(*Received* 16 *January* 1989; *accepted* 4 *May* 1989)

Abstract—Linear relationships between the ^{19}F NMR chemical shifts of *p*-substituted *p'*-fluorobiphenyls and the theoretically calculated net charges, Δq_t, Δq_π and Δq_σ, on the *p*-carbon atoms of the substituted benzenes were established. A method for evaluating the net charge on the benzene ring in non-paramagnetic η^6-arene metal complexes, based on the ^{19}F NMR data for respective *p*-fluorophenyl derivatives, is presented. For arene metal complexes, the benzene net charges are: +0.26e for $[Cr(CO)_3(\eta\text{-}C_6H_6)]$, +0.11e for $[Cr(CO)_2(PPh_3)(\eta\text{-}C_6H_6)]$, +0.12e for $[Cr(CO)_2(AsPh_3)(\eta\text{-}C_6H_6)]$ (benzene) and +0.42e for $[Fe(\eta\text{-}C_5H_5)(\eta\text{-}C_6H_6)]PF_6$ (CH_3NO_2, acetone). For these complexes, the data obtained give evidence for the total charge shift in the arene → ML_n direction. This method has the advantage of producing reasonable results without using complicated calculations. The validity of the method is confirmed by comparison of the data obtained with the results of physical investigations and the relative reactivity of the free and coordinated arenes.

We have previously proposed[1–3] an approach for examining the η^5-cyclopentadienyl metal compounds which enables one to characterize the metal–ring bond with respect to its polarity and stability.

An analogous strategy may be developed for η^6-arene metal complexes. The present work focusses on the first stage of the problem, namely, on the evaluation of the polarity of the metal–ring bond in arene metal complexes in terms of the net charges.

As in the case of cyclopentadienyl compounds,[1] the present method for estimating the net charge on the benzene ring in arene metal complexes on the basis of fluorine shielding in respective *p*-fluorobenzene derivatives stems from the known linear relationships between theoretically calculated net charges and ^{19}F NMR chemical shifts in the substituted benzenes.[4,5] The above linear dependences for a benzene system have suggested that a linear correlation should also exist in a biphenyl system. Indeed, we have shown that good linear relationships are observed between ^{19}F chemical shifts in *p*-substituted *p'*-fluorobiphenyls and the net charges on the *p*-carbon atom in the substituted benzenes.

EXPERIMENTAL

Data on the fluorine chemical shift in *p*-fluorobiphenyl are available in the literature.[6–9] With a view to obtaining the mean value of the fluorine chemical shift for *p*-fluorobiphenyl in a larger set of solvents normally used for organometallic compounds, than that in ref. 6 (Table 1, column 3), we recorded the ^{19}F chemical shift of 4-$FC_6H_4C_6H_4F$-4′ in different solvents relative to fluorobenzene (Table 1, column 4) and, making use of the data[7] on the chemical shift induced by a fluorine substituent (Table 1, column 5), we have calculated the ^{19}F chemical shift of *p*-fluorobiphenyl for nine different solvents relative to fluorobenzene (Table 1, column 6). The mean value of the fluorine chemical shift for *p*-$FC_6H_4C_6H_5$ in 11 widely varying solvents is calculated to be 2.79 ± 0.17 ppm (here and below a positive sign corresponds to the upfield shift); this value slightly differs from that obtained by Taft *et al.*[6] (2.75 ± 0.22 ppm).

We have borrowed the data for dioxane and methanol solutions of *p*-$FC_6H_4C_6H_5$ from ref. 6 owing to the close agreement between our values (Table 1, column 6) and those reported by Taft *et al.*[6] for cyclohexane, CCl_4 and acetone solutions

Table 1. ^{19}F NMR chemical shifts[a] in 4-$RC_6H_4C_6H_4F$-4′

N	Solvent	R = H[6b]	R = F	SCS for R = F[7c]	R = H
1	Cyclohexane	3.00	2.75	0.27	3.02
2	CCl_4	2.90	2.69	0.28	2.97
3	Benzene		2.82	0.12	2.94
4	THF		2.76	0.08	2.84
5	Acetone	2.70	2.63	0.08	2.71[d]
6	CH_3CN		2.53	0.06	2.59
7	DMF		2.64	0.03	2.67
8	DMSO		2.48	0.00	2.48
9	CH_2Cl_2		2.68	0.10	2.78
10	Dioxane	2.90			2.90[6]
11	Nitrobenzene	2.10			
12	CH_3OH	2.80			2.80[6]
	The mean value	2.75			2.79
	Standard error	±0.22			±0.17

[a] Recorded in ppm relative to C_6H_5F, the positive sign indicates the upfield shift.

[b] For ~ 5% solutions relative to C_6H_5F as an internal standard, experimental error ±0.08 ppm.[6]

[c] For solutions of concentration ⩽ 0.03 M.[7]

[d] In ref. 9, the value of the fluorine chemical shift of *p*-$FC_6H_4C_6H_5$ relative to C_6H_5F is equal to 2.72 ppm (deuteroacetone).

(see Table 1, column 3). The data[6] for the $C_6H_5NO_2$ solution were not included due to the possible ability of nitrobenzene, as an electron acceptor, to specifically interact with the solute to form charge-transfer complexes.

A Bruker WP-200 spectrometer was used for 188.31 ^{19}F NMR spectra. Locking was accomplished on the deuterium signal of D_2O, introduced into a 5 mm NMR tube. The sample solution was inserted into a 4 mm sealed ampoule in the tube, and ^{19}F shifts for ~ 0.2 M solutions were referenced to C_6H_5F at the same concentration and in the same solvent, and presented without correction for volume diamagnetic susceptibility. The accuracies of the ^{19}F chemical shifts are ±0.01 ppm or better.

RESULTS

The relationship between the ^{19}F shifts in p-fluorobiphenyls and the change in electron density on the benzene ring

Comparison of the data on the fluorine chemical shifts for 4-$RC_6H_4C_6H_4F$-4′ (R = NO_2, CN, F, H, CH_3, OH, NH_2; see Table 2) with the calculated[4] net charges on the *p*-carbon atoms in RC_6H_5 (Δq_π, Δq_σ, Δq_t; Table 3) has shown that there are linear relationships between the ^{19}F chemical shifts of *p*-substituted *p*′-fluorobiphenyls and the net charges, Δq_π, Δq_σ, Δq_t, on the *p*-carbon atom in the substituted benzenes (*r* is 0.966, 0.960 and 0.974, respectively; Table 4).

The relationship between the ^{19}F shifts in p-fluorophenyl-substituted arene metal complexes and the change in electron density on the benzene ring in non-substituted arene metal complexes

The above linear correlations led us to conclude that the fluorophenyl fragment can serve as a reference for determining the electron density on the carbon atom carrying this fragment. In turn, this allows a linear relationship between the ^{19}F chemical shift in *p*-fluorophenyl-substituted arene metal complexes and the net charge on the benzene ring in the above complexes to be postulated.

Indeed, by taking into consideration the symmetry of a benzene ligand in arene metal complexes, one may obtain the net charge on the ring by mere multiplication of the CH-fragment charge, f_{CH}, by six. As far as the charge distribution in the CH-fragment itself is concerned, different possibilities are conceivable. One may neglect the changes in charge-transfer along the C—H σ-bond and consider that the charge on the hydrogen atom remains

Table 2. Fluorine chemical shifts (ppm) in 4-$RC_6H_4C_6H_4F$-4′

N	R	Solvent	Relative to p-$FC_6H_4C_6H_5$[7]	Relative to C_6H_5F
1	NO_2	Cyclohexane	−3.11	−0.09[a]
2	CN	Cyclohexane	−2.71	0.31[a]
3	F	Cyclohexane	−0.27	2.75[a]
4	H	Cyclohexane		3.02
5	CH_3	$(CD_3)_2CO$		3.21[b]
6	OH	$(CD_3)_2CO$		4.12[b]
7	NH_2	Cyclohexane	1.99	5.01[a]

[a] Estimated by using the fluorine chemical shift of p-$FC_6H_4C_6H_5$ (3.02 ppm) relative to fluorobenzene (cyclohexane) (Table 1, column 6).

[b] 4-Substituted 4′-fluorobiphenyls were obtained by UV irradiation of RC_6H_4I in C_6H_5F or FC_6H_4I in C_6H_5R; the reaction mixture was evaporated, the residue was dissolved in deuteroacetone and inserted into an NMR tube. Measurements on solutions of individual compounds were not carried out.[9,10]

Table 3. The net charges on the p-carbon atom in RC_6H_4[4]

N	R		Δq_π[a]	Δq_σ[a]	Δq_t[a]
1	NO_2		0.043	−0.087	−0.044
2	CN		0.028	−0.078	−0.050
3	F		−0.021	−0.050	−0.071
4	H		0	−0.063	−0.063
5	CH_3		−0.012	−0.056	−0.068
6	OH		−0.039	−0.039	−0.078
		sq[b]	−0.057[d]	−0.029[d]	−0.086[d]
7	NH_2	pyr[c]	−0.035[d]	−0.042[d]	−0.077[d]

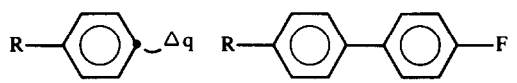
[a] The values of Δq are given relative to 1 for q_π, relative to 5 for q_σ and relative to 6 for q_t; the negative sign points to an increase in electron density.

[b] For a planar configuration of $H_2NC_6H_5$.

[c] For a pyramidal configuration of the nitrogen atom in $H_2NC_6H_5$.

[d] Following the authors of ref. 4, who used the mean value of the calculated charges for a planar and non-planar configuration of the nitrogen atom to plot correlations with ^1H, ^{13}C and ^{19}F NMR shifts, in calculations we have also used the mean value.

Table 4. Parameters of correlation equations $\Delta q = b(\delta\ ^{19}F)+a$



R = NO_2, CN, F, H, CH_3, OH, NH_2

$\Delta q = b(\delta\ ^{19}F)+a$	r	S
$\Delta q_\pi = -0.0170(\delta\ ^{19}F)+0.0378$	0.966	0.010
$\Delta q_\sigma = 0.0097(\delta\ ^{19}F)-0.0839$	0.960	0.006
$\Delta q_t = -0.0073(\delta\ ^{19}F)-0.0462$	0.974	0.004

unchanged (f_H = constant). On the contrary, it is possible to consider the charge distribution on the CH-fragment to be invariable (f_H/f_C = constant). Finally, one may consider an intermediate assumption to be the most plausible [$f_H = f_H^0 + k(f_C - f_C^0)$].

Either of these viewpoints suggests that the existence of a linear relationship between the fluorine chemical shift of the corresponding fluorophenyl-substituted compounds and the electron density on the carbon atom bound to the fluorophenyl fragment should result in a linear dependence between the fluorine shift and the net charge on the CH-fragment, f_{CH}.

To plot the linear dependence of the benzene net charges in arene metal complexes on fluorine screening in respective p-fluorophenyl derivatives, at least two reference points with known charge values must be available. For such points, we have chosen benzene and the cyclopentadienyl anion against the ^{19}F chemical shifts of p-fluorobiphenyl and a free p-fluorophenylcyclopentadienyl anion.[11] It is not possible unfortunately to compare ^{19}F chemical shifts for cation and anion radicals of p-fluorobiphenyl with fluorine screening in non-paramagnetic fluorophenyl-substituted arene metal complexes.* The net charge on the CH-fragment

* For the same reason, to establish any relationships between chemical shift and charge density in the frame of the NMR method, a number of monocyclic aromatic 6π-electron systems, $C_5H_5^-$, C_6H_6 and $C_7H_7^+$, are under comparison (see, for example refs 12–14 and references therein).

in a free cyclopentadienyl anion is equal to −0.2 (corresponds to the fluorine shift value, 17.9 ppm, for *p*-fluorophenylcyclopentadienyllithium and sodium in hexamethylphosphoramide[11]), and the net charge on the benzene CH-fragment is equal to zero (δ ^{19}F for *p*-$FC_6H_4C_6H_5$ is 2.79 ppm; Table 1), giving rise to eq. (1) and the equivalent eq. (2). The latter represents our definition of the net charge on the benzene ring in arene metal complexes which fixes this charge via the ^{19}F chemical shift of their *p*-fluorophenyl-substituted derivatives:

$$f_{CH} = -0.0132(\delta\ ^{19}F)+0.0369 \qquad (1)$$

$$f_{C_6H_6} = -0.0792(\delta\ ^{19}F)+0.2214, \qquad (2)$$

where f_{CH} is the net charge on the CH-fragment and $f_{C_6H_6}$ refers to the benzene net charge in arene metal complexes (in a.u.); δ ^{19}F denotes the fluorine chemical shift of the respective *p*-fluorophenyl derivatives (in ppm relative to fluorobenzene).

Data on ^{19}F chemical shifts for some *p*-fluorobiphenyl metal complexes are available in the literature[15–17] (Table 5). In accordance with eq. (2), the net charge on the benzene ligand in benzene tricarbonyl chromium is equal to +0.26e (in benzene), and substitution of the *n*-donor triphenylphosphine or -arsine group for a CO ligand leads to a positive charge decrease (i.e. an increase in electron density) on the ring to +0.11 and +0.12, respectively (in benzene). The electron-withdrawing action of $CpFe^+$ on the benzene ring is much stronger than that of a $Cr(CO)_3$ group, hence, the net charge on the benzene ligand in the benzene-(cyclopentadienyl)iron cation is equal to +0.42e (CH_3NO_2, acetone; Table 5). The data obtained give evidence on the total charge displacement in the arene → ML_n direction in arene metal complexes, and are in a good agreement with results of physical investigations and the relative reactivity of the free and coordinated arenes.

DISCUSSION

Comparison of the net charges obtained on the benzene ring in arene metal complexes with those given by quantum-chemical calculations is difficult due to discord in the latter results; on the benzene ring in benzene tricarbonyl chromium: +0.572[18] (SCCC MO); +0.261[19] (SCCC MO); +0.102[20] (INDO); +0.06[21] (CNDO/2); −0.078[22] (CNDO/2); −0.133[23] (SCCC MO); −0.84[24] (*ab initio*); for the benzene(cyclopentadienyl)iron cation: +0.654[25] (INDO); +0.888[26] (INDO). The ESCA data are consistent with the positive charges being based on the arene carbon atoms in benzene

Table 5. The net charges on the benzene ring (a.u.) in arene metal complexes

Compound	Solvent	δ ^{19}F[a]	References	$f_{C_6H_6}$[b]
$[Cr(CO)_3(\eta\text{-}C_6H_6)]$	Benzene	−0.50	15[c]	+0.261
	Benzene	−0.55	16[d]	+0.265
	$CDCl_3$	−1.19	15[c]	+0.316
	DMSO	−0.44	16[d]	+0.256

	$CDCl_3$	+0.95	15[c]	+0.146
$[Fe(\eta\text{-}C_5H_5)(\eta\text{-}C_6H_6)]PF_6$	CH_3NO_2	−2.53	17[e]	+0.422
	Acetone	−2.45	17[e]	+0.415

[a] For corresponding $[ML_n(\eta^6\text{-}C_6H_5C_6H_4F\text{-}p)]$ in ppm relative to C_6H_5F; the positive sign indicates the upfield shift.

[b] For the linear relation $f_{C_6H_6} = -0.0792\ (\delta\ ^{19}F)+0.2214$, the net charges in terms of our definition are accurate to ±0.0792 ($\Delta\delta$ ^{19}F) (for $\Delta\delta$ ^{19}F see footnotes *c*, *d* and *e*) and, hence, the accuracy of all the given values is not less than ±0.008e.

[c] Relative to the external standard of C_6H_5F;[15] the measurements are accurate to ±0.1 ppm.

[d] The accuracy of the measurement cited in ref. 16 is ±0.05 ppm.

[e] The accuracy of the measurements cited in ref. 17 is ±0.08 ppm.

tricarbonyl chromium and substituted arene complexes.[27-30]

Relevance of X-ray crystallographic and dipole measurements

A remarkably large value of the dipole moment in benzene tricarbonyl chromium (4.31 D, cyclohexane;[31] 4.38 D, heptane;[32] 4.56 D, cyclohexane[33]) and the substituent effects on dipole moments in the substituted analogues (for these, the values range from 3.5 to 6.3 D, benzene) are attributed to electron charge drift from the arene ligand to the carbonyl groups via the metal atom.[31-39] The dipole moment of monosubstituted benzene complexes differs from the vectorial sum $\mu[Cr(CO)_3(C_6H_6)]+\mu(C_6H_5X) = \mu_O+\mu_X$; in the complexes, both the components, μ_O and μ_X, adopt modified values.[34,38] According to the values of dipole moments in symmetrical *p*-disubstituted complexes[31-34,36,38] (with the μ_X component equal to zero), electron-releasing substituents cause an increase in the μ_O component, whereas electron-withdrawing substituents exert an opposite effect; hence, μ_O can reflect a degree of electron displacement from the arene ligand to the carbonyl groups.[38]

Unfortunately, the value of these quantitative measurements is, as yet, unclear. The method used for determining dipole moments suffers from inherent complications (see, for instance refs 33–38). In addition, the dipole moments of arene tricarbonyl chromium complexes, to a great extent, are solvent-dependent; the maximum values are observed in solvents such as dioxane and the minimum—in heptane; benzene gives intermediate values.[32,35]

This peculiarity in behaviour of arene tricarbonyl chromium complexes has been explained by Strohmeier in the early 1960s as being due to the formation of donor–acceptor compounds between a solvent and the π-complex whose aromatic ring can act a potential electron acceptor.[32,35] On the other hand, benzene tricarbonyl chromium compounds were shown to form charge-transfer complexes with electron acceptors rather than with electron donors.[40-43] A study of the molecular complex of (η^6-anisole)$Cr(CO)_3$ and 1,3,5-trinitrobenzene (1,3,5-TNB) by X-ray crystallography,[43] performed in 1966, has revealed a structure of "face-to-face" stacking of the benzene rings of coordinated anisole and 1,3,5-TNB, which is similar to the complexes with the free arenes; therefore, by analogy with organic compounds, the examination of dipole moments in arene tricarbonyl chromium complexes was carried out in benzene[37,38] and even in dioxane.[39]

Only in 1981 did Japanese authors[44] prove, on the basis of electronic absorption spectra, that tricarbonyl (η^6-[2.2]paracyclophane)chromium and even chromium–carbonyl complexes without an η^6-coordinated aromatic ring, $(Me_3PCr(CO)_5$, $Ph_3PCr(CO)_5$, $[Ph_2PCH_2CH_2PPh_2]Cr(CO)_4)$, form charge-transfer complexes with 1,3,5-TNB which are closely related to the complexes of benzene tricarbonyl chromium. The aforementioned authors supposed that, in solution, the acceptor molecule sits beneath the base of the pyramid formed by three metal–carbonyl bonds; by revising the results of Carter *et al.*,[43] they showed that in the crystal where a molecule of (anisole)$Cr(CO)_3$ is sandwiched between two 1,3,5-TNB molecules, the distance (4.70 Å) between the chromium and the centre of the 1,3,5-TNB in contact with the carbonyl groups is, in fact, shorter than the distance (5.14 Å) between chromium and the 1,3,5-TNB located on the η^6-coordinated anisole. An analogous result was obtained by X-ray analysis of the molecular complex of (phenanthrene)tricarbonyl chromium with 1,3,5-TNB.[45]

The formation of complexes between (benzene)$Cr(CO)_3$ and electron donor molecules has eventually been discovered.[46] The 1 : 1 complex formation between benzene-d_6 and $[Cr(CO)_3(\eta$-arene)], where arene is C_6H_5R (R = H, Me, OMe, Cl) and $C_{10}H_8$, has been observed by ^1H NMR spectroscopy. It is notable that the value of the equilibrium constant in the case of the $[Cr(CO)_3(\eta$-$C_6H_6)]$–benzene-d_6 system is almost identical to that found for the nitrobenzene–benzene-d_6 system.

Consequently, the data on the dipole moments of arene tricarbonyl chromium compounds in benzene and dioxane do not reflect an intrinsic polarity of the organometallic derivatives under investigation but the polarity of their complexes with the solvent, the force of the interaction being controlled by the arene structure (for instance, by substituents inserted into the ring).

Thus, arene tricarbonyl chromium compounds were shown[46] to be a relatively rare example of molecules which can reveal both electron donor and electron acceptor properties during charge-transfer complex formation. It should be noted that in these complexes electron flow from the benzene ligand to the carbonyl groups is in accord with their ability to form complexes with electron acceptor and electron donor molecules (based on carbonyl groups and the coordinated benzene ring, respectively).

The data available (see Table 5) show that by changing the solvent from $CHCl_3$ to benzene for arene–carbonyl complexes of chromium, fluorine

shielding is increased, i.e. in our opinion, an increase in electron density occurs on the ring (Table 5); this can be treated as a direct consequence of a molecular complex being formed with the donor benzene molecule. Substitution of the electron donor triphenylphosphine for a CO group in $[Cr(CO)_3(C_6H_6)]$ also brings about an increase in electron density on the benzene ring (from +0.26 to +0.11e, benzene; Table 5), a low-frequency shift of the CO stretching vibrations (ν(CO) for $[Cr(CO)_3(C_6H_6)]$ 1891, 1970 and for $[Cr(CO)_2(PPh_3)(C_6H_6)]$ 1825, 1884 cm^{-1} (CH_2Cl_2)[48]) and a corresponding decrease in dipole moment of the molecule (for $[Cr(CO)_3(C_6H_6)]$, μ is 4.81[32,36] ÷ 5.08[34] and for $[Cr(CO)_2(PPh_3)(C_6H_6)]$, μ is 4.13 D[49] (in benzene).

Charge density correlation with other indicators such as pK_a and S-coefficients

Traditional chemical methods for investigation, in most cases, provide evidence for the electron-withdrawing effect of the ML_n unit on the benzene ring upon complexation. From this viewpoint, arene tricarbonyl chromium complexes[50,51] and the benzene(cyclopentadienyl)iron cation[52] have been thoroughly considered in the reviews. We shall focus our attention on the most essential examples and emphasize some important points.

A classical approach, involving an acidity/basicity comparison of coordinated and free acids and amines, demonstrates that upon coordination with the $Cr(CO)_2PPh_3$ group, the acidity of the benzoic acid is increased by *ca* 0.4 pK_a units,[53] with the $Cr(CO)_3$ group—by *ca* 0.9 pK_a units[47] and with the $CpFe^+$ group—by *ca* 2.7 pK_a units[54] (50% aqueous ethanol); coordination of aniline with the $Cr(CO)_3$ group lowers its basicity by approximately 1.6 pK_a units (potentiometry, 82% aqueous ethanol)[55] and with the $CpFe^+$ group—by 5.6 pK_a units (spectrophotometry, H_2SO_4).[56] An alternative classical approach is based on the determination of the electron effects of organometallic groups as substituents. Here again the variation in the σ_I and σ_R^0 constants, as calculated from ^{19}F chemical shifts for corresponding *m*- and *p*-fluorophenyl derivatives by the Taft method, in proceeding from a free Ph group (σ_I+0.08; σ_R^0−0.09; "inert" solvents[57]) to that coordinated with $Cr(CO)_2PPh_3$ and $Cr(CO)_2AsPh_3$ fragments (σ_I+0.13, σ_R^0+0.048 and σ_I+0.13; σ_R^0+0.043, respectively; $CDCl_3$[15]) and further with the $Cr(CO)_3$ and $CpFe^+$ units (σ_I+0.27; σ_R^0+0.005; $CDCl_3$[15] and σ_I+0.38; σ_R^0 +0.01 respectively; acetone[17]) speaks for a pronounced increase in the electron-withdrawing action of the phenyl group  in the series: X = H < π-$Cr(CO)_2PPh_3$ ≈ π-$Cr(CO)_2AsPh_3$ < π-$Cr(CO)_3$ < π-$CpFe^+$. As was expected, our data indicate that electron density on the benzene ring decreases in the same order: $f_{C_6H_6}$ = 0; +0.14; +0.15; +0.32 ($CDCl_3$); +0.42e (acetone) (Table 5).

Discussion of kinetics effects

Some cyclopentadienyl and arene metal complexes are known to stabilize the adjacent charged centres.

An increase in the ability of the benzene ring to stabilize the adjacent carbanionic centres on coordination with the ML_n fragment (see, for example refs 58–61) is consistent with our results.

On the contrary, what is surprising is a sharp enhancement in the ability of the coodinated benzene ring to stabilize the adjacent carbocationic centres.

Solvolysis of $BtCH_2Cl$ and BtCH(Cl)Ph (Bt designates benzene tricarbonyl chromium) in aqueous acetone (S_N1) proceeds 10^5 and 10^3 times as fast as that of the corresponding free benzyl analogues;[62] the rate of non-catalysed isomerization of $BtCH_2SCN$ to $BtCH_2NCS$ (via $BtCH_2^+$) is increased by a factor of more than 2.5×10^4 compared to $PhCH_2SCN$.[63] A mechanism for stabilization of α-carbocationic centres by an electron-withdrawing benzene tricarbonyl chromium group is under discussion. The INDO MO calculations for $[Cr(CO)_3(\eta\text{-}C_6H_5CH_2)]^+$ and a free benzyl cation[64] did not confirm either of the following assumptions: direct interaction of the lone pair electrons on the chromium atom with the cationic centre or stabilization by π-conjugation of the α-carbonium atom with the ring.[50]

Substantial enhancement of the ability of the phenyl group to stabilize the α-carbocationic centres upon complexation with the $Cr(CO)_3$ unit clearly demonstrates an ambivalent ability of benzene tricarbonyl chromium to behave not only as an electron-withdrawing group, but also as an electron-releasing group. A systematic study of the dipole moments of (benzene)$Cr(CO)_3$ and a number of its methyl- and *t*-butyl-substituted derivatives in cyclohexane (which was not reported until 1985[33]) has shown that molecular optical anisotropy, as determined from the experimental molar Kerr constants (in cyclohexane), for all the complexes examined is opposite in sign to that predicted from additivity of the anisotropies of the component arene and $Cr(CO)_3$ fragments. These authors[33] came to

the conclusion that the electron system of the chromium–arene bond is highly polarizable along the bond and provides a channel of relatively free electron movement between the arene and $Cr(CO)_3$. Now it is worth mentioning that the dipole moments[31–39] and the CO stretching frequencies for substituted benzene tricarbonyl chromium complexes (see, for example, refs 50 and 51, and refs therein) can be both larger or smaller than for benzene tricarbonyl chromium, depending on the donor–acceptor character of the inserted substituents. Analogously, the ability of the benzene tricarbonyl chromium group to stabilize carbocations varies over a wide range, decreasing as the cation stability increases. The pK_R^+ values for the ionization equilibria (in aqueous acids)

$$R^+ + H_2O \overset{K_{R^+}}{\rightleftharpoons} ROH + H^+$$

for Ph_2CH^+, $PhCHBt^+$ and Bt_2CH^+ are equal to -13.3, -10.4 and -9.5, respectively, whereas $FcCHBt^+$ (Fc is ferrocenyl) is noticeably less stable than $FcCHPh^+$ (pK_{R^+} equals -1.0 and 0.49, respectively).[65]

The study on relative acelation rates for $[Cr(CO)_3(RC_6H_5)]$ (R = H, Me, Et, *i*-Pr, *t*-Bu) and free arenes under Friedel–Crafts conditions ($MeCOCl$, $AlCl_3$, CH_2Cl_2) indicated that the complexed arenes are far less reactive compared to the free molecules, owing to electron-withdrawing effects of the $Cr(CO)_3$ unit.[66,67]

The mechanism of electrophilic substitution in cyclopentadienyl and arene metal complexes is under discussion;[68] it should be emphasized that a decrease in reactivity of the coordinated benzene upon electrophilic substitution falls into line with a pronounced decrease in electron density on the benzene ring on coordination (up to +0.32, $CDCl_3$; Table 5). Similarly, the rate of electrophilic isotope exchange of the benzene tricarbonyl chromium aromatic hydrogen, occurring in media of high acidity such as $BF_3/D_2O/CF_3CO_2D/D_2SO_4$, is seven orders of magnitude lower than that of benzene.[69] By contrast, replacement of one carbonyl group by a triphenylphosphine ligand increases the rate of H/D exchange by three orders of magnitude, which allows the exchange to be performed in less acidic CF_3CO_2D.[69] This is in accord with an increase in electron density on the ring in $[Cr(CO)_2(PPh_3)(C_6H_6)]$ (up to +0.14, $CDCl_3$) compared with benzene tricarbonyl chromium (+0.32, $CDCl_3$, Table 5).

Upon nucleophilic aromatic substitution, the complexed arenes, on the contrary, are far more reactive than the free ones. (It is of note that an activating effect of halo-arene coordination to the metals often exceeds the influence of strong electron-withdrawing substituents introduced into the ring.) The synthetic potential of such reactions is well recognized, the mechanism being, perhaps, more involved than that of S_NAr reactions has attracted more attention.[50–52,68,70] Kinetic studies on the reactions of the complexed halo-arenes with the methoxide ion in methanol (refs 68, 70, 71 and refs therein) agree with a two-step mechanism for the addition–elimination process where the nucleophilic addition appears to be a rate-determining step. Chlorobenzene tricarbonyl chromium was shown to be more reactive than chlorobenzene by a factor of *ca* 10^{11},[68] and $[CpFe(C_6H_5Cl)]^+$ is approximately 10^5 times as reactive as chlorobenzene tricarbonyl chromium.[71] Replacement of PPh_3 for a CO group in chlorobenzene tricarbonyl chromium substantially hinders the chlorine substitution. Exchange of the chlorine in $[Cr(CO)_3(C_6H_5Cl)]$ upon interaction with NaOMe in a MeOH–THF mixture (3:2) readily occurs at 62.5°C over 7 h, whereas $[Cr(CO)_2(PPh_3)(C_6H_5Cl)]$ remains unchanged under these conditions.[72] As in the case of electrophilic substitution reactions, these data are again in accord with the net charge values on the benzene ring which we have obtained for the parent non-substituted molecules: 0 for benzene, +0.14e for $[Cr(CO)_2(PPh_3)(C_6H_6)]$, +0.32e for $[Cr(CO)_3(C_6H_6)]$ and +0.42e for $[CpFe(C_6H_6)]^+$ (Table 5). The same electron mechanisms are presumably responsible for the electron-withdrawing effects of π-$Cr(CO)_2PPh_3$, π-$Cr(CO)_3$ and π-$CpFe^+$ fragments on the benzene ring of arene metal complexes in the ground state, and for stabilization of transition states in electrophilic substitution and nucleophilic addition in the arene ring (which is the rate-determining step in the nucleophilic substitution of $[L_nM(C_6H_5Hal)]$ with MeO^- in MeOH, see above).

Therefore, we can conclude that the values obtained for the net charges on the benzene ring in arene complexes of transition metals agree well with all the data under consideration.

(*Received* 3 *July* 1989; *accepted* 31 *July* 1989)

Abstract—An improved synthesis of $(\eta^3\text{-}C_3H_5)_4W$ from $W(OPh)_6$ and allylmagnesium bromide is reported. The further reaction with HX (X = Cl, Br) or iodine leads to $[(\eta^3\text{-}C_3H_5)_3WX]_2$ compounds, which in turn react with donor ligands to form the adducts $(\eta^3\text{-}C_3H_5)_3W(L)X$. Treatment of $(\eta^3\text{-}C_3H_5)_3W(PMe_3)Cl$ with RMgX (R = Me, Et) produces the tungsten–alkyl compounds $(\eta^3\text{-}C_3H_5)_3W(PMe_3)R$.

Although $(\eta^3\text{-}C_3H_5)_4W$ (**1**) was first isolated by Oberkirch and Wilke over 25 years ago as one of a series of homoleptic η^3-allyl–transition metal compounds,[1,2] its inaccessibility has resulted in an almost complete neglect of its chemistry which is apparently limited to the report in a patent of the reaction with HCl[3] and its use as a catalyst component for polymerization reactions.[4,5]

As part of a programme aimed at extending the chemistry of the η^3-allyl complexes of the Group VI metals, we have developed an improved synthesis for **1**, and in this and the following publication we present some of its reactions. This paper is concerned with the conversion into the $(\eta^3\text{-}C_3H_5)_3WX$ system and the further reaction with donor ligands.

RESULTS AND DISCUSSION

The original synthesis of $(\eta^3\text{-}C_3H_5)_4W$ (**1**) from WBr_5 and allylmagnesium chloride, in ether at room temperature, is tedious and unreliable and the yield varies between a high of 20% and zero.[1] This can be increased to *ca* 30% by reacting WCl_6 in THF at 60°C,[5] however, in both cases the product is contaminated with an oil (presumably the result of the tungsten-catalysed oligomerization of liberated alkenes or the ring-opening oligomerization of THF) which is difficult to remove. The situation can, however, be improved by reacting $W(OPh)_6$ with allylmagnesium bromide in THF at 60°C [eq. (1)]: the yield is consistently *ca* 60% and practically no oily side-products are formed:

$$W(OPh)_6 + 6C_3H_5MgBr \rightarrow \underset{(\mathbf{1})}{(\eta^3\text{-}C_3H_5)_4W} + C_6H_{10} + 6Mg(OPh)Br. \quad (1)$$

$(\eta^3\text{-}C_3H_5)_4W$ is a pale yellow, crystalline solid which is soluble in most organic solvents and which can be sublimed at 60°C in high vacuum. The compound decomposes above *ca* 100°C and is slowly oxidized in air. NMR spectroscopic investigations have shown that both $(\eta^3\text{-}C_3H_5)_4Mo$ and $(\eta^3\text{-}C_3H_5)_4W$ have similar structures, that the four allyl groups are magnetically equivalent and that they are bonded asymmetrically to the metal atom.[6] We have recently reported the crystal structure of $(\eta^3\text{-}C_3H_5)_3MoOAc$[7] and one may suppose that the tetra-η^3-allyl derivatives of tungsten and molybdenum have the structure shown below (Fig. 1) in which the allyl groups are arranged pair-wise in a distorted tetrahedral manner around the central metal atom.

$(\eta^3\text{-}C_3H_5)_4W$ reacts with gaseous HCl in pentane at −78°C with the initial protonolysis of one allyl group to give $[(\eta^3\text{-}C_3H_5)_3WCl]_2$ (**2**) [eq. (2)]:

$$2(\eta^3\text{-}C_3H_5)_4W + 2HCl \rightarrow \underset{(\mathbf{2})}{[(\eta^3\text{-}C_3H_5)_3WCl]_2} + 2C_3H_6. \quad (2)$$

It is essential that this reaction be carried out in the presence of a large excess of HCl but, since further reaction occurs in an uncontrollable manner, the

† Author to whom correspondence should be addressed.

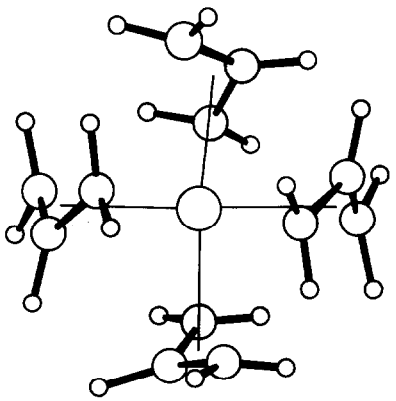

Fig. 1. The proposed structure for $(\eta^3\text{-}C_3H_5)_4M$ (M=Mo, W).

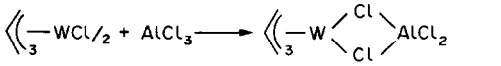
product must be isolated as quickly as possible. The bromide, $[(\eta^2\text{-}C_3H_5)_3WBr]_2$ (**3**), can be prepared in an analogous reaction with gaseous HBr, while the iodide $[(\eta^3\text{-}C_3H_5)_3WI]_2$ (**4**) is accessible through reaction of **1** with iodine in ether. Neither the reaction of **1** with Br_2 nor with HI led to the desired products; instead material with a high halogen content is obtained which has not been investigated further. It did not prove possible to prepare the fluoride; treatment of **1** with HF led to decomposition, while no reaction was observed between the chloride and NaF or AgF. The stability of the $(\eta^3$-allyl$)_3WX$ compounds decreases in the order Cl > Br > I, the iodide decomposing above *ca* −40°C.

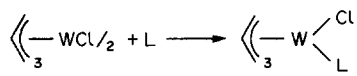
Addition of one equivalent of $AlCl_3$ to a suspension of the chloride, **2**, in toluene produces a brown solution whose ^1H NMR spectrum (see Table 1) indicates the presence of three η^3-allyl groups and which is assumed to contain the binuclear species **5** [eq. (3)] by analogy to similar reactions involving $(\eta^3\text{-}C_3H_5)_3MoCl$[7] and $(\eta^6\text{-}MeC_6H_5)(\eta^3\text{-}C_3H_5)WCl$[8] and $AlCl_3$ or $EtAlCl_2$.



2 **5** (3)

The corresponding $(\eta^3$-allyl$)_3W$–acetate (**6**), –trifluoroacetate (**7**) and –acetylacetonate (**8**) have been prepared from the chloride by anion exchange reactions with silver acetate, thallium trifluoroacetonate and thallium acetylacetonate, respectively. The ^1H NMR spectrum of the acetylacetonate indicates that it is formed as a mixture of two isomers in the ratio 73 : 27.

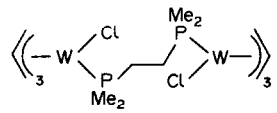
Adducts **9**–**14** are formed by reacting the chloride with P-, N- or C-donor ligands [eq. (4)]:



(4)

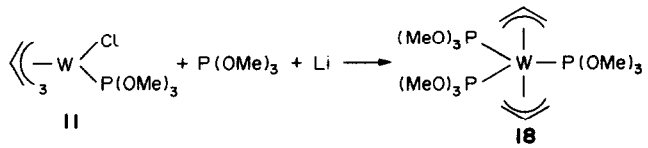
9, L = PF_3; **10**, L = PMe_3
11, L = $P(OMe)_3$; **12**, L = pyridine
13, L = MeCN; **14**, L = C_4H_9NC

The product of the reaction with 1,2-bis(dimethylphosphino)ethane is the binuclear species **15** in which the bidentate ligand bridges the two metal atoms. Trimethylphosphine adducts (**16**, **17**) to $[(\eta^3\text{-}C_3H_5)_3WBr]_2$ and $[(\eta^3\text{-}C_3H_5)_3WI]_2$ have also been prepared.



15

Reaction of $(\eta^3\text{-}C_3H_5)_3W(P(OMe)_3)Cl$ (**11**) with further phosphite and lithium-sand resulted in the formation of a yellow compound, **18**, whose NMR spectroscopic data (A_2B spin system in the ^{31}P NMR spectrum, equivalent but asymmetric η^3-allyl groups in the ^1H NMR spectrum—see Experimental) indicate that it has a structure in which the ligands are arranged in a trigonal bipyramidal manner around the central metal atom with the allyl groups occupying the apices [eq. (5)]. Similar behaviour has been reported for the corresponding molybdenum system.[7]



11 **18** (5)

Reaction of the trimethylphosphine adduct, **10**, with Grignard reagents led to the formation of the tungsten–methyl and –ethyl compounds, **19** and **20** [eq. (6)]. These pale yellow compounds are relatively stable, decomposing slowly at room temperature.

$(\eta^3\text{-}C_3H_5)_3W(PMe_3)Cl + RMgI \rightarrow$

[a] 
SPECTROSCOPIC INVESTIGATIONS

The structure of the $[(\eta^3\text{-}C_3H_5)_3WX]_2$ compounds **(2)**–**(4)** is not known. Conventionally they would be regarded as dimeric with the halide atoms bridging the tungsten atoms and this assumption is supported by their dissolution upon adding $AlCl_3$ in toluene. However, a monomeric structure cannot be ruled out particularly in view of the large number of stable organometallic compounds in which the metal atom has only 16-electrons in its valence shell, while the mass spectra all show a signal assignable to a monomeric species $[(\eta^3\text{-}C_3H_5)_3WX]^+$ with no higher fragments being detected. The IR spectra of these compounds have been recorded between −90 and −30°C (see Experimental) and compared to those of the trimethylphosphine adducts (**10**, **16**, **17**). The strongest absorption is assigned to the W—X stretching frequency. Although there is a shift to shorter wavelengths upon forming the PMe_3-adducts, there is insufficient data available to decide whether the absorptions should be assigned to terminal or bridging halide atoms. In the absence of a crystal structure determination, we will assume that the compounds are dimeric.

The complexity of the ^1H NMR spectra of the various $(\eta^3\text{-}C_3H_5)_3W$ compounds reported in this publication (see, for example, Fig. 2 and Table 1) is a result of the inequivalence and asymmetric bonding of the three allyl groups: the 15 allylic hydrogen atoms generate 15 multiplets. The hydrogen atoms have been assigned to a particular allyl group by means of homo-decoupling and the assignment of the *meso*-, *syn*- and *anti*-protons is based upon experience, the chemical shift (frequently $\delta meso\text{-H} > \delta syn\text{-H} > \delta anti\text{-H}$) and the ^1H–^1H-coupling constants [frequently ^3J(*meso*-H, *syn*-H) ~8–9 Hz, ^3J(*meso*-H, *anti*-H) ~10–13 Hz; ^3J(*syn*-H, *anti*-H) <5 Hz]. A full stereochemical assignment has, however, not been attempted.

The ^{183}W chemical shifts of compounds **10**, **16**, **17** and **19** have been measured using indirect two-dimensional (^{31}P, ^{183}W) NMR spectroscopy[9] and in all cases only one tungsten chemical shift is observed. The δ ^{183}W values lie within the range observed for other tungsten(IV) complexes.[10] The halogen dependence is normal and is associated with the effect of the electronegativity of the substituents upon the charge density dependence of the nuclear shielding term.

EXPERIMENTAL

All experiments were carried out under an atmosphere of argon. Solvents (ether, THF, pentane, toluene) were dried and freed from dissolved oxygen by distillation from diethylmagnesium. Acetonitrile and CH_2Cl_2 were dried with P_4O_{10}, hexane with $CaCl_2$, d_8-THF with K/Na-alloy and d_6-acetone with a 0·4 nm molecular sieve.

The NMR spectra were measured on Bruker–FT machines: ^1H NMR, mainly WM 400 (400·13 MHz), ^{31}P NMR, mainly WP 80 (32·4 MHz), ^{13}C NMR, mainly WM 300 (75·5 MHz). The ^{183}W NMR spectra were recorded with a WM 400 machine at the ^{183}W-resonance of 16·6 MHz by

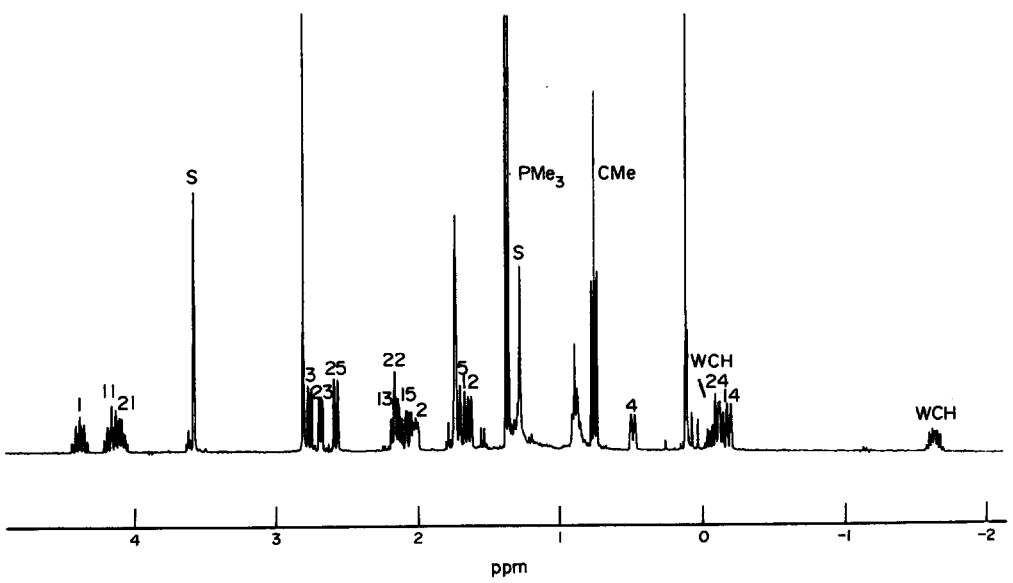

Fig. 2. The ^1H NMR spectrum of $(\eta^3\text{-}C_3H_5)_3W(PMe_3)Et$ (**20**) (d_8-THF, −30°C); S = solvent, for assignment see Table 1, footnote *a*.

means of indirect 2D–^{31}P–^{183}W-correlated NMR spectroscopy using an aqueous solution of sodium tungstate as the external standard.

IR spectra were recorded with a Nicolet–FT–IR 7199 as a KBr mull (4000–400 cm^{-1}) or as a polyethylene mull (400–100 cm^{-1}). Raman spectra were recorded with a Coderg-LTR-800. Mass spectra were measured at 70 eV with a Varian CH-5.

Microanalyses were carried out by Dornis and Kolbe, Microanalytical Laboratory, Mülheim a.d. Ruhr.

$(\eta^3\text{-}C_3H_5)_4W$ (1)

Allylmagnesium bromide (11·8 g, 81·3 mmol) was dissolved in THF (150 cm^3) at 60°C and $W(OPh)_6$ (80 g, 10·8 mmol)[11] was added over 5 min. The solution was kept at 60°C for 1 h, cooled and evaporated to dryness at room temperature. The pale beige residue was dried *in vacuo* for 14 h and extracted with 4 × 100 cm^3 of pentane. The pentane solution was evaporated and the pale yellow product crystallized five times from hexane to remove completely the magnesium salts. Yield 2·33 g (62% theory). Found: C, 41·4; H, 5·9; W, 52·6. Calc. for $C_{12}H_{20}W$: C, 41·4; H, 5·8; W, 52·8%.

IR (KBr, −50°C): ν 3080, 3020, 3010, 1498, 1470, 1310, 1235, 1205, 1012, 905, 585. Raman (−30°C): ν 1498, 1235, 1205, 1012, 585, 360. MS: m/z 348 [M^+], 306 [$M^+ - C_3H_6$], 301 (100%), 275, 261, 42, 41, 39. ^{1}H NMR (d_8-toluene): δ 3·89 (H1, m), 2·82 (H2, m), 1·66 (H3, m), 2·82 (H4, m), −0·19 (H5, m), J(1,2) 8·5, J(1,3) 8·5, J(1,4) 13·0, J(1,5) 10·5, J(2,3) 1·8, J(3,5) 1·8—For numbering scheme, see Table 1. ^{13}C NMR (d_8-toluene): δ 99·4 (*meso*-C1), 61·19/43·07 (CH_2), J(C1, H) 156, J(C2/3, H), 160/152, ^1J(C2/3, W) 7·4/13·8. ^{183}W NMR (d_8-toluene, 166 MHz): δ −3186.

The compound can also be prepared in 29–45% yield by reacting allylmagnesium bromide with WCl_6 (12 : 1) in THF at 60°C, followed by removal of the solvent and extraction of the residue with pentane. Oily side-products were removed by treating the solution with active charcoal and the compound was isolated by repeated recrystallization from pentane.

$[(\eta^3\text{-}C_3H_5)_3WCl]_2$ (2)

$(\eta^3\text{-}C_3H_5)_4W$ (3·0 g, 8·62 mmol) was dissolved in pentane (350 cm^3) and the solution cooled to −78°C. Dry gaseous HCl was passed over the stirred solution for 20 min. The resulting yellow product was isolated and washed with cold pentane. Pure samples were obtained by repeatedly suspending the compound in ether at −78°C, warming the solution briefly to room temperature and precipitating the compound at −78°C until the ether solution was pale yellow. The product was dried *in vacuo* at −78°C and decomposes rapidly if warmed above 0°C. Yield 1·49 g (50% theory). Found: C, 31·6; H, 4·3; Cl, 10·3; W, 53·7. Calc for $C_9H_{15}ClW$: C, 31·6; H, 4·4; Cl, 10·4; W, 53·7%.

IR (KBr, −45°C): ν 3080–3025, 1500, 1012, 585. FIR (polyethylene, −80°C): ν(WCl) 251—see text. MS: m/z 342 (M^+), 300 ($M^+ - C_3H_6$), 272, 109, 42, 41 (100%). ^{1}H NMR spectrum: see Table 1. Magnetic susceptibility (−80°C): diamagnetic.

$[(\eta^3\text{-}C_3H_5)_3WBr]_2$ (3)

$(\eta^3\text{-}C_3H_5)_4W$ (0·20 g, 0·57 mmol) was dissolved in pentane (150 cm^3) at −78°C and treated with gaseous HBr for 15 min. A beige–brown solid precipitated immediately and was isolated, washed with pentane (5 × 40 cm^3) and dried for 2 days *in vacuo*. The compound was isolated as a dark beige voluminous powder and decomposes slowly above −20°C. Yield 0·13 g (58% theory). Found: C, 27·8, H, 3·8; Br, 20·7; W, 47·6. Calc. for $C_9H_{15}BrW$: C, 27·9; H, 3·9; Br, 20·6; W, 47·5%.

IR (KBr, −50°C): ν 3080–3025, 1500, 1010, 596. FIR (polyethylene, −90°C): ν(WBr) 170. MS: m/z 386 (M^+), 356 ($M^+ - 42$), 80, 79, 42, 41 (100%). ^{1}H NMR spectrum: see Table 1.

$[(\eta^3\text{-}C_3H_5)_3WI]_2$ (4)

$(\eta^3\text{-}C_3H_5)_4W$ (0·73 g, 2·10 mmol) was dissolved in ether (60 cm^3) at −78°C. Iodine (0·27 g, 1·05 cm^3) dissolved in ether (10 cm^3) was added slowly to the stirred solution, which was left for a further 14 h at −78°C. The precipitated beige–brown solid was isolated and washed with pentane (4 × 50 cm^3) at −78°C and dried *in vacuo*. Yield 0·52 g (57% theory). Found: C, 24·7; H, 3·7; I, 29·1; W, 42·4. Calc. for $C_9H_{15}IW$: C, 24·9; H, 3·5; I, 29·2; W, 42·4%.

IR (KBr, −50°C): ν 3080–3025, 1498, 1010, 590. FIR (polyethylene, −90°C): ν(WI) 149. MS: m/z 434 (M^+), 392 ($M^+ - 42$), 301 (100%), 261, 42. ^{1}H NMR spectrum: see Table 1.

$(\eta^3\text{-}C_3H_5)_3WCl_2AlCl_2$ (5)

This compound is presumed to be present in the brown solution formed upon reacting $[(\eta^3\text{-}C_3H_5)_3WCl]_2$ with $AlCl_3$ (1 : 1) in d_8-toluene.

^{1}H NMR spectrum: see Table 1.

$(\eta^3\text{-}C_3H_5)_3WO_2CMe$ (6)

$[(\eta^3\text{-}C_3H_5)_3WCl]_2$ (2·90 g, 8·47 mmol) was stirred in ether (60 cm^3) with silver acetate (1·41 g, 8·45 mmol) at −20°C for 8 days. The solvent was distilled off *in vacuo* and the residue extracted with pentane (4 × 30 cm^3) at −30°C. The combined extract was evaporated and the resulting yellow solid recrystallized from hexane at −30°C. A second fraction was obtained by treating the mother liquor with active charcoal to remove oily impurities. The compound is relatively stable and is not immediately oxidized by air. Combined yield 2·32 g (75% theory). Found: C, 36·1; H, 5·0; W, 50·1. Calc. for $C_{11}H_{18}O_2W$: C, 36·1; H, 5·0; W, 50·2%.

IR (KBr, −45°C): *v* 3080–3000, 1530 (OAc), 1480 (OAc), 1465, 1375, 1010, 585. MS: *m/z* 366 (M^+), 342 (M^+ −42), 281, 253, 60, 43 (100%), 41. ^1H NMR spectrum: see Table 1.

$(\eta^3\text{-}C_3H_5)_3WO_2CCF_3$ (7)

$[(\eta^3\text{-}C_3H_5)_3WCl]_2$ (0·95 g, 2·77 mol) was stirred in ether (60 cm^3) with thallium trifluoroacetate (0·87 g, 2·74 mmol) at −40°C for 4 days. The reaction mixture was filtered to remove TlCl, evaporated to dryness and the product dissolved in pentane at −50°C and precipitated out at −78°C. A second impure fraction could be obtained by reacting the mother liquor with Avicel. The compound decomposes above −40°C. Yield 0·50 g (43% theory). Found: C, 31·3; H, 3·7; F, 13·7; W, 43·6. Calc. for $C_{11}H_{15}F_3O_2W$: C, 31·5; H, 3·6; F, 13·6; W, 43·8%.

IR (film, RT): *v* 3080–3000; 1670 (CO), 1610 (CO), 1498, 1210, 1165, 1015, 600, 585. MS: *m/z* 420 (M^+), 378 (M^+ −42), 69, 50, 42, 41, 39 (100%). ^1H NMR spectrum: see Table 1.

$(\eta^3\text{-}C_3H_5)_3W(acac)$ (8)

$[(\eta^3\text{-}C_3H_5)_3WCl]_2$ (0·96 g, 2·80 mmol) was stirred in dichloromethane (50 cm^3) with thallium acetylacetonate (0·85 g, 2·80 mmol) at −40°C for 18 h. The solvent was removed *in vacuo* and the residue extracted with pentane (3 × 40 cm^3) at −40°C. The combined extract was concentrated and cooled to −78°C to give the product as a bright yellow solid. The compound decomposes at room temperature. Yield 0·68 g (60% theory). Found: C, 41·3; H, 5·5; W, 45·1. Calc. for $C_{14}H_{22}O_2W$: C, 41·4; H, 5·5; W, 45·3%.

IR (KBr, −45°C): *v* 3080–3000, 1598 (CO), 1525 (CO), 1498, 1370, 1012, 580. MS: *m/z* 406 (M^+), 364 (M^+ −42), 42, 41 (100%). ^1H NMR spectrum: see Table 1. The compound is formed as a mixture of two isomers in the ratio 73:27.

$(\eta^3\text{-}C_3H_5)_3W(PF_3)Cl$ (9)

Trifluorophosphine was passed over a solution of $[(\eta^3\text{-}C_3H_5)_3WCl]_2$ (0·15 g, 0·43 mmol) in ether (30 cm^3) at −50°C. A yellow solution was formed from which the compound was isolated as a pale yellow solid. Yield 0·18 g (95% theory). The instability of the compound prevented its analysis.

^1H NMR spectrum: see Table 1. ^{31}P NMR (d_8-THF, −30°C): δ 113·7 (dt, *J*(P,F) 1334·6, *J*(P,W) 350·9).

$(\eta^3\text{-}C_3H_5)_3W(PMe_3)Cl$ (10)

Trimethylphosphine (5 cm^3, 47·7 mmol) was added dropwise at −30°C with stirring to $[(\eta^3\text{-}C_3H_5)_3WCl]_2$ (1·0 g, 2·92 mmol). A yellow solid was formed immediately. The excess phosphine was removed *in vacuo* and the residue dissolved in ether. The compound crystallized out at −30°C as a yellow solid and a second fraction was obtained by concentrating the mother liquor. The compound is stable at room temperature and does not react with air. Yield 1·20 g (98% theory). Found: C, 34·3; H, 6·0; Cl, 8·4; P, 7·3; W, 43·9. Calc. for $C_{12}H_{24}ClPW$: C, 34·4; H, 5·8; Cl, 8·5; P, 7·4; W, 43·9%.

IR (KBr, RT): *v* 3080–3020, 1500, 1425, 1015, 935, 595. FIR (polyethylene, RT): *v*(WCl) 206. MS: *m/z* 418 (M^+), 376 (M^+ −42), 76, 41 (100%). ^1H NMR spectrum: see Table 1. ^{13}C NMR (d_8-THF, RT): δ 101·6 (C-*meso*), 67·4 (C-1), 55·4 (C-2)-allyl-1; 95·1 (C-*meso*), 64·9 (C-1), 47·9 (C-2)-allyl-2; 88·4 (C-*meso*), 63·0 (C-1), 41·7 (C-2)-allyl-3; 14·8 (PMe, *J*(C,P) *ca* 30·5). ^{31}P NMR (d_8-THF, −30°C): δ −29·1. 2D-^{31}P-^{183}W NMR (d_8-THF, 27°C): δ −2263 (^1J(P,W) 173·5).

$(\eta^3\text{-}C_3H_5)_3W(P(OMe)_3)Cl$ (11)

Trimethylphosphite (2 cm^3, 16·9 mmol) was added to $[(\eta^3\text{-}C_3H_5)_3WCl]_2$ (0·55 g, 1·59 mmol) at −30°C. The reaction mixture was stirred for 30 min and the excess phosphite removed *in vacuo*. The residue was washed with pentane (5 × 5 cm^3) at −80°C and dissolved in ether (20 cm^3) at −30°C. The resulting green solution was concentrated and cooled to −50°C. The product precipitated as a pale green solid. Yield 0·51 g (68·7% theory). Found: C, 30·9; H, 5·2; Cl, 7·6; P, 6·6; W, 39·4. Calc. for $C_{12}H_{24}ClO_3PW$: C, 30·8; H, 5·2; Cl, 7·6; P, 6·7; W, 39·6%.

IR (KBr, −30°C): *v* 3040, 1495, 1100–1000, 1005, 575. ^1H NMR spectrum: see Table 1.

$(\eta^3\text{-}C_3H_5)_3W(py)Cl$ (**12**)

$[(\eta^3\text{-}C_3H_5)_3WCl]_2$ (0·55 g, 1·59 mmol) was suspended in pyridine (2·2 cm^3) at −30°C and dichloromethene (20 cm^3) was added. The reaction mixture was stirred for 30 min, the solution evaporated and the resulting yellow–green residue washed with ether (3 × 2 cm^3) and dried *in vacuo*. Yield 0·48 g (71·6% theory). Found: C, 39·9; H, 4·8; Cl, 8·4; N, 3·3; W, 43·6. Calc. for $C_{14}H_{20}ClNW$: C, 39·8; H, 4·8; Cl, 8·3; N, 3·4; W, 33·7%.

IR (KBr, −30°C): *v* 3060, 3010, 1600, 1485, 1440, 1060, 1020, 1010, 760, 700. ^1H NMR spectrum: see Table 1.

$(\eta^3\text{-}C_3H_5)_3W(NCMe)Cl$ (**13**)

$[(\eta^3\text{-}C_3H_5)_3WCl]_2$ (0·59 g, 1·72 mmol) was suspended in acetonitrile (4 cm^3) and dichloromethene (15 cm^3) was added at −50°C. The resulting solution was stirred for 5 h, warmed to −30°C and concentrated to 5 cm^3, to give a white solid which was washed with acetonitrile and ether and dried under high vacuum. Yield 0·46 g (69·7% theory). Found: C, 34·5; H, 4·7; Cl, 9·2; N, 3·7; W, 47·9. Calc. for $C_{11}H_{18}ClNW$: C, 34·5; H, 4·8; Cl, 9·3; N, 3·5; W, 47·8%.

IR (KBr, −30°C): *v* 3060, 2318 (NC), 2280(NC), 1495, 1015. ^1H NMR (CD_2Cl_2, −30°C): δ 3·95 (*anti*-H), 0·56 (*anti*-H), 0·41 (*anti*-H), 2·20 (Me), 2·39 (Me). The compound is formed as a mixture of two isomers (55 : 45).

$(\eta^3\text{-}C_3H_5)_3W(CNC_4H_9)Cl$ (**14**)

$[(\eta^3\text{-}C_3H_5)_3WCl]_2$ (1·34 g, 3·91 mmol) and *n*-butylisocyanide (0·42 cm^3, 4·0 mmol) were suspended in ether (30 cm^3) at −78°C and stirred for 5 days. The resulting grey–beige suspension was evaporated to dryness at −78°C and the residue washed with pentane (2 × 20 cm^3) at −30°C and dried *in vacuo*. Yield 1·56 g (94% theory). Found: C, 39·7; H, 5·0; Cl, 8·5; N, 3·4; W, 43·3. Calc. for $C_{14}H_{24}ClNW$: C, 39·5; H, 5·7; Cl, 8·3; N, 3·3; W, 43·2%.

IR (KBr, −50°C): *v* 3080–3025, 2205 (CN), 1498, 1465, 1010, 590. MS: *m/z* 425 (M^+), 383 (M^+ −42), 300, 86 (100%), 42, 41. ^1H NMR spectrum: see Table 1.

$[(\eta^3\text{-}C_3H_5)_3WCl]_2(Me_2PC_2H_4PMe_2)$ (**15**)

$[(\eta^3\text{-}C_3H_5)_3WCl]_2$ (0·59 g, 1·72 mmol) and 1,2-bis(dimethylphosphino)ethane (0·26 g, 1·74 mmol) were stirred at −60°C in ether (50 cm^3) for 6 days. The reaction mixture was evaporated *in vacuo* at −30°C and the resulting grey–beige residue washed with pentane (3 × 30 cm^3). Yield 0·61 g (85% theory). Found: C, 34·6; H, 5·7; Cl, 8·4; P, 7·3; W, 43·9. Calc. for $C_{24}H_{46}Cl_2P_2W_2$: C, 34·5; H, 5·6; Cl, 8·5; P, 7·4; W, 44·0%.

IR (KBr, −50°C): *v* 3080–3025, 1498, 1430, 1015, 940, 595. MS: *m/z* 449, 95, 55, 42, 41. ^1H NMR spectrum: see Table 1. ^{31}P NMR (d_8-THF, 27°C): δ −19·3, ^1J(P,P) 12·6, ^1J(P,W) 169·9.

$(\eta^3\text{-}C_3H_5)_3W(PMe_3)Br$ (**16**)

$[(\eta^3\text{-}C_3H_5)_3WBr]_2$ (0·24 g, 0·62 mmol) was suspended in ether (4 cm^3) at −60°C and treated with trimethylphosphine (0·30 cm^3, 2·87 mmol). The reaction temperature was allowed to reach 0°C over 8 h. The solvent was removed at −40°C *in vacuo* and the beige residue was recrystallized from ether. Yield 0·27 g (94% theory). Found: C, 31·2; H, 5·3; Br, 17·2; P, 6·6; W, 39·6. Calc. for $C_{12}H_{24}BrPW$: C, 31·1; H, 5·2; Br, 17·3; P, 6·7; W, 39·7%.

IR (KBr, −25°C); *v* 3080–3025, 1498, 1420, 1010, 960. FIR (polyethylene, −90°C): *v*(WBr) 133. MS: *m/z* 462 (M^+), 420 (M^+ −42), 76, 61, 42, 41 (100%). ^1H NMR spectrum: see Table 1. ^{31}P NMR (d_8-THF, 25°C): δ −34·3, *J*(P,W) 171·5. 2D–^{31}P–^{183}W (d_8-THF, 25°C): δ ^{183}W −2244.

$(\eta^3\text{-}C_3H_5)_3W(PMe_3)I$ (**17**)

$[(\eta^3\text{-}C_3H_5)_3WI]_2$ (0·20 g, 0·46 mmol) was suspended in ether (5 cm^3) at −60°C and treated with trimethylphosphine (0·25 cm^3, 2·39 mmol). The reaction mixture was allowed to warm to −30°C over 3 h and the resulting solution was filtered and evaporated to dryness at −40°C to give the product as a yellow powder. Yield 0·22 g (93% theory). Found: C, 28·4; H, 5·0; I, 24·7; P, 6·0; W, 35·9. Calc. for $C_{12}H_{24}IPW$: C, 28·3; H, 4·7; I, 24·9; P, 6·1; W, 36·1%.

IR (KBr, 25°C): *v* 3080–3025, 1495, 1425, 1010, 945. FIR (polyethylene, −50°C): *v*(WI) < 100. MS: *m/z* 510 (M^+), 468 (M^+ −42), 76, 61, 42, 41 (100%). ^1H NMR spectrum: see Table 1. ^{31}P NMR (d_8-THF, 25°C): δ −40·0, ^1J(P,W) 170·9. 2D–^{31}P–^{183}W NMR (d_8-THF, 25°C): δ ^{183}W −2172.

$(\eta^3\text{-}C_3H_5)_2W(P(OMe)_3)_3$ (**18**)

$(\eta^3\text{-}C_3H_5)_3W(P(OMe)_3)Cl$ (0·43 g, 0·92 mmol) and trimethylphosphite (2·5 cm^3, 21 mmol) were dissolved in THF (40 cm^3) at −30°C. Excess lithium powder was added and the solution stirred at −50°C for 18 h. The unreacted lithium was filtered off and the solution was evaporated to

dryness. The solid residue was extracted with ether (20 cm^3) at −30°C and the extract evaporated to dryness to give the product which was washed repeatedly with pentane. Yield 0·19 g (41·8% theory).

^1H NMR (d_8-toluene, −80°C): δ 5·36 (H1, br), 2·19 (H2, t), 2·39 (H3, d), 1·74 (H4, d), 1·35 (H5, d), 3·45 (Me, d), 3·35 (Me, s), J(1,2) 5·9, J(1,3) 5·6, J(2,3) 3·8, J(1,4) 7·6, J(1,5) 7·1, J(Me,P) 9·8, ΣJ(Me′,P) 8·6. ^{31}P NMR (d_8-toluene, 50°C): δ_P 159·0, $\delta_{P'}$, 141·3, J(P,W) 486·5, J(P′,W) 445·9, J(P,P′) 44·2.

$(\eta^3\text{-}C_3H_5)_3W(PMe_3)Me$ (**19**)

$(\eta^3\text{-}C_3H_5)_3W(PMe_3)Cl$ (0·30 g, 0·72 mmol) was dissolved in ether (50 cm^3) at −30°C and methylmagnesium iodide in ether (0·22 cm^3, 0·72 mmol) was added dropwise. The reaction mixture was stirred for 12 h, the solvent removed *in vacuo* and the residue extracted with pentane (4 × 30 cm^3) at −30°C. Cooling the concentrated extract gave the product as a yellow powder. Yield 0·19 g (66% theory). Found: C, 39·3; H, 6·9; P, 7·6; W, 46·4. Calc. for $C_{13}H_{27}PW$: C, 39·2; H, 6·8; P, 7·8; W, 46·2%.

IR (KBr, 25°C): ν 3080–3025, 1498, 1475, 1425, 1012, 940, 598. MS: m/z 398 (M^+), 383 (M^+ −Me), 355, 302, 276, 76, 61 (100%), 42, 41. ^1H NMR spectrum: see Table 1. ^{31}P NMR (d_8-THF, −80°C): δ −26·4, ^1J(P,W) 166·0, 2D–^{31}P–^{183}W NMR (d_8-THF, 27°C): δ ^{183}W −2999.

$(\eta^3\text{-}C_3H_5)_3W(PMe_3)Et$ (**20**)

$(\eta^3\text{-}C_3H_5)_3W(PMe_3)Cl$ (0·63 g, 1·50 mmol) was dissolved in ether (100 cm^3) at −24°C and treated dropwise with ethylmagnesium iodide in ether (1·0 cm^3, 1·50 mmol). The reaction mixture was stirred for a further 16 h, the solvent evaporated *in vacuo* and the residue extracted with pentane (5 × 20 cm^3) at −30°C. The compound was obtained as a yellow powder by cooling the concentrated extract. Yield 0·48 g (77% theory). Found: C, 40·9; H, 6·9; P, 7·4; W, 44·5. Calc. for $C_{14}H_{29}PW$: C, 40·8; H, 7·1; P, 7·5; W, 44·6%.

IR (KBr, 25°C): ν 3080–3025, 1498, 1425, 1012, 950, 598. MS: m/z 412 (M^+), 370 (M^+ −42), 366, 328, 76, 61, 42, 41, 29, 28, 27 (100%). ^1H NMR spectrum: see Table 1. ^{31}P NMR (d_8-THF, 30°C): δ −28·0, ^1J(P,W) 179·4.

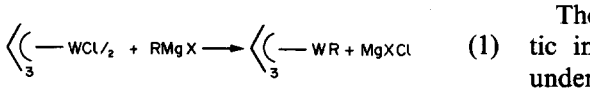
(*Received* 3 *July* 1989; *accepted* 31 *July* 1989)

Abstract—$[(\eta^3\text{-}C_3H_5)_3WCl]_2$ reacts with alkylmagnesium halides to give $(\eta^3\text{-}C_3H_5)_3WR$ species in which the β-H-atoms of the alkyl group interact with the metal atom in an agostic manner. $(\eta^3\text{-}C_3H_5)_3WEt$ reacts with trimethylphosphine with intramolecular protonation of an allyl group to give $(\eta^3\text{-}C_3H_5)_2(\eta^2\text{-}CH_2:CH_2)W(PMe_3)_2$ with elimination of propene, and with butylisocyanide with insertion into the W—Et bond to give $(\eta^3\text{-}C_3H_5)_3(\eta^2\text{-}EtC:NC_4H_9)W$. Methyl-substituted allylmagnesium halides react with $[(\eta^3\text{-}C_3H_5)_3WCl]_2$ to give $(\eta^3\text{-}C_3H_5)_3(\eta^3\text{-}MeC_3H_4)W$ and $(\eta^3\text{-}C_3H_5)_3(\eta^3\text{-}1,3\text{-}Me_2C_3H_3)W$ as a mixture of isomers.

In the preceding publication we described the preparation of $[(\eta^3\text{-}C_3H_5)_3WCl]_2$ (**1**) from $(\eta^3\text{-}C_3H_5)_4W$ and gaseous HCl and the further reaction with trimethylphosphine and alkylmagnesium halides to give $(\eta^3\text{-}C_3H_5)_3W(PMe_3)R$ species.[1] Here we discuss the course of reaction in the absence of donor ligands.

RESULTS AND DISCUSSION

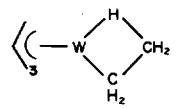
$[(\eta^3\text{-}C_3H_5)_3WCl]_2$ (**1**) reacts readily with alkylmagnesium halides to give yellow compounds having the composition $(\eta^3\text{-}C_3H_5)_3WR$ [**2–7**, eq. (1)]:



(1)

R=Et, **2**; R=CH_2CD_3, **3**; R=C_3H_7, **4**;
R=C_3H_7-*i*, **5**; R=C_4H_9, **6**; R=C_5H_{11}, **7**

The thermal stability and the yield of these compounds decrease with increasing length of the alkyl chain and whereas the ethyl compound, **2**, can be handled briefly at 0°C, the pentenyl derivative, **7**, decomposes at this temperature within a few seconds. A 3-butenyl derivative, **8**, could not be obtained pure and we were unable to isolate a cyclohexyl derivative. The NMR spectroscopic results described in the following section indicate that the compounds have a structure in which the β-H atoms of the alkyl group interact with the metal in an agostic manner,[2] e.g. **2**. However, in contrast to the analogous molybdenum system,[3] rotation of the β-alkyl group with proton-exchange could not be frozen out on the NMR time scale even at −125°C.

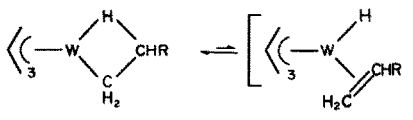


2

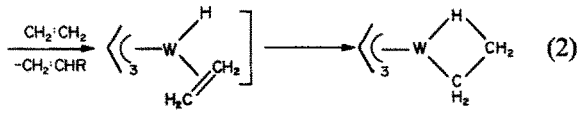
The importance of the 2-electron, 3-centred agostic interaction in stabilizing the compounds is underlined by attempts to prepare $(\eta^3\text{-}C_3H_5)_3WMe$ (**9**): the reaction between **1** and methylmagnesium iodide produced a violet compound which could not be obtained analytically pure and which decomposed if warmed above −78°C. The ^1H NMR spectrum of this species (δ 4.91/4.31/3.54 (*syn*-H), *ca* 0.1/0.3 (*anti*-H), 0.74 (s, Me, d_8-THF, −80°C), the mass spectrum (*m/z* 322, M^+) and the IR spectrum are consistent with the presence of **9** and moreover, the addition of trimethylphosphine to the reaction mixture led to the formation of $(\eta^3\text{-}C_3H_5)_3W(PMe_3)Me$ (spectroscopic comparison) which we had previously prepared by reacting $(\eta^3\text{-}C_3H_5)_3W(PMe_3)Cl$ with methylmagnesium iodide.[1] Related compounds containing a Me_3C- or $(Me_3Si)_3C$-group could not be prepared.

* Author to whom correspondence should be addressed.

The $(\eta^3\text{-}C_3H_5)_3WR$ compounds do not react with alkenes, alkynes or CO with insertion into the W—C bond. In the case of the propyl, **4**, and butyl, **6**, derivatives it has been shown spectroscopically that a slow reaction occurs with ethylene (1.1 at, −50°C, 8 days) to give the ethyl derivative, **2**. This reaction is presumably the result of alkene exchange in an intermediate $(\eta^3\text{-}C_3H_5)_3$(alkene)WH species; the less strongly bonded substituted alkene being displaced by ethylene [eq. (2)]:



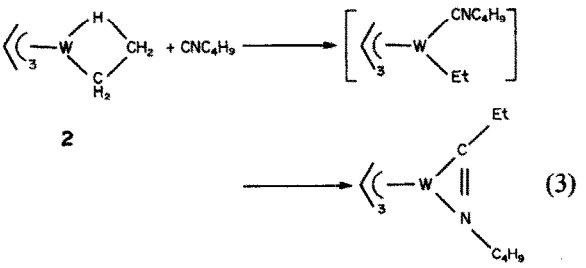
4, 6



(2)

2

In contrast, the ethyl derivative **2** does react with butylisocyanide with insertion into the W—C bond and compound **10** containing an η^2-N-butylpropyliminoacyl group is formed [eq. (3)]. This reaction presumably involves the initial formation of an adduct which reacts further with isonitrile insertion.



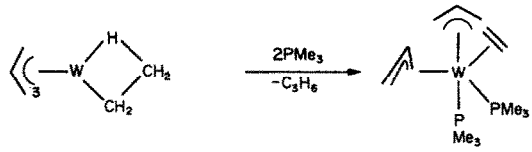
2

(3)

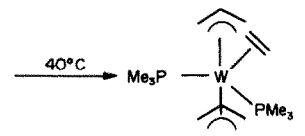
10

The suggested structure for **10** is supported by a comparison of the IR and ^{13}C NMR data (ν(C:N) 1680, δ(C:N) 211.5) with, for example, those for a related molybdenum compound $CpMo(CO)_2(\eta^2$-MeC:NMe: (ν(C:N) 1720, δ(C:N) 195.2), as well as for $CpMo(CO)_2(P(OMe)_3)(\eta^1$-PhC:NMe): ($\nu$(C:N) 1570, δ(C:N) 155.5).[4,5]

$(\eta^3\text{-}C_3H_5)_3WEt$ (**2**) reacts at low temperature with trimethylphosphine. The product is not, however, the expected adduct $(\eta^3\text{-}C_3H_5)_3W(PMe_3)Et$, instead intramolecular protonation of an allyl group by the agostic hydrogen atom occurs to give $(\eta^3\text{-}C_3H_5)_2(\eta^2\text{-}CH_2\text{:}CH_2)W(PMe_3)_2$ [eq. (4)]. The initial isolated product is an unsymmetrical isomer (**11**; ^{31}P NMR, ABX-spin system) which rearranges above −40°C to a symmetrical form (**12**; ^{31}P NMR, A_2X-spin system), whereby the mutual arrangement of the two allyl groups in these species has not been established.



2 **11**

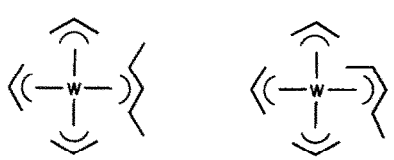


(4)

12

A similar reaction is observed with bis(dimethylphosphino)ethane, but in this case the product, $(\eta^3\text{-}C_3H_5)_2(\eta^2\text{-}CH_2\text{:}CH_2)W(Me_2PC_2H_4PMe_2)$ (**13**), has an unsymmetrical structure related to **11** and moreover, shows no tendency to rearrange.

Reaction of $[(\eta^3\text{-}C_3H_5)_3WCl]_2$ with allylmagnesium halides does not lead to compounds containing an η^1-allyl group, instead the allyl group isomerizes and the mixed tetra(η^3-allyl)tungsten compounds: $(\eta^3\text{-}C_3H_5)_3(\eta^3\text{-}2\text{-}MeC_3H_4)W$ (**14**), $(\eta^3\text{-}C_3H_5)_3(\eta^3\text{-}1\text{-}MeC_3H_4)W$ (**15**) and $(\eta^3\text{-}C_3H_5)_3(\eta^3\text{-}1,3\text{-}Me_2C_3H_3)W$ (**16**) are formed. Compounds **15** and **16** are formed as a mixture of two isomers. The NMR spectroscopic investigations indicate that in the case of the 1-methylallyl system, **15**, the methyl group occupies a *syn* position in both isomers and that these differ in the arrangement of the substituted allyl group with respect to the other three allyl groups. The isomers containing an η^3-1,3-$Me_2C_3H_3$ group differ in the configuration of the methyl groups: in **16a** these both occupy a *syn* position while in **16b** one methyl group is *syn* and the other *anti*.



16a **16b**

The arrangement of the allyl groups with respect to each other has been confirmed in these compounds by COSY and NOESY experiments (see below) which indicate that the organic ligands adopt a pseudo-tetrahedral arrangement around the central metal atom similar to that suggested for $(\eta^3\text{-}C_3H_5)_4W$.[1]

SPECTROSCOPIC INVESTIGATIONS

The structural identification of the compounds described above is based largely upon the interpretation of the NMR spectra and this is discussed in more detail here. The ^{1}H NMR spectroscopic data have been listed in Table 1.

Of particular interest in the NMR spectra of the $(\eta^3\text{-}C_3H_5)_3WR$ compounds are those signals due to the agostic system. We will limit ourselves to discussing briefly the ethyl compound $(\eta^3\text{-}C_3H_5)_3WEt$ (**2**). The ^{13}C NMR spectrum of this compound shows, in addition to nine signals for the three inequivalent allyl groups, a signal at 25.6 ppm(t) which is assigned to the metal-bonded methylene group (C-10) and a signal at −1.2 ppm(q) which is assigned to the methyl group (C-11, J(C,H) 122). The ^{1}H NMR spectrum consists of 15 signals for the allylic hydrogen atoms, signals at 2.08 and 1.36 ppm which are assigned to the methylene hydrogen atoms (H-6, H-7) and a high field doublet at −2.95 ppm which is associated with the methyl group (H-8). This signal broadens on cooling the sample to −125°C but, in contrast to the analogous molybdenum systems,[3] it did not prove possible to stop the exchange process. The IR spectrum of **2** has a characteristic absorption at 2328 cm^{-1} (m) which is assigned to the agostic system and indicates a significant weakening of the C—H bond. This absorption is as expected shifted to 1736 cm^{-1} ($\Delta\nu$ 592 cm^{-1}) in the deuterated compound $(\eta^3\text{-}C_3H_5)_3WCH_2CD_3$ (**3**). Deuteration also causes a shift of two further signals out of the 3000 cm^{-1} area to 2237 and 2137 cm^{-1}. Comparison of the combined data with other systems indicates that we are dealing here with a typical example of an agostic system.[2]

The NMR spectra of $(\eta^3\text{-}C_3H_5)_3(\eta^3\text{-}1\text{-}$

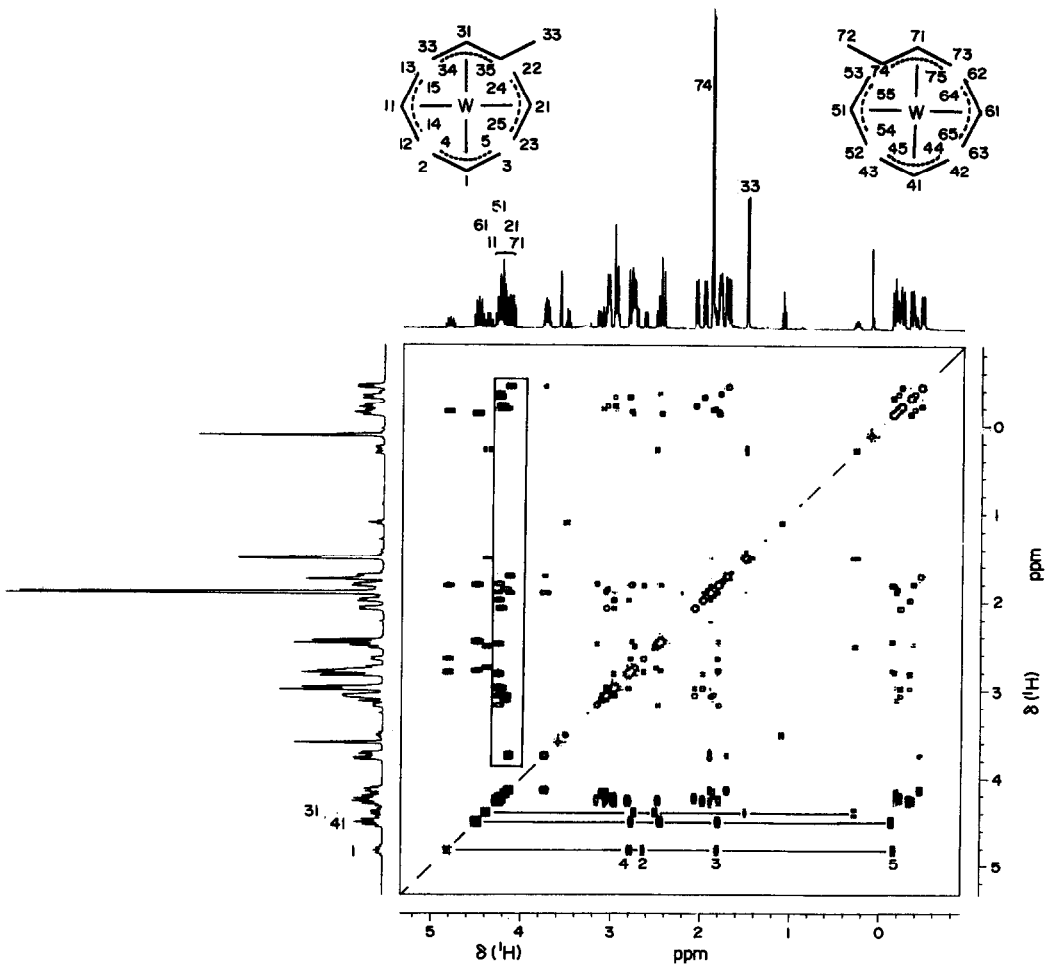

Fig. 1. 400.13 MHz COSY spectrum (symmetrized) of **15** in d_8-THF at 243 K. The data points in the F_1-direction are derived from 512 spectra each consisting of eight scans. The external one-dimensional spectrum is shown at the top of the figure and the internal projection of the two-dimensional matrix is shown in the F_1-dimension.

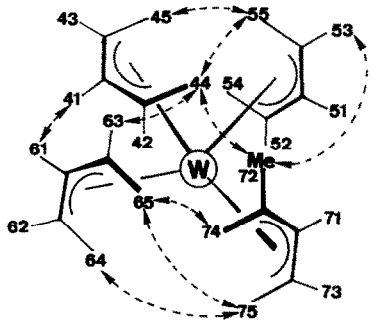

Fig. 2. Suggested structure for the major $(\eta^3\text{-}C_3H_5)_3(\eta^3\text{-}1\text{-}MeC_3H_4)W$ isomer (**15a**) based upon a two-dimensional NOE experiment carried out at 243 K. The NOE interactions are indicated by the dotted arrows.

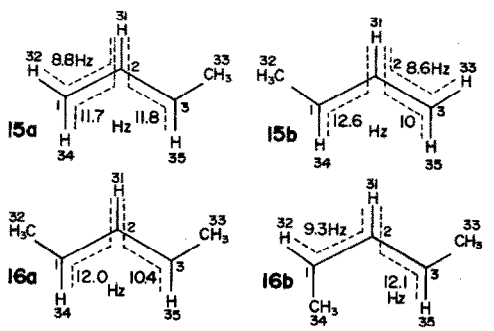
$MeC_3H_4)W$ (**15**) and $(\eta^3\text{-}C_3H_5)_3(\eta^3\text{-}1,3\text{-}Me_2C_3H_3)W$ (**16**), which are both formed as a mixture of two isomers, contain a multitude of signals. For example, the ^1H NMR spectrum of **15** consists of 40 signals all of which have been identified and assigned using two-dimensional COSY and NOESY techniques.[6] The COSY spectrum is shown in Fig. 1 and allows the position of the methyl group and each individual allylic proton to be immediately assigned.

The stereochemical arrangement of the allyl group for the major isomer, **15a**, can be deduced from the NOESY spectrum and the results are summarized in Fig. 2.

The assignment of the ^{13}C NMR spectrum of **10**, **15** and **16** is based upon the chemical shifts, the values for J(C,W) and the two-dimensional (^1H, ^{13}C) spectra. The methyl groups in the two isomers of **15** give rise to two signals at 14.7(q) and 19.0(q) ppm in the ^{13}C NMR spectrum, while those for **16** appear as two pairs at 14.4(q)/19.0(q) and 14.6(q)/21.3(q). The arrangement of the methyl groups (*syn* or *anti*) follows from the H,H-coupling constants in the substituted allyl group and the values are reproduced schematically below.



As can be seen from the data, in both **15a** and **15b** the methyl group occupies a *syn* position and consequently the only difference between these two isomers is the arrangement of the 1-methylallyl group (Me at C-1 or C-3) with respect to the other three allyl groups in the distorted tetrahedron. In the case of **16**, the coupling constants suggest that the isomers differ in the *syn* or *anti* position of one of the methyl groups. Interestingly, a third isomer in which the *syn*-methyl group is at C-1 and the *anti*-methyl group at C-3 is not observed and underlines the steric restrictions placed upon the system by the asymmetric arrangement of the allyl groups around the metal atom.

EXPERIMENTAL

The experimental conditions and spectrometers used have been described earlier.[1]

$(\eta^3\text{-}C_3H_5)_3WEt$ (2)

$[(\eta^3\text{-}C_3H_5)_3WCl]_2$ (1.30 g, 3.80 mmol) was stirred in ether at −78°C and treated with a solution of ethylmagnesium bromide in ether (2.10 cm^3, 3.50 mmol). The solution was stirred for a further 15 min at −78°C, the solvent was removed under high vacuum and the residue extracted with pentane (4×30 cm^3). The solvent, after being treated with Avicel was evaporated to give the product as a yellow powder which decomposes above 0°C. Yield 1.03 g (81% theory). Found: C, 39.0; H, 6.0; W, 54.7%. Calc. for $C_{11}H_{20}W$: C, 39.3; H, 6.0; W, 54.7%.

IR (KBr, −50°C): ν 3080, 3025, 2238, 1495, 1012, 590. SYNTHESIS OF POLYPHOSPHINE LIGANDS CONTAINING TRIMETHYLENE LINKAGES AND PLATINUM(II)–POLYPHOSPHINE COMPLEXES

LISA M. GREEN* and DEVON W. MEEK†

Department of Chemistry, The Ohio State University, Columbus, OH 43210, U.S.A.

(*Received* 24 *February* 1989; *accepted* 7 *August* 1989)

Abstract—The addition of lithium diisopropylamide (LDA) to solutions of 1-bromo-3-chloropropane and a primary or secondary phosphine in THF at −78°C provides a new, inexpensive and time efficient method for the synthesis of high-purity 3-chloropropylphosphines in high yield. The monophosphine intermediate $C_6H_5P[CH_2CH_2CH_2Cl]_2$ was used for the synthesis of the known chelating triphosphine ligands $C_6H_5P[CH_2CH_2CH_2P(C_6H_5)_2]_2$ (ttp) and $C_6H_5P[CH_2CH_2CH_2P(C_6H_{11})_2]_2$ (Cyttp). This method was extended to the synthesis of two new polyphosphine ligands that contain electron-withdrawing groups, i.e. $(p\text{-}CF_3C_6H_4)_2PCH_2CH_2CH_2P(H)C_6H_5$ (CF_3PPH) and $C_6H_5P[CH_2CH_2CH_2P(p\text{-}CF_3C_6H_4)_2]_2$ (CF_3ttp). Platinum(II) complexes of CF_3PPH and CF_3ttp were synthesized and the spectral properties of these complexes are compared to known platinum(II) complexes.

Following the pioneering work of Mann and Millar[1–3] on the syntheses of trivalent phosphorus derivatives, many tertiary phosphines have become available and these compounds have become important ligands in coordination chemistry and catalysis.[4] Research in our laboratory has focused on the chemistry of polyphosphine ligands containing trimethylene linkages,[4–6] which have proven to be valuable chelating agents for Group VIII metal ions. A properly designed chelating polyphosphine ligand can accentuate the special effects of phosphine ligands as it simultaneously provides: (1) more control on the coordination number, stoichiometry and stereochemistry of the resulting metal complexes; (2) an increased basicity (or nucleophilicity) at the metal centre; (3) slower intra- and intermolecular exchange processes; and (4) detailed structural and bonding information in the form of metal–phosphorus and phosphorus–phosphorus coupling constants.

The chemistry of polyphosphine ligands has been slower to evolve than the monophosphine analogues, primarily because the synthetic procedures for their preparation are more complicated. During the past 15 years several synthetic strategies have begun to emerge.[7–15] However, the straightforward coupling reaction between 3-chloropropylphosphines and phosphide nucleophiles is still the most common method for preparing many common polyphosphine ligands (Scheme 1). The range of application of this method has been limited by the stability of the 3-chloropropylphosphine intermediates which have been available only with bulky substituents such as phenyl or cyclohexyl on phosphorus. In addition, this method has a number of disadvantages: (1) the synthesis of 3-chloropropylphosphine intermediates, $R_2PCH_2CH_2CH_2Cl$, requires a 10-fold excess of 1,3-dichloropropane to inhibit subsequent substitution of both Cl atoms to form $R_2PCH_2CH_2CH_2PR_2$; (2) 1,3-dichloropropane is expensive; (3) impurities, such as phosphine oxides, disubstituted species, e.g. $R_2PCH_2CH_2CH_2PR_2$, and $R_2PCH_2CH_2CH_2P(H)Ph$ are generated; (4) the ligands require purification by column chromatography and vacuum distillation; and (5) the method is time consuming.

$$R_2PH + CH_3CH_2CH_2CH_2Li \longrightarrow LiPR_2 + CH_3CH_2CH_2CH_3$$

$$LiPR_2 + \text{xs } ClCH_2CH_2CH_2Cl \longrightarrow R_2PCH_2CH_2CH_2Cl$$

$$R'PH_2 + 2CH_3CH_2CH_2CH_2Li \longrightarrow Li_2PR' + 2CH_3CH_2CH_2CH_3$$

$$2R_2PCH_2CH_2CH_2Cl + Li_2PR' \longrightarrow R'P[CH_2CH_2CH_2PR_2]_2$$

Scheme 1.

This paper presents a new, general method for the synthesis of 3-chloropropylphosphine intermediates, ttp and Cyttp. In addition, this method is extended to the synthesis of two new chelating phosphine ligands, 3-bis(4-trifluoromethylphenylphosphino)propylphenylphosphine (CF_3 PPH) and bis(3-bis(4-trifluoromethylphenylphosphino)propyl)phenylphosphine (CF_3ttp), which contain the electron-withdrawing CF_3 group in the *para* position of the phenyl ring. The syntheses of platinum(II) complexes of CF_3PPH and CF_3ttp are described.

EXPERIMENTAL

(a) *General procedures*

Reagent grade chemicals were used without further purification where possible. 1-Bromo-3-chloropropane was purified by distillation from anhydrous $MgSO_4$ under Ar and diisopropylamine was purified by distillation from anhydrous BaO under Ar. The purchased phosphines, which were sealed under an Ar atmosphere, were used without further purification. Stock solutions of lithium diisopropylamide were prepared[16] in hexane and titrated[17] using published procedures. Reagent grade solvents were purified by distillation under N_2 over the appropriate drying agents.[18] Distilled water and absolute ethanol were purged with an Ar stream for 20 min prior to use. General procedures for the manipulation of air-sensitive compounds, under an Ar atmosphere, were used in the following synthetic procedures.[19]

The ^{31}P NMR spectra were recorded on a Bruker HX-90 FT spectrometer operating at 36.43 MHz in 10 mm tubes fitted with co-axial inserts containing trimethylphosphate in d_6-acetone or on a Bruker AM-250 FT spectrometer operating at 101.256 MHz in 5 mm tubes. The $^{31}P\{^1H\}$ NMR spectra are referenced to external 85% phosphoric acid. The ^1H NMR spectra were recorded on a Bruker WP-80 FT spectrometer operating at 80.07 MHz or on a Bruker AM-250 FT spectrometer operating at 250.134 MHz in 5 mm tubes. The ^1H spectra are referenced to external TMS. The ^{13}C NMR spectra were recorded on a Bruker MSL-300 FT spectrometer operating at 75.479 MHz in 10 mm tubes or on a Bruker AM-250 FT spectrometer operating at 62.896 MHz in 5 mm tubes. The $^{13}C\{^1H\}$ NMR spectra are referenced to external TMS. IR spectra were recorded neat or as Nujol mulls between KBr or CsI plates on a Perkin–Elmer model 283B grating spectrometer and the spectra were referenced to the sharp 1601 cm^{-1} peak of a polystyrene film.

(b) *Synthesis of polyphosphine ligands and ligand intermediates*

(1) *Synthesis of* $(C_6H_5)_2PCH_2CH_2CH_2Cl$. A stock solution of 0.547 M LDA (22.5 cm^3, 12.3 mmol) was added dropwise over a 15 min period to a solution of $(C_6H_5)_2PH$ (2.00 cm^3, 11.5 mmol) and $Br(CH_2)_3Cl$ (1.20 cm^3, 12.0 mmol) in 40 cm^3 of THF cooled to −78°C in a dry ice–isopropanol bath. The solution was warmed to room temperature and the solvent was removed *in vacuo*. The yellow–orange oil was dissolved in 30 cm^3 of toluene and hydrolysed with 30 cm^3 of water. After 10 min of rapid stirring, the organic layer was transferred to a flask containing anhydrous $MgSO_4$. The aqueous layer was extracted three times with 15 cm^3 aliquots of toluene and the extracts were combined over anhydrous $MgSO_4$ and dried overnight. The solution was filtered through neutral alumina (60 mesh) on a Schlenk frit to remove the $MgSO_4$ and the solvent was removed *in vacuo* to give a clear pale yellow oil. Yield: 2.86 g, 95.0%. $^{31}P\{^1H\}$ NMR data: $\delta P = -17.4$ ppm. $R_f = 1.4$ in 1:1 toluene–hexane solvent mixtures.

(2) *Synthesis of* $(CH_3CH_2)_2PCH_2CH_2CH_2Cl$. This compound was prepared like (1), starting with a stock solution of 0.2398 M LDA (34.0 cm^3, 8.15 mmol), 0.070 g (7.8 mmol) of $(CH_3CH_2)PH$ and 0.80 cm^3 (8.1 mmol) of $Br(CH_2)_3Cl$ in 20 cm^3 of THF which was cooled to −78°C in a dry ice–isopropanol bath. Yield: 0.62 g, 48%. $^{31}P\{^1H\}$ NMR data: $\delta P = -24.6$ ppm.

(3) *Synthesis of* $C_6H_5P(CH_2CH_2CH_2Cl)_2$. This compound was prepared like (1), starting with a

stock solution of 0.654 M LDA (65.0 cm^3, 42.5 mmol), 2.30 cm^3 (20.9 mmol) of $C_6H_5PH_2$ and 4.10 cm^3 (41.5 mmol) of $Br(CH_2)_3Cl$ in 150 cm^3 of THF which was cooled to −78°C in a dry ice–isopropanol bath. The resulting oil was heated *in vacuo* for several hours at 45°C to remove all volatile materials. Yield: 5.40 g, 100%. $^{31}P\{^1H\}$ NMR data: $\delta P = -26.6$ ppm. $R_f = 2.0$ in 1:1 toluene–hexane solvent mixtures.

(4) *Synthesis of* $(C_6H_5)(H)PCH_2CH_2CH_2Cl$. This compound was prepared like (1), starting with a stock solution of 0.2398 M LDA (29.0 cm^3, 18.7 mmol), 2.00 cm^3 (18.2 mmol) of $(C_6H_5)PH_2$ and 1.80 cm^3 (18.2 mmol) of $Br(CH_2)_3Cl$ in 40 cm^3 of THF which was cooled to −78°C in a dry ice–isopropanol bath. The liquid was purified by Kugelrohr distillation. Yield: 3.40 g, 100%. ^{31}P NMR data: $\delta P = -53.9$ ppm, $^1J(P—H) = 208$ Hz.

(5) *Synthesis of* $(C_6H_{11})(H)PCH_2CH_2CH_2Cl$. This compound was prepared like (1), starting with a stock solution of 0.645 M LDA (24.0 cm^3, 15.5 mmol), 2.00 cm^3 (15.1 mmol) of $(C_6H_{11})PH_2$ and 1.50 cm^3 (15.1 mmol) of $Br(CH_2)_3Cl$ in 40 cm^3 of THF which was cooled to −78°C in a dry ice–isopropanol bath. The colourless liquid was purified by Kugelrohr distillation. Yield: 2.35 g, 78.6%. ^{31}P NMR data: $\delta P = -51.9$ ppm, $^1J(P—H) = 193$ Hz.

(6) *Synthesis of* $C_6H_5P[CH_2CH_2CH_2P(C_6H_5)_2]_2$, ttp. A stock solution of 1.6 M *n*-BuLi (120 cm^3, 192 mmol) was added dropwise, over a 1 h period, to a solution of $(C_6H_5)_2PH$ (31.6 cm^3, 182 mmol) in 800 cm^3 of THF cooled to 0°C. The red solution was stirred for an additional 30 min and then it was added dropwise, over a 2.5 h period, to a solution of $C_6H_5P(CH_2CH_2CH_2Cl)_2$ (23.88 g, 90.75 mmol) in 200 cm^3 of diethyl ether. The resulting bright orange solution was stirred overnight and then refluxed for 6 h. The solvent was removed *in vacuo*, and the resulting yellow–orange oil was dissolved in 300 cm^3 of toluene and hydrolysed with 100 cm^3 of absolute ethanol followed by 400 cm^3 of water. After 30 min of rapid stirring, the organic layer was transferred to a flask containing anhydrous $MgSO_4$. The aqueous layer was extracted three times with 150 cm^3 aliquots of toluene, and the extracts were combined over anhydrous $MgSO_4$ and dried overnight. The solution was filtered through neutral alumina (60 mesh) on a Schlenk frit to remove the $MgSO_4$ and the solvent was removed *in vacuo* to give a white oil. Yield: 51 g, 100%. $^{31}P\{^1H\}$ NMR data: $\delta PPh = -28.7$ ppm, $\delta PPh_2 = -18.1$ ppm. $R_f = 8.1$ in 1:1 toluene–hexane solvent mixtures.

(7) *Synthesis of* $C_6H_5P[CH_2CH_2CH_2P(C_6H_{11})_2]_2$, Cyttp. This triphosphine was prepared by a procedure analogous to that used for ttp, (method 6), by starting with a stock solution of 1.6 M *n*-BuLi (100 cm^3, 160 mmol) and a solution of $(C_6H_{11})_2PH$ (33.5 cm^3, 153 mmol) in 600 cm^3 of THF which was cooled to 0°C. This compound required only 1 h of reflux (as compared to 6 h for ttp) in order to completely react. Yield: 40 g, 91%. $^{31}P\{^1H\}$ NMR data: $\delta PPh = -27.7$ ppm, $\delta PCy_2 = -7.2$ ppm. $R_f = 6.2$ in 1:1 toluene–hexane solvent mixtures.

(8) *Synthesis of* $(p\text{-}CF_3C_6H_4)_2PH$. A Grignard solution of 4-bromobenzotrifluoride was prepared by the dropwise addition of a solution containing 31.0 cm^3 (221 mmol) of 4-bromobenzotrifluoride in 100 cm^3 of diethyl ether to 5.83 g (240 mmol) of Mg turnings and a crystal of I_2 in 50 cm^3 of diethyl ether. Gentle heat was applied to initiate the reaction and 100 cm^3 of additional diethyl ether were added. The resulting Grignard solution was filtered through celite on a frit and the filtrate was cooled to 0°C. A solution of 10.0 cm^3 (77.6 mmol) of diethyl phosphite in 100 cm^3 of diethyl ether was added dropwise to the Grignard solution. The resulting viscous solution was refluxed for 2 h (40–50°C) during which it became thick and waxy. The waxy mixture was cooled to 0°C and it was slowly hydrolysed with 150 cm^3 of an aqueous 10% HCl solution. The hydrolysed solution was warmed to room temperature, the layers were allowed to separate and the deep red organic layer was transferred to a flask containing anydrous $MgSO_4$. The aqueous layer was extracted six times with 50 cm^3 aliquots of benzene. The organic layers were combined over anhydrous $MgSO_4$ and dried overnight. The red solution was filtered to remove the $MgSO_4$ and the solvent was removed *in vacuo*. The resulting red oil was dissolved in 200 cm^3 of diethyl ether and the solution was cooled to 0°C. Solid lithium aluminium hydride (3.03 g, 79.8 mmol) was added *very slowly*, via a solid addition funnel, to the cold red solution; gas bubbles evolved (**NOTE**: extreme caution should be exercised when using solid lithium aluminium hydride due to its corrosive, highly flammable nature). The cold slurry was stirred for 1 h and then hydrolysed slowly with 6 cm^3 of water, 6 cm^3 of an aqueous 10% NaOH solution, and then by 12 cm^3 of water. The slurry was warmed to room temperature and the orange phosphine solution was filtered into a flask containing anhydrous $MgSO_4$. The remaining salts were washed six times with 30 cm^3 aliquots of benzene and the aliquots were combined over anhydrous $MgSO_4$ and dried. The orange solution was filtered through a Schlenk frit to remove the $MgSO_4$ and the solvent was removed from the filtrate *in vacuo* to yield an orange oil. The clear liquid product, $(p\text{-}CF_3C_6H_4)_2PH$, was extracted from the orange oil by Kugelrohr dis-

tillation. Yield: 13.9 g, 58.6%. ^{31}P NMR data: $\delta P = -42.2$ ppm, $^{1}J(P—H) = 227$ Hz.

(9) *Synthesis of* $(p\text{-}CF_3C_6H_4)_2PCH_2CH_2CH_2Cl$. A stock solution of 0.2398 M LDA (83.0 cm^3, 19.9 mmol) was added dropwise, over a 3.5 h period, to a solution of 6.08 g (18.9 mmol) of $(p\text{-}CF_3C_6H_4)_2PH$ and 1.90 cm^3 (19.2 mmol) of $Br(CH_2)_3Cl$ in 150 cm^3 of THF cooled to −78°C in a dry ice–isopropanol bath. The resulting solution was allowed to warm slowly in the dry ice–isopropanol bath and it was stirred overnight at room temperature. The solvent was removed *in vacuo*, and the resulting yellow oil was redissolved in 100 cm^3 of toluene and hydrolysed with 120 cm^3 of water. The organic layer was transferred to a flask containing anhydrous $MgSO_4$. The aqueous layer was extracted four times with 50 cm^3 aliquots of toluene. The extracts were combined over anhydrous $MgSO_4$ and dried overnight. The solution was filtered through a small amount of neutral alumina (60 mesh) on a Schlenk frit to remove the $MgSO_4$. The solvent was removed from the clear, colourless filtrate *in vacuo* to give a clear oil. The oil was warmed *in vacuo* to remove all volatile materials. Yield: 7.54 g, 100%. $^{31}P\{^{1}H\}$ NMR data: $\delta P = -16.7$ ppm.

(10) *Synthesis of* $(p\text{-}CF_3C_6H_4)_2PCH_2CH_2CH_2P(H)C_6H_5$, CF_3PPH. A stock solution of 0.523 M LDA (38.0 cm^3, 19.9 mmol) diluted with 40 cm^3 of hexane was added slowly, dropwise to a solution of 7.54 g (18.9 mmol) of $(p\text{-}CF_3C_6H_4)_2PCH_2CH_2CH_2Cl$ and 2.10 cm^3 (18.9 mmol) of $C_6H_5PH_2$ in 200 cm^3 of THF cooled to −78°C in a dry ice–isopropanol bath. The resulting red solution was allowed to warm to room temperaure and it was stirred overnight. The solution was refluxed for 3 h (80°C) and then the solvent was removed *in vacuo* to give a light orange oil. The oil was dissolved in 200 cm^3 of toluene and hydrolysed with 200 cm^3 of water. The yellow organic layer was transferred to a flask containing anhydrous $MgSO_4$. The aqueous layer was extracted four times with 50 cm^3 aliquots of toluene and the extracts were combined over $MgSO_4$ and dried overnight. The solution was filtered through neutral alumina (60 mesh) on a Schlenk frit to remove the $MgSO_4$ and the solvent was removed from the filtrate *in vacuo* to give a white oil. The oil was heated *in vacuo* for 1 h to remove volatile materials. Yield: 7.13 g, 79.8%. ^{31}P NMR data: $\delta HPPh = -54.5$ ppm, $^{1}J(P—H) = 207$ Hz, $\delta P(p\text{-}CF_3C_6H_4)_2 = -16.6$ ppm.

(11) *Synthesis of* $C_6H_5P[CH_2CH_2CH_2P(p\text{-}CF_3C_6H_4)_2]_2$, CF_3ttp. This triphosphine was prepared by a procedure analogous to that used for CF_3PPH, (method 10), by starting with a stock solution of 0.525 M LDA (34.0 cm^3, 17.8 mmol) diluted with 40 cm^3 of hexane, 6.34 g (15.9 mmol) of $(p\text{-}CF_3C_6H_4)_2PCH_2CH_2CH_2Cl$ and 0.90 cm^3 (8.2 mmol) of $C_6H_5PH_2$ in 300 cm^3 of THF cooled to −78°C in a dry ice–isopropanol bath. The oil was gently heated *in vacuo* to remove remaining volatile materials. Yield: 5.5 g, 82%. $^{31}\{^{1}H\}P$ NMR data: $\delta PPh = -28.0$ ppm, $\delta P(p\text{-}CF_3C_6H_4)_2 = -16.9$ ppm.

(c) *Synthesis of platinum complexes of* CF_3PPH *and* CF_3ttp

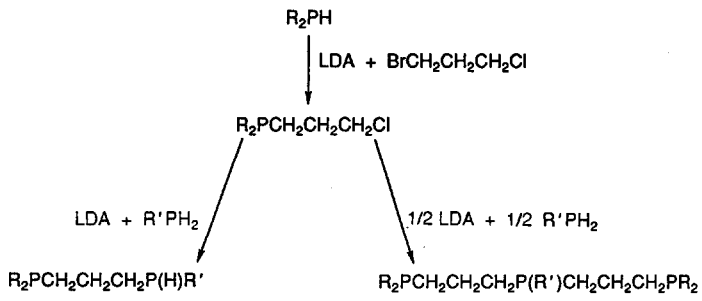
(1) *Synthesis of* $PtCl_2(CF_3PPH)$. A solution of 0.30 M CF_3PPH ligand in benzene (1.8 cm^3, 0.54 mmol) was added to a slurry containing 0.2032 g (0.5431 mmol) of $PtCl_2COD$[20] and 1 drop of a 6 M HCl solution in 20 cm^3 of benzene. A yellow colour was observed which quickly disappeared and a white solid precipitated. The solution was concentrated under an Ar stream to 1 cm^3 and then 10 cm^3 of hexane were added to complete the precipitation of the white solid. The white solid was collected on a Schlenk frit, washed twice with 2.0 cm^3 aliquots of hexane and dried *in vacuo*. Yield: 0.37 g, 92%. Calc. (Found): C, 37.4(37.4); H, 2.7(3.0); Cl, 9.6(9.4); F, 15.4(15.2); P, 8.4(8.2).

(2) *Synthesis of* $[PtCl(CF_3ttp)]Cl$. A stock solution of 0.10 M CF_3ttp ligand in benzene (14.0 cm^3, 1.40 mmol) was added to a slurry containing 0.52 g (1.40 mmol) of $PtCl_2COD$[20] in 40 cm^3 of benzene via a syringe. A faint yellow colour appeared and then a fine white solid precipitated. The slurry was refluxed for 3 h and then it was concentrated *in vacuo* to one-half its initial volume. The white solid was collected by vacuum filtration, washed with benzene and diethyl ether and dried in a desiccator. Yield: 1.5 g, 62%. Calc. (Found): C, 43.6(43.1); H, 3.0(3.4); Cl, 6.4(6.8); P, 8.4(8.0).

RESULTS AND DISCUSSION

(a) *Synthesis of phosphine ligands*

Traditionally, 3-chloropropylphosphines have been prepared by adding the lithium salt of the appropriate phosphine (Cy_2PH or Ph_2PH) to an excess of 1,3-dichloropropane (1 : 10 molar ratio) over a 15–24 h period (Scheme 1).[8] The triphosphine ligands were prepared by coupling reactions between the 3-chloropropylphosphine intermediates and phosphide nucleophiles. We have developed a new method for the synthesis of 3-chloropropylphosphines and polydentate phosphine ligands (Schemes 2 and 3) which is less expensive, requires less operator time and results in



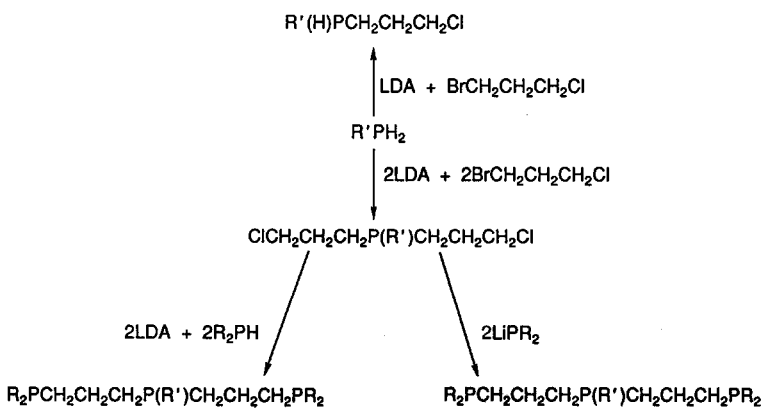
Scheme 2.

high-yield, high-purity products. The route is based on work by Kyba and co-workers on the synthesis of phosphino macrocycles.[21,22]

Compared to the original procedure for the synthesis of 3-chloropropylphosphines,[7,8] we have implemented two important modificiations. First, 1-bromo-3-chloropropane has been substituted for 1,3-dichloropropane. The bromine atom of 1-bromo-3-chloropropane undergoes nucleophilic substitution reactions faster than chlorine, consequently, a more selective substitution reaction and minimization of disubstitution of 1,3-dichloropropane, which is a side reaction that commonly occurs in the original method, can be accomplished. Replacing *n*-BuLi with LDA is the second modification of the original method.[7,8] Because LDA is a more sterically hindered, weaker base than *n*-BuLi, it can be used to generate the lithium organophosphides (i.e. R_2PLi) *in situ* at cold temperatures (*ca* $-78°C$) in the presence of 1-bromo-3-chloropropane or 3-chloropropylphosphine intermediates. Hence, the reaction procedures for generating 3-chloropropylphosphines and polydentate phosphine ligands are now one-step, one-flask reactions.

The new method of preparing 3-chloropropylphosphines (Scheme 2) leads to $(C_6H_5)_2PCH_2CH_2CH_2Cl$ in near quantitative yield from $(C_6H_5)_2PH$. The spectral data agreed with previously reported data for this compound.[8,23] The purity of $(C_6H_5)_2PCH_2CH_2CH_2Cl$ was tested using thin-layer chromatography; no trace impurities were observed. This method also leads to $(CH_3CH_2)_2PCH_2CH_2CH_2Cl$ from diethyl phosphine, however, traces of solvent remained in the product after vacuum distillation. It was characterized by its $^{31}P\{^1H\}$ NMR and IR spectra. Reactions of $[(CH_3)_2CH]_2PH$ and $(C_6H_{11})_2PH$ with 1-bromo-3-chloropropane in the presence of LDA did not give clean samples of the known compounds $[(CH_3)_2CH]_2PCH_2CH_2CH_2Cl$[24] and $(C_6H_{11})_2PCH_2CH_2CH_2Cl$,[8] apparently because of the high basicity of these phosphines and their significant steric requirements.[25]

The reaction of $C_6H_5PH_2$ with two equivalents each of 1-bromo-3-chloropropane and LDA yields $C_6H_5P(CH_2CH_2CH_2Cl)_2$ in near quantitative yield and high purity. The ^1H and $^{31}P\{^1H\}$ NMR data for this compound have been reported previously by Kyba and co-workers,[19] the $^{13}C\{^1H\}$ NMR data



Scheme 3.

are reported in Table 1. The compound was tested for trace impurities by thin-layer chromatography; no impurities were detected. A similar reaction was used to prepare $C_6H_{11}P(CH_2CH_2CH_2Cl)_2$ from $C_6H_{11}PH_2$. However, only 17% (based on ^{31}P NMR intensities) of the desired product was formed ($\delta^{31}P = -20.8$ ppm); the major product was the monoalkylated species, $C_6H_{11}(H)PCH_2CH_2CH_2Cl$ ($^{31}P = -51.9$ ppm).

The monoalkylated compounds $C_6H_5(H)PCH_2CH_2CH_2Cl$ and $C_6H_{11}(H)PCH_2CH_2CH_2Cl$, were prepared by addition of one equivalent each of LDA and 1-bromo-3-chloropropane to the corresponding primary phosphine (Scheme 3). These ligands are bifunctional due to reactive P—H and C—Cl bonds, hence they are useful intermediates for the synthesis of chelating polydentate ligands. IR spectra for both species exhibit characteristic P—H stretching absorptions; in addition, the doublets due to P—H spin–spin coupling in the ^1H NMR spectra confirm the presence of the P—H bond. The data are reported in Table 2.

As a result of the new procedures for the synthesis of 3-chloropropylphosphines, a new method, utilizing $C_6H_5P(CH_2CH_2CH_2Cl)_2$, can be envisioned for the synthesis of the chelating triphosphine ligands ttp and Cyttp (Scheme 3). Samples of ttp and Cyttp were obtained in high yield. The purities of ttp and Cyttp were tested by thin-layer chromatography and $^{31}P\{^1H\}$ and ^1H NMR spectroscopy. The $^{31}P\{^1H\}$ and ^1H NMR data for Cyttp and ttp corroborated data reported previously for these ligands.[8] The $^{13}C\{^1H\}$ NMR data for ttp agreed with those reported by Arapac and Dahlenburg,[23] the $^{13}C\{^1H\}$ data for Cyttp is reported in Table 1.

We have extended the above synthetic procedures to the synthesis of two new ligands, CF_3PPH and CF_3ttp, which incorporate an electron-withdrawing CF_3 group in the *para* position of the phenyl rings on the terminal phosphorus atom. The first step in preparing these new ligands is the synthesis of a new secondary phosphine, bis[4-(trifluoromethyl)-phenyl]phosphine, $(p\text{-}CF_3C_6H_4)_2PH$. Kapoor and co-workers[26–28] have generated secondary phosphines containing electron-withdrawing groups (i.e. $(p\text{-}FC_6H_4)_2PH$, $(m\text{-}FC_6H_4)_2PH$ and $(m\text{-}CF_3C_6H_4)_2PH$), and incorporated these phosphines into bidentate ligands; however, $(p\text{-}CF_3C_6H_4)_2PH$ has not been reported. Based on Hammett substituent constants, a CF_3 group in the *para* position of a benzene ring is more electron-attracting ($\sigma = 0.54$) than the same group in the *meta* position of a benzene ring ($\sigma = 0.43$).[29] Thus, the $(p\text{-}CF_3C_6H_4)_2P$ group incorporated into a chelating triphosphine ligand will provide the greatest contrast to ttp.

Kapoor and co-worker's[26–28] method for preparing secondary phosphines involves isolation of the secondary phosphine oxides (i.e. $(p\text{-}FC_6H_4)_2P(O)H$, $(m\text{-}FC_6H_4)_2P(O)H$ and $(m\text{-}CF_3C_6H_4)_2P(O)H$). Although the oxide of bis[4-(trifluoromethyl)phenyl]phosphine has been reported,[30] the synthetic details provided were very vague. The method reported here for the synthesis of (*p*-

$CF_3C_6H_4)_2PH$ does not rely on the isolation of the phosphine oxide, but incorporates an *in situ* reduction of the oxide to form the desired secondary phosphine.

The first three steps in the synthesis of (p-$CF_3C_6H_4)_2PH$; the formation of a Grignard, followed by addition of diethyl phosphite to the Grignard solution and subsequent reaction with a strong acid, are standard procedures for the synthesis of secondary phosphine oxides.[31,32] The presence of the phosphine oxide, (p-$CF_3C_6H_4)_2P(O)H$, can be detected *in situ* by ^{31}P NMR spectroscopy (δP = 16.4 ppm, ^{1}J(P—H) = 495 Hz). The final step of the scheme involves an *in situ* reduction of the phosphine oxide with $LiAlH_4$[31] to form the secondary phosphine. The clear liquid product, (p-$CF_3C_6H_4)_2PH$, has been characterized by ^{31}P and ^{1}H NMR and IR spectroscopies (Table 3) and $^{13}C\{^{1}H\}$ NMR spectroscopy (Table 4).

The second step in preparing CF_3PPH and CF_3ttp is the synthesis of the 3-chloropropylphosphine intermediate, (p-$CF_3C_6H_4)_2PCH_2CH_2CH_2Cl$. Reactions involving the secondary phosphine, (p-$CF_3C_6H_4)_2PH$, are complicated by side reactions which involve the CF_3 group and n-BuLi or LDA to give uncharacterized products. These complications have also been observed by Higgins and Levason.[34] By employing dilute solutions of LDA and by adding LDA very slowly to a solution of (p-$CF_3C_6H_4)_2PH$ and 1-bromo-3-chloropropane, these side reactions can be eliminated and high yields of (p-$CF_3C_6H_4)_2PCH_2CH_2CH_2Cl$ are obtained. The NMR and IR spectroscopic data for (p-$CF_3C_6H_4)_2PCH_2CH_2CH_2Cl$ are given in Tables 3 and 4.

Reactions of (p-$CF_3C_6H_4)_2PCH_2CH_2CH_2Cl$ with one equivalent each of LDA and $C_6H_5PH_2$ give the bidentate ligand (p-$CF_3C_6H_4)_2PCH_2CH_2CH_2P(H)C_6H_5$, CF_3PPH (Scheme 3). The synthesis of CF_3ttp is similar to the procedure used to prepare CF_3PPH, however, two equivalents each of $(C_6H_5)_2PH$ and LDA are used. The ^{1}H NMR and IR spectroscopic data for these ligands are given in Table 3 and the $^{13}C\{^{1}H\}$ NMR data are given in Table 4.

(b) *Synthesis of platinum complexes of* CF_3PPH *and* CF_3ttp

In order to compare the coordination properties of metal complexes coordinated to the new chelating phosphine ligands that contain (p-$CF_3C_6H_4)_2P$ groups, and to complete the characterization of these ligands, platinum complexes of CF_3PPH and CF_3ttp were prepared. The platinum complex of CF_3PPH, $PtCl_2(CF_3PPH)$, was pre-

[c] Solvent = CD_3NO_2.

pared from $PtCl_2COD$[20] [eq. (1)] using a procedure similar to the method used to prepare $PtCl_2(PPH)$ (PPH = $(C_6H_5)CH_2CH_2CH_2P(H)C_6H_5$) and $PtCl_2(CyPPH)$ (CyPPH = $(C_6H_{11})_2PCH_2CH_2CH_2P(H)C_6H_5$):[35]

$$PtCl_2COD + CF_3PPH \longrightarrow PtCl_2(CF_3PPH) + COD. \quad (1)$$

The $^{31}P\{^1H\}$ NMR spectrum of $PtCl_2(CF_3PPH)$ is a first-order AM spin system, and it consists of two doublets with the corresponding ^{195}Pt satellites (Fig. 1, Table 5). In order to evaluate the inductive effect of the $(p\text{-}CF_3C_6H_4)_2P$ groups, the ^{31}P NMR data obtained for $PtCl_2(CF_3PPH)$ are compared to data[34] for $PtCl_2(PPH)$ and $PtCl_2(CyPPH)$. The ^{31}P chemical shift of the $(p\text{-}CF_3C_6H_4)_2P$ group (−5.2 ppm) shifts to slightly higher field than the $(C_6H_5)_2P$ group (−5.7 ppm) of $PtCl_2(PPH)$. However, the effect is minimal. The electronegative effect of the $p\text{-}CF_3C_6H_4$ groups is also observed in the one-bond coupling constant, ^1J[Pt—P(2)], which is slightly larger for the $(p\text{-}CF_3C_6H_4)_2P$ group of $PtCl_2(CF_3PPH)$ [^1J[Pt—P(2)] = 3422 Hz vs 3403 Hz for the $(C_6H_5)_2P$ group of $PtCl_2(PPH)$]. However, the effect is not as dramatic as the difference between the platinum–phosphorus coupling of $PtCl_2(CyPPH)$ (^1J[Pt—P(2)] = 3303 Hz) and $PtCl_2(PPH)$ (^1J[Pt—P(2)] = 3403 Hz).

The platinum complex of the triphosphine ligand CF_3ttp, $[PtCl(CF_3ttp)]Cl$, was prepared also from $PtCl_2COD$ [eq. (2)] by use of a procedure similar to the method[36] employed for the synthesis of [PtCl(ttp)]Cl:

$$PtCl_2COD + CF_3ttp \longrightarrow [PtCl(CF_3ttp)]Cl + COD. \quad (2)$$

The $^{31}P\{^1H\}$ NMR spectrum of $[PtCl(CF_3ttp)]Cl$ is a first-order A_2M spin system, and it consists of a triplet and the corresponding ^{195}Pt satellites and a doublet and the corresponding ^{195}Pt satellites (Fig. 2, Table 5). Once again, the ^{31}P chemical shift of the $(p\text{-}CF_3C_6H_4)_2P$ groups (−2.8 ppm) is slightly down-

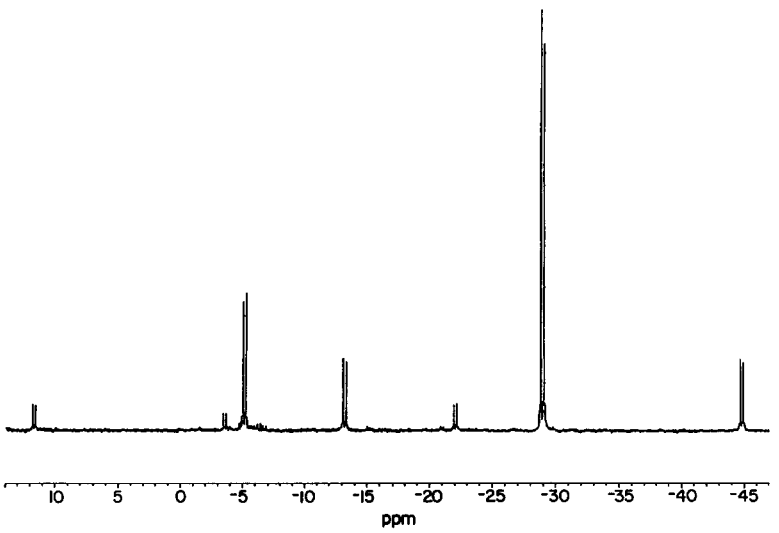

Fig. 1. 250 MHz $^{31}P\{^1H\}$ NMR spectrum of $PtCl_2(CF_3PPH)$ in d_6-acetone.

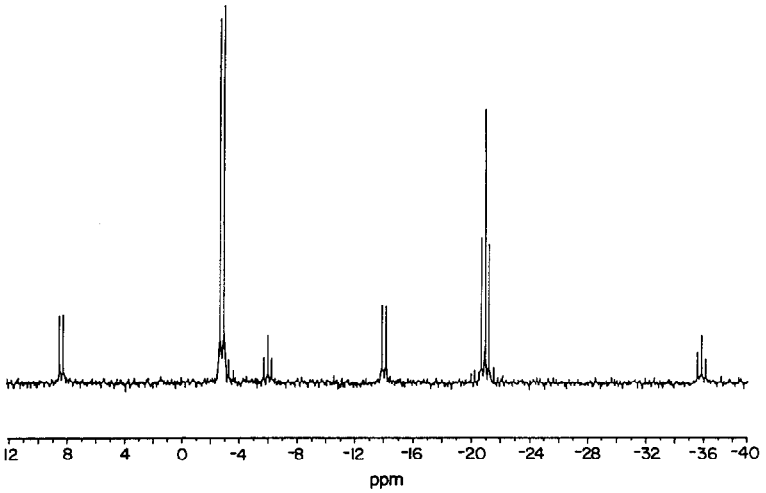

Fig. 2. 250 MHz $^{31}P\{^1H\}$ NMR spectrum of [PtCl(CF_3ttp)]Cl in CD_3NO_2.

field from the chemical shift of the $(C_6H_5)_2P$ groups (−3.9 ppm) of [PtCl(ttp)]Cl due to the electron-withdrawing effect of the *p*-$CF_3C_6H_4$ groups. In addition, the ^1J[Pt—P(2)] coupling constant for [PtCl(CF_3ttp)]Cl (^1J[Pt—P(2)] = 2264 Hz) is larger than the same coupling constant for [PtCl(ttp)]Cl (^1J[Pt—P(2)] = 2229 Hz). However, like $PtCl_2$(CF_3PPH), the difference between the ^1J[Pt—P(2)] coupling constants of [PtCl(CF_3ttp)]Cl and [PtCl(ttp)]Cl is not as dramatic as the difference between [PtCl(ttp)]Cl (^1J[Pt—P(2)] = 2229 Hz) and [PtCl(Cyttp)]Cl[36] (^1J[Pt—P(2)] = 2152 Hz).

In conclusion, the electron-withdrawing character of the *p*-CF_3 group on the phenyl ring of CF_3PPH and CF_3ttp is small compared to the difference in electron-withdrawing character between aryl and alkyl substituted phosphorus atoms in ttp and Cyttp, and PPH and CyPPH. Also, the *p*-CF_3 group does not impart increased solubility to the platinum complexes of CF_3PPH and CF_3ttp, relative to the platinum complexes of PPH and ttp.

SYNTHESIS, THERMAL DECOMPOSITION AND POWDER DIFFRACTION DATA OF AMMONIUM DECAFLUOROURANATE(VI), $(NH_4)_4UF_{10}$

SVETOZAR MILIĆEV* and BRANKO DRUŽINA

(*Received* 8 *June* 1989; *accepted* 4 *August* 1989)

Abstract—The synthesis of $(NH_4)_4UF_{10}$ is described. Thermal decomposition proceeds through four steps giving $(NH_4)_3UF_8$ at 200°C, $(NH_4)UF_6$ at 280°C, $(NH_4)U_3F_{13}$ at 380°C and finally UF_4 at 600°C. $(NH_4)UF_6$ decomposes through an intermediate to UF_4 and not directly. Powder data of $(NH_4)_4UF_{10}$ were indexed on the basis of a monoclinic cell [a = 12.87(2), b = 8.36(2), c = 13.60(7) Å, β = 121.5(3)°].

In 1984 we reported the synthesis and vibrational spectra of $(NH_4)_4UF_{10}$.[1] This is, as far as we are aware, the first monomeric hexavalent uranium compound with so high a coordination number (larger than eight). There were reports[2] of attempted syntheses of such a species, but in our case the Raman spectrum of a definitely stoichiometric diamagnetic compound clearly indicates a coordination number larger than eight, and the broad IR N—H stretching absorption showing moderate hydrogen bonding suggests a distorted UF_{10}^{4-} ion, with one of the fluorine atoms having significant ionic character. The radius of hexavalent uranium[3] should be comparable for higher coordination numbers with the intramolecular nonbonded atomic radius of fluorine,[4] allowing space for even more than 10 fluorine atoms. Nevertheless, it is an unexpected result (see also the discussion on the unlikeliness of nonacoordination in isolated anions of actinide fluorides in ref. 5). We report more details of the synthesis, the thermal behaviour and the powder diffraction data of the compound. Attempts to prepare a single crystal suitable for X-ray structure determination were unsuccessful.

EXPERIMENTAL

Synthesis

White $(NH_4)_4UF_{10}$ was synthesized by the procedure, described previously.[1] The results were better if the argon arc-welded copper vessel equipped with a Teflon packed nickel valve containing $(NH_4)_4UF_8$ and XeF_2 in excess (added by sublimation) was held at 55°C for a prolonged time, even for a few days. For reliable synthesis, one should start from very active UF_4, with a large specific surface (obtained by thermal decomposition[6] of $(N_2H_5)UF_5$), from which $(NH_4)_4UF_8$ is prepared.[7] More coarse UF_4, prepared by the usual hydrofluorination[8] of UO_2, results in $(NH_4)_4UF_8$ of insufficient purity, giving, at the end, impure and very unstable $(NH_4)_4UF_{10}$. $(NH_4)_4UF_{10}$ decomposes rapidly in air, changing colour to green. Found: U, 47.9; $(NH_4)^+$, 13.9; F, 37.7. Calc. for $(NH_4)_4UF_{10}$: U, 47.6; $(NH_4)^+$, 14.4; F, 38.0%.

Thermoanalysis

A 100 mg sample was referenced on a Mettler TA–1 thermoanalyser against a 100 mg sample of α-Al_2O_3. The heating rate was 4°C min^{-1} in a

Unit cell[9] of $(NH_4)_4UF_8$: monoclinic, $a = 13.126$, $b = 6.692$, $c = 13.717$ Å, $\beta = 121.32°$, $V = 1029$ Å^3; unit cell of $(NH_4)_4UF_{10}$ (this paper): monoclinic, $a = 12.87(2)$, $b = 8.36(2)$, $c = 13.60(7)$ Å, $\beta = 121.5(3)°$; $V = 1248$ Å^3.

Intensities of $(NH_4)_4UF_{10}$ and of the decomposition product are estimated visually.

stream of dried argon (5 $dm^3 h^{-1}$). The DTA range was 10 μV and the DTG range was 10 mg min^{-1}.

Thermal decomposition was also followed, confirming the results of the Mettler thermoanalyser, by weighing 2 g of $(NH_4)_4UF_{10}$ into a Ni crucible (100 cm^3) in an Ar dry-box. The crucible was held at successive temperatures for 1 h at each step (starting at 60°C, with steps of 10°C). Volatile products were pumped off in a dynamic vacuum. At each stage it was cooled down and samples were taken for powder data and chemical analysis.

Powder data

Debye–Scherrer X-ray diffraction patterns were obtained from a sample sealed in a quartz capillary using graphite monochromatized Cu-K_α radiation on an Enraf–Delft instrument. Intensities were estimated visually.

RESULTS AND DISCUSSION

In the series of known ammonium fluorouranates, $(NH_4)_4UF_{10}$ has the highest NH_4:U mol ratio and the highest valency state of uranium. Of the possible NH_4:U mol ratios for uranium in IV, V and VI valency states, only the lowest two (1:1 and 2:1) are fully represented by six compounds.[7,9,10] Within the higher ratios (3:1 and 4:1) there are, except for $(NH_4)_4UF_{10}$, only two compounds known; $(NH_4)_3UF_8$[9] and $(NH_4)_4UF_8$,[7] both synthesized by heating NH_4F and the fluoride of uranium in the proper valency state. This is not surprising since higher NH_4:F

ratios and higher valency states tend to make these compounds increasingly less stable. The synthesis of $(NH_4)_4UF_{10}$ by oxidizing $(NH_4)_4UF_8$ with XeF_2 under very mild conditions is a new approach in the chemistry of these compounds, which in this case, using the proper starting compounds, overcame the problem of stability.

The powder diffraction data of $(NH_4)_4UF_8$ from which $(NH_4)_4UF_{10}$ was prepared, of $(NH_4)_4UF_{10}$ itself and of its first proved decomposition product at 200°C, identified as $(NH_4)_3UF_8$, are of a similar kind (Table 1). Such a degree of similarity was already observed in some potassium, and also in sodium fluorouranates. It was suggested that variations in valency and coordination of the actinide ions may leave their positions virtually unchanged.[5] Probably this is also happening in our case, particularly as the synthesis of $(NH_4)_4UF_{10}$ from $(NH_4)_4UF_8$ occurs through a relatively mild fluorinating agent under mild conditions. Powder data of $(NH_4)_4UF_{10}$ were indexed on the basis of a monoclinic unit cell. Its dimensions are similar to those[9] of $(NH_4)_4UF_8$ (Table 1), with the *b* axis significantly enlarged (by more than 25%).

$(NH_4)_4UF_{10}$ decomposes through three steps (at 200, 280 and 380°C) (Fig. 1) in which we could clearly identify the intermediate products by weight loss and powder data (Tables 1 and 2) and through a fourth at 600°C to UF_4. Additionally, we always noticed on the Mettler thermoanalyser an endothermic effect at *ca* 110°C, accompanied with a small weight loss, and the powder data at 110°C showed a mixture of $(NH_4)_4UF_{10}$ and an unknown compound. Nevertheless, we were not able to isolate this intermediate, even by slowly decomposing $(NH_4)_4UF_{10}$ in bulk. The actual decomposition path is not surprising. Uranium is reduced in the first step to a valency of V and in the third to IV. The N:U ratio diminishes from 4:1 to 3:1, 1:1 and in the last intermediate to 1:3. The 3:1 compound, $(NH_4)_3UF_8$, is known, and although its thermal decomposition was not investigated in detail, it has been observed[9] that on heating it under certain conditions, $(NH_4)UF_6$ was obtained. This is in accordance with our decomposition path. But it has not yet been observed that $(NH_4)UF_6$ decomposes through an intermediate to UF_4.[12] This last intermediate, $(NH_4)U_3F_{13}$, is identical with the last intermediate in the decomposition of $(NH_4)_4UF_8$,[7] where it was obtained from $(NH_4)UF_5$.

Acknowledgements—We are grateful to Professor B. Žemva for helpful discussions, to Mrs A. Rahten for taking the thermal decomposition curves and to Mrs B. Sedej for making chemical analyses. The financial support of the Research Community of Slovenia is gratefully acknowledged.

REORIENTATIONAL PROCESSES IN SOLID $(C_6H_6)_2Cr$, $(C_6H_6)Cr(CO)_3$ AND $(C_6H_5Me)Cr(CO)_3$

DARIO BRAGA* and FABRIZIA GREPIONI

Dipartimento di Chimica "G. Ciamician", Università di Bologna, via F. Selmi 2, 40126 Bologna, Italy

(*Received* 13 *June* 1989; *accepted* 4 *August* 1989)

Abstract—The reorientational motion of the benzene rings in solid $(C_6H_6)_2Cr$ (**1**) and $(C_6H_6)Cr(CO)_3$ (**2**) and of the tricarbonyl group in solid $(C_6H_5Me)Cr(CO)_3$ (**3**), proposed on the basis of solid-state NMR experiments (wide-line ^1H and ^{13}C MAS) is studied by means of the pairwise potential energy method. Starting from the known crystal structures of the three species, relative potential energy barriers to motion and root mean square librational amplitudes at the bottom of the potential energy wells are evaluated and compared with the available anisotropic displacement parameters of the atoms involved in the process. The results show that the crystal packing in **2** and **3** forbids rotation of the $Cr(CO)_3$ group as a whole, while benzene reorientation encounters low potential energy barriers in both **1** and **2**, in agreement with the spectroscopic information. An alternative interpretation of the dynamic behaviour shown by **3**, based on large amplitude librations of both C_6H_5Me and $Cr(CO)_3$ groups, is put forward.

There is an increasing awareness that the understanding of the dynamic behaviour shown by many organometallic species in the solid state depends on combined efforts of both spectroscopic and diffraction methods.[1] The motion of groups of atoms or of entire molecules in a molecular crystal is controlled primarily by the distribution of the molecules within the crystal lattice, that is to say by the complicated balance of attractive and repulsive intermolecular forces at work between each atom and the environment.[2] Without this idea in mind it is difficult to understand the reasons for many, sometimes contradictory, dynamic processes in the condensed state of matter when compared with analogous behaviour in solution. For instance, $Fe_3(CO)_{12}$ and $Ru_3(CO)_{12}$, which in solution undergo CO-exchange at very low temperature,[3] are, respectively, "dynamic"[4] and "static"[5] in the solid state; while the *cis*- and *trans*-isomers of $(C_5H_5)_2Fe_2(CO)_4$, which interconvert via CO-bridge opening in solution,[6] show "static" CO's and rapidly rotating C_5H_5 ligands in the solid.[7]

Difficulties also arise from the conceptual difference between a spectroscopic experiment which yields time-averaged structural information depending on the working frequency span, and a diffraction experiment which operates an average over time and space of the entire content of the crystal lattice under examination.[8,9] Recently, it has been possible to demonstrate that the results of X-ray or neutron diffraction and solid-state NMR spectroscopy can be correlated by examining the dynamic information contained in the anisotropic displacement parameters (atomic "thermal" parameters, hereafter a.d.p.) in the light of spectroscopic results.[1,10]

A similar approach has also been applied to investigate the relationship between diffraction data and solution behaviour of a high nuclearity rhodium cluster.[11]

Moreover, semi-quantitative methods for the evaluation of the potential energy (p.e. hereafter) terms associated with molecule or fragment reorientations, widely employed in organic solid-state chemistry, have proved their extreme usefulness in the study of the collective effect of the molecules packed in a crystal on the occurrence of dynamic processes in solid organometallic species,[1,12] at least in cases where *intra*-molecular interactions play a limited role.

* Author to whom correspondence should be addressed.

In this paper the procedures mentioned above are applied to three closely related species: $(C_6H_6)_2Cr$ (**1**), $(C_6H_6)Cr(CO)_3$ (**2**) and $(C_6H_5Me)Cr(CO)_3$ (**3**), whose crystal structures are well documented by room- and low-temperature or neutron diffraction studies,[13-17] and whose solid-state dynamic behaviours have been studied either by wideline proton NMR (**1**, **2**)[18,19a] or by ^{13}C MAS NMR (**3**).[20] Results of quasi-elastic neutron scattering and of low-frequency Raman vibrational studies are also available for **2**.[19b] On the basis of the spectroscopic studies benzene reorientation around the molecular axes has been proposed for **1** and **2**,[18,19] while rotation of the tricarbonyl group has been invoked for **3**.[20]

Our purpose is to investigate the control exerted by the crystal packing on such dynamic processes in terms of p.e. barriers to motion, and to study the "shape" of the p.e. wells associated with the ground-state structures. In order to evaluate preferential displacement directions, use will also be made of the a.d.p.[21] of the atoms involved in the motions (when the available data are found of sufficient quality).

Finally, an alternative interpretation of the dynamic behaviour shown by **3**, which does not require rotation of the whole $Cr(CO)_3$ unit in the solid but only large amplitude librations of both the C_6H_5Me and $Cr(CO)_3$ fragments around their equilibrium positions, is proposed.

METHODS

The p.e. terms associated with molecular fragment reorientation of solid, neutral transition metal complexes or clusters can be evaluated by the pairwise p.e. method widely used in organic solid-state chemistry.[22] The method is well documented and will not be described in detail. The reader seeking more details of the computational procedures is referred to refs 23–26, while refs 1 and 27 contain more information about their application to organometallic species. The basic assumption is that the crystal packing of such species is dominated by purely van der Waals' interactions with no contribution of an ionic nature arising from permanent ionic charges or bond polarities. The p.e. is thus obtained as a simple function of the intermolecular separation in the crystal by summing up repulsive and attractive intermolecular energy terms between a reference molecule and the surrounding ones falling within a 10 Å cutoff and distributed by space group symmetry. The values of the coefficients to be used in the p.e. expression

$$\text{p.e.} = \sum_i \sum_j (A\, e^{-Br_{ij}} - Cr_{ij}^{-6})$$

for hydrogen, carbon and oxygen atoms are taken from the current literature.[24,26] The metal atom contribution is not taken into account. We have previously shown[1,27] that this rather drastic simplification affects only the values of the p.e. minima (the metal atoms contributing a constant attractive background), while it has no effect on the "shape" of the p.e. wells or on the heights of the p.e. barriers we are interested in (which are obviously dominated by the most external atoms). On the other hand, it must be stressed that we have no means for a correct evaluation of the "true" potential energy of an organometallic molecule in a crystal. We have chosen, by comparing closely related species of similar geometry and containing the same metal, to work on a *relative* scale. This is why the attention will be focused on the *relative* heights of the p.e. barriers (ΔE) and on changes in the p.e. profiles caused by temperature on crystals of the same species.

On these grounds, it should be clear that without "exterior" information, from spectroscopic methods, this kind of approach might have little to say. When such information is available, however, the feed-back to the comprehension of the averaging mechanisms at work in the solid state becomes of paramount importance.[28]

Atomic coordinates and space groups for all the species discussed herein were taken from the original structural reports (see Table 1 and refs therein). In the cases of **1** and **2**, where the molecules lie on crystallographic symmetry elements, the crystals were described in sub-groups of the actual space groups as required in order to operate on the entire molecules,[29] while keeping the packing distribution unaltered. Reorientations were performed by $\pm 180°$ rigid-body rotations of the molecular fragments or entire molecules around appropriately defined molecular axes and by calculating the p.e. values at 10° steps. The molecular packing was considered static during the motion, in such a way that the environment around the reorienting fragment retains the space-group symmetry and no cooperation by neighbouring molecules is involved. Because this limitation is known to cause an overestimation of the p.e. barriers,[30] the effect of cooperation was carefully explored in the controversial case of **3** (see below). This was carried out by allowing the first neighbouring molecules around the reference one to have the same kind of motion as the latter, and surrounding such a "molecular cluster" by an outer shell of static molecules in order to avoid undue freedom of the inner ones. Potential energy minimization was then performed by the steepest-descent method until convergence occurred.[30]

[a] Non-isomorphous subgroups of lower symmetry used to treat the molecules as independent units (see text) are reported in parentheses.

Because p.e. calculations are very sensitive to the atomic positions, hydrogen atoms of the C_6H_6 (**1** and **2**) and C_6H_5Me groups (**3**) were added in calculated, neutron-derived positions (C—H, 1.08 Å), with the exception of **2a** (see Table 1) whose original coordinates from the neutron diffraction study were used. All calculations were performed by using a slightly modified version of the program OPEC.[23] The relative p.e., ΔE = p.e. − p.e.$_{min}$, where p.e. is obtained as a function of the rotation angle and p.e.$_{min}$ is its minimum value (which invaraibly corresponds to the observed structure), is shown in Figs 1, 2 and 3 for **1**, **2** and **3**, respectively (see next section). The scale of energy is not the same in the three graphs.

In order to put this on a semi-quantitative basis the comparison of the p.e. wells corresponding to 0° rotation, root mean square (r.m.s.) librational amplitudes were evaluated as suggested by Shmueli and Kroon,[31] from the expression $\langle\varphi^2\rangle^{1/2} = kT/2c$, where k is Boltzmann's constant and the coefficient c is obtained by a least-squares fit of the polynomial

$$E(\varphi) = a + b\varphi + c\varphi^2 + d\varphi^3 + c\varphi^4$$

near the bottom of the p.e. well. The anharmonic contribution to libration (contained in the fourth and fifth coefficients) is not considered at the present stage of this study, although it can be anticipated that it appears to be relevant in **2** and **3** at room temperature. Finally, packing coefficients were calculated from the ratio $(V_{mol}Z)/V_{cell}$, where V_{mol} is evaluated by the method of intersecting caps from Kitaigorodsky.[2] Van der Waals radii taken from the literature (C, 1.75; O, 1.40; H, 1.15 Å) were used,[32] while the chromium atom was attributed a radius of 2.15 Å. Once again these choices allow comparison of the packing efficiency of the molecules in the crystals on a relative basis.[33] Packing coefficients provide, *inter alia*, an alternative and straightforward way of looking at the effects of a temperature decrease on the crystal packing.

RESULTS AND DISCUSSION

Dynamic processes in solid $(C_6H_6)_2Cr$ **(1)**, $(C_6H_6)Cr(CO)_3$ **(2)** *and* $(C_6H_5Me)Cr(CO)_3$ **(3)**

Dibenzene chromium has been the subject of many structural studies, mainly owing to the controversy on its molecular symmetry (D_{3d}/D_{6h}) in the solid state.[34] As listed in Table 1, we have adopted the room-temperature (r.t.) coordinates first reported by Jellinek in 1963 (**1a**),[13] and the low-temperature (100 K) X-ray determination coordinates (**1b**).[14] The dynamic behaviour in solid $(C_6H_6)_2Cr$ has been ascertained by wideline NMR spectroscopy providing evidence that the arene groups undergo "essentially free rotation" about

the principal molecular axis in the temperature range 178–381 K.[18]

Similar behaviour has been detected in solid $(C_6H_6)Cr(CO)_3$ (**2**), in the range 77–439 K.[19a] An activation energy of 4.2 kcal mol^{-1}, obtained from spin–lattice relaxation times, has been reported for the process. Comparable values have been obtained from quasi-elastic neutron scattering (3.9 kcal mol^{-1} at 300 K) and from Raman spectroscopy (4.7 kcal mol^{-1} at 300 K, 6.2 kcal mol^{-1} at 120 K).[19b] Results of two independent structural studies are available for **2**: a r.t. determination (**2a**),[15] and a combined X-ray/neutron refinement carried out at 78 K (**2b** in Table 1).[16]

While the C_6H_6 groups show essentially the same behaviour on the NMR time scale in **1** and **2**, it has been suggested that the $Cr(CO)_3$ unit of this latter species is static because of the steric hindrance to rotation caused by the spatial distribution of the CO groups.[19a]

$(C_6H_5Me)Cr(CO)_3$ (**3**) has been recently studied by ^{13}C MAS NMR. In order to account for the spectral features observed in the temperature range 196–333 K,[20] the authors have invoked a rotational motion of the $Cr(CO)_3$ unit while the C_6H_5Me ligand remains static. From line-width analysis a rotational energy barrier of 15.5 kcal mol^{-1} has been obtained for the process.[20] The close relationship between the structures of **2** and **3** and the difference in their solid-state dynamic behaviour prompted us to the investigation of the proposed equilibration mechanisms. Figure 1 shows a comparison of the p.e. barriers calculated for **1a** and **1b** for a complete rotation of the arene group around the molecular axis. Barrier heights and r.m.s. librational amplitudes are listed in Table 2.

The p.e. profiles show minima of almost identical energies every 60° rotation, corresponding to jumps by the carbon atoms to the neighbouring positions. The p.e. barrier for each rotational jump increases from 2.0 to 3.9 kcal mol^{-1} on decreasing the temperature to 100 K. This change is accompanied by a decrease of the r.m.s. librational amplitudes from 7.5 to 3.5° which indicates that the p.e. well at r.t. is not only less deep but also somewhat flatter.

The same trend in barrier heights and r.m.s. librational amplitudes is found for C_6H_6 rotation in **2** (see Fig. 2, top) on passing from r.t. (**2a**) (4.6 kcal mol^{-1}, 5.6°) to 78 K (**2b**) (7.5 kcal mol, 2.2°). The slight increase of the p.e. barrier to benzene rotation in **2**, with respect to **1**, can be attributed to the different packing requirements of the $(CO)_3$ group in the former molecule with respect to the flat benzene rings in **1**, as also shown by the value of the packing coefficient, which is larger for **2** than for **1** (see Table 2).

As shown in Fig. 2 (bottom), rotation of the $Cr(CO)_3$ unit around the molecular axis in **2** is prevented by high p.e. barriers centred at $\pm 60°$ from the minimum. Minima of equivalent energy are otherwise observed at $\pm 120°$, which correspond to site "exchange" between the CO ligands in accord with the three-fold symmetry. Therefore a rotational motion of this kind is not possible for **2**. The barrier height, however, shows the expected decrease on passing from 78 K to r.t. The r.m.s. librational amplitudes indicate that the librational freedom of the $Cr(CO)_3$ unit increases extensively with the temperature (more than for the C_6H_6 ligand), although rotational jumps are forbidden by the steeply rising walls of the p.e. well. It is worth noting, at this stage, that the lowering of the p.e. barrier to motion, caused by a temperature increase in both **1** and **2**, is invariably accompanied by an increase of the r.m.s. librational amplitudes. This is an indication that, although there is no direct relationship between barrier height and extent of motion at the bottom of the p.e. well, the barrier decrease allows the atoms to "spend more time" further away from the equilibrium positions. In agreement with this observation the a.d.p. of the C_6H_6 and $(CO)_3$ groups in **2** are found to be larger at r.t. than at 78 K (see Fig. 4), thus providing an important indication that such parameters reflect, at least in the present case, true atomic motion and

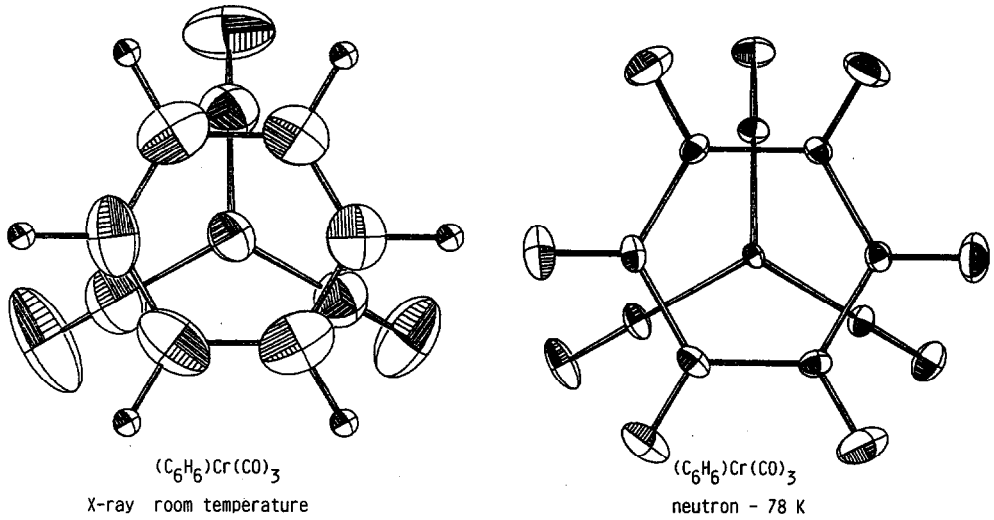

Fig. 4. Comparison of a.d.p. for $(C_6H_6)Cr(Co)_3$ at r.t. and 78 K (from refs 15 and 16).

not static disorder.[35] The same relationship between a.d.p. and p.e. barriers had previously been found for C_5H_5 reorientation in the *cis*- and *trans*-isomers of $(C_5H_5)_2Fe_2(CO)_4$.[1] Furthermore, in accordance with a preferential libration of the two fragments around the molecular symmetry axis, the a.d.p. for **2** clearly shows the presence of a strongly anisotropic librational motion around the three-fold axis (r.m.s. amplitudes obtained from thermal motion analysis are 7.7 and 3.5° around the three-fold axis, and 3.7 and 1.8° around the other axes for **2a** and **2b**, respectively).[15,16]

Let us now consider $(C_6H_5Me)Cr(CO)_3$. Potential energy profiles for independent rotations of the C_6H_5Me and $Cr(CO)_3$ units around the three-fold axis of this latter fragment are shown together in Fig. 3. [It should be pointed out that this axis is neither a molecular symmetry axis (the molecule possesses only *m*-symmetry) nor an inertia axis of the molecule, but rather the "coordination" axis of the chromium atom.] It appears that both C_6H_5Me and $Cr(CO)_3$ fragment reorientations are forbidden. However, as seen for **2**, minima at $\pm 120°$ are found which correspond to the three CO positions of the $Cr(CO)_3$ group.

These results play against the proposed rotation of the $Cr(CO)_3$ unit as the equilibration mechanism at work in solid **3**. As mentioned in the previous section, cooperation to the motion by the molecules surrounding the reference one was tested for **3** by allowing: (a) rigid-body rotation of the molecule as a whole around its major inertia axis; (b) rigid-body rotation around the "coordination" axis; and (c) reorientation of the two fragments as described above but in a cooperating environment.[30] In no cases were the p.e. barriers found to decrease significantly with respect to those obtained in a static environment.

Let us examine the p.e. wells in more detail (see Fig. 3). The calculated p.e. remains below the reference activation energy (*ca* 16 kcal mol^{-1}) yielded by the MAS experiment on **3**[20] within large angular ranges [-33, $+50°$ for C_6H_5Me; -28, $+24°$ for $Cr(CO)_3$]. This is an indication that the crystal packing, while effectively blocking reorientation of the two fragments, does allow extensive angular displacements from their equilibrium positions. It is also worth noting that the two p.e. wells are asymmetric with respect to the origin (0° rotation), although in opposite directions. On these premises and by taking advantage of the "exterior" spectroscopic information, which clearly indicates that an averaging mechanism is operating in solid **3**, we suggest that what is really taking place in the solid state is an extensive *swinging* of the two fragments in opposite directions around the chromium coordination axis. Such an extremely large amplitude librational motion can easily afford an exchange mechanism between the observed "*cis*" rotameric configuration and the one in which the CO's are staggered with respect to the ring atoms ($\pm 15°$ torsions of the two fragments, see Fig. 5). Incidentally, this latter rotameric configuration is the one observed in solid **2**. In the absence of exchange processes, the staggered configuration in **3** is expected to give rise to three resonances for the CO

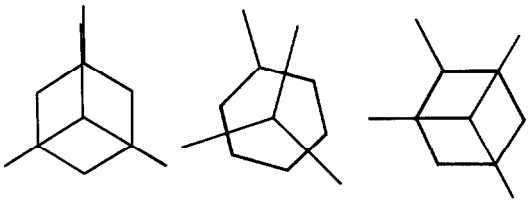

Fig. 5. Schematic representation of the proposed mechanism of interconversion (rotation of the two moieties in opposite directions) between the different rotameric configurations of $(C_6H_5Me)Cr(CO)_3$ in the solid state. The "*cis*" configuration is the one observed in the solid state.

groups. As the temperature is increased the limiting "*trans*" configuration may also be attained ($\pm 30°$ torsions, see Fig. 5), thus further contributing to the spectral features above coalescence (298 K).[20] In such a way the equilibration mechanism between the various rotameric configurations ("*cis*" eclipsed, staggered, "*trans*" eclipsed) does not necessitate full rotational freedom of either fragments. On decreasing the temperature, the swinging motion is reduced and finally stopped and a static structure is seen on the NMR time scale.

We trust that a full assessment of this phenomenon will be made possible by collection of low-temperature diffraction data of **3** [or of the analogous species $(C_6H_5Me)Mo(CO)_3$[20]] which is presently under way.

Finally, it is interesting to speculate on the fact that **2** might show similar behaviour under MAS NMR experimental conditions. We have, in fact, shown that the $Cr(CO)_3$ unit in **2** behaves in very much the same way as in **3**, possessing a very large librational freedom in its crystal. Therefore we can predict that a large amplitude librational motion of the tricarbonyl group will accompany rotation of the benzene ring in **2**.

CONCLUSIONS

We have shown that information of a dynamic nature can be extracted either from a.d.p. alone, when data collected at different temperatures are available, or by studying the molecular organization within the crystal lattice and the way in which the crystal packing controls the reorientational motions. The atom–atom p.e. method appears to be a powerful complementary tool to investigate such dynamic processes. What is more, the method, although based on several non-trivial approximations, is able to provide reliable semi-quantitative criteria to discriminate between genuine rotational freedom and large amplitude librational motions in the solid state. It should be stressed that both p.e. calculations and thermal motion analysis can be carried out by simply taking advantage of the *entire* structural information (atomic positions but also a.d.p. and crystal packing) yielded by a conventional diffraction experiment of reasonable quality. On this basis, we would like to emphasize that the commonplace belief that "X-ray diffraction techniques can not detect dynamic processes occurring in the solid state" should be definitively put aside.

POLY(BENZOTRIAZOLYL)BORATES—I. LIGAND SYNTHESIS AND CHARACTERIZATION

FERGUS J. LALOR,† S. M. MILLER and (in part) N. GARVEY

Department of Chemistry, University College, Cork, Republic of Ireland

(*Received* 13 *June* 1989; *accepted* 4 *August* 1989)

Abstract—The preparation and characterization of the new potassium poly(azolyl)borate salts $KH_2B(C_6H_4N_3)_2$, $KHB(C_6H_4N_3)_3$ and $KB(C_6H_4N_3)_4$ ($C_6H_4N_3$ = benzotriazolyl) and their thallium(I) derivatives is described. ^{13}C NMR spectroscopy identifies the anions as the N(1)-regioisomers and suggests a similar structure for the tetrakis(indazolyl)borate anion $[B(C_7H_5N_2)_4]^-$. The unexpected regioisomerism of the anions—which differs from that of related species—is attributed to the importance of electronic effects.

Heating a mixture of pyrazole or its C-substituted derivatives (i.e. Hpz*) with an alkali metal tetrahydroborate salt leads to elimination of hydrogen and the formation of B—N bonds:

$$BH_4^- + n\text{Hpz}^* \xrightarrow{\Delta} [H_{4-n}B(\text{pz}^*)_n]^- + nH_2. \quad (1)$$

In his pioneering studies of this reaction Trofimenko[1] demonstrated that the resulting anionic poly(1-pyrazolyl)borates possess unusual ligand characteristics, combining aspects of the properties of classical σ-bonding chelating ligands such as acetylacetonate with those of the π-bonding cyclopentadienide anion. The results summarized in several recent reviews[2] testify to a continuing growth of interest in these compounds. The poly(1-pyrazolyl)borate anions may be considered to be a subgroup of a wider class of ligands which are potentially accessible via the reaction of BH_4^- with heterocyclic compounds containing both an acidic ring NH group and an adjacent ring heteroatom with at least one available lone pair of elecrons. The range of such compounds reported to date consists of derivatives of indazole,[3] nitroindazoles,[4,5] imidazoles,[6,7] benzimidazole[6] and 1,2,4-triazole.[1] In a number of cases[1,4,5] the ligand itself has not been isolated but was characterized in the form of its transition metal complexes. None of these ligands nor their derived complexes have been structurally characterized by X-ray crystallographic methods and there is only a single report[8] of the formation of an organometallic derivative. Recent work in their laboratories has shown that the chemical properties of organometallic complexes containing poly(1-pyrazolyl)borate ligands may be dramatically altered by relatively minor changes in the substitution pattern of the pyrazole ring[9] and this has impelled us to investigate the behaviour of organometallic complexes of analogous ligand systems with modified steric and/or electronic properties. In this communication we describe the preparation and characterization of a new series of poly(azolyl)borate ligands derived from benzotriazole. The ligating properties of the new compounds will be discussed in a forthcoming paper.[10] Some of the results described here have been published in an abbreviated form.[11]

RESULTS AND DISCUSSION

When an intimate mixture of benzotriazole and potassium borohydride (*ca* 4–5 : 1 molar ratio) is heated in a closed system, melting and evolution of hydrogen takes place at *ca* 90°C. If this temperature is maintained the gas evolution ceases after *ca* one equivalent of hydrogen has been released. However, work-up at this stage gave no evidence for the formation of a mono(benzotriazolyl)borate anion (see below). Further heating causes a second equivalent of hydrogen to be evolved between *ca* 98–130°C, a third between 170–200°C, and a fourth between 240–260°C. Work-up at each stage gave the

† Author to whom correspondence should be addressed.

potassium salts of the bis-, tris-, and tetrakis (benzotriazolyl)borates $K[H_2B(C_6H_4N_3)_2]$ (**1**), $K[HB(C_6H_4N_3)_3]$ (**2**) and $K[B(C_6H_4N_3)_4]$ (**3**), respectively ($C_6H_4N_3$ = benzotriazolyl). Only the bis-derivative **1** and unreacted KBH_4 could be detected when the reaction was interrupted after evolution of a single equivalent of hydrogen. The new poly(benzotriazolyl)borates are white (**1**, **2**) or off-white (**3**) solids and were isolated in *ca* 75–80% yield. Purification by crystallization was not satisfactory but traces of unreacted benzotriazole could be removed by washing with boiling methylcyclohexane. Prolonged heating with this solvent or attempts to sublime out unreacted benzotriazole under high vacuum appeared to cause slow decomposition. Both the bis- and tris(benzotriazolyl) compounds **1** and **2** are hygroscopic and the presence of water could be detected by IR and NMR spectroscopy in samples which had been dried at *ca* 80°C *in vacuo*. Microanalytical data (Table 1) were in agreement with the formulation of both these compounds as monohydrates. All three potassium salts were readily converted into the analogous anhydrous thallium(I) derivatives $Tl[H_2B(C_6H_4N_3)_2]$ (**4**), $Tl[HB(C_6H_4N_3)_3]$ (**5**) and $Tl[B(C_6H_4N_3)_4]$ (**6**). Acidification of an aqueous solution of **2** with acetic acid yielded an unstable off-white solid which was insoluble in all the usual organic solvents except dimethylsulphoxide in which it decomposed with evolution of gas. Microanalytical data (Table 1) were in approximate agreement with a formulation as the trihydrate of the parent acid of **2** i.e. $H[HB(C_6H_4N_3)_3]\cdot 3H_2O$ (**7**). Further attempts to characterize the material were not successful.

Since benzotriazole exists as a mixture of N(1)—H and N(2)—H tautomers, B—N bond formation (in the reaction with borohydride anion) can occur potentially at either of these atoms with

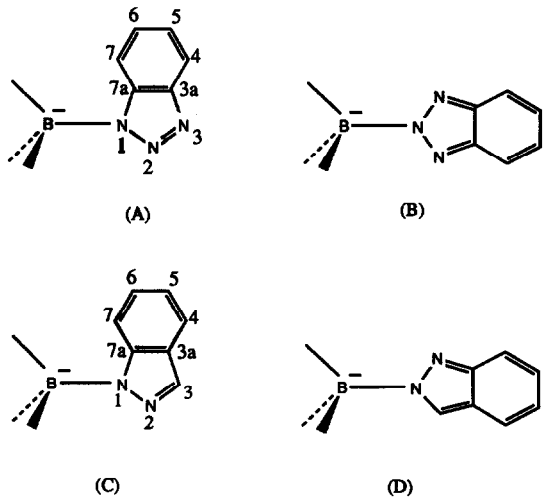

Fig. 1. Regioisomeric structures and numbering system for (benzotriazolyl)- and (indazolyl)borates.

formation of one or other of the pair of regioisomeric structures A and B, illustrated in Fig. 1. A similar possibility of regioisomerism exists for the reaction of the borohydride anion with 3-monosubstituted pyrazoles. In all such systems studied to date, the reaction is strictly regiospecific. The critical factor appears to be the degree of steric crowding at the boron since the regioisomer with the ring-substituent in the more remote 3-position is formed exclusively.[12] We, therefore, anticipated that compounds **1**–**6** would exist in the B—N(2) regioisomeric form (i.e. B, Fig. 1) in which steric hindrance at boron is minimized. The structures of **1**–**6** were readily established by ^{13}C NMR spectroscopy. Six distinct carbon resonances would be predicted for exclusively N(1)-bonded regioisomers as against three for the more symmetrical N(2)-bonded alterna-

tive and nine for structures with both forms of bonding. The fully-decoupled ^{13}C NMR spectra of complexes **1–5** are summarized in Table 2. (The thallium tetrakis(benzotriazolyl)borate compound, **6**, was insufficiently soluble in the usual solvents for its spectrum to be recorded.) All of the compounds studied give similar six-line spectra and they are therefore shown to involve N(1)-bonded benzotriazolyl groups. (Assignment of the resonances in the spectra of **1–5** to individual carbon atoms was made by reference to the very similar spectrum of 1-methylbenzotriazole.[13])

The ^1H NMR spectra of complexes **1–5** (see Experimental) were all similar in showing a complicated series of resonances in the aromatic region, generally separable into two highly asymmetric multiplets centred on *ca* δ 7.5 and 8.0 ppm. The observed pattern is compatible with the proposed N(1)-bonded structures in that the more symmetrical N(2)-regioisomers should exhibit a relatively simple AA^1BB^1 spectrum, similar to that of 2-methylbenzotriazole.[14] Apart from the absorption at *ca* 3400 cm^{-1}, characteristic of water of hydration in **1** and **2**, and ν(BH) bands in **1** (2450, 2430, 2390 cm^{-1}, broad) and **2** (2480 cm^{-1}), the IR spectra of the potassium salts **1–3** (KBr disc) show considerable similarity in the 1600–650 cm^{-1} region. Noticeable differences from the spectra of benzotriazole itself are medium to strong bands at *ca* 1490, 1450, 1350, 1290 and 1270 cm^{-1}, as well as strong bands at *ca* 1145, 1127, 1057 and (in **3**) 930 and 840 cm^{-1} which are either weak or absent in the spectrum of the free heterocycle. The IR spectra of the thallium salts **4–6** in pressed polyethylene discs are virtually identical to those of the potassium salts in KBr.

The series of (indazolyl)- and (nitroindazolyl)borate ligands described by Zaidi and coworkers[3–5] possess the same potential for regioisomerism as do the (benzotriazolyl)borates (i.e. C and D of Fig. 1). This possibility receives no mention in the original literature, where B—N(1) bonding is assumed without explicit discussion of evidence in favour of that conclusion. While our results with benzotriazole do suggest that the structurally similar indazole would also form the N(1)-regioisomer we have attempted to gather more definite evidence on the point. The tetrakis(indazolyl) borate salt $K[B(C_7H_5N_2)_4]$ (**8**) ($C_7H_5N_2$ = indazolyl) was prepared in improved yield and purity by a modification of the published procedure and was readily converted into its thallium(I) derivative (**9**). We chose compound **8** as the most sterically crowded of the (indazolyl)borates and, therefore, the most likely to exist wholly or partly as the N(2)-regioisomer. Since the structure of **8** may not be deduced directly from its ^{13}C NMR spectrum (see below), we attempted to grow crystals suitable for an X-ray crystallographic study but were not successful. Neither could crystals of suitable quality be obtained of the thallium salt **9** which, like its benzotriazolyl analogue **6**, is insoluble in

common organic solvents. The IR spectrum of **8** shows strong bands at 1450, 1410, 1325, 1260, 1155, 1140, 1100 and 820 (broad) cm^{-1} which are either absent or of low intensity in the spectrum of indazole. The IR spectrum of **9** is similar to that of **8**. A singlet in the ^1H NMR spectrum of **8** in acetone-d_6, integrating for four protons, is assigned to the unique proton at C(3) of the indazole nucleus and indicates that all four indazolyl groups are equivalent in the anion. The protons of the benzene portion of the indazolyl nucleus appear as a pair of complex multiplets centred on δ 6.8 (4H) and 7.7 (12H) ppm, respectively. Because the inherent asymmetry of the indazole nucleus is such that—unlike **1**–**6**—neither N(1)—B nor N(2)—B regioisomers of **8** possess a plane of symmetry bisecting the aromatic ring, the ^1H NMR spectrum cannot be simply interpreted in terms of the regioisomeric structure of the anion. A similar problem affects the ^{13}C NMR spectrum of **8** which is summarized in Table 2. The observed seven-line spectrum is compatible with either regioisomer and the positions of the resonances themselves are sufficiently close to those of both 1- and 2-methylindazole[13a] to prevent any firm conclusion being drawn as to the structure present. Extrapolation from the ^{13}C NMR spectrum of the potassium tetrakis(1-benzotriazolyl) borate (**3**), however, does provide some tentative evidence in favour of an analogous structure for **8**. From a comparison of the spectra of $K[B(1\text{-}C_6H_4N_3)_4]$ (**2**) and 1-methylbenzotriazole[13b] in acetone-d_6 we can derive a set of empirical correction factors, $\Delta\delta$, reflecting the change in chemical shift of the carbon nuclei on formal replacement of the N(1)–methyl group by the N(2)—B bond in **3**. Applying these correction factors to the ^{13}C NMR spectrum of 1-methyl indazole† produces calculated chemical shift values for **8** which are in good agreement with the observed spectrum (Table 2). While not to be regarded as proof, we believe that this result is strongly suggestive of an N(1)-bonded regioisomeric structure for **8** and, by extension, for the other reported indazolylborate ligands. A further interesting aspect of the ^1H decoupled ^{13}C NMR spectrum of **8** is the observation that the resonances of C(3) and C(7a) appear as two broadened quartets with a line-separation of *ca* 3.0 Hz. In addition, the singlet resonance of C(3a) is also noticeably broadened. We ascribe the splitting of the C(3) and C(7a) resonances to long-range coupling with the ^{11}B nucleus (80.22%, $I = 3/2$). While such coupling is not unexpected in four-coordinate anionic boron compounds,[15] it is strange that it is not observed in the spectrum of the closely related $K[B(1\text{-}C_6H_4N_3)_4]$ (**3**). The broadening of all three resonances is likely to be due to the effects of partial quadrupolar collapse of the coupling.[16]

With the regiospecificity of the benzotriazole–borohydride reaction firmly established as involving B—N(1) bonding and with the probability being that the reaction with indazoles follows the same pattern, we are left with a question: Why does the regiospecificity of this reaction depart from well-established precedent and produce the most sterically crowded anion, even in the highly congested tetrakis(azolyl)borates? We believe that the answer lies in a trade-off between steric and electronic effects in the anions. While N(2)—B bonding minimizes steric crowding, it does so at the expense of forcing the heterocycle into a quinonoid form with a resulting loss of aromatic delocalization energy. It seems clear that this produces an unacceptable net destabilization of the anion. It remains to be seen whether we can force the formation of the N(2)-bonded isomers by making the heterocycle even more sterically demanding, e.g. by the introduction of substituents at C(4) and C(7).

EXPERIMENTAL

Potassium borohydride, benzotriazole and indazole were commercially available. KBH_4 was dried *in vacuo* at 110°C for 12 h before use. Benzotriazole was recrystallized from benzene and indazole was sublimed in high vacuum. IR spectra were recorded on Perkin–Elmer 257 and 628 spectrophotometers. ^1H and ^{13}C NMR spectra were measured on Perkin–Elmer Hitachi R20-A and Jeol FX-60 instruments operating at ambient temperature and are referenced to internal trimethylsilane. Elemental

† The data in ref. 13(b) were chosen for comparison with the spectrum of **3** because of the common solvent employed for the two measurements. We note that this paper does not explain the origin of the assignments of the individual resonances to particular carbon atoms. The quoted assignments for C(5) and C(6) differ by 4.1 and −2.7 ppm, respectively, from the resonances assigned to these carbon atoms in ref. 13(a) where the individual assignments are justified. The measurements in ref. 13(a) were made on solutions in deuterochloroform. Comparison of the data on compounds common to both studies and of spectra recorded in both solvents and quoted in ref. 13(b) shows that a solvent shift of *ca* 1.0 ppm is to be expected for the carbon nuclei in question and that resonances measured in chloroform are invariably displaced to high field with respect to those determined in acetone. We conclude that the assignments for C(5) and C(6) quoted in ref. 13(b) are in error. Since the anomaly is removed if the assignments are simply reversed, this is assumed in the subsequent discussion.

analyses were determined by the staff of the Microanalytical Laboratory of University College, Cork.

Potassium dihydrobis(1-benzotriazolyl)borate monohydrate (**1**)

Finely powdered benzotriazole (10.0 g, 84 mmol) and potassium borohydride (1.13 g, 21 mmol) were intimately mixed in a three-necked, round-bottomed flask fitted with a magnetic stirring bar, a nitrogen inlet valve, a thermocouple well and a 30-cm air condenser, the top of which was connected to a wet-test meter. Thermocouple probes for a digital thermometer and temperature-control device were placed in the well which extended close to the bottom of the flask. The apparatus was flushed with nitrogen, sealed off from the atmosphere and placed in an oil-bath. Gentle heating to *ca* 100°C with stirring caused the mixture to melt with vigorous evolution of gas. When *ca* 470 cm^3 of gas (*ca* 21 mmol) had been evolved the rate of gas evolution slackened considerably. The temperature was slowly raised to 130°C during which a further 470 cm^3 of gas were measured before the evolution ceased once more. Nitrogen was admitted to the apparatus and the melt was allowed to cool slightly before being poured into *ca* 250 cm^3 of stirred toluene. The fine white precipitate of $K[H_2B(C_6H_4N_3)_2]\cdot H_2O$ (**1**) which formed after a few minutes was collected by filtration, washed with 2×50 cm^3 of hot toluene and dried *in vacuo* over P_4O_{10}. Yield, 5.23 g, 81%. The compound is soluble in water and acetone but insoluble in chloroform and dichloromethane. The ^1H NMR spectrum in acetone-d_6 consists of a pair of broad unsymmetrical complex multiplets centred on δ 7.75 and 8.40 ppm and integrating for equal numbers of protons.

Potassium hydrotris(1-benzotriazolylborate)monohydrate (**2**)

The general procedure was as described above for **1** except that heating was continued at *ca* 130°C and the reaction mixture eventually solidified. On raising the temperature to 170°C, the mixture melted again and between this temperature and 200°C a further 470 cm^3 of hydrogen was slowly evolved. Work-up as described for **1** produced 9.0 g (76%) of **2**. Compound **2** is soluble in water, alcohols, acetone, chloroform and dichloromethane but insoluble in petroleum. The ^1H NMR spectra in chloroform-d consisted of a single broad complex multiplet centred on *ca* δ 7.7 ppm.

Potassium tetrakis(1-benzotriazolyl)borate (**3**)

The general procedure was as described for **2** but employing 12.5 g (100 mmol) of benzotriazole, i.e. a 1 : 5 ratio of KBH_4 to triazole. From 200°C the temperature was raised to *ca* 260°C and held there for 24 h during which *ca* 470 cm^3 of hydrogen was released. Work-up as before yielded a brown solid which was dissolved in hot methanol, heated with activated charcoal and reprecipitated with water to yield 8.34 g (76%) of pure $K[B(1\text{-}C_6H_4N_3)_4]$ (**3**). Compound **3** is soluble in acetone and alcohols but insoluble in water, chloroform and dichloromethane. The ^1H NMR spectrum in acetone-d_6 showed two multiplets centred on δ 7.4 and 8.4 ppm and integrating for four and 12 protons, respectively.

Preparation of the thallium(I) derivatives (**4**–**6**)

A solution of the potassium(benzotriazolyl) borate in distilled water (**1**, **2**) or methanol (**3**) was treated with an equimolar quantity of thallium(I) formate in distilled water. A white precipitate usually formed immediately but occasionally an oil was formed which converted into a fine white solid when kept at 0°C overnight. $Tl[H_2B(1\text{-}C_6H_4N_3)_2]$ (**4**) and $Tl[HB(1\text{-}C_6H_4N_3)_3]$ (**5**) were recrystallized from methanol–water and chloroform–petroleum, respectively, while $Tl[B(1\text{-}C_6H_4N_3)_4]$ (**6**) was microanalytically pure as formed. Compound **4** is soluble in methanol only, while compound **5** is also soluble in chloform and dichloromethane. Compound **6** is insoluble in all common organic solvents. The ^1H NMR spectra of **4** and **5** are similar to those of the potassium analogues.

Potassium tetrakis(1-indazolyl)borate (**8**)

The literature preparation of **8** involves heating a 1 : 4 mixture of KBH_4 and indazole to 215°C, but the quoted volume of hydrogen evolved appears to be in error.[3c] In our hands, these conditions did not prove successful. Three equivalents of hydrogen were evolved while the mixture was heated slowly to *ca* 200°C but continued heating at this temperature or slightly above caused it to solidify and carbonize and no further hydrogen was released. In contrast, gradual heating of a 1 : 5 mixture of reactants, 0.84 g KBH_4 (15.6 mmol) and 9.2 g indazole (78 mmol), and holding the mixture at 220°C for 24 h caused the elimination of *ca* 1.2 litres of hydrogen (*ca* 86% of the theoretical volume) before there was any sign of solidification and carbonization. Work-up as described for the benzotriazolylborates gave crude **8** as a yellow solid.

Recrystallization of the yellow product from a mixture of ethanol and 1-hexene gave **8** in *ca* 70% yield as an off-white microanalytically pure solid. The material described by earlier workers is yellow, has a lower m.p. than our product, was isolated in only 48% yield and gives microanalytical results outside the normally acceptable limits.[3c] Compound **8** is soluble in alcohol and acetone but only sparingly so in chloroform and dichloromethane. It is insoluble in water and hydrocarbons. The ^{1}H NMR spectrum is described in the text. The thallium(I) derivative **9** was prepared as described for the benzotriazole analogue.

URANIUM POLY(PYRAZOL-1-YL)BORATE COMPLEXES: X-RAY CRYSTAL STRUCTURES OF $UCl_2Cp[HB(3,5\text{-}Me_2Pz)_3]$ AND $UCl_3[HB(3,5\text{-}Me_2Pz)_3]$

ÂNGELA DOMINGOS,* NOÉMIA MARQUES and A. PIRES DE MATOS

Departamento de Química, ICEN, LNETI, 2686 Sacavém Codex, Portugal

(*Received* 26 *June* 1989; *accepted* 4 *August* 1989)

Abstract—The crystal and molecular structures of $UCl_2Cp[HB(3,5\text{-}Me_2Pz)_3]$ (**1**) and $UCl_3[HB(3,5\text{-}Me_2Pz)_3]$ (**2**) have been determined by single crystal X-ray diffraction. Compound **1** crystallizes in space group $P\bar{1}$, $a = 10.770(1)$, $b = 11.146(5)$, $c = 11.820(4)$ Å, $\alpha = 114.53(2)$, $\beta = 91.70(2)$, $\gamma = 107.45(2)°$, $V = 1211.77$ Å^3, $Z = 2$; compound **2** crystallizes in space group $P2_1/c$, $a = 8.173(1)$, $b = 14.279(3)$, $c = 19.167(7)$ Å, $\beta = 100.17(2)°$, $V = 2201.71$ Å^3, $Z = 4$. In both compounds the uranium centre is six-coordinate and displays octahedral geometry, close to C_s symmetry for complex **1** and to C_{3v} symmetry for complex **2**. For compound **1** the average U—Cl, U—N and U—C(Cp) bond distances are 2.60(1), 2.51(2) and 2.74(1) Å; for **2** the average U—Cl and U—N bond distances are 2.56(1) and 2.43(1) Å.

Since the synthesis and X-ray structural characterization of $UCl_3[HB(3,5\text{-}Me_2Pz)_3](THF)$,[1] actinide poly(pyrazolyl)borate chemistry has experienced a continuing progress. Although derivatives of this complex with cyclopentadienide, dialkylamides, alkoxides and aryloxides have been described,[2–4] few structural data are available on these complexes. These include the seven-coordinate $UCl(OC_6H_5)_2[HB(3,5\text{-}Me_2Pz)_3](THF)$ complex[4] and the related eight-coordinate $UCl(OBu^t)(HBPz_3)_2$ and $UCl(OC_6H_5)(HBPz_3)_2$ complexes.[5]

During the course of our investigation on uranium poly(pyrazolyl)borate compounds we have found that the ligand $[HB(3,5\text{-}Me_2Pz)_3]$ can be used as a probe in ^1H NMR spectroscopy. In particular, the ^1H NMR spectra of the previously reported $UCl_2Cp[HB(3,5\text{-}Me_2Pz)_3]$ and $UCl_3[HB(3,5\text{-}Me_2Pz)_3]$ complexes[2] exhibited signals which were consistent with C_s and C_{3v} point symmetries, respectively. In order to verify if the structures found in solution were the same in the solid state, we have undertaken the X-ray crystallographic study of these compounds.

EXPERIMENTAL

The syntheses and characterization of **1** and **2** have been reported earlier.[2]

Crystals of the compounds suitable for X-ray diffraction were obtained by slow diffusion of *n*-pentane into saturated solutions of $UCl_2Cp[HB(3,5\text{-}Me_2Pz)_3]$ in THF and of $UCl_3[HB(3,5\text{-}Me_2Pz)_3](THF)$ in CH_2Cl_2, at room temperature. The crystals were sealed in thin-walled glass capillaries in a nitrogen-filled glove-box.

Data were collected at room temperature on an Enraf–Nonius Cad 4 diffractometer with graphite-monochromatized Mo-K_α radiation, in the $1.5 < \theta < 25°$ range, using a ω–2θ scan mode. Crystal data, data collection and refinement for both complexes are presented in Table 1. Data reduction was carried out using the Enraf–Nonius program; for complex **1** a decay of 80% (in 83.3 h) in the intensities of three standard reflections monitored every 100 measurements was observed and linearly corrected; empirical absorption corrections were applied based on ψ scans. The structures were solved by Patterson and Fourier methods and refined by full-matrix least-squares.[6] All non-hydrogen atoms were refined anisotropically, and the contributions of the hydrogen atoms were included in calculated positions, not refined but con-

strained to ride on their carbon atoms with group U_{iso} values assigned. A weighting scheme $W = (\sigma^2(F_o)+0.0001F_o^2)^{-1}$ was used in both structures. In the final difference Fourier maps the highest peaks were 1.84 and 1.11 e Å^{-3} for compounds **1** and **2**, respectively, close in both cases to the uranium atom. Atomic scattering factors and anomalous dispersion terms were taken from *International Tables for X-ray Crystallography*.

Tables of final atomic positional and thermal parameters, full lists of bond lengths and angles, equations of mean-least-square planes and tables of F_o/F_c values have been deposited as supplementary material with the Editor.

RESULTS AND DISCUSSION

Figures 1 and 2 show perspective views of the molecules with their atomic numbering schemes. Molecule **1** has approximately C_s symmetry with a non-crystallographic mirror plane passing through uranium, boron, pyrazolyl (2) and C_3(Cp). Molecule **2** has approximately C_{3v} symmetry.

By considering that the Cp ligand occupies a single coordination site, the coordination geometry about uranium is, in both compounds, octahedral. The three nitrogens of the tridentate pyrazolyl borate ligand occupy one three-fold face while the remaining ligands form the staggered triangular face on the other side of the central atom. However, in view of the rigid nature of the tripodal ligand and of its relatively small bite (1.24 for **1** and 1.25 for **2**), distortions from the regular octahedron are observed in both compounds. The twist angles between the two previous triangular faces are 57.8 and 58.4° for complex **1** and **2**, respectively, close to 60° as observed in the regular octahedron. The planes of these two faces are inclined by 2.9 and 3.2°, respectively, for **1** and **2**. The angles at the metal atom from the pyrazolyl donor atoms are much lower than 90°, allowing the opening of the face formed by the other ligands. In fact, the N—U—N angles are 73.5(2), 85.0(2), 72.6(2)° (av. 77.0°) and 79.2(2), 76.3(2), 76.3(2)° (av. 77.3°) for complexes **1** and **2**, respectively; the Cl—U—Cl/Cp angles in complex **1** are 91.2(2), 99.9(3), 102.0(3)° (av. 97.7°), while for complex **2** the corresponding Cl—U—Cl angles are 96.4(2), 99.6(2), 95.0(2)° (av. 97.0°). Thus, a higher distortion from the regular octahedron is observed for the mixed-Cp derivative. Figures 3 and 4 show views of the molecules emphasizing the octahedral geometry of the inner coordination sphere.

Selected bond lengths and bond angles are given in Tables 2 and 3. Slightly longer U—Cl and U—N bond lengths are observed for the Cp derivative (average 2.60(1), 2.51(2) Å compared with 2.56(1), 2.43(1) Å for **2**), probably due to the replacement of a chlorine atom by the more sterically demanding

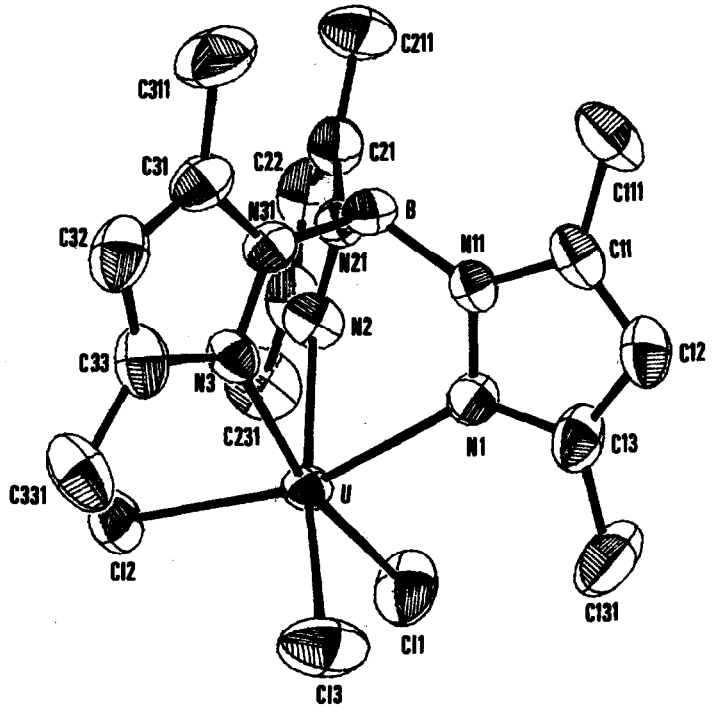

Fig. 2. ORTEP plot of $UCl_3[HB(3,5\text{-}Me_2Pz)_3]$ with 50% probability thermal ellipsoids.

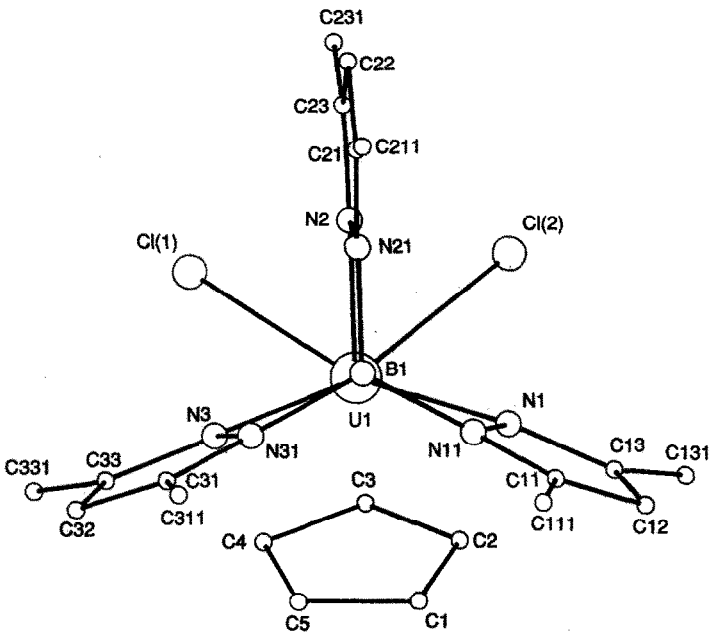

Fig. 3. A B–U view (PLUTO) of $UCl_2Cp[HB(3,5\text{-}Me_2Pz)_3]$.

Cp ligand. Compound **2** has slightly shorter U—Cl and U—N bond distances compared with the values of 2.60(1) and 2.49(2) Å in seven-coordinate $UCl_3[HB(3,5\text{-}Me_2Pz)_3](THF)$, which is consistent with the smaller effective radius of uranium in a lower coordinate complex. The angles at the uranium centre in **1** are also affected by the bulkier Cp, as can be seen with the values of the Cl—U—Cl/Cp and N—U—N angles.

The U—Cp and the C—C(Cp) bond lengths (average 2.74(1) and 1.40(1) Å, respectively) are in the range observed in other cyclopentadienyl com-

plexes.[7,8] The pyrazolyl and the Cp rings are planar, with root mean-square deviations from their least-square planes of 0.0102, 0.0049, 0.0136 and 0.0042 Å (pyrazolyl (1), (2) (3) and Cp). The angle between the plane of the Cp and the plane of the donor atoms of the pyrazolyl ligand is 123.3°. The Cp and the pyrazolyl (2) ring are nearly perpendicular, the angle between their least-square planes being 90.94°.

For compound **2**, each of the three pyrazolyl rings is also planar, with root mean-square deviations from their least-square planes of 0.0116, 0.0066, and 0.0144 Å.

There are no short intermolecular contacts in both compounds. The closest intramolecular non-bonded contacts are, in compound **1**, 3.29 and 3.41 Å for Cl(1)···C(4) and Cl(2)···C(2) and 3.18, 3.14 Å for N(1)···C(1) and N(3)···C(5).

Abstract—The dianion $[Os_6(CO)_{18}]^{2-}$ (**1**) reacts with $[Cu(NCMe)_4]^+$ to form $[Os_6(CO)_{18}(CuNCMe)_2]$ (**2**). Treatment of **1** with $[(PPh_3Me)I]$ followed by reaction with $[Cu(NCMe)_4]^+$ gives $[Os_6(CO)_{18}(CuI)_2]^{2-}$ (**3**). An X-ray crystal structure determination of **3** shows that a hexaosmium octahedral arrangement has opposite faces capped by CuI groups. Both **2** and **3** are susceptible to (CuL) loss in the presence of nucleophiles such as organophosphines, THF or acetonitrile.

Reactions of carbonyl cluster anions with mononuclear cationic metal complexes usually give clusters in which one or more electrophiles are simply added to the anionic complex as, for example, in the formation of $[Os_{10}C(CO)_{24}(CuNCMe)]^-$ and $[Os_{10}C(CO)_{24}(CuNCMe)_2]$ from the reaction of the decaosmium dianion $[Os_{10}C(CO)_{24}]^{2-}$ with $[Cu(NCMe)_4]^+$.[1] However, condensation reactions between anionic carbonyl clusters and electrophilic mononuclear metal complexes may also occur, and are an important route for the formation of very large heteronuclear carbonyl complexes.[2–4] A number of clusters with core stoichiometry $M_6M'_2$ have been synthesized by the reaction of M_6 carbonyl anions (M = Rh,[5] Ru,[6–8] Os[4,9]) with $M'L_n$ cations such as $[Cu(NCMe)_4]^+$, $[AuPPh_3]^+$. A variety of metal core geometries have been found for these clusters, including those in which the heterometal atoms are directly bound to one another,[6] and those in which these atoms are on opposite sides of the M_6 polyhedra.[4,5,7] We now report two new $M_6M'_2$ compounds, $[Os_6(CO)_{18}(CuNCMe)_2]$ (**2**) and $[Os_6(CO)_{18}(CuI)_2]^{2-}$ (**3**), in which the opposite faces of the octahedral cluster dianion, **1**, are capped by the CuL ligands.

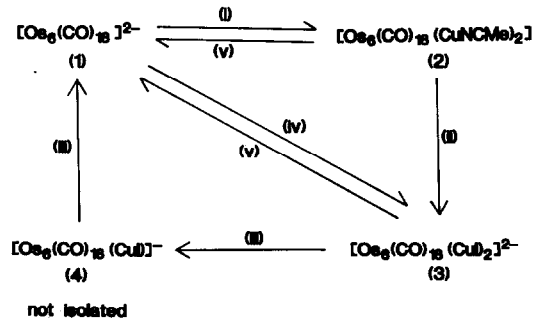
RESULTS AND DISCUSSION

Reaction of the $[Ph_3PMe]^+$ salt of the hexaosmium dianion $[Os_6(CO)_{18}]^{2-}$ (**1**) with $[Cu(NCMe)_4]^+$ in CH_2Cl_2 or acetone (Scheme 1) gives a product which we tentatively identify as



Scheme 1. (i) Excess $[Cu(NCMe)_4]^+$; (ii) e.g. CsI; (iii) rapid addition of dppm; (iv) excess $[PPh_3MeI]$ followed by excess $[Cu(NCMe)_4]^+$; (v) donor molecules, e.g. THF, MeCN.

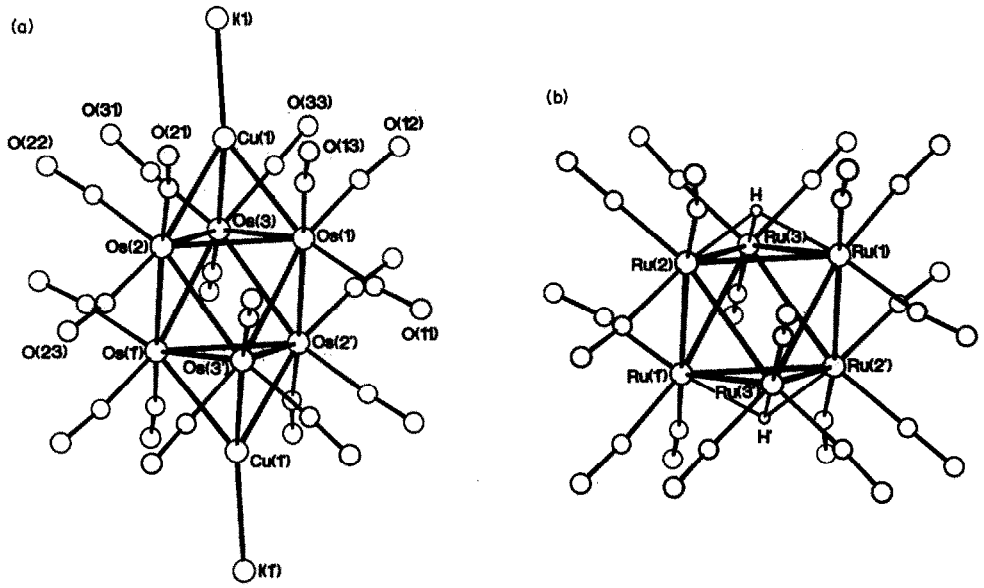


Fig. 1. The structures of (a) the dianion $[Cu_2Os_6(CO)_{18}I_2]^{2-}$ (**3**) and (b) the dihydride $[H_2Ru_6(CO)_{18}]^{2-}$ (**6**) (from ref. 13). In the numbering scheme for **3** the carbonyl carbon atoms have the same number as the relevant oxygen atoms.

$[Os_6(CO)_{18}(CuNCMe)_2]$ (**2**). Isolation and characterization of **2** is hampered by its instability; for example, this compound decomposes to **1** on silica TLC plates. Fast-atom bombardment (FAB) mass spectra of solutions of **2** gave $[Os_6(CO)_{18}]$ as the largest fragment, and in acetone **2** reacted with the halide salts of IR windows to produce the dianions $[Os_6(CO)_{18}(CuX)_2]^{2-}$ (X = Br or I), which were identified by their IR spectra. Our formulation of **2** as $[Os_6(CO)_{18}(CuNCMe)_2]$ is based primarily on the observation that further reaction with $[PPh_3Me]I$ gave the dianion **3**, and on the similarity of the IR spectrum of **2** to that of the dianion, **3**, which has been fully characterized by X-ray structure analysis (*vide infra*).

The dianion, **3**, was also somewhat unstable, and its reaction with donor molecules such as amines or organophosphines, or its dissolution in THF or acetonitrile regenerates the dianion $[Os_6(CO)_{18}]^{2-}$ quantitatively. An intermediate, **4**, is observed in the reaction with phosphines (see Experimental); the major IR peaks of **4** are at frequencies between those in **1** and **3**, which is consistent with this compound being the monoanion $[Os_6(CO)_{18}(CuI)]^-$. IR peaks at energies similar to those of **4** have also been observed for a mixture of **1** and **3** in dichloromethane, although an accurate measurement of these absorptions was not possible as they overlap with those of **1** and **3**.

X-ray structure analysis of **3** establishes the overall structure shown in Fig. 1(a), and selected bond lengths and interbond angles are given in Table 1.

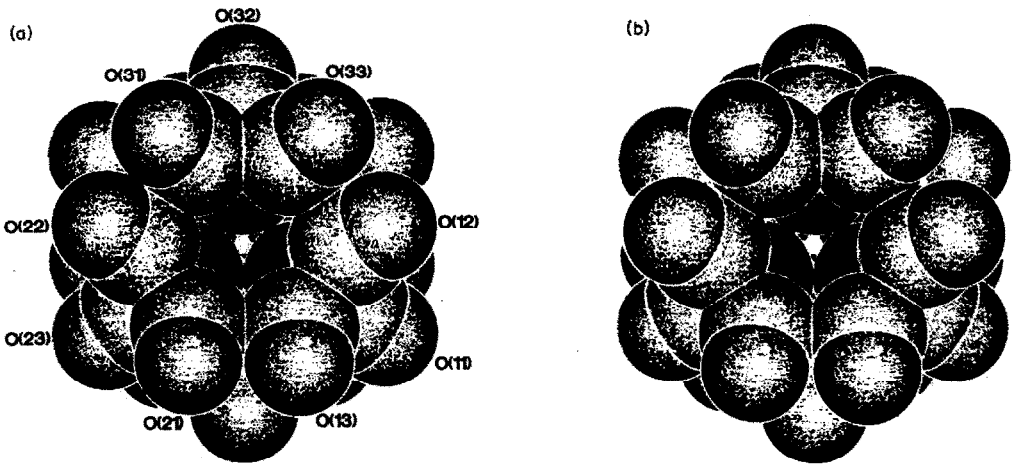

Fig. 2. Computed space filling models of (a) $[Cu_2Os_6(CO)_{18}I_2]^{2-}$ and (b) $[H_2Ru_6(CO)_{18}]^{2-}$. The μ_3-Cu and μ_3-H are not included and the metal atoms have been calculated with covalent radii.

The metal framework of **3** consists of an Os_6 octahedron with the copper atoms capping opposite faces, giving a similar metal core to that in $[Ru_6(CO)_{18}(CuC_6H_5CH_3)_2]$[7] and $[Os_6(CO)_{18}(AuPMe_3)_2]$ (**5**).[10] Overall, the molecule has virtual D_{3d} symmetry although the crystallographic symmetry is only C_i. The isolobal analogy between Group IB metals and the hydride ligand in clusters is well established,[11] and it is possibly surprising that **3** adopts a completely different Os_6 framework from the capped square pyramidal geometry of its dihydrido analogue $[Os_6(CO)_{18}H_2]$.[12] However, the overall structure of **3** does bear a remarkable similarity to that of the related dihydride ruthenium cluster $[Ru_6(CO)_{18}(\mu_3\text{-}H)_2]$ (**6**) shown in Fig. 1(b).[13] An alternative arrangement, in which the two copper atoms are bonded to each other has been observed, for example, in the ruthenium compound $[Ru_6C(CO)_{18}(CuNCMe)_2]$.[6] In **3**, as in the *trans*-capped cluster $[Ru_6(CO)_{18}(CuC_6H_5CH_3)_2]$,[7] the metal–metal bonds of the capped faces (mean 2.943(1) Å) are somewhat longer than those of the other edges (mean 2.874(1) Å), and are very close in value to the analogous bridged and unbridged lengths in the dihydride $[Ru_6(CO)_{18}(\mu_3\text{-}H)_2]$ (2.954 and 2.867 Å, respectively).[13] An unanticipated similarity in the steric requirement of the hydrogen and the copper ligands is evident in the computed space-filling models shown in Fig. 2(a) and (b).

The two symmetry related Cu—I vectors lie close to the virtual S_6 axis of the molecule; two of the Cu—Os bond distances do not differ significantly (Os(1)—Cu and Os(2)—Cu, mean 2.664(2) Å), but the third is rather shorter (Os(3)—Cu 2.643(2) Å).

A number of reactions of **2** and **3** were tried in an attempt to form even higher nuclearity clusters. Further reaction of **3** with electrophiles such as $[Cu(NCMe)_4]^+$ and $[AuPPh_3]^+$ does not occur. This may be attributed to steric factors, because although the carbonyl ligands can accommodate two groups, this causes surface ligand congestion [Fig. 2(a)]. Reaction of heteronuclear clusters with cluster dianions has sometimes been shown to lead to formation of giant clusters,[3] but substitution reactions of the acetonitrile ligands in **2** by $[Os_6(CO)_{18}]^{2-}$ does not occur. We are currently investigating the possibility that less sterically demanding nucleophiles, such as $[Os(CO)_4]^{2-}$ or $[Mn(CO)_5]^-$, may be capable of displacing the NCMe ligands.

EXPERIMENTAL

All manipulations were carried out in open flasks. $[Os_6(CO)_{18}]$[14] and $[NEt_4]_2[Os_6(CO)_{18}]$[15] were prepared according to standard literature procedures. Triphenylphosphine and bis(diphenylphosphinomethane) (dppm) were used as purchased. All solvents were distilled prior to use. IR spectra were recorded on a Perkin–Elmer 1710 and FAB mass spectra were recorded on a Kratos MS890.

Preparation of $[Os_6(CO)_{18}(CuNCMe)_2]$ (**2**)

$[Cu(NCMe)_4][PF_6]$ (30 mg, 0.094 mmol) was added to a solution of $[NEt_4]_2[Os_6(CO)_{18}]$ (20 mg, 0.010 mmol) in 10 cm^3 of acetone. After 20 min the solvent was removed on a rotary evaporator and the orange residue was extracted with CH_2Cl_2. Attempts to purify **2** by chromatography resulted in decomposition to $[Os_6(CO)_{18}]^{2-}$ (**1**). IR: ν(CO) in CH_2Cl_2: 2038s, 2022m, 1983w(br) cm^{-1}. FAB m/z: 1656 corresponding to $(Os_6(CO)_{18})$.

Preparation of $[PPh_3Me]_2[Os_6(CO)_{18}(CuI)_2]$ (3)

Dichloromethane (20 cm^3) was added to $Os_6(CO)_{18}$ (30 mg, 0.018 mmol) and $[PPh_3Me]I$ (100 mg, 0.250 mmol). After 2 h $[Cu(NCMe)_4][PF_6]$ (48 mg, 0.15 mmol) was added and the solution stirred for an additional 2 h. The solution was then filtered and the solvent was removed *in vacuo*. The remaining solid was taken up in the minimum of acetone. Methanol was added and the resulting orange precipitate was collected by filtration. Yield: 26 mg, 0.010 mmol, 56%. IR: ν(CO) in CH_2Cl_2: 2029s, 2015m, 1959w(br) cm^{-1}. FAB *m/z*: 1656 ($Os(CO)_{18}$). Found: C, 26.4; H, 1.6. Calc.: C, 26.1; H, 1.4%.

Other reactions of **2**

The acetonitrile ligands in **2** were easily replaced by weak nucleophiles such as halides. Reactions of **2** with stronger nucleophiles (e.g.) phosphines resulted in the loss of the $[Cu(NCMe)]^+$ groups and formation of $[Os_6(CO)_{18}]^{2-}$ (**1**).

Reactions of **3**

In separate experiments, compound **3** (5 mg) in CH_2Cl_2 (10 cm^3) was reacted with slightly more than 2 equivalents of $[Os_6(CO)_{18}]^{2-}$, dppm or PPh_3. No reaction was observed with $[Os_6(CO)_{18}]^{2-}$. With the phosphines, $[Os_6(CO)_{18}]^{2-}$ (**1**) was always the ultimate product, although an unisolated intermediate **4** was often identified in the IR spectrum (ν(CO) in CH_2Cl_2: 2018s, 2006m, 1946w(br) cm^{-1}). Compound **4** could be made virtually quantitatively (as determined by IR) by rapid addition of dppm to a solution of **3**. However, after a few minutes **1** began to form, and **4** disappeared completely within 0.5 h. Compound **3** was also reacted with THF and acetonitrile by dissolution in the neat solvent, and in both cases only **1** was detected in the IR spectrum.

Crystal data for **1**

$C_{56}H_{36}Cu_2I_2O_{18}Os_6P_2$, $M = 2580.92$, triclinic, space group $P\bar{1}$ (no. 2), $a = 14.218(3)$, $b = 12.369(3)$, $c = 10.073(2)$ Å, $\alpha = 88.18(2)$, $\beta = 91.31(2)$, $\gamma = 113.52(4)°$, $U = 1623.61$ $Å^3$, $Z = 1$, $D_c = 2.64$ g cm^{-3}, $F(000) = 1166$. An orange crystal of size $0.22 \times 0.22 \times 0.35$ mm, μ(Mo-K_α) = 132.93 cm^{-1}, was used in the data collection.

Data collection

Data were collected in the θ-range 3–25°, with a scan width of 0.80°, using the technique described previously.[16] Equivalent reflections were merged to give 4119 data with $I/\sigma(I) > 3.0$.

Structure solution and refinement[17]

The coordinates of the three independent osmium atoms were deduced from a Patterson synthesis, and the remaining non-hydrogen atoms were located from subsequent difference-Fourier syntheses. The methyl and phenyl groups of the counterion were constrained to idealized geometry (C—C 1.395 and C—H 1.08 Å); the hydrogen atoms were given a common isotropic thermal parameter of 0.1 $Å^2$. Absorption corrections were applied to the data after initial refinement with isotropic thermal parameters for all atoms.[18] The non-hydrogen atoms were assigned anisotropic thermal parameters in the final cycles of full-matrix refinement which converged at $R = 0.0385$ and $R' = 0.0402$, with weights of $w = 1/\sigma^2 F_o$ assigned to the individual reflections.

(*Received* 28 *November* 1988 ; *accepted* 16 *August* 1989)

Abstract—The equilibria in the system L-aspartic acid $+VO^{2+}$ in aqueous solution for $1.5 \leqslant pH \leqslant 11$ have been studied by a combination of pH-potentiometric and spectroscopic methods [electron paramagnetic resonance (EPR), visible absorption and circular dichroism (CD)]. For $pH > 4$, high ligand-to-metal ratios were used. The results of the various methods are made self-consistent, then rationalized assuming an equilibrium model including the species MDH_2, MDH, MD, MD_2H_3, MD_2H and MD_2 (where H_2D denotes L-aspartic acid) and several hydrolysis products; their formation constants and individual electronic spectra (isotropic and CD) are given. Plausible isomeric structures for each of the stoichiometries are discussed.

Although knowledge of the complex equilibria of VO^{2+} in the presence of amino acids is relevant in understanding its possible interaction with likely biological ligands, few reliable data exist.

The first part of this study[1] introduced our work and gave detailed results for the system (L-Ala)+VO^{2+} in the pH range 2–12. Part II[2] concerned the L-serine and L-threonine+VO^{2+} systems. The present paper describes our study of the L-Asp+VO^{2+} system, which combined the results of potentiometric and spectroscopic techniques. Part of this work has been presented in a preliminary form.[3]

Some work has been published concerning the L-Asp+VO^{2+} system.[4–7] Tewari and Srivastava[4] determined $\log\beta(ML) = 8.98$, $\log\beta(ML_2) = 14.47$ and $\log\beta(ML_3) = 19.89$, based on titration in the range $3.2 < pH < 8.6$ with $L/M = 4$ and $C_{VO} = 10^{-3}$ M. Even assuming no precipitation of vanadyl hydroxide and/or oxidation in those conditions, the observed values of $\bar{n}$ probably arise from extensive hydrolysis and not the formation of ML_3 complexes. Tak *et al.*[5] determined $\log\beta(ML) = 8.39$ and $\log\beta(ML_2) = 14.44$, based on titration with $C_{VO} = C_{Asp} = 5\times10^{-3}$ M (C_{VO} and C_{Asp} denote total concentration of oxovanadium(IV) and aspartic acid, respectively), in the pH range 3–11. Clearly, one would expect vanadyl hydroxide precipitation and/or oxidation in these conditions.

Johnson and Shepherd[7] recorded EPR spectra at room temperature of solutions containing L-Asp and VO^{2+} (C_{VO}, C_{Asp} and pH unspecified), detecting only one species; it had $A_0 = 96$ gauss. In solutions containing glycine (Gly) and VO^{2+}, where $VO(GlyO)_2$ would predominate, $A_0 = 98$ gauss. Assuming in both cases N_2O_2 coordination in the equatorial plane, they concluded that the decrease by 2 gauss in A_0 is owing to the axial coordination of a β-COO^- group.

* For Parts I and II, see refs 1 and 2, respectively.

† Author to whom correspondence should be addressed.

Our results with the L-Asp + VO^{2+} system differ completely from those for the L-Ala,[1] L-Thr,[2] L-Cys, D-Pen (Pen = penicillamine)[8] and L-glutamic acid[9] systems over practically the whole pH range studied (1.6–11). This probably results from coordination of the β-COO^- group at quite low pH ($\sim$2) (coordination of the α-COO^- group starts at pH < 2).

Several experimental difficulties in systems involving oxovanadium(IV) + amino acids are discussed in Part I.[1] Between pH 4 and 8, relatively high ligand-to-metal (L/M ratios) must be used to avoid extensive hydrolysis of VO^{2+} and eventually precipitation of $VO(OH)_2$. However, such precipitation and/or the presence of a soluble oxovanadium(IV) hydrolysis product for pH $\gtrsim$5 is clearly not so important in the present system as for other amino acids, and much lower L/M ratios may be used.

Since pK_{a1} (α-COOH), pK_{a2} (β-COOH) and pK_{a3} (R—NH_3^+) can easily be determined, the calculated formation constants correspond to the general reaction:

$$xM^{2+} + yD^{2-} + zH^+ \rightleftharpoons M_xD_yH_z. \qquad (1)$$

We abbreviate L-aspartic acid as H_2D and the aspartate ion is then D^{2-}. For the formulation $(VO)_x(AspO)_y(H)_z$ we normally use the abbreviation $M_xD_yH_z$. For each $M_xD_yH_z$ proposed in our final equilibrium model, possible structures are discussed.

When needed we also abbreviate L-alanine and L-serine as HA and HS, and alaninate and serinate as A^- and S^-, respectively.

MATERIALS AND METHODS

For the refinement of formation constants and calculation of spectra of individual species the MINIQUAD,[10] SUPERQUAD[11] and the SQUAD[12] programs were used. In order to estimate formation constants to use as initial values for MINIQUAD and SUPERQUAD we followed a procedure described later which is summarized in Table 1.

All solutions were prepared in an inert atmosphere (high purity dinitrogen passed through soda-lime and glass wool). All measurements were performed at 25°C with solutions containing 2.25 M $NaNO_3$. The instruments used and calibration procedure for pH measurements were described in Part I.[1] We continue to assume that the EMF values (E) depend on $[H^+]$ according to

$$E = E^{ol} + Q \log [H^+] + J_H[H^+] + J_{OH}[OH^-].$$

The maximum pH value for the titration curves of solutions containing L-Asp + VO^{2+} was 8.4.

Seven titration curves ($4.7 \times 10^{-3} \lesssim C_{Asp} \lesssim 80 \times 10^{-3}$ M) (C_{Asp}—total aspartic acid concentration) were obtained to determine the protonation constants in 2.25 M $NaNO_3$; NaOH (2.2 M) was used in most cases. As $J_H \sim 20$, the corrections in the acid range are only significant for pH < 2.0.

As for the systems L-Ala, L-Ser and L-Thr + VO^{2+},[1,2] two types of titration curves were obtained: those involving measurements in the range 2.2 $\lesssim$ pH $\lesssim$ 4.2 (with 0.9 $\lesssim$ L/M $\lesssim$ 4 and $2.3 \times 10^{-3} \lesssim C_{VO} \lesssim 5.0 \times 10^{-3}$ M) and those involving pH measurements in the range 4.5 $\lesssim$ pH $\lesssim$ 8.4 (12 $\lesssim$ L/M $\lesssim$ 26 and $1.3 \times 10^{-3} \lesssim C_{VO} \lesssim 2.6 \times 10^{-3}$ M).

A total of 80 visible absorption spectra and 90 CD spectra (visible region) were used for the calculation of spectra of individual species, with concentrations in the ranges $4 \times 10^{-3} \lesssim C_{VO} \lesssim 5.0 \times 10^{-2}$ M and 0.013 $\lesssim C_{Asp} \lesssim$ 0.17 M, respectively. Ligand-to-metal ratios were in the range 0.4 $\lesssim$ L/M $\lesssim$ 26.

RESULTS

EPR spectra

The EPR spectra recorded with frozen "solutions" containing L-Asp and VO^{2+} at 77 K are typical VO^{2+} axial spectra. The field region that corresponds to $A_\parallel$ and $M_I = 5/2$ and 7/2 gives more information about the type and number of species present.

In Fig. 1, we include the high-field region of the EPR spectra of frozen "solutions" containing L-Asp + VO^{2+} with a L/M ratio of 10 at several values of pH. Analysing Figure 1 in terms of the distinct EPR components DI to DV detected and the corresponding g and A values (a single EPR component, e.g. DI, may well, of course, arise from different vanadium complexes with approximately the same g and A parameters):

(i) for pH $\lesssim$ 3, the spectra of solutions containing L-Asp + VO^{2+} with L/M = 10.0 are of the same type as those for solutions of L-Ala + VO^{2+} with L/M = 53.9;[1]
(ii) for pH $\gtrsim$ 3, the spectra differ from those for the systems involving L-Ala, L-Ser, L-Thr, L-Cys and D-Pen + VO^{2+} at similar pH values.

For DI, DIII and DIV, we estimate[12,13] $g_\parallel \sim$ 1.938, 1.937 and 1.943 and $A_\parallel \sim$ 179, 173 and 161×10^{-4} cm^{-1}, respectively. Although the $g_\parallel$ values seem rather low, this could suggest a $VO(O_4)$

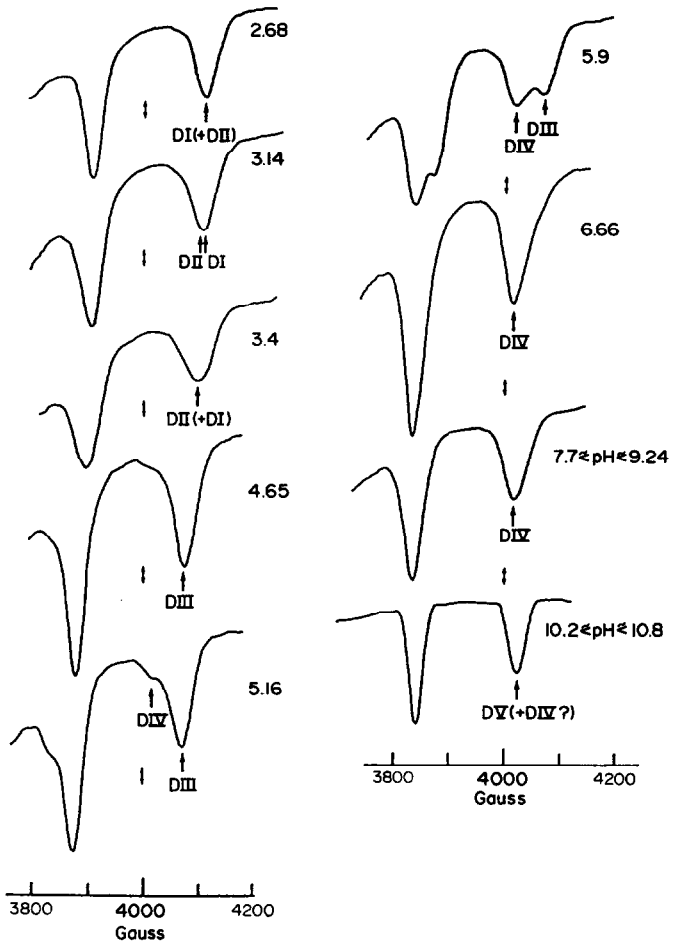

Fig. 1. High field range (3800–4200 gauss) of the first derivative EPR spectra at 77 K of frozen "solutions" containing L-Asp and VO^{2+} with a L/M ratio of 10.0. The total vanadium concentration is in the range $(1.1–1.5) \times 10^{-2}$ M. Gain and modulation are in the range $(2.5–3.2) \times 10^5$ and 1.6–3.2 depending on the spectra. pH values are indicated and ↕ represents a field marker for 4000 gauss.

coordination for those species which give rise to DI and to DIII and a $VO(N_2O_2)$ coordination for DIV.

CD and visible absorption spectra

Most visible and CD spectra for the L-Asp+VO^{2+} system differ completely from those for the systems containing L-Ala, L-Ser, L-Thr, L-Cys, D-Pen and L-Glu+VO^{2+} under similar experimental conditions.

Figure 2 includes visible spectra of L-Asp+VO^{2+} solutions with a L/M ratio of 12.9. As the pH increases, band II gradually separates from band I revealing a progressive increase in the ligand field around VO^{2+}. Although the L/M value is rather low, at pH ~ 3.4 band II is no longer a shoulder on band I. For solutions of L-Ala+VO^{2+} with L/M = 53.9 a similar situation occurs only for pH > 4.6.

Over the range $6.8 \lesssim pH \lesssim 8.5$, the spectra almost coincide and λ_{max} for bands I and II are ~740 and ~538 nm, respectively. For pH > 8.6, the increase in ε_m for $450 < \lambda < 600$ nm suggests hydrolysis of VO^{2+}.

Figures 3 and 4 include CD spectra of L-Asp+VO^{2+} solutions with L/M = 12.9. Only for $pH \lesssim 2.2$ may one observe similarities with spectra in the systems containing L-Ala, L-Ser and L-Thr+VO^{2+}.[1,2] For pH > 2.2, the spectra are completely different, which means that the type of complexes formed and their coordination geometries also differ.

In the range $6.8 \lesssim pH \lesssim 8.0$, the CD, visible and EPR spectra of solutions containing L-Asp+VO^{2+} with high L/M values coincide (Fig. 5). This probably means that 100% of oxovanadium(IV) is in the form of a single species. Its CD and visible spectra are therefore known, which simplifies the calculations with the SQUAD program.

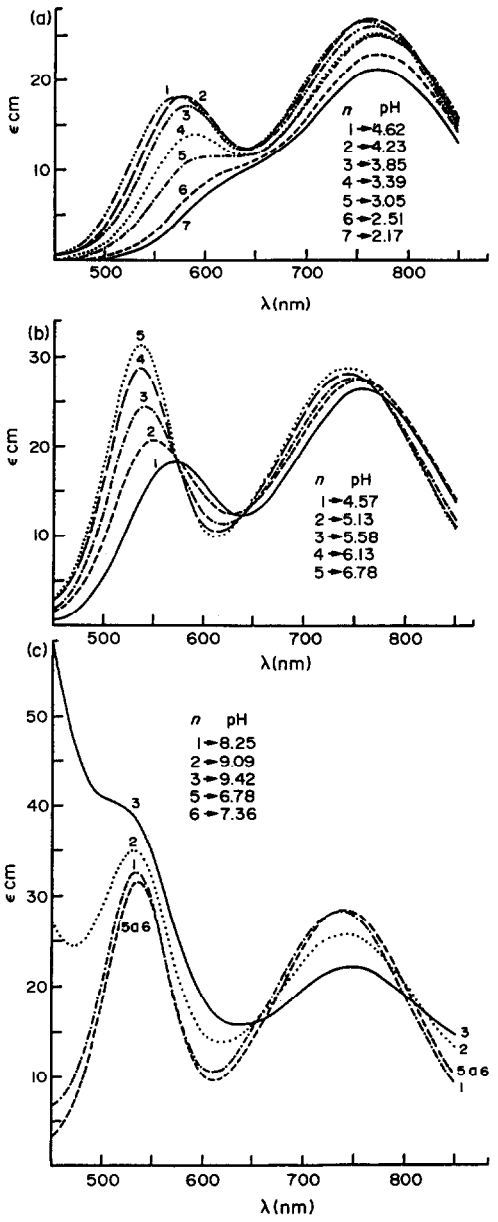

Fig. 2. Visible spectra of solutions containing L-Asp+VO^{2+} with the L/M ratio of 12.9 and $C_{VO} = (8–12) \times 10^{-3}$ M. The pH corresponding to each spectrum is indicated. The CD spectra for the same solutions are shown in Figs 3 and 4.

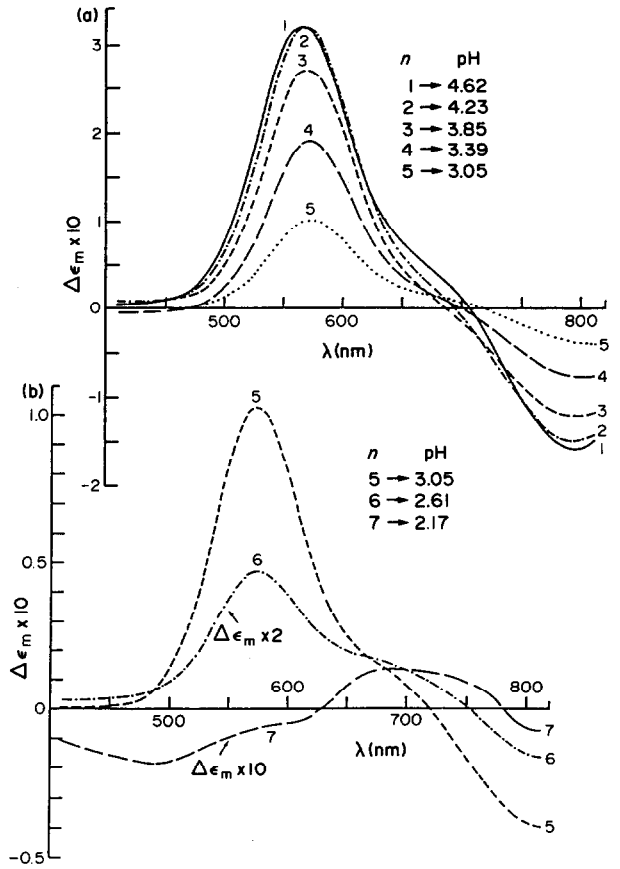

Fig. 3. Circular dichroism spectra of solutions containing L-Asp+VO^{2+} with the L/M of 12.9 and $C_{VO} = (8–12) \times 10^{-3}$ M. The isotropic absorption spectra of these solutions are shown in Fig. 2.

For pH $\gtrsim$ 11, the $\Delta\varepsilon_m$ values in the range $400 < \lambda < 800$ nm are zero; therefore no aspartate is coordinated to VO^{2+}.

Visible and CD spectra have also been recorded at fixed pH (pH = 1.6, 2.18, 3.06 and 5.4) for varying amino acid-to-vanadium ratios, and at fixed L/M values (1.0 and 2.0) varying the pH. Figures 6 and 7 include some of these spectra.

The visible spectra of solutions at pH 1.6 are similar to the spectrum of $[VO(H_2O)_5]^{2+}$ and the changes of the ε_m values as L/M increases are not pronounced. Some corresponding CD spectra are shown in Fig. 6(a). These are relatively similar to those recorded with L-Ala+VO^{2+} for pH 2.62[1] although—in the present case—the band with $\Delta\varepsilon < 0$ is relatively more important.

The visible spectra of solutions at pH 2.18 are also similar to the spectrum of $[VO(H_2O)_5]^{2+}$, but band II is more pronounced and the ε_m values increase with L/M. The corresponding CD spectra are shown in Fig. 6(b). The relative importance of the band with $\lambda_{max} \sim 700$ nm ($\Delta\varepsilon > 0$) increases with L/M. This can be explained only by the existence of at least two optically active complexes with differing L/M stoichiometry, probably 1 : 1 and 2 : 1, the 2 : 1 complex being responsible for the band with $\varepsilon_{max} \sim 700$ nm.

The visible spectra of solutions at pH 3.06 [Fig. 7(a)] change significantly as L/M increases. The corresponding CD spectra [Fig. 7(b)] manifest a general increase of the [$\Delta\varepsilon_m$] values with L/M; however the spectral profile remains the same.

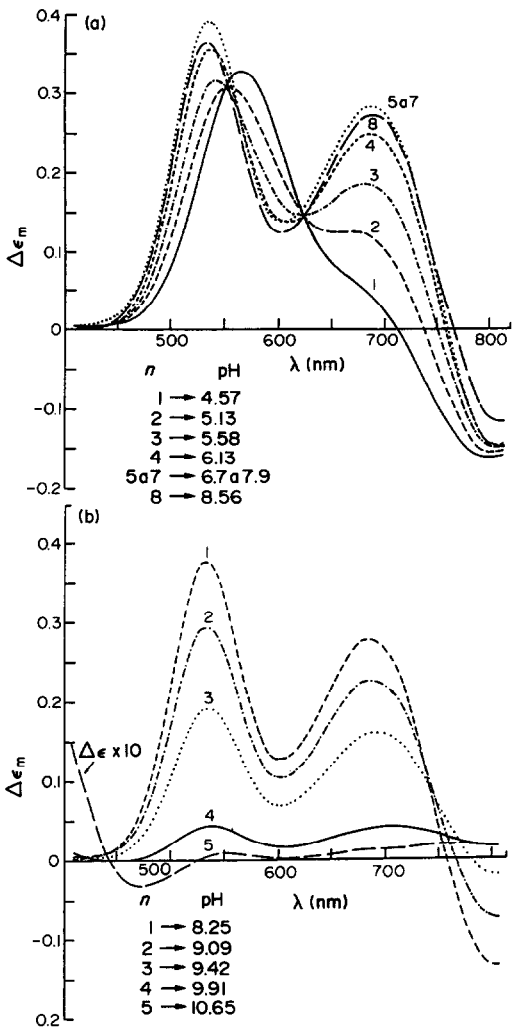

Fig. 4. Circular dichroism spectra of solutions containing L-Asp+VO^{2+} with L/M of 12.9 and $C_{VO} = (1.0–1.2) \times 10^{-2}$ M. The isotropic absorption spectra of these solutions are shown in Fig. 2.

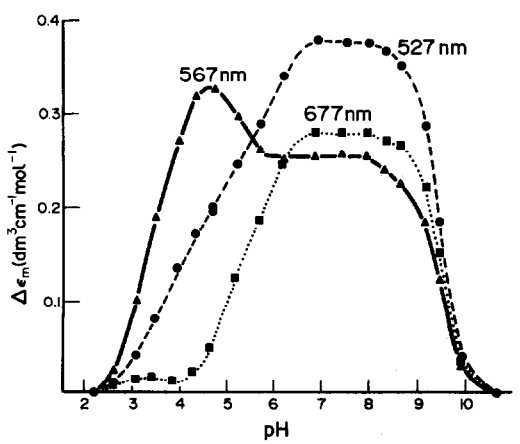

Fig. 5. Change with pH of the $\Delta\varepsilon_m$ values of L-Asp+VO^{2+} solutions with a L/M ratio of 12.9 from Figs 3 and 4 at three different wavelengths.

The visible spectra of solutions with L/M = 1 or 2 change significantly as the pH varies from 1.7 to 4; one starts with spectra similar to the spectrum of $VO(H_2O)_5^{2+}$ but values of ε_m gradually increase and bands I and II become distinct. For pH > 3, the two bands are quite distinct. For pH $\gtrsim$ 3.2, the ε_m values in the range 450 $\lesssim \lambda \lesssim$ 550 nm are greater for the solutions with L/M = 1. This effect probably results from VO^{2+} hydrolysis, $(VO)_2(OH)_2^{2+}$ being formed, which is less important for the solutions with L/M = 2. The CD spectra of the corresponding solutions with L/M = 2 are shown in Fig. 8. At pH 1.78, the CD spectrum is similar to those of Fig. 6(a) but for pH > 2 the pattern changes completely.

Several CD spectra were recorded with solutions containing L-aspartic acid-β-methyl ester and VO^{2+} in the range 1.5 $\lesssim$ pH $\lesssim$ 3.8 with a 1 : 1 mole ratio. The ester was probably partially hydrolysed and hydrolysis also took place while the spectra were being recorded. However the spectra for pH $\lesssim$ 2 may be explained assuming coordination of the α-COO^- group since they resemble those for 1 : 1 solutions of L-Ala+VO^{2+}.[1] For pH > 2, the spectra are consistent with the existence of two types of complexes (**A** and **B**) both contributing to the overall Cotton effect:

A—a VO^{2+}–L-aspartate-β-methyl ester complex with a CD spectrum similar to those obtained in the L-Ala+VO^{2+} system for pH > 2;

B—a VO^{2+}–L-aspartate complex with a CD spectrum similar to those shown in Fig. 8(b).

In spite of the ester hydrolysis, these experiments clearly show that for aspartate the β-COO^- group is certainly involved in the coordination to VO^{2+} for pH > 2.

Potentiometry

The protonation constants calculated by the MINIQUAD[10] and SUPERQUAD[11] programs practically coincide. From SUPERQUAD, for L-Asp in solutions containing 2.25 M $NaNO_3$ (at 25°C): $pK_{a1} = 2.124$, $pK_{a2} = 3.881$ and $pK_{a3} = 9.771$ values, used in all calculations.

Figure 9 shows formation curves calculated for three of the titration curves with "low" L/M values.

The EMF readings are no longer stable for pH $\gtrsim$ 4.0 and 4.6 for titration curves with L/M = 0.897 and 3.92, respectively. As for the L-Ala, L-Ser and L-Thr+VO^{2+} system under similar conditions, such instability is probably due to oxidation and/or extensive hydrolysis of oxovanadium(IV). No precipitation was detected in these cases.

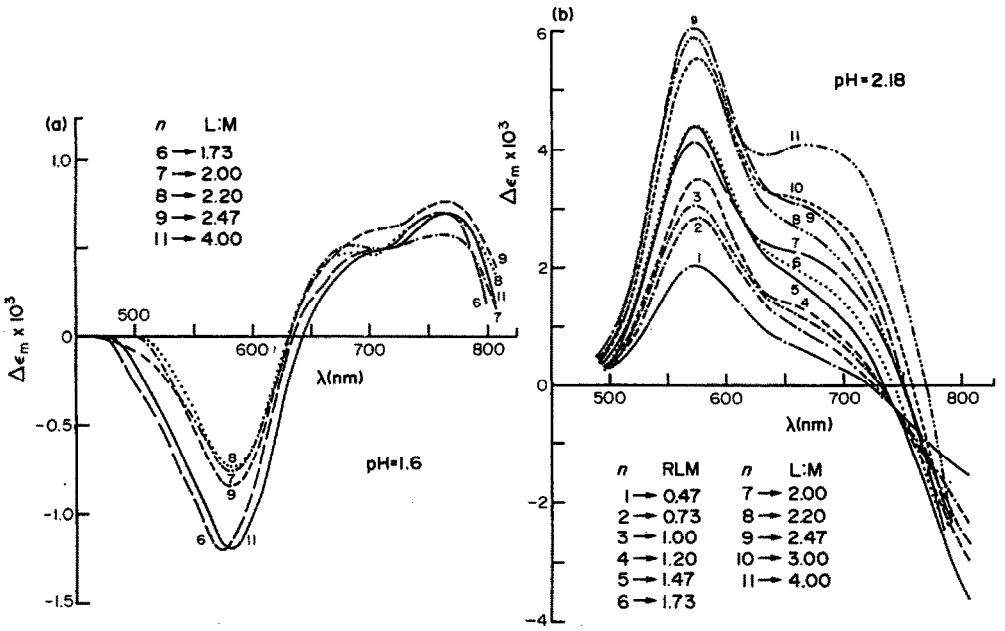

Fig. 6. Circular dichroism spectra of solutions containing L-Asp + VO^{2+} with varying L/M and fixed pH. (a) pH ~ 1.6 and $C_{VO} = (1.8–2.8) \times 10^{-2}$ M; (b) pH ~ 2.18 and $C_{VO} = (2.4–2.8) \times 10^{-2}$ M.

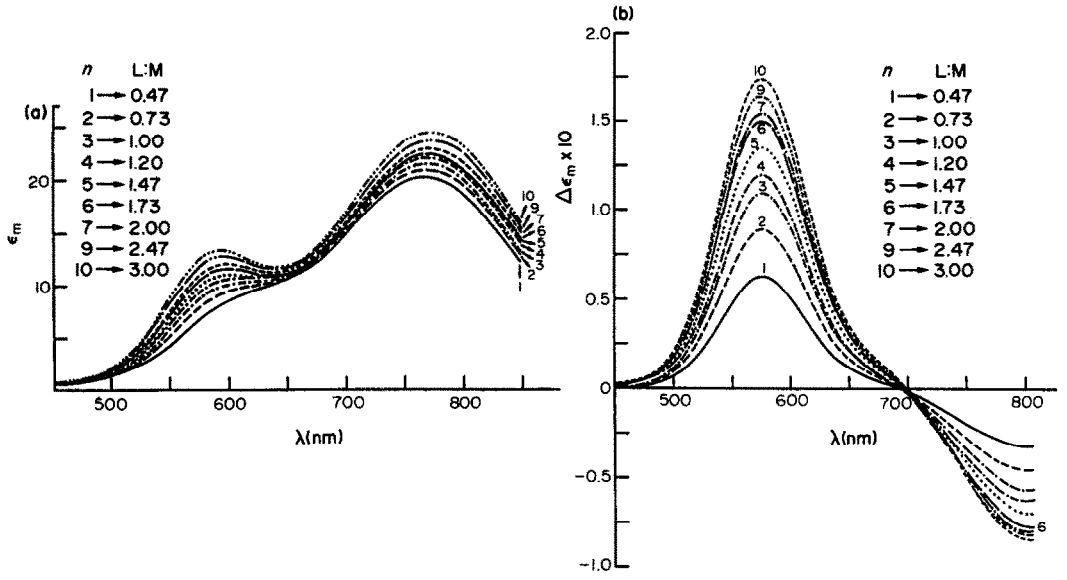

Fig. 7. Visible absorption (a) and CD spectra (b) of solutions containing L-Asp and VO^{2+} at pH 3.06 with varying L/M [$C_{VO} = (2.6–2.7) \times 10^{-2}$ M].

Comparing the formation curves in Fig. 9:

(i) The $\bar{n}$ values are higher than those calculated from titration curves in the other systems (L-Ala, L-Ser, L-Thr, L-Cys and D-Pen + VO^{2+}) in similar conditions.

(ii) For different C_{VO} and C_{Asp}, the formation curves do not coincide; this probably results from formation of protonated complexes (e.g. MDH_2, MDH, MD_2H, etc.).

(iii) Values for $\bar{n} > 1$ are obtained, which may indicate either that species like MD and MD_2H predominate, or more complex situations: e.g. MD_2H and/or M_2H_{-2} form in parallel with protonated complexes such as MD_2H_2 and MD_2H_3 (and eventually dimeric complexes).

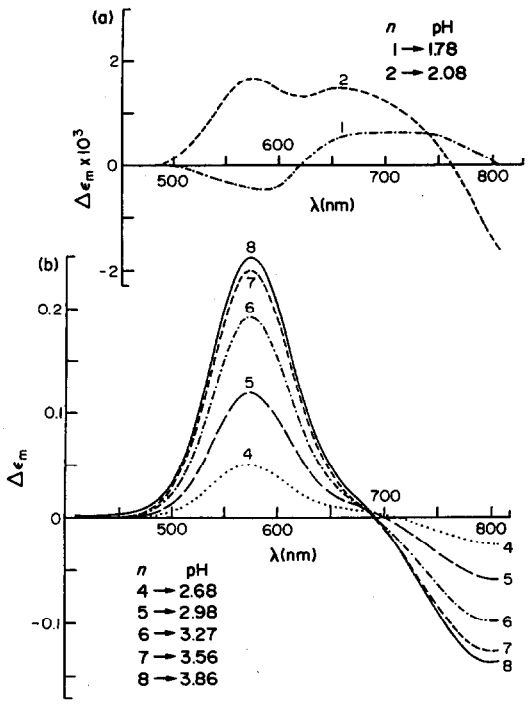

Fig. 8. Circular dichroism spectra of solutions containing L-Asp+VO^{2+} with the L/M ratio of 2.0 and $C_{VO} = (2.5–2.7) \times 10^{-2}$ M. The pH corresponding to each spectrum is indicated.

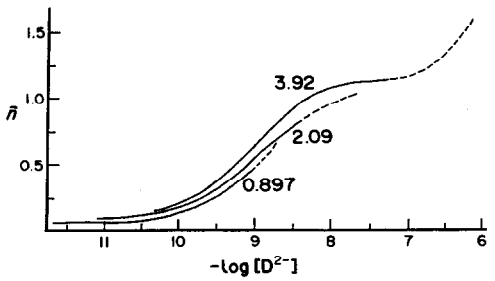

Fig. 9. Formation curves calculated for three titration curves with "low" L/M values. The dashed lines correspond to "titration points" where the EMF readings were no longer stable. The ligand-to-metal ratios are indicated.

For titration curves with "high" L/M values, $\bar{n} \sim 2.0$ for pH $\gtrsim$ 7.0. This indicates that MD_2H and MD_2 form.

Calculations

Potentiometry. Calculations involving the refinement of β_{xyz} values of all possible species (i.e. $M_xL_yH_z$ with x, y and z quite general) always gave results with no physical meaning. We therefore started with the titration curves corresponding to "low" L/M values (1–4). The results of all calculations may be summarized as follows:

(i) Consistent formation constants for MDH, MD and MD_2H are always calculated with low standard deviations for all equilibrium models tested.

(ii) Species MDH_2 is normally accepted and the corresponding $\log\beta$ is obtained with an intermediate standard deviation (SD). As for the systems with L-Ala, L-Ser, L-Thr, L-Cys, D-Pen and L-Glu+VO^{2+} [1,2,8,9] this species is important in describing the system. The sizeable SD values probably result from the L-Asp being mainly in the H_2D form in the pH range 2.2–3.5, so that no H^+ is involved in the formation of MDH_2.

(iii) Species MD_2H_4, MD_2H_3, MD_2H_2, MD_2, M_2D_2 and MDH_{-1} are accepted in some models but with a relatively high SD; in other cases they are rejected. The inclusion of any has practically no effect on the χ^2 and σ values. These species probably form but not in significant amounts in the experimental conditions used.

(iv) No other stoichiometries were accepted in any of the calculations with the SUPERQUAD program.

We conclude that only MDH_2, MDH, MD and MD_2H form in significant amounts in the conditions used to record the titration curves with "low" L/M values. Therefore we used SUPERQUAD to refine simultaneously: $\log\beta_{112}$, $\log\beta_{111}$, $\log\beta_{110}$ and $\log\beta_{121}$. Once these were calculated, the values for $\log\beta_{112}$ and $\log\beta_{111}$ were considered correct and included as fixed constants in all further calculations with MINIQUAD and SUPERQUAD. Analysing all results obtained now including all available titration curves (with high and "low" L/M values):

(i) Formation constants (β_{110} and β_{121}) for species MD and MD_2H are always derived with values practically coincident with those obtained using only the titration curves with "low" L/M values; the corresponding SD's are low.

(ii) A consistent value for the formation constant of MD_2 is always obtained with a low SD.

(iii) Species MD_2H_3 is usually accepted and β_{123} is consistently calculated with an intermediate SD, but models not including this species seem equally acceptable.

(iv) Species MDH_{-1}, M_2D_2, $M_2D_2H_{-1}$ and MDH_{-2} are normally rejected.

(v) Species MD_2H_4 and MD_2H_2 are not obtained in a consistent manner; the SD's are large and these species are frequently rejected. Probably

they do not exist in significant amounts in the experimental conditions used.

(vi) When included, species M_2D_3 is frequently accepted and the corresponding models normally have a reasonable χ^2 value.

Overall, from the calculations with MINIQUAD and SUPERQUAD, species with stoichiometries MDH_2, MDH, MD, MD_2H and MD_2 certainly exist. The potentiometric results are not clear in deciding if MD_2H_3 and/or M_2D_3 form or not. The values obtained for the formation constants of all these species, χ^2 and σ are almost unaffected whether MD_2H_2 is included or not.

From the potentiometric results we selected three models (I, II and III) included in Table 1. It is not possible to choose among these three on the sole basis of these calculations with MINIQUAD and SUPERQUAD. However, by incorporating spectroscopic results, the choice can be made.

Spectrometry. If M_2D_3 existed with log $\beta_{230} \sim 28.6$, this stoichiometry would be quite important in the pH ranges 5–9: it would then be impossible to explain why the visible and CD spectra of solutions with L/M = 12.9 do not change in the range 6.8–7.9 and why, at pH ~ 5.4, the visible and CD spectra with $7 \lesssim$ L/M $\lesssim 26$ practically coincide. Therefore, model III in Table 1 (which includes M_2D_3) is unable to explain the experimental visible and CD spectra and will not be discussed further.

In choosing between models I and II, one is deciding if MD_2H_3 exists.

As mentioned above, the CD spectra in Fig. 6(b) can only be explained if a species with an aspartate–vanadium stoichiometry of two gradually forms as L/M increases. The only 2:1 complexes that may form in significant amounts at pH ~2.2 are MD_2H_4 and MD_2H_3. Since the potentiometric results suggest that MD_2H_4 does not form in these conditions, these CD spectra indicate that MD_2H_3 should indeed be included in the equilibrium model. Furthermore, when SQUAD is used to calculate the visible or CD spectra of the several species that may exist, the SD in the absorbance data and spectra calculated and the sum of squares of the (experimental − calculated) spectra are much better for model II than for model I. Therefore MD_2H_3 must be included in the equilibrium model.

According to model II (and I), for solutions with high L/M values in the range $4.5 \lesssim$ pH $\lesssim 8$ the main stoichiometries are MD_2H and MD_2. MD and MD_2H_2 (if it is included) are in much lower concentrations. Using experimental visible and CD spectra in the range $4.5 \lesssim$ pH $\lesssim 7.8$ and $9.4 \lesssim$ L/M $\lesssim 25.7$, the visible and CD spectra for MD_2H and MD_2 may be very easily calculated with SQUAD and obtained with very low SD. These calculated spectra are included in Fig. 10.

Once these visible (and CD) spectra of MD_2H and MD_2 are known, they can be considered as fixed and included in the input file of SQUAD, to

Table 1. Compositions and formation constants of the species in the L-Asp+VO^{2+} system, assuming various equilibrium models (I–III) and for L-Asp+Cu^{2+} system (IV and V). Values for log β_{xyz} of eq. (1) are given[a]

	Species	I	II	III	IV[b]	V[c]
1	MDH_2	15.55	15.55	15.55	12.48	—
2	MDH	12.56	12.56	12.56	8.80	12.82
3	MD	9.05	9.05 (0.03)	9.05	—	9.08
4	MD_2H	21.49	21.49 (0.02)	21.49	—	21.21
5	MD_2	16.25	16.25 (0.2)	16.25	15.96	16.25
6	MD_2H_3	[d]	27.77 (0.3)	[e]	—	—
7	M_2D_3	[d]	[d]	28.6 (0.2)	—	—
8	MD_2H_2	[d]	24–25	[d]	—	25.15
9	MD_2H_4	[d]	29	[d]	—	—
10	M_2D_2	[d]	19–20	[d]	—	—
11	MDH_{-1}	[d]	2–3	[d]	—	—

[a] In the L-Asp+VO^{2+} system species 1–5 certainly form. Species 8–11 are not necessary to explain the experimental potentiometric results.

[b] From ref. 26 (T = 25°C and I = 0.2 M in KCl).

[c] From ref. 25 (T = 25°C and I = 0.10 M in KNO_3).

[d] Not included in calculations on this model.

[e] If β_{123} is included as a constant to be refined it is accepted with log $\beta_{123} \sim 27.8$; β_{123}, σ and χ^2 are not greatly affected by this.

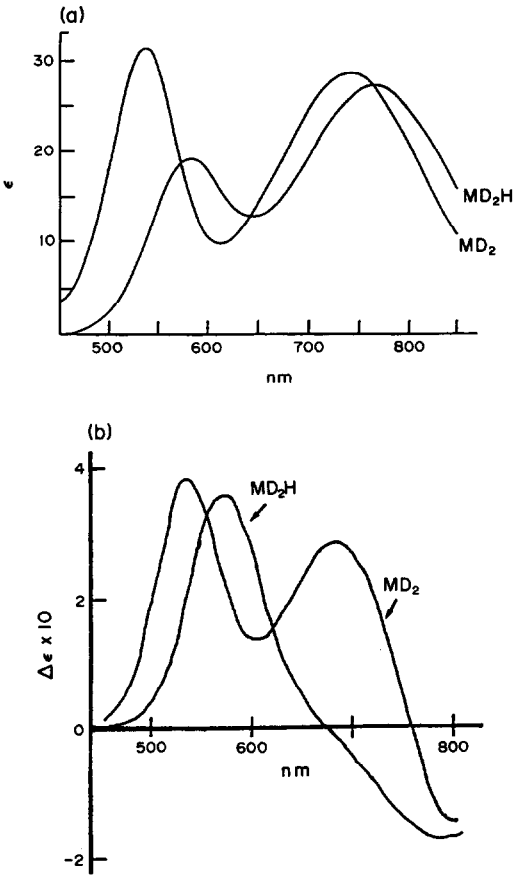

Fig. 10. Visible absorption (a) and CD (b) spectra (calculated using the SQUAD[10] program) for species MD_2H and MD_2, using the formation constants in model II—Table 1, and experimental visible and CD spectra in the pH and L/M ranges 4.5–7.8 and 9.4–25.7, respectively.

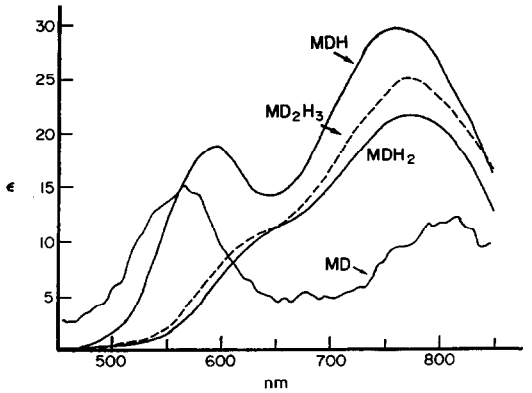

Fig. 11. Visible absorption spectra (calculated using the SQUAD[10] program) for species MDH_2, MDH, MD and MD_2H_3 using the formation constants in model II—Table 1, and experimental visible spectra in the pH and L/M ranges 1.6–3.9 and 0.47–12.9, respectively. The SD of the calculated ε_{xyz} values follow the order: $\varepsilon_{110} \gg \varepsilon_{111} > \varepsilon_{123}, \varepsilon_{112}$. As for Figs 10 and 12, all spectra are represented exactly as they were obtained using SQUAD. For MD the irregularities do not represent vibrational structure but are the result of the high SD associated with the ε_{110} values.

help calculate the visible (and CD) spectra of the species that predominate in the range $1.5 \lesssim pH \lesssim 4$. The problem is not simple; this is a rather narrow range of pH and the spectra of the four species MDH_2, MDH, MD_2H and MD_2H_3 must be calculated. Further, MDH and MD_2H_3 have "parallel concentrations" (i.e. their concentration ratio is constant).

While the ε_{xyz} values for several species in the range $450 < \lambda < 850$ nm all have the same order of magnitude, the $\Delta\varepsilon_{xyz}$ values may be quite different and for a given solution the contribution to the experimental $\Delta\varepsilon_m$ values of a species that exists in a low concentration may be as important as the contribution of another species that exists in high concentration. Therefore small errors in the formation constants may introduce large errors in the calculated $\Delta\varepsilon_{xyz}$ values.

This probably accounts for the fact that—while for the visible spectra the results are quite satisfactory and the calculated visible spectra are reasonably well defined (except for MD (Fig. 11), where the SD of the ε_{110} values are relatively high)—the results for the CD spectra are not so good.

The calculated CD spectra show differences as the pH range of the experimental spectra included is expanded from $1.6 \lesssim pH \lesssim 3$ to $1.6 \lesssim pH \lesssim 3.9$. In fact, while the CD spectra of MDH_2, MDH and MD_2H_3 are calculated in a consistent manner and with relatively low SD values (Fig. 12), the spectrum for MD is calculated with very high $\Delta\varepsilon_{110}$ and SD values. The SD's of the calculated $\Delta\varepsilon_{111}$ values are always intermediate between those of $\Delta\varepsilon_{112}$, $\Delta\varepsilon_{123}$ and those of $\Delta\varepsilon_{110}$. If the pH of the experimental spectra included is <3.4 then spectrum MD(1) in Fig. 12 is obtained. However, if the experimental spectra up to pH 3.9 are also used, the spectrum derived for MD changes (spectrum MD(2) in Fig. 12).

DISCUSSION

Speciation

The equilibrium model—the set of species that should be included to explain all the experimental potentiometric and spectroscopic results (with plausible values for their formation constants)—is contained in Table 1 (model II). For low L/M ratios, other complex species might possibly be important.

Figure 13 gives the concentration distribution

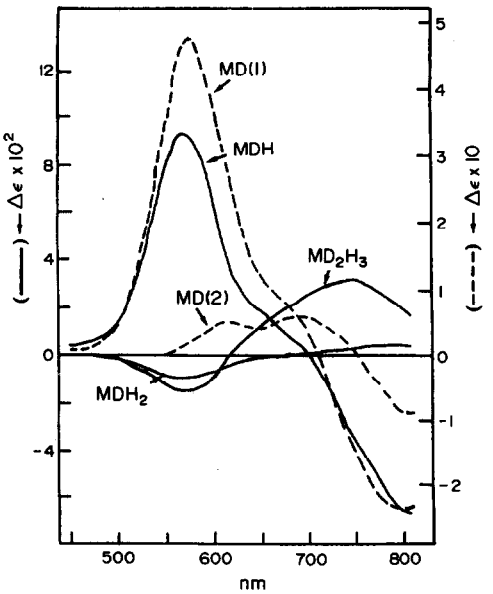

Fig. 12. Circular dichroism spectra (calculated using the SQUAD[10] program) for species MDH_2, MDH, MD and MD_2H_3 using the formation constants in model II—Table 1, and experimental CD spectra in the pH and L/M ranges 1.6–3.9 and 0.47–12.9, respectively. The SD of the calculated $\Delta\varepsilon_{xyz}$ values follow the order: $\Delta\varepsilon_{110} \gg \Delta\varepsilon_{111} > \Delta\varepsilon_{123}$, $\Delta\varepsilon_{112}$. The $\Delta\varepsilon_{xyz}$ values should only be considered as an order of magnitude and are not exact values.

calculated for L/M = 12.9 and a total oxovanadium(IV) concentration of 0.01 M.

As the pK_a values of α- and β-COOH are relatively low and VO^{2+} has a strong affinity for oxygen-containing ligands,[14,15] the complexes that form generally differ from those in the systems containing VO^{2+} with L-Ala, L-Ser, L-Thr, L-Cys, D-Pen and L-Glu.[1,2,8,9] Besides, and exceptionally in the present case, a relatively low L/M ratio (e.g. 10) is adequate to avoid precipitation of $VO(OH)_2 \cdot xH_2O$ and/or extensive hydrolysis of the Asp–VO^{2+} complexes.

The experimental CD spectra obtained in the range $3 \lesssim pH \lesssim 4.6$ and the MD_2H spectrum calculated are relatively similar to those recorded in the L-malate+VO^{2+} system[16] with L/M = 38 in the range $3 \lesssim pH \lesssim 5$. The only differences are:

(i) bands I and II in the L-malate+VO^{2+} system are observed at ~745 and 550 nm, respectively, and

(ii) the pattern of the CD bands are (+, +, −) in the L-Asp+VO^{2+} system and (+, −) (or probably: +, −, −) in the L-Mal+VO^{2+} system, the separation of the d_{xz}, d_{yz} levels being greater in the former system.

On a semi-quantitative basis, the concentration distribution shown explains the evolution of the visible and CD spectra of Figs 2–8, i.e. that the spectra are unchanged in the pH range 6.8–8.0.

For solutions with L/M = 12.9, Fig. 13 shows that for $pH \gtrsim 3$ the MD_2H stoichiometry begins to predominate. $|\Delta\varepsilon_{121}|$ is high, explaining why there is such a rapid evolution of the CD spectra in the pH range 2–4.

We emphasize that the contribution of MD_2H to the CD spectra is so pronounced that we can not eliminate the possibility that a small error in β_{121} or in the pH of the solutions may result in incorrectly calculated CD spectra for MDH and MD (similar to the dominant spectrum of MD_2H).

In solutions containing L-Asp+VO^{2+} with

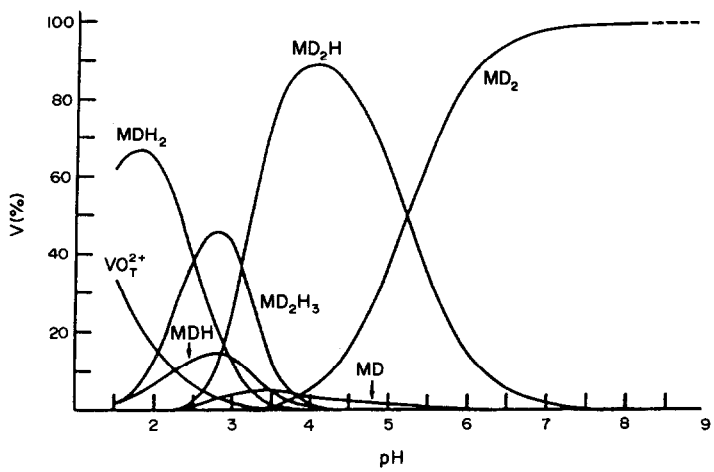

Fig. 13. Concentration distributions of the complexes formed in the VO^{2+} + L-Asp system in solutions with C_{VO} = 0.01 M and L/M = 12.9, calculated using the β_{xyz} values of model II—Table 1. The EPR components abbreviated as DIII and DIV in Fig. 1, correspond to MD_2H and MD_2 stoichiometries, respectively.

L/M = 12.9, the hydrolysis of MD_2 starts for pH $\gtrsim$ 8 and for pH $\gtrsim$ 10.5 there is almost no aspartate coordinated to oxovanadium(IV). Apart from a slight shift of band I to longer wavelengths as the pH increases, for pH $\lesssim$ 10 nothing suggests the formation of intermediate species in the "complete" hydrolysis of MD_2.

In the pH range 8–10, there is a drastic decrease of the $|\Delta\varepsilon_m|$ values but for 450 $\lesssim \lambda \lesssim$ 750 nm the type of spectra recorded is always the same. This suggests that hydrolysis of MD_2 may involve an intermediate (e.g. MD_2H_{-1}) with the same coordination geometry in the equatorial plane. For the solutions with L/M = 12.9 there is no indication of any complex with a stoichiometry MDH_{-n}. If this does occur, its $\Delta\varepsilon_{11-n}$ must be such that its contribution to the observed CD spectra is not obvious.

On a quantitative basis, the visible and CD spectra calculated by SQUAD using the formation constants of Table 1 and the visible and CD spectra of Figs 10–12 practically coincide with the corresponding experimental spectra.

Structures

A most valuable indication of structure for each $M_xD_yH_z$ species in the L-Asp + VO^{2+} system comes from comparison of its measured β, visible and CD spectra with those obtained or estimated for other systems. We consider four possible modes of coordination:

Group 1—the α-COO^- group (aspartate acting as a monodentate ligand) and/or both α-COO^- and $-NH_2$ groups (aspartate bidentate). Comparison should be with the L-Ala[1] and/or L-Ser[2] + VO^{2+} systems.

Group 2—the α-COO^- and β-COO^- groups. Ideally, comparison should be with the system succinate + VO^{2+},[17–19] where a seven-membered ring is also involved. However, those are EPR results and mainly qualitative; we may more usefully compare our results with the malonate + VO^{2+} systems.[20]

Group 3—the NH_2 and β-COO^- groups: a six-membered ring may form. Ideally, comparisons should be made with results obtained from the β-Ala + VO^{2+} system.

Group 4—L-Asp acting as a tridentate ligand. Comparisons to give predicted formation constants are difficult, because there are so few results from other L-Asp + M systems (e.g. M = Cu^{2+}) or other VO^{2+} systems with suitable ligands.

Virtually no information is available from visible and CD spectra of suitable VO^{2+} complexes except for the L-Ala[1] and L-Ser[2] + VO^{2+} systems. We will therefore compare available values of β_{xyz}, defined as in eq. (1). We first estimate values of β_{xyz} for each possible structure to compare with those in Table 1.

To compare with the L-Ser + VO^{2+} system, one should consider

$$xM + yL' + zH^+ \overset{\beta'_{xyz}}{\rightleftharpoons} M_xL'_yH_z, \qquad (2)$$

where $L' = NH_2CH(CH_2COOH)COO^-$.

To compare with dicarboxylate systems,[19,20] we must consider:

$$xM + yL^* + zH^+ \overset{\beta^*_{xyz}}{\rightleftharpoons} M_xL^*_yH_z, \qquad (3)$$

where $L^* = NH_3^+CH(CH_2COO^-)COO^-$.

For structures of group 1 complexes, the linear plot based on the pK_a (NH_3^+) and pK_a (α-COOH) provides estimated constants (included in Table 2) $\log\beta'_{xyz}$ (Asp) from each known $\log\beta_{xyz}$ (Ser)[2] for the $M_xS_yH_z$.

A similar plot based on the pK_a's of the R-COOH

Table 2. Estimation of formation constants for aspartato–VO^{2+} complexes with a coordination geometry similar to complexes formed in the L-Ser + VO^{2+} system

$M_xS_yH_z$[a] stoichiometry	$\log\beta_{xyz}$ (L-ser)[b]	$\log\beta'_{xyz}$ estimated	Calculation of β_{xyz} (L-asp)[c]	$\log\beta_{xyz}$ estimated	$M_xD_yH_z$ stoichiometry

ML_2H_{-1}	2.56	2.0	$\beta^* \times (K_{a3})^{-2}$	21.5	MD_2H

[a] In this context, L = malonate^{2-} or succinate^{2-}.
[b] All log β's for malonate except the one with succinate.
[c] $pK_{a3} = pK_a(NH^+_3) = 9.77$.

groups gives estimated constants β^*_{xyz} (included in Table 3) for aspartato complexes with "group 2" structures similar to the succinato[19]– or malonato[20]–VO^{2+} complexes.

To estimate the constants which would correspond to aspartato–VO^{2+} structures of group 3 requires the unknown β_{xyz} for the system β-Ala+VO^{2+}. We use values for Cu^{2+} or Ni^{2+}.[21] Here, β_{110} (L-Ala)/β_{110} (β-Ala) ~ 10 and β_{120} (L-Ala)/β_{120} (β-Ala) ~ 10^2, so we estimate log β_{111} ~ 9.5 and log β_{122} ~ 17.4 for complexes of VO^{2+} coordinating via the β-COO^- and —NH_2 groups.

We now discuss (on the basis of Figs 14 and 15) the structures for each stoichiometry in model II—Table 1. Potentiometry alone cannot distinguish between different structures of the same stoichiometry, except in favourable cases. Table 4 includes possible structures for each stoichiometry $M_xD_yH_z$ and the corresponding estimated β_{xyz}.

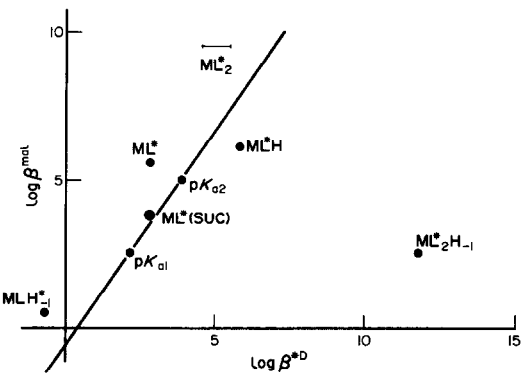

Fig. 15. Representation of $\log \beta_{xyz}$(Mal) vs $\log \beta^*_{xyz}$(L-Asp). The β^*_{xyz}(L-Asp) are defined according to eq. (3) and were obtained multiplying the β_{xyz} values by $(K_{a3})^{-y}$. The straight line is based solely on the pK_a of the COOH groups of the two ligands.

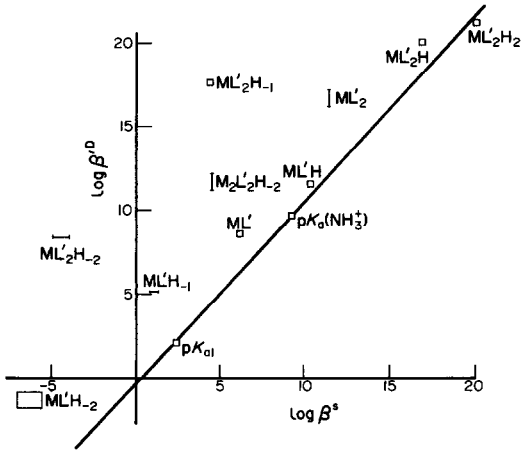

Fig. 14. Representation of $\log \beta'_{xyz}$(L-Asp vs $\log \beta_{xyz}$(L-Ser).[2] The β'_{xyz}(L-Asp) are defined according to eq. (2) and were obtained by multiplying the β_{xyz} values by $(K_{a2})^{-y}$. The straight line is based solely on the pK_a(α-COOH) and $pK_a(NH^+_3)$ values for the amino acids.

MDH_2. This stoichiometry probably has the α-COO^- group equatorial. Writing the formation as

$$VO^{2+} + nH_2D \rightleftharpoons VO(H_2D)^{2+}_n, \qquad (4)$$

K_1 ~ 78, higher than for Gly (14.8),[22] L-Ala (15.6),[1] L-Ser (12.5) and L-Thr (12.9).[2] The point [log β'_{112} (Asp), log β_{111} (Ser)] in Fig. 14 is slightly above the line. Higher values of K_1 (300–480) have also been obtained for the 1:1 complex VO^{2+}–lactate, another case where coordination involving only the R-COO^- group is expected.[23,24]

The visible spectra of MD_2 for L-Ala,[1] L-Ser,[2] and L-Asp are alike. However, the CD spectrum (Fig. 12) is different and is like that of the bidentate 1:1 L-alaninate (MA stoichiometry). This CD spec-

trum and the high value of K_1 suggest either that another complex should be included in the model (e.g. with MD_2H_4 stoichiometry) or that in $VO(H_2D)(H_2O)_n^{2+}$ (i.e. MDH_2) there is some favourable interaction of the β-COOH group with a coordinated water molecule, stabilizing a structure "similar" to that of a bidentate amino acid.

We give our reasons for preferring the latter explanation, i.e. for excluding MD_2H_4, which would correspond to two aspartate ligands coordinated via the α-COO^-.

In the L-Ala,[1] L-Ser and L-Thr[2] + VO^{2+} systems (and[25] in L-lactic acid + VO^{2+}) the corresponding species have been considered to exist. In the L-Asp + VO^{2+} system, a value for β_{124} has been refined in some models but with a high SD and much less consistently. It is possible to calculate potentiometric formation constants for the stoichiometries MDH_2 and especially for MD_2H_4 only because in this pH range part of the aspartic acid exists as H_3D^+. MD_2H_4 does not form in significant concentrations in our conditions. For conditions which would favour MD_2H_4 (pH ~ 2, L/M = 12.9), MDH and MD_2H_3 are quite important and probably "repress" its formation.

MDH. This corresponds to MA and MS stoichiometries in the L-Ala and L-Ser + VO^{2+} systems. However, the visible spectrum and especially the CD spectrum (Figs 11 and 12) are quite different from those for MA[1] and MS;[2] thus the structure of MDH is different.

Table 4 includes its possible structures. The point [log β_{110} (Suc), log β_{111} (Asp)] is near the line in Fig. 15. The EPR spectra also suggest a $VO(O_4)$ coordination geometry in this pH range. Thus all the results indicate that the MDH stoichiometry involves complexes with the α- and β-COO^- groups coordinated, both probably equatorial.

While MDH_2 and MD_2H_4 have not been included in equilibrium models for the L-Asp + Cu^{2+} system, CuDH is normally considered.[25-27]

MD_2H_3. The visible spectrum (Fig. 11) is similar to that of $[VO(H_2O)_5]^{2+}$. However, its CD spectrum differs from that expected for structure[1,2] **XXVII** implied by this and $|\Delta\varepsilon_{123}| \gg |\Delta\varepsilon_{112}|$.

The estimated formation constants for **XII** and **XIII** (Table 4) would be ~24.8 and 28. Our measured log β_{123} = 27.77 favouring **XIII** and the EPR spectra where MD_2H_3 is one of the most important species indicate $VO(O_4)$ coordination. However, structures such as **XXVIII** and **XXIX** cannot be ruled out.

MD. This is never important in any solutions used for spectra. Visible and CD spectra MD(1) are ill-defined but mutually consistent: λ_{max} (visible) are ~560 and 810 nm, and in the CD spectrum, ~570 ($\Delta\varepsilon > 0$) and ~800 ($\Delta\varepsilon > 0$).

Some plausible structures **VII–IX** are included in Table 4. We choose **IX** by elimination. Structure **VII** is similar to those of MA and MS. The CD for MD differs completely from those for MA[1] and MS[2] and the point [log β'_{110} (Asp), log β_{111} (Ser)] (Fig. 14) is well above the line, so **VII**, the structure for MA and MS, is not correct for MD.

For **VIII**, the estimated formation constant is too low. In Fig. 15, the point [log β_{111}(Mal), log β^*_{110} (Asp)] is well above the line, i.e. the structures for VO(Mal) and VO(Asp) differ. Structure **IX** is likely because it has an estimated formation constant close to that measured for β_{110}(Asp) suggesting that aspartate is tridentate. Other donor atoms could of course be coordinated equatorial.

Tridentate coordination of aspartate is familiar elsewhere. The formation constant of Cu(Asp) is considerably greater than those of Cu(Gly) and Cu(norvalinate), evidence for tridentate coordination,[26] although NMR relaxation suggested that aspartate interacted through —NH_2 and β-COO^- groups.[28] Several solid Cu^{2+} and Ni^{2+} complexes e.g. $[Cu(L\text{-}Asp)(Im)]\cdot 2H_2O$,[29] $[Cu(L\text{-}Asp)(Phen)(H_2O)]\cdot 4H_2O$,[30] $[Ni(L\text{-}Asp)(H_2O)_2]$[31] and $[Ni(L\text{-}Asp)(Im)_3]$,[32] contain terdentate aspartate, where Im = imidazole and Phen = 1,10-phenanthroline.

MD_2H_2. Structures are included in Table 4 with estimated formation constants. The log β_{122} for some models is ~24–25, suggesting that if MD_2H_2 does form, it does not involve N_2O_2 equatorial coordination.

The point [log β_{120}(Mal), log β^*_{122}(Asp)] in Fig. 15 is well above the line, so the structures in solution of $VO(Mal)_2^{2-}$ and $VO(HAsp)_2$ (if it forms) differ. Solid $(H_2tmen)\cdot[VO(Mal)_2(H_2O)]\cdot 2H_2O$[33] ($H_2tmen$ = N,N,N′,N′-tetramethylethylenediamine)

		(XXVI)	(?)	$\beta^{XXVIII} > \beta^{XXV}$ (?)

[a] There is no published formation constant for β_{120}(succinate); $\log\beta$ for **XV** was therefore estimated assuming $(\beta_{120}(\text{malonate})/\beta_{120}(\text{succinate}) \simeq [\beta_{110}(\text{malonate})/\beta_{110}(\text{succinate})]^2$.

[b] $pK_{a1}{}^{c}$, $pK_{a2}{}^{c}$ and pK_{a3} are the dissociation constants of coordinated aspartic acid (coordination involving the other groups), which we assume to be ~2, ~3 and ~8, respectively. If the dissociation of the coordinated ligand is followed by the coordination of that group, we assume that the corresponding $\log\beta$ increases by 2–3 units.

[c] The measured formation constants (Table 1, model II) are written as $\log\beta$ alongside the stoichiometry of the macro-species to which they refer.

[d] For many stoichiometries, and particularly for species involving chelated L-aspartate, the orientation of the oxygen of oxovanadium relative to the substituents on the asymmetric carbon atom of the chelated amino acid gives further isomeric possibilities: we discuss these elsewhere but pay no heed to them here.

[a] Approximate asymmetry factor calculated for each band according to: $\Delta\varepsilon$ (at λ_{max})/ε (at λ_{max}).

[b] The g and A parameters for the EPR components abbreviated as DI and DII are not sufficiently different to be distinguished as distinct peaks. As pH increases the peaks corresponding to $A_{\parallel} = 5/2$ and $7/2$ gradually shift to lower strength and no clear concordance can be established.

[c] Two types of spectra [(1) and (2)] were obtained for MD (see Fig. 12). The λ and $\Delta\varepsilon$ were calculated with quite high SD.

[d] Two bands of opposite sign are observed in the CD spectrum; these partly cancel.

[e] In the experimental conditions corresponding to the speciation of Fig. 13, from which these electronic spectra were derived, MD would not be detected in the EPR spectra.

contains the oxygens of the COO^- groups in equatorial positions, though this is not necessarily relevant to the solution geometry of the ion.

Brookes and Pettit[25] included the MD_2H_2 stoichiometry in the equilibrium model for the L-Asp+Cu^{2+} system, but earlier potentiometric work[26,27] did not. In the L-Ala,[1] L-Ser and L-Thr[2]+VO^{2+} systems, the corresponding species is the most important in the pH ranges 5–7 for solutions with high L/M ratios, and probably involves an equatorial N_2O_2 coordination. However, in the L-Asp+VO^{2+} system, species of this stoichiometry are apparently unimportant in our conditions.

MD_2H. MD_2H is the most important stoichiometry in the pH range 3–6 with L/M = 12.9 (Fig. 13), and has EPR spectrum DIII. Some possible structures for MD_2H are included in Table 4. The CD spectrum of MD_2H (Fig. 10) differs completely from those for MA_2[1] and MS_2.[2] Thus, the EPR spectra, and the β_{121} value eliminate **XVIII**. Structures **XXX** and **XXXI** cannot be utterly ruled out, although the other structures **XIX–XXI** involving terdentate aspartate seem more plausible.

MD_2 (giving DIV in EPR). This is the most important stoichiometry in the pH range 6–9 with L/M = 12.9 (Fig. 13). Its values of $g_\parallel$ and $A_\parallel$ suggest a N_2O_2 equatorial coordination. Band II in its visible spectrum is at 537 nm, lower than for MD_2H, so the ligand field increases from MD_2H to MD_2 (consistent with the EPR spectra): equatorial coordination of one or two R—NH_2 groups is certainly involved; structures like **XXIII** may be ruled out.

Its CD spectrum (Fig. 10) shows three bands (450–800 nm). The splitting of the d_{xz},d_{yz} levels is thus clearly observed, partly because one transition has $\Delta\varepsilon > 0$ and the other $\Delta\varepsilon < 0$ (and cf. Table 5). In the isotropic spectrum, two bands only are observed, with band I broader than band II, as usual. The splitting in the CD spectrum suggests that the equatorial coordination does not involve *cis* ligands. This effect has been seen in the visible spectrum, in low symmetry complexes involving other coordinating groups,[15] but the perturbation in ligand field induced here by the coordination of R—COO^- and R—NH_2 groups is probably not so large.

(*Received* 27 *February* 1989; *accepted* 16 *August* 1989)

Abstract—The kinetics of the oxidation of Co^{II}DTPA (DTPA = diethylenetriaminepentaacetate) by periodate in acetate buffer showed the formation of a long-lived intermediate. The formation of the intermediate exhibited a first-order dependence on the Co^{II} complex concentration. The variation of the pseudo-first-order rate constant, k_{obs}, with periodate concentration at constant $[H^+]$, $[CH_3CO_2^-]$, ionic strength and temperature, is governed by eq. (i):

$$k_{obs} = \frac{a[IO_4^-]^2}{b + c[IO_4^-]}. \quad \text{(i)}$$

The decrease in the magnitude of k_{obs} with increasing acetate ion concentration seems to be due to its coordination with the Co^{II} complex. The value of k_{obs} increases with decreasing pH, indicating that the protonated form of the Co^{II} complex is the more reactive species. A mechanism consistent with the kinetic results is proposed.

Oxidation of organic substrates by periodate ion proceeds through the formation of cyclic intermediates when bridging groups (e.g. OH, NH_2 and CO) are in the 1,2-positions.[1] Oxygen atom transfer with the formation of HOI as an intermediate was invoked in periodate oxidation of the iodide ion.[2] Thus, it seems that periodate oxidations proceed via an inner-sphere mechanism.

Inner-sphere electron-transfer was also suggested in the reactions of the aqua-ions vanadium(IV)[3] and iron(II)[4] and some (aminopolycarboxylato) cobalt(II) complexes with periodate. The formation of intermediates in the iron(II),[4] $[Co^{II}EDTA]^{2-}$ (EDTA = ethylenediaminetetraacetate),[5] $[Co^{II}HEDTA]^-$ [HEDTA = N-(2-hydroxyethyl)ethylenediaminetriacetate],[6] Co^{II}EDDA (EDDA = ethylenediaminediacetate)[6] and $[Co^{II}NTA]^-$ (NTA = nitrilotriacetate)[7] oxidations lends support to this mechanism. Additional support for this mechanism may also be drawn from a consideration of the rate laws for the oxidation of $[Co^{II}EDTA]^{2-}$, $[Co^{II}HEDTA]^-$ and Co^{II}EDDA. The rate law for the $[Co^{II}EDTA]^{2-}/IO_4^-$ reaction requires a rapid equilibrium preceding the slow intramolecular electron-transfer step. The kinetics of the oxidation of both $[Co^{II}HEDTA]^-$ and Co^{II}EDDA by IO_4^- proceed by two parallel pathways;[6] one first-order in each reactant and the other first-order in each cobalt(II) complex and second-order in the oxidant concentration. The pathway which is first-order in each reactant concentration, almost certainly, proceeds via an inner-sphere electron-transfer process. This is necessitated by the pathway showing a second-order dependence on $[IO_4^-]$ since a rapid pre-equilibrium between both $[Co^{II}HEDTA]^-$ and Co^{II}EDDA with IO_4^- is required to account for the termolecular reaction.[8]

The second-order dependence on the reductant concentration observed in periodate oxidation of $Cr(H_2O)_6^{3+}$ [9] and in one pathway of $Fe(H_2O)_6^{2+}$,[4] where two one-electron-transfers in a single activated complex were proposed, seems to support an inner-sphere mechanism. Two-electron-transfer is believed to be obtained by way of this mechanism.

* Author to whom correspondence should be addressed.

A common mechanism for the oxidation of aminopolycarboxylatocobalt(II) complexes is further supported by an excellent isokinetic relationship obtained on plotting composite $\Delta H^{\ddagger}$ vs composite $\Delta S^{\ddagger}$.[7] The composite $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values contain contributions from the pre-equilibrium step between periodate and the cobalt(II) complexes as well as from the intramolecular electron-transfer step.

In this study we report the kinetics of the oxidation of (diethylenetriaminepentaacetato) cobaltate(II), $Co^{II}DTPA$, by periodate. This study furnishes direct kinetic evidence for inner-sphere oxidation by periodate.

EXPERIMENTAL

Materials and solutions

Reagent grade sodium metaperiodate was used for preparing fresh solutions by weight and these were wrapped with aluminium foil to avoid photochemical decomposition.[10] Cobalt(II) nitrate was standardized against EDTA volumetrically.[11] A stock solution of the ligand, DTPA, was prepared as the disodium salt by weighing the acid and neutralizing with the appropriate amount of sodium hydroxide. Sodium acetate and sodium nitrate solutions were prepared by weight from reagent grade chemicals. A stock solution of acetic acid was made up by dilution and standardized against sodium hydroxide.

Apparatus

A Unicam SP 8000 spectrophotometer equipped with thermostatted cell holders was used for recording the UV–vis absorption spectrum of the product of oxidation of $Co^{II}DTPA$ and for monitoring the change in absorbance of the product as a function of time. The pH of the reaction was measured using a Radiometer digital pH meter model PHM 62.

Kinetics measurements

The kinetics of oxidation of $Co^{II}DTPA$ by IO_4^- was carried out under pseudo-first-order conditions with $[IO_4^-] \geqslant 20\,[Co^{II}DTPA]$. $Co^{II}DTPA$ solutions were made up by adding a 10% excess of the ligand to the Co^{II} solution immediately before each kinetic run as this complex was reported to be air sensitive.[12] However, over the pH 4–5 range, where the kinetics of the reactions were investigated, no significant air oxidation of the cobalt(II) complex was observed.

The formation of the intermediate was followed either at 564 nm or at 380 nm, where appreciable changes in absorbance were observed. The final absorbance (A_∞) was constant at each of these wavelengths for a period of 30 min and decreased by 0.01 units absorbance 1 h after the reaction was complete at 564 nm. The conversion of the Co^{III} intermediate was not studied in detail.

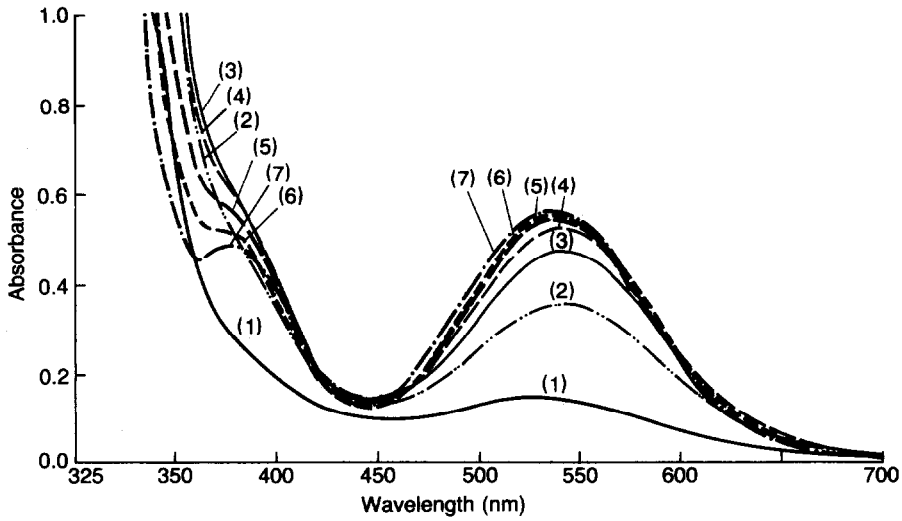

Fig. 1. Change in absorbance as a function of time. Curves 1–6 were recorded at 3, 6, 10, 16, 28 and 60 min, respectively, from the time of starting the reaction. Curve 7 shows the absorbance of the final Co^{III} product. $[Co^{II}DTPA] = 5.0 \times 10^{-4}$ M, $[IO_4^-] = 0.03$ M, pH = 4.10, $\mu = 0.55$ M and $T = 25°C$ (4 cm path length).

Reaction product

The UV–vis absorption spectrum of the oxidation of $Co^{II}DTPA$ by periodate is shown in Fig. 1. It is evident from this spectrum that this reaction proceeds via the formation of an intermediate which is slowly converted to a final product. A similar behaviour was found in the oxidation of $[Co^{II}EDTA]^{2-}$, $[Co^{II}HEDTA]^{-}$, $Co^{II}EDDA$ and $[Co^{II}NTA]^{-}$ by the same oxidant.[5-7] The final product showed two peaks at 377 and 538 nm. These peaks are almost identical to those exhibited by $[Co^{III}(HEDTA)(H_2O)]$[6] and it thus seems that the final product of the oxidation of $Co^{II}DTPA$ by periodate has a pentacoordinated DTPA.

RESULTS

Figure 1 shows that the oxidation of $Co^{II}DTPA$ by periodate leads to the formation of an intermediate Co^{III} product which slowly converts to the final Co^{III} product at pH 4.10. The final product is fully formed when the reaction solution is left overnight.

Under conditions of a large excess of $[IO_4^-]$ at fixed pH, ionic strength and temperature, plots of $\ln(A_\infty - A_t)$ against time were linear up to $\geqslant 90\%$ of reaction (correlation coefficient >0.99). The results in Table 1 show that the magnitude of the pseudo-first-order rate constant, k_{obs}, does not vary with the initial concentration of the Co^{II} complex. A first-order dependence on $[Co^{II}DTPA]_T$ is deduced. The magnitude of k_{obs} was not affected by changes of the wavelength at which the reaction was followed.

Table 2 shows that the variation of k_{obs} with $[IO_4^-]$ is not linear. A plot of $k_{obs}/[IO_4^-]$ vs $[IO_4^-]$, using the results in Table 2, is curved. However, a plot of $[IO_4^-]/k_{obs}$ vs $[IO_4^-]^{-1}$ is linear with an intercept, as shown in Fig. 2. The dependence of k_{obs} on $[IO_4^-]$ is consistent with eq. (1) which can be rearranged to the form of eq. (2):

$$k_{obs} = \frac{a[IO_4^-]^2}{b + c[IO_4^-]} \quad (1)$$

$$[IO_4^-]/k_{obs} = \frac{c}{a} + \frac{b}{a[IO_4^-]}. \quad (2)$$

From eq. (2) and Fig. 2 it could be shown that the intercept is $I = c/a$ and the slope is $S = b/a$. The values of I and S were calculated, using a linear least-squares fit to eq. (2), as 8.77 ± 0.16 M s and $(8.64 \pm 0.17) \times 10^{-2}$ M^2 s, respectively, at pH 4.52, $[CH_3CO_2^-] = 0.50$ M, $\mu = 0.55$ M and $T = 25.0°C$.

The results in Table 3 show that k_{obs} decreases with increasing pH. The decrease in k_{obs} over the pH 4.0–4.5 range is very small. At pH $\geqslant 5$, however, the value of k_{obs} was greatly decreased. From plots

	3.0	1.81±0.02
	4.0	2.45±0.02
	5.0	3.15±0.04

[a] $[Co^{II}DTPA]_T = 5.0 \times 10^{-4}$ M, $\mu = 0.55$ M, $[CH_3CO_2^-] = 0.50$ M, $T = 25.0$°C.

similar to that in Fig. 2, the values of I and S at different pH values were calculated and these are collected in Table 4. A plot of I vs $[H^+]^{-1}$, shown in Fig. 3, was found to be linear with an intercept $I_1 = 6.34 \pm 0.18$ M s and a slope, $S_1 = (7.60 \pm 0.30) \times 10^{-5}$ M^2 s.

The effect of the acetate ion on the reaction rate was investigated over the concentration range 0.10–0.50 M at fixed reaction conditions. The results in Table 5 show that k_{obs} decreases with increasing acetate ion concentration. The variation of k_{obs} with $[CH_3CO_2^-]$ is governed by eq. (3), where a plot of $1/k_{obs}$ vs $[CH_3CO_2^-]$ is linear:

$$1/k_{obs} = 1/k^0 + 1/k'[CH_3CO_2^-]. \quad (3)$$

The values of $1/k^0$ and $1/k'$ at various periodate

DISCUSSION

The oxidation of Co^{II}DTPA by periodate proceeds via the formation of an intermediate Co^{III} product as is evident from Fig. 1. This behaviour is analogous to that observed in the oxidation of the Co^{II} complexes of EDTA,[5] HEDTA,[6] EDDA[6] and NTA[7] by the same oxidant. The intermediate Co^{III} product of the oxidation of Co^{II}DTPA converts to the final product with a half-life >3 h.

The structure of Co^{II} complexes of DTPA in solution, until recently, has not been reported. It was shown by an NMR study that the three nitrogens of deprotonated DTPA coordinate to Co^{II} and that proton addition decreases the number of coordinated nitrogens.[13] This is in agreement with the structure proposed by Chabarek *et al.*[14] for Cu^{II} DTPA complexes, where three nitrogens and one carboxylate group coordinate in the unprotonated form and two nitrogens and two carboxylate groups coordinate in the protonated form. Huchital and Hodges[12] proposed that in the unprotonated form of the Co^{II} complex, three nitrogens and three carboxylate groups are bound to the metal ion as shown in Fig. 4(A). Protonation of this complex, it is believed, would occur at a terminal nitrogen resulting in the formation of a free iminodiacetate group, leaving only two nitrogens and three carboxylate groups coordinated to Co^{II} as in Fig. 4(B). The sixth coordination site would be occupied by a water molecule. The two forms, (A) and (B), are in equilibrium with each other with an acid dissociation constant $\sim 10^{-5}$ M.[12]

The protonated form (B), of the Co^{II}DTPA complex seems to be the reactive species since the magnitude of the pseudo-first order rate constant decreased with increasing pH. The unprotonated form reacts very slowly with periodate. The decrease in the value of k_{obs} with increasing acetate ion concentration most likely arises from coordination of this ion with the protonated form (B) by replacing the water molecule. Substitution of a coordinated H_2O by an acetate ion was reported in the $[Co^{II}(NTA)(H_2O)_2]^-$ complex.[7]

A mechanism for the oxidation of Co^{II}DTPA by IO_4^- could be described by the reaction scheme in eqs (4)–(8):

$$[Co^{II}DTPA]^{3-} + H^+ \rightleftharpoons [Co^{II}(DTPAH)(H_2O)]^{2-} \quad K_a \quad (4)$$

$$[Co^{II}(DTPAH)(H_2O)]^{2-} + CH_3CO_2^- \rightleftharpoons [Co^{II}(DTPAH)(CH_3CO_2)]^{3-} + H_2O \quad K_1 \quad (5)$$

$$[Co^{II}(DTPAH)(H_2O)]^{2-} + IO_4^- \rightleftharpoons [Co^{II}(DTPAH)(IO_4)]^{3-} + H_2O \quad K_2 \quad (6)$$

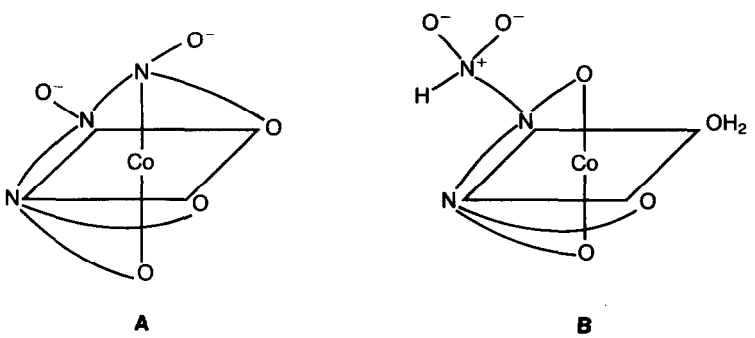

Fig. 4. Structural forms of Co^{II}DTPA complexes.

$$[Co^{II}(DTPAH)(IO_4)]^{3-} + IO_4^- \rightleftharpoons [Co^{II}(DTPAH)(IO_4)_2]^{4-} \quad K_3 \quad (7)$$

$$[Co^{II}(DTPAH)(IO_4)_2]^{4-} \rightarrow [(DTPAH)(IO_4)Co^{III}—I^{VI}]^{4-}. \quad k_{et} \quad (8)$$

In this mechanism it is assumed that the species $[Co^{II}(DTPAH)(IO_4)]^{3-}$ has a negligible contribution towards the formation of an intermediate Co^{II} product. Separate kinetic runs at pH ~ 6, where the hexacoordinated form (A) is the dominant species, are extremely slow. It could therefore be concluded that a reaction pathway involving form (A) and IO_4^- is of minor importance. The formation of $[Co^{II}(DTPAH)(IO_4)_2]^{4-}$ requires that in addition to the replacement of H_2O, an acetate group be set free with DTPA functioning as a tetradentate ligand. Inner-sphere electron-transfer is supported by the formation of the intermediate which exhibited high absorption below 400 nm. This high absorption may arise from ligand-to-metal (LTM) charge-transfer, in this case I^{VI} to Co^{III}. An outer-sphere electron-transfer between $[Co^{II}(DTPAH)(IO_4)]^{3-}$ and IO_4^- is not expected to show the formation of an intermediate with LTM charge-transfer. The I^{VI} in the intermediate would be coordinated to Co^{III} via an oxygen atom. Second-order dependence on $[IO_4^-]$ is not unique to this system; it was found in the oxidation of $[Co^{II}HEDTA]^-$,[6] $Co^{II}EDDA$[6] and V^{IV}.[15]

The rate law given in eq. (9) is derived from the above mechanism assuming that K_3 is small:

$$\frac{d[Co^{III}]}{dt} = \frac{k_{et}K_aK_2K_3[H^+][Co^{II}]_T[IO_4^-]^2}{1+K_a[H^+]+(K_1+K_1K_a[H^+])[CH_3CO_2^-]+(K_2+K_2K_a[H^+])[IO_4^-]^-}. \quad (9)$$

The dependence of k_{obs} on $[IO_4^-]$, $[H^+]$ and $[CH_3CO_2^-]$ is given in eq. (10),

$$k_{obs} = \frac{k_{et}K_aK_2K_3[H^+][IO_4^-]^2}{1+K_a[H^+]+(K_1+K_1[H^+])[CH_3CO_2^-]+(K_2+K_2K_a[H^+])[IO_4^-]}. \quad (10)$$

At fixed $[H^+]$ and $[CH_3CO_2^-]$, eq. (10) could be rearranged to the form of eq. (11) which is identical to the experimental form of eq. (2),

$$[IO_4^-]/k_{obs} = \frac{K_2+K_2K_a[H^+]}{k_{et}K_aK_2K_3[H^+]} + \frac{1+K_a[H^+]+(K_1+K_1K_a[H^+])[CH_3CO_2^-]}{k_{et}K_aK_2K_3[H^+][IO_4^-]}. \quad (11)$$

From eqs (2) and (11) it can be shown that the plot of $[IO_4^-]/k_{obs}$ vs $[IO_4^-]^{-1}$ should be linear with an intercept and a slope given by eqs (12) and (13), respectively:

$$\text{Intercept} = I = c/a = \frac{1+K_a[H^+]}{k_{et}K_aK_3[H^+]} \quad (12)$$

$$\text{Slope} = S = b/a = \frac{1+K_a[H^+]+(K_1+K_1K_a[H^+])[CH_3CO_2^-]}{k_{et}K_aK_2K_3[H^+]}. \quad (13)$$

The variation of the intercept, I, with $[H^+]$ is given by eq. (14) which is consistent with the variation of I with $[H^+]$ shown in Fig. 3:

$$I = \frac{1}{k_{et}K_3} + \frac{1}{k_{et}K_aK_3[H^+]}. \quad (14)$$

From eq. (14) a plot of I vs $[H^+]^{-1}$ gives an intercept $I_1 = 1/k_{et}K_3$ and a slope, $S_1 = 1/k_{et}K_aK_3$. The value of K_a, the protonation constant for the $Co^{II}DTPA$ complex, is calculated from I_1/S_1 as $(8.34 \pm 0.3) \times 10^4$ M^{-1} which is in excellent agreement with the pK_a value of 4.92 reported for this complex.[12]

Equation (10) could be rearranged to the form of eq. (15) which would account for the linear dependence of $1/k_{obs}$ on $[CH_3CO_2^-]$ at fixed $[IO_4^-]$ and $[H^+]$.

$$1/k_{obs} = \frac{1+K_a[H^+]+(K_2+K_aK_2[H^+])[IO_4^-]}{k_{et}K_aK_2K_3[H^+][IO_4^-]^2} + \frac{(K_1+K_1K_a[H^+])[CH_3CO_2^-]}{k_{et}K_aK_2K_3[H^+][IO_4^-]^2}. \quad (15)$$

A comparison of eqs (3) and (15) shows that:

$$k^0 = \frac{k_{et}K_aK_2K_3[H^+][IO_4^-]^2}{1+K_a[H^+]+(K_2+K_aK_2[H^+])[IO_4^-]} \quad (16)$$

and

$$k' = \frac{k_{et}K_aK_2K_3[H^+][IO_4^-]^2}{(K_1+K_1K_a[H^+])}. \quad (17)$$

From eq. (16) a plot of $[IO_4^-]/k^0$ vs $[IO_4^-]^{-1}$ should be linear with an intercept I_2 and a slope S_2 given in eqs (18) and (19), respectively:

$$\text{Intercept} = I_2 = \frac{1+K_a[H^+]}{k_{et}K_aK_3[H^+]} \quad (18)$$

$$\text{Slope} = S_2 = \frac{1+K_a[H^+]}{k_{et}K_aK_2K_3[H^+]}. \quad (19)$$

The magnitude of K_2 is obtained from I_2/S_2 as

372 ± 37, 146 ± 15 and 99 ± 6 M^{-1} at 25, 20 and 15°C, respectively. The decrease in the value K_2 with decreasing temperature indicates that entry of the periodate ion is an endothermic process. From the slope of the plot k' vs $[IO_4^-]^2$ of eq. (17) and S_2 of eq. (19) the value of K_1 is calculated as ~ 8 M^{-1} at 25°C. Nearly the same value is obtained when the same slope is used with eq. (18) and substituting K_2 as 372 M^{-1} at 25°C.

In the reaction of $Co^{II}DTPA$ with $Fe^{III}(CN)_6^{3-}$ it was proposed that form (B) does not decompose to final products.[12] In the reaction reported here, however, the conversion of the intermediate to the final product may occur via the coordination of free carboxylate group at one site and by a water molecule at the other. Thus, I^{VII} or I^{VI} may be attacked by a water molecule and hydrolysis takes place without Co—O bond cleavage. Periodate is known to exchange oxygen atoms with water quite rapidly.[16]

A PM3 SCF–MO STUDY OF THE STRUCTURE AND BONDING IN THE CAGE SYSTEMS S_4N_4 AND S_4N_4X ($X = N^+$, N^-, S, N_2S, P^+, C, Si, B^- AND Al^-)

HENRY S. RZEPA* and J. DEREK WOOLLINS

Department of Chemistry, Imperial College, London SW7 2AY, U.K.

(*Received* 6 *April* 1989; *accepted* 16 *August* 1989)

Abstract—Short S—S interactions in S_4N_4 and related S···S bridged systems S_4N_4X ($X = N^+$, N^-, N_2S, S, P^+, B^-) are rationalized in terms of localized orbitals derived using the PM3 semi-empirical SCF–MO method. Two localized orbitals which correspond to an S—S single bond and to one of the two lone pairs on X can be identified when the bridging group is associated with six valence electrons ($X = N^-$, S). In contrast, two valence isomers are found for the four electron substitutents ($X = N^+$, P^+, C, Si, B^- and Al^-) which differ in having *either* an S—S bond (the closed form) *or* a lone pair on X (the open form). As the electronegativity of X decreases, the closed form is increasingly favoured in energy, being the lowest energy isomer for $X = B^-$, Al^- or Si. Unusual structures with X = Si and Al^- in particular are predicted.

In both the gas and the solid state, tetrasulphur tetranitride (S_4N_4) exists in a cage geometry of D_{2d} symmetry, involving a square-planar arrangement of nitrogen atoms and an approximately tetrahedral arrangement of sulphur atoms exhibiting significant S—S bonding interactions.[1] The bonding in S_4N_4 specifically has been discussed in many papers, of which a particularly appropriate explanation involving a localized orbital approach is that due to Gopinathan and Whitehead,[2] and subsequently discussed by Palmer.[3] A related series of cage molecules S_4N_4X is known[1] which can be considered to be derived from S_4N_4 by bridging one of the two S···S bonds with $X = N^-$, N_2S or N^+. In these compounds, the remaining S—S bonding interaction is retained with the first two substituents but is entirely lost with $X = N^+$. In this paper, we extend such an approach to these cage systems, employing the PM3 semi-empirical SCF–MO method,[4] and investigating a range of four and six electron substituents X.

RESULTS AND DISCUSSION

A number of theoretical analyses of S_4N_4 and related molecules have been reported at *ab initio* and semi-empirical SCF–MO levels.[2,3] Gopinathan and Whitehead[2] were the first to analyse an SCF–MO wavefunction in terms of localized orbitals using the CNDO–BW method and similar subsequent calculations at the *ab initio* level gave essentially the same result.[3] These studies established several features of the bonding in S_4N_4. Importantly, the inclusion of *d*-orbitals in the basis set was found not to be necessary unless a quantitative description of the molecular geometry is required, and would not be expected to modify any bonding scheme qualitatively.[3] Thus *s*/*p* basis orbital localization schemes indicated that of the 44 valence electrons in S_4N_4, 16 occupy the eight S—N bonds, eight correspond to sulphur lone pairs, 16 to two lone pairs each on nitrogen and four to two S—S bonds (resonance structure **1**). A further refinement which is not obvious from a resonance structure such as **1** is that the two lone pairs on nitrogen are actually quite different in character, one of these overlapping with the two adjacent sulphur atoms to give appreciable p_π–p_π S=N=S double bond character. This scheme provides a rationalization for the relatively short experimental S—S distance of 2.58 Å observed for S_4N_4.

We wished to extend this analysis to molecules of the type S_4N_4X. However, the Gopinathan and Whitehead CNDO–BW procedure was applied

* Author to whom correspondence should be addressed.

without geometry optimization, and so cannot be used to predict molecular geometries and relative enthalpies of formation of new species for which no molecular structure is available. Geometry optimization at the *ab initio* level would in turn require considerable computer resources for such species. Recently a new semi-empirical SCF–MO procedure termed PM3 has been reported[4] which is computationally much faster than the *ab initio* level and which is reported to reproduce both the energies and molecular geometries of a wide range of "hypervalent" compounds. The method represents a significant advance over older semi-empirical procedures such as MNDO, but is based only on the use of an *s/p* orbital basis set. For this reason, we wished to establish firstly that PM3 yields a similar interpretation of the bonding in S_4N_4 to that described above and, if so, to use this technique to investigate the series of cage molecules S_4N_4X.

(i) *The parent molecule* S_4N_4

At the PM3 level, the parent molecule S_4N_4 is a stable minimum with D_{2d} symmetry, the calculated Hessian matrix having only positive eigenvalues.[5] This compares with the results obtained using the earlier MNDO method, which predicted this structure not to be a stable minimum.[6] Somewhat surprisingly, the "inverse" structure in which the four nitrogen atoms are tetrahedral is 29.4 kcal mol^{-1} lower in energy using PM3, a result not obtained at, for example, the *ab initio* level.[3] This particular failing may be associated with the tendency of nitrogen in the PM3 parametrization to significantly underestimate rotational barriers in species such as amides.[5] For comparison between systems containing the same number of S—N bonds, such an error might be expected to cancel. The PM3 calculated S···S bonding and S···S edge distances for the "normal" isomer of S_4N_4 are similar to the experimental values (Table 1), with the calculated S—N distances (1.69 Å) being longer than those observed (1.59 Å), but nevertheless significantly shorter than typical calculated S—N single bond lengths.

The scheme introduced by Perkins and Stewart[7] was used to obtain localized orbitals. In this terminology, a localization index (LI) of 1.0 indicates a one-centre (lone pair) orbital, and a value of 2.0 a two-centre covalent bond. Our results using PM3 are in complete agreement with earlier treatments,[2,3] showing S_4N_4 to have one lone pair orbital localized almost entirely (LI $\leqslant$ 1.11) on each of the S and N atoms and eight S—N covalent σ type orbitals (LI $\sim$ 2.1). Four of the remaining 12 electrons are associated with two S—S localized orbitals (LI $\sim$ 2.1). The last eight electrons correspond to four further nitrogen lone pairs, but with a value of the localization index (1.37) that indicates significant π type interactions with *two* adjacent sulphur atoms and hence partial p_π–p_π S=N=S bonding. A σ/π partitioning of the PM3 wavefunction[5] also confirms this result, with predicted S—N π bond orders of 0.24. The associated short S—S distance is due to compression by the SNS unit, rather than to specific S—S bonding.

(ii) *The six electron groups* $X = N^-$, S, N_2S

The predicted PM3 structures for S_4N_4X also reproduce the known trends in bond lengths (Table 1). With $X = N^-$ and particularly for N_2S, shorter S···S distances than in S_4N_4 are predicted. The largest discrepancy with experiment is for $X = N^-$, where all six S—S edges are known to have similar lengths, whereas the calculation predicts two sets of values differing by 0.43 Å. Localized orbital analysis of these systems for the six electron substituents, $X = N^-$, S and N_2S, reveals in each case one S—S localized orbital of the type found for S_4N_4 and π

Table 1. Calculated PM3 properties for S_4N_4 and S_4N_4X

X	None	N^+	N^-	S	N_2S
ΔH_f[a]	81.0	268.4	−14.3	85.5	70.3
S—S[b]	2.638 (2.58)	4.393 (4.01)	2.492 (2.73)	2.480	2.430 (2.43)
S—S_{edge}[c]	2.878 (2.69)	3.077 (2.81)	2.923 (2.71)	2.966	3.007
Localized Orbital[d]	1.375 (85.0)	1.866 (68.5)	1.221 (90.4)	1.262 (88.9)	1.259 (89.0)

[a] Standard calculated heat of formation, in kcal mol^{-1}.

[b] S—S distance, in Å. Experimental values are given in parentheses.

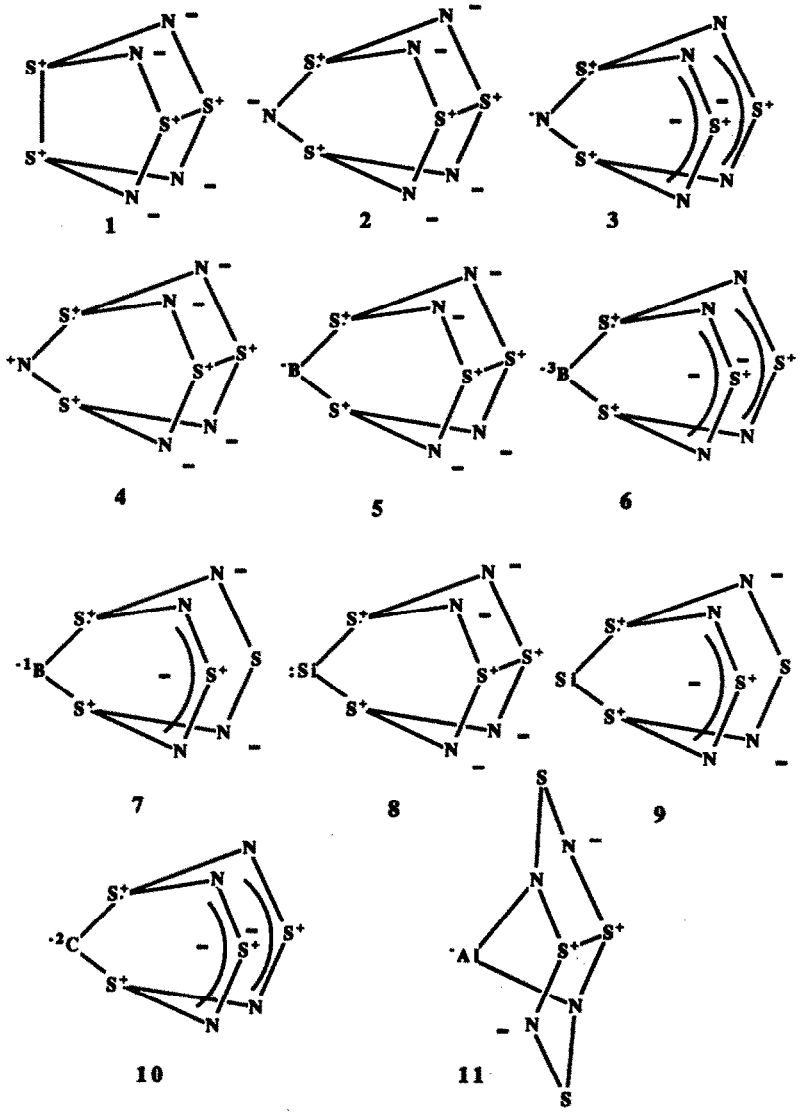
[d] Localization index of highest energy localized orbital.[7] Percentage contribution from nitrogen is given in parentheses.



type lone pairs on each nitrogen atom, as well as two lone pairs (for $X = N^-$) for the bridging group. This corresponds approximately to resonance structure **2**. The six electrons associated with, for example, $X = N^-$, plus the two electrons from the adjacent S—S bond result in eight valence electrons for group X, leaving the remaining S—S bond intact.

(iii) *The four electron groups* $X = N^+$, P^+, C, Si, B^-, Al^-

For the known substitutent $X = N^+$, the S—S bond length is correctly predicted to correspond to a long non-bonding interaction (Table 1). Unlike $X = N^-$, no S—S localized orbital is revealed with $X = N^+$ and what were largely four nitrogen lone pairs in S_4N_4 become essentially four two-centre orbitals (LI = 1.87) corresponding to S=N π bonds (Table 1). These S—N bonds are calculated (1.60 Å) to be significantly shorter than the length in S_4N_4 itself. As with $X = N^-$, a localized lone pair on the bridging "N^+" substituent is found and the bonding can be approximated by **3**. Electron counting indicates that the N^+ substituent has only four valence electrons, which together with the two electrons from the adjacent S—S bond would give a bridging six electron nitrenium ion. The electronegativity of such a group is clearly greater than that of the remaining S—S bond, and hence the two electrons associated with this bond are transferred to the N^+ to increase the valence electrons of X to eight. The S—S region no longer has two associated electrons, and the resultant S—S bond length is typical of a non-bonding interaction.

This analysis raises the possibility that these two electrons may partition either on group X, or between the S—S region, but not both! We were indeed able to locate a series of second stationary points for a range of four electron groups (Fig. 1).

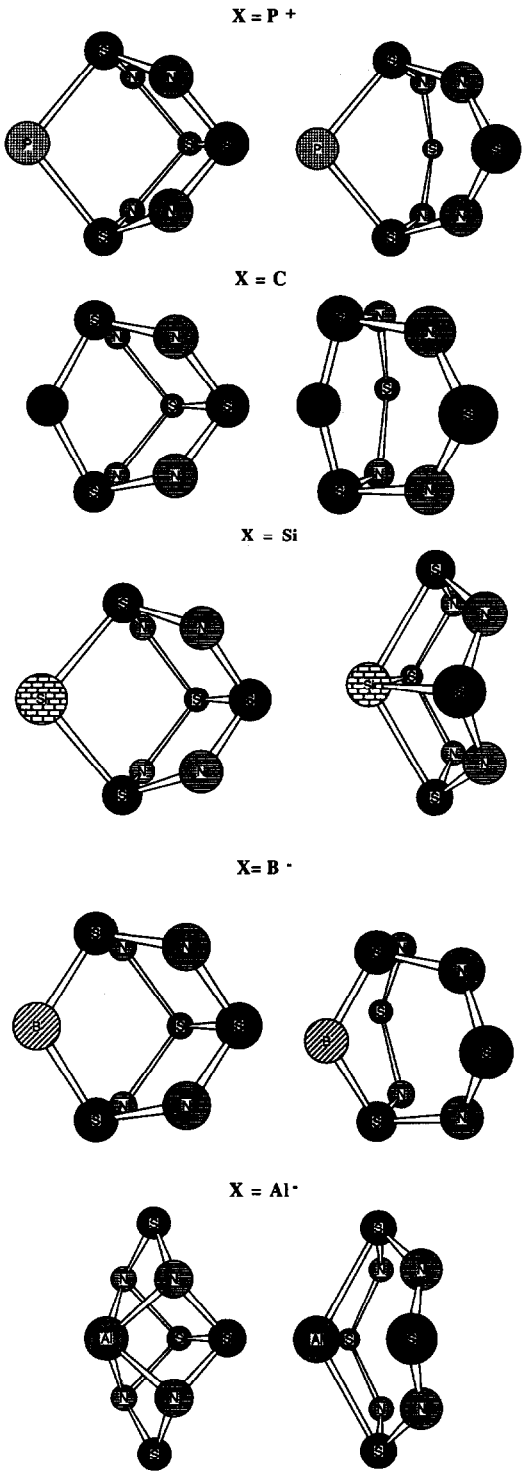


Fig. 1. Structural forms of the cyclic systems S_4N_4X.

That for $X = N^+$ (Table 2) has localized orbitals which show the presence only of an S—S single bond and no second nitrogen lone pair. However, the energy of this "closed" valence isomer is sufficiently high that it is unlikely to be experimentally accessible. This does raise the possibility that less electronegative bridging groups than N^+ might result in the alternative valence isomers being more stable. For example, the analogue $X = P^+$ shows a much smaller energy difference between the two valence isomers (Table 2). With the isoelectronic group $X = B^-$, the stability reverses completely, and the isomer **5** containing an S—S bond is predicted to be *more* stable than the open form. If the analogy with $X = N^+$ were to be followed, this open form would have a formal 3^- charge on the boron as in **6**. However, the localized orbitals show not two but *one* lone pair on boron, corresponding to the alternative resonance form **7**. No minimum corresponding to **6** could be located. Indeed the calculated boron charge for **7** reveals only a small negative value (−0.33). Presumably, the low nuclear charge on boron cannot compensate for the considerable electron repulsion resulting from two adjacent lone pairs in **6**. A similar situation is predicted for the neutral group X = Si, where the closed form **8** is closely analogous to divalent silylene systems, and represents an interesing candidate for isolation. The open form with X = Si has only one localized lone pair giving a formally six electron silicon species. However, the structure of this open form is quite different from the B^- analogue (Fig. 1), with four equal weak ($r_{Si—S}$ 2.47 Å) bonds predicted to each sulphur atom and overall four-fold symmetry corresponding to two or more equal contributions from resonance forms such as **9**. With the substituent X = C, the closed isomer is in fact the high energy form, consistent with the known relative instability of carbenes relative to the silylenes. The open isomer in this case actually corresponds to an eight electron carbon, with a calculated charge on this atom of −1.80 and, as such, is unlikely to represent an isolable species. The Al^-

Table 2. Relative PM3 calculated energies of open and closed forms for S_4N_4X with four electron bridging groups X

X	ΔH_{Closed}[a]	ΔH_{Open}[b]
N^+	98.7 (2.65)	0.0 (4.39) [268.4]
P^+	32.4 (2.54)	0.0 (4.36) [293.1]
C	49.6 (2.50)	0.0 (4.35) [142.1]
Si	−7.8 (2.44)	0.0 (4.24) [118.4]
B^-	−7.8 (2.45)	0.0 (4.67) [62.2]
Al^-	−7.3 (2.44)	0.0 (4.39) [−81.4]

[a] Energy relative to open form, in kcal mol^{-1}. The S—S bond distances are given in parentheses in Å.

[b] Enthalpy of formation of open isomer in square brackets.

homologue has a similar electronic structure for the open form, with a calculated charge of −1.25 on Al. The closed isomer however adopts another unique geometry, with four equal Al—N bonds (2.017 Å) corresponding to an average of resonance forms such as **11**.

In conclusion, we have shown that analysis of the unusual bonding in these types of third period caged compounds, using a combination of the PM3 SCF–MO procedure and orbital localization schemes, can result in valuable insight into the bonding of such species and the prediction of unusual geometries for several of the substituents.

Acknowledgement—We thank the SERC for the award of a grant for graphics equipment, including a Vaxstation 3200, on which all the calculations were performed.

KINETICS OF OXIDATION OF ASCORBIC ACID BY OCTACYANOMOLYBDATE(V) IN AQUEOUS METHANOL—A COMPARATIVE STUDY

R. A. EL-ZARU* and H. A. HODALI

Department of Chemistry, Faculty of Science, University of Jordan, Amman, Jordan

(*Received* 24 *April* 1989; *accepted* 17 *August* 1989)

Abstract—The oxidation of ascorbic acid (AH_2) by octacyanomolybdate(V) in a buffered acidic aqueous methanolic medium has been studied and compared with that of hexacyanoferrate(III) and octacyanotungstate(V). The reaction has been found to be first-order with respect to both oxidant concentration and ascorbic acid concentration. The dependence on acidity suggested a rate law of the form:

$$-d[OX]/2dt = (k_a + k_b/[H^+])[OX][AH_2],$$

where k_a is the rate constant of the reaction with molecular ascorbic acid and approximately equals zero for $[Fe(CN)_6]^{3-}$ and $[W(CN)_8]^{3-}$ and k_b is the rate constant of the reaction with the ascorbate anion. The rate measurements for the three oxidants were used to calculate the entropies and enthalpies of activation. The differences in the rates of oxidation of ascorbic acid by the three oxidants, which are in the order $Mo^V \gg Fe^{III} > W^V$, are discussed.

The oxidation of ascorbic acid (AH_2), to dehydroascorbic acid (A), has been the subject of interest for many years.[1–6] With its 1,2-enediol group, ascorbic acid is a powerful reducing agent and is widely used as a reductometric reagent in the titration of various oxidants:

$$AH_2 + 2[OX] \rightarrow A + 2H^+ + 2[RED].$$

On the other hand, many methods for the quantitative determination of ascorbic acid by a variety of oxidizing agents have been described.[7–11] Particular interest has been devoted to the use of potassium hexacyanoferrate(III) in the oxidimetric determination of ascorbic acid in acidic, neutral, and alkaline media.[12] In line with our interest in the kinetics of the oxidation of acyloins (1,2-enediol),[13–15] this kinetic study has been undertaken to compare the rates of oxidation of ascorbic acid with the cyano complexes of Mo^V, Fe^{III} and W^V in acidic aqueous methanol medium. The study is an attempt to obtain additional information about the mechanism, thermodynamic and reactivity parameters of the reactions of these oxidants with ascorbic acid. This might help the selection and choice of the optimum conditions in the use of these cyano complexes in the titrimetric determination of ascorbic acid and other related compounds.

EXPERIMENTAL

Materials

The L-ascorbic acid and $K_3Fe(CN)_6$ used in this investigation were B.D.H. Analar grade and were used without further purification. The cyano complexes, $K_4W(CN)_8 \cdot 2H_2O$, $K_4Mo(CN)_8 \cdot 2H_2O$,[16] $Cs_3W(CN)_8 \cdot 2H_2O$ and $Cs_3Mo(CN)_8 \cdot 2H_2O$[17] were prepared by literature methods. The latter were pure after only one crystallization and were used as primary standards. Analytical grade reagents and doubly distilled water were used throughout the measurements. The aqueous methanolic solutions of ascorbic acid and the oxidizing agent were freshly prepared and bubbled with purified nitrogen for a period of 10 min before use. The desired buffer solutions for varying the pH of the reaction medium were prepared by mixing suitable

* Author to whom correspondence should be addressed.

volumes of 0.05 M potassium hydrogen phthalate and 0.1 M HCl (pH = 2.2–3.0) or 0.2 M KCl and 0.2 M HCl (pH = 1.0–1.6). The pH was measured with a Metrohm 632 pH meter. The measured pHs were corrected for 50% v/v aqueous methanol using the relationship:[18] $pH_{corr.} = pH_{meas.} + 0.08$.

Kinetic measurements

The reactions were carried out in buffered acidic aqueous methanol (50% v/v) using a thermostatted bath to regulate the temperature to ±0.2°C. The ionic strength was adjusted to a constant value of 0.06 M (for $K_3Fe(CN)_6$ and $Cs_3W(CN)_8 \cdot 2H_2O$) or 0.12 M (for $Cs_3Mo(CN)_8 \cdot 2H_2O$) by the addition of NaCl. The progress of the reaction was followed by measuring the absorbance (A_t) of the unconsumed $[Mo(CN)_8]^{3-}$, $[Fe(CN)_6]^{3-}$ and $[W(CN)_8]^{3-}$ at 390, 420 and 357 nm, respectively. The experiments were carried out with a thermostatted Unicam SP8-500 spectrophotometer. Solutions of ascorbic acid and the cyano complexes were protected from light during the preparation and kinetic measurements.

Stoichiometry

By maintaining stoichiometric amounts (1 : 2) of ascorbic acid and the oxidizing agent and performing spectrophotometric measurements at the proper wavelength, the following stoichiometric equation[19] was found to hold for the three oxidants:

$$H_2A + 2[M(CN)_n]^{3-} = A + 2[M(CN)_n]^{4-} + 2H^+.$$

Where $n = 6$, M = Fe; $n = 8$, M = Mo or W. The dehydroascorbic acid was identified by TLC as the final product.

RESULTS AND DISCUSSION

The oxidation of ascorbic acid was investigated at a constant concentration of hydronium ion and at a constant ionic strength. The concentration of the oxidants $[Mo(CN)_8]^{3-}$, $[Fe(CN)_6]^{3-}$ and $[W(CN)_8]^{3-}$ were kept constant at 1.0×10^{-3} M while ascorbic acid concentrations were varied to fulfil pseudo first-order conditions. The results for the three oxidants are shown in Table 1 and pseudo first-order plots for $[Mo(CN)_8]^{3-}$ are linear to about 80% of the reaction (Fig. 1). Similar plots were obtained for $[Fe(CN)_6]^{3-}$ and $[W(CN)_8]^{3-}$.

Absorption measurements carried out at stoichiometric amounts of the reactants ($[OX]^{3-}$: $[H_2A] = 2:1$) and at different pH values are shown in Table 2. The second-order plots for $[Mo(CN)_8]^{3-}$ are also linear for about 80% completion (Fig. 2), thus confirming a first-order dependence on both reactants. Similar plots were also obtained for $[Fe(CN)_6]^{3-}$ and $[W(CN)_8]^{3-}$. The second-order rate constant (k') has been found to depend on $[H^+]$ (Table 2). It is found that k' decreases with increasing acidity (other variables were constant). Plots of k' vs $1/[H^+]$ are straight lines (Fig. 3) with a positive intercept in the case of $[Mo(CN)_8]^{3-}$ and almost with zero intercept in the cases of both $[Fe(CN)_6]^{3-}$ and $[W(CN)_8]^{3-}$.

From these results, the reaction of ascorbic acid with the cyano complexes under study, in buffered 50% v/v aqueous methanol is considered to proceed via two parallel pathways and the overall mechanism for the reaction can be represented by eqs (1)–(4):

$$AH_2 \overset{K_1}{\rightleftharpoons} AH^- + H^+ \quad (1)$$

$$AH_2 + [OX]^{3-} \xrightarrow{k_2} AH\cdot + [OX]^{4-} + H^+ \quad (2)$$

[a] $[Mo(CN)_8^{3-}] = [Fe(CN)_6^{3-}] = [W(CN)_8^{3-}] = 1.0 \times 10^{-3}$ M, $t = 10$°C.
[b] $[H^+] = 1.0$ M, $I = 0.12$ M.
[c] pH = 2.2, $I = 0.06$ M.

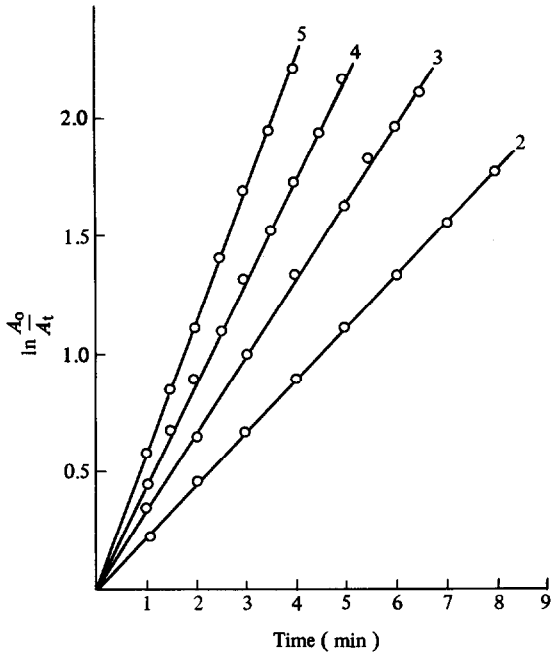

Fig. 1. Plots of $\ln(A_o/A_t)$ vs time for the oxidation of ascorbic acid by $[Mo(CN)_8]^{3-}$ at different concentrations of ascorbic acid.

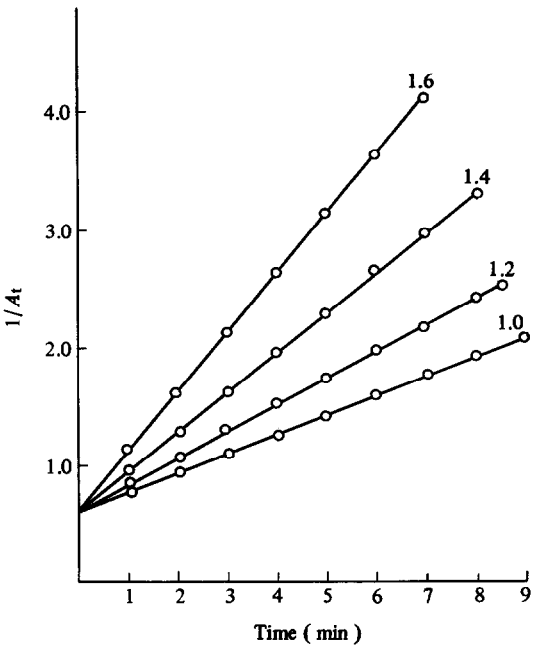

Fig. 2. Plots of $(1/A_t)$ vs time at different pH values. Acid dependence of oxidation of ascorbic acid by $[Mo(CN)_8]^{3-}$.

$$AH^- + [OX]^{3-} \xrightarrow{k_3} AH\cdot + [OX]^{4-} \quad (3)$$

$$AH\cdot + [OX]^{3-} \xrightarrow{\text{fast}} A + [OX]^{4-} + H^+. \quad (4)$$

In view of the above scheme and assuming a stationary steady-state condition for the radical, the following rate law can be readily derived.

$$-d[OX^{3-}]/2dt = (k_2 + K_1k_3/[H^+])[AH_2][OX^{3-}] \quad (5)$$

and

$$-d[OX^{3-}]/dt = (k_a + k_b/[H^+])[AH_2][OX^{3-}] \quad (6)$$

$$= (k_a + k')[AH_2][OX^{3-}], \quad (7)$$

where

$$k' = k_b/[H^+]$$

and

$k_a = 0$ for $[Fe(CN)_6]^{3-}$ and $[W(CN_8]^{3-}$.

From plots of k' vs $1/[H^+]$ (Fig. 3) the values of k_b at constant temperature (15°C) and constant ionic strength (0.06 M for $[Fe(CN)_6]^{3-}$ and $[W(CN)_8]^{3-}$; 0.12 M for $[Mo(CN)_8]^{3-}$), are:

$$k_b([Mo(CN)_8]^{3-}) = 0.310\ s^{-1}$$

$$*k_b([Mo(CN)_8]^{3-})_{corr.} = 0.258\ s^{-1}$$

$$k_b([Fe(CN)_6]^{3-}) = 4.97 \times 10^{-3}\ s^{-1}$$

$$*k_b([Fe(CN)_6]^{3-})_{corr.} = 4.17 \times 10^{-3}\ s^{-1}$$

$$k_b([W(CN)_8]^{3-}) = 2.87 \times 10^{-3}\ s^{-1}$$

$$*k_b[W(CN)_8]^{3-})_{corr.} = 2.42 \times 10^{-3}\ s^{-1}.$$

The first dissociation constant[19] of ascorbic acid (K_1) corrected for 50% v/v aqueous methanol at 15°C was found to be 6.7×10^{-5} and 6.9×10^{-5} M at $I = 0.06$ and 0.12 M, respectively. Therefore,

$$k_3([Mo(CN)_8]^{3-}) = 1.58 \times 10^4\ M^{-1}\ s^{-1}$$

$$k_3([Fe(CN)_6]^{3-}) = 2.63 \times 10^2\ M^{-1}s^{-1}$$

$$k_3([W(CN)_8]^{3-}) = 1.53 \times 10^2\ M^{-1}s^{-1}.$$

The variation of rate constant with ionic strength was investigated in the presence of NaCl and for a range of ionic strengths (from $I = 1.0$–1.3 M for $[Mo(CN)_8]^{3-}$ and $I = 0.06$–0.12 M for $[Fe(CN)_6]^{3-}$ and $[W(CN)_8]^{3-}$). Plots of $\log k'$ vs $\sqrt{I}$ for the above three oxidants are straight lines with slopes of +2.6, +3.0 and +1.7, respectively. Thus the addition of neutral salts accelerates the rate of the reaction and

[d] pH = 2.2, $\Delta\log k/\Delta\sqrt{I} = 1.72$.

indicates a positive salt effect. A slope of +3.0 for $[Fe(CN)_6]^{3-}$ confirms that the reaction takes place through the interaction of a −3 and −1 charged species.[20] However, in the case of $[Mo(CN)_8]^{3-}$ and $[W(CN)_8]^{3-}$, slopes of +2.6 and +1.7 indicate the formation of ion-pairing[21] such as $Na_n[M(CN)_8]^{n-3}$ ($n = 0.4$, M = Mo; $n = 1.3$, M = W) in the activated complex.

Reactions were investigated at 5, 10, 15 and 20°C at 5:1 molar ratios of ascorbic acid to oxidant, constant pH (2.2) and constant ionic strength. From the observed data, enthalpies and entropies of activation were obtained (Table 4) using Eyring's equation, from plots of $-\log k/T$ vs $1/T$, where k is the pseudo first-order rate constant (Fig. 4). Values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ were obtained from the slopes and intercepts, respectively.

The rate of oxidation of ascorbic acid with $[Mo(CN)_8]^{3-}$ has been found to be exceptionally faster than that with $[Fe(CN)_6]^{3-}$ or $[W(CN)_8]^{3-}$ under similar conditions. The calculated relative rates of the three oxidants at pH = 2.2, $I = 0.06$ M,

	0.101	1.68	10		
	0.135	2.25	15		
	0.184	3.07	20		

[a] $[Mo(CN)_8^{3-}] = [Fe(CN)_6^{3-}] = [W(CN)_8^{3-}] = 1.0 \times 10^{-3}$ M, $[AH_2] = 5.0 \times 10^{-4}$ M.
[b] $[H^+] = 1.0$ M, $I = 1.0$ M.
[c] pH = 2.2, $I = 0.060$ M.

and 15°C are:

$$k'(M^{-1}s^{-1}) = \underset{27.5}{[Mo(CN)_8]^{3-}} \gg \underset{0.412}{[Fe(CN)_6]^{3-}} > \underset{0.320}{[W(CN)_8]^{3-}}.$$

The high reactivity of $[Mo(CN)_8]^{3-}$ could be explained in view of the following facts. First, the ability of $[Mo(CN)_8]^{3-}$ to oxidize both the ascorbate monoanion (AH^-) and the undissociated ascorbic acid (AH_2) as shown clearly in the plot of k' vs $1/[H^+]$ (Fig. 3). In this figure straight lines are obtained with intercepts close to zero in the case of $[Fe(CN)_6]^{3-}$ and $[W(CN)_8]^{3-}$ but with a positive intercept in the case of $[Mo(CN)_8]^{3-}$. This is also consistent with the higher reduction potential[3] of $[Mo(CN)_8]^{3-}$ compared with $[Fe(CN)_6]^{3-}$ or $[W(CN)_8]^{3-}$.

The second factor seems to be the closest

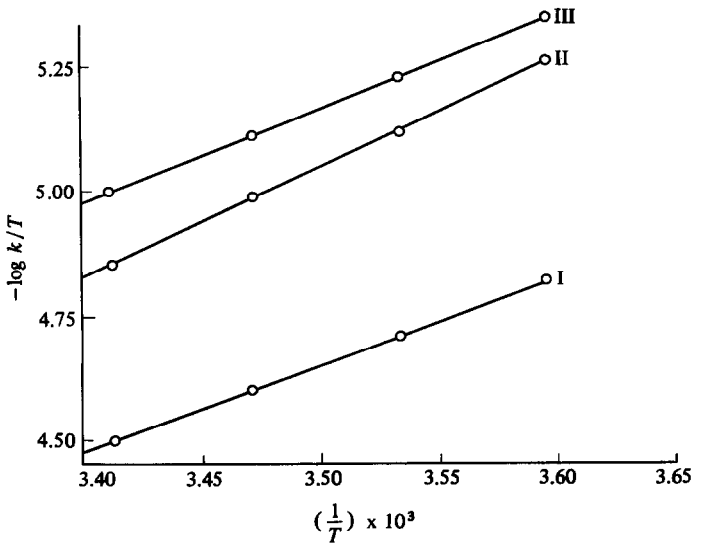

Fig. 4. Plots of $-\log k/T$ vs $(1/T)$ for $[Mo(CN)_8]^{3-}$ (I), $[Fe(CN)_6]^{3-}$ (II) and $[W(CN)_8]^{3-}$ (III).

approach between the reacting species in the activated complex. This is shown by the values of $\Delta S^{\ddagger}$, with $[Mo(CN)_8]^{3-}$ having the most negative value. Also, in favour of the highest reactivity for $[Mo(CN)_8]^{3-}$ is the smallest value of $\Delta H^{\ddagger}$ (Table 4).

A STUDY OF THE REACTION BETWEEN CHROMIUM(III) HEXAAMMINE AND GLYCINE IN A MELT

PAUL O'BRIEN* and NIGEL B. SELLERS

Department of Chemistry, Queen Mary College, University of London, Mile End Road, London E1 4NS, U.K.

(*Received* 23 *June* 1989; *accepted* 17 *August* 1989)

Abstract—Powdered mixtures of glycine and $[Cr(NH_3)_6](NO_3)_3$ melt and react at temperatures between 130 and 180°C to produce a glassy, purple material $[Cr(NH_3)_3(O_2CCH_2NH_3)_3](NO_3)_3$ (**I**), which on dissolution in water, yields *fac*-$[Cr(glyO)_3]$ (**II**) as a precipitate. The initial reaction between the ammine and glycine had previously been reported to occur in the solid state. The method has been used to prepare fully deuterated **II**.

For some time we have been interested, both in the reactions of various coordination complexes in the solid state[1–4] and in the coordination chemistry of chromium(III).[5–8] We were consequently intrigued by the report of an alleged solid state reaction between powdered mixtures of glycine and $[Cr(NH_3)_6](NO_3)_3$, which could be used to prepare *fac*-tris-glycinatochromium(III)[9] and, by extension, a series of related tris-amino acidates.[10] We have re-investigated this reaction and our results show that the reaction proceeds in a melt and apparently stops after three molecules of ammonia have been lost. The dissolution in water of the glass obtained on cooling the reaction mixture leads to the precipitation of red **II**.[9] The method can be used to prepare this complex on a small scale; such syntheses are often a problem with chromium(III).[7] The procedure has been used to prepare the complex from fully deuterated glycine, which may be a useful compound for ^2H NMR studies.[11]

RESULTS AND DISCUSSION

Initial experiments and observations

Preliminary experiments rapidly confirmed that heating a 3:1 mixture of glycine and $[Cr(NH_3)_6](NO_3)_3$ (142°C, 20 min) yielded a purple material **I**. **I** was glassy on cooling to room temperature and was readily soluble in cold water. On standing overnight a precipitate of **II** was obtained. The fact that **I** appeared glassy led us to observe the course of the reaction using a hot stage microscope.

Mixtures of glycine and $[Cr(NH_3)_6](NO_3)_3$ (3:1) were prepared by direct weighing and ground for 5 min in an agate mill. On heating (*ca* 5°C min^{-1}) the mixture clearly melted at *ca* 135°C, just after the decomposition of the ammine had started. This experiment was repeated using a range of glycine to hexaammine ratios and melting was observed for compositions between 40 and 90 mol % of glycine. These results are summarized in Fig. 1 and Table 1. Clearly some kind of a reactive eutectic mixture is formed by mixtures of glycine and $[Cr(NH_3)_6](NO_3)_3$, which is surprising as both of the compounds are polar species which decompose, char (glycine) or deaminate ($[Cr(NH_3)_6](NO_3)_3$), before melting. In isothermal experiments, on the hot stage microscope, we observed that there was a slight induction time, during which some reaction occurred before melting and these results are summarized in Table 1.

Thermal studies

Thermogravimetric analysis (10°C min^{-1}, static air) of various samples of glycine and $[Cr(NH_3)_6](NO_3)_3$ confirmed that the reaction proceeded with the loss of three equivalents of ammonia under a variety of reaction conditions. Typical results are shown in Fig. 2. The reaction in the melt occurs at

* Author to whom correspondence should be addressed.

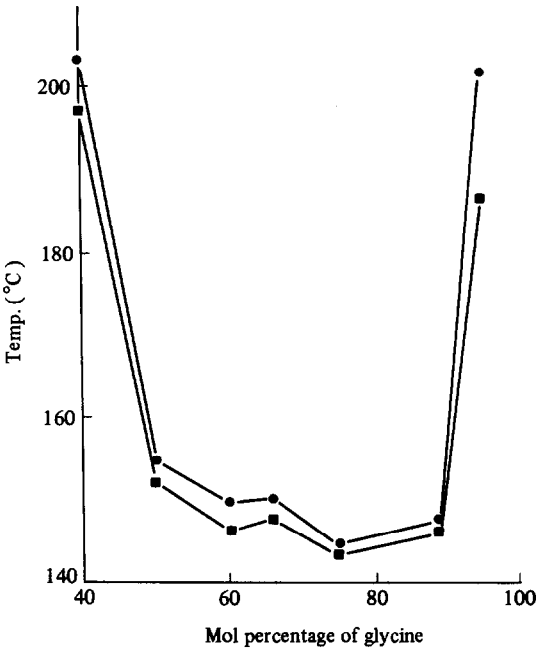

Fig. 1. Melting behaviour of various mixtures of $[Cr(NH_3)_6](NO_3)_3$ and glycine: ■ initial appearance of liquid; ● final disappearance of solid.

a lower temperature than the deammination of the hexaammine (170°C)[12] or the decomposition of glycine (245°C), when heated separately under similar conditions. Differential thermal analysis of mixtures of glycine and the hexaammine (10°C min^{-1}, static air) resulted in the traces shown in Fig. 2. Two endotherms are observed, the second of these (extrapolated onset temperature 154°C) is concurrent with the reaction in the melt. The first (extrapolated onset temperature 106°C) occurs before melting and is independent of any mass loss. This may be associated with some sintering of the fine powders of glycine and the hexaammine; no changes in the IR spectra of such samples are detected (4000–400 cm^{-1}).

Isothermal studies of the decomposition were then carried out to investigate the effect of varying the temperature and the composition of the reaction mixture on the reaction rate. The progress of the reaction was plotted as α vs time (α, fraction of reaction, $\alpha = 1$, 100% reaction, corresponding to the loss of three molecules of ammonia from each hexaammine). Figure 3 shows some typical results for various temperatures and compositions. The reaction profile is approximately linear ($0.15 > \alpha > 0.75$) and attempts to fit the whole profile to successive first-order reactions produced ill-defined results. Reaction profiles were similar at temperatures between 134 and 151°C and estimated zero-order rate constants for the reaction are summarized in Table 1. Rate constants derived from experiments under a wide range of conditions are shown on the Arrhenius plot, Fig. 4. The activation energy derived from this plot is *ca* 115 kJ mol^{-1}. The reaction of the hexaammine with alanine was exactly similar. These results indicate:

(1) a zero-order rate, relatively independent of the amino acid concentration in the melt (Table 1, 1:3–1:8 ratios of chromium complex to glycine, Fig. 4);

(2) a zero-order rate, relatively independent of the amino acid used (Table 2);

(3) a fairly high enthalpy of activation and an entropy of activation close to zero.

Taken together the results suggest that the reaction in the melt may proceed by a dissociative reaction

Table 1. Characterization of reaction in melt and zero-order rate constants

[Gly]:[Cr]	Temperature (°C)	Time to completion (10^3 s)	Time to melt (s)	% Reaction in melt	10^3k (s^{-1})

in which the rate-determining step is the loss of ammonia molecules from the ammine complex. Thus it resembles, in being dissociative, the reaction of glycine with $[Cr(NH_3)_5H_2O]^{3+}$, as studied by Sykes *et al.*,[13] in which water is lost dissociatively. Given the markedly different conditions of the reaction (melt vs aqueous solution) the activation parameters are remarkably similar to those for the aquopentammine, an enthalpy of activation of 106 kJ mol^{-1}, compared to our value of *ca* 115 kJ mol^{-1} and an entropy of activation close to zero (Table 2). The linearity of plots of α vs time for the majority of the reaction suggests the ammonia molecules are lost at a similar rate from each of the intermediate complexes in the reaction.

IR and electronic spectra

The IR and electronic spectra are summarized in Tables 3 and 4. The IR spectra of the mixture before heating is simply an addition of the spectra of free glycine and the hexaammine nitrate, all of the bands can be assigned by reference to the literature (Table 3). After heating, the spectrum is considerably modified. The antisymmetric stretch of the COO^- group is shifted from 1604 cm^{-1} in the mixture to 1659 cm^{-1} in the product and the new position is consistent with coordination of the carboxylate function to the metal.[14] New bands are also observed at 534, 518 and 412 cm^{-1} and may be assigned tentatively to M—O stretches.[14] The

modes of vibration associated with the NH_3^+ of glycine remain essentially unchanged; 1587, 1142, 518 cm^{-1} (Table 3).

The electronic spectra of various complexes with chromophores from CrN_6 to CrN_3O_3 are summarized in Table 3; the lowest energy *d–d* transition ($^4A_{1g} \rightarrow {}^4T_{2g}$ in O_h symmetry) gives an approximate measure of the ligand field strength.[15] The initial product of the reaction, **I**, can be assigned as a CrN_3O_3 chromophore. The fact that the lowest energy transition is not split suggests a facial arrangement of the donor atoms.[5,16]

Taken together with the thermo-analytical results the spectroscopic data support the formulation of the intermediate as a ring open facial complex of zwitterionic glycine and chromium(III).

Preparation of deuterated $[Cr(gly)_3]$

The method proved to be a facile way of preparing fully deuterated *fac*-$[Cr(gly)_3]$ from solid D_5-glycine and the hexaammine. Small scale preparations (see Experimental) were feasible and deuteration was confirmed by IR spectroscopy.

CONCLUSIONS

The reaction between chromium hexaammine and glycine proceeds in a melt. Earlier suggestions that this was a solid state reaction are erroneous. The fact that this reaction proceeds in a homogeneous phase explains why the reaction effectively stops after the reaction of three mols of glycine with the hexaammine, i.e. at the electrically neutral N_3O_3 chromophore (the overall complex is presumably charged due to pendant $-NH_3^+$ groups). This material **I** presumably ring closes in aqueous solution to give substantial yields of the red *fac*-tris-glycinatochromium(III) complex. The method is useful for preparing this complex on a small scale and has been used to prepare the fully deuterated complex.

EXPERIMENTAL

Materials

Reagent grade D_5-glycine was purchased from Goss Chemicals, all other reagents were purchased from B.D.H. Chemicals Ltd. $[Cr(NH_3)_6](NO_3)_3$ was prepared by the literature method.[17]

Physical measurements

Electronic spectra were recorded with a Perkin–Elmer 330 spectrophotometer; IR spectra were recorded on a Mattson Polaris FT–IR spectrometer; as Nujol mulls or KBr disks (*ca* 2%, 200 mg). Thermogravimetric studies were carried out using a Stanton Redcroft TG-750 (in static air). Differential thermal analysis was undertaken using a DTA 671B, calibrated with high purity indium metal.

Methods

Mixtures ([gly]:[Cr], 3:1; 5:1; 8:1; and [ala]:[Cr], 3:1) were prepared by direct weighing of the components, glycine or alanine and the hexaammine. The mixture was preground in an agate mortar and ground to a fine mixture in an agate mill (Speci-Mill, Specac) for 5–10 min. This procedure led to reproducible results in kinetic and other experiments. All mixtures were used immediately and reaction was followed by thermogravimetry. In general, the mixtures used lost the equivalent of 3 mols of ammonia per mol of chromium. There was some slight evidence of further reaction in the 8:1 [gly]:[Cr] mixtures. Activation parameters were calculated as described by Edwards *et al.*[18]

Table 4. Electronic spectra[a]

Compound	Energy	
$[Cr(NH_3)_6]^{3+}$	21.6	28.3
$[Cr(NH_3)_6]^{3+}$/glycine (1:3 before heating)	21.7	28.6
Purple glass (I) (cooled to RT)	19.6	26.1
fac-$[Cr(glyO)_3]$	19.2	25.3

[a] $10^3 \times cm^{-1}$, by diffuse reflectance, for the two lowest energy bands.

Preparation of fully deuterated fac-$[Cr(gly_3)]$

$[Cr(NH_3)_6](NO_3)_3$ (0.43 g) and deuterated glycine (0.3 g) were ground together with pestle and mortar and then ground in an agate mill for 10 min.

The mixture was placed in an oven for 45 min at 135°C. The glass formed was dissolved in deuterium oxide and the solution left overnight, after which time red crystals of deuterated *fac*-[$Cr(gly)_3$] had precipitated. These were filtered off, washed with D_2O, and air dried. Yields, based on chromium, were 30–40%.

SYNTHESIS, CHARACTERIZATION AND ^{1}H NMR (EXPERIMENTAL AND THEORETICAL) SPECTRAL STUDIES OF SOME NEUTRAL AND ANIONIC COMPLEXES OF DIPHENYL TIN ISOCYANATE CHLORIDE

P. C. SRIVASTAVA,* A. TRIVEDI and P. SINGH

Chemistry Department, Lucknow University, Lucknow-226007, India

(*Received* 3 *August* 1989; *accepted* 17 *August* 1989)

Abstract—Neutral adducts and anionic complexes of $Ph_2Sn(NCO)Cl$ of the general formula $Ph_2Sn(NCO)Cl \cdot nL$ ($n = 1$, L = 2,2′-bipyridyl, Me_4NCl; $n = 2$, L = DMSO and DMF) have been isolated. These complexes have been characterized through elemental analysis, molecular weight, molar conductance, IR and ^{1}H NMR data. Experimental ^3J [$Sn^{119}CCH(O)$] ($^3J_{exp.}$) has been computed from the ^{1}H NMR spectra and it has been observed that there is an increase in $^3J_{exp.}$ ($Ph_2Sn(NCO)Cl$) on complexation. Further, $^3J[Sn^{119}CCH(O)]$ has been calculated ($^3J_{theor.}$) and it is seen that there is close agreement between $^3J_{theor.}$ and $^3J_{exp.}$ values.

Diphenyl tin mixed halide pseudohalides [$Ph_2Sn(X)X'$] (X = NCO, NCS, N_3; X′ = Cl, Br) were recently reported by us.[1] We also reported another complex, $Ph_2Sn(NCS)Br \cdot 2DMSO$. Thus, the coordination chemistry of these diphenyl tin mixed halide pseudohalides has not been studied in detail and no coordination compound of $Ph_2Sn(NCO)Cl$ is known. Therefore, we prepared coordination compounds of $Ph_2Sn(NCO)Cl$ with DMSO, DMF and 2,2′-bipyridyl yielding neutral complexes $Ph_2Sn(NCO)Cl \cdot nL$ ($n = 1$, L = 2,2′-bipyridyl; $n = 2$, L = DMSO and DMF) and with $[Me_4N]^+[Cl]^-$ yielding anionic complexes $[Me_4N]^+$ $[Ph_2Sn(NCO)Cl_2]^-$. These complexes have been characterized through elemental analysis, molecular weight, molar conductance, IR and ^{1}H NMR data.

The ^{1}H NMR spectral data have been interpreted in terms of *o*-, *m*- and *p*-phenyl proton chemical shifts and ^3J[SnCCH(*ortho*)] coupling constants (^3J). Semi-empirical calculations have been made for $^3J_{theor.}$ and correlated with experimentally observed $^3J_{exp.}$ for these complexes. It is observed that there is an increase in coupling constant $^3J[Sn^{119}CCH(O)]$ of $Ph_2Sn(NCO)Cl$ on complexation.

EXPERIMENTAL

Ph_3SnCl (E. Merck), ICl (E. Merck), KNCO and Lewis bases (BDH) used in the present investigation, were procured commercially. $Ph_3Sn(NCO)$ was prepared according to the reported method.[2] $Ph_2Sn(NCO)Cl$ was prepared by the cleavage of $Ph_3Sn(NCO)$ with ICl in chloroform[1] and the physico-chemical measurements were carried out as before.[1]

The complexes were prepared by the interaction of $Ph_2Sn(NCO)Cl$ with ligands under nitrogen in the following manner:

$$Ph_2Sn(NCO)Cl + nL \rightarrow Ph_2Sn(NCO)Cl \cdot nL$$

($n = 1$, L = 2,2′-bipyridyl, Me_4NCl; $n = 2$, L = DMSO and DMF).

A typical preparation of the complex $Ph_2Sn(NCO)Cl \cdot 2,2'$-bipyridyl is described below.

Preparation of $Ph_2Sn(NCO)Cl \cdot 2,2'$-*bipyridyl*

$Ph_2Sn(NCO)Cl$ (1.00 g, 2.85 mmol) was taken in ~30 cm^3 of anhydrous acetone. To this 2,2′-bipyridyl (0.44 g, 2.85 mmol) was added in ~20 cm^3 of the same solvent. The resulting reaction mixture was stirred for 1 h, refluxed for 3 h and excess solvent was removed by distillation. To the remaining ~4–5 cm^3 of the solution petroleum ether (40–60°C) was added. The complex formed

was separated, washed with petroleum ether (40–60°C) and dried *in vacuo* (yield 0.80 g, 55.55%).

RESULTS AND DISCUSSION

The complexes with their characterization data are listed in Table 1. These complexes are white, crystalline solids and are soluble in DMF, DMSO, nitrobenzene and chloroform+DMSO solvent mixtures. They are sharp melting, thermally stable and sensitive to atmospheric oxygen and moisture.

The molar conductance of a 10^{-3} M solution in DMSO at 30°C and molecular weight of these complexes in nitrobenzene indicate the monomeric and non-electrolytic nature of the neutral complexes,[3,4] whereas $[Me_4N]^+[Ph_2Sn(NCO)Cl_2]^-$ is a 1 : 1 electrolyte. The Van't Hoff factor (i) = 2.05 indicates the presence of two ions in the solution.

IR spectra

In $Ph_2Sn(NCO)Cl$, the cyanate group bonded by nitrogen is evident by the presence of a strong band corresponding to $\nu_{asym.}NCO$ at 2230 cm^{-1}. In potassium cyanate, the $\nu_{asym.}NCO$ appears at 2165.[6] A shift to higher wave number has been found to occur for the N-bonded cyanate group and a shift to lower wave number occurs for the O-bonded NCO group.[7,8] Thus from the above values of $\nu_{asym.}NCO$, it is evident that the bonding of the NCO group has taken place through nitrogen, indicating Sn—NCO bonding, in agreement with earlier reports.[9-12]

In the neutral and anionic complexes synthesized, $\nu_{asym.}NCO$ appears as a strong band at 2205 ± 5 cm^{-1}. Thus, a negative shift of about 25 ± 5 cm^{-1} indicates an increase in the coordination number of tin.[13] The $\nu_{sym.}NCO$ is found at 1322 ± 13 cm^{-1} and δNCO is found at 622 ± 13 cm^{-1}.

In order to decide the coordination site in DMSO adducts, the (S=O) stretching absorption frequencies is of diagnostic value. The νSO in free DMSO has been assigned at 1050 cm^{-1}.[14] In the adduct the νSO is found at 940 cm^{-1}. A distinct negative shift of the (S=O) stretching frequency is observed, which proves (Sn ← O) bonding in the complex.[1,14-16] In the complex $Ph_2Sn(NCO)Cl$ with DMF, the νCO in free DMF appears at 1666 cm^{-1} while in the adduct νCO is found at 1645 cm^{-1}. The shift to lower wave number indicates coordination through the oxygen atom of the carbonyl group of the ligand.[17]

In the case of 2,2′-bipyridyl, C=C, C=N and ring stretching appear at 1582, 1560 and 1540 cm^{-1}. On coordination through both nitrogens of the ligand, these bands show a positive shift and appear

at 1610, 1600 and 1545 cm^{-1}, respectively, in the spectrum of the adduct, in agreement with the observations of previous workers.[18-20]

^1H *NMR spectra*

The ^1H NMR spectra of the complexes of $Ph_2Sn(NCO)Cl$ with DMSO and DMF show two multiplets centred at 7.69 and 7.09, and 7.85 and 7.45 ppm, respectively; the lower field multiplet corresponding to *o*-phenyl protons and the higher field multiplet corresponding to *m*- and *p*-phenyl protons.[21-23] The singlet for CH_3 protons appears at 2.35 ppm in the case of DMSO whereas in DMF two singlets centred at 2.90 and 3.02 ppm appear for $—CH_3$ protons [$—N(CH_3)_2$]. The $—(CH_3)_2$ doublet separation is 10.8 Hz. In the case of free DMF, two singlets are centred at 2.79 and 2.94 ppm, the doublet separation is 9.0 Hz.[24] The aldehyde proton of DMF appears at *ca* 7.90 ppm[24] but in the complex it is probably smothered by the multiplets of the phenyl protons. The experimental ^3J[SnCCH(O)] for the $Ph_2Sn(NCO)Cl \cdot 2DMSO$ complex is 85.20 Hz, whereas for the $Ph_2Sn(NCO)Cl \cdot 2DMF$ complex its value is 84.60 Hz.

The ^1H NMR of the anionic complex $[Me_4N]^+[Ph_2Sn(NCO)Cl_2]^-$ shows two multiplets centred at 8.19 and 7.45 ppm due to the *o*-protons, and the *m*- and *p*-protons of the phenyl groups, respectively, and a singlet at 3.25 ppm is due to the CH_3 protons. The experimental ^3J[SnCCH(O)] for this anionic complex is 78.30 Hz.

The integration of the peak areas corresponds to the proposed stoichiometry of the above complexes.

Semi-empirical calculations

On the basis of the Scherr and Oliver relationship,[25] the theoretical value of the metal proton coupling constant of R_4M type compounds may be calculated. Since the metal proton coupling constant depends upon (i) the hybridization and (ii) electronegativity of the groups attached to the metal,[26a] it is obvious that the value of J for all those related derivatives which possess the same hybridization as that of R_4M ([e.g. R_nMX_{4-n} or $[R(R')]_n\ MX_{4-n}$ or $R_nM\ [(X')X]_{4-n}$) type compounds where (n = 1–4), could be obtained by including the electronegativity term (Δx). It is thus possible to conceive the general relationship:

$$^3J\text{ compound} = {}^3JR_4M \pm A\Delta x, \qquad (1)$$

where A is a constant, $\Delta x = \Sigma x_A - \Sigma x_B$;
Σx_A = sum of electronegativities of the groups attached to the metal in the compound whose J is to be calculated;
Σx_B = sum of the electronegativities of the groups attached to the metal in the parent compound (R_4M). Thus ^3J of $Ph_2Sn(X')X$ (X = Cl, X' = NCO) will be given by the following relationship:

$$^3JPh_2Sn(NCO)Cl = {}^3JPh_4Sn + A\Delta x. \qquad (2)$$

^3J of Ph_4Sn equals 68.17 Hz has been previously reported by us.[22] The value of Δx ($\Delta x = \Sigma x_A - \Sigma x_B$ = 12.39 − 9.96 = 2.43) in $Ph_2Sn(NCO)Cl$ is 2.43. Assuming that the constant A = 3, ^3J of $Ph_2Sn(NCO)Cl$

$$= 68.17 + 3 \times 2.43$$
$$= 68.17 + 7.29$$
$$= 75.46 \text{ Hz}.$$

The theoretical value of ^3J of $Ph_2Sn(NCO)Cl$ is in close agreement with the experimentally observed 75.60 Hz; ^3J value for $Ph_2Sn(NCO)Cl$.

$^3J_{theor.}$ *of the complexes of* $Ph_2Sn(NCO)Cl$

As stated above, the coupling constant mainly depends upon (i) hybridization or *S*-character and (ii) electronegativity of the group attached to the metal.[26a] Therefore, both these factors should be taken into consideration when calculating the coupling constants of the complexes of $Ph_2Sn(NCO)Cl$. However, it has been established in the case of the adducts of Me_3SnCl by Bolles and Drago[27] that the total amount of tin *S*-orbital participation in bonding in the adduct and free Me_3SnCl is constant. We believe that a similar situation exists in the complexes of $Ph_2Sn(NCO)Cl$ and free $Ph_2Sn(NCO)Cl$ and conclude that the change in the coupling constant of $Ph_2Sn(NCO)Cl$ on complex formation will occur because of the electronegativity of the groups surrounding the tin metal atom. Thus $^3J_{theor.}$ for the complexes could be obtained by the following relationship:

$$^3J\text{ complex} = {}^3JPh_2Sn(NCO)Cl + A'n\chi p_{X'}, \qquad (3)$$

where constant A' is equal to unity, in the present study; n = number of ligating atoms = 1 and 2; $\chi p_{X'}$ = electronegativity of the ligating atom X' on the Pauling scale.

The theoretically calculated ^3J values of the (neutral and anionic) complexes of $Ph_2Sn(NCO)Cl$ using eq. (3) are listed in Table 2 and are in close agreement with the experimental values of ^3J.

Although the calculations are crude because the ring current effect which would also affect the values of coupling constant has not been taken into account, there is reasonably good agreement between the theoretical and experimental values of ^3J. Such calculations on the complexes of

Table 2. ^{1}H NMR data of neutral and anionic complexes of $Ph_2Sn(NCO)Cl$

Number	Complex	C_6H_5 protons (δ) (ppm) *o*-protons	*m*- and *p*-protons	CH_3-protons (ppm)	$^3J_{exp.}$ (Hz)	$^3J_{theor.}$ (Hz)
1[a]	$Ph_2Sn(NCO)Cl \cdot 2DMSO$	7.69(m)	7.09(m)	2.35(s)	85.20	86.54
2	$Ph_2Sn(NCO)Cl \cdot 2DMF$	7.85(m)	7.45(m)	2.90(s) 3.02(s)	84.60	86.54
4	$[Me_4N]^+[Ph_2Sn(NCO)Cl_2]^-$	8.19(m)	7.45(m)	3.25(s)	78.30	78.41

Multiplicity; m = multiplet; s = singlet.

(i) The position of the phenyl multiplets is the approximate centre of the multiplet.

[a](ii) The spectrum of this complex is at 60 MHz, the rest are at 90 MHz.

(iii) $\chi p_{X'}$ = electronegativity of X′ atom of the ligand bound to tin; χp of oxygen (sp^2 hybrid orbital of DMSO and DMF, 5.54,[26b], 2.95.[26b]

$Ph_2Sn(NCO)Cl$ have been performed for the first time and form a basis for calculating the coupling constants of several such complexes. Furthermore, there is an increase in $^3J_{theor.}$ and $^3J_{exp.}$ values of $Ph_2Sn(NCO)Cl$ on complexation. This could serve as a general parameter for predicting coordination through ^{1}H NMR spectral studies.

FURTHER STUDIES OF THE KINETIC COORDINATION TEMPLATE EFFECT IN THE METAL-ION CATALYSED FORMATION OF ARYLPHOSPHONIUM SALTS

DAVID W. ALLEN* and PAUL E. CROPPER

Department of Chemistry, Sheffield City Polytechnic, Pond Street, Sheffield S1 1WB, U.K.

(*Received* 4 *April* 1989; *accepted* 15 *August* 1989)

Abstract—The reactions of a series of bis-imines (derived from *o*-bromobenzaldehyde and α,ω-diamines) with tertiary phosphines in the presence of nickel(II) bromide in ethanol proceed with replacement of the *o*-halogen to form the related bis(arylphosphonium) salts, each *o*-haloarylimino moiety providing a kinetic coordination template for the substitution process. Only for bis-imines able to form five-, six- or seven-membered chelate systems with the metal ion is the substitution reaction inhibited or the yield reduced. Kinetic template effects in arylphosphonium salt formation have also been observed in the related reactions of 2,3-bis(*o*-chlorophenyl)quinoxaline, 1-(N-benzylidene)amino-8-bromonaphthalene and *o*-iodobenzoic acid. The structural requirements of the coordination template are discussed in the light of these and earlier results.

We have shown that the *o*-haloaryl imines (**1**, R^1 = H or Me; R^2 = aryl or benzyl; X = Cl, Br or I) undergo facile replacement of the *o*-halogen on heating under reflux in ethanol with tertiary phosphines in the presence of nickel(II) bromide to form the related arylphosphinium salts (**2**; R^1 = H or Me; R^2 = aryl or benzyl; R^3 = alkyl or aryl).[1] The corresponding *p*-haloarylimines are inert under these conditions. Related regiospecific replacement of halogen under mild conditions occurs in the nickel(II) and copper(II) promoted reactions of tertiary phosphines[2] (and trialkylphosphites)[3,4] with *o*-haloarylazo dyestuffs (**3**; R^1 = H or Me; R^2 = H or NHAc) and the bipyridyl system (**4**)[5] and in the nickel (II) promoted reactions of the 2-(2-bromophenyl)benzimidazole (**5**).[6] We have suggested that these reactions involve the operation of a kinetic template effect in which metal-ion promoted replacement of the halogen *ortho* to the imino groups is assisted by coordination of the metal to

(7)

the imino-nitrogen atom. We have also shown that introduction of a second donor atom or group into the substituent R^2 present at the imino-nitrogen of related imines inhibits these reactions, presumably owing to the diversion of the metal ion in other modes of coordination. Thus, e.g. the bis-imines (**6**, $n = 2$) and (**7**) undergo hydrolysis rather than phosphonium salt formation on heating in ethanol with tertiary phosphines in the presence of nickel(II) bromide. In this paper, we report related studies of a range of bis-imines in which diversion of the metal ion by chelation becomes less likely and also studies of the reactions of some new kinetic template systems.

RESULTS AND DISCUSSION

The synthesis of a range of bis-imines (**6**; $n = 0$, 3–8 or 12) was achieved by heating together the appropriate α,ω-diamine (1 mol equiv.) with *o*-bromobenzaldehyde in ethanol. The ^{1}H NMR spectra of these compounds exhibited the characteristic signal at *ca* δ 8.6 corresponding to the imino protons. On heating the bis-imines under reflux in ethanol with triphenylphosphine in the presence of a catalytic amount of nickel(II) bromide, the related bis(phosphonium) salts (**8**) and (**9**; $n = 3$–8, or 12) were isolated. The yield of the salt from the trimethylene-bridged template (**6**; $n = 3$) was significantly lower than from the other bis-imine templates, presumably reflecting competition for the metal ion catalyst by chelation to form a six-membered ring system. The constitution of the bis (phosphonium) salts was confirmed by ^{1}H and ^{31}P NMR studies, the integrated spectra being consistent with the introduction of two phosphine moieties. ^{31}P NMR spectra exhibited only one signal in each case at 24–26 ppm (characteristic of tetraarylphosphonium salts). Apart from the bis(triphenylphosphonio) salt derived from the bis(azine) (**6**; $n = 0$) great difficulty has been experienced in characterizing the above alkylene-bridged salts by microanalysis. Repeated microanalyses of these compounds, although within acceptable limits for %H and %N, gave consistently low %C results, possibly as a consequence of the difficulty in ensuring full combustion of such materials or as a result of their hygroscopic nature. Attempts to characterize them by analysis following conversion to the related mercury(II) bromide adducts, i.e. R_4P^+ $HgBr_3^-$, also failed to give acceptable microanalytical data. However, from the above spectroscopic data, it is clear that as the tendency for the alkylene-bridged bis(imines) to act as chelating ligands towards the metal ion decreases, then each *o*-haloarylimine functions independently of the other in promoting the template-substitution process. Predictably, the two aryl-bridged bis-

imines (**10**; X = Br) and (**11**; X = Br), also behaved normally in the nickel(II) catalysed reactions with tertiary phosphines in giving the related bis(phosphonium) salts (**10** and **11**; X = $Ph_3P^+Br^-$ or $Bu_3^+PBr^-$) in good yield.

We have also explored the reactivity of a series of new potential template molecules towards tertiary phosphines in the presence of nickel(II) or copper(II) ions. The synthesis of the 2,3-disubstituted quinoxaline (**12**) was achieved by heating together equimolar amounts of 2,2′-dichlorodibenzoyl and *o*-phenylenediamine in ethanol, the product crystallizing on cooling in quantitative yield.

On heating the quinoxaline (**12**) in ethanol with excess triphenylphosphine or tributylphosphine in the presence of nickel(II) chloride, the colourless phosphonium salts (**13**; R = Ph or Bu, X = Br, Y = $PR_3^+Br^-$ or Cl) were produced in good yields.

No reaction occurred in the absence of nickel(II) chloride or in the presence of copper(II) acetate as the sole catalyst.

The ^{31}P NMR spectra of both products exhibited two signals (of differing intensities) with chemical shifts of 26.7 and 25.2 ppm (R = Ph; in a 3 : 1 ratio) and 34.2 and 32.6 ppm (R = Bu; in a 3 : 4 ratio), respectively. It is likely that these signals arise from a mixture of mono- and diphosphonium salts since **12** contains two possible reaction sites where the substitution reaction could occur. Integration of the ^1H NMR spectra of these products lent support to this suggestion. It was not possible to separate the mixed salts into the mono- and di-species. Isolation of the diphosphonium salts (**13**; R = Ph or Bu, X = Br^-, Y = $R_3P^+Br^-$) was only possible when the quinoxaline was heated in ethanol with the preformed nickel(II) phosphine complexes (**14**; R = Ph and Bu) and an additional quantity of the free phosphine (1 mol equiv.). The latter complexes were prepared by mixing together nickel(II) chloride (1 mol equiv.), dissolved in hot ethanol with the appropriate tertiary phosphine (2.2 mol equiv.), dissolved in ethanoic acid.[7]

The reaction of equimolar amounts of the quinoxaline (**12**) with (**14**) but excluding the extra mol of tertiary phosphine, again led to a mixture of the mono- and diphosphonium salts.

The reaction of the 8-bromo-1-iminonaphthalene (**15**) (prepared by the condensation of 1-amino-8-bromonaphthalene with benzaldehyde in ethanol) with triphenylphosphine also gave a phosphonium salt (**16**) when heated under reflux in ethanol with nickel(II) bromide. Again, no reaction occurred in the absence of nickel(II), and copper(II) acetate failed to catalyse the reaction. In contrast, *neither* 1-amino-8-bromonaphthalene *nor* the reduction product (**17**) of the imine (**15**) functioned as active templates, again indicating rather specific requirements of the donor centre in the template system as was also apparent in systems related to **1**.[1]

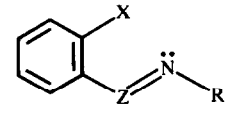
(19)



(20)

Whereas the reactions of both *o*-chloro- and *o*-bromobenzoic acids with triphenylphosphine or tributylphosphine in the presence of *either* nickel(II) bromide *or* copper(II) acetate failed to give rise to phosphonium salts, the related reactions of *o*-iodobenzoic acid in the presence of nickel(II) bromide gave the phosphonium salts (**18**; R = Ph or Bu) and for R = Ph, the related betaine (**19**).

The ^{31}P NMR spectrum of the product from the reaction with triphenylphosphine exhibited two signals of equal intensity at 26.2 ppm corresponding to the expected phosphonium salt (**18**) and 21.7 ppm, respectively, corresponding to the betaine (**19**). Addition of a strong acid to the solution resulted in the loss of the signal at 21.7 ppm, thus confirming that this signal was due to the presence of **19**. The ^{31}P NMR of the butylphosphonium salt (**18**; R = Bu) exhibited a signal at 33.2 ppm. Copper(II) acetate failed to catalyse these substitution reactions.

Other simple derivatives of *o*-iodobenzoic acid e.g. the corresponding methyl ester, amide, or hydrazide, did not function as active templates in the presence of either nickel(II) or copper(II) catalysts.

All the molecules which promote a kinetic template effect in arylphosphonium salt formation, with the exception of the 1,8-disubstituted naphthalene (**15**) and *o*-iodobenzoic acid, conform to the generalized structure (**20**) which we suggested earlier on the basis of our studies of the reactions of a series of *o*-haloarylimines.[1]

It is also necessary to recognize the role of the group bound to the sp^2-hybridized nitrogen atom. For the imine substrates (**20**; Z = CR) this is clearly of importance, since it has been shown that the presence of bulky groups at the nitrogen, *or* the presence of an additional donor within that group, which can divert the metal from its catalytic role, have adverse effects on the substitution reaction.[1] In the case of the azo dyestuffs and the *o*-halophenylbipyridyl substrate (**4**), the presence of additional donors does not seem to matter.

There is also a crucial interrelation between the template and the specific metal ion which is required. In general, for donors with only one donor atom, only nickel(II) is effective as the catalyst [as for the *o*-haloarylimines (**1**),[1] the benzimidazole (**5**)[6] and the quinoxaline (**12**)], whereas for the two donor systems, e.g. the *o*-halophenylbipyridyl system (**4**)[5] and many of the azo dyestuffs (**3**),[2] the reactions are catalysed by both copper(II) and nickel(II) ions.

Only two other types of effective template are left, the oxygen donor system of *o*-iodobenzoic acid and the 1,8-haloiminonaphthalene (**15**) which do not conform to the general design (**20**). It is interesting that the reactions of these single donor templates are catalysed solely by nickel(II) ions. It is clear that the oxygen template of *o*-iodobenzoic acid is at the margin of reactivity, since if the halogen is changed to bromine or chlorine, or if the acid function is methylated or converted to the amide/hydrazide derivative, then the template reactivity disappears. The "unexpected" reactivity of the haloiminonaphthalene (**15**) can doubtless be attributed to the 1,8- (or *peri*-) position of the substituents on the naphthalene ring. In view of the geometry of the naphthalene system, substituents located at these positions are in much closer proximity than similar substituents located *ortho* to each other on a benzene ring. This closer proximity has been responsible for the appearance of several unique properties of *peri*-substituted naphthalenes. Such "proximity effects" have been observed in *peri*-cyclization reactions[8] as well as in the *peri*-effects on 1,2-cyclizations[9] and investigations of the chemical reactivity of *peri*-substituted naphthalene derivatives.[10–12,13]

EXPERIMENTAL

^{31}P NMR spectra were recorded on a Bruker WP80SY instrument. Chemical shifts are reported with respect to 85% orthophosphoric acid as external standard; shifts to high frequency are positive in sign. ^1H NMR spectra were recorded on the same instrument, and chemical shifts are reported on the δ scale with respect to tetramethylsilane as internal standard in deuteriochloroform solution.

Preparation of potential templates

The following compounds were prepared as previously described: 8-bromo-1-naphthylamine,[14] bis(tertiary phosphine) nickel(II) chloride (**14**; R = Ph or Bu),[7] 2-iodomethylbenzoate[15] and 2-iodobenzamide.[16] 2-Halobenzoic acids were obtained commercially.

The synthesis of the bis-imines

These were prepared by heating together 2-bromobenzaldehyde (2 mol) with the appropriate α-ω diamine (1 mol) in refluxing ethanol for 60–90 min. Compounds (**10**) and (**11**) were prepared using the same conditions with replacement of the α-ω diamine by 4,4′-methylenedianiline, and *p*-phenylenediamine, respectively. In all cases, the bis-imines crystallized on cooling and were purified by recrystallization.

N,N′-bis-(2-bromobenzylidene)azine (**6**; $n = 0$). This was isolated as yellow crystals (98%), m.p.

177°C (from $CHCl_3$–EtOH) (Found: C, 45.7; H, 2.6; N, 7.5. $C_{14}H_{10}N_2Br_2$ requires: C, 45.9; H, 2.7; N, 7.6%), δ^1H($CDCl_3$): 8.6 (s, 2H), 8.1–7.1 (m, 8ArH) ppm.

N,N′ - bis - (2 - bromobenzylidene)propane - 1,3 - diamine (**6**; $n = 3$). (88%) m.p. 65°C (from EtOH) (Found: C, 50.0; H, 3.9; N, 6.9. $C_{17}H_{16}N_2Br_2$ requires: C, 50.0; H, 3.9; N, 6.9%), δ^1H($CDCl_3$): 8.6 (s, 2H), 8.1–7.2 (m, 8ArH), 3.8 (t, 4H), 2.1 (q, 2H) ppm.

N,N′ - bis - (2 - bromobenzylidene)butane - 1,4 - diamine (**6**; $n = 4$). (81%), m.p. 51°C (from EtOH) (Found: C, 51.2; H, 4.3; N, 6.5. $C_{18}H_{18}N_2Br_2$ requires: C, 51.2; H, 4.3; N, 6.6%), δ^1H($CDCl_3$): 8.6 (s, 2H), 8.1–7.2 (m, 8ArH), 3.7 (s, 4H), 1.8 (s, 4H) ppm.

N,N′ - bis - (2 - bromobenzylidene)pentane - 1,5 - diamine (**6**; $n = 5$). This was obtained as a pale cream solid (74%), m.p. 48°C (from EtOH) (Found: C, 52.3; H, 4.6; N, 6.3. $C_{19}H_{20}N_2Br_2$ requires: C, 52.3; H, 4.6; N, 6.4%), δ^1H($CDCl_3$): 8.6 (s, 2H), 8.1–7.2 (m, 8ArH), 3.7 (t, 4H), 1.8 (q, 6H) ppm.

N,N′ - bis - (2 - bromobenzylidene)hexane - 1,6 - diamine (**6**; $n = 6$). (85%), m.p. 73°C (from EtOH) (Found: C, 53.4; H, 4.9; N, 6.1. $C_{20}H_{22}N_2Br_2$ requires: C, 53.3; H, 4.9; N, 6.2%), δ^1H($CDCl_3$): 8.6 (s, 2H), 8.1–7.1 (m, 8ArH), 3.6 (t, 4H), 1.6 (m, 8H) ppm.

N,N′ - bis - (2 - bromobenzylidene)heptane - 1,7 - diamine (**6**; $n = 7$). (73%), m.p. 48°C (from EtOH) (Found: C, 54.5; H, 5.2; N, 6.0. $C_{21}H_{24}N_2Br_2$ requires: C, 54.3; H, 5.2; N, 6.0%), δ^1H ($CDCl_3$): 8.6 (s, 2H), 8.1–7.2 (m, 8ArH), 3.6 (t, 4H), 1.6 (m, 10H) ppm.

N,N′ - bis - (2 - bromobenzylidene)octane - 1,8 - diamine (**6**; $n = 8$). (81%), m.p. 52°C (from EtOH) (Found: C, 55.3; H, 5.5; N, 5.9. $C_{22}H_{26}N_2Br_2$ requires: C, 55.2; H, 5.5; N, 5.8%), δ^1H($CDCl_3$): 8.6 (s, 2H), 8.1–7.2 (m, 8ArH), 3.7 (t, 4H), 1.1 (m, 12H) ppm.

N,N′ - bis - (2 - bromobenzylidene)dodecane - 1,12 - diamine (**6**; $n = 12$). This was obtained as pale yellow crystals (65%), m.p. 53°C (from EtOH) (Found: C, 58.5; H, 6.4; N, 5.2. $C_{26}H_{34}N_2Br_2$ requires: C, 58.4; H, 6.4; N, 5.2%), δ^1H($CDCl_3$): 8.6 (s, 2H), 8.1–7.1 (m, 8ArH), 3.7 (t, 4H), 1.5 (m, 20H) ppm.

N,N′ - bis - (2 - bromobenzylidene)4,4′ - diaminodiphenylmethane (**10**). This was isolated as pale yellow crystals (83%), m.p. 142°C (from EtOH) (Found: C, 60.7; H, 3.7; N, 5.2. $C_{27}H_{20}N_2Br_2$ requires: C, 60.9; H, 3.8; N, 5.3%), δ^1H($CDCl_3$): 8.8 (s, 2H), 8.3–7.2 (m, 16ArH), 4.0 (s, 2H) ppm.

N,N′ - bis - (2 - bromobenzylidene)1,4 - diaminobenzene (**11**). This was obtained as bright yellow crystals (92%), m.p. 157°C (from petrol 60:40) (Found: C, 54.3; H, 3.1; N, 6.1. $C_{20}H_{14}N_2Br_2$ requires: C, 54.3; H, 3.2; N, 6.3%), δ^1H($CDCl_3$): 8.9 (s, 2H), 8.4–7.3 (m, 12ArH) ppm.

The synthesis of other potential templates

2,3-*Bis*(2-*chlorophenyl*)*quinoxaline* (**12**). To a stirred solution of *o*-phenylene diamine (2.2 g, 0.02 mol) in ethanol (50 cm^3) 2,2′-dichlorodibenzoyl (5.58 g, 0.02 mol) was added. The solution was heated under reflux under nitrogen for 2 h. On cooling, pale cream crystals formed. These were recrystallized from ethanol to give the 2,3-bis-(2-chlorophenyl)quinoxaline (6.9 g, 98%), m.p. 116–118°C (from EtOH) (Found: C, 68.5; H, 3.4; N, 8.0. $C_{20}H_{12}N_2Cl_2$ requires: C, 68.4; H, 3.4; N, 8.0%).

1-(*N-benzylidene*)*amino*-8-*bromonaphthalene* (**15**). A mixture of 8-bromo-1-naphthylamine (1.0 g, 4.5×10^{-3} mol) and benzaldehyde (0.48 g, 4.5×10^{-3} mol) in ethanol (10 cm^3) with a catalytic amount of *p*-toluene sulphonic acid was heated under reflux under nitrogen for 2 h. After filtration, the solid was recrystallized (0.9 g, 59%), m.p. 97°C (from MeOH) (Found: C, 66.1; H, 4.0; N, 4.4. $C_{17}H_{12}NBr$ requires: C, 65.8; H, 3.9; N, 4.5%), δ^1H($CDCl_3$): 8.4 (s, 1H), 8.1–6.8 (m, 11ArH) ppm.

1-*Bromo*-8-*benzylaminonaphthalene*. To a solution of 1-(N-benzylidene)amino-8-bromonaphthalene (0.5 g) in ethanol (5 cm^3) was added sodium borohydride (0.5 g) and the mixture heated under reflux for 1 h. The resulting solution was poured into water, and the amine extracted into ether. Evaporation of the dried ether extract gave an oil. δ^1H($CDCl_3$): 4.5 (s, 2H, $PhCH_2$), and 6.5–8.0 (m, 7H); *m/z* 300 (M^+).

2-*Iodobenzhydrazide*. (Prepared by a modification of a general procedure.[17]) To a flask containing redistilled thionyl chloride (32.6 g, 20 cm^3, 0.28 mol), 2-iodobenzoic acid (10 g, 0.04 mol) was added slowly and the mixture heated on a water bath for 30 min. On addition of all the acid the mixture was heated for a further 30 min. Isolation of the crude acid chloride was achieved by distilling off the excess thionyl chloride. On standing overnight red crystals of 2-iodobenzoylchloride formed. The crystals were filtered and washed with petrol (9.17 g, 86%). The crude acid chloride (5.0 g, 0.02 mol) was added dropwise, with excessive stirring, to a freezing solution of hydrazine hydrate (25 cm^3, 64% w/v). Following the exothermic reaction, the hydrazide crystallized out on standing. After filtration, the product was recrystallized giving 2-iodobenzhydrazide (3.1 g, 63%), m.p. 192°C (Found: C, 33.0; H, 2.6; N, 10.1. $C_7H_7ON_2I$

requires: C, 32.1; H, 2.7; N, 10.7%), δ^1H($(CD_3)_2CO$): 10.0 (s, 1H), 7.9 (d, 1ArH), 7.4 (m, 3ArH), 2.1 (s, 2H) ppm.

Preparation of bis-phosphonium salts

General procedure for the reactions of bis-imines with phosphines. The bis-imine (10^{-3} mol), tertiary phosphine (5×10^{-3} mol) and nickel(II) bromide (2×10^{-4} mol equiv.) were heated together under reflux in ethanol (10 cm^3) in a nitrogen atmosphere for 5–8 h and the progress of the reaction was monitored by TLC (Kieselgel; $CHCl_3$–EtOH (90 : 10) as the eluant). The reaction mixture was then poured into water (50 cm^3) containing KBr (0.5 g), and extracted with ether (2×20 cm^3) in order to remove non-ionic impurities. The aqueous layer was then extracted with chloroform (3×10 cm^3) and discarded. The chloroform layer was dried ($MgSO_4$) and evaporated. The oily residue was then triturated several times with sodium-dried ether until it solidified. On filtration, most of the bis-phosphonium salts, when in contact with the atmosphere, changed almost instantaneously from light-brown solids into dark-brown sticky amorphous compounds. Several of the bis-phosphonium salts that were not hygroscopic were recrystallized from chloroform–ethyl acetate (except as stated otherwise). Characterization by microanalysis proved to be impossible on the hygroscopic salts even on conversion to their related mercuric bromide, tetrafluoroborate, perchlorate or picrate salts. The following salts have been characterized:

N,N′ - bis - (2 - triphenylphosphoniobenzylidene) azine dibromide (**8**). This was isolated as bright yellow crystals (70%), m.p. 300°C (from $CHCl_3$–ether) (Found: C, 63.3; H, 4.6; N, 3.0. $C_{50}H_{40}N_2Br_2P_2 \cdot 3H_2O$ requires: C, 63.6; H, 4.9; N, 3.0), δ^{31}P($CDCl_3$): 26.34 ppm; δ^1H($CDCl_3$): 8.6 (s, 2H), 8.2–7.1 (m, 38ArH) ppm.

N,N′ - bis - (2 - triphenylphosphoniobenzylidene) propane - 1,3 - diamine dibromide. (**9**; $n = 3$). This was isolated as a brown hygroscopic solid (~ 25%), δ^{31}P($CDCl_3$): 24.60 ppm; δ^1H($CDCl_3$): 8.65 (s, 2H), 8.2–7.2 (m, 38ArH), 2.2 (t, 4H), 0.4 (qn, 2H) ppm.

N,N′ - bis - (2 - triphenylphosphoniobenzylidene) butane - 1,4 - diamine dibromide. (**9**; $n = 4$). This was isolated as a brown hygroscopic solid (65%), δ^1H($CDCl_3$): 8.7 (s, 2H), 8.1–7.0 (m, 38ArH), 2.2 (s, 4H), 0.8 (s, 4H) ppm.

N,N′ - bis - (2 - triphenylphosphoniobenzylidene) pentane - 1,5 - diamine dibromide. (**9**; $n = 5$). This was isolated as a brown hygroscopic solid (~ 60%), δ^{31}P($CDCl_3$): 24.68 ppm; δ^1H($CDCl_3$): 8.6 (s, 2H), 8.2–7.2 (m, 38ArH), 2.5 (t, 4H), 0.5 (q, 6H) ppm.

N,N′-bis - (2 - triphenylphosphoniobenzylidene) hexane - 1,6 - diamine dibromide. (**9**; $n = 6$). This was isolated as a brown hygroscopic solid (~ 68%), δ^{31}P($CDCl_3$): 24.69 ppm; δ^1H($CDCl_3$): 8.8 (s, 2H), 8.5–7.4 (m, 38ArH), 2.2 (t, 4H), 0.8 (m, 8H) ppm.

N,N′ - bis - (2 - triphenylphosphoniobenzylidene) heptane - 1,7 - diamine dibromide. (**9**; $n = 7$). This was isolated as a hygroscopic brown solid (~ 70%), δ^{31}P($CDCl_3$): 24.78 ppm; δ^1H($CDCl_3$): 8.5 (s, 2H), 8.2–7.1 (m, 38ArH), 2.6 (t, 4H), 0.7 (m, 10H) ppm.

N,N′ - bis - (2 - triphenylphosphoniobenzylidene) octane - 1,8 - diamine dibromide. (**9**; $n = 8$). This was isolated as a brown hygroscopic solid (~ 62%), δ^{31}P($CDCl_3$): 24.69 ppm; δ^1H($CDCl_3$): 8.6 (s, H), 8.1–7.2 (m, 38ArH), 2.7 (t, 4H), 0.7 (m, 12H) ppm.

N,N′ - bis - (2 - triphenylphosphoniobenzylidene) dodecane - 1,12 - diamine dibromide. (**9**; $n = 12$). This was isolated as a brown hygroscopic solid (~ 63%), δ^{31}P($CDCl_3$): 25.05 ppm; δ^1H($CDCl_3$): 8.35 (s, 2H), 8.1–7.3 (m, 38ArH), 2.7 (t, 4H), 0.8 (m, 20H) ppm.

N,N′ - bis - (2 - triphenylphosphoniobenzylidene) 4,4′-diaminodiphenylmethane dibromide. (**10**; X = $Ph_3P^+Br^-$). This was isolated as yellow crystals (70%), m.p. > 300°C (from EtOH–EtOAc) (Found: C, 67.1; H, 4.6; N, 2.5. $C_{63}H_{50}N_2Br_2P_2 \cdot 4H_2O$ requires: C, 67.0; H, 5.1; N, 2.5%), δ^{31}P($CDCl_3$): 25.89 ppm; δ^1H($CDCl_3$): 8.65 (s, 2H), 8.2–7.2 (m, 38ArH), 6.75–5.95 (8ArH) (deceptively simple $[AX]_2$ system), 3.65 (s, 2H) ppm. (Found: $(M - {}^{81}Br)^+$, 975.2647. $C_{63}H_{50}N_2P_2Br_2$ requires: $(M - {}^{81}Br)^+$, 975.2632).

N,N′ - bis - (2 - tributylphosphoniobenzylidene) 4,4′-diaminodiphenylmethane dibromide. (**10**; X = $Bu_3P^+Br^-$). This was isolated as yellow crystals (67%), m.p. > 300°C (from $CHCl_3$–EtOAc) (Found: C, 63.8; H, 7.9; N, 2.9. $C_{51}H_{74}N_2Br_2P_2$ requires: C, 64.1; H, 8.0; N, 2.9%), δ^{31}P($CDCl_3$): 34.01 ppm; δ^1H($CDCl_3$): 8.8 (s, 2H), 8.0 (m, 8ArH), 7.3 (s, 8ArH), 4.1 (s, 2H), 2.95 (m, 12H), 1.50 (m, 24H), 0.8 (m, 18H) ppm.

N,N′ - bis - (2 - triphenylphosphoniobenzylidene) 1,4 - diaminobenzene dibromide. (**11**; X = $Ph_3P^+Br^-$). This was isolated as orange crystals (76%), m.p. > 300°C (from $CHCl_3$–EtOAc) (Found: C, 67.6; H, 4.6; N, 2.8: $C_{56}H_{44}N_2Br_2P_2 \cdot 2H_2O$ requires: C, 67.1; H, 4.8; N, 2.8%) δ^{31}P($CDCl_3$): 25.86 ppm; δ^1H($CDCl_3$) 8.75 (s, 2H) 7.9–7.3 (m, 42ArH) ppm.

N,N′ - bis - (2 - tributylphosphoniobenzylidene) 1,4 - diaminobenzene dibromide. (**11**; X = Bu_3P^+

Br^-). This was isolated as an orange hygroscopic solid, $\delta^{31}P(CDCl_3)$: 33.60 ppm; $\delta^1H(CDCl_3)$: 8.7 (s, 2H), 8.1–7.3 (m, 12ArH), 2.80 (m, 12H), 1.40 (m, 24H), 0.9 (m, 18H) ppm.

General preparation of quinoxaline diphosphonium salts

The quinoxaline (10^{-3} mol), bis(tertiary phosphine) nickel(II) chloride (10^{-3} mol) and an extra mol of the appropriate tertiary phosphine were heated together under reflux in ethanol in a nitrogen atmosphere for 6–8 h. The product isolation procedure described above was employed and the following salts were isolated:

2,3 - *Bis* - (2 - *triphenylphosphoniophenyl)quinoxaline dibromide.* (**13**; R = Ph; X = Br; Y = $Ph_3P^+Br^-$). A cream solid (50%), m.p. 270°C decomposes (from $CHCl_3$–EtOAc) (Found: C, 69.1; H, 4.9: $C_{56}H_{42}N_2Cl_2P_2$. $CHCl_3$ requires: C, 68.8; H, 4.3%), $\delta^{31}P(CDCl_3)$: 26.73 ppm.

2,3-*Bis*-(2-*tributylphosphoniophenyl)quinoxaline dibromide.* (**13**; R = Bu; X = Br; Y = $Bu_3P^+Br^-$). A cream solid was collected (41%), m.p. 240°C (from $CHCl_3$–ether) (Found: C, 64.3; H, 8.4; N, 3.3. $C_{44}H_{66}N_2Cl_2P_2 \cdot 4H_2O$ requires: C, 63.8; H, 8.9; N, 3.4%), $\delta^{31}P(CDCl_3)$: 32.96 ppm; $\delta^1H(CDCl_3)$: 8.1 (m, 4ArH), 7.6 (m, 8ArH), 2.85 (m, 12H), 1.45 (m, 24H), 0.8 (m, 18H) ppm.

Preparation of mono-phosphonium salts

General procedure. The template (10^{-3} mol), tertiary phosphine (3×10^{-3} mol) and nickel(II) bromide (2×10^{-3} mol) were heated together under reflux in ethanol (10 cm^3) in a nitrogen atmosphere for 6–8 h. The phosphonium salt products were isolated as described above, except that the aqueous solutions of the salts derived from 2-iodobenzoic acid were acidified with hydriodic acid prior to extraction with chloroform.

2 - *Carboxyphenyltriphenylphosphonium iodide.* (**18**; R = Ph). This was isolated as a cream coloured solid (44%), m.p. 120°C (from $CHCl_3$–EtOAc) (Found: C, 57.2; H, 4.7. $C_{25}H_{20}IO_2P \cdot H_2O$ requires: C, 56.8; H, 4.2%), $\delta^{31}P(CDCl_3)$: 26.18 ppm; $\delta^1H(CDCl_3)$: 9.8 (s, 1H), 7.8 (m, 19ArH) ppm.

2 - *Carboxyphenyltributylphosphonium iodide.* (**18**; R = Bu). This was obtained as a light-brown solid (56%), m.p. 184°C (from $CHCl_3$–ether) (Found: C, 51.2; H, 7.5. $C_{19}H_{32}IO_2P$ requires: C, 50.7; H, 7.1%), $\delta^{31}P(CDCl_3)$: 34.98 ppm; $\delta^1H(CDCl_3)$: 9.7 (s, 1H), 8.6–7.7 (m, 4ArH), 2.7 (m, 6H), 1.5 (m, 12H), 0.9 (m, 9H) ppm.

8 - (*N - benzylidene)amino - 1 - naphthyltriphenylphosphonium bromide* (**16**). This was isolated as a pale yellow solid 67%), m.p. 90–95°C decomposes (from $CHCl_3$–EtOAc) (Found: C, 72.2; H, 4.7; N, 2.4. $C_{35}H_{27}N_1P_1Br_1$ $0.5H_2O$ requires: C, 72.3; H, 4.8; N, 2.4%), $\delta^{31}P(CDCl_3)$: 24.1 ppm; $\delta^1H(CDCl_3)$: 8.5 (d, 1H), 8.3–6.3 (m, 26ArH) ppm.

KINETICS AND MECHANISM OF THE REACTION OF NITRILOTRIACETATOCHROMIUM(III) WITH SOLOCHROME YELLOW 2G

ZHANG HUALIN* and ZHANG XU

Department of Chemistry, Fudan University, Shanghai, China

(*Received* 16 *May* 1989; *accepted after revision* 22 *August* 1989)

Abstract—The kinetics of the mixed-ligand complex formation reaction of [Cr(NTA)(H_2O)(H_2O/OH)] (NTA = nitrilotriacetic acid) with Solochrome Yellow 2G [salt of 2-hydroxy-5-[4-sulphophenyl)azo]benzoic acid, $Na(C_{13}H_9N_2O_6S \cdot 2H_2O)$] were investigated in the pH range 5–7 at 40°C and ionic strength 0.1 mol dm^{-3} ($NaClO_4$). The protonation constant of [Cr(NTA)(H_2O)(OH)] at these conditions was determined photometrically and the value $K_a = 2.69 \times 10^5$ mol^{-1} dm^3 was obtained. TLC was also used to monitor the reaction. The pseudo-first-order rate constants (k_{obs}) were found to follow the equation:

$$k_{obs}^{-1} = b_i + a_i C_{Cr(NTA)}^{-1}$$

where a_i and b_i were varied with pH. The results conform to the following scheme:

$$\begin{array}{lll} [Cr(NTA)(H_2O)_2] + HL^{2-} \overset{Q_1}{\rightleftharpoons} [Cr(NTA)(H_2O)(HL)]^{2-} & \xrightarrow{k_1} & H_3O^+ \\ K_a \Big\| \Big\downarrow & & [Cr(NTA)L]^{3-} + \\ [Cr(NTA)(H_2O)(OH)]^- + HL^{2-} \overset{Q_2}{\rightleftharpoons} [Cr(NTA)(OH)(HL)]^{3-} & \xrightarrow{k_2} & H_2O \end{array}$$

and hence gives:

$$b_i = \frac{Q_1 K_a [H^+] + Q_2}{Q_1 K_a k_1 [H^+] + k_2 Q_2}; \quad a_i = \frac{K_a [H^+] + 1}{Q_1 K_a k_1 [H^+] + k_2 Q_2}.$$

The constants of mixed-ligand formation reaction determined were:

$$Q_1 = 1970\ mol^{-1}\ dm^3, \quad Q_2 = 650\ mol^{-1}\ dm^3,$$
$$k_1 = 2.3 \times 10^{-2}\ s^{-1}, \quad k_2 = 1.7 \times 10^{-2}\ s^{-1}.$$

The values of the Q_1, Q_2 and TLC results indicate that the reaction underwent two consecutive steps which involved a rapid formation of the monodentate coordinated dye intermediate followed by the rate-determining ring closure. Similar to TAPP, EDTA etc. as a primary ligand, the coordination of NTA can also greatly enhance the reaction activity of chromium(III) to form the mixed-ligand complex. It can be explained by the increasing electron density of the central chromium(III) and the hydrogen bond formation between the free oxy ion and the adjacent coordinated water.

Azo dyes are widely used in the dyeing industry and chromium(III) azo dye complexes are common mordant dyes.[1] Substitution inertness of $[Cr(H_2O)_6]^{3+}$ is well known.[2] However, it was reported that the anation reactions of $[Cr^{III}Y(H_2O)_n]$, Y represents NH_3 and $C_2O_4^{2-}$, with unidentate ligands are about 10 times faster than that of $[Cr(H_2O)_6]^{3+}$.[3] Moreover, in the case of porphin[4] or EDTA[5] as primary ligand, the rates of anation of the secondary ligand to the chromium(III) complex

* Author to whom correspondence should be addressed.

increases by three to six orders of magnitude. Few studies on the substitution reactions of chromium(III) with dyes have been reported[6] and the kinetic behaviour of chromium(III) mixed-ligand complexes containing azo dyes has not been noticed. The thermodynamic equilibria of reactions of Solochrome Yellow 2G with metal ions have been investigated extensively, but the kinetic and mechanism studies on complexation reactions between them have not been reported so far. In the present work, the kinetics and mechanism of the reaction which involves mixed-ligand complex formation between $[Cr(NTA)(H_2O)(H_2O/OH)]$ and Solochrome Yellow 2G (NaH_2L) have been studied in order to learn how the primary ligand, NTA, affects the lability of chromium(III).

EXPERIMENTAL

Materials

Solochrome Yellow 2G was prepared by following a procedure published elsewhere[7] and the purity was checked by elemental analysis.

$(NH_4)[Cr(NTA)(H_2O)(OH)]\cdot 2H_2O$ was synthesized by the known method.[8] The chromium analysis and visible spectrum of the complex were in good agreement with those in the literature.[8]

All other chemicals used were analytical reagent grade. All solutions were made in deionized water.

Apparatus

Spectra and absorbance of prepared solutions were recorded using a UV-240 recording spectrophotometer (Shimadzu, Japan). The pH measurements were made using a PHM84 research pH meter (Radiometer, Copenhagen).

Visible spectra

The absorption spectra of Solochrome Yellow 2G, CrNTA complexes and their mixture (Cr (NTA)–Solochrome Yellow 2G = 10 : 1) are shown in Fig. 1. Spectral observation indicates the light yellow species of Solochrome Yellow 2G HL^{2-} [Fig. 1(a)] which exists in the pH range 5–7 changes to the orange species, L^{3-} [Fig. 1(b)] in solution at pH 11. Figure 1(c) and (d) are the absorption spectra of $[Cr(NTA)(H_2O)(OH)]^-$ and $[Cr(NTA)(H_2O)_2]$, respectively. Figure 1(e) and (f) show the spectra of a mixture of Cr(NTA) and Solochrome Yellow 2G at pH 6.5 at the beginning of mixing and after completion of the reaction. By comparison of the curves in Fig. 1 it is shown that curve (e) is similar to curve (a), while curve (f) is closed to curve (b) which reveals that Solochrome Yellow 2G in the reaction product is a bidentate ligand. Hence, the reaction kinetics were followed by monitoring the growth in absorbance due to the bidentate Solochrome Yellow 2G mixed-ligand complex at 400 nm and the K_a of $[Cr(NTA)(H_2O)(OH)]$ was determined at 555 nm.

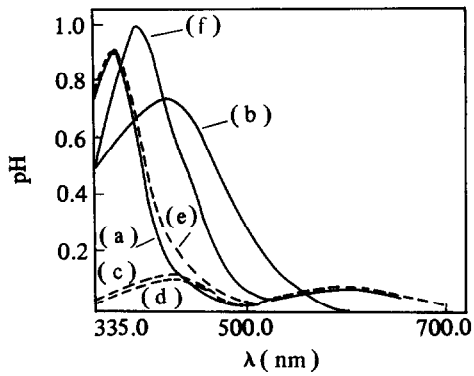

Fig. 1. The absorption spectra of Solochrome Yellow 2G, Cr(NTA) complexes and their mixture at different pH. (a) Solochrome Yellow 2G; $c = 3\times10^{-4}$ mol dm^{-3}, pH = 5–7; (b) Solochrome Yellow 2G; $c = 3\times10^{-4}$ mol dm^{-3}, pH = 11; (c) $[Cr(NTA)(H_2O)_2]$; $c = 3\times10^{-3}$ mol dm^{-3}; (d) $[Cr(NTA)(H_2O)(OH)]^-$; $c = 3\times10^{-3}$ mol dm^{-3}; (e) Solochrome Yellow 2G; $c = 3\times10^{-4}$ mol dm^{-3}, pH = 6.5, 2 min after mixing; (f) 24 h after mixing.

K_a *of* $[Cr(NTA)(H_2O)(OH)]$

The protonation constant of $[Cr(NTA)(H_2O)(OH)]$ was determined photometrically by the published method[9] at 40°C and $\mu = 0.1$ ($NaClO_4$). The equilibrium constant K_a is given as 2.69×10^5 mol^{-1} dm^3.

Kinetic measurements

The curve of the anation reaction in the pH range 5–7 at 40°C and an ionic strength of 0.1 ($NaClO_4$) was followed by observing the increase in absorbance at 400 nm, where the product and the reactants differ appreciably. All experiments were carried out in excess of Cr(NTA) complex and the pseudo-first-order rate constants, k_{obs}, were computed from the gradients of the linear plots of $\ln(A_\infty - A_t)$ vs time by means of a least-squares program. The concentration of Solochrome Yellow 2G is 3.36×10^{-5} mol dm^{-3} and the concentration of Cr(NTA) complex ranges from 3.40×10^{-4} to 12.8×10^{-4} mol dm^{-3}.

TLC analysis

The chromatography of samples was carried out using a silica gel 60 F_{254} (E. Merck) chromatosheet

and ethanol was applied as the developing solvent. The colour and R_f value of Solochrome Yellow 2G (pH 5, HL^{2-}) and Cr(NTA) complex were light yellow, 0.53, purple and zero, respectively. The mixed solution of the Cr(NTA) complex and Solochrome Yellow 2G (10 : 1) at pH 5 was spotted at (a) $t = 2$ min, (b) $t = 1$ h and (c) $t = 24$ h after mixing and then chromatographed. The chromatograms showed the constituents in the reaction mixture were separated to form two or three well-defined zones with different colours. Three coloured spots were shown in situations (a) and (b), the colours and R_f values were as follows: light yellow, 0.48; orange, 0.30; and purple, zero. However, the light yellow substance disappeared and another two coloured species still remained in situation (c). Moreover, the colour intensity of the light yellow species decreased until it disappeared when the reaction time increased and the colour intensity of the orange substance increased with increasing reaction time. Hence, it is reasonable to assume that the orange and purple species are the final product; $[Cr(NTA)L]^{3-}$ and remaining Cr(NTA) complex. The light yellow species which formed quickly when the reactants were mixed and has a R_f value close to HL^{2-} may be assumed to be a steady intermediate.

RESULTS AND DISCUSSION

The pseudo-first-order rate constants, k_{obs}, were measured at various pH values and concentrations of the Cr(NTA) complex. The results are listed in Table 1.

Table 1 shows that k_{obs} decreases with an increase of pH at a given concentration of Cr(NTA), while it increases with an increase of Cr(NTA) concentration at the same pH. In the pH range studied, the plots of k_{obs}^{-1} vs $[Cr(NTA)]_T^{-1}$ at interpolated pH values were linear and some examples are shown in Fig. 2; the slopes, a_i, and intercepts, b_i, of the straight lines were both increased with the increase of pH.

According to the acid dissociation constant of Solochrome Yellow 2G and K_a of $[Cr(NTA)(H_2O)(OH)]$, we can consider that the main species of these in the pH range 5–7 are HL^{2-}, $[Cr(NTA)(H_2O)(OH)]^-$ and $[Cr(NTA)(H_2O)_2]$. As a result of the consistent dependence of k_{obs} on the Cr(NTA) complex concentrations and pH of solutions with an ion-pair mechanism, the complexation reaction probably progresses along the following two parallel paths:

$$[Cr(NTA)(H_2O)_2] + HL^{2-} \overset{Q_1}{\rightleftharpoons} I_1 \xrightarrow{k_1} [Cr(NTA)L]^{3-} \quad (1)$$

$$K_a \uparrow\downarrow$$

$$[Cr(NTA)(H_2O)(OH)]^- + HL^{2-} \overset{Q_2}{\rightleftharpoons} I_2 \xrightarrow{k_2} [Cr(NTA)L]^{3-}. \quad (2)$$

Table 1. Pseudo-first-order rate constants k_{obs} (s^{-1}) for the reaction of Solochrome Yellow 2G with Cr(NTA) at different concentrations of Cr(NTA) and pH values

	Concentration of Cr(NTA) 3.40×10^{-4} mol dm^{-3}						
pH	7.70	6.92	6.71	6.05	5.76	5.50	4.70

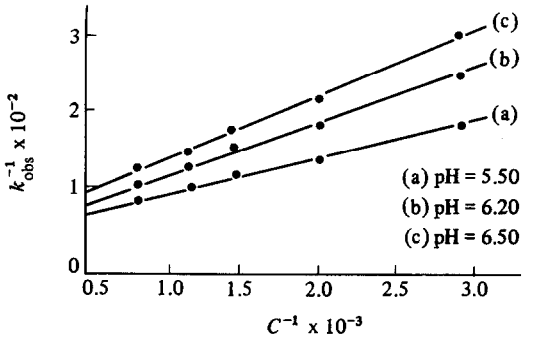

Fig. 2. Linear dependence of k_{obs}^{-1} on $[Cr(NTA)]_T^{-1}$ at different pH.

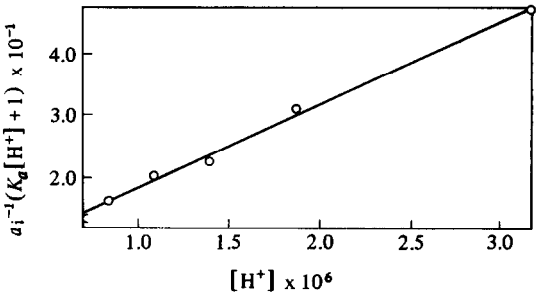

Fig. 3. A plot of $a_i^{-1}(K_a[H^+]+1)$ vs $[H^+]$.

The rate equation derived on the basis of the above mechanism under the pseudo-first-order conditions is given by eq. (3):

$$\frac{d \ln [Cr(NTA)L]}{dt} = k_{obs}[NaH_2L]_T$$

and

$$k_{obs} = \frac{(Q_1K_ak_1[H^+]+k_2Q_2)[Cr(NTA)]_T}{1+K_a[H^+]+(Q_1K_a[H^+]+Q_2)[Cr(NTA)]_T}, \quad (3)$$

where $[NaH_2L]_T$ and $[Cr(NTA)]_T$ are the total concentrations of Solochrome Yellow 2G and Cr(NTA) complex added. Equation (3), on arrangement, gives eq. (4) which satisfies the observed results (Fig. 2):

$$k_{obs}^{-1} = \frac{Q_1K_a[H^+]+Q_2}{Q_1K_ak_1[H^+]+k_2Q_2} + \frac{K_a[H^+]+1}{Q_1K_ak_1[H^+]+k_2Q_2} \times \frac{1}{[Cr(NTA)]_T}. \quad (4)$$

Hence, the slope, a_i, and intercept, b_i, can be expressed as eqs (5) and (6):

$$a_i = \frac{K_a[H^+]+1}{Q_1K_ak_1[H^+]+k_2Q_2} \quad (5)$$

and

$$b_i = \frac{Q_1K_a[H^+]+Q_2}{Q_1K_ak_1[H^+]+k_2Q_2}, \quad (6)$$

which on arrangement give eqs (7) and (8)

$$\frac{K_a[H^+]+1}{a_i} = Q_1K_ak_1[H^+]+k_2Q_2 \quad (7)$$

and

$$b_i(A_1[H^+]+B_1) = Q_1K_a[H^+]+Q_2. \quad (8)$$

Figures 3 and 4 show a plot of $a_i^{-1}(K_a[H^+]+1)$ and $b_i(A_1[H^+]+B_1)$ as a function of $[H^+]$, which give straight lines, and the straight lines obtained have the slopes $A_1 = Q_1K_ak_1$, $A_2 = Q_1K_a$ and intercepts $B_1 = k_2Q_2$, $B_2 = Q_2$. From the slopes and intercepts we can obtain k_1, k_2 and Q_1, Q_2. The results are listed in Table 2.

The calculation of electrostatic interaction involving the 0, 2− and 1−, 2− charges (we ignore the negative charge on the SO_3^- group), as developed by Fuoss, shows that the ion-pair formation constants, K_0, are less than 0.2.[10] However, the Q_1 and Q_2 values obtained for the present system far exceed the K_0 calculated and can be compared with the stability constants of the chromium(III) acetate complex (log K_1 = 4.67, log K_2 = 2.52, log K_3 = 2.69).[11] Hence, it may be reasonable to assume that I_1 and I_2 could not be ion-pairs, but rapidly formed intermediates, $[Cr(NTA)(H_2O)(HL)]^{2-}$ and $[Cr(NTA)(OH)(HL)]^{3-}$, in which only the carboxylate of HL^{2-} is coordinated to chromium(III). $Q_1 > Q_2$ indicates that the coordinated hydroxyl group weakens the coordinate ability of central metal chromium(III). Furthermore, the TLC results also supported the process in which the carboxylate complex formed rapidly and then gradually changed to the product, i.e. the mixed-ligand complex formation reaction underwent two consecutive steps; the rapid formation of unidentate carboxylate complex and then the slow chelate ring closure. Consequently, it is suggested that the rate-determing step is chelate ring closure

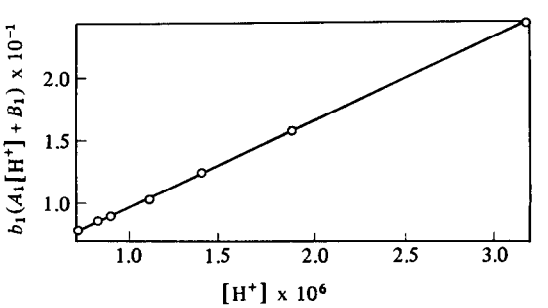

Fig. 4. A plot of $b_i(A_1[H^+]+B_1)$ vs $[H^+]$.

Table 2. Resolved rate constants for formation of the [Cr(NTA)L] complex

$A_1(1.2\pm0.1)\times10^7$	$B_1(11.0\pm0.5)$
$A_2(5.3\pm0.1)\times10^8$	$B_2(650\pm9)$
$k_1(2.3\pm0.2)\times10^{-2}\ s^{-1}$	$Q_1(1970\pm40)\ mol^{-1}\ dm^3$
$k_2(1.7\pm0.1)\times10^{-2}\ s^{-1}$	$Q_2(650\pm9)\ mol^{-1}\ dm^3$

and the rate constants of carboxylate complex formation k_1 are far greater than those of the second step ($k_{I_1} \gg 2.3\times10^{-2}$, $k_{I_2} \gg 1.7\times10^{-2}$).

It is well known that the substitution reactions of chromium(III) ion are inert. But the reaction activity can increase greatly for mixed-ligand complex formation reactions from the coordinated chromium(III) ion, the rate constants of the anation reaction of $[Cr(TAPP)(H_2O)_2]$ with NCS^- and $[Cr(EDTA)(H_2O)]$ with OAc^- are 1.56×10^{-2} $mol^{-1}\,dm^3\,s^{-1}$[4] and $3\ mol^{-1}\,dm^3\,s^{-1}$,[5] respectively, and they are $10^{3.6}$ and 10^5 times faster than that of $[Cr(H_2O)_6]^{3+}$.[12,13] In our work, the rate constants for the anation reaction of $[Cr(NTA)(H_2O)_2]$ and $[Cr(NTA)(H_2O)(OH)]^-$ with the carboxylate of Solochrome Yellow 2G are much greater than $2.3\times10^{-2}\ mol^{-1}\ dm^3\ s^{-1}$. This fact indicates that NTA can labilize the anation reaction of chromium (III) also. The results can be explained reasonably by the increasing electron density of the central chromium(III) owing to the electron donation from NTA, and this makes it more like a labile chromium(II) ion.[3] On the other hand, the free oxy ion existing in the complex ion can act as a nucleophile to form a hydrogen bond with adjacent coordinated water to weaken the $Cr—OH_2$ bond and this makes it easy for the water to leave.

COMMUNICATION

MONOTUNGSTONONAVANADATE AND *MER*-TRITUNGSTOTRIVANADATE

OLIVER W. HOWARTH* and JEREMY J. HASTINGS

Department of Chemistry, University of Warwick, Coventry CV4 7AL, U.K.

(*Received* 7 *September* 1989; *accepted* 21 *September* 1989)

Abstract—Two new tungstovanadates, $[WV_9O_{28}]^{5-}$ and *mer*-$[W_3V_3O_{19}]^{5-}$, have been identified in equilibrated aqueous solutions. ^{51}V–^{51}V COSY spectra support structures analogous to known molybdovanadates, although the tungstovanadate species more readily support a higher anionic charge.

Several tungstovanadates [tungsten(VI), vanadium(V)] have been reported in the solid state and also in aqueous solution, where they persist for some time after dissolution before chemical equilibrium is reached. These species include three with the Lindqvist structure,[1] $[W_5VO_{19}]^{3-}$, $\delta_V = -522.9$; *cis*-$[W_4V_2O_{19}]^{4-}$, $\delta_V = -508.3$; its monoprotonated form, $\delta_V = -526$ ($pK_a \approx 2.7$) and *fac*-$[W_3V_3O_{19}]^{5-}$, $\delta_V = -500$.[2] At lower pH there are also many Keggin-type species,[2] such as $[V \cdot V_2W_{10}O_{40}]^{5-}$, with a central tetrahedral vanadium and a full range of isomeric forms.

An alternative approach to the investigation of tungstovanadates is to work with fully equilibrated solutions, preferably at more than one temperature, and over a wide range of pH and metal ratios. This approach has been used with simple vanadates,[3] peroxo-[4] and sulphidovanadates[5] and molybdovanadates.[6] In this latter case the dominant species at a high V–Mo ratio were $[MoV_9O_{28}]^{5-}$, its protonated form ($pK_a \approx 2.8$, 0.6 mol dm^{-3} NaCl), and *cis*- and *trans*-$[Mo_2V_8O_{28}]^{4-}$, each with the decavanadate structure.[7] At lower V–Mo ratios a wide variety of species are found,[8,9] including $[Mo_5VO_{19}]^{3-}$ and *cis*-$[Mo_4V_2O_{19}]^{4-}$ ($pK_a = 3.9$) but not $[Mo_3V_3O_{19}]^{5-}$. However, Keggin structures are only found in small amounts. We report here two major new species apparent from a similar investigation of the tungstovanadate system, which are found in the medium pH range 3–7, alongside the (5,1) and *cis*-(4,2)† species reported earlier.

$[WV_9O_{28}]^{5-}$ AND $[HWV_9O_{28}]^{4-}$

Figure 1 shows the ^{51}V NMR spectrum of a pH 4.97 solution raised to 99°C, with 20 mmol dm^{-3} of tungsten and 80 mmol dm^{-3} of vanadium. The sharp peak at −503.5 ppm arises from *cis*-(4,2), with weaker peaks from decavanadate (0,10) at −418.3, −495.4 and (in part) −511.6 ppm. The broad peak at −564 ppm arises from exchange-averaged tetrahedral vanadate species. The remaining peaks are in the area ratios 2:2:2:1:1:1, and Table 1 shows their shifts to be close to those of $[MoV_9O_{28}]^{5-}$. Figure 2, part of a ^{51}V–^{51}V COSY spectrum[6] at pH 3.56, reveals the connectivities of the vanadium atoms in this species. The full spectrum also shows the connectivities (1,9)1–2, 1–3 and 5-6, albeit more weakly. A *fac*-(3,3) peak prob-

† (*n*,*m*) is shorthand for the species $[W_nV_mO_x]^{(2x-6n-5m)-}$.

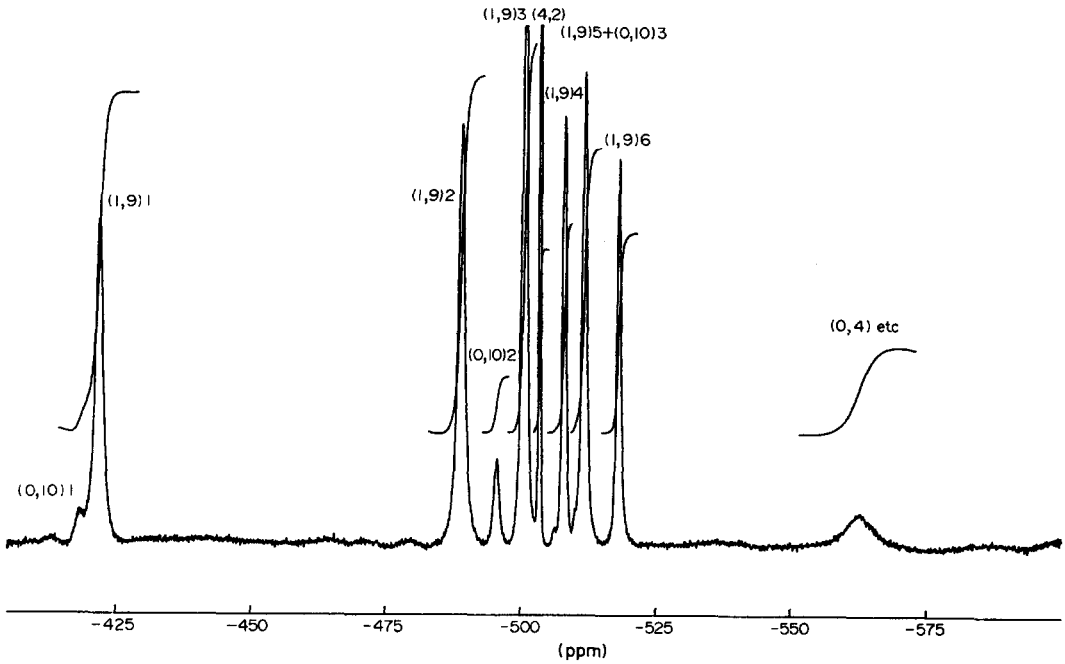

Fig. 1. ^{51}V NMR spectrum at pH 4.97, 99°C, 20 and 80 mmol dm^{-3} in tungsten and vanadium, respectively, showing predominantly $[WV_9O_{28}]^{5-}$.

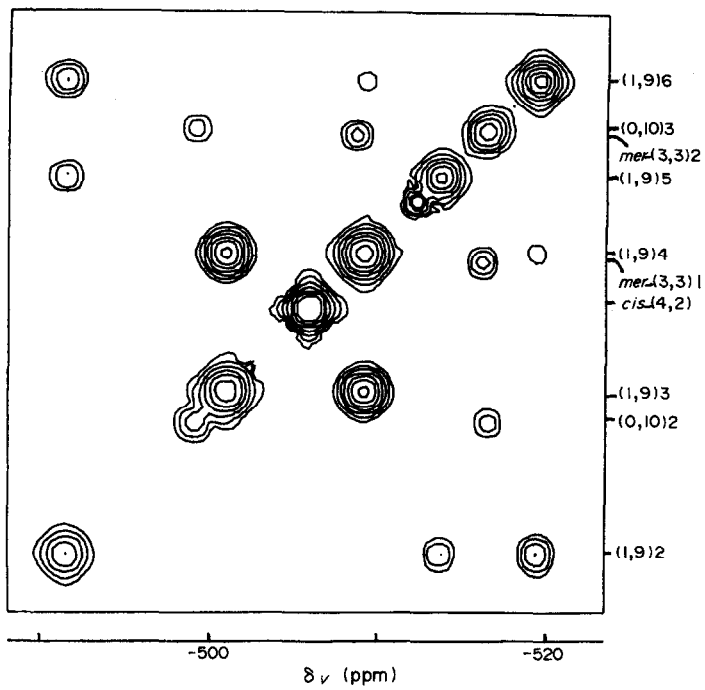

Fig. 2. 99°C ^{51}V–^{51}V COSY-90 spectrum of $[WV_9O_{28}]^{5-}$, together with some $[W_5VO_{19}]^{3-}$, $[W_4V_2O_{19}]^{4-}$ and *fac*- and *mer*-$[HW_3V_3O_{19}]^{4-}$. 400 mmol dm^{-3} in vanadium, 125 mmol dm^{-3} in tungsten; pH 3.56.

ably lies under the (1,9)3 peak, but of course has no coupling to reveal it. Thus the (1,9) tungstovanadate must be isostructural with the corresponding (1,9) molybdovanadate, and have the structure shown in Fig. 3. At lower pH the species protonates, and although decomposition occurs before protonation is complete, the pK_a (20°C) is *ca* 2.3.

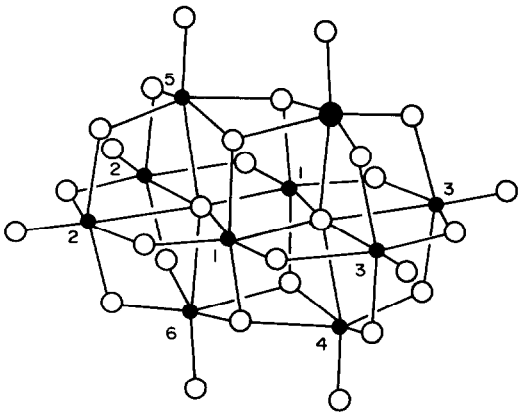

Fig. 3. Structure of $[WV_9O_{28}]^{5-}$ (● = W, • = V, ○ = O).

MER-$[W_3V_3O_{19}]^{5-}$

Figure 4 shows the ^{51}V NMR spectrum of a pH 6.51 solution, raised to 99°C, with 50 mmol dm^{-3} of both tungsten and vanadium. The dominant peaks are those from *cis*-(4,2) (truncated in the figure) and tetrahedral (0,*n*) species. Weak peaks from (1,9) are also apparent. There is also a peak at −496.7 ppm arising from *fac*-(3,3). The (4,2) and *fac*-(3,3) peaks at 20°C arise at −511.4 and −501.4 ppm, respectively, and thus correspond adequately with the values reported by Leparulo-Loftus and Pope.[2] They also have the correct relative dependence upon the tungsten–vanadium ratio.

However, two further peaks also appear strongly in Fig. 4, at −504.7 and −509.2 ppm, in the area ratio 1 : 2. The corresponding 20°C values are −513 and −518 ppm. The latter resonance was observed but not explained by Pope.[2] They have the same dependence on concentration and metal ratio as the *fac*-(3,3) peak, and show a strong ^{51}V–^{51}V coupling in COSY spectra (see Fig. 2 for one example). We therefore propose that they arise from *mer*-(3,3) (Fig. 5). The ^{51}V shifts of the resonances are consistent with Pope's observation[2] that a neighbouring VO_6 octahedron increases δ_V. They decrease below pH 6.5, at the onset of protonation.

CONCLUSIONS

Although the tungstovanadate species mirror the molybdovanadates in many ways, there are also significant differences. Judging from the relative proportions of species under comparable conditions, tungsten fits somewhat less readily into the decavanadate structure than does molybdenum. Indeed, we have little evidence yet for (2,8) tungstovanadate species. In contrast, tungstovanadate Keggin species are more stable than molybdovanadate Keggins.

Also, in all the cases where isostructural species exist, the pK_a is lower in the tungsten case [(1,9), 2.3 vs 2.8; (2,4) 2.7 vs 3.9].[6,9] Concomitantly, (3,3) species are only found with tungsten. Evidently the tungstovanadate species prefer to bear a higher

anionic charge, perhaps because of stronger π-bonding from oxygen to tungsten.

EXPERIMENTAL

^{51}V NMR spectra were obtained at 105.2 MHz on a Bruker WH400 spectrometer, typically with 2000 transients. ^{51}V–^{51}V COSY-90 spectra[6] were obtained at 99°C to minimize linewidths. All pH values refer to the solutions at 20°C.

Acknowledgement—We thank Lage Pettersson for helpful discussion.

BOOK REVIEW

Gmelin Handbook of Inorganic Chemistry, 8th edn, Boron Compounds, Formula Index for 3rd Supplement Volumes 1–4. Springer, Berlin, 1988. ISBN 3-540-93576-2. 960.0 DM.

Volumes 1–4 of the 3rd supplement covered compounds between boron and hydrogen, boron and oxygen, boron and nitrogen or fluorine, and boron and chlorine, bromine, iodine, sulphur, selenium and tellurium, and carboranes, respectively, all up to the end of 1984. The present volume provides, in 240 pages, the index to their listings.

The first column of the tabulation gives the empirical formula of the compound, the second gives the linear molecular formulae, and the third gives the page reference in the appropriate volume. The authors are R. Warncke with R. Bohrer, H. Hartwig, R. Jonuschat, B. Kalbskopf, R. Nohl, V. Nohl, H.-J. Richter-Ditten and P. Velić.

This will enhance the value of these volumes to people working in the field of boron chemistry.

FOREWORD

Having been "asked" by Malcolm Chisholm to act as a guest editor for a Polyhedron Symposium-in-Print on "main group chemistry, or something" one is left with the problem of narrowing this brief so as to cover something a little more manageable in scope. The choice of the chemistry of the heavier group III (13) elements aluminium, gallium and indium arose from the desire to put together a multi-disciplinary symposium which would inform and stimulate as wide a readership as possible. The often quoted, renewed interest in the chemistry of aluminium, gallium and indium is perhaps unique in that it does, indeed, cover many areas of research: inorganic, biological, organic, organometallic and solid-state chemistry. The breadth and quality of papers submitted are, I believe, due testament to this.

I have tried to give the authors as much freedom as possible in the style and content of their contributions, allowing for both timely reviews and original research to be presented. The papers are not placed in any specific order. I have, however, tried to group together related topics.

I would like to acknowledge the help of Professor Malcolm Chisholm (Executive Editor), Miss Sheryl Fellows (Polyhedron Production Editor) and Mr Mark Perigard (my secretary) for their advice and assistance with this symposium.

COMPARISON OF LIGANDS OF DIFFERING DENTICITY AND BASICITY FOR THE *IN VIVO* CHELATION OF ALUMINIUM AND GALLIUM

DAVID J. CLEVETTE*† and CHRIS ORVIG*

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, British Columbia V6T 1Y6, Canada

Abstract—Twenty-eight chelating ligands for aluminium, gallium and indium have been evaluated as binders of the M^{3+} ions in a simple human blood plasma model. Effective formation constants (at pH 7.4) and values of pM ($-\log[M^{3+}]$) were not found to be convenient tools for the comparison of all ligands under certain conditions. Speciation modelling allowed a direct comparison amongst ligands of the binding efficacy towards these metal ions under blood plasma conditions (50 μM transferrin sites, 0.1 M citrate, pH 7.4, 25°C). Applications of speciation computer modelling to animal studies are also discussed.

We are interested in the speciation and chelation of the trivalent metal ions of aluminium, gallium and indium *in vivo*. The presence of abnormally high concentrations of aluminium in the nuclei of brain cells of Alzheimer disease patients[1,2] and the inherent neurotoxicity of aluminium,[3] as well as the wide use of radioisotopes of gallium and indium as diagnostic agents in nuclear medicine, have spawned considerable interest in the chelation chemistry of these metal ions in recent years. This Symposium-in-print is a testament in general to the burgeoning chemistry of the group 13 (IIIA) elements.

In vivo chelation of Al, Ga and In requires a basic chemical knowledge of the properties of the potential chelating ligand. If the purpose of the ligand is decorporation of the ion then considerable water solubility is needed in addition to high thermodynamic stability of the metal–ligand complex. If a complex is to be a radioactive imaging agent, lipophilicity is usually necessary to prevent washout and the stability should be such that the complex is not demetallated before it reaches its ultimate biological target. Thus, the determination of thermodynamic stability constants is a critical component of the design of complexes which will interact with biological systems in any manner.

Since we are involved in ligand design and synthesis, we have found it necessary to compare the metal-binding affinities of ligands which we have prepared with those of ligands in the literature (Fig. 1). Often it is difficult to compare directly formation constants of different ligands for a metal ion because of variations in denticity and in the number of ionizable protons. Our approach to ligand comparisons has been adopted from that pioneered by Perrin and co-workers[4,5] and refined extensively by May and Williams.[6,7] In this contribution we demonstrate a very simple blood plasma model which we have found extremely useful in comparing ligands which bind the group 13 metal ions.

THE METAL IONS

The coordination chemistry of Al, Ga and In in aqueous solution reflects the acidity of these trivalent metal ions, M^{3+}. Infinite dilution pK_a values for the hydrolysis reaction (1)

$$[M(H_2O)_6]^{3+} = [M(OH)(H_2O)_5]^{2+} + H^+ \quad (1)$$

are, in order of decreasing acidity, 2.6 for Ga, 3.9 for In and 5 for Al.[8] This is a measure of the bond strength between the metal ion and the oxygen atoms from bound water molecules. The stronger the M—O bond, the weaker the O—H bond, and the acidity increases. The reason that Ga and In are more acidic than Al has been explained classically in terms of the relative deshielding of the positive metal centres of Ga and In by the more diffuse *d*-electrons, with a concomitant higher effective

nuclear charge. The great affinity of the Al^{3+}, Ga^{3+} and In^{3+} ions for oxygen donor ligands has been well documented[9,10] and this paper concentrates in large part on ligands of this type.

We have used a large number of formation constants from the literature to calculate linear free energy relationships (LFERs) for the formation constants of two similar metal ions with each of two groups of ligands. The two groups of ligands are ligands which incorporate exclusively oxygen-donor groups and those which incorporate both oxygen and nitrogen coordinating atoms. (The

complexation of the ferric ion has been extensively studied; Fe^{3+}, with a pK_a of ~ 2.5,[8] is a convenient reference metal ion for the group 13 ions.[11–13]) Constants for Al, Ga and In were plotted individually versus Fe^{III} and the linear equations were found for O-donor ligands to be (with regression coefficients R):

$$\log K_{Al} = (0.795)\log K_{Fe} + 0.02 \quad R = 0.994 \quad (2)$$

$$\log K_{Ga} = (0.954)\log K_{Fe} - 0.65 \quad R = 0.987 \quad (3)$$

$$\log K_{In} = (0.970)\log K_{Fe} + 0.68 \quad R = 0.996 \quad (4)$$

and for O,N-donor ligands:

$$\log K_{Al} = (0.617)\log K_{Fe} + 2.48 \quad R = 0.929 \quad (5)$$

$$\log K_{Ga} = (0.991)\log K_{Fe} - 0.57 \quad R = 0.959 \quad (6)$$

$$\log K_{In} = (1.034)\log K_{Fe} - 0.73 \quad R = 0.994. \quad (7)$$

The slopes of these plots give a relative ordering of the affinity towards O- or O,N-donor ligands. The slope with O,N ligands for Al^{3+} is lower than that with O ligands, whereas the reverse is true for Ga^{3+} and In^{3+}. The slopes of the O-donor LFERs give the relative affinity as Fe > In > Ga ≫ Al. Indium is misplaced before Ga when compared with the order of metal ion acidities and this might be explained by size considerations. Indium forms stronger complexes than Fe (slope > 1) with the O,N-donor ligands in this study; they are mostly hexadentate ligands (edta derivatives) with large "bites" which tend to favour In chelation.

THE LIGANDS

In describing the equilibrium between a metal ion and a ligand, a formation constant (K' or K) is reported either in terms of the reaction with the fully protonated ligand [HL—eq. (8)]:

$$M + HL = ML + H \quad K' = \frac{[ML][H]}{[M][HL]} \quad (8)$$

or more commonly, with the fully deprotonated ligand [L—eq. (9)]:

$$M + L = ML \quad K = \frac{[ML]}{[M][L]} \quad (9)$$

where charges have been omitted for clarity. Direct comparison of constants (either K or K') for a set of ligands with a metal ion does not demonstrate the differences in binding strength at a particular pH. The competition between H^+ and M^{n+} for the ligand must be considered and the fraction of protonated ligand at any specific pH becomes very important.

An effective, or conditional, formation constant is one that corrects K or K' by the fraction of ligand deprotonated at a particular pH,[14,15]

$$K_{eff(pH)} = \alpha K \quad (10)$$

or

$$\log K_{eff(pH)} = \log K + \log \alpha, \quad (11)$$

where α is the fraction of deprotonated ligand ($0 < \alpha \leqslant 1$) as governed by the pK_a values. (Similarly, one may obtain $\log K_{eff(pH)} = \log K' - \log \alpha$.) This provides a more direct comparison of formation constants within a set of ligands (of same denticity) at a set pH value (obviously, pH 7.4 is commonly chosen). In Table 1, $\log K_{eff(7.4)}$ values are given for some multidentate O-donor ligands that are known[9] to be reasonable chelators for trivalent metal ions in aqueous solution. For consistency, these values were calculated from formation constants* determined as close to 25°C and 0.15 M ionic strength (isotonic) as possible. Table 2 presents similar calculations for bidentate ligands. Each ligand (except transferrin) is shown in Fig. 1. The discussion is limited to ligands with C or N atoms adjacent to the bonding O atoms (phosphate ligands are not considered, *vide infra*).

Another commonly used comparison of the strengths of metal–ligand complexes is the pM value. The pM is the negative log of the concentration of the free metal ion (i.e. the negative log of the concentration of $Al(H_2O)_6^{3+}$, $Ga(H_2O)_6^{3+}$ or $In(H_2O)_6^{3+}$). This value is computed from formation constants at a given pH (again, often 7.4) with known total metal and ligand concentrations. Commonly, pM is calculated for a solution containing 1 μM total metal and 10 μM ligand. These concentration levels are used to calculate pM values at pH 7.4 for the ligands listed in Tables 1 and 2. The higher the pM value, the stronger the chelator. Values of pM allow a direct comparison between ligands of different denticities as long as each ligand prevents hydrolysis of the metal ion. Figure 2 graphs the pM "excess" over that allowed by hydrolysis for a selected set of ligands with Al^{3+}, Ga^{3+} and In^{3+} at pH 7.4. (Care must be taken in comparing pM values such that the ligand-to-metal ratio is the same; if the ligand–metal ratio increases, the pM value increases accordingly.) When comparing pM values with weaker ligands, the hydroxide ion (OH^-) limits the upper amount of free metal ion in solution (i.e. the lower limit on pM) so that weak ligands have the same pM value as does OH^-. Water may be excluded from the calculations in order to compare the relative strength of these

* All formation constants have been taken from ref. 9 unless otherwise stated.

Table 1. Values of pM and log K_{eff} for the multidentate ligands with Al^{3+}, Ga^{3+} and In^{3+}. log K_{eff} is the effective formation constant at pH 7.4 calculated from data obtained from ref. 9, unless otherwise indicated. Values of pM are calculated for 1 μM total metal and 10 μM total ligand at pH 7.4 and 25°C. The minimum pM values allowed by hydrolysis are 12.6 (Al), 18.4 (Ga), and 15.3 (In)[a]

weaker ligands; however, as Martell and Motekaitis have pointed out,[16] these results are irrelevant to a real situation.

Comparison of $\log K_{eff}$ values can determine the differences among the weaker ligands as well as the stronger ones; however, this is limited in that it cannot be used to directly compare ligands of varying denticities. There does exist a linear relationship between $\log K_{eff}$ (or $\log \beta_{3eff}$) and pM for those ligands that prevent hydrolysis. For ML complexes (Table 1), $\log K_{eff}$ was close to pM -1.1 while for ML_3 complexes $\log \beta_{3eff}$ was close to pM $+9.0$. (Citrate was not included; an anomalously high pM is found because of the formation of ternary hydroxo–citrato–metal complexes.) The slopes of these pM vs $\log K_{eff}/\log \beta_{3eff}$ correlations are found to be (and can be analytically derived as) unity in both cases; however, the intercept differs by $\sim 10^{10}$ which is why a comparison of multi- and bidentate ligands using $\log K_{eff}$ or $\log \beta_{3eff}$ values is not useful.

Although the pM "excess" approach of Fig. 2 works for many ligands, we sought through speciation modelling a direct comparison of all types of ligands regardless of denticity, number of ionizable protons, or relative binding strength.

BLOOD PLASMA SPECIATION MODELLING

Ultimately, the speciation of a metal in the presence of potential chelators will provide insights into

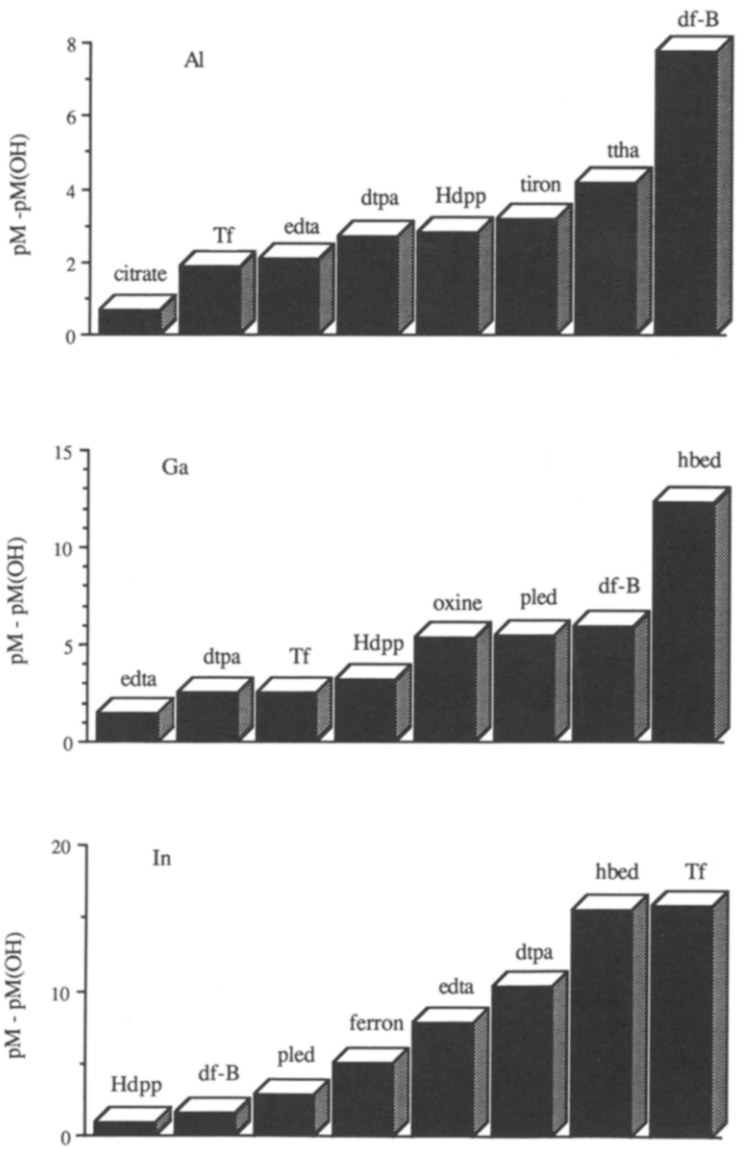

Fig. 2. The pM "excess" [pM − pM(OH)] plotted for a select group of ligands for Al (top), Ga (middle) and In (bottom) systems at pH 7.4 and 25°C.

the *in vivo* behaviour. The multi-equilibrium blood plasma model chosen for the speciation of Al^{3+}, Ga^{3+} and In^{3+} contains citrate (0.1 mM) and transferrin (abbreviated Tf, a two-sited protein[17] present at 37 μM) which are assumed to be the principal low molecular weight and high molecular weight chelators of trivalent metal ions in blood plasma, respectively.[15,18] Only 30% of the sites on Tf are saturated with Fe^{3+},[19] and the ferric ion is assumed to remain complexed with Tf in the presence of other chelating agents for modelling purposes. This leaves 50 μM empty sites on Tf available for chelation with Al, Ga or In. Transferrin binding constants in the literature are measured as effective formation constants at pH 7.4 under a quantified excess of bicarbonate. These are listed and referenced in Table 1 (one constant for each site). Citrate equilibrium constants are taken from refs 20 and 21 for Al and Ga, respectively. The often quoted first binding constant for In with Tf ($10^{30.5}$)[22] is anomalously high and is most likely inaccurate. Other workers have deduced the first formation constant for In with Tf to be $10^{23.8}$[23] or $10^{18.8}$.[24] Since values for this constant are discrepant (there may be a bicarbonate dependence), this discussion is limited to the speciation modelling of Al and Ga. (Iron is a concern in modelling Al and Ga,[13] so we have compared some calculations which include separate concentrations of Fe^{3+} and Tf and we have found results very similar to those for the simple model with 50 μM empty Tf sites.) Human serum albumin was not included in the model because of a lack of good numbers for Al-binding and because it is generally agreed not to be a good competitor for Al in the presence of the other ligands commonly found in blood.[15,18] Phosphate, although present in total at about 1.5 mM in plasma (as $H_2PO_4^-$ and HPO_4^{2-}), was excluded from the model because of a lack of reliable formation constant data which consider hydrolysis. Data and constants recorded at 25°C are compared as these are the most prevalent in the literature.[9] Not many potentiometric studies have been carried out at 37°C.

The calculated speciation distribution in our blood plasma model for Al and Ga in the absence of exogenous ligands is shown in Fig. 3. Ga^{3+} should be completely complexed by Tf; however, a significant amount of Al^{3+} may be complexed by citrate in the form of $Al(OH)(H_{-1}Cit)^{2-}$. There are no reports of a similar citrate species of Ga^{3+}; the Ga–citrate system[21] has not been studied in nearly as much detail as has the Al–citrate system.[20,25–30] It should be noted that the distribution of the Al^{3+} ion between citrate and Tf depends on whether the total Al concentration is above the saturation level of Tf (50 μM). If it is more then Al^{3+} would be bound to citrate (*vide infra*). There have been discrepancies in the speciation of the Al–citric acid–H_2O system. In a review of Al–citrate studies current in 1986, Martin[29] agreed with Motekaitis and Martell[27] that the major species present at pH 7.4 was $Al(H_{-1}Cit)^-$, while subsequently both $Al(H_{-1}Cit)^-$ and $Al(OH)(H_{-1}Cit)^{2-}$ (the major form at pH 7.4) were found by Öhman.[20] The latter complex was also postulated by Martin[18] in his reconsideration of the available data. We use Öhman's results[20] in our blood plasma model. Based on the protocol of Fig. 3, the results of Martin,[18] Motekaitis and Martell,[27] and Öhman[20] all give percentages of total Al as citrate in the 13–16 range.

The concentration required for each ligand in Table 1 to complex Al or Ga in the presence of citrate and Tf in the blood plasma model has been calculated. The results are presented visually in ligand competition diagrams; these plot the percentage of the metal ion complexed with a particular ligand against the concentration of ligand. For Al^{3+} (Fig. 4), the diagram is divided into two regions,

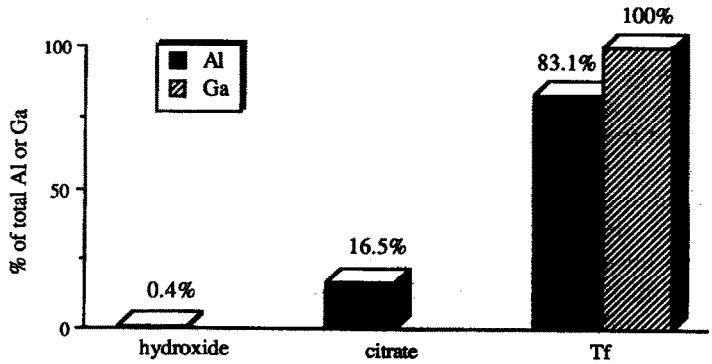

Fig. 3. Calculated blood plasma distribution of 1 μM total Al or Ga between 0.1 mM total citrate and 50 μM available Tf binding sites at pH 7.4 and 25°C.

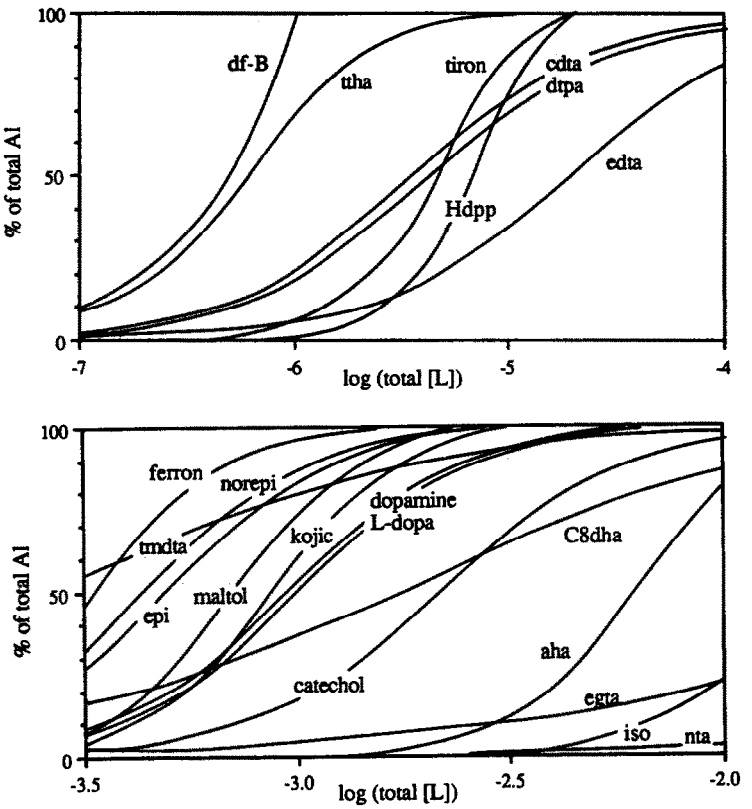

Fig. 4. Plots of the total ligand concentration required to complex a dilute (< 50 μM) solution of Al in the presence of 0.1 mM citrate and 50 μM available Tf binding sites at pH 7.4 and 25°C. The top figure shows those ligands that require < mM concentration levels, while the ligands in the bottom figure require ⩾ mM levels.

those of low (μM) and high (mM) concentrations. The ligands of particular relevance to chemistry in plasma are those that do not require a large excess (< mM) to complex Al (or Ga) in the presence of citrate and transferrin. For Al, those ligands include the multidentate ligands desferriferrioxamine-B (a trihydroxamate siderophore), edta and its derivatives ttha, cdta and dtpa (aminocarboxylates), and the bidentate ligands tiron (a disulphonated catechol) and Hdpp (a 3-hydroxy-4-pyridinone). The curves in Fig. 4 for the bidentate ligands have steeper slopes than those for the multidentate ligands. The thermodynamics of forming a 3 : 1 complex versus a 1 : 1 complex dictate that a large excess of a multidentate ligand is required to complex 80–100% of the metal ion, whereas only a small excess of multidentate ligand is required in the 0–20% range. The chelate effect mandates that the multidentate ligands should require a lower concentration than a bidentate ligand to completely bind the metal ion if the binding groups are similar. It is interesting to note that the two bidentate ligands Hdpp and tiron (both of which benefit from considerable resonance stabilization that increases the negative charge on the binding oxygens) compete with edta and its derivatives in the binding of Al^{3+} in our plasma model.

The more weakly complexing ligands for Al^{3+} in Fig. 4 require at least millimolar concentrations in the blood to complex a significant amount of the ion. The poorer ligands include the neurologically active catecholamines dopamine, L-dopa, epinephrine and norepinephrine.[31] In the brain, Tf and citrate are present in vanishingly small quantities; therefore it seems plausible that these ligands could compete with weaker ligands (such as hydroxide) for Al and Ga in the brain.

Comparison of the analogous results for Ga^{3+} (Fig. 5) with those for Al^{3+} shows that the curves for a given ligand are generally shifted to the right (higher concentrations required) in the Ga diagram. The ratio of log K_{eff}(Ga/Al) for Tf is 1.50, while the same ratio (log K_{eff} or log β_{3eff}) is 1.31 ± 0.11 with all other ligands in Tables 1 and 2. (This is significantly different at the 98% level based on unpaired t-tests.) Hence it is more difficult to remove Ga from Tf than it is to remove Al from Tf with the same ligand. For example, an edta concentration of 10 μM in the

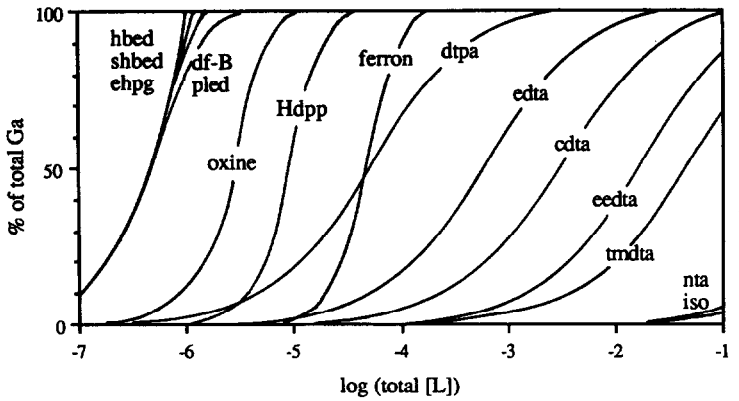

Fig. 5. Plots of the ligand concentrations required to complex a dilute (< 50 μM) solution of Ga in the presence of 0.1 mM citrate and 50 μM available Tf binding sites at pH 7.4 and 25°C.

blood should complex approx. 30% of Al^{3+}, but would complex less than 3% of Ga^{3+} under the same conditions. Great care should be taken when using Ga^{3+} biodistributions as a marker for Al^{3+} in the blood unless a large excess of ligand is present.

Martell and co-workers have determined very high stability constants for some edta derivatives with Ga^{3+}, Fe^{3+} and In^{3+} (hbed, shbed, ehpg and pled).[9,24] A recent reevaluation[32] of the pled formation constants has detailed some of the difficulties in obtaining accurate formation constants with these ligands because the numbers are so large. As is shown in Fig. 5, because of the high formation constants, these ligands (along with df-B) are excellent candidates for Ga chelation. Welch, Martell and co-workers[33,34] and Hunt[35] have been studying them. The next best set of ligands are the bidentate ligands, oxine, Hdpp and ferron. Oxine (8-hydroxyquinoline), a well-known chelator of trivalent metal ions,[9] is widely used in nuclear medicine with isotopes of Ga and In, and is a gravimetric agent for Al. Dtpa and edta both complex > 50% of the total Ga at 1 mM ligand concentration in blood plasma. We have examined the biodistribution of complexes of Hdpp and some of its analogues.[36]

These curves allow the determination of the ligand concentration required to retain a certain percentage of the metal ion in the metal–ligand complex in human blood plasma. The quantity R_n is the amount of ligand (in μM) required to complex n% of 1 μM metal ion at pH 7.4 in a solution of 0.1 mM citrate and 50 μM available Tf binding sites (R_n = [total ligand]/1 μM total metal). Tables 3 and 4 list, for Al^{3+} and Ga^{3+} respectively, R_{20}, R_{50} and R_{90} values for the ligands in this study. For those ligands with $R_n > 1$ (not the best ligands), the R_n values are independent of the metal ion concentration when the latter is below 1 μM and the R_n values are nearly independent in the range 1–50 μM (50 μM being the concentration at which all the empty sites of Tf should be saturated). What is really being measured is the competition between excesses of ligands for a small quantity of metal ion. As long as the concentration of the metal ion is low (a good assumption with biomedical applications), these values may be taken as the lower limit of concentration (in μM) required to retain the given percentage of the ion as the metal–ligand complex

Table 3. Comparison of calculated ligand complexation with Al^{3+} in the blood plasma model consisting of 1 μM Al^{3+}, 0.1 mM citrate, 50 μM empty Tf sites, pH 7.4, and 25°C. R_n is the ratio of total ligand concentration to total metal concentration required to complex n% of the metal

in the blood plasma. For example, a 13 μM Hdpp solution in blood plasma should complex about 90% of 1 μM Al^{3+}, whereas it would take a 1.3 or 1.5 mM (100-fold increase) epinephrine or maltol solution to complex a comparable percentage of Al^{3+}. Similarly, df-B would complex 100% Al with a slight excess over 1 μM. With the very powerful chelating agents, df-B, hbed, shbed and ehpg, these R_n values do not represent the lower limit of concentration. Much lower total metal concentrations would have to be considered to calculate the lower limits.

APPLICATIONS

Obviously in applying the above calculations from *in vitro* data to *in vivo* behaviour, certain limitations are unavoidable. Almost all *in vivo* laboratory work with Al^{3+} and Ga^{3+} is conducted in mice, rats or rabbits, not people. Physiological differences (pH concentrations) from humans will render the above calculations less precise and, regardless of species, Fe^{3+} transport has been assumed to be governed by human transferrin. Temperature differences may alter slightly the actual concentrations required but should not affect the relative ligand positions unduly. Kinetics have been ignored as workers are just beginning to address[37] this aspect in the calculation of the biological chelation of metal ions.

We have performed two *in vivo* ^{67}Ga biodistribution studies in laboratory mice,[36] in which Hdpp solutions were injected (by tail vein) such that the ligand concentrations in the blood plasma were 0.2 μM in one study and 4.0 mM in the other ($\approx 10^{-12}$ M $^{67}Ga^{3+}$ in the blood in each study). Based on the R_n values in Table 4, $^{67}Ga^{3+}$ would be removed to Tf in dilute Hdpp but $^{67}Ga^{3+}$ would be retained as $^{67}Ga(dpp)_3$ in the concentrated case. With the concentrated solution, we found a significant difference (99% level by unpaired *t*-tests) in the biodistribution of eight organs from those animals that were injected with a weak complexing agent (citrate).[36] The Ga–citrate biodistribution was the same as that of ^{67}Ga–Tf (lots of liver),[38] while the concentrated Ga–Hdpp preparation was cleared very rapidly via the kidneys. With the dilute Hdpp injection, no difference from the citrate biodistribution was found; the dilute Hdpp biodistribution also reflected that of Ga–Tf. These results support the predictions based on the above calculations. In fact, nothing less than a 100-fold increase over the dilute case, to 20 μM Hdpp, should have altered the biodistribution drastically.

In a recent study of oral administration,[39] tris-(maltolato)aluminium(III) was found to transport Al^{3+} across the gastrointestinal tract into the blood plasma in rabbits much more effectively than aluminium chloride or aluminium citrate. Assuming that the Al found in the blood was transported in the form of the tris(maltolato) complex, the nature of the Al speciation in the blood after the transport was of considerable interest because the urine of the rabbits showed abnormally high Al levels for a month after the single oral administration. The Al concentration in the blood (average of five animals) peaked at 67 μM, 1–3 h after administration (by AAS). Based on three molecules of maltol per Al^{3+} ion, there were 200 μM maltol in the blood. From Table 3 it can be estimated that 720 μM maltol would be required to complex 50% of Al. Speciation modelling using the plasma model presented in this contribution estimates that only 6.4% of the Al should remain as maltol-containing species (Fig. 6), the remainder being distributed between citrate complexes and transferrin. (Transport and storage due to protein saturation would be consistent with the long biological half-life.) The same calculation with Hdpp instead of maltol as the complexing agent shows that about 94% of the Al should be complexed with Hdpp in the blood (Fig. 6). (Hdpp is also bidentate and monoprotic and thus also forms an Al^{3+} complex which possesses a net neutral charge.)

Calculations such as these have prompted us to examine a variety of 3-hydroxy-4-pyridinones as *in vivo* chelating agents for Al and Ga transport. The blood plasma model presented here is crude when compared with a more comprehensive system such as "fully-loaded" ECCLES,[6] but for

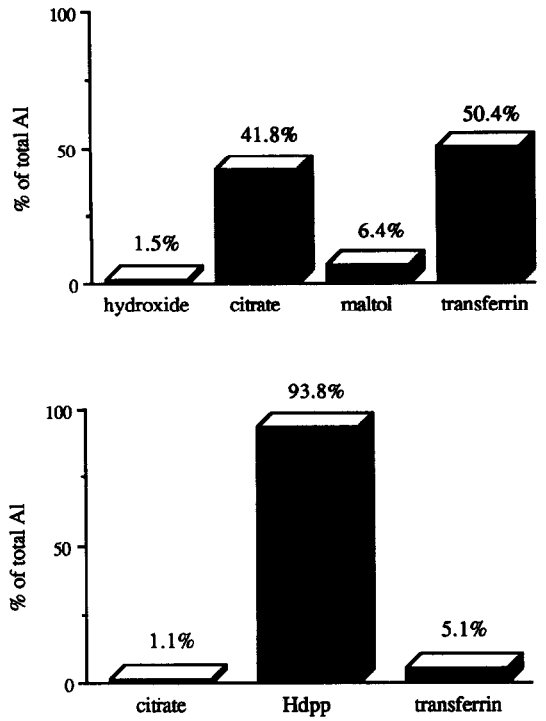

Fig. 6. Calculated distribution of 67 μM Al in blood plasma (citrate and Tf at pH 7.4). The top figure includes 200 μM maltol, while the bottom figure includes 200 μM Hdpp.

estimations of relative metal binding it has proven invaluable.

ALUMINIUM, GALLIUM AND INDIUM IN BIOLOGICAL FLUIDS—A COMPUTER MODEL OF BLOOD PLASMA

GRAHAM E. JACKSON

Department of Chemistry, University of Cape Town, Rondebosch 7700, South Africa

Abstract—A computer model of the solution equilibria involving Al^{3+}, Ga^{3+} and In^{3+} in blood plasma has been constructed and used to investigate the *in vivo* fate of these metal ions. The effect of a series of chelating agents on the species distribution of Al^{3+} is reported. Chemical explanations are given for a number of clinical observations on the use of $^{67}Ga^{3+}$ and $^{111}In^{3+}$ in nuclear medicine.

In recent years, as evidenced by this special publication, there has been a renaissance in the chemistry of aluminium, gallium and indium. Because of their favourable decay characteristics and availability, $^{67,68}Ga^{3+}$ and $^{111}In^{3+}$ have been used in nuclear medicine, but it is only recently that the significance of the aqueous chemistry of these metal ions has been recognized. The biological importance of the sister elemental Al^{3+} has long been ignored. However, this element has now been linked to the aetiology of a number of neurological and skeletal disorders in man. First recognized in patients undergoing long-term haemodyalisis the effects of aluminium are now known to be more widespread.[1–8]

This paper investigates, using a computer model of blood plasma, the aqueous chemistry of Al^{3+}, Ga^{3+} and In^{3+}. Whereas these three metal ions show very similar chemical behaviours, their *in vivo* functions differ considerably from each other. Aluminium can be regarded as a polluting metal *in vivo*, whereas gallium and indium are clinically very useful. For this reason the metal ions are discussed separately.

COMPUTER MODEL OF BLOOD PLASMA

May *et al.*[9,10] have published a computer model of blood plasma and have used this model to explain several clinical observations.[11] The model consists of 40 ligands, nine metal ions and *ca* 5000 complexes. To this model we have added the appropriate formation constants for Al^{3+}, Ga^{3+} and In^{3+}. These constants were, as far as possible, abstracted from the literature.[12] In cases where the same constants had been published by several authors the values of these constants were evaluated critically. In cases where a complex was potentially important, but for which no constants were available, values were estimated. This was done mainly using linear free-energy relationships[13] between Al^{3+}, Ga^{3+}, In^{3+} and Fe^{3+}, but in certain cases appropriate interpolations were made based on chemical analogies. Amino acid complexes of Al^{3+} and Ga^{3+} were not included in the model as previous experiments have shown these complexes to be unimportant.[14] The final set of constants used in this simulation study is given in Table 1. The constants for the chelating agents N,N′-bis(*o*-hydroxylbenzyl)ethylenediamine-N,N′-diacetic acid (HBED),[29,30] ethylene-1,2-bis(*o*-hydroxyphenylglycine) (EHPG),[12] desferrioxamine (DFO),[31,32] N,N′-bis(pyridoxyl)ethylenediamine-N,N′-diacetic acid (PLED),[29,33] N-phosphonomethylglycine (PMG),[34] 1,2-dihydroxybenzene-3,5-disulphonate (TIRON),[35] ethylenedinitrilo-N,N′-diacethylhydroxamic-N,N′-diacetic acid (EDDO)[12] and catechol (CAT)[36] were obtained from the literature and used without modification.

Mixed-ligand (ternary) complex formation occurs widely in systems containing metal ions and two or more different ligands. These complexes have been shown to be important in blood plasma.[37] Since very little data are available on ternary complex formation of Al^{3+}, Ga^{3+} and In^{3+} the relevant binary constants were used to calculate the ternary constants. This was achieved using the prescan facilities (MIX)[38] of the computer program ECCLES with a ternary stabilization factor of 1.0.

[a] Estimated.

In addition to this automatic calculation of ternary stability constants, the constants given in Table 2 were calculated[40] and included in the model.

Aluminium

Aluminium readily undergoes extensive hydrolysis in aqueous solution forming an insoluble salt $Al(OH)_3$. Being amphoteric at higher pH this salt redissolves to form $[Al(OH)_4]^-$. In the presence of phosphate aluminium can also form the highly insoluble complex $Al(OH)_2(H_2PO_4)$. Based on the solubility products and stability constants of these two complexes it is possible to calculate the concentration at which they will begin to precipitate (or the solution becomes supersaturated). The solubility product, K_{sp}, of amorphous $Al(OH)_3$ is given by:[23]

$$K_{sp} = [Al^{3+}]/(H^+)^3 = 10^{10.7},$$

while the equilibrium constant β_3 for the reaction

$$Al(H_2O)_3^{3+} = Al(OH)_3 + 3H^+$$

is given by[26]

$$\beta_3 = [Al(OH)_3](H^+)^3[Al^{3+}]^{-1} = 10^{-15.9}.$$

Substituting the solubility product expression into this equation we get for the maximum concentration of $Al(OH)_3$

$$[Al(OH)_3]_{max} = \beta_3 K_{sp} = 10^{-5.2} \text{ mol dm}^{-3}.$$

At pH 7.4 the highest permitted concentration of free Al^{3+} from amorphous $Al(OH)_3$ is $10^{10.7} \times 10^{-3\times 7.4} = 10^{-11.5}$ mol dm^{-3}. Similarly, the concentration of $Al(OH)_2(H_2PO_4)$ at which precipitation occurs can be calculated.[41]

$$K_{sp} = [Al^{3+}][H_2PO_4^-][H^+]^{-2} = 10^{-1.5}$$

and[27]

$$\beta = \frac{[Al(H_2PO_4)(OH)_2][H^+]^2}{[Al^{3+}][H_2PO_4^-]} = 10^{-3.6},$$

therefore, $[Al(H_2PO_4)(OH)_2]_{max} = \beta K_{sp} = 10^{-5.1}$ mol dm^{-3}.

At pH 7.4 in blood plasma with a total phosphate concentration of 1.6 mmol dm^{-3} the concentration of $H_2PO_4^-$ is estimated, using the computer model, to be 2.1×10^{-5} mol dm^{-3}. This leads to an estimated maximum free Al^{3+} concentration permitted by $[Al(H_2PO_4)(OH)_2]$ of 2.5×10^{-12} mol dm^{-3}. If no account is taken of metal ion, particularly Ca^{2+}, binding, then the concentration of $H_2PO_4^-$ becomes 2.8×10^{-4} mol dm^{-3} and the maximum free Al^{3+} concentration is estimated to be 1.8×10^{-13} mol dm^{-3}.

The avidity of transferrin for Al^{3+} has been measured, under physiological conditions, to be 12.9 and 12.3 for log K_1 and log K_2, respectively.[16] At 1 μmol total Al^{3+} per litre of plasma, Martin[41] has shown that this leads to a permitted free Al^{3+} concentration of $10^{-14.6}$ mol dm^{-3}. However, if competition with the other components of blood plasma is taken into account a lower free metal concentration is obtained. At pH 7.4 our results have shown that within the total aluminium concentration range 10^{-13}–10^{-5} mol dm^{-3}, *ca* 50% of the aluminium is bound to transferrin in the 1 : 1 complex. Using this information, after suitable manipulation of the relevant equation we arrive at the conclusion that the free Al^{3+} concentration is $\sim 10^{-9} \times [Al^{3+}]_{Total}$. At a total Al^{3+} concentration of 1 μmol this means a free Al^{3+} concentration of 10^{-15} mol dm^{-3}.

Since Al^{3+} readily undergoes hydrolysis in aqueous solution its complexes are likely to be similarly affected. In certain cases this has been explicitly determined, but in the majority of cases stability

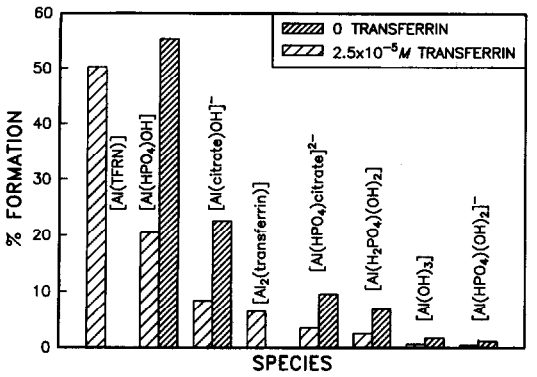

Fig. 1. Calculated blood plasma species distribution of Al^{3+}. Total $[Al^{3+}] = 10^{-9}$ mol dm^{-3}, [transferrin sites] $= 2.5 \times 10^{-5}$ mol dm^{-3}, [phosphate] = 1.6 mmol dm^{-3}, other component concentrations taken from ref. 9.

constants have been determined under acid conditions where little or no hydrolysis takes place. In these cases hydrolysis constants for the complexes have been estimated (see Table 1).[39] Similarly Al^{3+} forms very stable binary[27,42] and ternary phosphate[28,39] complexes. Because of the high plasma concentration of phosphate ($\sim$ 1.6 mmol dm^{-3}) it is important that these ternary complexes be included in any model of plasma (see Table 2).

Figure 1 shows the calculated species distribution of Al^{3+} in blood plasma. This distribution is independent of aluminium concentration within the range 10^{-13}–10^{-5} mol dm^{-3}. Since transferrin uptake of the metal is inevitable, but slow, we have considered the species distribution before and after equilibrium with this protein becomes established. In the absence of transferrin binding the neutral $[Al(HPO_4)OH]$ species predominates. This is contrary to a previous analysis[43] in which citrate complexes were predicted to predominate. Once transferrin binding is included in the calculation, the concentration of the low molecular weight species decreases but their relative distribution remains fairly constant. The effect of the transferrin is to decrease the amount of Al^{3+} available to the low molecular weight pool.

The effect of pH upon the Al^{3+} species distribution is shown in Fig. 2. At low pH the $[Al(H_2PO_4)]^{2+}$ species is formed exclusively. The concentration of this species decreases with increasing pH such that at pH 5 it accounts for only 1% of the total aluminium. Between pH 4 and 6.5 the $[Al(H_2PO_4)citrate]^-$ species predominates. As the pH is raised this species deprotonates to give $[Al(HPO_4)citrate]^{2-}$. Between pH 6 and 8, $[Al(citrate)OH]^-$ and hydrolysed phosphate complexes predominate. Beyond pH 8 hydroxy–aluminium species are formed.

The potential toxicity of aluminium has led to the development of protocols for its removal from the body. Clinical success has been limited.[44] At present the reagent of choice is desferrioxamine,[45,46] a naturally occurring siderophore. Since the primary objective in decreasing the body burden of Al^{3+} is to increase urinary excretion of the metal ion, we have tested, using our computer model, the effect of various chelating agents upon the Al^{3+} species distribution. Various chelating agents have been investigated using the Plasma Mobilizing Index,[11] *PMI*, which is defined as the increase in the low molecular weight concentration of a metal ion brought about by a chelating agent relative to the metal ion concentration in the absence of the chelating agent. Figure 3 shows the *PMI*

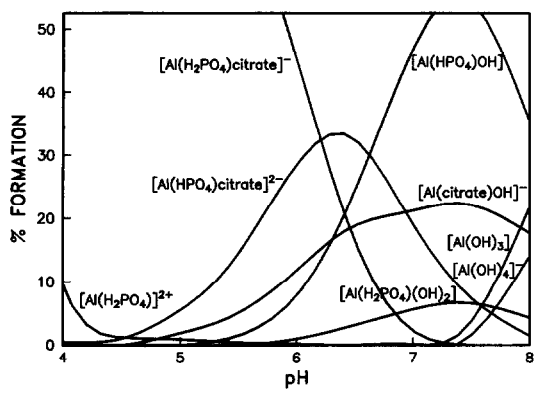

Fig. 2. Calculated low molecular weight blood plasma species distribution of Al^{3+} as a function of pH. Total $[Al^{3+}] = 10^{-9}$ mol dm^{-3}, [phosphate] = 1.6 mmol dm^{-3}, other component concentrations taken from ref. 9.

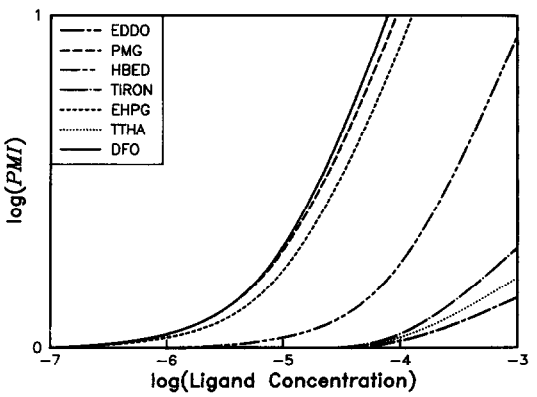

Fig. 3. Plasma Mobilizing Index of Al^{3+} with several chelating ligands. Fixed free $[Al^{3+}] = 10^{-14}$ mol dm^{-3}, [phosphate] = 1.6 mmol dm^{-3}, other component concentrations taken from ref. 9.

curves for the various reagents tested. The polyaminopolycarboxylates (EDTA, DTPA, CDTA etc.) showed little or no mobilization below a concentration of 10^{-3} mol dm^{-3}. Only with the analogue triethylenetetramine hexa-acetic acid (TTHA) did mobilization occur at this concentration. A similar mobilization was exhibited by the substituted catechol TIRON and the hydroxamate EDDO. Of intermediate ability was HBED. Good mobilization was exhibited by the catechol derivative EHPG and the phosphonate PMG. These calculations were based on a free Al^{3+} concentration of 10^{-14} mol dm^{-3}. If this concentration is lowered the Al^{3+} *PMI* curves shown in Fig. 3 will move to the left, but their position relative to each other will remain unchanged.

Desferrioxamine, which is clinically used to increase Al^{3+} excretion,[46] was found to be the most efficient mobilizer of Al^{3+}. This is true, however, only if the equilibrium constants of Garrison and Crumbliss[31] are used in the calculations. If the much lower equilibrium constants of Schwarzenbach[32] are used instead, desferrioxamine is predicted to give rise to little or no aluminium mobilization.

Clinically, several side effects have been noted with the use of desferrioxamine to increase urinary excretion of aluminium. Figure 4 shows the effect of the chelating ligands considered in this study on the low molecular weight concentration of Zn^{2+} and Fe^{3+}. As expected the catechol derivatives, HBED and EHPG, cause a large increase in the low molecular weight concentration of Fe^{3+} but only a small increase in the low molecular weight concentration of Zn^{2+}. A much larger increase in Zn^{2+} mobilization was shown by the polyaminopolycarboxylate TTHA. Of the chelating ligands considered, DFO appears to have the most potential as an *in vivo* Al^{3+} chelating agent. This ligand causes the largest increase in low molecular weight Al^{3+} yet has very little effect on the Fe^{3+} or Zn^{2+} biodistribution. If the concentration of Al^{3+} is lowered, DFO will begin to mobilize Fe^{3+} such that in the absence of Al^{3+} extensive Fe^{3+} mobilization occurs. This has been observed clinically. With a high (> 200 μmol dm^{-3}) plasma concentration of Al^{3+}, DFO preferentially causes Al^{3+} excretion,[47] but with a high plasma concentration of Fe^{3+} (haemosiderosis, β-thalassemia) DFO treatment results in increased Fe^{3+} excretion.[48]

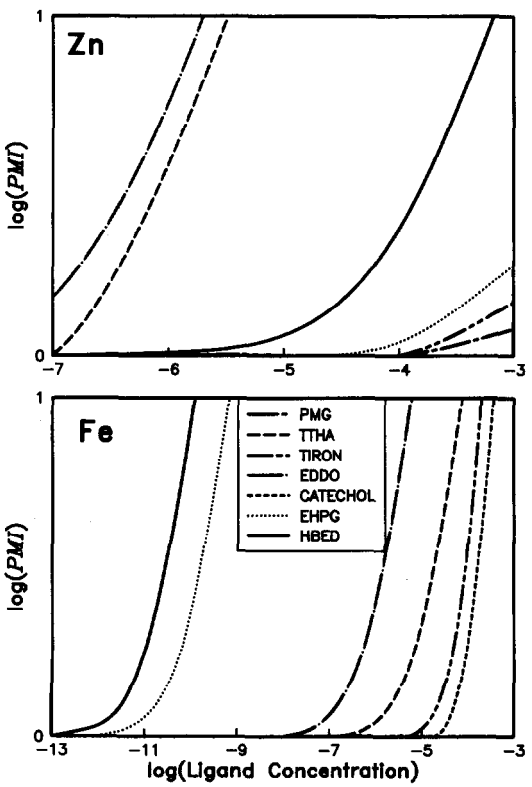

Fig. 4. Plasma Mobilizing Index curves for Fe^{3+} and Zn^{2+} with several chelating agents. Fixed free $[Fe^{3+}] = 10^{-23}$ and fixed free $[Zn^{2+}] = 10^{-9}$ mol dm^{-3}.

Gallium and indium

Like Al^{3+}, In^{3+} and Ga^{3+} undergo extensive hydrolysis in aqueous solution[23,24] forming the insoluble salts $In(OH)_3$ and $Ga(OH)_3$. It is for this reason that the radionuclides ^{67}Ga and ^{111}In are supplied with a high background concentration of acid or citrate. Based on the solubility products of these two salts ($10^{-35.3}$ and 10^{-37}, respectively)[23] the maximum solution concentration of $In(OH)_{3(aq)}$ and $Ga(OH)_{3(aq)}$ can be estimated to be 2×10^{-9} and 5×10^{-9} mol dm^{-3}, respectively. This is higher than the maximum concentration of the insoluble phosphate salts, $InPO_4$ ($K_{sp} = 10^{-21.6}$)[12] and $GaPO_4$ ($K_{sp} = 10^{-21}$),[12] which is estimated to be $10^{-11.6}$ and 10^{-11} mol dm^{-3}, respectively. At pH 7.4, in blood plasma, the maximum concentration of free Ga^{3+} and In^{3+} permitted by $Ga(OH)_3$ and $In(OH)_3$ is $\sim 10^{-18}$ and 10^{-16} mol dm^{-3}, respectively, whereas the maximum free concentration permitted by $GaPO_4$ and $InPO_4$ is 3×10^{-13} and 7×10^{-15} mol dm^{-3}, respectively.

In nuclear medicine scanning procedures, in the absence of carrier Ga^{3+}, blood, $^{67 \text{ or } 68}Ga^{3+}$ concentrations are between 1 and 100 pmol, depending on the procedure and administered dose. At this concentration, our computer model of blood plasma shows the metal ion is bound almost exclusively to transferrin. The predominant low molecular weight complexes are hydrolysed phosphate and citrate complexes. At mg/kg levels, $Ga(NO_3)_3$ has been found to be effective in a variety of murine

tumour models.[49] Preclinical studies showed the dose-limiting toxicity to be renal. In addition, while not the method of choice, high levels of carriers Ga^{3+} have been used in bone scanning.[50] At these elevated levels of Ga^{3+} the transferrin binding sites are saturated and the excess Ga^{3+} is distributed as shown in Table 3. At these high concentrations the solubility of $Ga(OH)_3$ and $GaPO_4$ is exceeded and the formation of colloidal gallium is expected. Clinically[51] rapid excretion in the urine and deposition in the bone is seen at mg/kg levels of Ga^{3+}. Other agents which block binding sites on transferrin, e.g. carrier levels of scandium[52] or hyperferremia associated with whole-body X-ray irradiation,[53] have a similar effect on Ga^{3+} biodistribution.

^{67}Ga as the citrate complex is used extensively as a tumour imaging agent.[54] Computer simulation shows that even with an elevated citrate concentration (10^{-3} mol dm^{-3}) the Ga–citrate complexes are not able to survive in plasma and release the $^{67}Ga^{3+}$ to transferrin. It is the labelled transferrin which is accumulated by the tumour. This conclusion is supported by clinical observations.[55] Addition of carrier Ga^{3+} or Fe^{3+} displaces the $^{67}Ga^{3+}$ from the transferrin complex, resulting in increased excretion and a lower tumour uptake of the radioactive isotope.

Recently, numerous ligands have been designed for the selective chelation of radionuclides.[33,56,57] Since the major *in vivo* chelator of Ga^{3+} and In^{3+} is transferrin, we have calculated the ability of a range of chelating agents to remove the metal ions from this protein. The results for Ga^{3+} are given in Fig. 5 in the form of *PMI* curves. The substituted catechol derivatives HBED, PLED and EHPG are able to prevent protein binding of Ga^{3+} at very low ligand concentrations. Desferrioxamine is also predicted to be a strong *in vivo* chelator of Ga^{3+}. DTPA, its analogues, and TIRON are ineffective at removing Ga^{3+} from transferrin.

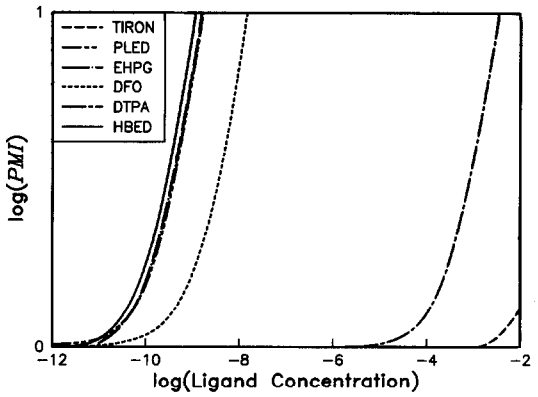

Fig. 5. Plasma Mobilizing Index curves for Ga^{3+} with several chelating agents. Fixed free $[Ga^{3+}] = 10^{-24}$ mol dm^{-3}. Total $[Ga^{3+}]$ in absence of chelating agent = $\sim 10^{-10}$ mol dm^{-3}.

Simple hydroxamic acids form stable Ga^{3+} complexes. Our simulation studies have shown, however, that these complexes are not stable enough *in vivo* to prevent exchange of Ga^{3+} with transferrin. Animal studies[58] support this conclusion in that the biodistribution of $^{67}Ga^{3+}$–hydroxamic acid complexes follow closely the distribution of ^{67}Ga–citrate.

Attempts have been made to use DTPA as a complexing agent for $^{67}Ga^{3+}$ and $^{111}In^{3+}$ radioimaging.[59] Alternatively DTPA, as the anhydride, has been coupled to proteins as a means of radiolabelling the macromolecule.[60] These attempts have to a large extent been unsuccessful. DTPA is unable to prevent loss of the metal ion *in vivo*.[61] Computer simulation of this system has shown that the metal ion in the Ga^{3+} DTPA complex is lost to transferrin. The driving force for this reaction is the high *in vivo* concentration of Ca^{2+} which displaces Ga^{3+} from its DTPA complex. As a check of our blood plasma model the species distribution of Ca was calculated and compared with measured values obtained in the literature, a satisfactory agreement being obtained (Table 4). The fact that $^{111}In^{3+}$ labelled DTPA and EDTA protein conjugates have been used clinically[62,63] can be attributed to the slow decomposition of these complexes relative to the duration of the diagnostic procedure. Any dissociation though leads to increased background radiation and hence decreased contrast. Similar results have been obtained with $^{67}Cu^{2+}$ labelled DTPA– and EDTA–protein conjugates.[64] The fast exchange kinetics of Cu^{2+}, however, limit the clinical usefulness of these complexes. Here our computer model predicts that the metal ion is lost to albumin.

Table 3. Calculated species distribution of Ga^{3+} complexes in blood plasma. Total $[Ga^{3+}] = 0.18$ mmol dm^{-3}, total [phosphate] = 1.6 mmol dm^{-3}, other component concentrations taken from ref. 9

Species	Concentration (mol dm^{-3})	Total Ga^{3+} (%)
$[Ga(OH)_4]^-$	1.3×10^{-4}	70.3
$[Ga_2(TFRN)]$	2.5×10^{-5}	26.6
$[Ga(OH)_3]$	4.9×10^{-7}	2.9
$[Ga(TFRN)]$	2.5×10^{-8}	0.3
$[Ga(HPO_4)(OH)_2]$	1.0×10^{-8}	0.0
$[Ga(OH)_2]^+$	5.4×10^{-9}	0.0
$[Ga]^{3+}_{free}$	5.0×10^{-17}	0.0

Table 4. Calculated and observed citrate species concentrations present in blood plasma. Component concentrations taken from ref. 9

Complex	Concentration (mol dm^{-3}) Calculated	Observed[59]
Ca–citrate	0.058	0.038
Mg–citrate	0.032	0.044
Na–citrate	0.031	0.039

Finally, at a DFO concentration of 10^{-5} mol dm^{-3} our computer model predicts that 81% of Ga^{3+} will be complexed to DFO and 19% bound to transferrin. Clinical studies have shown, however, that the ^{67}Ga labelled DFO–IgG conjugate is stable *in vivo* with no loss of radionuclide after incubation with serum or following intravenous injection.[65] The high charge and stability of the Ga–DFO complex is consistent with the rapid renal excretion of the metal ion. DFO is used to reduce ^{67}Ga background radiation from the blood-pool in diagnostic imaging.[66]

In conclusion, in this study we have used computer simulation in an attempt to explain and predict the *in vivo* fate of Al^{3+}, Ga^{3+} and In^{3+} complexes. However a word of caution is necessary. Computer models are only as good as the data upon which they are based. Many of the constants used in this study have been estimated or determined under inappropriate conditions. Also, kinetic factors which affect the metal ion species distribution have not been taken into account. Much work therefore needs to be done on the aqueous chemistry of Al^{3+}, Ga^{3+} and In^{3+} to improve our model. Notwithstanding these limitations, our model has been successful in explaining many clinically observed phenomena.

ALUMINIUM COMPLEXES OF HYDROXYALIPHATIC AND HYDROXYAROMATIC LIGANDS IN AQUEOUS SYSTEMS—SOME PROBLEMS AND SOLUTIONS

ARTHUR E. MARTELL,* RAMUNAS J. MOTEKAITIS and ROBERT M. SMITH

Department of Chemistry, Texas A&M University, College Station, TX 77843–3255, U.S.A.

Abstract—The stabilities of aluminium(III) complexes of ligands with hard oxygen donors are analysed and an up-to-date compilation of critical stability constants of aluminium(III) complexes of hydroxyaliphatic and hydroxyaromatic chelating agents is presented. The interferences with complex formation caused by hydrolysis of the metal ion to form soluble mononuclear and polynuclear hydroxo complexes, and by aluminium(III) hydroxide precipitation, are illustrated. In view of contradictory reports in the literature, a unified treatment of aluminium(III) citrate complexes is presented, and the formation of stable and metastable forms of mononuclear and ternuclear hydroxo citrate complexes is illustrated. The limitations in the use of normal formation constants for representing equilibrium data involving ligands with very high pK's is explained, and the use of hydrogen ion displacement equilibrium constants for such systems is recommended. Comparison of the effectiveness of several ligands for aluminium(III) complexation shows that desferriferrioxamine B (Desferal®)†, recommended for the treatment of aluminium(III) overload is by far the superior ligand over a very broad pH range.

The aquo aluminium(III) ion is the "hardest" of the trivalent ions commonly found in biological systems and the environment. Its effective ionic radius of 0.54 Å is considerably smaller than other commonly encountered trivalent metal ions (Table 1) such as Fe^{3+} (0.64 Å) and In^{3+} (0.80 Å). Trivalent boron, with an ionic radius of 0.23 Å, does not occur as an electropositive ion in aqueous solution.

Because of its small ionic radius, aluminium(III) polarizes solvated water molecules very strongly, giving rise to several hydrolytic species (hydroxo complexes), which are described by the equilibrium constants presented in Table 2. The monohydroxo complex, $Al(OH)(H_2O)_n^{2+}$, formed in the first

step, is converted to several more complex hydrolytic species as the pH is increased. The following complexes listed in Table 2 have been detected: $Al(OH)_2^+$, $Al_3(OH)_4^{5+}$, $Al(OH)_3$ (insoluble), $Al(OH)_4^-$, and the unique polynuclear complex $Al_{13}O_4(OH)_{24}^{7+}$. The rates of formation of the polynuclear complexes are quite slow, and the complexes may persist in solution for long periods of time as metastable species even when the pH has been changed to the conditions where they are no longer the most stable complexes.

A review of the early literature on the coordination chemistry of aluminium(III) reveals considerable stability data of questionable validity. In many cases the strong hydrolytic tendencies of aluminium(III) had not been considered in data processing and in deciding on the complex species present in solution. Workers at that time were not completely aware of the tendency of aluminium(III) to form long-lasting yet metastable hydrolytic complexes which may persist for hours or even days.

The slowness of substitution reactions in the coordination sphere of aluminium(III) is further aggravated when the donors are multidentate ligands, which involve steric effects as well as cooperative donor group coordination about the metal ions. Equilibrium measurements of aluminium(III)–ligand interactions are almost invariably slow, and studies that do not take this factor into account are generally in error.

EFFECTIVE LIGAND DONOR GROUPS FOR ALUMINIUM(III)

Because aluminium(III) is probably the "hardest" metal ion frequently encountered in aqueous complex systems, it is apparent that it is most strongly bound by ligands with hard donor groups. The most effective donor groups are therefore, negative oxygen donors, having a single negative charge, HO^- or RO^-, but even more effective is the oxide O^{2-} ion. Thus the hydroxide ion (Tables 1 and 2) forms many complexes of aluminium(III), while the oxide anion, which is more difficult to generate (i.e. to replace both H^+ ions from water) may be

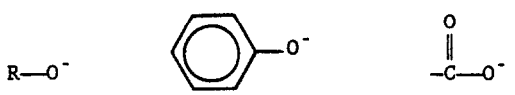
found in polymeric hydrolytic species bridging two (or more) aluminium(III) ions.

The fluoride ion is also small, negative and isoelectronic with OH^-. It is seen in Table 2, however, that binding of fluoride to aluminium(III), while quite strong, is considerably weaker than that of hydroxide ion. This difference is due to the polarity of the hydroxide ion, whereby its negative charge is directed toward the electron acceptor (the metal ion), whereas the fluoride ion is more symmetrical. Thus the metal ion sees less negative charge density with fluoride binding than it does with hydroxide coordination.

ORGANIC LIGANDS

The following are some of the donor groups which are most frequently present in organic ligands which have been found to be very effective in binding aluminium(III) in aqueous solution, presented in the order of decreasing hardness, which is also the order of decreasing metal ion affinity.

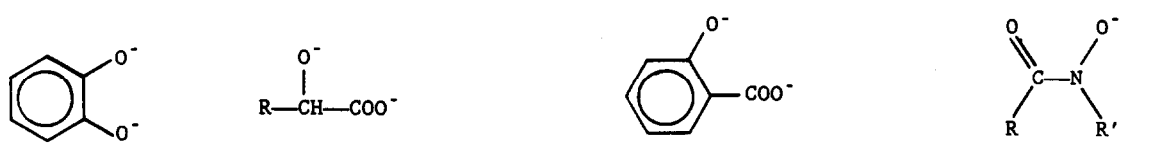
Monodentate donor groups



Alkoxide $\gtrsim 14$ Phenoxide ~ 10 Carboxylate ~ 4

The following are some of the more frequently encountered bidentate pairs containing these donor groups. They are found in both natural and synthetic ligands which are effective for aluminium(III) and other trivalent metal ions (e.g. siderophores).

Bidentate combinations



Catecholate ~ 22 Hydoxy acid anion ~ 18 Aromatic hydroxy acid anion ~ 16 Hydroxamate ~ 9

Hard donor groups also have very high affinities for the hardest positive ion of all—the hydrogen ion—so that coordination of a metal ion such as Al^{3+} with these donor groups in aqueous solution always involves strong competition with hydrogen ions. The intensity of that competition for the hard oxygen donors presented above is measured quantitively by the log protonation constants (pK's) listed under each donor (ΣpK is given for the bidentate pairs). These protonation constants also provide a quantitative measure of the hardness of each monodentate donor and the pK sum indicates the hardness of the bidentate donor pairs.

A survey of the literature indicates that organic ligands having sufficient affinity for Al^{3+} to form complexes stable enough to resist its strong hydrolytic tendencies (and consequent precipitation) are generally multidentate and contain arrangements of several donor groups selected from the hard oxygen donors listed above. Table 2 contains a new up-to-date compilation of the critical (selected) equilibrium constants for the aluminium(III) complexes of various types of ligands with the functional groups of interest. A variety of ligands is selected so that the complexes listed represent a considerable variation of structural types and a wide range of stabilities. In order to keep the table within limits, many well-known ligands having structures very similar to those listed have been omitted. The successive log protonation constants are presented in the order of decreasing pK's. In most cases, the normal stability constants (as log values) are given, corresponding to reaction of the aquo metal ion with the most basic (most fully deprotonated) form of the ligand as indicated by eq. (1):

$$Al^{3+} + L^{n-} \rightleftharpoons AlL^{(3-n)+}$$

$$K = [AlL^{(3-n)+}]/[Al^{3+}][L^{n-}]. \quad (1)$$

When possible, stability constants are presented in this form, but such is not always the case. For ligands with very hard donor groups it is sometimes not possible to determine or calculate the concentration of the most basic form of the ligands, L^{n-}, because the highest pK's are too high for accurate measurement in aqueous solution. Since one or more of the highest protonation constants are either unknown or inaccurately known, calculation of the value of log K_1 is either not possible, or the value is an inaccurate estimate. This difficulty is circumvented by listing equilibrium constants for the displacement of hydrogen ions, as in eqs (2) and (3), in place of the normal stability constants:

$$Al^{3+} + HL^{(n-1)-} \rightleftharpoons AlL^{(3-n)+} + H^+$$

$$K_1^H = [AlL^{(3-n)+}][H^+]/[Al^{3+}][HL^{(n-1)-}] \quad (2)$$

$$Al^{3+} + H_2L^{(n-2)-} \rightleftharpoons AlL^{(3-n)+} + 2H^+$$

$$K_2^H = [AlL^{(3-n)+}][H^+]^2/[Al^{3+}][H_2L^{(n-2)-}]. \quad (3)$$

These equilibrium constants [eqs (2) and (3)] can be determined with the full precision of the potentiometric methods in the p[H] range 2–12, with no dependence on the uncertain values of the ligand protonation constants measured above p[H] 12. The potentiometric procedure, and the limitations involved are described in detail elsewhere.[33] An alternate type of formalism is now employed for expressing stability constants for ligands with pK's too high to measure. This procedure designates the most basic form of the ligand attainable in aqueous solution by titration with alkali metal hydroxide as L^{n-}, and subtracting any additional protons displaced by the metal ions by the formalism $H_{-1}L^{(n+1)-}$, $H_{-2}L^{(n+2)-}$, etc. This procedure makes a clear distinction between protons that may be titrated with base in aqueous solution and the additional protons displaced by metal ions. It is seen in Table 2 that displacement reactions such as eqs (2) and (3) have been employed to describe equilibria between the aluminium(III) ion with catechol and catechol derivatives, and that the proton subtraction formalism is also used for several complexes.

The main reason why potentiometric pH measurements cannot be carried out accurately above pH 12 and below pH 2 (for 0.10 M ionic strength) is that the liquid junction potentials change considerably in the presence of high concentrations of hydrogen ion or hydroxide ion. This may be avoided in some cases when the protonated and unprotonated ligands differ considerably in UV–vis absorbance, as with phenols and some catechols. In such cases the extent of dissociation can be measured spectrophotometrically while the $[H^+]$, $[OH^-]$ concentrations are determined from the stoichiometry of the solution. Even this method has its limitations, however. For a solution at 0.10 M ionic strength, a pK of 13.0 with equal concentrations of ligand acid and basic forms (maximum buffering), the hydroxide ion concentration would be approximately 0.2 M, so that the ionic strength is greatly exceeded merely due to this anion alone. It is obvious that under these conditions the ionic strength cannot be controlled and the equilibrium constant cannot be determined accurately.

This problem was encountered with aluminium(III) complexes of L-DOPA and its analogues in a paper by Kiss *et al.*[28] In this case the ionic strength was "controlled with KCl" to 0.2 M. The value of $\log K_1^H$ (first protonation constant) of L-DOPA was given as 13.4, quite properly with one significant figure. If it is realized, however, that hydroxide ion concentration at p[H] 13.4 is nearly 0.5 M, which is probably in addition to the 0.2 M KCl present, it is seen that the ionic strength is way out of control, even if lower concentrations of base were employed. Thus the uncertainty in the 13.4 value is considerable. Unfortunately, the authors used this high pK to calculate the stability constant, β_3 as 38.36, implying considerable accuracy, in spite of the uncertainty in the ligand protonation constants. It would have been better to eliminate the high pK's from the metal ion equilibria and express them more accurately as proton displacement reactions, as is done in Table 2. The more precise proton displacement constants can be used for accurate equilibrium calculations of molecular species formed in interactions of the Al^{III}–L-DOPA complexes with other ligands and metal ions.

ALIPHATIC HYDROXYL GROUPS AS LIGANDS

The aliphatic alkoxide donor has such high proton affinity that in some molecules it remains protonated and does not combine with Al^{3+} even at extremely high pH, while on the other hand in other ligands it is an effective partner in aluminium(III) coordination. Proton binding in aliphatic alcohols is so strong that simple alkoxide complexes of Al^{3+} resulting from proton dissociation are not formed, nor are the bis-alkoxides such as complexes of ethyleneglycolate, $^-O—CH_2CH_2—O^-$. (In the latter case, complexes do form with the very hard B^{3+} centre, which was noted above as not forming an electropositive ion in aqueous solution.) However, alkoxide donor groups participate in coordination of hard metal ions such as Al^{3+}, with proton dissociation, when they function in conjunction with other donor groups, which are more easily dissociated (less hard), so that the chelate effect provides sufficient incremental metal ion affinity to overbalance the strong proton affinity. Common examples are tartaric acid and citric acid, which complex metal ions through adjacent alkoxide and carboxylate donor groups.

In many cases it is difficult to determine by equilibrium measurements whether the displacement of a hydrogen ion occurs at the aliphatic hydroxyl group or at a coordinated water molecule, as follows:

Thus far most of the evidence presented has been indirect or circumstantial, such as the occurrence of strong coordination with the alkoxyl group, and lack of strong coordination in its absence, and argu-

ments based on relative hydrolytic tendencies of metal ions, such as in the case of aluminium(III) citrate described below.[16]

MICROSCOPIC EQUILIBRIA OF CATECHOL COMPLEXES

Much has been stated in recent publications that the knowledge of microscopic equilibrium constants is essential for the "proper" interpretation of metal ion [including aluminium(III)] complexes of ligands containing phenolic and catechol donor groups. While microscopic equilibrium constants are interesting and useful in the interpretation of metal complex equilibria in solution, and knowledge of the structures of individual microspecies in solution is useful in the interpretation of protonation constants and metal ion stability constants, they are certainly not necessary for the accurate determination of equilibrium constants and stability constants of solution components, and for measuring the thermodynamic parameters for the conversion of one component to another. An interesting example is the acid–base equilibria and the formation of aluminium(III) complexes of L-DOPA, recently described by Kiss *et al.*[28] The ligand, designated as H_3L, dissociates in three steps, in accordance with Scheme 1. H_3L itself actually consists of four microspecies, the one shown, and three species with the carboxyl protonated and one of the other three donor groups deprotonated. The concentrations of these latter three species can be estimated from the differences in pK's of the carboxylate and the other proton acceptors as about 10^{-6} times the concentration of the species H_3L indicated in the scheme, and hence they can be ignored without appreciable error, thus greatly simplifying the microscopic treatment of the remaining species present. In the paper by Kiss *et al.*,[28] the difference between $H_2L_a^-$ and $H_2L_b^-$ were ignored and grouped together as a single species. The total concentrations of these two species was estimated from the change in phenolate (catecholate) absorbance in going from H_3L to $[H_2L_a^- + H_2L_b^-]$. It was not stated if the absorbances measured were considered to involve equal contributions from the two microspecies, or whether it was merely assumed that an average value would be satisfactory. In any case these authors reported a pseudo microscopic distribution constant $[H_2L_c^-]/([H_2L_a^-]+[H_2L_b^-])$ of 1/1.6. In the first deprotonation step the ammonium group is somewhat less dissociated than the sum of the two phenolic groups (i.e. the catechol group).

The product of the second deprotonation consists of three microspecies, but a single species was assumed.[28] The elimination of HL_c^{2-} is reasonable since its concentration is about 10^{-4} of that of the sum of $[HL_a^{2-}]$ and $[HL_b^{2-}]$. Although ignored at this point, its existence at low concentrations was invoked later in the paper[28] to calculate a special microscopic aluminium(III) stability constant. The grouping of the two phenolate forms together for the microscopic treatment of both H_2L^- and HL^{2-} was convenient, because there does not exist at the present time experimental data for determining the relative concentrations of these two species.

For the aluminium(III) complexes of L-DOPA, six distinct complexes may be determined directly from potentiometric p[H] measurements. Three of these macrospecies are $AlHL^+$, $Al(HL)_2^-$ and $Al(HL)_3^{3-}$, in which the aluminium(III) ion is recognized as combining with the catecholate donor groups, with the proton moving entirely to the α-amino group. The other three are the stepwise dissociation constants of $Al(HL)_3^{3-}$. Unfortunately, these dissociation constants for the complexes of the monoprotonated ligand were not reported by Kiss *et al.*[28] The formation reactions of these three complexes overlap, but the individual constants can easily be sorted out and calculated by modern computer methods. At higher pH, the complex $Al(HL)_3^{3-}$ undergoes three successive dissociations to eventually form the completely deprotonated complex, as follows:

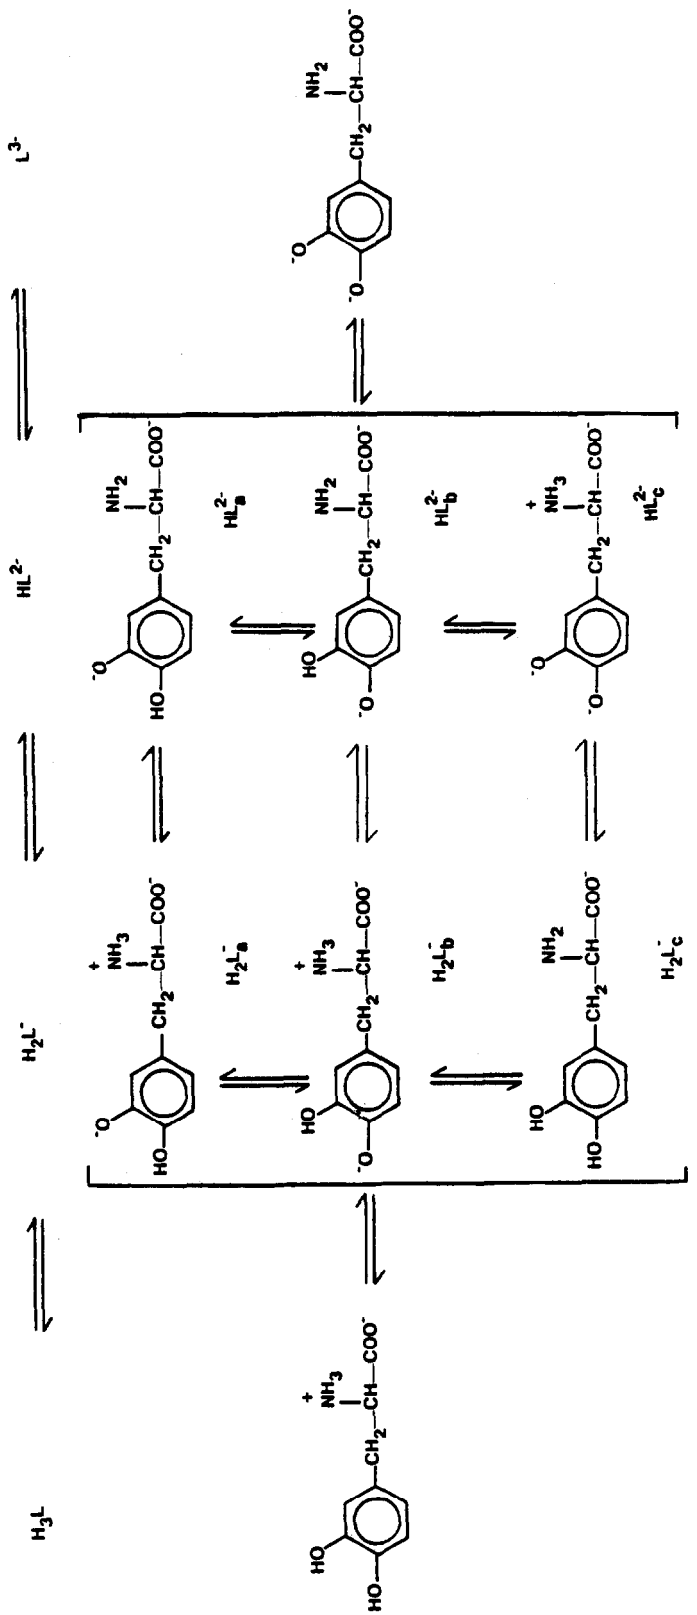
$$Al(HL)_3^{3-} \overset{9.75}{\rightleftharpoons} AlL(HL)_2^{2-} \overset{10.15}{\rightleftharpoons}$$

$$AlHL(L)_2 \overset{10.65}{\rightleftharpoons} AlL_3.$$

These pK's differ approximately by the calculated statistical values (log 3 units) showing that they have little influence on each other. The pK's (protonation constants) are in the pH range accessible by potentiometry and the values reported are reliable.

The formation constants of the protonated complexes, which can be measured accurately, were not given in the paper. Instead, the overall constants, β_1, β_2 and β_3 were reported.[28] These constants involve combination of the metal ion with the fully deprotonated ligand, which cannot be determined accurately (such calculations required pK_{3a} which is known only approximately).

With respect to microscopic equilibria involving aluminium(III) complexes, Kiss *et al.*[28] chose to estimate the concentrations of species HL_c^{2-}, and from this calculate what they term as "proper" stability constants with this microspecies, obtained log values of 16.03, 13.21 and 9.12 for $[Al(HL)^+]/[Al^{3+}][HL_c^{2-}]$, $[Al(HL)_2^-]/[Al(HL)^+][HL_c^{2-}]$, and $[Al(HL)_3^{3-}]/[Al(HL)_2^-][HL_c^{2-}]$, respectively. While such constants are interesting for comparison with



Scheme 1. Microscopic acid–base equilibria of L-DOPA.

binding constants of other ligands such as catechol, it should be remembered that they are approximations and cannot (in fact need not) be employed for the calculation of metal complex species in solution. (Although the original experimental data were accurate, the derived microscopic constants are only estimates, requiring the inaccurate value of pK_{3a} and an "estimated" pK for the microspecies HL_c^{2-}.)

METASTABLE EQUILIBRIA

The tendency of aluminium(III) ions to form several hydrolytic species leads to the formation of mononuclear and polynuclear hydroxo complexes, indicated in Table 2. The small size of the Al^{3+} ion, the strong interactions with the hydroxide ion and the tendency of the hydroxide ion to bridge Al^{3+} centres to form polynuclear arrays—all contribute to very slow attainment of equilibrium. Thus the experience of the author and his associates, and the reports of other investigators[15,17] indicate that complex formation of aluminium(III) complexes of simple ligands may take hours, or up to a day, to come to equilibrium. For this reason the conversion of polynuclear hydroxo complexes to still larger oligomeric species which are necessary precursors of the macromolecular polymer, solid $Al(OH)_3$, takes still longer, so that soluble hydroxo complexes may be maintained almost indefinitely under conditions such that solid aluminium hydroxide is the thermodynamically stable species. Such solutions revert back to the true equilibrium state (i.e. precipitation occurs) if they are seeded with solid hydrous aluminium hydroxide. The nature of the complexes that form in such metastable solutions, and their relative concentrations are expressed by the equilibrium constants in Table 2. In order to describe these metastable systems in greater detail two sets of species distribution curves calculated from the data in Table 2 are presented for the same solutions, with and without the use of K_{sp} for solid aluminium(III) hydroxide.

Relative molar concentrations of aluminium(III) species at a total analytical concentration of 1.00×10^{-6} M, with the concentration of the complex $Al(OH)_3$ plotted as a soluble (supersaturated) complex, are illustrated in Fig. 1. At this dilution polynuclear species are not represented in the succession of increasingly hydroxylated complexes, all of which are monodentate. At a T_M of 1.0×10^{-3} M, however, the polymeric complex $Al_{13}(OH)_{32}^{7+}$, sometimes written as the partially dehydrated form $Al_{13}O_4(OH)_{24}^{7+}$, dominates the system from p[H] 5 to 8, as indicated in Fig. 2. When the equilibria between the species formed includes the solid phase, the distribution curves are very different. Figure 3 shows that the solid precipitate is present from pH 4.5 to 10, and dominates the system over most of that range. Precipitation provides the driving force for conversion of aluminium(III) species to $Al(OH)_3$. It is also seen that the excess solid maintains a constant concentration of the soluble $Al(OH)_3$ complex (at saturation). An interesting aspect of the distribution curves in Fig. 3 is the fact that the free aluminium(III) in solution under precipitation conditions is around 5×10^{-8} M (as the $Al(OH)_3$ complex), a not insignificant con-

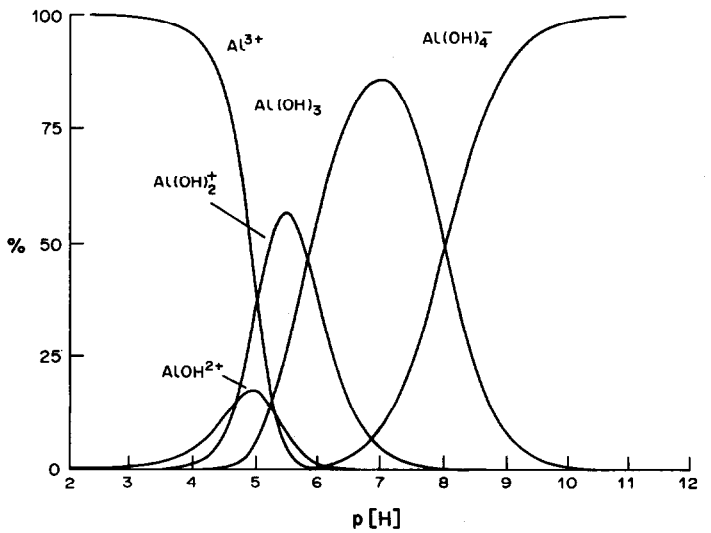


Fig. 1. Relative molar concentrations of hydrolytic species formed from the aquo aluminium(III) ion as a function of $-\log[H^+]$. Total analytical concentration of aluminium(III) species is 1.00×10^{-6} M. The concentration of $Al(OH)_3$ is plotted as a supersaturated solution. $T = 25.0°C$, $\mu = 0.100$ M.

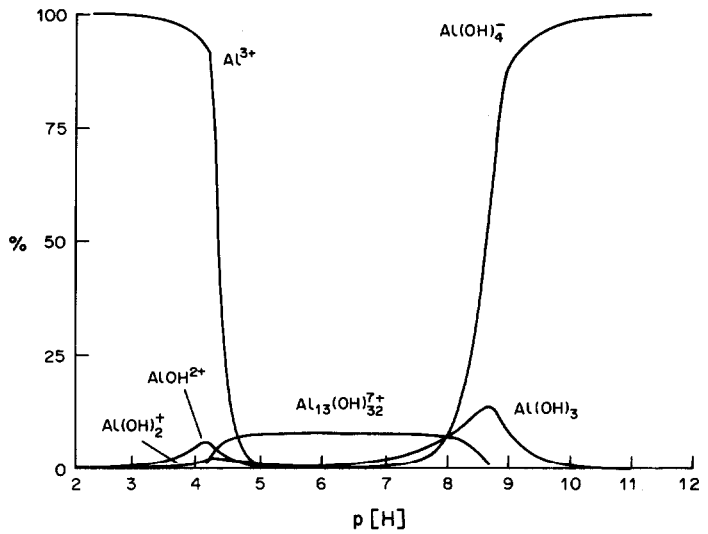

Fig. 2. Relative molar concentrations of hydrolytic species formed from the aquo aluminium(III) ion as a function of $-\log[H^+]$. Total analytical concentration of aluminium(III) species is 1.00×10^{-3} M. The molar concentration of $Al_{13}(OH)_{32}$ constitutes 98.8% of the aluminium(III) present. The concentration of $Al(OH)_3$ is plotted as a supersaturated solution. $T = 25.0°C$, $\mu = 0.100$ M.

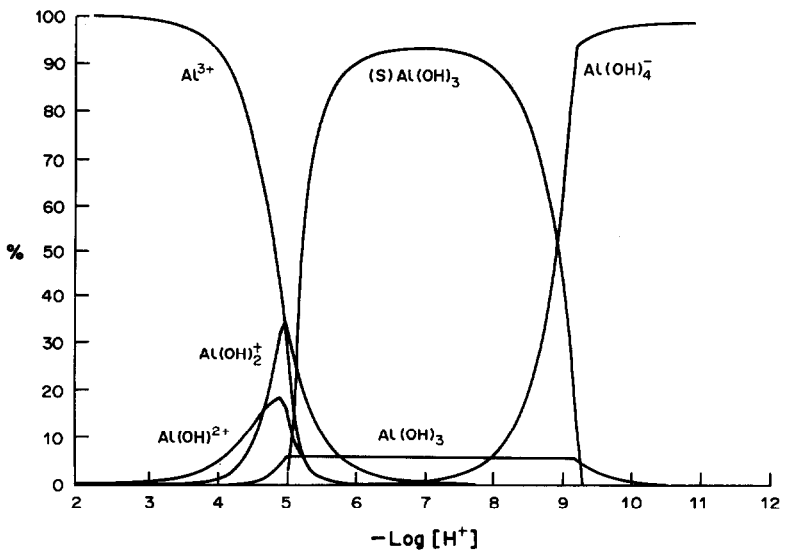

Fig. 3. Relative molar concentrations of hydrolytic species formed from the aquo aluminium(III) ion as a function of $-\log[H^+]$. Total analytical concentration of aluminium(III) species is 1.00×10^{-6} M. (S)$Al(OH)_3$ represents the relative quantity of precipitate. $T = 25°C$; $\mu = 0.100$ M.

centration, which indicates that aluminium(III) is free to move about in aqueous solution in the environment, in the absence of more effective precipitating agents.

Because of the presence of fluoride in natural waters, it is of interest to consider what happens to aluminium(III) hydrolysis in the presence of the F^- ion. Figure 4, calculated from the data in Table 2, indicates considerable formation of fluoride complexes in acid solution. Comparison with Fig. 3 shows that fluoride narrows the pH range of $Al(OH)_3$ precipitation considerably, and increases the pH of initial precipitation of $Al(OH)_3$ by a full unit. It is obvious from these effects that the fluoride ion greatly increases the concentration and mobility of aluminium(III) in natural waters.

TYPICAL HYDROXY ORGANIC LIGANDS AND THEIR ALUMINIUM(III) COMPLEXES

The data in Table 2 indicate the affinities of a wide variety of hydroxy aliphatic and hydroxy aromatic

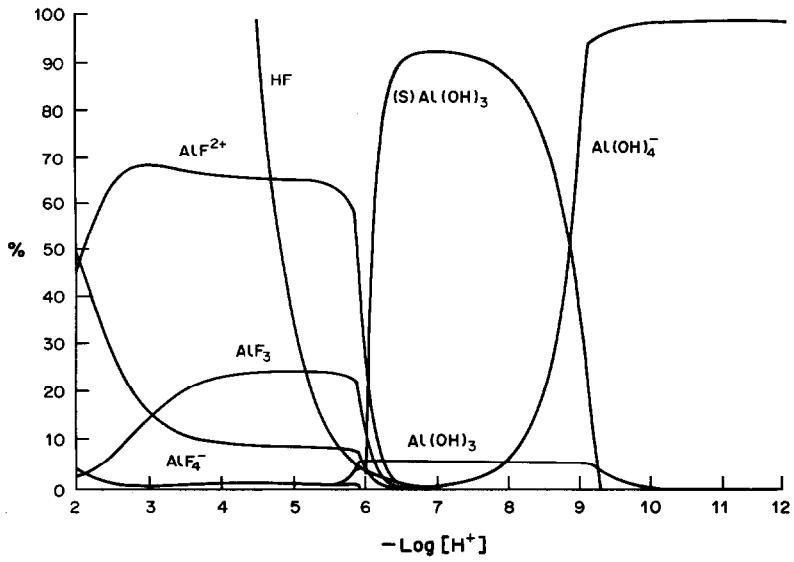

Fig. 4. Relative molar concentrations of complex species formed from 1.0×10^{-6} M aquo aluminium(III) ion and 5.0×10^{-5} M fluoride ion. (S)Al(OH)$_3$ represents the relative quantity of precipitated Al(OH)$_3$. $T = 25.0°C$; $\mu = 0.100$ M.

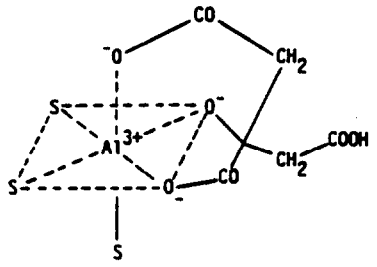
ligands for aluminium(III). These data may be employed to determine the speciation (at equilibrium) of aluminium(III) in systems containing two or more competing ligands. In all cases, the use of ligand pK's and aluminium(III) hydrolysis constants in the equilibrium analysis takes the corresponding side reactions (hydroxo complexing and proton competition) into account, and the relative effectiveness of the coordinating ligands thus depends on many factors, as indicated above, and are not easily judged by the magnitudes of the stability constants themselves.

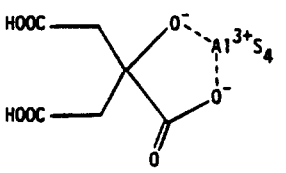
Because of space limitations, this analysis of aluminium(III) speciation in complex systems is restricted to several well-known ligands of some importance in aluminium(III) chemistry: citric acid, EDTA, catechol, and a hydroxamic acid, desferriferrioxamine B (DFB). Citric acid forms several interesting complexes of aluminium(III), and is present in blood serum and other biological fluids. EDTA is a well-known universal chelating agent with surprisingly high aluminium(III) affinity. Catechol has the highest affinity for aluminium(III) by virtue of its hard oxygen donors, but its coordination with metal ions is countered by high proton affinity. Hydroxamic acids such as DFB have weaker (less hard) oxygen donors but have the advantage of relatively low proton affinities compared to catechols.

Citrate complexes

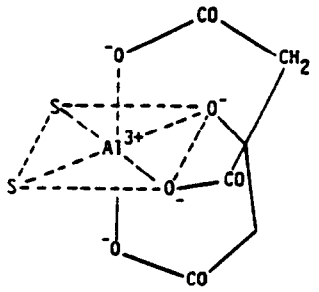
The chemistry of aluminium(III)–citrate complexes has been characterized by much inconsistent data and conflicting interpretations. This situation is due at least in part to the fact that substitution reactions, equilibria with hydrolytic species and the formation of hydroxo-bridged polynuclear species, are extremely slow. A definitive paper on aluminium(III) citrate, and other hydroxy acid complexes of aluminium(III) was that of Motekaitis and Martell,[16] who demonstrated that the potentiometric equilibrium data, obtained over a wide range of conditions, may be explained by three aluminium(III) complexes **1**, **2** and **3**, the 1 : 1 complex AlL (citric acid = H_3L), and its protonated ($AlHL^+$) and deprotonated ($AlH_{-1}L^-$) forms. The protonation site in AlL is suggested as a carbonyl group, thus liberating the aliphatic alkoxy group for strong aluminium(III) coordination through hydrogen ion displacement. The coordinate bond strength of this configuration was considered strong enough to withstand addition of a second proton, which is indicated as going to a second carboxyl group in $AlHL^+$, **2**. Deprotonation of AlL results in the completely deprotonated complex $AlH_{-1}L^-$, **3**, in which all four donor oxygens are considered to be coordinated to aluminium(III). Strong evidence for the involvement of the ligand hydroxyl group in **1** and **3** was demonstrated by Motekaitis and Martell from potentiometric equilibrium measurements. At p[H] values considerably below 4, the potentiometric equilibrium data show the neutralization of one more proton than the three available from the carboxylic acid groups of the ligand. This neutralization reaction is complete well below the p[H] value of the first hydrolysis step of the uncoordinated (aquo) aluminium(III) ion, so



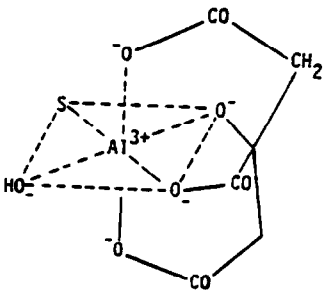
1



2



3



4

that it could not come from coordinated water, and deprotonation of the aliphatic hydroxyl group is the only other possibility. Moreover, it was found that potentiometric data for higher ratios (2 : 1, 3 : 1) of the ligand to metal ion are fully explained by the mononuclear species and the protonation equilibria of the free, uncoordinated excess ligand, so that there is no need to invoke 2 : 1 or 3 : 1 ligand to metal species for the aluminium(III)–citrate system.

The above reasoning based on potentiometric data and hydrolytic tendencies of aluminium(III) demonstrates the presence of the ligand deprotonated aliphatic hydroxyl donor in both ML and $MH_{-1}L^{-}$. Further comparisons[16] with other citrate complexes of other metal ions, and aluminium(III) complexes of other hydroxy ligands suggests that the complex MHL^{+} also contains the deprotonated ligand hydroxyl donor and two protonated carboxyl groups.

Detailed and exhaustive potentiometric studies of the aluminium(III)–citrate system by Ohman and Sjöberg,[15] and Ohman[17] have demonstrated the formation of additional complex species, mainly at somewhat higher pH and considerably higher complex concentration: a trinuclear complex which slowly forms, with up to 20 h required to reach equilibrium, $Al_3(OH)(H_{-1}L)_3^{4-}$. This species dominates the solution from p[H] 3 to 8, at 10^{-3} M concentration, when the system is allowed a long period of time to come to equilibrium. Another, less stable ternuclear complex, $Al_3(OH)_4(H_{-1}L)_3^{7-}$, was detected at higher pH, as well as an additional mononuclear complex, $Al(OH)(H_{-1}L)^{2-}$ (**4**). The formation of polynuclear complexes are of course very sensitive to concentration, as may be seen from the distribution curves, Figs 5 and 6, for 1 : 1 aluminium(III)–citrate solutions at 1.0×10^{-3} and 1.0×10^{-6} M. It is seen that the polynuclear complexes which are dominant at the higher concentration are completely absent when the solution is diluted 1000-fold.

It is quite possible that the potentiometric measurements that have led to the detection of the hydrolytic aluminium(III)–citrate species, $Al_3(OH)(H_{-1}L)_3^{4-}$, $Al_3(OH)_4(H_{-2}L)_3^{7-}$ and $Al(OH)(H_{-1}L)^{2-}$, have in fact been dealing with metastable equilibria, as described above. The distribution curves in Figs 5 and 6 were calculated without consideration of the possibility of $Al(OH)_3$ precipitation, and indeed the authors[15,17] were very careful in excluding data taken from solutions containing even a trace of a solid phase. On the other hand, if one recalculates the distribution in Fig. 5 taking the K_{sp} of $Al(OH)_3$ into consideration, a completely different picture emerges (Fig. 7). The concentrations of $Al_3(OH)(H_{-1}L)_3^{4-}$ and $Al(OH)(H_{-1})^{2-}$ are greatly reduced, and the less stable trinuclear species $Al_3(OH)_4(H_{-1}L)_3^{7-}$ is completely eliminated.

Aluminium(III)–*catechol complexes*

As suggested above, of the common ligands available for binding aluminium(III), the stability of the aluminium(III)–catechol complexes is the highest. However, its full effectiveness cannot be observed

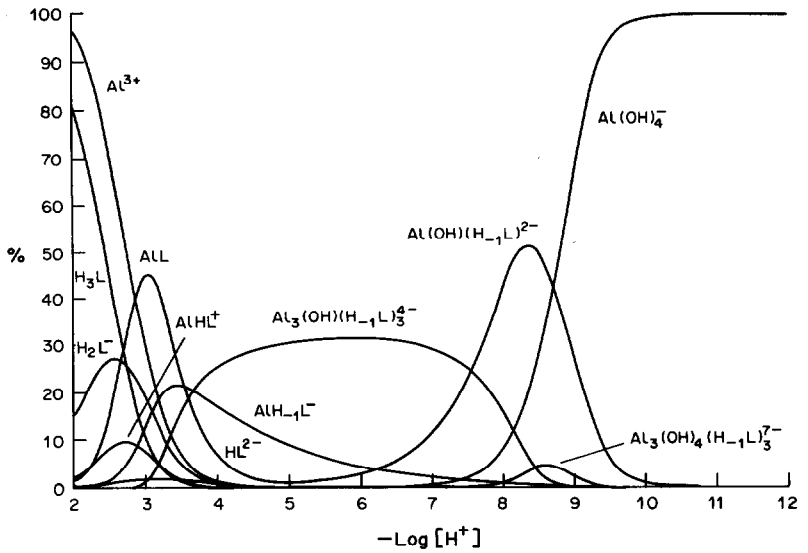


Fig. 5. Relative molar concentrations of complex species formed from 1.00×10^{-3} M aquo aluminium(III) and 1.00×10^{-3} M citric acid as a function of p[H]. The $Al(OH)_3$ formed (max %, 0.1) is considered as remaining in solution. $T = 25.0°C$; $\mu = 0.100$ M.

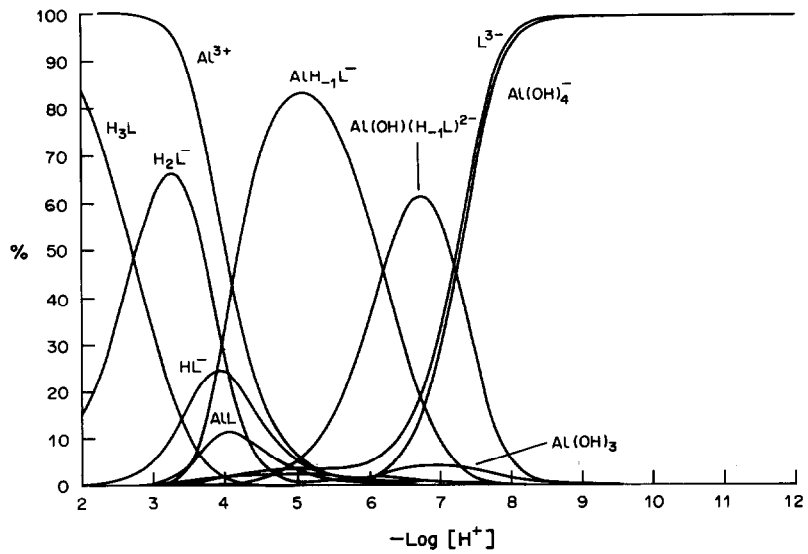

Fig. 6. Relative molar concentrations of complex species formed from 1.00×10^{-6} M aquo aluminium(III) and 1.00×10^{-6} M citric acid as a function of p[H]. The $Al(OH)_3$ formed (max %, 3.9) is considered as remaining in solution. $T = 25.0°C$; $\mu = 0.100$ M.

except at high pH, because of its high pK's, and consequent strong competition by hydrogen ions, even in alkaline solution. The first protonation constant of the catecholate ligand is too high to be measured accurately, and the conventional stability constants based on catechol = H_2L, which require both pK's for calculation [eq. (1)], cannot be reported with accurate constants. More accurate equilibrium data may be obtained for hydrogen ion displacement reactions. These factors may be perceived in the pK's and stability constants listed in Table 3.

EDTA has surprisingly high affinity for aluminium(III), with a binding constant of $10^{16.3}$. Part of the high affinity is due to the formation of a stable hydroxo complex (pK 5.87) so that the monohydroxo species is the most stable form above pH 6. In competition with citric acid the EDTA complexes dominate, and very little aluminium(III) citrate forms. Species distribution curves of a 1 : 1 : 1 aluminium(III)–citrate–EDTA system[34] shows that aluminium(III)–citrate never forms to more than about 15% of the total, and is present only in acid solution.

Table 3. pK's and stability constants of aluminium(III)–catecholate complexes (catechol = H_2L)

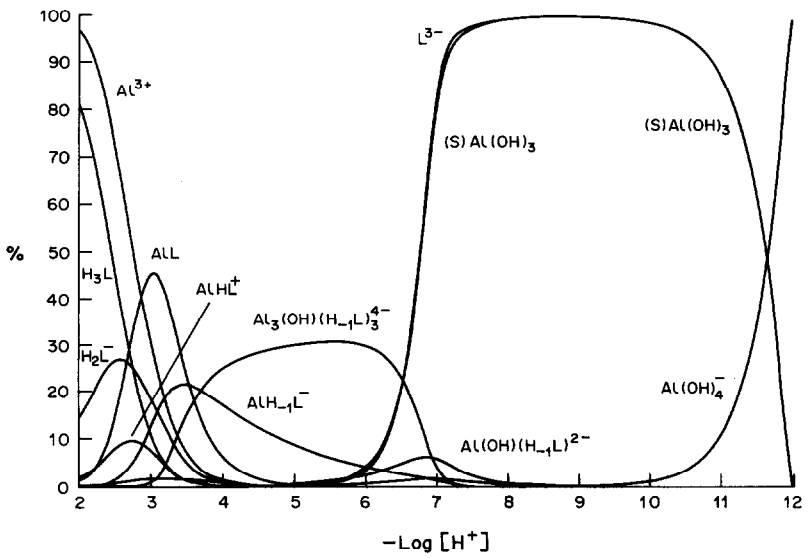

Fig. 7. Relative molar concentrations of complex species formed from 1.00×10^{-3} M aquo aluminium(III) and 1.00×10^{-3} M citric acid as a function of p[H]. (S)$Al(OH)_3$ represents the relative quantity of precipitated $Al(OH)_3$. T = 25.0°C; μ = 0.100 M.

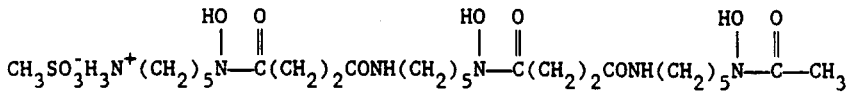
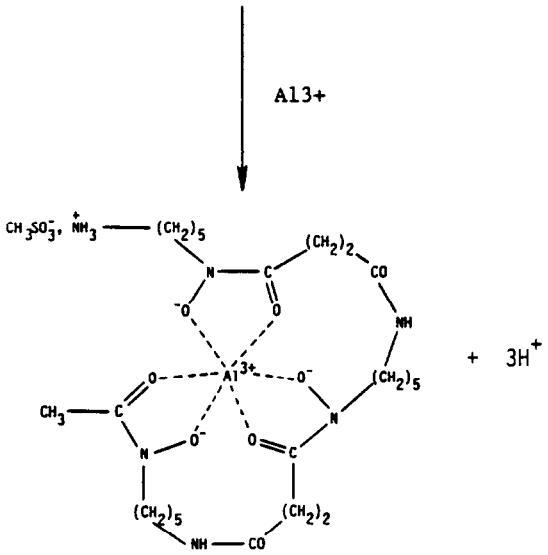
When EDTA competes with catechol for aluminium(III), however, the catechol dominates, although only at high pH, where there is less proton competition. The distribution curves of the 1 : 1 : 3 aluminium(III)–EDTA–catechol system [a 3 M ratio of catechol is needed to supply six donor groups to aluminium(III)], illustrated in Fig. 8, show that the aluminium(III)–EDTA chelates are the major species up to pH 8.5. Beyond that the 3 : 1 aluminium(III)–catechol complex dominates up to and above pH 12, with only minimal interference by $Al(OH)_4^-$.

The Desferriferrioxamine B–aluminium(III) *complex*

Desferriferrioxamine B (Desferal® DFB) is a microbial siderophore which has long been used for the treatment of Cooley's anaemia.[35,36] It is now also being used for the treatment of aluminium overload.[37] Because of its medicinal importance it is of interest to compare its affinity for aluminium(III) with that of other ligands. The stability constant for the aluminium(III) chelate, formed in accordance with the following reaction, has been reported



Desferriferrioxamine B, methanesulphonate salt



recently[28] as $10^{24.14}$ for the species with a protonated terminal aliphatic amino group. It is this form which exists at physiological pH. With these data it is possible to calculate the species present in solutions containing DFB and a competing chelating agent.

$$\log\left(\frac{[\mathrm{AlHL}^{+}]}{[\mathrm{Al}^{3+}][\mathrm{HL}^{2-}]}\right) = 24.14$$

$$\log\left(\frac{[\mathrm{AlHL}^{+}]}{[\mathrm{AlL}][\mathrm{H}^{+}]}\right) = 9.43.$$

Figures 9 and 10 clearly demonstrate the remarkable affinity of DFB for aluminium(III). The aluminium(III)–DFB chelate predominates over the EDTA chelate between pH 3 and 11.5 (Fig. 9), with the latter ([MHE]+[ME^{-}]) accounting for about 50% of the metal ion only below pH 3, and dis-

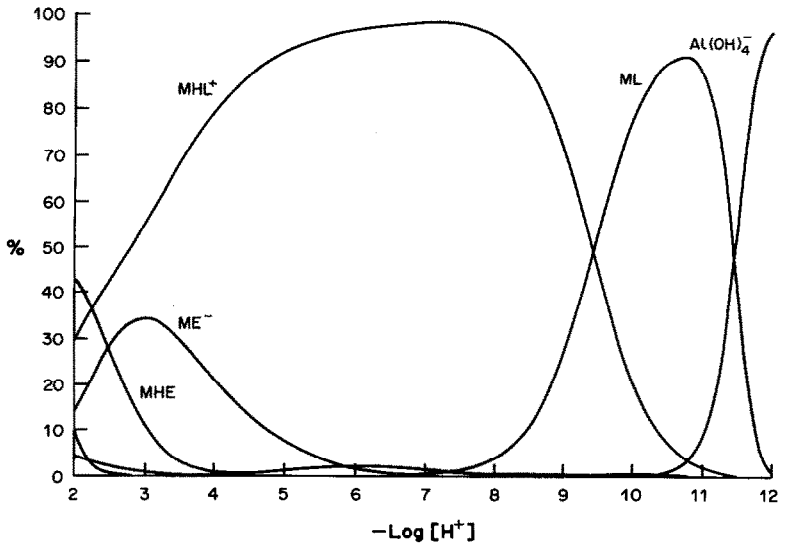

Fig. 9. DFB more effective than EDTA for binding aluminium(III). EDTA = H_4E; DFB = H_3L or H_4L^+; $Al^{3+} = M^{3+}$. Total concentrations of components, $T_{EDTA} = T_{DFB} = T_{Al^{III}} = 0.0010$ M; $T = 25.0°C$, $\mu = 0.100$ M (KCl).

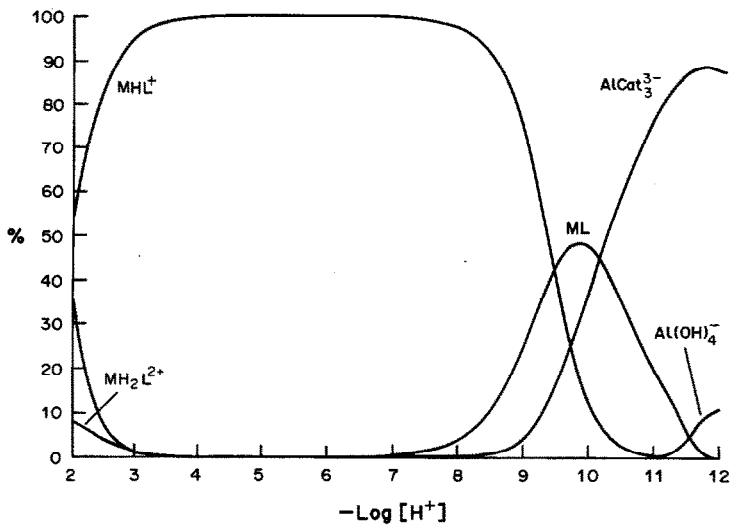

Fig. 10. Catechol more effective than DFB only at very high pH. DFB = H_3L—H_4L^+; catechol = H_2Cat; $Al^{3+} = M^{3+}$. Total concentrations $T_{DFB} = T_{Al^{III}} = 1.0 \times 10^{-3}$ M; $T_{Cat} = 3.0 \times 10^{-3}$ M; $T = 25.0°C$, $\mu = 0.100$ M(KCl).

appearing entirely at and above pH 6. The aluminium(III)–DFB chelate is eventually converted to $Al(OH)_4^-$, but only above pH 11. Even with catechol as a competing ligand (Fig. 10), the aluminium(III)–DFB complex predominates over the entire pH range from pH 2 to 10, and is the only complex present at physiological pH. Only above pH 9 does the catechol ligand begin to grow in, but it does not become the major aluminium(III) complex until the pH is increased to above 10.

Abstract—The blood red cell contains millimolar amounts of 2,3-diphosphoglycerate, yet no metal ion stability constants appear to have been determined. We show that in the free ligand the 2-phospho group is about six times more basic than the 3-phospho group. We have determined the stability constants for the binding of Zn^{2+} which occurs at about 0.2 mM in the red cell, and of Al^{3+} which reduces red cell size and inhibits haemoglobin synthesis. At physiological pH both metal ions occur predominantly as MA_2 complexes. The free Zn^{2+} concentration permitted within the red cell by the 2:1 complex is about 0.3 μm. 2,3-Diphosphoglycerate binds Al^{3+} strongly enough so that at equilibrium there should be comparable concentrations of Al^{3+} on both sides of the red cell membrane.

In addition to well-known dementias and osteodystrophy, toxicity due to aluminium has also been associated with anaemia.[1] The cause of Al^{3+}-induced anaemia is uncertain: iron levels are normal, but the red blood cells are reduced in size (microcytosis), and the condition improves upon use of reduced Al^{3+} levels in dialysis fluids.[2–4] Al^{3+} lowers haemoglobin levels,[5] and it has been suggested that the metal ion interferes with haemoglobin synthesis.[6] In the blood plasma, the predominant small molecule Al^{3+} carrier is citrate,[7,8] while the major protein carrier is transferrin.[7,9,10] If a pathway exists for Al^{3+} transport from the plasma to inside the red cell, 2,3-diphosphoglycerate (DPG), $^{-2}O_3POCH_2CH(COO^-)OPO_3^{2-}$, present at 2–4 mM concentration, seems likely to be the predominant small ligand. Since on a molar basis, the amount of DPG considerably exceeds haemoglobin, with which it interacts in the deoxygenated form, Al^{3+} levels probably would not rise high enough to withdraw significant quantities of DPG from interacting with haemoglobin. However, a DPG complex of Al^{3+} may become an active deleterious species. Since we know of no stability constant information with the important DPG ligand, we have determined its stability constants with Al^{3+} and Zn^{2+}. Zn^{2+} occurs at a concentration of 0.2 mM in the red cell, and much of it may occur as a DPG complex. Mg^{2+} and Ca^{2+}, also present in the red cell, bind more weakly to DPG, and their stabilities have not been determined.

EXPERIMENTAL

The pentasodium salt of 2,3-diphospho-D-glyceric acid was purchased from Sigma Chemical Company in St. Louis Mo. Potentiometric titrations were performed with a Radiometer PHM 64 pH meter and a TTA 80 automatic titration unit equipped with G2040B glass and K4040 calomel electrodes. Precipitation occurs even at 6:1 molar ratios of DPG to Al^{3+}. The DPG concentration was 6 mM and the metal ion concentrations were adjusted to give DPG-to-metal ion molar ratios of 2, 3 and 4 for Zn^{2+} and 8, 9 and 10 for Al^{3+}. At these ratios precipitation occurs above pH 8.5 for Zn^{2+} and pH 7.5 for Al^{3+}. In the soluble region, fits between experimental and calculated (PSEQUAD[11]) titration curves were excellent. The temperature used was 25°C and the ionic strength was controlled with 0.2 M KCl. All pH meter readings were made on a concentration scale. To convert pK_a values in this paper to the more common mixed scale based on NBS buffers,[12]

add 0.13 log units. Metal ion stability constants require no conversion.

RESULTS

Table 1 shows the overall stability constants in the standard log β_n format. Under the experimental conditions MA complexes of penta-anionic DPG and either Zn^{2+} or Al^{3+} were not detected; protonated complexes such as MA_2H intervene. Inspection of Table 1 reveals that Al^{3+} complexes bind significantly more strongly to DPG than does Zn^{2+}. This behaviour is typical of many ligands containing mainly oxygen donor atoms.[7]

From the log β values in the footnote to Table 1 the successive concentration pK_a values from dianionic DPG are 3.19, 5.96 and 7.14 to give the penta-anionic ligand designated A. Successive stability constants for binding to monoprotonated ligand species AH are for Zn^{2+}, log $K_1 = 3.24$ and log $K_2 = 2.46$, and for Al^{3+}, log $K_1 = 5.98$ and log $K_2 = 4.16$. Successive deprotonations from the protonated 2 : 1 complex $MA_2H_2 \rightarrow MA_2H \rightarrow MA_2$ occur with concentration pK_a values of 5.45 and 6.94 for Zn^{2+}, and of 5.64 and 6.32 for Al^{3+}. In the case of Zn^{2+}, MA_2 forms MA_2H_{-1} with p$K_a = 8.44$, either by proton loss from a coordinated water molecule or by coordination of a hydroxide ion.

Figures 1 and 2 show the species distribution curves for DPG complexes of Zn^{2+} and Al^{3+}.

Table 1. 2,3-Diphosphoglycerate acidity constants and Zn^{2+} and Al^{3+} complex stability constants (log β)[a]

Species	Zn^{2+}	Al^{3+}
MAH	10.38	13.12
MA_2H_2	19.98	24.42
MA_2H	14.53	18.78
MA_2	7.59	12.46
MA_2H_{-1}	−0.85	—

[a] At 25°C and 0.2 M ionic strength. Standard deviations are less than 0.03 log units. For protonation of the penta-anionic ligand A we obtain the following concentration log β values: HA, 7.14; H_2A, 13.10; and H_3A, 16.29.

DISCUSSION

We can assign the pK_a values to the functional groups in 2,3-diphosphoglyceric acid by comparing its values with those of two model compounds. The first two ionizations occurring from a neutral DPG molecule are essentially strong acid deprotonations from each of the phosphate groups, yielding the dianionic species $^{-}HO_3POCH_2CH(COOH)OPO_3H^{-}$. To assist comparisons on a common pH scale, we add 0.13 log units (for 0.20 ionic strength) to the concentration pK_a constants reported in this paper, to obtain the mixed constants commonly appearing in the literature. Thus the successive mixed pK_a values from the dianionic DPG species become 3.32, 6.09 and 7.27. These values may be compared directly with successive pK_a values of 3.55 and 7.0 reported for 2-phosphoglyceric acid[13] and of 3.5 and 6.25 for 3-phosphoglyceric acid,[14] all values were obtained under similar but not identical conditions. Since glyceric acid[15] has a p$K_a = 3.5$,

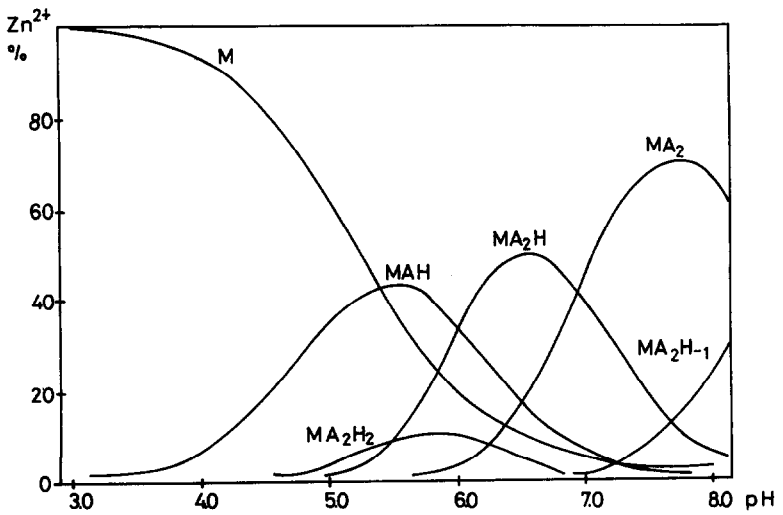

Fig. 1. Species distribution curves for 2 mM total zinc(II) and 6 mM 2,3-diphosphoglycerate using the constants in Table 1. The symbol A refers to the penta-anionic ligand, so that MA_2 bears a net eight-minus charge.

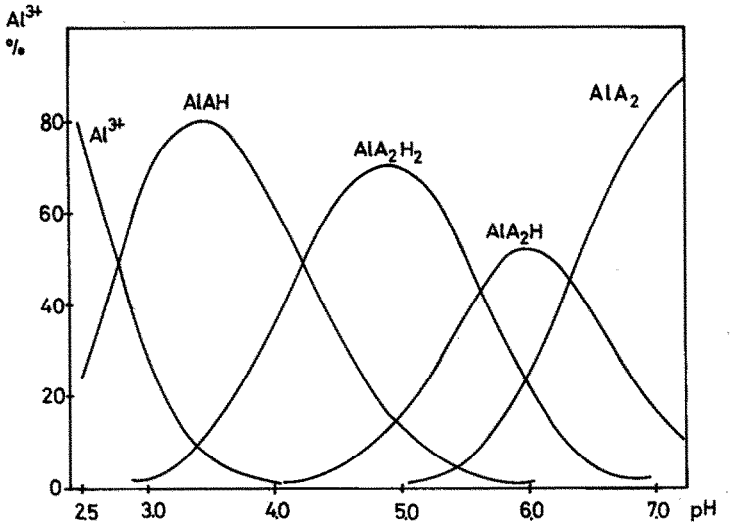

Fig. 2. Species distribution curves for 0.6 mM total aluminium(III) and 6 mM 2,3-diphosphoglycerate using the constants in Table 1. The symbol A refers to the penta-anionic ligand, so that AlA_2 bears a net seven-minus charge.

the deprotonation with pK_a ranging from 3.32 to 3.55 in the three phosphoglyceric acids may be identified mainly with the carboxylic acid group. The two remaining DPG pK_a values of 6.09 and 7.27 pertain to both phosphate groups. Comparison with the values for 2- and 3-phosphoglyceric acids suggests that in DPG the $pK_a = 6.09$ corresponds predominantly to deprotonation of the 3-phosphate group and the $pK_a = 7.27$ predominantly to the 2-phosphate group. Thus the main monoprotonated DPG tautomer is $^{-2}O_3POCH_2CH(COO^-)OPO_3H^-$.

A more quantitative analysis confirms the last conclusion. We set up the usual microconstant scheme for the last two phosphate ionizations in DPG with the last subscript on a microconstant (small k) indicating the group undergoing deprotonation. Thus we have $10^{-6.09} = K_2 = k_2 + k_3$, $10^{7.27} = K_3^{-1} = k_{23}^{-1} + k_{32}^{-1}$, and $K_2K_3 = k_2k_{23} = k_3k_{32} = 10^{-13.36}$. If we allow a 0.3 log unit intrinsic interaction between the phosphate groups $pk_{23} - pk_3 = pk_{32} - pk_2 = 0.3$, we find $pk_3 = 6.16$, $pk_2 = 6.92$, $pk_{32} = 7.20$ and $pk_{23} = 6.44$. In monoprotonated DPG the ratio of deprotonated 3-phosphate to deprotonated 2-phosphate groups is given by $k_3/k_2 = 6$. The negatively-charged carboxylate group renders the closer 2-phosphate group more basic than the 3-phosphate group.

Stability constant comparisons indicate that metal ion binding to phosphoglyceric acids involves more than the carboxylate group. For Zn^{2+} binding, the first stability constant logs are glycerate,[15] 1.8; 3-phosphoglycerate,[14] 2.9; 2-phosphoglycerate,[13] 3.4; and DPG, 3.24 to the monoprotonated species AH. The much weaker metal ion binding in glycerate indicates phosphate involvement in all the other ligands. The 0.5 log unit stronger Zn^{2+} binding favouring 2- over 3-phosphoglycerate may be accounted for by a combination of the 0.8 log unit greater basicity of the phosphate group in 2-phosphoglycerate and its ability to form a seven-membered phosphate–carboxylate chelate ring vs an eight-membered chelate ring in 3-phosphoglycerate.

We may estimate a stability constant for Zn^{2+} binding to a single phosphate group species in MAH of DPG from a linear relationship found for Zn^{2+} binding to simple phosphate esters,[16] $\log K = 0.35\ pK_a$. For a $pK_a = 6.1$ we estimate $\log K = 2.1$. Since the observed stability constant is $\log K = 3.24$, the strengthening by about one log unit indicates that Zn^{2+} is not simply complexed to a single phosphate but is chelated by DPG.

Additional insights into the structures of the 2:1 DPG complexes may be obtained by considering the successive pK_a values for deprotonations in the series $MA_2H_2 \rightarrow MA_2H \rightarrow MA_2$. For Al^{3+} the successive mixed pK_a values of 5.77 and 6.45 differ by 0.68, little more than the statistical difference of 0.60, and the average value of 6.1 is close to the microconstant value ($pk_3 = 6.16$) for the 3-phosphate group in the free ligand. Thus the most straightforward interpretation is that of the carboxylate and 2-phosphate groups in both DPG molecules chelating Al^{3+} and deprotonations taking place from the two unchelated 3-phosphate groups. In this complex the Al^{3+} is chelated by a minor tautomer of the monoprotonated DPG. A

full analysis of a situation in which a metal ion binds to a minor tautomer appears in a study of Al^{3+} binding to catecholamines.[17]

This simple structural interpretation of the 2:1 DPG complexes of Al^{3+} appears inadequate to account for the corresponding Zn^{2+} complexes. The successive mixed pK_a values of 5.58 and 7.07 differ by 1.5 log units with the first value less and the second value greater than the corresponding values of Al^{3+}. The $pK_a = 7.07$ for deprotonation to give MA_2 is in the range of microconstants for deprotonation of the more basic 2-phosphate group in the free ligand, while the $pK_a = 5.45$ value is significantly more acidic than any free ligand phosphate microconstant. This low value may be due to chelation of a 3-phosphate group upon its deprotonation. The pK_a values for the 2:1 DPG complexes suggest that increases in ligand denticity and Zn^{2+} coordination number occur upon successive deprotonations in the MA_2H_2 complex. After forming the MA_2 complex, Zn^{2+} picks up a hydroxide ion with mixed $pK_a = 8.57$ to yield MA_2H_{-1}.

Figures 1 and 2 show that under physiological conditions neutral solutions of DPG contain predominantly the fully deprotonated MA_2 species for both Zn^{2+} and Al^{3+}. Under conditions of excess of a relatively strong binding ligand in the MA_2 complex region, we may approximate the free metal ion concentration by $[M] \simeq C_M/(\beta_2 C_A^2)$ where C_M and C_A are the total metal ion and ligand concentrations, respectively. The log β_2 values (Table 1) are 7.6 for Zn^{2+} and 12.5 for Al^{3+}. Taking the red cell total DPG concentration as 4 mM and the total Zn^{2+} concentration as 0.2 mM, we find permitted free $[Zn^{2+}] \simeq 0.3$ μM. For a total Al^{3+} concentration of 1 μM we find the free $[Al^{3+}] \simeq 2 \times 10^{-14}$ M. This value is comparable to the free Al^{3+} concentration allowed in the blood plasma by citrate or transferrin.[7,10] Stronger mixed complexes not considered here may form within the red cell. Therefore, at equilibrium there should be comparable concentrations of Al^{3+} on both sides of the red cell membrane.

ALUMINOSILICATE STABILITIES UNDER BLOOD PLASMA CONDITIONS

R. BRUCE MARTIN

Chemistry Department, University of Virginia, Charlottesville, VA 22903, U.S.A.

Abstract—Aluminosilicates occur in the core of plaques in the brains of Alzheimer victims, This paper shows that under conditions prevailing in the blood plasma, the free Al^{3+} concentrations permitted by six aluminosilicates ($6–100 \times 10^{-14}$ M) are competitive with those from citrate and transferrin at 10 μM or greater total aluminium concentrations. With equilibria in a competitive range, kinetic effects play a significant role. Aluminosilicates probably form at bound Al^{3+} sites bathed in a silicic acid-containing fluid.

Up to 20% each of aluminium and silicon co-reside as aluminosilicates in the cores of senile plaques found extracellularly in the brains of individuals with Alzheimer's disease.[1] This paper compares the solubility properties of six aluminosilicate systems with the combining capabilities of other aluminium ligands that occur in the blood plasma. Reliable equilibrium data are difficult to obtain in aluminosilicate systems. Results reported by geochemists applicable to fresh waters of low ionic strength are adjusted to apply to the 0.16 ionic strength of blood plasma and the activity H^+ scale used by most chemists and all biochemists. These adjustments are identical to those made earlier.[2,3]

RESULTS

Silicic acid, $Si(OH)_4$, occurs at about 20 μM in the blood plasma.[4] It loses its first proton with $pK_a = 9.6$; hence only the acidic form occurs in neutral solutions. The plasma concentration is sufficiently low that only mononuclear silicic acid matters; there is no tendency to form amorphous or colloidal silica. The anions of silicic acid bind Mg^{2+} and Ca^{2+} so weakly[5] that a negligible amount of their complexes occurs in blood plasma. Only in insoluble silicates do significant interactions with metal ions take place.

Before discussing insoluble aluminosilicates, we consider the extent of soluble complex formation between Al^{3+} and silicic acid. The stability constant for the soluble complex of Al^{3+} with silicic acid remains unknown, but an estimate may be derived from the known stability constant of Fe^{3+}. (Since Al^{3+} does not exhibit the UV spectral changes that Fe^{3+} does in different environments, measurement of the stability constant for Al^{3+} binding to silicic acid is difficult.) For the displacement equilibrium

$$Fe^{3+} + Si(OH)_4 \rightleftharpoons FeOSi(OH)_3^{2+} + H^+$$

a reported stability constant at 25°C and 0.1 ionic strength is $K_{1H} = 0.25$.[6] Taking $pK_a = 9.6$ for silicic acid, we deduce that the stability constant for the iron complex is $\log K_{1Fe} = 9.0$. Stability constants for Al^{3+} complexes have been found to be linearly related to those of Fe^{3+} by $\log K_1(Al^{3+}) = 0.3 + 0.71 \log K_1(Fe^{3+})$; this correlation is obeyed by hydroxide ion.[3] Applying this equation to silicic acid we find for the Al^{3+} complex, $\log K_1 = 6.7$ and $\log K_{1H} = -2.9$. In acidic and neutral solutions where $pH \ll pK_a = 9.6$, we obtain for the conditional stability constant described by

$$K_{1c} = [AlOSi(OH)_3^{2+}]/[Al^{3+}][Si(OH)_4],$$

$\log K_{1c} = \log K_1 - pK_a + pH = 6.7 - 9.6 + 7.4 = 4.5$ at pH 7.4. With ambient 20 μM silicic acid the molar ratio of bound to unbound Al^{3+} becomes

$$[AlOSi(OH)_3^{2+}]/[Al^{3+}] = 10^{4.5} \times 10^{-4.7} = 0.6.$$

Thus we estimate that in the plasma the amount of Al^{3+} bound to the monoanion of silicic acid is about 60% of the free aqueous Al^{3+}.

Several studies disagree over the Al/Si molar ratio, r, in synthetic aluminosilicates. The variations probably arise from differences in solution conditions used in the preparations. A non-dialysable species with $r = 2$(imogolite) formed from pH 4.5 to 5.5 when the silicic acid concentration exceeded 0.1 mM,[7,8] five times that found in the plasma. The same laboratory reports $r < 1$ in alkaline solutions.[9] Another study shows r dropping from very high values near pH 5 and levelling off to $r = 3$–

4 near pH 7.[10] This study also reported that citrate inhibited aggregation but not formation of aluminosilicates. At pH 6.6 experiments showed a switch of Al^{3+} binding from silicate to phosphate when the latter is present.[10] This last result agrees with conclusions reached below. Finally, a reversible, metastable, amorphous aluminosilicate exhibits a variable r that rises from pure silica with $r = 0$ at pH 2 and increases with pH, reaching $r = 3.0$ at pH 7.33.[11] Thus, although the last two studies reveal similar r values at pH 7.4, they differ depending on whether the trend from acidic solutions shows r decreasing or increasing. Extensive quantitative information provided in the last study permits its analysis in greater detail.

According to one study, the Al and Si concentrations in natural waters are controlled by reversible formation of a metastable, amorphous aluminosilicate whose composition depends upon pH: high Si, low Al at low pH, and low Si, high Al at high pH.[11] The reversible dissolution of the amorphous aluminosilicate may be written as

$$(SiO_2)_{1-f}(Al(OH)_3)_f + 3fH^+ \rightleftharpoons (1-f)Si(OH)_4 + fAl^{3+} + (5f-2)H_2O, \quad (1)$$

where f is the fraction of solid that contains Al and $1-f$ the fraction that contains Si. The ratio of Al to Si in the solid is given by $r = f/(1-f)$.

From analyses of solutions, the fraction f in the variable composition solid is well approximated by a linear relation between f and pH[11] that may be written as

$$f = -0.24 + 0.135\,pH. \quad (2)$$

At pH 1.8, $f = 0$ and the solid silicic acid contains no Al. At pH 9.2, $f = 1$ and the solid $Al(OH)_3$ contains no Si. The right-hand ordinate of Fig. 1 shows f, the fraction of Al in the solid, for the straight line that rises from pH 4 to 9. For equimolar Al and Si, $f = 0.50$, and eq. (2) yields pH = 5.5. For $f = 0.75$, eq. (2) yields pH = 7.33, close to that of blood plasma; we employ $f = 0.75$ and $r = f/(1-f) = 3.0$ in subsequent calculations. Corresponding to the pH values along the abscissa, r values for the metastable aluminosilicate appear across the top of Fig. 1.

An equilibrium solubility constant for the reversible reaction may be written as

$$K_s = K_{Si}^{1-f}K_{Al}^{f} = [Si(OH)_4]^{1-f}[Al^{3+}]^f/(H^+)^{3f}, \quad (3)$$

where we use concentrations in the numerator and activity for H^+. From analyses of solutions at low ionic strength the data suggest $K_{Si} = (Si(OH)_4) = 10^{-3.0}$ and $K'_{Al} = (Al^{3+})/(H^+)^3 = 8.7$, where the parentheses indicate activities.[11] To adjust to the

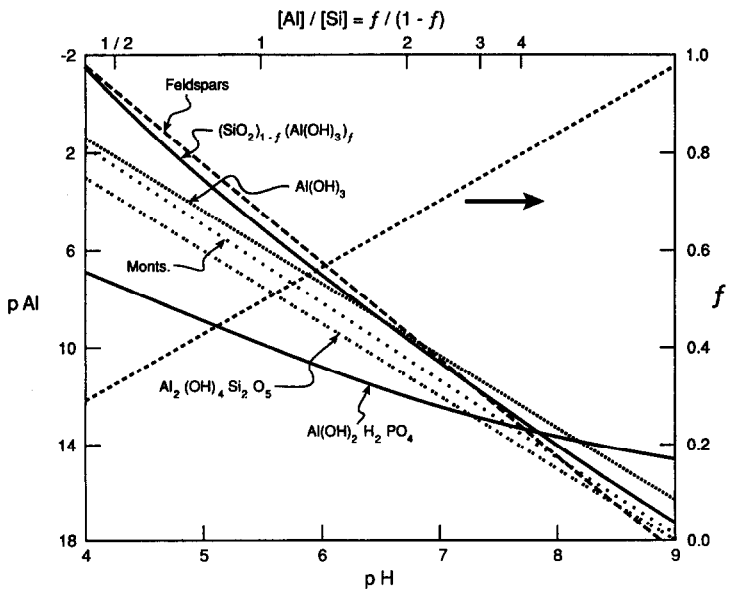

Fig. 1. Negative logarithm of free Al^{3+} molar concentration, pAl, permitted by eight insoluble Al compounds as a function of pH. Starting in the upper left hand corner the eight compounds are two feldspars, variable composition metastable aluminosilicate, amorphous aluminium hydroxide, two montmorillonites (Monts), kaolinite and variscite. The left hand pAl ordinate applies to the six descending curves. The mole fraction aluminium, f, for the metastable aluminosilicate is represented by the ascending straight line with f values on the right hand ordinate. The ratio $r = f/(1-f) =$ [Al]/[Si] in the metastable component appears across the top of the figure. The f and r values apply only to the variable composition metastable aluminosilicate. Dashes indicate straight lines.

molar concentration scale at 0.16 ionic strength, we use the above K_{Si} for uncharged $Si(OH)_4$, and adjust K'_{Al} to $K_{Al} = [Al^{3+}]/(H^+)^3 = 10^{9.7}$, similar to earlier adjustments.[2,3]

Solving the solubility constant, eq. (3), for the free aqueous Al^{3+} concentration, we obtain

$$[Al^{3+}] = (H^+)^3 10^{9.7}(10^{-3.0}/[Si(OH)_4])^{1/r}, \quad (4)$$

where $r = f/(1-f)$. At pH 7.33 when $r = 3.0$, and without a common ion, we find $[Si(OH)_4] = 4.6 \times 10^{-11}$ M and $[Al^{3+}] = 14 \times 10^{-11}$ M. For the latter value, the negative logarithm of the free $[Al^{3+}]$ is pAl = 9.9.

In the blood plasma the $Si(OH)_4$ concentration is close to 20 μM[4] so we now fix this quantity and solve eq. (4) for the free Al^{3+} concentration in solutions of different acidities. Figure 1 shows the results in the form of a plot of the negative logarithm of the free $[Al^{3+}]$, pAl, as a function of $4 < pH < 9$. The descending curve for the metastable aluminosilicate begins in the uppermost left corner of Fig. 1. Lower free Al^{3+} concentrations, greater pAl, appear closer to the bottom of Fig. 1. At pH 7.4 of blood plasma with 20 μM silicic acid and $r = 3.0$, eq. (4) yields pAl = 12.0. This value is listed as the second entry in Table 1.

Table 1 lists the negative logarithm of the free Al^{3+} concentration as pAl under blood plasma conditions. For amorphous $Al(OH)_3$, $K_s = [Al^{3+}]/(H^+)^3 = 10^{10.7}$ was used as in previous articles.[2,3] This value representing an adjustment of a low ionic strength value to 0.16 ionic strength and an activity H^+ scale has recently received confirmation in a study performed at 0.6 ionic strength.[12]

Table 1. Negative logarithm of free Al^{3+} molar concentration under blood plasma conditions[a]

	pAl
Amorphous $Al(OH)_3$	11.5
Metastable $SiO_2(Al(OH)_3)_3$	12.0
Anorthite, $CaAl_2Si_2O_8$	12.0
Albite, $NaAlSi_3O_8$	12.2
Ca-montmorillonite, $CaAl_{14}Si_{22}O_{60}(OH)_{12}$	12.4
Na-montmorillonite, $NaAl_7Si_{11}O_{30}(OH)_6$	12.7
Variscite, $Al(OH)_2H_2PO_4$	12.9
Gibbsite, $Al(OH)_3$	13.0
Kaolinite, $Al_2(OH)_4Si_2O_5$	13.2
0.1 mM Citrate	13.4[b]
Transferrin	13.6[c]

[a] pH 7.4, 0.16 ionic strength, 20 μM $Si(OH)_4$, 140 mM Na^+, 1.3 mM Ca^{2+} and 2 mM total phosphate.

[b] 10 μM total Al^{3+}.

[c] 10 μM total Al^{3+} with 50 μM unoccupied transferrin sites.

Adjustment of this high ionic strength value to 0.16 ionic strength and the activity H^+ scale yields a K_s constant identical to the above. This value is 10 times greater than that found for the best linear fit to experimental points over a range of compositions in the low ionic strength variable composition, metastable aluminosilicate study. As a result the straight line for amorphous $Al(OH)_3$ in Fig. 1 rides 1.0 log unit higher than a line consistent with the metastable aluminosilicates. For the slowly forming crystalline gibbsite form of $Al(OH)_3$ the $K_s = 10^{9.2}$, so that pAl is 1.5 log units greater than that for amorphous $Al(OH)_3$. The gibbsite pAl value appears near the bottom of Table 1.

The pAl values in Table 1 refer to the negative logarithm of the hexaaquo Al^{3+}. Since most solvated Al at $pH > 6.2$ occurs as tetrahedral $Al(OH)_4^-$, the total solvated Al concentration is much greater. At pH 7.4 we calculate[3,2] the molar ratio $[Al(OH)_4^-]/[Al^{3+}] = 2.5 \times 10^6$. Thus for a solution saturated with amorphous $Al(OH)_3$ at pH 7.4, we find from Table 1 pAl = 11.5, and calculate $[Al^{3+}] = 3 \times 10^{-12}$ M and $[Al(OH)_4^-] = 8$ μM. Though the free hexaaquo Al^{3+} species enters calculations, at $pH > 6.2$ the tetrahedral $Al(OH)_4^-$ species should be the starting point for discussions of Al speciation.

Silica was introduced into solutions containing $Al(OH)_3$ and after lengthy aging to achieve equilibrium, the results analysed in terms of a solid equivalent to halloysite (kaolinite).[13] The reverse of the synthesis reaction is

$$Al_2(OH)_4Si_2O_5 + 6H^+ \rightleftharpoons 2Al^{2+} + 2Si(OH)_4 + H_2O,$$

for which the solubility constant may be defined as

$$K_s = [Al^{3+}][Si(OH)_4]/(H^+)^3,$$

where the brackets represent concentrations. At a fixed silicic acid concentration we may write

$$K_s/[Si(OH)_4] = [Al^{3+}]/(H^+)^3, \quad (5)$$

which is of the same form as the previous K_s equation. In order to stabilize halloysite against microcrystalline gibbsite the silicic acid concentration must be 150 μM.[13] This value is 7.5 times the 20 μM $Si(OH)_4$ that occurs in blood plasma. Two factors may reduce or even invert this factor.[13] Formation of a well-organized kaolinite would require a nine-fold lower silicic acid concentration. Moreover, gibbsite forms with difficulty in biological systems, and amorphous $Al(OH)_3$ is more than 10 times more soluble than gibbsite. These results suggest that in extracellular fluids formation of halloysite and especially kaolinite become favoured in

comparison with amorphous $Al(OH)_3$. These comparisons are borne out by the quantitative results in Table 1.

We may apply eq. (5) to kaolinite by adjusting the low ionic strength K_s[14] to concentration at 0.16 ionic strength to obtain $K_s = 10^{4.3}$. With $Si(OH)_4$ held at 20 μM eq. (5) may be solved for $[Al^{3+}]$ as a function of H^+. The results plotted as pAl vs pH appear in Fig. 1. Both kaolinite and amorphous $Al(OH)_3$ solubilities exhibit an identical dependence on $(H^+)^3$, and both display a slope of three in Fig. 1. The straight line for kaolinite shows a lower free Al^{3+} than does the line for amorphous $Al(OH)_3$.

The plagioclase feldspars constitute a continuous series of six aluminium silicate mixtures in a common triclinic lattice from $NaAlSi_3O_8$ (albite) to $CaAl_2Si_2O_8$ (anorthite). Equilibrium constants for the terminal members of the series establish their stabilities relative to kaolinite.[15] We combine these constants with our kaolinite value adjusted to blood plasma conditions. For albite we obtain

$$NaAlSi_3O_8 + 4H^+ + 4H_2O \rightleftharpoons Na^+ + Al^{3+} + 3Si(OH)_4,$$

for which

$$K_b = [Na^+][Al^{3+}][Si(OH)_4]^3/(H^+)^4 = 10^{2.4}. \quad (6)$$

For anorthite we write

$$0.5CaAl_2Si_2O_8 + 4H^+ \rightleftharpoons 0.5Ca^{2+} + Al^{3+} + Si(OH)_4,$$

for which

$$K_n = [Ca^{2+}]^{0.5}[Al^{3+}][Si(OH)_4]/(H^+)^4 = 10^{11.5}. \quad (7)$$

We now substitute into eqs (6) and (7) the blood plasma conditions of 140 mM Na^+, 1.3 mM Ca^{2+}, and 20 μM $Si(OH)_4$ to obtain for albite

$$[Al^{3+}] = 10^{17.4}(H^+)^4 \quad (8)$$

which gives at pH 7.4, pAl = 12.2, and for anorthite

$$[Al^{3+}] = 10^{17.6}(H^+)^4 \quad (9)$$

which yields at pH 7.4, pAl = 12.0. The pair of pAl values appear in Table 1. Equations (8) and (9) exhibit identical fourth power dependencies on H^+ and constant terms that differ by only 0.2 log units. The average result of pAl = 4pH − 17.5 appears as the straight line labelled Feldspars in Fig. 1.

A treatment similar to that for the Feldspars may be applied to Na– and Ca–montmorillonites. The compositions appear in Table 1. Equilibrium constants for conversion to kaolinite have been tabulated.[15] We obtain for the Na compound, pAl = 10.5–3.14 pH, and for the Ca compound, pAl = 10.8–3.14 pH. Since the pair of equations display an identical pH dependence (22/7) and exhibit constant terms within 0.3 log units of each other, we plot an average of the two in Fig. 1 with the label Monts. Separate entries for the two-layered montmorillonites appear in Table 1.

Figure 1 also plots the pAl curve for insoluble variscite, $Al(OH)_2H_2PO_4$. For this salt the free Al^{3+} concentration from pH 3 to 11 is given by[2,3]

$$[Al^{3+}] = (H^+)[(H^+) + 10^{-6.77}]/30Tp,$$

where the total phosphate concentration, Tp, is taken as 2 mM, typical of that in blood plasma. The variscite curve is the lowest one in Fig. 1 over most of the pH range, and this insoluble salt permits the lowest free Al^{3+} concentration until pH 7.2 when the variscite curve crosses that for kaolinite. At pH > 7.2 kaolinite permits a lower free Al^{3+} concentration than does variscite. Between 7.2 < pH < 8.1 the curve for variscite crosses all the other pAl curves in Fig. 1.

DISCUSSION

The results of this paper dispel much of the mystery regarding appearance of aluminosilicates in senile plaques. Near a blood plasma pH of 7.4, also typical of other body fluids external to cells, Fig. 1 and Table 1 show that six aluminosilicates display comparable affinities for Al^{3+}. The lower free Al^{3+} (higher pAl) allowed by variscite at low pH no longer prevails in neutral solutions. The physiological pH region shows the greatest congestion of pAl curves in Fig. 1. The equilibrium constants used to define the curves in Fig. 1 are made only with difficulty on heterogeneous systems. The systems used to determine the equilibrium constants are much simpler than blood plasma. In the plasma, kinetic effects become more important and supersaturation occurs. The crystalline gibbsite form of $Al(OH)_3$ is unlikely to form in the plasma. Although the presence of organic molecules often hinders precipitation processes, aged, neutral solutions containing silicic acid and $Al(OH)_4^-$ at 25°C gave well-formed kaolinite plates in the presence of 5 μM quercetin (an organic flavone), while no plates were found in parallel experiments without quercetin.[16]

Values for pAl taken as a pH 7.4 slice through Fig. 1 appear in Table 1. The free Al^{3+} concentrations permitted by the six aluminosilicates range from (6 to 100) × 10^{-14} M. Table 1 also lists additional pAl values, including those for amorphous and crystalline (gibbsite) $Al(OH)_3$, variscite, and the ligands citrate and transferrin.

Blood plasma contains two strong ligands that bind Al^{3+} in soluble complexes. Citrate (at 0.1 mM

in plasma) is the strongest small molecule Al^{3+} ligand[2,3,17] and transferrin the strongest protein Al^{3+} binder.[2,3,18] Table 1 lists pAl values for binding of 10 μM total Al, an amount typical of an Al excess condition. These last two pAl values in Table 1 are comparable with the previous ones. The free Al^{3+} concentration is proportional to the total metal ion concentration. For each doubling of the total Al concentration, the pAl values for citrate and transferrin decrease by 0.3 log units. Thus for 20 μM total Al, pAl values in Table 1 for citrate and transferrin become 13.1 and 13.3, respectively. A difference of 0.5 pM units between two entries in Table 1 means that the stronger binding ligand of greater pAl allows 1/3 the free Al^{3+} concentration of the weaker binding ligand. Therefore, at Al levels of 10 μM and greater, citrate and transferrin no longer sequester Al^{3+} sufficiently to prevent its precipitation as an aluminosilicate. In the cerebrospinal fluid with little citrate and no transferrin, Al^{3+} is complexed weakly by other ligands,[19] and the tendency toward aluminosilicate formation becomes much greater than in the plasma.

By what process do aluminosilicate plaques form? A possible scenario is that Al^{3+} first binds at sites on phosphorylated proteins, the most likely matrix forming Al^{3+} site.[20] Al^{3+} at these sites is bathed in excess silicic acid which reacts with the Al^{3+}, sometimes releasing it, forming some kind of amorphous aluminosilicate that possibly rearranges to a less soluble form. Once formed, the aluminosilicate may become coated with protective agents stabilizing a non-equilibrium status. By this scenario Al remains the primary culprit in formation of aluminosilicate plaques. The inverse process is unlikely because there are no evident silicic acid sites without Al^{3+}. Nature holds many aluminosilicates; it will be interesting to learn the composition of aluminosilicates in plaques. As mentioned above, a well-formed kaolinite forms slowly but more rapidly in the presence of an organic compound. Of the many other aluminosilicates those containing Na^+, Ca^{2+}, or Mg^{2+} may be important, as these ions are relatively concentrated in the blood.

The analysis and conclusions in this paper are based on systems at equilibrium or in metastable equilibrium. Though mentioned, kinetic effects are hard to include in extended analysis. This problem occurs in all biological systems. Many substances that theoretically should precipitate in body fluids do not readily do so. When they occasionally do, we consider the result an abnormality, such as kidney stones, gallstones, gout and atherosclerotic plaques. The Ca^{2+} concentration in extracellular fluids is more than 200 times greater than the saturation concentration from hydroxyapatite.[21] On an equilibrium basis body fluids should contain many more precipitates and gels. Their precipitation evidently requires a nucleation site with appropriate geometry. In the case of aluminosilicates, an abnormally phosphorylated protein in the brain[22,23] may provide the requisite nucleation site.

EQUILIBRIUM AND STRUCTURAL STUDIES OF SILICON(IV) AND ALUMINIUM(III) IN AQUEOUS SOLUTION—XXIII. A POTENTIOMETRIC STUDY OF THE COMPOSITION AND STABILITY OF ALUMINIUM COMPLEXES WITH NITRILOTRIACETIC ACID

LARS-OLOF ÖHMAN

Department of Inorganic Chemistry, University of Umeå, S-901 87 Umeå, Sweden

Abstract—Equilibria between H^+, aluminium(III) and nitrilotriacetic acid [$N(CH_2COOH)_3$, H_3L] were studied in 0.6 M Na(Cl) medium at 25°C. The measurements were performed as EMF titrations (glass electrode) within the limits $1.4 \leqslant -\log[H^+] \leqslant 9.4$; $0.0006 \leqslant B \leqslant 0.04$ M; $0.0007 \leqslant C \leqslant 0.04$ M and $0.25 \leqslant C/B \leqslant 5$ (B and C stand for the total concentrations of aluminium(III) and nitrilotriacetic acid, respectively). All data can be explained with a series of mononuclear species $AlL(H_2O)_2^0$ ($\log \beta_{-3,1,1} = -1.853 \pm 0.007$), $AlL(OH)(H_2O)^-$ ($\log \beta_{-4,1,1} = -7.28 \pm 0.026$) and $AlL(OH)_2^{2-}$ ($\log \beta_{-5,1,1} = -15.47 \pm 0.032$) together with a dimer of $AlL(OH)(H_2O)^-$, i.e. $Al_2(OH)_2L_2^{2-}$ ($\log \beta_{-8,2,2} = -12.74 \pm 0.038$). (The formulae given are based on an assumed resemblance with species found in the solid state.) The acidity constants of nitrilotriacetic acid were studied in separate titrations ($0.003 \leqslant C \leqslant 0.02$ M) and were found to be $\log \beta_{-1,0,1} = -1.74 \pm 0.023$, $\log \beta_{-2,0,1} = -4.04 \pm 0.015$ and $\log \beta_{-3,0,1} = -12.95 \pm 0.016$. All equilibrium constants given are defined according to the general reaction $pH^+ + aAl^{3+} + rH_3L \rightleftarrows H_pAl_q(H_3L)_r^{p+3q}$ and the uncertainties reported are $3\sigma(\log \beta_{p,q,r})$. Data were analysed with the least-squares computer program LETAGROPVRID. In a series of calculations with the modelling program SOLGASWATER, the potential ability of the nitrilotriacetate ion to increase the solubility of gibbsite, is illustrated.

In a current research project at this department, the ability of Al^{3+} to form complexes with ligands of geo- and biochemical relevance is being investigated. The goal of our studies performed with ligands of geochemical importance, is to gain a better understanding of the processes affecting the mobility and acute toxicity of this element in natural waters influenced by natural or anthropogenic acidity[1] ("acid rain"). Correspondingly, the intention behind our studies of biochemically interesting ligands, is to provide data of relevance to aluminium-toxicological studies in man.[1]

As these aims put certain demands on the experimental conditions under which the data must be collected, i.e. at low concentrations and near-neutral pH-values, we spend a lot of effort collecting and analysing data with as large a variation in pH, aluminium and ligand concentration and aluminium–ligand ratio as possible. Through these studies the common occurrence of mono- and polynuclear mixed Al–OH–ligand complexes has been demonstrated.[2–4] Furthermore, in several of the systems studied, the occurrence of ternary solid phases has been identified near the precipitation boundary of aluminium hydroxide.[5–7]

The aim of the present investigation is to interpret the complexation features of nitrilotriacetic acid, NTA, towards Al^{3+}. As the sodium salt of this compound is a commonly used additive in washing powder (as a detergent builder) in several countries, it can be regarded as a potential anthropogenic complex former in the biosphere. Furthermore, as it has recently been shown that NTA under certain circumstances forms a water-soluble, net-neutral species with Al^{3+},[8] there is a risk that NTA might induce an elevated aluminium-toxicity towards aquatic biocenoses and superior organisms.

A final reason for undertaking this investigation is the need from clinical chemists and biochemists for a well-defined system to set the free Al^{3+} concentration when for instance the binding constants of Al^{3+} to transferrin are evaluated[9] or when the

influence of Al^{3+} on the promotion of tubulin into microtubules is being studied.[10] The formal analogy between pH-buffers for proper pH-control and aluminium–ligand systems for Al^{3+} control has been discussed by Martin,[11] who also illustrated this point with NTA and citrate as two suitable complex formers. In view of the complexity and time-dependence of the reactions between Al^{3+} and citrate ions[12,13] as compared to those reported in the Al^{3+}–NTA system, NTA promises to be a much better choice of buffer than citrate in such studies.

Several reports on the complexation of NTA to Al^{3+} have appeared in the literature.[14–16] In none of these articles has, however, the experimental data base been wide enough to permit a comprehensive and unbiased search for a speciation model. Furthermore, since the deprotonation and aluminium-complexation of NTA commence at very low pH-values, comparable to the behaviour of oxalic acid,[3] an investigation of this system with the potentiometric method places very high demands on the analytical precision as well as on the measuring equipment.

EXPERIMENTAL

Chemicals and analysis

Nitrilotriacetic acid, NTA [$N(CH_2COOH)_3$, H_3L] (Merck p.a.), was used after drying at 80°C. Stock solutions were prepared by dissolving H_3L and sodium chloride in water and the L content was determined potentiometrically. The titrated amount was in good agreement (within 0.1%) with the value expected from weighing. Stock solutions of sodium chloride and aluminium chloride, as well as the dilute hydrochloric acid and sodium hydroxide solutions, were prepared and standardized as described earlier.[17]

Apparatus

The automatic system for precise EMF titrations, the thermostat and the electrodes have been described earlier.[17]

Temperature and medium

The measurements were carried out at 25.00 ± 0.05°C in a constant ionic medium of 0.6 M Na(Cl).

Method

The present investigation was carried out as a series of potentiometric titrations. The titration procedures, including a special procedure to calibrate the glass electrode, have been described in earlier papers.[17,18] The reproducibility and reversibility of equilibria were tested by performing both forward (increasing $-\log[H^+]$ by means of additions of OH^-) and backward (decreasing $-\log[H^+]$ with H^+) titrations. The acidity constants of nitrilotriacetic acid were determined in separate titrations.

The three-component titrations were performed at a constant ratio between the total concentration of aluminium (B) and nitrilotriacetic acid (C). The upper $-\log[H^+]$ limits in these titrations were set by the formation of a precipitate or by the appearance of extremely sluggish equilibria. These phenomena were presumed to originate from the precipitation and polynuclear hydrolysis of aluminium, respectively.

Data treatment

In order to visualize experimental results, the data sets Z_c vs $-\log[H^+]$ were calculated and some of them are presented in Fig. 1; Z_c is defined as the average number of OH^- ions reacted per nitrilotriacetic acid and is given by the relation $Z_c = (h - H - k_w h^{-1})/C$, where $h = [H^+]$ and H denotes the total concentration of protons calculated over the zero level H_2O, Al^{3+} and H_3L. The term $k_w h^{-1}$, where k_w is the ionic product of water in 0.6 M Na(Cl) medium, corresponds to the free concentration of hydroxide ions. These curves reflect the total complexation behaviour of the system, comprising binary [eqs (1) and (2)] as well as ternary [eq. (3)] equilibria:

$$H_3L \rightleftarrows H_{3-n}L^{n-} + nH^+ \quad (\beta_{-n,0,1};\ n = 1, 2 \text{ and } 3) \tag{1}$$

$$pH^+ + qAl^{3+} \rightleftarrows H_pAl_q^{p+3q} \quad (\beta_{p,q,0}) \tag{2}$$

$$pH^+ + qAl^{3+} + rH_3L \rightleftarrows H_pAl_q(H_3L)_r^{p+3q} \quad (\beta_{p,q,r}). \tag{3}$$

For the acidity constants of nitrilotriacetic acid [i.e. eq. (1)], results from separate experiments will be used, while for the hydrolytic equilibria of Al^{3+} [i.e. eq. (2)], results obtained in earlier papers of this series[13,19,20] will be used. This hydrolytic scheme of Al^{3+} comprises the species $[Al(OH)]^{2+}$ (log $\beta_{-1,1,0} = -5.52$), $Al(OH)_2^+$ (log $\beta_{-2,1,0} = -11.3$), $Al(OH)_3$ (log $\beta_{-3,1,0} = -17.3$), $Al(OH)_4^-$ (log $\beta_{-4,1,0} = -23.46$), $Al_3(OH)_4^{5+}$ (log $\beta_{-4,3,0} = -13.57$) and $Al_{13}O_4(OH)_{24}^{7+}$ (log $\beta_{-32,13,0} = -109.2$).

In the evaluation of the three-component experimental data [i.e. eq. (3)] the binary complex models were considered as known and all effects above this

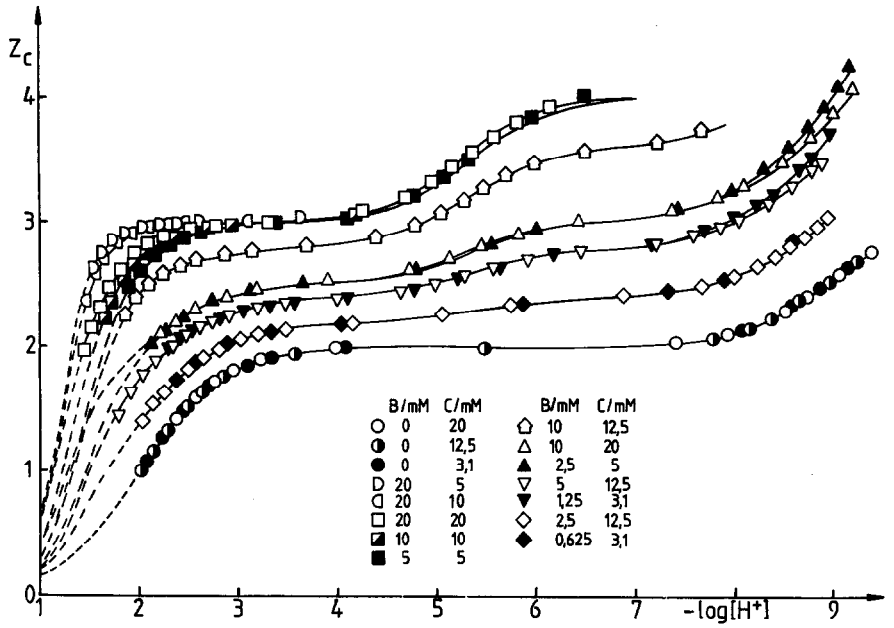

Fig. 1. Part of the experimental data plotted as curves $Z_c(-\log[H^+])$. All symbols represent initial concentrations and the lines have been calculated using the set of proposed constants in Table 1. The dashed lines at low $-\log[H^+]$ denote extrapolated values where no measurements have been performed.

level treated as being caused by ternary species. The mathematical analysis of data was performed with the least-squares computer program LETAGROPVRID[21] (version ETITR[22,23]). The *p,q,r*-triplets and corresponding equilibrium constants that "best" fit the experimental data were determined by minimizing the error squares sum $U = \Sigma(H_{calc} - H_{exp})^2$, where H_{calc} and H_{exp} denote calculated and experimental values of the analytical H^+ concentrations, respectively. The standard deviations $\sigma(H)$ and $3\sigma(\log \beta_{p,q,r})$ obtained in the LETAGROP calculations, were defined and calculated according to Sillén.[24,25] The computations were performed on a CD Cyber 850 computer.

DATA, CALCULATIONS AND RESULTS

Binary H^+–H_3L *equilibria*

The data comprise 99 experimental points collected via three potentiometric titrations within the range $0.003 \leqslant C \leqslant 0.020$ M and $2.0 \leqslant -\log[H^+] \leqslant 9.4$. The LETAGROP calculation ended at $\sigma(H) = 0.06 \times 10^{-3}$ M and the following equilibrium constants were obtained: $\log(\beta_{-1,0,1} \pm 3\sigma) = -1.744 \pm 0.023$, $\log(\beta_{-2,0,1} \pm 3\sigma) = -4.037 \pm 0.015$, $\log(\beta_{-3,0,1} \pm 3\sigma) = -12.950 \pm 0.016$.

Ternary H^+–Al^{3+}–H_3L *equilibria*

These data comprise 15 titrations (462 experimental points) within the ranges $0.0006 \leqslant B \leqslant 0.040$ M, $0.0007 \leqslant C \leqslant 0.040$ M and $1.4 \leqslant -\log[H^+] \leqslant 9.2$. The following C/B ratios have been covered: 0.25, 0.5, 1, 1.25, 2, 2.5 and 5. In order to visualize experimental data, Z_c vs $-\log[H^+]$ were calculated and some of these data are illustrated in Fig. 1. From the fact that Z_c values exceeding the value of three are obtained, it can be directly concluded that the formation of aluminium hydrolytic products and/or ternary aluminium–nitrilotriacetate–hydroxide complexes are significant. On the basis of this plot, the evaluation of data was accordingly divided into three parts, corresponding to data with $-\log[H^+] \leqslant 3.2$; $3.2 \leqslant -\log[H^+] \leqslant 6.5$ and $-\log[H^+] \geqslant 6.5$, respectively.

In the first calculation, performed on data with $-\log[H^+] \leqslant 3.2$, the stability constants for the species $(-1, 1, 1)^{2+}$, $(-2, 1, 1)^+$ and $(-3, 1, 1)^0$ were simultaneously varied. It did, however, turn out that only the stability constant for $(-3, 1, 1)^0$ attained a positive value ($\log(\beta_{-3,1,1} \pm 3\sigma) = -1.852 \pm 0.005$), i.e. the species AlH_2L^{2+} and $AlHL^+$ were rejected. This value for AlL^0 was then regarded as known when data with $3.2 \leqslant -\log[H^+] \leqslant 6.5$ were examined.

From the shapes of the $Z_c(-\log[H^+])$ curves in this region it was directly concluded that the species $(-4, 1, 1)^-$ had to be the predominating one. As these curves, however, also showed a small but systematic dependence on total concentrations, it was also apparent that a simultaneous formation of the corresponding dimer, $(-8, 2, 2)^{2-}$, had to be taken into consideration. For this reason, the original data base was supplemented with two titrations at $C/B = 1$ and $Z_c = 3.50$, the first in which an initially $B = C = 0.040$ M solution was titrated with pure ionic medium and a second in which the burette and vessel solutions were switched. Through these titrations it was found that on increasing $B = C$ from 0.7×10^{-3} to 40×10^{-3} M, $-\log[H^+]$ decreased from 5.40 to 5.12, i.e. a clearly measurable effect. On all data in this region, a LETAGROP calculation was then performed in which the formation constants for $(-4, 1, 1)^-$ and $(-8, 2, 2)^{2-}$ were simultaneously refined. The result of this calculation [$\log(\beta_{-4,1,1} \pm 3\sigma) = -7.26 \pm 0.035$; $\log(\beta_{-8,2,2} \pm 3\sigma) = -12.75 \pm 0.048$; $U = 3.95$], as compared to the results obtained when only one of the complexes was considered [$\log(\beta_{-4,1,1} \pm 3\sigma) = -7.01 \pm 0.019$, $U = 30.2$; $\log(\beta_{-8,2,2} \pm 3\sigma) = -12.36 \pm 0.036$, $U = 41.8$] showed that both of these species were needed to give a satisfactory fit to the data.

Finally, with $C/B \geqslant 1.25$, it was found that a species with an even higher degree of deprotonation was formed (cf. Fig. 1). These data were fully explained by the appearance of a species with the composition $(-5, 1, 1)^{2-}$. The LETAGROP calculation on these data gave $\log(\beta_{-5,1,1} \pm 3\sigma) = -15.46 \pm 0.031$.

To obtain the "best" equilibrium constants for all ternary species, a final calculation was performed in which the equilibrium constants for all species detected above were co-refined on all data. This calculation ended at $\sigma(H) = 0.13 \times 10^{-3}$ M and with the equilibrium constants given in Table 1. With this final model, no remaining systematic deviations could be observed.

In order to visualize the amounts of the different species, the computer program SOLGASWATER,[26] equipped with plotting procedures, has been used to calculate some distribution diagrams. These are presented in Fig. 2.

DISCUSSION

Equilibria and structures

The present investigation has shown that nitrilotriacetic acid (NTA, H_3L) at 25°C and in a 0.6 M Na(Cl) medium titrates as a triprotic weak acid with successive pK_a values of 1.74, 2.30 and 8.91. The surprisingly high value of pK_{a_3} can probably be explained by the appearance of NTA as a zwitterion in aqueous solution, i.e. one of the three protons is actually positioned on the imino nitrogen group. A qualitative observation which gives support to this assumption is the fact that the solubility of NTA is significantly increased in the presence of excess strong acid.

In its interaction with the aluminium ion, the present study has shown that the first complex NTA forms is the uncharged species $H_{-3}Al(H_3L)$. A previously reported species[14] $H_{-2}Al(H_3L)^+$ could not be verified and is probably an artifact caused by experimental difficulties at the low $-\log[H^+]$ values at which it was interpreted.

According to a recent report[8] on the structure of $H_{-3}Al(H_3L)$, the nitrilotriacetate ion acts as a tribasic, tetradentate (via the three carboxylate groups and the imino group) ligand in its interaction with Al^{3+} and that, accordingly, this species should be written $AlL(H_2O)_2^0$. Since the ligand thus occu-

Table 1. Binary and ternary complexes in the three-component system H^+–Al^{3+}–NTA. The formation constants are related according to the reaction $pH^+ + qAl^{3+} + rH_3L \rightleftarrows H_pAl_q(H_3L)_r^{p+3q}$, where H_3L stands for nitrilotriacetic acid

Number of titrations/ Number of points	p	q	r	Tentative formula	$\log(\beta_{pqr} \pm 3\sigma)$
3/99	−1	0	1	H_2L^-	−1.74±0.023
	−2	0	1	HL^{2-}	−4.04±0.015
	−3	0	1	L^{3-}	−12.95±0.016
15/462	−3	1	1	$AlL(H_2O)_2^0$	−1.853±0.007
	−4	1	1	$AlL(OH)(H_2O)^-$	−7.28±0.026
	−5	1	1	$AlL(OH)_2^{2-}$	−15.47±0.032
	−8	2	2	$Al_2(OH)_2L_2^{2-}$	−12.74±0.038

pies four of the six coordination positions around the aluminium ion, the absence of a bis-ligand complex in this system can be readily understood.

Also, in view of the appearance of $AlL(H_2O)_2^0$, it is logical to assume that the two succeeding species $H_{-4}Al(H_3L)^-$ and $H_{-5}Al(H_3L)^{2-}$ are hydrolysis products of this species, i.e. that they should be written $AlL(OH)(H_2O)^-$ and $AlL(OH)_2^{2-}$, respectively. The corresponding pK_a values for $AlL(H_2O)_2^0$ and $AlL(OH)(H_2O)^-$ then becomes 5.43 and 8.19.

These values are considerably lower than those previously determined for $Al(salicylate)_2^-$ (7.60, 9.32)[18] or $Al(H^{-1}\ citrate)^-$ (6.2).[13] In fact, the acidity of $AlL(H_2O)_2^0$ exceeds the acidity of $Al(H_2O)_6^{3+}$ ($pK_a = 5.52$).[19] The reason for this high acidity is uncertain but a possible explanation is the high electron demand from the coordinated imino

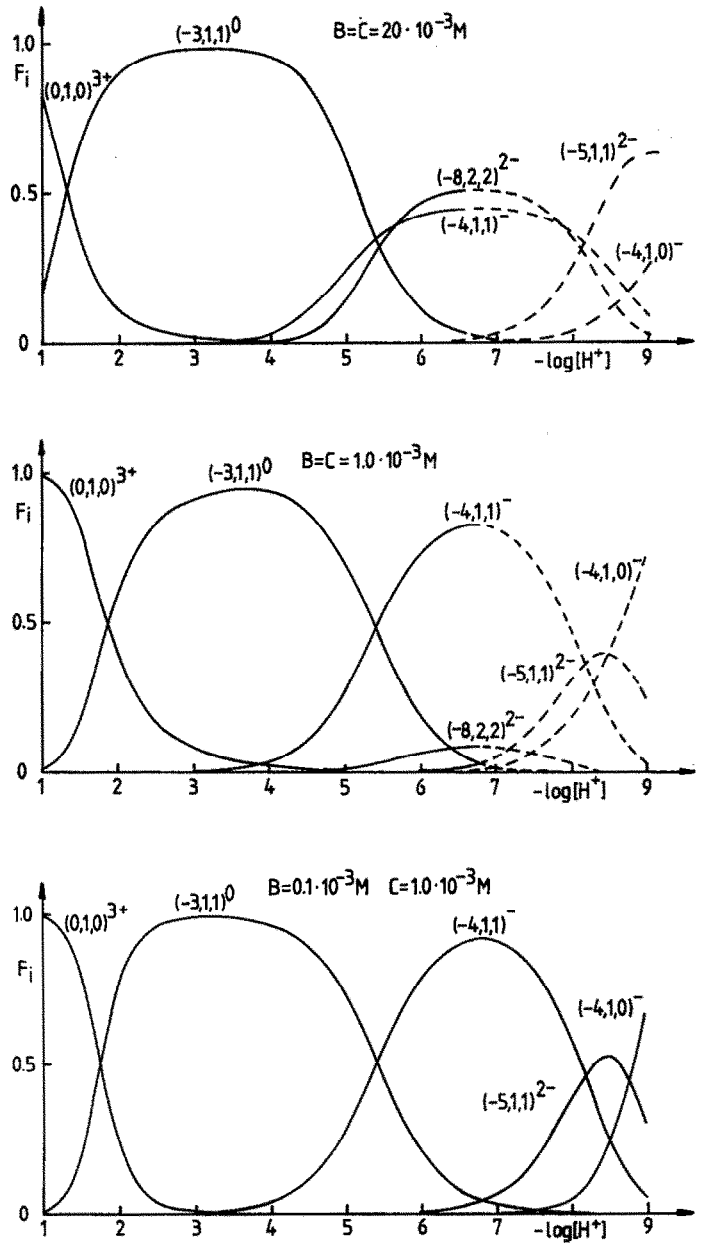

Fig. 2. Distribution diagrams $F_i(-\log[H^+])$. F_i is defined as the ratio between aluminium(III) in a species and the total aluminium(III). The calculations were performed with the computer program SOLGASWATER using the equilibrium constants given in Table 1. Dashed curves denote precipitation ranges.

group. This hypothesis is supported by the fact that the Al—OH_2 distance for the water molecule coordinated *trans* to the nitrogen in $AlL(H_2O)_2^0$ (1.829 Å)[8] is shorter than the corresponding distance in $Al(H_2O)_6Cl_3$ (1.88 Å).[27]

Also with regard to the dimer $H_{-8}Al_2(H_3L)_2^{2-}$, the structure report cited above[8] provides its structure in the solid state. This species is shown to consist of two AlL-units bridged by a dihydroxo bridge, i.e. $Al_2(OH)_2L_2^{2-}$, thus creating an octahedral coordination around both aluminium ions. By writing the formation of this species as $2AlL(OH)(H_2O)^- \rightleftarrows Al_2(OH)_2L_2^{2-} + 2H_2O$, log $K = 1.82$, the connection with its corresponding monomer is emphasized. From the resulting equilibrium constant, it can furthermore be concluded that the monomer dominates in solutions with $B = C < 15 \times 10^{-3}$ M. The pronounced concentration dependence of the dimer is also illustrated in Fig. 2 where it is shown that the formation of $Al_2(OH)_2L_2^{2-}$ is negligible at $B = 10^{-4}$ and $C = 10^{-3}$ M.

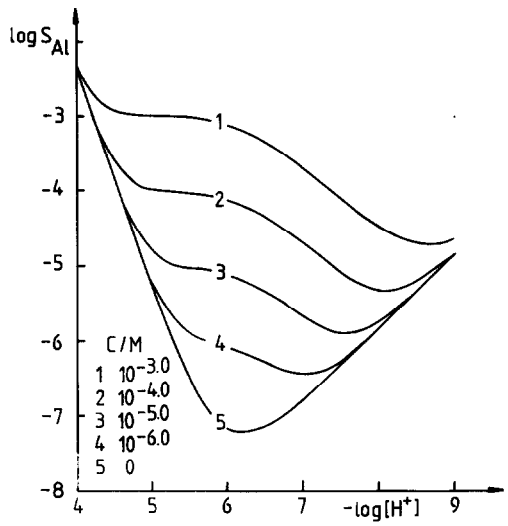

Fig. 3. Solubility of gibbsite (log* $K_{so} = 9.6$) expressed as log S_{Al} vs $-\log[H^+]$ for different total concentrations of nitrilotriacetic acid, C.

Modelling calculations

The concentration of aluminium under most natural conditions is regulated by the occurrence of secondary formed hydroxo phases. Therefore, the potential ability of a given ligand to affect its aquatic behaviour can be suitably indicated via computerized modelling in which aluminium hydroxide or some clay mineral, e.g. kaolinite ($Al_2(OH)_4Si_2O_5$), is used as a solubility regulating phase. Under such conditions, the presence of a complex-forming substance will raise the total solubility of the solid phase but leave concentrations of Al^{3+} and hydrolytic species unaffected.

In Fig. 3, the ability of various amounts of NTA to increase the solubility of gibbsite (log* $K_{so} = 9.6$)[28] is illustrated. From this figure it can be concluded that even very low concentrations of NTA can be expected to cause a substantial solubilization of gibbsite in near-neutral solutions. Compared to previously investigated ligands within the present series,[29] it can be stated that the complexation strength of the nitrilotriacetate ion is somewhat weaker than that of the citrate ion[13] but considerably stronger than that of the oxalate ion,[3] especially in slightly alkaline solutions.

From Fig. 4, which correspondingly gives areas for the predominating aluminium-containing species in solutions equilibrated with gibbsite, it can be concluded that the solubilization in near-neutral solutions is mainly caused by the occurrence of the species $Al(OH)L^-$. In this figure also, the restricted predominance of $Al_2(OH)_2L_2^{2-}$ to solutions of high ligand concentrations is emphasized.

With regard to human bio-uptake considerations, a main concern has been devoted to the occurrence of water-soluble, net-neutral species of low (<650) molecular weight,[11,30] as these might pass cell membranes via a passive diffusion mechanism.[31] The formation of such aluminium species with citrate,[13] tartrate[32] and maltolate[33] has been suggested[11] as the reason why these substances ele-

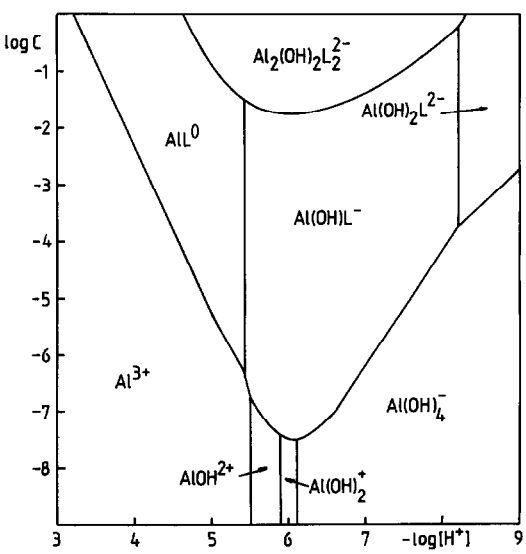

Fig. 4. Predominance area diagram showing the dominating aqueous aluminium species in equilibrium with gibbsite as a function of log C and $-\log[H^+]$.

vate the bio-availability[34] and toxicity[35,36] of aluminium. Also in the present system, the formation of such a species is highly predominant (cf. Figs 2 and 4) in slightly acidic solutions. It is therefore probable that nitrilotriacetate ions may also cause an elevated aluminium absorption from the gastrointestinal tract.

SPECTROSCOPIC STUDIES OF GALLIUM COMPLEXES IN SOLUTION

MICHAEL J. TAYLOR*

Department of Chemistry, University of Auckland, Private Bag, Auckland, New Zealand

Abstract—High-field ^{71}Ga NMR spectra at 122.03 MHz of aqueous solutions of Ga^{3+} in the presence of oxyanions reveal sulphate, phosphate or citrate complexes. In halogen acid solutions the $[Ga(H_2O)_6]^{3+}$ signal is accompanied by that of a mixture of $[GaX_n(H_2O)_{4-n}]^{3-n}$ (X = Cl or Br; n = 1–4) from which a single NMR peak is observed. Aqueous solutions of $[GaCl_4]^-$ and $[GaBr_4]^-$ in combination yield one peak due to mixed halides undergoing ligand exchange. The diethyl ether extract of this solution displays the five signals of the complex acids $H^+(aq)[GaCl_nBr_{4-n}]^-$ (n = 0–4). The Raman spectrum of this system provides a set of $\nu(Ga—Cl)_{sym}$ and $\nu(Ga—Br)_{sym}$ frequencies. The ^{17}O chemical shift of the $[H_9O_4]^+$ ion occurs at 15 ppm. Attempts to investigate the halogen exchange process of gallium mixed-halide species by a two-dimensional ^{71}Ga NMR technique are described. ^{71}Ga NMR spectra of mixed-ligand halide/thiocyanate complexes are attributable to species $[GaX_n(NCS)_{4-n}]^-$ (X = Cl or Br; n = 0–4). Chemical shift trends show the gallium(III) shielding order, Cl < NCS < Br < I.

Gallium forms a variety of soluble complexes[1] and, like aluminium, has an extensive and complicated hydrolysis chemistry.[2] Stability constants have been determined for various systems,[3] but there is often uncertainty about the total coordination number, the extent of inner- and outer-shell solvation, and the structure of the gallium(III) complexes formed by a given ligand. The behaviour of gallium(III) with simple and chelating ligands is a relatively undeveloped aspect of post-transition element chemistry, and many of the species which are thought to exist are inadequately characterized.

Complex formation plays an important part in the analytical chemistry of gallium, and has a specific function in the mechanism of solvent extraction of gallium(III).[4] The discovery that radioactive ^{67}Ga administered as the citrate becomes localized in soft tumour tissue[5] has prompted extensive clinical research, with corresponding efforts to elucidate the fundamental chemistry pertaining to the use of gallium complexes in disease diagnosis.[6–8] The *in vivo* behaviour of Ga^{3+} vis-à-vis Al^{3+} and Fe^{3+} requires thorough study of the species formed by this element, especially in aqueous solutions at near neutral pH.

This paper is directed towards the better understanding of the coordination chemistry of gallium to which structural studies, especially those of solutions by multinuclear NMR and Raman spectroscopy, can contribute.

EXPERIMENTAL

Materials

Stock 2.5 mol dm^{-3} solutions of gallium(III) in HCl or HBr were prepared by dissolving a known weight of powered gallium metal in concentrated hydrochloric or hydrobromic acid, and finally heating the solution to ensure the oxidation of any gallium(II) species.[9] Excess aqueous ammonia was added to a portion of gallium(III) in HCl solution and the precipitate of $Ga(OH)_3$ was washed to remove chloride. Portions of freshly prepared, wet $Ga(OH)_3$ were dissolved in the appropriate acids to obtain solution of gallium(III) nitrate, sulphate, phosphate or citrate. $Bu_4N[GaCl_4]$ and $Bu_4N[GaBr_4]$ were prepared as described previously.[10]

Solvent extracts were obtained by shaking 5 cm^3 of the gallium(III) aqueous halogen acid solution with an equal volume of diethyl ether. Laboratory grade diethyl ether was used without purification.

Spectroscopy

^{71}Ga NMR spectra were recorded at 122.03 MHz using a 10-mm broadband probe in a Bruker AM400 spectrometer at 295 K. 4K data points were collected over 100,000 Hz using a 60° pulse (10 μs) and a pulse recycle time of 20 ms. Spectra were processed with 10–20 Hz line broadening. Two-dimensional NOESY-type spectra were obtained using a standard pulse sequence with 90° mixing and detection pulses. 128 increments of 512 data points each, were collected and processed with shifted sine-bell window functions in both dimensions. Mixing times were varied, in separate experiments, from 1 to 50 ms. Cross peaks were detected only with a mixing time of 10 ms. ^{71}Ga spectra are referenced to $Ga(NO_3)_3$ in D_2O/HNO_3. ^{17}O NMR spectra were recorded at 54.24 MHz using a 10 mm broadband probe. 4K data points were collected over 85,000 Hz using a 50° pulse (11 μs) and a pulse recycle time of 0.11 s. Spectra were processed with 20–50 Hz line broadening. ^{17}O spectra were referenced to external H_2O at 295 K.

Raman spectra were excited by 488.0 nm radiation from a Coherent Radiation CR4 Ar^+ laser and recorded with a Jasco R300 Raman spectrometer.

RESULTS AND DISCUSSION

Aqueous gallium solutions with oxyanion ligands

Aqueous solutions contain the aquagallium cation $[Ga(H_2O)_6]^{3+}$. It is a labile species with a lifetime to the exchange of a water molecule of 5.6×10^{-4} s at 25°C.[11] A value of 6.1 ± 0.2 has been measured for the coordination number of gallium(III) ions by means of ^{17}O NMR studies.[11,12] ^{1}H NMR studies also support the existence of $[Ga(H_2O)_6]^{3+}$.[13] The hexaqua cation undergoes self-hydrolysis to $[Ga(OH)(H_2O)_5]^{2+}$ with the hydrolysis constant $pK_{1,1} = 2.6$.[2] Further reaction yields $[Ga(OH)_2(H_2O)_4]^+$ ($pK_{1,2} \sim 7.5$).[14] The hexaqua cation is the reference standard for ^{71}Ga NMR measurements ($\delta = 0$ ppm). Because of hydrolysis the line width of this resonance varies with pH. When hydrolysis is suppressed by the addition of acid, the $[Ga(H_2O)_6]^{3+}$ resonance has a minimum line width of 53 Hz but this increases greatly above pH 1.[15] Interaction of gallium(III) with perchlorate may contribute to the line broadening, but there is no other evidence of association between Ga^{3+} and ClO_4^-. Addition of base to gallium(III) solutions produces a signal with a line width of *ca* 300 Hz and a chemical shift of 233 ppm which is that of $[Ga(OH)_4]^-$.[16,17]

A 1.0 mol dm^{-3} solution of gallium(III) nitrate gives a single ^{71}Ga NMR line due to $[Ga(H_2O)_6]^{3+}$. Broadening of the line in nitric acid may be due to exchange processes with gallium-containing species of lower symmetry, such as $[Ga(NO_3)(H_2O)_5]^{2+}$. Gallium(III) solutions in sulphuric acid show a hexaquagallium signal which broadens from 150 to 400 Hz with an increase of H_2SO_4 concentration.[17] In this case a second signal occurs 13 ppm upfield of the $[Ga(H_2O)_6]^{3+}$ line and increases in intensity with sulphuric acid concentration to account for almost 50% of the gallium in a solution of $Ga_2(SO_4)_3$ in 8 mol dm^{-3} H_2SO_4, the spectrum of which is given in Fig. 1(a). Assuming bidentate attachment of the sulphate ion, a possible six-coordinate structure is $[Ga(SO_4)(H_2O)_4]^+$.

The ^{71}Ga NMR spectra of gallium(III) solutions in phosphoric acid have a markedly different appearance from the nitrate or sulphate solutions and consist of a very broad signal. In *ca* 0.5 mol dm^{-3} gallium(III) phosphate solution this band has a half-width exceeding 5000 Hz and extends from +75 to −100 ppm, Fig. 1(b). The $[Ga(H_2O)_6]^{3+}$

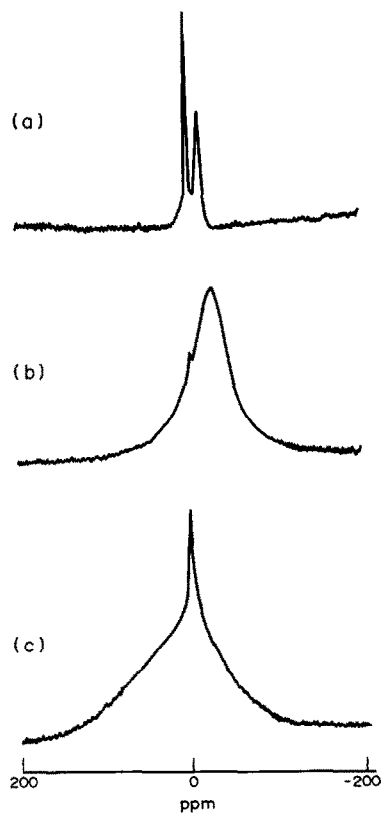

Fig. 1. ^{71}Ga NMR spectra: (a) aqueous gallium(III) sulphate in 8 mol dm^{-3} H_2SO_4; (b) aqueous gallium(III) phosphate solution; (c) aqueous gallium(III) citrate solution.

peak at 0 ppm is detected as a shoulder on the main band. The separate signal shows that exchange reactions between the hexaqua cation and gallium phosphate complexes are slow on the NMR timescale. The gallium phosphate band centre moves from -20 to -30 ppm on adding H_3PO_4 to the solution, which demonstrates that several Ga^{3+} phosphate species are involved but provides little information as to their structures. Glickson and co-workers,[7] using ^{31}P NMR, have detected as many as four gallium-containing species each giving a distinct peak, and consider that $[Ga(H_3PO_4)]^{3+}$ and $[Ga(H_2PO_4)]^{2+}$ are two of the principal complexes formed in this system. The likelihood of water molecules in the coordination sphere should be considered in assigning structures to these complexes. Gallium citrate has also been studied in the context of cellular binding of gallium(III), and the inhibition of this process by citrate and other buffers. There is support for 1 : 1 gallium–citrate complexes and also gallium citrate polymers.[6] The ^{71}Ga NMR evidence of complex formation was indirect and depended on loss of intensity of the hexaquagallium peak. The gallium citrate resonance was broadened beyond detection in spectra obtained at 27.45 MHz. Figure 1(c) shows the ^{71}Ga NMR spectrum of a gallium citrate solution recorded at 122.03 MHz in which the sharp peak due to $[Ga(H_2O)_6]^{3+}$ co-exists with a very broad peak extending from $+150$ to -100 ppm (centre *ca* $+25$ ppm), which presumably arises from gallium citrate complexes. Further work, including the investigation of solutions at low temperature to slow the rate of chemical exchange reactions, is needed to ascertain the number and identity of the species concerned, and ^{1}H, ^{13}C, and ^{17}O NMR spectra should be brought to bear on the problem.[18,19] The extension of NMR studies to biologically active systems of greater complexity has made good use of variable-pH ^{27}Al NMR and variable-temperature ^{1}H NMR, but attempts to employ ^{71}Ga NMR have been less successful.[8] Only resonances of gallium in a rather symmetrical local environment are sharp enough to be detected, as shown by the results for systems with simple ligands.

Aqueous gallium halide solutions

Gallium(III) exists in conc. HCl solution as the tetrahedral complex anion $[GaCl_4]^-$, and the corresponding complexes, $[GaBr_4]^-$ and $[GaI_4]^-$, are formed in HBr or HI solutions. All three of these complexes are well characterized by various methods, including Raman spectra.[1,20] The ^{71}Ga NMR signal of gallium in conc. HCl occurs at 245 ppm, close to the value for the $[GaCl_4]^-$ ion in CH_3CN (250 ppm).[21] Without a large excess of chloride, the ^{71}Ga NMR spectrum of aqueous gallium chloride shows a strong, sharp signal due to $[Ga(H_2O)_6]^{3+}$ and a second much broader signal between 150 and 250 ppm whose position depends on the Cl–Ga ratio in the solution.[16] Figure 2(a) is a typical high-field NMR spectrum of this system. The second signal probably arises from a rapid equilibrium between $[GaCl_4]^-$ and other chloro complexes, $[GaCl_n(H_2O)_{4-n}]^{3-n}$ ($n = 1$–3). The situation is similar to that of gallium(III) chloride in acetonitrile where the gallium ion exists as $[Ga(CH_3CN)_6]^{3+}$, which gives a NMR signal at -75 ppm, accompanied by $[GaCl_4]^-$ formed by autocomplexing.[21] Figure 2(b) illustrates the behaviour of gallium(III) in HBr solutions. Again there is evidence of a mixture of complexes, $[GaBr_n(H_2O)_{4-n}]^{3-n}$, which is converted into one complex, $[GaBr_4]^-$ ($\delta = 65$ ppm), when excess bromide is added.

Investigations by Lincoln *et al.*[22] of chloride exchange on gallium(III) in concentrated aqueous chloride solutions have shown that the dynamics of this process can be rationalized in terms of an associative exchange of chloride on $[GaCl_4]^-$. The energetics of formation of the transition state are more favourable for a tetrahedral than an octahedral species. This is borne out by the fact that the rate constant for chloride exchange of $[GaCl_4]^-$ is as high as 10^6 s^{-1},[22] whereas that of the aqua-

Chemical shifts: $[GaCl_4]^-$, 245; $[GaCl_3Br]^-$, 206; $[GaCl_2Br_2]^-$, 162; $[GaClBr_3]^-$, 112; $[GaBr_4]^-$, 57 ppm.

ligand in $[Ga(H_2O)_6]^{3+}$ is *ca* 10^4 s^{-1} at the same temperature.[11] Since the tetrahedral complex is highly labile it is not surprising to find, as first noted by Colton *et al.*,[23] that a mixture of $(GaCl_4]^-$ and $[GaBr_4]^-$ in aqueous solution gives only an exchange-averaged signal, indicating rapid halogen exchange on the NMR time scale. Figure 3 gives the ^{71}Ga NMR spectrum at 122.03 MHz of an equimolar $[GaCl_4]^-$ and $[GaBr_4]^-$ mixture showing the band which replaces the signals of $[GaCl_4]^-$ at 245 ppm and $[GaBr_4]^-$ at 65 ppm, when these species are observed separately. The presence of a small amount of $[Ga(H_2O)_6]^{3+}$ is indicated by the small peak close to 0 ppm. Under the conditions of a temperature of 295 K and an operating frequency of 122.03 MHz the exchange-averaged signal has a line width of 1200 Hz, which is some 1000 Hz greater than the line width of the $[GaCl_4]^-$ or $[GaBr_4]^-$ peaks in aqueous solution at the same temperature. The signals of the halide complexes are separated by 23,000 Hz in the present spectra. These data allow an estimate of the exchange rate, k, for ligand scrambling of 8×10^5 s^{-1}, using $k = \pi\Delta\nu^2/2\Delta W$, where $\Delta\nu$ is the signal separation and ΔW is the line broadening due to exchange.[24] This is in close agreement with the value of 10^6 s^{-1} for chloride exchange in $[GaCl_4]^-$ in aqueous acid solution obtained by ^{35}Cl NMR methods.[22] The average signal from the Ga/Cl/Br aqueous solution is ascribed to the mixture of species $[GaCl_nBr_{4-n}]^-$ (where n = 0–4), and as expected this peak changes its position if the composition of the mixture is varied.

Gallium halide complex anions in non-aqueous solutions and solvent extracts

Several groups have carried out ^{71}Ga NMR studies of the anionic gallium(III) chloride, bromide

and iodide mixed-halide complexes.[10,23,25] Distinct peaks are observed in acetonitrile or dichloromethane solutions, and chemical shifts have been obtained for the 15 possible four-coordinate halide species $[GaCl_xBr_yI_z]^-$ (where $x+y+z=4$). Obviously this implies that the ligand exchange reactions between the individual members of the series are slow on the NMR time scale, and in fact these reactions are slow enough that their progress can be followed by NMR after mixing a given pair of complexes, $[GaX_4]^-$ and $[GaY_4]^-$.[10] The previously reported spectra of the gallium(III) mixed-halide anions were obtained with NMR spectrometers operating at 27.45 MHz[10] or 30.36 MHz[23] for ^{71}Ga, and under these conditions some overlapping of the bands of chemically distinct complexes was evident. In the present work the ^{71}Ga NMR spectrum of the same mixture of anions, as Bu_4N^+ salts in dichloromethane or in acetonitrile, was recorded at 122.03 MHz. All 15 species were present, and the signals which were overlapping in the earlier spectra (those of the pairs $[GaCl_3I]^-$ and $[GaClBr_3]^-$, $[GaCl_2BrI]^-$ and $[GaBr_4]^-$, and $[GaCl_2I_2]^-$ and $[GaBr_3I]^-$) were now resolved to the level of the base line, Fig. 4. This work confirmed the previous assignments and chemical shift values.[10,23]

Gallium(III) is efficiently extracted from aqueous hydrogen halide solutions by ether and ketone solvents. Extraction takes place in the form of an ion-pair complex $H^+[GaX_4]^-$ (where X = Cl, Br, or I), as has been demonstrated by vibrational spectra.[4,26] ^{71}Ga NMR results provide further support for this mechanism. The diethyl ether extract of a gallium(III) solution in 8 mol dm^{-3} HCl gives a signal at 245 ppm due to $[GaCl_4]^-$ and that of a gallium(III) solution in 8 mol dm^{-3} HBr gives a signal at 58 ppm due to $[GaBr_4]^-$. Extraction of the combined aqueous solution, gallium(III) in 4 mol dm^{-3} HCl and 4 mol dm^{-3} HBr, yielded an ether phase whose ^{71}Ga NMR spectrum is given in Fig. 3(d). This shows the five separate peaks due to the species $[GaCl_nBr_{4-n}]^-$ (where $n = 0$–4) with relative intensities close to the statistical ratio of 1:4:6:4:1. The spectrum is in contrast to that of the aqueous phase prior to extraction, which consists of one rather broad band extending from 150 to 200 ppm [Fig. 3(c)]. Evidently the halide exchange, which is rapid in the aqueous solution, becomes very much slower when the species are transferred to the low dielectric constant medium of the diethyl ether phase.

An attempt was made to determine the rate of ligand exchange between the gallium mixed-halide complexes by using a two-dimensional NMR technique. This approach can be employed to investigate intermolecular scrambling reactions and has been successfully applied, using ^{119}Sn NMR spectra, to study the kinetics and mechanism of halide redistribution in a mixture of $SnCl_4$ and $SnBr_4$.[27] In this two-dimensional experiment, halide scrambling causes magnetization transfer between the various spin-labelled sites, which gives rise to cross peaks in the spectrum. A series of such experiments, using different magnetization mixing times, gives rise to cross peaks of varying intensity. This allows interpretation of the exchange kinetics. ^{119}Sn is a spin 1/2 nucleus with a T_1 relaxation time in the order of several seconds, and so presents a favourable case for this type of experiment. We are not aware of this technique having been applied to

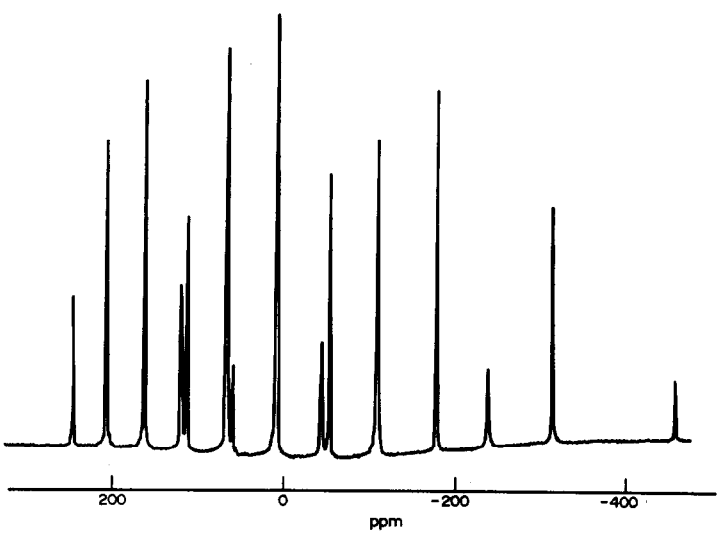

Fig. 4. ^{71}Ga NMR spectrum of a mixture of the complexes $[GaY_nY_{4-n}]^-$ and $[GaX_2YX]^-$ (where X, Y or Z = Cl, Br or I) in dichloromethane. For the chemical shift data see ref. 10.

nuclei other than spin 1/2 systems, but thought it worthwhile to test the possibility of using the ^{71}Ga nucleus which has a spin of 3/2 and a short relaxation time in the millisecond range. The details of the parameters which were tried are given in the Experimental. Problems were encountered principally because the nuclear relaxation time tends to be short in comparison with the time for chemical exchange between sites (the gallium atoms of pairs of the mixed-halide complex anions). This was certainly the case when the $[GaCl_nBr_{4-n}]^-$ mixtures were present in a diethyl ether extract, or in dichloromethane solution. Acetonitrile offered a more promising medium to which small amounts of water could be added to increase the polarity, and hence the rate of reaction, while retaining the separate NMR signals of the chemically distinct species. In this solvent we obtained a cross peak between $[GaCl_4]^-$ and $[GaCl_3Br]^-$ although various factors, including the composition of the particular sample which was relatively deficient in bromide, meant that a full set of off-diagonal peaks could not be detected. The observation of a cross peak is consistent with a halide exchange mechanism which involves association between the reacting species, perhaps via a four-centred transition state as suggested for the $SnCl_4/SnBr_4$ example.[27] In that example the rate of halide exchange from $SnCl_4$ to $SnCl_3Br$ was shown to be significantly greater than that of $SnBr_4$ to $SnClBr_3$. This may explain why the only cross peak seen in the present work was that between the pair $[GaCl_4]^-$ and $[GaClBr_3]^-$.

The two-dimensional ^{71}Ga NMR experiment was also attempted using as the sample a mixture of $[GaCl_4]^-$ and $[GaBr_4]^-$ (as Bu_4N^+ salts) in methanol containing a small amount of water. No cross peaks could be found, although all five halide complexes were present and a separate peak near 0 ppm revealed that part of the gallium now existed as $[Ga(H_2O)_6]^{3+}$. In this spectrum the chemical shifts of the species $[GaCl_nBr_{4-n}]^-$ had almost the same values as in other solvents. However, the line widths were increased by *ca* 1000 Hz, implying a life-time of the tetrahalogallate complex of less than 1 ms.

NMR spectra of ^{17}O at natural abundance can be detected easily using a high-field spectrometer and used to investigate cation solvation.[28] In the present work ^{17}O NMR spectra at 54.42 MHz were recorded from samples of the diethyl ether extracts containing $H^+(solv)[GaCl_4]^-$ or $H^+(solv)[GaBr_4]^-$ to gain information on the cationic complex. The spectrum contains a peak at 7 ppm from Et_2O[29] and a peak at 15 ppm (line width 200 Hz) due to water molecules associated with the hydrogen ion. Measurements of the amount of water which accompanies the ion-pair complex during this type of solvent extraction[20] suggest that the cation is $[H_9O_4]^+$, i.e. the H_3O^+ ion to which three additional water molecules are hydrogen bonded. The downfield shift of the ^{17}O resonance by 15 ppm from the value in liquid water at neutral pH reflects the influence of the H^+ cation on the associated water molecules within the highly acidic species $[H_9O_4]^+$.

Raman studies of gallium(III) *mixed-halide systems*

The Raman spectra of gallium(III) solutions in concentrated HCl, or concentrated HBr, are those of $[GaCl_4]^-$ and $[GaBr_4]^-$, respectively.[20] The spectrum of a mixture of these two solutions contains bands in the 400–200 cm^{-1} range assignable to the ν(Ga—Cl) and ν(Ga—Br) stretching modes of the mixed-halide complexes $[GaCl_nBr_{4-n}]^-$ (where $n = 0$–4). Because the time scale of vibrational spectroscopy is very much shorter than that of NMR there is no possibility of averaging between the signals of the individual members of the series of complexes. An additional band at 560 cm^{-1} is reasonably assigned to ν(Ga—O) stretching of the $[Ga(H_2O)_6]^{3+}$ ion.[30]

The Raman spectrum of the diethyl ether extract of the mixed-chloride/-bromide system, whose composition was known from the NMR investigation, was similar to that of the aqueous solution prior to extraction. Measurement of the spectrum of the ether extract furnished the frequencies of the gallium(III) mixed-halide complexes in Table 1. Only an incomplete set was known from earlier work.[31,32]

Gallium thiocyanate complex anions

Gallium(III) forms two types of thiocyanato complexes,[1] $[Ga(NCS)_4]^-$ and $[Ga(NCS)_6]^{3-}$. These contain nitrogen-bonded NCS^- and the choice in solid compounds seems to be dictated by the nature, and particularly the size, of the counter-ion. In the present study an attempt was made to observe the ^{71}Ga NMR spectrum of $(Et_4N)_3[Ga(NCS)_6]$ in acetonitrile as solvent. Only a very broad band was obtained which may indicate that partial dis-

sociation of $[Ga(NCS)_6]^{3-}$ occurs to give a mixture of four- and six-coordinate thiocyanato complexes.

Mixed-ligand halide/thiocyanate complexes were also investigated. ^{71}Ga NMR chemical shift data have been reported for the series $[GaX_n(NCS)_{4-n}]^-$ (where X = Cl or I; n = 1–3).[33] Dissolution of potassium thiocyanate in a solution of $Bu_4N[GaCl_4]$ in acetonitrile led to a mixture with the ^{71}Ga NMR spectrum shown in Fig. 5(a). Sharp peaks due to $[GaCl_4]^-$ at 247 ppm and $[GaCl_3(NCS)]^-$ at 220 ppm were accompanied by a broad peak at 185 ppm responsible for the remaining gallium. The position of the broad peak depends on the amount of thiocyanate present and this signal can be attributed to an exchange-averaged mixture of $[GaCl_2(NCS)_2]^-$ and $[GaCl(NCS)_3]^-$, the individual chemical shifts of which have been observed at 194 and 157 ppm, respectively.[34] Similar results were obtained by adding NCS^- to $[GaBr_4]^-$ in CH_3CN solution, Fig. 5(b). The $[GaBr_4]^-$ signal is at 61 ppm and a new sharp peak at 99 ppm is assigned to $[GaBr_3(NCS)]^-$. The remaining peak at *ca* 120 ppm is broad and appears to be the exchange-averaged signal of $[GaBr_2(NCS)_2]^-$, $[GaBr(NCS)_3]^-$ and perhaps $[Ga(NCS)_4]^-$. The present results enable thiocyanate to be placed between chloride and bromide in the order in which the ligands confer shielding of the gallium nucleus. The sequence of increased shielding, Cl < NCS < Br < I, is consistent with the "hard acid" character of the Ga^{3+} ion which bonds to the thiocyanate ligand through nitrogen rather than sulphur.

Abstract—The mechanism of ligand substitution reactions of tervalent ion complexes of these main group elements has been mostly discussed on the basis of activation parameters, including volume of activation, but the experimental work has been almost limited to the reactions of unidentate ligands. We have undertaken kinetic studies of the ligand isotopic exchange of tris(β-diketonato) complexes by the isotope labelling method and compared the mechanism and rate of substitution with those in the literature. Mutual relationships among the activation parameters are also discussed.

Substitution reactions of these main group metal complexes have drawn rather limited attention of coordination chemists. Since Taube first advocated the idea of substitution lability and inertness in 1952,[1] the complexes of tervalent metal ions of aluminium, gallium and indium had been explicitly understood to be substitution labile until *ca* 1960. One of the present authors studied the exchange of ^{69}Ga and ^{114m}In between the tervalent aqua ions and their complexes with EDTA in aqueous solution.[2,3] The rates were immeasurably low at pH 2–8 and 2–10 for the Ga and In systems, respectively. They exhibited different dependencies upon H^+ and OH^- concentration in the pH regions below 2 and above 8 or 10, respectively, but were always independent of the concentration of the aqua ions. Their complexes with the related multidentate ligand *N*-2-hydroxyethylethylene-diamine-*N*,*N*′,*N*′-triacetate gave essentially similar results.[2,4] We considered, rather simply, that the rate was governed by the ease with which the metal–ligand bond was broken. [$\Delta H^{\ddagger}$(kJ mol^{-1}), 92 and 104 at pH 1.5 and 63 and 75 at pH 8 and 10 for the Ga and In complexes, respectively].

Since then, a considerable amount of work was performed on the substitution reactions of the complexes of tervalent Al, Ga and In. The systems studied in aqueous solutions include the replacement of the aqua ligand, not only by a simple unidentate ligand such as sulphate (with Al[5,6]), but also by bi- and multidentate chelating agents such as salicylate (with Al[7] and Ga[8]), its derivatives (Al,[9] Ga[10]), citrate (Al[11]), aromatic dyes used as metal indicators in analytical chemistry (Al,[12–15] Ga[16] and In[17,18]) and tropolone[19] and its 3-isopropyl derivative.[20] There has been a good deal of discussion about the comparison of lability among the three metal ions and the mechanism of substitution. Most dispute has been based on the activation enthalpies and entropies, and on the dependence of the rate-constant upon the concentration of incoming ligands.

Through these studies, it was made clear that there is an overall trend towards greater rates in the order Al, Ga and In. It was also found that the hydrolysed species, $[M(OH)(H_2O)_5]^{2+}$, undergo anation reaction faster than the aqua ions, $[M(H_2O)_6]^{3+}$, by more than two orders of magnitude, and the reason is attributed to the mutual

ligand interaction due to the OH^- ligand (Al,[21] Ga[22]).

The substitution lability and the reaction mechanism of the metal complexes as an intrinsic property of the metal ion are best discussed on the basis of the results of ligand isotopic exchange reactions, because such reactions involve no net change of the existing species in the reaction system. Since Fiat and Connick gave the result of their pioneering experiment in the 1960's,[23] a significant amount of work has been performed on the kinetics of exchange between solvated molecules and bulk solvent, mostly by the NMR relaxation method. The results are summerized in Table 1.

The usefulness of activation volume in discussing the mechanism of substitution reactions was nicely demonstrated in recent review with a huge accumulation of experimental data.[29,30] It seems most promising to make use of the $\Delta V^{\ddagger}$ data for ligand isotopic exchange reactions for clarifying the mechanism of substitution. Merbach and his co-workers successfully applied such a consideration to the solvated tervalent ions of Al, Ga and In.[21,22,25-28] These studies, however, are limited to unidentate ligands. The only available $\Delta V^{\ddagger}$ data involving bidentate ligands are those for the anation of tropolone upon hexaaqua,[19] and of 3-isopropyltropolone upon hexakis (dmso) complexes of Al and Ga.[20] Since the rate-determining step of these anation reactions is claimed to be the formation of the first M—O (tropolone) bond, these systems may be included in the anation of unidentate ligands.

KINETIC STUDIES OF LIGAND ISOTOPIC EXCHANGE OF TRIS(ACETYLACETONATO) COMPLEXES

We have been undertaking kinetic studies of the isotopic exchange of a variety of tris(acetylacetonato) complexes of tervalent metal ions by the use of acetylacetone [^{14}C] in organic solvents, including neat acetylacetone (Hacac).[31] This method is useful only for slow reactions, and the available data are limited because of the experimental difficulty. Complexes with chelating ligands, however, often exhibit a different rate and mechanism of substitution from those of the complexes with unidentate ligands. Hence, such work must complement the other studies mentioned above, particularly when the data of activation volume are available. On the basis of such results we proposed a universal empirical parameter "metal ion lability constant" which indicates the lability of tervalent metal ions, including Al, Ga and In.[32]

Our data, which is related to Al, Ga and In, are listed in Table 2. Tris(bidentate) type complexes often undergo fluxional site exchange and the rate has been estimated by the observation of the NMR signals of ^1H or ^{19}F at various temperatures. These data are summarized in Table 3.

Mechanism of substitution

Related reactions. When Fiat and Connick gave the enthalpies and entropies of activation for the exchange of coordinated water molecules in aqueous solution,[23] a dissociative and an associative mechanism were envisaged for Al^{3+} and Ga^{3+} complexes, respectively. Recent data of the volume of activation suggest a dissociative nature for the substitution mechanism of both ions. New data for the entropy of activation were added to the exchange of water[21,22] and there now seems to be a rather unanimous understanding that the complexes of both tervalent ions undergo ligand exchange through a dissociative (D) or a dissociative interchange (I_d) mechanism. Discrimination between D and I_d is discussed on a stereochemical basis; the greater the ionic radius of the central metal ion and the less bulky the ligand, the greater the extent to which the incoming ligand participates in the formation of the transition state. It is claimed that such a trend is reflected in the decrease of entropy of activation.

The data in Table 3 are understood to indicate that the fluxional site exchange takes place through an intra-molecular mechanism. The activation parameters are thought to reflect the ease with which one M—O bond is broken to give a reaction intermediate, which undergoes fluxional rearrangement to result in isomerization or racemization. Although not explicitly discussed, a modestly positive entropy of activation is in accord with the discussion given above, that the dissociative break of the M—O bond should be the rate-determining step. (The big positive $\Delta S^{\ddagger}$ for the racemization of $[Al(acac)_3]$ in mixed pentane–ethanol or –diethyl ether are unusual.[39] A recent study on the resolution and racemization in methanol gave no $\Delta S^{\ddagger}$ value.[44])

Ligand exchange of acetylacetonate. The process of this ligand exchange was discussed elsewhere[32] and is given here only briefly (Fig. 1). The observed first-order rate constant k_0 is proportional to the concentration of water (<0.15 mol kg^{-1}) and is expressed by eq. (1):

$$\text{Rate} = k_0[Al(acac)_3] = [Al(acac)_3](k_1 + k_2[H_2O]). \quad (1)$$

For the exchange to take place, proton transfer between $acac^-$ and Hacac is essential and most

[a] k_2, second-order rate constant for the water assisted path. $k_0 = k_1 + k_2[H_2O]$.

[b] Observed first-order rate constant increases with the increase in Hacac concentration in THF.

[c] By NMR relaxation method; [In] = 0.001–0.1 M, [Hacac] = 0.1–2 M, [Sc] = 0.5 M. The rate was measured in acetonitrile containing Hacac and extrapolated to neat Hacac concentration (9.4 M).

[d] At 273°C.

[e] The activation parameters were measured for k_0. Since the contribution of k_1 is very small they are thought to be those for the k_2 value.

[a] CD = circular dichroism, ^{1}H, ^{19}F NMR relaxation with these nuclei.

[b] Values in parentheses, Arrhenius activation energy.

[c] Extrapolated values.

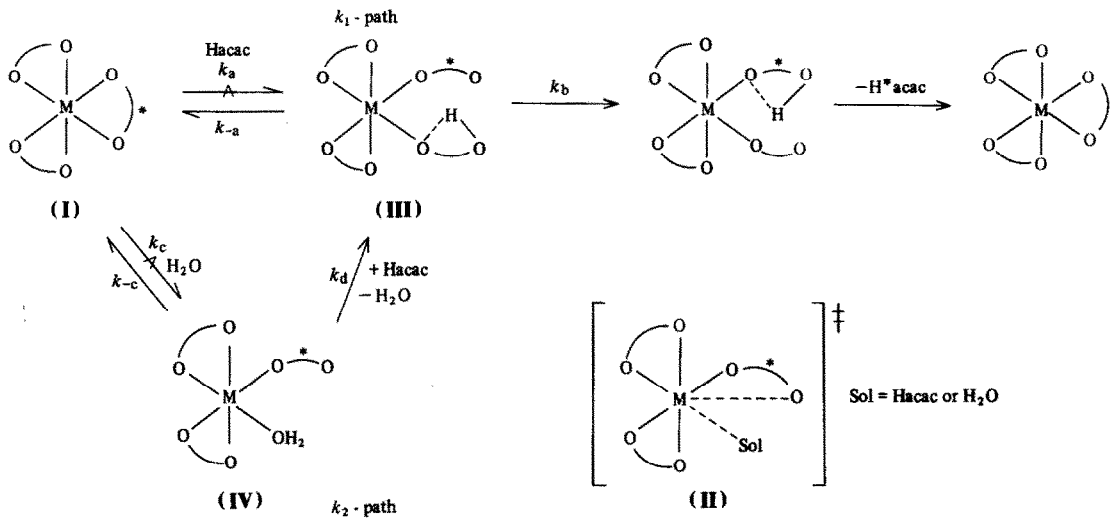

Fig. 1. Plausible mechanism of the ligand exchange of [Al(acac)$_3$] (**I**) in acetylacetone (Hacac). Asterisks denote the ^{14}C-labelling and arrows with circumflexes show the rate-determining step.

likely proceeds on the intermediate, **III**, which has two bidentate, one unidentate acac$^-$ and one unidentate Hacac as ligands. A very small deuterium isotope effect ($k_H:k_D$ ratio, 1.6 and 1.5 for the k_1 and k_2 paths, respectively) excludes the possibility of rate-determining proton transfer. Hence, the k_1 is related to the rate of individual reaction steps (Fig. 1) by eq. (2):

$$k_1 = k_a k_b/(k_{-a}+k_b), \qquad (2)$$

where $k_b/(k_{-a}+k_b)$ represents the branching ratio at the intermediate **III**. We have considered that the formation of **III** from the original complex **I** is the rate-determining step, and have illustrated the structure of a plausible transition state, **II**, in Fig. 1. The water-assisted path may be interpreted by considering a route through **IV** (Fig. 1), i.e. the breaking of the Al—O bond is facilitated by the water molecule to give **IV**, which quickly reacts with Hacac to give **III**.

A characteristic feature of our experimental results is that the entropy of the activation values is always negative throughout the systems for Al, Ga and In. We have discussed that the rate-determining step in the spontaneous path is the first breaking of the Al—O bond to give intermediate **III**.[31] Since the $\Delta V^\ddagger$ values for the spontaneous and water-assisted exchange of acetylacetonate in neat Hacac are moderately positive, we consider that the breaking of the Al—O bond takes place through a dissociative mechanism, most likely to be the I_d mechanism.[33] Although $\Delta V^\ddagger$ values are not available for the experiments in other solvents, absence of the dependence of the rate upon the Hacac concentration supports the dissociative nature of the ligand exchange.

The large differences between our $\Delta S^\ddagger$ values (Table 2) and those in the literature (Table 1) should be interpreted by considering the different nature of the ligands. One of the reasons for a negative $\Delta S^\ddagger$ should be due to the I_d (not D) nature of the mechanism. Since Hacac (and naturally acac$^-$, too) is a bulky ligand, an I_d-like mechanism is feasible, as discussed, for the substitution of unidentate ligands. There should be, however, an additional contribution based on the nature of our particular reaction.

An I_d mechanism suggests the approach of free Hacac to the central metal ion during the rate-determining step. Such access is not only motivated by the electrostatic interaction between Al^{3+} and incoming Hacac, but also by the stacking between incoming Hacac and coordinated acac$^-$. After the breaking of one Al—O bond, that particular acac$^-$ ligand does not become entirely free, but is linked to the Al^{3+} ion through the other Al–O bond. This is the reason why the backward reaction (rate constant, k_{-a}, cf. Fig. 1) takes place, and the branching ratio of eq. (2) contributes to the overall reaction rate. Both forward and backward reactions between **I** and **III** have a common transition state and a decrease in the branching ratio does not change the $\Delta H^\ddagger$ value but only decreases the $\Delta S^\ddagger$ value. (These interactions are not involved in the reactions in Tables 1 and 3.) Quantitative assessment of such contributions is difficult but the magnitude should be big enough to make the $\Delta S^\ddagger$ values negative.

Comparison of the rates

We have found a linear relationship on the log–log scale between the first-order rate constants of the ligand exchange of tris(acetylacetonato) complexes in Hacac and those of the water exchange of hexaaqua complexes of 12 kinds of tervalent main group and transition metal ion. (When such data were missing, first-order rate-constants of relevant reactions were used in their places.)[32] This fact implies that each ion has its own characteristic lability and each ligand exchange reaction has its own characteristic velocity. Thus first-order rate-constants of a given ligand exchange reaction can be expressed by eq. (3),

$$\log(k_1/s^{-1}) = \sigma + \kappa, \qquad (3)$$

where σ and κ are empirical parameters representing the individual lability of the metal ion and the individuality of the given ligand exchange, respectively. Ligand exchange reactions have their own enthalpies of activation and hence, different temperature coefficients of the rate from one another. Therefore, comparison of the rate constants at one temperature gives only approximate values of σ, which may be expressed by the integer or half integer.

By setting the κ value of water exchange of aqua complexes in water to zero, σ values of tervalent metal ions were estimated on the linear log–log diagram involving 12 tervalent metal ions by the method of least squares. Thus, tervalent ions of Al, Ga and In are given σ values 0.5, 2 and 5, respectively. (The same diagram gave κ values of -4.5 and -1 for the exchange of $acac^-$ in Hacac and of dmf in dimethylformamide, respectively.) These σ values may represent the relative lability of tervalent ions of these three main group elements.

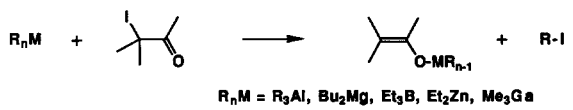
A NEW PREPARATIVE METHOD FOR VARIOUS METAL ENOLATES

KEIJI MARUOKA, NAOKI HIRAYAMA and HISASHI YAMAMOTO*

Department of Applied Chemistry, Nagoya University, Chikusa, Nagoya 464-01, Japan

Abstract—A variety of metal enolates including magnesium, boron, aluminium, zinc and gallium have been prepared from α-iodo carbonyl compounds and organometallic reagents under mild conditions. The metal enolates thus obtained have been utilized for the stereoselective aldol reaction with aldehydes with the object of elucidating the influence of metal and solvent effects on the erythro/threo selectivity.

Metal enolates are undoubtedly one of the most valuable intermediates in organic synthesis and a number of preparative methods have been developed for generating a variety of metal enolates.[1] Lithium enolates are most commonly employable and produced from carbonyl compounds with lithium dialkylamides or from enol silyl ethers with methyllithium in ethereal solvents.[2] Boron enolates, which are indispensable in aldol chemistry, are obtained from carbonyl compounds and dialkylboron triflates in the presence of tertiary amines.[3] Other metal enolates such as magnesium, zinc, titanium, zirconium, etc., were conveniently prepared from the corresponding lithium enolates by ligand exchange with metal halides.[4] In most methodologies, the metal enolates suffer from the co-existence of side-products such as amines, ammonium salts and inorganic metal salts that might influence the reactivity and selectivity in the subsequent reaction with electrophiles.[1] Here we wish to disclose a new method for preparing various metal enolates which involves the reaction of α-iodo carbonyl compounds with organometallic reagents as illustrated in Scheme 1.[5–7] In this methodology, the only side-product is alkyl iodide that, if necessary, can be readily removed from the reaction system by simple vacuum evaporation.[8]



Scheme 1.

When *trans*-4-*tert*-butyl-2-iodocyclohexanone[9] in CH_2Cl_2 was treated with Me_3Al (1.2 equiv.) in hexane, at −40°C for 1.5 h and at −20°C for 1.5 h, 4-*tert*-butylcyclohexanone was obtained in 69% yield after acidic work-up. Other organometallic reagents such as Bu_2Mg, Et_3B, R_3Al (R = Et, *i*-Bu), Et_2Zn and Me_3Ga are equally effective for dehalogenation of α-iodo ketones (Table 1). However, α-bromo ketones were totally recovered under similar conditions to those described above. As revealed in Table 1, the α-iodo ester is also susceptible towards dehalogenation. It should be noted that α-iodo carbonyl substrates such as α-iodoacetophenone are not employable due to the facile self-condensation resulting predominantly in formation of the aldol adduct, 1,3-diphenyl-3-hydroxy-4-iodo-1-propanone. This finding suggests the *in situ* generation of the metal enolate and alkyl halide as depicted in Scheme 1, and hence prompted us to investigate the stereoselective aldol reaction of these metal enolates with aldehydes with the object of elucidating the influence of metal and solvent effects on the erythro/threo selectivity. The selected data are listed in Table 2 where a direct comparison can be made for the influence of the metal on the degree of diastereoselection. For a given metal little enhancement in stereoselectivity was observed on changing the polarity of the solvent from toluene to THF (entries 2–4 and 7–9). In contrast, in a given solvent there appears to be a large metal effect (entries 3, 6, 10 and 11). It is apparent that the boron enolates are superior to the corresponding aluminium, zinc and gallium enolates in stereoselective bond construction. This tendency is even more clear with isobutyraldehyde as an electrophile except for the case of zinc enolates (entries 12–15).

In a similar fashion, the aldol condensation of ester enolate with aldehyde appears to be feasible.

[a] The metal enolates were prepared under the same conditions as described in Table 1 and treated with 2 equiv. of aldehyde.
[b] Isolated yield.
[c] The erythro/threo ratio was determined by ^1H NMR analysis.

EXPERIMENTAL

General

IR spectra were recorded on a Hitachi 260-10 spectrometer. ^{1}H NMR spectra were measured on a Varian GEMINI-200 (200 MHz) spectrometer. Reactions involving air- or moisture-sensitive compounds were conducted in appropriate round-bottomed flasks with magnetic stirring bars under an atmosphere of dry argon. In experiments requiring dry solvents, ether and THF were freshly distilled from sodium metal using benzophenone ketyl as indicator. Hexane and toluene were dried over sodium metal. Methylene chloride was stored over 4-Å molecular sieves. Organometallic reagents such as R_3Al (R = Me, Et and *i*-Bu), Et_3B, Bu_2Mg, Et_2Zn and Me_3Ga were obtained from Toyo Stauffer Chemical Company Ltd, Japan.

Preparation of α-iodo carbonyl compounds

trans-4-*tert*-Butyl-2-iodocyclohexanone,[8] 2-iodocyclododecanone, 2-iodo-2′,4′,6′-trimethylacetophenone and 2-iodocyclohexanone[7] were synthesized from the corresponding ketones by sequential treatment with lithium diisopropylamide, trimethylsilyl chloride and N-iodosuccinimide in THF. Benzyl iodoacetate was prepared by reaction of bromoacetyl bromide and benzyl alcohol with triethylamine in CH_2Cl_2 and subsequent halogen exchange with sodium iodide in acetone.

Dehalogenation of α-iodo carbonyl compounds

A representative reaction is as follows. A 2 M hexane solution of Me_3Al (0.6 mmol) was added, at −78°C, to a solution of *trans*-4-*tert*-butyl-2-iodocyclohexanone (0.5 mmol) in CH_2Cl_2 (2 cm^3) and the resulting mixture was stirred at −40°C for 1.5 h and at −20°C for 1.5 h. The mixture was poured into 1 N HCl and extracted with CH_2Cl_2. The combined CH_2Cl_2 extracts were concentrated and purified by column chromatography on silica gel (ether–hexane as eluant) to furnish 4-*tert*-butylcyclohexanone in 69% yield.

Other dehalogenation experiments were carried out in a similar manner to describe the above and the results are listed in Table 1.

Aldol reaction of 2-iodocyclohexanone with aldehydes

A typical procedure is provided by the synthesis of 2-(α-hydroxybenzyl)cyclohexanone with Me_3Al (entry 3). The dimethylaluminium enolate of cyclohexanone (0.5 mmol) in CH_2Cl_2 (2 cm^3) was prepared as described above. To this solution was added, at −78°C, benzaldehyde (1 mmol). The resulting solution was stirred at −78°C for 2 h and poured into 1 N HCl. The crude product was extracted with CH_2Cl_2, concentrated and purified by column chromatography on silica gel to furnish an erythro/threo mixture of 2-(α-hydroxybenzyl)cyclohexanone in 57% yield. The ^{1}H NMR spectrum of the aldol products showed the ratio of the erythro and threo isomers to be 3 : 2. This analysis was based on an absorption due to the benzylic proton peaks at δ4.73 and 5.30. Column chromatography on silica gel (ether–hexane = 1 : 4) separated two isomers. The first fraction was the erythro isomer: IR (CCl_4): 3570 cm^{-1} (OH), 1700 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$): δ7.20–7.40 (5H, m, aryl CH), 5.41 (1H, broad t, CH—O), 3.05 (1H, d, J = 3.2 Hz, OH), 2.27–2.67 (3H, m, CH_2C=O and CHC=O), 1.38–2.18 (6H, m, CH_2); mass m/z(%): 77 (100), 186 (2.5, $M^+ - 18$); m.p. 103–105°C (recrystallized from hexane–ethyl acetate; ref. 10 m.p. 103.5–104.5°C). From the second fraction the threo isomer was obtained: IR (CCl_4): 3570 cm^{-1} (OH), 1690 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$): δ7.25–7.43 (5H, m, aryl CH), 4.80 (1H, d, J = 9.0 Hz, CH—O), 3.99 (1H, s, OH), 2.28–2.70 (3H, m, CH_2C=O and CHC=O), 1.18–1.83 (6H, m, CH_2); mass m/z(%): 77 (100), 186 (3.5, $M^+ - 18$); m.p. 75.5–77.5°C (recrystallized from hexane; ref. 10 m.p. 75°C).

Similarly, the erythro/threo ratio of 2-(1-hydroxy-2-methylpropyl)cyclohexanone was determined by ^{1}H NMR analysis based on an absorption due to the hydroxy methyne proton peaks at δ3.74 and 3.56.

THE EFFECT OF ALUMINIUM ALKOXIDES ON SINGLE ELECTRON TRANSFER REACTIONS. A CONVENIENT SYNTHETIC ROUTE TO (N,N-DIALKYLCARBOMOYL)GERMANES

A. V. SELEZNEV, D. A. BRAVO-ZHIVOTOVSKII,* T. I. VAKUL'SKAYA and M. G. VORONKOV

Institute of Organic Chemistry, Siberian Branch of the U.S.S.R. Academy of Sciences, 664033 Irkutsk, U.S.S.R.

Abstract—Aluminium alkoxides are shown to prominently influence the selectivity of reactions involving a single electron transfer (SET) stage. Triethylgermyllithium (**I**) reacts with amides $R_2NC(O)X$ (*II*) (X = Cl, OMe, NMe_2, Ph) by a mechanism which includes a free-radical stage. The radical anion salt of N,N-diethylbenzamide, which is thermally stable in hydrocarbons, was detected. An efficient synthesis of the interesting reagents, (N,N-dialkylcarbamoyl)germanes, based on the reaction of **I** with **II** (*X* = Cl, OMe), in the presence of an equimolar amount of $(s\text{-BuO})_3Al$, has been developed.

Metal alkoxides often influence the reactions of various organomagnesium and organolithium compounds. Some recent papers in this field deserve mention. McGarrity *et al.* have shown that a mixed *n*-butyllithium–lithium *n*-butylate aggregate is more reactive than a tetrameric *n*-butyllithium in reactions with benzaldehyde.[1]

The effect of lithium and magnesium 2-ethoxyethoxides on the reactions with participation of organolithium compounds and Grignard reagents has been studied.[2,3] The addition of these agents to dimethylformamide followed by the Oppenauer oxidation of $RCH(OM)NMe_2$ leads to an acceptable yield of N,N-dialkylamides if the reaction is carried out in the presence of one of the above mentioned alkoxides. In the absence of alkoxides, no successful carboxamidation of the reagent takes place. In the authors' opinion, the roles of alkoxides are the catalysis of the Oppenauer oxidation and stabilization of the $RCH(OM)NMe_2$ intermediate. The stabilization is performed via involvement of the intermediate into the alkoxide cluster.

In the presence of magnesium 2-ethoxyethoxide, the *n*-butyllithium metallating ability sharply drops. The additives of this alkoxide are shown to facilitate the yield of organolithium compounds in the synthesis of the latter from alkyl halides and lithium metal in THF.[3]

Some aluminium alkoxide/organolithium reagent systems have been studied. Ashby and Noding have examined the selectivity of methylation of 4-tert-butylcyclohexanone with methyllithium in diethyl ether in the presence of various alkoxides including $(i\text{-PrO})_3Al$.[4] The latter does not affect the axial alcohol–equatorial alcohol ratio whereas a t-BuOLi additive increases this ratio.

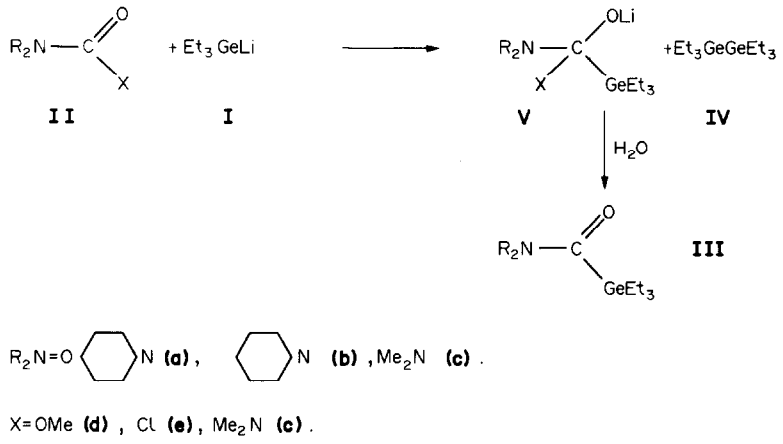
The addition of organolithium reagents to α,β-unsaturated ketones occurs preferably at the 1,4-position if bis(2,6-di-tert-butyl-4-alkylphenoxide) methylaluminium was previously added to the ketone.[5]

Analysis of the literature data allows us to conclude that lithium, magnesium and aluminium alkoxides do affect the reactivity of organolithium compounds. However, the character of this effect cannot be predicted, as a rule, due to the scarcity of any systematic research in this field.

RESULTS AND DISCUSSION

We have studied the effect of aluminium and lithium alkoxides on the reaction of **I** with **II** in hydrocarbons, eq. (1).

* Author to whom correspondence should be addressed.



(1)

The reaction displays insufficient selectivity with respect to carbamoylgermane (**III**). The interaction of compound **I** with substrate **IIc,e** in hexane at −50°C leads to 9% of (N,N-dimethylcarbamoyl)triethylgermane and 72% of hexaethyldigermane (**IV**) with a **III** : **IV** ratio of 0.13.[6]

It should be noted that the carbamoylgermanes, **III**, represent a scanty and poorly studied class of organogermanium compounds. This is, firstly, due to synthetic problems.[6] Our research has suggested a synthetic route to these organogermanium compounds.

Addition of equimolar quantities of aluminium or lithium alkoxides changes the reaction selectivity (Table 1). The reaction results depend upon both the metal in the alkoxide and the alkoxy group.

The **III** : **IV** ratio changes over time. Thus, in the reaction with **IIb,d** it is 3.8 after 15 min, whereas 20 h later, this value is 0.4, the total conversion increasing simultaneously. Evidently, the intermediate **V** is the product of a reversible addition reaction, formed under kinetically controlled conditions.

Compound **I** and t-BuOLi give a non-volatile complex, $Et_3GeLi \cdot 3t\text{-}BuOLi$, which is insoluble in hexane. Examination of the mass spectra of an analogous relatively volatile silicon complex, $Me_3Si\text{-}Li \cdot 3t\text{-}BuOLi$, shows the latter to be aggregated in an associate, $(Me_3SiLi)_2(t\text{-}BuOLi)_6$.[7] Compound **I** and $(s\text{-}BuO)_3Al$ form a non-volatile complex of approximate composition $Et_3GeLi \cdot 1.5(s\text{-}BuO)_3Al$, which is insoluble in hexane.

Table 1. The effect of alkoxide on the **III** : **IV** ratio in the reaction of **I** with 1-carbomethoxymorpholine at 20°C[a]

Alkoxide	**III** : **IV** ratio after 15 min	Conversion (%)
—	1.6	100
$(n\text{-}BuO)_3Al$	2.0	60
$(s\text{-}BuO)_3Al$	8.5	32
$(t\text{-}BuO)_3Al$	0.8	81
s-BuOLi	1.6	57
t-BuOLi	0.3	100

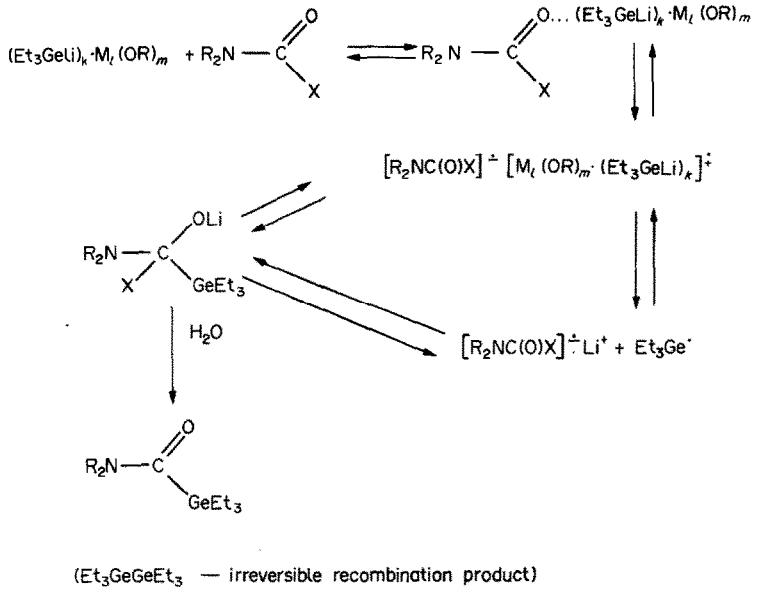
[a] Hexane–benzene solution (1 : 1, v/v).

The reaction seems to follow a radical pathway (Scheme 1). This suggestion is valid since metal alkoxides favour electron transition and can be involved in it.[8] They are also able to efficiently stabilize the radical-anion[9] due to insertion of the latter into the alkoxide aggregate. The *k*, *l* and *m* symbols in the Scheme indicate the associative nature of the reagents and intermediates under consideration.[10–13]

Previously, a possible retention of associate alkyllithium structures in the reaction with ethylbenzoates and an accelerating effect of EtOLi have been reported.[14]

The radical pathway of the reaction is proved by ESR-detected paramagnetism of the reaction mixtures. The ESR spectrum of a mixture of **I** and **IIa,d** at −70°C shows a broad signal without hyperfine components. At −30°C the signal disappears. The ESR spectrum of the **I** : **IIc,e** mixture displays a strongly broadened triplet (Fig. 1). The signals in the spectrum do not disappear for some time (0.25 h), even at room temperature. The signal broadening is caused by a high degree of association of **I** and the intermediate radical ion pairs[10,13] in inert solvents at negative temperatures.

Unexpectedly, we have observed fairly well resolved ESR spectra of N,N-diethylbenzamide radical anions in the reactions of elemento-organolithium compounds with N,N-diethylbenzamide (**VI**), at room temperature. These reactions proceed in hydrocarbons according to a scheme analogous to that described above, giving (benzoyl) triethylgermane after the hydrolysis of the corresponding $PhC(OLi)(GeEt_3)NEt_2$.[15] Triethylsilyl-



Scheme 1.

lithium and **VI** in a hexane–toluene mixture give an ESR spectrum (Fig. 2) showing HFS: $^2H_p \times {}^3H_o \times {}^3H_m \times {}^3N$ with constants 9.84, 5.19, 2.63 and 1.25 G $\{[PhC(O)NEt_2]^-Li^+\}$. The spectrum of a mixture of triethylgermylpotassium and **VI** in benzene contains a quintet of $^2H_p \times {}^3H_o$ with constants 7.56 and 4.86 G $\{[PhC(O)NEt_2]^-K^+\}$; HFS: $^2H_p \times {}^3H_o \times {}^3H_m \times {}^3N$ and constants 7.56, 4.86, 1.5 and 0.7 G. (The last two figures are obtained from a simulated spectrum.)

Reagent **I** completely reduces substrate **VI** in the HMPA–THF mixture. The latter spectrum shows a hyperfine structure $^2H_p \times {}^3H_o \times {}^3H_m \times {}^5H_{Et} \times {}^3N$ with constants 7.92, 4.86, 1.2, 0.6 and 0.6 G, respectively. This spectrum of the N,N-diethylbenzamide radical anion is in good agreement with that of the radical anion produced electrochemically.[16]

The N,N-diethylbenzamide radical anion is thermally stable in both hydrocarbon and solvating media. In hydrocarbons at room temperature the signal intensity of the spectra does not change much over 2–3 days. It should be noted that in the reaction of **I** with **VI**, since the reducing system of **I** is relatively weak in hydrocarbons,[17] the adduct : digermane ratio is 9.0, which means a minimal formation of reduced products in a free-radical reaction. A stronger reducing agent, triethylgermylpotassium, in benzene gives a 1.0 ratio and in HMPA only traces of adduct were detected. A similar result is observed if one increases the electron-withdrawing ability of the substrate instead of the reducibility of the organometallic reagent (Table 2).

Among the amides studied, **IIc,e** is the strongest

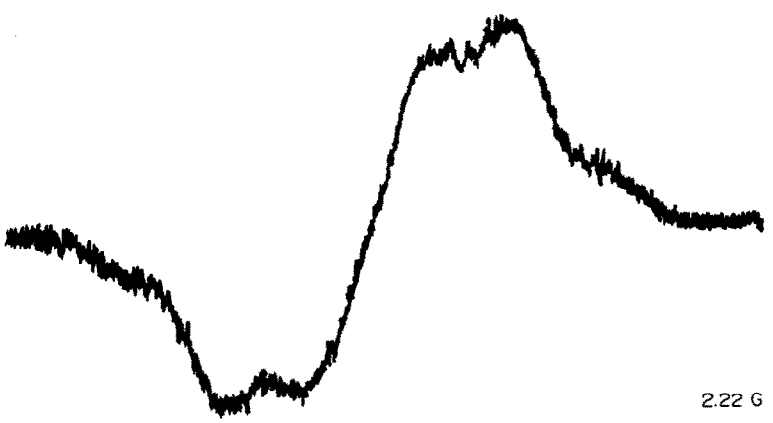


Fig. 1. ESR spectrum of a mixture of reagent **I** and **IIa,d**.

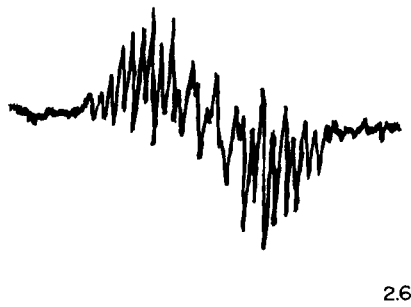

Fig. 2. ESR spectrum of the N,N-diethylbenzamide radical anion $[PhC(O)NEt_2]^{\cdot-}Li^+$ in a hexane–toluene solution.

electron acceptor, and the minimal **III**:**IV** ratio was fixed in the reaction with this substrate. A (s-BuO)$_3$Al additive only slowed down the reaction. (s-BuO)$_3$Al is highly efficient in reactions with the less electron-withdrawing but more basic amides **IIa,d**, **IIb,d** and **IIc,e**. This fact allows us to offer a preparative synthesis of **III**; a considerably simpler one than that employed previously.[18]

The dependence of the reaction results from the nature of the alkoxide and substrate and is caused by the formation of a triple complex, $R_2NC(O)X(Et_3GeLi)_kM_l(OR)_m$, whose stability governs further conversion. The stability of this complex increases with an increase in the substrate basicity. The different effects of aluminium and lithium alkoxides is related to the higher coordination possibility of the aluminium atom, which leads to strengthening of the triple complex. The rigid steric demands of the alkoxy groups can be explained by the fact that the latter are responsible for both the triple complex stability and the probability of intra-complex transformations (at a cluster cell level).

Table 2. Dependence of the **III**:**IV** product ratio upon the structure of substrate in the reaction of **I** with **II**

Substrate	(s-BuO)$_3$Al, equimolar amount	**III**:**IV** for 15 min	Conversion (%)
IIa,d	—	1.6	100
	1	8.5	32
IIb,d	—	0.8	94
	0.5	0.4	70
	1	3.8	41
IIc,e	—	1.1	100
	0.25	6.0	40
	1	—	0
IIc,c	—	0.1	100
	1	0.1	15

The approach of the donor molecule to the $(Et_3GeLi)_kM_l(OR)_m$ associate is most hindered with tert-butoxy groups.

EXPERIMENTAL

All tests were performed in evacuated systems. Quantitative determination of aluminium was carried out by gravimetry with 8-oxyquinoline.[19] IR spectra were recorded on a Specord 75 IR spectrometer as thin films. ^1H and ^{13}C NMR spectra were run on a JEOL FX-90Q spectrometer, chemical shifts are given against TMS. ESR spectra were recorded on RE-1307 and Radiopan instruments. ESR spectra simulation was performed by a modified program.[20] Mass spectra were recorded on a Varian MAT-212 instrument (70 eV). GLC analysis was performed on a Chrom-5 chromatograph.

Reaction of **I** *with* **II** *in the presence of the corresponding alkoxide (general procedure)*

To a degassed solution of alkoxide in hexane a solution of **I** in benzene was added. As a result, an amorphous transparent precipitate was formed. If 0.25 mol of alkoxide was added, the precipitate dissolved immediately. When (*n*-BuO)$_3$Al was used, no precipitate was observed at all.

To the resultant reagent the corresponding amide, **II**, was added and the whole mixture was shaken. An exothermic reaction took place. After 15 min an aliquot of the reaction mixture was taken and hydrolysed, and the **III**:**IV** ratio was determined by GLC data. Complete analysis of the mixture was performed by GLC–MS.

Synthesis of **IIIa**

To a degassed solution of (s-BuO)$_3$Al (2.43 g, 9.86 mmol) in 18 cm^3 of hexane a solution of **I** (1.65 g, 9.9 mmol) in 15 cm^3 of benzene was added, which simultaneously gave an amorphous transparent precipitate. To the resultant reagent, compound **IIa,d** was added and the mixture was stirred, first at room temperature (1 h) and then at 70–80°C (3 h). The reaction mixture was left overnight and then it was treated with 2 cm^3 of water. The aluminium hydroxide precipitate was separated by centrifugation, then it was extracted twice with benzene. The supernatant layer and extracts were dried over anhydrous sodium sulphate. A yellow liquid which was stable in air was isolated, 1.45 g (54%), by fractionation at a reduced pressure. The yellow colour was caused by a slight impurity of bis(triethylgermyl)ketone, since the product is normally colourless. B.p. 115–118°C/1–2 mm Hg. Found:

IR (ν, cm^{-1}): 1575 (C=O).

Synthesis of **IIIb**

To the reagent obtained from **I** (1.4 g, 8.4 mmol) and $(s\text{-}BuO)_3Al$ (2.0 g, 8.1 mmol) in a mixture of hexane–benzene (1 : 1, v/v), amide **IIb,d** (1.2 g, 8.4 mmol) was added. The reaction mixture was stirred at room temperature for 40 min and then treated with water. Further operations were performed as described above. As a result, 0.75 g (33%) of yellow liquid was obtained. B.p. 105–108°C/1 mm Hg. Found: C, 53.48; H, 9.16; Ge, 26.79; N, 4.58. Calc. for $C_{12}H_{25}GeNO$: C, 53.00; H, 9.27; Ge, 26.70; N, 5.15%. STERICALLY CROWDED ARYLOXIDE COMPOUNDS OF ALUMINIUM—REACTIVITY OF COORDINATED BENZALDEHYDE

MICHAEL B. POWER and ANDREW R. BARRON*

Department of Chemistry, Harvard University, 12 Oxford Street, Cambridge, MA 02138, U.S.A.

Abstract—The interaction of aluminium complexes containing the sterically hindered phenoxide ligand 2,6-di-*tert*-butyl-4-methylphenoxide (BHT) with benzaldehyde has been investigated. Interaction of benzaldehyde with $AlR(BHT)_2$ leads to the Lewis acid–base adduct $AlMe(BHT)_2[O{=}C(H)Ph]$, R = Me. When R = Et, reduction of coordinated benzaldehyde is observed. The addition of benzaldehyde to $AlMe_2(BHT)$ leads to the formation of the acetophenone complex, $AlMe_2(BHT)[O{=}C(Me)Ph]$. A mechanism for this unique aldehyde to ketone transformation is proposed. The dimeric compound $[AlEt(BHT)(OCH_2Ph)]_2$ is formed from the interaction of $AlEt_2(BHT)$ and benzaldehyde.

Organoaluminium compounds are of synthetic importance in organic chemistry,[1] in particular the reactions of alkyl aluminium compounds with organic carbonyls. These reactions are often complicated because of the presence of multiple reaction pathways and the dimeric nature of many organoaluminium compounds. Recent work reported in the literature[2–4] has focused on the use of monomeric aluminium complexes, derived from the sterically hindered 2,6-di-*tert*-butyl-4-methylphenol (BHT-H, from the trivial name butylated hydroxytoluene), as bulky Lewis acids for the modification of the reactivity of coordinated ketones.

We report here the reaction of benzaldehyde with the organoaluminium aryloxide compounds $AlR_x(BHT)_{3-x}$ (R = Me, Et; x = 1, 2) (Scheme 1).

RESULTS AND DISCUSSION

The interaction of $AlMe(BHT)_2$[5] with benzaldehyde in pentane allows the isolation of the Lewis acid–base complex $AlMe(BHT)_2[O{=}C(H)Ph]$ (**1**), as a bright orange crystalline solid. As has been observed[5] for other complexes of $AlMe(BHT)_2$, compound **1** can be handled in air for several minutes without appreciable decomposition.

The ^1H NMR signal for the aluminium methyl ligand of **1** (δ +0.73 ppm) is downfield of that found for $AlMe(BHT)_2$ (δ −0.43 ppm).[5] This downfield shift is consistent with an increase in p character in the Al—C bond in going from a planar sp^2 to a tetrahedral sp^3 aluminium centre.[6]

The complex shows a decreased carbonyl stretch, ν(CO), in the IR spectrum and a downfield shift in the ^{13}C NMR spectrum for the carbonyl α-carbon, in comparison to the "free" ligand, consistent with coordination of the organic carbonyl to aluminium. An upfield shift for the α-proton of benzaldehyde on coordination to $AlMe(BHT)_2$ is perhaps an indication of the increased hydridic nature of the proton.

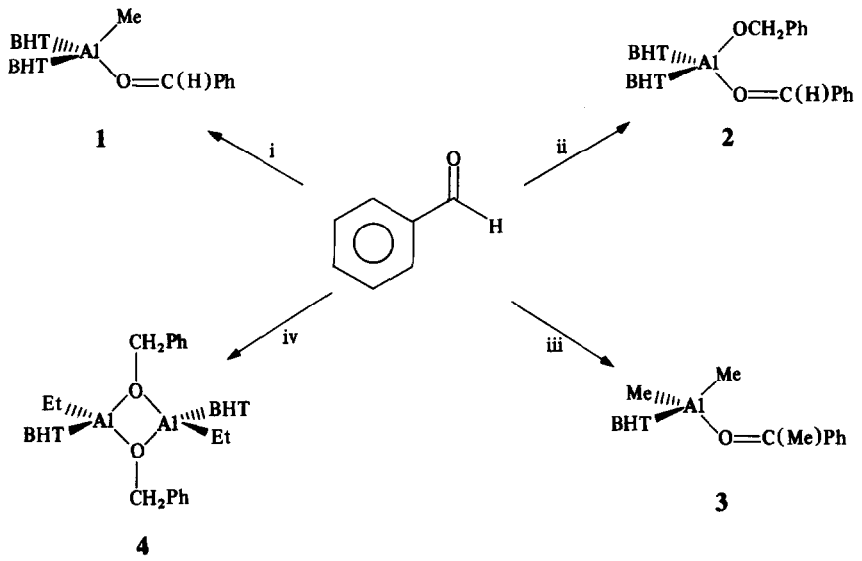
Adduct formation is not observed between benzaldehyde and $AlEt(BHT)_2$; instead, reduction of the aldehyde occurs to give a coordinated alkoxide. Interaction of $AlEt(BHT)_2$[7] with one equivalent of benzaldehyde results in an equimolar mixture of $AlEt(BHT)_2$ and $Al(BHT)_2(OCH_2Ph)[O{=}C(H)Ph]$ (**2**). If, however, the reaction is carried out with two equivalents of benzaldehyde, **2** is the only product observed. All NMR and IR spectroscopy (see Experimental) are consistent with the proposed structure of **2**.

Compound **2** is presumably formed as a result of the reduction of one coordinated benzaldehyde with the concomitant elimination of ethylene [eq. (1)], followed by the subsequent coordination of a second benzaldehyde molecule [eq. (2)]:

$$AlEt(BHT)_2 + O{=}C(H)Ph \longrightarrow \text{“}Al(BHT)_2(OCH_2Ph)\text{”} + C_2H_4. \quad (1)$$

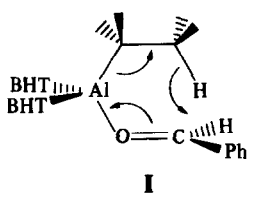
$$\text{“}Al(BHT)_2(OCH_2Ph)\text{”} + O{=}C(H)Ph \longrightarrow Al(BHT)_2(OCH_2Ph)[O{=}C(H)Ph]. \quad (2)$$

* Author to whom correspondence should be addressed.

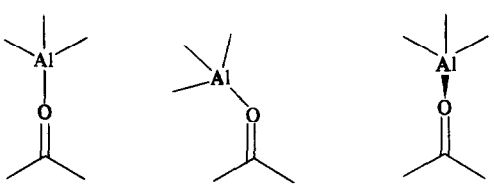


Scheme 1. (i) $AlMe(BHT)_2$; (ii) $AlEt(BHT)_2$; (iii) $AlMe_2(BHT)$; (iv) $AlEt_2(BHT)$.

Because the steric bulk of the two BHT ligands in $AlEt(BHT)_2$ would preclude the formation of any dimeric species, the reduction must occur in an intra-molecular fashion,[1] presumably involving a cyclic six-membered transition state (**I**).



I



II **III** **IV**

An organocarbonyl group can coordinate to a Lewis acid such as aluminium, by one of three modes of bonding, sp (**II**), sp^2 (**III**) and via the C=O π-bond (**IV**).

Theoretical calculations for the model system $H_3Al(O{=}CH_2)$ have predicted that sp^2 coordination (**II**) is energetically favoured,[7] yet Ittel and co-workers have reported the X-ray structure of the methyltolueneoate complex of $AlEt_2(BHT)$ in which the carbonyl is coordinated perpendicular to the π-nodal plane of the ester (**IV**).[8] It is not inconceivable, therefore, that such a coordination mode would be accessible for the transition state **I**.

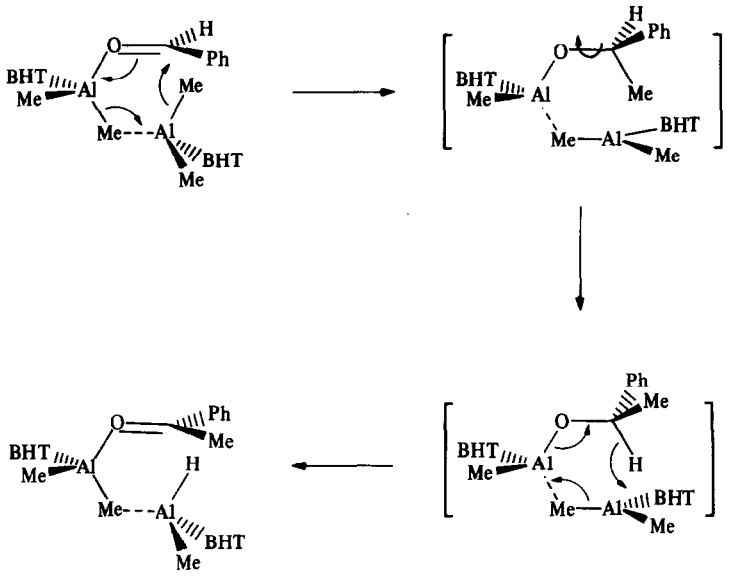
The room temperature ^1H NMR spectrum of an equimolar solution of $AlMe_3$ and BHT-H contains a single peak due to Al—Me protons;[5,8] integration consistent with the stoichiometry $AlMe_2(BHT)$. If, however, the sample is cooled to $-80°C$, four peaks are observed that have been assigned as $AlMe(BHT)_2$, $AlMe_2(BHT)$, $Al_2Me_5(BHT)$ and Al_2Me_6.[5,8] It is proposed, therefore, that two concurrent disproportionations occur in solution [eqs (3) and (4)]:

$$Al_2Me_5(BHT) \rightleftharpoons 0.5Al_2Me_6 + AlMe_2BHT \quad (3)$$

$$3AlMe_2(BHT) \rightleftharpoons Al_2Me_5(BHT) + AlMe(BHT)_2. \quad (4)$$

Despite the presence of these equilibria we have shown that the reaction of an equimolar solution of $AlMe_3$ and BHT-H at room temperature with Lewis bases (L) results in the formation of the Lewis acid–base adduct $AlMe_2(BHT)(L)$.[5,9] We have, therefore, investigated the reaction of this equilibrium mixture with benzaldehyde.

Addition of one equivalent of benzaldehyde to an equimolar mixture of $AlMe_3$ and BHT-H at room temperature, in the presence of diethyl ether, results in the isolation of $AlMe_2(BHT)[O{=}C(Me)Ph]$ (**3**), in *ca* 60% yield (Scheme 1). Compound **3** can be made directly by the interaction of acetophenone in place of benzaldehyde (see Experimental).



Scheme 2.

The conversion of an aldehyde to the corresponding methylketone in a single step, represents, we believe, a unique reaction in organic chemistry and we are presently investigating the generality of this C—C bond formation.

In order to obtain stoichiometric conversion of the benzaldehyde to acetophenone, 1.5 equivalents of "$AlMe_2(BHT)$" are required; suggesting that the aldehyde coordinates to one molecule of $AlMe_2$(BHT) while a second equivalent acts as the methyl source. A speculative mechanism for this transformation based on previously reported alkylations of ketones via dimeric intermediates is proposed in Scheme 2. The presence of a transient species, formed immediately on mixing $AlMe_2(BHT)$ and benzaldehyde, with a peak at δ 5.11 ppm in the ^1H NMR, is consistent with the presence of a OCH(Me)Ph ligand.[9]

The interaction of benzaldehyde with $AlEt_2$(BHT)[7] does not result in a clean reaction. We can conclude from the NMR data, however, that the major product arises from the reduction of the coordinated benzaldehyde, to give AlEt(BHT)(OCH_2Ph) (**4**) (see Experimental). There is no evidence for the further coordination of benzaldehyde to **4**. We propose therefore that **4** is dimeric involving bridging alkoxides (Scheme 1).[10]

EXPERIMENTAL

Microanalyses were performed by Oneida Research Services Inc., Whitesboro, New York. Melting points were determined in sealed capillaries and are uncorrected. IR spectra (4000–600 cm^{-1}) were recorded on a Perkin–Elmer 137 grating spectrometer as Nujol mulls. NMR spectra, in C_6D_6, were recorded on Bruker AM-250 (^1H) and AM-300 (^{13}C) spectrometers (δ in ppm relative to $SiMe_4$). All manipulations were carried out under nitrogen. Solvents were dried, distilled and degassed before use.

Trimethylaluminium and triethylaluminium were used as 2.0 M and 1.0 M solutions in hexane, respectively. $AlMe(BHT)_2$ and $AlEt(BHT)_2$ were prepared by literature procedures.[5,7]

$AlMe(BHT)_2[O{=}C(H)Ph]$ (1)

To a pentane (40 cm^3) solution of $AlMe(BHT)_2$ (2.00 g, 4.16 mmol) was added a pentane (30 cm^3) solution of benzaldehyde (0.46 cm^3, 4.16 mmol). A deep red solution resulted, from which an orange solid precipitated after 1 h of stirring. Filtration, followed by recrystallization from hexane (−20°C) resulted in crystals. Yield *ca* 80%; m.p. 107–108°C. Found: C, 77.3; H, 9.5. Calc. for $C_{38}H_{55}O_3Al$: C, 77.8; H, 9.4%.

IR (Nujol, NaCl, cm^{-1}): 1630 (s), 1600 (s), 1575 (s), 1530 (w), 1320 (m), 1250 (s), 1200 (s), 1170 (m), 1120 (m), 1020 (m), 950 (w), 900 (sh), 890 (s), 860 (s), 840 (s), 800 (w), 770 (m), 750 (m), 660 (s).

NMR (δ, C_6D_6). ^1H: 8.86 (1H, s, O=C*H*), 7.31 [2H, d, J(H—H) = 7.5 Hz, *o*-C_6H_2], 7.20 (4H, s, BHT, C_6H_2), 6.90 [1H, t, J(H—H) = 7.5 Hz, *p*-C_6H], 6.69 [2H, t, J(H—H) = 7.5 Hz, *m*-C_6H_2], 2.29 (6H, s, CH_3), 1.66 (36H, s, CCH_3), 0.73 (3H, s, Al—CH_3). ^{13}C: 201.67 (*C*=O), 154.87 (O—*C*, BHT), 140.02 (*C*—C=O), 139.08 (*o*-*C*, BHT),

134.17 (*o-C*, PhCHO), 132.70 (*m-C*, PhCHO), 129.61 (*p-C*, PhCHO), 126.40 (*m-C*, BHT), 125.89 (*p-C*, BHT), 35.45 (CH_3, BHT), 31.89 [$C(CH_3)_3$, BHT], 21.40 [$C(CH_3)_3$, BHT], −6.08 (Al—CH_3).

$Al(BHT)_2(OCH_2Ph)[O{=}C(H)Ph]$ (2)

To $AlEt(BHT)_2$ (2.0 g, 4.04 mmol) in pentane (30 cm^3) at room temperature was added benzaldehyde (0.94 cm^3, 8.08 mmol) in pentane (30 cm^3). The resulting deep red solution was allowed to stir for 24 h. The solution was then reduced in volume *in vacuo* and then cooled to −20°C. This yielded a deep red microcrystalline solid. Yield: *ca* 70%; m.p. 110–112°C. Found: C, 76.9; H, 8.6. Calc. for $C_{43}H_{39}O_4Al$: C, 77.4; H, 8.9%.

IR (Nujol, NaCl, cm^{-1}): 1620 (s), 1595 (s), 1570 (m), 1355 (w), 1310 (m), 1290 (sh), 1260 (s), 1225 (s), 1210 (sh), 1165 (m), 1120 (m), 1075 (w), 1020 (w), 950 (w), 905 (s), 885 (m), 855 (m), 840 (m), 800 (w), 765 (m), 755 (m), 710 (m), 690 (m), 670 (s), 640 (m).

NMR (δ, C_6D_6). ^1H: 9.07 (1H, s, C*H*O), 7.40 [2H, d, J(H—H) = 7.5 Hz, *o*-C_6H_2], 7.30 [2H, d, J(H—H) = 7.5 Hz, *o*-C_6H_2], 7.20 (4H, s, C_6H_2, BHT), 7.09 (1H, t, J = 7.5 Hz, *p*-C_6H), 6.90 (1H, t, J = 7.5 Hz, *p*-C_6H), 6.68 (2H, t, J = 7.5 Hz, *m*-C_6H_2), 5.09 (2H, s, OCH_2Ph), 2.27 (6H, s, CH_3), 1.69 (36H, s, CCH_3). ^{13}C: 203.95 (*C*=O), 154.45 (O—*C*, BHT), 144.8 (*C*—CH_2O), 139.87 (*C*—C=O), 139.12 (*o-C*, BHT), 134.25 (*o-C*, PhCHO), 132.53 (*m-C*, PhCHO), 129.47 (*p-C*, PhCHO), 128.41 (*o-C*, $PhCH_2O$), 127.55 (*m-C*, $PhCH_2O$), 126.75 (*p*-C, $PhCH_2O$), 126.41 (*m-C*, BHT), 126.24 (*p-C*, BHT), 65.95 (CH_2), 35.50 (CH_3, BHT), 31.70 [$C(CH_3)_3$, BHT], 21.37 [$C(CH_3)_3$, BHT].

$AlMe_2(BHT)[O{=}C(Me)Ph]$ (3)

Method 1. To a solution of BHT-H (2.2 g, 10.0 mmol) in pentane (25 cm^3) was added $AlMe_3$ (5 cm^3, 10.0 mmol) in hexane. After the solution was stirred for 0.5 h, acetophenone (1.23 cm^3, 10.0 mmol) was added. A yellow precipitate gradually formed as the addition proceeded. The reaction mixture was then stirred for 1 h. Filtration, followed by washing with pentane (2 × 20 cm^3), and drying *in vacuo* gave an orange solid. Yield: *ca* 90%.

Method 2. To a solution of $AlMe_2(BHT)$ (5.70 mmol), prepared as described above, in the presence of Et_2O was added benzaldehyde (0.63 cm^3, 5.70 mmol) at room temperature. A deep orange–red coloured solution formed immediately. Removal of the solvent *in vacuo* yielded an oily residue, which when washed with pentane (15 cm^3), formed a yellow solid. Yield: *ca* 60%; m.p. 106–107°C. Found: C, 74.8; H, 9.1. Calc. for $C_{25}H_{37}O_2Al$: C, 75.7; H, 9.4%.

IR (Nujol, NaCl, cm^{-1}); 1625 (s), 1600 (m), 1575 (m), 1310 (sh), 1275 (s), 1220 (w), 1200 (sh), 1185 (m), 1100 (w), 1020 (w), 965 (w), 865 (s), 780 (w), 755 (w), 710 (m), 670 (s), 600 (m).

NMR (δ, C_6D_6). ^1H: 7.50 [2H, d, J(H—H) = 7.5 Hz, *o*-C_6H_2], 7.29 (2H, s, C_6H_2, BHT), 6.98 [1H, t, J(H—H) = 7.5 Hz, *p*-C_6H], 6.76 [2H, t, J(H—H) = 7.5 Hz, *m*-C_6H_2], 2.38 (3H, s, CH_3), 2.12 (3H, s, $OCCH_3$), 1.65 (18H, s, CCH_3), −0.05 (6H, s, Al—CH_3). ^{13}C: 210.71 (*C*=O), 155.75 (O—*C*, BHT), 138.77 (*o-C*, BHT), 137.42 (*C*—C=O), 134.39 (*o-C*, Ph), 131.12 (*m-C*, Ph), 129.01 (*p-C*, Ph), 126.09 (*m-C*, BHT), 125.15 (*p-C*, BHT), 35.11 (CH_3, BHT), 31.30 [$C(CH_3)_3$, BHT], 26.0 (CH_3, PhMeCO), 21.53 [$C(CH_3)_3$, BHT], −5.52 (Al—CH_3).

$AlEt(BHT)(OCH_2Ph)$ (4)

To an equimolar mixture of $AlEt_3$ (5.28 cm^3, 5.28 mmol) and BHT-H (1.16 g, 5.28 mmol) in pentane (30 cm^3) was added a pentane (20 cm^3) solution of benzaldehyde (0.58 cm^3, 5.28 mmol). The resulting deep orange solution was stirred overnight during which time it lightened in colour to pale orange. The resulting solution was evaporated to dryness *in vacuo* to leave an orange oil.

NMR (δ, C_6D_6) Crude mixture, ^1H: 7.30 [2H, d, J(H—H) = 7.5 Hz, *o*-C_6H_2], 7.21 (2H, s, C_6H_2, BHT), 7.03 [1H, t, J(H—H) = 7.5 Hz, *p*-C_6H_2], 6.98 [2H, t, J(H—H) = 7.5 Hz, *m*-C_6H_2] 5.17 (2H, s, OCH_2Ph), 2.33 (3H, s, CH_3), 1.47 (18H, s, CCH_3), 1.02 (3H, t, J(H—H) = 7.5 Hz, Al—CH_2CH_3), 0.08 [2H, q, J(H—H) = 7.5 Hz, Al—CH_2CH_3]. ^{13}C: 154.03 (O—*C*, BHT), 138.42 (*o-C*, BHT), 136.5 (*C*—CH_2O, OCH_2Ph), 129.94 (*o-C*, Ph), 129.29 (*m-C*, Ph), 128.68 (*p-C*, Ph), 126.22 (*m-C*, BHT), 125.77 (*p-C*, BHT), 68.48 (OCH_2Ph), 35.28 (CH_3, BHT), 31.81 [$C(CH_3)_3$, BHT], 21.52 [$C(CH_3)_3$, BHT], 9.54 (CH_3, Al—Et), 1.76 (CH_2, Al—Et).

BUTYL METAL ARYLOXIDES, ARYLAMIDES, AND SULPHUR AND PHOSPHORUS ANALOGUES—II.* SYNTHESIS AND CHARACTERIZATION OF NOVEL BULKY ALKOXIDES AND ARYLOXIDES OF ALUMINIUM; X-RAY STRUCTURE OF $[Al(\mu\text{-}OCH_2Ar)Me_2]_2$ (Ar = $C_6H_2Bu^t_3$-2,4,6)

BEKIR ÇETINKAYA, PETER B. HITCHCOCK, HATAM A. JASIM, MICHAEL F. LAPPERT† and HUGH D. WILLIAMS

School of Chemistry and Molecular Sciences, University of Sussex, Brighton BN1 9QJ, U.K.

Abstract—The alkoxide, (2,4,6-tri-t-butylbenzoxo)dimethylaluminium, $[Al(\mu\text{-}OCH_2Ar)Me_2]_2$ (Ar = $C_6H_2Bu^t_3$-2,4,6), (**1**), has been prepared from the corresponding benzyl alcohol $ArCH_2OH$ and trimethylaluminium in C_6H_{14} at *ca* 25°C. Even using an excess of the alcohol, only one of the methyl groups of $AlMe_3$ was replaceable under these conditions. By contrast, using the bulky phenol Ar′OH (Ar′ = $C_6H_3Bu^t_2$-2,6) and an excess of $AlMe_3$ yielded the bis-aryloxide, bis-[2,6-di(t-butyl)phenoxo]methylaluminium, $AlMe(OAr')_2$ (Ar′ = $C_6H_3Bu^t_2$-2,6), (**2**). The less hindered phenol Ar″OH (Ar″ = $C_6H_3Bu^t_2$-2,4) and an excess of $AlMe_3$ gave the expected aryloxide, (2,4-di-t-butylphenoxo)dimethylaluminium, $AlMe_2(OAr'')$ (Ar″ = $C_6H_3Bu^t_2$-2,4) (**3**). Compounds **1**–**3** have been characterized spectroscopically and in the case of the crystalline alkoxide **1**, also by X-ray crystallography; some selected geometric parameters are: Al—O 1.841(3) and 1.858(2), Al—C 1.939(5) and 1.959(6), Al···Al′ 2.84, O···O 2.37 Å; O—Al—O′ 79.8(1), Al—O—Al′ 100.2(1)°. Complex **1** has the structure $[AlMe_2(\mu\text{-}OCH_2Ar)]_2$, both as the solid and at 30°C in C_6D_6 solution. Less complete data on the aryloxides **2** and **3** suggest that the former is a monomer, whereas the latter is a dimer, probably by virtue of OAr″-bridging.

We have been interested for a long time in making compounds containing sterically hindered ligands. Our earlier work on the aryloxides bearing t-butyl substituents in the 2- and 6-positions is summarized in ref. 1. Complexes which we have investigated in this context have involved Li, Na, Mg, Ti^{III}, Ti^{IV}, Zr^{IV}, Rh^{I} (affording a tautomeric η^5-cyclohexadienonyl complex), Ge^{II}, Sn^{II}, Pb^{II}, P^{III}, Sc^{III}, Y^{III}, La^{III}, Pr^{III}, Nd^{III}, Dy^{III}, Ho^{III}, Er^{III}, Yb^{II}, Yb^{III}, Th^{IV} and U^{IV}.

Three 2,6-di-t-butylphenols are readily available having the formula 2,6-Bu^t_2-4-R-C_6H_2OH (R = H, Me, or Bu^t), because they are used as antioxidants. They have proved to be the source of interesting metal aryloxides which in general are hydrocarbon-soluble and often are available in an unusually low metal oxidation state and/or coordination number and have a low degree of molecular aggregation. For example, whereas the lanthanide elements (Ln) are characterized by having large ionic radii and hence normally form complexes having high Ln coordination numbers, the appropriate lanthanum(III) aryloxides are the three-coordinate complexes $[Ln(OC_6H_2Bu^t_2\text{-}2,6\text{-}R\text{-}4)_3]$,[2] and related ytterbium(II) aryloxides have a four- or five-coordinate metal environment, $[Yb(OAr''')_2(L)_n]$ (Ar‴ = $C_6H_2Bu^t_2$-2,6-Me-4; $n = 2$ and L = Et_2O or THF; or $n = 3$ and L = THF).[3] Another reason why such aryloxides have proved to be of interest is that a methyl group of one or more of the *o*-Bu^t groups is capable of participating in cyclometallation reactions.[4]

There are previous records of the use of two of these phenols in aluminium chemistry. The reaction between $AlPh_3$ and OAr (Ar = $C_6H_2Bu^t_3$-2,4,6) yielded $AlPh_{3-n}(OAr)_n$ ($n = 1$ or 2); it was proposed that the reaction proceeds by a free radical pathway on the basis of ESR data and the detection of biphenyl.[5] The monomeric compounds

* For Part I, see ref. 1a.

† Author to whom correspondence should be addressed.

$AlR_2(OAr''')$ (R = Me or Bu^i) and $AlBu^i(OAr''')_2$ were prepared from the appropriate alkyl AlR_3 and Ar'''OH,[6] while $AlMe_2Cl$ and Ar'''OH afforded $[AlMe(\mu\text{-}Cl)(OAr''')]_2$.[7] The reaction between various aluminium alkyls and Ar'''OH was followed by NMR[8] in the $AlMe_3$/Ar'''OH system; the compounds $Al_2Me_5(OAr''')$, $AlMe_2(OAr''')$ and $AlMe(OAr''')_2$ (monomeric in crystal; X-ray) were identified and some have application in synthesis and as catalysts for polymerization of C_3H_6.[8] X-ray data are also available on $AlMe_2(OAr''')(PMe_3)$ and $[NHMe_3][AlCl_2(Me)OAr''']$.[9]

The benzylic alcohol $ArCH_2OH$ has not, as far as we are aware, been used previously as a source of metal alkoxides. The intervention of the methylene group between the *ipso*-carbon and the OH group no doubt alleviates the steric effects of the two t-butyl groups in the 2- and 6-positions. A cyclometallation reaction involving one of the methyl groups of a metal complex L_nMOCH_2Ar would result in the formation of a seven-membered C_5OAl ring fused to the 1,2-positions of the aromatic nucleus; such a ring might well have been expected to be strainless.

EXPERIMENTAL

Materials, measurements and techniques

(2,4,6-Tri-t-butyl)benzyl alcohol was prepared according to a published synthesis.[10] Manipulative procedures of air-sensitive materials and the purification of the phenols were described in Part I.[1a] High resolution electron impact mass spectra and NMR spectra were run on a Kratos MS80RF and a Bruker WP80 or Bruker WM360 instrument, respectively.

Synthesis of **1**

A solution of the benzyl alcohol (2.65 g, 9.60 mmol) in hexane (25 cm^3) was slowly added to a solution of trimethylaluminium (2.4 mmol Al_2Me_6) in hexane (4.8 cm^3). An exothermic reaction took place and a gas was evolved. After stirring for *ca* 2 h, volatiles were removed *in vacuo*. The residue was dissolved in warm hexane (25 cm^3) and the suspension was filtered. The filtrate gave white needles of **1** (1.1 g, 94%) (Found: C, 75.0; H, 10.4. Calc. for $C_{21}H_{37}AlO$: C, 75.9; H, 11.1%). ^{1}H NMR (C_6D_6): 0.60 (s, 12H, $AlMe_2$), 1.40 (s, 18H, *p*-Bu^t), 1.50 (s, 36H, *o*-Bu^t), 5.52 (s, 4H, CH_2Ar), 7.6 [s, 4H, 3,4-*H*(Ar)].

Synthesis of **2**

2,6-Di-t-butylphenol was distilled at 100°C and 10^{-3} torr prior to use. The distillate solidified upon cooling. Trimethylaluminium (20 cm^3, 2 mol dm^{-3}, 400 mmol) was added to a hexane solution (150 cm^3) of the phenol (5.00 g, 24 mmol). The reaction mixture was warmed to 60°C for 8 h, then stirred for 24 h at *ca* 25°C and filtered. The filtrate was concentrated (to *ca* 10 cm^3) and cooled (−78°C) to give white crystals of **2** (4.1 g, 74%), m.p. 95–97°C (Found: C, 77.1; H, 9.4. Calc. for $C_{29}H_{45}AlO_2$: C, 76.9; H, 10.0%). The white crystals rapidly turned dark green in air.

Synthesis of **3**

2,4-Di-t-butylphenol was distilled at 120°C and 5×10^{-3} torr prior to use. The preparation, scale and work-up were as described for the bisaryloxide **2**. Crystals of **3** (4.3 g, 68%), m.p. 158–159°C, were obtained from hexane. The mass spectrum gave the following peaks (*m/z*) (assignments in parentheses): 509 $[\{AlMe_2(OAr'')\}_2\text{-}Me]^+$; 262 $[\{AlMe_2(OAr'')\}]^+$; 247 $[AlMe(OAr'')]^+$ and 232 $[Al(OAr'')]^+$.

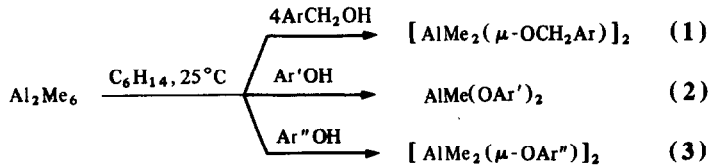
X-ray structure of **1**

X-Ray quality crystals of the alkoxide **1** were recrystallized from *n*-hexane at −30°C. A crystal of dimensions *ca* $0.40\times0.20\times0.22$ mm was mounted and sealed under argon in a Lindemann capillary. Intensities for $+h\pm k\pm l$ reflections with $2<\theta<25°$ were measured in the $\theta/2\theta$ mode with a scan width of $\Delta\theta=(0.8+0.35\tan\theta)°$, with a maximum scan time of 1 min.

Two standard reflections monitored every hour showed no significant variation. Data were corrected for Lp effects but not for absorption and, after averaging any equivalent reflections, 2663 reflections with $|F^2|>\sigma(F^2)$ were used in the structure refinement. The values of $\sigma(F^2)$ were taken as $[\sigma^2(I)+0.02(I)^2]^{1/2}$/Lp.

Crystal data. $C_{42}H_{74}Al_2O_2$, $M=665.02$, triclinic, $a=10.043(2)$, $b=10.399(2)$, $c=12.446(2)$ Å, $\alpha=103.50(1)$, $\beta=98.41(2)$, $\gamma=113.63(1)°$, $U=1115.3$ Å^3, $Z=1$, $D_c=0.99$ g cm^{-3}, $F(000)=368$. Monochromated Mo-K_α radiation, $\lambda=0.71069$ Å, $\mu=0.90$ cm^{-1}. Space group $P\bar{1}$.

The structure was solved by direct methods using the MULTAN program.[11] The Al, O and C atoms were refined with anisotropic temperature factors by full-matrix least-squares. The H atoms were initially located by a difference map and then refined isotropically, except for those in the 4-Bu^t group which were fixed at calculated positions (C—H, 1.08



Scheme 1. Reactions of Al_2Me_6 with 2,4,6-$Bu^t_3C_6H_2CH_2OH$ ($ArCH_2OH$), 2,6-di-t-butylphenol (Ar'OH) or 2,4-di-t-butylphenol (Ar"OH).

Å). Refinement converged at $R = 0.074$, $R' = 0.087$ when the maximum shift/error was 0.3 and the weighting scheme was $w = 1/\sigma^2(F)$. A final difference map showed no peaks at > 0.5 e Å^{-3}. The structure solution and refinement were carried out using a PDP 11/34 computer and the Enraf–Nonius Structure Determination Package. Scattering factors for neutral atoms were taken from ref. 12. Tables of atom coordinates, thermal parameters and remaining bond lengths and angles are available from the Cambridge Crystallographic Data Centre. A list of final structure factors is available from one of the authors (P.B.H.).

RESULTS AND DISCUSSION

The routes to the new aluminium alkoxides and aryloxides **1–3** are summarized in Scheme 1. Selected interatomic distances and angles for the alkoxide **1** are in Table 1, the molecular structure being illustrated in Fig. 1 together with the atom numbering scheme.

Noteworthy features relating to the formation of the alkoxide **1** are, firstly, that reaction with an excess of the benzylic alcohol $ArCH_2OH$ under ambient conditions did not lead to further substitution of a methyl group on aluminium and, secondly,

Table 1. Selected intramolecular distances (Å) and angles (°) with ESDs in parentheses for $[Al(\mu\text{-}OCH_2Ar)Me_2]_2$ (Ar = $C_6H_2Bu^t_3$-2,4,6) (**1**)

that the compound was at least moderately thermally stable and showed no inclination to undergo cyclometallation below 100°C. Regarding the lack of reactivity with an excess of the alcohol, this may reflect the strength of the bridging and the limited nucleophilicity of the reagent. NMR data showed no evidence of dissociation of the dimer in solution. The fact that bridging is through the oxygen rather than involving one of the methyl groups attached to the aluminium is not surprising. Related compounds include $[AlMe_2(\mu\text{-}OBu^t)]_2$ (**4**),[13] $[AlBr_2(\mu\text{-}OSiMe_3)]_2$ (**5**)[14] and $[AlMe_2(\mu\text{-}OAlMe_2)]$ (**6**).[15]

The reactions involving the two phenols were carried out using an excess of trimethylaluminium because we sought to obtain the mono-aryloxides. Rather similar reaction conditions were employed to those for the benzoxide, namely the use of a hydrocarbon solvent at ambient temperature. Nevertheless, unexpectedly, the more hindered phenol Ar′OH (Ar′ = $C_6H_3Bu^t_2$-2,6) reacted to yield the bisaryloxide **2**. This suggests that Ar′OH reacts much faster with $AlMe_2(OAr')$ than with $AlMe_3$, perhaps because the former, unlike the latter, is a monomer, as established by X-ray crystallography for the related compound $AlMe(OC_6H_2Bu^t_2\text{-}2,6\text{-}Me\text{-}4)_2$.[8] Consistent with this is the observation that the isomeric and less hindered phenol Ar″OH (Ar″ = $C_6H_3Bu^t_2$-2,4) gave the mono-substituted compound **3**, which is believed to be a dimer and, based on analogy with complex **1**, is formulated as having the structure $[AlMe_2(\mu\text{-}OAr'')]_2$. The evidence for the dimeric formulation comes from the EI mass spectrum which shows the highest peak corresponding to a dimeric parent (*P*) minus a methyl, $(P-Me)^+$.

The aryloxide **3** was reasonably stable in air. By contrast, the bisaryloxide **2** rapidly turned dark green upon exposure to the atmosphere, consistent with the monomer formulation. Heating either the melt of **2** at 200°C for 1 h, or a benzene solution under reflux for 30 days, provided no evidence for cyclometallation, but only slight decomposition. Likewise, the monoaryloxide **3** did not eliminate methane when heated in a benzene solution under reflux for 3 weeks; under these conditions, $AlMe_2(NHAr)$ gave the cyclometallated product $AlMe(NHAr)$.[16]

The centrosymmetric dimeric crystalline molecule **1** (Fig. 1) has a planar Al_2O_2 framework. The four-membered ring mean plane bisects the two methyl groups bonded to the aluminium atom. The carbon atom C(19) bonded to the oxygen atom is *ca* 0.03 Å below the plane. The aromatic plane [C(1) to C(6)] forms an angle of 89.3° with the Al_2O_2 plane. The central carbon atoms C(7) and C(9) of the 2- and 6-Bu^t groups are *ca* 0.35 and 0.37 Å below the aromatic plane, respectively, whilst C(19) is *ca* 0.54 Å above the aromatic plane, as a result of the steric strain.

The Al—O and Al—O′ bond lengths of 1.841(3) and 1.858(2) Å, respectively, are similar to that [1.864(6) Å] found by electron diffraction in the same ring in gaseous **4**,[13] but are significantly longer than those found in crystalline **5** [1.80(2) Å],[14] or **6** [1.80(2) Å].[15] The C—O bond distance, 1.443(4) Å, is unexceptional. The intramolecular non-bonded Al···Al′ distance, 2.84 Å, is similar to that found in gaseous **4**, 2.82 Å,[13] while the corresponding non-bonded O···O′ distance of 2.37 Å is slightly shorter than that in **4**, 2.44 Å; this may be a reflection of steric effects. The internal angles within the Al_2O_2 ring are rather similar to those found in gaseous **4**, that at aluminium, 79.8(1)°, being smaller than that at oxygen, 100.2(2)°; these values may be compared with those of 81.9(7) and 98.1(7)° for the corresponding angles in **4**.[13]

The tetrahedral coordination environment at the Al atom is extremely irregular, as evident from the following values: O—Al—O′ 79.8(1), O—Al—C(20) 118.2(5), O—Al—C(21) 117.1(2) and C(20)—Al—C(21) 114.8(2)°. The sum of the angles at the O atom is 360°; corresponding to a trigonal planar environment at O.

The two substituted benzyl groups on the O atom are in a mutually *trans* position.

The endocyclic angles at the 2-, 4- and 6-C atoms of the Ar group are smaller than those in the other positions, presumably because of the bulky substituents.

BULKY METAL ARYLOXIDES, ARYLAMIDES AND SULPHUR AND PHOSPHORUS ANALOGUES—III.* ALUMINIUM COMPOUNDS DERIVED FROM 2,4,6-TRI-t-BUTYLANILINE; X-RAY STRUCTURE OF $[AlMe\{\mu\text{-}NHC_6H_2Bu^t_2\text{-}4,6\text{-}C(Me)_2CH_2\text{-}2\}]_2$

PETER B. HITCHCOCK, HATAM A. JASIM, MICHAEL F. LAPPERT† and HUGH D. WILLIAMS

School of Chemistry and Molecular Sciences, University of Sussex, Brighton BN1 9QJ, U.K.

Abstract—Treatment of $AlMe_3$ with $ArNH_2$ ($Ar = C_6H_2Bu^t_3$-2,4,6) in C_6H_{14} at 60°C afforded $[AlMe_2(\mu\text{-}NHAr)]_2$ (**1**). Heating the amide **1** either at 200°C for 3 h or (NMR) in C_6D_6 at 80°C for 3 weeks in a sealed tube led to methane elimination and formation of the cyclometallated compound $[AlMe\{\mu\text{-}NHC_6H_2Bu^t_2\text{-}4,6\text{-}C(Me)_2CH_2\text{-}2\}]_2$ (**2**); unexpectedly, the hydrogen atom abstracted from the NHAr ligand of **1** originated from the 2-t-butyl group rather than the NH. Deuterolysis of **2** yielded $D_2NC_6H_2Bu^t_2$-4,6-$C(Me)_2CH_2D$-2. $AlCl_3$ and $ArNH_2$ gave the 1:1 adduct $AlCl_3(NH_2Ar)$ (**3**), which upon heating either at 150°C and 10^{-4} torr or (NMR) in C_6D_6 at 80°C for 24 h gave isobutene and the retro-Friedel Crafts product $AlCl_3(NH_2C_6H_3Bu^t_2$-2,4) (**4**). An excess of LiNHAr did not react with $AlMe_3$, but with $AlCl_3$ furnished $Al(NHAr)_2Cl$ (**5**). The X-ray structure of the cyclometallated compound **2** showed it to be a pentacyclic centrosymmetric dimer, containing a central $(AlN)_2$ square [⟨Al—N⟩ 1.965(6) Å], with the adjacent six-membered unsaturated alumino-heterocycles in a twisted boat conformation, one below and the other above the $(AlN)_2$ plane and the two anilido ligands in a *transoid* arrangement. The preparation of the metal anilides M(NHAr) [M = Li (**6**), $SiMe_3$ (**7**) or $SnMe_3$ (**8**)] is described.

We have introduced the sterically demanding arylamido ligand NHAr ($Ar = C_6H_2Bu^t_3$-2,4,6) into coordination chemistry in the context of complexes of Li,[1,2] B,[3] Sn^{II},[1] P^{III},[4,5] As^{III},[4,5] P^{III}/Li,[5] P^{III}/Al^5 and Ni^{II}.[1]

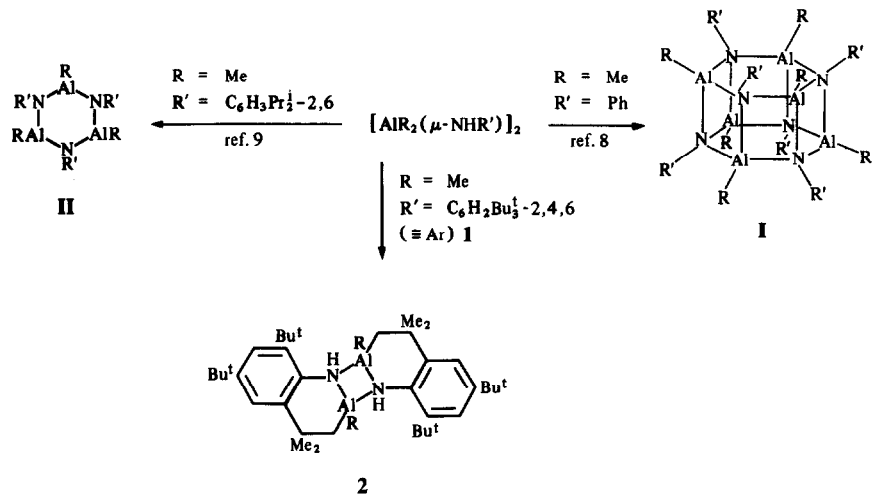
Secondary amido–metal complexes L_nM—NHR are much less well known than tertiary analogues (L_nM—NRR′), because of their frequently encountered intermolecular amine elimination to form the bis(metallo)amine L_nM—N(R)—ML_n;[6] a bulky group R, such as R = Ar, is expected to hinder such an associative decomposition pathway. Alternatively, the amide L_nM—NHR, by virtue of its NH proton, may participate in alkane elimination, as in the conversion of an alkylaminoalane into an alkyliminoalkane [e.g.[7] *cis*- or *trans*-$\{AlMe_2(\mu\text{-}NHPr^i)\}_2 \rightarrow$ *trans*-$\{AlMe(\mu\text{-}NPr^i)\}_{4 \text{ or } 7}$].

The NHAr ligand is of further interest because of its potential for geometrical isomerism; for example, $[Li(\mu\text{-}NHAr)(OEt_2)]_2$ has the two aryl groups arranged in a *transoid* fashion.[1] Another feature, directly attributable to its substantial steric requirements, is the capacity of the ligand NHAr to stabilize unusual partners; e.g. the compounds $B(NHAr)X_2$ (X = F, Cl, or NH_2) were found to be unexpectedly thermally stable with respect to HX elimination.[3]

The reaction between trimethylaluminium and a series of anilines was first investigated by Smith and co-workers.[8] They observed that the reaction between $AlMe_3$ and the aniline $R'NH_2$ afforded $[AlMe_2(NHR')]_m$ ($m = 2$ for $R' = 2\text{-}MeC_6H_4$; X-ray), which on heating, yielded $[AlMe(NR')]_n$ [$n = 6$ for R′ = Ph (**I**) (see Scheme 1); X-ray] [R′ = R′ 2- or 4-MeC_6H_4, or 2,6-$Me_2C_6H_3$]. Using the more sterically hindered 2,6-di(isopropyl)aniline Ar″NH_2, Power and co-workers found that the ambient temperature product $[AlMe_2(\mu\text{-}NHAr'')]_2$ upon heating at 170°C afforded the iminoalane $[AlMe(\mu\text{-}NAr'')]_3$ (**II**) (Scheme 1); this was of special interest, because it

* For Part II, see ref. 13.

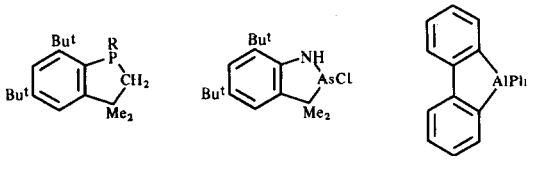
† Author to whom correspondence should be addressed.



Scheme 1. Thermolysis products of three arylamino(dimethyl)alanes; in each case methane was the co-product.

provided the first example of an Al—N compound having both Al and N in a three-coordinate environment, an AlN borazine analogue.[9] Curiously we have found[10] that for the even more sterically crowded 2,4,6-tri-t-butylaniline system, an iminoalane was not observed but instead **1** afforded the cyclometallated product (**2**) (Scheme 1); these results are now presented in full.

Cyclometallation in the context of a 2,4,6-tri-t-butylphenyl derivative of P^{III} (**III**) [R = CH(SiMe$_3$)$_2$][11] or As^{III} (**IV**)[5] had previously been noted; and the topic has been reviewed in the context of 2,6-di-t-butylphenoxometal complexes.[12] However, the complexes [AlMe$_2$(μ-OC$_6$H$_3$Bu$^t_2$-2,4)]$_2$ were thermally stable.[13] A rare example of a cyclometallation in aluminium chemistry is the formation of **V** by thermolysis of 2-phenyl-1-(diphenylalumino)benzene.[14]



The chemistry[15] and spectroscopy[16] of base adducts of AlCl$_3$ is well documented. The crystalline pyridine adduct of AlCl$_3$ has the structure [AlCl$_2$(py)$_4$][AlCl$_4$].[17]

Numerous chloro(amino)alanes and chloro(imino)alanes are known,[6] such as the dimeric AlCl(NMe$_2$)$_2$[18] and the tetrameric AlCl(NPr^i).[19]

EXPERIMENTAL

Materials, measurements and techniques

2,4,6-Tri-t-butylaniline, ArNH$_2$ (from ArH, via ArNO$_2$),[20] and [Li(μ-NHAr)(OEt$_2$)]$_2$[1] were prepared by published methods. Manipulative procedures for the air-sensitive aluminium compounds and their precursors were described in Part II;[13] IR, NMR and EI mass spectra were obtained using Perkin–Elmer FT1700, Bruker WP80 or WM360 and Kratos MS80RF, respectively.

Synthesis of Li(NHAr) (**6**)

LiBu^n in hexane (20 cm^3, 1.5 mol dm^{-3}, 30 mmol) was syringed into a solution containing the freshly sublimed ArNH$_2$ (6.00 g, 22.98 mmol) in hexane (100 cm^3) at *ca* 25°C. A white precipitate was immediately formed. The reaction mixture was refluxed for 3 h, cooled and filtered. The insoluble 2,4,6-tri-t-butylanilidolithium (**6**) (5.6 g, 92%), m.p. *ca* 300°C (decomp.), was washed with hexane (20 cm^3) to remove any residual n-butyl-lithium and then pumped dry. In repeat experiments, the yield was in the range 85–95%. Compound **6** was not sublimable at 250°C and 10^{-4} torr without complete decomposition.

Synthesis of Me$_3$Si(NHAr) (**7**)

Freshly distilled chloro(trimethyl)silane (1.05 cm^3, 0.90 g, 8.37 mmol) was added to a solution of **6** (2.2 g, 8.24 mmol) and triethylamine (5 cm^3) in

diethyl ether (150 cm^3). The reaction mixture was refluxed for 3 days and the precipitated LiCl was filtered off. Volatiles were removed from the filtrate *in vacuo*. The residue comprised 2,4,6-tri-t-butylanilino(trimethyl)silane (**7**) (2.39 g, 87%), m.p. 88°C (Found: C, 75.8; H, 11.5; N, 4.3. Calc. for $C_{21}H_{39}NSi$: C, 75.6; H, 11.8; N, 4.1%); it was purified by sublimation at 130°C and 10^{-3} torr.

Synthesis of $Me_3Sn(NHAr)$ (**8**)

The procedure was that used for the preparation of the anilinosilane (**7**), using **6** (1.00 g, 3.74 mmol), triethylamine (5 cm^3) and chloro(trimethyl)tin (1.00 g, 5.02 mmol). The 2,4,6-tri-t-butylanilido(trimethyl)tin (**8**) (1.16 g, 73%), m.p. 66–67°C, was crystallized from hexane at −30°C, but with difficulty, due to its high solubility; it sublimed at 250°C and 10^{-4} torr, but there was extensive decomposition.

Synthesis of **1**

A trimethylaluminium solution in hexane (10 cm^3, 2 mol dm^{-3}, 20 mmol) was added (10 min) to a hexane solution (100 cm^3) of $ArNH_2$ (4.00 g, 15.3 mmol). A white precipitate gradually (30 min) formed. The reaction mixture was heated with stirring at 60°C for 48 h and filtered whilst warm. Cooling the filtrate yielded colourless crystals of 2,4,6-tri-t-butylanilino(dimethyl)alane (**1**) (3.40 g, 89%), m.p. 241–244°C. ^1H NMR (C_6D_6): −0.38 (s, 6H, $AlMe_2$), 1.37 (s, 18H, 2-, 4- and 6-Bu^t), 3.8 (br, 1H, NH), 7.37 (s, 2H, 3- and 5-H).

Synthesis of
$[AlMe\{\mu\text{-}NHC_6H_2Bu^t_2\text{-}4,6\text{-}C(Me)_2CH_2\text{-}2\}]_2$ (**2**)

The anilinoalane **1** (4.00 g, 12.6 mmol) was slowly heated for *ca* 4 h at 210°C, using a Wood's alloy bath. Some foaming was observed. The cooled residue was crystallized from hexane (50 cm^3, −78°C) to furnish colourless crystals of the cyclometallated aminoalane **2** (2.5 g, 66%), m.p. 240–243°C [Found: *M* (Signer method in Et_2O), 294. $C_{18}H_{29}AlN$ requires *M*, 301]. IR (Nujol): ν(N—H) 3349(vs) cm^{-1}. ^1H and $^{13}C\{^1H\}$ NMR data are summarized in Figs 1 and 2, respectively.

In a separate experiment, the anilinoalane **1** was heated at 80°C in a sealed NMR tube. After 3 weeks, the cyclometallation to produce **2** was 75% complete. After a further 1 week, no trace of **1** was detectable.

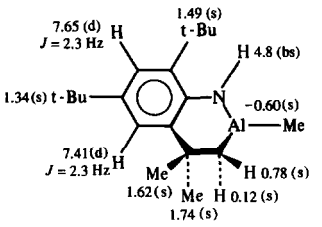


Fig. 1. Assignments of the ^1H NMR signals of **2**; spectrum at 360 MHz and 305 K.

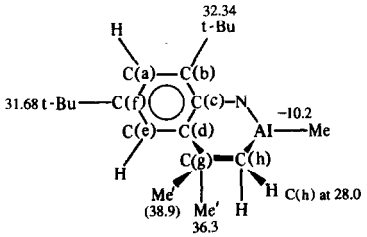

Fig. 2. Assignments of the $^{13}C\{^1H\}$ NMR signals of **2**; spectrum at 90.67 MHz and 305 K; chemical shifts only for the methyl groups of the Bu^t groups are shown.

Deuterolysis of the cyclometallated aminoalane **2**

Deuterium oxide (1 cm^3) was added dropwise to a solution of compound **2** (0.4 g, 1.33 mmol) in diethyl ether (30 cm^3). An immediate white precipitate was formed. After stirring for 3 days, the ether was removed *in vacuo* and the residue extracted into hexane (30 cm^3). The extract was concentrated and cooled to give colourless crystals of $D_2NC_6H_2Bu^t_2$-4,6-$C(Me)_2CH_2D$-2, m.p. 139°C (m.p. 137°C for the deuterium-free aniline). IR (Nujol) (trideuterated amine): ν(N—D) at 2620(m) and 2520(m) cm^{-1} [cf. for the deuterium-free amine, ν(N—H) at 3510(m) and 3440(m) cm^{-1}]. MS for the deuterium-free amine gave (*m/z*, e = 1): P^+ at 261.2457 ($C_{18}H_{31}N$ requires 261.2456) and $(P-Me)^+$ at 246.2221 [$(P-Me)^+$ requires 246.2222]; the trideuterated amine gave $(P-Me)^+$ at 249.2410 [$C_{17}H_{25}D_3N$ requires $(P-Me)^+$ at 249.2387].

Synthesis of $AlCl_3(NH_2Ar)$ (**3**)

Aluminium trichloride (1.3 g, 9.74 mmol) (sublimed twice prior to use) was added to freshly sublimed $ArNH_2$ (2.2 g, 8.43 mmol) in toluene (100 cm^3). The reaction mixture was stirred for 48 h and filtered. The filtrate upon concentration (to *ca* 20 cm^3) yielded colourless needles of **3** (2.6 g, 74%), m.p. 140°C (Found: C, 53.9; H, 8.3; N, 3.2. Calc. for $C_{18}H_{31}AlCl_3N$: C, 54.7; H, 7.9; N, 3.5%). IR (Nujol): ν(N—H) 3380(s) and 3150(br) cm^{-1},

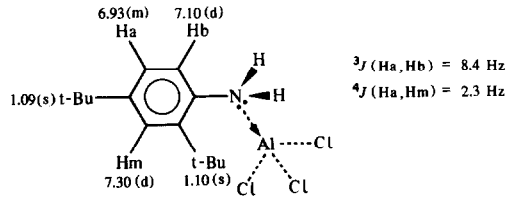

Fig. 3. Assignments of the ^{1}H NMR signals of **4**; spectrum at 80 MHz and 305 K.

$\nu(AlCl_3)$ 570(s) cm^{-1}. ^{1}H NMR data are summarized in Fig. 3.

Thermolysis of **3**, *a retro-Friedel Crafts reaction*

The adduct **3** (0.5 g, 1.26 mmol) was slowly heated for 3 h *in vacuo* at 150°C at 10^{-4} torr in a sublimation apparatus. This yielded white crystals of the sublimate $AlCl_3(H_2NC_6H_3Bu^t_2$-2,4) (**4**) (0.2 g, 47%), m.p. 110–115°C (Found: C, 48.5; H, 6.5; N, 4.2. Calc. for $C_{14}H_{23}AlCl_3N$: C, 49.6; H, 6.8; N, 4.1%). IR (Nujol): ν(N—H) 3315(s), $\nu(AlCl_3)$ 570(s) and 290(s) cm^{-1}. MS (*m/z*, e = 1; assignments in parentheses): 337 and 339 (P^+), 281 and 283 ($P-Bu)^+$, 148 $[C_6H_4(t\text{-}Bu)NH_2]^+$ and 133 $[\{C_6H_4(t\text{-}Bu)NH_2\}-Me]^+$.

In another experiment, a solution of **3** in C_6D_6 was heated at 80°C in a sealed NMR tube. After 24 h no trace of **3** was detected; complete conversion into **4** and 2-methylpropene had been effected.

Synthesis of $Al(NHAr)_2Cl$ (**5**)

LiNHAr (2.29 g, 8.57 mmol) was added to freshly sublimed $AlCl_3$ (0.4 g, 2.99 mmol) in toluene (100 cm^3) and diethyl ether (20 cm^3). The reaction mixture was stirred for 6 days, whereafter volatiles were removed *in vacuo*. The residue was extracted into hexane (50 cm^3). The extract was concentrated and cooled (to *ca* 30 cm^3 at 5°C) to afford colourless crystals of the di(anilido)aluminium chloride **5** (1.8 g, 36%), m.p. 199–201°C (Found: C, 74.6; H, 10.2; N, 4.3. Calc. for $C_{36}H_{60}AlClN_2$: C, 74.1; H, 10.3; N, 4.8%). IR (Nujol): ν(N—H) 3430(s) cm^{-1}.

X-ray structure of
$[AlMe\{\mu\text{-}NHC_6H_2Bu^t_2\text{-}4,6\text{-}C(Me)_2CH_2\text{-}2\}]_2$ (**2**)

X-ray quality crystals of the cyclometallated anilide **2** were crystallized from n-hexane at −30°C. A crystal of dimensions *ca* 0.20 × 0.30 × 0.15 mm was mounted and sealed under argon in a Lindemann capillary. Intensities of $+h \pm k \pm l$ reflections with $2 < \theta < 55°$ were measured in the $\theta/2\theta$ mode with a scan width of $\Delta\theta = (0.8+0.14\tan\theta)$ and a maximum scan time of 1 min.

Two standard reflections monitored every hour showed no significant variation. Data were corrected for Lp effects but not for absorption and, after averaging any equivalent reflections, 2711 reflections with $|F^2| > \sigma(F^2)$ were used in the structure refinement. The values of $\sigma(F^2)$ were taken as $[\sigma^2(I)+(0.02I)^2]^{1/2}$/Lp.

Crystal data. $C_{38}H_{64}Al_2N_2$, $M = 602.95$, triclinic, $a = 9.309(2)$, $b = 9.860(1)$, $c = 22.132(4)$ Å, $\alpha = 80.03(2)$, $\beta = 81.43(2)$, $\gamma = 73.84(1)°$, $U = 1910.7$ Å^3, $Z = 2$, $D_c = 1.044$ g cm^{-3}, $F(000) = 664$, Cu-K_α radiation (Ni filter), $\lambda = 1.5418$ Å, $\mu = 8.4$ cm^{-1}. Space group $P\bar{1}$.

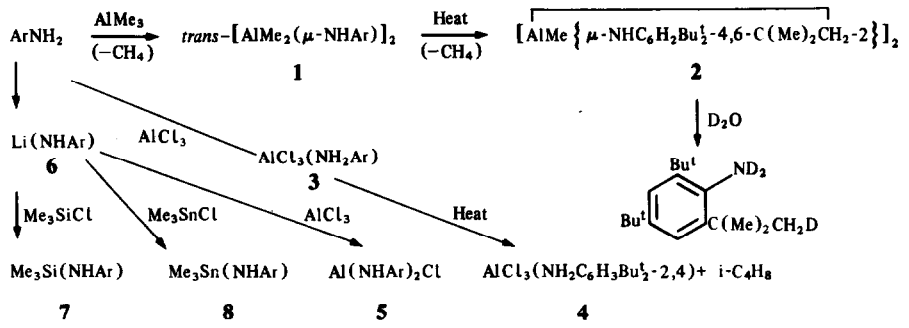
The structure was solved by direct methods using the MULTAN program.[21] The Al, N and C atoms were refined with anisotropic temperature factors by full-matrix least-squares. The H atoms were placed at calculated positions (C—H = 1.08 Å) and held fixed with a common isotropic temperature of $B = 8.0$ Å^2. Refinement converged at $R = 0.083$, $R' = 0.095$ when the maximum shift/error was 6.9 and the weighting scheme was $w = 1/\sigma^2(F)$. A final difference map was everywhere < 0.44 e Å^{-3}. The structure solution and refinement were carried out using a PDP 11/34 computer and the Enraf–Nonius Structure Determination Package. Scattering factors were taken from ref. 22. Tables of atom coordinates, thermal parameters and remaining bond lengths and angles are available from the Cambridge Crystallographic Data Centre. A list of final structure factors is available from one of the authors (P.B.H.).

RESULTS AND DISCUSSION

The reactions leading to the new compounds **1**–**8** are summarized in Scheme 2.

The formation of *trans*-$[AlMe_2(\mu\text{-}NHAr)]_2$ (**1**) by aminolysis of trimethylaluminium with an equivalent portion of 2,4,6-tri-t-butylaniline ($ArNH_2$) is unexceptional. The structure of **1** has not been unambiguously elucidated. It is based on analogy with data from the literature[6–9] and on the ^{1}H NMR spectrum, which showed that the following pairs were magnetically equivalent: (i) the methyls on Al, (ii) the 2- and 6-Bu^t groups of Ar and (iii) the 3- and 5-hydrogens of Ar. In diethyl ether, compound **1** appeared to be the monomer $AlMe_2(NHAr)(OEt_2)_n$.

The thermolysis of the aminoalane **1** afforded the cyclometallated aminoalane **2**. This is surprising, as an iminoalane was expected: cf. the formation of the crystallographically characterized compounds **I** and **II**, from apparently analogous reactions of $[AlMe_2(\mu\text{-}NHPh)]_2$ and $[AlMe_2(\mu\text{-}NHC_6H_3Pr^i_2$-2,6)]$_2$, respectively (Scheme 1).



Scheme 2. Reactions of 2,4,6-tri-t-butylaniline ($ArNH_2$) leading to the aluminium derivatives **1**–**5**, and some related reactions.

The formation of **2** from **1** demonstrates an unusual cyclization in aluminium chemistry, involving unprecedented aliphatic C—H bond cleavage. It is remarkable that the methane elimination from **1** results from capture of a C*H* rather than the N*H* hydrogen by an aluminium-bound methyl group. This is attributed to a steric, rather than an electronic, effect. As for the latter, it is well known that Al—Me bonds are readily cleaved by protic reagents; the NH proton of **1** is in all probability acidic (cf. the two related reactions in Scheme 1), as is the case in P(NHAr)(:NAr) which is readily N-deprotonated by treatment with $LiBu^n$ or $AlMe_3$.[5]

The evidence for the structure of the cyclometallated anilinoalane (**2**) rests ultimately on single crystal X-ray diffraction data, *vide infra*. The ^1H and $^{13}C\{^1H\}$ NMR spectra are readily assigned, Figs 1 and 2, respectively. The fact that the pair of *C*-methyl substituents in the $AlNC_4$ ring are diastereotopic is consistent with this ring being non-planar (boat-shaped in the crystal). The presence of the NH protons is inferred both from the ^1H NMR and the IR spectra, ν(NH) 3349 cm^{-1}.

Confirmation of the cyclometallation was further demonstrated by the deuterolysis of **2** (Scheme 2). It is interesting that the *N,N*-dideuteration of $ArNH_2$ was slow, the half-life of ArNHD in C_6D_6 in the presence of D_2O being > 1 day at 300 K. This is attributed to the steric protection afforded by the 2- and 6-Bu^t groups.

The chlorobis(anilino)alane $AlCl(NHAr)_2$ (**5**) was obtained from $AlCl_3 + 2Li(NHAr)$, but was not accessible from $AlCl_3(NH_2Ar)$ (**3**). Thermolysis of **3**, did not cause the expected dehydrochlorination, but instead the retro-Friedel Crafts product, **4**, was obtained in quantitative yield.

Compound **4** was identified *inter alia* by its ^1H NMR spectrum; for assignments, see Fig. 3. The formation of **4** was shown to be accompanied by 2-methylpropene elimination, derived site-selectively from the 2-Bu^t group of **3**. When the thermolysis of **3** was carried out in C_6D_6, no $C_6D_5Bu^t$ was formed. This retro-Friedel Crafts reaction for a Group 13 metal halide–arylamine complex appears to be unprecedented. A dealkylation has been observed in a Fries rearrangement.[23]

The X-ray structure of **2** reveals two independent dimers, each lying on a crystallographic inversion centre, the mid-point of the almost square AlNAlN ring. The molecular geometry and atom numbering scheme for one of the dimers is illustrated in Fig. 4; they have the same basic features, hence the following discussion will refer to only one of the dimers. Selected geometric parameters are in Table 1.

The dimensions of the planar AlNAlN ring are very similar to those in $[AlMe_2(\mu\text{-}NMe_2)]_2$ [AlN: 1.948(7) and 1.967(7) Å, Al···Al 2.823 and N···N 2.735 Å],[24] or $[AlMe_2(\mu\text{-}NHC_6H_4Me\text{-}2)]_2$ [AlN: 1.949(7) and 1.965(7) Å].[8] The tetrahedral coor-

Symmetry element ′ is $\bar{x}$, $1-y$, $1-z$.
Symmetry element ″ is $1-x$, $1-y$, z.

dination environment at Al is extremely irregular: N(1)AlN(1)′ 88.1(3), N(1)AlC(18) 99.8(3), N(1)Al(1)C(19) 120.9(3) and C(18)Al(1)C(19) 115.5(4)°; likewise the nitrogen environment is also distorted tetrahedral.

The anilido ligands are mutually *transoid* and there is disorder in the Me moieties of the 4-Bu^t groups of dimer (a) only. Each of the two six-membered rings NAlC(18)C(9)C(2)C(1) containing the Al atoms is in a twisted boat conformation, one being below and the other above the $(AlN)_2$ plane; C(1) and C(18) are *ca* 0.98 and 1.74 Å above the $(AlN)_2$ plane. The methyl group bonded to Al is 1.48 Å out of the $(AlN)_2$ plane in a direction opposite to that of the six-membered ring. The C(1)—C(6) plane forms an angle of 105.7° with respect to the $(AlN)_2$ plane in dimer (a), while in dimer (b) this angle is 103.2°.

The endocyclic angles at the substituted carbons of the aromatic ring are smaller than the others, presumably because of steric effects. The central carbon atoms of the *o*-Bu^t group, C(7), lies in the

aromatic plane; while C(9), the central carbon of the CMe_2 moiety, is *ca* 0.11 Å above the plane and the N atom is *ca* 0.17 Å below the plane.

KINETIC CONTROL IN THE ALCOHOLYSIS REACTION INVOLVING HEXAKISDIMETHYLAMIDODIALUMINIUM AND TERT-BUTANOL. PREPARATION, CRYSTAL AND MOLECULAR STRUCTURES OF $Al(OBu^t)_3(HNMe_2)$ AND $Al_2(NMe_2)(OBu^t)_5$

MALCOLM H. CHISHOLM,* VINCENT F. DiSTASI and WILLIAM E. STREIB

Department of Chemistry and Molecular Structure Center, Indiana University, Bloomington, IN 47405, U.S.A.

Abstract—Addition of excess Bu^tOH to hydrocarbon solutions of $Al_2(NMe_2)_6$ yields $Al(OBu^t)_3(HNMe_2)$ and $Al_2(OBu^t)_6$ as kinetic and thermodynamic products, respectively, by way of a remarkably persistent intermediate $Al_2(NMe_2)(OBu^t)_5$.

The addition of alcohols to metal amides provides a general route to metal alkoxides and often is successful where other routes based on metathetic reactions involving metal halides fail.[1] We report here some observations of the addition of Bu^tOH to $Al_2(NMe_2)_6$[2] that reveal some rather interesting mechanistic aspects of the alcoholysis reaction leading to $Al_2(OBu^t)_6$.[3]

Addition of excess Bu^tOH (as the benzene/Bu^tOH azeotrope, 37% by weight Bu^tOH) to hydrocarbon solutions of $Al_2(NMe_2)_6$ generates an exothermic reaction. Removal of the solvent under a dynamic vacuum yields a white solid $Al(OBu^t)_3(HNMe_2)$ that sublimes at 40–50°C, 10^{-1} torr (house vacuum).† Crystals of $Al(OBu^t)_3(HNMe_2)$ were obtained from toluene at −15°C. In the solid state there are two crystallographically-independent hydrogen bonded dimers $[Al(OBu^t)_3(HNMe_2)]_2$, each having a centre of symmetry‡ (see Fig. 1). The two crystallographically different monomer units $Al(OBu^t)_3(HNMe_2)$ differ little with respect to the central AlO_3N core. The greatest variation in structural parameters is associated with the Al—O—C angles.

$Al(OBu^t)_3(HNMe_2)$ loses $HNMe_2$ in refluxing toluene with an N_2 purge, and the white crystalline compound $Al_2(OBu^t)_6$ is obtained upon subsequent crystallization at −15°C. $Al_2(OBu^t)_6$ does not react with $HNMe_2$(excess) in hydrocarbon solutions at room temperature and by ^1H NMR in benzene-d_6

† Dry and oxygen-free solvents and atmospheres (N_2) were used throughout. Satisfactory elemental analyses have been obtained for C, H and N. ^1H NMR data at 22°C, 300 MHz in C_6D_6: $Al(OBu^t)_3(HNMe_2)$: OBu^t, δ 1.46, s, 27H; $HNMe_2$, δ 1.84, d, 6H, $^3J_{HH}$ = 6.3 Hz; $Al_2(NMe_2)(OBu^t)_5$: NMe_2, δ 2.41, s, 6H; OBu^t, δ 1.50, s, 9H; δ 1.37, s, 36H.

‡ Crystal data for $Al(OBu^t)_3(HNMe_2)$ at −155°C: a = 17.244(2), b = 13.033(1), c = 17.674(2) Å, β = 111.16(1)°, Z = 8, D_{calc} = 1.045 g cm^{-3} and space group $P2_1/c$. Of 5947 reflections collected using Mo-K_α ($6° < 2\theta < 45°$), 4853 reflections were unique and the 4003 reflections having $F > 3\sigma(F)$ were used in the full least-squares refinement leading to $R(F)$ = 0.058 and $R_w(F)$ = 0.062. The hydrogen atoms were refined isotropically; all other atoms were refined anisotropically. The unit cell contains two independent $Al(OBu^t)_3(HNMe_2)$ molecules. Each molecule is present as a symmetry related hydrogen-bonded dimer. There is a disorder in one of the Bu^t groups in one molecule involving carbons numbered 23–25 and hydrogen atoms 35–43. Crystal data for $Al_2(NMe_2)(OBu^t)_5$ at −159°C: a = 9.967(2), b = 15.016(3), c = 9.874(1) Å, α = 91.99(1), β = 95.61(1), γ = 97.14(1)°, Z = 2, D_{calc} = 1.056 g cm^{-3} and space group $P\bar{1}$. Of the 4501 reflections collected, 3822 reflections were unique and the 2786 reflections having $F > 3\sigma(F)$ were used in the refinement leading to $R(F)$ = 0.059 and $R_w(F)$ = 0.068. There appears to be a disorder among the hydrogen atoms of the C(17) and C(22) Bu^t ligands. All hydrogen atoms were placed in calculated positions and were assigned thermal parameters equal to one plus the isotropic equivalent of the atom to which they were bonded. In the final least-squares refinement, the non-hydrogen atoms were varied with anisotropic thermal parameters. General operating procedures have been previously described: M. H. Chisholm, K. Folting, J. C. Huffman and C. C. Kirkpatrick, *Inorg. Chem.* 1984, **23**, 1021. Fractional coordinates have been deposited with the Director, Cambridge Crystallographic Data Centre.

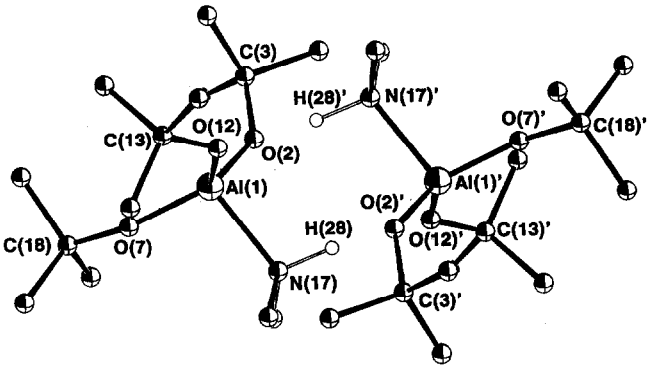

Fig. 1. An ORTEP drawing of one of the hydrogen-bonded (H(28)---O(2)′) centrosymmetric dimers found in the unit cell of $Al(OBu^t)_3(HNMe_2)$. Selected distances (Å) are: Al(1)—O(2), Al(1)—O(7), Al(1)—O(12) and Al(1)—N(17) = 1.711(2), 1.699(2), 1.744(2) and 1.977(3) and the angles (°) at Al(1) involving O(2) to O(7), —O(12) and —N(17) are 120.7(1), 114.4(1) and 98.0(1) and O(7) to O(12), —N(17) are 113.8(1) and 103.4(1), respectively.

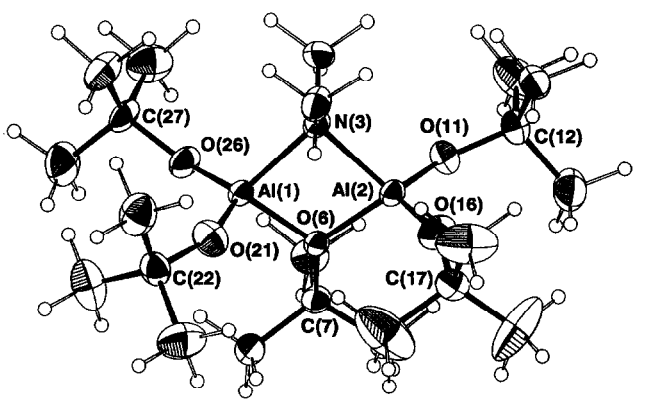

Fig. 2. An ORTEP drawing of the $Al_2(NMe_2)(OBu^t)_5$ molecule. Selected bond distances (Å) and angles (°) are: Al(1)—N(3), Al(1)—O(6), Al(1)—O(21), Al(1)—O(26) = 1.942(4), 1.819(3), 1.676(4), 1.690(4); Al(2)—N(3), Al(2)—O(6), Al(2)—O(11), Al(2)—O(16) = 1.943(4), 1.823(3), 1.697(3) and 1.671(3); O(6)—Al(1)—N(3) = 84.3(1), O(6)—Al(2)—N(3) = 84.2(1), Al(1)—O(6)—Al(2) = 98.8(1) and Al(1)—N(3)—Al(2) = 90.9(2).

the signals associated with $HNMe_2$ and $Al_2(OBu^t)_6$ are quite distinct. Thus it appears that $Al(OBu^t)_3(HNMe_2)$ is the kinetic product of the alcoholysis reaction involving $Al_2(NMe_2)_6$ and tert-BuOH, and $Al_2(OBu^t)_6$ is the thermodynamic product.

A plausible explanation of the above seemed to be that $Al(OBu^t)_3(HNMe_2)$ had a memory of the last step in the alcoholysis reaction, namely the alcoholysis of a bridged compound of formula $Al_2(\mu\text{-}NMe_2)_2(OBu^t)_4$. This notion led us to examine the alcoholysis reaction by both NMR tube experiments at low temperatures and also on the bench top with varying equivalents of added Bu^tOH. From these studies it became apparent that there is a kinetically persistent intermediate in the formation of $Al(OBu^t)_3(HNMe_2)$ but it is $Al_2(\mu\text{-}NMe_2)(\mu\text{-}OBu^t)(OBu^t)_4$ and not $Al_2(\mu\text{-}NMe_2)_2(OBu^t)_4$. $Al_2(NMe_2)(OBu^t)_5$ is the major product of the reaction between $Al_2(NMe_2)_6$ and Bu^tOH (4–5 equiv), and is present for considerable periods (2–6 h) in the presence of an excess of Bu^tOH at room temperature. $Al_2(NMe_2)(OBu^t)_5$ was crystallized from toluene at −15°C. The presence of the bridging NMe_2 and OBu^t ligands, inferred from ^1H NMR data,* was confirmed by the single crystal X-ray determination† (see Fig. 2).

Thus the kinetically slow alcoholysis step

* See footnote † on page 253.

† See footnote ‡ on page 253.

involves the replacement of the bridging NMe_2 ligand in $Al_2(NMe_2)(OBu^t)_5$. This must surely yield 1 equiv of $Al(OBu^t)_3(HNMe_2)$ and a reactive fragment $Al(OBu^t)_3$, which under reaction conditions reacts preferentially with liberated $HNMe_2$ present in solution rather than dimerizing to form $Al_2(OBu^t)_6$, the thermodynamic product.

Alcoholysis reactions involving the less sterically demanding alcohols, cyclohexanol and isopropanol are kinetically more labile and do not reveal such insight into the related steps of NMe_2 for OR substitution. The anticipated dimeric structure of $Al_2(OBu^t)_6$ has been confirmed by a single crystal X-ray structure and will be reported in a full account of this work.

STRUCTURAL AND SPECTROSCOPIC CHARACTERIZATION OF THE COMPOUNDS $[Al(NMe_2)_3]_2$, $[Ga(NMe_2)_3]_2$, $[(Me_2N)_2Al\{\mu\text{-}N(H)1\text{-}Ad\}]_2$ (1-Ad = 1-ADAMANTANYL) AND $[\{Me(\mu\text{-}NPh_2)Al\}_2NPh(\mu\text{-}C_6H_4)]$

K. M. WAGGONER, M. M. OLMSTEAD and P. P. POWER*

Department of Chemistry, University of California, Davis, CA 95616, U.S.A.

Abstract—The compounds $[Al(NMe_2)_3]_2$ (**1**), $[Ga(NMe_2)_3]_2$ (**2**), $[(Me_2N)_2Al\{\mu\text{-}N(H)1\text{-}Ad\}]_2$ (**3**) and $[\{Me(\mu\text{-}NPh_2)Al\}_2NPh(\mu\text{-}C_6H_4)]\cdot 0.5PhMe$ (**4**) have been structurally and spectroscopically characterized by X-ray crystallography, ^1H, ^{13}C, ^{27}Al, ^{69}Ga and ^{71}Ga NMR. A new synthesis is also provided for the previously known compound **1**. The structures of **1** and **2** are the first reported structures of tris-dialkylamides of aluminium or gallium. Both possess dimeric structures in the solid with dimethylamide bridges and distorted tetrahedral geometry at the metal. The terminal $-NMe_2$ groups display significant deviation from planarity in both compounds. The transamination reaction between **1** and 1 equiv. of 1-$AdNH_2$ affords **3** in high yield. The compound **4** was synthesized by treatment of $AlMe_3$ with 2 equiv. of $HNPh_2$ in refluxing toluene. The *ortho*-metallated product, **4**, is somewhat surprising in view of the prior synthesis of $Al(NPh_2)_3$ via a similar reaction. Crystal data at 130 K with Mo-K_α ($\lambda = 0.71069$ Å) radiation are as follows; **1**, triclinic, $a = 7.224(3), b = 8.545(3), c = 8.792(3)$ Å, $\alpha = 61.61(2), \beta = 85.02(3), \gamma = 88.76(3)°$, $Z = 1$, space group $P\bar{1}$, $R = 0.041$; **2**, triclinic, $a = 7.306(4)$, $b = 8.514(4)$, $c = 8.809(4)$ Å, $\alpha = 61.11(3), \beta = 85.13(4), \gamma = 89.14(4)°$, space group $P\bar{1}$, $Z = 1$, $R = 0.035$; **3**, monoclinic, $a = 8.420(5)$, $b = 18.487(6)$, $c = 10.319(5)$ Å, $\beta = 108.44(4)°$, space group $P2_1/c$, $Z = 2$, $R = 0.047$; **4**, monoclinic, $a = 16.069(6)$, $b = 13.053(5)$, $c = 16.424(4)$ Å, $\beta = 97.57(2)°$, space group $P2_1/c$, $Z = 4$, $R = 0.066$.

Compounds involving Al—N bonds have been studied for many years.[1,2] Although they are of interest in their own right they have also attracted attention because of their possible applications in catalysis,[3] as reducing agents[4] and as synthetic intermediates.[5] More recently they have engendered interest as precursors for a low temperature route to aluminium nitride.[6] Currently, aluminium amides (aminoalanes) constitute, perhaps, the most important class of Al—N compounds although the related iminoalanes $(RAlNR')_n$ display a wider variety of interesting structures whose chemistry has only been partially developed.[7,8] The structures of aluminium amides have also attracted considerable attention. A characteristic feature of most of the structures reported to date is their association through bridging of the amide ligands.[1,2] In spite of this interest there are a number of classes of aluminium amides of fundamental importance which have not been adequately characterized and on which more information, expecially structural, is desirable. For example, there are no data currently available for monomeric aminoalanes of formula $R_2AlNR'_2$. These compounds are isoelectronic to the corresponding B—P and Si—C multiply bonded compounds $R_2PBR'_2$[9] and $R_2SiCR'_2$[10] which are of considerable current interest. In addition, the number of structurally characterized trisamide derivatives of Al or the heavier main group III congeners is very few. For example, there is only one instance of a structurally characterized trisamide of Al,[11] Ga,[12] In[12] or Tl.[13]

In this paper, we report the structural characterization of compounds $[M(NMe_2)_3]_2$ (M = Al **1**, M = Ga **2**), $[(Me_2N)_2Al\{\mu\text{-}N(H)1\text{-}Ad\}]_2$ (**3**) and $[\{Me(\mu\text{-}NPh_2)Al\}_2NPh(\mu\text{-}C_6H_4)]\cdot 0.5$ PhMe (**4**). The unusual *ortho*-metallated compound **4** was synthesized during the alkane elimination reaction between 2 equiv. of $HNPh_2$.

EXPERIMENTAL

General procedures

All reactions were performed using modified Schlenk techniques under an inert atmosphere of N_2. Solvents were freshly distilled from drying agents and degassed before use. $HNMe_2$ (Matheson), $HNPh_2$, H_2N(1-Ad), $AlCl_3$, $AlMe_3$ (Aldrich) and $GaCl_3$ (Strem) were used as received. $LiNMe_2$ was synthesized by the passage of dry $HNMe_2$ through *n*-BuLi (0.8 M) in hexane and isolation of the precipitated $LiNMe_2$ by filtration. NMR data were recorded in C_6D_6 solution on a General Electric QE-300 spectrometer. All compounds gave satisfactory C, H and N analysis.

Preparation of $[Al(NMe_2)_3]_2$ (**1**)[14] *and* $[Ga(NMe_2)_3]_2$ (**2**).[15] A hexane (40 cm^3) slurry of $LiNMe_2$ (30 mmol, 1.53 g) was added slowly, with stirring, to a cooled (ice bath) hexane (40 cm^3) solution of $AlCl_3$ (10 mmol, 1.33 g). The reaction mixture was allowed to warm to room temperature and stirred for a further 10 h. After filtration the solution was concentrated under reduced pressure to a volume of *ca* 20 cm^3. Cooling in a $-20°C$ freezer afforded **1** as colourless crystals. Yield, 1.28 g, 80.5%. M.p. = 88–89°C (ref. 14 = 87–89°C). ^1H NMR:[14] $\delta = 2.34$ (s, μ-NMe_2), 2.68(s); ^{13}C NMR: $\delta = 41.98$, 42.2 (μ-NMe_2); ^{27}Al NMR: $\delta = 107$ ($\nu_{1/2} = 840$ Hz).

$[Ga(NMe_2)_3]_2$ was synthesized in an identical manner as described in the literature[15] to afford the product as colourless crystals. Yield, 1.6 g, 79.6%. M.p. 90–91°C (ref. 15 = 90–92°C). ^1H NMR:[15] $\delta = 2.46$ (s, μ-NMe_2), 2.84(s); ^{13}C NMR: $\delta = 43.97$, 44.35 (μ-NMe_2); ^{69}Ga NMR: $\delta = 274$ ($\nu_{1/2} = 29000$ Hz); ^{71}Ga NMR: $\delta = 276$ ($\nu_{1/2} = 8400$ Hz).

Preparation of $[(Me_2N)_2Al\{\mu\text{-}N(H)1\text{-}Ad\}]_2$ (**3**). A toluene (30 cm^3) solution of H_2N(1-Ad) (0.3 g, 2 mmol) was added to a toluene (20 cm^3) solution of **1** (2 mmol, 0.318 g). The mixture was then refluxed for 18 h. The solution was slowly (over 4 h) allowed to cool to room temperature whereupon colourless crystals of the product, **3**, were observed to form. Yield, 0.36 g, 68%. M.p. dec. slowly > 350°C. ^1H NMR: $\delta = 0.3$ (s, tentative NH), $\delta = 1.9$ (complex multiplets due to 1-Ad group), $\delta = 2.75$ (s, NMe_2); ^{13}C NMR: $\delta = 30.55$, 36.54, 41.41, 45.30 (complex pattern owing to 1-Ad and NMe_2 groups); ^{27}Al NMR was not observed owing to poor solubility of **3** in C_6D_6.

Preparation of $[\{Me(\mu\text{-}NPh_2)Al\}_2NPh(\mu\text{-}C_6H_4)]\cdot 0.5PhMe$ (**4**). A toluene solution (30 cm^3) of $HNPh_2$ (10 mmol, 1.69 g) was added to a toluene (20 cm^3) solution of $AlMe_3$ (5 mmol, 2.5 cm^3 of a 2 M $AlMe_3$ solution in toluene). The mixture was then refluxed for 18 h. Upon cooling the solution was concentrated under reduced pressure to incipient crystallization. Filtration followed by cooling overnight in a $-20°C$ freezer afforded the product **4** as colourless crystals. Yield, 2.46 g (4.19 mmol), 83.7%. M.p. = 201–202°C. ^1H NMR: $\delta = -0.3$ (s, μ-AlMe), $\delta = 0.12$ (s, AlMe), $\delta = 1.8$ (s, Me, PhMe), $\delta = 5.78$–7.32 (complex multiplets); ^{13}C NMR: complex series of peaks observed between $\delta = 113.6$ and 136.86; ^{27}Al NMR: $\delta = 152$ ($\nu_{1/2} = 16000$ Hz).

X-ray crystallography

All X-ray data were collected on a Syntex $P2_1$ diffractometer equipped with a graphite monochromator and a locally modified LT-1 device for low temperature work. Important crystallographic parameters and refinement data are provided in Table 1. An omega scan method was used as described in ref. 16. Crystallographic programs used were those of SHELXTL, Version 5, installed on a Data General Eclipse computer. Scattering factors were from common sources.[17] An absorption correction was applied by using the method described in ref. 18. Final refinement was carried out using an isotropic thermal parameter for all non-hydrogen atoms and a riding model for the inclusion of hydrogen atoms in which the hydrogen isotropic thermal parameters were set at 1.2 times those for the bonded carbon. All compounds were coated with a layer of hydrocarbon oil upon removal from the Schlenk tube. A suitable crystal was selected, attached to a glass fibre with silicone grease and immediately placed in the low temperature nitrogen stream. The important metric features of **1**–**4** are provided in Table 2.

RESULTS

The compounds **1** and **2** were synthesized in excellent yields by treatment of the metal trihalide with three equivalents of $LiNMe_2$. The novel compound **3** was obtained in high yield by the transamination reaction between H_2N(1-Ad) with **1**. The *ortho*-metallated compound **4** was synthesized by treatment of $AlMe_3$ with 2 equiv. of $HNPh_2$.

Description of the structures of **1**–**4**

Drawings of structures **1** and **2** are presented in Figs 1 and 2. Important bond distances and angles for **1** and **2** are provided in Table 2. The compounds are isomorphous and they have very similar centrosymmetric, dimeric structures with dimethyl-

amide bridges. The metals possess a distorted tetrahedral coordination with the angles at the metal varying from 88.2(1) to 114.9(1)° in **1** and from 87.7(1) to 117.2(1)° in the case of **2**. The terminal and bridging Al—N distances average 1.802(2) and 1.965(2) Å, and the corresponding Ga—N bond lengths average 1.855(4) and 2.013(3) Å. The M_2N_2 cores display only minor distortions from perfectly square configurations. In both **1** and **2** the N—C distances in the bridging -NMe_2 groups are 0.03–0.04 Å longer than they are in the terminal groups. In addition, the angle between the normals to the NC_2 planes in the terminal -NMe_2 groups is 74.8° in **1** and 73.8° in **2**. The terminal -NMe_2 groups display small but significant distortions from planarity that are greatest in the gallium species. The sum of the nitrogen angles in the terminal-NMe_2 groups in **1** are: N(2) = 356.4°,

						C(2)—C(1)—N(1)	117.9(4)

N(3) = 358.8° and in **2** they are 350.2 and 357.5°. Thus, N(2) and N(3) deviate 0.172 and 0.065 Å from the AlC(4)C(5) and AlC(5)C(6) planes and in the gallium compound the corresponding deviations are 0.288 and 0.145 Å. The Al···Al separation is 2.822 Å; the Ga···Ga distance is significantly greater at 2.902 Å.

The structure of **3** is illustrated in Fig. 3. It has many similarities to that of **1**. The molecule possesses an inversion centre with bridging -N(H)1-Ad ligands. The coordination of the aluminium is distorted tetrahedral with the angles at the metal varying from 85.3(1) to 120.2(2)°. The terminal Al—N distances average 1.793(4) Å and the bridging bond lengths average 1.948(3) Å. The internal angles in the Al_2N_2 core are 85.3(1)° at aluminium and 94.7(1)° at nitrogen. The angle between the normals to the NC_2 in the terminal -NMe_2 group is 72°. The Al···Al separation is 2.864 Å.

The structure of **4** comprises a central $\{AlMe(\mu\text{-}NPh_2)\}_2$ core in which one of the aluminiums is also bonded to a terminal -NPh_2 group which in turn is linked to the remaining Al through an Al—C bond to one of its *ortho*-carbons. The structure includes a half molecule of toluene packed around an inversion centre. The presence of this molecule was confirmed by ^1H NMR data. Important bond distances and angles are provided in Table 2, and the structure is illustrated in Fig. 4. Both aluminiums possess distorted tetrahedral configurations. However, Al(1) differs from Al(2) in that it is bound to three nitrogens and one carbon whereas Al(2) is bonded to two nitrogens and two carbons. Within the central Al_2N_2 core the Al—N distances average 1.994(4) Å. However, the Al(1)—N distances are marginally shorter than the Al(2)—N bonds. The terminal Al(1)—N(1) distance is 1.842(4) Å. The

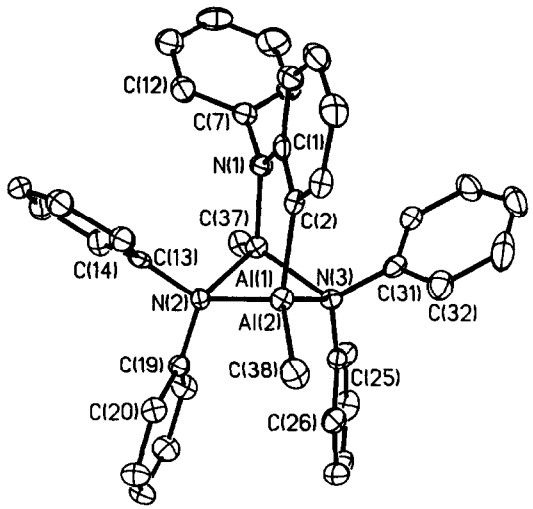

Fig. 4. Structure of $[\{Me(\mu\text{-}NPh_2)Al\}_2NPh(\mu\text{-}C_6H_4)]$ (**4**).

two Al—C(methyl) bonds are 1.947(4) Å for Al(1) and 1.954(4) Å for Al(2) and the Al(2)—(C)phenyl distance, 1.955(4) Å, is not statistically different. The Al_2N_2 core is non-planar and there is a distance of 0.3 Å between the Al(1)···Al(2) and N(2)···N(3) vectors. The atoms Al(1), N(1), C(1), C(2), Al(2) are virtually coplanar, and this plane, which includes the C(1) phenyl ring, is almost perpendicular (88.7°) to the N(2)···N(3) vector. There are large asymmetries in the angles at N(2) and N(3). For example, C(13)—N(2)···N(3) and C(31)—N(3)···N(2) angles average 147.6° whereas the C(19)—N(2)···N(3) and C(25)—N(3)···N(2) angles average 103.3°. In other words the (phenyl) C—N···N angles on the side of the *ortho*-metallated $N(Ph)C_6H_4$ group are more open by about 34°.

DISCUSSION

The X-ray crystal structures of **1** and **2** represent, apparently, the first structures of neutral tris-dialkylamides of aluminium and gallium. Both compounds **1** and **2** have been known for a number of years. However, the only other triamides of aluminium or gallium that have been structurally characterized are the bulky silylamide derivatives $M[N(SiMe_3)_2]_3$ (M = Al[11] or Ga[14]). These are monomeric, whereas both **1** and **2** are dimeric. The difference in structure is presumably due to the difference in size between $-NMe_2$ and $-N(SiMe_3)_2$. The ready availability of the acceptor *p*-orbitals and the relatively large size of both aluminium and gallium encourage dimerization in the case of the $-NMe_2$ ligand. On the other hand, in the case of the smaller boron atom a monomeric structure is observed for $B(NMe_2)_3$.[19] Longer N—C distances are observed in the bridging $-NMe_2$ groups presumably because of the change in hybridization from sp^2 to sp^3. The M—N bond lengths for $Al[N(SiMe_3)_2]_3$[11] and $Ga[N(SiMe_3)_2]_3$[12] are 1.78(1) and 1.857(8) Å, respectively. These distances are comparable to the terminal M—N bonds found in **1** and **2**. Longer M—N bonds would have been expected in the latter owing to the higher coordination number of the metal. It has been argued that the bond distances in the trisilylamide complexes are lengthened somewhat owing to the large size of these groups. Another explanation for the longer bonds concerns the silyl nitrogen substituents. In the case of these ligands, N⇄Si bonding competes with and may reduce N⇄M bonding. These arguments may have some validity since it appears that the bridging lengths in **1** and **2** are relatively normal when compared to other four-coordinate aluminium and gallium compounds containing the $-NMe_2$ group. For example, the bridging Al—N bonds in the dimer $(Cl_2AlNMe_2)_2$ are 1.961(6) Å long.[20] In $(Me_2AlNMe_2)_2$ they are 1.955 Å[21] and in the trimer $(H_2AlNMe_2)_3$[22] they are a little shorter at 1.93 Å. Similar observations are possible in the case of the gallium species **2**. However, the structure of the closely related $(H_2GaNMe_2)_2$[23] gives a Ga—N bond length of 2.027(4) Å which is very close to the value observed in **2**. The geometry of the terminal ligands in **1** and **2** is also of significant interest. All the terminal nitrogens show deviation from planarity and this is a rare phenomenon in metal amide chemistry. It has not, to our knowledge, been well established in other main group metal $-NMe_2$ derivatives.[23] Some non-planarity at nitrogen has however been observed in certain phosphorus amides and in geometrically restricted ligand systems.[24] It is notable that the greater deviation is observed in the gallium compound. It is thus arguable that the more diffuse *d*-orbitals in gallium may not participate in N→M interactions to as great an extent as those in the aluminium compound. This reduction might lead to the observed differences in pyramidicity. An alternative explanation is that the barriers to deformation of the nitrogen centres are small (cf. low inversion of NH_3) and crystal packing effects may give rise to the small deviations that are observed.

The reaction between **1** and 1 equiv. of H_2N(1-Ad) gives an excellent yield of the transaminated product **3**. The -N(H)1-Ad groups were observed exclusively in the bridging position and in a *trans*-configuration. A consequence of the asymmetric substitution of the bridging nitrogen atom is the tilting of the AlN(2)N(3) plane by 9.3° from the perpendicular relative to the AlN(1)Al′N(1)′ core. The tilt is, as expected, toward the least crowded (N—H) groups on both sides of the Al_2N_2 plane. The reasons for the preference of the -N(H)1-Ad ligand for the bridging position are not clear. However, it may be that the basicity of the -N(H)1-Ad ligand is greater than that of the $-NMe_2$ group and is more likely to bridge for that reason. It is unlikely that steric effects play a major role since apparently the $-NMe_2$ group readily behaves as a bridging ligand without undue steric crowding as observed in **1** and **2**. It is also perhaps noteworthy that the aluminiums are further apart in **3** than they are in **1** which is suggestive of slightly greater crowding in **3**.

The compound **4** was obtained as a somewhat unexpected product from the reaction of $AlMe_3$ with 2 equiv. of $HNPh_2$. Moreover, the product **4** is the major one from this reaction. Compounds related to **4** which have already been reported in the literature are $Al(NPh_2)_3$,[14(b)] $Al_2Me_5(\mu\text{-}NPh_2)$ **(5)**[25] and $(Me_2AlNPh_2)_2$.[26] All were synthesized by alkane elimination using various aluminium alkyls. However, no *ortho*-metallated products were observed in any of these cases. To our knowledge only one aluminium compound involving *ortho*-metallation of an $-NPh_2$ has been reported. This is the species $Cl_2AlN(Ph)(\mu\text{-}C_6H_4)Al(Cl)N(Ph)(\mu\text{-}C_6H_4)Al(Cl)NPh_2$ which was characterized on the basis of Raman and ^1H NMR spectroscopy.[27] The compound **5** has been characterized by X-ray crystallography and has an interesting dimeric structure with both a methyl and a $-NPh_2$ bridge. The complex **4** also possesses a dimeric structure and, owing to the different coordination of each aluminium, there is asymmetry in the bond distances and angles in the Al_2N_2 core. The Al(1) centre bonded to three nitrogens and one carbon has the longer bonds

owing perhaps to its greater electron density. For example, the terminal Al(1)—N(1) distance in **4** is 1.842(4) Å whereas in **1** and **3** they are about 1.8 Å long. The bridging Al—N bonds in **4** are also marginally longer than they are in **1** or **3**. Surprisingly, the three Al—C bonds have almost equal lengths even though a shorter Al(2)—C(2) bond might have been predicted on the basis of the sp^2 hybridization at carbon. Another interesting feature of this structure is that the C—C bonds in the C(1) phenyl ring are, on average, longer than those in the other five phenyl rings. There is also some evidence for an alternating pattern in the C—C ring distances suggesting some lessening of delocalization in the *ortho*-metallated ring. Although this is consistent with the somewhat lengthened average C—C bond length, it is difficult to account for this phenomenon in terms of any multiple bonding with aluminium since this bond is not unusually short.

POLY(PYRAZOLYL)HYDROBORATO AND POLY(PYRAZOLYL)METHANE ALUMINIUM ALKYL DERIVATIVES

ADRIAN LOONEY and GERARD PARKIN*

Department of Chemistry, Columbia University, NY 10027, U.S.A.

Abstract—Bis- and tris(pyrazolyl)hydroborato aluminium methyl derivatives, $\{\eta^3$-HB(3,5-$Me_2pyz)_3\}Al(CH_3)_2$, $\{\eta^2$-HB(3-$Bu^tpyz)_3\}Al(CH_3)_2$ and $\{\eta^2$-H_2B(3-$Bu^tpyz)_2\}Al(CH_3)_2$ have been prepared by metathesis of $Al(CH_3)_3$ with either $K\{HB(3,5\text{-}Me_2pyz)_3\}$, $Tl\{HB(3\text{-}Bu^tpyz)_3\}$ or $K\{H_2B(3\text{-}Bu^tpyz)_2\}$, respectively. In contrast to the formation of these 1 : 1 complexes, the isostructural but neutral ligand $HC(pyz)_3$ readily coordinates three equivalents of $(CH_3)_3Al$ giving $\{HC(pyz)_3\}[Al(CH_3)_3]_3$. ^1H NMR studies provide evidence for the formation of the mono- and bis-complexes $\{HC(pyz)_3\}[Al(CH_3)_3]$ and $\{HC(pyz)_3\}[Al(CH_3)_3]_2$ as products of the reaction of $HC(pyz)_3$ with less than three equivalents of $Al(CH_3)_3$. The aluminium–carbon bonds of $\{\eta^3$-HB(3,5-$Me_2pyz)_3\}Al(CH_3)_2$ are readily cleaved by H_2O to give $\{\eta^3$-HB(3,5-$Me_2pyz)_3\}Al(OH)_2$ and CH_4. However, the reaction of $\{\eta^3$-HB(3,5-$Me_2pyz)_3\}Al(CH_3)_2$ with D_2O gives CH_4 in addition to CH_3D and thus demonstrates that a secondary process involving coupling of the aluminium–methyl ligand with one of the hydrogen atoms of the pyrazolyl methyl group must be competitive with the direct reaction of the aluminium–carbon bond with D_2O. The complex $\{\eta^2$-H_2B(3-$Bu^tpyz)_2\}Al(CH_3)_2$ undergoes a unimolecular rearrangement of the bis(3-t-butylpyrazolyl)hydroborato ligand to give the more stable isomer, $\{\eta^2$-H_2B(3-Bu^tpyz)(5-Bu^tpyz)$\}Al(CH_3)_2$. The kinetics of this rearrangement are first-order with the activation parameters $\Delta H^\ddagger = 34.5(8)$ kcal mol^{-1} and $\Delta S^\ddagger = 6(2)$ e.u. and the proposed mechanism consists of steps involving a 1,2-shift of the t-butylpyrazolyl group.

There has been a long-standing interest in aluminium alkyl derivatives which has stemmed from their importance as co-catalysts in the Ziegler–Natta polymerization of olefins[1] and also as reagents in organic synthesis.[2] More recently, these derivatives have shown promise for producing thin films of pure metal by chemical vapour deposition,[3] thus providing a means of forming conductive contacts on silicon-based devices.[4] Furthermore, aluminium alkyl derivatives have also found use as precursors in the controlled synthesis of materials, e.g. aluminium nitride ceramics.[5] A detailed understanding of the structures of organoaluminium derivatives and the mechanisms of their transformations at the molecular level is critical if these processes are to be truly controlled. In this respect, the coordination chemistry of aluminium alkyls with multidentate macrocyclic and non-macrocyclic nitrogen, oxygen and sulphur ligands is an area of considerable current interest. Alkylaluminium derivatives of these ligands are frequently complex molecules that are either oligomeric or multinuclear, in which each of the donor sites coordinates to an individual aluminium centre. For example, coordination of macrocyclic amines, crown ethers and crown thioethers to $Al(CH_3)_3$ results in the formation of complex mono-, bis-, tris- and tetrakis(trimethylaluminium) derivatives, e.g. $[Al(CH_3)_3][12]aneS_4$,[6] $[Al(CH_3)_3]_4[12]aneS_4$,[7] $[Al(CH_3)_3]_4[14]aneN_4Me_4$,[8] $[Al(CH_3)_3]_2$[dibenzo-18-crown-6],[9] $[Al(CH_3)_3]_3$[dibenzo-18-crown-6],[10] $[Al(CH_3)_3]_4$[18-crown-6],[10] $[Al(CH_3)_3]_4$[15-crown-5],[9] $[Al(CH_3)_3]_2$[12-crown-4],[11] $[Al(CH_3)_3]_2$[dicyclohexyl-18-crown-6][12] and $[Al(CH_3)_3][14]aneS_4$[13] and also a variety of more unusual complexes, e.g. $[Al(CH_3)]_2[C_{10}H_{20}N_4][Al(CH_3)_3]_2$, $[(CH_3)_2AlCl]_2[Al\cdot C_{10}H_{20}N_4][Al(CH_3)_2]$ and $[Al(CH_3)][C_8H_{19}N_4][Al(CH_3)_2]$.[14] Thus, chelation of multidentate ligands to a *single* aluminium alkyl centre is rather rare, of which the macrocyclic phthalocyanine derivatives $Al(C_{22}H_{23}N_4)(CH_2CH_3)_2$ and $Al(C_{22}H_{22}N_4)(CH_2CH_3)$[15] and the non-

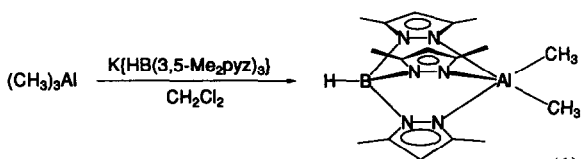
macrocyclic tetradentate Schiff-base* complexes Al(SALEN)(C_2H_5), Al(SALOPHEN)(C_2H_5), Al(SALPN)(C_2H_5), Al(ACEN)(C_2H_5) and Al(ACEN)(C_2H_5)$_2$ are examples.[16] We have recently described the synthesis and reactivity of tris(pyrazolyl)hydroboratomagnesium alkyl complexes.[17] In particular, these studies have shown that coordination of the {η^3-tris(pyrazolyl)hydroborato} ligand to magnesium provides well-defined monomeric complexes that are suitable for mechanistic investigations and also exhibit novel reaction pathways. Therefore, we wished to extend these studies to aluminium alkyl derivatives and this paper describes synthetic and mechanistic studies of alkylaluminium complexes containing poly(pyrazolyl)hydroborato and poly(pyrazolyl)-methane co-ligands.

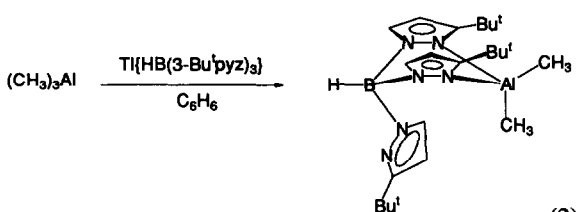
RESULTS AND DISCUSSION

Synthesis of alkyl derivatives

(1) *Preparation of bis- and tris(pyrazolyl)hydroborato aluminium alkyl derivatives.* The tris(pyrazolyl)hydroborato aluminium methyl derivatives {η^3-HB(3,5-Me_2pyz)$_3$}Al(CH_3)$_2$ and {η^2-HB(3-Bu^{t}pyz)$_3$}Al(CH_3)$_2$ are readily prepared by metathesis of Al(CH_3)$_3$ with either K{HB(3,5-Me_2pyz)$_3$},[18] (3,5-Me_2pyz = 3,5-$C_3N_2(CH_3)_2H$) or Tl{HB(3-Bu^{t}pyz)$_3$}[19] (3-Bu^{t}pyz = 3-$C_3N_2Bu^tH_2$), respectively [eqs (1) and (2)]:



(1)



(2)

* SALEN, SALOPHEN and SALPN are the 2 : 1 condensation products of salicylaldehyde with ethylenediamine, *o*-phenylenediamine and propylenediamine, respectively, and ACEN is the 2 : 1 condensation product of acetylacetone with ethylenediamine.

† Calculations have estimated that decomposition of $TlCH_3$ by either disproportionation to thallium and Tl(CH_3)$_3$ or by reductive coupling to give thallium and C_2H_6 are thermodynamically favoured.[20]

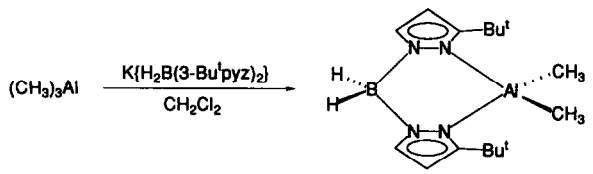
The reaction of (CH_3)$_3$Al with Tl{HB(3-Bu^{t}pyz)$_3$} is also accompanied by the deposition of thallium metal, which is presumably a decomposition product of unstable $TlCH_3$.†

The tris(t-butylpyrazolyl)hydroborato aluminium methyl derivative has been characterized by NMR spectroscopy as the four-coordinate η^2-complex, {η^2-HB(3-Bu^{t}pyz)$_3$}Al(CH_3)$_2$. For example, the ^{1}H NMR spectrum (in benzene-d_6) shows two sets of t-butylpyrazolyl groups (δ 1.26 and 1.53 ppm) in the ratio 2 : 1 and two inequivalent Al—CH_3 groups (δ 0.01 and −0.11 ppm) in the ratio 1 : 1. In contrast, the ^{1}H and ^{13}C NMR spectra (in benzene-d_6) of the tris(3,5-dimethylpyrazolyl) hydroborato aluminium methyl derivative indicate only one environment for both Al—CH_3 and 3,5-dimethylpyrazolyl groups. The Al—CH_3 group is observed at δ −0.05 and −7.1 ppm ($^1J_{C-H}$ = 113 Hz) in the ^{1}H and ^{13}C NMR spectra, respectively. Variable-temperature ^{1}H NMR studies down to *ca* −90°C show no indication of inequivalent pyrazolyl or methyl groups. This data cannot unequivocally distinguish between the structure in solution as five-coordinate {η^3-HB(3,5-Me_2pyz)$_3$}Al(CH_3)$_2$, or highly fluxional four-coordinate {η^2-HB(3,5-Me_2pyz)$_3$}Al(CH_3)$_2$. However, the complex [{η^3-HB(3,5-Me_2pyz)$_3$}$_2$Al][$AlCl_4$] which possesses two {η^3-tris(3,5-dimethylpyrazolyl)hydroborato} ligands has recently been reported[21] and thus provides a precedence for the five-coordinate, η^3-description, i.e. {η^3-HB(3,5-Me_2pyz)$_3$}Al(CH_3)$_2$. Other evidence in favour of the η^3-description of {η^3-HB(3,5-Me_2pyz)$_3$}Al(CH_3)$_2$ is that the structurally characterized four-coordinate gold complex, {η^2-HB(pyz)$_3$}Au(CH_3)$_2$ (pyz = $C_3N_2H_3$), which also exhibits only one pyrazolyl group environment in the ^{1}H NMR spectrum at room temperature, exhibits the fully frozen-out spectrum at −90°C.[22] Thus, if {HB(3,5-Me_2pyz)$_3$}Al(CH_3)$_2$ is four-coordinate in solution, it must possess significantly lower barriers to rearrangement than both {η^2-HB(pyz)$_3$}Au(CH_3)$_2$ and {η^2-HB(3-Bu^{t}pyz)$_3$}Al(CH_3)$_2$. The activation barrier ($\Delta G^{\ddagger}$) for the rearrangement process for {η^2-HB(3-Bu^{t}pyz)$_3$}Al(CH_3)$_2$ has been estimated by magnetization transfer studies to be 17(2) kcal mol^{-1} at 40°C.

The formation of an η^2-complex for the tris(t-butylpyrazolyl)hydroborato derivative, rather than an η^3-complex, is not surprising in terms of the steric demands of the tris(t-butylpyrazolyl)hydroborato ligand. The cone angles of the tris(pyrazolyl) hydroborato ligands {η^3-HB(pyz)$_3$}, {η^3-HB(3,5-Me_2pyz)$_3$} and {η^3-HB(3-Bu^{t}pyz)$_3$} have been estimated. as 184, 224 and 244°C, respectively, and the tris(t-butylpyrazolyl)hydroborato ligand

has been described as effectively restricting a metal to having a maximum coordination number of four.[23]

The related bis(t-butylpyrazolyl)hydroborato complex, $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)_2\}Al(CH_3)_2$, is synthesized by the analogous reaction of $(CH_3)_3Al$ with $K\{H_2B(3\text{-}Bu^tpyz)_2\}$ [eq. (3)]:



(3)

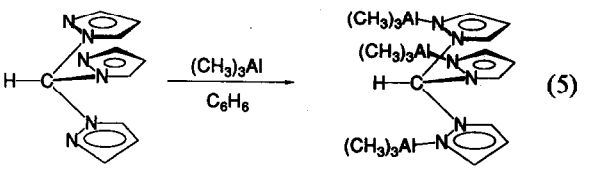
Only one type of Al—CH_3 and t-butylpyrazolyl groups are observed in both the ^1H and ^{13}C NMR spectra of $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)_2\}Al(CH_3)_2$. Thus, the Al—$CH_3$ group is observed at δ −0.06 ppm in the ^1H NMR spectrum (in benzene-d_6) and the t-butylpyrazolyl group appears as a singlet at δ 1.30 ppm, corresponding to the t-butyl substituent, and two doublets at δ 5.83 and 7.39 ppm ($^3J_{H-H}$ = 2.2 Hz), corresponding to the pyrazolyl hydrogens at the four- and five-positions, respectively. Assignment of the pyrazolyl resonances at δ 5.83 and 7.39 has been completed using Nuclear Overhauser enhancement experiments.

^{27}Al NMR has been suggested as a probe for determining the coordination number of aluminium[24] and the ^{27}Al NMR spectra of $\{\eta^3\text{-HB}(3,5\text{-}Me_2pyz)_3\}Al(CH_3)_2$ and $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)_2\}Al(CH_3)_2$ show broad resonances at δ 133 (ω = 5000 Hz) and 140 (ω = 5000 Hz) ppm (relative to $Al(acac)_3$), respectively, with the four-coordinate complex having the slightly larger chemical shift.

$\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)_2\}Al(CH_3)_2$ has also been obtained from the reaction of $(CH_3)_2AlCl$ with $K\{H_2B(3\text{-}Bu^tpyz)_2\}$, thus demonstrating that metathesis of the chloride ligand is favoured over the alkyl ligand [eq. (4)]:

$$(CH_3)_2AlCl \xrightarrow[CH_2Cl_2]{K\{H_2B(3\text{-}Bu^tpyz)_2\}} \{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)_2\}Al(CH_3)_2. \quad (4)$$

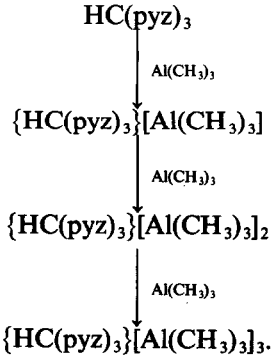
(2) *The reaction of* $(CH_3)_3Al$ *with tris(pyrazolyl) methane.* Treatment of $HC(pyz)_3$[25] with more than three equivalents of $(CH_3)_3Al$ allows the complex $\{HC(pyz)_3\}[Al(CH_3)_3]_3$ to be isolated [eq. (5)]:



(5)

Hence, in contrast to the formation of monomeric mononuclear aluminium alkyl derivatives using poly(pyrazolyl)hydroborato ligands, the isostructural but neutral poly(pyrazolyl)methane ligand readily coordinates to three aluminium alkyl centres.

In order to investigate the formation of mono- and bis(trimethylaluminium) complexes as intermediates in the formation of the tris-adduct, $\{HC(pyz)_3\}[Al(CH_3)_3]_3$, the reaction between $(CH_3)_3Al$ and $HC(pyz)_3$ in benzene-d_6 has been monitored using ^1H NMR spectroscopy at room temperature, as shown in Figs 1 and 2. The spectra have been obtained as a function of the $(CH_3)_3Al:HC(pyz)_3$ molar ratio. The results show that upon increasing the molar ratio of $(CH_3)_3Al:HC(pyz)_3$, there is a smooth shift of the resonances of the hydrogen atoms of the pyrazolyl and methine groups. The tris(pyrazolyl) methane resonances that are most sensitive are those of the methine hydrogen, $HC(pyz)_3$ (i.e. H_a) and the doublet at δ 7.21 in the free ligand (i.e. H_{dorb}), which shift to low and high field, respectively, upon increasing the $(CH_3)_2Al:HC(pyz)_3$ molar ratio. Interestingly, H_{dorb} is relatively insensitive to the concentration of $(CH_3)_3Al$ until the molar ratio of $(CH_3)_3Al:HC(pyz)_3$ reaches *ca* 1 : 1, after which it shifts dramatically to high field (*vide infra*). The shifts of the pyrazolyl resonances are also accompanied by a shift of the resonance of the coordinated $(CH_3)_3Al$ to higher field. These changes in chemical shift level off at a molar ratio of $(CH_3)_3Al:HC(pyz)_3$ of 3 : 1, as shown in Fig. 2. Removal of the solvent (and excess $(CH_3)_3Al$) *in vacuo* from samples containing up to a 3 : 1 molar ratio, followed by redissolving in benzene-d_6 regenerates the original spectrum. However, samples with molar ratios greater than 3 : 1 give spectra corresponding to the 3 : 1 product after performing this procedure. These results demonstrate that $HC(pyz)_3$ may coordinate up to three equivalents of $(CH_3)_3Al$ via the three nitrogen atom donors [eq. (6)]:



(6)

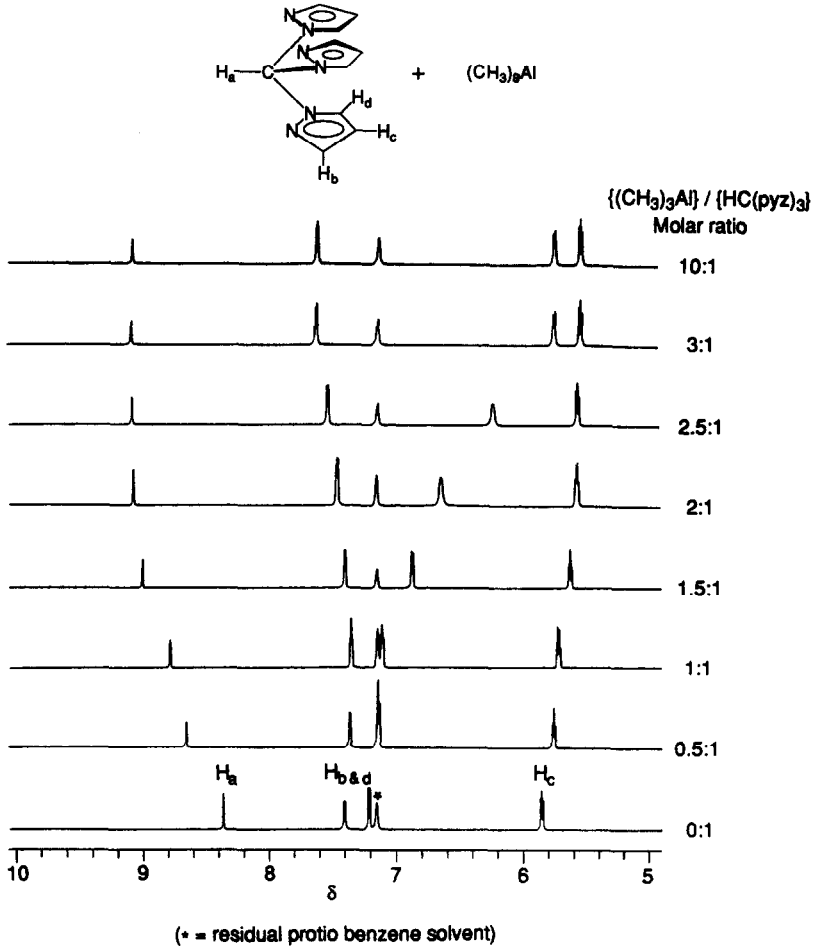


Fig. 1.

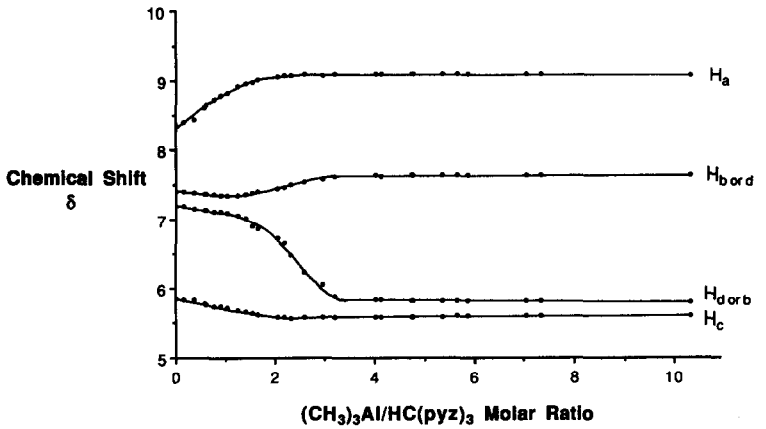

Fig. 2.

The room temperature ^1H NMR spectra of solutions derived from stoichiometric and non-stoichiometric amounts of $HC(pyz)_3$ and $(CH_3)_3Al$ show only one type of pyrazolyl and $(CH_3)_3Al$ environment at each $(CH_3)_3Al:HC(pyz)_3$ molar ratio, thus suggesting that the $(CH_3)_3Al$ is highly mobile and may readily transfer between the mono-, bis- and tris(trimethylaluminium)tris(pyrazolyl)-methane complexes. Although the mono- and bis-complexes cannot be unequivocally observed, the irregular variation of the chemical shifts of the pyrazolyl hydrogens provides evidence for

the existence of such complexes in solution. For example, as shown in Fig. 2, whereas the resonance attributed to $\{HC(pyz)_3\}$ (i.e. H_a) shifts progressively to low field, the pyrazolyl resonance H_{bord} shifts initially to high field until a molar ratio $(CH_3)_2Al:HC(pyz)_3$ of *ca* 1 : 1 is reached, at which point it shifts to low field. Similarly, the pyrazolyl resonance H_{dorb} initially shifts slowly to high field until a molar ratio for $(CH_3)_3Al:HC(pyz)_3$ of *ca* 1 : 1 is reached, at which point the shift to high field is more dramatic. If the solutions contained only the tris-complex $\{HC(pyz)_3\}[Al(CH_3)_3]_3$ and free ligand $HC(pyz)_3$ in rapid exchange, then a regular variation of each of the chemical shifts, H_a, H_{bord}, H_c and H_{dorb}, would have been predicted. These conclusions are supported by the observation that lowering the temperature of a solution of molar ratio $(CH_3)_3Al:HC(pyz)_3$ *ca* 2 : 1 to −60°C results in the broadening of the resonances of the pyrazolyl hydrogens, but unfortunately the low temperature limit was not achieved. Thus, while it is likely that the product of composition, $\{HC(pyz)_3\}[Al(CH_3)_3]_3$, consists of three $(CH_3)_3Al$ units bonded to the three pyrazolyl nitrogen atom donors, for the products $\{HC(pyz)_3\}[Al(CH_3)_3]$ and $\{HC(pyz)_3\}[Al(CH_3)_3]_2$ the data do not permit distinction between chelation, e.g. $\{\eta^3\text{-}HC(pyz)_3\}[Al(CH_3)_3]$ and unidentate coordination, e.g. $\{\eta^1\text{-}HC(pyz)_3\}[Al(CH_3)_3]$.

Reactivity and mechanistic studies

(1) *Reaction of* $\{HB(3,5\text{-}Me_2pyz)_3\}Al(CH_3)_2$ *with* H_2O. The reaction of $\{HB(3,5\text{-}Me_2pyz)_3\}Al(CH_3)_2$ with water results in cleavage of both aluminium–carbon bonds to give the dihydroxy derivative $\{HB(3,5\text{-}Me_2pyz)_3\}Al(OH)_2$ and methane [eq. (7)]. A monohydroxy aluminium complex, $Al(C_{22}H_{22}N_4)OH$, has recently been reported.[15]

$$\{HB(3,5\text{-}Me_2pyz)_3\}Al(CH_3)_2 + 2H_2O \longrightarrow \{HB(3,5\text{-}Me_2pyz)_3\}Al(OH)_2 + 2CH_4. \quad (7)$$

Similarly, the deuteriated comlex $\{HB(3,5\text{-}Me_2pyz)_3\}Al(OD)_2$ may be prepared by the treatment of $\{HB(3,5\text{-}Me_2pyz)_3\}Al(CH_3)_2$ with D_2O. The ^1H NMR spectrum (in benzene-d_6) of $\{HB(3,5\text{-}Me_2pyz)_3\}Al(OH)_2$ possesses a resonance at δ 15.95 ppm which is absent for the complex $\{HB(3,5\text{-}Me_2pyz)_3\}Al(OD)_2$ and is thus assigned to the Al–OH group. A broad IR absorption at *ca* 3300 cm^{-1} (KBr disc) for $\{HB(3,5\text{-}Me_2pyz)_3\}Al(OH)_2$ shifts to *ca* 2380 cm^{-1} for $\{HB(3,5\text{-}Me_2pyz)_3\}Al(OD)_2$ ($\nu_H/\nu_D = 1.4$) and is thus assigned to the AlO–H stretch. The hydrolysis reaction has also been examined using $^{17}OH_2$ (*ca* 45% enriched).

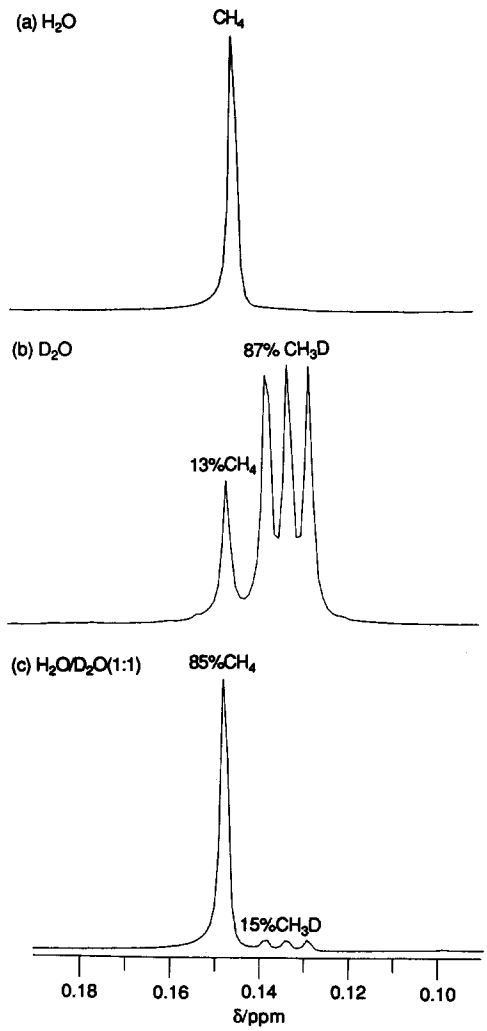

Fig. 3.

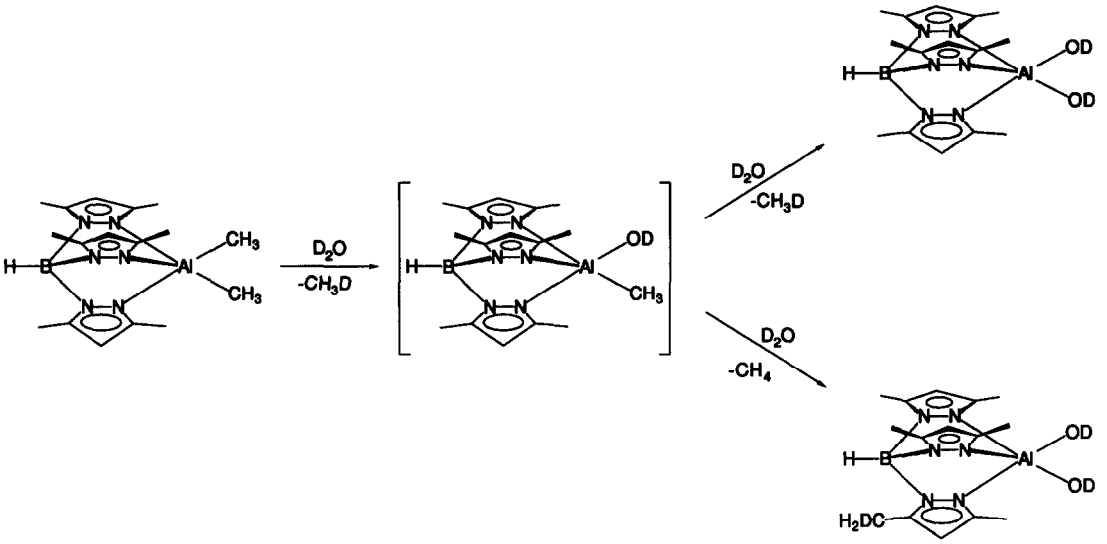
Unfortunately, a ^{17}O NMR resonance could not be observed for the product, presumably as a result of quadrupolar broadening.

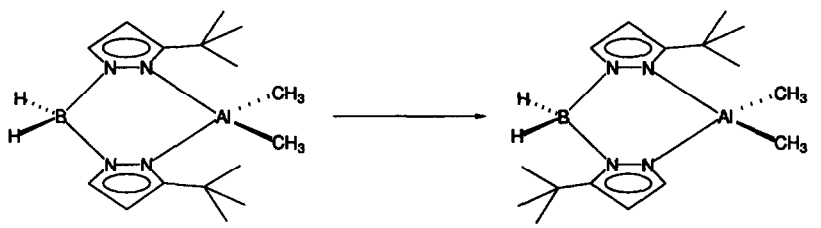
The reaction of $\{HB(3,5\text{-}Me_2pyz)_3\}Al(CH_3)_2$ with D_2O is of particular interest since the methane eliminated is not solely CH_3D, the product of direct attack by D_2O at the Al–C bond. Figure 3 shows the ^1H NMR spectrum (400 MHz, benzene-d_6) of the methane eliminated from (a) $\{HB(3,5\text{-}Me_2pyz)_3\}Al(CH_3)_2$ with H_2O, (b) $\{HB(3,5\text{-}Me_2pyz)_3\}Al(CH_3)_2$ with D_2O (99.8%) and (c) $\{HB(3,5\text{-}Me_2pyz)_3\}Al(CH_3)_2$ with excess of a mixture of $H_2O:D_2O$ (1 : 1 molar ratio). Remarkably, the reaction between $\{HB(3,5\text{-}Me_2pyz)_3\}Al(CH_3)_2$ and D_2O generates significant quantities (*ca* 13%) of CH_4 (Scheme 1). The ^2H NMR spectrum of the product of $\{HB(3,5\text{-}Me_2pyz)_3\}Al(CH_3)_2$ and D_2O was measured in order to determine the source of the extra hydrogen in the CH_4 and demonstrates that one of the methyl groups of the pyrazolyl



Scheme 1.

groups is selectively enriched in deuterium. These results suggest that the formation of CH_4 in the reaction of $\{HB(3,5\text{-}Me_2pyz)_3\}Al(CH_3)_2$ with D_2O may arise by a coupling of the aluminium–methyl ligand with one of the hydrogen atoms of the pyrazolyl methyl group and that this process must be competitive with the direct reaction of the aluminium–carbon bond with D_2O. Although we can not identify which one of the two methyl group substituents is attacked in this manner, a potential mechanism for this competitive formation of CH_4 vs CH_3D is illustrated in Scheme 2, in which abstraction of a hydrogen atom from one of the methyl groups of the tris(3,5-dimethylpyrazolyl)-hydroborato ligand by the Al—CH_3 group occurs. Similar abstractions of hydrogen from ligand methyl groups have been observed in other systems.[26] Models suggest that metallation of one of the dimethylpyrazolyl groups by the aluminium centre would be more favourable after initially dissociating one of the pyrazolyl groups from the aluminium. In view of the competitive elimination of CH_4 in the reaction with D_2O, an upper limit of $k_H : k_D = 5.3$ has been estimated for the kinetic isotope effect for the hydrolysis by examining the ratio of $CH_4 : CH_3D$ eliminated in the reaction with excess $H_2O : D_2O$ (1 : 1 molar ratio).

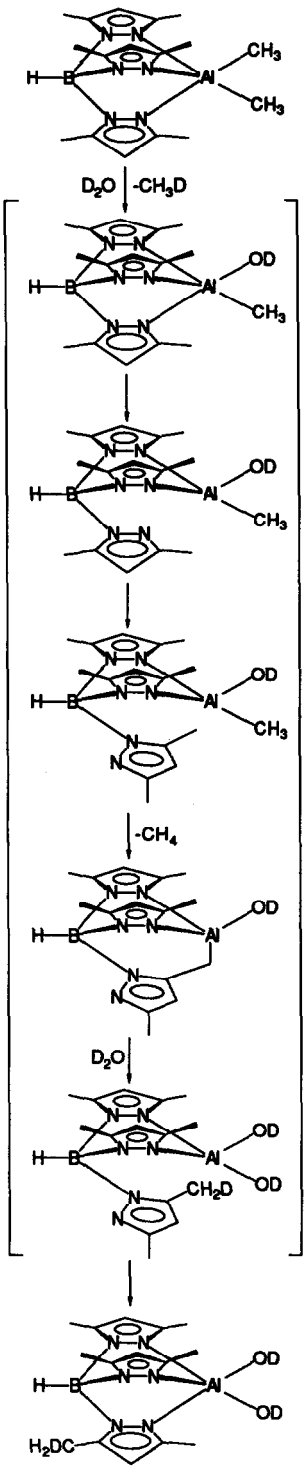
(2) 3,5 *Isomerization of the bis*(3-t-butylpyrazolyl)*hydroborato ligand.* The methyl complex $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)_2\}Al(CH_3)_2$ undergoes a rearrangement of the bis(3-t-butylpyrazolyl)hydroborato ligand upon heating at *ca* 100°C to give the more stable isomer, $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)(5\text{-}Bu^tpyz)\}Al(CH_3)_2$, as shown in eq. (8):



(8)

The ^1H NMR spectrum of the rearranged isomer, $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)(5\text{-}Bu^tpyz)\}Al(CH_3)_2$, in benzene-$d_6$ shows a single resonance at δ −0.01 ppm for the $Al(CH_3)_2$ groups and two sets of resonances for the t-butylpyrazolyl groups. The pyrazolyl hydrogens of each of these t-butylpyrazolyl groups has been identified by nuclear Overhauser enhancement experiments (see Table 1). Although we cannot unequivocally distinguish which set of resonances corresponds to the (3-t-butylpyrazolyl) and (5-t-butylpyrazolyl) groups, comparison with the ^1H NMR spectrum of $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)_2\}Al(CH_3)_2$ suggests that the sets of resonances at δ 1.35, 5.85 and 7.41 and δ 1.22, 5.74 and 7.33 are assigned to the (3-t-butylpyrazolyl) and (5-t-butylpyrazolyl) groups, respectively.

Similar rearrangement processes have also been observed for copper and cobalt complexes of a related ligand system, i.e. $\{\eta^3\text{-}HB(3\text{-}Pr^ipyz)_3\} \rightarrow \{\eta^3\text{-}HB(3\text{-}Pr^ipyz)_2(5\text{-}Pr^ipyz)\}$.[27] A potential mech-



Scheme 2.

anism for this apparent 1,3-migration of the alkyl group (either Bu^t or Pr^i) from the 3-position to the 5-position of the pyrazolyl ring may involve an indirect process involving a 1,2-shift of the boron substituent from N(1) to N(2) [or alternatively of the aluminium substituent from N(2) to N(1)], as shown in Scheme 3.

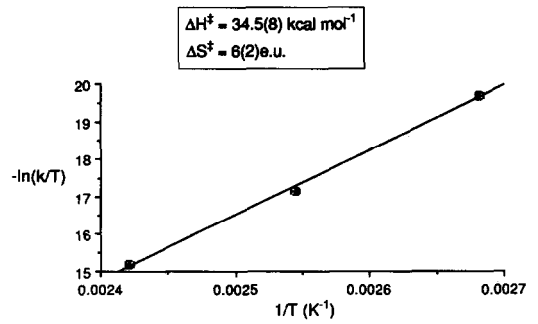


Fig. 4.

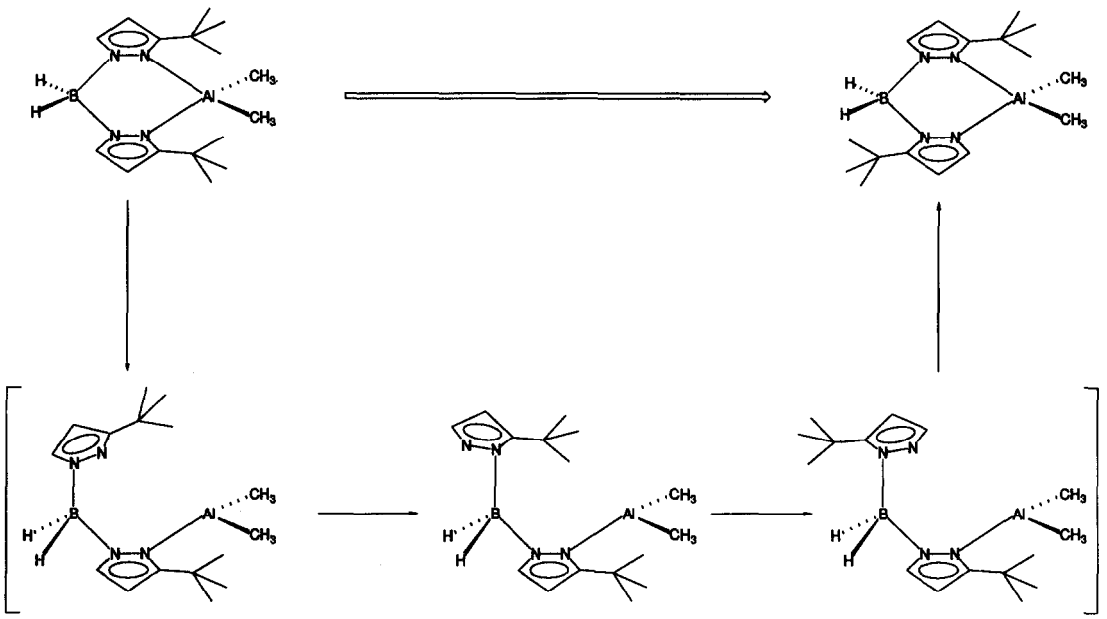
In order to obtain more information about the nature of the above 3,5-rearrangement process, we have examined the kinetics of the transformation of $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)_2\}Al(CH_3)_2$ to $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)(5\text{-}Bu^tpyz)\}Al(CH_3)_2$. The data show that the reaction exhibits first-order kinetics over *ca* 3 half-lives. First-order kinetics have also been confirmed by the observation that the same rate constant (within experimental error) is obtained for solutions of initial concentration 63 and 6.3 mmol. The temperature-dependence of the rate constant has been measured over a 40°C temperature range (Table 2), from which the activation parameters $\Delta H^{\ddagger} = 34.5(8)$ kcal mol^{-1} and $\Delta S^{\ddagger} = 6(2)$ e.u. have been derived (Fig. 4). In particular, the small positive value of $\Delta S^{\ddagger}$ suggests that the transition state is not highly ordered, consistent with the proposed mechanism involving dissociation of one of the pyrazolyl groups.

CONCLUSIONS

Poly(pyrazolyl)hydroborato aluminium methyl derivatives, $\{\eta^3\text{-}HB(3,5\text{-}Me_2pyz)_3\}Al(CH_3)_2$, $\{\eta^2\text{-}HB(3\text{-}Bu^tpyz)_3\}Al(CH_3)_2$ and $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)_2\}Al(CH_3)_2$, have been prepared by metathesis of $Al(CH_3)_3$ with either $K\{HB(3,5\text{-}Me_2pyz)_3\}$, $Tl\{HB(3\text{-}Bu^tpyz)_3\}$ or $K\{H_2B(3\text{-}Bu^tpyz)_2\}$, respectively. In contrast to the formation of these 1 : 1 complexes, the isostructural but neutral ligand $HC(pyz)_3$ readily coordinates up to three equivalents of $(CH_3)_3Al$ giving $\{HC(pyz)_3\}[Al(CH_3)_3]_3$.

The aluminium–carbon bonds of $\{\eta^3\text{-}HB(3,5\text{-}Me_2pyz)_3\}Al(CH_3)_2$ are readily cleaved by H_2O to give $\{\eta^3\text{-}HB(3,5\text{-}Me_2pyz)_3\}Al(OH)_2$ and CH_4. However, the reaction of $\{\eta^3\text{-}HB(3,5\text{-}Me_2pyz)_3\}Al(CH_3)_2$ with D_2O demonstrates that a secondary process involving coupling of the aluminium–methyl ligand with one of the hydrogen atoms of the pyrazolyl methyl group must be competitive with the direct reaction of the aluminium–carbon bond with D_2O.



Scheme 3.

The complex $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)_2\}Al(CH_3)_2$ has been shown to undergo a unimolecular rearrangement of the bis(3-t-butylpyrazolyl)hydroborato ligand to give the more stable isomer, $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)(5\text{-}Bu^tpyz)\}Al(CH_3)_2$. The kinetics of this rearrangement are first-order with the activation parameters $\Delta H^{\ddagger} = 34.5(8)$ kcal mol^{-1} and $\Delta S^{\ddagger} = 6(2)$ e.u. and the proposed mechanism consists of steps involving a 1,2-shift of the t-butylpyrazolyl group.

EXPERIMENTAL

General considerations

All manipulations were performed using a combination of glovebox, high-vacuum or Schlenk techniques.[28] Solvents were purified and degassed by standard procedures. ^1H, ^2H, ^{13}C, ^{17}O and ^{27}Al NMR spectra were measured on Varian VXR 200, 300 and 400 spectrometers. IR spectra were recorded as KBr discs or Nujol mulls on a Perkin–Elmer 1420 spectrophotometer. Elemental analyses were obtained from Galbraith Laboratories, Inc. (Knoxville, Tennessee, U.S.A.) and Desert Analytics (Tucson, Arizona, U.S.A.).

$K\{HB(3,5\text{-}Me_2pyz)_3\}$,[18] $Tl\{HB(3\text{-}Bu^tpyz)_3\}$,[20] $K\{H_2B(3\text{-}Bu^tpyz)_2\}$[18] and $HC(pyz)_3$[25] were prepared as described previously.

Preparation of $\{\eta^3\text{-}HB(3,5\text{-}Me_2pyz)_3\}Al(CH_3)_2$

A solution of $(CH_3)_3Al$ in hexane (2.0 M, 2.5 cm^3, 5 mmol) was added to a stirred suspension of $K\{HB(3,5\text{-}Me_2pyz)_3\}$ (1.0 g, 2.97 mmol) in CH_2Cl_2 (30 cm^3) at room temperature. The $K\{HB(3,5\text{-}Me_2pyz)_3\}$ dissolved and was replaced by a fine white precipitate. The mixture was filtered after 1 h. The solvent was removed from the filtrate under reduced pressure giving $\{HB(3,5\text{-}Me_2pyz)_3\}Al(CH_3)_2$ as a white solid (0.47 g, 45%) which may be recrystallized from toluene. Found: C, 53.5; H, 7.6; N, 22.8. Calc.: C, 57.6; H, 7.9; N, 23.7%. IR data (Nujol mull, KBr plates, cm^{-1}): 2505 (ν_{B-H}).

Preparation of $\{\eta^2\text{-}HB(3\text{-}Bu^tpyz)_3\}Al(CH_3)_2$

$(CH_3)_3Al$ (0.3 cm^3, 3.1 mmol) was added to a solution of $Tl\{HB(3\text{-}Bu^tpyz)_3\}$ (1.0 g, 1.7 mmol) in C_6H_6 at room temperature, giving a black deposit of thallium metal. The mixture was filtered after 15 min. The solvent was removed from the filtrate under reduced pressure giving $\{\eta^2\text{-}HB(3\text{-}Bu^tpyz)_3\}Al(CH_3)_2$ as a white solid (0.36 g, 48%) which may be recrystallized from pentane. Found: C, 55.8; H, 8.7; N, 20.2. Calc.: C, 63.0; H, 9.2; N, 19.2%. IR data (Nujol mull, KBr plates, cm^{-1}): 2465 (ν_{B-H}).

Preparation of $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)_2\}Al(CH_3)_2$

A solution of $(CH_3)_3Al$ in hexane (2.0 M, 6 cm^3, 12 mmol) was added to a solution of $K\{H_2B(3\text{-}Bu^tpyz)_2\}$ (500 mg, 1.7 mmol) in CH_2Cl_2 (80 cm^3) at room temperature giving a fine white precipitate. The mixture was filtered after 10 min. The solvent

Table 2. Rate constants and activation parameters for the isomerization of $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)_2\}Al(CH_3)_2$ to $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)(5\text{-}Bu^tpyz)\}Al(CH_3)_2$

T (K)	k (s^{-1})	$\Delta G^{\ddagger}$ (kcal mol^{-1})
373	$1.04(5) \times 10^{-6}$	32.2(1)
393	$1.40(7) \times 10^{-5}$	32.0(1)
413	$1.04(5) \times 10^{-4}$	32.0(1)

$\Delta H^{\ddagger} = 34.5(8)$ kcal mol^{-1}; $\Delta S^{\ddagger} = 6(2)$ e.u.

was removed from the filtrate under reduced pressure giving $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)_2\}Al(CH_3)_2$ as a white solid (200 mg, 38%). Found: C, 60.0; H, 8.7; N, 17.1. Calc.: C, 60.7; H, 9.6; N, 17.7%. IR data (Nujol mull, KBr plates, cm^{-1}): 2470 (ν_{B-H}).

Reaction of $K\{H_2B(3\text{-}Bu^tpyz)_2\}$ *with* $(CH_3)_2AlCl$

A solution of $(CH_3)_2AlCl$ in hexane (1 M, 0.42 cm^3, 0.42 mmol) was added to a solution of $K\{H_2B(3\text{-}Bu^tpyz)_2\}$ (100 mg, 0.33 mmol) in CH_2Cl_2 (25 cm^3) at room temperature giving a fine white precipitate. The mixture was filtered after 10 min and the solvent was removed from the filtrate under reduced pressure giving $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)_2\}Al(CH_3)_2$ as a white solid (47 mg, 44%) which was identified by ^1H NMR spectroscopy.

Preparation of $\{HB(3,5\text{-}Me_2pyz)_3\}Al(OH)_2$

H_2O (0.02 cm^3, 1.1 mmol) was added to a solution of $\{HB(3,5\text{-}Me_2pyz)_3\}Al(CH_3)_2$ (200 mg, 0.56 mmol) in C_6H_6 (20 cm^3). The solvent was removed from the solution under reduced pressure giving $\{HB(3,5\text{-}Me_2pyz)_3\}Al(OH)_2$ as a white solid (90 mg, 45%). Found: C, 49.6; H, 6.7; N, 22.3. Calc.: C, 50.3; H, 6.8; N, 23.5%. IR data (Nujol mull, KBr plates, cm^{-1}): 3300 (very broad) (ν_{O-H}), 2480 (ν_{B-H}).

Similar procedures were followed for the reactions with D_2O, $H_2{}^{17}O$ and $H_2{}^{18}O$.

The reactions between $\{HB(3,5\text{-}Me_2pyz)_3\}Al(CH_3)_2$ and H_2O and D_2O were also carried out in benzene-d_6 and monitored by ^1H NMR spectroscopy.

Isomerization of $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)_2\}Al(CH_3)_2$ *to* $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)(5\text{-}Bu^tpyz)\}Al(CH_3)_2$

A solution of $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)_2\}Al(CH_3)_2$ (*ca* 50 mg, 0.16 mmol) in benzene (2 cm^3) was heated at 140°C for 1 day. The solvent was removed under reduced pressure giving $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)(5\text{-}Bu^tpyz)\}Al(CH_3)_2$ as a white solid (*ca* 40 mg, 80%).

Kinetics of the rearrangement of $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)_2\}Al(CH_3)_2$ *to* $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)(5\text{-}Bu^tpyz)\}Al(CH_3)_2$

Reactions were followed using ^1H NMR spectroscopy by monitoring the decrease in intensity of the t-butyl resonance of the starting complex, $\{\eta^2\text{-}H_2B(3\text{-}Bu^tpyz)_2\}Al(CH_3)_2$, in benzene-$d_6$ solutions (63 mM and 6.3 mM) in sealed 5 mm NMR tubes. Reaction temperatures were maintained by using temperature baths which were constant to within ± 0.1°C. $\Delta G^{\ddagger}(T)$ was calculated from the Eyring equation, $\Delta G^{\ddagger} = RT\ln(\kappa k_B T/kh)$, assuming a transmission coefficient, κ, of 1. Plots of $\ln(k/T)$ vs $1/T$ were constructed to yield the activation parameters $\Delta H^{\ddagger} = 34.5(8)$ kcal mol^{-1} and $\Delta S^{\ddagger} = 6(2)$ e.u.

Preparation of $\{HC(pyz)_3\}[Al(CH_3)_3]_3$

A solution of $HC(pyz)_3$ (200 mg, 0.93 mmol) in C_6H_6 (20 cm^3) was treated with excess $(CH_3)_2Al$ (1.5 ml, 20.8 mmol). The mixture was filtered after 15 min at room temperature and the solvent was removed under reduced pressure giving $\{HC(pyz)_3\}[Al(CH_3)_3]_3$ as a white solid (260 mg, 65%). IR data (Nujol mull, KBr plates, cm^{-1}): 3140 (ν_{C-H}).

SYNTHESIS AND MOLECULAR STRUCTURE OF A BIS[DI(ALKYL)ALANYL]METHANE; $R_2Al—CH_2—AlR_2$ [R = $CH(SiMe_3)_2$]

MARCUS LAYH and WERNER UHL*

Institut für Anorganische Chemie der Universität Stuttgart, Pfaffenwaldring 55, FRG-7000 Stuttgart 80, F.R.G.

Abstract—Reaction of $Cl_2Al—CH_2—AlCl_2$ with lithium-bis(trimethylsilyl)methyl in *n*-pentane yields $[(Me_3Si)_2CH]_2Al—CH_2—Al[CH(SiMe_3)_2]_2$ (**1**), the first stable organometallic derivative of the starting tetrahalide. The crystal structure of **1** shows monomeric molecules with two trigonal planar coordinated metal atoms. The coordination sphere of the central carbon atom deviates significantly from tetrahedral geometry with an Al—C—Al angle of 129.6°. Further experiments for the synthesis of methylene bridged dialanes were not successful with R = mesityl, *tert*-butyl, tris(trimethylsilyl)methyl and trimethylsilyl.

Organometallic compounds of aluminium which contain a methylene bridge between two aluminium atoms have been isolated and well characterized only for the tetrachloro and tetrabromo derivatives.[1] These compounds are easily synthesized by the reaction of dichloro or dibromo methane with elemental aluminium [eq. (1)] and are potential starting materials for the preparation of the corresponding tetra(alkyl)alanes by metathesis with lithium alkyls. There are, however, only a few and discouraging reports in the literature dealing with such reactions: lithium–methyl or lithium– ethyl[2,3] give products of unknown composition, probably mixtures of the symmetrically substituted tri(alkyl)alanes and oligomeric or polymeric methylene bridged species.[3] Distillation leads to complete decomposition into triorganyls, AlR_3.

$$4Al + 4CH_2Cl_2 \longrightarrow 2Cl_2Al—CH_2—AlCl_2 + \text{“}CH_2{=}CH_2\text{”} \quad (1)$$

Recently we succeeded in the synthesis of a dialane(4) with an aluminium–aluminium bond, kinetically stabilized by the high sterical shielding of four bulky bis(trimethylsilyl)methyl groups.[4] This ligand appears to be also suitable for obtaining a stable molecule containing the $Al—CH_2—Al$ fragment, because it should prevent the formation of intermediates with coordination numbers higher than three at the metal atoms and therefore the dismutation process, as it occurs with the methyl or ethyl derivatives.

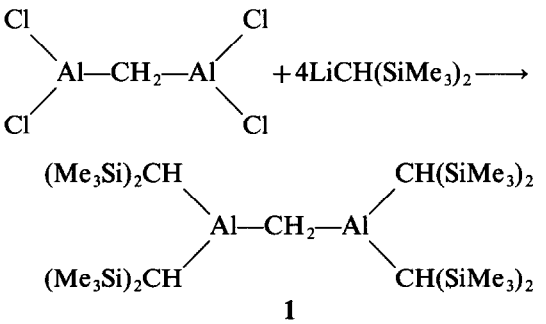
Interestingly there are two recent reports[5] concerning the addition of Al—H bonds to alkynes. which should lead to molecules with three aluminium atoms bonded to one carbon atom. Unfortunately the products were not isolated and only investigated by hydrolysis experiments, therefore they need further characterization.

$[(Me_3Si)_2CH]_2Al—CH_2—Al[CH(SiMe_3)_2]_2$ (1)

Compound **1** is best obtained by reaction of lithium-bis(trimethylsilyl)methyl with $Cl_2Al—CH_2—AlCl_2$ in a molar ratio of 4:1 in *n*-pentane. Since the synthesis of the lithium compound takes place in diethyl ether,[6] the solvent was completely removed by distillation and the remaining solid evacuated for several hours at room temperature until a final pressure of 10^{-3} torr was reached. A suspension of the prepared ether-free lithium-organyl in *n*-pentane was then treated at −50°C with solid $Cl_2Al—CH_2—AlCl_2$ (only slightly soluble in hydrocarbons) to produce, after warming to room temperature and recrystallization from *n*-pentane, the title compound **1** [eq. (2)] in 45% yield. Solubility of the colourless crystals of **1** is high in *n*-pentane but only moderate in benzene, in which, cryoscopically, a monomeric molecular weight was observed. The ^1H NMR spectrum shows three signals with intensities of 36:2:1. The resonance of the central bridging CH_2-group is shifted to high field ($\delta = -0.55$ ppm) and broadened due to the quadrupole moment of aluminium. Very pure fractions of **1**, obtained after repeated recrystallization,

* Author to whom correspondence should be addressed.

reveal a splitting of the $SiMe_3$ singulet into three lines with intensities of 1:2:1. This effect may be due to hindered rotation about the bonds between the aluminium atoms and the central carbon atom, and we assume a staggered conformation of the alanyl substituents (see, also, crystal structure below). Compound **1** is thermally very resistant and melts at 152°C without decomposition.



1

$+4LiCl.$ (2)

Because of the low yield, the mother liquor remaining after the isolation of **1** was investigated. A yellow liquid of high viscosity was left after removal of the solvent. Its ^1H NMR spectrum showed, besides some small signals, mainly the resonances of **1** and lithium-bis(trimethylsilyl)methyl in a 1:1 ratio. We did not succeed, however, in isolating a second fraction of crystalline **1**. The surplus lithium compound led us to extend the time of reaction and even to work in boiling solvent, but in no experiment did we find a higher yield than mentioned above. Tris[bis(trimethylsilyl) methyl]alane, $Al[CH(SiMe_3)_2]_3$, expected as a dismutation product, was not detectable.

Other ligands

Subsequent to the successful synthesis of **1** we tried to obtain further organometallic derivatives containing the Al—CH_2—Al fragment. The reaction of lithium–*tert*-butyl with the starting tetrahalide leads to complete decomposition of the lithium compound via β-elimination into lithium hydride and *iso*-butene, without any detectable attack at the halogen alane. This result is in accord with observations made in similar experiments with alkyl alanes or alkyl halogenalanes.[7,8] Mesityl-Grignard produces trimesitylalane[9] as the only isolable product in 30% yield. Lithium–tris(trimethylsilyl)methyl—only available as an etherate[10]—reacts in the presence of the halogen alane with complexed tetrahydrofuran or tetramethylethylenediamine, thereby forming tris(trimethylsilyl)methane, $HC(SiMe_3)_3$.

Reaction with lithium–trimethylsilyl $LiSiMe_3$, also does not lead to the desired compound. A brown oil was obtained, from which after repeated recrystallization colourless, highly air-sensitive crystals of $Li[Al(SiMe_3)_4]$ (**2**) were isolated in 35% yield applied to $LiSiMe_3$. In addition to usual characterization, this result was ascertained through the specific reaction of aluminium tribromide with four equivalents of $LiSiMe_3$ [eq. (3)] yielding the analytically and spectroscopically identical product:

$$AlBr_3 + 4LiSiMe_3 \longrightarrow Li[Al(SiMe_3)_4] + 3LiBr. \quad (3)$$

2

The synthesis of **2**, in 35% yield, has already been described in the literature[11] starting from aluminium amalgam, trimethylchlorosilane and lithium metal, although in parts the published properties of **2** differ significantly from our observations. Therefore, we repeated the characterization. The trimethylsilyl alanate is easily soluble in non-polar solvents like *n*-pentane and sublimes in a closed capillary under normal pressure at 220°C before melting. Cryoscopic molecular weight measurement reveals a non-dissociated, monomeric molecule in benzene solution.

There is only one further lithium derivative which reacts with the starting halogen alane to form a methylene bridged dialane. This is lithium–(trimethylsilyl)methyl, $LiCH_2SiMe_3$; but the product will not be discussed in this report for two reasons: first, in solution with benzene it shows an equilibrium between monomeric and dimeric species and we hope to get crystals suitable for X-ray diffraction to prove whether this compound is dimeric in solid state. Second, in solution, it decomposes slowly at room temperature to unknown solid products, and a thorough study of this reaction may lead to a better understanding of the dismutation processes already mentioned for the methyl and ethyl derivatives.

MOLECULAR STRUCTURE OF 1

Single crystals suitable for X-ray diffraction studies were grown directly from the reaction mixture at 0°C. Buerger precession photos indicated the centrosymmetric orthorhombic space group *Pcca* with four molecules in the unit cell and half a molecule in the asymmetric unit. Further details of structure determination and refinement are listed in Table 2 (Experimental). All positions of the hydrogen atoms were found in a Fourier synthesis and refined isotropically to reasonable values.

Figure 1 shows a stereoscopic view of one molecule of **1**. It is located on a crystallographic two-

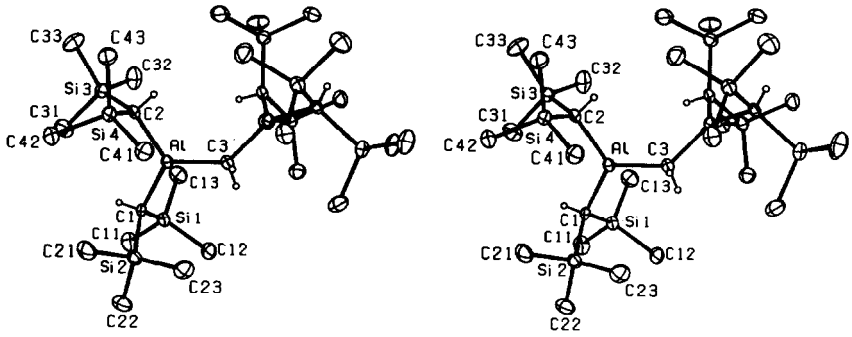


Fig. 1. ORTEP[29] stereo diagram of **1** with labelling scheme. The atoms are represented by 40% probability thermal ellipsoids. The hydrogen atoms have been omitted for clarity except for the four α-H (with arbitrary radius) of the element–organic substituents. They clearly show the orientation of the ligands.

fold axis bisecting the angles H—C—H and Al—C—Al at the central carbon atom C(3) and transferring both halves of the molecule into one another. The bis(trimethylsilyl)methyl substituents at one aluminium atom are arranged in such a way that the inner C—H bonds point in one direction, so that one hydrogen is in the neighbourhood of the trimethylsilyl groups of the second ligand. This arrangement corresponds to that found in tetrakis[bis(trimethylsilyl)methyl]dimetal(4) derivatives of aluminium,[4] gallium[12] and indium[13] as well as in $In[CH(SiMe_3)_2]_3$[14] and $\{Sn[CH(SiMe_3)_2]_2\}_2$,[15] but differs from the conformation in (TMEDA) $Li(\mu\text{-}Br)_2In[CH(SiMe_3)_2]_2$[13] or in $K\{Cl_2Al[CH(SiMe_3)_2]_2\}$.[8] Unlike the just mentioned dimetal(4) derivatives of Al, Ga and In, the central atoms Al, C(1), C(2), C(3) and the symmetrically dependent atoms do not lie in a plane. Instead, we observe a nearly staggered conformation of the two alanyl substituents (torsion angles C(1)—Al···Al′—C(1)′ 113.1°; C(2)—Al···Al′—C(2)′ 74.9°). The aluminium atom lies only 1.6 pm above the plane defined by the three inner carbon atoms; this fact and the sum of the three angles, C—Al—C (360.0°), verifies a nearly ideal planar coordination.

The angles at the central carbon atom, C(3), show significant deviations from the values expected for sp^3 atoms with Al—C—Al 129.6° (Table 1). Steric repulsion between the bulky substituents cannot be the only reason for this, because the usual lengthening of the corresponding Al—C bond is not observed, but a very short bond length of 193.8 pm is found. This is 2 pm shorter than the terminal Al—C bonds. Tri(organyl)alanes usually have Al—C bond lengths longer than 195 pm: e.g. $(AlMe_3)_2$ 195.3 pm,[16] tri(mesityl)alane 199.5 pm,[9] $Al(CH_2C_6H_5)_3$ 198.9 pm.[17] Shorter distances are observed only in dimeric tri(cyclopropyl)alane (192.8–195.9 pm,[18] the shortest one to a disordered cyclopropyl group) and in compounds with at least one electronegative substituent at aluminium: e.g. $(Me_2AlCl)_2$ 193.5 pm,[19] $[Cl_2Al—CH(SiMe_3)_2]_2$ 191.2 pm,[8] $K[MeAlCl_3]$ 193.9 pm[20] and $[(C_5Me_5)AlMeCl]_2$ (Al—Me) 191.6 pm.[21]

A possible explanation for the large angle at C(3), on the one hand, and the short Al—C(3) distance, on the other, is the separation of charge due to the high difference in electronegativities between aluminium and carbon. Both aluminium atoms lead to an accumulation of negative charge at the central carbon atom. Additional coulombic attraction should therefore decrease the Al—C distance and repulsion between the positively charged metal atoms should increase the Al—C—Al angle. Furthermore, hyperconjugation has to be considered between the C—H bonds at the central carbon atom, C(3), and the empty *p*-orbitals of both aluminium atoms, because each of the two C—H σ-bonds is nearly parallel to one of these orbitals (torsion angles: C(1)—Al—C(3)—H(3) −95.3°; C(2)—Al—C(3)—H(3) 83.1°).

Recently the crystal structures of similar methylene bridged indium compounds $Cl_2In—CH_2—InCl_2 \cdot 2TMEDA$ and $Cl(Br)In—CH_2—InCl_2 \cdot 2TMEDA$ were published.[22] They also show large angles at the central carbon atom of 117.6 and 117.5°.

EXPERIMENTAL

Preparation of **1**

A suspension of 8.43 g (0.0507 mol) of ether-free lithium–bis(trimethylsilyl)methyl in 100 cm^3 of *n*-pentane was treated at −50°C with 2.66 g (0.0127 mol) of solid $Cl_2Al—CH_2—AlCl_2$. After warming to room temperature and stirring for 19 h, the lithium

SYNTHESIS AND CRYSTAL STRUCTURE OF A MIXED BIS(ARENE)GALLIUM(I) COMPLEX: DIMERIC (η^6-1,2,4,5-TETRAMETHYLBENZENE) (η^6-TOLUENE)GALLIUM(I) TETRACHLOROGALLATE(III)

H. SCHMIDBAUR,* R. NOWAK, B. HUBER and G. MÜLLER

Anorganisch-chemisches Institut der Technischen Universität München, Lichtenbergstraße 4, D-8046 Garching, F.R.G.

Abstract—The title compound (η^6-1,2,4,5-tetramethylbenzene)(η^6-toluene)gallium(I) tetrachlorogallate(III) (**1**) crystallizes from dilute solutions of equimolar quantities of gallium(I) tetrachlorogallate(III) and 1,2,4,5-tetramethylbenzene (durene) in toluene on slow cooling to 0°C. More concentrated solutions yield the 1 : 1 complex (1,2,4,5-$C_6H_2Me_4$)$Ga^+GaCl_4^-$ (**2**). The crystals of compound **1** contain centrosymmetrical dimers, $\{[(\eta^6\text{-}C_6H_2Me_4)(\eta^6\text{-}C_6H_5Me)Ga]GaCl_4\}_2$, in which each gallium(I) centre is hexahapto-bonded to one durene and one toluene molecule. The two aromatic hydrocarbons of these bent-sandwich moieties form an interplane angle of 58°. With a metal-to-ring distance of 2.642 Å, the durene ring is much closer to the Ga^+ atom than the toluene ring (3.039 Å). The Ga^+ atoms are bridged via two slightly distorted $GaCl_4^-$ tetrahedra through contacts with three of the four chlorine atoms. The structure resembles that of the $[(C_6H_6)_2Ga]GaX_4$ complexes with X = Cl, Br.

Salts of the low-valent heavy Group 13 metal cations with counter-ions of low polarizability are unique in showing high solubility in aromatic hydrocarbons.[1] Extensive work in recent years has provided evidence that these phenomena have their origin in the formation of arene complexes of gallium(I), indium(I) and thallium(I), in which the metal is η^6-bonded to the aromatic system, i.e. with the metal positioned exactly above the ring centre in most cases.[2–7] Apart from the 1 : 1 stoichiometry with only one arene in the first coordination sphere of the metal, an increasing number of bent-sandwich complexes with a 2 : 1 ratio of arene-to-metal has been discovered. As a rule, the two aromatic rings show an interplane angle of *ca* 60° in these complexes, with counter-ion contacts of the metal roughly in the plane bisecting the interarene angle. This mode of coordination was first detected for the benzene adducts of $Ga[GaCl_4]$[2] and $Ga[GaBr_4]$,[3] but has meanwhile also been found even in complex networks with donors like the small cyclophanes.[8–9] Compounds of the alternative 1 : 2 stoichiometry arene–metal, with a metal on both sides of a given arene ring, seems to be restricted to the neighbouring elements in Groups 14 and 15.[10] An extreme situation of arene coordination has been reached in the complex of gallium(I) with the large-ring [2,2,2]-paracyclophane, however, where the metal is no less than η^{18}-bonded to the carbon atoms of three benzene rings.[11]

We report here the synthesis and structure determination of a dimeric bent-sandwich gallium(I) complex, in which each metal is η^6-coordinated to two benzene molecules with a different pattern of methyl substitution. This complex is of interest since it allows a direct comparison of metal bonding to ligands with different donor capacity, as determined by the inductive effect of the substituents. There is only one precedent for this situation,[12] with both toluene and hexaethylbenzene present at the gallium(I) centre. The extreme steric crowding at the C_6Et_6 ligand makes this example rather special, however, and a study was therefore initiated with ligand combinations where the steric bulk should play a minor rôle.

SYNTHESIS AND PROPERTIES OF COMPLEXES

Gallium(I) tetrachlorogallate(III) dissolves readily in anhydrous toluene to give a solution probably

* Author to whom correspondence should be addressed.

containing toluene complexes of unknown stoichiometry and structure which have not yet been isolated. $Ga[GaCl_4]$ can also be dissolved in solutions of 1,2,4,5-tetramethylbenzene (durene) in toluene on heating. Rapid cooling of these mixtures containing high concentrations of durene and the gallium salt to room temperature leads to the separation of a heavy liquid phase which is difficult to crystallize. Slow cooling to *ca* 0°C (refrigerator) gives a fine microcrystalline precipitate which analyses as the 1:1 complex of durene and $Ga[GaCl_4]$, m.p. 15–16°C. Its structure could not be determined. From dilute solutions in toluene a macrocrystalline product can be crystallized on cooling to 0°C, whose microanalysis data indicate the presence of the title compound with mixed arenes present (m.p. 5°C). The transparent, colourless crystals are extremely hygroscopic, and decomposition starts immediately on contact with air. The black colour developed, thereby, indicates disproportionation to metallic gallium. The ^1H NMR spectrum of benzene solutions shows the resonances of toluene and durene in a 1:1 molar intensity ratio.

Experiments with benzene–durene mixtures gave only oily products which were not characterized any further.

DETERMINATION AND DESCRIPTION OF THE CRYSTAL STRUCTURE

A single crystal X-ray diffraction study of the compound confirmed the stoichiometry inferred from analytical and spectroscopic data. Details of the structure determination and crystal data are summarized in Table 1. Selected interatomic distances and angles are presented in Table 2.

The analysis has shown that the complex forms discrete molecules composed of two formula units related by a centre of symmetry (Fig. 1). The packing of the molecules in the unit cell is displayed in Fig. 2. There are no specific contacts between the dimers, and no extra interstitial hydrocarbon—a common phenomenon in Group 13 arene crystal chemistry—could be detected.

The molecular structure of the title compound is very similar to that of the $[(C_6H_6)_2Ga(GaX_4)]_2$ units in the two crystalline phases $[(C_6H_6)_2Ga(GaX_4)]_2\cdot(C_6H_6)_3$ with X = Cl, Br.[2,3] Apart from the absence of an interstitial hydrocarbon, the main variation stems from the fact that two different arenes are present at each metal(I) centre. The structure thus features two heteroleptic bent-sandwich moieties with interplane angles of 58°, a value typical for this class of compounds.[1]

The most important structural detail is the finding that the metal-to-arene distances are significantly different at each unit, with the durene ring much closer to the metal than the toluene ring (2.642 vs 3.039 Å!). This result is in contrast to expectations on steric grounds (with durene as the more bulky ligand as compared to toluene), and must imply that durene is much more tightly bonded than toluene for electronic reasons.

A simplified molecular orbital description of bonding[1,12] proposes a charge transfer from the arene to the metal, which should be enhanced by electron-donating substituents like methyl groups. This would allow durene to overrule toluene as a donor ligand, especially since its site symmetry is more favourable than that of the toluene competitor (C_{2v} as compared to C_s for durene and toluene, respectively). Along with the differences in metal-to-ring distances, the positioning of the gallium(I)

Interarene angle 58.0.
E: centres of the arenes.

centre above each ring is also not the same, as can be shown by the angles between the normals to the planes and the line connecting the arene centres with the metal (1.3 and 6.7°, respectively). Durene is closer to true η^6-bonding than toluene. It remains an intriguing observation, however, that the benzene molecules in the $(C_6H_6)_2Ga^+GaX_4^-$ complexes show non-equivalent bonding to the metal as judged from significant differences in metal–arene distances in both phases (X = Cl, Br).[2,3] There is no obvious explanation for this deviation from an equivalent interaction, though distortion of the highest

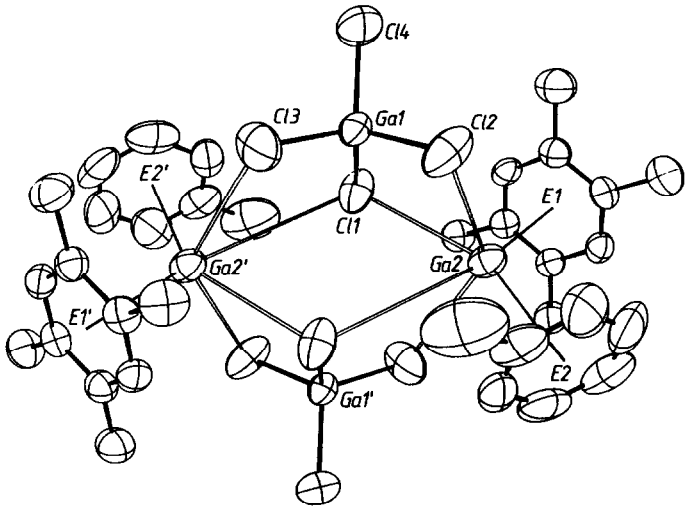

Fig. 1. Molecular structure and atomic numbering of the title compound (ORTEP, 50% probability; the atoms are related by a centre of symmetry).

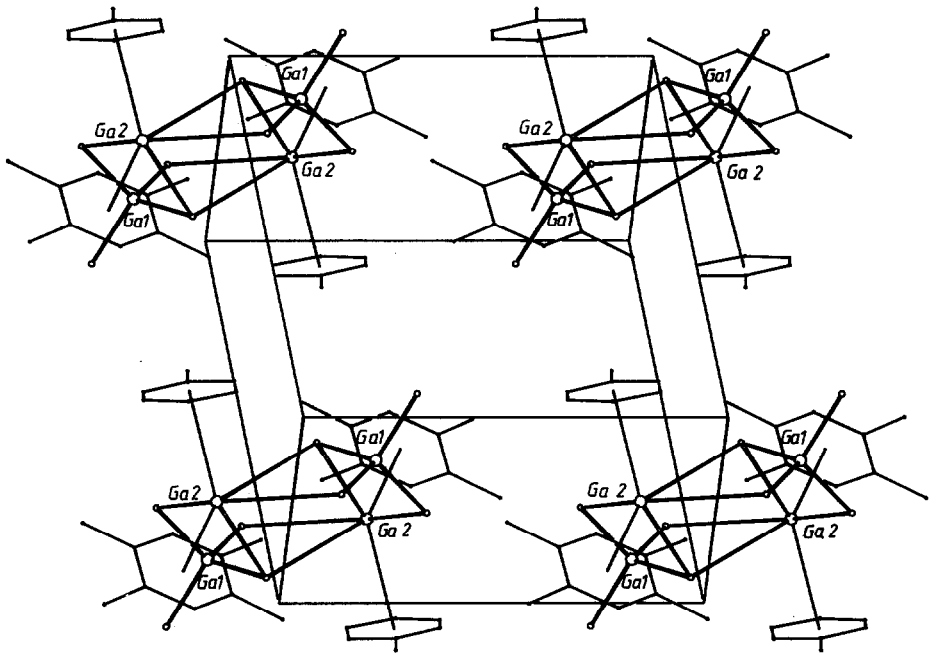

Fig. 2. Molecular packing of the molecules in the unit cell of the title compound (**1**).

symmetry has been shown to be associated with a gain in energy in various related and unrelated species.[13] The complexity of the present systems has discouraged us to produce any more detailed analyses.

The tetramethylbenzene–gallium(I) distance in the title compound (**1**) is the shortest found in bis (arene)gallium(I) complexes, and the toluene–gallium(I) distance is shorter than that in the mixed (toluene)(hexaethylbenzene)gallium(I) complex. These relations show the strengthening influence of an increase in methyl substitution for the *ipso*-ring bonding on one hand, and the weakening effect for the bonding of neighbouring arene ligands on the other. Relatively long C_6H_5Me–Ga^I and C_6Et_6–Ga^I distances (2.960/3.145 Å) in the mixed C_6H_5Me/C_6Et_6 complex appear to be of steric origin,[8] however. 2:1 complexes of gallium(I) with penta- or hexamethylbenzene have not yet been observed, probably due to severe steric interactions of the methyl substituents in a bent-sandwich structure.

The two Ga^+ centres of the dimers are bridged by two $GaCl_4^-$ tetrahedra through contacts with all but one of the chlorine atoms at each anion (Fig. 1). Three of these contacts, the distances Cl(2)—Ga(2) (3.109(1) Å), Cl(1)—Ga(2) (3.259(1) Å) and Cl(3)—Ga(2*) (3.370(2) Å) are much shorter than the fourth one, Cl(1)—Ga(2) = 3.991(2) Å, which originates from a bridgehead position of Cl(1). Taking into account only the short contacts, the structure is based on an eight-membered ring with the sequence of atoms Ga(2)—Cl(2)—Ga(1)—Cl(3)—Ga(2*)—Cl(2*)—Ga(1*)—Cl(3*). This pattern is not only present in the bis(benzene)gallium(I) complexes,[2,3] but also in a bis(arene) complex of tin(II) reported recently[14] from this laboratory.

As expected, the $GaCl_4^-$ tetrahedra in the title complex are distorted with minor deviations of the Cl—Ga(1)—Cl angles from the tetrahedral norm, and with a variation of the Ga(1)—Cl distances within narrow limits (Table 2). The non-bridging chlorine atom Cl(4) has the shortest distance to Ga(1) (2.148(2) Å), while Cl(1) with its bridgehead function has the largest (2.173(1) Å).

With Cl(1) considered as a ligand to Ga(2) and Ga(2*), the environment of Ga^+ can be described as distorted octahedral (trigonal-antiprismatic), as indicated by an almost parallel orientation of the planes Cl(1)—Cl(2)—E(1)(centre of durene) and Cl(1*)—Cl(3*)—E(2)(centre of toluene).

EXPERIMENTAL

General

All experiments were carried out under an atmosphere of pure dry nitrogen. Glassware, as well as solvents and reagents, were treated accordingly. Gallium metal was received from Preussag AG and converted to $Ga[GaCl_4]$ by following literature procedures.[15]

(η^6 - 1,2,4,5 - *Tetramethylbenzene*)(η^6 - *toluene*) *gallium*(I) *tetrachlorogallate*(III)

Gallium(I) tetrachlorogallate(III) (1.88 g, 6.68 mmol) and durene (0.9 g, 6.68 mmol) were dissolved in 20 cm^3 of toluene and heated under reflux for 1 h. On slow cooling to 0°C crystallization occurred after a few days. The mother liquor was decanted and the colourless crystalline product dried in a stream of dry nitrogen. Yield 2.58 g (76%), m.p. 5°C.

^{1}H NMR (C_6D_6): δ = 2.20, s, 3H (*Me*Ph); 2.30, s, 12H (C_6H_2*Me*$_4$); 6.9, m, 5H (Me*Ph*); 7.05, s, 2H (C_6*H*$_2$Me$_4$). ^{71}Ga NMR (C_6D_6): δ = −680 ppm rel. $Ga(NO_3)_3$ in aqueous HNO_3, s. $C_{17}H_{22}Ga_2Cl_4$ (507.62): Found: C, 39.7; H, 4.1. Calc. C, 40.2; H, 4.3%.

A solution of the same components in toluene at higher concentrations (1.40 mol dm^{-3}) yielded a microcrystalline precipitate on cooling to 0°C in *ca* 80% yield (m.p. 15–16°C). $C_{10}H_{14}Ga_2Cl_4$ (415.48): Found: C, 27.2; H, 3.15. Calc. C, 28.9; H, 3.4.

Structure determination of $\{[(\eta^6\text{-}1,2,4,5\text{-}C_6H_2Me_4)(\eta^6\text{-}C_6H_5CH_3)Ga]GaCl_4\}_2$

A suitable crystal was sealed in a capillary under argon at −60°C and mounted on a CAD-4 diffractometer (Mo-K_α radiation, graphite monochromator, λ = 0.71069 Å). Crystal data and details of the structure determination are summarized in Table 1. The integrated intensities of the reflections were corrected for Lorentz polarization and empirically for absorption effects (relative transmission 0.76–1.00; $(\sin\vartheta/\lambda)_{max}$ = 0.616 $Å^{-1}$, *hkl*: 14, ±14, ±14; ϑ–2ϑ scan, $\Delta\omega = 0.8 + 0.35\tan\vartheta$). The structure was solved by direct methods (SHELXS-86). Thirteen out of a total of 22 hydrogen atoms could be located in difference Fourier maps, the remainder were calculated at idealized positions. In the refinement with anisotropic displacement parameters the hydrogen atoms were included in constant positions (U_{iso} = 0.05 $Å^2$). The maxima of the residual electron density and the relatively large displacement parameters of the toluene carbon atoms suggested a minor disorder of this molecule, which was too small, however, to justify treatment using a split model. A similar situation was encountered in the structure of $[(\eta^6\text{-}C_6Et_6)(\eta^6\text{-}C_6H_5Me)Ga]Cl_4$.[12] Further crystal structure data have been deposited.*

MULTINUCLEAR NMR STUDIES OF THE REACTIONS OF $(Me_3Al)_2$ WITH Me_2AsNMe_2, $MeAs(NMe_2)_2$ AND $As(NMe_2)_3$

L. K. KRANNICH,* C. L. WATKINS and D. K. SRIVASTAVA

Department of Chemistry, University of Alabama at Birmingham, Birmingham, AL 35294, U.S.A.

Abstract—The reactions of $(Me_3Al)_2$ with Me_2AsNMe_2, $MeAs(NMe_2)_2$ and $As(NMe_2)_3$ were studied as a function of time at room temperature and over the temperature range of −95 to 24°C by using ^1H and ^{13}C NMR spectroscopy. At −95°C, all the aminoarsines form the respective mono Al—N bonded adducts. In addition, $MeAs(NMe_2)_2$ and $As(NMe_2)_3$ form bis Al—N bonded adducts and $As(NMe_2)_3$ forms an Al—As bonded adduct. The bis adducts readily decompose and the Al—As bonded adduct dissociates at low temperature. All the mono Al—N bonded adducts decompose by a pathway that transfers a methyl group from the aluminium to the arsenic atom, cleaves the As—N bond, and yields the next higher methyl homologue in the arsine series [$MeAs(NMe_2)_2$, Me_2AsNMe_2 or Me_3As]. The bis Al—N bonded adducts decompose to the next higher methyl homologue in the mono adduct series [$MeAs(NMe_2)NMe_2 \cdot AlMe_3$ or $Me_2AsNMe_2 \cdot AlMe_3$]. The other product in both cases is the unstable Me_2AlNMe_2, which dimerizes or undergoes further reaction with excess $(Me_3Al)_2$ or aminoarsine. The role of numerous competing side reactions and adduct/aminoarsine exchange equilibria in affecting the rate of adduct decomposition, overall rate of formation of the final product arsine, and final product distribution was established for each aminoarsine/$(Me_3Al)_2$ system. The initial stoichiometry of the reaction greatly influences the relative importance of the various reactions that occur in solution. Only when the moles of available Me_3Al molecules equal those of Lewis base nitrogen sites, do the reactions proceed in a straightforward manner to give Me_3As and $(Me_2AlNMe_2)_2$. The results from the NMR studies were used to design a new, high yield synthetic route to Me_3As.

Organoaluminium chemistry has been extensively reviewed due to its importance in catalysis and chemical synthesis,[1–4] as well as in more recent applications for the preparation of semiconducting[5–7] and ceramic materials.[8] The physical and chemical properties of the trialkylaluminium species, $(R_3Al)_2$, in addition to their reactions with compounds containing Group 15 elements have been reported.[1,2,4] With primary and secondary amines, simple R_3Al–amine 1:1 adducts form. Upon heating, these yield Al—N bonded cyclic dimers and oligomers.[4,9–17] The 1:1 addition product of Me_3Al and Me_2NH, for example, forms the cyclic dimer, $(Me_2AlNMe_2)_2$, at 120°C with the elimination of methane.[18,19] The structure of the dimer has been confirmed by IR,[20] X-ray[21] and NQR[22] studies. Stable 1:1 adducts between R_3Al and tertiary amines have also been well characterized.[1,2,18,22–25] The reactions with bidentate nitrogen-containing ligands, such as substituted hydrazines[26,27] and diamines,[1,2,28–30] as well as multidentate open-chain and cyclic amines,[31–34] lead to Al—N bonded adducts, which in certain cases have been proposed to form five- and six-coordinate aluminium.

Several 1:1 adducts of R_3Al (R = Me, Et) with tertiary organophosphines have also been characterized.[1,2,4,5,18,22,24,25,35–40] Interestingly, $(Me_3Al)_2$ and $(Et_3Al)_2$ react with secondary organophosphines and arsines in some instances to form cyclic dimers, as expected from the analogous secondary amine reactions, but in other cases trimeric species are formed.[18,19,35,41,42] Me_3Al and Et_3Al adducts with diphosphines,[5,43–45] bis(diphenylphosphino)methane[46,47] and polyphosphines[5,48] have been reported. However, only a few Me_3Al

adducts of tertiary arsines[22,49] and diarsines[44] are known.

Limited information is available concerning the reactions of aluminium alkyls with molecules containing adjacent, competing, heteroatom Lewis base sites, such as bisphosphinoamines,[43,50–52] aminophosphines,[43] hydrazinophosphines[53] and aminoarsines. $(Et_3Al)_2$ reacts with $(Ph_2P)_2NR$ (R = Me, Et, Pr^n, Bu^n) to give Al—P bonded 1 : 1 adducts, regardless of the reaction stoichiometry.[43,50] The NMR data suggest that bonding involves pentacoordinate aluminium. When the bulkiness of R is increased (R = PhCHMe, Ph CH_2, Me_2N), no reaction occurs with $(Et_3Al)_2$.[43,50] The reaction of $(R_3Al)_2$ (R = Me, Et) with $(Ph_2P)_2NH$ results in ethane evolution and the formation of a dimeric product, $[R_2AlN(PPh_2)_2]_2$.[52] X-ray data for the methyl derivative indicate a six-membered AlNOAlNP ring in a twist-conformation.[52] Such hydrocarbon elimination results typically when Lewis bases that contain an N—H bond react with aluminium alkyls.

With Ph_2PNHPr^i, $(Et_3Al)_2$ reacts with ethane evolution to yield the trimeric species $[Ph_2P(Et_2Al)NPr^i]_3$.[43] In contrast, with the more bulky Bu^t moiety, (Ph_2PNHBu^t) yields the isolable 1 : 1 adduct. Upon heating, this adduct eliminates ethane to give the monomeric $Ph_2P(AlEt_2)NBu^t$.[43] NMR data suggest that the reaction of Me_2PNMe_2 with $(Et_3Al)_2$ yields a mixture of the Al—P and Al—N bonded 1 : 1 adducts with the Al—N bonded adduct being favoured thermodynamically.[43] However, a simple molecular addition product of Et_3Al and Ph_2PNEt_2 is not obtained.[43] For the hydrazinophosphines, $P(MeNNMe)_3P$ and $PhP(MeNNMe)_2PPh$, triethylaluminium gives only the 2 : 1 Al—P bonded adducts where each phosphorus atom is bound to a Et_3Al group.[53]

To our knowledge, no reactions of $(R_3Al)_2$ with aminoarsines have been reported, although the reaction of $(Me_3Al)_2$ with the As—N bond containing arsa(III)azene, ArNH—As=NAr (Ar = $C_6H_2Bu^t_3$-2,4,6), has been reported.[54] The reaction proceeds with As—N bond cleavage and the formation of $Me_2AlNHAr$ and uncharacterized arsenic-containing species.

In view of this, we were interested in establishing Me_3Al bonding site preference in multiple Lewis base site compounds that contain the As—N bond, determining the nature and relative stability of any resulting adducts, and elucidating subsequent decomposition pathways that lead to the thermodynamically stable products. Thus, we have undertaken a systematic ^1H and ^{13}C NMR study of the interaction of $(Me_3Al)_2$ with the following series of aminoarsines: Me_2AsNMe_2, MeAs $(NMe_2)_2$ and $As(NMe_2)_3$, as a function of temperature and reaction stoichiometry. The course of each reaction was followed by the disappearance of reactant peaks and the appearance of new peaks assignable to reaction products. Independent reactions were carried out to establish proposed reaction pathways. A new synthetic route to the high yield synthesis of Me_3As has resulted from these investigations.

EXPERIMENTAL

Standard high vacuum-line techniques and a Vacuum Atmospheres Model HE-43-Dri lab equipped with a Model HE-493 Dri-Train were used for storing and handling of all compounds. Me_2NH (Matheson Gas Products), $(Me_3Al)_2$ (Ethyl Corporation) and $AsCl_3$ (Alfa Products) were used as obtained. Diethyl ether was dried over sodium and distilled before use. Benzene-d_6, toluene-d_8 and Me_4Si were purchased from Aldrich Chemical Company and stored over molecular sieves. Me_2AsCl (106°C)[55] and $MeAsCl_2$ (61–63°C/50 mm Hg)[56] were synthesized by previously reported methods. Me_2AsNMe_2, $MeAs(NMe_2)_2$ and $As(NMe_2)_3$ were synthesized by the aminolysis of the appropriate chloroarsine or $AsCl_3$.[57] All the arsines were distilled on a spinning band column prior to use and their purity was checked by ^1H and ^{13}C NMR spectroscopy (see ^1H and ^{13}C NMR spectral data). $(Me_2AlNMe_2)_2$[18] was independently synthesized to confirm its existence in the studied reaction system (see ^1H and ^{13}C NMR spectral data).

^1H and ^{13}C NMR spectra were recorded on a Nicolet 300 MHz multinuclear FT NMR spectrometer operating at 300.1 and 75.4 MHz, respectively. The chemical shifts were measured with respect to Me_4Si as an internal reference. Table 1 contains the ^1H and ^{13}C NMR spectral data of the Al—N and Al—As adducts observed in the various reaction systems. All reaction systems were studied in NMR tubes that were not acid-washed to minimize the occurrence of acid-catalysed exchange processes. The reaction mixtures were protected from exposure to light. The room-temperature studies were conducted in NMR tubes (10 mm, Pyrex) equipped with screw tops containing a PTFE insert to exclude moisture and air over long periods of time. All variable-temperature studies were carried out in NMR tubes (10 mm, Pyrex) purchased from Wilmad that were equipped with the J. Young VNMR valves. These were attached to the vacuum-line through a specially designed side-arm septum adapter that permitted addition of the aminoarsine reactant solution with a hypodermic syringe.

Reactions of $(Me_3Al)_2$ *with* Me_2AsNMe_2, MeAs$(NMe_2)_2$ *and* As$(NMe_2)_3$

The reactions of $(Me_3Al)_2$ with various stoichiometric ratios of Me_2AsNMe_2, MeAs$(NMe_2)_2$ and As$(NMe_2)_3$ were carried out in benzene-d_6 and toluene-d_8 using the following procedures. In the room-temperature studies, the appropriate amount of the respective aminoarsine was weighed into the screw-topped NMR tube and benzene-d_6 was added to give 2 cm^3 of solution. The correct stoichiometric amount of $(Me_3Al)_2$ was weighed into a 1 cm^3 volumetric flask and 1 cm^3 of benzene-d_6 solution was prepared. Using a disposable pipette, the $(Me_3Al)_2$ solution was added rapidly to the aminoarsine solution to achieve thorough mixing of the solutions. These reactions were very exothermic. Each reaction system was then monitored by ^1H and ^{13}C NMR spectroscopy as a function of time.

In the variable-temperature studies, the appropriate amount of $(Me_3Al)_2$ was weighed into the J. Young NMR tube and toluene-d_8 was added to give 2 cm^3 of solution. The correct stoichiometric amount of the aminoarsine was weighed into a 1 cm^3 volumetric flask and toluene-d_8 was added to give a 1 cm^3 solution. The aminoarsine solution was loaded into a hypodermic syringe, which was sealed by inserting the needle into a rubber stopper. After the NMR tube was cooled to −110°C (ethanol–liquid nitrogen slush) up to 2 cm below the VNMR valve and degassed, the space in the working manifold of the vacuum line and the adapter was brought to atmospheric pressure using prepurified nitrogen. The aminoarsine solution was then injected into the adapter space above the VNMR valve. The septum was sealed with stopcock grease and the VNMR valve was opened to allow a trickle of the aminoarsine solution to run down the inside wall of the NMR tube and be cooled to −110°C prior to coming into contact with the $(Me_3Al)_2$ solution. After the addition was complete, the valve was closed, the tube was agitated gently at −110°C, and the tube was inserted within 10 min into the precooled (−95°C) probe of the NMR spectrometer. The reaction was then monitored at the selected 5 or 10°C temperature intervals by ^1H and ^{13}C NMR spectroscopy as a function of time.

Reactions of $Me_2AsNMe_2 \cdot AlMe_3$ *with* MeAs$(NMe_2)_2$ *and* As$(NMe_2)_3$

The reactions of $Me_2AsNMe_2 \cdot AlMe_3$ (I) with MeAs$(NMe_2)_2$ and As$(NMe_2)_3$ in 1 : 1 mmol ratios were carried out in benzene-d_6 at room temperature using the following procedure. The appropriate amount of Me_2AsNMe_2 was weighed into a screw-topped NMR tube and benzene-d_6 was added to give 1 cm^3 of solution. The correct stoichiometric amount of $(Me_3Al)_2$ was weighed into a 1 cm^3 volumetric flask and a 1 cm^3 benzene-d_6 solution was prepared. The $(Me_3Al)_2$ was added slowly to the aminoarsine solution and the ^1H and ^{13}C NMR spectra were obtained on the mixture to establish that the reaction had gone to completion to form I. The appropriate amount of MeAs$(NMe_2)_2$ or

$As(NMe_2)_3$ was weighed into a 1 cm^3 volumetric flask and a 1 cm^3 benzene-d_6 solution was prepared. This solution was then added to the solution of **I**. The reactions were then monitored with time using ^1H and ^{13}C NMR spectroscopy.

Competition studies of $(Me_3Al)_2$ *with* Me_2AsNMe_2, $MeAs(NMe_2)_2$ *and* $As(NMe_2)_3$ *mixtures*

The competition reactions of 1 and 2 mmol of $(Me_3Al)_2$ for the Lewis base sites in a 1 : 1 : 1 mixture of Me_2AsNMe_2, $MeAs(NMe_2)_2$ and $As(NMe_2)_3$ were carried out in benzene-d_6 at room temperature and at −95°C in toluene-d_8 using the following procedures. 1 mmol each of Me_2AsNMe_2, $MeAs(NMe_2)_2$ and $As(NMe_2)_3$ were weighed into a screw-topped NMR tube and benzene-d_6 was added to give 2 cm^3 of solution. The correct stoichiometric amount of $(Me_3Al)_2$ was weighed into a 1 cm^3 volumetric flask and a 1 cm^3 benzene-d_6 solution was prepared. The $(Me_3Al)_2$ was added to the aminoarsine solution. In the low temperature study, the analogous aminoarsine mixture in toluene-d_8 was added to a VNMR valve NMR tube. After degassing the solution at −110°C, the 1 cm^3 toluene-d_8 solution of $(Me_3Al)_2$ was introduced slowly by using the previously described procedure. The reactions were then monitored using ^1H and ^{13}C NMR spectroscopy.

Synthesis of Me_3As

$As(NMe_2)_3$ (0.048 mol) was added to a 100 cm^3 three-necked round-bottom flask equipped with a condenser, nitrogen by-pass adapter, magnetic stirrer and dropping funnel containing 0.072 mol of $(Me_3Al)_2$. After cooling the reaction flask to 0°C, the $(Me_3Al)_2$ was added dropwise to the $As(NMe_2)_3$ over a 1 h period with constant stirring. Solid formed during the addition. After the addition was complete, the reaction mixture was warmed to room temperature and stirred for 6 h. Distillation of the reaction mixture using a 140°C oil bath gave an 84% yield of Me_3As (52°C/760 mm Hg). The purity was checked by ^1H and ^{13}C NMR spectroscopy.

The following is a list of NMR spectral data (values in ppm) determined independently in our laboratory at room temperature in benzene-d_6 solution (concentrations are approximately 0.2 M) on synthesized compounds that were identified in the reaction mixtures. The NMR data for the Al—N and Al—As bonded adducts are given in Table 1.

^1H *NMR spectral data*

Me_3As: 0.76 (MeAs). Me_2AsNMe_2: 0.82 (MeAs) and 2.43 (MeN). $MeAs(NMe_2)_2$: 0.96 (MeAs) and 2.63 (MeN). $As(NMe_2)_3$: 2.59 (MeN). $Me_3As \cdot AlMe_3$: −0.36 (MeAl) and 0.60 (MeAs). $Me_2AlNMe_2 \cdot AlMe_3$: −0.49 (MeAl) and 2.05 (MeN). $(Me_2AlNMe_2)_2$:[58,59] −0.64 (MeAl) and 2.08 (MeN).

^{13}C *NMR spectral data*

Me_3As: 11.22 (MeAs). Me_2AsNMe_2: 9.93 (MeAs) and 41.91 (MeN). $MeAs(NMe_2)_2$: 12.39 (MeAs) and 42.76 (MeN). $As(NMe_2)_3$: 39.72 (MeN). $Me_3As \cdot AlMe_3$: −8.41 (MeAl) and 6.41 (MeAs). $Me_2AlNMe_2 \cdot AlMe_3$: −8.06 (MeAl, bd) and 40.17 (MeN). $(Me_2AlNMe_2)_2$:[59] −11.7 (MeAl, vbd) and 41.49 (MeN).

RESULTS AND DISCUSSION

Reaction of $(Me_3Al)_2$ *with* Me_2AsNMe_2

The ^1H and ^{13}C NMR spectra of the room-temperature reactions of $(Me_3Al)_2$ with Me_2AsNMe_2 in 0.5:1, 1:1, 2:1 and 3:1 mmol Me_3Al–Me_2AsNMe_2 mixtures indicated immediate formation of a 1 : 1 adduct **I**. In the 0.5 : 1 case, peaks assignable to Me_3As, unreacted Me_2AsNMe_2 and $MeAlNMe_2$ moiety containing species (δ_H values at 2.21, 2.19 and −0.40 ppm; δ_C at 38.92 ppm) are observed. Spectral line broadening of the Me_2N and Me_2As moiety peaks suggest exchange averaging involving Me_2AsNMe_2 and **I**. In the 2 : 1 and 3 : 1 reaction systems, peaks assignable to trace amounts of $Me_3As \cdot AlMe_3$ and $Me_2AlNMe_2 \cdot AlMe_3$, along with those for unreacted $(Me_3Al)_2$, are observed.

When a solution of the 1 : 1 system stands at room temperature, **I** slowly decomposes to yield Me_3As and $(Me_2AlNMe_2)_2$. Complete adduct decomposition occurs within 1 week. In the 0.5 : 1 system, as **I** undergoes decomposition to produce Me_3As and the $MeAlNMe_2$ moiety containing species, the line widths of the Me_2N and Me_2As moiety peaks narrow, the peak positions gradually shift toward those of Me_2AsNMe_2, and the peak intensities for **I** decrease as those for Me_3As and the $MeAlNMe_2$ species increase. After 1 week, decomposition is complete with the final products being Me_3As, unreacted Me_2AsNMe_2 and the $MeAlNMe_2$ containing species.

However, in the 2 : 1 and 3 : 1 systems, decomposition is slower (about 60% decomposition within 1 month). The spectra indicate that $Me_3As \cdot AlMe_3$ and $Me_2AlNMe_2 \cdot AlMe_3$ are the initial decomposition products, but with time, $Me_2AlNMe_2 \cdot AlMe_3$ decomposes to $(Me_2AlNMe_2)_2$ and $(Me_3Al)_2$. After three months, the product composition in the respective systems is: [2 : 1 system]—41%

$Me_3As \cdot AlMe_3$, 26% $Me_2AlNMe_2 \cdot AlMe_3$, 5% $(Me_2AlNMe_2)_2$, 28% **I**; [3:1 system]—43% $Me_3As \cdot AlMe_3$, 36% $Me_2AlNMe_2 \cdot AlMe_3$, 9% **I**, 12% $(Me_2Al)_2$.

A variable-temperature study of a 1:1 mmol Me_3Al—Me_2AsNMe_2 ratio sample indicates that **I** is formed in 90% yield at −95°C with reaction being complete by −60°C. No further significant changes in the spectra occur upon heating to room temperature. Thereafter, **I** slowly decomposes to Me_3As and $(Me_2AlNMe_2)_2$ and the results are identical to those of the room temperature 1:1 study. Variable-temperature studies on 2:1 and 3:1 mol ratio systems indicate exclusive formation of **I** at −95°C.

In each case, the NMR spectral and product composition data suggest that $(Me_3Al)_2$ readily reacts with Me_2AsNMe_2 to form an Al—N bonded adduct, **I** [eq. (1)]. This is consistent with the known bonding affinities of $(Me_3Al)_2$ towards Group 15 containing bases ($Me_3N > Me_3P > Me_3As$)[49] and MeN proton chemical shift changes due to complex formation with alanes in benzene solution.[24] Regardless of the stoichiometry used, there was no spectral evidence for the formation of Al—As or Al—As—N—Al bonded adducts. Although **I** subsequently decomposes, the specific decomposition pathway is very dependent upon the reaction stoichiometry. When the moles of the available Lewis acid, Me_3Al, equal those of available Lewis base nitrogen sites (1:1 system), **I** is the sole product. Decomposition then proceeds in a straightforward manner to yield Me_3As [eq. (2)] and $(Me_2AlNMe_2)_2$. The latter probably arises via the initial generation of Me_2AlNMe_2 [eq. (2)], which readily undergoes bisamino bridge dimerization [eq. (3)]. Since peaks could not be assigned to the Me_2AlNMe_2 monomer in the NMR spectra, we assume that it is quite unstable relative to dimerization under the reaction conditions.[18]

The results from the 0.5:1, 2:1 and 3:1 mol ratio studies are readily explained in terms of competing side reactions and exchange equilibria that involve either Me_2AsNMe_2 or $(Me_3Al)_2$. In the presence of excess Me_2AsNMe_2 (0.5:1 mmol system), **I** exchange averages with Me_2AsNMe_2. This process continues throughout the temperature range until **I** has decomposed. Such exchange averaging has been previously noted in aluminium alkyl adducts of bases, when the Lewis base is in excess.[1,2,24,25] Compound **I** decomposes according to eq. (2). Instead of dimerizing, Me_2AlNMe_2 preferentially reacts with the excess Me_2AsNMe_2 to produce additional Me_3As, and the $MeAlNMe_2$ moiety containing species. We propose that this species is the $MeAl(NMe_2)_2$[58] dimer. This assignment is based upon the fact that the observed δ_H and δ_C peaks are in the region expected for the $MeAlNMe_2$ group,[59] the δ_H peaks at 2.21 and 2.19 ppm are in a 1:1 area ratio, as expected for the bis-amino bridged dimer; and the δ_H at −0.40 is associated with a terminal AlMe.[58] We have, however, been unsuccessful in preparing and isolating this species. We postulate the Me_2AlNMe_2 forms an unstable, Al—N bonded intermediate adduct, $Me_2AsNMe_2 \cdot Me_2AlNMe_2$ [eq. (4)], which decomposes to Me_3As and $MeAl(NMe_2)_2$ [eq. (5)]. $MeAl(NMe_2)_2$ is expected to undergo bis-amino bridge dimerization [eq. (6)] to $[MeAl(NMe_2)_2]_2$, similar to Me_2AlNMe_2, H_2NAlMe_2, $Al(NMe_2)_3$, $Me_2AlNHNMe_2$ and $Me_2AlNMeNMe_2$.[9,12,27,58-61]

In the presence of excess $(Me_3Al)_2$ (2:1 and 3:1 mmol systems), the Me_2AlNMe_2, which forms from the decomposition of **I** [eq. (2)], does not dimerize, but preferentially reacts with the excess $(Me_3Al)_2$ to give $Me_2AlNMe_2 \cdot AlMe_3$ [eq. (7)]. This result is consistent with those obtained by Schram *et al.*[61] in the reactions of $B_2(NMe_2)_4$ with large excesses of $(Me_3Al)_2$. Also in the presence of excess $(Me_3Al)_2$, Me_3As forms $Me_3As \cdot AlMe_3$[49] [eq. (8)]. $Me_2AlNMe_2 \cdot AlMe_3$ then decomposes to $(Me_2AlNMe_2)_2$ and $(Me_3Al)_2$ [eq. (9)][61] as $(Me_3Al)_2$ is consumed with time. Although $Me_2AlNMe_2 \cdot AlMe_3$ is unstable at room temperature,[61] it is stabilized by the presence of excess $(Me_3Al)_2$ in solution; thereby retarding its decomposition.

The following equations summarize the reactions that are unique for the indicated mmol ratio systems:

Me_3Al/Me_2AsNMe_2; 1:1 mmol ratio:

$$Me_2AsNMe_2 + Me_3Al \longrightarrow Me_2AsNMe_2 \cdot AlMe_3 \quad (1)$$

$$Me_2AsNMe_2 \cdot AlMe_3 \longrightarrow Me_3As + Me_2AlNMe_2 \quad (2)$$

$$2Me_2AlNMe_2 \longrightarrow (Me_2AlNMe_2)_2; \quad (3)$$

Me_3Al/Me_2AsNMe_2; 0.5:1 mmol ratio:

$$Me_2AlNMe_2 + Me_2AsNMe_2 \longrightarrow Me_2AsNMe_2 \cdot Me_2AlNMe_2 \quad (4)$$

$$Me_2AsNMe_2 \cdot Me_2AlNMe_2 \longrightarrow Me_3As + MeAl(NMe_2)_2 \quad (5)$$

$$2MeAl(NMe_2)_2 \longrightarrow [MeAl(NMe_2)_2]_2; \quad (6)$$

Me_3Al/Me_2AsNMe_2; 2:1 and 3:1 mmol ratios:

$$Me_2AlNMe_2 + Me_3Al \longrightarrow Me_2AlNMe_2 \cdot AlMe_3 \quad (7)$$

$$Me_3As + Me_3Al \longrightarrow Me_3As \cdot AlMe_3 \quad (8)$$

$$Me_2AlNMe_2 \cdot AlMe_3 \longrightarrow (Me_2AlNMe_2)_2 + (Me_3Al)_2. \quad (9)$$

Reaction of $(Me_3Al)_2$ *with* $MeAs(NMe_2)_2$

The ^1H and ^{13}C NMR spectra of the room-temperature reactions of $(Me_3Al)_2$ with $MeAs(NMe_2)_2$ in 0.5:1, 1:1, 1:0.5, 2:1 and 3:1 mmol Me_3Al–$MeAs(NMe_2)_2$ ratios indicate the immediate formation of **I** amongst other products. The most straightforward results occur in the 2:1 system where the moles of available Lewis acid Me_3Al molecules equal those of available Lewis base $MeAs(NMe_2)_2$ nitrogen sites, and competing side reactions and exchange equilibria are minimal. Here, the initial producs are **I** and $(Me_2AlNMe_2)_2$. Over a period of 1 week, **I** decomposes completely to Me_3As and $(Me_2AlNMe_2)_2$.

In the 0.5:1 and 1:1 systems, where the available nitrogen base sites are in stoichiometric excess relative to the Me_3Al molecules, the initial NMR spectra of the reaction solutions contain peaks assignable to **I**, Me_2AsNMe_2, $MeAs(NMe_2)_2$, $(Me_2AlNMe_2)_2$ and the mono Al—N adduct, $MeAs(NMe_2)NMe_2 \cdot AlMe_3$ (**II**). Additional peaks suggest the presence of a trace amount of the postulated $[MeAl(NMe_2)_2]_2$, as in the 0.5:1 mmol Me_3Al/Me_2AsNMe_2 system. Considerable line-width broadening in the ^1H NMR spectra and shifts in δ_H and δ_C position assignments for the peaks associated with the Me_2N, Me_2As and MeAs moieties suggest exchange averaging that involves the Me_2AsNMe_2/**I** and $MeAs(NMe_2)_2$/**II** systems. Intensity data suggest that the 0.5:1 system contains more $MeAs(NMe_2)_2$ and **II** relative to Me_2AsNMe_2 and **I** than does the 1:1 system. With time, spectral line-width narrowing occurs with the concomitant shifts in the exchange averaged δ_H and δ_C values toward the assignments for $MeAs(NMe_2)_2$ and Me_2AsNMe_2. This is also accompanied by increases in the intensities of the $(Me_2AlNMe_2)_2$ and Me_2AsNMe_2 peaks and decreases in the intensities of the **II** and $MeAs(NMe_2)_2$ peaks. After 1 month, the reactions are almost complete with the respective product compositions being: [0.5:1 system] = 47% $MeAs(NMe_2)_2$, 37% Me_2AsNMe_2, 16% $(Me_2AlNMe_2)_2$; [1:1 system] = 3% $MeAs(NMe_2)_2$, 58% Me_2AsNMe_2, 5% **I**, 33% $(Me_2AlNMe_2)_2$. There is no evidence for the formation of Me_3As in either system.

In the 3:1 system, the NMR spectra indicate the presence of **I**, $(Me_2AlNMe_2)_2$, $Me_2AlNMe_2 \cdot AlMe_3$ and unreacted $(Me_3Al)_2$. With time, decomposition of **I** produces $Me_3As \cdot AlMe_3$ and $Me_2AlNMe_2 \cdot AlMe_3$ with the concomitant consumption of $(Me_3Al)_2$. After $Me_2AlNMe_2 \cdot AlMe_3$ no longer forms, it dissociates to yield $(Me_2AlNMe_2)_2$. After 3 months, the product composition is 36% $Me_3As \cdot AlMe_3$, 33% $(Me_2AlNMe_2)_2$, 19% $Me_2AlNMe_2 \cdot AlMe_3$ and 12% $Me_2AsNMe_2 \cdot AlMe_3$.

Variable-temperature, multinuclear NMR studies for 0.5:1, 1:1, 1:0.5, 2:1 and 3:1 mmol Me_3Al–$MeAs(NMe_2)_2$ ratios were carried out to elucidate the reaction pathway to **I**, determine concentration effects and identify possible low-temperature stable adducts of $MeAs(NMe_2)_2$. In a 2:1 system, there is exclusive formation of **II** at −95°C with unreacted $MeAs(NMe_2)_2$ and $(Me_3Al)_2$ remaining. With increasing temperature, more **II** forms and ^1H spectral line-width broadening and shifts in δ_H and δ_C position assignments for the Me_2N moieties suggest $MeAs(NMe_2)_2$/**II** exchange averaging. By −80°C, decomposition of **II** begins to give **I** and $Me_2AlNMe_2 \cdot AlMe_3$. This continues, with the consumption of $(Me_3Al)_2$, as the temperature is increased. Beginning at −60°C, $(Me_2AlNMe_2)_2$ forms and $Me_2AlNMe_2 \cdot AlMe_3$ is consumed as **II** decomposes to **I**. This process continues with increasing temperature until at room temperature the solution contains predominantly **I** and $(Me_2AlNMe_2)_2$ with some $MeAs(NMe_2)_2$, **II** and $Me_2AlNMe_2 \cdot AlMe_3$. Overnight, the conversion to **I** and $(Me_2AlNMe_2)_2$ is almost complete. The product composition is then similar to that of the 2:1 room-temperature system.

The analogous 1:0.5 mmol system, which represents a lower concentration system still having a 2:1 mol ratio of reactants, gives different low temperature results. At −95°C, there is a 5% yield of **II** and a 90% yield of the bis-adduct, $MeAs(NMe_2 \cdot AlMe_3)_2$ (**III**), along with some remaining unreacted $MeAs(NMe_2)_2$ and $(Me_3Al)_2$. With time (2 h) at −95°C, the spectra indicate extensive decomposition of **III** with the formation of **I** and $Me_2AlNMe_2 \cdot AlMe_3$. The decomposition of **III** goes to completion within 1 h at −90°C. ^1H spectral line-width broadening and chemical shift (δ_H and δ_C) positions suggest that $MeAs(NMe_2)_2$ and **II** exchange average. Beginning at −60°C and continuing up to room temperature, $Me_2AlNMe_2 \cdot AlMe_3$ dissociates to form $(Me_2AlNMe_2)_2$. At room temperature, **II** decomposes to **I** and $(Me_2AlNMe_2)_2$ while $MeAs(NMe_2)_2$ is consumed. The composition of the product mixture, at this point, is the same as that of the 2:1 variable-temperature study.

The 0.5:1 mmol system at −95°C gives a mixture of **I**, **II**, **III**, $(Me_2AlNMe_2)_2$, Me_2AsNMe_2 and unreacted $MeAs(NMe_2)_2$. Compounds **III**, **II** and **I** are

in approximately a 5:5:1 mol ratio, respectively. Decomposition of **III** continues with time and goes to completion at −90°C. At −70°C, ^{1}H line-width broadening suggests exchange averaging between $MeAs(NMe_2)_2$ and **II**. Decomposition of **II** begins at −60°C with formation of $(Me_2AlNMe_2)_2$ and Me_2AsNMe_2, which exchange averages with **I**. The product composition at room temperature is that observed in the room-temperature 0.5:1 system.

At −90°C, a 1:1 mmol system contains $MeAs(NMe_2)_2$, $(Me_3Al)_2$ and an equimolar mixture of **II** and **III**. A trace of **I** and Me_2AsNMe_2 are also observed. (In a separate 2:2 mmol system experiment, **II** is exclusively formed at −95°C.) By −80°C, **III** completely decomposes to **I** and $Me_2AlNMe_2 \cdot AlMe_3$. Exchange averaging that involves the Me_2AsNMe_2/**I** and $MeAs(NMe_2)_2$/**II** systems continues as long as Me_2AsNMe_2 and $MeAs(NMe_2)_2$ are present with **I** and **II**. Decomposition of **II** at −70°C gives **I** and $Me_2AlNMe_2 \cdot AlMe_3$ as $(Me_3Al)_2$ is consumed. By −60°C, very little $(Me_3Al)_2$ remains and $(Me_2AlNMe_2)_2$ forms as $Me_2AlNMe_2 \cdot AlMe_3$ dissociates and **II** continues to decompose. At −20°C, the peaks associated with $MeAs(NMe_2)_2$ and $Me_2AlNMe_2 \cdot AlMe_3$ decrease as those associated with **I** and $(Me_2AlNMe_2)_2$ increase. At room temperature, the product composition is similar to that of the 1:1 room-temperature study. Exchange averaging continues with a shift in composition towards $MeAs(NMe_2)_2$ and Me_2AsNMe_2.

In the 3:1 mmol variable-temperature study, only about a 10% yield of **II** results at −95°C. No bis-adduct, **III**, forms. At −90°C, the reaction goes to completion to give exclusively **II**. Compound **II** begins to decompose at −80°C to form Me_2AsNMe_2 (**I**) and $Me_2AlNMe_2 \cdot AlMe_3$ and continues until room temperature. Compounds **I** and Me_2AsNMe_2 exchange average until −60°C, when all the Me_2AsNMe_2 is converted to **I**. The product composition at room temperature is analogous to that in the 3:1 mmol room-temperature system.

Analysis of the room-temperature and variable-temperature data for the various stoichiometric ratio systems suggests that $MeAs(NMe_2)_2$ preferentially forms the mono adduct, **II**, [eq. (10)] at higher $(Me_3Al)_2$ concentrations (2:2, 2:1 and 3:1 mmol ratios) and the bis-adduct, **III**, [eq. (11)] at lower $(Me_3Al)_2$ concentrations (0.5:1, 1:0.5 and 1:1 mmol systems). These concentration effects imply that adduct formation proceeds via the reaction of $MeAs(NMe_2)_2$ with Me_3Al, whose concentration is determined by the $(Me_3Al)_2/Me_3Al$ equilibrium distribution in solution. At lower temperatures and higher alane concentration, the $(Me_3Al)_2/Me_3Al$ equilibrium indicates only slight dissociation to Me_3Al.[62] Thus, the resulting low Me_3Al concentration should favour the formation of the monoadduct, **II**, over that of **III**. Although we tend to prefer this pathway, this is insufficient data to eliminate a reaction mechanism that involves the direct interaction of $MeAs(NMe_2)_2$ with $(Me_3Al)_2$.

In those cases where the bis-adduct, **III**, is observed (0.5:1, 1:0.5 and 1:1 mmol systems), it is quite unstable and readily decomposes at or below −90°C into **I** and Me_2AlNMe_2 [eq. (12)]. The presence of **I**, Me_2AsNMe_2 and $(Me_2AlNMe_2)_2$ at −95°C in the 0.5:1 system suggests that **III** formed and had already decomposed slightly prior to spectral data acquisition.

The NMR spectral and decomposition product data suggest that **II** and **III** are Al—N bonded adducts. The magnitudes and directions of shifts in δ_H and δ_C for the Me_2N and Me_2As groups upon adduct formation are consistent with those observed in the formation of **I**.

In all cases, the mono adduct, **II**, exchange averages with $MeAs(NMe_2)_2$ and/or decomposes to Me_2AsNMe_2 and Me_2AlNMe_2 [eq. (13)]. Decomposition begins typically at −80°C and continues up to room temperature. When the amount of $(Me_3Al)_2$ is low (0.5:1 system), Me_2AlNMe_2 dimerizes [eq. (3)]. Me_2AsNMe_2 exchange averages with **I** formed from the decomposition of **III**. When there are appreciable amounts of $(Me_3Al)_2$ (1:0.5, 1:1, 2:1 and 3:1 systems), Me_2AlNMe_2 reacts to give $Me_2AlNMe_2 \cdot AlMe_2$ [eq. (7)] and Me_2AsNMe_2 forms **I** [eq. (1)]. As the amount of $(Me_3Al)_2$ is depleted through side reactions [eqs (1) and (7)], $Me_2AlNMe_2 \cdot AlMe_3$ dissociates to Me_3Al and Me_2AlNMe_2 [eq. (9)], which dimerizes [eq. (3)]. This dissociation begins around −60°C and continues up to room temperature.

In those systems containing appreciable amounts of $MeAs(NMe_2)_2$ in the presence of **I**, two important competition reactions occur to influence the final product composition. The first [eq. (14)] is the reaction of $MeAs(NMe_2)_2$ and **I** to generate Me_2AsNMe_2 and **II**, which then decomposes according to eq. (13). This process continues until all the $MeAs(NMe_2)_2$ and **I** are consumed to give the final thermodynamically-stable products, Me_2AsNMe_2 and $(Me_2AlNMe_2)_2$. The $MeAs(NMe_2)_2$/**I** reaction has been carried out independently and shown to be more facile than the decomposition of **I**. Thus, it is very important in establishing the final distributions of Me_2AsNMe_2, $MeAs(NMe_2)_2$ and $(Me_2AlNMe_2)_2$ in the 0.5:1 and 1:1 systems where **I** does not decompose to Me_3As at room temperature. Undoubtedly, eq. (14) is also important as a competition reaction at those temperatures

in the 0.5 : 1, 1 : 0.5 and 2 : 1 systems where MeAs$(NMe_2)_2$ and **I** are present. In the 1 : 0.5 and 2 : 1 systems, a second competition reaction plays a significant role in regenerating **I** [eq. (15)]. Here Me_2AsNMe_2 competes effectively for the bound Me_3Al in $Me_2AlNMe_2 \cdot AlMe_3$ [eq. (15)]. After all the MeAs$(NMe_2)_2$ and $Me_2AlNMe_2 \cdot AlMe_3$ are consumed, **I** then slowly decomposes to give Me_3As and $(Me_2AlNMe_2)_2$ [eq. (2)]. Equation (14) does not play a role in the 3 : 1 system, since all the MeAs$(NMe_2)_2$ is consumed by $-90°C$. The presence of a species that we propose is $[MeAl(NMe_2)_2]_2$ in the 0.5 : 1 and 1 : 1 cases suggests that a possible third, but much less important, competition reaction occurs. This involves the reaction of Me_2AlNMe_2 with MeAs$(NMe_2)_2$ [eq. (16)]. The route to $[MeAl(NMe_2)_2]_2$ does not involve Me_2AsNMe_2 [eqs (4) and (5)], since Me_3As is not observed in these systems.

The following reactions are unique to the Me_3Al/MeAs$(NMe_2)_2$ reaction systems:

$$MeAs(NMe_2)_2 + Me_3Al \longrightarrow MeAs(NMe_2)NMe_2 \cdot AlMe_3 \quad (10)$$

$$MeAs(NMe_2)_2 + 2Me_3Al \longrightarrow MeAs(NMe_2 \cdot AlMe_3)_2 \quad (11)$$

$$MeAs(NMe_2 \cdot AlMe_3)_2 \longrightarrow Me_2AsNMe_2 \cdot AlMe_3 + Me_2AlNMe_2 \quad (12)$$

$$MeAs(NMe_2)NMe_2 \cdot AlMe_3 \longrightarrow Me_2AsNMe_2 + Me_2AlNMe_2 \quad (13)$$

$$MeAs(NMe_2)_2 + Me_2AsNMe_2 \cdot AlMe_3 \longrightarrow MeAs(NMe_2)NMe_2 \cdot AlMe_3 + Me_2AsNMe_2 \quad (14)$$

$$Me_2AsNMe_2 + Me_2AlNMe_2 \cdot AlMe_3 \longrightarrow Me_2AsNMe_2 \cdot AlMe_3 + Me_2AlNMe_2 \quad (15)$$

$$2Me_2AlNMe_2 + 2MeAs(NMe_2)_2 \longrightarrow 2Me_2AsNMe_2 + [MeAl(NMe_2)_2]_2 \quad (16)$$

Reaction of $(Me_3Al)_2$ *with* $As(NMe_2)_3$

The ^1H and ^{13}C NMR spectra of the room-temperature reactions of $(Me_3Al)_2$ with $As(NMe_2)_3$ in 1 : 1, 2 : 1, 3 : 1 and 4 : 1 mmol Me_3Al–$As(NMe_2)_3$ ratios indicate the immediate formation of **I** and $(Me_2AlNMe_2)_2$ in all cases. The 1 : 1 and 2 : 1 systems also contain unreacted $As(NMe_2)_3$, as well as exchange averaging of Me_2AsNMe_2 and **I**. In the 4 : 1 case, all the $As(NMe_2)_3$ is consumed and $Me_2AlNMe_2 \cdot AlMe_3$, $Me_3As \cdot AlMe_3$ and Me_3As are also present. ^1H spectral line-width broadening and the δ_H and δ_C peak positions suggest that $Me_3As \cdot AlMe_3$ and Me_3As exchange average. The most straightforward reaction occurs as expected in the 3 : 1 ratio system. Here, **I** decomposes completely with time to yield Me_3As and $(Me_2AlNMe_2)_2$ as the sole reaction products.

In the 1 : 1 case, decomposition of **I** and consumption of $As(NMe_2)_3$ proceeds with time to give a mixture containing Me_2AsNMe_2, MeAs$(NMe_2)_2$, $As(NMe_2)_3$ and $(Me_2AlNMe_2)_2$. For the 2 : 1 system, decomposition is very slow and after 3 months the solution contains **I**, Me_2AsNMe_2 and As$(NMe_2)_3$, with Me_2AsNMe_2/**I** exchange averaging. When excess $(Me_3Al)_2$ is used (4 : 1 system), **I** decomposes and $Me_2AlNMe_2 \cdot AlMe_3$ dissociates within 2 days to give a solution containing $(Me_2AlNMe_2)_2$, Me_3As and $Me_3As \cdot AlMe_3$.

Variable-temperature, multinuclear NMR studies for 1 : 1, 1 : 0.33 and 3 : 1 Me_3Al–$As(NMe_2)_3$ ratios were carried out to elucidate the reaction pathway to **I** and determine concentration effects upon adduct formation. In the 3 : 1 system, there is exclusive formation of the Al—As adduct $(Me_2N)_3As \cdot AlMe_3$ (**IV**), in about 10% yield at $-95°C$. By $-90°C$, the amount of **IV** has greatly increased and a mono Al—N adduct, $(Me_2N)_2AsNMe_2 \cdot AlMe_3$ (**V**), and a bis Al—N adduct, $Me_2NAs(NMe_2 \cdot AlMe_3)_2$ (**VI**), form. The mol ratio of **IV** : **V** : **VI** is 3.5 : 3.3 : 1. The magnitudes of the δ_C changes for the Me_2N groups upon complexation are significantly larger for the formation of **V** (3.08 ppm) and **VI** (4.57 ppm) than for the Al—As bonded adduct, **IV** (0.36 ppm). At $-85°C$, **IV** begins to dissociate with the concomitant formation of more **V** and **VI** in a 1 : 1 mol ratio. This process continues up to $-40°C$. From -80 to $-60°C$, ^1H spectral line-width broadening and δ_H and δ_C peak positions suggest exchange averaging involving $As(NMe_2)_3$, **V** and **VI**. From -70 to $-60°C$, **V** and **VI** decompose to **II**, **III**, $Me_2AlNMe_2 \cdot AlMe_3$ and MeAs$(NMe_2)_2$. Spectral data suggest that **VI** decomposes faster than **V**. Compound **I** also forms as the temperature increases. Above $-60°C$, **II** and **III** decompose with the formation of **I** and Me_2AsNMe_2. ^1H spectral line-width broadening and δ_H and δ_C peak positions suggest that MeAs$(NMe_2)_2$, **II** and **III** exchange average. Decomposition of **III** is complete by $-50°C$, while that of **II** is complete by 0°C. At $-40°C$, peaks associated with $Me_2AlNMe_2 \cdot AlMe_3$ begin to decrease in intensity and peaks assigned to $(Me_2AlNMe_2)_2$ appear. Above $-40°C$, the Me_2AsNMe_2/**I** exchange averaging indicates increasing conversion of Me_2AsNMe_2 to **I**. The room-temperature product composition is analogous to that in the 3 : 1 mmol room-temperature system. The 1 : 0.33 mmol system gives results analogous to those in the 3 : 1 system. The only sig-

nificant difference is the formation of a mixture of **IV**, **V** and **VI** at −95°C.

The 1 : 1 mmol system at −95°C yields a mixture of **IV**, **V** and **VI** in a 0.6 : 1 : 1 mol ratio with unreacted $As(NMe_2)_3$ and $(Me_3Al)_2$. More **V** and **VI** form in a 1 : 1 mol ratio with increasing temperature. Above −80°C, decomposition of **V** and **VI** gives a mixture of **I**, **II**, **III**, $MeAs(NMe_2)_2$, Me_2AsNMe_2 and $Me_2AlNMe_2 \cdot AlMe_3$, with exchange averaging of the Me_2AsNMe_2/**I** and $MeAs(NMe_2)_2$/**II** systems. Dissociation of **IV** begins and is complete by −60°C. At −40°C, $As(NMe_2)_3$ and $Me_2AlNMe_2 \cdot AlMe_3$ are being consumed with increased formation of **I**, $MeAs(NMe_2)_2$ and $(Me_2AlNMe_2)_2$. By room temperature, the solution contains the product composition of the 1 : 1 room-temperature study—only **I**, Me_2AsNMe_2, $(Me_2AlNMe_2)_2$ and unreacted $As(NMe_2)_3$.

Analysis of the room- and variable-temperature NMR spectral data for the various stoichiometric ratio systems suggests that $As(NMe_2)_3$ forms an Al—As bonded adduct, **IV**, and the mono, **V**, and bis, **VI**, Al—N bonded adducts [eqs (17)–(19)]. Analogous adducts form in the reaction of $BH_3 \cdot THF$ with $As(NMe_2)_3$.[63] The Al—As adduct is unstable relative to dissociation [eq. (20)] at low temperatures (> −85°C). At a slightly higher temperature (−70°C), **V** and **VI** decompose. The $As(NMe_2)_3/(Me_3Al)_2$ reaction systems are complicated by the occurrence of not only the decomposition of **V** and **VI**, but the simultaneous participation of many of the competing reactions and exchange equilibria observed in the MeAs $(NMe_2)_2/(Me_3Al)_2$ and $Me_2AsNMe_2/(Me_3Al)_2$ reactions.

By analogy to the decomposition pathways of **II** and **III** and considering the species observed at −70 and −60°C, we postulate that **V** and **VI** decompose according to eqs (21) and (22). The Me_2AlNMe_2, **II**, and $MeAs(NMe_2)_2$ formed can then react with available $(Me_3Al)_2$ to give $Me_2AlNMe_2 \cdot AlMe_3$ [eq. (7)], **III** [eq. (11)] and additional **II** [eq. (10)]. At a slightly higher temperature (−60°C), **II** and **III** begin to decompose to Me_2AsNMe_2, **I** and Me_2AlNMe_2 [eqs (12) and (13)]. Exchange averaging again occurs between Me_2AsNMe_2 and **I**, and $MeAs(NMe_2)_2$ and **II**. In addition to the reaction of $MeAs(NMe_2)_2$ with **I** [eq. (14)], $As(NMe_2)_3$ can also react with **I** [eq. (23)] to provide an alternate route to Me_2AsNMe_2. This reaction [eq. (23)], which is very slow, has been confirmed independently. $As(NMe_2)_3$ competes for the Me_3Al bound in **I** to yield Me_2AsNMe_2 and **V**, which then decomposes to $MeAs(NMe_2)_2$ [eq. (21)]. $MeAs(NMe_2)_2$ now reacts with **I** [eq. (14)] to give **II**, which decomposes to Me_2AsNMe_2 [eq. (13)]. The overall reaction [eq. (23)] is much slower than the rate of decomposition of **I**. Thus, in the 1 : 1 and 2 : 1 systems, the final product composition contains Me_3As in addition to Me_2AsNMe_2 and $(Me_2AlNMe_2)_2$. Since, in the 3 : 1 case, the additional available $(Me_3Al)_2$ converts all the Me_2AsNMe_2 to **I**, only Me_3As and $(Me_2AlNMe_2)_2$ are obtained. In the 4 : 1 system, the amount of $(Me_3Al)_2$ in stoichiometric excess reacts with an equimolar amount of Me_3As [eq. (8)] to give a final product composition containing Me_3As, $Me_3As \cdot AlMe_3$ and $(Me_2AlNMe_2)_2$.

The following reactions are unique to the $(Me_3Al)_2/As(NMe_2)_3$ reaction systems:

$$As(NMe_2)_3 + Me_3Al \longrightarrow (Me_2N)_3As \cdot AlMe_3 \quad (17)$$

$$As(NMe_2)_3 + Me_3Al \longrightarrow (Me_2N)_2AsNMe_2 \cdot AlMe_3 \quad (18)$$

$$As(NMe_2)_3 + 2Me_3Al \longrightarrow Me_2NAs(NMe_2 \cdot AlMe_3)_2 \quad (19)$$

$$(Me_2N)_3As \cdot AlMe_3 \longrightarrow As(NMe_2)_3 + AlMe_3 \quad (20)$$

$$(Me_2N)_2AsNMe_2 \cdot AlMe_3 \longrightarrow MeAs(NMe_2)_2 + Me_2AlNMe_2 \quad (21)$$

$$Me_2NAs(NMe_2 \cdot AlMe_3)_2 \longrightarrow MeAs(NMe_2)NMe_2 \cdot AlMe_3 + Me_2AlNMe_2 \quad (22)$$

$$As(NMe_2)_3 + 2Me_2AsNMe_2 \cdot AlMe_3 \longrightarrow 3Me_2AsNMe_2 + (Me_2AlNMe_2)_2. \quad (23)$$

Reactions of **I** *with* $MeAs(NMe_2)_2$ *and* $As(NMe_2)_3$

The ^1H and ^{13}C NMR spectra of the room-temperature reaction of **I** with $MeAs(NMe_2)_2$ indicate that a 68% conversion of **I** to Me_2AsNMe_2 and of $MeAs(NMe_2)_2$ to **II** occurs rapidly upon mixing. ^1H spectral line-width broadening and the δ_H and δ_C peak positions suggest that the Me_2AsNMe_2/**I** and $MeAs(NMe_2)_2$/**II** systems are exchange averaging. Within 2 days, there is an 81% conversion to Me_2AsNMe_2. The reaction goes to completion in 16 days to give Me_2AsNMe_2, $(Me_2AlNMe_2)_2$ and a trace of Me_3As. The presence of only a trace of Me_3As suggests that the rates of the competition reaction [eq. (14)] and the decomposition of **II** [eq. (13)] are much greater than that of the decomposition of **I** [eq. (2)]. The stabilizing of **I** through exchange averaging may be an important factor. Thus, the reaction of **I** with $MeAs(NMe_2)_2$ is important in determining the final product distribution

and the overall rate of reaction in the reactions of $(Me_3Al)_2$ with $MeAs(NMe_2)_2$ and $As(NMe_2)_3$, and in the $Me_2AsNMe_2/MeAs(NMe_2)_2/As(NMe_2)_3$ competition reactions.

The NMR spectral data for the reaction of **I** with $As(NMe_2)_3$ indicate approximately a 10% conversion of **I** to Me_2AsNMe_2 and the presence of $MeAs(NMe_2)_2$ and **II** within 2 h of mixing. Exchange averaging that involves the Me_2AsNMe_2/**I** and $MeAs(NMe_2)_2$/**II** systems is observed. The $MeAs(NMe_2)_2$ is rapidly consumed and peaks assigned to $[MeAl(NMe_2)_2]_2$ and Me_3As appear. After 2 days, a 90% conversion to Me_2AsNMe_2 has occurred with further formation of $[MeAl(NMe_2)_2]_2$ and Me_3As, and the appearance of peaks associated with uncharacterized Me_2N moiety containing species. With time, the intensities of peaks assigned to Me_2AsNMe_2 decrease while that associated with Me_3As increases. After 1 month, the reaction mixture contains Me_3As, Me_2AsNMe_2, $MeAs(NMe_2)_2$. $[MeAl(NMe_2)_2]_2$, $(Me_2AlNMe_2)_2$ and considerable unreacted As $(NMe_2)_3$. These data suggest that the reaction of **I** with $As(NMe_2)_3$ is initially slow. At room temperature, the Me_3Al adduct(s) of $As(NMe_2)_3$ are unstable and decompose to $MeAs(NMe_2)_2$, **II** and Me_2AlNMe_2 [eqs (21) and (22)]. The $MeAs(NMe_2)_2$ reacts with **I** [eq. (14)] to give **II** and Me_2AsNMe_2. The Me_2AlNMe_2 that also forms from the decomposition of **II** [eq. (13)] probably reacts with the large amount of available $As(NMe_2)_3$ to give $MeAs(NMe_2)_2$ and $[MeAl(NMe_2)_2]_2$ [eq. (24)]. This would be analogous to the Me_2AlNMe_2/$MeAs(NMe_2)_2$ reaction [eq. (16)], where $[MeAl(NMe_2)_2]_2$ was detected only when there was a large amount of $MeAs(NMe_2)_2$ present in solution. It can also react with Me_2AsNMe_2 [eqs (4) and (5)] and $MeAs(NMe_2)_2$ [eq. (16)]. The following reaction is unique to the $I/As(NMe_2)_3$ reaction system:

$$2Me_2AlNMe_2 + 2As(NMe_2)_3 \longrightarrow 2MeAs(NMe_2)_2 + [MeAl(NMe_2)_2]_2. \quad (24)$$

Because this reaction is very slow, it does not play a significant role in the variable temperature $As(NMe_2)_3/(Me_3Al)_2$ reactions nor in the $Me_2AsNMe_2/MeAs(NMe_2)_2/As(NMe_2)_3/(Me_3Al)_2$ competition reactions.

Competition studies of $(Me_3Al)_2$ *with* Me_2AsNMe_2, $MeAs(NMe_2)_2$ *and* $As(NMe_2)_3$ *mixtures*

At −95°C, the NMR spectra of the 1:1:1:1 and 1:1:1:2 mmol Me_2AsNMe_2–$MeAs(NMe_2)_2$–$As(NMe_2)_3$–$AlMe_3$ mixtures indicate the presence of **I**, **II**, **III**, Me_2AsNMe_2, $MeAs(NMe_2)_2$ and $As(NMe_2)_3$. There is no spectral evidence for any reaction of $(Me_3Al)_2$ with $As(NMe_2)_3$. Integration data for both systems suggest that Me_2AsNMe_2 and $MeAs(NMe_2)_2$ react in a 1:1 mol ratio and that approximately 15% of **III** decomposes [eq. (12)]. In the 1:1:1:1 system, equal amounts of **II** and **III** form; in the 1:1:1:2 system, **II** and **III** form in a 1.5:1 mol ratio, respectively. Upon increasing the temperature, further decomposition of **III** occurs. At room temperature, the spectra suggest that Me_2AsNMe_2 is exchanging with **I**, $MeAs(NMe_2)_2$ is exchanging with **II**, and $(Me_2AlNMe_2)_2$ and $As(NMe_2)_3$ are present. After 1 week, new peaks are observed for Me_3As and $[MeAl(NMe_2)_2]_2$ and peaks associated with **I** and **II** are absent in the spectra of the 1:1:1:1 system. The final composition indicates a 1:2:3 mol ratio of Me_3As, $MeAs(NMe_2)_2$ and Me_2AsNMe_2, respectively. In the 1:1:1:2 system, only traces of Me_3As and $MeAs(NMe_2)_2$ are present after 1 week. Me_2AsNMe_2 is the arsenic-containing product from the reaction. In both cases, significant amounts of $As(NMe_2)_3$ remain.

These data suggest that $(Me_3Al)_2$ preferentially reacts with Me_2AsNMe_2 and $MeAs(NMe_2)_2$ as compared with $As(NMe_2)_3$. After the initial formation of **I**, **II** and **III**, these adducts decompose [eqs (2), (12) and (13)]. Since the $(Me_3Al)_2$ is stoichiometrically deficient relative to available nitrogen base sites, all the previously described exchange and competing reactions [eqs (3)–(6), (14), (16) and (24)] for such systems can occur with time and influence the final product composition.

CONCLUSIONS

The results of these studies establish the mode of reaction of $(Me_3Al)_2$ with Me_2AsNMe_2, $MeAs(NMe_2)_2$ and $As(NMe_2)_3$, and the role of competing reactions and exchange equilibria in determining the final product distributions. In all the variable-temperature studies, we have been able to establish the formation of initial Me_3Al adducts at −95°C and to determine their subsequent decomposition pathways. All the aminoarsines form the expected mono Al—N bonded adducts, i.e. **I**, **II** and **V**, with the following order of thermal stability: **I** > **II** > **V**. $MeAs(NMe_2)_2$ and $As(NMe_2)_3$ also form bis Al—N bonded adducts, i.e. **III** and **VI**. These readily decompose at low temperature. The only observed Al—As bonded adduct, **IV**, occurs with $As(NMe_2)_3$ and it dissociates at low temperature. Thus, the nitrogen Lewis base site in the aminoarsines is the preferred bonding site for the Me_3Al Lewis acid.

These results are in contrast to those obtained for the Et_3Al adducts of the bisphosphinoamines and Me_2PNMe_2.[43] For these cases, Al—P bonded 1:1 addition compounds form. However, Me_2PNMe_2, which is the phosphorus analogue of Me_2AsNMe_2, also gives an Al—N bonded adduct. It is apparently more thermodynamically stable than the Al—P bonded adduct.[43]

All the Al—N bonded adducts decompose by a pathway that involves cleavage of the As—N bond and transfer of a methyl group from the aluminium to the arsenic. Whether this proceeds through a four-centred intermediate with simultaneous bond cleavage and formation of a concerted mechanism that involves interaction of the aminoarsine and Me_3Al molecules in an appropriate low energy conformation could not be determined from our study. In each case, the decomposition of a mono adduct yields the next higher methyl homologue in the arsine series [$MeAs(NMe_2)_2$, Me_2AsNMe_2 or Me_3As] and the postulated unstable Me_2AlNMe_2. Decomposition of a bis adduct yields the next higher methyl homologue in the mono adduct series (**I** or **II**) and unstable Me_2AlNMe_2.

Since $(Me_3Al)_2$ is usually in excess at low temperatures, Me_2AlNMe_2 forms $Me_2AlNMe_2 \cdot AlMe_3$, which eventually dissociates and then provides an alternative source of Me_3Al when the $(Me_3Al)_2$ is consumed. When the amount of $(Me_3Al)_2$ is low, either through the initial reaction stoichiometry or further reaction, Me_2AlNMe_2 dimerizes to $(Me_2AlNMe_2)_2$. If the aminoarsine is in stoichiometric excess, we propose the attack of Me_2AlNMe_2 at the arsine amino-nitrogen base site to give a very facile route to the next higher methyl homologue in the arsine series and $(Me_2AlNMe_2)_2$. The relative importance of these side reactions was demonstrated by carrying out the aminoarsine/$(Me_3Al)_2$ reactions in varying stoichiometric ratios. In large excesses of the aminoarsines, the Me_2AlNMe_2 can further react to give $[MeAl(NMe_2)_2]_2$ and the next higher methyl homologue in the arsine series. These results further support the general conclusion that the Al—N bond is more stable than the Al—C bond.[9,12]

In all the studied reaction systems, the Al—N bonded adducts exchange average with their respective parent aminoarsines. This exchange averaging slows dow the rate of adduct decomposition, influences the overall rate of formation of the final product arsine, and affects the final product distribution when other facile competing side-reactions can occur.

The reactions of $(Me_3Al)_2$ with $As(NMe_2)_3$ and $MeAs(NMe_2)_2$ are further complicated by the simultaneous presence of Me_2AsNMe_2, $MeAs(NMe_2)_2$ and $As(NMe_2)_3$, and the mono- and bis-adducts that can enter into separate exchange averaging, decomposition and competing side-reactions. These are all described by eqs (1)–(24). The initial stoichiometry of the reaction greatly influences the relative importance of the various reactions, which ultimately affect the rate of formation and final distribution of products. Only in those systems where the moles of available Me_3Al molecules equal those of Lewis base nitrogen sites, are the overall reactions straightforward and the influence of competing side-reactions minimized. Then the final products are always Me_3As and $(Me_2AlNMe_2)_2$.

We have been successful in adapting the results from these reactions of $(Me_3Al)_2$ with aminoarsines to a new, high-yield synthetic route to Me_3As. By carrying out the neat reaction at 0°C with slow addition of $(Me_3Al)_2$ followed by heating and distillation of the mixture at 140°C, the competing side reactions are driven rapidly to completion and pure Me_3As is obtained in an 84% yield (see Experimental). This is a higher yield route to Me_3As that eliminates the need for a complexing agent for removal of Me_3As from the reaction solution.[64]

Based upon these results, we are also adapting these reactions to the synthesis of mixed tertiary arsines and other symmetric tertiary arsines. Research is also underway on other $R'_nAs(NR_2)_{3-n}$ ($n = 0$–2) arsines to establish the influence of the nature of R and R′ on the binding of Me_3Al. Preliminary work has also established that Me_3Ga reacts in an analogous manner with the aminoarsines. This work is being pursued to establish the nature of the adducts formed and the subsequent decomposition pathways.

EXCHANGE REACTIONS BETWEEN DIALKYLZIRCONOCENE AND ALKYLALUMINIUM COMPOUNDS

A. R. SIEDLE,* R. A. NEWMARK, W. M. LAMANNA and J. N. SCHROEPFER

3M Corporate Research Laboratories, St. Paul, MN 55144, U.S.A.

Abstract—The dimethylmetallocenes $Cp_2Zr(^{13}CH_3)_2$, $(Me_5Cp)_2Zr(^{13}CH_3)_2$, $(indenyl)_2Zr(^{13}CH_3)_2$, $Me_2Si(C_5H_4)_2Zr(^{13}CH_3)_2$ and $Cp_2Hf(^{13}CH_3)_2$ undergo degenerate methyl exchange with the methyl-acceptor materials Me_6Al_2, $(MeAlO)_x$ and MeAl(2,6-di-t-butyl-4-methylphenoxy)$_2$. Free energies, enthalpies and entropies of activation for these processes have been obtained in two solvents by ^{13}C NMR. Increased steric hindrance at zirconium increases the free energy of activation. There appears not to be a correlation with electronic effects as assessed by gas phase appearance potentials for the $(P-CH_3)^+$ ions.

The role of cationic, coordinatively unsaturated zirconium(IV) compounds, as the active species in the catalytic polymerization of ethylene, has recently received considerable attention.[1,2] The cation $Cp_2ZrCH_3^+$ is of special interest. In fluid solution, it may be generated by oxidation or protonation of Cp_2ZrMe_2 but it has been characterized only in solvated form, for example, as $Cp_2ZrMe(S)^+$ (S = CH_3CN or THF).[1a] In the gas phase, successive detachment of methyl groups occurs upon electron impact ionization to afford Cp_2ZrMe^+ and Cp_2Zr^+.[3] It is open to question whether Cp_2ZrMe^+ is stable in solution in the absence of coordinating solvents and if it is, whether it might not exhibit an agnostic Zr—H—CH_2 interaction involving the α-hydrogen on the methyl group.[4] Previously, we reported that Cp_2ZrMe_2 readily exchanges methyl groups with Me_6Al_2 and that it reacts with $(Me_2AlEt)_2$ in neat Me_6Al_2 to form $Cp_2Zr(\mu\text{-}CH_3)(\mu\text{-}1,2\text{-}CH_2CH_2)AlMe_2$.[5] We surmise that methyl exchange may proceed via an ionic intermediate as shown conceptually (i.e. complexation by solvent or by Al_2Me_6 is neglected) in eq. (1):

$$Cp_2ZrMe_2 + Me_3Al \rightleftharpoons Cp_2ZrMe^+AlMe_4^- . \quad (1)$$

This equilibrium lies far to the left. In principle, eq. (1) is generally applicable to any Lewis acid capable of (formally) accepting a CH_3^- group. In order to gain further understanding of the interaction of Cp_2ZrMe_2 with such Lewis acids, we have undertaken a study of methyl exchange reactions with dimethylzirconocene and related compounds with a series of methylaluminium reagents.

RESULTS AND DISCUSSION

Rates of methyl exchange in the systems reported here were studied in two ways; $Cp_2Zr(^{13}CH_3)_2$ was combined with the methylaluminium compound in toluene and diminution of the Zr—CH_3 signal was followed as a function of time by ^{13}C NMR spectroscopy. In some cases, equilibrium was reached in too short a time (< 5 min) for this technique to be useful. In these situations, rates usually could be obtained by total line-shape analysis of the Zr—CH_3 resonance which was exchange-broadened. The methylaluminium compounds were used in large excess, typically 10–20 fold (cf. Experimental), so that kinetics of the exchange reactions are pseudo-first order with respect to the zirconium compound. Toluene was selected as the least interactive solvent capable of producing requisite concentrations of the reactants notwithstanding that it may weakly solvate three-coordinate aluminium(III) (*vide infra*). In the context of eq. (1), we refer to Cp_2ZrMe_2 and its congeners as methyl *donors*, and to Me_3Al and its congeners as methyl *acceptors*. This allows one to view methyl transfer processes in the framework of more generalized acid–base chemistry. The reactions studied are fully reversible and, in the kinetic experiments, no new products are detectable by NMR.

The aluminium-containing methyl acceptors employed in this work are Me_6Al_2, $MeAl(BHT)_2$

* Author to whom correspondence should be addressed.

(BHT = 2,6-di-t-butyl-4-methylphenoxy) and $(MeAlO)_x$. The first of these, Me_6Al_2, exists primarily as a methyl-bridged dimer. Nevertheless, the energetics of bridge–terminal methyl exchange in the dimer are quite solvent-dependent, differing significantly even between cyclopentane and toluene. It is thought that toluene may behave as a π-base toward $AlMe_3$ and thus lead to higher steady-state concentrations of solvated monomer.[6] We believe that it is with monomeric, i.e. solvated, Me_3Al that methyl exchange occurs and that the presence of three-coordinate aluminium is necessary for this reaction (*vide infra*). For this reason, we refer below to Me_3Al and express aluminium concentrations in terms of this monomer. Methylaluminoxane, $(MeAlO)_x$, is a substance produced by the controlled hydrolysis of Me_6Al_2. It is difficult to purify and characterize. Even today, its nature remains an enigma; it is not established whether it is a single substance or whether it has a static or a dynamic structure. However, acting with Cp_2ZrMe_2, it is a powerful if not unique, co-catalyst for the polymerization of ethylene.[7] Its inclusion in this study is warranted on technological grounds alone. Methylaluminoxane represents a special case of methyl acceptor molecules in two regards. First, its reaction with Cp_2ZrMe_2 in toluene leads to slow phase separation; a denser, orange layer contains all the $(MeAlO)_x$. A kinetic study in such a heterogeneous system is fraught with difficulty. Of the compounds studied, only Cp_2HfMe_2 remained homogeneous in toluene in the presence of $(MeAlO)_x$. Methyl exchange chemistry involving $(MeAlO)_x$ was, therefore, examined in dichloromethane. This choice of solvent limits the accessible temperature range so that only free energy data are available (*vide supra* and Experimental). Second, $(MeAlO)_x$ (unlike other organoaluminium compounds studied) and Cp_2ZrMe_2 undergo a *non*-equilibrium reaction that is much slower than the methyl exchange chemistry and which, therefore, does not affect the kinetic results. This reaction is still under investigation and will be described in detail elsewhere. Midway between Me_3Al and $(MeAlO)_x$ is $MeAl(BHT)_2$. The steric effects of the BHT groups prevent dimerization and this compound has been shown to be monomeric by X-ray crystallography (in the solid state)[8] and ^{27}Al NMR spectroscopy (in solution).[9] It is an uncommon and unambiguous example of a material containing three-coordinate aluminium for which reason it has been studied here. We consider, notwithstanding the ability of aryloxy groups to π-backbond, that it may be a heuristically useful model for $(MeAlO)_x$ for it features a MeAl moiety bonded to two oxygen atoms.

The dimethylmetallocene compounds employed include $Cp_2Zr(^{13}CH_3)_2$, $(Me_5Cp)_2Zr(^{13}CH_3)_2$, $(indenyl)_2Zr(^{13}CH_3)_2$, $Me_2Si(C_5H_4)_2Zr(^{13}CH_3)_2$, $(Me_3SiCp)_2Zr(^{13}CH_3)_2$ and $Cp_2Hf(^{13}CH_3)_2$. Using dimethylzirconocene as a reference point, the pentamethylcyclopentadienyl analogue is expected to be considerably more sterically hindered. Also, X-ray photoelectron spectroscopic studies indicate that the metal centre is much more electron-rich in this compound, perhaps approaching zirconium(III).[10] The η^5-indenyl ligand *can*, optionally, "slip" or move laterally so that C_9H_7 becomes a four-electron donor but in a $\leqslant$16-electron system, it is more probable that the η^5 structure is more stable and that the annelated benzo ring will be electron-withdrawing.[11] On the basis of a curious shielding of the C_1 (*ipso*) carbon atom in $Me_2Si(C_5H_4)_2ZrCl_2$ (this shielding is also seen in the $ZrMe_2$ analogue) as well as cyclic voltammetry results, it was concluded that the bridging Me_2Si group is electron-withdrawing.[12] Chemical and structural studies on $[Me_2Si(Me_4C_5)_2ThH_2]_2$ indicate that Me_2Si ring chelation significantly opens the thorium coordination sphere and is associated with enhanced reactivity of Th—H and Th—C σ bonds lying in the equatorial girdle.[13] Thus, the structural modifications to Cp_2ZrMe_2 available in the series under study here can alter relative reactivity through either steric or electronic effects. We shall argue below that the former is more important. It is difficult to predict with confidence the relative reactivity of Cp_2ZrMe_2 and Cp_2HfMe_2 towards a methyl acceptor. It has been noted that the metal–carbon σ bonds in the latter are short[14] and perhaps, therefore, more stable than in the zirconium analogue.

The free energies, enthalpies and entropies of activation of reversible methyl exchange between these materials and Me_3Al (*vide supra*) and $MeAl(BHT)_2$ in toluene are shown in Table 1. All of the reactions exhibit large, negative entropies of activation. This indicates that the transition state has a substantial loss of translational and rotational freedom, consistent with the bimolecular nature of the reaction.

The trends in free energies of activation reveal several correlations between reactivity and structure. First, the relative order of strength of methyl acceptors decreases in the order $(MeAlO)_x > Me_3Al > MeAl(BHT)_2$. This is in agreement with the expectation that two adjacent, electronegative oxygen atoms will increase Lewis acidity, and with the finding that, based on ^1H NMR chemical shifts and changes in ν_{CN} in benzonitrile complexes, that $(Me_2Al)_2O$ is a stronger Lewis acid than Me_3Al.[15] The alkoxide derivative MeAl

Table 1. Free energies,[a] enthalpies and entropies of activation of methyl exchange in toluene[b]

Methyl donor	Methyl acceptor Me_6Al_2	Methyl acceptor $MeAl(BHT)_2$
Cp_2ZrMe_2	$\Delta G^{\ddagger}$ 16.7 $\Delta H^{\ddagger}$ 11 $\Delta S^{\ddagger}$ −21	$\Delta G^{\ddagger}$ 22.4 $\Delta H^{\ddagger}$ 5 $\Delta S^{\ddagger}$ −59
$(Me_5Cp)_2ZrMe_2$	$\Delta G^{\ddagger}$ 22.3 $\Delta H^{\ddagger}$ 9 $\Delta S^{\ddagger}$ −46	No exchange $\leqslant$80°C
$Me_2Si(C_5H_4)_2ZrMe_2$	$\Delta G^{\ddagger}$ 14.3 $\Delta H^{\ddagger}$ 8 $\Delta S^{\ddagger}$ −22	$\Delta G^{\ddagger}$ 21.5 at 22°C
$(indenyl)_2ZrMe_2$	[c]	$\Delta G^{\ddagger}$ 27.7 at 81°C
$(Me_3SiCp)_2ZrMe_2$	No exchange $\leqslant$81°	$\Delta G^{\ddagger}$ 27.7 at 81°C
Cp_2HfMe_2	$\Delta G^{\ddagger}$ 20.4 $\Delta H^{\ddagger}$ 12 $\Delta S^{\ddagger}$ −30	No exchange

[a] At 22°C.
[b] Free energies and enthalpies in kcal mol^{-1}, entropies in cal K^{-1} mol^{-1}.
[c] Too slow for DNMR, too fast for kinetics; $\Delta G^{\ddagger}$ = 17–19 kcal mol^{-1} at 22°C.

$(BHT)_2$ is especially interesting. $\Delta S^{\ddagger}$ for methyl exchange is unusually large, −59 e.u., but $\Delta H^{\ddagger}$, 5 kcal mol^{-1}, is quite small. We interpret these data as meaning that a large fraction of the free energy of activation goes towards twisting the 2,6-di-t-butyl-4-methylphenoxy groups so that the peripheral alkyl groups do not, as the transition state is approached, block access to aluminium. This aluminium atom, being three-coordinate, is expected to be a powerful Lewis acid and accordingly, the activation enthalpy for transfer of a methyl group to it should be, and is, very low.

Again using free energies of activation to illustrate trends, methyl donor strength decreases in the order $Me_2Si(C_5H_4)_2ZrMe_2$ > $(indenyl)_2ZrMe_2$ > Cp_2HfMe_2 > $(Me_5Cp)_2ZrMe_2$.

Free energies of activation at 22°C for methyl exchange between some dimethylmetallocenes and $(MeAlO)_x$ in dichloromethane are shown in Table 2. In contrast to data for Me_3Al in toluene, they are very similar, ranging from 13 to 15 kcal mol^{-1}. We interpret this as a levelling effect; that is, the tendency of a very strong Lewis acid to make all bases appear to be of equal strength. This phenomenon has been long recognized in proton donors and acceptors.[16]

With a weak methyl acceptor, solvent effects are manifest. It would be expected that going from toluene to the more polar solvent dichloromethane should accelerate methyl transfer between Cp_2ZrMe_2 and $MeAl(BHT)_2$ if the transition state involved appreciable charge separation; otherwise, the solvent change should have minimal effect. In fact, the exchange rate in CH_2Cl_2 is immeasurably slow. We suggest that this striking change is due to weak complexation between $MeAl(BHT)_2$ and the lone electron pairs on chlorine in CH_2Cl_2. Organometallic complexes containing halocarbon donors are now well known.[17] Solvent effects exhibited by the stronger methyl acceptor $(MeAlO)_x$ are much less pronounced. For Cp_2HfMe_2, $\Delta G^{\ddagger}$ at 22°C is 15.3 kcal mol^{-1} ($\Delta H^{\ddagger}$ = 7 kcal mol^{-1}, $\Delta S^{\ddagger}$ = −29 e.u.) in toluene and 15.4 kcal mol^{-1} in dichloromethane.

Table 2. Free energies of activation for methyl exchange with $(MeAlO)_x$ in dichloromethane at 22°C

Compound	$\Delta G^{\ddagger}$ (kcal mol^{-1})
Cp_2ZrMe_2	13.9
$(Me_5Cp)_2ZrMe_2$	13.4
$(indenyl)_2ZrMe_2$	13.8
$Me_2Si(C_5H_4)_2ZrMe_2$	13.0
Cp_2HfMe_2	15.4
$(Me_3SiCp)_2ZrMe_2$	Irreversible reaction

In order to help estimate the relative roles of steric and electronic effects in these methyl exchange processes, we have measured the gas phase appearance potentials for ions formed by loss of CH_3^- from dimethylmetallocenes as illustrated in eq. (2):

$$Cp_2ZrMe_2 \rightarrow Cp_2ZrMe^+ + CH_3^-. \quad (2)$$

This was carried out in a mass spectrometric experiment by plotting the integral of the $(P-CH_3)^+$ ion as a function of ionizing voltage and extrapolating the linear portion of the curve to zero intensity, at which point the intercept is the appearance potential. The reaction in eq. (2) can be viewed as proceeding in several steps. These are (1) homolytic cleavage of a Zr—CH_3 bond, (2) ionization of the resulting $Cp_2ZrCH_3^{\cdot}$ radical and (3) electron capture by $CH_3^{\cdot}$. If it is assumed that, in the group of structurally similar compounds studied, the Zr—CH_3 bond dissociation energies are essentially constant, then trends in these appearance potentials reflect relative stabilities of the $(P-CH_3)^+$ ion, that is, the ability of a Cp_2ZrR group to support a positive charge. Typical data for $Me_2Si(C_5H_4)_2ZrMe_2$ are shown in Fig. 1 and appearance potentials are collected in Table 3. Their estimated uncertainties are ± 0.15 eV. In the zirconium compounds, there is no apparent correlation between appearance potentials for $(P-CH_3)^+$ and free energies of activation for methyl exchange. $(Me_5Cp)_2ZrMe_2$ should, because of the electron-releasing effect of the 10 ring-methyl groups, form a more stable $(P-CH_3)^+$ ion than Cp_2ZrMe_2,[10] and this ion does have, accordingly, a 0.5 eV lower appearance potential. But in fact, $(Me_5Cp)_2ZrMe_2$ undergoes methyl exchange with both Me_3Al and $MeAl(BHT)_2$ more slowly than does Cp_2ZrMe_2. As noted above, $(Me_5Cp)_2ZrMe_2$ is sterically more hindered than Cp_2ZrMe_2 and $Me_2Si(C_5H_4)_2ZrMe_2$ less so, and this is reflected in values of $\Delta G^{\ddagger}$ for methyl exchange. Conspicuous is $(Me_3SiCp)_2ZrMe^+$ which has a quite low appearance potential, yet $(Me_3SiCp)_2ZrMe_2$, which contains two large, bulky trimethylsilyl groups, has a large $\Delta G^{\ddagger}$ for exchange with $MeAl(BHT)_2$. This raises the question of whether this ion might not be stabilized in the gas phase by intramolecular Zr—H—C agnostic interactions. We believe that the major determinant of methyl donor ability of a dimethyl zirconium metallocene is comprised of steric effects. The hafnium compound Cp_2HfMe_2 forms a $(P-CH_3)^+$ ion with a lower appearance potential than any of the zirconium compounds studied, except $(Me_3SiCp)_2ZrMe_2$, yet it exchanges more slowly. This may be associated with a higher Hf—CH_3 bond energy noted above. In qualitative agreement with this, we find that the asymmetrical and symmetrical M—CH_3 stretching frequencies in Cp_2MMe_2 are 462 and 422 cm^{-1}, respectively (M = Zr); and 470 and 441 cm^{-1} (M = Hf), cf. Table 3.

Table 3. Gas phase appearance potentials for $(P—CH_3)^+$ ions and metal–carbon stretching frequencies

Compound (precursor)	$\nu_{M—C}$ (as) (cm^{-1})	$\nu_{M—C}$ (s) (cm^{-1})	E_{app} (eV)
Cp_2ZrMe_2	462	422	8.5 ± 0.15
$(Me_5Cp)_2ZrMe_2$	458	427	8.0
$Me_2Si(C_5H_4)_2ZrMe_2$	458	Not resolved	8.1
$(indenyl)_2ZrMe_2$	464	439	8.1
$(Me_3SiCp)_2ZrMe_2$	462	Not resolved	6.9
Cp_2HfMe_2	470	441	6.9

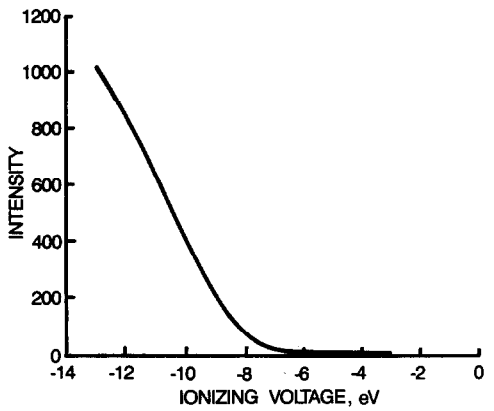

Fig. 1. Plot of integrated ion current of $(P-^{13}CH_3)^+$ from $(^{12}CH_3)_2Si(C_5H_4)_2Zr(^{13}CH_3)_2$ vs ionizing voltage.

What chemical and structural features of aluminium are needed to observe rapid methyl exchange? The issue of reactivity and solvation of Me_6Al_2 has been mentioned above. Aluminium compounds in which four-coordination is maintained by strong bridge bonds, e.g. $(Et_2AlOEt)_2$ and $\{[N(CH_2CH_2O)_3]Al_2Me_3\}_2$[19] are unreactive toward Cp_2ZrMe_2. In contrast, methyl exchange does occur in compounds in which aluminium participates in weak bridge bonds, e.g. $(Me_2AlCl)_2$ (Cp_2ZrCl_2 is produced) or where dissociation of an ancillary ligand is possible, e.g. $Me_2Al(BHT)\cdot PMe_3$.[8] We therefore suggest that three-coordinate aluminium acts as a methyl acceptor with Cp_2ZrMe_2 and its analogues.

Another way of assessing electronic effects, one that leads to the same general conclusions, is X-ray photoelectron spectroscopy (XPS).[10] Here, chloro- rather than methylzirconocenes were studied because the former are less volatile and less susceptible to air oxidation. We consider it probable that zirconium core levels in the two types of

compounds would parallel one another. The Zr($3d_{5/2}$, $3d_{3/2}$) binding energies in Cp_2ZrCl_2, $Me_2Si(C_5H_4)_2ZrCl_2$ and $(Me_3SiCp)_2ZrCl_2$ are 182.0, 184.4; 182.7, 185.1; and 181.8, 184.1 ± 0.1 eV, respectively. This is consistent with the NMR data which indicate that introduction of a Me_2Si bridge into Cp_2ZrCl_2 reduces electron density at the metal centre.[12] The electron-releasing effect of the Me_3Si group as assessed by XPS is almost insignificant. The Cl($2p_{3/2}$) binding energies in the same series of compounds, 199.0, 199.7 and 198.5 eV, parallel the zirconium core energies. Again, if electronic effects contributed significantly to activation energies for methyl exchange, it would be difficult to explain why $(Me_3SiCp)_2ZrMe_2$ exchanges as slowly as it does.

We have also investigated by NMR the reactions of Cp_2ZrMe_2 with other, potential, Group III acceptor compounds. No alkyl exchange is observed with Me_3Ga or Et_3B. Reasoning that substitution of alkyl by alkoxy on boron might increase methyl acceptor strength, Et_2BOMe was examined, but another reaction, methyl–methoxy exchange, eq. (3), supervenes. It is calculated to be exothermic by 44 kcal mol^{-1}.[18]

$$Cp_2ZrMe_2 + 2Et_2BOMe \rightarrow Cp_2Zr(OMe)_2 + 2Et_2BMe. \quad (3)$$

The product Et_2BMe may be recognized by its ^{11}B chemical shift, 86 ppm;[20] $Cp_2Zr(OMe)_2$[21] has $\delta^{13}C$ 61.3, 111.9 and $\delta^{91}Zr$ −447 ppm ($w/2$ 6500 Hz at 55°C). In neat Et_2BOMe, the kinetics of the above reaction are pseudo first-order in Cp_2ZrMe_2 and $k = 1.5 \times 10^{-4}$ min^{-1} at 22°C; $\Delta H^{\ddagger} = 15$ kcal mol^{-1} and $\Delta S^{\ddagger} = -33$ e.u. This exchange reaction involves as an intermediate $Cp_2Zr(OMe)Me$ which can be recognized by its NMR spectra: δ^1H 5.77, 3.65 (OMe), 0.23 (Zr—CH_3); $\delta^{13}C$ 111.9, 63.3 (OMe), 19.0 (Zr—Me); $\delta^{91}Zr$ −127 ($w/2$ 2500 Hz). Cleavage of B—O bonds by Cp_2ZrMe_2 appears to be a general reaction and also occurs with $(C_8H_{14}B)_2O$, $(MeBO)_3$ and $(CF_3SO_3)_3B$. It emerges that $Cp_2Zr(OMe)_2$ undergoes facile exchange of methoxy groups with Et_2BOMe. In neat Et_2BOMe, i.e. under pseudo-first order conditions, thermodynamic parameters determined by ^{13}C DNMR spectroscopy are $\Delta H^{\ddagger} = 7$ kcal mol^{-1} and $\Delta S^{\ddagger} = -21$ e.u.

Dimethylzirconium and -hafnium metallocenes are thus seen to undergo facile exchange of alkyl groups with methylaluminium reagents.[22] This exchange is general in that other (for example ethylaluminium) compounds may be used, but in this case the products are unstable because Cp_2ZrR_2, in which the R group has β-hydrogens, undergoes β-elimination to form olefin and numinous zirconium hydrides. A survey of the kinetics of degenerate methyl exchange reactions indicates that steric effects are important determinants of the free energy of activation relative to electronic effects. We suggest that, according to Hammond's postulate, the transition states in the endothermic equilibrium reactions of the type depicted in eq. (1) lie close along the reaction coordinate to the products. If we assume that a linear free energy relationship of the Brönsted type obtains (a reasonable postulate given the deliberately narrow structural range of the compounds studied), then the activation parameters for methyl exchange can provide insight into the effects of modification of the metallocene ligand set, as well as the choice of Lewis acid, on the position of the equilibrium depicted in eq. (1). This in turn may reflect the relative amounts of catalytically active metallocene cations formed in these systems.

EXPERIMENTAL

^1H, ^{11}B, ^{13}C and ^{91}Zr NMR spectra were recorded on a Varian XL-400 instrument, with a ^1H/multinuclear switchable probe, whose ^1H operating frequency is 400 MHz. External neat $BF_3 \cdot OEt_2$, $(CH_3)_4Si$ in $CDCl_3$ and 1 M Cp_2ZrBr_2 in THF were used as references with positive shifts being to lower field. Appearance potential measurements were made using a Nicolet model 2000 Fourier transform mass spectrometer and associated software. In some cases [$(Me_5Cp)_2ZrMe_2$, $Me_2Si(C_5H_4)_2ZrMe_2$] the Zr—$^{13}CH_3$ derivatives were used to ensure that ions actually derived from the loss of the Zr—Me group were observed. Integrals of the ^{90}Zr isotopomers were measured. Because no significant ion current at 1 mass unit lower was seen, one can be confident that the ions observed were not due to loss of $^{12}CH_3$ from the ^{91}Zr isotopomer. In the case of $(Me_5Cp)_2ZrMe_2$, the $(P-2CH_3)^+$ ion cluster appears to contain ions from loss of ring-methyl groups.

X-ray photoelectron spectra were obtained on a Surface Science Laboratories SSX-100-1 instrument using monochromatic Al-$K_{\alpha_{1,2}}$ radiation. For high resolution spectra, the concentric hemispherical analyser was operated at 25 eV pass energy. The binding energy scale is such that the Au($4f_{7/2}$) photoelectron line occurs at 83.96 ± 0.1 eV and the difference between the Cu($2p_{3/2}$) and 3s photoelectron lines is 810.0 ± 0.1 eV. The C(1s) spectra showed only one component and, for charge referencing purposes, it is assigned an energy of 285.0 eV.[23]

The solvents toluene and 1,2-dimethoxyethane,

and dichloromethane were distilled under nitrogen from Na–K alloy and CaH_2, respectively. Reactants were weighed in a nitrogen-filled dry-box and combined with the solvent in NMR tubes fitted with re-sealable Teflon Young valves (Brunfeldt Co., Bartlesville, Oklahoma). Temperatures were calibrated by substitution of methanol for the analytical sample and the temperature was determined from the data of van Geet.[24] In experiments with $MeAl(BHT)_2$ in toluene-d_8, the [Al]:[Zr] ratio used (10:1), is limited by the solubility of the aluminium reagent. The metallocene concentrations were 0.08 M. In experiments with Me_3Al, 0.5 cm^3 2 M Me_3Al in toluene, 0.1 cm^3 C_6D_6 (to provide a ^2H lock signal) and 0.05 mmol of the metallocene were combined. Thus, [Al]:[Zr] was 20:1 with [Zr] = 0.083. For work with $(MeAlO)_x$, [Al]:[Zr] was 15:1 with [Zr] = 0.11. Kinetic runs in CH_2Cl_2 utilized 0.5 cm^3 of this solvent plus 0.1 cm^3 C_6D_6 or 0.03 cm^3 toluene. ^{13}C DNMR spectra were obtained using a 5–10 s acquisition time (for maximum possible resolution), Waltz-modulated ^1H decoupling and the optimum pulse width for maximum signal:noise. The linewidth of (internal) toluene was taken as the natural linewidth due to field inhomogeneity. [Zr—CH_3] and [Al—CH_3] were determined by weighing the reactants. Slow methyl exchange was followed by recording ^{13}C spectra as a function of time with kinetics being measured directly from integrated spectra. Relaxation times and nuclear Overhauser enhancements (nOe) were measured on equilibrated samples. Single scan spectra were obtained with continuous low-power Waltz decoupling because the nOe was necessary for adequate signal:noise. The nOe corrections were not significant. For Cp_2ZrMe_2 and $(Me_5Cp)_2ZrMe_2$, the Zr—CH_3 nOe decreases from 2.9 at 22°C to 2.5 at 81°C. For $AlMe_3$, it decreases from 2.5 at 22°C to 1.9 at 70°C and from 2.6 to 2.5 over the same temperature range for $MeAl(BHT)_2$.

IR spectra were obtained on *ca* 1 M solutions of the organometallic compound in $CHCl_3$ (vacuum transferred from P_2O_5) on a Beckman 983 spectrometer. A 0.017 mm pathlength cell having KBr windows was employed. Assignment of M—CH_3 symmetric and asymmetric stretching bands was made by use of the M—$^{13}CH_3$ and M—CD_3 isotopomers.

$MeAl(BHT)_2$,[8] Et_2BOMe[25] and $(MeAlO)_x$[7a] were prepared by literature methods. In the synthesis of the latter, $MgCl_2 \cdot 6H_2O$ was used as the water-carrier. Residual Me_6Al_2 was removed at $\leqslant 40°C$ at $< 5 \times 10^{-6}$ mm. Cp_2ZrCl_2, $(Me_5Cp)_2ZrCl_2$, $Me_2Si(C_5H_4)_2ZrCl_2$[12] and $(indenyl)_2ZrCl_2$ were converted using the method of Samuel and Rausch[26] to the corresponding $Zr(^{13}CH_3)_2$ derivatives employing $^{13}CH_3Li$. We used an improved synthesis of $(C_9H_7)_2ZrCl_2$, described below.

Indenyllithium was prepared by the addition of 44 cm^3 2.5 M n-BuLi in hexane to 12.8 g redistilled indene in 100 cm^3 toluene at −78°C. The reaction mixture was stirred overnight as the cooling bath warmed up. The product was collected on a Schlenk filter, washed with hexane and vacuum dried. Yield 12.3 g (99%).

A mixture of 5.5 g C_9H_7Li (50 mmol), 5.8 g (25 mmol) $ZrCl_4$ and 100 cm^3 toluene was stirred for 2 h at room temperature and for 70 h at 90°C. This was then cooled to room temperature and filtered. The solids were *rapidly* washed with two 25 cm^3 portions of absolute ethanol, then with hexane and vacuum dried. Yield: 4.2 g (58%). It is important that the ethanol washing, which removes LiCl, is done rapidly, for otherwise the product dissolves and hydrolyses. $(C_9H_7)_2ZrCl_2$ in wet CH_3CN produces a quantitative yield of indene (^1H NMR analysis). Thus, $(C_9H_7)_2ZrCl_2$ *is* stable in organic solvents provided that they are dry.[27] (The method described in ref. 27 failed in our hands.)

$Me_2Si(C_5H_4)_2ZrMe_2$

$^{13}CH_3Li$ was prepared in diethyl ether under Ar from 2 g (14 mmol) $^{13}CH_3I$ and excess Li wire (1% Na). Ether was removed by pumping in a high vacuum line. Toluene (50 cm^3) and 1.74 g $Me_2Si(C_5H_4)_2ZrCl_2$ (5 mmol) were added. The reaction mixture was stirred for 24 h at room temperature then filtered. The filtrate was evaporated and the residue sublimed (100°C/10^{-3} mm) onto a 20°C probe. The yield of resublimed product was 0.72 g (47%). Yields using diethyl ether solvent were inferior. This is due to cleavage of the Me_2Si bridge, because when the reaction is quenched with Me_3SiCl, $(Me_3SiCp)_2ZrMe_2$ is also formed.

$(Me_3SiCp)_2ZrCl_2$[28]

Me_3SiCl (purified by fractional distillation on a vacuum line to remove HCl) (6.54 g, 60 mmol) in 20 cm^3 THF was added slowly to 60 mmol NaCp in 90 cm^3 THF at −78°C. The reaction mixture was warmed to room temperature then recooled to −78°C. n-BuLi (24 cm^3 2.5 M in hexane) was added dropwise. After stirring for 30 min at room temperature, the temperature was reduced to 0°C and $ZrCl_4$ (7 g, 30 mmol) in 40 cm^3 1,2-dimethoxyethane added dropwise. After stirring overnight, solvents were removed *in vacuo*. The residue was extracted with hexane in a Soxhlet apparatus. The extracts were concentrated to 50 cm^3 and filtered to give 9.2 g crude product. Recrystallization from boiling

methylcyclohexane yielded 6.2 g (48%) pure product. Found: C, 43.7; H, 5.9. Calc. C, 44.0; H, 6.0%. Mass spectrum (11 eV): 436 (P^+), 421 ($P-Cl^+$).

New NMR data for zirconium metallocenes are listed below: $Me_2Si(C_5H_4)_2ZrMe_2$: ^1H: 0.17 ($SiCH_3$), 0.14 ($ZrCH_3$), 5.39 (m), 6.65 (m). ^{13}C: 120.9, 112.5 (Cp), 101.3 (C_{ipso}), 30.0 (Zr—CH_3), −5.30 (Si—CH_3). ^{91}Zr: 440 ($w/2$ 8100 Hz) (toluene-d_8). $(C_9H_7)_2ZrCl_2$: ^{13}C: 127.3 ($C_{3a,7a}$), 126.7, 125.6 ($C_{4,6}$), 122.2 (C_2), 104.4 ($C_{1,3}$) (CD_2Cl_2). $(C_9H_7)_2ZrMe_2$: ^{13}C: 125.1 ($C_{4,7}$), 124.5 ($C_{5,6}$), 124.2 ($C_{3a,7a}$), 115.0 (C_2), 100.0 ($C_{1,3}$), 35.8 ($ZrCH_3$). ^{91}Zr: 500 ($w/2$ 2500 Hz) (toluene-d_8). $(Me_3SiCp)_2ZrCl_2$: ^1H: 6.39, 5.94 (Cp), 0.32 ($SiCH_3$). ^{13}C: 126.3 (C_{ipso}), 126.0, 115.3 (Cp), 0.06 ($SiCH_3$). ^{91}Zr: −85 ($w/2 \cdot 1300$ Hz) (C_6D_6). $(Me_3SiCp)_2ZrMe_2$: ^1H: 6.07, 5.93 (Cp), 0.18 ($SiCH_3$), −0.16 ($ZrCH_3$). ^{13}C: 119.3 (C_{ipso}), 118.2, 113.5 (Cp), 31.0 ($ZrCH_3$), 0.36 ($SiCH_3$). ^{91}Zr: 420 ($w/2$ 3600 Hz) (toluene-d_8).

REDUCTION OF SUGARS WITH ALUMINIUM ALKYLS. PREPARATION AND STRUCTURE OF $[AlCl_2(NC_5H_5)(OEt)]_2(\mu\text{-}O)(\mu\text{-}AlCl\cdot 2NC_5H_5)$

C. MITCHELL MEANS, SIMON G. BOTT and JERRY L. ATWOOD*

Department of Chemistry, University of Alabama, Tuscaloosa, AL 35487–0336, U.S.A.

Abstract—Reaction of ethylaluminium dichloride with glucose in a 10% pyridine solution in toluene leads to the unique compound $[AlCl_2(NC_5H_5)(OEt)]_2(\mu\text{-}O)(\mu\text{-}AlCl\cdot 2NC_5H_5)$, formed through "fermentation" of the sugar and exchange reactions of the aluminium species. This product, which contains two five- and one six-coordinate aluminium, crystallizes in the monoclinic space group $C2/c$ with $a = 16.253(8)$, $b = 11.832(5)$, $c = 16.94(2)$ Å, $\beta = 94.35(9)°$. Full-matrix least-squares refinement using 1640 reflections led to $R = 0.051$. The Al—O bond lengths range from 1.782(2) to 1.891(3) Å, the Al—N lengths from 2.094(4) to 2.132(4) Å and the Al—Cl lengths from 2.188(3) to 2.240(3) Å.

Aluminium alkyls have long been used in the reduction of both organic and inorganic species.[1] However, presumably because of solubility problems, their interaction with sugars has not been extensively investigated.[2] As part of a general programme on the generation of chiral aluminium-containing species with special aromatic solution properties,[3] we have begun a detailed study of the reaction of a range of aluminium alkyls and aluminium alkyl halides with sugars. We report here the unexpected result of the reaction of ethylaluminium chloride ($EtAlCl_2$) with glucose in a toluene solution to which a small amount of pyridine was added.

EXPERIMENTAL

Synthesis of $[AlCl_2(NC_5H_5)(OEt)]_2(\mu\text{-}O)(\mu\text{-}AlCl\cdot 2NC_5H_5)$

$EtAlCl_2$ (0.06 mol) was added to a slurry of $C_6H_{12}O_6$ (0.01 mol) in 100 cm^3 of a 10% pyridine/toluene mixture. This was carried out in a screw-top tube, which was heated to 100°C for 2 days. Colourless crystals of the title compound were obtained in *ca* 10% yield.

X-ray structure determination of $[AlCl_2(NC_5H_5)(OEt)]_2(\mu\text{-}O)(\mu\text{-}AlCl\cdot 2NC_5H_5)$

A single, colourless crystal was mounted in a thin-walled glass capillary. Final lattice parameters as determined from the least-squares refinement of $(\sin\theta/\lambda)^2$ values for 24 reflections ($2\theta > 25°$) accurately centred on an Enraf–Nonius CAD-4 diffractometer are given in Table 1. Data were collected by the θ–2θ scan technique described previously.[4] A summary of data collection and structure solution parameters is also given in Table 1. The intensities were corrected for Lorentz and polarization effects, but not for absorption. Calculations were carried out using the SHELX system of computer programs.[5] Neutral atom scattering factors were taken from ref. 6 and the scattering for the aluminium and chlorine atoms was corrected for the real and imaginary components of anomalous dispersion.[6]

Structure solution was accomplished initially by application of the direct methods program MULTAN,[7] which revealed the positions of most of the non-hydrogen atoms. Difference Fourier maps phased upon these atoms readily afforded the positions of the remaining atoms. Treatment of all atoms with anisotropic thermal parameters enabled the location of all the hydrogen atoms from a further difference map. These were constrained to "ride" upon the appropriate carbon atom. Further refinement converged at reliability values of $R = \Sigma(|F_o| - |F_c|)/\Sigma(F_o) = 0.051$ and $R_w = \{\Sigma w(|F_o| - |F_c|)^2/\Sigma w(F_o)^2\}^{1/2} = 0.051$. A final difference Fourier showed no feature greater than 0.2 e/Å^3. The weighting scheme was based upon unit weights and no systematic variation of $w(|F_o| - |F_c|)$ vs $|F_o|$ or $\sin(\theta/\lambda)$ was noted. Further structural details have been deposited.

DISCUSSION

From the Experimental it is clear that the reaction of glucose with $EtAlCl_2$ in the presence of pyridine affords the title compound. The sequence of reactions which accomplishes this is not understood. However, it is interesting to view the product as the result of reaction (1):

$$2EtAlCl_2 + Et_2AlCl + 2EtOH + H_2O + 4NC_5H_5 \longrightarrow 4C_2H_6 + [AlCl_2(NC_5H_5)(OEt)]_2(\mu\text{-}O)(\mu\text{-}AlCl\cdot 2NC_5H_5). \quad (1)$$

The presence of species such as Et_2AlCl in $EtAlCl_2$ is well known,[8] and the reduction of glucose to ethanol and water is simply the fermentation process. Thus, the above reaction serves to indicate that the components of the title compound could be generated from the reactants. We are currently attempting to generate $[AlCl_2(NC_5H_5)(OEt)]_2(\mu\text{-}O)(\mu\text{-}AlCl\cdot 2NC_5H_5)$ directly as in reaction (1).

The structure, shown in Fig. 1, lies on a crystallographically-imposed two-fold rotation axis and contains a planar $(Al—O)_3$ ring in which two four-membered $(Al—O)_2$ rings share an Al—O bond. To our knowledge, this is the first example of this aluminium–oxygen framework. Important bond lengths and angles are given in Table 2.

The coordination of Al(1) is distorted octahedral with the major deviation being the O(2)—Al(1)—O(2)′ angle of 155.7(1)° imposed by the Al(2)—O(2) coordination. The two *trans*-pyridine rings are tilted slightly in the direction of Cl(1) [N(1)—Al(1)—N(1)′ angle, 173.5(1)°], presumably due to C(1)—H···O(ring) contacts. The Al(1)—Cl(1) bond distance, 2.240(3) Å, is long for a terminal Al—Cl bond (cf. the Al—Cl distances in the seven-coordinate $[AlCl_2\cdot$benzo-15-Crown-5$]^+$ cation are 2.197(7) and 2.202(5) Å[9]) presumably due to the strong *trans*-influence of the μ-oxo ligand. Indeed, the value in the title compound is near the short end of the range of Al—Cl(bridging) lengths in the six-coordinate aluminium atom of $(Me_2AlCl)_2(Al\cdot C_{10}H_{20}N_4)(AlMe_2)$.[10] The Al(1)—O(1) distance of 1.890(5) Å falls in the range found by Healy and Barron for six-coordinate aluminium, 1.837(8) and 1.982(9) Å,[11] and the Al(1)—N(1) length, 2.132(4) Å, is longer than those of 1.952(3) and 1.981(3) Å in the above-mentioned cyclam complex.[10]

The coordination of Al(2) is slightly distorted trigonal bipyramidal. The largest deviation is the 167.3(2)° N(2)—Al(2)—O(2) angle which is produced by the constraint of the bond between Al(1) and O(2). The Al(2)—O(2) distance of 1.891(3) Å is well within the normal range of Al—O lengths,[12] whereas the Al(2)—O(1) (1.782(2) Å) distance is at

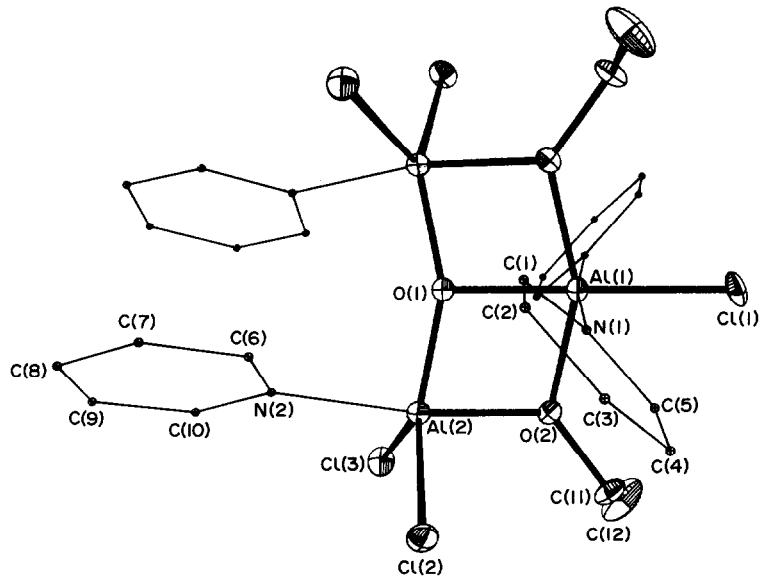

Fig. 1. Molecular structure of $[AlCl_2(NC_5H_5)(OEt)]_2(\mu\text{-}O)(\mu\text{-}AlCl\cdot 2NC_5H_5)$. Pyridine rings are shown as points and hydrogen atoms are omitted for clarity.

Table 2. Selected bond lengths (Å) and angles (°) for $[AlCl_2(NC_5H_5)(OEt)]_2(\mu\text{-}O)(\mu\text{-}AlCl\cdot 2NC_5H_5)$

Bond lengths			
Al(1)—Cl(1)	2.240(3)	Al(1)—O(1)	1.890(5)

O(1)—Al(2)—N(2)	90.9(2)	O(2)—Al(2)—N(2)	167.3(2)
Al(1)—O(1)—Al(2)	101.1(1)	Al(2)—O(1)—Al(2)′	157.7(2)
Al(1)—O(2)—Al(2)	98.1(2)		

the short end of the range (cf. 1.679(2) Å in (μ-oxo)bisphthalocyaninatoaluminium(III) in which there is substantial multiple bond character[13]). The Al—O lengths can be profitably compared with that of 1.772(4) Å for four-coordinate aluminium and 2.174(4) Å for five-coordinate aluminium found by Robinson *et al.*[14] The Al(2)—N(2) distance, 2.094(4) Å, is at the long end of the range for four-coordinate aluminium[15] and may be compared to 2.055(2) and 2.135(2) Å in $(AlMe)(C_8H_{19}N_4)(AlMe_2)$[16] and 1.976(9) and 2.04(1) Å in $(AlMe)_2(C_8H_{20}N_6)(AlMe_2)_2$.[17] Thus, while coordination number is an important consideration in determining bond length, there are other important factors which are discussed in detail elsewhere.[18]

Further work examining both this reaction and those of aluminium species with other carbohydrates is in progress.

Department of Chemistry, Clemson University, Clemson, SC 29634-1905, U.S.A.

Abstract—Reaction of trimethylaluminium with bis(diphenylthiophosphinoyl)methane and bis(diphenylthiophosphinoyl)ethane affords the crystalline compounds $[Al(CH_3)_2][(C_6H_5)_2P(S)CHP(S)(C_6H_5)_2][Al(CH_3)_3]$ (**I**) and $[Al(CH_3)_3]_2[(C_6H_5)_2P(S)CH_2CH_2P(S)(C_6H_5)_2]$ (**II**), respectively. Compound **I** crystallizes in the monoclinic space group $P2_1/n$ (No. 14) with unit cell parameters $a = 18.126(2)$, $b = 9.569(2)$, $c = 19.394(3)$ Å, $\beta = 110.20(1)°$, $V = 3156.7(7)$ Å^3, and $\rho = 1.21$ g cm^{-3} for $Z = 4$. Least-squares refinement based on 2891 observed reflections $[I > 3\sigma(I)]$ converged at $R = 0.040$, $R_w = 0.051$. Compound **II** crystallizes in the triclinic space group $P\bar{1}$ (No. 2) with unit cell parameters $a = 12.076(3)$, $b = 13.148(3)$, $c = 13.114(3)$ Å, $\alpha = 98.32(2)$, $\beta = 100.55(2)$, $\gamma = 116.41(2)°$, $V = 1772.1(7)$ Å^3, and $\rho = 1.14$ g cm^{-3} for $Z = 2$. Least-squares refinement based on 3012 observed reflections $[I > 3\sigma(I)]$ converged at $R = 0.049$, $R_w = 0.056$. Compound **I** results from a unique condensation reaction in which one of the central methylene C—H bonds was cleaved in addition to one Al—CH_3 bond, resulting in an unusual Al—P—S—C four-membered ring. The length of the hydrocarbon chain in bidentate phosphine ligands appears to play an important role in their reactivity with organoaluminium species, as reaction of bis(diphenylthiophosphinoyl)ethane with trimethylaluminium did not facilitate condensation, but resulted in an addition compound, **II**. These results demonstrate a comparatively greater acidity of the hydrocarbon chain hydrogen atoms of bis(diphenylthiophosphinoyl)methane relative to bis(diphenylthiophosphinoyl)ethane.

The ability of bidentate phosphine ligands to facilitate unique behaviour in bimetallic systems has recently generated considerable activity in organo-transition metal chemistry.[1–5] The organo-main group chemistry in general, and organoaluminium chemistry in particular, of bidentate phosphine ligands has not developed in parallel with that of the transition metals. Although the bidentate phosphine ligand bis(diphenylphosphino)methane has been shown to play a role in a few organoaluminium catalytic systems,[6–8] the organoaluminium chemistry of the sulphur derivatives of bis(diphenylphosphino)methane and bis(diphenylphosphino)ethane remains largely unexplored. Herein we report the synthesis and molecular structure of $[Al(CH_3)_2][(C_6H_5)_2P(S)CHP(S)(C_6H_5)_2][Al(CH_3)_3]$ (**I**) and $[Al(CH_3)_3]_2[(C_6H_5)_2P(S)CH_2CH_2P(S)(C_6H_5)_2]$ (**II**). Both compounds were isolated from reaction of trimethylaluminium with bis(diphenylthiophosphinoyl)methane and bis(diphenylthiophosphinoyl)ethane, respectively. Compound **I** is interesting in that it results from a unique condensation reaction in which one of the central methylene C—H bonds and one Al—CH_3 bond were cleaved resulting in an Al—S—P—C four-membered ring. The length of the hydrocarbon chain in bidentate phosphine ligands appears to affect such reactivity, in that condensation was not observed in compound **II** as only the addition product was isolated.

EXPERIMENTAL

Synthesis

Standard Schlenk techniques were employed in conjunction with an inert atmosphere dry box (Vacuum Atmospheres HE-43 DriLab). Trimethylaluminium, generously donated by the Ethyl Corporation, was used as received. Both phosphine ligands were prepared in our laboratory. Single crystal X-ray data were collected on a Nicolet R3m/V diffractometer. ^{1}H NMR data were recorded on a JEOL-FX90Q NMR spectrometer. Solid state ^{31}P NMR were recorded on an IBM 200 MHz spectrometer. Solvents were purified and degassed in the usual manner.

(1) $[Al(CH_3)_2][(C_6H_5)_2P(S)CHP(S)(C_6H_5)_2][Al(CH_3)_3]$ (I)

Inside the dry box a reaction vessel was charged with bis(diphenylthiophosphinoyl)methane (0.50 g, 1.1 mmol) and heptane (15 cm^3). Trimethylaluminium (0.25 cm^3, 2.2 mmol) was slowly added to the white suspension. Reaction was immediate and quite vigorous resulting in a clear colourless solution. The reaction vessel was subsequently removed from the dry box and heated in an oil bath (120°C) for 24 h. Upon cooling to room temperature, a multitude of colourless, rectangular, extremely air-sensitive crystals formed (80% based on the phosphine ligand). M.p. = 162–163°C. ^{1}H NMR ($CDCl_3$, $Si(CH_4)$ external reference): δ −0.65 (s, 15H, $Al(CH_3)_2/Al(CH_3)_3$); 1.93 (s, 1H, P—C*H*—P), 7.51 (m, 20H, C_6H_5). ^{31}P {^{1}H} NMR ($CDCl_3$, H_3PO_4 external reference): δ 34.2 (s). ^{31}P NMR (solid state) (Na_2HPO_4 external standard): δ 25.03 (s, $P(S)Al(CH_3)_2$); 36.01 (s, $P(S)Al(CH_3)_3$).

(2) $[Al(CH_3)_3]_2[(C_6H_5)_2P(S)CH_2CH_2P(S)(C_6H_5)_2]$ (II)

A reaction vessel was charged with trimethylaluminium (0.20 cm^3, 2.2 mmol), bis(diphenylthiosphosphinoyl)ethane (0.5 g, 1.1 mmol) and a toluene–heptane mixture (15 cm^3 : 15 cm^3) inside the dry box. The reaction tube was removed from the dry box and heated in an oil bath (120°C) for 24 h. Upon cooling to 0°C, a multitude of small, colourless, rectangular, air-sensitive, X-ray quality crystals resulted in quantitative yield (based on the phosphine ligand). M.p. = 133–135°C. ^{1}H NMR ($CDCl_3$): δ −0.92 (s, 18H, $Al(CH_3)_3$), 2.77 (d, 4H, P—(CH_2)$_2$—P, J_{P-CH} = 2.2 Hz), 7.59 (m, 20H, C_6H_5). ^{31}P {^{1}H} NMR ($CDCl_3$): δ 45.13 (s, 2P, P(S)).

X-ray structural solution and refinement for $[Al(CH_3)_2][(C_6H_5)_2P(S)CHP(S)(C_6H_5)_2][Al(CH_3)_3]$ (I)

A colourless parallelepiped crystal of **I** was mounted in a thin-walled glass capillary under an inert atmosphere of argon. Cell constants and an orientation matrix for data collection, obtained from a least-squares refinement of the setting angles of 42 carefully centred reflections in the range $25.29 < 2\theta < 37.13°$, corresponded to a monoclinic cell. The space group was determined to be $P2_1/n$ (No. 14). The structure was solved by direct methods using SHELXTL PLUS.[9] Non-hydrogen atoms were refined anisotropically and hydrogen atoms were refined isotropically. The weighting scheme was based on counting statistics and included a factor ($p = 0.0005$) to downweight the intense reflections. The maximum and minimum peaks on the final difference map corresponded to 0.20 and −0.19 e$^-$ Å^{-3}, respectively. Refinement converged at $R = 0.040$, $R_w = 0.051$. Relevant crystallographic data is given in Table 1. The X-ray crystal structure of **I** is given in Fig. 1.

X-ray structural solution and refinement for $[Al(CH_3)_3]_2[(C_6H_5)_2P(S)CH_2CH_2P(S)(C_6H_5)_2]$ (II)

A single crystalline sample of **II** was prepared for X-ray examination in the same manner as employed for **I**. Cell constants and an orientation matrix for data collection, obtained from a least-squares refinement of the setting angles of 35 carefully centred reflections in the range $24.48 < 2\theta < 34.60°$, afforded a triclinic cell. The compound crystallized in the triclinic $P\bar{1}$ (No. 2), with two molecules per unit cell. The asymmetric unit consists of two half-molecules situated about inversion centres at ($x = 0.5$, $y = 1.0$, $z = 0.5$) and ($x = 0.5$, $y = 1.0$, $z = 0.0$), respectively. The main difference in the conformation of the two unique molecules involves the orientation of the phenyl rings, as defined by the dihedral angles between their planes, 90.1° for molecule 1 and 84.8° for molecule 2. No uncharacteristically short intermolecular contacts or unusual packing interactions were observed. The structure was solved by direct methods using SHELXTL PLUS.[9] Non-hydrogen atoms were refined using anisotropic thermal parameters. Hydrogen atoms were located by standard difference Fourier techniques, and were included in the structure factor calculation at idealized positions (d_{C-H} = 0.96 Å). An isotropic group thermal parameter [U_{iso} = 0.124(4)] was refined for the hydrogen atoms. The final cycle of full-matrix least-squares refinement, based on 3012 observed reflections [$I > 3\sigma I$)], converged at $R = 0.049$,

RESULTS AND DISCUSSION

This laboratory has long had an interest in the organoaluminium chemistry of oxygen-,[10–12] sulphur-[13–15] and nitrogen-based multidentate ligands.[16–25] These studies revealed a particularly rich and varied chemistry often involving condensation reactions which resulted in novel organoaluminium cage compounds. The fact that an examination of the organoaluminium chemistry of multidentate phosphorus ligands is a natural extension of this work, coupled with the relative paucity of studies concerning organoaluminium–bidentate phosphine systems, prompted us to initiate a probe into this chemistry.

The initial study from this laboratory regarding the organoaluminium chemistry of bidentate phosphine ligands concerned the 2:1 (AlR_3–ligand) addition product $[Al(CH_3)_3]_2[(C_6H_5)_2PCH_2P(C_6H_5)_2]$ isolated from reaction of trimethylaluminium with bis(diphenylphosphino)methane.[26] As the organoaluminium chemistry of the chalcogen derivatives of bidentate phosphine ligands is largely unexplored, our attention shifted to the oxygen and sulphur derivatives of these ligands. Our next study concerned the di-oxygen analogue of bis(diphenylphosphino)methane, bis(diphenylphosphinoyl)methane. A particularly significant point about bis(diphenylphosphinoyl)methane is the fact that the presence of an oxygen atom on each of the two phosphorus atoms serves to sufficiently increase the acidity of the central methylene CH_2 hydrogen atoms so as to undergo Al—R/C—H condensation upon reaction with trimethylaluminium, thus resulting in the unusual organoaluminium product $[Al(CH_3)][(C_6H_5)_2P(O)CP(O)(C_6H_5)_2]_2[Al(CH_3)_2]_2$.[27] We have also recently reported the triethylaluminium–bis(diphenylphosphinoyl)methane condensation product.[28] The isolation of the trimethylaluminium and triethylaluminium condensation products of bis(diphenylphosphinoyl)methane raised two questions: (1) Would the dithio derivatives of bidentate phosphine ligands react in a similar fashion towards organoaluminium species? (2) Does the length of the hydrocarbon chain in the bidentate phosphine ligands affect the reactivity of these systems? The

present study was undertaken to address these points.

Reaction of trimethylaluminium with bis(diphenylthiophosphinoyl)methane results in $[Al(CH_3)_2][(C_6H_5)_2P(S)CHP(S)(C_6H_5)_2][Al(CH_3)_3]$ (**I**). The X-ray crystal structure of **I** is given in Fig. 1. The first point of note concerning **I** is the presence of two different types of organoaluminium species: one trimethylaluminium and one dimethylaluminium fragment. Indeed, **I** results from a condensation reaction in which one of the central methylene hydrogen atoms and one of the Al—CH_3 bonds were cleaved resulting in an Al—S—P—C four-membered ring. This suggests, qualitatively, that the central methylene hydrogen atoms of the dithio derivatives are not as acidic as those of the di-oxygen derivatives. The aluminium–central methylene carbon [Al(1)—C(13)] bond distance at 2.097(4) Å is somewhat longer than the aluminium–carbon bond in the dimethylaluminium fragment (1.943(6) and 1.949(6) Å for Al(1)—C(26) and Al(1)—C(27), respectively). The Al(1)—S(1) bond distance is 2.388(2) Å, while the Al(2)—S(2) bond is 2.460(2) Å. The P—C—P bond angle in **I** is worthy of note. The P—C—P bond angle in **I** of 121.3(2)° is somewhat distorted from the value of 118.3(2)° obtained for the uncomplexed ligand.[29]

Compound **II** (Fig. 2), isolated from reaction of trimethylaluminium with bis(diphenylthiosphosphinoyl)ethane, represents the first report of an organoaluminium – bis(diphenylthiophosphinoyl) ethane complex. In marked contrast to **I**, condensation did not occur in **II** as only the 2:1 addition compound was isolated. It appears that the length of the hydrocarbon bridge in bidentate phosphine ligands plays a role with respect to

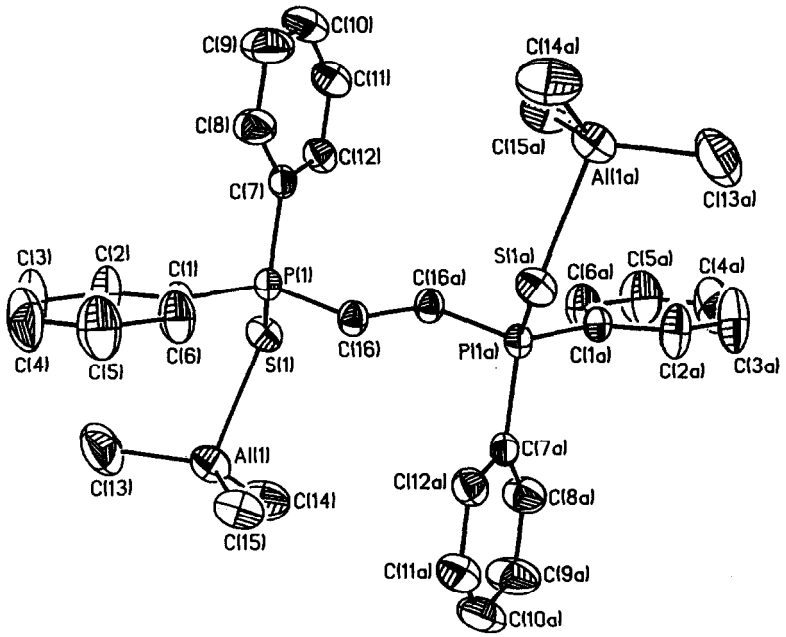

Fig. 2. A view of the $[Al(CH_3)_3]_2[(C_6H_5)_2P(S)CH_2CH_2P(S)(C_6H_5)_2]$ (**II**) molecule showing the atom labelling scheme. Thermal ellipsoids show 35% probability levels; hydrogen atoms have been omitted. Selected bond distances (Å) and angles (°):

S(1)—P(1)	1.989(2)	C(16)—C(16a)	1.530(9)
S(1)—Al(1)	2.506(3)	Al(1)—C(13)	1.965(7)

C—H/Al—R bond cleavage, in that condensation appears to be disfavoured if the length of the hydrocarbon bridge exceeds one $—CH_2—$ fragment. The Al—S bond distances in both **I** and **II** are comparable to other reported values.[13–15]

The trialkyls of the Group III (13) metals, as well as their adducts with various amines and phosphines, have been employed for the Metal–Organic Chemical Vapour Deposition (MOCVD) of III–V materials.[30,32] An interesting alternative method to the practice of employing volatile Group III (13) adducts in MOCVD processes[33–36] has recently been reported wherein metal alkyl adducts with relatively involatile bases, such as multidentate phosphine ligands, having weak donor–acceptor bonds, have been examined.[37] As M—S (M = Al, Ga, In; S = sulphur) interactions are generally rather weak, the organo-main group chemistry of thio derivatives of multidentate phosphine ligands resulting in complexes like **I** and **II** may offer unique possibilities in such processes.

PREPARATION AND CHEMISTRY OF $Me_3SiCH_2AsH_2$; PREPARATION OF $[Me_3SiCH_2(H)AsGaPh_2]_3$, A TRIMERIC MONO(ARSINO)GALLANE CONTAINING A HYDROGEN BONDED TO ARSENIC. ISOLATION AND X-RAY CRYSTAL STRUCTURE OF $(Me_3SiCH_2As)_5$

RICHARD L. WELLS,* CHONG-YUN KWAG, ANDREW P. PURDY, ANDREW T. McPHAIL and COLIN G. PITT

Department of Chemistry, Paul M. Gross Chemical Laboratory, Duke University, Durham, NC 27706, U.S.A.

Abstract—Reduction of $Me_3SiCH_2AsCl_2$ (**I**) with $LiAlH_4$ at −78°C afforded $Me_3SiCH_2AsH_2$ (**II**) and reaction of **II** with Ph_3Ga produced $[Me_3SiCH_2(H)AsGaPh_2]_3$ (**III**) which was characterized by partial elemental analysis (C and H), ^1H NMR spectroscopy and a cryoscopic molecular weight determination. Based on ^1H NMR data, $[Me_3SiCH_2(H)AsGaMe_2]_3$ (**IV**) was produced by the reaction of **II** with Me_3Ga; however, only H_2, Me_4Si, $(Me_3SiCH_2As)_5$ (**VI**) and unreacted $(Me_3SiCH_2)_3Ga$ were identified after allowing the latter to react with **II**. Reaction of 2 equiv. of Me_3SiCl with a mixture of **II** and *n*-BuLi (1:2 mole ratio) afforded $Me_3SiCH_2As(SiMe_3)_2$ (**V**). The monosilylated arsine was not isolated when 1 equiv. of Me_3SiCl was allowed to react with combined **II** and *n*-BuLi (1:1 mole ratio); rather, a mixture of **II** and **V** resulted. Attempted preparations of $(Me_3SiCH_2AsGaPh)_n$ are described. The ring compound, **VI**, was prepared by reaction of **I** with a mixture of Me_3SiCl and Mg in THF. The molecular structure of this cycloarsane was determined by single-crystal X-ray diffraction methods. Pale yellow crystals of **VI** belong to the monoclinic system with four molecules occupying the general positions of space group $P2_1/c(C_{2h}^5)$ with cell constants: $a = 9.952(1)$, $b = 30.245(9)$, $c = 13.000(3)$ Å, $\beta = 91.69(1)°$, $V = 3911.3$ Å^3, $Z = 4$.

In recent years, after a hiatus of approximately two decades,[1] there has been a considerable amount of activity in the area of gallium–arsenic chemistry,[2] some of which was prompted by the search for new gallium arsenide precusors. As a result, a number of new and interesting compounds have been prepared and characterized. To date, however, the literature contains no reports regarding the isolation and characterization of monomeric or oligomeric compounds of the type $[R(H)AsGaR'_2]_n$ and $(RAsGaR')_n$. As described by Beachley and Coates, the reactions of $MeAsH_2$ and $PhAsH_2$ with Me_3Ga gave only polymers,[1b] whereas we found that the reaction of $PhAsH_2$ with $(Me_3SiCH_2)Ga$ gave a complex mixture of products from which $(PhAs)_6$ and the novel cluster $[(PhAsH)(R_2Ga)(PhAs)_6(RGa)_4]$ ($R = Me_3SiCH_2$) were isolated.[2a]

Here we report the preparation of **I** and its conversion to **II**. Also, the reaction of **II** with Ph_3Ga to prepare **III**, as well as some other reactions, including its conversion to **V** are described. In addition, attempts to prepare $(Me_3SiCH_2AsGaPh)_n$ are reported. Furthermore, we found that an attempted preparation of **V** from **II** resulted in the formation of the cycloarsane **VI**, the crystal structure of which is described herein.

EXPERIMENTAL

General information

All manipulations and reactions were carried out either in Schlenk apparatus, I^2R glove bags or a Vacuum/Atmospheres HE-43 Dri Lab under an inert atmosphere (argon or nitrogen), or on a vacuum line. Quantities of volatile products were measured on a vacuum line. Deionized water was degassed prior to use. All organic solvents were distilled from sodium benzophenone ketyl under nitro-

* Author to whom correspondence should be addressed.

gen. $AsCl_3$, perfluorohexane, Me_3SiCH_2Cl and Et_2NH were purchased from Strem Chemicals Inc., Specialty Chemicals, Petrarch Systems Inc. and EM Science, respectively. $LiAlH_4$, *n*-BuLi and Me_3Ga were obtained from Alfa Products Inc. All commercially available reagents were not further purified. The concentration of the *n*-BuLi was determined each time before use by titration[3] with *sec*-BuOH in C_6H_6 using 1,10-phenanthroline as the indicator. Me_3SiCH_2MgCl was prepared in 97% yield by a slight modification (i.e. baking the I_2 initiator and Mg metal turnings with a flame) of the literature method.[4] $(Et_2N)_2AsCl$,[5] $PhGaCl_2$,[6] Ph_2GaCl,[7] Ph_3Ga[8] and $(Me_3SiCH_2)_3Ga$[9] were also prepared by literature methods. ^1H NMR spectra were recorded on either an IBM NR–80 (80 MHz) or a Varian XL-300 (299.943 MHz) spectrometer, the latter being used to obtain variable temperature spectra. ^{13}C NMR spectra were obtained on either a JEOL FX-90Q spectrometer at 22.5 MHz or a Varian XL-300 spectrometer at 75.429 MHz. All spectra were referenced to TMS using the residual protons or the carbons of the deuterated solvents as the chemical shift reference; for ^1H, C_6D_5H δ 7.15, $C_6D_5CD_2H$ δ 2.09; for $^{13}C\{^1H\}$, C_6D_6 δ 128.0, $C_6D_5CD_3$ δ 20.4. All NMR tubes were flame-sealed under vacuum. A Normag 2029 apparatus was used to determine the molecular weight of **III** (cryoscopically in cyclohexane). All m.p. measurements were performed by using a Buchi 510 apparatus and flame-sealed capillaries. Elemental analyses were performed by E+R Microanalytical Laboratory, Inc., Corona, New York.

Syntheses

$Me_3SiCH_2AsCl_2$ (**I**). Me_3SiCH_2MgCl (249 cm^3, 0.398 mol) was added dropwise with stirring to an Et_2O (300 cm^3) solution of $(Et_2N)_2AsCl$ (99.6 g, 0.391 mol) at −78°C. An exothermic reaction occurred as the Grignard reagent was added dropwise. After stirring for 8 h at RT, the reaction mixture was hydrolysed with a large excess of conc. HCl and the organic layer was separated and combined with a hexane/Et_2O extract of the acid layer. Removal of solvents gave a yellow liquid (77.8 g) which was vacuum distilled to yield pure $Me_3SiCH_2AsCl_2$ as a colourless liquid (73.5 g, 81% yield, b.p. 30°C/0.1–0.2 torr). Calc. for $C_4H_{11}AsCl_2Si$: C, 20.62; H, 4.76; Cl, 30.43. Found: C, 20.67; H, 4.70; Cl, 30.26%. ^1H NMR (C_6D_6, 80.06 MHz): δ −0.070 (s, CH_3), 1.5 (s, CH_2).

$Me_3SiCH_2AsH_2$ (**II**). To a stirred suspension of $LiAlH_4$ (6.68 g, 0.176 mol) in Et_2O (250 cm^3) at −78°C was added, dropwise, a solution of **I** (20.5 g, 0.0880 mol) in Et_2O (50 cm^3). After the addition was complete, the mixture was hydrolysed with a large excess of deionized water at 0°C. A white solid [presumably $Al(OH)_3$ and LiOH] was separated from the mixture by filtration and washed with Et_2O. Addition of $MgSO_4$ to the separated organic layer, followed by filtration and removal of the solvent from the filtrate, afforded a yellow liquid which was vacuum distilled (30–40°C/20–50 torr) to give impure **II** as a colourless liquid. Purification was achieved by trap-to-trap fractionation, with pure **II** (6.81 g, 47.2% yield) being retained in a trap at −63°C. Calc. for $C_4H_{13}AsSi$: C, 29.27; H, 7.98. Found: C, 29.56, 29.41; H, 8.03, 7.92%. ^1H NMR (C_6D_6, 299.944 MHz): δ −0.021 (s, CH_3), 0.301 $^3J_{HH}$ = 7.44 Hz (t, CH_2), 2.054 (t, AsH_2). $^{13}C\{^1H\}$ NMR (C_6D_6, 75.429 MHz): δ −5.425 (CH_2), −1.246 (CH_3).

Treatment of **I** with $LiAlH_4$ at RT afforded **II** in lower yield (25%) as well as some **VI**.

$[Me_3SiCH_2(H)AsGaPh_2]_3$ (**III**). 1. Compound **II** (1.78 g, 10.8 mmol) and Ph_3Ga (3.26 g, 10.8 mmol) were combined in benzene (25 cm^3) and, after stirring the mixture overnight at 55–57°C, the solvent was stripped off, leaving a colourless sticky residue. Volatiles were then removed *in vacuo* over a 4 day period to yield **III** as a less sticky material. Attempts to crystallize the product from C_6H_{14} or a mixture of ligroin and C_6F_{14} were unsuccessful. Melting point measurement: the colourless **III** became mobile at 57–59°C and it started to change to light yellow at 68°C; it became a transparent liquid at 75–77°C. Calc. for $C_{48}H_{66}As_3Si_3Ga_3$: C, 49.65; H, 5.73. Found: C, 51.00, 51.05; H, 5.75, 5.77%. Mol. wt (0.303 g in 13.97 g of cyclohexane): Calc. 1161. Found: 1172±23%. ^1H NMR (C_6D_6, 299.944 MHz): δ −0.329, −0.332, −0.359 (3 s, CH_3), 0.768, 0.818, 0.882 $^3J_{HH}$ = 5.86, 5.88, 5.76 Hz (3 d, CH_2), 2.334, 2.451, 2.600 (3 t, AsH), 7.2–7.4 and 7.7–7.9 (m, Ph).

Reaction of Ph_3Ga (0.550 g, 1.83 mmol) with an excess of **II** (0.324 g, 1.97 mmol) yielded the same sticky product, with all Ph_3Ga being consumed. Drying the product under high vacuum for 5 days afforded colourless sticky **III** (0.708 g, 100% yield; ^1H NMR spectrum same as that of an authentic sample).

2. Slow addition of *n*-BuLi (1.56 cm^3, 2.34 mmol) to a stirred THF solution of **II** (0.384 g, 2.34 mmol) which was cooled in a −78°C bath resulted in a slightly yellow solution. [Note: Treatment of **II** with *n*-BuLi in various solvents (hexane, ligroin, and THF) at RT and even at 0°C, resulted in a complex reaction mixture.] After stirring for 3 h, Ph_2GaCl (0.607 g, 2.34 mmol) was added by means of a side-

arm dumper to the vessel. The bath was removed after stirring for another 3 h and the mixture was stirred for 1 h at RT, yielding a white solid (presumably LiCl). The mixture was filtered and washed with C_6H_6. Removal of solvents *in vacuo* from the filtrate afforded a yellow solid. The ^1H NMR spectrum of the latter revealed that **III** and an adduct of the gallium reactant (presumably $Ph_2GaCl \cdot THF$) were present. Recrystallization of the yellow solid from hexane or a mixture of ligroin and THF provided light yellow crystals of the adduct.

$[Me_3SiCH_2(H)AsGaMe_2]_3$ (**IV**). Me_3Ga (3.42 mmol), measured on a vacuum line, was condensed into a reaction vessel containing a pentane solution of **II** (0.551 g, 3.36 mmol) at −196°C. The mixture was warmed to RT and stirred for 39 h. The evolved CH_4 (3.26 mmol) was measured and volatiles were removed *in vacuo* leaving a mixture of a colourless liquid and a very small amount of a solid. A second experiment using Me_3Ga (1.80 mmol) with an excess of **II** (0.307 g, 1.87 mmol) gave a colourless mixture of a liquid and solid (0.400 g, 84.6% yield) and CH_4 (1.45 mmol). The ^1H NMR spectra of both mixtures showed the same type of coupling pattern as that observed in the spectrum of **III**. ^1H NMR (C_6D_6, 299.944 MHz): δ 0.047 (s, Me_3Si); 0.206, 0.247, 0.294 (3 s, Me_2Ga); 0.785, 0.805, 0.823 $^3J_{HH}$ = 5.80 Hz (3 overlapping d, CH_2As); 1.697, 1.748, 1.790 (3 overlapping t, AsH).

Reaction of **II** *with* $(Me_3SiCH_2)_3Ga$. Compound **II** (0.25 g, 1.5 mmol) and $(Me_3SiCH_2)_3Ga$ (0.05 g, 1.5 mmol) were transferred into a 50 cm^3 bulb equipped with a Teflon stopcock and a magnetic stir bar. The bulb was attached to a vacuum line, cooled to −196°C and degassed. Stirring the mixture for a day at RT, followed by heating and stirring for 2 days at 51–63°C, gave a yellow liquid, H_2 (1.2 mmol, 80% yield) and Me_4Si (0.21 mmol, 14% yield). After the liquid was transferred into a 50 cm^3 flask to which a solution of the remaining liquid and pentane used for rinsing the bulb was added, a few small particles [presumably unreacted $(Me_3SiCH_2)_3Ga$] were removed by filtration. Removal of the pentane *in vacuo* from the filtrate afforded a yellow liquid, the ^1H NMR spectrum of which revealed that **VI** and $(Me_3SiCH_2)_3Ga$ were present. The liquid residue was mixed with ligroin and perfluorohexane and stored at −15°C. A few months later, a crystal was isolated; its ^1H NMR spectrum showed a broad hump and many lines between δ 1.8 and −0.5.

$Me_3SiCH_2As(SiMe_3)_2$ (**V**). To a stirred THF solution of **II** (1.171 g, 7.13 mmol) at −78°C was slowly added *n*-BuLi (4.74 cm^3, 14.26 mmol). After stirring for 3 h, Me_3SiCl (1.8 cm^3, 14.28 mmol) was introduced into the mixture which turned colourless immediately after the addition. After stirring for another 3 h, the mixture was warmed to RT and stirred for 2 h. A white solid (presumably LiCl) was removed by filtration and washed with benzene. Volatiles were removed from the filtrate and the liquid residue was distilled *in vacuo* to give **V** as a colourless liquid (1.82 g, 83% yield, b.p. 52–53°C/0.1–0.2 torr). Calc. for $C_{10}H_{29}AsSi_3$: C, 38.93; H, 9.47. Found: C, 38.72, 38.95; H, 9.55, 9.62%. ^1H NMR (C_6D_6, 299.944 MHz): δ 0.177 (s, Me_3SiC), 0.254 (s, Me_3SiAs), 0.559 (s, CH_2). $^{13}C\{^1H\}$ NMR (C_6D_6, 75.429 MHz): δ −5.690 (s, CH_2), −0.322 (s, Me_3SiC), 1.415 (s, Me_3SiAs).

Attempted preparation of $Me_3SiCH_2As(H)SiMe_3$. *n*-BuLi (1.42 cm^3, 4.14 mmol) was added to a THF solution of **II** (0.680 g, 4.14 mmol) which was cooled with a −78°C bath. After stirring for 3 h, Me_3SiCl (0.52 cm^3, 4.14 mmol) was added to the mixture. The bath was removed and the mixture was stirred for 3 h. A white solid (presumably LiCl) was separated by filtration and removal of solvents from the filtrate gave a liquid mixture of **II** and **V** (based on a ^1H NMR spectrum). Removal *in vacuo* of **II** from the mixture gave **V** (0.777 g, 61% yield).

When this reaction was repeated at RT, **VI**, $(Me_3Si)_3As$ and an unidentified black precipitate were formed.

Attempted preparation of $(Me_3SiCH_2AsGaPh)_n$. 1. Heating **III** at 55–62°C for 2 days in a Dri Lab produced a light yellow solid which on further heating at 76–82°C for 2 days turned more yellow. The ^1H NMR spectrum of the yellow solid revealed that the coupling pattern of the trimer was collapsed and a hump appeared at δ 0.5 to −0.5. Heating the yellow solid at 90–100°C for another 2 days left the colour unchanged and a similar ^1H NMR spectrum was obtained (three peaks at δ 3.106, 0.188, 0.128; two humps at δ 1.0 to 0.8 (small), 0.5 to −0.5 (larger, broad), and a shoulder at δ 2.4–1.0). Melting point measurement: the yellow solid turned brownish at 170°C, red at 190°C and became a liquid at 210–225°C. Calc. for $C_{10}H_{16}SiAsGa$: C, 38.87; H, 5.22. Found: C, 40.44, 40.30; H, 5.41, 5.35%.

2. *n*-BuLi (0.88 cm^3, 2.67 mmol) was added with stirring to an Et_2O solution of **II** (0.219 g, 1.34 mmol) in a reaction vessel which was immersed in a dry ice/acetone bath. After stirring for 1 h, $PhGaCl_2$ (0.292 g, 1.34 mmol) was added to the mixture by means of a side-arm dumper. The bath was removed 1 h later and the precipitation of a white solid (presumably LiCl) was observed. The white solid (0.10 g, 88% yield) was removed by filtration and removal *in vacuo* of solvents from the filtrate gave a light yellow sticky residue. The ^1H NMR spectrum of the residue was relatively simple showing

one peak at δ −0.024 and two broad humps between δ 2.0 and −0.5.

3. (a) A toluene solution of **V** (0.309 g, 1.00 mmol) was combined with a toluene solution of $PhGaCl_2$ (0.218 g, 1 mmol) at −15°C. After 18 h at −15°C, followed by stirring for 27 h at RT, 1.36 equiv. of Me_3SiCl were formed. Heating for 13 h at 66°C increased the amount of Me_3SiCl formed to 1.68 equiv. and afforded a colourless sticky residue. Attempts to crystallize the product from hexane or ligroin were unsuccessful. The ^1H NMR spectrum of the residue was similar to that of the material obtained when **III** was decomposed at 80°C (2 peaks at δ 2.104 and 0.294; 3 humps at δ 3.4 to 3.0, 2.0 to 1.0, and 0.5 to −0.5).

(b) After 12 h at −15°C, a mixture similar to that described in (a) was stirred for 4 days at RT and 1.53 equiv. of Me_3SiCl resulted. Alternating the reaction temperature between RT and −15°C four times in 12 days, with removal of Me_3SiCl after each period, increased the total amount of Me_3SiCl formed to 1.79 equiv. Removal of volatiles *in vacuo* afforded an off-white sticky residue. The ^1H NMR spectrum of the residue showed two peaks at δ 0.254 and 0.176, three humps at δ 2.3–1.1, 1.1–0.8, 0.5 to −0.5 and a small peak at δ 0.559.

$(Me_3SiCH_2As)_5$ (**VI**). Compound **I** (15.0 g, 0.0644 mol) was slowly added to a THF solution of Me_3SiCl (120 cm^3) and Mg turnings (3.14 g, 0.129 mol). The resulting mixture was refluxed for 1 h and then stirred at RT for an additional 8 h. Removal of volatiles *in vacuo* gave a mixture of an off-white solid and a yellow liquid which was filtered and washed with pentane. Removal of solvents from the filtrate afforded crude **VI** as a yellow liquid. Some of the diarsine $[(Me_3SiCH_2)_2As]_2$[2b] was produced during the attempted purification (distillation at 100–120°C/0.1–0.2 torr) of the crude product; but after a week at RT, pale yellow crystals of **VI** formed in the yellow distillate. The crystals (3.28 g, 31.4%; m.p. 47–48°C) were removed mechanically from the liquid. Calc. for $C_{20}H_{55}As_5Si_5$: C, 29.63; H, 6.84. Found: C, 29.61; H, 6.67%. ^1H NMR (C_6D_6, 299.944 MHz): δ 0.185, 0.213, 0.219 (3 s, CH_3), 1.602 (s, CH_2), 1.515 and 1.738 $^2J_{HH}$ = 13.63 Hz, 1.538 and 1.687 $^2J_{HH}$ = 13.55 Hz (2 AB patterns, CH_2). $^{13}C\{^1H\}$ NMR (C_6D_6, 75.429 MHz): δ 0.079, 0.266, 0.349 (3 s, CH_3), 8.145, 10.240, 12.736 (3 s, CH_2). The ^1H NMR spectrum of the remaining liquid showed the presence of the diarsine and **VI** (36 : 64%, based on integral ratios). Total yield of **VI**: 5.53 g, 53%.

X-ray crystal structure determination

$(Me_3SiCH_2As)_5$ (**VI**). All measurements were performed on an Enraf–Nonius CAD-4 diffractometer (Cu-K_α radiation, λ = 1.5418 Å; incident-beam graphite monochromator; ω–2θ scans, θ_{max} = 67°). Unit-cell parameters were derived from the diffractometer setting angles for 25 reflections ($40° < \theta < 55°$) widely separated in reciprocal space. Lorentz, polarization and empirical absorption corrections were applied to the data. The crystal structure was solved by direct methods. Approximate positions for the non-hydrogen atoms were obtained from an *E*-map. Hydrogen atoms were included at their calculated positions in the final rounds of full-matrix least-squares refinement of non-hydrogen atom positional and anisotropic temperature factor parameters. Crystallographic calculations were performed on PDP11/44 and Micro Vax II computers by use of the Enraf–Nonius Structure Determination Package incorporating the direct methods program MULTAN11/82. Neutral atom scattering factors used in the structure-factor calculations were taken from *International Tables for X-Ray Crystallography*, Vol. IV, The Kynoch Press, Birmingham, U.K. (1974). In the full-matrix least-squares iterations, $\Sigma w\Delta^2$ [$w = 1/\sigma^2(|F_o|)$, $\Delta = (|F_o| - |F_c|)$] was minimized. Further details of data collection and refinement are in Table 1. Bond lengths, bond angles and torsion angles are listed in Table 2. Supplementary material: atomic coordinates, thermal parameters, bond lengths and angles and crystal data have been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Syntheses and reactions

Reduction of **I**, which was prepared according to eqs (1)–(3), with $LiAlH_4$ in Et_2O at −78°C afforded **II** [eq. (4)]. In contrast, the reduction at RT resulted in a significantly lower yield of **II**, as well as some of the cycloarsane, **VI**.

$$4Et_2NH + AsCl_3 \longrightarrow (Et_2N)_2AsCl + 2Et_2NH\cdot HCl \quad (1)$$

$$(Et_2N)_2AsCl + Me_3SiCH_2MgCl \longrightarrow (Et_2N)_2AsCH_2SiMe_3 + MgCl_2 \quad (2)$$

$$(Et_2N)_2AsCH_2SiMe_3 + 4HCl \longrightarrow \underset{\mathbf{I}}{Me_3SiCH_2AsCl_2} + 2Et_2NH\cdot HCl \quad (3)$$

$$2Me_3SiCH_2AsCl_2 + LiAlH_4 \longrightarrow \underset{\mathbf{II}}{2Me_3SiCH_2AsH_2} + LiCl + AlCl_3. \quad (4)$$

[a] The torsion angle A—B—C—D is defined as positive if, when viewed along the B—C bond, atom A must be rotated clockwise to eclipse atom D.

The reaction of primary arsine **II** with Ph_3Ga in benzene proceeded slowly at RT; however, the cleavage of a single Ga—C bond occurred quantitatively at 55–57°C, yielding benzene and **III**. This trimer was isolated as a colourless sticky material and it did not eliminate benzene at RT. Monitoring of a sample of the reaction mixture between 43 and 80°C by ^1H NMR spectroscopy revealed that the decomposition of the single cleavage product started at 58–60°C and was completed at 80°C. Efforts to crystallize **III** were not successful but it could be characterized on the basis of molecular weight, ^1H NMR and analytical data. It is interesting to note that, whereas **III** is a trimer, $[(Me_3SiCH_2)_2AsGaPh_2]_2$ is a dimer.[2c] The ^1H NMR spectrum of **III** shows that two diastereoisomers exist depending on the disposition of As—H groups, i.e. axially or equatorially oriented on the $(Ga—As)_3$ ring. One isomer has three equivalent As—H protons, whereas the other has two equivalent As—H protons which are non-equivalent to the third As—H proton. It has been demonstrated by selective decoupling experiments that three different coupling patterns between the CH_2 protons and the As—H protons take place. In addition, reaction of $Me_3SiCH_2(H)AsLi$ with Ph_2GaCl afforded a yellow solid which, on the basis of its ^1H NMR spectrum, contains **III**; however, recrystallization of the yellow solid did not yield **III**.

Reaction of **II** with Me_3Ga in pentane at RT also gave a single cleavage product which was isolated as a colourless liquid containing a small amount of solid that slowly melted/dissolved at RT. On the basis of its ^1H NMR spectrum, we believe this product is $[Me_3SiCH_2(H)AsGaMe_2]_3$ (**IV**). The spectrum shows the same coupling pattern as that exhibited in the spectrum of **III**, but three peaks for the Me_3Si protons are merged into one peak. The four peaks at δ 0.774, 0.795, 0.814 and 0.832 can be explained by the overlapping of three doublets. Also, the three triplets for the As—H protons are partially overlapped. After storing this single cleavage product at −15°C for 9 weeks, it was observed that one of the three peaks in the NMR spectrum for the Me_2Ga protons was split into a doublet and another one appeared to have some splitting. Also, two additional doublets and one singlet appeared in the methylene region, while one more multiplet appeared up-field adjacent to the three As—H triplets. These observations imply that the trimer **IV** underwent the loss of CH_4.

Only H_2, Me_4Si, **VI** and unreacted $(Me_3SiCH_2)_3Ga$ were identified after allowing the latter to react with **II**. These results compare, in part, with those obtained by us in some related earlier work using the same tri(alkyl)gallane. Thus, with $PhAsH_2$, the products were H_2, Me_4Si, $(PhAs)_6$ and the cluster $[(PhAsH)(R_2Ga)(PhAs)_6(RGa)_4]$ ($R = Me_3SiCH_2$);[2a] with Ph_2AsH, the products were H_2, Me_4Si, $(Ph_2As)_2$ and impure $[Ph_2AsGa(CH_2SiMe_3)_2]_n$.[2b] On the other hand no side products were observed in the preparation of $[(Me_3SiCH_2)_2AsGaPh_2]_2$ from the reaction of $(Me_3SiCH_2)_2AsH$ with Ph_3Ga.[2c]

In a one-pot synthesis, **V** was obtained in a high yield from **II** via dilithiation followed by silylation at −78°C. In contrast, efforts to isolate the monosilylated arsine, $Me_3SiCH_2As(H)SiMe_3$, were unsuccessful. Thus, using a procedure similar to that used to prepare **V**, afforded only **II** and **V**. It is reasonable to assume that, in fact, monosilylated **II** was formed at low temperature but on warming to RT it underwent disproportionation. When the entire procedure was repeated at RT, **VI**, $(Me_3Si)_3As$ and an unidentified black precipitate were formed.

Three approaches were utilized in attempts to prepare and isolate an oligomer of the type $(RAs GaR')_n$. First, compound **III** was slowly heated in an effort to eliminate 1 mole equiv. of benzene. A ^1H NMR spectrum of a sample of **III** which had been heated for 2 days at 55–62°C revealed that the elimination had started to occur, but **III** was still the predominant species. On subsequent heating for 2 days at 76–82°C, a yellow solid formed and its ^1H NMR spectrum contained broad peaks indicative of a polymer or mixture of oligomers/polymers. Although a completely "satisfactory elemental analysis" (C and H) was not obtained, the data strongly support a formulation of $(Me_3SiCH_2As GaPh)_n$ for the yellow solid. Second, the reaction of $Me_3SiCH_2AsLi_2$ (prepared *in situ*) with $PhGaCl_2$, was investigated. There was also evidence in this case for the desired reaction product(s), but none was isolated in "pure" form. Third, dechlorosilylation reactions between **V** and $PhGaCl_2$ were carried out. In one experiment, a total of 1.68 equiv. of Me_3SiCl were evolved, leaving a colourless sticky residue. Attempts to crystallize the latter were unsuccessful; however, its ^1H NMR spectrum compares favourably to that obtained for the 80°C decomposition product of **III**.

In an effort to prepare **V** by an alternate and more direct method, the reaction of **I** with a mixture of Me_3SiCl and Mg in THF was carried out. No evidence for the desired product **V** was obtained; rather, the reaction afforded **VI**. This result conforms with the report that the reaction of *t*-$BuAsCl_2$ with Mg in THF or Et_2O yields $(t\text{-BuAs})_5$, in addition to $(t\text{-BuAs})_4$ and *t*-Bu_6As_8.[10] On the other hand, *t*-$BuP(SiMe_3)_2$ has been synthesized in high yield by the reaction of Me_3SiCl with Mg and *t*-

$BuPCl_2$.[11] In the purification of **VI** by distillation *in vacuo*, a small amount of the diarsine $[(Me_3SiCH_2)_2As]_2$ was formed and a mixture of the two products was obtained as a yellow liquid. After 1 week, **VI** crystallized from the liquid at RT and single crystals suitable for an X-ray diffraction study were obtained.

Crystal structure of $(Me_3SiCH_2As)_5$ (VI)

An ORTEP drawing of **VI** is shown in Fig. 1. Crystallographic data and a summary of data collection and refinement are presented in Table 1, bond lengths, bond angles and torsion angles are in Table 2 and a comparison of corresponding lengths and angles in **VI** and $(MeAs)_5$[12] is provided in Table 3. The As—As bond lengths are not all equal, As(1)—As(2) ≃ As(2)—As(3) < As(3)—As(4) ≃ As(4)—As(5) ≃ As(5)—As(1) and their mean at 2.437 Å is slightly longer than that of 2.428 Å in $(MeAs)_5$ as is the mean As—C distance at 1.99 Å in **VI** *vs* 1.96 Å in $(MeAs)_5$ Endocyclic torsion angles are related by an approximate C_s-symmetry axis passing through As(1) and the mid-point of the As(3)—As(4) bond, and thus the ring has an envelope-like conformation although it is clearly twisted somewhat as reflected in the distinctly non-zero value of 6.2° for the As(2)—As(3)—As(4)—As(5) torsion angle. As reflected in the values of corresponding torsion angles for **VI** and $(MeAs)_5$ (Table 3), the five-membered rings have similar conformations in both compounds.

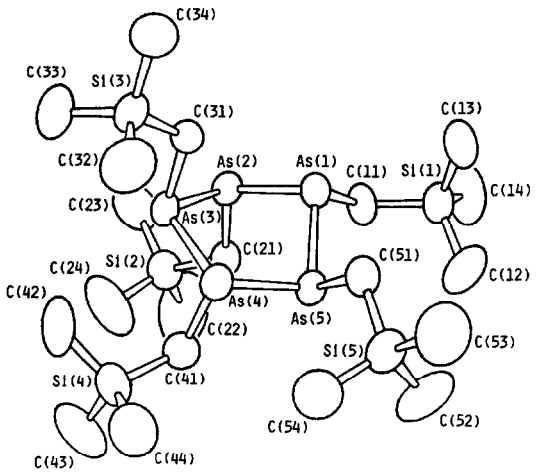

Fig. 1. ORTEP drawing of $(Me_3SiCH_2As)_5$ (**VI**); hydrogen atoms are omitted for clarity.

NMR spectra of $(Me_3SiCH_2As)_5$ (VI)

If the solid-state structure were to persist in solution, the ^1H NMR spectrum of **VI** would be ex-

[a] The bond length and bond angle values for $(MeAs)_5$ were calculated using positional parameters contained in ref. 12.

pected to be very complex; however, it was found to be quite non-complex. It consisted of three singlets (intensity ratio 2:1:2)[13] [δ 0.185, 0.213 and 0.219 (CH_3)], two distinct AB patterns [δ 1.515 and 1.738, $^2J_{HH}$ = 13.63 Hz (CH_2); δ 1.538 and 1.687, $^2J_{HH}$ = 13.55 Hz (CH_2)]. The $^{13}C\{^1H\}$ NMR spectrum of **VI** shows three singlets each for CH_3 and CH_2 carbons, proving that three types of Me_3SiCH_2 groups are present. In the presence of a symmetry-generating torsional (restricted pseudorotational) motion proposed by Rheingold,[14] the symmetrical intermediate of **VI** would give exactly the same resonances as shown in the ^1H NMR spectrum which was obtained. The steric restrictions imposed by bulky Me_3SiCH_2 groups have a dampening effect on pseudorotation[15] of the ring puckering. As a result, a limited pseudorotation responsible for a time-averaged plane of symmetry takes place. According to Rheingold, there are four possible inversional isomers for the five-membered ring in $(ClCH_2As)_5$.[14] Interestingly, compound **VI** in the solid state has the conformation which corresponds to that isomer with the lowest internal energy.

Abstract—Reaction of InCl with the phospholyl anion, K(18-crown-6)$^+$[PC_4Me_4]$^-$, yielded the indium(III) ate complex K(18-crown-6)$^+$[$(Me_4C_4P)_2InCl_2$]$^-$. Its structure was determined by X-ray diffraction.

Recent interest in the organometallic chemistry of the group 13 elements aluminium, gallium and indium has been fuelled in part by the use of simple alkyls of these elements in the chemical vapour deposition (CVD) of III–V semiconductors (e.g. gallium arsenide, indium phosphide, etc.).[1] Thin films of indium phosphide, for example, are currently grown epitaxially by the high-temperature reaction of $InMe_3$ with PH_3.[2] We are exploring the potential of precursors which contain both of the elements of the desired semiconductor in the same molecule.[3] Herein we report the synthesis and characterization of an indium compound containing phosphorus ligands.

The CVD process requires volatile compounds. In designing synthetic targets we were thus attracted to cyclopentadienyl derivatives of indium(I), which have appreciable vapour pressures.[4] We reasoned, that substitution of a phosphorus atom for a carbon of the cyclopentadienyl ring (see Scheme 1) might yield a volatile molecule containing both indium and phosphorus which might also feature a fragmentation pathway with a low activation barrier and relatively unreactive products. The latter would seem to provide a solution to the persistent problem of carbon incorporation into the growing semiconductor film.[5]

RESULTS AND DISCUSSION

We have recently described convenient syntheses of the phospholyl anion salts $M^+[PC_4Me_4]^-$.[6] Addition of 1.0 equivalent of InCl to a toluene solution of the potassium salt, K(18-crown-6)$^+$[PC_4Me_4]$^-$, yielded a dark precipitate and a colourless solution. Filtration, evaporation of solvent and recrystallization from THF gave colourless crystals of a new material. Based on the spectroscopic and analytical data it was assigned the formula K(18-crown-6)$^+$[$(Me_4C_4P)_2InCl_2$]$^-$ (**1**), an ate complex of indium(III). Complex **1** was isolated in 24% yield based on InCl.

The crystal structure of **1** has been determined by X-ray diffraction and the result is shown in Fig. 1.† Interatomic distances and angles are listed in Tables 1 and 2, respectively. The coordination environment of indium in the complex anion is a distorted tetrahedron consisting of the two phosphorus atoms of η^1-phospholyl ligands and two chlorides. The angles about indium range between 98.7(1)° (between the chloride ligands) to 131.2(1)° (between the bulky phospholyl groups). The indium–phosphorus bond distances of 2.481(3) and 2.491(3) Å closely approximate the sum of the covalent radii of the two elements (In, 1.44 Å; P, 1.06 Å). However, they are significantly shorter than the corresponding distances in comparable molecules. Phosphido-bridged dimers of the type $[R_2In(\mu_2\text{-}PR'_2)]_2$ feature In—P distances in the range 2.59–2.66 Å,[7] while monomeric molecules exhibit slightly shorter bonds, i.e. 2.588(14), 2.574(11) and 2.613(12) Å in the neutral $In(P^tBu_2)_3$[7b] and 2.585(2), 2.576(2),

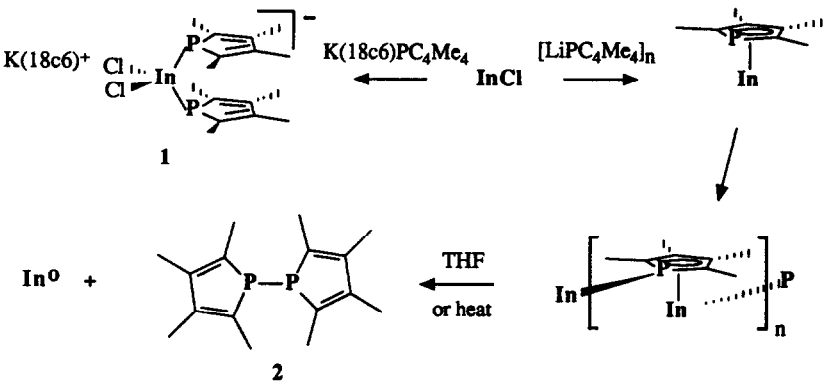
2.586(2) and 2.556(2) Å in the ate complex $Li(THF)_4[In(PPh_2)_4]$.[8] The latter values probably reflect the steric bulk of the respective phosphide ligands.

η^1-Coordination of the phospholyl moiety to metals is rare.[9] However, in this case it parallels the bonding of the all carbon analogue; i.e. the pentamethylcyclopentadienyl ligand binds to indium(III) in a η^1-fashion also.[10] The bond distances within the heterocycles are very similar to the ones found in the structurally characterized benzylphosphole[11] and unlike those of the delocalized phospholyl anion found in $Li(TMEDA)^+[PC_4Me_4]^-$.[6] The small difference in electronegativity between indium and phosphorus (In, 1.7; P, 2.1) also points to the covalent nature of the In—P bonds in **1**. The phosphorus atoms assume trigonal pyramidal configurations, the sum of the bond angles about them being 291.4° for P(1) and 289.3° for P(2). Their lone pairs are apparently not interacting with the indium, making the phospholyl groups formally one-electron donors.

The In—Cl bond length [In—Cl(1), 2.427(4) Å; In—Cl(2), 2.441(3) Å] are typical for this element combination (sum of covalent radii = 2.43 Å) and similar to the distances reported for the $[MeInCl_3]^-$ ion (In—Cl_{av}, 2.40 Å).[12] One of the chloride ligands [Cl(2)] is interacting weakly with the potassium cation, the distance of 3.244(4) Å being only slightly longer than the sum of the ionic radii (K^+, 1.33 Å; 1.81 Å). The coordination sphere of the potassium is completed by the six oxygen atoms of the crown ether. The bond distances and angles found for this part of the molecule are normal [see for example the structure of $K(18\text{-crown-6})^+SCN^-$].[13]

Complex **1** is obviously the result of a disproportionation reaction (see Scheme 2). The desired indium(I) derivative $(Me_4C_4P)In$, while probably formed initially, may be unstable under the reaction conditions. Beachley *et al.* have found that $(\eta^5\text{-}C_5Me_5)In$ decomposes in donor solvents (THF, pyridine), yielding products consistent with a ligand induced disproportionation.[14] It is possible that free crown ether has a similar effect upon $(Me_4C_4P)In$. In an attempt to eliminate any donor molecules, we have combined InCl with $[LiPC_4Me_4]_n$ in toluene. This reaction yielded an off-white precipitate and a yellow solution, from which a yellow powder precipitated upon standing. This material did not contain chloride and the IR spectrum of the solid as a KBr pellet exhibited bands characteristic of the phospholyl group. The yellow powder was almost completely insoluble in nonpolar organic solvents; however, a very dilute solution in C_6D_6 exhibited resonances consistent with a coordinated phospholyl moiety [1.84 (s), 2.40, (d, J_{PH} = 11 Hz)]. Addition of THF to the yellow solid initially gave a yellow solution, followed by the formation of a black precipitate (indium metal?) and 1,1′-biphospholyl (**2**).[6] Similarly, an attempted sublimation yielded a grey residue and a white sublimate of 1,1′-biphospholyl. Based on these obser-



Scheme 2.

vations, we believe that $(Me_4C_4P)In$ is indeed formed. However, in non-polar solvents it apparently polymerizes, while donor solvents or heating lead to its decomposition.

EXPERIMENTAL

All manipulations involving air-sensitive organometallic compounds were carried out in a Vacuum Atmospheres inert-atmosphere box under N_2 or on a Schlenk line using Ar or N_2. Solvents were distilled under N_2 from purple benzophenone ketyl. NMR: Bruker WM 300 spectrometer (300 MHz for ^1H, 75.47 MHz for ^{13}C and 121.49 MHz for ^{31}P). Shifts are reported in ppm downfield of TMS (for ^1H and ^{13}C) using the solvent resonances as reference and relative to an external PCl_3 reference at 219 ppm for ^{31}P. IR: Mattson Alpha Centauri FT–IR. InCl and 18-crown-6 (Aldrich) were used as received.

Potassium(18 - *crown* - 6)*bis*(*chloro*)*bis*(η^1 - 2,3,4,5 - *tetramethylphospholyl*)*indate*(I) (**1**)

To a toluene solution of K(18-crown-6)PC_4Me_4 (451 mg, 1.0 mmol) was added InCl (150 mg, 1.0 mmol) and the reaction mixture was stirred at ambient temperature for 1 h. The dark precipitate was filtered off, the solvent evaporated under vacuum, and the residue recrystallized from THF at −30°C (185 mg, 24% yield). ^1H NMR (CD_2Cl_2): 3.65 (s, 24 H), 2.07 (d, 12 H, J_{PH} = 10.4 Hz), 1.91 (s, 12 H); ^{31}P NMR (CD_2Cl_2): −19.16 (s); ^{13}C NMR (CD_2Cl_2): 140.61 (s), 133.09 (d, J_{PC} = 15.1 Hz), 70.75 (s), 14.38 (d, J_{PC} = 31 Hz), 14.18 (s). IR (KBr): 2897 (vs), 2788 (m), 1974 (m), 1471 (s), 1453 (s), 1351 (vs), 1284 (s), 1120 (vs), 962 (vs), 837 (s), 804 (w), 553 (w), 530 (m), 513 (m) cm^{-1}. Found: C, 43.91; H, 5.72. Calc. for $C_{28}H_{48}Cl_2InKO_6P_2$: C, 43.82; H, 6.26%.

X-ray structure determination of **1**

Crystallographic data are summarized in Table 3. A colourless specimen mounted in a glass capillary was found to belong to the orthorhombic crystal system. Systematic absences in the reflection data uniquely determined the space group as $P2_12_12_1$. No correction for absorption was required. The structure was solved by direct methods and refined with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were treated as idealized contributions ($d_{CH} = 0.96$ Å). All software is contained in the SHELXTL library, version 5.1 (G. Sheldrick, Nicolet XRD, Madison, WI).

THE CHEMISTRY OF DIPHENYLPHOSPHINE ADDUCTS OF TRIS(NEOPENTYL) AND TRIS(TRIMETHYLSILYLMETHYL)GALLIUM AND -INDIUM INCLUDING THE CRYSTAL AND MOLECULAR STRUCTURE OF $(Me_3CCH_2)_3Ga \cdot P(H)Ph_2$

Abstract—The adducts $(Me_3CCH_2)_3Ga \cdot P(H)Ph_2$ and $(Me_3SiCH_2)_3Ga \cdot P(H)Ph_2$ have been prepared as crystalline solids at room temperature and characterized by cryoscopic molecular weight measurements in benzene solution and ^1H NMR, ^{31}P NMR and IR spectroscopic data. The molecular weight studies demonstrate that both adducts are extensively dissociated in solution and that $Ga(CH_2CMe_3)_3$ is a stronger Lewis acid than $Ga(CH_2SiMe_3)_3$. An X-ray structural study defined the nature of $(Me_3CCH_2)_3Ga \cdot P(H)Ph_2$ in the solid state. The colourless crystal contains two discrete molecules in each unit cell. The compound crystallizes in the triclinic space group $P\bar{1}$ with unit cell dimensions of $a = 9.564(8)$, $b = 12.208(5)$, $c = 12.946(9)$ Å, $\alpha = 100.00(5)$, $\beta = 100.41(8)$, $\gamma = 102.97(7)°$ and $D_{calc} = 1.10$ g cm^{-3}. The adduct has a relatively long Ga—P distance of 2.683(5) Å and the α-carbon atoms of the substituents on gallium and phosphorus are essentially but not perfectly eclipsed. The syntheses of $(Me_3CCH_2)_3In \cdot P(H)Ph_2$ and $(Me_3SiCH_2)_3In \cdot P(H)Ph_2$ were attempted but room temperature elimination reactions, which produced CMe_4 and $SiMe_4$, respectively, and the appropriate organoindium phosphides, precluded the isolation of adducts. Simple kinetic studies revealed that $In(CH_2CMe_3)_3 - P(H)Ph_2$ eliminated CMe_4 at 17°C significantly faster than $In(CH_2SiMe_3)_3 - P(H)Ph_2$ produced $SiMe_4$.

The compound semiconductors GaAs and InP have spurred a renewed interest in the chemistry of gallium and indium. Much of the characteristic chemistry of these group 13 elements can be related to the ability of the metal atom to accept an electron pair. Thus, organo-gallium and -indium compounds react with Lewis bases to form adducts. If the Lewis base has an acidic proton, an elimination reaction can occur typically at elevated temperatures to produce compounds of the type R_2MER_2. Thus, it is logical that compounds of the type MR_3,[1] $R_3M \cdot ER_3$[2] and R_2MER_2[3] have been used as precursors for making the compound semiconductors.

A review of the literature[4] suggests that all of the physical measurements of thermodynamic parameters related to stabilities of adducts and of the structural studies of homoleptic organo-gallium and -indium compounds with phosphorus and arsenic bases have involved $GaMe_3$ or $InMe_3$. The enthalpies of dissociation of $Me_3Ga \cdot L$ and $Me_3In \cdot L$ (L = PMe_3 and $AsMe_3$) were measured by vapour pressure techniques.[5] Even though ^1H NMR studies[6] have been used to relate the ΔH_{diss} of $Et_3Ga \cdot PMe_3$ to $Me_3Ga \cdot PMe_3$, no quantitative studies have verified the early predictions. It is regrettable but no quantitative studies permit comparisons of the effects of different organic substituents on the Lewis acidities of organo-gallium and -indium compounds to a common Lewis base.

* Authors to whom correspondence should be addressed.

There is also a surprising lack of structural information on adducts of gallium or indium. Only the adducts $Me_3M \cdot P(Ph)_2C_2H_4(Ph_2)P \cdot MMe_3$ (M = Ga, In),[7,8] $Me_2ClGa \cdot P(Ph)_2CH_2P(Ph)_2$[9] and $Cl_3Ga \cdot PMe_3$[10] have been the subject of X-ray structural studies, whereas $Me_3Ga \cdot NMe_3$[11] and $Me_3Ga \cdot PMe_3$[11] have been investigated by electron diffraction techniques.

In this paper, we report the synthesis and characterization of two gallium–phosphorus adducts, $(Me_3CCH_2)_3Ga \cdot P(H)Ph_2$ and $(Me_3SiCH_2)_3Ga \cdot P(H)Ph_2$, and the attempted synthesis of $(Me_3CCH_2)_3In \cdot P(H)Ph_2$ and $(Me_3SiCH_2)_3In \cdot P(H)Ph_2$. The indium-containing adducts were not sufficiently stable at room temperature to permit characterization due to the occurrence of elimination reactions. It is noteworthy that the X-ray structural study of $(Me_3CCH_2)_3Ga \cdot P(H)Ph_2$ provides the first structure of an adduct of a heavier group 13 element with a Lewis base which incorporates an acidic hydrogen. Cryoscopic molecular weight studies of $(Me_3CCH_2)_3Ga \cdot P(H)Ph_2$ and $(Me_3SiCH_2)_3Ga \cdot P(H)Ph_2$ permit calculations of the per cent dissociation of the adducts and, in turn, of the equilibrium constants for dissociation of the adducts. Thus, the effects of the neopentyl and trimethylsilylmethyl substituents on the Lewis acidities of the organo-gallium compounds have been evaluated quantitatively.

EXPERIMENTAL

All compounds described in this investigation were extremely sensitive to oxygen and moisture and were manipulated in a standard vacuum line or in a purified argon atmosphere. The gallium and indium alkyls, $Ga(CH_2CMe_3)_2$,[12] $Ga(CH_2SiMe_3)_3$,[13] $In(CH_2CMe_3)_3$[14] and $In(CH_2SiMe_3)_3$[15] were prepared and purified by literature methods. Diphenylphosphine was purchased from Strem Chemicals Inc. and purified by vacuum distillation. Solvents were dried by conventional procedures. Elemental analyses were performed by Schwarzkopf Microanalytical Laboratory, Woodside, New York. IR spectra of Nujol mulls between CsI plates were recorded by means of a Perkin–Elmer 683 spectrometer. Absorption intensities are reported with the abbreviations vs (very strong), s (strong), m (medium), w (weak) and sh (shoulder). The ^1H NMR spectra were recorded at 90 or 300 MHz by using either a Varian EM-390 or a Varian Gemini-300 spectrometer, respectively. Proton chemical shifts are reported in δ units (ppm) and are referenced to $SiMe_4$ as δ 0.00 and benzene as δ 7.13. The ^{31}P NMR spectra were recorded at 36.23 or 161.90 MHz by using either a JEOL FX-90Q or a Varian VXR-400 spectrometer, respectively. Phosphorus chemical shifts are reported relative to 85% H_3PO_4 as δ 0.00 ppm. Negative values are assigned for shifts upfield of H_3PO_4. All samples for NMR spectra were contained in sealed NMR tubes. Melting points were observed in sealed capillaries. Molecular weights were measured cryoscopically in benzene by using an instrument similar to that described by Shriver and Drezdzon.[16]

Synthesis of the tris(neopentyl)gallium(III) *diphenylphosphine adduct*, $(Me_3CCH_2)_3Ga \cdot P(H)Ph_2$

A 100 cm^3 Schlenk flask was charged with 0.377 g (1.33 mmol) of $Ga(CH_2CMe_3)_3$ in the glove box. A tared screw-cap vial was used to weigh 0.248 g (1.33 mmol) of $HPPh_2$. Anhydrous pentane was used to assure quantitative transfer of the $HPPh_2$ to the reaction flask. The tared- screw-cap vial was rinsed five times with aliquots of pentane (4 cm^3 each time). The flask was fitted with an adapter, cooled to −196°C and evacuated on the vacuum line. The resulting mixture was stirred for 10 min at ambient temperature and the pentane was then removed by vacuum distillation to leave 0.591 g of a colourless crystalline solid [1.26 mmol, 94.7% yield based on $Ga(CH_2CMe_3)_3$] of $(Me_3CCH_2)_3Ga \cdot P(H)Ph_2$. Crystals suitable for an X-ray crystallographic study of $(Me_3CCH_2)_3Ga \cdot P(H)Ph_2$ were obtained by allowing a melted sample of the compound to slowly flow down the wall of a Pyrex tube.

Synthesis of the tris[(trimethylsilyl)methyl]gallium(III) *diphenylphosphine adduct*, $(Me_3SiCH_2)_3Ga \cdot P(H)Ph_2$

A 100 cm^3 round-bottom flask equipped with a 15 mm Solv-Seal joint was charged with 0.390 g (1.18 mmol) of $Ga(CH_2SiMe_3)_3$. A tared screw-cap vial charged with 0.220 g (1.18 mmol) of $HPPh_2$. The $HPPh_2$ was transferred quantitatively to the round-bottom flask by multiple washings with anhydrous pentane (20 cm^3). The flask was fitted with an adapter and evacuated. The reaction mixture was stirred for 15 min and the pentane was removed by vacuum distillation. A colourless, crystalline solid (0.514 g, 0.992 mmol, 84.4% of $(Me_3SiCH_2)_3Ga \cdot P(H)Ph_2$) was isolated.

$(Me_3SiCH_2)_3Ga \cdot P(H)Ph_2$. Melting point: 23.5–24.2°C. ^1H NMR (C_6D_6, δ): 0.0689 m: 0.05 (s, $-CH_2-$), 0.12 (s, $-CMe_3$), 5.21 (d, $J_{PH} = 232$ Hz, H—P), 6.98–7.37 (m, Ph); 0.138 m: 0.03 (s, $-CH_2-$), 0.13 (s, $-CMe_3$), 5.23 (d, $J_{PH} = 240$ Hz, H—P), 6.98–7.37 (m, Ph). ^{31}P NMR (C_6D_6, δ) 0.0689 m: −38.4 (d, $J_{PH} = 232$ Hz); 0.138 m: −37.7 (doublet of pentets, $J_{PH} = 240$ Hz, $^3J_{PCCH} = 8$ Hz). Reaction of $Ga(CH_2SiMe_3)_3$ *with* $HPPh_2$, *an NMR scale reaction*

An NMR tube was charged with an aliquot of a solution containing 0.105 g (0.318 mmol) of $Ga(CH_2SiMe_3)_3$ and 0.0593 g (0.318 mmol) of $HPPh_2$ in 5 cm^3 of benzene. The NMR tube was flame-sealed with a torch, then both ^1H and $^{31}P\{^1H\}$ NMR spectra were recorded. ^1H NMR (0.07 m, C_6H_6, δ): 0.08 (s, 6 H, $-CH_2-$), 0.15 (s, 27 H, $-CMe_3$), 4.93 (one line of the doublet for H—P). ^{31}P NMR (C_6H_6, δ): −39.3 (doublet, $J_{PH} = 240$ Hz).

Attempted synthesis of the tris(neopentyl)indium(III) *diphenylphosphine adduct*, $(Me_3CCH_2)_3In \cdot P(H)Ph_2$

A 100 cm^3 round-bottom flask was charged with 0.357 g (1.09 mmol) of $In(CH_2CMe_3)_3$, 0.203 g (1.09 mmol) of $HPPh^2$ and 10 cm^3 of pentane. The flask was evacuated and the mixture was stirred for 30 min at ambient temperature. Pentane was removed by vacuum distillation and 0.484 g of a colourless solid was isolated. The ^{31}P NMR spectra indicated that both the adduct $(Me_3CCH_2)_3In \cdot P(H)Ph_2$ and compound $(Me_3CCH_2)_2InPPh_2$[17] were present.

Mixture of $(Me_3CCH_2)_3In \cdot P(H)Ph_2$ *and* $(Me_3CCH_2)_2InPPh_2$. Melting point: partial melting at 48.2–48.8°C, followed by melting with decomposition of solid particles at 150–155°C. ^{31}P NMR (C_6H_6, δ): −31.1 (s, 1.4, $(Me_3CCH_2)_2InPPh_2$), −40.0 (doublet of pentets, 2.6, $J_{PH} = 260$ Hz, $(Me_3CCH_2)_3In \cdot P(H)Ph_2$), −50.6 (s, 1.0, $[(Me_3CCH_2)_2InPPh_2]_2$).

Rates of elimination studies for $(Me_3CCH_2)_3In \cdot P(H)Ph_2$

Equimolar amounts of $In(CH_2CMe_3)_3$ (0.346 g, 1.05 mmol) and $HPPh_2$ (0.197 g, 1.05 mmol) were combined in 0.963 g of benzene by using the procedure described for the preparation of $(Me_3CCH_2)_3Ga \cdot P(H)Ph_2$. After the reagents were thoroughly mixed, an aliquot of the 1.09 m (0.96 M) solution was transferred to an NMR tube. The tube was flame-sealed and the ^{31}P NMR spectra were recorded. The intensities of the lines for $(Me_3CCH_2)_2InPPh_2$,[17] $[(Me_3CCH_2)_2InPPh_2]_2$[17] and $(Me_3CCH_2)_3In \cdot P(H)Ph_2$ and/or free $HPPh_2$ were used to calculate the extent of reaction at a variety of times after mixing. Time, extent of reaction (17°C): 19 h 35 min, 0.221; 41 h, 0.325; 65 h, 0.436; 90 h 15 min, 0.543; 115 h, 0.831; 138 h, 0.948; 161 h 30 min, 0.971; 185 h 30 min, 0.988.

Rate of elimination studies for $(Me_3SiCH_2)_3In \cdot P(H)Ph_2$

A benzene solution of $In(CH_2SiMe_3)_3$ (0.397 g, 1.06 mmol, 1.09 m, 0.96 M) and $HPPh_2$ (0.197 g, 1.06 mmol, 1.09 m, 0.96 M) was prepared as described previously. The intensities of the lines for $(Me_3SiCH_2)_2InPPh_2$,[17] $[(Me_3SiCH_2)_2InPPh_2]_2$[17]

and $(Me_3SiCH_2)_3In \cdot P(H)Ph_2$ and/or $HPPh_2$ were used to calculate the extent of reaction. Time, extent of reaction (17°C): 19h 35 min, 0.0942; 45 h 20 min, 0.257; 67 h 45 min, 0.269; 91 h 25 min, 0.325 185 h 30 min, 0.501; 209 h 35 min, 0.537.

X-ray data collection, structure determination and refinement for $(Me_3CCH_2)_3Ga \cdot P(H)Ph_2$

A transparent single crystal of $(Me_3CCH_2)_3Ga \cdot P(H)Ph_2$ was mounted in a thin-walled glass capillary under argon and transferred to the goniometer. The space group was determined to be either the centric $P\bar{1}$ or acentric $P1$. Statistical tests indicated that the space group was centric and the subsequent solution and successful refinement of the structure in the space group $P\bar{1}$ confirmed this. A summary of data collection parameters is given in Table 1.

The geometrically constrained hydrogen atoms were placed in calculated positions 0.95 Å away from the bonded carbon atom and allowed to ride on that atom with B fixed at 5.5 Å^2. Due to the relatively high thermal motion, the methyl and phosphorus hydrogen atoms were not included in the final refinement. Refinement of the non-hydrogen atoms with anisotropic temperature factors led to final values of $R = 0.102$ and $R_w = 0.114$. The low melting point is consistent with the observed high thermal motion in the 20°C data collected. Resolvable static disorder was not evident.

[c] Neutral scattering factors and anomalous dispersion corrections from ref. 19.

RESULTS AND DISCUSSION

Tris(neopentyl)gallium(III) reacts with diphenylphosphine to form the adduct, $(Me_3CCH_2)_3Ga \cdot P(H)Ph_2$, a colourless, crystalline compound with a relatively low melting point of 33.0–34.0°C. The structure of this compound as determined by an X-ray structural study and the labelling of the atoms is presented in Figs 1 and 2. Bond distances and bond angles are collected in Tables 2, 3 and 4. The low melting point of this compound was manifested in high thermal motion and relatively poor crystal quality. No resolvable disorder was observed and the rather large thermal parameters resulted in high standard deviations in bond lengths. Even so, this structure is significant because it is the first of an adduct of a heavier group 13 element compound with a group 15 Lewis base having an acidic proton.

Table 4. Torsion angles (°) for $(Me_3CCH_2)_3Ga \cdot P(H)Ph_2$

C(1)—Ga—P—C(16)	−19.2
C(1)—Ga—P—C(22)	−150.0
C(6)—Ga—P—C(16)	−138.0
C(6)—Ga—P—C(22)	91.2
C(11)—Ga—P—C(16)	100.1
C(11)—Ga—P—C(22)	−30.7

The most striking structural feature of $(Me_3CCH_2)_3Ga \cdot P(H)Ph_2$ is the extremely long Ga—P distance of 2.683(5) Å. Other addition compounds exhibit shorter Ga—P distances of 2.353(2) Å for $Cl_3Ga \cdot PMe_3$,[10] 2.52(2) Å for $Me_3Ga \cdot PMe_3$[11] (electron diffraction studies), 2.535(2) Å for $Me_2ClGa \cdot P(Ph)_2CH_2P(Ph)_2$[9] and 2.563(3)[7] or 2.54(4) Å[8] for $Me_3Ga \cdot P(Ph)_2C_2H_4(Ph)_2P \cdot GaMe_3$ (two structural studies of the same compound). The long gallium–phosphorus distance suggests that $(Me_3CCH_2)_3Ga \cdot P(H)Ph_2$ is a relatively weak adduct.

The second feature of interest in this structure relates to the observation that the α-carbon atoms of the substituents on gallium and phosphorus are essentially but not perfectly eclipsed. Thus, this observation suggests that the long gallium–phosphorus distance is probably not related to extreme steric stress. The other adduct with an eclipsed conformation, $Cl_3Ga \cdot PMe_3$,[10] has the shortest of the known Ga—P bond distances. In contrast, $Me_3Ga \cdot P(Ph)_2C_2H_4(Ph)_2P \cdot GaMe_3$[8,9] is staggered. Both the gallium and phosphorus centres

have rather distorted tetrahedral coordination environments. The C—Ga—C angles [117.0(7)–119.8(7)°] are typically greater than the normal tetrahedral values but not much smaller than the angle predicted for the uncoordinated trigonal planar monomeric Lewis acid. The C—P—C bond angle [103.4(7)°] is less than the typical tetrahedral angle. In turn, the average P—Ga—C angle of 98(1)° is less than tetrahedral, whereas the average Ga—P—C angle of 120(4)° is greater than tetrahedral. Although the hydrogen bonded to phosphorus was not located, the phosphorus atom is 0.48 Å above the plane defined by Ga, C(16) and C(22). The two phenyl substituents are nearly perpendicular to each other, the dihedral angle between the planes defined by the aryl atoms is 85°. The neopentyl groups arrange themselves in propellar fashion around the Ga—P bond vector.

The elemental analyses of $(Me_3CCH_2)_3Ga \cdot P(H)Ph_2$ for carbon and hydrogen were investigated but non-reproducible results were obtained. The observed per cent carbon was low (69.08, calc.; 65.77, 66.76 found) whereas the observed per cent hydrogen was within the range considered acceptable (9.47, calc.; 9.42, 9.13 found). These results suggest that the sample did not quantitatively decompose during analysis. Alternatively, the observation that the per cent carbon is low might suggest that the sample was deficient in $HPPh_2$. Diphenylphosphine has a higher per cent carbon (77.40) than $Ga(CH_2CMe_3)_3$ (63.61 or the adduct (69.08). A deficiency in $HPPh_2$ would be inconsistent with the observation that $HPPh_2$ is significantly less volatile than $Ga(CH_2CMe_3)_3$. If the sample was not $(Me_3CCH_2)_3Ga \cdot P(H)Ph_2$ because one component was lost during isolation and purification, the more volatile component should have been lost and the experimental per cent carbon should have been higher than that calculated for the adduct. The existence of a crystalline solid at room temperature with a sharp melting point (33.0–34.0°C) and the results of the X-ray structural study support the existence of a pure compound. Since non-reproducible analyses were obtained for $(Me_3CCH_2)_3Ga \cdot P(H)Ph_2$, the related compound $(Me_3SiCH_2)_3Ga \cdot P(H)Ph_2$ was not analysed. It is noteworthy that other adducts of group 13 organometallic compounds have exhibited low elemental analyses for carbon.[7,20]

Crysoscopic molecular weight studies of dilute benzene solutions of $(Me_3CCH_2)_3Ga \cdot P(H)Ph_2$ and $(Me_3SiCH_2)_3Ga \cdot P(H)Ph_2$ suggest that these adducts are significantly dissociated in solution. Tris(neopentyl)gallium–diphenylphosphine is less dissociated than the corresponding tris(trimethylsilylmethyl)gallium–diphenylphosphine adduct. The calculated (based on adduct) and the observed molalities of the solutions permit calculations of an apparent equilibrium constant for dissociation:

$$R_3Ga \cdot P(H)Ph_2 \overset{K}{\rightleftharpoons} R_3Ga + P(H)Ph_2.$$

Thus, $(Me_3CCH_2)_3Ga \cdot P(H)Ph_2$ had an average constant of 0.0410 m (0.0360 M) whereas $(Me_3SiCH_2)_3Ga \cdot P(H)Ph_2$ was 0.0505 m (0.0443 M). These results are consistent with the earlier suggestion[12,14,21] that the neopentyl group has either stronger electron-withdrawing or weaker electron-donating properties, but larger steric effects than the corresponding trimethylsilylmethyl substituent. Apparently, the electron-withdrawing properties of the neopentyl group is the more important factor as $Ga(CH_2CMe_3)_3$ is observed to be the stronger Lewis acid.

The ^{31}P NMR spectra of solutions of $(Me_3CCH_2)_3Ga \cdot P(H)Ph_2$ and $(Me_3SiCH_2)_3Ga \cdot P(H)Ph_2$ support the hypothesis of equilibria between the adduct and the free acid and base, as well as the conclusion that $Ga(CH_2CMe_3)_3$ is the stronger Lewis acid. As the concentrations of the adduct systems increase, the chemical shifts of the ^{31}P NMR lines move to higher field and away from the chemical shift of the line for free $P(H)Ph_2$. Similarly, $^1J_{PH}$ increases as the concentrations of the adduct systems increase. It is noteworthy that $\Delta\delta$ $[R_3Ga \cdot P(H)Ph_2 - P(H)Ph_2]$ is greater for $R = CH_2CMe_3$ (2.6 ppm), the stronger Lewis acid according to molecular weight studies, than for $R = CH_2SiMe_3$ (2.0 ppm). At the higher concentrations (0.138 m) $\Delta\delta$ increases to 3.9 ppm ($R = CH_2CMe_3$) and 2.7 ppm ($R = CH_2SiMe_3$). These studies clearly demonstrate that all investigations of Lewis acidities of group 13 compounds and/or Lewis basicities of phosphines by ^{31}P NMR spectroscopy must include concentration dependencies of the spectra.

An attempt was also made to synthesize and fully characterize the neopentyl- and trimethylsilylmethyl-indium adducts of diphenylphosphine. However, the occurrence of elimination reactions at room temperature to form R_2InPPh_2 and RH precluded the isolation of pure adducts. The ^{31}P NMR spectra clearly revealed the presence of R_2InPPh_2,[17] $[R_2InPPh_2]_2$[17] and $HPPh_2$, either free or as the adduct. The intensities of the lines related to the products of the elimation reaction, R_2InPPh_2 and $[R_2InPPh_2]_2$, increased with time, whereas the line related to $HPPh_2$ decreased. When a solution at 17°C, which was 1.09 m in both $In(CH_2CMe_3)_3$ and $HPPh_2$, was followed in a time dependent study, the elimination reaction was 54.3% complete after

90.2 h from the time of combining the reagents in benzene. In contrast, a 1.09 m solution of $In(CH_2SiMe_3)_3$ and $HPPh_2$ was 53.7% complete after 209.5 h. Thus, $In(CH_2CMe_3)_3-P(H)Ph_2$ undergoes the elimination reaction at a significantly faster rate than does $In(CH_2SiMe_3)_3-P(H)Ph_2$. If the rate law which is appropriate for the $AlMe_2H-N(Me)(Ph)H$ system[22] is applicable to these organoindium–phosphine systems, then the rate constant for the elimination reaction and the equilibrium constant for the formation of the adduct will influence the rate of reaction. If the equilibrium constants in the two indium–phosphorus systems are of similar magnitude to that observed for the related gallium–phosphorus systems, then the dominant factor to influence the rate of elimination will be the rate constant for reaction. The rate constant should be influenced by the charge on the α-carbon atom of the substituents bound to indium. The more strongly electron-withdrawing neopentyl substituted derivative would, in turn, be expected to have the faster rate of elimination, as observed. Kinetic studies for these indium–phosphorus systems will be the subject of a future publication.

ADDUCTS OF TRIMETHYLGALLIUM AND PERDEUTERIOTRIMETHYLGALLIUM WITH AMINE LIGANDS AND SOME DIMETHYLGALLIUM ORGANYL PNICTIDES (N, P, As). X-RAY CRYSTAL STRUCTURES OF $[Me_3Ga \cdot NH(C_6H_{11})_2]$ and $[Me_3Ga \cdot \overline{NH(CHMe)(CH_2)_3CHMe}]$

DONALD C. BRADLEY,* HELEN M. DAWES, MICHAEL B. HURSTHOUSE,* LESLEY M. SMITH and MARK THORNTON-PETT

Department of Chemistry, Queen Mary College, Mile End Road, London E1 4NS, U.K.

Abstract—The adducts $Me_3Ga \cdot L$ [where $L = NH(C_6H_{11})_2$ (**1**), $\overline{NHCHMe(CH_2)_3CHMe}$ (**2**), $N(CH_2CH_2)_3CH$ (**3**) and $0.5\ N(CH_2CH_2)_3N$ (**4**)] have been prepared by displacement of either (a) ether from $Me_3Ga \cdot Et_2O$ or (b) diphos from $(Me_3Ga)_2 \cdot$diphos (diphos = bisdiphenyl phosphino ethane) and the X-ray crystal structures of **1** and **2** determined. $(CD_3)_3Ga$ and the adducts $(CD_3)_3Ga \cdot L$ [$L = NMe_3$, $NH(C_6H_{11})_2$, $\overline{NHCHMe(CH_2)_3CHMe}$ and $N(CH_2CH_2)_3CH$], were similarly prepared from $[(CD_3)_3Ga]_2 \cdot$diphos. The covalently bonded dimethylgallium organyl pnictides $(Me_2GaL')_n$ [$L' = NPr^i_2$, $\overline{NCHMe(CH_2)_3CHMe}$, PMe_2 and $AsMe_2$] were prepared by reactions of either (c) Me_2GaCl and LiL' or (d) $Me_3Ga \cdot Et_2O$ and HL'. All compounds were characterized by elemental analyses, IR, NMR and mass spectroscopy. The Ga geometry in both **1** and **2** is distorted tetrahedral.

As part of our programme of synthesizing and characterizing a range of volatile precursors for the deposition of III–V semiconductors by Metallo-organic Chemical Vapour Deposition (MOCVD) we have prepared a number of new adducts of trimethylgallium, $Me_3Ga \cdot L$, and some covalently bound dimethylgallium organyl pnictides, $(Me_2GaL')_n$. The extensive literature on these compounds has recently been reviewed[1–3] showing the upsurge in activity in this field following the pioneering work of Manasevit *et al.*[4,5] who demonstrated the feasibility of depositing GaAs from the reaction of Me_3Ga and AsH_3.

We have been exploring the scope for pacifying the exceptional air-sensitivity of trimethylgallium by coordinating various Lewis bases without incurring the penalty of the loss in volatility which may result.[6]

RESULTS AND DISCUSSION

The nitrogen base adducts **1**, **2**, **3** and **4** have been obtained as sublimable white solids (Table 1) by either or both of the following reactions:

$$Me_3Ga \cdot Et_2O + L \longrightarrow Me_3Ga \cdot L + Et_2O \quad (1)$$

$$(Me_3Ga)_2 \cdot \text{diphos} + 2L \longrightarrow 2Me_3Ga \cdot L + \text{diphos}. \quad (2)$$

The details of the synthesis and characterization of the diphos adduct have already been published.[7] The perdeuteriotrimethylgallium·diphos adduct (**9**) was also prepared in this work and converted to the new adducts $[(CD_3)_3Ga \cdot NMe_3]$ (**5**), $[(CD_3)_3Ga \cdot NH(C_6H_{11})_2]$ (**6**), $[(CD_3)_3Ga \cdot \overline{NHCHMe(CH_2)_3CHMe}]$ (**7**) and $[(CD_3)_3Ga \cdot N(CH_2CH_2)_3CH]$ (**8**), which were required for deuterium labelled reactions. In addition the new dimethylgallium organyl pnictides $(Me_2GaNPr^i_2)_2$ (**10**) and $[Me_2Ga\overline{NHCHMe(CH_2)_3CHMe}]_2$ (**11**) and the known compounds $(Me_2GaPMe_2)_3$ (**12**) and $(Me_2GaAsMe_2)_3$ (**13**) were prepared by the following reactions:

$$Me_2GaCl + LiL' \longrightarrow (Me_2GaL')_2 + LiCl \quad (3)$$

$$Me_3Ga \cdot Et_2O + HL' \longrightarrow (Me_2GaL')_3 + Et_2O + CH_4. \quad (4)$$

[h] $(CD_3)_3$ Ga evolved at >85°C/0.01 mm Hg.

All of the adducts, **1–8**, were volatile white solids which could be sublimed unchanged. It is noteworthy that compounds **1**, **2**, **6** and **7**, which have NH groups, did not eliminate methane. There was no significant difference in melting point or volatility between the Me_3Ga and $(CD_3)_3Ga$ derivatives.

Apart from the expected differences in the C—H and C—D stretching frequencies (2950–2840 cm^{-1} and 2089–2014 cm^{-1}, respectively) there were no discernible differences in the characteristic Ga—CH_3/Ga—CD_3 stretches (*ca* 521, 570 cm^{-1}), rocking modes (*ca* 612, 727, 759 cm^{-1}) or deformation modes (*ca* 163 cm^{-1}).

In the ^{1}H NMR spectra, the CH_3—Ga protons give resonances slightly to lower field in the secondary amine adducts (**1** and **2**) than in the tertiary amine complexes (**3** and **4**). However, it is notoriously difficult to relate these chemical shifts to bonding parameters in these molecules.

It is interesting to note that the bifunctional ditertiary amine, 1,4-diazabicyclo[2.2.2]octane (dabco) forms a stable 2:1 complex [$Me_3Ga \cdot N(CH_2CH_2)_3N \cdot GaMe_3$] (**4**) which sublimed unchanged at 60–80°C/0.03 mm Hg and which did not melt but sublimed (179–180°C) under normal atmospheric pressure of nitrogen. There was no detectable parent molecular ions in its mass spectrum but significant concentrations of Me_2Ga^+, $MeGa^+$ and Ga^+ ions. The formation of the 2:1 complex by Me_3Ga is in marked contrast to trimethylindium which forms an insoluble 1:1 compound [$Me_3In \cdot N(CH_2CH_2)_3N$] which is an infinite linear polymer with five-coordinated (trigonal bipyramidal) indium.[8] We could find no evidence for gallium forming an analogous compound and it

appears that the smaller gallium atom cannot expand its coordination to five with this ligand. The indium compound contained very long (weak) In—N bonds and could be sublimed *in vacuo*.

Turning now to the dimethylgallium organyl amides, **10** and **11**, which were obtained from Me_2GaCl and the lithio derivatives of the ligands [eq. (3)], these compounds appeared to be dimeric according to the fragment ions in their mass spectra. Although the parent molecular ions of the dimers could not be detected there were significant concentrations of the species $(dimer - Me_2Ga)^+$ and $(dimer - L' - Me)^+$. The latter species contained the peaks appropriate to the three isotopic species $^{71}Ga_2$, $^{71}Ga^{69}Ga$ and $^{69}Ga_2$.

Not surprisingly these dimers were less volatile than the mononuclear trimethylgallium adducts (Table 1) but they could be sublimed *in vacuo*. These compounds have potential as precursors for MOMBE (or very low pressure MOCVD) and we have demonstrated that the aluminium complex $(Me_2AlNPr^i_2)_2$ can be used as a precursor for the deposition of AlN.[9]

With regard to the dimethylgallium organyl pnictides **12** and **13** we have found, using ^1H NMR, a significant difference in the fluxionality of the six-membered rings of these trimeric compounds. Even at room temperature ($C_6D_5CD_3$) compound **12** shows two singlets for equatorial and axial methyl groups on gallium and two doublets ($^2J_{HP} = 3$ Hz) for the equatorial and axial methyl groups on the phosphorus atoms. In the arsenic derivative, **13**, only two singlets were observed (δ −0.10, CH_3—Ga; 0.90, CH_3—As) from room temperature down to −70°C in $C_6D_5CD_3$, although the gallium methyls moved to lower field (δ 0.07) and the arsenic methyls moved to higher field (δ 0.84) as the temperature was lowered. Beachley and Coates[10] had previously shown this NMR behaviour of **13** at 60 MHz and we have confirmed it using much higher field equipment (250 MHz). Compound **13** is a white solid which can be sublimed at 100–110°C (0.02 mm Hg) and it gives a rich mass spectrum showing the trimeric molecular ion (with all isotopic species corresponding to $^{71}Ga_3$, $^{71}Ga_2^{69}Ga$, $^{71}Ga^{69}Ga_2$ and $^{69}Ga_3$) in low abundance and also $(trimer - methyl)^+$ species showing that the integrity of the six-membered ring is maintained in the vapour. The fragmentation pattern showed several interesting species such as $(trimer - AsMe_2)^+$, $(trimer - Me_2Ga - 2Me)^+$, $(dimer - Me)^+$, $(dimer - AsMe_2)^+$, $(dimer - AsMe_2 - Me)^+$ and major peaks for $As_2Me_4^+$, $As_2Me_3^+$ and Me_2Ga^+.

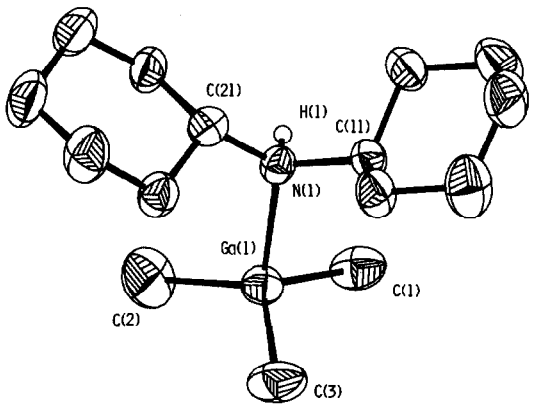

Fig. 1.

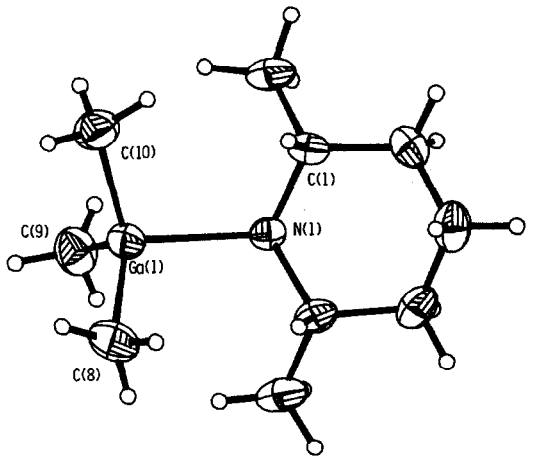

Fig. 2.

X-ray crystal structures

The structure of **1** is shown in Fig. 1; selected bond lengths and angles are in Table 2. The structure of **2** is shown in Fig. 2; selected bond lengths and angles are in Table 3.

In both adducts the geometry at Ga is distorted tetrahedral but there are some interesting similarities and differences between the two structures. In compound **1** the configuration about the Ga—N bond is staggered but in compound **2** it is eclipsed. The latter structure presumably results from minimization of methyl–methyl interactions between the $GaMe_3$ unit and the 2,6-methyls on the piperidine.

The distortions in the Ga coordinations are quite marked. In each case the GaC_3 pyramid is slightly unsymmetrical with angles varying between 111.8–116.1° for **1** and 108.1–119.8° for **2**, whilst the N—Ga—C angles vary between 97.1–108.0° for **1** and 99.9–106.7° for **2**. These deformations are likely to arise from packing and steric effects, and demonstrate considerable deformability in the Ga—amine bonding. The Ga—N bond length also shows flexibility, the values in **1** and **2** differing by ~0.05 Å (cf. the Ga—C range for both compounds 1.964–1.989 Å).

EXPERIMENTAL

All operations were carried *in vacuo* or under an atmosphere of specially dried oxygen-free nitrogen

using Schlenk type glass apparatus and a glove box.

Solvents were dried using the sodium ketyl of benzophenone and were freshly distilled prior to use. Melting points were determined in soda glass capillaries sealed under nitrogen using an electrothermal apparatus.

Analyses for C, H, N, P and Cl were obtained from the Microanalytical Laboratory of University College, London. For the deuteriated compounds the "H"% quoted is the weighted sum of the hydrogen and deuterium percentages since combustion gave rise to a mixture of H_2O, HDO and D_2O which was detected as "H_2O". Gallium analyses were determined either gravimetrically as the oxinate or by complexometric titration against Na_2EDTA using "gallocyanine" as indicator.[11]

Gallium trichloride was purchased from Johnson–Matthey Chemicals Ltd and was sublimed before use. Methyl lithium (solution in Et_2O low in halide) was purchased from Alfa Chemicals and *n*-butyl lithium (in hexane) was obtained from Aldrich Chemicals and standardized by titration using the Gilman technique.[12] CD_3I was purchased from Goss Chemicals Ltd, and the organic ligands from Strem Chemicals Inc. and Aldrich Chemicals Ltd. Dimethylarsine was prepared using Feltham and Silverthorn's method.[13] The sample of $(Me_2GaPMe_2)_3$ was donated by Dr Dario M. Frigo. $(Me_3Ga)_2$·diphos was prepared as previously described.[7]

IR spectra were measured as Nujol mulls and CsI windows using Perkin–Elmer 225 or 577 spectrophotometers over the range 4000–200 cm^{-1}. NMR spectra were obtained using Bruker WP80, WM250 or WH400 FT spectrometers using deuteriated solvents. Chemical shifts were measured internally against the trace undeuteriated solvent peaks and referenced against TMS.

Mass spectra were obtained using an AEI MS 902 spectrometer and gallium containing species were identified by the isotopic pattern for ^{71}Ga and ^{69}Ga.

Preparation of trimethyl(dicyclohexylamine)gallium (**1**)

(a) *From* $Me_3Ga \cdot Et_2O$ *and* $HN(C_6H_{11})_2$. Methyl lithium (26.6 cm^3 of a 1.67 M solution in Et_2O) was added dropwise to a stirred solution of $GaCl_3$ (2.6 g, 14.8 mmol) in diethyl ether (100 cm^3) at 0°C. After warming to room temperature and filtering to remove LiCl, hexane (100 cm^3) was added and the solution cooled to −20°C. Dicyclohexylamine (3.5 cm^3, 17.6 mmol) was added with stirring via a syringe and the mixture was allowed to stand overnight at room temperature. On evaporating off the ether under reduced pressure, the solution was concentrated and white crystals (3.0 g, 10 mmol, 68% based on $GaCl_3$) of **1** were obtained which sublimed at 40–60°C/0.01 mm Hg (m.p. 78–79°C).

(b) *From* $(Me_3Ga)_2 \cdot$ *diphos and* $HN(C_6H_{11})_2$. $(Me_3Ga)_2$·diphos (3.12 g, 5 mmol) was heated to 85–110°C under reduced pressure (0.02 mm Hg) and the Me_3Ga thus liberated was condensed onto $HN(C_6H_{11})_2$ (1.6 cm^3, 8 mmol) dissolved in pentane (15 cm^3) at −196°C. After warming to room temperature overnight the pentane was evaporated *in vacuo* leaving a white crystalline solid (2.13 g, 7.2 mmol, 88% yield based on the amine) which sublimed at 40–50°C/0.02 mm Hg (m.p. 78.0–78.5°C).

IR spectra: 3250m, 1365w sh, 1350w sh, 1340w, 1320w, 1310w, 1280w, 1260m, 1220m, 1190s br, 1170m sh, 1165w, 1155w, 1120m, 1080m, 1065m br, 980m, 945s, 898s, 850m, 845m, 800m, 730vs br, 655m br, 620w, 540vs, 520m, 460w, 415w cm^{-1}. ^1H NMR (C_6D_6): δ 0.12(9H, s, Me_3Ga), 0.25 (1H, s, NH), 1.08–1.95(20H, m, CH_2), 2.53–2.85(2H, m, NCH_2). Mass spectra (only major peaks quoted): *m/z* 282(9%, parent ion − Me, ^{71}Ga), 280(13%, parent ion − Me, ^{69}Ga), 182(17%, $(C_6H_{11})_2NH_2$), 181(100%, $(C_6H_{11})_2NH$), 138(57%, $C_9H_{16}N$), 116(3%, $Me_3{}^{71}Ga$), 114(3%, $Me_3{}^{69}Ga$), 101(41%, $Me_2{}^{71}Ga$), 99(65%, $Me_2{}^{69}Ga$).

Preparation of trimethyl(2,6-dimethylpiperidine)gallium (**2**)

(a) *From* Ma_3Ga, Et_2O *and* 2,6-*dimethylpiperidine*. Methyl lithium (20.2 cm^3 of a 1.1 M solution in Et_2O, 22 mmol) was added dropwise to a stirred solution of $GaCl_3$ (1.3 g, 7.4 mmol) in diethyl ether (50 cm^3) at 0°C. After several hours standing at room temperature and filtration to remove LiCl, 2,6-dimethylpiperidine (1.0 cm^3, 7.4 mmol) was added via a syringe at 0°C and allowed to attain room temperature. Removal of ether *in vacuo* left an oily liquid which was extracted with pentane (20 cm^3) from which **2** crystallized (1.05 g, 46 mmol, 62% yield). The white crystals sublimed at 30°C/0.01 mm Hg (m.p. 49.5–50°C).

(b) *From* $(Me_3Ga)_2 \cdot$ *diphos and* 2,6-*dimethylpiperidine*. $(Me_3Ga)_2$·diphos (2.48 g, 3.9 mmol) was heated at 85–110°C *in vacuo* for 2 h and the Me_3Ga liberated was condensed onto a solution of 2,6-dimethylpiperidine (0.83 cm^3, 6.1 mmol) in pentane (15 cm^3) at −196°C. After standing overnight at room temperature the pentane was evaporated *in vacuo* leaving a white solid (1.1 g, 4.8 mmol, 79% based on amine) which sublimed at 25–35°C/0.02 mm Hg (m.p. 49–50°C).

IR spectra: 3255m sh, 1318w sh, 1280w sh, 1220w sh, 1195s br, 1175s br, 1108m br, 1064m sh, 1009m

br, 980m br, 954m br, 918w sh, 870m sh, 835vw sh, 790w sh, 730s vbr, 665m vbr, 570w sh, 550s br, 532s br, 510m sh, 330w br, cm^{-1}. ^1H NMR (C_6D_6): δ 0.0(9H, s, Me_3Ga), 0.95(6H, d, $J = 8$ Hz, $CHCH_3$), 2.2–2.6(3H, m, $NH+CHCH_3$), 0.4–1.4(6H, m, $CH_2CH_2CH_2$). Mass spectra (major peaks): *m/z*, 113(30%, ligand), 112(14%, ligand−H), 101(59%, $Me_2{}^{71}Ga$), 99(89%, $Me_2{}^{69}Ga$), 97(100%, ligand−CH_4), 71(17%, ^{71}Ga), 70(25%, C_5H_{10}), 69(26%, ^{69}Ga).

Preparation of trimethyl(1-azabicyclo[2.2.2]octane) gallium (**3**)

This was prepared as for **1** (method b) from $Me_3Ga \cdot$ diphos (3.15 g, 50 mmol) and quinuclidine (0.9 g, 8.1 mmol) giving **3** as white crystals (1.15 g, 5.9 mmol, 63% based on ligand) which sublimed at 70–90°C/0.02 mm Hg (m.p. 112.7–113.5°C).

IR spectra: 1350w, 1335m, 1315m, 1265w sh, 1260s, 1200m sh, 1190m, 1180m, 1160w, 1080s br, 1045s br, 1020s br, 980m, 865w br, 826m, 800vs br, 730m br, 660w, 635w, 580m, 540s, 515m, 400w br, 325w, 305w cm^{-1}. ^1H NMR (C_6D_6): δ −0.1(9H, s, Me_3Ga), 0.8–1.0 [7H, m, $CH(CH_2CH_2)_3N$], 2.3–2.6(6H, t, $J = 6$Hz, NCH_2). Mass spectra (major peaks): *m/z* 212(41%, ^{71}Ga parent ion−Me), 210*(62%, ^{69}Ga parent ion−Me), 111(41%, ligand), 110(20%, ligand−H), 101(66%, $Me_2{}^{71}Ga$), 99(100%, $Me_2{}^{69}Ga$), 71(22%, ^{71}Ga), 69(36%, ^{69}Ga).

Preparation of hexamethyl(1,4-diazabicyclo[2.2.2] octane)digallium (**4**)

Methyl lithium (36 cm^3 of a 1.83 M solution in Et_2O, 65.9 mmol) was added dropwise to a stirred solution of $GaCl_3$ (3.9 g, 22 mmol) in diethyl ether (80 cm^3) at 0°C. After removal of LiCl by filtration, 1,4-diazabicyclo[2.2.2]octane (2.47 g, 22 mmol) was added to the filtrate at −70°C. Ether was removed *in vacuo* and the product recrystallized from pentane (50 cm^3) giving white crystals (1.9 g, 7.0 mmol, 64% based on $GaCl_3$) which sublimed at 60–80°C/0.03 mm Hg or at 179–180°C under atmospheric N_2.

IR spectra: 1450s, 1370w sh, 1320s, 1260w, 1190vs, 1180s, 1175m, 1080w sh, 1055s, 1010s, 924m, 838s, 800s, 755s sh, 710s br, 540vs, 512m, 420w cm^{-1}. ^1H NMR (C_6D_6): δ −0.35(18H, s, Me_3Ga), 1.98(12H, s, CH_2CH_2). Mass spectra (major peaks): *m/z* 112(18%, ligand), 101(69%, $Me_2{}^{71}Ga$), 99(100%, $Me_2{}^{69}Ga$), 86(7%, $Me^{71}Ga$), 84(11%, $Me^{69}Ga$), 71(25%, ^{71}Ga), 69(34%, ^{69}Ga).

Preparation of tri(methyl-d_3)(trimethylamine) gallium (**5**)

NMe_3 (0.83 g, 14 mmol) was condensed onto $[(CD_3)_3Ga]_2 \cdot$ diphos (5.45 g, 8 mmol) at −196°C. As the reaction mixture warmed to room temperature, a white solid appeared to coat the diphos adduct **9** and it sublimed at 25°C/0.02 mm Hg as product **5** (1.86 g, 10 mmol, 63% based on **9**, m.p. 96.5–97°C).

IR spectra: 3000s, 2780s, 2700w, 2680w, 2310w sh, 2180s br, 2090s br, 2060m sh, 1815w, 1520w sh, 1470s br, 1440s br, 1245s, 1218s, 1095s, 1000vs br, 920s br, 815s br, 570vs br, 480vs br cm^{-1}. Mass spectra (major peaks): **5** gave no gallium containing species (similar behaviour to $Me_3Ga \cdot NMe_3$), the dominant fragment ion was at *m/z* 44(100%, NMe_2).

Preparation of tri(methyl-d_3)(dicyclohexylamine) gallium (**6**)

This was prepared as for **1** (method b) from **9** (2.56 g, 4 mmol) and $HN(C_6H_{11})_2$ (1.3 cm^3, 6 mmol) which gave white crystals of **6** (1.48 g, 4.8 mmol, 80% based on ligand) which sublimed at 40–60°C/0.03 mm Hg (m.p. 79.5–80°C).

IR spectra: 3240m, 2660w, 2220m, 2210m, 2100w, 1350m sh, 1330w, 1320w, 1310w, 1295w, 1265w, 1260m, 1215w, 1170w, 1110m br, 1080m, 1060m, 1015s br, 975m, 930s br, 890m, 850m, 840m, 798s, 710w br, 560vs br, 498s br, 465w, 410w, 335w cm^{-1}. Mass spectra (major peaks): *m/z* 181 (20%, ligand), 107(26%, $(CD_3)_2{}^{71}Ga$), 105(39%, $(CD_3)_2{}^{69}Ga$), 71(8%, ^{71}Ga), 69(12%, ^{69}Ga).

Preparation of tri(methyl-d_3)(2,6-dimethylpiperidine)gallium (**7**)

This was prepared as for **2** (method b) from **9** (3.49 g, 5.4 mmol) and 2,6-dimethyl piperidine (1.64 cm^3, 12 mmol) which gave white crystals of **7** (2.25 g, 9.5 mmol, 88% based on **9**) which sublimed at 25°C/0.02 mm Hg (m.p. 49.5–51°C).

IR spectra: 3240m, 2200m, 2100m, 1450s, 1440m, 1420w, 1365m, 1310w, 1275w, 1255w, 1210m, 1170s, 1130m, 1105s, 1060m, 1005s, 980m, 950m sh, 925s, 855s, 785m, 660m br, 565vs br, 530s, 500s, 480s, 460m, 320w cm^{-1}.

* Accurate mass = 210.0773; calc. 210.0763.

Preparation of tri(methyl-d_3)(1-azabicyclo[2.2.2]octane)gallium (**8**)

This was prepared as for **1** (method b) from **9** (3.98 g, 6.2 mmol) and quinuclidine (1.10 g, 9.9 mmol) giving white crystals of **8** (2.10 g, 8.9 mmol, 91% based on ligand) which sublimed at 70°C/0.02 mm Hg (m.p. 113–113.5°C).

IR spectra: 2198s, 2096s, 1472w, 1365m, 1360w, 1345m, 1330m, 1312s, 1262m, 1255s br, 1198s, 1158w, 1090m br, 1042vs, 1015s br, 995s, 980vs, 960m, 920vs br, 880w, 825s, 805s, 790s, 632m, 570vs br, 500vs br, 490s sh, 464m, 390w br cm^{-1}. Mass spectra (major peaks): *m/z* 218(10%, parent ion $^{71}Ga-CD_3$), 216(13%, parent ion $^{69}Ga-CD_3$, 111(37%, ligand), 107(65%, $(CD_3)_2{}^{71}Ga$], 105(100%, $(CD_3)_2{}^{69}Ga$), 89(7%, $CD_3{}^{71}Ga$), 87(11%, $CD_3{}^{69}Ga$), 71(23%, ^{71}Ga), 69(34%, ^{69}Ga).

Preparation of hexa(methyl-d_3)-μ-[1,2-bis(diphenylphosphino)ethane]digallium (**9**)

A solution of CD_3I (53 cm^3, 833 mmol) in diethyl ether (100 cm^3) was added dropwise to a stirred suspension of magnesium turnings (20.3 g, 833 mmol) in ether (200 cm^3) at 0°C, at a rate to maintain a gentle reflux. The solution was refluxed for another hour and then added to a stirred (magnetically) solution of $GaCl_3$ (43 g, 244 mmol) in ether (300 cm^3) at 0°C. The solution was kept at room temperature overnight and then the solvent and $(CD_3)_3Ga \cdot Et_2O$ separated by fractional distillation. The $(CD_3)_3Ga \cdot Et_2O$ (44.9 g, 227 mmol, 93% based on $GaCl_3$) was added via a transfer tube to a solution of diphos (47.9 g, 120 mmol) in benzene (200 cm^3). The remaining ether was distilled off and the solution concentrated to *ca* 150 cm^3. $[(CD_3)_3Ga]_2 \cdot$ diphos (**9**) was deposited as large white crystals which were recrystallized (54.5 g, 74% based on $GaCl_3$, m.p. 163–163.5°C).

IR spectra: 2200w, 2100w, 1580w, 1480m, 1430vs, 1418m, 1305w, 1280w, 1255m br, 1180w, 1165m, 1095s br, 1080m sh, 1020m br, 1010m sh, 995m, 920m, 795m br, 745vs, 720vs, 692vs, 680w, 570m br, 505s, 490m, 480m, 460m, 450m, 330w cm^{-1}. Mass spectrum showed peaks corresponding to $(CD_3)_3Ga$ (major peaks): *m/z* 107(80%, $(CD_3)_2{}^{71}Ga$), 105(100%, $(CD_3)_2{}^{69}Ga$), 89(10%, $CD_3{}^{71}Ga$), 87(13%, $CD_6{}^{69}Ga$), 71(29%, ^{71}Ga), 69(42%, ^{69}Ga).

Preparation of bis-μ-(diisopropylamido)tetramethyldigallium (**10**)

$LiNPr^i_2$ (8 mmol, prepared from $HNPr^i_2$ and Bu^nLi) in Et_2O (20 cm^3) was added to a stirred solution of Me_2GaCl (13.0 cm^3 of a 0.63 M solution in hexane, 8 mmol) in Et_2O (20 cm^3) at 0°C and a white solid was precipitated. After stirring for 1 h at room temperature the product was extracted with ether (100 cm^3) and the extract evaporated *in vacuo* to remove the ether. The white solid product (contaminated with $LiNPr^i_2$) was purified by sublimation *in vacuo* (90°C/0.03 mm Hg, 0.83 g, 4.2 mmol, 52% yield, m.p. 123.5–124.5°C). The product $(Me_2Ga\ NPr^i_2)_2$ (**10**) was unstable and decomposed over a period of *ca* one month.

IR spectra: 2850s, 1450s br, 1380s, 1300m, 1255m, 1200s, 1160s br, 1130s, 1030m br, 955m, 910m, 830m, 790m, 740s br, 670m br, 630m, 545m, 525m, 425w, 370w cm^{-1}. ^1H NMR spectrum (C_6D_6): δ 0.3(12H, s, Me_2Ga), 1.18 (24H, d, $J = 8$ Hz, Pr^i methyls), 3.58(4, q, $J = 8$ Hz, Pr^i methines). Mass spectra (major peaks): *m/z* 302(7%, dimer $(^{71}Ga_2)-Me_2{}^{71}Ga$), 299(14%, dimer $(^{71}Ga{}^{69}Ga)-Me_2{}^{71}Ga$), 287(6%, dimer $(^{71}Ga_2)-NPr^i_2-Me$), 285(9%, dimer $(^{71}Ga, {}^{69}Ga)-NPr^i_2-Me$), 283(10%, dimer $(^{69}Ga_2)-NPr^i_2-Me$), 186(11%, $Me_2{}^{71}GaNPr^i_2-Me$), 184(17%, $Me_2{}^{69}GaNPr^i_2-Me$), 101(33%, $Me_2{}^{71}Ga$), 99(49%, $Me_2{}^{69}Ga$), 86(5%, $Me^{71}Ga$), 84(6%, $Me^{69}Ga$), 71(11%, ^{71}Ga), 69(18%, ^{69}Ga), 58(15%, $NHPr^i$), 44(100%, CH_2CMe_2).

Preparation of bis-μ-(2,6-dimethylpiperido)tetramethyldigallium (**11**)

The lithio derivative of 2,6-dimethylpiperidine (8 mmol, prepared from the ligand and Bu^nLi) in diethyl ether (20 cm^3) was added to a stirred solution of Me_2GaCl (13.0 cm^3 of 0.63 M solution in hexane, 8 mmol) in Et_2O (30 cm^3) at 0°C. The green amide solution became colourless and some white solid was deposited and the system was stirred at room temperature for 1 h. The product was extracted with Et_2O (40 cm^3) which was filtered through celite and concentrated to *ca* 20 cm^3 and white crystals were deposited and were sublimed at 118–125°C/0.02 mm Hg, m.p. 131.5–132.5°C.

IR spectra: 1460s, 1355m, 1350m, 1314m, 1300m, 1250m, 1184w, 1140s, 1120s, 1110s, 1020m, 990m, 975m, 840s, 815w, 740s br, 670m br, 632m, 542m, 525m, 424w, 370w cm^{-1}. ^1H NMR spectrum (C_6D_6): δ 0.1 (12H, s, Me_2Ga), 0.8–1.6 (12H, m, CH_2), 1.2(12H, d, $J = 8$ Hz, $CHCH_3$), 3.40(4H, m, $CHMe$). Mass spectra (major peaks): *m/z* 325(8%, dimer $(^{71}Ga_2)-Me_2{}^{71}Ga$), 323(12%, dimer $(^{71}Ga{}^{69}Ga)-Me_2{}^{71}Ga$), 299(7%, dimer $(^{71}Ga_2)-$ligand$-$Me), 297(10%, dimer $(^{71}Ga{}^{69}Ga)-$ligand$-$Me), 295(11%, dimer $(^{69}Ga_2)-$ligand$-$Me), 198(12%, monomer $(^{71}Ga)-$Me),

196(15%, monomer (^{69}Ga)−Me), 113(89%, protonated ligand), 112(64%, ligand), 101(34%, $Me_2{}^{71}Ga$), 99(48%, $Me_2{}^{69}Ga$), 86(10%, $Me^{71}Ga$), 84(12%, $Me^{69}Ga$).

Preparation of tris-μ-(dimethylarsenido)hexamethyltrigallium

A solution of Me_2AsH (2.4 g, 24 mmol) in toluene (80 cm^3) was added to a stirred solution of $Me_3Ga \cdot Et_2O$ (4.6 g, 24 mmol, prepared from MeLi and $GaCl_3$ in Et_2O) in toluene (80 cm^3). Warming to 70°C caused effervescence which lasted *ca* 1 h and the solution was maintained at 70°C for a further 2 h. Toluene and ether were removed under reduced pressure at room temperature and the resulting white solid was sublimed at 100–110°C/0.02 mm Hg (17 mmol, m.p. 198°C dec., 77% yield based on $Me_3Ga \cdot Et_2O$). Found: C, 22.5; H, 5.6. $C_{12}H_{36}As_3Ga_3$ requires: C, 23.5; H, 5.9%.

IR spectra: 1422m, 1262w, 1249w, 1191m, 902s, 867s, 750s, 725vs, 593m, 579m, 562s, 524s, 253w cm^{-1}. ^1H NMR spectrum (80 MHz, C_6D_6): δ 0.25(18H, s, Me_2Ga), 0.75(18H, s, Me_2As). At 250 MHz ($C_6D_5CD_3$) at various temperatures: 30°C (δ −0.10 Me_2Ga, 0.90 Me_2As), −60°C (0.02 Me_2Ga, 0.86 Me_2As), −70°C (0.7 Me_2Ga, 0.84 Me_2As). Mass spectra (major peaks): *m/z* 618(190, trimer $^{71}Ga^{69}Ga_2$), 612(2%, trimer $^{69}Ga_3$), 603(2%, trimer ($^{71}Ga_3$)−Me), 601(9%, trimer ($^{71}Ga_2{}^{69}Ga$)−Me), 599(16%, trimer ($^{71}Ga^{69}Ga_2$)−Me), 597(8%, trimer ($^{69}Ga_3$)−Me), 513(5%, trimer ($^{71}Ga_3$)−Me_2As), 511(21%, trimer ($^{71}Ga_2{}^{69}Ga$)−Me_2As), 509(29%, trimer ($^{71}Ga^{69}Ga_2$)−Me_2As), 507(15%, trimer ($^{69}Ga_3$)−Me_2As), 487(3%, trimer ($^{71}Ga_3$)−$Me_2{}^{71}Ga$−2Me), 485(7%, trimer ($^{71}Ga_2{}^{69}Ga$)−$Me_2{}^{7}Ga$−2Me), 483(5%, trimer ($^{71}Ga^{69}Ga_2$)−$Me_2{}^{71}Ga$−2Me), 397(dimer ($^{71}Ga_2$)−Me), 395(12%, dimer ($^{71}Ga^{69}Ga$)−Me), 393(9%, dimer ($^{69}Ga_2$)−Me), 307(10%, dimer ($^{71}Ga_2$)−Me_2As), 305(28%, dimer ($^{71}Ga^{69}Ga$)−Me_2As), 303(21%, dimer ($^{69}Ga_2$)−Me_2As), 210(47%, Me_4As_2), 195(34%, Me_3As_2), 191(18%, $^{71}GaAsMe_3$), 189(28%, $^{69}GaAsMe_3$), 180(13%, Me_2As_2), 105(27%, Me_2As), 101(64%, $Me_2{}^{71}Ga$), 99(100%, $Me_2{}^{69}Ga$), 90(34%, MeAS), 86(4%, $Me^{71}Ga$), 84(7%, $Me^{69}Ga$), 71(44%, ^{71}Ga), 69(68%, ^{69}Ga).

X-ray crystallography

X-ray measurements for both compounds were made on crystals sealed under argon in thin walled glass capillaries using an Enraf–Nonius CAD 4 diffractometer operating in the ω–2θ scan mode with graphite monochromated Mo-K_α radiation

($\lambda = 0.71069$ Å) following previously detailed procedures.[14] The structures were solved via the heavy atom method and refined by full-matrix least-squares. Non-hydrogen atoms were assigned anisotropic displacement factor coefficients, hydrogens isotropic. For **1** all hydrogens but the amine hydrogen were included in idealized positions and refined as parts of rigid groups; the amine hydrogen was located experimentally and freely refined. For **2** all hydrogens were freely refined except for those on methyl C(8), which were idealized to obtain stable refinement.

Crystal data and details of intensity measurement and refinement are given in Table 4.

Acknowledgements—We thank the Ministry of Defence (D.C.V.D.), through the sponsorship of R.S.R.E. (Malvern), for financial support (L.M.S.) and also SERC. We are indebted to Mr Greg Coumbarides for obtaining 80 and 250 MHz ^{1}H NMR spectra and to Dr G. E. Hawkes for 400 MHz ^{1}H NMR using the University of London Intercollegiate Research facility at Queen Mary College. Finally we thank Mr Peter Cook for his skill and perseverance in obtaining mass spectra on air-sensitive compounds.

NOVEL INTRAMOLECULARLY STABILIZED ORGANOGALLIUM AND ORGANOINDIUM COMPOUNDS AND THEIR USE IN MOVPE

HERBERT SCHUMANN,* UWE HARTMANN and WILFRIED WASSERMANN

Institut für Anorganische und Analytische Chemie, Technische Universität Berlin, D-1000 Berlin 12, F.R.G.

Abstract—Novel organogallium and organoindium compounds containing the intramolecularly stabilizing dimethylaminopropyl, diethylaminopropyl or dimethylaminobutyl ligand have been synthesized for use in MOVPE. Syntheses and NMR investigations of the moderately air-stable compounds are reported. Using those compounds, GaAs and InP semiconductor layers of good quality could be grown in initial experiments.

III–V semiconductor layers of GaAs and InP for use in optoelectronic devices can be grown by the technique of MOVPE (Metal Organic Vapour Phase Epitaxy). Currently, trimethylgallium (TMG) and trimethylindium (TMI) are used as group III sources in combination with AsH_3 and PH_3 as group V sources.[1,2] However, both TMG and TMI are pyrophoric and extremely sensitive to oxygen and moisture because of their coordinative unsaturation. Formation of Lewis base adducts with NMe_3, PMe_3 and $AsMe_3$ greatly enhances the stability of TMG and TMI. Unfortunately, these adducts are solids at room temperature, thus allowing their use only in apparatus with heated gas lines in order to avoid condensation.

We describe the use of organic ligands containing a terminal Lewis basic group, like dimethylaminopropyl,[3] which allows intramolecular coordination to gallium or indium via a five- or six-membered ring formation. The vapour pressure of the new compounds is high enough for the use in MOVPE without additional heating of the source. Thus, new moderately air-stable precursors for the production of III–V semiconductor layers are now available.

RESULTS AND DISCUSSION

The reaction of dimethylgallium chloride, diethylgallium chloride, di-n-propylgallium chloride, the newly prepared di-iso-propylgallium chloride (**1**), diphenylgallium chloride and the corresponding diorganoindium chlorides, including the new di-iso-propylindium chloride (**2**), with dimethylaminopropyllithium in pentane, first at 0°C, then 12 h at room temperature results in the formation of intramolecular coordinatively saturated triorganogallium and triorganoindium compounds, which are isolated in high yields as liquids or very low melting solids, eqs (1) and (2):

$$R_2GaCl + LiCH_2CH_2CH_2NMe_2 \longrightarrow \underset{\textbf{3–7}}{\text{R}_2\text{Ga(N(Me)(Me))}} + LiCl \quad (1)$$

R = CH_3 (**3**), C_2H_5 (**4**), C_3H_7 (**5**), i-C_3H_7 (**6**), C_6H_5 (**7**)

$$R_2InCl + LiCH_2CH_2CH_2NMe_2 \longrightarrow \underset{\textbf{8–11}}{\text{R}_2\text{In(N(Me)(Me))}} + LiCl \quad (2)$$

R = CH_3 (**8**), C_2H_5 (**9**), C_3H_7 (**10**), i-C_3H_7 (**11**)

The use of diethylaminopropyllithium results in the formation of the corresponding diorgano (diethylaminopropyl)derivatives of gallium and indium, eq. (3):

* Author to whom correspondence should be addressed.

$$R_2MCl + LiCH_2CH_2CH_2NEt_2 \longrightarrow \underset{\textbf{12-16}}{\overset{R_2M}{\underset{Et}{\overset{N}{\underset{Et}{}}}}} + LiCl$$

M = Ga, R = CH_3 (**12**); M = In, R = CH_3 (**13**), C_2H_5 (**14**), C_3H_7 (**15**), i-C_3H_7 (**16**) (3)

These new compounds show almost no decomposition in air. They are readily soluble in organic solvents like ether, benzene or hexane. Slow decomposition occurs in contact with water or alcohol. Cryoscopic molecular weight determinations in benzene for (3-dimethylaminopropyl)dimethylgallium[4] and (3-dimethylaminopropyl)dimethylindium reveal the monomeric constitution in solution. This clearly indicates that the compounds are stabilized intramolecularly via a five-membered ring conformation and not by dimerization.

(3-Dimethylaminopropyl)dimethylindium shows a higher vapour pressure compared to tetrameric TMI, which is commonly used as an indium source in MOVPE.[5,6] The vapour pressures of **3** and **8** in comparison to some compounds commonly used in MOVPE are shown in Table 1.

Six-membered rings formed by this type of intramolecular coordination were expected to be even more stable against oxygen and moisture because of reduced ring strain. An example for this type of compound is (4-dimethylaminobutyl)dimethylgallium (**18**), which is synthesized via hydrogallation[12] of dimethylaminobutene-3[13] with dichlorogallane, followed by methylation with methyllithium, eqs (4) and (5):

$$Cl_2GaH + CH_2{=}CHCH_2CH_2NMe_2 \longrightarrow \underset{\textbf{17}}{Cl_2Ga(CH_2)_4NMe_2} \quad (4)$$

$$\underset{\textbf{17}}{Cl_2Ga(CH_2)_4NMe_2} + 2\,MeLi \longrightarrow \underset{\textbf{18}}{Me_2Ga(CH_2)_4NMe_2} + 2\,LiCl. \quad (5)$$

In comparison to (3-dimethylaminopropyl) dimethylgallium, a solid, this compound has similar physical properties, yet it is a liquid at room temperature.

Triorganogallium- or indium derivatives containing two 3-dimethylaminopropyl or 3-diethylaminopropyl ligands should show an even higher stability against moisture and air because of the possible formation of five-coordinated gallium and indium compounds. This structural feature has been shown already for organoindium compounds with dimethylaminobenzyl[14] or 2,6-bis(diethylaminomethylene)phenyl[15] ligands. Methylgallium dichloride reacts with 2 equivalents of 3-dimethylaminopropyllithium yielding bis(3-dimethylaminopropyl)methylgallium (**19**). Bis(3-alkylaminopropyl)methylindium derivatives were obtained by the reaction of indium trichloride with 2 equivalents of 3-alkylaminopropyllithium to give the bis(3-alkylaminopropyl)indium chlorides (**20**, **21**), which were converted to the corresponding bis(3-alkylaminopropyl)methylindium derivatives (**22**, **23**) by reaction with methyllithium, eqs (6)–(8):

$$CH_3GaCl_2 + 2\,Me_2N(CH_2)_3Li \longrightarrow \underset{\textbf{19}}{CH_3Ga[(CH_2)_3NMe_2]_2} + 2\,LiCl \quad (6)$$

$$InCl_3 + 2\,R_2N(CH_2)_3Li \longrightarrow \underset{\textbf{20, 21}}{ClIn[(CH_2)_3NR_2]_2} + 2\,LiCl \quad (7)$$

$$ClIn[(CH_2)_3NR_2]_2 + MeLi \longrightarrow \underset{\textbf{22, 23}}{CH_3In[(CH_2)_3NR_2]_2} + LiCl \quad (8)$$

R = CH_3 (**20**, **22**), C_2H_5 (**21**, **23**).

The NMR spectra of the new compounds, almost all recorded in C_6D_6, show the expected results. The intensity of signals caused by carbon atoms directly bound to a metal atom is diminished to about 20% as compared to other carbon atoms. This is due to the spin of 3/2 and 9/2 of the gallium and indium atom, respectively.[16] Moreover, those carbon signals are broadened and show peak widths up to 10 Hz as compared to normally about 2 Hz. The intramolecular stabilization of **3**–**16** by formation of five- or six-membered ring systems was also confirmed by variable-temperature ^1H NMR studies as is shown for 3-dimethylaminopropyldi-i-propylgallium (**6**) (Fig. 1).

Two sets of doublets were observed at room temperature for the two i-propyl groups present in **6**. At the coalescence temperature of 56°C, only one broad doublet was detected indicating splitting of the internal coordination and causing a free rotation of the 3-dimethylaminopropyl ligand around the metal–carbon bond. Furthermore, the signal of the $(CH_3)_2N$ group is shifted to lower field with increasing temperature. This is most likely due to a break-up of the metal–nitrogen coordination. Spectroscopic evidence for intramolecular coordination was also obtained from NMR investi-

Table 1. Vapour pressure of organogallium and organoindium compounds used as gallium or indium sources in MOVPE

Compound	Temperature (°C) 20	50	75
$Me_2Ga(CH_2)_3NMe_2$	40 [Pa]	230 [Pa]	1050 [Pa]
$Me_3Ga \cdot NMe_3$[7]	2.4 [Pa]	12.1 [Pa]	37.8 [Pa]
Me_3Ga[8]	178 [Pa]	615 [Pa]	1432 [Pa]
$Me_2In(CH_2)_3NMe_2$[9]	~30 [Pa]	—	~500 [Pa]
$Me_3In \cdot NMe_3$[10]	1.2 [Pa]	8.1 [Pa]	28.7 [Pa]
Me_3In[11]	4.9 [Pa]	31.3 [Pa]	89.9 [Pa]

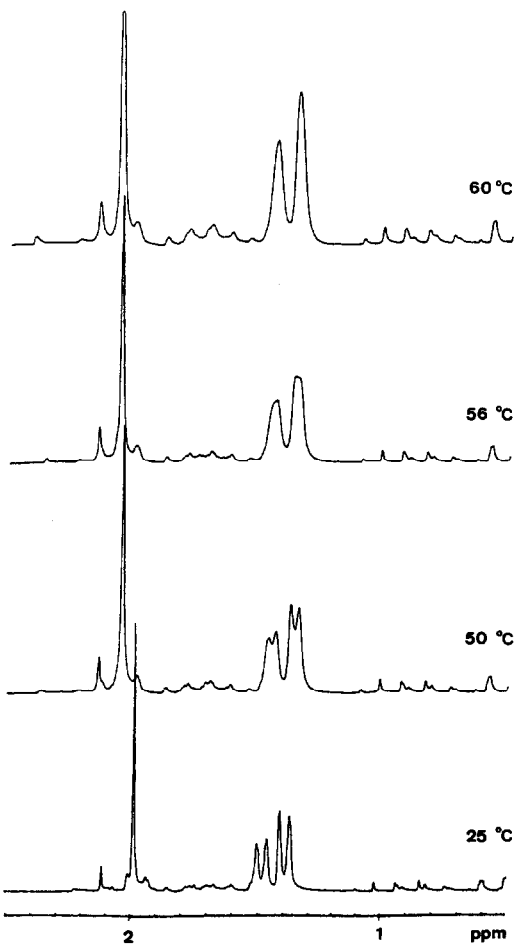

Fig. 1.

gations using the potentially five-coordinated bis(3-dimethylaminopropyl)methylgallium and -indium compounds **19** and **22**. In those compounds either a tetrahedral coordination around the metal centre (one of the ligands is bound, the other rotates freely) or a trigonal-bipyramidal coordination (both ligands are coordinating) is possible. The presence of just one signal for the protons in the $(CH_3)_2N$ moiety in the spectra of **19** and **22**, even at low temperature, clearly indicates that both dimethylamino groups are coordinated to the metal atom.

(3-Dimethylaminopropyl)dimethylindium (**8**) was tested as an indium source for InP layers in MOVPE.[9] Layers of InP were grown at a bubbler temperature of 30°C and a growth temperature of nearly 600°C. The growth rate was 1.2 μm h^{-1}. Hall measurements gave electron mobilities of μ_{77K} = 49,900 $cm^2\ V^{-1}\ s^{-1}$ and carrier concentrations of $n = 3.3 \times 10^{14}\ cm^{-3}$. The layers were of good quality as confirmed by photoluminescence measurements. Zinc was shown to be the main residual acceptor impurity. Further investigations using the other new compounds as precursors for GaAs and InP layers are in progress.[17]

EXPERIMENTAL

All reactions were carried out under the exclusion of oxygen and moisture in an atmosphere of argon using Schlenk tube techniques. Solvents were dried over $LiAlH_4$ or Na/benzophenone and distilled prior to use. The NMR spectra were recorded on a Bruker WH 270 at 270 MHz (^1H NMR) or at 67.93 MHz (^{13}C NMR). For carbon, hydrogen and nitrogen analyses a Perkin–Elmer elemental analyser 240 C was used, and for the determination of the gallium and indium contents a Perkin–Elmer 2380 atomic absorption spectrophotometer was employed. Mass spectra were recorded on a Varian MAT 311 A mass spectrometer. Molecular weights were measured by cryoscopy in benzene solutions, and vapour pressures were determined by the entrainment method.[18]

The starting materials used for the syntheses of the novel compounds were prepared according to literature procedures. The required triorganometal compounds were obtained either by alkylation of the metal trihalides with triorganoaluminium compounds[19] (Me_3Ga, Et_3Ga) or by Grignard reactions (n-Pr_3Ga, i-Pr_3Ga,[20] Et_3In, n-Pr_3In, i-Pr_3In).[21]

Triphenylgallium was made by reaction of diphenylmercury with gallium metal.[22] The corresponding diorganometal chlorides were prepared by redistribution reactions of the triorganometal compounds with the metal trichlorides.[23,24] Dimethylindium chloride could be obtained directly from indium trichloride and methyllithium.[25] The lithium reagents used were synthesized from the corresponding chlorides and lithium powder.[3]

Di-i-propylgallium chloride (**1**)

2.5 g (9.2 mmol) tri-*i*-propylgallium etherate were added via syringe to 0.8 g (4.6 mmol) gallium trichloride. The mixture was heated at 90°C for 5 h. The ether was removed *in vacuo*, and **1** remained as a colourless liquid. Yield: 2.5 g (95%). Found: C, 37.8; H, 7.4. Calc. for $C_6H_{14}ClGa$: C, 37.7; H, 7.4%. ^1H NMR (C_6D_6): δ 1.32–1.36 ppm (m). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 19.8 (CH_3), 21.0 ppm (CH).

Di-i-propylindium chloride (**2**)

3.0 g (12.4 mmol) tri-*i*-propylindium were added via syringe to 1.4 g (6.2 mmol) of indium trichloride. 30 cm^3 pentane were added, and the mixture was refluxed for 30 min. After decanting, the residue was refluxed with 50 cm^3 of benzene. Upon cooling, **2** was obtained as a colourless solid. M.p. 204°C. Yield: 4.2 g (95%). Found: C, 30.8; H, 6.1; In, 48.0. Calc. for $C_6H_{14}ClIn$: C, 30.5; H, 6.0; In, 48.6%. ^1H NMR (C_6D_6): δ 1.04 (m, CH_3CHIn), 1.55 ppm (d, CH_3CHIn). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 22.0 (CH_3CHIn), 22.6 ppm (CH_3CHIn).

(3-*Dimethylaminopropyl*)*dimethylgallium* (**3**)

A solution of 12 g (89.0 mmol) dimethylgallium chloride in 80 cm^3 pentane was added to a stirred suspension of 8.3 g (89.0 mmol) 3-dimethylaminopropyllithium in 50 cm^3 pentane at 0°C. After stirring for 12 h at room temperature, the solution was decanted from lithium chloride, the solvent removed *in vacuo*, and the residue distilled under reduced pressure. Compound **3** was obtained as a colourless liquid, which slowly solidified. B.p. 65°C/10 hPa. M.p. 49°C. Yield: 11.8 g (71%). Found: C, 45.2; H, 9.7; N, 7.8; Ga, 37.2. Calc. for $C_7H_{18}GaN$: C, 45.2; H, 9.8; N, 7.5; Ga, 37.5%. ^1H NMR (C_6D_6): δ −0.16 (s, CH_3Ga), 0.57 (t, CH_2Ga), 1.70 (tt, CH_2), 1.86 (s, CH_3N), 1.98 ppm (t, CH_2N). $^{13}C\{^1H\}$ NMR (C_6D_6): δ −6.2 (CH_3Ga), 9.3 (CH_2Ga), 24.4 (CH_2), 45.9 (CH_3N), 64.0 ppm (CH_2N). MS (70 eV): *m/e* (rel. intensity, %) 170/172* (100) [M $-CH_3$], 58 (55) [$Me_2N^+CH_2$], 84 (50) [$Me_2N^+CHCHCH_2$], 86 (14) [$Me_2N^+(CH_2)_3$], 69/71* (10) [Ga^+], 99/101* (8) [Me_2Ga^+], 44 (6) [$C_2H_6N^+$]; *isotope pattern clearly visible. Mol. wt (cryosc./benzene) Found: 178. Calc. for $C_7H_{18}GaN$: 185.95.

(3-*Dimethylaminopropyl*)*diethylgallium* (**4**)

In analogy to the synthesis of **3**, the reaction between 2.8 g (17.1 mmol) diethylgallium chloride and 1.7 g (18.3 mmol) 3-dimethylaminopropyllithium yielded **4** as a colourless liquid. B.p. 75°C/0.5 hPa. Yield: 2.4 g (65%). Found: C, 50.5; H, 10.5; N, 6.8; Ga, 31.9. Calc. for $C_9H_{22}GaN$: C, 50.5; H, 10.4; N, 6.6; Ga 32.6%. ^1H NMR (C_6D_6): δ 0.37 (q, CH_3CH_2Ga), 0.40 (t, CH_2Ga), 1.35 (t, CH_3CH_2Ga), 1.75 (m, CH_2), 1.97 (s, CH_3N), 2.08 ppm (t, CH_2N). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 3.6 (CH_3CH_2Ga), 5.2 (CH_2Ga), 11.3 (CH_3CH_2Ga), 24.5 (CH_2), 45.9 (CH_3N), 64.5 ppm (CH_2N). MS (70 eV): *m/e* (rel. intensity, %) 184/186* (100) [M $-C_2H_5$], 156/158* (75) [$M^+ - C_2H_5$, $-C_2H_4$], 58 (70) [$Me_2N^+CH_2$], 69/71* (62) [Ga^+], 84 (28) [$Me_2N^+CHCHCH_2$], 86 (26) [$Me_2N^+(CH_2)_3$], 44 (18) [$C_2H_6N^+$]; *isotope pattern clearly visible.

(3-*Dimethylaminopropyl*)*di*-n-*propylgallium* (**5**)

In analogy to the synthesis of **3**, the reaction between 2.26 g (11.8 mmol) di-*n*-propylgallium chloride and 1.2 g (13.0 mmol) 3-dimethylaminopropyllithium yielded **5** as a colourless liquid. B.p. 98°C/0.01 hPa. Yield: 1.8 g (63%). Found: C, 54.4; H, 10.3; N, 6.5; Ga, 28.0. Calc. for $C_{11}H_{26}GaN$: C, 54.6; H, 10.8; N, 5.8; Ga, 28.8%. ^1H NMR (C_6D_6): δ 0.45 (m, $CH_3CH_2CH_2GaCH_2$), 1.17 (t, $CH_3CH_2CH_2Ga$), 1.72 (m, CH_2), 1.98 (s, CH_3N), 2.08 ppm (t, CH_2N). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 6.6 (CH_2Ga), 15.9 ($CH_3CH_2CH_2Ga$), 20.5 ($CH_3CH_2CH_2Ga$), 21.2 (CH_2), 24.5 ($CH_3CH_2CH_2Ga$), 46.1 (CH_3N), 64.6 ppm (CH_2N). MS (70 eV): *m/e* (rel. intensity, %) 198/200* (100) [M $-C_3H_7$], 58 (80) [$Me_2N^+CH_2$], 156/158* (78) [$M^+ - C_3H_7$, $-C_3H_6$], 69/71* (70) [Ga^+], 84 (33) [$Me_2N^+CHCHCH_2$], 86 (32) [$Me_2N^+(CH_2)_3$], 42 (22) [$C_2H_4N^+$], 44 (15) [$C_2H_6N^+$]; *isotope pattern clearly visible.

(3-*Dimethylaminopropyl*)*di*-i-*propylgallium* (**6**)

In analogy to the synthesis of **3**, the reaction between 4.6 g (24.0 mmol) di-*i*-propylgallium chloride and 2.46 g (26.4 mmol) 3-dimethylaminopropyllithium yielded **6** as a colourless liquid. B.p. 86°C/0.01 hPa. Yield: 3.36 g (58%). Found: C, 54.3;

H, 10.4; N, 6.2; Ga, 28.1. Calc. for $C_{11}H_{26}GaN$: C, 54.6; H, 10.8; N, 5.8; Ga, 28.8%. ^{1}H NMR (C_6D_6): δ 0.48 (t, CH_2Ga), 0.82 (sept, CHGa), 1.39 (d) and 1.43 (d, [CH_3]$_2$CH), 1.68 (tt, CH_2), 1.98 (s, CH_3N), 2.01 ppm (t, CH_2N). ^{13}C{^{1}H} NMR (C_6D_6): δ 3.2 (*C*H_2Ga), 14.0 (*C*HGa); 22.4 and 22.5 ([*C*H_3]$_2$CH), 24.2 (*C*H_2), 46.1 (*C*H_3N), 64.8 ppm (*C*H_2N). (3-*Dimethylaminopropyl*)*diphenylgallium* (**7**)

In analogy to the synthesis of **3**, the reaction between 4.8 g (18.6 mmol) diphenylgallium chloride and 1.9 g (20.4 mmol) 3-dimethylaminopropyllithium yielded **7** as a colourless solid after crystallization from hexane. M.p. 137°C. Yield: 4.38 g (76%). Found: C, 65.2; H, 7.1; N, 4.9; Ga, 22.1. Calc. for $C_{17}H_{22}GaN$: C, 65.9; H, 7.2; N, 4.5; Ga, 22.5%. ^{1}H NMR (C_6D_6): δ 0.54 (t, CH_2Ga), 1.68 (m, CH_2), 1.83 (s, CH_3N), 1.96 (t, CH_2N), 7.28–7.96 ppm (m, phenyl). ^{13}C{^{1}H} NMR (C_6D_6): δ 10.1 (*C*H_2Ga), 24.6 (*C*H_2), 45.3 (*C*H_3N), 64.5 (*C*H_2N), 125.7, 127.7, 137.1, 143.3 ppm (phenyl).

(3-*Dimethylaminopropyl*)*dimethylindium* (**8**)

In analogy to the synthesis of **3**, the reaction of 9.8 g (54.3 mmol) dimethylindium chloride and 5.06 g (54.3 mmol) 3-dimethylaminopropyllithium yielded **8** as a colourless liquid. B.p. 57°C/5 hPa. M.p. 12°C. Yield: 8.3 g (67%). Found: C, 36.4; H, 8.1; N, 6.3; In, 49.0. Calc. for $C_7H_{18}InN$: C, 36.4; H, 7.9; N, 6.1; In, 49.7%. ^{1}H NMR (C_6D_6): δ -0.28 (s, CH_3In), 0.57 (t, CH_2In), 1.75 (tt, CH_2), 1.88 (s, CH_3N), 1.93 ppm (t, CH_2N). ^{13}C{^{1}H} NMR (C_6D_6): δ -7.5 (*C*H_3In), 10.7 (*C*H_2In), 25.9 (*C*H_2), 46.3 (*C*H_3N), 64.8 ppm (*C*H_2N). MS (70 eV): *m/e* (rel. intensity, %) 58 (100) [$C_3H_8N^+$], 216 (84) [M $-CH_3$], 86 (43) [$Me_2N^+(CH_2)_3$], 115 (31) [In^+], 84 (16) [$Me_2N^+CHCHCH_2$], 42 (15) [$C_2H_4N^+$], 145 (11) [Me_2In^+], 44 (9) [$C_2H_6N^+$], 201 (6) [M -2 CH_3], 130 (2) [$MeIn^+$]. Mol. wt (cryosc./benzene) Found: 247. Calc. for $C_7H_{18}InN$: 231.05.

(3-*Dimethylaminopropyl*)*diethylindium* (**9**)

In analogy to the synthesis of **3**, the reaction of 7.9 g (37.9 mmol) diethylindium chloride and 3.53 g (37.9 mmol) 3-dimethylaminopropyllithium yielded **9** as a colourless liquid. B.p. 80°C/3 hPa. Yield: 6.1 g (62%). Found: C, 41.9; H, 8.5; N, 5.7; In, 44.0. Calc. for $C_9H_{22}InN$: C, 41.7; H, 8.6; N, 5.4; In, 44.3%. ^{1}H NMR (C_6D_6): δ 0.50 (q, CH_3CH_2In), 0.57 (t, CH_2In), 1.41 (t, CH_3CH$_2$In), 1.78 (tt, CH_2), 1.91 (s, CH_3N), 1.93 ppm (t, CH_2N). ^{13}C{^{1}H} NMR (C_6D_6): δ 5.3 (CH_3CH_2In), 7.8 (*C*H_2In), 13.2 (*C*H_3CH$_2$In), 26.2 (*C*H_2), 46.3 (*C*H_3N), 65.3 ppm (*C*H_2N).

(3-*Dimethylaminopropyl*)*di*-n-*propylindium* (**10**)

In analogy to the synthesis of **3**, the reaction of 13.0 g (55.0 mmol) di-*n*-propylindium chloride and 5.19 g (55.0 mmol) 3-dimethylaminopropyllithium yielded **10** as a colourless liquid. B.p. 62°C/0.05 hPa. Yield: 8.2 g (52%). Found: C, 45.7; H, 9.4; N, 5.1; In, 40.5. Calc. for $C_{11}H_{26}InN$: C, 46.0; H, 9.1; N, 4.9; In, 40.0%. ^{1}H NMR (C_6D_6): δ 0.66 (t, CH_2In), 0.73 (t, CH_3CH_2CH_2In), 1.18 (t, CH_3 CH_2CH_2In), 1.62 (m, CH_3CH_2CH_2In), 1.84 (tt, CH_2), 1.94 (s, CH_3N), 1.98 ppm (t, CH_2N). ^{13}C{^{1}H} NMR (C_6D_6): δ 9.2 (*C*H_2In), 17.9 (CH_3CH_2 *C*H_2In), 20.8 (*C*$H_3CH_2CH_2$In), 22.6 (CH_3*C*H_2 CH_2In), 26.1 (*C*H_2), 46.3 (*C*H_3N), 65.1 ppm (*C*H_2N).

(3-*Dimethylaminopropyl*)*di*-i-*propylindium* (**11**)

In analogy to the synthesis of **3**, the reaction of 1.2 g (5.1 mmol) di-*i*-propylindium chloride and 0.47 g (5.1 mmol) 3-dimethylaminopropyllithium yielded **11** as a colourless liquid. B.p. 54°C/0.2 hPa. Yield: 0.8 g (55%). Found: C, 46.2; H, 9.0; N, 4.6; In, 39.8. Calc. for $C_{11}H_{26}InN$: C, 46.0; H, 9.1; N, 4.9; In, 40.0%. ^{1}H NMR (C_6D_6): δ 0.68 (t, CH_2In), 1.12 (sept, C*H*In), 1.62 (d, CH_3CHIn), 1.81 (tt, CH_2), 1.93 (s, CH_3N), 2.02 ppm (t, CH_2N). ^{13}C{^{1}H} NMR (C_6D_6): δ 6.4 (*C*H_2In), 18.9 (CH_3*C*HIn), 24.4 (*C*H_2CHIn), 25.9 (*C*H_2), 46.3 (*C*H_3N), 65.2 ppm (*C*H_2N).

(3-*Diethylaminopropyl*)*dimethylgallium* (**12**)

In analogy to the synthesis of **3**, the reaction of 4.0 g (30 mmol) dimethylgallium chloride and 3.6 g (30 mmol) 3-diethylaminopropyllithium yielded **12** as a colourless solid after sublimation at 45°C onto a 15°C cold finger at 0.01 hPa. M.p. 56°C. B.p. 227°C. Yield: 4.5 g (70%). Found: C, 50.7; H, 10.0; N, 6.7; Ga, 32.2. Calc. for $C_9H_{22}GaN$: C, 50.5; H, 10.4; N, 6.6; Ga, 32.6%. ^{1}H NMR (C_6D_6): δ -0.05 (s, CH_3Ga), 0.60 (t, CH_2Ga), 0.63 (t, CH_3CH$_2$N), 1.81 (tt, CH_2), 2.09 (t, CH_2N), 2.43 ppm (q, CH_3CH_2N). ^{13}C{^{1}H} NMR (C_6D_6): δ -5.6 (*C*H_3Ga), 7.8 (*C*H_3CH_2N), 8.1 (*C*H_2Ga), 23.4 (*C*H_2), 43.7 (CH_3*C*H_2N), 56.6 ppm (*C*H_2N).

MS (70 eV): *m/e* (rel. intensity, %) 198/200* (100) [M $-CH_3$], 86 (91) [$Et_2N^+CH_2$], 112 (37) [$Et_2N^+CHCHCH_2$], 99/101* (15) [Me_2Ga^+], 69/71* (15) [Ga^+]; *isotope pattern clearly visible.

(3-*Diethylaminopropyl*)*dimethylindium* (**13**)

In analogy to the synthesis of **3**, the reaction of 4.0 g (22.2 mmol) dimethylindium chloride and 2.69 g (22.2 mmol) 3-diethylaminopropyllithium yielded **13** as a colourless liquid, which slowly solidified. B.p. 101°C/5 hPa. Yield: 3.9 g (68%). Found: C, 41.8; H, 8.6; N, 5.8; In, 43.7. Calc. for $C_9H_{22}InN$: C, 41.7; H, 8.6; N, 5.4; In, 44.3%. ^{1}H NMR (C_6D_6): δ −0.27 (s, CH_3In), 0.50 (t, CH_2In), 0.62 (t, CH_3CH_2N), 1.73 (CH_2), 2.04 (t, CH_2N), 2.29 ppm (q, CH_3CH_2N). $^{13}C\{^1H\}$ NMR (C_6D_6): −7.3 (CH_3In), 8.4 (CH_3CH_2N), 9.3 (CH_2In), 25.0 (CH_2), 44.4 (CH_3CH_2N), 57.5 ppm (CH_2N). MS (70 eV): *m/e* (rel. intensity, %) 244 (100) [M $-CH_3$], 86 (84) [$Et_2N^+CH_2$], 114 (62) [$Et_2N^+(CH_2)_3$], 112 (52) [$Et_2N^+CHCHCH_2$], 115 (43) [In^+], 58 (21) [$C_3H_8N^+$], 145 (17) [Me_2In^+], 56 (16) [$C_3H_6N^+$], 98 (14) [$C_6H_{12}N^+$], 42 (12) [$C_2H_4N^+$], 44 (5) [$C_2H_6N^+$], 130 (4) [MeIn$^+$].

(3-*Diethylaminopropyl*)*diethylindium* (**14**)

In analogy to the synthesis of **3**, the reaction of 3.70 g (17.8 mmol) diethylindium chloride and 2.16 g (17.8 mmol) 3-diethylaminopropyllithium yielded **14** as a colourless liquid. B.p. 85°C/0.3 hPa. Yield: 3.5 g (68%). Found: C, 45.8; H, 9.1; N, 4.7; In, 40.7. Calc. for $C_{11}H_{26}InN$: C, 46.0; H, 9.1; N, 4.9; In, 40.0%. ^{1}H NMR (C_6D_6): δ 0.57 (q, CH_3CH_2In), 0.58 (t, CH_3CH_2N), 0.73 (t, CH_2In), 1.47 (t, CH_3CH_2In), 1.73 (tt, CH_2), 2.01 (t, CH_2N), 2.28 ppm (q, CH_3CH_2N). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 5.7 (CH_2In), 6.3 (CH_3CH_2In), 8.5 (CH_3CH_2N), 13.3 (CH_3CH_2In), 25.2 (CH_2), 44.4 (CH_3CH_2N), 57.9 ppm (CH_2N).

(3-*Diethylaminopropyl*)*di*-n-*propylindium* (**15**)

In analogy to the synthesis of **3**, the reaction of 3.1 g (13.1 mmol) di-*n*-propylindium chloride and 1.59 g (13.1 mmol) 3-diethylaminopropyllithium yielded **15** as a colourless liquid. B.p. 88°C/0.03 hPa. Yield: 2.1 g (51%). Found: C, 49.1; H, 9.7; N, 4.6; In, 36.8. Calc. for $C_{13}H_{30}InN$: C, 49.5; H, 9.6; N, 4.4; In, 36.4%. ^{1}H NMR (C_6D_6): δ 0.53 (t, $CH_3CH_2CH_2$In), 0.63 (t, CH_3CH_2N), 0.65 (t, CH_2In), 1.10 (t, $CH_3CH_2CH_2$In), 1.77 (m, $CH_3CH_2CH_2$In), 1.80 (tt, CH_2), 2.06 (t, CH_2N), 2.32 ppm (q, CH_3CH_2N). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 7.7 (CH_2In), 8.5 (CH_3CH_2N), 18.0 ($CH_3CH_2CH_2$In), 20.9 ($CH_3CH_2CH_2$In), 22.7 ($CH_3CH_2CH_2$In), 25.1 (CH_2), 44.4 (CH_3CH_2N), 57.9 ppm (CH_2N).

(3-*Diethylaminopropyl*)*di*-i-*propylindium* (**16**)

In analogy to the synthesis of **3**, the reaction of 1.4 g (5.9 mmol) di-*i*-propylindium chloride and 0.72 g (5.9 mmol) diethylaminopropyllithium yielded **16** as a colourless liquid. B.p. 81°C/0.3 hPa. Yield: 0.9 g (53%). Found: C, 49.6; H, 9.5; N, 4.6; In, 36.7. Calc. for $C_{13}H_{30}InN$: C, 49.5; H, 9.6; N, 4.4; In, 36.4%. ^{1}H NMR (C_6D_6): δ 0.58 (t, CH_3CH_2N), 0.59 (t, CH_2In), 1.04 (m, CH_3CHIn), 1.56 (d, CH_3CHIn), 1.75 (tt, CH_2), 2.00 (t, CH_2N), 2.36 ppm (q, CH_3CH_2N). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 4.9 (CH_2In), 8.6 (CH_3CH_2N), 19.4 (CH_3CHIn), 24.8 (CH_3CHIn), 25.1 (CH_2), 44.3 (CH_3CH_2N), 57.9 ppm (CH_2N).

(4-*Diethylaminobutyl*)*gallium dichloride* (**17**)

Dichlorogallane, freshly prepared from 5.2 g (29.5 mmol) gallium trichloride and 2.4 g (32.7 mmol) trimethylsilane, was suspended at −20°C in 50 cm^3 pentane. 2.9 g (29.5 mmol) dimethylaminobutene-3 in 10 cm^3 pentane were added dropwise. The reaction mixture was stirred at this temperature for 1 h and then for 1 h at room temperature. Removal of the solvent *in vacuo* yielded **17** as a colourless oil. Yield: 3.9 g (55%). Found: C, 29.6; H, 5.6; N, 6.0. Calc. for $C_6H_{14}Cl_2Ga$: C, 29.9, H, 5.9; N, 5.8%. ^{1}H NMR (D_8-THF): δ 0.72 (CH_2Ga), 1.27–1.68 (m, CH_2CH_2), 1.92 (s, CH_3N), 2.04 ppm (t, CH_2N). $^{13}C\{^1H\}$ NMR (D_8-THF): δ 2.0 (CH_2Ga), 22.2 (CH_2CH_2Ga), 27.1 (CH_2CH_2N), 45.4 (CH_3N), 62.3 ppm (CH_2N).

(4-*Dimethylaminobutyl*)*dimethylgallium* (**18**)

16.2 cm^3 (29.2 mmol) of a methyllithium solution in ether (1.8 mol dm^{-3}) were added to a stirred solution of 3.5 g (14.6 mmol) (4-dimethylaminobutyl)gallium dichloride in 10 cm^3 ether at 0°C. After stirring for 12 h at room temperature, the solution was decanted. Distillation yielded **18** as a colourless liquid. B.p. 80°C/10 hPa. Yield: 1.4 g (56%). Found: C, 48.0; H, 10.0; N, 7.1. Calc. for $C_8H_{20}GaN$: C, 48.1; H, 10.1; N, 7.0%. ^{1}H NMR (C_6D_6): δ −0.05 (s, CH_3Ga), 0.54 (t, CH_2Ga), 1.19–1.66 (m, CH_2CH_2), 1.93 (s, CH_3N), 2.08 ppm (t, CH_2N). $^{13}C\{^1H\}$ NMR (C_6D_6): δ −5.9 (CH_3Ga), 9.0 (CH_2Ga), 21.2 (CH_2CH_2Ga), 28.1 (CH_2CH_2N), 45.5 (CH_3N), 63.3 ppm (CH_2N). MS (70 eV): *m/e* (rel. intensity,

%) 184/186* (100) [M $-CH_3$], 58 (60) [$Me_2N^+CH_2$], 100 (56) [$Me_2N^+C_4H_8$], 98 (15) [$Me_2N^+C_4H_6$], 69/71* (7) [Ga^+], 99/101* (5) [Me_2Ga^+], 44 (5) [$C_2H_6N^+$]; *isotope pattern clearly visible.

Bis(3-dimethylaminopropyl)methylgallium (**19**)

A solution of 4 g (25.7 mmol) methylgallium dichloride in 20 cm^3 benzene was added dropwise to a stirred suspension of 5 g (53.7 mmol) 3-dimethylaminopropyllithium in 40 cm^3 pentane. The reaction mixture was stirred for 1 h at room temperature and the refluxed for a further 6 h. Filtration and removal of the solvent *in vacuo* left a residue, which was sublimed at 40°C onto a 15°C cold finger at 0.01 hPa to yield **19** as a colourless solid. M.p. 52°C. Yield: 4.5 g (68%). Found: C, 50.8; H, 10.0; N, 10.5. Calc. for $C_{11}H_{27}GaN_2$: C, 51.4; H, 10.6; N, 10.9%. ^{1}H NMR ($CD_3C_6D_5$): δ −0.26 (s, CH_3Ga), 0.49 (t, CH_2Ga), 1.79 (tt, CH_2), 2.04 (CH_3N), 2.13 ppm (t, CH_2N). $^{13}C\{^1H\}$ NMR ($CD_3C_6D_5$): δ −7.1 (CH_3Ga), 9.8 (CH_2Ga), 24.7 (CH_2), 46.0 (CH_3N), 63.6 ppm (CH_2N).

Bis(3-dimethylaminopropyl)indium chloride (**20**)

A solution of 16.8 g (180.8 mmol) 3-dimethylaminopropyllithium in 300 cm^3 ether was added dropwise to a stirred suspension of indium trichloride in 300 cm^3 ether at 0°C. After stirring for 24 h, the reaction mixture was filtered. Cooling at −30°C yielded **20** as colourless crystals, which were washed with cold pentane and dried *in vacuo*. M.p. 92°C. Yield: 19.2 g (66%). Found: C, 37.0; H, 7.5; N, 8.5; In, 35.4. Calc. for $C_{10}H_{24}ClInN_2$: C, 37.2; H, 7.5; N, 8.7; In, 35.6%. ^{1}H NMR (C_6D_6): δ 0.62 (t, CH_2In), 1.71 (tt, CH_2), 1.95 (s, CH_3N), 2.08 ppm (t, CH_2N). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 9.4 (CH_2In), 23.7 (CH_2), 45.3 (CH_3N), 61.8 ppm (CH_2N). MS (70 eV): *m/e* (rel. intensity, %) 58 (100) [$C_3H_8N^+$], 86 (85) [$Me_2N^+(CH_2)_3$], 287 (40) [M^+-Cl], 115 (35) [In^+], 42 (35) [$C_2H_4N^+$], 244 (34) [$M^+ -Cl-C_4H_{10}N$], 236 (32) [$M^+ -C_5H_{12}$], 44 (17) [$C_2H_6N^+$], 264 (16) [$M^+ -C_3H_8N^+$], 114 (14) [$C_7H_{16}N^+$].

Bis(3-diethylaminopropyl)indium chloride (**21**)

In analogy to the synthesis of **20**, the reaction of 17.5 g 3-diethylaminopropyllithium and 16.0 g (72.3 mmol) indium trichloride yielded **21** as colourless crystals. M.p. 94°C. Yield: 14.6 g (53%). Found: C, 44.1; H, 8.7; N, 7.9; In, 30.2. Calc. for $C_{14}H_{32}ClInN_2$: C, 44.4; H, 8.5; N, 7.4; In, 30.3%. ^{1}H NMR (C_6D_6): δ 0.59 (t, CH_2In), 0.78 (t, CH_3CH_2N), 1.75 (tt, CH_2), 2.20 (t, CH_2N), 2.47 ppm (q, CH_3CH_2N). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 8.4 (CH_3CH_2N), 12.3 (CH_2In), 23.2 (CH_2), 43.9 (CH_3CH_2N), 55.4 ppm (CH_2N).

Bis(3-dimethylaminopropyl)methylindium (**22**)

20.7 cm^3 (31.0 mmol) of a methyllithium solution in ether (1.55 mol dm^{-3}) were added dropwise to a stirred solution of 10.0 g (31.0 mmol) bis(3-dimethylaminopropyl)indium chloride in 100 cm^3 diethyl ether. After stirring for 12 h, the ether was removed *in vacuo*. 100 cm^3 hexane were added, the mixture was filtered and the solvent removed. Distillation yielded **22** as a colourless liquid. B.p. 57°C/0.1 hPa. Yield: 5.6 g (60%). Found: C, 43.9; H, 9.0; N, 9.4; In, 38.1. Calc. for $C_{11}H_{27}InN_2$: C, 43.7; H, 9.0; N, 9.3; In, 38.0%. ^{1}H NMR ($CD_3C_6D_5$): δ −0.24 (s, CH_3In), 0.54 (t, CH_2In), 1.91 (tt, CH_2), 2.00 (s, CH_3N), 2.10 ppm (t, CH_2N). $^{13}C\{^1H\}$ NMR ($CD_3C_6D_5$): δ −7.6 (CH_3In), 10.7 (CH_2In), 25.9 (CH_2), 46.1 (CH_3N), 64.6 ppm (CH_2N).

Bis(3-diethylaminopropyl)methylindium (**23**)

In analogy to the synthesis of **22**, the reaction of 17.0 cm^3 (26.4 mmol) methyllithium solution and 10.0 g (26.4 mmol) bis(diethylaminopropyl)indium chloride yielded **23** as a colourless liquid. B.p. 52°C/0.03 hPa. Yield: 5.3 g (56%). Found: C, 50.1; H, 9.9; N, 7.6; In, 32.3. OXYGEN- OR SULPHUR-CONTAINING ORGANOINDIUM COMPOUNDS FOR PRECURSORS OF INDIUM OXIDE AND SULPHIDE THIN FILMS

RYOKI NOMURA,* SATORU FUJII, KOUICHI KANAYA and HARUO MATSUDA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-Oka, Suita, Osaka 565, Japan

Abstract—Dibutylindium carboxylates and butylindium thiolates are prominent precursors for the preparation of indium oxide and sulphide thin layers via a solution pyrolysis process. Their application has been enlarged to include the preparation of ternary compound thin films, taking advantage of the formation of binuclear complexes with organotin oxides or copper(II) dithiocarbamate complexes. Thus, addition of $Bu^n_2In(OCOEt)$ to Bu^n_2SnO gave the mixed stannoxane $Bu^n(EtCOO)In—O—SnBu^n_3$ (**I**). While, $Bu^i_2InSPr^n$ and $Cu(S_2CNBu^n_2)_2$ afforded similar bimetallic complexes $Bu^i_2In(SPr^n)Cu(S_2CNBu^n_2)$ (**VI**). Solution pyrolysis of **I** and **VI** gave uniform indium–tin oxide and copper–indium sulphide thin films, respectively. The course of thermal decomposition of **I** and **VI** was also investigated.

Although an increasing interest has been shown in the utilization of organometallics as precursors in the fabrication of several compound semiconductor materials,[1] only limited numbers of metal alkyls such as trimethylgallium and trimethylindium, etc., are practically employable.[1–3] Recently, more sophisticated organometallic precursors than these single metal alkyls have been developed and introduced in order to prepare thin films of binary or ternary compounds, via the OMCVD process, avoiding "premature reaction"; for example, trialkylindium phosphine adducts[4,5] and, more advanced, dialkylphosphinodialkylindium derivatives[6,7] were exploitable for the preparation of InP epitaxial layers. It should be emphasized that these binuclear organometallic precursors already contain all the necessary elements to construct the target compounds. This is the most characteristic feature of such one-source systems. Further, they possess the large advantage of diminishing undesired reactions during the film deposition. However, few attempts have been made on the application of the one-source systems for the preparation of compounds other than some group III pnictides such as InP, etc. Thus, conventional inorganic and metallorganics precursors such as indium salts, alkoxides and acetylacetonates are predominantly utilized in the preparation of the oxide or chalcogenide derivatives of indium.[8–10]

The success of binuclear organometallics in the fabrication of the pnictide thin films stimulated our studies on the utilization of organoindium compounds for preparation of oxide or chalcogenide materials. In this paper, we describe the effectiveness of organoindium precursors in the preparation of III/VI semiconductor thin films. In addition, the reaction of organoindium compounds such as dibutylindium propionate, $Bu^n_2In(OCOEt)$, or butylindium propylthiolates, $(Bu^i_{3-x}In(SPr^n)_x$, $x = 1$ or 2), with dibutyltin oxide or copper dithiocarbamate complexes, respectively, are also reported.

EXPERIMENTAL

General

^1H and ^{13}C NMR, and IR spectra were recorded on a Hitachi R90H FT spectrometer and on a Hitachi 260–30 spectrophotometer, respectively. Mass spectra were obtained by the use of a JEOL JMS–DX303 (Faculty of Engineering, Osaka University). Molecularity was measured by a VPO method using a Corona 117 type vapour pressure osmometer, and TG/DTA measurements were made using a SEIKO TG/DTA 20 type thermal

analyser. All reactions were carried out under a dry N_2 atmosphere.

Materials

Dibutylindium propionate was prepared directly from tributylindium with propionic acid in an ether solution.[11,12] Dibutylindium thiolates and butylindium dithiolates were synthesized from the reaction of tributylindium with the corresponding alkane thiols in 1 : 1 and 1 : 2 molar ratios, respectively.[13] Copper dithiocarbamate complexes were prepared by direct condensation of copper(II) oxide with dithiocarbamic acids as reported previously.[14-17]

*Reaction of di-*n*-butylindium propionate with di-*n*-butyltin oxide*

To a suspension of di-*n*-butyltin oxide (5 mmol) in *p*-xylene (20 cm^3), di-*n*-butylindium propionate (5 mmol) was added slowly with stirring at 0°C, then the mixture was heated under reflux for 3.5 h. After evaporation of *p*-xylene, $Bu^n(EtCOO)In—O—SnBu^n_3$ (**I**) was obtained at room temperature as a gummy solid and further purified by distillation *in vacuo*.

Reaction of diisobutylindium n*-propylthiolate with copper*(II) *bis(di-*n*-butyldithiocarbamate)*

Into a solution of copper bis(di-*n*-butyldithiocarbamate) (5 mmol) in *p*-xylene (20 cm^3), diisobutylindium *n*-propylthiolate (5 mmol) was added dropwise at 0°C and the resulting solution was stirred at room temperature. After stirring for 6 h, the resulting yellowish-brown viscous oils were chromatographed on a silica gel column by eluting with chloroform. The binuclear complex **VI** was obtained in a quantitative yield.

RESULTS AND DISCUSSION

Organoindium carboxylates for indium oxide thin films

It is well known that indium oxide and tin-doped indium oxide (ITO) have a wide range of applications as transparent conductors in planar display panels and solar cell windows, etc.[8] Solution pyrolysis is one of the most facile processes suitable for preparation of large areas of thin films and patterned layers. The merits of such a process in contrast to some physical processes and spray pyrolysis, are less highlighted, because of a lack of adequate precursors. An introduction of the fully organometallic precursor systems, however, would compensate for such a defect and their use could give high quality ITO films under milder conditions than those of the existing precursor systems.[12]

Highly conductive and transparent ITO films ($\rho \fallingdotseq 10^{-3}$ Ω cm, $T_v > 90\%$) have been prepared as follows: (1) dissolve dibutylindium carboxylates and dibutyltin oxide (5 wt% with respect to dibutylindium carboxylate employed) in *p*-xylene, (2) coat the resulting *p*-xylene solution onto a substrate such as borosilicate glass or quartz, (3) heat the coated substrate at 100°C for 40 min, then (4) pyrolyse the organometallics on the substrate at 450°C for 1 h to form uniform oxide layers. We expected that the formation of inorganic In—O—Sn networks should be preceded by the formation of organometallic In—O—Sn linkages as indicated in Scheme 1.

A model reaction using equimolar amounts of dibutylindium propionate and dibutyltin oxide in *p*-xylene was carried out. It was found that these two organometallics readily coupled together to form a novel mixed stannoxane (**I**),* associated with a butyl migration from indium to tin as shown in Scheme 2. One should compare this addition with the telomerization of dibutyltin oxide with di-

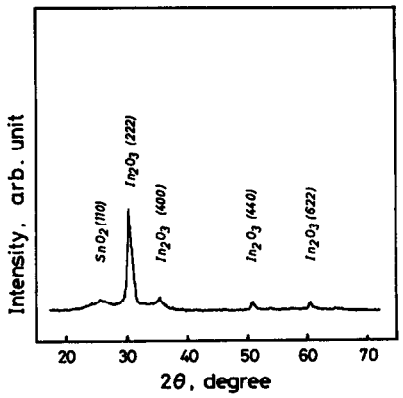

Fig. 1. XRD patterns of the pyrolysate of copolymer **III** at 400°C for 1 h under air.

butyltin halides and with the formation of the mixed metallastannoxanes, in which it can be seen that electronegative groups generally migrated onto tin nuclei.[18] Similar migrations of alkyl groups from indium centres were reported for the reactions of trimethylindium with trimethylstibine sulphide[19] and of triethylindium with thiobenzophenone.[20] The investigations of the coupling reactions of other dibutylindium derivatives and tributylindium with several organotin oxides other than dibutyltin oxide is now in progress and the detailed aspects of the reactions will be published elsewhere.

Bimetallic stannoxane **I** was formed as a gummy solid. In addition, **I** is only moderately air-sensitive and can be stored unchanged for months under an inert atmosphere. Compound **I** gradually solidified to give a wet gel[21] after contact with moist air for several days and immediately formed gels when an equimolar amount of water was added to a solution of **I**. The increase of molecularity of **I** on standing under moist air is displayed in Table 1. The gelation was considered to result from the formation of copolymer **II**. The bimetallic μ-oxo compound **I** also reacted with 9 equivalents of $Bu_2InOCOEt$ in the presence of *ca* 100 ppm of water and gave copolymer **III**, as illustrated in Scheme 2. During the course of the copolymerization, a quantitative evolution of butane was detected by GLC analysis.

Stepwise weight loss curves associated with the two exothermic peaks (265 and 348°C) were observed in TG/DTA analysis of **I**, and the composition of the pyrolysates at 265, 350 and 400°C are summarized in Table 2. Thus, **I** was converted into indium–tin oxide on heating by releasing the butyl moieties bound to the metal centres (~265°C) and carboxylates (~350°C) in this order, as shown in Scheme 2. Further, pyrolysis of the copolymer **III** at 400°C gave indium–tin oxide (ITO) powders as shown in Fig. 1.

Organoindium thiolates for indium sulphide thin films

We can prepare both di-*n*-butylindium isopropylthiolate (**IV**) and *n*-butylindium bis(isopropylthiolate) (**V**) by changing the mole ratios

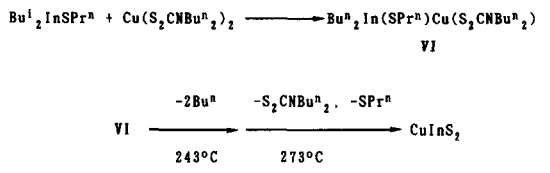

Scheme 4.

of the starting tributylindium and thiols[13,22] as shown in Scheme 3. These two butylindium thiolates are liquids at room temperature and are distillable under reduced pressure, which is a desirable property for their application as precursors of semiconductor materials via chemical procedures e.g. OMCVD.[23] Further, **IV** and **V** are only moderately air-sensitive and exist as monomers in aprotic solvents such as benzene or chloroform at room temperature.[13] Pyrolysis of **IV** under an Ar atmosphere below 300°C, afforded orthorhombic InS powders, in contrast, that of **V** gave tetragonal In_2S_3 powders at *ca* 300°C.[23]

The indium sulphides, InS and In_2S_3, possess medium band gap energies, 2.44[24] and 2.07 eV,[25] respectively, and are promising materials for optoelectronics and photovoltaics.[26,27] Solution pyrolysis of **IV** gave InS thin films at 250°C under Ar, but gave transparent and conducting In_2O_3 films at above 300°C.[27] Thus, InS films obtained from the pyrolysis of $Bu^n_2InSPr^n$ should be fairly oxidizable and deposited InS was easily converted into In_2O_3 films even by trace amounts of oxygen contained in Ar (99.9% purity). Further, indium oxide films occurring at 375°C showed high transparency and low resistivity ($T_v > 90\%$, and $\rho \fallingdotseq 10^{-3}\ \Omega$ cm).

Preparation of $CuInS_2$ *thin films via solution pyrolysis of* $Bu^i_2InSPr^n$—$Cu(S_2CNBu^n_2)_2$ *systems*

Indium sulphide, InS, is also employed as a component of binary sulphides, especially $CuInS_2$ which is one of the best suited materials for photovoltaics.[28,29] Thus, we attempted to prepare $CuInS_2$ thin films using dibutylindium thiolates. It was found that solution pyrolysis of the $Bu^i_2InSPr^n$—$Cu(S_2CNBu^n_2)_2$ system at 350°C successfully gave stoichiometric $CuInS_2$ thin films.[17] We tentatively assumed that initial formation of a binary complex between two organometallic sources affected the stoichiometry and homogeneity of the final pyrolysates.

Reaction of copper(II) dibutyldithiocarbamate with dibutylindium propylthiolate gave a novel bimetallic complex $Bu^i_2In(SPr^n)Cu(S_2CNBu^n_2)$ (**VI**), as shown in Scheme 4. Analytical and spectral data* were consistent with the formula but we could not determine the identity of the bridge between the copper and indium nuclei. It is interesting that reduction of the copper(II) species occurred during the coupling. The reduction was confirmed by disappearance of the black colour, characteristic of copper(II) dithiocarbamates,[16] and by significant line-sharpening observed in ^1H and ^{13}C NMR spectra, indicating the reduction of paramagnetic copper(II) to copper(I) species. Further, lower $\delta(^{13}CH_2N)$ at 55.8 indicated the formation of copper(I) dithiocarbamate.[30] Although molecularity measurements showed that **VI** existed as a monomer in solution, a set of peaks assignable to the trimer of **VI** could be detected at around $m/z = 1721$ in FAB MS.

Thermal decomposition of **VI** was observed by TG/DTA and the compositions of pyrolysates were estimated by microanalysis and XRD. The results obtained are summarized in Tables 3 and 4. As can be seen in Table 3, **VI** decomposed with the appearance of exothermic and endothermic peaks, which appeared at lower temperatures than those of the parent compounds, and gave $CuInS_2$ in quantitative yield. Analysis of the pyrolysates suggested that two butyl groups bonded to indium were released below 250°C which coincided with the exothermic peak, and the dithiocarbamate and thiolate moieties were successively released at 300°C which agreed with the endothermic peak.

SUMMARY

Based on the model reactions, it is concluded that solution pyrolysis of $Bu_2InOCOEt$—Bu_2SnO and

FORMATION OF ALKOXY-DERIVED $NbAlO_4$

OSAMU YAMAGUCHI* and MASAKAZU SHIRAI

Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Kyoto 602, Japan

Abstract—In the system Nb_2O_5–Al_2O_3, δ-Nb_2O_5 (hexagonal) solid solutions crystallize at low temperatures (with up to 50 mol% Al_2O_3) from amorphous materials prepared by the simultaneous hydrolysis of niobium and aluminium alkoxides. The lattice parameter a is relatively constant regardless of composition, whereas parameter c decreases linearly with increasing Al_2O_3. The δ- to γ-Nb_2O_5 (orthorhombic) phase transformation occurs at $\approx$ 640 to $\approx$ 700°C. The solid solution containing 50 mol% Al_2O_3 transforms to $NbAlO_4$ (monoclinic) at 800–860°C.

Niobium pentoxide, Nb_2O_5, exists in many polymorphic modifications: α-, α'-, β-, γ-, δ-, ε-, ζ-, η-, N- and R-phases.[1,2] The exact relationships of the polymorphs are still uncertain because of the lack of suitable crystals needed to properly characterize the phases. However, it has been concluded that α-Nb_2O_5 (monoclinic) is stable and all other forms transform to it at $\approx$ 1100°C regardless of the preparation method. Little attention has been paid to the formation of solid solutions in the system Nb_2O_5–Al_2O_3. Goldschmidt[3] reported that Nb_2O_5 took up to $\approx$ 15 mol% Al_2O_3 into solution, resulting in a slight distortion of the Nb_2O_5 lattice. On the other hand, Layden[4] suggested that little or no solid solution of Al_2O_3 in Nb_2O_5 occurred. Niobium aluminate, $NbAlO_4$,[3–12] is one of the compounds in this system. Four preparation methods were used: a solid-state reaction,[3,6,7,10,12] a fusion technique,[3,12] oxidation of a compound metal[7] and a co-precipitation method.[10] We now report, here, the formation of $NbAlO_4$ at low temperatures by the transformation of a Nb_2O_5 solid solution containing 50 mol% Al_2O_3 from an amorphous material prepared by the simultaneous hydrolysis of niobium and aluminium alkoxides.

EXPERIMENTAL

Niobium isopropoxide, $Nb(OC_3H_7)_5$ (99.999% pure), was used as received. Aluminium isopropoxide, $Al(OC_3H_7)_3$, was synthesized by heating aluminium metal (> 99.9% pure) in an excess of analytical-grade 2-propanol with mercury(II) chloride (10^{-4} mol/mol of metal) as a catalyst for 10 h at 82°C.[13] The mixed alkoxides of the various compositions were heated under reflux for 10 h and then hydrolysed by adding conductivity water at room temperature. The temperature was slowly increased to 75°C while the resulting suspensions were stirred. The hydrolysis products were separated from the suspensions by filtration, washed 10 times with hot water, and dried at 100°C under reduced pressure. The powders obtained are termed "starting powders". Their average particle size, determined by electron microscopy, was $\approx$ 30 nm for A and $\approx$ 90 nm for B–F.

Differential thermal analysis (DTA) was conducted in air at a rate of 10°C min^{-1}; α-alumina was used as the reference. The starting powders and specimens, obtained from the DTA studies and then quenched, were examined by X-ray diffraction (XRD) using Ni-filtered Cu-K_α radiation. Interplanar spacings were measured with the aid of an internal standard of silicon, and unit cell values were determined by a least-squares refinement. IR spectroscopy was performed on a dispersion in potassium bromide using the pressed-disc technique.

RESULTS AND DISCUSSION

Differential thermal analysis

Figure 1 shows the DTA curves for powders A, C and F; they reveal sharp exotherms resulting from the crystallization of δ-Nb_2O_5 (δ-Nb_2O_5 solid solution), although the peaks decreased successively in height from A to F. The crystallization temperature of each starting powder is listed in Table 1.

* Author to whom correspondence should be addressed.

Table 1. Chemical composition of starting powders, and temperatures of crystallization and transformation

Starting powder	Composition mol% Nb_2O_5–Al_2O_3	Crystallization temperature (°C)	Transformation temperature (°C)
A	100 : 0	560–585	640–700[a]
B	90 : 10	645–675	800–830
C	80 : 20	690–730	790–830
D	70 : 30	705–755	790–830
E	60 : 40	725–780	790–845
F	50 : 50	745–800	800–860

[a] Determined by X-ray analysis.

As can be seen from the data, with increasing Al_2O_3 the crystallization was shifted to higher temperatures and increased in the peak temperature range. Although no peak for A was observed at higher temperatures, other starting powders showed the second exothermic peaks (Fig. 1). Contrary to the peaks of crystallization, they increased in height from B to F. As will be described, the second peaks were confirmed to result from the transformation of δ-Nb_2O_5 solid solutions into $NbAlO_4$. The transformation temperature is shown in Table 1.

X-ray analysis

XRD analysis showed that all starting powders were amorphous. No significant change in structure was observed up to the temperatures of the first exothermic peaks. When the starting powders were heated at temperatures above the first exothermic peaks, the specimens gave the XRD pattern of the only δ-Nb_2O_5 phase; these results suggest that δ-Nb_2O_5 solid solutions were formed up to 50 mol% Al_2O_3.* Metastable δ-Nb_2O_5 was first found in the commercial sample by Frevel and Rinn.[14] Later this modification was prepared by heating or hydrothermal treatment of amorphous Nb_2O_5[1,15] and by oxidation of NbO_2 or Nb metal.[16–18] The X-ray data for δ-Nb_2O_5 prepared from A by heating for 2 h at 585°C were in agreement with those reported.[1,14,17,18] The diffraction lines were indexed as a hexagonal unit cell with $a = 0.3604$ and $c = 0.3923$ nm. Compositional changes result in a significant variation in the cell dimensions. Figure 2 shows the variation of lattice parameters of the δ-Nb_2O_5 phases obtained from each starting powder. The lattice parameter a was relatively constant regardless of composition, whereas parameter c decreased linearly with increasing Al_2O_3.

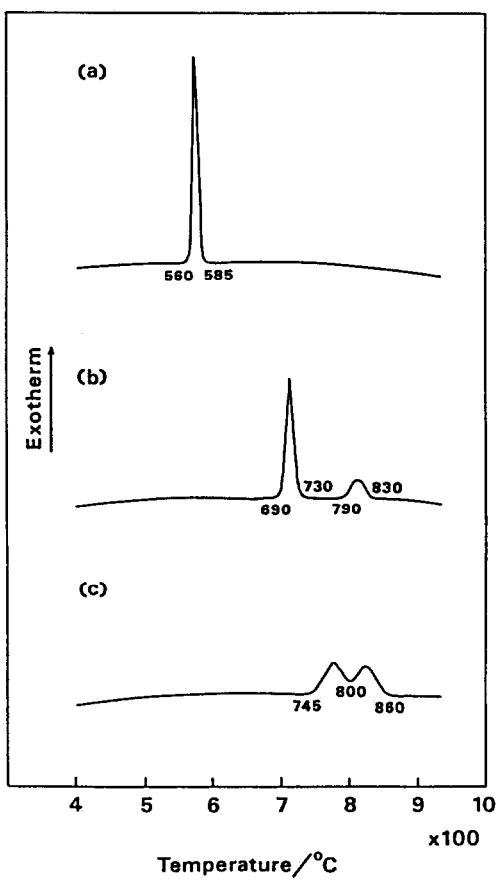

Fig. 1. Differential thermal analysis curves for (a) A, (b) C and (c) F. Sample weight 45 mg.

The δ- to γ-Nb_2O_5 phase transformation in A occurred at ≈ 640°C, although no peak was detected in the DTA; only γ-Nb_2O_5 was present above 700°C. The δ-Nb_2O_5 phases from other start-

*In the Al_2O_3-rich region, although the starting powder prepared in 55 mol% Al_2O_3 was amorphous, α-Al_2O_3 was observed when it was heated above 1200°C. Above 60 mol% Al_2O_3, boehmite AlO(OH) was present in the starting powder.

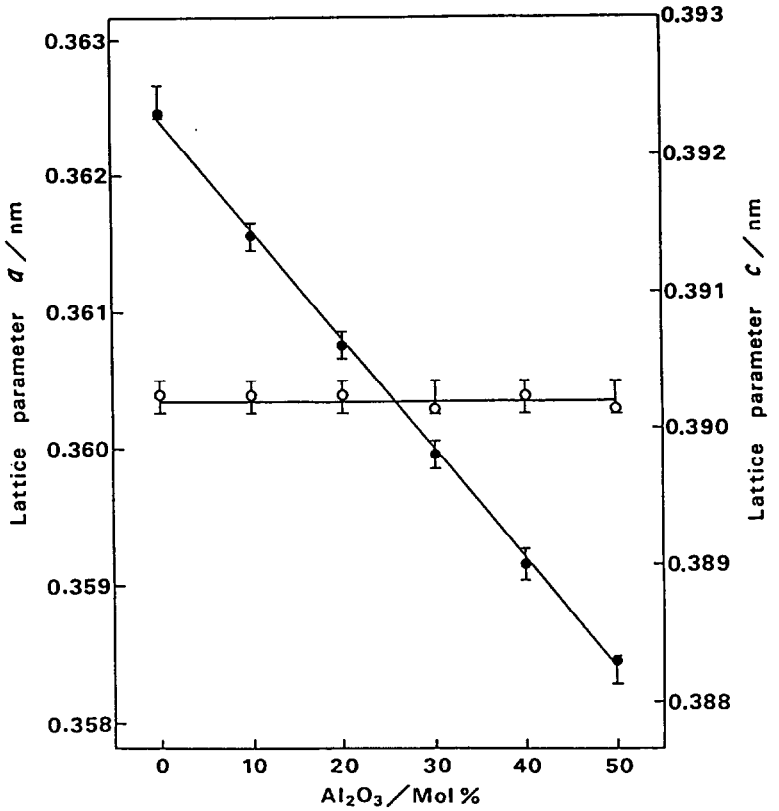

Fig. 2. Lattice parameters (○) a and (●) c for the δ-Nb_2O_5 phase as a function of composition.

ing powders were observed up to the temperatures of the second exothermic peaks. When B–E were heated at temperatures above the second exothermic peaks, the specimens were mixtures of $NbAlO_4$ and γ-Nb_2O_5. The specimen gave an XRD pattern characteristic of $NbAlO_4$. These indicate that the solid solutions were transformed into $NbAlO_4$. The X-ray data for $NbAlO_4$ are presented in Table 2. On the crystal structure of $NbAlO_4$, Whiston and Smith,[12] and Pedersen[8] determined it as a monoclinic unit cell by the use of single crystals, while Burdese and Borlera[9] indexed on the basis of an orthorhombic unit cell from the powder diffraction data. The compound in the present study was classified into the monoclinic system with $a = 1.2174$, $b = 0.3708$, $c = 0.6476$ nm and $\beta = 107.50°$. The dimensions of the monoclinic unit cell determined were in agreement with the parameters reported.[8,12] Thus $NbAlO_4$ could be easily prepared at low temperatures by transformation of the δ-Nb_2O_5 solid solution formed from alkoxides in the mole ratio $Nb^{5+} : Al^{3+} = 1 : 1$.

Infrared spectrum

Three absorption bands in pure δ-Nb_2O_5 obtained from A were present at 850, 800 and 560

[a] Monoclinic; $a = 1.2174$, $b = 0.3708$, $c = 0.6476$ nm, $\beta = 107.50°$.

cm^{-1}, agreeing with the spectral data of α-Nb_2O_5.[19] In the spectra of δ-Nb_2O_5 solid solutions, the intensity of the bands decreased with increasing Al_2O_3. On the other hand, the spectrum of $NbAlO_4$ showed the absorption bands at 975, 835, 725, 555 and 505 cm^{-1}. No spectral data for $NbAlO_4$ have been reported; however, the spectrum is very similar to that of $TaAlO_4$[20] in which the bands are located at 984, 840, 750, 562 and 505 cm^{-1}. According to the data of Povarennykh,[20] $TaAlO_4$ contains octahedral TaO_6 groups and the strong band at ≈ 980 cm^{-1} is a characteristic frequency. Accordingly, it must be suggested that $NbAlO_4$ contains octahedral NbO_6 groups in the structure.

COORDINATION STRUCTURE OF THE ALUMINIUM ATOMS OF POLY(METHYLALOXANE), POLY(ISOPROPOXYLALOXANE) AND POLY[(ACYLOXY)ALOXANE]

Y. KIMURA,* S. TANIMOTO, H. YAMANE and T. KITAO

Department of Polymer Science and Engineering, Kyoto Institute of Technology, Matsugasaki, Kyoto 606, Japan

Abstract—Poly(methylaloxane) (**1**), prepared by hydrolytic polymerization of trimethylaluminium (TMA), was reacted with isopropanol (IP) to obtain poly(isopropoxylaloxane) (**2**). This was further reacted with propionic acid (PA) to prepare poly[(propionyloxy)aloxane] (**3**), with various ratios of PA ligands. By gasmetry of the methane produced in the reaction, as well as by the ^{1}H NMR spectroscopy of the products, both **1** and **2** were found to contain less reactive terminal Al—Me and Al—OH groups. For **3**, the unit structure and molecular weight were controlled by the PA/TMA ratio reacted. The ^{27}Al NMR spectra of these products revealed that the coordination states of the aluminium atoms are different, depending on the O/Al atomic ratio in the products. In the case of **1**, which has a low O/Al ratio, the aluminium atoms are penta-coordinated, while in **2** and **3** hexa-coordination is involved. Based on these data the structures of poly(aloxanes) (**1–3**) are discussed.

Poly[(acyloxy)aloxane], consisting of an Al—O backbone and acyloxy pendants, has been utilized as the preceramics for alumina.[1–3] It is readily prepared by substitution of the side groups of the poly(alkylaloxane) which is the product of hydrolytic polycondensation of trialkylaluminium [eq. (1)]:

$$R_3Al \xrightarrow{H_2O} \left(\text{Al—O}\right)_n \xrightarrow{R'COOH} \left(\text{Al—O}\right)_n \quad (1)$$

(R on Al; OCOR′ on Al)

However, the structure of poly[(acyloxy)aloxane], as well as that of poly(alkylaloxane), is known to be very complex because of their intermolecular aggregation and has not yet been clarified completely. Recently,[2] we found that the coordination of their aluminium atoms could be changed by variation of the ligands. For example, the poly[(acyloxy)aloxane] with an appropriate amount of carboxylic acid ligand has a hexa-coordinate aluminium by chelation of both carboxylato and carboxyl ligands. In the present study, **1** was prepared by hydrolytic polymerization of trimethylaluminium (TMA) and was then converted to **2** and further to **3** by the substitution reactions of the side groups [eq. (2)]. For these three poly(aloxanes) the structural changes were studied in detail, especially by the application of ^{27}Al NMR spectroscopy.

$$Me_3Al \xrightarrow{H_2O} \left(\text{Al—O}\right)_n \xrightarrow{i\text{-PrOH}} \left(\text{Al—O}\right)_n$$

(Me on Al) **1** (OPr-i on Al) **2**

$$\xrightarrow{EtCOOH} \left[\begin{array}{c}(HOCOEt)_z\\ |\\ \text{—Al—O—}\\ |\\ OCOEt\end{array}\right]_n \quad (2)$$

3 ($0 < z < 1$).

EXPERIMENTAL

Materials

TMA was provided by Toso–Akzo Chemical Corp. (Tokyo, Japan) and was used without further purification. Tetrahydrofuran (THF) and 1,4-dioxane (DOX) were distilled over sodium metal under a nitrogen atmosphere. Isopropanol (IP) and propionic acid (PA) were supplied from Tokyo Kasei

* Author to whom correspondence should be addressed.

Kogyo, Ltd (Tokyo, Japan), and were purified by distillation.

Measurements

^{27}Al NMR spectra were measured at 20.7 MHz on a Varian FT-80 spectrometer. The chemical shift of the signals was recorded relative to an external standard: deuterated hexa-aqua-aluminium chloride $[Al(D_2O)_6]Cl_3$ in D_2O (50 wt%) at pD 1. ^{1}H NMR spectra were measured at 200 MHz on a Varian XL–200 spectrometer with tetramethylsilane as the external standard. IR spectra were measured by a JASCO IRA–1 spectrometer. Dilute solution viscosity was measured with a Ubbelohde type viscometer at 30°C for solutions (0.4 g dl^{-1}) of the polymer in a mixture of 1:1 (w/w) phenol (PhOH): 1,1,2,2-tetrachloroethane (TCE). Molecular weights were determined cryoscopically[4] with DOX as the solvent.

Poly(methylaloxane) (**1**)

All of the following reactions were carried out under an argon atmosphere. A solution of 0.56 g of water in 12.0 cm^3 of THF was added to a stirred solution of 2.24 g (31 mmol) of TMA at −40°C over a period of 1 h. The methane gas produced was collected for volumetry in one side of a U-tube containing glycerol as the liquid seal. The levels of the glycerol in both sides of the U-tube were balanced as the gas was introduced to determine the gas volume. After the addition was over, the solution was stirred at room temperature for 0.5 h to complete the reaction. The total amount of methane gas obtained was *ca* 1270 cm^3 (57 mmol). The solvent was then removed *in vacuo* to isolate the white powdery product (yield: ~ 2 g).

Poly(isopropoxylaloxane) (**2**)

The solution finally obtained in the above experiment was cooled to 0°C and the solution of 1.86 g (31 mmol) of IP in 2.0 cm^3 of THF was added dropwise over a period of 1 h. Methane gas of *ca* 700 cm^3 (*ca* 31 mmol) in volume evolved from the system. After the addition was over, the solution was stirred at 60°C for 1 h. The solvent was then removed *in vacuo* to isolate the white powdery products.

Poly[(propionyloxy)aloxane] (**3**)

Into the solution finally obtained in the above experiment, a THF solution containing a predetermined amount of PA (50 wt%) was added dropwise at room temperature. In the first stage of the addition a small amount of methane gas was produced. As PA was added further, the gas evolution ceased, and the solution gradually became viscous. When the PA ratio was over 0.7 relative to TMA a gel was formed. The gel turned to sol again at a PA/TMA ratio of around 2.0. After standing overnight at room temperature, the reaction system was poured into an excess amount of *n*-hexane to precipitate out the polymeric products, which were filtered and dried *in vacuo*.

RESULTS AND DISCUSSION

Primary structure of poly(aloxanes)

It is known that poly(aloxanes) are prepared by hydrolytic polycondensation of organoaluminium compounds.[4–9] In these reactions a stepwise hydrolysis and condensation mechanism has been considered as indicated in Scheme 1. However, the product obtained is usually an oligomer with a degree of polymerization less than 50, or a cross-linked polymer with poorer solubility.[4] We reinvestigated the hydrolysis of TMA with an equimolar amount of H_2O in THF at −40°C. The total amount of methane produced during the reaction was 1.84 mol relative to TMA, a little lower than the theoretical value of 2.0 obtained by assuming the complete condensation. The molecular weight of the condensate **1** was determined to be *ca* 570–650 by cryoscopy, which corresponds to *ca* 10 in degree of polymerization. Figure 1(a) shows the ^{1}H NMR spectrum of **1** in C_6D_6. The signals at δ −0.2 and 0.4 ppm were assigned to the pendent methyl and terminal hydroxy groups, respectively. From

$$AlMe_3 + H_2O \longrightarrow Me_2Al{-}OH + MeH \quad (3)$$

$$Me_2AlOH + Me_2AlOH \longrightarrow Me_2Al{-}O{-}Al(Me)OH + MeH \quad (4)$$

$$Me_2Al{-}O{-}Al(Me)OH + (n-2)Me_2AlOH \longrightarrow Me\text{-}(\text{-}Al(Me)\text{-}O\text{-})_n\text{-}OH + (n-2)MeH \quad (5)$$

Scheme 1.

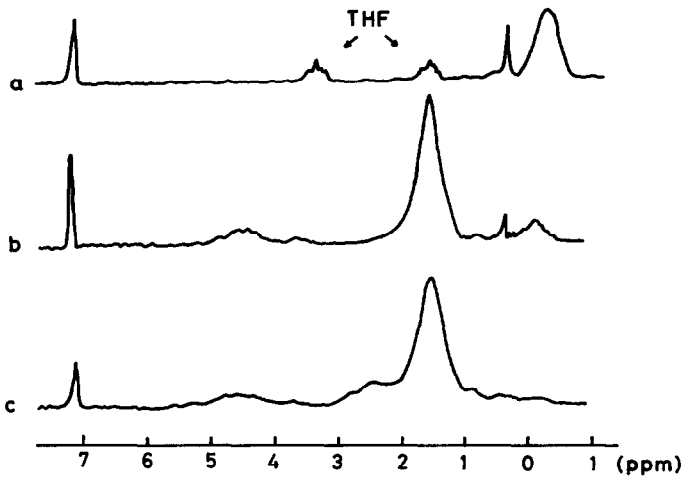

Fig. 1. ^{1}H NMR spectra of (a) **1**, (b) **2** (run 1) and (c) **3** with a PA/TMA ratio of 0.25 (run 2) in C_6D_6.

the integral ratio of these signals the degree of polymerization was calculated as 15, which is not so far from that determined by cryoscopy. These findings suggested that the condensation of the hydroxy groups and aluminium–methyl groups was incomplete, and that **1** comprises not only hydroxy groups, but also methyl groups in the terminals. The THF signals observed in the spectrum indicated that the complexation of THF and **1** is very strong.

In the second step, **1** was reacted with an equimolar amount of IP relative to TMA to obtain **2**. During the reaction almost one equivalent mol of methane gas was produced. The viscosity of the system, however, was not increased. Figure 1(b) shows the ^{1}H NMR spectrum of the product **2** in C_6D_6. Besides the signals of the isopropoxy group at δ 1.5 and 4.5 ppm, the signals at δ −0.2 and 0.5 ppm, which are ascribed to the Al—Me and Al—OH groups, respectively, were still noted. These peaks were found to appear even if an excess amount of IP was reacted with **1**. It is therefore assumed that **2** has both inactive methyl and hydroxyl groups in the chain terminals. Unfortunately, the molecular weight of **2** could not be determined by cryoscopy because of its poor solubility in DOX. Judging from its solution viscosity (see Table 1), **2** was considered to be an oligomer with a similar degree of polymerization to **1**.

In the third step **2** was reacted with various ratios of PA relative to TMA to substitute the side groups from isopropoxyl to propionyloxyl. On addition of the first portion of PA, evolution of a small amount of methane was observed. Its amount was *ca* 0.1 mol relative to TMA, which was slightly lower than the estimated value (0.16 mol relative to TMA) for the Al—Me remaining in **2**, perhaps due to experimental error. When the molar ratio (x) of PA relative to TMA was over 0.7, the system formed a gel state. The gel was re-solubilized to a viscous sol, as the PA/TMA ratio rose above 2.0. Table 1 shows the yield and the solution viscosity of the isolated product **3** as a function of the PA/TMA ratio. As the substitution reaction proceeded, the amount of the product increased because all reacted PA was taken up by the product. The solution viscosity also increased with increasing PA/TMA ratio. Figure

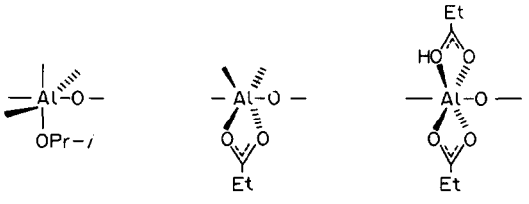
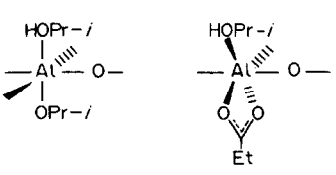
[d] Determined by the ^{1}H NMR spectra.
[e] At 0.4 g dl^{-1} in PhOH/TCE (50:50, v/v) at 30°C.

1(c) shows the ^{1}H NMR spectrum of **3** with $x = 0.2$ in C_6D_6. The methylene signal of the propanoyl group showed up around δ 2.5 ppm, and the signals at δ −0.2 ppm became negligibly small. It was therefore noted that both the terminal and isopropoxy groups were replaced by propionyloxy groups.

As we reported previously,[1] the poly[(acyloxy)aloxanes] (**3**) occurring as PA ratios below 1.0 should consist of both isopropoxylaloxane (I) and (propionyloxy)aloxane (P) units in a ratio corresponding to the feed ratio of PA. Similarly, the polymers occurring at PA ratios above 1.0 should comprise the PA-coordinated (propionyloxy)aloxane (PP) units and P units. With these assumed and with the presence of the terminal groups neglected, the theoretical yield of the product could be estimated for each run. On this estimated value the net yield was calculated, and is



shown in per cent in Table 1. As noted in runs 4–7 the yields exceeded 100%. This was ascribed to the incorporation of IP in the products even after the purification. Since the products with the higher PA/TMA ratios were insoluble in most organic solvents, their ^{1}H NMR spectra were measured in D_2O. The signals due to the isopropoxyl were shown at δ 1.3 (d, $J_H = 6$ Hz, CH_3, 6H) and 4.1 ppm (m, CH, 1H) in relatively larger intensities, together with the propionyl signals at δ 1.1 (t, $J_H = 6$ Hz, CH_3, 3H) and 2.3 ppm (q, CH_2, 2H). Although partial hydrolysis of their molecular chain had occurred in D_2O, the ratios of the isopropoxyl to propionyloxyl could be determined from these spectra, which are also shown in Table 1. With an increasing PA ratio in feed, the IP ligand ratio in the products decreased and became zero at the PA ratio of 2.0 where only PP units are involved. Therefore, it was supported that a considerable amount of IP was incorporated in the product as the ligands. In the present case the IP-coordinated



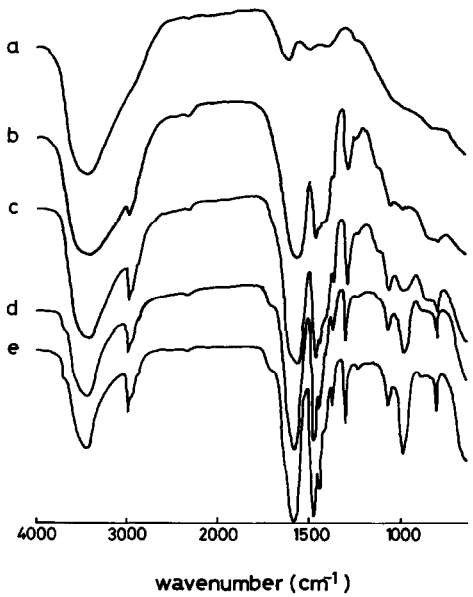


Fig. 2. IR spectra of (a) **2** and **3** with PA ratios of (b) 0.5, (c) 1.0, (d) 1.5 and (e) 2.0.

units like I′ and P′ are thought to be formed by the coordination of IP with aluminium atoms. As the PA/TMA ratio increased from 1.0 to 2.0, the units with two chelate ligands (PP) were formed and the IP ligands were eliminated.

Figure 2 shows the IR spectra of the products of runs 1, 3, 5, 7 and 9. The absorptions at 1570 and 1460 cm^{-1} are ascribed to the carboxylate groups. Even at a PA/TMA ratio higher than 1.0 only the carboxylate absorptions were detected, without any absorption of carboxylic acid noted. This is more support for the PA coordination with the aluminium atom in the PP unit. As the PA ratio increased, the absorption at 980 cm^{-1} due to ν_{Al-O} increased and the broad absorption at 3400 cm^{-1} due to Al—OH decreased. This suggests that the poly(aloxane) chain extended with an increasing PA ligand ratio. This is compatible with the increase of the solution viscosity shown in Table 1. The chain extension at higher PA/TMA ratios is considered to be allowed because intermolecular aggregation was dissociated by the coordination of PA with aluminium atoms and the chain terminals are freed to react with each other.

Coordination states of the aluminium atoms

It was indicated in the above section that the poly(aloxanes) (**1**–**3**) with a lower ratio of PA ligands, have tight chain aggregation. This aggregation may be ascribed to the sharing of the ligand by more than two aluminium atoms whose coor-

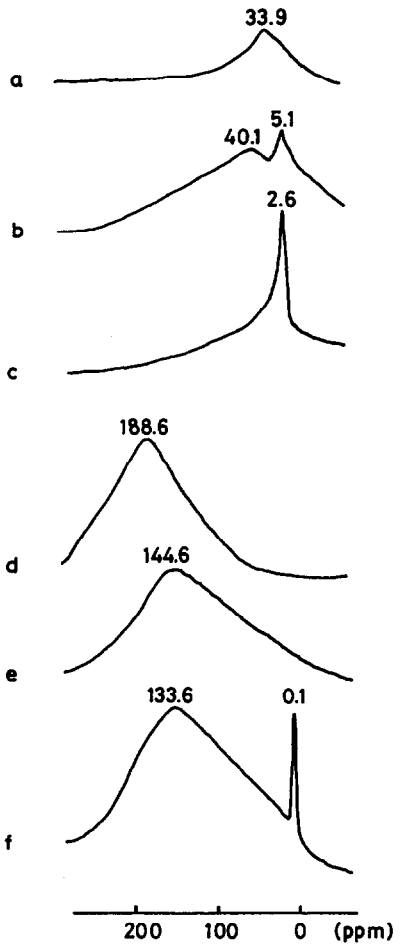

Fig. 3. ^{27}Al NMR spectra of (a) **1**, (b) **2** and (c) **3** with the PA ratio of 1.0 and their TMA complexes of (d) **1**, (e) **2** and (f) **3**.

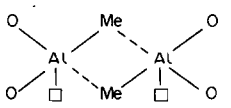
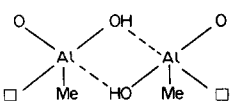
dination sites are unfilled. Therefore, knowledge of the coordination states of the aluminium atoms should be essential information for the structure analysis of those polymers. Figure 3 shows the typical ^{27}Al NMR spectra of **1**, **2** and **3** ($x = 1.0$) in THF/C_6D_6 (50:50, v/v). The spectrum of **1** consisted of a broad signal centred at δ 33.9 ppm, indicating the coordination state of the aluminium atoms to be penta-coordinate.[10–13] Since the aluminium atom of one unit of **1** is bonded with two oxygen atoms in the main chain and with one methyl side group, at least two other sites should be filled by other ligands. They may be inactive terminal hydroxy groups and the methyl groups which are known to occur in bridge formations as below (see Structures M and M′). The solvent THF



(M)



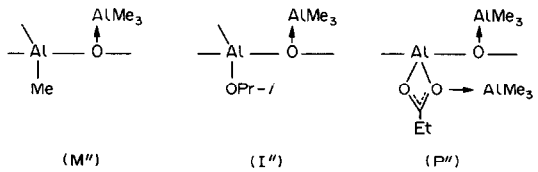
(M′)

and the oxygen atom of the main chain are also available for the coordination. So, the steric structure of **1** should be three-dimensional and possibly takes on various forms of coordination structure, as was discussed by Lasserre and Derouault[4] based on their IR data. This may be one reason for the various catalytic activities of **1** which acts as the cationic initiator and as the co-catalyst of Kaminsky catalysts.[14]

The ^{27}Al NMR of **2** showed two signals centred at δ 40.1 and 5.1 ppm. The broad low-field signal is ascribed to the penta-coordinated aluminium atoms, while the relatively sharp upfield signal is ascribed to the hexa-coordinated ones. Therefore, the aggregation state of **2** is intrinsically similar to that of **1**, except that the isopropoxy groups having higher coordination ability than Al—Me are able to be used as the ligands, so as to form the more stable hexa-coordination states.

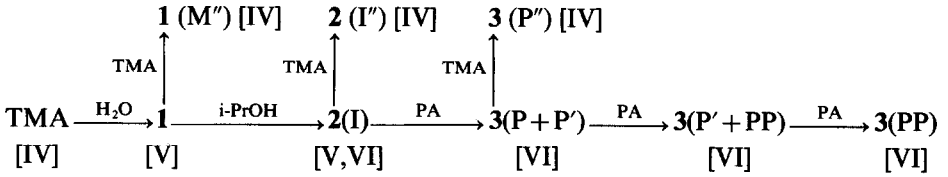
The ^{27}Al NMR of **3** with a PA/TMA ratio of 1.0, in return, showed a relatively sharp signal at δ 2.6 ppm, and most of the aluminium atoms of **3** are thought to be in a hexa-coordinate state. In this case four of the six coordination sites of the aluminium atoms are filled with two main chain oxygen atoms and a bidentate carboxylate ligand as shown in the P unit. Therefore, the vacant sites are filled with the eliminated IP and by mutual coordination of ligands. At higher PA/TMA ratios, the vacant sites are filled by the coordination of the carboxylic acid ligand to form the PP units. The signal of its ^{27}Al NMR spectrum, centred at δ 0 ppm, became broader and broader with an increasing PA ratio and finally undetectable at a PA/TMA ratio of 2.0.

When the products **1–3** were reacted with TMA, their signals shifted to lower fields as shown in Fig. 3(d)–(f). It is therefore known that the penta- and hexa-coordination states of their aluminium atoms had turned to tetra-coordinated ones. In the presence of TMA, many of the oxygen atoms of **1–3** which were effective ligands for aluminium atoms are complexed with TMA, and the aluminium atoms in the system turn to the tetra-coordination states, as shown in M″, I″ and P″. The hydroxy groups especially, are blocked by reaction with



(M″) (I″) (P″)

TMA. Thus, the coordination geometry of the aluminium atoms, either tetra-, penta-, or hexa-coordinated, seems to be determined by the O/Al atomic ratio in the system. In the case of **3**, a sharp signal



Scheme 2. (The Roman numerals indicate the coordination states.)

was shown at δ 0.1 ppm together with a broad peak at δ 134 ppm. The former should be assigned to the reaction products of TMA and IP or some unknown by-products occurring by the reaction of carbonyl groups and TMA. These results suggest that how the coordination sites of the aluminium atoms are filled is responsible for the aggregation structure of poly(aloxanes).

CONCLUSIONS

Scheme 2 shows the structural changes of the products on the basis of the above analyses. Poly(methylaloxane) **1** obtained by hydrolytic polymerization is an oligomer, consisting of the penta-coordinated aluminium atoms, with OH groups in the terminals. Poly(isopropoxylaloxane) **2** is also an oligomer, having both penta- and hexa-coordinated units, with OH and Me terminals. On the other hand, poly[(propionyloxy)aloxane] **3** consists of hexa-coordinate aluminium atoms, having the carboxylate ligand. When the PA/TMA ratio was above 1.0 the aluminium atoms are coordinated with carboxyl groups to form the units with the double chelate ligands. In the case of **1**, **2** and **3**, with relatively low PA ligand ratios, the oligomeric molecular chains are cross-linked tightly through ligand–aluminium atom coordination. The aggregation was released at high PA ratios, so that inter-oligomer condensation was allowed to give the high molecular weight product **3**. If **1**, **2** and **3**, with lower PA ligand ratios, are reacted with TMA, the coordination states of their aluminium atoms turn to tetra-coordination states because of the coordination of TMA with the oxygen ligands.

1. INTRODUCTION

A "Symposium-in-Print" on the chemistry of aluminium, gallium and indium is an opportunity to discuss one of the interesting problems which arises in any discussion of the low oxidation states of these elements, namely, the structure of the dihalides. By way of a starting point, it would be generally accepted that the synthetic and structural chemistry of the +III oxidation state of all three elements has now been developed to a high level of sophistication in both the inorganic and organometallic fields, although this should not conceal the fact that many of the experimental problems still present fascinating challenges. Both the possible lower oxidation states, +I and +II, are known, although the extent of the published information varies considerably from one element to another. It is well established that thallium(I) compounds are the dominant feature for this element in both the solid state and in aqueous solution, whereas much less is known about indium(I) species, and gallium(I) compounds are few in number. For aluminium and boron, there is little evidence to date of a significant M(I) chemistry.

The situation with the +II state is rather different. Boron dihalides are well known, but the aluminium analogues are not, while a small number of gallium, indium and thallium compounds have been prepared and investigated. The present paper, therefore, reviews the known structural and reaction chemistry of these species in the cases of gallium and indium, attempts to understand why some of the lacunae in this area exist, suggests a rationalization of the experimental data, and identifies some matters on which future research might prove fruitful. The treatment is not intended as a definitive review of the literature and relies heavily on earlier review articles[1–5] as sources of background information.

2. BINARY M^{II} COMPOUNDS

Little is known about the dihalides of aluminium, presumably because the large (estimated) negative enthalpy change in the process[1]

$$AlX_2(s) \longrightarrow \frac{1}{3}Al(s) + \frac{2}{3}AlX_3(s)$$

($\Delta H \sim -225$ kJ mol^{-1}) has prevented any detailed study of these substances. The dihalides of gallium can be made by heating equimolar quantities of GaX_3 and Ga metal (X = Cl, Br, I), or by halogenation of the metal, directly or by using mercury halides. Similarly, InX_2 compounds (X = Br, I) can be prepared by halogenation of the metal, by reduction of InX_3 by the metal in the liquid or solution state, or by the reaction between InX and InX_3. The study of phase diagrams has helped to some extent in the elucidation of the various lower halides of indium and in addition to InX_2, a variety of compounds such as In_2Cl_3, In_4X_7 (X = Cl, Br) and In_7Br_9 have been reported; there is serious doubt about the existence of $InCl_2$ as a pure substance.[5] Some, if not all, of these latter compounds clearly involve mixed oxidation state structures, as do the InX_2 species (see below), but we shall not consider them further in this discussion.

The solid-state structure of these dihalides of the Group III elements is one of the classical problems of main group chemistry. The conventional starting point for any discussion is that a M^{2+} ion of such an element must be paramagnetic and since the MX_2 compounds are without exception diamagnetic, one must postulate dimeric structures, either containing an M—M bond ($X_2M—MX_2$), or in the form of the mixed oxidation state ionic species $M^+[MX_4]^-$. The gallium compounds are all of this latter type for X = Cl, Br and I, on the basis of X-ray and spectroscopic data,[2] while for indium, InI_2 has been shown to be so by X-ray crystallography,[5,6,7] and the Raman spectrum of $InBr_2$ confirms the presence of the $InBr_4^-$ anion.[8] The only dihalide about which any structural question remains is $InCl_2$, but as indicated above the existence of this substance is in some doubt. Indium dicyanide is also reported to be $In[In(CN)_4]$, again from the vibrational spectrum.[9]

3. DERIVATIVES OF MX_2 COMPOUNDS

Both gallium and indium dihalides are now known to form a number of neutral and anionic halide derivatives for which M—M bonding has been established beyond question by crystallographic or spectroscopic methods. The most useful diagnostic tool, apart from a complete structural analysis, is Raman spectroscopy, which under favourable conditions can be used to identify both M—X and M—M vibrations; ν(Ga—Ga) decreases[10] from 235 cm^{-1} in $Ga_2Cl_6^{2-}$ to 122 cm^{-1} in $Ga_2I_6^{2-}$, and ν(In—In) modes have been assigned in the 150–120 cm^{-1} region.[11] Force constants have been reported for the M—M and M—X vibrations.

Hexahalogenogallate(II) anions have been identified as the intermediates in the reaction between the metal and aqueous HX, but a more convenient preparative route involves the direct electrochemical oxidation of a metal anode in aqueous or non-aqueous solutions of HX.[12] All three $Ga_2X_6^{2-}$ anions (X = Cl, Br, I) are known, with Me_4N^+, i-Pr_4N^+ or Ph_3PH^+ cations and the structures have been established by X-ray crystallography.[13–15] The $Ga_2X_6^{2-}$ anions are ethane-like molecules, with staggered configurations and the M—M bonds distances are approx. 2.4 Å (see Table 1 for actual values), with a significant lengthening in the order Cl < Br < I. The stretching force constant for the Ga—Ga bond also shows a significant softening in the same order.[10] Neutral M—M bonded derivatives of Ga_2X_4 can be prepared by simple methods which essentially involve the addition of N, P, As, O or S-donors to GaX_2 in benzene, in which these latter compounds are readily soluble. The identification of the Ga—Ga bond by Raman spectroscopy lead to the formulation of these species as $Ga_2X_4L_2$, or $X_2(L)GaGa(L)X_2$, and in the case of $Ga_2X_4(diox)_2$ (X = Cl, Br; diox = 1,4-dioxane) and $Ga_2Br_4(py)_2$, four-coordination at the metal and the presence of an M—M bond were confirmed by X-ray crystallography.[4,17–19]

The situation with indium(II) derivatives is rather similar. Neutral adducts of In_2X_4 can be prepared, either by direct reaction of a N- or P-donor ligand with In_2X_4,[21] or by reaction between InX and InX_3 in the presence of the donor (not for X = Cl),[22] and the structure of $In_2Br_3I \cdot 2tmen$ involves M—M bonding between five-coordinate indium atoms.[20] The anions $In_2X_6^{2-}$ have been prepared by treating InX_2 in solution with n-Bu_4NX, and the vibrational spectra confirm the $[X_3InInX_3]^{2-}$ structure in the solid state.[11] Anions containing Ga—In bonds have also been prepared and stabilized as the salts $(n\text{-}Bu_4N)_2[X_3InGaX_3]$ (X = Cl, Br).[23]

No analogous Al—Al bonded species appear to have been reported, but the compounds $Me_6Al_4B(NMe_2)_3$ and $Me_3Al_3(NMe_2)_3$, prepared by the reduction of Me_3Al by $(Me_4N)_4B_2$, have

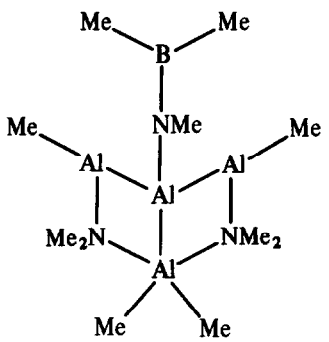
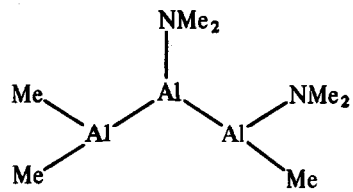
[a] See references for the details of these calculations; cross-comparisons between results for different metals may not be valid.

been formulated as[24,25]





The absence of simple dinuclear derivatives of Al_2^{4+} contrasts sharply with the behaviour of gallium and indium, and of boron, since there is an extensive chemistry based on B_2X_4 compounds (X = F, Cl, Br, NMe_2, OMe, OH) and their derivatives, which include both neutral adducts (e.g. $B_2Cl_4 \cdot 2Me_3N$) and anionic species (e.g. $B_2Cl_6^{2-}$).[16]

In the light of this information on the complex derivatives of the binary dihalides, the structures reported for various lower chalcogenides of gallium and indium are interesting. The crystalline compounds GaS, GaSe and GaTe all apparently involve species in which Ga—Ga bonding is significant, with Ga—Ga distances in the range 2.4–2.5 Å, and similarly, In—In distances in the order of 2.75 Å have been reported for In_6S_7 and In_6Se_7, in which formally In_2^{4+} units are present. These compounds might well prove to be useful starting materials for the synthesis of compounds containing M—M bonds.[4,5,12]

4. THE PROPERTIES OF THE M—M BONDS

The structural data presented thus far show that the binary halides of gallium and indium form ionic structures $M^+[MX_4^-]$ in the solid state, but that reaction with either neutral or anionic donor ligands invariably gives rise to derivatives of M—M bonded species. In trying to arrive at the reasons for this behaviour, it is important to consider the properties of the M—M bonds of gallium and

Table 2. Spectroscopic properties of M_2(g) molecules[a]

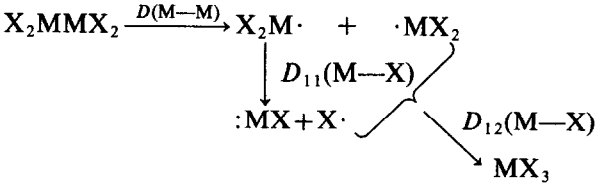
[a] Data from ref. 26.

indium, and to a lesser extent of the other elements of this group. A useful starting point is the spectroscopic information on M_2 molecules in the gas phase, given in Table 2. Although many important details are lacking, a number of useful conclusions do emerge. The ground state triplet identified for B_2, Al_2 and In_2 corresponds to the simple MO bonding scheme (e.g.) $(\sigma_g 2s)^2(\sigma_u^* 2s)^2(\pi_u 2p)^2$. The bond dissociation energies, D, decrease monotonically down the group and although the uncertainties in the values are substantial, there can be little doubt that M_2 molecules are all reasonably stable against dissociation into the atoms in the gas phase. There is unfortunately an absence of results on D(M—M) in M_2X_4 compounds, with the exceptions of B_2F_4 and B_2Cl_4, for which D is 303 and 330 kJ mol^{-1}, respectively.[16] These values are only slightly higher than D for B_2 itself (280 kJ mol^{-1}) and if this correspondence were to extend to other M_2X_4 species, one would conclude that M—M bonding in M_2X_4 molecules and their derivatives will be weak but certainly not negligible. A further similarity between the B—B bond in B_2 and that in B_2X_4 lies in the bond length, which shows an increase of 0.1–0.2 Å in the dihalide relative to B_2. There are two obvious factors which could explain both the weak bonding and the effect of the atomic number (Z) on the bond strength. Firstly, the atomic orbital overlap terms presumably become smaller as Z increases and secondly, the decreasing electronegativity of the elements implies an increasing Coulombic repulsion between the constituent atoms. We shall return to this latter point below.

The caveat that obviously applies to such arguments is that all the values have been derived for the gas phase, where little inorganic chemistry is actually studied. We can gain some idea of the other factors involved by considering the overall thermodynamics of the processes, acknowledging from the outset that the lack of bond dissociation energies will prevent any definitive quantitative analysis. The component parts of the enthalpy changes in

$$X_2MMX_2 \xrightarrow{(1)} MX + MX_3 \xrightarrow{(2)} M^+MX_4^-$$

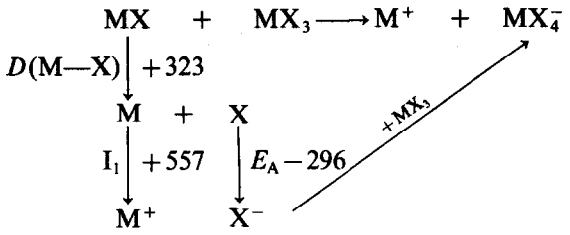
can be broken down into two arguments, the first of which is;



The bond energies D(M—M) for gallium and indium in M_2X_4 are presumably 150–100 kJ mol^{-1} (c.f. Table 2). The energies for removing a halogen atom from MX_2 to form MX (D_{11}) and for adding the same atom to MX_2, giving MX_3 (D_{12}), should be similar to each other, so that $D_{11}-D_{12} \approx 0$. Finally, if M_2X_4 has the same planar D_{2h} stereochemistry as B_2X_4,[16] there should be no significant rearrangement of energy terms in the formation of either MX or MX_3. At a conservative estimate, the overall ΔH for the disproportionation of X_2MMX_2 in the gas phase can

be taken as being in the order of $+200$ kJ mol^{-1}.

The remaining step is the formation of the ions by



and here some of the terms are known, as exemplified in the cycle for M = In, X = I, but again the uncertainties constitute a major difficulty. The energy for the formation of the $X_3M—X^-$ bond and for the subsequent rearrangement from C_{3v} to T_d symmetry, should contribute large negative enthalpy terms (see Table 3) and a reasonable conclusion is that ΔH for eq. (2) does not exceed $+100$ kJ. The very tentative conclusion then is that ΔH for the gas phase process

$$X_2MMX_2 \longrightarrow M^+ + MX_4^- \tag{3}$$

is of the order of $+300$ kJ. The difference between this value and that for the analogous solid state process

$$M_2X_4(c) \longrightarrow M^+[MX_4]^-(c) \tag{4}$$

lies in $\Delta H_{sub}[M_2X_4(c)]$ and U, the lattice energy for the ionic solid $M^+[MX_4]^-$. If $-[U+\Delta H_{sub}] > 300$ kJ, then eq. (4) will lie to the right, ignoring any entropy factors, which will in any case presumably favour the formation of the ionic species. The calculated lattice energy[28] for $Ga[GaCl_4]$ is 547 kJ mol^{-1}, and similar values are found for $Cs[AlCl_4]$ (486 kJ mol^{-1}) and $Cs[GaCl_4]$ (495 kJ mol^{-1}), so that there is every reason to conclude that in the solid state, $M[MX_4]$ will indeed be the stable form of the gallium and indium dihalides.

This highly simplified argument has the virtue of emphasizing that the lattice energy, together with the various M—X bond energies, affect the direction of eq. (4) to a much greater extent than does the dissociation energy of the weak M—M bond. The identification of the ionic structure for M = Ga and X = Cl, Br or I, and for M = In and X = Br or I, appears to give some credence to the above argument and the apparent absence of $In^+[InCl_4]^-$ from the list (see above) may be a consequence of the magnitude of the D(In—Cl) terms in that particular system. Table 3 shows the variations in some of the terms used in the above argument.

Table 3. Metal–halogen bond dissociation energies and related data (in kJ mol^{-1})[a]

5. INTRAMOLECULAR HALIDE TRANSFER

The above arguments give a credible rationale for the existence of "MX_2" as the ionic $M[MX_4]$ mixed oxidation state species in the solid state. The only known authenticated derivatives of this same structural type are those compounds $[InL][InX_4]$ (L = 18-crown-6, cyclam; X = Cl, Br, I) in which the ligands were deliberately chosen to stabilize the In^+ cation. What additional factors beyond those just discussed must be considered to explain the apparently complete dominance of M—M bonded structures in the derivatives of M_2X_4 with neutral or anionic ligands? One arises immediately from the Coulombic repulsion in the M—M bond, namely, that by adding negative charge to the metal atoms the process of ligation would be expected to stabilize the M—M bond and hence affect the balance of the terms in the thermodynamic arguments. Furthermore, equations such as eq. (4) now become

$$M_2X_2L_2 \rightarrow [ML][MX_4L], \tag{5}$$

and eq. (1) must be rewritten as

$$M_2X_4L_2 \rightarrow MX \cdot L + MX_3 \cdot L \tag{6}$$

with a new set of enthalpies of complexation, themselves dependent upon ligand, halide and coordination number, to be considered. In sum, it is safe to conclude that the M—M bond dissociation energy is certainly not the single most important factor involved.

A different type of argument can now be considered. There are two investigations which bear upon the mechanism of halide transfer processes such as eq. (6). The first involved the study of the equilibria

$$In_2X_6^{2-} \rightleftharpoons InX_2^- + InX_4^- \tag{7}$$

in non-aqueous media by ^{115}In NMR spectroscopy[29] and showed that K lies in the order I > Br > Cl. The second approach[30] concentrated upon the inverse, namely the reaction

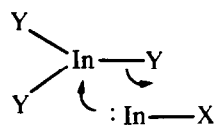
$$InX + InY_3 \longrightarrow X(Y)InInX_2, \tag{8}$$

which corresponds formally to the oxidative insertion of In^I into the In^{III}—Y bond of the trihalide. A number of similar oxidation reactions are known,[31] including

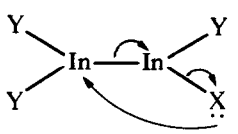
$$In + \begin{cases} Ph_2S_2 \longrightarrow XIn(SPh)_2 \\ Ph_3SnX \longrightarrow Ph_3SnInX_2 \\ RI \longrightarrow RIn(X)I, \end{cases}$$

and in all these cases one can write a scheme which allows for electron counting,

e.g.



but which does nothing to explain the detailed electron transfer processes (see below). Equally relevant to the present discussion is that the intermediate



can be used to explain both oxidative addition and its reverse, the reductive elimination process of eq. (1). The second important role of donor ligands on the metal is that coordinative saturation must minimize, and in the ultimate case, prevent the halide transfer process which is an essential accompaniment to the disproportionation (or reductive elimination).

It follows that coordination at the metal centres in M_2X_4 must favour stabilization, both thermodynamically and kinetically. The coordinative saturation argument suggests that Ga_2X_4 species should be more readily stabilized than the In_2X_4 analogues, since gallium typically forms

complexes of lower coordination number than indium. The stabilization of M_2X_4 as $M_2X_6^{2-}$ anions is also interesting in this context, since one would again predict a higher stability against disproportionation for $Ga_2X_6^{2-}$ than for $In_2X_6^{2-}$, for the reason just stated and it has been reported[12] that $Ga_2X_6^{2-}$ anions do not disproportionate in solution, unlike their indium analogues. Furthermore, lattice energy effects should serve to stabilize salts in the solid state even if the anions are of marginal stability in terms of disproportionation in solution, and the salts of $In_2X_6^{2-}$ follow this pattern of behaviour. Finally, these arguments suggest that the preparation of stable M—M bonded derivatives of gallium and indium is likely to be achieved most easily by using ligands which are good donors and poor leaving groups. Steric bulk will also obviously help in preventing ligand transfer. The results obtained to date, including the recent preparation of $[M(O_2C_6X_4)phen]_2$ (M = Ga, In; $O_2C_6X_4$ = substituted *o*-diolate; X = Cl, Br) confirm these conclusions.[32] The topic of organometallic derivatives is beyond the scope of the present discussion (cf. ref. 12) except to note that the recent[33] preparation and characterization of the uncomplexed In—In bonded molecule $In_2[CH_3(SiMe_3)_2]_4$, for which r(In—In) = 2.828(1)Å, underlines the above conclusions.

It is interesting and helpful to look at the chemistry of the M—M bonded molecules of tin. Firstly, the bond dissociation energy of Sn_2 in the gas phase is 192 kJ mol^{-1}, while in the R_6Sn_2 species (R = Me, Ph) the corresponding values are 265 ± 15 kJ mol^{-1}, so that the parallel arguments for Ga—Ga etc. receive some justification. Secondly, while the organotin species are stable, the inorganic compounds Sn_2X_6 (X = H, Cl) are unstable, and Sn_2Cl_6 disproportionates above -65°C to give $SnCl_2 + SnCl_4$, although the acetato compound is more stable. As in Group III, the M—M bonded inorganic germanium compounds are apparently more stable than their heavier analogues.[34]

6. MONONUCLEAR DERIVATIVES OF M^{2+} IONS

As noted earlier, there are no authenticated instances of stable mononuclear compounds of M^{2+} ions for M = Al, Ga or In, and it is worth considering the reasons for this situation, other than the issue of dimerization. The absence of bond energy data is again a handicap, but it is possible to arrive at one useful conclusion from the ionization and other spectroscopic data given in Table 4, and by treating the M—X bonds as being purely ionic. The thermodynamics of forming MX_2 or MX_3 in the gas phase involve the sequences

$$\left.\begin{array}{l} M(g) \rightarrow M^{2+}(g) \\ X_2(g) \rightarrow 2X(g) \rightarrow 2X^-(g) \end{array}\right\} \rightarrow MX_2(g)$$

and

$$\left.\begin{array}{l} M(g) \rightarrow M^{2+}(g) \rightarrow M^{3+}(g) \\ \tfrac{3}{2}X_2(g) \rightarrow 3X(g) \rightarrow 3X^-(g) \end{array}\right\} \rightarrow MX_3(g),$$

Table 4. Ionization energies (I_n) and related data for elemental Al, Ga, In and the halogens (in eV)

Element	I_1	I_2	I_1+I_2	I_3	$I_1+I_2+I_3$	$ns^1 \rightarrow np^1$ for $M^{2+}(g)$
Al	5.98	18.82	24.80	28.44	53.24	6.70
Ga	6.00	20.51	26.51	30.70	57.21	8.19
In	5.79	18.86	24.65	28.03	52.68	7.36

Element	Bond dissociation energy D	Electron affinity E_A	$-(D-2E_A)$	$-(\frac{3}{2}D-3E_A)$
F	1.65	3.45	5.25	13.28
Cl	2.51	3.61	4.71	10.37
Br	2.00	3.37	4.74	11.22
I	1.57	3.06	4.55	12.00

Table 5. Total energies for the formation of ionic components of $MX_2(g)$ and $MX_3(g)$

System		$M^{2+}+2X^-$	$M^{3+}+3X^-$
Al	F	19.6	40.0
	Cl	20.1	42.9
	Br	20.1	42.0
	I	20.3	41.2
Ga	F	21.3	43.9
	Cl	21.8	46.8
	Br	21.8	46.0
	I	22.0	45.2
In	F	19.4	39.4
	Cl	19.9	42.3
	Br	19.9	41.5
	I	20.1	40.7

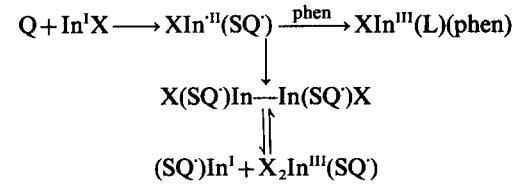
and the various atomic terms can be easily evaluated and compared. The energy differences between the formation of $[M^{2+}+2X^-]$, and of $[M^{3+}+3X^-]$, are surprisingly constant for the three elements, with the average values for X = Cl, Br or I being 21.9 eV for Al, 24.2 eV for Ga and 21.1 eV for In, and it may be relevant that the largest energy differences found for gallium, the element for which M^{II} compounds are apparently most easily prepared. For MX_2 to be stable in the gas phase, $\bar{D}(M^+—X^-)$ must be *ca* 11 eV, since the total energy input to form the $M^{2+}+2X^-$ ions is of the order of 19–22 eV (Table 5). By the same token, $\bar{D}(M—X)$ for MX_3 should be *ca* 14 eV for Al, 15 eV for Ga, and 14 eV for In.

The actual $\bar{D}$ values for a number of MX_3 molecules are given in Table 3 and are substantially lower than the values required by this ionic argument. The most important conclusion to be drawn is that there is no reason to conclude that the non-existence of MX_2 molecules arises from an inaccessible set of atomic states, or from the lack of thermodynamically stable M—X bonds. The absence of simple derivatives of M^{2+} in the solid state must therefore come down to lattice energy effects which promote disproportionation (see above), and/or to the reactivity inherent in the unpaired electron, which as Table 4 shows, can be promoted in the gaseous ion into a *p*-orbital at the cost of 600–800 kJ mol^{-1}.

This raises the possibility of the preparation of a kinetically stable monomeric M^{II} compound. In the light of the arguments developed here, any such compound would require bulky ligands to hinder dimerization and should be covalent in order to minimize lattice effects. The ligands should transfer minimum electron density to the metal, since this would tend to constrict whichever orbital contains the unpaired electron and thereby reduce the tendency to dimerize or to react with electrophilic reagents. Such requirements should not be beyond experimental reach.

7. M^{II} SPECIES AS REACTION INTERMEDIATES

We have recently studied some reactions in which good evidence has been obtained for indium(II) species as intermediates and the general conclusions are relevant to the present discussion. The reaction of In^IX (X = Cl, Br, I) with tetrahalogeno-*o*-quinones (*o*-$O_2C_6X_4$; X = Cl, Br) in non-aqueous media yields derivatives of $XIn(O_2C_6X_4)$, in which indium is in the +III state and the ligand is the *o*-diolate.[35] These conclusions depend on spectroscopic (especially ^{13}C NMR) and crystallographic studies. There are clear indications of paramagnetic species as intermediates, but these systems are much less suitable for study than are those involving InX and *o*-$O_2C_6H_2Bu^t_2$ or phenanthrene-9,10-quinone, for which electron spin resonance spectroscopy has demonstrated unequivocally that semiquinone radicals are involved in these processes.[36] The details of the argument have been given elsewhere, but can be summarized in Scheme 1. Strong oxidants, aided by electron pair donors, yield the indium(III)-*o*-diolato derivative, but with milder oxidants the final solution



Q = *o*-quinone; $SQ^{\cdot -}$ = *o*-semiquinonate anion; L = *o*-diolato anion; phen = 1,10-phenanthroline.

Scheme 1.

contains both In^{I} and In^{III} species, which have quite different and identifiable coupling constants for the unpaired electron. The ESR results have been supported by the independent preparation and study of $(SQ^{\cdot})In^{I}$ and $(SQ^{\cdot})InX_2$ compounds of $o\text{-}O_2C_6H_2Bu^{t}_2$, including a crystallographic investigation of $(SQ^{\cdot})InBr_2 \cdot (\gamma\text{-picoline})_2$ which confirmed the presence of the semiquinone form of the ligand.[36,37] These results are in good agreement with the arguments presented in the present paper, in that the one-electron oxidation of InX can and does occur and the resultant indium(II) complex is thermodynamically stable, but dimerizes rapidly to an In—In bonded molecule which undergoes intramolecular halide transfer as a means of disproportionation.

The identification of one-electron transfer in these reactions with *ortho-* (and *para-*) quinones and in others involving low oxidation state main group compounds such as tin[38,39] raises the question of the generality of such processes, as opposed to the two-electron transfer generally assumed to occur with these molecules. It should be emphasized that detailed mechanistic evidence is often lacking for this latter premise, since it is generally the stoichiometry alone (e.g. $InX + X_2 \rightarrow InX_3$) which provides the basis for the assumed mechanism. One critical experimental factor is that the oxidizing agents themselves generally imply a two-electron stoichiometry (e.g. $X_2 \rightarrow 2X^{-}$) and only when one-electron oxidants are used is the M^{II} state identified. There is clearly considerable scope for developments in this field and for other developments in the area of the low oxidation states of these elements.

1. INTRODUCTION

Structural features of transition metal alumohydrides evaluated by X-ray structural analysis are summarized and discussed. The role of these compounds in the catalysis of homogeneous hydrogenation and isomerization of hexene-1 is also considered.

2. STRUCTURAL CHEMISTRY OF TRANSITION METAL ALUMOHYDRIDES

More than 40 years have passed since the first publication of the synthesis of a novel type of coordination compound—alkali metal alumohydrides.[1] These have had a considerable impact on various branches of modern chemistry including both synthetic routines and the theory of chemical bonding. As reagents, alkali metal alumohydrides have found various applications not only in inorganic chemistry as a main source of hydrogen in the preparation of many molecular and ionic metal hydrides, but also in organic chemistry as a powerful and selective reducing agent. Accordingly, the considerable practical and scientific significance of these compounds stimulated intensive studies in the field of aluminium hydrides, the highest research activity being in the mid-sixties. One of the fundamental results obtained was the evidence for the ionic nature of all alumohydrides of alkali and rare earth metals as well as of "onium" cations both in solution and the crystalline state.[2–5] Even in lithium alumohydride, the most "covalent" compound in this series, the tetrahedral anion AlH_4^- has an almost ideal structure ($r_{Al-H} = 1.55 \pm 0.03$ Å, $\angle_{HAlH} = 109.5°$).[2] Interatomic distances, Li—H, in $LiAlH_4$ being in the range 1.84–2.16 Å are comparable with those in ionic lithium hydride (2.04 Å[6]), providing further evidence for the ionic structure of the former compound. Taking into account the structural data, the splitting of the F_2 stretching frequency in the IR spectrum of $LiAlH_4$ may be rationalized in terms of the crystal-field effect, the symmetry of which decreases in the series Cs–Li,[3] rather than in terms of the "self-symmetry" of the anion[7] on assumption of the covalent Li—H—Al bridging mode.

Alumohydride cations are solvated in aprotic donor solvents. As a result, the effective radii increases leading to the formation of contact or separated ion-pairs.[8,9] Elimination of the crystal-field effect eliminates the degeneracy, and spectra of all alumohydrides contain two (IR) or four (Raman) bands which are allowed for an ideal T_d tetrahedron of AlH_4. As a rule, rare earth

alumohydrides crystallize as ionic solvates $L_nM^{2+}(AlH_4)_2^-$ and the L—M bond strength decreases in the series Mg → Ba. The alkali metal solvates $L_nM^+AlH_4^-$,[9-12] where L = Et_2O, THF, etc., decompose on crystallization (Na, K, Rb, Cs) or on mild heating (Li).[6] Whereas ionic solvates, $MAlH_4$, with the macrocyclic polyether (15-crown-5) are rather stable and soluble even in aromatic solvents.[13] To this end, there is only ionic bonding between the metals in non-transition metal alumohydrides and onium cations, and all the data available provide no hope for discovering novel structural types.

In marked contrast with the impressive achievements in the chemistry of non-transition metal complexes, progress in the chemistry of transition metal alumohydrides (TMA) has not been as evident. This was the time of preliminary search. During the fifties, sixties and seventies, the publications were rare and were mostly descriptive (see the references cited in 14). The slow progress in this field was probably due to unclear perspectives in the utilization of TMA, their low stability and the absence of physico-chemical methods for structural analysis. The only method for structural determinations was IR spectroscopy. There are many examples in chemistry, however, when erroneous conclusions have been made on the basis of only one type of structural information. Such a conclusion concerning the ionic structure of TMA has been made on the basis of the Al—H stretching frequencies in the region 1600–1850 cm^{-1}, i.e. in the region typical of non-transition metal alumohydrides. This rationalization seems to be very strange now since even in the sixties it was known that the compounds closely related to alumohydrides, i.e. transition metal borohydrides, form molecular complexes $L_mMH_{3-n}BH_{1+n}$ with bridging hydrogens (see ref. 15). Despite this, until the late seventies (and in some cases until now) there has been a point of view that TMA obtained by exchanging the corresponding chlorides with $M'AlH_4$ in aprotic solvents (δ-donors) appear to be salt-like hydrides with ionic structure. This early stage, the stage of creation and preliminary studies, may be termed *synthetic*.

The ligands which stabilize TMA came into use in the mid-seventies. This stimulated studies under ambient conditions and posed the question of possible applications of TMA. This work manifested a *structural* stage in the chemistry of TMA, and was associated with the direct structural investigations of the compounds obtained. The crucial point in the isolation of TMA was the utilization of two different ligands, i.e. a π-donor cyclopentadienyl (C_5H_5 = Cp) ligand and σ-donor phosphines and phosphites. Table 1 shows both the composition and some typical structural characteristics of TMA evaluated by X-ray crystallography. There is also a large body of data obtained by spectral means (NMR, IR, ESR) which will be used in the present review as illustrations to structural works.

Experimental evidence reveals that despite the different nature of cyclopentadienyl and phosphine ligands the general features of complex formation, structural types and the bonding between metal heteroatoms, as well as some chemical and physico-chemical properties of TMA are very similar. This provides confidence to assume that in all other cases when the synthesis of TMA is carried out in common σ-donor solvents (Et_2O, THF, DME, etc.) the reactivity patterns and the structure of the products formed will not differ markedly from the complexes with cyclopentadienyl and phosphine ligands considered below.

There are three main types of reactions leading to TMA, mixed hydridoalkyl transition metal complexes or halohydride transition metal complexes. These are various exchange reactions, eqs (1)–(3):

$$2(Me_3P)_4OsCl_2 + 4LiAlH_4 \xrightarrow{THF} [(Me_3P)_3HOs(AlH_4)]_2 + 2AlH_3 \cdot L + 2LiCl \quad (1)$$

$$(Cp_2TiCl)_2 + 2M'AlH_4 \xrightarrow{L} 2Cp_2TiAlH_4 \cdot L + 2M'Cl \quad (2)$$

$$Cp_2TiBH_4 + LiAlH_4 \xrightarrow{L} Cp_2TiAlH_4 \cdot L + 2LiCl, \quad (3)$$

exchange redox reactions, eqs (4) and (5)

$$Cp_2NbCl_2 + 2LiAlH_4 \xrightarrow{L} Cp_2NbAlH_4 \cdot L + AlH_3 \cdot L + \tfrac{1}{2}H_2 + 2LiCl \quad (4)$$

$$Cp_2TiCl_2 + AlH_3 \xrightarrow{L} Cp_2TiH_2AlCl_2 \cdot L + \tfrac{1}{2}H_2, \quad (5)$$

and addition reactions, eqs (6) and (7), in which metal halide or alkyl halide behaves as a pseudobase

$$(Cp_2TiX)_2 + AlH_{3-n}X_n \cdot L \xrightarrow{L} Cp_2TiH_2AlH_{1-n}Cl_{n+1} \cdot L \quad (6)$$

$$Cp_2WH_2 + AlR_3 \xrightarrow{ArH} Cp_2WH_2AlR_3. \quad (7)$$

In some cases the addition and exchange reactions may be accompanied by redox processes, eq. (8):

$$(Me_2PhP)_2ReH_7 + AlR_3 \xrightarrow{ArH} (Me_2PhP)_2H_4ReH_2AlR_2 + RH. \quad (8)$$

Solvents play an important role in all reactions and their successful choice often guarantees isolation of products as monocrystals suitable for structural determinations. In particular, the interaction between Cp_3UBH_4 and $LiAlH_4$ to yield Cp_3UAlH_4 occurs in ether, while in THF the product undergoes decomposition with hydrogen evolution.[46] In contrast, reaction (1) can be carried out in THF but not in ether.[47] It should be pointed out, however, that oxygen-containing solvents and especially THF appear to be very "fine" ones for reactions of metal hydrides, since the latter can undergo ready solvolysis to afford the corresponding alkoxides. This phenomenon has already been mentioned in the literature in connection with the investigation of homonuclear aluminium hydrides (see, for example, ref. 48), although this observation was not supported by structural data. In the case of TMA, the complexes $[(Me_3P)_3H_3W(AlH_3OBu)]_2$[26] and $[Cp_2TiH_2Al(H)OMe]_2$[25] were isolated from THF and DME solutions (and then characterized by X-ray crystallography) as a result of decomposition of solvent molecules.

The literature also contains many examples of the formation of TMA as intermediates or unstable products, the decomposition of which provides homonuclear transition metal hydrides.[49-51,52]

Preliminary information about the presence of terminal Al—H bonds in TMA is available from IR spectral data. It should be remembered, however, that the known Dautel–Zeil rule which links the Al—H stretching frequency in molecular complexes and the coordination number of aluminium in TMA[52] does not hold. In particular, the wavenumbers of $AlH_3 \cdot L \cdot L'$ complexes, the coordination number of aluminium in which is five, occupy the range 1670–1750 cm^{-1},[53] while for the majority of TMA complexes having the same coordination number they are higher than 1750 cm^{-1}, i.e. as typical of the compounds with a coordination number of four. The assignment of bridging M—H—Al bonds in TMA becomes a rather reliable method when deuterium labelled species are used, since, as a rule, the corresponding bands do not overlap with those from the organic portions of the molecules. The bands due to the bridging μ_2-H ligands are seen at 1200–1650 cm^{-1}, while those due to the μ_3-H ligands are observed at 950–1200 cm^{-1}. Different types of M—H bond can also be observed by NMR, which usually provides more reliable information {as in the case of $[(Me_3P)_3H_3WH_2AlH_2]_2$} compared with IR data. Various applications of NMR to TMA are discussed in detail elsewhere.[52] It should be pointed out that because of the specific magnetic properties of the aluminium nucleus and because of the technical problems involved with the preparation of solutions of required quality, the use of NMR for analysis of TMA is strongly limited. Paramagnetic TMA can be investigated but in some cases is not successful using ESR. For example, it was concluded on the basis of ESR data that hydride and alkyl complexes of aluminium and titanocene afford heterometallic compounds with  bridges.[54] Until now ESR was the main diagnostic tool for investigation of solutions of these compounds.[55]

Unfortunately, neither of the spectral methods aimed at M—H bridges gives a true structural picture without making assumptions. Therefore application of diffraction structural methods involving monocrystals is necessary for further progress in the chemistry of TMA, since it is the case that even with a vivid imagination one cannot design the structures which are in fact realized.

The structures of TMA disclosed by X-ray crystallography show that they are all molecular compounds. In general, TMA can be classified according to the number of metal nuclei in a molecule, starting from the simplest dinuclear species to the more complex polynuclear complexes.

Table 1. Composition and main bond distances (in Å) in TMA according to X-ray structural data

Compound	M—Al	M—H	Al—H	Al—X	M—M	Al—E	M—L	References

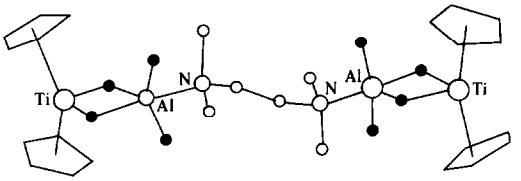
Terminal X = H, Cl, Alk; bridging and terminal E = O, N; L is any ligand except hydride bound to the transition metal.

[a] The distance from the mid-point of the Cp-ring.

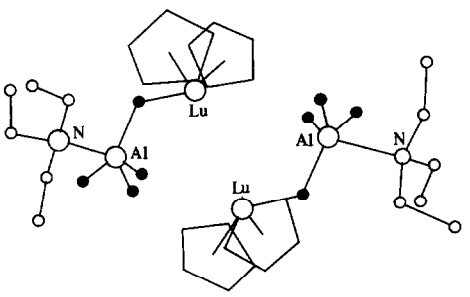
2.1. Dinuclear transition metal alumohydrides

Dinuclear TMA with a purely hydridic environment around the aluminium atoms are probably formed in solution in all exchange reactions of transition metal halides with alkali metal alumohydrides under carefully controlled conditions. On crystallization, however, the products may undergo either dimerization liberating solvent molecules, or decomposition producing hydrogen to afford polynuclear conglomerates or homonuclear hydrides.

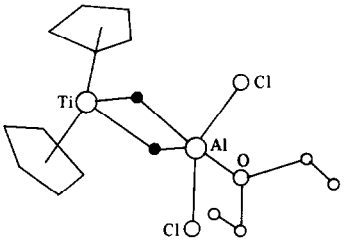
Because of the low stability of the dinuclear complexes with a hydridic environment, the structures of only two such compounds are presently available. The first compound is formed at the expense of stabilization of the alumohydride molecule by a bidentate base (TMEDA) and its formula is $[Cp_2TiH_2AlH_2]_2 \cdot TMEDA$ (I).[16] The titanium and aluminium atoms are bonded through the double, strongly asymmetric Ti—H_2—Al bridge. The polyhedron around aluminium is a trigonal



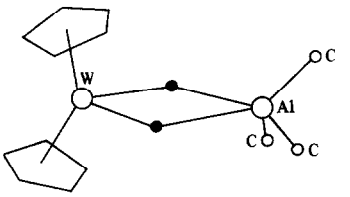
(I)



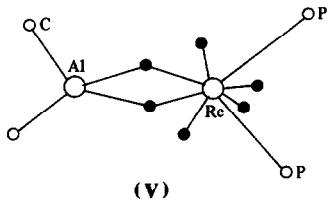
(II)



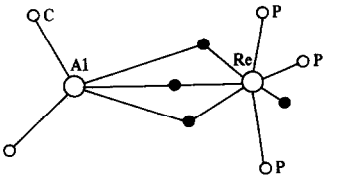
(III)



(IV)



(V)



(VI)

bipyramid with nitrogen and a bridging hydrogen in the axial positions. The second complex, $Cp_2LuHAlH_2 \cdot NEt_3$ (II), is a unique example of the lutetium and aluminium bonding through a single Lu—H—Al bridge,[17] although the coordination polyhedron around aluminium is the same as in I. This compound, however, is produced by the homolytic cleavage of the Lu  Lu fragment in the tetranuclear complex $(Cp_2LuH)_2(AlH_3 \cdot NEt_3)_2$ under the action of high-energy X-rays, eq. (9):

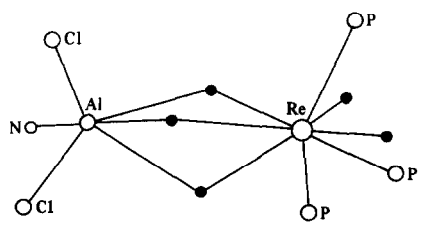
$$(Cp_2LuH)_2(AlH_3 \cdot NEt_3)_2 \xrightarrow{h\nu} 2Cp_2LuHAlH_3 \cdot NEt_3. \quad (9)$$

Substitution of halo or alkyl ligands for terminal hydrides leads to some stabilization of dinuclear complexes. These compounds are generally obtained by addition reactions. The complexes Cp_2Ti $H_2AlCl_2 \cdot OEt_2$ **(III)** and $Cp_2WH_2AlMe_2$ **(IV)** can be prepared by reacting the corresponding transition metal species, $(Cp_2TiCl)_2$, and Cp_2WH_2 with $AlH_3 \cdot L$[18] and $(AlMe_3)_2$,[19] respectively. As in **I**, the metal heteroatoms in complexes **III** and **IV** are bonded via the double M—H_2—Al bridge, suggesting an intramolecular rearrangement with chlorine migration from titanium to aluminium during the formation of **III**. It should be emphasized that the migration of chloro, alkyl and other ligands from titanium to aluminium and vice versa plays an important role in titanocene chemistry and in some cases the process is a key factor for understanding the high reactivity of these species in the hydrogenation and isomerization of alkenes.[36–38]

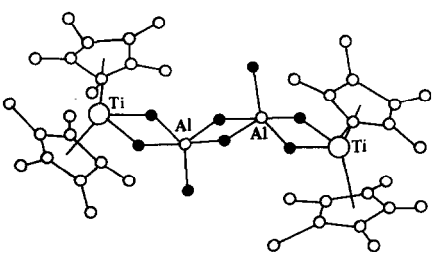
In $(Me_3P)_3H_4ReH_2AlMe_2$ **(V)**[20] the aluminium atom has a rare tetrahedral environment with a double Re—H_2—Al bridge, although also known is the related compound $(Ph_2MeP)_3HReH_3AlMe_2$ **(VI)**[20] where aluminium is five-coordinated and its bonding with rhenium occurs through a triple Re—H_3—Al bridge. An example of octahedral coordination at aluminium is seen in $(Me_3P)_3H_3WH_2AlCl_2 \cdot NMe_3$ **(VII)**, obtained by treating $[(Me_3P)_3H_3WH_2Al(H)H]_2$ with $HCl \cdot NMe_3$.[21] It should be pointed out that due to the short M—Al contacts in complexes **III** and **V–VII** (Table 1), close to or even less than the corresponding covalent radii, a true bonding mode in these compounds may be more complex than that described in terms of the multi-centred model. This may be true for TMA in which multi-centred bonding is realized together with the short M—Al contacts providing direct metal–metal interactions. The latter is also possible when a transition metal in a complex has either unshared pairs of electrons or one electron (d^1–d^4 bases). In complexes where this condition does not hold, for example, in all rare earth alumohydrides (d^0 bases), the M—Al distances are always much greater than the sum of the covalent radii ($r_{Lu—Al} = 3.23$ Å in **II**[17]).

2.2. *Tetranuclear transition metal alumohydrides*

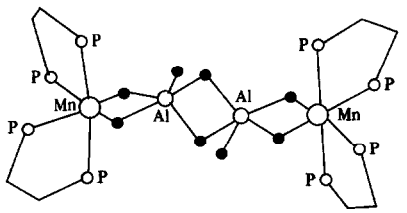
As was mentioned in the previous section, dinuclear TMA with a purely hydridic environment around aluminium are rather unstable and undergo various transformations on crystallization. Dimerization is accompanied by desolvation (dissociation of a coordinated solvent molecule or other aluminium bound organic ligand) and formation of the Al—H_2—Al fragment. The existence of the latter among other hydridic aluminium compounds caused prolonged debates between the supporters of the bridging association of trialkylaminealkanes ($AlH_3 \cdot L$) via  Al bridges[56,57] and the supporters of dipole–dipole interactions.[58] The question, however, remained unresolved due to the lack of conclusive evidence from both sides involved. In addition, the observation of  Al bridges in TMA does not support the conclusions made in refs 56 and 57, since this may reflect a change in the electronic properties of these particular heterometallic compounds, but not for homonuclear ones.



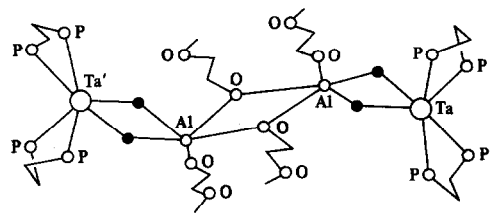
(VII)



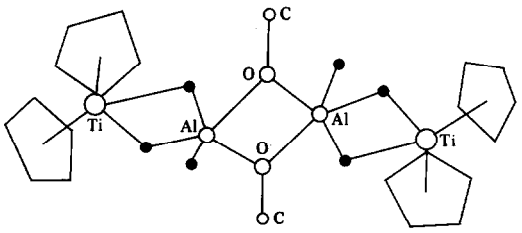
(VIII)



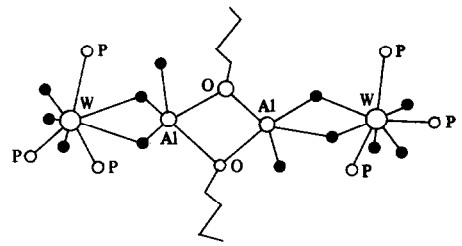
(IX)



(X)



(XI)



(XII)

Desolvation and dimerization of dinuclear compounds can probably be realized when a transition metal in the species is coordinated with a strong donor ligand which is able to increase the electron density at the metal to greater than the critical value. In particular, coordination of permethylcyclopentadiene instead of the usual cyclopentadiene is equivalent to a decrease in the charge at the metal by one unit.[59] In fact, permethylated titanocene alumohydride is crystallized as the non-solvated dimer $[(C_5Me_5)_2TiH_2Al(H)H]_2$ **(VIII)** with two different hydrogen bridges, namely Ti—H_2—Al, and Al—H_2—Al.[22] Similar structural types are realized in the complex with Bis(dimethylphosphino)ethane $[(dmpe)_2MnH_2Al(H)H]_2$ **(IX)**.[23] In both cases the coordination around aluminium is a strongly distorted trigonal bipyramid.

A crucial role of the ligand on the transition metal in the chemistry of heterometallic hydridic complexes (and apparently not only of hydridic) is illustrated by the compounds $(C_5H_5)_2TaH_3$ $ZnCl_2 \cdot THF$ and $[(C_5H_4Bu^t)_2TaH_3ZnCl_2]_2$.[60] Both are crystallized from THF, but the former as a monomer and the latter as a non-solvated dimer containing a  fragment.

Phosphines so strongly stabilize some valent states of transition metals that the reactions of $MCl_4(PMe_3)_x$ (M = Mo, W) with $LiAlH_4$ occur without reduction of the transition metals in refluxing THF and afford dimeric species $[(PMe_3)_3H_3MH_2Al(H)H]_2$, eq. (10):[33]

$$2MCl_4(PMe_3)_3 + 8LiAlH_4 \xrightarrow{L} [(PMe_3)_3H_3MH_2AlH_2]_2 + 6AlH_3 \cdot L + 8LiCl. \qquad (10)$$

The reduction takes place in a large excess of $LiAlH_4$ and is better in Li_3AlH_6,[61] but even in this case the last chloride is not substituted by hydride and the compound formed has the formula $[(PMe_3)_4ClMH_2AlH_2]_2$.

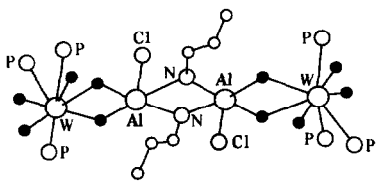
Fully substituted alumohydrides of divalent Cr, Mo, W,[61] Ru and Os[47] are prepared from the corresponding divalent chlorides and $LiAlH_4$, eq. (11):

$$2MCl_2(PR_3)_4 + 4LiAlH_4 \xrightarrow{L} [(PR_3)_4HMH_2AlH_2]_2 + 3AlH_3 \cdot L + 4LiCl. \qquad (11)$$

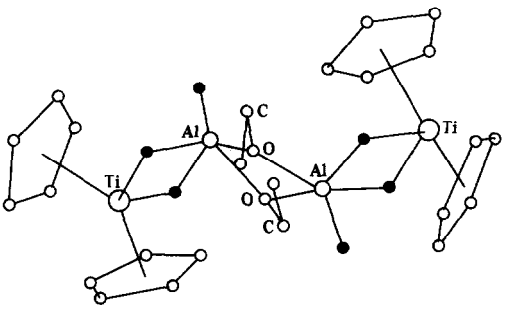
Additionally, an exchange reaction between $(dmpe)_2FeCl_2$ and $LiAlH_4$ affords a very unstable alumohydride which on decomposition gives $(dmpe)_2FeH_2$.[52]

The present literature contains more examples of structural studies on dinuclear complexes, the dimerization of which involves oxygen and nitrogen heteroatoms. The process can occur both with and without a change in the composition of dinuclear complexes. The former is observed in the

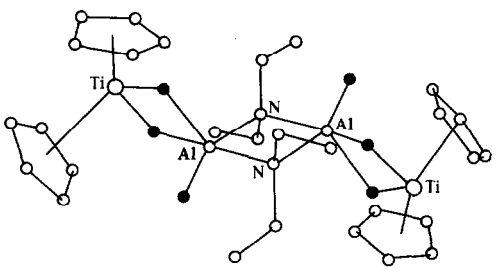
case of $[(dmpe)_2TaH_2Al(OC_2H_4OMe)_2]_2$ (**X**), with bridging and terminal alkoxides, obtained from $(dmpe)_2TaCl_2$ and $LiAlH_2(OC_2H_4OMe)_2$.[24] The latter is typical of the complexes formed either by the cleavage of the organic ligand coordinated to aluminium or by the attack of organic proton donors. For example, the synthesis of some dinuclear TMA in DME, THF or nitrile media occurs with the cleavage of solvent molecules, departure of one hydride and formation of the compounds with alumoxane fragments—$[Cp_2TiH_2Al(H)OMe]_2$ (**XI**),[25] $[(Me_3P)_3H_3WH_2Al(H)OBu]_2$ (**XII**),[26] or with imine—$[(Me_3P)_3H_3WH_2Al(Cl)NCHEt]_2$ (**XIII**)[21] fragments (hydride coordinates were not determined). Similar compounds $[Cp_2TiH_2Al(H)OEt]_2$ (**XIV**) and $[Cp_2TiH_2Al(H)NEt_2]_2$ (**XV**) can be obtained from $Cp_2TiH_2AlH_2 \cdot OEt_2$ by reacting with ethanol[27] or diethylamine,[27] respectively, in ether at a Cp_2TiAlH_4HR ratio of 1 : 0.25.



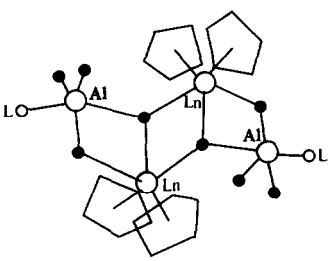
XIII



XIV



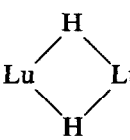
XV



(**XVI**) Ln = Y; L = THF; (**XVII**) Ln = Y; L = NEt_3
(**XVIII**) Ln = Lu; L = NEt_3

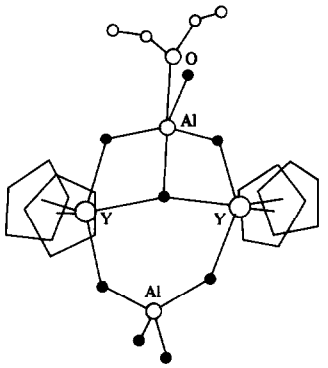
Dimerization of sandwich rare earth alumohydride complexes takes place in a rather peculiar way. The typical feature of these compounds is the fragment Ln—μ_3-X_2—Ln, in which the X atom (H,Cl) is three-coordinated and bound to three metal atoms. This structural difference of hydridic rare earth metals compared with other non-transition metal complexes is, apparently, a result of a symmetry change of three frontal (valent) molecular orbitals a_1, b_2 and $2a_1$ located in the bisector plane of the wedge-like sandwich Cp_2M.[62]

The composition and structure of hydridic rare earth complexes formed from Cp^*_2LuCl and $MAlH_4$ strongly depend on the molar ratio of reagents used, solvent donicity and the nature of the cyclopentadienyl ligand. The reaction between Cp_2LnCl and $LiAlH_4$ at Ln : Al = 1 : 1 in THF or an equimolar amount of NEt_3 affords the compounds of practically identical composition $(Cp_2LnH)_2(AlH_3 \cdot L)$ (Ln = Y, L = THF (**XVI**);[28] Ln = Y, L = NEt_3 (**XVIII**)[17]) and structure. All metal atoms and hydrides are located in the plane of a wedge-like sandwich. The lanthanide atom makes up the 18-electron shell by coordinating the third hydrogen atom. As above, the aluminium atom in **XV–XVII** has trigonal bipyramidal coordination with axial oxygen and nitrogen atoms. The unique behaviour of the lutetium complex **XVIII** which decomposes under high-energy X-rays along the diagonal of the

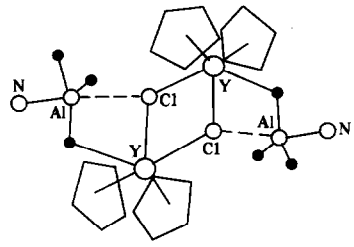


fragment to afford monomer **II** of greater density (the volume

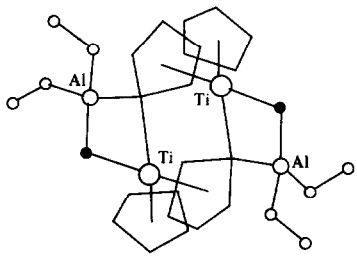
decreases by 15%) without loss of monocrystalline properties of the sample (there are two monomeric molecules of complex **II** in the diagram) should be noted.[17] Other examples having similar behaviour, to our knowledge, are unknown. The transition described in ref. 63 is characterized by only a 2–3% volume decrease.



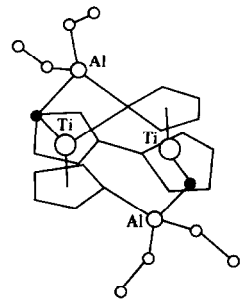
(XIX)



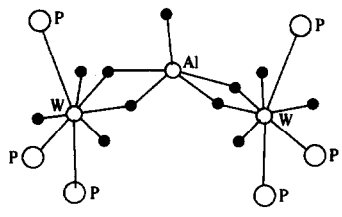
(XX)



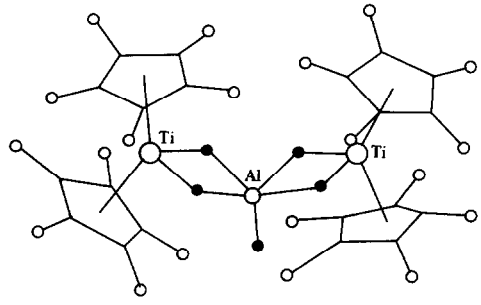
(XXI)



(XXII)



(XXIII)



(XXIV)

The reaction of $(Cp_2YCl)_2$ with $LiAlH_4$ in ether at a Y:Al ratio of 1:1 also leads to the tetranuclear complex $(Cp_2YAlH_4)_2 \cdot OEt_2$ (**XIX**). This contains two different aluminium centres, namely the trigonal bipyramid AlH_4O and trigonal pyramid AlH_4.[29] It seems likely that this compound arises from partial desolvation of the "normal" dimer $(Cp_2YH)_2(AlH_3 \cdot OEt_2)_2$ which is built in the same way as **XVI–XVIII**.

Introduction of two bulky donor t-butyl groups markedly changes the course of the reaction between Cp^*_2LnCl and $LiAlH_4$. Interaction of $(Bu^t_2C_5H_3)_2LuCl$ with $LiAlH_4$ in ether leads to at least three products: $[(Bu^t_2C_5H_3)_2LuHAlH_3 \cdot OEt_2]_4$, $(Bu^t_2C_5H_3)LuCl_2Li \cdot L$ and $[(Bu^t_2C_5H_3)_2LuH]_2$.[42,50] The formation of these species is a result of the exchange reaction giving unstable $(Bu^t_2C_5H_3)_2LuAlH_4 \cdot nOEt_2$. Its decomposition proceeds with loss of both the fragments containing aluminium hydride and one $Bu^t_2C_5H_3$ ligand.

In contrast to the reaction of $(Cp_2TiCl)_2$ with $AlH_3 \cdot L$, the reaction of $(Cp_2YCl)_2$ with $AlH_3 \cdot L$ (L = THF, NEt_3) affords the tetranuclear species $(Cp_2YCl)_2(AlH_3 \cdot L)_2$ (L = NEt_3) (**XX**)[30] which may be considered as an adduct of two alane molecules to yttricene chloride. The coordination sphere of aluminium in **XX** is a trigonal bipyramid achieved by formation of a weak "secondary" Al—Cl bond (3.01 Å).

Hydridoalkyl titanocene complexes are different from the majority of compounds considered. These are very unstable and in solution or even under uncontrolled conditions decompose liberating alkane and hydrogen to form structures with σ–π bonded cyclopentadienyl rings. For example, interaction of Cp_2TiX (X = Cl, Ph) with $AlEt_3$ provides $[(C_5H_5)(C_5H_4)TiHAlEt_2]_2$ (**XXI**), where titanium and aluminium are σ-bound to the cyclopentadienyl ligand of the second titanium atom.[31] It is assumed that the structurally related compound is formed from $[(C_5H_5)(C_5H_4)NbH]_2$ and $AlEt_3$.[64]

High-temperature thermolysis of titanocene hydridoalkyl complexes obtained from the so-called "stable titanocene" $(CpTiH)_2(C_{10}H_8)$ and $AlEt_3$ leads to several products, one of which is the fulvalene derivative $[(C_5H_4)TiHAlEt_2]_2(C_{10}H_8)$ (**XXII**). Other structural characteristics of this compound are very similar to those of **XXI**.[32] The formation of these compounds, from our point of view, perfectly illustrates the extreme lability of the Ziegler systems used as catalysts in alkene polymerization. The tetranuclear fulvalene alumohydride $(CpNbAlH_4)_2(C_{10}H_8)$ was also postulated to account for the reaction between $[CpNb]_2(H)Cl(C_{10}H_8)$ and $LiAlH_4$.[65]

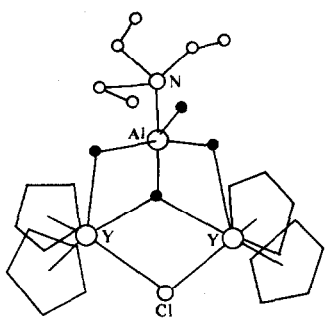
2.3. *Trinuclear transition metal alumohydrides*

Dinuclear and tetranuclear TMA and especially hydrido alkyl alumohydrides are rather unstable and when dissolved they spontaneously, or in the presence of strong bases such as TMEDA, decompose to afford trinuclear M : Al = 2 : 1 complexes together with alanes $AlH_3 \cdot L$, eq. (12).

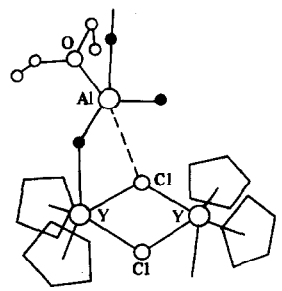
$$2L_nMH_2AlH_2 + L' \longrightarrow L_nMH_2Al(H)H_2ML_n + AlH_3 \cdot L' \qquad (12)$$

Titanium and tungsten compounds obtained in this way have a practically identical arrangement of the M_2AlH_5 fragment: $[(Me_3P)_3H_3W]_2AlH_5$ (**XXIII**)[33] and $[(C_5Me_5)_2Ti]_2AlH_5$ (**XXIV**).[22] In these species aluminium has common although strongly distorted trigonal-bipyramidal coordination, but the complexes may be rationalized as adducts of a Lewis acid (AlH_3) with two base molecules L_nMH.

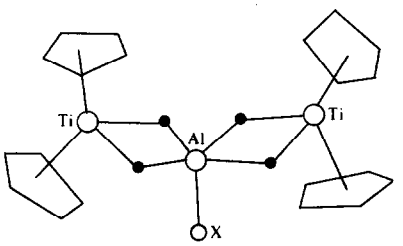
Mixed hydridochloro trinuclear sandwich transition metal complexes are available either from the exchange reactions of the corresponding dimeric chlorides with $M'AlH_4$ at M : Al = 2 : 1 and the addition reactions of alanes with two L_nMX molecules, or by decomposing several dinuclear hydridochlorides, for example $Cp_2TiH_2Al(H)Cl$. In particular, substitution of AlH_4^- for one bridging chloride of $(Cp_2YCl)_2$, which takes place in the presence of an equimolar amount of NEt_3, leads to the trinuclear cyclic complex $(Cp_2Y)_2AlH_4ClNEt_3$ (**XXVI**) where μ_2-chloride co-exists with μ_2- and μ_3-hydrogens.[34] Surprisingly, the geometry of the central nucleus of **XXVI** comprised of three metals and one chloride is very similar to that of $(Cp_2ErH)_3Cl^-$.[66] Complex **XXV** can even be prepared by



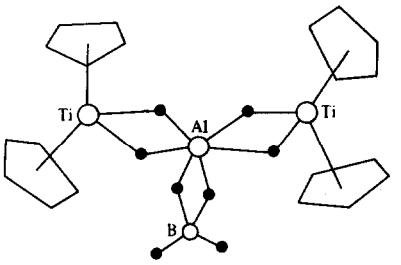
(**XXV**)



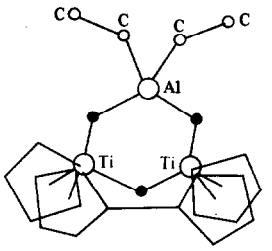
(**XXVI**)



(**XXVII**) X = Cl; (**XXIX**) X = CH_3



(**XXVIII**)



(**XXX**)

the addition of $AlH_3 \cdot NEt_3$, eq. (13):

$$(Cp_2YCl)_2 + 2AlH_3 \cdot NEt_3 \longrightarrow (Cp_2Y)_2AlH_4Cl \cdot NEt_3 + AlH_2Cl \cdot NEt_3. \quad (13)$$

The analogous reaction with $AlH_3 \cdot THF$ gives, probably, the trinuclear linear complex $Cp_2Y(THF)H_2Al(Cl)H_2(THF)YCp_2$,[34] while the same reaction in ether affords polymeric $[(Cp_2YCl)_2AlH_3 \cdot OEt_2]_n$ (**XXVI**),[35] in which three metals are also localized in one structural unit. Trigonal bipyramid geometry around aluminium in **XXVI**, as in **XX**, is accomplished by the "secondary" Al—Cl bond.

The synthesis of hydridochloro titanocene complexes is in principal identical to that of the yttricene complexes. In this case, however, all possible reactions in ether [eqs (14)–(16)] lead to the same non-solvated product $(Cp_2Ti)_2AlH_4Cl$ (**XXVII**).[36]

$$(Cp_2TiCl)_2 + LiAlH_4 \xrightarrow{Et_2O} \mathbf{XXVII} + LiCl \quad (14)$$

$$(Cp_2TiCl)_2 + 2AlH_3OEt_2 \xrightarrow{Et_2O} \mathbf{XXVII} + AlH_2Cl \cdot OEt_2 \quad (15)$$

$$2Cp_2TiH_2Al(H)Cl \xrightarrow{Et_2O} \mathbf{XXVII} + AlH_2Cl \cdot OEt_2. \quad (16)$$

Addition of alkenes or rather strong bases (NR_3) to a solution of **XXVII** induces the cleavage of the trinuclear complex yielding $(\alpha\text{-CpTiCl})_2$ and $Cp_2TiH_2AlH_2 \cdot L$.[36,37] The degree of decomposition is greater in the presence of PPh_3. One of the products formed is the fulvalene chloro derivative $(C_{10}H_8)(C_5H_5TiCl)_2$.

The terminal chloride in **XXVII** favours the introduction of other substituents. For example, the trinuclear complex $(Cp_2Ti)_2AlH_4BH_4$ (**XXVIII**) with a hydridic octahedron around aluminium is obtained either by reactions (17) and (18), or by decomposing the very unstable species $Cp_2TiH_2Al(H)_n(BH_4)_{2-n}$ ($n = 0, 1$), eq. (19):[37]

$$(Cp_2Ti)_2AlH_4Cl + LiBH_4 \xrightarrow{L} (Cp_2Ti)_2AlH_4BH_4 + 2LiCl \quad (17)$$

$$2[Cp_2TiH_2Al(H)Cl] + 2LiBH_4 \xrightarrow{L} (Cp_2Ti)_2AlH_4BH_4 + 2LiCl + AlH_2BH_4 \cdot L \quad (18)$$

$$2[Cp_2TiH_2Al(BH_4)_2] \xrightarrow{L} (Cp_2Ti)_2AlH_4BH_4 + Al(BH_4)_3 \cdot L. \quad (19)$$

Complex **XXVIII** is unprecedently stable compared with other titanium alumohydrides. All the metals in this complex are bonded by double hydrogen bridges and the complex may be treated as a heterometallic derivative of aluminium borohydride.

Substitution of a methyl group for chloride occurs in a more complex manner. Direct reaction of **XXVIII** with LiMe affords a hexanuclear complex[38] (its structure is considered below) rather than the expected trinuclear one. The complex $(Cp_2Ti)_2AlH_4CH_3$ (**XXIX**) was prepared by decomposing the unstable tetranuclear alkyl complex, the product of reaction of **XXV** with $LiAlMe_4$, eq. (2):

$$(Cp_2Ti)_2AlH_4Cl + LiAlMe_4 \xrightarrow{L} \{(Cp_2Ti)_2AlH_4(AlMe_4)\} + LiCl$$
$$\longrightarrow (Cp_2Ti)_2AlH_4Me + AlMe_3 \cdot L. \quad (20)$$

In this compound, which is in fact similar to **XXVII** and **XXVIII**, the coordination number of trigonal bipyramidal aluminium is five. It seems likely that a change of coordination polyhedron, the coordination number staying the same, is due to donor properties of the methyl group. This is also supported by very high catalytic activity of **XXIX** in the homogeneous hydrogenation of alkenes.[38]

By reactions similar to eq. (17), trinuclear species $(Cp_2Ti)_2AlH_4X$ (X = OR, NR_2, Ph, R) have been prepared and characterized by IR, ESR and analytical data.[41]

As in the above section, the fulvalene hydridoalkyl complex $[(C_5H_5)TiH](H_2AlEt_2)(C_{10}H_8)$ (**XXX**)[32] occupies a separate position. It is obtained from $(CpTiH)_2(C_{10}H_8)$ and $AlEt_3$ at room temperature. Therefore, compound **XXII** is the product of decomposition of **XXX**, whereas the majority of other trinuclear species, on the contrary, are derived from di- or tetranuclear complexes.

The unsymmetrical trinuclear zirconium–aluminium μ-ketene complex $[Cp_2Zr(C,O\text{-}\eta^2\text{-}OCR)]_2(\mu\text{-}HAlEt_2)$ (**XXXI**), obtained from $[Cp_2Zr(C,O\text{-}\eta^2\text{-}OCR)]_2$ and $AlEt_2H$, is also an example of an organometallic hydride.[39] When thermolysed in toluene, **XXXI** isomerizes into the symmetric trinuclear complex $[Cp_2Zr(C,O\text{-}\eta^2\text{-}OCR)]_2(\mu\text{-}H)(\mu\text{-}AlEt_2)$ (**XXXII**).[36]

2.4. *Polynuclear transition metal alumohydrides*

Polynuclear TMA with more than four metals in a molecule are formed on decomposition of metal complexes of lower nuclearity. One of them, the hexanuclear compound $[Cp_2TiH_2AlH(C_5H_4)TiCpH]_2$ **(XXXIII)**, was recovered from a toluene solution of binuclear $Cp_2TiH_2AlH_2 \cdot L$ in the presence of TMEDA, 1,4-dioxane or water (in the latter case no more than 0.5 M H_2O per 1 M $Cp_2TiH_2AlH_2$), eq. (21):[40]

$$4Cp_2TiH_2AlH_2 \cdot L \longrightarrow [Cp_2TiH_2Al(H)(C_5H_4)TiCpH]_2 + 2AlH_3 \cdot L + 2H_2. \quad (21)$$

An easier route to the compound, although with other crystalline modifications, involves decomposition of trinuclear $(Cp_2Ti)_2AlH_4X$ (X = Me, Ph,[38] NR_2).[41] As seen from the diagram, the structure of **XXXIII** accumulates all types of M—H and L—M bonds considered above. The metal core is reminiscent of the spread wings of a seagull which are tied up at five-coordinated aluminium atoms by the Al—H—Al bridge. It is assumed that decomposition of dinuclear complexes occurs via trinuclear hydrides $(Cp_2^*Ti)_2AlH_5$, followed by rearrangement into the intermediate $\{Cp_2Ti^{III}AlH_4Ti^{II}Cp_2\}$ which contains bi- and trivalent titanium.[38,40] If Cp = C_5Me_5, only the first step of decomposition takes place and $[(C_5Me_5)_2Ti]_2AlH_5$ **(XXIV)** is isolated from solution.[22] If Cp = C_5H_5, the process always goes to completion. The formation of **XXXIII** from $(Cp_2Ti)_2AlH_4X$ is accounted for by equilibrium (22)[38] which affords unstable organometallic derivatives of titanium(III) such as Cp_2TiR, Cp_2TiPh and Cp_2TiNR_2:

$$(Cp_2Ti)_2AlH_4X \rightleftharpoons Cp_2TiAlH_4 + Cp_2TiX \quad (22)$$

Decomposition of the latter promotes the formation of the mixed-valent titanium intermediate and, correspondingly, of **XXXIII**. Since **XXXIII** is the final product of decomposition of practically all known titanocene alumohydrides [except of $(Cp_2Ti)_2AlH_4BH_4$[37]], it could be assumed that **XXXIII** is kinetically the most stable compound formed in the systems Cp_2TiCl_2–$LiAlH_4(AlH_3)$—L and $(Cp_2TiCl)_2$—$LiAlH_4(AlH_3)$—L.

Decomposition of $[Cp_2^*LuAlH_4 \cdot OEt_2]_2$ with two bulky t-butyl substituents in the Cp-rings occurs in its own original way. Together with the mononuclear dimer $[(Bu^t_2C_5H_3)_2LuH]_2$, the octanuclear complex $[(Bu^t_2C_5H_3)LuHAlH_4AlH_3 \cdot OEt_2]_4$ **(XXXIV)** with one di-t-butylcyclopentadienyl ring was isolated from solution.[42] Unfortunately, hydrogen coordinates in **XXXIV** were not determined, but there is strong IR evidence for the presence of bridging and terminal hydrogen atoms. It is also obvious that the formation of **XXXIV** requires not only the loss of one Cp* ring but a considerable rearrangement of the whole skeleton of the starting molecule.

As was mentioned above, the controlled hydrolysis of the dinuclear titanocene alumohydride affords **XXXIII**, whereas hydrolysis of the permethyltitanocene alumohydride [eq. (23)] gives the beautiful octanuclear cluster $\{[(C_5Me_5)(C_5Me_4\overline{CH_2})\overline{TiH_2}\overline{Al}]_2O\}_2$**(XXXV)** with a C—Al σ-bond.[43]

$$2[(C_5Me_5)_2TiH_2AlH_2]_2 + 2H_2O \longrightarrow \mathbf{XXXII} + 8H_2. \quad (23)$$

Besides the alumoxane AlO_2Al fragment, complex **XXXV** contains two coordination polyhedrons around aluminium, namely trigonal bipyramid and trigonal pyramid. The formation of **XXXV**

shows also that the methyl protons of the cyclopentadienyl rings are not as inert as is usually assumed and under certain conditions may undergo substitution reactions.

Metallocene hydrides Cp_2MH_{3-n} (M = Ta, Nb, Mo, W, Re; n = 0–2) of groups **V–VII** react with alanes and haloalanes to form unstable compounds of unknown composition. Their stability decreases in the series Ta ≪ Mo < Re.[68,69] In turn, Cp_2MH_{3-n} complexes react with AlR_3 to afford compounds which are quite stable under ambient conditions and are probably dinuclear species.[64,70] In solution, on heating they, however, eliminate hydrogen and in the case of Cp_2MoH_2 and $AlMe_3$ the pentanuclear complex $C_{25}H_{35}Al_3Mo_2$ (**XXXVI**) is produced at 80°C, while the heptanuclear complex $C_{26}H_{34}Al_4Mo_2$ is formed in refluxing toluene.[44,45] Hydrogen atoms were not localized in these compounds but their presence in **XXXVI** is supported by IR data and the complex stoichiometry. Tridentate cyclopentadienyl ligands in **XXXIII** and **XXXVI** bind molybdenum and two aluminium atoms (coordination numbers four and five) through a π-bond and a four-centred σ-bond, respectively. Although $C_{25}H_{35}Al_2W_2$ is not isostructural with **XXXVI**, its composition is probably similar to the molybdenum analogue.[71]

Concluding the consideration of structural data of TMA, two generalizations can be made. At present TMA of all groups, except for iron, uranium and actinoid subgroups, have been isolated and structurally characterized. The lack of structural data on transuranium alumohydrides seems to be temporary since the synthesis of Cp_3UAlH_4 has been already reported.[46] Concerning heterometallic hydrides of iron, more powerful stabilizing ligands compared with phosphines are probably needed. In any case, however, despite the generally accepted view of the ease of rupture of the Al—H bonds by transition metal salts, this bond appeared to be rather stable in the complexes considered. At the same time TMA themselves, if added even in catalytic amounts to solutions of aluminium hydride, decompose the latter. This suggests the existence of an intermediate coordination of TMA by monomeric molecules of a simple hydride providing activation of Al—H bonds. Such species were registered in the systems Cp_2TiCl_2–$LiAlH_4$, $CpTiCl_3$–$LiAlH_4$[72] and $MAlH_4$–AlH_4–crown (M = Li, Na).[73]

The second remark concerns a phenomenological description of the formation of TMA and their structures. In all cases considered the formation of TMA may be accounted for in terms of acid–base interactions, in which a transition metal with its ligand environment behaves as a Lewis base sometimes containing two basic centres, i.e. nucleophilic hydridic hydrogens or alkyl groups and/or unshared pairs of *d*-electrons, the aluminium-containing fragment being a Lewis acid. In addition to its own ligands, aluminium can coordinate one or two organometallic ligands of the Cp_2MX type as, for example, seen in complexes **IV–VI** and in all trinuclear complexes; organometallic and hydridic ligands as seen in the tetranuclear complexes **VIII** and **IX**; or organometallic and terminal or bridging organic ligands as observed in complexes **I**, **II**, **X–XX**, **XXV**, etc. Despite such diversity, the binding between metal heteroatoms of TMA both in the solid (X-ray and IR data) and in solution (NMR and ESR data) occurs through the single or double μ_2-bridges or the triple μ_3-bridge. Therefore, all the compounds considered refer to covalent alanes, $AlXX'X'' \cdot L$ or $L \cdot AlXX'X'' \cdot L'$ derived from aluminium hydride rather than to alumohydrides (tetrahydroaluminates) with discrete AlH_4^- anions which comprise ionic structures. Since in neither case, solid or solution, was the formation of AlH_4^- detected, one may conclude that ionic structures with complete charge separation are not typical of TMA and all the so-called "salt-like alumohydrides" are also covalent transition metal species which are solvated by alanes. The only difference between the compounds from **I** to **XXXVI** is that because of a weaker stabilizing effect of the "common" ligands (Et_2O, THF, etc.) they are unstable and undergo ready decomposition liberating hydrogen, binary transition metal hydrides and aluminium metal. Accordingly, the term "transition metal alumohydrides" may only exist as a term of trivial nomenclature. These considerations rule out the structural models of $Cp_2Zr(H)AlH_4$[74] and Cp_3UAlH_4[46] according to which the compounds were treated as polymers with a bidentate or ionic AlH_4 moiety. The spectral data reported may be naturally interpreted in terms of the four-centred model involving the  fragment or M—H_2—Al bridges between metal heteroatoms.

It is clear now that the stabilization of TMA is due to an increase in electron density at the transition metal nuclei which is achieved by coordination of donor ligands. In addition to the

evidence presented above there is an additional observation supporting this point of view. Permethyltitanocene alumohydrides are stable in air for 20–40 min, while complexes with "common" cyclopentadienyl ligands are oxidized within seconds under these conditions. It is the controlled selection of ligands with different electronic and stereochemical properties which seems to be most promising for further progress in the synthetic and structural chemistry of TMA. Another breakthrough in TMA chemistry is associated with practical utilization of these compounds. It is unlikely that the compounds can compete with alkali metal alumohydrides as synthetic reagents. Instead, they find reasonable applications in catalysis, and from this point of view detailed structural studies of TMA become extremely important since only such studies provide the relationship between the substance composition and its catalytic activity. Some results of this approach for the investigation of catalytic properties of TMA are presented below.

3. CATALYTIC PROPERTIES OF TRANSITION METAL ALUMOHYDRIDES

Studies of catalytic properties of TMA which are characterized by direct structural methods are presently limited to the sandwich complexes, rare earth and yttrium derivatives. In addition to their stabilizing function, the cyclopentadienyl ligands are involved in the rigid fixation of the three molecular orbitals (MOs) of the Cp_2M moiety ($1a_1$, b_2 and $2a_1$) in the plane of the wedge-like sandwich which are involved in binding other ligands. This structural feature is responsible for the wide variation in acidic properties of transition metal atoms (from d^0 to d^4 configurations with 14-, 15-, 16-, 17- and 18-electron environments), although the general structural type is the same.

As discussed above, all sandwich, rare earth and yttrium alumohydrides are d^0 18e species. Therefore, taking into account the general postulates of metal complex catalysis, these compounds, if not modified, can hardly display catalytic activity in transformations of alkenes. In fact, reactions of rare earth alumohydrides with linear and cyclic alkenes under a variety of conditions (e.g. in hydrogen atmosphere) are stoichiometric and result in formation of hydrido alkyl complexes, eq. (24):

$$(CpLnH)_2(AlH_3 \cdot L)_2 + 2RCH{=}CH_2 \longrightarrow (Cp_2LnH)_2(AlHR_2)_2 + 2L. \qquad (24)$$

Alkenes undergo insertion into terminal Al—H bonds liberating a ligand and preserving bridging hydrogens as confirmed by IR data.[75] Better reactivity of terminal Al—H bonds compared with bridging ones is nicely illustrated by the reaction of $Cp_2^*TiH_2AlH_2$ with water,[43] alcohols and secondary amines.[27] Evidently, reaction (24) begins with π-coordination of the alkene by aluminium. This leads to the labilization of the Al—L bond, elimination of L and then to insertion of alkene into the Al—H bond. Although π-coordination of unsaturated hydrocarbons to non-transition metals caused some doubt before recent experimental evidence.[76]

Interaction of 17-electron $Cp_2TiH_2AlH_2 \cdot OEt_2$ with isomerization resistant cyclohexene also occurs as a stoichiometric reaction and, according to ESR, IR and GLC data, affords non-solvated $Cp_2TiH_2Al(H)C_6H_{15}$ with the unchanged fragment  [77] Also, the reaction between $Cp_2TiH_2AlH_2 \cdot OEt_2$ and linear hexene-1 is catalytic and results in isomerization of the latter.[77] As seen from Table 2, the rate of isomerization at the dinuclear complex has a clear-cut tendency to decrease as the number of terminal hydrogen atoms decreases, as the steric bulk of ligands increases (at linked Cp-ligands, for example), and as the donor ability of ligands or substituents increases also. As in the previous case, the first step of catalysis is undoubtedly associated with the formation of the hydroalkyl complex. The rate of isomerization by the mixed hydroalkyl complex $Cp_2TiH_2Al(C_7H_{15})_2$ obtained by reaction (25) ($L = OEt_2$) is practically indistinguishable from that by $Cp_2TiH_2AlH_2 \cdot OEt_2$:

$$Cp_2TiH_2AlCl_2 \cdot L + 2C_7H_{15}MgBr \xrightarrow{L} Cp_2TiH_2Al(C_7H_{15})_2 + MgClBr. \qquad (25)$$

In the presence of NR_3 or THF the insertion does not occur. This is suggested by identical ESR spectra for the treated complex and for those treated by alkene titanocene alumohydride.

Table 2. The rates of isomerization and hydrogenation of hexene-1 catalysed by titanocene alumohydrides

Compound	$W\left(\frac{\text{mol } C_6H_{12}}{\text{g.a.Ti} \cdot \text{min}}\right)$	$W\left(\frac{\text{mol } H_2}{\text{g.a.Ti} \cdot \text{min}}\right)$

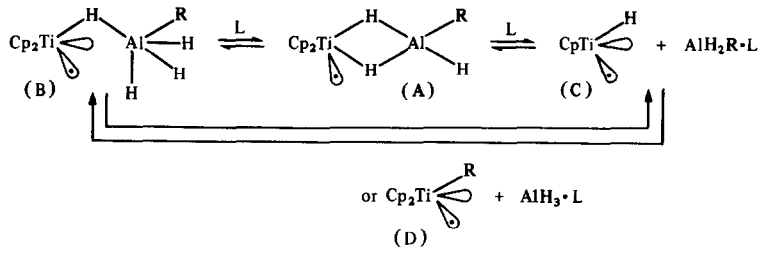
[a] Not determined.

Additionally the system shows no catalytic activity.[77] The hydroalkyl complex obtained by reaction (25) is also not active in the presence of these ligands.

The rationalization of subsequent steps of the catalytic reaction is less straightforward. Taking into account literature data[78,79] one can propose four different active sites able to carry out the migration of double bonds. These are the hydroalkyl complex itself (**A**) generated during the first step of the process and the products of either partial (**B**) or complete (**C,D**) dissociation ("classical" centres), see Scheme 1. The possibility of ligand drift from titanium to aluminium has received considerable evidence.[18,36,80] Therefore, the formation of a $15e^-$ centre **D**, as well as **C**, is also probable. In contrast, the centre of type **B** with a bridging alkyl group should be extremely unstable in donor solvents and, therefore, is not considered here.

Dissociation of dinuclear titanocene alumohydrides in aromatic solvents in the presence of dienes to form unstable titanocene hydrides has been postulated, since without this assumption one could not account for the various rearrangements leading to the fulvalene structures.[81] Nevertheless, for the catalytic isomerization of hexene-1 in ether, one should reject all "classical" centres for reasons which could not be neglected, although they do not directly support the mechanism chosen. The major reason is that dinuclear titanocene alumohydrides do not catalyse hydrogenation,

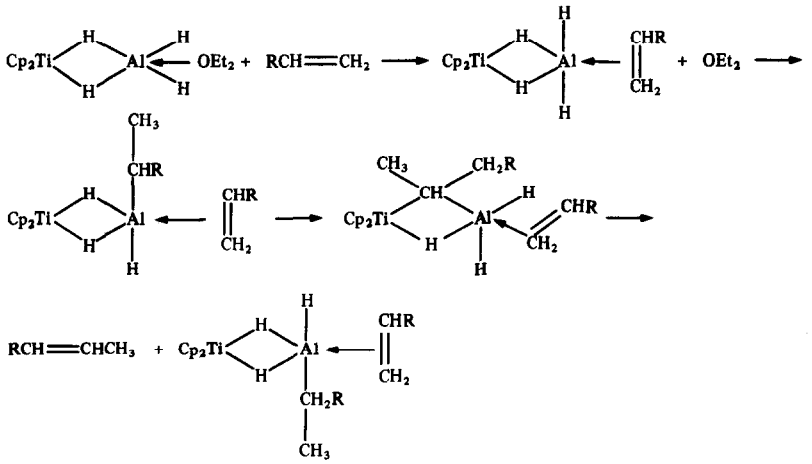


Scheme 1.

although it is known that mononuclear titanocene and rare earth hydrides, which may be formed on dissociation of dinuclear molecules, are the effective catalysts.[82,83] Thus, catalysis should occur if the mononuclear centres **B**, **C** and **D** (Scheme 1) are formed. Moreover, $[(Bu^t_2C_5H_3)_2LuH]_2$, which is the catalyst of hexene-1 isomerization (40–50 mol H_2/g.a.Ti·min), does not isomerize it. Furthermore, an alkyl group in the dinuclear hydrido alkyl complex is directly involved in isomerization. In particular, the products of the reaction between $Cp_2TiH_2Al(C_7H_{15})_2$ and hexene-1 contain hexene-2. Therefore, the active site of type **A**, in which both metals are equal partners, seems to be more probable. The corresponding mechanism of isomerization is shown in Scheme 2. It is assumed that alkene is coordinated with aluminium during the catalytic act, but it is the isomerization that proceeds in the coordination sphere of titanium.[77]

Despite the fact that there are neither terminal hydrogens or good leaving ligands in trinuclear alumohydrides of the type $Cp^*_2TiH_2Al(X)H_2TiCp^*_2$, these species are rather active in the isomerization of olefins (Table 2).[41] However, taking into account their ability to decompose in the presence of alkenes and bases according to eq. (22),[38] the catalysis by trinuclear complexes may be rationalized by the method carried out for dinuclear titanocene alumohydrides. The data in Table 2 show that the specific rate of isomerization of hexene-1 by $Cp_2TiH_2Al(X)H_2TiCp_2$, which is close to 10 mol C_6H_{12}/g.a. Ti·min, is similar to that by $Cp_2TiH_2AlH_2 \cdot OEt$, corrected in accordance with the stoichiometry of reaction (22). Lower values of W for some complexes may be associated with a decrease in the rate of reaction (22), while higher values of W may be associated with the catalytic activity of Cp_2TiX formed in this reaction. However, taking into account the significant uncertainty in determining W, the rate differences observed do not allow more specific conclusions to be made.

As has already been mentioned, all dinuclear titanocene alumohydrides except for $Cp_2TiH_2Al(H)(Cl) \cdot OEt_2$ are inactive in alkene hydrogenation. Since $Cp_2TiH_2Al(H)(Cl) \cdot OEt_2$ dissociates in solution to give $Cp_2TiH_2Al(Cl)H_2TiCp_2$ [eq. (16)],[36] it can be assumed that only the trinuclear clusters $Cp_2TiH_2Al(X)H_2TiCp_2$ catalyse hydrogenation.[41,85] The rates of hydrogenation of hexene-1



Scheme 2.

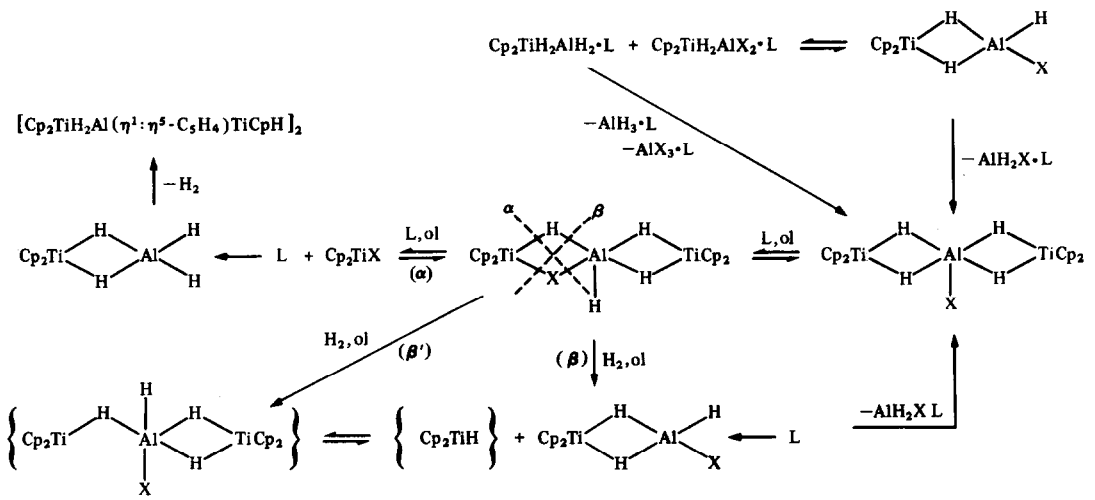
in the presence of these compounds are much higher than those when the Cp_2TiCl_2–AlR_3 system is used,[78,79] and as seen from Table 2 depends on the nature of the X substituents and cyclopentadienyl rings. In particular, substitution of alkyl groups for chloride in $Cp_2TiH_2Al(Cl)H_2TiCp_2$ increases the reaction rate by a factor of nearly 1.5. Greater effects are achieved on introducing OR and NR_2 functions into the coordination sphere of aluminium. The introduction of one methyl group into the Cp ring brings about the same result. Hence, in contrast to the catalysts of isomerization, the activity of catalysts of hydrogenation increases with increasing electron density at the metal centres. A relative change of the electron density at titanium may be characterized by the value of the H—Ti—H bond angle, which becomes lower as the population of an a_1 orbital increases.[86] For the structurally characterized complexes the angle decreases in the series X = BH_4 (73°) > Cl (63.5°) > Me (60°), and inversely the specific rate of hexene-1 hydrogenation varies (Table 2).

Introduction of bulky tert-butyl groups into cyclopentadienyl rings decreases the rate of hydrogenation on one hand and levels off the activity of complexes with high and moderate reactivity, on the other. The same effect is observed in sterically hindered permethyl cyclopentadienyl complexes and also in complexes which contain sterically demanding X substituents, such as OiPr, NR_2 and Ph.

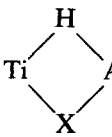
Since all the metal centres in the trinuclear complexes are coordinately saturated, the compounds are probably not the true catalysts of hydrogenation but rather their precursors. ESR data suggest the equilibria in solutions of $Cp_2^*TiH_2Al(X)H_2TiCp_2^*$ involving less stable species.[85] In particular, under the action of cyclohexene, THF or tertiary amines on trinuclear compounds, the crystallization of $[\alpha\text{-}Cp_2TiCl]_2$ occurs while the mother liquor contains paramagnetic species which from the ESR spectra correspond to the individual compounds $Cp_2TiH_2AlH_2 \cdot L$ or $Cp_2TiH_2Al(H)C_6H_{13}$.[38]

Apparently, the formation of the latter two involves the mixed bridged intermediate 
(Scheme 3) which further dissociates along the α-diagonal. (The formation of  hetero-

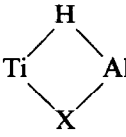
metallic species was previously observed by ESR in the system Cp_2TiCl_2–$AlEt_3$.[87]) It is this process which accounts for the catalytic activity of trinuclear complexes in isomerization reactions. Since neither of the compounds formed in this way catalyses the hydrogenation, it may be assumed that when both alkene and hydrogen are present another pathway of dissociation of the



Scheme 3.

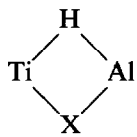


fragment is realized, for example, via the β-diagonal, providing monomeric titanocene hydrides. Unfortunately, all attempts to register such species by ESR after treating the latter with phosphines (PR_3 or PPh_3) in the way described above for alkyl systems based on Cp_2TiCl_2[82] were not successful. This is probably due to the partial bridge cleavage in the



fragment and the association of Cp_2TiH with dinuclear complex **B** (second "classical" centre, Scheme 1) which has the same structure as the 14-electron complex $Cp_2LuHAlH_4 \cdot NEt_3$.[17] Indirect evidence in favour of the formation of intermediate titanocene hydrides is the isolation, in high yield, of the structurally characterized fulvalene complex, $(\eta^1:\eta^5\text{-}C_5H_4\text{-}\eta^1:\eta^5\text{-}C_5H_4)Ti_2Cl_2Cp_2$, which has been formed in the system $Cp_2TiH_2Al(Cl)H_2TiCp_2$–hex-1-ene–H_2–PPh_3.

The dissociation of trinuclear compounds along the α- and β-diagonals should be apparently facilitated by the presence of donor groups which destabilize the bridging bonds. This is nicely illustrated when acceptor chlorine atoms in **XXVII** are substituted by donor methyl or alkoxide groups, thus increasing the catalytic activity by a factor of 2–3. The role of steric factors in catalysis is also apparent: bulky X groups prevent the formation of



bridges, whereas bulky substituents on cyclopentadienyl rings prevent coordination and further transformations of alkenes.

To this end, the experimental data concerning catalytic activity of di- and trinuclear aluminium and titanocene hydride complexes in homogeneous isomerization and hydrogenation of alkenes are best accounted for in terms of the dimetallic mechanism. Although, aluminium behaves as an equal partner in isomerization, the centre is truly dimetallic, it is a part of the well-known monometallic centre in hydrogenation, and its role is the creation of such ligand environments which on simultaneous reaction with alkenes and hydrogen provides partial or complete dissociation of the bridging hydrogens.

In conclusion, the following remarks can be made. The catalytic mechanisms involving di- and trimetallic aluminium and titanocene hydrides in homogeneous isomerization and hydrogenation of alkenes should not pretend to represent "true mechanisms". In tandem with the experimental data, they allow the prediction of a proportion of the catalytic properties of certain compounds. Questions about the true mechanisms are still open, but, obviously, it cannot be solved without finding out the relationship between the structure of the catalyst and its catalytic activity. In turn, it requires the necessary evaluation of the structures of the compounds used as homogeneous catalysts by direct structural methods. Of course, the complete preservation of all structural elements during the catalysis is an exception rather than a rule. Nevertheless, straightforward structural data create the basis for interpretation of spectral information obtained during the catalysis. From our point of view, the virtue of such an approach is well illustrated by the example of catalysis by aluminium and titanocene hydrides. Due to the high catalytic activity of the latter or their precursors there is hope for discovering the catalytic properties of other TMA. Obviously, further development of the catalytic chemistry of these compounds is associated with the expansion of the direction of research of the catalytic reactions, among which the most important are alkene and alkyne polymerization, and with structural modification of complexes by a variation of the ligand environment of both metal centres.

1. INTRODUCTION

The chemistry of organoaluminium compounds which contain either a group 15 or 16 element has been under investigation for many years. The earlier work has been extensively reviewed by Mole and Jeffery,[1] Eisch,[2] Bradley,[3] and Oliver.[4,5] A very extensive discussion of exchange processes, including those of the group 13 elements has been presented by Matteson.[6] The group 15 containing derivatives of aluminium and the heavier group 13 metals have come under intensive investigation for the past several years because of the interest in 13–15 semiconductor material. The 13–16 compounds, on the other hand, have received only modest attention. The recent recognition that the 13–16 compounds may serve as precursors for ceramic materials, as models for aluminium oxide catalysts, and in applications for regio- and stereoselective organic synthesis has led to a renewed interest in the synthesis and characterization of these derivatives.

This short review is not intended to be comprehensive, but will emphasize the structures and exchange reactions of these derivatives. We hope to outline some of the past observations and provide new information based on our recent work, much of which has not yet appeared in the literature. With these data in hand, we will then discuss some of the future directions anticipated for work on 13–16 compounds.

There are several general classes of derivatives to be discussed: (1) three-coordinate species; (2) simple four-coordinate $R_3Al \cdot ER'_2$ addition compounds; (3) bridged four-coordinate derivatives of the general form $[R_2Al(-\mu-ER')]_2$; (4) compounds containing five-coordinate aluminium; and (5) compounds with six-coordinate aluminium. Further, under each of these broad classifications, both structural studies and exchange processes will be discussed.

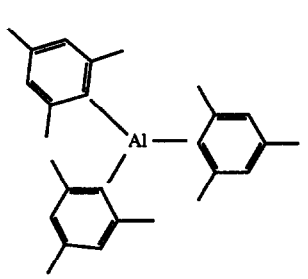
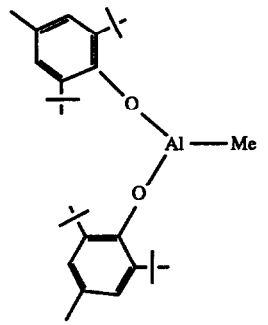
2. THREE-COORDINATE ALUMINIUM DERIVATIVES

The formation of electron deficient three-coordinate organoaluminium compounds has been invoked in many cases to account for the reactivity of these derivatives. Until recently, the only structural data for the three-coordinate derivatives was that obtained by Haaland and co-workers for Me_3Al in the gas phase.[7] Recent studies have shown that species can be stabilized in this configuration by the use of suitable bulky ligands such as mesityl,[8] BHT (2,6-di-*t*-butyl-4-methylphenoxide),[9] or bis(trimethylsilyl)amide.[10] Two of the known structures are depicted below. In the trimesityl derivative no secondary interaction with the ligands should occur. Thus, providing suitable ligands are available, addition compounds should form. This is the case with both THF and 4-picoline forming stable addition compounds.

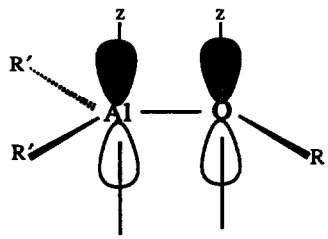


I



II

The structures of these three-coordinate derivatives show some distortion with a support for modest steric interference between the base and the mesityl group. With the BHT and bis(trimethylsilyl)amide derivative, delocalization of electron density from the oxygen (nitrogen) might be expected. The extent of the delocalization will depend on several factors, including the separation of the atoms, the relative energies of the orbitals involved in bond formation, and the orientation of the orbitals. These mesomeric effects in the alkoxide, as illustrated in **III**, should be reflected in



III

two ways; first, the Al—O bond should decrease in length as the electron delocalization increases, and second, the formation of addition compounds should become less favourable with the increasing electron delocalization.

Several structures of BHT derivatives have appeared in the literature. In the $MeAl(BHT)_2$ monomer, the Al—O bond distance is short in comparison with other Al—O distances which supports the proposed interaction between the π-electrons on the oxygen and the vacant *p*-orbital of aluminium (compare data in Tables 1 and 2). It should be noted, however, that aluminium BHT derivatives readily form addition compounds in which the aluminium has become four-coordinate, precluding the back donation of electron density from the oxygen to the aluminium. Furthermore, the Al—O bond distance increases only slightly with addition compound formation and remains less than that observed in many Al—O bonded compounds. Both the ease of formation of the addition compounds and the limited increase in the Al—O bond distance on adduct formation are indicative of limited back donation.

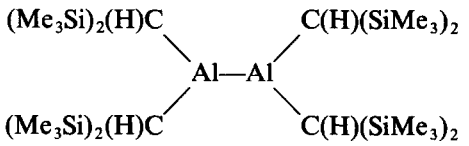
Only one significant NMR study has been reported which involves these compounds.[9] In this study it was demonstrated that there is an equilibrium between *mono* and *di* BHT species in solution.

This equilibrium is depicted in eq. (1) with all four species in the equilibrium mixture observed:

$$Al_2R_6 + RAl(BHT)_2 \rightleftharpoons R_2AlBHT + R_5Al_2BHT. \quad (1)$$

Further, it was noted that the simple alkylaluminium dimers such as Al_2Me_6 undergo very fast exchange with the R_2AlBHT derivative, but that exchange is relatively slow on the NMR time scale for the $RAl(BHT)_2$ species. It appears that this may be accounted for in terms of the ease of bridge formation with the BHT containing compound. With only one BHT group present, alkyl bridged dimers can form, providing a path for exchange, but with two BHT moieties present, formation of the bridged intermediate becomes far more difficult and slows the exchange process. Additional studies in this area seem warranted because of the interest in the use of these species in catalytic processes and for stereo-controlled synthesis. A better understanding, both of the structures and of the reaction mechanisms of these sterically hindered derivatives, is required in order to establish the role played by the bulky ligands in these systems.

The third class of three-coordinate aluminium compounds is that containing a direct Al—Al bond. Only one compound of this type, shown in **IV**, has been characterized by X-ray crystallography.[11] Other Al—Al bonded compounds have been described which are stabilized with bulky ligands.[12]



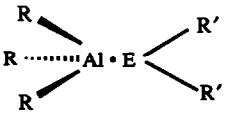
IV

The formation of these species once again illustrates the ability of sterically demanding ligands to stabilize highly reactive species.

Studies on three-coordinate compounds in the future will go in at least two directions, the exploration of alkoxides, and perhaps other species containing group 15 or 16 elements bound to the aluminium atom, for use in catalysts and materials precursors and, second, the study of compounds containing Al—Al bonds to explore the chemistry of this metal–metal bond.

3. $R_3Al \cdot ER'_2$ ADDITION COMPOUNDS

The $R_3Al \cdot ER'_2$ addition compounds can be represented by the generalized structure shown in **V**. The Al—E bond is best described in terms of a simple donor–acceptor bond with the aluminium



V

atom seving as the Lewis acid site and E serving as the Lewis base. The chemistry of these complexes is best represented in terms of the simple dissociative process shown in eq. (2). The reactivity of these compounds is associated with the free trialkylaluminium derivative formed and is therefore determined by the ease of dissociation of the complex.

$$R_3Al \cdot ER'_2 \rightleftharpoons R_3Al + ER'_2 \quad (2)$$

The structures, the stability of the addition compounds, and their dissociation/exchange have been studied. The most significant factor is the nature of E, with the stability of the compounds formed following the order N > P ≥ O > S > Se > Te based on the reaction of the methyl derivatives, Me_nE, with trimethylaluminium. This order may be altered when other ligands are present, either on the aluminium or on the Lewis base. Thus, the energy for the formation of the adduct $Me_3Al \cdot$ Base falls from approximately 100 to 50 kJ mol^{-1} on going from Me_2O to Bu_2O.[2] Similar qualitative observations have been made for a number of derivatives but only limited quantitative data are available. These have been summarized in refs 1 and 2.

The structures of a variety of simple adducts have been determined and are listed in Table 2 for the ether derivatives and in Table 3 for the sulphur complexes. No structures for selenium compounds

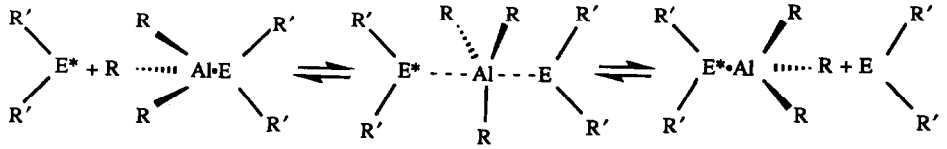
have been reported at this time. Careful examination of the data presented in Table 2 shows that the average Al—O bond distance observed in these derivatives is approximately 1.95 Å. There appears to be some modest bond shortening when a halogen is present, while slightly longer bonds are observed when two R_3Al units are bound to a polyether. There is a small but significant decrease in both the Al—O and Al—C bond lengths in the limited series of compounds $Mes_3Al \cdot THF$,[13] $Mes_2(Et)Al \cdot THF$[14] and $Mes_2(Cl)Al \cdot THF$.[14] This decrease in bond length can be attributed to two factors, a decrease in steric hinderance on substitution of a smaller group for the mesityl moiety and substitution of a better electron-withdrawing group for the mesityl unit which leads to a further decrease in bond length. When an alkoxide is present, substantial bond shortening is observed with bond distances in the range of 1.7–1.8 Å.

Another measure of the stability of these complexes is afforded by study of the exchange of ether with the addition compound. The exchange appears to go through a rate-determining dissociation step when excess aluminium alkyl is present or even when only the addition compound is in solution. This mechanism has been discussed extensively elsewhere.[4,6] In the presence of excess base, a bimolecular mechanism may become dominant as illustrated in eq. (3). Unfortunately, only very limited information is available from this type of study and even this is complicated by the additional reaction of R_3Al to form dimeric molecules, Al_2R_6.



(3)

For the sulphur derivatives substantially less information is available. The structures are listed in Table 3. The Al—S bond distance observed in two addition compounds is 2.52 and 2.72 Å. Additional information needs to be obtained to provide a basis for comparison with adduct stability and to establish a better base for these systems. No quantitative exchange studies have been carried out on the thioether derivative, but exchange has been reported to be fast on the NMR time scale in keeping with the lower dissociation energy for these compounds.

Further examination of the simple addition compounds will be relatively limited. Structures of the complexes are well established, especially for the oxygen derivatives. Some studies on hindered complexes of the heavier group 16 derivatives and on complexes with unusual ligands could be justified. Further studies on exchange processes are also warranted to better establish the kinetic parameters for exchange, both in the presence of excess alkylaluminium and with excess base present. The major interest in these derivatives is likely to be in their use as precursors to other materials, especially where volatile, easily decomposed materials can be prepared.

4. BRIDGED DERIVATIVES

The reaction of an aluminium alkyl with an alcohol or thiol leads to the formation of an aluminium alkoxide or thiolate with alkane elimination as indicated in eq. (4):

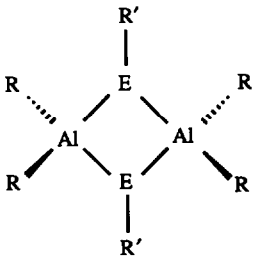
$$nR_3Al + nR'EH \rightarrow (R_2AlER')_n + nRH. \quad (4)$$

The degree of aggregation, n, is dependent on the nature of E and on the groups R and R′.

The derivatives are typically dimeric for simple alkoxides as shown in **VI**, although $(Me_2AlOMe)_3$ forms a six-membered ring in a chair conformation[15] and higher aggregates with $n = 4$ have been reported in solution.[1,2] As noted in the previous section, monomers are formed when R or R′ becomes sufficiently bulky.

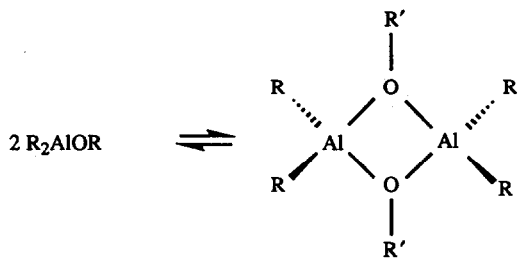
The Al_2O_2 ring system is normally planar, with this plane perpendicular to the plane described by the four R groups and the two aluminium atoms. Some modest deviations from this have been observed in sterically hindered species where the ring is distorted from the planar geometry. The bond distances and angles in selected four-coordinate derivatives containing aluminium–oxygen bonds are given in Table 4.

The stability of the Al—O—Al bridge is quite high with values for the Al—O—Al bond energy



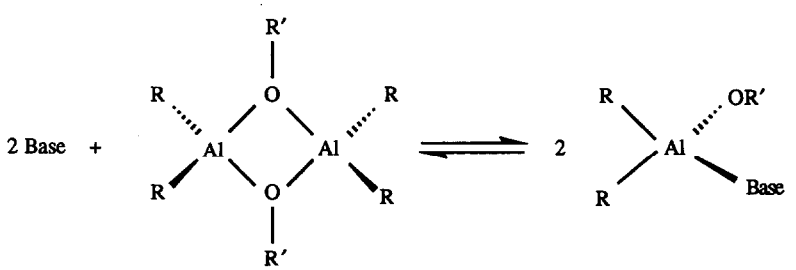
VI

typically in the range of 80–150 kJ mol^{-1}, thus making it difficult to disrupt this bond. Earlier studies established a lower limit of 131.5 kJ mol^{-1} for the Al—O—Al bridge bond in $[Al(O\text{-}i\text{-}Pr)_3]_4$,[16] which is in mid-range for these bridge bond energy. The stability of these bonds inhibits the interchange between bridge and terminal sites. Further, in the monomer–dimer equilibrium shown in eq. (5), the dimer is predominant in most cases. Formation of a larger ring system is not



(5)

common since little additional energy of stabilization is gained, and the entropy change for the formation of larger aggregates is unfavourable. The reactions of alkoxides are typically dependent on the dimer concentration, and the compounds tend to be far less reactive than those of more readily dissociated species. Another manifestation of the strength of the alkoxide bridge is shown by the difficulty in disruption of the bridge by a base. Thus, the equilibrium for the reaction shown in eq. (6) typically lies far to the left with the alkoxide bridged dimer favoured. This indicates that



(6)

the alkoxide oxygen bound to the aluminium atom serves as a stronger Lewis base than the ether molecule. An alternative way to view this is that the energy provided from the formation of two $R_2(R'O)Al \cdot$ Base molecules is less than that derived from the formation of two Al—O—Al bridge bonds. Again, it should be noted that the entropy change is favourable for the last process as well.

An interesting feature that is readily observed because of the stability of the Al—O—Al bridge is the formation of *syn* and *anti* conformers. Both forms have been observed in the solid state and

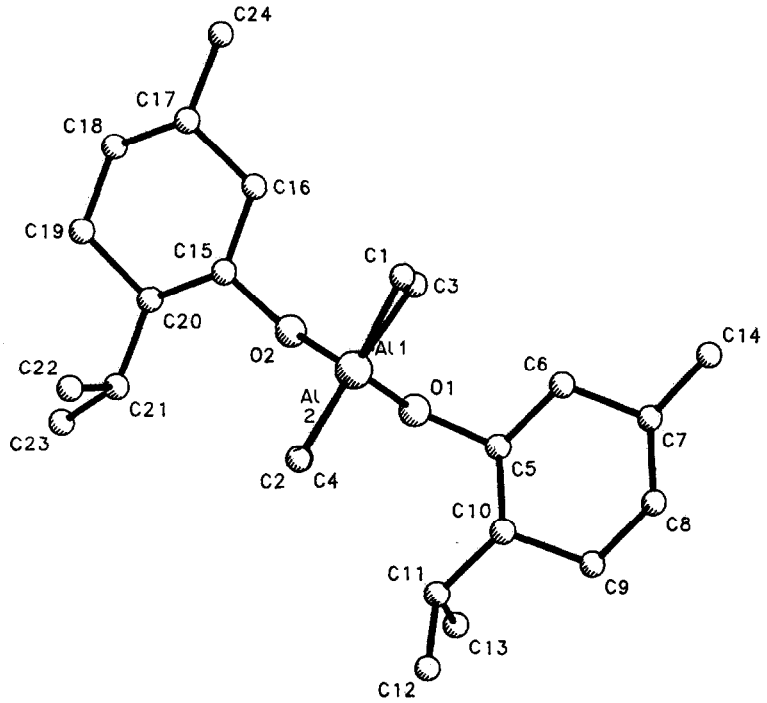

Fig. 1. A PLUTO diagram of tetramethyl-bis(μ-*l*-mentholato)dialuminium showing the *syn* configuration.

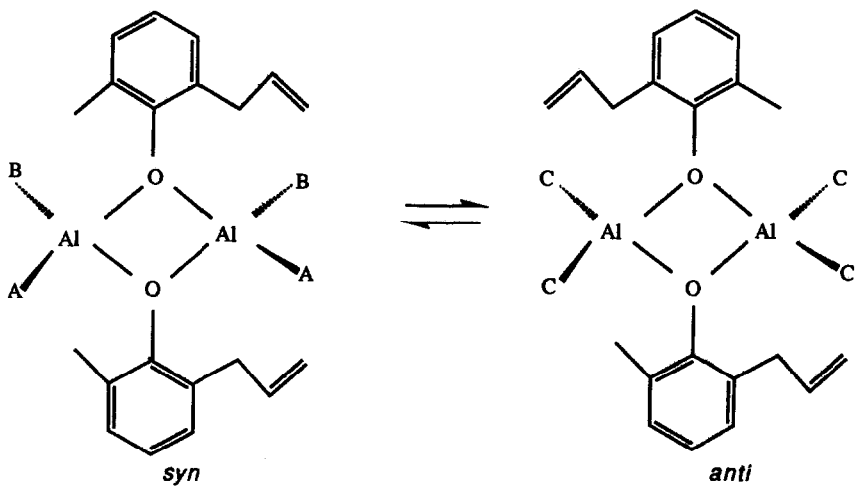
are illustrated by the *l*-menthol and *l*-borneol derivatives shown in Figs 1 and 2. The observation of these two conformations raises the question of their behaviour in solution. Recent variable-temperature NMR studies on a series of 2-methyl-6-allylphenoxide derivatives of aluminium clearly establish the presence of both *syn* and *anti* conformations in solution.[17,18] Further, the relative populations of the *syn* and *anti* forms are temperature dependent, giving a measure of the difference in energy of the two conformers. This is illustrated in Fig. 3 which shows the temperature dependent ^{1}H NMR spectrum of tetraethyl-bis(μ-2-allyl-6-methylphenoxy)dialuminium. The difference in populations of the two forms depicted in eq. (7) is very small with a ratio of 1 : 1.1 at −30°C and 1 : 1 at −75°C for the dimethylaluminium derivative. This shows the minor effects of the substituent groups both on the phenoxide and on the aluminium. One anticipates that, as the asymmetry of the substituents and their bulk increases, larger deviations will be observed. Studies are presently underway in our laboratory to assess some of these factors in more detail by examination of a number of related systems where the substituent on the aluminium has been modified.

A further point to be made is that *syn* and *anti* conformations interconvert through rotation of the bridging group without apparent disruption of the Al—O—Al bridge bond. The rotational



(7)

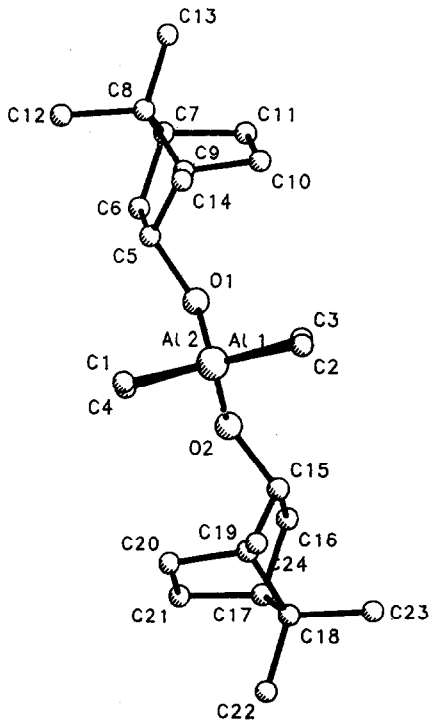


Fig. 2. A PLUTO diagram of the tetramethyl-bis(μ-*l*-borneolato)dialuminium showing the *anti* configuration.

barrier is in the range of 30–50 kJ mol^{-1},[18] which is clearly less than the energy required for disruption of the bridge bond, but of the same order of magnitude as reported for rotation of the bridging groups in tricyclopropylaluminium.[19] Further examination of the *l*-menthol and *l*-borneol derivatives cited earlier provides additional information on these systems. The ^{1}H NMR spectrum of the *l*-menthol derivatives shows the influences of the optically active centre on the terminal alkyl groups giving rise to diastereotopic protons. Variable-temperature NMR studies show that the chemical shifts of the various groups are temperature dependent, but also indicate that over the

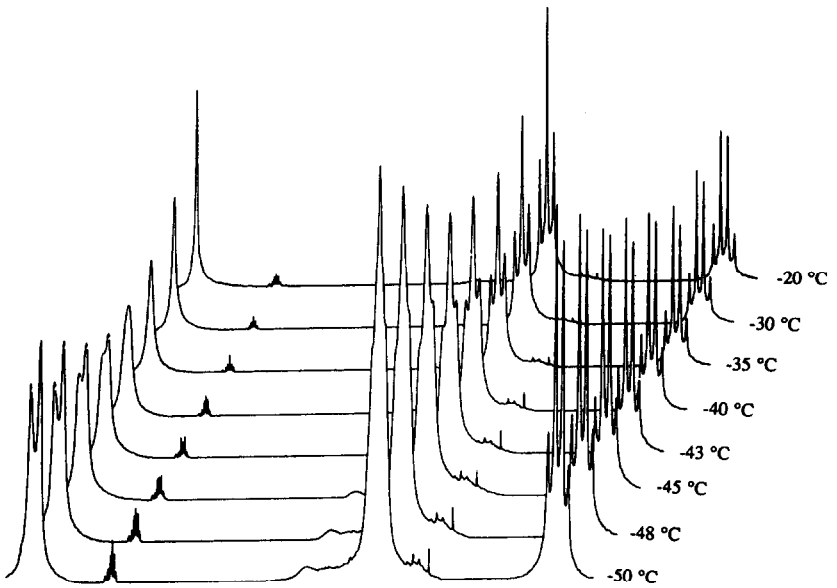

Fig. 3. Variable-temperature ^{1}H NMR spectra of tetraethyl-bis(μ-2-allyl-6-methylphenoxy) dialuminium. The region shown is for the 6-methyl group and the ethyl groups attached to aluminium.

temperature range studied, the protons remain diastereotopic. In contrast, the ^{1}H NMR spectrum of the *l*-borneol derivatives shows no effect from the optically active centre even as the temperature is decreased to −75°C. At the same time, no evidence for stable *syn* and *anti* conformers in these systems is indicated. The interpretation of these results is discussed in detail elsewhere,[20] but they appear to arise from two facts. First, the optically active centre in *l*-borneol is at a substantial distance from the alkyl groups attached to the aluminium and, second, the *l*-borneol group has a low barrier to rotation about the Al—O—Al bridge and O—C bonds, giving rise to rapid rotation on the NMR time scale even at low temperature. The *l*-menthol derivative is in close proximity to the alkyl groups attached to the aluminium, thus permitting interaction with the optically active centre in this moiety causing the protons on the alkyl groups to become diastereotopic. Rotation about the O—C and Al—O—Al bridge bond remains rapid on the NMR time scale, however, so *syn* and *anti* forms could not be observed.

5. THIOLATES

The chemistry of binary thiolato derivatives of aluminium compounds has not received significant attention. Structures of only three simple derivatives have been reported: the solid-state structure of $(Me_2AlSMe)_n$;[21] its structure in the gas phase where it is a dimer;[22] and the recently characterized $(Me_2AlSC_6F_5)_2$.[23]

There are three interesting features of these systems which should be commented upon. First, the Al—S—Al bridge bond distances range from 2.35 to 2.41 Å and are much shorter than the Al—S bond lengths observed for the adducts. The bond lengths and angles for all compounds containing direct aluminium to sulphur bonds are listed in Table 5. Second, the Al—S—Al bridge bonds are substantially weaker than the Al—O—Al bridge bonds. Thus, they can be readily cleaved or disrupted by ethers and amines as indicated in eq. (8). For example, the aluminium thiolate may react with aldehydes or esters via eq. (8) to yield the simple adduct followed by a rearrangement to yield the dialkylaluminium thioalkoxide shown in eq. (9).[23] One also should anticipate that monomer–dimer equilibria should be observed in these systems with monomers favoured with increasing size of the organic substituents. This has not been tested. Third, the Al_2S_2 ring system is puckered or butterfly shaped with the angle between the two planes described by Al—S(1)—Al and Al—S(2)—Al atoms near 150°. This deviation from planarity is substantial and clearly results from the substitution of sulphur for oxygen in the bridging site.

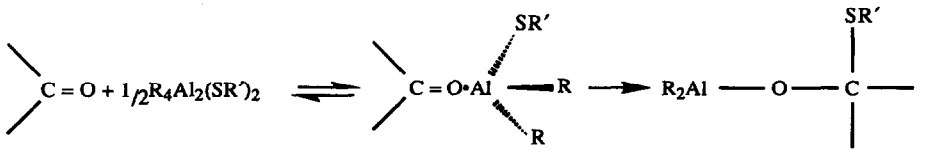
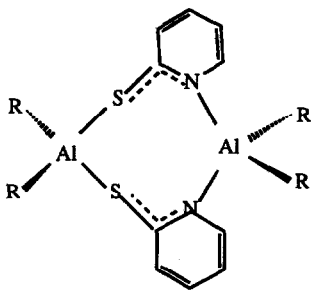
(8)



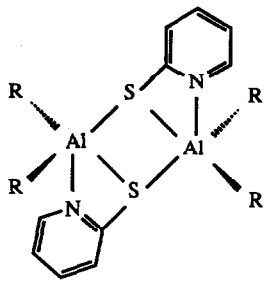
(9)

In addition to the simple derivatives discussed above, recent studies in our laboratory have shown that reaction of 2-thiopyridine with alkylaluminium compounds yield the dimeric molecule shown in **VII**.[24] The central core of this compound contains an $Al_2S_2C_2N_2$ ring with the bridging

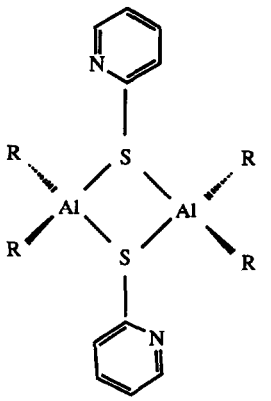


VII

2-thiolatopyridine ligand arranged in an unexpected head-to-head fashion. Further, variable-temperature NMR studies have established that the 2-thiopyridine ligand is fluxional on the NMR time scale. This exchange appears to involve some type of bridge reorganization with probable involvement of either the five-coordinate complexes shown in **VIII** or the uncoordinated dimer shown in **IX**, although other isomers may be participants in the rearrangement. These results show the wide



VIII



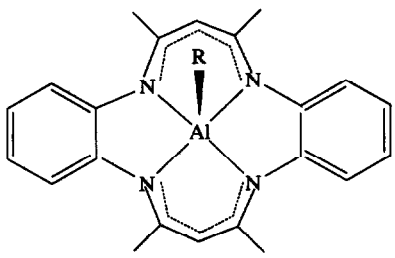
IX

range of possible structures for thiol derivatives of aluminium and of systems containing mixed ligands.

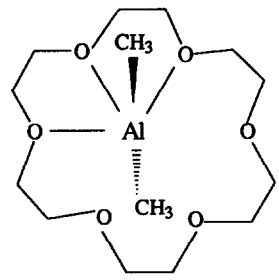
Additional studies on the simple bridged species will continue with interest in the effects of bridging groups on the reactivity of the bridged dimeric molecules, especially for use in asymmetric synthesis, and on the factors which control the conformations and barriers to exchange. Studies involving the heavier group 16 species will also become a focus of attention because of the renewed interest in formation of new materials for semiconductors and other applications.

6. FIVE-COORDINATE ALUMINIUM DERIVATIVES

Five-coordinate aluminium derivatives have been proposed for a number of years, and structural evidence for species of this type has been reported by a number of groups with the compounds listed in Table 6. These compounds have two general structures, the first of which involves the coordination of the metal centre by several donor ligands from nitrogen-containing macrocycles[25–27] or crown ethers[28] as illustrated in **X** and **XI**. Other systems, which may be represented by the square pyramidal structure depicted in **X**, have been reported, and in one case the complex contains both four- and five-coordinate aluminium atoms.[27]



X



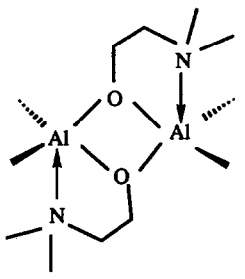
XI

The crown ether complexes show additional complexity with high coordination in the case of the 15-crown-5 complex which has the AlR_2 unit trapped in the central region with five oxygen atoms surrounding it in addition to the two methyl groups.[28]

Both the nitrogen and oxygen macrocyclic and polydentate acyclic ligands offer the potential for the formation of a variety of new complexes with unusual coordination around the aluminium. Little is known about the reactivity of these complexes, but it is anticipated that substantial differences between the reactivity of these complex species and other organoaluminium compounds will be observed. Further, introduction of other hetero-atoms can lead to additional changes in structure and reactivity. Thus, there is a new area of chemistry to explore on the organoaluminium complexes formed with macrocyclic and polydentate acyclic ligands. Studies on the ease of exchange and reactivity of these species seem very promising in terms of new reagents which may offer methods for control of the reaction path.

At this writing, several such complexes have already been described by Goedken,[25] by Robinson *et al.*,[26,27] and by Atwood *et al.*[28] These represent the majority of simple cationic organoaluminium derivatives. Further exploration of their chemistry appears to be very promising since they provide relatively stable cationic aluminium species with active alkyl groups which may be used in reactions.

The second class of five-coordinate compounds has been studied by several groups including our own and is best represented by structures of the type shown in **XII**. Examples have been reported



XII

in which the bridging site is occupied by either oxygen or nitrogen. Similarly, the secondary coordination illustrated in **XII** could be occupied in principle by any Lewis base. In practice, only nitrogen and oxygen have been observed to form stable complexes of this type, but it seems likely that sulphur and phosphorus will also be found to participate in structures of this type under suitable conditions.

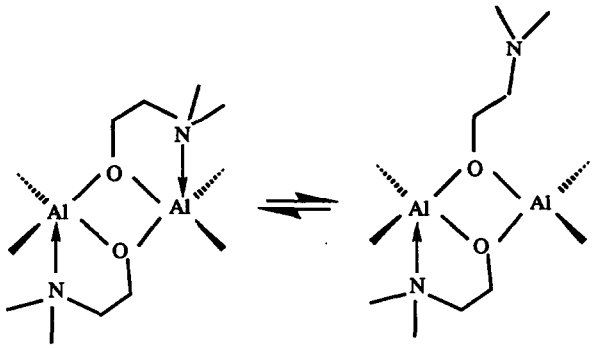
These complexes afford a variety of interesting features to explore. Among these are the potential for rearrangement from five- to four-coordinate complexes. This is illustrated by eq. (10) in which



(10)

the second coordination site has undergone dissociation. This can be easily observed in the variable-temperature NMR spectra of complexes of this type. In the five-coordinate species the protons in the CH_2 units connecting the two coordination sites become diastereotopic giving rise to complex NMR spectra. On dissociation full rotation becomes possible, and this non-equivalence of the CH_2 groups disappears. This is shown qualitatively in Fig. 4 in which the methyl region of the ^1H NMR spectrum of tetramethyl-bis(μ-1*R*,2*S*)(−)-λ-(1-methylaminoethyl)benzylalkoxide dialuminium is shown as a function of temperature.[29] A detailed examination of a number of systems showing this type of behaviour is underway in our laboratory, but sufficient data have already been obtained to provide some insight into these systems.[30] We have found that the ease of dissociation is a function of the substituents on the nitrogen and on the aluminium centres, and the activation energies range from approximately 40 to 100 kJ mol^{-1} for the systems studied in our laboratory. Further, the energy of activation for the exchange is directly related to the heat of formation of the five-coordinate aluminium and provides a measure of the steric interactions between the substituent groups on the

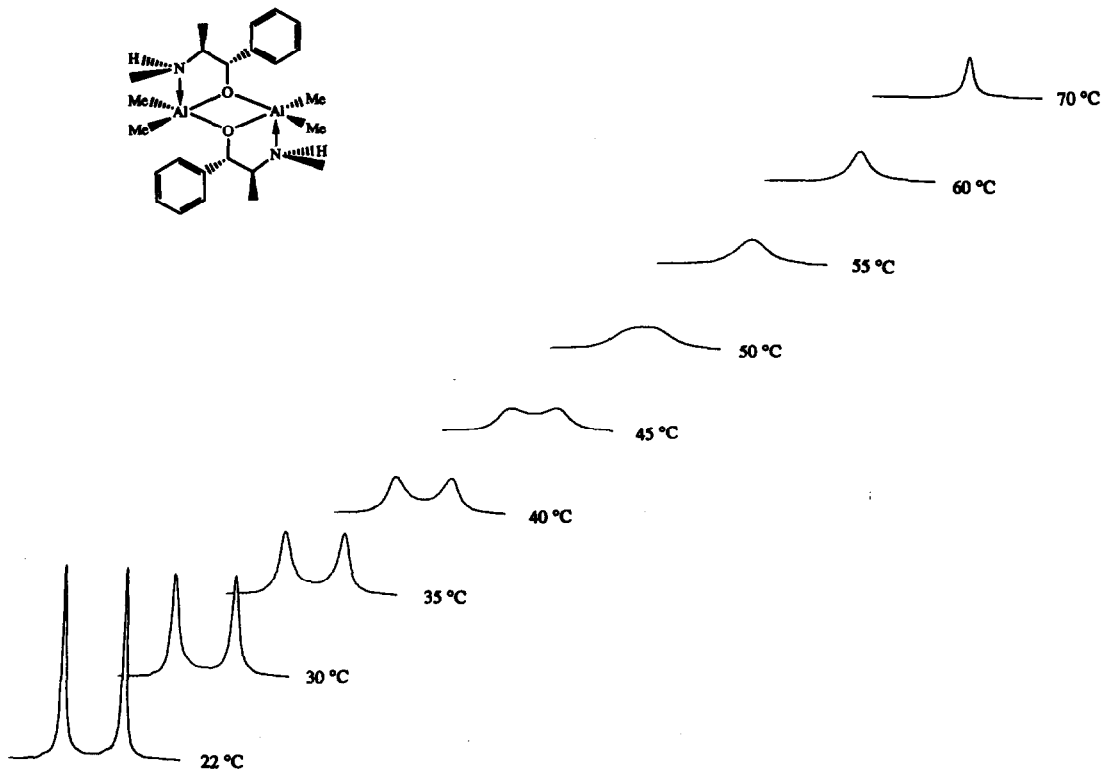


Fig. 4. A variable-temperature ^1H NMR spectrum of the Al–Me region of tetramethyl-bis(μ-1*R*,2*S*)-(−)-λ-(1-methylaminoethyl)benzylalkoxide dialuminium.

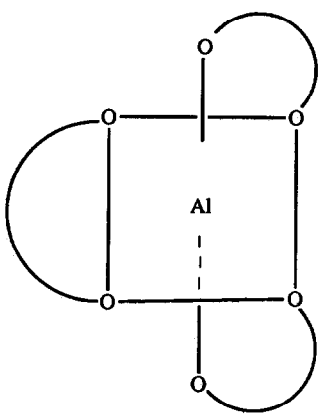
aluminium and on the coordination centre. Thus, it appears that the order of coordination is O > N > S, with the steric interactions playing an important role to reduce the activation energy when nitrogen is present. In fact, in our efforts to obtain other five-coordinate species containing a thiol ether, we have observed other classes of reactions occurring as noted in the section on six-coordinate complexes.

An additional feature of the five-coordinate aluminium complexes is that one may readily introduce optically active centres in the bridging ligands at the same time one causes the aluminium atom to become an optically active centre. Thus, both the ligand and the aluminium centre may be optically active. This feature makes use of these reagents in stereospecific synthesis particularly attractive. Further work is needed to establish the use of these complexes as reagents. At the same time, detailed studies of a number of these systems should provide substantial information on the reaction paths and make it possible to design specific reagents for reduction and/or alkyl transfer reagents.

7. SIX-COORDINATE ORGANOALUMINIUM COMPOUNDS

Until quite recently, the few six-coordinate aluminium derivatives known contained only bonds between the metal and electronegative atoms such as oxygen or nitrogen. Recently, however, several more complex species have been characterized which contain aluminium atoms bound to alkyl or silyl groups in addition to a central metal surrounded only by the electronegative groups. In two instances derivatives containing a carbon atom directly bonded to the six-coordinate aluminium atom have been observed. These derivatives, along with a number of those described earlier are listed in Table 7.

In all cases the six-coordinate aluminium atom is in an octahedral or pseudo-octahedral environment as shown in **XIII** surrounded by oxygen, nitrogen or carbon atoms from the ligands.



XIII

In the initial studies, the ligands were typically bidentate with two oxygen or nitrogen coordination sites. Complexes of this type remain of interest because of their potential use in biological systems,[31-33] but do not contain metal–carbon bonds. The second class of six-coordinate derivatives is made up of systems which contain aluminium in two different environments. These systems commonly have a central six-coordinate aluminium surrounded by three AlR_4^- groups which can be thought of as bidentate chelating ligands. This class of compounds has been illustrated by several of the species listed in Table 7 and was unexpectedly obtained.

Recently our research group has been exploring the reaction of bidentate ligands with R_3Al. The reaction of 2-thiophenemethanol and of furfuryl alcohol with R_3Al eliminates RH and presumably R_2AlOR'. The latter product then goes through a rearrangement process yielding the tetrameric complex with both four- and six-coordinate aluminium atoms shown in Fig. 5.[34] Compounds with similar structures have been obtained by other research groups using silylaluminium derivatives reacted with ammonia.[35] When tetrahydrofurfuryl is used rather than furfuryl, the reaction originally anticipated, i.e. the formation of a dimeric bridged molecule, occurred.[34] This suggests that the energy differences between the complex species observed for the furfuryl alcohol and

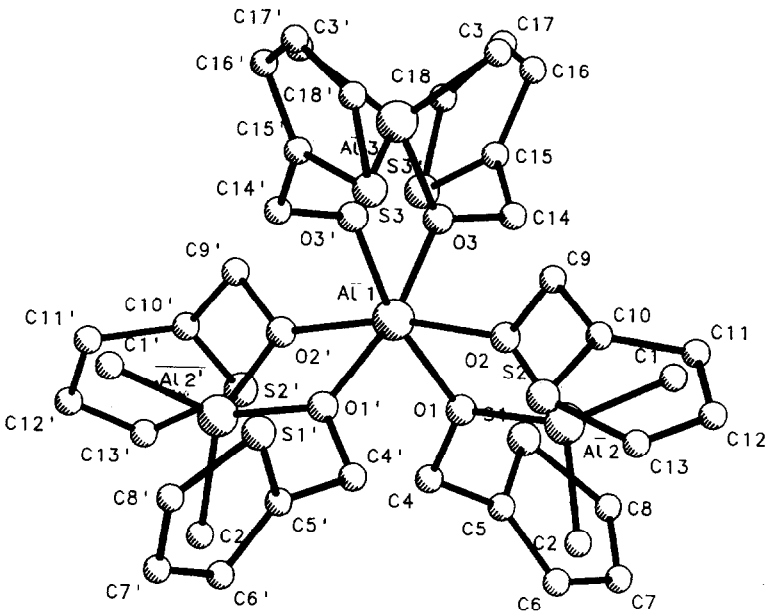

Fig. 5. A PLUTO diagram of $[(Me_2Al)_3(\mu\text{-}OCH_2C_4H_3S)_6Al]$.

2-thiophenemethanol and the tetrahydrofurfuryl alcohol are quite small. In the $(Et_2Al)_3(\mu\text{-}OCH_2C_4H_3S)_6Al$ derivative, the methylene protons are diastereotopic.[30] Variable-temperature NMR studies have established that exchange does not occur on the NMR time scale below 75°C, indicating that the complex does not undergo dissociation under these conditions. This is surprising in view of the rapid rearrangement observed for tris(tropolonato)aluminium(III) by Mutterties and Guggenberger some years ago.[37] It implies that the "bidentate" group $R_2Al(\mu\text{-}OR)_2$ forms stable bridges with the central aluminium atom, similar to those observed for other stable bidentate chelating groups.

Two other interesting compounds have been recently reported by Barron and co-workers.[38,39] The first is a relatively simple six-coordinate derivative with a methyl group directly attached to the aluminium atom which has five nitrogen atoms coordinated to fill out the coordination sphere, and the other is a tetramer which contains two types of aluminium centres, one bound to a single methyl group with four oxygen atoms and a nitrogen atom completing the coordination while the other aluminium is bound to two methyl groups and two oxygen atoms, giving a four-coordinate centre. Preparation of these systems indicates that other new and unusual products may be obtained and shows that even the limited effort that has gone into investigation of the higher coordinate organoaluminium compounds has been very fruitful.

Exploration of these higher coordinate organoaluminium derivatives seems likely to yield exciting new developments in several directions. First, the work of Rettig points out the potential use of some of the more stable compounds in biological systems. Second, the group of derivatives with aluminium in several coordination sites indicates the possibility of forming systems in which two or more metals are bound in close proximity to one another. This may allow for a more rational development of catalysts. Third, the formation of six-coordinate aluminium with direct carbon–aluminium bonds opens a whole new area to study.

INTRODUCTION

By alumoxanes we understand species containing an oxygen bridge binding two aluminium atoms, Al—O—Al. Alkoxyaluminium compounds, R_2AlOR, having an oligomeric structure in which the aluminium atoms are bonded by the alkoxy group oxygen bridge Al—O(R)—Al will not be included in this paper. Any alkyl, aryl, halide alkoxy or other group can, however, be the pendent ligand bonded to the aluminium atoms.

Alumoxanes, obtained from the reactions of organoaluminium compounds and water, were extensively studied in the 1960s as active catalysts in the polymerization of propylene oxide, monosubstituted epoxides, acetaldehyde, butadiene, propylene, isobutylene, etc. Renewed interest in alumoxanes has arisen in the 1980s, mainly resulting from the works of Kaminsky. He applied methyl alumoxanes as components of highly active catalysts for the polymerization of ethylene and propylene.

Alumoxanes easily undergo association yielding di-, tri-, tetra- and oligoalumoxanes. They also easily undergo disproportionation reactions at elevated temperatures, or when one of the disproportionation components is removed from the reaction medium by precipitation or distillation

under reduced pressure. These properties of alumoxanes make the preparation of a respective alumoxane in a crystalline form and the determination of its crystal structure difficult. It is not surprising, therefore, that the experimental data and proposed structure of alumoxanes differ and depend on the synthetic conditions, isolation methods, solvents used and many other factors. Discussion concerning the structure of alumoxanes recalls the controversies surrounding the structure of Grignard reagents which lasted for many years, before it was established that the Schlenk equilibrium depends on many factors.

The catalytic properties of alumoxanes result from the simultaneous presence of acidic and basic centres in an alumoxane molecule. The fact that the catalytically active centres may be separated from each other by any distance probably plays a considerable role.

Alumoxanes are intermediates in the hydrolysis of organoaluminium compounds to aluminium hydroxides. Materials of a high thermal or mechanical resistance can be obtained by converting alumoxanes to a suitable form, e.g. a fibre, and then hydrolysing or thermally decomposing them.

Taking the above into account it seems timely to review the preparation methods, structure, complexes and reactions of alumoxanes.

SYNTHESIS

Two main methods of synthesis of alumoxanes are known. The first method includes the reactions of organoaluminium compounds with water and the second one includes the reactions of organoaluminium compounds with species containing reactive oxygen.

Reactions with water

Organoaluminium compounds react violently with water yielding only decomposition products:

$$R_3Al + 3H_2O \longrightarrow Al(OH)_3 + 3RH. \quad (1)$$

A number of methods were applied to decrease the hydrolysis rate and to stop the hydrolysis at a required stage. Saegusa *et al.*[1] added a precise amount of water to a stirred solution of triethylaluminium in hexane containing diisopropyl ether. The reduction product was further stirred for an additional 3 h at 0°C. Saegusa proposed that triethylaluminium reacts with a controlled amount of water as follows:

$$(C_2H_5)_3Al + H_2O \longrightarrow (C_2H_5)_2AlOH + C_2H_6 \quad (2)$$

$$(C_2H_5)_2AlOH + (C_2H_5)_3Al \longrightarrow (C_2H_5)_2AlOAl(C_2H_5)_2 + C_2H_6 \quad (3)$$

$$(C_2H_5)_2AlOAl(C_2H_5)_2 + H_2O \longrightarrow (C_2H_5)_2AlOAl(C_2H_5)OH + C_2H_6. \quad (4)$$

Ishida obtained alumoxanes in a similar manner,[2] while Longiave and Castelli[3] described the synthesis of tetraethylalumoxane and diethyldichloroalumoxane as follows. A benzene solution (10%) of $(C_2H_5)_2AlCl$ was added dropwise to a saturated solution of water in benzene (0.4 g dm^{-3}). The compounds obtained were isolated by distilling off the solvent. Sakharovskaya *et al.*[4] hydrolysed the organoaluminium compound, cooled to −40°C, with a mixture of nitrogen and a small amount of water vapour for 18 h. The unreacted organoaluminium compound was then distilled off. A modified method consisted of carrying out the above reaction in an etheral medium.[5] The method we have developed[6] consisted of the introduction of wet toluene vapours (b.p. of azeotrope, 84°C) into a toluene solution of the organoaluminium compound cooled to −78°C. The condensed vapours introduced to the vigorously stirred, cooled solution of the organoaluminium compound caused the slow hydrolysis reaction. Storr *et al.*[7] have developed a method for treating water with an organoaluminium compound which enables the reaction to proceed very slowly and minimizes the risk of precipitation of highly polymeric material from the reaction sphere. The hydrolysis was carried out under high vacuum and at low temperatures. Water vapour was introduced very slowly into the organoaluminium compound solution at 5°C. This method permitted Storr to carry out the reaction in such a way to avoid the formation of higher oligomers.

Razuvaev *et al.*[8] described the now widely used method of alumoxane synthesis. The reactions of organoaluminium compounds with water of copper sulphate pentahydrate were carried out in

aromatic hydrocarbons as the medium. The reaction proceeded according to eq. (5):

$$8AlR_3 + CuSO_4 \cdot 5H_2O \longrightarrow 4 \begin{matrix} \diagdown \\ Al—O—Al \\ \diagup \end{matrix} + CuSO_4 \cdot H_2O + 8RH. \quad (5)$$

Reactions with oxygen-containing oxygen compounds

Ziegler[9,10] first mentioned the formation of tetraethylalumoxane in the reaction of triethylaluminium with carbon dioxide:

$$3Et_3Al + CO_2 \longrightarrow Et_2AlOAlEt_2 + Et_3COAlEt_2. \quad (6)$$

An alumoxane was not, however, isolated in this reaction. Zakharkin *et al.*[11] obtained tetraisobutylalumoxane by reaction (7):

$$RCONR_2 + 2i\text{-}Bu_2AlH \longrightarrow i\text{-}Bu_2AlOAl\text{-}i\text{-}Bu_2 + RCH_2NR_2, \quad (7)$$

while Mole *et al.*[12] used carboxylic acids in the reaction with Me_3Al:

$$MeCO_2H \xrightarrow{Me_3Al} MeCO_2AlMe_2 \xrightarrow{Me_3Al} Me_2AlOAlMe_2 + Me_2CO. \quad (8)$$

We found[13] that reactions of alkylaluminium compounds, $Me_x(OMe)AlCl_{2-x}$ (where $x = 0$–2), with Me_yAlCl_{3-y} ($y = 1$–3) and Et_3Al lead to the formation of alumoxanes with the evolution of alkanes and methyl chloride.

Another method of alumoxane synthesis, without using water, consists of using the oxygen atom bonded to the metal. By treating PbO with an organoaluminium compound a corresponding alumoxane[14] can be obtained from reaction (9):

$$2R_3Al + PbO \longrightarrow R_2AlOAlR_2 + R_2Pb. \quad (9)$$

A similar reaction takes place with alkylaluminium chlorides.[15] By treating the post-reaction mixture with an excess of diethyl ether the trimethylchloroalumoxane ether complex was obtained:

$$4PbO + 8Me_2AlCl \longrightarrow \text{post-reaction mixture} \xrightarrow{Et_2O} 4Me_3ClAl_2O \cdot OEt_2 + Me_4Pb + 2PbCl_2 + Pb. \quad (10)$$

Araki and co-workers [16,17] disclosed a method for preparing alkali metal dialuminates (R_2AlOM) by equimolar reactions of trialkylaluminium and alkali metal hydroxide. Equimolar condensation of R_2AlOLi with R_2AlCl, in toluene at $-20°C$, proceeded without formation of gaseous products, eq. (11):

$$R_2AlOLi + R_2AlCl \longrightarrow R_2AlOAlR_2 + LiCl \quad (11)$$

(R = Me, Et, *i*-Bu).

An interesting method of alumoxane synthesis was reported by Serwatowski.[18] Tetraethylalumoxane is formed in good yield from the reaction of tetraorganodiboroxane with triethylaluminium, eq. (12):

$$R_4B_2O + 2Et_3Al \xrightarrow[\text{toluene}]{20°C} Et_4Al_2O + 2R_2BEt \quad (12)$$

(R_2 = Et_2, 1,5-cyclooctadienyl).

The alumoxane formed was isolated and studied by means of molecular weight and ^{27}Al and ^{17}O NMR.

The methods described above are those most often applied to alumoxane synthesis.

STRUCTURE

Only a few alumoxane structures, determined by single-crystal X-ray investigations, are known. Alumoxanes of a determined structure usually contain bulky ligands or are ionic.

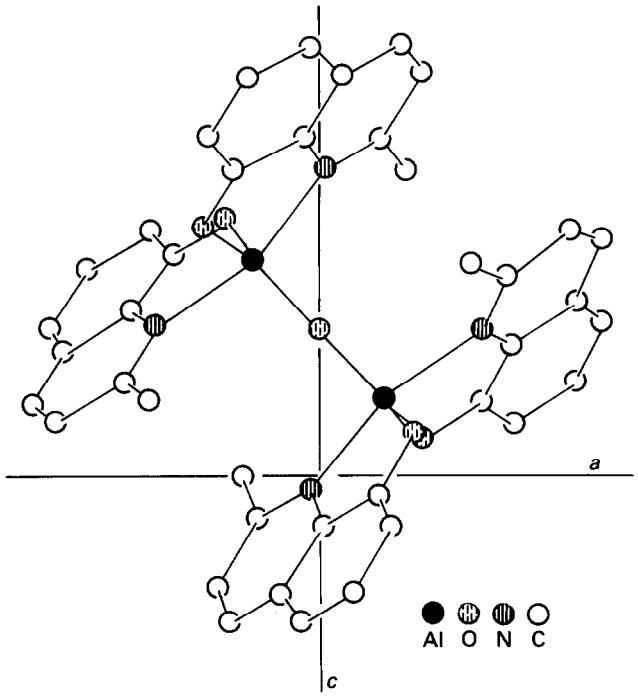

Fig. 1. Structure of μ-oxo-di[bis(2-methyl-8-quinolinato)]aluminium.

Kushi and Fernando[19] have synthesized a complex formed by the reaction of aluminium chloride and 2-methyl-8-quinolinol in a non-aqueous medium. The complex was found, by X-ray investigation, to be μ-oxo-di[bis(2-methyl-8-quinolinolato)]aluminium, containing two penta-coordinated aluminium atoms. The structure consists of discrete molecules of $Al_2O(C_{10}H_8NO)_4$ as shown in Fig. 1. Each of the two aluminium atoms is coordinated to two molecules of 2-methyl-8-quinolinol which act as a bidentate ligand. The two aluminium atoms in the molecule are also connected by an oxo-bridge and it is therefore an alumoxane. The coordination around each of the aluminium atoms is trigonal bipyramidal; the three oxygen atoms and the aluminium atoms are in a plane and the two nitrogen atoms occupy the apical positions (Fig. 2). The stability of the complex, at room temperature on exposure to air and X-rays, was unexpectedly high. The bond angle, Al—O—Al, is 180°. This angle, which is unusual for alumoxanes, is probably caused by the bulky groups, which, when mutually repulsing, straighten the Al—O—Al bond which normally exhibits an angle smaller than 180°.

An interesting alumoxane, occurring as a dimer, was obtained by Bulychev *et al.*[20] $\{[(C_5Me_5)Ti(C_5Me_4CH_2)H_2Al]_2O\}_2 \cdot 2C_6H_6$ has been obtained by treating $(C_5Me_5)_2TiCl$ with $LiAlH_4$ in a 2 : 1 mole ratio. The composition and structure of this compound was identified by X-ray structural

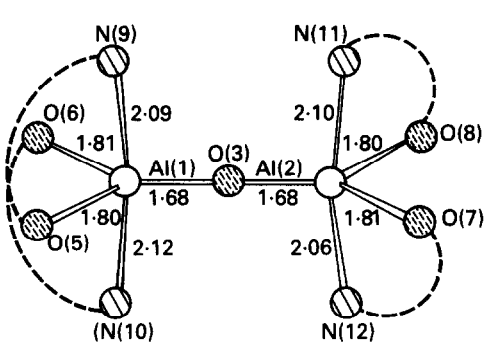

Fig. 2. Arrangement of oxygen and nitrogen atoms around aluminium atoms in $Al_2O(C_{10}H_8NO)_4$.

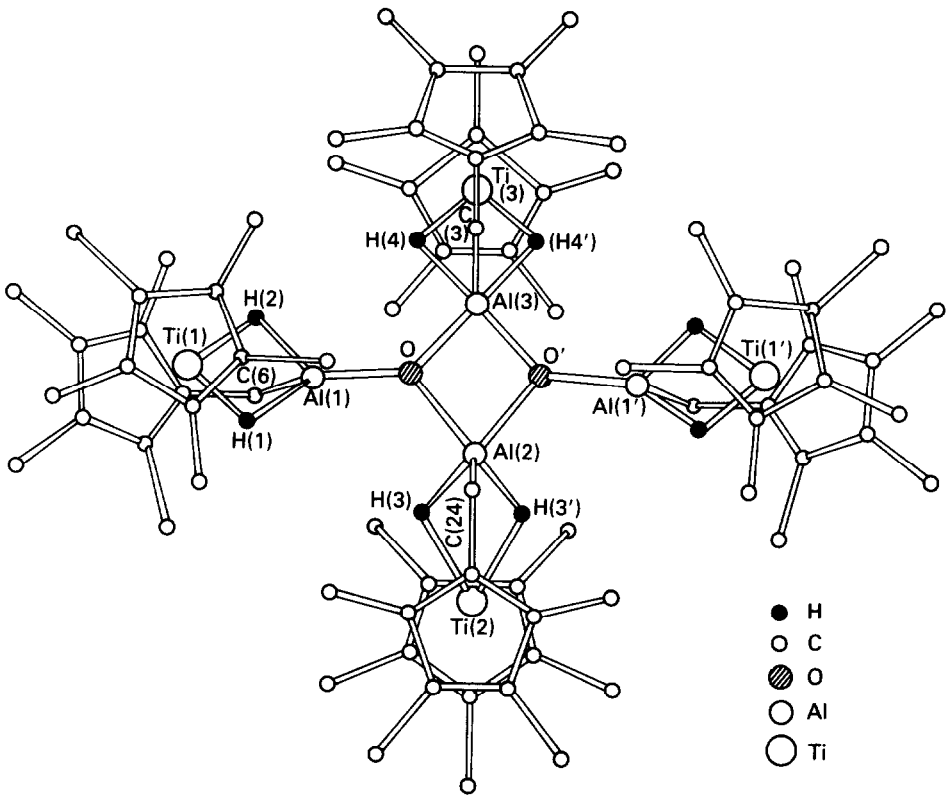

Fig. 3. Molecular structure of the complex $\{[(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_5Me_4CH_2)Ti(\mu_2\text{-}H)_2Al]_2\text{-}\mu_3\text{-}O\}_2 \cdot 2C_6H_6$.

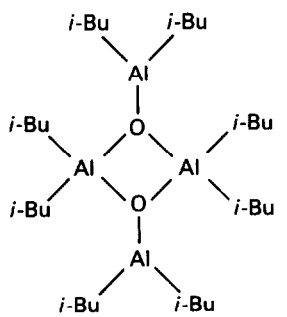
analysis. The presence of oxygen atoms in the molecule is, as the authors suggest, most likely to be caused by the partial hydrolysis of the reaction products by traces of water.

The crystal structure of the complex is a sandwich of $\{[(C_5Me_5)Ti(C_5Me_4CH_2)H_2Al]_2O\}_2$ molecules and two crystallographically independent benzene molecules (Fig. 3). All aluminium atoms in the molecule are arranged in pairs with coordination numbers of four and five. The molecule has a typical structure postulated for an alumoxane dimer of $i\text{-}Bu_4Al_2O$.[21] Obviously, the molecule



shown in Fig. 3 consists of aluminium atoms with coordination numbers four and five, instead of those with coordination numbers three and four. This causes a stabilization of the molecule obtained by Bulychev.

A typical system for alumoxanes containing three aluminium atoms bonded via μ_3-oxygen bridges occurs in the $[Al_7O_6Me_{16}]^-$ anion obtained by Atwood *et al.*[22] If KO_2 and $AlMe_3$ in a 1 : 2 molar ratio are placed in refluxing benzene, large, colourless crystals are deposited on the walls of the flask. X-ray diffraction studies have shown the product to be $K[Al_7O_6Me_{16}] \cdot C_6H_6$. The structure of this anion is shown in Fig. 4. The anion essentially consists of an open Al_2O_6 ring capped by a

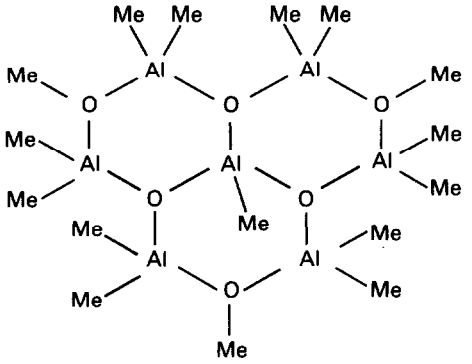


Fig. 4. Structure of the anion of $K[Al_7O_6Me_{16}]\cdot C_6H_6$.

seventh aluminium atom which is bonded to three alternate oxygen atoms in the ring. The six ring aluminium atoms are each bonded to two terminal methyl groups, while the unique aluminium atom is attached to only one methyl group. Each oxygen atom is three-coordinate. The ones on the exterior (not bonded to the unique aluminium atom) bridge two aluminium atoms and are also each bonded to one methyl group, while the interior three oxygen atoms each bridge three aluminium atoms; which is a typical system for alumoxane.[5] Both types of oxygen atom exhibit bond angles as expected for sp^2-hybridization. The angles at the oxygen atoms range from 117 to 123°. The bond angles at the aluminium atoms of the Al_6O_6 unit are near the tetrahedral value, except for the O—Al—O interior angles which range from 97 to 90°. The O—Al—O values, for the unique aluminium atom, 106–108°, are close to those predicted for sp^3-hybridization.

Atwood *et al.*[23] have also obtained the novel alumoxane anion $[Me_2AlOAlMe_3]_2^{2-}$. This result is significant for a better understanding of the structure, stability and oligomerization tendency of the alumoxanes. Trimethylaluminium methylates the cacodylate anion, $[AsMe_2O_2]^-$, with formation of $[AsMe_4]_2[Me_2AlOAlMe_3]_2$, and an X-ray crystal structure has shown the alumoxane anion to consist of a planar Al_2O_2 ring with $AlMe_3$ molecules coordinated to the oxygen atoms (Fig. 5).

The stability of the anion in comparison with the dimeric form of tetramethylalumoxane is much greater since in the anion both aluminium atoms are four-coordinate, and in the tetramethylalumoxane dimer two atoms are three-coordinate and coordinatively unsaturated. The formation of a 3c–2e bond by one of the methyl groups not only causes an increase of the aluminium coordination number to four, but also facilitates the abstraction of a Me_3Al molecule and $Me_3Al_2O_2$, which subsequently oligomerizes (Scheme 1).

The structure of the $[Me_2AlOAlMe_3]_2^{2-}$ anion resembles those of the trimethylchloroalumoxane–diethyl ether[24] and methylchloroalumoxane–diethyl ether[25] complexes (Fig. 6).

The formation of the etheral complex causes an increase in the coordination number of the exterior of two aluminium atoms and stabilizes the alumoxane molecule, as in the $[Me_2AlO Me_3]_2^{2-}$ anion. Despite many papers concerning the synthesis and structural studies of alumoxanes,

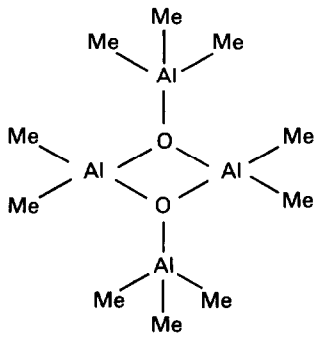

Fig. 5. Crystal structure of the alumoxane anion.

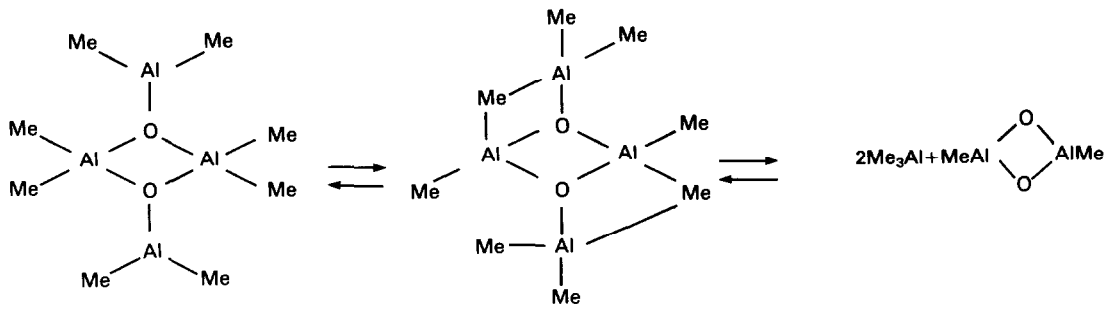
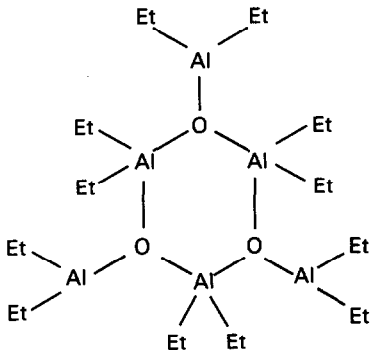


Scheme 1.

the number of structures determined by X-ray investigations is small. This is caused by the ease of disproportionation and association reactions of monomeric alumoxanes.

Storr *et al.*[7] first proposed a trimeric structure for $(Et_2Al)_2O$, on the basis of molecular weight determination.



Then Araki and co-workers[16] found that molecular weight determination indicated $(Et_2Al)_2O$ to be on average a tetrameric aggregate, at a given concentration. Proton magnetic resonance and cryoscopic studies lead us to propose the structure shown in Fig. 7 for $(Et_2Al)_2O$.[26] In this structure each aluminium atom has a coordination number of four. Independence of the character of the spectra on the concentration of alumoxane in toluene solution (2–20 wt%), indicates that the bridging ethyl groups occur inside the trimer. Further ^{17}O and ^{27}Al NMR studies carried out by Serwatowski[18] confirmed the structure shown in Fig. 7. A narrow signal at 59 ppm occurs in the ^{17}O NMR spectrum, characteristic of the signals for a three-coordinated oxygen atom and typical for a symmetrical structure. A single signal is observed at 156 ppm in the ^{27}Al NMR spectrum corresponding to the four-coordinated aluminium atom.[27] No signals corresponding to the three-

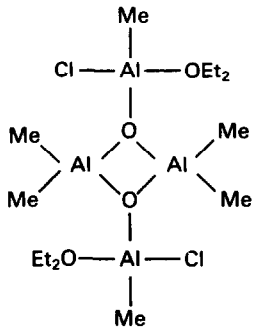


Fig. 6. Structure of methylchloroalumoxane–diethyl complex.

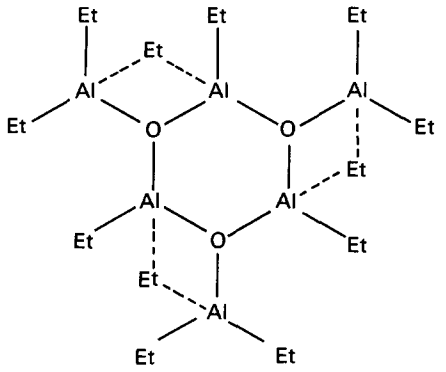

Fig. 7. Proposed structure for the $(Et_2Al)_2O$ trimer.

coordinated aluminium atom are present. The failure in establishing a method of synthesis of $(Et_2Al)_2O$ so as to obtain it in a crystalline form, meant that various structures were assigned to tetraethylalumoxane,[28-30] not always based on comprehensive and exhaustive studies.

Siergiejczyk and Synoradzki[31] have found by means of gel permeation chromatography that raw tetraethylalumoxane consists of ethyloligoalumoxanes (**I**), a tetraethylalumoxane trimer (**II**) and triethylaluminium (**III**). The mass ratio of phases **I/II/III** was 15:65:20. The first phase consisted of a mixture of ethyloligoalumoxanes of average molecular weight, *ca* 1670, the second corresponded to that of trimeric tetraethylalumoxane (Found: 562; Calc. for Et_4Al_2O: 186) and the third phase was triethylaluminium, mol. wt 228. Almost all the triethylaluminium could be distilled off from the raw tetraethylalumoxane at room temperature in high vacuum, and no change in the position of equilibrium was observed. However, after heating pure tetraethylalumoxane up to 80°C for 2 h, small amounts of ethyloligoalumoxane and triethylaluminium appeared. The investigations carried out showed that the trimer of tetraethylalumoxane is stable at room temperature, and at elevated temperatures an equilibrium is established between the trimer and the oligomer and triethylaluminium, eq. (13):

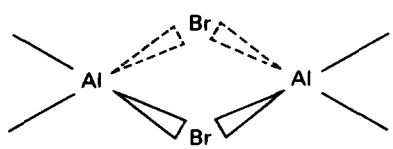
$$(Et_4Al_2O)_3 \rightleftharpoons 3Et_3Al + (EtAlO)_3. \tag{13}$$

Storr *et al.*[7] and Araki and co-workers[16] showed that a compound of the type $R_2AlOAlR_2$ disproportionates readily into AlR_3 and polymeric $(RAlO)_n$ substances on heating under reduced pressure and slowly on storage at room temperature.

An interesting structure of alumoxane has been proposed for $Me_2Br_2Al_2O$.[32] A viscous yellow liquid was obtained from reaction (14) carried out in boiling toluene; after filtering off lead bromide and removal of toluene, white cubic-like crystals appeared. The association degree of $n = 3.86$ was determined by means of cryoscopic measurements [MW = 1002 in benzene (2%)]:

$$2MeAlBr_2 + PbO \xrightarrow[\text{Toluene}]{110°C} Me_2Br_2Al_2O + PbBr_2. \tag{14}$$

The proposed structure of the alumoxane tetramer is shown in Fig. 8. The results of spectroscopic (IR and ^1H NMR) studies are in agreement with the proposed structure. The structure presented in Fig. 8 consists of two $(Me_2Br_2Al_2O)_2$ dimers linked via bromide bridges. The terminal aluminium atoms have the coordination number four and are bonded by a stable bromide bridge:



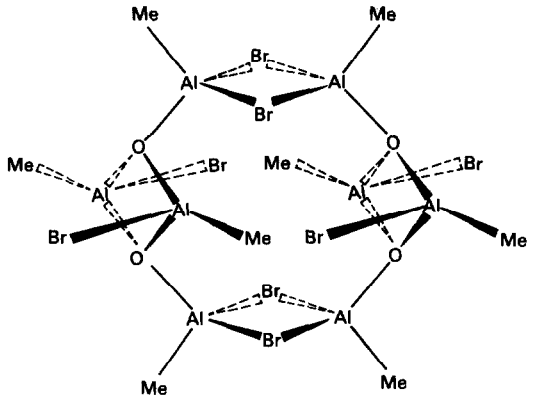


Fig. 8. The hypothetical molecular structure of the crystalline dimethyldibromodialumoxane tetramer.

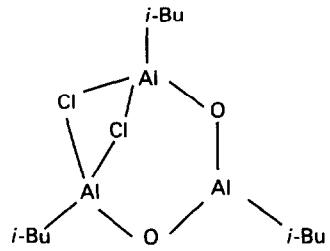
A similar structure to the one above was proposed for triisobutyldichloroalumoxane.[33] The crystalline alumoxane in *ca* 20% yield was obtained from reaction (15):

$$3(i\text{-Bu})_2AlCl + 2H_2O \xrightarrow[\text{Toluene}]{-78°C} (i\text{-Bu})_3Cl_2Al_3O_2 + \text{side products.} \quad (15)$$

The results of elemental analysis, molecular weight determination and spectroscopic measurements confirm the proposed structure (Fig. 9). In this case the monomer contains three aluminium atoms connected via two oxygen atoms:



The presence of the three-coordinated aluminium atom and the two-coordinated oxygen atom causes the association of the monomer to trimerize.

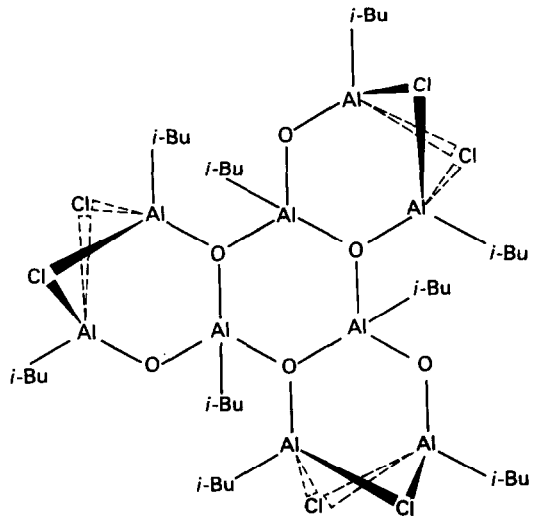


Fig. 9. The hypothetical molecular structure of the crystalline triisobutyldichlorooligoalumoxane trimer.

REACTION MECHANISMS OF ORGANOALUMINIUM COMPOUNDS WITH WATER

A basic synthetic method for alumoxanes sys is the reaction of organoaluminium compounds with water. The homogeneity of the synthesized alumoxane depends on the hydrolysis procedure. The milder the reaction conditions (lower temperature, low reactant concentration, vigorous stirring, long reaction time, presence of a solvent decreasing the reactivity of the organoaluminium compound) the more homogeneous will the alumoxane be and thus there will be less side products such as higher oligomers and even aluminium hydroxide. Many difficulties which cannot easily be avoided are encountered while carrying out the reaction. The type of alumoxane formed depends on the method of hydrolysis. The organoaluminium compound/water molar ratio has a great effect on the hydrolysis product formed. This is presented in a simplified way in Scheme 2.

Sakharovskaya *et al.*[4] have proposed a two-step reaction course in which the dialkylaluminium hydroxide is the relevant intermediate, eqs (16) and (17):

$$R_3Al + H_2O \longrightarrow R_2AlOH + RH \tag{16}$$

$$R_2AlOH + R_3Al \longrightarrow R_2AlOAlR_2 + RH. \tag{17}$$

Amdurski *et al.*[34] have postulated on the basis of the stoichiometry and kinetics of the Et_3Al hydrolysis reaction (1 : 1) the presence of a hydroxyl group in the final product. Such a possibility was confirmed by radioisotopic investigation of the Et_3Al/T_2O system.[35] Ueyama *et al.*[16] have even observed the weak resonance signal of the hydroxyl group protons ($\tau = 6$ ppm) in the ^1H NMR spectrum of the products of the reaction of *i*-Bu_3Al with water (2 : 1). We have also observed in the IR and ^1H NMR spectra dimethylaluminium hydroxide as an intermediate product of Me_3Al hydrolysis in dimethoxyethane.[36] Petrova *et al.*[37,38] have limited their investigations to the analysis of complex formation of Et_2AlCl and $EtAlCl_2$ with water. The hydrolysis of R_3Al (R = CH_3, C_2H_5, *i*-C_6H_9) at 1 : 1 and 2 : 1 mol ratios was studied by ^1H NMR spectroscopy in the temperature range -70–$0°C$.[39] A multi-step reactions course was found: in the first step a 1 : 1 complex of R_3Al with water is formed. This complex undergoes intramolecular elimination of alkane to produce dialkylaluminium hydroxide, R_2AlOH. In the next step R_2AlOH forms stable auto-associates (in 1 : 1 system) or reacts with the excess of R_3Al to give alumoxane.

On the basis of literature data and our studies, the mechanisms of R_3Al and water reactions at 2 : 1 and 1 : 1 mole ratios can be presented as follows.

$R_3Al + H_2O$, 2 : 1 *system*

In the first reaction step a water molecule attacks the $[R_3Al]_2$ dimer forming complex **I** (Scheme 3). At $-72°C$ and in diethyl ether medium, complex **I** can be observed by ^1H NMR.[39] At higher temperatures it undergoes reaction yielding **II** and RH. Dialkylaluminium hydroxide forms an intramolecular complex with R_3Al via carbon and oxygen bridges. Complex **II** is quite stable and reacts with the evolution of RH only at *ca* 0°C. The $[R_3Al]_2$ dimer reacts more readily with water than complex **II**. The reactivity of the R groups is lower in **II** due to the basicity of the oxygen atoms. Thus it can be assumed that the formation of complex **II** is the dominating reaction until the water is used up (Al/H_2O mole ratio = 2 : 1).

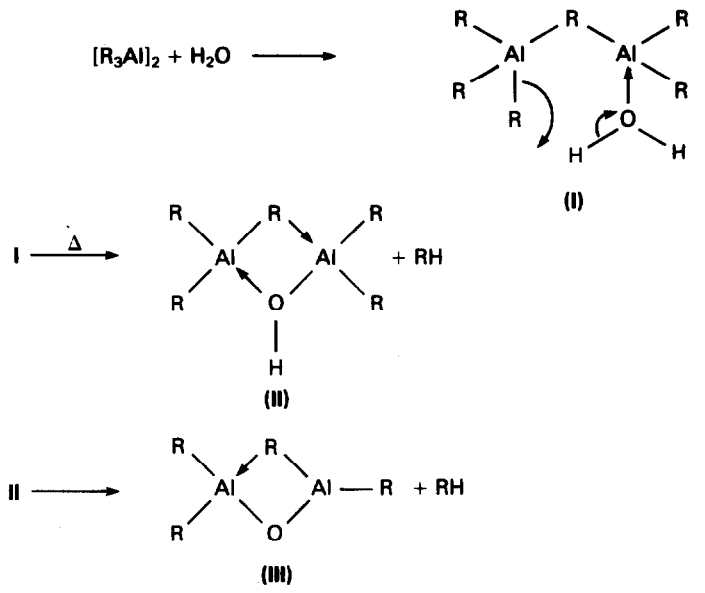
At *ca* 0°C complex **II** undergoes reaction yielding RH. An intramolecular reaction is the most probable one (Scheme 3). A number of reactions of **II** [eq. (18)] and of all of the intermediate and

$$\underset{2:1}{2R_3Al + H_2O} \longrightarrow R_2Al{-}O{-}AlR_2 + 2RH$$

$$\underset{1:1}{R_3Al + H_2O} \longrightarrow [RAlO] + 2RH$$

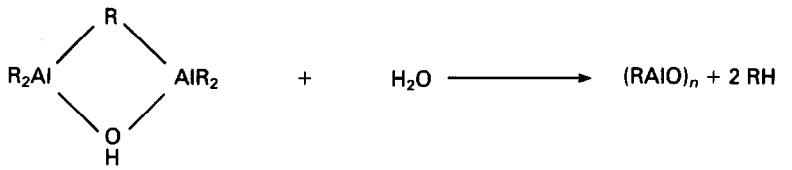
$$\underset{1:3}{R_3Al + 3H_2O} \longrightarrow Al(OH)_3 + 3RH$$

Scheme 2.



Scheme 3.

final products [eqs (19) and (20)] with water can take place:



(18)

$$R_2AlOAlR_2 + H_2O \longrightarrow (RAlO)_n + 2RH \quad (19)$$

$$(RAlO)_n + H_2O \longrightarrow (HOAlO)_n + RH. \quad (20)$$

Nearly all of the intermediate and final products of the hydrolysis of organoaluminium compounds may also react with trialkylaluminium, eq. (21), yielding tetraalkylalumoxane:

$$(RAlO)_n + nR_3Al \rightleftharpoons (R_2AlOAlR_2)_n. \quad (21)$$

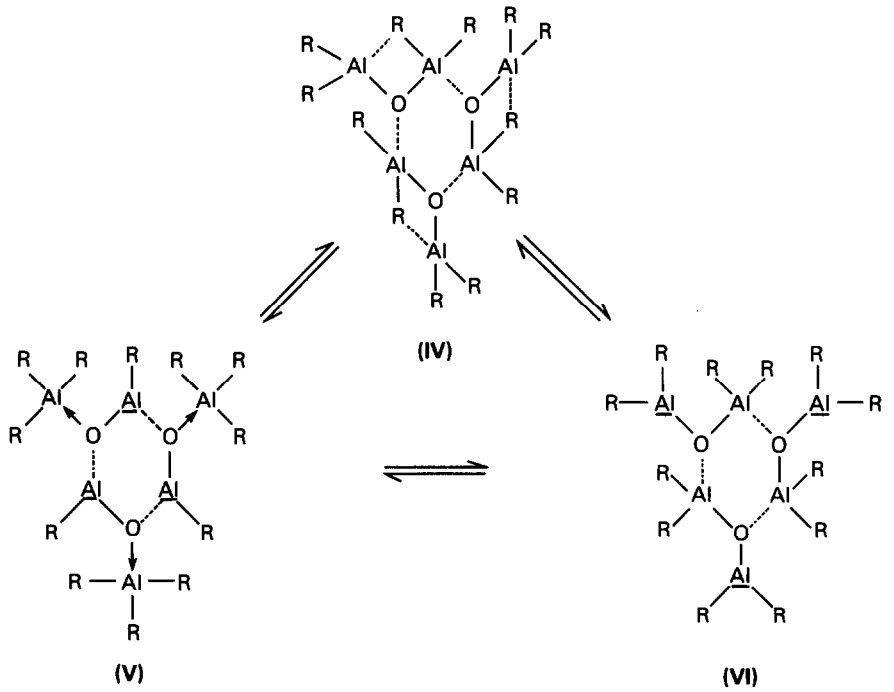
An equilibrium, dependent on many parameters, is probably established. In the case when a highly associated oligomer $(RAlO)_n$ is formed, the shift of the equilibrium of reaction (21) to the right is a very slow process. Further hydrolysed products, such as $Al(OH)_3$ or Al_2O_3, practically do not react with R_3Al.

Compound **III** easily forms associates due to the acidic, three-coordinated aluminium atom and basic, two-coordinated oxygen atom. The smallest ring strain and steric hindrance occur for the trimer of **III** forming structure **IV** (Scheme 4).

In compound **IV** the aluminium and oxygen atoms are four- and three-coordinated, respectively, so this compound is structurally stable. Due to strain occurring in the carbon bridge, its cleavage does not require much energy and proceeds easily. Depending on the position of cleavage of the Al—C—Al bridge, compounds **V** or **VI** can be formed from complex **IV** (Scheme 4).

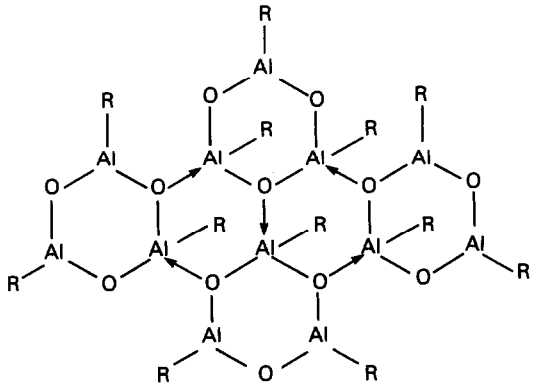
No bridge strains appear in **V**, but three aluminium atoms in the ring are three-coordinated and can easily form complexes. A similar situation occurs in the case of structure **VI**, but here three terminal aluminium atoms are three-coordinated.

From the above it appears that mutual transformations of structures **IV**, **V** and **VI** proceed easily at or below room temperature. A number of signals with small differences in chemical shifts, occur in the ^1H NMR spectrum. A considerable decrease of temperature causes a retardation of



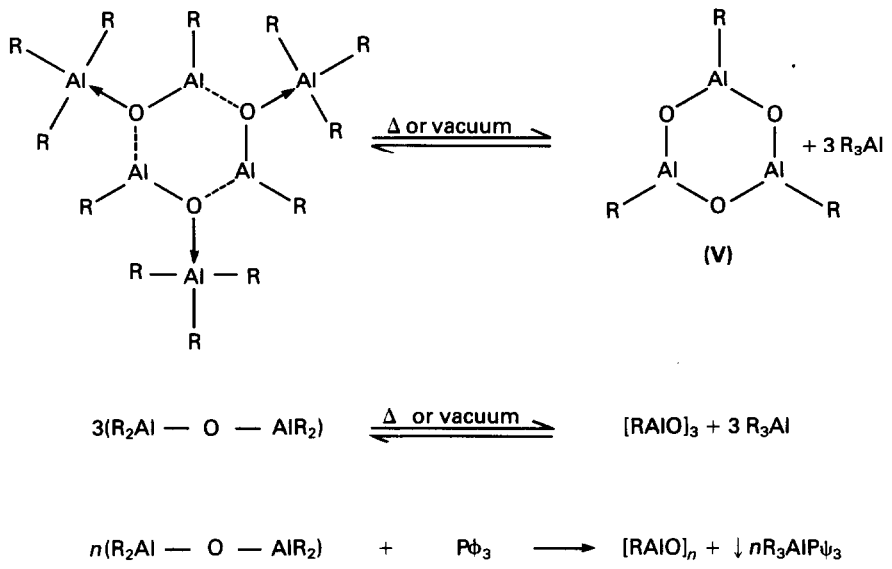
Scheme 4.

these mutual transformations, but still all three structures are present. This has a decisive effect on the ^{1}H NMR spectrum pattern, which still consists of many signals from different protons.



Structure **V** can be treated as a six-membered system consisting of three [RAlO] monomeric units and three R_3Al molecules coordinated via the bridging oxygen atoms. Thus, there exists a possibility of R_3Al abstraction under the influence of temperature, high vacuum or a respective electron donor (Scheme 5). Alumoxane (**VII**) associates immediately, since it has three-coordinated aluminium atoms and two-coordinated oxygen atoms. Structure **VIII** is the most probable structure for the $[RAlO]_n$ associate, in which all the aluminium and oxygen atoms are four- and three-coordinated, respectively. It should be noted that the six-membered Al_3O_3 rings are not planar. Structure **VIII** can be extended and does not exhibit strain. It is formed from four cyclic $[RAlO]_3$ monomeric units forming six six-membered rings. In general, the reaction product has the formula $[RAlO]_n$.

It is obvious that the two-coordinated oxygen atoms are still capable of coordinating R_3Al



Scheme 5.

molecules. By treating **VIII** with an equimolar amount of trialkylaluminium ($RAlO/R_3Al = 1:1$), the equilibrium of reaction (21) shifts to the right:

$$[RAlO]_{3n} + 3n\,R_3Al \rightleftharpoons n(R_4Al_2O)_3. \tag{21}$$

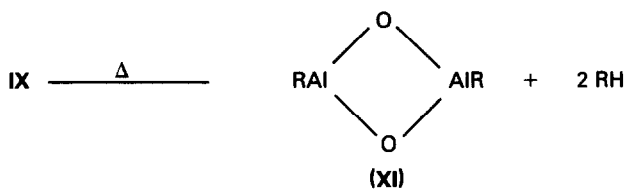
The decomposition of alumoxane with the liberation of trialkylaluminium, as well as the facility of the reverse reaction, eq. (21), indicate a comparable acidity of the aluminium atoms in R_3Al and RAlO. The Al—O—Al bridging oxygen is the base with which these Lewis acids react. Its basicity for different bridging systems can be assumed to be constant.

The equilibrium of reaction (21) is shifted to the right because R_3Al is a stronger Lewis acid than $[RAlO]_n$. When removing trialkylaluminium from the reaction medium $(RAlO)_n$ is formed as the final product. This can be achieved by the distillation of R_3Al at elevated temperatures or under reduced pressure, or by precipitating it in the form of a complex with PPh_3 (Scheme 5). Attack of the aluminium atom of R_3Al on the ring oxygen atom can be assumed as the probable reaction mechanism of **VIII** with trialkylaluminium. Further cleavage of the O—Al bond in the bridge and formation of a new Al—O bond with trialkylaluminium takes place. Consecutive formation and cleavage of Al—O bonds does not require high energy and is kinetically controlled. The equilibrium described by eq. (21) results from these reactions.

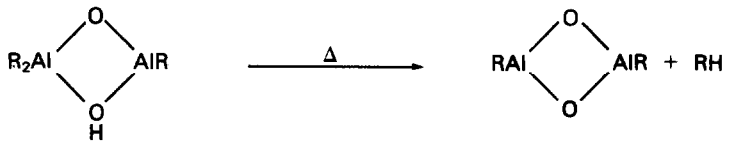
As can be seen from the above, the complexity of alumoxane structures, as a result of the reaction presented in Scheme 4, become still more complicated due to the equilibrium presented by eq. (21). This is the main reason precluding the preparation of methyl, ethyl or butyl alumoxane in crystalline froms or their isolation by distillation.

$R_3Al + H_2O$, 1 : 1 *system*

The first step of the reaction proceeds according to Scheme 6. Further reactions proceed, in which the next water molecule reacts with **II** (Scheme 6) and **III** yielding **IX**, **X**, respectively. Both **IX** and **X** undergo further reactions at higher temperatures [eqs (22) and (23)]:



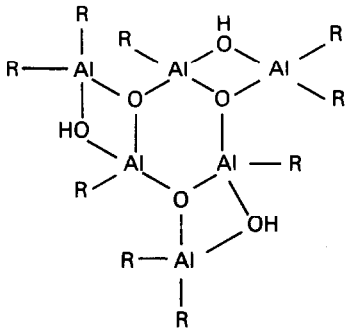
(22)



(X) (XI) (23)

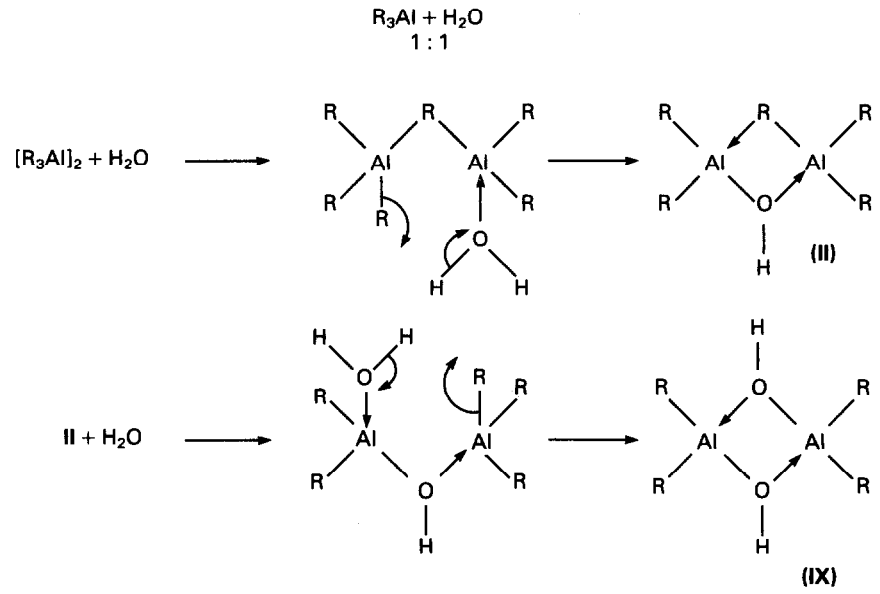
Compound **XI** undergoes association since it has two aluminium and two oxygen atoms, three- and two-coordinated, respectively (Scheme 7).

Compound **X** can also undergo association since it has one three-coordinated aluminium atom and one two-coordinated oxygen atom. A structure analogous to **IV** can be formed in which the OH group oxygen atom bridges the terminal aluminium atom and the ring aluminium atom (**XII**).

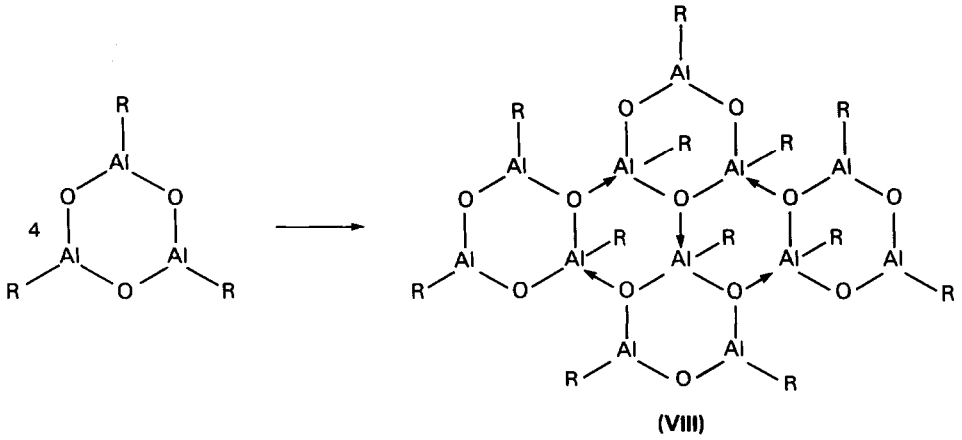


(XII)

The reactivity of the OH groups is considerably decreased in compound **XII** because the aluminium and oxygen atoms are coordinatively saturated. This is the reason why a number of OH groups do not react easily and remain in the products of hydrolysis of R_3Al. Structure **XII** is more stable than **IV** since the stability of the oxygen bridges is higher than that of the carbon bridges. The association of **XI** can proceed in many ways (Scheme 8).



Scheme 6.



(VIII)

$4(RAlO)_3 \longrightarrow [RAlO]_{12}$

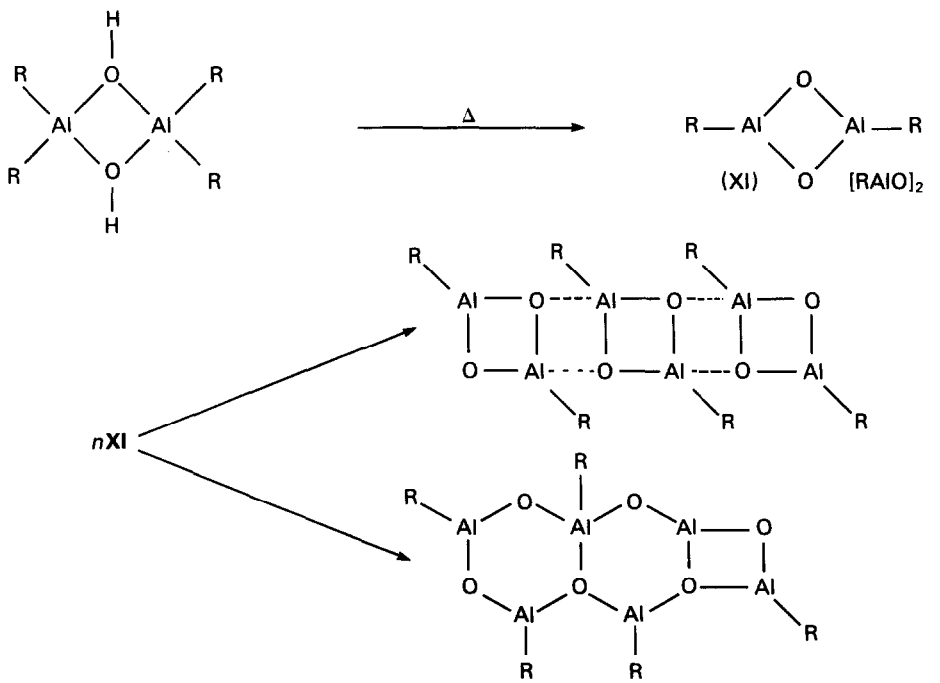
found : n = 10–12

Scheme 7.

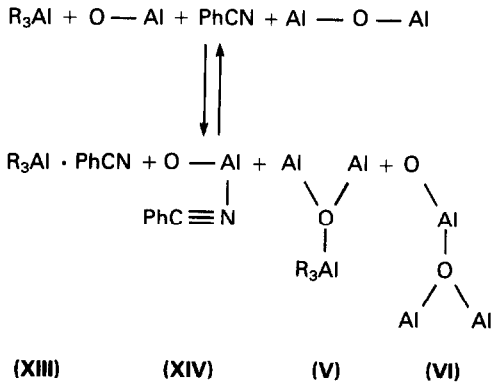
The associate which is formed without cleavage of the bridge has aluminium and oxygen atoms coordinatively saturated with the exception of terminal atoms, thus stabilizing the associate. Strain in the four-membered bridges acts against the stability of the associates. This strain may be the reason for the cleavage of internal Al—O bonds and for the formation of a more stable six-membered system (Scheme 8). Internal three-coordinated aluminium atoms and two-coordinated oxygen atoms occur in this associate. This may be the driving force for further association to compound **VIII**.

Assuming that compounds formed in the reaction of R_3Al with water have a chain structure with a variable number of [RAlO] units, then the chains formed will immediately react giving the structure shown in Scheme 8. Formed associates with $[RAlO]_n$ can undergo reactions with R_3Al yielding alumoxane, **IV**. These are reversible reactions and can be presented by eq. (21).

For ethyl alumoxanes at room temperature and under normal pressure, the equilibrium of reaction (21) is shifted further to the right compared with that of the methyl alumoxane.



Scheme 8.



Scheme 9.

COMPLEXES OF ALUMOXANES WITH ELECTRON DONORS

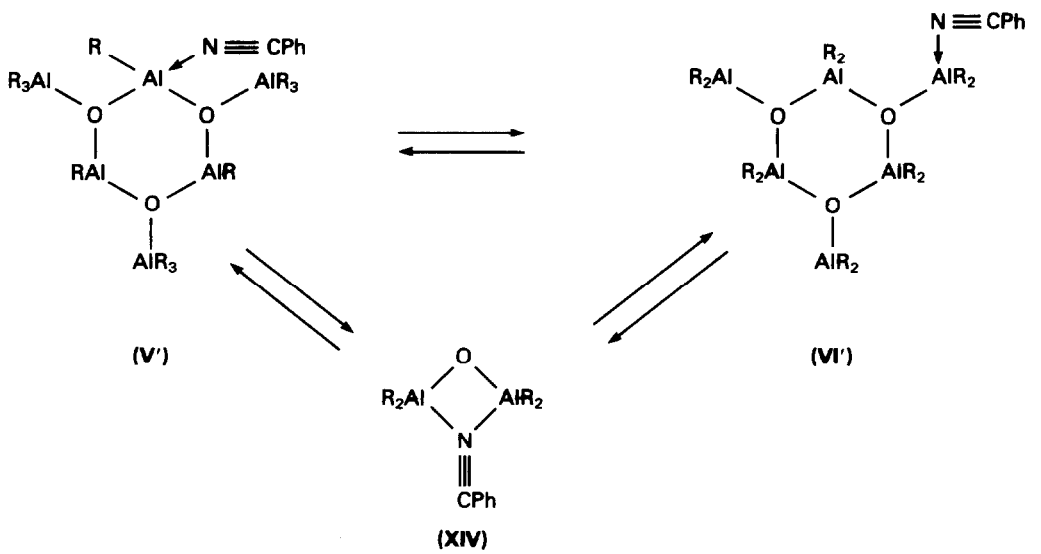
The reactions of alumoxanes with bases are of a complex character. Two Lewis acids and two bases are present in the reaction medium, which are denoted as A and A′, B and B′, respectively. These can react with each other forming donor–acceptor complexes and the reaction may be represented by eq. (24):

$$A+A'+B+B' \rightleftharpoons AB+A'B+AB'+A'B'. \qquad (24)$$

If the aluminium atom of R_3Al is denoted as A, and that of O—Al—O alumoxane as A′, the nitrogen in PhCN as B and the Al—O—Al alumoxane oxygen as B′, then eq. (24) can be represented as in Scheme 9. The equilibrium between forms **V** and **VI** has already been presented in Scheme 4.

By considering that from amongst the three possible structures of the alumoxane trimer (**IV**, **V** and **VI**, Scheme 4) benzonitrile can react with **V** and **VI**, then complexes **V′** and **VI′** should be formed (Scheme 10). Both dimeric complexes, **V′** and **VI′**, can, however, dissociate forming the monomeric complex **XIV**.

A nearly monomeric ($n = 1.325$) complex was obtained by Storr *et al.*[7] for $(Et_4Al_2O)_3$ and trimethylamine. Ueyama *et al.*[16] isolated and determined the crystalline monomeric complex of $(Et_4Al_2O)_3$ with 5,6-benzoquinoline and also the complexes $(Et_4Al_2O)_3$ and $(Me_4Al_2O)_3$ with styrene oxide in a crystalline form soluble in benzene. We have isolated a similar monomeric complex from the reaction of $(Et_4Al_2O)_3$ with benzonitrile.[40,41]

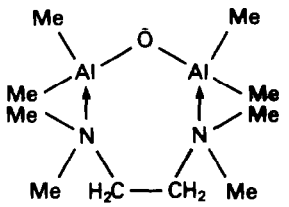


Scheme 10.

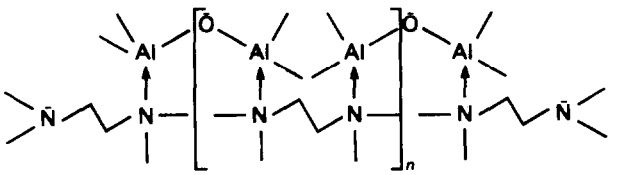
A complex of tetramethylalumoxane and N,N,N′,N′-tetramethylethylenediamine (TMEDA) was obtained[42] by the partial hydrolysis of trimethylaluminium, eq. (25):

$$2Me_3Al + H_2O \xrightarrow[-30°C]{TMEDA} Me_4Al_2O \cdot TMEDA + 2CH_4. \quad (25)$$

Pale crystals (m.p. 78–82°C) in 5–10% yield were obtained (RT, high vacuum sublimation). Spectral data, mol. wt and mass spectra of the sublimate correspond to the alumoxane complex, $Me_4Al_2O \cdot TMEDA$. The data obtained prove the existence of the monomeric tetramethylalumoxane–TMEDA complex of structure **XV**.



(XV)



(XVI)

The highly viscous residue of sublimation which is also insoluble in hydrocarbons seems to be of the donor–acceptor type polymers like **XVI**.

The Et_4Al_2O alumoxane reacts with triphenylphosphine and acridine to give mainly $Et_3Al \cdot PPh_3$ and $Et_3Al \cdot$acridine complexes, respectively,[43] which precipitate from the post-reaction mixture upon cooling. The results obtained confirm the existence of the equilibrium presented in Scheme 9. Therefore, complexes of type **XIII** or **XIV** are the reaction products depending on the kind of alumoxane and base used, as well as on the solubility and volatility of complexes formed.

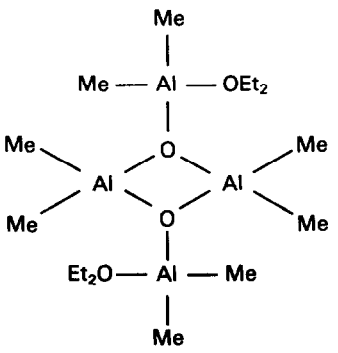
The alumoxanes Et_4Al_2O and Me_4Al_2O form 1 : 1 complexes with primary amines.[43] They are unstable and undergo reaction at *ca* 0°C with the evolution of ethane and methane, respectively. The complexes of deuterated amines are more stable and their association degrees are: for $Et_4Al_2O \cdot PhCH_2ND_2$ ($n = 1.20$) and for $Me_4Al_2O \cdot PhCH_2ND_2$ ($n = 2.23$).

The tertiary amines[41] N,N-dimethylaniline (NMe_2Ph) and benzylidene-*n*-butylamine (PhHC=N—*n*-Bu) form equimolar complexes with Et_4Al_2O. The *i*-Bu_4Al_2O alumoxane, however, does not form a complex with NMe_2Ph, probably due to steric hindrance.

Complexes of alumoxanes with ethers have been described in the literature. Ueyama *et al.*[16] described the crystalline complex of Me_4Al_2O with anisole having a melting point of −16°C and decomposing during distillation with the formation of $Me_3Al \cdot PhOMe$. The alumoxane Et_4Al_2O yields a complex with THF, which during vacuum distillation affords $Et_3Al \cdot THF$.

The $Me_4Al_2O \cdot OEt_2$ complex was obtained by Sadownik[44] in the form of a viscous liquid whose mol. wt was near to that of the dimer. Complexes of Me_4Al_2O with dimethoxymethane and dimethoxyethane have also been described.[44] Both complexes are viscous liquids of the association degree $n \approx 2$.

Structure **XVII** has been proposed for $Me_4Al_2O \cdot Et_2O$, analagous to $Me_2Cl_2Al_2O \cdot Et_2O$.[25]

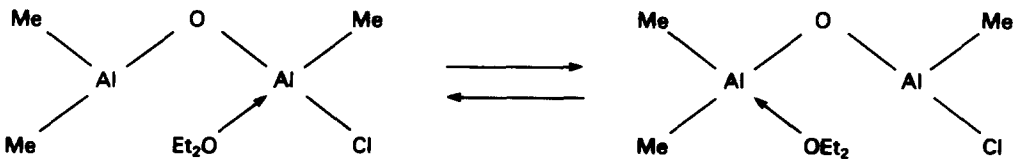


(XVII)

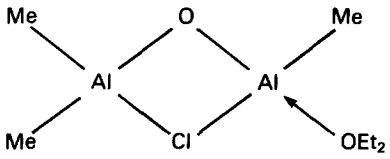
All the aluminium and oxygen atoms in the dimer are four- and three-coordinated, respectively, and hence the dimer should be stable.

A decrease in the tendency to form internal associates is observed for chlorine derivatives of alumoxanes. For Me_3ClAl_2O complexes with ethyl ether[24] the monomer slowly undergoes transformation to the dimer, and after 60 h the degree of association, n, equals 1.45.

This can be explained in two ways. Either by the dynamic coordination of etheral oxygen to both aluminium atoms in the alumoxane, thus stabilizing of the monomeric form, or by the formation



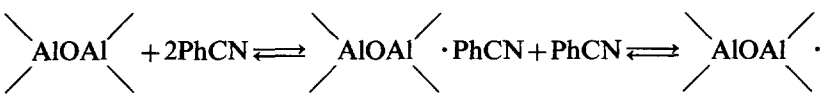
of a quite stable bridge via the chlorine atom, thus coordinative saturation of both aluminium atoms in the alumoxane monomer is attained. Dimerization or association is difficult but possible for both these structures. $Me_2Cl_2Al_2O$ forms a complex with diethyl ether, the association degree of which



is $n = 1.89$. The $Me_3ClAl_2O \cdot O(CH_2CH_2Cl)_2$ complex is less associated ($n = 1.64$).[44] Complexes of methylchloroalumoxanes with dimethoxymethane are unstable and decompose at *ca* 0°C.[44]

Diethyldichloroalumoxane was obtained by Storr *et al.*,[7] who found that its association degree is $n = 4.9$. $Et_2Cl_2Al_2O$ and trimethylamine form a 1 : 1 complex as a viscous liquid, which is stable up to 150–200°C. The mol. wt of the complex was not determined.

Methylchloroalumoxanes form complexes with benzonitrile with variable reactant mole ratios.[45] Tetrachloroalumoxane forms a complex with benzonitrile having a nearly 1 : 2 ratio; $Me_2Cl_2Al_2O$ with an excess of benzonitrile forms both complexes with the alumoxane/benzonitrile mole ratios of 1 : 1 and 1 : 2. However, Me_3ClAl_2O forms a nearly 1 : 1 complex. The various mole ratios of these complexes can be explained by the increased acidity of the aluminium atoms in the chloroalumoxanes. The complexes of chloroalumoxanes with benzonitrile are, therefore, mixtures of complexes in equilibrium with the substrates. The formation and dissociation of alumoxane complexes is shown in eq. (26):



(26)

REACTIONS OF ALUMOXANES WITH ELECTRON DONORS

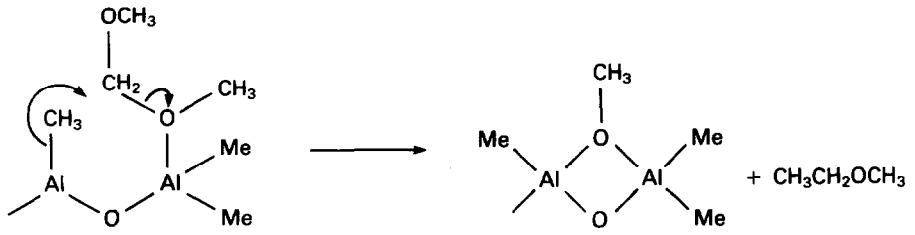
Ethers

Tetramethylalumoxane,[44] obtained from the reaction of trimethylaluminium with water in a dimethoxymethane (DMM) medium, reacts with DMM at *ca* 75°C. Methyl ether and traces of methane result from reaction (27):

$$Me_4Al_2O \cdot (MeO)_2CH_2 \xrightarrow{75°C} Me_3(MeO)Al_2O + MeOEt. \qquad (27)$$

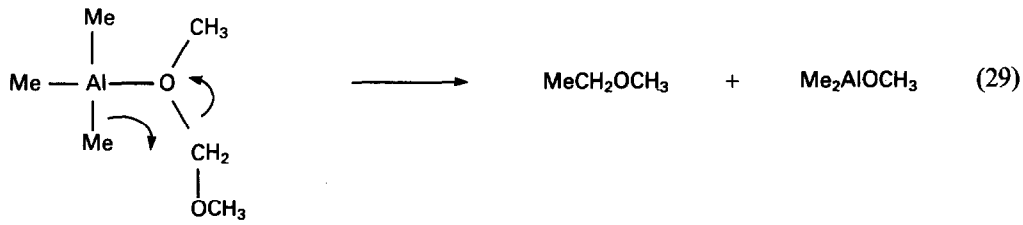
No ethane was found in the reaction products. This indicates the cleavage of the CH_2—O bond and not the CH_3—O bond in DMM. The formation of the $CH_3OCH_2^+$ carbocation is easier than

the CH_3^+ carbocation, due to its stabilization.[46,47] The reaction course is presented in eq. (28):



(28)

It can also be assumed that $(Me_4Al_2O \cdot DMM)_2$ decomposes forming the monomeric $Me_3Al \cdot DMM$ complex and $[RAlO]_n$. This complex undergoes reaction yielding methylethyl ether and the methoxyaluminium derivative, eq. (29):



(29)

The reaction of the alumoxane with diethyl ether is more probable than that of monomeric trimethylaluminium with diethyl ether because it proceeds more easily in a six-membered system than in a four-membered one.[46,47]

Methylchloroalumoxanes react with DMM much more easily than Me_4Al_2O. For $Me_3ClAl_2O \cdot DMM$ the reaction proceeds at $-10°C$, and for $Me_2Cl_2Al_2O \cdot DMM$ at $-20°C$. Chloroalumoxanes are more reactive than the corresponding methylaluminium chlorides. $Me_2AlCl \cdot DMM$ and $MeAlCl_2 \cdot DMM$ react with complexed DMM at 50 and 10°C. This confirms the conclusion that a favourable six-membered system is formed in alumoxanes, compared with the less favourable four-membered system in methylaluminium chlorides.

Methylchloromethyl ether decomposes further yielding methyl chloride and formic aldehyde, eq. (30):

$$ClCH_2OCH_3 \longrightarrow CH_3Cl + HCHO. \tag{30}$$

Therefore, methylethyl ether and methyl chloride are the main reaction products. The aldehyde reacts further in the reaction medium.

Acetylacetone

Tetraalkylalumoxanes,[48] R_4Al_2O (where R = Me, Et, *i*-Bu), react easily with acetylacetone (acac) in a diethyl ether or 1,2-dimethoxyethane (DME) medium, eq. (31):

$$R_4Al_2O \cdot DME + acacH \xrightarrow[DME]{-70°C} R_3(acac)Al_2O + RH. \tag{31}$$

$Me_3(acac)Al_2O$ is stable in solution up to 0°C. Above 0°C it slowly decomposes forming aluminium triacetylacetonate and $(MeAlO)_n$, eq. (32):

$$3\,Me_3(acac)Al_2O \xrightarrow[DME]{0°C} Al(acac)_3 + [MeAlO]_3 \cdot 2AlMe_3. \tag{32}$$

$Et_3(acac)Al_2O$ and $i\text{-}Bu_3(acac)Al$, obtained by the same method, are more stable than the methyl derivative and slowly disproportionate at room temperature. These are colourless, viscous liquids, very soluble in ethers, benzene, toluene, etc. $Et_3(acac)Al_2O$ is a dimer to a great extent: mol. wt: 460. Calc. for the dimer: 512.

The reactions of R_4Al_2O with acetyloacetone for the 1:2 and 1:4 mole ratios proceed at low temperatures, from −70 to −40°C. No products of the $R_2(acac)_2Al_2O$ or $(acac)_4Al_2O$ type were isolated from the reaction mixtures. They appear to undergo disproportionation forming aluminium triacetylacetonate and $[RAlO]_n$, eq. (33):

$$Me_2(acac)_2Al_2O \xrightarrow{-15°C} Al(acac)_3 + \text{oligomers.} \tag{33}$$

$(acac)_4Al_2O$ decomposes at low temperature during formation. Aluminium triacetylacetonate and aluminium oxide are the final decomposition products, eq. (34):

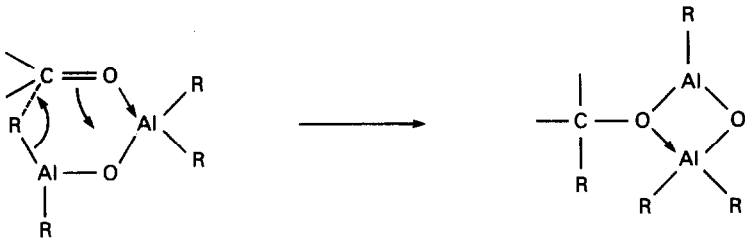
$$3\,(acac)_4Al_2O \longrightarrow 4\,(acac)_3Al + Al_2O_3. \tag{34}$$

The stability of alumoxane acetylacetonates increases in the following order for various alkyl substituents, R: $Me_3(acac)Al_2O < Et_3(acac)Al_2O < i\text{-}Bu_3(acac)Al_2O$, and decreases in the following order depending on the number of acac groups bonded to aluminium: $R_3(acac)Al_2O > R_2(acac)_2Al_2O \gg (acac)_4Al_2O$.

Ketones

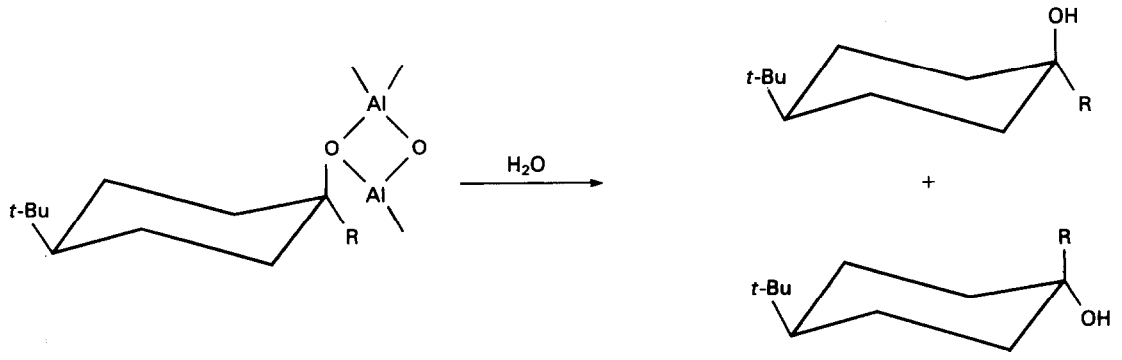
The reactions of methylalumoxanes, $Me_nCl_{4-n}Al_2O$ ($n = 4, 3, 2$), with 4-*t*-butylcyclohexanone in the presence of diethyl ether have been studied.[49]

It was found that alumoxane alkylate ketones react in a similar manner to alkylaluminiums. The reaction yield decreases with an increase in the number of chlorine atoms bonded to the aluminium atom, in agreement with the previously found reactivity of organoaluminium compounds.[50] The reaction yield with alumoxane does not depend on the reactant mole ratios, unlike for organoaluminium compounds. This can be explained by the formation of a six-membered system irrespective of the reactant mole ratio, eq. (35):



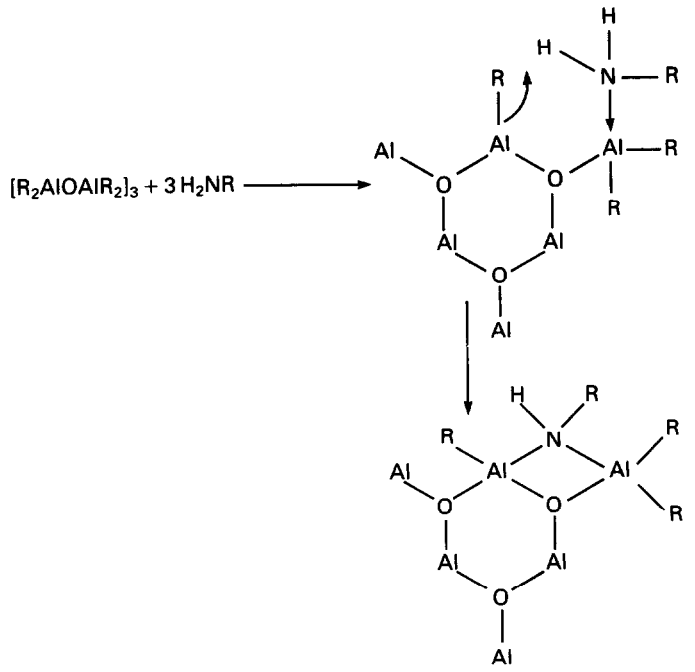
(35)

A mixture of an equatorial and axial alcohol is formed upon hydrolysis, with considerable predominance of the axial form (*ca* 65%), eq. (36):



(36)

The lack of a relationship between the reaction yield and reactant mole ratios confirms that the reaction proceeds between the alumoxane and the ketone, and not with an organoaluminium compound abstracted from the alumoxane.



Scheme 11.

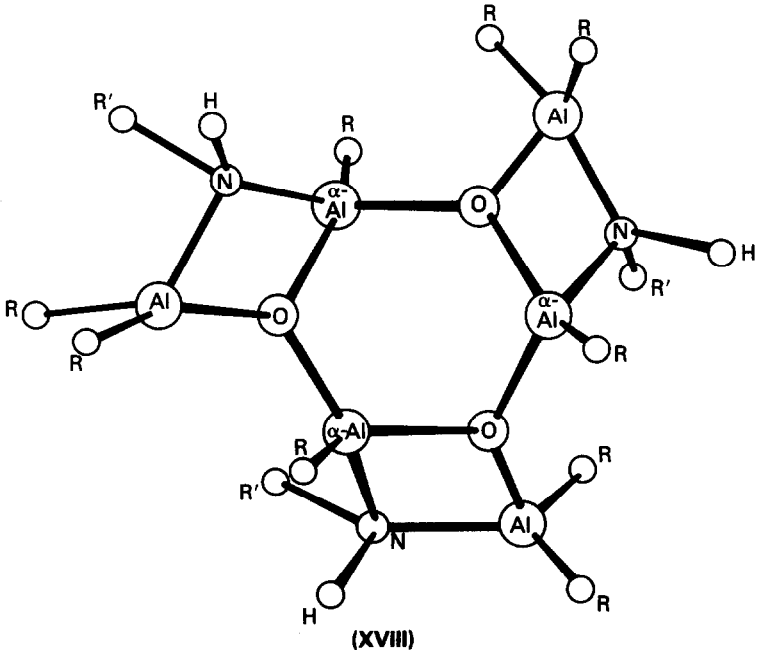
Amines

Tetraethylalumoxane and diethyldichloroalumoxane form complexes with trimethylamine.[7] These complexes are thermally stable and do not decompose up to 170°C.

The reactions of Et_4Al_2O and Me_4Al_2O with methylamine and benzylamine have been studied.[51] The complexes react at 40–80°C forming a corresponding hydrocarbon and an alumoxane with nitrogen substituted at aluminium, eq. (37):

$$Et_4Al_2O + PhCH_2NH_2 \longrightarrow Et_4Al_2O \cdot PhCH_2NH_2 \xrightarrow{>60°C} Et_2AlOAl(Et)NHCH_2Ph + C_2H_6. \quad (37)$$

Spectroscopic studies and molecular weight determinations indicate that triethylaminoalumoxane is a trimer and has a cyclic structure (**XVIII**). Alumoxane can react as a monomer or as a trimer yielding the same product (Scheme 11).



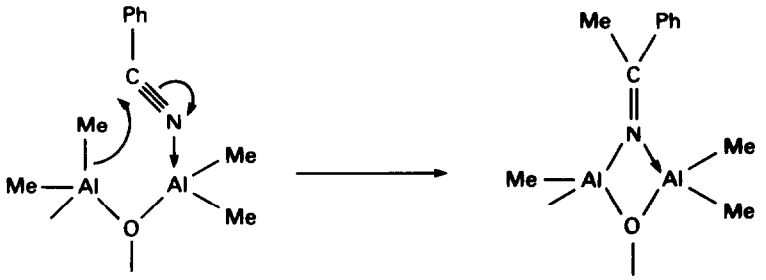
(XVIII)

All the aluminium and oxygen coordination sites are saturated in the trimeric product **XVIII**. The nitrogen bridge between two aluminium atoms is stable enough not to undergo cleavage under the influence of benzonitrile. Therefore, benzonitrile does not form a complex with any of the aluminium atoms in trialkylaminoalumoxane.

Nitriles

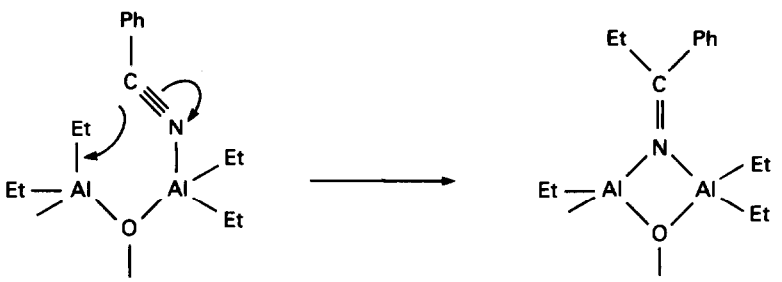
The reactions of Me_4Al_2O and Et_4Al_2O with benzonitrile have been studied.[52] Methylalumoxane reacts with benzonitrile at 80°C producing acetophenone, similar to trimethylaluminium.[53,54]

After heating at 120°C for 12 h $Me_4Al_2O \cdot PhCN$ yields, upon hydrolysis, acetophenone (24%) and unreacted benzonitrile (70%), eq. (38):



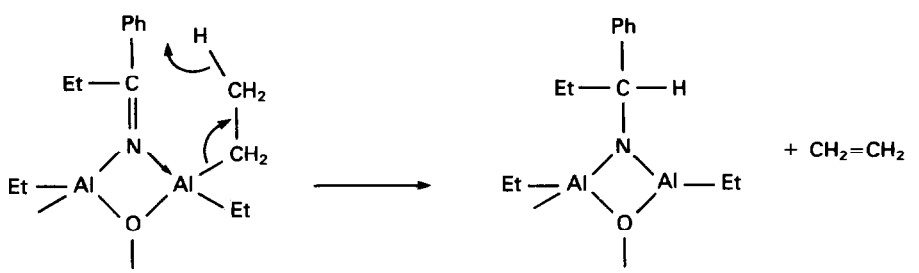
(38)

Ethylalumoxane reacts with benzonitrile in a different way to methylalumoxane, with the formation of a number of products. Nitrogen derivatives (66%) are formed in addition to small amounts of ketone and aldehyde (5%); mostly 1,3,5-triphenyl-2,4-diaza-1-aminoheptadiene-1,4 (40%). The alkylation of benzonitrile by ethylalumoxane probably proceeds in a similar manner to that for methylalumoxane, eq. (39):



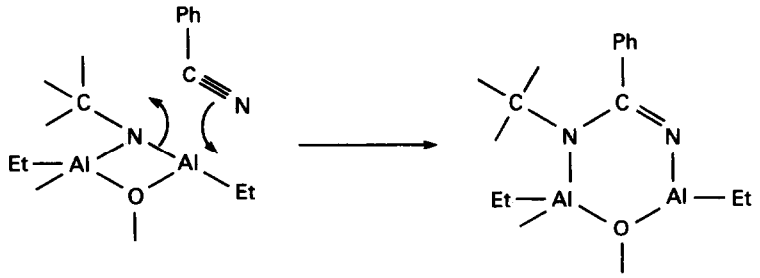
(39)

The alumoxane formed can react further, hydrogenating the nitrile carbon, eq. (40):



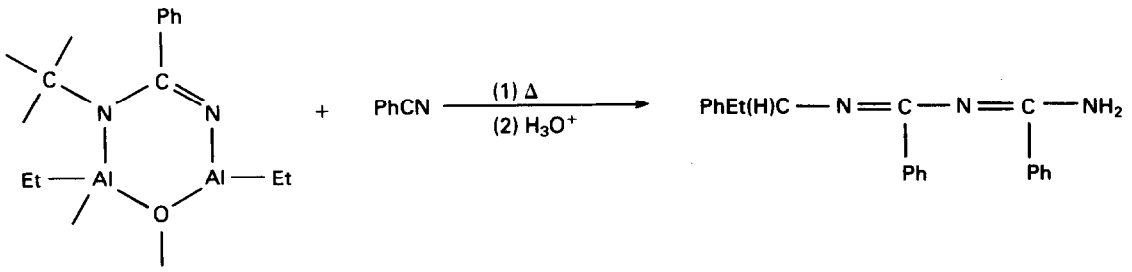
(40)

Benzonitrile, present in the reaction medium, undergoes insertion into the N—Al bond of the product formed, as a result of the decomposition of the $Et_4Al_2O \cdot PhCN$ complex, eq. (41):



(41)

The insertion of benzonitrile into the N—Al bond may be repeated several times affording a mixture of products, in which 5-methyl-2,4,6-triphenylpyrimidine and 1,3,5-triphenyl-2,4-diaza-1-aminoheptadiene-1,4 [eq. (42)] are present:



(42)

Similar insertion reactions of benzonitrile into N—Al bonds for organoaluminium compounds proceed only for strong acids, e.g. CH_3AlCl_2.[55] This indicates the role played by the Al—O—Al system in reactions of nitriles with alumoxanes.

APPLICATION OF ALUMOXANES

As it has already been mentioned, alumoxanes have been applied as catalysts for polymerization of propylene oxides,[56] monosubstituted epoxides,[57] acetaldehyde,[1,2] butadiene,[3] propylene and isobutene,[58] epichlorohydrin,[17] etc.

Recently alumoxanes, and especially methylalumoxane, have found a wider and wider application as components of catalysts for olefin polymerization.[59–67]

Zambelli and co-workers[68] have recently succeeded in preparing highly syndiotactic polystyrene in the presence of catalytic systems consisting of tetrabenzyltitanium and methylalumoxane. Catellani *et al.*[69] have used catalytic systems with $Ti(OBu)_4$ and alumoxanes as cocatalysts for the synthesis of polyacetylene films, which have interesting mechanical properties and improved air stability.

Despite many attempts of using alumoxanes as components of highly active soluble catalysts, the role of alumoxane in the catalysts' formation has not been yet fully understood, and further studies are required.

4. CONCLUSIONS 471

ACKNOWLEDGEMENTS 471

1. INTRODUCTION

The area of cluster electrochemistry has been the subject of but four reviews in the last 7 years.[1–4] Since these reviews were published considerable progress has been made in the now burgeoning area of cluster electrochemistry. The aim of this report is to summarize some of the important results obtained in the electrochemistry of the iron-triad carbonyl clusters, and to point out potential future trends.

Transition metal carbonyl clusters have been shown to behave as electron "sinks",[5,6] stabilizing reversible one-electron transfer reactions and hence a range of oxidation states.[7] In addition to this, unsaturated coordination sites on a cluster may enhance the reactivity of these species. Hence for the chemist, there are several fundamentally important reasons for investigating these molecular compounds, e.g. multiple oxidation states and unsaturated coordination sites.

It has previously been shown that the highest occupied molecular orbital (HOMO) is usually a σ-bonding MO of metal–metal bonding character, and the lowest unoccupied molecular orbital (LUMO) is a MO of metal–metal antibonding character.[5] As a result of this, it has been found that clusters are subject to fragmentation by electrochemical oxidation or reduction, with consequent metal–metal bond cleavage, leading to metal carbonyl fragments of lower nuclearity.[8,9] It has been shown by us[10] and others,[11] that the metal core cohesion may be reinforced towards fragmentation by chelation, capping by donor ligands or interstitial heteroatoms (C, H, N, P, As, O, S, etc.) bonded to the metal framework.[12] These examples provide information on the effects of ligands on the electrochemistry of clusters.

A variety of clusters undergo multiple one-electron redox steps, including $[FeCpS]_4$ and $[FeCp(CO)]_4$,[13,14] and several examples of multi-electron reactions, involving structural changes have been reported.[15] Many of these electron-transfer reactions take place according to an ECE mechanism. Where two-electron reduction steps are considered to occur, formally the mechanism has been interpreted to occur via stepwise one-electron transfers, in which the product of the first electron transfer is unstable, and may rearrange and is in turn further reduced.[6,16,17] When a multi-electron reduction occurs, the cluster is often degraded, leading to fragments of lower nuclearity.[18]

The activation of clusters induced by electron-transfer processes are important routes for finding new processes or alternatively improving earlier synthesis.[19,20] Electron induced nucleophilic substitution (via the Na/Ph_2CO technique)[19,20] in metal carbonyl clusters is an efficient and rapid method for the synthesis of cluster derivatives. A considerable number of results in this area have appeared over the last 6 years, with a growing interest in the elucidation of the mechanism of electron-transfer catalysed reactions involving paramagnetic intermediates. Related studies concerning the activation of iron-triad carbonyl cluster anions have been reported, via a process of oxidative addition.[21] Both of the above studies are directly connected with those using redox reagents, photochemistry, or sonochemistry in homogeneous redox catalysis.

The relationship between the structure and electrochemical activity in transition metal carbonyl clusters is discussed herein. Electrochemical redox reactions in clusters may be divided broadly into two main areas, which correspond to sections 2 and 3 of this report.

In the first section, it is noted that the vast majority of clusters undergo reversible one-electron transfer reactions (either oxidation or reduction). Generally these compounds have "closed" structures or contain ligands or heteroatoms able to stabilize the different oxidation states electrochemically generated. Examples of such clusters include the sulphur capped clusters with Fe_3S_2 cores and their derivatives, the nitrogen capped cluster $[Ru_3(CO)_9(\mu_3\text{-}NAr)_2]$,[22] tetrahedral ruthenium clusters and cubane-like clusters. Clusters of both low and high nuclearity have also been shown to be subject to stepwise one-electron transfers, and may consequently be considered as "sinks" and "sources" of electrons. Radical anions have been found to be considerably more reactive than the parent species towards nucleophilic substitution, which are often very unreactive, or only react under extreme thermal or photochemical conditions.

A considerable number of one-step multi-electron transfer reactions have been reported in the literature. These clusters may be either "open" or "closed", with the possibility of a variety of electrochemical pathways being available, leading to either cluster fragmentation or a stabilization via reinforcement by heteroatoms. The oxidized forms of a series of iron-triad carbonyl cluster dianions, were found to be more reactive towards nucleophiles than the starting materials. Thus, electron-induced oxidative addition of presumably unsaturated highly reactive materials, is a novel and extremely efficient method for the synthesis of new compounds.[21,23] Clusters with heterometallic cores are also subject to multi-electron processes which can be related again to the electrochemistry of metal–metal bonded carbonyl clusters.[24] The mechanism of a single two-electron transfer including structural changes has also been extensively studied.

2. ONE-ELECTRON TRANSFER PROCESSES

2.1. *Reversible electrochemical processes*

It has frequently been concluded that the observation of a reversible electron-transfer reaction by using techniques such as cyclic voltametry, that there is little overall change in structure between the electrochemical reactant and the product. It has recently been shown by Geiger,[3] that the observation of a reversible electrochemical wave implies that any structural change accompanying the electron transfer is chemically reversible and rapid with respect to the time scale of the electrochemical experiment.

The currents used in a cyclic voltammetry experiment may be determined by the Nernst equation and mass transport at potentials close to $E^{\ominus}$, but predominantly by the latter (i.e. convection or diffusion controlled) at relatively high potentials (e.g. very negative of $E^{\ominus}$, for a reduction). Consider the electrode processes in which it is recognized that either the oxidized or reduced form of a redox couple is in equilibrium with another compound, considering them to be initially non-redox active:

$$Ox_1 + ne^- \rightleftharpoons Red_1 \rightleftharpoons Red_2 \quad (1)$$

$$Ox_2 \rightleftharpoons Ox_1 + ne^- \rightleftharpoons Red_1. \quad (2)$$

These are the well-known CE and EC mechanisms, in which the symbol E designates a heterogeneous electron-transfer step, and C is a chemical reaction (generally taking place in solution, e.g. homogeneous). Equations (1) and (2) are mirror images, in that the CE process of eq. (2) for Ox_1 becomes an EC process when looked at from the viewpoint of the oxidation of Red_1. Hence some components of their theoretical treatments will be identical; and thus if the coupled chemical reactions and electron transfer are both rapid, a Nernstian process is observed.

Two types of equilibria are generally best considered, either intermolecular or intramolecular reactions. This area of electrochemistry has been covered in great detail by Geiger in an excellent review.[3]

In the following literature survey, it may be seen that there is a considerable number of unambiguous examples of four component (ECEC) schemes and also a number of quasi-reversible processes having well-defined structural changes between the reactants and products. These reactions provide a fascinating insight into the relationship between oxidation state and structure of the clusters under study.

2.2. *The redox chemistry of trinuclear metal carbonyl clusters of* Fe, Ru *or* Os

The clusters $[Fe_3(CO)_{12-n}L_n]$ ($n = 0$–3; L = PPh_3, $P(OMe)_3$ or $P(OPh)_3$) all undergo a chemically reversible one-electron reduction step, leading to radical anions of the type, $[Fe_3(CO)_{12-n}L_n]^{-\cdot}$.[25] These species were extensively investigated by variable-temperature ESR spectroscopy.[26] Further reduction of these radical species to the dianions $[Fe_3(CO)_{12-n}L_n]^{2-}$ occurred readily, and these species rapidly disintegrated, as shown below:

$$[Fe_3(CO)_{12-n}L_n] + e^- \overset{195\,K}{\rightleftharpoons} [Fe_3(CO)_{12-n}L_n]^{-\cdot}$$

$$[Fe_3(CO)_{12-n}L_n]^{-\cdot} + e^- \overset{195\,K}{\rightleftharpoons} [Fe_3(CO)_{12-n}L_n]^{2-} \xrightarrow{Fast} \text{Products.}$$

For one of this series of clusters, $[Fe_3(CO)_9\{P(OMe)_3\}_3]$, a one-electron reversible oxidation leads to the cationic species $[Fe_3(CO)_9\{P(OMe)_3\}_3]^+$. Presumably in this case, the replacement of three carbonyl groups by three $P(OMe)_3$ ligands results in a sufficient increase in electron density on the iron atoms to raise the energy of the highest occupied level to a point where oxidation can occur within the potential range of the solvent. The related heterometallic species $[Fe_2Ru(CO)_{12}]$ and $[FeRu_2(CO)_{12}]$ were also both readily reduced *in situ* in an ESR spectrometer cavity to produce the radical anions $[Fe_2Ru(CO)_{12}]^{-\cdot}$ and $[FeRu_2(CO)_{12}]^{-\cdot}$. These species are all active in nucleophilic substitution and electron-induced reactions.[27] It has also recently been shown by theoretical calculations that the additional electron of the radical anion occupies an antibonding orbital centred on the metallic core.[28–30]

The sulphido-capped cluster radical anion $[FeCo_2(\mu_3\text{-}S)(CO)_9]^{-\cdot}$ has a very long half-life, although the unpaired electron density is unequally distributed over the metallic cluster core.[28] A related series of clusters $[RPCoMM'(CO)_9]$ (R = Me, Ph; M = Fe; M′ = Mo, Ni) has been investigated by electrochemical and spectroscopic measurements.[31] It has been noticed that the incorporation of another metal into the trinuclear cobalt framework induces kinetic instability into the resulting radical anions, and the behaviour of these clusters has been further correlated with a mixture of steric and electronic effects of the heterometal atom and the capping groups.[31]

Thus clusters which were Lewis base derivatives exhibited one-electron reversible oxidation at fast scan rates and/or at low temperatures. In the heteronuclear clusters discussed here, the electrochemical behaviour of most mixed-metal systems was extremely complex, thereby making cyclic voltammetry data very difficult to analyse.

2.3. *Nucleophilic substitution in clusters*

The process of single electron-transfer is commonly regarded as a highly important pathway in the fields of organic chemistry, biochemistry and inorganic chemistry,[32,33] and the reactivity of the electrochemically generated radical species is a field of considerable and current interest, with much

controversy surrounding the use of radical probes and traps.[34] Classically, metal carbonyl clusters were activated only under extreme thermal conditions in their reactions with simple donor ligands. The conditions employed often resulted in polysubstitution or substantial transformation of the ligand after complexation to the metal cluster. In recent years, Lewis and co-workers have devised elegant low temperature synthesis of substituted clusters via the trimethyl amine N-oxide approach.[35] Photochemistry, redox reagents and sonochemistry have all been successfully applied to enhance the reactivity of metal carbonyl clusters in substitution reactions.[20]

As previously mentioned, the thermal reaction of ligand substitution often produces a vast range of substituted products in low yield; whereas the electron-induced nucleophilic substitution reaction is a more convenient route for the synthesis of a single product at a controlled potential. It has also been noted that the carbonyl groups around the cluster may be replaced stepwise by more basic ligands. For instance, the electron-induced replacement of carbonyl groups by $\{P(OMe)_3\}$ ligands in the tri-iron cluster $[Fe_3S_2(C_3H_2S_2)]$ has been found to proceed in a stepwise manner, leading to the new compounds, $[Fe_3S_2(C_3H_2S_2)\{P(OMe)_3\}_n]$ ($n = 1$, 2 or 3) in high yield according to the reaction sequence below.[36,37]

The addition of catalytic amounts of sodium diphenylketyl in THF to a mixture of the cluster and stoichiometric amounts of Lewis base, generates the radicals *in situ*, hence this technique may replace the electrode in the electron-induced reaction. The thermal reactions of $[H_4Ru_4(CO)_{12}]$ and $[Ru_3(CO)_{12}]$ with Lewis bases, L, give all possible derivatives $[H_4Ru_4(CO)_{12-n}L_n]$ ($n = 1$–4) and predominantly the trisubstituted complex $[Ru_3(CO)_9L_3]$, whereas stoichiometric products are obtained by the addition of catalytic amounts of diphenylketyl.[19,20] The range of new Lewis base complexes prepared numbers over 80 by this technique, and includes, tertiary phosphines and phosphites, chelating phosphines, arsines and stibines. The reactions were found to have a degree of specificity, and up to four ligands could be introduced into a cluster. This technique was also extended to $[M_3(CO)_{12}]$ (M = Fe or Os) and $[H_4Os_4(CO)_{12}]$, giving improved yields of the primary substitution products.

The mechanism proposed for these reactions is essentially one of electron-transfer chain-catalysed reactions; as an example eqs (1)–(3) give the chain reaction for $[Ru_3(CO)_{12}]$:

$$[Ru_3(CO)_{12}] + Ph_2CO^{-\cdot} \longrightarrow [Ru_3(CO)_{12}]^{-\cdot} + Ph_2CO \quad (1)$$

$$[Ru_3(CO)_{12}]^{-\cdot} + L \longrightarrow [Ru_3(CO)_{11}L]^{-\cdot} + CO \quad (2)$$

$$[Ru_3(CO)_{11}L]^{-\cdot} + [Ru_3(CO)_{12}] \longrightarrow [Ru_3(CO)_{11}L] + [Ru_3(CO)_{12}]^{-\cdot}. \quad (3)$$

The reactive species is considered to be the radical anion $[Ru_3(CO)_{12}]^{-\cdot}$, where the excess electron density is in a Ru—Ru (σ^*) antibonding orbital, which leads to a weakened bond. The cleavage of a Ru—Ru metal bond gives a 17-electron centre which readily undergoes attack by a ligand, L, and elimination of CO [eq. (2)]; and reformation of the Ru—Ru metal bond gives $[Ru_3(CO)_{11}L]^{-\cdot}$ which rapidly transfers an electron to $[Ru_3(CO)_{12}]$ to continue the catalytic cycle [eq. (3)].

Electron-induced substitution has also been found to occur in the bicapped cluster $[Ru_3(CO)_9(\mu_3\text{-NAr})_2]$, with isocyanides at an axial site, and with PR_3 at an equatorial site.[22] The radical anion of the bicapped tri-iron cluster $[Fe_3(\mu_3\text{-PPh})_2(CO)_9]^{-\cdot}$ undergoes rapid ligand substitution by CO replacement with various phosphine ligands.[38,39] Two isomeric forms of the tri-iron radical anion have been described,[39] and it is considered that the opening of the μ_3-PPh capping ligand to μ_2-coordination plays a role in the mechanism of ligand substitution, and in the reaction of the dianion formed.

The formally unsaturated clusters $[Os_4(CO)_{12}(AuPR_3)_2]$ ($PR_3 = PEt_3$, PPh_3, $PMePh_2$) undergo two reversible one-electron reductions to the radical monoanion $[Os_4(CO)_{12}(AuPR_3)_2]^{-\cdot}$ and finally the dianion $[Os_4(CO)_{12}(AuPR_3)_2]^{2-}$.[24] The existence of the radical anion was confirmed by low-temperature ESR spectroscopy at 4.2 K. The reduction could also be achieved chemically by the use of Na–Hg amalgam.[41]

A related cluster, $[Os_3(CO)_{10}(AuPPh_3)_2]$, has been studied in MeCN and it was shown that this cluster undergoes a quasi-reversible one-electron reduction at -1.31 V and a second one-electron irreversible reduction at -1.58 V (vs Ag/AgCl). On cooling to -20°C, the first reduction to the radical anion $[Os_3(CO)_{10}(AuPPh_3)_2]^{-\cdot}$ becomes reversible.[40]

The increased reactivity of anionic cluster carbonyls has recently been used in the catalytic

reduction of terminally unactivated alkenes. In the reaction sequence, the first step is loss of CO,[41] which represents the first example of a catalytic reaction that proceeds under mild enough conditions that the cluster integrity remains intact in the cycle.

2.4. *Irreversible one-electron transfer reactions*

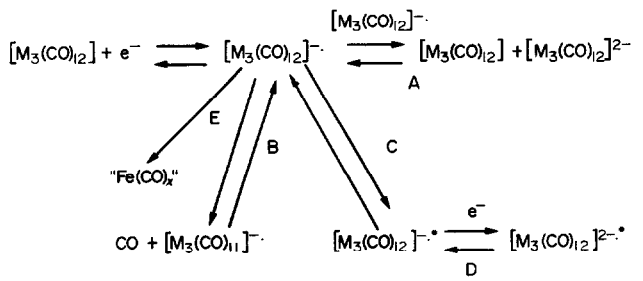
The electrochemical generation of short lived radical anions often leads to ireversible one-electron transfers on the cyclic voltammetry time scale. An early report of the preparation of metal carbonyl cluster radical anions, $[M_3(CO)_{12}]^{-\cdot}$ (M = Fe, Ru, or Os), prepared via alkali metal reduction in THF, appears to be at variance with later results.[42] For instance the redox properties of the series of clusters $[M_3(CO)_{12}]$ (M = Ru or Os) have been extensively studied.[19,20,29,43] The latest study[44] has confirmed the generality of an overall two-electron ECE process for $[M_3(CO)_{12}]$ (M = Ru or Os) and $[M_3(CO)_{12-n}(PPh_3)_n]$ in all solvents, which probably involves a metal–metal bond cleavage step. Concomitant with reduction of the $M_3(CO)_x$ unit one finds solvent dependent, CO dissociative and ligand dissociative pathways as well as nucleophilic attack on a coordinated CO group.

Trends in the redox chemistry of the initially formed $[M_3(CO)_{12}]^{-\cdot}$ (M = Ru or Os) are summarized in Scheme 1 below, (where * represents an "opened" structure). In step A, conproportionation is only important for $[Fe_3(CO)_{12}]$, and it is only with this cluster that the $[M_3(CO)_{12}]^{-\cdot}$ radical anion has been characterized.[26,45] The thermodynamic driving force for conproportionation is probably the instability of a triangulo $[Fe_3(CO)_{12}]^{2-}$ complex. Pathway B decreases in importance from iron through to osmium which may simply be due to steric factors; also, solvent effects on this pathway are expected. The increasing thermodynamic strength of the metal–metal bond down a group is reflected in the absence of pathway E (other than M = iron) and the increasing rate for pathway C from iron through to osmium.

Reports of irreversible electrode processes but efficient electron-transfer chain (ETC)-catalysed reactions for $[Ru_3(CO)_{12}]$ contradicted the view that suitable substrates are those that exhibit chemically reversible redox behaviour. It is clear that the important criteria are relative, rather than absolute, rates of nucleophilic substitution and alternative pathways involving the key radical anions. ETC-catalysed reactions with $[Fe_3(CO)_{12}]$ are fast and efficient because of the high $[M_3(CO)_{12}]^{-\cdot}$ concentration through pathway A; the low yields are due to fragmentation reactions E, while pathway C reduces the available $[M_3(CO)_{12}]^{-\cdot}$ (M = Ru or Os) with consequential lower ETC efficiency.

Thus the reduction step has been shown to include a two-electron exchange and ring opening to yield $[Ru_3(CO)_{12}]^{2-}$, which then undergoes CO loss followed by ring closure to give the $[Ru_3(CO)_{11}]^{2-}$ anion. The intermediates in the scheme are the linear $[Ru_3(CO)_{12}]^{-\cdot}$ and the triangulo-anions $[Ru_3(CO)_{12}]^{-\cdot}$ and $[Ru_3(CO)_{11}]^{-\cdot}$. Selective and apparently fast nucleophilic substitution with $[Ru_3(CO)_{12}]$ via K/Ph_2CO has possibly been shown to be due to the intermediacy of $[\eta^1\text{-}C(O)(X)Ru_3(CO)_{11}]^{2-}$ species as well as an ETC-catalysed reaction. These trends in the electrochemical mechanisms correlate well with those attendant upon photochemical initiation.

The hydrido-anion $[HRu_3(CO)_{11}]^-$ undergoes a chemically irreversible but diffusion controlled first oxidation, and a further irreversible oxidation at higher potential. The first oxidation process becomes more reversible as the temperature is decreased and at fast scan rates, yielding a radical anion.[44]



Scheme 1. The redox chemistry of $[M_3(CO)_{12}]$.

The triangulo-anionic cluster $[HRu_3(CO)_{10}(SiEt_3)_2]^-$ has been extensively studied by a variety of physical measurements, including electrochemical techniques.[46] The reaction was monitored *in situ* by cyclic voltammetry. The one-electron oxidation of the anion leads to the neutral cluster $[HRu_3(CO)_{10}(SiEt_3)_2]$ which has an extremely short lifetime.

The unsaturated clusters $[Os_4(CO)_{12}(AuPR_3)_2]$ ($PR_3 = PEt_3$, PPh_3 or PMe_2Ph) undergo two irreversible one-electron oxidation steps at $-40°C$.[24]

The linear tri-iron cluster $[Fe_3(CO)_7\{\alpha\text{-}C_6H_4(S)(N_2)\}]$ undergoes a single one-electron reduction to produce the radical anion $[Fe_3(CO)_7\{\alpha\text{-}C_6H_4(S)(N_2)\}]^{-\cdot}$, which decomposes at temperatures greater than $-10°C$ by an ECE mechanism. A single one-electron oxidation produces the radical cation $[Fe_3(CO)_7\{\alpha\text{-}C_6H_4(S)(N_2)\}]^{+\cdot}$, which is also unstable, decomposing completely at room temperature by an EC mechanism.[47]

3. MULTI-ELECTRON TRANSFER PROCESSES

3.1. *The mechanism of electrochemical metal–metal bond cleavage*

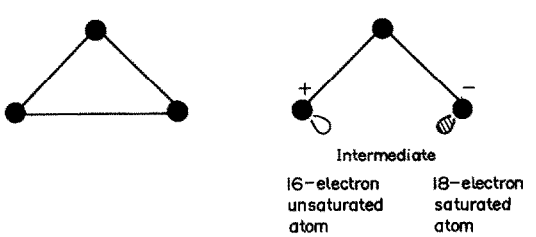
While most metal carbonyl clusters undergo one-electron redox steps, a considerable number of clusters also exhibit two-electron waves that involve structural changes, which are often extremely difficult to characterize. For a single two-electron reduction process to occur, it is necessary for the addition of the second electron to be at a potential more negative than the first. As the first electron "enters" a σ-antibonding molecular orbital of metal–metal bond character, the metal bond order is decreased, and the energy of the lowest unoccupied molecular orbital is lowered. This ensures that the second reduction is thermodynamically more favoured than the first. Cluster reduction or oxidation is in principle a useful approach to study structure and or redox relationships.

In view of their obvious importance, structural studies of redox-related pairs of clusters are still not widespread, which is possibly due to the difficulties involved in the isolation and full characterization of the usually reactive anions obtained in redox processes. A variety of examples involving dielectronic processes has appeared in the literature, and will be discussed here.

The complex $[Fe_2(CO)_6(PPh_2)_2]$ is a non-planar species, which shows in its cyclic voltammogram a single two-electron reduction to the dianion $[Fe_2(CO)_6(PPh_2)_2]^{2-}$.[48] The crystal structure of this compound showed the Fe_2P_2 core to be planar, with the Fe—Fe bond now being non-bonding. Hence the two-electron reduction causes cleavage of a metal–metal bond rather than loss of CO. The presence of the bridging diphenylphosphine ligands ensures that no fragmentation occurs, but the reduced species has a different geometry. The mechanism of electrochemical metal–metal bond cleavage in other related complexes without bridging ligands has also been investigated.[49,50]

In a related series of trimetal carbonyl clusters $[M_3(CO)_{12}]$ (M = Fe, Ru or Os) an alternative mechanism for chemical substitution of the carbonyl ligands by more basic ligands has been demonstrated.[51] The key step was the heterolytic cleavage of a metal–metal bond in the trimer unit, as shown in Scheme 2 below.

The hexanuclear osmium cluster $[Os_6(CO)_{18}]^{2-}$ has an octahedral structure, as predicted for an 86-electron cluster. Cyclic voltammetry studies show that the neutral complex and dianion are interrelated by a quasi-reversible two-electron couple. The ΔE_p values were found to follow closely the predictions of slow charge-transfer kinetics as the scan rate is increased, and the resulting change



Scheme 2. A mechanism for chemical substitution of the carbonyl ligands by more basic ligands in $[M_3(CO)_{12}]$ (M = Fe, Ru, or Os).

in cathodic peak potential is consistent with a two component scheme (as shown below):[17]

$$Ox_1 + ne^- \rightleftharpoons Red_2.$$

It was concluded that, on the time scale of the cyclic voltammetry experiment, the neutral bicapped tetrahedron $[Os_6(CO)_{18}]$ and the dianionic octahedron $[Os_6(CO)_{18}]^{2-}$ appear to be interconverting directly in the electron-transfer step.

This mechanism may also apply to clusters of higher nuclearity discussed elsewhere in this review, e.g. $[Os_7(CO)_{21}]$.

3.2. *Structural change induced by electron transfer*

A series of organotriruthenium clusters, namely, $[HRu_3(CO)_9(\mu_3\text{-allenyl})]$, $[HRu_3(CO)_9(\mu_3\text{-allyl})]$ and $[HRu_3(CO)_9(\mu_3\text{-akynyl})]$, have been studied by cyclic voltammetry techniques at mercury and platinum microelectrodes.[52] A correlation between the resulting electrode potentials and both ^{13}C NMR and $\nu(CO)$ frequencies were presented. The lifetimes of all the radicals generated (e.g. $[HRu_3(CO)_9(\mu_3\text{-allenyl})]^{\cdot}$) were qualitatively longer on the electrochemical timescale than that of $[Ru_3(CO)_{12}]$, indicating that the capping organic chains favour the retention of the cluster framework on reduction. The products isolated from controlled potential electrolysis at negative potentials were found to yield dimeric complexes (e.g. $[Ru_2(CO)_6(C_6H_8)]$) which may possibly have resulted from the work-up procedures.

The tetranuclear cluster $[H_3Os_4(CO)_{12}]^-$ is irreversibly oxidized in MeCN ($E_p = 0.44$ V vs $Ag/AgNO_3$), and bulk electrolysis at this potential provides the cationic cluster $[H_3Os_4(CO)_{12}(NCMe)_2]^+$ in high yield. The cation was the first example of an osmium cluster with an unsupported butterfly structure; it was also prepared via an independent chemical route, involving chemical oxidation of $[H_3Os_4(CO)_{12}]^-$ in MeCN using $[NO]BF_4$.[53,54]

The irreversible reduction of the cation $[H_3Os_4(CO)_{12}(NCMe)_2]^+$ in MeCN ($E_p = -1.69$ V vs $Ag/AgNO_3$) leads to the regeneration of $[H_3Os_4(CO)_{12}]^-$, hence the two clusters are related by a chemically reversible electron-transfer reaction:

$$[H_3Os_4(CO)_{12}]^- + MeCN \rightleftharpoons [H_3Os_4(CO)_{12}(NCMe)_2]^+ + 2e^-.$$

The tetrahydrido clusters $[H_4Ru_4(CO)_{12}]$ and $[H_4Os_4(CO)_{12}]$ appear to be non-redox active complexes in CH_2Cl_2 and THF, with the latter cluster being nearly insoluble in both solvents.[55]

The chemistry of pentanuclear clusters has recently been extensively studied.[56,57] The cluster $[Os_5(CO)_{16}]$ and its corresponding dianion $[Os_5(CO)_{15}]^{2-}$ have related trigonal bipyramidal structures, as shown in Fig. 1.[58]

The dianion $[Os_5(CO)_{15}]^{2-}$ was found to undergo ready chemical or electrochemical oxidation to yield a radical anion $[Os_5(CO)_{15}]^{\cdot-}$ via a reversible one-electron oxidation process ($E_p = +0.08$ V). A second irreversible oxidation was also shown to occur ($E_p = +0.47$ V vs Ag/AgCl) and associated with this one-electron oxidation step was a consequent reduction. Oxidation of the dianion $[Os_5(CO)_{15}]^{2-}$ under a CO atmosphere yields the neutral cluster $[Os_5(CO)_{16}]$ in high yield. The corresponding reduction of $[Os_5(CO)_{16}]$ ($E_p = -0.65$ V) is an irreversible two-electron reduction process, and yields the dianion in high yield with loss of a carbonyl ligand.

In the oxidation of the hexanuclear octahedral ruthenium cluster $[Ru_6(CO)_{18}]^{2-}$,[59] an overall two-electron process is involved, which is chemically irreversible under normal conditions ($E_p = -0.35$ V). However, this process was shown to become chemically reversible in dilute CH_2Cl_2 solutions at 293 K providing water and oxygen are removed from the system. Even so it was

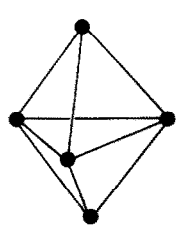


Fig. 1. The metal framework core of $[Os_5(CO)_{15}]^{2-}$.

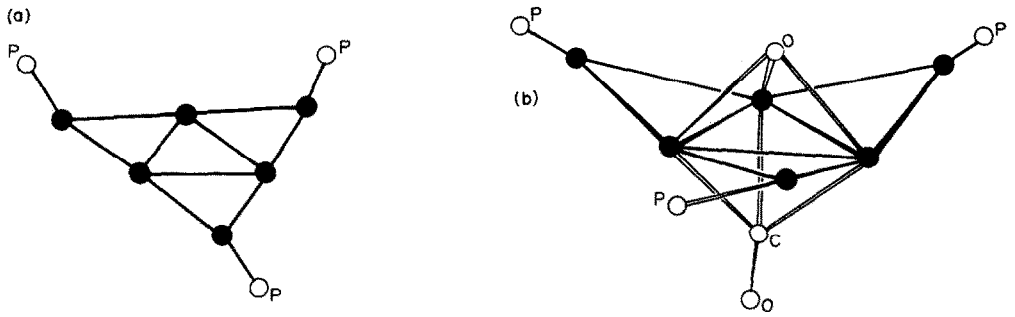

Fig. 2. The metal and phosphorus framework cores of (a) $[Os_6(CO)_{18}\{P(OMe)_3\}_3]$ and (b) $[Os_6(\mu_3\text{-}O)(CO)_{14}(\mu_3\text{-}CO)(PPh_3)_3]$.

considered that the half-life of "$[Ru_6(CO)_{18}]$" on the electrochemical timescale is less than 10^{-3} s and it seemed unlikely that it could be isolated. A simultaneous two-electron transfer is unlikely, but no paramagnetic intermediates were detected by ESR at low temperatures.[44]

A related hexanuclear osmium cluster $[Os_6(CO)_{18}]$ and its related dianion $[Os_6(CO)_{18}]^{2-}$ are notable since the structural change from the bicapped tetrahedron of $[Os_6(CO)_{18}]$ to the octahedron of $[Os_6(CO)_{18}]^{2-}$ is exactly that predicted by polyhedral skeletal electron-pair theory.[60]

The reduction of $[Os_6(CO)_{18}]$ with iodide ion proceeds by an inner-sphere process involving pre-reductive association. The electrochemical reduction involves a single, chemically reversible two-electron transfer at 0.0 V. The large peak splittings observed in the cyclic voltammograms of $[Os_6(CO)_{18}]$ at Hg, Pt or Au electrodes, are due to slow charge-transfer kinetics for the reduction process. The slowness of the electron-transfer may arise from the accompanying structural re-arrangement.[17]

The hexanuclear osmium rafts have a rich redox chemistry. Using polagraphic and cyclic voltammetry, a series of 14 compounds in the series, $[Os_6(CO)_{21-x}L_x]$ (L = $P(OMe)_3$, $P(OPh)_3$, MeCN and x = 1–4) were studied, as illustrated in Fig. 2(a).[61] In general, the compounds undergo two quasi-reversible one-electron transfer steps, to finally yield dianionic clusters. It was observed that as the number of ligands L increases, then the reduction potentials are shifted to more negative values. This was taken to be indicative of an increase in energy of the LUMO caused by inductive effects due to the donor ligands.

The observation that these raft compounds may be readily reduced to the corresponding dianions provides experimental confirmation of Mingos' theoretical calculations; which predicted the existence of such a low-lying unfilled molecular orbital in the hexanuclear raft systems.[63]

The related complexes $[Os_6(\mu_3\text{-}O)(CO)_{18-x}L_x]$ [see Fig. 2(b)] were also studied by cyclic voltammetry, and all the species studied (where L = PPh_3; x = 0–3) were shown to undergo a quasi-reversible two-electron oxidation. Additionally, as the phosphine substitution increases in this oxide species, the reduction becomes less reversible. If we assume that an empty low-lying orbital of a_2' symmetry is still present in the oxide compounds, then the steric constraints of the capping oxygen oppose the effect of addition of two electrons into the antibonding orbitals of the inner triangle, hence a less stable system is produced.[62,64]

The heptanuclear cluster $[Os_7(CO)_{21}]$ has a structure comprising of a monocapped octahedron,[65] as shown in Fig. 3, and it may be readily chemically reduced to the related dianionic species $[Os_7(CO)_{20}]^{2-}$.

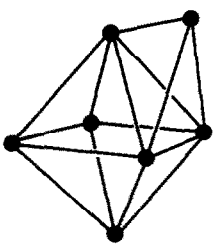

Fig. 3. The metal core geometry of the heptanuclear cluster $[Os_7(CO)_{21}]$.

The electrochemical reduction of $[Os_7(CO)_{21}]$ at a platinum electrode involves a single, chemically irreversible two-electron transfer at -0.10 V to yield the related dianion $[Os_7(CO)_{20}]^{2-}$.[66] Very complex electrochemical behaviour is observed at a hanging drop mercury electrode, possibly indicative of "non-innocent" electrode behaviour.

3.3. *Oxidative addition in clusters*

The relationship between the structure and redox state of a molecule has an impact on a wide variety of chemical, physical and biological phenomena. There is a need for more studies on the interconversion of structurally characterized pairs of clusters. This need arises in part from the difficulty of determining structures of reduction or oxidation products, which are generally quite reactive. Additionally, structural changes are often minor in chemically reversible redox couples. Thus there is increasing interest in redox processes involving more drastic, yet reversible, molecular changes during charge-transfer reactions.[3]

The approach employed in studying controlled synthesis in osmium and ruthenium carbonyl cluster chemistry has been the utilization of stable intermediates that allow the displacement of ligand groups under mild conditions. The ready preparation of $[M_3(CO)_{11}NCMe]$ and $[M_3(CO)_{10}(NCMe)_2]$ (M = Ru or Os) by trimethylamine *n*-oxide oxidation of the carbonyl groups in acetonitrile has led to an extensive chemistry of these trinuclear clusters.[35] More recently this approach has been extended to $[H_4Os_4(CO)_{12}]$, $[Os_5(CO)_{16}]$ and $[Os_6(CO)_{18}]$ clusters.[35] Our attempts to extend this technique to iron, ruthenium and osmium cluster anions have so far proved unsuccessful, possibly because the trimethylamine *n*-oxide mediated reactions go via an anionic intermediate, involving nucleophilic attack of trimethylamine *n*-oxide at a metal carbonyl.[67]

Recent studies[6] on the redox chemistry of the deca-osmium carbido cluster $[Os_{10}C(CO)_{24}]^{2}$ have shown that it has a diverse electrochemistry. This observation prompted us to investigate a series of iron, ruthenium and osmium anionic clusters, namely, $[Fe_5C(CO)_{14}]^{2-}$, $[Ru_3(CO)_{11}]^{2-}$, $[Ru_5C(CO)_{14}]^{2-}$, $[Ru_6C(CO)_{16}]^{2-}$, $[Os_5(CO)_{15}]^{2-}$, $[Os_5C(CO)_{14}]^{2-}$, $[Os_7(CO)_{20}]^{2-}$ and $[Os_{10}C(CO)_{24}]^{2-}$. An alternative technique to activate iron, ruthenium and osmium clusters by the use of either electrochemical or chemical oxidative addition is discussed here.

Previous studies by Bruce *et al.* demonstrated the use of electrochemically stimulated substitution reactions of trinuclear ruthenium clusters,[20] and prompted us initially to investigate the hexanuclear ruthenium carbido cluster $[Ru_6C(CO)_{16}]^{2-}$.[23]

The dianionic cluster $[Ru_6C(CO)_{16}]^{2-}$ (as illustrated in Fig. 4) shows an irreversible two-electron oxidation wave in dichloromethane at $E_p = +0.48$ V (vs Ag/AgCl), and associated with this wave is the consequent reduction at $E_p = -0.47$ V, i.e. the reduction wave of the oxidized product. Ferrocene was used as a one-electron standard, since it is known to be oxidized reversibly to a stable monocation. Quantitative oxidation of $[Ru_6C(CO)_{16}]^{2-}$ at a platinum gauze electrode in CH_2Cl_2 under a steady stream of carbon monoxide, yields the desired product $[Ru_6C(CO)_{17}]$ in near quantitative yield as the oxidative addition product. Oxidation at a platinum gauze at $+0.50$ V consumed 1.9 ± 0.2 electrons as the solution changed from orange to red. Cyclic voltammograms after bulk electrolysis were the reverse of those prior to electrolysis. Reduction of this solution of $[Ru_6C(CO)_{17}]$ at -0.50 V consumed 1.9 ± 0.2 electrons and re-established the original cyclic voltammogram of $[Ru_6C(CO)_{16}]^{2-}$.

Likewise, the neutral cluster $[Ru_6C(CO)_{17}]$ (see also Fig. 4) shows an irreversible two-electron reduction at $E_p = -0.46$ V vs Ag/AgCl, and also associated with this reduction step is an oxidation wave at $E_p = +0.45$ V, i.e. the oxidation wave of the reduced product $[Ru_6C(CO)_{16}]^{2-}$. The reduction of this cluster to the dianion at a platinum gauze electrode in CH_2Cl_2 under a constant

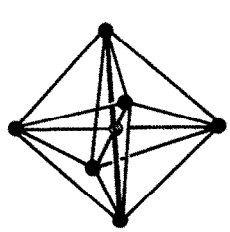

Fig. 4. The ruthenium carbide cores of $[Ru_6C(CO)_{16}]^{2-}$ and $[Ru_6C(CO)_{17}]$.

stream of argon gas occurs in quantitative yield. No paramagnetic species could be detected by ESR during the formation of the dianion. On the same electrochemical scale the $Fe(Cp)_2/[Fe(Cp)_2]BF_4$ couple is +0.54 eV.[6] These simple experiments demonstrate that the wave observed at −0.46 V is due to a two-electron process resulting in the formation of $[Ru_6C(CO)_{16}]^{2-}$, which can be anodically oxidized back to the starting material. These results are consistent with the previously established stability of both the neutral and dianionic forms of the hexanuclear ruthenium cluster.

Treatment of $[Ru_6C(CO)_{16}]^{2-}$ with Lewis base donor ligands such as CO, $P(OMe)_3$, PPh_3, PPh_2Me, dppm, RCCR′ or C_5Me_5H, in the presence of two equivalents of the oxidant $[Fe(CP)_2]BF_4$, results in the formation of a series of new substituted compounds in excellent yield. These derivatives may also be prepared by controlled potential electrolysis at +0.50 V in the presence of the required ligand using a platinum electrode in CH_2Cl_2, followed by chromatographic separation of the products.

Thus an alternative method of synthesis using either chemical (with a suitably matched oxidant—see Table 1) or electrochemical oxidation of iron, osmium or ruthenium cluster dianions in the presence of the ligand is possible at room temperature.

Table 1 summarizes (all oxidations were found to be irreversible) electrochemical data for the clusters examined, with E_p oxidation being the second oxidation wave (for Ru_6 and Os_7 clusters only a single two-electron irreversible oxidation wave is observed) and E_p reduction being the reduction wave of the oxidized cluster. The chemical oxidation routes were generally preferred to the electrochemical oxidation as preparative methods, since isolation of the products from electrochemical solutions is complicated by the presence of an excess of base electrolyte.

The dianions $[Os_7(CO)_{20}]^{2-}$ and $[Os_{10}C(CO)_{24}]^{2-}$ were found to be less reactive than the smaller iron, osmium and ruthenium anionic clusters. This could possibly be due to the increasing carbonyl saturation of the cluster surface. However, the lower temperature used results in moderate yields of several new compounds.

The redox reactions described above appear to be general for systems satisfying the following requirements:

(i) The oxidation potential of the cluster anion is between −0.5 to +1.5 V vs Ag/AgCl.
(ii) The reduction potential of the oxidant is higher than the oxidation potential of the cluster to ensure that the redox reaction may occur.
(iii) The oxidant does not react with the cluster anion, i.e. it acts as an "innocent" oxidant.
(iv) The metal carbonyl cluster bears at least a dinegative charge.

The mechanism proposed for these reactions is essentially one of electron transfer between the cluster anion and the oxidant. As an example, for $[Ru_6C(CO)_{16}]^{2-}$ the reactive species is presumably the electron-deficient cluster "$[Ru_6C(CO)_{16}]$" (containing a vacant coordination site) which may

Table 1.

Cluster	E_p(Oxidation) (V)[a,b]	E_p(Reduction) (V)[a,c]	Oxidant
$[PPN]_2[Fe_5C(CO)_{14}]$	+0.60	−0.60[68]	$AgBF_4$
$[PPN]_2[Ru_3(CO)_{11}]$	+0.22	−0.20[43]	$[C_7H_7]BF_4$
$[PPN]_2[Ru_5C(CO)_{14}]$	+0.15	−1.78	Ph_3CBF_4 or $[C_7H_7]BF_4$
$[PPN]_2[Ru_6C(CO)_{16}]$	+0.48	−0.47	$Fe(Cp)_2BF_4/FeCl_3$
$[PPN]_2[Os_5(CO)_{15}]$	+0.47	−0.65	$Fe(Cp)_2BF_4/FeCl_3$
$[PPN]_2[Os_5C(CO)_{14}]$	+0.35	−1.50	$Fe(Cp)_2BF_4$
$[PPN]_2[Os_7(CO)_{20}]$	+0.41	−0.10	$Fe(Cp)_2BF_4/FeCl_3$
$[PPN]_2[Os_{10}C(CO)_{24}]$	+1.11	−1.30	$AgBF_4$

[a] Recorded at a Ag/AgCl reference electrode in CH_2Cl_2, all solutions used for electrochemical experiments were 0.1 M in electrolyte (tetrabutylammonium tetrafluoroborate). All potentials are uncorrected for solution resistance and junction potentials. Typical scan rates were 100 or 200 mV s^{-1}.

[b] Controlled potential electrolysis performed using a platinum basket electrode.

[c] E_p(reduction) is the reduction wave of the oxidized cluster.

lose or gain more carbonyl ligands as necessary:

$$[Ru_6C(CO)_{16}]^{2-} + Fe(Cp)_2^+ \longrightarrow \text{"}[Ru_6C(CO)_{16}]\text{"} + Fe(Cp)_2 \quad (1)$$

$$\text{"}[Ru_6C(CO)_{16}]\text{"} + L \longrightarrow [Ru_6C(CO)_{16}L] \quad (2)$$

$$\text{"}[Ru_6C(CO)_{16}]\text{"} + L{-}L \longrightarrow \text{"}[Ru_6C(CO)_{16}L{-}L]\text{" etc.} \quad (3)$$

$$\text{"}[Ru_6C(CO)_{16}L{-}L]\text{"} \longrightarrow [Ru_6C(CO)_{15}L{-}L] + CO. \quad (4)$$

(where L is a two-electron donor and L—L is a four-electron donor).

Thus rapid, and large, stoichiometric preparations in non-polar solvents may be performed using simple chemical redox reagents. It is now possible to tune a redox reagent to a potential slightly higher than that of the redox potential of the reaction. The metal cyclopentadienyl cations $[Fe(C_5R_5)_2]^+$ (R = H, Me, Et, etc.) readily spring to mind, with a wide range of electrochemical potentials, and are easily removed at the end of the reaction and most importantly act as "innocent" oxidants. Tropyllium ($C_7H_7^+$) and trityl (Ph_3C^+) salts have also found limited application, but both are known to cause further complications in that they can both act as "non-innocent" oxidants, either by reacting with the cluster to form an adduct, e.g. $[Ru_6C(CO)_{14}(C_{14}H_{14})]$,[69] or by hydride abstraction in the case of the trityl cation.

A wide variety of other cationic redox reagents are still largely unexplored territory or conversely, widely misunderstood! Salts of Ag^+ have been used for a long time as oxidants because of their strong oxidizing power, but caution is necessary in their use, since their relative oxidizing power is strongly solvent dependent, and because they are well known to react with the cluster being studied.

Nitrogen cations of the type $[N(C_6H_4Br\text{-}p)_3]^+PF_6^-$ and $[N_2C_6H_4NO_2\text{-}p]^+PF_6^-$ are also readily obtained, and are powerful oxidizing agents (E_p = +1.32 and +0.48 V vs Ag/AgCl in CH_2Cl_2),[70] and nitrosonium salts $[NO]^+BF_4^-$ are also good oxidants, but it has also been observed that they can react with the cluster, rather than oxidize it.

Thus for anionic metal carbonyl clusters where the above conditions are favourable, the fast reaction time and mild reaction conditions should readily facilitate a vast expansion in their chemistry.

3.4. *Heteronuclear metal clusters*

The role of solvent donicity has been shown to be of some considerable importance in the stabilization of reduced and oxidized cluster species. Results obtained for the $[RuCo_3(CO)_{12}]^-$ complex in donor solvents such as DMF or DMSO show that the anion undergoes two one-electron reduction steps;[71] while in the poorer donor solvent, 1,2-dichloroethane, a single two-electron wave is obtained. Hence it is possible to separate a single two-electron wave into two one-electron waves by careful choice of the solvent.[72]

A number of formally unsaturated heteronuclear clusters containing metals of group 1b have been characterized.[73–75] These clusters contain fewer electrons than is formally required by the effective atomic number rule if the metal–metal bonds are considered as localized two-centre two-electron interactions. For the clusters $[HOs_3(CO)_{10}AuPPh_3]$ and $[Os_3(CO)_{10}(AuPEt_3)_2]$,[75] there is a close analogy with the hydrido carbonyl complex $[H_2Os_3(CO)_{10}]$,[76] which contains two electrons fewer than the 48 electrons required for three two-centre two-electron bonds. In these compounds the supposed "unsaturation" is considered to be localized in the Os—Os "double" bond, which is itself doubly-bridged by two one-electron donor groups, either hydrides or $AuPR_3$ groups. A similar explanation has been offered for the anion $[(HOs_3(CO)_{10})_2Au]^-$ (as shown in Fig. 5), where the gold

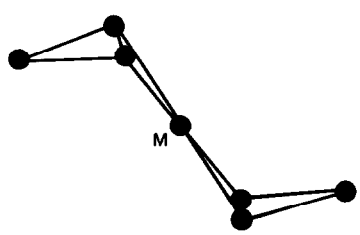

Fig. 5. The metal framework geometries of $[(HOs_3(CO)_{10})_2M]^-$ (M = Au, Ag or Tl).

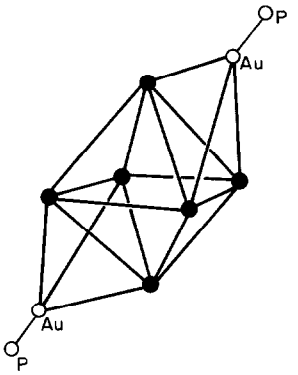

Fig. 6. The metal core structure of $[Os_6(CO)_{18}(AuPMe_3)_2]$.

atom links the two Os_3 units via bonding across two short Os—Os bonds.[74] In view of this "unsaturation" it should be readily possible to add electron pairs either chemically or electrochemically without causing cluster breakdown.

For the monoanion $[(HOs_3(CO)_{10})_2Ag]^-$ (see Fig. 5),[77] the cyclic voltammogram in MeCN at 293 K shows a single irreversible reduction step ($E_p = -1.35$ V). On cooling the solution to 268 K the reduced species is stabilized, and two quasi-reversible reduction steps ($E_p = -1.29$ and -1.38 V) are observed, leading to the corresponding di- and trianionic species, respectively. These results indicate that the anion can accept an electron pair without fragmentation occurring.

The related mixed-metal bow-tie complex $[AsPh_4][(HOs_3(CO)_{10})_2Tl]$ (as illustrated in Fig. 5), has also been studied by cyclic voltammetry. This thallium containing compound was investigated in CH_2Cl_2, and at 293 K, a single irreversible reduction step is observed at $E_p = -1.07$ V. For this species a quasi-reversible oxidation was observed at $E_p = +0.39$ V leading to the neutral cluster.[78]

The heterometal gold derivative $[PPN][(HOs_3(CO)_{10})_2Au]$ was similarly studied. Surprisingly at 293 K this cluster has two reduction steps, the first is reversible ($E_p = -1.19$ V) and the second is a quasi-reversible reduction ($E_p = -1.41$ V) leading to the trianion species $[(HOs_3(CO)_{10})_2Au]^-$. While above +0.6 V degradative oxidation waves are observed, resulting in cluster decomposition.[79]

For the digold cluster $[Os_6(CO)_{18}(AuPMe_3)_2]$ (see Fig. 6) the cyclic voltammogram in CH_2Cl_2 at 293 K, showed an irreversible one-electron oxidation at $E_p = +0.61$ V, which led to cluster decomposition, rather than the hoped for isolation of a radical cation.[66,80]

Finally the giant planar cluster $[Os_9Hg_3(CO)_{33}]$ was investigated exhaustively via cyclic voltammetry, and no redox chemistry was observed.[81]

3.5. *Clusters containing interstitial main group atoms*

Changes in structure accompanying electrochemical oxidation or reduction of clusters have been reviewed recently.[46] A wide variety of compounds were discussed, including triangular, cubane, octahedral and larger clusters. There is an increasing interest in redox processes involving more drastic, yet reversible, molecular transfer reactions.[82]

The presence of heteroatoms (C, H, N, P, As, S) in metal carbonyl clusters may be responsible for some of their unusual electrochemical behaviour and stabilization of a wide range of oxidation states.

The ruthenium cluster $[Ru_4C(CO)_{13}]$ has a butterfly geometry, with the carbide atom attached to all four ruthenium atoms (see Fig. 7). It shows a reversible one-electron oxidation step at +0.63

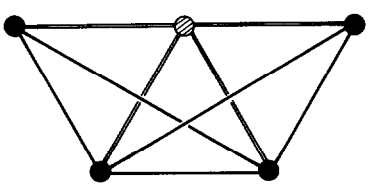

Fig. 7. The Ru_4C geometry adopted by $[Ru_4C(CO)_{13}]$.

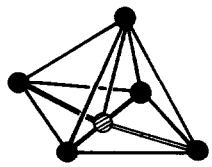

Fig. 8. The core geometry of the M_5E clusters (E = C or N) $[M_5C(CO)_{15}]$, $[M_5C(CO)_{14}]^{2-}$ and $[M_5N(CO)_{14}]^{-}$ (where M = Fe, Ru, or Os).

V (vs Ag/AgCl) to yield the cationic cluster $[Ru_4C(CO)_{13}]^+$, which may also be prepared via Ag^+ oxidation of the parent compound. Surprisingly no readily discernible reduction waves could be interpreted, apart from those leading to probable cluster decomposition.[83]

In the clusters $[M_5C(CO)_{15}]$ (M = Fe, Ru and Os), the carbido atom sits at the bottom of the square-based pyramid (see Fig. 8). It is formally considered to donate four electrons to the cluster framework, and thereby "hold" the cluster together.

The cluster $[Fe_5C(CO)_{15}]$ has recently been shown to be reduced to the dianion $[Fe_5C(CO)_{14}]^{2-}$ in a single quasi-reversible two-electron reduction step, followed by the loss of one carbonyl ligand.[68] The chemical and electrochemical reduction of $[M_5C(CO)_{15}]$ (M = Ru or Os) likewise proceeds via a two-electron reduction to yield the corresponding dianions $[M_5C(CO)_{14}]^{2-}$ (as shown in Fig. 8) with structures identical to that of the iron analogue.[84] All three pentanuclear carbido clusters $[M_5C(CO)_{14}]^{2-}$ have recently been activated via the oxidative addition technique, to produce the parent cluster $[M_5C(CO)_{15}]$.[21] Thus yielding three more pairs of interconvertible structurally characterized clusters, which may be further studied.

The related nitrido anionic clusters $[M_5N(CO)_{14}]^-$ (M = Fe or Ru) (see Fig. 8), have also been investigated by electrochemical techniques; they undergo an irreversible one-electron oxidation (for iron only), and an irreversible two-electron reduction step to the trianion $[M_5N(CO)_{14}]^{3-}$.[68,85] This difference in electrochemical behaviour on changing the heteroatom may possibly be ascribed to the difference in overall anionic charge between the two series of clusters:

$$\text{"}[Fe_5N(CO)_{14}]\text{"} \longleftarrow [M_5N(CO)_{14}]^- + 2e^- \longrightarrow [M_5N(CO)_{14}]^{3-}.$$

For hexanuclear clusters, the dianion $[PPN]_2[Fe_6C(CO)_{16}]$ has an octahedral structure (see Fig. 9), and undergoes two irreversible oxidation steps. Controlled potential electrolysis at the second oxidation step leads to the known pentanuclear cluster $[Fe_5C(CO)_{15}]$ by cluster fragmentation (see below). This is consistent with previous observations[86] that the chemical oxidation of $[Fe_6C(CO)_{16}]^{2-}$ generates the neutral cluster $[Fe_5C(CO)_{15}]$:

$$[Fe_6C(CO)_{16}]^{2-} \longrightarrow \text{"}[Fe_6C(CO)_{16}]\text{"} + 2e^- \longrightarrow [Fe_5C(CO)_{15}] + \text{other products.}$$

This cluster also shows an irreversible reduction step, initially forming the tetraanionic species $[Fe_6C(CO)_{16}]^{4-}$, which rapidly fragments to yield the dianion $[Fe_5C(CO)_{14}]^{2-}$.[18]

The dianionic cluster $[Ru_6C(CO)_{16}]^{2-}$ has an octahedral geometry, with the carbide at the centre. This cluster has an irreversible two-electron oxidation, and associated with this is a consequent reduction at $E_p = -0.47$ V, i.e. the reduction wave of the oxidized product. Quantitative oxidation of $[Ru_6C(CO)_{16}]^{2-}$ at a platinum gauze electrode in CH_2Cl_2 under a steady stream of CO, gives the desired product $[Ru_6C(CO)_{17}]$ in near quantitative yield as the oxidative addition product.

In a similar manner, the neutral cluster $[Ru_6C(CO)_{17}]$ shows an irreversible two-electron

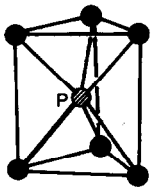

Fig. 9. The Os_6P framework of $[PPh_3Me][Os_6P(CO)_{18}]$.

reduction. Also associated with this reduction step is an oxidation wave at $E_p = +0.45$ V, i.e. the oxidation wave of the reduced product $[Ru_6C(CO)_{16}]^{2-}$. These redox processes have yielded another pair of interconvertible structurally characterized complexes.[21,23]

The substituted ruthenium cluster $[Ru_6C(CO)_{14}(\eta^6\text{-}C_6H_3Me_3)]$ shows a two-electron reduction step in CH_2Cl_2 at $E_p = -0.84$ V (vs Ag/AgCl) to yield the dianion $[Ru_6C(CO)_{13}(\eta^6\text{-}C_6H_3Me_3)]^{2-}$. Associated with this reduction is the oxidation wave of the reduced product at -0.07 V. These results are in accord with the chemical reduction of $[Ru_6C(CO)_{14}(\eta^6\text{-}C_6H_3Me_3)]$ with Na_2CO_3/MeOH to yield the dianionic species $[Ru_6C(CO)_{13}(\eta^6\text{-}C_6H_3Me_3)]^{2-}$.[87]

The related nitrido complex $[PPN][Ru_6N(CO)_{16}]$ has recently been shown to consist of an octahedron of ruthenium atoms, with the nitride at the centre.[85] The cyclic voltammogram of this cluster shows one irreversible two-electron reduction step, and potential electrolysis at the required potential yields the trianionic cluster $[Ru_6N(CO)_{16}]^{3-}$.[85]

Recent elegant studies in this laboratory have yielded the first encapsulated phosphorus cluster of the iron-triad, namely $[PPh_3Me][Os_6P(CO)_{18}]$, which has a trigonal prismatic geometry, as illustrated in Fig. 9.[88] Electrochemical investigations on this cluster revealed the presence of a quasi-reversible two-electron reduction ($E_p = -1.24$ V) to yield the trianionic complex $[Os_6P(CO)_{18}]^{3-}$.

Oxidized and reduced states of large metal carbonyl clusters are of increasing interest. This is due in part to their higher reactivity and also, as mentioned earlier, to the possible analogy between the binding of ligands to a metal cluster and the binding of ligands to a metal surface. The chemistry and reactivity of high nuclearity osmium clusters has been extensively reported, but little information on the redox chemistry of these species is available. However, of the larger clusters that have been studied by electrochemical techniques it has been reported that the addition or removal of electrons is often associated with changes in structure. Well-defined examples include $[FeCpS]_4$ and $[FeCp(CO)]_4$ which both show several reversible one-electron steps, each associated with a small change in the structure of the cluster.[13,14] For osmium carbonyl clusters evidence is accumulating, which suggests that the stronger Os—Os bonds lead to higher activation energies for structural changes generating electrochemically irreversible features in the cyclic voltammogram.[6,17]

The decanuclear ruthenium cluster $[PPN]_2[Ru_{10}(C)_2(CO)_{24}]$ has a structure comprising two Ru_6 octahedra joined by one common edge, as shown in Fig. 10(a).[89] This dianionic cluster undergoes three quasi-reversible one-electron reduction–oxidation steps, as shown by cyclic voltammetry; two cathodic one-electron reductions yield the paramagnetic species $[Ru_{10}(C)_2(CO)_{24}]^{3-}$ and the diamagnetic cluster $[Ru_{10}(C)_2(CO)_{24}]^{4-}$. The dianionic species also shows one quasi-irreversible oxidation wave to the radical anion $[Ru_{10}(C)_2(CO)_{24}]^{-\cdot}$. Thus four oxidation states $-1/-2/-3/-4$ of this cluster may be reached and stabilized.[90]

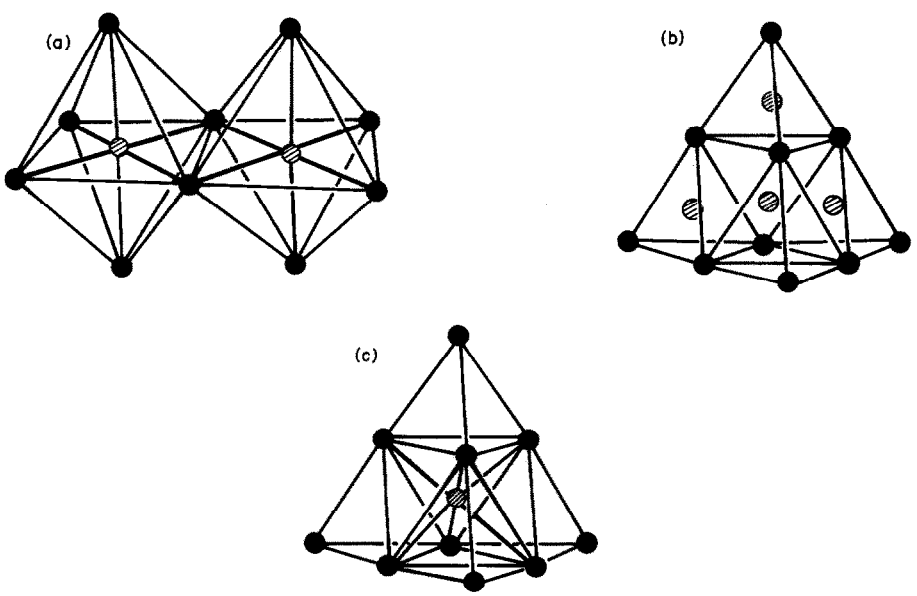

Fig. 10. The metal-heteroatom cores of (a) $[PPN]_2[Ru_{10}(C)_2(CO)_{24}]$, (b) $[PPN]_2[H_4Os_{10}(CO)_{24}]$ and (c) $[PPN]_2[Os_{10}C(CO)_{24}]$.

Two other related decanuclear clusters have been extensively studied, namely the complexes $[PPN]_2[H_4Os_{10}(CO)_{24}]$ and $[PPN]_2[Os_{10}C(CO)_{24}]$. These two compounds have related tetracapped octahedral structures, with the main group heteroatoms in interstitial sites as shown [see Figs 10(b) and (c)].[91,92] The latter cluster has been investigated more extensively, possibly because its mode of preparation is a little more straightforward. Both of these dianionic decanuclear osmium clusters were found to undergo ready chemical or electrochemical oxidation to yield a radical anion $[Os_{10}X(CO)_{24}]^{-\cdot}$ (X = H_4 or C) via a reversible one-electron oxidation process.[93,94] A second irreversible oxidation was also shown to occur for both clusters, and associated with this one-electron oxidation step was a consequent reduction.

The dianionic cluster $[PPN]_2[Os_{10}C(CO)_{24}]$ was oxidized at a hanging drop mercury electrode with "non-innocent" behaviour by the electrode occurring. The resultant cyclic voltammograms showed two quasi-reversible oxidations, indicating that a new species had been generated on the mercury surface.[16] Mercury is known to interact strongly with many organometallic complexes,[95,96] and to speed up the kinetics of some electrochemical reactions.[95] It is possible that a similar interaction in this case may lead to the incorporation of mercury into an oxidized form of $[Os_{10}C(CO)_{24}]^{2-}$. Evidence for the strong interaction between this cluster and a mercury electrode were also found in the reductive electrochemistry.[16]

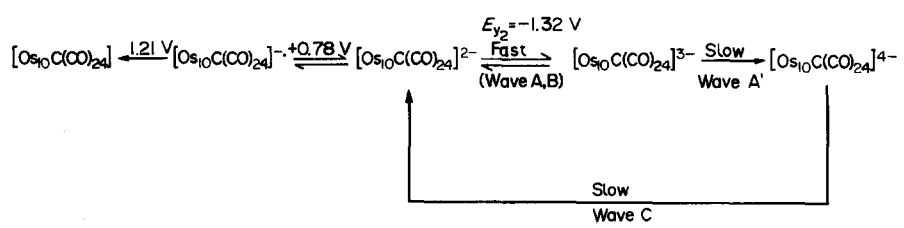
This dianonic complex was readily reduced in THF or CH_2Cl_2 at a platinum electrode (see Fig. 11(a), wave A in the cyclic voltammogram), by two electrons (in a chemically reversible reduction) to yield the tetraanionic species $[Os_{10}C(CO)_{24}]^{4-}$. This reduction was studied at a variety of electrodes and in different media and was found to be associated with an oxidation at more positive potentials (wave C). When a solution of $[Os_{10}C(CO)_{24}]^{2-}$ is cooled [see Fig. 11(b)–(d)] the two-electron wave (wave A) is split into a quasi-reversible one-electron process (wave A) and an irreversible wave (wave A′) which moved to a more negative potential as the temperature is reduced. The broad wave was linked to the oxidative feature (wave C) and demonstrated that the structural change occurs on the addition of the second electron to $[Os_{10}C(CO)_{24}]^{2-}$, as illustrated in Scheme 3. The quasi-reversible electrochemical process was associated with the formation of the trianion $[Os_{10}C(CO)_{24}]^{3-}$, which could be independently synthesized by the slow chemical reduction of $[PPN]_2[Os_{10}C(CO)_{24}]$.

The above study demonstrated that the electrochemical reduction of $[Os_{10}C(CO)_{24}]^{2-}$ occurs in two chemically reversible steps. The addition of the first electron is fast and reversible while the addition of the second is kinetically slow because of a small change in structure of the cluster during this step. The surprising result is that such a minor change in structure is associated with such a substantial peak separation between the reduction and oxidation waves of this second reduction step.

It should be noted that $[Os_{10}C(CO)_{24}]^{2-}$ is the only osmium cluster to date and one of few clusters of any type to have been characterized in five oxidation states. The sequence $[Os_{10}C(CO)_{24}]^{0/-1/-2/-3/-4}$ contains three diamagnetic species and two radical species. The impressive range of redox states for this cluster (Scheme 3) testifies to the great stability of the "$[Os_{10}C(CO)_{24}]$" core, and also the ability of this decanuclear cluster to act as an electron reservoir.

3.6. *The electrochemical preparation of clusters*

There are now a wide variety of clusters that have been prepared using this technique, of which the following are but a choice selection. The cluster $[PPh_4][Fe_3(CO)_9(\mu_3\text{-}CCH_3)(\mu_3\text{-}CO)]$ undergoes



Scheme 3. The electrochemical interconversion of $[PPN]_2[Os_{10}C(CO)_{24}]$ to its other related redox states.

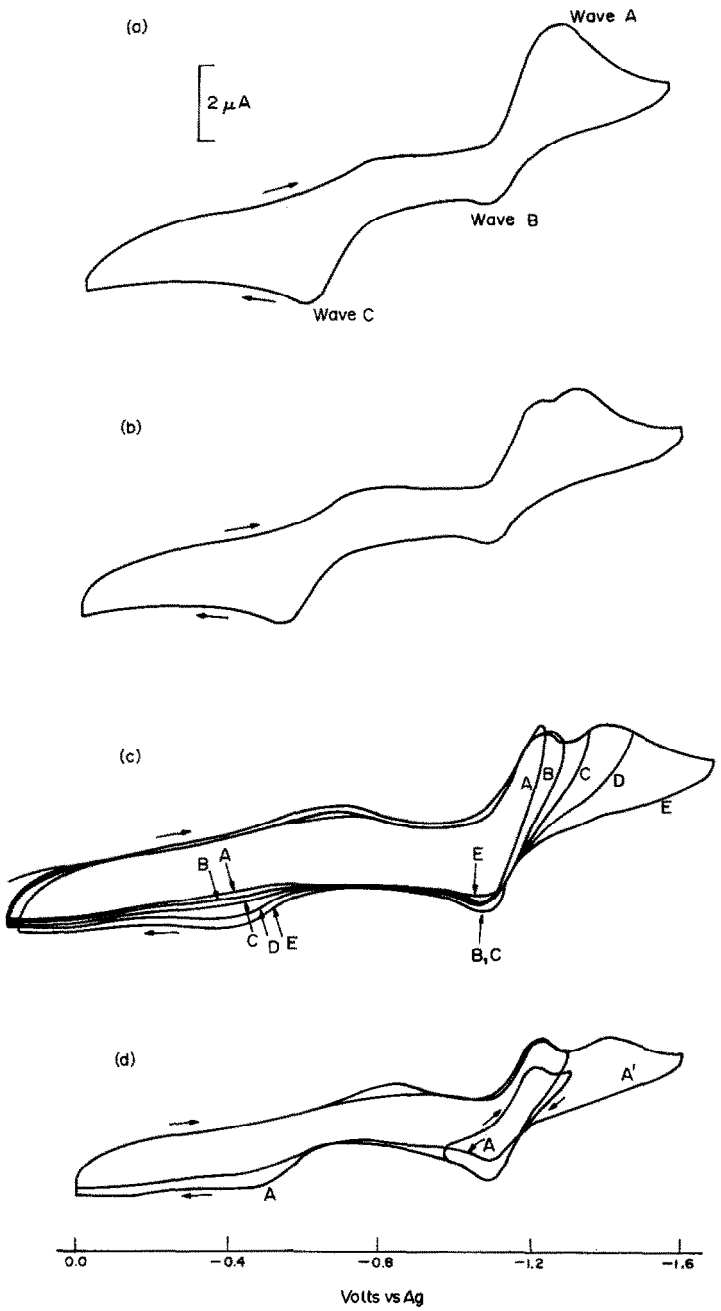


Fig. 11. The cyclic voltammogram of $[PPN]_2[Os_{10}C(CO)_{24}]$ in THF–0.1 M TBAF, showing the effect of temperature on the shape of wave A: (a) −5°C, (b) −25°C, (c) −35°C with a range of switching potentials, (d) −50°C. All scan rates are 100 mV s^{-1}, and the voltammograms are recorded against a silver wire pseudo-reference.

a one-electron reduction leading to an unstable paramagnetic dianion $[Fe_3(CO)_{10}(\mu_3\text{-}CCH_3)]^{2-}$; this complex regenerates the starting material on exposure to air. While treatment of the electrochemically generated complex $[Fe_3(CO)_{10}(\mu_3\text{-}CCH_3)]^{2-}$ with MeOH yields the cluster anion $[Fe_3(CO)_9(\mu_3\text{-}CCCH_3)]^-$.[97]

Tetranuclear clusters with four triply-bridging ligands have a cubane-like structure and show rich electrochemistry, often undergoing multiple reversible electron-transfer reactions. The complex $[Cp_4Fe_4(\mu\text{-}CO)_4]$ is oxidized in four reversible one-electron steps from the neutral complex through to a tetracation.[4] This complex may thus be viewed as an "electron sponge". Structural data is

limited to the neutral and monocationic complexes. An increase in metal–metal bond length is observed as the cluster goes from a slightly distorted tetrahedral to a tetragonal geometry.[98]

Oxidative addition reactions offer a rapid and convenient route for the synthesis of new compounds or modified clusters. For example, the alkyne substituted cluster $[Ru_6C(CO)_{15}(RCCR')]$ is formed via reaction of $[Ru_6C(CO)_{16}]^{2-}$ with $Fe(Cp)_2BF_4$ in the presence of the appropriate alkyne.[21]

4. CONCLUSIONS

A great number of electrochemical investigations into a wide variety of iron-triad clusters have been discussed in this review. In particular, high nuclearity clusters have finally been studied in some detail. A variety of clusters were shown to undergo multiple one-electron oxidation and reductions, the mechanisms of which have been extensively probed.

It has been shown that a host of transition metal carbonyl clusters of the iron-triad undergo reversible one-electron reactions. These species may be considered as "sinks" for electrons. The major problem being in their isolation, since electrochemically generated radicals are often unstable and/or air-sensitive. However, recent advances in techniques of electrocrystallization,[99] now make it possible to crystallize unstable species electrochemically. The added possibility of stabilizing or alternatively bridging clusters with charge-transfer cation–anions (TCNQ or TTF etc.) may also be pursued. Although it seems likely that by adding these species to the electrochemical cell, the resulting crystals may show unusual conducting properties and in different crystal packing to the parent compound.

The synthesis and chemistry of clusters with organic fragments attached is now well developed,[100] and it seems timely for detailed electrochemical investigations into their redox properties. The use of dichelating ligands ligand is well precedented, with the use of chelating phosphine ligands, e.g. dppm; but very little work has appeared on the corresponding dialkyne bridged clusters, e.g. the use of long chain acetylenes (or possibly polyacetylene) to link clusters and then to study their electrochemical properties.

These developments could, if successful, be applied to doping clusters into polymeric supports and their subsequent use as electrode materials in their own right. Microelectrodes are slowly finding application in electrochemistry,[101] and it seems possible that for clusters which are stable to air and moisture and have a known set of potentials which they may be oxidized at or conversely reduced at could be used as electrodes.[102]

The use of variable temperature cyclic voltammetry is still in its infancy, but the few papers which report the use of this technique, show its great potential for a deeper understanding and knowledge of electrochemical processes. This technique coupled with variable temperature ESR and optical studies would allow a more precise evaluation of electrochemically generated complexes, and also the evaluation of the onset of band-like properties in these complexes.[103]

The observation of an electrochemical–chemical–electrochemical reaction, in which the chemical step involves a structural change in the cluster, has been discussed. The cluster geometry changes induced by electron-transfer are now being actively investigated. Although a study of a series of clusters containing different heteroatoms (e.g. C, H, P, N, or S; or alternatively Fe, Ru and Os)[104] has not yet been properly undertaken; or more pertinently how does the value of E_p reduction/oxidation change with increasing size of the cluster?

The behaviour of heterometal carbonyl clusters is still very poorly understood. This may possibly be because their electrochemical behaviour is more complex than their corresponding homonuclear clusters, and cluster decomposition or fragmentation is more often the norm.

In conclusion, the field of cluster metal carbonyl electrochemistry is a one of growing interest, with many novel applications now becoming possible in the areas of electrosynthesis, the isolation of paramagnetic species and in electrocatalysis.

THE NEW TRIAZA MACROCYCLIC COMPLEX OF YTTRIUM

WANDA RADECKA-PARYZEK† and EMILIA LUKS

Faculty of Chemistry, Adam Mickiewicz University, 60–780 Poznań, Poland

(*Received* 19 *July* 1989; *accepted* 8 *August* 1989)

Abstract—The new triaza macrocyclic ligand complex of formula $[YL^1(NO_3)_3]\cdot 3H_2O$, where L^1 is Me_2bzopyo[10]tetraeneN_3, has been prepared by template condensation of 2,6-diacetylpyridine with *m*-phenylenediamine in the presence of a yttrium salt. In the absence of the yttrium ion as a template agent, only the open-chain compound L^2 with partially uncondensed carbonyl and amine groups was formed. The IR, UV–vis, ^{1}H NMR and MS data along with elemental and thermogravimetric analysis were used to characterize the compounds obtained in this work.

Until the late 1970's there have been relatively few reports of complexes containing tridentate macrocyclic ligands when compared with the large number of papers involving tetradentate macrocycles.[1]

Recently, very interesting reviews have appeared covering the literature dealing with the coordination chemistry of the tridentate macrocycles.[2,3] However, the coordinating ability of triaza macrocyclic ligands towards the rare earth elements has received little attention. The investigations have been limited to potential application of lanthanide triazacyclononane complexes as water soluble axially symmetric shift reagents.[4–6]

As a continuation of our studies on the effectiveness of metal ions of varying radius and electron configuration in the synthesis of macrocyclic compounds we have previously reported the first example of the template action of the yttrium ion in the synthesis of a tetradentate NNNN-donor macrocycle.[7]

In this paper, the template synthesis and characterization of the new 10-membered triaza macrocyclic complex of yttrium nitrate is described.

EXPERIMENTAL

The hydrated yttrium nitrate was prepared from Y_2O_3 in the manner described previously.[7]

Preparation of the yttrium macrocyclic complex of L^1

To a solution of $Y(NO_3)_3\cdot 6H_2O$ (0.1 mmol) in methanol (10 cm^3), 2,6-diacetylpyridine (0.1 mmol) in methanol (10 cm^3) and *m*-phenylenediamine (0.1 mmol) in methanol (10 cm^3) were added dropwise with stirring. The reaction was carried out for 8 h. Removal of the solvent left a yellow oily solid which, on washing with ether, gave a yellow powder. This was dried *in vacuo*. Found: C, 32.4; H, 3.4; N, 14.9. Calc. for $YC_{15}H_{19}N_6O_{12}$: C, 32.0; H, 3.4; N, 14.9%.

Preparation of the compound L^2

The reaction of 2,6-diacetylpyridine (0.1 mmol) with *m*-phenylenediamine (0.1 mmol) in methanol (20 cm^3) was carried out in the absence of the yttrium salt for 24 h. Solvent was then removed and the residue washed with ether. Recrystallization from ethanol gave yellow crystals. Found: C, 70.9; H, 5.9; N, 16.7. Calc. for $C_{15}H_{15}N_3O$: C, 71.1; H, 6.0; N, 16.6%.

Measurements

IR spectra were recorded using CsI pellets in the range 4000–200 cm^{-1} on a Perkin–Elmer 580 spectrophotometer. Electronic absorption spectra were measured on a Beckman 25 spectrophotometer. ^{1}H NMR spectra were run on a Varian EM–360 60 MHz spectrometer for solutions in DMSO-d_6 using TMS as internal standard. Mass spectra were obtained on a JEOL–JMS mass spectrometer. Thermogravimetric measurements were performed using the Derivatograph OD–102, MOM.

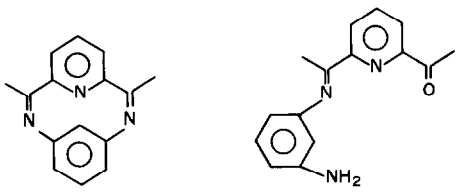
RESULTS AND DISCUSSION

Condensation of 2,6-diacetylpyridine with *m*-phenylenediamine with the use of $Y(NO_3)_3 \cdot 6H_2O$ as a template agent gave the new 10-membered triaza macrocyclic complex of stoichiometry $[YL^1(NO_3)_3] \cdot 3H_2O$, where L^1 is Me_2bzopyo[10] tetraeneN_3 ligand. The complex was identified by spectral data (IR, UV–vis, ^{1}H NMR, MS) and thermal and elemental analysis.



L^1 L^2

The IR spectrum of this complex shows significant bands at 1630, 1605 and 1450 cm^{-1}, which may be assigned to C=N stretching modes and two high energy pyridine vibrations. The low energy pyridine bands observed at 625 and 440 cm^{-1} suggest coordination of pyridine.[8] Absence of bands characteristic of carbonyl and amine groups confirms the formation of the macrocyclic compound. A broad diffuse band of strong intensity in the 3500–3100 cm^{-1} region may be assigned to an O—H stretching vibration for lattice water. The absorption characteristic of coordinated water does not appear. The thermogravimetric analysis confirms this observation, indicating the loss of three water molecules at 45–75°C.

The IR spectrum of this complex gives valuable information on the type of nitrate binding. The separation of two combination bands in the 1700–1800 cm^{-1} region is about 35 cm^{-1}. The two strong bands associated with the asymmetric stretch appear at 1480 and 1310 cm^{-1}. The magnitude of the separation, which is proportional to the strength of the yttrium–oxygen bond, along with absorption at 818 cm^{-1} gives evidence for chelating bidentate behaviour of the nitrate groups in this complex.[9,10]

The electronic spectrum of the yttrium complex of L^1 for a solution in methanol exhibits an absorption band at 226 nm with a shoulder at 280 nm attributable to the $\pi \rightarrow \pi^*$ transitions of the coordinated macrocycle.[11]

The ^{1}H NMR spectrum of this complex shows the pyridine ring protons at δ 8.1–8.5, the benzene ring protons at δ 6.4–6.8 and the methyl protons at δ 2.3 and 2.6. The integrated relative intensities of the above signals are in the ratio 3:4:6, respectively, consistent with the proposed formulation of the complex.

Further evidence for the formulation of the macrocyclic complex comes from the mass spectrum. The highest fragment with 100% relative intensity is observed at *m/z* 235 and corresponds to the molecular weight of the uncoordinated macrocycle.

Attempts to obtain a free macrocycle in the reaction of the 2,6-diacetylpyridine with *m*-phenylenediamine without using the yttrium nitrate as a template agent were unsuccessful and resulted in the formation of the acyclic compound L^2. This product was identified by IR, UV–vis, ^{1}H NMR and MS as well as elemental analysis.

The band characteristic of the C=N stretching mode is observed in the IR spectrum of this compound at 1620 cm^{-1}, indicating the partial condensation reaction. An important feature is the occurrence of the strong band at 1695 cm^{-1} assigned to the C=O stretching vibration and the bands at 3350 and 3210 characteristic of antisymmetric and symmetric stretching modes of the NH_2 group. The electronic spectrum of L^2 in methanol consists of two bands at 220 and 275 nm.

The ^{1}H NMR spectrum shows pyridine protons at δ 8.0–8.4, the benzene protons at δ 6.3–7.1 and methyl protons at δ 2.3 and 2.7, with integrated intensities in the ratio 3:4:6, respectively. The parent ion in the mass spectrum of L^1 observed at *m/z* 253 corresponds to the formula $C_{15}H_{15}N_3O$.

Treatment of the yttrium nitrate with L^2 in methanol for 10 h leads to isolation of the product, which turns out to be the yttrium complex of L^1.

This finding appears to be in accordance with the general observation, that for the majority of macrocyclic compounds, the use of a metal ion to direct the steric course of the condensation process, which ultimately ends with ring closure, remains the best way of preparation.

On the basis of spectral and analytical data along with the molecular model analysis it seems reasonable to tentatively assign the coordination number of nine for the yttrium ion in this complex. The metal ion is presumably coordinated to the three nitrogen donor atoms of the 10-membered macrocycle and to the six oxygen atoms of the three bidentate nitrate groups. Reference to the known structure of nine-coordinate yttrium complexes allows us to predict the tricapped trigonal prism geometry for this new complex with the tridentate macrocycle occupying the triangular face.[12]

It may be possible to obtain the lanthanide complexes of this triaza macrocyclic with the sandwich structure and we are pursuing that line of investigation.

STUDIES ON ORGANOLANTHANIDE COMPLEXES—XXIV.* SYNTHESES OF 1,1′-(XYLYLENE)BIS-η^5-CYCLOPENTADIENYL RARE EARTH CHLORIDES

CHANGTAO QIAN,† XIURAN WANG,‡ YUQIN LI and CHANGQING YE

Shanghai Institute of Organic Chemistry, Academia Sinica, 345 Lingling Lu, 200032 Shanghai, China

(*Received* 1 *August* 1989; *accepted* 15 *August* 1989)

Abstract—THF-solvated 1,1′-(xylylene)bis-cyclopentadienyl rare earth chlorides [$C_5H_4CH_2C_6H_4CH_2C_5H_4$]LnCl·THF (Ln = La, Pr, Nd, Dy, Y, Er and Yb), were synthesized by using 1,1′-(*m*-xylylene)bis-cyclopentadiene and 1,1′-(*p*-xylylene)bis-cyclopentadiene as ligands. Disproportionation of early lanthanocene chlorides (Ln = La, Pr, Nd) is thus successfully prevented and stable early lanthanocene chlorides are obtained. Their structures were verified by elemental analyses, IR, ^{1}H NMR, MS and XPS spectroscopy; they are possibly dimeric. The solubility of these complexes in aromatic hydrocarbons is lower than the corresponding 1,1′-(trimethylene)bis-cyclopentadienyl lanthanide chlorides.

Recently, the syntheses of early organolanthanide complexes has attracted much attention. In order to stabilize the bis-cyclopentadienyl early lanthanide chlorides and to prevent their disproportionation, bulky pentamethylcyclopentadienyl,[1–6] bis-(trimethylsilyl)cyclopentadienyl[6,7] and hexamethylindenyl[9] have been used as ligands. Another way is to use bridged cyclopentadienyl as the ligand. Previously, we have reported that the stabilization of early organolanthanide complexes has been achieved by using 1,1′-(trimethylene)bis-cyclopentadienyl[10,11] and 1,1′-(3-oxapentamethylene) bis-cyclopentadienyl as ligands. Marks *et al.*[13] succeeded in stabilizing early lanthanocene chlorides by generating an anionic complex. The THF-solvated mid- or late-organolanthanide chlorides can be isolated using 1,1′-(pentamethylene)bis-cyclopentadienyl as ligand. Unfortunately, under similar conditions, we did not succeed in obtaining the early lanthanocene chloride with this chelating ligand.[14] We found by ^{1}H NMR that the flexibility of the pentamethylene chain is more than that of 1,1′-trimethylene ones; put in another way, the mobility of bridged cyclopentadienyl is larger. In order to increase the rigidity of the pentamethylene chain, a benzene ring was introduced into the chain and, therefore, we studied the syntheses of early lanthanocene chlorides using 1,1′-(*m*-xylylene)bis-cyclopentadienyl and 1,1′-(*p*-xylylene)bis-cyclopentadienyl as ligands. At the same time we have attempted to improve the solubility of lanthanocene chlorides in aromatic hydrocarbons by using a ligand containing a benzene ring. It is very important to study their reactivity. Herein, we would like to report the syntheses and identification of nine new THF-solvated 1,1′-(xylylene)bis-cyclopentadienyl rare earth chlorides.

RESULTS AND DISCUSSION

The preparation of 1,1′-(xylylene)bis-cyclopentadienyl disodium salt/THF solution is similar to the methods reported in the literature.[11,12,15] It could be stored for over 1 month with the exclusion of moisture and oxygen. Anhydrous lanthanide chlorides, $LnCl_3$, reacted with disodium salt/THF solution in THF at −50°C to give complexes **1–6**,

* For part XXIII, see ref. 25.

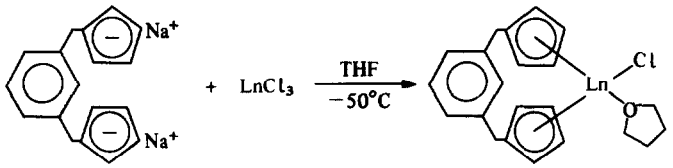
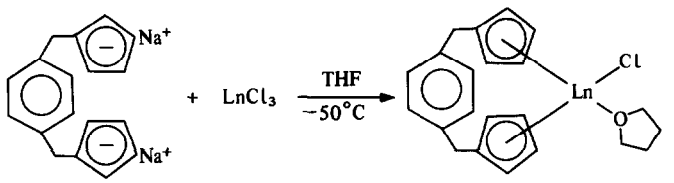
which are shown in eq. (1):



(1)

Ln = La (**1**), Nd (**2**), Dy (**3**), Er (**4**), Y (**5**), Yb (**6**).

We have succeeded in synthesizing the early lanthanum and neodymium chlorides, thus confirming that the rigidity of a pentacarbon chain which contains a benzene ring is much greater than that of a pentamethylene chain. Considering the coordination effect, this ligand not only matches the early lanthanide ions with a larger ionic radii but also matches the later lanthanide ions with a smaller ionic radii. However, using 1,1′-(*p*-xylylene)biscyclopentadienyl as a ligand, only the chlorides of early lanthanides having larger ionic radii were isolated, the later lanthanide chlorides were not obtained under similar reaction conditions. The reaction is shown in eq. (2):



(2)

Ln = La (**7**), Pr (**8**), Nd (**9**).

The IR spectra of complexes **1–9** were measured from 4000 to 50 cm^{-1}. The spectral features are very similar. The complexes exhibit four to six characteristic absorption peaks in the low frequency, 50–500 cm^{-1} region. The data of absorption peaks are listed in Table 1. The strong absorption peak at about 250–260 cm^{-1} was assigned to a characteristic absorption of a π-bonded cyclopentadienyl group to Ln metal.[16] It is noticeable that the characteristic absorption of the π-bond in complex **5** is shifted to 290 cm^{-1}, which is in agreement with those of Cp_2YCl, $(CH_3C_5H_4)_2YCl$, $[C_5H_4(CH_2)_3C_5H_4]YBu^t \cdot THF$ and $(C_5H_4CH_2CH_2OCH_2CH_2C_5H_4)YCl$ reported in our previous work.[12] It is probably caused by a difference between yttrium and lanthanide metals. The characteristic absorption peaks of coordinated tetrahydrofuran appear at 890 and 1046 cm^{-1}. Four characteristic cyclopentadienyl absorptions at 760–780, 1012, 1440 and 3080 cm^{-1} are apparently present. The characteristic absorptions of *m*-xylylene are evidently different from *p*-xylylene. The characteristic absorption peaks of *m*-xylylene appear at 720 and 1585 cm^{-1}, respectively, all absorption peaks at 720, 1458, 1585, 1603 and 3060 cm^{-1} were contributed by *m*-xylylene. Whereas *p*-xylylene exhibits four characteristic absorption peaks at about 805, 1500–1510, 1600–1610 and 3040 cm^{-1}. Therefore, the cyclopentadienyl, benzene ring and coordinated THF in complexes are evidently present.

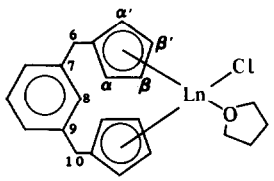
[a] w: weak; m: medium; s: strong; vs: very strong.

The ^1H NMR spectra of complexes **1** and **7** were measured using perdeuterotetrahydrofuran as solvent and the results are similar. For example in complex **1** protons of the benzene ring appear at δ 6.85; cyclopentadienyl at δ 6.03 and 5.80; THF at δ 3.45 and 1.62; and CH_2 at δ 2.75 and 2.62. ^1H NMR of the organic ligand obtained via hydrolysis of complex **7** was also recorded. The chemical shift of the benzene ring is at δ 7.05; cyclopentadienyl at δ 6.45 becoming a single peak; THF at δ 3.60 and 1.80; and CH_2 becoming a single peak at δ 2.87 from two multiple peaks of the corresponding complex. The four protons of the ring-bridged cyclopentadienyl exhibit a characteristic AA′BB′ pattern which is two groups of multiple peaks. Martin *et*

al.[17] assigned the resonance peak of the cyclopentadienyl β-proton at high field. The four hydrogens at positions 6 and 10 exhibit two groups of



equal proton peaks, which indicates that the electrons of the benzene ring partly transfer to the metal. Therefore, these hydrogens are not homomagnetic.

Smith *et al.*[18] found that in the case of ring-bridged bis-cyclopentadienyl titanium dichlorides, increasing the length of the methylene chain [—$(CH_2)_n$—; $n = 1$–3], decreases the $\Delta\delta$ values between α and β of cyclopentadienyl. Owing to the increasing chain length, β-protons are closer to the central metal than α-protons.

The $\Delta\delta$ values for different ring-bridged lanthanocene chlorides are compared and the data are listed in Table 2.

From Table 2 we found that (1) by increasing the chain length, the angle between the two rings and the torsional ring mobility of cyclopentadienyl increases, therefore, the $\Delta\delta$ values between the α- and β-protons evidently decreases and (2) the type of chain effects a change in $\Delta\delta$. When a chain containing oxygen is introduced to the bridged bis-cyclopentadienyl ligand, because of the formation of an intramolecular coordination bond, the mobility of the ring decreases. Moreover, the $\Delta\delta$ value obviously increases compared with the complexes with the same chain length. In the case of the chain containing the benzene ring, the rigidity of the chain is strengthened; this results in $\Delta\delta$ increasing. In conclusion, the ring proton splitting degree is related to the chain length and different kinds of chain.

The mass spectra of 1,1′-(trimethylene)bis-cyclopentadienyl lanthanide chlorides did not show the parent molecular ion and gave only some fragments.[11] However, the complete mass spectra of 1,1′-(3-oxa-pentamethylene)bis-cyclopentadienyl lanthanide chlorides were obtained.[12] The mass spectra of the title complexes are between 1,1′-(trimethylene)bis-cyclopentadienyl and 1,1′-(3-oxa-pentamethylene)bis-cyclopentadienyl lanthanide chlorides. Complexes **1** and **2** gave the complete mass spectra which exhibited the monomeric parent molecular ion $[M]^+$ and related fragments. Mass spectra data of complex **2** are listed in Table 3. It is different from the mass spectra of 1,1′-(3-oxa-pentamethylene)bis-cyclopentadienyl lanthanide chlorides in that the relative intensity of $[M—Cl]^+$ is very weak and the relative intensity of $[C_5H_6]^+$ is very strong. Therefore, it is similar to the mass spectra of $(CH_3C_5H_4)_2LnCl$ and Cp_2LnCl in that the cyclopentadienyl is first cleaved.[22] Moreover, in the mass spectra of **1**, **2**, **5**, **7** and **9**, related fragments including m/z being larger than the monomeric fragment $[M]^+$ and being equal to 72 or 73, all appear. These indicate that they are THF-solvated dimers.

In general, the organolanthanide complexes are able to coordinate with a Lewis base because of their coordination unsaturation and the oxyphilicity of the metal in these complexes. In our previous work, Cp_2LnCl and $[C_5H_4(CH_2)_3C_5H_4]$

65	39.04	$[C_5H_5]^+$
42	35.02	$[C_3H_6]^+$

[a] Mass number is based upon ^{142}Nd, ^{35}Cl, ^{12}C and ^{1}H.

LnCl·THF coordinate with α,α′-bipyridine affording bipyridine complexes[11,23] and the lone pair of electrons on the oxygen atom in $[C_5H_4CH_2CH_2OCH_2CH_2C_5H_4]LnCl$ are partly transferred to the rare earth metal centre forming an intramolecular coordination bond.[12] Although the title complexes do not contain a heteroatom rich in electrons there is an electron-rich benzene ring. XPS of complexes **3**–**6** were measured and the results are listed in Table 4. We found that the binding energies of the rare earth metal atoms all decrease and that those of Cl_{2p} are unchanged compared with those in the corresponding bis-cyclopentadienyl rare earth chlorides. This is probably caused by the electrons in the benzene ring in this complexes partly shifting to the rare earth metal.

Table 4. Binding energy data (eV) for complexes and Cp_2LnCl

Complex	$Ln_{3d5/2}$ Binding energy	ΔE[a]
3	154.4	−0.9
Cp_2DyCl	155.3	
4	170.5	−0.5
Cp_2ErCl	171.0	
5	159.4	−0.4
Cp_2YCl	159.8	
6	186.7[b]	−0.4
Cp_2YbCl	187.1[b]	

[a] E = B.E.($Ln_{3d5/2}$) − B.E.[Ln(Cp_2LnCl)].
[b] Yb_{4d}.

The solubility of complex **4** (Ln = Er) was measured in a variety of organic solvents, showing that the solubility decreases in the order: THF > $CHCl_3$ > $(C_2H_5)_2O$ > C_6H_6 > $CH_3(CH_2)_4CH_3$. The solubility of complex **4** in benzene is evidently not improved compared with the corresponding 1,1′-(trimethylene)bis-cyclopentadienyl erbium chloride complex.

EXPERIMENTAL

All operations were carried out under purified argon by use of Schlenk techniques or in a glovebox. Tetrahydrofuran was refluxed and distilled, either over finely divided $LiAlH_4$ or over blue sodium benzophenone under argon immediately before use. Anhydrous lanthanide chlorides were prepared from the hydrates by the published procedure.[16] α,α′-Dibromo-*m*-xylene and α,α′-dibromo-*p*-xylene were obtained by the method of Atkinson and Thorpe.[24]

Thermal decomposition temperatures were deter-

mined in sealed argon-filled capillaries and were uncorrected. IR spectra were recorded on a Perkin–Elmer 983 and a Digilab FTS-20/E Fourier transform IR spectrometers with Nujol and Fluorolube mulls and were examined between disc-shaped CsI crystals; the mulls were prepared in an argon-filled glovebox. Mass spectra were recorded on a Finnigan 4021 spectrometer; recorded at EI, T = 50–300°C, EM = 1.3 KV. ^{1}H NMR spectra were obtained on a EM 360L (60 MHz) spectrometer referenced to external Me_4Si in THF-d_8. THF-d_8 (E. Merck for NMR spectroscopy) was dried over Na/K alloy and was degassed by freeze–thaw cycles on a vacuum line. X-ray photoelectron spectra were recorded on a Np-1 spectrometer equipped with a Mg-K_α X-ray source.

Analyses of rare earth metal complexes were accomplished using a direct complexometric titration procedure with disodium EDTA.[16] Carbon and hydrogen analyses were performed by the combustion method in an aluminium tube.

Disodium 1,1′-(xylylene)bis-cyclopentadienide, $C_6H_4(CH_2)_2(C_5H_4Na)_2$

C_5H_5Na (45.2 mmol) was prepared in the usual manner from cyclopentadiene and sodium sand in 50 cm^3 of THF at room temperature. The solution of C_5H_5Na was added to α,α′-dibromoxylene (5.7 g, 21.6 mmol) in 50 cm^3 of THF at 0–50°C and the mixture stirred for 2 h. The mixture was centrifuged and the precipitate separated from the solution. The red solution thus obtained was allowed to react again with an excess of sodium hydride (3.95 g, 163.8 mmol) in 140 cm^3 of THF at 30°C for about 2.5 h. The concentration of this solution was 0.1106 M by titration with standard hydrochloric acid. The 1,1′-(xylylene)bis-cyclopentadienyldisodium/THF solution was stored under argon for use as an intermediate.

1,1′-(m-*Xylylene)bis-cyclopentadienyl lanthanum chloride · THF* (**1**)

A THF solution of an equivalent of 1,1′-(*m*-xylylene)bis-cyclopentadienyl disodium was added slowly to anhydrous $LaCl_3$ (1.26 g, 5.14 mmol) in 30 cm^3 of THF at −50°C. The reaction mixture was stirred for 2 h at −45 to −50°C, then allowed to warm up to room temperature and stirred overnight. The Schlenk flask was centrifuged, the precipitate separated from solution, and the THF solution reduced in volume to about 10 cm^3. Addition of 30 cm^3 of *n*-hexane gave a white solid product which was dried *in vacuo* to give a white solid, 1.10 g. Yield 50%; melting point 170–175°C (decomposed). Found: La, 29.6; Cl, 6.9. Calc. for $C_{22}H_{24}OClLa$: La, 29.0; Cl, 7.4%. EPOXIDATION OF OLEFINS USING A CrO_3/TBHP SYSTEM

D. D. AGARWAL,* SAVITA SRIVASTAVA and POONAM CHADHA

School of Studies in Chemistry, Jiwaji University, Gwalior–474011, M.P. India

(*Received* 28 *April* 1989; *accepted* 31 *August* 1989)

Abstract—The epoxidation of cyclohexene using CrO_3/TBHP gave cyclohexene oxide, cyclohexenol and cyclohexenone in the ratio 3 : 1 : 40. The nature of the solvent affects the yield of the product. Pyridine, imidazole, NaH_2PO_4 and surfactants were found to have negative effects on the yield of epoxide while sodium bicarbonate increases the yield of the epoxide. The relative rate of epoxidation of cyclic olefins was norbornene > cycloheptene > cyclooctene > cyclopentene > cyclohexene.

The catalytic functionalization of hydrocarbons is of chemical and biochemical significance.[1] Within such functionalization epoxidation of olefins using a metal catalysed system poses a synthetic and theoretical challenge.[2] Recently porphyrin and non-porphyrin metal catalysts[3–12] using iodosylbenzene, hypochlorite, tert-butylhydroperoxide, sodium periodate, sodium ascorbate/O_2, etc., have been studied. Studies with chromium(III) complexes using iodosylbenzene gave epoxide, and chromium(V) is the active oxidizing species.[2] But chromium(IV) with TBHP has been found to give only the hydroperoxide of cyclohexene.[13] CrO_2Cl_2 and $CrO_2(NO_3)_2$ have been studied as stoichiometric reagents for epoxidation.[14] In continuation of our studies[15,16] on the epoxidation of olefins, we extended our studies to a CrO_3/TBHP system which has recently been used for the oxidation of alcohols.[17] The system has been studied in detail and a possible mechanism suggested.

EXPERIMENTAL

Materials

Cyclopentene, cyclohexene, cyclooctene, cycloheptene and norbornene were commercial samples from Aldrich. Tert-butylhydroperoxide (70%) was purchased from Aldrich and dried by a literature procedure.[18] All the olefins were purified[19] from sodium hydride before use and stored at −30°C. All the standard samples of olefins were prepared[20,21] using *m*-chloroperbenzoic acid. Sodium bicarbonate, sodium dihydrogen phosphate, pyridine, imidazole, sodium lauryl sulphate, Triton X–100 and cetyltrimethylammonium bromide were obtained from Aldrich, Glaxo and Loba chemical laboratories.

Procedure for catalytic epoxidation

A typical procedure for carrying out the catalytic epoxidation of cyclohexene is heating cyclohexene (20 mmol), benzene (10 cm^3), CrO_3 (0.02 mmol) and tert-butylhydroperoxide (2.0 mmol) at 80°C under a nitrogen atmosphere for 4 h with continuous stirring. After 4 h the contents were worked-up by adding sodium sulphite to destroy tert-butylhydroperoxide and then extracted with ether, followed by drying with anhydrous magnesium sulphate. The samples were analysed by gas chromatography (GC) using an XE–60 column at 120°C. The retention times were 3.46 min (epoxide), 6.5 min (cyclohexenol) and 10.44 min (cyclohexenone).

In a separate experiment, epoxidation of cyclohexene was carried out using CH_2Cl_2 as the solvent in place of benzene, but using the same compositions and conditions as stated above. Also, in another experiment, epoxidation of cyclohexene using 70% TBHP was studied. The effect of various additives, *viz.* pyridine, imidazole, NaH_2PO_4, $NaHCO_3$, sodium lauryl sulphate, Triton X–100 and cetyltrimethylammonium bromide, on the epoxidation of cyclohexene was studied by adding 100 mg of additive to the epoxidation system.

The competitive epoxidation of cyclic olefins, *viz.* cyclopentene, cyclohexene, cycloheptene, cyclo-

* Author to whom correspondence should be addressed.

octene and norbornene, was carried out by heating CrO_3 (0.04 mmol), cyclohexene (20 mmol), other cyclic olefins (20 mmol), tert-butylhydroperoxide (4.0 mmol), dodecane (0.1 cm^3) at 80°C under nitrogen for 4 h. The products were analysed by GC.

RESULTS AND DISCUSSION

The epoxidation of cyclohexene using a CrO_3/TBHP system in benzene shows the formation of three products: cyclohexene oxide, cyclohexenol and cyclohexenone in a 3:1:40 ratio, but when the epoxidation was carried out in dichloromethane instead of benzene the yield of cyclohexenol was higher and the yield of cyclohexenone lower. The selectivity of epoxide was 16%. The epoxidation when 70% TBHP was used showed that selectivity of epoxide was 20% and the yield of cyclohexenone was 0.059 mmol compared to 0.016 mmol for cyclohexenol. These results show that the medium for epoxidation has an effect on the selectivity of epoxide. The fact that commercial TBHP, which is as good an epoxidizing agent as water, has no detrimental effect on epoxidation is contrary to an inhibitory effect found in molybdenum catalysed reactions.[1] The formation of cyclohexenol and cyclohexenone shows that a free radical pathway[1] is operative. The reaction of CrO_3 with cyclohexene in the absence of TBHP did not give any product and neither did the reaction between cyclohexene and TBHP in the absence of CrO_3. The secondary alcohol was found to oxidize to ketone under these conditions. When the kinetics of the cyclohexene epoxidation were studied (Fig. 1) it was observed that in the first 10 min the formation of cyclohexenol is greater than that of cyclohexenone, but as the reaction continues the ratio of cyclohexenone: cyclohexenol increases; this suggests that the cyclohexenol being formed in the reaction is being oxidized to cyclohexenone.

The results of the effects of the additives pyridine, imidazole, NaH_2PO_4 and $NaHCO_3$ on the epoxidation of cyclohexenene are incorporated in Table 1. This shows that pyridine, imidazole and NaH_2PO_4 have negative effects on the yield of epoxide, while the addition of $NaHCO_3$ increases the yield of the epoxide. This behaviour of CrO_3 is in contrast to that observed with OMo(TPP)OMe/TBHP[7] and OTi(TPP)/TBHP[7] systems which lower the yield of epoxide.

The effect of surfactant shows that sodium lauryl sulphate and Triton X–100 decrease the yield of all three products, but the addition of cetyltrimethylammonium bromide gave high selectivity for cyclohexenol, thus showing that it retards the oxidation of cyclohexenol to cyclohexenone.

The competitive epoxidation of cycloolefins shows the reactivity order: norbornene (6.3) > cycloheptene (4.0) > cyclooctene (3.2) > cyclopentene (2.4) > cyclohexene (1.0). The higher rates of epoxidation observed with norbornene, cyclooctene and cycloheptene compared with cyclohexene show that the olefin is not coordinated to the metal centre during the rate-determining step.[13,15] The observed results shows that torsional strain and

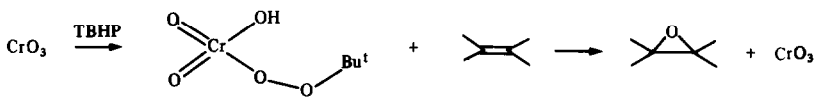
Cetyltrimethylammonium bromide	Nil	0.023	0.047	3.5

bond angle strain play an important role in determining the relative reactivity of cyclic olefins.[15]

As far as the mechanism of epoxidation is concerned, the CrO_3 reacts with tert-butylhydroperoxide resulting in the development of a deep orange–red colour which can be attributed to a peroxo–metal intermediate:



(1)

A similar kind of species has been reported in the OTi(TPP)/TBHP[7] and OMo(TPP)OMe/TBHP[7] systems which are responsible for epoxidation. This species has also recently been reported to oxidize alcohols;[17] it transfers oxygen to the olefin resulting in the formation of epoxide. The formation of allylic oxidation products, cyclohexenone and cyclohexenol, has also been reported by Groves *et al.*[22] in the Cr^{III}(TPP)Cl/PhIO system (96%). In the present system too, the cyclohexenone is obtained as a major product. Thus it shows that this system can be used as an effective reagent for the oxidation of alkenes.

SYNTHESIS AND CRYSTAL STRUCTURE OF 10-COORDINATE $[Th(C_5H_5NO)_6(NO_3)_2](NO_3)_2$ (C_5H_5NO = 2-(1H)-PYRIDONE)

DAVID M. L. GOODGAME,* SALLY NEWNHAM, CAROLINE A. O'MAHONEY and DAVID J. WILLIAMS*

Chemistry Department, Imperial College of Science, Technology and Medicine, London SW7 2AY, U.K.

(*Received* 1 *August* 1989; *accepted* 31 *August* 1989)

Abstract—Attempts to prepare polynuclear, heterometallic Cu^{II}/Th^{IV} complexes with 2-pyridone (= L) bridges, analogous to those formed by Cu^{II}/Dy^{III} and Cu^{II}/Gd^{III} gave instead $[ThL_6(NO_3)_2](NO_3)_2$, which has been characterized by X-ray diffraction. The Th atom is 10-coordinate with two bidentate nitrates and the six pyridone oxygen atoms forming a distorted bicapped square antiprism.

We recently described[1] some heterometallic hexanuclear compounds containing unusual $Cu_4^{II}M_2^{III}$ arrays, where M^{III} = Dy or Gd. These green complexes were obtained by the reaction of copper(II) hydroxide, 2-pyridone, and Dy (or Gd) nitrate in methanol. The use of other lanthanide(III) nitrates has also given green materials, full characterization of which has been hindered by poor crystal quality. However, use of the same synthetic method with the tetravalent metal ion Th^{IV} gave a quite different reaction, in which colourless crystals of stoichiometry $Th(C_5H_5NO)_6(NO_3)_4$ (**1**) were formed. We report here the structure of this compound.

EXPERIMENTAL

Preparation

Reaction of copper hydroxide (1 mmol), 2-pyridone (6 mmol) and hydrated thorium nitrate (2 mmol) in refluxing methanol (100 cm^3) gave a blue solution from which colourless needles formed. Found: C, 33.6; H, 2.7; N, 13.0. Calc. for $Th(C_5H_5NO)_6(NO_3)_4$: C, 34.3; H, 2.9; N, 13.3%.

X-ray study

Crystals of **1** form as colourless needles. The crystal data are: $C_{30}H_{30}N_{10}O_{18}Th$, M_r = 1050.7, monoclinic, a = 19.749(6), b = 9.802(4), c = 20.339(6) Å, β = 100.77(2)°, V = 3868 $Å^3$, space group $C2/c$, Z = 4 (the molecule is disposed about a two-fold axis), D_c = 1.80 g cm^{-3}, Cu radiation, λ = 1.54178 Å, μ(Cu-K_α) = 132 cm^{-1}, $F(000)$ = 2040. Data were measured on a Nicolet R3m diffractometer with Cu-K_α radiation (graphite monochromator) using ω-scans.

A crystal of dimensions 0.10 × 0.10 × 0.27 mm was used. 1997 independent reflections ($2\theta \leqslant 116°$) were measured, of which 1958 had $|F_o| > 3\sigma(|F_o|)$ and were considered observed. The data were corrected for Lorentz and polarization factors; a numerical absorption correction (face-indexed crystal) was applied; maximum and minimum transmission factors 0.401 and 0.174.

The structure was solved by the heavy atom method. The non-hydrogen atoms were refined anisotropically. The protons on N(2), N(9) and N(16) were located from a ΔF map and refined isotropically subject to a distance constraint of 0.98 Å. The positions of the remaining hydrogen atoms were idealized, C—H = 0.98 Å, assigned isotropic thermal parameters, $U(H) = 1.2U_{eq}(C)$ and allowed to ride on their parent carbon atoms. Refinement was by block-cascade full-matrix least-squares to R = 0.034, R_w = 0.033 [$w^{-1} = \sigma^2(F) + 0.00050F^2$]. The maximum and minimum residual electron densities in the final ΔF map were 1.95 and −1.95 e $Å^{-3}$, respectively. The mean and maximum shift/error in the final refinement were 0.003 and 0.015, respectively. Computations were carried out on an Eclipse S140 computer using the SHELXTL pro-

gram system.[2] Selected bond lengths and angles are listed in Table 1.

RESULTS AND DISCUSSION

The X-ray structural analysis shows that the Th atom in **1** is coordinated to 10 oxygen atoms (Fig. 1). Four of these are from two bidentate nitrates and the remaining six are from the 2-pyridone ligands. The Th—O(nitrate) bonds [2.610(5) and 2.686(5) Å] are distinctly longer than the Th—O bonds to the pyridone ligands [2.365(4)–2.413(5) Å]. A similar difference has been observed in other Th complexes containing combinations of bidentate nitrates and organic oxygen donor ligands in the coordination sphere.[3,4]

The coordination polyhedron about the Th atom

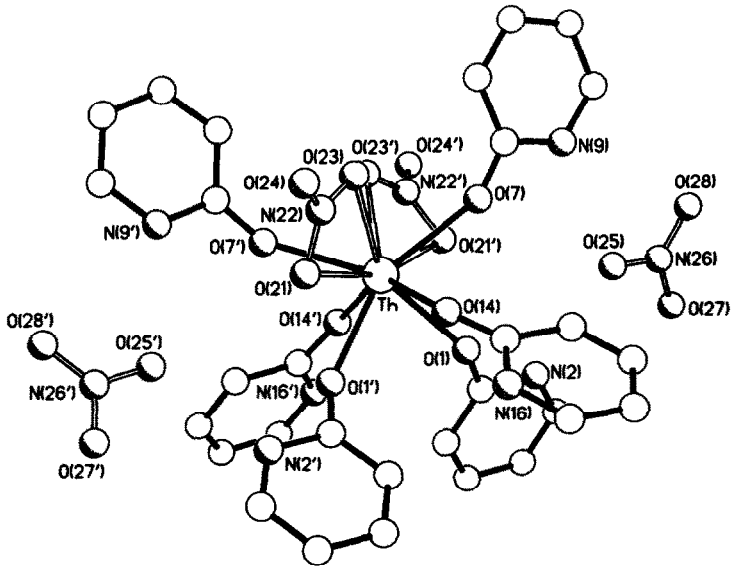

Fig. 1. The molecular structure of $[Th(C_5H_5NO)_6(NO_3)_2](NO_3)_2$, showing the crystallographic numbering scheme.

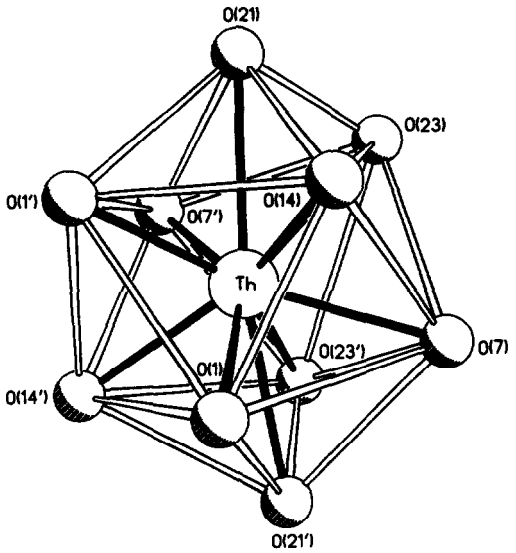

Fig. 2. The distorted bicapped square antiprismatic coordination geometry about Th. The non-bonded O···O distances are in the range 2.14 Å (nitrate)–3.14 Å for O(1)···O(7) (pyridone).

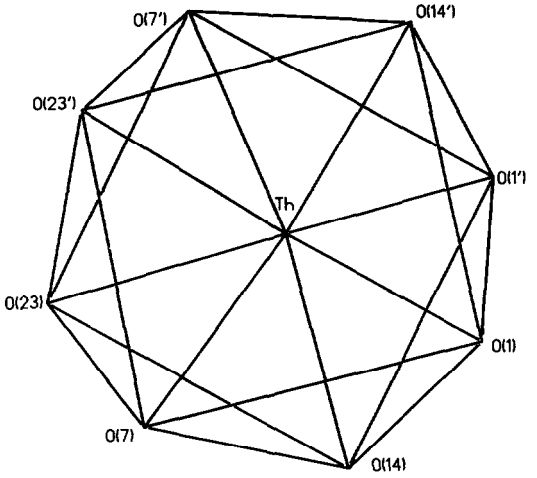

Fig. 3. Plan view of the Th coordination showing the degree of square antiprismatic register.

is best described as a distorted bicapped square antiprism (Fig. 2), one plane of which comprises O(1), O(14′), O(23′) and O(7) capped by O(21′); the other comprising O(1′), O(14), O(23) and O(7′) capped by O(21). The maximum distortion from planarity of each of these planes is 0.17 Å. The two planes are almost parallel, being inclined by only *ca* 4°. The Th and apical O atoms lie 1.18 and 1.46 Å, respectively, from these planes. The two planes deviate from idealized mutual square antiprismatic register by *ca* 5° (Fig. 3). The O(21)—Th—O(21′) angle is 163.6(2)° [cf. 171.4° for the corresponding angle in $Hg_2Th(C_4H_6NO)_4(NO_3)_4$ (**2**)[4] and 174.7° for that in $K_4[Th(C_2O_4)_4]\cdot 4H_2O$ (**3**)[5]].

As both the capping oxygen atoms, O(21) and O(21′), are provided by bidentate nitrate groups there is a significant reduction in one of the pyramid edge angles [O(21)—Th—O(23) 47.6(1)°] whilst the others [64.9(1)–66.3(2)°, mean 65.5°] are more normal (cf. 62–66°, mean 64.0°, in the oxalato complex, **3**[5]). The small coordination "bite" of the bidentate nitrates does not appear to influence the other angles subtended at the Th atom. The square edge angles are 71.9(2)–82.3(1)°, mean 76.8° (cf. 71.6–91.0°, mean 78.9°, in **3**). The equatorial edge angles are 67.9–79.7°, mean 72.3° (cf. 63.6–75.8°, mean 68.1°, in **3**).

The other two nitrate groups are present as non-coordinated ions which are linked by H-bonding to the NH groups of the pyridones. These H-bonds are of two types. In one, the nitrate oxygen atom, O(25), serves to bridge adjacent pyridone ligands [N(2) and N(9)] within the same coordination sphere.* The other pyridone ligand links intermolecularly to O(27) via N(16).*

As compound **1** resulted from attempts to make a Th/Cu polynuclear complex related to the Ln compounds $Cu_4Ln_2L_8(LH)_4(OH)_2(NO_3)_4(H_2O)_2$ (**4**, Ln = Dy, Gd; LH = 2-pyridone)[1] it is pertinent to compare the Th environment in **1** with the Ln environment in **4**. Although the Ln atoms in **4** are only nine-coordinate, they also contain six oxygen bonded pyridone ligands (the rest of the coordination sphere comprises one bidentate nitrate and a water molecule). An important difference is that in **4**, four of the pyridone ligands are deprotonated and it is the oxygen atoms of those pyridones which serve to link each Ln ion to two copper(II) ions. In **1** none of the pyridones bonded to Th is deprotonated and a mononuclear compound results. The compounds of type **4** were obtained by using copper(II) hydroxide and more forcing deprotonation conditions may be more conducive to the formation of pyridone bridged Th/Cu compounds.

Acknowledgement—We thank the SERC for funds for the diffractometer and for a Research Studentship (to C.A.O'M).

* N(2)···O(25) = 2.85, H(2)···O(25) = 1.87 Å, N(2)—H(2)···O(25) angle = 176°, N(9)···O(25) = 2.81, H(9)···O(25) = 1.84 Å, N(9)—H(9)···O(25) angle = 171°, N(16)···O(27′) = 2.88, H(16)···O(27′) = 1.97 Å, N(16)—H(16)···O(27′) angle = 153°.

(*Received* 12 *June* 1989; *accepted* 5 *September* 1989)

Abstract—The aniline derivative 1-(NMe_2)-4-MeC_6H_4 on *ortho*-mercuration followed by reaction with $ArTeCl_3$ (Ar = C_6H_5, 4-$MeOC_6H_4$ or 4-$EtOC_6H_4$) gives 1-(NMe_2)-2-($ArTeCl_2$)-4-MeC_6H_3 which on reduction with sodium metabisulphite gives hybrid telluride ligands—telluroamines (**1–3**). These newly synthesized asymmetric tellurides were characterized by elemental analysis, typical reaction with MeI, IR, ^1H and ^{13}C NMR spectra, molecular weight and conductance measurements. The (Te, N) ligands react with Na_2MCl_4/K_2MCl_4 (M = Pt or Pd) resulting in $MCl_2 \cdot L$ (L = telluroamines) type complexes. These complexes are monomeric, non-electrolyte and diamagnetic, indicating a square-planar arrangement of ligands around the metal, which is supported by electronic spectra. ^1H NMR data in conjunction with IR spectra suggest that these telluroamines behave as bidentate ligands in the present complexes.

A lot of interest has been developing in the ligand chemistry of tellurium[1–4] for the last one and a half decades but very few hybrid bidentate or polydentate ligands[5–6] containing the element are known and explored for their complexation behaviour. We were interested in synthesizing potentially bidentate ligands containing both Te and donor atoms such as N or O for two reasons. First, these donor atoms may strongly ligate with the hard metals of the first and second transition series and consequently generate a system in which the forced interaction (if any) of Te with such metals can be investigated. Second, they can favourably influence catalytic activity of Pt group metallic centres (e.g. for hydrogenation) if incorporated into their coordination sphere. This is expected on the basis of the larger size of Te due to which the formation and reaction of intermediates may be facilitated in comparison to complexes containing donors like (P, N) or (P, O). Thus asymmetric tellurides **1–3** have been prepared by mercuration of N,N-dimethyl-*p*-toluidine followed by transmetallation with suitable aryltellurium(IV) chloride in good yield. Their complexation with Pd^{II} and Pt^{II} has been investigated. The synthesis and spectra of these new (Te, N) donors and their complexes are the subject of the present paper.

EXPERIMENTAL

Published methods[7] were used to synthesize $C_6H_5TeCl_3$, 4-$MeOC_6H_4TeCl_3$ and 4-$EtOC_6H_4$ $TeCl_3$. The chloride, mercury and tellurium were estimated by standard methods.[8] The C, H and N analyses were carried out with a Perkin–Elmer elemental analyser 240C. ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded on a JEOL FX 100 FT–NMR spectrometer, at 99.55 and 25 MHz, respectively. IR spectra (of Nujol mulls between

* Author to whom correspondence should be addressed.

CsI windows or KBr/CsI discs) in the range 4000–200 cm^{-1} were recorded on a Nicolet 5DX FT-IR spectrometer. Electronic spectra in $CHCl_3$ were recorded on a Hitachi 330 UV–vis spectrophotometer. The conductivity measurements were made on *ca* 1 mM solutions in acetonitrile with a Pye conductivity bridge. The molecular weights were determined in chloroform for 5–20 m solutions with a Knauer vapour pressure osmometer.

Procedure for mercuration[9]

N,N-Dimethyl-*p*-toluidine (Riedal) (0.1 mol) was dissolved in 50 cm^3 methanol and mixed with a solution of mercuric acetate (0.1 mol) made in 200 cm^3 methanol. The mixture was heated on a water bath at 60–70°C for 0.5 h after adding 2 cm^3 of glacial acetic acid to avoid the formation of HgO. Sodium chloride (0.1 mol), dissolved in a minimum amount of water, was added to this mixture. The white precipitate thus formed was filtered, washed with water, dried and extracted with chloroform. The extract was concentrated to crystallize 1-(NMe_2)-2-(HgCl)-4-MeC_6H_3 as white needles. Yield 50%, m.p. 165–167°C. Found: Hg, 53.8; Cl, 9.2; Calc: Hg, 54.2; Cl, 9.6%. NMR (^1H, $CDCl_3$, 25°C): δ, 2.29 (s, 3H, Me), 2.71 (s, 6H, NMe_2), 7.06–7.25 (m, 3H, phenyl).

Procedure for transmetallation with aryltellurium(IV) chloride

Mercurated aniline (10 mmol) was refluxed with equimolar amounts of $C_6H_5TeCl_3$, 4-$MeOC_6H_4TeCl_3$ or 4-$EtOC_6H_4TeCl_3$ in 60 cm^3 of chloroform for 6 h. The solution was cooled and the precipitated $HgCl_2$ was filtered off. On concentrating the filtrate the pale yellow/yellowish brown $ArAr'TeCl_2$ type derivative crystallized, which was filtered off, washed with 5–10 cm^3 of cold methanol and recrystallized from a benzene–chloroform (30:70) mixture. The yield, melting point, results of elemental analysis, characteristic IR bands, ^1H and $^{13}C\{^1H\}$ NMR data are given below.

Reduction of **4–6**

The aqueous suspension of **4–6** was stirred with a five-fold molar excess of sodium metabisulphite dissolved in water for 2 h at 50°C. Compound **4** yielded a dense liquid which was separated, washed with water and extracted with hexane. The hexane was removed *in vacuo* to give a yellow oil. Compounds **5** and **6** yielded pale yellow solids which were filtered, washed with water, dried and extracted with petroleum ether (40–60°C) or hexane. The extract on concentration gave a pale yellow crystalline solid, which was filtered and dried *in vacuo*. The yield, melting point, results of elemental analysis, IR, ^1H and ^{13}C NMR data are given below.

Synthesis of platinum(II) *and palladium*(II) *complexes of* (Te, N) *donors* (**1–3**)

Sodium tetrachloropalladate (0.147 g, 0.5 mmol) or potassium tetrachloroplatinate (0.20 g, 0.5 mmol) was dissolved in 5 cm^3 of water. The solution of $\simeq$ 0.5 mmol ligand **1–3** in 10 cm^3 of acetone was added dropwise with stirring at room temperature. The mixture was further stirred for 2–3 h. The resulting orange (palladium) or pale yellow (platinum) coloured precipitate was filtered, washed with water and dried *in vacuo*. It was recrystallized from a chloroform–hexane (90:10) mixture. The yield, melting point, results of elemental analysis, IR and ^1H NMR data are recorded below.

$PdCl_2$·**1**: Yield, 80%; m.p. 185–190°C (dec.). Found: C, 33.6; H, 3.5; N, 2.6. Calc. for $C_{15}H_{17}NTe \cdot PdCl_2$: C, 34.9; H, 3.3; N, 2.7%. Mol. wt, Found: 480–535; calc.: 516. RESULTS AND DISCUSSION

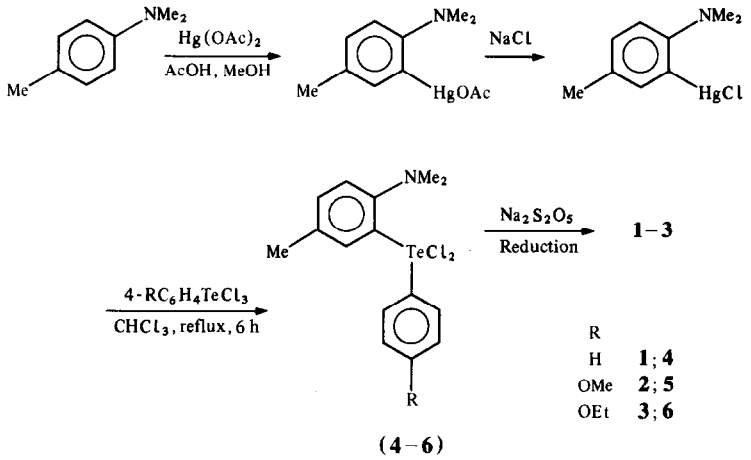
The number of asymmetric tellurides known[1–4] at present is a lot less than the symmetric ones. Telluroamines **1–3** belonging to this rare class have been synthesized by following the sequence of reactions given in Scheme 1.

Telluroamines **1–3** and their respective dichlorides, **4–6**, are fairly soluble in non-polar organic solvents. Like other tellurides and diaryltellurium(IV) chlorides, they all behave in solution as non-electrolytes. ^1H NMR spectra of **1–3** and their respective dichlorides are as expected for such compounds. The NMe_2 protons undergo a small upfield ($\simeq$ 0.1–0.2 ppm) shift on *ortho*-mercuration of the dimethylaniline derivative. In the ^1H NMR spectra of *ortho*-tellurated anilines **4–6**, however, the NMe_2 protons appear at a position almost identical to that of the parent aniline. Prob-



Scheme 1.

ably, the substitution of an aryl proton *ortho* to NMe_2 with HgCl group increases the electron density at nitrogen which seems to marginally shield the NMe_2 protons. The Te in the dichlorides **4–6** being more electronegative than mercury fails in affecting these protons. On reduction of **4–6** into tellurides **1–3**, respectively, the NMe_2 protons are again shielded ($\simeq$ 0.2 ppm). This may be due to a decrease in electronegativity of Te and strength of Te···N interaction, which otherwise seems to be very weak in nature. $^{13}C\{^1H\}$ NMR spectra of **1–3** and their dichlorides are characteristic of them.[10] The shielding of NMe_2 carbons on the reduction of dichlorides, **4–6** to **1–3** supports ^1H NMR spectra. IR spectra of **1–3** have two ν(Te—C) bands around 260 and 295 cm^{-1} as expected for such compounds.[11] Two bands occur for C—N stretching also; the one around 1280 cm^{-1} seems to originate from N—C(aryl) and the other between 1200–1250 cm^{-1} from N—C(methyl) bond. Methyl iodide reacts with asymmetric tellurides **1–3** according to eq. (1) which is typical of telluride characteristics:

$$\text{ArAr'Te} + \text{MeI} \xrightarrow[\text{overnight}]{\text{RT}} \text{ArAr'MeTeI} \quad (1)$$

(Yield = 90%).

Complexation of **1–3** *with platinum*(II) *and palladium*(II)

The tetrachloroplatinate or palladate reacts with telluroamine ligands **1–3** according to eq. (2):

$$[MCl_4]^{2-} + L \xrightarrow[\text{RT, } \simeq 3\text{h.}]{\text{aq. acetone}} MCl_2 \cdot L + 2Cl^- \quad (2)$$

(M = Pt or Pd; L = **1–3**).

The resulting Pt and Pd complexes were fairly soluble in chloroform, dichloromethane and acetonitrile, and were found to be diamagnetic. The specific conductance of their solutions in acetonitrile ($\simeq$ 1 mmol range) has been found to be almost equal to that of the pure solvent. This observation in conjunction with molecular weights suggests that the Pd and Pt complexes are monomeric and non-electrolytes. The comparison of IR spectra of the ligands with those of complexes exhibits that the ν[N—C(Me)] vibrations shift to lower frequency by 30–50 cm^{-1}, indicating the coordination of Pd or Pt with NMe_2. The red shift also occurs in ν[N—C(Ar)] vibrations but of 10–15 cm^{-1} only, concurring with the hypothesis of coordination. The two ν(Te—C) bands appear at 10–30 cm^{-1} lower frequency in the Pd and Pt complexes. The presence of two broad peaks around 330 and 290 cm^{-1}, assignable to M—Cl vibrations, indicates that two M—Cl bonds in the complexes are in a *cis*-conformation of a square-planar arrangement of the ligands around the metal atoms,[12] if presumed in view of magnetic properties, molecular weights and molar conductance values. The electronic spectra of these Pd and Pt complexes exhibit three bands around 25, 30 and 42 kK and 25, 38 and 42 kK, respectively. The first band in both the complexes seems to arise from $^1A_{1g} \rightarrow {}^1B_{1g}$ transitions, further supporting the square-planar arrangement of ligands around Pt and Pd. On comparison with the electronic spectra of the ligands (bands at *ca* 35.7 and 41.7 kK) it appears that second and third bands of each of these complexes probably originate from intraligand transitions.

In the ^1H NMR spectra of Pd–telluroamine complexes the NMe_2 protons have been found deshielded ($\simeq$ 0.7–0.8 ppm) in comparison to the free ligand, suggesting that the NMe_2 group coordinates

with Pd as inferred by IR data. Moreover, the two methyl signals separated by 0.07–0.13 ppm appeared, indicating the non-equivalence of two methyl groups after involvement of nitrogen in coordination. The proton *ortho* to the tellurium in the aniline ring of **1–3** on chelation has been found to be significantly deshielded ($\simeq$ 0.5 ppm). The other ring protons also appear at a lower field (0.10–0.15 ppm). In the Pt complexes, also, the ligands seem to chelate through N and Te. The coordination through N is supported by the appearance of NMe_2 protons down field by $\simeq$ 1 ppm, in comparison to the free ligand. However, the NMe_2 signals in the spectra of Pt complexes have some interesting features. In the spectrum of $PtCl_2 \cdot$ **1** it appears as two peaks of equal intensity at 3.61 and 3.65 ppm with side bands due to $^3J(^{195}Pt—H)$ couplings (Fig. 1), whereas an unresolved doublet at 3.64 ppm is observed for these protons in the spectrum of $PtCl_2 \cdot$ **2**, with a side band of a similar type. The other side band probably merges with the methoxy signal as indicated by the enhanced intensity of the latter. In the $PtCl_2 \cdot$ **3** complex, the NMe_2 signal appears as a singlet but with the expected side bands. The coupling constant $^3J(^{195}Pt—H)$ in these complexes was between 28 and 26 Hz, concurring with the earlier reports.[14,16] The aniline ring proton *ortho* to Te was also found deshielded by $\simeq$ 1 ppm. The large deshielding in Pt complexes indicates that **1–3** ligate more strongly with Pt in comparison to Pd.

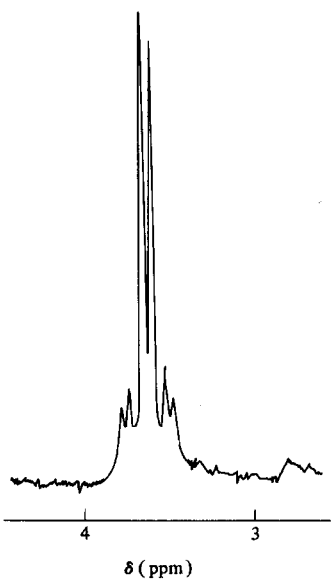


Fig. 1. ^1H NMR spectrum of $PtCl_2 \cdot$ **1** showing $^3J[^{195}Pt—H(NMe_2)]$ coupling.

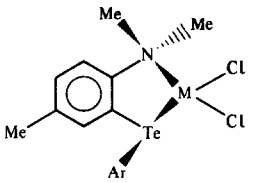
The two methyl signals for the NMe_2 group probably originate because the inversion of the pyramidal Te in these complexes is slow at the temperature of NMR measurement in the five-membered chelate ring rigid structure **7**. The aryl



M = Pt or Pd
Ar = C_6H_5, 4-$MeOC_6H_4$ or 4-$EtOC_6H_4$

(**7**)

groups attached to Te thus result in the different magnetic environments for the two methyl groups fixed sterically above and below the five-membered ring because there is no possibility of inversion at the four-coordinate ring nitrogen atom. For the NMe_2 group coordinated to Pt and Pd, such behaviour has been reported[13–16] earlier in a few cases.

CONCLUSION

The dimethyl aniline derivative on *ortho*-mercuration followed by transmetallation with $ArTeCl_3$ and reduction of the resulting $ArAr'TeCl_2$ type derivatives with sodium metabisulphite give interesting (Te, N) donors which behave as bidentate neutral ligands with Pt^{II} and Pd^{II}.

COMPLEXATION EQUILIBRIA BETWEEN CADMIUM(II) AND 4-(4′-METHYL-2′-THIAZOLYLAZO)-2-METHYL-RESORCINOL. A SPECTROPHOTOMETRIC STUDY

Mª J. SÁNCHEZ, B. SANTANA, F. JIMÉNEZ and F. GARCÍA MONTELONGO*

Department of Analytical Chemistry, University of La Laguna, E–38204 La Laguna, Spain

(*Received* 12 *June* 1989; *accepted* 5 *September* 1989)

Abstract—The complexation equilibria between Cd^{II} and 4-(4′-methyl-2′-thiazolylazo)-2-methyl-resorcinol have been spectrophotometrically studied in an ethanol–water medium (50:50, v/v) at $I = 0.25$ M ($NaClO_4$) and species $CdHR_2$ ($\log\beta_{112} = 20.38 \pm 0.09$) and CdH_2R_2 ($\log\beta_{122} = 27.00 \pm 0.09$) are established by a numerical calculation method.

Heteroazo compounds have been widely used as chromogenic reagents for several metal ions but only in recent times have the equilibria involved been studied.[1,2] The ligand 4-(4′-methyl-2′-thiazolylazo)-2-methyl-resorcinol, MTAMR, has been previously synthesized and complexation equilibria with V^{V}, Zn^{II} and Cu^{II} studied.[3–6] The kinetics of the ligand-substitution reaction of the Zn–MTAMR complex by DCTA has also been studied.[7]

In this paper the acid–base equilibria of MTAMR and its complexation equilibria with Cd^{II} in an ethanol–water medium (50:50, v/v) at $I = 0.25$ M $NaClO_4$ are reported. Graphical and numerical calculation methods are used to establish the nature of the species in solution and to calculate the stability constants which have not previously been reported in the literature.

EXPERIMENTAL

Absorption measurements were performed on a Perkin–Elmer 550S recording spectrophotometer provided with 1 cm matched quartz cells. A Radiometer PHM64 digital pHmeter with glass–calomel combination electrode, calibrated by the Gran method,[8] was used for pH measurements. Measurements were performed at 25±0.1°C. Calculations were carried out on a Digital VAX/VMS 11/780 (V.4.8) computer.

A 10^{-3} M solution of MTAMR in absolute ethanol, standard 10^{-2} M $Cd(ClO_4)_2$ (prepared from the nitrate by perchloric acid treatment and standardized complexometrically), analytical reagent grade chemicals and deionized water were used throughout with no further purification.

RESULTS AND DISCUSSION

Acid–base behaviour of MTAMR

To study the acid–base behaviour of MTAMR in ethanol–water medium (50:50, v/v) at $I = 0.25$ M $NaClO_4$, a method of graphical analysis of the absorbance–pH curves was first used.[9] Values calculated for pK_{ax} together with the optical characteristics of each species are listed in Table 1. The experimental data were further refined using the LETAGROP–SPEFO numerical calculation method.[10] The results obtained are included in Table 1 along with the pK_{ax} values previously determined in methanol–water medium (50:50, v/v).[4]

Complexation equilibria in the Cd^{II}–MTAMR system

Cd^{II} and MTAMR react to give violet coloured species in solutions of pH 4. The absorption spectra at pH 8.5 of solutions with several $C_{Cd}:C_R$ ratios show the presence of an absorption maximum at 520 nm for $C_{Cd}:C_R \geqslant 10$ and an absorption maximum at 550 nm for solutions with $C_{Cd}:C_R = 0.1$, Fig. 1, which may indicate the presence of at least two complex species in solution. However, the stoichiometry as established by the continuous variation and mole ratio methods shows only the presence of 1:2 Cd:R complex species in solution. Thus, taking into account the formation

pH range, the most probable mechanism of complex formation will be:

$$Cd^{2+} + 2H_2R \rightleftarrows CdH_2R_2 + 2H^+;$$

K_{122} being the equilibrium constant. To check the validity of this equilibrium, the method of graphical analysis of the absorbance–pH dependences of Hnilickova and Sommer[9] was first used, from which the presence of species CdH_2R_2 results and two protons are split off during complexation and $\log \beta_{122} = 26.18$ was calculated as the mean value for the stability constant. Next, the experimental data were analysed by application of the LETAGROP–SPEFO program[10] using the species and β_{122} value obtained by the graphical method as starting values. The species model was then modified by introducing new species in order to ascertain which one of the proposed models would fit the experimental data with a minimum sum of squares of residuals, U, and of standard deviation, $\sigma(A)$. Using the values obtained for the minimal U and $\sigma(A)$ it can be seen from Table 2 that the model including the species CdH_2R_2 and $CdHR_2$ fits the experimental data best. Calculations for other models assuming the formation of hydroxo-complexes, mixed ligand complexes and/or polynuclear species in addition to the CdH_2R_2 and $CdHR_2$ species, did not converge. Calculated values for the stability constants and molar absorptivities of these complex species are included in Table 2.

When compared with the cadmium complexes of TAR[9] and TAMR[11] the Cd^{II}–MTAMR species are the most stable and show higher molar absorptivities.

COMPUTER MODELS OF BIOFLUIDS—AN EXPERIMENTAL VERIFICATION

GRAHAM E. JACKSON* and M. SINGH

Department of Chemistry, University of Cape Town, Rondebosch 7700, South Africa

(*Received* 6 *April* 1989; *accepted after revision* 7 *September* 1989)

Abstract—Ultrafiltration of blood serum has been used as a test of the computer model ECCLES. Both coordinating polyaminocarboxylate ligands and anti-inflammatory drugs used in the treatment of rheumatoid arthritis have been evaluated. For the polyaminocarboxylates the computer model is able, to a large extent, to explain the experimental results for copper(II), calcium(II) and zinc(II). However, for the anti-inflammatory drugs, the model fails to predict the observed mobilization of copper(II) and zinc(II). In this case it is postulated that the metal ions are released via an allosteric mechanism.

In recent years computer models have been developed which attempt to mirror the various metal-ion equilibria occurring in biofluids.[1–4] These models, which are based on thermodynamic considerations, have been used in discussions of therapeutic chelating agents.[5] Indeed, the ability of these models to screen promising chelating agents and to explain the failure of existing chelating agents is very impressive. However, animal tests have shown that computer model predictions are not always correct. There are many reasons for these failures. Certainly the small size of the earlier models was a contributing factor. The development of the model by May *et al.*[4] overcame this size limitation. Jones[6] has proposed an alternative model for the selection of therapeutic chelating agents in which he emphasized the importance of rate processes. The majority of these rate processes, such as rate of absorption of the chelating agent, excretion and metabolism of the chelating agent, transport of the chelating agent into cellular compartments and excretion and reabsorption of chelate complexes, are all *in vivo* processes. Attempts have been made[7] to include some of these factors into a computer model. However, to date, no direct experimental verification of these complex biomodels has been attempted. In this paper we have devised an *in vitro* test of the thermodynamic model of blood plasma, ECCLES.[4] Ultrafiltration of pooled human blood serum has been carried out and the experimental results correlated with those predicted by the computer model.

EXPERIMENTAL

Human blood serum was obtained from the Western Province Blood Transfusion Service. Drugs involved in this study were kindly donated by pharmaceutical companies and used without further purification. These drugs were prednisolone, piroxicam and mefanamic acid (Warner Lambert), aspirin (May and Baker), indomethacin (Beecham Pharmaceuticals), tiaprofenic acid (Russel Laboratories) and D-penicillamine (Lilly Laboratories, U.S.A.).

Ultrafiltration was carried out using a low cost ultrafiltration apparatus designed in our laboratory. Centrifugal pressure at 3000 r.p.m. (~900 g) allowed a filtration rate of 1×10^{-2} cm^3 min^{-1} through YMT (Amicon) membranes to be achieved. Varying concentrations of drug/ligand were added to 10 cm^3 aliquots of pooled human serum at pH 7.5. The pH was measured before and after the experiment and found not to vary by more than 0.07 pH units. The solutions were incubated at 37°C for 15 min to allow the system to come to equilibrium and then ultrafiltered. Each titration was repeated four times. The ultrafiltrates (~0.1 cm^3) were collected and immediately analysed for copper, zinc and calcium by atomic absorption spectrometry. Calcium was measured using a N_2O/C_2H_2 flame at 422.7 nm. A 100-fold excess of lanthanum nitrate was added to each of the ultra-

* Author to whom correspondence should be addressed.

filtrate samples, so as to suppress ionization of the analyte. Zinc was measured at 213.9 nm using a very lean (oxidizing) air/C_2H_2 flame. Copper was measured by atomic absorption on a Perkin–Elmer 5000 atomic absorption spectrophotometer (graphite furnace) coupled to a HGA 500 programmer.

The presence of protein in the filtrate was monitored using Coomassic Brilliant Blue G-250.[8]

A 5-cell spectrum equilibrium dialysis apparatus together with Spectrapor membranes were used for equilibrium dialysis experiments. The membranes were boiled in 2% EDTA and 5% $NaHCO_3$, followed by copious rinsing and boiling for 3×1 h in double-distilled deionized water. This treatment removed all contaminating metal ions and nucleases from the dialysis membranes. Finally, the membranes were soaked for 15 min in 0.1 M N-ethylmorpholine HCl buffer. After charging, the dialysis cells were allowed to rotate at 5 r.p.m. for 24 h at 37°C.

Theoretical predictions of the mobilization of metal ions in blood plasma by chelating agents and drugs were obtained using the ECCLES program and data base.[4] In the cases of the drugs, where equilibrium constants were not available, they were estimated from analogous model compounds in the literature[9] and, where necessary, adjusted to 37°C and an ionic strength of 0.15.

RESULTS AND DISCUSSION

It is generally believed that ultrafiltration gives only approximate results and that only small amounts of filtrate should be removed so as not to disturb the initial equilibrium. This belief has recently been shown to be unfounded.[10,11]

If we consider a system involving the metal/protein equilibrium

$$M + P \rightleftharpoons MP,$$

the conditional equilibrium constant is given by,

$$K = [MP]/[M][P]$$

and $T_P = [MP]+[P]$ and $T_M = [MP]+[M]$, where T_M and T_P are the total concentration of metal and protein, respectively.

Upon rearrangement we get:

$$K = \frac{T_M - [M]}{[M](T_P - T_M + [M])}.$$

Considering the situation before (i) and after (o) removal of a small amount (dV) of ultrafiltrate we can write,

$$T_P^i = T_P^o V/(V - dV) \quad \text{and}$$

$$T_M^i = VT_M^o - dV[M^o]/(V - dV),$$

where V is the initial volume.

Substituting into the equilibrium expression we get:

$$K^o = (T_M^o - [M^o])/[M^o](T_P^o - T_M^o + [M^o])$$

and

$$K^i = \frac{T_M^o V - dV[M^o] - [M^i](V - dV)}{[M^i]\{T_P^o V - VT_M^o + dV[M^o] + [M^i](V - dV)\}}.$$

But the equilibrium constant before and after ultrafiltration must be the same and hence the two expressions are equivalent. This condition is satisfied if $[M^o] = [M^i]$, a result which is independent of dV. Clearly then the free metal concentration is independent of the percent ultrafiltration. However, if a substantial volume of solution is removed, changes in ionic strength etc. could occur which would modify the conditional equilibrium constant.

Table 1 lists the results for an example of the above calculation. From these results it is clear that while the total concentrations of protein and metal increase, the free metal concentration remains constant. We have checked this result experimentally

Table 1. Species concentrations calculated for the equilibrium $M + P \rightleftharpoons MP$ following the removal of dV cm^3 of solution by ultrafiltration. Initial total metal (T_M) = total protein (T_L) = 0.1 mM, conditional equilibrium constant $K = 10^3$ and initial volume = 2 cm^3

(Table 2) by analysing successive aliquots of filtrate for the Cu–HSA system. Similar results have been found for other systems.[12] In addition we have compared our ultrafiltration technique with the more established technique of equilibrium dialysis. While the results for equilibrium dialysis (Fig. 1) are consistently lower than the results for ultrafiltration, there is good agreement between the two methods. Subsequent experiments have shown that the discrepancy between the two methods is a result of metal-ion binding to the dialysis membrane.

Figure 2(a) shows the calculated copper(II) PMI curves for four chelating agents in blood plasma. The order of ability of these agents to mobilize copper(II) at pH 7.5 and 37°C is calculated to be:

TRIEN > EDDA > DTPA > EDTA.

Apart from structural considerations, the mobilizing order can be rationalized by taking into account the binding of zinc(II) and calcium(II) by these ligands. The computer model, ECCLES, predicts that both TRIEN and EDDA are unable to mobilize calcium(II) (see Fig. 4), and that TRIEN is a weaker mobilizer of zinc(II) than DTPA and EDTA [see Fig. 3(a)]. Therefore, the high mobilization of copper(II) by TRIEN is a consequence of its limited calcium(II) and zinc(II) complex formation and hence, most of the TRIEN in blood plasma is available for copper(II) mobilization. It must be remembered that the concentration of calcium(II) and zinc(II) in blood plasma, is several orders of magnitude higher than that of copper(II).

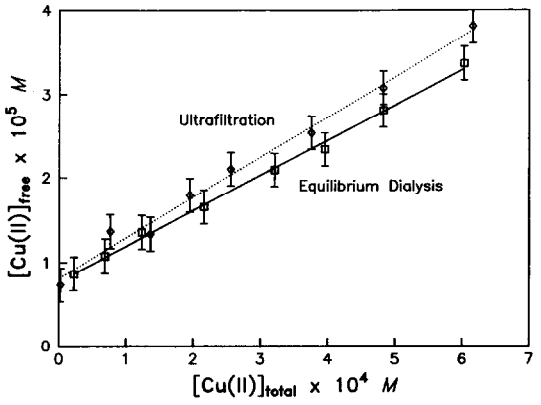

Fig. 1. Comparison of ultrafiltration and equilibrium dialysis study of copper(II) binding to HSA in 0.1 M N-ethylmorpholine HCl at pH 7.5 and 37°C.

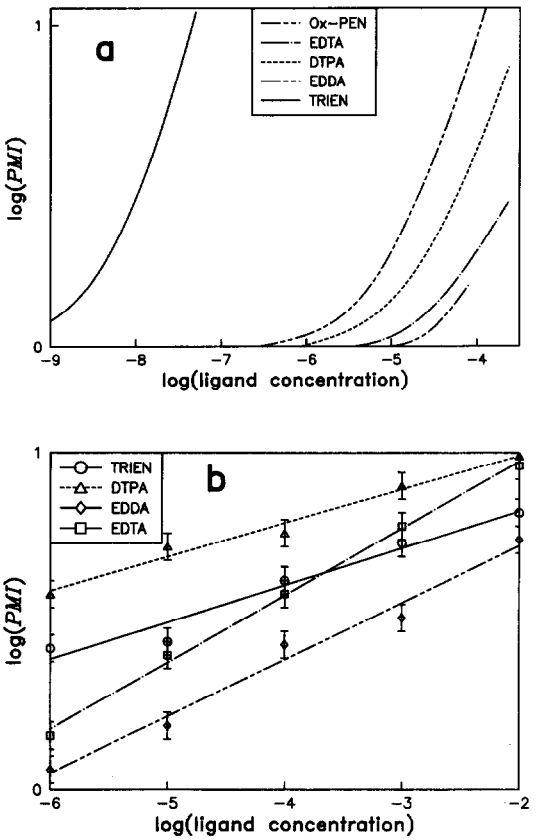

Fig. 2. (a) Calculated and (b) experimental copper(II) PMI curves for chelating ligands in pooled human blood serum.

Similarly, although EDDA forms weaker copper(II) complexes than DTPA and EDTA, it has a greater ability to mobilize copper(II). Hence, the powerful copper(II) binding abilities of EDTA and DTPA are suppressed in plasma by competition with zinc and calcium. The higher mobilization of copper(II) by DTPA rather than EDTA is expected as DTPA forms more stable copper(II) complexes than EDTA.

Figure 2(b) shows the experimental copper(II) PMI curves for the same four chelating agents in human blood serum under physiological conditions of pH and temperature. From a comparison of Figs 2(a) and (b) it is evident that there are a number of discrepancies between the experimental and theoretical results. Firstly, the order of ability of the chelating agents to mobilize copper(II) in serum

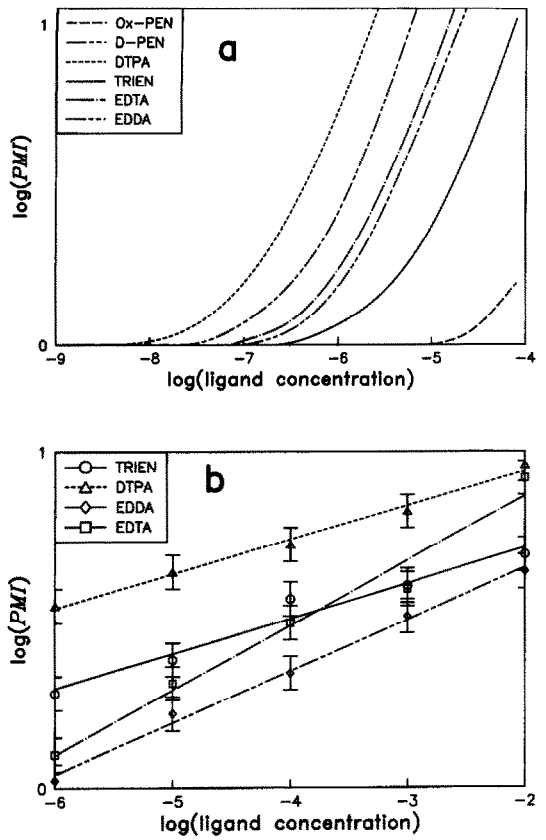

Fig. 3. (a) Calculated and (b) experimental zinc(II) PMI curves for chelating ligands in pooled human blood serum.

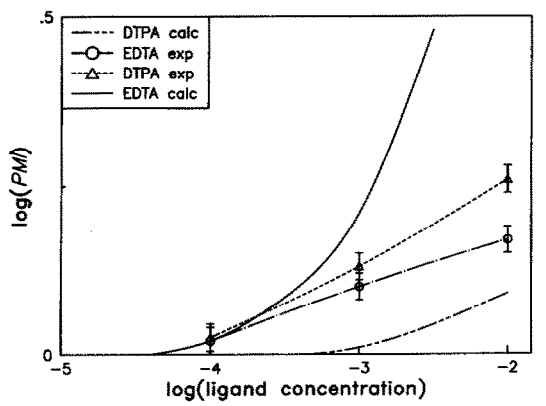

Fig. 4. Calculated and experimental PMI curves for calcium(II).

is now found to be:

DTPA > TRIEN > EDTA > EDDA.

Secondly, the shape of the experimental PMI curves are distinctly different from the theoretical curves. At first sight there appears to be no correlation between the experimental and theoretical results. However, a careful examination of the data shows that, with the exception of TRIEN, the amount of copper(II) mobilized by the polyaminopolycarboxylic acids is similar to the amount of copper(II) predicted to be mobilized by ECCLES, i.e. copper(II) starts to be mobilized at a ligand concentration of between 10^{-5} and 10^{-6} M. In both the theoretical and experimental plots, above a threshold value of PMI = 0.2, the curves are linear, but the theoretical curves are much steeper than the experimental curves. Thus, the model is partially correct in that it predicts the right order of magnitude for the PMI values, but fails to predict the finer details of mobilization.

Calculated zinc(II) PMI curves for chelating agents in blood plasma are shown in Fig. 3(a). The order of ability of these chelating agents to mobilize zinc(II) from serum albumin at pH 7.5 and 37°C is calculated to be:

DTPA > EDDA > EDTA > TRIEN.

The experimental results confirm the computer predictions, in that the chelating agents are found to mobilize zinc(II) in blood serum, but once again there are discrepancies between the theoretical and experimental results [Fig. 3(b)] with respect to the relative order in which these agents mobilize zinc(II), as well as the shapes of the PMI curves. Experimentally the order in which zinc(II) is found to be mobilized in blood serum is the same as that found for copper(II).

At the same time that the zinc(II) and copper(II) mobilizing ability of these ligands was monitored, the calcium(II) mobilization was also determined. In the absence of any administered chelating agent the computer model predicts a citrate species distribution of 58 mM calcium citrate, 32 mM magnesium citrate and 31 mM citrate. This is in good agreement with measured values of 38, 44 and 39 mM, respectively.[13] In the presence of the chelating agent, with the exception of EDTA and DTPA, none of the ligands studied is predicted to be able to mobilize calcium(II). Experimentally this prediction is confirmed in that only DTPA and EDTA are found to increase the amount of ultrafilterable calcium(II) in blood serum (Fig. 4). The experimental results are well supported by the fact that DTPA and EDTA are known to form very stable complexes with "hard" metal ions in blood serum.[14] This property of the chelating agents has been exploited in their use as antidotes for heavy metal poisoning.[15] DTPA is also the most effective known chelating agent for the removal of internally deposited transuranium elements in humans.[16] The chelating agents are invariably administered as the calcium(II) complex so as to prevent calcium

depletion in the body. Experimentally, DTPA is found to be more efficient in mobilizing calcium(II) than EDTA. This is to be expected as DTPA is a higher homologue of EDTA and the stability constant for the calcium DTPA complex is higher than the corresponding EDTA complex.[9]

In a second series of experiments, theoretical and experimental PMI curves were generated for several drugs which are currently used in the treatment of rheumatoid arthritis. From the results (Figs 5 and 6) it is clear that these drugs are capable of mobilizing endogenous copper and zinc. These results are supported by the findings of Fiabane and Williams,[17] who reported that non-steroidal anti-inflammatory drugs (NSAIDs) are capable of releasing copper ions from serum albumin. The order of ability of the various drugs to mobilize copper(II) in blood serum is found to be:

D-penicillamine > aspirin > mefanamic acid > indomethacin > piroxicam > tiaprofenic acid > prednisolone.

By comparison with Fig. 2(b) the NSAIDs are found to be approximately equivalent to EDDA, with respect to copper(II) mobilization, while D-penicillamine is equivalent to EDTA. Contrary to these findings, the computer model predicts that these drugs would be incapable of mobilizing copper(II) in blood plasma. Of course D-penicillamine, because of its tendency to undergo reductive chelation with copper(II), could not be included in the computer model for copper(II). If instead oxidized penicillamine is used in the calculation then a weak mobilization of copper(II) is seen [Fig. 2(a)]. Even this is much lower than the observed increase in ultrafiltrable copper.

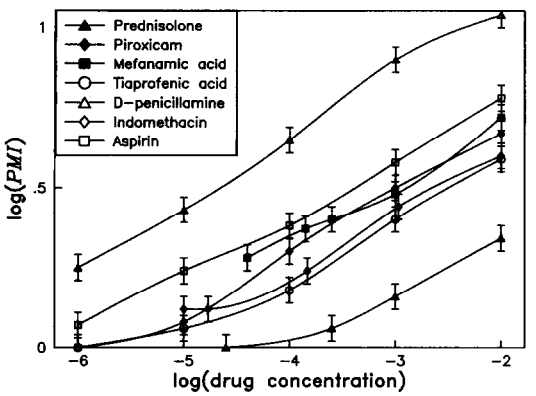

Fig. 5. Experimental copper(II) PMI curves for anti-inflammatory drugs in pooled human blood serum.

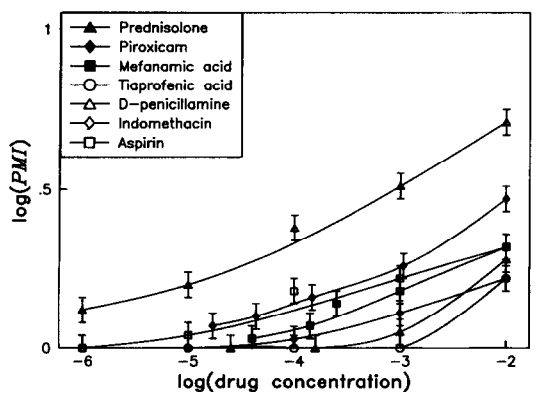

Fig. 6. Experimental zinc(II) PMI curves for anti-inflammatory drugs in pooled human blood serum.

Experimental PMI curves for zinc(II) with anti-inflammatory drugs are shown in Fig. 6. The order of ability of these drugs to mobilize zinc(II) under physiological conditions is found to be:

D-penicillamine > aspirin > piroxicam > mefanamic acid > indomethacin > prednisolone > tiaprofenic acid.

D-Penicillamine exhibits a similar zinc(II) mobilizing ability to EDDA. Clinically, D-penicillamine has been shown to increase zinc excretion.[18] The NSAIDs and prednisolone are found to be much weaker mobilizers of zinc(II) than the polyaminocarboxylates. It is interesting to note that, with the exception of piroxicam and prednisolone, the order in which these drugs mobilize zinc(II) is remarkably similar to the order in which copper(II) is mobilized in blood serum. Computer simulation of these drugs shows that only D-penicillamine increases the low molecular weight fraction of zinc(II) in blood plasma.

CONCLUSION

Comparison between experimental and theoretical results has shown that the computer model, ECCLES, with a few notable exceptions, is surprisingly good at calculating metal-ion mobilization in blood plasma. The model is able to, within an order of magnitude, predict the ligand concentration at which mobilization begins, and predict the observed linear dependence of PMI upon ligand concentration. On the other hand, the computer model fails to simulate some of the finer details of metal-ion mobilization. Notably the model calculates a much higher ligand concentration dependence than is actually seen. This is a consequence of the assumption that the free metal-ion concentration is perfectly buffered by the protein–metal interactions. While this assumption may be valid for small increases in the concentration of low molecular weight metal species, as more and more mobilization occurs the buffer capacity of the

protein will be exceeded. Also the model does not take into consideration ligand binding by protein or the binding of low molecular weight complexes to protein. In addition we have shown that not all metal–protein interactions can be described by simple equilibria and that as metal ions are removed from the protein, it may become progressively more difficult to remove the remaining metal ions bound to the protein.[19] These three factors would explain why the limiting slopes of the experimental PMI curves are less than the slopes of the theoretical PMI curves.

Serum albumin is known to be a versatile carrier protein, not solely for copper ions, but also for long chain fatty acids and for smaller molecules. In addition, Brown's structural elucidation of serum albumin,[20,21] suggests that serum albumin binds to drug molecules of the type used in our studies.[17] If this binding is not taken into account in the computer model, then an overestimation of the amount of metal ion mobilized would occur.

A further point to note has been raised by Duffield *et al.*,[22] who showed that the current knowledge concerning the interaction of polyaminopolycarboxylic acids with metal ions, under biological conditions, is imperfect, mainly due to the interaction of the background electrolyte. Since the computer model relies on thermodynamic data any error in this data will affect the accuracy of the model.

Finally, the ECCLES computer model of blood plasma is a model of the complex coordination equilibria occurring in blood plasma. It is possible that metal ions are removed from protein by means other than chelation. The ultrafiltration studies of the NSAIDs and prednisolone, which complex metal ions only weakly, showed that these agents are capable of mobilizing copper(II) and zinc(II) in blood serum. Fiabane and Williams[17] have observed the same phenomenon with aspirin and have postulated that in this case the release of copper(II) from serum albumin is via an allosteric mechanism.

In conclusion, while there are some notable differences between the experimental and calculated results for blood plasma, the computer model is surprisingly good at explaining observed physical phenomena.

(*Received* 20 *June* 1989; *accepted* 7 *September* 1989)

Abstract—The stability constants of copper(II)–cyclopolyphosphate complexes were determined by the spectrophotometric and cation-exchange methods. For cyclohexa- and cyclo-octaphosphate complexes, the stability constants by the above two methods did not agree. The stability constants determined by spectrophotometry were somewhat lower and depended on the wavelength measured. The definition of a constant molar absorption coefficient for the complex formed contains various problems.

Cyclopolyphosphate ions presented as $P_nO_{3n}^{n-}$ are known[1] as very interesting materials which have high negative charges on their relatively compact molecules from the viewpoint of electrolyte solution chemistry.

We have been investigating various properties of these phosphates and have reported some results about the interactions between the phosphate anions and various cations by various methods.[2–6] In our previous paper,[5] we determined the stability constants of the cyclopolyphosphate complexes with cerium(III) ion by both ion-exchange and spectrophotometric methods. The two methods gave different stability constants for the same complex. The difference between the stability constants for the cyclohexa- and cyclo-octaphosphate complexes were remarkable. The stability constants determined by the spectrophotometric method were lower for all cases. A satisfactory explanation of the above experimental results has not yet been obtained.

In this paper, complex formation between copper(II) ion and cyclopolyphosphate ions was investigated by cation-exchange and spectrophotometric methods. The stability constants of the copper(II)–cyclopolyphosphate ion complexes have already been determined by the potentiometric method using an ion-selective electrode.[6] We have compared the stability constants determined by the three different methods for the same complexes and have discussed the observed difference.

For the copper(II)–cyclotri- and cyclotetraphosphate complexes, the stability constants determined by the three methods agreed well with each other. For the copper(II)–cyclohexa- and cyclo-octaphosphate complexes, the coincidence between the values obtained by the potentiometric and cation-exchange methods was satisfactory. However, the stability constants determined by the spectrophotometric method depended on the wavelength at which the stability was determined. Even the highest value obtained at 230 nm was somewhat lower than those determined by cation-exchange or potentiometric method. We do not know the details of the wavelength dependence of the stability constants by spectrophotometry, however, the origin of the difficulty is supposed to arise from the assumption that the various types of complexes (e.g. inner- and outer-sphere types) formed have an identical molar absorption coefficient.

* Author to whom correspondence should be addressed.

The stability constants obtained by both cation-exchange and potentiometric methods for the copper(II)–cyclopolyphosphate complexes increase linearly with the anion charge.[6] We have concluded that complex formation is due to the electrostatic force between the copper(II) ion and cyclopolyphosphate anion. The light absorption of the complex in the UV might be considered to be due to the charge-transfer. The wavelengths of maximal absorption are shifted to longer ones as the anionic charge on the ligands increases.

In this paper the cyclopolyphosphates are abbreviated as P_{nm}, where n is the polymerization degree.

EXPERIMENTAL

The absorption spectra and quantitative absorbance were measured at about 25°C with a Hitachi-228A spectrophotometer by the use of 1 cm quartz cells. The distribution ratio of the copper(II) ion on the cation-exchanger was determined by measuring the copper concentration with a Hitachi 180-80 atomic absorption spectrophotometer. Copper(II) perchlorate as a copper(II) source was prepared from copper(II) carbonate hydroxide and perchloric acid. The standard solution of copper(II) was determined by complexometric titration with EDTA. Sodium cyclopolyphosphates were prepared by the usual methods and their purity was checked by liquid chromatography.[7] As a supporting electrolyte to keep the ionic strength constant in each experiment, sodium perchlorate was used. As a cation-exchange resin, BIO-RAD AG 50W X-8, 100–200 mesh was used. The other chemicals used in this study were reagent grade and commercially available. The distribution ratio of copper(II) between the resin and solution phase was measured by the usual batch equilibrium method.

RESULTS AND DISCUSSION

The stability constants of copper(II)–cyclopolyphosphate complexes can be estimated from the distribution ratio of copper(II) between the cation-exchange resin and solution phase[8] which contained copper(II) ion and excess ligands. Under these conditions, the possibility of more than two copper(II) ions combining with one ligand ion can be ignored, while that of more than two ligand anions binding to one copper(II) ion must be considered. However, the possibility of the formation of higher complexes in which more than three ligands bind seemed to be low since the anionic complex must bind to the multi-valent anionic ligand. Therefore the formation of 1:1 and 1:2 (copper(II)–cyclopolyphosphate ratio) complexes was considered.

Since the complexes thus formed which have an anionic charge are not absorbed on the cation-exchanger, the distribution ratio, D, of copper(II) on the cation-exchange resin can be presented as

$$D = \frac{[Cu^{2+}]_r}{[Cu^{2+}]+[CuP]+[CuP_2]}, \quad (1)$$

where $[Cu^{2+}]_r$ is the concentration of the copper(II) ion in the exchanger phase and $[Cu^{2+}]$, [CuP] and $[CuP_2]$ denote the concentration of the free copper(II) ion, the 1:1 complex and the 1:2 complex in the solution phase, respectively. Equation (1) can be rewritten as

$$D = \frac{[Cu^{2+}]_r/[Cu^{2+}]}{1+[CuP]/[Cu^{2+}]+[CuP_2]/[Cu^{2+}]}.$$

This equation is finally presented as

$$\frac{1}{D}\frac{[Cu^{2+}]_r}{[Cu^{2+}]} - 1 = \beta_1[P]+\beta_2[P]^2. \quad (2)$$

The distribution ratio of the free copper(II) ion, $[Cu^{2+}]_r/[Cu^{2+}]$ depends only on the concentration of sodium ion added as the supporting electrolyte, and can be easily determined by the separate experiments. In the equations, the charges of the complexes are omitted and P denotes the cyclopolyphosphate ion.

The stability constants are defined as

$$Cu^{2+} + P \rightleftarrows CuP \quad \beta_1 = \frac{[CuP]}{[Cu^{2+}][P]} \quad (3)$$

$$Cu^{2+} + 2P \rightleftarrows CuP_2 \quad \beta_2 = \frac{[CuP_2]}{[Cu^{2+}][P]^2}. \quad (4)$$

From the variation of the distribution ratio with the quantity of excess ligands added, the stability constants, β_1 and β_2, can be determined by the use of eq. (2). In eq. (2), the concentration of the free ligands, [P], is not known if the stability constants are not found. In this study, as a first approximation, the formation of only 1:1 complex was assumed and the free ligand concentration is equal to the total ligand concentration. Thus, from the linear relation between $1/D([Cu^{2+}]_r/[Cu^{2+}])-1$ and $[P]_t$, the first approximate value of β_1 was obtained. From this stability constant, the approximate value of the free ligand concentration can be calculated. Next, $1/D([Cu^{2+}]_r/[Cu^{2+}])-1$ and [P] thus calculated were newly plotted and a new stability constant was obtained. This procedure was repeated until the true stability constant was obtained. The final plots are shown in Fig. 1. Except for the Cu^{2+}–$P_3O_9^{3-}$ complex, the linear plots of

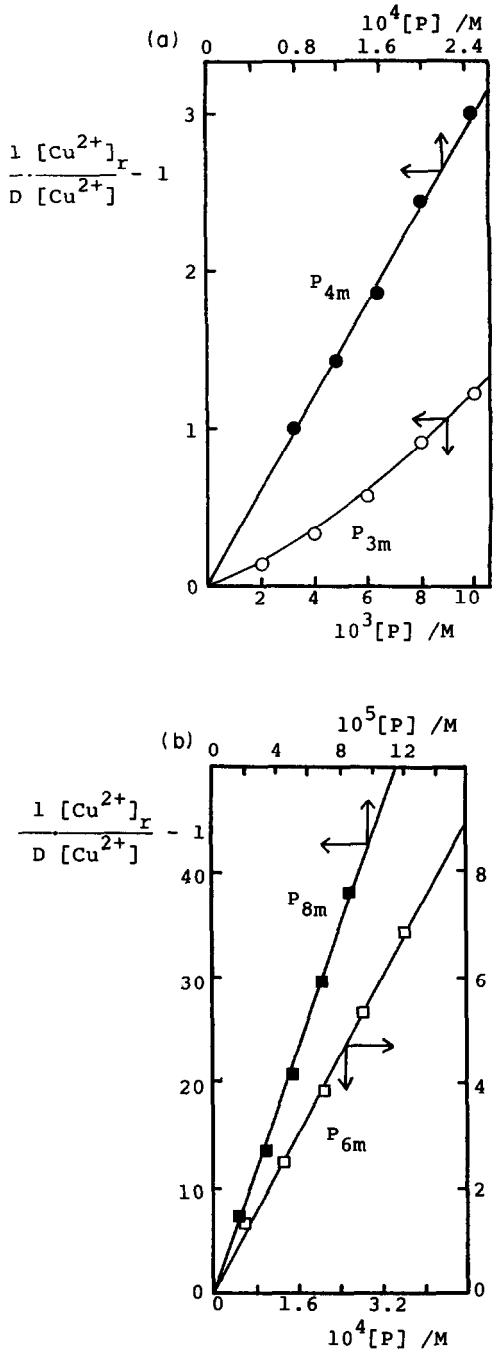

Fig. 1. Determination of the stability constants by the cation-exchange method.

$1/D([Cu^{2+}]_r/[Cu^{2+}])-1$ vs [P] were obtained, and the approximation of the formation of only the 1 : 1 complex is reasonable. For the Cu^{2+}–$P_3O_9^{3-}$ system, a linear relation was not obtained. This suggested the presence of higher complexes in which more than two ligand anions combine with one copper(II) ion. We have assumed formation of the 1 : 1 and 1 : 2 complexes in this case, and β_1 and β_2 are simultaneously determined from the following equation using the successive approximations mentioned above:

$$((1/D)\cdot([Cu^{2+}]_r/[Cu^{2+}])-1)[P] = \beta_1+\beta_2[P]. \quad (5)$$

The stability constants at each ionic strength thus obtained are summarized in Table 1. The reason for the formation of the 1 : 2 complex, $Cu(P_3O_9)_2^{4-}$, only in the case of Cu^{2+}–$P_3O_9^{3-}$ system is speculated as follows. The negative charge of the 1 : 1 complex is low and the electrostatic repulsion between the complex and the secondary ligand to bond is relatively small compared with other cases. Furthermore, steric hindrance between the first ligand and second ligand approaching each other to form a complex is minimal since cyclo-triphosphate is a relatively compact molecule.

It was observed that the UV spectrum of the copper(II) ion was markedly affected by the addition of cyclopolyphosphate anions. The aquo ion of copper(II) also absorbs UV light and a marked increase in absorption occurred by the addition of the ligands. We have estimated the stability constants of the complexes by analysing the increase in absorbance.[9–11] The values of absorbance at 230 nm, measured experimentally, on changing the ligand concentration at a constant copper(II) ion concentration are shown in Table 2. It was assumed that the complex formed has a constant molar absorption coefficient at a measured wavelength. For Cu^{2+}–$P_4O_{12}^{4-}$, Cu^{2+}–$P_6O_{18}^{6-}$, Cu^{2+}–$P_8O_{24}^{8-}$ systems, the formation of only a 1 : 1 complex was reasonably assumed from the results by the cation-exchange method described above. The absorbance (Abs) can be represented as

$$Abs = \varepsilon_0[Cu^{2+}]+\varepsilon_1[CuP], \quad (6)$$

where ε_0 and ε_1 are molar absorption coefficient of free copper(II) ion and the complex, respectively. The stability constant of the 1 : 1 complex is defined as β_1 and the apparent molar absorption coefficient of copper(II) ion, ε_{app}, is written as in eq. (7):

$$\varepsilon_{app} = \frac{Abs}{[Cu^{2+}]_t}, \quad (7)$$

Table 1. Stability constants determined by the cation-exchange method at 25°C; P_{3m}, P_{4m}: $I = 0.3$; P_{6m}, P_{8m}: $I = 0.15$

		$P_{4m'}$ $[Cu^{2+}]_t = 2.1\times10^{-3}$ M, $I = 0.3$					
$[P]_t$/M	0	2×10^{-3}	4×10^{-3}	6×10^{-3}	8×10^{-3}	1.0×10^{-2}	1.4×10^{-2}
Abs.	0.5477	1.2938	1.7052	1.9290	2.0618	2.1480	2.2731
		$P_{6m'}$ $[Cu^{2+}]_t = 5.0\times10^{-4}$ M, $I = 0.15$					
$[P]_t$/M	0	2×10^{-4}	4×10^{-4}	8×10^{-4}	1.2×10^{-3}	1.6×10^{-3}	2.4×10^{-3}
Abs.	0.1348	0.3832	0.5641	0.7210	0.7640	0.7794	0.8037
		$P_{8m'}$ $[Cu^{2+}]_t = 4.0\times10^{-4}$ M, $I = 0.15$					
$[P]_t$/M	0	1×10^{-4}	2×10^{-4}	4×10^{-4}	6×10^{-4}	8×10^{-4}	1.0×10^{-3}
Abs.	0.1041	0.3738	0.6339	1.0795	1.1402	1.1587	1.1591

where $[Cu^{2+}]_t$ is the total concentration of copper(II). Substituting β_1 and ε_{app} in eq. (6) yields the following equation:

$$\frac{[P]}{\varepsilon_{app}-\varepsilon_0} = \frac{[P]}{\varepsilon_1-\varepsilon_0} + \frac{1}{\beta_1(\varepsilon_1-\varepsilon_0)}, \qquad (8)$$

where [P] is the concentration of free ligands which is not known if the stability constants are not determined. Initially, $[P]_t$ was substituted in eq. (8) instead of [P] and plotting $[P]_t/(\varepsilon_{app}-\varepsilon_0)$ vs $[P]_t$ yielded the first approximate values of β_1 and ε_1. Next, from these stability constants, the free ligand concentration was calculated, then $[P]/(\varepsilon_{app}-\varepsilon_0)$ vs [P] was re-plotted and new β_1 and ε_1 values were calculated. The above procedure was successively repeated until constant values of β_1 and ε_1 were obtained. As an example, the final plot of $[P]/(\varepsilon_{app}-\varepsilon_0)$ vs [P] for the Cu^{2+}–$P_4O_{12}^{4-}$ system is shown in Fig. 2. The data follow a good straight line. The stability constants and ε_1 obtained at the wavelengths 230, 240 and 250 nm are shown in Table 3. For the Cu^{2+}–$P_3O_9^{3-}$ system, the above treatment was difficult since the 1:2 complex was evidently formed. Then from the stability constants, β_1 and β_2, determined by the cation-exchange method, the concentrations of CuP, CuP_2 were calculated and using the data in Table 2 and eq. (9), the molar absorption coefficients for the 1:1 and 1:2 complexes, ε_1 and ε_2, were calculated by the least-squares method:

$$\text{Abs} = \varepsilon_0[Cu^{2+}]+\varepsilon_1[CuP]+\varepsilon_2[CuP_2]. \qquad (9)$$

At 230 nm, ε_1 and ε_2 were 523 and 724, respectively.

Except for the Cu^{2+}–$P_3O_9^{3-}$ system in which a 1:2 complex was formed, absorbance at the same wavelength approaches a constant value when excess ligand is added to copper(II) ions. The results for the Cu^{2+}–$P_8O_{24}^{8-}$ system are shown in Fig. 3. This constancy can be explained by the 1:1 complex formation of all the copper(II) ions in the solution.

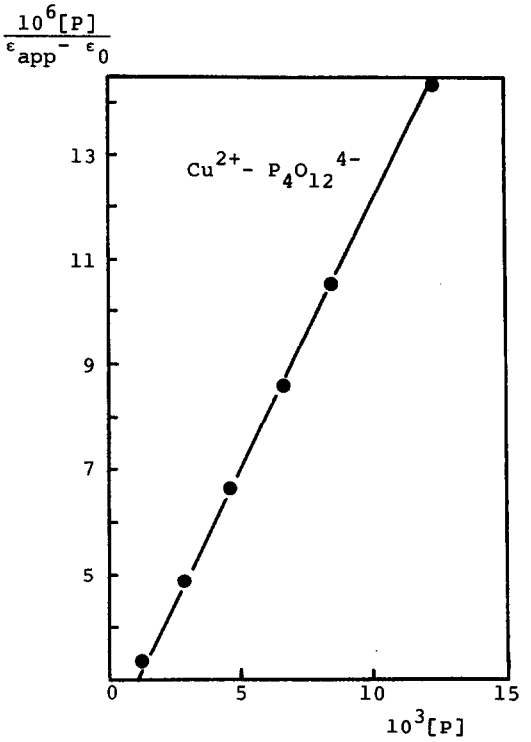

Fig. 2. Spectrophotometric determination of the stability constant for the Cu^{2+}–$P_4O_{12}^{4-}$ system.

Table 3. Stability constants and molar absorption coefficients at 230, 240 and 250 nm

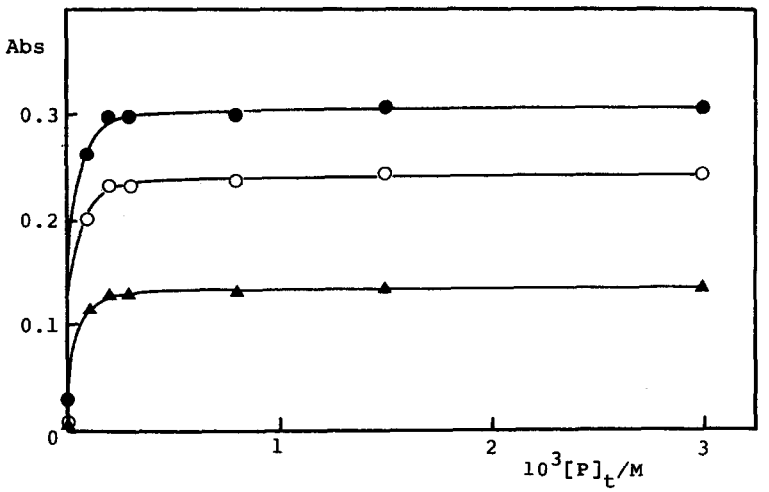

Fig. 3. Absorbance for the Cu^{2+}–$P_8O_{24}^{8-}$ system as a function of total ligand concentration at constant $[Cu^{2+}]_t$. ▲, 250 nm; ○, 240 nm; ●, 230 nm.

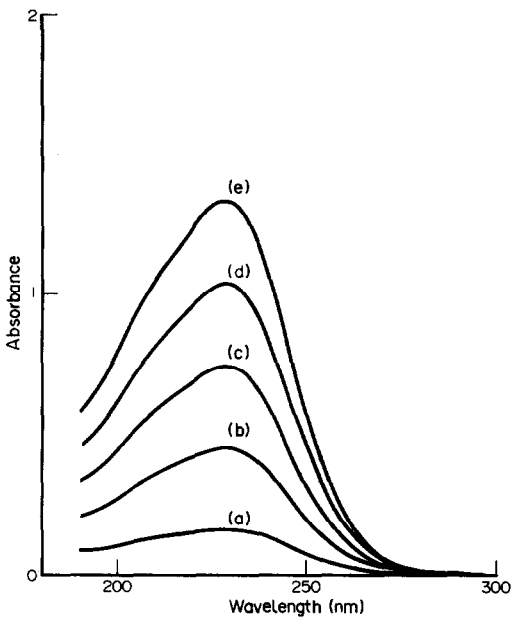

Fig. 4. Absorption spectra for the $CuP_8O_{24}^{6-}$ complex. $[P]_t = 1 \times 10^{-3}$ M; $[Cu^{2+}]_t$: (a) 5×10^{-5} M; (b) 1.5×10^{-4} M; (c) 2.5×10^{-4} M; (d) 3.5×10^{-4} M; (e) 4.5×10^{-4} M.

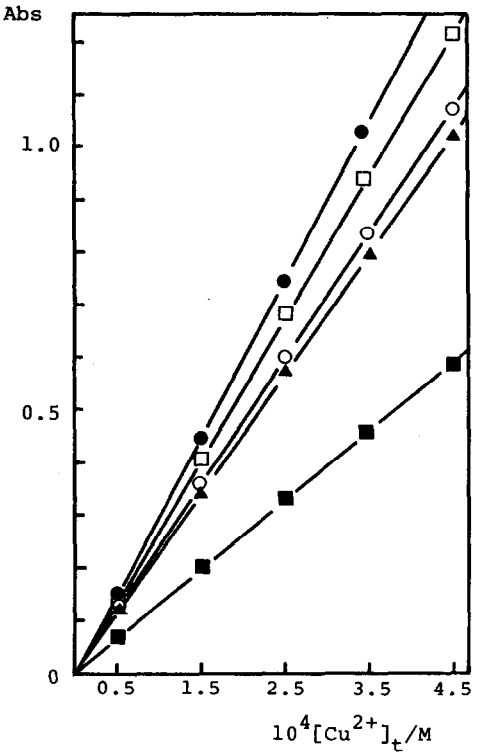

Fig. 5. Variation of absorbance with $[Cu^{2+}]_t$ for the Cu^{2+}–$P_8O_{24}^{8-}$ system with excess ligand. ■, 250 nm; ▲, 240 nm; ○, 230 nm; □, 220 nm; ●, 210 nm.

The absorption spectra for the Cu^{2+}–$P_8O_{24}^{8-}$ system shown in Fig. 4, where the concentration of copper(II) ion was varied in the presence of excess and constant ligand anions. These spectra contain only the 1:1 complex. At wavelengths from 210 to 250 nm, the relationship between absorbance and total copper(II) ion concentration is shown in Fig. 5 for the Cu^{2+}–$P_8O_{24}^{8-}$ system. At all the wavelengths, good straight lines through the origin were obtained. The slope of the line is expected to be identical to the molar absorption coefficient, ε_1, of the $CuP_8O_{24}^{6-}$ complex. The ε_1 value from the slope at 230 nm was 2940 and is consistent with that obtained by the equilibrium method using eq. (8). The ε_1 values for the $CuP_4O_{12}^{2-}$ and $CuP_6O_{18}^{4-}$ complexes, determined by the above same method, agreed with the respective values in Table 3.

For the Cu^{2+}–$P_3O_9^{3-}$ system, a linear relation-

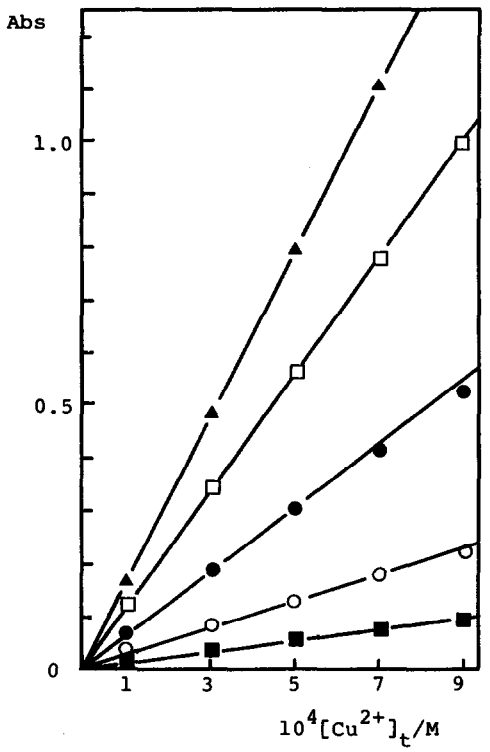

Fig. 6. Variation of absorbance with $[Cu^{2+}]_t$ for the Cu^{2+}–$P_3O_9^{3-}$ system with excess ligand. ■, 250 nm; ○, 240 nm; ●, 230 nm; □, 220 nm; ▲, 210 nm.

ship, as shown in Fig. 6, was observed when the copper(II) ion concentration was varied in the presence of excess ligand. Since both $CuP_3O_9^-$ and $Cu(P_3O_9)_2^{4-}$ form under these conditions, ε_1 and ε_2 could not be directly determined from the slopes. The slopes obtained from the results in Fig. 6 were not in agreement with the ε_1 and ε_2 values calculated by using β_1 and β_2 in the cation-exchange method. For the Cu^{2+}–$P_3O_9^{3-}$ system, the following equations can be derived.

$$\frac{[CuP]}{[Cu^{2+}]} = \beta_1[P]$$

$$\frac{[CuP_2]}{[CuP]} = \frac{\beta_2}{\beta_1}[P]$$

$$[Cu^{2+}]+[CuP]+[CuP_2] = [Cu^{2+}]_t.$$

Substituting the values of $[Cu^{2+}]$, $[CuP]$ and $[CuP_2]$ calculated from the above three equations into eq. (9) yields the following equation:

$$\text{Abs} = \frac{\varepsilon_0+\varepsilon_1\beta_1[P]+\varepsilon_2\beta_2[P]^2}{1+\beta_1[P]+\beta_2[P]^2}[Cu^{2+}]_t. \quad (10)$$

If the ligand added is in large excess compared with the copper(II) ion and the free ligand concentration is assumed to be constant, the absorbance should increase linearly with the total copper(II) ion concentration through the origin. The slope calculated from eq. (10) was 20% lower than that experimentally determined from Fig. 6. This difference may arise from the assumption that the free ligand concentration is constant.

Any differences between the stability constants for the Cu^{2+}–$P_nO_{3n}^{n-}$ complexes determined by the cation-exchange method and potentiometry are not observed. However, the values determined even at 230 nm by the spectrophotometric method in Table 3 are somewhat lower than those by the above two methods. For the previous Ce^{3+}–$P_nO_{3n}^{n-}$ systems, the stability constants obtained by spectrophotometry were lower than those determined by the ion-exchange method. We have no clear explanations about the incomprehensible difference in the stability constants. Perhaps the difference may originate from the assumption that the complex formed has a constant molar absorption coefficient at a constant wavelength. In the case studied here, the formation of various types of complexes, e.g. inner-sphere and outer-sphere complexes, is known. In outer-sphere complexes, a contact ion-pair and solvent separated ion-pairs are included. We must define different molar absorption coefficients for the respective different types of complexes when applying the spectrophotometric method to the analysis of complex formations of systems such as copper(II)–cyclopolyphosphate.

^{29}Si MASNMR INVESTIGATIONS OF THE THERMOCHEMISTRY OF LAPONITE AND HECTORITE

ARVIND-PAL S. MANDAIR, PAUL J. MICHAEL and WILLIAM R. McWHINNIE*

Department of Chemical Engineering and Applied Chemistry, Aston University, Aston Triangle, Birmingham B4 7ET, U.K.

(*Received* 21 *August* 1989; *accepted* 7 *September* 1989)

Abstract—^{29}Si MASNMR spectra were used (together with some ^{23}Na MASNMR spectra and XRD and IR measurements) to monitor the thermolysis of laponite–RD and hectorite. For laponite, even at 400°C, some breakdown of the silicate (Q^3) lattice is observed although this is reversible on rehydration. Lithium ions migrate from trioctahedral positions at 600°C and by 800°C irreversible breakdown to polymorphs of enstatite occurs. At 1300°C *ortho*- and *clino*-enstatite co-exists with a glassy phase. The thermal behaviour of hectorite is broadly similar. ^{23}Na MASNMR spectra reveal that the location of sodium ions in rehydrated specimens, particularly for laponite heated to 400 and 600°C, may be very "solution"-like. The exchange-doping of hectorite with paramagnetic ions such as Cu^{2+}, Ni^{2+}, Mn^{2+} was explored; the loading level beyond which resolution of the silicon spectra is lost was defined in terms of gramme magnetic susceptibilities. The combined use of ^{29}Si MASNMR and ESR to monitor the thermolysis to 1200°C of a sample of hectorite with a Cu^{2+} loading of 10.5 mg g^{-1} clay is illustrated.

Non-invasive resonance spectroscopies are proving powerful techniques for the study of non- or poorly-crystalline materials and also of the reactions that such materials undergo. For example, greater insight into the dehydroxylation of kaolinite has recently been obtained[1,2] by the application of ^{29}Si and ^{27}Al MASNMR spectroscopy. Although, in broad terms the thermal decomposition of kaolinite was well understood from more classical investigations notably those of Brindly and Nakahira,[3,4] the application of the NMR technique has produced a more detailed understanding particularly of the transition to the metakaolinite phase.[2] We have recently demonstrated that ^{57}Fe Mössbauer spectroscopy is also sensitive to the phase changes that accompany the thermal decomposition of clay minerals such as montmorillonite and illite.[5]

Our interest in the thermal decomposition of clay minerals relates to our use of resonance spectroscopies to examine the chemical changes that occur in the formation of ceramic glazes. This objective is more readily accomplished if a reasonable understanding of the thermochemistry of the individual glaze components is available, at least up to the firing temperature of 1300°C. In this paper we turn our attention to two species which are attractive for NMR study due to an extremely low paramagnetic content: the synthetic lithium magnesium clay, laponite, and the naturally occurring counterpart, hectorite (obtained from Hector, California). Our objective was to investigate how accurately the ^{29}Si MASNMR spectra mirror the various stages of thermal decomposition of the clay, and we carried out the NMR studies in parallel with XRD and IR investigations. Further, since both laponite and hectorite have significant ion exchange capacities, the opportunity existed to exchange varying quantities of ESR active ions such as Cu^{2+} onto the clay and thereby (a) explore the influence of the paramagnetic ion on the resolution of the ^{29}Si MASNMR spectra, and (b) attempt to use ESR spectroscopy to obtain information on the fate of the interlamellar ions on decomposition of the clay mineral (we also report preliminary ^{23}Na MASNMR data on laponite).

EXPERIMENTAL

Materials

Laponite–RD was obtained from Laporte Industries Ltd and was in the sodium form. Hectorite was a natural specimen obtained from Hector, California. The ideal composition is $Na_{0.33}[(Mg_{2.67}Li_{0.33})Si_4O_{10}(OH)_2]$, the actual composition determined by XRF analysis is in Table 1. The XRD trace was typical of hectorite with $d(001) = 12.83$ Å, but evidence of a small calcite impurity was seen; this was removed on treatment with dilute acetic acid. Although 0.18% Fe_2O_3 was detected, this did not interfere with the resolution of the ^{29}Si MASNMR spectra.

Methodology

Samples of laponite–RD (5 g) were placed in a porcelain crucible and fired in a carbolite furnace for 3 h at constant temperatures of 200, 400, 600, 800 and 1300°C. Fired samples were removed from the furnace, covered, and cooled overnight in a desiccator. The 200, 400, 600 and 800°C samples were divided into two parts; following grinding one part was retained for analysis and the other was immersed in distilled water for 1 h. Excess water was decanted off and the samples were air-dried for 1 week. The rehydrated samples were then analysed. Samples of hectorite were treated similarly, but no rehydration experiments were attempted.

Samples of hectorite were exchanged with Cu^{2+}, Ni^{2+}, Mn^{2+}, Co^{2+} and Zn^{2+} by treating the clay with solutions of the appropriate metal chloride. The amount of cation taken up by the clay was determined from atomic absorption measurements of cation concentration of the supernatant liquid following exchange. Table 2 lists the cation-exchanged hectorites considered. Each specimen was then heated to 1200°C following the procedure detailed above (1200°C rather than 1300°C was selected in these instances to avoid instances of glass formation).

Physical measurements

MASNMR spectra were obtained with a Bruker AC(E) 300 MHz spectrometer. The "magic angle" was set with KBr and Delrin rotor spinning rates were 5 kHz. Frequencies were 59.580 MHz (^{29}Si) and 79.392 MHz (^{23}Na). Some ^{29}Si MASNMR spectra were obtained at the University of Durham using Varian VH 300 MHz and Bruker CPX 200 spectrometers. (We thank the SERC for time allocation and M. B. Say, Dr D. Apperly and Dr R. Young for their help and hospitality.) ESR spectra were recorded with a JEOL PE-1X spectrometer; g values were recorded using a manganese(II) standard. IR spectra were recorded for KBr discs with a Perkin–Elmer 1710 FTIR instrument. XRD data were obtained with a Philips X-ray diffractometer using Co-K_α radiation with a typical scan speed of 1° 2θ min^{-1}. The d-spacings of the various phases

present were calculated from 2θ values using standard Co-K_α charts.[7]

RESULTS

The ^{29}Si MASNMR parameters for the heated laponite samples (together with data for rehydrated samples) are shown in Table 3. The data are interpreted in terms of the number of SiO_4 tetrahedra linked to a central SiO_4 tetrahedron via bridging oxygen atoms, thus Q^3 denotes an SiO_4 group with one terminal oxygen and three forming common vertices with three other SiO_4 tetrahedra.[8] Some ^{23}Na MASNMR data for dehydrated and rehydrated laponite constitute Table 4. Figure 1 shows a well resolved spectrum of laponite and Fig. 2 shows the changes in spectra that occur on heating laponite. Figure 3 shows the ^{23}Na spectra of the de- and rehydrated samples. Figure 4 illustrates the spectral changes (^{29}Si) which occur on heating hectorite.

Varying quantities of divalent paramagnetic ions were exchanged onto hectorite (Table 2). One objective was to see to what extent the resolution in the ^{29}Si MASNMR spectra would tolerate the paramagnetic presence; Table 5 summarizes our observations. These observations have been quantified by Dr P. A. Gillespie[9] in terms of the simple gramme susceptibility of the specimen, thus:

$\chi_g < 1.4 \times 10^{-6}$ cgs units g^{-1}
—signal always obtained;

χ_g 1.4–2.2×10^{-6} cgs units g^{-1}
—signal may or may not be obtained;

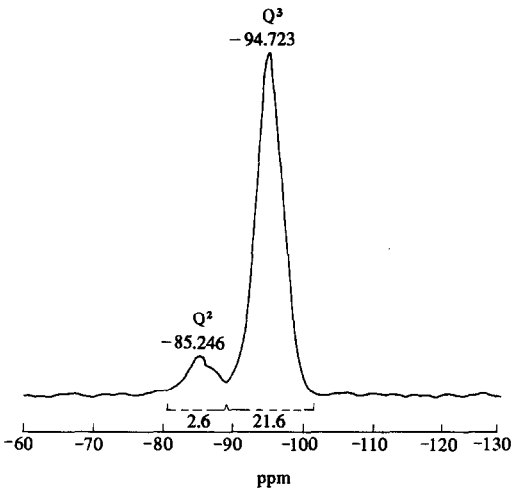

Fig. 1. ^{29}Si MASNMR spectrum of laponite–RD.

$\chi_g > 2.2 \times 10^{-6}$ cgs units g^{-1}
—signal never obtained.

Figure 5 shows the effect of exchanged ions on samples of hectorite heated to 1200°C and Fig. 6 illustrates the ESR spectrum of hectorite with a copper(II) loading of 10.5 mg g^{-1} heated to 1200°C.

DISCUSSION

Laponite–RD

Laponite is a synthetic trioctahedral clay related to the naturally occurring hectorite but free from

the extraneous elements which are normally present in samples of that mineral (see Table 1). The clay used was in the sodium-exchanged form. The ^{29}Si MASNMR spectrum of laponite (Fig. 1) shows two

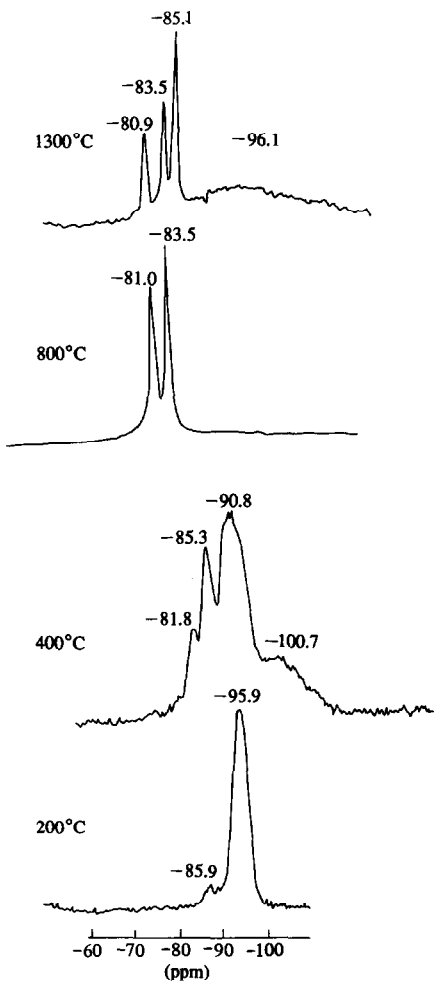

Fig. 2. ^{29}Si MASNMR spectra of laponite–RD heated to the indicated temperatures.

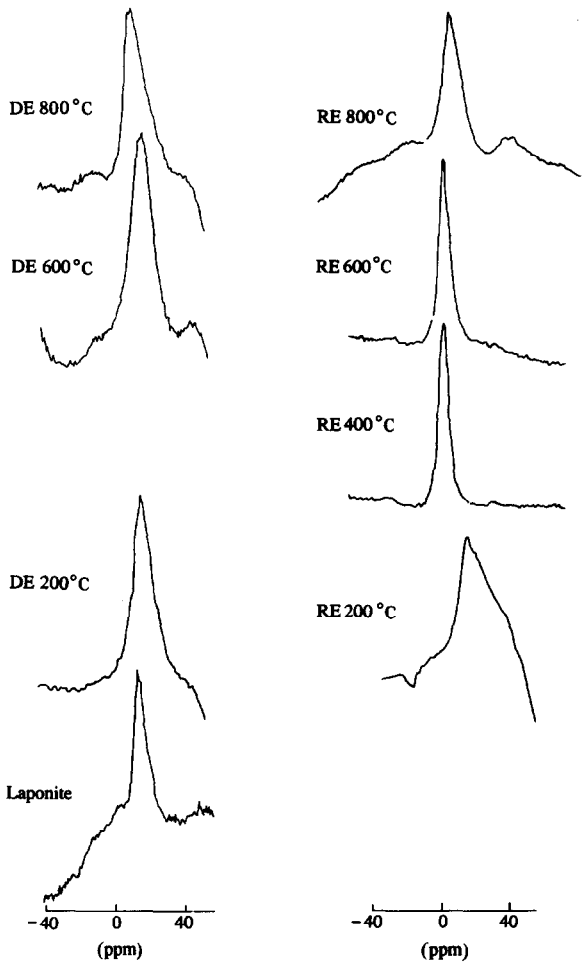

Fig. 3. ^{23}Na MASNMR spectra of dehydrated and rehydrated laponite–RD.

resonances in the intensity ratio 1 : 10. The more intense band at −93.6 ppm arises from Q^3 silicons and may be compared with the resonances reported for hectorite at −95.3 ppm for a sample containing 0.09 aluminium atoms per 10 oxygen atoms,[10] or −94.2 ppm for a sample containing no tetrahedral aluminium, but with a small quantity of Fe^{2+} substituting for Mg^{2+} in the trioctahedral layer.[11] The influence of other ions in the tetrahedral layer (Al) or the octahedral layer (Fe^{2+}) is then to increase the shielding at silicon. In a sense, the parent substance of laponite is talc which shows a Q^3 resonance at −98 ppm; thus the substitution of Mg^{2+} by Li^+ (together with the influence of fluoride) leads to a deshielding of the silicon atoms in the tetrahedral layer. It has been argued[11] that, in trioctahedral minerals, the replacement of one cation with another of lower electronegativity will cause a deshielding of the layer silicon atoms; given that, on the Pauling scale, the electronegativities of magnesium and lithium are 1.2 and 1.0, respectively,

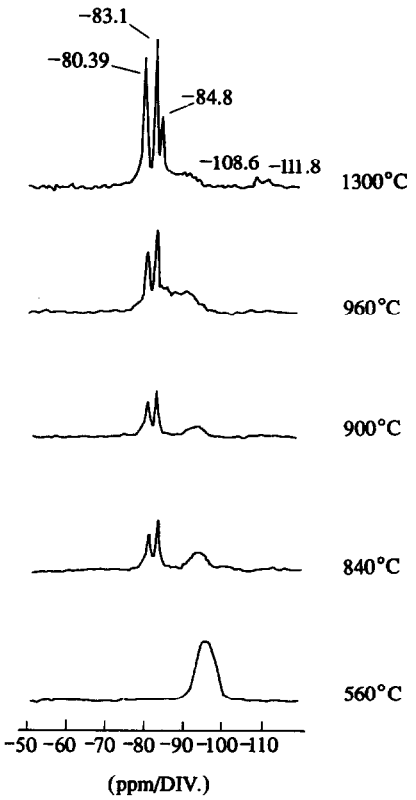

Fig. 4. ^{29}Si MASNMR spectra of hectorite heated to the indicated temperatures.

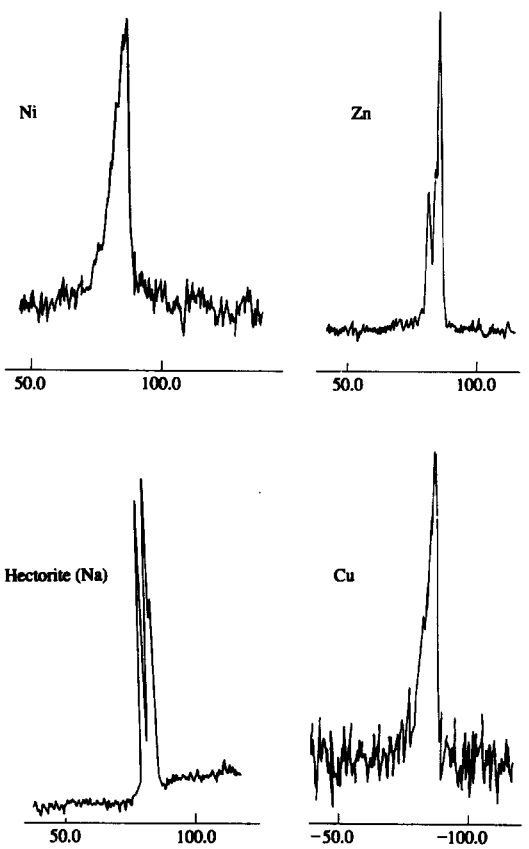

Fig. 5. ^{29}Si MASNMR of ion-exchanged hectorite (Ni^{2+}, Cu^{2+}, Zn^{2+}) heated to 1200°C (see Table 5).

then the observed deshielding from talc to laponite is consistent with that view, i.e. the deshielding can be attributed to slightly more covalent Li—O than Mg—O bonds.

A weak Q^2 resonance is seen at -84.9 ppm and we attribute this to Q^2 sites which must occur at the silicate sheet edges. Indeed, we suggest that an average sheet size can be calculated from the NMR data. If the starting point is a single siloxane ring, $(SiO_3)_6^{12-}$ and other rings are then condensed concentrically, it can be shown that the ratio of edge (Q^2) to sheet (Q^2) silicon sites becomes 1 : 10 when a total of 271 condensed rings are present.

The changes in the ^{29}Si MASNMR spectra which occur on heating the clay to temperatures of 200, 400, 600, 800 and 1300°C are illustrated in Fig. 2 and tabulated in Table 3. XRD data suggest that there is significant loss of crystallinity at 400°C but, by contrast, those samples fired to 800 and 1300°C give evidence of well-developed crystalline phases.

Table 5. Hectorite exchanged with divalent metal ions—some observations on the quality of ^{29}Si MASNMR spectra

Sample (all heated to 1200°C)	χ_g (cgs units $g^{-1} \times 10^6$)	Cation loading (mg g^{-1})	^{29}Si spectrum
Hectorite	—	—	Good[a]
Hectorite/Mn^{2+}	3.209	9.1	No signal
Hectorite/Co^{2+}	1.998	9.7	No signal
Hectorite/Ni^{2+}	—	17.1	Broad[a]
Hectorite/Cu^{2+}	—	19.3	Broad
Hectorite/Cu^{2+}	2.100	11.2	Poor[a]
Hectorite/Zn^{2+}	—	18.7	Good[a]

[a] See Fig. 5 for illustration of the spectra.

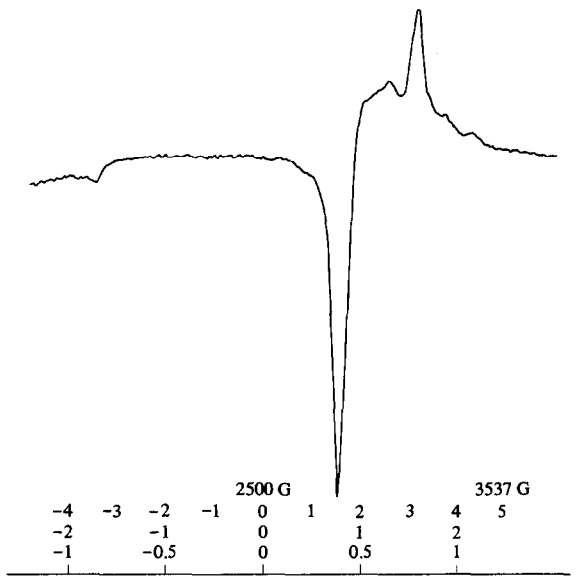

Fig. 6. ESR spectrum of copper(II)-exchanged hectorite (10.5 mg g^{-1}) heated to 1200°C.

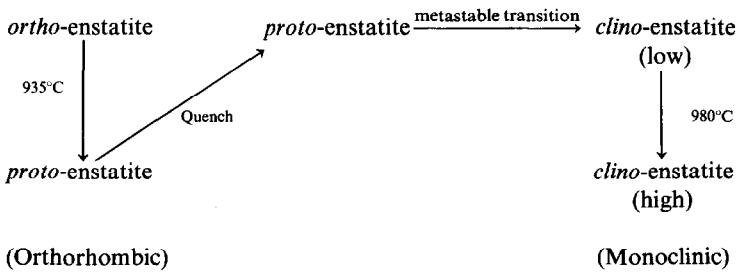
Trioctahedral magnesium-containing minerals are expected to give enstatite ($MgSiO_3$), a pyroxene mineral, on topotactic reaction at 800°C, and indeed clear XRD evidence for this is obtained for laponite heated to this temperature. Enstatite exists in four polymorphic forms, see Scheme 1.[12] The orthorhombic form has two crystallographically distinct silicon sites, the monoclinic form one site. The XRD trace for the sample of laponite fired to 1300°C does in fact contain extra reflections which are consistent with the presence of low *clino*-enstatite, which is quite consistent with Scheme 1.

The IR data provide further confirmation of the formation of enstatite polymorphs at 800 and 1300°C. Thus, for *ortho*-enstatite, diagnostic bands have been reported by Gadsden[13] and Saksena[14] at 1056–1070 cm^{-1}, 1010–1020 cm^{-1} and 928–942 cm^{-1}. We observe bands at 1079 cm^{-1} (s, br), 1012 cm^{-1} and 932 cm^{-1} for the sample fired to 800°C. In addition to those bands, the sample fired to 1300°C also contains bands at 1152 cm^{-1} (sh), 900 cm^{-1} (s), 737, 725 cm^{-1} and 684 cm^{-1} (w). These may be compared with diagnositic bands for *clino*-enstatite:[13,14] 1160 cm^{-1} (sh), 899 (s), 737, 724 cm^{-1} and 683 cm^{-1} (w).

The ^{29}Si MASNMR data may now be discussed. On heating laponite to 200°C the silicon resonances become more negative and line widths increase by 150 Hz. Similar effects have been observed for the onset of dehydroxylation for kaolinite and sepiolite and, in those cases, have been attributed to loss of hydrogen bonding between the basal oxygen atoms and surface hydroxyl groups of the next layer. It is possible to invoke a similar explanation, although in this case the loss of interlayer water would be the critical factor. We attempted to rehydrate the sample (see Experimental and Table 3) and indeed the Q^3 resonance does undergo a positive shift of 1 ppm; however, it does not recover the value for laponite nor does the Q^2 resonance show any sensitivity to the rehydration attempts. The specimen heated to 400°C gives a poor XRD trace indicating loss of crystallinity; this is reflected also in large line widths for the silicon spectra (> 1000 Hz); however, the spectra are well enough resolved to reveal that even at this temperature major structural breakdown is beginning, interestingly, however, this is reversible since rehydration generates a specimen with a ^{29}Si MASNMR spectrum indistinguishable from that of the rehydrated 200°C specimen. Hence the initial stages of the loss of structural water are accompanied by some breakdown of the Q^3 structure. The specimen heated to 600°C is in some respects the most peculiar in the set. The Q^2 resonance was not resolved but a relatively sharp ($\Gamma_{1/2}$ < 50 Hz) Q^3 resonance is seen at −97.7 ppm; rehydration gives a specimen with two Q^2 sites and a Q^3 resonance similar to that for talc. We suggest that the lithium ions have become labile and been removed from their "structural" octahedral sites to edge sites and that this is reflected in the shielding of the silicon Q^3 sites. By 800°C new crystalline phases are present and we assign the −81.4 and 83.5 ppm resonances to orthorhombic *ortho*-enstatite, the two signals arising from the two crys-



Scheme 1.

tallographically distinct silicon sites.[12] The intensity ratio for the two resonances, 2 : 3, is in good agreement with data reported by Lippmaa *et al.*[15] and Oldfield *et al.*[16] Not surprisingly, the spectrum proved insensitive to attempts to rehydrate; the region of irreversible structural breakdown having been reached. Heating laponite to 1300°C gave a specimen in which the presence of *ortho*-enstatite was detected (−80.9, −83.5 ppm), together with a new resonance at −85.1 ppm. We assign this new resonance to *clino*-enstatite, for which good IR and XRD evidence is available. Inspection of Scheme 1 suggests that it arose via *proto*-enstatite which was quenched and then underwent a metastable transition to low *clino*-enstatite.

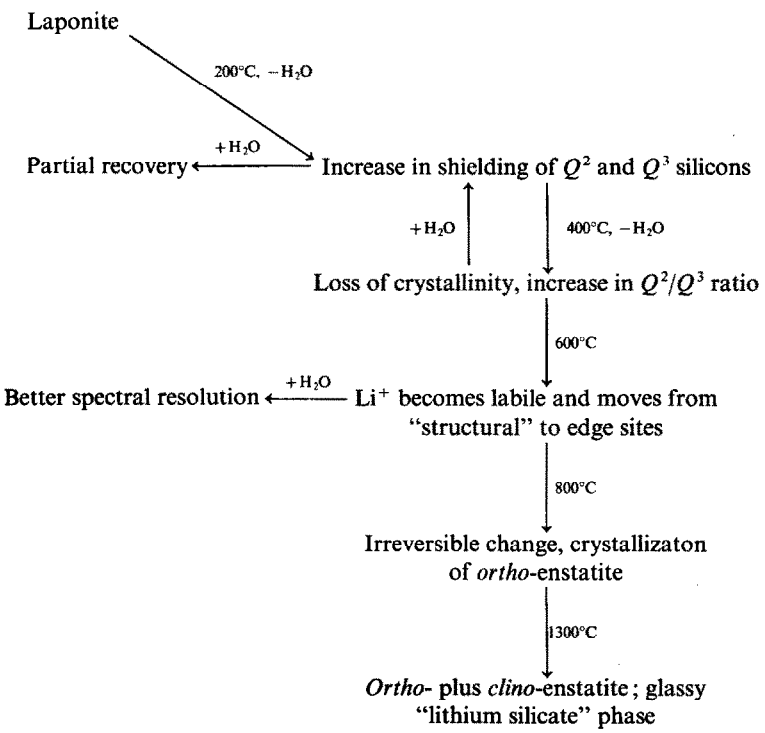
Inspection of Fig. 2 shows that the three well-resolved enstatite resonances are superimposed on a very broad resonance which spans the Q^2, Q^3 and Q^4 regions, and is centred at approximately −96 ppm. We propose that this arises from a glassy phase based on a mixture of lithium and sodium silicates.

The conclusions from XRD, IR and ^{29}Si NMR data are summarized in Scheme 2.

^{23}Na *MASNMR data*

The ^{29}Si NMR data enabled the fate of the silicate network to be monitored as laponite underwent thermal decomposition. We report in this section some preliminary results on attempts to monitor the fate of the exchanged ions, in this instance, sodium. ^{23}Na is a quadrupolar nucleus ($I = 3/2$) with a substantial quadrupole moment. Although magic-angle spinning is expected to average first-order quadrupole effects to zero, this is not true for second-order effects. Inspection of Fig. 3 indicates that the majority of the spectra show clear signs of quadrupole broadening. Thus it must be recognized that the peak maxima in Table 4 (the apparent chemical shifts) are not the isotropic chemical shifts.

Laponite in the sodium form has sodium ions associated with a monolayer of water [$d(001) = 12.5$ Å], thus the ^{23}Na MASNMR spectrum of the clay may be taken as characteristic of the ions in that environment. The changes that occur on heating are such as to increase the second-order quadrupole line broadening thus implying, quite reasonably, that the environment of Na^+ in the dehydroxylated clay is of lower symmetry. It was the rehydrated samples that produced the more interesting results. Even for the 800°C specimen the peak maximum was sensitive to the water treatment but the resonance remained broad. The rehydrated 400 and 600°C specimens gave relatively sharp spectra ($\Gamma_{1/2} \simeq 1$ kHz) and the change in apparent chemical shift is sufficiently great to suggest a real change in shielding. It is, however, the sharpness of the spectra that is the most striking aspect—this, coupled with the more positive centre shift, suggests



Scheme 2.

that the ions might even experience a more "solution"-like environment in which some motional narrowing of the line may be possible; similar phenomena have been observed for a sodium-exchanged Y-zeolite (Si/Al = 2.36).[17] The ^{29}Si studies suggested that, on rehydration, the samples heated to 200°C and 400°C became virtually indistinguishable; however the ^{23}Na MASNMR spectra of the two samples are clearly very different—thus the rehydration mechanism of the 400°C sample which leads to a decrease in the Q^2/Q^3 silicon ratio, leads to a very different solution-type environment for the sodium ions compared to that which these ions experience in the rehydrated 200°C specimen. In the latter specimen, quadrupole effects are greater than for any other spectrum in the series, implying that the sodium ions are constrained to an environment (or environments) of low symmetry with little motional freedom.

In one sense this preliminary ^{23}Na NMR study has raised more questions than it has answered. It has, however, highlighted the necessity to consider the fate of the exchanged ions as well as the structural ions if a complete picture of the thermal behaviour of clay minerals is to emerge. We address this question again in the following section.

Hectorite

Some ^{29}Si MASNMR spectra illustrating the changes which occur on heating a natural sample of hectorite (Table 1) are shown in Fig. 4. It is clear that very similar behaviour to that discussed in detail for laponite is observed, although there are some differences worthy of comment. The breakdown of the Q^3 lattice occurs at a higher temperature for hectorite, e.g. compare the 400°C spectrum for laponite in Fig. 2 with the 580°C spectrum for hectorite in Fig. 4. At 1300°C, the *clino*-enstatite phase is less prominent than is the case for laponite (however, that may be a function of the extraneous ions in hectorite, *vide infra*); also the glassy phase is less obvious, indeed there is evidence of the presence of two Q^4 crystalline phases. The resonance at −108.6 ppm may be assigned to cristobalite,[18,19] an expected product. The assignment of the −111.8 ppm resonance is less obvious, but tentatively β_2 tridymite is proposed.[19]

Partially ion-exchanged hectorites

It is clear from the above sections that a complete picture of the thermolysis of smectite clays will only emerge if the fate of exchanged as well as of structural ions can be monitored. A possible experimental approach is to exchange the clay either completely or partially with an ion which may be suitable for study by either NMR (e.g. ^{23}Na) or another resonance spectroscopy such as Mössbauer[20] or ESR. In this work we opted for ESR spectroscopy, but first addressed the question as to what paramagnetic loading of hectorite would be possible before resolution of the ^{29}Si MASNMR spectra was totally lost. The data in Tables 3 and 5 summarize the experiments and observations and, with the assistance of Dr P. A. Gillespie of the University of Durham, it was found that the data could be best quantified in terms of the gramme susceptibility of the specimen (see Results). Provided, therefore, that the constraints on the value of χ_g were observed, it was possible to obtain both ^{29}Si MASNMR data and copper(II) ESR data on the same sample. Thus the ^{29}Si NMR spectrum of the Cu^{2+}-exchanged hectorite heated to 1200°C, illustrated in Fig. 5, is the same specimen for which the ESR spectrum is given in Fig. 6.

XRD examination of the partially-exchanged hectorites heated to 1200°C does *not* reveal new phases which are directly attributable to the dipositive ions, thus it is likely that the ion isomorphically substitutes, probably for magnesium, in existing silicate phases. It would appear that the presence of these ions increases the proportion of *clino*-enstatite in the fired product as shown in Fig. 5 where, even for the Cu^{2+}- and Ni^{2+}-exchanged specimens, the resolution of the −84.8 ppm resonance is sufficiently good to illustrate this point.

The ESR spectrum of the partially exchanged Cu^{2+}–hectorite is typical of copper(II) in a rhombic environment;[21] g values are 2.005 (A = 154 Hz), 2.197 and 2.335. The observation of the lowest g value close to the free electron value is indicative of a d_{z^2} ground state for the copper(II) ion which, in the present case, could arise from a rhombic distortion superimposed on a compressed tetragonal environment. This observation is consistent with copper(II) being located in the enstatite structure.

CONCLUSIONS

The paper illustrates the value of solid-state NMR spectroscopy for following the thermolysis of mineral species. Not only can the fate of the silicate network be determined, but information on the behaviour of the interlayer ions may also be obtained as illustrated by a recent study of Na^+ and Li^+ montmorillonites;[22] of particular interest are the results of our rehydration experiments which indicate that the environment of the interlayer cation following rehydration may be very different to that prior to water loss.

(*Received* 22 *August* 1989 ; *accepted* 7 *September* 1989)

Abstract—The complexes [Mo(NO)LCl(NHC$_6$H$_4$-3-Z)] (L = HB(3,5-Me$_2$C$_3$N$_2$H)$_3$; Z = F, Cl, Br, Me, OMe, CF$_3$, NO$_2$), [W(NO)L(NHC$_6$H$_4$-3-Z)] (Z = F, Cl, Br, Me, OMe, COMe, CF$_3$, NO$_2$) and [W(NO)L(NHC$_6$H$_4$-3-CF$_3$)$_2$] have been synthesized and characterized by spectroscopic methods. All of the monoarylamide complexes undergo one-electron reduction processes at potentials which vary according to the nature of Z. A linear correlation was found between the reduction potentials within each of the two series and the Hammett *meta* substituent parameters, σ_m, for Z. The respective reaction constants, ρ_m, and intercepts, E_f^0, are for [Mo(NO)LCl(NHC$_6$H$_4$-3-Z)], ρ_m = 5.50 (0.39), E_f^0 = −0.848 (0.009) V and for [W(NO)L(NHC$_6$H$_4$-3-Z)], ρ_m = 4.75 (0.50), E_f^0 = −1.291 (0.011) V.

An extensive chemistry has been developed for complexes containing the {M(NO)L}$^{2+}$ (M = Mo or W, L = hydrotris(3,5-dimethylpyrazol-1-yl)borate) moiety[1] in which a formally 16-electron metal centre is present. A wide variety of monometallic derivatives of general formula [M(NO)LXY] (M = Mo and X = Cl, I or Y; M = W and X = Cl or Y; Y = aryloxide, thiophenoxide or arylamide) has been prepared. These species are all redox active undergoing a one-electron reduction process at potentials which are strongly dependent upon the nature of M, X and Y.[2] EPR measurements on the molybdenum complexes indicate that the electron is largely localized in a metal-centred orbital in the reduced species.[3,4] The {Mo(NO)L}$^{2+}$ redox centre has now been incorporated into a variety of larger molecules which are of considerable current interest because of their novel physical properties. Thus homobimetallic species, in which the two metal centres may be present in different oxidation states, have been prepared.[5–8] The extent of interaction between the two metal centres has been shown by electrochemical studies to be highly sensitive to the nature of the bridging ligand linking the metal centres. Redox responsive compounds containing the {Mo(NO)L} centre incorporated into a cyclic polyether have been synthesized and the reduction potentials of these species have been shown to respond to the binding of cationic substrates.[9,10] More recently, the {Mo(NO)L} moiety has been attached as a peripheral substituent in tetraphenylporphyrin derivatives. The presence of the redox centre causes fluorescence quenching of the porphyrin.[11] Finally, materials which exhibit substantial second-order non-linear optical properties have been obtained by linking {Mo(NO)LCl} to a ferrocenyl substituent via a polarizable diazadiaryl bridge.[12]

Electrochemical measurements are often useful in providing a more quantitative basis for understanding the properties of the new materials described above. In order to more fully interpret the results of such electrochemical studies, it is necessary to define the way in which the reduction potential of the metal-based redox centre changes with variations in ligand substituents. The sen-

sitivity of transition metal redox centres to variations in ligand substituents is now well established in a number of examples,[13–16] including metallocene derivatives,[17,18] metal isonitrile derivatives[19–21] and substituted aryldiazenido complexes of molybdenum.[22] We have previously established that a linear correlation exists between the reduction potentials of [M(NO)LX(NHC$_6$H$_4$-4-Z)] [M = Mo and X = I or Cl; M = W and X = Cl) and the Hammett substituent parameters, σ_p, for the substituent Z.[23] We now report the results of a similar study of [M(NO)LCl(NHC$_6$H$_4$-3-Z)] involving *meta*-substituted arylamide ligands.

EXPERIMENTAL

All reagents were used as supplied. [Mo(NO){HB(3,5-Me$_2$C$_3$N$_2$H)$_3$}Cl$_2$] and [W(NO){HB(3,5-Me$_2$C$_3$N$_2$H)$_3$}Cl$_2$] were prepared according to previously described methods.[24] Solvents used as reaction media were dried according to standard methods and freed of oxygen before use. All reactions were carried out under nitrogen but purification procedures were carried out in air. Activated alumina UGI (100 mesh) or silica gel 60 (70–230 mesh) were used as the stationary phase for column chromatography. Elemental analyses were carried out by the Microanalytical Laboratory, University of Birmingham.

IR spectra were recorded using a PE 297 spectrometer with samples as KBr discs. 270 MHz ^{1}H NMR spectra were obtained from solutions in $CDCl_3$ using a Jeol GX 270 spectrometer. Mass spectra were recorded using a Kratos MS80 spectrometer and cyclic voltammetric measurements were made using a PAR 174A polarograph. Solutions in MeCN were *ca* 10^{-3} mol dm^{-3} in complex and 0.2 mol dm^{-3} in [Bu^{n}N]BF$_4$ as base electrolyte. A Pt bead test electrode was used with an SCE reference electrode. Potentials are quoted relative to the SCE and under these conditions E_f for the oxidation of ferrocene was found to be 0.42 V with ΔE_p in the range 60–120 mV. No compensation for internal cell resistance was made.

[Mo(NO){HB(3,5-Me$_2$C$_3$N$_2$H)$_3$}Cl(NHC$_6$H$_4$-3-F)]

A mixture of [Mo(NO){HB(3,5-Me$_2$C$_3$N$_2$H)$_3$}Cl$_2$] (0.5 g, 1.0 mmol) and 3-fluoroaniline (0.24 g, 2.2 mmol) in dichloromethane (50 cm^3) was stirred at room temperature for 6 days. After this time the mixture was filtered and the solvent removed from the filtrate under reduced pressure. The resulting dark brown solid was purified by column chromatography on alumina using 3:7 *n*-hexane–dichloromethane as the eluant and collecting the major dark brown fraction. Further purification of this material could be effected by recrystallization from dichloromethane–hexane mixtures to give the black crystalline product (0.23 g, 41%). Found: C, 41.6; H, 4.5; N, 18.2. $C_{21}H_{27}N_8BOFClMo \cdot 0.5\ CH_2Cl_2$ requires: C, 42.2; H, 4.6; N, 18.3%.

Spectroscopic data. ^{1}H NMR (δ_{TMS} ppm):* amide NH 12.44 (1 b); aryl protons 7.35 (1 m), 7.22 (2 m), 6.89 (1 m); CH_2Cl_2 5.25 (1 s); pyrazolyl-4-H 5.87 (2 s), 5.81 (1 s); pyrazolyl-3- and 5-Me 2.67 (3 s), 2.42 (3 s), 2.38 (3 s), 2.37 (6 s), 2.03 (3 s). IR: ν_{NO} = 1655, ν_{NH} = 3300 cm^{-1}. *Mass spectra*: m/z = 570, 540, 444. *Electrochemical data*:† E_f = −0.735 V, ΔE_p = 90 mV.

[Mo(NO){HB(3,5-Me$_2$C$_3$N$_2$H)$_3$}Cl(NHC$_6$H$_4$-3-Cl)]

This compound was prepared according to the procedure for [Mo(NO){HB(3,5-Me$_2$C$_3$N$_2$H)$_3$}Cl(NHC$_6$H$_4$-3-F)] using 3-chloroaniline (0.27 g, 2.1 mmol) in place of 3-fluoroaniline and a reaction time of 3 days. Chromatography on alumina was carried out using dichloromethane as the eluant. A brown product was obtained (0.21 g, 37%). Found: C, 43.0; H, 4.6; N, 19.0. $C_{21}H_{27}N_8BOCl_2Mo$ requires: C, 43.1; H, 4.6; N, 19.2%.

Spectroscopic data. ^{1}H NMR (δ_{TMS} ppm): amide NH 12.38 (1 b); aryl protons 7.46 (1 d, $^3J_{HH}$ = 9 Hz), 7.39 (1 s), 7.36 (1 dd, $^3J_{HH}$ = 8 and 9 Hz), 7.15 (1 d, $^3J_{HH}$ = 8 Hz); pyrazolyl-4-H 5.87 (2 s), 5.81 (1 s); pyrazolyl-3- and 5-Me 2.67 (3 s), 2.42 (3 s), 2.38 (3 s), 2.37 (6 s), 2.02 (3 s). IR: ν_{NO} = 1660, ν_{NH} = 3240 cm^{-1}. *Mass spectra*: m/z = 586, 556, 460. *Electrochemical data*: E_f = −0.720 V, ΔE_p = 140 mV.

[Mo(NO){HB(3,5-Me$_2$C$_3$N$_2$H)$_3$}Cl(NHC$_6$H$_4$-3-Br)]

This compound was prepared according to the procedure for [Mo(NO){HB(3,5-Me$_2$C$_3$N$_2$H)$_3$}Cl(NHC$_6$H$_4$-3-F)] using 3-bromoaniline (0.35 g, 2.0 mmol) in place of 3-fluoroaniline. Chromatography on alumina was carried out using dichloromethane as the eluant. A dark brown product was obtained (0.21 g, 37%). Found: C, 39.9; H, 4.6; N, 17.5.

* Relative area and multiplicity given in parentheses; s = singlet, d = doublet, t = triplet, m = multiplet with couplings not fully resolved, b = broad.

† Electrochemical data, E_f = formal electrode potential for reduction, ΔE_p = separation between cathodic and anodic peak potentials of cyclic voltammogram.

$C_{21}H_{27}N_8BOClBrMo$ requires: C, 40.1; H, 4.3; N, 17.8%.

Spectroscopic data. ^{1}H NMR (δ_{TMS} ppm): amide NH 12.36 (1 b); aryl protons 7.52 (2 m), 7.30 (2 m); pyrazolyl-4-H 5.87 (2 s), 5.81 (1 s); pyrazolyl-3- and 5-Me 2.67 (3 s), 2.42 (3 s), 2.38 (3 s), 2.36 (6 s), 2.02 (3 s). IR: ν_{NO} = 1655, ν_{NH} = 3245 cm^{-1}. *Mass spectra*: *m/z* = 630, 600, 504. *Electrochemical data*: E_f = −0.710 V, ΔE_p = 80 mV.

[Mo(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl(NHC_6H_4-3-Me)]

This compound was prepared according to the procedure for [Mo(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl(NHC_6H_4-3-F)] using 3-methylaniline (0.23 g, 2.1 mmol) in place of 3-fluoroaniline and a reaction time of 2 days. A dark brown product was obtained (0.52 g, 91%). Found: C, 47.1; H, 5.4; N, 20.6. $C_{22}H_{30}N_8BOClMo$ requires: C, 46.8; H, 5.3; N, 19.8%.

Spectroscopic data. ^{1}H NMR (δ_{TMS} ppm): amide NH 12.69 (1 b); aryl protons 7.33 (1 s), 7.26 (2 m), 7.00 (1 d, $^3J_{HH}$ = 7 Hz); pyrazolyl-4-H 5.87 (2 s), 5.79 (1 s); pyrazolyl-3- and 5-Me 2.69 (3 s), 2.42 (3 s), 2.38 (3 s), 2.37 (6 s), 2.01 (3 s), aryl Me 2.41 (3 s). IR: ν_{NO} = 1650, ν_{NH} = 3270 cm^{-1}. *Mass spectra*: *m/z* = 566, 536, 440. *Electrochemical data*: E_f = −0.875 V, ΔE_p = 60 mV.

[Mo(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl(NHC_6H_4-3-OMe)]

This compound was prepared according to the procedure for [Mo(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl(NHC_6H_4-3-F)] using 3-methoxyaniline (0.26 g, 2.1 mmol) in place of 3-fluoroaniline and a reaction time of 4 days. Chromatography on alumina was carried out using 2:8 *n*-hexane–dichloromethane as the eluant. A red–brown product was obtained (0.25 g, 43%). Found: C, 45.4; H, 5.4; N, 19.2. $C_{22}H_{30}N_8BO_2ClMo$ requires: C, 45.5; H, 5.2; N, 19.3%.

Spectroscopic data. ^{1}H NMR (δ_{TMS} ppm): amide NH 12.64 (1 b); aryl protons 7.33 (1 s), 7.25 (1 m), 6.77 (2 m); pyrazolyl-4-H 5.88 (1 s), 5.87 (1 s), 5.79 (1 s); aryl OMe 3.94 (3 s); pyrazolyl-3- and 5-Me protons 2.69 (3 s), 2.42 (3 s), 2.39 (3 s), 2.38 (3 s), 2.37 (3 s), 2.02 (3 s). IR: ν_{NO} = 1640, ν_{NH} = 3240 cm^{-1}. *Mass spectra*: *m/z* = 582, 552, 456. *Electrochemical data*: E_f = −0.825 V, ΔE_p = 70 mV.

[Mo(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl(NHC_6H_4-3-CF_3)]

This compound was prepared according to the procedure for [Mo(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl(NHC_6H_4-3-F)] using 3-(trifluoromethyl)aniline (0.34 g, 2.1 mmol) in place of 3-fluoroaniline and a reaction time of 4 days. Chromatography on alumina was carried out using 2:8 *n*-hexane–dichloromethane as the eluant. A brown product was obtained (0.16 g, 27%). Found: C, 42.6; H, 4.6; N, 18.2. $C_{22}H_{27}N_8BOF_3ClMo$ requires: C, 42.7; H, 4.4; N, 18.1%.

Spectroscopic data. ^{1}H NMR (δ_{TMS} ppm): amide NH 12.43 (1 b); aryl protons 7.85 (1 d $^3J_{HH}$ = 8 Hz), 7.57 (1 t $^3J_{HH}$ = 8 Hz), 7.50 (1 s), 7.43 (1 d $^3J_{HH}$ = 8 Hz); pyrazolyl-4-H 5.88 (2 s), 5.82 (1 s); pyrazolyl-3- and 5-Me 2.67 (3 s), 2.42 (3 s), 2.38 (3 s), 2.37 (6 s), 1.98 (3 s). IR: ν_{NO} = 1650, ν_{NH} = 3245, ν_{CF} = 1120 cm^{-1}. *Mass spectra*: *m/z* = 620, 590, 494. *Electrochemical data*: E_f = −0.710 V, ΔE_p = 140 mV.

[Mo(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl(NHC_6H_4-3-NO_2)]

This compound was prepared according to the procedure for [Mo(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl(NHC_6H_4-3-F)] using 3-nitroaniline (0.27 g, 2.1 mmol) in place of 3-fluoroaniline and a reaction time of 8 days under reflux. Chromatography on silica gel was carried out using 3:7 *n*-hexane–dichloromethane as the eluant. A green product was obtained (0.29 g, 48%). Found: C, 42.5; H, 4.5; N, 20.7. $C_{21}H_{27}N_9BO_3ClMo$ requires: C, 42.3; H, 4.6; N, 21.2%.

Spectroscopic data. ^{1}H NMR (δ_{TMS} ppm): amide NH 12.26 (1 b); aryl protons 8.05 (3 m), 7.63 (1 t $^3J_{HH}$ = 8 Hz); pyrazolyl-4-H 5.89 (2 s), 5.81 (1 s); pyrazolyl-3- and 5-Me protons 2.69 (3 s), 2.43 (3 s), 2.40 (3 s), 2.38 (3 s), 2.37 (6 s), 1.99 (3 s). IR: ν_{NO} = 1665, ν_{NH} = 3280, ν_{NO_2} = 1.540 cm^{-1}. *Mass spectra*: *m/z* = 597, 567, 471. *Electrochemical data*: E_f = −0.620 V, ΔE_p = 80 mV.

[W(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl(NHC_6H_4-3-F)]

A mixture of [W(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl_2] (0.29 g, 0.5 mmol) and 3-fluoroaniline (0.15 cm^3, 1.6 mmol) was stirred under reflux in toluene (50 cm^3) for 24 h. The reaction mixture was cooled and filtered and the filtrate evaporated to dryness under reduced pressure. The resulting brown solid was redissolved in the minimum of dichloromethane and the product slowly precipitated by dropwise addition of *n*-hexane to the solution. The brown crystalline solid produced was collected by filtration, washed with a little *n*-pentane and dried *in vacuo* (0.13 g, 40%). Found: C, 36.3; H, 4.1; N, 15.8. $C_{21}H_{27}N_9BOFClW \cdot 0.5\ CH_2Cl_2$ requires: C, 36.9; H, 4.0; N, 16.0%.

Spectroscopic data. ^{1}H NMR (δ_{TMS} ppm): amide NH 10.59 (1 b); aryl protons 7.33 (1 m), 7.14 (2 m), 6.77 (1 m, $^3J_{HH}$ = 8 Hz); pyrazolyl-4-H 5.94 (1 s), 5.88 (1 s), 5.84 (1 s); CH_2Cl_2 5.25 (1 s); pyrazolyl-3- and 5-Me 2.71 (3 s), 2.44 (3 s), 2.42 (3 s), 2.37 (3 s), 2.36 (3 s), 2.15 (3 s). IR: ν_{NO} = 1625, ν_{NH} = 3310 cm^{-1}. *Mass spectra*: *m/z* = 656, 572, 542. *Electrochemical data*: E_f = −1.185 V, ΔE_p = 75 mV.

[W(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl(NHC$_6H_4$-3-Cl)]

A mixture of [W(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl_2] (0.58 g, 1.0 mmol) and 3-chloroaniline (0.30 cm^3, 2.8 mmol) was stirred under reflux in toluene (75 cm^3) for 24 h. The reaction mixture was cooled and filtered and the filtrate evaporated to dryness under reduced pressure. The resulting brown solid was purified by column chromatography on silica gel using 1 : 1 dichloromethane–hexane as the eluant and collecting the major brown fraction. The material obtained was then recrystallized from dichloromethane–*n*-hexane mixtures to give the brown crystalline product, which was washed with a little *n*-pentane and dried *in vacuo* (0.30 g, 45%). Found: C, 37.7; H, 4.0; N, 16.6. $C_{21}H_{27}N_8BOCl_2W$ requires: C, 37.5; H, 4.0; N, 16.7%.

Spectroscopic data. ^{1}H NMR (δ_{TMS} ppm): amide NH 10.54 (1 b); aryl protons 7.41 (1 d, $^3J_{HH}$ = 8 Hz), 7.33 (1 t, $^3J_{HH}$ = 8 Hz), 7.27 (1 m), 7.05 (1 d, $^3J_{HH}$ = 8 Hz); pyrazolyl-4-H 5.94 (1 s), 5.88 (1 s), 5.84 (1 s); pyrazolyl-3- and 5-Me 2.71 (3 s), 2.43 (3 s), 2.42 (3 s), 2.37 (3 s), 2.36 (3 s), 2.15 (3 s). IR: ν_{NO} = 1630, ν_{NH} = 3255 cm^{-1}. *Mass spectra*: *m/z* = 674. *Electrochemical data*: E_f = −1.200 V, ΔE_p = 80 mV.

[W(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl(NHC$_6H_4$-3-Br)]

This compound was prepared according to the procedure for [W(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl(NHC$_6H_4$-3-Cl)] using 3-bromoaniline (0.3 cm^3, 2.7 mmol), in place of 3-chloroaniline, in toluene (50 cm^3). A red–brown product was obtained (0.40 g, 56%). Found: C, 35.3; H, 3.8; N, 15.3. $C_{21}H_{27}N_8BOClBrMo$ requires: C, 35.1; H, 3.8; N, 15.6%.

Spectroscopic data. ^{1}H NMR (δ_{TMS} ppm): amide NH 10.52 (1 b); aryl protons 7.49 (1 d, $^3J_{HH}$ = 8 Hz), 7.39 (1 m), 7.28 (1 t, $^3J_{HH}$ = 8 Hz), 7.19 (1 d, $^3J_{HH}$ = 8 Hz); pyrazolyl-4-H 5.94 (1 s), 5.88 (1 s), 5.84 (1 s); pyrazolyl-3- and 5-Me 2.71 (3 s), 2.43 (3 s), 2.42 (3 s), 2.37 (3 s), 2.35 (3 s), 2.15 (3 s). IR: ν_{NO} = 1625, ν_{NH} = 3295 cm^{-1}. *Mass spectra*: *m/z* = 718, 622, 592. *Electrochemical data*: E_f = −1.175 V, ΔE_p = 80 mV.

[W(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl(NHC$_6H_4$-3-Me)]

This compound was prepared according to the procedure for [W(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl(NHC$_6H_4$-3-Cl)] using [W(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl_2] (0.87 g, 1.5 mmol) and with 3-methylaniline (0.3 cm^3, 2.7 mmol) in place of 3-chloroaniline and a reaction time of 18 h. A red–brown product was obtained (0.35 g, 36%). Found: C, 40.3; H, 4.5; N, 17.2. $C_{22}H_{30}N_8BOClW$ requires: C, 40.5; H, 4.6; N, 17.2%.

Spectroscopic data. ^{1}H NMR (δ_{TMS} ppm): amide NH 10.79 (1 b); aryl protons 7.27 (1 t, $^3J_{HH}$ = 8 Hz), 7.24 (1 s), 7.18 (1 d, $^3J_{HH}$ = 8 Hz), 6.89 (1 d, $^3J_{HH}$ = 8 Hz); pyrazolyl-4-H 5.93 (1 s), 5.88 (1 s), 5.84 (1 s); aryl-3-Me with pyrazolyl-3- and 5-Me 2.73 (3 s), 2.45 (3 s), 2.42 (3 s), 2.38 (3 s), 2.36 (3 s), 2.35 (3 s), 2.14 (3 s). IR: ν_{NO} = 1645, ν_{NH} = 3295 cm^{-1}. *Mass spectra*: *m/z* = 652, 556, 526. *Electrochemical data*: E_f = −1.325 V, ΔE_p = 70 mV.

[W(NO){HB(3,5 - $Me_2C_3N_2H)_3$}Cl(NHC$_6H_4$ - 3 - OMe)]

This compound was prepared according to the procedure for [W(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl(NHC$_6H_4$-3-F)] using [W(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl_2] (0.58 g, 1.0 mmol) in toluene (75 cm^3) and with 3-methoxyaniline (0.3 cm^3, 2.7 mmol) in place of 3-fluoroaniline and a reaction time of 18 h. A red–brown product was obtained (0.33 g, 49%). Found: C, 39.6; H, 4.2; N, 16.9. $C_{22}H_{30}N_8BO_2ClW$ requires: C, 39.5; H, 4.5; N, 16.8%.

Spectroscopic data. ^{1}H NMR (recorded in CD_2Cl_2, δ_{TMS} ppm): amide NH 10.76 (1 b); aryl protons 7.28 (1 t, $^3J_{HH}$ = 8 Hz), 7.23 (1 m), 7.72 (1 m), 7.64 (1 m); pyrazolyl-4-H 5.94 (1 s), 5.88 (1 s), 5.82 (1 s); aryl-3-OMe 3.94 (3 s); pyrazolyl-3- and 5-Me 2.72 (3 s), 2.45 (3 s), 2.42 (3 s), 2.37 (3 s), 2.36 (3 s), 2.15 (3 s). IR: ν_{NO} = 1625, ν_{NH} = 3255 cm^{-1}. *Mass spectra*: *m/z* = 668, 572, 542. *Electrochemical data*: E_f = −1.280 V, ΔE_p = 70 mV.

[W(NO){HB(3,5 - $Me_2C_3N_2H)_3$}Cl(NHC$_6H_4$ - 3 - CF_3)]

A mixture of [W(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl_2] (0.5 g, 0.86 mmol) and 3-(trifluoromethyl) aniline (0.28 g, 1.7 mmol) was stirred under reflux in toluene (50 cm^3) for 2 days. Sodium hydride (*ca* 100 mg) was then added and the reaction mixture heated under reflux for a further 8 days. The reaction mixture was cooled and filtered and the filtrate evaporated to dryness under reduced pressure. The resulting brown solid was purified by column chromatography on successive columns

of silica gel then alumina using 3:7 *n*-hexane–dichloromethane as the eluant and collecting the major brown fraction in each case. The material obtained was then recrystallized from dichloromethane–*n*-hexane mixtures to give the brown crystalline product (0.04 g, 6%). Found: C, 37.9; H, 3.7; N, 15.4. $C_{22}H_{27}N_8BOF_3ClW$ requires: C, 37.4; H, 3.9; N, 15.9%.

Spectroscopic data. IR: ν_{NO} = 1630, ν_{NH} = 3265, ν_{CF} = 1120 cm^{-1}. *Mass spectra*: m/z = 704, 611. *Electrochemical data*: E_f = −1.135 V, ΔE_p = 150 mV.

[W(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl(NHC_6H_4-3-COMe)]

This compound was prepared according to the procedure for [W(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl(NHC_6H_4-3-Cl)] using 3-acetylaniline (0.4 g, 3.0 mmol) in place of 3-chloroaniline in toluene (50 cm^3). Chromatography on silica gel was performed using 3:7 *n*-hexane–dichloromethane as eluant. A brown product was obtained (0.27 g, 40%). Found: C, 40.9; H, 4.5; N, 16.2. $C_{23}H_{30}N_8BO_2ClW$ requires: C, 40.6; H, 4.4; N, 16.5%.

Spectroscopic data. ^{1}H NMR (δ_{TMS} ppm): amide NH 10.72 (1 b); aryl protons 7.98 (1 s), 7.70 (1 d, $^3J_{HH}$ = 8 Hz), 7.62 (1 d, $^3J_{HH}$ = 8 Hz), 7.49 (1 t, $^3J_{HH}$ = 8 Hz); pyrazolyl-4-H 5.95 (1 s), 5.89 (1 s), 5.83 (1 s); aryl-3-COMe with pyrazolyl-3- and 5-Me 2.72 (3 s), 2.71 (3 s), 2.45 (3 s), 2.43 (3 s), 2.37 (3 s), 2.36 (3 s), 2.10 (3 s). IR: ν_{NO} = 1620, ν_{NH} = 3275 cm^{-1}. *Mass spectra*: m/z = 680, 584, 554. *Electrochemical data*: E_f = −1.200 V, ΔE_p = 70 mV.

[W(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl(NHC_6H_4-3-NO_2)]

This compound was prepared according to the procedure for [W(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl(NHC_6H_4-3-Cl)] using 3-nitroaniline (0.35 g, 2.5 mmol) in place of 3-chloroaniline in toluene (50 cm^3). Unreacted 3-nitroaniline was removed from the crude reaction product by sublimation *in vacuo* prior to purification. A red–brown product was obtained (0.16 g, 25%). Found: C, 37.8; H, 3.8; N, 17.7. $C_{21}H_{27}N_9BO_3Mo$ requires: C, 37.6; H, 4.2; N, 18.2%.

Spectroscopic data. ^{1}H NMR (δ_{TMS} ppm): amide NH 10.49 (1 b); aryl protons 8.04 (1 d, $^3J_{HH}$ = 8 Hz), 7.93 (1 d, $^3J_{HH}$ = 8 Hz), 7.91 (1 s), 7.60 (1 t, $^3J_{HH}$ = 8 Hz); pyrazolyl-4-H 5.96 (1 s), 5.90 (1 s), 5.86 (1 s), pyrazolyl-3- and 5-Me 2.71 (3 s), 2.43 (6 s), 2.38 (3 s), 2.37 (3 s), 2.12 (3 s). IR: ν_{NO} = 1645, ν_{NH} = 3290, ν_{NO_2} = 1.540 cm^{-1}. *Mass spectra*: m/z = 683, 587, 557. *Electrochemical data*: E_f = −1.130, −1.440 V.

[W(NO){HB(3,5-$Me_2C_3N_2H)_3$}(NHC_6H_4-3-$CF_3)_2$]

A mixture of [W(NO){HB(3,5-$Me_2C_3N_2H)_3$}Cl_2] (0.5 g, 0.86 mmol), 3-(trifluoromethyl)aniline (0.28 g, 1.7 mmol) and sodium hydride (*ca* 100 mg) was stirred under reflux in toluene (50 cm^3) for 2.5 days. The reaction mixture was cooled and filtered and the filtrate evaporated to dryness under reduced pressure. The resulting brown solid was purified by column chromatography on alumina using 3:7 *n*-hexane–dichloromethane as the eluant and collecting the major scarlet fraction. The material obtained was then recrystallized from dichloromethane–*n*-hexane mixtures to give the scarlet crystalline product (0.16 g, 25%). Found: C, 42.2; H, 3.7; N, 15.1. $C_{29}H_{32}N_9BOF_6W$ requires: C, 41.9; H, 3.9; N, 15.2%.

Spectroscopic data. ^{1}H NMR (δ_{TMS} ppm): amide NH 8.37 (2 b); aryl protons 7.68 (2 d, $^3J_{HH}$ = 8 Hz), 7.39 (2 t, $^3J_{HH}$ = 8 Hz), 7.31 (2 s), 7.04 (1 d, $^3J_{HH}$ = 8 Hz); pyrazolyl-4-H 6.04 (1 s), 5.80 (2 s); pyrazolyl-3- and 5-Me 2.48 (3 s), 2.40 (3 s), 2.35 (6 s), 2.30 (6 s). IR: ν_{NO} = 1615, ν_{NH} = 3260, ν_{CF} = 1120 cm^{-1}. *Mass spectra*: m/z = 799, 734, 702.

DISCUSSION

Synthetic studies

The new complexes were synthesized according to previously established procedures.[1] Generally 2 molar equivalents of arylamine, $ArNH_2$, were reacted with 1 molar equivalent of [M(NO)LCl_2], acording to eq. (1):

$$[M(NO)LCl_2] + 2ArNH_2 \Rightarrow [M(NO)LCl(NHAr)] + ArNH_3Cl. \quad (1)$$

The second equivalent of amine being present to consume the HCl liberated during the reaction. Under these reaction conditions there was no evidence for the formation of bis-amide complexes. However, the reaction between [W(NO)LCl_2] and $H_2NC_6H_4$-3-CF_3 proved to be very slow and NaH was added to stimulate the reaction. Only a very low yield of the monoamide complex [W(NO)LCl(NHC_6H_4-3-CF_3)] could be obtained, therefore this material was characterized by IR and elemental analysis measurements only. The primary product of the reaction in the presence of sodium hydride proved to be the bis-amide complex [W(NO)LCl(NHC_6H_4-3-$CF_3)_2$]. This finding is unusual since in a previous study we were unable to prepare

bis-arylamide derivatives of the $\{W(NO)L\}^{2+}$ moiety.[25] However, such species could be obtained from reactions involving 2-aminopyridine[26] and it seems that the outcome of reactions between $[W(NO)LCl_2]$ and aryl amines is surprisingly sensitive to the nature of the aryl group.

The new complexes all exhibited ν_{BH} at *ca* 2550 cm^{-1} in their IR spectra, in addition to other bands attributable to the presence of the ligand L. The values observed for ν_{NO} were in accord with expectations, in that molybdenum monoarylamide derivatives typically have ν_{NO} in the range 1645–1665 cm^{-1}, while their tungsten analogues exhibit somewhat lower NO stretching frequencies. The IR spectra also contained ν_{NH} in the range 3260–3320 cm^{-1} due to the amide moiety, in addition to other bands attributable to the presence of the substituted aryl group.

The ^1H NMR spectra of the monosubstituted complexes $[M(NO)LCl(NHC_6H_4\text{-}3\text{-}Z)]$ exhibit signals consistent with the presence of the 1,3-disubstituted aryl group in the region 6.5–7.5 ppm. In addition, the molybdenum amide complexes exhibit a broad signal at *ca* 12.5 ppm due to the amide proton. In the case of the tungsten derivatives this resonance is shifted to *ca* 10.5 ppm. In the bis-amide complex, $[W(NO)LCl(NHC_6H_4\text{-}3\text{-}CF_3)_2]$, the amide protons were observed at 8.37 ppm. The pyrazolyl 4-H protons are observed in the range 5.5–6.0 ppm and, in the molybdenum complexes, often appear as two signals of relative area 2:1 despite the absence of a plane of symmetry in the molecule. However, the observation of at least five pyrazolyl–methyl resonances in the region 1.9–2.8 ppm establishes unequivocally that the monoamide derivatives have been obtained. In the case of $[W(NO)LCl(NHC_6H_4\text{-}3\text{-}CF_3)_2]$ the pyraxolyl-4-H and methyl signals appear as singlets of relative area 1:2:3:3:6:6 in accord with the presence of a plane of symmetry as required for a bis-amide derivative.

The mass spectra of all of the new complexes contained polyisotopic ion envelopes at the expected m/z values for the molecular ion. In addition, the mass spectra of the molybdenum complexes exhibited ions in the m/z range expected for $[M-(NO)]^+$ and for $[M-\{(NO)+(Me_2C_3N_2H)\}]^+$. In contrast, the tungsten complexes exhibited ions attributable to $[M-(Me_2C_3N_2H)]^+$ due to the loss of dimethylpyrazole rather than nitric oxide, in addition to $[M-\{(NO)+(Me_2C_3N_2H)\}]^+$.

Electrochemical studies

It is now well established that complexes of the type $[M(NO)LCl(NHC_6H_4Z)]$ undergo a one-electron reduction process at potentials which are sensitive to the nature of the aryl substituent Z.[6,7] The reduction potentials of the *meta*-substituted arylamide complexes in acetonitrile solution were determined by cyclic voltammetry. In accord with expectations[6,7] the molybdenum complexes have formal reduction potentials, E_f, in the region of -0.8 V, while the tungsten complexes have E_f values which are *ca* 450 mV more cathodic. Plots of $i_p v^{-1/2}$ (i_p = peak current and v = scan rate) against v for the reduction wave are linear over the scan rate range 100–500 mV, indicating that the electron transfer process is reversible. Deviations of the shape parameter ΔE_p (the separation between the cathodic and anodic peak potentials) from the ideal value of 59 mV are thus primarily ascribed to uncompensated cell resistance. With the exception of $[W(NO)LCl(NHC_6H_4\text{-}3\text{-}NO_2)]$, the reduction processes are judged to be chemically reversible since the ratio of anodic to cathodic peak currents is close to one. In the case of $[W(NO)LCl(NHC_6H_4\text{-}3\text{-}NO_2)]$ the first wave with a cathodic peak potential $E_{pc} = -1.13$ V gives an anodic peak current substantially less than for the cathodic process. In addition a second irreversible wave is observed at -1.44 V. On the basis of previous results[7] we assign the first wave to the reduction of the tungsten centre. The second wave may be associated with the reduction of the nitro group thus giving rise to the irreversible behaviour. In the data analysis described below the value $E_{pc} - 30$ mV $= -1.1$ V is used as an approximation for the E_f of $[W(NO)LCl(NHC_6H_4\text{-}3\text{-}NO_2)]$. Removal of this point from the data set produces no significant change in the outcome of the calculations, hence it has been retained in the data analysis.

A linear regression analysis of the formal reduction potentials, $E_f^z(Mo)$, for the molybdenum complexes against the appropriate values of the Hammett *meta*-substituent parameter, σ_m, for Z was carried out. The data used, and the best fit line obtained, are presented in Fig. 1. The regression gave a correlation coefficient $r = 0.9858$ indicative of a good correlation between E_f^z and σ_m. At the intercept with $\sigma_m = 0$ the value of E_f is given by $E_f^0(Mo) = -0.848(0.009)$, standard errors being given in parentheses. The slope, $S(Mo)$, of the line is 326(23) mV giving a reaction constant, $\rho_m(Mo)$, 5.50(0.39) according to eq. (2):

$$E_f^z - E_f^0 = \rho_m \sigma_m (2.303RT/F), \qquad (2)$$

where R, T and F have their usual meaning. The value of $E_f^0(Mo)$ agrees, within experimental error, with that of $-0.833(0.011)$ obtained[7] for $[Mo(NO)LCl(NHC_6H_4\text{-}4\text{-}Z)]$. However, the reaction constant is somewhat reduced compared to that

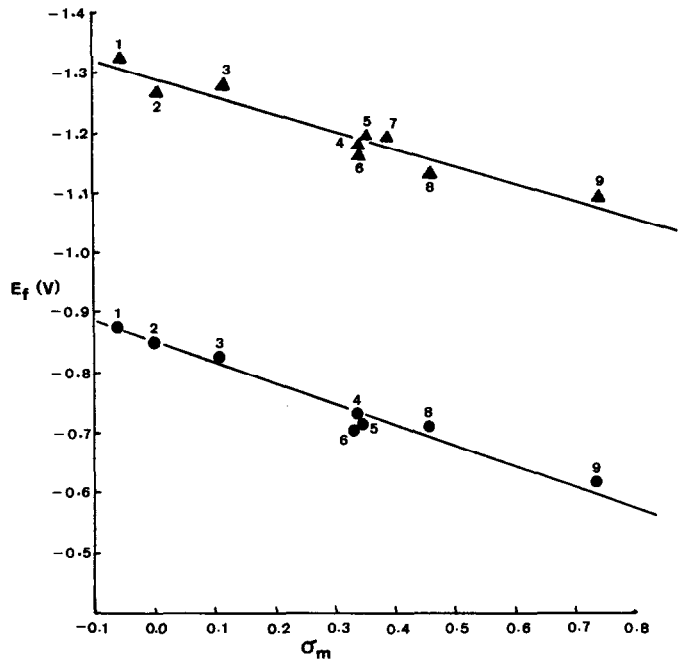

Fig. 1. Plots of E_f against σ_m for [Mo(NO)L(NHC$_6$H$_4$-3-Z)] (●) and [W(NO)L(NHC$_6$H$_4$-3-Z)] (▲) for Z = Me (**1**), H (**2**), OMe (**3**), F (**4**), Cl (**5**), Br (**6**), COMe (**7**), CF_3 (**8**) and NO_2 (**9**). The lines shown are for $E_f = -0.848 + 0.326\ \sigma_m$ (●) and $E_f = -1.291 + 0.281\ \sigma_m$ (▲).

of ρ_p(Mo) = 6.68(0.47) obtained for the *para*-substituted arylamide complexes; although the errors on these figures preclude definitive comment. A dual parameter analysis was also carried out using the inductive and resonance substituent parameters σ_I and σ_R.[27] This analysis gave a χ^2 statistic of -4.64×10^{-4} for six degrees of freedom, compared with -2.03×10^{-3} for the linear regression. Thus the dual parameter model gave a better fit to the data than the linear model but the errors of *ca* ± 10 mV in the measurement of E_f suggest that this finding may have no physical significance. The value of E_f^0(Mo) obtained from the dual parameter model was $-0.851(0.006)$, in good agreement with that obtained from the linear model. The reaction constants, ρ_I and ρ_R, for the respective inductive and resonance parameters according to eq. (3) were ρ_I(Mo) = 5.62(0.21) and ρ_R(Mo) = 2.01(0.21). The value of ρ_R being 36% that of ρ_I, close to the normal value of 40%

$$E_f^z - E_f^0 = (\rho_I \sigma_I + \rho_R \sigma_R)(2.303RT/F) \qquad (3)$$

for *meta*-substituent effects.[27] Unlike the case for [Mo(NO)LCl(NHC$_6$H$_4$-4-Z)], where σ_I and σ_{R-} gave a better fit to the E_f data than σ_I and σ_R, use of the σ_{R-} parameter in place of σ_R gave a substantially poorer model for the E_f data.

A similar analysis of the E_f data obtained from the tungsten complexes was carried out and the best fit line and data are shown in Fig. 1. In this case the linear regression gave a slightly reduced correlation coefficient of 0.9636. The value of E_f^0(W) is $-1.291(0.011)$ V which agrees, within experimental error, with the value of $-1.301(0.011)$ obtained from [W(NO)LCl(NHC$_6$H$_4$-4-Z)].[7] The slope of the best fit line is S(W) = 281(30) mV, giving a reaction constant of ρ_m(W) = 4.75(0.50) according to eq. (2). As with the molybdenum complexes this is smaller than that of ρ_p(W) = 6.44(0.57) obtained for [W(NO)LCl(NHC$_6$H$_4$-4-Z)].[7] The dual parameter analysis provided a better model for the E_f data with a χ^2 statistic of -1.84×10^{-3} for seven degrees of freedom, compared to -2.46×10^{-3} for the linear regression. However, taking into account the errors, this finding may have no physical significance. The value of E_f^0(W) from the dual parameter model is $-1.287(0.012)$ V, in good agreement with that obtained from the linear model. The values of ρ_I(W) and ρ_R(W) are, respectively, 4.72(0.50) and 2.06(0.43). The value of ρ_R is 44% that of ρ_I and, as with the molybdenum complexes, this is close to the normal value of 40%.[27] Also in accord with the findings for molybdenum, a dual parameter model using σ_{R-} in place of σ_R gave a substantially poorer description of the E_f(W) data. The differences between the values of E_f^0(W) and E_f^0(Mo) obtained, respectively, from the linear and dual parameter models are 443 and 436 mV, in good agreement

with the previously determined value of 429 mV for [M(NO)LCl(NHC$_6$H$_4$-4-Z)].[7]

In conclusion, the results presented here show that the reduction potentials of the *meta*-substituted arylamide complexes [M(NO)LCl(NHC$_6$H$_4$-3-Z)] (M = Mo or W) may be satisfactorily correlated with the Hammett *meta*-substituent constant, σ_m, using a simple linear model. The reaction constants for the molybdenum and tungsten series are consistently smaller than for the *para*-substituted systems [M(NO)LCl(NHC$_6$H$_4$-4-Z)], but the errors on these values preclude any quantitative conclusions. The dual parameter model shows that the substituent effects on E_f conform to the normal pattern. Thus, in the *para*-substituted systems, the value of the reaction constant ρ_R is approximately equal to that of ρ_I.[7] However, in the *meta*-substituted systems the value of ρ_R is only *ca* 40% that of ρ_I. The data presented here, and in previous papers,[6,7] provide a basis for using E_f data to evaluate the effects on the $\{M(NO)LCl\}^+$ moiety of other groups linked through arylamide bridging ligands. Substituent effects on E_f are also apparent in substituted phenoxide complexes of the type [M(NO)LCl(OC$_6$H$_4$Z)], although the reaction constants appear to be smaller than for the arylamide derivatives.[28]

SYNTHESIS, PROPERTIES AND X-RAY CRYSTAL STRUCTURES OF COPPER(II) AND NICKEL(II) THIOCYANATE COMPLEXES WITH ETHANOLAMINE: A NEW STRUCTURE FOR AN AMINOALKOXIDE CLUSTER

MICHAEL B. HURSTHOUSE,* KEITH J. IZOD, M. A. MAZID and PETER THORNTON*

Department of Chemistry, Queen Mary and Westfield College, Mile End Road, London E1 4NS, U.K.

(*Received* 25 *August* 1989; *accepted* 7 *September* 1989)

Abstract—The new antiferromagnetic polymer $[Cu(NH_2C_2H_4O)(NCS)]_\infty$ has been prepared and shown by X-ray crystallography to contain a new polymeric linkage of pairs of copper(II) atoms linked alternately by two oxygen bridges and one weaker thiocyanate bridge. Electronic, ESR and IR spectra and temperature-variable magnetochemical data are described. $[Ni(NH_2C_2H_4OH)_2(NCS)_2]$ is fully characterized by its magnetism, electronic and IR spectra and crystal structure as a centrosymmetric octahedral monomer with nitrogen-coordinated thiocyanates.

When reviewing[1] structures of complexes with the formula $[Cu\{R_2N(CH_2)_nO\}X]$ (R = alkyl; $n = 2$, 3; X = halide, pseudohalide) Haase and co-workers recognized three general types of structure. These were (a) dimers with two oxygen bridges; (b) cubane tetramers, also with oxygen bridges; and (c) polymers, which were dimers of the (a) type linked by two X bridges. Despite many compounds having been found with different alkyl groups, R, and numbers of methylene linkages, n, there are no reports of structures and physical studies on the unalkylated alkoxide $H_2N(CH_2)_nO$ complexes. We report here the preparation, structure, magnetic properties, electronic, ESR and IR spectra of $[Cu(H_2NC_2H_4O)(NCS)]_\infty$, which we find has a new form of interdimer bridging for this type of compound. We have also studied the corresponding nickel(II) system and report the characterization of $[Ni(NH_2C_2H_4OH)_2(NCS)_2]$, which has only been partly characterized previously.[2]

RESULTS AND DISCUSSION

$[Cu(NH_2C_2H_4O)(NCS)]$

This compound is prepared by the addition of methanolic KNCS (1 mol) to a methanolic solution of $[Cu(H_2O)(O_2CCH_3)_4]$ (1 mol) and $NH_2C_2H_4OH$ (2 mol), using a procedure[3] which is successful for complexes with N-substituted aminoalcohols. An analogous azide complex was also prepared; its properties are rather different and it will be described elsewhere. Attempts to prepare NCO^- and $NCSe^-$ complexes failed. The IR spectrum of the NCS^- complex shows bands for NH_2 and NCS moieties but no OH vibrations, in keeping with the formulation as an alkoxide rather than alcohol complex. The NCS symmetric stretching mode at 803 cm^{-1} is consistent with bridging coordination.[4] This indicates a dimeric structure (I) with S—Cu interactions making a polymeric arrangement of type (c) described by Haase and co-workers,[1] but it is also consistent with non-bridging thiocyanate coordinating through the nitrogen atom only.

The diffuse reflectance electronic spectrum shows a broad absorption centred at 14,700 cm^{-1}, typical of copper(II) in many geometries, and a shoulder at 26,300 cm^{-1} on the stronger ultraviolet ligand absorption. This shoulder has been attributed[3] to O—Cu charge-transfer in bridging aminoalkoxo complexes. In solution, in DMSO, these absorptions are found at 15,000 cm^{-1} ($\varepsilon = 514$ cm^{-1} dm^3 mol^{-1}) and 26,300 cm^{-1} ($\varepsilon = 1550$), suggesting some change in structure in solution but with retention of oxygen bridging. The X-band ESR spectrum

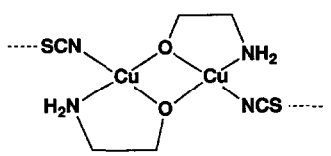
of the solid complex consists of a very weak $\Delta M_s = 1$ signal at $g = 2.05$ with a much weaker $\Delta M_s = 2$ signal at $g \sim 4.0$, which indicates the presence of the expected antiferromagnetic copper–copper spin interaction in a dimer structure.

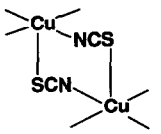
Details of the antiferromagnetism are given by magnetic susceptibility measurements down to 70 K (Table 1) where the magnetic moment is seen to fall from its room temperature value of 1.55 μ_B and the susceptibility is seen to achieve its maximum value near 120 K. The data can be fitted to the Bleaney–Bowers treatment[5] for an antiferromagnetic $S = 1/2$ dimer, showing good agreement with parameters of $g = 2.05$ (from the ESR data), $J = -42$ cm^{-1} and $N_\alpha = 60 \times 10^{-6}$ emu mol^{-1}. This shows that the principal path for antiferromagnetism is through the bridging oxygen atoms and that the thiocyanate bridges between dimers have an insignificant role in spin coupling. An alternative interpretation in which the thiocyanate bridges provide the principal route for antiferromagnetism is unlikely in view of the propensity of alkoxide bridges for generating strong antiferromagnetism in copper(II) dimers.[6] Indeed, polymerized dimers of type **I** are commonly more



I

antiferromagnetic than our complex, even with chloride interdimer bridges, less effective exchange propagators than our thiocyanates.

To confirm our assignment we undertook an X-ray crystal structure determination. This reveals the dimeric structure we anticipated and shows interdimer bonding through thiocyanate bridges, but these bridging units are more interesting than we expected. Instead of configuration **II** in which two



II

thiocyanate ligands linked neighbouring dimers, as found in $[Cu(R_2NC_2H_4O)(NCS)]_\infty$ (R = Me,[7] Et,[8] Pr[9]), polymerization is much more elaborate, each dimer being linked to four other dimers by single NCS bridges (Fig. 1).

The dimer units are centrosymmetric and the copper coordination is best described as distorted tetragonal pyramidal (4+1). Important bond lengths and angles are listed in Table 2. The Cu—O and Cu—N distances are all much shorter than the weaker axial Cu—S interaction of 2.872(5) Å. The bond lengths are generally similar to those in the previously reported $[Cu(R_2NC_2H_4O)(NCS)]$ complexes[7-9] despite the difference in interdimer linkage. The Cu—Cu separation of 2.974(4) Å is also typical of this kind of structure and shows that the antiferromagnetic exchange interaction between the copper atoms must be transmitted through the ligands.

$[Ni(NH_2C_2H_4OH)_2(NCS)_2]$

The previous report[2] of this compound describes briefly, without analytical data, the preparation,

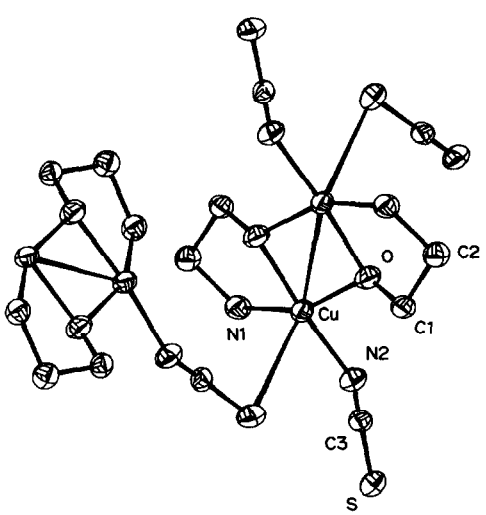


Fig. 1. Structure of $[Cu_2(NH_2C_2H_4O)_2(NCS)_2]_\infty$.

Table 2. Bond lengths and angles for $[Cu_2(NH_2C_2H_4O)_2(NCS)_2]$

Bond lengths (Å)			
Cu—S	2.872(5)	Cu—N(1)	1.983(6)
Cu—O	1.942(5)	Cu—N(2)	1.976(6)
Cu—Cu	2.974(4)		
Bond angles (°)			
O—Cu—S	101.9(2)	N(1)—Cu—S	100.1(2)
N(1)—Cu—O	156.2(2)	N(2)—Cu—S	81.8(2)
N(2)—Cu—O	98.9(3)	N(2)—Cu—N(1)	93.4(3)
C(3)—S—Cu	102.2(3)	C(1)—O—Cu	131.0(3)
C(2)—C(1)—O	107.0(5)		

electronic spectra and room temperature magnetic moment. Our method of preparation is slightly different; we used the addition of ethanolic $NH_2C_2H_4OH$ to ethanolic $Ni(NCS)_2$, prepared *in situ* by mixing ethanolic solutions of $[Ni(H_2O)_6](NO_3)_2$ and KNCS and filtering precipitated $KNO_3 \cdot NH_2$ and OH stretching modes occur at 3330, 3260, 3200 and 3160 cm^{-1}, the strong antisymmetric NCS mode occurs at 2085 cm^{-1} and the symmetric mode at 773 cm^{-1}. The diffuse reflectance electronic spectrum shows the expected transitions for a tetragonally-distorted octahedral complex from the $^3B_{1g}$ ground state to ^3E_g (10,800), $^3B_{2g}$ (11,900), ^3E_g (15,600 sh), $^3A_{2g}$ (17,200) and $^3T_{1g}$(P) (27,500 cm^{-1}). The room temperature magnetic moment is 3.23 μ_B; this value is constant down to 90.4 K and the value of θ of 5 K indicates no antiferromagnetism. These data are generally similar to those in ref. 2 but are different in detail and show the complex has octahedral coordination for nickel, probably with N-bonding for thiocyanate.[4]

We have also confirmed these conclusions by a crystal structure determination. The nickel atom occupies a crystallographic centre of symmetry. Important bond lengths and angles are listed in Table 3 and the structure is illustrated in Fig. 2. The chelating aminoethanol gives a bite angle of 81.7(2)° at nickel, but the other bond lengths and angles are all normal values for this type of complex and require no further comment.

EXPERIMENTAL

Physical measurements were made using magnetic[10] and spectroscopic[11] equipment already described.

$[Cu(NH_2C_2H_4O)(NCS)]$

A methanolic solution of KNCS (1.94 g, 0.02 mol) was added to a hot solution of $NH_2C_2H_4OH$ (2.44 g, 0.04 mol) and $[Cu_2(H_2O)_2(O_2CCH_3)_4]$ (4.0 g, 0.01 mol) in methanol (60 cm^3). Slow cooling over 3 days gave dark green crystals of the product, which was filtered, washed with ethanol and air-dried. The compound could not be recrystallized. Yield 1.8 g, 50%. Found: C, 19.8; H, 3.3; N, 15.2; S, 17.0. $C_3H_6CuN_2OS$ requires C, 19.8; H, 3.35; N, 15.4; S, 17.6%.

operating in the θ–2θ mode with graphite-monochromated Mo-K_α radiation. The structures were solved by the application of routine heavy-atom methods and refined by full-matrix least-squares techniques. In the refinement cycles all non-hydrogen atoms were refined anisotropically; hydrogen atoms were inserted in idealized positions and constrained to ride on the atoms to which they were bonded at a distance of 1.08 Å. The weighting scheme $\omega = 1/[\sigma^2(F_o)+g(F_o)^2]$ was used in each case, with the parameter g determined in the refinement process so as to give flat analyses of variance with $\sin\theta$ and F_o/F_{max}. Experimental details are summarized in Table 4.

THE X-RAY CRYSTAL STRUCTURES OF THE CADMIUM COMPLEXES OF PYRIDINE-1-THIOL AND MERCAPTOBENZOTHIAZOLE, $[Cd(C_5H_4NS)_2]_n$ AND $[Cd(C_7H_4N_2S_2)_2]_n$: TWO UNUSUAL VOLATILE POLYMERIC COMPLEXES

(*Received* 27 *July* 1989; *accepted* 12 *September* 1989)

Abstract—The structures of the 2:1 complexes formed by pyridine-1-thiol (**I**) and mercaptobenzothiazole (**II**) with cadmium(II) are polymeric but both sublime at reduced pressure and decompose cleanly to CdS in air. Both structures contain approximately octahedrally-coordinated cadmium atoms (CdN_2S_4) and involve bridging and chelating modes for the ligand.

There is considerable current interest in the structures adopted by thiolate complexes of the main group elements.[1,2] In this context we report the X-ray crystal structures of the title complexes; the mercaptobenzothiazolato complex has been previously reported,[3,4] but no equivocal structural information is available, and the pyridine thiolato complex is a new compound. In addition, both of the compounds can be sublimed; the surprising volatility of these materials may mean that they are of interest for MOCVD, MOMBE and related crystal growth processes.

RESULTS AND DISCUSSION

In the pyridine-1-thiolato complex, coordination at each cadmium is close to octahedral (N_2S_4) with two different ligand coordination modes; one approximately parallel and the other perpendicular to the polymer chain, Fig. 1. The ligand perpendicular to the chain chelates one cadmium with Cd(1)—S(1) 2.81 Å and Cd(1)—N(2) 2.34 Å (bite angle 60.80°) and bridges to the adjacent cadmium Cd(1′)—S(1) 2.65 Å. The second ligand, approximately parallel to the chain, also chelates Cd(1) with Cd(1)—S(2) 3.04 Å and Cd(1)—N(1) 2.34 Å (bite angle 57.10°), and bridges to the adjacent cadmium in the opposite direction along the chain to the first ligand Cd(1″)—S(2) 2.54 Å. The two nitrogens on Cd(1) are *cis*. The compound is hence a genuine inorganic polymer with the shorter Cd—S

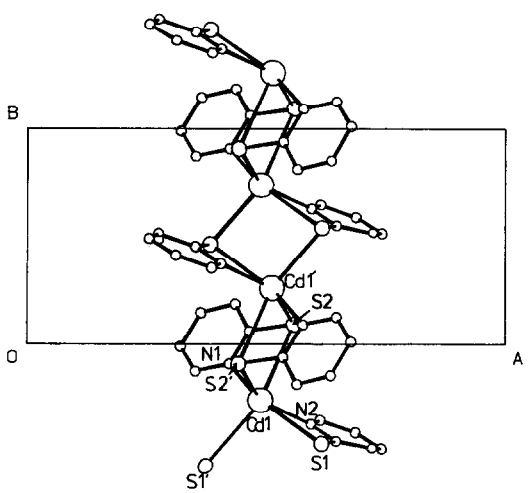

Fig. 1. A short section of the polymeric chain in the pyridine thiolatato complex, viewed down *c*; selected bond lengths (Å) and angles (°) are as follows: Cd(1)—S(1) 2.809(4), Cd(1)—S(1′) 2.649(4), Cd(1)—S(2) 3.038(4), Cd(1)—S(2′) 2.543(5), Cd(1)—N(1) 2.342(4), Cd(1)—N(2) 2.343(4), S(1′)—Cd(1)—S(2′) 103.4(3), S(1′)—Cd(1)—N(1) 93.57, S(2′)—Cd(1)—N(1) 101.6(3), S(1′)—Cd(1)—N(2) 100.06(3), N(2)—Cd(1)—S(1) 60.6(2), N(1)—Cd(1)—S(2) 57.2(2).

distances forming the chain. The four proximal sulphurs are within the sum of the van der Waals' radii[5] (3.4 Å). The shorter distances are similar to those found in other thiolate complexes of cadmium[1,6] (2.5–2.7 Å) and the Cd—N distances are typical of those found in relevant coordination complexes of cadmium[7] (2.27–2.36 Å). The bonding modes of mercaptopyridine have recently been surveyed,[8] the doubly bridging, five-electron, mode of bonding has only been unequivocally characterized in one other case,[8] the complex $[(pyS)_2CO_6Re_2]$, and there are no other complexes showing this kind of polymeric network developed in this structure.

The structure of the mercaptothiopyrazolato complex is similar, with the short ligand-to-metal contacts (Cd—N and Cd—S) to different cadmium atoms. Again, a polymeric structure is developed but in this case the ligands take up a helical pattern, Fig. 2. The two nitrogens are coordinated *cis* to each approximately octahedral cadmium atom (2.28 and 2.33 Å), the exocyclic sulphur atoms of each of the ligands coordinate with short Cd—S distances (2.55 and 2.60 Å) to adjacent cadmium atoms in opposite directions along the polymer chain. The distances from the first cadmium (3.06 and 3.12 Å) are within the sum of the van der Waals' radii[5] for cadmium and sulphur (3.4 Å). The two additional Cd—S contacts are unusually long, the cadmium atoms are separated by 3.77 Å, well outside the sum of the van der Waals' radii (3.2 Å). The mode of ligation is very different from the chelate mode shown in the anionic tris complex with cadmium(II),[4] Cd—S 2.66 Å and Cd—N 2.47 Å, with a bite angle of 62°

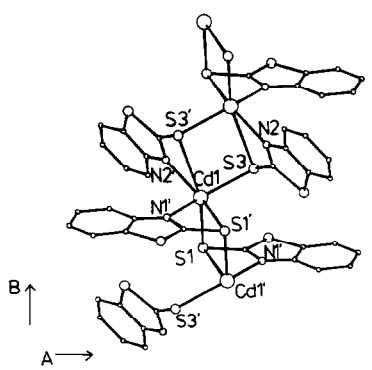

Fig. 2. A short section of a polymeric chain in the mercaptopyrazolato complex, viewed down *c*; selected bond lengths (Å) and angles (°) are as follows: Cd(1)—S(1) 2.606(4), Cd(1)—S(1′) 3.061(5), Cd(1)—S(3) 2.547(4), Cd(1)—S(3′) 3.129(4), Cd(1)—N(1′) 2.283(4), Cd(1)—N(2′) 2.328(3), S(1)—Cd(1)—S(1′) 96.8(3), S(1)—Cd(1)—N(1) 98.2(3), S(1′)—Cd(1)—N(1′) 57.7(3), S(1)—Cd(1)—S(3) 102.3(4).

and strict C_3 symmetry (distorted from trigonal prismatic toward octahedral by 25.8°).

The two structures presented are remarkably similar in terms of both coordination mode and symmetry. Both structures are based on extended networks of $—Cd_2S_2—$ four-membered rings.

Further characterization of the compounds has been carried out by a range of spectroscopic techniques. Solid-state NMR spectra have been impossible to obtain for compound **I**, the explanation for this lies in the long relaxation time for protons (*ca* 31 s) in this rigid complex which makes MAS/CP experiments difficult. The mercaptobenzothiazolato complex (**II**) gave excellent solid-state NMR spectra for both ^{13}C and ^{113}Cd. The ^{113}Cd chemical shift of the crude powdered complex showed that there were two cadmium sites characterized by chemical shifts of 340.1 and 329.3 ppm. The crystalline material gave a single peak at 325 ppm, as would be expected from the crystal structure. Possible explanations for the two sites observed include, the system is dimorphic or that the microcrystalline powder as initially obtained contains a relatively large number of terminal or chain-bridging cadmium atoms with a different chemical shift from that found for a cadmium centre within the polymer. In either case the environment of the cadmium in both sites is similar and consistent with the coordination geometry observed in the structure of the crystalline material (CdN_2S_4). Earlier workers may have studied a mixture of phases by IR spectroscopy[3] and ^{113}Cd NMR is clearly a powerful technique for detecting different cadmium centres in such compounds.

Mass spectra (electron impact) were recorded for both complexes. The spectrum of the pyridine-1-thiolato complex (**I**) showed a highest mass peak for the molecular ion of the 2:1 complex (m/z = 335.9 ^{115}Cd, 25%), with adjacent peaks for all the other common isotopes of cadmium. The mercaptobenzothiazole complex (**II**) gave a small clear peak for the molecular ion of the bis complex (m/z = 445 ^{113}Cd), with satellite peaks for the other isotopes of cadmium; this may indicate that the bis complex is a significant vapour phase species, however, other peaks trailing off to higher mass were seen. Thermogravimetric analysis of the complexes in a stream of air (Stanton–Redcroft TG750, 10°C min^{-1}, air 10 cm^3 min^{-1}) gave rise to cadmium sulphide (as a mixture of hexagonal and cubic phases). The yield was close to that theoretically required 43.3% (**I**) 230–500°C and 32.5% (**II**) 250–500°C, although the volatility of CdS made precise measurements difficult. These complexes are further examples of cadmium thiolates decomposing cleanly to CdS.[9]

Table 1. Crystal data

$(C_{20}H_{16}N_4S_4Cd_2)_n$: $M_w = 665.42$ (for the monomer), space group $C2/c$, $a = 17.464(2)$, $b = 7.323(1)$, $c = 18.981(2)$ Å, $V = 2270.45$ Å^3, $\beta = 110.72(1)°$, $D_c = 1.95$ g cm^{-3}, $Z = 4$, μ(Mo-K_α) = 22.36 cm^{-1}.
$R = 0.0295$, $w = 1/(\sigma^2(F_o)+0.000033(F_o)^2)$, $R_g = 0.0289$, for 2796 of 3308 reflections with $F_o > 3\sigma(F_o)$.

$(C_{28}H_{16}N_4S_8Cd_2)_n$: $M_w = 761.52$ (for the monomer), space group $C2/c$, $a = 19.452(3)$, $b = 7.203(1)$, $c = 23.962(3)$ Å, $V = 3142.75$ Å^3, $\beta = 110.60(2)°$, $D_c = 1.60$ g cm^{-3}, $Z = 4$, μ(Mo-K_α) = 15.95 cm^{-1}.
$R = 0.024$, $w = 1/(\sigma^2(F_o)+0.000706(F_o)^2)$, $R_g = 0.037$, for 2211 of 2640 reflections with $F_o > 3\sigma(F_o)$.

The atomic coordinates for the two structures reported in this communication are available from The Director of the Cambridge Crystallographic Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K. Any request for information should be accompanied by the full literature citation for this communication.

EXPERIMENTAL

Materials and methods

IR spectra were taken as either Nujol mulls or KBr discs (1%, 200 mg) between 4000 and 400 cm^{-1} using a Matteson Polaris FTIR, and solid-state NMR spectra were recorded with a Brüker MSL-300 instrument (equivalent proton frequency 300 MHz). ^{113}Cd shifts are in ppm relative to an external $Cd(ClO_4)_2$ reference. Mass spectra were recorded by electron bombardment using an AEI MS902.

Preparation of the complexes

The compounds both immediately precipitated on the stoichiometric reaction of an ethanolic solution of the ligand with an aqueous solution of cadmium acetate (room temperature 10^{-2}–10^{-3} mol dm^{-3} in cadmium). The use of cadmium acetate avoids the co-precipitation of basic complexes, a problem noted in earlier studies of **II**.[4] Single crystals were obtained by slow recrystallization of the crude complexes from hot pyridine (**I**) or dimethylformamide (**II**), both compounds could also be purified by sublimation (160°C and 0.01 torr); specimens large enough for diffraction studies could not be obtained by this method. The complexes, both before and after recrystallization, had satisfactory microanalyses (C,H,N,S) for the 2:1 ligand-to-metal stoichiometry.

Crystallography

All measurements were made on samples mounted in glass capillaries using a CAD4 diffractometer operating in the ω–2θ scan mode with graphite monochromated Mo-K_α radiation ($\lambda = 0.70169$ Å) as previously described.[10] The structures were solved via standard heavy-atom procedures and refined using full-matrix least-squares methods[11] with scattering factors calculated using data from ref. 12. All non-hydrogen atoms were refined with anisotropic displacement factors; many hydrogen atoms were identified in difference maps and included with geometric constraints, whilst the remainder were included in geometrically required positions. Details of the crystal data and intensity measurements are given in Table 1.

Acknowledgements—We thank the SERC and Polaron Equipment Ltd for a CASE Award to O.F.Z.K. and the SERC for support of crystallography at Queen Mary and Westfield College. Solid-state NMR spectra were recorded by Dr C. J. Groombridge of the ULIRS solid-state NMR service of the University of London, whom we thank for his enthusiastic help.

Abstract—The reactions of anhydrous HX (X = Br, Cl) with *trans*-$Mo(N_2)_2$(triphos)(PPh_3) (**1**) where triphos = $PhP(CH_2CH_2PPh_2)_2$, yield $[MoX(NNH_2)$(triphos)$(PPh_3)]X$ as a mixture of isomers: **1A(X)** and **1B(X)**. In solution, PPh_3 dissociates rapidly from the **B** isomer. Addition of PPh_3 to a mixture of **1A(X)** and **1B(X)** enabled the separation of the isomers by fractional crystallization. Addition of PPh_2Me to a mixture of **1A(X)** and **1B(X)** led to the isolation of **1A(X)** and $[MoX(NNH_2)$(triphos)$(PPh_2Me)]X$ [**2B(X)**]. Amber **1A(Cl)** crystallizes with one molecule of toluene in the monoclinic space group $P2_1$ with $a = 13.714(2)$, $b = 13.924(2)$, $c = 14.279(3)$ Å, $\beta = 102.44(1)°$, and $Z = 2$. Olive-green **2B(Cl)** crystallizes with two molecules of solvation; one each of pentane and toluene, in the triclinic space group $P\bar{1}$ with $a = 12.922(2)$, $b = 13.552(3)$, $c = 18.067(4)$ Å, $\alpha = 106.04(1)$, $\beta = 107.65(1)$, $\gamma = 97.22(1)°$, and $Z = 2$. Loss of PPh_3 from **1B(X)** is proposed to be due to steric factors. Yields of ammonia and hydrazine formed from all the nitrogen hydride complexes are summarized.

The reduction of N_2 to ammonia occurs where mono-[1,2] and bis-N_2[3–6] complexes of molybdenum and bis-N_2 complexes of tungsten[3,4] are treated with strong acids. The only nitrogen hydride species to have been definitively characterized for molybdenum in these reactions contain the hydrazido(2−), NNH_2, ligand.[7] Although a number of complexes containing an N_2H_2 fragment[8] have been structurally characterized,[9] it is only the hydrazido(2−) ligand, *which is so far unique to molybdenum and tungsten*, that has been shown to react further to yield ammonia. Studies of the reaction of *trans*-$Mo(N_2)_2$(triphos)(PPh_3) (**1**)[10] with strong acids have led to (i) establishment of the stoichiometry of the reaction with HBr in THF to yield ammonia [eq. (1)][5,11]

$$\mathbf{1} \xrightarrow[\text{THF}]{\text{HBr}} NH_4Br + \tfrac{1}{2}N_2 + MoBr_3(\text{triphos}) + PPh_3 \qquad (1)$$

and (ii) recognition of nitrogenase-like behaviour,[12] namely the hydrazine-forming property of nitrogenase, in these systems.[5] The reactions of **1** with HX (X = Br, Cl) yield a pair of isomeric hydrazido(2−) complexes, $[MoX(NNH_2)(triphos)(PPh_3)]X$ [**1A(X)**] and [**1B(X)**]. Triphenylphosphine dissociates readily at room temperature from **1B(X)**, a key step in the reaction that produces ammonia, and can be replaced by PPh_2Me or PMe_2Ph, but not from **1A(X)**; see Scheme 1.[13] Full details are given of the crystal structures of $[MoCl(NNH_2)(triphos)(PPh_3)]Cl$ [**1A(Cl)**] and $[MoCl(NNH_2)(triphos)(PPh_2Me)]Cl$ [**2B(Cl)**] which have been communicated previously.[14]

RESULTS AND DISCUSSION

Formation of hydrazido(2−) complexes

Reactions of **1** with HX (X = Br, Cl) resulted in the loss of 1 mol of N_2 and rapid formation of a pair of isomeric hydrazido(2−) complexes (Scheme 1). In solution at room temperature with acid present, PPh_3 dissociated from the **B** isomer and within *ca* 0.5 h the ^{31}P NMR spectrum revealed resonances due to only the **A** isomer and PPh_3 (Scheme 1). No resonances due to the triphos-containing residue from **B** were observed. In THF solution a gold coloured solid began to form slowly following the loss of PPh_3. Precipitation was complete within *ca* 1 h.

Separation and isolation of **1A(X)** and **1B(X)** were affected by adding PPh_3 to a mixture of **1A(X)** and **1B(X)** in THF or toluene solution in the absence of acid. **1A(X)** precipitated first and reduction of the volume of solution resulted in precipitation of **1B(X)**. PPh_3 was added to maintain the equilibrium [eq. (2)] in favour of **1B(X)** in solution. Addition of PPh_2Me to a mixture of **1A(X)** and **1B(X)** in toluene solution in the absence of acid

$$\mathbf{1B(X)} \rightleftharpoons PPh_3 + \{[Mo(NNH_2)(triphos)]X\} \quad (2)$$

resulted in the formation of crystals of **1A(X)** and after reduction of the volume of solution crystals of $[MoX(NNH_2)(triphos)(PPh_2Me)]X$ [**2B(X)**] formed. Complex **2B(X)**, formed by displacement of PPh_3 in **1B(X)** by PPh_2Me, has the same ^{31}P NMR spectrum as **2B(X)** made by the reaction of *trans*-$Mo(N_2)_2(triphos)(PPh_2Me)$ (**2**) with HX, which afforded a mixture of **2A(X)** and **2B(X)**.[5]

Description of structures

The structures of the molecular cations of **1A(Cl)** and **2B(Cl)** are illustrated in Figs 1 and 2. Crystal data are given in Table 1 and relevant bond lengths and angles in Table 2.

Both complex cations display similar pseudo-octahedral coordination environments about the molybdenum atom, with the four phosphorus atoms defining the equatorial plane about molybdenum, while the chloride donor and N(1) of the end-on bonded hydrazido(2−) ligand occupy axial positions. In either case, the Mo—N(1) distance is short and the N(1)—N(2) distance is intermediate between calculated single and double bond

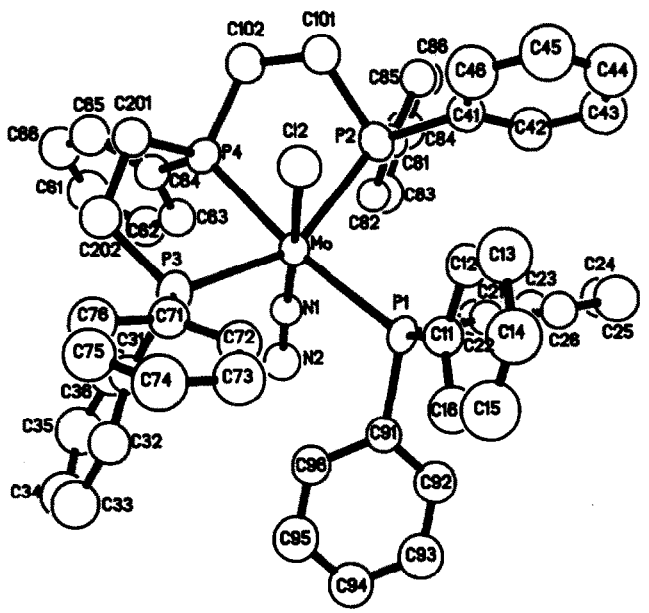

Fig. 1. Perspective view of the structure of the cation *syn*-$[MoCl(NNH_2)(triphos)(PPh_3)]^+$ of **1A(Cl)**.

distances, indicating a high degree of delocalization and significant multiple bond character throughout the Mo—N(1)—N(2) moiety; in fact very similar to other structurally characterized molybdenum hydrazido(2−) complexes.[15] The NNH_2 hydrogen atoms were located but not refined. Their positions and that of the chloride counterions, to which hydrogen bonding is indicated in the IR spectra, are shown in Fig. 3.

The occurrence of isomers arises because of the configuration at P(4), the central phosphorus atom of triphos. Thus in **1** (see Fig. 4) the two N_2 ligands are in different environments. One N_2 is on the same side of the P_4 plane as the Ph group (*syn*) on P(4),

whereas the other N_2 is on the opposite side of the plane *anti* to the Ph group. In the crystal structure of a related complex, *trans*-$Mo(N_2)_2[PhP(CH_2CH_2PPh_2)_2]$, the two Mo—N distances are different; 1.998(4) and 2.018(4) Å.[16] The particular hydrazido(2−) complex formed will depend upon which N_2 ligand is protonated. Protonation of N_2 *syn* to the Ph group yields the **A** (*syn*) isomer, whereas protonation of the other N_2 affords the **B** (*anti*) isomer. The results from experiments indicate that formation of the **B** isomer is favoured, 2:1. The observation of isomers resulting from the orientation of the Ph group on the central phosphorus atom has been reported for an iridium and ruthenium complex containing $PhP(CH_2CH_2CH_2PR_2)_2$, where R = Ph and c-C_6H_{11}.[17]

An important geometrical feature that was revealed in the crystal structure but not reported previously[14] is the position of the molybdenum atom relative to the P_4 plane. Thus, in both **1A(Cl)** and **2B(Cl)** molybdenum sits above the P_4 plane on the same side as five Ph groups that create a pocket. These displacements are 0.28 and 0.08 Å respectively (see Table 3). Below the plane there are three Ph groups in **1A(Cl)** and in **2B(Cl)** the Me and two Ph groups. The net result is that in **1A(Cl)** the hydrazido(2−) group is on the same side of the P_4 plane as Mo with Cl below the plane. When these two ligands change places, as observed in **2B(Cl)**, the hydrazido(2−) ligand is below the plane and

on the *opposite side to* Mo. Frequently, metal ions are displaced from an equatorial plane, particularly towards a strongly π-bonding ligand[15a,18] In **2B(Cl)** the π-bonding ligand is on the opposite side of the plane. N(1) is 1.95 Å out of the P$_4$ plane in **1A(Cl)**, whilst in **2B(Cl)** N(1) is only 1.69 Å out of the plane on the other side and therefore much closer to atoms about Mo. Molybdenum is probably displaced from the plane for two reasons: (i) because of the acute P(2)—Mo—P(4) and P(3)—Mo—P(4) angles ($\leqslant 81°$) and (ii) to minimize steric interactions between the five Ph groups.

The one significant difference in the chemical behaviour of **1A(Cl)** and **1B(Cl)** that we have observed is the relative rate of loss of PPh$_3$. In the absence of acid **1A(Cl)** does not dissociate PPh$_3$ in solution at room temperature, whereas **1B(Cl)** does. Unfortunately, while we could isolate **1B(Cl)** we were unable to obtain suitable crystals for a structure study. However, we were able to displace PPh$_3$ with PPh$_2$Me to form **2B(Cl)** and obtain suitable crystals. The PPh$_2$Me ligand has a choice of four coordination orientations depending upon the positions of the Me and two Ph groups relative to triphos. It is notable that the two Ph groups occupy positions above the plane just like PPh$_3$ in **1A(Cl)**. The Me group is *syn* to NNH$_2$. This geometric arrangement which arises both from the ligand exchange reaction [**1B(Cl)** + PPh$_2$Me → **2B(Cl)** + PPh$_3$] and direct protonation of **2** [**2** + HCl (excess) → **2A(Cl)** + **2B(Cl)**] suggests that the Me rather than the Ph group occupies the *syn* position in the **B** isomer for steric reasons. The closest non-bonding distance to N(1) is with P(2) at 2.873 Å. However, a simple calculation using trigonometry to determine nearest-neighbour interactions when a phenyl group is present instead of the methyl group in **2B(Cl)** places an *ortho* hydrogen within 1.7 Å of N(2) when the phenyl ring and Mo—N(1)—N(2) atoms are coplanar. Therefore, we propose that PPh$_3$ is labile in the **1B** isomers because of steric interactions between the hydrazido(2−) ligand and the Ph group of PPh$_3$.

Reactions of hydrazido(2−) complexes to form ammonia and hydrazine

Previously we reported yields of N$_2$, ammonia and hydrazine from the reactions of **1** and mixtures of **A** and **B** isomers with acid.[5] More recently we have been able to separate **A** and **B** and study them individually in reactions with acids (HBr, HCl, CF$_3$COOH and CF$_3$SO$_3$H), in various solvents (THF, benzene, toluene, CH$_2$Cl$_2$, MeOH and CF$_3$COOH), and at different temperatures. The general observations made previously and conclusions drawn hold true for this work.

Table 3. Mean least-square plane calculation for **1A(Cl)** and **2B(Cl)**

1A(Cl): Plane through P(1), P(2), P(3), P(4)	**2B(Cl)**: Plane through P(1), P(2), P(3), P(4)
$10.817x + 8.548y - 2.862z = 3.758$	$3.448x - 6.586y + 14.479z = 1.238$
Mo: −0.28 Å out of plane	Mo: +0.08 Å out of plane
N(1): −1.948 Å out of plane	N(1): −1.69 Å out of plane
Mo displaced towards N(1)	Mo displaced towards Cl

EXPERIMENTAL

General procedures

All preparations and reactions were carried out under a N_2 atmosphere or *in vacuo*. Compounds were handled in a water- and oxygen-free environment which was provided by use of Schlenk equipment, glovebags, and a Vacuum Atmospheres Corp. drybox. Specific procedures for carrying out acid reactions with **1** and quantitative determination of yields of N_2, ammonia and hydrazine have been reported elsewhere.[5]

Elemental analyses were performed by Galbraith Laboratories Inc., Knoxville, Tennessee.

Instrumentation

IR spectra (4000–250 cm^{-1}) were recorded on a Perkin–Elmer 283 spectrophotometer. Solid samples were run as KBr pellets. ^1H NMR spectra were recorded using a Nicolet NMC 360 spectrometer operating at 361.06 MHz. ^{31}P NMR spectra were run either on a Nicolet 360 (146.17 MHz) or Varian XL-200 (80.984 MHz) spectrometer. All spectra were recorded at ambient temperature. All chemical shifts are reported in ppm relative to Me_4Si (^1H) or 85% H_3PO_4 (^{31}P), with positive values being to low field. Phosphorus atom designations are as follows: $PhP_a(CH_2CH_2P_bPh_2)_2$, P_xR_3. No $^2J_{P_aP_b}$ was observed in these complexes. Similar observations have been noted for other complexes of molybdenum containing *mer*-triphos.[5,14,19]

Reagents and materials

Details have been given elsewhere.[5] The following complexes were prepared by published procedures: *trans*-$Mo(N_2)_2$(triphos)(PR_3), where PR_3 = PPh_3 and PPh_2Me, **1A(Cl)**, **3B(Cl)**, and mixtures of **1A(X)** and **1B(X)**.[5]

[$MoBr(NNH_2)$(*triphos*)(PPh_3)]Br [**1A(Br)**] *and* [**1B(Br)**]

To a mixture of **1A(Br)** and **1B(Br)** prepared from **1** (0.25 g, 0.25 mmol) was added PPh_3 (0.13 g, 0.5 mmol). THF (8 cm^3) was condensed (−196°C) onto the solid and the reaction mixture warmed to room temperature with swirling. The clear solution was allowed to stand (1 h) undisturbed. A brown solid was filtered off and washed with THF (10 cm^3) and pentane (10 cm^3) and dried *in vacuo*. The yield of **1A(Br)** was 33% (0.09 g, 0.08 mmol). ^{31}P NMR (CH_2Cl_2): δ 90.5 (d, 1, $^2J_{P_aP_x}$ = 146.2 Hz, P_a), 54.1 (d, 2, $^2J_{P_bP_x}$ = 16.7 Hz, P_b), 31.5 (dt, 1, P_x). ^1H NMR (CD_2Cl_2): δ 0.76 (t, CH_2, THF), 2.5 (br, PCH_2), 3.6 (t, CH_2, THF), 6.5–7.5 (m, Ph), 8.4 (br, NH_2: disappeared upon addition of D_2O).

The filtrate from the above reaction was transferred to a Schlenk tube, cooled to −196°C and evacuated. After the solution had frozen, pentane (20–30 cm^3) was added via cannula. The tube was warmed to −78°C and left undisturbed (24 h). The green solid which precipitated was filtered off, washed with pentane (10 cm^3) and dried *in vacuo*. The yield of **1B(Br)** was 65% (0.18 g, 0.16 mmol). ^{31}P NMR (THF): δ 72.75 (d, 1, $^2J_{P_aP_x}$ = 163.25 Hz, P_a), 34.55 (d, 2, $^2J_{P_bP_x}$ = 17.48 Hz, P_b), 7.96 (dt, 1, P_x). ^1H NMR (CD_2Cl_2): δ 2.5 (br, PCH_2), 6.5–7.7 (m, Ph).

[$MoCl(NNH_2)$(*triphos*)(PPh_3)]Cl [**1A(Cl)**] *and* [**1B(Cl)**]

To a mixture of **1A(Cl)** and **1B(Cl)** prepared from **1** (0.22 g, 0.22 mmol) was added PPh_3 (0.12 g, 0.45 mmol). THF (6 cm^3) was condensed in at −196°C and the reaction mixture warmed to room temperature with swirling. The clear solution was allowed to stand (18 h) undisturbed. The resulting brown solid was filtered off, washed with THF (10 cm^3) and pentane (10 cm^3) and dried *in vacuo* to afford **1A(Cl)** (18%, 0.04 g, 0.04 mmol).

Crystals of **1A(Cl)**, analytically pure and suitable for X-ray diffraction studies, were prepared by the addition of PPh_2Me in toluene rather than PPh_3 in THF.[5] The presence of a toluene of crystallization was inadvertently omitted from the original report of the structure.[14]

A sample of **1B(Cl)** was obtained in 33% yield by treating the filtrate from the above reaction as per the isolation of **1B(Br)** described above. **1B(Cl)**: ^{31}P NMR (THF): δ 84.4 (d, 1, $^2J_{P_aP_x}$ = 170.17 Hz, P_a), 37.9 (d, 2, $^2J_{P_bP_x}$ = 16.17 Hz, P_b), 32.8 (dt, 1, P_x).

[$MoBr(NNH_2)$(*triphos*)(PPh_2Me)]Br [**2B(Br)**]

To a mixture of **1A(Br)** and **1B(Br)** prepared from **1** (405 mg, 0.40 mmol) was added toluene (40 cm^3) and the suspension was filtered. To the dark greenish-amber filtrate was added dropwise PPh_2Me (0.15 cm^3, 4 equiv.). Amber microcrystals of **1A(Br)** formed almost immediately and were collected by filtration, washed with toluene and pentane. Further solid formed from the filtrate (2.5 h) and was collected as described above. The ^{31}P NMR spectrum indicated that this solid was a mixture of **1A(Br)** and **2B(Br)**. The volume of the green filtrate was reduced by *ca* 25% *in vacuo*. Lime-green microcrystals began to form and were collected

(15 h) to yield 103 mg (0.01 mmol, 24%) of **2B(Br)**. ^{31}P NMR (CD_2Cl_2): δ 67.17 (d, 1, $^2J_{P_aP_x}$ = 162.4 Hz, P_a), 32.50 (d, 2, $^2J_{P_bP_x}$ = 18.5 Hz, P_b), 3.42 (dt, 1, P_x).

[MoCl(NNH$_2$)(*triphos*)(PPh$_2$Me)]Cl [**2B(Cl)**]

Toluene (17 cm^3) was added to a mixture of **1A(Cl)** and **1B(Cl)**, prepared from **1** (298 mg, 0.30 mmol), and the suspension filtered. To the filtrate was added PPh$_2$Me (0.25 cm^3, 6 equiv.). After 15 h, **1A(Cl)** (54 mg) was removed by filtration as described in the previous experiment. The filtrate was allowed to stand for 15 h, after which time olive-green "layered" rectangular prisms of **2B(Cl)** (58 mg, 0.06 mmol, 20%) were isolated, washed with pentane and dried *in vacuo*. These crystals were suitable for an X-ray diffraction study. Found: C, 62.23; H, 5.54; N, 2.11. Calc. for $C_{47}H_{48}Cl_2MoN_2P_4 \cdot 0.5C_7H_8$: C, 62.04; H, 5.36; N, 2.87%. ^{31}P NMR (CD_2Cl_2): δ 68.97 (d, 1, $^2J_{P_aP_x}$ = 169.1 Hz, P_a), 35.52 (d, 2, $^2J_{P_bP_x}$ = 18.4 Hz, P_b), 7.32 (dt, 1, P_x). IR: ν(NH) 3205 (w), 2708 (sbr) cm^{-1}.

X-ray crystallography

Full details of the crystallographic methodologies may be found in ref. 20. Crystallographic data are given in Table 1. Molybdenum atom positions were located in a three-dimensional sharpened Patterson map; all non-hydrogen atoms were located on subsequent difference Fourier maps. Hydrogen atoms were included as fixed contributors in the final refinement cycles. Data were corrected for background, attenuators, Lorentz and polarization effects.

Since **1A(Cl)** crystallized in the non-centric space group $P2_1$, it was necessary to refine the alternative enantiomorph. Although the two structures presented no statistically significant differences in the final metrical parameters, the reported structure is that associated with the slightly lower value of R_w.

PHOSPHORUS–CARBON NUCLEAR MAGNETIC COUPLING CONSTANTS IN PHOSPHORUS(III) CYANIDES

BRUCE W. TATTERSHALL

Department of Chemistry, The University, Newcastle upon Tyne NE1 7RU, U.K.

(*Received* 21 *August* 1989; *accepted* 18 *September* 1989)

Abstract—Coupling constants $|^1J(^{31}P-^{13}C)|$ have been found to have unexpectedly large values, 60.2, 102.5 and 152.4 Hz, for $P(CN)_3$, $P(CN)_2Cl$ and $P(CN)Cl_2$, respectively, in MeCN. Significantly different values were found for solutions in 1-iodopropane. Secondary isotope shifts $^1\Delta^{31}P(^{13/12}C)$ and ^{13}C chemical shifts are also reported.

Values of $^1J(^{31}P-^{13}C)$ nuclear magnetic coupling constants in simple phosphorus(III) cyanides were required for comparison with that in a phosphorus–sulphur cage compound, α-$P_4S_3(CN)_2$.[1] The compounds $P(CN)_2Cl$ and $P(CN)Cl_2$ were made in solution with $P(CN)_3$ and PCl_3 in either MeCN or Pr^nI by Dillon *et al.*,[2] but they were identified only by rationalization of their observed ^{31}P chemical shifts by empirical interpolation methods. The ^{31}P NMR spectra were obtained for mixtures of the solutions with solid silver salts in unspun tubes, so only chemical shift information could be obtained. I have now approximately repeated this work, but with filtration of the solutions (obtained by reaction of PCl_3 with AgCN) to allow high resolution ^{31}P and ^{13}C (natural abundance) NMR spectra to be measured, and hence $^{31}P-^{13}C$ coupling constants to be obtained. The sequence of coupling constants found confirmed the original assignment of ^{31}P chemical shifts by Dillon *et al.*, and hence has established more firmly the identity of the compounds. ^{13}C chemical shifts could be assigned because of observation of similar splittings of doublets in the ^{13}C spectra, as in the ^{13}C satellite doublets in the ^{31}P spectra.

EXPERIMENTAL

All operations were carried out under nitrogen by Schlenk methods. Appropriate care was exercised in handling Pr^nI and solutions containing cyanides. PCl_3 (BDH) was used as received. AgCN (BDH) was dried by heating to 70°C under vacuum for > 5 h. MeCN was distilled from CaH_2, and Pr^nI (Aldrich) was dried over $MgSO_4$, before use. NMR spectra were measured in 10-mm diameter tubes using a Bruker WM300WB spectrometer, operating at 121.5 MHz for ^{31}P and 75.47 MHz for ^{13}C. A $(CD_3)_2CO$ capillary was used for locking. ^{31}P chemical shifts, obtained by substitution experiments using the same capillary and frequency offset, are reported relative to H_3PO_4–H_2O. ^{13}C shifts are reported relative to TMS in the external $(CD_3)_2CO$.

Typical procedure

AgCN (1.95 g, 14.6 mmol) was dried in a Schlenk tube, then suspended in MeCN (10 cm^3) and stirred rapidly while PCl_3 (0.6 cm^3, 6.9 mmol) was added slowly by pipette. Stirring was continued at 20°C for 24 h, then the mixture was filtered and the filtrate sampled for NMR.

RESULTS AND DISCUSSION

Preparation of compounds

The ^{31}P NMR spectrum of the solution of $P(CN)_nCl_{3-n}$ ($n = 0$–3) in MeCN (see Experimental), accumulated between 1 and 17 h after filtration, showed PCl_3 (37.0% of total P), $P(CN)Cl_2$ (3.9%), $P(CN)_2Cl$ (4.1%) and $P(CN)_3$ (37.1%), an unknown product with singlet absorption at −98.24 ppm (8.2%), and several unidentified more minor products. The product distribution resembled that reported by Dillon *et al.* "shortly after preparation",[2] but while they found that "by the following day" their mixture (still in the presence of silver salts) had undergone a redistribution reaction to produce more $P(CN)Cl_2$ and $P(CN)_2Cl$, in what was believed to be a state of equilibrium, I have found that the filtered solution showed prac-

tically the same low concentrations (3.5 and 3.9%, respectively) of $P(CN)Cl_2$ and $P(CN)_2Cl$ in a second accumulation of the spectrum started 48 h after the first. [$P(CN)_3$ now represented 32.9% of the phosphorus content, and PCl_3 42.5%.] Since it is hard to believe that the relative concentrations now reported could have been those of thermodynamic equilibrium, it is probable that the rates of redistribution reactions were negligible at room temperature, and that the measured concentrations of cyanide-containing products reflected the relative rates at which these products originally left the surface of the silver salt particles.

Broadening of the ^{31}P NMR peaks by scalar coupling relaxation by quadrupolar chlorine nuclei was as expected in the order $PCl_3 > P(CN)Cl_2 > P(CN)_2Cl$, and this broadening, together with low concentration and low natural abundance of the ^{13}C isotopomer, made it impossible to distinguish the satellite ^{31}P NMR spectrum of $P(^{13}CN)Cl_2$ from noise, although a small doublet was tentatively assigned to this compound in the corresponding ^{13}C NMR spectrum, where the complication of an overlying main spectrum was absent. In order to confirm this assignment, by observation of the satellite doublet in the ^{31}P NMR spectrum, a higher concentration of $P(CN)Cl_2$ was required. Consequently, the preparative reaction was repeated, but with Pr^nI instead of MeCN as solvent, since this was reported to yield $P(CN)Cl_2$ rather than $P(CN)_3$ as the initial product.[2] In order to observe this, the reaction mixture was filtered after stirring for only 100 min after addition of the PCl_3, and a 16 h ^{31}P NMR accumulation was started immediately. The spectrum showed 93.9% of total phosphorus remaining as PCl_3, but already the concentration of $P(CN)_3$ (3.0%) exceeded that of $P(CN)Cl_2$ (0.3%). Clearly the use of MeCN as solvent favoured the production of $P(CN)_3$, but use of Pr^nI was not a good way of making $P(CN)Cl_2$ instead. The solution was reunited with the precipitate of silver salts, and stirred at 20°C for a further 4 days. Concentrations were now PCl_3 (75.8%), $P(CN)Cl_2$ (7.1%), $P(CN)_2Cl$ (4.5%) and $P(CN)_3$ (6.6%), along with other minor products. These concentrations allowed satellite doublets to be found in the ^{31}P NMR spectrum for all three cyano compounds. The ^{13}C NMR spectrum of $P(CN)Cl_2$ was now clearly distinguishable from noise, but surprisingly that of $P(CN)_2Cl$ could not be found in this case.

Chemical shifts

^{31}P chemical shifts of the cyano compounds in MeCN were different from those in Pr^nI (Table 1) by much more than the appropriate magnetic susceptibility corrections. Dillon *et al.* proposed that this reflected specific interactions between MeCN and these solutes, but that only $P(CN)_3$ was "markedly affected".[2] The present, more detailed data showed the following trends (Table 1): (a) the decrement in shift on replacing Cl by CN was in each case less for solution in Pr^nI than in MeCN; (b) these differences in decrements accumulated so that while PCl_3 absorbed to higher frequency in MeCN than in Pr^nI, $P(CN)_3$ absorbed 8.11 ppm to lower frequency in MeCN than in Pr^nI; and (c) the decrement between $P(CN)_2Cl$ and $P(CN)_3$ was for both solvents much less than the other decrements.

The ^{13}C chemical shifts (Table 1) formed a regular series. There was little change in shift in going from solution in MeCN to solution in Pr^nI, though the decrement in chemical shift between $P(CN)Cl_2$ and $P(CN)_3$ was slightly less (9.10 ppm) in solution in MeCN than in Pr^nI (10.73 ppm).

Table 1. Chemical shifts and chemical shift differences (ppm) for $P(CN)_nCl_{3-n}$ ($n = 0$–3)

	^{31}P chemical shifts					^{13}C chemical shifts	
	In solution in MeCN		In solution in Pr^nI		Difference	Solution	Solution
Compound	Shifts	Differences	Shifts	Differences	$\delta(MeCN)-\delta(Pr^nI)$	in MeCN	in Pr^nI
PCl_3	220.63		218.81		1.82		
		126.83		125.98			
$P(CN)Cl_2$	93.80		92.83		0.97	119.64	116.93
		128.26		125.01			
$P(CN)_2Cl$	−34.46		−32.18		−2.28	115.29	[a]
		103.37		97.54			
$P(CN)_3$	−137.83		−129.72		−8.11	110.54	106.20

[a] Not observed.

Coupling constants

The relatively wide range of ^{31}P NMR chemical shifts for the mixtures, the broadening of the ^{31}P NMR peaks by scalar coupling relaxation by chlorine, and the difficulties inherent in observing satellite spectra, made the accuracy of ^{31}P–^{13}C coupling constants obtained from the ^{31}P spectra considerably less than of those obtained from the ^{13}C spectra. Consequently, except for the case of $P(CN)_2Cl$ in Pr^nI, the values presented in Table 2 are from the ^{13}C spectra, and comparison with those from the ^{31}P spectra was used to confirm the ^{13}C shift assignments.

Absolute values of the $^1J(^{31}P–^{13}C)$ coupling constants (Table 2) increased strongly as cyanide ligands were replaced by the more electronegative chloride. This trend was consistent with, but more extreme than, increases in $^1J(^{31}P–^{15}N)$ in going from $P(^{15}NCS)_3$ to $P(^{15}NCS)_2Cl$,[1] or from $P(^{15}NMe_2)(^{14}NMe_2)_2$ to $P(^{15}NMe_2)Cl_2$,[3] and with the algebraic decrease in $^1J(^{31}P–^{13}C)$ in going from $P(^{13}CH_3)(^{12}CH_3)_2$ (−13.6 Hz) to $P(^{13}CH_3)Cl_2$ (−45 Hz).[4] Most reported $^1J(^{31}P–^{13}C)$ couplings for three-coordinate phosphorus compounds are for alkyl derivatives, and values differ little from that for Me_3P, except in cases of ring strain or steric crowding (typical range 0 to −40 Hz).[5] Orbital involvement in P—C bonding in phosphorus(III) cyanides will clearly be very different from that in alkyl derivatives, but some similarity in size of $^1J(^{31}P–^{13}C)$ might have been expected between phosphorus(III) cyanides and corresponding acetylides. However, $^1J_{PC}$ has been reported as +8.8 Hz for $(MeC{\equiv}C)_3P$, moving to relatively small negative values with substitution of more electronegative groups [as in e.g. $(MeC{\equiv}C)P(OEt)_2$ (−39.1 Hz) or $(HC{\equiv}C)P(OEt)_2$ (−50.0 Hz)].[6] It is very probable that the numerically larger coupling constants reported here are negative.

Changes of chemical shift with solvent, such as those reported here, are common and could reflect only a comparatively weak solute–solvent interaction. However, $^1J_{PC}$ was also strongly affected by solvent (Table 2), the couplings for solution in MeCN being consistently 5–7 Hz numerically larger than for solution in Pr^nI. This was a stronger pointer to specific interaction between MeCN and the phosphorus(III) cyanides. If numerically increased coupling constants here reflected stronger P—C bonds, then these would have been consistent with the favouring of the formation of P—CN bonds by the use of MeCN as a solvent.

Table 2. Coupling constants $|^1J(^{31}P–^{13}C)|$ (Hz) for $P(CN)_nCl_{3-n}$ (n = 1–3)

Compound	In solution in MeCN	In solution in Pr^nI	Difference $\|J(MeCN)-J(Pr^nI)\|$
$P(CN)Cl_2$	152.4	145.7	6.7
$P(CN)_2Cl$	102.5	96.9	5.6
$P(CN)_3$	60.2	55.1	5.1

Secondary isotope shifts

Isotope shifts $^1\Delta^{31}P(^{13/12}C)$, for solution in Pr^nI, increased numerically slowly in the sequence $P(CN)_3 < P(CN)_2Cl < P(CN)Cl_2$ (−0.043, −0.049 and −0.053 ppm, respectively), probably corresponding to increasing bond strengths as the series of $^1J_{PC}$ coupling constants did for these compounds. In contrast to the couplings, for the two cases measured [$P(CN)_3$ and $P(CN)_2Cl$], the secondary isotope shifts in solution in MeCN were not significantly different from those in Pr^nI.

Acknowledgements—Miss C. J. Dodds is thanked for her contribution during an undergraduate product, and Dr M. N. S. Hill for obtaining the NMR spectra.

STUDIES ON TETRAMETALLIC COMPLEXES OF FERROCENE

P. P. SINGH* and N. B. SINGH

Chemistry Department, Bareilly College, Bareilly—243001, India

(*Received* 13 *April* 1989; *accepted* 12 *September* 1989)

Abstract—Tetrametallic complexes having four different metals, mercury, iron, M and M′ (M = Ni^{II}, Co^{II}, Cu^{II}, Zn^{II} and Mn^{II}; M′ = Co^{II} and Ni^{II}) have been prepared by reacting $Fe(C_5H_4HgSCN)_2M(NCS)_2$ with M′(salen) [salen = $(C_6H_4CH{=}NCH_2O)_2$]. All the complexes have been characterized by elemental analyses, molar conductance, magnetic moment, IR and electronic spectral studies. The studies indicate that the geometry around M in the complexes is octahedral. Additional support for the proposed structure has been provided by softness parameters.

In this paper studies on a new class of complexes containing four different metals are presented, for the first time.

EXPERIMENTAL

Reagent grade solvents were purified before use. $M(NCS)_2$ (M = Ni^{II}, Co^{II}, Cu^{II}, Zn^{II} and Mn^{II}) were prepared by reacting their respective nitrates with KNCS in ethanol. Co(salen) and Ni(salen) were prepared and recrystallized by the method described elsewhere.[1] $Fe(C_5H_4HgSCN)_2M(NCS)_2$ and the tetrametallic complexes [$Fe(C_5H_4HgSCN)_2M(NCS)_2M'(C_6H_4CH{=}NCH_2O)_2$] were prepared as given below.

Preparation of $Fe(C_5H_4HgSCN)_2M(NCS)_2$ (M = Ni^{II}, Co^{II}, Cu^{II}, Zn^{II} *and* Mn^{II})

To a solution of 18.4 g (0.1 mol) of ferrocene in dry benzene, a homogeneous suspension of 32.8 g (0.1 mol) of mercuric acetate in methanol was slowly added with stirring. A dark brown solution was obtained, to which a water solution of 9.7 g (0.1 mol) of KSCN was added and stirred. An orange precipitate was formed, which was separated. This precipitate was subjected to Soxhlet extraction using 1,2-dichloroethane as solvent, several times until the extract became colourless. The residue was FMBT, which was purified by dissolving in DMSO, followed by addition of water. FBMT was dissolved in a small quantity of DMSO and diluted to 100 cm^3 with acetone. To this solution an acetone solution of an equimolar quantity of $M(NCS)_2$ was added and stirred for 24 h. A precipitate which appeared in each case was filtered, washed with ethanol and dried *in vacuo*. The compounds were recrystallized from an acetone–ethanol mixture.

Preparation of tetrametallic complexes [$Fe(C_5H_4HgSCN)_2M(NCS)_2M'(C_6H_4CH{=}NCH_2O)_2$] (M = Ni^{II}, Co^{II}, Cu^{II}, Zn^{II} *and* Mn^{II}; M′ = Co^{II} *and* Ni^{II})

$Fe(C_5H_4HgSCN)_2M(NCS)_2$ (1 mmol) was dissolved in 10 cm^3 of DMSO and diluted to 100 cm^3 with 1,2-dichloroethane. An equimolar quantity of $M'(C_6H_4CH{=}NCH_2O)_2$ was dissolved in the same solvent. The two solutions were mixed and stirred for 36 h at room temperature. In each case a precipitate appeared which was filtered, washed with petroleum ether and dried *in vacuo*. The compound was recrystallized by dissolving in DMSO, followed by the addition of water.

Analyses of the complexes

The compounds were analysed for cobalt as anthranilate, nickel as dimethylglyoximate, sulphur as sulphate and mercury as sulphide. Nitrogen was estimated by semi-micro Kjeldahl's method. Analytical results along with melting points are presented in Table 1.

[a] All the complexes are decomposed.

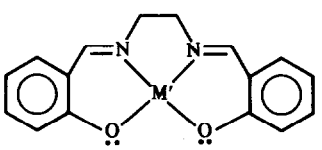
Physical measurements

The molar conductance of the complexes were measured in DMSO using a Toshniwal conductivity bridge type CL01/02A. The magnetic susceptibility measurements were carried out at room temperature by Gouy's method using $CoHg(SCN)_4$ as standard. The diamagnetic corrections were made using Pascal's constants. IR spectra of the compounds were recorded as Nujol mulls on a Pye Unicam SP-3-300 spectrophotometer in the range 4000–200 cm^{-1}. Electronic spectra in the range 200–999 nm were recorded on a Pye Unicam SP-5-500 spectrophotometer.

RESULTS AND DISCUSSION

M′(salen)[M′ = Ni^{II} *and* Co^{II}; salen = $(C_6H_4CH{=}NCH_2O)_2$]

These compounds are reported to act as bidentate ligands through oxygen atoms towards transition and non-transition metals.[2-4] The coordination geometry around M′ in M′(salen) is square-planar[4] as shown in Fig. 1. The Co(salen) has one unpaired electron and the magnetic moment value is 2.10 BM whereas the Ni(salen) is diamagnetic. The IR spectral band at 1536 cm^{-1} in M′(salen) has been assigned to C—O bond stretching[5] and the frequency of this absorption is expected to increase, when it is involved in coordination. The IR spectral bands at 1380 and 1340 cm^{-1} are assigned to the imino group in M′(salen). The electronic spectral bands of Co(salen) are present at 18,750 and 10,240 cm^{-1} and are assigned to $^2A_{1g} \rightarrow {}^2E_g$ and $^2A_{1g} \rightarrow {}^2B_{2g}$ transitions, respectively.



(M′ = Ni^{II} and Co^{II})

Fig. 1.

$Fe(C_5H_4HgSCN)_2M(NCS)_2$ (M = Ni^{II}, Co^{II}, Cu^{II}, Zn^{II} *and* Mn^{II})

These compounds are reported to act as Lewis acids.[6-8] The IR spectra, magnetic moment values, molar conductance and electronic spectral data are presented in Table 2, which indicate that the geometry[8-11] around M is tetrahedral when M is Co^{II}, Mn^{II} and Zn^{II}, and octahedral when Cu^{II} or Ni^{II}, through axial bonding as shown in Fig. 2(a) and (b), respectively.

Tetrametallic complexes $Fe(C_5H_4HgSCN)_2M(NCS)_2$ $M'(C_6H_4CH{=}NCH_2O)_2$ (M = Ni^{II}, Co^{II}, Cu^{II}, Zn^{II} *and* Mn^{II}; M′ = Co^{II} *and* Ni^{II})

The coordination number of M in $Fe(C_5H_4HgSCN)_2M(NCS)_2$, where M is Co^{II}, Zn^{II} and Mn^{II}, is four against the maximum of six. Due to this unsaturation at M, they have been referred to as Lewis acids. When M is Ni^{II} or Cu^{II} the six coordination has been achieved through weak axial bonding which can easily be replaced by ligands. Accordingly, both types of compounds have the potentiality of behaving as an acceptor, and reacting with ligands. Ni(salen) and Co(salen) act as bidentate ligands. On reaction with these acceptors they form adducts of the general formula $Fe(C_5H_4HgSCN)_2M(NCS)_2M'(C_6H_4CH{=}NCH_2O)_2$, which have four different metals and are the first of their types.

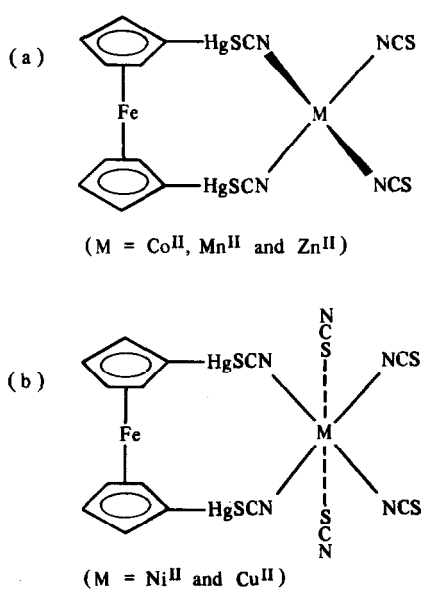

Fig. 2.

A change in the phenolic C—O stretching mode in the 1500–1600 cm^{-1} region can be used to indicate coordination through the oxygen of M′(salen). A comparison of the IR spectra of Co(salen) and Ni(salen) with the spectra of adducts show that there is a positive shift in the bands assigned to phenolic C—O stretching (Table 2). The positive shift in phenolic C—O stretching indicates coordination of M′(salen) through the oxygen atom to M of $Fe(C_5H_4HgSCN)_2M(NCS)_2$. The other possible site of coordination is the imino group of M′(salen). The bands at 1380 and 1340 cm^{-1} assigned to the imino group remain unaltered.

The position of IR bands diagnostic of thio-

s = strong, m = medium, sh = shoulder, w = weak.

Bands at 18,750 and 10,240 cm^{-1} in the electronic spectra are assigned to ν_3 and ν_2 in Co(salen) and are also observed in the corresponding adducts.

cyanate regions have also been examined, to see the effect of coordination through the oxygen atom of M′(salen) to M of $Fe(C_5H_4HgSCN)_2M(NCS)_2$. The coordination of M′(salen) will change the geometry of Co^{II}, Mn^{II} and Zn^{II} from tetrahedral in the Lewis acids to octahedral in the adducts. The change will affect the positions of IR spectral bands and also the electronic spectral parameters. The positions of the δ (M—NCS) bands, where M is Co^{II}, Zn^{II} and Mn^{II}, is changed from 280–325 to 230–290 cm^{-1}. This negative shift is on account of a change in the tetrahedral geometry around M in the Lewis acids to octahedral[9–11] in the adducts. Such a change is not observed when M is Ni^{II} or Cu^{II}, because the geometry around M remains octahedral both in the Lewis acids and the adducts. The IR

spectra of adducts (Table 2) show that there is no significant change in the positions of the ν(C—N), ν(C—S) and δ(NCS) bands. This shows that the bridging nature of thiocyanate in the Lewis acids is retained in the adducts.

The electronic spectral data of the Lewis acids and the adducts, where M is Co^{II} and Ni^{II}, are presented in Table 2. Adducts where M is Co^{II} show the presence of two bands in the region 21,740–22,220 and 15,150 cm^{-1}, which are assigned to $^4A_{2g} \rightarrow {}^4T_{2g}$ (F) (ν_3) and $^4A_{2g} \rightarrow {}^4T_{1g}$ (P) (ν_2) transitions, respectively. In the Lewis acids of Co^{II}, two intense bands were present in the region 15,400 and 6100 cm^{-1} assigned to $^4A_2 \rightarrow {}^4T_2$ (F) (ν_3) and $^4A_2 \rightarrow {}^4T_1$ (P) (ν_2) transitions, respectively. This shows that the positions of the electronic spectral bands have changed from the tetrahedral to octahedral region. Accordingly, spectral parameters Dq, β and B' have also changed. The adducts where M is Ni^{II} show the presence of three bands in the region 24,250–25,640, 16,250–16,380 and 10,400–10,640 cm^{-1} which are assigned to $^3A_{2g} \rightarrow {}^3T_{1g}$ (P)

Table 3. $\Delta E^{\ddagger}_{nm(\text{eff})}$ derived from $E^{\ddagger}_{n(\text{eff})}$ of M in $Fe(C_5H_4HgSCN)_2M(NCS)_2$ and the oxygen centre of Ni(salen) and Co(salen) in the formation of adducts

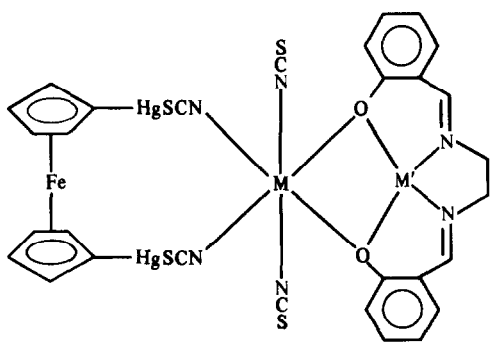
L = $Co(C_6H_4CH{=}NCH_2O)_2Co$(salen) and $Ni(C_6H_4CH{=}NCH_2O)_2Ni$(salen).

(ν_3), $^3A_{2g} \rightarrow {}^3T_{1g}(F)$ (ν_2) and $^3A_{2g} \rightarrow {}^3T_{2g}(F)$ (ν_1) transitions, respectively. In the Lewis acid of Ni^{II} these bands were contained in the regions 27,790, 16,650 and 10,400 cm^{-1}. This shows that the electronic spectral bands and spectral parameters (Dq, β and B') in adducts are changed slightly but are in the octahedral region, indicating octahedral geometry around M in Lewis acids and adducts also.

The magnetic moment value of $Fe(C_5H_4HgSCN)_2Ni(NCS)_2$ is 3.07 BM and that of the Ni(salen) adduct is 3.25 BM. Since the two values are very similar, it can be inferred that the diamagnetic nature of Ni(salen) is not disturbed and it does not contribute to the magnetic moment value of the adduct. The cobalt analogue, however, causes an increase in the magnetic moment value to 6.70 BM, which is the sum of the magnetic moment values of the Lewis acid and of the Co(salen). Thus the magnetic moment value of $Fe(C_5H_4HgSCN)_2M(NCS)_2Ni(C_6H_4CH{=}NCH_2O)_2$ is entirely due to paramagnetism of M, because $Ni(C_6H_4CH{=}NCH_2O)_2$ does not contribute on account of its diamagnetic character. The magnetic moment values of M in $Fe(C_5H_4HgSCN)_2M(NCS)_2Co(C_6H_4CH{=}NCH_2O)_2$ are raised because $Co(C_6H_4CH{=}NCH_2O)_2$ contributes to the magnetic moment in the range of 2.1–2.8 BM.[12] All the adducts are non-conducting in nature. On the basis of these results the structure shown in Fig. 3 is proposed for the adducts.



(M = Ni^{II}, Co^{II}, Cu^{II}, Zn^{II} and Mn^{II}; M' = Co^{II}, Ni^{II})

Fig. 3.

Quantitative softness parameters

The effective softness values of metal and base ions have been denoted by $E^{\ddagger}_{n(\text{eff})}$ and $E^{\ddagger}_{m(\text{eff})}$, respectively and the difference between the two by $\Delta E^{\ddagger}_{nm(\text{eff})}$. These values have been derived by adopting the procedure described elsewhere.[13] The $\Delta E^{\ddagger}_{nm(\text{eff})}$ between $E^{\ddagger}_{n(\text{eff})}$ of M in $Fe(C_5H_4HgSCN)_2M(NCS)_2$ and $E^{\ddagger}_{m(\text{eff})}$ at oxygen in Ni(salen) and Co(salen) have been derived, and are presented in Table 3. The $\Delta E^{\ddagger}_{nm(\text{eff})}$ values of Ni(salen) adducts are higher than Co(salen) adducts, indicating that Ni(salen) forms more stable M—L bonds than Co(salen). $\Delta E^{\ddagger}_{nm(\text{eff})}$ values are highest when M is Ni^{II} and lowest when M is Mn^{II}. This indicates that nickel forms more stable bonds with these ligands than manganese, and the sequence is as follows: nickel > cobalt > zinc > manganese.

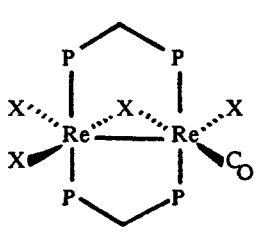
(*Received* 15 *June* 1989; *accepted* 11 *September* 1989)

Abstract—The 1 : 1 carbonyl adduct $Re_2Cl_4(dppm)_2(CO)$ reacts with PMe_3 in CH_2Cl_2 at room temperature to afford the green diamagnetic complex $[Re_2Cl_3(dppm)_2(CO)(PMe_3)_2]Cl$. When similar reactions are carried out in the presence of $NaBPh_4$ or $TlPF_6$, with THF or CH_2Cl_2 as the reaction solvents, respectively, the salts $[Re_2Cl_3(dppm)_2(CO)(PMe_3)_2]X$ (X = BPh_4 or PF_6) are produced. Similar procedures have been used to prepare the bromo-derivative $[Re_2Br_3(dppm)_2(CO)(PMe_3)_2]PF_6$, and the phosphite complexes $\{Re_2Cl_3(dppm)_2(CO)[P(OR)_3]_2\}PF_6$ (R = Me or Et). IR spectroscopy shows that the CO ligand is bridging the two metal centres (ν(CO) *ca* 1635 cm^{-1} for the PMe_3 complexes and *ca* 1680 cm^{-1} for the $P(OR)_3$ derivatives). This conclusion has been confirmed by a crystal structure determination on $[Re_2Cl_3(dppm)_2(CO)(PMe_3)_2]Cl \cdot 1/2CH_2Cl_2$. The crystallographic data are as follows: triclinic space group $P\bar{1}$, $a = 13.261(1)$, $b = 19.246(2)$, $c = 11.860(2)$ Å, $\alpha = 97.57(1)$, $\beta = 98.98(1)$, $\gamma = 79.08(1)°$, $V = 2919(1)$ $Å^3$ and $Z = 2$. The structure was refined to $R = 0.043$ ($R_w = 0.056$) for 5949 data with $I > 3.0\sigma(I)$. The dirhenium cation has the structure of an edge-shared bioctahedron with virtual C_{2v} symmetry. There is a *trans* disposition of bridging dppm ligands. The equatorial plane contains a bridging carbonyl and a bridging chloride ligand. The three chloride ligands are in an all-*cis* arrangement to one another on one side of this plane; the two PMe_3 ligands are *cis* to the μ-CO ligand. The Re—Re distance is 2.602(1) Å.

The monocarbonyl complexes of stoichiometry $Re_2X_4(dppm)_2(CO)$ (**1**; X = Cl or Br; dppm = $Ph_2PCH_2PPh_2$),[1,2] which are formed upon treating the triply bonded dirhenium(II) complexes



1

$Re_2X_4(dppm)_2$[3,4] with CO, react with additional equivalents of the π-acceptor CO ligand to form, sequentially, $Re_2(\mu\text{-}X)(\mu\text{-}CO)(\mu\text{-dppm})_2X_3(CO)$ (**2**)[1] and $[Re_2(\mu\text{-}X)(\mu\text{-}CO)(\mu\text{-dppm})_2X_2(CO)_2]^+$ (**3**),[5] species in which a metal–metal bonded dimetal unit is preserved. In a recent study,[6] in which the dicarbonyl complexes **2** were reacted with PMe_3 and $P(OR)_3$ ligands (R = Me or Et) in the presence of $TlPF_6$, the "phosphine-rich" species $[Re_2(\mu\text{-}X)(\mu\text{-}CO)(\mu\text{-dppm})_2X_2(CO)(L)]PF_6$ (L = PMe_3, $P(OMe)_3$ or $P(OEt)_3$) were isolated. These complexes were found to contain a semi-bridging CO ligand, a bonding mode which is probably a consequence of the charge disparity that is introduced in these unsymmetric species because of the disparate donor/acceptor properties associated with the terminal CO and PR_3 (or $P(OR)_3$) ligands.

In the present report, we describe the reactions of **1** (**a**, X = Cl; **b**, X = Br) with PMe_3, $P(OMe)_3$

*Author to whom correspondence should be addressed.

and $P(OEt)_3$ to give salts of the $[Re_2X_3(dppm)_2(CO)(L)_2]^+$ cations, in which the metal–metal bonded dirhenium unit is retained. The properties of these complexes are described, including a report on the X-ray crystal structure of the chloride salt $[Re_2Cl_3(dppm)_2(CO)(PMe_3)_2]Cl$.

EXPERIMENTAL

Starting materials

The monocarbonyl complexes $Re_2X_4(dppm)_2(CO)$ (X = Cl or Br) were prepared from the reactions of $Re_2X_4(dppm)_2$ with CO according to the established procedure.[1,2] Carbon monoxide (99.9%) was purchased from Matheson Gas Products. The tertiary phosphine and phosphite ligands were obtained from Strem Chemicals and Aldrich Chemical Co., respectively. Solvents used in the preparation of the complexes were of commercial grade and were thoroughly deoxygenated prior to use.

Reaction procedures

All reactions were performed under an atmosphere of dry dinitrogen.

(a) *Synthesis of* $[Re_2Cl_3(dppm)_2(CO)(PMe_3)_2]Cl$. A mixture of **1a** (0.047 g, 0.036 mmol) and PMe_3 (0.010 cm^3, 0.10 mmol) in dichloromethane (10 cm^3) was stirred at room temperature for 48 h. The green precipitate that resulted was filtered off, washed with a diethyl ether–methanol mixture (10:1, 10 cm^3), then with diethyl ether (25 cm^3), and finally dried *in vacuo*, yield 0.019 g (36%). Found: C, 46.7; H, 4.5. Calc. for $C_{57}H_{62}Cl_4OP_6Re_2$: C, 46.8; H, 4.3%.

(b) *Synthesis of* $[Re_2Cl_3(dppm)_2(CO)(PMe_3)_2]BPh_4$. A mixture of **1a** (0.079 g, 0.060 mmol), $NaBPh_4$ (0.021 g, 0.060 mmol) and 2 equiv. of PMe_3 (0.012 cm^3, 0.120 mmol) in THF (15 cm^3) was stirred at room temperature for 48 h. The colour of the reaction mixture changed from amber to green. The resulting green mixture was filtered to remove the white precipitate of NaCl. The filtrate was evaporated to dryness and the residue was extracted with 10 cm^3 of dichloromethane. The extract was filtered and the product isolated as green crystals by allowing cyclohexane vapour to diffuse into the solution contained within a closed system; yield 0.03 g (29%). Found: C, 56.1; H, 5.4. Calc. for $C_{81}H_{82}BCl_3OP_6Re_2$: C, 55.7; H, 4.7%.

(c) *Synthesis of* $[Re_2X_3(dppm)_2(CO)(PMe_3)_2]PF_6$ (X = Cl *or* Br). (i) X = Cl: A mixture comprising **1a** (0.019 g, 0.083 mmol), $TlPF_6$ (0.029 g, 0.083 mmol), and *ca* 3.6 equiv. of PMe_3 (0.03 cm^3, 0.295 mmol) in dichloromethane (10 cm^3) was stirred at room temperature for 48 h. The resulting green reaction mixture was filtered to remove the precipitated TlCl and the filtrate evaporated to dryness. The residue was extracted with a small volume of dichloromethane and filtered. The filtrate was transferred to a test tube that was, in turn, placed inside another tube of larger diameter that contained 10 cm^3 of hexane. The larger tube was capped under N_2(g) with a septum. The slow diffusion of hexane vapour into the dichloromethane solutions of the complex was allowed to take place. After 2 weeks, the green crystals that had formed on the side and at the bottom of the inner tube were collected, then washed with a 10 cm^3 portion of a diethyl ether–dichloromethane mixture (10:1) followed by 5 cm^3 of diethyl ether, and finally dried *in vacuo*; yield 0.068 g (52%). Found: C, 43.4; H, 4.2. Calc. for $C_{57}H_{62}Cl_3F_6OP_7Re_2$: C, 43.5; H, 4.0%.

(ii) X = Br: This complex was prepared from **1b** with the use of a procedure similar to that described in section c(i); yield, 52%. Found: C, 40.3; H, 4.0. Calc. for $C_{57}H_{62}Br_3F_6OP_7Re_2$: C, 40.1; H, 3.7%.

(d) *Synthesis of complexes of the type* $\{Re_2Cl_3(dppm)_2(CO)[P(OR)_3]_2\}PF_6$. These complexes were prepared, in the case of R = Me or Et, by the reaction of **1a** with the appropriate phosphite ligand with the use of a procedure very similar to that described in c(i). In all instances, the products were obtained as green crystals or powders.

(i) R = Me: Yield, 26%. Found: C, 40.6; H, 3.8. Calc. for $C_{57}H_{62}Cl_3F_6O_7P_7Re_2$: C, 41.0; H, 3.8%.

(ii) R = Et: Yield, 24%. Found: C, 42.4; H, 4.1. Calc. for $C_{63}H_{74}Cl_3F_6O_7P_7Re_2$: C, 43.2; H, 4.3.%.

Preparation of single crystals of $[Re_2Cl_3(dppm)_2(CO)(PMe_3)_2]Cl \cdot 1/2CH_2Cl_2$. A solution of PMe_3 (2 equiv.) in 5 cm^3 of CH_2Cl_2 was carefully layered over a similar solution containing **1a** (1 equiv.). This mixture was sealed under a N_2(g) atmosphere; diffusion of the solutions resulted in a colour change from amber to green. When the solvent was allowed to slowly evaporate from this mixture, suitable crystals of the title complex were obtained.

X-ray crystallographic studies

The structure of $[Re_2Cl_3(dppm)_2(CO)(PMe_3)_2]Cl \cdot 1/2CH_2Cl_2$ was determined with the use of general procedures that are described elsewhere.[7] A summary of the crystallographic data is given in Table 1. The cell constants are based on 25 reflections with $21° < \theta < 23°$. Three standard reflections were measured after every 5000 s of beam time during data collection. There was no systematic variations in intensity. Calculations were performed

[e] Goodness-of-fit $= [\Sigma w(|F_o| - |F_c|)^2 / (N_{obs} - N_{parameters})]^{1/2}$.

on a MicroVAX II computer using the Enraf–Nonius structure determination package.

The crystal selected for the structure determination belongs to the triclinic space group $P\bar{1}$ with $Z = 2$. As a check on crystal quality, omega scans of several intense reflections were measured; the width at half-height was 0.78° with a take-off angle of 1.9°, indicating relatively poor crystal quality. The structure was solved by the use of the Patterson heavy-atom method, which revealed the positions of the rhenium atoms in the asymmetric unit. The remaining atoms were located in succeeding difference Fourier syntheses. Refinement of the outer-sphere chloride anion [Cl(1000)] proceeded satisfactorily. Lorentz and polarization corrections were applied to the data. An empirical absorption correction was applied,[8] the linear absorption coefficient being 46.49 cm^{-1}. No corrections for extinction were applied. The structure was refined in full-matrix least-squares where the function minimized was $\Sigma w(|F_o| - |F_c|)^2$, where w is the weighting factor defined as $w = 1/\sigma^2(F_o)$.

During the course of the refinement, it became apparent that residual electron density at non-

bonding distances to the dirhenium cation and Cl^- anion could be satisfactorily modelled as lattice dichloromethane. This was located on a general position, and it refined to a site of half occupancy, the carbon and chlorine atoms having satisfactory thermal parameters. Accordingly, the unit cell contains one molecule of CH_2Cl_2 for the pair of $[Re_2Cl_3(dppm)_2(CO)(PMe_3)_2]Cl$ molecules that are present. Hydrogens were not included in the refinement. With the exception of the lattice CH_2Cl_2 molecules, all non-hydrogen atoms were refined anisotropically; corrections for anomalous scattering were applied to all atoms so refined.[9]

Further details concerning the data set and the structure solution and refinement may be obtained from Dr P. E. Fanwick. Table 2 lists important bond distances and angles.*

Physical measurements

IR spectra were recorded as Nujol mulls between KBr plates on an IBM Instruments IR/32 Fourier transform spectrometer or a Perkin–Elmer Model 1420 spectrophotometer. Electrochemical measurements were carried out on dichloromethane solutions that contained 0.1 M tetra-*n*-butylammonium hexafluorophosphate (TBAH) as supporting electrolyte. $E_{1/2}$ values, determined as $(E_{p,a}+E_{p,c})/2$, were referenced to the silver/silver chloride (Ag/AgCl) electrode at room temperature and are uncorrected for junction potentials. Under our experimental conditions $E_{1/2} = +0.47$ V vs Ag/AgCl for the ferrocenium/ferrocene couple. Voltammetric experiments were performed with a Bioanalytical Systems Inc. Model CV-1A instrument in conjunction with a Hewlett–Packard Model 7035 B *x–y* recorder. Conductivity measurements were performed on 1×10^{-3} M acetone solutions of the complexes on an Industrial Instruments Inc. Model RC-16B2 conductivity bridge. $^{31}P\{^1H\}$ NMR spectra were recorded on a Varian XL-200 spectrometer operated at 80.98 MHz with the use of an internal deuterium lock and 85% H_3PO_4 as an external standard. ^1H NMR spectra were obtained on a Varian XL-200 spectrometer. Resonances were referenced internally to the residual protons in the incompletely deuterated solvent.

Analytical procedures

Elemental microanalyses were performed by Dr H. D. Lee of the Purdue University Microanalytical Laboratory.

* Atomic positional and thermal parameters and full listings of bond lengths and angles have been deposited with the Editor and with the Director, Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

(a) *Reactions of* $Re_2X_4(dppm)_2(CO)$ (1) *with* PMe_3, $P(OMe)_3$ *and* $P(OEt)_3$

The complex $Re_2Cl_4(dppm)_2(CO)$ (**1a**) reacts with PMe_3 in CH_2Cl_2 at room temperature to afford the green diamagnetic complex $[Re_2Cl_3(dppm)_2(CO)(PMe_3)_2]Cl$ in isolated yields of *ca* 40%. This complex dissolves in acetone ($c_m = 1.0 \times 10^{-3}$ M) to give a solution that has a conductivity ($\Lambda_m = 101\ \Omega^{-1}\ cm^2\ mol^{-1}$) characteristic of a 1:1 electrolyte.[10] When similar reactions are carried out in the presence of $NaBPh_4$ or $TlPF_6$, with THF or CH_2Cl_2 as the reaction solvents, respectively, the analogous salts $[Re_2Cl_3(dppm)_2(CO)(PMe_3)_2]X$ (X = BPh_4 or PF_6) are produced. The hexafluorophosphate salt dissolved in DMF to give a solution with properties characteristic of a 1:1 electrolyte,[10] with $\Lambda_m = 89\ \Omega^{-1}\ cm^2\ mol^{-1}$ for $c_m = 1.0 \times 10^{-3}$ M. Similar procedures have been used to prepare the diamagnetic bromo-derivative $[Re_2Br_3(dppm)_2(CO)(PMe_3)_2]PF_6$, as well as the analogous phosphite complexes $\{Re_2Cl_3(dppm)_2(CO)[P(OR)_3]_2\}PF_6$ (R = Me or Et).

The complexes mentioned above have very similar IR spectra (Nujol mulls) which show a single ν(CO) mode at frequencies characteristic of a bridging carbonyl ligand (Table 3). The electrochemical properties of these complexes, as measured by the cyclic voltammetric (CV) technique are strikingly similar. Solutions of these complexes in 0.1 M TBAH/CH_2Cl_2 show three well-defined electrochemical processes, one of which corresponds to a one-electron oxidation of the bulk complex while the other two processes are one-electron reductions. Compared to the related CV properties of the dicarbonyl complexes $[Re_2X_3(dppm)_2(CO)_2(L)]PF_6$ (X = Cl or Br; L = PMe_3, $P(OMe)_3$ or $P(OEt)_3$),[6] the monocarbonyl derivatives reported in the present work have their redox processes shifted by 0.4–0.5 V to more negative potentials. This reflects the relative electron-richness of the metal centres in the monocarbonyl complexes as a result of replacing a CO ligand (in $[Re_2X_3(dppm)_2(CO)_2(L)]PF_6$) by the better σ-donor PMe_3 and $P(OR)_3$ ligands.

In the case of $[Re_2Cl_3(dppm)_2(CO)[P(OEt)_3]_2PF_6$, we observed that the formation of the carbonyl-bridged form is favoured by the use of a fairly large excess of $P(OEt)_3$ (i.e. a stoichiometric ratio for **1a**–$P(OEt)_3$ of *ca* 1:6). The formation of this species is preceded by the generation of an intermediate that is characterized by a terminal CO ligand (ν(CO) at 1870(s) cm^{-1}) and quite different CV properties from those presented in Table 3 for the carbonyl-bridged form (i.e. $E_{1/2}(ox) = +1.42$ V, $E_{1/2}(ox) = +0.80$ V, $E_{1/2}(red) = -0.32$ V and $E_{1/2}(red) = -1.42$ V vs Ag/AgCl). This could be the 1:1 complex $\{Re_2Cl_3(dppm)_2(CO)[P(OEt)_3]\}PF_6$, or a structural variation of the 1:2 complex in which there is no bridging CO ligand.

The complexes $[Re_2Cl_3(dppm)_2(CO)(PMe_3)_2]PF_6$ and $\{Re_2Cl_3(dppm)_2(CO)[P(OMe)_3]_2\}PF_6$ gave good quality ^1H and ^{31}P NMR spectra that are representative of this group of complexes as a whole. The ^1H NMR spectrum of $[Re_2Cl_3(dppm)_2(CO)(PMe_3)_2]PF_6$ in CD_2Cl_2 shows a

Table 3. IR spectra and electrochemical properties of salts of the $[Re_2X_3(dppm)_2(CO)(L)_2]^+$ cations (X = Cl or Br; L = PMe_3, $P(OMe)_3$ or $P(OEt)_3$)

Complex	IR (cm^{-1})[a]	CV half-wave potentials (V)[b]		
	ν(CO)	$E_{1/2}$(ox)	$E_{1/2}$(red)(1)	$E_{1/2}$(red)(2)
$[Re_2Cl_3(dppm)_2(CO)(PMe_3)_2]Cl$	1637 s	+1.03(110)	−0.47(140)	−1.47(140)
$[Re_2Cl_3(dppm)_2(CO)(PMe_3)_2]BPh_4$	1630 s	+1.02(100)[c]	−0.48(90)	−1.49(110)
$[Re_2Cl_3(dppm)_2(CO)(PMe_3)_2]PF_6$	1638 s	+1.03(130)	−0.49(130)	−1.50(150)
$[Re_2Br_3(dppm)_2(CO)(PMe_3)_2]PF_6$	1635 s	+1.04(120)	−0.43(140)	−1.44(150)
$\{Re_2Cl_3(dppm)_2(CO)[P(OMe)_3]_2\}PF_6$	1683 s	+1.04(130)	−0.44(120)	−1.40(150)

[a] Recorded as Nujol mulls. The hexafluorophosphate salts show a characteristic intense ν(P—F) mode between 837 and 842 cm^{-1}.

[b] Measured in 0.1 M TBAH/CH_2Cl_2 and referenced to the Ag/AgCl electrode, with scan rate (ν) of 200 mV s^{-1} at a Pt-bead electrode. Numbers in parentheses are the $E_{p,a} - E_{p,c}$ values.

[c] An additional irreversible oxidation at $E_{p,a} = +0.92$ V is associated with the BPh_4^- anion; for $NaBPh_4$ this process is at $E_{p,a} = +0.86$ V.

[d] This process overlaps with one that arises from another species which is present in the solution (see text).

resonance at δ +1.24 due to the PMe_3 ligands, an $ABM_2X_2X'_2$ pattern centred about δ +3.8 (with individual multiplets at $\delta \simeq +4.3$ and $\simeq +3.3$) that arises from the bridgehead —CH_2— resonances of the dppm ligands, as well as several well-resolved phenyl resonances located between δ +7.9 and +6.8. The $^{31}P\{^1H\}$ NMR spectrum (recorded in CD_2Cl_2) exhibits multiplets at δ −33.2 and −57.8 (relative intensity 2:1; $J_{P-P} \simeq 6.5$ Hz) that are assigned to the dppm and PMe_3 phosphorus ligand atoms, respectively. The downfield resonance shows three resolved components, while that at δ −57.8 shows at least five components. The NMR spectrum of the trimethylphosphite complex (recorded in $(CD_3)_2CO$) is very similar to the aforementioned spectrum of its PMe_3 analogue. For example, the methyl resonance of the $P(OMe)_3$ ligands is a doublet at δ +3.34, while the —CH_2— resonance of the dppm ligands is centred at about δ +4.6 (multiplets at $\delta \simeq +5.02$ and $\simeq +4.18$) and appears as an $ABM_2X_2X'_2$ pattern. In the $^{31}P\{^1H\}$ NMR spectrum (in $(CD_3)_2CO$), multiplets at δ +62.5 and −23.8 (relative intensity ratio 1:2) are due to the $P(OMe)_3$ and dppm ligands, respectively.

(b) *Crystal structure of* $[Re_2Cl_3(dppm)_2(CO)(PMe_3)_2]Cl$

The structure of the crystallographically unique dirhenium cation, as present in the crystals of $[Re_2Cl_3(dppm)_2(CO)(PMe_3)_2]Cl \cdot 1/2CH_2Cl_2$, is that of an edge-shared bioctahedron. An ORTEP representation of the structure of the monocation is shown in Fig. 1 and gives the full atomic numbering scheme. There is no crystallographically imposed symmetry for the asymmetric unit. The important structural parameters are listed in Table 2. The bridging dppm ligands are in a *trans* disposition to one another, and the bridgehead methylene carbon atoms of this ligand fold over on the side of the cation that contains a bridging carbonyl ligand and two PMe_3 ligands. The three chloride ligands (one in a bridging disposition, the other two present in terminal Re—Cl bonds) are in an all-*cis* arrangement to one another. The virtual symmetry of the cation is C_{2v}.

The Re—Re distance is 2.602(1) Å, a value which is very similar to the values reported previously for structurally related dirhenium complexes that contain edge-shared bioctahedral geometries, e.g. 2.582(1) Å in $[Re_2Cl_3(dppm)_2(CO)_3]PF_6$[5] and 2.593(1) Å in $[Re_2Cl_3(dppm)_2(CO)_2(PMe_3)]PF_6$.[6] The structural parameters associated with the $[Re_2(\mu\text{-}Cl)Cl_2(\mu\text{-}dppm)_2]$ moiety are also very similar to those reported for related complexes.[5,6,11] Small differences between the chemically equivalent sets of Re—P and Re—Cl distances do not appear to be statistically significant (within 3σ).

The CO ligand symmetrically bridges the two metal centres. The Re—C distances are within ex-

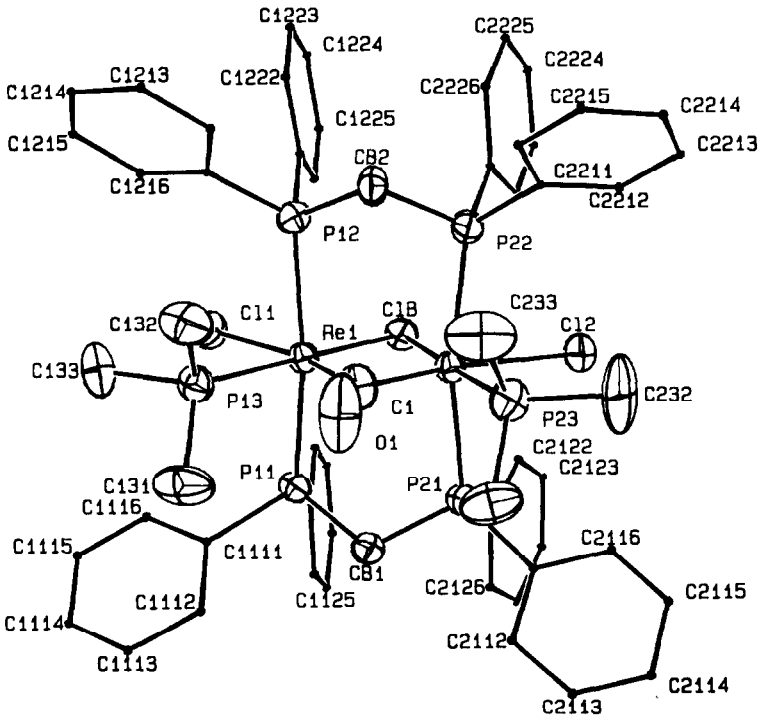

Fig. 1. ORTEP representation of the structure of the $[Re_2Cl_3(dppm)_2(CO)(PMe_3)_2]^+$ cation showing the atomic numbering scheme. The thermal ellipsoids are drawn at the 50% probability level.

perimental error the same (Re(1)—C(1) = 2.02(1) Å and Re(2)—C(1) = 2.00(1) Å), and are much longer than the Re—C bond distance of 1.90(1) Å associated with the terminal Re—CO unit in $[Re_2Cl_3(dppm)_2(CO)_2(PMe_3)]PF_6$.[6] The latter complex also contains an *unsymmetrical* CO ligand bridge whose Re—C distances are 1.96(1) and 2.16(1) Å; the Re—C distances for $[Re_2Cl_3(dppm)_2(CO)(PMe_3)_2]Cl$ are intermediate between these. The Re—P distances involving the PMe_3 ligands are essentially the same (Re(1)—P(13) = 2.434(3) Å and Re(2)—P(23) = 2.427(3) Å) and are, in turn, shorter than those associated with the dppm ligands which are in the range 2.473(3)—2.486(3) Å. These differences may largely reflect the stronger σ-donor characteristics of the more basic PMe_3 ligand (compared to dppm).

CONCLUDING REMARKS

This work shows that the sort of charge disparity that exists in the dirhenium(II) complexes of the type $[Re_2(\mu\text{-}X)(\mu\text{-}CO)(\mu\text{-}dppm)_2X_2(CO)(L)]PF_6$ (X = Cl or Br; L = PMe_3, $P(OMe)_3$ and $P(OEt)_3$), and which leads to an unsymmetrical structure (including a semibridging CO ligand),[6] is no longer present in the analogous series of complexes in which the terminal CO ligand has been replaced by PMe_3 or $P(OR)_3$. The dirhenium cations $[Re_2(\mu\text{-}X)(\mu\text{-}CO)(\mu\text{-}dppm)_2X_2(PMe_3)_2]^+$ contain a symmetrically bridging CO ligand and a symmetric disposition of dppm, PMe_3 and terminal halide ligands. Based upon the similarity of the Re—Re distances in these two groups of complexes, it seems reasonable to conclude that the electronic structures of the dirhenium cores are the same.

(*Received* 10 *July* 1989; *accepted* 11 *September* 1989)

Abstract—The synthesis of the triply bonded dirhenium(II) complexes $Re_2X_4(dpam)_2$ (X = Cl or Br; dpam = $Ph_2AsCH_2AsPh_2$) has been accomplished through the reactions of $Re_2(O_2CCH_3)_2X_4(H_2O)_2$ with dpam in hot methanol. Solutions of these complexes, and of $Re_2X_4(dppm)_2$ (X = Cl or Br; dppm = $Ph_2PCH_2PPh_2$) and $Re_2Cl_4(dppa)_2$ (dppa = $Ph_2PNHPPh_2$), in n-Bu_4NPF_6/CH_2Cl_2 have been oxidized electrochemically (at *ca* +0.5 V vs Ag/AgCl) to generate solutions of the paramagnetic, ESR-active monocations. The salts $[Re_2X_4(dppm)_2]PF_6$ have been prepared by the reaction of $Re_2X_4(dppm)_2$ with $[(\eta^5\text{-}C_5H_5)_2Fe]PF_6$ in acetone. Cyclic voltammetric data for solutions of all these complexes in 0.1 M n-Bu_4NPF_6/CH_2Cl_2 are reported. The crystal structure of $Re_2Cl_4(dppa)_2 \cdot (CH_3)_2CO$ has been determined and shown to resemble that of $Re_2Cl_4(dppm)_2$. The crystallographic data are as follows: monoclinic space group $P2_1/n$, $a = 11.382(2)$, $b = 23.273(5)$, $c = 19.212(3)$ Å, $\beta = 92.429(8)°$, $V = 5084(3)$ Å^3 and $Z = 4$. The structure was refined to $R = 0.031$ ($R_w = 0.036$) for 4490 data with $I > 3.0\sigma(I)$. The complex has a Re—Re bond distance of 2.2417(5) Å, and contains intramolecular dppa ligand bridges. A staggered rotational geometry is characterized by average Cl—Re—Re—Cl and P—Re—Re—P torsional angles of 51.7[2] and 41.8[5]°, respectively.

The triply bonded dirhenium(II) complexes $Re_2X_4(PR_3)_4$ (X = Cl, Br or I; PR_3 = monodentate phosphine) are readily converted to salts of their mono- and dicationic species $[Re_2X_4(PR_3)_4]PF_6$ and $[Re_2X_4(PR_3)_4](PF_6)_2$ that possess Re—Re bond orders of 3.5 and 4, respectively, with associated ground-state electronic configurations of $\sigma^2\pi^4\delta^2\delta^{*1}$ and $\sigma^2\pi^4\delta^2$.[1–4] The complexes $Re_2X_4(\mu\text{-}LL)_2$, where LL represents an intramolecular bridging ligand such as $Ph_2PCH_2CH_2PPh_2$ (dppe) that has a $-(CH_2)_2-$ unit linking the donor atoms of the ligands LL, have also been oxidized in this fashion and salts of the corresponding cations can be isolated in certain circumstances.[5,6]

Although $Re_2Cl_4(dppm)_2$ (dppm = $Ph_2PCH_2PPh_2$) has been oxidized to $Re_2Cl_5(dppm)_2$ and subsequently to $Re_2Cl_6(dppm)_2$, by controlled potential electrolysis in the presence of chloride ion,[7] the simple monocation $[Re_2Cl_4(dppm)_2]^+$ has never been isolated, in spite of the accessibility of two sequential one-electron oxidations as shown by electrochemical measurements on this complex.[7] The same is true for other complexes of dirhenium(II) in which there is a *single* bridgehead group linking the two phosphorus atoms of the bidentate phosphine ligand.[7]

In view of the importance of $Re_2Cl_4(dppm)_2$ and related complexes as synthetic precursors to a wide range of dirhenium complexes,[8,9] we have examined the redox chemistry of such complexes with a view

to generating and characterizing their oxidized derivatives. In the present report we describe (1) the syntheses of the new complexes $Re_2X_4(dpam)_2$ (X = Cl or Br; dpam = $Ph_2AsCH_2AsPh_2$), (2) the electrochemical and chemical oxidations of these complexes and of $Re_2X_4(dppm)_2$ (X = Cl, Br or I) and $Re_2Cl_4(dppa)_2$ (dppa = $Ph_2PNHPPh_2$), and (3) the crystal structure of $Re_2Cl_4(dppa)_2 \cdot (CH_3)_2CO$.

EXPERIMENTAL

Starting materials

The complexes $Re_2(O_2CCH_3)_2X_4(H_2O)_2$ (X = Cl, Br or I),[10] $Re_2Cl_4(dppa)_2$,[11] $Re_2X_4(dppm)_2$[12] and ferrocenium hexafluorophosphate $[(\eta^5\text{-}C_5H_5)_2Fe]PF_6$,[13] were prepared according to the reported methods. Bis(diphenylarsino)methane (abbreviated dpam) was purchased from Pressure Chemicals and was used without further purification. Solvents used in the preparation of the complexes were of commercial grade and were thoroughly deoxygenated with dinitrogen prior to use.

Reactions procedures

All reactions were performed under an atmosphere of dry dinitrogen.

(a) *Preparation of* $Re_2X_4(dpam)_2$. (i) $Re_2Cl_4(dpam)_2$: A mixture of $Re_2(O_2CCH_3)_2Cl_4(H_2O)_2$ (0.20 g, 0.24 mmol) and 4 equiv. of dpam (0.45 g, 0.96 mmol) in methanol (20 cm^3) was refluxed for 24 h. The resulting purple–brown precipitate was filtered hot and washed with 3×15 cm^3 portions of hot methanol. Recrystallization from dichloromethane–methanol at 0°C gave the product as a purple powder; yield, 0.045 g (10%). Found: C, 39.8; H, 2.9. Calc. for $C_{50}H_{44}Cl_4As_4Re_2$: C, 41.2; H, 3.0%. This sample probably contains some dichloromethane of crystallization, thereby accounting for the slightly low carbon and hydrogen elemental microanalyses.

(ii) $Re_2Br_4(dpam)_2$: The preparation of this complex was carried out in exactly the same manner as that described in section a(i); yield, 40%. Found: C, 35.7; H, 2.7; Br, 19.8. Calc. for $C_{50}H_{44}Br_4As_4Re_2$: C, 36.7; H, 2.7; Br, 19.5%.

(b) *Oxidation of* $Re_2X_4(dppm)_2$ *with* $[(\eta^5\text{-}C_5H_5)_2Fe]PF_6$. (i) $[Re_2Cl_4(dppm)_2]PF_6$: A quantity of $Re_2Cl_4(dppm)_2$ (0.20 g, 0.16 mmol) was allowed to react with 1 equiv. of $[(\eta^5\text{-}C_5H_5)_2Fe]PF_6$ (0.052 g, 0.16 mmol) in acetone (15 cm^3) for 5 min at room temperature. The resulting green–brown solution was filtered into a large excess of diethyl ether ($\simeq$ 100 cm^3) to yield a green precipitate. This was filtered off, washed with diethyl ether and dried *in vacuo*; yield, 0.19 g (85%). Found: C, 41.9; H, 3.3. Calc. for $C_{50}H_{44}Cl_4F_6P_5Re_2$: C, 42.1; H, 3.1%.

(ii) $[Re_2Br_4(dppm)_2]PF_6$: The preparation of this complex was carried out in exactly the same manner as that described in section b(i); yield, 70%. Found: C, 37.9; H, 3.0. Calc. for $C_{50}H_{44}Br_4F_6P_5Re_2$: C, 37.4; H, 2.8%.

(c) *Bulk electrolysis of* $Re_2X_4(dppm)_2$, $Re_2Cl_4(dppa)_2$ *and* $Re_2Br_4(dpam)_2$. Approximately 0.02 g quantities of these compounds were dissolved in 0.1 M *n*-Bu_4NPF_6–CH_2Cl_2 (20 cm^3) contained in an H-cell. Exhaustive electrolysis was performed on these solutions at *ca* +0.50 V for approximately 15 min at room temperature. Cyclic voltammograms were recorded and found to be essentially the same as those for their neutral precursors except that the processes at $E_{1/2} \simeq +0.3$ V (vs Ag/AgCl) now corresponded to reductions of the bulk complexes, thereby confirming that a one-electron oxidation had taken place.

Preparation of single crystals of $Re_2Cl_4(dppa)_2 \cdot (CH_3)_2CO$

Crystals were grown by diffusion of heptane vapour into a toluene solution of the complex that also contained a small amount of acetone.

X-ray crystallographic studies

The structure of $Re_2Cl_4(dppa)_2 \cdot (CH_3)_2CO$ was determined with the use of general procedures that are described elsewhere.[14] A summary of the crystallographic data is given in Table 1. The cell constants are based on 25 reflections with $20° < \theta < 23°$. Three standard reflections were measured after every 5000 s of beam time during data collection. There was no systemmatic variations in intensity. Calculations were performed on a Micro VAX II computer using the Enraf–Nonius structure determination package.

The crystal selected for the structure determination belonged to the monoclinic space group $P2_1/n$ with $Z = 4$. As a check on crystal quality, omega scans of several intense reflections were measured; the width at half-height was 0.70° with a take-off angle of 2.4° indicating relatively poor crystal quality. The structure was solved by the use of the Patterson heavy-atom method, which revealed the positions of the rhenium atoms in the asymmetric unit. The remaining atoms were located in succeeding difference Fourier syntheses. Lorentz and polarization corrections were applied to the data. An empirical absorption correction was

[c] $R = \Sigma ||F_o| - |F_c|| / \Sigma |F_o|$.

[d] $R_w = [\Sigma w(|F_o| - |F_c|)^2 / \Sigma w|F_o|^2]^{1/2}$; $w = 1/\sigma^2(F_o)$.

[e] Goodness-of-fit $= [\Sigma w(|F_o| - |F_c|)^2 / (N_{obs} - N_{parameters})]^{1/2}$.

applied,[15] the linear absorption coefficient being 51.97 cm^{-1}. No corrections for extinction were applied. The structure was refined in full-matrix least-squares where the function minimized was $\Sigma w(|F_o| - |F_c|)^2$; w is the weighting factor defined as $w = 1/\sigma^2(F_o)$.

During the course of the refinement, it became apparent that residual electron density at a fairly close contact to the bridgehead NH group of one of the dppa ligands could be satisfactorily modelled as lattice acetone. This was located on a general position, and it refined to a site of full occupancy, the carbon and oxygen atoms having satisfactory thermal parameters. Accordingly, the unit cell contains one molecule of acetone for each dirhenium molecule. Positions for the hydrogen atoms of the dppa ligands and the lattice acetone were calculated by assuming idealized geometry and a C—H bond distance of 0.95 Å. We also assumed that the value of B(H), i.e. the isotropic equivalent thermal parameter for the hydrogen atoms, was equal to $1.3[B_{eqv}(C)]$ at the time of the inclusion of this parameter in the refinement procedure. While these hydrogen atoms were used in the calculation of F_o, they were not included in the least-squares refinement. With the exception of the lattice acetone molecules, all non-hydrogen atoms were refined anisotropically; corrections for anomalous scattering

were applied to all atoms so refined.[16] The largest peak in the final difference Fourier map was 0.83 e $Å^{-3}$.

Further details concerning the data set and the structure solution and refinement may be obtained from Dr P. E. Fanwick. Table 2 lists important bond distances and angles.†

Physical measurements

IR spectra were recorded as Nujol mulls between KBr plates on an IBM Instruments IR/32 Fourier transform spectrometer or a Perkin–Elmer Model 1420 spectrophotometer. Electrochemical measurements were carried out on dichloromethane solutions that contained 0.1 M tetra-*n*-butylammonium hexafluorophosphate (*n*-Bu_4NPF_6 or TBAH) as supporting electrolyte. $E_{1/2}$ values, determined as $(E_{p,a}+E_{p,c})/2$, were referenced to the silver/silver chloride (Ag/AgCl) electrode at room temperature and are uncorrected for junction potentials. Under our experimental conditions, $E_{1/2} = +0.47$ vs Ag/AgCl for the ferrocenium/ferrocene couple. Voltammetric experiments were performed with a Bioanalytical Systems Inc. Model CV-1A instrument in conjunction with a Hewlett–Packard Model 7035 B *x-y* recorder. Conductivity measurements were performed on 1×10^{-3} M methanol solutions of the complexes on an Industrial Instruments Inc. Model RC-16B2 conductivity bridge. $^{31}P\{^1H\}$ NMR spectra were recorded on a Varian XL-200 spectrometer operated at 80.98 MHz with the use of an internal deuterium lock and 85% H_3PO_4 as an external standard. ^1H NMR spectra were obtained on a Varian XL-200 spectrometer. Resonances were referenced internally to the residual protons in the incompletely deuterated solvent.

Analytical procedures

Elemental microanalyses were performed by Dr H. D. Lee of the Purdue University Microanalytical Laboratory.

RESULTS AND DISCUSSION

(a) *Preparation and characterization of* $Re_2X_4(dpam)_2$

The bidentate arsine ligands 1,2-bis(diphenylphosphino)ethane (dpae; $Ph_2AsCH_2CH_2AsPh_2$) and 1-diphenylphosphino-2-diphenylarsinoethane

† Atomic positional and thermal parameters and full listings of bond lengths and angles have been deposited with the Editor and with the Director, Cambridge Crystallographic Data Centre.

(arphos; $Ph_2PCH_2CH_2AsPh_2$) have been shown to react with $(n\text{-}Bu_4N)_2Re_2Cl_8$ to yield $Re_2Cl_6(dpae)_2$ and $Re_2Cl_4(arphos)_2$, respectively.[17] However, with the use of similar reaction conditions to these, we have been unable to synthesize the corresponding derivatives with 1,2-bis(diphenylarsino) methane (dpam; $Ph_2AsCH_2AsPh_2$). The synthetic approach we successfully employed followed the one we have recently developed for the preparation of $Re_2X_4(dppm)_2$,[12] i.e. the reactions of the bis (acetate) complexes $Re_2(O_2CCH_3)_2X_4(H_2O)_2$ with an excess of dpam in hot methanol. The chloride derivative was produced in only a 10% yield. The use of different reaction solvents, and also $Re_2Cl_6(P\text{-}n\text{-}Bu_3)_2$ or $Re_2Cl_4(PEt_3)_4$ in place of $Re_2(O_2CCH_3)_2Cl_4(H_2O)_2$, failed to generate any identifiable products. Despite this rather low preparative yield for $Re_2Cl_4(dpam)_2$, satisfactory elemental microanalyses and cyclic voltammetric (CV) data were obtained for this complex. Two reversible one-electron oxidations, at $E_{1/2} = +0.32$ V and +0.84 V vs Ag/AgCl, were observed; these redox potentials are very close to those obtained for $Re_2Cl_4(dppm)_2$ as shown in Table 3. The bromide derivative $Re_2Br_4(dpam)_2$ was obtained in a much higher yield (*ca* 40%) than its chloride analogue. Its CV properties and electronic absorption spectrum are very similar to those for $Re_2Br_4(dppm)_2$ (Table 3). Accordingly, it may be concluded that $Re_2X_4(dpam)_2$ and $Re_2X_4(dppm)_2$ are structurally and electronically closely related.

The NMR spectral properties for $Re_2X_4(dppm)_2$ (X = Cl, Br or I) and $Re_2Br_4(dpam)_2$ are also listed in Table 3, and show a close similarity to one another. Note that electrochemical and spectroscopic data for $Re_2Br_4(dppm)_2$ and $Re_2I_4(dppm)_2$ are reported here for the first time. A comparison is also made with the corresponding data for $Re_2Cl_4(dppa)_2$.

(b) *Preparation and characterization of* $[Re_2X_4(dppm)_2]PF_6$

Nitrosonium hexafluorophosphate ($NOPF_6$) has been successfully used to oxidize dirhenium(II) complexes that contain monodentate and bidentate phosphines. Examples include $[Re_2Cl_4(PEt_3)_4]PF_6$,[18] $[Re_2Cl_4(PMe_2Ph)_4]PF_6$,[2] $[Re_2Cl_4(PMe_2Ph)_4](PF_6)_2$,[2] $[Re_2Cl_4(dppe)_2]PF_6$[5] and $[Re_2Cl_4(arphos)_2]PF_6$,[5] all of which can be prepared from their neutral precursors. However, acetone or THF solutions of $Re_2Cl_4(dppm)_2$ react readily with $NOPF_6$ to give unidentifiable products that may contain the nitrosyl ligand but which were not the desired oxi-

Table 3. Electrochemical and spectroscopic data for $Re_2X_4(LL)_2$ (X = Cl, Br or I; LL = dppm, dppa or dpam) and for $[Re_2X_4(dppm)_2]^+$ (X = Cl or Br)

[h] Spectrum recorded in $CDCl_3$.

[i] Data similar to that reported in ref. 11.

[j] Not measured.

[k] Paramagnetic complex.

dized product. By resorting to the milder oxidant ferrocenium hexafluorophosphate, $[(\eta^5\text{-}C_5H_5)_2Fe]PF_6$, we have found that this reagent cleanly oxidizes acetone solutions of $Re_2X_4(dppm)_2$ to $[Re_2X_4(dppm)_2]PF_6$ (X = Cl or Br). A similar strategy in the case of $Re_2Cl_4(dppa)_2$ and $Re_2Br_4(dpam)_2$ (acetone or dichloromethane as solvents) failed to give pure products, even when low reaction temperatures were employed. The monocations are apparently very unstable and prone to decomposition under these reaction conditions, although they can be generated electrochemically (*vide infra*).

Conductivity measurements on methanol solutions of $[Re_2X_4(dppm)_2]PF_6$ ($c_m \simeq 1 \times 10^{-3}$ M) show them to be 1:1 electrolytes ($\Lambda_m \simeq 105\ \Omega^{-1}\ cm^2\ mol^{-1}$).[19] Also, the IR spectra of these complexes confirm the presence of the PF_6^- anion (ν(P—F) at $\simeq 840\ cm^{-1}$). The electrochemical properties of these salts (Table 3) resemble those of $Re_2X_4(dppm)_2$; the only difference being that the process at $E_{1/2} \simeq +0.3$ V (vs Ag/AgCl) now corresponds to a reduction of the bulk complex. Their electronic absorption spectra (Table 3) show a broad absorption at $\simeq 1500$ nm in the near-IR region. This band appears to be typical of species that contain a $\sigma^2\pi^4\delta^2\delta^{*1}$ electronic configuration[18,20] and may be assigned to a $\delta \rightarrow \delta^*$ transition. This is further evidence that the Re_2^{5+} moiety is present in these oxidized species.

Magnetic moments of dichloromethane solutions of these monocations (determined by the Evans method[21]) were found to be 1.5 ($\pm$0.1) BM at room temperature. X-band ESR spectra of frozen dichloromethane solutions (−160°C) also confirm the paramagnetism of these complexes. Complex patterns showing a considerable amount of hyperfine structure were observed. The spectra are centred at 2750 G ($g \simeq 2.35$) for the chloride and 2700 G ($g \simeq 2.40$) for the bromide derivative, and have a spectral width of approximately 3500 G.

(c) *Electrochemical generation of* $[Re_2X_4(dppm)_2]^+$ (X = Cl *or* Br), $[Re_2Cl_4(dppa)_2]^+$ *and* $[Re_2Br_4(dpam)_2]^+$

Bulk electrolyses of purple solutions of $Re_2X_4(dppm)_2$ (X = Cl or Br), $Re_2Cl_4(dppa)_2$ and $Re_2Br_4(dpam)_2$ in n-Bu_4NPF_6–CH_2Cl_2 generated solutions of the paramagnetic monocations that are green–brown in colour, except for $[Re_2Cl_4(dppa)_2]^+$ which is red. In all instances, CV measurements confirmed that oxidation had proceeded with little evidence for decomposition. In view of the reversibility of the couple at *ca* +0.3 V (Table 3), it is apparent that the oxidations proceed with retention of the staggered rotational geometry that is characteristic of the structurally characterized derivatives $Re_2Cl_4(dppm)_2$[22] and $Re_2Cl_4(dppa)_2$ (*vide infra*).

The X-band ESR spectra of these solutions, recorded at −160°C (Fig. 1), verified the paramagnetism of these species. The spectrum of $[Re_2Cl_4(dppa)_2]^+$ (not shown) is similar to that of the other derivatives; in all instances, the spectra are centred at *ca* 3000 G (i.e. $g \simeq 2.16$) with a spectral width of *ca* 3500 G. As can be seen in Fig. 1, the spectra are very similar and, in spite of the poorer resolution of the spectrum of $[Re_2Br_4(dppm)_2]^+$, it is apparent that the hyperfine structure must primarily be associated with the rhenium nuclei; an eleven-line pattern is expected for coupling to two rhenium nuclei with $I = 5/2$. There is little evidence for coupling to phosphorus or halogen nuclei in these spectra. Further confirmation that these signals are due to the monocations was shown by cycling between the oxidized and neutral species

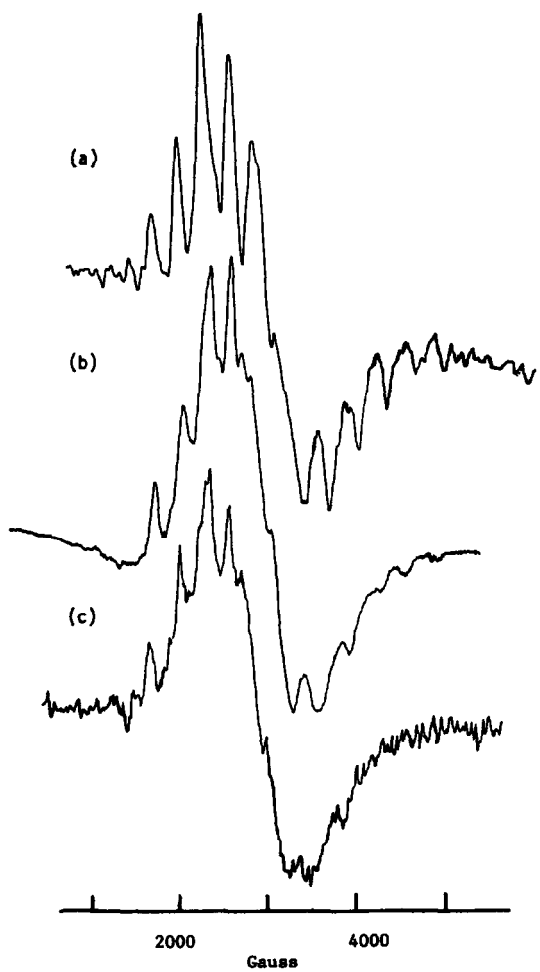

Fig. 1. The X-band ESR spectra, in frozen dichloromethane solutions at −160°C, for (a) $[Re_2Br_4(dpam)_2]^+$, (b) $[Re_2Cl_4(dppm)_2]^+$ and (c) $[Re_2Br_4(dppm)_2]^+$. All species were generated electrochemically.

and monitoring the growth and disappearance of the spectra.

(d) *Structural considerations*

At the outset, we had hoped to obtain crystals of one or more derivatives of the type $[Re_2X_4(LL)_2]PF_6$ (LL = dppm, dppa or dpam) in order to confirm that they did indeed possess a structure similar to that of $Re_2Cl_4(dppm)_2$.[22] Unfortunately, all attempts to grow such crystals led to the decomposition of the complexes. However, during the course of this aspect of our work we obtained crystals of $Re_2Cl_4(dppa)_2 \cdot (CH_3)_2CO$ and took the opportunity to determine its structure and compare it to $Re_2Cl_4(dppm)_2$.[22]

The structure of the dirhenium complex $Re_2Cl_4(dppa)_2$, as present in the crystals of $Re_2Cl_4(dppa)_2 \cdot (CH_3)_2CO$, is that of a multiply bonded M_2L_8 complex.[3] An ORTEP representation of the structure is shown in Fig. 2 and gives the full atomic numbering scheme. There is no crystallographically imposed symmetry for the asymmetric unit. The important structural parameters are listed in Table 2. While the bridging dppa ligands are in a *trans* disposition to one another, the molecule assumes an overall staggered rotational geometry. This geometry can best be defined in terms of the averages of the torsional angles Cl(11)—Re(1)—Re(2)—Cl(21) and Cl(12)—Re(1)—Re(2)—Cl(22), and P(11)—Re(1)—Re(2)—P(21) and P(12)—Re(1)—Re(2)—P(22), which are 51.7[2] and 41.8[5]°, respectively. These can be compared with average Cl—Re—Re—Cl and P—Re—Re—P angles of 56[1] and 47[1]°, respectively, in the structure of $Re_2Cl_4(dppm)_2$.[22]

The Re—Re distance of 2.2417(5) Å is similar to that of 2.234(3) Å in the structure of $Re_2Cl_4(dppm)_2$.[22] Very close similarities are also seen between the sets of Re—Cl and Re—P distances and the corresponding angles of these two structures. The compounds have essentially identical average Re—P and Re—Cl distances; these are 2.43[2] and 2.356[5] Å for the dppa derivative and 2.45[3] and 2.360[11] Å for the analogous dppm complex.

One molecule of acetone per formula unit of $Re_2Cl_4(dppa)_2$ was found in the unit cell. The oxygen atom of the acetone molecule was found to be 3.12(1) Å away from N(1) of the dirhenium complex. This represents, at best, a very weak hydrogen-bonding interaction. Typical lengths of N—H···O hydrogen bonds fall in the range 2.81–3.04 Å.[23] Recently, Usón *et al.*[24] have reported a case of a diplatinum(I)–dppa complex that

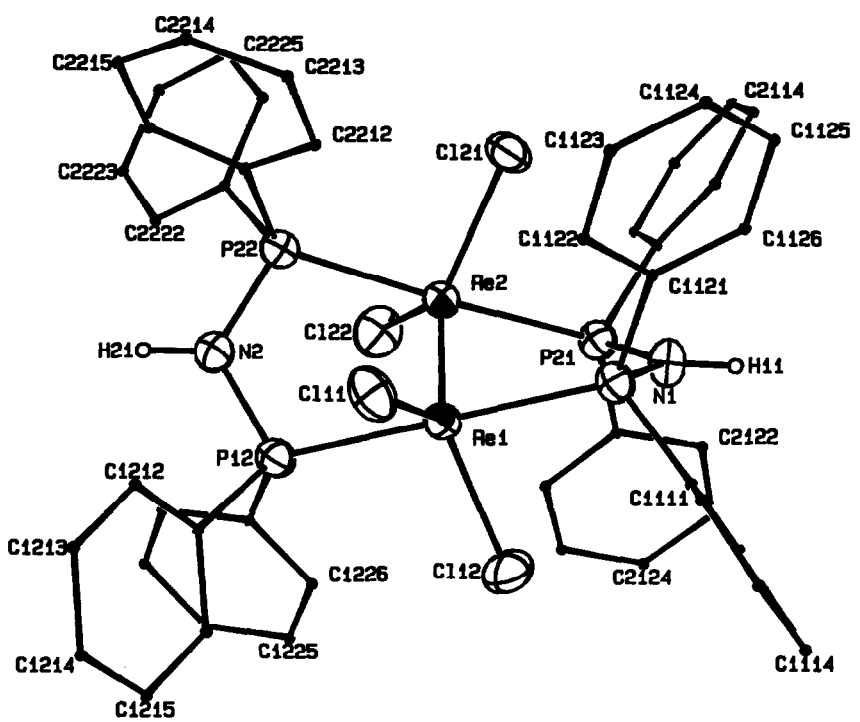

Fig. 2. ORTEP representation of the structure of the complex $Re_2Cl_4(dppa)_2$ showing the atomic numbering scheme. The thermal ellipsoids are drawn at the 50% probability level. The molecule of lattice acetone is not shown.

exhibits $(CH_3)_2CO\cdots H—N$ hydrogen-bonding; the $N—H\cdots O$ distance (for $Pd_2Cl_2(\mu\text{-dppa})_2\cdot(CH_3)_2CO$) was determined to be 2.915(7) Å. To our knowledge, there are only five other reports describing the structures of dimetal complexes that contain bridging dppa ligands. These are the aforementioned diplatinum complex,[24] the dirhenium(II) complexes *cis*-$Re_2(O_2CCH_3)_2Cl_2(\mu\text{-dppa})_2$ and *cis*-$[Re_2(O_2CCH_3)_2Cl_2(\mu\text{-dppa})_2]PF_6$,[11] $Au_2Cl_2(C_6F_5)_2(\mu\text{-dppa})$[25] and $Rh_2(\mu\text{-CO})(\mu\text{-Cl})(\mu\text{-dppa})_2(CO)_2$;[26] several of these contain solvent of crystallization hydrogen-bonded to the N—H group of dppa.

ELECTRON PARAMAGNETIC RESONANCE STUDIES OF THE 19-ELECTRON COMPLEXES, $(\eta^5\text{-}C_5H_5)NiL_2$ (L = PR_3, $P(OR)_3$)

ANNA BECALSKA, JEFF D. DEBAD, HALEH K. SANATI and ROSS H. HILL*

Department of Chemistry, Simon Fraser University, Burnaby, B.C. Canada, V5A 1S6

(*Received* 12 *April* 1989; *accepted* 11 *September* 1989)

Abstract—Photolysis of $(\eta^5\text{-}C_5H_5)Ni(R)PPh_3$ (R = Me, Et) in air-free benzene leads to the production of the stable radical $(\eta^5\text{-}C_5H_5)Ni(PPh_3)_2$. In the presence of free ligands, L (L = PPh_3, $P(p\text{-}FPh)_3$, $P(p\text{-}MeOPh)_3$, $P(n\text{-}Bu)_3$, $P(OEt)_3$, $P(OPh)_3$, $P(OMe)_3$, dppe/2, bipy/2, C_2Ph_2 and HCCPh), photolysis of $(\eta^5\text{-}C_5H_5)Ni(R)PPh_3$ leads to the production of $(\eta^5\text{-}C_5H_5)Ni(L)_2$. The ESR spectra of several derivatives of the radical, $(\eta^5\text{-}C_5H_5)NiL_2$, have been analysed and the variation of the *sp* hybridization of the phosphorus donor atom determined.

Herein we report the results of our study of the photochemistry of $C_5H_5Ni(R)PPh_3$ (R = Me, Et). We previously studied the photochemistry of $(\eta^5\text{-}C_5H_5)Co(PPh_3)Me_2$ and found that photolysis in air-free benzene led to the production of the stable cobalt radical $(\eta^5\text{-}C_5H_5)Co(PPh_3)Me$.[1] Literature describing both the photolysis and thermolysis of the nickel complexes indicated that the production of nickel radicals in the photochemistry of $(\eta^5\text{-}C_5H_5)Ni(R)PPh_3$ may be observable under the right conditions.

The photolysis of $(\eta^5\text{-}C_5H_5)Ni(Me)PPh_3$ was reported by Emad and Rausch[2] to lead to the production of methyl radicals, whereas the same authors reported $(\eta^5\text{-}C_5H_5)Ni(Et)PPh_3$ when irradiated produced ethylene and ethane in a near 1:1 ratio. In both cases the presumed organometallic intermediate would be $(\eta^5\text{-}C_5H_5)NiPPh_3$. The thermolysis of these complexes was reported by Thomson and Baird[3] to lead to Ni—CH_3 bond homolysis for the methyl derivatives and β-hydride elimination from the ethyl derivative. The indication here is that once again, at least in the thermolysis of the methyl derivative, $(\eta^5\text{-}C_5H_5)NiPPh_3$ should be produced. In neither of these reports were the identities of the nickel-containing products determined.

Barefield *et al.* reported[4] that reaction of nickelocene with NiL_4 led to the production of radicals of the general formula $(\eta^5\text{-}C_5H_5)NiL_2$. The paper also contained evidence suggestive of $(\eta^5\text{-}C_5H_5)NiL$ being an intermediate in the equilibrium between $(\eta^5\text{-}C_5H_5)_2Ni$ and NiL_4 with $(\eta^5\text{-}C_5H_5)NiL_2$. Considering the reported result of either photolysis or thermolysis of $(\eta^5\text{-}C_5H_5)Ni(R)PPh_3$ it seemed reasonable that in the presence of a suitable two-electron donor either thermolysis or photolysis of $(\eta^5\text{-}C_5H_5)Ni(R)PPh_3$ should produce these radicals.

Initial results indicated that the nickel radicals could be prepared via photolysis of the alkyl complexes. The ESR indicated a large variation of isotropic hyperfine coupling constants in this system. In order to investigate if this was a result of a change in the orbital content of the singly occupied molecular orbital (SOMO) we prepared a variety of complexes and studied their anisotropic ESR spectra.

RESULTS

Characterization of the products

Photolysis ($\lambda > 413$ nm) of $(\eta^5\text{-}C_5H_5)Ni(Me)PPh_3$ in degassed benzene solutions containing PPh_3 was monitored by ^1H NMR spectroscopy. Due to the production of radicals, spectra were obtained with relaxation delays of 60 s. Use of a long relaxation delay ensures that the changes in the relaxation times due to the presence of radicals had only minimal effects on the integrals of the signals allowing the use of NMR to monitor the extent of reaction. Irradiation resulted in loss of ^1H NMR signals associated with substrate and the

*Author to whom correspondence should be addressed.

appearance of weak NMR signals due to methane, ethane and other unidentified products. The use of cyclopentane as an internal standard allowed calculation of the extent of reaction by measuring the remaining intensity in the NMR due to the starting complex. When the reaction was complete the NMR was obtained over a wider sweep width using short acquisition times and pulse angles of 30°, allowing observation of the NMR signals due to the paramagnetic products.

The absorptions due to the cyclopentadienyl protons from $(\eta^5\text{-}C_5H_5)_2Ni$ (−255.3 ppm) and $(\eta^5\text{-}C_5H_4Me)_2Ni$ (−247.5 ppm) were observed.[5] The approximate ratio of methylated to unmethylated cyclopentadienyl in the nickelocenes was 1 : 1.3. Although this region did not confirm the existence of the mixed derivative, $(\eta^5\text{-}C_5H_4Me)(\eta^5\text{-}C_5H_5)Ni$, examination of the methyl group resonances indicated that the mixed derivative was also formed. In this region, absorptions at 208 ppm and 209 ppm were observed. In addition to the signals due to the nickelocene derivatives, signals due to phosphine-substituted derivatives were also observed.

The new absorption at −265 ppm was found to be consistent with the known complex, $(\eta^5\text{-}C_5H_5)Ni(PPh_3)_2$, by comparison with a sample prepared by independent synthesis via a known thermal route.[4,6] We assign the new peaks at −262 and 218.5 ppm to the complex $(\eta^5\text{-}C_5H_4Me)Ni(PPh_3)_2$. In the case of these derivatives the ratio of methylated to unmethylated cyclopentadienyl was found to be 1 : 1.

The ESR spectrum of the sample was obtained after photolysis when the NMR resonance due to the methyl group of $(\eta^5\text{-}C_5H_5)Ni(Me)PPh_3$ was no longer discernible in the baseline. The ESR showed a triplet centred at $g = 2.060$ with hyperfine, $a = 111$ G, due to coupling with two phosphorus nuclei. This ESR signal is characteristic of the known complex, $(\eta^5\text{-}C_5H_5)Ni(PPh_3)_2$, however, as it is the only signal observed in these solutions, it must also be degenerate with the signal from $(\eta^5\text{-}C_5H_4Me)Ni(PPh_3)_2$. In order to confirm the assignment a sample of $(\eta^5\text{-}C_5H_5)Ni(PPh_3)_2$ was prepared by a published procedure[4,6] and its ESR signal was found to be identical with that of our product.

In order to measure the yield of the radical, $(\eta^5\text{-}C_5H_4R)Ni(PPh_3)_2$ (R = H, Me), the integral of the ESR signal was compared with that of degassed standard solutions of $Ti(acac)_3$. This gave a yield of 9% for the production of $(\eta^5\text{-}C_5H_4R)Ni(PPh_3)_2$. In the absence of excess PPh_3 this yield dropped to ~ 0.3%. The low yield is presumably a result of the instability of the radical product under these conditions.

Similar results were obtained upon photolysis of the ethyl derivative, $(\eta^5\text{-}C_5H_5)Ni(Et)PPh_3$. In this case the nickelocene products were a mixture of nickelocene and its ring-substituted ethyl derivatives.[5] Ring protons were found to resonate at −256 and −248 ppm, respectively, and the α-protons of the ethyl group were seen at 208.6 ppm. The ratio of $(\eta^5\text{-}C_5H_4Et)$ to $(\eta^5\text{-}C_5H_5)$ was 1 : 1.8 in the nickelocene products. Unfortunately, direct detection of $(\eta^5\text{-}C_5H_4Et)Ni(\eta^5\text{-}C_5H_5)$ was not possible. Presumably the signals due to the mixed derivative are degenerate with the signals of the two symmetrical nickelocenes. The signals due to both $(\eta^5\text{-}C_5H_5)Ni(PPh_3)_2$ and $(\eta^5\text{-}C_5H_4Et)Ni(PPh_3)_2$ were also observed. Resonance due to ring protons was observed at −263 ppm and the α-protons of the ethyl group were seen at 217 ppm. Weak NMR signals due to ethane and ethylene were also observed.

The spectroscopic yields of the 19-electron radical, $(\eta^5\text{-}C_5H_4R)Ni(PPh_3)_2$ (R = H, Et), were determined by comparison of the ESR signal with the signal produced by stock $Ti(acac)_3$ solutions. The yields were approximately the same as observed for the previous system accounting for 6% of the original nickel. Once again in the absence of free PPh_3 the yield dropped to ~ 0.5%.

The yields in each case represent maximum yields based on total organometallic complex. If the spectroscopic yields are calculated using the integration in the NMR to determine the amount of $(\eta^5\text{-}C_5H_5)Ni(Me)PPh_3$ lost, the calculated yield is ~ 20% in the early stages of the reaction (this is not true in the absence of free PPh_3 where the yield calculated by this method is only ~ 8%). The apparent low yields are due, in part, to the photosensitivity of the compounds. Solutions containing $(\eta^5\text{-}C_5H_5)Ni(PPh_3)_2$, stored at room temperature in the dark, are stable for at least 1 year; however, photolysis leads to loss of the ESR signal over the course of days. The initial reaction in the presence of excess ligand is given by eq. (1):

$$(\eta^5\text{-}C_5H_5)Ni(R)PPh_3 \xrightarrow[h\nu]{PPh_3} (\eta^5\text{-}C_5H_5)Ni(PPh_3)_2 + R^{\cdot} \quad (1)$$

Several derivatives were obtained by photolysis of either $(\eta^5\text{-}C_5H_5)Ni(R)PPh_3$ (R = Me or Et) in benzene solutions containing free phosphines or phosphites. Photolysis ($\lambda > 413$ nm) of the methyl derivative in the presence of 5 equivalents of free phosphine or phosphite led to the production of the disubstituted derivatives $(\eta^5\text{-}C_5H_5)NiL_2$, [L = P(*p*-FPh)$_3$, P(*p*-MeOPh)$_3$, P(*n*-Bu)$_3$, P(OMe)$_3$, P(OEt)$_3$, P(OPh)$_3$, dppe/2 (dppe = bis-diphenylphosphinoethane)]. The phosphine-con-

taining compounds all showed ^{31}P hyperfine coupling due to the presence of two equivalent phosphorus donors. The ESR signals from the phosphite derivatives were split into a doublet of doublets, indicating that the two phosphites are not equivalent. This inequivalence has been noted previously.[4] In each case the products were established not to be mixed phosphine/phosphite derivatives by comparison of the ESR obtained with the ESR produced when the free ligand was mixed with nickelocene in benzene. The ESR spectra of each of the derivatives were also obtained at $-120°C$. Figure 1 shows the room-temperature and low-temperature ESR spectra due to $(\eta^5\text{-}C_5H_5)Ni(P(OEt)_3)_2$. The ESR parameters for these complexes are given in Table 1. The yields for the various phosphine and phosphite derivatives were also measured and varied from less than 1–11% (see Experimental).

Degassed NMR samples containing $(\eta^5\text{-}C_5H_5)Ni(R)PPh_3$ [R = Me, Et, and 2,2′-bipyridyl (bipy)] in benzene were also prepared and photolysed. During the course of the reaction the samples turned from the green colour of $(\eta^5\text{-}C_5H_5)Ni(Me)PPh_3$ to blue. The reaction was monitored by NMR which indicated the loss of intensity due to substrate and the production of free phosphine, ethane and methane. No peaks attributable to a new metal cyclopentadienyl group were observed. We were unable to obtain the NMR for the radical products. The ESR spectrum of the reaction mixture was obtained and a single peak, $g = 2.084$, showing no hyperfine coupling, was observed. We identify this peak as due to the known complex $(\eta^5\text{-}C_5H_5)Ni(bipy)$. Comparison of the anisotropic ESR obtained in toluene glass, where nitrogen hyperfine is observed,[4] of our product with that independently synthesized via the known thermal route[4,6] confirmed the identity of the product as $(\eta^5\text{-}C_5H_5)Ni(bipy)$. The chemical yield of the nickel radical was estimated by comparison of the integral of its ESR signal with that of stock solutions of $Ti(acac)_3$ and found to be 80%. The photochemical reaction of $(\eta^5\text{-}C_5H_5)Ni(Me)PPh_3$ with bipy must involve methyl radical cleavage and bipy substitution for phosphine. The overall reaction is given as eq. (2):

$$(\eta^5\text{-}C_5H_5)Ni(R)PPh_3 \xrightarrow[h\nu]{bipy} (\eta^5\text{-}C_5H_5)Ni(bipy) + R^{\cdot} + PPh_3. \quad (2)$$

[a] For molecules of rhombic symmetry, a_1 is calculated from the known isotropic hyperfine.

In the presence of diphenylacetylene, irradiation of $(\eta^5\text{-}C_5H_5)Ni(R)PPh_3$ leads to a similar result. The major radical product is characterized by its room-temperature ESR spectrum which shows a simple singlet $g = 2.090$. This product is assigned as $(\eta^5\text{-}C_5H_5)Ni(C_2Ph_2)_2$. The maximum yield observed for this product was 1%. In addition to this a doublet was also observed at $g = 2.028$, characterized by a phosphorus hyperfine of 120 G. This we assign as due to the mixed phosphine acetylene adduct, $(\eta^5\text{-}C_5H_5)NiPPh_3(C_2Ph_2)$. The yield of the mixed radical in this system was found to be 0.1%. Over a period of time the mixed phosphine diphenylacetylene adduct was found to convert to the bis-diphenylacetylene radical.

Similar results were obtained when photolysis was carried out in solutions containing phenylacetylene. Once again signals due to both a disubstituted adduct, $(\eta^5\text{-}C_5H_5)Ni(HCCPh)_2$, $g = 1.992$, and a monosubstituted adduct, $(\eta^5\text{-}C_5H_5)NiPPh_3(HCCPh)$, $g = 2.016$, $a = 80$ G, were observed. Once again, only low yields, $\sim 0.1\%$, were obtainable for either derivative. Unfortunately in neither case was the mixed adduct sufficiently concentrated to obtain the anisotropic ESR parameters.

Photolysis in the presence of $AsPh_3$ was also done and the ESR of the resultant solutions obtained. The product was primarily the bis-phosphine adduct. The ESR spectrum did however indicate that the production of $(\eta^5\text{-}C_5H_5)NiPPh_3AsPh_3$ had also occurred, albeit to a much lesser extent ($< 1/8$). The mixed phosphine arsine derivative was characterized by $g = 2.071$ and the observation of hyperfine to both ^{71}As, 150 G, and ^{31}P, 95 G. As the signals due to the mixed arsine phosphine derivative were always less intense than those due to the bis-phosphine complex we were unable to obtain its anisotropic ESR spectrum.

DISCUSSION

The photochemically initiated reactions of $(\eta^5\text{-}C_5H_5)Ni(Me)PPh_3$ and $(\eta^5\text{-}C_5H_5)Ni(Et)PPh_3$ were studied earlier by Emad and Rausch[2] and the thermal reaction by Thomson and Baird.[3] However, in neither of these studies were the metal-containing products identified. Herein we have found the products of both thermal and photochemical decomposition of $(\eta^5\text{-}C_5H_5)Ni(R)PPh_3$ (R = Me, Et) to consist of the nickel(I) species, $(\eta^5\text{-}C_5H_5)NiL_2$ (in the absence of added ligand or in the presence of PPh_3, L = PPh_3; in the presence of bipy, L_2 = bipy), eq. (3). The complexes where L = PPh_3, L_2 = bipy, are known and can be synthesized by reactions of L with nickelocene:[4,6]

$$(\eta^5\text{-}C_5H_5)Ni(R)PPh_3 \xrightarrow[h\nu]{L} (\eta^5\text{-}C_5H_5)NiL_2 + R^{\cdot} + PPh_3. \quad (3)$$

At longer photolysis times nickelocene and its ring-substituted derivatives are formed. The complexes, $(\eta^5\text{-}C_5H_5)NiL_2$, have previously been reported to be unstable towards disproportionation to nickelocene and NiL_4.[7] The net reaction is hence

given by eq. (4):

$$(\eta^5\text{-}C_5H_5)Ni(R)PPh_3 \xrightarrow[h\nu]{PPh_3} (\eta^5\text{-}C_5H_4R')Ni(PPh_3)_2 + (\eta^5\text{-}C_5H_4R')_2Ni + Ni(PPh_3)_4 + HR$$

R = Me, R′ = H and Me; R = Et, R′ = H and Et. (4)

Each of the nickel(I) complexes is best described as having a 19-electron configuration with an η^5-cyclopentadienyl ring.[8] An alternative formulation, a 17-electron system with an η^3-cyclopentadienyl ring, is considered less likely based on the following considerations. The crystal structure of the bipyridine derivative, $(\eta^5\text{-}C_5H_5)Ni(bipy)$, has been reported and establishes that the C_5H_5 ligand is pentahapto in this derivative.[4] Since the anisotropic shifts in the bipy complex ($g_1 = 2.184$, $g_2 = 2.080$, $g_3 = 2.033$ G) are in the range of those found for the phosphine substituted complexes (Table 1), the electronic structures are also expected to be similar. In addition it has been demonstrated that association of a ligand and a 17-electron complex to form a 19-electron complex is generally facile.[9] Here we find no evidence for formation of 19-electron complexes of the formula $(\eta^3\text{-}C_5H_5)NiL_3$ even for the smaller ligands such as $P(OMe)_3$. This lack of formation of $(\eta^3\text{-}C_5H_5)NiL_3$, even at low temperatures, is most consistent with a pentahapto arrangement for the C_5H_5 moiety.

It should also be noted that a variety of 19-electron complexes containing the $(\eta^5\text{-}C_5H_5)$ ligand have been structurally characterized.[8] We are aware of no example of a 17-electron complex with an $(\eta^3\text{-}C_5H_5)$ group. There is precedent for the existence of the related η^3-indenyl group.[8,9] Given the above factors, the most reasonable formulation of these complexes is as 19-electron complexes with $(\eta^5\text{-}C_5H_5)$ ligands.

The stabilities of the radicals are surprising. The bipy substituted radical is indefinitely stable. It should be noted, however, that significant disproportionation to nickelocene and $Ni(PR_3)_4$ does occur and the phosphite radicals are particularly unstable, undergoing complete decomposition over several hours. The phosphine radicals were much more stable. Solutions containing $(\eta^5\text{-}C_5H_5)Ni(PPh_3)_2$ were stored at room temperature in sealed tubes with no noticeable decomposition for periods of 1 year. The unsymmetrical derivative, $(\eta^5\text{-}C_5H_5)Ni(PPh_3)(C_2Ph_2)$, is less stable and reacts thermally to produce the $(\eta^5\text{-}C_5H_5)Ni(C_2Ph_2)_2$ derivative in the presence of excess diphenylacetylene. Solutions of $(\eta^5\text{-}C_5H_5)Ni(C_2Ph_2)_2$ are stable for periods of greater than 1 year when stored at 4°C.

In each derivative no evidence was found in the ESR spectra for an effect due to the methylation (or ethylation) of the $(\eta^5\text{-}C_5H_5)$ ring. This was determined by thermal synthesis of each (non-mixed) derivative from nickelocene and free ligand. The ESR in each case was identical to that found from the photochemical preparations.

The ESR spectra of the phosphine derivatives show hyperfine coupling to the phosphine, both in the isotropic and anisotropic spectra. For the alkyl and aryl phosphines a simple triplet, due to hyperfine coupling to two ^{31}P nuclei, is observed in the isotropic ESR. The anisotropic spectra, in frozen benzene or toluene, of the phosphine complexes display rhombic symmetry. In each of these cases overlap between the high-field components of g_1 and absorptions due to g_2 and g_3 made the direct assignment of a_1 difficult. Since the isotropic and anisotropic hyperfine constants are related, we have calculated values of a_1 for use in the analysis. The extent of phosphorus *s*-orbital contribution to the SOMO has been assessed by the standard method[10] using the atomic values of Morton and Preston.[11] The contribution for the triaryl phosphines is ~ 2.4%, whereas dppe and $P(n\text{-}Bu)_3$ are both slightly higher at 2.7%. The phosphorus *p*-orbital contribution to the SOMO, determined from the anisotropic spectra, is ~ 8% in these derivatives, with both dppe and $P(n\text{-}Bu)_3$ being somewhat higher.

Phosphite complexes display apparent axial symmetry in their ESR spectra. The two phosphorus donor atoms are inequivalent as evidenced by the appearance of a doublet of doublets in both the isotropic and anisotropic ESR, Fig. 1. The spectra were analysed as above but using the individual constants, giving rise to the individual contribution of each phosphite donor of a given compound. The analysis was carried out on the related hyperfines, giving the phosphorus *s*- and *p*-orbital contribution to the SOMO from each of the individual phosphites. In each case the contribution to the SOMO from the phosphorus *s*-orbital was ~ 4.5%. The phosphorus *p*-orbital contribution was similarly in the region of 4%.

The results are summarized in Table 2. We can see that in each case the total contribution to the SOMO from *s*-phosphorus and *p*-orbitals remains approximately 9% for both the phosphites and the aryl phosphines. The only variation that is significant is that of the trialkyl phosphine which is slightly higher at ~ 12%. However, the relative *s* and *p* contributions vary considerably. For the alkyl and aryl phosphines the phosphorus donor orbital is composed of approximately 25% *s* character. For the phosphites the *s* contribution is increased to ~ 50%. This is the expected result as more elec-

Table 2. Calculated contributions of *s*- and *p*-orbitals on phosphorus to the SOMO

L	*s*(%)	*p*(%)	*s*+*p*(%)	*s*/(*s*+*p*)
P(*p*-FC_6H_4)$_3$	2.4	7.1	9.5	25
P(*p*-$OMeC_6H_4$)$_3$	2.4	6.8	9.2	26
P(C_6H_5)$_3$	2.4	5.2	7.6	31
P(*n*-Bu)$_3$	2.7	9.0	11.7	23
dppe	2.7	7.9	10.6	34
P(OMe)$_3$	4.2	5.2	9.4	45
	4.6	4.1	8.7	53
P(OEt)$_3$	4.2	3.2	7.5	56
	4.5	4.6	9.1	49
P(OPh)$_3$	4.5	3.3	7.8	58
	5.0	3.8	8.8	56

tronegative substituents on the phosphorus should cause an increase in the amount of phosphorus *s* character in the donor orbital. This result indicates that the variation in isotropic hyperfine constants observed, the phosphites being much larger than the phosphines, is the result of changes in hybridization at the phosphorus and not a result of varying content of donor orbital participation in the SOMO. Similar findings have been reported earlier in studies of monophosphine adducts of cobalt.[12,13] The relative hybridization found there is in agreement with our results.

The phosphites are interesting in that the two donors in each bis-phosphite complex are inequivalent. The contribution to the SOMO is 9.4 and 8.7%, respectively, for each P(OMe)$_3$ in (η^5-C_5H_5)Ni(P(OMe)$_3$)$_2$. In (η^5-C_5H_5)Ni(P(OEt)$_3$)$_2$ a similar result is obtained, the contribution to the SOMO by each P(OEt)$_3$ differing by 1.6%. The two triphenylphosphite ligands in (η^5-C_5H_5)Ni(P(OPh)$_3$)$_2$ show that the total contribution to the SOMO from the two donor atoms differs by $\sim$ 1%. The average difference in participation in the SOMO from phosphorus atomic orbitals is $\sim$ 1% in these compounds. Surprisingly, the hybridization also is significantly different in the two inequivalent phosphites for both of the trialkyl phosphites. For the trimethylphosphite the donor orbital of one phosphite is $\sim$ 45% *s* whereas the other is $\sim$ 53% *s*. The triethyl derivative shows similar variation in that the *s* character varies from 49 to 56%. Only in the triphenylphosphite is the hybridization near constant with the donor orbitals comprised of 58 and 56% *s* character.

This inequivalence, only observed for the phosphites, may be a result of the greater *s* character in the donor orbital. The higher *s* content in the donor orbital is expected to result in a shorter P—Ni bond. This in turn would lead to more steric interaction between the phosphites and the metal centre. It may be as a result of this steric interaction that the phosphites are inequivalent. Of the inequivalent phosphites, the one having more *s* character makes a smaller contribution to the SOMO than the phosphite with less *s* character. One might expect that a higher *s* contribution to the donor orbital would lead to shorter bond lengths and hence a greater contribution to the SOMO. The dominant effect, however, appears to be the greater extension into space of the *p*-orbital causing greater overlap of the resultant donor orbital with the metal *d*-orbital.

CONCLUSIONS

Photolysis of (η^5-C_5H_5)Ni(R)PPh$_3$ (R = Me, Et) in air-free benzene solution leads to the production of (η^5-C_5H_5)Ni(PPh$_3$)$_2$. If irradiated in the presence of a variety of ligands, L, the corresponding complexes (η^5-C_5H_5)NiL$_2$ may be produced.

Various phosphine derivatives have been prepared by this method and both the isotropic and anisotropic ESR spectra obtained. Analysis of the nuclear hyperfine data indicates that the SOMO in all the various phosphorus ligand derivatives contains a $\sim$ 20% contribution from the phosphorus donor orbital. The variation in the observed isotropic hyperfine is due not to the amount of donor orbital character in the SOMO but to differing degrees of *sp*-hybridization in the PR$_3$ donor orbital. The *s*-orbital content of the phosphite donor orbital is much higher than in the phosphines giving a higher isotropic ^{31}P hyperfine.

EXPERIMENTAL

Triphenylphosphine was obtained from BDH and recrystallized from hexane prior to use. The ligands P(*p*-OMePh)$_3$ and P(OMe)$_3$ were obtained from Strem Chemical and Eastman Kodak, respectively. All other ligands were obtained from Aldrich Chemical. The complexes (η^5-C_5H_5)Ni(Et)PPh$_3$, (η^5-C_5H_5)Ni(Me)PPh$_3$ and Ti(acac)$_3$ were synthesized by published procedures.[2,14,15] Benzene was distilled from sodium prior to use.

^{1}H NMR spectra were obtained using Bruker SY100 or WM400 spectrometers. Chemical shifts are reported relative to TMS. UV–vis spectra were measured with a Cary 17 spectrophotometer. ESR data were collected with a Varian E4 equipped with an E-257 variable temperature accessory.

Photolysis of $(\eta^5\text{-}C_5H_5)Ni(Me)PPh_3$

A sample of $(\eta^5\text{-}C_5H_5)Ni(Me)PPh_3$ (0.0030 g) in d_6-benzene (1.0 cm^3) was degassed and flame sealed into a 5 mm NMR tube. The sample was then photolysed with the filtered (5 cm H_2O in Pyrex and bandpass $\lambda > 413$ nm) output of a 150 W xenon lamp. The sample was cooled by immersion in an H_2O bath at $\sim 6°C$ during photolysis. The reaction was monitored by both NMR and ESR. Similar experiments were conducted in the presence of PR_3, (R = *n*-Bu, Ph, *p*-OMePh, *p*–FPh, OMe, OEt, OPh, dppm, dppe, C_2Ph_2, HCCPh and bipy). Spectroscopic yields were calculated by comparison of the double integral of the ESR signal, obtained as a first derivative, with that of stock solutions of $Ti(acac)_3$ of known concentration. In the absence of added ligand the spectroscopic yield of $(\eta^5\text{-}C_5H_5)Ni(PPh_3)_2$ was 0.3%. In experiments where ligands were added the yields were: $P(n\text{-}Bu)_3$, $\sim 0.1\%$; PPh_3, 9%; $P(p\text{-}OMePh)_3$, 6%; $P(p\text{-}FPh)_3$, 11%; $P(OMe)_3$, 0.3%; $P(OEt)_3$, 1%; $P(OPh)_3$, 0.5%; dppm, 0.1%; dppe, 8%; C_2Ph_2, 1%; HCCPh, 0.3%; bipy, 80%. Similar experiments were conducted with $(\eta^5\text{-}C_5H_5)Ni(Et)PPh_3$.

SELENIUM CHLORIDE AND BROMIDE EQUILIBRIA IN APROTIC SOLVENTS; A ^{77}Se NMR STUDY

MARC LAMOUREUX and JOHN MILNE*

Department of Chemistry, University of Ottawa, Ottawa, Ontario, Canada, K1N 6N5

(*Received* 26 *June* 1989; *accepted* 18 *September* 1989)

Abstract—The ^{77}Se NMR spectra of solutions with stoichiometries near those for SeX_2 and Se_2X_2 (X = Br, Cl) formation in aprotic solvents of varying basicity have been recorded. Chemical shifts for $SeCl_4$, SeX_2, Se_2X_2, Se_3X_2 and Se_4X_2 are reported. The constants for the equilibria,

$$2SeBr_2 \rightleftharpoons Se_2Br_2 + Br_2$$

$$3SeCl_2 \rightleftharpoons SeCl_4 + Se_2Cl_2$$

$$2Se_2X_2 \rightleftharpoons SeX_2 + Se_3X_2$$

$$3Se_2X_2 \rightleftharpoons 2SeX_2 + Se_4X_2$$

have been determined in various solvents from NMR spectra and chemical analysis. The position of the equilibria is very sensitive to solvent donor strength, with the selenium halide of stronger Lewis acidity favoured in the more basic solvent. Selenium bromide chloride, Se_2BrCl, has been shown to exist in equilibrium with Se_2Br_2 and Se_2Cl_2 in dichloromethane.

The oxidation state +2 is uncommon for selenium and none of the dihalides are known as pure compounds. The presence of selenium dichloride and dibromide in solution in non-aqueous solvents[1,2] and in the gas phase[3,4] has been demonstrated. It has recently been shown that pure liquid diselenium dichloride and dibromide disproportionate to a small extent and contain equilibrium concentrations of the selenium dihalide and polyselenium dihalides.[5] Selenium(II) is known in chloro- and bromoselenate(II) compounds[6] where it is apparently stabilized by halo coordination. Selenium(II) has been shown to be in equilibrium with selenium(IV) and Se_2X_2 in aqueous HCl and HBr also.[7,8] Stabilization by solvent coordination may also occur and have an important influence on the selenium dihalide concentration in solution. This present study was carried out, to determine the influence of solvent on the equilibrium distribution of selenium, diselenium and polyselenium dichlorides and dibromides in solution.

Few ^{77}Se NMR studies of inorganic selenium compounds have been made[9] and this study relies principally on this technique.

EXPERIMENTAL

Elemental selenium (99.999, Aldrich) was used directly. Selenium tetrachloride was prepared from chlorine and selenium.[10] Bromine (Fisher reagent) was distilled from phosphorus pentoxide before use. Dimethylformamide (DMF) (Fisher certified) and pyridine (py) (BDH assured) were dried over, and distilled from Dreirite. Carbon tetrachloride (Fisher certified), dichloromethane (Fisher certified) and acetonitrile (BDH assured) were dried over and distilled from phosphorus pentoxide. Solutions of the desired stoichiometry were made up by weight from selenium and $SeCl_4$ or selenium and Br_2 and the solvent, using a balance accurate to ± 2 mg. In a typical experiment 82 mg of selenium were combined with 228 mg of $SeCl_4$ in 3.993 g of acetonitrile to yield a solution of $SeCl_x$ composition with $x = 2.00 \pm 0.003$, where $c(SeCl_2) = 0.41 \pm 0.01$ M. The solution volume was considered to be that of the solvent alone. All solutions were made up in a dry box. In several cases

* Author to whom correspondence should be addressed.

an initial precipitate of red selenium was produced, which dissolved to yield clear yellow–brown coloured solutions.

Analyses for chloride and selenium were carried out, respectively, by Volhard and gravimetric methods.[11] For the pyridine mixture of 2:1 Cl/Se mole ratio, containing the insoluble $SeCl_4$ adduct (see below), dilution in aqueous acid (1 in 10) resulted in disproportionation to elemental selenium and selenate(IV). After gravimetric analysis for the precipitated selenium, the supernatant was analysed for chloride.

The bis(pyridine) adduct of $SeCl_4$, $SeCl_4 \cdot 2py$, was prepared by shaking $SeCl_4$ and dry pyridine (1:50 mol ratio) together for 12 h and filtering out the yellow product in a dry atmosphere. The product was very difficult to filter and free of solvent. Found: Se, 36.3; Cl, 20.0. Calc.: Se, 37.4; Cl, 20.8%.

Raman spectra were recorded using equipment described earlier.[2] ^{77}Se NMR spectra were recorded in 10 mm tubes, using a Varian FT300 spectrometer operating at 57.28 MHz. All shifts are reported with respect to the reference shift of saturated aqueous selenous acid solution at 20°C. The chemical shifts were determined by sample replacement and are accurate to ± 0.7 ppm. The shift of saturated selenous acid is at 1282 ppm with respect to dimethyl selenium.[12]

RESULTS AND DISCUSSION

Selenium chlorides

Selenium tetrachloride exhibits a broad range of solubility in aprotic solvents. Saturation molarities at 20($\pm$1)°C have been determined for several solvents and these are CCl_4: insoluble; CH_2Cl_2: 1.36×10^{-3}; CH_3CN: 2.05×10^{-2}; py: 5.82×10^{-2}; DMF: >1.15. The solubility increases with the donor strength of the solvent, reflecting the Lewis acidic nature of $SeCl_4$. In the case of CCl_4, CH_2Cl_2 and CH_3CN, the insoluble phase is pure $SeCl_4$ as shown by the Raman spectrum, which has characteristic strong bands at 387, 340 and 97 cm^{-1}.[13] However, in the case of pyridine the insoluble phase is a yellow adduct, $SeCl_4 \cdot 2py$, with Raman bands at 119 (6), 149 (7), 247 (9) and 279 (10) cm^{-1} (intensities in parentheses). In CH_2Cl_2 and CH_3CN solutions, even at such low concentrations, Raman bands corresponding to $SeCl_4$ species are observed,[2,14] but the ^{77}Se NMR signal could only be observed for the DMF solution, as given in Table 1 (solution No. 1). The signal observed at 153.7 ppm, which is 25 ppm to low field of that reported by Birchall *et al.*[9] for $SeCl_4$ in DMF, is broad (width at half-height = 3.4 ppm). The earlier measurement was carried out with a saturated solution, using broad-line techniques, which may account for the difference between the two results. Because of low solubility and signal breadth, the $SeCl_4$ shift could not be detected in CH_2Cl_2, CH_3CN and py. $SeCl_4$, which is known to be monomeric in CH_3CN,[15] is expected to give a broad NMR signal due to coupling to the 4 Cl's ($I = 3/2$ for both ^{35}Cl and ^{37}Cl), which will be quadrupole relaxed, and due to intramolecular chlorine exchange via a Berry mechanism. Intermolecular exchange may also occur. Similar processes causing broadening will occur with $SeCl_4$ in other solvents.

When elemental selenium is added to a saturated solution of $SeCl_4$ in CH_3CN, CH_2Cl_2 or CCl_4, there is reaction to give lower selenium chlorides:

$$SeCl_4 + Se \rightleftharpoons 2SeCl_2 \quad (1)$$

$$SeCl_4 + 3Se \rightleftharpoons 2Se_2Cl_2. \quad (2)$$

After sufficient selenium has been added all of the $SeCl_4$ reacts and the solution becomes saturated with respect to elemental selenium. The Raman spectra[14] of the Se/$SeCl_4$ solutions saturated with $SeCl_4$ exhibit peaks characteristic of $SeCl_2$ (417, 397 and 164 cm^{-1})[2] and those, saturated with selenium, peaks characteristic of Se_2Cl_2 (373 and 131 cm^{-1}).[2] The ^{77}Se NMR spectra of Se/$SeCl_4$ solutions saturated with $SeCl_4$, consist of two signals as given in Table 2 (solutions Nos 2, 4, 6). The weaker signal to highest field has a chemical shift corresponding to that of Se_2Cl_2[5,9] and that at lowest field arises from $SeCl_2$.[5] The chemical shifts of these two compounds in Se_2Cl_2 as solvent[5] are given for comparison (No. 9). The UV–vis spectra of CH_3CN solutions of 2:1 Cl/Se stoichiometry have been interpreted in terms of the equilibrium,

$$3SeCl_2 \overset{K(SeCl_2)}{\rightleftharpoons} Se_2Cl_2 + SeCl_4. \quad (3)$$

The ^{77}Se NMR spectra of the solutions in CH_3CN and CH_2Cl_2 may be interpreted similarly. The equilibrium constant at 20($\pm$1)°C may be calculated from the saturation concentration for $SeCl_4$ in each solvent, the ratio of the concentrations of Se_2Cl_2 and $SeCl_2$ calculated from NMR signal intensities and from the stoichiometric concentration of elemental selenium dissolved, c_{Se} (Table 1), which is related to the Se_2Cl_2 and $SeCl_2$ concentrations by,

$$c_{Se} = \frac{[SeCl_2]}{2} + \frac{3[Se_2Cl_2]}{2}. \quad (4)$$

The calculated values of $K(SeCl_2)$ are given in Table 2. The ^{77}Se NMR signals for pyridine were too weak for observation but chemical analysis for

selenium and chlorine in the supernatant over $SeCl_4\cdot 2py$ to which elemental selenium had been added ($c_{Se} = 0.204$ M) gave $[SeCl_2] = 0.0090$ M and $[Se_2Cl_2] = 0.0083$ M. The equilibrium constant, $K(SeCl_2)$, in pyridine, is given in Table 2. The value of $K(SeCl_2)$ for the CCl_4 solution is also given in Table 2 for comparison.

Solutions of $SeCl_4$ saturated with Se give the ^{77}Se NMR spectra shown in Fig. 1 and listed in Table 1 (Nos 3, 5, 7 and 8). In these solutions the low field shift due to $SeCl_2$ is now much weaker in intensity than that due to Se_2Cl_2. However, in addition to these peaks, there are several peaks to higher field, which may be assigned to Se_nCl_2 species ($n = 3, 4$). These signals have also been observed in solutions of selenium in Se_2Cl_2[5] and there is Raman spectroscopic evidence for Se_nCl_2 species in Se/Se_2Cl_2 mixtures.[5,17] The strongest ^{77}Se signals, and the only ones observed in this work, will arise from Se_nCl_2 species with one ^{77}Se in the chain. For Se_3Cl_2 ($ClSe^{\alpha}Se^{\beta}Se^{\alpha}Cl$), two chemical shifts, from α- and β-selenium atoms, of relative intensity 2 : 1, respectively, are expected. For Se_4Cl_2 ($ClSe^{\alpha}Se^{\beta}Se^{\beta}Se^{\alpha}Cl$), two chemical shifts of equal intensity are expected. The two weak chemical shifts which bracket the Se_2Cl_2 shift may be assigned to Se_3Cl_2 on the basis of their 2 : 1 intensity ratio with the α-selenium shift lying to high field of the Se_2Cl_2 shift in all cases. The chemical shifts of Se_3Cl_2 lie close to that of Se_2Cl_2 in pure Se_2Cl_2 also[5] and these shifts have been listed in Table 1 for comparison. The chemical shifts for Se_4Cl_2 lie to high field of those of Se_3Cl_2.[5] These are not observed for CH_3CN solutions but for CH_2Cl_2, a pair of weak signals of equal intensity at −356.5 and −374.9 ppm are observed. The lowest field signal of these two, while of the same intensity as that at −374.9 ppm, is the broader of the two and is therefore assigned to the α-selenium, which is expected to be broader due to greater coupling to the spin 3/2 chlorine nuclei, which undergo quadrupole relaxation.

In CCl_4, three signals, −353.0, −372.7 and −391.0 ppm are observed in the Se_4Cl_2 region of the spectrum. The low intensity of these signals precludes a definite interpretation, but it is not possible to assign the peaks in terms of the overlapping spectra of Se_4Cl_2 and Se_5Cl_2 (three signals of 2 : 2 : 1 relative intensity). The spectra of Se_4Br_2 in liquid Se_2Br_2, containing dissolved selenium, has a similar appearance and that of Se_4Cl_2 in liquid Se_2Cl_2 consists of a single broad peak.[5] The spectrum in CCl_4 may be accounted for by the presence of the chain form of Se_4Cl_2 and some other isomer, or higher homologue, undergoing rapid intramolecular exchange.

As in the case of pure Se_2Cl_2,[5] disproportionation equilibria of the type,

$$2Se_2Cl_2 \overset{K(Se_2Cl_2)}{\rightleftharpoons} SeCl_2 + Se_3Cl_2 \qquad (5)$$

$$3Se_2Cl_2 \overset{K'(Se_2Cl_2)}{\rightleftharpoons} 2SeCl_2 + Se_4Cl_2 \qquad (6)$$

take place in these solutions. From the relative intensities of the signals, $K(Se_2Cl_2)$ and $K'(Se_2Cl_2)$ may be determined and these are given in Table 2 along with the equilibrium constants determined for liquid Se_2Cl_2.[5]

Selenium bromides

Selenium tetrabromide is known as a crystalline solid but in the gas phase or when dissolved in

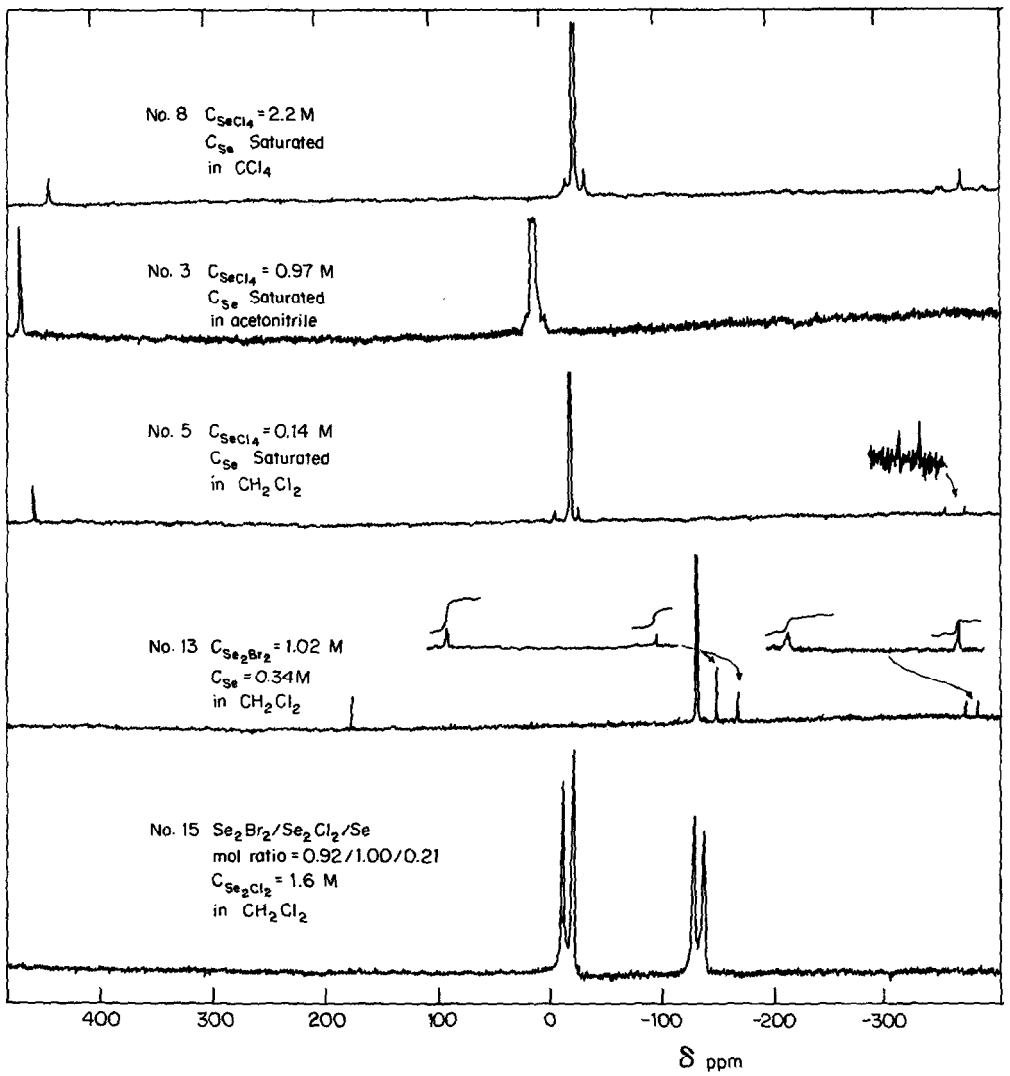

Fig. 1. ^{77}Se NMR spectra of solutions of selenium chlorides, bromides and bromide chlorides in aprotic solvents.

aprotic solvents at 25°C, it dissociates according to,

$$SeBr_4 \rightleftharpoons SeBr_2 + Br_2. \quad (7)$$

The $SeBr_2$ dissociates further to Se_2Br_2:[1,2,18]

$$2SeBr_2 \overset{K(SeBr_2)}{\rightleftharpoons} Se_2Br_2 + Br_2. \quad (8)$$

The chemical shifts for selenium bromide solutions are given in Table 1. The spectrum of a solution with a 1 : 4 atomic ratio of Se/Br (No. 12) in CH_3CN consists of a strong signal at 194.7 ppm and a very weak signal at −110.5 ppm, which is near to the reported shift for pure Se_2Br_2[5,9] and Se_2Br_2 in CH_3CN. The strong, low field signal is assigned to $SeBr_2$. For a solution in acetonitrile of 1 : 2 Se/Br atomic ratio (No. 11), the same two chemical shifts are observed but the Se_2Br_2 signal has become stronger, compared to that of $SeBr_2$, reflecting a shift of equilibrium (8) to the right due to a decrease in Br_2 concentration. The equilibrium constant, $K(SeBr_2)$, for equilibrium (8) was determined from the signal intensities of solution No. 11 and this is given in Table 3. There is excellent agreement between the value calculated here and that for the CH_3CN solution determined from UV–vis spectrophotometry.[2] The spectrum of a solution of Se_2Br_2 in acetonitrile (No. 10) had only one signal. No signals for Se_3Br_2 of Se_4Br_2 were observed due to the small number of transients collected.

The ^{77}Se NMR spectrum of a solution of a 1.17 : 1.00 Se/Br atomic ratio in CH_2Cl_2 is shown in Fig. 1 and the chemical shifts and intensities are given in Table 1 (No. 13). In addition to signals for $SeBr_2$ and Se_2Br_2, at 173.9 and −132.5 ppm, respectively, there are two sets of two signals each to high field of the Se_2Br_2 signal, which may be

Table 3. Disproportionation equilibria for $SeBr_2$ and Se_2Br_2 at 20(±1)°C in aprotic solvents

Solvent	Donor number	Dielectric constant (25°C)	$K(SeBr_2)^a$	$K(Se_2Br_2)^b$	$K'(Se_2Br_2)^c$

[e] Spectrophotometric determination.[2]

clearly assigned to Se_3Br_2 and Se_4Br_2 on the basis of their relative intensities. The assignment of the α- and β-selenium signals for Se_3Br_2 is readily made on the basis of signal intensity and width at half-height and, for Se_4Br_2 on the basis of width at half-height alone. There is an additional weak signal at −133.2 ppm, which may be due to an isotope shift in Se_2Br_2, although the shift is large compared to that observed in other compounds.[19] The signals are all assigned in Table 1. The spectra show that the diseleniumdibromide disproportionates in CH_2Cl_2 in an analogous manner to diselenium dichloride:

$$2Se_2Br_2 \overset{K(Se_2Br_2)}{\rightleftharpoons} SeBr_2 + Se_3Br_2 \qquad (9)$$

$$3Se_2Br_2 \overset{K'(Se_2Br_2)}{\rightleftharpoons} 2SeBr_2 + Se_4Br_2. \qquad (10)$$

From the signal intensities of solution No. 13, $K(Se_2Br_2)$ and $K'(Se_2Br_2)$ have been determined and these are listed in Table 3 along with analogous constants for disproportionation in pure Se_2Br_2.[5]

Diselenium bromide chloride

The ^{77}Se NMR spectrum of a 0.92:1.00:0.21 $Se_2Br_2/Se_2Cl_2/Se$ mol ratio mixture dissolved in CH_2Cl_2 is shown in Fig. 1 and the chemical shifts are listed in Table 1. Four signals are observed corresponding to the chemical shifts of pure Se_2Cl_2 and Se_2Br_2 in CH_2Cl_2 at −22.1 and −128.5 ppm, respectively, and, to ^{77}Se α to chlorine and bromine in Se_2BrCl, respectively, at −13.6 and −137.5 ppm. No signals were observed for any triselenium compound in this routine spectrum. The spectrum shows that the following equilibrium is established,

$$Se_2Br_2 + Se_2Cl_2 \overset{K_d}{\rightleftharpoons} 2Se_2BrCl. \qquad (11)$$

This equilibrium occurs in mixtures of liquid Se_2Cl_2 and Se_2Br_2 also.[5] The equilibrium constant, K_d, calculated from the intensities listed in Table 1, is 3.0.

CONCLUSIONS

For the selenium dihalide compounds in general, the chemical shifts for ^{77}Se move to higher field with increasing chain length. For the dialkyl polyselenides, the change in shift is in the opposite sense.[19] Since chlorine and bromine are more electronegative than selenium while carbon is of equivalent or lower electronegativity,[20] it appears that these trends are due to changing shielding effects arising from greater withdrawal of electrons from the selenium by chlorine and bromine than by carbon. The chemical shift of $SeCl_4$ in DMF lies to high field of that of $SeCl_2$, which is in the opposite direction of that expected on the basis of electron shielding. Birchall *et al.*[9] have noted that ^{77}Se resonance of selenium(VI) compounds lies in general to high field of those of the selenium(IV) compounds.

The change in chemical shift with changing solvent is much greater than that which can be accounted for by bulk susceptibility changes and must arise from solute–solvent interactions. For each of the Se_nX_2 species (n = 1, 2, 3) in aprotic solvents at comparable concentrations, the shift is to low field with increasing solvent donor strength.

Tables 2 and 3 list the values of the various disproportionation constants, $K(SeX_2)$, $K(Se_2X_2)$ and $K'(Se_2X_2)$, determined for selenium bromides and chlorides, as well as the dielectric constants and donor numbers for the different solvents.[21] In all cases, except for $K(SeBr_2)$, the disproportionation

is favoured by greater solvent donor strength. The dielectric constant appears to play a less important role as shown by a comparison of the CH_3CN and pyridine values for $K(SeCl_2)$ in Table 2. This is expected for these equilibria where no ions are involved. The Lewis acidity of the selenium halides is expected to follow the order,

$$SeX_4 > SeX_2 > Se_2X_2. \quad (12)$$

Thus, in pyridine, the Lewis acid base adduct formation is so favourable for $SeCl_4$ that, in spite of the weak interaction of Se_2Cl_2 with pyridine, $SeCl_2$ disproportionates extensively. Similarly, the relatively strong Lewis acidities of $SeCl_2$ and $SeBr_2$ favour the disproportionation of Se_2Cl_2 and Se_2Br_2 in more strongly donating solvents. Ultimately one of the disproportionation products is elemental selenium, which is insoluble in the solvents studied. The addition of Cl^- or Br^- to their respective selenium halides will promote disproportionation of the lower halides in some cases as well:[6]

$$Se_2Cl_2 + Cl^- \underset{CH_3CN}{\rightleftharpoons} Se^0 + SeCl_3^- \quad (13)$$

$$2SeCl_3^- \underset{\substack{Et_4NSeCl_3 \\ solid}}{\rightleftharpoons} SeCl_6^{2-} + Se^0. \quad (14)$$

In the vapour phase where there is no Lewis acid–base stabilization, $SeCl_2$ disproportionates to a very small extent.[16] No doubt in CCl_4, $K(SeCl_2)$ has a small value also and not, as shown in Table 2, zero, which is a result of the immeasurably small solubility of $SeCl_4$ in this solvent.

Selenium dibromide dissociates to Se_2Br_2 and Br_2, according to eq. (8). The dissociation constant in CCl_4[1] is greater than that in CH_3CN (Table 3). This may also be accounted for by the strong solvent–$SeBr_2$ interaction in the stronger donor solvent, CH_3CN. Apparently the Lewis acid–base interaction of the solvent with either of the two products of dissociation is weaker than that with $SeBr_2$. The Br^- ion acts to stabilize selenium(II) as well,[6] and halo coordination even permits the stabilization of bromoselenate(IV) anions,[22] while $SeBr_4$ is unstable.

The previous ^{77}Se NMR study by Birchall *et al.*[9] concluded that no Se_2BrCl was formed in a mixture of Se_2Cl_2 and Se_2Br_2. Recently it has been shown, however, that Se_2BrCl is formed.[5] The present study shows that Se_2BrCl is also formed in CH_2Cl_2. The equilibrium constants for Se_2BrCl formation, eq. (11), are both 3.0 in the two media, indicating that a small change in the polarity of the solvent has little effect on equilibrium (11).

Acknowledgement—Raj Kapoor is thanked for recording the NMR spectra.

MERCURY AND METHYLMERCURY COMPLEXES OF THE 1-BUTYL AND 1-HEXADECYL ESTERS OF L-CYSTEINE AND 2,3-DIMERCAPTOSUCCINIC ACID

KEITH WILLE, JUSTIN K. MORAN and D. MAX ROUNDHILL*

Department of Chemistry, Tulane University, New Orleans, LA 70118, U.S.A.

(*Received* 5 *July* 1989 ; *accepted* 12 *September* 1989)

Abstract—The 1-butyl and 1-hexadecyl esters of l-cysteine have been synthesized from l-cysteine hydrochloride and the corresponding alcohol. These compounds [$HSCH_2CH(NH_3)CO_2R$]Cl (R = 1-C_4H_9, 1-$C_{16}H_{33}$) complex to methylmercury via the thiolate sulphur. The complexes [$CH_3HgSCH_2CH(NH_3)CO_2R$]Cl show bands in the IR spectrum in the 300–350 cm^{-1} region due to ν(Hg—S), and in the 500–550 cm^{-1} region due to ν(Hg—C). The ethyl, 1-butyl and 1-hexadecyl esters of 2,3-dimercaptosuccinic acid have been synthesized. Complexation with mercuric ion yields polymers $(CH(SHg)CO_2R)_n$, and complexation with methylmercury gives bimetallic complexes $(CH(SHgCH_3)CO_2R)_2$. The partition coefficients between 1-octanol and water for the complexes $CH_3HgSCH_2CH(NH_2)CO_2R$ have been measured, and the values compared with that of the analogous cysteine complex $CH_3HgSCH_2CH(NH_2)CO_2H$.

The toxicity of methylmercury compounds and their ability to cross the blood–brain barrier are well known phenomena.[1] The presence of these compounds in nature continues to be a persistent problem because of their tendency to be biosynthesized and accumulated by marine organisms.[2] Ingestion of these compounds by humans results in the occurrence of neurological and other medical problems. These toxic effects are further aggravated by the fact that methylmercury compounds are only slowly expelled by the body.[3] The most commonly used therapeutic agents for ingested heavy metals are thiols. These compounds are being effective agents because the mercuric ion forms complexes of high stability by coordination via the thiolate moiety.[4]

The ability of methylmercury complexes to pass through the blood–brain barrier is a consequence of both their small size and of their lipophilicity. We have, therefore, prepared ester derivatives of l-cysteine with both short (1-C_4H_9) and long (1-$C_{16}H_{33}$) chain alkyl substituents,[5] and we have prepared the complexes of these ligands with methylmercury. The lipophilicity of these methylmercury complexes has then been compared with that of the methylmercury complex of cysteine itself.

EXPERIMENTAL

Methylmercuric acetate was purchased from Morton Thiokol Inc. L-Cysteine hydrochloride was purchased from Aldrich and stored under refrigeration. 2,3-Dimercaptosuccinic acid was synthesized by the literature procedure.[6] 1-Butanol was purchased from Mallinkrodt, and 1-hexadecyl alcohol from Aldrich. IR spectra were measured on a Mattson Cygnus 100 spectrometer. Mid-range spectra were measured with the sample coated on sodium chloride plate as a Nujol mull; in the far IR range the sample was coated on a polyethylene sheet as a vaseline mull. ^1H NMR spectra were measured in $CDCl_3$ (ligands) or d^6-DMSO (methylmercury complexes) solvent. Mercury analysis was carried out on a Beckman Spectrospan 5 direct current plasma spectrometer. Conductivity measurements were obtained with an Industrial Instruments Inc. conductivity bridge (model RC 16B2). Dimethyl sulphoxide (Mallinkrodt) was used as solvent in a cell containing platinized electrodes (cell constant

0.417). Microanalyses were performed by Galbraith Laboratories, Knoxville, Tennessee.

1-Butyl-1-cysteine hydrochloride: [$HSCH_2CH(NH_3)CO_2C_4H_9$-1]Cl

1-Cysteine hydrochloride (3.000 g, 20 mmol) and 1-butanol (15.000 g, 200 mmol) were mixed and heated under reflux in a stream of hydrogen chloride for 2 h according to published procedures.[7] The clear solution was allowed to cool, and any excess 1-butanol was removed on a rotary evaporator at 50°C. The resulting solution was cooled to 0°C to give a white precipitate. This precipitate was filtered and washed several times with diethyl ether. Yield 1.240 g (35%), m.p. 88–89°C. Found: C, 39.3; H, 7.70; N, 6.48; S, 15.4. Calc. for $C_7H_{16}ClNO_2S$: C, 39.3; H, 7.55; N, 6.55; S, 15.0%.

1-Hexadecyl-1-cysteine hydrochloride: [$HSCH_2CH(NH_3)CO_2C_{16}H_{33}$-1]Cl

1-Cysteine hydrochloride (1.000 g, 6.4 mmol) and 1-hexadeconal (8.500 g, 35 mmol) were mixed and heated gently under reflux in a stream of hydrogen chloride for 2 h. The clear solution was allowed to cool and solidify, and any excess 1-hexadecanol was removed by dissolution in benzene. The solid product was washed with acetone and collected by filtration. Yield 1.590 g (65%), m.p. 81–82°C. Found: C, 59.6; H, 10.8; N, 3.66; S, 9.11. Calc. for $C_{19}H_{40}ClNO_2S$: C, 59.7; H, 10.6; N, 3.67; S, 8.39%.

Diethyl-2,3-dimercaptosuccinate: $(CH(SH)CO_2C_2H_5)_2$

Dimercaptosuccinic acid (0.360 g, 1.98 mmol), ethanol (10 cm^3) and sulphuric acid (0.5 cm^3) were refluxed under nitrogen for 5 h. The solution was allowed to cool to room temperature, and anhydrous magnesium sulphate added. The solution was filtered, and the solvent evaporated to give the compound as colourless crystals which were washed with brine. Yield 0.240 g (51%). Found: C, 39.5; H, 5.68; S, 26.9. Calc. for $C_8H_{14}O_4S_2$: C, 40.3; H, 5.92; S, 26.9%.

Dibutyl-2,3-dimercaptosuccinate: $(CH(SH)CO_2C_4H_9$-$1)_2$

This compound was prepared by an analogous procedure to the diethyl ester using dimercaptosuccinic acid (0.390 g, 2.16 mmol) and 1-butanol (10 cm^3). Yield 0.290 g (45%). Found: C, 48.9; H, 7.35; S, 21.7. Calc. for $C_{12}H_{22}O_4S_2$: C, 49.0; H, 7.53; S, 21.8%.

Diecetyl-2,3-dimercaptosuccinate: $(CH(SH)CO_2C_{16}H_{33}$-$1)_2$

Dimercaptosuccinic acid (0.470 g, 2.59 mmol), cetyl alcohol (1.870 g, 7.66 mmol) and hydrochloric acid (0.5 cm^3) were refluxed under nitrogen until all of the dimercaptosuccinic acid had dissolved. The solution was allowed to cool to room temperature, when the reaction mixture solidified. The solid was dissolved in benzene, and magnesium sulphate added. The solution was filtered and the benzene solvent removed on a rotary evaporator. The solid residue was stirred with ethanol to remove excess cetyl alcohol, then filtered. The crude solid product was recrystallized from chloroform solution by the addition of ethanol. Yield 0.780 g (48%). Found: C, 68.8; H, 11.4; S, 10.2. Calc. for $C_{36}H_{70}O_4S_2$: C, 68.5; H, 11.2; S, 10.2%.

1-Butyl-1-cysteinato methylmercury hydrochloride: [$CH_3HgSCH_2CH(NH_3)CO_2C_4H_9$-1]Cl

Methylmercury acetate (0.155 g, 0.57 mmol) and 1-butyl-1-cysteine hydrochloride (0.100 g, 0.57 mmol) were dissolved in dichloromethane (8 cm^3) and the solution stirred for 5 h. The white precipitate which formed was collected by filtration and washed with dichloromethane. Yield 0.145 g (60%), m.p. 142–144°C. Found: C, 22.5; H, 4.23; N, 3.26; S, 8.22. Calc. for $C_8H_{18}HgNO_2S$: C, 22.4; H, 4.23; N, 3.26; S, 7.49%.

1-Hexadecyl-1-cysteinato methylmercury hydrochloride: [$CH_3HgSCH_2CH(NH_3)CO_2C_{16}H_{33}$-1]Cl·$H_2O$

Methylmercuric acetate (0.072 g, 0.26 mmol) and 1-hexadecyl-1-cysteine hydrochloride (0.100 g, 0.26 mmol) were dissolved in dichloromethane (8 cm^3), and the solution stirred for 5 h. The white precipitate which formed was collected by filtration, and washed with dichloromethane. Yield 0.101 g (65%), m.p. 117–119°C. Found: C, 39.5; H, 7.07; N, 2.58. Calc. for $C_{20}H_{43}ClNO_3HgS$: C, 39.1; H, 7.06; N, 2.28%.

Diethyl-2,3-dimercaptosuccinato mercury: $(CH(SHg)CO_2C_2H_5)_n$

A solution of diethyl-2,3-dimercaptosuccinate (0.079 g, 0.33 mmol) in nitrogen saturated methanol

($3\ cm^3$) was added to a stirred solution of mercuric chloride (0.089 g, 0.33 mmol) in nitrogen saturated methanol ($7\ cm^3$). A white precipitate formed immediately. After 3 h the solution was filtered and the precipitate washed with methanol. Yield 0.780 g (54%). Found: C, 21.9; H, 2.75; S, 15.0. Calc. for $C_8H_{12}HgO_4S_2$: C, 22.0; H, 2.77; S, 14.7%.

Dibutyl-2,3-dimercaptosuccinato mercury: $(CH(SHg)CO_2C_4H_9\text{-}1)_n$

A solution of dibutyl-2,3-dimercaptosuccinate (0.129 g, 0.439 mmol) in acetonitrile ($3\ cm^3$) was added to a stirred solution of mercuric chloride (0.119 g, 0.441 mmol) in acetonitrile ($6\ cm^3$). After 24 h the white precipitate was filtered and washed with acetonitrile. Yield 0.087 g (40%). Found: C, 27.5; H, 3.87; S, 12.6. Calc. for $C_{12}H_{26}HgO_4S_2$: C, 29.2; H, 4.09; S, 13.0%.

Dicetyl-2,3-dimercaptosuccinato mercury: $(CH(SHg)CO_2C_{26}H_{33}\text{-}1)_n$

A solution of dicetyl-2,3-dimercaptosuccinate (0.237 g, 0.375 mmol) in benzene ($3\ cm^3$) was added to a stirred solution of mercuric chloride (0.102 g, 0.377 mmol) in benzene ($8\ cm^3$). The white precipitate which formed was filtered and washed with benzene. Yield 0.118 g (38%). Found: C, 52.1; H, 8.47; S, 7.97. Calc. for $C_{36}H_{68}HgO_4S_2$: C, 52.1; H, 8.26; S, 7.73%.

Diethyl-2,3-dimercaptosuccinato methylmercury: $(CH(SHgCH_3)CO_2C_2H_5)_2$

A solution of methylmercuric acetate (0.113 g, 0.414 mmol) in water ($4\ cm^3$) was added to a stirring solution of diethyl-2,3-dimercaptosuccinate (0.099 g, 0.414 mmol) in water ($10\ cm^3$). A white precipitate formed immediately. This precipitate was filtered and washed with water. Yield 0.062 g (45%). Found: C, 18.6; H, 2.78. Calc. for $C_{10}H_{18}O_4Hg_2S_2$: C, 18.0; H, 2.72%.

Dibutyl-2,3-dimercaptosuccinato methylmercury: $(CH(SHgCH_3)CO_2C_4H_9\text{-}1)_2$

A solution of dibutyl-2,2-dimercaptosuccinate (0.129 g, 0.439 mmol) was added to a stirred solution of methylmercuric acetate (0.119 g, 0.435 mmol) in acetonitrile ($6\ cm^3$). The solution was stirred for 24 h, filtered and washed with acetonitrile. Yield 0.067 g (42%). Found: C, 22.4; H, 3.81. Calc. for $C_{14}H_{26}Hg_2O_4S_2$: C, 23.2; H, 3.62%.

RESULTS AND DISCUSSION

Cysteine esters

The 1-butyl and 1-hexadecyl esters of l-cysteine were prepared by standard esterification procedures from the alcohols in the presence of hydrogen chloride [eq. (1)]. The product esters were collected as solids, and their purity confirmed by both melting point and by microanalysis. Both compounds react with methylmercuric acetate in a 1 : 1 stoichiometric ratio to to form a colourless complex. The same complexes are obtained when a 2 : 1 ratio of ligand–methylmercuric acetate is used. Complexation occurs to mercury via the thiolato anion of the cysteinyl ester [eq. (2)]. This complexation is verified by loss of the IR band due to ν(SH), and its replacement by an IR band due to ν(HgS) at 323 cm^{-1} (R = 1-C_4H_9) and at 322 cm^{-1} (R = 1-$C_{16}H_{33}$). The frequencies of these bands closely correlate with that found at 325 cm^{-1} for the thiolate bonded complex formed between cysteine and methylmercury.[7] The methyl group is not displaced from mercury in these complexes as evidenced by the presence of IR bands at 541 cm^{-1} (R = 1-C_4H_9) and 538 cm^{-1} (R = 1-$C_{16}H_{33}$), along with a methyl resonance in the ^1H NMR spectrum at δ 0.6 for the methyl group bonded to mercury. By comparison, the analogous complex with cysteine shows ν(Hg—S) at 538 cm^{-1} (Table 1).

The complexes $[CH_3HgSCH_2CH(NH_3)CO_2R]Cl$ (R = 1-C_4H_9, 1-$C_{16}H_{33}$) are isolated as their hydrochloride salts. These stoichiometries are confirmed by analytical and conductivity data, the salts having the molar conductivity of a 1 : 1 electrolyte in dimethyl sulphoxide solvent (Table 2).[8] The complexes are only very slightly soluble in water, but solutions can be prepared in aqueous potassium hydroxide. Solutions of each complex, along with the complex synthesized from free cysteine, in aqueous potassium hydroxide (pH 12) have been shaken with 1-octanol and the partition coefficient between the solvent layers measured for each.[9] The complexes with R = H, 1-C_4H_9 are insoluble in 1-octanol, but the complex with R = 1-$C_{16}H_{33}$ has a 9:1 distribution coefficient between 1-octanol and water. the lipophilicity of the 1-hexadecyl complex, as measured by this parameter, is therefore greater than that of the analogous complexes with cysteine itself, or with the 1-butyl ester.

2,3-Dimercaptosuccinic acid esters

Two of the more commonly used therapeutic agents for heavy metal toxicity are compounds which are chelating dithiols. These compounds are dimercaprol and 2,3-dimercaptosuccinic acid.[10–12] We have prepared both short and long chain aliphatic esters of 2,2-dimercaptosuccinic acid. The ethyl, 1-butyl and 1-hexadecyl esters have been prepared by standard esterification procedures in acidic medium [eq. (3)]. The compounds shows IR bands due to both ν(SH) and ν(CO) (Table 3). In addition to resonances due to the ester functionalities, the compounds show resonances in the ^{1}H NMR spectra due to both the SH and the backbone CH groups. These resonances each show a six-line multiplicity pattern centre around δ 2.3 (SH) and 3.6 (CH) and the spectral lines can be fitted to an AA′XX′ spectrum. This multiplicity is therefore not a consequence of the two hydrogens being bonded to diastereotopic carbons. Furthermore, solutions of the compounds in D_2O/OD^- show a single resonance in the C—H region.

The compounds $(CH(SH)CO_2R)_2$ (R = Et, 1-C_4H_9, 1-$C_{16}H_{33}$) react with methylmercuric acetate and mercuric chloride to form thiolate-coordinated complexes. The complexes have the respective stoichiometries $(CH(SHgCH_3)CO_2R)_2$ and $(CH(SHg)CO_2R)_n$ [eqs (4) and (5)]. All of the complexes exhibit poor solubility in organic solvents, and all are insoluble in 1-octanol. We have, therefore, been unsuccessful in increasing the lipophilicity of the mercury complexes of 2,3-dimercaptosuccinic acid by esterification of the carboxylic acid functionality with either short or long chain alkyl functional groups.

$$HO_2CCH(SH)CH(SH)CO_2H + 2ROH \longrightarrow RO_2CCH(SH)CH(SH)CO_2R + 2H_2O \quad (3)$$

(R = C_2H_5, 1-C_4H_9, 1-$C_{16}H_{33}$)

$$2\,CH_3HgOAc + [CH(SH)CO_2R]_2 \longrightarrow$$

ORGANOIMIDO COMPLEXES OF TUNGSTEN(IV) CONTAINING π-ACCEPTOR LIGANDS

ALASTAIR J. NIELSON* and DAVID C. WARE

Department of Chemistry, University of Auckland, Private Bag, Auckland, New Zealand

(*Received* 19 *July* 1989; *accepted* 18 *September* 1989)

Abstract—Reaction of PhC≡CPh with $[WCl_2(NR)(PMe_3)_3]$ gives the *cis*-dichloro-*trans*-phosphine complexes $[WCl_2(NR)(PhC{\equiv}CPh)(PMe_3)_2]$ [R = Ph (**1**), R = $CHMe_2$ (**3**)] in which the π-acceptor acetylene ligand lies *cis* to the imido function. For **1** ν(C≡C) is at 1760 cm^{-1} and for **3**, 1740 cm^{-1}. $Me_3SiC{\equiv}CSiMe_3$ and PhC≡CPh do not replace phosphine ligands from $[WCl_2(NPh)(PMe_3)_3]$ or $[WCl_2(NPh)(PMePh_2)_3]$. Reaction of PhC≡CPh with $[WCl_2(NPh)(PMe_2Ph)_3]$ gives $[WCl_2(NPh)(PhC{\equiv}CPh)(PMe_2Ph)_2]$ (**2**). Alkyl substituted acetylenes do not react cleanly with $[WCl_2(NPh)(PMe_3)_3]$ but HC≡CH gives $[WCl_2(NPh)(HC{\equiv}CH)(PMe_3)_2]$ (**4**). Reaction of PhC≡CH with $[WCl_2(NR)(PMe_3)_3]$ gives $[WCl_2(NR)(PhC{\equiv}CH)(PMe_3)_2]$ [R = Ph (**5**), R = $CHMe_2$ (**6**)]. The phenylacetylene ligand gives rise to asymmetry in **5** and **6** leading to AB system $^{31}P\{^1H\}$ NMR spectra. Different values of ^1J(PW) for the two phosphine ligands in both complexes indicate small differences in W—P bonding. The acetylenic protons and carbons in the ^1H and $^{13}C\{^1H\}$ NMR spectra of the phenylacetylene complexes couple differently to the two phosphines. For **5** ^3J(HP) *cis* and *trans* = 5.90 and 17.26 Hz, ^2J(C[H]P) *cis* and *trans* = 5.29 and 21.99 Hz and ^2J(C[Ph]P) *cis* and *trans* = 4.88 and 15.63 Hz. The $^{13}C\{^1H\}$ NMR acetylenic carbon resonance positions in complexes **1**, **3**, **5** and **6** suggest that an isopropylimido ligand is a better π-donor than a phenylimido ligand, allowing more metal–acetylene π-back donation. Reduction of $[WCl_3(NPh)(PMe_3)_2]$ with Na/Hg amalgam under CO gives $[WCl_2(NPh)(C{\equiv}O)(PMe_3)_2]$ (**7**) for which ν(C≡O) at 1925 cm^{-1} indicates considerable π-backbonding.

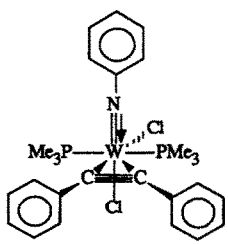
High valence state complexes which contain both a strong π-donor and a π-acceptor ligand constitute an emerging area of study in early transition metal chemistry. These complexes presently form a basis for studies involving the interaction of multiple bonded organic compounds with high valent metal species in various catalytic processes.[1] Although strong π-donation is normally associated with high valent complexes and π-acceptor ligands with metals in low valency states, there are nevertheless examples known which contain both ligand types. These complexes which mostly contain the terminal oxo ligand and have the d^2 electron configuration include $[Mo(O)(alkyne)(S_2CNR_2)_2]$,[2,3] $[W(O)Cl_2(L)(PMePh_2)_2]$ (L = $CH_2{=}CH_2$, $CH_2{=}CHMe$, $CH_2{=}CH{-}CH{=}CH_2$, C≡O, Me_3CNC),[4] $[W(O)Cp(C_6H_5)(PhC{\equiv}CPh)]$,[5] $[W(O)Cp(HC{\equiv}CH)R]$ (R = Me, COMe),[6] and $[W(S)(PhC{\equiv}CPh)(S_2CNMe_2)_2]$.[7] Several organoimido complexes (M≡NR)[8] are also known including $[W(NR)(L)(S_2CNR_2)_2]$ (L = $MeO_2CC{\equiv}CCO_2Me$,[9] C≡O[10]), $[ReCl_3(NPh)(C{\equiv}O)(PPh_3)]$,[11] $[TaCl_2(NPh)(CH_2{=}CHR)(PMe_3)_2]$ (R = Me, Ph)[12] and $[W_2Cl_4(\mu{=}N{-}N{=})(PhC{\equiv}CPh)_2(MeOCH_2CH_2OMe)_2]$.[13] As part of our continuing studies of organoimido chemistry[14] we have prepared complexes containing acetylene or carbon monoxide ligands in conjunction with an organoimido function. In particular, the scope of the reaction of $[WCl_2(NR)(P)_3]$ complexes (R = phenyl, alkyl; P = phosphine) with various acetylene ligands and the NMR spectra of the resulting complexes has been studied. A preliminary report of this work has appeared.[15]

RESULTS AND DISCUSSION

When $[WCl_2(NPh)(PMe_3)_3]$[16] was refluxed in benzene with dimethyl acetylenedicarboxylate, a

* Author to whom correspondence should be addressed.

brown intractable material formed for which spectral data indicated decomposition of the acetylene component. However, with diphenylacetylene, one phosphine ligand was replaced giving rise to $[WCl_2(NPh)(PhC{\equiv}CPh)(PMe_3)_2]$ (**1**) which, in contrast to $[WCl_2(NPh)(PMe_3)_3]$, is air stable. The IR spectrum showed $\nu(C{\equiv}C)$ for the diphenylacetylene ligand as a weak absorption at 1760 cm^{-1} and $\nu_{sym}(W{-}N{-}C)$ for the phenylimido ligand at 1350 cm^{-1}[17] (Table 1). W—Cl stretches at 268 and 245 cm^{-1} indicated a *cis* orientation of the two chloro ligands.[18] The presence of virtually coupled triplets for the PMe_3 ligands in both the ^1H and $^{13}C\{^1H\}$ NMR spectra[19] and a singlet with associated tungsten-183 sidebands in the $^{31}P\{^1H\}$ NMR spectrum, indicated equivalent *trans* phosphines (Table 2). Based on this *cis*-dichloro-*trans*-phosphine geometry the diphenylacetylene ligand in the complex lies *cis* to the imido function [Structure (a)].



(a)

Symmetry inherent in complex **1** and the bonding modes of the imido and acetylene ligands are apparent from the $^{13}C\{^1H\}$ NMR spectrum. The acetylenic carbons appear as a ^{31}P-coupled triplet with associated ^{183}W satellites ($^1J(CW) = 28.52$ Hz) and are shifted 66 ppm downfield compared with the free ligand. While the *ipso*-carbon of the aromatic ring is somewhat broadened by poorly resolved coupling to ^{31}P, the *ortho*-carbons and *ipso*-carbon of the phenylimido ligand aromatic ring appear as well-defined triplets ($^4J(CP)_{ortho} = 1.89$ Hz and $^3J(CP)_{ipso} = 2.36$ Hz). Only the *ipso*-carbon shows coupling to ^{183}W ($^2J(CW) = 36.29$ Hz). The position of the phenylimido ligand *ipso*-carbon (154.76 ppm) indicates the imido ligand acts as a four-electron donor to the central tungsten atom.[20] Thus for the complex to attain an 18-electron configuration the acetylene ligand must represent a two-electron donor. This formalism is evident from the position of the acetylenic carbon resonance (155.77 ppm) which is similar to that shown by two-electron donor diphenylacetylene complexes of molybdenum and tungsten.[21]

An X-ray crystal structure determination of $[WCl_2(NPh)(PhC{\equiv}CPh)(PMe_3)_2]$ (**1**)[15] has confirmed the *cis*-dichloro-*trans*-phosphine geometry about the tungsten centre as well as the *cis* orientation of the phenylimido and diphenylacetylene ligands. The $W{-}N{-}C_{imido}$ bond angle of

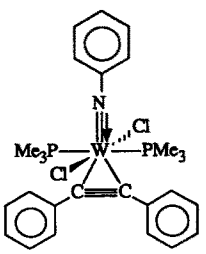
[e] $\nu(C{\equiv}O)$ 1925 cm^{-1}.

176.3(1.5)° and the W—N_{imido} bond length of 1.770(14) Å supports the assignment of the phenylimido ligand as a four-electron donor, while the W—$C_{acetylene}$ and C≡C bond lengths (2.128(20), 2.123(21) and 1.26(2) Å, respectively) are consistent with a two-electron donor diphenylacetylene ligand. This indicates that the +4 oxidation state prevails in the complex, which would make available two *d*-electrons for π-backbonding to the acetylene. The +4 oxidation state is thought to be present in $[WCl_4(PhC{\equiv}CPh)]$.[22] The structure of **1** contrasts with that of $[Mo(N\text{-}p\text{-tolyl})(MeO_2CC{\equiv}CCO_2Me)(S_2CNEt_2)_2]$ where the acetylene ligand competes with the imido ligand in contributing π-electron density to the metal.

Coordination of the acetylene ligand *cis* to the strongly π-donating imido function rather than *trans* [Structure (b)] is also found in the related



(b)

oxoacetylene complexes of tungsten and is the configuration expected on simple MO grounds. The electronic influence of the imido group forces the metal non-bonding *d*-electrons to lie in the d_{xy}-orbital where they are only available to π-backbond with the unsaturated ligand if it is in the *cis* position.[23]

The position of ν(C≡C) in the complex (1760 cm^{-1}) suggests considerable backbonding to the acetylene takes place. It is significantly lower than in the molybdenum oxo complexes $[Mo(O)(PhC{\equiv}CPh)(S_2CNR_2)_2]$ (R = Et, Me, ν(C≡C) 1870–1790 cm^{-1})[2,3] for which dissociation of the alkyne ligand readily occurs. It is only slightly higher than for the tungsten complex $[W(S)(PhC{\equiv}CPh)(S_2CNEt_2)_2]$ (ν(C≡C) 1745 cm^{-1}) where the ^1H NMR spectrum suggests alkyne rotation is appreciable only at 100°C in *p*-xylene solution (activation energy 18 kcal mol^{-1}).[7] The barrier to alkyne rotation in complex **1** is expected to be similarly large as the π-backbonding component would be lost when the ligand rotates 90°.

Bis(trimethylsilyl)acetylene does not replace a phosphine ligand from $[WCl_2(NPh)(PMe_3)_3]$ and diphenylacetylene fails to react with $[WCl_2(NPh)(PMePh_2)_3]$ suggesting that steric effects are important in the reaction. Diphenylacetylene does, however, react with $[WCl_2(NPh)(PMe_2Ph)_3]$ under reflux in benzene to give $[WCl_2(NPh)(PhC{\equiv}CPh)(PMe_2Ph)_2]$ (**2**). The green complex is again air stable and spectral data indicate the *cis*-dichloro-*trans*-phosphine geometry of complex **1** (ν(W—Cl) 260 and 235 cm^{-1}; ^1H and $^{13}C\{^1H\}$ NMR spectrum: two virtually coupled PMe_3 triplets; $^{31}P\{^1H\}$ NMR spectrum: one singlet) and a similar degree of π-back donation to the acetylene ligand (ν(C≡C) 1760 cm^{-1}). In the $^{13}C\{^1H\}$ NMR spectrum the *ipso*- and *ortho*-carbons of the phosphine aromatic ring appear as ^{31}P-coupled triplets as do the acetylenic carbon resonances and the *ipso*-carbon of the phenylimido ligand aromatic ring.

$[WCl_2(NCHMe_2)(PhC{\equiv}CPh)(PMe_3)_2]$ (**3**) was prepared for spectral comparison with the phenylimido analogue (**1**). In the IR spectrum ν(C≡C) occurs at 1740 cm^{-1} which is 20 cm^{-1} lower than complex **1** and may represent a slight increase in π-backbonding to the acetylene. The IR and NMR spectral features indicate the usual *cis*-dichloro-*trans*-phosphine geometry. No asymmetry is present in the complex so the isopropylimido ligand methyl groups are a single doublet in the ^1H NMR spectrum. In the $^{13}C\{^1H\}$ NMR spectrum the methyl carbons and the CH carbon appear as triplets, the latter showing coupling to ^{183}W ($^2J(CW) = 30.97$ Hz). The acetylenic carbons appear as a ^{31}P-coupled triplet lying slightly upfield to those in complex **1** (151.41 cf. 155.77 ppm) which also suggests a small increase in π-backbonding.[24]

Alkyl substituted acetylenes (e.g. $CH_3CH_2C{\equiv}CCH_2CH_3$, $CH_3CH_2CH_2C{\equiv}CCH_3$) do not react cleanly with $[WCl_2(NPh)(PMe_3)_3]$ but $[WCl_2(NPh)(HC{\equiv}CH)(PMe_3)_2]$ (**4**) forms when acetylene gas is used. Spectral data indicate the usual *cis*-dichloro-*trans*-phosphine geometry and ν(C≡C) in the IR spectrum is at 1632 cm^{-1} (cf. 1974 cm^{-1} for free acetylene). Features of the ^1H NMR spectrum are the ^{31}P-coupled triplet for the acetylenic protons ($^3J(HP) = 3.26$ Hz) and the deceptively simple phenylimido aromatic ring pattern. The *ortho*-protons appear as a doublet lying upfield of the other resonances and the *meta*- and *para*-protons are triplets both of which approximate the A part of an AX_2 system.[25]

Reaction of phenylacetylene with $[WCl_2(NPh)(PMe_3)_3]$ gives rise to $[WCl_2(NPh)(PhC{\equiv}CH)(PMe_3)_2]$ (**5**) which has the usual *cis*-dichloro-*trans*-phosphine geometry. However, coordination of this unsymmetrical acetylene leads to asymmetry in the complex which is reflected in the NMR spectra of the phosphine ligands. The ^1H, $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectra each show two doublets suggesting *cis*-phosphines but on the basis of the large P—P coupling constant ($^2J(PP) = 164.31$ Hz)

Table 2. NMR spectral data

[a] Spectra obtained in $CDCl_3$.

[b] d = doublet, dd = doublet of doublets, m = multiplet, prt = poorly resolved triplet, s = singlet, sept = septet, t = triplet.

[c] Aromatic ring resonances assigned by spectral comparisons of complexes; *meta*-Cs based on δ128.5, *para*-Cs from relative peak height, *ortho*-Cs as triplets for phenylimido ligands, otherwise tentative.

[d] ^2J(PP) = 164.31 Hz.

[e] ^2J(PP) = 156.45 Hz.

the phosphines are *trans*,[26] with the doublets arising from non-equivalent PMe_3 ligands.* The ^1H and $^{13}C\{^1H\}$ NMR spectra of the PMe_3 ligands show virtual coupling and the $^{31}P\{^1H\}$ NMR spectrum represents an AB system which has been simulated.[28] The two phosphines show different ^{31}P–^{183}W couplings ($^1J(PW) = 209.6$ and 222.7 Hz) suggesting small differences in the W—P bonding modes.[27,29]

Asymmetry present in the complex has a marked effect on the appearance of the acetylenic carbons and proton in the NMR spectra. The CH proton in the ^1H NMR spectrum is a doublet of doublets showing different coupling to the phosphines which lie *cis* and *trans* to it ($^3J(HP)_{cis} = 5.90$ Hz, $^3J(HP)_{trans} = 17.26$ Hz).

Variable-temperature studies to 80°C (353 K) show no change in the spectrum ruling out fluxional processes such as rotation or dissociation. Simulation shows that the doublet of doublets is the X part of an AMX system while the coupling pattern is confirmed in the proton coupled ^{31}P NMR spectrum. Each line of the phosphine doublet of doublet AB system splits further with the lower field portion ($\delta = -13.30$ ppm) showing $^3J(HP)$ of 17.26 Hz while for the higher field portion, $^3J(HP)$ is 5.90 Hz. Simulation shows the expected 20-line spectrum consisting of 10 doublet sets.

The acetylenic CH carbon in the $^{13}C\{^1H\}$ NMR spectrum appears as a doublet of doublets for which $^2J(CP)_{cis}$ is 5.29 Hz and $^2J(CP)_{trans}$ is 21.99 Hz, and the phenyl substituted acetylenic carbon is also a doublet of doublets with $^2J(CP)_{cis}$ 4.88 Hz and $^2J(CP)_{trans}$ 15.63 Hz. Simulation of these carbon–phosphorus coupled spectra show they are AMX systems. The two acetylenic carbons exhibit different C—W coupling constants ($^1J(C[H]W) = 23.11$ Hz, $^1J(C[Ph]W) = 31.26$ Hz) which is consistent with the two different carbons being non-equivalent. Of the remaining ^{31}P-coupled carbon resonances in the spectrum, the phenylimido *ortho*- and *ipso*-carbons and the phenylacetylene *ipso*-carbons all appear as triplets.

$[WCl_2(NCHMe_2)(PhC{\equiv}CH)(PMe_3)_2]$ (**6**) was prepared for spectral comparison with phenylimido complex **5**. The isopropylimido ligand methyl groups of this *cis*-dichloro-*trans*-phosphine complex appear in the ^1H NMR spectrum as two doublets which arise due to asymmetry present in the molecule. Similar to the phenylimido complex **5**, the acetylenic proton for **6** is a doublet of doublets in the ^1H NMR spectrum ($^3J(HP)_{cis} = 5.97$ Hz, $^3J(HP)_{trans} = 16.60$ Hz), the acetylenic carbons in the $^{13}C\{^1H\}$ NMR spectrum are doublet of doublets and the phenylacetylene *ipso*-carbon is a triplet. However, the positions of the acetylenic carbon resonances in **5** and **6** are different (i.e. for **5** and **6**, CH at 140.22 and 135.33 ppm, respectively, CPh at 152.80 and 148.54 ppm, respectively) which suggests a small increase in π-backbonding in **6**.[24] This feature was also found for complexes **2** and **1** and indicates that the isopropylimido ligand is a slightly better π-donor than the phenylimido ligand.

The $^{31}P\{^1H\}$ NMR spectrum AB systems are similar in both complexes, but $^2J(PP)$ for **6** is smaller (156.45 Hz cf. 164.31 Hz for **5**). The $^1J(PW)$ values of 214.5 and 228.5 Hz for **6** again suggest small differences in the W—P bonding modes.[27,29]

Carbon monoxide also replaces one phosphine ligand from $[WCl_2(NPh)(PMe_3)_3]$ under reflux in benzene, but a cleaner reaction occurs when $[WCl_3(NPh)(PMe_3)_2]$ is reduced in the presence of C≡O with one equivalent of Na/Hg amalgam. This reductive process does not give the previously described acetylene complexes cleanly but does give good yields of olefin–imido complexes.[27]

$[WCl_2(NPh)(C{\equiv}O)(PMe_3)_2]$ (**7**) is a purple, air-stable solid for which IR and NMR spectral data show the same *cis*-dichloro-*trans*-phosphine geometry exhibited by the acetylene complexes which places the C≡O ligand *cis* to the imido function. $\nu(C{\equiv}O)$ lies at 1925 cm^{-1} in the IR spectrum indicating significant backbonding to C≡O.[30] In comparison, $\nu(C{\equiv}O)$ is found at 2006 cm^{-1} for $[WCl_2(O)(C{\equiv}O)(PMePh_2)_2]$,[4] 2040 cm^{-1} for $[ReCl_3(NPh)(C{\equiv}O)(PPh_3)]$,[11] and 1912 cm^{-1} for $[W(NPh)(S_2CNEt_2)_2(C{\equiv}O)]$.[10] In the $^{13}C\{^1H\}$ NMR spectrum the phenylimido ligand *ipso*- and *ortho*-carbons show the normal triplet as does the C≡O carbon ($^2J(CP) = 4.78$ Hz).

EXPERIMENTAL

$[WCl_2(NPh)(PMe_3)_3]$, $[WCl_2(NPh)(PMe_2Ph)_3]$ and $[WCl_2(NCHMe_2)(PMe_3)_3]$ were prepared by Na/Hg amalgam reduction of $[WCl_4(NPh)]_2$ or $[WCl_4(NCHMe_2)]_2$ in the presence of the appropriate phosphine, and $[WCl_3(NPh)(PMe_3)_2]$ by reaction of $[WCl_4(NPh)]_2$ with PMe_3 in THF.[16] Commercial acetylene and carbon monoxide were used as supplied. Petroleum ether (b.p. 40–60°C) and benzene were distilled from sodium wire. All distillations and bench-top manipulations were carried out under N_2 treated to remove oxygen and water.[31] IR spectra were recorded on a Perkin–Elmer 597 spectrometer and ^1H NMR (400 MHz),

* The $^2J(PP)$ coupling constant value is similar to that found for $[WCl_2(NPh)(Me_2C{=}CH_2)(PMe_3)_2]$ which shows an AB pattern in the $^{31}P\{^1H\}$ NMR spectrum for *trans*-orientated PMe_3 ligands, confirmed by an X-ray crystal structure.[27]

$^{13}C\{^1H\}$ NMR (100.6 MHz) and $^{31}P\{^1H\}$ NMR (162 MHz) spectra on a Bruker AM400 spectrometer. Analytical data were obtained by Professor A. D. Campbel and his associates, University of Otago, New Zealand. Melting points were determined in sealed tubes under N_2 on an electrothermal melting point apparatus and are uncorrected.

Dichloro(diphenylacetylene)phenylimidobis(trimethylphosphine)tungsten(IV) (**1**)

Diphenylacetylene (0.5 g, 2.8 mmol) in benzene (30 cm^3) was added to dichloro(phenylimido) tris(trimethylphosphine)tungsten(IV) (1.0 g, 1.74 mmol) in benzene (80 cm^3) and the mixture was refluxed for 20 h. The solution was filtered and the solvent removed to give a yellow gum which solidified on washing with petroleum ether (50 cm^3). Crude yield, 1.0 g (85%). An analytically pure sample was obtained by extracting the crude product with petroleum ether (5 × 100 cm^3), combining the extracts, and reducing the volume to give the complex as yellow crystals (0.35 g).

IR (Nujol) 1760bm, 1578m, 1570m, 1555w, 1460s, 1400m, 1330s, 1292m, 1271s, 1140w, 1085w, 1055m, 1010m, 995w, 975m, 935vs, 904m, 878w, 845m, 836m, 768s, 757s, 750s, 740m, 727s, 690s, 678s, 672m, 620w, 611w, 583w, 564m, 554m, 538w, 527w, 480w, 458w, 395w, 373w, 345w, 258m, 255s, 230s and 215m cm^{-1}.

Dichlorobis(dimethylphenylphosphine)diphenylacetylene(phenylimido)tungsten(IV) (**2**)

Diphenylacetylene (0.25 g, 1.4 mmol) and dichlorotris (dimethylphenylphosphine) phenylimidotungsten (IV) (0.9 g, 1.2 mmol) were refluxed in benzene (30 cm^3) for 16 h. The solution was filtered, the solvent removed and the residue washed with petroleum ether (100 cm^3). Crude yield, 0.8 g (84%). Concentration of the petroleum ether extracts (5 × 100 cm^3) gave the complex as yellow crystals (0.2 g).

IR (Nujol) 1760w, 1590w, 1564w, 1345m, 1294w, 1272w, 1255w, 1134w, 1100w, 1060w, 1018w, 988w, 944m, 922s, 910s, 904s, 864w, 845w, 830w, 795w, 775m, 760s, 742s, 718m, 690m, 680s, 670m, 684s, 585w, 570m, 560m, 544w, 525w, 484m, 455w, 415w, 378w, 335w, 260m and 235m cm^{-1}.

Dichloro(diphenylacetylene)isopropylimidobis(trimethylphosphine)tungsten(IV) (**3**)

Diphenylacetylene (0.2 g, 1.1 mmol) and dichloro (isopropylimido) tris (trimethylphosphine) tungsten (IV) (0.4 g, 0.74 mmol) were refluxed in benzene (80 cm^3) for 18 h. The solution was filtered, the volume reduced to *ca* 15 cm^3 and petroleum ether (100 cm^3) added. On standing, colourless crystals of the complex were formed. Yield, 0.36 g (76%).

IR (Nujol) 1740bw, 1595w, 1480m, 1420m, 1378m, 1300m, 1275s, 1155w, 1110w, 1068w, 1024w, 950s, 865m, 785s, 778m, 755s, 722s, 705s, 680w, 632w, 584m, 565w, 558w, 510m, 475w, 458w, 410w, 270s and 245s cm^{-1}.

Acetylenedichlorophenylimidobis(trimethylphosphine)tungsten(IV) (**4**)

Dichloro (phenylimido) tris (trimethylphosphine) tungsten(IV) (0.7 g, 1.2 mmol) was refluxed in benzene (80 cm^3) for 16 h under an acetylene atmosphere (balloon). The solution was filtered while hot, and the volume reduced to *ca* 40 cm^3 keeping the solution hot. On standing, yellow microcrystals of the product separated (0.4 g) which were filtered off and washed with petroleum ether (50 cm^3). Addition of petroleum ether (50 cm^3) to the filtrate gave a further crop of yellow microcrystals (0.2 g). Total yield, 94%.

IR (Nujol) 1632w, 1582w, 1482s, 1462s, 1423m, 1348s, 1305w, 1294m, 1288m, 1282m, 1173w, 1256w, 1074w, 1028w, 1008w, 996m, 988m, 955vs, 868m, 860m, 777m, 768s, 750m, 745s, 725w, 700s, 683w, 675w, 630w, 625w, 560w, 538w, 496w, 398w, 355w, 285m, 275s and 240s cm^{-1}.

Dichloro(phenylacetylene)phenylimidobis(trimethylphosphine)tungsten(IV) (**5**)

Phenylacetylene (0.16 g, 1.6 mmol) in benzene (30 cm^3) was added to dichloro(phenylimido) tris(trimethylphosphine)tungsten(IV) (0.8 g, 1.4 mmol) in benzene (80 cm^3) and the mixture was refluxed for 18 h. The solution was filtered and the solvent removed to give a gum which solidified on standing under petroleum ether (100 cm^3). Crude yield, 0.74 g (88%). Combination of petroleum ether extracts (3 × 100 cm^3) and reduction of the volume gave the complex as yellow crystals (0.3 g).

IR (Nujol) 1731bw, 1595w, 1580w, 1462m, 1415s, 1354s, 1308w, 1285m, 1162w, 1071m, 1028m, 990m, 950vs, 857m, 784s, 770s, 745s, 730w, 710s, 700s, 682w, 635w, 628w, 565w, 552w, 538w, 528w, 515w, 398w, 353w, 271s, 248m, 230s and 208m cm^{-1}.

Dichloro(isopropylimido)phenylacetylenebis(trimethylphosphine)tungsten(IV) (**6**)

Dichloro(isopropylimido)tris(trimethylphosphine) tungsten(IV) (0.9 g, 1.7 mmol) and phenylacetyl-

ene (0.2 g, 2.0 mmol) in benzene (100 cm^3) were refluxed for 16 h. The solution was filtered, the volume reduced to *ca* 25 cm^3 and petroleum ether (100 cm^3) added, giving the complex as a yellow non-crystalline solid which was filtered off, washed with petroleum ether (30 cm^3) and dried *in vacuo*. Yield, 0.53 g (55%).

IR (Nujol) 1730m, 1590w, 1475s, 1412s, 1350m, 1300m, 1268s, 1165w, 1145w, 1110w, 1068w, 1020w, 950vs, 858m, 800w, 760s, 750s, 735s, 704s, 675m, 630m, 618w, 565w, 520w, 345w, 265s and 220m cm^{-1}.

Carbonyldichloro (phenylimido) bis (trimethylphosphine)tungsten(IV) (7)

Trichloro(phenylimido)bis(trimethylphosphine) tungsten(V) (1.0 g, 1.9 mmol) in benzene (100 cm^3) was reduced with Na/Hg amalgam (50 mg Na, 2.2 mmol; 40 g Hg) under carbon monoxide (20 p.s.i.) for 5 h. The solution was filtered and the solvent removed to give a purple–brown crystalline solid which was extracted with warm petroleum ether (5×200 cm^3). The combined extracts were filtered and the solvent reduced to *ca* 5 cm^3 giving the complex as a purple crystalline solid. Yield, 0.7 g (70%).

IR (Nujol) 1925s, 1464s, 1418s, 1345s, 1305m, 1284s, 1160w, 1070w, 1025w, 945s, 860m, 855m, 775s, 742s, 695s, 670m, 570m, 558m, 460w, 380w, 340w, 305s and 260s cm^{-1}.

(*Received* 27 *July* 1989; *accepted* 12 *September* 1989)

Abstract—Volatile amino–alkoxide complexes $Cu[OCH_2CH_2NMe_2]_2$ (**1**), $Cu[OCHMeCH_2NMe_2]_2$ (**2**) and $Cu[OCH_2CH_2NMeCH_2CH_2NMe_2]_2$ (**3**) have been prepared. X-ray crystal structures reveal a mononuclear, square-planar geometry for **2**, and a mononuclear, distorted, square-pyramidal geometry for **3**. Thermal decomposition (25–300°C) of **1** gives a mixture of copper, CuO and Cu_2O whereas thermal decomposition of **2** gives copper.

Efforts to prepare films of cuprate oxide superconductors by metal–organic chemical vapour deposition have used β-diketonate complexes as the volatile metal-containing sources.[1–6] These precursors require decomposition in the presence of O_2,[2–5] H_2O,[6] or both,[1] to successfully deposit oxides. Since alkoxide complexes of some metals, such as yttrium(III),[7] zirconium(IV)[8,9] and hafnium(IV),[9] pyrolyse cleanly to the corresponding oxides, alkoxides may provide a general, *direct* vapour-deposition route to metal oxides when suitably volatile derivatives can be identified.[10] Thus, we began to investigate means of volatilizing copper(II) alkoxides, which are typically non-volatile, insoluble solids,[11] for testing as cupric oxide (CuO) sources. The first volatile example, $Cu[OCH_2CH_2NEt_2]_2$, was recently obtained elsewhere, although structural characterization and pyrolysis behaviour were not addressed.[12] We now describe three volatile copper(II) amino–alkoxides and preliminary studies of their thermal decomposition. To our knowledge, this work provides the first X-ray crystal structures of mononuclear copper(II) alkoxides.

We initially attempted to prepare mononuclear ether–alkoxide complexes of type **I** or **II** (see below). However, $Cu[OCH_2CH_2OMe]_2$ was a non-volatile, insoluble solid, and $Cu[OCH_2CH_2OCH_2CH_2OMe]_2$ was a non-volatile, soluble oligomer; in the latter case ^1H NMR established the presence of dangling ligands.[13] Replacement of ether-type oxygens with more basic NMe units resulted in chelated structures of types **III** and **IV** (see below).
