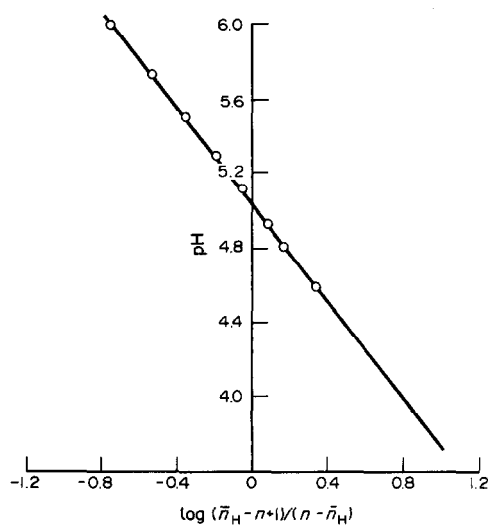

Fig. 1. Evaluation of stepwise stability constants by graphical method.

a single proton. There is evidence, based on shifts in the UV spectra, that it accepts a second proton in more concentrated acid ($pk_a = -1.6$); this proton cannot be detected by pH metry. Hence in the pH range of 2–10, phen exists as monoprotonated form and its equilibrium can be represented as

$$L + H^+ \rightleftharpoons LH^+ ; K_1^H = [LH^+]/[L][H^+]. \quad (1)$$

Secondary formation function $\bar{n}_H$ is the average number of protons bound per mole of ligand, and the equilibrium constants are related by eq. (2):

$$\bar{n}_H = K_1^H \times FHi/(1 + K_1H \times FHi), \quad (2)$$

where FHi is the free hydrogen ion concentration. $\bar{n}_H$ in terms of ligand concentration can be represented as

$$\bar{n}_H = (Ei + OHi - ALKi - FHi)/TLEi, \quad (3)$$

where TLEi, Ei and OHi are the total ligand, total acid and hydroxyl ion concentrations due to autoionization of water, respectively. ALKi is the concentration of alkali. The formation curves along with alkalimetric titration curves for a typical system are given in Fig. 2. The overlapping of formation curves indicates the precision of the titrations and the existence of a single equilibrium.

Binary complexes

The complexation of phen with Pb^{II} or Cd^{II} can be represented as

$$pM^{2+} + qLH^+ \rightleftharpoons MpL_q^{2+} + qH^+. \quad (4)$$

The formation function $\bar{n}$ (average number of ligands bound per mole of metal ion) is given by eq. (5):

$$\bar{n}_i = \frac{TLEi \times nHi - (Ei + OHi - ALKi - FHi)}{nHi \times TMEi}. \quad (5)$$

Since phen is a neutral base and in the experimental conditions only one proton is attached to the nitrogen atom, there is no possibility for the existence of protonated species, which is corroborated by the overlapping of formation curves

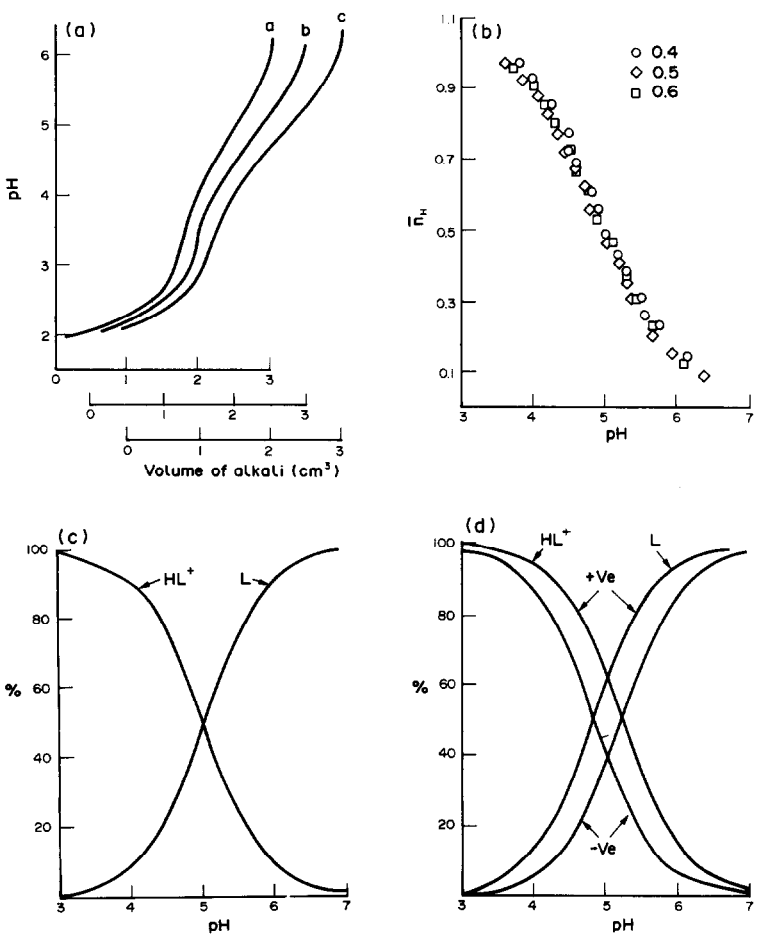

Fig. 2. Alkalimetric titration curves: (a) formation curves; (b) species distribution diagrams; and (c) effect of errors in $\log \beta$ on the concentration of species (d) of phen in aqueous solution.

for different ratios of the metal and ligand concentrations. Since the ratio of TLO and TMO is greater than unity in all those experiments the formation of polynuclear complexes is not considered. The chemical models for proton–ligand and metal–ligand equilibria from MINIQUAD 75 are given in Tables 2 and 3, respectively. 1,10-Phenanthroline contains two imine nitrogen atoms which are potential sites for coordination of metal ligands. Since each ligand molecule satisfies two coordination positions of a metal ion, the highest complex expected will be ML_3. Hence three species [ML, ML_2 and ML_3) are tried for modelling purposes. Very low standard deviations in $\log\beta$ and small values of U—the sum of squares of deviations in concentrations of ligand and hydrogen atom at all experimental points—indicate precision in $\log\beta$ and the best fit model for the experimental data, respectively. Since each of the χ^2 values in this study is less than $\chi^2_{\nu 0.5}$ it can be inferred that residuals form a part of normal distribution. Very small values of the mean (-9.324×10^{-7}), the standard deviation (2.244×10^{-4}) and the mean deviation (1.936×10^{-4}) for a typical system (phen in a 20.31% urea–water mixture) corroborate that the residuals are around a zero mean with little dispersion. For an ideal distribution, the values of kurtosis and skewness should be 3.0 and 0.0, respectively. Small deviation of kurtosis from the ideal value indicates that the residual forms a leptokurtic or platikurtic pattern which are similar to those found by Cassasas *et al.*[23] These statistics thus show that the best fit mathematical models given in Tables 2 and 3 are adequate for the representation of present equilibria.

Global stability constants

Since many titrations were performed with different initial ligand concentrations, there is a

possibility that the difference in log β values of the separate experiments was due to the inter and intra titration variability. Braibanti *et al.*[24] subjected the stability constants obtained from different experiments to ANOVA and named the resulting constants as population stability constants or global stability constants; these are of practical utility for either inter comparison or for critical compilation in spite of their higher SD's. Population stability constants are given in Table 2 for protonation equilibria and in Table 4 for a typical system of metal–ligand equilibria.

Effect of systematic errors in the best fit model

MINIQUAD 75 does not have provision to study the effect of systematic errors in the concentrations of ingredients and electrode calibration on the magnitude of equilibrium constant. In order to rely upon the best chemical model for critical evaluation and application under varied experimental conditions with different accuracies of data acquisition, an investigation was made by introducing pessimistic errors in the concentration of alkali, mineral acid, ligand and in the correction factor, log F. The results of a typical sample in Table 5 emphasise that the errors in alkali and mineral acid affect the stability constants more than those in ligand and correction factor.

Effect of urea on the equilibria

(a) *Acido–basic equilibria.* The results show that log formation constant decreases with an increase in dielectric constant. Since 1/D is a linear function of (D−1)/(2D+1) [see Fig. 3(b)] the analysis of variation of $\log K^H$ with dielectric constant is confined to only 1/D using ESOCE[25] and Forsethe[26] computer programs. As the shape of the curves [Fig. 3(d)] do not suggest a higher polynomial trend,

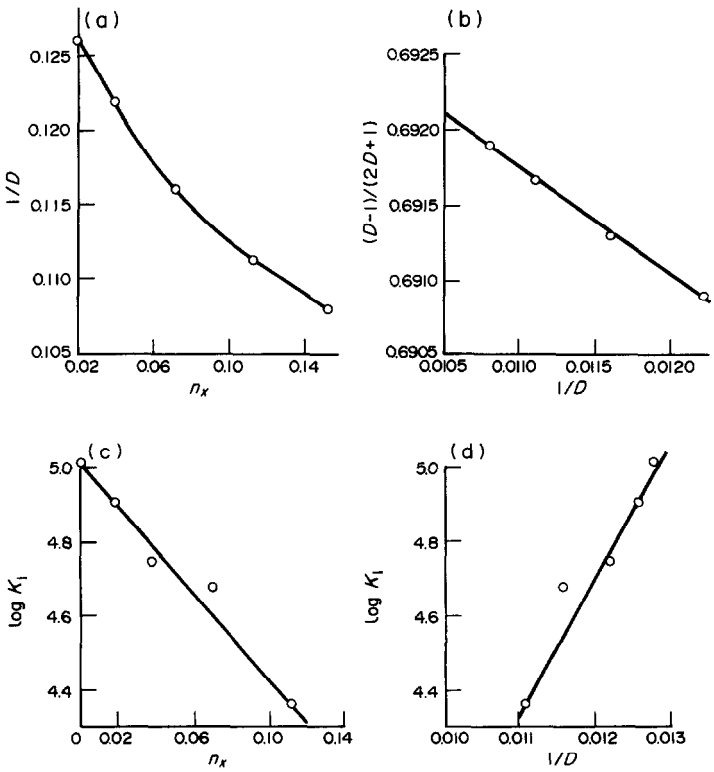

Fig. 3. Correlation of log K with mole fraction and reciprocal of dielectric constant in urea–water mixtures.

we arrived at a linear model based on the standard deviation. The changes in $\log K^H$ for the protonation equilibria of phen with mole fraction (n_x) of urea are also linear with monotonic decrease [Fig. 3(c)].

Cationic weak acids (HL^+) formed from a neutral base and protons are isoelectric processes and, as such, electrostatic charging effects should have minimal influence on the equilibrium. Thus electrostatic considerations alone reveal that $\log K^H$, in binary mixed solvents, should either remain constant or increase by a small amount. As such they are good model compounds to study specific solute–solvent interactions as a function of cosolvent content. An increase in cosolvent content increases the ion–dipole forces between the proton and nitrogen atom of the solute to a lesser extent than ion–dipole forces between a proton and the more electronegative donor oxygen atom of the solvent. Thus a decrease in $\log K^H$ with cosolvent content is expected and for systems in which it passes through a minimum, it has been assumed that the interaction between proton and nitrogen would be greater than that between proton and oxygen atom of water.

The heat capacity studies indicate that urea neither decreases nor increases the water structure[16] and it is well known[27] that structure breaking solutes shift the water PMR signal up field and structure making solutes shift it down field. It was observed that the addition of urea does not alter the chemical shift of water protons until the solute concentration is 7 M.[16,28] This supports the view that urea mixes freely with water so as to leave the solution as much structured as water. Even beyond 7 M the change in the chemical shift is very meagre which is probably due to the aggregation of urea molecules. The flickering cluster model was proposed[29] for water, wherein each water molecule is considered to be an integral part of flickering clusters instead of belonging solely to monomeric or cluster species. Introduction of urea molecules into the heart of flickering clusters can be achieved without prejudice to the geometry of urea molecules. Due to this interposition of urea in the cluster the life time of the clusters may be extended and the dimensions of the voids may be changed, which accounts for the increased solubility of hydrocarbons in aqueous urea over that in water.

Dielectric relaxation studies show that the number of water molecules around urea with a relaxation time different from that of pure water is usually small.[30] The calculations of molecular dynamics suggest that there is only a slight difference in aqueous solution of urea and pure water and hence urea can enter into water without appreciable distortion of the solvent structure.[31] The only difference is in urea–water mixtures, the water molecule is firmly fixed to urea. That means the hydration structure around the urea molecule is more rigid than that of pure water. It is observed[32] that five water molecules are attached to one molecule of urea in the first hydration shell whose positions are in the direction of *trans* H, *cis* H and carbonyl lone pair. Water molecules in the second hydration shell are also fixed rather firmly. From these observations it appears that the urea molecule can enter into the water structure without breaking it noticeably as a whole. So the water structure may be certainly changed in the vicinity of urea within the first or second hydration shell, though the potential energy of the whole system is almost the same as that of pure water. Urea molecules do not affect the water structure beyond the secondary hydration shell.

(b) *Metal–ligand equilibria.* The change in stepwise formation constants ($\log K^M$) of complexes of phen with Pb^{II} and Cd^{II} with variation of concentration of urea are depicted in Figs 4 and 5. In the case of Pb^{II}, $\log K_1^M$ and $\log K_2^M$ monotonically increased and decreased, respectively, with the mole fraction of the solute, whereas for Cd^{II}, a minimum for ML and maxima for ML_2 and ML_3 are observed. A similar trend is observed in the case of $\log K_n^M$ vs 1/D. These results show the predominance of non-electrostatic forces.

Distribution of species

The distribution diagrams obtained from DISPLOT[33] [Fig. 2(c)] show that the dissociation of the proton which is associated with nitrogen takes place in the pH range 3.0–5.0. The ionization begins at 2.5 and ends at 7.0. As the concentration of the protonated ligand (HL^+) decreases, the concentration of free ligand (L) increases. As such, 50% of each of these species exist at that pH where it is equal to $\log K$. Since the second protonation constant is -1.9 the species LH_2^{2+} does not exist in the pH range of investigation (2.5–7.0).

The effect of systematic errors on the concentrations of the species is given in [Fig. 2(d)]. It is evident from this figure that even the small changes in determination of stability constants may lead to large variations in the concentration of the species. This type of study is significant in determining total parenteral nutrition.

Since HL is the predominant form of the ligand in the pH range 2.0–7.0, there is no scope for the formation of protonated metal complexes in these systems. The best fit model contains mononuclear, unprotonated, unhydroxylated species, viz. ML and ML_2 in the case of Pb^{II}, and ML, ML_2 and

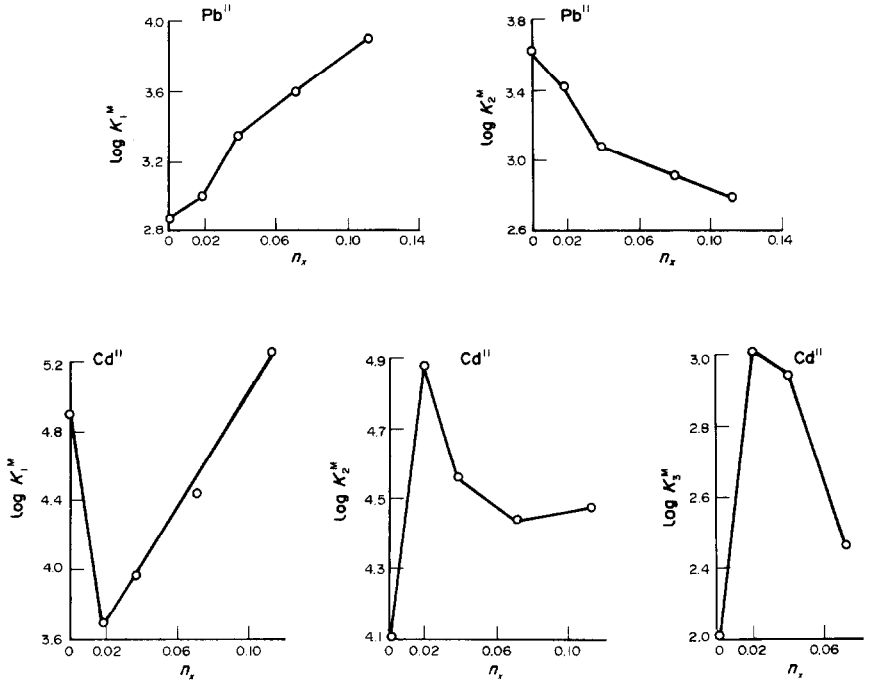

Fig. 4. Variation of log K^M of M^{II}–phen complexes with mole fraction of urea.

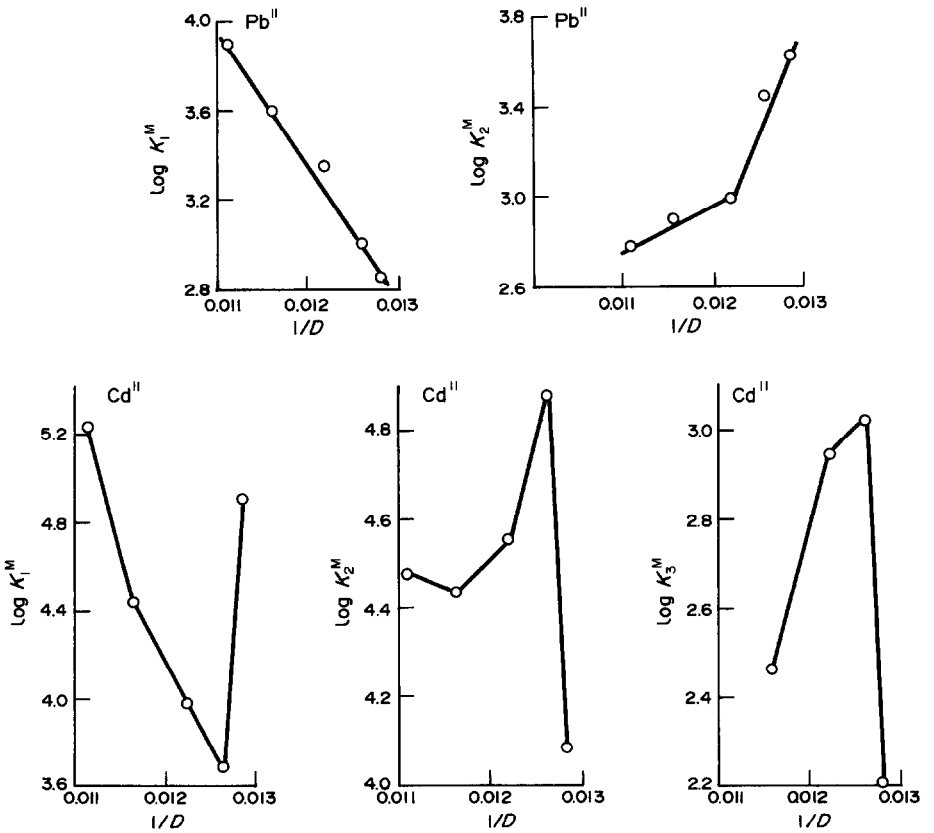

Fig. 5. Correlation of log K^M of M^{II}–phen complexes with the reciprocal of the dielectric constant of urea–water mixtures.

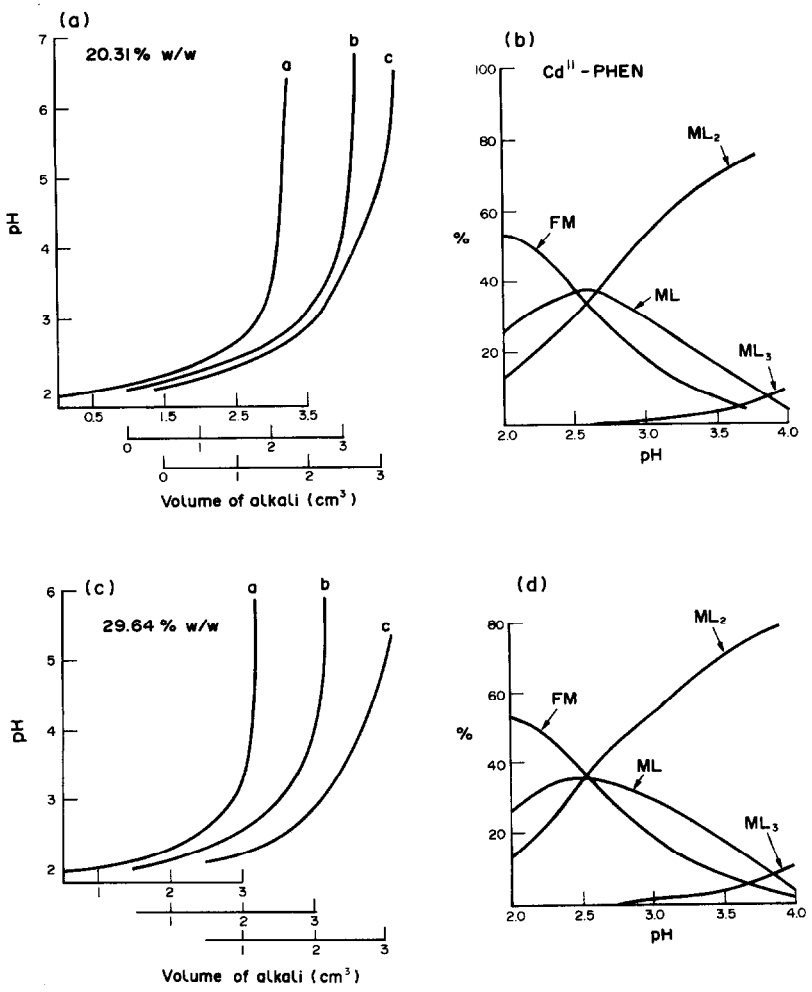

Fig. 6. Alkalimetric titration curves and species distribution diagrams of urea–water mixtures.

ML_3 for Cd^{II} (Table 3). The hydroxylated complexes such as ML(OH) and $ML_2(OH)$ were rejected by MINIQUAD 75 in the pH range studied.

It is clear from the typical distribution diagrams (Fig. 6) that the equilibria correspond to the simultaneous formation of ML, ML_2 and ML_3. As the concentration of urea is increased, the stability of the metal–ligand complex is decreased which is concluded from the distribution diagrams. Although the same species are formed in the entire range of the concentration of urea, the difference in the pH region and the extent of formation of the species are due to the effect of the metal ion, characteristic intermediate complexes and solute on the different processes existing in the solution.

ML_3 species could not be detected for the Pb^{II} ion, may be because of the following reasons: (1) the small size of the lead ion cannot accommodate three molecules of phen around itself due to steric hindrance of the ligand molecules, (2) as there are no *d* electrons, the overlap of metal–ligand orbitals are very small which leads to the formation of no complexes at all or of very weak complexes which in no time may become dissociated, the dissociation being much faster than formation. On the other hand the Cd^{II} ion has filled *d* orbitals which have $d\pi$–$p\pi$ interaction with the ligand and so the formation of ML_3 species is observed though not with considerable stability. However, at higher concentrations of urea (29.64%) there is no formation of ML_3 species even in the case of Cd^{II}. This may be due to the competition between the ligand (phen) and the solute (urea) molecules towards the metal ion.

Abstract—Two equivalents of the cationic monobut-2-yne complex $[WI(CO)(NCMe)(dppm)(\eta^2\text{-}MeC_2Me)][BF_4]$ react with one equivalent of the bidentate phosphine ligands L—L {L—L = $Ph_2P(CH_2)_nPPh_2$, n = 1–6 or $[Fe(\eta^5\text{-}C_5H_4PPh_2)_2]$} in CH_2Cl_2 at room temperature, to rapidly afford the bimetallic phosphine-bridged compounds $[W_2I_2(\mu\text{-L—L})(CO)_2(dppm)_2(\eta^2\text{-}MeC_2Me)_2][BF_4]_2$ (**1–7**) in high yield. Equimolar quantities of $[WI(CO)(NCMe)(dppm)(\eta^2\text{-}MeC_2Me)][BF_4]$ and dppm react in CH_2Cl_2 at room temperature to afford a mixture of $[W_2I_2(\mu\text{-dppm})(CO)_2(dppm)_2(\eta^2\text{-}MeC_2Me)_2][BF_4]_2$, $[WI(CO)(\eta^1\text{-dppm})(dppm)(\eta^2\text{-}MeC_2Me)][BF_4]$ and unreacted dppm. ^{13}C NMR spectroscopy shows that each but-2-yne ligand in these bimetallic complexes are utilizing both their filled $p\pi$-orbitals and donating four electrons to the tungsten in these compounds.

Although the preparation and reactions of cationic alkyne complexes of molybdenum(II) and tungsten(II) have been much studied in recent years,[1–14] hitherto no examples of complexes of this type containing bimetallically bridged-phosphine ligands have been reported. Bimetallic complexes containing bridging bidentate phosphines such as $Ph_2P(CH_2)PPh_2$ (dppm) have received considerable attention in recent years; in particular by Shaw and co-workers.[15] In this paper we describe the synthesis and spectral properties of some new dicationic bimetallic phosphine-bridged alkyne compounds of the type $[W_2I_2(\mu\text{-L—L})(CO)_2(dppm)_2(\eta^2\text{-}MeC_2Me)_2][BF_4]_2$ {L—L = $Ph_2P(CH_2)_nPPh_2$, n = 1–6 and $[Fe(\eta^2\text{-}C_5H_4PPh_2)_2]$}.

EXPERIMENTAL

All reactions were carried out using standard Schlenk-line techniques. The cationic but-2-yne complex, $[WI(CO)(NCMe)(dppm)(\eta^2\text{-}MeC_2Me)][BF_4]$, was prepared by the published method.[16] All chemicals were purchased from commercial sources except dppm which was prepared by the literature method.[17] The solvent CH_2Cl_2 was dried and distilled over P_4O_{10}. Elemental analyses for carbon, hydrogen and nitrogen were determined using a Carlo Erba Elemental Analyser MOD 1106 (using helium as a carrier gas). IR spectra were recorded on a Perkin–Elmer 1430 ratio recording IR spectrophotometer. ^1H and ^{13}C NMR spectra were recorded on a Bruker AC250 CP/MAS NMR spectrometer (all spectra were calibrated against tetramethylsilane). ^{31}P NMR spectra were recorded on a Bruker WH 400 NMR spectrometer at the University of Warwick (spectra calibrated against 85% H_3PO_4).

$[W_2I_2(\mu\text{-dppm})(CO)_2(dppm)_2(\eta^2\text{-}MeC_2Me)_2][BF_4]_2$ (1)

To $[WI(CO)(NCMe)(dppm)(\eta^2\text{-}MeC_2Me)][BF_4]$ (0.5 g, 0.552 mmol) dissolved in CH_2Cl_2 (15 cm^3), with continuous stirring under a stream of dry nitrogen, was added $Ph_2P(CH_2)PPh_2$ (0.106 g, 0.276 mmol). After stirring for 5 h the solution was filtered and the solvent volume reduced to 2 cm^2 *in vacuo*. Dropwise addition of dry Et_2O precipitated the orange–brown cationic complex $[W_2I_2(\mu\text{-dppm})$

$(CO)_2(dppm)_2(\eta^2\text{-MeC}_2\text{Me})_2][BF_4]_2$ (**1**), which upon recrystallization from CH_2Cl_2–Et_2O yielded 0.25 g (43%) of pure product.

Similar reactions of $[WI(CO)(NCMe)(dppm)(\eta^2\text{-MeC}_2\text{Me})][BF_4]$ with $Ph_2P(CH_2)_nPPh_2$ (n = 2–6) and $[Fe(\eta^5\text{-C}_5\text{H}_4\text{PPh}_2)_2]$ (2:1 molar ratio), in CH_2Cl_2 at room temperature, afforded the analogous cationic complexes $[W_2I_2\{\mu\text{-Ph}_2\text{P(CH}_2\text{)}_n\text{PPh}_2\}(CO)_2(dppm)_2(\eta^2\text{-MeC}_2\text{Me})_2][BF_4]_2$ and $[W_2I_2\{\mu\text{-[Fe}(\eta^5\text{-C}_5\text{H}_4\text{PPh}_2)_2]\}(CO)_2(dppm)_2(\eta^2\text{-MeC}_2\text{Me})_2][BF_4]_2$ (**2–7**) (see Table 1 for physical and analytical data).

RESULTS AND DISCUSSION

The starting material for this research is $[WI(CO)(NCMe)(dppm)(\eta^2\text{-MeC}_2\text{Me})][BF_4]$, which is prepared by reacting the neutral di-iodide compound $[WI_2(CO)(dppm)(\eta^2\text{-MeC}_2\text{Me})]$ with an equimolar amount of $Ag[BF_4]$ in acetonitrile at room temperature to afford the iodide displaced product $[WI(CO)(NCMe)(dppm)(\eta^2\text{-MeC}_2\text{Me})][BF_4]$.[16] The complex $[WI(CO)(NCMe)(dppm)(\eta^2\text{-MeC}_2\text{Me})][BF_4]$ reacts with L—L {L—L = $Ph_2P(CH_2)_nPPh_2$, n = 1–6 and $[Fe(\eta^5\text{-C}_5\text{H}_4\text{PPh}_2)_2]$} in a 2:1 molar ratio in CH_2Cl_2 at room temperature to give the novel bimetallic compounds $[W_2I_2(\mu\text{-L—L})(CO)_2(dppm)_2(\eta^2\text{-MeC}_2\text{Me})_2][BF_4]_2$ (**1–7**) in high yield. Complexes **1–7** have been fully characterized by elemental analysis (C, H and N) (Table 1), IR (Table 2), ^1H and, in selected cases, ^{13}C NMR spectroscopy (Tables 3 and 4). Complexes **1–7** are stable in the solid state when stored under nitrogen, however, they slowly decompose when exposed to air in solution. Complexes **1–7** are all moderately soluble in CH_2Cl_2 or $CHCl_3$, but they are insoluble in hydrocarbon solvents and Et_2O. The bidentate ferrocenylphosphine complex is less soluble than its $Ph_2P(CH_2)_nPPh_2$ counterparts.

The IR spectra of **1–7** showed broad, single carbonyl bands between 1955 and 1960 cm^{-1}, which would be expected since the two tungsten atoms in **1–7** are well separated by phosphine and carbon linkages. The IR spectra also show weak $\nu(C{\equiv}C)$ alkyne stretching bands at a considerably lower wavenumber compared with free but-2-yne, which

Table 2. IR data[a] for the compounds $[W_2I_2(\mu\text{-L—L})(CO)_2(dppm)_2(\eta^2\text{-MeC}_2\text{Me})_2][BF_4]_2$
