depending on the initial set of parameters. If LIS is contact by nature, eq. (1) transforms into $\delta_{calc.i} = FA_i$, from which a set of A_i for all nuclei with measured LIS can be obtained. In the case of Ce-, Pr- and Nd-HPA A_i is $\simeq 0.3$ Oe for $O_{2,3,4,9}$ atoms and A is $\simeq 0.01$ Oe for P atom. The geometry of HPA from ref. 6 was taken as the initial geometry for the calculations.

A dipolar axial model of the complex cannot explain the ^{183}W and ^{31}P LIS values observed. Calculations for the non-axial complex led us to $D' < D''$, which means that the z axis is not the principal magnetic axis of the complex. This disagreement led us to the axial model with Δ^c and Δ^{pc} contributions of LIS, and eq. (1) transforms the forms into $\delta_{calc.i} = D'(3\cos^2\theta_i - 1)r_i^{-3} + FA_i$. Agreement of calculated and observed parameters is achieved, if the contact contribution dominates for O atoms (about 99%) and both Δ^c and Δ^{pc} are comparable in the LIS of the P atom.

The presence of the paramagnetic ion in the HPA shortens the magnetic relaxation times of ^{183}W nuclei and makes conditions for obtaining NMR spectra more favourable in general. Except for Gd-HPA, distant atoms peaks observed are narrow (≤ 10 Hz) and peaks of neighbouring $W_{2,3,4,9}$ atoms are broader. The ^{183}W NMR data are listed in Table 2. HPA may be divided into four groups, which have similar ^{183}W NMR spectra: La—Nd, Sm—Gd, Tb—Er, Tm—Lu. The first and second HPA groups have six-peak spectra typical of PW_{11} complexes with other cations.[11] These spectra have five double intensity peaks of the atom pairs $W_{4,9}$, $W_{2,3}$ $W_{5,8}$, $W_{6,7}$ and $W_{10,12}$, which are situated symmetrically from the plane of atoms La, P, W_{11}, and the peak of atom W_{1} (Fig. 1). $W_{2,3,4,9}$ atom peaks are arranged either away from other peaks of the spectrum or are broader (the spectrum of Gd-HPA is not full). Supposing the order of peaks for all W atoms except $W_{2,3,4,9}$ is the same as in the La-HPA

[b] In ppm.

spectrum (it is evident for La-, Ce-, Pr- and Nd-HPA[12]), we assigned peaks to definite W atoms of HPA. For diamagnetic $La(PW_{11})_2$-HPA the assignment has been carried out earlier[12]: Ce-, Pr-, Nd-HPA atoms W_4 and W_9, W_2 and W_3 are slightly non-equivalent, because their peaks are resolved at 323 K as doublets (Fig. 1). Their location can be supposed to be not fully symmetrical.

The sign of LIS changes in the Sm–Gd group compared to groups 1 and 2. The peak positions of Sm-HPA are nearly the same as those of La-HPA. Besides narrow peaks with an intensity corresponding to 1, 2, 2, 2 W atoms we observed two broader peaks with $\delta = -140$ and -159 ppm (2 and 2 atoms); the last peak is broader. We suppose that these peaks belong to $W_{2,3,4,9}$ atoms. The Gd-HPA spectrum consists of four broad peaks. They are assigned to seven distant ligand atoms. In contrast to the spectra mentioned above those of Tb-Yb-HPA consist of 11 peaks. They correspond to fully non-equivalent W atoms in each PW_{11} ligand, while the single ^{31}P NMR peak demonstrates that the ligands are identical.

The change of ^{183}W spectra character in the lanthanide series (Table 2) is similar to the "gadolinium break" in the other properties of lanthanide compounds. One may suppose that the appearance of an 11-peak spectrum is caused by distortion of the ligand in the Ln-HPA series after Gd. This distortion corresponds to a square antiprism surrounding of Ln, *ie.* absence of the symmetry plane of the whole complex ($\phi = 45°$ or 135°, Fig. 1), and $Ln(PW_{11})_2$ complexes before Gd have the symmetry plane and cubic surrounding of Ln ($\phi = 0°$ or 180°). The structure of HPA[6] supports this suggestion, because it has a square antiprism surrounding of the central ion, with the radius corresponding to the heavy lanthanide radii.

Comparison of the Golding constant $\langle S_z \rangle$ and ^{183}W CS of atoms $W_{2,3}$, $W_{10,12}$, $W_{6,7}$ and W_{11} (Fig. 3) shows that contribution of Δ^c predominates in the LIS. LIS and $\langle S_z \rangle$ do not exactly correspond to one another. However, the contribution of Δ^c appears to predominate in the LIS of atoms $W_{2,3}$ and $W_{4,9}$. LIS ^{183}W Tb-HPA have an opposite sign to LIS Tm-HPA for distant W atoms, which is typical for a dipolar contribution, which is more important for more distant W atoms.

As was shown above, LIS ^{31}P Ln-HPA are mainly dipolar and the change of Ln radius is included in them. Because Δ^{pc} is a function only of geometry for a given Ln, we calculated the ratio $\Delta^{pc}_W/\Delta^{pc}_P$ and list them in Table 4. LIS ^{183}W and Δ^{pc} of HPA with full ^{183}NMR spectra are also listed. It is seen from Table 4 that Δ^c predominates in LIS of atoms $W_{2,3,4,9}$ neighbouring Ln. Apparently it predominates in LIS of Ce-, Pr- and Nd-HPA for the distant atoms $W_{5,8}$, $W_{6,7}$ and $W_{10,12}$. Both Δ^c and Δ^{pc} are comparable in LIS of atoms $W_{10,12}$ of Er-, Tm- and Yb-HPA, but Δ^c in LIS of $W_{10,12}$ predominates for other Ln-HPA. The importance of both contributions is seen for all W atoms of Yb-HPA. The data obtained allow the peaks of the ^{183}W NMR spectrum of Th^{IV}-HPA to be assigned as it is isostructural to Ln-HPA. Because LIS ^{31}P of Ln-HPA are very different (see Tables 1 and 4) and the sensitivity of ^{31}P NMR is quite high, the method of lanthanide mixture analysis can be developed when lanthanide compounds are transformed into $Ln(PW_{11})_2$ complexes and their relation can be determined from peak intensities of the ^{31}P NMR spectra (as in ref. 14).

MIXED-LIGAND COMPLEXES OF COPPER(II) WITH PYRIDINE

EDUARDO ALMEIDA NEVES* and MORENA PINTO PETERS

Instituto de Química da Universidade de São Paulo, Cx. Post. 20780, São Paulo, Brazil

(*Received* 21 *November* 1988; *accepted* 15 *December* 1989)

Abstract—The copper(II)–pyridine–azide system was studied at 1.0 M ionic strength (sodium methanesulphonate) and 25°C under conditions which favour the formation of CuN_3^+ and mixed species up to $[Cu(py)_4N_3]^+$. The treatment of data led to several types of equilibrium constant (also for the binary copper(II)–pyridine complexes), spectral data and evidence that the formation of mixed complexes overcomes statistical effects.

This paper is an extension of the systematic studies carried out in this laboratory for the copper(II)–azide reaction[1–7] from an analytical or inorganic viewpoint. The affinity of azide ion for copper(II) complexed with pyridine, to form monoazide species is presented and possible analytical application discussed. All equilibrium studies were performed at 1.0 M ionic strength, held constant with sodium methanesulphonate.

We also tested a new experimental condition for studying the mixed-ligand complex equilibrium using methods of calculation which made the data treatment unusually simple and accurate.

Experimental values of equilibrium constants of mixed-ligand complexes are important for the development of coordination chemistry in a number of ways. In fact, there is an up-to-date trend in equilibrium studies, as has been pointed out by specialists such as Beck[8] and Marcus and Eliezer.[9]

EXPERIMENTAL

CP or AR chemicals were normally used.

Copper(II) methanesulphonate was prepared by reaction of 2 M methanesulphonic acid with excess of copper(II) carbonate under constant stirring for 24 h, at room temperature. After filtering, strong acid was added in millimolar quantities to avoid hydrolysis. Standardization was carried out electrogravimetrically.

Sodium methanesulphonate was prepared by neutralization of the acid with sodium hydroxide, followed by evaporation. The solid was recrystallized twice from water, and standardization of a 3 M solution was carried out by titration of the acid eluted from a cationic exchanger (Amberlite I-R-30).

Pyridine was purified according to Vogel,[10] distilled and kept in dark bottles. Aqueous solutions were prepared with water previously bubbled with nitrogen. Standardization was performed potentiometrically with hydrochloric acid.

Sodium azide was standardized by boiling an aliquot with excess of 0.1 N H_2SO_4 and back-titrating the excess with sodium hydroxide.

All equilibrium studies (potentiometric or spectrophotometric) were performed at a controlled temperature, 25.0±0.1°C.

A digital potentiometer, Orion Research 801 A, was used for the pH measurements with a glass electrode combined with a reference electrode of Ag/AgCl/NaCl(sat). In the equilibrium studies the glass electrode was calibrated with 0.01000 M $HClO_4$ in 0.99 M $NaClO_4$ (conditional pH = 2.000), as described in previous studies,[3,11] in order to measure the hydrogen ion concentration rather than its activity. A precision of 0.002 pH units was attained.

The spectrophotometric equilibrium studies were carried out with an initial solution of pH 5.5–6, 10 mM $C_{Cu^{II}}$ with a C_{py} containing the desired $\bar{n}$ level (ionic strength 1.0 M). A sodium azide concentration, usually lower than 1 mM, was maintained so that the transmittance obtained was never lower than 15% in the 370–400 nm range. 3.00 cm^3 of this

* Author to whom correspondence should be addressed.

solution were placed in a quartz cuvette (1 cm light path) which was modified to hold a few more cm^3 of added reagent. Measurements at eight different wavelengths were carried out vs the blank with the background electrolyte. The initial solution was diluted with 0.5 cm^3 volumes of a blank with the same free pyridine concentration and measured. The copper(II) and azide concentrations in this solution were decreased but the $C_{Cu^{II}}/C_{N_3^-}$ ratio as well as the $\bar{n}$ value were maintained. The pH was slightly changed but could be followed by using the glass electrode in a parallel experiment. The transmittance of the initial solution increased with dilution to a maximum value of 70%. This procedure has proved to be very rapid and accurate.

Other instruments used were a Zeiss PM QII spectrophotometer, and the treatment of data required the use of programmable calculators (e.g. HP 97 or HP 41 CV from Hewlett Packard).

RESULTS AND DISCUSSION

An outline of the equilibrium studies

A number of spectrophotometric studies of complex formation have been shown in the literature as performed at conditions which favour the mono-ligand species by maintaining an excess of metal cations over the total ligand concentration. It is expected that if an excess of copper(II), complexed with pyridine, is in equilibrium with a lower azide concentration, a mixture of monoazide mixed complexes, $Cu(py)_iN_3^+$, is formed. The composition of the excess copper(II) is controlled by the free ligand, pyridine, and is expressed by its $\bar{n}$ values (Bjerrum's function), average ligand number:

$$\bar{n} = \frac{\beta_{10}[py]+2\beta_{20}[py]^2+3\beta_{30}[py]^3+4\beta_{40}[py]^4}{1+\beta_{10}[py]+\cdots+\beta_{40}[py]^4}, \quad (1)$$

where β_{i0} is the well known overall formation constant[8,12] with i pyridine ligands and no azide

$$\beta_{i0} = \frac{[Cu(py)_i^{2+}]}{[Cu^{2+}][py]^i}. \quad (2)$$

The following conditional equilibrium takes place for a $C_{Cu^{II}} \gg C_{N_3^-}$:

$$Cu(py)_{\bar{n}}^{2+} + N_3^- \rightleftharpoons Cu(py)_{\bar{n}}N_3^+.$$

A conditional equilibrium constant is defined at each $\bar{n}$ value,

$$K_{\bar{n}1} = \frac{[Cu(py)_{\bar{n}}N_3^+]}{[Cu(py)_{\bar{n}}^{2+}]N_3^-} = \frac{[Cu(py)_{\bar{n}}N_3^+]}{C_{Cu^{II}}[N_3^-]} \quad (3)$$

and represent the average tendency of azide to be added to a copper(II) concentration, $C_{Cu^{II}}$, complexed with pyridine at a particular $\bar{n}$ condition, in order to form a mixture of monoazide complexes such as CuN_3^+, $Cu(py)N_3^+$, $Cu(py)_2N_3^+$, etc. As $C_{Cu^{II}}$ is relatively high, the complexation with azide has no significant effect on its $\bar{n}$ value. This $K_{\bar{n}1}$ constant can be spectrophotometrically determined as for the CuN_3^+ species[5,13] with excess of Cu^{2+}, with the only difference being that now copper(II) is complexed with pyridine at a desired $\bar{n}$ level. However, this constant changes with $\bar{n}$ because the per cent distribution of the copper(II) species is altered and each species is expected to have a different affinity for the azide ion. The free pyridine concentration used to set the copper(II) at a $\bar{n}$ level can be calculated iteratively by eq. (1) if the β_{i0} formation constants are known.

The following equation can be developed with mass balance and equilibrium constants for the copper(II)/pyridine complexes:

$$C_{Cu^{II}} = [Cu(py)_{\bar{n}}^{2+}] = [Cu^{2+}]+[Cu(py)^{2+}] + [Cu(py)_2^{2+}]+[Cu(py)_3^{2+}]+[Cu(py)_4^{2+}]. \quad (4)$$

Each complex concentration is related to β_{10} [eq. (2)]. For the monoazide complexes in equilibrium with this $C_{Cu^{II}}$ the following mass balance is applied:

$$[Cu(py)_{\bar{n}}N_3^+] = [CuN_3^+] + [Cu(py)N_3^+]+\cdots+[Cu(py)_4N_3^+]. \quad (5)$$

From eq. (3) the total concentration of the monoazido complexes is:

$$[Cu(py)_{\bar{n}}N_3^+] = C_{Cu^{II}}[N_3^-]K_{\bar{n}1}. \quad (6)$$

Each monoazido complex concentration is related to an addition constant referred to a copper(II) cation with i pyridine ligands:

$$K(+N_3)_{i1} = \frac{[Cu(py)_iN_3^+]}{[Cu(py)_i^{2+}][N_3^-]} \quad (7)$$

and to the equilibrium

$$Cu(py)_i^{2+} + N_3^- \rightleftharpoons Cu(py)_iN_3^+.$$

Of course, if $i = 0$, $K(+N_3)_{0i}$ is the conventional formation constant of CuN_3^+. The combination of eqs (5), (6) and (7) leads to

$$[N_3^-]K_{\bar{n}1}C_{Cu^{II}} = \{K(+N_3^-)_{01}[Cu^{2+}] + K(+N_3^-)_{11}[Cu(py)_1^{2+}]+\cdots+K(+N_3^-)_{41} \times [Cu(py)_4^{2+}]\}[N_3^-]. \quad (8)$$

By eliminating $[N_3^-]$ and considering that the following function can be taken for the copper(II)/

pyridine complexes,

$$\frac{[Cu^{2+}]}{C_{Cu^{II}}} = \alpha_0 \qquad (9)$$

and

$$\frac{[Cu(py)_i^{2+}]}{C_{Cu^{II}}} = \alpha_i, \qquad (10)$$

eq. (8) can be modified to

$$K_{\bar{n}1} = \alpha_0 K(+N_3^-)_{01} + \alpha_1 K(+N_3^-)_{11} + \cdots + \alpha_4 K(+N_3^-)_{41}. \qquad (11)$$

This is the final equation, and is surprisingly simple for dealing with mixed-ligand complexes. Simultaneous equations can be used to solve the $K(+N_3^-)_{i1}$ constants from α_1 and the experimental $K_{\bar{n}1}$ data. These α_1 data are calculated with the free ligand which places copper(II) as the derived $\bar{n}$, and the β_{i0} constants:

$$(\alpha_0)^{-1} = 1 + \beta_{10}[py] + \cdots + \beta_{40}[py]^4 \qquad (12)$$

$$\alpha_i = \beta_{i0}\alpha_0[py]^i. \qquad (13)$$

Determination of β_{i0} constants

The overall formation constants in the copper(II)/pyridine system, β_{10}, has been studied[14-18] and the majority of the authors agree with the existence of four stepwise species.

We obtained the formation constants at 1.0 M ionic strength, held with sodium methanesulphonate. The main reason for using this medium is the low tendency of this anion to precipitate with the $Cu(py)_i^{2+}$ cations. Perchlorate precipitates for some copper(II) concentrations used in the spectrophotometric study. As methanesulphonic acid is recognized as a strong one, its salts can eventually be used to adjust the ionic strength in equilibrium studies, preferably to nitrate.

Experimental $\bar{n}$ data vs the free ligand (formation curve) presented in Fig. 1 were taken from an indirect method based on the pH change in several py/Hpy^+ buffers by addition of Cu^{2+}. The experimental procedure, calculation and advantages of the method are described in detail by Neves *et al.*[11] The Leden function, $F_o(X)$, was obtained and treated by the classical graphical method[8,12] and by the modern process of weighted simultaneous equations.[19] The log β_{i0} data are given in Table 1 along with literature values for comparison. Good agreement with literature data is found at 1.0 M ionic strength and supports the use of methanesulphonate ion as the background electrolyte.

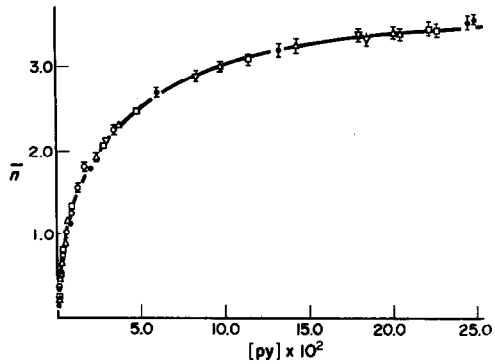

Fig. 1. Formation curve of the copper(II)/pyridine complexes in 1.0 M ionic strength held constant with NaO_3S–CH_3 at 25°C.

Spectrophotometric study

The monoazido species was formerly studied under conditions of low and high ionic strength.[3,13] The McConnel and Davidson[20] spectrophotometric method was applied at constant pH by Saini and Ostacoli[13] in order to correct for HN_3 formation. As this is a cumbersome process, the introduction of a correction factor, $F = 1 + [H^+]/K_i$, with the ionization constant (K_i) of the hydrazoic acid, directly into the equation allows us to work at variable pH,[3]

$$\underbrace{\underbrace{\frac{C_{Cu^{II}}C_{N_3^-}}{AF}}_{y} + \frac{A}{\varepsilon_1^2 F}}_{y'} = \frac{1}{\varepsilon_1\beta_1} + \frac{1}{\beta_1}\underbrace{\frac{C_{Cu^{II}} + C_{N_3^-}}{F}}_{x}, \qquad (14)$$

where A is the absorbance and ε_1 the molar absorptivity of the complex (or an average value $\bar{\varepsilon}_1$, for the mixture of monoazide mixed complexes).

The term including ε_1^2 is normally neglected, as a virtually linear relationship is maintained between "y" and "x". However we found it convenient to find the true "y" value iteratively, and more accurate final values were obtained. The final β_1 is about 10% higher than the initial value.

The $C_{Cu^{II}}/C_{N_3^-}$ ratio was about ten (see Experimental) in the working solution containing pyridine. In order to maintain the desired $\bar{n}$ level the following total pyridine concentration is required:

$$C_{py} = C_{Cu^{II}}\bar{n} + [py] + [Hpy^+]. \qquad (15)$$

At pH 6–6.5, $[Hpy^+]$ is a small fraction of [py] as can be inferred from the $pK = 5.45$ (Table 1) and $C_{Cu^{II}} = 10$ mM.

The ionization constant of hydrazoic acid,

Table 1. Literature values for pK of Hpy^+ and overall formation constants in the copper(II)/pyridine system at 25°C in aqueous medium

[a] Present paper.

measured as described in ref. 3, is $(3.94+0.04)\times 10^{-5}$ M^{-1} taken at 1.0 M ionic strength held constant with sodium methanesulphonate.

The $K_{\bar{n}1}$ constants were obtained for $\bar{n}$ levels from 0 to 3.5 using this spectrophotometric method, with iterative correction of the "y" term in eq. (14). Measurements were taken at eight wavelengths in the region around the maximum (370–400 nm). The standard deviation of each average result is $\pm 1.7\%$. The graphical interpolations of the constants at small increments are presented in Table 2 and these were used in simultaneous equations (see next section).

The constant in the absence of pyridine is the conventional β_1, but has other notations when mixed-ligand equilibria are considered:

$$\beta_1 = \beta_{01} = K_{01} = K(+N_3^-)_{01} = \frac{[CuN_3^+]}{[Cu^{2+}][N_3^-]} = 111.5\,M^{-1}. \quad (16)$$

This value agrees, within experimental error, with that found by Maggio *et al.*,[21] 112 M^{-1}, at the same ionic strength (held constant with sodium perchlorate).

The spectra of the CuN_3^+ species in the UV region[3] are similar to those obtained for the mixed complexes with pyridine, as the round maxima of charge-transfer are always observed. Although the $K_{\bar{n}1}$ constants decrease for $\bar{n} > 1$, the $\bar{\varepsilon}_1$ (average molar absorptivity) increases markedly with the level of $\bar{n}$, with a discrete shift of λ_{max} to higher wavelengths. This means that the power of oscillation ($N_3^- \rightarrow Cu^{II}$) is increased under mixed-ligand conditions.

From an analytical viewpoint the spectral shift to higher wavelengths favours the sensitivity of a qualitative test for the azide on the basis of mixed species formation. However, a compromise exists between the stability of the mixed complexes, its $\bar{\varepsilon}_1$ and the masking effect of the deeper blue colour of the pyridine mixed complexes, when the sensitivity of the human sight is considered. In fact, the best conditions for a qualitative test of azide is found at $\bar{n} = 2$ for copper(II) complexed with pyridine.[22] In

a quantitative spectrophotometric procedure higher $\bar{n}$ levels can be maintained for higher sensitivity in the UV range at 380 nm.

Calculations of equilibrium constants from $K_{\bar{n}1}$

As the $K(+N_3^-)_{01}$ constant is known, 112 M^{-1}, it can be introduced into eq. (11) to decrease the number of unknowns in each simultaneous equation. A weighting factor $1/K_{\bar{n}1}$ can be introduced in order to ensure that all dependent terms are of the same magnitude. This is justifiable on the basis that the same relative uncertainty can be attributed to the experimental $K_{\bar{n}1}$ constants and the intermediate data obtained by interpolation (Table 2). The free concentrations of pyridine at defined $\bar{n}$ levels corresponding to the interpolated constants, calculated iteratively from eq. (1), are also included in Table 2. These [py] data were then used in eqs (12) and (13) to obtain the fraction of all species containing pyridine in order to prepare the simultaneous equations.

In the treatment of data two possibilities were considered: whether the $Cu(py)_4N_3^+$ species exists or not, defining a system with four or three unknowns. The best solution is consistent with the contribution of the $Cu(py)_4N_3^+$ complex. Thus, a 4×4 matrix was built with four simultaneous equations with the available $K_{\bar{n}1}$ and α_i data:

$$\sum\frac{K_{\bar{n}1}-\alpha_0\cdot K(+N_3^-)_{01}}{K_{\bar{n}1}} = K(+N_3^-)_{11}\sum\frac{\alpha_1}{K_{\bar{n}1}} + \cdots + K(+N_3^-)_{41}\sum\frac{\alpha_4}{K_{\bar{n}1}}. \quad (17)$$

The four simultaneous equations are shown in Table 3 with the solution for the $K(+N_3^-)_{i1}$ constants. The obtained equilibrium constants are in agreement with interpolated $K_{\bar{n}1}$ data within $\pm0.7\%$.

Final comments on the results

Figure 2 shows that the formation of $Cu(py)N_3^+$ is particularly favoured and that a marked decrease in affinity for azide occurs when more than two pyridine ligands fill coordination sites on Cu^{2+}. Conversely, the average molar absorptivities increase in the reverse direction as already stated.

Interesting relationships can also be seen in Fig. 3, where other equilibrium situations are considered, indicating the spontaneous processes. The backbonding copper(II)/pyridine favours the

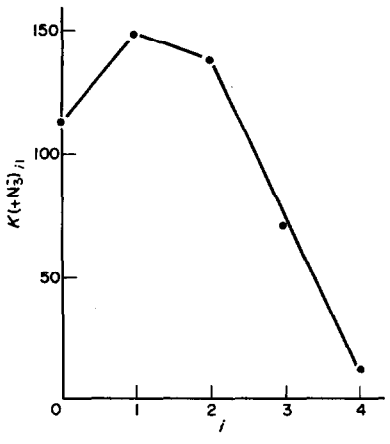

Fig. 2. Change of $K(+N_3^-)_{i1}$ constants vs the number of pyridine molecules coordinated to copper(II).

Table 4. Stabilization constants K_e, eq. (19), for some monoazido complexes

Equilibrium	log $K_{M(i1)}$	log $K_{Stat(i1)}$	log $K_{E(i1)}$
$1/2\ Cu(py)_2^{2+} + 1/2\ Cu(N_3)_2 \rightleftharpoons Cu(py)(N_3)^+$	0.445	0.301	0.144
$2/3\ Cu(py)_2^{2+} + 1/3\ Cu(N_3)_3^- \rightleftharpoons Cu(py)_2(N_3)^+$	0.809	0.477	0.333
$3/4\ Cu(py)_4^{2+} + 1/4\ Cu(N_3)_4^{2-} \rightleftharpoons Cu(py)_3(N_3)^+$	0.859	0.602	0.257

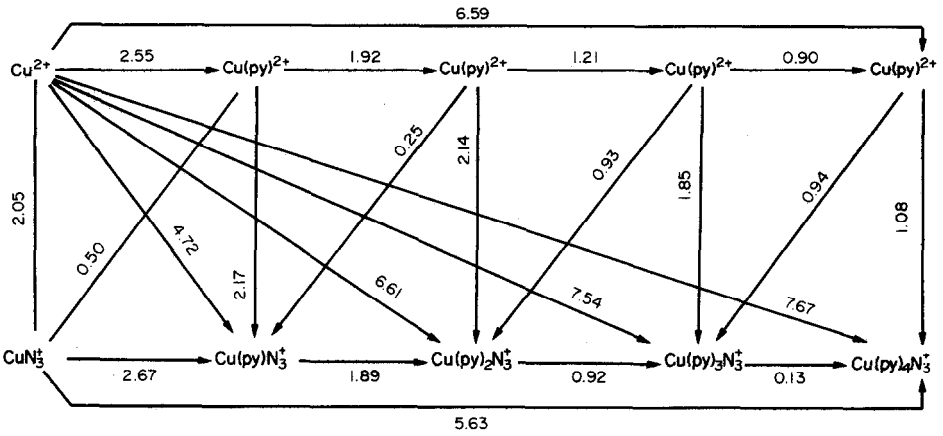

Fig. 3. Spontaneous processes of complex formation in copper(II) systems, on the basis of positive values of log K.

azide bond more than predicted by statistical effects, and is considered as follows.

When two complexes of the same cation MA_m and MB_n exchange ligands according to

$$(i/n)\,MA_n + (j/n)\,MB_n \rightleftharpoons MA_iB_j$$

to form one mole of MA_iB_j, an equilibrium constant $KM_{(ij)}$ is

$$K_{M(ij)} = \frac{\beta_{ij}}{\beta_{n0}(\beta_{0n})^{j/n}} = \frac{\beta(+j\beta - jA)_{ij}}{(\beta(+n\beta - nA)_{0n})^{j/n}}. \quad (18)$$

With regard to such equilibrium, Marcus and Eliezer[9] have proposed a stabilization constant K_e

$$\log K_e = \log K_{M(ij)} - \log \frac{n!}{i!j!}, \quad (19)$$

where

$$K_{stat} = \frac{n!}{i!j!}. \quad (20)$$

A positive value for log K_e indicates a true stabilization of the mixed-ligand complex, higher than predicted by statistical factors.

The combination of present equilibrium data with that from the copper(II)/azide system,[7] although taken at an ionic strength of 2.0 M, leads to the conclusion that there is a true stabilization of the monoazido mixed species, as shown in Table 4.

FLUOROGERMANATE(IV) EQUILIBRIA IN ACID MEDIA

LIBERATO CIAVATTA,† MAURO IULIANO, RAFFAELLA PORTO and ERMANNO VASCA

Dipartimento di Chimica dell'Università, Via Mezzocannone 4, 80134 Napoli, Italy

(*Received* 21 *November* 1989; *accepted* 22 *December* 1989)

Abstract—The equilibria between $Ge(OH)_4$, HF and H^+ ions in aqueous solution have been investigated, at 25°C in $NaClO_4$ as well as in $LiClO_4$ media, by potentiometric measurements with a fluoride ion-selective electrode. The perchlorate ion molal concentration was kept constant at 3. The molalities of Ge^{IV} and of the H^+ ion were chosen, respectively, between 10^{-3} and 10^{-2} and from 0.03 to 2.9.

The potentiometric data have been explained by the presence of GeF_4, $Ge(OH)F_4^-$, GeF_6^{2-}, $HGeF_6^-$ and a minor complex to which the composition $Ge(OH)F_2^+$ has been tentatively ascribed. Equilibrium constants for their formation in the inert 3 molal $NaClO_4$ and in 3 molal $LiClO_4$ are reported.

Little quantitative information exists on the reaction between the fluoride ion and $Ge(OH)_4$, the relevant form in which germanium(IV) is present in acid non-complexing media.[1] The most extensive investigation is that of Benoit and Place[2] who employed solvent extraction, solubility and potentiometry to establish the composition of the reaction products and their formation constants. The results from solutions of acidities exceeding 0.5 molar were interpreted with $Ge(OH)_rF_4^{r-}$ and $Ge(OH)_rF_5^{(r+1)-}$, but no attempt was made to estimate the most probable number of OH^- groups in the complexes. On the other hand, the existence of GeF_6^{2-} is supported by Raman spectroscopy[3] in concentrated H_2GeF_6 solutions as well as by Raman, IR and NMR measurements[4] in concentrated $(NH_4)_2GeF_6$ solutions. Further evidence comes from the potentiometric studies by Ryss and Kulish.[5,6] These authors calculated (25°C in dilute solution and in molar units) a constant of $10^{-5.3}$ for

$$GeF_6^{2-} + H_2O \rightleftharpoons Ge(OH)F_4^- + HF + F^-$$

using acidity measurements and chemical analysis, and a constant of $10^{-25.8}$ for

$$GeF_6^{2-} + 2H_2O \rightleftharpoons GeO_2(s) + 6F^- + 4H^+$$

through activity determinations of the H^+ and F^- ions.

The aim of the present work was to investigate the fluorogermanate(IV) equilibria by methods developed in this laboratory and concerning the complex formation of titanium(IV)[7] and silicon(IV)[8] with fluoride ions.

METHOD

The equilibria were studied at 25°C by measurements with cell(I)

$$-EF/TS,QQH_2(s)/Au+ \qquad (I)$$

where EF and QQH_2 stand, respectively, for a fluoride ion-selective electrode and quinhydrone, while TS designates a test solution of the general composition (molal units and $Me^+ = Li^+$ or Na^+)

$$TS = Ge^{IV}: m_M,\ MeF: m_F,$$

$$HClO_4: (m_H + m_F),\ MeClO_4: (3 - m_H - m_F).$$

In TS the molality of the perchlorate ion was kept constant in order to minimize variations of activity coefficients. In the initial stage of the work $LiClO_4$ was chosen as the inert salt. In the course of the measurements, with the main purpose to extend the acidity range to m_H values inferior to 0.3 molal, where LiF is of limited solubility in an excess of Li^+ ions, it was thought of value to carry out experi-

† Author to whom correspondence should be addressed.

ments also in 3 molal $(Na)ClO_4$. The standard states are so chosen that the activity of solute species tends to molality as the composition of TS approaches 3 molal $MeClO_4$.

The molality of germanium was varied from 10^{-3} to 10^{-2}. Values of m_H, the analytical molality excess of H^+ counting HF, H_2O, $MeClO_4$ and $Ge(OH)_4$ as zero level, were chosen in the intervals 0.03–2.9, in $NaClO_4$, and 0.3–2.9 in $LiClO_4$.

The EMF of cell(I) at 25°C can be expressed by (1)

$$E = E'_0 + 0.05916 \log([HF] y_{HF}) + E_q \quad (1)$$

where E'_0 is a constant, y is the symbol of the activity coefficient and E_q is a correction term for the basicity of p-benzoquinone.[9] In our solutions y_{HF} can be assumed to be a function of $[H^+]$ and of [HF]. In order to gain an idea of the dependence of y_{HF} on $[H^+]$ the EMF of cell(I), containing no Ge^{IV}, was measured as a function of m_H ranging from 0.1 to 2.9, while m_F was kept constant at 10^{-2}. These data could be explained by the relationships (2a,b), by assuming for $Q + H^+ \leftrightarrows QH^+$ a constant of 0.1 as proposed by Biedermann,[9]

$$\log y_{HF}([H^+]) = (0.061 \pm 0.005)[H^+] \quad (\text{in } NaClO_4) \quad (2a)$$

$$\log y_{HF}([H^+]) = (0.020 \pm 0.010)[H^+] \quad (\text{in } LiClO_4). \quad (2b)$$

The dependence of y_{HF} on [HF] was determined by measuring at constant m_H and for $m_M = 0$ the EMF of cell(I) where $10^{-3} \leqslant [HF] \leqslant 0.1$. The data were described by eq. (3)

$$0.05916 \log y_{HF}([HF]) = (9 \pm 2) \times 10^{-3}[HF]. \quad (3)$$

In each experiment, carried out conveniently as a potentiometric titration, m_H was kept constant, while [HF] was varied. According to $Ge(OH)_4 + nHF \leftrightarrows Ge(OH)_t F_n^{(4-t-n)} + pH^+$, hydrogen ions are formed when the complex formation proceeds. Since, however, $m_M < 0.1 m_H$, the concentration of the H^+ ion did not change sensibly during a run to cause variations in $y_{HF}([H^+])$ and E_q. Consequently, the EMF of cell(I) can be expressed as eq. (4)

$$E = E_0 + 0.05916 \log[HF] + 9 \times 10^{-3}[HF] \quad (4)$$

where $E_0 = E_o(m_H)$ includes E_q and $y_{HF}([H^+])$.

Each titration was divided into two parts. In the first, E_0 was determined in the absence of Ge^{IV}. For $m_H \geqslant 0.3$, [HF] was approximated with m_F to calculate E_0. At lower acidities the equilibria

$$H^+ + F^- \leftrightarrows HF, \quad [HF] = 1.4 \times 10^3 [H^+][F^-] \quad (5)$$

$$HF + F^- \leftrightarrows HF_2^-, \quad [HF_2^-] = 5.5[HF][F^-] \quad (6)$$

were assumed to find [HF] from the m_F and m_H values. The constants in eqs (5) and (6) were evaluated for 3 molal $NaClO_4$ by interpolation of literature data.[10] E_0 values constant to within $\pm 10^{-4}$ V were obtained in the m_F range from 5×10^{-4} to 0.1.

In the second part, germanium(IV) was added and the complex formation was followed by varying the m_F/m_M ratio. With E_0 being known, [HF] could be evaluated from (4) and $\bar{n}$, the average number of fluoride ions bound per Ge^{IV}, could be obtained, using (5) and (6), by

$$\bar{n} = (m_F - [HF] - [F^-] - 2[HF_2^-])/m_m. \quad (7)$$

In (7), $[F^-]$ and $[HF_2^-]$ represent only small correction terms and were neglected for $m_H \geqslant 0.3$.

EXPERIMENTAL

Materials and analysis

The germanium source was the hexagonal form of GeO_2, Fluka, 99.9% purity. Stock solutions were obtained by dissolving weighed amounts of the product previously ignited at 1000°C.

Sodium perchlorate was prepared and analysed as described by Biedermann.[11]

Sodium fluoride, lithium fluoride, lithium perchlorate, perchloric acid and quinhydrone were obtained as described previously.[7,8]

Details of the EMF measurements

The cell arrangement, electrodes and titration procedure were the same as described in preceding papers.[7,8] The EMF values of cell(I) were measured to within 10^{-5} V with a computer-controlled data acquisition unit 3421 A, furnished by Hewlett and Packard. The silicon oil thermostat, in which cell(I) was immersed, had a temperature of 25.00 ± 0.02°C.

DATA AND CALCULATIONS

The $\bar{n}(\log[HF], m_M)_{m_H}$ data, which are the basis for the calculation of the composition of the reaction products and their formation constants, are collected in Table 1. The graph in Fig. 1, representing the measurements at $m_H = 0.1$, indicates that the points for different m_M and for $m_M \ll m_H$, within the limits of experimental error, fall on the same curve and the $\bar{n}$ values tend to 6 as [HF] increases. Hence, $Ge(OH)_t F_n^{4-t-n}$ species with $n \leqslant 6$ predominate. Furthermore, data of forward titrations (m_F/m_M increasing) practically coincide with those of back tirations (m_F/m_M decreasing) which implies that we are measuring true equilibria.

To assess the prevailing t and n in the complexes

as well as the $^*\beta_{n,p}$ constants for their formation according to (8)

$$Ge(OH)_4 + nHF \rightleftharpoons Ge(OH)_tF_n^{4-t-n} + pH^+ + (4-t)H_2O \quad (8)$$

where $p = n+t-4$, the experimental data were treated as follows. By considering, firstly, data at a given m_H, the most important n values and the conditional constants K_n, eq. (12), were ascertained. Then, the t and $^*\beta_{n,p}$ values were calculated by examining the dependence of the K_n-s on m_H.

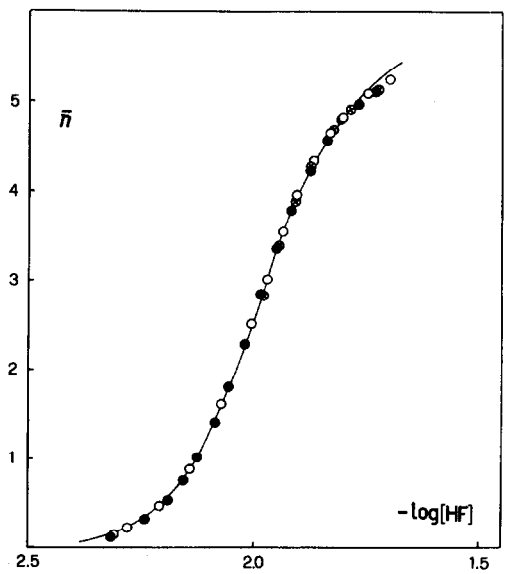

Fig. 1. Experimental data at $m_H = 0.1$ in $NaClO_4$ media. $\bar{n}$, the average number of fluoride ions bound per germanium, as a function of log [HF] for different m_M. Dots: titration (a), points: titration(b), crosses: back titration (c). The curve has been calculated with the constants of Table 3 setting $[H^+] = 0.103$.

Treatment of the data at constant m_H

If only mononuclear complexes in germanium are present $\bar{n}$ may be expressed as (9)

$$\bar{n} = \sum nQ_{n,p}[HF]^n[H^+]^{-p} \Big/ \left(1 + \sum Q_{n,p}[HF]^n[H^+]^{-p}\right) \quad (9)$$

where for brevity $Q_{n,p}$ stands for

$$Q_{n,p} = {}^*\beta_{n,p} y_{HF}^n y_H^{-p} y_M y_{n,p}^{-1} a_W^{(t-4)} \quad (10)$$

a_W is the water activity and y_H, y_M, $y_{n,p}$ are, respectively, the activity coefficients of H^+, $Ge(OH)_4$, $Ge(OH)_tF_n^{4-t-n}$.

For a constant m_H value, since $m_M < 0.1m_H$, $Q_{n,p}$ is with good approximation constant and $[H^+]$ must be very close to m_H. As a consequence, we have from (9)

$$\bar{n} = \sum nK_n[HF]^n \Big/ \left(1 + \sum K_n[HF]^n\right) \quad (11)$$

in which

$$K_n = K_n([H^+]) = \sum Q_{n,p}[H^+]^{-p}. \quad (12)$$

The graphical approach, described in detail in preceding papers[7,8] and founded on the comparison of the experimental data with normalized functions,[12] indicated the predominance of complexes with $n = 4$ and 6 at $m_H \leqslant 0.3$ and of additional species with $n = 2$ at higher acidities. The conditional constants, K_n, evaluated by curve-fitting are listed in Table 2. The errors represent maximal deviations from mean values.

Table 2. Survey of the conditional constants, K_n

As a check, the experimental data were treated with the general minimizing program Letagrop.[13] To avoid the introduction of uncertainties connected with the estimation of activity coefficients the least-squares procedure separately considered data at constant m_H. The minimum of the sum

$$U = \sum (m_{F_{calc}} - m_F)^2 \qquad (13)$$

where $m_{F_{calc}}$ denotes a value calculated with a given set of constants, was sought for by assuming a series of species with various n and t. Owing to the essential constancy of $[H^+]$ comparable minima were recorded in testing complexes with identical n but different t. Furthermore, the constant $Q_{n,p}$ computed for a given set (n,p) is in reality the series: $Q_{n,p} + Q_{n,p-1}[H^+] + \cdots = K_n[H^+]^p$. Therefore, from the numerical treatment of data at constant m_H only conclusions concerning the most probable n and K_n values can be drawn.

The minimizing procedure yielded results in perfect agreement with those found graphically. No significant lower minima were recorded on testing hypotheses including also species with $n = 1$, 3 and 5. The constants reported in Table 2 are averages of K_n deduced from a series of $K_n[H^+]^p$ calculated by assuming the same n, *i.e.* 2, 4 and 6, but various p for each n. The errors represent three times the standard deviation. These were found to exceed the deviations from the average of every single K_n. Mean $[H^+]$ values, as furnished by Letagrop, were employed to obtain K_n from $K_n[H^+]^p$. In Table 2 are listed $[H^+]$ values calculated as mean when assuming $Ge(OH)_2F_4^{2-}$ and GeF_6^{2-}, *i.e.* the species producing the largest changes in the medium acidity. This may serve to get an idea on the constancy of the hydrogen ion concentration at a given m_H. The mean $[H^+]$ and the K_n values derived from the least-squares procedure were selected for the following treatment.

Calculation of the most important t *and* $*\beta_{n,p}$ *values*

To determine t and $*\beta_{n,p}$ the dependence of K_n with $[H^+]$ [eqs (10) and (12)] was examined. The correct treatment requires the knowledge of the medium changes when Me^+ is replaced by H^+. The activity coefficient of HF was accounted for by eq. (2a,b) and the water activity was evaluated from

$$\log a_W = -7.0 \times 10^{-3}[H^+]\,(\text{in } NaClO_4)$$
$$= 2.1 \times 10^{-4}[H^+]\,(\text{in } LiClO_4). \qquad (14)$$

Relationships (14) were established from the osmotic coefficients listed by Robinson and Stokes[14] by assuming a linear change with composition from values relevant to the pure 3 molal $MeClO_4$ and $HClO_4$ solutions. Medium effects on other reagents were estimated by the specific interaction theory SIT.[15] Thus, due to the unchanged ionic strength and ClO_4^- molality, the activity coefficient of positively charged ions was taken as unity in the medium scale. For anions and uncharged species we put

$$y_i = 10^{b_i[H^+]} = 1 + 2.3 b_i[H^+] + \cdots \qquad (15)$$

where b_i is the difference of the interaction coefficient of i with $HClO_4$ and $MeClO_4$. Since b_i is expected to be less than 0.1 higher terms in (15) can be neglected. The b_i values were considered as unknown parameters to be established simultaneously with $*\beta_{n,p}$.

With these assumptions eqs (12) and (10) for

$n = 6$ may be rearranged to give eq. (16)

$$K_6 a_W^4 [H^+] y_{HF}^{-6} = {}^*\beta_{6,1} y_M y_{6,1}^{-1} + {}^*\beta_{6,2} [H^+]^{-1} y_M y_{6,2}^{-1} + \cdots$$
$$= {}^*\beta_{6,1} + 2.3 {}^*\beta_{6,2} (b_M - b_{6,2}) + {}^*\beta_{6,2} [H^+]^{-1} + 2.3 {}^*\beta_{6,1} (b_M - b_{6,1}) [H^+]. \quad (16)$$

Figure 2 shows the dependence of $K_6 a_W^4 [H^+] y_{HF}^{-6}$ on $[H^+]^{-1}$ for data in $NaClO_4$ media. Within the limits of experimental error the points form a straight line, thus indicating the presence of GeF_6^{2-} and $HGeF_6^-$ and that the last term of eq. (16) is small. Furthermore, the slope of the straight line (${}^*\beta_{6,2}$) is about 0.45 times the intercept $[{}^*\beta_{6,1} + 2.3 {}^*\beta_{6,2} (b_M - b_{6,2})]$ which, being $b_M - b_{6,2}$ expected inferior than 0.1, can be approximated with ${}^*\beta_{6,1}$. The neglect of the $(b_M - b_{6,2})$ term does not introduce an uncertainty greater than the error of the intercept. The most probable ${}^*\beta_{6,1}$ and ${}^*\beta_{6,2}$ constants are given in Table 3.

A similar treatment of data in $LiClO_4$ led to the presence of $HGeF_6^-$ with the constants of Table 3. The absence of GeF_6^{2-} in $LiClO_4$ solutions seems understandable due to the high acidities investigated.

Equation (12) for $n = 4$ can be written as (17)

$$K_4 a_W^4 y_{HF}^{-4} = {}^*\beta_{4,0} y_M y_{4,0}^{-1} + {}^*\beta_{4,1} [H^+]^{-1} y_M a_W y_{4,1}^{-1} + \cdots$$
$$= {}^*\beta_{4,0} + {}^*\beta_{4,1} 2.3 (b_M - b_{4,1}) a_W + {}^*\beta_{4,1} a_W [H^+]^{-1} + {}^*\beta_{4,0} [H^+] 2.3 (b_M - b_{4,0}). \quad (17)$$

From the plot of $K_4 a_W^4 y_{HF}^{-4}$ against $a_W [H^+]^{-1}$, Fig. 3, it is concluded that GeF_4 and $Ge(OH)F_4^-$ are formed and the last term of (17) must be negligible. From the slope and intercept of the best straight line the ${}^*\beta_{4,1}$ and ${}^*\beta_{4,0} \simeq {}^*\beta_{4,0} + {}^*\beta_{4,1} 2.3 (b_M - b_{4,1}) a_W$ listed in Table 3 were evaluated.

Table 3. The equilibrium constants, ${}^*\beta_{n,p}$

	$NaClO_4$ media	$LiClO_4$ media
$\log {}^*\beta_{2,-1}$	2.9±0.1	3.2±0.2
$\log {}^*\beta_{4,0}$	7.18±0.10	7.73±0.02
$\log {}^*\beta_{4,1}$	6.65±0.05	
$\log {}^*\beta_{6,1}$	9.94±0.10	10.8±0.1
$\log {}^*\beta_{6,2}$	9.59±0.05	

The K_4 values in $LiClO_4$ yielded as predominant GeF_4.

Lastly, we attempted to ascribe a plausible t in the $Ge(OH)_t F_2^{2-t}$ species which are important only at $m_H \geqslant 1$. Assuming a single t, eq. (12) can be written

$$\log {}^*\beta_{2,p} = \log K_2 + p \log [H^+] - 2 \log y_{HF} - \log y_M + \log y_{2,p} + (4-t) \log a_W \quad (18)$$

from which values of ${}^*\beta_{2,p}$ were computed by putting $y_M = y_{2,p} = 1$ and $p = 0, 1, 2, -1, -2$. Approximately constant ${}^*\beta_{2,-1}$ values were obtained, thus the $Ge(OH)F_2^+$ species would be present. In consideration, however, of the various sources of uncertainty, the proposal of such a complex must be understood as tentative.

DISCUSSION

The main conclusion of this investigation is that in the acidity interval from 0.03 to 3 molal the

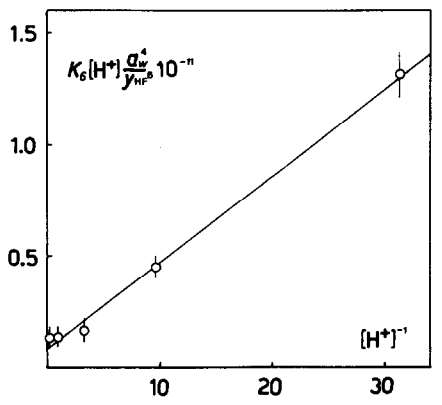

Fig. 2. $K_6 [H^+] a_W^4 y_{HF}^{-6}$, eq. (16), as a function of $[H^+]^{-1}$ for data in $NaClO_4$. The straight line represents: $8.7 \times 10^9 + 3.9 \times 10^9 [H^+]^{-1}$.

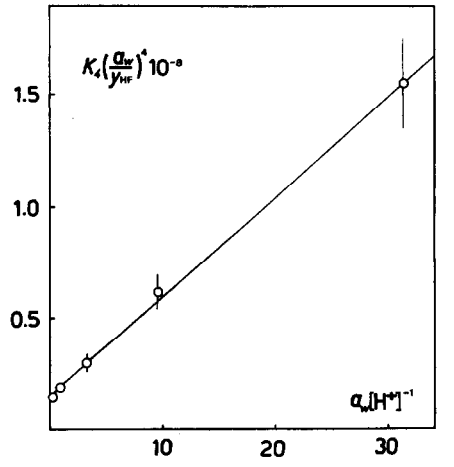

Fig. 3. $K_4 a_W^4 y_{HF}^{-4}$, eq. (17), as a function of $a_W [H^+]^{-1}$ for data in $NaClO_4$. The line is: $1.5 \times 10^7 + 4.5 \times 10^6 a_W [H^+]^{-1}$.

fluorogermanate(IV) equilibria lead to the formation of GeF_4, $Ge(OH)F_4^-$, GeF_6^{2-}, $HGeF_6^-$ and a minor species $Ge(OH)F_2^+$ which becomes significant only at the highest m_H. Figure 4 illustrates the distribution of the complex species. It is evident how at increasing m_H the curves representing GeF_6^{2-} and $HGeF_6^-$ are displaced to leave room for intermediate species.

The remarkable differences between constants deduced in $NaClO_4$ and $LiClO_4$ solutions are accounted for mainly by the salting effect on the activity of HF. It is recalled that according to the SIT,[15] 0.061 in eq. (2a) is the difference between the interaction coefficient of HF with $HClO_4$ and that of HF with $NaClO_4$. The analogous quantity for $LiClO_4$ is given by 0.020 in eq. (2b). Consequently, for a 3 molal salt concentration we have

$$\log y_{HF}(LiClO_4) - \log y_{HF}(NaClO_4) = (0.061 - 0.020) \times 3 = 0.123. \quad (19)$$

By assuming no appreciable changes in the activity coefficient of other reagents, the differences between

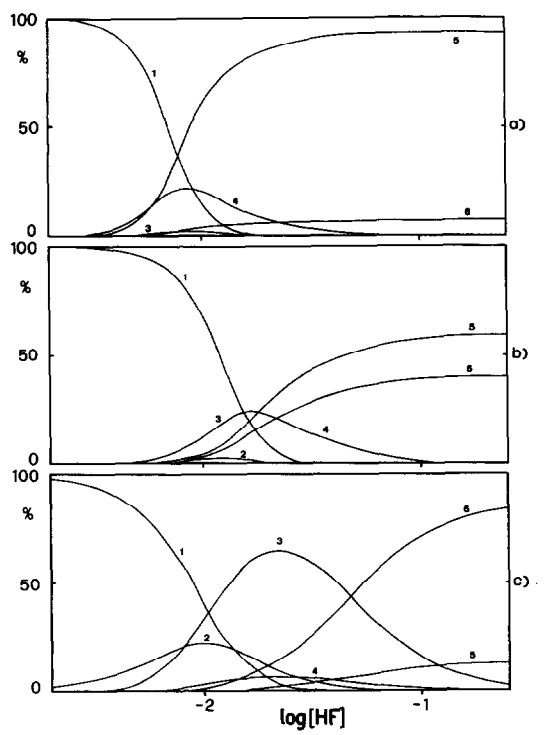

Fig. 4. Distribution of the fluorogermanates as a function of the free hydrofluoric acid concentration at different acidities: 0.03 (a), 0.3 (b), 3 (c). (1) $Ge(OH)_4$ (2) $Ge(OH)F_2^+$ (3) GeF_4 (4) $Ge(OH)F_4^-$ (5) GeF_6^{2-} (6) $HGeF_6^-$. The curves have been calculated with the constants relevant to the inert 3 molal $NaClO_4$ medium, Table 3, and assuming y_{HF} of eq. (2a) and a_w from eq. (14). Other activity coefficients have been set equal to unity.

$^*\beta_{n,p}$ values determined in $NaClO_4$ and $LiClO_4$ are explained, within the limits of error, by relationship (19).

The results of the present work are to a certain extent in contrast with those by Benoit and Place[2] who proposed species with 5 instead of 6 fluoride ions. The serious discrepancy led us to undertake a recalculation of their potentiometric measurements in 0.5 molar $HClO_4$. Comparison of the $\bar{n}(\log[HF])$ data with normalized functions,[12] constructed by assuming only two predominating complexes, clearly indicates that the curves representing $n = 4$ and 6 fit the data much better than those calculated with $n = 5$ and 6. In position of best agreement values of $\log K_4 = 7.5 \pm 0.1$ and $\log K_6 = 10.2 \pm 0.1$ were determined which on account of the different experimental conditions are not very far from the constants of Table 2.

The complexation pattern of the Ge^{IV}–HF, Si^{IV}–HF and Ti^{IV}–HF systems has close resemblance. Apparently, a very stable MF_6^{2-} complex is formed by all of these metals and the formation function is accomplished within less than 2 logarithm units of the ligand concentration, which involves a narrow range of existence for intermediate species. We have been able to detect some of the complexes bearing less than 6 fluoride ions by exploring the equilibria in acid media where the formation of MF_6^{2-} is disfavoured. Notwithstanding this, even at $m_H = 3$, the highest acidity studied, every complexation step could not be characterized with an equilibrium constant. Noticeably, in no case could species with 3 and 5 fluoride ions be identified. The irregularities in the stepwise addition of ligand has to be connected probably to structural changes on passing from lower to higher complexes.

Finally, in all of the systems investigated the existence of HMF_6^-, with an acid constant ranging from 0.1 to 1, has been demonstrated. This seems unexpected on account of the generalized belief that the H_2MF_6 acids behave as strong electrolytes.

A CONVENIENT SYNTHESIS OF TRIALKYLALKYLIDYNE TUNGSTEN (6+) COMPOUNDS AND THE X-RAY CRYSTAL STRUCTURE OF $(Me_3CCH_2)_3W{\equiv}CPh(py)$

MALCOLM H. CHISHOLM,* JOHN C. HUFFMAN and JEFFREY A. KLANG

(*Received* 27 *September* 1989; *accepted* 9 *January* 1990)

Abstract—A convenient synthesis for trialkylalkylidyne tungsten compounds is reported based on the metathetic reaction between alkyllithium or alkyl-Grignard reagents and $(^tBuO)_3W{\equiv}CR$ compounds. The success of the strategy is limited to alkyl ligands that lack β-hydrogen atoms. The X-ray crystal structure of $(Me_3CCH_2)_3W{\equiv}CPh(py)$ is reported. Cell dimensions at $-155°C$: $a = 13.657(7)$, $b = 13.897(9)$, $c = 14.115(7)$ Å, $Z = 4$ and space group $P2_12_12_1$. The central WC_4N unit is based on a distorted trigonal bipyramid with axial alkylidyne and pyridine ligands, with W—C = 1.74(3) and W—N = 2.57(3) Å, respectively.

As part of our long-standing interest in Group VI organometallic and inorganic chemistry we have become interested in exploring new, molecular routes to carbides, nitrides and oxides of molybdenum and tungsten.[1] We believe that trialkyltungstenalkylidynes, R'_3WCR, will serve as low temperature precursors to tungsten carbides (WC or W_2C). Girolami and his co-workers[2] have reported the formation of titanium carbide in the decomposition of $Ti(CH_2CMe_3)_4$ at temperatures as low as 150°C.

As we begin this work there are only a few examples of tungsten alkylidynes supported exclusively by alkyl ligands. These are prepared by reactions involving multiple α-hydrogen abstractions and are specific for Me_3SiCH_2 and Me_3CCH_2 ligands.[2] We require a more general method and chose to investigate metathetic reactions involving $(^tBuO)_3WCR$ complexes.

RESULTS AND DISCUSSION

Synthesis

Reaction of the alkoxide supported alkylidyne $(^tBuO)_3WCR$ with alkyl-Grignard or alkyl-lithium reagents of the type RCH_2M results in the formation of the desired trialkylalylidynes as shown in eq. (1). As the complexes $(^tBuO)_3WCR$ can be made with a wide variety of different R groups by the reaction of $W_2(O^tBu)_6$ with RCCR,[3] this route has the potential to be quite general. Table 1 lists the compounds made by this route so far, along with selected ^{13}C NMR data for their alkylidyne ligands. All of the new compounds have been characterized by ^1H and ^{13}C NMR spectroscopies, elemental analysis in most cases, and for $(Me_3CCH_2)_3WCPh(py)$ by single crystal X-ray crystallography.

Table 1. New alkylalkylidyne tungsten compounds with selected ^{13}C NMR data for the alkylidyne carbon

	Chemical shift (ppm)	J_{WC} (Hz)
$(PhCH_2)_3WC^tBu$	297.5	n.o.
$(Me_3CCH_2)_3WCSiMe_3$	338.3	188.7
$(Me_3SiCH_2)_3WCPh$	303.6	221.0
$((Me_3SiCH_2)_3WC)_2$	314.4	n.o.

$$(^tBuO)_3W{\equiv}CR + 3\,LiR' \longrightarrow (R')_3W{\equiv}CR + 3\,{}^tBuOLi. \quad (1)$$

Compounds containing benzyl or neopentyl ligands have only been prepared using the Grignard or lithium reagents, respectively. This is simply due to the convenience of these reagents relative to benzyllithium or neopentyl-Grignard. Compounds with Me_3SiCH_2 ligands can be made equally well from Me_3SiCH_2MgCl or Me_3SiCH_2Li. In some cases, when alkyl-lithium reagents were used it was difficult to separate the ^tBuOLi formed from the desired product. A useful procedure in this situation was to add a stoichiometric amount of $BF_3 \cdot OEt_2$ to a cooled hexane solution of the mixture. This quantitatively precipitated $BF_3(^tBuO)Li$ which was then removed by filtration.

As expected, the stability and physical properties of the trialkylalkylidynes depended markedly on the substituents R and R′. Although combinations of large R and R′ groups give the best stability, steric and electronic factors cannot be separated at this point. The importance of the alkylidyne substituent, R, in determining the stability of these complexes is underscored by the relative stabilities of $(PhCH_2)_3WCR$ (R = ^tBu, Me_3Si, Ph). The neopentylidyne is a yellow crystalline solid which is indefinitely stable in the absence of air or moisture. The trimethylsilylmethylidyne can be detected in solution (^1H NMR: $PhCH_2$ 2.18 ppm, J_{WH} = 7.7 Hz) but decomposes at a rate similar to that of its formation from $(^tBuO)_3WCSiMe_3$ and $PhCH_2MgCl$ and cannot be isolated. The benzylidyne has never been detected. Likewise, no evidence for a complex with an ethylidyne ligand $(RCH_2)_3WCMe$ has ever been seen with any alkyl ligand.

Of the alkyl ligands investigated, Me_3CCH_2 and Me_3SiCH_2 most effectively stabilize the alkylalkylidynes. In these series even compounds with relatively small alkylidyne substituents such as phenyl, and the dimers $(RCH_2)_3WC\text{-}CW(CH_2R)_3$, can be made and are relatively stable. The mixed neopentyl/trimethylsilylmethyl complexes $(Me_3CCH_2)_3WCSiMe_3$ and $(Me_3SiCH_2)_3WCCMe_3$ are both quite volatile, the latter subliming with little or no decomposition at *ca* 10^{-3} Torr and 50–55°C. The former compound is an oil and although small amounts of it can be distilled onto a cold finger condenser, attempted distillation on larger scales causes extensive decomposition. The benzylidynes, $(Me_3SiCH_2)_3WCPh$ and $(Me_3CCH_2)_3WCPh$, are oils at room temperature and decompose upon attempted distillation. Their pyridine adducts are, however, crystalline allowing purification of these compounds. The X-ray crystal structure of one of these is presented below.

We have not had as much success with other alkyl ligands. Only one complex containing benzyl ligands has been isolated, and with smaller alkyl groups or those with β-hydrogens (Me_2CHCH_2, Me_2CH) we have found no evidence for formation of R'_3WCR complexes.

NMR studies

The ^1H and ^{13}C NMR spectra are consistent with the formulation of these complexes as being monomeric with C_3 symmetry. The ^{13}C NMR spectra show characteristic far downfield chemical shifts and large values of J_{WC} for the alkylidyne carbon atoms (see Table 1). The alkylidyne chemical shifts range from 283.8 to 327.0 ppm; in each case this is about 30 ppm downfield of the corresponding $(^tBuO)_3WCR$ complex. Tungsten coupling of 75–90 Hz is also observed to the carbon atoms of the methylene groups. In the ^1H NMR spectra, small ^{183}W–^1H couplings (6–11 Hz) are seen to the hydrogen atoms of the methylene groups.

Molecular structure of $(Me_3CCH_2)_3W{\equiv}CPh(py)$

A summary of crystal data is given in Table 2 and selected bond distances and bond angles are given in Table 3. A ball-and-stick drawing of the molecule is shown in Fig. 1.

The central WC_4N core is a distorted trigonal pyramid in which the alkylidyne carbon and pyridine nitrogen occupy *trans* positions: N(15)—W—C(21) = 179.5(10)°. The W—C triple bond distance, 1.74(3) Å, and the W—C (neopentyl) distances, 2.13(4) Å, are well within the range expected based on other alkylalkylidyne compounds of tungsten (6+). The W—N (pyridine) distance of 2.575(25) Å is very long, indicative of a relatively weak donor interaction. The alkylidyne—C—W—C (alkyl) angles of *ca* 100° are similar to those seen in related trigonal bipyramidal structures such as $[(^tBuO)_3W{\equiv}N]_\infty$[3] and $(^tBuO)_3W(NO)(py)$[4] where the equatorial ligands bend away from the multiple bond in one axial site and toward the weak donor ligand in the other axial position.

Concluding remarks

The reported procedure provides a convenient synthesis for a number of trialkylalkylidyne tungsten compounds. Studies of their modes of thermal decomposition are currently underway.

EXPERIMENTAL

General operating procedures and techniques have been given previously.[5] Elemental analyses were performed by Oneida Research Services, Whitesboro, New York.

Crystallographic studies

General operating procedures and listings of programs have been described previously.[7] A summary of crystal data is given in Table 2. A suitable crystal was cleaved from a larger multicrystalline conglomerate and transferred to the goniostat using standard inert atmosphere handling techniques employed by the Indiana University Molecule Structure Center and cooled to −155°C for characterization and data collection.

A systematic search of a limited hemisphere of reciprocal space located a set of diffraction maxima with symmetry and systematic absences corresponding to the unique orthorhombic space group $P2_12_12_1$. Subsequent solution and refinement

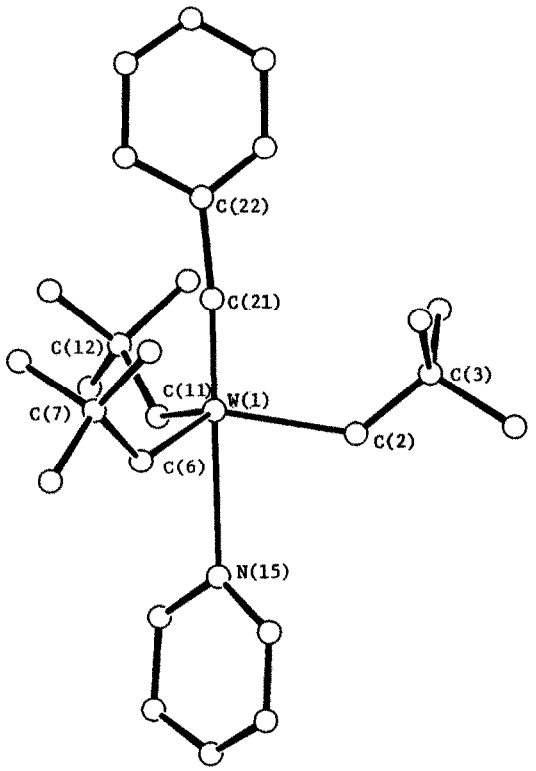

Fig. 1. A ball-and-stick drawing of the $(Me_3CCH_2)_3W{\equiv}CPh(py)$ molecule.

of the structure confirmed this choice. There were several weak peaks present which could not be accounted for based on the chosen cell, or a supercell based on the known cell. Some of these were identified as a second well-ordered fragment of *ca* 10% the intensity of the located cell, and other peaks indicated other fragments were possibly present. Examination of the bulk sample indicated that it would be difficult to find a more homogenous sample, so the mounted specimen was utilized.

Data were collected using a continuous θ–2θ scan with fixed backgrounds and reduced to a unique set of intensities and associated sigmas in the usual manner. The structure was solved by a combination of direct methods (MULTAN78) and Fourier techniques. A difference Fourier synthesis revealed the location of some, but not all, hydrogen atoms. All hydrogen atom positions were therefore calculated using idealized geometries and d(C—H) = 0.95 Å. These calculated positions were fixed for the final cycles of refinement. The data were corrected for absorption based on measurements made on the diffractometer, but use of the absorption corrected data led to non-positive definite thermal parameters for many of the atoms. For the final cycles, the uncorrected data were used. The poor quality of the refinement is partially due to the large thermal motion present, as well as to interference from the fragments known to be present.

Chemicals

The alkylidynes $(^tBuO)_3WCR$ were made by the method of Schrock;[6b] $(CH_3)_3CCH_2Li$ and Me_3SiCH_2Li were made by published procedures. $PhCH_2MgCl$ and Me_3SiCH_2MgCl were purchased from Aldrich Chemical Co.

Preparation of $(PhCH_2)_3WC^tBu$

In a 50 cm^3 Schlenk flask, $(^tBuO)_3WC^tBu$ (1.56 g, 3.3 mmol) was dissolved in Et_2O (20 cm^3), the solution was cooled to 0°C and $PhCH_2MgCl$ (3.3 equiv, 2.0 M in THF) was added via syringe. After stirring for 1 h at 0°C, the volatile components were removed *in vacuo* and the residue was extracted with 4×10 cm^3 of hexane at room temperature. The combined hexane filtrates were concentrated and cooled to *ca* −20°C for 2 days to give 1.05 g (60% yield) of $(PhCH_2)_3WC^tBu$ as yellow crystals.

$(PhCH_2)_3WC^tBu$: ^1H NMR (C_6D_6) δ: C_6H_5 7.18 (m, 3H); 6.93 (m, 6H); 6.78 (m, 6H); $PhCH_2$ 1.95 (s, J_{WC} = 6.5 Hz, I = 20%, 6H); $C(CH_3)_3$ 1.36 (s, 9H). $^{13}C\{^1H\}$ NMR (C_6D_6) δ: $WCC(CH_3)_3$ 297.5 (s); C_6H_5 131.6(s); 131.1(s); 129.7(s); 127.1(s); $PhCH_2$ 57.1 (s, J_{WC} = 77.1 Hz, I = 15%); $C(CH_3)_3$ 38.1 (s); $C(CH_3)_3$ 30.9 (s). IR (KBr) cm^{-1}: 2960(s); 2940(s); 2900(m); 1580(m); 1485(s); 1450(s); 1155(m); 1030(m); 1005(m); 980(m); 815(m); 800(m); 710(s); 695(s); 515(s). Found: C, 59.5; H, 5.7. Calc. for $WC_{26}H_{30}$: C, 59.3; H, 5.7%.

Preparation of $(Me_3CCH_2)_3WCSiMe_3$

A solution of $(^tBuO)_3WC(SiMe_3)$ (0.466 g, 0.96 mmol) in Et_2O (10 cm^3) was cooled to 0°C and an Et_2O (5 cm^3) solution of Me_3CCH_2Li (0.246 g, 3.15 mmol) was added via cannula. The mixture was stirred at 0°C for 1.5 h and the volatile components were removed *in vacuo*. Sublimation of the residue onto a water cooled cold-finger at *ca* 10^{-3} Torr and 50–55°C provided 315 mg (68% yield) of analytically pure $(Me_3CCH_2)_3WCSiMe_3$.

$(Me_3CCH_2)_3WCSiMe_3$: ^1H NMR (C_6D_6) δ: $C(CH_3)_3$ 1.15 (s, 27H); 0.91 (s, J_{WH} = 11.0 Hz, I = 20%, 6H); $Si(CH_3)_3$ 0.44 (s, J_{SiH} = 6.6 Hz, I = 8.6%, 9H). $^{13}C\{^1H\}$ NMR (C_6D_6) δ: $CSi(CH_3)_3$ 338.3 (s, J_{WC} = 188.7 Hz, J_{SiC} = 42.7 Hz); $^tBuCH_2$ 105.2 (s, J_{WC} = 91.7 Hz); $C(CH_3)_3$ 34.7(s); $C(CH_3)_3$ 33.9(s); $Si(CH_3)_3$ 1.95 (s, J_{SiC} = 41.9 Hz). IR (KBr) cm^{-1}: 2975(s); 2900(m); 2865(m); 1460(m); 1385(m); 1360(s); 1265(m); 1245(s);

1235(s); 1195(s); 1120(m); 840(s); 755(m). Found: C, 47.0; H, 8.7. Calc. for $WC_{19}H_{42}Si$: C, 47.3; H, 8.8%.

Preparation of $(Me_3SiCH_2)_3WCPh$

A solution of $(^tBuO)_3WCPh$ (0.70 g, 1.4 mmol) in Et_2O (10 cm^3) was cooled to 0°C and Me_3SiCH_2MgCl (1.0 M in Et_2O, 4.3 cm^3) was added via syringe. The mixture was stirred at 0°C for 1.5 h and the volatile components were removed *in vacuo*. The residue was extracted with 2×10 cm^3 hexane, filtered through a Celite pad and the hexane removed *in vacuo* to give $(Me_3SiCH_2)_3WCPh$ as a dark red oil. This oil could not be induced to crystallize and decomposed upon attempted sublimation/distillation but was approximately 95% pure as judged by ^1H NMR. The pyridine adduct $(Me_3SiCH_2)_3WCPh \cdot py$ was made by adding 1 cm^3 of pyridine and 5 cm^3 of DME to the oil obtained above. The dark red solution was reduced in volume by about 1/2 and cooled to −20°C overnight to give 410 mg (48% yield) of yellow–brown $(Me_3SiCH_2)_3WCPh \cdot py$ as a tacky solid.

$(Me_3SiCH_2)_3WCPh$: ^1H NMR (C_6D_6) δ: C_6H_5 7.44 (m, 2H); 7.29 (m, 2H); 6.93 (m, 1H); CH_2 0.69 (s, $J_{WH} = 9.3$ Hz, $I = 20\%$, 6H); $Si(CH_3)_3$ 0.15 (s, $J_{SiH} = 7.6$ Hz, $I = 8.0\%$, 27H). $^{13}C\{^1H\}$ NMR (C_6D_6) δ: $C(C_6H_6)$ 303.6 (s, $J_{WC} = 221.0$ Hz, $I = 14.4\%$); phenylipso 150.0 (s, $J_{WC} = 51.7$ Hz, $I = 15.1\%$); C_6H_5 130.4(s); 126.3(s); CH_2 76.2 (s, $J_{WC} = 76.4$ Hz, $I = 13.5\%$; $J_{SiC} = 40.0$ Hz, $I = 6.6\%$); $Si(CH_3)_3$ 2.7 (s, $J_{SiC} = 51.5$ Hz, $I = 7.8\%$). IR (film on NaCl) cm^{-1}: 2980(s); 2900(m); 1360(m); 1245(s); 1195(m); 945(s); 840(s); 750(s); 690(s). No analysis was attempted; compound is an oil.

$(Me_3SiCH_2)_3WCPh \cdot py$: ^1H NMR (C_6D_6) δ: C_6H_5 and py 8.89 (m, 2H); 7.65 (m, 2H); 7.38 (m, 2H); 6.96 (m, 1H); 6.92 (m, 1H); 6.67 (m, 2H); CH_2 1.17 (s, $J_{WH} = 9.1$ Hz, $I = 18\%$, 6H); $Si(CH_3)_3$ 0.21 (s, $J_{SiH} = 6.0$ Hz, $I = 8.3\%$, 27H). $^{13}C\{^1H\}$ NMR (C_6D_6) δ: C_6H_5 and py 150.5(s); 149.8(br, s); 131.5(s); 125.9(s); 124.5(br, s); CH_2 72.3 (s, $J_{WC} = 81.8$ Hz, $I = 16\%$); $Si(CH_3)_3$ 3.2(s).

Preparation of $((Me_3SiCH_2)_3W{\equiv}C)_2$

An Et_2O (10 cm^3) solution of $((^tBuO)_3WC)_2$ (0.50 g, 0.60 mmol) was cooled to 0°C and solid Me_3SiCH_2Li (0.34 g, 3.6 mmol) was added from a side arm over about 20 min. The mixture was stirred at 0°C for 3 h, and volatiles removed *in vacuo*, the residue dissolved in *ca* 3 cm^3 hexane and placed in a −20°C freezer. After about 24 h black crystals (290 mg, 52% yield) of $((Me_3SiCH_2)_3WC)_2$ were isolated by filtration and dried *in vacuo*.

$((Me_3SiCH_2)_3W{\equiv}C)_2$: ^1H NMR (C_6D_6) δ: CH_2 1.13 (s, $J_{WH} = 7.7$ Hz, $I = 22\%$, 12H); $(CH_3)_3Si$ 0.30 (s, $J_{SiH} = 6.2$ Hz, $I = 12\%$, 54H). $^{13}C\{^1H\}$ NMR (C_6D_6) δ: W≡*C*— 314.4(s); CH_2 77.8 (s, $J_{WC} = 79.4$ Hz, $I = 14.6\%$). IR (KBr) cm^{-1}: 2970(s); 2880(m); 2820(m); 1395(m); 1380(m); 1245(s); 1210(m); 940(s); 840(s); 750(s); 685(s). Found: C, 33.8; H, 7.0. Calc. for $W_2C_{26}H_{66}Si_6$: C, 34.1; H, 7.2%.

Preparation of $(Me_3CCH_2)_3WCPh \cdot py$

An Et_2O (10 cm^3) solution of $(^tBuO)_3WCPh$ (0.4 g, 0.813 mmol) was cooled to 0°C and solid Me_3C-CH_2Li (0.176 g, 2.26 mmol) was added from a side arm over about 20 min. The mixture was stirred at 0°C for 1 h and the volatile components were removed *in vacuo*. The residue was dissolved in hexane (3 cm^3) at 0°C and $BF_3 \cdot OEt_2$ (0.2 cm^3, 3.25 mmol) was added via syringe to precipitate $BF_3 \cdot O^tBu^-Li^+$ as a light brown solid which was filtered off and discarded. The filtrate was reduced in volume to about 1 cm^3 and pyridine (0.2 cm^3) was added. Cooling to −20°C overnight caused 244 mg (54% yield) of $(Me_3CH_2)_3WCPh \cdot py$ to precipitate as a light brown solid.

Crystals of $((CH_3)_3CCH_3)_3WCPh \cdot py$ suitable for X-ray diffraction analysis were obtained by cooling a solution of *ca* 250 mg of the compound in *ca* 2 cm^3 of 1 : 1 hexane–pyridine to −20°C for several days.

$(Me_3CCH_2)_3WCPh \cdot py$: ^1H NMR (C_6D_6) δ: C_6H_5 and py 8.69 (m, 2H); 7.82 (m, 2H); 7.32 (m, 2H); 7.0 (m, 1H); 6.93 (m, 1H); 6.63 (m, 2H); $C(CH_3)_3$ 1.28 (s, 27H); CH_2 1.11 (s, $J_{WH} = 10.1$ Hz, $I = 25\%$, 6H). $^{13}C\{^1H\}$ NMR (C_6D_6) δ: ≡*C*(C_6H_5) 283.4 (br. s); C_6H_5 and py 150.5(s); 149.8(s); 136.8(s); 132.5(s); 125.6(s); 124.4(s); CH_2 104.2 (s, $J_{WC} = 89.2$ Hz, $I = 13.7\%$); $C(CH_3)_3$ 36.4(s); $C(CH_3)_3$ 34.6(s). IR (KBr) cm^{-1}: 2945(s); 2850(s); 1595(m); 1580(m); 1480(s); 1440(s); 1380(s); 1355(s); 1235(s); 1225(s); 1115(m); 1065(m); 940(m); 750(s); 690(s). Found: C, 57.1; H, 7.5; N, 2.4. Calc. for $WC_{27}H_{43}N$: C, 57.4; H, 7.6; N, 2.5%.

Preparation of $((Me_3CCH_2)_3WC)_2$ *and* $((Me_3CCH_2)_3WC)_2 \cdot py_2$

An Et_2O (5 cm^3) solution of $((^tBuO)_3WC)_2$ (0.875 g, 1.05 mmol) was cooled to 0°C and an Et_2O (5 cm^3) solution of Me_3CCH_2Li (0.532 g, 6.82 mmol) added via cannula. The mixture was stirred at 0°C for 1.5 h, the volume of the solution reduced by

about 1/2 and placed in a −20°C freezer. After 2 days 608 mg (71% yield) of dark red $((Me_3CCH_2)_3WC)_2$ was collected by filtration and dried *in vacuo*. The bis-pyridine adduct was formed by addition of excess pyridine to a suspension of $((Me_3CCH_2)_3WC)_2$ in toluene and by removing the volatile components *in vacuo*.

$((Me_3CCH_2)_3WC)_2$: ^1H NMR (C_6D_6) δ: $C(CH_3)_3$ 1.28 (s, 54H); CH_2 1.18 (s, J_{WH} = 9.2 Hz, I = 16.6%, 12H). $^{13}C\{^1H\}$ NMR (C_6D_6) δ: CH_2 105.5 (s, J_{WC} = 91 Hz, I = 15%); $C(CH_3)_3$ 35.9(s); $C(CH_3)$ 34.5(s). IR (KBr) cm^{-1}: 2950(s); 2895(s); 2875(s); 2750(m); 1465(m); 1360(s); 1340(s); 1230(s); 1220(m); 1105(m); 750(m); 600(m); 520(m). Satisfactory analysis not obtained.

$((Me_3CCH_2)_3WC)_2 \cdot py_2$: ^1H NMR (C_6D_6) δ: py 8.63 (m, 2H); 6.97 (m, 1H); 6.64 (m, 2H); $C(CH_3)_3$ 1.43 (s, 27H); CH_2 1.34 (s, 6H). $^{13}C\{^1H\}$ NMR (C_6D_6) δ: $\equiv C-$ 305.3(s); py 150.0(s); 136.0(s); 124.0(s); CH_2 105.3 (s, J_{WC} = 89.8 Hz, I = 12.8%); $C(CH_3)_3$ 35.9(s); $C(CH_3)_3$ 34.5(s).

Preparation of $(Me_3SiCH_2)_3WC^tBu$

An Et_2O (5 cm^3) solution of $(^tBuO)_3WC^tBu$ (0.643 g, 1.4 mmol) was cooled to 0°C and Me_3SiCH_2MgCl (5.0 mmol, 1.0 M in Et_2O) was added via syringe. The mixture was stirred at 0°C for 1.75 h and the volatile components were removed *in vacuo*. The residue was extracted with 2×5 cm^3 hexane and the solid filtered off and discarded. The volatile components were removed from the filtrate under a dynamic vacuum to leave a red oil that is approximately 95% pure as judged by ^1H NMR. Small amounts can be distilled onto a water cooled cold finger at *ca* 10^{-3} Torr and 55–60°C but, attempts to purify $(Me_3SiCH_2)_3WC^tBu$ by short path distillation lead to decomposition.

$(Me_3SiCH_2)_3WC^tBu$: ^1H NMR (C_6D_6) δ: CMe_3 1.55 (s, 9H); CH_2 0.78 (s, J_{WH} = 9.8 Hz, I = 16%, 6H); $SiMe_3$ 0.14 (s, 27H). $^{13}C\{^1H\}$ NMR (C_6D_6) δ: WC^tBu 319.5 (s, J_{WC} = 215.0 Hz, I = 15%); CH_2 74.7 (s, J_{WC} = 78.9 Hz, I = 16%, J_{SiC} = 40.6, I = 11%); $C(CH_3)_3$ 33.2(s); $C(CH_3)$ 32.5(s): $Si(CH_3)_3$ 2.9(s).

CRITICAL EVALUATION OF EMPIRICAL FORCE-FIELD MODELS FOR SIMULATION OF PLASTICITY OF COPPER(II) COORDINATION

J. SABOLOVIĆ and N. RAOS*

Institute for Medical Research and Occupational Health, University of Zagreb, M. Pijade 158, 41001 Zagreb, Croatia, Yugoslavia

(*Received* 18 *May* 1989; *accepted* 11 *January* 1990)

Abstract—The plasticity of the copper(II) coordination sphere was simulated with the empirical force-field (molecular mechanics) method. Altogether five models for copper coordination were checked on the *trans*-CuN_2O_2 "complex": (1) a simple model with an angle-bending potential for only *cis* (N–Cu–O) angles, (2) a "dummy" atom model with two apically placed "dummy" atoms, (3) a model with a distortion potential (defined as quadratic function of the angle between bisectors of two opposite valence angles) and a quadratic function for bending of *cis* angles, (4) a model with a distortion potential and an angle-bending potential with two minima (at 90 and 109.47°) for O–Cu–N angles and (5) a newly proposed model with a distortion angle and an angle-bending potential with two minima for all valence angles around copper. The simplest model (1) did not give geometrically defined minima, and model (2) yielded besides the *trans* configuration three minima with superimposed atoms. Models with a distortion potential yielded better results: with model (3) only the *trans* configuration was obtained upon minimization, and model (4) yielded *trans* and tetrahedral configurations besides three "false" configurations of the same (zero) energy. Improving model (4), by proposing model (5), only two configurations (*trans* and tetrahedral) with zero energy were obtained. Model (5) was also proved best in reproducing the crystal geometry and diastereoselectivity of copper(II) bis-aminoacidates.

The plasticity of the copper(II) coordination sphere,[1] i.e. the fact that copper usually does not form "regular" (planar, tetrahedral or octahedral) coordination polyhedra, is a well-known feature of copper stereochemistry.[2] Because of plasticity, copper compounds form crystal modifications with differently distorted coordination polyhedra (distortion isomerism),[3] and show less pronounced stereoselectivity effects than corresponding complexes of nickel(II) and cobalt.[4,5]

Besides classical model compounds for the study of tetracoordinated copper(II) distortion (planar/tetrahedral), bis-(N-alkylsalicylaldiminato)copper (II) complexes,[6] most of our research was done on copper(II) complexes with N,N-dimethylated β-branched amino acids (valine[6–9] and isoleucine[10,11]). In those complexes,[12] as well as in the other chelates with N-alkylated amino acids,[12–14] there is a very pronounced diastereoselectivity effect.†[15–17] In apolar solvents, incapable of coordinating, the diastereoselectivity effect could be totally attributed to the steric strain in the molecule; therefore it can be estimated from the difference in conformational energy between diasteroisomers.

In order to estimate the energy and geometry of those complexes, we used two kinds of empirical force fields: (1) a "dummy" atom model which treats tetracoordinate, a virtually planar complex, as pseudo-octahedral by placing two "dummy" atoms in apical positions[18] and (2) a model with a distortion coordinate potential,[9] dependent on distortion coordinate (defined as an angle between bisectors of two opposite valence angles around the

* Author to whom correspondence should be addressed.

† Defined as $\Delta G = -RT\ln(\beta_{MLL}/\beta_{MDL})$, L and D denoting ligand diastereomers (usually enantiomers) and β cumulative stability constants.

central atom). The "dummy" atom model proved good for predicting thermodynamic stability of bis-(N,N-dimethylvalinato)copper(II),[6,8] but not so good for predicting its crystal geometry.[8] It seems that the sterical strain in the molecule, computed with such a model, leads to a distorted pyramid instead of to a distorted tetrahedron. Recently proposed models[9] with a distortion coordinate potential (Models 3 and 4), overcome that obstacle, but the angles around copper and the thermodynamic stability of the complex do not seem to be reproduced with higher accuracy.

The aim of this paper is to critically evaluate all of the proposed models by analysing the surface of potential (i.e. conformational) energy for planar/tetrahedral distortion. For that purpose we used the simplest system, "complex" *trans*-CuN_2O_2, which corresponded to the coordination polyhedron in copper(II) chelates with amino acids.

METHODS

The conformational (strain) potential energy was calculated from the basic formula:

$$V = 1/2\sum_i k_{b,i}(b_i - b_{0,i})^2 + 1/2\sum_j k_{\theta,j}(\theta_j - \theta_{0,j})^2 + 1/2\sum_k V_n(1 \pm \cos n\varphi_k) + \sum_l [A_l \exp(-B_l r_l) - C_l r_l^{-6}] + 1/2\sum_m k_{\chi,m}\chi_m^2 + 1/2k_\beta(\beta - \beta_0)^2 + V_{XMY} \quad (1)$$

in which b, θ, φ, and χ stand for bond lengths, valence, torsional and out-of-plane angles, respectively; r is non-bonded distance, and β is a distortion coordinate defined as an angle between bisectors of two opposite (N–Cu–O and N′–Cu–O′, see Fig. 4) valence angles around copper. K_b is an empirical parameter for bond stretching and k_θ for valence angle bending. Torsional interactions were determined with parameters V_n and n (height and multiplicity of the torsional barrier, respectively) and non-bonded interactions were computed from a Buckingham function with parameters A, B and C. In addition, the out-of-plane deformation potential for the carboxyl groups and aromatic rings with a quadratic function dependent on parameter k_χ and distortion potential (parameters k_β and β_0) in Models 3–5 (Table 1) were also computed.

The last term in eq. (1) is angle-bending potential for the angles around copper, which can be quadratic (Models 1–3) or in the form of cosine power series (Models 4 and 5), see below (eqs 2 and 3). Contrary to models with a quadratic angle-bending function which have only one minimum (for planar configuration), models with an angle-bending function in the form of cosine power series have two minima which correspond to planar and tetrahedral configurations.

The parameters not shown in Table 1 were the same as those used in our first paper,[18] with the exception of C–N–C bending parameters which were taken to be equal to the parameters for C–C–C bending. The empirical constant k_χ is taken to be

Table 1. Parameters for force-field calculations[a]

β (Models 3–5)	37.50	3.142

[a] "Dummy" atom is denoted with *X*. Only the most specific parameters were presented here, for other parameters see Methods. The parameters for Model 2 were taken from Ref. 6 and for Models 3 and 4 from Ref. 9. Parameters for models with distortion coordinate potential (Models 3, 4 and 5) were obtained by systematical variation of parameters k_θ, k_s, k_z and k_β until the best reproduction of crystal structure of bis-(L-N,N-dimethylvalinato)copper(II) in terms of $\varepsilon_{r.m.s.}(\Delta\theta)$ and $\varepsilon_{r.m.s.}(\Delta\theta, \Delta\varphi, \Delta\beta)$ was obtained. Bonding parameters for all models were taken from Ref. 18.

100 kcal mol^{-1} rad^{-2} for both kinds of out-of-plane deformation. Other empirical parameters specific to aromatic compounds were taken from modified Dashevsky force field (FF2).[19]

Calculations were performed with a program developed by Kj. Rasmussen and co-workers,[20] which was further modified to cope with new empirical potentials (distortion potential and two-well angle-bending potential).[9]

The two-well angle-bending potential for the N–Cu–O angle (with minima at 90 and 109.47°) is given by the expression:

$$V_z = 1/2k_z(9z^4+6z^3+z^2) \qquad (2)$$

where k_z is empirical parameter (Table 1) and $z = \cos\theta$. For angles N–Cu–N and O–Cu–O (with minima at 109.47 and 180°) the two-well angle-bending function has the form:

$$V_s = 1/2k_s(9/8s^4+3\sqrt{2}/2s^3+s^2) \qquad (3)$$

where k_s is empirical parameter (Table 1) and $s = \sin\theta$. Both potentials, V_z and V_s, have two minima of equal (zero) energy and a maximum at symmetry axis between them. The parameters for the potential (3) were chosen so that potential (3) had the same maximum value as potential (2). The full mathematical description of the potentials is given elsewhere.[9]

Root-mean-square deviation between crystal and theoretical structures was calculated from:

$$\varepsilon_{\text{r.m.s}}(\Delta X) = \left(1/N \sum_{i=1}^{N} (\Delta X_i)^2\right)^{1/2} \qquad (4)$$

where X stands for angles around copper [valence angles, θ, distortion angle β and "torsional angle" φ(ONNO)] when comparing the copper coordination geometry, or the interatomic distance, r, when checking the overall similarity. Mark Δ denotes the difference between the values of the observable X in two structures.

The average Gibbs energy of the diastereomer (MLL or MDL) was calculated from the formula:

$$\langle G \rangle = \sum w_i G_i \Big/ \sum w_i \qquad (5)$$

where G_i denotes the Gibbs energy of the ith conformer, and w_i stands for the statistical weight calculated from Boltzmann formula. Details of calculations were given elsewhere.[10]

The potential energy surface for distortion of the copper coordination polyhedron was constructed from the values of potential energy and appropriate values of two internal coordinates obtained after every iteration during the minimization of potential energy (procedure of Rasmussen and co-workers,[21] modified). As the starting points for minimization, arbitrary conformations of the "complex" CuN_2O_2 in the whole conformational space were constructed. The value of potential energy on the conformational hypersurface (i.e. on the energy diagram) was taken to be equal to the lowest energy value obtained in the given region of the conformational space. The procedure was repeated until a stable shape of energy diagrams (in the frame of different internal coordinates) was reached.

For construction of an energy diagram it was necessary to perform 200–300 minimizations, with 80 steepest descent and approximately 20 Newton-Raphson iterations; therefore some 100 energy values per point (covering an area of $12.5 \times 12.5°$) on the diagram were needed.

RESULTS AND DISCUSSION

In order to check our empirical force-field models, we had to answer four principal questions: (1) did the minima of the CuN_2O_2 system correspond to the experimentally obtained configurations (planar, tetrahedral) of copper(II) coordination, (2) did the shape of the potential energy surface show that the tetrahedral distortion was preferred to the pyramidal one (Fig. 1), (3) how well were theoretical models able to reproduce the geometry of real molecules and, finally, (4) did they give values of the diastereoselectivity effect close to the experimental results.

We checked altogether five models (Fig. 2, Tables 1 and 2). The simplest model, Model 1 (harmonic potential only for N–Cu–O bending) yielded an indefinite number of conformations with zero potential energy. All of the conformations were characterized by N–Cu–N = 0 or 180° or O–Cu–O = 0 or 180°. That means that the model permits more degrees of freedom than the real system, i.e. $V = 0$ for every configuration with all N–Cu–O angles equal to 90°.

Model 2 ("dummy atom" model) yielded four minima, all with N–Cu–O = 90°, but only one of the minima (No. 4) corresponded to the real molecular conformation, i.e. to the *trans*-configuration (N–Cu–N = O–Cu–O = 180°). Another three minima of potential energy had superposed ligand atoms.

Model 3 (distortion potential included) seems to satisfy our conditions because it yielded only the *trans*-configuration upon minimization. However, it failed to converge to the tetrahedral configuration, although it yielded tetrahedral distortion when applied to bis-(L-N,N-dimethylvalinato)copper (II).[9] In our previous paper[9] we improved Model 3 by introducing a two-well angle-bending poten-

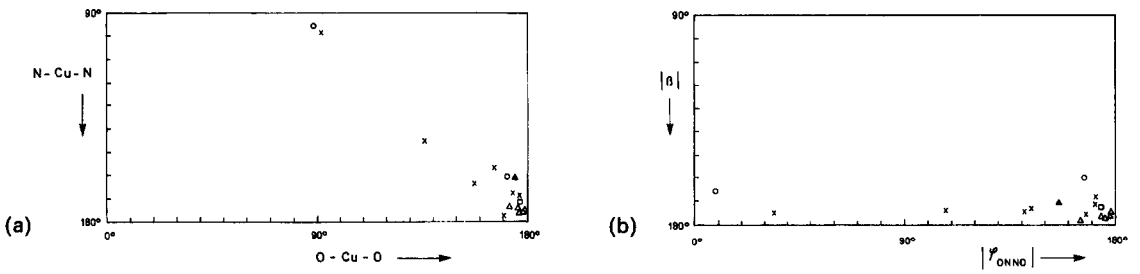

Fig. 1. The coordination polyhedra of copper(II) complexes with CuO_2N_2 chromophore: in the space of *trans* angles (a) and in the space of internal coordinates β (angle between bisectors of O–Cu–N angles in opposite chelate rings) and "torsional" angle O–N–N–O (b). Mark × denotes N-alkylsalicylaldiminates,[22] mark △ stands for tetracoordinated aminoacidates and N-alkylated aminoacidates [see Table 3; bis-(L-N,N-dimethylvalinato)copper(II)[9] is marked with ▲], and mark ⊙ for pentacoordinated bis-(L-isoleucinato)aquacopper(II)[25] and bis(N-benzylvalinato)copper(II).[15] Mark □ denotes hexacoordinated bis-(L-threoninato)copper(II) monohydrate.[26] Symmetrical distortion of coordination polyhedron (a) and very small variation of β angle comparing with O–N–N–O angle (b) show preference for tetrahedral distortion.

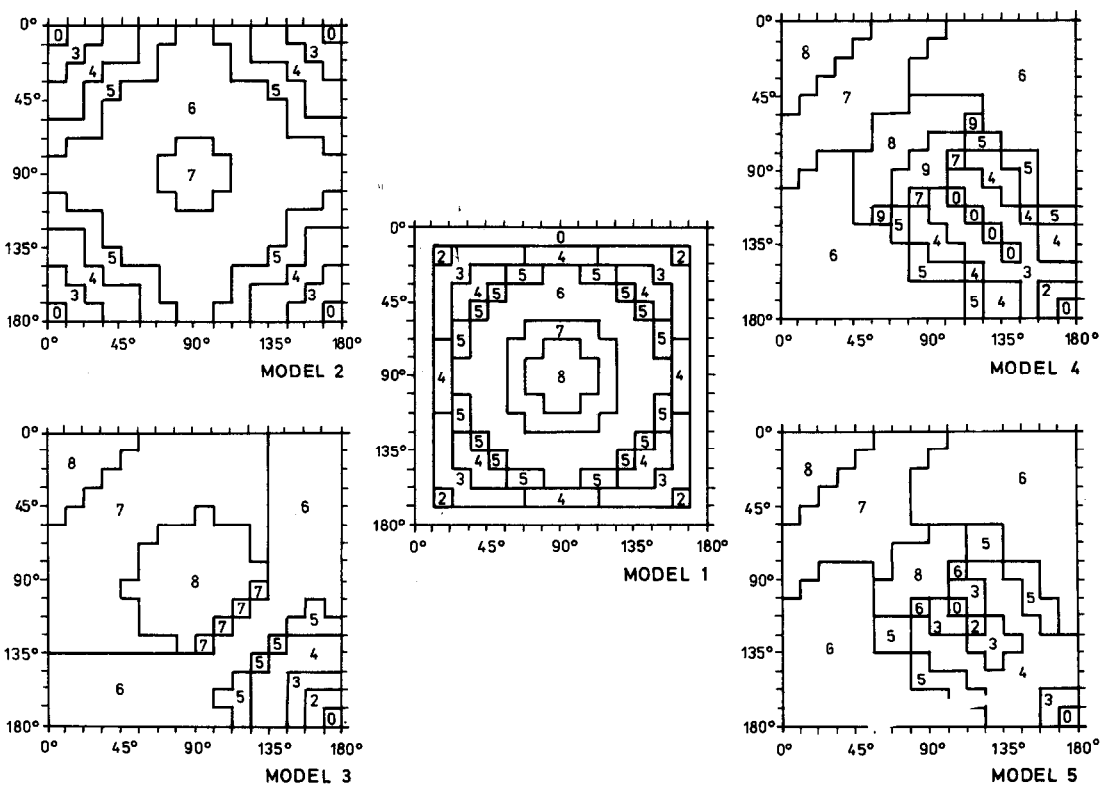

Fig. 2. The diagram of potential (conformational) energy of the *trans*-CuO_2N_2 "complex" in the frame of O–Cu–O and N–Cu–N coordinates obtained by five models for simulation of distortion of the copper coordination polyhedron (see Table 1 and Methods). Ranges of energy in appropriate regions of diagrams are denoted with numbers (values given in parentheses are expressed in kcal mol^{-1}): 0 (< 0.001), 1 (0.001–0.01), 2 (0.01–0.1), 3 (0.1–1), 4 (1–5), 5 (5–10), 6 (10–50), 7 (50–100), 8 (100–1000), 9 (> 1000).

[a] All angles are expressed in ° and $\varepsilon_{r.m.s.}$ (Δr) values in Å (only non-hydrogen atoms were taken into account).
[b] References for crystal structures are given in parentheses.

tial for N–Cu–O angles (minima at 90 and 109.47°). The improved model, Model 4 (Table 2, Fig. 2), yielded not only minima with *trans* and tetrahedral configuration, but all combinations (altogether five) of values 90 and 109.47° for N–Cu–O angles. Transition from *trans* to tetrahedral conformation was characterized with trajectory $\beta = 180°$ with a very low transition barrier.

With Model 5 we went a step further by introducing to Model 4 a two-well angle-bending potential (with minima at 109.47 and 180°) for "*trans*" (N–Cu–N and O–Cu–O) angles. The model yielded only two minima (*trans* and tetrahedral) with zero potential energy; however, "false" minima (combination of 90 and 109.47° for N–Cu–O angles) again appeared but with a higher energy (1–5 kJ mol^{-1}).

The models were further checked on crystal structures of all tetracoordinated *trans* copper(II) bisaminoacidates which showed no pronounced inter-

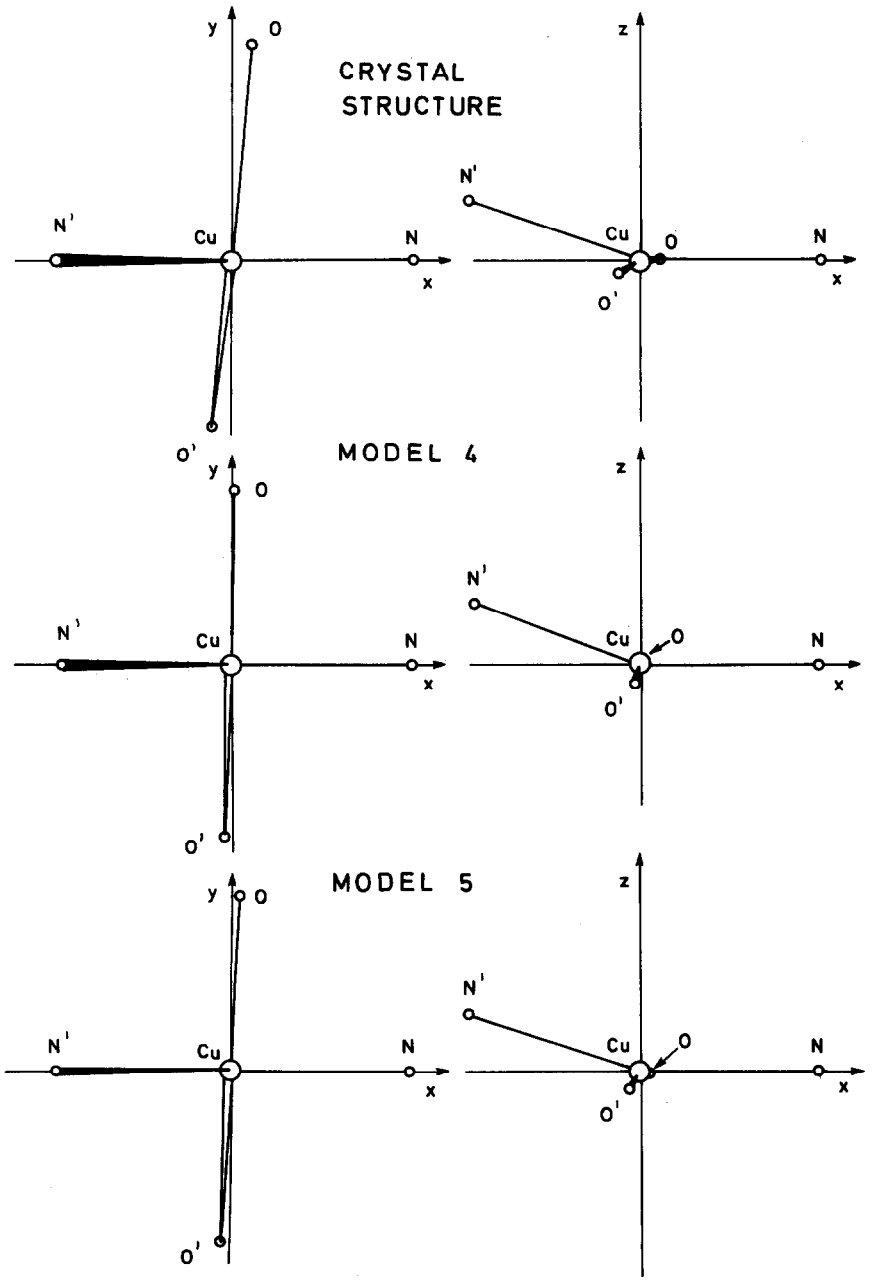

Fig. 3. Coordination polyhedra of bis-(N,N-dimethylvalinato)copper(II) as obtained experimentally[8] and using the models with a distortion coordinate potential (Model 4[9] and Model 5, this paper). Mark ′ denotes Ring 1 (see Fig. 4).

Estimated diastereoselectivity			8.53		5.42	
Experimental value[12]				2.9...4.0		

[a] All energy values are expressed in kJ mol^{-1}. Statistical weights are given in parentheses. The minima of the conformational energy are denoted as in Ref. 7. Zero points: $V = 33.957$ kJ mol^{-1}, $G = 1099.101$ kJ mol^{-1}. Diastereoselectivity was calculated from the energy of all 21 conformers; for conformers with high energy (not referred to here) energies were not computed after minimization, but approximative values for both strain and Gibbs energy were taken (approximation $E(n-m) = 1/2[E(n-n)+E(m-m)]$, where n and m were code numbers of the conformers).

molecular interactions (Table 3). The geometry of the copper(II) coordination polyhedron was best reproduced with Model 5 and worst with Model 4 for all, both planar and non-planar molecules. That also holds true for overall structure agreement expressed as r.m.s.-deviation with respect to all interatomic distances between non-hydrogen atoms. The only exception was bis-(L-N-benzylprolinato) copper(II), and to some degree bis-(L-phenylalaninato)copper(II), which showed preference (in decreasing order) for Models 5, 4 and 3. The very high $\varepsilon_{r.m.s.}(\Delta r)$ for the latter molecule is due to altered orientation of the phenyl ring in theoretical structures. Inspection of crystal structure[28] revealed that orientation of phenyl rings was determined by crystal packing, i.e. by stacking of phenyl rings.

All three models better reproduced geometry of planar than of non-planar molecules. Of all non-planar molecules the geometry of heavily distorted bis-(L-N,N-dimethylvalinato)copper(II) was most successfully reproduced (Figs 3 and 4), which was not surprising having in mind that all force fields were adjusted on that molecule. The angles determining the copper(II) coordination geometry did not fit equally well. The experimental vs theoretical values for *trans* angles (O–Cu–O and N–Cu–N) and distortion angle were highly correlated ($r > 0.8$ for non-planar molecules), less successfully correlated was the angle O′–N′–N–O ($r = 0.6$), and the worst correlation coefficients were obtained for *cis*-angles O–Cu–N ($r = 0.1$). The force fields appear to be "too stick"; they gave values for valence angles systematically closer to their equilibrium values (90 and 180°). That is possibly due to the fact that parameters determining the force fields were adjusted mostly to reproduce the *trans* angles and distortion coordinate β, which are the most critical internal coordinates for description of coordination polyhedron distortion.

The diastereoselectivity effect in copper(II)/N,N-dimethylvaline system was estimated with Model 5 (Table 4) nearly in the range of experimental error. It gave substantially better results than other models with distortion coordinate potential (Model 3 gave 7.43 and Model 4 gave 6.56 kJ mol^{-1}).[9]

In conclusion, we can state that of all the models checked, Model 5 seemed to be best because: (1) it yielded only two (planar and tetrahedral) minima with zero potential energy for "complex" CuN_2O_2, (2) it showed tetrahedral distortion to be preferred over the pyramidal one, (3) it reproduced the crystal geometry of *trans* copper(II) bis-aminoacidates with the highest accuracy and (4) it gave the best value for the diastereoselectivity effect of copper(II) N,N-dimethylvalinates of all models with distortion coordinate potential. Therefore, we recommend Model 5 for further development of force field for coordination compounds with distorted geometry.

THIOPHENE RING CYCLOPALLADATION OF N,N-DIMETHYL-2(OR 3)-THIOPHENECARBOTHIOAMIDE

HIROYUKI MIZUNO and MATSUO NONOYAMA*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya, 464 Japan

(*Received* 26 *September* 1989; *accepted* 11 *January* 1990)

Abstract—N,N-Dimethyl-2(or 3)-thiophenecarbothioamide [abbreviated as Hatt (or Hbtt)] was conveniently prepared by the reaction of the corresponding carboxaldehyde with dimethylamine hydrochloride and sulfur. The thioamides reacted with lithium tetrachloroplalladate(II) in methanol to give PdCl(att) and PdCl(btt). Their derivatives of tri-n-butylphosphine, pyridine, and pentane-2,4-dione were prepared. The new complexes were characterized spectroscopically. The palladium atom is bound to the thiophene ring 3(or 2)-carbon atom and simultaneously coordinated with the sulfur atom of the thioamide group to form a five membered palladathiaheterocycle. Geometrical isomers [*cis*(C,X) and *trans*(C,X)] were identified for $PdX(att)(PBu_3)$ (X = Cl, I; PBu_3 = tri-n-butylphosphine) and some other derivatives in $CDCl_3$ solutions.

Thiophene lies in chemical reactivity between benzene and furan.[1] The latter two substituted with an N,N-dimethylthiocarbamoyl group, that is, N,N-dimethylbenzthioamide (abbreviated as Hpht), and N,N-dimethyl-2(or 3)-furancarbothioamide [Haft (or Hbft)], are cyclopalladated with lithium tetrachloropalladate(II) in methanol to give, respectively, PdCl(pht) and PdCl(aft) [or PdCl(bft)]. The compositions are apparently similar to each other but the site of palladation is quite different: Hpht is palladated at the N-methyl substituent of the thioamide group[2] while Haft (or Hbft) at the furan ring[3] [Structures I and II (or III), respectively].

III

* Author to whom correspondence should be addressed.

These results indicate that the benzene ring is less reactive than the N-methyl group but the furan ring is more reactive than that. How the thiophene analogue reacts attracts our interest: N,N-dimethyl-2(or 3)-thiophenecarbothioamide [abbreviated as Hatt(or Hbtt)] will be cyclopalladated either at the N-methyl group or at the thiophene ring.

RESULTS AND DISCUSSION

N,N-Dimethylthiophenecarbothioamide has been prepared by thiation of the carboxamide with diphosphorus pentasulfide[4] but one pot reaction of commercially available thiophenecarbaldehyde with dimethylamine hydrochloride and sulfur affords the thioamide more conveniently.[5] The thioamide reacted easily with lithium tetrachloropalladate(II) in methanol at room temperature to give PdCl(att) or PdCl(btt) (Table 1). Their solubilities are generally poor but they are slightly soluble in dmso (dimethylsulfoxide).

The ^1H NMR spectra of dmso-d_6 solutions of PdCl(att) and PdCl(btt) (Table 2) show clearly that one of the thiophene ring protons is lost in the complexes while the N-methyl substituent of the thioamide group remains intact. In the $^{13}C\{^1H\}$ NMR spectra (Table 3) the 3-C signal of the thiophene ring of PdCl(att) and the 2-C signal of

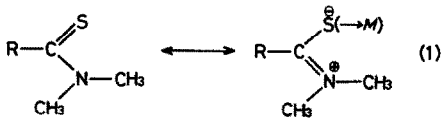
[e] ν(Pd—O).

PdCl(btt) are significantly deshielded compared with those of free Hatt and Hbtt. The deshielding is very similar to that observed for cyclopalladation of Haft and Hbft (c.f. Structures II and III).[3] The chemical shifts of 4-C and 5-C coincide for each complex.

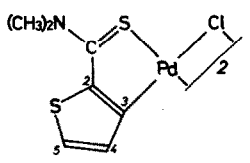
In the IR spectra (Nujol mull) of the complexes a higher frequency shift of ν(C–N) for the thioamide group is notable (Table 1). The shift is characteristic of S-coordination of the thioamide group and originates from an increase in double bond character of the C–N bond in a coordinated form (eq. 1, B).[6]



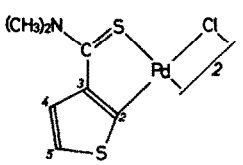
(1)

A B

The above data suggest Structures IV and V for PdCl(att) and PdCl(btt), respectively. Coordination of Cl is supported by the presence of strong ν(Pd–Cl) bands (Table 1).

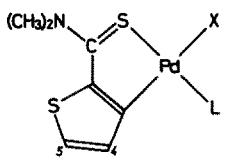


IV



V

The spectroscopic data of the pentane-2,4-dionato derivatives, Pd(att)(acac) and Pd(btt)(acac), show that the acac ligand is coordinated in a normal way, while the two halves of acac are not spectroscopically equivalent: one half is *trans* to C and the other to S donor atoms. The palladated att and btt remain in the same coordination modes as those of the parent complexes (Tables 2 and 3). Structure VI (X,L = acac) is proposed for Pd(att)(acac) and



trans(C,X)
VI

a similar one for Pd(btt)(acac). The structures, where the Pd—O bonds are arranged *trans* to the C and S atoms, are compatible with the lower frequencies of ν(Pd–O) (Table 1) than those of Pd $(acac)_2$ because the *trans* influences of the C and S atoms are superior to that of the O atoms of acac.[7]

The ^1H NMR spectrum of PdCl(att)(PBu_3), measured a few hours after dissolution in $CDCl_3$, is shown in Fig. 1. The spectrum measured immediately after dissolution gives, however, no lower field weak signals and changes into the above spectrum

[a] Only the signals due to Hatt and Hbtt are given in this Table. Figures in parentheses are coupling constants, J(H—H) and those in square brackets J(P—H) in Hz. Abbreviations: s = singlet, d = doublet, m = multiplet, and dmso-d_6 = deuterated dimethylsulfoxide.

[b] These signals are singlets unless otherwise noted.

[c] The 3-H signal is at 7.09 ppm (dd: 3.7, 1.3 Hz).

[d] The 2-H signal is at 7.35 ppm (dd: 3.1, 1.3 Hz).

[e] Obscured by the signals due to $Ptol_3$.

[f] Accompanied by a very weak signal at 14.7 ppm.

[g] Very weak signals are observed at 6.35 ppm (d: 5.1 Hz, 4-H) and 7.60 (d: 5.1, 5-H).

[h] Accompanied by a very weak signal at 4.1 ppm.

[i] Assignment is not definite.

within a few hours. This fact indicates that PdCl(att)(PBu_3) in the solid state consists only of one species which gives the major signals in the spectrum of Fig. 1 and dissolution results in an equilibrium between one major and the other minor isomers (the ratio is about 85:15). The ^1H NMR spectrum of the corresponding iodo complex PdI(att)(PBu_3) is unchangeable with time and shows that nearly equal amounts of two isomers are present in a $CDCl_3$ solution (Fig. 1). The assignment of the spectra is given in Table 2.

The $^{13}C\{^1H\}$ NMR spectrum of PdCl(att)(PBu_3) (Table 3) suggests that the minor isomer is *cis*(C,Cl), because J(P–C) for the 3-C signal is very large: PBu_3 is *trans* to the palladated 3-C atom (Structure VII, L = PBu_3). The two isomers of PdI(att)(PBu_3) are similarly assigned. The ^1H chemical shift difference (Δ) of 4-H of the *cis*(C,X) isomers between X = Cl and I is remarkable: Δ = 0.43 ppm. A similar downfield shift upon replacement of Cl with I has been reported for related cyclopalladated complexes[8] and attributed to the fact that the hydrogen in question is situated in the proximity of X. In Structure VII, proposed on the basis of the ^{13}C NMR spectra, the 4-H is also situated near to X. In contrast, in Structure VI the 4-H is far away from X and should be insensitive to X. The major isomer of PdCl(att)(PBu_3) has, therefore, a *trans*(C,Cl) arrangement (Structure VI, X = Cl, L = PBu_3). For this complex the assignment of the ^{13}C signals is certified by the ^1J(C—H) values: 167.4 Hz for 4-C

at 135.3 ppm and 185.3 Hz for 5-C at 132.3 ppm.[9]

The $^{31}P\{^1H\}$ NMR spectrum of PdCl(att)($Ptol_3$) (Table 2) shows that there are also two isomers in a $CDCl_3$ solution: one major and the other minor (less than 10%). The ^1H signals of att and $Ptol_3$ overlap in the region of aromatic proton resonances but the 4-H of the major isomer resonates separately significantly to higher field. This shielding may be attributed to the anisotropic effect of the neighbouring aromatic ring of $Ptol_3$ (Structure VI, L = $Ptol_3$). The minor isomer is not characterized so far because of its low concentration in the solution but may be a *cis*(C,Cl) isomer (Structure VII). The presence of its weak ^{31}P signal at a higher field (δ = 14.7 ppm) than that of the major isomer supports the structure by analogy with the ^{31}P NMR chemical shifts of PdCl(att)(PBu_3): the P atom *trans* to the palladated C atom resonates at a higher field than that *cis* to the C atom.

The shielding of the 4-H is similarly remarkable for Pd(att)$(py)_2(BF_4)$ (Table 2) where the 4-H is in the shielding region of py (Structure VI, X = L = py), because the py ring is sterically restricted perpendicular to the coordination plane. Contrastingly the signal of the 4-H of PdX(att)(py) is deshielded and depends strongly upon X like that of *cis*(C,X)-PdX(att)(PBu_3). Structure VII (L = py, X = Cl, I) is suggested for PdX(att)(py). The weak signal at 6.35 ppm indicates the presence of a second isomer (less than 10%) and the shielding of the 4-H signal suggests Structure VI (X = Cl, L = py) for the isomer because the 4-H is in the shielding region of py as in the case of Pd(att)$(py)_2(BF_4)$.

The isomer ratios of PdCl(att)(L) (L = py, PBu_3) in $CDCl_3$ solutions depend markedly upon L: the dominant isomer is *cis*(C,Cl) for L = py but *trans* (C,Cl) for PBu_3. The donor properties of L (py or PBu_3) may be a major influence. The ratios are also affected by X as observed for PdX(att)(PBu_3) [*trans*/*cis*(C,X) = 85/15 (X = Cl) and 45/55 (I)]. We have no certain explanation for these trends at present and more investigations will be required.

Spectroscopic information available for PdCl (btt)(PBu_3) and PdCl(btt)(py) is less revealing because the signals due to 4-H and 5-H are overlapped (Table 2). The ^{31}P NMR spectrum of PdCl(btt)(PBu_3) shows that in a $CDCl_3$ solution two isomers [one major and the other minor (less than 10%)] coexist and the chemical shifts [15.6 (strong) and 4.1 (weak) ppm] suggest that the major isomer is *trans*(C,Cl) and the minor one *cis*(C,Cl) by analogy with the isomerism of PdCl(att)(PBu_3). The *trans*(C,Cl) structure is consistent with the fact that no J(P—C) is detected for the 2-C signal of the major isomer of PdCl(btt)(PBu_3) (Table 3). The assignment of 4-C and 5-C of the major isomer is

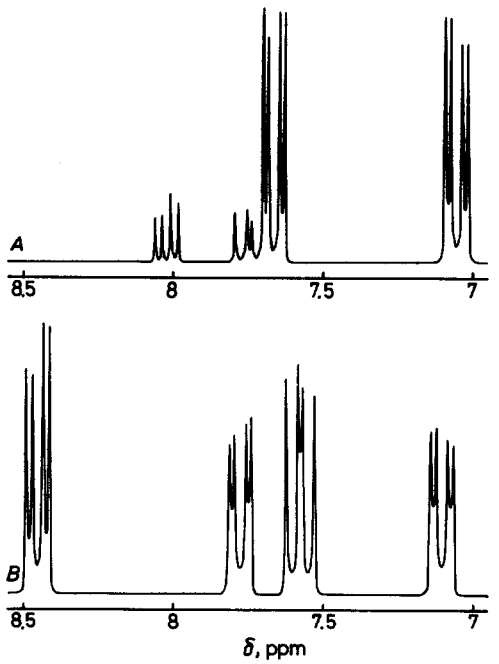

Fig. 1. ^{1}H NMR spectra (90 MHz) of A : PdCl(att)(PBu_3) and B : PdI(att)(PBu_3) measured a few hours after dissolution in $CDCl_3$ at room temperature.

confirmed by the values of ^1J(C—H) : 167.5 Hz for 4-C at 125.5 ppm and 187.7 Hz for 5-C at 124.7 ppm.[9] The structure of PdCl(btt)(py) cannot be assigned unambiguously.

In summary, under the conditions of this experiment both Hatt and Hbtt are cyclopalladated at the thiophene ring and there are no indications of cyclopalladation of the N-methyl substituent of the thioamide group. The thiophene derivatives are similar to the furan derivatives,[3] Haft and Hbft, in that the aromatic heterocycles are exclusively cyclopalladated, but quite different from the benzene derivative, Hpht, where the N-methyl substituent is cyclopalladated.[2] All these thioamides are sterically similar and the quite different reactivity should be attributed to electronic origin.[1]

EXPERIMENTAL

Measurements

IR spectra were recorded on JASCO IR-A3 and HITACHI EPI-L spectrometers. NMR spectra were recorded on HITACHI R-90H (^{1}H, 90 MHz; ^{13}C, 22.6 MHz; ^{31}P, 36.4 MHz) and JEOL PMX-60 (^{1}H, 60 MHz) spectrometers. Chemical shifts, δ ppm, were relative to internal tetramethylsilane (^{1}H, ^{13}C) and to external 85% H_3PO_4(^{31}P). Melting points were not corrected.

Synthesis of ligands, Hatt and Hbtt

Analytical results, yields, and melting points are given in Table 1 and spectroscopic data in Tables 2 and 3.

The two thioamides were prepared from appropriate aldehydes by application of the method of Amupitan.[5] Hatt was obtained as a yellow oily substance and Hbtt as yellow crystals (from dichloromethane/n-hexane).

Synthesis of complexes

PdCl(att) *and* PdCl(btt). To a solution of 1 mmol of lithium tetrachloropalladate in 30 cm^3 of methanol, prepared *in situ* from 1 mmol of palladium(II) chloride and 2 mmol of lithium chloride, was added 1 mmol or Hatt (or Hbtt) and the mixture was stirred at room temperature overnight. The yellow precipitate was washed with methanol and dried in air.

PdCl[att(*or* btt)](L) (L = PBu_3, $Ptol_3$, *and* py). To a suspension of PdCl[att(or btt)] in dichloromethane was added a stroichiometric amount of PBu_3 (or $Ptol_3$) or an excess of py and the mixture was stirred until it had become clear. The filtrate was concentrated to a small volume and addition of n-hexane precipitated the yellow product, which was washed with n-hexane and dried in air. The iodo complexes were obtained by metathesis of the chloro complexes with a fourfold excess of lithium iodide in acetone.

Pd(att)$(py)_2(BF_4)$. To a suspension of 1 mmol of PdCl(att) in a mixture of 20 cm^3 of acetone and 20 cm^3 of water was added an excess of py and the mixture was stirred until it had become clear. To the solution was added 1 mmol of silver tetrafluoroborate and the mixture was stirred for a few hours. The silver chloride precipitated was removed and the filtrate was concentrated to a small volume to give the product, which was washed with water and dried in air.

Pd(att)(acac) *and* Pd(btt)(acac). To a solution of 1 mmol of sodium pentane-2,4-dionate in a mixture of 25 cm^3 of methanol and 50 cm^3 of dichloromethane was added 1 mmol of PdCl[att(or btt)] and the mixture was stirred for 4 h. The filtered solution was evaporated to dryness and the residue was dissolved in dichloromethane. The undissolved material was removed by filtration and the filtrate was concentrated to a small volume. Upon addition of n-hexane a yellow precipitate was obtained, which was washed with n-hexane and dried in air.

The IR and NMR data due to the acac moiety are as follows: ν(C=O, C=C) at 1572 and 1516 cm^{-1}(att) and at 1567 and 1515(btt). δ(^{1}H) = 1.98,

2.09, and 5.38 ppm(att), and 1.98, 2.09, and 5.39(btt). $\delta(^{13}C\{^{1}H\}) = 27.7$, 27.8, 100.1, 186.1, and 187.5 ppm(att), and 27.4, 27.7, 100.4, 186.2, and 187.5(btt).

MIXED-LIGAND COMPLEXES OF COPPER(II) CONTAINING A MONOCONDENSED SCHIFF BASE AND AN AMINO ACID OR AMINE

W. L. KWIK* and ALICE W. N. TAY

Department of Chemistry, National University of Singapore, Lower Kent Ridge Road, Singapore 0511, Republic of Singapore

(*Received* 9 *June* 1989; *accepted* 15 *January* 1990)

Abstract—A series of mixed-ligand complexes of Cu^{II} containing a monocondensed Schiff base and an amino acid/amine have been isolated and characterised via molar conductance, magnetic susceptibility, IR and electronic spectral measurements.

As part of our continuing interest in the study of four-coordinate Schiff bases,[1,2] condensation reactions of 1,3-diacetylbenzene with phenylalanine methyl ester, tyrosine ethyl ester, histamine, histidine methyl ester and 2-(2-aminoethyl)pyridine, have now been examined. Whereas benzene 1,3-dicarbaldehyde condenses with two moles of l-histidine methyl ester or N-methylhistidine methyl ester[3] along with hydroxylation of the aromatic nucleus at position 2 producing binuclear phenoxy-bridge copper(II) complexes, 1,3-diacetylbenzene forms only monocondensed Schiff bases under similar experimental conditions. The resultant mono-Schiff base in each case readily forms mixed-ligand complexes of copper(II) with a second amino acid or amine molecule. In the following we report on the synthesis and spectral properties of several such mixed-ligand complexes of copper(II).

EXPERIMENTAL

Synthesis

Both 1,3-diacetylbenzene and 2-(2-aminoethyl) pyridine (Aldrich Chemical Co.) were used as received. Phenylalanine methyl ester hydrochloride, tyrosine ethyl ester hydrochloride, histidine methyl ester dihydrochloride and histamine dihydrochloride (Sigma Chemical Co.) were treated to remove the hydrochloride.

The syntheses of all the copper(II) and zinc(II) complexes are similar to those described previously.[1] The complexes 1–5 (Table 1) containing the mono-Schiff bases L^1–L^5 (Scheme 1) were prepared by prolonged reflux of a dry methanolic solution of 1,3-diacetylpyridine and two moles of an appropriate amino acid or amine, in the presence of a stoichiometric amount of the metal salt. The complex was recrystallised twice using 5 : 1 MeOH : isopropanol. The Cu^{II} complexes have been characterised by elemental analysis, conductance measurements in MeOH and DMSO, magnetic susceptibilities and electronic spectral determinations (Table 1).

Physical and spectral measurements

Conductivities of 10^{-3} M solutions of the complexes were measured at 30°C using a CM-115 conductivity bridge meter. Infrared spectra in the region 4000–400 cm^{-1} were recorded on a Perkin–Elmer model 1710 Fourier Transform Infrared spectrometer. Spectra extending into the Far IR region of 200 cm^{-1} were recorded on a Perkin–Elmer model 567 spectrometer calibrated with polystyrene film. CsI and KBr pellets were employed throughout. Electronic spectra were recorded on a Perkin–Elmer Lambda 9 UV–vis/near IR spectrophotometer. Magnetic susceptibilities for the complexes in the solid state were determined by the Faraday technique at 25°C on a Cahn Model RTL No. 7050 magnetic susceptibility system. Both ^1H and ^{13}C NMR spectra were recorded on a Joel 90 MHz spectrophotometer.

RESULTS AND DISCUSSION

Evidence for the presence of a monocondensed Schiff base in the coordination sphere of Cu^{II} with an amino acid or an amine taking up the remaining coordination sites, are derived from a careful analysis of the IR spectral data. Thus all the complexes are characterised by a strong absorption at 1685 cm^{-1} attributable to the $\rangle C{=}O$ stretching and at 1620/1597 cm^{-1} due to the imino $\rangle C{=}N$ stretching of the mono-Schiff base.[5,6] The $-NH_2$ vibrational modes[5,6] due to the coordinated amino acid or amine appear at 3320–3260 and 1608 (ν_{NH_2}), 1151/1058 (δ_{NH_2}) and 644 (ρ_{NH_2}) cm^{-1}. Furthermore in complexes containing the PME/TEE* moieties the absorption band at 1740 cm^{-1} characteristic of the uncoordinated carboxylate group[7] is of reduced intensity relative to that of $\nu_{C=N}$. This implies that the carboxylate ester group in the amino acid ester of complexes 1 and 2 are probably hydrolysed as has previously been observed.[1,2] The stretching of the coordinated carboxylate occurs at 1610–1590 cm^{-1} which overlaps with those of the $\rangle C{=}N$. However from the electronic spectral data as well as the known preferred coordination geometry for Cu^{II}, complexes containing PME/TEE attain at least four coordination with the carboxylate oxygen of the amino acid being one of the donor atoms (Fig. 1). Those of HME, HMN and AEP* contain at least four-coordinated $Cu^{II}N_4$ chromophore with possible interaction of the carbonyl oxygen (Fig. 2).

The expected absorptions[8] for ν_{Cu-N} and ν_{Cu-O} are found at 480, 415, 340, 318 and 280 cm^{-1}.

Isolation of the corresponding Zn^{II} complexes proves to be elusive. However the ^1H and ^{13}C NMR spectral data for the complex derived from L^2 and TYR are consistent with the formula $Zn[L^2(TYR)](ClO_4)_2$ which was first established from elemental analysis. Thus the two groups of methyl protons of the dicarbonyl became inequivalent in the complex, appearing at 2.52 and 2.65 ppm;[9,10] the change of 0.13 ppm in going from the free carbonyl to the imino group is consistent with the fact that the oxygen atom of 1,3-diacetylbenzene is replaced[2] by the less electronegative nitrogen in the Schiff base formed. The non-equivalence of the two methine

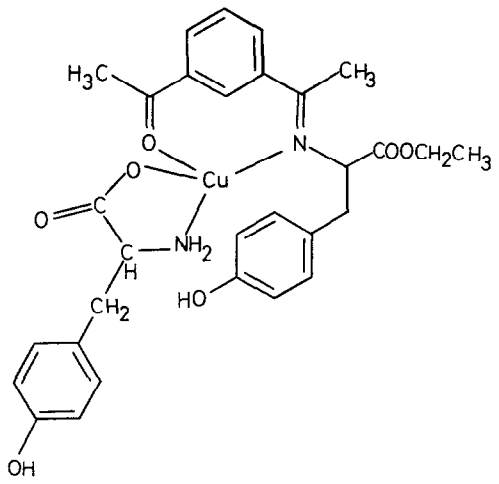

Fig. 1.

H(7) as well as the methylene H(8) protons due to the two different TYR moieties resulted in the somewhat broad absorption peaks at 4.1 and 3.0 ppm respectively, whereas in the Schiff base complexes derived from the 2,6-diacetylpyridine[1,2] one sharp absorption each was observed. The shifts of 0.5 ppm for H(7) and of 0.3 ppm for H(8) in going from the precursor to the complex are, however, comparable in these cases.[1,2]

The imino and carbonyl carbons C(5) of the monocondensed Schiff base L^2 in the Zn^{II} complex appear at 169 and 197 ppm respectively, in contrast to those of the bis-Schiff bases Zn^{II} complexes[1,2] displaying only one signal at 172 ppm. Two absorptions at 176 and 197 ppm are observed for C(13) in the mono-Schiff base and the coordinated amino acid, respectively. The relatively large shift of the latter from that of the precursor clearly demonstrates interaction of the carboxylate oxygen with the Zn^{II}.

Abstract—A study of the metallation of *meso* 10-(4′-N-pyridyl)-5,15,20-triphenylporphyrin with indium is reported. The crystal structure of the title compound has been determined by single-crystal X-ray diffraction. The complex crystallizes in the space group $P2_1/n$ with $Z = 4$ and $a = 10.146(2)$, $b = 16.096(4)$, $c = 20.861(2)$ Å, $\beta = 90.33(1)°$ and $V = 3407$ Å^3. The crystal structure was refined to a conventional $r(F) = 0.059$ for 6355 out of 8613 reflections having $\sigma(I)/I < 0.5$. The indium–chlorine distance is 2.374(2) Å, whereas the indium atom lies 0.608 and 0.7214 Å from the plane of the four porphyrin nitrogens and the 24-atom porphyrin plane, respectively. The four outer-sphere aromatic substituents exhibit some degree of distributional disorder.

The extensive electronic delocalization which occurs in the porphinato ligand leads to a substantial planarity of the macrocycle and an essentially square-planar environment for the metal ion in four-coordinated complexes. Coordination numbers greater than four occur by addition of extra ligands. As with the indium derivative, 5,10,15,20-(tetraphenylporphynato)indium(III) chloride,[1] the five-coordinate complex obtained has a square-pyramidal geometry with the single axial ligand occupying the apex. The In—N bonds are restricted by the constraints of the macrocycle ring which limits the radial expansion or contraction of the core.

In addition to this, the porphinato core has been observed to undergo substantial deformations normal to the mean plane. As it possesses some flexibility and variability in size, structural changes in the core must produce variations in the size of the central hole characterized by the average distance between the centre of the ring and nitrogen atoms.

The present analysis was undertaken to elucidate the consequences of the presence of a dissymmetry at the periphery of the porphinato core. We have chosen to study 10-(4′-N-pyridyl)-5,15,20-triphenylporphinato indium chloride ($P_3PyPInCl$).

EXPERIMENTAL

Physicochemical measurements

^{1}H NMR spectra were obtained at room temperature on a Brucker AC 200 in the Fourier transform mode using 32 K data points; chemical shifts in ppm were referenced to internal tetramethylsilane (TMS); abbreviations used were: S: singlet, D: doublet, M: multiplet. Optical spectra in the Soret and visible region were recorded on a Beckman-25 spectrophotometer using 2×10^{-4} mol dm^{-3} chloroformic solutions. The IR spectrum was obtained on a Perkin–Elmer 683 spectrometer; the sample was prepared as a 0.5% dispersion in KBr pellets. Desorption chemical ionization mass spec-

tra (DCI) were obtained on a Nermag R10-10B; samples were dissolved in methylene chloride and an aliquot was deposited on the desorption ("in beam") probe; the solvent was then evaporated; ammonia was used as the DCI reactant gas.

Synthesis of the free base P_3PyPH_2

P_3PyPH_2 was obtained from the mixed condensation of 4-pyridine carboxaldehyde (0.42 mol), benzaldehyde (0.11 mol) and pyrrole (0.4 mol) in refluxing propionic acid (1.2 dm^3). Reflux was maintained for 1 h and subsequently propionic acid was removed under reduced pressure. The solid obtained was dissolved in DMF and the resulting solution kept at 0°C overnight; porphyrinic materials precipitated. After filtration the crude mixture contained the six possible macrocycles $P_{4-x}Py_xPH_2$, $x = 0$–4, as seen by CCM on silica gel (eluent: MeOH–$CHCl_3$, 2.5%).

The separation was realized by flash chromatography on silica gel (230–400 mesh) with a gradient elution. The first fraction contained tetraphenylporphyrin (eluent: light petroleum–$CHCl_3$, 80:20). A subsequent elution with light petroleum–$CHCl_3$, 60:40, gave a violet moving band from which, on evaporation, was obtained P_3PyPH_2 as violet crystals in 3.6% yield.

Electronic absorption spectrum ($CHCl_3$): λ_{max} nm ($\varepsilon\ 10^{-3}$): 418.5 (385), 515.5 (15.9), 550 (6.3), 590 (4.9), 646 (3). IR (cm^{-1}):[2] ν(N—H) 3333, ν(aromatic CH) 3065, ν8a (phenyl and pyridyl) 1603, ν(C=C pyrrole) 1567, ν(C=N pyrrole) 1480, ν19b (pyridyl) 1410, ν(=C—N pyrrole) 1357, ν9a (phenyl) 1160, δ(NH pyrrole) 1077, δ (skeleton) 1008, ν11 (pyrrole) 972, γ(CH pyridyl) 855, δ (ring) and δ(CH pyrrole) 805, ν4 (mono substituted phenyl) 707, ν6b (pyridyl) 662. DCI MS m/z (relative intensity): 616 $(M+1)^{+\cdot}$, 100.

Metallation of P_3PyPH_2 *with indium*

The free base (1.22×10^{-3} M) was dissolved in acetic acid; three equivalents of indium trichloride were added and the solution was maintained under stirring and heated at 140°C for 2 h. The cooled reaction mixture was then poured into water and extracted with chloroform to eliminate unreacted indium salts. After neutralization with a saturated solution of sodium hydrogenosulphate, the organic phase was dried ($MgSO_4$), filtered and evaporated to dryness. The crude product was chromatographed on a silica gel column prepared in chloroform. A first elution with chloroform removed the free base; a subsequent elution with MeOH 5% in chloroform gave pure $P_3PyPInCl$. After evaporation of the solvent, the violet crystals of the indium derivative were dried at 180°C, *in vacuo* (0.05 mmHg) for 8 h (yield: 87%).

Electronic absorption spectrum ($CHCl_3$): λ_{max} nm: 423 (Soret), 518.5, 557, 596. DCI MS m/z (relative intensity): 764 $(M+1)^{+\cdot}$, 91.9, 728 $(M-35)^+$, 100.

Crystal structure determination

A suitable crystal of $P_3PyPInCl$ was obtained from very slow evaporation of a methylene chloride solution of the complex, at room temperature (several weeks). The crystallographic data and the experimental conditions are given in Table 1. Reference reflections showed a loss of intensity at about 7%; for which a correction was applied.

The structure was solved by direct methods (SHELX-86).[3] Indium scattering factors were taken from ref. 5. Indium, chlorine and N(1)—C(20) were refined with anisotropic temperature factors and isotropic ones for the remaining carbon and nitrogen atoms of the phenyl and pyridyl substitutents. Positions of hydrogens were calculated geometrically and considered with one isotropic temperature factor for all porphinato hydrogens, and one for all phenyl/pyridyl hydrogens.

Tables of final coordinates and thermal parameters and a list of observed and calculated structure factor amplitudes have been deposited as supplementary data with the Editor, from whom copies are available.

RESULTS AND DISCUSSION

Synthesis of $P_3PyPInCl$ (*Fig.* 1)

The starting free base was synthesized by a modification of the method reported by Hambright and co-workers[6] based on the porphyrin condensation procedure of Loach and co-workers.[7]

For metallation with indium, we applied the method we have already used for substituted phenylporphyrins by refluxing an excess of the metal salt

with the porphyrin base in glacial acetic acid.[8] This reaction was conducted with indium trichloride:

$$P_3PyPH_2 + InCl_3 \xrightarrow{CH_3COOH} P_3PyPInCl.$$

Progress of the metallation was monitored by visible spectrometry following the disappearance of the 418.5 and 515.5 nm bands in the free base and the concomitant increased bands of the indium derivative, e.g. α- and β-bands between 500 and 600 nm. Metallation reaction times were optimized as a function of free base concentration and temperature. Results are summarized in Tables 2 and 3, respectively.

Metallation is fastest when a concentration of 1.22×10^{-3} M and a temperature of 140°C are used. Using these experimental conditions and after purification, $P_3PyPInCl$ was synthesized in 87% yield.

Spectral measurements

The desorption chemical ionization mass spectrometry (DCI MS) with ammonia as the reagent gas confirmed the formation of the indium derivative. Initial attack by the reactant gas results in the formation of the protonated metalloporphyrin molecular ion $(M+1)^{+\cdot}$, m/z 764, while the base

peak (*m/z* 728) corresponds to the loss of the axial chloride ligand.

^{1}H NMR characteristics of P_3PyPInCl at ambient temperature are listed in Table 4 with those of its corresponding free base.

As in other dissymmetrically substituted macrocycles,[8] a splitting pattern for the pyrrolic protons is observed in the free base. H(7) and H(8) are, respectively, pairwise equivalent to H(12) and H(13) and lead to two asymmetrical doublets, each corresponding to two protons. The equivalent H(2), H(3), H(17), H(18) lead to a singlet. Chemical shifts of these protons in the free base are in disagreement with the values observed in literature[6] which are roughly 0.4 ppm smaller. However, our values fit much better with what is expected for pyrrolic protons (around 9 ppm).

The pyridyl protons give two doublets corresponding to H(3′), H(5′) and H(2′), H(6′), respectively; the more deshielded doublet, centred at 9.02 ppm, corresponds to protons 3′ and 5′ in α-position from nitrogen. The doublet at higher field [8.16 ppm, H(2′), H(6′)] in superposed to the resonance peak of *ortho* phenyl protons (8.2 ppm). *Meta* and *para* phenyl protons resonate at 7.76 ppm. To higher field than TMS, is the signal of pyrrolic N—H protons.

Upon formation of the chloro indium porphyrin complex, the ^{1}H NMR spectrum of pyrrolic protons retains the same multiplicity of signals with a downfield chemical shift of *ca* 0.22 ppm.

At room temperature, the resonance of the *ortho* aryl protons is theoretically split into two signals, this inequivalence being due to the restricted rotation of the aryl groups;[9] in our case, the resonance of these protons is broad, this broadening being enhanced by the superposition of phenyl and pyridyl proton signals at 8.36 and 8.08 ppm. The splitting difference between the resonance frequencies of the non-equivalent *ortho* protons (0.24 ppm) agrees with those observed in the literature (0.25 ppm).[10]

Molecular structure description

Figures 2 and 3 show the structure of P_3PyPInCl in directions perpendicular and parallel to the porphyrin plane. Table 5 gives the bond lengths and angles within the coordination polyhedron. Those for the porphyrinic system are all within three ESDs the same as in TPPInCl.[1]

Indium is five-coordinated in a square pyramid by the porphinato ligand and chlorine. The essentially equivalent In—N distances of 2.154 Å are

Table 5. Selected interatomic distances (Å) and angles (°) around In(1) with ESDs in parentheses

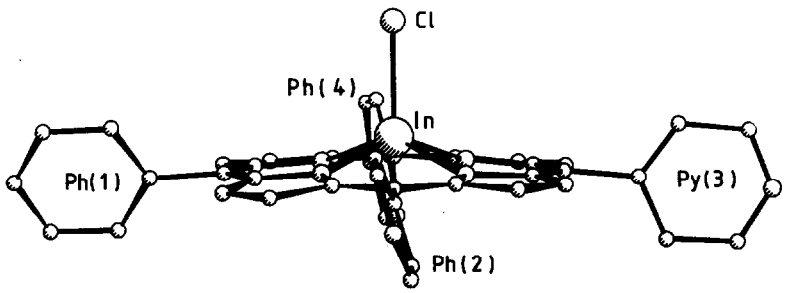

Fig. 3. View of $P_3PyPInCl$, parallel to the porphyrin plane, showing the "doming" of the molecule.

comparable to those in TPPInCl;[1] the average N—In—N bond angles are 85 and 147°. The four pyrrole nitrogens are approximately coplanar, the indium atom is displaced out of this Δ(4N) mean plane by 0.608(1) Å toward the chlorine ligand and lies 0.721(1) Å above Δ (porphyrin). Thus, the porphinato core displays a net doming of 0.11 Å away from the indium atom as illustrated in Fig. 3. The chlorine atom occupies the apical position of the square pyramid with In—Cl = 2.374(2) Å. This bond is considerably shorter than in the five-coordinate anionic chloro complex $InCl_5^{2-}$ (square-pyramidal arrangement with apical In—Cl = 2.415 Å[11]).

Structural changes in the porphinato core do not produce variation in the size of the central hole. The main distance between Ct, the centre of the nitrogens, and N is 2.07 Å, which is in the normal range of values for Ct—N suggested by Collins and Hoard.[12]

The distribution of the four outer-sphere aromatic substituents at carbons (5), (10), (15) and (20) demands some special comment. Table 6 lists their geometrical data. The aromatic group in the four-position is definitely phenyl. The group in the three-position exhibits the normal geometry of *p*-pyridyl.[12,13] The rings in the two- and one-positions are both somewhat distorted from regular

[a] Some adding of pyridyl: distributional disorder.

phenyl geometry. A low degree of disorder must be assumed for the distribution of the four substituents.

As normal for a metallotetraarylporphyrin[14] the aryl rings are rotated considerably out of plane of the macrocycle (local torsion angles 63–104°).

Crystal structure description

The crystal structure of $P_3PyPInCl$ contains discrete molecules with no short In... Cl interactions. The intermolecular distribution of the pyridyl substituents is noticeable.

In Fig. 4, the $P_3PyPInCl$ molecule is divided into shells for the indium, chlorine, nitrogen and carbon atoms of the porphyrinic system and the *ortho*, *meta* and *para* atoms of the aromatic *meso* substituents. The shortest intermolecular distances are given from each of these shells to the *para* positions of the four different aromatic substituents in the surrounding $P_3PyPInCl$ molecules. All of these distances are longer than van der Waals' distances.

Regardless of this reservation, the position of the pyridyl(3) group is a special one: the N... In distance of 4.58 Å is the shortest, the N... Cl distance of 5.58 Å is the longest of these distances. Further, some of the intermolecular contacts between atoms of the porphyrinic system and the pyridyl nitrogen are shorter than 4 Å, all related distances to the phenyl groups are longer than 4 Å.

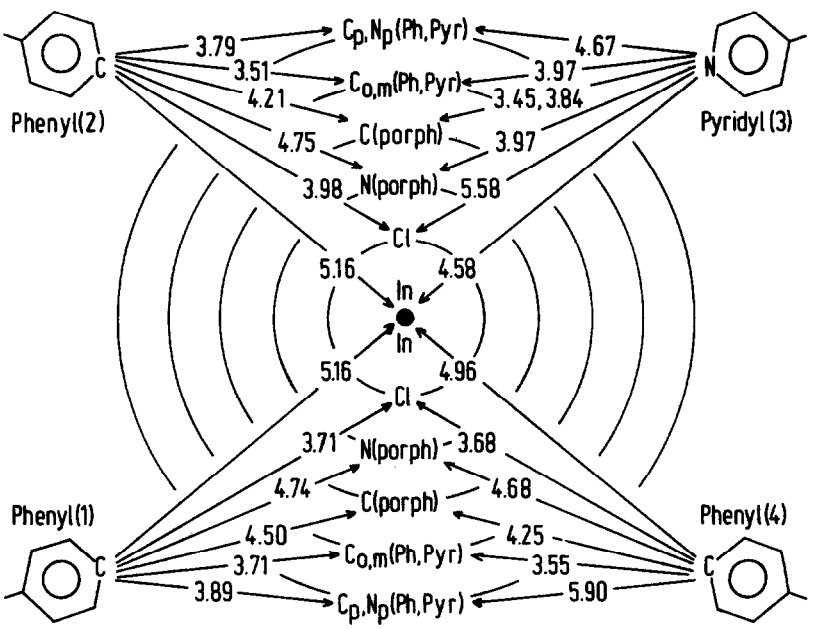

Fig. 4. Shortest intermolecular distances (Å) from the *para* positions of the four aromatic substituents to different regions of the neighbouring $P_3PyPInCl$ molecule.

CONCLUSION

$P_3PyPInCl$ crystallizes in the monoclinic crystal system; it is isomorphic to a series of tetraphenylporphyrin derivatives of the $P2_1/n$ series very recently presented by Scheidt and Lee.[15] No strong degree of overall distortion of the macrocyclic ligand is induced by introduction of a pyridyl group at C(10). Nevertheless, this pyridyl group is in a very special site seen from an intermolecular point of view. We can suppose a complete change of the crystal structure on going to the *cis* and *trans* dipyridyl derivatives; their crystal structures are under investigation.

(*Received* 10 *November* 1989; *accepted* 17 *January* 1990)

Abstract—Reaction between $Y_5O(O^iPr)_{13}$ and acetylacetone at room temperature under anhydrous conditions, produced in high, reproducible yield a compound characterized—by ^1H and ^{13}C NMR, as well as X-ray diffraction—as $Y_2(\mu_2\text{-}OAc)_2(acac)_4(H_2O)_2$. It crystallizes in the orthorhombic *Pcnb* system, with unit cell dimensions $a = 13.385(3)$, $b = 15.107(4)$, $c = 16.100(4)$ Å and $Z = 4$. Least-squares refinement converged to a final $R = 0.0356$. The molecule is a centrosymmetric dimer with chelating tridentate acetato groups in the bridging positions. The yttrium atoms are eight-coordinated, with a distorted square antiprism geometry. Intra- as well as intermolecular hydrogen bonding between the water molecules and the β-diketonato ligands is observed. The formation of this acetatoacetylacetonate derivative as well as its behaviour in solution are discussed.

Yttrium and lanthanide oxides are of great interest for a variety of high technology materials such as superconductors, yttrium iron garnets (YIG), etc.[1] Chemical routes to such materials using well-defined molecular precursors should allow better control of their properties and larger flexibility of the products (ceramics, coatings, etc.) in comparison with the solid-state synthesis.[2] The structural characterization of a pentanuclear oxoisopropoxide, $Y_5O(O^iPr)_{13}$,[3] prompted us to investigate its reactivity, especially towards ligands such as β-diketones, which can offer volatile precursors of oxides for use in MOCVD techniques,[4] or which may act as additives in order to control the sol–gel process.[5]

Reaction between $Y_5O(O^iPr)_{13}$ and acetylacetone at room temperature under anhydrous conditions, produced in high, reproducible yield a compound characterized by X-ray diffraction as $Y_2(\mu_2\text{-}OAc)_2(acac)_4(H_2O)_2$ (acacH = $C_5H_8O_2$, acetylacetone).

EXPERIMENTAL

All operations were carried out under an argon atmosphere using standard Schlenk techniques. All solvents were dried, degassed and distilled prior to use. Acetylacetone was purified as reported in the literature in order to remove trace amounts of acetic acid as well as water.[6] IR spectra were recorded on a Bruker IR S45 spectrometer. The ^1H and ^{13}C NMR spectra were measured on a Bruker AC-200E spectrometer. Elemental analyses were performed by the Centre de Microanalyse du CNRS.

Synthesis of $Y_2(OAc)_2(acac)_4(H_2O)_2$

Excess acetylacetone (4.5 cm^3, 43.3 mmol) in 10 cm^3 toluene was added slowly to a solution of $Y_5O(O^iPr)_{13}$ (1.6 g, 1.30 mmol) in 30 cm^3 of toluene.

* Author to whom correspondence should be addressed.

Stirring at room temperature was maintained for 24 h, and the reaction medium evaporated to dryness. Recrystallization in acetone led to 1.12 g (87%) of white, air-sensitive crystals of $Y_2(OAc)_2(acac)_4(H_2O)_2$, slightly soluble in hexane or toluene, more soluble in alcohol, acetone, CH_2Cl_2 and $CHCl_3$. Found: C, 40.7; H, 5.7. Calc. for $C_{24}H_{38}O_{14}Y_2$: C, 39.6; H, 5.5%. IR (Nujol, cm^{-1}): 3438 $\nu(H_2O)$, 1607, 1590 sh $\nu_s(C{=}O)$, 1522 $\nu_s(C{-}C)$; 1460, 1263 $\nu_{as}(C{-}O)$; 1168, 1099, 1016, 922, 760, 727, 656 $\delta(CO_2)$, 535 $\nu(M{-}O)$. ^1H NMR ($CDCl_3$, ppm): 5.55 (CH, 4H), 4.40 (H_2O, 4H), 2.28 (OAc, 6H), 2.08 (CH_3(acac), 24H). $^{13}C\{NMR\}$ ($CDCl_3$, ppm): 205 (CO_2), 192 (CO); 100 (CH); 27.5 [$CH_3(CO_2)$]; 25 [$CH_3(CO)$].

Crystallography of $Y_2(OAc)_2(acac)_4(H_2O)_2$

Crystals suitable for X-ray were obtained from recrystallization in acetone at room temperature. A transparent crystal was mounted on a Nonius CAD-4 diffractometer and cooled at −105°C for characterization and data collection. Accurate unit cell dimensions and crystal orientation matrix were obtained from least-squares refinements of the setting angles of 25 reflections. Three standard reflections were monitored periodically; they showed no change during data collection. Crystallographic data and other pertinent information are summarized in Table 1. Corrections were made for Lorentz, polarization and absorption[7] effects.

Computations were performed using CRYSTALS' adapted on a MICROVAX II.[8] Atomic-form factors for neutral Y, O, C and H atoms were taken from *International Tables for X-ray Crystallography*.[9] The structure was solved using SHELXS.[10] Hydrogen atoms were located on difference electron density maps. Their coordinates were refined with an overall isotropic thermal parameter. Anisotropic temperature factors were introduced for all non-hydrogen atoms. Least-squares refinements were carried out by minimizing the function $\Sigma w([F_o]-[F_c])^2$. Heavy atoms (Y, O and C) and H atoms were refined alternately. The criteria for a satisfactory complete analysis were the ratio of the rms shift to standard deviation being less than 0.1 and no significant features in the final

RESULTS AND DISCUSSION

Although reactions between alkoxides and β-diketones often lead to partial substitution with formation of mixed alkoxo β-diketonate derivatives as a result of steric hindrance,[11] the reaction between $Y_5O(O^iPr)_{13}$ and excess acetylacetone in toluene, proceeds to complete substitution of the isopropoxo groups even at room temperature. The reaction, achieved in anhydrous conditions, offered in high, reproducible yield (≃ 85%), an acetylacetonate derivative whose IR spectra appeared to be different from that reported for $Y(acac)_3$ or $Y(acac)_3,3H_2O$.[12] The main modification is the presence of additional absorption around 660 cm^{-1}. ^1H NMR spectra are also puzzling, especially regarding the integration between methyl and methine groups and the presence of an additional peak at 4.40 ppm.

The structure of the compound was established by X-ray diffraction, which showed it to be an acetatoacetylacetonate compound of formula $Y_2(\mu_2\text{-}OAc)_2(acac)_4(H_2O)_2$. It is, to our knowledge, the first example of a lanthanide carboxylatodiketonate reported.

Molecular structure of $Y_2(OAc)_2(acac)_4(H_2O)_2$

The molecule is a centrosymmetric dimer, the most salient feature being the presence of acetate ligands, which bridge the yttrium atoms in a bridging tridentate mode; this coordination mode has previously been observed for lanthanide derivatives.[13] Table 2 lists selected bond lengths and angles, while Fig. 1 shows an ORTEP diagram. The yttrium atoms are octacoordinated and separated by 4.054(1) Å. The metal atoms have a distorted square antiprism geometry and bear two chelating acetylacetone ligands and a water molecule. The Y—O bond lengths range from 2.271(5) to 2.505(5) Å, the longest one corresponding to the bridging, chelating acetato ligand. The Y—O distances involving the acetate ligand are significantly different (2.412(5) and 2.505(5) Å), and longer than those observed for simply bridging acetate groups, as in $\{[HB(pz)_3]Y(\mu\text{-}O_2CCH_3)_2\}_2$ (2.279(6) Å).[14] The Y—O(acac) values are close to those observed for $Y(acac)_3,3H_2O$.[15] Intra- as well as intermolecular hydrogen bonding is observed between water and the oxygen atoms of the β-diketonato ligands. The intermolecular interactions (H(11)···O(11):

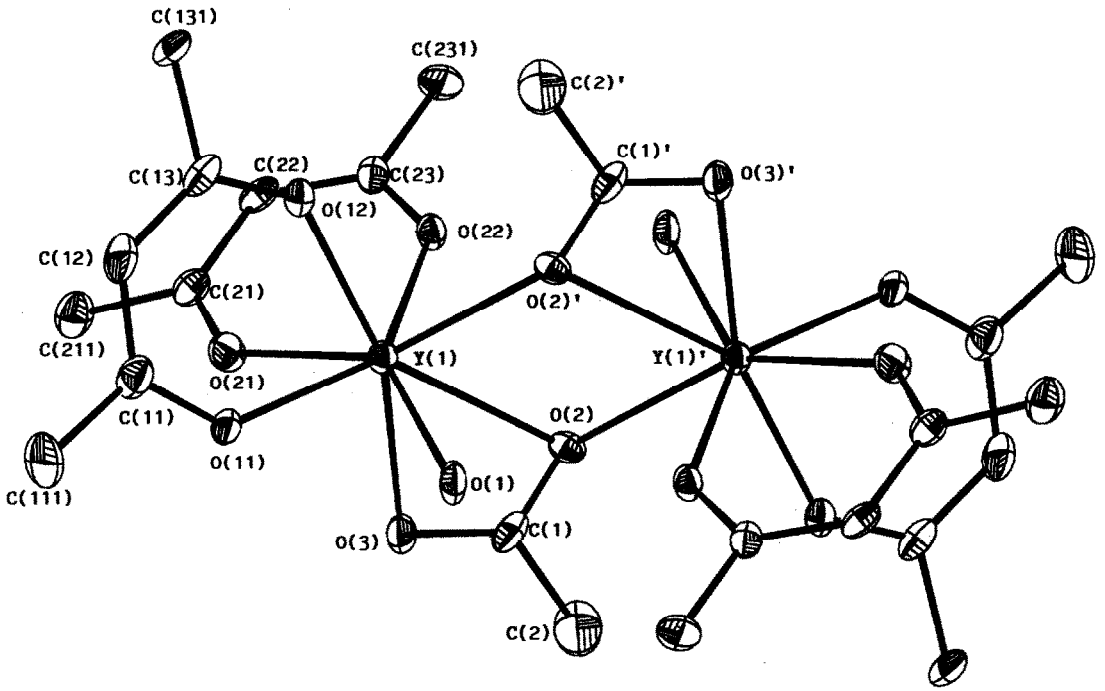

Fig. 1. ORTEP view of $Y_2(\mu\text{-OAc})_2(acac)_4(H_2O)_2$, showing the numbering of atoms other than C and H. The hydrogens of the water molecule [O(1)] interact with O(22) and O(11) via intra- and intermolecular hydrogen-bonding, respectively.

2.015(4) Å) appear weaker than the intramolecular one (H(12)···O(22): 1.866(4) Å), but give rise to extended chains along the *b* axis (Fig. 2).

The rest of the bonding of the β-diketone ligand appears normal, with C—O and C—C bond lengths ranging from 1.257(8) to 1.273(8) and from 1.38(1) to 1.53(1) Å, respectively. Close intermolecular contacts are noted between most oxygen atoms, as often observed for β-diketonate derivatives.

The question which arises concerns the origin of the acetato and water ligands. Although other hypotheses might be considered, acetylacetone is most probably the source of the acetato ligand. Comparison of the spectroscopic data (IR, ^1H NMR) of the crude and recrystallized product established that the transformation of the β-diketone had already occurred in the crude product. ^1H NMR monitoring experiments have shown that an excess of β-diketone is not required for the formation of $Y_2(\mu\text{-OAc})_2(acac)_4(H_2O)_2$ from $Y_5O(O^iPr)_{13}$, since this compound is already formed in a large amount for a molar ratio such as acacH/Y = 10, and its formation is probably favoured by its poor solubility in toluene. Generation of the acetato moieties is probably due to retro-Claisen type reactions,[16] induced either by trace amounts of alkoxo or hydroxo anions (water may result from the reaction of the oxo ligand) stabilized by a highly basic medium. Further esterification can then provide additional water molecules. Formation of carboxylatodiketonato derivatives from a yttrium oxoalkoxide seems relatively specific to acetylacetonates: the reaction between $Y_5O(O^iPr)_{13}$ and dipivaloylmethane (dpmH) yielded only $Y(dpm)_3$. However, reaction between an oxo neodymium isopropoxide and excess of acetylacetone also offered an unexpected derivative, a hydroxoacetylacetonate $Nd(\mu_3\text{-OH})_2(acac)_{10}$, as established by X-ray structure determination.[17] The remarkable behaviour of the lanthanide acetylacetonates, as compared with their more crowded counterparts, may thus be related to a higher susceptibility to the water molecules generated during their synthesis from oxoalkoxides. These observations are also in agreement with their behaviour when used as MOCVD precursors.

The $Y_2(\mu_2\text{-OAc})_2(acac)_4(H_2O)_2$ hydrate is stable in the solid state at room temperature and under an inert atmosphere for periods of up to one year. However, its stability in solution and in the absence of additional acetylacetone is more limited. Rapid evolution of the NMR spectra requires characterization in fresh as well as concentrated solutions. Indeed, the presence of water molecules in the coordination sphere induces spontaneous hydrolysis—and probably also condensation—reactions upon dissolution, thus giving several molecular species in rapid equilibrium on the NMR

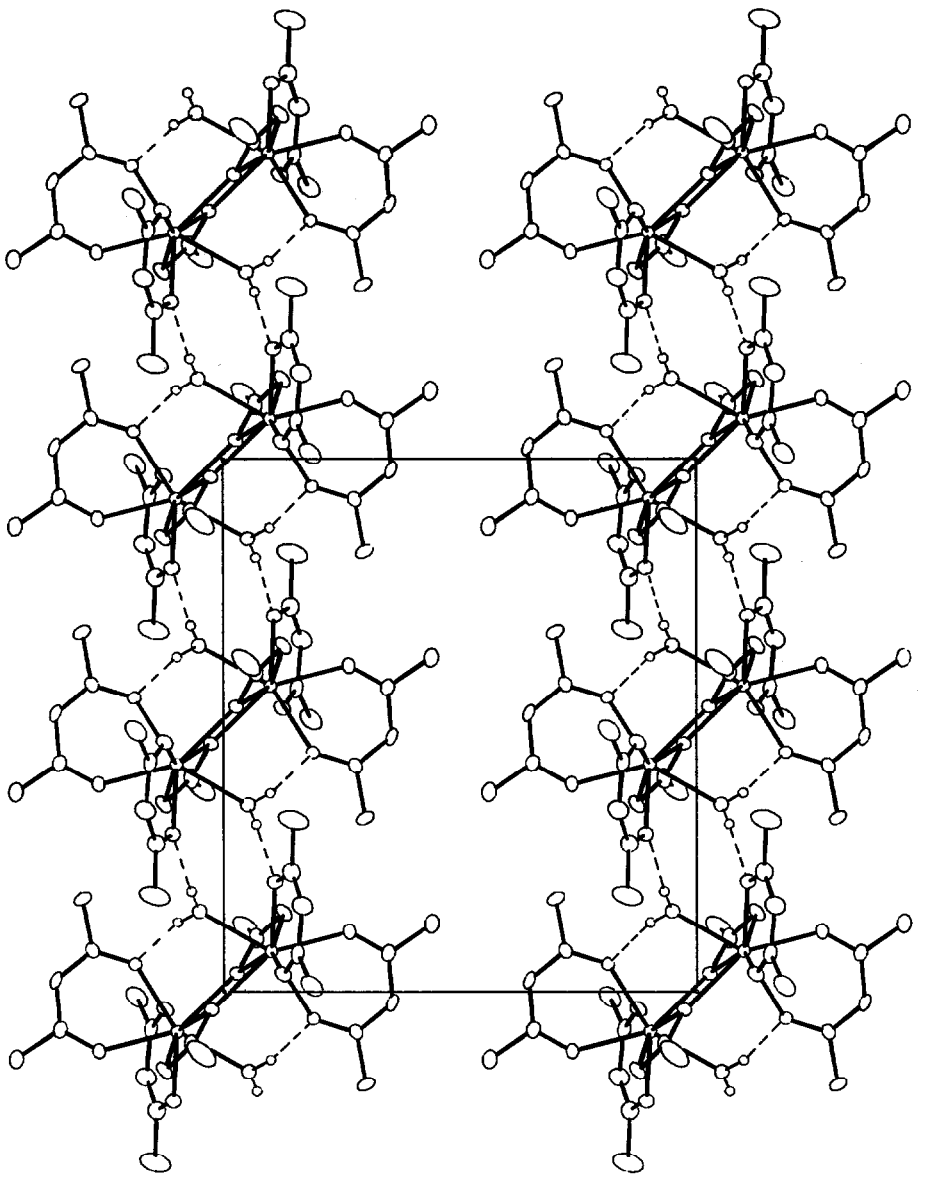

Fig. 2. Packing of $Y_2(\mu_2\text{-}OAc)_2(acac)_4(H_2O)_2$ showing the intra- and intermolecular hydrogen-bonding (dotted lines).

time scale and a complex behaviour. Formation of $Y_2(\mu_2\text{-}OAc)_2(acac)_4(H_2O)_2$ is evidenced in the ^1H NMR by the appearance of free acetylacetonate and its enol (OH = 15.6, CH_2 = 3.6, CH_3 = 2.02 ppm), as well as by the progressive disappearance of the peak of the water molecules at 4.4 ppm. A very broad resonance, located between 6.8 and 2.7 ppm, has been tentatively attributed to the hydrogen of the metal hydroxo bond. Thus although β-diketones are generally considered as poorly hydrolysable ligands,[18] they appear more susceptible to hydrolytic attack than acetato ligands in $Y_2(\mu_2\text{-}OAc)_2(acac)_4(H_2O)_2$. Its thermal decomposition gives $[Y(acac)_3]_m$ as volatile, metallic derivatives, as shown by mass spectrometry.

The facile, total substitution, at room temperature, of the alkoxo groups of rare earth oxoalkoxides, even with a polynuclear *closo*-framework, by β-diketones might be attributed to the propensity of these metals to achieve octacoordination. The results, obtained on yttrium and neodymium derivatives, also suggest further investigation on acetylacetonate derivatives obtained by using oxo compounds as starting material and might bring some insight into the degradation of acetylacetonates during catalysis experiments. In addition, acetylacetonate is often used in the sol–gel process as a "modifier";[19] more careful investigation of the metallic species formed in the presence of this ligand and water seems warranted.

SYNTHESIS AND X-RAY STRUCTURE OF MONOMERIC ARYLOXIDE COMPLEXES OF MANGANESE(II) AND CHROMIUM(II)

D. MEYER, J. A. OSBORN* and M. WESOLEK

Institut Le Bel, Université Louis Pasteur, 4, rue Blaise Pascal, 67070 Strasbourg, France

(*Received* 20 *November* 1989; *accepted* 17 *January* 1990)

Abstract—Two monomeric alkoxide complexes of manganese(II) and chromium(II) have been synthesized and their structure determined by X-ray methods. In both cases, the bond distances and, in particular, the large M—O—C angles are most consistent with a dominant role of steric effects.

In recent years alkoxo- and aryloxo-ligands have been used in the stabilization of high oxidation state organometallic complexes.[1] The origin of the stabilizing effect, which is accompanied by shortening of the metal–oxygen bond lengths and opening of the bond angle at oxygen, is attributed to the existence of a π-donor interaction from the non-bonding oxygen electrons to an empty *d* orbital of the metal. For intermediate oxidation states where the *d* orbitals are partially occupied, the effects of such a π-interaction on the structure and on the stabilization (or destabilization) of the molecule is less evident.[1a]

We report here the synthesis and structure of two monomeric alkoxide compounds of manganese(II) (d^5) and chromium(II) (d^4). Few simple monomeric alkoxide complexes of these metals in their divalent state have, until recently, been reported, since, for the most part, oligomers or polymers are formed. The use of sterically bulky aryloxide ligands originally developed by Horvath[2] appears to impede polymer formation, although full characterization of these apparently monomeric complexes by X-ray diffraction methods had not been carried out.

We have isolated two such derivatives, $Mn(OR)_2(CH_3CN)_2$ (**1**) and $Cr(OR)_2(Py)_2$ (**2**) (where R = 2,4,6-tri-t-butylphenoxide) and characterized them using X-ray analysis. Very recently, the structure of a closely analogous complex of chromium(II) has been described.[3]

* Author to whom correspondence should be addressed.

RESULTS AND DISCUSSION

The complexes are simply prepared by treating $MnCl_2(CH_3CN)_2$ or $CrCl_3(THF)_3$ with, respectively, two or three equivalents of the phenolate as the sodium salt in an ether solvent. The manganese acetonitrile derivate gave colourless crystals of **1** suitable for a structural determination, whereas for chromium(II), addition of pyridine yielded the light blue–green crystalline adduct, **2**. Both complexes are extremely sensitive to oxygen and manipulations were carried out under nitrogen in a glovebox.

The ORTEP diagram of **1** is shown in Fig. 1 and selected bond distances and angles are given in Table 1. The complex crystallizes as a discrete monomer unit, along a two-fold axis, with a distorted tetrahedral arrangement about manganese. Although the organometallic chemistry of manganese(II) with alkoxo- and aryloxo-ligands has been widely developed during the last few years,[4] only recently have monomeric[5] alkoxo-complexes of manganese(II), $[Li_2(THF)_2MnBr_2(OC^tBu_3)_2]$ and $[LiMn(OC^tBu_3)_2(N(SiMe_3)_2)]$ been reported. The first of these complexes shows the expected quasi-tetrahedral arrangement about manganese, but the angles subtended at manganese show clear differences with those in **1**. Whereas the $\angle$ O—Mn—O in **1** is 121.2(3)°, the corresponding angle in $[Li_2(THF)_2MnBr_2(OC^tBu_3)_2]$ is 87.9(3)°, chelation of the lithium cation by the alkoxy ligands causing the severe reduction of this angle in the complex. The smallest subtended angle about

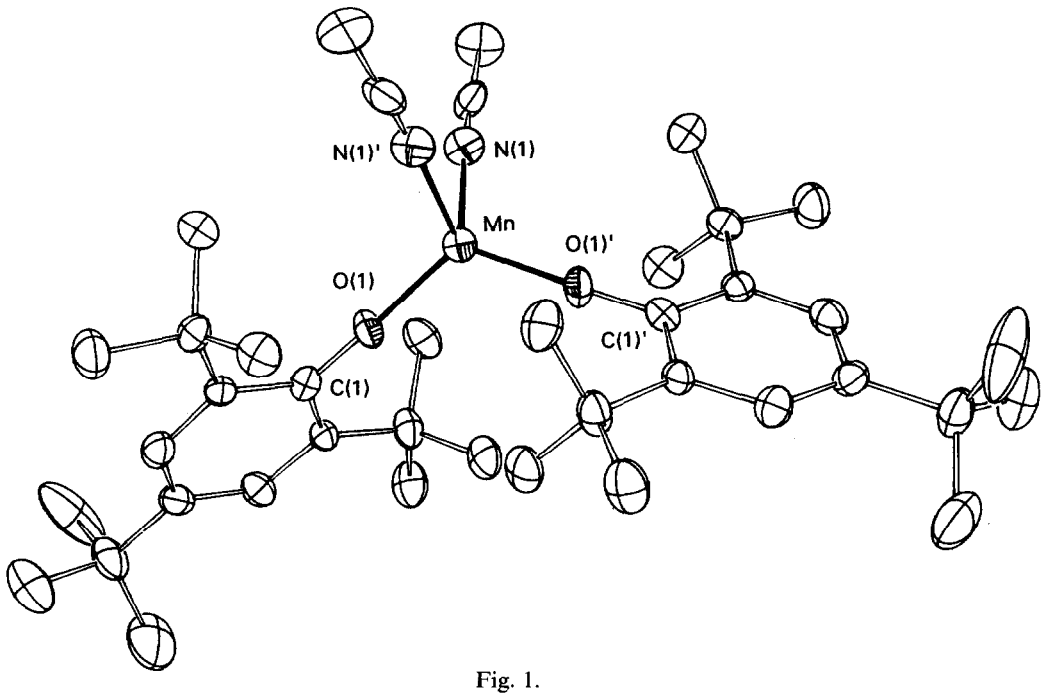

Fig. 1.

manganese in **1** is that between the two CH_3CN ligands (93.8(4)°).

However, the most interesting aspect of **1** is the almost linear Mn—O—C entity (179.1(5)°), the largest yet reported, although in $Cr_2(OCH(^tBu)_2)_4$,[4e] angles of 171.0(3) and 174.9(3)° were found. The Mn—O bond distances for **1**, however, show no real shortening (1.910(6) Å), being effectively longer than the terminal alkoxy–manganese(II) bonds in $Mn_3(OCH(^tBu)_2)_6$ (1.856(4) and 1.852(4) Å), although it could be argued,[6] that these complexes show values that are a little lower than expected for manganese(II) complexes. However, the terminal Mn—O—C bond angles in $Mn_3(OCH(^tBu)_2)_6$ are much smaller (151.2(5) and 148.2(4)°) than in **1** despite the presemnce of shorter Mn—O bond lengths. Clearly it is difficult to make comparisons between complexes of different structures, but it would seem that the bond length/bond angle variations are not consistent with the existence of a classical π-donor interaction, and probably result from steric effects. Finally, the magnetic susceptibility using Evans' method in C_6D_6 ($\mu_{eff} = 5.8\mu_B$) is in agreement with a normal high-spin manganese(II) in a tetrahedral environment.

The X-ray structure of the chromium compound $Cr(OR)_2(Py)_2$ (**2**) is shown in Fig. 2, with selected bond distances and angles presented in Table 2. These compounds were originally synthesized and proposed to be monomeric by Horvath,[2b] and this was recently confirmed by an X-ray diffraction analysis of an analogue[3] whose structural features are very similar to those we describe here. Compound **2** consists of a square arrangement of ligands about chromium; the two oxygen atoms, the two nitrogen atoms and the chromium atom being coplanar. The phenoxo-ligands occupy *trans* positions and the N—Cr—N vector is nearly perpendicular to the O—Cr—O axis (84.45(7)°).

As was found for $Cr(OR)_2(THF)_2$ (R = 2,6-$(^tBu)_2$ 4-Me),[3] the Cr—O bond lengths in **2** are also long (1.952(2) Å) despite the rather open Cr—O—C bond angles (143.4(1)°). The Cr—N bond lengths (2.201(2) Å) are notably longer than in (lutidine)$_2$Cr$(CF_3COO)_2$ (2.111(3) Å)[7] with the plane of the pyridine ligand lying almost in the plane of the

Table 1. Selected bond distances and angles for **1**

O—C(1)	1.342(3)		

complex, making an angle of only 6.29(3)° to it. These results again do not point to any significant π-interactions, steric effects sufficing to explain the small distortions observed.

Hence **2** provides a further example of simple monomeric tetracoordinate chromium(II) species with a square-planar ligand arrangement which has become relatively common in recent years.[3,8] The square arrangement is expected for a d^4 high-spin tetracoordinate complex where (as in d^8 low-spin systems) electron occupancy of the antibonding $d_{x^2-y^2}$ orbital is avoided.

Conclusion

The structural features found for the two alkoxide compounds indicate that at least for high-spin d^4 and d^5 electronic configurations, the π-donor effects are either small or largely dominated by steric factors. However, the effect of the presence of the alkoxide ligands on the chemical reactivity of such compounds, particularly in oxidative processes, is important and under study.

EXPERIMENTAL

All manipulations were carried out in a Vacuum Atmosphere glove-box under a nitrogen atmosphere. Solvents were distilled under nitrogen over sodium/benzophenone for THF, pentane and diethyl ether, and over calcium hydride for acetonitrile and pyridine.

$[(2,4,6\text{-}(^tBu)_3C_6H_2O)_2Mn(CH_3CN)_2] \cdot 2[CH_3CN]$ (1)

A slurry of $MnCl_2(CH_3CN)_2$ (1.0 g, 4.8 mmol) in 100 cm^3 of THF was magnetically stirred and two equivalents of $Na[2,4,6\text{-}(^tBu)_3C_6H_2O)] \cdot THF$ (3.43 g), dissolved in 50 cm^3 of THF, were added, and the solution stirred for 3 h at room temperature. The NaCl precipitate was removed by decantation and the solution filtered through celite, and evaporated to dryness. The resultant solid was crystallized from acetonitrile to give colourless crystals of the biacetonitrile adduct (yield: 2.85 g, 80%).

The IR spectrum (Nujol mull) shows, in particular, absorptions at 2310, 2285 and 2255 cm^{-1}. The magnetic moment was determined by Evans' method[9] in C_6D_6 ($\mu_{eff} = 5.8\ \mu_B$). The compound is slightly soluble in benzene and reacts rapidly with oxygen, changing from a colourless to a black solution.

$[(2,4,6\text{-}(^tBu)_3C_6H_2O)_2Cr(Py)_2]$ (2)

$CrCl_3(THF)_3$ (2 g, 2.67 mmol) was dissolved in 100 cm^3 of THF and three equivalents of $Na[2,4,6\text{-}(^tBu)_3C_6H_2O] \cdot THF$ (2.85 g), dissolved in 50 cm^3 of

THF, were slowly added under magnetic agitation. A deep blue–black solution was obtained after complete addition of the sodium salt, pyridine (3 cm^3, 37 mmol) was added over 2 h with stirring, and the colour changed slowly to green. After filtration over celite the solvent was evaporated under vacuum and a crude green product obtained. The major part was very soluble in pentane and green needles could be recovered at low temperature. Further recrystallization of the green needles in pentane at low temperature, in order to produce crystals suitable for X-ray analysis, led to compound **2**, as well as some white crystalline material.

X-ray crystallographic studies

All X-ray data were collected on a Philips PW1100/16 automated diffractometer with a local-built gas flow device for low temperature measurements. The resulting data-set was transferred to a VAX computer, and for all subsequent calculations the Enraf–Nonius SDP/VAX[10] package was used, with the exception of a local data reduction program which converts the raw step-scan data to intensities using the Lehmann–Larson method,[11] and then corrected for Lorentz and polarization factors. For both structures absorption corrections using empirical methods were performed.[12] Details of the crystal data are given in Table 3.

Crystal data for $C_{44}H_{70}N_4O_2Mn$ (**1**). $M_R = 742.01$, orthorhombic, space group *Iba*2, $a = 19.519(6)$, $b = 15.364(5)$, $c = 15.717(5)$ Å, $V = 4713.4$ Å^3, $Z = 4$, $D_c = 1.046$ g cm^{-3}, graphite monochromized Cu-K_α with $\lambda = 1.5404$ Å and $\mu = 25.339$. Intensities of 1045 reflections were collected ($2\theta_{max} = 50°$, ω–2θ flying step scan) at -100°C. A total of 794 independent reflections with $I > 3\sigma(I)$ were used in the structure determination. The structure was solved by direct methods (MULTAN) and refined by full-matrix least-square techniques (SDP) to $R = 0.039$ ($R_w = 0.052$). Hydrogen atoms were included in structure factor calculations at idealized positions ($d_{C-H} = 0.95$ Å) and were assigned isotropic thermal parameters $B(H) = 1.3\ B_{equ}(C)$ Å^2.

Crystal data for $C_{46}H_{68}N_2O_2Cr$ (**2**). $M_R = 733.06$, monoclinic, space group $P2_1/c$, $a = 9.567(3)$, $b = 10.6373(6)$, $c = 21.502(6)$ Å, $\beta = 93.20(2)°$, $V = 2184.7$ Å^3, $Z = 4$, $D_c = 1.114$ g cm^{-3}, graphite monochromized Cu-K_α with $\lambda = 1.5404$ Å and $\mu = 24.363$. Intensities of 2790 reflections were collected ($2\theta_{max} = 50°$, ω–2θ flying step scan) at -100°C. A total of 2044 independent reflections with $I > 3\sigma(I)$ were used in the structure determination. The structure was solved by Patterson function interpretation and Fourier synthesis, and refined by full-matrix least-square techniques (SDP) to $R = 0.036$ ($R_w = 0.062$). Hydrogen atoms were included in structure factor calculations at idealized positions ($d_{C-H} = 0.95$ Å) and were assigned isotropic thermal parameters $B(H) = 1.3\ B_{equ}(C)$ Å^2.

Abstract—Heterobimetallic complexes can be prepared in an extremely straightforward fashion by the use of the binucleating hexatertiaryphosphine ligand $(Et_2PCH_2CH_2)_2PCH_2P(CH_2CH_2PEt_2)_2$, eHTP. The following mixed-metal dimers have been prepared in at least 50% yields: $NiPtCl_2(eHTP)^{2+}$ and $Co(CO)_2NiCl(eHTP)^{2+}$. The CoNi mixed-metal complex is the first example of these metals bridged by a bis(phosphino)methane-type linkage. Two-dimensional ^{31}P COSY NMR spectra are presented to conclusively demonstrate the formation of mixed-metal dimer species. The yields of the heterobinuclear complexes in some cases are dependent upon the reaction conditions and the order of reagent addition. The $NiPtCl_2(eHTP)^{2+}$ complex, for example, is produced statistically in about 50% yield when K_2PtCl_4 is added first to eHTP, whereas it is produced in 67% yield when $NiCl_2 \cdot 6H_2O$ is added first. Reasons for this effect on the yield of the mixed-metal dimer species are discussed. The production of an unusual tetrametallic intermediate $Ni_2Pt_2Cl_8(eHTP)$ is also presented.

Heterobimetallic compounds have attracted a considerable amount of attention over the last few years for applications in both homogeneous[1] and heterogeneous catalysis.[2] Most rational syntheses rely on the use of bridging ligand systems that can act as templates for dimers. High yields are generally only obtained when one is using a mixed functionality hybrid ligand such as Pr_2–$C_5H_4^-$ which has a large difference in binding abilities for two different metal centres.[3] The syntheses of mixed-metal dimers using bridging ligands with similar donor functionalities such as $Ph_2PCH_2PPh_2$ (dppm) are usually only readily accessible if an η^1-dppm metal complex for one of the metal centres can be prepared.[4] We would like to report the straightforward synthesis of heterobimetallic transition metal systems based on the powerful binucleating hexatertiaryphosphine ligand eHTP, which we have used in the past to prepare a variety of homobimetallic complexes.[5–9]

The reaction of one equivalent of $NiCl_2 \cdot 6H_2O$ with eHTP in ethanol followed by one equivalent of $CoCl_2$ produces a mixture of the heterobimetallic complex $CoNiCl_2(eHTP)^{2+}$ and the analogous two homobimetallic systems. This red–brown solution was reacted with H_2/CO (50 bar, 80°C, 24 h) which selectively carbonylated and reduced the cobalt centres to cobalt(I), producing an orange mixture of $Co(CO)_2NiCl(eHTP)^{2+}$ and the previously characterized dimers: $Co_2(CO)_4(eHTP)^{2+}$ (yellow)[5] and $Ni_2Cl_2(eHTP)^{2+}$ (red).[6] ^{31}P NMR on the crude reaction mixture shows that the mixed cobalt–nickel eHTP dimer is produced in *ca* 50% yield while the homobinuclear cobalt and nickel systems are each present in 25% yield.† These are the yields

† Spectroscopic data on $Co(CO)_2NiCl(eHTP)^{2+}$: IR (KBr) ν_{CO}: 2005 and 1955 cm^{-1}; $^{31}P\{^1H\}$ NMR (acetone-d_6, δ ppm, H_3PO_4 ref.): 58.5 ($2P_{ext}$—Ni, d, J_{P_P} = 39.3 Hz), 84.3 ($2P_{ext}$—Co, d, J_{P_P} = 48.8 Hz), 110.1 (P_{int}—Ni, pseudo-quartet, J_{P_P} = 34.7 Hz) 121.8 (P_{int}—Co, pseudo-quartet, J_{P_P} = 34.7).

expected based on simple statistical distributions of the metal centres in the eHTP ligand.

The presence of the heterometallic $Co(CO)_2NiCl(eHTP)^{2+}$ dimer is most clearly seen through the use of two-dimensional $^{31}P\{^1H\}$ COSY NMR spectroscopy. Figure 1 shows an expanded portion of the $^{31}P\{^1H\}$ COSY spectrum on $Co(CO)_2NiCl(eHTP)^{2+}$ for the two internal methylene-bridged phosphorus atoms of the eHTP ligand. The mixed-metal $Co(CO)_2NiCl(eHTP)^{2+}$ dimer is uniquely identified by two features in this spectrum: the off-diagonal connectivities which clearly demonstrate that the two internal phosphorus centres are coupled to one another; and from the fact that cobalt is a quadrupolar nucleus that selectively broadens the phosphorus atoms bound to the cobalt, as can be plainly seen in the spectrum. This quadrupolar broadening is also seen for the terminal phosphorus groups bound to the cobalt atom and all the expected off-diagonal couplings from the ^{31}P COSY spectrum consistent with the $Co(CO)_2NiCl(eHTP)^{2+}$ formulation are observed. The pseudo-quartet pattern observed for the central phosphines arises from essentially equivalent coupling of the internal phosphorus atom to the two equivalent linked terminal phosphines and the other methylene-bridged internal phosphorus centre.

Transition metal dimers based on eHTP usually

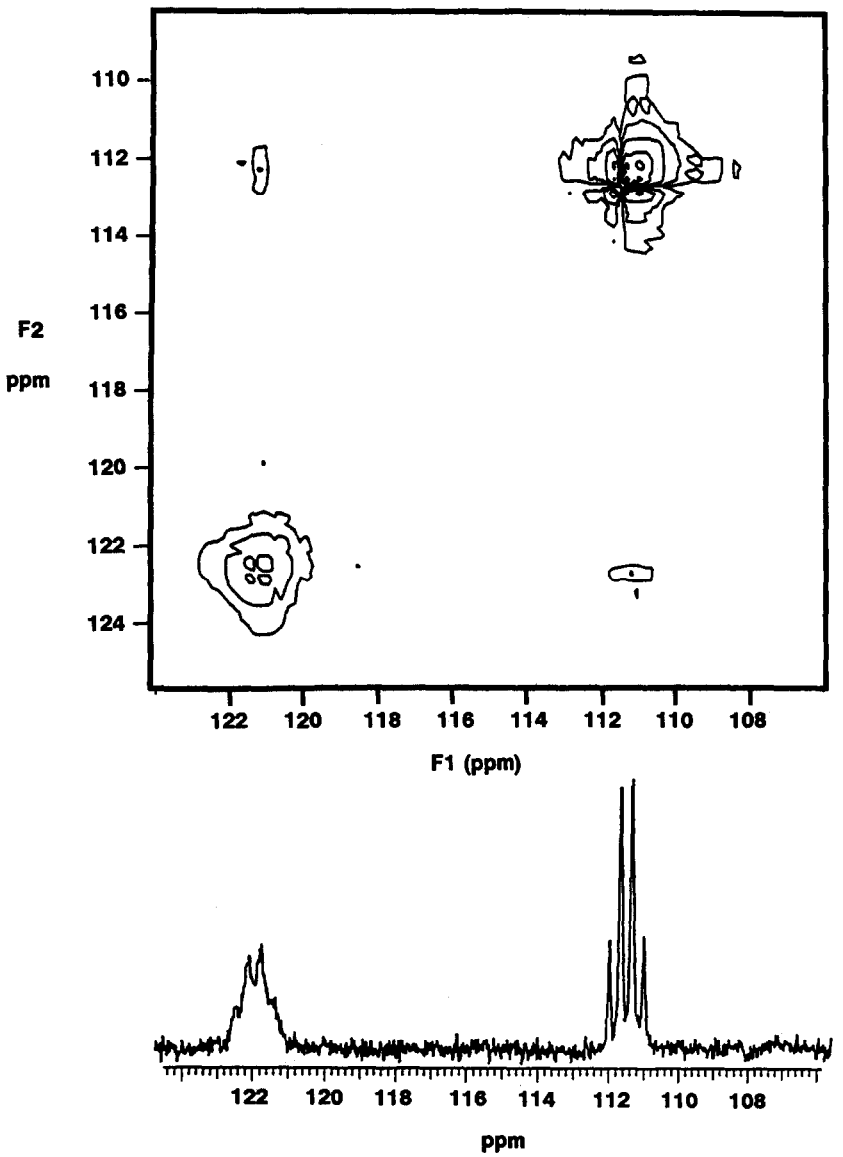

Fig. 1. Expanded portion of the two-dimensional ^{31}P–^{31}P shift correlated (COSY) spectrum for the two inner phosphorus atoms of $Co(CO)_2NiCl(eHTP)^{2+}$ in acetone-d_6. The 1-D $^{31}P\{^1H\}$ NMR spectrum of the same region is shown below the 2-D spectrum for reference.

form open-mode conformations in which the metal centres are separated by 4–7 Å with a variety of rotational orientations about the central methylene bridge. Van der Waals' (VDW) energy calculations have proved to be extremely valuable in probing the possible low-energy conformations for eHTP dimer complexes[6,9,10] and the $Co(CO)_2NiCl(eHTP)^{2+}$ dimer represents an ideal system to probe since the crystal structures on both homobimetallic parent systems are known.[5,6] We used the SYBYL[11] molecular graphic/mechanics program set to fuse half of the $Ni_2Cl_2(eHTP)^{2+}$ structure with half of the $Co_2(CO)_4(eHTP)^{2+}$ structure to create a computer model of the hybrid $Co(CO)_2NiCl(eHTP)^{2+}$ dimer. Terminal methyl groups were used instead of the existing ethyl groups on eHTP as in previous VDW calculations and calculations were carried out with central methylene bridge angles of 123, 125 and 127°, with similar results being obtained. The VDW energy calculation predicts that there are two low energy conformers connected by a pathway with a 34 kcal mol^{-1} barrier (P—CH_2—P = 125°). Parallel and perpendicular views of these two conformers are shown in Fig. 2. Conformer **A** has a structure analogous to $Co_2(CO)_4(eHTP)^{2+}$,[5] while conformer **B** has a structure most similar to that observed for $[Ni_2Cl_2(eHTP)^{2+}][2BF_4^-]$.[6] We are attempting to grow X-ray quality single crystals for a structural analysis on this system.

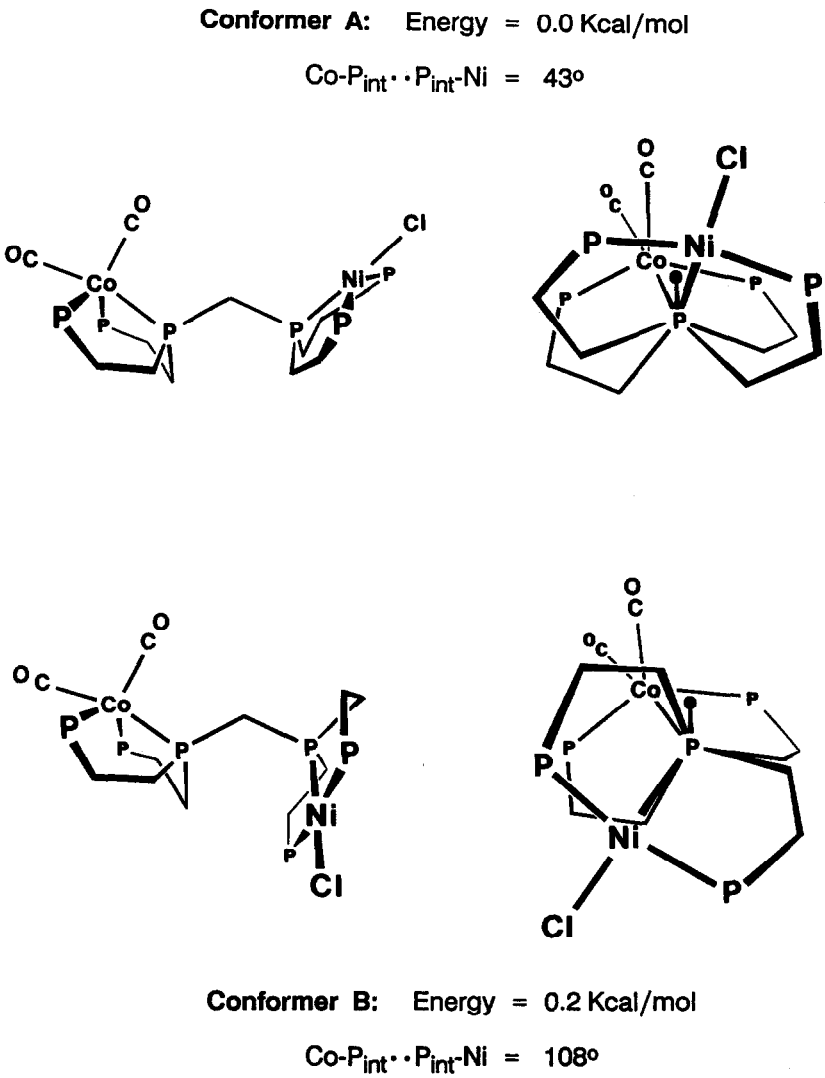

Fig. 2. Calculated low-energy rotational conformations for $Co(CO)_2NiCl(eHTP)^{2+}$ from a van der Waals' (VDW) energy calculation on a model complex using the SYBYL molecular mechanics program package. Views which are parallel and perpendicular to the $P_{int}\cdots P_{int}'$ vector are shown for each conformer to clearly show the rotational orientations. The relative VDW energy and $M—P_{int}\cdots P_{int}'—M'$ torsional angle for each conformer is also listed.

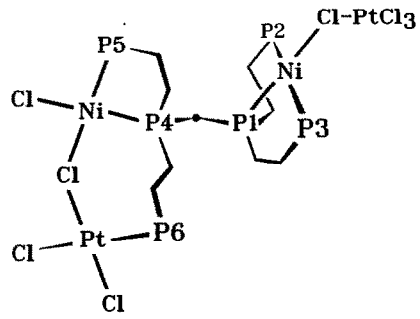
A nickel–platinum(II) mixed-metal dimer system was obtained in a similar fashion to the cobalt–nickel complex. One equivalent of K_2PtCl_4 was reacted with one equivalent of eHTP followed by the addition of one equivalent of $NiCl_2 \cdot 6H_2O$ in ethanol. This gives a statistical product distribution of $NiPtCl_2(eHTP)^{2+}$ (orange, 50%), $Ni_2Cl_2(eHTP)^{2+}$ (red, 25%)[6] and $Pt_2Cl_2(eHTP)^{2+}$ (colourless, 25%).[7] The production of the heterobimetallic $NiPtCl_2(eHTP)^{2+}$ system was confirmed once again by ^{31}P COSY NMR.* Most interestingly, there are deviations observed from the statistical product distribution depending on reaction conditions, particularly with respect to the order of metal reagent addition. Use of $NiCl_2 \cdot 6H_2O$ first instead of K_2PtCl_4, for example, gives a higher production of the mixed-metal species with a product ratio for $Ni_2/Pt_2/NiPt$ of 1 : 1 : *4* (67% yield of the heterobinuclear complex).

We initially believed that this selectivity came about from the partial deactivation of the polyphosphine ligand to the coordination of a second metal centre after complexation of the first metal atom. Optimum formation of mixed-metal dimers occurs for the case when the metal species which has the *weakest* M—P coordination is added *first*, followed by some equilibrium period to allow distribution of the metal centres into the maximum number of monomer species. The metal species which has the weakest M—P bonds will be the most selective at coordinating to the most electron-rich eHTP ligand which will, of course, be one that has *not* coordinated to another metal atom. Metal atoms (such as platinum) which have a considerably higher binding affinity for phosphines will be less sensitive and selective to whether they are coordinating to an empty eHTP or one that already has a bound metal centre.

It was suggested to us by a NSF proposal reviewer, however, that what might actually be happening to produce enhanced yields of the Ni/Pt mixed-metal system when nickel(II) is added



Scheme 1.

first to eHTP is that some of the homobimetallic $Ni_2Cl_2(eHTP)^{2+}$ complex formed can react directly with platinum(II) to form $NiPtCl_2(eHTP)^{2+}$. We tested this by taking pure $Ni_2Cl_2(eHTP)^{2+}$ and adding three equivalents of K_2PtCl_4 in H_2O. There was an immediate reaction with the precipitation of an orange–red material. Based on the elemental analysis and ^{31}P NMR spectral data† of this orange–red material we have assigned this new molecule to the *tetra*metallic species $Ni_2Pt_2Cl_8(eHTP)$, which is shown above.

On standing in CH_3CN solution, $Ni_2Pt_2Cl_8(eHTP)$ slowly and almost quantitatively converts to $Pt_2Cl_2(eHTP)^{2+}$ and $NiCl_2 \cdot 6H_2O$ over the course of 1–2 weeks. This observation is consistent with the proposed presence of two platinum atoms in the complex. Interestingly, we do see small quantities of the heterobimetallic system $NiPtCl_2(eHTP)^{2+}$ in the ^{31}P NMR spectra during the conversion of $Ni_2Pt_2Cl_8(eHTP)$ to $Pt_2Cl_2(eHTP)^{2+}$. It is, therefore, quite reasonable to assume that in the reaction of $NiCl_2 \cdot 6H_2O$ with eHTP, followed by the addition of K_2PtCl_4, some $PtCl_4^{2-}$ (or $PtCl_3(solvent)^-$) did directly attack some of the bimetallic $Ni_2Cl_2(eHTP)^{2+}$ present to form the tetrametallic species $Ni_2Pt_2Cl_8(eHTP)$. This could then further react to displace one of the nickel atoms to form the heterobimetallic complex $NiPtCl_2(eHTP)^{2+}$, resulting in an enhanced yield of the heterobimetallic product. This raises the intriguing possibility of obtaining nearly quantitative yields of the mixed NiPt complex by starting with pure $Ni_2Cl_2(eHTP)^{2+}$ and reacting it with only a *single* equivalent of K_2PtCl_4. We are currently exploring this possibility.

Although this general method for preparing heterobimetallic complexes may appear to be somewhat inelegant, it should be noted that it is virtually assured to work for any pair of transition metal centres that will coordinate a bis(phosphino)-ethane-type moiety to give at least a 50% yield of the mixed-metal compound. The NiCo bimetallic complex reported here is the first example of these

* Spectroscopic data on $NiPtCl_2(eHTP)^{2+}$: $^{31}P\{^1H\}$ NMR (CD_2Cl_2, δ ppm, H_3PO_4 ref.): 52.2 ($2P_{ext}$—Pt, s, J_{Pt-P} = 1145.2 Hz), 57.5 ($2P_{ext}$—Ni, d, J_{P-P} = 27.5 Hz), 80.0 (P_{int}—Pt, d, J_{P-P} = 27.1 Hz, J_{Pt-P} = 1580.9 Hz), 104.9 (P_{int}—Ni, pseudo-quartet, J_{P-P} = 27.3 Hz).

† $^{31}P\{^1H\}$ NMR data for $Ni_2PtCl_6(eHTP)$, CD_3CN (numbering of the phosphorus atoms corresponds to those used in the text figure): 20.4 (P6, dd, J_{P-P} = 24.3 Hz, J_{Pt-P} = 1215.4 Hz), 61.6 (P2, 3, d, J_{P-P} = 55.3 Hz), 74.3 (P4, m, J_{P-P} = unresolvable), 82.8 (P5, dd, J_{P-P} = 64.1, 15.5 Hz), 110.1 (P1, dt, J_{P-P} = 55.3, 15.5 Hz). Calc. for $C_{25}H_{58}Cl_8Ni_2P_6Pt_2$: C, 22.48; H, 4.38; P, 13.91. Found: C, 23.51; H, 4.96; P, 12.85.

two metal centres linked by a bis(phosphino)-methane group, and there are only two recently reported examples of bis(phosphino)methane-bridged NiPt dimers: $NiPtCl_2(\mu\text{-dppm})_2(\mu\text{-CO})$ by Holah *et al.*,[12] and $[Ni(CH_3CN)_2(\mu\text{-dppm})Pt(\eta^2\text{-dppm})]^{2+}$ by Miedaner and DuBois.[13]

One reaction that is potentially well suited to mixed-metal binuclear systems is hydroformylation and there have been several reports on the effects of heterobimetallic homogeneous catalysts on the rate and selectivity of hydroformylation reactions.[14] We are particularly interested in studying the hydroformylation activity of homo- and heterobimetallic Group VIII metal complexes based on our new, less sterically hindered binucleating tetratertiaryphosphine ligand system $(Et_2PCH_2CH_2)(Ph)PCH_2P(Ph)(CH_2CH_2PEt_2)$, eLTTP.[15-17] This ligand should have extremely similar coordinating properties as eHTP and we plan to study the reaction conditions required to optimize the syntheses of heterobimetallic eHTP and eLTTP bimetallic complexes.

Abstract—The rhenium(V) complex $[ReO(O_2C_6H_4)_2]^-$ has been synthesized by reaction of $[ReOCl_3(PPh_3)_2]$ with excess catechol in methanol in the presence of triethylamine under N_2. If the reaction is carried out in air the rhenium(VII) complexes $[ReO_2(O_2C_6H_2R_2)_2]^-$ (R = H, Bu^t) can be isolated with a range of cations. Cyclic voltammetry coupled with convolution analysis showed that the rhenium(VII) complexes undergo a reversible diffusion-controlled one-electron reduction. The X-ray crystal structure of the rhenium(VII) derivative with R = H revealed a distorted octahedral geometry with *cis*-oxo groups.

Catechol complexes are well known for most of the transition elements, including iron, molybdenum, osmium, manganese and chromium and a comprehensive review has appeared.[1] The recent research effort in this area has in part been due to the established wide occurrence of catechol-based metal ion siderophores in biological systems. However, catechol complexes are also of intrinsic interest from the standpoint of their redox chemistry. Catecholate† ligands are suspect in Jorgensen's classification and redox reactions may occur either at the metal centre or within the catecholate ligand. We are currently interested in the chemistry of rhenium due to its close analogy with technetium which is used extensively as a radionuclide imaging agent.

Recently some six-coordinate cathecholate complexes of rhenium of the type $[Re(O_2C_6H_4)_3]^{2-}$ were reported,[2] prepared by reaction of $[ReCl_6]^{2-}$ with catechol in the presence of base. The synthesis of neutral, formally rhenium(VI) complexes $[Re(O_2C_6H_2Bu^t_2)_3]$ and $[Re(O_2C_6Cl_4)_3]$ have also recently been reported by oxidative addition of the corresponding quinones to $[Re_2(CO)_{10}]$.[3] Monomeric oxo-catecholato-complexes are comparatively rare, being restricted to $[OsO_2(cat)_2]^{2-}$,[4] $[OsO_2(cat)py_2]$,[4] $[MoO_2(cat)_2]^{2-}$ [5] and $[WO_2(cat)_2]^{2-}$.[4] We here report the synthesis and characterization of some simple monomeric oxo- and dioxo-catecholato-complexes of rhenium.

RESULTS AND DISCUSSION

Synthesis of complexes

The reaction of $[ReOCl_3(PPh_3)_2]$ with excess catechol under N_2 in the presence of base in refluxing ethanol yields a pale olive-green anionic complex of apparent stoichiometry $[ReO(cat)_2]^-$ (**I**). This can be isolated as a microcrystalline, somewhat air-sensitive solid by the addition of

$[Me_4N]Cl$, and analogues with other substituted catechols can be prepared in a similar manner. These complexes and others discussed below are summarized in Table 1, together with relevant analytical and spectroscopic properties.

If the above reaction was carried out in air, or the mono-oxo-complex allowed to stand in air, the deep purple rhenium(VII) dioxo-anion $[ReO_2(cat)_2]^-$ (**II**) is formed in high yield. These could be precipitated from solution with a range of large cations, and their properties are summarized in Table 1.

A range of other rhenium precursors with metal nitrogen multiple bonds such as $[ReCl_2N(PPh_3)_2]$, $[ReCl_3(NPh)(PPh_3)_2]$ and $[ReCl_2(N_2COPh)(PPh_3)_2]$ were reacted under similar conditions with the catecholate anion generated *in situ*. No nitrogen-containing products could be isolated and in air the dioxo-rhenium(VII) complex was formed. It seems probable that anionic species such as $[ReN(cat)_2]^{2-}$ may be transiently generated but that the overall negative charge activates the nitrogen ligand to protonation and subsequent loss as ammonia or amine. Similar results have been observed for the reaction of such species with anionic thiolato-ligands.[6]

SPECTROSCOPIC PROPERTIES

(i) *IR and UV–vis spectra*

Both types of anion exhibit intense bands in the 1250–1270 cm^{-1} region attributable to the C—O stretching frequencies for coordinated catecholato-anions. There was no evidence for bands assignable to ν(O—H) confirming that the catecholate ligands are completely deprotonated.

The mono-oxo-complexes such as **I** show a single intense band in the region 980–1000 cm^{-1} due to a terminal Re=O group. By contrast, the rhenium(VII) complexes such as **II** have two strong bands at 925 and 985 cm^{-1} confirming the presence of a *cis*-ReO_2 dioxo-moiety.

The rhenium(VII) dioxo-complexes are an intense purple colour in solution which is reflected in the presence of intense charge-transfer absorptions in the region 540–550 nm.

(ii) *NMR spectra*

The rhenium(VII) dioxo-catecholato-anion shows two broad resonances at 6.6 and 7.5 ppm assigned to the 3,6- and 4,5-phenyl protons of the catecholate ligand, respectively. By contrast, the complex $[MoO_2(cat)_2]^{2-}$ shows only one broad multiplet at 6.59 ppm assigned to coordinated catechol.

For the corresponding rhenium(VII) complex of 3,5-ditertiarybutyl catechol, two sharp singlets are observed for the Bu^t hydrogens. This indicates that at room temperature only one of the two possible stereoisomers is present in solution. There was no sign of broadening of these resonances on lowering the temperature suggesting that the system is not fluxional. Presumably steric effects are responsible for the selection of one isomer and we propose the structure shown in Fig. 1. Here the catechol is ligated so that the oxygens at position two are *trans* thereby minimizing repulsions between Bu^t groups at the *cis*-oxygen positions. Similarly only one singlet resonance is observed for the complex of monotertiarybutyl catechol, again suggesting the presence of a single isomer in solution.

Structure of rhenium(V) *mono-oxo-complex* [ReO $(O_2C_6H_4)_2]^-$

This complex is formally analogous to $[\{MoO(O_2C_6H_4)_2\}_2]$ which has been shown to have a dimeric catechol oxygen-bridged structure in the solid state.[7] The molybdenum complex shows *four* resonances due to Bu^t groups which decrease to two on solution in coordinating solvents such as acetone due to the formation of mono-oxo-complex monomers. However, the rhenium(V) complex shows no colour change in solution on addition of donor

$[ReO_2(C_6H_2(t.Bu)_2)_2]$

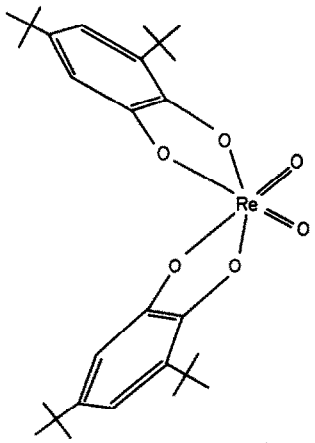

Fig. 1.

$[ReO(O_2C_6H_4)_2]$

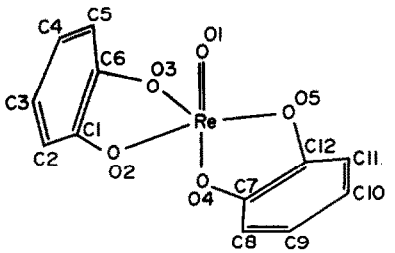

Fig. 2.

solvents and we tentatively propose the monomeric square-pyramidal structure in Fig. 2.

Structure of $[ReO_2(O_2C_6H_4)_2]^-$

Crystals of $[Et_4N][ReO_2(O_2C_6H_4)_2]$ suitable for an X-ray crystal structure determination were grown from dichloromethane–diethyl ether as purple needles. Data pertinent to the structure determination are summarized in Table 2 and selected bond lengths and angles appear in Table 3. Tables of atomic coordinates and full bond lengths and angles have been deposited as supplementary data. An ORTEP representation of the structure is shown in Fig. 3 together with the atom labelling scheme. Both ions lie on two-fold axes of symmetry.

The overall geometry about the rhenium is distorted octahedral with the two terminally bonded oxo-groups occupying *cis* positions. Two distortions from idealized octahedral geometry are evident. Repulsion between the two *cis*-oxo-groups occurs due to the high concentration of electron density in the Re=O bonds and the O(3)—Re—O(3)′ angle is 99.4(5)°. The high *trans*-influence of the oxo-ligands causes the catecholato-ligands to be asymmetrically coordinated with Re—O(1) = 2.031(7) Å and Re—O(2) = 1.952(6) Å.

The Re—O distances for the catecholate ligand not lengthened by the *trans*-influence are very similar to those found in other related catecholato-complexes such as $[\{MoO(S_2C_6H_2Bu^t_2)_2\}_2]$ (1.945 Å). The C—O distances of 1.324(9) and 1.357(9) Å are consistent with the presence of the dianionic catecholato- rather than ligated semiquinone or benzoquinone ligands. The lengthening of the Re—O distances *trans* to the oxo-groups is reflected in a concomitant slight decrease in the C—O bonds.

Examples of complexes with the *cis*-ReO_2 moiety are rare although many are known for molybdenum and tungsten. To our knowledge this is the first structurally characterized example of such a complex.

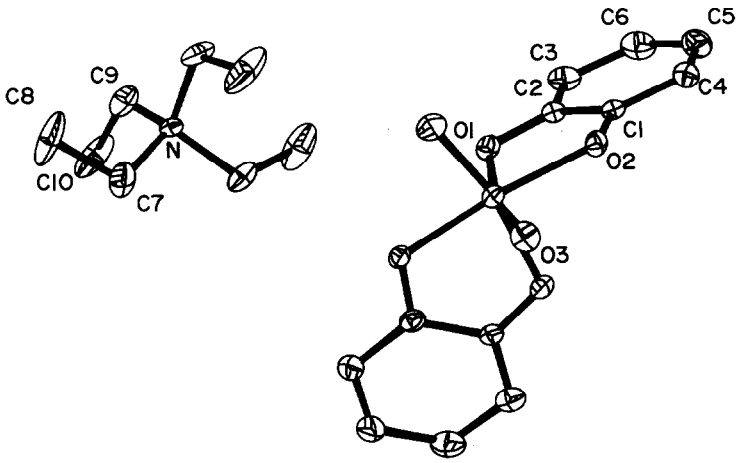

Fig. 3.

Table 4 compares X-ray structural data for isoelectronic $[ReO_2(O_2C_6H_4)_2]^-$ and $[MoO_2(O_2C_6H_4)_2]^{2-}$.[8] The general features of the complexes are very similar with asymmetric coordination of the catecholato-ligands due to the *trans*-influence of the oxo-ligands. A surprising feature of the molybdenum complex is the Mo—O distance of the Mo=O groups of 1.77 Å, which is about

[c] Averaged value.

0.1 Å longer than that found in other molybdenum oxo-complexes. The reasons for this are far from clear, but the potassium ions are co-ordinated by water molecules and the oxygen atoms of the Mo=O groups. This interaction might possibly remove sufficient electrons from the Mo=O bond to rationalize the observed long Mo—O distance.

Cyclic voltammetric studies

The redox characteristics of the $[ReO_2(cat)_2]^-$ complexes were studied using convolution analysis coupled to cyclic voltammetry. The measurements were carried out in a standard three-electrode cell under dinitrogen, using platinum wire working and auxilliary electrodes and a silver wire pseudo-reference electrode. Generally dry acetonitrile was used as solvent with $[Bu^n_4N][BF_4]$ as support electrolyte, measurements of peak potential were made relative to ferrocene ($E_{1/2}$ for oxidation +0.54 V relative to SCE in THF). A standard commercial software package CONDECON was used to analyse the cyclic voltammetric responses by convolution analysis. Full details of the theory of convolution analysis have appeared elsewhere[9,10] and will not be discussed here.

The complexes all undergo a complex series of irreversible oxidation processes which will not be considered further. In addition each complex undergoes a fully reversible diffusion-controlled one-electron reduction process between −0.78 and −1.01 V depending on the catechol substituent. The observed $E_{1/2}$ values observed at a scan rate of

50 mV s^{-1} are summarized in Table 5 together with convolution/deconvolution data. The cyclic voltammogram of $[ReO_2(O_2C_6H_4)_2]^-$ is shown in Fig. 4 with the convolution I_1 superimposed.

A number of factors confirm that the reduction is indeed a fully reversible, diffusion-controlled, one-electron process. Table 6 summarizes data for three complexes over a wide range of scan rates. The $[ReO_2(cat)_2]^-$ complexes become progressively harder to reduce with increasing alkyl substitution of the catecholato-ligand as expected with the inductive effect of the alkyl groups. Virtually independent of scan rate all complexes show a peak separation of about 60 mV, close to the theoretical value of 59 mV for the Nernstian process. The fact that the I_1 convolution returns to the same point confirms that there are no homogeneous kinetic processes accompanying the simple electron-transfer. The deconvolution (dI/dt) vs E plot gives maxima at identical E values, indicating that the heterogeneous electron-transfer processes are fast. Moreover, the half-height peak widths of about 90 mV (Table 1) confirm that one electron is involved in the reduction process. These data suggest reasonable stability for the formally 17-electron rhenium (VI) species $[ReO_2(cat)_2]^{2-}$. Experiments are currently in progress to attempt to isolate this species by controlled potential electrolysis and to examine the EPR spectrum of the d^1 complex.

The rhenium(V) complexes $[ReO(cat)_2]^-$ proved to be too unstable in solution for detailed investigation of their redox characteristics.

P_a—anodic peak; P_c—cathodic peak.

In 0.2 M $[Bu^n_4N][BF_4]$ in acetonitrile at 20°C using a platinum wire as working electrode and a silver wire pseudo-reference electrode. Potentials calibrated vs the ferrocene/ferrocenium couple.

Reactions of complexes $[ReO_2(cat)_2]^-$

The purple rhenium(VII) complexes, $[ReO_2(cat)_2]^-$, react rapidly with triphenylphosphine or hydrazine hydrate in refluxing ethanol to give the rhenium(V) species $[ReO(cat)_2]^-$ in high yield. This reaction is rapidly reversed by aerobic oxidation. Attempts to synthesize hydrazido- or diazenido-complexes by reaction of $[ReO_2(cat)_2]^-$ with 1,1-dialkylhydrazines or phenylhydrazine, gave distinct colour changes but no pure complexes could be isolated.

EXPERIMENTAL

All reactions were carried out under dinitrogen in conventional Schlenk apparatus using dry solvents. Elemental analyses were carried out by the analytical services of The University of Sussex. IR spectra were recorded on a Perkin–Elmer 1330 spectrophotometer as Nujol mulls or KBr discs and NMR spectra were measured on a Brukker WP80SY spectrometer.

Cyclic voltammetry was performed using a PAR 362 potentiostat interfaced to an OPUS 2 IBM-compatible computer system via an *A/D* converter. The data was analysed using the CONDECON software package. A standard three-electrode cell was used with platinum wire working and auxiliary electrodes and a silver wire pseudo-reference electrode. Dry acetonitrile was used as solvent with recrystallized $[Bu^n_4][BF_4]$ as support electrolyte (10^{-1} M).

The rhenium precursors $[ReOCl_3(PPh_3)_2]$,[11] $[ReCl_2N(PPh_3)_2]$[12] and $[ReCl_2(N_2COPh)(PPh_3)_2]$[13] were prepared using standard literature methods.

Tetraethylammonium bis(catecholato)di(oxo)rhenate(VII)

$[ReOCl_3(PPh_3)_2]$ (0.5 g), catechol (0.17 g) and diethylamine (0.35 cm^3) in ethanol (25 cm^3) were heated under reflux for 3 h in air. The clear purple solution was cooled and tetraethylammonium chloride (0.5 g) dissolved in ethanol (10 cm^3) was added. The solution was left to stand for 20 h, depositing purple crystals of the dioxo-complex which were then recrystallized from dichloromethane–diethyl ether.

The tetraphenylphosphonium analogue was prepared similarly by addition of tetraphenylphosphonium bromide. Analogues with 4-tert-butylcatechol and 3,5-ditert-butylcatechol were also prepared in a directly similar manner.

Use of $[ReCl_2N(PPh_3)_2]$ or $[ReCl_2(N_2COPh)(PPh_3)_2]$ as precursors under similar conditions also gives the rhenium(VII) dioxo-complexes in high yield.

Tetramethylammonium bis(catecholato)oxorhenate (V)

$[ReOCl_3(PPh_3)_2]$ (0.65 g), catechol (0.17 g) and triethylamine (0.35 cm^3) in methanol (20 cm^3) were heated under reflux under dinitrogen for 3 h to give a clear green solution. A solution of 0.5 g of tetramethylammonium chloride in methanol was added under dinitrogen to give a green microcrystalline precipitate. This was washed with methanol after filtration under N_2 and dried *in vacuo*.

The tetraphenylphosphonium complex was prepared analogously by addition of tetraphenylphosphonium bromide.

(*Received* 2 *January* 1990; *accepted* 29 *January* 1990)

Abstract—^{1}H NMR data are reported for the series of octahedral tin(IV) complexes Sn(TPP)(OCOH)X, where TPP is 5,10,15,20-tetraphenylporphyrin and X = OSO_2CF_3, ONO_2, NCS, $OCOCF_3$, OCOH, $OCOC_6H_4$-*o*-OH, $OCOC_6H_5$, $OCOCH_3$, OC_6H_4-*p*-CH_3, OH, OCH_3, F, Cl, Br and I. The mixed-ligand complexes were generated as mixtures also containing the symmetrical complexes Sn(TPP)$(OCOH)_2$ and Sn(TPP)X_2. The chemical shifts of the formate protons and the tin–proton coupling constants, ^3J(Sn—O—C(O)—H), show a fair correlation with the basicity of the ligand X for the O-bound ligands, but the halide complexes demonstrate the importance of π-bonding. The *trans*-influence and *cis*-influence are in the same direction, ie. a ligand which weakens the bond to the *trans*-formate ligand, also weakens the tin–porphyrin coordination.

The tin(IV) complexes of porphyrins and related ligands are proving useful in a range of chemical and biological fields. For example, tin(IV) protoporphyrin is an inhibitor of haem oxygenase, making it a possible agent for treatment of neonatal jaundice.[1,2] Tin complexes of modified porphyrins such as purpurins are being studied as photodynamic therapy drugs, and show good efficacy *in vitro*.[3] Meyerhoff and co-workers reported that poly(vinyl chloride) membrane electrodes impregnated with tin porphyrins display excellent but unexplained selectivity for salicylate over various other anions.[4,5] The determination of salicylate in blood and urine is an important measurement for patients undergoing aspirin therapy. The complexes of water-soluble synthetic porphyrins such as tetrakis(N-methyl-4-pyridyl)porphyrin were studied as possible solar energy capture agents.[6] Lastly, the favourable chemical and spectroscopic properties of tin(IV) porphyrins enable the study of metal–ligand interactions and electronic effects of porphyrin substituents. An understanding of these properties should be useful in extending the uses of these complexes.

Previous investigations have generated an NMR and electronic absorption spectroscopic *cis*-influence series for a number of anionic axial ligands, especially O-donors.[7] A preliminary report suggested the use of the formato ligand as an NMR probe of *trans*-influences,[8] while the instructional value of these complexes has also been pointed out.[9] We now report the results of studies of a series of formato complexes, Sn(TPP)(OCOH)X (Table 1), which yield the *trans*-influence data and allow the comparison of *cis*- and *trans*-influences in the same series.

RESULTS AND DISCUSSION

Preparations of complexes

The most general method for the preparation of tin(IV) porphyrins with identical axial ligands, Sn(TPP)X_2, is the acidolysis of Sn(TPP)$(OH)_2$

* For Part II, see ref. 7.

[d] Literature value.[8]

with excess HX.[8,9] Reactions are rapid and quantitative even with carboxylic acids and phenols. The corresponding reaction of the mixed complex Sn(TPP)(OCOH)(OH) with one equivalent of HX, was investigated as a route to the required complexes Sn(TPP)(OCOH)X. Since the complex Sn(TPP)(OCOH)(OH) is always contaminated with the symmetrization products $Sn(TPP)(OCOH)_2$ and $Sn(TPP)(OH)_2$, the resulting product will likewise be contaminated with the diformato species and $Sn(TPP)X_2$. In any case, redistribution will occur to give more or less of these complexes. These will be the only three complexes present as long as (i) acidolysis is fast and (ii) only OH groups are protonated and displaced by X^-. This method was found to be satisfactory for the carboxylic acids, which could be added as solutions in CH_2Cl_2 or $CHCl_3$, and complexes **6**, **8** and **12** were prepared by this route.

When stronger acids (eg. HNO_3, HCl, HBr) were used as aqueous solutions in a two-phase reaction, the other two possible products, $Sn(TPP)(OH)_2$ and Sn(TPP)(OH)X, were also found as products. This could be due to either incomplete reaction with the dihydroxo complex or displacement of formic acid rather than water because of locally distorted stoichiometric ratios at the water–CH_2Cl_2 interface. The presence of five complexes in such cases was considered undesirable, so this method was subsequently abandoned. A cleaner method applicable to all species is the redistribution reaction between the two bis(acido) complexes

$$Sn(TPP)(OCOH)_2 + Sn(TPP)X_2 \rightleftharpoons 2Sn(TPP)(OCOH)X.$$

The extents and rates of these reactions varied considerably with the ligand X. More rigorous studies will be required before the significance of such variation can be determined. The redistribution reaction makes it virtually impossible to purify the mixed complexes, as the latter are usually the most soluble components in the mixtures. Since the complexes of interest in this study give unmistakable NMR spectra, the mixtures are just as suitable as the pure complexes for our purposes, provided there is no exchange broadening nor any extreme concentration dependence (see below).

NMR spectra (*Table* 1)

General

The formate resonances of the mixed complexes were easily assigned in all cases, since the diformato

complex (**5**) was present in all samples. Comparison of peak heights and knowledge of chemical shift trends enabled assignment of the β-pyrrole resonances. In some cases, there was severe overlap of β-pyrrole peaks and/or satellites, making measurements of ^4J(Sn—H) difficult or impossible (eg. in **7** and **9**). Other axial ligand resonances were assigned by expected coupling patterns, peak heights, and comparison with pure samples of Sn(TPP)X_2 complexes.[7-10]

Concentration effects on chemical shifts and coupling constants were assessed by observing the signals due to the diformato complex. Over all the mixed samples, the range was 2.65–2.75 ppm, while pure samples of **5** gave a chemical shift of 2.75 ppm at 0.1 M and 2.63 ppm at 0.01 M. Comparisons of peak heights and known starting concentrations gave approximate values for the concentration of **5** in the mixed samples, but these showed extreme scatter when plotted against the chemical shift. The conclusion must therefore be that specific intermolecular effects are blurring the concentration dependence of this shift. As there are no apparent line broadening effects, this is presumably not a shift due to chemical exchange. Since the individual concentrations of the various species in each mixture are uncontrollable because of variations in equilibrium constants, the quoted shifts must be regarded as precise to only *ca* ±0.05 ppm. The extreme values of the ^3J(Sn—H) values for **5** were 42.6 and 43.2 Hz (average of ^{119}Sn and ^{117}Sn coupling constants), so concentration and ligand specific effects on the coupling constants appear to be of less significance, and the precision is *ca* ±0.2 Hz. The chemical shifts of the β-pyrrole protons also show a concentration dependence, for example, for **5**, $\delta = 9.33$ at 0.1 M and 9.24 at 0.01 M. This explains the small discrepancies between the present data and those reported previously,[7,8] the latter having been recorded at concentrations less than 0.02 M. Concentration effects on porphyrin chemical shifts are well known.[11]

The trans-*influence*

The *trans*-influence gives a relative estimate of the ability of a ligand to weaken the bond *trans* to itself in the ground-state of a complex.[12] In this series, the relative strengths of the tin–formate bonds are being studied. The *trans*-influence of a ligand can be examined by considering the chemical shift of the formate proton and the coupling constant ^3J(Sn—H). There is a strong correlation between these two parameters (Fig. 1, $r = 0.986$). It should be noted that the coordination of carboxylate anions to tin(IV) porphyrins is unidentate.

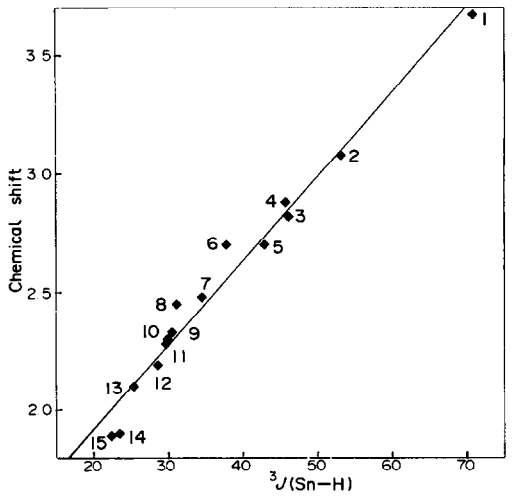

Fig. 1. Plot of chemical shift (δ, ppm) of the formate protons vs ^3J(Sn—H) (Hz) for Sn(TPP)(OCOH)X complexes. Numbering as in Table 1.

This has been shown by IR spectra[13] and crystal structures.[10] The chemical shift presumably reflects the electron density at the nucleus of the formate proton, effects of *trans* ligands being transmitted by contact interactions through the σ-bonds of the Sn—O—C(O)—H fragment. Lengthening of the Sn—O bond (reflecting a strong *trans*-influence of X) might be expected to shift the formate signal downfield, as it would reside on average farther out in the shielding zone of the macrocycle. Clearly this is outweighed by the electronic effects. There is a limit to such lengthening, but bases stronger than methoxide would be required to probe any curvature in Fig. 1. The determination of bond distances in mixed complexes may prove impossible as they cannot be crystallized pure, so the relative magnitudes of these effects may not be assessable. Because of the relationship between δ_H and ^3J(Sn—H), discussion of the reasons for the *trans*-influence order will be confined from now on to the coupling constants, as these enable more precise comparison with *cis*-influences.

The coupling constant ^3J(Sn—H) is quite sensitive to changes in the *trans* ligand, varying from 22.4 to 70.8 Hz. Figure 2 shows the relationship between ^3J(Sn—H) and the pK_a of the conjugate acid of the ligand X.[14-16] The O-bound ligands and thiocyanate yield a fair correlation ($r = -0.940$), while the halides are quite different and appear to fit on another line of near-zero slope. The behaviour of the O-bound ligands appears to be broadly explicable in terms of the proton basicity of X^-. It has been assumed that the triflate ion is coordinated to the tin atom in complex **1**. The Sn(TPP) complexes containing triflate or perchlorate have very

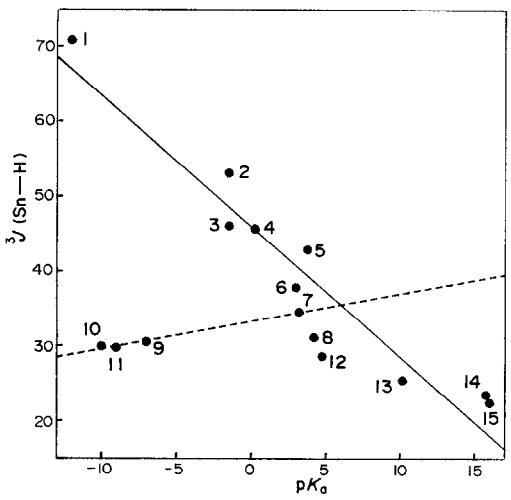

Fig. 2. Dependence of ^3J(Sn—H) (Hz) for formate protons in Sn(TPP)(OCOH)X complexes on the pK_a of the conjugate acids HX. Numbering as in Table 1. Solid line: linear regression for O-ligands; dashed line: linear regression for halides.

low solubility in chloroform, while they are readily soluble in acetone and THF. This is presumably due to coordination of solvent molecules (or adventitious water), with dissociation of the weakly basic anions. No other complexes in these series exhibit such behaviour. Kadish *et al.* have reported perchlorate dissociation in electrochemical studies of similar complexes.[17] The major species giving rise to sharp NMR lines in $CDCl_3$ solutions of **1** does seem to be the "covalent" form, since the chemical shifts and coupling constants fit in with other O-bound ligands for a pK_a of -12 rather than -1.74 as would be expected for X = H_2O. Slow crystallization of the bis(triflate) complex led, on the other hand, to the bis(aqua) salt.[10] In the present study, we could not obtain the data for the mixed formato/perchlorato complex because of dissociation and consequent precipitation.

The σ-bonding capacity of the ligands (as reflected by their donor strength to the proton) is probably the dominant factor for the first row donors. In fact, fluoride and N-bound thiocyanate also fit well with the trend shown by the O-donors. There are some notable deviations. The most surprising is the large difference between formate (**5**) and acetate (**12**). Complex **12** was prepared by both methods described above, with identical results. The scatter exhibited by the O-bound ligands is such that there are some less obvious effects at work, but the reasons for the formate/acetate discrepancy are particularly elusive. The difference between these ligands is apparent not only in the formate and β-pyrrole signals, but also in the acetate signals. The methyl group appears at -0.88 ppm in **12** and at -0.99 ppm in Sn(TPP)$(OCOCH_3)_2$, a shift consistent with that shown by the other protons.

The halides clearly exhibit very different effects from the O-donors. This is the first series of tin(IV) porphyrins examined by NMR which includes (i) all the halides and (ii) a range of O-ligands which spans such a spectrum of donor strengths. Gouterman *et al.* studied excited-state properties of the dihalo complexes of electron-rich porphyrins,[18] while other reports have examined more restricted sets of ligands.[7,17,19] The *trans* bond weakening abilities of Cl^-, Br^- and I^- are much greater than their proton basicity would suggest. This is not surprising since they possess unfilled *d*-orbitals available for π-backbonding from the filled tin d_{z^2} orbital, or molecular orbitals derived from it. However, the similarity of the coupling constants (and chemical shifts) for **9**, **10** and **11** argues that π-donation from filled p_π ligand orbitals to empty p_π and d_π orbitals on Sn is also important. The exact energies of the various orbitals will control the interplay of these effects. The ability of the TPP ligand to act as a π-acceptor presumably "softens" the tin centre (ie. it is very unlike a hard Sn^{4+} ion), and hence relatively strong interactions would be expected for the softer halides Br and I.

The cis-*influence vs the* trans-*influence*

These two effects can now be assessed *in the one series* of complexes Sn(TPP)(OCOH)X, by comparing ^4J(Sn—H) (β-pyrroles) with ^3J(Sn—H) (formates). The chemical shifts could also be used, but suffer from the concentration effects noted above. Unfortunately, the changes in the former coupling constants are rather small compared with their precision. Figure 3 shows this comparison, and the clustering of values around *ca* 15.5 Hz is apparent. There is a broad trend, although the correlation is not well defined. Greater sensitivity would be possible by using ^4J(Sn—H) in the series Sn(TPP)X_2, as the range of values is wider, but this is not a valid comparison, since the *trans*-interactions of the X ligands may be convoluted with the *cis*-influences. Figure 3 does show that the two influences are generally in the *same direction*, which is not necessarily the case for other complexes, for example, in various platinum(II) alkylbis(tertiary phosphine) and similar complexes, the two influences are often in opposite directions.[20] This implies that a ligand which weakens the *trans* Sn—O bond also weakens the bonding in the porphyrin plane, presumably by placing a higher demand on the electrons of the tin atom. The quantities being mea-

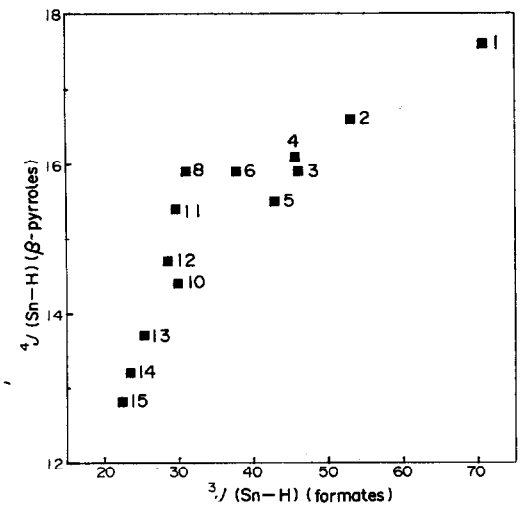

Fig. 3. Relationship between ^4J(Sn—H) (Hz) for the β-pyrrole protons and ^4J(Sn—H) (Hz) for the formate protons in Sn(TPP)(OCOH)X complexes. Numbering as in Table 1. The data for complexes **7** and **9** are missing because of peak overlap.

sured, ie. tin–proton coupling constants, are intrinsically dependent only on *s* orbital electron density or the *s* character of relevant molecular orbitals, since these are the only orbitals with non-zero coefficients at the nuclei.[12] However, it is clear from these data that π-effects are transmissible through the tin–porphyrin and tin–formate bonding orbitals, and can be felt at the β-pyrrole and formate proton nuclei.

In summary, the two series Sn(TPP)X_2[7] and Sn(TPP)(OCOH)X have demonstrated the utility of NMR chemical shifts and metal–proton coupling constants in probing metal–ligand binding. Further studies are now required to relate these ground state effects to data such as redistribution and ligand substitution equilibrium constants.

EXPERIMENTAL

General

Instruments were as described previously.[7] Chloroform was distilled from anhydrous Na_2CO_3. Other solvents, acids, etc., were A.R. or "zur Synthese" grade. Starting materials (Sn(TPP)$(OH)_2$, Sn(TPP)(OCOH)(OH), and various Sn(TPP)X_2 complexes) were available from previous studies.[7,8] The preparations and crystal structures of Sn(TPP)$(OSO_2CF_3)_2$, Sn(TPP)$(OCOC_6H_5)_2$ and Sn(TPP)$(OCOC_6H_4$-*o*-$OH)_2$ will be described elsewhere.[10]

Preparation of new Sn(TPP)X_2 *complexes*

X = F. A solution of Sn(TPP)$(OH)_2$ (38 mg, 0.05 mmol) in CH_2Cl_2 (20 cm^3) was shaken in a separating funnel with aqueous HF (1 M, 5 cm^3) for 30 min. The organic layer was separated, dried over anhydrous Na_2SO_4 and the solvent was evaporated. The residue was recrystallized from CH_2Cl_2–hexane to yield shiny purple prisms (31 mg, 80%). (Found: C, 68.8; H, 3.6; N, 7.3. $C_{44}H_{28}F_2N_4Sn$ requires: C, 68.7; H, 3.7; N, 7.3%); δ_H *ca* 7.8 (m, *meta-*, *para*-H), *ca* 8.4 (m, *ortho*-H) and 9.24 (s, β-pyrrole, ^4J(Sn—H) 14.9 Hz); λ_{max} ($\varepsilon \times 10^{-3}$) ($CHCl_3$) 419 (695), 514 (3.5), 553 (24.4) and 591 (9.8) nm.

X = $OCOCF_3$. Trifluoroacetic acid (3.1×10^{-2} cm^3, 0.4 mmol) was added dropwise with stirring to a solution of Sn(TPP)$(OH)_2$ (77 mg, 0.1 mmol) in CH_2Cl_2 (10 cm^3). After 15 min, the solution was dried over anhydrous Na_2SO_4 and the solvent was evaporated. The residue was recrystallized from CH_2Cl_2–hexane to yield sparkling purple prisms (52 mg, 54%). (Found: C, 61.1; H, 2.9; N, 5.7. $C_{48}H_{28}F_6N_4O_4Sn$ requires: C, 60.2; H, 3.0; N, 5.9%); δ_H *ca* 7.8 (m, *meta-*, *para*-H), *ca* 8.3 (m, *ortho*-H) and 9.25 (s, β-pyrrole, ^4J(Sn—H) 16.9 Hz); λ_{max} ($\varepsilon \times 10^{-3}$) ($CHCl_3$) 420 (622), 514 (3.4), 553 (23.1) and 592 (8.3) nm; ν_{max} (KBr) 1718, 1202, 1174 and 1148 (all vs) cm^{-1} ($OCOCF_3$).

Preparations of Sn(TPP)(OCOH)X *complexes*

(a) *By acidolysis of* Sn(TPP)(OCOH)(OH). A solution of the acid HX (one equivalent) in CH_2Cl_2 was added dropwise to a solution of Sn(TPP)(OCOH)(OH) (38 mg, 0.05 mmol) in CH_2Cl_2 (5 cm^3). After stirring for 30 min, the solution was filtered through anhydrous Na_2SO_4, and the solvent was evaporated. The vacuum-dried residue was dissolved in $CDCl_3$ (0.5 cm^3) and filtered into an NMR tube.

(b) *By redistribution of* Sn(TPP)$(OCOH)_2$ *and* Sn(TPP)X_2. Equimolar amounts of the two complexes (0.01–0.025 mmol) were separately dissolved in $CDCl_3$, mixed, filtered into an NMR tube, and the volume was made up to *ca* 0.5 cm^3. In this way, the *total* Sn(TPP) concentration was in the range 0.02–0.1 M. The reactions were monitored by NMR until no further change was apparent.

(*Received* 13 *November* 1989; *accepted* 26 *February* 1990)

Abstract—PPN salts of $[SiCl_3(PPh_3)Fe(CO)_3]^-$ (I) and $[SiCl_3\{P(OPh)_3\}Fe(CO)_3]^-$ (II) have been prepared by literature procedures from the hydride precursors. Each crystallizes in the monoclinic space group $P2_1/c$ with the following respective unit cell constants: I, $a = 16.087(3)$, $b = 15.334(2)$, $c = 22.804(2)$ Å, $\beta = 109.45(1)°$, $V = 5304.0(1)$ Å^3, $Z = 4$; II, $a = 18.623(3)$, $b = 13.449(6)$, $c = 23.447(6)$ Å, $\beta = 109.91(2)°$, $V = 5528.8(1)$ Å^3, $Z = 4$. Both anions are trigonal bipyramidal with the silicon and phosphorus ligands in the axial positions.

Hydridophosphine-and-phosphite iron tricarbonyl anions were synthesized recently. Crystal structure determination showed that in $[H(PPh_3)Fe(CO)_3]^-$ the hydrido and phosphine ligands are *trans*, while in $[H\{P(OPh)_3\}Fe(CO)_3]^-$ the hydrido and phosphite ligands are *cis*.[1,2] By contrast, we report here the structures of the trichlorosilyltriphenylphosphine and trichlorosilyltriphenylphosphite iron carbonyl anions, I and II, both of which are *trans* in the solid state.

EXPERIMENTAL

Standard vacuum line techniques were used throughout. All solvents were dried and deaerated prior to use.

Photochemical preparation of the hydride precursor of I has been reported.[3] The precursor to II, OC-6-23-$H(SiCl_3)\{P(OPh)_3\}Fe(CO)_3$, was prepared similarly. Tetracarbonylirontriphenylphosphite (5.0 g, 10.4 mmol) was dissolved in 200 cm^3 of hexane along with 4 cm^3 of trichlorosilane (excess). Photolysis of this mixture in a glass Schlenk tube with a 150 W mercury lamp for 2 h gave a cloudy red solution. This solution was filtered and reduced to 50 cm^3 by evaporation. The resulting solution was stored at −15°C for several weeks and 2.0 g (3.4 mmol) of product (33%) crystallized out. Found: C, 43.3; H, 3.0. Calc.: C, 43.1; H, 2.8%. NMR ^{1}H (300 MHz) Fe—H −8.9 ppm (d) $^2J_{P-H}$ 36 Hz; $^{13}C\{H\}$ (75.4 MHz) 204.7 ppm (d), $^2J_{P-C}$ 26 Hz *axial CO*, 203.7 ppm (d), $^2J_{P-C}$ 13 Hz *equatorial CO* (axial and equatorial CO assignments are based on the 2:1 intensity ratio); $^{31}P\{H\}$ (121.4 MHz) 160 ppm; $^{29}Si\{H\}$ (59.6 MHz) 54.6 ppm (d), $^2J_{P-Si}$ 95 Hz; m.p. 75°C; $\bar{\nu}$(CO) (hexane) 2085 (w), 2050 (sh), 2040 (s) cm^{-1}.

PPN salts I and II were prepared from their hydride precursors by treating the hydride with PPNCl and sparging the solution with argon until the reaction was complete. In a typical experiment 1.2 g (2.05 mmol) of $H(SiCl_3)\{P(OPh_3)\}Fe(CO)_3$

was dissolved in 30 cm^3 of methylene chloride along with a 20% excess of PPNCl in a Schlenk tube under argon. Argon was bubbled through the solution and the solvent was replenished periodically. The reaction was worked-up when the carbonyl bands of the starting material (*vide supra*) were replaced by the 1875 cm^{-1} band of **II** (1 h in this experiment). Work-up was accomplished by cannulating 30 cm^3 of hexane onto the reaction mixture, causing the ionic materials to precipitate. After removal of the liquid, 50 cm^3 of THF was added and the resulting cloudy solution was filtered through celite. The product was then precipitated from solution by addition of 50 cm^3 of hexane. In this way 1.8 g (1.6 mmol) of **II** were obtained (78%).

Preparation of **I** this way gave only a 39% yield since it was necessary to repeat the solution–precipitation cycle several times. Crystals were grown by diffusing gaseous hexane into a methylene chloride solution of the salts.

Data for the PPN salts are as follows. **I**, Found: C, 62.6; H, 4.5. Calc.: C, 63.5; H, 4.5%. **II**, Found: C, 60.4; H, 4.2. Calc.: C, 60.9; H, 4.0%. NMR $^{13}C\{H\}$: **I**, 214.9 ppm (d), $^2J_{P-C}$ 23.4 Hz; **II**, 211 ppm (broad); $^{31}P\{H\}$: **I**, 81.5 ppm; **II**, 187 ppm (broad). $\bar{\nu}$(CO) (CH_2Cl_2): **I**, 1850; **II**, 1875 cm^{-1}.

The structures were determined by X-ray crystallography according to procedures already described.[4]*

A small crystal of **I** or **II** was mounted in a glass capillary and the capillary was then mounted on the goniometer head of a CAD-4 diffractometer. Preliminary examination showed the space group to be $P2_1/c$ and data collection was carried out in each case as indicated in Table 1. Phenyl groups were refined isotropically, the other atoms were refined anisotropically.

RESULTS AND DISCUSSION

ORTEP diagrams for anions **I** and **II** are shown in Fig. 1 and the relevant bond lengths and angles are listed in Table 2. The PPN structures are unexceptional and the cation is well separated from the anion in both **I** and **II**. The Fe—Si bond lengths of

* Supplementary material available: tables of atomic coordinates, thermal parameters, and bond lengths and angles have been deposited with the Director, Cambridge Crystallographic Centre.

Table 2. Selected bond lengths and angles for I and II

	I	II
Bond lengths		
Fe—P	2.207(3)	2.121(4)
Fe—Si	2.197(3)	2.206(4)
Fe—C(1)	1.754(8)	1.73(1)
Fe—C(2)	1.765(7)	1.70(1)
Fe—C(3)	1.744(8)	1.76(1)
C(1)—O(1)	1.17(1)	1.21(2)
C(2)—O(2)	1.53(9)	1.21(2)
C(3)—O(3)	1.17(1)	1.14(2)
Bond angles		
P—Fe—Si	174.19(9)	173.7(1)
P—Fe—C(1)	92.7(3)	95.4(4)
P—Fe—C(2)	97.1(3)	96.1(4)
P—Fe—C(3)	89.9(3)	88.6(5)
Si—Fe—C(1)	86.9(3)	88.2(4)
Si—Fe—C(2)	88.2(3)	86.9(4)
Si—Fe—C(3)	85.3(4)	85.2(5)
C(1)—Fe—C(2)	117.3(4)	125.7(8)
C(1)—Fe—C(3)	120.5(3)	115.0(6)
C(2)—Fe—C(3)	121.3(3)	118.3(8)

I and II are comparable to the value of 2.224(9) Å reported for $[SiCl_3Fe(CO)_4]^-$, the Fe—C bond lengths of I and II are similar to the value of 1.75(4) Å reported for $[HFe(CO)_4]^-$ [6] and the Fe—P bond length in I is longer than the value of 2.187(1) Å reported for $[H(PPh_3)Fe(CO)_3]^-$.[1] It is reasonable to assume that the *trans*-$SiCl_3$ group has a greater share in the π-electron density along the z-axis in I than the hydrogen atom does in $[H(PPh_3)Fe(CO)_3]^-$. Therefore, the Fe—P π-bond will be weaker in I and it is to be expected that the Fe—P distance in I will be longer. In II, both the range of C—O bond lengths and the unexpectedly large C(1)—Fe—C(2) bond angle indicate a greater distortion from the ideal trigonal bipyramidal configuration than in I. That is probably due to the location of the phenyl groups. From the figure it can be seen that the plane of each phenyl group in I nearly bisects the CO—Fe—CO angle directly above it. This is reflected in an oxygen to nearest phenyl carbon distance of 3.8 ± 0.3 Å for each carbonyl oxygen. In the case of anion II, two of the phenoxy-phenyl groups are directed toward the iron–carbonyl plane, while the third one is directed away from it. Therefore in II the shortest carbonyl-oxygen to phenyl-carbon distances are (respectively) O(1): 6.8 Å, O(2): 3.3 Å and O(3): 3.6 Å.

These structures (I and II) do not show the remarkable *trans*-to-*cis* configuration change which has been observed with $[H(PPh_3)Fe(CO)_3]^-$ and $[H\{P(OPh)_3\}Fe(CO)_3]^-$. Since the trichlorosilyl group differs from the hydrido group both sterically and electronically, it is not possible to determine at this point what causes these structural differences.

Solution IR measurements on both I and II show only a single intense band in the carbonyl region, consistent with approximate C_{3v} symmetry in solution as well as in the solid state. The broad NMR signals observed for II, which are not due to paramagnetic impurities since the cation signals in this solution are sharp, indicate the occurrence of a rearrangement which is slow on the NMR time scale. Investigation of the nature of this rearrangement process is planned.

(*Received* 29 *January* 1990; *accepted* 1 *March* 1990)

Abstract—The structure determination of $[Ni(S_2COC_6H_{11})_2(PMePh_2)]$ shows the presence of one asymmetrically coordinating O-cyclohexylxanthate ligand in this complex, which presents a distorted square-pyramidal geometry.

We have previously studied the behaviour of O-alkyldithiocarbonato complexes, $[Ni(S_2COR)]_2$, towards several phosphines.[1] Depending on the S_2COR derivative (xanthate) and phosphine used, complexes with different stoichiometries and geometries have been obtained. The reaction of $[Ni(S_2COC_6H_{11})]_2$ with $PMePh_2$ gives a dark brown compound, $[Ni(S_2COC_6H_{11})_2(PMePh_2)]$, with IR spectroscopic and magnetic properties similar to those found for square-planar complexes of palladium(II) and platinum(II). These compounds contain mono- and bidentate xanthate ligands. Since this type of complex had not been reported for nickel, it was important to determine its crystal structure.

Figure 1 shows the geometry of the structure and the atom labelling of the title complex. The structure† consists of individual molecules of the title compound held together by van der Waals' forces. The structure determination confirms the stoichiometry of the complex but shows that the nickel atom is five-coordinated in a distorted square-pyramidal geometry, in which the four atoms, S(1), S(2), S(3) and P, describe an approximate basal plane and the apical position is occupied by the S(4) atom from an asymmetrically coordinating xanthate ligand. The nickel atom exhibits a deviation from the basal plane of −0.1455 Å.

† Crystal data: $C_{27}H_{35}NiO_2PS_4$, M = 609.496, triclinic, space group $P\bar{1}$, with $a = 9.704(3)$, $b = 10.733(1)$, $c = 14.533(2)$ Å; $\alpha = 81.94(12)$, $\beta = 79.00(23)$, $\gamma = 84.65(6)°$; $U = 146.7$ Å^3, $Z = 2$, $D_c = 1.35$ g cm^{-3}; μ(Mo-K_α) = 7.49 cm^{-1}, $F(000) = 640$. A total of 4154 unique reflections were measured in the range $0 < \theta < 26$ on an Enraf–Nonius CAD 4 diffractometer using ω–2θ scans and Mo-K_α radiation ($\lambda = 0.71069$ Å); 2708 reflections were considered observed [$I < 2\sigma(I)$] after data reduction, and used in subsequent calculations. The structure was solved by Patterson and Fourier techniques and refined by full-matrix least-squares procedures in the XRAY 80 system to $R = 0.033$ and $R_w = 0.032$. The hydrogen atoms were refined with fixed atomic coordinates and isotropic temperature factors.

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited with the Cambridge Crystallographic Data Centre.

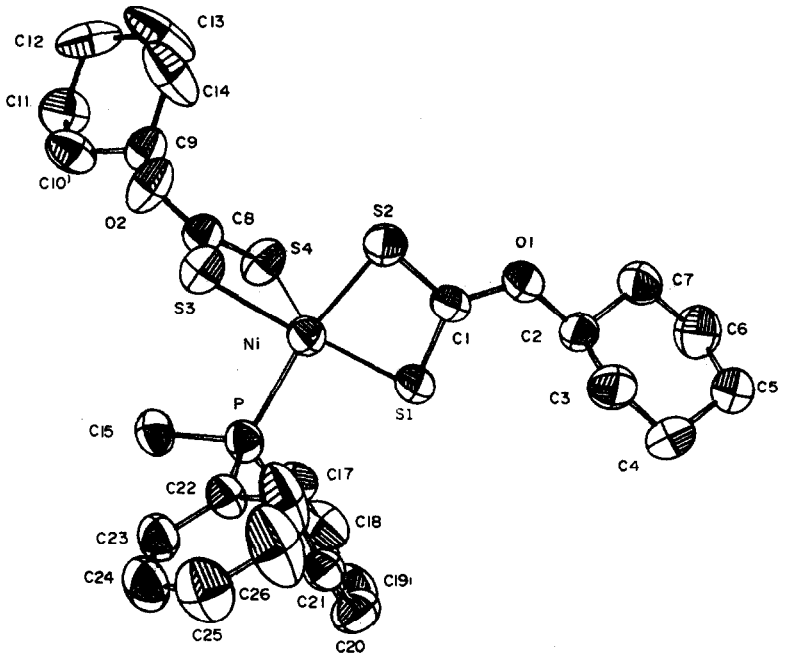

Fig. 1. ORTEP perspective of $[Ni(S_2COC_6H_{11})_2(PMePh_2)]$, showing the atom numbering scheme. Important bond distances and angles:

Bond distances (Å)

Ni—P	2.1746(23)	C(1)—S(1)	1.6826(55)
Ni—S(1)	2.2099(18)	C(8)—S(3)	1.7085(53)
Ni—S(2)	2.2441(27)	C(8)—S(4)	1.6570(44)
Ni—S(3)	2.2221(20)	O(1)—C(1)	1.3312(54)
Ni—S(4)	2.7223(43)	O(2)—C(8)	1.3267(53)
C(1)—S(2)	1.6645(43)		

Bond angles (°)

S(1)—Ni—S(2)	78.14(29)	C(1)—O(1)—C(2)	119.79(59)
S(3)—Ni—S(4)	71.92(27)	C(8)—O(2)—C(9)	120.75(82)

In the complex, the two xanthates are chelate ligands, however, one of the ligands presents gross asymmetry in its sulphur–nickel bonding, e.g. Ni—S(3) = 2.2221(20) and Ni—S(4) = 2.7223(43) Å, compared to the near equivalence of the Ni—S bonds, Ni—S(1) = 2.2099(18) and Ni—S(2) = 2.2441(27) Å in the second xanthate.

In the transition metal compounds, the asymmetric xanthate coordination occurs infrequently. To date, this type of coordination has only been described for the complex $[Ni(S_2COEt)_2(PPh_3)]$.[2] A comparison of the Ni—S distances in both complexes indicates a higher asymmetry in the O-cyclohexylxanthate ligand of the complex reported by us. In the platinum(II) complexes of analogous stoichiometry, $[Pt(S_2CNEt)_2(PPh_3)]$, the Pt—S(4) = 3.457 Å distance shows clearly the existence of a monodentate dithiocarbamate.[3] On the other hand, the bond lengths and angles are different in the complex studied in this work with respect to those found in the $[Ni(\eta^5\text{-}C_5H_5)(S_2COEt)(PPh_3)]$ complex, which contains one monodentate xanthate.[4]

The Ni—P distance of 2.1746(23) Å lies in the range 2.16–2.24 Å found in other related systems.[2,4,5]

The structure solution leads to an explanation of the reported IR spectroscopic and magnetic data.[1] Thus, the compound is a five-coordinated complex of low spin, in which the two IR ν(C—OR) vibrations observed (1275 and 1190 cm^{-1}) are consistent with the two different modes of coordination exhibited by the xanthate ligands.

We are currently investigating other five-coordinated nickel complexes.

7. CONCLUSIONS 1360

1. INTRODUCTION

Although the well-known Grignard reagents (RMgX) are perhaps the most widely used of any organometallic species in the modern synthetic laboratory, their heavier Group II analogues, compounds of calcium, strontium and barium, have until very recently languished in the backwaters of organometallic chemistry. First described in 1905 by Beckman,[1] the dialkyls and alkyl halides of the heavy alkaline-earth metals were studied by Gilman and his co-workers from the mid-1920s through the mid-1940s with a view toward developing more active versions of Grignard reagents.[2] These investigations were generally disappointing, as many of the compounds prepared were therm-

ally unstable and either insoluble or only slightly soluble in organic media. Their difficult synthesis and apparently limited usefulness provided little incentive to develop and refine their chemistry.

Despite the impetus given to the field of inorganic chemistry by the discovery of ferrocene in the early 1950s, progress with organoalkaline-earth complexes remained slow. Cp_2Ca was described in 1956,[3] and the strontium and barium analogues followed in 1961,[4] but the metallocenes were not easy to obtain [e.g. Cp_2Ba was only available through a high-temperature synthesis which provided a yield of 0.2%(!)]. Not until 1974 was the solid state structure of Cp_2Ca published,[5] and it remained the only structurally characterized heavy organoalkaline-earth compound until the gas-phase structure of $(Me_5C_5)_2Ca$ was reported in 1986.[6] With a fair degree of accuracy, an inorganic chemistry textbook summarized the state of the field in 1980 with the observation that "the organic compounds of calcium, strontium and barium are relatively obscure and of little utility . . .".[7]

With increased understanding of the principles required to synthesize and manipulate the compounds of these large, electropositive metals, this situation is now rapidly changing, and the organometallic chemistry of calcium, strontium and barium is poised for considerable expansion in the coming years as the distinctive attributes of these compounds become more accessible and appreciated. The area was last comprehensively surveyed in 1982,[8] although several earlier reviews are available.[9,10] This Report will concentrate on developments in the area since 1982. As the organometallic chemistry of magnesium and beryllium differs considerably from that of the heavier metals, their compounds will not be explicitly covered here, except where useful comparisons can be made.

2. DISTINCTIVENESS OF THE HEAVY ALKALINE-EARTH METALS

2.1. *Properties of the divalent ions*

In retrospect, one of the most serious impediments to the development of organoalkaline-earth chemistry was the expectation that the behaviour of calcium, strontium and barium compounds should parallel that of their organomagnesium counterparts. Attempts dating from the turn of the century to prepare synthetically useful "pseudo-Grignard reagents", RAeX (R = Me, Et, etc.; Ae = Ca, Sr, Ba; X = Cl, Br, I) from the Ae metals were repeatedly frustrated by their low solubility and poor stability, and the production of Wurtz-coupled species during their synthesis.[11]

Many of the observed differences in reactivity can be traced to the small size of the Mg^{2+} ion (0.72 Å) relative to that of the other Ae cations [1.00 Å (Ca^{2+})–1.35 Å (Ba^{2+})].[12] The consequences of this are at least two-fold. To begin with, the lower charge/size ratios of Ca^{2+}, Sr^{2+} and Ba^{2+} suggest that their compounds will be even more ionic than those of Mg^{2+}. With little or no orbital involvement from their $ns^0(n-1)d^0$ cores, kinetic lability and the possibility of ligand loss will be high. Secondly, the small ligands such as methyl or ethyl which are typically found in Grignard reagents will leave the large Ae cations coordinatively unsaturated. As has been frequently observed in organolanthanide and actinide chemistry, the lack of steric saturation can lead to irreversible oligomerization or decomposition of compounds (e.g. via hydrogen abstraction reactions).[13–15] Evidence of such coordinative unsaturation in an Ae complex is provided by the solid-state structure of Cp_2Ca; unlike the monomeric sandwich geometry possessed by Cp_2Mg,[16] Cp_2Ca is an insoluble, polymeric solid, in which each calcium ion is surrounded by various bridging cyclopentadienyl rings [see Section 4.1(a)].[5]

As will be examined in more detail below, the use of large, sterically bulky ligands has allowed the preparation of a wide range of thermally stable, hydrocarbon-soluble complexes.

2.2. *Comparisons with the lanthanide elements*

Although the chemistry of the heavy alkaline-earth elements was originally developed along the lines established by organomagnesium compounds, a compelling case can be made that a natural relationship exists between calcium, strontium and barium and the *f*-elements, especially with the divalent lanthanide ions.[15] The alkaline-earth, lanthanide and actinide families of metals are large

and highly electropositive, and the similarity in radii between Ca^{2+} and Yb^{2+} (1.00 and 1.02 Å, respectively) and between Sr^{2+} (1.22 Å) and Sm^{2+} or Eu^{2+} (1.22 and 1.21 Å, respectively)[12] is noteworthy. The restricted radial functions of the *f*-orbitals insure that they are not energetically accessible enough to participate significantly in bonding,[17] and hence organolanthanide compounds, like those of the alkaline earths, tend to be highly ionic. The similarity in size has also permitted the construction of compounds with related structures, especially among the pentamethylcyclopentadienyl derivatives (see Sections 4.1(b), 4.2). The combination of similar size and ionic bonding means that many of the problems encountered by early workers in the organolanthanide and actinide fields, including poor solubility and low volatility of compounds, are identical to those found with the organoalkaline-earth systems. For both the Ae and the *f*-element metals, the remedy was the same—the employment in complexes of large, sterically bulky ligands, which help to block open coordination sites, thus attenuating strong intermolecular interactions. Both decomposition via hydrogen-elimination pathways and the insolubility arising from polymerized materials are thus minimized.

Although instructive, the analogy with the lanthanides has limitations. Only the divalent oxidation state is readily accessible in Ae compounds, although species containing monovalent calcium and strontium have been identified in the gas phase (see Section 4.4). In contrast, oxidation states ranging from +2 to +4 and from +3 to +6 are known in organolanthanide and organoactinide complexes, respectively.[14,18] In addition, the change in ionic radii from Ca^{2+} to Ba^{2+} is approximately 35%, considerably larger than the difference between the smallest and largest trivalent lanthanides (Lu^{3+} (0.86 Å)–La^{3+} (1.03 Å); 20% change), or the nearly equally sized U^{4+} (0.89 Å) and Th^{4+} (0.94 Å) (a 6% difference).[12] In particular, Ba^{2+} is approximately 15% larger than that of the largest divalent lanthanide (Sm^{2+}). The large size differential between Ca^{2+} and Ba^{2+} significantly affects their relative Lewis acidities. The Ca^{2+} ion is the most acidic of the three Ae^{2+} species, and is observed to form more robust adducts with Lewis bases than does Ba^{2+}. This becomes of synthetic importance when removing coordinated ethers from organocalcium and -barium complexes, or when attempting to isolate organobarium adducts of particularly weak bases, such as unsaturated hydrocarbons (see Section 4.1(d).3).

A further difference between the chemistry of the alkaline-earth metals and that of the *f*-elements is that the noble gas configuration of the Ca^{2+}, Sr^{2+} and Ba^{2+} cations insures that nearly all of their compounds will be diamagnetic, and therefore easily studied by NMR spectroscopy. In contrast, with the exception of Ce^{4+}, La^{3+}, (Y^{3+}),[19] Yb^{2+}, Lu^{3+} and Th^{4+}, the paramagnetism of the majority of lanthanide and actinide ions may restrict detailed spectroscopic analysis of reaction rates and mechanisms.

Even though the comparisons which can be drawn between calcium, strontium and barium and the *f*-elements are more revealing than with magnesium, it is probably best to regard the organometallic compounds of the Ae metals as a distinct class of complexes, related to, but not identical with, their ionically-bonded neighbours.

3. SYNTHETIC APPROACHES TO ORGANOALKALINE-EARTH COMPLEXES

The traditional starting point for organoalkaline-earth chemistry has been the bulk metals, either used alone or activated by amalgamation or iodine.[8] Impurities in the common grades of calcium and the other metals have been cited as the source of some of the variability in reaction rates and yields for RAeX species,[20,21] but higher purity metals are now commercially available (up to 99.98% for calcium). Nevertheless, other synthetic methods have appeared during the period under review. Those compounds discussed elsewhere will be given only brief mention here.

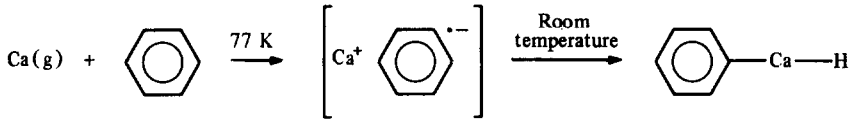
3.1. *Metal vapour methods*

The use of metal vapour methods to prepare organoalkaline-earth compounds was first described for the synthesis of solvent-free alkyl metal halides, metallocenes and bis(indenyls), for which yields were gratifyingly high ($\geq 90\%$).[11] Condensation of calcium vapour and aryl halides, ArX (Ar = C_6H_5, *o,m,p*-$(CH_3)C_6H_4$ and *o,m,p*-$(CF_3)C_6H_4$ for X = F, Cl; Ar = C_6H_5 for X = F, Cl, Br),

produces the solvent-free aryl calcium halides in 38–50% yield for all except the trifluorotolylcalcium chlorides, where the yields are < 10%.[22] Although phenylcalcium bromide and chloride have been prepared by solution methods, the metal vapour route is currently the only one to arylcalcium fluorides. Subsequent studies have extended these results to various aryldihalides, benzylhalides and β-napthylhalides, and underscored the dramatic effects of solvents and metal vapour techniques on the yields of products.[23] Thus chlorobenzene and calcium vapour produces no phenylcalcium chloride in the presence of THF, although a 42% yield is obtained in its absence.[22] Conversely, *n*-octylbromide yields the corresponding RCaBr species in 70% yield in the presence of THF, but only in 0.5% yield if toluene is used as the solvent.[23]

Condensation of calcium vapours into an excess of solvent so as to generate metal slurries, rather than adding solvents after the metal has been deposited, also affects yields. For example, when added to a slurry of calcium metal in THF, chlorobenzene produces phenylcalcium chloride in 32% yield, although, as noted above, no reaction is observed if the chlorobenzene and THF are added after the condensation of the metal.[24]

Benzene and calcium vapour will react with organic halides (RCl, RBr) to yield on work-up both phenyl-substituted products (PhR) and reduced species (RH), and with ketones (RR'CO) to yield the alcohols PhRR'COH and RR'CHOH. With benzaldehyde, Ph_2CHOH and $PhCH_2OH$ are generated.[25] Further study of this reaction with other aromatic hydrocarbons (alkylbenzenes, phenyltrimethylsilane, xylenes) has determined that the initial condensation product gives an ESR signal at −60°C, but becomes diamagnetic on warming to room temperature. Decomposition and deuteration experiments suggest that the room temperature materials are arylcalcium hydrides, formed by insertion of Ca^+ into the arene C—H bond, and it is the latter which reacts with organic halides and carbonyls, eq. (1):[26,27]



(1)

Slurries of calcium and barium prepared by co-condensation of the metal vapour with toluene at −196°C were allowed to react with various organotransition metal complexes at room temperature.[28] A number of reduced organotitanium species were identified, and a benzyl–calcium species was suggested as a product from a calcium–toluene slurry, but no organoalkaline-earth complexes were isolated.

Co-condensation of $(SiMe_3)_2C_5H_4$ and calcium, strontium or barium vapour at −196°C followed by warming to room temperature yields the base-free metallocenes $[(SiMe_3)_2C_5H_3]_2Ae$ in moderate to good yields [see Section 4.1(f)].[29]

Cyclooctatetraenyl complexes can be formed from the condensation of calcium, strontium and barium vapour with cyclooctatetraene (COT) and THF at −196°C. The cream-coloured Ae(COT)$(THF)_n$ complexes release THF on heating (see Section 4.3).[30]

Reaction of alkaline-earth metal vapours with the cyclopentadiene monomer,[31] pyrrole,[32] Me_4Sn and Me_2Hg[33] produces a variety of organometallic free radicals which have been characterized by laser excitation spectroscopy. These are discussed in Section 4.4.

3.2. *Activated metal powders*

Alkali metal reduction in organic solvents of many main group and transition metal halides will produce powders which are substantially more reactive than bulk or amalgamated metals.[34] Although the first application of this method was to magnesium,[35] only recently has an extension of the technique to the heavier alkaline-earth metals been reported.

Stirring a mixture of potassium metal and an anhydrous alkaline-earth diiodide in dry THF or toluene under nitrogen at ambient or reflux temperatures produces suspensions of black or grey powders, eq. (2):[36]

$$2K + AeX_2 \rightarrow Ae\downarrow + 2KX\downarrow. \quad (2)$$

The metal powders react with triphenylmethylchloride to generate the corresponding $Ph_3CAeCl(THF)_n$ complexes 12–16 times more rapidly than the analogous syntheses using metal amalgams.[37,38] Activated calcium powder reacts with trifluoroacetylacetone {H[TFA]} and hexafluoroacetylacetone {H[HFA]} to form the respective $Ca[TFA]_2$ and $Ca[HFA]_2$ salts in 1 h, compared to the 5 days or greater required from the use of bulk calcium and the parent acid.[39] Barium powder reacts with Cp*H in THF to produce the $Cp^*_2Ba(THF)_2$ metallocene; bulk barium, in contrast, does not react with Cp*H.[40]

3.3. *Halide metathesis*

The reaction of the anhydrous metal halides with the alkali metal salt of an organic anion in THF or ether has become one of the most extensively used methods for the preparation of organoalkaline-earth compounds; metallocenes, alkoxides and amides, among others, have been prepared via this route, eq. (3):

$$2\,RM + AeX_2 \xrightarrow{\text{ether}} R_2Ae(THF)_2\,(\text{or } RAeX) + 2\,MX\downarrow \quad (M = Li, Na, K). \tag{3}$$

With the proper systems, this method has the advantage of offering high, reproducible yields, and if the organometallic product is soluble in aromatic hydrocarbons or can be sublimed, removal of residual halides is simplified. If not, halide by-products can represent significant contamination.[41]

4. ORGANOALKALINE-EARTH COMPLEXES

4.1. *Bis(cyclopentadienyl) complexes*

The cyclopentadienyl ligand (Cp) and its substituted analogues serve organoalkaline-earth chemistry as well as they do *d*- and *f*-block organometallics, by obstructing coordination sites which might otherwise serve as sites for decomposition, by offering a range of steric bulk, and by improving the crystallinity of complexes. Not too surprisingly, the greatest increase in the number of organoalkaline-earth compounds in recent years has been with those containing Cp ligands, and most of these are derivatives of the decamethylmetallocenes, Cp^*_2Ae ($Cp^* = Me_5C_5$). The chemistry of Cp derivatives will probably continue to experience considerable growth in the coming years.

4.1(a). *Metallocenes containing unsubstituted cyclopentadienyl rings*

Although "calciocene" (Cp_2Ca), "strontiocene" (Cp_2Sr) and "bariocene" (Cp_2Ba) have been known for over 25 years and are thermally stable, only recently have the strontium and barium derivatives been available in quantities which make them more than curiosities. A metal vapour route to these compounds has been developed,[11] but they are also readily prepared by the metathetical exchange of an alkali metal cyclopentadienide with an Ae dihalide. The reaction of CaI_2 or $CaCl_2$ with two equivalents of KCp or TlCp in THF produces crude $Cp_2Ca(THF)_2$ in 75% (CaI_2) or 14% ($CaCl_2$) yield along with the alkali halide which is removed by filtration, eq. (4):[41]

$$2\,KCp + CaX_2 \xrightarrow{THF} Cp_2Ca(THF)_2 + 2\,KX\downarrow. \tag{4}$$

The lower yield from the chloride probably stems from the lower solubility of $CaCl_2$ in THF.

The insolubility of strontiocene and bariocene in ethers requires that the alkali metal halide, rather than the metallocene, be extracted from the reaction mixture. This can be accomplished by reacting lithium cyclopentadienide with the alkaline-earth metal halide; the resulting LiI is then removed with THF, eq. (5):[41]

$$2\,LiCp + AeI_2 \xrightarrow{THF} Cp_2Ae(THF)_x\downarrow + 2\,LiI \quad (Ae = Sr, Ba). \tag{5}$$

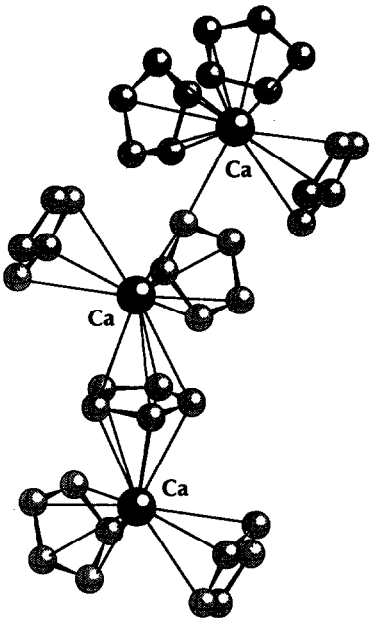


Fig. 1. A portion of the structure of Cp_2Ca, indicating the polymerized nature of the complex. Four Cp rings surround each calcium in the extended structure, displaying $2 \times \eta^5, \eta^3$ and $\eta^1(\sigma)$ coordination.

Interestingly, the strontium and barium derivatives are isolated from the reaction mixtures with less than two equivalents of THF; $x \approx 1$ for Sr and ≈ 0.25 for Ba. The size of the strontium and barium ions may preclude the formation of stable monomeric disolvated complexes, so that oligomerized structures form.

Cp_2Ca has also been prepared in 46% yield from the reaction of either $(Me_3Si)C_5H_5$ or $(Me_3Si)_2C_5H_4$ and $Ca(NH_2)_2$ in liquid ammonia, eq. (6):[42]

$$Ca(NH_2)_2 + 2(Me_3Si)_nC_5H_{6-n} \xrightarrow[-n(Me_3Si)_2NH\uparrow]{THF,\ NH_{3(l)}} Cp_2Ca(THF)_2 \qquad (6)$$

$$(n = 1, 2).$$

All of the metallocenes exhibit well-resolved ^1H and ^{13}C NMR spectra, with highly solvent-dependent chemical shifts. Ring exchange occurs between Cp_2Ca and KCp in THF.[41]

Some of the reactions of Cp_2Ca with nitrogen and oxygen donors have been examined,[43] and the oligomeric nature of the unsolvated complex has been established by X-ray crystallography (Fig. 1).[5] The low volatility and the insolubility of the strontium and barium analogues in any but the most polar liquids (DMSO, HMPA) has made their chemistry difficult to study.

4.1(b). *Decamethylmetallocenes*

The increase in steric bulk provided by the Cp* ring greatly improves the solubility, volatility and kinetic stability of its associated compounds. All three Cp^*_2Ae complexes have been prepared in > 65% yield from the reaction of sodium or potassium pentamethylcyclopentadienide and the metal diiodides in THF or ether, eq. (7):[41,44]

$$2(Na, K)Cp^* + AeI_2 \xrightarrow{ether} Cp^*_2Ae(ether)_2 + 2(Na, K)I\downarrow. \qquad (7)$$

An alternate preparation of Cp^*_2Ba, although in lower yield, is from finely divided metal powders and the diene (see Section 3.2).

Cp^*_2Ca has been prepared in moderate yield from the reaction of Cp*H and $Ca(NH_2)_2$ in liquid ammonia, eq. (8):[42]

$$Ca(NH_2)_2 + 2\,Cp^*H \xrightarrow{THF,\ NH_{3(l)}} Cp^*_2Ca(THF)_2 \quad (48\%). \qquad (8)$$

The THF can be displaced from $Cp^*_2Ca(THF)_2$ by dissolution in DME to yield the $Cp^*_2Ca(DME)$ solvate,[42] although complete removal of ethers is more difficult [see Section 4.1(c)]. The disolvated decamethylmetallocenes of all three elements are white, thermally stable solids, slightly (Ba) to moderately (Ca) soluble in alkanes, and readily soluble in aromatics. Their solubility in non-polar solvents greatly eases their purification, since they can be obtained free of insoluble by-products by extracting them into hydrocarbons. As expected for diamagnetic compounds, they display well-resolved NMR spectra, with appreciable chemical shift dependences on the solvent; as the polarity of the solvents increases ($C_6D_6 \rightarrow$ THF-$d_8 \rightarrow$ DMSO-d_6) the ^1H NMR methyl proton resonances move upfield.

The decamethylmetallocenes are highly air- and moisture-sensitive, and $Cp^*_2Ca(THF)_2$ decomposes in solution on contact with O_2 or N_2O to form intractable oily yellow solids. No reaction is observed with CO in THF or toluene solution.[40]

4.1(c). *Base-free decamethylmetallocenes*

Removal of coordinated ether from $Cp^*_2Ae(OEt_2)$ can be accomplished by refluxing the compounds in toluene under vacuum[44] or at atmospheric pressure.[45] Removal of coordinated THF from $Cp^*_2Ba(THF)_2$ has also been accomplished by slow sublimation at 190°C under a dynamic vacuum of 10^{-6} torr.[45,46] Coordinated THF is difficult to remove from $Cp^*_2Ca(THF)_2$; prolonged heating at 100°C and 10^{-5} bar will remove one of the THF ligands; the resulting monosolvate $Cp^*_2Ca(THF)$ is even more air- and moisture-sensitive than the starting material.[42] Complete removal of THF from the calcium complex by sublimation has not been accomplished.[45]

The decamethylmetallocenes, because of their position as archetypal organoalkaline-earth complexes, have received considerable attention. Their structures have been examined by both gas electron diffraction and by X-ray crystallography. Cp^*_2Ca, Cp^*_2Sr and Cp^*_2Ba are bent in the gas phase, with ring centroid–metal–ring centroid angles ranging from 148 to 156°.[6,47,48] In the solid state, Cp^*_2Ca and Cp^*_2Ba are somewhat more bent (147 and 131°, respectively) (Figs 2 and 3).[45,46] Although the monomeric Cp^*_2Ca units are well separated in the crystalline state, and individual Cp^*_2Ba units can be identified in the lattice, the latter are grouped together to form "quasi-polymeric" chains (Fig. 3). Within a chain, the shortest intermolecular Ba—C(methyl) distance is 3.349(5) Å; this is only 0.28 Å longer than the shortest intramolecular Ba—C distance, and there is probably some degree of solid-state interaction between the complexes.

A comparison of the bending angles in the solid-state structures of Cp^*_2Ca and Cp^*_2Ba with that of the similarly bent organolanthanide species Cp^*_2Sm, Cp^*_2Eu[49,50] and Cp^*_2Yb[51] reveals a linear relationship between the bending angles and the metal ionic radii.[45] There is no intuitively obvious explanation for the bending of any of the Ae or Ln decamethylmetallocenes, as simple steric

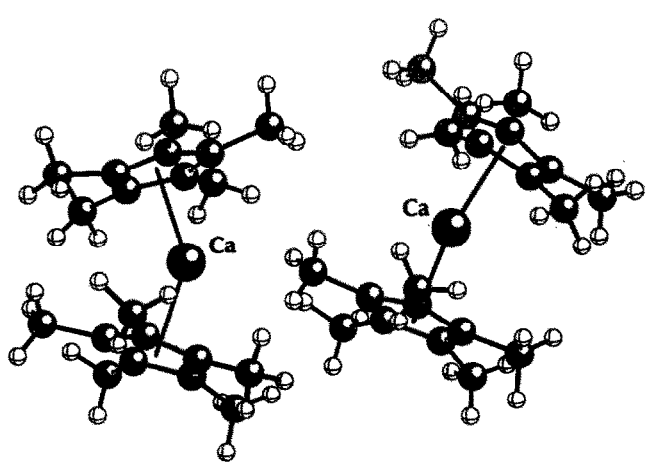

Fig. 2. Solid-state structure of Cp^*_2Ca, indicating the relative orientation of the two independent molecules in the unit cell.

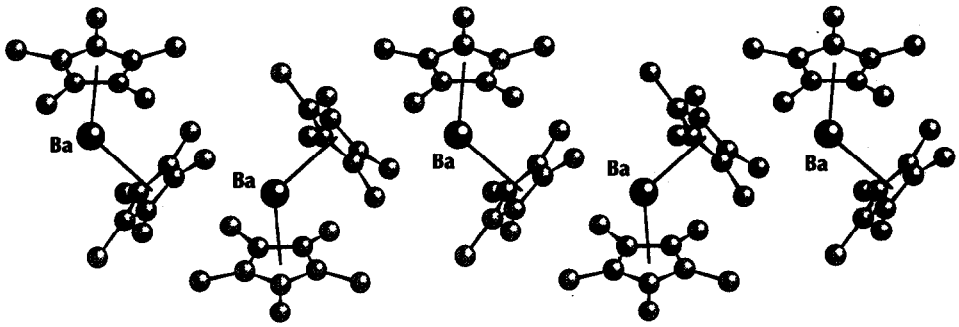

Fig. 3. Structure of Cp^*_2Ba, indicating the "chain-like" structure observed in the solid state.

considerations would suggest that structures with parallel rings should be favoured, thus minimizing intramolecular repulsions. No energetic reason for the bending in these molecules has emerged from molecular orbital calculations on the structures of Cp_2Sm, Cp_2Eu and Cp_2Yb, performed at the extended Hückel[52] and quasi-relativistic SW-Xα levels.[53]

The gas-phase structural studies have established that if the equilibrium structures of Cp^*_2Ca, Cp^*_2Sr and Cp^*_2Ba do have parallel rings, then less than 2 kJ mol^{-1} would be required to bend the complexes by 20°;[47,48] crystal packing forces or other intermolecular interactions might be able to supply this small amount of energy. Detailed comparisons between the solid-state structures of the alkaline-earth and organolanthanide molecules have not revealed any pattern in the intermolecular contacts that would provide an adequate rationalization for the bent geometries, however. Explanations for the bending based on "reverse polarization" effects have been proposed; viz. that negatively charged Cp^- rings will induce a dipole in a large, polarizable cation, thus favouring a bent geometry.[50,53] This is the same reasoning offered for the bending observed in the gas-phase Ae dihalides.[54] Recent Hartree–Fock–Slater calculations on CaH_2, CaF_2, CeO_2 and $YbCl_2$ have successfully predicted bent geometries for these species, and related explanations for the bending in the metallocenes based on *sd* hybrid orbitals have been suggested.[55]

4.1(d). *Adducts of the decamethylmetallocenes with Lewis bases*

The decamethylmetallocenes, either solvated or base-free, form adducts with a variety of Lewis bases, including ethers, aromatic amines, phosphines, isonitriles and unsaturated hydrocarbons. These can generally be formed by dissolving the base-free complex in the neat bases or in a solution of the base in a hydrocarbon solvent.

4.1(d).1. *Phosphine and isonitrile adducts.* Reaction of excess PEt_3 with base-free Cp^*_2Ae (Ae = Ca, Sr, Ba) produces 1 : 1 adducts as white, crystalline solids.[44] The $^{31}P\{^1H\}$ NMR shifts of the phosphine ligands, close to that of free PEt_3, indicates that the complexes may be extensively dissociated in solution. Variable-temperature NMR studies down to −80°C were not successful in halting the exchange.

2,6-Dimethylphenylisonitrile reacts with the decamethylmetallocenes to produce yellow 2:1 adducts, $Cp^*_2Ae(C{\equiv}NC_6H_3Me_2\text{-}2,6)_2$.[44] These all display two $\nu(C{\equiv}N)$ stretching frequencies in the solid state, one at 2115 cm^{-1}, and a second in the range 2138–2145 cm^{-1}. The former is close to the value for the free isonitrile (2120 cm^{-1}), suggesting that some dissociation may be occurring. NMR studies again indicate that the free and coordinated ligand are in fast exchange, which is not completely suppressed at −80°C.

4.1(d).2. *Aromatic amine adducts.* Adducts have been generated from the decamethylmetallocenes and a number of aromatic nitrogen heterocycles, including pyridine, pyrazine and dimethyl- and tetramethyl-substituted pyrazines, pyridazine, 2,2-bipyridine (bipy) and 2,2′:6′,2″-terpyridine (terpy).[40] In aromatic solvents, pyrazine will displace one THF from $Cp^*_2Ba(THF)_2$ to yield the orange complex $[Cp^*_2Ba(THF)]_2(\mu\text{-}NC_6H_4N)$. Bipy will displace both coordinated THF ligands from $Cp^*_2Ba(THF)_2$ to yield an orange adduct.[40] Bipy complexes can also be formed from reaction of the base-free metallocenes with the ligand in toluene.[44]

The base-free Cp^*_2Ae(Ca, Sr, Ba) complexes react readily with pyrazine and alkyl-substituted

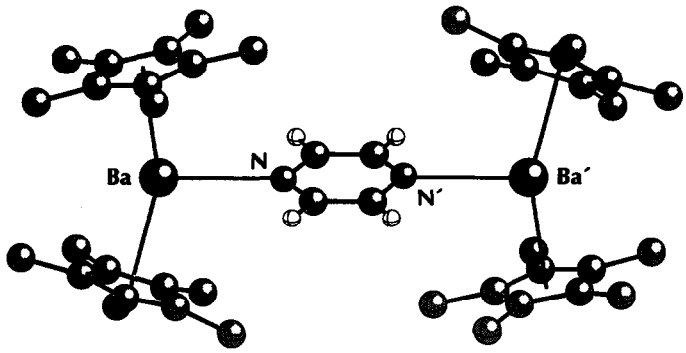

Fig. 4. Structure of the $[Cp^*_2Ba]_2(\mu\text{-}NC_6H_4N)$ dimer.

pyrazines to form the corresponding 2 : 1 adducts. The solid-state structure of the barium pyrazine adduct has been determined, and it is found to be a centrosymmetric dimer (Fig. 4).[56] The pyrazine unit is coordinated to the barium at a distance of 2.867(7) Å, with a Ba—N—N′ angle of 175°. The two N—C distances average 1.34(2) Å and the unique C—C′ distance is 1.381(19) Å, values which are indistinguishable from those in free pyrazine.

The stability of the adducts does not depend solely on the basicity of the heterocycles; excess THF will displace both pyrazine ($pK = 0.65$) and tetramethyl pyrazine ($pK = 3.55$) from the barium centre, but leaves the pyridazine adduct ($pK = 2.24$) unaffected; a chelate effect may be operating here.[40] An interesting point of comparison with the Ca—Ba systems is provided by Cp^*_2Mg, which forms a 1 : 1 complex with bipy, although no adducts with PMe_3 or 2,6-dimethylphenylisonitrile have been identified. Cp^*_2Mg may be too sterically crowded to permit adduct formation with comparatively bulky ligands.[44]

4.1(d).3. *Adducts with unsaturated hydrocarbons.* It might initially be surprising that organo-alkaline-earth complexes should display any appreciable interaction with hydrocarbons, a realm of organometallic chemistry usually restricted to the *d*-block and some *f*-block metal complexes.[57] These elements lack the orbitals of appropriate energy considered to be a prerequisite for covalent metal–ligand interactions, and particularly for the π-backbonding so characteristic of olefin and alkyne complexes. Nevertheless, some evidence for interaction is available from the fact that base-free Cp^*_2Ba, colourless in the solid state, is yellow in aromatic hydrocarbons. The yellow colour arises from a broad tailing from the UV to the blue region of the spectrum; removal of the solvent leaves the colourless metallocene, and no adducts have been isolated.[40]

Alkynes display somewhat stronger interactions than do alkenes. The reaction of 2-butyne with Cp^*_2Ca in pentane produces the 1 : 1 adduct $Cp^*_2Ca(\eta^2\text{-}MeC{\equiv}CMe)$ as a colourless solid. Proton NMR in C_6D_6 reveals only a single peak for the butyne, and no $\nu(C{\equiv}C)$ stretch is evident in the IR spectrum, an indication that the symmetry of the alkyne is not degraded on coordination.[51]

The first structurally characterized alkyne complex was formed from the reaction of Cp^*_2Ca and $Me_3SiC{\equiv}C{-}C{\equiv}CSiMe_3$ (BTMSBD) in toluene.[58] NMR evidence supports a 1 : 1 stoichiometry for the yellow adduct; addition of extra BTMSBD generates an averaged set of resonances for the alkyne carbons, indicating that the free and complexed diyne are in fast exchange even at −80°C. In the solid-state IR spectrum of the complex, $\nu(C{\equiv}C)$ appears at 2068 and 2053 cm^{-1}, a change from the uncomplexed value of 2067 cm^{-1}, and an indication that the symmetry around the triple bonds has been reduced. The diyne is readily displaced by oxygen and nitrogen donors, such as ethers and amines.

Details of the alkyne coordination were revealed in a single-crystal X-ray structure determination at −155°C.[58] Two crystallographically independent molecules are present in the asymmetric unit; both contain a calcium atom flanked by two η^5-Cp* rings, with the BTMSBD unit wedged between them (Fig. 5). In the "A" adduct, the diyne is symmetrically disposed around the ring centroid—Ca—ring centroid plane, with the two centre methyne carbons at nearly identical distances to the calcium (3.02 and 2.99 Å), and the outer methyne carbons substantially farther away (3.53 and 3.60 Å) (see Table 1). In the "B" adduct, the diyne has slipped *ca* 0.8 Å to one side of the plane,

[g] Average distance in each dimer.

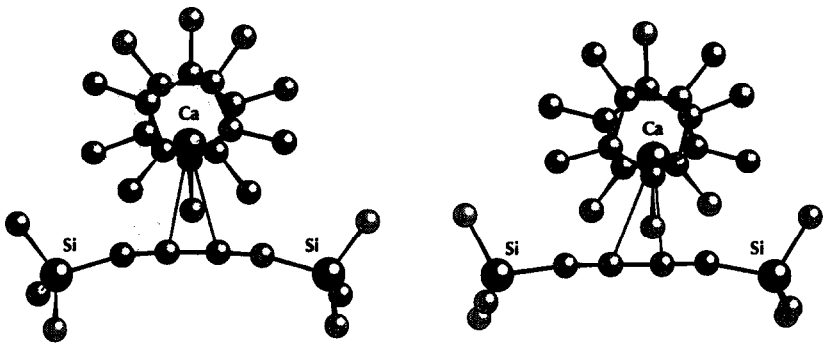

Fig. 5. Schematic view of the two independent complexes of $Cp^*_2Ca(Me_3SiC{\equiv}C{-}C{\equiv}CSiMe_3)$, indicating the different bonding modes of the diyne.

so that the distances from the calcium to the centre methyne carbons now differ significantly (2.88 and 3.10 Å), and a third methyne carbon is brought to within 3.17 Å of the metal centre. Crystal packing forces may be responsible for the occurrence of two conformers.

Interestingly, although adduct formation apparently occurs between Cp^*_2Ba and BTMSBD in alkanes, as evidenced by the formation of orange-coloured solutions, evaporation of the solutions causes Cp^*_2Ba to precipitate, and attempts to crystallize an adduct have not been successful.[40]

4.1(e). *Metallocenes containing alkyl-substituted cyclopentadienyl rings*

By using metathesis procedures analogous to those for the unsubstituted metallocenes, the bis(methylcyclopentadienyl) metallocenes, $(MeCp)_2Ae(THF)_n$, have been produced from (MeCp)(Li, K) and (Ca, Sr, Ba)I_2.[41] The calcium compound has also been prepared from the reaction of calcium metal in liquid ammonia with methylcyclopentadiene, and isolated as the DME adduct; its IR spectrum has been assigned.[59] The change in solubility from the parent compounds is slight: $(MeCp)_2CaL$ (L = 2THF, DME) has some solubility in aromatic hydrocarbons, $(MeCp)_2Sr(THF)_x$ is slightly soluble in THF, and $(MeCp)_2Ba(THF)_x$, like $Cp_2Ba(THF)_x$, is insoluble in THF. Loss of DME from $(MeCp)_2Ca(DME)$ begins at 65–70°C; the unsolvated complex is insoluble in hydrocarbons. The X-ray crystal structure of $(MeCp)_2Ca(DME)$ reveals calcium in a pseudo-tetrahedral coordination environment, with distances to the ring centroids and the oxygen atoms of the DME ligand of 2.399 and 2.404 Å, respectively (Fig. 6).[59] The compound is isostructural with the $Cp_2Yb(DME)$ analogue.[60]

The benzene-soluble t-butyl-substituted $[1,3\text{-}(Me_3C)_2C_5H_3]_2Ca(THF)$ has been prepared in 11% yield from the reaction of $[1,3\text{-}(Me_3C)_2C_5H_4]$ and $Ca(NH_2)_2$ in liquid ammonia/THF, eq. (9):[42]

$$Ca(NH_2)_2 + 2[1,3\text{-}(Me_3C)_2C_5H_4] \xrightarrow{THF,\ NH_{3(l)}} [1,3\text{-}(Me_3C)_2C_5H_3]_2Ca(THF). \qquad (9)$$

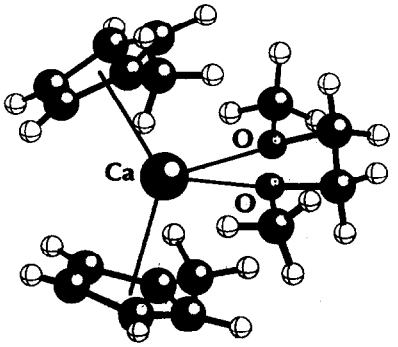

Fig. 6. Structure of $(MeCp)_2Ca(DME)$. The two ring centroids and the oxygen atoms of the DME ligand are at nearly identical distances from the calcium centre (*ca* 2.40 Å).

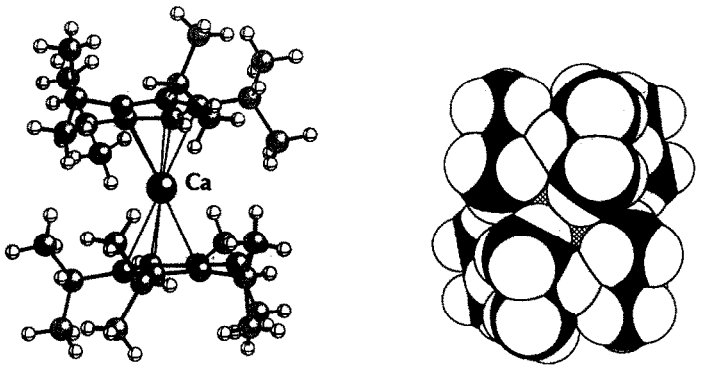

Fig. 7. Ball and stick drawing of $[(i\text{-}Pr)_4C_5H]_2Ca$ on the left; on the right, a space-filling view of the same complex, indicating the near-total encapsulation of the calcium (crosshatched area).

The complex $[(i\text{-}Pr)_4C_5H]_2Ca$ has been synthesized via halide metathesis from $K[(i\text{-}Pr)_4C_5H]$ and CaI_2 in diethyl ether, and purified by sublimation.[61] It provides an interesting example of the kinetic stability which can be produced in an organoalkaline-earth complex with ligands of sufficient steric bulk. In stark contrast to the extreme air sensitivity of the decamethylmetallocenes, crystalline bis(tetraisopropylcyclopentadienyl)calcium can be handled for several minutes in dry air without decomposition. A space-filling drawing based on the X-ray crystal structure of the complex reveals that the steric bulk of the $(i\text{-}Pr)_4Cp$ rings effectively encapsulates the metal centre (Fig. 7). The resulting blockage is presumably responsible for the inability of $[(i\text{-}Pr)_4C_5H]_2Ca$ to form adducts with ethers and aromatic amines, unlike the analogous Cp^*_2Ca species [see Section 4.1(c)]. Also of note is the ring centroid–metal–ring centroid bending angle of 162°; this represents a smaller deviation from a structure with parallel rings than is observed with Cp^*_2Ca (147°); the bulk of the rings may serve to force a more open angle.

4.1(f). *Metallocenes containing trimethylsilyl-substituted cyclopentadienyl rings*

A variety of trimethylsilyl-substituted metallocenes have been prepared by both solution routes and metal vapour methods. Calcium amide reacts with trimethylsilyl cyclopentadienes in THF with loss of NH_3 and formation of the corresponding metallocenes, eq. (10):[42]

$$Ca(NH_2)_2 + 2(Me_3Si)_nC_5H_{6-n} \xrightarrow[-2NH_3]{THF} [(Me_3Si)_nC_5H_{5-n}]_2Ca(THF) \qquad (10)$$

$$n = 1\ (12\%)$$

$$n = 2\ (30\%).$$

Displacement of the indenyl rings from $(C_9H_7)_2Ca$ with $Me_3SiC_5H_5$ also yields the trimethylsilyl-substituted metallocene, eq. (11):

$$(C_9H_7)_2Ca + 2\,Me_3SiC_5H_5 \xrightarrow[-2C_9H_8]{THF} (Me_3SiC_5H_4)_2Ca(THF). \qquad (11)$$

Bis(indenyl)calcium will not react with bis(trimethylsilyl)cyclopentadiene to form the corresponding metallocene.

Co-condensation of $1,3\text{-}(SiMe_3)_2C_5H_4$ and calcium, strontium or barium vapour at −196°C, followed by warming to room temperature, yields the base-free metallocenes $[(SiMe_3)_2C_5H_3]_2Ae$ in moderate to good yields.[29] Recrystallization of the metallocenes from THF yields the mono-THF adducts, which can be rendered base-free again by sublimation under vacuum. For the calcium derivative, repeated sublimations are necessary to obtain a base-free material; this is similar to the behaviour observed with $Cp^*_2Ca(THF)_2$, although the latter cannot be obtained completely base-free by sublimation. The calcium and strontium derivatives, whether solvated or base-free, are readily soluble in C_6D_6 and THF; curiously, the unsolvated barium metallocene is reported as more soluble than the THF adduct, for which NMR spectra could not be obtained.[29]

The X-ray crystal structures of $\{C_5H_3\text{-}1,3\text{-}(SiMe_3)_2\}_2Ca(THF)$[29,42] (Fig. 8) and $\{C_5H_3\text{-}1,3\text{-}$

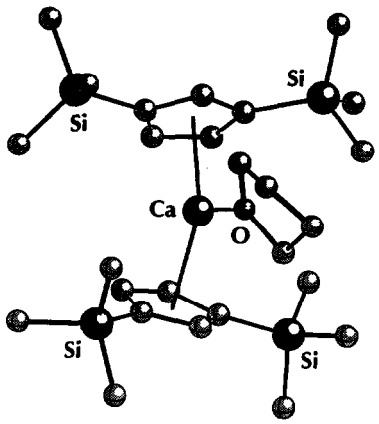

Fig. 8. Structure of $\{C_5H_3\text{-}1,3\text{-}(SiMe_3)_2\}_2Ca(THF)$.

$(SiMe_3)_2\}_2Sr(THF)$[29] have been obtained. The calcium and strontium compounds are isomorphous and isostructural, and possess crystallographically imposed C_2 symmetry. They display typical "bent metallocene" geometries, with ring centroid–metal–ring centroid angles of 135° (Ca) and 134° (Sr). These are, not unexpectedly, smaller than in the unsolvated Cp^*_2Ca and Cp^*_2Sr metallocenes (Table 1), a reflection of the steric demands imposed by the THF ligand.

4.2. *Monocyclopentadienyl complexes*

Interest in monocyclopentadienyl complexes (CpAeX) stems from the potential richness of the chemistry from these complexes. In the ideal case, the single Cp ring would supply solubility by blocking extensive oligomerization, while the X group would supply functionality not available from the metallocenes.

A general difficulty with the synthesis of monocyclopentadienyl complexes is the occurrence of Schlenk equilibria, which causes disproportionation into a metallocene and a metal salt, for example, eq. (12):

$$2\,CpAeX \rightleftharpoons Cp_2Ae + AeX_2. \tag{12}$$

The position of the equilibrium is sensitive to the nature of the solvent and the temperature; in those cases where all three components of the Schlenk equilibria are comparably soluble, the equilibrium constant for the exchange approaches that expected from complete scrambling of the ligands.[62]

Monopentamethylcyclopentadienyl complexes have been prepared in solution by a variety of routes:

(1) Reaction of an alkali metal cyclopentadienide with an Ae dihalide, for example, eq. (13):[62]

$$KCp^* + CaI_2 \xrightarrow{THF} Cp^*CaI(THF)_2 + KI. \tag{13}$$

(2) Reaction of a metallocene with an Ae dihalide, for example, eq. (14):[62]

$$Cp^*_2Ca + CaI_2 \xrightarrow{THF} 2\,Cp^*CaI(THF)_2. \tag{14}$$

Methods (1) and (2) are functionally related because of the Schlenk equilibrium which exists between Cp^*CaI, Cp^*_2Ca and CaI_2. In order to obtain pure $Cp^*CaI(THF)_2$, a reaction can be run according to eq. (13), but with excess KCp^*; this insures that the amount of free CaI_2 will be negligible. The resulting mixture of Cp^*CaI and Cp^*_2Ca can be freed from the decamethylmetallocene by a hexane wash.[62] $Cp^*CaI(THF)_2$ was found to dissociate in dioxane-d_8 to form Cp^*_2Ca and a white precipitate, presumably the solvate $CaI_2(dioxane)_n$. Such behaviour is reminiscent of Grignard reagents.[63] Dilute hydrocarbon solutions are unstable, yielding a precipitate of CaI_2 and a solution of Cp^*_2Ca.

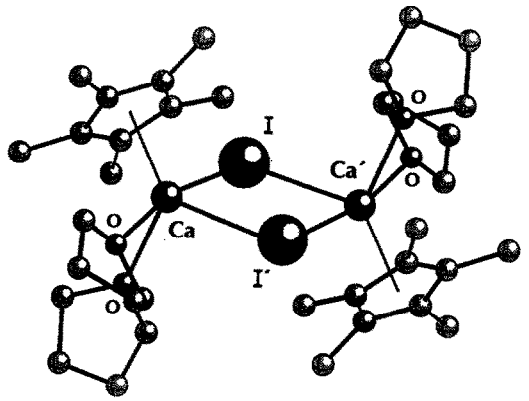

Fig. 9. Structure of $[Cp^*Ca(\mu\text{-}I)(THF)_2]_2$.

(3) Selective precipitation of a Cp* ring from a metal centre, eq. (15):[64]

$$Cp^*_2Ca + LiR \xrightarrow{THF} Cp^*CaR(THF)_n + LiCp^*\downarrow \quad (15)$$
$$[R = N(SiMe_3)_2,\ CH(SiMe_3)_2].$$

Interestingly, similar reactions performed with Cp^*_2Ba yield organometallic salts rather than monocyclopentadienyl species, eq. (16):

$$Cp^*_2Ba + LiR \xrightarrow{THF} Li^+[Cp^*_2BaR(THF)_n]^- \quad (16)$$
$$[R = N(SiMe_3)_2,\ CH(SiMe_3)_2].$$

The organobarium salts are not soluble in hydrocarbons, but disproportionate in THF to produce the metallocenes and LiR.[64] The difference between the calcium and barium reactions may be an indication that a "Cp*BaR" complex may be too coordinatively unsaturated to be stable under these conditions.

$[Cp^*Ca(\mu\text{-}I)(THF)_2]_2$ crystallizes from toluene as a halide-bridged dimer, in which each calcium atom is coordinated by a single pentamethylcyclopentadienyl ring, two THF molecules and two bridging iodides (Fig. 9). The complex is isostructural with a divalent organosamarium compound.[65] Two independent dimers appear in the asymmetric cell, each with a crystallographically imposed centre of inversion. The average (η^5-Cp*)—Ca distances for both species is 2.67 Å, whereas the average Ca—O(THF) distance is 2.422(6) Å in one dimer and 2.387(7) Å in the second dimer. The $[Ca(\mu\text{-}I)]_2$ core is asymmetric, the Ca—I distances differing by 0.062 Å in one dimer and by 0.146 Å in the other. The significance of these distances has been discussed in terms of a parameter based on relative bond lengths (see Section 5).

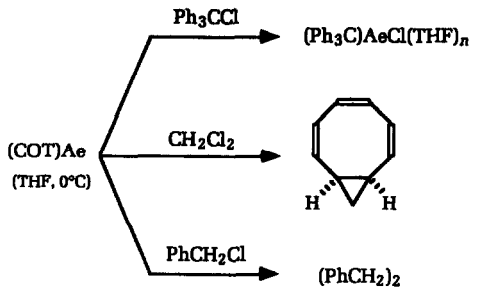
A species identified as $[(MeCp)CaNH_2]_n$ has been prepared by the careful addition of MeCpH to a solution of calcium in liquid ammonia; it is believed to be an intermediate in the formation of $(MeCp)_2Ca$.[59]

4.3. *Cyclooctatetraenyl complexes*

The bis(cyclooctatetraenyl)calcium anion $[(C_8H_8)_2Ca]^{2-}$ has been prepared in 90% yield from the reaction of C_8H_8 with Ca and K in liquid ammonia, and isolated as a THF adduct, eq. (17):[66]

$$Ca + K + C_8H_8 \xrightarrow{THF,\ NH_{3(l)}} [K(THF)_2]_2[(C_8H_8)_2Ca]. \quad (17)$$

The same compound can also be prepared from the reaction of K_2COT and CaI_2 in THF.[67] The solvated complex easily loses THF to generate the base-free complex, which can be recrystallized from DME to produce the stable monosolvate $[K(DME)]_2[(C_8H_8)_2Ca]$. The IR spectra of both the base-free material and the DME solvate are identical to those of the corresponding Yb^{2+} complex; the X-ray powder patterns of the calcium and ytterbium DME adducts are also similar, suggesting

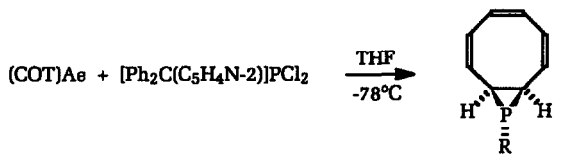


Scheme 1.

that the calcium species possesses a symmetrical sandwich geometry analogous to the structurally characterized $[(\eta\text{-}C_8H_8)_2Yb]^{2-}$ complex.[66]

Monocyclooctatetraenyl complexes can be formed from the condensation of calcium, strontium and barium vapour with cyclooctatetraene (COT) and THF at $-196°C$.[30] The calcium compound has also been isolated from the reaction of calcium metal in liquid ammonia with COT.[59] The sparingly-soluble, pyrophoric (COT)Ae$(THF)_n$ complexes can be rendered base-free by heating at 60°C under vacuum. (COT)Ca is stable up to 350°C, and its IR spectrum is similar to that of K^+, La^{3+} and Th^{4+} analogues.[68] These complexes form orange adducts with pyridine and can act as a source of soluble Ae^{2+} or as an organic nucleophile (Scheme 1).

Reaction of (COT)Ae with $RPCl_2$ produces a stable phosphacyclopropane which has been structurally characterized, eq. (18):[30]



(18)

4.4. *Organoalkaline-earth species containing monovalent calcium and strontium*

A relatively recent development in alkaline-earth chemistry has been the production and characterization of radical species containing formal calcium(I) and strontium(I). These have been generated from the gas-phase reactions of calcium and strontium metal vapours with the organic oxidizing agent, and include monoalkoxides,[69,70] monoalkylamides,[71] monomethyl,[33,72] monoacetylide,[73,74] monoisocyanate,[75,76] monoazide,[77] monocyclopentadienide,[31] monopyrrolate,[32] monoformamidate[78] and monocarboxylate complexes.[79] Of those species containing Ae—C bonds, the monocyclopentadienyl free radicals CpCa$^\bullet$ and CpSr$^\bullet$ are of special interest, as laser-induced fluorescence spectroscopy indicates that these gas-phase species are "half-sandwich" complexes with C_{5v} symmetry.[31] Comparisons of the spectra obtained for these species with that from the reaction of calcium and strontium vapour with pyrrole indicates that the latter should be formulated as $(\eta^5\text{-}C_4H_4N)Ae^\bullet$ species rather than as σ-bonded complexes.[32]

Rotational analysis of gas-phase $HC{\equiv}CCa^\bullet$ [74] and $CH_3Ca^\bullet$ [33] have found Ca—C bond lengths of 2.25 and 2.349(13) Å, respectively. The longer length of the Ca—methyl bond was taken as a reflection of the weakness of the Ca—C interaction, estimated at < 45 kcal mol^{-1}.

5. STRUCTURAL STUDIES

The number of structural studies of organoalkaline-earth complexes increased considerably during the period under review; many of these represent decamethylmetallocenes and their adducts with various neutral donors. A complete listing of the available structures is given in Table 1.

An analysis of over 200 structurally characterized compounds of the alkaline-earth and *f*-elements revealed that metal–ring centroid distances can be predicted with high accuracy in those

complexes with divalent metal centres by adding an effective Cp radius of 1.33(3) Å to the coordination number-adjusted metal ionic radii. This correlation was found to hold regardless of the coordination environment. In contrast, equally effective correlations could only be established for trivalent complexes if their coordination numbers were eight or higher.[80]

By assuming that the Cp ligand is a "ball" of radius 2.04 Å attached to a metal centre, various structural features of di-, tri-, and tetravalent ionic cyclopentadienyl complexes have been rationalized.[59] This model has been used to predict the values of ring centroid–metal–ring centroid angles and the tendency of certain metal/ligand combinations to exist as monomeric or polymeric solids.

A method for ranking structural distortions in bridged homometallic dimers based on calculations of the relative difference in effective ionic radii of the ligands has been proposed.[62] It uses relative differences in metal–ligand bond lengths in order to compensate for changes in metal radii and coordination numbers. The method has been used to compare the Ca—I bond lengths in $[Cp^*CaI(THF)_2]_2$ with those in related organolanthanide complexes.

6. APPLICATIONS

The applications of organoalkaline-earth compounds have traditionally been limited to the use of the RAeX species as adjuncts to Grignard reagents in organic synthesis,[8,81] and a review in this area has recently appeared.[82] Organoalkaline-earth species, especially those with barium, have found a small niche as initiators of anionic polymerization reactions; studies of such systems and the ion pairing processes associated with them continue to appear.[83–85]

A potentially vast new field of use may exist for organoalkaline-earth compounds in chemical vapour deposition (CVD) technology. The gas-phase decomposition of volatile organometallic substances may be useful in the preparation of thin films of alkaline-earth containing materials, including the recently discovered high-temperature superconducting ceramics.[86,87] The vapour-phase reaction of Cp^*_2Ca with SiF_4 or NF_3 at 150°C has been used to deposit polycrystalline films of CaF_2 on glass and Si(100) surfaces.[88] Depending on the deposition conditions, such films can be varied in thickness from 10 to 100 μm. The calcium, barium and strontium complexes of trifluoroacetylacetone {H[TFA]} and hexafluoroactylacetone {H[HFA]} have been prepared and show promise in CVD applications.[39]

7. CONCLUSIONS

The compounds of the heavy alkaline-earth metals, which for many years represented a nearly dormant branch of organometallic chemistry, have steadily grown in number and interest as the special steric and electronic requirements of these metals have been recognized. These advances have forced the realization that the compounds of calcium, strontium and barium possess attributes distinct from those of magnesium or the alkali metals, and that their combination of large size, high Lewis acidity and dipositive charge can generate chemistry with distinct differences from that of their neighbouring metal families. Much remains to be done in extending and systematizing organoalkaline-earth reactions and structures and refining their relationships with the alkali metals and the lanthanides and actinides, but the potential for growth in this field looks bright.

Note added in proof: A recent report describes in detail the gas-phase structures of Cp^*_2Sr and Cp^*_2Ba (R. Blom, K. Faegri Jr and H. V. Volden, *Organometallics* 1990, **9**, 372). *Ab initio* calculations were performed on Cp_2Mg and Cp_2Ca; structures with parallel rings represented energy minima for both molecules. The failure of the calculations to identify a bent structure for Cp_2Ca (as occurs with Cp^*_2Ca) was ascribed to the inability to model *d*-orbital interactions adequately.

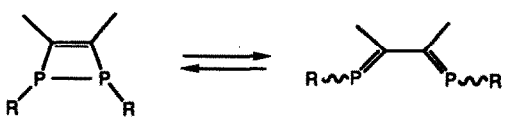
(*Received* 4 *September* 1989; *accepted* 15 *December* 1989)

Abstract—As its $P_2W_2(CO)_{10}$ dicomplex, the ring of 1,2,3,4-tetraphenyl-1,2-dihydro-1,2-diphosphete undergoes a reversible conrotatory opening to give the corresponding 1,4-diphosphadiene dicomplex which can be trapped as [4+2] cycloadducts with *N*-phenylmaleimide, maleic anhydride, acrylonitrile and benzaldehyde. X-ray crystal structure analysis indicates a weakening of the P—P bond of the 1,2-dihydro-1,2-diphosphete upon complexation: the P—P bond length increases from 2.248(1) Å in the free ring to 2.281(3) Å in the complex explaining why this reversible opening takes place only in the complex.

Several indications in the literature pointed to a possible equilibrium between the 1,2-dihydro-1,2-diphosphete ring and its 1,4-diphosphadiene open-chain isomer [eq. (1)]:

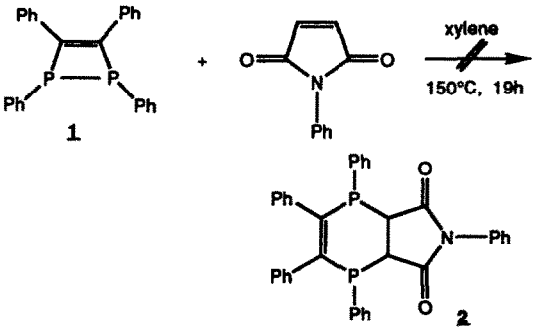


(1)

Indeed, one of the various syntheses of the 1,2-dihydro-1,2-diphosphete ring involves the spontaneous ring-closure of a transient 1,4-diphosphadiene.[1,2] When using the same synthetic scheme with bulky R-substituents at phosphorus, the 1,4-diphosphadiene can be isolated because it does not spontaneously cyclize anymore.[3] Unfortunately, the Diels–Alder reactivity is simultaneously lost as a consequence of the steric hindrance at the terminal 1,4-positions. On the other hand, the related 1,2-dihydrophosphete ring can similarly be prepared via the spontaneous cyclization of the corresponding 1-phosphadienes.[4,5] Besides, as a P—$W(CO)_5$ complex, this ring is in equilibrium with its phosphadienic isomer. The existence of this equilibrium was demonstrated by a series of trapping reactions of the open-chain complex.[6,7] These results strongly suggested the possibility of using 1,2-dihydro-1,2-diphosphetes as synthetic equivalents of 1,4-diphosphadienes. This idea has been successfully checked as hereafter reported.

RESULTS AND DISCUSSION

Our starting product was the easily prepared 1,2,3,4-tetraphenyl-1,2-dihydro-1,2-diphosphete **1**.[8] A preliminary attempt involved the reaction of **1** with *N*-phenylmaleimide. The expected cycloadduct **2** was not obtained [eq. (2)]:



(2)

A complicated and useless mixture of oxidized products was recovered instead. Modelling our approach on the 1,2-dihydrophosphete case,[6] we thus prepared the *P,P* dicomplex **3** from **1**. According to the results of a X-ray crystal structure analy-

* Author to whom correspondence should be addressed.

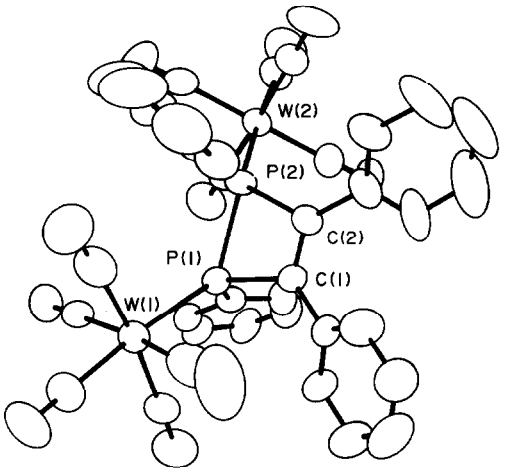


Fig. 1. X-ray structure of **3**.

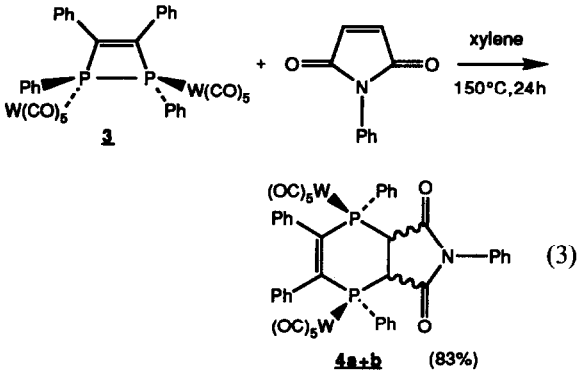
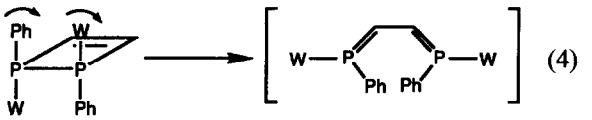
sis of **3** (Fig. 1), the prospects of achieving an equilibrium such as the one depicted in eq. (1) were far better with **3** than with **1**. Indeed, the P—P bond distance in **3** [2.281(3) Å] is significantly longer than in **1** [2.248(1) Å].[9] Besides, the complexation of the two phosphorus atoms prevents side-reactions such as oxidation at the phosphorus lone pairs and stabilizes the P=C double bonds of the postulated open-chain isomer.[10] In line with our expectations, the reaction of **3** with *N*-phenylmaleimide indeed produces the corresponding cycloadduct as a mixture of two isomers **4a,b** [eq. (3)] which have been separated by chromatography and completely characterized:



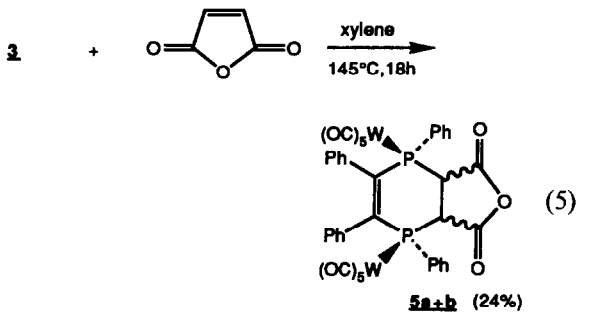
(3)

The various spectroscopic data unambiguously indicate that both isomers have a plane of symmetry bisecting the (Ph)C=C(Ph) double bond of the former 1,2-dihydro-1,2-diphosphete ring. For example, only one resonance is observed on the ^{31}P NMR spectra of **4a** and **4b** respectively at +49.9 and +53.7 ppm in CD_2Cl_2. On the other hand, the C*H* protons at the junction of the two heterocycles give either a pseudo-triplet at 4.57 ppm for **4a** or a singlet at 4.59 ppm for **4b** ($CDCl_3$). Thus, it appears that **4a** and **4b** have the stereochemistries depicted in eq. (3). This result demonstrates that a conrotatory opening of the ring of **3** has taken place in agreement with the classical Woodward–Hoffmann rules [eq. (4)]:



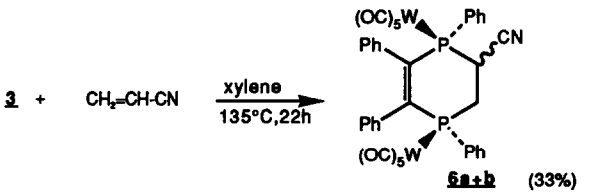
(4)

Very similar results have been obtained with maleic anhydride [eq. (5)]:

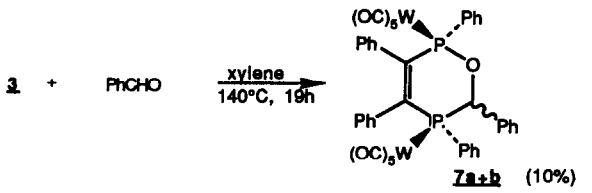


(5)

In that case, it is necessary to purify the products by recrystallization and the final low yields result from heavy losses during the purification procedure. This kind of chemistry has also been extended to acrylonitrile and benzaldehyde [eqs (6) and (7)]:



(6)

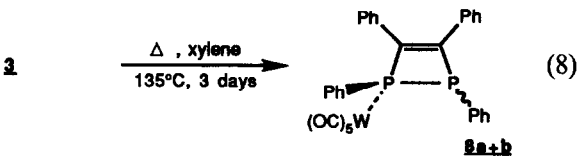


(7)

In these cases, a part of the starting product can be recovered due to the lower reactivity of the dienophiles.

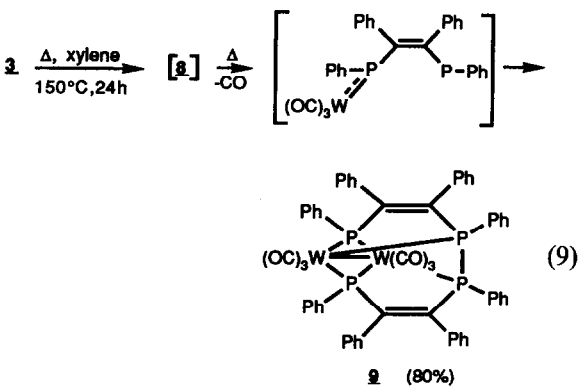
It was, of course, interesting to study what happens when complex **3** is heated alone under the same conditions which are used for performing the [4+2] cycloadditions. At 135°C for 3 days, **3** loses one of its $W(CO)_5$ complexing groups to give the mono complex **8** [eq. (8)] which was partly characterized

by ^{31}P NMR and mass spectrometry:



(8)

At 150°C, a further evolution takes place with loss of CO to give a green complex **9** whose structure has been studied by X-ray analysis [eq. (9)]. Due to a substantial decomposition of the crystal during the data collection, it has been impossible to calculate significant structural parameters but the overall geometry of the central skeleton of the molecule has been unambiguously established (Fig. 2). Complex **9** probably results from the dimerization of a transient diradical as shown in eq. (9):



(9)

Since **9** is diamagnetic, electron book-keeping implies the existence of a W—W bond as indicated.

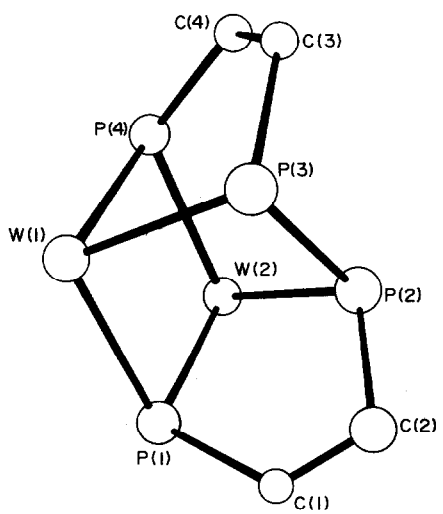


Fig. 2. Central skeleton of complex **9** as established by X-ray crystal structure analysis.

EXPERIMENTAL

All reactions were carried out under argon. Chromatograhic separations were performed on silica gel columns (70–230 mesh Merck) under argon. NMR spectra were recorded on Brucker WP 80 and AC 200. Chemical shifts are reported in parts per million from internal Me_4Si for ^1H and ^{13}C and from external 85% H_3PO_4 for ^{31}P. Downfield shifts are noted positive in all cases. IR spectra were recorded on a 297 Perkin–Elmer spectrometer and mass spectra on a Shimadzu GCMS-QP 1000 spectrometer at 70 eV.

1,2,3,4-*Tetraphenyl*-1,2-*dihydro*-1,2-*diphosphete*-1,2-*bis*(*pentacarbonyl*)*tungsten* **3**

A solution of 7.9 g of **1** in 30 cm^3 of anhydrous THF was added to 4/100 mol of $W(CO_5)THF$.[11] The mixture was stirred for 2 h. The solvent was removed by evaporation and complex **3** was purified by chromatography with hexane: Yield: 60%, m.p. 228°C. Found: C, 41.6; H, 1.7. Calc. for $C_{36}H_{20}O_{10}P_2W_2$: C, 41.5; H, 1.9%. ^{31}P NMR ($CDCl_3$) δ 46.2 ($^1J_{P-^{183}W} = 249$ Hz, $^2J_{P-^{183}W} = 17$ Hz). X-ray structure: for $C_{36}H_{20}O_{10}P_2W_2$ (Fig. 1).

X-ray structure determination for **3**

Crystals of **3**, $C_{36}H_{20}O_{10}P_2W_2$, were grown at room temperature by slow diffusion of hexane into a toluene solution of the compound. Data were collected at $18 \pm 1°$ on an Enraf Nonius CAD4 diffractometer. The crystal structure was solved and refined using the Enraf Nonius supplied SDP package. The compound crystallizes in space group $P2_1/c$, $a = 16.108(1)$, $b = 11.981(1)$, $c = 20.367(2)$ Å, $\beta = 112.19(1)°$, $V = 3639.64(1.1)$ Å^3; $Z = 4$; $D_{calc} = 1.902$ g cm^{-3}; Mo-K_α radiation ($\lambda = 0.71073$ Å) graphite monochromator; $\mu = 65.9$ cm^{-1}; $F(000) = 1976$. A total of 10,579 unique reflections were recorded in the range $2° \leqslant 2\theta \leqslant 60°$ of which 5019 were considered as unobserved [$F^2 < 3\sigma(F^2)$], leaving 5560 for solution and refinement. The structure was solved by Patterson methods, yielding a solution for the tungsten and phosphorus atoms. The hydrogen atoms were included as fixed contribution in the final stages of least-squares refinement while using anisotropic temperature factors for all other atoms. A non-Poisson weighting scheme was applied with a p factor equal to 0.08. The final R factors were $R = 0.038$, $R\omega = 0.054$, G.O.F. = 1.04.

2,3,4,5,8 - *Pentaphenyl* - 7,9 - *dioxo* - 8 - *aza* - 2,5 - *diphosphabicyclo*[4,3,0] - 3 - *nonene* - 2,5 - *bis(pentacarbonyl)tungsten.* **4a,b** $C_{46}H_{27}NO_{12}P_2W_2$

The bis complex **3** (1.3 g, 1.2 mmol) and *N*-phenylmaleimide (1.04 g, 6 mmol) were heated in a sealed tube at 150°C for 24 h in 2 cm^3 of xylene. After removal of the solvent, the residue was chromatographed on silica gel with hexane–dichloromethane (40 : 60) as eluent. The isomers **4a** and **4b** (83% total-yield) were separated.

Compound **3** (1 g, 0.96 mmol) and acrylonitrile (0.15 cm^3) in 2 cm^3 of xylene were heated at 135°C for 22 h in a sealed tube. After work-up, the residue was chromatographed on silica gel with toluene to yield 0.3 g of **1** followed by 0.250 g of **6a** (1st isomer). The second isomer 0.100 g of **6b** was obtained using dichloromethane as eluent. The global yield amounts to 33%.

6a: yellow solid, m.p. 210°C dec.; ^{31}P NMR ($CDCl_3$) δ 53.7 ($^1J_{P1-^{183}W}$ = 231 Hz, $^1J_{P1P2}$ = 58.6 Hz, P_1), 35.2 ($^1J_{P2-^{183}W}$ = 224 Hz, P_2); ^1H NMR ($CDCl_3$) δ 3.25 ($^2J_{HAHB}$ = 12.9 Hz, $^3J_{HAHC}$ = 3.8 Hz, J_{HAP1} = 9.7 Hz, J_{HAP2} = 5.0 Hz, 1H, H_ACH), 3.04 ($^3J_{HBHC}$ = 10.8 Hz, J_{HBP1} = 7.8 Hz, J_{HBP2} = 0.3 Hz, 1H, H_BCH), 3.72 (J_{HCP1} = 2.4 Hz, J_{HCP2} = 7.1 Hz, 1H, H_CCCN); ^{13}C NMR ($CDCl_3$), 33.62 (J_{CP} = 24.4 Hz, J_{CP} = 10.3 Hz, CH_2), 30.84 (J_{CP} = 14.0 Hz, J_{CP} = 12.8 Hz, HCCN), 120.76 (J_{CP} = 7 Hz, J_{CP} = 7 Hz, C≡N), 157.2 (J_{CP} = 25 Hz, J_{CP} = 18 Hz, :C), 160.9 (J_{CP} = 25 Hz, J_{CP} = 18 Hz, :C); 200.8 (C≡O), 208.5 (C≡O).

6b: yellow solid, m.p. 210°C dec.; ^{31}P NMR ($CDCl_3$) δ 60.83 ($^1J_{P1-^{183}W}$ = 239 Hz, $^1J_{P1P2}$ = 53.7 Hz, P_1), 37.81 ($^1J_{P2-^{183}W}$ = 224 Hz, P_2); ^1H NMR ($CDCl_3$) δ 3.5 ($^2J_{HAHB}$ = 11.9 Hz, $^3J_{HAHC}$ = 10.5 Hz, J_{HAP1} = 12.6 Hz, J_{HAP2} = 10.4 Hz, 1H, H_ACH), 2.83 ($^3J_{HBHC}$ = 4.5 Hz, J_{HBP1} = 2.8 Hz, J_{HBP2} = 2.5 Hz, 1H, H_BCH), 3.89 (J_{HCP1} = 9.9 Hz, J_{HCP2} = 3.9 Hz, 1H, H_CCCN); ^{13}C NMR ($CDCl_3$) δ 32.3 (J_{CP} = 24.3 Hz, J_{CP} = 11.3 Hz, CH^2), 30.1 (J_{CP} = 18.8 Hz, J_{CP} = 13.3 Hz, HCCN), 118.15 (J_{CP} = 9 Hz, CN), 158.9 (J_{CP} = 25 Hz, J_{CP} = 24 Hz, :C), 160.0 (J_{CP} = 24.5 Hz, J_{CP} = 22 Hz, :C), 200.1 (C≡O), 208.7 (C≡O).

1,3,4,5,6 - *Pentaphenyl* - 1,2,3,4 - *tetrahydro* - 2 - *oxa* - 1,4 - *diphosphinine* - 1,4 - *bis(pentacarbonyl)tungsten.* **7a,b** $C_{34}H_{26}O_{11}P_2W_2$

Benzaldehyde (0.2 cm^3, 2 mmol) and complex **3** (1 g, 0.9 mmol) in 2 cm^3 of xylene were heated at 140°C in a sealed tube for 19 h. After evaporation of the solvent, chromatography of the residue on silica gel with hexane–dichloromethane (1 : 1) as eluent, yields 50% unreacted **3** and 0.100 g (10%) **7a** and **7b** as a mixture of isomers.

7a major isomer (90%); ^{31}P NMR ($CDCl_3$) δ 153.0 ($^3J_{P1P4}$ = 29.3 Hz, $^1J_{P1-^{183}W}$ = 261 Hz, P_1), 52.7 ($^1J_{P4-^{183}W}$ = 216 Hz, P_4); ^1H NMR (CD_2Cl_2) δ 5.58 (J_{HP1} = 3.7 Hz, J_{HP4} = 9.3 Hz, 1H, HCO); ^{13}C NMR (CD_2Cl_2) δ 82.6 (J_{CP4} = 18 Hz, OCP_4), 155.9 (:C), 166.5 (:C), 196.1 (C≡O), 209.9 (C≡O); mass spectrum (^{184}W), *m/z* (relative intensity) 796 [M—W(CO)$_6$, 14], 684 [M—W(CO)$_{10}$, 52].

7b: minor isomer (10%); ^{31}P NMR ($CDCl_3$) δ 154.4 ($^3J_{P1P4}$ = 24.4 Hz, P_1), 60.9 (P_4).

1,2,3,4-Tetraphenyl-1,2-dihydro-1,2-diphosphete-1-(pentacarbonyl)tungsten **8a,b** $C_{31}H_{20}O_5P_2W$ *and complex* **9** $C_{58}H_{40}O_6P_4W_2$

Complex **3** was heated for 3 days at 135°C in xylene. The mono complex (**8a**, **8b**) is produced as a mixture of two isomers.

8a: ^{31}P NMR ($CDCl_3$) δ 8.0 ($^1J_{P1P2} = 85$ Hz, P_1), −3.5 (P_2); **8b**: δ 5.0 ($^1J_{P1P2} = 73$ Hz, P_1), −0.5 (P_2); mass spectrum (^{184}W), *m/z* (relative intensity) 718 (M^+, 12) 690 (M—CO, 29) 634 (M—3CO, 30) 606 (M—4CO, 10) 578 (M—5CO, 100).

The same reaction conducted at 150°C yields the green complex **9**. Compound **9** crystallizes in the monoclinic space group $P2_1/n$ with $a = 13.635(1)$, $b = 26.026(2)$, $c = 18.046(1)$ Å, $\beta = 106.02(1)°$, $V = 6155.3(1.6)$ Å^3, $Z = 4$. Mo-K_α radiation ($\lambda = 0.71073$ Å). Due to extensive decomposition under X-ray irradiation (60% over 2 days) data collection was conducted at high speed (20 s reflection^{-1}) in a limited θ range (2–18°).

The data set so obtained allows establishment of the formulation of the compound as $C_{58}H_{40}O_6P_4W_2$ (present isotropic $R = 0.092$). Poor resolution does not allow location of the solvent molecules or further refinement. The structure will be redetermined at low temperatures in the near future.

(*Received* 21 *November* 1989; *accepted* 15 *January* 1990)

Abstract—The stability constants of the complexes of the alkali and alkaline-earth cations with the cryptands containing two propylene (L-H) or 2-hydroxypropylene (L-OH) chains between the nitrogen bridgeheads and the adjacent oxygen atoms in one of the bridges were determined by pH-metry in 95% aqueous methanol.

In most cases (L-H) and (L-OH) form less stable complexes as compared to classic cryptands (L) with the same number of donor atoms. Unlike the latter compounds the (L-H) and (L-OH) series do not show any regular alteration of complex stability dependent on the ratio of cavity and complexed cation sizes. All (L-H) and (L-OH) form the most stable complexes with Na^+ and K^+ in the series of alkali cations, and with Sr^{2+} and Ba^{2+} along the alkaline-earth cation series. Complexes of alkali cations with cryptands (L-H) are more stable than those with (L-OH). For the complexes of the alkaline-earth cations the opposite dependence is observed. Stability of alkaline-earth cryptates of (L-OH) increases with the increase of a ligand's conformational flexibility and decreases with the increasing radius of a cation. The cause of this is the possibility of endo–endo and exo–exo cryptates formation, differing by the orientation of hydroxyl groups toward the inside or the outside of the cryptands cavity. Conformational changes of an exo–exo form into endo–endo one lead to a decrease of the ligand's cavity size changing the number and nature of the binding sites.

Preferable interaction of more charge-dense cations with the polar OH-groups in endo–endo cryptates results in unusually high M^{2+}/M^+ complexation selectivity of (L-OH). As opposed to (L-OH), (L-H) cryptands exhibit the unique for neutral ligands Na^+/Ca^{2+} selectivity which is probably due to kinetic reasons.

Complexation of mono- and divalent cations by cryptands has been intensively investigated since the discovery of their ability to form very stable complexes.[2] The stability of cryptand complexes as well as the selectivity of complexation depend on a number of factors including the size of the intramolecular cavity. Generally, it is suggested that metal ions which better fit the cryptand cavity will form the most stable complexes. However, these classical considerations explain only partly the observed complexation selectivity.[3–5]

It is known that the decrease of molecular symmetry and the increase of the crown ether size by the introduction of one or several propylene chains between the oxygen atoms have drastic and different effects on its cation binding ability.[6]

One should expect that complexing properties of classic cryptands will also change with the introduction of extra methylene groups between two adjacent donor atoms, though this effect was not studied.

We have recently described a convenient synthesis of cryptands with two propylene (L-H) and 2-hydroxypropylene (L-OH) chains between the nitrogen bridgeheads and the adjacent oxygen atoms in one of the bridges.[7] Now we discuss the

results of a pH-metric study of the stability of their complexes with the alkali and alkaline-earth cations in 95% aqueous methanol.

EXPERIMENTAL

Synthesis and properties of the studied cryptands (L-H) and (L-OH) were described earlier.[7] Dihydroxycryptands (L-OH) were obtained and studied as a mixture of meso- and (±)stereoisomers. For (L-H) and (L-OH) we use the nomenclature which is shown in Fig. 1. This nomenclature is very close to that proposed for the classic cryptands (L) but unlike it the first figure always represents the number of oxygen atoms in the bridge with two propylene fragments.

Alkali and alkaline-earth metals chlorides of reagent grade were used. The protonation constants of the ligands and the formation constants of the complexes β_{xyz} referring to the general equilibrium of complexation:

$$xM^{n+} + yL + zH^{+} \rightleftharpoons M_xL_yH_z^{(nx+z)+},$$

$$\beta_{xyz} = \frac{[M_xL_yH_z]^{(nx+z)+}}{[M^{n+}]^x[L]^y[H^+]^z}$$

have been determined from pH-metric data during the neutralization by $N(C_4H_9)_4OH$ of acidic solution of ligands dihydrochloride in 95% aqueous methanol with or without metal salts at 25.0 ± 0.1°C under an argon stream as described in Ref. 5. During the titration the ionic strength was kept constant at 0.05 M using $N(C_4H_9)_4Br$ as the supporting electrolyte. The ratio of metal to ligand concentrations C_M/C_L was generally 0.8–1.2.

Measurements have been performed using pH-meter OP208/1 (Radelkis) connected to a combined glass electrode OP0808P (Radelkis) in which the standard solution in the reference cell was replaced by a 0.05 M $N(C_2H_5)_4Cl$ methanol solution saturated with AgCl. Parameters (a and S) of electrode function $pH_{meas} = a + S * \log[H^+]$, activity coefficients of H^+ in 95% methanol and the ionic product $[H^+][OH^-]$ were determined by measuring the standard buffer for 95/5 (v/v) methanol/water mixture with the reference value of pH 7.10 (0.01 M succinic acid plus 0.01 M lithium hydrogensuccinate in 95% methanol)[8] and from the titration curve of 0.01 M $N(C_4H_9)_4OH$ plus 0.05 M $N(C_4H_9)_4Br$ solution by a 0.01 M HCl solution in 95% methanol. $\log[H^+][OH^-]$ was found to be $-15.2 + 0.1$. pH-Metric data were treated by the least squares method using the program SIRKO allowing simultaneous adjustment of the electrode parameters, ligand and cation concentrations.[9] For computer processing the whole titration curve over the pH range 2.5–10.5 was used. Within this pH range only complexes 1 : 1 have been found. Results are expressed as the consequent ligands' protonation constants K_i* and complexes' stability constants K_s* are listed in Table 1.

The confidence interval calculated by the program was not more than 0.1 for all cases.

RESULTS AND DISCUSSION

CPK molecular models analysis shows that the extention of one of the cryptand bridges by introducing two propylene fragments between the nitrogen bridgeheads and adjacent oxygen atoms leads to an increase of the radius of the cryptand intramolecular cavity by 0.1–0.2 Å (Table 2) and makes the spatial arrangement of donor atoms less symmetrical as compared with the classic cryptands with the same number of donor atoms.

* $K_1 = \beta_{011}$ and $K_2 = \beta_{012}/\beta_{011}$; $K_s = \beta_{110}$.

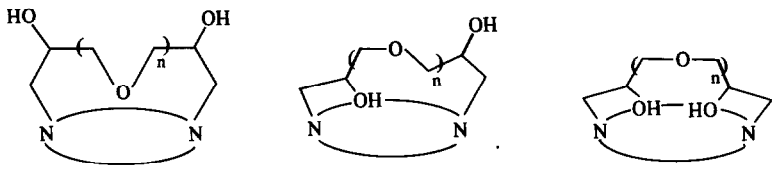
[c] Exo–endo form.

Dihydroxycryptands (L-OH) and their complexes may exist in three forms: exo–exo, exo–endo, and endo–endo differing by orientation of hydroxyls toward the inside or the outside of the intramolecular cavity.

Endo–endo conformation is readily realized in (322-OH) and (321-OH). In (222-OH) and especially in (221-OH) this conformation is more rigid. For (122-OH) and (121-OH) only endo–exo and endo–endo forms can exist. Conformational transformation of exo–exo form of (L-OH) into endo–endo form leads to the decrease of the intramolecular cavity radius by 0.2–0.5 Å (Table 2). In the exo–exo cryptates of (L-OH) the cation may interact with all the ether oxygen atoms. However, in endo–exo and endo-endo cryptates the interaction of cation with the ether oxygens of the extended bridge is impossible (Fig. 2).

Thus, the main features of the studied cryptands distinguishing them from the classic ones, are: (i) large radius of intramolecular cavity of (L-H) and exo–exo (L-OH), (ii) less symmetric spatial arrangement of donor atoms, and (iii) possibility to realize the endo–endo forms of (L-OH) which results in



exo–exo exo–endo endo–endo

Fig. 2. Different conformational forms of dihydroxycryptands (L-OH).

the decrease of the radius of their intramolecular cavity and changes the number and the nature of the binding sites. These factors will perhaps determine the differences in the complexing abilities of the studied and classic cryptands.

The additional effect on the cryptand complexing ability should be also contributed by the change of nitrogen atom basicity due to the introduction of two propylene or 2-hydroxypropylene fragments into one of the bridges. As compared with the classic cryptands with the same number of donor atoms, (L-H) in most cases form less stable complexes with alkali and alkaline-earth cations (Table 1). This may be due to at least two reasons: (i) the less symmetrical spatial arrangement of the binding sites and (ii) the presence of less favourable for complexation fragments $N\text{-}(CH_2)_3\text{-}O$, since it is known that five-membered ring chelates are more stable than six-membered ones.

Linking our results with those obtained earlier for crown ethers[6] it can be concluded that the observed decrease of the complex stability by substitution of the ethylene chain between the adjacent heteroatoms for the propylene one is a general feature of the macrocyclic ligands. However, there are some exceptions in the series of cryptands (L-H): cryptand (121-H) gives more stable complexes with K^+, Sr^{2+}, Ba^{2+}, and (222-H) with Cs^+, as compared with (211) and (222) (Table 1). Probably, in these cases the relative complex stability is determined by a better size correspondence of the ligand cavity and the cation (Table 2). For example, the ratio of the cation ionic radius and the (121-H) cavity radius is equal to 0.89, 1.15 and 1.3 for Na^+, Sr^{2+}, and Ba^{2+}, respectively. For the cryptand (211) these values are considerably higher: 1.23, 1.59, and 1.79, respectively. Thus, the unfavourable effect of the ligand propylene fragments may be compensated and even exceeded due to the better cation–cavity size relation.

Electronegative hydroxyls in cryptands (L-OH) decrease basicity of the adjacent nitrogen and oxygen atoms and as a result, should lead to the decrease of the complex stability of these ligands as compared with (L-H). Indeed, in most cases stability of alkali cation complexes with cryptands (L-H) is larger than with cryptands (L-OH) (Table 3).

As opposed to this, alkaline-earth cation complexes with (L-OH) are more stable than with (L-H). This contradiction becomes clear if one takes into consideration the possibility of the formation of endo- and exo-cryptates of (L-OH), differing in their stability. In general, the measured stability constants of (L-OH) complexes reflect the thermodynamic equilibrium with respect to conformation as well as to complexation.

$$[\text{L-OH}]+[\text{M}]^{n+} \rightleftharpoons [(\text{exo–exo})\text{ML-OH}]^{n+} + [(\text{exo–endo})\text{ML-OH}]^{n+} + [(\text{endo–endo})\text{ML-OH}]^{n+}.$$

In exo–exo cryptates of (L-OH) the size of the intramolecular cavity is equal to that of (L-H). However, due to the lower basicity of the binding sites of (L-OH), their complexes, in principle, should be less stable than (L-H) ones. In endo-cryptates (L-OH) the cavity size and the nature of binding sites differ from those of (L-H): in endo-cryptates the cavity radius is less, and the cation interacts with the oxygen atoms of hydroxyls. The most important factors determining the relative stability of endo- and exo-cryptates of (L-OH) are: (i) correspondence of the ligand cavity and cation sizes, (ii) energies of the conformational changes of exo–exo form into endo–endo or endo–exo form, and (iii) energy difference of cation interaction with ether or hydroxyl oxygens. The latter can be of great importance for the stability of complexes with high charge density cations. The preferred interaction of such cations with the polar hydroxyl is clearly shown for N,N′-bis(2-hydroxyethyl)diaza crown ethers.[10]

Cryptands (121-H), (221-H), and (122-H) give more stable complexes with the alkali cations than their (L-OH) partners. However, (321-OH) form more stable complexes with Li^+, Na^+, K^+ and Rb^+, (322-OH) with Na^+ and K^+; (222-OH) with Na^+, as compared with the corresponding (L-H). This suggests that depending on the cycle size, (L-OH) form the cryptates of the different structures. Probably, the cause of this is the differing ligand flexibility. As we have noted, endo–exo conformations

Table 3. Difference (δ) between the stability constants of the complexes of cryptands (L-H) and (L-OH) with cations, $\delta = \log K_s(ML\text{-}H^{n+}) - \log K_s(ML\text{-}OH^{n+})$

Rb^+	1.12	−0.05	> 1.41	0.83	1.05	
Cs^+			0.12	> 0.32	> 1.71	> 2.05
Mg^{2+}		> −2.32	> −1.24		> −1.63	> −1.71
Ca^{2+}	−0.54	−1.27	−3.09	−0.72	−2.89	−4.61
Sr^{2+}	−1.04	−1.39	−2.73	−0.14	−2.40	−2.41
Ba^{2+}	> 1.34	−0.59	−1.87	1.42	−1.09	−1.79

of (121-OH) and (122-OH) and endo–endo form (221-OH) are quite rigid, while endo–endo conformation of (222-OH), (321-OH) and (322-OH) are readily realized. It gives evidence for the preferable formation of exo-cryptates by the former which are less stable than the complexes of the corresponding (L-H). In the case of more flexible (222-OH), (321-OH), and (322-OH) the possibility of endo-cryptate formation increases which leads to the increase of the observed stability constant of the complexes with charge-dense cations. Along the series of alkaline-earth cations all (L-OH) form more stable complexes than their (L-H) analogues with the exception of Ba^{2+} complexes with (121-OH) and (122-OH). Since the divalent cations are more charge dense than monovalent ones, the former should interact more strongly with the polar hydroxyls in endo-cryptates. Thus, achieved energetic advantage is probably more than the energy of unfavourable conformational transformation of exo–exo forms of small cryptands (121-OH), (122-OH), and (221-OH) into endo–exo or endo–endo forms. As a result, these cryptands form preferably endo-cryptates of the alkaline-earth cations in contrast to exo-cryptates of the alkali cations. The formation of endo–endo alkaline-earth cryptates is more evident for (222-OH), (321-OH), and (322-OH). This is proved by the increase of the relative stability of cryptates of each alkaline-earth cation in the series: (121-OH) < (221-OH) < (321-OH) and (122-OH) < (222-OH) < (322-OH). This sequence corresponds to the decreased energy of the exo–endo conformational changes of the ligands. The formation of alkaline-earth endo-cryptates is also in agreement with the observed decrease of their relative stabilities with the increase of cation radius and thus with the decrease of the charge density on it (Table 3).

Thus, the stability of dihydroxycryptand complexes is determined by the ligand flexibility and the cation charge density. The latter is the cause of high preference of (L-OH) interaction with divalent cations as compared with the monovalent ones of the same size (Li^+ and Mg^{2+}; Na^+ and Ca^{2+}; K^+ and Ba^{2+}) (Table 4). The only exception is the relative stability of Mg^{2+} and Li^+ complexes with (321-OH). M^{2+}/M^+ selectivity of most dihydroxy-cryptands is much larger than that for the classic cryptands and crown ethers.

Cryptands (L-H) show less Ba^{2+}/K^+ selectivity as compared with the corresponding (L-OH). However, in contrast to (L-OH) all (L-H) form more stable complexes with Na^+ than with Ca^{2+}. This selectivity is the unique feature of these cryptands, since as we know amongst those previously described only (211) exhibits Na^+/Ca^{2+} selectivity.[5]

As was shown earlier[11] the formation rate constants k_f of alkaline-earth cation complexes and their dissociation rate constants k_d are lower than those of the alkali complexes. So, the relation may assume different values depending on the ratio of constants k_f and k_d. This means that Na^+/Ca^{2+} selectivity of (L-H) may result from $k_f(CaL\text{-}H^{2+})/k_f(NaL\text{-}H^+) < k_d(CaL\text{-}H^{2+})/k_d(NaL\text{-}H^+)$. The preferable complexation of Li^+ as compared to Mg^{2+} with cryptands (121-H) and (321-OH) is probably due to the same reasons.

By comparison of the cryptands (L-H) and (L-OH) with the same number of donor atoms it is obvious that the stability of their complexes depends considerably on the ligand symmetry. The less symmetrical (221-H), (221-OH), (321-H) and (321-OH) in most cases form less stable complexes as compared to the more symmetrical (122-H), (122-OH), (222-H) and (222-OH), respectively (Table 1).

Unlike the classic cryptands the stability of complexes of (L-H) and (L-OH) does not change regu-

Table 4. M^{2+}/M^{+} Selectivity of the cryptands (L-OH) and (L-H). Selectivity $\delta = \log K_s(ML^{2+}) - \log K_s(ML^{+})$

	$\log K_s$			$\log K_s$			$\log K_s$

221-H	< 2	< 2		4.36	4.83	−0.47	4.92	4.14	0.78
321-H	< 2	< 2		3.72	4.46	−0.74	5.21	3.23	1.98
122-H	< 2	< 2		5.20	6.13	−0.93	5.05	5.11	−0.06
222-H	< 2	< 2		3.75	4.36	−0.61	7.53	5.47	2.06
322-H	< 2	< 2		4.12	4.65	−0.55	6.64	5.15	1.4

larly with the increase of the cavity size. Irrespective of the cavity size (L-H) and (L-OH) form the most stable complexes with Na^{+} and K^{+} in the series of alkali cations and with Sr^{2+} and Ba^{2+} [with the exception of (121-H) and (121-OH) which interact preferably with Ca^{2+}] in the series of alkaline-earth cations (Table 1).

Thus, the studied cryptands (L-OH) and (L-H) are novel macrocyclic ligands forming rather stable complexes with alkali and alkaline-earth cations and showing the striking complexation selectivity in most cases.

Abstract—The visible absorption spectra and molar conductance curve for $Co(NCS)_2$ in acetone, together with the spectra for $Co(ClO_4)_2$–$Co(NCS)_2$–acetone, $Co(NCS)_2$–KNCS–acetone and $Co(NCS)_2$–acetone–benzene, have been determined at 25°C. The results indicate that $Co(NCS)_2$ probably exists in acetone as the complex electrolyte $Co(NCS)(acetone)_5^+Co(NCS)_3(acetone)^-$.

Our previous work on $Co(NCS)_2$ in N,N-dimethylformamide and dimethylsulphoxide has shown that in extremely dilute solutions the salts dissociate into the simplest ions, while the formation of mono- and tetra-thiocyanate complexes was observed even in dilute solution.[1,2] It has been shown by Libuś that the dissolution of anhydrous $Co(NCS)_2$ in acetonitrile results in formation of two complexes of cobalt(II), the octahedral $Co(NCS)(CH_3CN)_5^+$ cation, and the tetrahedral $Co(NCS)_3(CH_3CN)^-$ anion, both being considered as the 1 : 1 complex electrolyte.[3]

The present work was undertaken in order to establish a mode of ionization of $Co(NCS)_2$ in acetone solution. It has been reported previously[4] that $CoCl_2$ and $CoBr_2$ exist in acetone in the form of the electrically neutral tetrahedral species, $CoCl_2(acetone)_2$ and $CoBr_2(acetone)_2$, respectively.

EXPERIMENTAL

Acetone was purified by means of $KMnO_4$, dried over a molecular sieve, and distilled. The product was kept under dry-air. The specific conductance of the purified solvent was in the range of 8.2×10^{-9}–1.8×10^{-8} S cm^{-1}.

Ethanol solution of $Co(NCS)_2$ was obtained by metathesis of strictly equivalent amounts of ethanol solution of corresponding nitrate and KNCS. On cooling, the solid KNO_3 was filtered off. After removing any excess of solvent under reduced pressure the solid $Co(NCS)_2$ was obtained, recrystallized twice and dried *in vacuo*. KNCS was recrystallized twice from ethanol and dried *in vacuo* at 80°C.

The $Co(ClO_4)_2 \cdot 6H_2O$ was recrystallized from water, dried over phosphoric oxide *in vacuo* and dissolved in dry acetone. The resulting solution was dried using molecular sieves. After removing any excess of solvent the crystalline solvate was isolated and recrystallized from anhydrous acetone.

All details of the procedures for preparations of solutions and measurements were described previously.[1,2]

RESULTS AND DISCUSSION

Figure 1 shows the plot of the molar conductivity of $Co(NCS)_2$ in acetone at 25°C. In the same figure is presented the molar conductance curve of $Co(ClO_4)_2$ reported previously.[4] It has been shown recently that $Co(ClO_4)_2$ in acetone exhibits pronounced tendency to associate. However, as can be seen, the molar conductance curve for this highly associated electrolyte runs well above the points for $Co(NCS)_2$ indicating a high degree of complex formation over the range of $Co(NCS)_2$ concentration, and unusually high stability of the complexes, even in the lowest concentration range.

The most striking feature of the acetone solutions of $Co(NCS)_2$ consists in the fact that their visible absorption spectra are practically independent of

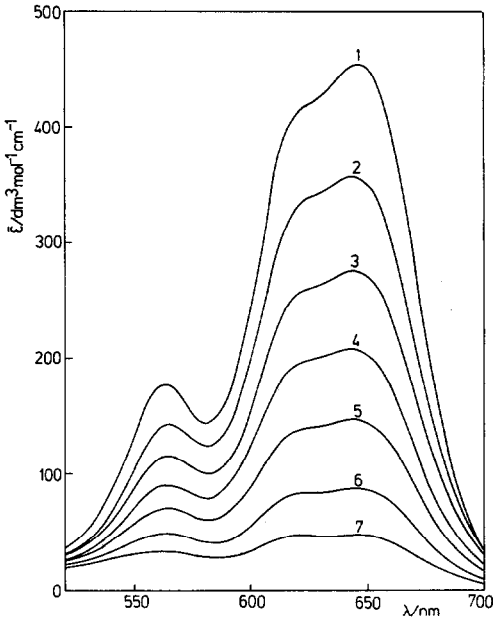

Fig. 2. Absorption spectra of cobalt(II) for a series of equimolar mixtures of $Co(ClO_4)_2$ with $Co(NCS)_2$ at 25°C. The total metal concentration is constant (*ca.* 0.012 mol dm^{-3}), while the NCS^-/Co^{2+} ratios are: (1) 2.0, (2) 1.770, (3) 1.571, (4) 1.371, (5) 1.185, (6) 0.972 and (7) 0.779.

the solute concentration, i.e. display optical constancy. However, they are very sensitive to change in a solvent composition as well as to change of the NCS^-/Co^{2+} ratio.

Figure 2 presents the visible absorption spectra of cobalt(II) for a series of equimolar mixtures of $Co(NCS)_2$ with $Co(ClO_4)_2$ covering the 2.0–0.8 range of the NCS^-/Co^{2+} ratio, with the total concentration of cobalt(II) being constant, *ca.* 0.012 mol dm^{-3}. The spectrum of cobalt(II) for pure $Co(NCS)_2$ is indicated by curve 1. As is seen, the latter spectrum of cobalt(II) consists of a broad band with maxima located at 564 and 646 nm. The band shows characteristics of the four-coordinated complexes of cobalt(II). Moreover, the spectrum is very similar to the spectrum of the $Co(NCS)_3(CH_3CN)^-$ complex reported by Libuś.[3] As is seen, substitution of $Co(ClO_4)_2$ for $Co(NCS)_2$ brings about distinct changes in the spectrum of cobalt (II). It is obvious that the spectrum of Co $(NCS)_2$ is gradually transformed into the known spectrum of $Co(ClO_4)_2$, due to the $Co(acetone)_6^{2+}$ solvate and exhibiting very low molar absorptivity.[4] However, the total decrease in intensity of the band with a decrease of the NCS^-/Co^{2+} is accompanied by a distinct broadening of the band, suggesting the coexistence of the second four-coordinated complex of cobalt(II) at a NCS^-/Co^{2+} ratio lower than 2.0.

Similar spectral changes were observed when the effect induced by a non-coordinating diluent of low polarity on the spectrum of $Co(NCS)_2$ dissolved in acetone was studied. The effects generated by addition of benzene up to mole fraction 0.75 are shown in Fig. 3. As is seen, the addition of diluent causes a decrease in intensity accompanied by the disappearance of the maximum at 564 nm and the broadening of the second component of the band. When the mole fraction of diluent exceeds 0.50, a further addition of benzene does not affect the spectrum of cobalt(II). It may be expected that the dilution of acetone with coordinatively inactive and non-polar solvent will shift the equilibria in solution towards existence of electrically neutral species. Thus, we infer that the four-coordinated species existing in the presence of benzene is the pseudo-tetrahedral $Co(NCS)_2(acetone)_2$ complex, and the identical spectra of cobalt(II) observed for 0.54 and 0.75 mole fractions of benzene is the single species spectrum. The same complex seems to be responsible for the broadening of the band observed for the $Co(NCS)_2$–$Co(ClO_4)_2$–acetone system, while the spectrum observed at the $NCS^-/Co^{2+} = 2.0$, i.e. for the $Co(NCS)_2$–acetone solution is due to the presence of $Co(NCS)_3(acetone)^-$.

Figure 4 shows the visible absorption spectra of

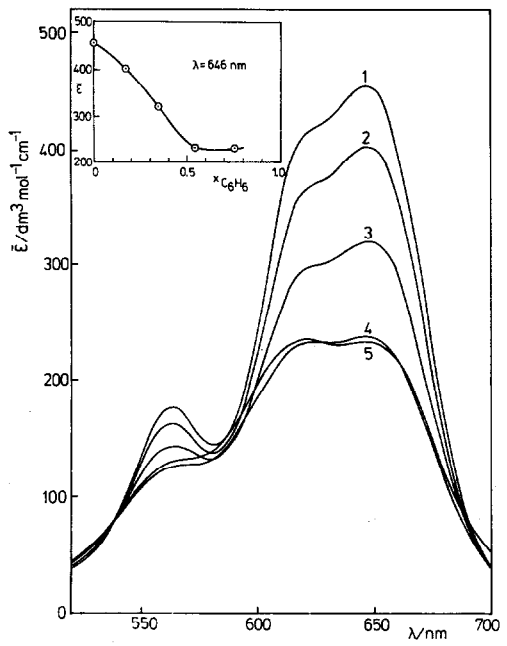

Fig. 3. Absorption spectra of $Co(NCS)_2$ in acetone–benzene mixtures at 25°C. The concentrations (mol dm^{-3}) of $Co(NCS)_2$ and the mole fractions of benzene in the mixed solvent are, respectively: (1) 0.00109, 0.00; (2) 0.00107, 0.169; (3) 0.00113, 0.349; (4) 0.00112, 0.544 and (5) 0.00110, 0.753.

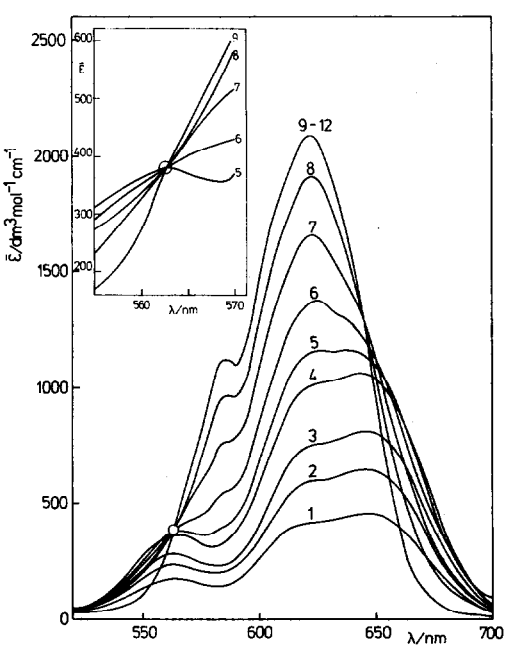

Fig. 4. Absorption spectra of $Co(NCS)_2$–KNCS solutions in acetone at 25°C. The concentration of $Co(NCS)_2$ is constant (0.001 mol dm^{-3}), the NCS^-/Co^{2+} ratios are: (1) 2.0, (2) 2.286, (3) 2.550, (4) 2.858, (5) 3.067, (6) 3.267, (7) 3.531, (8) 3.716, (9) 4.053, (10) 4.684, (11), 5.073 and (12) 10.701.

a series of solutions containing $Co(NCS)_2$ at an approximately constant concentration of 0.001 mol dm^{-3}, and KNCS at a number of different concentrations up to *ca.* 0.011 mol dm^{-3}. The addition of KNCS initially causes an increase in intensity of the band of the $[Co(NCS)_3(acetone)]^-$ complex. Further addition results in a marked change consisting of the disappearance of the maximum at 564 nm and the gradual shift of the second maximum from 646 nm to 623 nm. The changes are accompanied by the appearance of the maximum at 586 nm and the well-defined isosbestic point at 562 nm. When the NCS^-/Co^{2+} ratio exceeds 4.0, further increase in the KNCS concentration does not affect the spectrum, and the spectrum of cobalt(II) becomes almost identical to those of $Co(NCS)_4^{2-}$ in N,N-dimethylformamide,[1] dimethylsulphoxide[2] and acetonitrile.[3] However, it should be noted that the limiting spectrum of $Co(NCS)_4^{2-}$ was obtained at a NCS^-/Co^{2+} ratio as low as 4.0, while the values exceeding 190 were necessary for the transformation of cobalt(II) into $Co(NCS)_4^{2-}$ in DMF and DMSO, and higher than 7.0 in acetonitrile solutions. Analogous observations were reported by Gutmann and discussed in terms of the relative donor properties of both solvent molecules and pseudohalide anions.[5] The donor numbers of DMF and DMSO, 26.6 and 29.8, respectively, are much higher than the respective values of 14.1 for acetonitrile and 17.0 for acetone.[6] Unfortunately, the differences in the donor number explain the general trend only. As is seen, acetone exhibits a donicity higher than that of acetonitrile, while the respective NCS^-/Co^{2+} ratio form the opposite order. Furthermore, the donor number of N,N-dimethylacetamide (DMA) amounts to 28, while the NCS^-/Co^{2+} ratio higher than 13 is sufficient for the replacement of the solvent molecules of the Co^{2+} solvation sphere by the NCS^- anions and the change of the coordination number of the central metal atom from 6 to 4. The properties of the Co^{2+}–NCS^-–DMA system may be explained in terms of a relatively low stability of the $Co(DMA)_6^{2+}$ solvent-cation arising from the bulk properties of the solvent molecule.[7] The same factors seem to be responsible for the formation of the $Co(NCS)_3L^-$ (L = acetone or acetonitrile molecule) complexes, while only one tetrahedral complex, i.e. the $Co(NCS)_4^{2-}$ anion is present in the Co^{2+}–NCS^-–DMSO and Co^{2+}–NCS^-–DMF systems.

Further attempts to describe a coordination state of $Co(NCS)_2$ in acetone consists of a more detailed analysis of the electronic spectra. It may be seen that the molar absorption coefficient of cobalt(II) at the isosbestic point at 562 nm equals twice that of

a solution of $Co(NCS)_2$ at the same wavelength. As is known, an existence of the isosbestic point indicates a two-species equilibrium and is a consequence of the fact that the molar absorption coefficient of both the species are the same at the wavelength of this point. From the above and an assumption that a light absorption due to the octahedral species may be ignored, follows that 50% of cobalt(II) in acetone solution of $Co(NCS)_2$ is present in the form of the $Co(NCS)_3(acetone)^-$ complex. Assuming complete binding of the NCS^- anions the acetone solution of $Co(NCS)_2$ may be considered as a solution of the $Co(NCS)(acetone)_5^+ \cdot Co(NCS)_3(acetone)^-$ complex electrolyte. The appreciable stability of the monothiocyanate octahedral complexes of cobalt(II) was discussed previously.[3]

Using the values of the molar absorption coefficient of cobalt(II) at the isosbestic point the mole fraction of $Co(NCS)_3(acetone)^-$ may be calculated as

$$\frac{c_3}{c} = \frac{\bar{\varepsilon}}{\varepsilon_{34}} \quad (1)$$

where ε_{34} is the molar absorption coefficient at the isosbestic point and $\bar{\varepsilon}$ denotes the mean molar absorption coefficient of cobalt(II) at the same wavelength for the solutions in which only one tetrahedral complex of cobalt exists. Moreover, the values of the molar absorption coefficient for any other wavelength may be extracted from this spectra, and the spectrum of the $Co(NCS)_3(acetone)^-$ may be reconstructed. Figure 5 shows the results of such a treatment of the spectrophotometric data, presenting the spectra of the three tetrahedral complexes of cobalt(II) known to be formed in the Co^{2+}–NCS^-–acetone system. The respective mole fraction of the particular complexes were used to prepare the distribution diagram shown in Fig. 6.

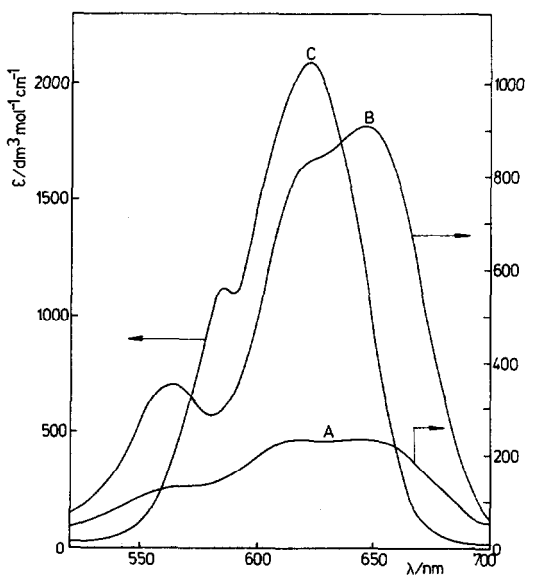

Fig. 5. Absorption spectra of the individual complexes of cobalt(II) in the Co^{2+}–NCS^2–acetone system: (a) $Co(NCS)_2(acetone)_2$, (b) $Co(NCS)_3(acetone)^-$, (c) $Co(NCS)_4^{2-}$.

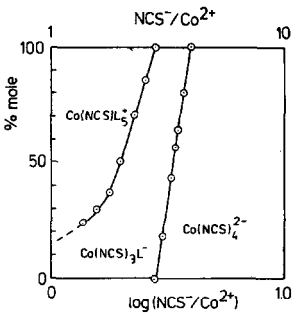

Fig. 6. Formation diagram of the thiocyanate complexes of cobalt(II) in the Co^{2+}–NCS^-–acetone system at 25°C.

Concluding, the results presented in this paper are an illustration of the fact that the electrolytic properties of the transition metal halides and pseudohalides in strongly polar donor solvents may be rationalized in terms of a relatively small number of modes of ionization.

(*Received* 22 *November* 1984; *accepted after revision* 11 *January* 1990)

Abstract—Interaction of *cis*-$[Co(AA)_2Cl_2]Cl$, *cis–trans*-$[Coen_2(H_2O)_2]Br_3$ and $[Co(CN)_5H_2O]^{2-}$ (where AA is α,α^1-bipyridyl or 1,10-phenanthroline, en—ethylenediamine) with NO_2^-, SO_3^{2-} ambidentate ligands and thiourea was studied by ^{59}Co NMR and linkage O,N-, O,S- and N,S-isomerization in bis-ethylenediamine Co^{III} complexes was found. No similar linkage isomerization was observed for bipyridyl or phenanthroline Co^{III} complexes.

At present there are many experimental data proving the existence of O,N and O,S linkage isomerism in aqueous solutions of Co^{III} complexes containing the NO_2^- and SO_3^{2-} groups.[1–7] It was found that the reactions of nitrito-nitro linkage isomerization in aqueous solutions occur spontaneously by an intramolecular mechanism[8] or are catalysed by bases.[9,10] We have also discovered linkage isomerism in the case of the reactions of different Co^{III} amine complexes and molecular ligands (urea, thiourea, acetamide, thioacetamide and thiosemicarbazide),[11,12] in which we assume O,N-linkage isomerism is caused by deprotonation of amine ligands and changing of electron density of the central atom.[13]

It seemed of interest to us to find out whether the linkage isomerism of Co^{III} complexes in which proton dissociation of coordinated ligands is improbable. We studied the interaction of NO_2^--, SO_3^{2-}- and thiourea with $[Cophen_2Cl_2]Cl$, $[Codipy_2Cl_2]Cl$, $[Coen_2(H_2O)_2]X_3$ ($X = ClO_4^-$ and Br^-) and $[Co(CN)_5H_2O]^{2-}$.

EXPERIMENTAL

The initial compounds were synthesized according to the known procedure: $[Co(AA)_2Cl_2]Cl$,[14,15] *cis*- and *trans*-$[Coen_2(H_2O)_2]X_3$[16] and aqueous solution containing 0.1 mol dm^{-3} of $[Co(CN)_5H_2O]^{2-}$.[17] ^{59}Co NMR spectra were recorded on "РЯ 2311" (19.76 MHz) and "BRUKER" AM-400 (95.45 MHz) spectrometers. Chemical shifts are presented relative to $[Co(NH_3)_6]Cl_3$. The attribution of resonance lines of ^{59}Co NMR spectra was based on the additivity method proposed by authors.[18] The constant of the nitrito-nitro isomerism rate was determined in buffer solution of (KH_2PO_4/Na_2HPO_4) at pH = 6.86 according to the changes in time of the integral intensity ratio of signals δ ^{59}Co of nitrito- and nitro- forms.

RESULTS AND DISCUSSION

Linkage O,N-isomerism (at different pH) was observed in the case of NO_2^--ions reaction with *cis*- and *trans*-$[Coen_2(H_2O)_2]X_3$. In basic solution coordination of the nitro-group with cobalt took place only through the nitrogen atom. Both isomers of diaqua-complex underwent hydrolysis, and the process was accompanied by *cis–trans*-isomerization (*cis*:*trans* = 1:2). While adding $NaNO_2$ ($Co:NO_2 = R = 1:2$) the formation of *trans*-isomers $[Coen_2(OH)NO_2]^+$ (363, 583 ppm *cis*:*trans* = 1:3) and $[Coen_2(NO_2)_2]^+$ (−1637, −1835 ppm, *cis*:*trans* = 1:5) took place mainly independently of the primary geometric configuration of the initial bis-ethylenediamine complexes. The period of semi-conversion of *cis*-$[Coen_2(NO_2)_2]^+$ complexes into the *trans*- form, as was found before[13] is 20 h at 86°C. The *trans*-isomer $[Coen_2(NO_2)_2]^+$ is not converted to the *cis*-configuration and is not catalytically effected by the bases due to the concurrent hydrolysis process. At

* Author to whom correspondence should be addressed.

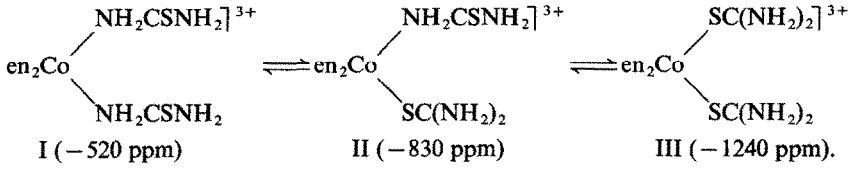
the same time similar to the reaction of *trans*-$[Coen_2(H_2O)_2]^{3+}$ with the nitro group in basic solution, both *cis*- and *trans*-$[Coen_2(NO_2)OH]^+$ are easily formed and then both *cis*- and *trans*-$[Co(en)_2(NO_2)_2]^+$ geometric isomers are produced in the presence of NO_2^- ions. The equilibrium observed in the process of nitrogen-complexes formation (*cis* $\rightleftharpoons$ *trans*) can be explained by the hydrolysis of the initial diaqua-complexes and regrouping of chelate rings.

Dinitrito-complexes of *cis*- and *trans*-$[Coen_2(ONO)_2]^+$ in neutral solution (pH = 7) are isomerized in time into nitrito-nitro- and dinitro- forms without changing its geometric configuration

$$\underset{\text{(or } trans\text{)}}{cis\text{-}[Coen_2(ONO)_2]^+} \xrightarrow[H_2O]{} \underset{\text{(or } trans\text{)}}{cis\text{-}[Coen_2(ONO)NO_2]^+} \xrightarrow[H_2O]{} \underset{\text{(or } trans\text{)}}{cis\text{-}[Coen_2(NO_2)_2]^+}.$$

When the solutions are alkalized (pH = 9) the rate of linkage isomerization increases considerably. Kinetic parameters of these reactions were discussed elsewhere.[13] Isomerization rate constants at 25°C determined by us for *cis*- and *trans*-$[Coen_2(X)ONO]^+$ (X = NH_3, Py and CH_3NH_2) are in good agreement with the results obtained[13,19] for similar complexes where X = ONO^-, NCS^-, NO_2^-, CN^-. As follows from Table 1, the isomerization rate for *cis*-complexes depends slightly on the nature of X and increases in the order Py < NH_3 < CH_3NH_2. The rate of isomerization of *trans*-complexes changes considerably for different X. Speeding up of the reaction of *trans*-$[Coen_2(ONO)CH_3NH_2]^{2+}$ isomerization can be evidently explained by stronger *trans*-effect of CH_3NH_2 as compared with ammonia and pyridine.

Reaction of *cis*-$[Coen_2(H_2O)_2]Br_3$ with thiourea (ratio = 2 and pH = 7) starts with the replacement of water and addition of thiourea through the nitrogen atom and then N,S-linkage isomerism occurs without changing its *cis*-configuration in time or on making the solution alkaline.

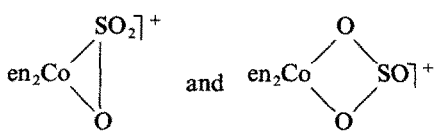


The isomer containing thiourea molecules coordinated to Co through the nitrogen atom is the dominating form in acid solutions (pH = 5; I : II : III = 5 : 2 : 1), but at pH = 9 the equilibrium shifts and complexes with Co—S bond are formed (I : II : III = 1 : 3 : 4). In the range of 3 < pH < 12 both N- and S-linkage isomers are present in the solution in commensurable quantities, while

$[Coen_2(ONO)_2]^+$ under similar conditions isomerizes in a more stable nitro-form in time.

It is known,[20-23] that in the reaction of $[Co(NH_3)_5H_2O]^{3+}$ and *cis*- and *trans*-$[Coen_2(H_2O)_2]^{3+}$ with SO_2 or $Na_2S_2O_5$, $NaHSO_3$ or Na_2SO_3 when 4 < pH < 7 the monosulfite complexes $[(NH_3)_5CoOSO_2]^+$[20,21] are formed, as well as *cis*-[22] and *trans*-[23] $[en_2CoOSO_2(H_2O)]^+$ in which coordination of SO_3-group is realized through the oxygen atom. But at pH < 6 they are not stable and decompose with the formation of Co^{2+} complexes. At pH > 6 only Co—SO_3 bonded complexes are formed in similar reactions.[24,25] O,S-linkage isomerism was previously observed at 6 < pH < 7.5 for α,β-$[Co(tetren)OSO_2]^+$[4] and $[Codien(OSO_2)_3]^{3-}$.[12]

Interaction of *cis*- and *trans*-$[Coen_2(H_2O)_2](ClO_4)_3$ with sodium sulfite (pH = 7, R = I) resulted in the formation of three complexes: two isomers $[Coen_2SO_3(H_2O)]^+$ (*cis*-, −1320 ppm; *trans*-, −1435 ppm) with the concentration ratio *cis* : *trans* = 1 : 3 and $[Coen_2SO_3]^+$ (−1538 ppm). Assumption of SO_3-group coordination as chelate ligand suggested previously[26]



was not confirmed because deshielding of the central atom would be observed in this case as was noted for $[Coen_2CO_3]^+$ (800 ppm). One can rather assume that $[Coen_2SO_3]^+$ is a pentacoordinated complex. High donor SO_3-group activity decreases the lifetime of the water molecule in the coordination sphere of *trans*-$[Coen_2(SO_3)H_2O]^+$ so that ^{59}Co NMR registers pentacoordinated monosulfite complex $[Coen_2SO_3]^+$ in equilibrium $[Coen_2(SO_3)H_2O]^+ \rightleftharpoons [Coen_2SO_3]^+ + H_2O$. The stable pentacoordinated complex of pseudo-tetragonal configuration was studied previously when *trans*-

Table 1. Isomerization rate constants at 25°C for *cis*- and *trans*-$[Co(en)_2X(ONO)]^{2+}$ complexes and parameters of NMR spectra

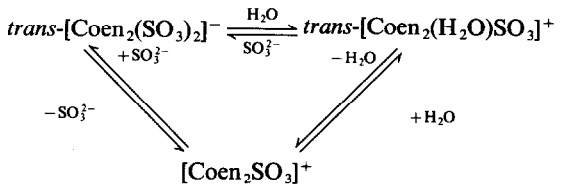
Py	1.11	0.32	−95	−160	−1115	−1135

$[Coen_2(SO_3)_2]^-$ were investigated.[27] It should be noted that for complexes $[Coen_2(H_2O)SO_3]^+$ and $[Coen_2SO_3]^+$ the *trans*-configuration is much preferable. *Cis*-$[Coen_2(H_2O)SO_3]^+$ was synthesized and its *cis*- to *trans*-isomerization was studied.[28] On substitution of the water molecule in *trans*-$[Coen_2(H_2O)SO_3]^+$ for the sulfite group (pH = 7.2) the latter is bonded to cobalt through oxygen atom and then O,S-isomerization occurs resulting in the formation of a complex with two Co—S bonds.

The equilibrium is given by the following scheme:



The presence in the Co^{III} coordination sphere of α,α′-bipyridyl or 1,10-phenanthroline chelate rings, being rather rigid, makes the formation of Co—NO_2 and Co—ONO bonds equally possible but for pentacyanide complex the equilibrium of O,N-linkage isomers shifts completely to the formation of the nitrito-complex.

It should be noted that all known tetramines $[Co(AA)_2X_2]^{n\pm}$ (AA = bipy or phen) exist only in the *cis*-configuration, due to steric reasons.[29–31] For $[Cophen_2(NO_2)_2]Cl$ and $[Codipy_2(NO_2)_2]Cl$[13,14] authors[32] made the assumption that both NO_2-groups are coordinated to cobalt through nitrogen atom. However, according to the values of chemical shifts of $[Cophen_2(NO_2)_2]^+$ (−1078 ppm) and $[Codipy_2(NO_2)_2]^+$ (−1212 ppm) both complexes are the compounds $[Co(AA)_2(NO_2)ONO]^+$, where one NO_2-group is coordinated to cobalt through nitrogen atom and another through oxygen atom. Unlike similar nitrito-nitro $[Coen_2(NO_2)ONO]^+$ complex, $[Co(AA)_2(NO_2)ONO]^+$ complexes are stable and do not undergo spontaneous O,N-linkage isomerization and are not affected catalytically by bases. On making the solutions of $[Co(AA)_2(NO_2)ONO]^+$ alkaline (diluted NaOH or ammonia up to pH = 9) hydrolysis of the nitrito-group easily occurs with the formation of $[Cophen_2(NO_2)OH]^+$ (δ = 525 ppm); $[Codipy_2(NO_2)OH]^+$ (δ = −694 ppm), and on further increase of alkaline concentration in the solutions of $[Co(AA)_2(NO_2)OH]^+$ (up to 2% NaOH) nitro-group undergoes hydrolysis accompanied by $[Co(AA)_2(OH)_2]^+$ dihydroxo-complexes formation.

Data available in the literature concerning displacement of the nitro-group for hydroxo-group in ethylenediamine Co^{III} complexes is related only to the alkaline concentration equal to 20%[31]; in that case both nitro-groups are replaced in isomeric *cis*- and *trans*-$[Coen_2(NO_2)_2]^+$ with the formation of *cis–trans*-$[Coen_2(OH)_2]^+$. In acid solution the Co—ONO bond is more stable than Co—NO_2. Short heating (for 12–15 min) of the solutions of $[Co(AA)_2(NO_2)ONO]^+$ with concentrated HCl up to 90°C resulted in the precipitation from the solution of the insoluble chloronitrito-complexes of $[Co(AA)_2(ONO)Cl]^+$. ^{59}Co NMR spectra of these complexes in DMFA and DMSO (δ = 388 ppm for $[Cophen_2(ONO)Cl]^+$) and (δ = 185 ppm for $[Codipy_2(ONO)Cl]^{\pm}$) showed that the NO_2-group is coordinated to cobalt through the oxygen atom.

Coordination of thiourea and sulfito-group to cobalt in phenanthroline and dipyridyl complexes of Co^{III} is realized through the sulfur atom and in all cases the changing of temperature or pH of the solution did not result in the formation of linkage isomers.

Deprotonation of aminoligand (en) causing the increase of electron density on Co^{III} atom and stabilization of Co—NO_2, Co—SO_3 and Co—SC

bonds play the essential role for linkage isomerization in bis-ethylenediamine complexes with NO_2^-, SO_3^{2-} and thiourea. No linkage isomerization was found in bipyridyl or phenanthroline complexes having no mobile protons at the nitrogen atoms coordinated to cobalt.

The interaction of SO_3-group with $[Co(CN)_5H_2O]^{2-}$ resulted in the formation of $[Co(CN)_5OSO_2]^{4+}$ ($\delta = -6385$ ppm) with Co—OSO_2 bond, which does not undergo isomerization within 7 days, but in the complexes with amine ligands the SO_3-group acts as a strong S-donor ligand.

Interaction of $[Co(CN)_5H_2O]^{2-}$ with KNO_2 is accompanied by coordination of NO_2-group to cobalt through the oxygen atom of $[Co(CN)_5ONO]^{3-}$ ($\delta = -6833$ ppm) and decrease of pH (< 12) does not result in the formation of the nitro-isomer, as was observed for $[Co(NH_3)_5ONO]^{2+}$.

However, when heating the solution of $[Co(CN)_5OSO_2]^{4-}$ and $[Co(CN)_5ONO]^{3-}$ (90°C, for 2–3 h) we observed the formation of linkage isomers of $[Co(CN)_5SO_3]^{4-}$ ($\delta = -7518$ ppm) and $[Co(CN)_5NO_2]^{3-}$ ($\delta = -7600$ ppm) which were isomerized into the initial oxygen coordinated forms upon cooling of the solutions.

(*Received* 28 *September* 1989; *accepted* 11 *January* 1990)

Abstract—The electronic absorption spectra of a series of divalent metal saccharinates of the type $[M^{II}(C_7H_4NO_3S)_2(H_2O)_4]\cdot 2H_2O$ (with M^{II} = Mn, Fe, Co, Ni, Cu) were recorded and briefly discussed. The obtained 10Dq-values were comparable to that of the respective hexaaqua complexes. Magnetic susceptibility measurements of these samples, in the temperature range between 4.2 and 300 K, were also undertaken and complemented, in some cases, with ESR data. The results of all these measurements could be explained on the basis of octahedral coordination of the metal centres, showing that the axial distortion introduced by the two saccharinate-ligands is very small.

The chemistry of saccharin (p-sulphobenzimide), commonly used as a non-nutritive sweeting agent, has attracted the attention in recent years due to its suspected carcinogenic nature (cf. for example ref. 1). Notwithstanding, studies on general physicochemical properties of saccharin complexes of transition metals of biological relevance are scanty.

We have recently investigated the ^{57}Fe-Mössbauer spectrum of the respective Fe^{II} complex and advanced some aspects of the magnetic behaviour of this and the corresponding Ni^{II} compound.[2]

Now we have investigated the electronic spectra of the Mn^{II}, Fe^{II}, Co^{II}, Ni^{II} and Cu^{II} saccharinate complexes as well as their magnetic behaviours in the temperature range between 4.2 and 300 K. The results are also complemented, in some cases with ESR measurements.

EXPERIMENTAL

The five complexes were obtained from the sodium salt of saccharine and the respective metal sulphates or acetates, in aqueous solution, according to the procedure described by Haider *et al.*[3] They were purified by double recrystallization from water and characterized by chemical analysis and IR spectroscopy.

The electronic spectra were recorded on a Shimadzu UV-300 spectrophotometer (UV–vis-range) and on a Cary 14 instrument (near IR-range) using freshly prepared solutions of the complexes in DMF, and concentrations ranging from 0.6 to 0.01 M.

* Author to whom correspondence should be addressed.

Magnetic susceptibility measurements in the temperature range 4.2–300 K were made using a fully automatic DSM 5 pendule susceptometer. The setup was calibrated with $NH_4Mn(SO_4)_2 \cdot 12H_2O$ and $Hg[Co(SCN)_4]$ as standards. The maximum field was 15 kG with $H\delta H/\delta z = 30\ kG^2 \cdot cm^{-1}$. In all cases the magnetic susceptibility was independent of the magnetic field strength. The susceptibilities were corrected for ionic diamagnetism.[4]

The ESR spectra were recorded at 77 and 300 K with a Bruker (Model ER 200D, X band) spectrometer. Only spectra measured at liquid nitrogen temperature, show adequate resolution and structure.

RESULTS AND DISCUSSION

1. *Structural characteristics*

The complexes have the general formula $[M(C_7H_4NO_3S)_2(H_2O)_4] \cdot 2H_2O$. They belong to the monoclinic space group $P2_1/c$ and $Z = 2$, as determined by single crystal X-ray diffraction methods.[5] The metal ions are located on crystallographic inversion centres and have distorted octahedral geometry. Each ion is bounded to four H_2O molecules and two nitrogen atoms, from the saccharinate ligands, in *trans* positions.

2. *Electronic spectra*

The electronic spectra of all these complexes can be discussed in terms of the tetragonally distorted octahedral configuration mentioned above. Data of the absorption maxima, and the proposed band assignments, together with the calculated 10Dq values are summarized in Table 1. Figure 1 shows the spectra of the cobalt and nickel complexes.

The proposed assignments were made by comparison with those of the respective hexaaqua-complexes which show very similar band positions and 10 Dq values.[6]

In the case of the Mn^{II} complexes, the $^6A_{1g} \rightarrow {}^4E_g(D)$ transition is overlapped by the tail of a charge transfer band located in the UV region, so direct calculation of the Racah parameters B and C was not possible. However, taking $C = 4.477B$ for an octahedral field[6] we were able to calculate $B = 760.5\ cm^{-1}$ and 10Dq (cf. Table 1).

$[Fe(Sac)_2(H_2O)_4] \cdot 2H_2O$ shows a broad absorption resolved into two components, due to the splitting of the excited ^5E_g state ($^5E_g \rightarrow {}^5A_{1g} + {}^5B_{1g}$). The value of 10Dq cannot be derived directly from that spectrum, except under the following suppositions: as there exists a *trans*-tetragonal distortion, and the axial field has lower σ-force than the equatorial one, the energy of the $^5A_{1g}$ level lies lower than that of

the $^5B_{1g}$. Assuming that the ground state is $^5B_{2g}$, the transition $^5B_{2g} \rightarrow {}^5B_{1g}$ (= 10,050 cm^{-1}) gives the value of 10Dq directly.[6]

For the Co^{II} complex there are three possible electronic transitions: ν_1 ($^4T_{1g} \rightarrow {}^4T_{2g}$) = 7634 cm^{-1}, ν_2 ($^4T_{1g} \rightarrow {}^4A_{2g}$) = 16,130 cm^{-1} and ν_3 [$^4T_{1g} \rightarrow {}^4T_{1g}(P)$] = 19,084 cm^{-1} with $10Dq = \nu_2 - \nu_1$ = 8496 cm^{-1}.

The irregularity of the ν_3 band at higher frequencies (see Fig. 1) is due to spin-orbit coupling of the $^4T_{1g}(P)$ state. The ν_2-transition is, as expected, very weak, because it involves a two-electron transition.

The presented data allow the calculation of a mean value of B = 821 cm^{-1} and C = 3804 cm^{-1} (assuming C = 4.633B).[6]

Three electronic transitions are also expected in the case of $[Ni(sac)_2(H_2O)_4] \cdot 2H_2O$. The spin-forbidden $^3A_{2g} \rightarrow {}^1E_g$ transition is expected to lie near the ν_2 band and this is the reason for the doublet structure observed in this region (cf. Fig. 1). ^1E_g and $^3T_{1g}$ states are scrambled by spin-orbit coupling and ν_2 was taken as the most intense band of the doublet.

The $^3A_{2g} \rightarrow {}^3T_{2g}$ transition gives the 10Dq value directly and the mean value for B calculated from all these data is 890 cm^{-1}. Considering C = 4.70B[6] gives C = 4193 cm^{-1}.

The spectrum of the Cu^{II} complex consists of a band with a main peak and a shoulder on the low energy side. Deconvolution of these bands, using Gaussian line-shapes and a least squares fitting procedure, suggested the assignments shown in Table 1. The calculated values for the tetragonal distortion parameters D_s and D_t were 78.8 and −682.5 respectively.

A comparison of the calculated 10Dq values with those known for the respective $[M(H_2O)_6]^{2+}$ complexes[6] is shown in Table 2. As can be seen, the absolute values are very similar in both series of compounds. Saccharinate values are slightly higher in the case of Mn^{II}, Co^{II} and Ni^{II} compounds and lower in the other two cases.

These results clearly show that the replacement of two of the water molecules in the hexaaqua moieties, by two saccharinate nitrogens has only a very small effect on the crystal fields of these cations. The spectroscopic results also show that the distortive effects on the overall octahedral symmetry are very low.

3. *Magnetic properties*

The magnetic behaviour of all these complexes is rather simple and could be directly explained on the

Table 2. Comparison of 10Dq values of the $[M(sac)_2(H_2O)_4]$ and the corresponding $[M(H_2O)_6]^{2+}$ complexes (values in cm^{-1})

	Mn	Co	Ni	Fe	Cu
$[M(sac)_2(H_2O)_4]$	8366	8496	8885	10,050	9091
$[M(H_2O)_6]^{2+}$	8000	7900	8500	10,400	10,650

Table 3. Magnetic parameters for the different investigated $[M(sac)_2(H_2O)_4]\cdot 2H_2O$ complexes

M	μ_S (B.M.)	μ_{S+L} (B.M.)	μ_{exp} (B.M)	θ (K)
Mn	5.92	5.92	5.98	−0.05
Fe	4.90	5.84	5.26	−5.16
Co	3.87	5.20	4.80	−3.08
Ni	2.83	4.47	2.99	−8.47
Cu	1.73	3.00	1.76	+9.10

basis of octahedral coordination of the different metal centres. The magnetic behaviour can also be interpreted neglecting the small axial distortion of the ligand field, in agreement with the results obtained from the electronic spectra discussed in the preceeding section.

Table 3 shows the relevant magnetic parameters including calculated spin-only values, $\mu_S = 2[S(S+1)]^{1/2}$ and values resulting by considering spin-orbit coupling, $\mu_{S+L} = [L(L+1)+4S(S+1)]^{1/2}$, which are compared with the experimental μ_{exp}-data. Values of the Weiss constant θ, are also included in this table.

The temperature dependence of the reciprocal molar susceptibility of $[Mn(sac)_2(H_2O)_4]\cdot 2H_2O$ is shown in Fig. 2. The magnetic susceptibility obeys a quasi-Curie law, $\chi = 0.22/T$ in the whole temperature range of measurements. The magnetic moment of 5.98 B.M. fairly agrees with that expected for the octahedral crystal field $^6A_{1g}$ term. This term arises from the free ion ^6S term associated with the Mn^{II} ion for which only a spin contribution is expected.

The ESR spectrum of this complex measured at 77 and 300 K shows a single broad isotropic signal with $g_{eff.} = 2.00$.

The magnetic susceptibility of $[Fe(sac)_2(H_2O)_4]\cdot 2H_2O$ follows a behaviour which is characteristic of the $^5T_{2g}$ term arising from a free ^5D term under octahedral field splitting. Although the susceptibility appears to follow a Curie–Weiss law, $\chi = 3.84/T - 5.2$, the magnetic moment slightly increases with decreasing temperature below 100 K, rising to a maximum of 5.83 B.M. in the temperature range between 90 and 30 K. The magnetic moment steadily decreases below this temperature taking a value of 5.56 B.M. at 12 K.

The average magnetic moment of 5.26 B.M. obtained from the Curie–Weiss behaviour is in good agreement with that usually observed for Fe^{II} complexes in octahedral environments[4,7] in which small spin-orbit coupling effects are present. The negative value of the Weiss-constant, $\theta = -5.2$ K can be primarily related to crystal field effects, and cooperative interactions, such as antiferromagnetic couplings, need not be considered.

The magnetic susceptibility also obeys a Curie–Weiss law, $\chi = 2.89/T - 3.08$, in the case of the cobalt complex in the temperature range between 300 and 60 K (see Fig. 3). Deviations from the

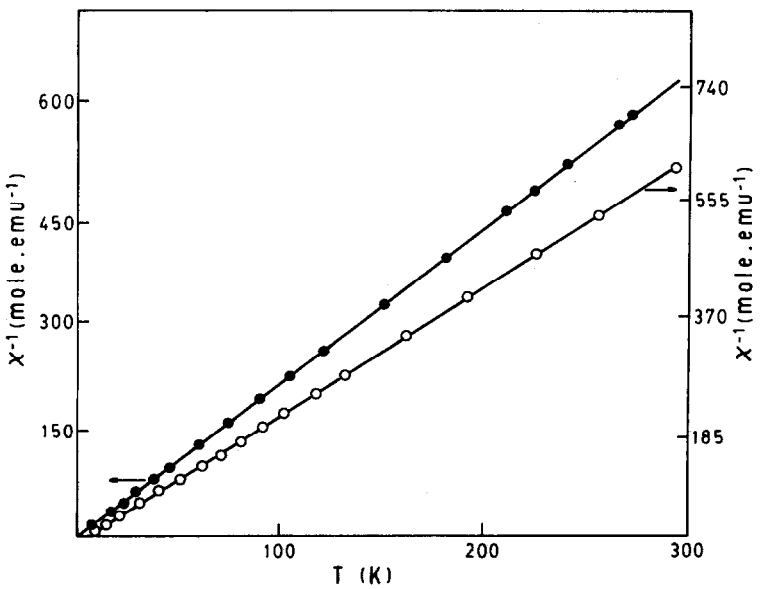

Fig. 2. Temperature dependence of the reciprocal molar susceptibility of $[Mn(sac)_2(H_2O)_4]\cdot 2H_2O$ (●) and $[Cu(sac)_2(H_2O)_4]\cdot 2H_2O$ (○).

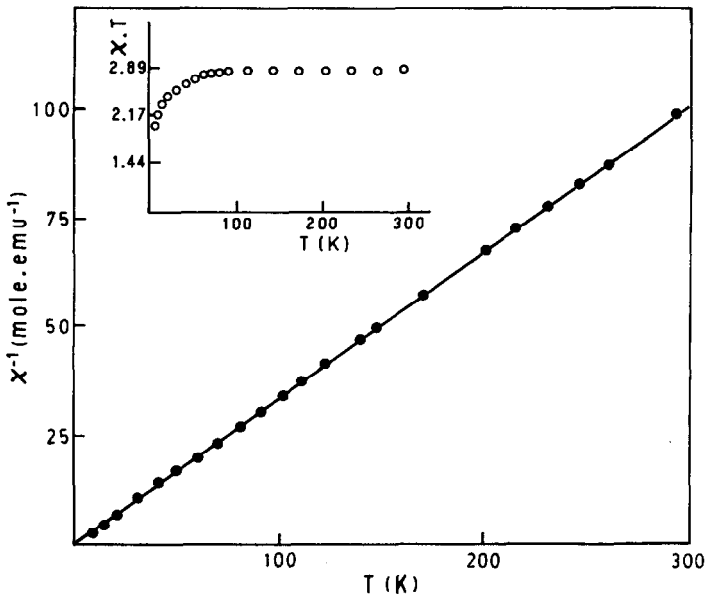

Fig. 3. Temperature dependence of the reciprocal molar susceptibility for $[Co(sac)_2(H_2O)_4]\cdot 2H_2O$. Inset: $\chi \cdot T$ vs T plot.

linearity are observed below 60 K, and the magnetic susceptibility increases more rapidly than required by this Curie–Weiss law. The magnetic moment remains almost constant between 300 and 60 K, taking a value of 4.80 B.M., which is indicative of important orbital contributions. The magnetic moment gradually decreases, below 60 K, taking a value of 3.56 B.M. at 4.2 K (cf. inset of Fig. 3).

Both the magnetic moment and the negative Weiss-constant are characteristic for a $^4T_{1g}$-term arising from the ^4F free ion state and, as in the case of iron-saccharinate, no magnetic interactions are operative for this compound.

The $[Ni(sac)_2(H_2O)_4]\cdot 2H_2O$ has been investigated earlier[2] and its magnetic susceptibility also follows a Curie–Weiss law, $\chi = 1.07/T - 8.47$, between 78 and 300 K. The magnetic moment of 2.99 B.M. points only to a very weak spin-orbit coupling, as is usual for octahedral Ni^{II} complexes.[4,7]

The variation of the reciprocal molar susceptibility against the temperature for the copper complex is shown in Fig. 2. The data are compatible with a Curie–Weiss behaviour, $\chi = 2.57/T + 9.10$. The value obtained for the magnetic moment (1.76 B.M.) is unusually low, suggesting some spin-orbit coupling.

The corresponding ESR spectrum (Fig. 4) shows a Lorentzian axial signal with $g_\parallel = 2.347$ and $G_\perp = 2.073$, $A_\parallel = 150 \times 10^{-4}$ and $A_\perp$ unobserved. Such signals are characteristic for the Cu^{II} ion with the unpaired electron placed in the $d_{x^2-y^2}$ orbital and is also typical for an axially distorted octahedral coordination sphere.[8] The broadening of the signal

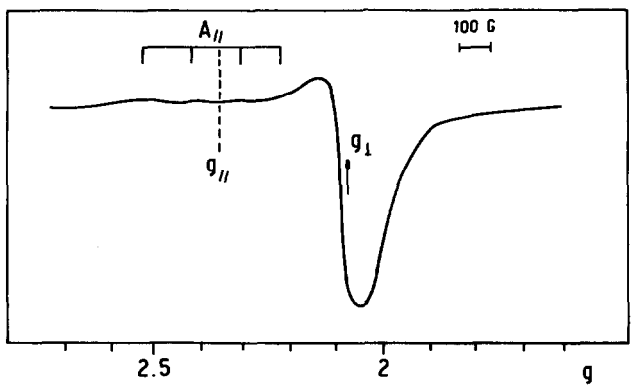

Fig. 4. ESR spectrum of a polycrystalline sample of $[Cu(sac)_2(H_2O)_4]\cdot 2H_2O$ at 77 K.

can be attributed to non-solved superhyperfine structure arising from the coupling of the copper-spin with those of the two coordinated nitrogen atoms ($I = 1$).

Using the known relations between g-values and electronic transition energies,[8] assuming the value of $-830\ cm^{-1}$ for the spin-orbit coupling constant[6] and values between 0.5 and 0.6 for the squares of the orbital reduction factors k, we calculated $g_\perp = 2.07$ and $g_\parallel = 2.36$, in excellent agreement with the experimental values.

SYNTHESIS, STRUCTURE AND $^{77}Se/^{119}Sn$ NMR SPECTROSCOPY OF THE NEW POLYSELENIDE, TRIS(TETRASELENIDO)STANNATE(IV), $[Sn(Se_4)_3]^{2-}$

SONG-PING HUANG, SANDEEP DHINGRA and MERCOURI G. KANATZIDIS*

Department of Chemistry, Michigan State University, East Lansing, MI 48824, U.S.A.

(*Received* 11 *September* 1989; *accepted* 18 *January* 1990)

Abstract—The reaction of sodium pentaselenide with $SnCl_4$ or $SnCl_2 \cdot 2H_2O$ in dimethylformamide (DMF), in a 3:1 ratio, forms the new soluble anion $[Sn(Se_4)_3]^{2-}$ in high (> 79%) yields. The compound $(Ph_4P)_2[Sn(Se_4)_3]$ (I) crystallizes in the monoclinic space group $P2_1/c$ with unit cell dimensions, $a = 13.320(2)$, $b = 11.678(3)$, $c = 34.817(9)$ Å, $\beta = 98.85(2)°$ and $V = 4535$ Å^3. A single-crystal X-ray diffraction study of I shows that three chelating Se_4^{2-} ligands provide an octahedral coordination about the central Sn^{4+} atom. The crystal structure was solved and refined with conventional techniques to $R = 6.0\%$ and $R_w = 7.0\%$. The average Sn—Se distance is 2.709(13) Å, while the average Se—Se bond distance is 2.324(12) Å. The IR spectrum of I (CsI pellet) shows two sets of absorptions at 273, 256 cm^{-1} and 181, 173 cm^{-1}, respectively, assigned tentatively to ν(Se—Se) and ν(Sn—Se) vibrations. The ^{119}Sn NMR spectrum of I in DMF, shows a single resonance at −723 ppm (vs Me_4Sn). The ^{77}Se NMR spectrum of I in DMF, shows two resonances at 618 and 459 ppm. Thermal decomposition of I results in formation of $SnSe_2$ at 510°C. Further heating, above 600°C, results in SnSe.

Interest in the synthesis of soluble transition-metal polychalcogenide compounds remains intense because of their astonishing tendency for structural and stoichiometric diversity. As a result, a number of polysulphide and to a lesser extent polyselenide and polytelluride complexes with transition metals have been isolated and structurally characterized.[1–8] By contrast, the preparation of soluble polychalcogenide compounds containing main-group elements has not been pursued to any considerable degree. The few existing examples are, the $[Bi_2S_{34}]^{4-}$,[9] $[Sn(S_4)_2(S_6)_{0.6}(S_4)_{0.4}]^{2-}$,[10] $[In_2Se_{21}]^{4-}$,[11] $[In_3Se_{15}]^{3-}$ [12] and $[Tl_3Se_{15}]^{3-}$.[12] Recently we have undertaken a systematic investigation of polychalcogenide chemistry of the late transition and main group metals.[11–15] Except for some cases, the solution chemistry of polyselenide or polytelluride complexes has proven to be at considerable variance from that of polysulphide chemistry. For example, while group 12 metals form isostructural complexes with all types of Q_4^{2-} ligands, group 11 metals form different structures with different polychalcogenide ligands.[3,13] The reasons for this deviation from polysulphide chemistry are not completely understood, although the size difference between sulphur and the heavier chalcogens is probably a strongly influencing factor. It would be useful to understand the role of the metal ion in determining similarities and differences in the chemistry of the various polychalcogenide ligands. ^{77}Se NMR spectroscopy appears to be a useful or even unique tool (not applicable to polysulphides) for the investigation of metal–polyselenide complexes.[5,8] In this paper we report the synthesis, molecular structure, ^{77}Se, ^{119}Sn NMR and other spectroscopic characterization of the new complex $[Sn(Se_4)_3]^{2-}$, the first group 14 polyselenide.

EXPERIMENTAL

All work was done in a glovebox (Vacuum Atmospheres, Inc.) under a nitrogen atmosphere. Dimethylformamide (DMF) was stored over 4 Å Linde molecular sieves for several days and distilled under vacuum. Ether was distilled over sodium (or potassium)/benzophenone under a nitrogen blanket. $SnCl_4$ (anhydrous) and $SnCl_2 \cdot 2H_2O$ were pur-

* Author to whom correspondence should be addressed.

chased from Alpha Products. Elemental analyses were performed by Galbraith Laboratories, Knoxville, Tennessee. Satisfactory elemental analyses were obtained. Sodium pentaselenide (Na_2Se_5) was prepared in liquid ammonia from sodium metal and elemental selenium in a 2:5 ratio. The X-ray powder diffraction patterns were recorded either with a standard Debye-Scherrer powder camera mounted on a Phillips Norelco XRG-5000 X-ray generator operating at 40 kV/20 mA, or a Phillips XRG-3000 computer-controlled powder diffractometer. Nickel filtered, copper radiation was used. Thermal gravimetric analyses were performed on a Cahn TG System 121 under flowing nitrogen. A typical heating rate of 5°C min^{-1} was used. IR spectra were recorded as KBr and CsI pellets on a Nicolet 740 FT–IR spectrometer. UV–vis spectra were recorded on a Hitachi U-2000 spectrophotometer.

Synthesis of $(Ph_4P)_2[Sn(Se_4)_3]$ **(I)**

Method A. A 10 cm^3 DMF solution of 0.051 g (~ 0.2 mmol) liquid $SnCl_4$ was added to a 50 cm^3 DMF solution of 0.270 g (~ 0.61 mmol) Na_2Se_5 in the presence of 0.150 g (0.40 mmol) Ph_4PCl. Filtration of NaCl precipitate, followed by slow addition of *ca* 60 cm^3 of ether, and storage at room temperature for several days, afforded analytically-pure red–brown hexagonal platelets in 85%. The X-ray diffraction (XRD) powder pattern obtained from this material matches extremely well that obtained from calculating the same pattern from the single-crystal coordinates, confirming the purity of the compound. A comparison between the calculated and observed *d* spacings for this material is shown in Table 1.

Method B. A 20 cm^3 DMF solution of 0.045 g (0.2 mmol) $SnCl_2 \cdot 2H_2O$ was added to a 30 cm^3 DMF solution of 0.270 g (0.61 mmol) Na_2Se_5 in the presence of 0.220 g (0.60 mmol) Ph_4PCl. The resulting red–brown solution was filtered to remove NaCl and the filtrate was diluted with 50 cm^3 ether to incipient crystallization. Upon standing at room temperature for a week, red–brown microcrystalline powder was obtained (0.275 g). Yield 79%. The product was recrystallized from DMF–ether to obtain large, hexagonal-shaped crystals. The XRD powder pattern of this product is identical to that obtained in method A.

Thermal decomposition of $(Ph_4P)_2[Sn(Se_4)_3]$ *to* $SnSe_2$

This decomposition was carried out inside an alumina boat in a tube furnace under flowing nitrogen at 510°C. The final black–grey microcrystalline product corresponds, by weight, to $SnSe_2$. It was characterized by X-ray diffraction. X-ray diffraction powder pattern spacings (in Å) follow; intensities are shown in parentheses: 6.17 (100.0), 3.076 (7), 2.25 (21), 2.050 (40), 1.906 (6), 1.742 (13).

Thermal decomposition of $(Ph_4P)_2[Sn(Se_4)_3]$ *to* SnSe

This decomposition was carried out inside an alumina boat in a tube furnace under flowing nitrogen at 600°C. The final black–grey microcrystalline is, by X-ray diffraction, SnSe. *d* Spacings (in Å) follow; intensities are shown in parentheses: 5.76 (1), 3.514 (3), 3.033 (2), 2.934 (10), 2.874 (100), 2.380 (6), 2.087 (4), 2.042 (3), 1.920 (1), 1.833 (7), 1.761 (3), 1.684 (2).

X-ray crystallographic studies

The crystallographic data for **I** were collected on a Nicolet four-circle diffractometer using a ω–2θ scan mode and Mo-K_α radiation (at Crystalytics Co., Lincoln, Nebraska by Dr C. S. Day). The crystals were mounted inside glass capillaries and sealed. Crystal data and details for data collection and refinement are shown in Table 2. The intensities of three check reflections were monitored every 100 reflections and did not show any appreciable decay during the data collection period. An empirical absorption correction was applied to all data based on ψ scans for seven reflections. The structure was solved with direct methods using SHELXS-86[16] and was refined with the SDP[17] package of crystallographic programs, using a VAXstation 2000 computer. All non-carbon and non-hydrogen atoms were refined anisotropically. The carbon atoms were refined isotropically. The hydrogen atom positions were calculated and included in the structure factor calculation but were not refined. There were no significant residual peaks in the final electron density difference map. The XRD powder pattern was calculated using the atom coordinates determined from the single-crystal data using the program POWD 10[18] (see Table 1).

NMR spectroscopy

^{77}Se ($I = 1/2$, nat. abund. 7.58%) and ^{119}Sn ($I = 1/2$, nat. abund. 8.58%) NMR spectra were obtained on a Varian VXR-500 (superconducting cryomagnet 11.74 Tesla) pulse spectrometer equipped with Sun/360 workstation. The spectra were recorded at ambient temperature using a broad band 5 mm probe (frequency range 50–202 MHz). The observing frequencies were 95.358 MHz for ^{77}Se and 186.250 MHz for ^{119}Sn. The aquisition time was 0.32 s with a spectral width of 38.35 KHz for ^{77}Se and 37.393 KHz for ^{119}Sn which gave data point resolution of 1.14 and 1.17 Hz, respectively. The pulse width used in these experiments was 6 μs for both ^{77}Se and ^{119}Sn spectra, and no relaxation delay was applied. The number of free induction decays accumulated was 30,000 and 72,000 for ^{77}Se and ^{119}Sn, respectively. A line broadening of 50 Hz was typically applied.

The spectra were referenced to Me_2Se for ^{77}Se and Me_4Sn for ^{119}Sn at $\delta = 0$ ppm in DMF. Solutions of Ph_2Se_2 ($\delta = 460$ ppm) and Me_4Sn in DMF were used as external reference. The convention used for the chemical shifts is that a positive sign signifies a shift to high frequency compared to the reference compound.

RESULTS AND DISCUSSION

Synthesis

The preparation of $(Ph_4P)_2[Sn(Se_4)_3]$ was carried out by reacting $SnCl_4$ with Na_2Se_5 in DMF in the presence of Ph_4P^+ according to eq. (1):

$$SnCl_4 + 3Na_2Se_5 + 2Ph_4PCl \longrightarrow (Ph_4P)_2[Sn(Se_4)_3] + 6NaCl. \quad (1)$$

The reaction was accompanied by a sharp colour change from dark green to red–brown. Interestingly the same compound can be obtained by using $SnCl_2 \cdot 2H_2O$ as starting material which indicates that possible Sn^{2+}–Se_x^{2-} ($x > 1$) complexes are unstable towards internal redox chemistry resulting in the formation of Sn^{4+} species. This is similar to

the behaviour of the corresponding Fe^{2+}/Se_x^{2-},[2] Au^{+}/Se_x^{2-}[14,15] and Tl^{+}/Se_x^{2-}[12] systems from which only Fe^{3+}, Au^{3+} and Tl^{3+} complexes have been isolated.

The UV–vis spectrum of **I** in DMF solution has no characteristic absorption bands (300–800 nm) and features a rising absorbance at higher energies. The absence of a band around 650 nm suggests that the complex does not dissociate in this solvent to form Se_x^{-} radical anions (as has been observed in $[In_2Se_{21}]^{4-}$[11]) which are responsible for this absorption.[11,19] In the far-IR region of the spectrum we observe two sets of two absorptions at 273, 256 cm^{-1} and 181, 173 cm^{-1}, respectively. According to other literature data[2,20] we assign these sets, respectively, to Se—Se and Sn—Se vibrations.

The ^{77}Se NMR spectrum of **I** in DMF solution at room temperature, shows two peaks at 618 and 459 ppm, respectively, indicating that all three Se_4^{2-} ligands in the complex are equivalent [Fig. 1(A)]. The various conformations of the $SnSe_4$ five-membered rings (*vide infra*) interconvert in solution at room temperature. This is common in complexes containing Se_4^{2-} ligands, as in the series $[MQ(Se_4)_2]^{2-}$ (Q = O, S, Se)[2] where the fluxional behaviour persists down to −60°C. Table 3 summarizes pertinent ^{77}Se NMR chemical shifts from MSe_4 systems known thus far. In all cases but one, the metal-bound selenium atom resonance occurs at lower field than the corresponding ring-selenium resonance.[5,8] It was found in the isostructural (but not isomorphous) $[Pt(Se_4)_3]^{2-}$, the platinum-bound ^{77}Se resonance occurs at higher field than the corresponding non-platinum-bound ^{77}Se resonance.[21] Since we could not observe Sn—Se satellite peaks, we cannot unequivocally assign the resonances for $[Sn(Se_4)_3]^{2-}$.

The ^{119}Sn NMR spectrum of $[Sn(Se_4)_3]^{2-}$, in DMF solution at room temperature, shows a single peak at −723 ppm, as expected, consistent with the notion that the integrity of the complex is maintained in solution [Fig. 1(B)]. We did not observe satellite peaks that could be attributed to ^{119}Sn–^{77}Se coupling. The observed ^{119}Sn NMR chemical

[a] Labelling scheme of the MSe_4 ring system:

shift for $[Sn(Se_4)_3]^{2-}$, correlates well with those of $[SnSe_3]^{2-}$ and $[SnSe_4]^{4-}$ anions[22] which occur at −264.3 and −476.6 ppm, respectively. The successive shift of the ^{119}Sn resonance toward more negative values with increasing tin coordination number is evident and suggests increased shielding on the tin centre. This is consistent with similar trends observed for other tin complexes (e.g. the tin–halide series).[23]

TGA examination of the thermolysis of **I** under flowing nitrogen shows that the compound begins to lose weight at ~ 335°C as shown in Fig. 2. This onset temperature of initial weight loss, is shared by other Ph_4P^+ salts of polyselenide complexes and is due to the nucleophilic attack on the Ph_4P^+ cation by the Se_x^{2-} ligands to generate the volatile Ph_3P, Ph_3PSe, Ph_2Se, Ph_2Se_2, etc. Following a smooth and continuous weight loss, the decomposition of **I** results, at 520°C, in the formation of $SnSe_2$. Further heating results in the loss of one selenium to yield SnSe at ~ 660°C. $SnSe_2$ and SnSe were unequivocally identified by X-ray powder diffraction.

Description of the structure of **I**

The monoclinic unit cell contains well-separated $[Sn(Se_4)_3]^{2-}$ anions and Ph_4P^+ cations. The latter have the usual tetrahedral structure and will not be discussed further. The structure of the anion in **I** is similar to the recently reported $[Pt(Se_4)_3]^{2-}$[21] and $[Sn(S_4)_3]^{2-}$.[10] However, the latter was not isolated in pure form. It was found co-crystallized in the same crystallographic site (and therefore disordered) with $[Sn(S_4)_2(S_6)]^{2-}$, respectively, in a 4:6 ratio. No such disorder was detected in the present study. The structure of the $[Sn(Se_4)_3]^{2-}$ anion is shown in Fig. 3, and consists of three four-membered selenium chains chelated to a central Sn^{4+}. The coordination geometry of the Sn^{4+} is octahedral approaching D_3 symmetry, with an average Sn—Se bond distance of 2.709(13) Å, and a Se—Sn—Se angle of roughly 90°. A listing of selected bond distances and angles for $[Sn(Se_4)_3]^{2-}$ is given in Table 4. The observed Se—Se bonds are in the normal range of single Se—Se bond distances reported for other metal–polyselenide compounds. To the best of our knowledge $[Sn(Se_4)_3]^{2-}$ is the first

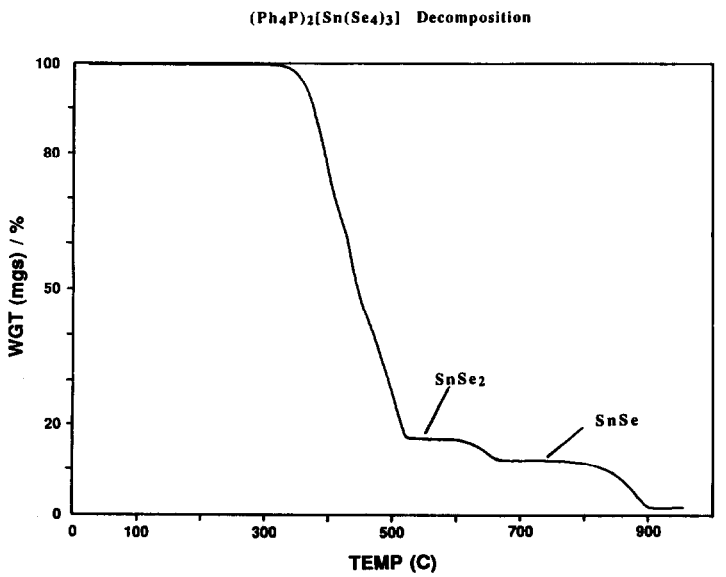

Fig. 2. Typical TGA diagram of **I** under flowing nitrogen.

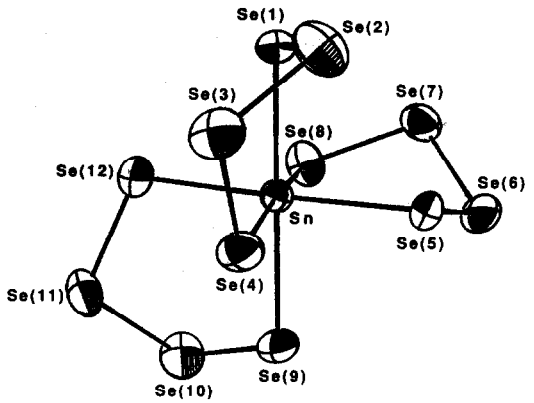

Fig. 3. ORTEP representation and labelling scheme of the structure of the $[Sn(Se_4)_3]^{2-}$ anion.

molecular example of a Sn^{4+} centre being coordinated in an octahedral fashion by six selenide atoms. A solid-state analogue is $SnSe_2$, in which the tin is coordinated octahedrally. The Sn—Se bond lengths in the anion of **I** are comparable to those found in $SnSe_2$[24] (2.683(2) Å) but shorter than those observed for SnSe[25] (2.793(2) and 2.744(3) Å). This difference is expected due to the Sn^{2+} oxidation state in SnSe. The Sn—Se bond, however, in $[Sn(Se_4)_3]^{2-}$ is much longer than that found in $[Sn_2Se_6]^{4+}$ (av. 2.508 Å) in which tin features a tetrahedral coordination.[26] The SnSe(1)Se(2)Se(3)Se(4) ring adopts the envelope comformation while the other two SenSe(5)Se(6)Se(7)Se(8) and SnSe(9)Se(10)Se(11)Se(12) adopt puckered conformations. Both of these conformations are common in Q_4^{2-} chemistry. For example, the envelope conformation is notable in the series $[M(Se_4)_2]^{2-}$[3] (M = Zn, Cd, Hg), while the puckered one is characteristic in the $[MQ(Se_4)_2]^{2-}$ (M = Mo, Q = Q, S, Se) series.[5]

With three *cis*-coordinated bidentate ligands, **I** can exist as optical isomers. The complex is a racemic mixture similar to the $[Pt(S_5)_3]^{2-}$[27] where

partial resolution of the optical isomers using (+)-$[Ru(Phen)_3]^{2+}$ as the counterion provided a carbon-free optically active inorganic molecule. Although we did not attempt it, the resolution of the optical isomers of $[Sn(Se_4)_3]^{2-}$ by a similar method should also be possible.

SYNTHESIS AND STUDY OF OXOVANADIUM(IV) COMPLEXES WITH DITHIOBIS(2,4-PENTANEDIONE)

RYSZARD GRYBOŚ* and WITOLD PAW

Faculty of Chemistry, Jagiellonian University, 30-060 Kraków, Poland

(*Received* 27 *February* 1989; *accepted after revision* 19 *January* 1990)

Abstract—Two vanadyl complexes of dithiobis(2,4-pentanedione), $H_2acac_2S_2$, with 1 : 1 : 1 (metal–$acac_2S_2$–L, where L = DMSO, py) stoichiometry have been characterized by elemental analysis, IR and optical spectral studies, field desorption mass spectrometry and magnetic susceptibility measurements. It is concluded that trinuclear complexes $[VO(acac_2S_2)DMSO]_3$ (**A**) and $[VO(acac_2S_2)py]_3$ (**B**) are formed, for which cyclic structural forms are proposed.

Polynuclear metal complexes in which metal ions are linked together by di- or polyfunctional organic ligands are an area of intense studies due to the potential possibility of applications of these complexes in electronics, microlithography or catalysis.[1] Various bis(β-diketones) and metal ions have been used for the synthesis of these complexes.[2–5] However, polynuclear metal complexes containing thiobis(β-diketones) as bridging ligands have not been numerous.[2,6,7] These complexes are insoluble in water and organic solvents, making difficult the study of their properties. In an attempt to explore in some detail the coordination chemistry of these ligands, vanadyl complexes were synthesized and characterized by spectroscopic methods in addition to the data based on analyses and magnetic susceptibility.

EXPERIMENTAL

Materials

3,3′-Dithiobis(2,4-pentanedione), $H_2acac_2S_2$, was prepared by the method described in the literature[6] and gave satisfactory analyses, ^1H NMR and IR spectra. Oxobis(2,4-pentanedionato)vanadium(IV), $VO(acac)_2$ (Alfa Products) was recrystallized from acetone. Dimethyl sulphoxide (DMSO) (Reachim, U.S.S.R.) was dried over CaO and distilled under reduced pressure. Pyridine (py) (POCh, Gliwice) was used without further purification.

* Author to whom correspondence should be addressed.

Preparation of $[VO(acac_2S_2)DMSO]_3$ (A)

Equivalent amounts of $VO(acac)_2$ (10 mmol) and $H_2acac_2S_2$ (10 mmol) were added to 200 cm^3 DMSO. The mixture was stirred until both reagents were completely dissolved. The solution was heated to 45°C using a hot plate. DMSO and 2,4-pentanedione were evaporated under reduced pressure until no solvent remained. The powder obtained was washed three times with 15 cm^3 portions of benzene to remove the brown by-product and/or unreacted reagents, then filtered and dried *in vacuo* at room temperature. The yield of crude product was 95%. The pure product was obtained by recrystallization from DMSO, washed with diethyl ether and dried *in vacuo* at room temperature. Found: V, 12.2; C, 34.7; H, 4.56; S, 23.6. Calc. for $[VO(acac_2S_2)DMSO]_3$: V, 12.6; C, 35.5; H, 4.48; S, 23.7%. The complex does not melt but decomposes on heating at about 150°C.

The same product was obtained when the reaction was carried out at the molar ratio $VO(acac)_2$–$H_2acac_2S_2$ equal to 1.5 : 1.

Preparation of $[VO(acac_2S_2)py]_3$ (B)

$[VO(acac_2S_2)DMSO]_3$ (1 g) was dissolved in 50 cm^3 of warm pyridine and then the solution was stored in a refrigerator for a few days. The solid obtained was filtered off, washed with diethyl ether and dried *in vacuo* at room temperature. Found: V, 12.3; C, 44.4; H, 4.55; S, 15.6; N, 3.8. Calc. for $[VO(acac_2S_2)py]_3$: V, 12.6; C, 44.3; H, 4.18; S,

15.8; N, 3.45%. The complex does not melt but decomposes on heating at about 200°C.

Analytical methods

Carbon, hydrogen, nitrogen and sulphur were determined by organic microanalysis procedures. Vanadium was determined by manganometric titration after decomposition of the complex with hot 3 M H_2SO_4.

Physical measurements

The attempted determination of melting points was performed on "Boetius" apparatus (MLW, VEB Analytik, G.D.R.). A Carl Zeiss Jena (G.D.R.) Model UR-10 IR spectrophotometer was used to obtain the spectra in the range 4000–400 cm^{-1}. The KBr disc method was employed for the preparation of the sample. The electronic absorption spectra in the range 400–1300 nm were recorded using a Perkin–Elmer, Lambda 9, UV–vis–NIR spectrophotometer. The field desorption (FD) mass spectra were obtained on a Varian MAT-711 mass spectrometer by desorption of the samples from 10 μm tungsten wire at 20 mA. Magnetic measurements were carried out on Bruker (F.R.G.) apparatus using the Faraday technique over the temperature range 98–293 K, with $Hg[Co(NCS)_4]$ as a calibrant. Diamagnetic corrections were estimated from Pascal's constants.[8]

RESULTS AND DISCUSSION

$[VO(acac_2S_2)DMSO]_3$ (**A**) and $[VO(acac_2S_2)py]_3$ (**B**) are yellow–green powders which are stable in air. They are soluble in pyridine and DMSO but insoluble in hydrocarbons, CCl_4, H_2O and benzene. Complexes **A** and **B** decompose in alcohols, acetone, THF and $CHCl_3$, and the rate of decomposition depends on the solvent, being very rapid in $CHCl_3$ and slow in acetone.

It is evident from the elemental analyses that oxovanadium(IV) forms complexes with 1:1:1 (metal–ligand–solvent) stoichiometry. Jones and Power[6] suggested a polymeric helical type structure for insoluble 1:1 complexes of cobalt, copper and nickel of $acac_2S_2^{2-}$ based on the spectral data in the visible region. Two structural forms which satisfied the metal to ligand ratio (1:1) are possible: polymeric and cyclic oligomeric. For the polymeric structure containing a chain of alternate ($acac_2S_2$) and (VOL) units this ratio is reached for the average degree of polymerization higher than ten. For the cyclic form, the metal to ligand ratio is equal 1:1 and is independent of the degree of polymerization. The best resolution of this problem would be to determine the molecular weight of the complexes. Unfortunately, attempts to determine the molecular weights of **A** and **B** in DMSO or pyridine by vapour pressure osmometry were unsuccessful due to the hygroscopic properties of the solvents and/or partial decomposition of the complexes under experimental conditions.

We tried to resolve this problem using FD technique. The mass spectral studies on $VO(acac)_2$[9] showed that electron ionization produced both parent and fragment ions, whereas field desorption produced molecular and dimeric ions (dimeric ions were present in low relative abundance). Thus the FD technique can be useful for the molecular weight determination of neutral complexes.[10] FD mass spectra of **A** and **B** show a signal for the molecular ion $[VO(acac_2S_2)]_3^+$ at m/z 981. Assuming that under FD conditions the solvent molecules (DMSO or pyridine) are liberated, both complexes could be regarded as trimeric species, $[VO(acac_2S_2)]_3$. It appears that the cyclic trimeric structure (Fig. 1) is more reliable for complexes **A** and **B** than the polymeric structure.

The IR spectroscopic data in the interesting 400–1700 cm^{-1} range and the possible assignments are given in Table 1.

The spectra exhibit two intense closely-spaced bands in the 1583–1560 cm^{-1} region. The high-frequency band is assigned to C···O and the lower-frequency one to the C···C stretching modes.[11,12] This is characteristic for chelation of the β-diketone to metal ion through oxygen atoms.

Interpretation of the spectrum of **A** in the 1100–900 cm^{-1} range is difficult because the V=O and S=O stretching, as well as CH_3 rocking modes, are expected to appear in this region. The strong absorption band observed in the spectrum of **A** at 990 cm^{-1} is assigned to ν(S=O). It is expected that the attachment of the DMSO molecule to a vanadium ion through oxygen should cause a

[a] Intensity designations: vs—very strong, s—strong, m—medium, w—weak, vw—very weak.

[b] ν, δ and π denote stretching, bending and out-of-plane bending modes, respectively. Not all the pyridine bands are listed.

decrease in the electron density on the DMSO oxygen atom, this results in the lowering of the S=O bond order and hence ν(S=O). The assignment is in agreement with the observed lowering of the ν(S=O) band from 1045 in free DMSO to the 1000 cm^{-1} region for transition metal complexes with DMSO.[13] It is also known that coordination of the additional ligand (e.g. substituted pyridines[14]) to $VO(acac)_2$ shifts the ν(V=O) band to lower frequencies, thus the strong band observed for **A** and **B** at 945 and at 965 cm^{-1}, respectively, is assigned to ν(V=O).

Two weak bands at 720 and 700 cm^{-1} which are observed in the spectrum of **A** can be assigned to the C—S stretching mode of DMSO.[15]

The weak band at 450 cm^{-1} observed in both the complexes and $H_2acac_2S_2$ we propose to assign to the —S—S— stretching mode which should occur in the 500–400 cm^{-1} region.[16] For S_2Cl_2 this band appears at 448 cm^{-1}.[17]

The spectrum of **B** shows the pyridine bands,[18] which are not listed in Table 1.

The electronic spectra of vanadyl complexes having a square pyramidal or a distorted octahedral structure are most often interpreted in terms of the energy level scheme proposed by Ballhausen and Gray.[19] Usually three optical bands are observed in the visible region, assigned to (I) $^2B_2(d_{xy}) \rightarrow {}^2E(d_{xz}, d_{yz})$; (II) $^2B_2(d_{xy}) \rightarrow {}^2B_1(d_{x^2-y^2})$; and (III) $^2B_2(d_{xy}) \rightarrow {}^2A_1(d_{z^2})$. Band III is often obscured by intense absorption tailing in from the UV.

The electronic spectra in the range 400–1300 nm of $[VO(acac_2S_2)DMSO]_3$ and $[VO(acac_2S_2)py]_3$ in DMSO and pyridine, respectively, are shown in Fig. 2 together with the spectra of $VO(acac)_2$. All the spectra show two bands and only the spectrum of $VO(acac)_2$ in DMSO exhibits three bands.

The first band, assigned to a $^2B_2 \rightarrow {}^2E$ transition, observed in the spectrum of $VO(acac)_2$ in DMSO at 784 ($\varepsilon = 45$) and in pyridine at 765 nm ($\varepsilon = 42$ $dm^3\ mol^{-1}\ cm^{-1}$) is displaced to 807 ($\varepsilon/V^{4+} = 40$) and 750 nm ($\varepsilon/V^{4+} = 46$) in complexes **A** and **B**, respectively.

The second band, assigned to a $^2B_2 \rightarrow {}^2B_1$ transition, observed for $VO(acac)_2$ in DMSO at 594 ($\varepsilon = 16$) and in pyridine at 580 ($\varepsilon = 29$) is shifted to 629 ($\varepsilon/V^{4+} = 21$) and 581 nm ($\varepsilon/V^{4+} = 29$ $dm^3\ mol^{-1}\ cm^{-1}$) in complexes **A** and **B**, respectively.

The electronic spectral data suggest that the vanadium(IV) ion in complexes **A** and **B** exists in the distorted octahedral local environment in agreement with Fig. 1.

The magnetic moments of both the complexes are found to be practically constant in the range 98–293 K. Complexes **A** and **B** have magnetic moment values of 1.78 and 1.77 BM (293 K) per metal atom, respectively, which are consistent with the spin-only value for a d^1 case. Furthermore, they are very

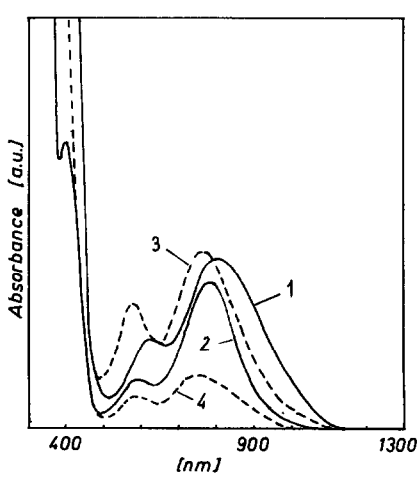

Fig. 2. The electronic spectra of (1) $[VO(acac_2S_2)DMSO]_3$ and (2) $VO(acac)_2$ in DMSO, and (3) $[VO(acac_2S_2)py]_3$ and (4) $VO(acac)_2$ in pyridine.

close to the reported values, 1.71–1.76 BM, for the oxovanadium(IV) β-diketones.[20] These results suggest that there are no direct V—V interactions in the solid complexes.

SYNTHESIS, CHARACTERIZATION AND CATALYTIC BEHAVIOUR OF THORIUM PEROXO COMPLEXES

D. D. AGARWAL,* SAVITA SRIVASTAVA and POONAM CHADHA

School of Studies in Chemistry, Jiwaji University, Gwalior 474011 (M.P.), India

(*Received* 18 *September* 1989; *accepted* 29 *January* 1990)

Abstract—Stable peroxo complexes of thorium are formed which are unreactive as stoichiometric reagents but active as catalysts in the presence of tert-butylhydroperoxide, resulting in the formation of cyclohexenone and cyclohexenol in substantial yields together with cyclohexene oxide. Competitive epoxidation of cyclo-olefins suggests that coordination of olefins to the metal centre does not take place.

In recent years there has been considerable interest in the investigation of peroxo complexes of transition metals.[1] The peroxo complexes of molybdenum,[2] titanium,[3–5] uranium,[6] chromium,[7,8] vanadium,[9] zirconium,[10] thorium,[11,12] etc., have been studied. In continuation of our efforts[13,14] to find new oxidizing systems we report here the synthesis, characterization and catalytic behaviour of some thorium peroxo complexes synthesized using the ligands, bis(salicylaldehyde)ethylene diamine (SALEN), bis(acetylacetone)ethylenediamine (ACEN), bis(anthranilic acid)acetylacetone (ANAC), 2 - carboxyphenylhydrazonopentane - 2,4 - dione (ANAC hydrazone), salicylaldehyde-O-aminophenyl (SAP), salicylaldehyde anthranilic acid (SAC), bis(salicylaldehyde)-1,3-diamino propane (SAPEN), bis(salicylaldehyde)-O-phenylene diamine (SALPHEN).

EXPERIMENTAL

All ligand components were used as obtained from commercial sources. Absolute alcohol was prepared following the method in ref. 15. $Th(NO_3)_4 \cdot 6H_2O$ was obtained from Loba Chemical Laboratories and 30% H_2O was purchaed from Glin India Ltd. All alkenes were checked by gas chromatography, and if needed purified[15] and stored under N_2. Tert-butylhydroperoxide (TBHP), Aldrich, was dried and estimated.[16] The reference sample of the epoxides were prepared following the methods in refs 17 and 18. Elemental analysis (C H N) was performed using a Carlo-Erba elemental analyser, and IR spectra were recorded using a Perkin–Elmer spectrophotometer in the range 4000–250 cm^{-1}. Analytical gas chromatography was carried out using a Nucon-Amil-5700 series gas chromatograph fitted with a Shimadzu CR-3A data processor. XE-60 and Carbowax-20M columns were used.

Synthesis of the complexes

The ligands were synthesized by literature procedures.[19] The complexes were synthesized by taking $Th(NO_3)_4 \cdot 6H_2O$ (0.02 mol) in water (10 cm^3) and adding the ligand (0.02 mol) in methanol (25 cm^3). To this mixture 12.5 cm^3 of 30% H_2O_2 was added. The resulting mixture was stirred and heated on a water bath for 15 min. The precipitated complex was filtered, washed with water, ether and then dried. The complexes of anthanilic acid and O-aminophenol were synthesized by the reported[12] method. The conductance, melting point and elemental analysis data are given in Table 1.

Epoxidation

Cyclohexene (0.02 mol), TBHP (0.002 mol), a catalyst (0.002 mmol) and benzene (20 cm^3) were heated at 70°C under N_2 for 4 h. The hydroperoxide was decomposed, the contents were than extracted in ether and the products identified. The effect of $NaHCO_3$ and NaH_2PO_4 was studied by adding 100 mg of the same.

[a] Calculated values are given in parentheses.
[b] d = decompose.

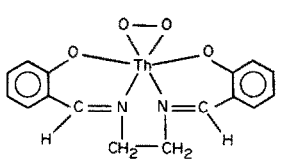
Competitive epoxidation

The competitive epoxidation of cyclopentene, cyclohexene, cycloheptene, cyclo-octene and norbornene was studied by mixing cyclohexene (20 mmol), another olefin (20 mmol), catalyst (0.004 mmol) and TBHP (0.004 mol) in benzene (10 cm^3) and heating this at 70°C under N_2 for 4 h.

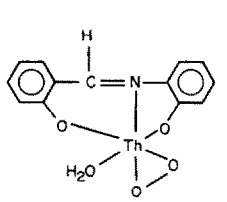
RESULTS AND DISCUSSION

Elemental analyses (Table 1) (C, H and N) are in accordance with the calculated values. The molar conductance data in DMSO (10^{-3} M) show that they are non-electrolytes[12] (1.5–4.5 Ω^{-1} cm^2 mol^{-1}), Table 1.

The IR spectra of ThO_2(SALEN) display the ν(C=N) band 20 cm^{-1} lower (1600 cm^{-1}) than in ligand.[20] The shifted stretching band at 1220 cm^{-1} suggests involvement of ν(C—O). The ν(OH) stretching dimer at 2690 cm^{-1} disappears in the ThO_2(ANAC) complex. The ν(C=O) band at 1660 cm^{-1}, due to the internally hydrogen-bonded carboxylic group, and the ν(OH) in-plane bending at 1320 cm^{-1} disappear, suggesting that the carboxyl group is involved. The IR spectra of ThO_2(ANAC hydrazone)·H_2O show a band at 1620 cm^{-1} [ν(C=O)], lower by 20 cm^{-1}. In this complex the possible involvement of C=O, NH and COOH takes place. The non-electrolytic nature of the complex also suggests that NH is coordinated.[14] The IR spectra of ThO_2(SAP)·H_2O show a band at 1625 cm^{-1}, lower by 25 cm^{-1}. Also, a band at 1230 cm^{-1} is assigned to the C—O group suggesting that C=N and OH groups are involved in coordination. The bands in the Raman spectra for all the complexes in the region 830–815 cm^{-1} are assigned to O—O and Th—O—O frequencies. The band at 405–390 cm^{-1} suggests a Th—O mode.[11] The IR spectra of ThO_2(SAPEN), ThO_2(ACEN) and ThO_2(SALPHEN) are similar to that observed for ThO_2(SALEN). The IR spectra of ThO_2(SAC)·H_2O, ThO_2(anthranilic acid)$_2$, ThO_2(O-aminophenol)$_2$ are the same as those reported by Tarafdar and co-workers.[11,12] The two representative structures are as follows:



ThO_2(SALEN)



ThO_2(SAP)·H_2O

Epoxidation

When thorium peroxo complexes were subjected to stoichiometric reaction with cyclohexene no product was observed even after 10 h. When the formation of products was followed using the ThO_2(anthranilic acid)$_2$/TBHP system it was observed that the yield of cyclohexenol and cyclohexenone was the same for the first 60 min, but as time passed the yield of cyclohexenone increased and after 4 h the yield of cyclohexenone (0.050 mmol) was 12.5 times greater than cyclohexenol (0.004 mmol). The yield of epoxide was 0.01 mmol and the catalyst turnover number 150. Similar behaviour was observed with the CrO_3/TBHP system.[21] ThO_2(O-aminophenol)$_2$, ThO_2(SAC)·H_2O and ThO_2(SALPHEN) produced no epoxide, but the allylic oxidation produced cyclohexenol (0.018, 0.006, 0.012 mmol) and cyclohexenone (0.055, 0.014, 0.040 mmol), respectively. ThO_2 (ACEN) and ThO_2(ANAC hydrazone)·H_2O produced epoxide (0.013, 0.002 mmol) together with cyclohexenol (0.081, 0.014 mmol) and cyclohexenone (0.202, 0.026 mmol), respectively. The high yield of allylic oxidation products shows that the peroxo complex/TBHP is a good system for the hydroxylation of alkenes.

Epoxidation of cyclo-olefins shows the relative rate of reactivity: cyclo-octene (13.65) > norbornene (11.0) > cyclopentene (3.20) > cycloheptene (1.60) > cyclohexene (1.0). The higher rates for norbornene, cyclo-octene and cycloheptene compared to cyclohexene show that the olefin is not coordinated to the metal centre during epoxidation.[9] Similar results to those for the ThO_2 (ACEN)/TBHP system have been observed with the O=Mo(TPP)OMe/cumene hydroperoxide[22] and the MoO_2(SALEN)/TBHP[13] systems. This shows that conformation bond angle strain and torsional strain play important roles in determining the relative rates for cyclic olefins.

Effect of additives

The addition of $NaHCO_3$ and NaH_2PO_4 reduces the yield of epoxide. This is explained by the fact, as observed in O=Mo(TPP)OMe,[22] O=Ti (TPP)/TBHP[5] and MoO_2(SALEN)/TBHP[13] systems, that $NaHCO_3$ retards the yield of epoxide because it promotes peroxo complex formation, which is inactive.[23] In the present case also it is preventing the opening of the peroxo linkage thereby reducing the yield.

A mechanism similar to the vanadium-catalysed reaction[24] is proposed.

SYNTHESIS AND CHARACTERIZATION OF SOME PEROXO COMPLEXES OF ZIRCONIUM

D. D. AGARWAL,* RAJEEV JAIN, R. P. BHATNAGAR and SAVITA SRIVASTAVA

School of Studies in Chemistry, Jiwaji University, Gwalior 474011 (M.P.), India

(*Received* 14 *September* 1989; *accepted* 8 *February* 1990)

Abstract—The peroxo complexes of zirconium using bidentate, tridentate and tetradentate ligands have been synthesized and characterized. Oxidation studies showed that when Ph_3P, cyclohexene and allylalcohol were involved, the peroxo complexes with the tetradentate ligand failed to oxidize Ph_3P while the one with the bidentate ligand did. The peroxo complexes involving bidentate and tetradentate ligands gave peroxide when cyclohexene (the substrate) in the presence of tert-butyl hydroperoxide as oxidant was oxidized. The peroxo complexes with the bidentate ligand gave higher yields of peroxide compared with the tetradentate ligand complex. The peroxo complexes failed to oxidize stoichiometrically allylalcohol and cyclohexene. This shows that peroxo complexes containing the tetradentate moiety are more stable.

The chemistry of oxo and peroxo complexes is of interest as they may be potential oxidants or oxidation catalysts for the oxygen atom transfer reaction to organic substrates.[1–16] The peroxo complexes of molybdenum tungsten, uranium, thorium and titanium have been studied.[17–21] Titanium compounds have been found to be potential catalysts for asymmetric synthesis, while O=Ti(TPP)[9] has been found to be a potential catalyst for olefin epoxidation,[22] and at the end of the reaction a peroxotitanium complex is obtained. Studies of zirconium peroxo complexes and their reactivity were needed to discover the catalytic potential of zirconium complexes. We have studied the catalytic behaviour of various oxo complexes of molybdenum and titanium[23,24] and we now report our studies on zirconium peroxo complexes of some tri- and tetradentate ligands and their reactivities with various substrates to test their oxygen atom transfer capabilities.

EXPERIMENTAL

Physical measurements

The elemental analyses (C, H, N) were determined using a Carlo-Erba elemental analyser. IR spectra were recorded with Perkin–Elmer IR spectrophotometer. Conductivities of the solutions in dimethylsulphoxide were measured using a conductivity bridge. The oxidation products were followed with a NUCON-Amil-5700 series gas chromatograph fitted with a CR-3A Shimadzu data processor. XE-60 was used as the column at 120°C.

Reagents

Zirconium nitrate dihydrate, anthranalic acid, acetylacetone, salicylaldehyde, ethylenediamine, *o*-aminophenol, acetoacetanilide, triphenylphosphine, cyclohexene, dodecane, etc., were from Aldrich, Merk or Fluka. Dry tert-butylhydroperoxide was prepared by a literature method.[25]

Preparation of the Schiff bases

All the Schiff bases were synthesized by condensing the respective aldehyde or ketone with amine in methanol following a published procedure.[24]

Preparation of the complexes

A solution of $Zr(NO_3)_4 \cdot 2H_2O$ (0.01 mol) in 30% H_2O_2 (30 cm^3) was added to a solution of the bidentate ligand (0.02 mol) in boiling acetone (50 cm^3). The contents were heated for *ca* 1 h. On cooling, a

* Author to whom correspondence should be addressed.

precipitate appeared which was washed successively with water and *n*-hexane and then dried *in vacuo*.

Peroxozirconium complexes of tridentate and tetradentate ligands were prepared by mixing $Zr(NO_3)_4 \cdot 2H_2O$ (0.01 mol) in 30% H_2O_2 (30 cm^3) and the ligand (0.01 mol) in boiling acetone (50 cm^3). The contents were heated for *ca* 1 h and on cooling a precipitate appeared which was washed successively with water, *n*-hexane and then dried.

Oxidation of triphenylphosphine

To a solution of triphenylphosphine (0.006 mol) in tetrahydrofuran (100 cm^3) was added the suspension of the peroxozirconium anthralinic acid complex (0.006 mol) to study stoichiometric oxidation. The contents were heated for 4 days. The thin-layer chromatographic study shows the conversion of triphenylphosphine to triphenylphosphine oxide. The product was isolated and purified and the melting point noted (153°C). In another set of reactions peroxozirconium salen (0.006 mol) was used and analysed.

Oxidation of cyclohexene using tert-butylhydroperoxide

The possible oxidation of cyclohexene using tert-butylhydroperoxide as oxidant and peroxozirconium salen as well as the peroxozirconium aniline 2-carboxylato complex was studied. The reaction was carried out in dry benzene using dodecane as internal standard. The product was followed by gas chromatographic analysis. The complex was isolated after the reaction and characterized by m.p. and IR studies.

Oxidation of allylalcohol using the peroxozirconium salen complex

To the peroxozirconium salen (0.006 mol) complex in dichloromethane was added allylalcohol (0.006 mol). The contents were refluxed at 70°C for 2 days, and at the end of the reaction the mixture was analysed, and the complex isolated and characterized by m.p. and IR studies.

Stoichiometric oxidation of cyclohexene

The possible oxidation of cyclohexene using stoichiometric amounts of peroxozirconium salen complex in benzene at 80°C for 24 h was studied. After the reaction the complex was isolated and characterized.

RESULTS AND DISCUSSION

The elemental analysis data (Table 1) obtained agree with the calculated values, suggesting a six-coordinate zirconium atom. The molar conductance values show these peroxo complexes to be non-electrolytes. Titration of methanolic solutions of the peroxo complexes with aqueous acidified standard ceric sulphate solution (~ 2) showed (Table 1) that the complexes were monoperoxo complexes. These peroxo complexes are quite stable and their reduction by iodide was slow and needed 10–12 h to impart a brown colouration to the solution.

The IR spectral data are shown in Table 1. The $Zr(O_2)$(ACEN) complex shows an absorption at 1620 cm^{-1} assigned to a C=N stretching, which decreased by 10 cm^{-1} on coordination, therefore, suggesting its involvement. The metal peroxo grouping gives rise to three IR vibration modes. These are predominantly O—O stretching (ν_1 850 cm^{-1}), symmetric M—O stretching (ν_3 650 cm^{-1}) and antisymmetric M—O stretching (ν_2 595 cm^{-1}), respectively.[26–28] The absorption bands at 412 and 390 cm^{-1} are assigned to Zr—O and Zr—N bonds in the complexes.[29–31]

The IR spectrum of the $Zr(O_2)$(salen) complex shows an absorption at 1620 cm^{-1} which is 15 cm^{-1} lower than the absorption found in the ligands, suggesting the involvement of the C=N group in coordination. The absorption bands observed in the complex at 810, 650 and 580 cm^{-1} are assigned to peroxo symmetric and antisymmetric O—O stretching modes. The absorption bands at 410 and 390 cm^{-1} may have arisen due to ligand-to-metal bond formation through the OH and C=N groups. The IR absorption bands of the ligand (ANAC) at 2699, 1660, 1440 and 1320 cm^{-1} are assigned to the ν(OH) stretching (dimer), the ν(C=O) frequency of the internally hydrogen-bonded carboxylic group, the ν(C—O) stretching and the OH in-plane bending of the carboxylic group, respectively. All these bands except that at 1440 cm^{-1} disappear on coordination. The peak at 1610 cm^{-1} is assigned to C=N in the ligand which moves to 1600 cm^{-1}, supporting its involvement in coordination. The absorption bands at 830, 645 and 575 cm^{-1} are assigned to various modes of the peroxo group, while the bands at 415 and 390 cm^{-1} are assigned to Zr—O and Zr—N modes.

The IR spectrum of $Zr(O_2)(SAP) \cdot H_2O$ contains bands at 1600, 840, 638 and 580 cm^{-1} which are assigned to —N=C, peroxo stretching, symmetric and antisymmetric modes, respectively. The bands at 420 and 375 cm^{-1} are assigned to Zr—O and Zr—N bonds, respectively.

[a] Calculated values in parentheses.
[b] Reference 32.

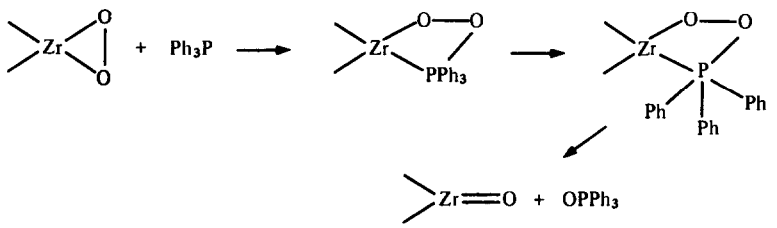
The IR spectrum of $Zr(O_2)$(A ACEN) contains bands at 1600, 850, 650 and 590 cm^{-1} which are assigned to C=N and three modes of the peroxo group. The bands at 410 and 380 cm^{-1} are assigned to Zr—O and Zr—N modes.

The IR spectral studies of the $Zr(O_2)(SAC)\cdot H_2O$ and $ZrO_2(AN)_2$ compounds are reported elsewhere.[32]

The IR spectrum of $Zr(O_2)$(SALPA) shows similar characteristics to those observed for $Zr(O_2)$ (salen), while the IR spectral bands of $Zr(O_2)$ (ANAAC) are similar to those observed for $Zr(O_2)$ (ANAC) (Table 1).

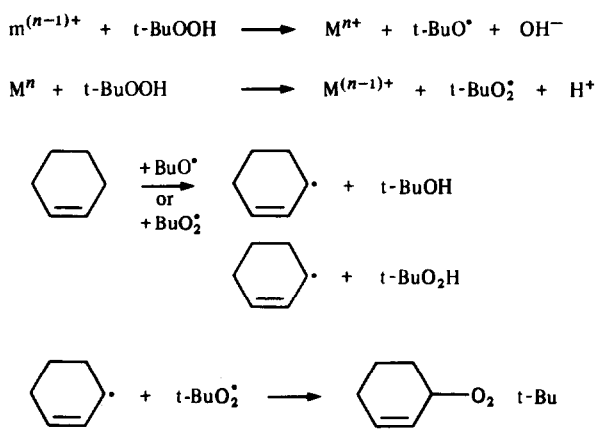
The IR studies suggest that all the complexes are six-coordinate and one peroxo group per ligand molecule is present.

The zirconium peroxo complexes with bidentate ligands were found to be active towards Ph_3P as it directly inserts into the metal–peroxide bond.[7,33]

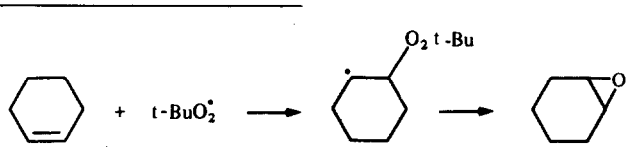


The formation of Ph_3PO (> 90%) was confirmed by the appearance of the IR band at 1190 cm^{-1} (P—O).[34] The zirconium complex after the reaction was separated and its IR spectra studied. The appearance of a band at 930 cm^{-1} is attributed to Zr—O and this has appeared due to the disappearance of the O—O band. In the absence of the zirconium peroxo complex no oxidation product was obtained. Zirconium peroxo complexes prepared with tetradentate ligands did not oxidize Ph_3P.

Zirconium peroxo complexes have been found to be excellent catalysts for the homolytic decomposition of hydroperoxide. When the oxidation of cyclohexene was studied using tert-butylhydroperoxide as oxidant and a zirconium peroxo complex as the catalyst, some epoxide formation takes place but the yield was very low and decomposition of tert-butylhydroperoxide gave a peroxide mixture as the major product. This reaction justifies a possible radical mechanism.[35]

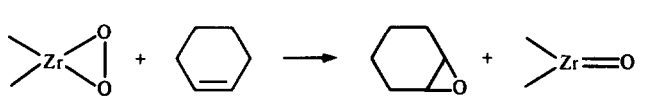


The epoxide which is obtained in small amounts may be due to the following mechanism:

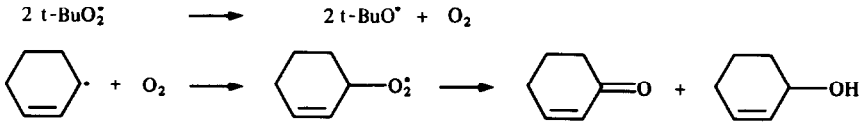


(1)

or to:



(2)



but when cyclohexene was stoichiometrically oxidized using a zirconium peroxo complex in benzene no epoxide was obtained, confirming that a mechanism, similar to eq. (1), is respnsible for the trace of epoxide obtained. Cyclohexene-2-ol and cyclohexene-2-one-1 were observed as products in small quantities. This formation can be explained by the mechanism above.

The evolution of peroxide increased rapidly 2 h after the reaction. Initially an induction period was observed, which shows that during this period free radical decomposition of hydroperoxide takes place. The peroxo complexes using a bidentate ligand (anthanilic acid) gave a higher conversion to peroxide compared with the tetradentate salen complex ($K_1/K_2 = 3.2$); this may be due to the enhanced stability of the zirconium peroxo moiety afforded by the tetradentate salen ligand. At the end of the reaction the complex was isolated and it was found that it had identical IR and m.p. values to those observed before the reaction, thereby showing that peroxo zirconium salen is not decomposed during this reaction. The peroxo zirconium salen complex was found to fail in the stoichiometric oxidation of cyclohexene and at the end of the reaction the unaltered complex was obtained (as is evident by its m.p. and IR spectra). The peroxo zirconium salen complex also failed to oxidize the allylalcohol. All these studies suggest that peroxo zirconium complexes are stable and peroxo complexes with tri- and tetradentate ligands are almost unreactive.

Abstract—The compounds of formula $[M(CH_3COO)_2L_I]Cl \cdot 4H_2O$, in which M is neodymium(III) or europium(III) and L_I is a six-nitrogen-donor macrocyclic ligand ($C_{22}H_{26}N_6$), have been investigated by single crystal X-ray diffraction, thermogravimetric analysis and nuclear magnetic resonance spectroscopy. The two compounds are isostructural and crystallize in the triclinic system, space group $P\bar{1}$. The complex cations present in the crystal lattice consist of a 10-coordinate metal centre linked to the six nitrogen-donor atoms of the macrocyclic ligand and to two bidentate chelating acetates, situated on opposite sides of the macrocycle and staggered by approximately 90°; an ionic chloride balances the residual metal charge. The paramagnetic-shifted NMR spectra of the complexes were measured in various solvents, and confirm that the metal–macrocycle moieties remain undissociated. Also, the spectra depend on the counterions, showing that, on average, at least one of the labile acetate ligands is bound to the metal ion even in aqueous solution.

The ability of the lanthanide(III) and yttrium(III) ions to act as templates for the cyclic (2+2) Schiff base condensation of 1,2-diaminoethane with 2,6-diacetylpyridine is well established and a considerable number of complexes of the resulting macrocycle L_I [Fig. 1(a)] have been described.[1–9] These complexes are unique among the compounds of the lanthanides in that the metal–macrocyclic entity is extremely inert with respect to release of the metal ion, whereas the exocyclic ligands (anions or solvent molecules) are labile and easily exchangeable. The inertness of the metal–L_I entity must arise from an especially favourable combination of metal ionic radius, cavity size of the 18-membered macrocyclic ligand L_I, and bonding ability of the six nitrogen-donor atoms. This suggestion is supported by the observation that the lanthanide complexes of an 18-membered tetraimine macrocycle similar to L_I, but having furan instead of pyridine head-units, are labile and decompose rapidly when dissolved in water.[10] Also, a lanthanum(III) complex of the L_{II} macrocycle [20-membered cavity, pyridine head-units, Fig. 1(b)] was found to undergo transmetallation with

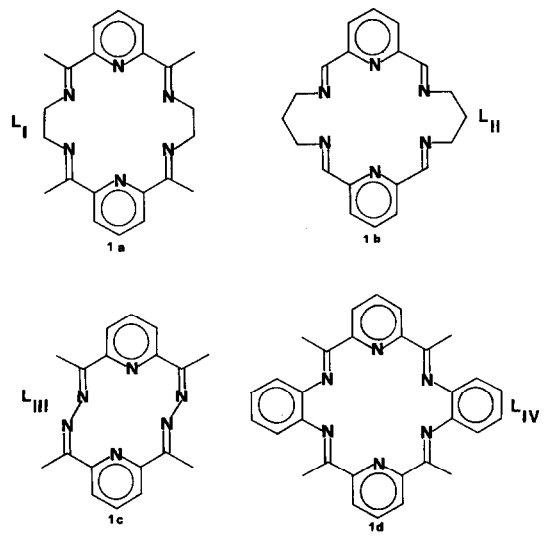

Fig. 1. Schematic formulae of macrocyclic ligands: $L_I = C_{22}H_{26}N_6$, $L_{II} = C_{18}H_{22}N_6$, $L_{III} = C_{18}H_{18}N_6$, $L_{IV} = C_{30}H_{26}N_6$.

copper(II),[11] while complexes of the smaller lanthanides (Tb–Lu) with the L_{III} macrocycle [14-membered cavity, pyridine head-units, Fig. 1(c)] are readily hydrolysed to complexes of an open-cycle diketone.[12] The flexibility of the $—CH_2—CH_2—$ diimine side-chains of the L_I macrocycle must also represent a favourable factor in the stabilization of its lanthanide complexes, as the derivatives of the L_{IV} macrocycle [18-membered cavity, pyridine head-units, rigid O-phenylenediamine side-chains, Fig. 1(d)] are both more difficult to synthesize and less inert to metal release or rearrangement.[13]

Crystal structures have been reported for a number of complexes of the lanthanide(III) and yttrium(III) ions with the L_I macrocycle and some trends begin to emerge. The 12-coordinate, neutral species $[La(NO_3)_3L_I]$, containing three bidentate chelating nitrates, was obtained by template synthesis with lanthanum(III) nitrate in methanol.[1,7] The 11-coordinate $[Ce(NO_3)_2(H_2O)L_I]^+$ cation, isolated as the nitrate salt, was formed by metal exchange from $Ba(ClO_4)_2L_I$ and cerium(III) nitrate in water.[7] Under similar conditions, the neodymium(III) ion gave instead a 10-coordinate (2+) cation,[7] isolated as a mixed nitrate–perchlorate salt of formula $[\{Nd(NO_3)(H_2O)_2L_I\}_2]NO_3(ClO_4)_3 \cdot 4H_2O$. With yttrium(III) and acetate ions, the metal-templated synthesis yielded crystals containing two nine-coordinate cationic species, $[Y(CH_3COO)(H_2O)L_I]^{2+}$ and $[Y(CH_3COO)_2L_I]^+$, the latter containing one bidentate and one monodentate acetate.[8] With europium(III) and yttrium (III), a pair of isostructural neutral complexes, $[Eu(NCS)_3L_I]$ and $[Y(NCS)_3L_I]$, were isolated by anion exchange from the diacetate–chlorides in methanol.[9] Finally the smallest lanthanide, lutetium(III), gave the two nine-coordinate monoacetate cationic species $[Lu(CH_3COO)(CH_3OH)L_I]^{2+}$ and $[Lu(CH_3COO)(H_2O)L_I]^{2+}$, obtained by template synthesis of the diacetate–chlorides followed by partial anion metathesis.[5] Thus, ligand L_I can form neutral or cationic complexes of coordination numbers ranging from 12 to nine, depending on the combination of metal ion, anion, and method of preparation.

To investigate how the structural aspects of the lanthanide–L_I complexes may relate to their solution properties, we carried out a crystallographic analysis of two representative examples, the diacetate–chlorides of Nd^{III}–L_I and Eu^{III}–L_I, which are very soluble in both water and organic solvents, and investigated their ^1H and ^{13}C NMR spectra. An understanding of the relationship among structure, metal–macrocycle inertness, and lability of exocyclic ligands is essential in the future design of functionalized complexes that may allow the attachment to biological substrates of selected lanthanides, such as europium(III) and terbium(III) as luminescent markers,[14] or Gadolinium(III) as a contrast agent for NMR imaging.[15]

EXPERIMENTAL

Diacetate–chloride complexes of europium(III) *and terbium*(III) *with the* L_I *macrocycle*

These compounds were prepared as previously described.[4] Single crystals suitable for X-ray analysis were obtained by slow crystallization from methanol–diethyl ether at *ca* 4°C.

$[Pr(NO_3)_2(H_2O)(L_I)](NO_3) \cdot 2H_2O$

This compound[7] was prepared as follows: the diacetate–chloride complex (0.5 mmol, *ca* 360 mg) was dissolved in water (10 cm^3) and mixed with $LiNO_3$ (3.0 mmol, *ca* 210 mg in 2 cm^3 of water). The resulting mixture was repeatedly filtered over a tight wad of cotton wool and the clear solution was allowed to stand undisturbed in an open container for several days at room temperature. The trinitrate complex precipitated as pale yellow crystals which were decanted, carefully washed with ice-cold water, and dried at 60°C. The compound had correct chemical analysis. IR absorption frequencies (cm^{-1}) and selected assignments: 3542s, sharp: 3510m $\nu(OH_2)$ of lattice water; 3366s, br; 3300sh $\nu(OH_2)$ of coordinated water; 3072w;

X-ray measurements and structure determination

Neodymium complex. A transparent, pale violet, prismatic single crystal of dimensions $0.14 \times 0.28 \times 0.40$ mm was used for data collection on a four-circle Philips PW 1100 diffractometer with graphite-monochromated Mo-K_α radiation. The intensity data were corrected for Lorentz-polarization effects and for absorption, following the method of North *et al.*[16] The structure was solved using three-dimensional Patterson and Fourier techniques and refined with full-matrix least-squares. Hydrogen atoms were introduced at the positions indicated from the final difference Fourier map and were refined with a fixed unique thermal parameter ($U = 0.08$ Å^2); however, the hydrogen atoms of the water molecules, which were disordered among two or three positions, were not introduced. The non-hydrogen atoms, except for the oxygens of the water molecules (refined isotropically), were allowed to vibrate anisotropically. The final difference Fourier map showed a few residuals of the order of 0.6e/Å^3, close to the water positions and assigned to the disordered hydrogens. The programs used were SHELX-76[17] for structure solution and refinement, ORTEP[18] and PLUTO[19] for drawings, and PARST[20] for geometrical calculations. Atomic scattering factors were taken from ref. 21.

Europium complex. A single crystal of dimensions $0.30 \times 0.44 \times 0.50$ mm was used for analysis; data collection and treatment were carried out as described for the neodymium analogue except for the hydrogen atoms of the macrocycle being introduced at calculated positions. In the final difference Fourier map two major residuals of about 1e/Å^3 were present near the europium(III) position. Crystallographic parameters are reported in Table 1. Bond lengths and bond angles are given in Table 2; torsion angles are given in Table 3;

Elmer TGS-4 system, under a dry helium flow of 60 cm^3 min^{-1}. IR spectra of the solid samples, as Nujol/hexachlorobutadiene mulls and KBr pellets, were recorded with a Perkin–Elmer Model 1500 FTIR instrument. NMR spectra were recorded on a GE QE-300 FT–NMR spectrometer in high-precision 5 mm glass NMR tubes. Observed frequencies were 300.65 MHz for ^1H and 75.60 MHz for ^{13}C. Internal standards were TMS for non-aqueous solutions and DSS for aqueous solutions.

RESULTS AND DISCUSSION

Crystal structures

In the series of diacetate–chloride complexes, $[Ln(CH_3COO)_2L_I]Cl \cdot nH_2O$ (Ln = La–Lu), the number of H_2O molecules varies from 3 to 6 depending on the metal ion and ambient conditions;[4] for the crystalline neodymium(III) and europium(III) complexes examined in this work, *n* is 4. The two complexes have the same coordination formula, $[M(CH_3COO)_2L_I]Cl \cdot 4H_2O$ (M = Nd or Eu), and are isostructural. Selected bond distances and angles are reported in Table 2; an ORTEP view of the $[Nd(Ac)_2L_I]^+$ complex cation is shown in Fig. 2. In these complexes the metal ion is 10-coordinated, being linked to the six nitrogen atoms of the macrocycle and to two bidentate chelating acetates situated on opposite sides of the macrocycle. The two acetates are staggered and the angle between their planes is 94.8(2)° for Nd and 94.8(2)° for Eu. The macrocycle itself has the "folded butterfly" configuration usually found in lanthanide complexes of the L_I ligand.[1–9] The structure consists of two approximately planar sections containing the pyridine rings and hinged at the $—CH_2—CH_2—$ side-chains, with dihedral angles of 132.82(6)° for Nd and 132.37(6)° for Eu.

The orientation of the coordinated acetates appears to be dictated primarily by steric requirements, as the OCO plane is aligned with the fold of the macrocycle for the acetate on the concave side and is perpendicular to it for the acetate on the opposite side. However, the plane of the acetate on the concave side is not symmetrically located but leans toward one of the two quasi-planar sections of the macrocycle. In the neodymium complex, the acetate plane [O(3), C(25), C(26), O(4)] forms a dihedral angle of 54.7(2)° with the C(1)···N(6)···C(13) macrocycle section and an angle of 101.8(2)° with the C(2)···N(3)···C(12)

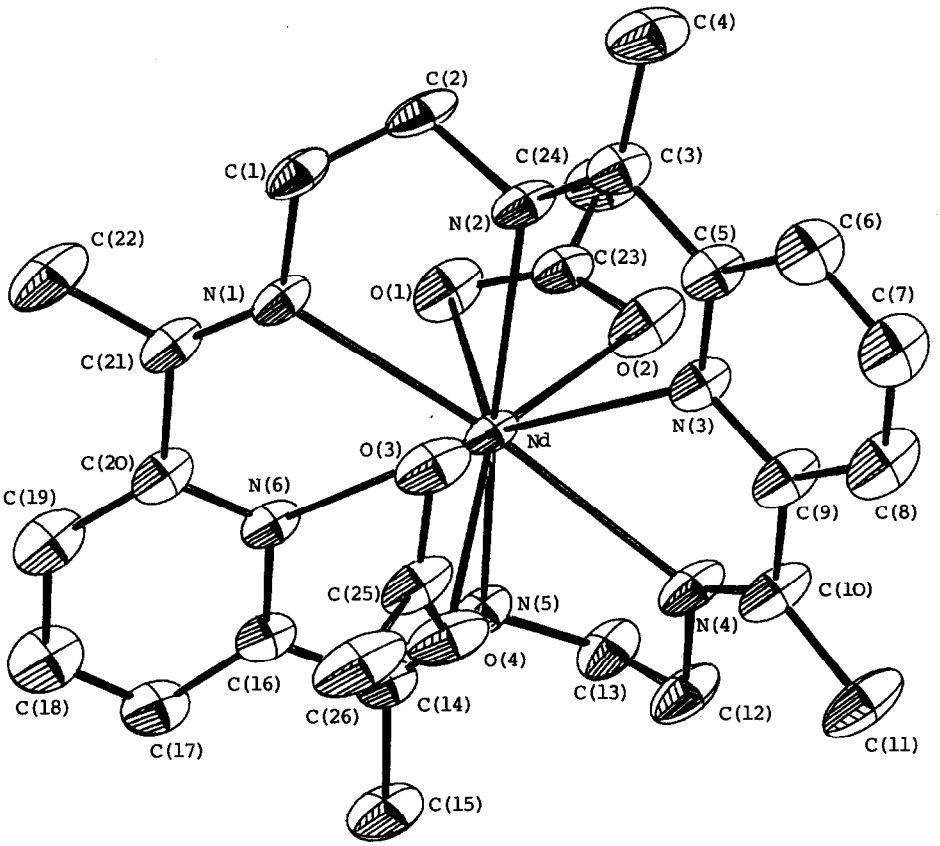

Fig. 2. ORTEP view of the $[Nd(CH_3COO)_2L_I]^+$ complex cation.

section; in the europium complex, the corresponding angles are 55.1(2) and 102.6(2)°. This lack of symmetry contrasts with the situation found in the $[Nd(NO_3)_2(18\text{-crown-6})]_3[Nd(NO_3)_6]$ complex.[22] The latter compound contains two cationic entities that have the same stoichiometry but differ slightly in their overall symmetry due to different conformations of the crown-ether ligand; in each entity, however, the two bidentate chelating nitrates on opposite sides of the crown-ether are essentially coplanar and perpendicular to the $\{NdO_6\}$ best plane of the macrocycle. A staggered arrangement of two bidentate chelating oxygen-donor anions is present in the pair of isostructural neodymium(III) and europium(III) complexes of formula $[M(NO_3)_2(C_{14}H_{30}N_2O_4)]_3[M(NO_3)_6]$ containing a diaza-crown-ether ligand.[23] Each of these compounds contains two $[M(NO_3)_2(ligand)]^+$ cations of different symmetry, one (C_{2v} symmetry) with the two N-methyl groups on the same side of the $\{MN_2O_4\}$ coordination plane, and the other (C_2 symmetry) with the N-methyl groups on opposite sides. In the C_2 cation, the angle between the planes of the two opposite NO_3^- groups is *ca* 90°, whereas in the C_{2v} cation the angle is *ca* 60°; in both cations, however, the planes of the NO_3^- groups are essentially perpendicular to the $\{MN_2O_4\}$ best plane of the macrocycle. A close examination of the crystal packing of the diacetate–chloride complexes described in the present work shows short intermolecular contacts among water oxygens, acetate oxygens and chloride ions (see Table 4 and Fig. 3). These non-bonding interactions may be responsible for the asymmetric arrangement of the concave-side acetate with respect to the folded macrocycle.

A ring-puckering analysis[24] for the six-nitrogen donor moieties of the Nd—L_I and Eu—L_I diacetate–chloride complexes showed that in each case the 6-N has a slightly twisted boat conformation with the boat vertices, N(2) and N(5), on the convex side of the macrocycle. The two sets of puckering constants were also quite similar: $Q = 0.907(4)$,

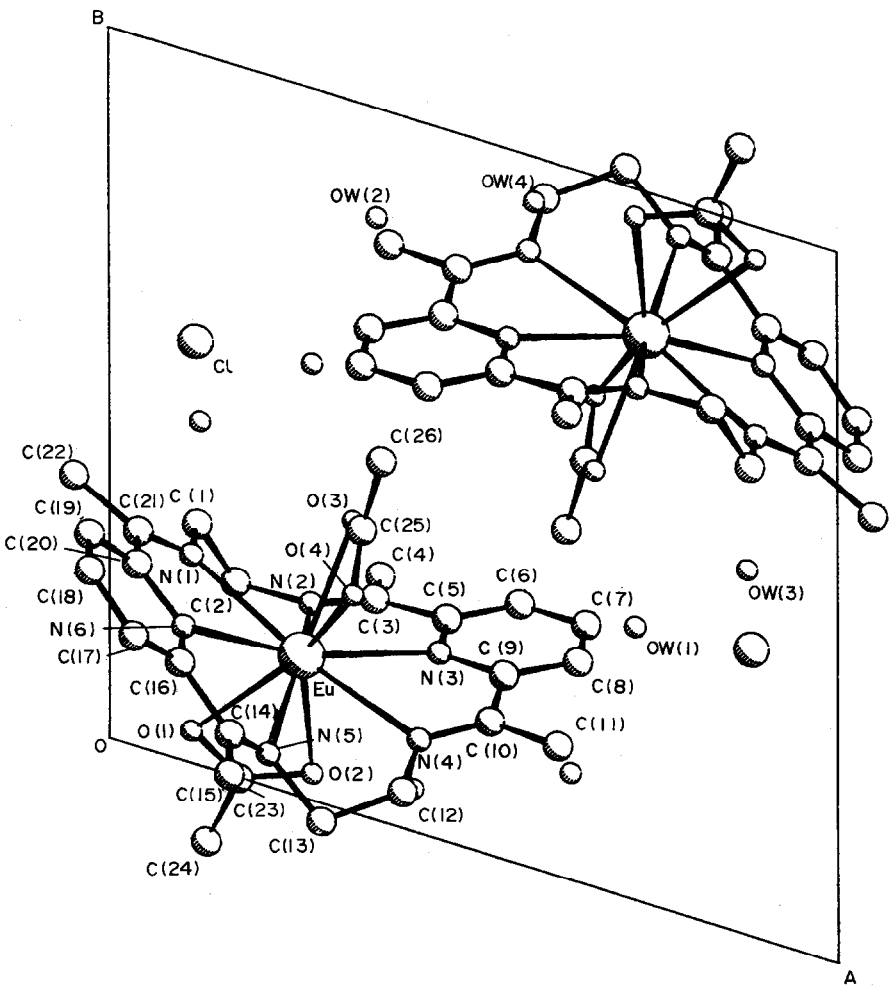

Fig. 3. PLUTO view down *c* of the cell content (europium derivative).

$\Theta = 91.8(2)$, $\Phi = 70.4(2)°$ for neodymium, and $Q = 0.957(3)$, $\Theta = 91.6(2)°$, $\Phi = 71.1(2)°$ for europium. Thus the difference in ionic radius between neodymium (1.303 Å) and europium (1.260 Å)[27] does not appreciably affect the 6-N ring conformation.

Comparison among the bond lengths listed in Table 2 shows that the metal–acetate distances are longer for neodymium (average Nd—$O_{acetate}$ = 2.514 Å) than for europium (average Eu—$O_{acetate}$ = 2.481 Å), in agreement with the decrease in metal ionic radius from neodymium to europium. In contrast, all metal–nitrogen distances are appreciably shorter for neodymium than for europium (average M—$N_{pyridine}$ = 2.589(4) Å for Nd; 2.639(4) Å for Eu; range of M—N_{imine} = 2.591(4)–2.641(3) Å for Nd; 2.590(3)–2.665(4) Å for Eu). For comparison, the following values were found in neodymium(III) and europium(III) complexes with the same L_I macrocycle but different counterions: Nd—$N_{pyridine}$ = 2.621 Å and Nd—N_{imine} = 2.1610 Å for $[\{Nd(NO_3)(H_2O)_2L_I\}_2](NO_3)(ClO_4)_3 \cdot 4H_2O$;[7] Eu—$N_{pyridine}$ = 2.622 Å and Eu—N_{imine} = 2.586 Å for $[Eu(NCS)_3L_I]$.[9] In the diacetate–chloride complexes considered in the present work, the intermolecular contacts (Table 4) are also on average shorter for the neodymium complex than for the europium analogue, and the cell volume is more compact. A comparative analysis of the thermal parameters of both compounds does not reveal particular features which might explain these irregularities. A smaller cell volume for the neodymium derivative has been also found in the isomorphous pair of neodymium and europium nitrate complexes with the macrocycle 4,13-dimethyl-1,7,10,16-tetraoxa-4,13-diazacyclooceadecane $Me_2(2,2)$.[25]

NMR spectra

The ^1H NMR spectra of the neodymium(III) and europium(III) diacetate–chloride complexes were recorded in three solvents of different coordinating abilities: deuterium oxide, deuterodimethylsulphoxide and deuterochloroform. ^1H resonances were assigned on the basis of integration and coupling (for the pyridine protons); they are reported in Table 5. Unlike the spectra of the diamagnetic complex of lanthanum(III)[4,7] and lutetium(III),[5] those of the paramagnetic neodymium(III) and europium(III) complexes were found to be strongly dependent upon the solvent. The CH_2 resonance of the europium complex, for example, occurs at −7.65 ppm in D_2O, at 1.47 ppm in DMSO-d_6 and at 0.62 ppm in $CDCl_3$. The ^1H spectra of the Eu—L_I complex were also recorded at several different concentrations, ranging from near saturation to the lower limit of convenient measurement; within this range, the spectra remained nearly constant.

Table 5 also lists the ^1H spectra of the diacetate–chloride and trinitrate complexes of lanthanum(III), as well as the spectra of the nitrate complexes of several paramagnetic lanthanides reported by Hart and co-workers.[7] We were initially surprised to find that the macrocycle resonance of the diacetate–chloride and nitrate complexes, which are virtually identical for the lanthanum(III) species, differ appreciably from one another in both the neodymium(III) and the europium(III) species. To eliminate the possibility of unaccounted experimental differences between our results and those in the literature, we prepared as a check a sample of the $[Pr(NO_3)_2(H_2O)(L_I)](NO_3) \cdot 2H_2O$ complex, which is isostructural with the cerium(III) complex of the same formula (analysed by single crystal X-ray diffraction[7]) and measured its ^1H spectrum in D_2O. The values we obtained were identical to those of Hart and co-workers, showing that for any given solvent the differences observed among macrocycle resonances of paramagnetic M—L_I entities associated with different counterions are indeed real. It may be concluded that for each metal the bonding and overall symmetry of the metal–macrocycle entity are essentially independent of the exocyclic ligands (anions and/or solvent molecules). In contrast, the folding of the macrocycle is affected both by the the nature and by the number of exocyclic ligands, resulting in different spatial positions of the hydrogen atoms relative to the paramagnetic centre and hence in different chemical shifts.

The ^{13}C spectra of the neodymium(III) and europium(III) diacetate–chloride complexes were recorded in $CDCl_3$ and D_2O; they are summarized in Table 6. This table also includes for comparison the spectra of the lanthanum(III) diacetae–chloride and of the praseodymium(III) diacetate–chloride and trinitrate. For the paramagnetic complexes, assignments of the resonances of the hydrogen-bound carbons were confirmed by heteronuclear correlation (HETCOR) experiments. The HETCOR spectrum and Attached Proton Test of the praseodymium(III) diacetate–chloride complex are shown in Fig. 4. The ^{13}C resonances of the paramagnetic species examined in this work appear to be much less sensitive than the ^1H resonances to changes in counterions; they still are, however, strongly solvent-dependent.

These results show that solvent and counterion effects are important in determining the NMR spectra of paramagnetic macrocyclic complexes

and cannot be ignored when comparing spectra of such complexes from different literature sources.

CONCLUSIONS

The X-ray analysis of these neodymium(III) and europium(III) diacetate–chloride macrocyclic complexes, when taken in conjunction with the structural data available for related compounds of the same or other lanthanides, points to some interesting generalizations. First, in the crystalline compound the coordinated exocyclic anions are bound to the central metal ion more strongly than are the six nitrogen-donor atoms of the uncharged macrocyclic ligand, and this is true for both oxygen-donor and nitrogen-donor anions. This observation confirms the kinetic origin of the extreme resistance to decomposition of the $\{ML_1\}$ entity, compared to the ease of exchange of the exocyclic anions. Second, the departure from planarity which exists, although in different measures, in all members of this macrocyclic series appears to result primarily from the requirement that all six nitrogen-donor atoms of the macrocycle remain within bond-distance from the central metal ion, while allowing close approach of as many exocyclic donor atoms as possible. Third, the fact that every compound of this series for which the crystal structure is known contains at least one anionic exocyclic ligand, suggests that its coordination greatly contributes to the stability of the complex and will occur whenever a suitable anion is available. Coordination of additional anionic ligands appears instead to be controlled by a fine balance of steric requirements and/or crystal lattice (solubility) effects, and may not take place even when "free" anions are present. For example, the mono-nitrato-diaquo complex $[\{Nd(NO_3)(H_2O)_2L_1\}_2](NO_3)(ClO_4)_3\cdot 4H_2O$ is obtained from solutions that contain a 1:3 $Nd:NO_3$ mole ratio,[7] even though there should be no forbidding steric hindrance to the coordination of two chelating oxygen-donor anions, as shown by the easy formation of the $[Nd(CH_3COO)_2L_1]Cl\cdot 4H_2O$ species.

These generalizations based on X-ray results are in good agreement with the NMR experiments, which show that the nature of the counterion affects the geometry of the macrocyclic moiety even in dilute aqueous solutions. Therefore the species present in these solutions cannot be the simple aquo-macrocycles, $[M(H_2O)_nL_1]^{3+}$, as previously postulated,[7] but rather must include at least one coordinated counterion, possibly in rapid exchange with the solvent. This conclusion provides a satisfactory rationalization for the observed fluorescence behaviour of the diacetate–chloride

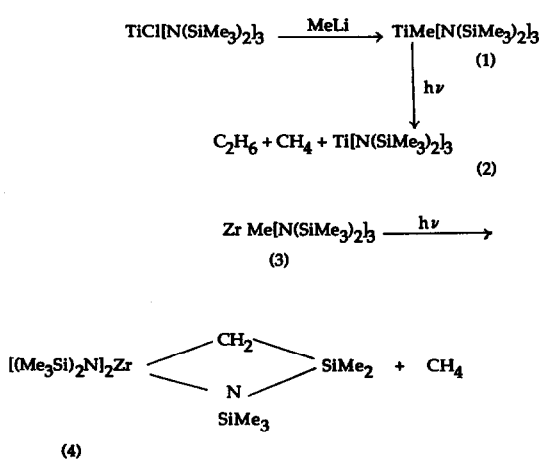
(*Received* 12 *January* 1990; *accepted* 8 *February* 1990)

Abstract—The synthesis and characterization of the compound methyltris[bis(trimethylsilyl)amido]titanium, $MeTi[N(SiMe_3)_2]_3$ (**1**), is reported. In the presence of UV radiation or sunlight, **1** decomposed rapidly to the titanium(III) species $Ti[N(SiMe_3)_2]_3$ (**2**). The X-ray crystal structures of the compounds $MeM[N(SiMe_3)_2]_3$, M = Ti and Zr (**3**), are reported. Compound **3** was stable in sunlight, but the cyclometallated product $[(Me_3Si)_2N]_2ZrN(SiMe_3)SiMe_2CH_2$ (**4**) was apparently formed (from ^1H and ^{13}C NMR data) when solutions of **3** were exposed to a source of UV radiation.

In the last decade or so there has been considerable interest in metal amide compounds incorporating the bulky bis(trimethylsilyl)amido—$N(SiMe_3)_2$, "silylamido", group. A number of reasons account for this interest, the most notable concerning the ability of the ligand to stabilize low coordination in transition metals and the lanthanides,[1] the utility of these compounds as precursors for a range of metalloorganic derivatives,[2] and of course the unusual intramolecular reactivity displayed by a number of bis(trimethylsilyl)amido species. A number of unusual thermally-promoted intramolecular reactions have been reported; for example, the thermal elimination of alkanes from compounds $R_2Zr[N(SiMe_3)_2]_2$, R = Me, Et or CH_2SiMe_3, and the isolation of a cyclometallated product $Cp_2TiN(SiMe_3)SiMe_2CH_2$ from the reaction between Cp_2TiCl_2 and $Li[N(SiMe_3)_2]$.[3] In this paper we report on the photoreactivity we have observed for the silylamido compounds $MeM[N(SiMe_3)_2]_3$ along with the X-ray crystal structures of the titanium and zirconium derivatives.

RESULTS AND DISCUSSION

The compound $MeTi[N(SiMe_3)_2]_3$ (**1**) was prepared by the reaction of methyllithium with the corresponding chloride (see Scheme 1) at temperatures in the range 0–7°C. Compound **1** was found to be photoactive in both the solid state and in solution, changing from colourless to blue on exposure to sunlight or a UV source. The formation of the titanium(III) compound $Ti[N(SiMe_3)_2]_3$ (**2**) was confirmed by comparison of its UV and ESR spectra with those of an authentic sample.[4] Photo-assisted reduction of titanium(IV) species is not unprecedented.[5] Hunt and Winter have shown that exposure to sunlight of a solution of $TiCl_4$ and butanol in petroleum-ether led to the formation



Scheme 1.

* Author to whom correspondence should be addressed.

of the compound $TiCl_3 \cdot 3BuOH$. Also mixtures of compounds $Ti(OR)_4$ and lithium halide in the parent alcohols were said to give insoluble titanium (III) species, $Ti(OR)_3$, on exposure to sunlight. Interestingly, sensitivity to sunlight was not a feature of the related dimethyl compound $Me_2Ti[N(SiMe_3)_2]_2$. The zirconium compound $MeZr[N(SiMe_3)_2]_3$ (**3**) was prepared as previously described.[6] Unlike the titanium analogue **1**, compound **3** was stable in the presence of sunlight. However the exposure of toluene solutions of **3** to a source of UV radiation for a period of approximately 25 min apparently resulted in the formation of the metallocycle **4** (from ^1H and ^{13}C NMR data), presumably via intramolecular elimination of methane. Similar thermally promoted cyclometallation reactions were reported for the compounds $R_2Zr[N(SiMe_3)_2]_2$[7] and $MeM[N(SiMe_3)_2]_3$,[8] M = U and Th, giving, respectively, $\{Zr[N(SiMe_3)SiMe_2CH]N(SiMe_3)_2\}_2$ and $MN(SiMe_3)SiMe_2CH_2[N(SiMe_3)_2]_2$, presumably via elimination of alkane. In contrast to the zirconium analogue, the compound $Me_2Ti[N(SiMe_3)_2]_2$ was found to be remarkably thermally stable, a feature which led Andersen to rule out the possibility of a radical mechanism for the thermal reactivity of the zirconium species. Our studies of the photoactivity of compound **1**, however, which resulted in the formation of the paramagnetic titanium(III) compound **2**, suggested a radical mechanism in this particular case. In an attempt to investigate the possibility of a radical mechanism, solutions of **1** and the radical trap nitrosotertiarybutane, Bu^tNO, in benzene, were exposed to sunlight until the blue colour of compound **2** appeared. The ESR spectrum was recorded at 15 min intervals from that point and while a strong signal due to the titanium(III) species (**2**) was observed, no signals associated with the nitroxide $MeBu^tNO$[9] or indeed $PhBu^tNO$ were detected.

In another experiment a solution of **1** in C_6D_6 was exposed to a source of UV light for 30 min and the gases produced examined by mass spectrometry. Peaks were observed at *m/z* 17 and 30 which may be tentatively assigned to CH_3D and C_2H_6, respectively. While the failure to trap any methyl radical in the previous experiment at best suggested the absence of a dissociated radical pair process, the observation of CH_3D and C_2H_6 formation was indicative of precursor methyl radical formation. The formation of a diamagnetic photoelimination zirconium(IV) product (**4**) from the zirconium compound (**3**) was in keeping with the relative inaccessibility of the lower oxidation state for zirconium compared with titanium and probably did not involve radical intermediates. However, the driving force for these photoeliminations of the methyl function from **1** and **3** was probably steric in both cases.

Restricted rotation of the silylamido ligands in compounds $[MCl\{N(SiMe_3)_2\}_3]$, M = Ti, Zr and Hf, was observed in solution at low temperature by NMR spectroscopy.[10] Similar fluxional behaviour was observed for the compounds $[MMe\{N(SiMe_3)_2\}_3]$, M = Ti and Hf. Lowering the temperature resulted in line broadening and the eventual splitting into a doublet of the single resonance, due to the silylamide group, observed at room temperature. This is consistent with the presence of a configuration having three equivalent silylamido ligands each with magnetically distinct trimethylsilyl groups, where one is distal and the other proximal to the coordinated methyl group. Andersen[6] has previously reported the coalescence temperature of *ca* −25°C for the hafnium complex and we have found, as expected, that the titanium compound has a much higher coalescence temperature (i.e. *ca* −2°C). This is consistent with a decrease in steric congestion with an increase in atomic radius from titanium to hafnium.

It is noteworthy that our attempts to introduce alkyl groups larger than methyl failed for a range of conditions and reagents explored in the case of zirconium.

The intramolecular ligand steric relationships were further highlighted by single crystal X-ray crystallographic analysis. The essential structural features closely resemble those of the related monochloride derivatives, $MCl[N(SiMe_3)_2]_3$, M = Ti, Zr and Hf.[10] The geometry in the isostructural compounds $MMe[N(SiMe_3)_2]_3$, M = Ti and Zr, was found to be distorted tetrahedral with the metal–methyl bond coincident with a three-fold rotation axis. The molecular structure is shown in Fig. 1

along with the atom numbering scheme, and the main bond lengths and angles are given in Table 1. Interligand repulsion was seen to be minimized in the manner previously found for the monochloride systems. Thus there was widening from tetrahedral values of the N—M—N angles to 115.6(2)° (Ti) and 115.4(2)° (Zr), and narrowing of the C—M—N angles to 102.4(3)° (Ti) and 102.6(3)° (Zr).

The trimethylsilyl groups of each silylamide had either a proximal or distal disposition, respectively, with respect to the coordinated methyl groups and a staggered arrangement in the distal and proximal directions.

The M—N—Si(1) (distal) angles were opened up to 126.7(4)° (Ti) and 125.8(3)° (Zr), while the M—N—Si(2) (proximal) angles were slightly compressed to 118.0(4)° (Ti) and 117.4(3)° (Zr), from trigonal planar values, probably to accommodate the tetrahedral distortion at the metal centres. Despite the C—M—N angle narrowing, the M—C bond distances were normal, being close to those previously observed in a range of titanium[11] or zirconium[12] compounds with metal–C(sp^3) bonds. The proposed photoelimination of methane from the zirconium compound (**4**) prompted a search for hydride type interactions but no such contacts were found.

EXPERIMENTAL

The compounds $[MCl\{N(SiMe_3)_2\}_3]$, M = Ti or Zr,[10] and $MeZr[N(SiMe_3)_2]_3$[6] were prepared as previously described. Solvents were dried over and distilled from the sodium ketyl of benzophenone. Microanalytical data was obtained from University College London. Instruments: NMR, Bruker WP80 and WM-250; ESR, Bruker 200D (X-Band); mass spectrometer, MS-902, EI, recorded at 70 eV. All reactions were carried out in an atmosphere of purified nitrogen using standard Schlenk techniques.

Methyltris[bis(trimethylsilyl)amido]titanium (1)

With exclusion of light a cooled (0–7°C) solution of $[TiCl\{N(SiMe_3)_2\}_3]$ (4.6 g, 8 mmol) in diethyl ether (150 cm^3) was treated with methyllithium (4.5 cm^3 of a 1.8 mol dm^{-3} solution in diethyl ether, 8 mmol). The reaction mixture was stirred for 16 h at 0–7°C, the ether evaporated and pentane (150 cm^3) added. The filtered pentane solution was concentrated to about 50 cm^3 and on cooling to −25°C colourless needles of **1** (3.14 g, 71%) were deposited (m.p. 202–205°C; sublimes 140°C/10^{-4} mm Hg). Found: C, 41.7; H, 10.0; N, 7.7; Ti, 8.8. Calc. for $C_{19}H_{57}N_3Si_6Ti_2$: C, 41.9; H, 10.6; N, 7.2; Ti, 8.8%. ^1H NMR (C_6D_6): δ 0.48 (54H, s, Me_3Si), 1.68 (3H, s, MeTi).

Photolysis of $MeZr[N(SiMe_3)_2]_3$

Solutions of $MeZr[N(SiMe_3)_2]_3$ in toluene in a quartz flask were exposed to a UV source (Hanovia Type 504/4 operating at 250 W) for 25 min. The colourless solution slowly changed to pale yellow. Removal of the toluene afforded a gold-coloured gummy residue. ^1H NMR (tol-d^8): δ 0.38 (36H, s, $(Me_3Si)_2N$), 0.40 (9H, s, Me_3SiN), 0.48 (6H, s, Me_2SiN), 1.4 (2H, s, CH_2). ^{13}C NMR (C_6D_6): δ 0.27 (q, Me_3SiN), 3.81 (q, Me_2SiN), 4.21 (q, $(Me_3Si)_2N$), 53.4 (t, CH_2); $J(^1H, ^{13}C)$ = 121 Hz

Crystallography

Measurements were made on crystals sealed under nitrogen in glass capillaries using a CAD4 diffractometer operating in the ω–2θ scan mode with graphite-monochromated Mo-K_α radiation

Table 2. Crystal data and details of intensity measurement and structure refinement for $[MMe\{N(SiMe_3)_2\}_3]$, M = Ti or Zr

	Ti	Zr

Final RG[c]	0.0425	0.0344

[a] $\omega = 1/[\sigma^2(F_o)+gF_o^2]$.
[b] $R = \Sigma|\Delta F|/\Sigma|F_o|$.
[c] $RG = [\Sigma w|\Delta F|^2/\Sigma w|F_o^2|]^{1/2}$.

($\lambda = 0.71069$ Å) as previously described.[13] The intensity data were corrected for absorption empirically using psi-scan profiles. The structures were solved using standard heavy-atom procedures and refined using full-matrix least-squares methods[14] with scattering factors calculated from data obtained from ref. 15. All non-hydrogen atoms were refined with anisotropic displacement factor coefficients. For structure **1**, hydrogens were included in idealized positions and refined as components of rigid groups and assigned a common isotropic displacement factor coefficient. For structure **3**, hydrogens were freely refined with individual U_{iso} values. Crystal data for **1** and **3** are given in Table 2.

Acknowledgements—We thank SERC and Queen Mary College for equipment grants and one of us (A.C.S.) thanks SERC for an Advanced Fellowship. The Sudan Government and the British Council are thanked for financial support (A.A.I.). We are also grateful to Mr Greg Coumbarides for the NMR spectra, Dr A. Oduwole for ESR spectra and Mr Peter Cook for mass spectra.

SILVER(I) CLUSTERS OF THE STERICALLY-HINDERED BIDENTATE LIGAND, 3-(DIMETHYLPHENYL)SILYL-2-PYRIDINETHIOL. THE CRYSTAL AND MOLECULAR STRUCTURES OF $[Ag(SC_5H_3N\text{-}3\text{-}SiMe_2Ph)]_6$ AND $[Ag_8(SC_5H_3N\text{-}3\text{-}SiMe_2Ph)_6][Ag(NO_3)_2]_2 \cdot 2CH_3OH \cdot CH_2Cl_2$

ERIC BLOCK, DEBORAH MACHERONE, SHAHID N. SHAIKH and JON ZUBIETA*

Department of Chemistry, State University of New York at Albany, Albany, NY 12222, U.S.A.

(*Received* 22 *January* 1990; *accepted* 26 *March* 1990)

Abstract—The reaction of $Ag(NO_3)$ with excess $HSC_5H_3N\text{-}3\text{-}SiMe_2Ph$ yields the hexanuclear $[Ag_6(SC_5H_3N\text{-}3\text{-}SiMe_2Ph)_6]$, a species exhibiting a molecular "paddlewheel" structure with a central Ag_6S_6 drum. In contrast, the reaction of excess $Ag(NO_3)$ with $HSC_5H_3N\text{-}3\text{-}SiMe_2Ph$ under otherwise identical conditions produces $[Ag_8(SC_5H_3N\text{-}3\text{-}SiMe_2Ph)_6][Ag(NO_3)_2]_2 \cdot 2CH_3OH \cdot CH_2Cl_2$. The eight silver centres of the $[Ag_8(SR)_6]^{2+}$ central core exhibit hexagonal bipyramidal geometry, with the two silver ions of the $[Ag(NO_3)_2]^-$ units associated as two weakly interacting appendages. Crystal data $[Ag_6(SC_5H_3N\text{-}3\text{-}SiMe_2Ph)_6]$: orthorhombic *Pbca*, $a = 17.576(3)$, $b = 18.634(3)$, $c = 25.845(6)$ Å, $V = 8464.4(11)$ Å^3, $Z = 4$, $D_{calc} = 1.66$ g cm^{-3}; structure solution and refinement based on 2945 reflections (Mo-K_α, $\lambda = 0.71073$ Å) converged at $R = 0.0420$. $[Ag_8(SC_5H_3N\text{-}3\text{-}SiMe_2Ph)_6][Ag(NO_3)_2]_2$: triclinic $P\bar{1}$, $a = 13.103(3)$, $b = 14.766(3)$, $c = 15.600(3)$ Å, $\alpha = 63.88(1)$, $\beta = 80.27(2)$, $\gamma = 72.35(1)°$, $V = 2580.5(9)$ Å^3, $Z = 1$, $D_{calc} = 1.95$ g cm^{-3}; 5251 reflections, $R = 0.0392$.

Thiolate ligands are of continuing interest in the modelling of enzyme active sites and in the synthesis of metal complexes of diversified structural types with varying nuclearities.[1] Although the chemistry of silver thiolates has been extensively studied in recent years, the types and structural patterns have not been fully realized. The silver thiolates described to date are exclusively anionic or neutral oligomers of the types $[Ag_x(SR)_y]^{x-y}$ or $[Ag(SR)]_n$, respectively. The anionic complexes $[Ag_5(SPh)_7]^{2-}$,[2] $[Ag_5(S\text{-}t\text{-}Bu)_6]^-$[3] and $[Ag_4(SRS)_3]^{2-}$[4,5] occur as molecular cages, while the hexaargentate species $[Ag_6(SPh)_8]_n^{2-}$ consists of a tubular framework of weakly associated $[Ag_{12}(SPh)_{16}]^{4-}$ units.[6] The uncharged compounds are frequently insoluble, polymeric materials or oligomers, of which the cyclic $[AgSC_6H_{11}]_{12}$ and the non-molecular $[AgSCMeEt_2]_n$ are examples.[7,8] However, the degree of aggregation of silver thiolate species may be controlled by tuning the steric bulk of the thiolate substituents R, as demonstrated by us in the structural characterization of the series of polynuclear species $[AgSC(SiPhMe_2)_3]_3$, $[AgSC(SiMe_3)_3]_4$, $[AgSCH(SiMe_3)_2]_8$ and $[Ag_4\{SCH_2(SiMe_3)\}_3]_n(OMe)_n$.[9] Furthermore, we would anticipate that the presence of a potentially chelating group on the substituent, such as a pyridine nitrogen donor, in addition to the steric bulk of the triorganosilyl substituent, should result in unusual structural types. Consequently, 3- and 3,6-silylated 2-pyridinethiols **1** and **2** were designed.[10] The reactions of the 3-(dimethylphenyl)silyl-2-pyridinethiol (**1b**) with $AgNO_3$ under various conditions yielded the complexes $[Ag(SC_5H_3N\text{-}3\text{-}SiMe_2Ph)]_6$ (**3**) and $[Ag_8(SC_5H_3\text{-}3\text{-}SiMe_2Ph)_6][Ag(NO_3)_2]_2 \cdot 2CH_3OH \cdot CH_2Cl_2$

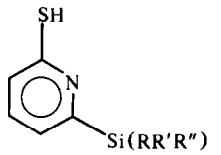
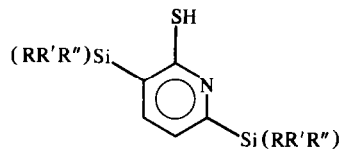
(**4**), whose preparations and structures we report in this paper. Although the structure of **3** is related to that of the previously reported copper complex $[Cu_6(SC_5H_3NSiMe_3)_6]$,[10] the structure of **4** is unique, exhibiting a cationic central core $[Ag_8(SC_5H_3N\text{-}3\text{-}SiMe_2Ph)_6]^{2+}$ weakly interacting with two $[Ag(NO_3)_2]^-$ units and two CH_3OH molecules.



1a R = R' = R" = $-CH_3$
1b R = R' = $-CH_3$, R" = $-C_6H_5$



2a R = R' = R" = $-CH_3$
2b R = R' = $-CH_3$, R" = $-C_6H_5$

The reaction of $Ag(NO_3)$ with an excess of **1b** yields the hexanuclear complex $[Ag_6(SC_5H_3N\text{-}3\text{-}SiMe_2Ph)_6]$,* whose structure is illustrated in Fig. 1.† The discrete molecular structure possesses a centre of symmetry at the centroid of the Ag_6S_6 drum, with a pseudo-three-fold axis passing through the centroids of the Ag_3S_3 rings. The overall geometry has been described as a molecular paddlewheel, a structure reminiscent of the cyclophanes.[11] The central drum of the paddlewheel is constructed from the two Ag_3S_3 rings, while the $-C_5H_3N(SiMe_2Ph)$ fragments of the ligands provide the six paddles. The organosilylated pyridinethiolate ligands bridge the Ag_3S_3 rings, alternating such that three thiolate donors and three pyridine donors ligate to each ring. The thiolate sulphur atoms bridge adjacent metal sites within an Ag_3S_3 ring, while a pyridine nitrogen provides the third ligand in the distorted trigonal planar geometry about each metal site.

In contrast, the reaction of excess $Ag(NO_3)$ with **1b** in CH_3CN, followed by crystallization from CH_2Cl_2–CH_3OH yields the unusual dodecanuclear aggregate **4**,‡ whose structure is illustrated in Fig. 2.§ The structure is best described as a $[Ag_8(SC_5H_3N\text{-}3\text{-}SiMe_2Ph)_6]^{2+}$ cation, associated via secondary interactions to two $[Ag(NO_3)_2]^-$ anions and two methanol molecules. Since there is a crystallographically imposed centre of symmetry at the midpoint of the Ag(1)···Ag(1a) vector, there are five chemically and crystallographically unique silver sites: Ag(1) enjoys distorted trigonal planar coordination to three thiolate donors; Ag(2) exhibits highly distorted trigonal planar geometry via coordination to a sulphur donor and a pyridyl nitrogen donor from different ligands and long, secondary bonding to O(3) of the nitrate group; Ag(3) is essentially digonally coordinated to a sulphur and a nitrogen from different ligand groups; Ag(4) presents [SNO] coordination geometry as a consequence of thiolate sulphur, pyridyl nitrogen and methanol oxygen bonding; Ag(5) bonds to oxygen donors from two nitrate groups and in a secondary interaction to a thiolate sulphur, producing $[SO_2]$ distorted trigonal planar geometry. Although the overall molecular geometry appears quite irregular, the arrangement of silver centres is elegantly simple

*All manipulations were carried out under argon atmosphere. Compound **3**: a degassed solution of **1b** (0.362 g, 1.48 mmol) and an equivalent amount of Et_3N in CH_3CN (15 cm^3) was added to a solution of $AgNO_3$ (0.25 g, 1.47 mmol) in CH_3CN (15 cm^3). A light yellow suspension formed immediately, and upon stirring at room temperature for 5 h, a bright yellow powder precipitated. After filtration and drying *in vacuo*, this yellow material was recrystallized from CH_2Cl_2–CH_3OH (1:4, v:v) to give bright yellow plates in 45% yield. Found: C, 44.0; H, 4.1; N, 4.1. Calc. for $C_{78}H_{84}N_6Si_6S_6Ag_6$: C, 44.3; H, 4.0; N, 4.0%. IR (KBr pellet, cm^{-1}): 2962(w), 1555(m), 1432(w), 1763(vs), 1131(s), 1105(m), 1069(s), 1022(s), 821(vs), 781(m), 740(m), 704(s), 470(w).

†Compound **3**: orthorhombic space group *Pbca*, $a = 17.576(3)$, $b = 18.634(3)$, $c = 25.845(6)$ Å, $V = 8464.4(11)$ $Å^3$, $Z = 4$, $D_{calc} = 1.66$ g cm^{-3}; structure solution and refinement based on 2945 reflections with $F_o \geqslant 6\sigma(F_o)$ (Mo-K_α, $\lambda = 0.71073$ Å), $R = 0.0420$ (265 variables).

‡Compound **4**: a degassed solution of **1b** (0.181 g, 0.74 mmol) and an equivalent amount of Et_3N in CH_3CN (15 cm^3) was added to a solution of $Ag(NO_3)$ (0.25 g, 1.47 mmol) in CH_3CN (15 cm^3). After stirring for 5 h, the yellow precipitate was filtered, dried *in vacuo*, and recrystallized from CH_2Cl_2–CH_3OH (1:2, v:v). Bright yellow block-shaped crystals of **4** were obtained in 40% yield. Found: C, 33.3; H, 3.0; N, 4.8. Calc. for $C_{81}H_{94}N_{10}Cl_2O_{14}Si_6S_6Ag_{10}$: C, 33.1; H, 3.2; N, 4.8%. IR (KBr pellet, cm^{-1}): 3041(w), 2957(w), 1562(m), 1548(m), 1422(m), 1365(vs), 1279(m), 1204(m), 1132(m), 1111(m), 1072(m), 1028(m), 819(s), 776(s), 737(s), 702(s), 648(m), 475(m).

§Compound **4**: triclinic space group $P\bar{1}$, $a = 13.103(3)$, $b = 14.766(3)$, $c = 15.600(3)$ Å, $\alpha = 63.88(1)$, $\beta = 80.27(2)$, $\gamma = 72.35(1)°$, $V = 2580.5(9)$ $Å^3$, $Z = 1$, $D_{calc} = 1.95$ g cm^{-3}; structure solution and refinement based on 5251 reflections with $F_o \geqslant 6\sigma(F_o)$ (Mo-K_α, $\lambda = 0.71073$ Å), $R = 0.0392$ (390 variables).

Tables of atomic coordinates, thermal parameters, bond lengths and bond angles have been deposited with the Editor and with the Cambridge Crystallographic Data Centre.

as shown in Fig. 3. The eight silver atoms of the $[Ag_8(SR)_6]^{2+}$ central core exhibit a hexagonal bipyramidal geometry, with the two silver ions of the $[Ag(NO_3)_2]^-$ units associated as two weakly interacting arms. The pyridinethiol ligands are disposed three above and three below the equatorial plane. Alternate "spokes" to the axial silver centres from the equatorial sites are bridged by thiolate donors, while the pyridine nitrogens provide connectivity to the adjacent silver ions of the hexagonal plane. Thus, the axial silver sites exhibit trigonal planar coordination geometry to an $[S_3]$ donor set, while the equatorial sites display [SN] coordination, more or less distorted by secondary bonding interactions.

The isolation and characterization of **3** and **4** demonstrate that variations in reaction conditions, as well as the introduction of steric constraints, can have profound influences on the structures of metal–thiolate complexes. The unique structure of **4** suggests that the presence of coordinating anions results in unexpected structural consequences, such that the already rich and varied chemistry of the group IIb thiolates may be further developed.

(*Received* 26 *June* 1989; *accepted* 15 *January* 1990)

Abstract—The reactions of the tertiary (amino)phosphines $(R_2N)_3P$ [$R_2N = C_4H_8N$-, $C_5H_{10}N$-, $C_6H_{12}N$-, OC_4H_8N-, and $CH_3NC_4H_8N$-] with S_4N_4 are described. The phosphiniminocyclotrithiazenes $(R_2N)_3PN\text{-}S_3N_3$ (**1–5**) are the only heterocyclic products isolated (60–80% yield). Excess (amino)phosphines cleave the heterocycles readily while norbornadiene reacts with them to give rise to the addition products, $(R_2N)_3PN\text{-}S_3N_3 \cdot C_7H_8$ (**6–9**) in small yields. The single crystal X-ray structure of $(C_5H_{10}N)_3PN\text{-}S_3N_3$ (triclinic system, space group $P_{\bar{1}}$) gave the unit cell dimensions: $a = 9.573(5)$, $b = 10.372(6)$, $c = 10.916(6)$ Å, $\alpha = 85.46(3)$, $\beta = 81.13(4)$, $\gamma = 79.73(4)°$, $V = 1052.25$ Å^3 and $Z = 2$. The structure has been compared with that of $Ph_3PN\text{-}S_3N_3$ which is the only other compound of this type ($R_3PN\text{-}S_3N_3$) whose X-ray structure is known.

Prior to our work, Ph_3P,[2–4] $(C_6H_{11})_3P$[4] and $(PhO)_3P$[5] are the only examples of symmetrically substituted tertiary phosphines, R_3P to be reacted with S_4N_4. Recently we have carried out a similar investigation using a few phosphines of this type (P–C bonded only) which have shown noticeable variation in their behaviour,[1] compared to Ph_3P, which is the only well studied example. Tertiary (amino) phosphines, $(R_2N)_3P$ by virtue of their labile P–N bonds and more basic nature also offer suitable examples for such studies.[6] To date, besides a brief mention on the formation of an acyclic species from the reaction of S_4N_4 with $(Me_2N)_3P$[7], no other information on such reactions is available in the literature.

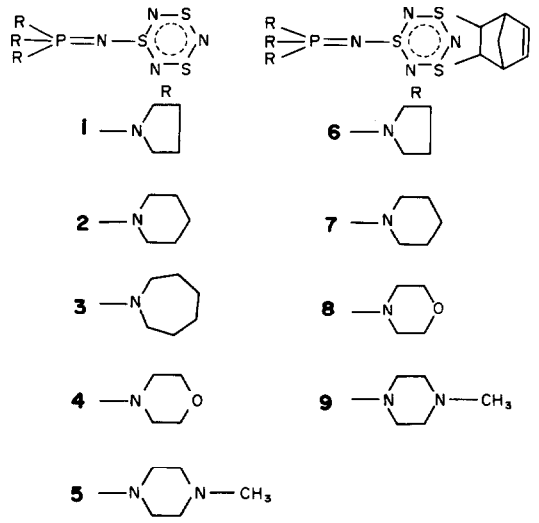
In this paper we report the detailed study of five different tertiary (amino)phosphines, $(R_2N)_3P$ [R_2N = (i) C_4H_8N-, (ii) $C_5H_{10}N$-, (iii) $C_6H_{12}N$-, (iv) OC_4H_8N- and (v) $CH_3NC_4H_8N$-] which has led to the isolation of phosphiniminocyclotrithiazene derivatives, $(R_2N)_3PN\text{-}S_3N_3$ (**1–5**) and their characterization and conversion to norbornadiene adducts (**6–9**). In addition, the X-ray crystal structure of $(C_5H_{10}N)_3PN\text{-}S_3N_3$ has been determined and compared with that of $Ph_3PN\text{-}S_3N_3$.[8]

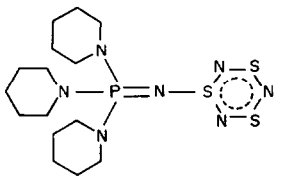
EXPERIMENTAL

General procedures and materials

Spectrophotometers were as follows: IR, Perkin–Elmer 983G and 1430 (spectra in Nujol mull, values in cm^{-1}); NMR, ^{1}H-Varian EM 390 and Bruker

* Author to whom correspondence should be addressed.





WH 250 (chemical shifts in ppm, relative to $SiMe_4$); ^{31}P-Varian XL 100, Varian FT 80A and Bruker WH 400 (chemical shifts in ppm, positive values downfield relative to 85% H_3PO_4); UV–vis, Shimadzu UV240 and Hitachi 220A (CH_2Cl_2 solutions); and mass spectra, Finnigan Matt 8280 GC-MS. CHN analyses were done by Messrs Beller, Goettingen, W. Germany and Department of Chemistry, University of Calgary, Calgary, Canada. Melting points were determined in sealed tubes and are uncorrected. All operations were performed under dry oxygen free argon atmosphere using glove bag/dry box and standard Schlenck techniques. Acetonitrile was twice distilled over P_4O_{10}, then over CaH_2 and stored over CaH_2 under argon. Benzene (AR) (**Caution!** potential carcinogen) was refluxed, distilled and stored over sodium wire.

S_4N_4 prepared by the literature method[9] was recrystallized from hot toluene before use. (**Caution!** S_4N_4 may explode. Recommended safety precautions have to be adopted.[10]) Aminophosphines (i)–(v) were prepared by employing the reported procedures.[11,12] $(C_5H_{10}N)_3P$, $(OC_4H_8N)_3P$ and $(CH_3NC_4H_8N)_3P$ were purified by recrystallization from a benzene–hexane (1 : 1) mixture and $(C_4H_8N)_3P$ and $(C_6H_{12}N)_3P$ by low pressure distillation. The physical and spectral properties of these phosphines have been published elsewhere.[12]

Reactions of S_4N_4 *and (amino)phosphines*

Reactions were carried out both in acetonitrile and benzene using different mole ratios of S_4N_4 and phosphine (1 : 2, 1 : 3.5 and 1 : 5) and different temperatures, [−5, 15, RT (*ca.* 30) and 45°C] with each of the phosphines. Only R_3PN–S_3N_3 and/or the corresponding phosphine sulphide were isolated from these reactions. The results of the reactions studied with each phosphine have been summarized in Table 1. Details of the synthesis in two specific cases are described here. The procedure given is adequate for the isolation of the corresponding derivatives in the other cases.

(a) *Reaction of* S_4N_4 *with tris(pyrrolidino)phosphine* [1 : 2, C_6H_6, RT]. Tetrasulphurtetranitride (0.56 g, 3.05 mmol) was added at room temperature as solid in aliquots to a stirred solution of $(C_4H_8N)_3P$ (1.47 g, 6.10 mmol) in benzene (30 cm^3). [WARNING: Direct addition of S_4N_4 to this liquid phosphine can cause sudden fire.] The reaction started at once with the evolution of heat and formation of a red colour which darkened with time. No precipitate formation was observed. The resulting dark

red solution was concentrated to one fourth the original volume and acetonitrile (20 cm^3) was added and cooled at 0°C (24 h). The red crystalline solid formed was separated by filtration under argon and recrystallized from CH_3CN–C_6H_6 (1 : 1, v/v) to obtain $(C_4H_8N)_3PN\text{-}S_3N_3$ (**1**) (0.96 g, 80%). [See Tables 2–4 for physical and spectral data.] From the residual mother liquor a colourless oily liquid was obtained by distillation under reduced pressure [b.p. 110°C/0.04 mm] which was identified as $(C_4H_8N)_3PS$ (see Table 4).

(b) *Reaction of* S_4N_4 *with tris(morpholino)phosphine* [1 : 2, CH_3CN, RT]. To a stirred solution of the phosphine (1.05 g, 3.62 mmol) in acetonitrile (25 cm^3) at room temperature, tetrasulphurtetranitride (0.33 g, 1.81 mmol) was added as solid in portions over a period of 15 min. The red colour formation was slow in this case. After *ca.* 8 h the formation of a red precipitate was observed which increased with time. After 24 h the reaction mixture was filtered under argon to isolate the red precipitate which on recrystallization from a mixture of CH_3CN–C_6H_6 (1 : 1, v/v) gave crystalline red blocks of $(OC_4H_8N)_3PN\text{-}S_3N_3$ (**4**) (0.41 g, 51%) (Tables 2–4).

The filtrate was concentrated to two thirds of the original volume and cooled in the refrigerator for 1 day to obtain further quantities of **4** (0.17 g, 21%). The concentrated residual mother liquor gave a small amount of S_4N_4 (10 mg) and $(OC_4H_8N)_3PS$ (0.39 g) when cooled at 0°C for 1 day.

(c) *Reaction of* $(OC_4H_8N)_3PN\text{-}S_3N_3$ *with* C_7H_8 [1 : 18, CH_2Cl_2, RT]. Tris(morpholino)phosphiniminocyclotrithiazene (0.35 g, 0.79 mmol) was stirred in CH_2Cl_2 (20 cm^3) in a side arm flask under argon and norbornadiene (1.31 g, 14.22 mmol) was added into it all at once. While it was stirred at room temperature, the intense red colour of the solution faded gradually and at the end of 36 h a pale red brown solution resulted. The solvent was removed *in vacuo* from this to obtain a pale brown semisolid which was vigorously stirred in diethylether (30 cm^3) for 30 min and filtered to get a slightly coloured powdery solid. This was recrystallized from a mixture of CH_2Cl_2–Et_2O (1 : 1, v/v) at 0°C to obtain $(OC_4H_8N)_3PN\text{-}S_3N_3\cdot C_7H_8$ (0.19 g, 45%) (Tables 2–4 for physical and spectral characteristics).*

X-ray crystallographic analysis

Crystal and refinement data for $(C_5H_{10}N)_3PN\text{-}S_3N_3$ are summarized in Table 5. Crystals suitable for X-ray analysis were prepared by slow recrystallization of the compound from a mixture of benzene and acetonitrile (1 : 1, v/v) at 0°C. Diffraction intensities were collected at 23°C using an Enraf–Nonius CAD 4 X-ray diffractometer with Cu-K_α radiation (λ = 1.5418 Å) and were corrected for Lorentz and polarization effects. Numerical absorption correction was applied using SHELX-76 program. The structure was solved by direct methods using SHELX-86 program and refined by full matrix least squares method, the minimized function being $\Sigma w(|F_o|-|F_c|)^2$. The weighting scheme employed was $w = 1/[\sigma^2(F_o)+0.0046F_o^2]$. The analytical scattering factors corrected for the real and imaginary parts of anomalous dispersions were taken from literature.[13,14] All hydrogens were located in difference Fourier maps synthesized after anisotropic refinement of non-hydrogen atoms. All computations were performed on a SIEMENS 7580 E computer.

* In the case of $(C_6H_{12}N)_3PN\text{-}S_3N_3$ the norbornadiene adduct could not be isolated.

RESULTS AND DISCUSSION

The reaction between the tertiary (amino)phosphines and S_4N_4 that proceed exothermically at room temperature can be represented as in eq. (1).

$$2(R_2N)_3P + S_4N_4 \longrightarrow (R_2N)_3PN\text{-}S_3N_3 + (R_2N)_3PS \quad (1)$$
(1–5)

[R_2N = (i) C_4H_8N-, (ii) $C_5H_{10}N$-, (iii) $C_6H_{12}N$-, (iv) OC_4H_8N- and (v) $CH_3NC_4H_8N$-].

Compounds **1–5** are the first examples of mono-substituted $-S_3N_3$ heterocycles to contain tertiary (amino)phosphine residues whose isolable yields lie in the range 60–80% and are best obtained from 1 : 2 [S_4N_4 : $(R_2N)_3P$] reactions. It is observed that only in the case of $(C_4H_8N)_3P$ and $(CH_3NC_4H_8N)_3P$, the corresponding $-S_3N_3$ derivatives were isolable from the reactions carried out at −5°C. Neither improvement in the yield nor any new heterocyclic product was observed when the reactions are done at higher temperature and mole ratio of reactants (Table 1). It may be noted that Ph_3P affords three types of cyclic derivatives [cf. $Ph_3PN\text{-}S_3N_3$; 1,5-$(Ph_3PN)_2S_4N_4$ and $(Ph_3PN)_3S^+S_4N_5^-$].[3] Also, the reaction of S_4N_4 with the phosphine containing only one amino residue, $(OC_4H_8N)Ph_2P$, gives $(OC_4H_8N)Ph_2PN\text{-}S_3N_3$ and $[(OC_4H_8N)Ph_2PN]_2S_4N_4$.[15] A ^{31}P-NMR spectrum of 1 : 5 reaction mixture [S_4N_4 : $(OC_4H_8N)_3P$] gives rise to only three signals (δ_P at 74.8, 34.9 and 18.8 ppm) with the most intense signal at 74.8 ppm which corresponds to $(OC_4H_8N)_3PS$.* It is noteworthy

* The origin of the other two peaks is not clear. Probably indicates decomposition products of **4**.

that the presence of either $(OC_4H_8N)_3P$ or $(OC_4H_8N)_3PN\text{-}S_3N_3$ was not detected. In addition, independent reactions of **1–5** with the corresponding phosphines lead to the destruction of the heterocycle. Only the sulphide of the respective phosphine was isolated from these reactions.

In all the cases, the corresponding phosphine sulphide $(R_2N)_3PS$ has been readily isolated and to the best of our knowledge $(C_4H_8N)_3PS$, $(C_6H_{12}N)_3PS$ and $(CH_3NC_4H_8N)_3PS$ were hitherto unknown.

Characterization of $R_3PN\text{-}S_3N_3$ *compounds* (**1–5**)

Characterization data on compounds **1–5** are given in Tables 2–4.

Similar to $R_3PN\text{-}S_3N_3$ (R = c-C_6H_{11}- and t-C_4H_9-)[1] the UV–vis spectra of compounds **1–5** also show the 285 nm absorption.[16] The failure to detect this absorption in the previously reported examples is conceivably due to its masking by the absorption of the phenyl groups. Phosphorus chemical shift data (Table 4) reveal that the phosphorus atom in a given series experiences increased shielding in going from the phosphine to the corresponding $R_3PN\text{-}S_3N_3 \cdot C_7H_8$. The changing amino substituents seem to exert only a modest influence on the observed chemical shift values. EI mass spectra of compounds **2**, **3** and **4** similar to $Ph_3PN\text{-}S_3N_3$ show the presence of the [M-SN_3] ion. A characteristic feature in these cases is that the mass peak due to R^+ appears in very high intensity [base peak in the cases of **2** and **4**] while that of R_3PN^+ is insignificant which is suggestive of a facile P—N< (amino) bond cleavage. The mass spectra of tertiary (amino)phosphines also exhibit similar features.[17]

Norbornadiene adducts of compounds **1–5**

$Ph_3PN\text{-}S_3N_3$ reacts with norbornadiene in refluxing methylenechloride to give rise to the addition product $Ph_3PN\text{-}S_3N_3 \cdot C_7H_8$.[18] Compounds **1–5** fail to afford the corresponding adducts under these conditions. However, these derivatives **6–9** are isolated in low yield (5–45%) from room temperature reactions. They are comparatively less stable than the parent heterocycles. The number of proton signals and their chemical shift values for the norbornadiene moiety in their ^{1}H-NMR spectra are in good agreement with those observed for $Ph_3PN\text{-}S_3N_3 \cdot C_7H_8$[18] (Table 3). A comparison of the ^{31}P-chemical shift values for the parent heterocycles **1–5** and the norbornadiene adducts **6–9** suggests only little influence by the olefin on the phosphorus shielding in these cases.

X-ray crystal structure of $(C_5H_{10}N)_3PN\text{-}S_3N_3$ (**2**)

Among the four crystal structure data reported on the monosubstituted cyclotrithiazenes,[8,19–21]

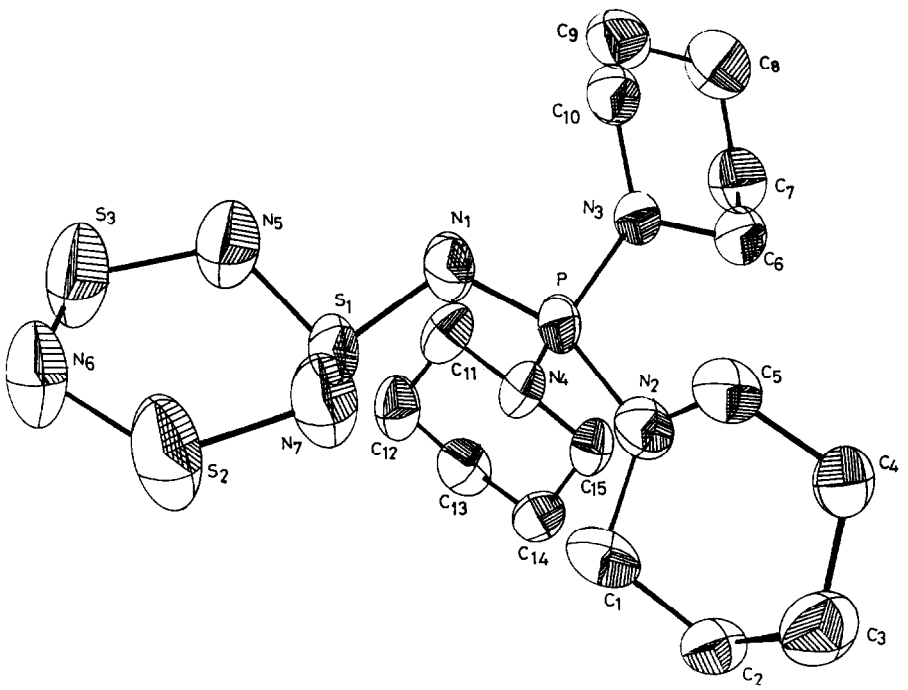

Fig. 1. ORTEP plot (50% probability ellipsoids) of $(C_5H_{10}N)_3PN\text{-}S_3N_3$ showing the atomic numbering scheme.

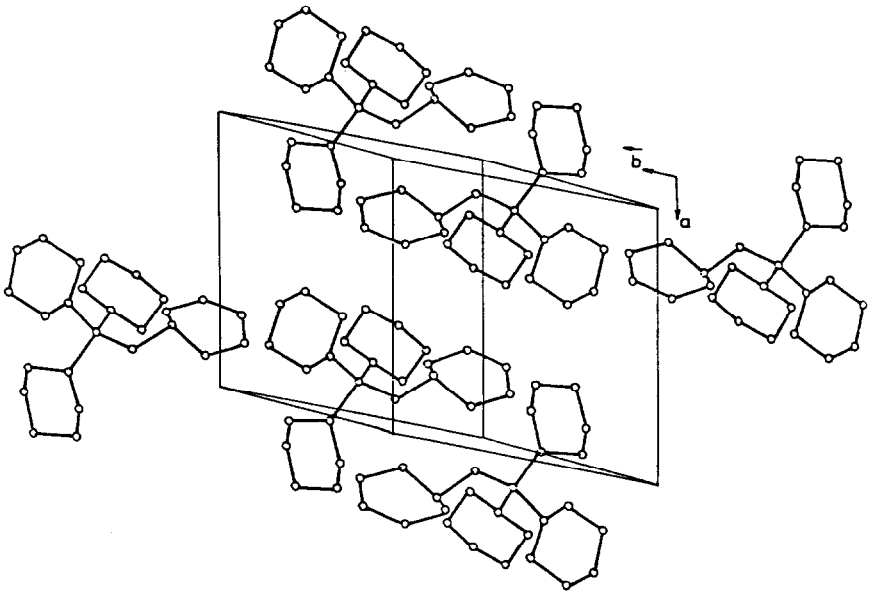

Fig. 2. Packing of the molecule in the unit cell (view down c^* axis).

$Ph_3PN\text{-}S_3N_3$ is the only example to possess a phosphinimino group. The ORTEP plot, the unit cell diagram (Fig. 2) and the selected bond distances and bond angles of the second example of such a type, $(C_5H_{10}N)_3PN\text{-}S_3N_3$ are given in Fig. 1 and Table 6 respectively. As in $Ph_3PN\text{-}S_3N_3$ the tricoordinate sulphur atom S(1) is deviated (by 0.65 Å) from the mean plane constituted by the other skeletal atoms N(5)—S(3)—N(6)—S(2)—N(7). In contrast to $Ph_3PN\text{-}S_3N_3$, the endocyclic bonds N(5)—S(3)—N(6)—S(2)—N(7) within experimental error have the same lengths (*ca.* 1.59 Å). In general the endocyclic bond lengths of the $\text{-}S_3N_3$ ring as well as the exocyclic bonds S(1)—N(1) and N(1)—P in **2** are shorter than the corresponding single bond distances[22,23] and $Ph_3PN\text{-}S_3N_3$. Interestingly, the three phosphorus–nitrogen distances P—N(2), P—N(3) and P—N(4) [1.638, 1.619 and 1.639 Å] of the phosphine moiety in **2** are noticeably shorter than the corresponding distances in the free phosphine [1.727, 1.692 and 1.705 Å][11] which is suggestive of more extended delocalization in $(C_5H_{10}N)_3PN\text{-}S_3N_3$. Another feature of the present structure is that the distance P—S(1) (non bonded)

Table 6. Selected bond distances (Å) and angles (°) with ESDs in parentheses for $(C_5H_{10}N)_3PN\text{-}S_3N_3$

Bond distances (Å)			
P—N(1)	1.595(3)	S(3)—N(6)	1.579(5)

PREPARATION AND SPECTROSCOPIC CHARACTERIZATION OF SOME HETEROBIMETALLIC COMPLEXES OF 1,1-DICARBOETHOXY-2,2-ETHYLENE DITHIOLATE INVOLVING DIVALENT AND MONOVALENT METAL IONS

NANHAI SINGH,* RAGINI VERMA and N. K. SINGH

Department of Chemistry, Faculty of Science, Banaras Hindu University, Varanasi—221005, India

(*Received* 14 *August* 1989; *accepted* 29 *January* 1990)

Abstract—Reaction of the anionic dithiolato complexes $[M'(DED)_2]^{2-}$ (M' = Cd^{II} or Pd^{II}; DED = 1,1-dicarboethoxy-2,2-ethylene dithiolate) with metal ions occurs forming a new series of heterobimetallic complexes $M[M'(DED)_2]$ (M = Co^{II}, Ni^{II}, Cu^{II}, Pb^{II}, $2Ag^{I}$ or $2Tl^{I}$). The precursor ions $[M'(DED)_2]^{2-}$ used for the synthesis of heterobimetallic complexes have been isolated as $(Et_4N)_2[M'(DED)_2]$ salts for the first time. The composition of the complexes has been determined by elemental analysis. The tendency for the anionic dithiolato complexes, $[M'(DED)_2]^{2-}$, to act as a bridging moiety via the sulphur atoms to form heterobimetallic complexes has been explored. Heterobimetallic compounds are non-conducting, while $(Et_4N)_2[M'(DED)_2]$ salts exhibit 2:1 electrolytic behaviour in nitrobenzene. The IR spectra indicate dinegative bidentate behaviour of DED with the presence of non-equivalent ester groups, while ^1H and ^{13}C NMR spectral studies suggest that the non-equivalent nature of the ester groups is not retained in solution. Magnetic moment and electronic spectral studies suggest a square-planar environment around cobalt(II), nickel(II), palladium(II) and copper(II).

The chemistry associated with low-dimensional heterometal assemblies in polynuclear complexes has attracted much attention owing to their potential to exhibit unique physicochemical properties. A resurgence of interest in heterobinuclear transition metal complexes has occurred for several reasons,[1–6] for example, in catalysis, models for active sites of many enzyme systems, magnetic exchange behaviour, electron-transfer reactions and electrically conducting materials. Planar transition metal bis(dithio) complexes have long been known as attractive precursors for the synthesis of highly conducting[7–9] molecular solids due to their highly delocalized electronic structure, range of stable oxidation states and propensity to adopt linear-chain structures in the solid state. Very interesting and novel mixed-metal polymeric catalysts containing dithiolene, porphoryn, acetamide and carboxylate units have evolved.[10]

Although much work[11] has been carried out on binary and ternary complexes of 1,1-dithio ligands including 1,1-dicarboethoxy-2,2-ethylene dithiolate (DED), comparatively less has been carried out on the heterobimetallic complexes of 1,1-dithio ligands. Coucouvanis[12] and co-workers have demonstrated that the substitution of the inert cations that accompany certain anionic 1,1- or 1,2-dithiochelates by coordinately unsaturated complex cations as Lewis acids, has proved to be a satisfactory approach to the synthesis of heteronuclear complexes. A few papers[13,14] from our laboratory have also been published on heterobimetallic complexes of some 1,1-dithio ligands, for example, xanthate and dithiocarbamate, where the two identical sulphur donor atoms of these ligands bridge the two different metal ions.

Compared to other 1,1-dithio ligands, the DED ligand is quite unique in its properties and appears to be more effective than other 1,1-dithio ligands in stabilizing[15,16] metal ions in unusually high oxi-

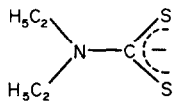
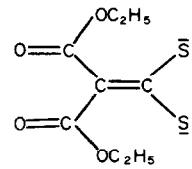
Xanthate



Dithiocarbamate



DED

dation states. The DED ligand by virtue of its conjugated π-system appears to exhibit different behaviour from that of the xanthate or dithiocarbamate.

We present here the synthetic and spectral properties of some novel heterobinuclear complexes formed with 1,1-dicarboethoxy-2,2-ethylene dithiolate.

EXPERIMENTAL

Materials and methods

The chemicals used were BDH (AR) or equivalent grades. The solvents were freshly distilled and where necessary dried before use. The ligand K_2DED was prepared according to the literature[17] procedure.

Preparation of the complexes

(i) $(Et_4N)_2[Cd(DED)_2]$. $K_2[Cd(DED)_2]$ was prepared *in situ* by gradual addition of 5 cm^3 of an aqueous solution of cadmium nitrate (0.61 g, 2 mmol) to a 30 cm^3 solution of K_2DED (1.25 g, 4 mmol) in 50 : 50 ethanol–water (v/v) with vigorous stirring. The dirty white precipitate which formed initially immediately dissolved giving a pale yellow solution of $K_2[Cd(DED)_2]$. The $K_2[Cd(DED)_2]$ thus obtained was added to a 10 cm^3 aqueous solution containing tetraethylammonium bromide (1.00 g, 4.5 mmol), whereby a yellow precipitate of the compound formed immediately. This was filtered off, washed with the above solvent mixture and air dried.

(ii) $(Et_4N)_2[Pd(DED)_2]$. $K_2[Pd(DED)_2]$ was prepared *in situ* by adding, with constant stirring, a 2 cm^3 aqueous solution of palladous chloride (0.18 g, 1 mmol) and potassium chloride (0.15 g, 2 mmol) to a 5 cm^3 solution of K_2DED (0.65 g, 2 mmol) in 60 : 40 ethanol–water (v/v). The orange–brown precipitate formed initially dissolved to give a brown solution of $K_2[Pd(DED)_2]$. This was immediately added to an aqueous solution containing tetraethylammonium bromide (0.5 g, 2.5 mmol). The orange–brown precipitate which formed immediately was filtered off, washed with the above solvent mixture and air dried.

(iii) $M[M'(DED)_2]$. In general, the heterobimetallic complexes were prepared by gradual addition of a 5–10 cm^3 aqueous solution containing $Co(NO_3)_2 \cdot 6H_2O$, $NiCl_2 \cdot 6H_2O$, $CuSO_4 \cdot 5H_2O$, $Pb(NO_3)_2$, Tl_2SO_4 or $AgNO_3$ (1 mmol/2 mmol), with constant stirring, to a solution of $K_2[Cd(DED)_2]$ or $K_2[Pd(DED)_2]$ prepared *in situ* as described above. All the heterobimetallic complexes which precipitated as microcrystalline material were suction filtered, washed with an ethanol–water mixture and air dried.

Analysis and physical measurements

Except for the palladium complexes all the others were analysed for their metal and sulphur contents following standard literature procedures.[18] Carbon, hydrogen and nitrogen were determined microanalytically on a Perkin–Elmer 240C model microanalyser.

The conductivity of soluble complexes was recorded in 10^{-3} M nitrobenzene solution on a WTW conductivity meter. Magnetic susceptibility measurements were made at room temperature on a Cahn–Farday electrobalance using $Hg[Co(NCS)_4]$ as calibrant. IR spectra were recorded in the region 4000–200 cm^{-1} in Nujol mulls using a Perkin–Elmer 783 spectrophotometer. Electronic spectra were recorded on a Cary-14 spectrophotometer as Nujol mulls following the procedure of Lee *et al.* ^1H and ^{13}C NMR spectra of $(Et_4N)_2[Cd(DED)_2]$ and $(Et_4N)_2[Pd(DED)_2]$ were obtained in $CDCl_3$ while that of K_2DED was obtained in $DMSO(d_6)$ on a JEOL FX 90Q spectrophotometer using TMS as internal reference. The relevant analytical and physicochemical data are given in Table 1.

RESULTS AND DISCUSSION

The formation of $(Et_4N)_2[M'(DED)_2]$ and the heterobimetallic complexes $M[M'(DED)_2]$ may be represented by the following equations:

$$Cd(NO_3)_2 + 2\,K_2DED \longrightarrow K_2[Cd(DED)_2] + 2\,KNO_3 \quad \text{(i)}$$

$$PdCl_2 + 2\,KCl + 2\,K_2DED \longrightarrow K_2[Pd(DED)_2] + 4\,KCl \quad \text{(ii)}$$

Table 1. Analytical data, physical properties and electronic spectral data of the complexes

$$K_2[M'(DED)_2] + 2\,Et_4NBr \longrightarrow (Et_4N)_2[M'(DED)_2] + 2\,KBr \quad \text{(iii)}$$

$$K_2[M'(DED)_2] + M(NO_3)_2/MSO_4 \longrightarrow M[M'(DED)_2] + 2\,KNO_3/K_2SO_4. \quad \text{(iv)}$$

All the complexes decompose in the temperature range 131–224°C. Except for the $(Et_3N)_2[M'(DED)_2]$ salts which are soluble in polar as well as non-polar solvents such as methanol, actone, DMF, DMSO, chloroform or nitrobenzene, all of the other complexes are insoluble in water and common organic solvents but slightly soluble in nitrobenzene. The electrical conductances[19] (Λ_M = 48–52 $cm^2\ \Omega^{-1}\ mol^{-1}$) in nitrobenzene at 10^{-3} M concentration are consistent with 2:1 electrolytic behaviour of $(Et_4N)_2[M'(DED)_2]$, whilst the heterobimetallic complexes (Λ_M = 2–4 $cm^2\ \Omega^{-1}\ mol^{-1}$) are non-conducting.

The diamagnetic nature and electronic spectral bands (Table 1) of $(Et_4N)_2[Pd(DED)_2]$, Pd[Cd $(DED)_2$], Ni[$Pd(DED)_2$] and Ni[$Cd(DED)_2$] suggest square-planar geometry[12,20] around nickel(II) and palladium(II) in these complexes.

The magnetic moment (2.2 BM) and the electronic spectral bands (Table 1) suggest square-planar geometry[21,22] around cobalt(II) in Co[Cd $(DED)_2$].

The μ_{eff} values of 1.66 and 1.70 BM for Cu[Cd $(DED)_2$] and Cu[$Pd(DED)_2$], respectively, indicate the presence of one unpaired electron. The somewhat lower magnetic moments as compared to the spin-only value may be attributed to metal–metal interaction or the presence of antiferromagnetism in the copper(II) complexes. The presence of bands in the visible region (Table 1) suggest the planar CuS_4 chromophore.[23]

The occurrence in general of two absorptions in the IR spectra of $(Et_4N)_2[M'(DED)_2]$ in the 1675–1730 cm^{-1} region is due to the C=O stretching vibration.[11,12] The presence of two bands in the carbonyl region was attributed to the twisting of one of the ester groups out of the plane containing the ethylene carbons.[12,16,17] There is little change of the ν(C=O) frequency in the heterobimetallic complexes $M[M'(DED)_2]$ indicating that the bonding mode of the carbonyl group is virtually unchanged on formation of the heterobimetallic complex.

The $\nu(C{=}CS_2)$ absorption band appearing at 1450 cm^{-1} in $(Et_4N)_2[M'(DED)_2]$ is observed in the range 1465–1470 cm^{-1} in the bimetallic complexes.[12,17] The appearance of the $C{=}CS_2$ stretching vibrations at somewhat higher frequencies in the heterobimetallic complexes, as compared to $(Et_4N)_2[M'(DED)_2]$, may be indicative of interaction of the sulphur atoms of the chelating group attached to M′ with the added metal ions, M, in a polymeric fashion.[12,24]

Three bands which are generally found for these complexes in the 890–1030 cm^{-1} region may be assigned to the $\nu(CS_2)$ group.[17] The occurrence of a single band in the 1010–1030 cm^{-1} region is related to the $\nu_s(=CS_2)$ group, while the presence of two bands in the 890–990 cm^{-1} region may be attributed to the $\nu_{as}(=CS_2)$ group. In all the complexes the bands occurring below 400 cm^{-1} have been tentatively assigned to metal–sulphur stretching vibrations. The lower one may be related to Tl—S, Pb—S, Ag—S, Cd—S, Pd—S and the higher one to Co—S, Ni—S or Cu—S stretching modes.[12]

The ^1H NMR spectra of $(Et_4N)_2[Cd(DED)_2]$ and $(Et_4N)_2[Pd(DED)_2]$ yield a triplet at δ 1.27 ppm for the CH_3 protons of Et_4N and the ester groups of the ligand which are mixed together. The protons of the $-NCH_2$ and $-OCH_2$ groups are not resolved as a sharp quartet but are observed as a doublet at δ 3.36 and 4.06 ppm, respectively, in both the complexes. The downfield shift observed for the protons compared to K_2DED ($CH_3 = \delta$ 1.11 ppm; $-OCH_2 = \delta$ 3.93 ppm) clearly indicates the deshielding of ethoxy protons in these complexes.

The ^{13}C NMR spectra gave signals at δ 8.0 and 53.04 ppm for $-CH_3$ and $-NCH_2(NEt_4)$. The $-CH_3$ and $-OCH_2$ carbons of the ester groups are observed at δ 14.25 and 60.08 ppm as singlets. The carbonyl carbon has δ 168.43 ppm in these complexes compared to δ 167.89 ppm in K_2DED, suggesting non-involvement of the C=O group in bonding on complex formation.

The number of peaks in the ^1H and ^{13}C NMR spectra clearly indicate that the non-equivalent nature of the ester group is not retained in solution in the above complexes.

Based on the chemical composition and physical measurements, the ionic structure $(Et_4N)_2[M'(DED)_2]$ and polymeric structure $M[M'(DED)_2]$ may be suggested for the complexes.

On the basis of the foregoing studies the following conclusions may be drawn regarding the present series of complexes:

(i) The S—S chelating site of the DED ligand in its anionic complexes shows a tendency to act as a bridging ligand via the sulphur atoms to form heterobimetallic complexes.
(ii) The low-spin planar geometry of cobalt(II), nickel(II) or palladium(II) are stabilized in their heterobimetallic complexes.
(iii) The average value of the ligand-field splitting

parameter, $\sim 19{,}350\ cm^{-1}$, for the planar NiS_4 chromophore places DED between trithiocarbonate and 1,1-cyanocarboethoxyethylenedithiolate[25] in the spectrochemical series of the sulphur donors.

(iv) IR spectral studies clearly indicate the dinegative bidentate behaviour of DED and the non-equivalent nature of the ester groups of the ligand in the complex.

(v) NMR studies indicate that non-equivalent nature of the ester group is not retained in solution.

NEUTRAL AMINOCARBENE COMPLEXES OF NICKEL FROM THE REACTION OF [Ni{η^2-C(NBu^t)CH$_2$CMe$_3$}(NC$_4$H$_2$Me$_2$)(PMe$_3$)] WITH DIPROTONIC ACIDS

(*Received* 18 *September* 1989; *accepted* 29 *January* 1990)

Abstract—The dihaptoiminoacyl complex [Ni{η^2-C(NBu^t)CH$_2$CMe$_3$}(NC$_4$H$_2$Me$_2$)(PMe$_3$)] (**1**), containing the coordinated 2,5-dimethylpyrrolyl ligand, reacts with CO_2, in the presence of water, with protolytic cleavage of the Ni—N bond and protonation of the iminoacyl nitrogen atom, to furnish an η^2-carbonate aminocarbene complex of composition [Ni(η^2-CO$_3$){C(NHBu^t)CH$_2$CMe$_3$}(PMe$_3$)] (**2**). This transformation has been shown to be a general reaction of **1** with diprotonic acids, and compounds related to **2** have been obtained using oxalic, parabanic and salicylic acids. The new compounds have been fully characterized by analytical and spectroscopic methods.

A recent contribution from our laboratory has described the formation of various η^1-iminoacyl complexes of nickel(II) with the composition [Ni{η^1-C(NBu^t)R}Cl(PMe$_3$)$_2$]. Substitution of the chloride ligand by the bulkier 2,5-dimethylpyrrolyl group induces a change in the coordination mode of the iminoacyl ligand and provides the dihaptoiminoacyl compounds [Ni{η^2-C(NBu^t)R}(NC$_4$H$_2$Me$_2$)(PMe$_3$)].[1] A characteristic feature of the chemistry of the η^1-iminoacyls is the extreme facility with which the coordinated iminoacyl nitrogen can be protonated, even by water, to form the cationic aminocarbene species,[1] [Ni{C(NHBu^t)R}Cl(PMe$_3$)$_2$]$^+$.

During studies aimed at the investigation of the chemical properties of the η^2-iminoacyl complexes containing the 2,5-dimethylpyrrolyl ligand, we have found that these can also be readily protonated and that action of commercial, high purity CO_2 on solutions of a representative member, [Ni{η^2-C(NBu^t)CH$_2$CMe$_3$}(NC$_4$H$_2$Me$_2$)(PMe$_3$)] (**1**), causes both iminoacyl protonation and Ni—N bond heterolysis, with formation of the neutral aminocarbene [Ni(η^2-CO$_3$){C(NHBu^t)CH$_2$CMe$_3$}(PMe$_3$)] (**2**), which contains a bidentate carbonate ligand. Herein we describe the formation and spectroscopic characterization of **2** and of other related aminocarbene complexes resulting from the protonation of **1** with various diprotonic acids. Analytical and selected IR and ^{1}H NMR data for the new compounds are given in the Experimental, selected ^{13}C and ^{31}P NMR data are collected in Table 1.

RESULTS AND DISCUSSION

Compound **1** is fairly unreactive towards both H_2O and CO_2 as independent reagents. However, upon bubbling CO_2 through a solution of **1** in Et_2O, small amounts of a yellow, finely divided solid, identified as complex **2**, precipitate out of the solution. The addition of one or two drops of water induces further precipitation of this sparingly soluble solid, while if the above transformation is carried out using acetone as the solvent and the reaction mixture is allowed to stand overnight without stirring, complex **2** is obtained in the form of yellow, needle-shaped crystals in good yields. After the reaction is complete, an NMR analysis of the mother liquor reveals the presence of free 2,5-dimethylpyrrole, while IR and NMR studies of the yellow complex **2** show the presence of an aminocarbene and a carbonate ligands (see below). Accordingly, the reaction occurs with both hydrolytic cleavage of the Ni—N bond and protonation of the iminoacyl functionality, presumably by the

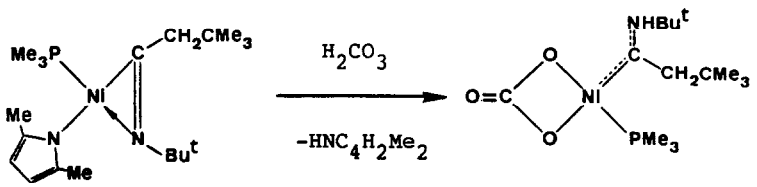
action of carbonic acid on complex **1**, as shown in eq. (1):

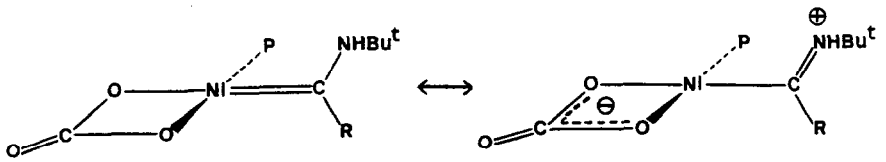


1 **2** (1)

Complex **2** is insoluble in most common organic solvents, but has appreciable solubility in polar solvents such as methanol or water. The presence of a carbonate ligand is indicated by the appearance of a strong IR absorption at *ca* 1580 cm^{-1}, whose frequency suggests bidentate coordination,[2,3] and by the observation of a ^{13}C resonance at *ca* 170 ppm (^{13}C enriched sample). On the other hand, the aminocarbene ligand gives a characteristic IR absorption at 3200 cm^{-1} due to the N—H stretching vibration, but the ν(C—N) band cannot be readily discerned since it overlaps with the strong carbonate absorption at 1580 cm^{-1}. Complex **2** crystallizes with one molecule of water of crystallization, and evidence for this and for the existence of a hydrogen-bonded network in the solid-state structure of **2** can be ascertained from IR data.[2]

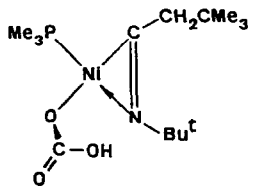
The nickel-bound carbon atom of the aminocarbene ligand gives a ^{13}C resonance at 243 ppm, that is, in the range characteristic of aminocarbene functionalities,[4] and appears as a doublet due to its coupling to the ^{31}P nucleus. The value of 37 Hz found for the phosphorus-to-carbon coupling constant is indicative of a *cis* distribution of the aminocarbene and phosphine ligands. Interestingly, the methylene protons of the CH_2CMe_3 group appear as an AB quartet in the ^1H NMR spectrum. The inequivalence of these protons indicates that the aminocarbene ligand occupies a rigid position in a plane perpendicular to that containing the nickel centre and the donor atoms of the other ligands, as shown below (**A**). This, and the low-field chemical shift found for the aminocarbene carbon atom are clearly in accord with an important contribution of the carbene resonance structure **A** to the ground-state structure of this molecule.

Some brief comments seem appropriate at this point on the formation of the aminocarbene complex **2**. The first step probably involves the protolytic cleavage of the Ni—N bond by carbonic acid, with formation of an intermediate bicarbonate complex of possible structure **C**. This could then be followed by protonation of the iminoacyl nitrogen, in an

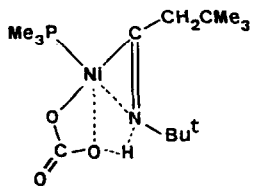


A B

intramolecular, concerted manner, as depicted in **D**.

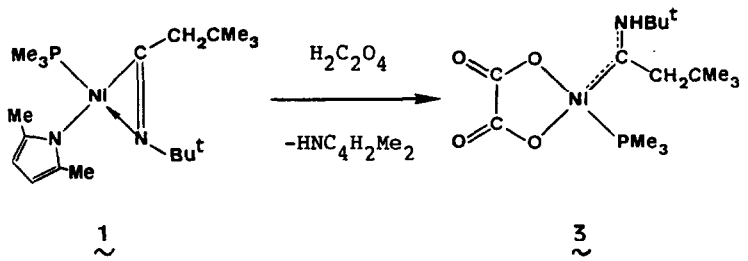


C



D

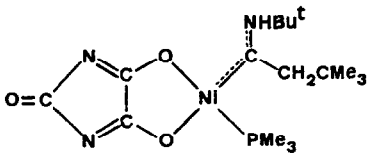
In an attempt to obtain aminocarbene complexes related to **2**, containing the larger, five-membered chelating O—C—C—O—Ni ring, the reactions of **1** with oxalic, $H_2C_2O_4$, and parabanic, $H_2C_3N_2O_3$, acids, have been investigated. Addition of oxalic acid to an acetone solution of **1** yields a yellow, microcrystalline precipitate of complex **3**, with solubility properties very similar to those of **2**. Microanalytical and spectroscopic data are in accord with bidentate oxalate coordination, as shown in eq. (2):



1 3 (2)

Thus, the IR spectrum of **3** displays several bands in the region 1700–1600 cm^{-1} which can be assigned to ν(C=O) of the bidentate oxalate ligand,[2,5] while the ^{13}C NMR spectrum of **3** exhibits two nearly coincident ^{13}C signals for the carbon atoms of the oxalate ligand in the proximity of 169 ppm. Other pertinent spectroscopic data for **3** are collected in the Experimental and in Table 1 and will not be discussed any further.

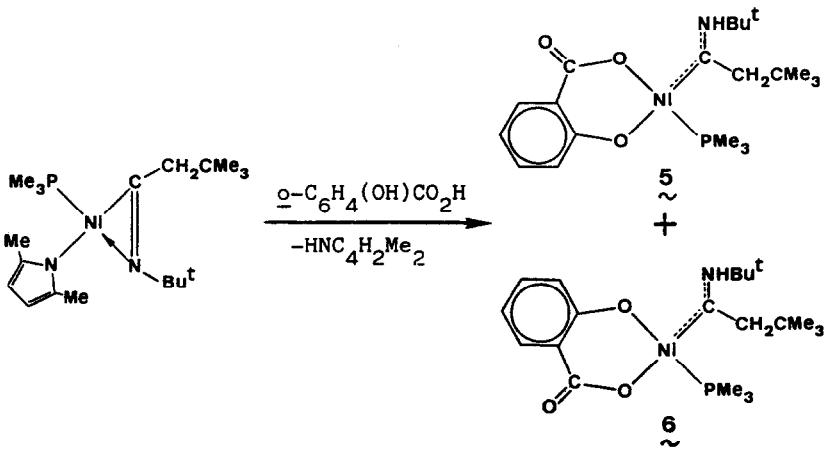
Parabanic acid, $H_2C_3N_2O_2$, provides an analogous species, **4**, for which the structure shown below can be proposed on the basis of analytical and spectroscopic data, and also by similarity with that assigned to the related compounds **2** and **3**. For complex **4**, however, its low solubility has prevented observation of the ^{13}C resonances of the parabanate ligand.



4

Finally, we have carried out the reaction of **1** with salicylic acid, to obtain a yellow, microcrystalline precipitate, which is shown by NMR to be composed of an isomeric mixture of compounds **5** and **6** [eq. (3)], in an approximate 3:2 ratio. The ^{13}C NMR spectrum of this isomeric mixture displays two doublets at 242.5 and 242.9 ppm ($^2J_{CP}$ = 42 and 44 Hz, respectively) that can be assigned to the nickel-bound aminocarbene carbon in both isomers, as well as two singlets at 173.5 and 172.7 ppm due to the carboxylate carbons. Similarly, the

$^{31}P\{^1H\}$ NMR shows two singlets at −4.9 and −3.9 ppm. The above data suggest that the isomerism is due to the geometric distribution of the salicylate group with respect to the other ligands, that is, to its positioning with the carboxylate functionality *trans* either to the phosphine or to the aminocarbene ligand, as indicated in eq. (3).



(3)

EXPERIMENTAL

Microanalyses were by Pascher Microanalytical Laboratory, Remagen (F.R.G.), and the Microanalytical Service of the University of Seville. The spectroscopic instruments used were Perkin–Elmer models 557 and 684 for IR spectra and Varian XL-200 for ^1H, ^{13}C and ^{31}P NMR spectra. All preparations and other operations were carried out under oyxgen-free nitrogen, following conventional Schlenk techniques. Solvents were dried and degassed before use. Complex **1** was prepared according to ref. 1 and parabanic acid following a literature method.[6]

Synthesis of [Ni(η^2-CO_3){C(NHBu^t)CH_2CMe_3}(PMe_3)]·H_2O (**2**)

A solution of [Ni{η^2-C(NBu^t)CH_2CMe_3}($NC_4H_2Me_2$)(PMe_3)] (**1**) (0.30 g, 1 mmol) in acetone (100 cm^3) was treated with a few drops of water and then transferred to a Fischer–Porter vessel. The N_2 atmosphere was replaced by CO_2, the CO_2 pressure increased to 3 atm and the solution was kept undisturbed overnight. The yellow, crystalline precipitate that formed was filtered off, washed with acetone and dried under vacuum. Yield: 90%. IR (Nujol mull): 3200 cm^{-1} (NH), 1580 cm^{-1} (br, CO_3 and C=N). Found: C, 45.4; H, 8.4; N, 3.7; O, 16.8. Calc. for $C_{14}H_{30}NO_3PNi \cdot H_2O$: C, 45.7; H, 8.7; N, 3.8; O, 17.4%. ^1H NMR (D_2O, 200 MHz): δ 1.12 (d, $^2J_{HP}$ = 11.4 Hz, PMe_3), 1.17 (s, CH_2CMe_3), 1.82 (s, CMe_3), 1.93, 2.65 (d, dd, $^2J_{HH}$ = 12.5, $^4J_{HP}$ = 2.8 Hz, diastereotopic CH_2 protons).

Preparation of [Ni(η^2-C_2O_4){C(NHBu^t)CH_2CMe_3}(PMe_3)]·H_2O (**3**)

Complex **1** (0.26 g, 0.7 mmol) was dissolved in acetone (40 cm^3) and treated with solid $H_2C_2O_4 \cdot 2H_2O$ (0.088 g, 0.7 mmol). The reaction mixture was stirred at room temperature for 4 h and the resulting yellow precipitate filtered off, washed with acetone and dried under vacuum. Yield: 60%. IR (Nujol mull): 3200 cm^{-1} (NH), 1700–1600 cm^{-1} (several bands, C_2O_4 and C=N). Found: C, 45.9; H, 7.5. Calc. for $C_{15}H_{30}NO_4PNi \cdot H_2O$: C, 45.5; H, 8.1%. ^1H NMR (CD_3OD, 200 MHz): δ 1.42 (d, $^2J_{HP}$ = 11.6 Hz, PMe_3), 1.50 (s, CH_2CMe_3), 2.12 (s, CMe_3), 2.35, 2.95 (d, dd, $^2J_{HH}$ = 12.3, $^4J_{HP}$ = 3.1 Hz, diastereotopic CH_2 protons).

Synthesis of [Ni(η^2-$C_3O_3N_2$){C(NHBu^t)CH_2CMe_3}(PMe_3)] (**4**)

A solution of parabanic acid (0.114 g, 1 mmol) in methanol (40 cm^3) was added via canula to a stirred solution of complex **1** (0.38 g, 1 mmol) in acetone (30 cm^3). After stirring overnight, the reaction mixture was taken to dryness and the residue triturated with Et_2O (30 cm^3). The resulting solid was filtered off and dried. Yield: 60%. IR (Nujol mull): 3200 cm^{-1} (NH), 1640 cm^{-1} (br, C=O and C=N). ^1H NMR (CD_3OD, 200 MHz): δ 1.43 (d, $^2J_{HP}$ = 11.4, PMe_3), 1.50 (s, CH_2CMe_3), 2.12 (s, CMe_3), 2.30, 2.94 (d, dd, $^2J_{HH}$ = 12.2, $^4J_{HP}$ = 3.2 Hz, diastereotopic CH_2 protons).

Synthesis of [Ni(η^2-$C_7H_4O_3$){C(NHBu^t)CH_2CMe_3}(PMe_3)] (**5**) *and* (**6**)

Complex **1** (0.18 g, 0.5 mmol) dissolved in acetone

($20\ cm^3$) was reacted with a solution of salicylic acid (0.05 g, 0.5 mmol) in acetone ($30\ cm^3$). A yellow solid started precipitating upon mixing of the reactants. The reaction mixture was allowed to stand overnight and the resulting microcrystalline solid filtered off, washed with acetone and dried. Yield: 60%. IR (Nujol mull): 3200 cm^{-1} (NH), 1600–1540 cm^{-1} (several bands, C=O and C=N). Found: C, 56.1; H, 7.9; N, 3.2. Calc. for $C_{20}H_{34}NO_3PNi$: C, 56.4; H, 8.0; N, 3.3%. ^1H NMR (CD_3OD, 200 MHz) major isomer: δ 1.37 (d, $^2J_{HP}$ = 11.1 Hz, PMe_3), 1.55 (s, CH_2CMe_3), 2.18 (s, CMe_3), 2.25, 2.93 (d, dd, $^2J_{HH}$ = 12.1, $^4J_{HP}$ = 3.0 Hz, diastereotopic CH_2 protons), 6.4–7.8 (m, aromatics); minor isomer: δ 1.37 (d, $^2J_{HP}$ = 11.1 Hz, PMe_3), 1.56 (s, CH_2CMe_3), 2.17 (s, CMe_3), 2.24, 2.90 (d, dd, $^2J_{HH}$ = 12.1, $^4J_{HP}$ = 3.0 Hz, diastereotopic CH_2 protons), 6.4–7.8 (m, aromatics).

SYNTHESES OF NEW ORGANO-LANTHANIDE COMPLEXES $[(CH_3OCH_2CH_2C_5H_4)_2LnCl]_2$ AND THEIR XPS

DAOLI DENG, BING LI and CHANGTAO QIAN*

Shanghai Institute of Organic Chemistry, Academia Sinica, 345 Lingling Lu, 200032 Shanghai, China

(*Received* 27 *October* 1989; *accepted* 29 *January* 1990)

Abstract—The substituted cyclopentadienyl sodium salt $CH_3OCH_2CH_2C_5H_4Na$ reacts with $LnCl_3$ (Ln = La, Nd, Gd, Ho, Er, Yb and Y) in THF at room temperature to give the new complexes $[(CH_3OCH_2CH_2C_5H_4)_2LnCl]_2$ in good yield. XPS (X-ray photoelectron spectroscopy) studies show that the metals in these complexes are coordinated through the oxygen atoms.

Since $[(C_5H_5)_2LnCl]_2$ complexes are important precursors to lanthanide alkyl and hydride species,[1–4] the syntheses of these complexes, especially, the syntheses of early organo-lanthanide complexes have attracted much attention. In order to stabilize bis-cyclopentadienyl early lanthanide chlorides and prevent their disproportionation, bulky pentamethylcyclopentadienyl,[5–10] bis(trimethylsilyl) cyclopentadienyl,[10,11] hexamethylindenyl[12] have been used as ligands. In another method, bridged cyclopentadienyl was used as the ligand. Previously, we have reported that the stabilization of early organo-lanthanide complexes has been achieved by using 1,1′-trimethylenebis-cyclopentadienyl,[13] 1,1′-(3-oxa-pentamethylene)bis-cyclopentadienyl,[14] 1,1′-(*m*-xylylene)bis-cyclopentadienyl, 1,1′-(*p*-xylylene)bis-cyclopentadienyl[15] and pyridine-2,6-di(methylenecyclopentadienyl)[16] as ligands. In this communication we wish to describe the synthesis of the new complexes $[(CH_3OCH_2CH_2C_5H_4)_2LnCl]_2$ (Ln = La, Nd, Gd, Ho, Er, Yb and Y) and XPS structural information of these complexes. The success of synthesizing bis(2-methoxyethylcyclopentadienyl) early lanthanide chlorides reveals 2-methoxyethylcyclopentadiene to be an efficient ligand to stabilize bis-cyclopentadienyl early lanthanide chlorides.

Two equivalents of $CH_3OCH_2CH_2C_5H_4Na$ and $LnCl_3$ (Ln = La, Nd, Gd, Ho, Er, Yb and Y) react in THF at room temperature to give the new complexes $[(CH_3OCH_2CH_2C_5H_4)_2LnCl]_2$ in good yields. The complexes have been fully characterized by elemental analyses (C, H and M), IR (Table 1), XPS (Table 2), MS, ^1H and ^{13}C NMR spectroscopy.[17]

The IR spectra of the complexes $[(CH_3OCH_2CH_2C_5H_4)_2LnCl]_2$ show two C—O—C bands at 1045 and 1060 cm^{-1}. Comparing the C—O—C bands of $CH_3OCH_2CH_2C_5H_4Na$ with the title complexes, the values of $\Delta\nu$ are about 50 and 60 cm^{-1}, respectively, which implies that an intramolecular coordination bond is present.[18]

The XPS data on the complexes given in Table 2 shows that the binding energies of O_{1s} increase in these complexes compared with that in $CH_3OCH_2CH_2C_5H_4Na$ and the binding energies of the lanthanide metal atoms all decrease on complexation, compared within the bis-cyclopentadienyl lanthanide chlorides. This obviously indicates that the lone pair of electrons of the oxygen atom in these complexes is partly transferred from the oxygen to the lanthanide metal centre and a O→M coordinate bond is formed. The decrease of charge densities around the oxygen atom causes the increase in the binding energies of the oxygen atom. Because of the increase of the charge densities around the lanthanide metal atom, the binding energies of the lanthanide metal atom decrease.

The binding energies of Cl_{2p} all decrease compared with those in the bis-cyclopentadienyl lanthanide chlorides. This demonstrates that the charge densities around the chlorine atom increase. This is due to the inductive effect, and the charge is partly transferred from lanthanide metal to the chlorine atom.[19] These results are similar to those

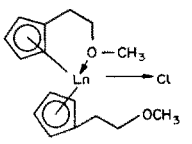
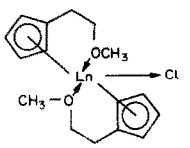
of 1,1′-(3-oxa-pentamethylene)bis-cyclopentadienyl lanthanide chlorides.[14] However, absolute values of ΔE in the title complexes are larger than that of 1,1′-(3-oxa-pentamethylene)biscyclopentadienyl lanthanide chlorides. Perhaps the good coordinative abilities and oxophilicity of the central lanthanide metals in the title complexes favour the formation of coordinate bonds, moreover, they strengthen the coordination bond and give greater stability. The XPS studies reveal that the metals in these complexes are coordinated through the oxygen atoms. There are two possible structures



I



II

of the title complexes (**I** and **II**). Very recently, the preliminary results of an X-ray crystal structure analysis indicated that the title complexes are probably similar to structure (**II**).[17]

COPPER COMPLEXES OF THE METHYL ESTER OF DITHIOCARBAZIC ACID AND ITS N(3)-SUBSTITUTED DERIVATIVES

LUCANTONIO PETRILLI and FRANCO TARLI*

Istituto di Teoria e Struttura Elettronica e Comportamento Spettrochimico dei Composti di Coordinazione del C.N.R., Area della Ricerca di Roma, C.P. 10, via Salaria km 29.500, 00016 Monterotondo Stazione, Rome, Italy

(*Received* 1 *September* 1989; *accepted* 8 *February* 1990)

Abstract—The ligand behaviour of the methyl esters of dithiocarbazic acids $NH_2NHC(S)SMe$ (L), NHPhNHC(S)SMe (PhL), $NHCH_2PhNHC(S)SMe$ ($PhCH_2L$) and $NMe_2NHC(S)SMe$ (Me_2L) in the copper complexes $CuLCl_2$, CuL_2Cl_2, $Cu(L-H)_2$, $Cu(PhCH_2L-H)_2$, $Cu(Me_2L-H)_2$, $Cu(PhL-2H)_2$, $Cu(PhL)_2Cl$, $Cu(Me_2L)_2Cl$ and $Cu(PhCH_2L)_2Cl$ have been investigated. The electronic and IR spectra have been obtained and magnetic moments calculated. Electrochemical measurements have been performed on $Cu(PhL-2H)_2$.

Derivatives of dithiocarbazic acid, $NH_2NHC(S)SH$, are the subject of many reports which confirm the interest in these multidentate ligands, whose ligating properties critically depend on the N- and S-substituents as we have already shown for the nickel and platinum complexes.[1,2]

Here we report a study of the ligating behaviour of N(3)-substituted derivatives of the methyl ester of dithiocarbazic acid in copper complexes.

The ligands considered are $NH_2NHC(S)SMe$ (L), NHPhNHC(S)SMe (PhL), $NHCH_2PhNHC(S)SMe$ ($PhCH_2L$) and $NMe_2NHC(S)SMe$ (Me_2L). Preliminary results have already been presented.[3] Previous literature reports on copper coordination compounds of esters of dithiocarbazic acids are limited to the X-ray structure of $Cu(Me_2L)_2Cl$[4] and to a study on the antifungal action of some copper complexes, whose complete characterization was not reported.[5] Copper complexes of the Schiff bases of esters of dithiocarbazic acid have been extensively studied.[6]

EXPERIMENTAL

Materials

The chemicals were commercial analytical grade reagents and used without further purification, except for the solvents employed for electrochemical measurements which were purified as described in ref. 8. Nitrogen gas was an ultra-high purity commercial product. All the compounds were dried *in vacuo* (1 torr) over P_4O_{10}, unless otherwise stated. Deuterated solvents were Aldrich Chem. Comp. or Merck UVASOL (99.9 atom % D).

Preparation of the ligands

The ligands L, PhL, $PhCH_2L$, Me_2L, L·HCl and PhCH=NNHC(S)SMe were prepared following the methods reported in ref. 1.

Preparation of the complexes

$CuLCl_2$. A solution of $CuCl_2 \cdot 2H_2O$ (2 mmol) in ethanol (15 cm^3) was added dropwise to a solution of L (4 mmol) in ethanol (15 cm^3). After a few minutes, the solution became pale green, and after 1.5 h of stirring the product was filtered off, washed with water–ethanol (1 : 2) and dried; yield 60%. IR bands; 3177s, 3175s, 3064s, 1597s, 1570sh, 1496s, 1177s, 1154s, 1075s, 1020m, 986s, 967s, 510m, 370m, 289s.

CuL_2Cl_2. A solution of $CuCl_2 \cdot 2H_2O$ (1.7 mmol) in ethanol (20 cm^3) containing 37% HCl (1 cm^3)

* Author to whom correspondence should be addressed.

was added to a solution of L (3.4 mmol) in ethanol (20 cm^3) containing 37% HCl (1 cm^3). The product separated immediately. After 2 h of stirring the product was filtered off, washed with benzene and dried; yield 80%. IR bands: 3210sh, 3196s, 3190sh, 3177s, 3069s, 2671s, 1619s, 1607s, 1598s, 1528w, 1501m, 1159s, 1084s, 986s, 969s, 538w, 320m.

$Cu(L-H)_2$ [L−H = NH_2N=C(S)SMe]. A solution of L (4 mmol) in ethanol (30 cm^3) was added to $Cu(CH_3COO)_2 \cdot H_2O$ (2 mmol) dissolved in ethanol (170 cm^3). After 3 h of stirring the product was filtered off, washed with water–ethanol (2:1) and dried; yield 90%. IR bands: 3213m, 3151m, 3108m, 3048w, 1559s, 1503w, 1190s, 989s, 964m, 924m, 529m, 354m.

$Cu(PhL)_2Cl$. A solution of $CuCl_2 \cdot 2H_2O$ (0.5 mmol) in ethanol (10 cm^3) was added to a solution of PhL (1 mmol) in ethanol (30 cm^3). The solution immediately turned dark green. After 2 h of stirring the product was filtered off, washed with ethanol and dried; yield 70%. IR bands: 3270sh, 3241s, 3150sh, 3124s, 3025sh, 1603s, 1523s, 1493m, 1353m, 1040s, 1030m, 1023m, 970sh, 962w, 247w.

$Cu(PhL-2H)_2$ [PhL−2H = NPhNC(S)SMe]. A solution of $Cu(CH_3COO)_2 \cdot H_2O$ (1.5 mmol) in ethanol (75 cm^3) was added to a solution of PhL (3 mmol) in ethanol (40 cm^3). After 1.5 h of stirring, in an open vessel in the dark, the green product was filtered off, washed with water and dried; yield 30%. IR bands: 3060m, 1586m, 1482s, 1450s, 1042m, 1031m, 985s, 950w, 466w, 372m.

$Cu(PhCH_2L)_2Cl$. A solution of $CuCl_2 \cdot 2H_2O$ (0.7 mmol) in ethanol (30 cm^3) was slowly added to a solution of $PhCH_2L$ (1.4 mmol) in 30 cm^3 of the same solvent. From the resulting green solution, a pale yellow product separated. After stirring (10 min) the product was filtered off, washed with water–ethanol (1:1, 5 cm^3) and dried; yield 50%. IR bands: 3248w, 3136s, 3086m, 3060w, 1600m, 1570w, 1534s, 1525s, 1493m, 1357sh, 1344s, 1030m, 1023m, 965m, 957m, 946m, 910w, 528w, 241w.

$Cu(PhCH_2L-H)_2$ [$PhCH_2L$−H = $NHCH_2$ PhN=C(S)SMe]. A solution of $Cu(CH_3COO)_2 \cdot H_2O$ (1 mmol) in a 1:1 water–ethanol mixture (20 cm^3) was added dropwise to a solution of $PhCH_2L$ (2 mmol) in ethanol (10 cm^3). After 1.5 h of stirring in the dark the product was filtered off, washed with ethanol and dried; yield 70%. IR bands: 3023s, 1598s, 1567w, 1518s, 1492m, 1030m, 1018m, 985w, 946s, 912sh, 455w, 371m.

$Cu(Me_2L)_2Cl$. A solution of $CuCl_2 \cdot 2H_2O$ (0.5 mmol) in ethanol (5 cm^3) was added slowly to a solution of Me_2L (1.5 mmol) in ethanol (5 cm^3). After 0.5 h stirring the product separated, and was filtered off, washed with ethanol and dried; yield 70%. IR bands: 3193m, 3155s, 3074s, 2791w, 2785w, 1525sh, 1516s, 1505sh, 1495m, 1091w, 1032s, 1017s, 961s, 376m, 284sh.

$Cu(Me_2L-H)_2$ [Me_2L−H = NMe_2N=C(S) SCH_3. A solution of $Cu(CH_3COO)_2 \cdot H_2O$ (0.8 mmol) in ethanol (40 cm^3) was added to a solution of Me_2L (1.6 mmol) in ethanol (5 cm^3). From the dark brown solution the product slowly separated. It was filtered off, washed with ethanol and dried; yield 70%. IR bands: 1516s, 1005sh, 982s, 923s, 452m, 353m.

$Cu(PhCH{=}NN{=}C(S)SMe)_2$. A solution of Cu $(CH_3COO)_2 \cdot H_2O$ (0.7 mmol) in water–ethanol (1:4, 100 cm^3) was added to a solution of PhCH=NNHC(S)SMe (1.4 mmol) in ethanol (40 cm^3). After 24 h of stirring a pale brown product was filtered off, washed with water–ethanol (1:4) and dried; yield 80%.

Analytical data are given in Table 1. Microanalyses were performed by the Microanalytical Service of the Area della Ricerca di Roma del C.N.R.

Physical measurements

The electronic solution spectra were recorded with a Perkin–Elmer 330 spectrophotometer. IR spectra were recorded in Nujol or poly(chlorotrifluoroethylene) mulls with a Perkin–Elmer 983 spectrophotometer. Reflectance spectra and room-temperature magnetic susceptibilities were measured as described in ref. 7.

Electrochemical measurements

D.C. and A.C. polarography and cyclovoltammetry were performed, as reported in ref. 8, with an Amel model 471 three-electrode multifunctional assembly. The working electrode was a standard Amel pulsing or stationary electrode and the counter electrode was a platinum wire. An Hg ‖ Hg_2Cl_2, NaCl (saturated, aq) ‖ agar–NaCl(aq) ‖ agar (1.5 %, w/v)–DMF–water (40%, v/v)–NEt_4ClO_4 (saturated) ‖ methyl cellulose (5%, w/v)–DMF–NEt_4ClO_4 (saturated) sintered glass-disk (DMF = dimethylformamide) served as reference electrode. Its potential was 40 mV vs an aqueous saturated calomel electrode (SCE), the liquid junction potential being included. All potentials reported in Table 2 are quoted with respect to the reference electrode with an accuracy of ±5 mV.

Conductivity measurements were carried out with a conductometer Metrohm model E 382.

Molecular weight determination was performed by the cryoscopic method as described in ref. 9.

RESULTS AND DISCUSSION

Preparation and properties of the copper complexes

All the ligands react readily with copper(II) salts in aqueous ethanol giving complexes whose constitution critically depends on the reaction conditions and on the substituents on N(3). L reacts with $CuCl_2 \cdot 2H_2O$ giving $CuLCl_2$, whereas the N(3)-substituted ligands give the compounds $Cu(PhL)_2Cl$, $Cu(PhCH_2L)_2Cl$ and $Cu(Me_2L)_2Cl$. Strong acidification of the reaction medium (HCl) influences the reaction of L and CuL_2Cl_2 is obtained. The same compound can be prepared starting from L·HCl. All the ligands react with $Cu(CH_3COO)_2 \cdot H_2O$ giving the complexes, containing the deprotonated ligands, $Cu(L-H)_2$, $Cu(PhCH_2L-H)_2$, $Cu(Me_2L-H)_2$, whereas Cu $(PhL-2H)_2$ contains the doubly-deprotonated ligand. Efforts to isolate the complexes containing the doubly-deprotonated ligands starting from $Cu(L-H)_2$ and $Cu(PhCH_2L-H)_2$, in strongly basic medium (NH_3), were unsuccessful. This differs from the reactions of similar compounds of nickel and platinum.[1,2] $Cu(PhCH{=}NN{=}C(S)SMe)_2$, containing the mono-deprotonated Schiff base of the dithiocarbazic ester as ligand, is obtained from the reaction of $Cu(PhCH_2L-H)_2$. Its formation suggests that the complex, containing the doubly-deprotonated ligand $Cu(PhCH_2L-2H)_2$ is formed as a labile intermediate, which rearranges, following the reaction pattern that we have reported for thermal disproportionation of $M(PhCH_2L-2H)_2$ (M = Pt, Ni), and leads to the accumulation of $M(PhCH{=}NNC(S)SMe)_2$.[10,11]

All the complexes decompose in organic solvents,

except $Cu(PhL-2H)_2$, $Cu(PhL)_2Cl$, $Cu(Me_2L)_2Cl$ and $Cu(PhCH_2L)_2Cl$. These complexes are non-electrolytes in CH_2Cl_2.

Infrared spectra

IR data are given in the Experimental and in Table 3. The IR spectra of ligands are reported in ref. 1 and references therein. In the spectrum of $CuLCl_2$, the bands attributable to ν(N—H) (at 3175, 3177 and 3064 cm^{-1}) and to δ(N—H)+ν(C⋯N) (at 1496 cm^{-1}) are shifted to lower frequencies with respect to the spectrum of the free ligand L, suggesting coordination of the NH_2 group and coordination of non-methylated sulphur. The appearance of new bands attributable to ν(Cu—N), ν(Cu—S) and ν(Cu—Cl) confirms that chelation of the ligand and coordination of chlorine occur.

In the spectrum of CuL_2Cl_2 several bands in the region 3210–2671 cm^{-1}, attributable to the quaternary ammonium group,[12] suggest that the ligand is coordinated in the form of an ammonium salt, as we have already found for PtL_2Cl_2.[1] A band at 1528 cm^{-1}, not shifted on deuteriation, is assigned to the ν(Cu⋯N) partial double bond of the ligand deprotonated at N(2). New bands attributable to ν(Cu—N) and ν(Cu—S) are found in the spectrum with respect to that of L·HCl, suggesting chelation of the ligand through N(2) and non-methylated sulphur, $Cu[NH_3N{=}C(S)SMe]_2Cl_2$.

$Cu(L-H)_2$ shows bands attributable to ν(N—H) (at 3213, 3151, 3108 and 3048 cm^{-1}) shifted to lower frequencies with respect to the spectrum of the free ligand and new bands, attributable to ν(Cu—N) and ν(Cu—S), suggesting chelation of the deprotonated ligand through N(3) and non-methylated sulphur. The band attributable to the ν(C⋯N) partial double bond is found at 1503 cm^{-1}.

The spectrum of $Cu(PhL)_2Cl$ shows bands attributable to ν(N—H) (at 3270, 3241, 3150 and 3124 cm^{-1}) shifted to higher frequencies with respect to the spectrum of the free ligand suggesting that NH groups are not coordinated. The shift of the δ(N—H)+ν(C⋯N) band (at 1523 cm^{-1}) to lower frequencies suggests coordination of non-methylated sulphur. New bands attributable to ν(Cu—S) and ν(Cu—Cl) confirm sulphur coordination and suggest chlorine coordination.

The spectrum of $Cu(PhL-2H)_2$ lacks all the bands attributable to ν(N—H), an indication that the ligand is doubly-deprotonated. ν(C⋯N) is found at 1450 cm^{-1}, in the same region as found previously for the ν(C⋯N) bands of platinum and nickel dithiolene-like complexes.[1,2] New bands attributable to ν(Cu—N) and ν(Cu—S) confirm N, S chelation of the ligand. In the spectrum of $Cu(PhCH_2L)_2Cl$, bands attributable to ν(N—H) (at 3248, 3136 and 3086 cm^{-1}) are not shifted to lower frequencies suggesting that NH groups are not coordinated. New bands attributable to ν(Cu—S) and ν(Cu—Cl) suggest coordination of non-methylated sulphur and chlorine.

In the spectrum of $Cu(PhCH_2L-H)_2$, the bands attributable to ν(N—H) (at 3032 cm^{-1}) are shifted to lower frequencies indicating that N(3) is coordinated. The new bands attributable to ν(Cu—N) and ν(Cu—S) suggest N,S chelation. In the spectrum of $Cu(Me_2L)_2Cl$, bands attributable to ν(N—H) (at 3193, 3115 and 3074 cm^{-1}) are not shifted to lower frequencies and the bands at 2790 and 2780 cm^{-1}, attributable to ν(C—H), which are characteristic of the NMe_2 group, are still present, suggesting that N(3) is not coordinated.[13] New bands attributable to ν(Cu—S) and ν(Cu—Cl) suggest coordination of non-methylated sulphur and chlorine, according to the X-ray structure, which shows the presence of bridges of thione sulphur between two copper atoms and coordination of chlorine.[4]

In the spectrum of $Cu(Me_2L-H)_2$, bands attributable to ν(N—H) are lacking, in agreement with deprotonation at N(2). The disappearance of ν(C—H) bands characteristic of NMe_2 groups indicates that the NMe_2 group is coordinated.[13] N,S chelation is confirmed by the presence of new bands attributable to ν(Cu—N) and ν(Cu—S).

Magnetic moments and electronic spectra

The magnetic moments (Table 4) of $CuLCl_2$, CuL_2Cl_2, $Cu(L-H)_2$, $Cu(Me_2L-H)_2$ and $Cu(PhL-2H)_2$ range from 1.70 to 1.97 BM, as expected for a +2 oxidation state of copper. The magnetic moment of $Cu(BzL-H)_2$ is abnormally low but consistent with the +2 oxidation state.[14] $Cu(PhL)_2Cl$, $Cu(BzL)_2Cl$ and $Cu(Me_2L)_2Cl$ are diagmag-

netic suggesting a +1 oxidation state of copper. The electronic spectra of Cu^{2+} complexes show broad bands which give little information. The spectrum of $CuLCl_2$ shows a broad band, which can be assigned simultaneously to the *d–d* transitions of a highly distorted octahedral chromophore. The close similarity of the spectrum with the spectrum of $CuTscCl_2$, for which a highly distorted octahedral polymeric structure was suggested,[15] the similarity of the ligands, and the high insolubility, also suggest a similar structure for our compound [Fig. 1(a)]. The spectra of CuL_2Cl_2, $Cu(L-H)_2$, $Cu(PhCH_2L-H)_2$ and $Cu(Me_2L-H)_2$ agree with the presence of quasi-planar structures

[Fig. 1(b)] containing N,S chelation of the ligands, as suggested by IR spectra. The spectrum of $Cu(PhL-2H)_2$ is characteristic of dithiolene-like complexes, which show very intense charge-transfer bands in the visible. A dithiolene-like complex, $Cu(NPhNC(S)NEt_2)_2$,[16] with a ligand similar to ours [Fig. 1(c)] has been described in the literature. Its structure was suggested to be tetrahedral and its spectrum is similar to that of our compound. The spectra of Cu^+ complexes do not show absorption bands in the visible, as expected, but $Cu(PhL)_2Cl$ [Fig. 1(d)], which is deeply coloured, shows a band at 15.0 kK which we assign to a L→M charge-transfer transition.

Electrochemical measurements

The electrochemical behaviour of $Cu(PhL-2H)_2$, in CH_2Cl_2 solution, shows electron-transfer properties as already found for other dithiolene-like copper complexes with a five-membered delocalized N—S ring.[16] It has been investigated by means of D.C. and cyclic voltammetry. Data are reported in Table 2. The voltage range +0.5 to −1.0 V was explored in reduction. The compound shows one well-defined polarographic wave corresponding to the one-step reduction process, which is electrochemically reversible and mono-electronic at the scan rates considered, as suggested by the cyclovoltammetric $i(cat)/i(an)$, by the ΔEp value ($\Delta Ep = Ep_c - Ep_a = 0.09$ V) and by the slope value in D.C. polarography. The coulometry in CH_2Cl_2 suggests a dimeric structure of the complex which was confirmed by the mol. wt determination in C_6H_6.[9] The reduction process is:

$$[Cu(PhL-2H)_2]_2^0 \underset{-1e}{\overset{+1e}{\rightleftharpoons}} [Cu(PhL-2H)_2]_2^-$$

Acknowledgements—We thank Mr F. Dianetti for microanalyses and Mr G. Chiozzini for help with the electrochemical measurements.

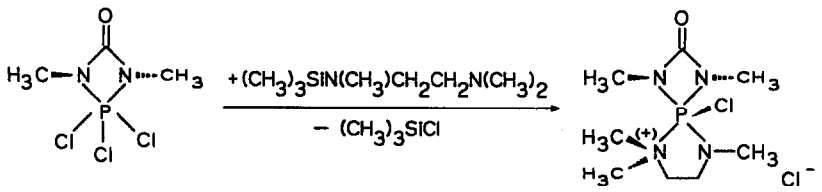
(*Received* 27 *October* 1989; *accepted* 8 *February* 1990)

Abstract—The ^{1}H NMR spectrum of the spirophosphorane **1** at room temperature indicates dynamic behaviour of the cation. From high and low temperature ^{1}H NMR spectra it is concluded that exchange between the $N(CH_3)_2$ groups and between the NCH_3 groups in the four-membered ring takes place. The free enthalpy of activation for this dynamic process was determined (62.4±2.5 kJ mol^{-1}). In the reaction of **1** with sodium tetraphenylborate the crystalline compound, **2**, involving the non-coordinating anion, $[B(C_6H_5)_4]^-$, was obtained. The X-ray crystal structure analysis of **2** reveals the presence of a five-membered ring, formally as a result of intramolecular donor–acceptor interaction between the nitrogen atom of the $N(CH_3)_2$ group and phosphorus.

We have recently reported[1] the unusual spirophosphorane **1**. The bicyclic structure of this compound is due to intramolecular donor–acceptor interaction between the nitrogen atom of the $(CH_3)_2N$ grouping and phosphorus which is accompanied by displacement of chloride ion [eq. (1)]:



(1)

1

Similar monocyclic compounds, involving phosphorus(III) as a central atom, have been reported.[2,3]

RESULTS AND DISCUSSION

The NMR spectroscopic investigation of **1** indicates the fluxional character of the ion in solution. The ^{1}H NMR spectrum of **1**, recorded in $CDCl_3$ solution at room temperature, reveals a sharp doublet (coupling with ^{31}P) and two broad resonances which indicate a dynamic process of medium rate. At lower temperature (243 K) five CH_3 doublets of equal intensity are observed (Table 1). Signals a and

* Author to whom correspondence should be addressed.

Table 1. ^{1}H NMR signals for the methyl groups of **1** (in $CDCl_3$)

Signal	δ(H)	^3J(PH) (Hz)
a	3.527	9.9
b	3.397	10.2
c	3.216	17.2
d	3.045	14.9
e	2.731	14.1

b were observed to coalesce at $T_c = 296 \pm 8$ K, and signals c and e at $T_c = 312 \pm 7$ K, while the shape of signal d was not temperature dependent (Fig. 1). The coalescence temperatures cannot be determined more accurately because the CH_2 resonances interfere with the a/b coalescence while doublet d interferes with the c/e coalescence. The free enthalpy of activation for the dynamic process has been estimated from both coalescences, using the Eyring equation,[4] to be 62 ± 2.5 kJ mol^{-1}. The high temperature spectrum ($T \gg 312$ K) exhibits three doublets of intensity ratio 2:2:1, and it is concluded that the structurally equivalent methyl groups, i.e. of the $N(CH_3)_2$ groups and of the NCH_3 groups, are exchanging with each other. Such an exchange process proceeds via an (idealized) transition state (or the appropriate intermediate) with tetra-coordinate phosphorus. Both phosphorus-bonded ligands which are not part of the four-membered ring, are situated in a plane, perpendicular to this ring, through phosphorus and the carbon atom of the carbonyl group (Scheme 1). Such a transition state/

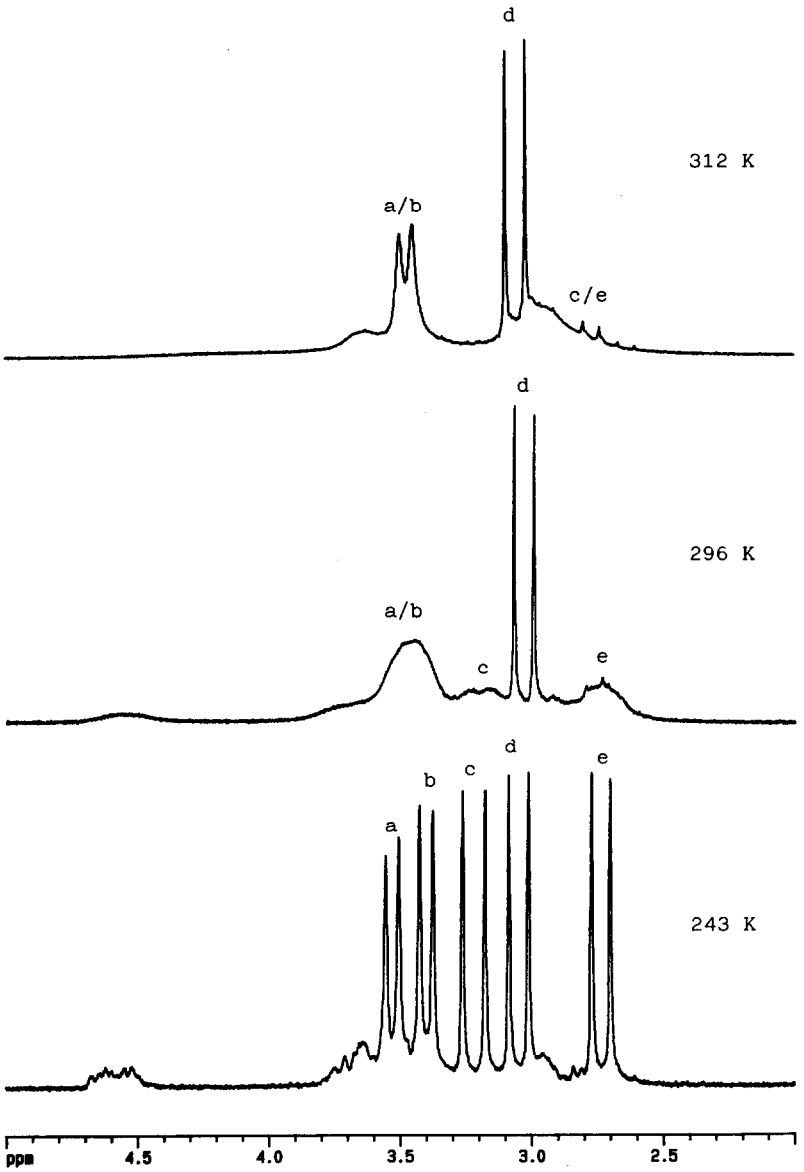


Fig. 1. Variable temperature ^{1}H NMR spectra of **1** (in $CDCl_3$).

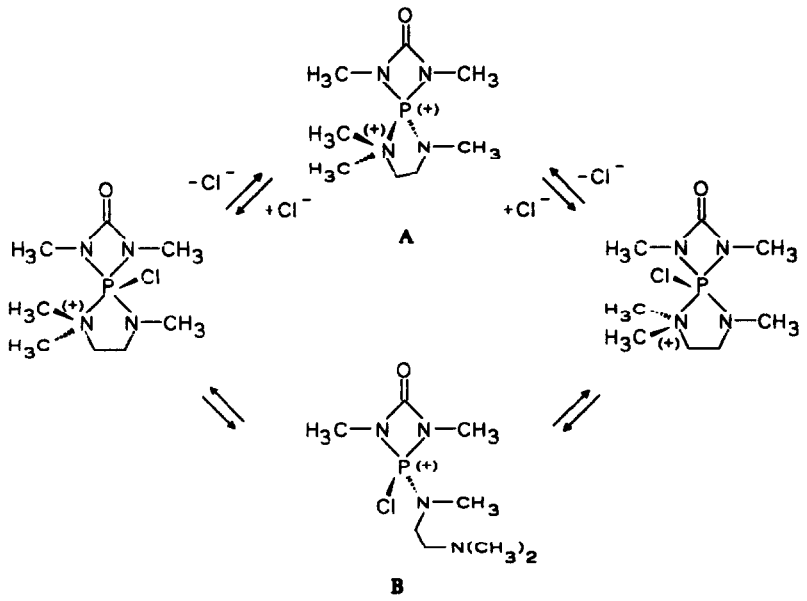
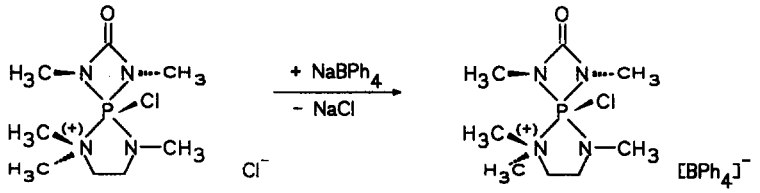


Scheme 1. Possible exchange mechanism of the N-methyl groups in **1**.

intermediate may be achieved either by the departure of chloride ion (with formation of the dication **A**) or by breaking the coordinative $PN(CH_3)_2$ bond (with formation of **B**). While these alternatives cannot be distinguished NMR-spectroscopically the pathway via **B** is considered energetically more favourable since it does not necessitate a species with positive charges on two neighbouring atoms. The structure of the cation of **1** was determined by a single crystal X-ray structure analysis. Because of the unsatisfactory quality of the crystals of **1** the chloride ion was replaced by the non-coordinating $[B(C_6H_5)_4]^-$ ion in a metathetical reaction with sodium tetraphenylborate [eq. (2)]:



(2)

1 **2**

It was thus possible to obtain crystals of **2**, suitable for the X-ray structure determination.

Discussion of the structure of **2**

The X-ray crystal structure determination of **2** (see Figs 2 and 3) reveals that the phosphorus atom is five-coordinate (λ^5) and that there is strong acceptor–donor interaction between λ^5P and the nitrogen atom of the $N(CH_3)_2$ grouping. The λ^5 phosphorus atom is present in a distorted trigonal-bipyramidal (TBP) environment. A deviation from the ideal TBP geometry is caused, especially, by a decrease of the axial bond angle to 170.2° which is accompanied by an increase of the angle between the two equatorial P—N bonds to 131.9°. A similar geometry has also been observed for a chlorospiro-tetraazaphosphorane[5] (N_{ax}—P—N_{ax} 169.2°; N_{eq}—P—N_{eq} 129.8°). The observed P—Cl bond length (203.7 pm) is identical to that in this chlorospiro-tetraazaphosphorane.[5] It should be noted that the equatorial geometry at the central phosphorus atom is exactly planar (i.e. the sum of the three angles, X_{eq}—P—Y_{eq} = 360°). On the other hand the bond lengths between phosphorus and the nitrogen atom reflect the unusual bonding situation at the central phosphorus atom. All four bond lengths are markedly different. While the bond, P—N_{eq} (167.6 pm), is slightly longer than in the chlorospiro-tetraazaphosphorane mentioned above

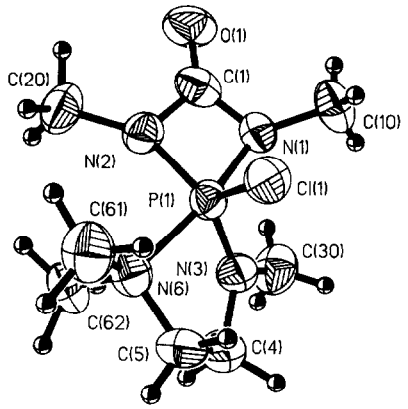


Fig. 2. Structure of the cation of **2** in the crystal.

(166.2 pm, ref. 5), the P—N_{ax} (N_{ax} belonging to N,N'-dimethylurea) bond length is decreased by *ca* 2 pm, compared to the axial P—N bond in the related chlorospiro-tetraazaphosphorane (mean value, 175.3 pm). The bond between phosphorus and the equatorially-bonded nitrogen atom, N(3) (161.5 pm), is remarkably short. Apparently the partial positive charge at phosphorus permits a particularly effective bond to the ideally planar nitrogen atom which may be rationalized in terms of $(d\text{–}p)_\pi$ interactions. A comparison of the distance between the nitrogen atom of the $(CH_3)_2N$ group, acting as an electron donor, and phosphorus (197.5 pm) with the sum of the van der Waals' radii (335 pm, ref. 6) suggests a strongly bonding interaction. It should be noted, though, that in the related intramolecular adduct, $[(CH_3)_2\overline{NCH_2}\,\overline{CH_2N(CH_3)}PCl]^+Cl^-$, a significantly shorter P—N distance (184.2 pm[7]) has been observed. No cation–anion interactions were observed. Other bond parameters which were not discussed here fell in the usually observed ranges.

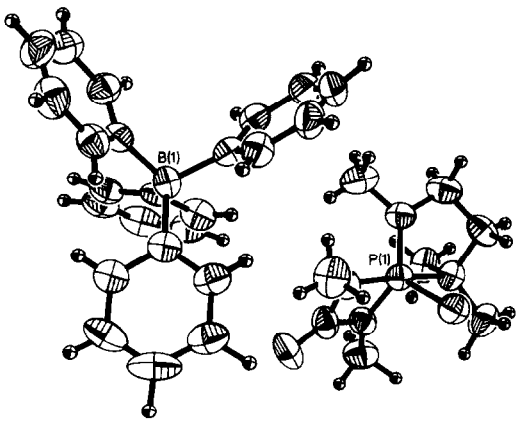

Fig. 3. Relative positions of the cation and anion of **2** in the crystal.

EXPERIMENTAL

The reaction, **1**→**2**, was conducted in conventional glass apparatus in an atmosphere of dry nitrogen. Solvents were dried by standard procedures,[8] and were stored over molecular sieves. NMR spectra were recorded on a Bruker AC 200 intrument at 200.1 (^{1}H) and 81.0 MHz (^{31}P). References: internal TMS and external 85% H_3PO_4. High-field shifts are defined as negative.

Reaction of **1** *with sodium tetraphenylborate: Synthesis of* 4-*chloro*-2-*oxo*-1,3,5,5,8-*pentamethyl*-1,3,8-*triaza*-5-*azonia*-4λ^5-*phosphaspiro*[3.4]*octyl tetraphenylborate* (**2**)

In a 50 cm^3 centrifuge flask a solution of sodium tetraphenylborate (1.62 g, 4.7 mmol) in 15 cm^3 of a mixture of CH_2Cl_2–CH_3CN (2:1) was added dropwise with magnetic stirring during 30 min to a solution of 1.37 g (4.7 mmol) of **1** in 10 cm^3 of CH_2Cl_2. Stirring at room temperature was continued for 1 h. Subsequently, the solid product was removed by centrifugation. The supernatant liquid was decanted, the solvents were stripped off *in vacuo* (0.1 mm), and the remaining solid was recrystallized from a CH_2Cl_2–CH_3CN (3:1) solvent mixture. Yield: 1.27 g (47%); m.p. 149°C.

^{1}H NMR (CD_3CN): δ = 7.33–7.22 (m, 8 H, *ortho*-H of $[B(C_6H_5)_4]^-$), 7.04–6.96 (m, 8 H, *meta*-H), 6.89–6.80 (m, 4 H, *para*-H), 3.64—*ca* 3.1 (m, 4H, CH_2CH_2), 3.05 [very broad d, J(PH) ≈ 17 Hz (partially hidden), NCH_3], 3.02 [broad d, J(PH) = 9.5 Hz, NCH_3], 2.96 [broad d, J(PH) = 9.4 Hz, NCH_3], 2.89 [d, J(PH) = 15.2 Hz, NCH_3], 2.69 [very broad d, J(PH) ≈ 14 Hz, NCH_3]. ^{31}P NMR (CD_3CN): δ = −38.5 (s). Found: C, 67.1; H, 7.0; N, 9.7. Calc. for $C_{32}H_{39}BClN_4OP$: C, 67.1; H, 6.9; N, 9.8%.

X-ray crystal structure determination

Compound **2** crystallized from CH_2Cl_2–CH_3CN (3:1) in the monoclinic space group C_c. Lattice constants [determined diffractometrically from 15 reflections ($\pm hkl$)]: a = 1584.8(2); b = 1016.1(1); c = 1940.6(2) pm; β = 99.387(9)°; Z = 4, d_{calc} = 1.234 g cm^{-3}. The diffraction intensities were measured at room temperature on a Syntex diffractometer (Type P3F), using monochromatic Cu-K_α radiation (λ = 154.18 pm) in the θ–2θ mode ($3° \leqslant 2\theta \leqslant 115°$). The scan speed varied between

2.93 and 29.3° min^{-1}, depending on the intensity of the reflection. The data were corrected for Lorentz, polarization and absorption effects ($\mu = 1.725$ mm^{-1}). For the refinement, 1859 out of 2207 measured reflections with $F \geqslant 4.0\sigma(F)$ were used. The structure was solved by direct methods and by difference Fourier synthesis. The hydrogen atom positions were determined from difference Fourier syntheses, and were refined, using isotropic temperature factors. The refinement converged at $R = 0.040$ ($R_w = 0.037$). In the final refinement cycle, the ratio of the change in the parameter, relative to the estimated standard deviation, was less than 1% for all parameters. A final difference map displayed no electron density higher than 0.17×10^6 e/pm³. The program SHELX-76[9] and our own programs were employed. Complex atom scattering factors[10] were used. Selected bond parameters are listed in Table 2, using the numbering scheme shown in Fig. 2.

Abstract—A series of copper(I) complexes with imine ligands resulting from the condensation of 3-formyl-1-phenyl-2-(1*H*)-pyridinethione with aminoalkylthioalkylbenzimidazoles has been synthesized and spectroscopically characterized. The redox propensity of the present copper(I) complexes, investigated by electrochemical techniques, confirms the relatively difficult access to the corresponding copper(II) complexes, as expected on the basis of their previously reported electrochemistry. Structural reorganizations accompanying the copper(I)/copper(II) redox change are discussed.

In the attempt to synthesize model complexes with a ligand donor set of some relevance in the context of the biomimetic chemistry of blue copper active sites, we have recently reported the preparation and physicochemical characterization of a family of copper(II) complexes with CuN_2SS' cores **1**.[1] The change in the length of the alkyl chain R produces significant variations in the coordination geometry of the copper(II) centres. The electrochemical properties of these complexes provided evidence for the stability of the corresponding copper(I) derivatives. For copper(II) complexes with longer R chains, however, some difficulty arose because of their instability in solution. This prompted us to synthesize the copper(I) analogues **2**–**4** in order to gain further insight into the physicochemical properties of these systems. The zinc complex **5** and the free ligand **6** were also synthesized for comparison purposes. Very often the lack of structural information for both the copper(II) and copper(I) forms of the redox couple limits the discussion of the redox change in terms of the usual tetrahedral-to-planar or tetrahedral-to-tetrahedral conversions.[2,3] We now have the opportunity to correlate more precisely structural information with redox parameters.

RESULTS AND DISCUSSION

Synthesis and spectroscopic characterization

The imine complexes were prepared by metal-ion template condensation between the aminoalkylthioalkylbenzimidazole derivatives and 3-formyl-1-phenyl-2-(1*H*)-pyridinethione, as described previously for the synthesis of the copper(II) complexes.[1] The copper(I) compounds are reasonably stable in the solid state but undergo slow oxidation reactions in solution. In the IR spectra, bands typical of the imine groups occur in the usual range (1635–1645 cm^{-1}) (Table 1), well separated from

the aromatic ring vibration modes, while the broad, ill-defined perchlorate bands near 1100 cm^{-1} indicate that, as expected, these anions are not coordinated to the metal centres.

As discussed previously for the bis(imine) ligands **7** and their copper(I) (**8**) and zinc(II) (**9**) complexes,[4] binding of the pyridinethione–imine residue to a metal results in an increase of the pyridinium thiolate character that is clearly indicated by the electronic and NMR spectra of the complexes. The aromatization and increased positive charge of the pyridine nucleus in the complexes produces, for

instance, downfield shifts of the ring proton NMR signals, while the azomethine signal is found at unusually low field in the ligand thione form (Table 1). Also, the signals of the methylene groups adjacent to the donor atoms of the ligands undergo downfield shifts on metal binding and it is interesting to note that in the series **2–4** the signal of the CH_2—N group moves progressively more downfield while that of the CH_2—S group undergoes the opposite effect. This probably reflects correspondingly stronger Cu—N interactions and weaker Cu—S interactions in the above series. The signals of the imine proton and the methylene group attached to the benzimidazole group do not appear to be similarly correlated but here the additional contributions to the shielding of the protons by the aromatic nuclei are difficult to rationalize. In general, the proton NMR signals of the zinc(II) complex occur at lower fields with respect to the corresponding signals of the copper(I) complexes because of the higher positive charge of the metal ion.

In the electronic spectra the absorption band of the aromatic $\pi \rightarrow \pi^*$ transition at lowest energy shifts from 408 nm in the free ligand **6** to 364 nm in the zinc(II) complex **5** (Table 2). This band probably occurs between 350 and 400 nm in the spectra of the copper(I) complexes **2–4**, but it is more difficult to locate because it overlaps with the charge-transfer transitions involving filled copper(I) *d* orbitals and the lowest π^* orbital of the conjugated imine ligands. These broad MLCT bands extend to above 500 nm in the visible region. For the series of copper(I) complexes **8** it was possible to relate the position of the MLCT bands to the degree of distortion of the metal chromophore from a flattened tetrahedral to a more regular tetrahedral geometry according to the length of the carbon chain R.[4] In the present case it is difficult to deduce any trend in the MLCT bands. Since the structure of the ligands is no longer symmetrical and the nature of the donor atoms is different in the two halves of the molecule, it is likely that the structures of the metal chromophores are of lower symmetry. Remarkable differences in the behaviour were actually found in the two series of copper(II) complexes **10**[5] and **1**[1] as a function of the R chain length. In the former case the change in copper(II) geometry on increasing R was rather regular from square-planar towards flattened tetrahedral, while for the series **1** a more complicated pattern was observed. The complexes, in fact, exhibited a tendency to assume five-coordinate structures with a solvent molecule in the coordination sphere, but the geometries varied from square-pyramidal ($n = 2$), to trigonal-bipyramidal ($n = 3$), to severely distorted ($n = 4$).

Electrochemistry

In view of the relative redox instability of the copper(II) forms of the present copper(I) complexes in acetonitrile solution, cyclic voltammetric measurements were performed in the temperature range from −20 to +20°C. The voltammetric profiles of complexes **2** and **3** parallel those found for the corresponding copper(II) species.[1] In fact, as shown in Fig. 1 for **3**, they display an uncomplicated quasireversible copper(II) oxidation. Irreversible

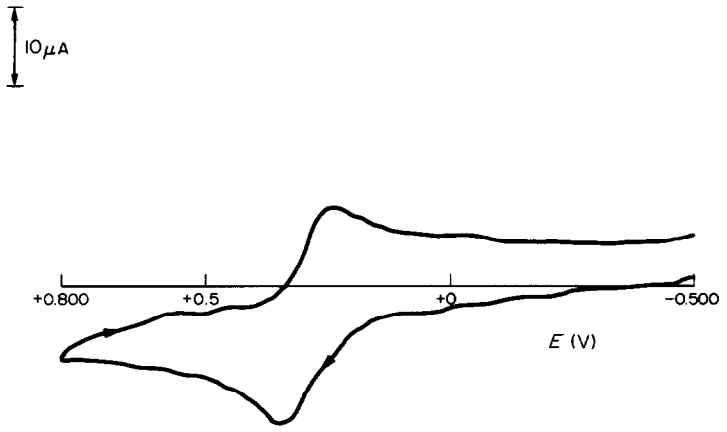

Fig. 1. Cyclic voltammogram recorded at a platinum electrode on an acetonitrile solution of **3** (2.0×10^{-3} mol dm^{-3}) and $[NEt_4]ClO_4$ (0.1 mol dm^{-3}). $T = -18°C$; scan rate 0.2 V s^{-1}.

processes also occur at more positive (Cu^{II}/Cu^{III}) and more negative (Cu^{I}/Cu^{0}) potential values, but these will not be further discussed here. As illustrated in Fig. 2, increasing the temperature makes the one-electron removal more difficult.

Less straightforward is the electrochemical behaviour of complex **4**, which is slightly soluble in acetonitrile at low temperatures. The cyclic voltammogram recorded at 13°C, Fig. 3, displays an ip_c/ip_a ratio significantly lower than unity (0.53), indicating the occurrence of a chemical reaction following the copper(II) electrogeneration.[6] Increasing the scan rate prevents such a chemical complication and at about 1 V s^{-1} the ip_c/ip_a ratio reaches unity, thus enabling a reliable computation of the formal electrode potential. Assuming the occurrence of a first-order reaction coupled with electron-transfer, a half-life of 1–2 s can be assigned[6] to the copper(II) complex analogue of **4**, which supports our previous difficulties in determining its redox behaviour.[1] Table 3 summarizes the most significant redox parameters for the copper(I) complexes studied.

Since the copper(II) complex corresponding to **4** is the most interesting among those of series **1**, we performed EPR measurements of the species electrogenerated by macroelectrolytic oxidation at −20°C of **4** in acetonitrile solution. The room-temperature EPR spectrum (Fig. 4) shows well-resolved hyperfine components with $g_{iso} = 2.087$ and $A_{iso} = 63.5 \times 10^{-4}$ cm^{-1}. The fourth hyperfine line ($I = +3/2$) additionally shows a superhyperfine structure of five equally spaced lines (relative intensity 1 : 2 : 3 : 2 : 1), attributable to coupling of the unpaired electron with two almost identical nitrogen nuclei in the coordination sphere. A coupling constant of 13.0 G was estimated by second derivative spectral analysis for the IS interaction. The frozen solution EPR spectrum displays a relatively

broad absorption that probably results from a mixture of species. It is possible to calculate the following EPR parameters of the major species from the spectrum: $g_{\parallel}$ 2.173, $A_{\parallel}$ 152×10^{-4} cm^{-1} and $g_{\perp} \sim 2.07$. The broadness of the perpendicular component of the signal indicates that it is probably rhombic. The EPR parameters are slightly different from those obtained for the copper(II) complex **1** with $n = 4$ ($g_{\parallel}$ 2.236, $A_{\parallel}$ 145×10^{-4} cm^{-1}, $g_{\perp} \sim 2.06$)[1] and in particular the latter spectrum was more typical of the axial type. We attribute this difference to the different solvent mixture employed in the latter case; it is known that the flexibility of the alkyl chain of the ligand with $n = 4$ allows a range of isomeric structures for the corresponding copper(II) complexes.[1] Under these conditions the composition of the solvent mixture forming the glass for the EPR measurement may be important in determining the structural arrangement preferred by the complex in the frozen state. The EPR parameters obtained here for the electrogenerated copper(II) species are indicative of a distorted five-coordinate structure, while those obtained previously for the same copper(II) complex agreed with a distorted tetrahedral structure. These are also the most likely structures for complexes of this type deduced from the solution spectral behaviour.[1]

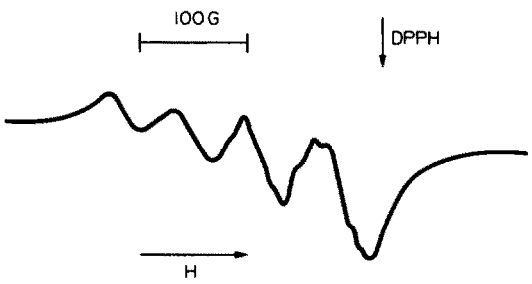

Fig. 4. X-band room temperature EPR spectrum recorded on an acetonitrile solution from exhaustive one-electron oxidation of **4** at −20°C.

A discussion of the structural reorganization accompanying the copper(I)/copper(II) electron-transfer on the basis of the relevant thermodynamic electrode potentials, implies the knowledge of the actual structures of the complexes in both oxidation states. In spite of the uncertainties mentioned above, the potential values for the couples extrapolated at 20°C:

$$E^{0\prime}_{n=2} = +0.366 \text{ V}$$

$$E^{0\prime}_{n=4} = +0.337 \text{ V}$$

$$E^{0\prime}_{n=3} = +0.299 \text{ V},$$

indicate an easier Cu^{I}/Cu^{II} redox change, and hence a lower structural reorganization,[7] in the system with $n = 3$. In this case the copper(II) species is trigonal-bipyramidal and the copper(I) species can be assumed as distorted tetrahedral. Although we expected an easier redox change for the system with $n = 4$, likely involving a similar structural reorganization, it may well be that other factors involving metal–solvent and ligand–solvent interactions play some role in determining the energy barrier to the one-electron removal. In any case, the highest energy barrier belongs to the system with $n = 2$ that involves a square-pyramidal copper(II) species and the least tetrahedral copper(I) complex in the series **2**–**4**, since it contains the shortest R chain and the least flexible ligand.

A final aspect of the Cu^{II}/Cu^{I} redox change that is of relevance in copper biomimetic chemistry, as we previously highlighted,[4] concerns the relevant electron-transfer entropy. Gray and co-workers pointed out that the Cu^{II}/Cu^{I} reduction of blue copper proteins in aqueous solutions (pH 6.5–7.0) is coupled to a negative entropy change.[8] In the present case, the variation of $E^{0\prime}$ values with temperature enables computation[9] of a ΔS_{tr} for the Cu^{II}/Cu^{I} reduction of 11.2 e.u. for the system with $n = 2$, 13.5 e.u. for the system with $n = 3$ and 36.8 e.u. for the system with $n = 4$. The opposite sign

with respect to the biological derivatives is indeed to be expected, because in low molecular weight model complexes the hydrophilic/hydrophobic environments responsible for solvent reordering effects upon charge variation are lacking.[8] The most straightforward explanation for the variation in ΔS_{tr} values observed throughout the series is that the longer alkyl chains can induce intrinsic disorder during the molecular reorganization.

EXPERIMENTAL

Elemental analyses were performed at the microanalytical laboratory of the University of Milano. IR spectra were recorded on a Nicolet MX-1E FT-IR instrument, electronic spectra on a Perkin–Elmer Lambda 5 spectrophotometer, and ^{1}H NMR spectra on a Bruker WP-80 spectrometer. The EPR spectra were obtained with a Bruker D-SRC instrument operating at 9.78 GHz (X-band), equipped with a Bruker variable-temperature ER 4111 VT unit. Both materials and apparatus for electrochemical measurements have been described previously.[1] Under the actual experimental conditions the ferrocenium/ferrocene couple which resulted was located at +0.38 V vs SCE.

The synthesis of the aminoalkylthioalkylbenzimidazole derivatives to be condensed with 3-formyl-1-phenyl-2-(1*H*)-pyridinethione[10] was reported previously.[1] The imine ligand **6** was prepared by refluxing equimolar amounts (1 mmol) of the formylpyridinethione and 3-(benzimidazol-2′-ylmethylthio)propylamine in ethanol for *ca* 1 h. The solution was evaporated to a small volume and chromatographed on silica gel (eluent: ethanol–chloroform, 1 : 1 v/v). The main yellow fraction was collected, evaporated to a small volume and precipitated with diethyl ether. The copper(I) complexes **2–4** were prepared according to the following procedure. A solution of the Schiff base was prepared under nitrogen by refluxing in ethanol for 2–3 h a mixture of equimolar amounts of formylpyridinethione and the appropriate aminoalkylthioalkylbenzimidazole (1 mmol) in Schlenk apparatus. Solid tetrakis(acetonitrile)copper(I) perchlorate (1 mmol) was then added and the mixture was allowed to reach room temperature. The brown precipitate thus formed was recovered by filtration under an inert atmosphere and dried *in vacuo*. The yellow zinc(II) complex **5** was prepared similarly in air using zinc(II) perchlorate hexahydrate. The elemental analyses of the compounds are reported in Table 1. All the complexes exhibited IR bands of medium or strong intensity near 1590, 1545 and 1490 cm^{-1} for the aromatic ring vibrations, and near 760, 750, 720 and 695 cm^{-1} for the aromatic C—H bending vibrations.

OPTICAL ABSORPTION SPECTRA OF COBALT(II) AND NICKEL(II) IONS IN LEAD ACETATE GLASSES

J. LAKSHMANA RAO,* G. L. NARENDRA and S. V. J. LAKSHMAN

Department of Physics, S.V. University, Tirupati 517 502, India

(*Received* 7 *November* 1989; *accepted* 14 *February* 1990)

Abstract—The optical absorption spectra of cobalt(II) and nickel(II) ions in lead acetate glasses have been studied both at room and liquid nitrogen temperatures. The absorption bands have been interpreted in terms of Ligand Field Theory. The crystal field-parameter (Dq) and Racah inter-electronic repulsion parameters (B and C) have been evaluated. From the spectral analysis it is found that cobalt(II) and nickel(II) ions substitute the lead(II) ions.

Ingram *et al.*[1] extensively studied the structural chemistry of a wide range of glass-forming molten acetates using cobalt(II) as a spectroscopic probe. From the observed features they concluded that acetate glasses vary considerably in ionic–covalent character. Cobalt(II) and nickel(II) ions are known to be good probes for optical absorption studies.[2–8] These ions can easily be dissolved in lead acetate glass systems. These probe ions may occupy sites both similar to and different from lead(II) sites in these glasses. The present study describes the detailed investigation of the optical absorption spectra of cobalt(II) and nickel(II) ions in lead acetate glasses.

EXPERIMENTAL

Glasses were prepared by taking the accurately weighed reagents of lead acetate mixed with cobalt acetate in the weight ratio Co/Pb 0.03. The mixture was melted in a crucible in an electric furnace at temperatures 50°C higher than the liquid temperatures. The melt was then quenched on porcelain plates. Similarly, lead acetate glasses doped with nickel acetate were also prepared in the weight ratio Ni/Pb 0.03.

Optical absorption spectra were recorded at room temperature (RT) and liquid nitrogen temperature (LNT) on Perkin–Elmer UV–vis and Carl-Zeiss NIR spectrophotometers. The optical measurements could be made with an accuracy of $\pm 5\ cm^{-1}$.

RESULTS AND DISCUSSION

Cobalt(II) : *lead acetate glass*

Cobalt usually occurs in glass as cobalt(II). The colour of the glasses containing cobalt(II) changes from pink to blue when the coordination number of cobalt decreases from six to four. In the present work, the glasses prepared were pink in colour and therefore the analysis of the spectrum has been carried out assuming that the cobalt(II) ion is in octahedral symmetry. The optical absorption spectra observed at RT and LNT are shown in Fig. 1. The spectrum observed at RT consists of two strong bands centred at 8000 and 18,865 cm^{-1}. These two broad, intense bands are assigned to the spin-allowed quartet–quartet transitions $^4T_{1g}(F) \rightarrow {}^4T_{2g}(F)$ and $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$, respectively. The positions of these bands at LNT are 8100 and 19,225 cm^{-1}, respectively. In addition, a number of weak bands are also observed. These bands are identified with the spin-forbidden quartet–doublet transitions. On cooling the glass to LNT the intensity of the bands decreased and the bands became sharper. A small blue shift of the order 100–500 cm^{-1} was observed for the band maxima. The assignments of the transition for all the observed bands are given in Table 1.

By diagonalizing the energy matrices[9] for the d^7 Co^{2+} ion configuration, the crystal-field parameter

(*Dq*) and the Racah inter-electronic repulsion parameters (*B* and *C*) have been evaluated. The *Dq* and *B* values obtained in the present work are as expected for cobalt(II) ions in octahedral symmetry.[4,8]

Nickel(II): *lead acetate glass*

Nickel occurs in glass as nickel(II) in octahedral, square-planar and tetrahedral symmetries depending upon the composition of the glass.[10] The colour of the high-spin octahedral nickel(II) glasses is olive green. In the present work the glasses were yellowish-green in colour and therefore the analysis of the spectrum has been carried out assuming the nickel(II) ion in octahedral symmetry. The spectra observed at RT and LNT are shown in Fig. 2. At room temperature three main bands are observed centred at 8300, 14,080 and 24,995 cm^{-1}. These three intense bands are assigned to the spin-allowed triplet–triplet transitions, $^3A_{2g}(F) \rightarrow {}^3T_{2g}(F)$, $^3A_{2g}(F) \rightarrow {}^3T_{1g}(F)$ and $^3A_{2g}(F) \rightarrow {}^3T_{1g}(P)$, respectively. These three bands observed at LNT are at 8400, 14,280 and 24,635 cm^{-1}, respectively. The remaining weak bands in the spectrum are identified with the spin-forbidden triplet–singlet transitions. On cooling the sample the bands became sharper and the intensities of the bands increased. The assignments of the transitions for all the observed bands are given in Table 2.

Table 1. The observed and calculated energies for the bands of cobalt(II) in lead acetate glasses; $Dq = 915$ cm^{-1}, $B = 820$ cm^{-1} and $C = 3444$ cm^{-1}

Transition $^4T_{1g}(F) \rightarrow$	Observed energy (cm^{-1}) RT	LNT	Calculated energy (cm^{-1})
$^4T_{2g}(F)$	8000	8100	8044
$^2T_{2g}(G)$	15,475	15,500	15,016
$^4A_{2g}(F)$	17,090	17,240	17,193
$^4T_{1g}(P)$	18,865	19,225	19,237
$^2T_{1g}(H)$	19,995	20,400	19,064
$^2A_{1g}(G)$	20,830	21,270	21,650
$^2T_{2g}(H)$	22,985	23,525	23,469
$^2E_g(H)$	26,310	26,800	26,561
$^2T_{2g}(D)$	29,840	29,405	29,450

By diagonalizing the energy matrices for the d^8 Ni^{2+} configuration[9] the crystal-field parameter (*Dq*) and the Racah inter-electronic repulsion parameters (*B* and *C*) have been evaluated. The *Dq* and *B* values obtained in the present work are as expected for nickel(II) ions in octahedral symmetry.[2]

The *Dq* values obtained in the present work for both cobalt(II) and nickel(II) ions follow the spectrochemical series.[11]

The inter-electronic repulsion parameter, *B*, for free cobalt(II) and nickel(II) ions is 1120 and 1080 cm^{-1}, respectively.[11] In the present work the *B* values obtained for cobalt(II) and nickel(II) are 820 and 980 cm^{-1}, respectively. This indicates that the

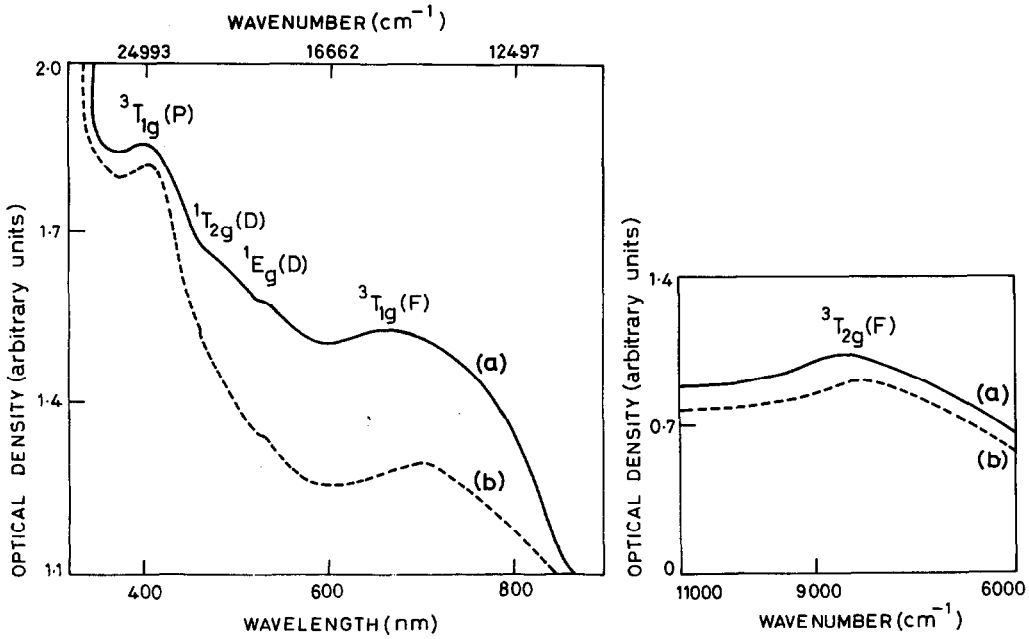

Fig. 2. Absorption spectra of nickel(II) in lead acetate glass: (a) at liquid nitrogen temperature; (b) at room temperature.

bonding between the metal ion and the ligand is more covalent for the cobalt(II) than for the nickel(II) ion, and in both the cases the site symmetry is octahedral.

CONCLUSION

In lead acetate glasses the ligand-field parameters for cobalt(II) were found to be $Dq = 915\ cm^{-1}$, $B = 820\ cm^{-1}$ and $C = 3444\ cm^{-1}$, and for nickel (II), $Dq = 840\ cm^{-1}$, $B = 980\ cm^{-1}$ and $C = 3920\ cm^{-1}$. The optical studies reveal that the cobalt(II) and nickel(II) ions go substitutionally into lead(II) ion sites and the site symmetry around these transition metal ions is octahedral.

(*Received* 21 *November* 1989; *accepted* 14 *February* 1990)

Abstract—The reaction of 2-pyridyldiphenylphosphine with iron carbonyl affords 2-$(C_5H_4N)P(C_6H_5)_2Fe(CO)_4$ in which the ligand is bonded through the phosphorus donor atom. Similar substitution reactions occur with $Mn_2(CO)_{10}$, $Re_2(CO)_{10}$, $Cr(CO)_6$ and $Mo(CO)_6$ to give 2-$C_5H_4NP(C_6H_5)_2Mn_2(CO)_8$, $[2\text{-}C_5H_4NP(C_6H_5)_2Re(CO)_4]_2$ and 2-$C_5H_4NP(C_6H_5)_2M(CO)_5$ (M = Cr, Mo), respectively.

2-Pyridyldiphenylphosphine (I) has attracted much interest as a ligand[1] especially in the synthesis of bridged heteroatomic transition metal complexes.[2–8] The present study sets out to investigate the coordinating properties of ligand I with various transition metal carbonyls under conditions similar to those reported in our earlier studies[9–13] involving the reactivities of (*o*-diphenylphosphinobenzyl)dimethylsilane and 2-pyridyldimethylsilane towards metal carbonyls. We report below the preparation and properties of complexes obtained from reactions of I with metal carbonyls of chromium, molybdenum, manganese, rhenium and iron.

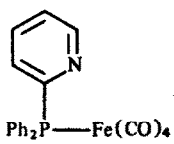
RESULTS AND DISCUSSION

Iron complex

Ligand I was prepared in this study by the reaction between the Grignard reagent 2-C_5H_4NMgBr and chlorodiphenyl phosphine in ether:

$$2C_5H_4NMgBr + ClP(C_6H_5)_2 \longrightarrow 2C_5H_4NP(C_6H_5)_2 + MgBrCl.$$

Treatment of the distillate at 120–140°C/0.5 mm Hg gave I as a crystalline solid. The reactions of I with iron pentacarbonyl in benzene proceeded at 125°C to give a monosubstituted iron carbonyl derivative, $C_5H_4NP(C_6H_5)_2Fe(CO)_4$ (II), formulated on the basis of IR data and elemental analysis. The same product was also obtained from the reaction of diiron nonacarbonyl with I at 40°C. Prolonged reaction of more than 18 h did not yield the disubstituted derivative. This is to be contrasted with the reaction[13] of *o*-chlorophenyldiphenylphosphine with iron pentacarbonyl and diiron nonacarbonyl wherein a disubstituted complex $[o\text{-}ClC_6H_4P(C_6H_5)_2]_2Fe(CO)_3$ (**A**) was obtained in the former case, while both monosubstituted *o*-$ClC_6H_4P(C_6H_5)_2Fe(CO)_4$ (**B**) and the disubstituted **A** derivatives were isolated in the latter. The IR spectra of complexes **A** and **B** display carbonyl stretching vibrations at 1970, 1930, 1890, 1870 cm^{-1} and 2050, 1975, 1946 cm^{-1}, respectively. The carbonyl stretching vibrations of II are located at 2050, 1980, 1940 and 1890 cm^{-1}. This suggests that bonding of I to iron is most likely to occur through the phosphorus atom only, as shown in structure II.



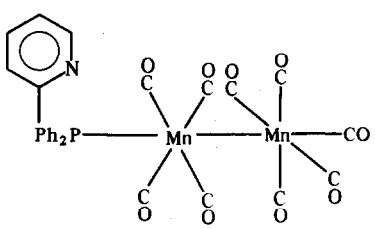
II

*Author to whom correspondence should be addressed.

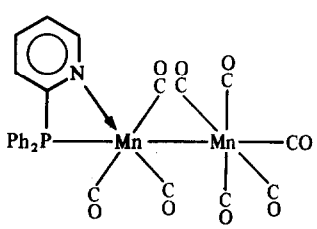
This mode of bonding is consistent with the basic reaction pattern established by Balch and co-workers[3] for formation of bridged heteronuclear-transition metal complexes. The first step invariably led to the formation of the monosubstituted derivative with **I** being bonded to the metal by the phosphorus atom. Moreover, the low affinity[14] of iron(0) for the pyridine nitrogen has been further demonstrated by a reaction of $(C_5H_4N)_2Si(CH_3)_2$ and diiron noncarbonyl in benzene at 100°C, from which only triiron dodecacarbonyl and unreacted ligand were isolated.[13] It is also noted that the pyridine vibrations at 604 and 405 cm^{-1} have not been appreciably affected in compound **II**.[15]

Manganese and rhenium complexes

The reactions of **I** with $Mn_2(CO)_{10}$ and $Re_2(CO)_{10}$ proceeded in benzene at a much higher temperature of 160°C. The manganese derivative **III** is an orange solid characterized by seven CO stretching vibrations at 2060, 2000, 1982, 1960, 1940, 1930 and 1902 cm^{-1}. Its analytical data do not differentiate it between the formula $C_5H_4NP(C_6H_5)_2Mn_2(CO)_9$ (**IIIa**) and $C_5H_4NP(C_6H_5)_2Mn_2(CO)_8$ (**IIIb**). The IR data are not consistent with structure **IIIa** which normally gives five bands.[16] However, the presence of seven bands suggests that the most probable structure is **IIIb**.

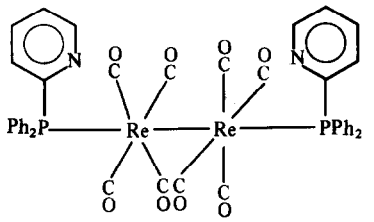


(IIIa)



(IIIb)

The complex formed with the rhenium carbonyl can be formulated as $[2\text{-}C_5H_4NP(C_6H_5)_2Re(CO)_4]_2$ (**IV**) on the basis of elemental analysis and CO stretching vibrations which gave bands located at 2080, 1980, 1940 and 1902 cm^{-1}. Following from the above discussion, structure **IV** is proposed. The lower number of CO stretching vibrations observed in this case is consistent with the high symmetry of structure **IV** compared to the manganese analogue (**IIIb**).



(IV)

Chromium and molybdenum complexes

The reactions between ligand **I** and chromium carbonyl proceeded in benzene at a temperature of 105°C to give a creamy crystalline solid which can be formulated as $C_5H_4NP(C_6H_5)_2Cr(CO)_5$ (**V**) on the basis of its IR data and elemental analysis. An analogous monosubstituted molybdenum(0) derivative (**VI**) was also obtained from a reaction with molybdenum hexacarbonyl at 125°C in benzene. As both chromium and molybdenum form monopyridine[17] as well as monotriphenylphosphine[18] complexes of the general formula $LM(CO)_5$ (L = pyridine/triphenylphosphine), attempts were made to ascertain the mode of coordination of **I** in **V** and **VI**. A careful comparison of the carbonyl stretching frequencies of several complexes (Table 1) reveals that synergic interactions of triphenylphosphine with chromium(0) and molybdenum(0) is apparently greater than with pyridine.

EXPERIMENTAL

The IR spectra of solids, as KBr pellets, were recorded on a Perkin–Elmer Model 337 IR spectrophotometer. The IR spectra of metal carbonyl complexes in the carbonyl region were recorded on chloroform solutions.

Synthesis of 2-pyridyldiphenylphosphine

A solution of ethyl bromide (2.2 g, 0.02 mol) in dry ether (50 cm^3) was added to dry magnesium turnings (15.0 g, 0.62 mol) placed in a three-necked flask. A few iodine crystals were added to initiate the reaction. A solution of 2-bromopyridine (76.9 g, 0.49 mol) and ethyl bromide (24.8 g, 0.23 mol) in ether (250 cm^3) was added over 75 min while keeping the reaction mixture under reflux. After a further reflux for another 2 h, the reaction mixture was cooled. A solution of diphenylchlorophosphine (70.6 g, 0.32 mol) in ether (275 cm^3) was added slowly and the resultant reaction mixture was

refluxed for a further 2 h. Upon cooling, the reaction mixture was treated with saturated ammonium chloride solution (275 cm^3). The ether layer was dried over anhydrous sodium sulphate overnight and fractional distillation at 180°C/1–2 mm Hg yielded 2-pyridyldiphenylphosphine (26.9 g), m.p. 84–85°C. (Found: C, 77.5; H, 5.3; N, 5.1. Calc. for $C_{17}H_{14}NP$: C, 77.6; H, 5.3; N, 5.3%.) IR (Nujol mull): 3050w, 2950s, 2920s, 2860s, 1565m, 1460s, 1435s, 1412s, 1090m, 1048m, 1025m, 998m, 772s, 746s, 716m, 695s, 620m.

Reaction of 2-pyridyldiphenylphosphine with chromium hexacarbonyl

A mixture of chromium hexacarbonyl (0.50 g, 2.27 mmol), 2-pyridyldiphenylphosphine (0.50 g, 1.90 mmol) and benzene (10 cm^3) was sealed in an evacuated tube and kept at 105°C for 20 h. The solution was then filtered and concentrated to yield a solid. Yellow crystals were obtained upon recrystallization from acetone, $C_5H_4NP(C_6H_5)_2Cr(CO)_5$, m.p. 107–109°C. (Found: C, 58.2; H, 3.3. Calc. for $C_{22}H_{14}CrO_5NP$: C; 58.0; H, 3.1%.) IR ($CHCl_3$ solution): 2060s, 1995m, 1920vs, 1660w, 1570s, 1480w, 1420m, 1320w, 1300w, 1090s, 990s, 630s.

Reaction of 2-pyridyldiphenylphosphine with molybdenum hexacarbonyl

A mixture of molybdenum hexacarbonyl (0.56 g, 2.12 mmol), 2-pyridyldiphenylphosphine (0.50 g, 1.90 mmol) and benzene (10 cm^3) was sealed in an evacuated tube at 126°C for 18 h. The solution was then filtered and concentrated to give a solid which upon recrystallization from acetone formed yellow crystals of $C_5H_4NP(C_6H_5)_2Mo(CO)_5$, m.p. 119–121°C. (Found: C, 53.5; H, 3.1. Calc. for $C_{22}H_{14}MoO_5NP$: C, 52.9; H, 2.8%.) IR: 2075s, 1995m, 1940vs, 1710w, 1580s, 1430m, 1329w, 1301w, 1151w, 1090s, 1000sh, 990s, 900m, 608s.

Reaction of 2-pyridyldiphenylphosphine with manganese carbonyl

A mixture of 2-pyridyldiphenylphosphine (0.59 g, 2.25 mmol), manganese carbonyl (0.899, 2.28 mmol) and benzene (15 cm^3) was sealed in a tube at 160°C for *ca* 10 min. The solution was filtered and the filtrate concentrated under nitrogen. The orange–brown solid obtained was subjected to vacuum sublimation at 50°C to remove the unreacted parent carbonyl. The residue was then recrystallized from hexane to yield bright orange crystals, m.p. 181–182°C. This compound was identified as 2-$C_5H_4NP(C_6H_5)_2Mn_2(CO)_8$. (Found: C, 50.1; H, 2.6; N, 2.2. Calc. for $C_{25}H_{14}PNMn_2O_8$: C, 49.9; H, 2.2; N, 2.2%.) IR ($CHCl_3$ solution): 2980m, 2060s, 2000m, 1985s, 1960s, 1940s, 1930s, 1902s, 1460m, 1430m, 1180w, 1160w, 1125w, 1095w, 1085w, 1020w, 1000w, 765m, 750m, 720m, 695m, 663s, 645s, 623s.

Reaction of 2-pyridyldiphenylphosphine with rhenium carbonyl

A mixture of 2-pyridyldiphenylphosphine (0.263 g, 0.89 mmol), rhenium carbonyl (0.695 g, 1.06 mmol) and benzene (10 cm^3) was sealed in an evacuated tube at 160°C for 2 h. The solvent was removed under vacuum and the residual was subjected to sublimation at 80°C to remove the unreacted rhenium carbonyl. The remaining solid was fractionally recrystallized from hexane to give white crystals, m.p. 219–220°C. This compound was identified as $[2\text{-}C_5H_4NP(C_6H_5)_2Re(CO)_4]_2$. (Found: C, 44.7; H, 2.0; N, 2.1. Calc. for $C_{42}H_{28}P_2N_2Re_2O_8$: C, 44.9; H, 2.5; N, 2.5%.) IR ($CHCl_3$ solution): 3050w, 2940s, 2845s, 2095w, 2060w, 2020sh, 2008m, 1980s, 1940vs, 1902s, 1565m, 1485m, 1420s, 1450s, 1418m, 1375m, 1185w, 1155w, 1095sh, 1078m, 1020w, 1000w, 988w, 765w, 743m, 720w, 698m, 625m, 615s.

Reaction of 2-pyridyldiphenylphosphine with iron pentacarbonyl

A mixture of 2-pyridyldiphenylphosphine (0.51 g, 1.92 mmol), iron pentacarbonyl (0.429 g, 2.51 mmol) and benzene (8 cm^3) was placed in a sealed tube at 125°C for 11 h. The resultant solution was filtered and the filtrate concentrated under nitrogen. The yellow crystals formed were recrystallized from acetone. The product (m.p. 155–157°C decomp.) was identified as $2\text{-}C_5H_4NP(C_6H_5)_2Fe(CO)_4$. (Found: C, 59.1; H, 3.5; N, 3.0. Calc. for $C_{21}H_{14}NPFeO_4$: C, 58.5; H, 3.2; N, 3.2%.) IR ($CHCl_3$ solution): 3060w, 3050w, 2940s, 2910s, 2850s, 1995w, 1970s, 1930m, 1890s, 1870s, 1570w, 1480m, 1465m, 1455m, 1435m, 1425s, 1375m, 1365w, 1270w, 1255m, 1180w, 1125w, 1108m, 1095m, 1038m, 995w, 873w, 758s, 738m, 715m, 708m, 695s, 638s.

(*Received* 30 *January* 1990; *accepted* 19 *February* 1990)

Abstract—The synthesis and characterization of the compound bis(2,2-dimethylpropyl) cadmium(II), {bis(neopentyl)cadmium(II)} and its 1:1 adduct with 2,2′-bipyridyl are reported. The alkyl is moderately volatile (vapour pressure *ca* 3 torr, 52°C) and may find application as a precursor for the deposition of cadmium-containing films by MOCVD.

Dimethyl cadmium is used as a precursor for the deposition of a wide range of II/VI materials by metallo-organic chemical vapour deposition, MOCVD.[1,2] The properties of this compound as a precursor have been somewhat modified by the use of adducts such as the dioxan[3] and the bis-tetrahydrothiophene,[4] but the only other alkyl of cadmium to have been used for MOCVD is the bis-ethyl.[5] This fact may reflect the unstable nature of the higher alkyls of cadmium, which are particularly prone to photochemical decomposition.[6] In view of all these factors it is surprising that there appear to be no literature reports[6,7] concerning the synthesis and properties of bis(neopentyl)cadmium(II). The neopentyl group is well known for its ability to form stable metal alkyl complexes, presumably because β-elimination reactions are precluded; for example it has been successfully used to prepare manganese(II) alkyls.[8] Moreover, the mercury[9] and zinc[10] neopentyls are both known compounds. In this report we describe, for the first time, the synthesis and characterization of bis(neopentyl)cadmium(II).

RESULTS AND DISCUSSION

Bis(neopentyl)cadmium(II) is a waxy solid melting at *ca* 40°C, and distilling at 50°C, 10^{-2} torr. The compound has been characterized by its ^{1}H NMR, mass (*m/z*, ^{116}Cd 258.02 found, 258.08 calc), and IR spectra; the NMR results are summarized in Table 1. The alkyl is remarkably thermally stable and discolours only slightly, in daylight, over a period of hours at 90°C, behaviour which may be contrasted with that of diethyl cadmium which deposits cadmium metal in minutes (*ca* 30°C, daylight). The thermal stability of the compound allowed a preliminary assessment of its vapour pressure to be made in a closed glass system. Typical values for the vapour pressure were *ca* 11.7 torr at 90°C and *ca* 3 torr at 52°C.

The compound shows the typical behaviour[11,12] of a group 12 alkyl and forms a solid, yellow adduct of 1:1 stoichiometry with 2,2′-bipyridyl; the spectroscopic results for this compound are also included in Table 1. The stoichiometry of the compound is confirmed by integration of the ^{1}H NMR spectrum. The adduct is remarkably stable and it is difficult to remove the alkyl by distillation under reduced pressure, which is markedly different

behaviour to that observed for similar adducts of dimethyl cadmium.[12,13]

CONCLUSIONS

Bis(neopentyl)cadmium(II) is a low-melting point solid (m.p., *ca* 40°C) which shows remarkable thermal and photolytic stability. It readily forms 1 : 1 adducts with bidentate nitrogen donors such as 2,2′-bipyridyl, but in contrast with the adducts of dimethyl[12] or diethyl cadmium[5] the neopentyl is not easily liberated on heating the adduct *in vacuo*. The compound is at present being evaluated* as a precursor for the growth of both wide and narrow band-gap compound semiconductors by MOCVD.

EXPERIMENTAL

Materials and methods

Neopentyl bromide was purchased from Fluka, all other chemicals were from BDH. Solvents were dried before use with molecular sieves. All manipulations were carried out using a vacuum line and standard Schlenk techniques.

Physical measurements. Electronic spectra were recorded with a Perkin–Elmer 330 spectrophotometer; IR spectra were recorded on a Mattson Polaris FT-IR spectrometer, as Nujol mulls or in a gas cell; NMR spectra were recorded using a Bruker WH 400, pulsed FT NMR instrument; and mass spectra were recorded with a Kratos MS50 TC instrument (only a weak spectrum was obtained but this showed a clear molecular ion). Microanalyses were performed by the University College, London, Service.

Preparation of compounds

Bis(neopentyl)cadmium(II). Neopentyl bromide (1-bromo-2,2-dimethylpropane, 300 g, 0.2 mol) was added dropwise to magnesium turnings (6 g, 0.2 mol) in 200 cm^3 of dry diethyl ether with stirring, to give a solution of the Grignard reagent (this reaction sometimes took some time to initiate, but was generally successful). The solution of the Grignard reagent in ether was then added dropwise to a suspension of cadmium iodide (33 g, 0.2 mol) in 100 cm^3 of diethyl ether. The resulting solution was stirred overnight to give a pale yellow solution and a white precipitate.

Approximately 80% of the ether was removed under reduced pressure leaving an off-white solid residue. The residue was distilled at 140–150°C giving an ethereal solution of bis(neopentyl)cadmium(II). The remaining ether was removed by pumping off the solution at −20°C and the alkyl was obtained as a waxy solid (m.p., 40°C). Major IR bands (cm^{-1}): 2925, 1260, 1096, 1036, 1007, 800, 682, 568.

2,2′-Bipyridyl adduct. 2,2′-Bipyridyl (6.1 g, 0.039 mol) was added to bis(neopentyl)cadmium (10 g, 0.04 mol) in 50 cm^3 of diethyl ether. Removal of the ether resulted in the precipitation of the adduct as a bright orange solid. Major IR bands (cm^{-1}):

* The alkyl has successfully been used in combination with H_2S to grow films of CdS on GaAs 111A at 350°C. The growth rate was low, *ca* 0.06 μm h^{-1}, and there was some homogeneous reaction between the alkyl and hydrogen sulphide; the films showed hexagonal features. The low growth rate obtained with the source at room temperature suggests that the alkyl is unsuitable for atmospheric pressure MOCVD. Bis(neopentyl)cadmium may have an application as a p-type dopant for InP and related III/V alloys.

SYNTHESIS OF A μ_3-η^1 ISOCYANIDE TRIANGULAR NICKEL CLUSTER: X-RAY CRYSTAL STRUCTURE OF $[Ni_3(\mu_3\text{-CNMe})(\mu_3\text{-I})(dppm)_3][I]$

KEVIN S. RATLIFF, PHILLIP E. FANWICK and CLIFFORD P. KUBIAK*

Department of Chemistry, Purdue University, West Lafayette, IN 47907, U.S.A.

(*Received* 29 *December* 1989; *accepted* 21 *February* 1990)

Abstract—The reaction of the trinickel cluster $[Ni_3(\mu_3\text{-CNMe})(\mu_3\text{-I})(CNMe)_2(dppm)_2][I]$ (**1**), which contains the first example of a linear, symmetrically triply-bridging (μ_3-η^1) isocyanide, with one equivalent of dppm ($PPh_2CH_2PPh_2$) in acetonitrile under reflux conditions, results in the formation of a more stable trinickel cluster, $[Ni_3(\mu_3\text{-CNMe})(\mu_3\text{-I})(dppm)_3][I]$ (**2**), which also possesses a linear μ_3-η^1 isocyanide ligand. The structure of **2** was established by X-ray crystallography.

Molecular clusters provide the opportunity to study the interactions of small molecules with metal surfaces in a homogeneous environment. Recently, the novel trinickel complex $[Ni_3(\mu_3\text{-CNMe})(\mu_3\text{-I})(CNMe)_2(dppm)_2][I]$ (**1**) was synthesized in our laboratory.[1] The complex demonstrated the first example of a linear, symmetrically triply-bridging methyl isocyanide. The μ_3-η^1 mode of isocyanide binding was unprecedented in both cluster chemistry and on metal surfaces. Muetterties found that methyl isocyanide absorbs on nickel surfaces by binding in an η^2 fashion, with considerable interaction between the isocyanide nitrogen atom and the metal surface.[2] Several clusters of the type $M_3(\mu\text{-dppm})_3$ (M = Pd,[4] Pt,[5] Cu,[6] Ag[7]) with planar triangular frameworks are known. The coordination chemistry at the triply-bridging site of the complex $[Pd_3(\mu_3\text{-CO})(dppm)_3]^{2+}$ has been investigated.[3] Our studies of the reactivity of complex **1** were hampered by the instability of the trinickel core. Therefore, in an effort to further stabilize the trinickel core of **1**, an additional diphosphine (dppm) was used to bridge the third side of the Ni_3 triangle.

$$[Ni_3(\mu_3\text{-CNMe})(\mu_3\text{-I})(CNMe)_2(dppm)_2]^+ + dppm \quad (1)$$

$$\xrightarrow[\text{vacuum}]{} [Ni_3(\mu_3\text{-CNMe})(\mu_3\text{-I})(dppm)_3]^+ + 2\,CNMe. \quad (2)$$

EXPERIMENTAL

The ligand dppm (0.19 g, 0.496 mmol) was added to a stirred solution of **1** (0.5 g, 0.496 mmol) in 50 cm^3 of acetonitrile at ambient temperature. The resulting solution was refluxed for 36 h with occasional purging of the apparatus with N_2(g) to aid in the removal of volatile CNMe. The solvent and any remaining free CNMe were then removed *in vacuo* and the crude product was recrystallized from CH_2Cl_2–pentane. The resulting crystals were then washed with a small amount of CH_3CN (5 cm^3), Et_2O (30 cm^3), and dried *in vacuo*. Yield 0.71 g, 84%.

NMR (CD_2Cl_2): ^1H (300 MHz) 4.01 ppm, 4.08 ppm (doublets, 6H, $PPh_2PC\mathit{H}_2PPh_2$), 4.25 ppm (s, 3H, $CNC\mathit{H}_3$), 6.8–7.3 ppm (m, 60H, Ph); $^{31}P\{^1H\}$ (89 MHz) 0.02 ppm (s). IR(KBr) ν(CN) = 1922 cm^{-1}.

* Author to whom correspondence should be addressed. Research Fellow of the Alfred P. Sloan Foundation, 1987–1991.

Crystals of **2** were obtained from CH_2Cl_2–pentane and contained one molecule of CH_2Cl_2 per unit cell. $I_2Ni_3Cl_2P_6NC_{78}H_{71}$, F.W. = 1709.13, monoclinic, $C2/c$, $a = 35.602(7)$, $b = 19.991(3)$, $c = 23.665(7)$ Å, $\beta = 120.10(1)°$, $V = 14571(1)$ Å^3, $Z = 8$, $d_c = 1.558$ g cm^{-3}, $\mu = 18.56$ cm^{-1} for Mo-K_α radiation ($\lambda = 0.71073$ Å). Intensity data: Enraf–Nonius CAD4 diffractometer, 9861 unique reflections. The structure of **2** was solved using the structure solution program SHELX-86 and refined by full-matrix least-squares using 5627 reflections with $I \geqslant 3.0\sigma(I)$. The final residuals were $R = 0.038$ and $R_w = 0.044$.

RESULTS AND DISCUSSION

The reaction of **1** with dppm under refluxing conditions affords **2** in excellent yield. An ORTEP of **2** is shown in Fig. 1. The molecule consists of a strongly bonding triangular nickel core with d(Ni—Ni)$_{av}$ = 2.41(2) Å. Each side of the nickel triangle is bridged by one dppm to form a nearly planar $[Ni_3L_6]^{2+}$ core. The triangle is capped by an iodide on one face of the nickel triangle. The most significant feature of the structure is the linear, symmetrically triply-bridging methyl isocyanide on the other face of the nickel triangle. A skeletal view of the $[Ni_3(\mu_3\text{-CNMe})(\mu_3\text{-I})]^+$ core with selected bond distances and bond angles is shown in Fig. 2. Aside from our earlier report of **1**, only one other claim of a symmetrically-bridged μ_3-η^1 isocyanide exists. Fortune and co-workers have described the complex $Co_3(C_5H_5)_3(\mu_3\text{-CNC}_6H_{11})(\mu_3\text{-S})$ (**3**) which

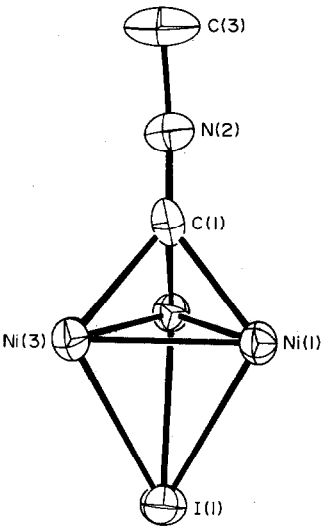

Fig. 2. Skeletal view of **2** with selected bond distances (Å) and bond angles (°): Ni(1)—Ni(2), 2.431(1); Ni(1)—Ni(3), 2.395(1); Ni(2)—Ni(3), 2.432(1); Ni(1)—C(1), 2.020(9); Ni(2)—C(1), 1.995(9); Ni(3)—C(1), 2.016(9); C(1)—N(2), 1.17(1); N(2)—C(3), 1.40(1); ∠C(1)—N(2)—C(3), 164.6(9).

was refined crystallographically to $R = 0.092$ and $R' = 0.120$. Complex **3** shows no apparent interaction between the nitrogen atom of the isocyanide and the triangular cobalt cluster.[7] However, the μ-isocyanide of **3** is significantly bent to angles of 141 and 129° for the two independent isomers refined. The π^* orbitals of a truly symmetric μ_3-η^1 iso-

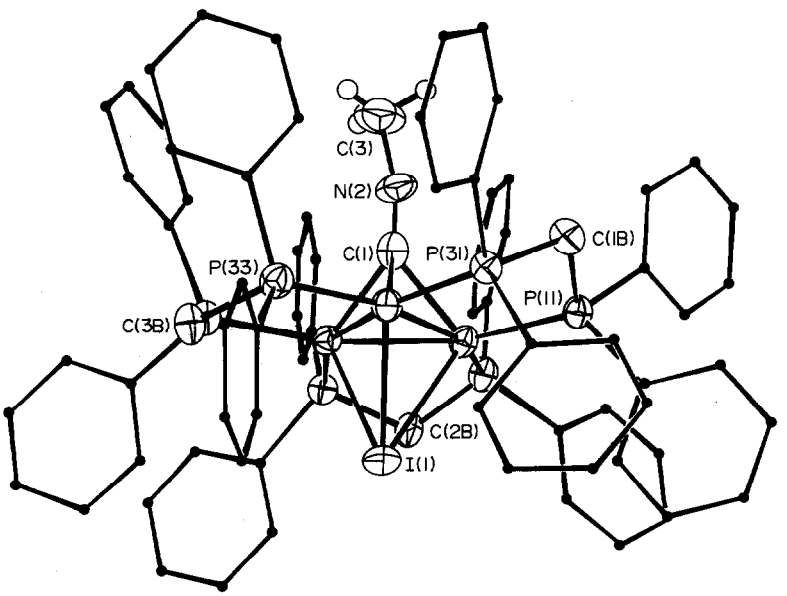

Fig. 1. ORTEP drawing of $[Ni_3(\mu_3\text{-CNMe})(\mu_3\text{-I})(dppm)_3]^+$ (**2**).

cyanide are degenerate and thus no bending should occur. The trinuclear nickel clusters, **1** and **2**, thus represent the only genuine examples of symmetric μ_3-η^1 isocyanide binding to metal clusters.[1] Complexes **1** and **2** are unique since there are no interactions between the nitrogen atom of the isocyanide and the metal clusters; and the bonding between the nickel triangles and the π^* orbitals of the isocyanides is sufficiently symmetric that no significant bending of the isocyanide occurs, $\angle$CNC = 164.6(9) for **2**. The IR spectrum of **2** reveals $\nu(\mu$-CN) = 1922 cm^{-1}, which is 20 cm^{-1} lower in energy than $\nu(\mu$-CN) = 1942 cm^{-1} for **1** and over 200 cm^{-1} higher than $\nu(\mu$-CN) = 1700 cm^{-1} for CNMe on the Ni(111) surface.[8] The unusually high energies of the CN stretching frequencies indicate that the out-of-plane *d* orbitals of the Ni_3 triangle do not interact extensively with the π^* orbitals of the isocyanide. Electrochemical studies reveal a reversible 1e$^-$ reduction of the Ni_3^{2+} core of complex **2** at $E = -1.07$ V vs Ag/AgCl. Chemical, electrochemical and theoretical studies of these unusual μ_3-η^1 isocyanide clusters are continuing.

SYNTHESIS AND CRYSTAL STRUCTURE OF A TETRANUCLEAR MIXED-METAL ALKYLIDENE COMPLEX $CpWOs_3(CO)_9(\mu\text{-}O)(\mu\text{-}H)(\mu\text{-}CHTol)$

SHIE-MING PENG*† and GENE-HSIANG LEE

Department of Chemistry, National Taiwan University, Taipei 10764, Taiwan, R.O.C.

and

YUN CHI*

Department of Chemistry, National Tsing Hua University, Hsinchu 30043, Taiwan, R.O.C.

(*Received* 21 *November* 1989; *accepted* 27 *February* 1990)

Abstract—The solid-state structure of a tetranuclear mixed-metal cluster $CpWOs_3(CO)_9(\mu\text{-}O)(\mu\text{-}H)(\mu\text{-}CHTol)$ (**2**) which possesses a bridging hydride, a bridging oxo and a bridging tolylalkylidene ligand is presented. Complex **2** crystallizes in the triclinic space group $P\bar{1}$, with $a = 9.763(5)$, $b = 10.759(4)$, $c = 13.336(3)$ Å, $\alpha = 88.00(3)$, $\beta = 108.56(3)$, $\gamma = 100.44(3)°$, $Z = 2$; 3463 observed reflections with $I > 3\sigma(I)$ were used in the refinement. The R values converged to $R_F = 0.057$, $R_w = 0.058$.

The reactivity of mixed-metal clusters has been of interest for many years.[1] Research in this area is stimulated by a belief that the combination of metals having very different chemical properties within one compound may induce unique chemical transformations. In seeking to develop a systematic way to prepare the mixed-metal clusters of higher nuclearity, Stone and co-workers have used $Cp(CO)_2W{\equiv}CR$ as a building block to prepare many mixed-metal clusters containing a bridging alkylidyne fragment.[2] As the number of the mixed-metal alkylidyne clusters has increased dramatically in the past few years, there is increasing interest in examining the chemistry of the alkylidyne clusters because of the possible roles of the alkylidynes as reaction intermediates in, and/or models of various catalytic processes.[3] In the present study we have explored the hydrogenation of a tetrahedral mixed-metal alkylidyne complex $CpWOs_3(CO)_9(\mu_3\text{-}CTol)_2(\mu\text{-}H)$ (**1**)[4] which produces an alkylidene complex $CpWOs_3(CO)_9(\mu\text{-}O)(\mu\text{-}H)(\mu\text{-}CHTol)$ (**2**) in low yield (Scheme 1). The single-crystal X-ray diffraction study on complex **2** suggests that its gross geometry and ligand configuration are complementary to those of the related, structurally characterized WOs_3 clusters $CpWOs_3(CO)_9(\mu\text{-}O)(\mu\text{-}H)(\mu\text{-}CHCH_2Tol)$ (**3**)[5] and $CpWOs_3(CO)_9(\mu\text{-}O)(\mu\text{-}Cl)(\mu\text{-}CHCH_2Tol)$ (**4**)[6] (Scheme 2).

RESULTS AND DISCUSSION

Hydrogenation of complex **1** in refluxing xylenes solution (1 atm, 6 h) produced an orange–brown solution. The solvent was removed *in vacuo* and the product purified by thin-layer chromatography (TLC), giving an orange product in low yield. The mass spectrum indicates a parent ion at m/z 1198, corresponding to a composition $C_{22}H_{14}O_{10}Os_3W$. The ^{13}C NMR spectrum ($CDCl_3$, 100.6 MHz, 213 K) exhibits nine Os—CO signals at δ 194.5, 184.4, 181.4, 180.9, 176.4, 173.2, 169.9, 169.7, 169.1 and the ^1H NMR spectrum ($CDCl_3$, 400 MHz, 294 K) shows two singlets at δ 5.52 and −18.05, in addition to signals corresponding to one Cp ligand and one tolyl fragment. The IR spectrum (C_6H_{12}) in the carbonyl region shows absorption bands at 2090(s), 2965(vs), 2028(vs), 2020(vs), 2014(s), 2007(m),

Scheme 1.

1991(w), 1958(w), 1940(m) cm^{-1}, indicating that the molecule is analogous to the recently reported dioxo cluster $CpWOs_3(CO)_9(\mu\text{-}O)_2(\mu\text{-}H)$.[7] Based on these spectroscopic data, a formulation $CpWOs_3(CO)_9(\mu\text{-}O)(\mu\text{-}H)(\mu\text{-}CHTol)$ is proposed for this complex. The exact source of the oxo ligand in **2** and the fate of the second alkylidyne in **1** are unknown. However, based on reports in the literature, we speculate that the oxo ligand may be derived from a CO ligand by C—O bond scission or from other possible sources (O_2 or H_2O)[8] in the solution and that the alkylidyne may be eliminated as a *para*-xylene molecule.[9]

The molecular structure of **2** was determined by a single-crystal X-ray diffraction study. The ORTEP diagram and the scheme used for labelling the atoms are shown in Fig. 1. The bond distances and angles are listed in Tables 1 and 2, respectively. The molecule consists of one tungsten atom and three osmium atoms which define a tetrahedral core associated with the expected 60 outer valence electrons. The tungsten atom is coordinated to a Cp, a bridging oxo and a bridging alkylidene ligand, whereas each of the three basal osmium atoms is associated with three terminal CO ligands arranged in a pseudo-octahedral geometry.

The oxo ligand O(10) bridges the W—Os(2) edge and the W—O(10)—Os(2) interaction is characterized by the short tungsten–oxygen bond distance (W—O(1) = 1.77 Å), the comparatively long Os(2)—O(10) bond length (2.13 Å) and the small W—O(10)—Os(2) angle (94.6°). These data are compatible with the parameters for the typical W=O→Os bonding interaction as has been found previously in the related WOs_3 complexes.[10] In addition, there is also a doubly bridging alkylidene ligand (μ-CHTol) which is associated with the second W—Os edge of the triangular face defined by the atoms W, Os(1) and Os(2). The W—C(22) distance (2.08 Å) is slightly shorter than the Os(1)—C(22) distance (2.24 Å) and the tolyl substituent is oriented toward the bridging oxo ligand. Finally, the structurally undetermined bridging hydride ligand is proposed to be associated with the third Os—Os edge of this WOs_2 triangle. Consistent with our postulate, this metal–metal vector displays a relatively large Os(1)—Os(2) distance (2.997 Å) and possesses two enlarged Os—Os—CO angles (113–114°) and two regular Os—Os—CO angles (89–94°). The other two Os—Os distances within the molecule are slightly smaller, with Os(1)—Os(3) = 2.844(2) and Os(2)—Os(3) = 2.846(2) Å. After the position of the bridging hydride ligand is established, the formal electron counts for the W, Os(1), Os(2) and Os(3) atoms are calculated to be 17, 18.5, 19.5 and 17e^-, respectively.

The structure of **2** is different from those of the analogous hydrido-alkylidene complex **3** and the chloro-alkylidene complex **4** in terms of the location of the bridging hydride and the configuration of the bridging alkylidene ligand (Scheme 2). In complex **3**, the bridging hydride is located on the Os—Os edge eclipsed to the W—Os edge which is associated with the alkylidene fragment; therefore, the metal–metal edges supporting the bridging hydride, oxo and alkylidene ligands are aligned in a zigzag

arrangement. In contrast, the bridging chloro ligand of complex **4** is located at a position similar to that of the bridging hydride in complex **2**; therefore, the respective metal–metal edges are arranged in a triangular pattern. In addition, because the bridging chloro ligand is a three-electron-donor, the bond distance between the osmium atoms linked by chloro ligand is not in the range of a typical Os—Os single bond.

On the other hand, the α-hydrogen of the alkylidene ligand in both complexes **3** and **4** is oriented toward the bridging oxo ligand; therefore, the configuration of the bridging alkylidene (denoted as *syn*) is in contrast to that of complex **2** (denoted as *anti*). We propose that the formation of the *anti* configuration for complex **2** is due to its greater thermodynamic stability with respect to the unobserved *syn* configuration, and the latter is destabilized because of the unfavourable steric repulsion between the tolyl substituent and the Cp ligand.

EXPERIMENTAL

IR spectra were recorded using a Perkin–Elmer 580 spectrometer calibrated using the absorption of cyclohexane at 2138.5 cm^{-1} and the absorption of polystyrene film at 1944.5 cm^{-1}. Both ^1H and ^{13}C NMR spectra were recorded using a Bruker AM-400 instrument. Mass spectra were obtained on a JEOL-HX110 instrument operating in electron impact, field desorption or fast atom bombardment modes. All reactions were performed under a nitrogen atmosphere using deoxygenated solvents dried with an appropriate reagent. The progress of reactions was monitored by analytical TLC (5735 Kieselgel 60 F_{254}, E. Merck) and the products were separated on the commercially available preparative TLC plates (Kieselgel 60 F_{254}, E. Merck). The mixed-metal complexes $CpWOs_3(CO)_9(\mu_3\text{-}CTol)_2(\mu\text{-}H)$ (**1**) were prepared according to the literature method.[4]

Preparation of $CpWOs_3(CO)_9(\mu\text{-}O)(\mu\text{-}H)(\mu\text{-}CHTol)$ (**2**)

A xylene solution (45 cm^3) of $CpWOs_3(CO)_9(\mu_3\text{-}CTol)_2(\mu\text{-}H)$ (**1**) (56 mg, 0.043 mmol) was heated at reflux under 1 atm of hydrogen. After refluxing for 6 h, the solvent was evaporated *in vacuo* and the residue was separated on a preparative TLC plate (hexane–dichloromethane, 3:2), giving the alkylidene complex **2** (6 mg, 0.005 mmol, 12%) as red–orange crystals after recrystallization from dichloromethane–methanol. In addition, some starting materials (10 mg, 0.008 mmol, 18%) were also recovered from the residue of the reaction mixture.

Spectroscopic data for complex **2**. Structural determination of complex **2**

Crystals suitable for diffraction analysis were obtained from a dichloromethane–methanol solution. A crystal was mounted on a glass fibre. Diffraction measurements were carried out on a Nonius CAD-4 fully automated four-circle diffractometer. The unit cell was determined and refined using setting angles of 25 randomly selected reflections, with 2θ angles in the range of 2.5–50°, obtained by using the CAD-4 automatic search, centre, index and least-squares routines. All data reduction and structure refinement were performed using the NRCC-SDP-VAX packages. The structure was solved by the Patterson method and refined by least-squares; all non-hydrogen atoms were refined with anisotropic thermal parameters. The data collection parameters are summarized in Table 3. Tables of atomic coordinates, anisotropic thermal parameters, structure factor amplitudes, and non-essential bond distance and angle parameters have been deposited as supplementary data and are available from the authors (S.M.P.).

(*Received* 29 *March* 1990; *accepted* 26 *April* 1990)

Abstract—The syntheses of several novel diazenido-, hydrazido- and imido- complexes of technetium are described. These precursors which contain technetium–nitrogen multiple bonds are derived directly from the appropriate organohydrazine or amine in good yield. Some of the chemistry has been extended to the metastable isotope ^{99m}Tc (γ, $t_{1/2}$ = 6 h) in highly dilute aqueous media to give single species in high radiochemical purity. These preparations are applicable to the synthesis of new technetium radiopharmaceuticals and should provide for the development of a whole new range of technetium-based diagnostic agents in nuclear medicine.

The development of the basic coordination chemistry of the synthetic radioactive element technetium has undergone a revolution in recent years owing to its expanding application in the diagnostic imaging of internal organs by γ-scintillation detection.[1,2] The combination of reasonable cost, extensive availability and optimal nuclear properties makes technetium-99m the radionuclide of choice for many applications in nuclear medicine.[1,2] Typical requirements for technetium complexes to be clinically useful radiopharmaceuticals are ease of preparation (to give a single radiochemically-pure

product), stability (under biological conditions), controllable overall charge (oxidation state) and redox properties, and useful biodistribution properties.[3] The biological targeting ability of such γ-emitting technetium species depends largely on the physical or metabolic properties of its coordinated ligands, which cause the complex to locate in a particular organ after intravenous injection.[1-4] The development of new technetium chemistry and subsequently the design of new or improved radiopharmaceutical reagents therefore depends crucially on the availability of both new ligand systems and new technetium central core moieties.

The chemistry of technetium in its higher and intermediate oxidation states is dominated by its tendency to form oxo-species. Indeed, several of the currently used clinical reagents are coordination compounds of the mono-oxo- $[Tc^{V}{=}O]^{3+}$ and dioxo- $[O{=}Tc^{V}{=}O]^{+}$ cores, and these are used to image all the major organs including kidney, liver, heart and brain.

Potential alternative cores for technetium are the nitrosyl moiety $[TcNO]^{4}$ and *trans*-$[Tc^{III}Cl_2]^{+}$,[3] but these are not currently utilized in any commercial radiopharmaceuticals. Baldas and Bonnyman[5] have reported the facile synthesis of the robust nitrido-moiety [Tc≡N], and demonstrated its ability to undergo various ligand substitution reactions. However, there have been few reports of derivatives of this core of potential use as imaging agents. We report here the synthesis of several novel ^{99}Tc precursors containing Tc—N multiple bonds (Fig. 1). These include mono- and bis-diazenido-, hydrazido(2−)- and imido- species. Some of this chemistry has been successfully extended to the metastable isotope ^{99m}Tc (γ emitter = 140 keV, $t_{1/2}$ = 6 h) in highly dilute (*ca* 10^{-8} M) aqueous media to give single compounds in high radiochemical purity. These novel technetium cores with their chemically robust metal–nitrogen bonds in combination with appropriate ancillary ligands to control biological targeting characteristics offer a whole new range of possibilities for the development of technetium-based diagnostic agents.

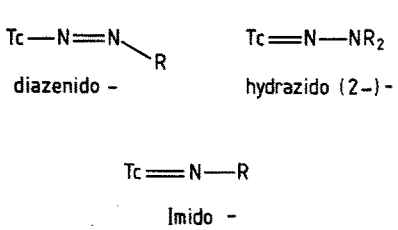

Fig. 1. New core moieties for technetium radiopharmaceuticals.

TECHNETIUM DIAZENIDO- COMPLEXES

Monosubstituted organodiazenido ligands, M—N=NR, may adopt several different bonding modes in transition metal complexes (Fig. 2).[6] The singly bent geometry (**I**) is the most common structure found. The doubly bent geometry (**II**) and bridging mode (**III**) are much less common. We have previously reported the synthesis and characteristics of the rhenium bis(diazenido)- complexes, $[ReCl(N_2Ar)_2(PPh_3)_2]$.[7] These rhenium(III) bis(diazenido)- complexes are easily protonated or alkylated at the β-nitrogen of one of the coordinated diazenido- ligands to give the rhenium(V) diazenido–hydrazido- complexes, $[ReCl_2(NNAr)(NNHAr)(PPh_3)_2]$, in quantitative yield. The complex with Ar = C_6H_5— was structurally characterized and shown to contain a linear (three-electron donor) diazenido- ligand and a bent (two-electron donor) hydrazido(2−)- ligand.[7]

Reaction of $[n\text{-}Bu_4N][TcOCl_4]$ with excess arylhydrazine and PPh_3 in alcohol gives air-stable, orange, crystalline $[TcCl(N_2Ar)_2(PPh_3)_2]$ complexes in 70–80% yield. These are entirely analogous to the rhenium complexes, $[ReCl(N_2Ar)_2(PPh_3)_2]$,[7] and HPLC analysis indicates that these technetium species form in > 95% yield in solution. They are diamagnetic five-coordinate technetium(III) d^4 compounds. The ^{31}P NMR spectrum exhibits a singlet consistent with a *trans*-arrangement of PPh_3 groups. A trigonal bipyramidal structure with *cis*-diazenido ligands in the equatorial plane is proposed by analogy with the known rhenium structure.[8] This has very recently been verified by the independent structural characterization of $[TcCl(NNC_6H_4Br)_2(PPh_3)_2]$.[9] These workers also investigated the facile protonation at N_β of these species,[9] which we demonstrated earlier for the $[ReCl(N_2Ar)_2(PPh_3)_2]$ complexes.[7] We have now shown that the chlorido and phosphine ligands may be displaced by a range

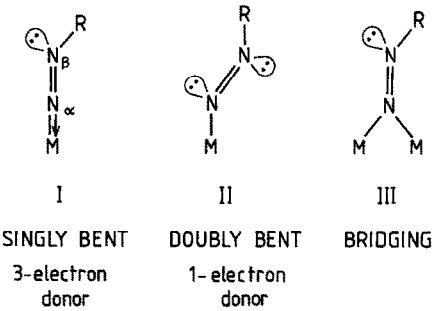

Fig. 2. Formal bonding modes for transition metal organodiazenido- complexes.

of other ligands to give new technetium(III) mono- and bis-diazenido- complexes. Indeed, subsequent reaction of $[TcCl(N_2Ar)_2(PPh_3)_2]$ with P—P (P—P = dppe, dmpe) under reflux in alcohol gives orange–yellow $[TcCl(N_2Ar)(P—P)_2]^+$ in high (70%) yield with loss of one $—N_2Ar$ ligand. HPLC analysis indicates that these species comprise > 95% of the reaction product in solution. These synthetic reactions can also be carried out directly from TcO_4^- in high yield and this chemistry has been extended to the ^{99m}Tc level. The monodiazenido- complex with Ar = C_6H_5— and P—P = dppe has been structurally characterized (Fig. 3) as its PF_6-salt.* This complex cation has slightly distorted *trans*-octahedral coordination geometry. Equatorial sites are occupied by phosphorus donor atoms of the two bidentate dppe ligands. The phenyldiazenido- and chlorido-ligands occupy the *trans*-axial sites. The diazenido-ligand is described as singly bent with an intermediate Tc—N_α—N_β angle of 162(2)° and is thus formally a three-electron donor.[6] The Tc—N bond length of 1.917(19) Å is much longer than that normally found for diazenido- complexes,[6] and may reflect the repulsive interaction with the four equatorial phosphorus atoms. This complex has the same overall structure as the isoelectronic technetium nitrosyl cation, $[TcCl(NO)(depe)_2]^+$.[10]

This behaviour of $[TcCl(N_2Ar)_2(PPh_3)_2]$ contrasts sharply with that of $[ReCl(N_2Ar)_2(PPh_3)_2]$ which reacts under similar conditions with bidentate phosphines to give the formally 20-electron rhenium(III) species $[Re(N_2Ar)_2(P—P)_2]^+$. The presence of two *trans*-diazenido-singly bent (formally three-electron donor) ligands bound to rhenium has been verified by the structural determination of the complex with Ar = $CH_3C_6H_4$— and P—P = dppe.[11]

TECHNETIUM HYDRAZIDO(2−)-COMPLEXES

1,1-Disubstituted organohydrazines (R_2NNH_2) may give rise to terminally bound hydrazido(2−)-ligands, M = NNR_2 (Fig. 4). These may also arise from the protonation or alkylation of N_β of organodiazenido- ligands.[6,12] Hydrazido(2−)- complexes are also proven intermediates in the protonation of coordinated dinitrogen to give ammonia.[13] The linear bonding mode (**IV**) M≡N—NR_2 is formally isoelectronic with the metal–oxo core, and there are

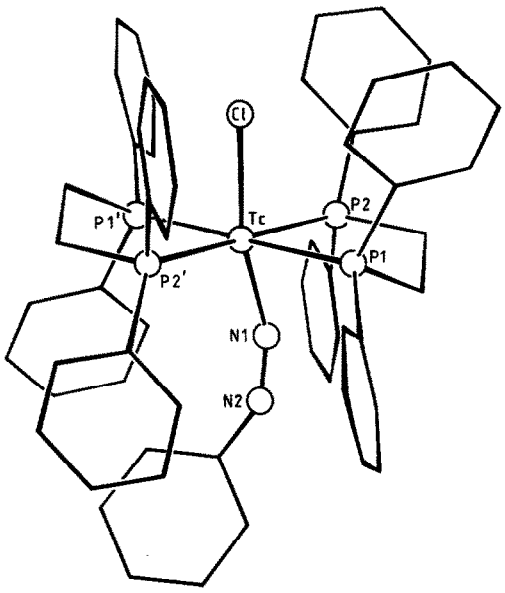

Fig. 3. Structural representation of the complex cation $[TcCl(NNC_6H_5)(dppe)_2]^+$.

many examples of essentially isostructural metal–oxo and metal–hydrazido(2−)- complexes.[14]

The addition of 1,1-disubstituted hydrazines to $[n\text{-}Bu_4N][TcOCl_4]$ in dry methanol gives a deep red solution which contains a single technetium-containing species (HPLC, β-detection). This species is tentatively presumed to be $[Tc(NNR_2)Cl_4]^-$. It is not easily characterized, but can be routinely generated *in situ* and further derivatized to give desired technetium hydrazido(2−)- products. Thus reaction of $[n\text{-}Bu_4N][TcOCl_4]$ with $MePhNNH_2$ in refluxing methanol with PPh_3 gives the technetium(V) species $[TcCl_3(NNMePh)(PPh_3)_2]$. Use of less bulky phosphines such as PMe_2Ph leads to the formation of the cationic species $[TcCl_2(NNMe$

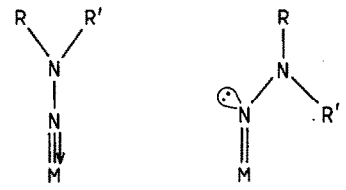

Fig. 4. Formal bonding modes of the terminally-bound hydrazido(2−)- moiety.

* Preliminary representations of all of the structures are given and full details will be reported at a later date.

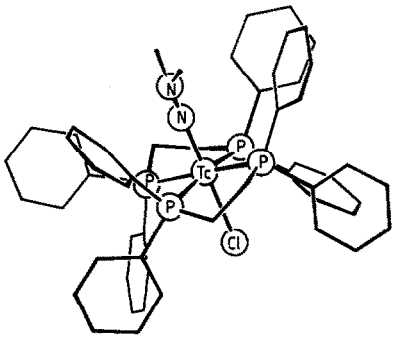

Fig. 5. Structural representation of the complex cation $[TcCl(NNMe_2)(dppe)_2]^+$.

Ph)$(PMePh)_3]^+$ in moderate yield. Excess hydrazine gives access to bis(hydrazido)- complexes believed to be analogous to the known rhenium complex $[ReCl_2(NNR_2)_2(PPh_3)]^+$.[15] Reaction of $[n\text{-}Bu_4N][TcOCl_4]$ with Me_2NNH_2 and dppe in methanol at room temperature gives good yields of the technetium(IV) cation $[TcCl(NNMe_2)(dppe)_2]^+$. This has been structurally characterized as its PF_6^- salt (Fig. 5). The synthetic chemistry is again easily extrapolated to ^{99m}Tc in high overall radiochemical purity.

Reactions of organohydrazines are notoriously dependent on reaction conditions,[6,12] and some unexpected products due to cleavage or loss of the hydrazido(2−)- moiety have been isolated. Thus, reaction of $[n\text{-}Bu_4N][TcOCl_4]$ with Me_2NNH_2 and dppe in methanol under reflux gives lower yields of the cationic $[TcCl(NNMe_2)(dppe)_2]^+$ together with a yellow neutral product, we believe to be

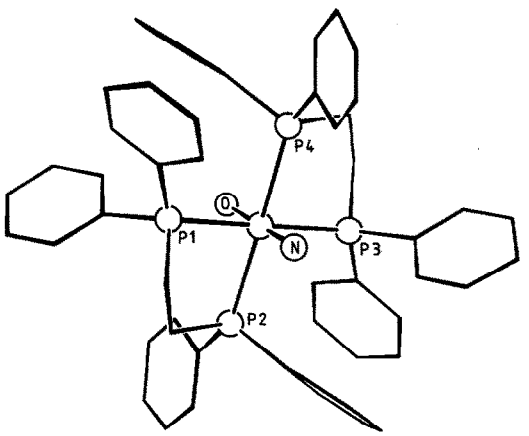

Fig. 6. Structural representation of the complex cation *trans*-$[TcO(NH)(dppe)_2]^+$.

$[TcCl(N_2)(dppe)_2]$, $\nu(N_2)$ 1980 cm^{-1}, which is not formed under argon. However, use of $MePhNNH_2$ and dppe in methanol under reflux yields *trans*-$[TcO(NH)(dppe)_2]^+$, which has the new oxo–imido-technetium(V) core moiety $[O{=}Tc^V{=}NH]^+$. This has also been confirmed by an X-ray structural analysis (Fig. 6). Although the structural data was better refined as a bis(imido)- complex $[Tc(=NH)_2]^+$, the marked asymmetry in the bonding of the two axial ligands and elemental analysis suggests that they should be assigned as oxo- and imido-, respectively.

TECHNETIUM IMIDO- COMPLEXES

The terminal imido(2−)- ligand is formally isoelectronic with the more common terminal oxo(2−)- group.[16] However, the imido- ligand is much more resistant to protic attack and rarely bridges between transition metal ions. The ligand may function formally as either a linear four-electron donor (**VI**) or as a bent two-electron donor (**VII**) where the M—N—C framework is generally about 140° and two electrons reside on the nitrogen (Fig. 7).[16] The R group is easily varied and derivatives with alkyl[12] and aryl[12] —COPh[17] and —SO_2Ph[18] are known. In the special case where R = NR_2' a dialkylamide, the ligand is more commonly named hydrazido(2−)-.

Reaction of $[n\text{-}Bu_4N][TcOX_4]$ (X = Cl, Br) with excess ArNCO in refluxing dry toluene under nitrogen gives $[Tc(NAr)X_4]^-$ as diamagnetic blue–black solids in virtually quantitative yield. These anionic technetium(V) complexes are quite sensitive to adventitious moisture but are useful starting materials for the preparation of a whole range of technetium(V) imido- species. The $[Tc(NAr)X_4]^-$ complexes contain the new core moiety $[Tc^V{=}NAr]^{3+}$, making $[Tc(NAr)X_4]^-$ a 16-electron species in which the imido- ligand functions as a linear four-electron donor.

In efforts to derive preparative routes more applicable for radiopharmaceutical synthesis, $[n\text{-}Bu_4N][TcOCl_4]$ was reacted with aromatic amines

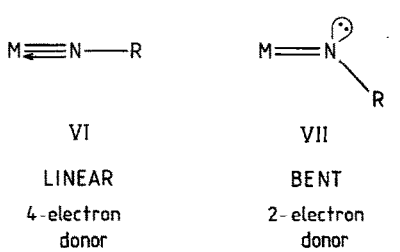

Fig. 7. Bonding modes of the imido(2−)- ligand

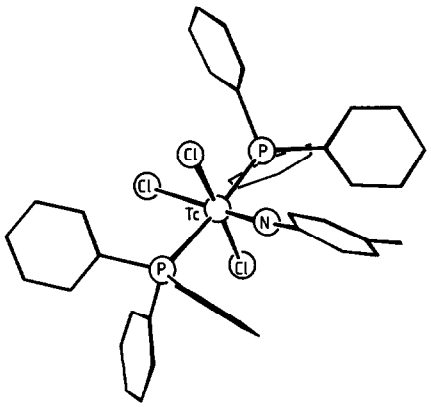

Fig. 8. Structural representation of $[TcCl_3(Ntol)(PPh_3)_2]$.

and PPh_3 in alcohols to give the neutral green–brown $[TcCl_3(NAr)(PPh_3)_2]$ complexes which are directly analogous to the known rhenium complexes $[ReCl_3(NAr)(PPh_3)_2]$.[19] These air-stable technetium(V) compounds are diamagnetic solids which exhibit a singlet in the ^{31}P NMR spectrum indicating two *trans*-PPh_3 groups. They are more stable than the $[Tc(NAr)X_4]^-$ species and consequently are superior starting materials for the preparation of a range of technetium imido- complexes. The derivative with $Ar = CH_3C_6H_4$— has been structurally characterized (Fig. 8), and is pseudo-octahedral with two *trans*-PPh_3 groups. The tolyl-imido- ligand is essentially linear with a Tc—N—C angle of 168° and a Tc—N distance of 1.7 Å, characteristic of a metal–nitrogen multiple bond. The imido- ligand is therefore functioning as a four-electron donor giving the technetium complex an overall 18-electron valence configuration. The analogous technetium oxo- complex is not known due to facile oxygen atom abstraction and reduction in the presence of monodentate tertiary phosphines.

Reaction of $[n\text{-}Bu_4N][TcOCl_4]$ with aromatic amines and dppe in refluxing alcohols gives cationic, purple technetium(IV) complexes, $[TcCl(NAr)(dppe)_2]^+$, in good yield. These air-stable complexes exhibit no ν(NH) and show broadened NMR spectra characteristic of paramagnetic metal centres. They are formally analogous to the structurally characterized technetium(IV) hydrazido (2−)- complex $[TcCl(NNMe_2)(dppe)_2]^+$ (Fig. 5).

Related technetium alkyl imido- complexes may be synthesized using phosphinimines,[17] alkylamines[20] and symmetrically substituted dialkyl hydrazines,[21] and these investigations will be reported at a later date.

CONCLUSION

We have described the synthesis and characterization of some novel technetium diazenido-, hydrazido- and imido- complexes derived directly from the appropriate organohydrazine or amine in good yield, and successfully extrapolatd the chemistry to the ^{99m}Tc level in some cases. These preparations are extremely applicable to the synthesis of new technetium radiopharmaceuticals.

Unlike previous core moieties these multiply-bonded nitrogenous ligands may carry a wide variety of different substituents attached to the nitrogen. This allows the coordination properties of these geometrically versatile ligands to be very effectively varied and also permits the complexes to be easily functionalized for suitable attachment to biological materials. We have as yet only directed the synthetic work of the new technetium cores to the generation of cationic species for possible use as potential myocardial imaging agents. However, the further substitution chemistry of these new cores will be reported at a later date. This work has been the subject of a recent patent application.[22]

1. INTRODUCTION

This article is not a comprehensive review of CO substitution of metal carbonyls, it is instead a report of research carried out in our laboratory on this topic during the past 34 years. However, reference will be made to articles that relate to our research. Furthermore, excellent review articles[1] and chapters in books[2] provide more detailed treatments of ligand substitution reactions of transition metal organometallic compounds.

When I arrived at Northwestern University, September 1946, I wanted to initiate a research programme on the kinetics and mechanisms of ligand substitution in octahedral and in square-planar metal complexes. The place to start seemed to be with Werner complexes of cobalt(III) and of platinum(II), respectively. At this time, physical organic chemists were investigating tetrahedral substitution, and they had arrived at the now well-known S_N1 and S_N2 mechanisms. It appeared that a similar kinetic and stereochemical approach could be used to obtain the mechanisms of octahedral and of square-planar substitutions.[3a] Thanks to the good work of our students and postdoctorates in inorganic chemistry, and to the collaboration with my colleague Ralph G. Pearson, some of the seminal research in this area was accomplished. Much of the work was discussed in 1958 in the book entitled *Mechanisms of Inorganic Reactions*.[3b]

In May 1955 at the *III International Conference on Coordination Chemistry*, a plenary lecture was given by the late Professor Walter Hieber, whom some of us consider to be the "father" of metal carbonyl chemistry. In response to a question as to the mechanisms of some of the reactions presented, he said almost nothing was known about the mechanisms. I immediately felt that the on-going research in our laboratory on the kinetics and mechanisms of ligand substitution reactions of metal amine complexes could be extended to metal carbonyls. This seemed like a golden opportunity for graduate students, because any kinetic study of CO substitution reactions of metal carbonyls would be new and readily lead to an acceptable doctorate thesis and to original scientific publications. In spite of this our students at first were somewhat hesitant to tackle a problem that involved compounds and experimental conditions foreign to our research group. Also recall that in the mid 50s there was little interest in the chemistry of metal carbonyls, and the designation of transition metal organometallic chemistry as an important area of chemistry had yet to be realized.

This article presents an overview of the saga of our investigations on CO substitution reactions of metal carbonyls.

2. BINARY METAL CARBONYLS

Research in our laboratory started with a study of the kinetics and mechanisms of CO exchange with well-known binary metal carbonyls. Initially it was decided to investigate metal carbonyls having different coordination numbers [$Ni(CO)_4$, $Fe(CO)_5$ and $Cr(CO)_6$], and systems with bridging and terminal COs [$Co_2(CO)_8$]. Since ^{13}C NMR was not then in use, it was decided to use ^{14}CO and follow the rates of CO exchange by monitoring changes in radioactivity of CO in the gas phase as it was being circulated through a solution of the metal carbonyl.[4a] This experimental method was later found[4b] to be flawed, particularly for studies on volatile metal carbonyls. Similar studies had been reported[5] earlier showing a wide range of rates of CO exchange with metal carbonyls, e.g. half-lives of exchange at room temperature are minutes for $Ni(CO)_4$ and years for $Fe(CO)_5$. However, this kinetic study did not investigate the mechanisms of CO exchange. Rates of CO exchange or replacement by a dissociative mechanism of some of the more common binary metal carbonyls are given in Table 1.

2.1. *Four-coordinate complexes*

Monomeric binary metal carbonyls are now known to generally react by a dissociative mechanism [eq. (1)]:

$$\underset{\text{18-electron}}{M(CO)_n} \xrightarrow[\text{Slow}]{-CO} \underset{\text{16-electron}}{M(CO)_{n-1}} \xrightarrow[\text{Fast}]{+L} \underset{\text{18-electron}}{M(CO)_{n-1}L}. \qquad (1)$$

Table 1. Dissociation rate constants (k_1) for CO substitution of some binary metal carbonyls

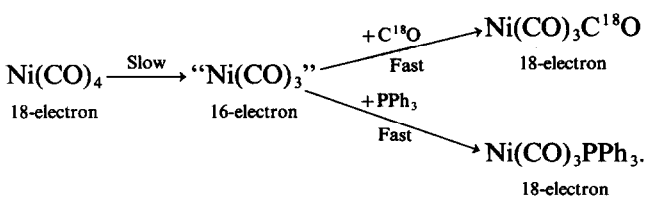
Carbonyl	Temperature (°C)	k (s^{-1})	Reference
$Ni(CO)_4$	10	1.2×10^{-3}	4b
$Fe(CO)_5$	50	6×10^{-11}	6
$Ru(CO)_5$	50	3.0×10^{-3}	7
$Os(CO)_5$	50	4.9×10^{-8}	6
$Cr(CO)_6$	131	1.4×10^{-4}	8
$Mo(CO)_6$	112	2.1×10^{-4}	8
$W(CO)_6$	166	1.1×10^{-4}	8
$Mn_2(CO)_{10}$	25	10 years[a]	5
$Fe_3(CO)_{12}$	50	9.8×10^{-4}	9
$Ru_3(CO)_{12}$	50	1.0×10^{-4}	9
$Os_3(CO)_{12}$	50	1.0×10^{-8}	9
$Co_2(CO)_8$	0	1.5×10^{-3}	4a
$V(CO)_6$	10	7 h[a]	10
$[V(CO)_6]^-$	80	N.R.[b]	11
$[Mn(CO)_5]^-$	40	N.R.[c]	12
$[Mn(CO)_6]^+$	30	N.R.[c]	12

[a] Values in h and years are for half-lives of CO exchange. $V(CO)_6$ (17-electron) reacts very fast with good nucleophiles by an associative mechanism.[13]

[b] No reaction in molten PPh_3.

[c] No CO exchange in one day.

This behaviour is readily understood in terms of the 16,18-electron rule,[14] which suggests that an associative mechanism is not involved because it requires the formation of a 20-electron transition state or intermediate instead of the more stable 16-electron system formed in a dissociative pathway. Yet a decade prior to the 16,18-electron rule the first study of ^{14}CO exchange with $Ni(CO)_4$ gave results that were not expected. Since $Ni(CO)_4$ has a low coordination number for nickel, it was felt that its coordination number could easily increase and allow for an associative mechanism. What was found[4a] is that the rate of exchange is first-order in $Ni(CO)_4$ and zero-order in CO concentrations, indicating a dissociative pathway. The result was explained in terms of the filled *d*, *s* and *p* orbitals of nickel leaving no empty low-energy metal orbital to accept a pair of electrons from the entering nucleophile (today expressed as an 18-electron system not adding a pair of electrons to form an unstable 20-electron species). It later became necessary to repeat these experiments in order to obtain correct kinetic data, but the rate law did not change. The later experiments[4b] involved monitoring the exchange of $C^{18}O$ with $Ni(CO)_4$ by following changes in the CO stretching region of the IR. Temperature dependence studies gave large values of $\Delta H^{\ddagger}$ (24 kcal mol^{-1}) and positive values of $\Delta S^{\ddagger}$ (+12 eu), both of which are indicative of a dissociative mechanism. This mechanism requires that in a competition experiment of different nucleophiles for the active intermediate "$Ni(CO)_3$", the sum of the rates of formation of the different products equals the rate of dissociation of $Ni(CO)_4$. This was tested[4b] by competing $C^{18}O$ against PPh_3, and it was found to be true [eq. (2)]:



(2)

The results showed that PPh_3 is five times a better nucleophile towards "$Ni(CO)_3$" than is CO. In fact it is now recognized that CO is a poor nucleophile, compared to phosphines and phosphites often used in CO substitution reactions of metal carbonyls.

Gray and Wojcicki,[15] with assistance from Angelici, when graduate students in Pearson and my research group and without our knowledge, investigated the ligand exchange of all three of the ligands in $Rh(CO)Cl(PPh_3)_2$. They observed that in individual experiments all three of the ligands exchange rapidly with the free labelled ligands, presumably by an associative process [eq. (3)]:

$$\underset{\text{16-electron}}{Rh(CO)Cl(PPh_3)_2} \xrightarrow[k_2]{+{}^{14}CO} \text{“}\underset{\text{18-electron}}{Rh(CO)({}^{14}CO)Cl(PPh_3)_2}\text{”} \xrightarrow[\text{Fast}]{-CO} \underset{\text{16-electron}}{Rh({}^{14}CO)Cl(PPh_3)_2}. \qquad (3)$$

This result was expected because the filled dps^2 hybrid orbitals on rhodium(I) leave a vacant low-energy p orbital to accept a pair of electrons from the entering nucleophile, similar to the then well-known S_N2 reactions of platinum(II) complexes.[3b]

2.2. *Five-coordinate complexes*

Binary metal carbonyls of the iron triad of transition metals are five-coordinate $M(CO)_5$ (M = Fe, Ru, Os). Metal carbonyls [$Ni(CO)_4$ and $Fe(CO)_5$] were discovered a century ago this year by Mond and co-workers.[16] Kept in the dark at room temperature $Fe(CO)_5$ is stable and its many different reactions have been extensively investigated.[17] Yet there has not been a detailed kinetic study of CO substitution of $Fe(CO)_5$, because of its extremely slow thermal reaction which would require high temperatures where it is both volatile and unstable. One attempt made at such a study allows an estimate of a 4 year[5] half-life for CO exchange at 25°C with $Fe(CO)_5$. Another attempt[18] suggests that CO substitution with phosphines proceeds by a dissociation mechanism, as was shown for the reaction of $Fe(CO)_4PPh_3$ with PPh_3 to form $Fe(CO)_3(PPh_3)_2$. Assuming that the difference in rates of CO substitution between $Fe(CO)_5$ and $Fe(CO)_4PPh_3$ is about the same as that between $Ru(CO)_5$[7] and $Ru(CO)_4PPh_3$,[19] then one can approximate a rate for $Fe(CO)_5$[6] (Table 1). The anomalously slow rate of reaction of the iron compound compared to the other members of its triad is briefly discussed at the end of this section.

Wilkinson and co-workers[20] reported that strong acids protonate some metals of organometallic compounds, and for some metal carbonyls the C—O stretching frequency may increase by as much as 140 cm^{-1} on protonation. This increase in ν(CO) suggests a decrease in metal-to-carbon π-bonding, and a weaker M—CO bond. We immediately wanted to test this hypothesis by investigating the exchange of ^{14}CO with $Fe(CO)_5$ in the presence of a strong protonic acid. Much to our satisfaction it was found[21] that CO exchange is extremely fast in the presence of added CF_3COOH (at -21°C $t_{1/2} = 20$ min, compared with $t_{1/2} = 4$ years at 25°C without added acid[5]). The kinetic results were explained on the basis of a rapid acid–base pre-equilibrium followed by the rate-determining dissociation of the protonated substitution labile intermediate (a S_N1CA mechanism or an S_N1 reaction of the conjugate acid) [eq. (4)]:

$$Fe(CO)_5 \underset{\text{Fast}}{\overset{+H^+}{\rightleftharpoons}} [HFe(CO)_5]^+ \xrightarrow[k_1]{-CO} \text{“}[HFe(CO)_4]^+\text{”} \xrightarrow[\text{Fast}]{+CO} Fe(CO)_5 + H^+. \qquad (4)$$

Years later it was suggested[22] that the tremendous increase in rate of CO exchange may be caused by the formation of substitution labile iron carbonyl radicals. Further study is needed to clarify the supposition of a radical chain reaction. Also, it should be of interest to attempt the use of Lewis acids as catalysts for CO exchange with certain other metal carbonyls. For example, Lewis acids are known to interact with the CO oxygen,[23] M—CO—BF_3, of certain metal carbonyls, and to enhance rates of alkyl migration onto a carbonyl carbon[24] (see Section 7).

The pentacarbonyls of the other members of the iron triad, $M(CO)_5$ (M = Ru, Os), are not stable relative to their respective trimeric clusters, $M_3(CO)_{12}$ (M = Ru, Os). However, photolysis of solutions of the trimeric clusters does afford the pentacarbonyls,[25] and the CO substitution reactions of both have recently been studied [eq. (5)]:

$$M(CO)_5 + L \xrightarrow{k_1} M(CO)_4L + CO. \qquad (5)$$
$$[M = Ru, Os;\ L = PR_3, P(OR)_3]$$

In both cases, as with $Fe(CO)_5$, the reactions involve a dissociative mechanism. The rate of reaction of $Ru(CO)_5$[7] is 10^5 times faster than that of $Os(CO)_5$[6] (Table 1). It is generally expected that the 2nd row metal of a given transition metal triad will react faster than the corresponding 3rd row metal complex (see Section 5). What is anomalous is that $Fe(CO)_5$ reacts 10^8 times slower than $Ru(CO)_5$, resulting in relative estimated rates in the order Fe <<< Ru >> Os.

The extreme slowness of CO substitution of $Fe(CO)_5$ compared with the other members of its triad may be due to its transition state/active intermediate, "$Fe(CO)_4$", being high-spin[26] while the other tetracarbonyls are low-spin.[27] Thus a partial explanation of the very slow rate of CO substitution of $Fe(CO)_5$ may be the much less favourable crystal-field activation energy (CFAE)[28] in going from low-spin $Fe(CO)_5$ to high-spin "$Fe(CO)_4$" relative to the CFAE in going from low-spin $M(CO)_5$ (M = Ru, Os) to low-spin "$M(CO)_4$". The electron spin change for $Fe(CO)_5$ corresponds to a spin-forbidden process, whereas for $M(CO)_5$ with no spin change, reaction takes place by a spin-allowed process.

2.3. *Six-coordinate complexes*

Independent studies at the same time were under way by the Italians[29] on the gas-phase CO exchange with $M(CO)_6$ (M = Cr, Mo, W), which they found to proceed by a dissociative pathway. This result was expected because studies of ligand substitution of cobalt(III) complexes[3b] had taught us that six-coordinate metal complexes generally react by predominantly a dissociative pathway. Furthermore, since the low-energy metal orbitals (*d*, *s* and *p*) are filled with electrons, there is no energetically favourable way to accommodate a pair of electrons that must attack the metal in an associative process. Today the 16,18-electron rule[14] makes it easier to say the same thing, by stating that a more stable 16-electron transition state (S_N1) is favoured over a 20-electron transition state (S_N2).

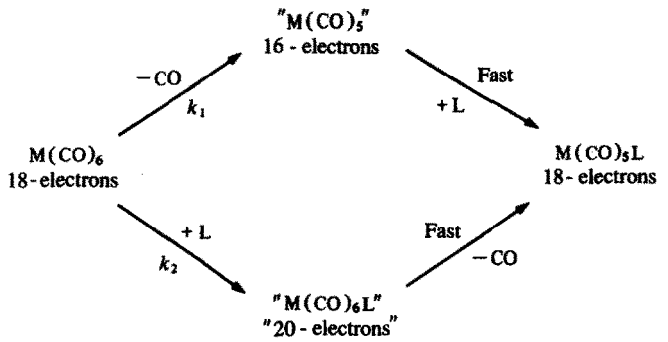
Graham and Angelici[8] (Table 1) investigated the CO substitution reactions [eq. (6)]:

$$M(CO)_6 + L \longrightarrow M(CO)_5L + CO \tag{6}$$

of $M(CO)_6$ (Cr, Mo, W) with various nucleophiles and found the reactions involve a two-term rate law [eq. (7)]:

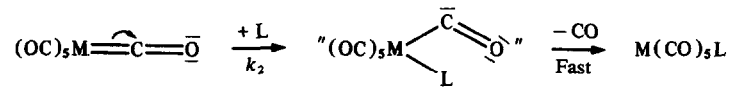
$$\text{Rate} = (k_1 + k_2[L])[M(CO)_6]. \tag{7}$$

This rate law suggests a competitive dual pathway reaction, that by k_1 which is zero-order in nucleophile is S_N1 and that by k_2 which depends on the nucleophile is S_N2. The parallel reactions are illustrated by eq. (8):



(8)

The dissociative pathway via a 16-electron intermediate is consistent with the 16,18-electron rule, but not so the associative pathway involving a 20-electron intermediate. However, it has been suggested[30] that the associative pathway can maintain an 18-electron count providing that a pair of electrons are localized on the carbonyl ligands in order to empty a low-energy metal orbital for attack by the entering nucleophile [eq. (9)] (see Section 3).



(9)

Investigations in our laboratory on six-coordinate metal carbonyls were carried out largely on CO substitution reactions of $Mn(CO)_5X$ (X = Cl, Br, I). Initial studies[31] involved rates of ^{14}CO exchange with $Mn(CO)_5X$, which showed the exchanges are S_N1 and the rates decrease in the order Cl > Br > I. It also appeared that the four radial COs exchange more readily than does the axial CO. This seemed reasonable at the time, because the axial Mn—CO bond is stronger than that with the radial COs. This difference in bond strength results from the axial CO being more strongly π-bonded due to its having to compete for such bonding with the poorer π-bonding *trans*-halogeno ligand, whereas the radial COs must compete with the strong π-acid CO in the *trans* positions. The result was further believable at the time, since the fluxional nature of organometallic compounds had not yet been discovered.[32] Had this been known, it would have suggested the five-coordinate intermediates "$Mn(CO)_4X$" are fluxional, thus rendering all COs equivalent in any slow ^{14}CO exchange process.

Unfortunately, as with our initial $Ni(CO)_4$ report,[4] the experiments of ^{14}CO exchanges with $Mn(CO)_5X$ were flawed. The saga of what followed is a long one and it will not be discussed in detail here, but relevant references are cited for the interested reader. This exchange was re-examined in three different laboratories using ^{13}CO or $C^{18}O$ and following the exchange with IR.[33] In all three cases, the IR studies show that the CO label is incorporated into both the axial and radial positions of $Mn(CO)_5X$. The most recent publications[34,35] on this subject deal with the principle of microscopic reversibility as applied to the kinetics and stereochemistry of the CO exchange. The challenge[34] that one of the proposed mechanisms could not be correct, because it was contrary to the law of microscopic reversibility, was based on our initial incorrect ^{14}CO exchange study. The reply by Brown[35] states "The application of ^{14}CO methods to the study of metal carbonyl reactions represented a pioneering foray into an important and previously unexplored area of organometallic chemistry.[36] However, the accuracy and degree of explicitness with which the incorporation of label can be discerned with use of IR methods that came later are far greater than can be achieved with the radiolabelling methods". Thus, hopefully ends the saga of CO exchange with $Mn(CO)_5X$.

Early kinetic studies[37] on the substitution of CO in $Mn(CO)_5X$ by various nucleophiles [eq. (10)]:

$$Mn(CO)_5X + L \longrightarrow \textit{cis}\text{-}Mn(CO)_4XL + CO \qquad (10)$$

(X = Cl, Br, I; L = phosphines and phosphites)

gave a first-order rate law, dependent only on the substrate concentration. It was suggested that the dissociative pathway involves the loss of a radial CO with the formation of a tetragonal pyramid intermediate, "$Mn(CO)_4X$", and addition of the entering nucleophile to afford *cis*-$Mn(CO)_4XL$. Now that we realize the intermediate is fluxional and could lead to either a *cis* or *trans* product or a mixture of the two, it appears the *cis*-isomer is formed because it permits the maximum amount of back π-bonding to the two COs *trans* to ligands X and L. It was further noted that the rates of substitution for $Mn(CO)_5X$ decrease in the order Cl > Br > I. This is also the order of decreasing C—O stretching frequency of the more intense IR band of the four radial COs, e.g. Cl, 2070; Br, 2064; I, 2056 cm^{-1}. The lowest frequency for the iodo compound suggests more π-bonding giving the strongest Mn—CO bond thus the slowest dissociation rate. This is understandable because the iodo ligand is the least electronegative and most polarizable, thus its manganese has the highest electron density and the greatest tendency to back π-bond to CO.

It was suggested[37] that the radial COs are more substitution labile than the axial CO in $Mn(CO)_5X$, because in the ground state the CO *trans* to X is more strongly π-bonded to Mn than are the COs *cis* to X. Later the difference in reactivity was explained in terms of *cis*-labilization[38] of COs in metal carbonyls *cis* to some other ligand. For example, CO substitution of $Mn(CO)_5X$ is faster than that of $[Mn(CO)_6]^+$, and $Cr(CO)_5L$ or $[Cr(CO)_5X]^-$ complexes react faster than $Cr(CO)_6$. The *cis*-labilization is attributed to a stabilization of the transition state for reaction, because in several cases X-ray structures show a shortening of the *cis*-M—CO bond in the ground state which then is less prone to M—CO bond rupture causing a slower rate of dissociation.

Rates of CO substitution of the monosubstituted compounds *cis*-$Mn(CO)_4LX$ were also found[39] to proceed by a dissociation mechanism, and for a given X the rates decrease with changes in L in the order: $PPh_3 > AsPh_3 > P(n\text{-}Bu)_3 \sim PPh_2Cl > P(OPh)_3 \sim SbPh_3 > PPhCl_2$ $P(O—n\text{-}Bu)_3 > P(OCH_2)_3CCH_3$. The results were interpreted loosely in terms of the well-known[3b] steric acceleration of dissociative reactions, where the driving force is a lowering of steric strain by decreasing the coordination number of the metal with the formation of the transition state. However, in this system there is, at best, only a rough qualitative correlation with the cone angle.[40] It was further observed[41] that *fac*-$Mn(CO)_3L_2X$ isomerizes to the *mer*-isomer [eq. (11)]:

Facial Meridional (11)

by an intermolecular mechanism involving the dissociation and re-entry of ligand L. The *fac*-isomer is expected to be electronically the more stable, because the three COs achieve their maximum π-bonding being *trans* to other less π-bonding ligands. Isomerization to the *mer*-isomer is driven by the bulkiness of L, as shown by steric acceleration of the rates of isomerization.

Finally, perhaps the first time a point was made of a correlation between the rates of dissociative CO exchange or substitution of metal carbonyls and their C—O stretching frequencies (Fig. 1) was in an article[42] dealing with ^{14}CO exchange with $Rh(PPh_3)_2COCl_3$. Ligand substitutions of all the six-coordinate complexes in Fig. 1 take place by M—CO bond rupture, and the one with the strongest bond is the slowest to react. This is also the one with the largest amount of π-bonding which means a lower C—O stretching frequency. One must note that this correlation does not apply if the mechanisms of CO substitution differ. For example, ^{14}CO exchange with $Rh(PPh_3)_2COCl$[15] is much faster than it is with $Rh(PPh_3)_2COCl_3$,[42] although the values of ν(CO) indicate that the bond of Rh^{I}—CO (ν(CO) = 1981 cm^{-1}) is stronger than that of Rh^{III}—CO (ν(CO) = 2108 cm^{-1}). This is understood, because the two substitution processes differ with bond breaking assisted by bond making (S_N2) involved for the rhodium(I) complex and only bond breaking (S_N1) for the rhodium(III) complex.

2.4. *Metal carbonyl clusters*

The earliest kinetic study of polymetal carbonyls was carried out on the dinuclear compounds $Co_2(CO)_8$ and on $Mn_2(CO)_{10}$. The two compounds represent two metal–metal bonded structures,

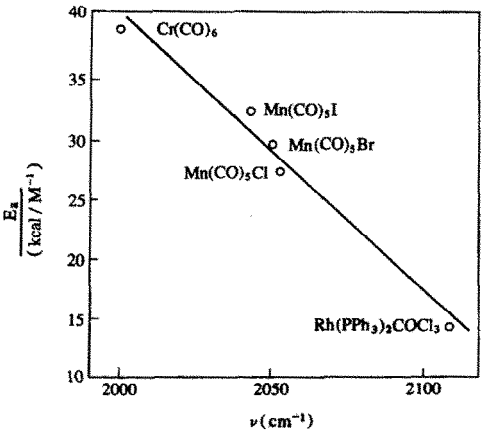


Fig. 1. The activation energies for the replacement of CO from metal carbonyls vs the C—O stretching frequencies.

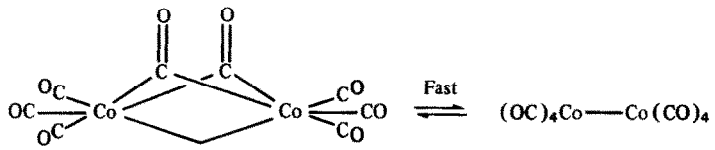
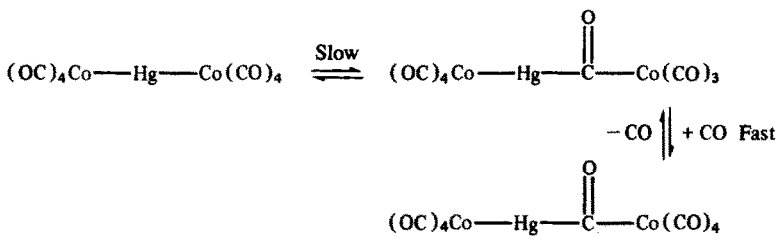
one with (Co)[43] and one without (Mn)[44] bridging carbonyls. Early kinetic studies[4a] of ^{14}CO exchange with $Co_2(CO)_8$ was carried out with the specific goal of seeing if the two bridging COs exchange at a different rate from the six terminal COs. Much time and effort was spent in an attempt to detect a difference, but what was found is that exchange is rapid and all eight of the COs exchange at the same rate. The futility of these experiments was recognized 2 years later when it was reported[45] that in solution $Co_2(CO)_8$ rapidly equilibrates [eq. (12)]:



(12)

Soon afterwards the fluxional nature[32] of organometallic compounds was recognized, which further suggests that all eight COs rapidly scramble and are equivalent in solution on the time scale of exchange with ^{14}CO.

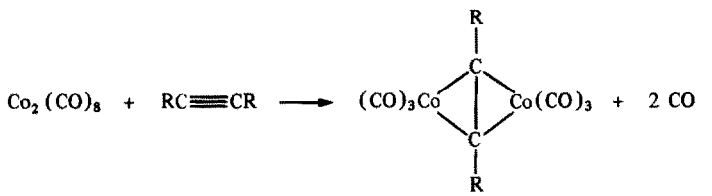
Somewhat related to the structure $(OC)_4Co—Co(CO)_4$ is the structure $(OC)_4Co—Hg—Co(CO)_4$,[46] and its exchange[47] with ^{14}CO is also rapid and proceeds by a first-order rate law dependent only on substrate concentration. One of the mechanisms suggested for CO exchange is represented by [eq. (13)]:



(13)

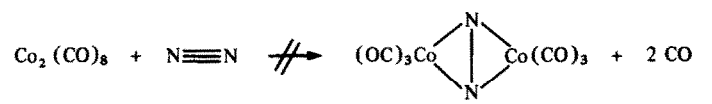
In this process, the rate-determining step involves CO insertion[48] (or ligand migration[49]) followed by the rapid addition and scrambling of CO. Studied[47] in less detail was the exchange of ^{14}CO with other heterometal–metal bonded carbonyls: $Cd[Co(CO)_4]_2$, $(CH_3)_3SnCo(CO)_4$, $(C_6H_5)_3SnCo(CO)_4$, $Ph_3PAuCo(CO)_4$ and $Ph_3PAuMn(CO)_5$. In all cases CO exchange was rapid at room temperature and below.

One other CO substitution of $Co_2(CO)_8$ was attempted in our laboratory, but unfortunately it did not work. The replacement of two COs by acetylenes had been reported[50] [eq. (14)]:



(14)

so it was decided to try using N_2 which is also triply bonded. This did not work [eq. (15)]:



(15)

and the behaviour of N_2 as a ligand in $[Ru(NH_3)_5N_2]^{2+}$ was left for Allen and Senoff[51] to discover 5 years later.

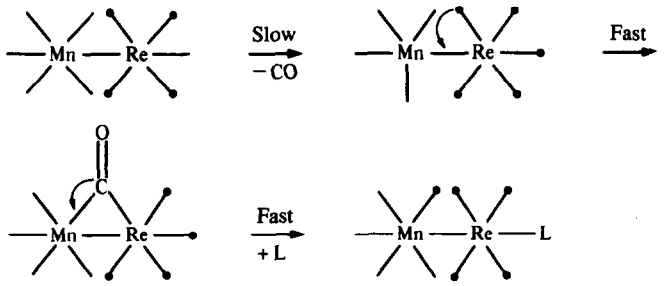
Our early investigation[52] of the kinetics of CO replacement in $Mn_2(CO)_{10}$ by various nucleophiles

in *p*-xylene solutions at 100–120°C was interpreted in terms of a simple S_N1 process [eq. (16)]:

$$Mn_2(CO)_{10} \xrightarrow[-CO]{\text{Slow}} \text{“}Mn_2(CO)_9\text{”} \xrightarrow[+L]{\text{Fast}} Mn_2(CO)_9L. \tag{16}$$

The reactions were first-order in $Mn_2(CO)_{10}$ and zero-order in nucleophile concentrations. In further support of a dissociative mechanism was the large enthalpy ($\Delta H^{\ddagger} = 37$ kcal mol^{-1}) and positive entropy ($\Delta S^{\ddagger} = +20$ eu) of activation, along with a retardation of the reaction rate with added CO.

What followed was a series of articles[53] on the kinetics of the thermal CO substitution reactions of $Mn_2(CO)_{10}$, $Re_2(CO)_{10}$ and $MnRe(CO)_{10}$, which were interpreted to take place with the rate-determining step being metal–metal bond cleavage. The substitution labile metal carbonyl radicals, $^{\cdot}M(CO)_5$ formed, would then rapidly react to give $^{\cdot}M(CO)_4L$ and rapidly recouple to form the product $M_2(CO)_9L$. This mechanism was first challenged in a report[54] on the kinetic study of CO substitution of $MnRe(CO)_{10}$. The conclusion reached in this paper was that dissociation of a Mn—CO is rate-determining, although the monosubstituted product has the entering ligand on rhenium [eq. (17)]:



(17)

This mechanism suggests the metal–metal bond rupture mechanism is incorrect.

Although one can never prove a mechanism is correct, it is possible to prove a mechanism is wrong. For example, the metal–metal bond cleavage mechanism proposed for CO substitution of $M_2(CO)_{10}$ carbonyls requires the formation of metal carbonyl radicals, $^{\cdot}M(CO)_5$, and their recoupling to form crossover products [eq. (18)]:

$$Re_2(CO)_{10} + Mn_2(CO)_{10} \not\longrightarrow 2MnRe(CO)_{10}. \tag{18}$$

Crossover experiments,[55] at reaction conditions where six half-lives of the reaction of $Re_2(CO)_{10}$ with PPh_3 to form $Re_2(CO)_9PPh_3$, would take place, showed no heterodimetal product in solutions containing equivalent amounts of the homodimetal decacarbonyls. Since no crossover resulted, this proves that the metal–metal bond cleavage is not correct. This thermal process contrasts with the photochemical cross-coupling reaction between $Mn_2(CO)_{10}$ and $Re_2(CO)_{10}$, which produces metal–metal bond homolysis and generates $MnRe(CO)_{10}$ in high yield.[56]

Muetterties and co-workers,[57] a year later, reported the elegant experiments using isotopic labelling to determine if crossover takes place with $Re_2(CO)_{10}$ and with $Mn_2(CO)_{10}$ at conditions known to yield monosubstituted phosphine products. Their results showed no crossover [eqs (19) and (20)]:

$$^{185}Re_2(CO)_{10} + {}^{187}Re_2(CO)_{10} \not\longrightarrow 2\,^{185}Re\,^{187}Re(CO)_{10} \tag{19}$$

$$Mn_2(CO)_{10} + Mn(^{13}CO)_{10} \not\longrightarrow Mn_2(CO)_5(^{13}CO)_5, \tag{20}$$

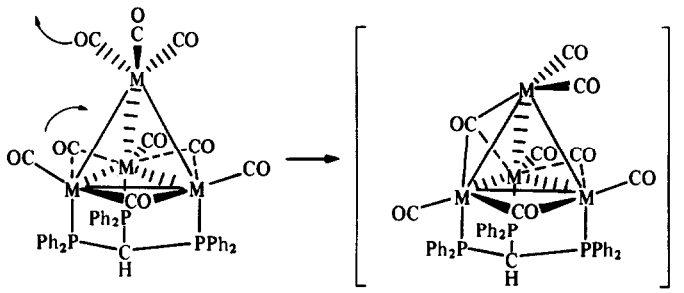
and they state “our results confirm the original Wawersik and Basolo[52] mechanistic proposal for $Mn_2(CO)_{10}$ ligand-substitution reactions”. The dissociative mechanism may further involve the intermediate formation of a $\underset{M—C—M}{\overset{O}{\|}}$ bridged species.[54] That such a CO bridged intermediate may form is supported by the observation[58] that solutions of $(OC)_5Mn—Re(^{13}CO)_5$ undergo CO migration between metals to give initially $(OC)_4(O^{13}C)Mn—Re(^{13}CO)_4(CO)$.

The kinetics and mechanisms of thermal CO substitution of metal carbonyl clusters have been the subject of detailed studies, mostly by Poë and co-workers.[59] Such studies are more complicated

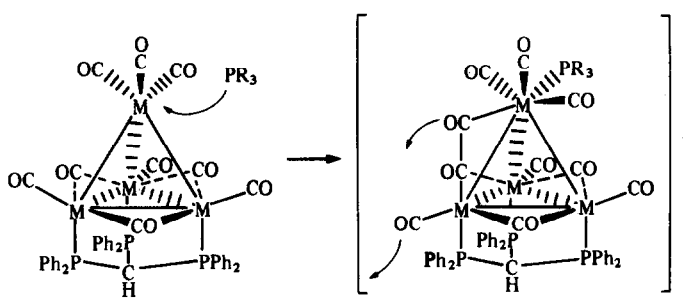
for metal clusters, which may fragment during substitution reactions, than with mononuclear or binuclear metal carbonyls. For this reason, it is also often not clear in using metal carbonyls as homogeneous catalysts[60] if the cluster or one of its fragmentation species is the catalyst. One attempt to avoid competing fragmentation reactions is to use the tripod ligand $HC(PPh_2)_3$ to stabilize clusters such as $M_4(CO)_9[HC(PPh_2)_3]$ (M = Co, Rh, Ir).[61] The initial study[62] of ^{13}CO exchange with $Co_4(CO)_9$(tripod) focused on the dissociative loss of CO in the cluster, our investigation[63a] extended this to CO substitution by phosphines and phosphites and to the corresponding rhodium and iridium clusters. Reactions of the clusters follow the two-term rate law [eq. (21)]:

$$\text{Rate} = (k_1 + k_2[\text{L}])[\text{M}_4(\text{CO})_9(\text{tripod})], \tag{21}$$

where k_1 and k_2 are dissociative and associative pathways, respectively. These assignments are further supported by the values of enthalpies and entropies of activation. Since the entering nucleophile is on the apical metal in the reaction products, it is possible to speculate as to the formations and structures of the dissociative [eq. (22)] and associative [eq. (23)] intermediates:



(22)



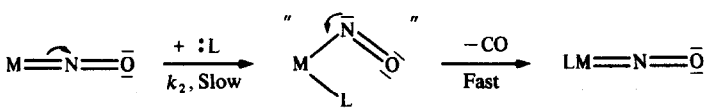
(23)

Perhaps the most notable chemical feature of this study is the exceptional reactivity of the rhodium cluster, whose substitution reactions proceed within seconds at room temperature (see Section 5). Similarly, studies on $M_4(CO)_{12}$ showed[63b] the rates of reaction vary in the order Co << Rh >>> Ir.

3. METAL NITROSYL CARBONYLS

3.1. *Four-coordinate complexes*

As discussed earlier, binary metal carbonyls (18-electron systems) undergo CO substitution by a dissociative process [eq. (1)]. Imagine the surprise when $Co(CO)_3(NO)$[64] and $Fe(CO)_2(NO)_2$,[68] isoelectronic and isostructural with $Ni(CO)_4$, which reacts by a dissociative mechanism, were found to react by an associative mechanism. This behaviour, prior to the X-ray structure of bent nitrosyls[65] and prior to the 16,18-electron rule,[14] was attributed to localizing a pair of electrons on the nitrogen in the transition state for reaction in order to vacate a metal orbital of low energy for nucleophilic attack [eq. (24)]:



(24)

18 - electrons 18 - electrons 18 - electrons

This S_N2 mechanism for ligand substitution reactions is general for metal nitrosyl carbonyls, with only the poorest of nucleophiles (e.g. $AsPh_3$) permitting a contribution by an S_N1 pathway. The metal nitrosyl carbonyls investigated in our laboratory are shown in Table 2, and their mechanism of CO substitution is compared with that of related (isoelectronic or pseudo-isoelectronic) metal carbonyls.

Since the reactions of $Co(CO)_3(NO)$ and $Fe(CO)_2(NO)_2$ are associative, this permitted the first attempts[64,68] to quantify the nucleophilic strengths of different entering ligands towards a metal carbonyl. The results showed that for a given ligand atom (P or N) there is a reasonable linear correlation of the log of the rate constant, k_2, vs the protonic basicity of the ligand (Fig. 2). For a given basicity, it is seen that the more polarizable P ligands are better nucleophiles than the N ligands. This is readily explained in terms of formally Co(−I) and Fe(−II) being class b[73] or soft[74] metals preferring the class b or soft ligands of P over the class a or hard ligands of N. Note that this was done before the added influence of the steric factor of the nucleophiles was stressed in terms of their cone angles.[75] A considerable amount of data has since been gathered on the reactivity of various nucleophiles towards metal carbonyls, and some success has been reported[76,77] in the development of empirical equations that take care of the contributions of basicity and steric factors to the nucleophilic strengths of various ligands.

3.2. *Five-coordinate complexes*

Although the first kinetic studies of CO substitution of metal nitrosyl carbonyls were carried out on tetra-coordinate systems, $Co(CO)_3(NO)$[64] and $Fe(CO)_2(NO)_2$,[68] it should be noted that subsequent studies showed (Table 2) that five- and six-coordinate systems likewise react predominantly by an associative mechanism. It seems reasonable that the five-coordinate trigonal bipyramid $Mn(CO)_4(NO)$ could readily expand its coordination number to six by the addition of the entering ligand in the trigonal plane to form the octahedral intermediate "$Mn(CO)_4(NO)L$" with a bent Mn—NO and an 18-electron count.[67]

3.3. *Six-coordinate complexes*

Somewhat more difficult are the associative reactions of six-coordinate metal nitrosyl carbonyls through a seven-coordinate 18-electron intermediate with a bent nitrosyl. However, even this is possible, for seven-coordinate metal carbonyls are known.[78]

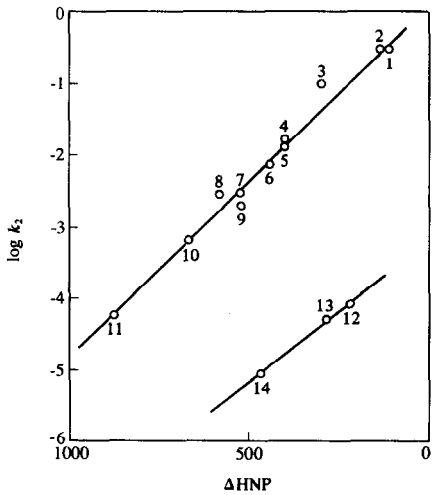


Fig. 2. The linear free-energy relationships of the rate of CO substitution with the basicity of P and of N nucleophiles for the reaction of $Co(CO)_3(NO)$. (1) PEt_3, (2) $P(n\text{-}Bu)_3$, (3) $PPhEt_2$, (4) PPh_2Et, (5) $PPh_2(n\text{-}Bu)$, (6) $P(p\text{-}CH_3OC_6H_4)_3$, (7) $P(O\text{-}n\text{-}Bu)_3$, (8) PPh_3, (9) $P(OCH_3)_3$, (10) $P(OCH_2)_3CCH_3$, (11) $P(OPh)_3$, (12) 4-picoline, (13) pyridine, (14) 3-chloropyridine. ΔHNP is the difference in half-neutralized potential between the nucleophile and N,N′-diphenylguanidine in nitromethane, so the smaller ΔHNP the more basic the nucleophile. C. A. Streuli, *Anal. Chem.* 1960, **32**, 985. R. C. Bush and R. J. Angelici, *Inorg. Chem.* 1988, **27**, 681.

Table 2. Mechanisms[a] of CO substitution of metal carbonyls compared with related metal nitrosyl carbonyls

Six-coordinate	Mechanism	Reference	Five-coordinate	Mechanism	Reference	Four-coordinate	Mechanism	Reference
$Cr(CO)_6$	S_N1	8	$Fe(CO)_5$	S_N1	6	$Ni(CO)_4$	S_N1	4
$V(CO)_5NO$	S_N2	66	$Mn(CO)_4(NO)$	S_N2	67	$Co(CO)_3(NO)$	S_N2	64
$Cr(CO)_5L$	S_N1	8				$Fe(CO)_2(NO)_2$	S_N2	68
trans-$V(CO)_4(NO)L$	S_N1[b]	66				$Mn(CO)(NO)_3$	S_N2	67
$Re(CO)_5X$	S_N1	69				$Ni(CO)_2L_2$	S_N1	70
$W(CO)_4(NO)X$	S_N2	71				$Co(CO)_2(NO)L$	S_N2	64
$PPh_3SnM(CO)_4(NO)$ (M = Cr, Mo, W)	S_N2	72						

[a] The predominate mechanism is indicated. For S_N1 some contribution of S_N2 may occur with strong nucleophiles, whereas for S_N2 some contribution of S_N1 may occur for poor nucleophiles.

[b] This dissociative process is attributed to the electron-rich $P(CH_3)_3$ *trans* to NO greatly reducing its ability in the transition state to accept a pair of electrons required for an associative pathway.

The nitrosyls $W(CO)_4(NO)X$ (X = Cl, Br, I) are pseudo-isoelectronic with $Mn(CO)_5X$ (X = Cl, Br, I) and isoelectronic with $Re(CO)_5X$ (X = Cl, Br, I). The CO substitution of the nitrosyl compound proceeds by a two-term rate law, with largely an S_N2 pathway for reactions with strong nucleophiles.[71] In comparison, the Mn (see Section 2) and the Re[69] carbonyls react by an S_N1 mechanism. One factor the three systems have in common is that for each compound the rates of reaction decrease in the order Cl > Br > I. This is explained in terms of the relative electronegativity and polarizabilities of the halogeno ligand. Since Cl is the most electronegative and the least polarizable, it puts the least electron density on the metal so there is less M—CO π-bonding resulting in the weakest and most substitution labile M—CO.

Finally, the most recent kinetic study[72] of CO substitution on metal nitrosyl carbonyls made in our laboratory was on the chromium triad of compounds $Ph_3SnM(CO)_4(NO)$ (M = Cr, Mo, W), which is believed to be the only transition metal triad reported to form the same corresponding metal nitrosyl carbonyls.[79] All of the reactions follow a two-term rate law, with the S_N2 pathway predominating for good nucleophiles. The most interesting result of this study was the finding that the rates of reaction vary in the order Cr << Mo >> W, which is the usual order of the 2nd row transition metal organometallic being the most substitution labile member of its triad of metals (see Section 5).

4. RING-SLIPPAGE ASSISTED REACTIONS

Our laboratory was the first to report[80] an associative ring-slippage mechanism for CO substitution of metal carbonyls. Ring-slippage has become an important fundamental part of certain organometallic reactions, and the extensive literature on this subject was recently reviewed by O'Connor and Casey.[81] Reported here are only the studies carried out in our laboratory, with some necessary literature references.

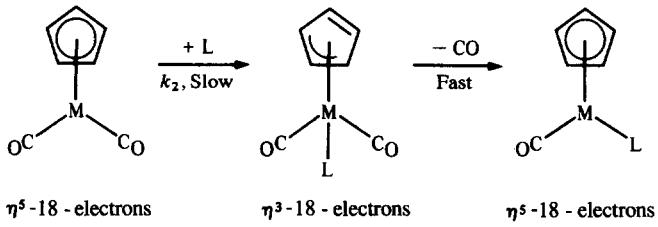
4.1. *Cyclopentadienyl metal carbonyls*

In the 1960s, Professor E. O. Fischer and I had a collaborative pre-doctoral exchange programme. One of his students, who had just prepared for the first time the compounds $(\eta^5\text{-}C_5H_5)M(CO)_2$ (M = Co, Rh, Ir), arrived to work in our research group. He knew these compounds readily react with phosphines to replace CO, which seemed strange at the time because if one considers an $\eta^5\text{-}C_5H_5$ ligand "equivalent" to three COs then these compounds are pseudo-isoelectronic with $Fe(CO)_5$ for which CO replacement is difficult. A kinetic study of the reactions of $(\eta^5\text{-}C_5H_5)M(CO)_2$ with phosphines and phosphites [eq. (25)]:

$$(\eta^5\text{-}C_5H_5)M(CO)_2 + L \longrightarrow (\eta^5\text{-}C_5H_5)M(CO)L + CO \qquad (25)$$

showed the reactions proceed by an associative mechanism. These results were obtained at a time when the associative reactions of metal nitrosyl carbonyls were being explained by localizing a pair of electrons on the nitrosyl in order to maintain an 18-electron count of the intermediate (see Section 3). An attempt was made to account for the associative reactions of $(\eta^5\text{-}C_5H_5)M(CO)_2$ by localizing a pair of electrons on the cyclopentadienyl ligand. Since there was no precedence for this and since the π-allyl-ene $\eta^3\text{-}C_5H_5$ metal bonding had yet to be discovered, the 18-electron intermediate was formulated[80] as a familiar diolefin metal complex with an $\eta^4\text{-}C_5H_5$ ligand and the pair of electrons localized on a ring carbon. This vacated a low-energy metal orbital for attack by the entering ligand, with the intermediate maintaining an 18-electron count. The intermediate was first formulated correctly several years later by Cramer and Seiwell[82] in this report on the replacement of C_2H_4 by phosphines and phosphites in $(\eta^5\text{-}C_5H_5)Rh(C_2H_4)_2$. Three years later, Brintzinger and co-workers[83] confirmed by means of an X-ray structural determination the presence of an $\eta^3\text{-}C_5H_5$ in the compound $(\eta^5\text{-}C_5H_5)(\eta^3\text{-}C_5H_5)W(CO)_2$. Today the associative reactions of $(\eta^5\text{-}C_5H_5)M(CO)_2$

(M = Co, Rh, Ir) are believed to proceed by an $\eta^5 \rightarrow \eta^3 \rightarrow \eta^5$ *slippage* mechanism [eq. (26)]:



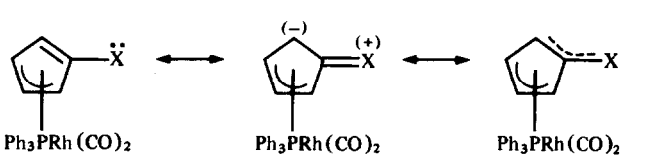
(26)

Casey and co-workers[84] have also observed $\eta^5 \rightarrow \eta^1$ slippage of the cyclopentadienyl ligand, which presumably involves an intermediate formation of the η^3 species. It is even possible for phosphines to displace the η^5-C_5H_5 ligand,[85] perhaps via the stepwise ring-slippage $\eta^5 \rightarrow \eta^3 \rightarrow \eta^1 \rightarrow \eta^0$.

More detailed kinetic studies were made in our laboratory of the $\eta^5 \rightarrow \eta^3 \rightarrow \eta^5$ ring-slippage mechanism [eq. (26)]. This mechanism predicts that electron-withdrawing substituents on the η^5-C_5H_5 ligand will enhance localization of electron density on the ring, and thus assist nucleophilic attack on the metal and increase the rate of ligand substitution. Just the opposite is predicted for electron-donating substituents, which are expected to retard nucleophilic attack and decrease the rate of reaction. In addition to this electronic effect of the substituents, steric factors may also become important and numerous, or bulky substituents on the ring may sterically hinder nucleophilic attack at the metal and retard the rate of reaction. These predictions were initially tested[86] using the compounds $(\eta^5\text{-}C_5H_5)Rh(CO)_2$, $(\eta^5\text{-}C_5H_4NO_2)Rh(CO)_2$ and $(\eta^5\text{-}C_5(CH_3)_5)Rh(CO)_2$ which gave the relative reaction rates of 1, 10^4 and 10^{-2}, respectively. This is as predicted, with the electron-withdrawing substituent NO_2 increasing the rate, and the electron-donating substituents CH_3 decreasing the rate. In the case of the η^5-$C_5(CH_3)_5$ system, it is not known how much of the 10^{-2} decrease in rate is due to electronic and how much to steric factors. In any case the results show it is possible to fine tune the rates of ligand substitution of organometallic compounds over a range of 10^6; this is important to note when considering the use of these compounds as homogeneous catalysts.[60]

A more recent investigation reports[87] results obtained on the rates of reaction of $(\eta^5\text{-}C_5H_4X)Rh(CO)_2$ [X = H, NO_2, CF_3, Cl, CH_3 or $N(CH_3)_2$] with PPh_3 to afford $(\eta^5\text{-}C_5H_4X)Rh(CO)PPh_3$. The monosubstituents on the ring are expected to have a negligible steric effect, so the rates of CO substitution are believed to be controlled by changes in electronic factors. Substituent effects on the reactivity of aromatic molecules have been studied by organic chemists for decades, and they have successfully found a linear free energy relationship between the log of the rate constants and the Hammett σ values of the substituents.[88] First, it was noted[87] that a good linear correlation exists between the values of CO stretching frequencies, ν(CO) and the Hammett σ values of the X ring substituents for the compounds $(\eta^5\text{-}C_5H_4X)Rh(CO)_2$ and their mono-PPh_3 derivatives. This is believed to mirror the electron density on Rh, which then results in greater or lesser π-backbonding from Rh → CO.

Solely on the basis of electron density on the metal, one expects the rates of associative CO substitution to show a similar linear correlation with changes in Hammett σ values of X (rates decreasing with increasing electron density on the metal). This is true for all the substituents used, except for Cl and $N(CH_3)_2$ which cause much more rapid reactions than expected on the basis of the linear correlation of the other substituents with Hammett σ. Beside the electron density on the metal affecting the rate of reaction, it is also affected by the stability of the slipped active intermediate "$(\eta^3\text{-}C_5H_4X)Rh(CO)_2L$". The substituents Cl and $N(CH_3)_2$ differ from the other substituents, being the only ones with one or more filled non-bonding p orbitals. It was suggested[87] that these two substituents can resonance stabilize the transition state [eq. (27)]:



(27)

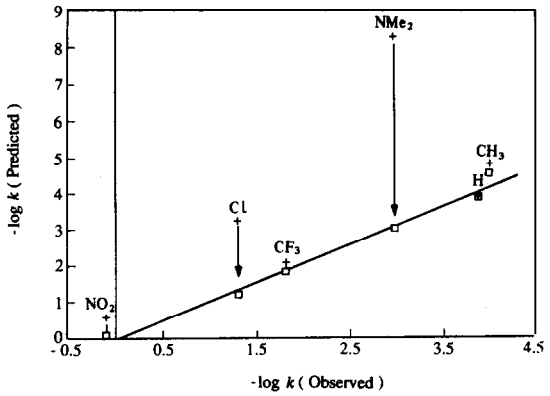


Fig. 3. □, correlation of observed rates of CO substitution to predicted rates from relative ionizations for the series of compounds $(\eta^5\text{-}C_5H_4X)Rh(CO)_2$. +, predicted rates with the σ term only, so the difference between the points + and □ represents the contribution of the π term to the predicted rates.

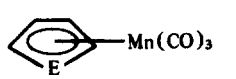
and enhance the reaction rate beyond that predicted by Hammett σ values. Lichtenberger *et al.*[89] have determined the photoelectron spectra of these $(\eta^5\text{-}C_5H_4X)Rh(CO)_2$ compounds, and they have obtained information on the extent of σ- and π-bonding in these systems. On the basis of this, a two parameter equation was used to estimate the rates of reaction for each substituent relative to the known value for the compound where X = H. The predicted rate constants, by this method of considering both σ- and π-bonding contributions, are in good agreement with the experimental values of k_2 (Fig. 3). If the π-contribution to bonding is not used, then the points for X = Cl and $N(CH_3)_2$ are far off the line. This supports the earlier suggestion[87] that Cl and $N(CH_3)_2$ are efficient in resonance stabilization of the slipped intermediates "$(\eta^3\text{-}C_5H_4X)Rh(CO)_2PPh_3$".

4.2. *Heterocycle metal carbonyls*

Other systems investigated in our laboratory relate to $(\eta^5\text{-}C_5H_5)Mn(CO)_3$. It had been shown earlier[90] that this compound does not react with PPh_3 at 140°C over a 3-day period. Based on the ring-slippage mechanism for CO substitution, it was felt that with a more electron-withdrawing ring the reaction rate would increase. Instead of putting electron-withdrawing substituents on the ring, it was decided to prepare and test some η^5-heterocyclic systems such as **I**. Unfortunately these compounds have been studied much less[91] than have their ubiquitous η^5-carbocyclic analogues, so several of the compounds investigated had to be prepared and characterized for the first time.[92] The results showed that only the N-heterocycle manganese compounds undergo CO substitution by phosphines and phosphites. These results were attributed to the greater electronegativity[93] of N (3.0) than that of C (2.5), P (2.1) and As (2.0). Since the latter three $(\eta^5\text{-ring})Mn(CO)_3$ compounds did not react, it was not possible to test the hypothesis that reactivity may correlate with the electronegativity of element E in the ring.

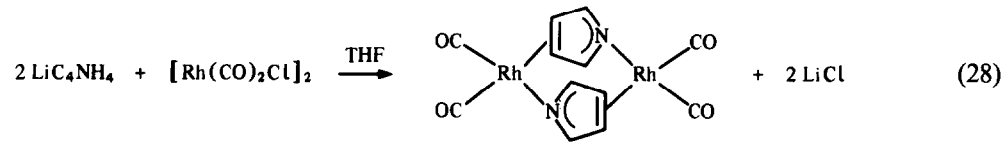


(E = N,P,As)

I

Knowing that $(\eta^5\text{-}C_5H_5)Rh(CO)_2$ reacts readily, it was decided to prepare and test the corresponding $(\eta^5$-heterocycle$)Rh(CO)_2$ compounds. A plausible approach to the syntheses of these compounds is that reported[94] for the preparation of $(\eta^5\text{-}C_5H_5)Rh(CO)_2$ by the reaction of $[Rh(CO)_2Cl]_2$ with $C_5H_5^-$. However, reaction with the pyrrole anion does not give the desired

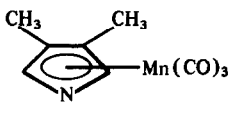
product, but affords a unique bridged dimer[95] [eq. (28)]:



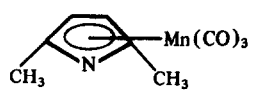
(28)

This leaves the hypothesis that the reaction rates of η^5-heterocycle metal carbonyls will correlate the electronegativity of the hetero-elements untested.

One question addressed for the $\eta^5 \rightarrow \eta^3 \rightarrow \eta^5$ ring-spillage mechanism of the associative reactions of the (η^5-pyrrolyl)$Mn(CO)_3$ compounds was the formulation of the η^3 intermediate. The question is does the N atom form part of the allyl, and if so is it an η^3-1-azaallyl or an η^3-2-azaallyl? In an attempt to obtain some information on this point the dimethylpyrrolyl manganese complexes **II** and **III** were prepared and examined.[92] The rate constants, k_2 (M^{-1} s^{-1}), of the reaction with $P(n\text{-}Bu)_3$ at 130°C of the parent compound **I** and of **II** and **III** are, respectively, 3.4×10^{-4}, 1.4×10^{-4} and 1.2×10^{-6}. The slower rates of the dimethyl derivatives, **II** and **III**, than the parent, **I**, is in accord with an $\eta^5 \rightarrow \eta^3 \rightarrow \eta^5$ mechanism where the methyl electron-donating substituents retard electron delocalization into the ring ligand. The slower rates are also consistent with an associative reaction where increased substitution on the η^5-ring leads to a more crowded transition state.

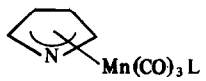


II



III

It is important to note that the position of the methyl substituents on the η^5-pyrrolyl ring has a marked effect on the rate of associative CO substitution. Thus, compound **II** reacts 10^2 times faster than does compound **III**, although both have two methyl groups on the η^5-cyclic ligand. This difference does not seem due to electronic factors because the C—O stretching frequencies of the two complexes are approximately equal in energy, suggesting the electron densities on the metals are about the same. Likewise, the pK_as of the two free pyrroles are almost identical, indicating comparable electronic characteristics of both rings. Therefore, it appears that steric factors are responsible for the reactivity differences of **II** > **III**. The more crowded transition state of **III** over **II** suggests an η^3-2-azaallyl bonding mode of the metal moiety to the pyrrolyl ring (**IV**). Further support for **IV** is provided[96] by the X-ray structure of **II**, which shows a "slip-distortion" of the $Mn(CO)_3$ moiety away from the ring centroid toward N. It appears this slippage is largely steric in origin, since no allylene type bonding is observed in the pyrrolyl ring of **II**.



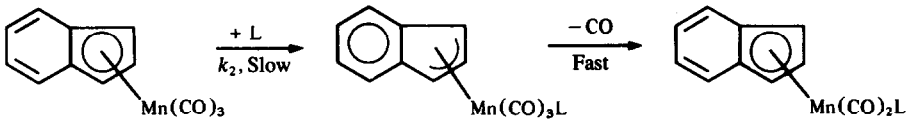
IV

4.3. *Indenyl ligand effect*

Mawby and co-workers[97] were the first to study the kinetics and mechanisms of reactions of η^5-indenyl metal carbonyls compared with the corresponding η^5-cyclopentadienyl compounds. They found[97a] that the methyl migration in $Mo(\eta^5\text{-}C_9H_7)(CO)_3CH_3$ was ligand assisted. The S_N2 nature of this reaction was attributed to the ability of indenyl ligand to undergo an η^5- to η^3-migration allowing associative attack on the metal centre. They believed that the benzene of the indenyl ring provided stabilization of the η^3-allyl intermediate; the cyclopentadienyl analogue reacted 10 times slower. They[97b] also compared CO substitution by phosphines for the compounds $Mo(\eta^5\text{-}C_5H_5)(CO)_3X$ and $Mo(\eta^5\text{-}C_9H_7)(CO)_3X$ (X = Cl, Br, I), and found that CO substitution for the

cyclopentadienyl compound proceeds by a purely dissociative (S_N1) pathway, whereas the indenyl compound is substituted by both an S_N1 and ligand association (S_N2) pathway. There is a rate enhancement of about 6000 for the S_N1 path for the indenyl compound, compared to the cyclopentadienyl compound, in addition to the previously observed creation of an S_N2 path by the indenyl ligand. In another study[97c] the rate of CO replacement by $P(OEt)_3$ for $Fe(\eta^5\text{-}C_5H_5)(CO)_2I$ and $Fe(\eta^5\text{-}C_9H_7)(CO)_2I$ was compared. In both cases the replacement of CO by $P(OEt)_3$ proceeds by an S_N1 pathway, with the indenyl compound reacting 575 times faster than the cyclopentadienyl compound. To show that the rate enhancement was due to the electronic nature of the indenyl ligand, the arene ring was hydrogenated and the rate of CO replacement for this compound was only half the rate observed for the cyclopentadienyl compound.

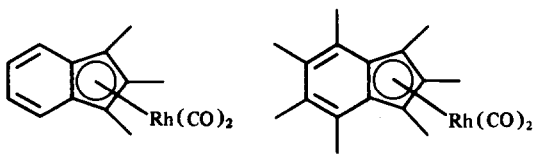
Our investigations[86,98] of the associative CO replacement reactions of the indenyl compound $(\eta^5\text{-}C_9H_7)Rh(CO)_2$ show it to react 10^8 times faster than does the corresponding cyclopentadienyl compound, so it was decided to refer to this large rate enhancement as the *kinetic indenyl ligand effect*. Since this rate effect for S_N2 ligand substitution is so large, it was felt that $(\eta^5\text{-}C_9H_7)Mn(CO)_3$ might react with phosphines and phosphites even though the cyclopentadienyl compound is inert[90] to thermal CO substitution at 140°C. This was found[99] to be correct, and it appears that the usual ring-slippage mechanism is involved [eq. (29)]:



(29)

As suggested earlier,[97] the driving force for this indenyl rate effect is the aromatization of the fused six-membered ring in the transition state for reaction. Further rate enhancement in going to two fused six-membered rings, fluorenyl, is only 10^3 times instead of the 10^8 times for addition of the first six-membered ring. Relative rates of CO substitution for analogous metal carbonyls with different η^5-ring ligands increase in the order cyclopentadienyl <<< indenyl < fluorenyl. Recent studies[100] show that in addition to the monosubstitution of CO, strongly basic nucleophiles react further to displace the fluorenyl ligand and give as the final product $HMn(CO)_3L_2$.

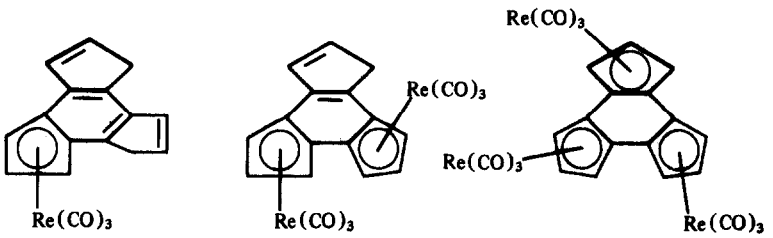
Research is now in progress[101] on the kinetics of CO substitution of eight different methyl substituted indenyl complexes, $(\eta^5\text{-Ind})Rh(CO)_2$, with a variety of different nucleophiles. As the number of methyl groups on the ring increases, there is the expected decrease in rate of substitution. The rate decrease is caused by the electron-donating properties of the methyl groups, but steric factors predominate when there are several methyl substituents and particularly if these are on the five-membered ring. With these sterically hindered systems, the nucleophilic strength of the entering ligand is largely controlled by its cone angle. For example, compounds **V** and **VI** react with $P(n\text{-}Bu)_3$ and with PCy_3 to give the ratio of rate constants $k(n\text{-}Bu)_3/kPCy_3 = 100$ for **V** and 250 for **VI**. Since the two phosphines are of about the same basicity, their nucleophilic strengths are sterically controlled with the larger PCy_3 being the poorer nucleophile towards these two substrates. The application of empirical equations developed earlier[76,77] for the correlation of nucleophilic reactivity based on basicity and steric factors, supports the predominance of steric factors for reactions with these crowded substrates.



V **VI**

Another interesting series of compounds is currently under investigation. These are metal carbonyl derivatives of trindene (Td),[102] with isolobal groups of $M(CO)_3$ or $M(CO)_2$. Preliminary results[103] show that each of these three compounds react with $PPhMe_2$ to afford slippage of $\eta^5 \rightarrow \eta^1$

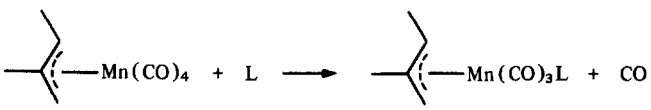
at one $Re(CO)_3$. At room temperature the relative rates of reaction are $(\eta^5\text{-Ind})Re(CO)_3$ > **VII** > **VIII** > **IX**, $(\eta^5\text{-Cp})Re(CO)_3$, where the latter two compounds do not react at these conditions. This result is consistent with the view that the step-wise reactions involve slippage of $\eta^5 \rightarrow \eta^3 \rightarrow \eta^1$, and that the fastest to react is the compound which allows the maximum amount of π-delocalization in the central six-membered ring.



VII **VIII** **IX**

4.4. *Allyl metal carbonyls*

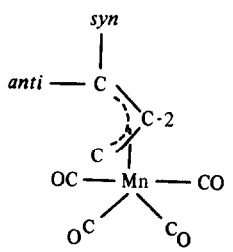
Finally, CO substitution reactions of π-allyl derivatives, $(\eta^3\text{-}C_3H_4X)Mn(CO)_4$, with different nucleophiles were investigated[104] [eq. (30)]:



(30)

Earlier studies indicated that CO replacement in $(\eta^3\text{-}C_3H_4X)Co(CO)_3$ takes place by an S_N1 process,[105] whereas $(\eta^3\text{-}C_3H_4X)Fe(CO)_2(NO)$[106] reacts by an $\eta^3 \rightarrow \eta^1 \rightarrow \eta^3$ associative mechanism.

Our studies[104] of the kinetics and mechanism of CO substitution in $(\eta^3\text{-}C_3H_4X)Mn(CO)_4$ show the rates of reaction are first-order in substrate and zero-order in reagent concentrations. This suggests either an S_N1 process, or an $\eta^3 \xrightarrow{\text{slow}} \eta^1 \xrightarrow{\text{fast}} \eta^3$ mechanism. Unequivocal proof that the latter mechanism is not correct was obtained by starting with $(\eta^1\text{-}C_3H_4X)Mn(CO)_4$ L and finding that its rate of CO loss is much too slow to account for the overall CO substitution rate of the reaction [eq. (30)]. Considering the effect of substituents in the 1- or 2-positions (X) of $(\eta^3\text{-}C_3H_4X)Mn(CO)_4$ on its rate of reaction gave some interesting results. Alkyl groups, electron-donating, on the allyl are expected to enhance the electron density on the metal, promoting more π-backbonding and a slower rate of CO substitution. This is what was found for ligands of the 1-*syn*-allyl type, but corresponding 1-*anti*-allyl ligands enhance the rate of reaction. It seems reasonable this should happen, because in the *syn* structure the substituent group points away from the metal and offers no steric destabilization to the CO ligands. In contrast, the *anti* structure has the group in towards the metal and does sterically promote loss of CO. Substituents in the 2-position of the allyl all increase the rate of reaction. This seems to be a steric effect because the rate increase correlates the substituent size, and because the X-ray structure of **X** shows that the group in the 2-position eclipses one of the CO ligands. The result is in keeping with the general steric rate acceleration of S_N1 reactions.[3b]



X

5. LIGAND SUBSTITUTION LABILITY OF 2ND ROW TRANSITION METAL CARBONYLS

Ligand substitution reactions of octahedral and of square-planar Werner metal complexes for a given transition metal triad generally decrease with increasing atomic number of the metal,[3,3b] for example, rates of Cl^- substitution of $[M(NH_3)_5Cl]^{2+}$ decrease in the order Co > Rh > Ir. As with most generalities, this one also has some exceptions with the 2nd row member of a given triad forming the most substitution labile metal complexes.[111]

5.1. *Mononuclear complexes*

However, it has now long been known[2] that for complexes of metals in low oxidation states, organometallic compounds, the 2nd row transition metal complex of a given triad is generally the most substitution labile, for example, rates of CO substitution of $CpM(CO)_2$ differ in the order Co < Rh > Ir. Table 3 gives specific examples, with appropriate references, which show that the rates of ligand substitution in these systems vary in the order *1st row < 2nd row > 3rd row*. To my knowledge, the only known exception to this general order of CO substitution in mononuclear metal carbonyls is for the vanadium triad of $CpM(CO)_4$[108,109] where the rates decrease in the order V > Nb > Ta.

Since rapid ligand substitution is essential in any use made of such compounds in homogeneous catalysis,[60] it is not surprising to find that most commercial processes make use of 2nd row transition metal (Mo, Ru, Rh or Pd) organometallics as homogeneous catalysts. This rate variation of 1st row < 2nd row > 3rd row seems to hold, regardless of mechanism. For example, the triads of $M(CO)_6$ and of $M[P(OEt)_3]_4$ react by a dissociative process, whereas the triad of $CpM(CO)_2$ reacts by an associative process. For the triad $Cp_2M(CO)_2$, the Ti compound reacts by an S_N1 mechanism but the Zr and Hf compounds react by an S_N2 process. Similarly, for $CpM(CO)_4$ an S_N1 reaction is involved with V, where Nb and Ta react by competing S_N1 and S_N2 pathways. In these two triads the associative reactions of the 2nd and 3rd row metal complexes are attributed to their larger size which permits nucleophilic attack at the metal, whereas this does not happen with the sterically more crowded 1st row metal complexes. The V triad of $CpM(CO)_4$ are anomalous[109] in that the rates decrease with increasing atomic number of the metal.

As to why 2nd row transition metal organometallic compounds are generally the most substitution labile for a given triad of metals remains somewhat of an open question. Early explanations were given in terms of σ- and π-bonding.[112] A similar explanation was given[113] in terms of the low electronegativity of 1st row metals as one factor, and a good matching of the orbital energy of 3rd row metals with the ligand as another factor. The latest word[114] on this is the detailed molecular orbital calculations based on density functional theory to estimate the first CO ligand dissociation energy ΔH of $M(CO)_n$ for the three binary metal carbonyl triads $M(CO)_6$ (M = Cr, Mo, W), $M(CO)_5$ (M = Fe, Ru, Os) and $M(CO)_4$ (M = Ni, Pd, Pt). For each triad of transition metals, the calculated ordering of the M—CO bond strengths (including relativistic effects) is $3d > 5d > 4d$. Whatever the reason, the fact remains that in general the 2nd row transition metal organometallic compounds react the fastest for a given triad.

Table 3. Relative CO substitution rates for corresponding metal carbonyls of a given transition metal triad

$Cp_2Ti(CO)_2$[107]	$CpV(CO)_4$[108]	$Cr(CO)_6$[8]	$Mn_2(CO)_{10}$[110]	$Fe(CO)_5$[6]	$CpCo(CO)_2$[80]	$Ni[P(OEt)_3]_4$[112]
∧	∨	∧	∧	⇈	∧	∧

∨	∨	∨	∨	⇊	∨	∨
$Cp_2Hf(CO)_2$[107]	$CpTa(CO)_4$[109]	$W(CO)_6$[8]	$Re_2(CO)_{10}$[110]	$Os(CO)_5$[6]	$CpIr(CO)_2$[80]	$Pt[P(OEt)_3]_4$[112]

5.2. *Metal carbonyl clusters*

Kinetic studies of CO substitution in metal carbonyl clusters have been largely limited to the clusters $M_3(CO)_{12}$ (M = Fe, Ru, Os)[9] and M_4CO_{12} (M = Co, Rh, Ir).[115] The rates of CO displacement by a dissociative process for $M_3(CO)_{12}$ decrease in the order Fe > Ru > Os (Table 1). It has been suggested[115] that bridging carbonyl groups may enhance cluster lability, because they withdraw more electron density from the metal than do terminal carbonyls.[116] Since $Fe_3(CO)_{12}$ is the only member of this triad to have bridging COs, it is expected to be the fastest to react. In accordance with this concept of bridging COs, the iron cluster reacts 10^8 times faster than does $Fe(CO)_5$. In contrast, the rates of reaction of the Ru and the Os clusters, without bridging COs, are about the same as the rates of the corresponding $Ru(CO)_5$ and $Os(CO)_5$ (Table 1). It should further be noted that the anomalously slow reaction of $Fe(CO)_5$ may result from a spin-forbidden dissociative process (see Section 2).

Extensive mechanistic studies[115,117] have been reported on $Ir_4(CO)_{12}$ where CO substitution occurs by a two-term rate law with a dominant second-order process for phosphorus and carbon nucleophiles. The mechanism of CO substitution in $Co_4(CO)_{12}$ and in $Rh_4(CO)_{12}$ is less well understood. The reaction of $Co_4(CO)_{12}$ with L to yield $Co_4(CO)_{11}L$ was too fast to measure, suggesting an associative mechanism.[118] Carbonyl substitution in $Rh_4(CO)_{12}$ occurs so rapidly that only a lower limit could be set on the rate of reaction.[115] We decided to investigate these systems, using stopped-flow spectrophotometry or a variable low temperature IR cell. The results[63] showed that both clusters react by two-term rate laws [eq. (7)]. Relative reactivities for the $M_4(CO)_{12}$ clusters by the dissociative pathway are Co < Rh > Ir, and by the associative pathway Co << Rh >> Ir. This is in accordance with the 2nd row transition metal cluster being the fastest to react, as is true of mononuclear metal complexes, but the differences in rate are larger for the clusters.

Similar results[62,63] were obtained by CO substitution of the more stable clusters $M_4(CO)_9[HC(PPh_2)_3]$ [see eqs (22) and (23) for structure]. Here relative reactivities for the k_1 pathways are Co (1), Rh (667), Ir (10^{-5}), and for the k_2 pathways are Co (1), Rh (10^6), Ir (10^{-3}). The most notable chemical feature is the exceptional reactivity of the rhodium cluster, whose substitutions proceed within seconds at room temperature. Also a unique aspect of substitution in cluster compounds compared to mononuclear metal carbonyls is the presence of rapid associative pathways for CO substitution. This may result from the presence of low-lying acceptor orbitals for nucleophilic attack derived from metal–metal antibonding orbitals of the cluster.

6. CATALYSIS OF CO SUBSTITUTION

6.1. *Acid catalysis*

As mentioned earlier [eq. (4)] the CO exchange of $Fe(CO)_5$ is acid catalysed. This is believed to involve protonation at the metal, to form $[HFe(CO)_5]^+$ which then is substitution labile. Albers, Coville and co-workers[119] have recently shown that a variety of transition metal salts catalyse CO substitution of $Fe(CO)_5$ and $Cr(CO)_6$ by different entering ligands. Catalysis perhaps involves attack of a CO oxygen by the metal ion to give M—CO---M^{2+}, which weakens the M—CO bond and enhances the rate of reaction. Lewis acids are known[23] to interact with certain metal carbonyls to form adducts of the type M—CO—BX_3 (see Section 7).

6.2. *Base catalysis*

The rate of CO substitution of $Fe(CO)_2(NO)_2$, with the poor nucleophile $AsPh_3$, was found[120] to markedly increase in the presence of added base [eq. (31)]:

$$Fe(CO)_2(NO)_2 + AsPh_3 \xrightarrow{B} Fe(CO)(NO)_2AsPh_3 + CO \qquad (31)$$

B = R_4NX (X = Cl, Br, I, N_3), $NaOCH_3$, pyrrolidine, imidazole.

The reactions followed the rate law given by eq. (32):

$$\text{Rate} = k_B[Fe(CO)_2(NO)_2][B]. \qquad (32)$$

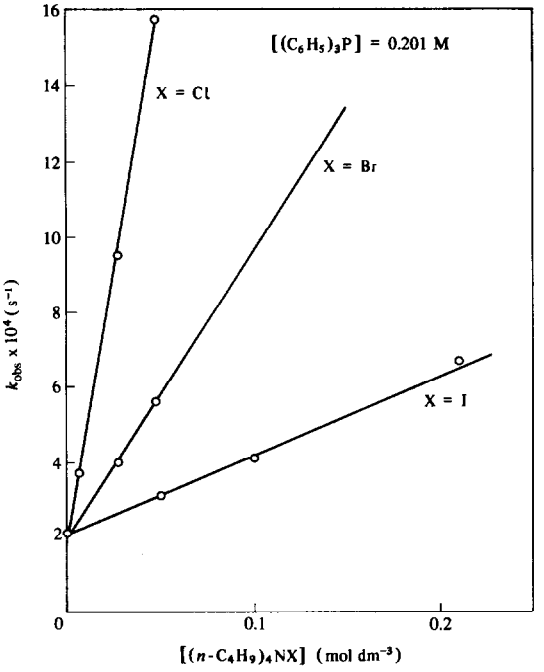

Fig. 4. Plot of k_{obs} vs $[(n\text{-}C_4H_9)_4NX]$ for the reaction of $Fe(NO)_2(CO)_2$ with $(C_6H_5)_3P$ in the presence of $(n\text{-}C_4H_9)_4NX$ in dichloromethane at 25°C.

A plot of the observed rate constants vs halide ion concentrations is shown in Fig. 4. The mechanism proposed for this catalytic pathway involves attack by the catalyst on the carbon of a CO ligand [eq. (33)]:

$$(ON)_2(OC)Fe{=}C{=}\bar{O} \xrightarrow[k_B]{+B} \text{“}(ON)_2(OC)Fe{-}\underset{\|}{\overset{O}{C}}{-}B\text{”} \xrightarrow[-B\ -CO]{+AsPh_3\ \text{Fast}} Fe(CO)(NO)_2AsPh_3. \tag{33}$$

This is believed to be the site of attack, because the rate decreases in the order $Cl^- > Br^- > I^-$. The hard base Cl^- is expected to preferentially attack the hard positive carbon site rather than the soft metal. Consistent with this is the observation that these same bases do not catalyse the reactions of $Co(CO)_3(NO)$, presumably because only one NO does not remove enough electron density from the metal to render the carbonyl carbons sufficiently positive for base attack. There are a large number of examples of base attack on the more positive carbons of metal carbonyls.[2]

For this base catalysis of CO substitution of $Fe(CO)_2(NO)_2$, it was suggested that the formation of $Fe{-}\underset{\|}{\overset{O}{C}}{-}B$ weakens the Fe—C bond and promotes the loss of the CO that was attacked by base. However, there is no evidence this is the CO that is replaced, and some years later it was suggested[121] that base catalysis results from the *cis*-labilization of a CO adjacent to the carbonyl attacked by base [eq. (34)]:

$$(OC)_{n-1}MCO \xrightarrow[k_B]{+B} (OC)_{n-1}M{-}\underset{B}{\overset{O}{C}} \xrightarrow[\text{Fast}]{-CO} (OC)_{n-2}M{-}\underset{B}{\overset{O}{C}} \xrightarrow[\text{Fast}]{+L} L(OC)_{n-2}M{-}\underset{B}{\overset{O}{C}} \xrightarrow[\text{Fast}]{-B} (OC)_{n-1}ML \tag{34}$$

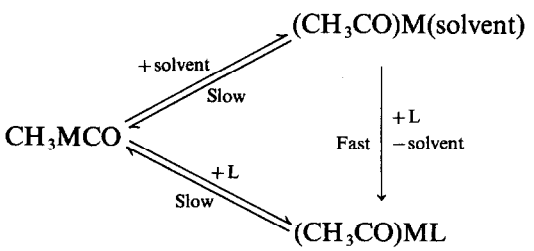
It has also been found[122] that base catalysis may involve attack on the metal followed by *cis*-labilization of an adjacent CO. For example, $(n\text{-Bu})_3PO$ catalyses ^{13}CO exchange with $M(CO)_5L$ (M = Cr, Mo, W) but not with $M(CO)_6$. This happens only if L is a good leaving group, which can readily be replaced by the catalyst $(n\text{-Bu})_3PO$.

7. MIGRATORY INSERTION REACTIONS

7.1. *Methyl migration*

Migratory CO insertion into transition metal alkyl bonds is one of the most fundamental and extensively studied reactions in organometallic chemistry[2] and in homogeneous catalysis.[60] The early discoveries[123] of insertion reactions in organometallic chemistry were soon followed by the elegant experiment[124] showing that the labelled CO added to convert $CH_3Mn(CO)_5$ into $(CH_3CO)M(CO)_5$ is not the CO acetyl, but one of the five terminal COs. The term insertion describes the overall result, but we felt it was mechanistically misleading and that the reactions really involve ligand migration. An experiment was designed in an attempt to learn if the reaction is mechanistically insertion or methyl migration.[125] This was done by decarbonylating *trans*-$(CH_3CO)Mn(CO)_4PPh_3$ and determining the isomeric structure of the $CH_3Mn(CO)_4PPh_3$ product. The product was the *cis*-isomer which, applying the law of microscopic reversibility, requires the reverse process to proceed by methyl migration and not CO insertion that would give the *trans*-isomer. Unfortunately it was later shown[126] that although the conclusion reached was correct, the experiment was flawed because at the conditions used the starting *trans*-acetyl isomerizes to the *cis*-acetyl prior to decarbonylation. A similar experiment using ^{13}CO has shown this to be a methyl migration reaction, and these reactions are now best described as ligand migratory insertion reactions.

Kinetic studies were made[127] of the methyl migration reactions of $CH_3Mn(CO)_5$, $(\eta^5\text{-}C_5H_5)Fe(CO)_2CH_3$ and $(\eta^5\text{-}C_5H_5)Mo(CO)_3CH_3$ with a variety of entering ligands. In all cases, the rates of reaction were found to depend on ligand concentration with the same limiting rate being reached at high ligand concentrations. The results were explained in terms of a solvent and/or ligand assisted mechanism, eq. (35):



(35)

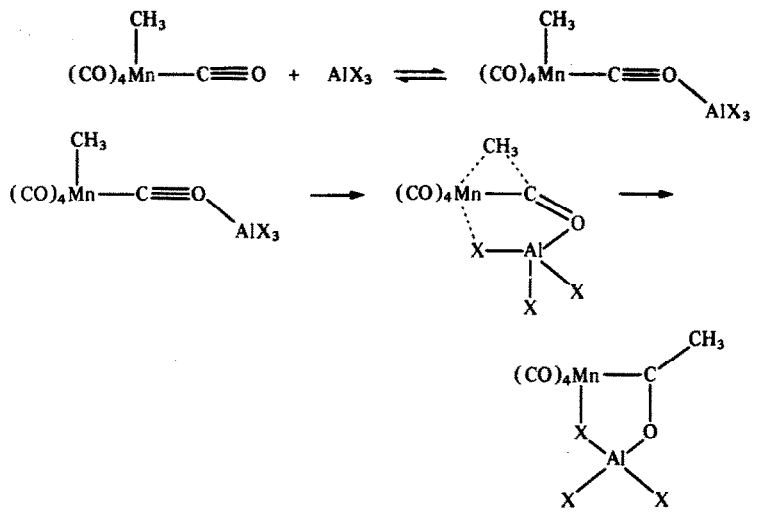
(other ligands not shown)

One of the more recent publications[128] on the mechanism of these reactions largely resembles that shown in eq. (35).

7.2. *Acid-induced reaction*

One final point is that CO migratory insertion reactions, like some CO substitution reactions, can be induced by Lewis acids. For example, the rate of methyl migration of $CH_3Mn(CO)_5$ in the presence of $AlCl_3$ or $AlBr_3$ is 10^8 times faster than in the absence of Lewis acid.[24] One possible mechanism for this rate enhancement is coordination of the Lewis acid to the oxygen atom of a

carbonyl in $CH_3Mn(CO)_5$, followed by methyl migration and coordination of one of the halide groups [eq. (36)].



(36)

8. 17-ELECTRON METAL CARBONYLS

8.1. $V(CO)_6$

It is well known that for molecular transition metal organometallic compounds, 18-electrons is the magic number for maximum stability. A decade ago Brown and co-workers[129] reported that, unlike 18-electron substitution inert metal carbonyls, 17-electron metal carbonyl radicals such as $Mn(CO)_5$ and $Re(CO)_5$ are substitution labile. These metal carbonyl radicals are formed, and studied, *in situ* by the photochemical homolytic metal–metal bond cleavage of $M_2(CO)_{10}$. We decided to investigate the kinetics and mechanism of CO substitution of $V(CO)_6$, the only known[130] stable homoleptic metal carbonyl radical. At the time it was believed that $Mn(CO)_5$ reacts by a dissociative process,[129] whereas $Re(CO)_5$ involves an associative process.[131] It was later found[132] that $Mn(CO)_5$ reacts by an associative process, and it is now generally agreed[133] that the rapid reactions of metal carbonyl radicals are S_N2. The reaction of $V(CO)_6$ with a variety of ligands [eq. (37)]:

$$V(CO)_6 + L \longrightarrow V(CO)_5L + CO \tag{37}$$

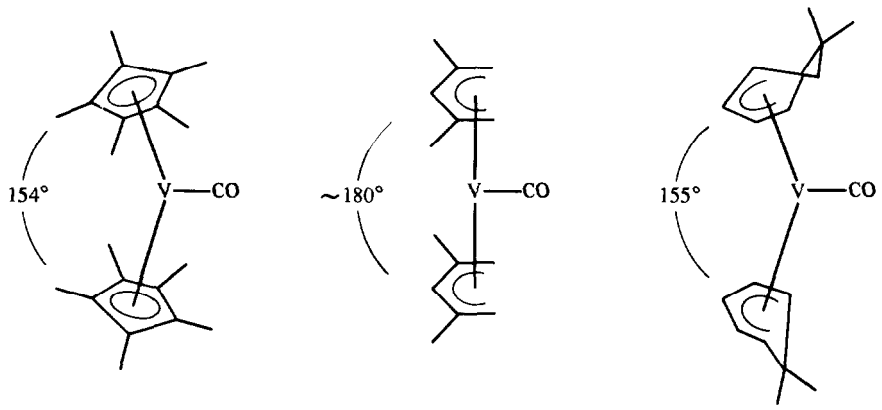
is first-order in carbonyl and first-order in ligand concentrations.[134] The most significant result of this study was that it allowed, for the first time, a quantification of the rates of CO substitution for corresponding 17- and 18-electron metal carbonyls. The relative rates of associative CO substitution by $P(n\text{-}Bu)_3$ of analogous metal carbonyls is as follows:

	$Cr(CO)_6$ (18-electrons)[8]	$V(CO)_6$ (17-electron)[134].
Relative rates	1	10^{10}

That the associative rate of reaction for a 17-electron system is faster than for the analogous 18-electron system is readily understood, because it surely is easier for a nucleophile to attack a 17-electron than an 18-electron substrate. What is not yet understood is the extremely large magnitude of the rate enhancement. Furthermore, the reactions of $V(CO)_6$ show only slight sensitivity to the steric properties of an attacking nucleophile. This is puzzling, because a mechanism that involves a seven-coordinate transition state is expected to exhibit steric preferences. This observation suggests that the transition state occurs at a relatively long V—nucleophile distance. Such may be the case, since the electron pair of the nucleophile is expected to attack a half-filled $d(t_g)$ orbital of $V(CO)_6$ and form a two-centre three-electron bond. This bond would have a bond order of 1/2, so the transition state would have a long V—nucleophile distance in keeping with the low sensitivity to the cone angle of the entering nucleophile.

8.2. (η^5-*ligand*)$_2$V(CO)

Our investigation of reactions of 17-electron systems have been exended to different (η^5-ligand)$_2$V(CO) compounds (**XI, XII** and **XIII**). The vanadocene and decamethylvanadocene (**XI**) carbonyls are substitution labile and react by an associative mechanism. The pentadienyl compounds (**XII**) are more inert and react at elevated temperatures by a dissociative pathway.[135] The cyclohexadienyl compound (**XIII**) affords a rare example[136] of a slow associative substitution for a 17-electron metal carbonyl.



XI **XII** **XIII**

The more rigid structure and shorter M—C bond lengths of **XII** cause steric retardation of nucleophilic attack, so substitution takes place by a slow dissociation process. Further, a dihedral angle of about 150° for **XI** and **XIII** compared to 180° for **XII** indicates that the former two have a more sterically accessible binding site for nucleophilic attack.

The IR carbonyl stretching frequencies and EPR isotropic coupling constants are also informative (Table 4). The greater electron-withdrawing ability of the dimethyl cyclohexadienyl ligand compared to cyclopentadienyl is reflected in the CO frequencies of 1912 and 1881 cm^{-1}, respectively. One might expect that the more positively charged vanadium in **XIII** would be more susceptible to nucleophilic attack than in **XI**. However, the opposite is observed. The rate of substitution of **XIII** is 10^{-4} times that of **XI**. This is believed to reflect the position of the unpaired electron. If this electron occupies a largely metal-based singly occupied orbital, then a more positively charged vanadium will lead to reduced delocalization of this unpaired spin from the metal centre. EPR data in Table 4 are consistent with this argument. It would appear that nucleophilic attack on a metal orbital containing an electron may be retarded relative to the same system with that electron largely delocalized onto the ligands. Thus, **XI** is expected to have a more favourable electronic distribution of the unpaired electron for nucleophilic attack (represented in Table 4 as + for electronic, relative − for **XII** and **XIII**).

Table 4. Associative rates of CO exchange and EPR data for (η^5-L)$_2$VCO complexes

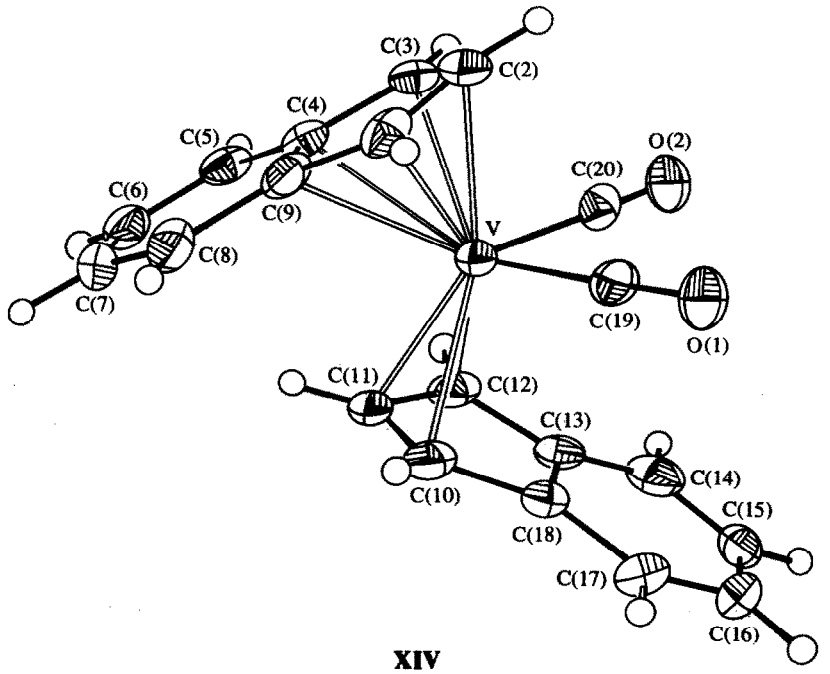
Complex	k_2[a] (M^{-1} s^{-1})	ν(CO) (cm^{-1})	A_{iso} (G)	Steric[b]	Electronic[b]
XI	*ca* 800	1881	28.8	+	+
XII	0.004	1959	79.1	−	−
XIII	0.073	1912	71	+	−

[a] At 60°C in decalin.

[b] Favourable for associative reaction represented by +, unfavourable represented by −.

Compound **XII** reacts almost exclusively by a dissociative pathway, in accordance with associative retardation by both steric and electronic factors. Complex **XIII** reacts entirely by an associative pathway, although its electronic retardation is expected to be similar to **XII**. This would suggest that the greater steric accessibility of **XIII** relative to **XII** permits **XIII** to react by an associative pathway. However, electronic factors are important, and in the case of **XIII** it gives us a rare example of a slow associative substitution reaction for a 17-electron metal carbonyl. The fastest to react is **XI** which experiences less steric and less electronic retardation than do compounds **XII** and **XIII** to associative substitution.

It appears[133] that the rapid S_N2 CO substitution reactions of 17-electron metal carbonyls take place via a 19-electron transition state (or intermediate). At one point it was believed that $(\eta^5\text{-}C_5H_5)_2VCO$ may react by a ring-slippage mechanism (see Section 4) in order to maintain an 18-electron count in the transition state. It was decided to prepare and investigate $(\eta^5\text{-indenyl})_2VCO$, thinking it would react more rapidly than the cyclopentadienyl compound due to the indenyl ligand effect. Much to our surprise, the indenyl compound rapidly reacts with CO to afford $(\eta^5\text{-indenyl})(\eta^3\text{-indenyl})V(CO)_2$ with the **XIV** structure determined by X-ray diffraction.[137] This shows the strong tendency towards $\eta^5 \rightarrow \eta^3$ slippage of the indenyl ligand in a 17-electron system, as is known in 18-electron systems.[81]



XIV

Although the rate of associative CO substitution of $V(CO)_6$(17e) is 10^{10} times faster than the corresponding reactions of $Cr(CO)_6$ (18e), we find[136] that the dissociative rates of $(\eta^5\text{-}C_5H_5)(\eta^5\text{-}C_5H_7)VCO$ (17e) and $(\eta^5\text{-}C_5H_5)(\eta^5\text{-}C_5H_7)CrCO$ (18e) are about the same. Qualitatively, the two contrasting results are readily understood on the basis of an energy/reaction coordinate diagram. For the rapid associative substitution of a 17- vs 18-electron system, it is clear that the less stable 17-electron substrate involves a 19-electron transition state which is more stable than the 20-electron transition state required by the more stable 18-electron substrate. The lower activation energy involved in the associative substitution reaction of the 17-electron system leads to a faster reaction rate compared to the 18-electron system [Fig. 5(a)]. Contrast this with the well-known fact that 16-electron compounds are generally more stable than their 15-electron counterparts, and it follows that the activation energies for dissociative substitution of 17- and 18-electron systems may be of similar magnitude [Fig. 5(b)]. Thus one expects differences in rates of dissociative ligand substitution of 17- and 18-electron systems to be smaller than for corresponding associative reactions.

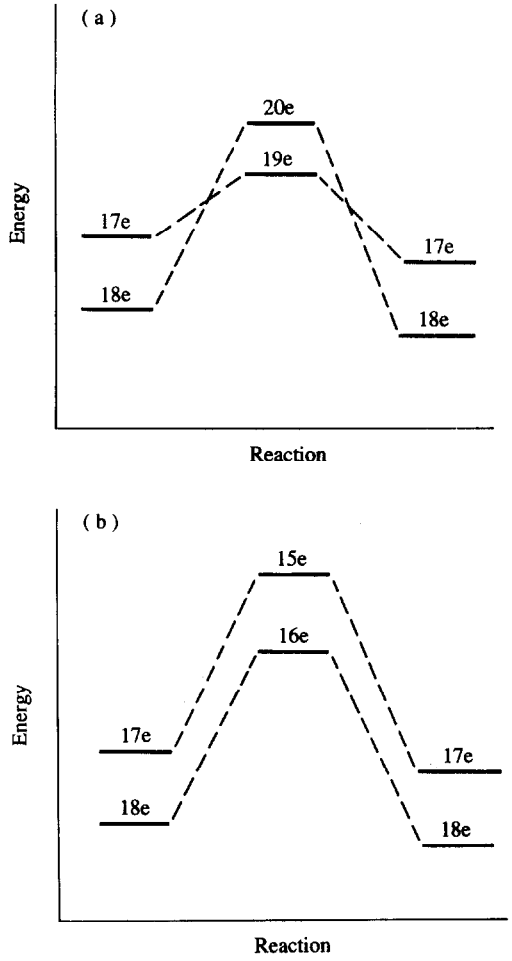


Fig. 5. (a) Energy/reaction coordinate diagram for an associative 18- and 17-electron ligand substitution reaction. (b) Energy/reaction coordinate diagram for a dissociative 18- and 17-electron ligand substitution reaction.

9. OXYGEN ATOM TRANSFER TO METAL CARBONYLS

9.1. $M(CO)_6$ (M = Cr, Mo, W)

Hieber and Lipp[138] first reported the use of pyridine N-oxide to facilitate CO release from $Fe(CO)_5$. A decade later, Alper and Edward[139] established the generality of the reaction and suggested a possible mechanism. Since that time the reaction has been extensively used for the syntheses of metal carbonyl derivatives.[119,140] In spite of this, ours was the first kinetic study[141] of the reaction.

The initial study was on the reactions of $M(CO)_6$ (M = Cr, Mo, W) with PPh_3 in the presence of $(CH_3)_3NO$ [eq. (38)]:

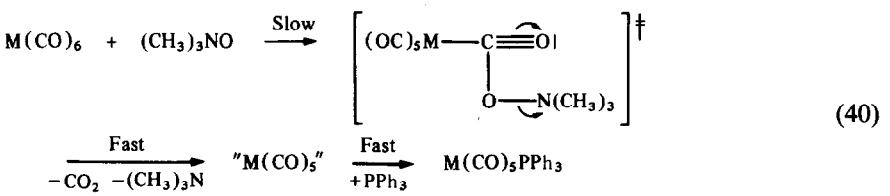
$$M(CO)_6 + PPh_3 + (CH_3)_3NO \longrightarrow M(CO)_5PPh_3 + CO_2 + (CH_3)_3N. \quad (38)$$

The reactions are extremely rapid compared with the rates[8] of thermal substitution in the absence of $(CH_3)_3NO$. The rapid substitution results from the efficient annihilation of one of the CO ligands by converting it into CO_2, which is a poor ligand and a good leaving group. The reactions [eq. (38)] have a second-order rate law [eq. (39)]:

$$-d[M(CO)_6]/dt = k[M(CO)_6][(CH_3)_3NO] \quad (39)$$

being first-order in carbonyl and in $(CH_3)_3NO$, but zero-order in entering ligand, PPh_3, concentration. The rate law is consistent with an associative process, where both bond-making by attack of the $(CH_3)_3NO$ nucleophile and bond-breaking of the M—C bond contribute to the energetics of the rate-determining step. This mechanism is supported by the low values of $\Delta H^{\ddagger}$ and negative values of $\Delta S^{\ddagger}$, which are typical of an associative reaction.

The nucleophilic attack of $(CH_3)_3NO$ is believed to be on C of a CO, because CO_2 is formed and there is ample precedence for such an attack by a variety of nucleophiles.[142] An oxygen atom transfer then forms CO_2, a good leaving group, and generates the very reactive coordinatively unsaturated "$M(CO)_5$" which readily adds the entering ligand [eq. (40)]:



(40)

An alternative four-centre mechanism was easily proven incorrect because it requires the intermediate formation of $M(CO)_5N(CH_3)_3$, which reacts with PPh_3 much too slowly to permit such a pathway for the formation of $M(CO)_5PPh_3$.

The rates of reaction of $M(CO)_6$ decrease in the order W > Mo $\gtrsim$ Cr. Previous studies[143] suggest the ease of nucleophilic attack on C of a metal carbonyl correlates with the C—O stretching frequency of the carbonyl. The higher the value of ν(CO), the more positive is C and the more readily is it attacked by an entering nucleophile. On this basis the rates are expected to vary in the order Mo ~ Cr > W. This is not what is found, and the more rapid rate for $W(CO)_6$ is seen to be due to a more favourable $\Delta S^{\ddagger}$ term, which is perhaps due to a less restricted transition state for the largest member of the triad, tungsten. One other point of interest is the unexpected nucleophilic strength of $(CH_3)_3NO$.[141] The nucleophilic strengths for attack on C of metal carbonyls decrease[142] in the order $CH_3Li > (CH_3)_3NO > PhCH_2MgBr >> N_3^- > NCO^- > NCS^- > Cl^- > Br^- > I^-$. That $(CH_3)_3NO$ is such a strong nucleophile is perhaps because of the high negative charge[144] on O in $(CH_3)_3N^{\delta+} \rightarrow O^{\delta-}$. What is further anomalous is that $(CH_3)_3NO$ is both a good nucleophile and a good oxidizing reagent, since these reactions involve oxidation of CO to CO_2 with reduction of $(CH_3)_3NO$ to $(CH_3)_3N$. Usually a good nucleophile is a good reducing agent,[145] because both processes require the release of electrons by the reagent towards the substrate.

Similar studies were carried out[146] on the monosubstituted compounds $Mo(CO)_5L$ [L = P(*c*-H)$_3$, PPh_3, P(*n*-Bu)$_3$, $N(CH_3)_3$, py, $AsPh_3$, $P(OC_2H_5)_3$, $P(OCH_3)_3$]. Reactions with L in the presence of $(CH_3)_3NO$ follow the same rate law [eq. (39)], and the rates of reaction are slower ($\sim 10^{-3}$) than for the reaction of $Mo(CO)_6$. For ligands L with cone angles less than 135°, the rates of reaction increase with increasing C—O stretching frequencies. For ligands of larger cone angles the rates of reaction are faster than expected on the basis of ν(CO) values, and this is believed to be due to the steric weakening of adjacent M—CO bonds both in the ground and in the transition states for reaction.

Considerable attention[147] has been given to the use of iodosobenzene (PhIO) as an oxygen atom transfer reagent to organic compounds, particularly in the presence of transition metal porphyrins. An example of the use of PhIO in organometallic chemistry is provided by its use[148] in the synthesis of $[(\eta^5\text{-}C_5(CH_3)_5)Re(CO)(NO)PPh_3]BF_4$. It was therefore felt that we should study the oxygen atom transfer properties towards metal carbonyls.

Iodosobenzene is an insoluble polymer,[129] $(PhIO)_n$, but it reacts with and dissolves in methanol as the ester $PhI(OCH_3)_2$. Addition of $Cr(CO)_6$ and CH_3CN to such a solution of $PhI(OCH_3)_2$ results in no reaction, but addition of water catalyses the formation of $Cr(CO)_5(NCCH_3)$.[150] A kinetic study of the reaction in CH_3OH–THF solvent shows the rate is first-order in concentrations of $Cr(CO)_6$, PhIO and H_2O, but inversely proportional to the square of CH_3OH and zero-order in CH_3CN concentrations. These observations are consistent with the following step-wise reactions

[eqs (41), (42), (43) and (44)]:

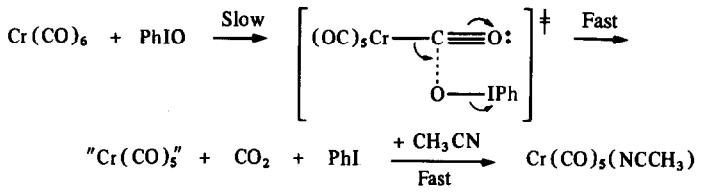
$$PhI(OCH_3)_2 + H_2O \overset{Fast}{\rightleftharpoons} PhIO + 2CH_3OH \tag{41}$$

$$Cr(CO)_6 + PhIO \xrightarrow{Slow} [Cr(CO)_6—PhIO]^{\ddagger} \tag{42}$$

$$[Cr(CO)_6—PhIO]^{\ddagger} \xrightarrow{Fast} \text{“}Cr(CO)_5\text{”} + PhI + CO_2 \tag{43}$$

$$\text{“}Cr(CO)_5\text{”} + CH_3CN \xrightarrow{Fast} Cr(CO)_5(NCCH_3). \tag{44}$$

The mechanism of the rate-determining step [eq. (42)] for the reaction, is believed to be similar to that for $(CH_3)_3NO$ [eq. (40)] with attack on C by the O atom of PhIO [eq. (45)]:



(45)

Not knowing the actual concentration of molecular PhIO in the reaction solutions, it was not possible to quantitatively compare the reactivity of PhIO with that of $(CH_3)_3NO$ towards $Cr(CO)_6$. However, qualitatively it is certain that PhIO is orders of magnitude more effective as an oxygen atom transfer reagent in this reaction than is $(CH_3)_3NO$.

9.2. $M_3(CO)_{12}$ *and* $M(CO)_5$ (M = Fe, Ru, Os)

Although kinetic studies of CO substitution of metal clusters have been extensive,[9,59] ours[151] is the only study of CO substitution in the presence of $(CH_3)_3NO$. In aprotic solvents the reactions [eq. (46)]:

$$M_3(CO)_{12} + L + (CH_3)_3NO \longrightarrow M_3(CO)_{11}L + CO_2 + (CH_3)_3N \tag{46}$$

$$[M = Fe, Ru, Os \text{ and } L = PPh_3, AsPh_3, P(OPh)_3]$$

are too fast to study by conventional spectroscopy, but the rates decrease with added protonic solvents. Reactions are readily monitored at room temperature in the mixed solvent $CHCl_3$–C_2H_5OH (v/v, 2:1), and the rates are inversely proportional to the concentration of C_2H_5OH. It appears this is caused by hydrogen bonding to give $(CH_3)_3NO—HOC_2H_5$, which is unreactive compared with the very reactive free $(CH_3)_3NO$.

The reactions [eq. (46)] follow a second-order rate law, with the rates being first-order in concentrations of metal cluster and of $(CH_3)_3NO$ but zero-order in entering ligand. This rate law is identical with that observed[141] for corresponding reactions of $M(CO)_6$, and it is believed the mechanisms of reaction are the same [eq. (40)]. One marked difference is that the rates of reaction of the clusters are orders of magnitude larger than for the mononuclear carbonyls. This is in agreement with previous studies[143] that show that rates of nucleophilic attack on carbon in metal carbonyls increase with increasing CO stretching frequencies.

In spite of the general correlation between increasing rates of nucleophilic attack on carbon in metal carbonyls with increasing values of ν(CO), just the opposite is observed for this cluster triad with relative rates of $Fe_3(CO)_{12} > Ru_3(CO)_{12} > Os_3(CO)_{12}$. Since the ground-state positive charge on carbon does not control the relative rates, it is necessary to consider factors that can affect the stabilities of the transition states. Gross and Ford[152] report the same rate order for the reactions of $M_3(CO)_{12}$ with CH_3O^- to form $[M_3(CO)_{11}C(O)CH_3]^-$. This reaction also involves attack of CH_3O^- on a C atom, and it was suggested that rates decrease in the order Fe > Ru > Os because the stability of the transition state for reaction decreases in this same order. The reason given for such an order of transition-state stability is that bridging carbonyls are more electron withdrawing[153] and can better accommodate the developing negative charge on the metal cluster as CH_3O^- attacks

a carbonyl carbon in the transition state. The ground-state structure of $Fe_3(CO)_{12}$ in solid and solution contains two bridging carbonyls, whereas $Ru_3(CO)_{12}$ and $Os_3(CO)_{12}$ contain only terminal carbonyls.[154] Because of the longer M—M bond distances going down the iron triad, it becomes increasingly difficult to form bridging carbonyls to delocalize negative charge accumulating in the transition state. For example, the mechanism proposed[155] for the intramolecular fluxional scrambling of COs in $M_3(CO)_{12}$ is believed to involve bridging carbonyls, and the rates of CO scramble decrease in the order Fe > Ru > Os. A more specific example[156] of a third-row transition metal carbonyl with only terminal carbonyls, which forms bridging carbonyls to accommodate negative charge, is provided by $Ir_4(CO)_{12}$ and $[Ir_4(CO)_{11}C(O)OCH_3]^-$, respectively.

Although the addition of Me_3NO to $M_3(CO)_{12}$ in the transition state does not develop a negative charge on the cluster, as does the addition of CH_3O^-, attack by the negative oxygen of $Me_3N^{\delta+}$—$O^{\delta-}$ does increase the electron density in the cluster. This may be sufficient to require carbonyl bridge formation in the transition state for reaction and to account for the relative rates observed. However, it should be noted that reaction of $M_3(CO)_{12}$ with Me_3NO requires breaking a M—C bond. Reactions that do require M—C bond cleavage are thermal CO substitution or exchange reactions of $M_3(CO)_{12}$, which also decrease in rate[9] in the order Fe > Ru > Os. These observations are consistent with the relative rates found for the reactions of $M_3(CO)_{12}$ with Me_3NO, which are believed to involve both O—C bond making and M—C bond breaking.

In an attempt to test the importance of bridging COs on the relative rates of reaction of $M_3(CO)_{12}$ with $(CH_3)_3NO$, it was decided to examine the corresponding reactions of $M(CO)_5$ (M = Fe, Ru, Os) where bridging COs can not be invoked. To begin with, the same second-order rate law [eq. (39)] and presumably the same mechanism [eq. (40)] was found[157] for the reactions of $M(CO)_5$ [eq. (47)]

$$M(CO)_5 + PPh_3 + (CH_3)_3NO \longrightarrow M(CO)_4PPh_3 + CO_2 + (CH_3)_3N. \quad (47)$$

The results show that for a given metal, except for osmium, the rates of reaction for $M_3(CO)_{12}$ are faster than for $M(CO)_5$. For iron the rate difference is about two orders of magnitude, whereas it is approximately one order of magnitude for ruthenium, and $Os_3(CO)_{12}$ reacts at about the same rate as does $Os(CO)_5$. This result is expected on the basis of the usual behaviour that rates of nucleophilic attack on carbon of metal carbonyls increase with increasing frequencies of C—O stretch.[143] The highest values of ν(CO) for $M_3(CO)_{12}$ are approximately 2055 cm^{-1}, compared with 2030 cm^{-1} for $M(CO)_5$.

That the largest rate difference between $M(CO)_5$ and $M_3(CO)_{12}$ is for iron and the smallest is for osmium can be rationalized in terms of formation of bridging carbonyls in the transition state for reaction of the metal carbonyl clusters.[151,152] Since it is known[154] that the degree of difficulty in forming bridging COs in $M_3(CO)_{12}$ clusters increases in the order Fe < Ru < Os, it follows that osmium would experience the greatest rate retardation. This then might explain why the osmium cluster reacts at about the same rate as does $Os(CO)_5$, whereas the largest difference in rate is for iron which has bridging COs in the cluster ground state, and ruthenium experiences an intermediate difference between that of iron and of osmium. Although the CO bridging concept in assisting to dissipate negative charge[153] brought to the transition state by nucleophilic attack is perhaps attractive, surely other factors affect differences in rate between corresponding monomeric and cluster metal carbonyls. Steric effects, symmetry requirements, coordination number and other factors can contribute to the stability of transition states for reactions.

Finally, the reactivities of $M(CO)_5$ with $(CH_3)_3NO$ increase in the order Fe < Ru < Os. This is in agreement with the general correlation[143] between increasing rates of nucleophilic attack on carbon in metal carbonyls with increasing values of ν(CO). The rate order is opposite to what was observed for similar reactions of $M_3(CO)_{12}$, where the rates decrease in the order Fe > Ru > Os. The difference in order of relative rates of reaction of $M(CO)_5$ and $M_3(CO)_{12}$ is consistent with the hypothesis that the ease of bridging COs in the transition state for reactions of clusters enhance their rates of reaction. It is further noteworthy that the mononuclear metal carbonyls $M(CO)_5$ (M = Fe, Ru, Os) and $M(CO)_6$ (M = Cr, Mo, W), respectively, have a similar order of reactivity with $(CH_3)_3NO$. Furthermore, for each triad the difference in rate is small (4 times for the iron triad and 2.5 times for the chromium triad), suggesting the metal plays an indirect role in these reactions where attack is on the carbonyl carbon. In contrast to these small differences, there are large differences[6–8] for rates of thermal CO substitution in the absence of $(CH_3)_3NO$ for each of the triads.

Acknowledgements—I wish to thank Professor M. H. Chisholm for inviting me to write this *Polyhedron Report*. More particularly, I want to thank all my co-workers over the years, without whose help with the experiments and the ideas this research would not have been possible. The research was thankfully supported by Northwestern University and by NSF, AEC, NIH, AFOSR, and PRF.

A POTENTIOMETRIC STUDY ON THE COMPLEXATION BETWEEN MERCURY(II) AND PHENOLATE IONS

F. BEDIA ERIM

Department of Chemistry, Technical University of Istanbul, Maslak 80626, Istanbul, Turkey

(*Received* 22 *January* 1990; *accepted* 19 *February* 1990)

Abstract—The stepwise stabilities of the complexes formed by mercury(II) with the phenolate and *p*-nitrophenolate ions have been determined potentiometrically in an aqueous sodium perchlorate medium of unit ionic strength at 25.0°C. In both of the systems studied, only the strong, mononuclear complexes were formed in the range of concentrations used. No evidence has been found for the formation of polynuclear and/or acid complexes.

Mercury(II)–phenolate complexes have been studied by Veselinović and Malešev at 20°C and various ionic strengths.[1] The mercury(II)–*p*-nitrophenolate system, on the other hand, seems to have not been studied so far.

The present investigation has been performed at 25°C and in an aqueous sodium perchlorate medium of ionic strength 1 mol dm^{-3}. The potentiometric measurements have been carried out by means of a glass electrode. Thus, the free ligand concentrations, [L], have been determined via pH measurements in metal ion solutions containing phenol–phenolate buffers.

EXPERIMENTAL

Chemicals

Mercury(II) perchlorate, sodium perchlorate, perchloric acid and Ag, AgCl electrodes were prepared and analysed as before.[2,3] The free acid concentrations in the stock solutions were determined both potentiometrically and by passing aliquots through a column containing Dowex 50 W cation-exchange resin in the hydrogen form and titrating the eluate with standard sodium hydroxide. Phenol (Merck for synthesis) was freshly distilled in vacuum. Stock solutions were analysed by the bromate method. *p*-Nitrophenol (Merck for synthesis) was recrystallized from chloroform (m.p. 114°C). Stock solutions of *p*-nitrophenol were prepared from weighed portions of the substances. Phenol–sodium phenolate buffer solutions were prepared by mixing phenol solutions with standard sodium hydroxide and adjusting the ionic strength with sodium perchlorate to 1 mol dm^{-3}.

Apparatus and procedure

A Metrohm 654 Digital pH Meter equipped with a Metrohm EA 109 glass electrode was used for measurements. The EMFs of the following cell were measured:

$$-\mathrm{RE}//C_M\mathrm{M\ Hg(ClO_4)_2},\ C_H\mathrm{M\ HClO_4},\ C_L\mathrm{M\ NaOC_6H_4X},\ C_{L'}\mathrm{M\ HOC_6H_4X}\ (\mathrm{X = H\ or\ NO_2}),\ \mathrm{NaClO_4\ to}\ I = 1\ \mathrm{M/GE+},$$

where

$$\mathrm{RE//Ag,\ AgCl/0.025\ M\ NaCl,\ 0.975\ M\ NaClO_4/1.0\ M\ NaClO_4/}.$$

The measurements have been arranged as titrations at constant metal ion and acid concentrations, C_M and C_H, respectively. Equal volumes of the solutions T_1 and T_2 were added to V_0 cm^3 of solution S. Solutions S, T_1 and T_2 have the following compositions:

$$\mathrm{S}: C_M\mathrm{M\ Hg(ClO_4)_2},\ C_H\mathrm{M\ HClO_4},\ (1-C_H-3\,C_M)\mathrm{M\ NaClO_4}$$

$$T_1: C_L\mathrm{M\ NaOC_6H_4X},\ C_{L'}\mathrm{M\ HOC_6H_4X}\ (\mathrm{X = H\ or}\ p\text{-}\mathrm{NO_2}),\ (1-C_L)\mathrm{M\ NaClO_4}$$

T_2: $2C_M$M $Hg(ClO_4)_2$, $2C_H$M $HClO_4$,
$(1-2C_H-6C_M)$M $NaClO_4$.

The titrations were carried out in a Metrohm titration vessel at 25 ± 0.05°C. A magnetic stirrer was used for mixing. Every titration was repeated at least four times with a reproducibility within ±0.2 mV.

Calculations

By measuring the EMFs of the above cell, the free hydrogen ion concentration, h, can be determined. In order to evaluate the formation constants from these measurements, the free ligand concentration, [L], and the average ligand number, $\bar{n}$, must first be calculated from

$$[L] = K_a(C_H + C_{L'} - h)/h \quad (1)$$

and

$$\bar{n} = (C_L - C_H + h - [L])/C_M, \quad (2)$$

respectively. Where C_H is the total acid concentration and C_L and $C_{L'}$ are total phenolate and phenol concentrations, respectively, after the addition of equal volumes of T_1 and T_2 to V_0 cm^3 of solution S.

Once the corresponding values of $\bar{n}$ and [L] are known, the function $X = 1+\Sigma_{j=1}^{N}\beta_j[L]^j$ can be evaluated from a graphical integration of the $\bar{n}$/[L] vs [L] plot. The constants are then obtained graphically[4] by plotting the functions $X_j = (X_{j-1}-\beta_{j-1})/[L]$ vs [L], where $1 \leqslant j \leqslant N$, $X_0 = X$, $\beta_0 = 1$.

RESULTS AND DISCUSSION

The proton–phenolate system

The measurements were carried out as a series of titrations of a solution of phenol varying concentrations, i.e. 300, 400 and 500 mM with a 100 mM NaOH solution ($I = 1$ M). For the *p*-nitrophenol, the concentrations were 30, 40 and 50 mM and titrations were performed with a 10 mM NaOH solution. From these measurements, the acidity constants of phenols can be calculated by the relation

$$K_a = h(C_{NaOH}+h-OH^-)/(C_L - C_{NaOH} - h + OH^-), \quad (3)$$

where C_L is the total phenol concentration.

The values of $K_a = (1.44\pm0.02)\times10^{-10}$ M obtained for phenol and $K_a = (9.17\pm0.08)\times10^{-8}$ M for *p*-nitrophenol from these measurements agree excellently with those reported in the literature under the same conditions.[5]

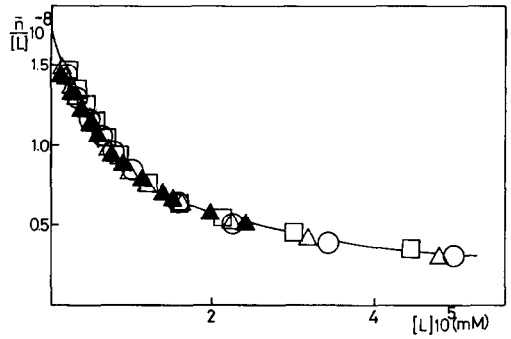

Fig. 1. Plot of $\bar{n}$/[L] vs [L] for the mercury(II)–phenolate system. (○) $C_M = 0.350$ mM, $C_H = 1.493$ mM; (□) $C_M = 0.461$ mM, $C_H = 1.540$ mM; (△) $C_M = 0.645$ mM, $C_H = 1.781$ mM; (▲) $C_M = 0.792$ mM, $C_H = 2.930$ mM.

The mercury(II)–phenolate system

The potentiometric titrations were performed with four different values for C_M. Various ratios of C_M/C_H have been used for each series. Experiments indicated that for values of C_M higher than 1 mM, the precipitation of $Hg(C_6H_5O)_2$ was formed. Therefore no high values of C_M could be used. Instead of using unbuffered sodium phenolate as a ligand solution, titrations were carried out by using phenolate–phenol buffers around pH ~ 8.5 in order to prevent the hydrolysis of mercury(II) ion.

The n/[L] vs [L] plot is shown in Fig. 1, and the complex formation function is presented in Fig. 2. No systematic deviations could be seen between the four titration series used, which shows that neither polynuclear nor acid complexes are formed in the range studied.

The variations of K_a within the limits of error have little effect on β_1, however, the uncertainties of the C_H values of solutions markedly influence the values of $\bar{n}$/[L] for small values of [L] making the

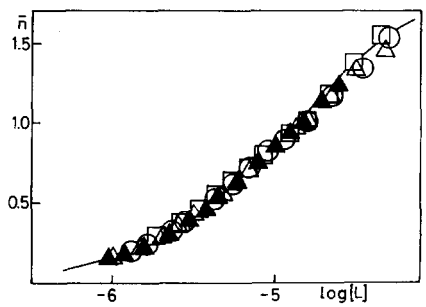

Fig. 2. The complex formation function of the mercury(II)–phenolate system. For symbols refer to Fig. 1 {[L] in mM}.

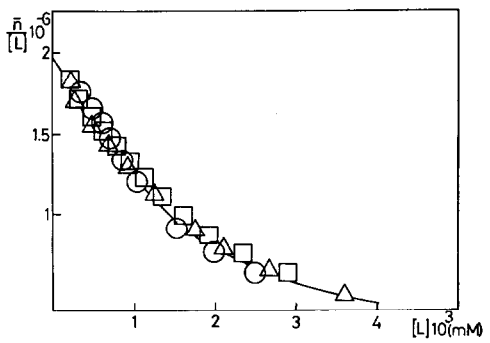

Fig. 3. Plot of $\bar{n}/[L]$ vs [L] for the mercury–*p*-nitrophenolate system. (○) $C_M = 0.739$ mM, $C_H = 2.982$ mM; (□) $C_M = 1.256$ mM, $C_H = 5.373$ mM; (△) $C_M = 1.497$ mM; $C_H = 5.436$ mM.

intercept rather uncertain. Though the C_H values of S solutions have been determined precisely, the uncertainty in β_1 is high. The value of β_2 is little affected by the value of β_1 and will therefore nevertheless be fairly precise.

The mercury(II)–p-*nitrophenolate system*

Three different mercury(II) solutions were employed. Different ratios of C_M/C_H have been used for each series. A buffered ligand solution having pH ~ 8 was used. The $\bar{n}/[L]$ vs [L] plot is shown in Fig. 3, and the complex formtion function, i.e. $\bar{n}$ vs log [L], is plotted in Fig. 4. The complex formation function is independent of both C_M and C_H, which indicates that no polynuclear or acid complexes exist.

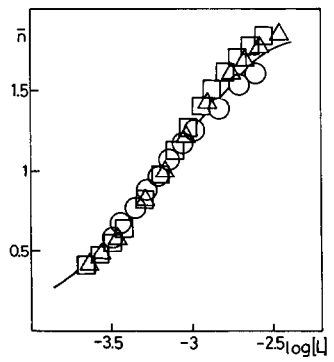

Fig. 4. The complex formation function of the mercury(II)–*p*-nitrophenolate system. For symbols refer to Fig. 3 {[L] in mM}.

Table 1. The overall formation constants for the consecutive steps of mercury(II)–phenolate and mercury(II)–*p*-nitrophenolate systems at 25.0°C and $I = 1$ M. The errors given correspond to estimated errors

System	j	β_j (M^{-j})
Mercury(II)–$C_6H_5O^-$	1	$(1.74 \pm 0.20) \times 10^8$
	2	$(5.60 \pm 0.15) \times 10^{15}$
Mercury(II)–$NO_2C_6H_4O^-$	1	$(1.96 \pm 0.10) \times 10^6$
	2	$(2.24 \pm 0.16) \times 10^{12}$

The constants obtained in this investigation are given in Table 1. The constants for mercury–phenolate complexes are considerably higher than the values found by Veselinović and Malešev, which is to be attributed to the different media used.

The β_1 value of $Hg(C_6H_5O)^+$ is approximately a hundred times larger than that of $Hg(NO_2C_6H_4O)^+$. With regard to the influence of the *p*-nitro group, the formation constants of complexes in general closely parallels that for the corresponding proton–phenolate association.

Acknowledgement—This paper is dedicated to Professor Efraim Avşar, whose stimulating advice and discussions led the Author to undertake the present research.

(*Received* 1 *November* 1989; *accepted* 21 *February* 1990)

Abstract—Reactions in methanol of $[TBA]_2[Mo_2O_7]$ with the appropriate branched polyhydroxylic and polycarboxylic ligands yielded the complexes $[MoO_2\{HOC_2H_4N(C_2H_4O)_2\}]$ (**3**), $[TBA]_2[Mo_2O_4\{O_2NC(CH_2O)_3\}_2]\cdot 2O_2NC(CH_2OH)_3$ (**4**), $[TBA]_2[Mo_2O_5\{HO_2CCH_2N(CH_2CO_2)_2\}_2]\cdot H_2O$ (**5**) and $[TBA][Mo_3O_6(OCH_3)\{CH_3C(CH_2O)_3\}_2]$ (**6**) [where TBA = $(n\text{-}C_4H_9)_4N$]. The deprotonation of **3** yields $[Et_3NH][MoO_2\{N(C_2H_4O)_3\}]$ (**3a**), while **4** was found to aggregate with additional molybdate to give $[TBA][Mo_3O_6(OCH_3)\{O_2NC(CH_2O)_3\}_2]$ (**4a**) and $[Mo_4O_8(OCH_3)_2\{O_2NC(CH_2O)_3\}_2]$ (**4b**). The structural interrelationship of this series of polymolybdate coordination compounds is discussed in terms of simple aggregation processes. Crystal data: **3**, monoclinic $P2_1/n$, $a = 10.688(2)$, $b = 7.559(3)$, $c = 11.386(7)$ Å, $\beta = 99.62(1)°$, $V = 905.2(5)$ Å^3, $Z = 4$, $D_{calc} = 2.02$ g cm^{-3}; 1786 reflections, $R = 0.0406$. **4**, triclinic $P\bar{1}$, $a = 10.965(2)$, $b = 11.850(3)$, $c = 13.247(3)$ Å, $\alpha = 84.72(1)$, $\beta = 89.52(2)$, $\gamma = 66.95(2)°$, $V = 1576.4(7)$ Å^3, $Z = 1$, $D_{calc} = 1.40$ g cm^{-3}; 4718 reflections, $R = 0.0389$. **5**, monoclinic $P2_1$, $a = 10.735(2)$, $b = 13.404(6)$, $c = 19.257(6)$ Å, $\beta = 90.61(2)°$, $V = 2770.9(16)$ Å^3, $Z = 2$, $D_{calc} = 1.36$ g cm^{-3}; 3212 reflections, $R = 0.0380$. **6**, monoclinic $P2_1/n$, $a = 10.908(2)$, $b = 25.674(5)$, $c = 13.059(2)$ Å, $\beta = 96.35(2)°$, $V = 3635.6(12)$ Å^3, $Z = 4$, $D_{calc} = 1.62$ g cm^{-3}; 3143 reflections, $R = 0.0490$.

Coordination complexes of polyoxomolybdates with alkoxy and carbonyl oxygen donor ligands[1–6] have been discussed as models for surface-bound intermediates in heterogeneous catalysis employing solid molybdenum oxides.[7–12] Studies of oxomolybdate(VI) coordination to branched polydentate ligands with oxygen and oxygen and nitrogen donor sets reveal a variety of structural types with features such as pendant donor groups, varying protonation of donor groups, and bridging donor groups, resulting in diverse degrees of aggregation.

Thermally-induced condensation reactions using MoO_3 have been demonstrated to afford a general synthetic method for obtaining Mo^{VI}–oxo complexes from deprotonated di- or polyhydroxylic ligands.[13–16] On the other hand, reactions of branched polydentate $[O_3]$ and $[NO_3]$ donor ligands with molybdate precursors soluble in common organic solvents have not been systematically investigated, nor has the influence of reaction conditions on the degree of aggregation of the molybdate products been addressed. In this paper, we describe the chemistry of $[TBA]_2[Mo_2O_7]$† with the branched polydentate ligands triethanolamine (**1a**), nitrilotriacetic acid (**1b**), tris-hydroxymethylethane (**2a**) and tris-hydroxymethylnitromethane (**2b**). Under identical reaction conditions these ligands give four different structural types, all

possessing the *cis*-dioxomolybdate(VI) core: the mononuclear $[MoO_2\{HOC_2H_4N(C_2H_4O)_2\}]$ **(3)**, the binuclear $[(n\text{-}C_4H_9)_4N]^+[TBA]_2[Mo_2O_4\{O_2NC(CH_2O)_3\}_2]\cdot 2O_2NC(CH_2OH)_3$ **(4)**, the binuclear $[TBA]_2[Mo_2O_5\{HO_2CCH_2N(CH_2CO_2)_2\}_2]\cdot H_2O$ **(5)** and the trinuclear $[TBA][Mo_3O_6(OCH_3)\{CH_3C(CH_2O)_3\}_2]$ **(6)**, whose structures are described herein.

RESULTS AND DISCUSSION

Synthesis and IR spectra

Studies of the coordination chemistry of molybdate with polyhydroxylic ligands and polycarboxylate ligands have generally employed MoO_3 as a synthetic precursor in the preparation of species of various nuclearities. Thus, the reaction of MoO_3 with **1b** in water affords $Na_2[Mo_2O_5\{HO_2CCH_2N(CH_2CO_2)_2\}_2]$[16] or $K_3[MoO_3\{N(CH_2CO_2)_3\}]\cdot H_2O$[17] depending on the base added. Likewise, the reaction of MoO_3 with **2a** in aqueous media yielded $[Mo_2O_2(OEt)_2\{CH_3C(CH_2O)_3\}_2]$[14] and $[Mo_4O_8(OEt)_2\{CH_3C(CH_2O)_3\}_2]$.[18] The chemistry exploits the tendency of molybdenum(VI) to develop distorted octahedral coordination with oxygen ligands through the use of combinations of terminal and bridging oxo groups and ligand oxygen donors. However, the core structure adopted by the complexes is determined by a subtle combination of ligand configurations and reaction conditions.

In an attempt to gain some insight into the influences of reaction conditions and ligand type on the core structures and degrees of aggregation of oxomolybdate complexes, we reacted the ligands **1a**, **1b**, **2a** and **2b** with $[TBA]_2[Mo_2O_7]$ under identical conditions. Thus, one equivalent of $[TBA]_2[Mo_2O_7]$ was reacted with two equivalents of the ligand in a minimum amount of refluxing methanol for 24 h. The products were isolated by carefully layering the resulting clear solutions with ether and allowing them to stand for periods of 3 days to a month. Complexes **3**–**6** were isolated as translucent colourless crystals.

As anticipated, the complexes themselves provided precursors for deprotonation and aggregation reactions. Complex **3** reacts with triethylamine to yield the anionic species $[MoO_2\{N(CH_2O)_3\}]^-$, isolated as the triethylammonium salt, $[Et_3NH][MoO_2\{N(CH_2O)_3\}]$ **(3a)**. However, attempts to deprotonate **5** by a similar route yielded intractable mixtures, and no further attempts were made to isolate products.

The binuclear species **4** was found to react with $[TBA]_2[Mo_2O_7]$ in methanol in the presence of excess $O_2NC(CH_2OH)_3$ to give the trinuclear species $[TBA][Mo_3O_6(OCH_3)\{O_2NC(CH_2O)_3\}_2]$ **(4a)**, which is structurally analogous to **6**. A by-product of this reaction is $[TBA]_2[Mo_3O_7\{O_2NC(CH_2O)_3\}_2]$ **(4b)**, which is presumably an analogue of the previously reported $[TBA]_2[Mo_3O_7\{CH_3C(CH_2O)_3\}_2]$.[19] In turn, reaction of **4a** with $[TBA]_2[Mo_2O_7]$ in methanol yielded a mixture of $[Mo_4O_8(OMe)_2\{O_2NC(CH_2O)_3\}_2]$ **(4b)** and the previously reported $[TBA]_2[Mo_4O_{10}(OCH_3)_6]$. Similarly, reaction of **6** with $[TBA]_2[Mo_2O_7]$ in methanol yielded $[Mo_4O_8(OCH_3)_2\{CH_3C(CH_2O)_3\}_2]$ **(6a)**, a species analogous to **4b** and to the structurally characterized $[Mo_4O_8(OEt)_2\{CH_3C(CH_2O)_3\}_2]$.[18]

The IR spectra of the complexes exhibit features characteristic of the *cis*-dioxomolybdate(VI) core common to the structures of these species. The spectrum of **3** displays strong bands at 920 and 940 cm^{-1}, characteristic of $\nu(Mo{=}O_t)$ for the *cis*-dioxomolybdate unit. Similar features at 923 and 908 cm^{-1} in the spectrum of **4** establish the presence of the *cis*-$[MoO_2]$ unit, while the absence of bands in the 700–800 cm^{-1} region precludes the presence of bridging oxo units. In contrast, the spectrum of **5** exhibits bands at 925 and 913 cm^{-1}, associated with the *cis*-$[MoO_2]$ unit, and an additional feature at 770 cm^{-1} assigned to $\nu(Mo{-}O{-}Mo)$, suggesting the presence of the common $[Mo_2O_5]^{2+}$ structural core. The spectrum of **6** displays a complicated pattern of bands associated with $\nu(Mo{=}O_t)$ in the 900–935 cm^{-1} range and no significant features in the 650–850 cm^{-1} region, consistent with the presence of chemically distinct $(Mo{-}O_t)$ moieties and the absence of $(Mo{-}O_b{-}Mo)$ units.

Structural studies

As illustrated in Fig. 1, the structure of **3** consists of discrete mononuclear $[MoO_2\{HOC_2H_4N(C_2H_4O)_2\}]$ units, with distorted octahedral geometry about the molybdenum centre. The metrical parameters tabulated in Table 1 are unexceptional for mononuclear *cis*-dioxomolybdenum(VI) species. The molybdenum–oxo distances are within the range of 1.66–1.76 Å commonly observed for structures with the *cis*-$[MoO_2]$ unit and the molybdenum–alkoxy oxygen distances, Mo—O(3) and Mo—O(4) are consistent for molybdenum(VI)–alkoxide interactions.[20] The long Mo—N distance is a consequence of the strong *trans* influence of

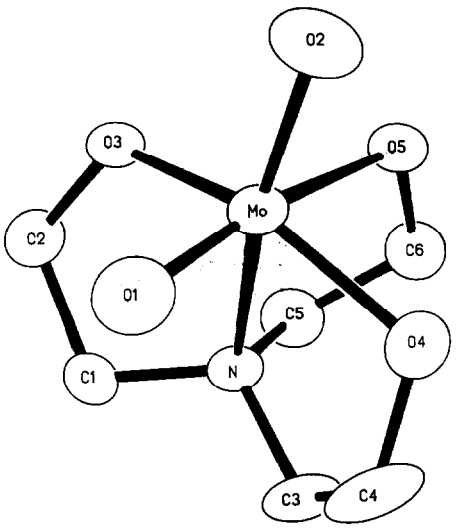

Fig. 1. ORTEP view of the structure of $[MOO_2\{HOC_2H_4N(C_2H_4O)_2\}]$ (3).

O(2) and in the range of other Mo—N distances for complexes with the *cis*-dioxomolybdenum core.

The most unusual feature of the structure is the long Mo—O(5) distance of 2.342(2) Å. Although O(5) is *trans* to the terminal oxo group, O(1), which should result in some lengthening from the normal Mo—O(alkoxide) distance of 1.92–1.96 Å to *ca* 2.10 Å, the significantly longer Mo—O(5) distance is attributed to the protonation of O(5). Since complex **5** is a neutral molybdenum(VI) species, charge requirements dictate that one of the ligand oxygen donors be protonated. Lengthening of the Mo—O distance is a well-documented consequence of the presence of the alcohol rather than the alkoxy form of the ligand.[21–25]

The structure of the molecular anion of **4** is shown in Fig. 2, and relevant bond lengths and angles are presented in Table 2. The molecular anion consists of discrete binuclear units $[Mo_2O_4\{O_2NC(CH_2O)_3\}_2]^{2-}$, with each molybdenum centre displaying $[MoO_6]$ distorted octahedral geometry. A centre symmetry located at the midpoint of the Mo(1)—Mo(1a) vector relates the symmetry equivalent halves of the molecule. The molybdenum centres again exhibit the *cis*-dioxomolybdate core with the polyhydroxyl ligand providing terminal and bridging alkoxy oxygen donors to complete the coordination geometry. The metrical parameters are not unusual, displaying the two short–two long–two intermediate pattern common to $[MoO_6]$ cores.[11] An unusual feature of the structure is the absence of bridging oxo groups; thus, the structure presents $[MoO_2]^{2+}$ moieties bridged by the alkoxy groups of the tridentate poly-

alkoxide ligand. The ligands are disposed so as to bridge the molybdenum centres symmetrically; hence, each ligand spans the Mo(1)—Mo(1a) distance by providing a terminal alkoxy donor to each molybdenum centre, while the third alkoxy group assumes a bridging coordination mode between the molybdenum centres.

Complex **5** also exhibits a binuclear molecular core, as illustrated in Fig. 3, with bonding parameters presented in Table 3. The complex anion exhibits the common $[Mo_2O_5]^{2+}$ core, with the terminal oxo groups in an *anti* configuration. In order to satisfy the coordination requirements of the molybdenum centres, each ligand functions in a tridentate mode through coordination of the nitrogen and of an oxygen of each of two carboxylate groups. The third carboxylate unit of each ligand assumes a pendant geometry and is protonated to satisfy the charge requirements of the molecular anion. Pendant carboxylate units have been described for molybdenum complexes of both the fully deprotonated and the monoprotonated forms of the nitrilo-

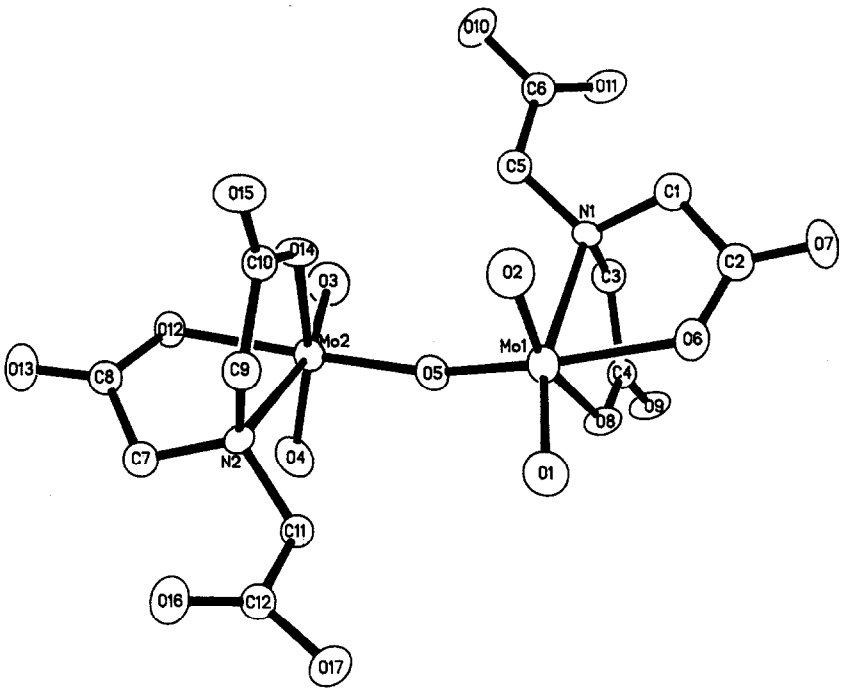

Fig. 3. ORTEP view of the structure of the molecular anion of (**5**), $[Mo_2O_5\{HO_2CCH_2N(CH_2CO_2)_2\}_2]^{2-}$.

triacetate ligands for the complexes $K_3[MoO_3\{N(CH_2CO_2)_3\}]\cdot H_2O$[17] and $Na_2[Mo_2O_5\{HO_2CCH_2N(CH_2CO_2)_2\}_2]\cdot 8H_2O$,[14] respectively. The latter possesses a molecular anion whose structure is essentially identical to that described for **5**.

The bonding parameters associated with the structure of **5** are unexceptional. The molybdenum–terminal oxo distances fall in the usual range, as do the Mo—O(5) distances. The strong *trans* influence of the terminal oxo groups is evident in the Mo(1)—N(1), Mo(2)—N(2), Mo(1)—O(8) and Mo(2)—O(14) distances (2.457(7), 2.488(6), 2.144(6) and 2.130(7) Å, respectively). The Mo—O distances for the alkoxy donors *trans* to the bridging oxo group are considerably shorter than those *trans* to the terminal oxo groups (2.077(7) and 2.060(7) Å vs 2.144(6) and 2.130(7) Å), but somewhat longer than molybdenum–alkoxy-oxygen distances observed for cases of co-ligands which exert no *trans* influence. The bond parameters for the pendant carboxylate groups establish O(10) and O(17) as the protonation sites.

Crystal structure analysis of **6** revealed the discrete trinuclear anion illustrated in Fig. 4. The molybdenum centres exhibit the usual $[MoO_6]$ distorted octahedral geometry with the bond parameters given in Table 4. There are two distinct molybdenum geometries: Mo(1) and Mo(2) each coordinate to two terminal oxo ligands and complete their coordination requirements through ligation to bridging and terminal alkoxy donors, while the Mo(3) centre bonds to two terminal oxo groups and to a terminal methoxy group while completing its coordination by ligating to three bridging alkoxy groups provided by the $\{CH_3C(CH_2O)_3\}^{3-}$ ligands. The ligands are inequivalent: one provides three doubly-bridging alkoxy donors O(1), O(2) and O(3), while the second exhibits a triply-bridging oxygen O(8), and two terminal alkoxy groups, O(6) and O(7).

These structural studies indicate that grossly different structural types result from minor variations in the ligand configuration, even under identical reaction conditions. The mononuclear nature of **3** is predicated by the tendency of the ligand to adopt a pyramidal tetradentate ligation mode. The protonation of one alkoxy group, resulting in a neutral complex, appears to be a function of the reaction conditions, since in the presence of triethylamine the anionic analogue $[MoO_2\{N(CH_2O)_3\}]^{2+}$ (**3a**) is obtained.

In contrast, the nitrilotriacetate ligand is known to function as tridentate, leaving one carboxylate function pendant. This type of coordination should favour the formation of binuclear oxo-bridged species, and the $[Mo_2O_5]^{2+}$ core is a predominant unit in the structural chemistry of binuclear molybdenum(VI) species.

Complexes **4** and **6** are perhaps the most unusual as examples of multinuclear molybdenum(IV)–oxo species with no bridging oxo ligands. In both instances, the cluster integrity is provided by alkoxy units which generate the framework bridging the $[MoO_2]^{2+}$ structural cores. The common feature of the four structures **3**–**6** is the presence of the *cis*-dioxomolybdate(VI) unit.

It is instructive to compare the structures of complexes **4** and **6**. Figure 5 illustrates the structures of **4**, **6** and the related $[Mo_4O_8(OEt)_2\{CH_3C(CH_2O)_3\}_2]$ viewed as the conventional ball and stick representations and the corresponding depiction as edge-sharing octahedra. Complex **4** is thus represented as two octahedra sharing an edge defined by the two bridging alkoxy oxygen donors. The structure of **6** is then constructed by condensing a $[MoO_2(OR)]^+$ unit onto the $[Mo_2O_4\{RC(CH_2O)_3\}_2]^{2-}$ core using three alkoxy groups so disposed as to provide facial tridentate coordination. Figure 5(a) and (b) illustrates the aggregation process, while Fig. 5(d) and (e) shows the simple relationship of edge-sharing otahedra which results. The structure shown in Fig. 5(b) may of

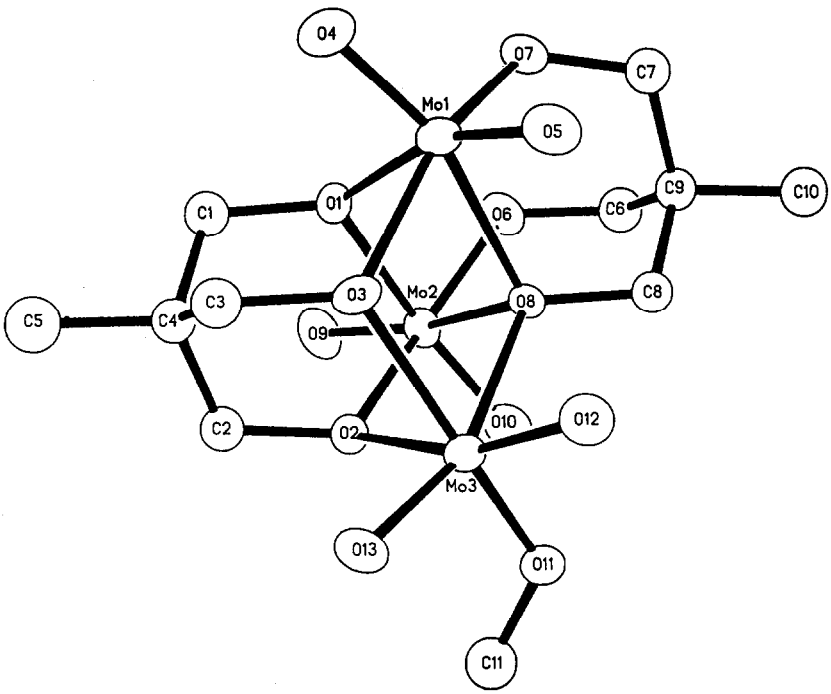

Fig. 4. ORTEP view of the structure of the molecular anion of **6**, $[Mo_3O_6(OCH_3)\{CH_3C(CH_2O)_3\}_2]^-$.

course accommodate an additional $[MoO_2(OR)]^+$ fragment on its opposite face by providing another set of alkoxy donors positioned in a vicinal tridentate grouping. The structure of $[Mo_4O_8(OEt)_2\{CH_3C(CH_2O)_3\}_2]$, shown in Fig. 5(c), may thus be viewed as a condensation product of **6** with an additional $[MoO_2(OR)]^+$ unit. The polyhedral model is illustrated in Fig. 5(f).

It is tempting to speculate on the mechanisms of aggregation processes of polyoxomolybdate coordination complexes based on these structural relationships between the binuclear, trinuclear and tetranuclear complexes of the tris-methoxyethane ligand. The principles underlying polyanion accretion are not understood in detail, although various condensation processes have been invoked.[26,27] In the present instance, the various aggregates may form according to the series of simple condensations outlined below, where H_3L is $CH_3C(CH_2OH)_3$:

$$[Mo_2O_7]^{2-} + 2H_3L \longrightarrow [Mo_2O_4L_2]^{2-} + 3H_2O$$

$$2[Mo_2O_4L_2]^{2-} + [Mo_2O_7]^{2-} + H_3L + MeOH \longrightarrow [Mo_3O_6(OMe)L_2]^{2-} + [Mo_3O_7L_2]^{2-} + 2H_2O + L^{3-}$$

$$2[Mo_3O_6(OMe)L_2]^{-} + [Mo_2O_7]^{2-} + 6MeOH \longrightarrow [Mo_4O_8(OMe)_2L_2] + [Mo_4O_{10}(OMe)_6]^{2-} + H_2O + 2H_2L^{-}.$$

The synthesis of $[TBA][Mo_3O_6(OMe)\{O_2NC(CH_2O)_3\}_2]$ from $[TBA]_2[Mo_2O_4\{O_2NC(CH_2O)_3\}_2]$ in a methanolic solution of $[Mo_2O_7]^{2-}$ and excess H_3L suggest that this sequence of condensation steps is not totally naive or a simple formalism. However, it is also apparent that, whatever the merit of this scheme in explaining the aggregation of the tris-methoxyethane type of clusters, it is specific to this set of complexes and cannot be applied to other ligand systems. Ligand geometry and donor groups appear to be dominant features in determining the structural type adopted. Hence, a general mechanistic description of aggregation in polyoxomolybdate coordination complexes remains elusive.

Although the tetranuclear core is a common feature of the chemistry of coordination complexes of polyoxomolybdates, the arrangement of octahedra in these species exhibits considerable variation, as shown in Fig. 6. The most common arrangement is that shown in Fig. 6(1); it may be significant that this is also the most compact structure[28] of the tetranuclear clusters described to date. The molybdenum(V) species $[Mo_4\{HB(pz)_3\}_2O_4(OCH_3)_2(CH_3OH)_2]$[21] exhibits the arrangement illustrated in Fig. 6(3), while the structure of Fig. 6(4) has been described for $[Me_3N(CH_2)_6NMe_3]_2[Mo_4O_{11}(citrate)_2]\cdot 12H_2O$.[29] Although corner-sharing of octahedra is unusual in polyoxometalate chemistry, several examples have been described in recent years in the course of the development of

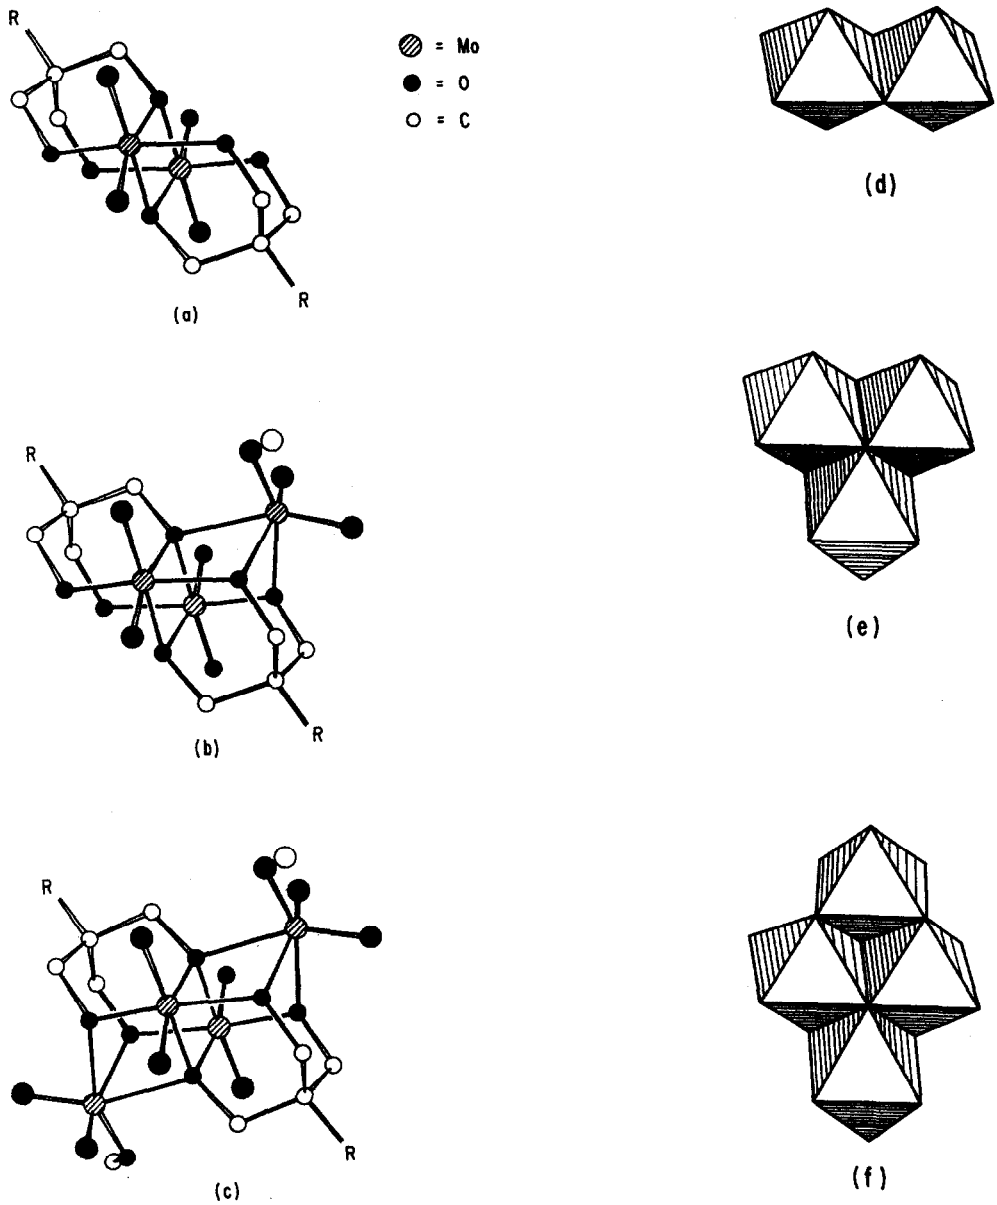

Fig. 5. Schematic ball and stick representations of the structures of (a) $[Mo_2O_4\{RC(CH_2O)_3\}_2]^{2-}$, (b) $[Mo_3O_6(OCH_3)\{RC(CH_2O)_3\}_2]^-$ and (c) $[Mo_4O_8(OCH_3)_2\{RC(CH_2O)_3\}_2]$. The corresponding polyhedral models (d) $[Mo_2O_4\{RC(CH_2O)_3\}_2]^{2-}$, (e) $[Mo_3O_6(OCH_3)\{RC(CH_2O)_3\}_2]^-$ and (f) $[Mo_4O_8(OCH_3)_2\{RC(CH_2O)_3\}_2]$.

the coordination chemistry of polyoxometalates. Other examples of corner-sharing interactions for tetranuclear species include $[Mo_4O_{12}\{CH_3C(NH)NO\}_2]^{2-}$ [30] and $[Mo_4O_{11}\{tolC(NH_2)NHO\}_2\{tolC(NH)NHO\}\{tolC(NH)NO\}]^-$ [31] shown diagrammatically in Fig. 6(5) and (6). This range of structural types for tetranuclear polyoxomolybdate coordination complexes emphasizes the dominant role played by the ligand donor set and geometrical constraints in determining the geometry of the complex.

CONCLUSIONS

Under identical reaction conditions, $[TBA]_2[Mo_2O_7]$ reacts with the branched polydentate ligands triethanolamine, tris-hydroxymethylnitromethane, nitrilotriacetic acid, and tris-hydroxymethylethane to give $[MoO_2\{HOC_2H_4N(C_2H_4O)_2\}]$ (**3**), $[TBA]_2[Mo_2O_4\{O_2NC(CH_2O)_3\}_2]\cdot 2O_2NC(CH_2OH)_3$ (**4**), $[TBA]_2[Mo_2O_5\{HO_2CCH_2N(CH_2CO_2)_2\}_2]\cdot H_2O$ (**5**) and $[TBA][Mo_3O_6(OCH_3)\{CH_3C(CH_2O)_3\}_2]$ (**6**). The type of molybdenum–

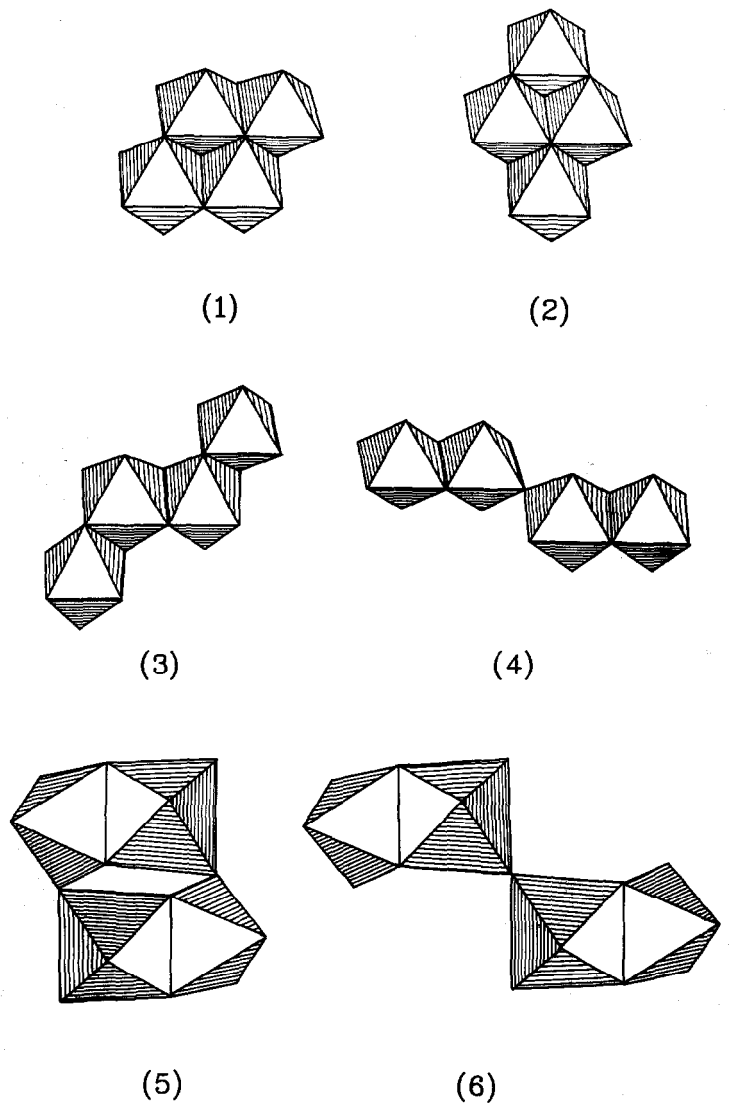

Fig. 6. Polyhedral representations of the structures of $[Mo_4O_{10}(OCH_3)_6]^{2-}$ (1), $[Mo_4O_8(OEt)_2\{CH_3C(CH_2O)_2\}_2]$ (2), $[Mo_4\{HB(pz)_3\}_2O_4(OCH_3)_2(HOCH_3)_2]$ (3), $[Mo_4O_{11}(citrate)_2]^{2-}$ (4), $[Mo_4O_{12}\{CH_3C(NH_2)NO\}_2]^{2-}$ (5) and $[Mo_4O_{11}\{tolC(NH_2)NHO\}_2\{tolC(NH)NHO\}\{tolC(NH)NO\}]^-$ (6).

oxo core isolated is determined in large part by the ligand donor set and configuration, although the $[MoO_2]^{2+}$ unit is a common feature of all the structures.

For the limited set of complexes **4**, **6** and $[Mo_4O_8(OR)_2\{R'C(CH_2O)_3\}_2]$, a common structural core is apparent, and aggregation appears to occur via a series of simple condensation-type processes. However, the detailed mechanisms of aggregation of polyoxomolybdate coordination complexes remain elusive, and general conclusions about interconversions of structural types cannot be drawn from the limited data available.

EXPERIMENTAL

Materials and methods

All reactions were performed in freshly dried and distilled solvents. Dichloromethane was technical grade and was redistilled from $CaCl_2$ and P_4O_{10}. All other solvents were reagent grade and were obtained from standard commercial sources without further purification. $[(n\text{-}C_4H_9)_4N]_2[Mo_2O_7]$ was prepared according to the published method.[32]

The following instruments were used in this work: IR, Perkin–Elmer 283B IR spectropho-

tometer; X-ray crystallography, Nicolet R3m/V diffractometer.

Preparation of compounds

$[MoO_2\{HOC_2H_4N(C_2H_4O)_2\}]$ (**3**). $[TBA][Mo_2O_7]$ (3.10 g, 5.7 mmol) was dissolved in methanol (20 cm^3) and added to a stirred solution of $N(C_2H_4OH)_3$ (**1a**) (1.70 g, 11.4 mmol) in methanol (5 cm^3). After refluxing for 24 h and filtering, the clear solution was layered with 30 cm^3 of diethyl ether and allowed to stand at room temperature for 5 days. Translucent, colourless crystals were collected in 42% yield. Found: C, 25.9; H, 4.6; N, 5.2. Calc. for $C_6H_{13}NO_5Mo$: C, 26.2; H, 4.7; N, 5.1%.

$[Et_3NH][MoO_2\{N(C_2H_4O)_3\}]$ (**3a**). Complex **3** (0.5 g, 1.8 mmol) was reacted with excess triethylamine (0.36 g, 3.6 mmol) in methanol (30 cm^3). After stirring for 3 h, the clear solution was layered with diethyl ether. After 2 weeks, a white powder was collected. Found: C, 38.5; H, 7.3; N, 7.2. Calc. for $C_{12}H_{28}N_2O_5Mo$: C, 38.3; H, 7.4; N, 7.4%.

$[TBA]_2[Mo_2O_4\{O_2NC(CH_2O)_3\}_2]\cdot 2O_2NC(CH_2OH)_3$ (**4**). $[TBA]_2[Mo_2O_7]$ (3.10 g, 5.7 mmol) was dissolved in methanol (20 cm^3) and added to a stirred solution of $O_2NC(CH_2OH)_3$ (**2b**) (1.72 g, 11.4 mmol) in methanol (5 cm^3). After refluxing for 24 h and filtering, the clear solution was layered with 30 cm^3 of diethyl ether. After standing for 2 weeks at room temperature, translucent, colourless crystals of **4** were obtained in 36% yield. Found: C, 43.6; H, 7.5; N, 5.9. Calc. for $C_{48}H_{102}N_6O_{24}Mo_2$: C, 43.0; H, 7.6; N, 6.3%.

$[TBA][Mo_3O_6(OCH_3)\{O_2NC(CH_2O)_3\}_2]$ (**4a**). Complex **4** (1.5 g, 1.1 mmol), dissolved in methanol (10 cm^3), was added to a solution of $[TBA]_2[Mo_2O_7]$ (0.60 g, 1.1 mmol) and **2b** (0.17 g) in methanol (20 cm^3). After refluxing for 3 h, the solution was cooled to room temperature and a white precipitate of $[Mo_4O_8(OMe)_2\{O_2NC(CH_2O)_3\}_2]$ was collected. The filtrate was treated with 30 cm^3 of diethyl ether and the solution was stored at −4°C for 2 days, whereupon a white microcrystalline precipitate of **4a** was collected. Found: C, 31.2; H, 5.4; N, 4.7. Calc. for $C_{25}H_{51}N_3O_{17}Mo_3$: C, 31.5; H, 5.3; N, 4.4%.

$[Mo_4O_8(OCH_3)_2\{O_2NC(CH_2O)_3\}_2]$ (**4b**). Complex **4a** (1.0 g, 1 mmol) was added to a solution of $[TBA]_2[Mo_2O_7]$ (0.54 g, 1 mmol) in methanol (20 cm^3). After refluxing for 4 h, the volume was reduced to 5 cm^3. Upon standing for 1 week at −4°C, the white powder of **4b** which precipitated was collected. Treatment of the filtrate with diethyl ether and standing at room temperature for 5 days yielded a small amount (10% yield) of $[TBA]_2[Mo_4O_{10}(OCH_3)_6]$. Found: C, 13.3; H, 1.9; N, 3.0. Calc. for $C_9H_{12}N_2O_{19}Mo_4$: C, 13.8; H, 2.1; N, 3.2%.

$[TBA]_2[Mo_2O_5\{HO_2CCH_2N(CH_2CO_2)_2\}_2]\cdot H_2O$ (**5**). The complex was synthesized using an identical procedure to that used for the synthesis of **3** and **4**. Thus, $[TBA]_2[Mo_2O_7]$ (3.10 g, 5.7 mmol) was reacted with $N(CH_2COOH)_3$ (**1b**) (2.18 g, 11.4 mmol) to give complex **5** in 40% yield as translucent, colourless needles. Found: C, 45.3; H, 7.3; N, 4.5. Calc. for $C_{44}H_{88}N_4O_{18}Mo_4$: C, 45.8; H, 7.6; N, 4.9%.

$[TBA][Mo_3O_6(OCH_3)\{CH_3C(CH_2O)_3\}_2]$ (**6**) The synthesis was identical to that employed for **3–5**, with the exception that $CH_3C(CH_2OH)_3$ (1.37 g, 11.4 mmol) was used as ligand. Complex **6** was isolated in 32% yield as translucent, colourless crystals. Found: C, 36.2; H, 6.3; N, 1.5. Calc. for $C_{27}H_{57}NO_{13}Mo_3$: C, 36.4; H, 6.4; N, 1.6%.

$[Mo_4O_8(OCH_3)_2\{CH_3C(CH_2O)_3\}_2$ (**6a**). Complex **6** (1.0 g, 1.1 mmol) was added to a solution of $[TBA]_2[Mo_2O_7]$ (0.60 g, 1.1 mmol) in methanol (20 cm^3). After refluxing for 24 h, the resulting clear solution was concentrated to 5 cm^3 and allowed to stand for 3 weeks at room temperature. Crystals of **6a** were collected in 23% yield. Found: C, 17.3; H, 2.6. Calc. for $C_{12}H_{24}O_{16}Mo_4$: C; 17.8; H, 3.0%.

X-ray crystallography

The details of the crystal data, data collection methods and refinement procedures are given in Table 5. (Supplementary Tables provide atomic positional parameters for the structures reported. Tables of bond lengths and angles, anisotropic thermal parameters and calculated and observed structure factors for all complexes are available.)* Full details of the crystallographic methodlologies may be found in ref. 33.

In no instance was an extinction correction applied for the data. Idealized hydrogen atom positions were used throughout the analysis, with the C—H and N—H distances set at 0.96 and 0.94 Å, respectively.

Acknowledgement—This research was supported by a grant from the National Science Foundation (CHE8815299).

* Supplementary materials available: Fractional coordinates have been deposited with the Director, Cambridge Crystallographic Centre. Complete listings of bond distances and angles are available from the Editor, Queen Mary and Westfield College, London.

^{31}P NMR STUDY ON THE BINDING ISOMERS OF CHROMIUM(III) PHOSPHINATE COMPLEXES IN SOLUTION

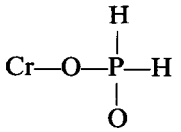
QI FENG and HIROHIKO WAKI*

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashiku, Fukuoka, Japan

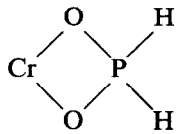
(*Received* 26 *September* 1989; *accepted* 22 *February* 1990)

Abstract—A ^{31}P NMR study on the structure of chromium(III) phosphinate complexes has been made. The formation of the outer-sphere complexes gave a downfield shift of the ^{31}P NMR signal, though the signal could not be separated from that of free phosphinate anion due to their great lability. On the other hand, the inner-sphere complexes gave an upfield shift of the signal separated from that of outer-sphere type. Furthermore, it was found that the signal for the inner-sphere complex has two peaks, one being due to non-chelate binding and the other being due to chelate binding. By distinguishing these binding modes, based on the experimental evidence, a large number of new isomers for chromium(III) phosphinate have been revealed.

For the complex formation between phosphorus oxo-anions and metal ions, a large number of stability constants have been reported.[1,2] However, it has not been clarified whether a monomeric phosphorus oxo-anion coordinates to a metal ion with a single oxygen atom (non-chelate binding) or with two or more oxygen atoms (chelate binding). Although chelation has been reported for phosphite in some crystalline compounds,[3–5] this is not the case for solution species. Recently we accomplished a complete equilibrium analysis on the chromium phosphinate complex system, $[Cr(PH_2O_2)_m(H_2O)_{6-m}\cdot(PH_2O_2)_x^{out}]^{(m+x-3)-}$, and evaluated a set of stability constants distinguishing inner-sphere and outer-sphere coordination;[6] but it was still unknown whether the phosphinate anion is bound as a monodentate (I) or as a bidentate (II) ligand. In the saturated inner-sphere complex $Cr(PH_2O_2)_6^{3-}$ all the ligands should be monodentate, but in the lower complexes the presence of other modes of binding can not be denied, considering the coordination number of chromium.



(I)



(II)

The purpose of this work is to clarify the binding mode of a phosphinate anion to a chromium ion and/or to prove the co-existence of non-chelate and chelate complexes. ^{31}P NMR spectrometry was employed in this study, since the NMR spectrum should be sensitive to different binding modes for the complexes in solutions. This information for the phosphinate ligand may lead to an understanding of the coordination for other phosphate ligands, for example orthophosphate and phosphite anions, and also for more general oxo-anion ligands.

EXPERIMENTAL

Chemicals

Chromium(III) perchlorate, sodium phosphinate and tetramethylammonium chloride were of commercially-available reagent grade. The chromium(III) phosphinate solution was prepared by passing a chromium perchlorate solution through a column of phosphinate form Dowex 1-4X (100–200 mesh).

^{31}P *NMR measurements*

^{31}P NMR spectra of the chromium(III) phosphinate complexes were recorded with a JEOL NMR spectrometer JNM-GX 400 operating at 161.86 MHz and 20°C in the pulsed mode. The

* Author to whom correspondence should be addressed.

chemical shifts were referred to standard 85% H_3PO_4. When necessary, integration was employed to increase the sensitivity of the NMR spectrometer.

Preparation of the sample solution of the inner-sphere chromium(III) phosphinate complexes for NMR measurements

The equilibrium mixture of the chromium(III) phosphinate complexes was prepared by leaving a solution containing chromium perchlorate or chromium phosphinate and sodium phosphinate in an appropriate ratio, at 100°C for 3 h to reach equilibrium. The sample solutions of individual inner-sphere complex species were obtained by separating the equilibrium mixture of the chromium phosphinate complexes by Donnan exclusion chromatography.[6-8] A column containing SP-Sephadex C-25 in the tetramethylammonium form (1.5 cm $\phi \times 90$ cm bed) was used. The chromium complex species in the effluent were automatically detected with an Atto variable-wavelength spectrophotometer LDC Model Spectromonitor III (420 nm), which was connected to the separating column. The purity of the NMR sample solution of a particular complex species was chromatographically checked by Donnan exclusion chromatography after the NMR measurements. These purities were above 95% in all cases. The average ligand number of the inner-sphere chromium phosphinate complex for the equilibrium mixture was determined in the same way as for the purity measurement.

Time-dependence measurement of the ^{31}P NMR spectra of chromium phosphinate complexes

The solutions of chromium perchlorate and sodium phosphinate were mixed to form a 0.02 M chromium perchlorate–0.5 M sodium phosphinate solution, which was kept at 100°C. The ^{31}P NMR spectrum of this solution was measured at appropriate time intervals. The spectrum of a 0.62 M sodium phosphinate solution was used as the standard spectrum of the free $PH_2O_2^-$ ion.

RESULTS AND DISCUSSION

Behaviour of the ^{31}P NMR spectra of chromium(III) phosphinate outer-sphere complexes

The NMR resonance of the chromium(III) phosphinate outer-sphere complex is not detected as a separate peak from free phosphinate ion, since outer-sphere complexes are very labile. Thus information on complexation could only be obtained from the shift of the ^{31}P NMR peak position. The chemical shift, δ_{obs}, for the one-to-one complexation is given by

$$\delta_{obs} = \alpha_0\delta_0 + \alpha_1{}^{out}\delta_1{}^{out},$$

where α_0 and $\alpha_1{}^{out}$ are mole fractions of free phosphinate anion and of phosphinate anion bound in the outer-sphere, respectively, and δ_0 and $\delta_1{}^{out}$ are their inherent chemical shifts.

Figure 1 shows the time dependence of the ^{31}P NMR chemical shift for the solution in which chromium perchlorate and sodium phosphinate were mixed at 100°C. The resonance first shifted downfield instantaneously after mixing and then returned to the free phosphinate resonance gradually. Clearly the downfield shift is due to outer-sphere complexation, and the subsequent upfield shift is due to decrease of α^{out} by its gradual conversion to inner-sphere complexation. This fact may support the results obtained from the absorption spectrum and equilibrium analysis in the previous report.[6]

^{31}P NMR spectra of the inner-sphere complexes

The inner-sphere chromium(III) phosphinate complexes are inert and the rate of ligand exchange is very low, different from the outer-sphere complexes, thus the NMR resonance can be observed as independent peaks separated from that of free phosphinate or its outer-sphere complexes. The ^{31}P NMR spectrum of the chromium phosphinate and sodium phosphinate solution, equilibrated at 100°C for 3 h, is shown in Fig. 2. The huge triplet peak, the centre signal being at 9.3 ppm, is due to free phosphinate anion present in large excess. Two smaller peaks also appeared and they were assigned to the inner-sphere complexes. The difference in chemical shift from the free anion was considerable, as in the case of other phosphate complexes,[9,10] and the shift was in the opposite direction to that of

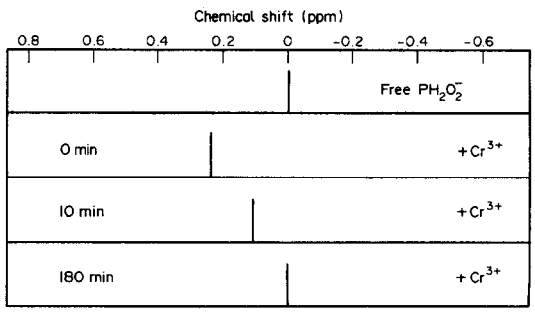


Fig. 1. Time dependence of the ^{31}P NMR chemical shift of a 0.02 M $Cr(ClO_4)_3$–0.5 M $NaPH_2O_2$ solution at 100°C, relative to free $PH_2O_2^-$ anion.

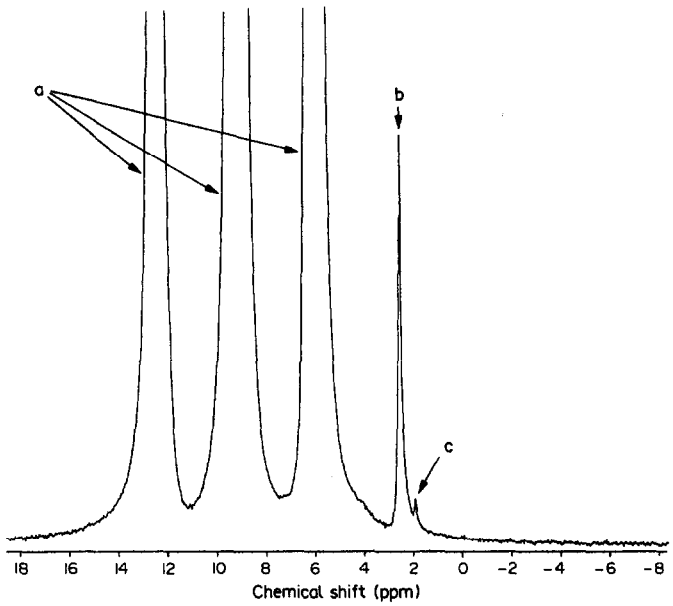

Fig. 2. ^{31}P NMR spectrum of a solution containing 0.05 M $Cr(PH_2O_2)_3$ and 1 M $NaPH_2O_2$ kept at 100°C for 3 h at pH 3.

the outer-sphere complexes, reflecting a different coordination sphere. It may be most important to clarify the assignment of the observed two inner-sphere peaks.

In order to obtain ^{31}P NMR spectra of the inner-sphere complex of a single composition, the mutual separation of inner-sphere complexes is necessary. The recently developed Donnan exclusion chromatography for separation of the inner-sphere complexes was employed.[6] The ^{31}P NMR spectrum of the $Cr(PH_2O_2)_4^-$ complex sample taken from the corresponding fraction of chromatographic effluent is shown in Fig. 3. The triplet, peak *a*, is due to the free phosphinate ion, and both peaks *b* and *c* are due to the $Cr(PH_2O_2)_4^-$ complex. The NMR spectra of other complexes were also recorded in the same way.

It was found that identification of the complexes

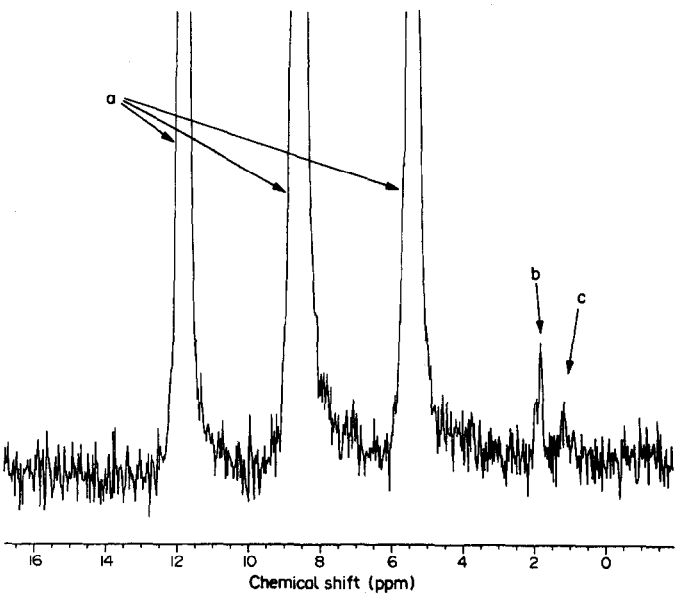

Fig. 3. ^{31}P NMR spectrum for the $Cr(PH_2O_2)_4^-$ fraction of chromatography.

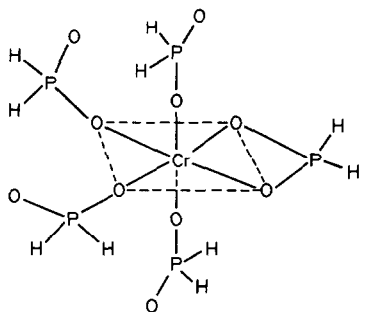
using the NMR spectrum becomes more difficult with decreasing ligand number, due to broadening of the spectrum arising from the long electron-spin relaxation time associated with the paramagnetic chromium(III) ion.[11] Fortunately, the higher complexes such as $Cr(PH_2O_2)_4^-$, $Cr(PH_2O_2)_5^{2-}$ and $Cr(PH_2O_2)_6^{3-}$ studied here, are considered more important for our purpose due to the above reason.

The chemical shift data for these higher complexes are summarized in Fig. 4. The chemical shift data for the equilibrium mixture of mean ligand number $n = 5.3$, in which $[Cr(PH_2O_2)_6^{3-}]$: $[Cr(PH_2O_2)_5^{2-}]$: $[Cr(PH_2O_2)_4^-] = 1 : 0.65 : 0.39$, are also shown for comparison. A single peak for the $Cr(PH_2O_2)_6^{3-}$ complex and two peaks for the $Cr(PH_2O_2)_5^{2-}$ or $Cr(PH_2O_2)_4^-$ complexes were observed, respectively. This indicates that there are two different types of ligand in these complexes. These will be discussed in detail in the following section. Also, for the mixture only two peaks were observed which have the same chemical shift values as those of $Cr(PH_2O_2)_5^{2-}$ and $Cr(PH_2O_2)_4^-$ samples. This indicates that the chemical shifts for the complexes are almost independent of the ligand number, in the system studied.

Binding modes of the inner-sphere complexes

In the spectrum of $Cr(PH_2O_2)_6^{3-}$ only one peak was observed, whereas in the spectra of $Cr(PH_2O_2)_5^{2-}$ and $Cr(PH_2O_2)_4^-$, in addition to a peak which has the same chemical shift as $Cr(PH_2O_2)_6^{3-}$ other peaks were also observed at higher field (Fig. 4). Since the coordination number of the chromium(III) complex is six, in $Cr(PH_2O_2)_6^{3-}$ all phosphinate ligands coordinate to chromium(III) using a single oxygen atom to form non-chelate binding, giving only one peak in the spectrum. On the other hand, in $Cr(PH_2O_2)_5^{2-}$,



$Cr(O_2PH_2)(OPH_2O)_4^{2-}$

Fig. 5. Binding mode of inner-sphere chromium(III) phosphinate complex.

besides non-chelate binding, chelate binding, in which the phosphinate ligand coordinates to chromium(III) with two oxygen atoms, may occur (Fig. 5). The chelate and non-chelate binding ligands have different effects on the phosphorus atom, thus two peaks were observed. For the same reason, two peaks were observed also in the spectrum of $Cr(PH_2O_2)_4^-$. Peak *b*, which is a common peak for the complexes $Cr(PH_2O_2)_6^{3-}$, $Cr(PH_2O_2)_5^{2-}$ and $Cr(PH_2O_2)_4^-$, can be assigned to the non-chelate binding ligand, and peak *c* to the chelate binding ligand. Since chelate binding is stronger than non-chelate binding, the resonance for the chelate binding ligand should appear at a higher field than for the non-chelate one. Also for the lower complexes such as $Cr(PH_2O_2)_3$, $Cr(PH_2O_2)_2^+$ and $Cr(PH_2O_2)^{2+}$, it may be possible to consider the co-existence of non-chelate and chelate isomers, although experimental evidence was not obtained due to low sensitivity.

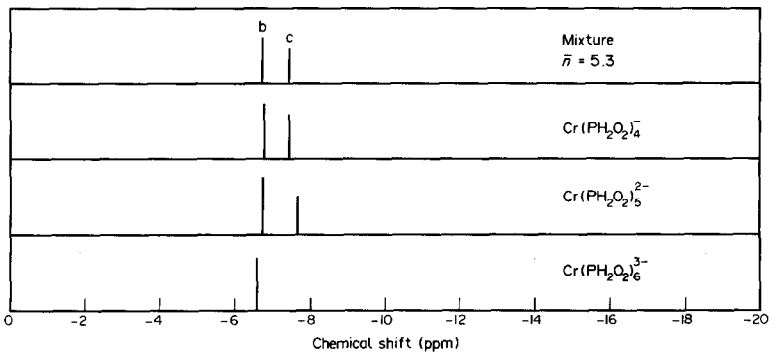


Fig. 4. ^{31}P NMR chemical shift for individual inner-sphere complexes and the mixture at pH 3, relative to free $PH_2O_2^-$ anion.

Table 1. Possible isomers of the inner-sphere complexes

$Cr:PH_2O_2^-$	Charge	Non-chelate	Mixed chelate–non-chelate	Chelate
1:1	+2	$Cr(OPH_2O)(H_2O)_5$		$Cr(O_2PH_2)(H_2O)_4$
1:2	+1	$Cr(OPH_2O)_2(H_2O)_4$	$Cr(O_2PH_2)(OPH_2O)(H_2O)_3$	$Cr(O_2PH_2)_2(H_2O)_2$
1:3	0	$Cr(OPH_2O)_3(H_2O)_3$	$Cr(O_2PH_2)(OPH_2O)_2(H_2O)_2$ $Cr(O_2PH_2)_2(OPH_2O)(H_2O)$	$Cr(O_2PH_2)_3$
1:4	−1	$Cr(OPH_2O)_4(H_2O)_2$	$Cr(O_2PH_2)(OPH_2O)_3(H_2O)$ $Cr(O_2PH_2)_2(OPH_2O)_2$	
1:5	−2	$Cr(OPH_2O)_5(H_2O)$	$Cr(O_2PH_2)(OPH_2O)_4$	
1:6	−3	$Cr(OPH_2O)_6$		

The presence of a variety of isomers for the inner-sphere complexes shown in Table 1 may theoretically be expected by distinguishing between chelate and non-chelate binding. Thus successful observation distinguishing these isomers is undoubtedly caused by a slow dehydration rate in the following steps

$$[Cr(OH_2)_6]^{3+} \xrightarrow[\text{fast}]{+PH_2O_2} [Cr(OH_2)_6 \cdot (PH_2O_2)]^{2+} \quad (1)$$

$$\xrightarrow[\text{slow}]{-H_2O} [Cr(OPH_2O)(OH_2)_5]^{2+} \quad (2)$$

$$\xrightarrow[\text{slow}]{-H_2O} [Cr(O_2PH_2)(OH_2)_4]^{2+}. \quad (3)$$

Equation (3), formation of the chelate binding complex from the non-chelate binding complex, is an intramolecular reaction, thus the concentration ratio of the chelate to non-chelate forms should be independent of the solution condition.

The presence of the same type of isomer could be possible in other moderately inert complex systems. Recently we found these isomers in the systems of aluminium phosphinate, phosphite and phosphate complexes, the details of which will be reported elsewhere.

THE PREPARATION OF MIXED-LIGAND DITHIOLENE COMPLEXES: X-RAY STRUCTURE OF $Pt(PMe_2Ph)_2(mnt)$ AND $[Bu_4N][Au(mnt)_2]$

JONATHAN C. FITZMAURICE, ALEXANDRA M. Z. SLAWIN, DAVID J. WILLIAMS and J. DEREK WOOLLINS*

Department of Chemistry, Imperial College of Science and Technology, South Kensington, London SW7 2AY, U.K.

and

ALAN J. LINDSAY

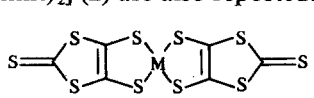
(*Received* 20 *October* 1989; *accepted* 21 *February* 1990)

Abstract—Reaction of $PtCl_2(PR_3)_2$ with sodium dithiolates gives mixed-ligand complexes such as $Pt(PR_3)_2(mnt)$ (**1**). Attempts to prepare mixed S—N/mnt complexes of gold were unsuccessful, $[Bu_4N][Au(mnt)_2]$ (**2**) being obtained. New compounds were characterized by IR and NMR spectroscopy and microanalyses, and in the case of **1** and **2** by X-ray crystallography. Both **1** and **2** are square planar. In **2**, one of the crystallographically independent anions lies over a symmetry related neighbour.

Transition-metal dithiolene complexes have been of interest for a number of years as they have potential for conductivity in the solid state.[1–5] In general, bis complexes have been most studied since they are planar and resemble compounds used in organic metals [e.g. if a metal replaces the central ethylene group atoms in tetrathiofulvalene (TTF), $M(dmit)_2$ complexes are formed. Complexes containing the ligand dmit (4,5-dimercapto-1,3-dithiole-2-thione) and dddt (4,5-dihydro-1,4-dithiin-2,3-dithiolate) have a high structural resemblance to the bis (ethylenedithio)tetrathiafulvalene molecule (ET)]. Recently, we have prepared complexes of the type $[Pt(S_2N_2H)(PR_3)_2]X$ and note that despite their lack of symmetry these materials stack in the solid state.[6,7] Here, we describe our investigations into the synthesis of mixed-ligand dithiolene complexes. The X-ray structures of $Pt(PMe_2Ph)_2(mnt)$ (**1**) and $[Bu_4N][Au(mnt)_2]$ (**2**) are also reported.



$M(dmit)_2$

EXPERIMENTAL

General conditions and spectroscopic methods were as described previously.[8] Na_2mnt,[9] Na_2edt,[10] quinoxaline-2,3-dithiol (QDT),[11] $S_4N_4H_4$,[12] $[Me_2SnS_2N_2]_2$[13] and $[Bu_4N][Au(mnt)Br_2]$[14] were prepared as described in the literature. $PtCl_2(COD)$ was prepared from K_2PtCl_4 and COD in the presence of $SnCl_2 \cdot 2H_2O$.[15] Compounds of the type *cis*-$PtCl_2(PR_3)_2$ were made by adding stoichiometric amounts of the appropriate free phosphine to $PtCl_2(COD)$.

Electrochemical work was performed at ambient temperature and pressure using a Princeton Applied Research (PAR) Model 273 and peripheral equipment on solutions which were deoxygenated by purging with argon. $[Bu_4N][PF_6]$ was prepared by mixing hot aqueous solutions of $[Bu_4N]I$ and $[NH_4][PF_6]$; the precipitate was recrystallized twice from methanol and vacuum dried at 100°C for 24 h. CH_2Cl_2 (distilled from CaH_2) was transferred to a voltammetry cell containing sufficient $[Bu_4N][PF_6]$ and electroactive compound to make the solution *ca* 0.1 and 5×10^{-4} M in these compounds, respectively. All potentials are referred to the Ag/Ag^+ electrode.

Preparation of $Pt(PR_3)_2(mnt)$ ($PR_3 = PEt_3$, PMe_2Ph)

In a typical reaction, $PtCl_2(PMe_2Ph)_2$ (70 mg, 0.129 mmol) was mixed with an equimolar amount of Na_2mnt (24 mg, 0.129 mmol) and CH_2Cl_2–MeOH (20 cm^3, 3:1). After 2 h, the orange–red solution was filtered and evacuated to dryness. The resulting solid was dissolved in $CDCl_3$ (2–3 cm^3). The orange solid was recrystallized from hot ethanol to give shiny pink microcrystals of $Pt(PMe_2Ph)_2(mnt)$ (51 mg, 65%). Layering a CH_2Cl_2 solution of the compound with *n*-hexane gave crystals suitable for X-ray diffraction. Found: C, 39.2; H, 3.5; N, 4.3. Calc. for $Pt(PMe_2Ph)_2(mnt)$: C, 39.3; H, 3.6; N, 4.3%. $^{31}P\{^1H\}$ (ppm): δ −19.34(s) $^1J(^{195}Pt—^{31}P)$ 2778 Hz; ^1H (ppm): δ 1.71 (s, 12H, Me) $^2J(^{31}P—^1H)$ 10 Hz $^3J(^{195}Pt—^1H)$ 29 Hz, 7.38 (m, 10H, Ph) *o* 7.35, *p* 7.39, *m* 7.42. IR (cm^{-1}): 2222m, 2205vs, 1492vs, 1436vs, 1420vs, 1385s, 1287m, 1154s, 1107vs, 946vs, 924vs, 851m, 807w, 741vs, 719vs, 691vs, 508w, 482s, 445m, 434m, 372w.

Pale pink crystals were obtained for the PEt_3 derivative. Found: C, 33.6; H, 5.2; N, 4.8. Calc. for $Pt(PEt_3)_2(mnt)$: C, 33.6; H, 5.3; N, 4.9%. $^{31}P\{^1H\}$ (ppm): δ 4.82(s) $^1J(^{195}P—^{31}P)$ 2749 Hz, ^1H (ppm): δ 1.12 (t, 3H, Me) $^3J(CH_2—CH_3)$ 8 Hz $^3J(^{31}P—^1H)$ 16 Hz, 2.05 (m, CH_2) with Pt—H and P—H couplings. IR (cm^{-1}): 2221m, 2202vs, 1497vs, 1453s, 1416m, 1384m, 1260m, 1152s, 1110m, 1035vs, 1011m, 870w, 804w, 768s, 752vs, 745s, 726s, 701m, 629m, 508m, 441m, 426m, 387w, 310w.

Preparation of $Pt(PR_3)_2(edt)$ ($PR_3 = PEt_3$, PMe_2Ph)

Na_2edt (27 mg, 0.2 mmol) was added to a stirred solution of $PtCl_2(PEt_3)_2$ (100 mg, 0.2 mmol) in CH_2Cl_2 (10 cm^3). An immediate yellow coloration resulted. After 2 h, the solution was filtered and evacuated to dryness. The $^{31}P\{^1H\}$ NMR revealed two peaks with accompanying Pt—P splittings; that of the desired product and the starting phosphine (δ 9.13 ppm, ^1J 3513 Hz). Evaporation of the solvent to *ca* 0.5 cm^3 resulted in the formation of white needle-shaped crystals. Yield 55 mg (57%). Found: C, 32.1; H, 6.0. Calc. for $Pt(PEt_3)_2(edt)$: C, 32.2; H, 6.2%. $^{31}P\{^1H\}$ (ppm): δ 4.35(s), $^1J(^{195}Pt—^{31}P)$ 2732 Hz. IR (cm^{-1}): 1523m, 1453m, 1415m, 1384m, 1376m, 1103w, 1033vs, 811s, 767vs, 760vs, 725vs, 675vs, 634m, 417m, 354w, 325w, 292w.

Addition of diethyl ether was required to precipitate the PMe_2Ph derivative as a yellow solid (63 mg, 61%). Found: C, 37.9; H, 4.2. Calc. for $Pt(PMe_2Ph)_2(edt)$: C, 38.5; H, 4.3%. $^{31}P\{^1H\}$ (ppm): δ −19.00(s) $^1J(^{195}Pt—^{31}P)$ 2722 Hz. IR (cm^{-1}): 1519w, 1475w, 1434m, 1417m, 1400m, 1312w, 1262w, 1155w, 1103vs, 945s, 905vs, 853w, 839w, 808m, 758m, 748s, 734s, 716m, 697s, 667s, 482m, 447m, 432m, 374w, 366w, 337w, 328w.

Preparation of $Pt(PR_3)_2(QDT)$ ($PR_3 = PMe_2Ph$, PEt_3)

To a stirred solution of QDT (30 mg, 0.154 mmol) in MeOH (5 cm^3) was added sodium (10 mg, 0.435 mmol). After 10 min, $PtCl_2(PMe_2Ph)_2$ was added together with CH_2Cl_2 (5 cm^3) and the resulting solution was stirred for 2 h. Evaporation of the solvent to 5 cm^3 and addition of Et_2O resulted in precipitation of the orange complex. Found: C, 43.1; H, 3.9; N, 4.2. Calc. for $Pt(PMe_2Ph)_2(QDT)$: C, 43.4; H, 3.9; N, 4.2%. $^{31}P\{^1H\}$ (ppm): δ −17.9(s) $^1J(^{195}Pt—^{31}P)$ 2835 Hz. IR (cm^{-1}): 1547m, 1482w, 1434m, 1414m, 1387w, 1356m, 1328w, 1313w, 1259s, 1172vs, 1121vs, 1105s, 1049w, 1024w, 948s, 907vs, 843w, 805w, 762m, 743m, 717m, 689m, 599m, 489m, 445m, 428m. PEt_3 derivative: Found: C, 38.1; H, 5.4; N, 4.4. Calc. for $Pt(PEt_3)_2(QDT)$: C, 38.5; H, 5.5; N, 4.5%. $^{31}P\{^1H\}$ (ppm): δ 5.5(s) $^1J(^{195}Pt—^{31}P)$ 2817 Hz. IR (cm^{-1}): 1550m, 1480w, 1458m, 1453m, 1417m, 1370w, 1365m, 1254s, 1179vs, 1123vs, 1038vs, 1025s, 1004m, 802w, 768vs, 757vs, 726vs, 638m, 598m, 444m, 426m.

Reaction of $[Bu_4N][Au(mnt)Br_2]$ *with* $S_4H_4N_4$/dbu

$[Bu_4N][Au(mnt)Br_2]$ (59.2 mg, 8.01×10^{-5} mol) was dissolved in CH_2Cl_2 (10 cm^3) to which was added $S_4N_4H_4$ (7.5 mg, 4.0×10^{-5} mol) and an excess of dbu (~ 5 drops). The solution darkened to an orange–brown colour. After filtration, the solvent was reduced *in vacuo* to 0.5 cm^3. Dark red crystals were formed. Found: C, 39.5; H, 5.0; N, 9.6. Calc. for $[Bu_4N][Au(mnt)_2]$: C, 40.0; H, 5.0; N, 9.7%. Mass spectrometry: M^- (FAB): 477 $Au(mnt)_2^-$.

Reaction of $[Bu_4N][Au(mnt)Br_2]$ *with* $[Me_2SnS_2N_2]_2$

$[Bu_4N][Au(mnt)Br_2]$ (87 mg, 0.105 mmol) and $[Me_2SnS_2N_2]_2$ (28.3 mg, 5.25×10^{-5} mol) were combined in degassed CH_2Cl_2 (15 cm^3). After 24 h, the yellow–brown solution was filtered through celite and reduced to ~ 5 cm^3 *in vacuo*. Ether was added slowly until a dark brown, crystalline solid was deposited. Recrystallization from acetone–EtOH followed by slow hexane diffusion into a dichloromethane solution of the com-

pound gave dark red crystals which analysed as $[Bu_4N][Au(mnt)_2]$.

Crystal data

$C_{20}H_{22}N_2P_2PtS_2$ (**1**), $M = 611.6$, triclinic, $a = 9.22(5)$, $b = 11.318(6)$, $c = 11.552(7)$ Å, $\alpha = 84.02(4)$, $\beta = 84.64(4)$, $\gamma = 71.73(4)°$, $U = 1149$ Å^3, space group $P\bar{1}$, $Z = 2$, $D_c = 1.77$ g cm^{-3}. Pink, air-stable prisms, μ(Cu-K_α) = 146 cm^{-1}, $\lambda = 1.54178$ Å, $F(000) = 592$. $C_{24}H_{36}AuN_5S_4$ (**2**), $M = 719.8$, triclinic, $a = 13.405(5)$, $b = 13.533(5)$, $c = 17.612(5)$ Å, $\alpha = 75.98(3)$, $\beta = 79.92(3)$, $\gamma = 78.37(3)°$, $U = 3089$ Å^3, space group $P\bar{1}$, $Z = 4$ (two crystallographically independent molecules), $D_c = 1.59$ g cm^{-3}, μ(Cu-K_α) = 120 cm^{-1}, $\lambda = 1.54178$ Å, $F(000) = 1432$.

Data collection and processing

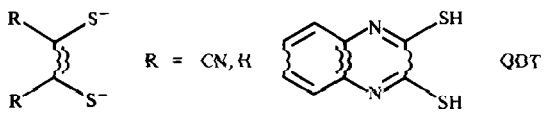
Nicolet R3m diffractometer, ω-scan method ($\theta \leqslant 50$ and 58°, respectively), graphite monochromated Cu-K_α radiation; for **1** 2662 and for **2** 8126 independent measured reflections, 2559 and 6883 observed ($|F_o| > 3\sigma(|F_o|)$), corrected for Lorentz and polarization factors; empirical absorption corrections based on 343 and 360 azimuthal measurements. Maximum and minimum transmission factors for **1** were 0.602 and 0.17, and for **2** 0.131 and 0.042, respectively.

Structure analysis and refinement

Complex **1** was solved by the heavy atom method and **2** by direct methods; in both cases all the non-hydrogen atoms were refined anisotropically. The hydrogen atoms were idealized (C—H = 0.96 Å), assigned isotropic thermal parameters $U(H) = 1.2\,U\text{eq}(C)$ and allowed to ride on their parent carbons. In **2** the methyl groups were refined as rigid bodies. Refinement was by block-cascade full-matrix least-squares to $R = 0.040$ ($R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$), $R_w = 0.042$ ($w^{-1} = \sigma^2(F) + 0.0010F^2$) for **1**, and to $R = 0.050$, $R_w = 0.55$ ($w^{-1} = \sigma^2(F) + 0.00144F^2$) for **2**. The maximum and minimum residual electron densities in the final ΔF maps were 1.67, 1.25 and −1.07, −1.77 eÅ^{-3}, and the mean and maximum shifts/error in the final refinement cycle were 0.002, 0.008 and 0.018, 0.048, respectively. Computations were carried out on an Eclipse S140 computer using the SHELXTL program system.[16]

RESULTS AND DISCUSSION

In the light of the observed stacking properties in $[Pt(S_2N_2H)(PR_3)_2]X$, we have prepared mixed-ligand complexes containing dithiolenes and phosphines as well as studying methods for the preparation of complexes containing dithiolenes and SN ligands. Reaction of $PtCl_2(PR_3)_2$ with the sodium salt of the appropriate dithiolene ligand (mnt, edt, QDT) gives the desired mixed-ligand complex in fair yield. The new compounds gave satisfactory microanalyses and had the expected spectroscopic properties. Their ^{31}P NMR spectra consist of singlets with platinum satellites ($^1J(^{31}P—^{195}Pt)$ *ca* 2800 Hz).



The IR spectra are as expected.[17] In the case of the mnt complexes the $\nu(C{\equiv}N)$ and $\nu(C{=}C)$ vibrations increase in frequency by *ca* 10 and 55 cm^{-1}, respectively, upon complexation indicating a decrease in bond length, whilst the $\nu(C{=}S)_{sym}$ vibration is reduced in frequency consistent with lengthening of the C—S bonds.

We have also attempted to prepare mixed dithiolene/SN complexes of gold. Thus reaction of $S_4N_4H_4$ or $[Me_2SnS_2N_2]_2$ with $[Bu_4N][Au(mnt)Br_2]$ was carried out by analogy with previous routes to $S_2N_2^{2-}$ complexes.[6-8] In both cases we observed formation of $[Bu_4N][Au(mnt)_2]$ (**2**) rather than the desired complex. Complex **2** has previously been obtained[18] from the reaction of auric acid and Na_2mnt.

A number of the compounds prepared have been studied by cyclic voltammetry. The cyclic voltammogram for $Au(mnt)_2^-/CH_2Cl_2$ was found to contain oxidative and reductive one electron reversible couples at $E_{1/2(oxid)} = +1.15$ V and $E_{1/2(red)} = -0.88$ V. This compares with the results obtained by Schlupp and Maki[19] for $Au(mnt)_2^-$/DMSO ($E_{1/2(red)} = -0.41$ V vs SCE).

Gold(III) is isoelectronic with platinum(II) (d^8) and it is probable that the gold and platinum mnt complexes have similar electronic structures. Schlupp and Maki have calculated that in the formal gold(III) complex $Au(mnt)_2^{3-}$ (d^8) the electron is largely based on the ligand orbital (80% A_g character). Geiger *et al.*[20] have noted the difficulty in assigning $Pt(mnt)_2^{3-}$ as platinum(I) (isoelectronic with $Au(mnt)_2^{2-}$) and have concluded that reduction of the platinum(II) complex could be either metal or ligand based. This is also likely for $Au(mnt)_2^-$.

The redox chemistry of $M[S_2C_2Ph_2]_2$ (M = Ni, Pd, Pt)[21] and $[M(S_2C_2Ph_2)(PPh_3)_2]$ (M = Pd, Pt) has been studied with the existence of the dithioketyl radical $C_2S_2Ph_2^-$ characterized by ESR.

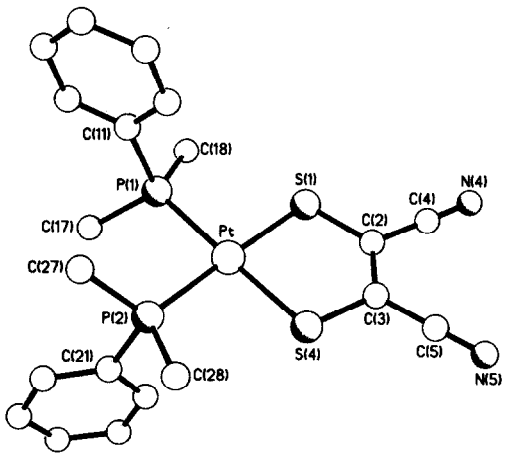


Fig. 1. The X-ray structure of **1**.

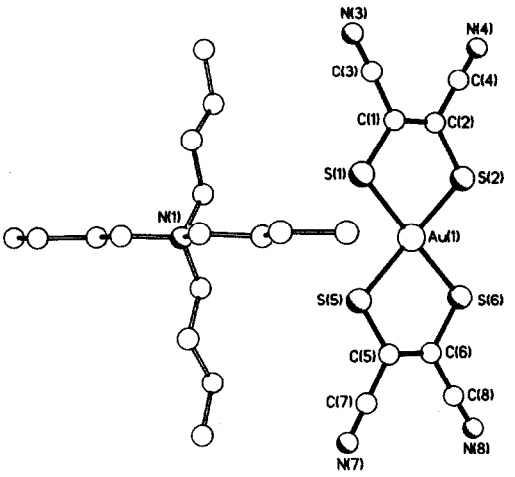

Fig. 2. The X-ray structure of **2**.

Reversible oxidation is found to occur on the dithiolene ligand and is relatively independent of the metal atom or phosphine. In the case of $Pt(PR_3)_2(mnt)$ studied here we observed irreversible oxidative peaks at +1.25 V indicating a secondary process (e.g. ligand dissociation).

The X-ray structures of $Pt(PMe_2Ph)_2(mnt)$ (**1**) and $[Bu_4N][Au(mnt)_2]$ (**2**) are shown in Figs 1 and 2, with selected bond lengths and angles in Tables 1 and 2. Complex **1** has the expected square-planar geometry with approximate non-crystallographic C_2 symmetry. There is a characteristic slight enlargement of the P—Pt—P angle (92.4(1)°) as a consequence of the bulk of the phosphine ligands. The Pt—P and Pt—S bond lengths are typical for platinum(II). The Pt—S bond length in **1** is slightly longer than in $Pt(mnt)_2^-$,[4] reflecting the difference in the *trans* effect of sulphur versus phosphorus rather than the difference in formal oxidation state. The transannular S···S distance is 3.23 Å. In **2** there are two crystallographicaly independent molecules. There are no significant differences in their geometries; both anions having approximate non-crystallographic D_{2h} symmetry. The bond lengths and angles are within statistical significance identical to those reported[22] for $[Au(S_2CNBu_2)_2][Au(mnt)_2]$. Replacement of platinum by gold does not appear to have any effect on the M—S distance in complexes of this type.[4,22] The transannular S···S distance in **2** (3.27 Å) is essentially identical to the *cis* inter-ring S···S distance (3.28 Å) underlining that mnt^{2-} is an almost optimum chelating ligand for the formation of undistorted bis complexes.

In **1** there are no close contacts and there is no evidence of any intermolecular stacking. In **2** there are no significant intermolecular interactions between the crystallographically independent anions (the planes of the anions are inclined *ca* 64°). However, centrosymmetrically related pairs of one of the anions pack parallel to each other (Fig. 3) with an interplanar separation of 3.7 Å; the C(5)—C(6) bond lying almost directly over, and parallel to, the S(5)″ ··· S(6)″ transannular vector of the symmetry related anion.

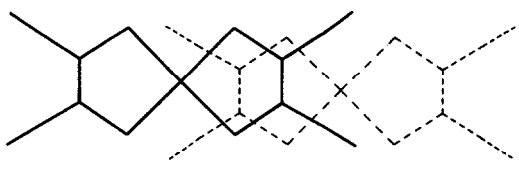

Fig. 3. Line drawing of the packing of centrosymmetrically related anions in **2**.

REACTION OF Se_4N_4 WITH $Pt(PPh_3)_3$: THE PREPARATION AND X-RAY STRUCTURE OF $[Pt(Se_2N_2)(PPh_3)]_2 \cdot CH_2Cl_2$

PAUL F. KELLY, ALEXANDRA M. Z. SLAWIN, DAVID J. WILLIAMS and J. DEREK WOOLLINS*

Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London SW7 2AY, U.K.

(*Received* 26 *January* 1990; *accepted* 1 *March* 1990)

Abstract—Reaction of $Pt(PPh_3)_3$ with Se_4N_4 in CH_2Cl_2 leads to a mixture of $Pt(Se_2N_2)(PPh_3)_2$ (**1**) and an intermediate species, which decomposes via loss of PPh_3 to give $[Pt(Se_2N_2)(PPh_3)]_2 \cdot CH_2Cl_2$ (**2**). X-ray crystallography reveals **2** to be dimeric, with $[Pt(Se_2N_2)(PPh_3)]$ units bridged by Pt—N bonds in a Pt_2N_2 ring. The central $[PtSe_2N_2]_2$ core is planar and the geometry of the individual $PtSe_2N_2$ rings is comparable to that in the only other example reported, $[Pt(Se_2N_2H)(PMe_2Ph)_2]Cl$.

In contrast to the chemistry of metalla–sulphur–nitrogen species, which has been extensively explored in the last 20 years, studies into analogous selenium–nitrogen complexes have only recently come to fruition, with the preparation of the first complexes of NSeCl, Se_3N^-, $Se_2N_2^{2-}$ and $Se_2N_2H^-$.[1-4] The most convenient of these preparations, which circumvents the praecidigitogenic Se_4N_4, involves the use of a solution of $SeCl_4$ in liquid ammonia, which acts as precursor to the $Se_2N_2^{2-}$ ligand.[4] Reaction of Se_4N_4 with $[PtCl_2(PMe_2Ph)]_2$ yields $Pt(Se_3N)Cl(PMe_2Ph)$ and $Pt(Se_2N_2H)Cl(PMe_2Ph)$, although the procedure is rendered somewhat unsatisfactory by the low yield and need for a high temperature (with consequent danger of Se_4N_4 detonation). Another drawback to this reaction is that it is not directly analogous to the equivalent S_4N_4 reaction, which proceeds via oxidative addition to give $Pt(S_4N_4)Cl_2(PMe_2Ph)$;[5] as a result, analysis of the reaction mechanism is difficult.

Here we report on the reaction of Se_4N_4 with the zerovalent platinum species $Pt(PPh_3)_3$, which proceeds at ambient temperature in a manner analogous to the same reaction of S_4N_4.[6,7] Reaction in CH_2Cl_2 results in the formation of a mixture of complexes, including the previously reported $Pt(Se_2N_2)(PPh_3)_2$ (**1**) and the dimeric species $[Pt(Se_2N_2)(PPh_3)]_2$, which we have characterized by X-ray crystallography [as the CH_2Cl_2 solvate (**2**)]. Compound **2** is the first example of a binuclear complex of the $Se_2N_2^{2-}$ ligand and only the second complex containing the $PtSe_2N_2$ ring to be crystallographically characterized.

EXPERIMENTAL

General reaction conditions were as described previously.[4] $Pt(PPh_3)_3$ was prepared from K_2PtCl_4 and PPh_3;[8] solutions in CH_2Cl_2 were made up immediately prior to reaction to avoid decomposition. Se_4N_4 was prepared by reaction of NH_3 with $(EtO)_2SeO$,[9] a method we have found to be less hazardous than the high pressure reaction of $SeCl_4$ with NH_3.

SAFETY NOTE: Se_4N_4 is substantially less stable than S_4N_4 and can explode on contact with a metal spatula. In contrast to the safety note in *Gmelin*,[10] which lists 100 mg as a safe amount, we have found that the destructive capacity of amounts as small as 20 mg is sufficient to warrant extreme care. Se_4N_4 residues are best destroyed by cautious addition of hypochlorite solution to a suspension in water.

In a typical reaction Se_4N_4 (40 mg, 0.11 mmol) was suspended in CH_2Cl_2 (30 cm^3) and stirred for $\approx$ 15 min to give a very fine dispersion which was

* Author to whom correspondence should be addressed.

then treated with a solution of $Pt(PPh_3)_3$ (106 mg, 0.11 mmol) in CH_2Cl_2 (30 cm^3). The resulting dark coloured mixture was stirred for 20 min then filtered (**NOTE**: filtrations were performed using sintered glass funnels with copious amounts of celite filter-aid, which must be present to trap unreacted Se_4N_4 and avoid its potentially explosive combination with the sintered glass), the volume of CH_2Cl_2 was reduced to 5 cm^3 *in vacuo*, and the products precipitated as a red–brown solid by addition of pentane (50 cm^3). At this point the ^{31}P NMR spectrum of a $CDCl_3$ solution of the products revealed the presence of $Pt(Se_2N_2)(PPh_3)_2$ (**1**) (AX spectrum δ_a 27.7 [$^1J\{^{195}Pt-^{31}P\}$ 2925], δ_b 6.4 [^1J 2757]; lit. δ_a 26.8 [^1J 2963], δ_b 6.2 ppm [^1J 2778 Hz]) together with a singlet at δ 26.2 ppm [^1J 3198 Hz] and another AX pattern δ_a 25.8 [^1J 2932], δ_b 3.3 ppm [^1J 2876 Hz].

The $CDCl_3$ solution was layered with pentane and slow diffusion resulted in a large crop of very dark green microcrystals (including some large enough to be suitable for X-ray crystallography) together with a smaller number of orange crystals. The solution was decanted from the product, which was washed with CH_2Cl_2 (3×30 cm^3) to remove any crystals of **1**. The remaining orange crystals were presumed to be Se_4N_4 and were carefully separated manually from the green crystals, which were shown by X-ray crystallography to be $[Pt(Se_2N_2)(PPh_3)]_2 \cdot CH_2Cl_2$ (**2**). Typical yield of **2** 20 mg ($\approx$ 30% based upon Pt). Found: C, 32.3; H, 2.1; N, 3.8. Calc. for $[Pt(Se_2N_2)(PPh_3)]_2 \cdot CH_2Cl_2$: C, 32.4; H, 2.4; N, 4.1%.

Crystal data

Compound **2**, $C_{36}H_{30}N_4P_2Se_4Pt_2 \cdot CH_2Cl_2$, M = 1371.6, monoclinic, $a = 9.336(2)$, $b = 14.982(4)$, $c = 14.744(4)$ Å, $\beta = 99.57(2)°$, $U = 2034$ Å^3, space group $P2_1/n$, $Z = 2$ (the molecule is disposed about a centre of symmetry), $D_c = 2.24$ g cm^{-3}. Crystal dimensions $0.07 \times 0.07 \times 0.40$ mm. μ(Cu-K_α) = 193 cm^{-1}, $\lambda = 1.54178$ Å, $F(000)$ = 1268.

Data collection and processing

Nicolet R3m diffractometer, ω-scan method, ($\theta \leqslant 58°$), graphite monochromated Cu-K_α radiation; 2733 independent measured reflections, 2530 observed [$|F_o| > 3\sigma(|F_o|)$], corrected for Lorentz and polarization factors; numerical absorption correction (face-indexed crystal). Maximum and minimum transmission factors: 0.390 and 0.153, respectively.

Structure analysis and refinement

The structure was solved by direct methods and all the non-hydrogen atoms refined anisotropically. A ΔF map revealed the presence of a disordered CH_2Cl_2 molecule; the hydrogen atoms of the solvent were not located. The positions of the remaining hydrogen atoms were idealized (C—H = 0.96 Å), assigned isotropic thermal parameters $U(H) = 1.2\ U\text{eq}(C)$ and allowed to ride on their parent carbons. Refinement was by block-cascade full-matrix least-squares to $R = 0.034$, ($R = \Sigma[|F_o| - |F_c|]/\Sigma|F_o|$), $R_w = 0.037$ ($w^{-1} = \sigma^2(F) + 0.00028F^2$). The maximum and minimum residual electron densities in the final ΔF map were 1.23 and -0.84 eÅ^{-3} and the mean and maximum shifts/error in the final refinement cycle were 0.003 and 0.086, respectively. Computations were carried out on an Eclipse S140 computer using the SHELXTL program system[11] and published scattering factors.[12]

RESULTS AND DISCUSSION

The zerovalent platinum complex $Pt(PPh_3)_3$ reacts with Se_4N_4 in a similar fashion to that previously reported for S_4N_4.[6,7] In the latter case reaction in CH_2Cl_2 results in the formation of $Pt(S_2N_2)(PPh_3)_2$ together with an intermediate which decomposes via loss of PPh_3 to give $[Pt(S_2N_2)(PPh_3)]_2 \cdot CH_2Cl_2$ (**3**), a binuclear complex bridged by Pt—N bonds. The intermediate has not been characterized by X-ray crystallography due to its instability; its ^{31}P NMR spectrum consists of a singlet and an AX pattern, both with ^{195}Pt satellites, and it analyses as $[\{Pt(S_2N_2)(PPh_3)_2\}\{Pt(S_2N_2)(PPh_3)\}]$. These observations have lead to suggestions that it may be a single dimeric complex, bridged by one platinum–nitrogen bond,[6] although work by us, using ^{15}N labelling techniques suggests that the structure may well be more complex than this. The above formulation is consistent with the observation that upon decomposition to **3** PPh_3 is lost from the intermediate (as shown by ^{31}P NMR), and that neither of the constituent NMR patterns have been observed separately.[13] The ^{31}P NMR spectrum of the products from the Se_4N_4 reaction, performed by addition of a solution of $Pt(PPh_3)_3$ in CH_2Cl_2 to a suspension of Se_4N_4 in the same solvent, shows the presence of both **1** and an intermediate of apparently similar structure to that formed in the S_4N_4 reaction. Again, the latter decomposes via loss of PPh_3 to give the dimeric species **2**. We have been unable to isolate a pure sample of the intermediate in the Se_4N_4 reaction, but its ^{31}P NMR spectrum is

so similar to that from the S_4N_4 case that we are confident that eq. (1) is a good description of the fate of the platinum-containing species in the reaction.

$$Pt(PPh_3)_3 + Se_4N_4 \longrightarrow Pt(Se_2N_2)(PPh_3)_2 + Pt_2(Se_2N_2)_2(PPh_3)_3$$
$$\text{(1)} \qquad \downarrow -PPh_3$$
$$[Pt(Se_2N_2)(PPh_3)]_2.$$

Compound **2** is a dark-green insoluble solid which can be obtained in crystalline form by slow pentane diffusion into a solution of the crude products of the reaction; also produced are a few small aggregations of orange crystals of Se_4N_4. In view of this, **2** is best prepared in crystalline form rather than as a powder, since otherwise it would prove impossible to separate from the Se_4N_4, and in consequence any manipulations, such as preparations of mulls etc., would be hazardous. Once pure **2** represents no explosive hazard and appears to be air-stable.

The colour of **2** provides an interesting correlation between the dimeric species, **2** and **3**, and the related species $Pt(S_3N)Cl(PMe_2Ph)$ and $Pt(Se_3N)Cl(PMe_2Ph)$. In the case of the sulphur species both are an intense red colour, while the selenium complexes are both dark green. The X-ray crystal structure of **2** (Fig. 1) shows the molecule to be isostructural with its sulphur analogue, **3**,[7] there being slight increases in each of the unit cell lengths but no change in the β angle. The molecule is dimeric with a central Pt_2N_2 ring. The $[PtSe_2N_2]_2$ core is planar to within 0.017 Å with the phosphorus atom lying 0.096 Å from this plane. Whereas in **3** in the Pt_2N_2 ring the Pt—N bonds are of the same length, in **2** the Pt—N(1) bond (2.005(8) Å, Table 1) is significantly shorter than that for Pt—N(1′) (2.062(7) Å). The N—Pt—N′ angle is slightly contracted in **2** (75.0(3)°, cf. 77.1(5)° in **3**) with a commensurate small increase in the Pt···Pt′ distance (3.23, cf. 3.21 Å in **3**) and decrease in the N···N′ separation (2.48, cf. 2.56 Å in **3**). It is surprising that the Pt—N bond *trans* to the chalcogen is unchanged on going from S to Se, whereas the Pt—P(1) and Pt—N(1) distances are both contracted. Within the $PtSe_2N_2$ ring the Pt—Se(2) bond is slightly shorter than in $[Pt(Se_2N_2H)(PMe_2Ph)_2]Cl$ (**4**)[3] (2.334(1) Å in **2** and 2.405(1) Å in **4**), reflecting the difference in the *trans* substituent (N vs PMe_2Ph). The remaining bond lengths within the ring do not differ significantly from those in **4**. The dimeric nature of the complex together with the presence of the bulky phosphine ligands and the solvated CH_2Cl_2 preclude any stacking of the $PtSe_2N_2$ rings.

Figure 2 shows the difference spectrum in which the IR spectrum of **2** has been subtracted from that of the sulphur analogue, **3**, in an attempt to distinguish the bands due to $S_2N_2^{2-}$ and $Se_2N_2^{2-}$ from those of the PPh_3 ligand. Although some peaks due to PPh_3 remain (dotted lines), the spectrum clearly shows the peaks due to $S_2N_2^{2-}$ (upper) and $Se_2N_2^{2-}$ (lower). The two most prominant in each case (Table 2) occur at 1034 and 724 cm^{-1} in **3** and at 815 and 550 cm^{-1} in **2**. Analogous bands are present in the IR spectra of the related complexes $Pt(E_2N_2)(PPh_3)_2$ (E = S, Se), although complexes **2** and **3** both show an extra peak, at 676 and 917 cm^{-1}, respectively, which is not present in the spectra of the bis-phosphine species. All these peaks can be assigned to S/Se—N stretches, with the

$[Pt(S_2N_2)(PPh_3)]_2$	$[Pt(Se_2N_2)(PPh_3)]_2$	Assignment
1034(vs)	815(s)	ν(N—S/Se)
917(m)	676(m)	ν(N—S/Se)
724(vs)	550(vs)	ν(N—S/Se)
640(m)	282(w)	δ(N—S/Se)
473(w)		ν(Pt—N)
379(w)		δ(N—S)
335(w)		ν(Pt—S)

expected decrease in frequency upon changing from S to the heavier Se, although it is not obvious why the dimeric species should show three such stretches and the monomers only two, especially as monomeric complexes of the type $M(S_2N_2H)_2$ show three (NS) stretches. By analogy with other systems the bands at 640, 473, 379 and 335 cm^{-1} in **3** can be assigned to δ(N—S), ν(Pt—N), δ(N—S) and ν(Pt—S), respectively; in conrast, the spectrum of **2** shows only a band at 282 cm^{-1} in this region, which is probably best assigned to δ(N—Se), and no obvious Pt—N stretch.

The reaction of Se_4N_4 with $Pt(PPh_3)_3$ is important since it shows that it is possible for Se_4N_4 to react via oxidative addition in a manner identical to S_4N_4. Although Se_4N_4 is undoubtedly much more inert than its sulphur counterpart, it would appear likely that its chemistry is substantially more diverse than has previously been imagined.

(*Received* 8 *December* 1989; *accepted* 27 *February* 1990)

Abstract—Photolysis of $Os_3(CO)_{12}$ and *t*-Bu_2PH in toluene yields the trisubstituted phosphine cluster $Os_3(CO)_9(t\text{-}Bu_2PH)_3$ (**1**) (63%). Reaction of *t*-Bu_2PH with $Os_3(CO)_{12}$ by heating in toluene (12 h) yields the disubstituted phosphine complex $Os_3(CO)_{10}(t\text{-}Bu_2PH)_2$ (**2**) (24%) and the bis-phosphido complex $Os_3(CO)_8(\mu\text{-}H)_2(\mu\text{-}t\text{-}Bu_2P)_2$ (**3**) (50%). Compound **3** may be converted into the 46-electron complex $Os_3(CO)_6(t\text{-}Bu_2PH)(\mu\text{-}H)_2(\mu\text{-}t\text{-}Bu_2P)_2$ (**4**) by further heating in refluxing toluene with *t*-Bu_2PH. Refluxing **1**, **2**, **3** or **4** in di-*n*-butylether (143°C) affords the phosphinidene complex $Os_3(CO)_7(t\text{-}Bu_2PH)_2(\mu_3\text{-}t\text{-}BuP)$ (**5**) (68%). The reaction of dicyclohexylphosphine (Cy_2PH) with $Os_3(CO)_{12}$ in refluxing toluene yields the tris-phosphido-bridged complex $Os_3(CO)_7(\mu\text{-}H)(Cy_2P)_3$ (**6**) (60%). The structures of **1**–**6** have been determined via single-crystal X-ray diffraction studies. The molecular structure of **1** is based on that of $Os_3(CO)_{12}$ with the three *t*-Bu_2PH ligands occupying equatorial sites on each osmium in order to minimize steric interactions. The structure of **2** has two *t*-Bu_2PH ligands in equatorial positions arranged *trans* to each other across an Os—Os bond. Complex **3** contains two bridging *t*-Bu_2P^- groups which lie above and below the Os_3 plane. Two bridging hydrides occupy positions *trans* to these groups. The coordination geometry of each metal is roughly octahedral if one ignores the Os—Os bonds. The structure of **4** is similar to that of **3** except that one CO groups has been replaced by an $Os(CO)_3$ unit and the adjacent $Os(CO)_3$ group now bears only two CO units. Complex **5** contains a μ_3-capping phosphinidene group (*t*-BuP^{2-}) in addition to two terminal phosphines (*t*-Bu_2PH) on adjacent metal atoms. The structure of **6** features three bridging Cy_2P^- groups which lie above, in and below the Os_3 plane.

There is presently considerable interest in the chemistry of ruthenium and osmium clusters.[1] Our interest was drawn to the chemistry of trinuclear species which feature phosphido, arsenido, phosphinidene and arsinidene ligands by the work of several groups.[2] In addition to unusual structural features in such complexes, interesting organometallic transformations have also been observed. These have included P—C or As—C bond cleavages as well as a variety of insertion reactions.[2]

A general observation is that both primary and secondary phosphines react with the trinuclear carbonyls of ruthenium and osmium [$M_3(CO)_{12}$] under mild conditions to give phosphido-bridged hydrido clusters such as $Ru_3(\mu\text{-}H)_2(\mu\text{-}PPh_2)(CO)_8$[3] and under more forcing conditions to give μ_3-PR (phosphinidene) species. These reactions no doubt involve an initial substitution of CO in $M_3(CO)_{12}$ to give phosphine adducts. This is followed by migration of hydrogen and further loss of CO molecules.

Huttner and co-workers have shown this sequence of reactions occurs with primary phosphines.[4] Thus RPH_2 (R = C_6H_5, *p*-$CH_3OC_6H_4$, C_6H_{11}) react with $Os_3(CO)_{12}$ in the presence of Me_3NO under mild conditions to give $Os_3(CO)_{11}(PRH_2)$ and $Os_3(CO)_{10}(\mu\text{-}H)(\mu\text{-}PRH)$. At higher

* Author to whom correspondence should be addressed.

temperatures $Os_3(CO)_9(\mu\text{-}H)_2(\mu_3\text{-}PR)$ is formed. Lewis and co-workers have shown that reacting $Os_3(CO)_{11}(MeCN)$ with PR_2H gives the corresponding phosphine-substituted clusters $Os_3(CO)_{11}(PR_2H)$ (R = C_6H_5, H).[5]

As part of a programme focused on the unusual behaviour of metal complexes containing bulky phosphido and arsenido ligands, we have studied the reactions of the ruthenium and osmium carbonyl clusters with *t*-Bu_2PH and *t*-Bu_2AsH. A preliminary report of our initial studies with $Ru_3(CO)_{12}$ has appeared.[6] We report here details of the reactions of $Os_3(CO)_{12}$ with *t*-Bu_2PH and Cy_2PH (Cy = cyclohexyl). These reactions produce a variety of new phosphine, phosphido and phosphinidene complexes (see Scheme 1). The tris-phosphine complex $Os_3(CO)_9(t\text{-}Bu_2PH)_3$ (**1**) is formed by photolysis of $Os_3(CO)_{12}$ with *t*-Bu_2PH in THF, while the disubstituted product $Os_3(CO)_{10}(t\text{-}Bu_2PH)_2$ (**2**) and the bis-phosphido complex $Os_3(CO)_8(\mu\text{-}H)_2(\mu\text{-}t\text{-}Bu_2P)_2$ (**3**) are formed by refluxing the mixture in toluene (12 h). More prolonged heating of the reaction mixture (24 h) affords **3** as well as the 46-electron cluster $Os_3(CO)_6(t\text{-}Bu_2PH)(\mu\text{-}H)_2(\mu\text{-}t\text{-}Bu_2P)_2$ (**4**). Interestingly, the 48-electron complex, **3**, may be converted into **4** by warming with excess *t*-Bu_2PH in THF. The reverse reaction occurs when **4** is reacted with CO (1 atm). The interconversions represent an unusual facile interconversion of 46- and 48-electron clusters.[7] The phosphinidene complex $Os_3(CO)_7(t\text{-}Bu_2PH)_2(\mu\text{-}H)_2(\mu_3\text{-}t\text{-}BuP)$ (**5**) is formed in good yields by heating either **1**, **2**, **3** or **4** in refluxing di-*n*-butylether (143°C) for 24 h. We have also investigated the possibility of using slightly less bulky phosphido groups. The use of dicyclohexyl phosphine (Cy_2PH) permits the isolation of $Os_3(CO)_7(\mu\text{-}H)(\mu\text{-}Cy_2P)_3$ (**6**) which contains three bridging phosphido units. The complexes have been characterized spectroscopically (IR, NMR) and their structures in the solid state determined by single-crystal X-ray diffraction studies.

RESULTS AND DISCUSSION

Synthesis of phosphine complexes: $Os_3(CO)_9(t\text{-}Bu_2PH)_3$ (**1**) *and* $Os_3(CO)_{10}(t\text{-}Bu_2PH)_2$ (**2**)

Complex **1** may be prepared in *ca* 63% yield by photolysis of a mixture of $Os_3(CO)_{12}$ and three equivalents of *t*-Bu_2PH in THF for 18 h. It may be crystallized as air-stable, red–orange crystals from hexane solutions at −30°C. In contrast, the thermal reaction of $Os_3(CO)_{12}$ with three equivalents of *t*-Bu_2PH in refluxing toluene (12 h) produces a mixture of the disubstituted phosphine complex **2** (24%) and the bis-phosphido species **3** (50%). The compounds may be separated by column chromatography (see Experimental). Both complexes may be recrystallized as orange (**2**) and yellow–orange (**3**), air-stable crystals from hexane (−30°C).

Spectroscopic data for both **1** and **2** are in accord with the solid-state structures as determined by X-ray crystallography. Thus the IR spectra contain terminal ν(CO) bands at 1973 (s), 1955 (s), 1918 (s) and 1873 (w) cm^{-1} for **1** and at 1990 (s), 1952 (s) and 1928 (s) cm^{-1} for **2**. Both **1** and **2** have P—H stretches in their IR spectra (2320 (w), 2300 (w) **1**; 2310 (w) **2**, cm^{-1}). The $^{31}P\{^1H\}$ NMR spectra of **1** and **2** consist of singlets at δ 17.93 and 21.46, respectively. These signals split into broad doublets in the ^{31}P spectra confirming the presence of phosphine (*t*-Bu_2PH) units.

X-ray structure of **1**

Table 1 gives pertinent X-ray data collection parameters for all the complexes. Figure 1 shows an ORTEP view of **1** with the atom numbering scheme. Key bond lengths and angles for **1** are given in Table 2. Complex **1** crystallizes in the orthorhombic space group *Pbca* with eight molecules in the unit cell. The molecular structure of **1** is similar to that of $Os_3(CO)_{12}$ with the three secondary phosphine ligands occupying equatorial sites on each metal so as to minimize the steric interactions between them. There is a distortion from the idealized D_{3h} symmetry found in $Os_3(CO)_{12}$ to D_3. This is achieved by a twisting of the "ML_4" [$Os(CO)_3(t\text{-}Bu_2PH)$] moieties about the Os—Os vectors. This is in agreement with the proposal by Lauer that the D_{3h} structure will be less stable than the D_3 structure from descriptions of surface force-fields applied to metal carbonyl clusters.[8] The Os—Os bond lengths are similar [2.920 Å (av.)] and may be compared with those found in $Os_3(CO)_{12}$ [2.877(3) Å].[9] The Os—P bond lengths are also similar and average 2.37 Å. The P-*H* hydrogen atoms of the *t*-Bu_2P-*H* units were not located in the X-ray structure, although their presence was confirmed by IR and NMR spectroscopic data.

X-ray structure of **2**

Figure 2 shows an ORTEP view of **2** with the atom numbering scheme. Table 3 contains selected bond lengths and angles for the molecule. Compound **2** crystallizes in the monoclinic space group $P2_1$ (No. 4) with two molecules in the unit cell. The molecular structure is based on the $Os_3(CO)_{12}$ framework as found for **1**. However, for **2** the two

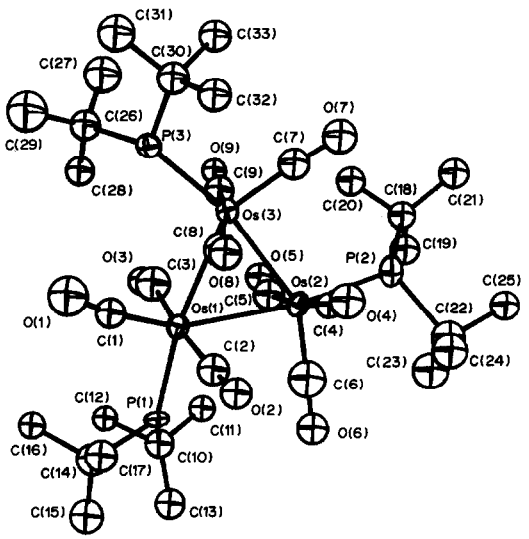

Fig. 1. ORTEP view of **1** showing the atom numbering scheme.

phosphine ligands occupy sites on adjacent metal atoms such that they are roughly *trans* to each other with respect to the Os—Os vector. The Os—Os bond lengths fall within normal limits [2.900(2)–2.925(1) Å] and the P—Os distances are similar to those found in **1** [Os(1)—P(1) = 2.335(9) Å, Os(2)—P(2) = 2.423(9) Å]. The *trans* arrangement of phosphines may again be in order to minimize steric interactions in the molecule.

Synthesis of phosphido complexes: $Os_3(CO)_8(\mu\text{-}H)_2(\mu\text{-}t\text{-}Bu_2P)_2$ (**3**) *and* $Os_3(CO)_6(t\text{-}Bu_2PH)(\mu\text{-}H)_2(\mu\text{-}t\text{-}Bu_2P)$ (**4**)

If the reaction of $Os_3(CO)_{12}$ with three equivalents of t-Bu_2PH in refluxing toluene is continued for 24 h, a dark red solution is obtained from which the bis-phosphido-bridged complex **3** (50%) as well as the 46-electron phosphido compound **4** (15%) may be isolated following column chromatography and recrystallization from hexane. The compound is a deep red, air-stable crystalline material. Interestingly yellow hexane solutions of **3** turn dark red when heated with excess t-Bu_2PH in THF and **4** may be isolated from this reaction in high yield by evaporation to dryness followed by recrystallization of the residue from hexane. The reverse transformation may be easily accomplished by simply bubbling CO (1 atm) through a hexane solution of **4**. Spectroscopic data for both **3** and **4** are in accord with the solid-state structures as determined by single-crystal X-ray diffraction studies.

The $^{31}P\{^1H\}$ NMR spectrum of **3** in C_6D_6 at 25°C is a sharp singlet at δ 147.0, indicating equivalent phosphido groups bridging metal–metal bonds.[10] The ^1H NMR shows a virtual triplet to high field (δ −17.50, apparent J_{P-H} = 11.5 Hz) which is assigned to the two hydride ligands. Similar resonances have been observed in the ^1H NMR spectra of $Os_3(CO)_8(\mu\text{-}H)_2(\mu\text{-}Ph_2P)_2$[11] and $Ru_3(CO)_8(\mu\text{-}H)_2(\mu\text{-}t\text{-}Bu_2P)_2$[7] and they have been attributed to an AA′XX′ type spectra. The $^{31}P\{^1H\}$ NMR spectrum of **4** contains two resonances to low field (δ 146.65, d d, $^2J_{P-P}$ = 91.6, 24.9 Hz and δ 183.04, d, $^2J_{P-P}$ = 91.6 Hz) and a doublet at δ 29.11 ($^2J_{P-P}$ = 24.2 Hz). The former two resonances are assigned to the two phosphido groups which are now inequivalent. In the ^{31}P NMR spectrum the latter resonance splits into a broad doublet ($^1J_{P-H}$ = 345.7 Hz), confirming its assignment to the terminal t-Bu_2PH ligand. The high-field region of the ^1H NMR spectrum of **4** contains two multiplets at δ −9.72 and −11.72 indicating that the μ-H ligands are also now non-equivalent.

Table 2. Selected bond lengths (Å) and angles (°) for **1**

Atom 1	Atom 2	Distance	Atom 1	Atom 2	Atom 3	Angle

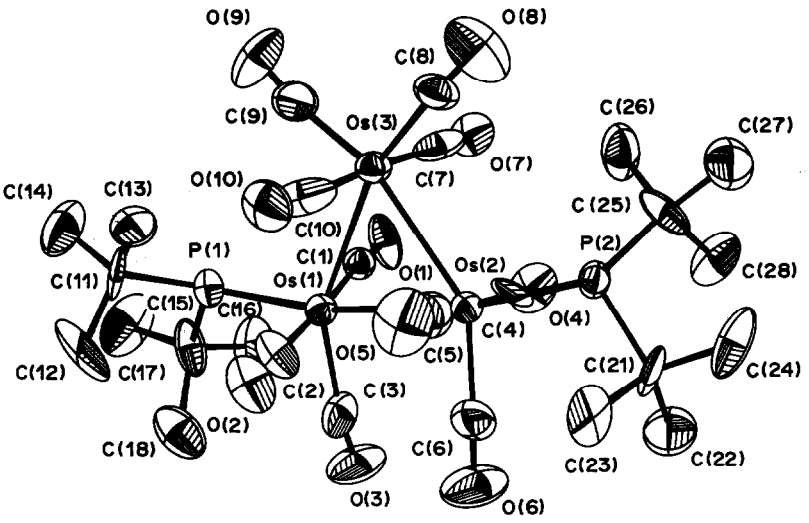

Fig. 2. ORTEP view of **2** showing the atom numbering scheme.

X-ray structures of $Os_3(CO)_8(\mu\text{-}H)_2(\mu\text{-}t\text{-}Bu_2P)_2$ **(3)** *and* $Os_3(CO)_6(t\text{-}Bu_2PH)(\mu\text{-}H)_2(\mu\text{-}t\text{-}Bu_2P)_2$ **(4)**

The molecular structures of **3** and **4** are shown as ORTEP views in Figs 3 and 4, respectively. Key bond lengths and angles for **3** and **4** are given in Tables 4 and 5, respectively. Complex **3** crystallizes in the triclinic space group $P\bar{1}$ with two molecules per unit cell. The molecular geometry of **3** consists of a closed 48-electron Os_3 cluster in which two of the Os—Os bonds are bridged by $\mu\text{-}t\text{-}Bu_2P^-$ units [Os(1)—Os(2) = 2.944(1) Å and Os(1)—Os(3) = 2.883(1) Å]. These groups lie above and below the Os_3 plane. The structure is similar to those of the diphenylphosphido and ruthenium analogues. The unique osmium atom [Os(1)] which is bonded to two phosphido groups also bears two *cis*-CO units. The other two osmium atoms each have three CO groups and are separated by a fairly long Os—Os bond of 3.010(1) Å. Although the hydrides were not located in the X-ray structure of **3**, it is reasonable to assume that they occupy the bridging sites across Os(1)—Os(2) and Os(1)—Os(3) and opposite to the $\mu\text{-}t\text{-}Bu_2P^-$ groups. Thus, the phosphido groups are roughly *trans* to each other [P(2)—Os(1)—P(1) = 151.15(9)°]. The coordination geometry of each metal is roughly octahedral if one ignores the metal–metal bonds for Os(2) but includes the Os(2)—Os(3) interaction for Os(2) and Os(3).

The striking difference between the structures of **3** and **4** is that in **4** one CO group on Os(2) has been replaced by a $t\text{-}Bu_2PH$ ligand and this is accompanied by the loss of a CO group on a *different* osmium atom [Os(3)]. Although formal electron counting procedures are sometimes misleading, one possible interpretation is that there are now two 18-electron osmium atoms [Os(1) and Os(2)] and a 16-electron atom [Os(3)], while the total electron count on the molecule is 46.

The Os—Os distances in **4** are, on the average, shorter than those in **3** (2.825 vs 2.962 Å). There is

Table 3. Selected bond lengths (Å) and angles (°) for **2**

Atom 1	Atom 2	Distance	Atom 1	Atom 2	Atom 3	Angle
Os(1)	Os(2)	2.900(2)	Os(3)	Os(1)	Os(3)	60.18(5)
Os(1)	Os(3)	2.925(1)	Os(2)	Os(1)	P(1)	168.5(2)
Os(2)	Os(3)	2.921(2)	Os(1)	Os(3)	Os(2)	59.49(4)
Os(1)	P(1)	2.335(9)	Os(3)	Os(2)	P(2)	109.6(2)
Os(2)	P(2)	2.423(9)	Os(1)	Os(2)	Os(3)	60.34(4)
			Os(1)	Os(2)	P(2)	169.8(2)
			Os(3)	Os(1)	P(1)	108.4(2)

Numbers in parentheses are ESDs in the least significant digits.

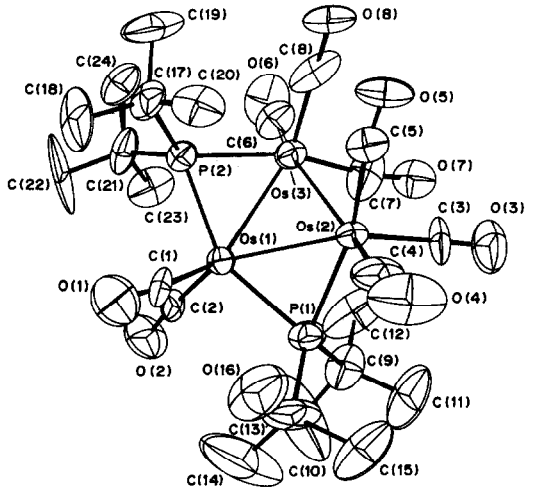

Fig. 3. ORTEP view of **3** showing the atom numbering scheme.

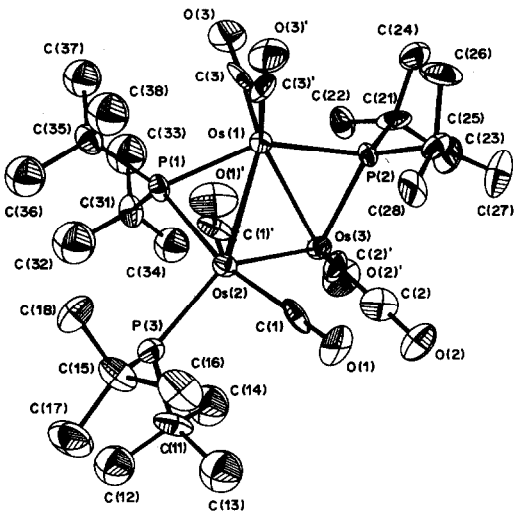

Fig. 4. ORTEP view of **4** showing the atom numbering scheme.

no particularly short Os—Os interaction, with the shortest now being Os(1)—Os(3) (2.706(1) Å). Os(2)—Os(3) which is not bridged by a phosphido group is now the second shortest (2.797(1) Å). The longest Os—Os bond is Os(1)—Os(2) at 2.971(1) Å. As for **3**, the coordination geometries of Os(1) and Os(2) may be described as roughly octahedral if one ignores the metal–metal interactions. The coordination geometry of Os(3) is roughly trigonal bipyramidal.

One question concerns the location of the two hydride ligands in **4**. Both spectroscopic and structural data do not permit unequivocal assignment of their positions. Consideration of space-filling

models suggest that there is room for a hydride to bridge any of the three of the Os—Os bonds. Since Os(3) is now both coordinatively and (formally) electronically unsaturated, we very tentatively assign the μ-H atoms to the two bridging locations which span Os(1)—Os(3) and Os(2)—Os(3).

The replacement of one CO in Os(2) by the bulky phosphine ligand might be expected to result in further loss of CO from Os(2) from that metal on steric grounds. However, the increased electron density on Os(2), caused by the presence of the σ-donating t-Bu_2PH ligand, may increase the strength of the Os(2)—CO π-backbonding interaction and prevent the loss of the two remaining CO ligands on Os(2). The loss of a CO ligand from Os(3) may still be due to steric effects since there is considerable steric congestion around the molecule caused by the two bulky t-Bu_2P^- units as well as the phosphine (t-Bu_2PH).

Synthesis of the phosphinidene complex $Os_3(CO)_7(t\text{-}Bu_2PH)_2(\mu\text{-}H)_2(\mu_3\text{-}t\text{-}BuP)$ **(5)**

The reaction of $Os_3(CO)_{12}$ with t-Bu_2PH (3 equiv.) in refluxing di-n-butylether (143°C) for 24 h affords the orange phosphinidene complex **5** in 68% yield. This compound may also be obtained by heating **1**, **2**, **3** or **4** in di-n-butylether (24 h). Spectroscopic data for **5** are in accord with the structure as determined by X-ray crystallography. The IR spectrum contains ν(CO) absorptions in the terminal CO region in addition to peaks at 2351 (w) and 2313 (w) cm^{-1} assigned to ν(P—H) stretching vibrations. The $^{31}P\{^1H\}$ NMR spectrum consists of two doublets at δ 208.12 and 14.08 ($^2J_{P-P}$ = 89.0 Hz) assigned to the phospinidene (t-BuP) and phosphine (t-Bu_2PH) nuclei, respectively. The ^1H NMR spectrum exhibits resonances assigned to the t-Bu_2PH and t-BuP ligands in addition to a triplet at δ −21.17 ($^2J_{P-H}$ = 10.2 Hz) which is assigned to the two bridging hydrides in the complex.

X-ray structure of **5**

Molecules of **5** crystallize in the triclinic space group $P\bar{1}$ with two independent molecules in the asymmetric unit, four per unit cell. The molecules have similar geometric parameters. The molecular structure of one molecule is shown as an ORTEP view in Fig. 5. Key bond lengths and angles are

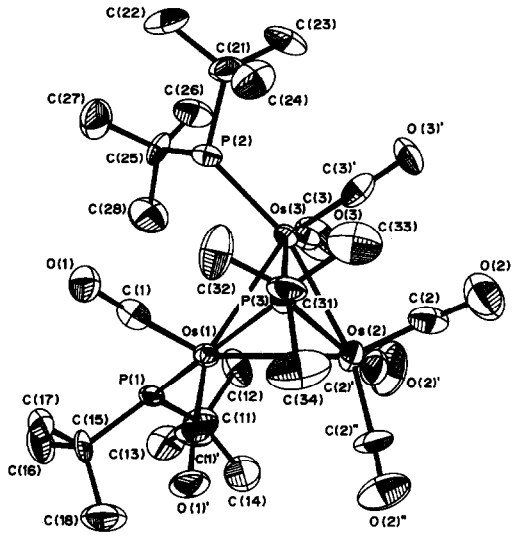

Fig. 5. ORTEP view of **5** showing the atom numbering scheme.

given in Table 6. The molecular structure of **5** consists of an Os_3 triangle (Os—Os = 2.954 Å, av.) capped by a μ_3-P(*t*-Bu) group. Two osmium atoms [Os(1), Os(3)] each bear two CO ligands as well as a terminal phosphine (t-Bu_2PH) ligand. The third osmium atom has three CO groups. There are several related analogues of this compound. They include $H_2Ru_3(CO)_9(\mu_3\text{-PPh})$,[12] $H_2Ru_3(CO)_9[\mu_3\text{-P}(p\text{-}CH_3OC_6H_4)]$[13] and $Ru_3(CO)_8(t\text{-}Bu_2PH)(\mu\text{-H})_2(\mu_3\text{-}t\text{-BuP})$.[6] The two hydride ligands were not located in the X-ray study although it seems reasonable to suggest that they occupy bridging positions between Os(1)—Os(2) (2.983(1) Å) and Os(2)—Os(3) (2.853(1) Å), below the Os_3 triangle opposite to the phosphinidene ligand. Both of these bonds are shorter than the remaining metal–metal bond [Os(1)—Os(3) = 3.025(1) Å]. The symmetrical triplet in the ^{1}H NMR spectrum for the hydrides is also consistent with their occupying chemically and magnetically equivalent positions. The Os—P(phosphinidene) distances for the osmium atoms which bear t-Bu_2PH ligands are slightly longer than those for the osmium atom which bears three CO units. Thus Os(1)—P(3) and Os(3)—P(3) are 2.330(4) and 2.329(4) Å, respectively, while Os(2)—P(3) is 2.306(4) Å. The second molecule of **5** exhibits a similar distortion. The Os—P(phosphine) distances are similar (Os(1)—P(1) = 2.411(4), Os(3)—P(2) = 2.364(4) Å) and fall within the normal limits for such bonds.

Table 6. Selected bond lengths (Å) and angles (°) for one molecule of **5**

Atom 1	Atom 2	Distance

Synthesis of $Os_3(CO)_7(\mu\text{-H})(Cy_2P)_3$ (**6**)

The interaction of $Os_3(CO)_{12}$ and dicyclohexylphosphine (Cy_2PH) in refluxing toluene (6 days) yields the tris-phosphido, 48-electron cluster $Os_3(CO)_7(\mu\text{-H})(Cy_2P)_3$ (**6**). Spectroscopic data for **6** are in accord with the structure as determined by X-ray crystallography. The IR spectrum exhibits ν(CO) absorptions in the terminal CO region at 2210, 1990, 1975, 1967 and 1932 cm^{-1}. The $^{31}P\{^1H\}$ NMR spectrum shows only a singlet at δ 112.75 at room temperature, indicating that the three phosphido bridges are equivalent in solution on the NMR time scale. The ^1H NMR shows only a simple quartet in the hydride region indicating that the hydride is fluxional and is equivalent to all three phosphides on the NMR time scale. The presence of three phosphido bridges, one across each Os—Os bond, contrasts with two phosphido bridges in **3** and **4** and with other Os_3 diphenylphosphido analogues.[2] The isolation of **6** further demonstrates that differences in steric bulk of phosphido ligands can result in major differences in stoichiometry and structure for the complexes they form.

X-ray structure of **6**

Figure 6 shows the molecular geometry and atom numbering scheme, while a view of the central core of **6** is shown in Fig. 7. Selected bond lengths and angles are given in Table 7. Complex **6** consists of a triangular core of osmium atoms with each edge of the triangle bridged by μ_2-P(Cy)$_2$ units and a μ_2-hydrido ligand bridging the Os(1)—Os(2) bond. One of the phosphido bridges [P(1)] is bent dramatically below the plane of the three osmium atoms, while the other two phosphido bridges, P(2) and P(3), are well above the Os_3 plane. To our knowledge, **6** is the first trinuclear osmium complex with a bridging phosphido group across each of the Os—Os vectors. In addition, Os(1) and Os(2) are each coordinated by two CO ligands, while Os(3) bears three carbonyl groups. Excluding metal–metal bonding, each osmium atom has a roughly

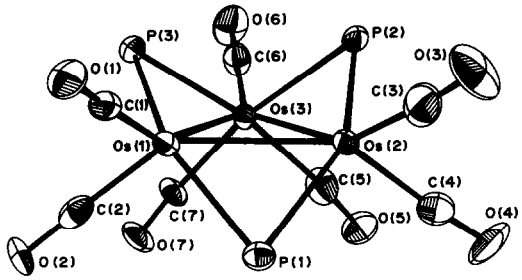

Fig. 7. View of the central core of **6** showing the arrangement of the phosphido ligands. Cyclohexyl groups have been omitted for clarity.

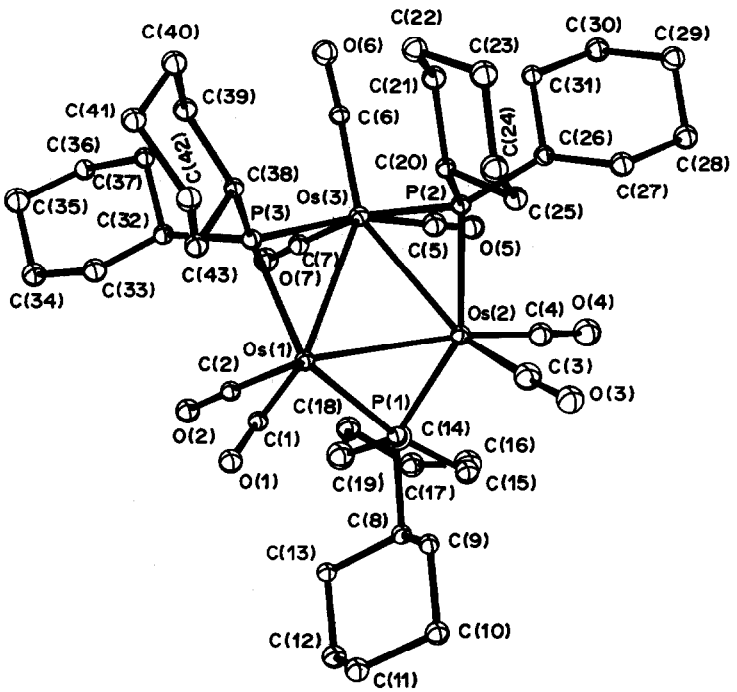

Fig. 6. ORTEP view of **6** showing the atom numbering scheme.

Table 7. Selected bond lengths (Å) and angles (°) for **6**[a]

			Os(1)	Os(3)	P(3)	49.39(8)
			Os(2)	Os(3)	P(2)	48.67(8)
			Os(2)	Os(3)	P(3)	94.81(8)
			P(2)	Os(3)	P(3)	99.3(1)

Numbers in parentheses are ESDs in the least significant digits.
[a] A complete listing is available in the supplementary material.

square-pyramidal coordination geometry. Os(1) and Os(2) may be considered to have formal oxidation states of (+1), while Os(3) would formally be (+2) with all three metal atoms attaining an 18-electron count.

The key structural parameters of the molecule all fall within normal limits. The Os—Os bonds range from 3.059(1) to 2.817(1) Å with an average of 2.966 Å, while the Os—P bonds range from 2.456(3) to 2.338(3) Å with an average of 2.387 Å. These values are comparable to analagous ones found in other phosphido-bridged trinuclear osmium complexes.

The position of the hydride ligand, although not located in the X-ray structure, is tentatively assigned a bridging position across the shorter Os(1)—Os(2) bond since this is clearly an open site as shown in Fig. 7.

EXPERIMENTAL

All operations were performed under dry nitrogen or *in vacuo*. Hexane and THF were dried over sodium benzophenone under nitrogen and distilled under nitrogen before use. The di-*n*-butylether was refluxed over potassium hydroxide pellets and the fraction with a boiling point in the range 142–143°C was collected. Melting points were determined in sealed capillaries under nitrogen (1 atm) and are uncorrected. $Os_3(CO)_{12}$[13] and *t*-Bu_2PH[14] were prepared as previously described. Dicyclohexylphosphine was purchased from the Strem Chemical Company, Newburyport, MA, and was used as received. Instruments, IR: Perkin–Elmer 1330; NMR: Varian EM-390 (^1H, 90 MHz), G.E. QE 300 (^1H, ^{31}P).

Synthesis of $Os_3(CO)_9(t\text{-}Bu_2PH)_3$ (1)

Dodecacarbonyltriosmium (0.20 g, 0.22 mmol) and di-*tert*-butylphosphine (0.09 cm^3, 0.66 mmol) in THF were photolysed with a 550 W Hanovia mercury vapour lamp for 18 h in a quartz Schlenk tube. During this time the colour of the solution deepened continuously until it was bright orange. The reaction mixture was evaporated to dryness under reduced pressure and extracted with hexane. The solution was filtered and evaporated (10 cm^3). Cooling (−30°C) yielded orange crystals which were collected and dried *in vacuo*. Yield: 0.17 g, 63.0%; m.p.: 170–172°C. X-ray quality crystals were prepared by slow evaporation of benzene in air. NMR ^1H (C_6D_6, δ rel. Me_4Si 300 MHz): δ 5.39 (d, 1H, J_{P-H} = 344 Hz, *t*-Bu_2PH), δ 1.28 (d, 54H, J_{P-H} = 16 Hz, *t*-Bu_2PH); $^{31}P\{^1H\}$ [in C_6D_6, amb. temp., rel. 85% H_3PO_4 (aq.)]: δ 17.93 (s, *t*-Bu_2PH). IR (Nujol mull, NaCl): 2320 w, 2300 w, 2040 w, 1973 s, 1955 s, 1918 s, 1873 w, 1255 m, 1203 w, 1175 w, 1090 m, 1017 m, 930 w, 903 m, 860 m, 805 m, 719 w, 610 m, 565 m (cm^{-1}).

Synthesis of $Os_3(CO)_{10}(t\text{-}Bu_2PH)_2$ **(2)** *and* $Os_3(CO)_8(\mu\text{-}H)_2(\mu\text{-}t\text{-}Bu_2P)_2$ **(3)**

Dodecacarbonyltriosmium (0.2 g, 0.22 mmol) and three molar equiv. of t-Bu_2PH (0.09 cm^3, 0.66 mmol) were heated in toluene (50 cm^3) under reflux for 12 h. During this time the colour of the solution deepened continuously until it was deep orange. The reaction mixture was allowed to cool and evaporated to dryness under vacuum. The residue was extracted with hexane, concentrated (10 cm^3), and poured onto a silica gel column. The column was first eluted with hexane to give a yellow fraction. Subsequent elution with toluene gave an orange–red fraction. The yellow fraction was evaporated to dryness *in vacuo* to give yellow–orange crystals of **3** which were recrystallized from hexane. Yield: 0.12 g, 50.0%; m.p. 203–205°C. The orange–red fraction was evaporated to dryness under vacuum to give orange crystals of **2** which were recrystallized from hexane. Yield: 0.06 g, 24.0%; m.p. 162–165°C. For **2**: NMR ^1H (C_6D_6, δ rel. Me_4Si at 300 MHz): δ 4.89 (d, 2H, J_{P-H} = 381 Hz, t-Bu_2PH), δ 1.16 (d, 36H, J_{P-H} = 15 Hz, t-Bu_2PH); $^{31}P\{^1H\}$ [in C_6D_6, amb. temp., rel. 85%, H_3PO_4 (aq.)]: δ 21.46 (s, t-Bu_2PH). IR (Nujol mull, NaCl): 2310 w, 2080 w, 2020 s, 1990 s, 1952 s, 1928 s, 1258 w, 1175 m, 1022 m, 852 m, 810 m, 768 w (cm^{-1}).

Reaction of $Os_3(CO)_{12}$ *with* t-Bu_2PH: *Synthesis of* **3** *and* **4**

An excess of di-*tert*-butylphosphine (0.09 cm^3, 0.66 mmol) was added to a toluene solution (40 cm^3) of $Os_3(CO)_{12}$ (0.2 g, 0.22 mmol). This mixture was refluxed for 24 h and turned red during this time. After the mixture was cooled, the solvent was removed *in vacuo*, and the residue was extracted into a minimum of hexane and applied to an alumina-packed column under nitrogen. The products were separated using hexane as an eluant. Two products, $Os_3(CO)_8(\mu\text{-}H)_2(\mu\text{-}t\text{-}Bu_2P)_2$ **(3)** and $Os_3(CO)_6(t\text{-}Bu_2PH)(\mu\text{-}H)_2(\mu\text{-}t\text{-}Bu_2P)_2$ **(4)** were obtained. In order of elution they were **3** (0.12 g, 50.0%) and **4** (0.02 g, 15.4%; m.p. 178–182°C). For **3**: NMR, ^1H (C_6D_6, δ rel. Me_4Si at 300 MHz): δ 1.31 (m, 36H, t-Bu_2P, J_{P-H} = 14 Hz), δ −17.50 (t, 2H, μ-H, J_{P-H} = 11.5 Hz); $^{31}P\{^1H\}$ [C_6D_6, amb. temp., rel. 85% H_3PO_4 (aq.)]: δ 147.00 (s, t-Bu_2P). IR (Nujol mull, NaCl): 2040s, 2000s, 1990s, 1955s, 1941s, 1919s, 1242m, 1150, 1080w, 1000w, 782w, 700w, 650m, 580m (cm^{-1}). For **4**: NMR, ^1H (C_6D_6, δ rel. Me_4Si at 300 MHz) δ 5.65 (d of d, 1H, t-Bu_2PH, $^1J_{P-H}$ = 339.0 Hz, $^3J_{P-H}$ = 9.61 Hz), δ 1.61 (d, 18H, t-Bu_2PH, $^2J_{P-H}$ = 14.3 Hz), δ 1.36 (d, 18H, μ-t-Bu_2P, $^2J_{P-H}$ = 14.3 Hz), δ 1.09 (d, 18H, μ-t-Bu_2P, $^2J_{P-H}$ = 14.6 Hz), δ −9.76 (m, 2H, μ-H, $^2J_{P-H}$ = 10.5 Hz), δ −11.72 (m, 2H, μ-H, $^2J_{P-H}$ = 10.3 Hz); $^{31}P\{^1H\}$ [C_6D_6, amb. temp., rel. 85% H_3PO_4 (aq.)]; δ 183.07 (d, μ-t-Bu_2P, $^2J_{P-P}$ = 88.5 Hz); δ 146.67 (d of d, μ-t-Bu_2P, $^2J_{P-P}$ = 92.7); δ 29.10 (br.t, t-Bu_2PH, $^2J_{P-P}$ = 15.5 Hz); ^{31}P (C_6D_6, amb. temp.) the δ 29.10 peak splits into a doublet of triplets, $^1J_{P-H}$ = 333.8 Hz. IR (Nujol mull, NaCl): 2347w, 2010s, 1971s, 1938s, 1915s, 1391w, 1310m, 1261m, 1169m, 1096m, 1023m, 936w, 889w, 862w, 843w, 806m, 598m, 573m, 549m (cm^{-1}).

Synthesis of the complex $Os_3(CO)_7(\mu\text{-}H)_2(t\text{-}Bu_2PH)(\mu_3\text{-}t\text{-}BuP)$ **(5)**

Dodecacarbonyltriosmium (0.2 g, 0.22 mmol) and di-*tert*-butylphosphine (0.9 cm^3, 0.66 mmol) in 100 cm^3 di-*n*-butylether were heated for several hours. The colour of the solution turned bright orange after 2 h and dull orange after 24 h. The reaction mixture was cooled and evaporated to dryness *in vacuo*. The residue was extracted into hexane, concentrated to 5 cm^3, and cooled (−35°C), producing an orange, air-stable crystalline material which was collected and dried *in vacuo*. Yield: 0.17 g, 68%; m.p.: 158–160°C. NMR, ^1H (C_6D_6, δ rel. Me_4Si, 300 MHz): δ 4.594 (d, 2H, J_{P-H} = 342.5 Hz, t-Bu_2PH), δ 1.547 (d, 9H, J_{P-H} = 20.7 Hz, μ^3-t-BuP), δ 0.916 (d, 36H, J_{P-H} = 15.0 Hz, t-Bu_2PH), δ −21.17 (t, 2H, $^2J_{P-H}$ = 10.2 Hz, μ-H); $^{31}P\{^1H\}$ [in C_6D_6, amb. temp., rel. 85%, H_3PO_4 (aq.)]: δ 208.12 (d, $^2J_{P-P}$ = 89.0 Hz, μ^3-t-BuP), δ 14.08 (d, $^2J_{P-P}$ = 89.1 Hz, t-Bu_2PH). IR (Nujol mull, NaCl): 2351 w, 2313 w, 2066 s, 2043 s, 2008 s, 1989 s, 1948 s, 1921 s, 1913 s, 1261 m, 1170 m, 1066 m, 1026 s, 860 m, 851 m, 813 s, 675 m, 569 s, 528 m, 521 s (cm^{-1}).

Synthesis of the complex $Os_3(CO)_7(\mu\text{-}H)(Cy_2P)_3$ **(6)**

Cy_2PH (0.41 cm^3, 1.9 mmol) was added to a suspension of $Os_3(CO)_{12}$ (0.57 g, 0.63 mmol) in toluene (100 cm^3). The mixture was heated under reflux (6 days) during which time the $Os_3(CO)_{12}$ dissolved producing a red–orange solution. Volatile materials were removed *in vacuo*, and the residue extracted into toluene (3 × 40 cm^3). The filtered combined extracts were reduced in volume under vacuum and cooled (−35°C), producing **5** as an orange, air-stable microcrystalline powder. The material was collected and dried *in vacuo*. Yield: 60%; m.p. 290–293°C (dec). NMR, ^1H (C_6D_6, rel. to Me_4Si δ 0.0, 25°C, 360 MHz): δ 1.8 (br. mult., 66H, μ-P(Cy)$_2$), δ −17.18 (quartet, 1H, μ-H);

$^{31}P\{^1H\}$ (C_6D_6, rel. to 85% H_3PO_4 (δ 0.0), 25°C, 32.384 MHz); δ 112.75 (s, μ-PCy_2).

X-RAY EXPERIMENTAL

General

Data for all six compounds were collected on an Enraf–Nonius CAD-4 diffractometer using graphite-monochromated Mo-K_α radiation. Data for the unit cell determinations were collected by the θ–2θ scan technique at 23 ± 1°C. Details of the standard data collection methods were similar to those outlined previously.[15] All calculations were performed on a PDP 11/44 computer using the Enraf–Nonius software package "SDP-PLUS".[16] Supplementary material is available for all six compounds.*

Suitable crystals were obtained by slow cooling of hexane solutions (−10°C), mounted in thin-walled glass capillaries, and sealed under inert atmospheres. Unit cell parameters were obtained from 25 strong reflections (**1**: $22° < 2\theta < 26°$; **2**: $22° < 2\theta < 28°$; **3**: $22° < 2\theta < 27°$; **4**: $8° < 2\theta < 25°$; **5**: $26° < 2\theta < 28°$; **6**: $20° < 2\theta < 24°$). The data were then corrected for Lorentz and polarization effects, and an anisotropic decay correction was applied for **1**, **2** and **5**. An empirical absorption correction (program EAC) was applied for each compound. The structures were obtained by direct methods (MULTAN)[17] except for **5** which was solved by Patterson methods, and successive cycles of difference Fourier maps followed by least-squares refinement. Hydrogen atoms were not located in the structure determinations although their contributions were included in the refinements. Data with intensities less than $3\sigma(I)$† and $\sin\theta/\lambda$ less than 0.05 were excluded, and a non-Poisson contribution weighting scheme with an experimental instability factor P set at 0.07 (**1**, **2** and **6**) and 0.03 (**3** and **5**) and 0.05 (**4**) were used in the final stages of refinement.* Crystal data and collection parameters are given in Table 1. Scattering factors were taken from ref. 18.

For **1**, the highest peak in the final difference Fourier map had a height of 0.899 e/Å^3 and was located 1.043 Å from Os(1). For **2**, the highest peak in the final difference Fourier map had a height of 1.140 e/Å^3 and was located 1.14 Å from Os(2). For **5**, the highest peak in the final difference Fourier map had a height of 3.393 e/Å^{-3} and was located 1.15 Å from Os(6). For **6**, the highest peak in the final difference Fourier map had a height of 0.895 e/Å^{-3} and was locatd 0.995 Å from C(35).

TRANS-CHLOROACETATONITROSYLBIS(TRIPHENYLPHOSPHINE)RHODIUM

ROBIN B. ENGLISH

Department of Chemistry and Biochemistry, Rhodes University, P.O. Box 94, Grahamstown 6140, South Africa

(*Received* 3 *August* 1989; *accepted* 1 *March* 1990)

Abstract—The synthesis and structural characterization of the tetragonal pyramidal complex $[Rh(O_2CCH_3)Cl(NO)(PPh_3)_2]$ are reported. This complex has a *trans* arrangement of basal ligands with a bent apical nitrosyl group inclined towards the *acetato* ligand.

We are currently investigating the stereochemistry and reactivity of the tetragonal pyramidal complexes $[RhX_2(NO)(PR_3)_2]$ (X is an anionic ligand and PR_3 *a secondary or tertiary phosphine*).[1] In one experiment we set out to prepare crystals of $[Rh(O_2CCH_3)_2(NO)(PPh_3)_2]$ (**I**) of diffraction quality, with the aim of comparing its structure with that of the *trifluoroacetato* analogue $[Rh(O_2CCF_3)_2(NO)(PPh_3)_2]$.[2] The synthesis of **I** is described in *Inorganic Syntheses*[3] and is straightforward. To our surprise, recrystallization of **I** from chloroform yielded crystals which were *not*, on microanalytical evidence, composed of **I**. A single crystal X-ray diffraction study was performed and revealed that a reaction had taken place during the crystallization to give the *chloro*-substituted derivative $[Rh(O_2CCH_3)Cl(NO)(PPh_3)_2]$ (**II**), whose structure is described in this communication.

EXPERIMENTAL

Green microcrystalline **I** (100 mg, 0.13 mmol) was dissolved in warm (40°C) chloroform (10 cm^3). The rate of dissolution appeared to depend inversely on the crystallite size, and of several batches of **I**, some were almost insoluble; dissolution was also extremely slow in carefully purified chloroform. A bright green solution was obtained which slowly and inexorably darkened to olive-green over 2 h. The solution was filtered and cooled to 2°C; over 12 h large, green–brown solvated crystals of the *product* formed in 10% yield [ν(N—O) 1612 cm^{-1}]. Manipulations were carried out in an atmosphere of nitrogen.

X-ray crystallography

$[Rh(O_2CCH_3)Cl(NO)(PPh_3)_2]\cdot 2CHCl_3$, $C_{40}H_{35}Cl_7NO_3P_2Rh$, $M_r = 990.9$, $P2_1/c$ (No. 14), $a = 9.797(5)$, $b = 23.20(1)$, $c = 19.45(1)$ Å, $\beta = 91.38(5)°$, $F(000) = 2000$, $U = 4420(6)$ Å^3, $Z = 4$, $\mu = 8.3$ cm^{-1}, crystal size $0.2\times0.2\times0.15$ mm, $N_{reflections} = 8240$ ($-11 \leqslant h \leqslant 11$, $0 \leqslant k \leqslant 23$, $0 \leqslant l \leqslant 22$), N(observed, unique with $I \geqslant 2.5\sigma(I)$) = 3651, $R = 0.098$, $R_w = 0.103$, $w = k/[\sigma^2(F_o) + g(F_o)^2]$ with $k = 0.629$, $g = 0.0233$. Data collection, structure solution and refinement methods have been described previously;[4] phenyl carbons and the nitrosyl oxygen atom were refined with isotropic temperature factors, otherwise full anisotropic refinement was employed; chloroform molecules exhibited thermal and possible disorder effects and were therefore treated as rigid groups with C—Cl 1.75 Å and Cl—C—Cl 109.5°. The rather high final R reflects the poor definition in the region of the solvent chlorine atoms, which contribute 20.4% of the total electron count in the unit cell. Two peaks, ~ 1.5 eÅ^{-3}, in the final difference map were associated with the nitrosyl oxygen atom, whose final temperature factor was quite large, 0.2 Å^2. Three other peaks with heights > 1 eÅ^{-3} were close to the rhodium atom; otherwise the map was featureless. Some bond lengths (Å) and angles (°):* Rh—N 1.91(1), Rh—Cl 2.355(4), Rh—P(1)

* Atomic coordinates, derived parameters and F_o/F_c data have been deposited with the Editor as supplementary data: atomic coordinates are also available from the Cambridge Crystallographic Data Centre.

2.377(4), Rh—P(2) 2.368(4), Rh—O(*acetato*) 2.05(1), N—O(nitrosyl) 0.92(3); Rh—N—O 130(2), P(1)—Rh—P(2) 171.0(1), Cl—Rh—O(*acetato*) 169.5(3), P(1)—Rh—Cl 88.3(1), P(2)—Rh—Cl 90.4(1), P(1)—Rh—O(*acetato*) 89.5(3), P(2)—Rh—O(*acetato*) 90.2(3), N—Rh—basal ligand angles range from 92.7(6) to 97.7(5)

RESULTS AND DISCUSSION

The structure of **II** is shown in Fig. 1. Like other complexes in the $[RhX_2(NO)(PR_3)_2]$ series, **II** is tetragonal pyramidal with a bent apical nitrosyl group. The geometry of the metal—N—O system has been the subject of considerable discussion.[5] In **II** the Rh—N—O angle is close to that in $[RhCl_2(NO)(PPh_3)_2]$,[6] 125(2)°, and indeed corresponding bond lengths and angles in the two molecules are not significantly different. However, the *direction* of bending of the NO group is different; in **II** NO bands in the N—Rh—O(*acetato*) plane (torsion angle O(nitrosyl)—N—Rh—O(*acetato*) 3.8°), whereas in $[RhCl_2(NO)(PPh_3)_2]$ the Rh—P bond is eclipsed [O(nitrosyl)—N—Rh—P 10(3)°]. If one discounts crystal packing as a secondary influence, the substitution of an acetate for a chloride ligand can be the only cause of this difference.

A theoretical analysis of the electronic structure of five-coordinate nitrosyl complexes, by Hoffmann *et al.*, was published some years ago.[5] The relevant conclusions in this treatment are as follows:

(a) in compounds of the type $ML_2L'_2(NO)$, L *trans* to L, the NO group should bend in the plane containing the poorer donors or, alternatively, the better π-acceptors; and
(b) in a compound of the type $ML_2DA(NO)$, D = π-donor *trans* to A = π-acceptor, if the NO group bends in the DMA plane then it should incline towards A.

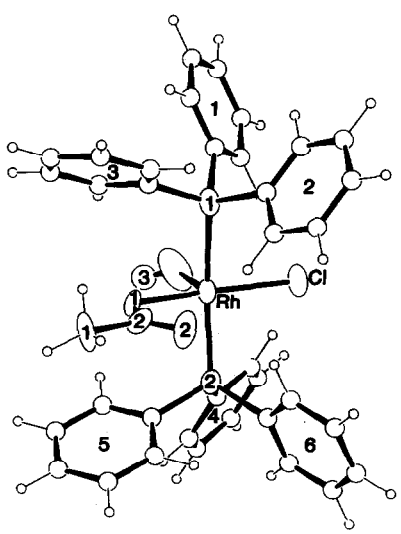

Fig. 1. Structure of $[Rh(O_2CCH_3)Cl(NO)(PPh_3)_2]$: numbers refer to the atomic coordinate list.

The structure of $[RhCl_2(NO)(PPh_3)_2]$ is then explained in terms of (a) by making the reasonable assumption that PPh_3 is a better π-acceptor than Cl.

Similarly, the Rh—N—O conformation in **II** follows if one makes the assumptions that the *acetato* ligand is a better π-acceptor and weaker donor than either PPh_3 or Cl^-, and that, taken together, Cl^- and $CH_3CO_2^-$ are weaker electron-donors than two PPh_3 groups. These statements are not quite so intuitively acceptable.

However, when both the Cl ligands are replaced by *trifluoroacetato* groups, which presumably are *better* π-acceptors and weaker donors than PPh_3 due to the powerful electron-withdrawing influence of the CF_3 substituents, the NO does not bend in the RhO_2 plane as expected: in $[Rh(O_2CCF_3)_2(NO)(PPh_3)_2]$ the torsion angle $O(CF_3CO_2)$—Rh—N—O(nitrosyl) is 43°, so the NO group bends in a plane bisecting a P—Rh—$O(CF_3CO_2)$ bond. The model fails to predict this geometry.

Hoffmann's conclusions are based on symmetry arguments combined with extended Hückel calculations carried out on the model compounds $[IrCl_4(NO)]^{2-}$, $[IrCl_2(NO)(PH_3)_2]$ and $Mn(CO)_4(NO)$, and do not take steric interactions into account. Certainly, the *bending* of the NO ligand must be due to electronic effects; however, the primary influence determining its *conformation* is probably steric in nature, while electrostatic interaction between the dipole of the NO and the resultant dipole of the rest of the molecule should also be considered. Orbital influences play a minor role.

Figure 2 depicts the molecules $[Rh(O_2CCH_3)Cl(NO)(PPh_3)_2]$, $[RhCl_2(NO)(PPh_3)_2]$ and $[Rh(O_2CCF_3)_2(NO)(PPh_3)_2]$ drawn with van der Waals' radii for the atoms, in "plan" and "elevation"; it is clearly apparent that rotation of the NO ligand round the Rh—N bond is hindered by the presence of the PPh_3 phenyl groups. It is also interesting to see how the conformational swivelling of the NO group becomes a very minor structural phenomenon when the molecules are depicted "realistically" rather than in the conventional ORTEP-style plots. In fact, such ball-and-stick plots can be quite misleading. For example, in ref. 5 the ". . . more sterically crowded Ph_3P—Ir—PPh_3 axes in $[IrCl_2(NO)(PPh_3)_2]$ . . ." are mentioned. Inspection of Fig. 2(b) shows that the

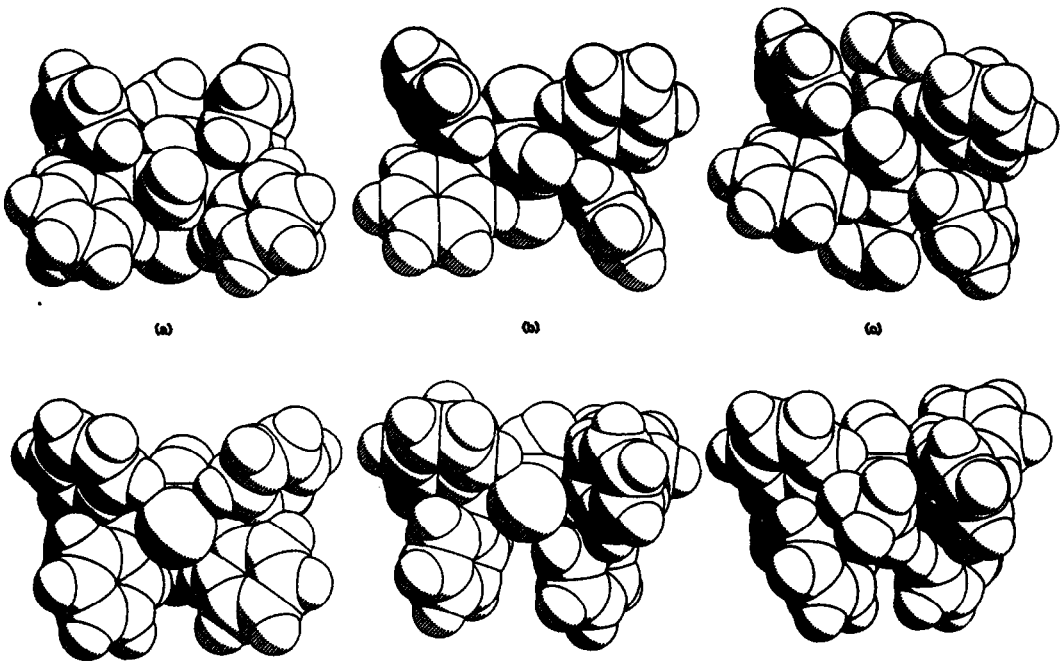

Fig. 2. The molecules **II** (a), $[RhCl_2(NO)(PPh_3)_3]$ (b) and $[Rh(O_2CCF_3)_2(NO)(PPh_3)_2]$ (c), drawn with van der Waals' radii for the atoms: top, viewed along the Rh—N vector, and bottom, viewed perpendicular to the Rh—N vector and parallel to the Rh—N—O plane.

Cl—Rh—Cl axes in $[RhCl_2(NO)(PPh_3)_2]$ (isostructural with the iridium analogue) are just as crowded by the phenyl groups, and in terms of steric hindrance there is little to choose between these two regions.

We feel that the structures observed in these complexes correspond to potential energy minima, that steric and electrostatic effects both play a part in determining NO conformation; the balance between the two effects obviously will vary with the nature of the basal ligands, and that orbital effects are minor in comparison.

The mechanism of formation of **II** from $[Rh(O_2CCH_3)_2(NO)(PPh_3)_2]$ is not obvious. Impurities *are* likely to be present in $CHCl_3$ which has been exposed to oxygen and light; these include HCl and Cl_2[7] and it is likely that **II** formed by dissociation of a $CH_3CO_2^-$ group and subsequent attack by Cl^-. In support of this suggestion we found that $[Rh(O_2CCH_3)_2(NO)(PPh_3)_2]$ was virtually insoluble in $CHCl_3$ which has been dried and stored away from light over K_2CO_3. We are currently examining the reactivity of $[Rh(O_2CCH_3)_2(NO)(PPh_3)_2]$ towards substitution of $CH_3CO_2^-$ by other weak nucleophiles including alkyls and metal-containing species.

COORDINATION CHEMISTRY OF N,N′-BIS (2-HYDROXYPHENYL)ETHYLENEDIAMINE-N,N′-DIACETIC ACID AND SOME RELATED LIGANDS

OWEN J. VAUGHAN and JOHN F. GIBSON*

Inorganic Chemistry Laboratories, Imperial College, London SW7 2AY, U.K.

(*Received* 7 *September* 1989; *accepted* 1 *March* 1990)

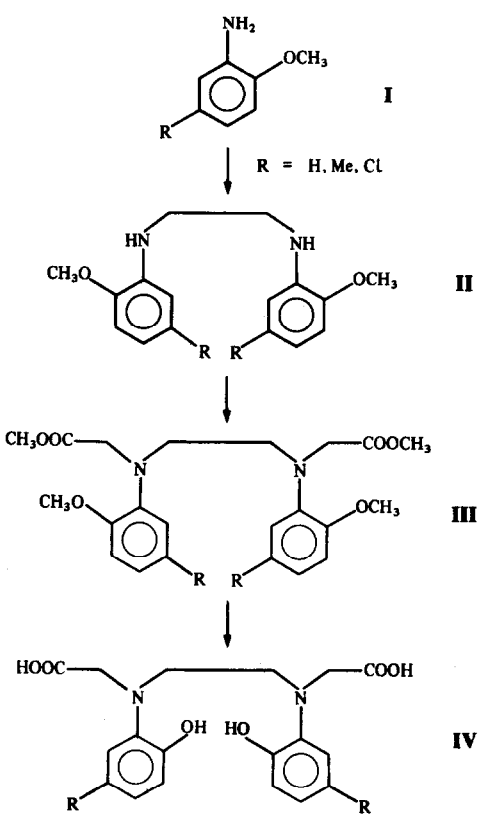
Abstract—Iron(III) complexes of new hexadentate phenolic aminocarboxylate ligands based upon N,N′-bis(2-hydroxyphenyl)ethylenediamine-N,N′-diacetic acid (HPED) have been synthesized. These iron(III) complexes have been characterized utilizing Raman, IR, Mössbauer and ESR spectroscopy. Copper(II)–HPED has been studied in solution, utilizing electronic and ESR spectroscopy.

The treatment of β-thalassaemia, a genetic disease originating from deficiencies in the biosynthesis of the β-chain of haemoglobin, requires indefinite transfusion therapy. However, this therapy leads to the toxic accumulation of iron in the tissues, which eventually results in the failure of vital organs, mortality being associated with cardiotoxicity, hepatic cirrhosis and pancreatic dysfunction.[1]

The current drug of choice for the treatment of this iron-overload condition is desferrioxamine (DFB).[2–4] However, the utility of this drug, a trihydroxamic acid, is limited by low oral activity, rapid metabolism and only moderate efficacy, as well as inconvenient and expensive modes of administration.

The symptoms of Wilson's disease, a condition associated with an excess of copper accumulated in the liver, brain and kidneys, include hepatic cirrhosis, lack of coordination, severe tremors and progressive mental deterioration.[5] The symptoms are dependent upon the amount of copper present, and may be reversed by the use of chelating agents, such as $Na_2CaEDTA$ and penicillamine, to remove excess amounts of copper from the body.

As a consequence of these and other metal-overload conditions, we have become involved in the search for more effective metal chelating agents; in particular, ones that are orally active. In this work we report the preliminary detailed investigation of the coordination chemistry of the iron(III) and copper(II) complexes of a series of hexadentate phenolic aminocarboxylate ligands, based upon N,N′-bis(2-hydroxyphenyl)ethylenediamine-N,N′-diacetic acid (HPED) (R = H, in **IV** of Scheme 1).



Scheme 1. Symmetric HPED ligands.

*Author to whom correspondence should be addressed.

EXPERIMENTAL

Symmetric ligands (*Scheme* 1, R = H, Cl, Me)

These were prepared using a substantially modified procedure to that described by Bao and coworkers,[6] and are shown in Scheme 1. All symmetric ligands were prepared in the same manner as described below for the formation of HPED (R = H).

Step 1. Using the procedure of Bennett *et al.*,[7] a solution of *o*-anisidine (**I**) (30.00 g, 0.24 mol) and 1,2-dibromoethane (11.44 g, 0.06 mol), in dimethylformamide (DMF) (100 cm^3), over calcium carbonate (10.00 g, 0.10 mol), was heated at 100°C for 2 h, under nitrogen and with vigorous stirring. After removal of the DMF by rotary evaporation, a solution of potassium hydroxide (100 cm^3, 5% w/w) was added and the mixture steam distilled for 2 h, before being extracted into dichloromethane (DCM). The DCM layer was separated off and dried. After removal of the DCM, the oil was recrystallized from ethanol–water to yield fine white crystals of N,N′-bis(2-methoxyphenyl)ethylenediamine (**II**) (11.36 g, 70%).

Step 2. A solution of **II** (8.00 g, 0.03 mol) and methyl bromoacetate (17.97 g, 0.12 mol), in DMF (100 cm^3), over calcium carbonate (6.00 g, 0.06 mol), was heated at 80°C for 2 h with vigorous stirring under nitrogen. After removal of the DMF by evaporation, the oil was taken up in DCM, washed with saturated sodium chloride solution and dried. After removal of the DCM, the semi-solid material was recrystallized from ethanol–water to yield white platelets of N,N′-bis (2-methoxyphenyl)N,N′ - bis(methylacetate)ethylenediamine (**III**) (11.44 g, 95%).

Step 3. At 0°C and under nitrogen, DMF (50 cm^3) was added dropwise to lithium powder (0.83 g, 0.12 mol) with stirring, followed by the dropwise addition of thioethanol (7.46 g, 0.12 mol) in DMF (25 cm^3). To the mixture, **III** (5.00 g, 0.012 mol), in DMF (25 cm^3), was added dropwise. The solution was then heated at 100°C for 8 h. After being cooled the solution was poured on to acetone (400 cm^3) with vigorous stirring, leading to the formation of a fine white precipitate. After filtration and drying, the solid was taken up in boiling water (15 cm^3). The solution was cooled to 4°C, and cold (0°C) concentrated hydrochloric acid (5 cm^3) added dropwise with stirring. Trituration of the solution yielded a fine white solid of N,N′-bis(2-hydroxyphenyl)ethylenediamine-N,N′-diacetic acid dihydrochloride (**IV**) (2.83 g, 54%). Microanalyses, IR and mass spectra were found to be satisfactory, see Tables 1 and 2.

[a] MH^+ refers to the parent molecular ion. In the case of chlorine substituents, MH^+ refers to the highest peak in the chlorine cluster. Values in parentheses are the relative intensities.

[b] Refers to the parent molecular ion. Values in parentheses are the relative intensities.

[c] Refers to the highest peak in the chlorine cluster.

Asymmetric ligands (*Scheme* 2, R_1 = H, Me, Cl, MeO; R_2 = H, Me, Cl; R_3 = H, Cl)

For the synthesis of these ligands (Scheme 2) a new procedure was developed. All asymmetric ligands were prepared in the same manner as described below for N-(2-hydroxy-5-methylphenyl) - N′ - (2 - hydroxyphenyl)ethylenediamine-N,N′-diacetic acid.

Step 1. To a stirred cold (0°C) solution of bromoacetic acid (14.59 g, 0.11 mol) in DCM (75 cm^3), dicyclohexylcarbodiimide (21.66 g, 0.11 mol) in DCM (25 cm^3) was slowly added. The mixture was stirred at 0°C for 30 min, and then 2-methoxy-5-methylaniline (**V**) (14.40 g, 0.11 mol), in DCM (100 cm^3), was added dropwise. Stirring was continued for a further 90 min, after which the mixture was warmed to room temperature. The mixture was filtered into 100 cm^3 of ice–water. The organic layer was washed successively with 2 M hydrochloric acid, saturated sodium bicarbonate, and saturated sodium chloride solutions, before being dried. Removal of the solvent and recrystallization of the material from ethanol–water yielded white

[a] Analysed as the dihydrochloride.

crystals of 2-methoxy-5-methyl-bromoacetanilide (**VI**) (14.40 g, 53%).

Step 2. A solution of *o*-anisidine (10.58 g, 0.09 mol), **VII** (11.10 g, 0.04 mol) and calcium carbonate (10.00 g, 0.10 mol), in DMF (100 cm^3), was heated at 80°C for 2 h, with stirring under nitrogen. After filtration and removal of the solvent, potassium hydroxide solution (40 cm^3, 10% w/w) was added to the oil. The mixture was steam distilled for 3 h. The remaining material was extracted into DCM, which was then washed with saturated sodium chloride solution, before being dried. The solvent was removed and the solid recrystallized from ethanol–water to yield white crystals of **VIII** (10.20 g, 79%).

Step 3. To a stirred cold (0°C) solution of lithium aluminium hydride (1.50 g, 0.04 mol) in tetrahydrofuran (THF) (50 cm^3) under nitrogen, a solution of **VIII** (3.55 g, 0.01 mol) in THF (50 cm^3) was added dropwise. The solution was refluxed for 2 h, before being cooled to 0°C. Ethyl acetate (50 cm^3) was added, followed by water (10 cm^3) and a further 50 cm^3 of ethyle acetate. Sodium sulphate (20.00 g) was added and the mixture was stirred for 60 min, before filtration and removal of the solvent. The solid was recrystallized from ethanol to yield fine white crystals of N-(2-methoxy-5-methylphenyl)-N′-(2-methoxyphenyl)ethylenediamine (**IX**) (3.01 g, 89%).

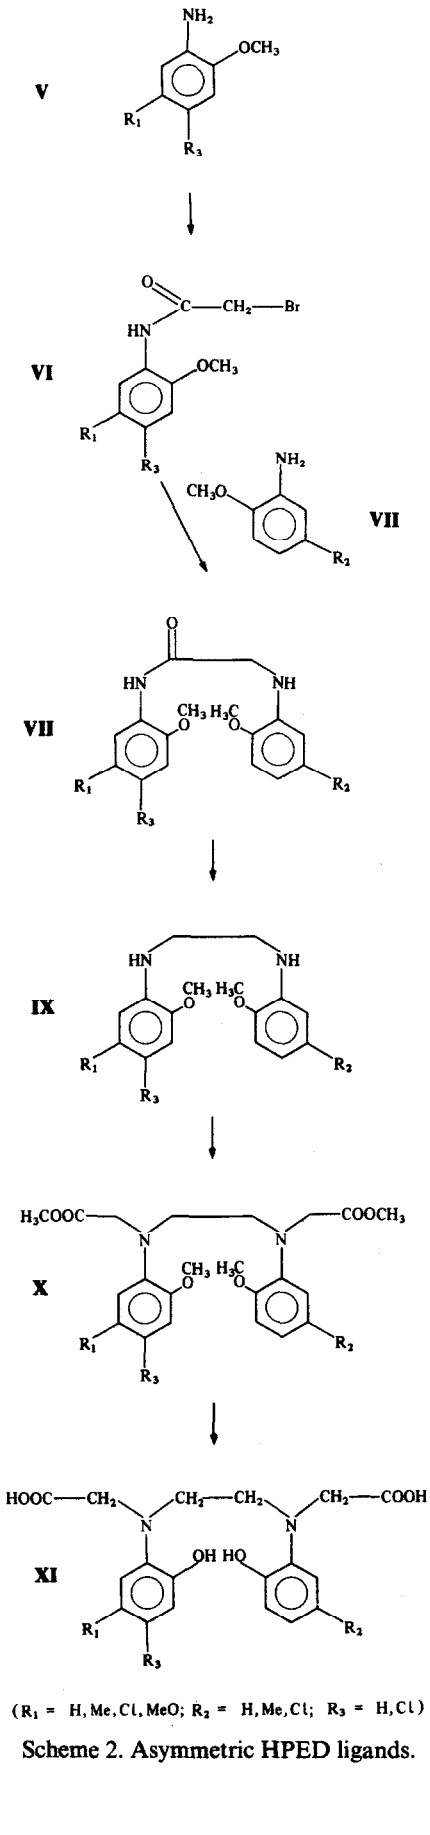
The synthesis was completed via **X** and **XI** utilizing steps 2 and 3 of Scheme 1. Analyses, IR and mass spectra were satisfactory, see Tables 1 and 2.

Dilactones (*Scheme* 3, R = H, Me, Cl)

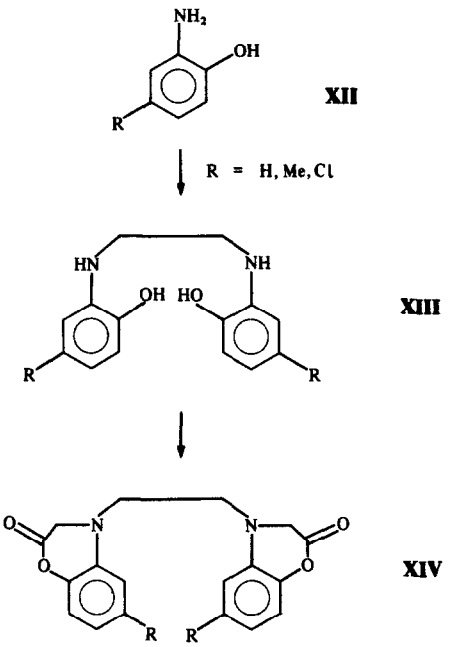
Because esterification of the carboxylic acid groups is likely to aid oral activity,[6] three dilactones of the symmetric HPED ligands were synthesized. They were prepared in a manner similar to that described by Freedman and Frost,[8] and are shown in Scheme 3, although the dilactone of HPED (R = H) has previously been prepared by another route.[6]

A mixture of 2-hydroxy-5-methylaniline (**XII**) (10.00 g, 0.08 mol) and 1,2-dibromoethane (15.25 g, 0.08 mol), in water (200 cm^3), was refluxed under nitrogen with stirring for 2 h. The solvent was decanted and the remaining oily material converted to a white solid by washing with diethyl ether. The solid was recrystallized from ethanol (400 cm^3) to yield fine white needles of N,N′-bis(2-hydroxy-5-methylphenyl)ethylenediamine (**XIII**) (4.30 g, 39%).

To a solution of chloroacetic acid (1.88 g, 0.02 mol) and sodium hydroxide (1.59 g, 0.04 mol), in water (75 cm^3), **XIII** (1.00 g, 0.004 mol) was added with stirring. The solution was refluxed under nitrogen for 2 h, before being cooled and made acidic by the addition, with stirring, of cold concentrated hydrochloric acid (10 cm^3). Trituration yielded



Scheme 2. Asymmetric HPED ligands.



Scheme 3. HPED dilactones.

fine white crystals of the dilactone (**XIV**) (0.51 g, 39%). Analyses, IR and mass spectra were all satisfactory, see Tables 1 and 2.

Iron(III) *complexes*

All iron(III) complexes were prepared from the symmetric and asymmetric HPED ligands using a method similar to that described by Gaber *et al.*[9]

Equimolar quantities of the ligand dihydrochloride (0.577 mM), freshly precipitated ferric oxide (0.577 mM) and potassium hydrogen carbonate (0.058 g, 0.577 mM), were stirred in a 3 : 1 water–methanol (40 cm^3) solution, under nitrogen, for 3 days. The solution was filtered and the solvent removed by evaporation. The resultant solid was extracted into ethanol. The solution was reduced to 15 cm^3 and left to stand for 12 h. Deep purple–red crystals were filtered off and washed with diethyl ether. A second crop was obtained upon the addition of diethyl ether to the remaining filtrate. The product was dried over phosphorus pentoxide *in vacuo*. Analyses and other physical data may be found in Tables 3, 4 and 5.

General procedures and techniques

All the anilines were purified by distillation before use. N,N-dimethylformamide (HPLC grade) was dried over sodium.

Resonance Raman spectra were measured at

ESR spectra were measured using a Bruker ER200D-SRC spectrometer operating at *ca* 34.2 GHz.

Mass spectra were performed by the Organic Mass Spectroscopy Laboratory, Imperial College, on a VG Micromass 7070E mass spectrometer.

Microanalyses were carried out by Mr K. I. Jones of the Microanalytical Department, Imperial College.

RESULTS AND DISCUSSION

The HPED ligand anion provides six binding sites for iron(III): two tertiary amine nitrogen atoms; two carboxylate oxygen atoms; and two phenolate oxygen atoms. The electronic spectrum of the iron(III)–HPED complex in aqueous solution at pH 2.7 is shown in Fig. 1. Spectra taken over the pH range 2.5–12.0, like those of the analogous iron(III) complexes of ethylene-1,2-bis(2-hydroxyphenylglycine) (EHPG),[10] and N,N′-bis(2-hydroxybenzyl)ethylenediamine-N,N′-diacetic acid (HBED),[11] show that the pH-dependent band of the ligand is replaced by a single band at 277.5 nm which is independent of pH. This is indicative of complete dissociation of the phenol groups which must be bound to the iron(III) ion over the entire pH range 2.5–13.0. The visible absorption of iron(III)–phenolate complexes has long been known,[10,11] and the deep-red colour of the iron(III)–HPED complex (Fig. 1) can thus confidently be assigned to the interaction of the two phenolate groups with the iron(III) ion, the amine and carboxylic acid binding sites providing no basis for an intense visible absorption. The visible absorption band of the iron(III)–HPED complex, at 484.6 nm, is assigned to a charge-transfer transition from the oxygen $p\pi$ orbital of the bound phenolate to the iron(III) $d\pi^*$ orbitals. It is therefore reasonable to infer that the resonance-enhanced Raman bands of iron(III)–HPED (Fig. 2) arise from phenolate vibrations. All of these vibrations correlate with phenolate modes.

The four high energy bands of the resonance

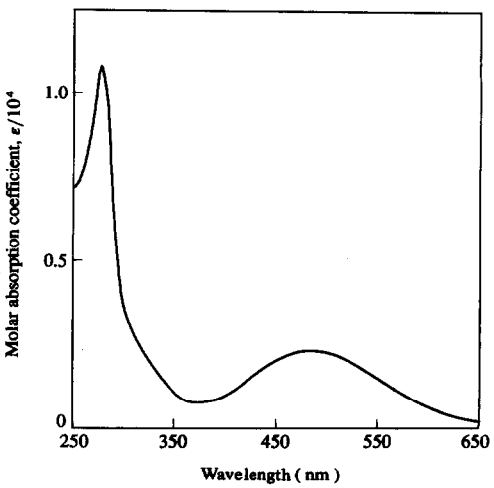

Fig. 1. UV–vis. spectrum of iron(III)–HPED. [Fe^{III}HPED] = 2×10^{-4} M, μ = 0.10 M (KNO_3), 25°C.

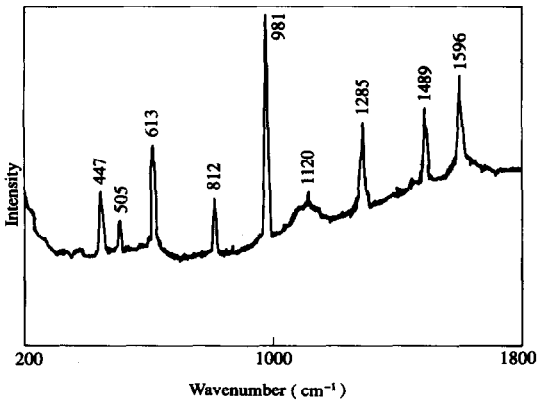

Fig. 2. Resonance Raman spectrum of K[Fe(HPED)]. Concentration = 2×10^{-4} M, in aqueous Na_2SO_4 (0.5 M) at 488 nm; spectral slit width, 8 cm^{-1}; scan rate, 1 cm^{-1} s^{-1}.

Raman spectrum of $[Fe(HPED)]^-$ (Fig. 2), which are also observed in both the iron(III)–EHPG and iron(III)–transferrin spectra, are assigned, by analogy,[9] as follows: 1120 cm^{-1}, in-plane C—O bending, with substantial ring character; 1285 cm^{-1} (phenol at 1281 cm^{-1}), phenolate C—O stretching; 1489 cm^{-1} (1502 cm^{-1} in phenol), symmetric ring stretch; and 1596 cm^{-1}, ring "quadrant" stretch (1614 cm^{-1} in *p*-cresol). The IR spectrum of iron(III)–HPED reveals associated bands at 1112, 1288, 1481 and 1590 cm^{-1}, as might be expected for a complex with no centre of symmetry. The resonance Raman bands for the related iron(III) complexes studied in this work are given in Table 4.

In iron(III)–EHPG, the ring deformation modes at 610 and 637 cm^{-1} are quite strong, but for the iron(III) complexes studied here, the deformation modes, in the regions 602–624 and 637–643 cm^{-1}, are mostly relatively weak. These modes are unobserved for iron(III)–transferrin, which, however, shows much greater relative intensity for the C—O in-plane bending mode at 1174 cm^{-1}. These differences probably arise from the fact that the phenolate groups in HPED and EHPG, are *ortho*-substituted, while those in transferrin and lactoferrin, in the form of tyrosine groups,[13] are *para*-substituted to the bulk of the molecule.

The ^{57}Fe Mössbauer spectra of K[Fe(HPED)], and of the two similar complexes with ligands L1 and L2 of Table 5, have isomer shifts of 0.57, 0.55 and 0.56 mm s^{-1}, respectively. These values are with respect to the iron metal, and clearly indicate the ionic nature of the bond between the ligand and the high-spin iron(III) in these complexes. For the analogous iron(III)–EHPG and iron(III)–HBED complexes the reported values are 0.37 and 0.38 mm s^{-1}, respectively, suggesting much more covalency in their bonding. These latter values lie close to those of iron(III)–transferrin, at 0.38 mm s^{-1}, and iron(III)–lactoferrin, at 0.39 mm s^{-1}. The higher isomer shift of the iron(III)–HPED complex is consistent with the higher ionic character expected with electron donation into the ring by the nitrogen *ortho* to the phenolic group; such a mechanism does not exist for EHPG, HBED or transferrin. All the complexes, listed in Table 5, have large quadrupole splittings, a characteristic of the unsymmetric ligand field around the iron(III) ion.

The ESR spectral data, also shown in Table 5, and the frozen solution ESR spectra, typified by that of iron(III)–HPED shown in Fig. 3, confirm the presence of high-spin iron(III) in these complexes. Effective g values in the region of 4.27 (Table 5) are quite typical of the resonance from the so-called rhombically distorted high-spin iron(III). In a situation with maximum rhombicity ($E/D = 1/3$), the large zero-field splitting (D) leaves the three Kramers doublets well separated, and an isotropic $g_{eff} = 4.27$ signal arises from the central doublet. The fact that the signals we observe in this region are anisotropic indicates a symmetry slightly more axial than fully rhombic ($E/D < 1/3$), and an approximation using the graphs of Dowsing and Gibson[18] yields $E/D = 0.325$ with a D value greater than about 0.60 cm^{-1}. The low-field feature

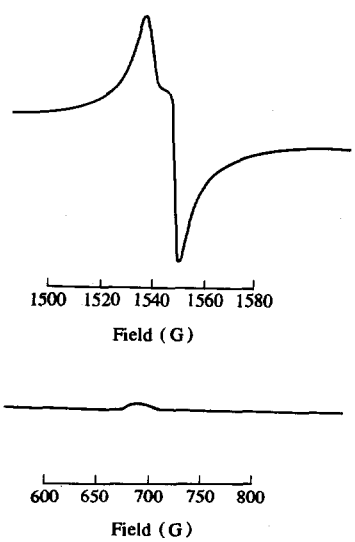

Fig. 3. X-band ESR spectrum of K[Fe(HPED)]. Concentration = 1×10^{-3} M, in a 5 : 1 glycerol–water matrix; temperature, 77 K; time constant, 0.3 s; modulation amplitude, 0.63×10^{-1} G; receiver gain, 2.5×10 (5×10^2 for low-field signal); microwave frequency, 9.233 GHz; microwave power, 200 mW; scan time, 4 min.

(g_{eff} = 9.63) arising from the other two doublets, is also nicely predicted by this procedure.

Copper(II)–HPED was also studied in solution by both electronic and ESR spectroscopy. At or below pH 5.5, the typical blue colour of a copper(II) complex was observed, and is characterized by a broad absorption band at 716 nm (14,000 cm^{-1}). The asymmetry of the observed absorption band indicates overlapping of at least two, probably three, absorption bands, since tetragonal distortion splits the e_g and t_{2g} levels of the d^9 copper(II) to give three possible *d–d* transitions.[10,11]. This band is likely to be associated with a two-proton displacement from the carboxylates of the HPED ligand by the copper(II) ion, to form the diprotonated complex $CuLH_2^0$ ($L = HPED^{4-}$). As compared with the hexaaquo ion,[19] the λ_{max} (716 nm) and the molar extinction coefficient, ε (80 M^{-1} cm^{-1}), of the complex are consistent with the increased ligand-field of lower symmetry at the copper(II) ion expected from nitrogen donation, as found in copper(II)–EHPG and copper(II)–HBED.[9,10] The coordination by LH_2^{2-} is therefore likely to be via the ethylenediamine nitrogen atoms and the carboxylate oxygen atoms, with possible loose coordination by water and/or protonated phenolic oxygens in the axial positions. However, as the pH is increased above 5.5, deprotonation of the phenol groups occurs allowing coordination to the copper(II) ion with the concomitant change in colour from blue to green. This colour change results from the added appearance of a new band at 361 nm, the intensity of which increases with pH, remaining constant above pH 10.5. It may be presumed to be associated with the conversion of $CuLH_2^0$ to CuL^{2-}, via the monoprotonated species $CuLH^-$.

For ESR spectroscopy aliquots of an equimolar solution of $Cu(NO_3)_2$ and HPED were adjusted in pH and frozen. Their X-band ESR spectra (Fig. 4), taken at 77 K, were found to be extremely sensitive to pH. Analysis of these spectra indicates the involvement of at least three copper(II) species in solution. At the low pH of 2.46, a relatively simple spectrum is obtained at both X- and Q-band frequencies, consistent with the copper(II) ion sited in an axial symmetric ligand field, where $g_\parallel = 2.28$, $A_\parallel = 0.016\ cm^{-1}$, and $g_\perp \sim 2.07$, $A_\perp < 0.007\ cm^{-1}$. The spectra are presumably associated with the $CuLH_2^0$ ($L = HPED^{4-}$) species, where the ethylenediamine bridging nitrogens and the carboxylate oxygens form a plane around the copper(II) ion. The weak features in the X-band spectrum of Fig. 4 are seen in $Cu(NO_3)_2$ solution alone, and indicate that only about 80% of the copper(II) is bound as $CuLH_2^0$ at this pH. As the pH is increased the ESR spectra become more complex. In the X-band spectrum recorded at pH 6.26 a second species is also observed. The formation of this new species is expected to involve the removal of a proton from one of the phenolic oxygens, which then binds to the copper(II) ion forming $CuLH^-$ and at the same time imparting some rhombicity to the observed ESR spectrum. At a pH of 10.90 a third species, presumably CuL^{2-}, is clearly seen; this would correspond to the removal of the second phenolic proton with consequent phenolate binding. The spectrum at pH 12.20 indicated the likely presence of primarily just this one species, and was further resolved using Q-band ESR. Our assignment provides evidence for a rhombic ligand-field, where $g_x = 2.31$, $A_x = 0.008\ cm^{-1}$; $g_y = 2.18$, $A_y = 0.004\ cm^{-1}$; $g_z = 2.01$, $A_z = 0.009\ cm^{-1}$.

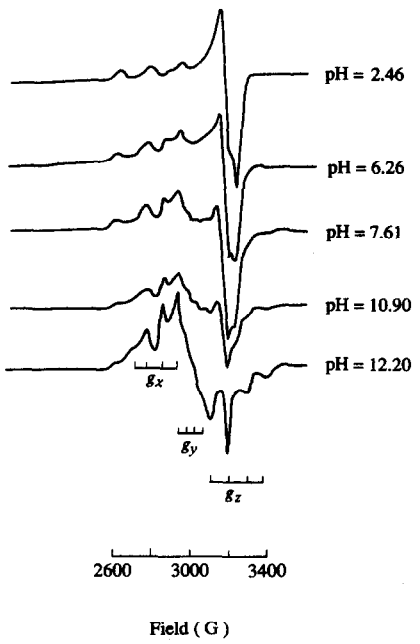

Fig. 4. X-band ESR spectra of copper(II)–HPED. Concentration = 2×10^{-4} M, in a 5:1 glycerol–water matrix; temperature, 77 K; time constant, 0.3 s; modulation amplitude, 0.63×10 G; receiver gain, 6.3×10^2; microwave frequency, 9.113 GHz; microwave power, 200 mW; scan time, 4 min.

The studies undertaken here indicate that HPED and its related ligands form well-defined stable complexes in aqueous solution, and thus merit further investigation of their potential in the treatment of metal-overload conditions, particularly iron.

Acknowledgements—We thank Mr J. N. Bilton for the mass spectra. We would also like to thank Dr B. W. Fitzsimmons and Mr C. M. Lawrence of Birkbeck

College for measuring the Mössbauer spectra. One of us (O.J.V) thanks the SERC for a grant.

(*Received* 2 *November* 1989; *accepted* 21 *March* 1990)

Abstract—The structure of bis(pentan-2,4-dionato)oxovanadium(IV), $VO(CH_3COCHCOCH_3)_2$, has been determined by gas-phase electron diffraction. Gaseous $VO(CH_3COCHCOCH_3)_2$ has C_{2v} symmetry with the vanadium atom terminally bound to one oxygen atom along the two-fold axis $\{r_\alpha[V{=}O(5)] = 1.565(17)$ Å$\}$ and four further oxygen atoms $\{r_\alpha[V{-}O(1)] = 1.990(6)$ Å$\}$ from two chelating $CH_3COCHCOCH_3$ groups. The angle $\angle_\alpha$ O(5)=V—O(1) is 105.1(13)° while the bite angle subtended by the ligands [i.e. $\angle_\alpha$ O(1)—V—O(2)] is 87.2(15)°. The ligand distances in the VOCCHCO ring are $r_\alpha[C(1){-}O(1)] = 1.271(8)$ Å, and $r_\alpha[C(1){-}C(2)] = 1.410(10)$ Å. In contrast to results obtained in the solid state, no evidence was obtained to indicate that the plane of the chelating moiety of the ligand was not co-planar with its associated O(1)—V—O(2) plane. Errors quoted are 2σ including estimates of systematic errors and correlation in the experimental data.

β-Diketonate complexes of the transition metals have, for coordination complexes, quite remarkably high thermal stability and volatility. Thus it has proved possible to use these complexes to separate metals by gas-chromatography.[1]

Numerous single crystal X-ray studies of β-diketonate complexes have been published and $VO(CH_3COCHCOCH_3)_2$ is the subject of two of the reports.[2,3] The first study yielded[2] a value of 1.56(4) Å for the V—O multiple bond. This value is much shorter than that observed in $VO(PhCOCHCOCH_3)_2$ [1.605(10) Å],[4] which is surprising as the dimensions of the VOCCHCO ring are the same in both compounds. The difference between the two values prompted an anisotropic refinement of the original X-ray data for $VO(CH_3COCHCOCH_3)_2$:[3] the accuracy of the value for the V—O multiple bond increased but the value remained statistically the same [1.571(20) Å]. Bond length values for related V—O multiple bonds cover a wide range [e.g. 1.584(10) Å in $VOCl_2(OPPh_3)_2$[5] to 1.620(12) Å in $(NH_4)_2VO(NCS)_4 \cdot 5H_2O$[6]] with the majority of the values being towards the higher end of the range. It was decided to determine the gas-phase structure of $VO(CH_3COCHCOCH_3)_2$ and so obtain an accurate value for the V—O multiple bond to ascertain if the value from the X-ray studies was influened by crystal packing forces.

In a number of the structural studies of β-diketonate complexes a non-zero value has been reported for the angle between the plane formed by the atoms of the ligand that form part of the chelate ring (i.e. OCCHCO) and that formed by the O—M—O fragment (M = metal ion). While it is possible that in the solid state packing forces may

* Author to whom correspondence should be addressed.

cause an angle between the two planes, it is questionable if such a deviation can be detected in the gas phase. Such an interplanar angle has been included, as a parameter, in a number of gas-phase electron diffraction studies,[7,8] but in our recent structural studies of gaseous $Cu\{S_2CN(CH_3)_2\}_2$ and $Zn\{S_2CN(CH_3)_2\}_2$[9] we found no advantage accrued from the inclusion of the angle between the CS_2 and MS_2 planes as a variable. A study by gas-phase electron diffraction of $VO(CH_3COCHCOCH_3)_2$ provides an ideal case for judging the relevance of inclusion of the angle between the OCCHCO and MO_2 planes as a parameter. The presence of the V—O multiple bond is expected to produce an angle greater than 90° between the V—O multiple and other V—O bonds, and so it is probable that the two $CH_3COCHCOCH_3$ fragments will be brought closer together than in, for example, $Cu(CH_3COCHCOCH_3)_2$[8] and thus increases the chances of observing a non-zero angle between the OCCHCO and MO_2 planes in $VO(CH_3COCHCOCH_3)_2$.

EXPERIMENTAL

Preparation of $VO(CH_3COCHCOCH_3)_2$

A slurry of V_2O_5 (5.0 g) in a mixture of water (12.0 cm^3), ethanol (25.0 cm^3) and concentrated sulphuric acid (9.0 cm^3) was heated under reflux for 1 h. The resulting blue precipitate was isolated by filtration and treated with an excess of pentan-2,4-dione. To the mixture was added dropwise a solution, formed by dissolving anhydrous Na_2CO_3 (20.0 g) in water (125.0 cm^3). Blue crystals of $VO(CH_3COCHCOCH_3)_2$ formed and these were isolated by filtration and recrystallized from $CHCl_3$.

Electron diffraction photographs were obtained using the Reading University apparatus,[10] which is fitted with a rotating sector whose angular opening is proportional to r^3. The nozzle-to-plate distances were 494.11 and 244.52 mm and the data were obtained with the nozzle in the temperature range 222–239°C. The electron wavelength (0.061781 Å) was calibrated against diffraction pictures of benzene.[11] Three plates from the long and four from the short camera distance were selected for use in the final analysis and were traced on the Joyce–Loebel microdensitometer at the Chemistry Department of the University of Oslo. The usable data, interpolated at intervals of $\Delta s = 0.25$ Å^{-1}, spanned the ranges $2.50 \leqslant s \leqslant 13.50$ Å^{-1} and $8.00 \leqslant s \leqslant 29.00$ Å^{-1}. The experimental data were processed as described previously[12] with scattering factors being taken from refs 13 and 14. Average curves were produced for each camera distance, and these are depicted in Fig. 1. Root-mean-square vibrational amplitudes (l), perpendicular amplitude corrections (K) and centrifugal distortions (δr) were calculated[15] from an assumed valence force-field using values for the force constants obtained for related molecules.[16] As a complete analysis of the vibrational spectra of $VO(CH_3COCHCOCH_3)_2$ has not been published, the calculated values must be regarded as approximate.

Analysis of the structure

The refinements of the structure were based upon the molecule depicted in Fig. 1, which contains the atom numbering scheme.

In the analysis of the structure the following assumptions were made:

(1) The molecule possesses C_{2v} symmetry.
(2) All the carbon and oxygen atoms in each of the $CH_3COCHCOCH_3$ fragments lie in a plane that has C_{2v} symmetry.
(3) The methyl groups have C_{3v} symmetry with the axis of symmetry lying along the Me—C bond.
(4) The hydrogen atoms of one methyl group are eclipsed with respect to those on the other methyl group of the same ligand.

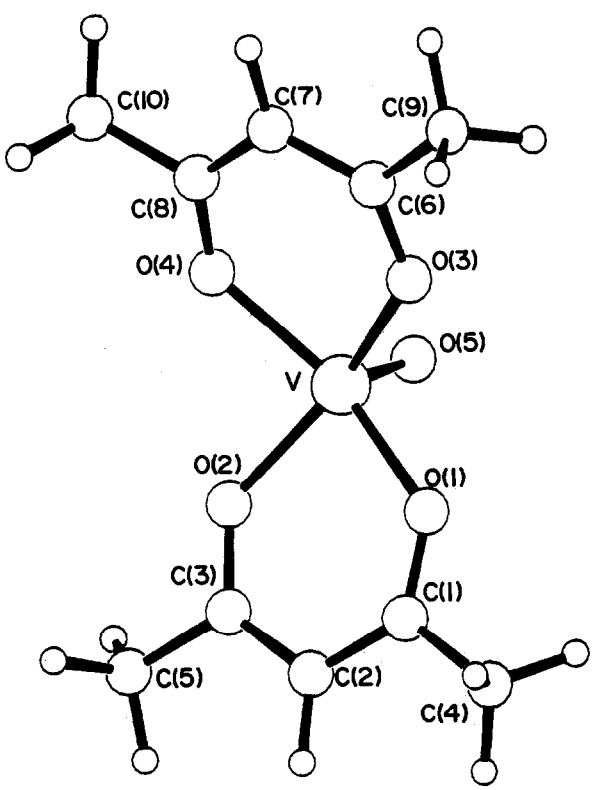

Fig. 1. The $VO(CH_3COCHCOCH_3)_2$ molecule with the atom numbering scheme.

(5) All the C—H bonds are of the same length.
(6) The hydrogen atom of the C(2)—H group lies in the plane of the O(1)C(1)C(2)C(3)O(2) moiety.

Using these assumptions a geometrical model was constructed which initially had 12 independent structural parameters that consisted of six distances {r[V—O(5)], r[V—O(1)], r[C(1)—O(1)], r[C(1)—C(2)], r[C(1)—C(4)] and r(C—H)}, five valence angles [$\angle$O(1)—V—O(2), $\angle$V—O(1)—C(1), $\angle$O(1)—C(1)—C(4), $\angle$C(1)—C(4)—H and $\angle$O(5)—V—C(2)] and a torsion angle, θ_1, to describe the position of the hydrogen atoms of the methyl groups with respect to the ligand skeleton. If $\theta_1 = 0°$, one of the hydrogen atoms on the methyl group bound to C(1) is eclipsed with respect to the C(1)—O(1) vector. At a later stage a further variable, θ_2, the angle between the VO(1)O(2) and O(1)C(1)C(2)C(3)O(2) planes was included as a variable. The model differs from that used by previous workers in that r(C—H) and $\angle$C(1)—C(4)—H were included as variables rather than being fixed at 1.10 Å and 110.0°, respectively.[7,8]

Refinements of the structure were carried out by the least-squares procedure based on the intensity curves by adjusting one theoretical curve to the two averaged experimental curves (one from each nozzle-to-plate distance) using a unit weight matrix. The average experimental and the theoretical curves are shown in Fig. 2. The radial distribution (RD) curve calculated in the usual manner by Fourier transformation of the $s[I_m(s)]$ values after multiplication by $(Z_V Z_O / f_V f_O)\exp(-0.0025s^2)$, is shown in Fig. 3, together with the appropriate difference curve.

In the early refinements θ_1 was set at zero, all the bonded distances and valence angles were refined, as were the vibrational amplitudes of all the bonded interactions. Of the non-bonded interactions only those thought to be most influential were refined, i.e. those involving the metal atom, l(C···C), l(C···O) and l(O···O) (see Table 1). In general all the amplitudes involving hydrogen atoms were held at calculated values. The results of these early refinements gave a good fit between the experimental and theoretical curves. After the initial study, in an effort to improve the fit, θ_1 was allowed to refine. The value it assumed was not significantly different from zero as the standard error was larger than the value of the parameter. Accordingly, further refinements were carried out in which all the variables, except θ_1, were allowed to refine, while θ_1 was varied in a stepwise manner over the interval $0 < \theta_1 < 120°$. The R factors for both short and long camera data were recorded as a function of θ_1. There was little variation in R factor with θ_1, however, such maximum value as there was occurred at 60° while the minimum was at 0°. Consequently θ_1 was kept at 0° in all further

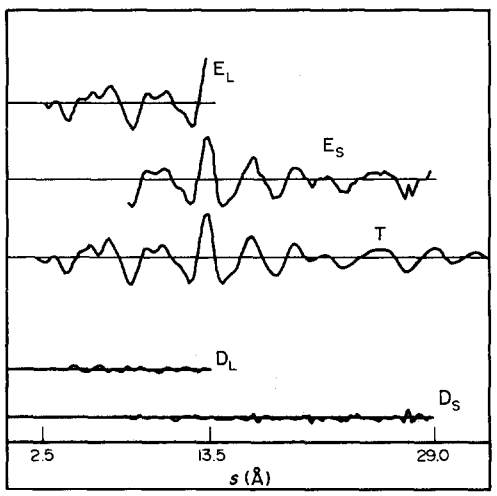

Fig. 2. Intensity curves $sI_m(s)$ for $VO(CH_3COCHCOCH_3)_2$. Experimental curves (E) are averages of all the data from the plates for the two camera distances. The theoretical curves (T) were calculated from the structural parameters shown in Table 1. The difference curves (D) result from subtracting the relevant part of the theory curve from the experimental curves.

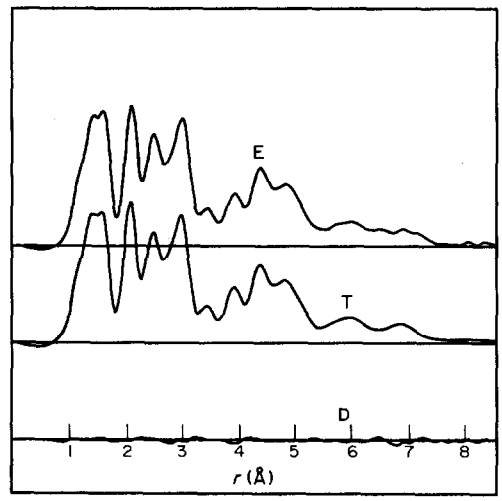

Fig. 3. Radial distribution curves for $VO(CH_3COCHCOCH_3)_2$ showing the experimental (E), and theoretical (T) and difference (D) curves. The radial distribution curves were calculated in the usual manner using the theoretical curves that yielded the data contained in Table 1. To obtain the radial distribution curves the theoretical curves were multiplied by $(Z_V Z_O / f_V f_O)\exp(-0.0025s^2)$ before carrying out the Fourier transformation. Theoretical data were used for the unobserved area $s \leqslant 2.50$ Å^{-1}.

[a] Distances (r_α and r_g) and amplitudes (l) in Ångstroms, and angles ($\angle_\alpha$) in degrees. Parenthesized uncertainties are 2σ and, for the electron diffraction data, include estimates of systematic errors and correlation in the experimental data.

[b] Data taken from ref. 3.

[c] θ_1 Describes the position of the hydrogen atoms of the methyl groups with respect to the ligand skeleton. If $\theta_1 = 0°$ one of the hydrogen atoms on the methyl group bound to C(1) is eclipsed with respect to the C(1)—O(1) vector. θ_2 Is the angle between the VO(1)O(2) and O(1)C(1)C(2)C(3)O(2) planes.

[d] $R = [\Sigma w_i\Delta_i^2/\Sigma w_i[s_iI_i(\text{obs.})]^2]^{1/2}$, where $\Delta_i = s_iI_i(\text{obs.}) - s_iI_i(\text{calc.})$.

refinements. With θ_1 fixed at 0°, θ_2, the angle between the VO(1)O(2) and O(1)C(1)C(2)C(3)O(2) planes, was included as a variable. Allowing it to refine led to a value of 4.9(11.2)° for θ_2, while the values for the remaining parameters were unchanged from the values obtained with θ_1 and θ_2 at 0°. Refinements were also carried out in which θ_2 was varied stepwise in a similar manner to that described above for θ_1. The range used for θ_2 was $-4 < \theta_2 < 10°$. The resulting R factors showed no significant change although there was an extremely shallow minimum in the region 0–5°. There was no significant change in the other variables with θ_2.

The results of the final refinement with θ_1 and θ_2 set at 0°, are recorded in Table 1. A correlation matrix (Table 2) which highlights the interdependence of distances and/or angles was obtained by fixing the vibrational amplitudes at the values obtained from the final refinement, having θ_1 and θ_2 set at 0° and allowing the other parameters to refine.

RESULTS AND DISCUSSION

The results of the present study are in accord with gaseous $VO(CH_3COCHCOCH_3)_2$ having C_{2v}

symmetry. Inspection of the correlation matrix (see Table 2) reveals that r[V—O(5)] and r [C(1)—C(4)] are highly correlated. Both distances occur under the same broad peak in the radial distribution curve (see Fig. 3) and since $Z_V Z_O / r_{VO(5)}$ has a very similar value to $4 \times Z_C Z_C / r_{C(1)C(4)}$ the errors associated with r[V—O(5)] and r[C(1)—C(4)] are quite large. Even so, the value determined for r[V—O(5)] (1.565(17) Å) is in good agreement with that obtained from the X-ray study (1.571(20) Å)[3] and should be compared with the V—O multiple bond distance found in $VO(PhCOCHCOCH_3)_2$ (1.605(10) Å).[4] The dimensions of the ligand part of the chelate rings, i.e. O(1)C(1)C(2)C(3)O(2), and the "bite" angles found in the present study are the same as those found from the X-ray studies of $VO(PhCOCHCOCH_3)_2$[4] and $VO(CH_3COCHCOCH_3)_2$[3] (see Table 1); however, the V—O distances in the chelate ring determined in the present structure {r[V—O(1)] = 1.990(6) Å} are longer than those found from the X-ray studies [1.969(16)].[3]

From the discussion given above it is clear that there is little change in the bonded distances with change in phase (see Table 1). An apparent difference appears to be in the value of the angle between the VO(1)O(2) and O(1)C(1)C(2)C(3)O(2) planes, i.e. θ_2, which was set at 0° in the present study (see section devoted to the analysis of the structure for the discussion relating to θ_2, where a value of 4.9(11.2)° was reported), while in the solid state a value of 10.9° was obtained but noticeably no error value was given (see Table 1). The failure to include an error value precludes a detailed comparison of the two values obtained for θ_2. These two values give rise to an apparent difference in the angles between the two ligand planes which is 145° in the present structure and 163° in the solid state. However, as we have shown that the analysis of the electron diffraction data is largely insensitive to small variations in the value of θ_2, we believe that the inclusion of θ_2 as an extra parameter is not justified as its inclusion only leads to a very slight improvement in the R factor. When values for θ_2 much greater than zero were included in refinement (e.g. 20°), noticeably large deviations between the experimental and theoretical RD curves occurred in the outer regions.

The carbon–carbon distance in the ring {r[C(1)—C(2)] = 1.410(10) Å} is comparable to the carbon–carbon distance in benzene[11] (1.395(2) Å) but longer than that in ethene[17] (1.335(4) Å). The carbon–oxygen distances {r[C(1)—O(1)] = 1.271(10) Å} are longer than those in propanone (1.210(4) Å)[18] and methanol (1.207(6) Å),[19] which are double bonds, but shorter than those in diethyl ether (1.415(1) Å)[20] and tetrahydrofuran (1.428(2) Å),[21,22] which are ordinary single bonds. The $CH_3COCHCOCH_3$ anion is usually depicted as having a delocalized charge over the OCCCO chain. However, in $VO(CH_3COCHCOCH_2)_2$ the possibility of further delocalization around the six-membered VOCCHCO rings can be envisaged as the rings are planar (i.e. $\theta_2 = 0°$), the metal ion has empty d orbitals of suitable symmetry to take part in π-bonding in the ring and there are six electrons available for π-bonding. The occurrence of this delocalization around the ring is in accord with the distances observed.

SYNTHESIS AND COPPER-63 NMR STUDIES OF COPPER(I) STIBINE COMPLEXES

A. HETHERINGTON, W. LEVASON* and M. D. SPICER

Department of Chemistry, The University, Southampton SO9 5NH, U.K.

(*Received* 15 *December* 1989; *accepted* 26 *March* 1990)

Abstract—The copper(I) stibine complexes $[CuL_4]BF_4$ (L = $SbPh_3$, $SbEt_3$, $SbMe_3$; L_2 = $Me_2Sb(CH_2)_3SbMe_2$, $Ph_2Sb(CH_2)_3SbPh_2$) as well as $[Cu(PMe_3)_4]BF_4$ and $[Cu(AsMe_3)_4]BF_4$ have been prepared from $[Cu(MeCN)_4]BF_4$ and the appropriate ligand. They have been characterized by analysis and IR spectroscopy. ^{63}Cu and ^{31}P NMR data are reported.

Copper(I) complexes of phosphine and arsine ligands are well known and readily prepared from the appropriate copper(I) salt and the ligand, or by reduction of a copper(II) salt with excess ligand.[1,2] Complexes with Cu–ligand ratios varying from 1 : 1 to 1 : 4 can be isolated in many cases, and in solution complex equilibria are usually present due to the lability of the d^{10} ion.[3] Further interest attaches to copper(I) complexes in that they are diamagnetic and contain two relatively sensitive NMR nuclei, ^{63}Cu and ^{65}Cu. However, both are quadrupolar ($I = 3/2$) and only in a limited number of cases where the metal environment approaches cubic symmetry are the lines sharp enough to be observed.[4] Due to this fast relaxation and also to rapid ligand exchange in solution, few copper NMR resonances have been observed from group 15 donor ligand complexes. Examples include the phosphites, phosphonites and phosphinites $[Cu\{P(OR)_{3-n}R_n\}_4]^+$ ($n = 0$, 1, 2)[5,6] and $[Cu(Ph_2PCH_2CH_2PEt_2)_2]^+$.[7] Here we report a number of stibine complexes and their spectroscopic characterization including ^{63}Cu NMR data.

EXPERIMENTAL

Physical measurements were made as described previously.[8] ^{63}Cu NMR spectra were recorded on a Bruker AM 360 spectrometer operating at 95.5 MHz, and are referenced to a solution of $[Cu(MeCN)_4]BF_4$ in MeCN ($\delta = 0$), with shifts reported using the high frequency positive convention.

$[Cu(MeCN)_4]BF_4$ was prepared by an adaption of the method of Kubas.[9] A suspension of Cu_2O (4 g) in acetonitrile (80 cm^3) was treated with 40% aqueous HBF_4, with cooling to maintain the temperature at *ca* 20°C. The unreacted Cu_2O was filtered off, and the pale blue filtrate refrigerated for 48 h. The white, crystalline product was filtered off, washed with diethyl ether and dried *in vacuo*. Yield 65%.

All the complexes were made by the same general method, and all manipulations and reactions were carried out under a dinitrogen atmosphere. A typical preparation is described below.

Preparation of $[Cu(SbEt_3)_4]BF_4$

$[Cu(MeCN)_4]BF_4$ (0.21 g, 0.67 mmol) was dissolved in MeCN (5 cm^3) and the ligand (0.565 g, 2.7 mmol) added dropwise with vigorous stirring. The solvent was removed *in vacuo* and the resulting solid washed with diethyl ether and vacuum dried. Found: C, 33.1; H, 6.8. Calc. for $C_{24}H_{60}BCuF_4Sb_4$: C, 33.0; H, 6.9%.

$[Cu(SbMe_3)_4]BF_4$, Found: C, 17.4; H, 4.5. Calc. for $C_{12}H_{36}BCuF_4Sb_4$: C, 17.6; H, 4.4%.

$[Cu(SbPh_3)_4]BF_4$, Found: C; 56.5; H, 3.9. Calc. for $C_{72}H_{60}BCuF_4Sb_4$: C, 55.3; H, 3.9%.

$[Cu(Me_2Sb(CH_2)_3SbMe_2)_2]BF_4$, Found: C, 19.9; H, 4.4. Calc. for $C_{14}H_{36}BCuF_4Sb_4$: C, 20.0; H, 4.3%.

$[Cu(Ph_2Sb(CH_2)_3SbPh_2)_2]BF_4$, Found: C, 48.6; H, 4.0. Calc. for $C_{54}H_{52}BCuF_4Sb_4$: C, 48.4; H, 3.9%.

$[Cu(AsMe_3)_4]BF_4$, Found: C, 22.9; H, 6.0. Calc. for $C_{12}H_{36}As_4BCuF_4$: C, 22.9; H, 5.8%.

$[Cu(PMe_3)_4]BF_4$, Found: C, 32.3; H, 8.1. Calc. for $C_{12}H_{36}BCuF_4P_4$: C, 31.7; H, 8.0%.

RESULTS AND DISCUSSION

The colourless or white $[Cu(SbR_3)_4]BF_4$ (R = Me, Et, or Ph) and $[Cu(R_2Sb(CH_2)_3SbR_2)_2]BF_4$ (R = Me or Ph) complexes were readily obtained by reaction of $[Cu(MeCN)_4]BF_4$ and the appropriate ligand in MeCN under nitrogen. The $SbPh_3$ complex has been reported previously[10] and $[Cu(SbPh_3)_4]ClO_4$ is also known.[11] Several attempts to prepare a $[Cu(L—L)_2]BF_4$ complex from o-$C_6H_4(SbPh_2)_2$ were unsuccessful, only greyish materials of approximate composition "$Cu_2(L—L)_3(BF_4)_2$" were obtained. The alkylstibine complexes decompose slowly in air, turning green over a few days, but the arylstibine complexes appear air-stable. The colourless $[Cu(PMe_3)_4]BF_4$ and $[Cu(AsMe_3)_4]BF_4$ complexes were made similarly, and like the alkylstibine complexes were unstable in air. All are 1:1 electrolytes in MeCN solution, and have IR spectra typical of complexes with ionic BF_4^- ions.[12]

Previous attempts to observe the ^{63}Cu NMR spectrum of $[Cu(PPh_3)_4]^+$ failed[5,6] and in this work no signals were observed from this complex nor from $[Cu(AsPh_3)_4]^+$ in CH_2Cl_2 either at room temperature or at 190 K. However, the ^{63}Cu NMR resonance of $[Cu(SbPh_3)_4]^+$ in CH_2Cl_2 solution is easily seen even at room temperature as a moderately sharp line at $\delta = -249$ ppm ($W_{1/2} = 250$ Hz). The resonance does not shift significantly on cooling the solution to 190 K and is unaffected by addition of $SbPh_3$. However, a mixture of this complex and $[Cu(MeCN)_4]^+$ in MeCN gave no resolvable resonances showing that exchange produced $[Cu(MeCN)_{4-x}(SbPh_3)_x]^+$, which undergo fast quadrupolar relaxation due to the lower symmetry environment. ^{63}Cu resonances were similarly readily recorded for $[Cu(SbMe_3)_4]^+$ and $[Cu(SbEt_3)_4]^+$ (Fig. 1). More surprisingly, the two complexes of the trimethylene backboned distibines, $[Cu(R_2Sb(CH_2)_3SbR_2)_2]BF_4$ (R = Me or Ph), also gave moderately sharp ^{63}Cu resonances. It is possible that the 3-carbon backbones of the ligands allow the donors to approach a "regular" tetrahedral arrangement, and slow the quadrupolar relaxation rate. It would be most interesting in this respect to know the Sb—Cu—Sb bond angle, but unfortunately attempts to grow crystals for an X-ray study have been unsuccessful. The crystals obtained have all been of poor quality, and deteriorated rapidly apparently due to loss of solvent when removed from the mother liquor.

Based upon these results we thought examination of the spectra of $[Cu(AsMe_3)_4]^+$, $[Cu(PMe_3)_4]^+$ and $[Cu(PEt_3)_4]^+$ worthwhile. The last showed no observable ^{63}Cu resonance, but the arsine shows a ^{63}Cu resonance at -42 ppm, whilst the ^{63}Cu and ^{31}P NMR spectra of the PMe_3 complex are shown in Fig. 2. Both clearly show well-resolved $^1J(^{63/65}Cu–^{31}P)$ coupling patterns consistent with a CuP_4 moiety, and the separate $^1J(^{63}Cu–^{31}P)$ and $^1J(^{65}Cu–^{31}P)$ couplings are just resolved upon the outer lines of the multiplet ($\gamma^{63}Cu/\gamma^{65}Cu = 0.934$).[4] Although such coupling has been observed in phosphite complexes, it is highly unusual in phosphines, indeed most copper(I) phosphines show very broad featureless ^{31}P NMR spectra, with the chemical shifts varying with concentration and the presence of free ligand, indicative of fast intermolecular

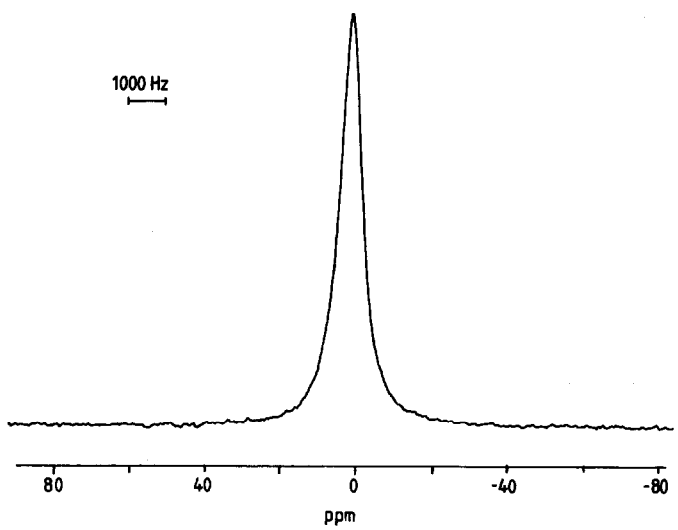

Fig. 1. ^{63}Cu NMR spectrum of $[Cu(SbEt_3)_4]BF_4$ in CH_2Cl_2/CD_2Cl_2.

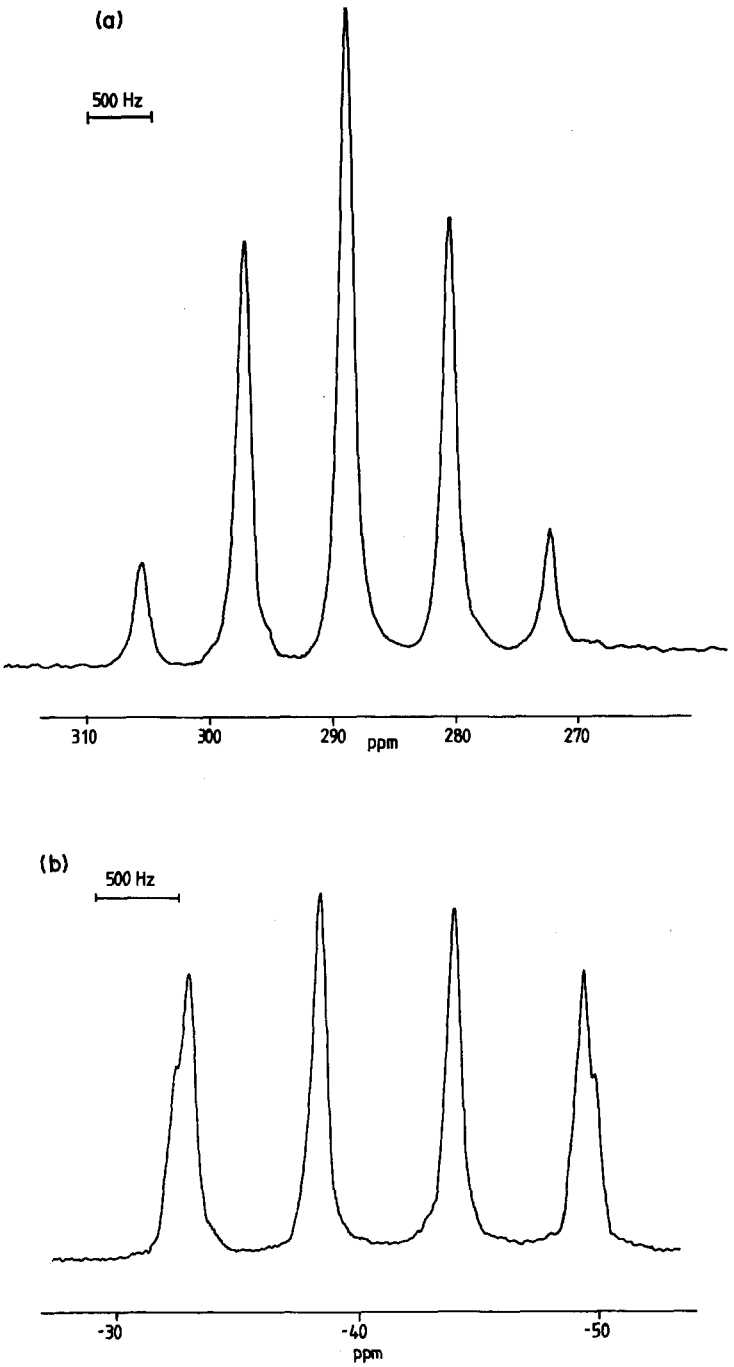

Fig. 2. (a) ^{63}Cu and (b) ^{31}P NMR spectrum of $[Cu(PMe_3)_4]BF_4$ in CH_2Cl_2/CD_2Cl_2.

exchange. Addition of PMe_3 to a solution of $[Cu(PMe_3)_4]^+$ had no effect on the resonance of the bound phosphines. The magnitude of the ^1J coupling in the phosphine complex is significantly smaller (790 Hz) than those reported for the phosphites[6] which range from *ca* 1100 to 1450 Hz. The NMR data are presented in Table 1.

Copper(I)–group 15 donor ligand bonds are believed to be of predominantly σ-type with any π-component small or absent,[13] and detailed studies both of the solid-state structures and of solution behaviour have been interpreted in terms of significant steric effects.

There is only one X-ray crystal structure of a copper(I) stibine, $[Cu(SbPh_3)_3Cl]$,[14] which shows a long Cu—Sb bond length of 2.554 Å. Based upon this structure we have calculated a cone angle for $SbPh_3$ of 127°. Comparable cone angles are PMe_3

Table 1. Selected NMR data

[e] Data from ref. 6.

(118°), PPh_3 (145°) and PEt_3 (132°).[15] Using the interatomic distances from the electron diffraction data[16] on Me_3Sb and Me_3As and the Cu—Sb and Cu—As distances from $[Cu(SbPh_3)_3Cl]$ and $[\{CuCl(PhMe_2As)_2\}_2]$,[13] respectively, corresponding cone angles of 113 and 116° result. Extrapolation suggests that the cone angle of $SbEt_3$ will be $120 \pm 4°$.

It thus seems likely that one major factor in our ability to record ^{63}Cu NMR spectra for the tertiary stibine complexes could be the reduced steric interactions, and the resulting reduced tendency to dissociate ligand. The cone angles of PMe_3 and $AsMe_3$ compared with those of other phosphines which fail[6] to give ^{63}Cu resonances from their CuP_4^+ complexes support this interpretation. The X-ray structure of $[Cu(PPh_3)_4]ClO_4$ shows a crowded cation with little deviation from regular tetrahedral angles,[17] and hence the failure of this complex to give a ^{63}Cu NMR signal would seem to be more likely due to ligand dissociation in solution rather than to a distorted geometry.

Abstract—The preparation, spectroscopic and electrochemical properties of the cyclometallated complex $[Rh(bipy)_2(ppy)][PF_6]_2$ are reported. The crystal and molecular structure of the complex are reported; the cation exhibits a six-fold disorder and closely resembles the $[Rh(bipy)_3]^{3+}$ cation.

Complexes containing 2,2′-bipyridine and related ligands have been of interest to coordination chemists for over a 100 years.[1,2] Recent interest has centred upon the redox, photochemical, photophysical and photoelectrochemical properties, with a particular view to incorporation into photoconversion and photocatalytic systems.[3] It has been found that the replacement of the N_2-donor ligand, 2,2′-bipyridine, by structurally analogous cyclometallated *C,N*-donors results in useful changes in the redox and photophysical properties of the complexes.[4] Remarkably few complexes containing a cyclometallated 2-phenylpyridine ligand have been structurally characterized,[5–7] and of these the majority refer to square-planar[5] or tellurium[6] species. In the octahedral complexes which have been characterized, substituents have been introduced onto the 2-phenylpyridine which perturb the metal–carbon interactions.[7] As part of our programme to develop synthetic methodology for the synthesis of cyclometallated compounds,[8] we have prepared and structurally characterized the complex $[Rh(bipy)_2(ppy)][PF_6]_2$ (Hppy = 2-phenylpyridine).

The reaction of $[Rh(bipy)_2(O_3SCF_3)_2][O_3SCF_3]$ with $[Hg_4(ppy)_4Cl_4]$ results in the deposition of metallic mercury and the formation of a pale pink solution from which $[Rh(bipy)_2(ppy)][PF_6]_2$ may be precipitated in 75–85% yield by the addition of $[NH_4][PF_6]$. Recrystallization from acetone resulted in the formation of X-ray quality pale pink crystals of the compound (λ_{max} 315, 304, 242 nm). The ^1H NMR spectrum of the complex in CD_3COCD_3 solution is shown in Fig. 1; assignments were made on the basis of double quantum filtered phase-sensitive COSY, TOCSY and CAMELSPIN spectra. The spectrum very closely resembles that of $[Ru(bipy)_2(ppy)]^+$ which we have reported previously,[8] although variations associated with the differences in formal charge are

observed.[9] The FAB mass spectrum (3-nitrobenzyl alcohol matrix) exhibited a peak at *m/z* 569 {(Rh (bipy)$_2$(ppy)]}. The complex is redox active, and the cyclic voltammogram (Fig. 2) exhibits a reversible one-electron reduction at -1.59 V (ΔE_p 70 mV, referenced to internal Fc/Fc$^+$) and a two-electron feature at -1.83 V; no variations in this feature were observed with variation of scan rate in the range 20–200 mV s^{-1}. This behaviour is in marked contrast to that of $[Rh(bipy)_3]^{3+}$ in which the first one-electron reduction occurs at -1.17 V,[10] and parallels the trend previously reported for $[Ru(bipy)_3]^{2+}$/$[Ru(bipy)_2(ppy)]^+$.[8]

The structure of the cation in $[Rh(bipy)_2$

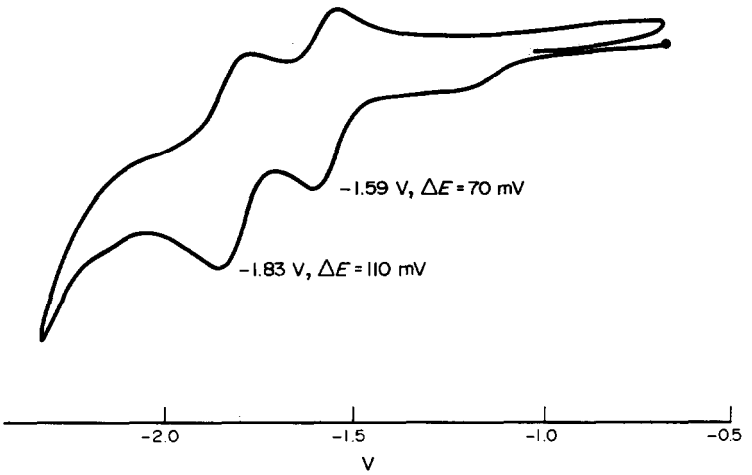

Fig. 2. Cyclic voltammogram of $[Rh(bipy)_2(ppy)][PF_6]_2$ (MeCN solution, 0.1 M[^{n}Bu$_4$N][BF_4] supporting electrolyte, referenced to internal ferrocene/ferrocinium added at the end of the experiment, scan rate 200 mV s^{-1}, room temperature).

(ppy)][PF_6]$_2$ is shown in Fig. 3, together with the numbering scheme adopted.* The cation exhibits apparent D_3 symmetry, with a six-fold crystallographic disorder associated with the phenyl and pyridyl rings. Examination of the thermal parameters associated with the donor atoms did not allow us to assign a single site to the metallated phenyl ring. However, only two $[PF_6]^-$ counterions are observed in the lattice, establishing unambiguously that the cation has a +2 charge, and hence contains the metallated ring. The final refinements were made with scattering factors for a 83.3 : 16.7 distribution of N : C for atom X. The Rh(1)—X(1) distance of 2.043(3) Å does not differ significantly from those of 2.031(8)–2.038(7),[11] 2.015[12] and 2.057 Å[12] reported in separate determinations of $[Rh(bipy)_3]^{3+}$ salts. The bite of 79.7° is typical for chelated 2,2′-bipyridine ligands.[1]

This structural determination is the first to be reported of a complex in which a 2,2′-bipyridine ligand has been replaced by a fully isostructural and isoelectronic cyclometallating ligand. The important conclusion is that such replacement has *no* significant effect upon the structure of the complex ion; in contrast, the observation of significantly different M—C and M—N distances in complexes of structurally developed ligands is an artefact introducted by their use. The useful and novel photophysical effects associated with cyclometallated 2-phenylpyridine complexes are thus a conse-

STRUCTURE AND SPECTROSCOPIC PROPERTIES OF $[(2,6\text{-}Ph_2C_6H_3O)_2Ti(\mu\text{-}Cl)_2Ti(OC_6H_3Ph_2\text{-}2,6)_2]$: EVIDENCE FOR A STRONG METAL–METAL INTERACTION

JOHN E. HILL, JOHN M. NASH, PHILLIP E. FANWICK and IAN P. ROTHWELL*

Department of Chemistry, Purdue University, West Lafayette, IN 47907, U.S.A.

(*Received* 19 *February* 1990; *accepted* 26 *April* 1990)

Abstract—The compound $[(2,6\text{-}Ph_2C_6H_3O)_2Ti(\mu\text{-}Cl)_2Ti(OC_6H_3Ph_2\text{-}2,6)_2]$ which is formed by sodium amalgam reduction of $Ti(OC_6H_3Ph_2\text{-}2,6)_2Cl_2$ ($OC_6H_3Ph_2$-2,6 = 2,6-diphenylphenoxide) contains a relatively short Ti—Ti distance of 2.9827(7) Å and acute Ti—(μ-Cl)—Ti angles of 77.79(3) and 78.05(3)°. Crystal data at −130°C: space group $P\bar{1}$; $a = 13.342(4)$, $b = 13.808(4)$, $c = 16.057(3)$ Å, $\alpha = 97.35(2)$, $\beta = 104.63(2)$, $\gamma = 91.64(2)°$, $Z = 2$; $\rho_{calc} = 1.346$ g cm^{-3}.

The last 10 years have seen dramatic developments in the chemistry of metal–metal bonded dinuclear complexes of the *d*-block elements.[1] Despite these advances there has been only limited success in the isolation and characterization of dinuclear Group 4 metal complexes containing metal–metal bonds and this area has been the focus of much recent attention.[2–4] During our studies of the low valent chemistry of titanium associated with aryloxide ligation[5] we have isolated an unusual di-titanium(III) complex which appears to contain a strong metal–metal interaction.

The reduction of the deep red dichloride $Ti(OC_6H_3Ph_2\text{-}2,6)_2Cl_2$ ($OC_6H_3Ph_2$-2,6 = 2,6-diphenylphenoxide)[6] with Na/Hg (1 Na per Ti) in toluene solution leads to the formation of a deep brown reaction mixture. Routine work-up allows the isolation of a deep purple crystalline product of composition $[(2,6\text{-}Ph_2C_6H_3O)_2Ti(\mu\text{-}Cl)_2Ti(OC_6H_3Ph_2\text{-}2,6)_2]$ (**1**).† A single crystal X-ray diffraction analysis of **1**† shows the compound to consist of a dinuclear unit with two bridging chloride atoms and four terminally bound aryloxide ligands (Fig. 1). The $Ti_2Cl_2O_4$ central core can best be described as a distorted edge-shared bis-tetrahedral structure. Several features of the structure of **1** are worthy of note. The Ti—Ti distance of 2.9827(7) Å is very short for two titanium atoms bridged by two chlorine atoms; cf. the Ti—Ti distances of 3.943(2) and 3.968(2) Å in the compound $Cp_2Ti(\mu\text{-}Cl_2)TiCp_2$.[7] Coupled with this surprisingly short distance are acute Ti—(μ-Cl)—Ti angles of 78.05(3) and 77.79(3)°. Both of these structural features indicate the presence of a strong interaction between the two d^1-metal centres. A survey of structurally characterized compounds containing a planar $Ti(\mu\text{-}Cl)_2Ti$ unit shows typical Ti—(μ-Cl)—Ti angles of 95–103° and Ti—Ti distances > 3.50 Å.[8–10] The bridging unit in compound **1** bears a striking resemblance to that found for the $[L_2Cl_2Zr(\mu\text{-}Cl)_2ZrL_2Cl_2]$ (L = phosphine) series of compounds, where Zr—Zr distances of 3.104–3.182 Å and Zr—(μ-Cl)—Zr angles of 75.4–77.4° have been taken as evidence for the presence of a zirconium–zirconium single bond.[4]

* Author to whom correspondence should be addressed.

† Found: C, 75.6; H, 4.7; Cl, 5.9. Calc. for $Ti_2Cl_2O_4C_{72}H_{52}$: C, 75.3; H, 4.6; Cl, 6.2%. Crystal data: Space group $P\bar{1}$; $a = 13.342(4)$; $b = 13.808(4)$; $c = 16.057(3)$ Å; $\alpha = 97.35(2)$; $\beta = 104.63(2)$; $\gamma = 91.64(2)°$; $Z = 2$; $\rho_{calc} = 1.346$ g cm^{-3}; 5634 unique data collected at −130°C with $I > 3\sigma(I)$ yielded $R = 0.039$, $R_w = 0.052$. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.

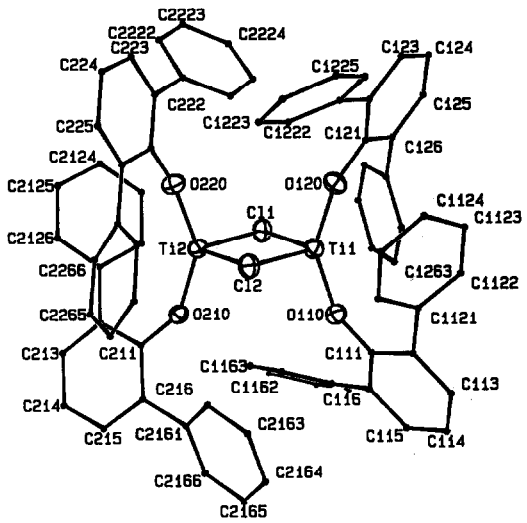

Fig. 1. ORTEP view of the molecular structure of **1** showing the numbering scheme used:

Distances (Å)

Ti(1)—Ti(2)	2.9827(7)	Ti(2)—Cl(1)	2.3712(9)
Ti(1)—Cl(1)	2.3660(9)	Ti(2)—Cl(2)	2.3743(9)
Ti(1)—Cl(2)	2.3761(9)	Ti(2)—O(210)	1.825(2)
Ti(1)—O(110)	1.820(2)	Ti(2)—O(220)	1.819(2)
Ti(1)—O(120)	1.805(2)		

Angles (°)

Cl(1)—Ti(1)—Cl(2)	102.13(3)
Cl(1)—Ti(2)—Cl(2)	102.02(3)
O(110)—Ti(1)—O(120)	144.27(9)
O(210)—Ti(2)—O(220)	144.17(9)
Ti(1)—Cl(1)—Ti(2)	78.05(3)
Ti(1)—Cl(2)—Ti(2)	77.79(3)
Ti(1)—O(110)—C(111)	153.4(2)
Ti(1)—O(120)—C(121)	152.0(2)
Ti(2)—O(210)—C(211)	146.9(2)
Ti(2)—O(220)—C(221)	155.3(2).

Further interesting features of the molecular structure of **1** are the large O—Ti—O angles of 144.17(9) and 144.27(8)° between the terminal aryloxide ligands. These large angles cannot be accounted for on steric grounds: cf. the O—Ti—O angle of 123.9(1)° in $(2,6\text{-}Ph_2C_6H_3O)_2Ti(C_6H_5)_2$.[11] A possible explanation of the opening up of this angle in **1** is based on the π-donor properties of aryloxide ligands when bound to early *d*-block metal centres.[12] The formation of a Ti—Ti σ-bond from overlap of the two d_{z^2} orbitals would be destabilized by the presence of terminal π-donor ligands in a regular edge-sharing bis-tetrahedral structure. Forcing the aryloxide ligands further out of the $Ti(\mu\text{-}Cl)_2Ti$ plane will reduce π-donation into this orbital and hence interfere less with the metal–metal interaction. An EHMO calculation on $(HO)_2Ti(\mu\text{-}Cl)_2Ti(OH)_2$ using O—Ti—O angles of 144 and 120° supports this bonding picture, clearly showing stabilization of the Ti—Ti σ-bond when this angle is increased. A further consequence of opening up the O—Ti—O angle is the presence of a considerable gap in the metal coordination sphere along the Ti—Ti axis. In compound **1** this space is occupied by two *ortho*-CH bonds of the aryloxide ligands. The distances to these groups are long, however, Ti(1)—C(1262) = 2.947(1) Å, Ti(1)—H(12621) = 2.83(1) Å and Ti(2)—C(2122) = 2.853(1) Å, Ti(2)—H(21221) = 2.84(1) Å, precluding the existence of an agostic interaction.[13] Similar close contacts have been observed for other metal derivatives of 2,6-diphenylphenoxide ligation.[14]

Solutions of **1** in hydrocarbon solvents exhibit an uninformative ^1H NMR spectrum with unresolvable resonances in the δ 6.5–7.5 ppm region. Studies using Evans' method[15] showed the solutions to be only weakly paramagnetic with $\mu_{obs} \simeq 0.5$ BM; a broad ESR signal was also observed at $g = 1.956$.

BOOK REVIEW

Reactions of Coordinated Ligands, Volume 2. Edited by P. S. Braterman, Plenum, New York, 1989, ISBN 0-306-43094-0, 414 pp., £79.20

This is the long-awaited second (and final) volume of this work describing the chemistry of coordinated ligands. The book contains five chapters discussing the reactivity of ligands which are bound to a metal through an atom other than carbon. The manuscript has been prepared in a camera-ready format, with the consequent inconsistencies between chapters by various authors. This is no real criticism, but the quality of structural diagrams varies very considerably between chapters.

The first chapter (Miller, 140 refs to 1983) discusses the chemistry of coordinated carbon dioxide. This is a well-written and interesting survey of an area of considerable interest and importance. The review is an excellent starting point for an entry into the chemistry of carbon dioxide, but the cut-off date of 1983 means that the reader will really have to look elsewhere for an up-to-date account.

The second chapter is concerned with the reaction of coordinated dinitrogen and related species (Hidai and Mizobe, 202 refs to 1985). The authors limit themselves to more recent progress and give adequate reference to previous reviews. I found this chapter particularly useful and informative, and recommend it strongly as providing a "taste" of an exciting and fast-moving area. Perhaps a small *caveat* should be issued; this review is concerned with the chemistry *not* the biochemistry of dinitrogen ligands.

The reactions of nitrosyl complexes are discussed in Chapter 3 (Bottomley, 518 refs to 1985). This is a truly excellent and useful article which must remain a key reference for anyone with a passing or all-consuming interest in nitrosyl chemistry. I was particularly impressed by the clear, readable and informative account of the plethora of reactions of nitroprusside ions, which is an area which has now been successfully demystified for me.

The penultimate chapter is an account of the hydrolysis and condensation reactions of oxygen- and nitrogen-bonded ligands (Hay, 543 refs to 1986). This is a superb discussion of the reactions of coordinated nitriles, amides and related compounds. To a newcomer to the area this is an excellent primer, whilst the comprehensive literature coverage (through 1986) provides a few gems for those who thought they knew the subject! The organization and content of this chapter is very similar to that by the same author in *Comprehensive Coordination Chemistry*. This is only to be expected, as the same material is covered, but I must confess to a preference for the typeset format of text and diagrams in *Comprehensive Coordination Chemistry*.

The final chapter concerns reactions of coordinated phosphorus and sulphur ligands (Minahan, Hill and McAuliffe, 150 refs to 1979). I found this to be the most disappointing chapter in the book. The coverage of the subject area is adequate, but the apparent cut-off at 1979 means that an entire decade's worth of extremely relevant chemistry has been omitted. The references to previous reviews are very comprehensive, but with the proviso that the literature later than 1979 is of no interest. I am sure that this is no fault of the editor or the authors, but I would have thought that the 1989 publication date would have merited an update of a chapter that was undoubtedly written much earlier. As it stands, the chapter is not a greatly helpful contribution to a very interesting area of ligand reactivity.

Overall, I liked this book. The omission of sections dealing with the reactions of heterocyclic ligands or the oxygenation and other metal-directed reactions of aromatic ligands somewhat reduce its utility in giving a general overview of the area. My main criticism concerns the cut-off dates of some of the literature coverage, but this is always unavoidable in a venture of this type. However, 10 years is a little extreme!

This book should be in all chemical libraries, and devotees of ligand reactivity will undoubtedly want their own copies. Well done to Paul Braterman and his team for a successful coverage of such a disparate area.

ANNOUNCEMENT

CALL FOR PAPERS

POLYHEDRON SYMPOSIUM-IN-PRINT

HOMOPOLYATOMIC SILICON, GERMANIUM AND TIN CHEMISTRY

Species containing bonds between Group 14 elements and their associated chemistry has been the subject of intense interest. In the last decade we have seen many exciting advances including the characterization of silenes, silaethenes, polyhedral polycyclic Group 14 compounds and network germanium polymers, new frontiers in the synthesis of strained cyclic Group 14 species and in the generation of heavy carbene analogues, and a better understanding of the properties of polysilane high polymers.

The purpose of this Symposium-in-Print is to bring together these recent advances in homopolyatomic and related chemistry of silicon, germanium and tin. Topics that are appropriate to this Symposium include synthesis, structure, reactivity, mechanistic studies, theoretical studies and properties of the title or related compounds.

The deadline for the submission of articles is 1 September 1990 and manuscripts should be mailed to Dr M. Hampden-Smith, Department of Chemistry, Clark Hall 103, University of New Mexico, Albuquerque, NM 87131, U.S.A. If you have any questions please call (505) 277-4713.

(*Received* 30 *November* 1989; *accepted* 18 *January* 1990)

Abstract—A bonding model has been developed for *d–p* π-conjugate interactions over the M_3X_3 skeleton. The orbitals forming *d–p* π- and *d–d* interactions have been constructed, and it has been found that the *d–p* π-conjugate interaction is in competition with *d–d* interactions. The weaker the *d–d* interactions between M—M atoms, the stronger is the *d–p* π-conjugate interaction over M_3X_3 (X = O, S); the contrary relations are true over M_3X_3 (X = Cl, Br). It is believed that the *d–p* π-conjugate interaction over M_3X_3 increases on descending each of the two vertical groups, X = VIA and X = VIIA, and is stronger for a X = VIA than a X = VIIA element in the periodic table. The increase is correlated with a corresponding increase in the *d–p* π-overlap population over the M_3X_3 ring skeleton.

Incomplete transition metal cubane-type cluster compounds (ICTMCTC) having a non-planar ring skeleton, M_3X_3 (M = Mo, W; X = O, S, Cl, Br), have been an active subject[1–15] in the chemistry of molybdenum and tungsten. Some of the experimental and theoretical results in this area have been published in two recent reviews.[16,17] It has been shown that the $M_3X_4^{4+}$ (X = O, S) core is stable to substitution of the terminal ligands,[1,12] and that the charge-transfer bands of the sulphur ligand to molybdenum are observed only with the bridging sulphur ligand but not with the capping sulphur ligand in the electronic specra[16] of ICTMCTC compounds. Therefore, the bonding in M_3X_3 cluster compounds is of interest in ICTMCTC compounds. We have suggested that a *d–p* π-conjugate interaction exists over M_3X_3 (X = O, S) and that this interaction is stronger over M_3S_3 than M_3O_3, and explained some of the physicochemical properties for ICTMCTC compounds, such as the cooperative effect among the triply bridging ligand X (X = O, S) in chemical reactions[1] and the average of bond lengths[1,2] between M—X atoms over M_3X_3, in the preceding publications.[18] In this paper we give bonding details for a non-planar ring skeleton M_3X_3 and construct the orbitals which are formed for *d–p* π- and *d–d* interactions under the local coordinate system. Also, we describe the relationship between the *d–p* π- and *d–d* orbital interactions in terms of the mixing orbitals and find that the Hückel rule $(4n+2)$ fits for the π-electrons over M_3X_3 (X = O, S). The balance between the *d–p* π-conjugate and *d–d* direct interactions over M_3X_3 is discussed using the bonding model presented here for ICTMCTC compounds.

RESULTS AND DISCUSSION

Mixing orbital determination

ICTMCTC compounds of the type $M_3X_{4-n}Y_nL_9^c$ are presented here and are shown in Fig. 1. They belong to the classification M_3 used in ref. 15. Each metal atom is generally six-coordinate, if M—M bonds are not considered in the M_3 triangle in ICTMCTC compounds. Hence, each M atom needs six valence orbitals to form the σ-framework bonds with capping and bridging ligands, as well as terminal ligands. Three valence orbitals are left on each M atom, two of them form M—M interactions and one of them forms π-interactions with the *p*-orbital of the neighbourhood bridging ligands within the non-planar ring skeleton M_3X_3. The σ-

† Author to whom correspondence should be addressed.

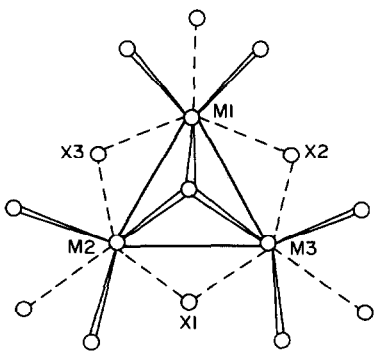

Fig. 1. $[M_3X_{4-n}Y_nL_9]^c$ cluster configuration.

bonds between metal and ligand atoms are generally stable in transition metal cluster compounds, so we only consider the M—M and *d–p* π-interactions within the M_3X_3 cluster. The question of how to pick out three valence orbitals on each metal atom is answered as follows.

Generally, the *d–p* π-interaction between the M and X bridging atoms is comparable in energy to the *d–d* interaction between M atoms. Therefore, three *d* typical mixing orbitals will be only considered to use *d–d* and *d–p* π-interactions within M_3X_3, and six d^2sp^3 hybrid orbitals are considered to form the σ-framework bonds with the ligand atoms. The local coordinate system, which is defined by a non-planar ring skeleton M_3X_3, is convenient in determining the three *d* typical mixing orbitals. As shown in Fig. 2, the M_3X_3 cluster consists of two parallel triangles (M_3 and X_3), all of the *y* axes are parallel to one another and perpendicular to the two triangles, the *z* axes on each M atom and on each X atom point towards the centre of the M_3 and X_3 triangle, respectively, and the tangential *x* axes on the two triangles are fixed by requiring a right-hand coordinate system. The expressions of the three mixing orbitals are as follows:

$$h_1^i = (2/3)^{1/2}(x^2-y^2)-(1/3)^{1/2}z^2 \qquad (1.1)$$

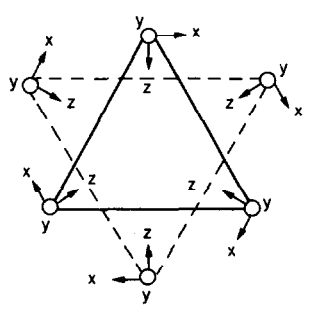

Fig. 2. Local atomic coordinate systems.

$$h_2^i = -(1/6)^{1/2}(x^2-y^2)-(1/3)^{1/2}z^2+(1/2)^{1/2}xz \qquad (1.2)$$

$$h_3^i = -(1/6)^{1/2}(x^2-y^2)-(1/3)^{1/2}z^2-(1/2)^{1/2}xz, \qquad (1.3)$$

and they are made up of three *d* orbitals (x^2-y^2, z^2 and xz). We find that the three *d* orbitals, centred on each M atom, have larger overlaps with both the *d* orbitals of the neighbourhood M atoms and the p_y orbitals of the neighbourhood bridging X ligand atoms. The p_y orbital on each *X* atom is perpendicular to the M_3X_3 non-planar ring skeleton, and the interactions between the p_y orbital on the X atom and x^2-y^2, z^2, as well as the *yz* orbital on the M atom, are homomorphic[19] (constant sign of overlap over M_3X_3); however, the interactions between the p_y and *xy*, *xz* orbital are heteromorphic[19] (alternating sign of overlap over M_3X_3), according to the definition of the local coordinate systems shown in Fig. 2. It is seen from Table 1, that the overlap integrals are smaller between the z^2 orbital on the M atom and the p_y orbital on the X atom than the *xy* orbital on the M atom and the p_y orbital on the X atom, however, the overlap integrals are larger between the z^2 orbitals than the *xy* orbitals on the two M atoms over M_3X_3. Moreover, it is found from Fig. 2, that the x^2-y^2, z^2 and *xz* orbitals on each M atom lie in the trimetal plane, and that the *xy* and *yz* orbitals on each M atom stand on the trimetal plane. The latter ones on each M atom have larger interactions with the capping or terminal ligands. Hence, the x^2-y^2, z^2 and *xz* orbitals are selected to construct three mixing orbitals, h_1^i, h_2^i and h_3^i on each metal atom. These mixing orbitals have larger overlaps between both the *d–d* orbitals on the M atoms and the *d* orbital on the M atom and p_y orbital on the X atom, and it is possible for the maximum binding energy among atoms within M_3X_3.

Qualitative analyses for the d–p *π-interaction between the* M_3 *and* X_3 *fragments*

From early qualitative analysis of the valence bond theory, we know that one of three *d* typical mixing orbitals is available for the π-interaction between the M and X atoms, and that two of them are available for direct M—M interactions. Now, the question will arise again; which is the mixing orbital available for the *d–p* π-interaction? The answer is provided by the overlap integrals: the mixing orbital h_1 on the M atom has the largest overlap with the p_y orbital on the neighbourhood X atoms, and the interactions amongst the h_1 and

$h_1 = \sqrt{2/3}d_{x^2-y^2} - \sqrt{1/3}d_{z^2}$.
$h_2 = -\sqrt{1/6}d_{x^2-y^2} - \sqrt{1/3}d_{z^2} + \sqrt{1/2}d_{xz}$.
$h_3 = -\sqrt{1/6}d_{x^2-y^2} - \sqrt{1/3}d_{z^2} - \sqrt{1/2}d_{xz}$.

p_y orbitals are homomorphic and available for d–p π-conjugate interaction over the M_3X_3 non-planar ring skeleton. Next, we will discuss the details of the d–p π-conjugate interaction over M_3X_3.

The h_1 mixing orbital is constructed from x^2-y^2 and z^2 atomic orbitals, and drawn in Fig. 3. According to the pictorial approach to molecular bonding developed by Verkade,[20] three MOs, $L^M{}_{\Gamma\gamma}$, symmetry-adapted linear combination of mixing atomic orbitals, are constructed in the trimetal atom skeleton under C_{3v} point group symmetry. It is necessary to declare that the choice of generator orbital (GO) is dependent on the coordinate orientation and some of the GOs presented here are different from those of Verkade.[20] Three MOs for the M_3 skeleton are drawn in Fig. 4 and written as

$$L^M{}_{a_1} = N_1/(3)^{1/2}(h_1{}^1 + h_1{}^2 + h_1{}^3) \quad (2.1)$$

$$L^M{}_{e1} = N_2/(6)^{1/2}[2h_1{}^1 - (h_1{}^2 + h_1{}^3)] \quad (2.2)$$

$$L^M{}_{e2} = N_3/(2)^{1/2}(h_1{}^2 - h_1{}^3), \quad (2.3)$$

where N_i is a normalization coefficient for MO in M_3 and dependent on d–d overlap integrals. It is found from Fig. 4, that $L^M{}_{a_1}$ is the d–d π-bonding MO and $L^M{}_{e1}$, $L^M{}_{e2}$ are the degenerate d–d π-antibonding MOs. The relative energy levels for π-MOs of the M_3 fragment are drawn on the left of Fig. 6, all of the π-MOs will be non-occupied orbitals if the M_3 skeleton has six electrons, and the $L^M{}_{a_1}$ MO will be the occupied orbital if the M_3 skeleton has eight electrons (the six electrons are considered to be d–d σ-sigma-bonds). The π-MOs are constructed for the X_3 fragment as for M_3, but the GO is the p_y orbital for $L^X{}_{a_1}$ MO, and the GO is, respectively, yz and xy for MOs $L^X{}_{e1}$ and $L^X{}_{e2}$. These MOs are drawn in Fig. 5 and written as

$$L^X{}_{a_1} = (1/3)^{1/2}(p_y{}^1 + p_y{}^2 + p_y{}^3) \quad (3.1)$$

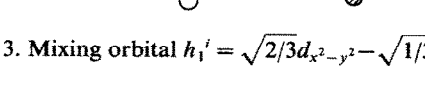

Fig. 3. Mixing orbital $h_1{}' = \sqrt{2/3}d_{x^2-y^2} - \sqrt{1/3}d_{z^2}$.

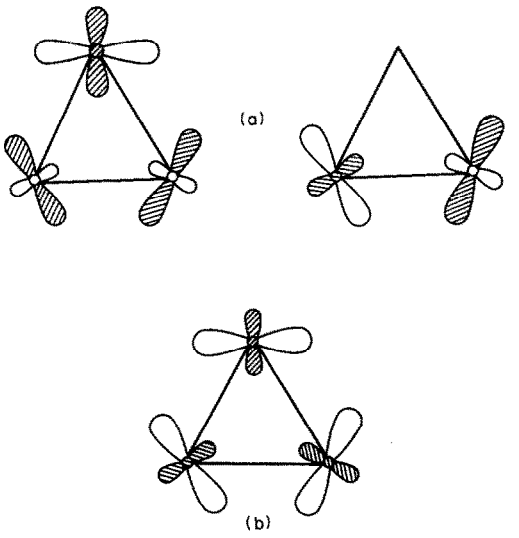

Fig. 4. (a) π-MO of e symmetry; (b) π-MO of a_1 symmetry ($3h_1 - e + a_1$).

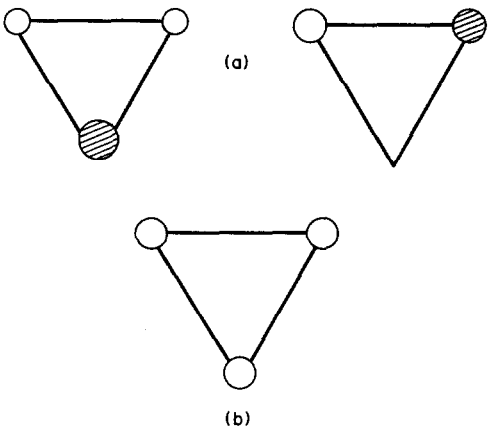

Fig. 5. (a) π-MO of e symmetry; (b) π-MO of a_1 symmetry ($3p_y - e + a_1$).

$$L^X_{e1} = (1/6)^{1/2}[2p_y^1 - (p_y^2 + p_y^3)] \quad (3.2)$$

$$L^X_{e2} = (1/2)^{1/2}(p_y^2 - p_y^3). \quad (3.3)$$

The relative energy levels for the π-MOs of the X_3 fragment are drawn on the right of Fig. 6, and the three lone-pair electrons will occupy three MOs. The normalization coefficients are not considered in Formula (3) because the interaction between X—X atoms is very weak. Now, the *d–p* π-conjugate interaction takes place between the two fragments, M_3 and X_3, under the symmetry rule for fragment interaction, and this interaction diagram is shown in Fig. 6. Because the M_3 and X_3 fragments are not co-planar, the interactions between the h_1 and p_y orbitals over M_3X_3 are not exact π-interactions due to the definition of the local coordinate of M_3X_3 as shown in Fig. 2, but we still call them π-interactions in our studies. The six π-MOs of the M_3X_3 non-planar ring skeleton are constructed from the π-MOs of M_3 and X_3 fragments, and the expressions of the MOs are written as

$$L^R_{a_1} = A_{1,2}L^M_{a_1} + - A_{2,1}L^X_{a_1} \quad (4.1)$$

$$L^R_{e1} = B_{1,2}L^M_{e1} + - B_{2,1}L^X_{e1} \quad (4.2)$$

$$L^R_{e2} = C_{1,2}L^M_{e1} + - C_{2,1}L^X_{e2}, \quad (4.3)$$

where the "$+-$" sign and the subscript "1,2" in turn correspond to the interaction of the bonding and antibonding MOs. The three bonding π-MOs only are drawn in Fig. 7. It is seen that the MO belonging to a_1 symmetry has no node and more stabilization for the bonding MO, and more destabilization for the antibonding MO. The relative energy levels are shown in the middle of Fig. 6. The three lone-pair electrons from the X_3 fragment will occupy three bonding π-MOs of the M_3X_3 cluster. Hence, the six π-electrons in the non-planar ring skeleton M_3X_3 (X = O, S) will fit the Hückel rule ($4n+2$). However, the order of the relative energy levels for antibonding π-MOs in the M_3X_3 (X = Cl, Br) cluster change between e and a_1 symmetry, and the eight π-electrons (two addtional π-electrons from M_3) in the M_3X_3 (X = Cl, Br) cluster will occupy four MOs and the Hückel rule will break down. The components of the occupied bonding π-MOs of the $[Mo_3X_3]^{6+}$, $[Mo_3X_4]^{4+}$ (X = O, S) and the $[Mo_3X_3]^{7+}$, $[Mo_3X_3O]^{5+}$ (X = Cl, Br) clusters are listed in Table 2.

Relation between the d–p *and* d–d *interactions*

It is believed that the principal bonding interaction between transition metal atoms in cluster

compounds is due to the metal d-electrons and the d-orbital overlaps.[21,22] Thus, the direct interaction between the M—M atoms is mostly contributed from the typical d-mixing orbitals, h_2^i or h_3^i, in ICTMCTC compounds. The Mulliken overlap populations between $h_2^i-h_2^j$ or $h_3^i-h_3^j$ for some species are listed in Table 3, and the above mentioned conclusion is supported by these populations. For instance, the $h_2^i-h_2^j$ (or $h_3^i-h_3^j$) populations, acting as a M—M σ-interaction, are far larger than the $h_1^i-h_1^j$ populations in ICTMCTC compounds containing six valence electrons of the trimetal atomic skeleton $[Mo_3]^{12+}$. It is understood that the $h_1^i-h_1^j$ interaction, acting as a d–d π-role, gives some contribution to the d–d bonding interactions, especially in the species with strong M—M bonding, like $[Mo_3X_3O]^{5+}$ (X = Cl, Br), in which the Mulliken overlap populations between

$h_1^i-h_1^j$ (0.020) are comparable to $h_2^i-h_2^j$ (or $h_3^i-h_3^j$) (0.030), as shown in Table 3. It is seen that the *d–d* ($h_2^i-h_2^j$ plus $h_1^i-h_1^j$) overlap populations are, respectively, larger in $[Mo_3X_3O]^{5+}$ (X = Cl, 0.049; X = Br, 0.050) and $[Mo_3X_3]^{7+}$ (X = Cl, 0.041; X = Br, 0.041) than in $[Mo_3X_4]^{4+}$ (X = O, 0.028; X = S, 0.034) and $[Mo_3X_3]^{6+}$ (X = O, 0.028; X = S, 0.035), and that the *d–d* ($h_1^i-h_1^j$) π-interaction between the M—M atoms is an obvious contribution to the *d–d* interactions over M_3X_3 (X = Cl, Br); however, the *d–d* π-interaction between the M—M atoms is a negligible contribution to the *d–d* interactions over M_3X_3 (X = O, S), by virtue of the Mulliken population analyses. This means that the M—M transannular interactions[23] are greater in M_3X_3 (X = Cl, Br) than in M_3X_3 (X = O, S), and this is also one reason why the M—M bond is stronger in ICTMCTC compounds containing M_3X_3 (X = Cl, Br) than in those containing M_3X_3 (X = O, S) ring skeletons.

There are two cases which contain the *d–p* π-conjugate interaction over the M_3X_3 non-planar ring skeleton, one has six valence electrons in the trimetal atom $[M_3]^{12+}$ cluster and the π-electrons over M_3X_3 (X = O, S) are contributed by the three lone-pair electrons in the X_3 fragment, the other one has eight valence electrons in the trimetal $[M_3]^{10+}$ cluster and the π-electrons over M_3X_3 (X = Cl, Br) are contributed by both the three lone-pair electrons in the X_3 fragment and the two electrons in the trimetal atom skeleton. The earlier case has six π-electrons over the M_3X_3 (X = O, S) cluster and fits the Hückel rule, whilst the latter case has eight π-electrons over the M_3X_3 (X = Cl, Br) cluster and reduces the *d–p* π-conjugate interaction over M_3X_3. In the $[M_3]^{10+}$ system, the eight π-electrons over M_3X_3 will occupy four π-MOs. The highest occupied π-MO, $2a_1$ in $[Mo_3X_3O]^{5+}$ (X = Cl, Br), as shown in Table 2, mainly consists of the three h_1 orbitals of the Mo_3 fragment and the p_y orbitals of the X_3 (X = Cl, Br) fragment. The $h_1^i-h_1^j$ (*d–d* π) interactions between the M—M atoms over M_3X_3 (X = Cl, Br) are bonding and contribute to *d–d* stabilization interactions in the $2a_1$ π-MO, however, the h_1–p_y (*d–p* π) interactions are antibonding, according to the contributions of the π-orbital characters shown in Table 2. The $2a_1$ π-MO is important in balancing *d–p* π-conjugate and *d–d* direct interaction over M_3X_3 (X = Cl, Br). It is also found, from the overlap populations (index of bond strength[24]) listed in Table 3, that the *d–p* π-conjugate interaction over the $[Mo_3S_3]^{6+}$ or $[Mo_3S_4]^{4+}$ species is stronger than over the $[Mo_3O_3]^{6+}$ or $[Mo_3O_4]^{4+}$ species; however, the *d–d* interactions between the M—M atoms are weaker over $[Mo_3S_3]^{6+}$ or $[Mo_3S_4]^{4+}$. The π-MOs belonging to the *e* irreducible representation have an important role in the balance between the *d–p* π- and *d–d* π-interactions over M_3X_3 (X = O, S). As shown in Fig. 4(a) and Table 2, the interactions between the $h_1^i-h_1^j$ orbitals (*d–d* π) are antibonding over the cross ring M_3, and the interactions between the h_1–p_y orbitals are bonding over the non-planar ring skeleton M_3X_3 in the MOs of *e* symmetry. In other words, the more contribution from the h_1 and p_y orbitals, the more stable is the *d–p* π-conjugate interaction over the M_3X_3 (X = O, S) non-planar ring skeleton; however, the *d–d* π-interaction between the M—M atoms over M_3X_3 in the MOs of *e* symmetry is less stable according to the orbital components of Table 2.

Conclusions

There are two different interactions between M—M and M—μ_2-X atoms in ICTMCTC compounds. It is seen from the bonding model that one interaction is due to the fact that the highest occupied π-MOs (*e* symmetry) consist of the in-phase overlaps among *d–p* π-orbitals over M_3X_3 (X = O, S) and the out-of-phase overlaps among the *d–d* π-orbitals over M_3, and that another interaction is because the highest occupied π-MO (a_1 symmetry) consists of the in-phase overlaps among the *d–d* π-orbitals over M_3 and the out-of-phase overlaps among the *d–p* π-orbitals over M_3X_3 (X = Cl, Br). It has also been shown that the π-conjugate interaction among metal and bridging ligand atoms is in competition with the M—M interaction, and that either M—M bonds or M—μ_2-X bonds are broken down in the two limiting cases in ICTMCTC compounds.

COMPUTATIONAL DETAILS

The calculations were based on the SCCC–EH MO method with weighted H_{ij}'s developed by Hoffmann *et al.*[25,26] There are nine VSIE(Q) functions for valence orbitals in transition metal atom in the calculations. The standard of convergence is 0.002 on the iterative procedure. All the atom and charge iteration parameters used in the calculations were taken from the default values of the program ICON8,[26] except those of the Mo, W and Br atoms. All the geometric parameters were taken from the crystal structural data[2,5–8] and idealized to C_{3v} symmetry, the $[M_3X_{4-n}Y_n]^c$ core or $[M_3X_3]^c$ ring conformations in the calculations were the same as those of the core or ring in cluster compound $[M_3X_{4-n}Y_nL_9]^c$ (M = Mo, W; X = O, S, Cl, Br; Y = O, S; L = terminal ligand; n = 1,0; c =

charge). The atomic parameters of Mo and W were taken from ref. 27. The charge iteration parameters of W atom were the same as those of the Mo atom and taken from ref. 28. The parameters for the valence 4*s* and 4*p* orbitals in the Br atom are as follows: orbital exponents are both 2.127 and the Coulomb integral is −24.1 eV and −12.5 eV respectively; the iterative parameter A, B, C is individually 0.0, 9.86, 23.79 for the 4*s* orbital and is individually 0.0, 9.86 and 11.84 for the 4*p* orbital.

The data presented here under the local coordinate is transformed from the calculated results by the ICON8 program. The subset (x^2-y^2, z^2, xz) of the *d* orbital set of atom 2 (as shown in Fig. 1) is transformed under C_{3v} symmetry

$$\begin{pmatrix} x^2-y^2 \\ z^2 \\ xz \end{pmatrix} = \begin{pmatrix} 5/8 & (3)^{1/2}3/8 & (3)^{1/2}/4 \\ (3)^{1/2}3/8 & -1/8 & -3/4 \\ -(3)^{1/2}/4 & 3/4 & -1/2 \end{pmatrix} \begin{pmatrix} x^2-y^2 \\ z^2 \\ xz \end{pmatrix}'$$

where the prime indicates the orbitals used in the calculations by the ICON8 program. The overlap population between the atomic orbitals under the local coordinate is given

$$\begin{aligned} P_{\mu\lambda} &= 2\sum_i C_{\mu i}C^*_{\lambda i}S_{\mu\lambda} \\ &= 2\sum_{i,t} T_{\mu_t i}C_{\mu_t i}C^*_{\lambda_i}\sum_l T_{\mu_l i}S_{\mu_l\lambda} \\ &= \sum_t (T_{\mu_t})^2 P_{\mu_t\lambda} + \sum_t [(P_{\mu_t\lambda}T_{\mu_t})/S_{\mu_t\lambda}] \sum_{l\neq t} (T_{\mu_l\lambda}S_{\mu_l\lambda}), \end{aligned}$$

where T_{μ_t} is the transformation coefficient, and $P_{\mu_t\lambda}$ and $S_{\mu_t\lambda}$ are, respectively, the overlap population and overlap integral from the calculated results using the ICON8 program. It must be noted that the coordinate orientation of the λth atom is selected to be the same as that of the molecular coordinate system in this formula. The overlap population between the mixing orbitals are transformed from $P_{\mu\lambda}$ and listed in Table 3.

REACTIONS OF SULPHUR DIOXIDE WITH PALLADIUM(II) COMPLEXES

FATIMA T. ESMADI* and MAHMOUD K. DOHAIDEL

Department of Chemistry, Yarmouk University, Irbid, Jordan

(*Received* 20 *November* 1989; *accepted* 14 *February* 1990)

Abstract—The reactions of sulphur dioxide with the salt K_2PdCl_4 and the anion $[HPd(CO)Cl_2]^-$ are described. The complexes were isolated either as salts of Ph_4As^+ and Ph_4P^+ cations or as complexes of neutral nitrogen donor ligands (L—L). The ligands used were bidentate or tridentate ligands such as 2,2′-bipyridine (bipy), 1,10-phenanthroline (phen), *o*-phenylenediamine (*o*-phen) and 2,2′ : 6,2″-terpyridine (terpy). Reaction of sulphur dioxide with K_2PdCl_4 in aqueous ethanol gave an ethoxysulphonyl dinuclear palladium anion, $[PdCl_2(SO_3C_2H_5)]_2^{2-}$, which reacted with nitrogen donor ligands giving the previously known palladium complexes, $Pd(L—L)Cl_2$. If sulphur dioxide was allowed to react with $Pd(L—L)Cl_2$ complexes suspended in aqueous ethanol, sulphato complexes of the formula $[Pd(L—L)SO_4]\cdot H_2O$ were obtained. Reaction of sulphur dioxide with a solution of the anion $[HPd(CO)Cl_2]^-$ and then addition of nitrogen donor ligands, led to the formation of sulphur dioxide complexes.

Due to the increased interest in sulphur dioxide as one of the major pollutants, many reports have appeared lately concerning its reactions with different species. It was found that SO_2 has variable coordination geometries and therefore the chemistry of SO_2 as a coordinating group became a fascinating topic worthy of study. Reviews[1,2] appeared that relate the coordination mode of SO_2 to the electronic characteristics of the parent molecule and correlate its bonding mode to its IR stretching frequencies.

Sulphur dioxide complexes are usually synthesized by reaction of SO_2 with metal salts, or by displacement of some labile groups from a complex or by addition to a coordinating unsaturated complex. Metal halocarbonyls were used as starting materials for preparation of many different complexes including SO_2 complexes. It is found that SO_2 can replace CO, as in the case of $(M(CO)_2Cl_2)^-$ (M = Rh, Ir), which reacts with SO_2 to produce SO_2 complexes.[3] Platinum carbonyl clusters were found to react with SO_2 to produce Pt—SO_2 clusters,[4] such as $[Pt_4(\mu\text{-}CO)_5(PMe_2Ph)_4]$, which produces $[Pt(\mu\text{-}SO_2)_3(PMe_2Ph)]$ upon reaction with SO_2, although in some reactions SO_2 can be replaced by CO.[5]

In spite of the large number of transition metal–SO_2 complexes which were synthesized and characterized, those of palladium and platinum are relatively few. The known Pd— and Pt—SO_2 complexes are mostly those of monodentate[3–5] or polydentate[6] phosphorus donor ligands and some are known that contain arsenic donor ligands.[7] $PdCl_2$ and $PtCl_2$ suspended in alcohol have been found to react with SO_2 to produce dinuclear complexes of the formula $[M_2Cl_4(SO_2OR)_2]^{2-}$ (M = Pd, Pt and R = Me, Et, *n*-Pr).[8] It is proposed that these dinuclear complexes are formed by insertion of SO_2 into a Pd—OR species present in solution. Pt— and Pd—SO_2 complexes containing nitrogen donor ligands are rare and we therefore tried to synthesize and characterize some of them. The complexes obtained depend upon reaction conditions. Pd–SO_2 complexes were obtained from reaction of SO_2 with the $[HPd(CO)Cl_2]^-$ anion, but sulphate complexes were obtained when SO_2 was reacted with $Pd(L—L)Cl_2$ complexes, and an ethoxysulphonyl complex was obtained upon reacting SO_2 with K_2PdCl_4 in aqueous ethanol.

EXPERIMENTAL

Sulphur dioxide was purchased from Matheson Division, dried over sulphuric acid and used without further purification. All solvents used were analytical reagent grade and were used as purchased. K_2PdCl_4 (Aldrich), terpyridine, 2,2′-bipyridine (Lancaster) and 1,10-phenanthrolinre (Aldrich) were purchased commercially and used as received. *o*-Phenylenediamine was purchased from Aldrich and crystallized from benzene before use.

$[HPd(CO)Cl_2]^-$ and $(C_6H_5CN)_2PdCl_2$ were prepared according to the methods described in the literature.[9,10]

Analyses for carbon, hydrogen, nitrogen, chlorine and sulphur were carried out by M-H-W Laboratories, Phoenix, Arizona, U.S.A. The IR spectra were recorded over the range 4000–200 cm^{-1}, on a Pye Unicam SP3-300 IR spectrophotometer using KBr and CsI pellets. ^1H NMR spectra were recorded on a Brucker WP 80Y instrument using d_6-dimethylsulphoxide as solvent. Conductivity measurements were carried out using 10^{-3} (M solutions in dimethylsulphoxide with a Harris conductivity meter. Melting points were measured on an electrothermal melting point apparatus and were not corrected.

Preparation of complexes

$[Ph_4E]_2[Pd_2Cl_4(SO_3C_2H_5)_2]$ (E = As, P). The complexes were prepared by the following two methods:

(a) K_2PdCl_4 (1 mmol) was dissolved in 20 cm^3 of water–ethanol (1 : 1 v/v) and then SO_2 was passed through it for 4 h when the colour changed to orange–red. Ph_4AsCl or Ph_4PCl (2 mmol) in 5 cm^3 of ethanol was added to the solution with stirring and the mixture was allowed to stand at 5°C overnight; orange crystals were formed in the case of the Ph_4P^+ salt and orange–brown crystals in the case of the Ph_4As^+ salt. The crystals were isolated by filtration, washed with ethanol, then diethyl ether and dried *in vacuo* at room temperture. The yield was 60–65%.

(b) The same procedure as described in (a) except $Pd(C_6H_5CN)_2Cl_2$ (1 mmol) dissolved in 15 cm^3 ethanol was used instead of K_2PdCl_4.

$[Pd(L—L)SO_4]\cdot H_2O$ (L—L = *phen*, o-*phen*, *bipy*). K_2PdCl_4 (1 mmol) was dissolved in 20 cm^3 of ethanol–water (1 : 1 v/v) and then a solution of the ligand (L—L) (1 mmol) dissolved in 5 cm^3 of ethanol was added to it with stirring. A yellow precipitate was formed immediately. Sulphur dioxide was passed through the suspension which dissolved and its colour faded. The solution was left at 5°C overnight when a yellow precipitate was formed. This was filtered, washed with ethanol then diethyl ether and dried *in vacuo* at room temperature. The yield was 60–70%.

$[Pd(phen)(SO_2)Cl]Cl$ *and* $[Pd(terpy)(SO_2)]Cl_2$. Sulphur dioxide was passed through the yellow solution containing $[HPd(CO)Cl_2]^-$ (1 mmol), which was prepared as reported in the literature.[9] The colour changed immediately from yellow to dark red. A solution of the ligand (1 mmol) dissolved in ethanol (10 cm^3) was added to the dark red solution and immediate formation of a precipitate was observed. The precipitate was isolated by filtration, washed with ethanol and diethyl ether and finally dried *in vacuo* at room temperature. The yield was 55–60%.

The analytical data for the obtained complexes along with their colour, melting points and molar conductivity are listed in Table 1. The important IR absorption bands and ^1H NMR data for the alkoxysulphonyl complexes are listed in Table 2.

RESULTS AND DISCUSSION

Reaction of SO_2 *with* K_2PdCl_4

Upon bubbling SO_2 through a solution of K_2PdCl_4 in ethanol–water, a red solution containing the anion $[Pd_2Cl_4(SO_2OC_2H_5)_2]^{2-}$ is formed. This anion was precipitated by addition of Ph_4AsCl or Ph_4PCl. Dinuclear ethoxysulphonyl palladium complexes were formulated on the basis of their IR and NMR spectra. IR spectra exhibit the absorption bands characteristic of the ethoxysulphonyl group [$\nu(S{=}O)_{asym}$ falls in the range 1266–1270 cm^{-1}, $\delta(S{=}O)_{sym}$ in the range 1108–1110 cm^{-1}, $\nu(S—O)$ in the range 905–908 cm^{-1} and $\delta(O—S—O)$ in the range 598–600 cm^{-1}]. There are also IR bands that are attributed to both bridging and terminal Pd—Cl bonds [$\nu(Pd—Cl)$ in the range 285–287, 350 and 265–270 cm^{-1}]. The absorption band occurring at lowest frequency is due to the bridging chloride, whereas the other two absorption bands are due to the terminal chlorides.[11]

The ^1H NMR spectra of the ethoxysulphonyl complexes obtained show absorptions due to the $—SO_2OC_2H_5$ group in agreement with the reported values for organic sulphonates. The band which falls in the range 4.09–4.10(q) is due to $—CH_2$ protons and the band which falls in the range 1.14–1.15(t) is due to $—CH_3$ protons. The α-proton chemical shifts are moved to a higher field relative to the free alcohol.[12]

[a] m is melting point; d is decomposition point.
[b] Λ_m stands for molar conductance in Ω^{-1} mol^{-1} cm^2 of 10^{-3} M solutions in dimethylsulphoxide at 25°C.

Conductivity measurements in dimethylsulphoxide show that the salts obtained are 2:1 electrolytes (Λ_m falls in the range 104–109 Ω^{-1} cm^2 mol^{-1}).

Reaction of this dinuclear ethoxysulphonyl anion with neutral nitrogen donor ligands resulted in the formation of the known complexes of the general formula Pd(L—L)Cl_2, where L—L = *o*-phen, phen, bipy.[13–16] It seems that the ethoxysulphonyl group is easily displaced by other ligands.

The anion $[Pd_2Cl_4(SO_2OR)_2]^{2-}$, were R = Me, Et, *n*-Pr, was reported by Ros *et al.*[8] to be formed by reaction of SO_2 with a suspension of $PdCl_2$ in alcohol for a long period of time. The formation of this anion was explained mainly as a result of SO_2 insertion into a postulated palladium alkoxide intermediate (>Pd—OR). Another possibility for the formation of this dinuclear complex is by an attack of an alkoxide group at a coordinated SO_2. A third possibility could be the formation of a monoester of sulphurous acid (RSO_3H group) in

alcoholic solution by reaction of SO_2 with ROH ($SO_2 + ROH \rightleftharpoons RSO_3H$)[17] and then coordination of this group to palladium.

Stable complexes containing the —SO_2OR group bonded to the metal were reported previously to be formed by reaction of $(Ph_3P)_2M(NCO)_2$ (M = Pd, Pt) with SO_2 in methanol, and the products were of the formula $(Ph_3P)_2M(SO_3Me)$.[18]

Reaction of SO_2 *with* Pd(L—L)Cl_2 (L—L = *phen, bipy,* o-*phen*)

Addition of the ligand (L—L) to K_2PdCl_4 in a 1:1 molar ratio results in the formation of complexes of the formula Pd(L—L)Cl_2.[13–16] Pd(L—L)Cl_2 complexes were prepared and while still suspended in solvent, SO_2 was allowed to pass through them. The resulted compounds were of the formula $[Pd(L—L)SO_4] \cdot H_2O$.

IR spectra of these complexes show four strong bands which fall in the following ranges 1215–1240, 1110–1148, 946–990; 870–880; 820–840 and 640–654 cm^{-1} which are in accord with the symmetry of the SO_4 group acting as a bidentate ligand (C_{2v})[19] and is in reasonable agreement with the spectrum reported by Barraclough and Tobe[20] for the complex $[Co(en)_2SO_4]Br$. It is observed that the highest frequency band is split into three.[21] The IR spectra of the isolated sulphato complexes also exhibit absorption bands due to lattice water [ν(O—H) falls in the range 3430–3450 cm^{-1} and δ(H—O—H) in the range 1620–1630 cm^{-1}].

Conductivity measurements of the sulphato complexes indicated that they are non-electrolytes (Table 1).

Formation of sulphate by oxidation of SO_2 is known and many examples are reported where the molecular oxygen complexes have been found to react with SO_2 to form coordinated sulphate.[19,22] Some SO_2 complexes are also found to react with O_2 to give sulphato complexes. The complexes $M(SO_2)(PPh_3)_2$ (M = Pd, Pt) have been found to undergo oxidation forming $M(SO_4)(PPh_3)_2$.[6] Many other transition metal–SO_2 complexes were also found to form sulphato complexes upon exposure to air.[23–25]

Reaction of SO_2 *with* $[HPd(CO)Cl_2]^-$

As SO_2 was allowed to pass through the yellow solution of $[HPd(CO)Cl_2]^-$ an immediate colour change was observed. Addition of Ph_4AsCl to the resulting solution gave a solid which was not easy to characterize but the addition of neutral ligands such as phen or terpy resulted in the formation of SO_2 complexes which are formulated as $[Pd(SO_2)(terpy)]Cl_2$ and $[Pd(SO_2)(phen)Cl]Cl$. Both compounds are water-soluble and conductivity measurements prove that they are ionic (Table 1).

IR spectra of both compounds exhibit the characteristic bands of SO_2 [$\nu(SO_2)_{asym}$ falls in the range 1200–1210 cm^{-1}, $\nu(SO_2)_{sym}$ in the range 1050–1060 cm^{-1} and δ(O—S—O) in the range 590–595 cm^{-1}]. These values are shifted to lower frequencies relative to free SO_2.

From comparison with other Pd—SO_2 complexes,[2] it is concluded that SO_2 is bonded in the η^1-pyramidal mode. Most of the reported Pd— and Pt—SO_2 complexes have η^1-pyramidal SO_2 which is commonly associated with the more basic transition metals.[1,2]

Reaction of SO_2 with K_2PtCl_4 has been tried and the results are found to be different from the K_2PdCl_4 reactions. The results of the reactions of SO_2 with the K_2PtCl_4 system will be reported as soon as they are complete.

(*Received* 16 *January* 1990; *accepted* 19 *February* 1990)

Abstract—A novel ligand, 3-[(2-hydroxy-5-chlorophenylamino)methoxy]methylchromone, Hbpcap, was obtained by reacting 4-oxo-4H-benzopyran-3-carboxyaldehyde, bpa, and 2-amino-4-chlorophenol, cap, in methanol. Elemental analysis and vibrational and NMR spectra revealed that Hbpcap is a cathecolamine derivative of bpa. Complexes, of general formula $Ln(bpcap)_2X \cdot nH_2O$ ($Ln^{3+} = Eu^{3+}$ and $n = 2$; $Ln^{3+} = Tb^{3+}$ and $n = 1$; $X^- = NO_3^+$, Cl^-, ClO_4^-), were isolated and characterized. Unlike the bpa complexes with Eu^{3+} and Tb^{3+}, they did not exhibit ionic emission due to the excitation of the ligand. In order to explain this behaviour, the ligand excited states have been examined.

Luminescent lanthanide complexes are presently the focus of attention in many laboratories, mainly because of their possible applications in bioinorganic chemistry.[2] For this purpose, it is necessary to bind Eu^{3+} or Tb^{3+} with chromophoric ligands, i.e. ligands able to absorb energy by radiation and then to transfer it effectively to the cation. Recently, we observed that pyrone ligands often fulfil these requirements. A promising ligand seemed to be bpa;[1a] but its lanthanide(III) complexes are not stable enough to allow future biological applications. An easy way to increase the stability of this type of complex could be the use of Schiff base derivatives of bpa as ligands. In order to verify the reliability of this strategy, we investigated the complexing and chromophoric properties of the novel ligand Hbpcap (see Scheme 1), obtained by condensing bpa and cap in methanol.

EXPERIMENTAL

Physicochemical measurements

Electronic absorption spectra were recorded with a Varian Cary spectrophotometer; the solid-state spectra were obtained by pasting the samples with Nujol and spreading them on strips of filter paper. Electronic emission and excitation spectra were recorded with an Aminco-Bauman MPF spectrophotofluorimeter. IR spectra were obtained with a 1130 Perkin–Elmer spectrophotometer as Nujol mulls. Conductometric measurements were carried out at 25 ± 0.1°C, on 6×10^{-5}–2×10^{-4} M solutions, in DMF, using a Radiometer CDM 80 conductometer, equipped with a Radiometer CDC

104 conductivity cell. NMR spectra were obtained with a Bruker WP80SY spectrometer.

Syntheses

The lanthanide salts were prepared as previously described;[3] bpa was prepared by literature methods;[4] cap was obtained from Fluka.

3-[(2-*Hydroxy*-5-*chlorophenylamino)methoxy*] *methylchromone*. 2-Amino-4-chlorophenol (6 mmol) was dissolved in 100 cm^3 of MeOH, and added to a solution of bpa (6 mmol) in 200 cm^3 of MeOH. This solution was stirred at room temperature, until a yellow solid began to separate; this mixture was filtered, after a period of 12 h, and Hbpcap was obtained in 70% yield. Decomposition point 215–218°C. Another less pure fraction of Hbpcap was obtained by evaporating the mother solution.

Complexes. 3-[(2-Hydroxy-5-chlorophenylamino) methoxy]methylchromone (3 mmol) and 3 mmol of LiOH were dissolved in 30 cm^3 of boiling MeOH. By adding a solution of 1.5 mmol of LnX_3 ($Ln^{3+} = Eu^{3+}$, Tb^{3+}; $X^- = NO_3^-$, Cl^-, ClO_4^-), an orange solid separated. The suspension thus obtained was refluxed for 1 h, stirred at room temperature for 12 h, and centrifuged. The solid product was washed with $CHCl_3$, MeOH and H_2O, and dried at room temperature and 0.5 mm Hg for 3 h.

Analytical and conductometric data are reported in Table 1.

RESULTS AND DISCUSSION

The bpa molecule has two electrophilic sites able to react with amino groups, i.e. the formyl function and the carbon in the two-position on the pyrone ring.[5] Aromatic 1,2-diamines are known to react with bpa, interacting first with the formyl group

Table 1. Elemental analyses and conductometric data

Compound	Found (calc.) (%)			Λ_M[a]
	C	H	N	
Hbpcap	61.0(61.5)	4.3(4.2)	4.3(4.2)	
$Eu(bpcap)_2NO_3 \cdot 2H_2O$	45.2(44.8)	3.5(3.3)	4.9(4.6)	68.3
$Eu(bpcap)_2Cl \cdot 2H_2O$	46.4(46.1)	3.3(3.4)	3.3(3.2)	79.2
$Eu(bpcap)_2ClO_4 \cdot 2H_2O$	43.4(43.0)	2.9(3.2)	3.2(2.9)	102.5
$Tb(bpcap)_2NO_3 \cdot H_2O$	45.4(45.3)	3.2(3.1)	4.9(4.7)	66.9
$Tb(bpcap)_2Cl \cdot H_2O$	46.8(46.7)	2.9(3.2)	3.3(3.2)	72.4
$Tb(bpcap)_2ClO_4 \cdot H_2O$	43.6(43.5)	3.1(3.0)	3.2(3.0)	90.4

[a] $\Omega^{-1}\,cm^2\,mol^{-1}$, in DMF.

and then with the two-position of the pyrone ring, to give benzodiazepines.[6] Only a few amines react with the formyl group of bpa without interacting with the two-position of the pyrone ring; examples of this include hydrazone, oxime, semicarbazone, etc.[7] In the present work, cap was selected as the reacting amine, because of the following properties: (i) its nucleophilicity is presumably low and (ii) the hydroxyl oxygen atom is a potentially good donor for lanthanide cations but interaction with bpa would not be probable. The expected product of the condensation between bpa and cap was molecule **I** (see Scheme 1). However, characterization of the isolated product indicates that it is better formulated as molecule **II** (see Scheme 1), which can be thought of as the methyl pseudo-hemiacetal of molecule **I**. Although this behaviour is uncommon in Schiff base compounds, a few similar cases have been reported.[8]

The formulation of Hbpcap as molecule **II** is based on the following experimental evidence. (i) The elemental analytical data indicate that the condensation product between bpa and cap implies a methanol molecule in the molecular formula. Of course this feature could be explained by the solvation of form **I**; however, form **II** is preferred, based on the spectroscopic evidence reported under points (ii) and (iii); moreover, ill-defined products are obtained by reacting bpa and cap in solvents other than methanol (acetonitrile, acetone, ethanol). (ii) In the ^{1}H NMR spectrum, in addition to the multiplets assignable to the aromatic and benzopyrone protons (6.96–7.25 and 7.45–8.25 ppm, respectively), which have no diagnostic value in discriminating between forms **I** and **II**, two signals at 5.8 and 3.3 ppm are present; these are not consistent with formulation **I**, while they can be assigned, respectively, to the pseudo-hemiacetal and the methoxyl protons of form **II**. Moreover, two other signals typical of acidic protons appear at 10.5 and 12.4 ppm; they can be assigned to the NH and OH protons of form **II**, while form **I** should show only one signal of an acidic proton strongly hydrogen bonded. (iii) Also, the IR spectral data may indicate that form **II** is preferred. The IR spectrum of bpa shows the following diagnostic stretchings: ν(CH=O) at 1700 cm^{-1}, ν(C=O, pyrone) at 1650 cm^{-1} and ν(C=C) at 1620 and 1560 cm^{-1}.[5] The IR spectrum of Hbpcap in addition to a broad OH and/or NH stretching band with transmission minimum at 3250 cm^{-1}, shows signals at 1640, 1600, 1580 and 1540 cm^{-1}; the first one is typical of a pyrone carbonyl stretching[9] and the other three should probably be assigned to C=C stretchings; an eventual C=N stretching, which should be present in the spectrum of compound **I** in the region 1613–1631 cm^{-1},[10] is absent, thus supporting formulation **II**.

Unfortunately, no Hbpcap crystals suitable for X-ray crystallographic studies were obtained, probably due to the instability of this molecule in solutions of the most common organic solvents (the initially yellow solution turns dark red after a few hours).

The complexes of Eu^{3+} and Tb^{3+} with Hbpcap were isolated as orange powders, and formulated as $Ln(bpcap)_2X \cdot nH_2O$ ($X^- = NO_3^-, Cl^-, ClO_4^-$; $n = 1$ for $Ln^{3+} = Tb^{3+}$; $n = 2$ for $Ln^{3+} = Eu^{3+}$; bpcap is the monodeprotonated form of the ligand Hbpcap), on the basis of the elemental analytical data. The water content, higher in the Eu^{3+} than in the Tb^{3+} complexes, could be indicative of the solution of continuity in the coordination number often observed in the lanthanide series at the Gd^{3+} level.[11]

All the complexes show very low solubility in the most common organic solvents (including DMSO and DMF). Their ionic conductivities in DMF indicate a 1:1 electrolyte behaviour.[12] (In effect, the ionic conductivities of the complexes containing ClO_4^- are slightly higher than the range commonly accepted for 1:1 electrolytes in DMF solution, 65–90 Ω^{-1} cm^2 mol^{-1}, but much lower than the range corresponding to 1:2 eletrolytes in the same solvent, 130–170 Ω^{-1} cm^2 mol^{-1}.)[12] From the ionic conductivity data, it can be seen that the freedom of the ionic pairs is higher for Eu^{3+} than for Tb^{3+} complexes (the inorganic anion being the same), according to the lower polarizing behaviour of Eu^{3+} compared with Tb^{3+}. Within each series of complexes (i.e. Eu^{3+} and Tb^{3+} complexes) the conductivity depends on the inorganic anion, being the highest in the case of ClO_4^- and the lowest for NO_3^-. This agrees with the observation that NO_3^- is a better ligand towards La^{3+} than Cl^-, which is a better ligand than ClO_4^-,[13] and appears more significant considering the different ionic equivalent conductivities of NO_3^-, Cl^- and ClO_4^- (71.5, 76.4 and 67.4 Ω^{-1} cm^2 mol^{-1}, respectively, in water at infinite dilution; it is probably not important to compare data from different solvents, because we are only interested in the differences between these values).

The IR spectra of all the complexes, superimposable in the double bond region, are similar to the Hbpcap spectrum. In addition to a ν(OH) band with two transmission minima at 3340 and 3190 cm^{-1}, they show signals at 1620, 1605, 1580 and 1545 cm^{-1}. The first of these bands can be assigned to the stretching of the pyrone carbonyl, shifted to lower frequencies with respect to the free ligand (1640 cm^{-1}) maybe because of a coordinative bond

with the cation. Similar shifts have been observed in other series of pyrone lanthanide complexes.[3] The frequencies of the other three signals are almost the same as those of the free ligand (1600, 1580 and 1540 cm^{-1}), as expected for bands due to vibration of bonds not directly involved in coordination to the metal. The complexes containing the ClO_4^- anion show the typical signals of the ionic perchlorate in *Td* symmetry (broad ν_3 at 1100 cm^{-1} and unsplit ν_4 at 620 cm^{-1},[14]) agreeing with the solution conductivity data. In the IR spectra of the nitrate-containing complexes, the expected NO_3^- bands are not clearly discernable from the other signals due to the organic moiety; therefore we cannot infer anything about the NO_3^- solid-state coordination to the metal.

In order to examine the chromophoric behaviour of Hbpcap towards Eu^{3+} and Tb^{3+}, we studied some of the excited state properties of the free ligand. Figure 1(a) shows the electronic absorption spectrum of Hbpcap in ethanol (λ_{max} at 209, 230(sh), 247, 267, 314(sh) and 397 nm, log ε 4.39, 3.96, 3.98, 3.88, 3.51 and 4.38, respectively). The high intensity of all the bands and the fact that they are red-shifted by the addition of water to the solution (and thus increasing the polarity of the solvent) indicate their π^*–π or charge-transfer character.[15] It is worthwhile to compare this spectrum with those of the parent compounds, bpa* (λ_{max} at 300, 294(sh) and 310(sh) nm, log ε 3.98, 3.96 and 3.89, respectively) and cap (λ_{max} at 206, 291 and 327(sh) nm, log ε 3.91, 3.50 and 3.16, respectively) which are shown in Figs 1(b) and (c). It can be seen that the intense band of Hbpcap at low energy is absent in the spectra of bpa and cap. This is probably indicative of the charge-transfer nature of this absorption.

The solid-state electronic absorption spectrum of Hbpcap [Fig. 2(a)] is different from that in solution, especially in the region at low energy, where a broad, very intense band with maximum at 432 nm and shoulders at 400 and 454 nm are present. This difference is difficult to explain with certainty, but if the charge-transfer nature of this transition is admitted, it may well be an effect due to the surroundings.

The electronic absorption spectra of all the complexes are identical, and those in DMF solution slightly differ from those in the solid state. In fact the main band at low energy is found at 412 nm in DMF solution and at 392 nm in the solid state. This

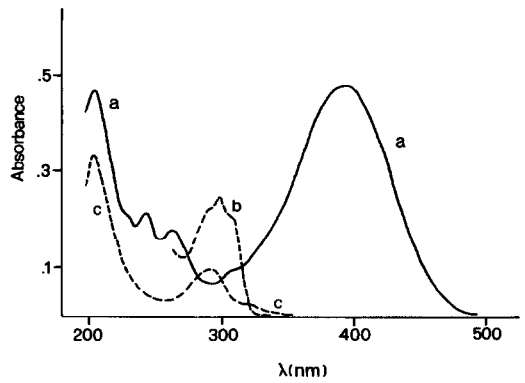

Fig. 1. Electronic absorption spectra of: (a) Hbpcap in EtOH; (b) bpa in CCl_4; (c) cap in EtOH.

indicates the instability of the complexes in solution and agrees with the conductometric data reported above. The solid-state spectrum of $Eu(bpcap)_2Cl \cdot 2H_2O$ [reported as an example in Fig. 2(b)] is different from that of solid Hbpcap: as a consequence of the deprotonation and/or the coordination of the ligand to the metal, in the spectra of the complexes all the bands at high frequencies which correlate with those of the free ligand are shifted to higher energies (from 217 to 216 nm, from 250 to 244 nm, and from 320 to 292 nm) and the shoulders at 268 and 284 nm disappear; moreover, the low energy charge-transfer band of the ligand changes its pattern considerably and appears less intense, with respect to the higher energy bands.

By exciting the complexes in the 350–450 region in DMF solution, no luminescence was observed. Although this may be due to many factors (non-radiative decay of the excited states of the cations via multiphonon-like processes,[16] dissociation of the complexes in solution,[17] etc.) there are two features that probably play the most important roles:

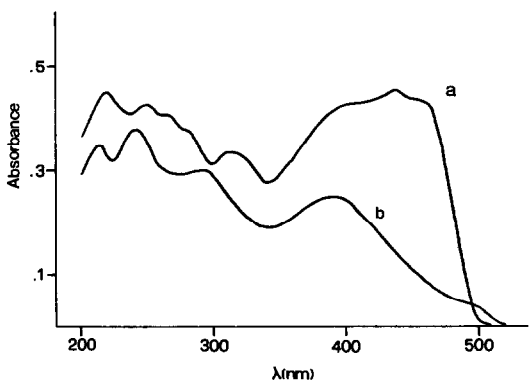

Fig. 2. Solid-state electronic absorption spectra of: (a) Hbpcap; (b) $Eu(bpcap)_2Cl \cdot 2H_2O$.

* The electron absorption spectrum of bpa is reported in CCl_4 instead of EtOH, because bpa in alcoholic solvents is in equilibrium with its hemiacetal and acetal (see ref. 1a).

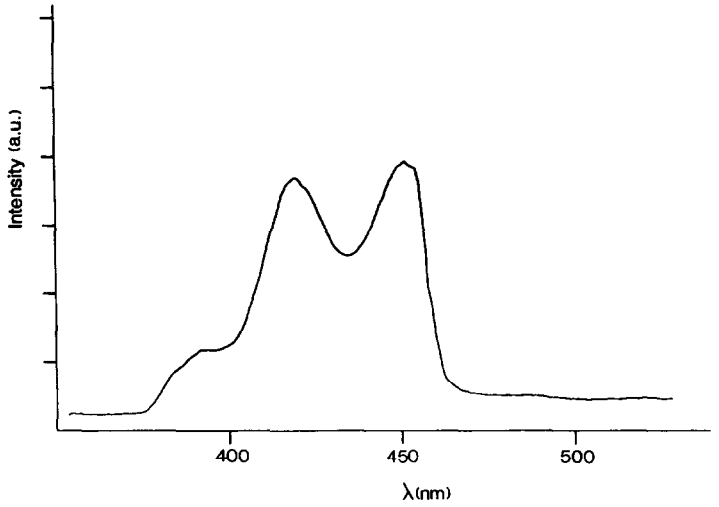

Fig. 3. Phosphorescence emission spectra of bpa in an epa mixture (ether, pentane, ethanol) at liquid nitrogen temperature (λ_{ex} = 300 nm).

(i) the energy of the ligand excited states, and (ii) the kinetics of their decays to the ground state.

(i) The phosphorescence emission spectrum of bpa in a glass of epa (ether, pentane, ethanol) at liquid nitrogen temperature is shown in Fig. 3. It shows a structured band with three maxima at 392, 420 and 452 nm. From this spectrum, it is possible to assign a value of about 26,700 cm^{-1} to the bpa triplet energy, which is high enough to populate the excited states of Eu^{3+} and Tb^{3+} (17,277 and 20,500 cm^{-1}, respectively[16]), which are not very much affected by the surrounding. Also as the coordinative bonds with lanthanide cations have been shown to be considerably covalent,[18] the electronic transitions observable in Tb^{3+} and Eu^{3+} ions involve only the 4*f* electrons which do not participate, in a first approximation, to coordinative bond formation. Contrary to bpa, the free Hbpcap does not show phosphorescence emission at liquid nitrogen temperature in a glass of epa; therefore, we do not know its triplet energy. Nevertheless, it is possible that the triplet energy of Hbpcap is too low to effectively populate the Eu^{3+} and Tb^{3+} excited states. In this regard, we can note that even the first singlet excited state of Hbpcap has too low an energy (20,400 cm^{-1}) to excite Tb^{3+}. Moreover, if the triplet-to-singlet stabilization energy of Hbpcap is of the same order as that of bpa (about 50 nm), it follows that the Hbpcap triplet energy probably drops to a value which is too low (about 18,500 cm^{-1}) to effectively excite Eu^{3+}.[1b]

(ii) Another less probable explanation for the lack of lanthanide emission in the Eu^{3+} and Tb^{3+} Hbpcap complexes could be the low yield of intersystem crossing between the first singlet excited state and the corresponding triplet state of Hbpcap. In fact, the lack of phosphorescence emission by Hbpcap, even at low temperatures, could indicate that the charge-transfer singlet excited state of this ligand is too short-lived to decay by intersystem crossing. Thus, also in the presence of a heavy atom, the yield of the ligand triplet population may be too low to give high populations of the Eu^{3+} and Tb^{3+} excited states.

CONCLUSIONS

As the chromophoric properties of bpa towards Eu^{3+} and Tb^{3+} are unavailable in the various fields of bioinorganic chemistry, because of the very low stability of the bpa complexes with these cations, we decided to transform bpa into its Schiff base. However, the Schiff base-like derivative reported here, Hbpcap, does not conserve the chromophoric behaviour of the parent aldehyde. This behaviour is probably a consequence of a low energy electronic charge-transfer absorption band, which is present in the Hbpcap spectrum, but which may not be present in other Schiff base derivatives of bpa. Thus, further studies are necessary, in order to establish if this type of functionalization can be effective in designing chromophoric ligands, based on the bpa structure, which could be of practical interest.

BIS[HYDROTRIS(PYRAZOLYL)BORATO]DICHLOROACTINIDE(IV) COMPLEXES: X-RAY CRYSTAL STRUCTURES OF $ThCl_2(HBPz_3)_2$ AND $UCl_2(HBPz_3)_2$

ÂNGELA DOMINGOS,* JOAQUIM MARÇALO, ISABEL SANTOS and A. PIRES DE MATOS

Departamento de Química, ICEN, LNETI, 2686 Sacavém Codex, Portugal

(*Received* 30 *November* 1989; *accepted* 27 *February* 1990)

Abstract—The crystal and molecular structures of $ThCl_2(HBPz_3)_2$ (**1**) and $UCl_2(HBPz_3)_2$ (**2**) have been determined by single-crystal X-ray diffraction. The crystals of **1** are orthorhombic, *Pbca*, $a = 14.406(2)$, $b = 18.523(3)$, $c = 18.947(4)$ Å, $V = 5055.9$ Å^3 and $Z = 8$. The crystals of **2** are triclinic, $P\bar{1}$, $a = 13.134(2)$, $b = 14.481(3)$, $c = 17.030(2)$ Å, $\alpha = 75.72(2)$, $\beta = 75.08(2)$, $\gamma = 68.20(2)°$, $V = 2864.3$ Å^3 and $Z = 4$. The actinide centre in both compounds is eight-coordinate and displays square antiprismatic geometry, distorted towards bicapped trigonal prismatic, with the thorium compound presenting a higher distortion relative to the uranium compound.

The tripodal ligands $(HBPz_3)^-$ and $[HB(3,5\text{-}Me_2Pz_3)]^-$ have been used in our laboratories as stabilizing ligands in the synthesis of organo compounds of thorium and uranium, giving stability to complexes through steric saturation. Using $AnCl_2(HBPz_3)_2$ and $AnCl_3[HB(3,5\text{-}Me_2Pz)_3](THF)$ (An = Th^{IV}, U^{IV}) as precursors, a large variety of derivatives namely alkyls, alkoxides, aryloxides, thiolates, amides and carboxylates, have been prepared.[1–7] For actinide complexes involving the $(HBPz_3)^-$ ligand, two compounds have already been structurally characterized, $UCl(OR)(HBPz_3)_2$ (R = Ph, Bu^t).[8] In both compounds the uranium centre is eight-coordinate displaying square antiprismatic geometries (SAP).

For the lanthanides (Ln) several eight-coordinate compounds of the type $Ln(HBPz_3)_2X$ (where X is a uninegative bidentate ligand) and $Ln(HBPz_3)_2ClL$ (where L = H_2O or PzH) have been structurally characterized.[9–15] The coordination geometries found for these complexes are predominantly SAP, although in a few cases bicapped trigonal prismatic geometries (BCTP) have been observed. The sizes of the metal atom and of the X ligand seem to be responsible for the differences found in the coordination geometries.

In order to obtain structural information on the complexes based on the $An(HBPz_3)_2^{2+}$ moiety and to ascertain if the different sizes of thorium and uranium atoms influence the coordination geometries of the complexes $AnCl_2(HBPz_3)_2$, we have undertaken the X-ray structural analyses of these compounds.

EXPERIMENTAL

The syntheses and characterization of **1** and **2** have been reported earlier.[2,16,17] Crystals suitable for X-ray diffraction were obtained by slow diffusion of *n*-pentane into saturated solutions of the compounds in CH_2Cl_2. The crystals were mounted in thin-walled glass capillaries in a nitrogen-filled glove box.

Data were collected at room temperature on a Enraf–Nonius CAD4 diffractometer with graphite-monochromated Mo-K_α radiation, using the ω–2θ scan mode, in the range $3.0 < 2\theta < 50°$. Unit cell parameters were determined from 25 reflections with $26 < 2\theta < 34°$. A summary of the crystal data and data collection and refinement is given in Table 1. Data were corrected for Lorentz-polarization, for absorption by empirical corrections based on ψ scans, and for linear decay using the Enraf–Nonius program. The structures were solved by Patterson and Fourier methods.[18] For **1** all the non-hydrogen atoms were refined anisotropically by full-matrix least-squares. For **2** all but the carbon atoms were

refined anisotropically by block full-matrix methods. The structural analysis of **2** revealed one CH_2Cl_2 molecule of crystallization in the unit cell, with high temperature factors and poorly localized. The contribution of the hydrogen atoms were included in calculated positions, constrained to ride on their carbon and boron atoms with group U_{iso} values assigned. Maximum and minimum heights in final difference Fourier maps were +1.99, −2.20 eÅ^{-3} and +2.43, −1.99 eÅ^{-3} for compounds **1** and **2**, respectively, close in both cases to the actinide atom.

Atomic scattering factors and anomalous dispersion terms were taken from *International Tables for X-ray Crystallography*.

Tables of final atomic positional and thermal parameters, full lists of bond lengths and angles, equations of mean-least-square planes, coordination polyhedron parameters and tables of F_o/F_c values have been deposited as supplementary material with the Editor.

DESCRIPTION OF THE STRUCTURES

In both compounds the crystal structures consist of discrete molecules in which the actinide atom is eight-coordinated by six nitrogens of the two tridentate ligands and by two chlorine atoms. The coordination geometries are described as SAP. The donor nitrogens of each pyrazolyl ligand occupy two triangular faces of the SAP while the chlorine atoms are in adjacent sites along a lateral edge.

The structure of the $ThCl_2(HBPz_3)_2$ is shown in Fig. 1, together with the atom numbering scheme. Figure 2 shows a view of the coordination polyhedron and Table 2 presents the normalized edge lengths. The values of the shape parameters for the normalized polyhedron,[19,20] namely the dihedral angles, δ, refered to the edges of the polyhedron and the ϕ values for the planarity of the two orthogonal trapezoids are presented in Table 3 along with the values for the three regular ML_8 polyhedra. Although these values compare satisfactorily with the values for the regular SAP geometry, there is a clear distortion. The face formed by Cl(1), N(3), N(1) and N(5) is approximately planar (root-mean-square deviation of 0.0021 Å) with δ values of 0.58° and diagonal distances of 1.69 Å, while the Cl(2) N(2) N(4) N(6) face is quite folded with δ values of 15.1 and 16.4° for the N(4)—Cl(2) and N(2)—N(6) diagonals, with lengths of 1.63 and 1.78 Å, respectively. The loss of the planarity of this face coupled

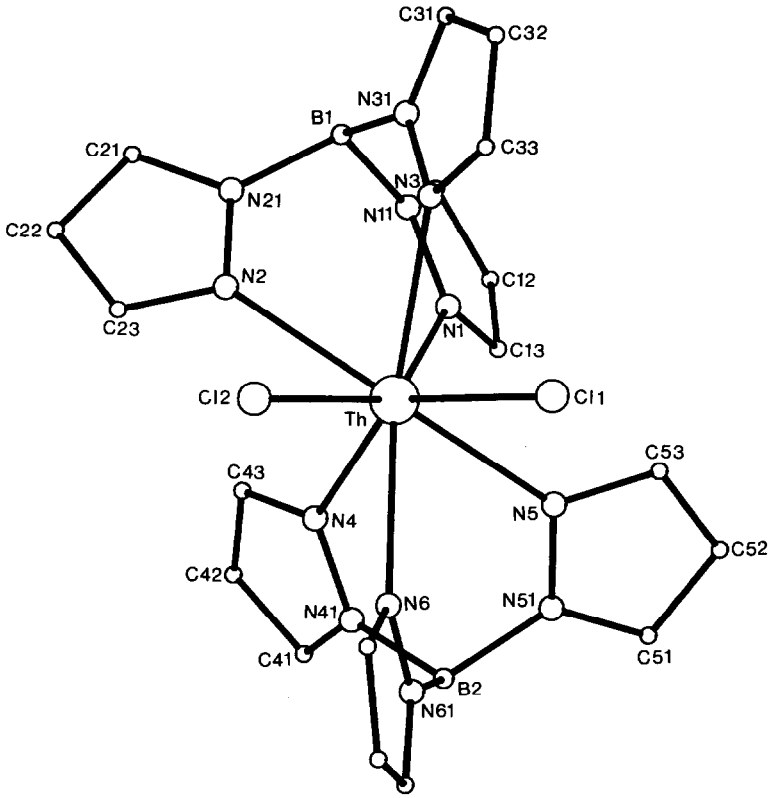

Fig. 1. PLUTO view of $ThCl_2(HBPz_3)_2$.

with the shortening of the N(4)—Cl(2) diagonal show that the distortion of the SAP is along the geometric pathway towards the BCTP.

Table 4 shows selected bond lengths and bond angles for **1**. The Th—N bond lengths range from 2.554(10) to 2.644(10) Å, with a mean value of 2.60(3) Å. The longest Th—N distance is the one opposite the chlorine atom on the planar square-face, while for the folded square-face the longest distances are those corresponding to the longer diagonal, which are, respectively, Th—N(2) and Th—N(6).

In the structure of $UCl_2(HBPz_3)_2 \cdot 0.5CH_2Cl_2$ there are two crystallographically independent mol-

ecules in the asymmetric unit. Figure 3 shows a view of the two molecules in the asymmetric unit, with the atom numbering scheme. The CH_2Cl_2 of crystallization does not interact with the uranium molecules and is not shown. In both molecules the coordination geometries around the uranium are best described as SAP as can be seen from the δ and ϕ values shown in Table 5. In molecule 1 (Fig. 4), one of the square-faces is nearly planar (root-mean-square deviation of 0.0064 Å) with a δ value of 1.8° and square diagonals of 1.67 and 1.68 Å, while the face Cl(2) N(3) N(4) N(5) with δ values of 5.9 and 6.1° is less planar (root-mean-square deviation of 0.0221 Å) and has diagonal distances of 1.67 and 1.72 Å. In molecule 2, one of the two square-faces is folded with δ values of 9.6 and 10.1° and diagonal distances of 1.63 and 1.72 Å, while the other remains planar (δ = 1.0° and diagonal distances of 1.69 Å). Both molecules are distorted SAP (Tables 5 and 6), giving the second molecule a greater distortion with considerable folding of one of its square-faces (δ = 10.1°).

Selected bond lengths and angles are presented in Table 7. Within three standard deviations, the two molecules have similar molecular dimensions. The U—N bond lengths range from 2.532(8) to 2.576(9) Å in molecule 1, and from 2.524(11) to 2.593(8) Å in molecule 2. The longest U—N distances are those opposite to the chlorine atoms in each square-face.

DISCUSSION

The An—Cl and An—N bond length differences between compounds **1** and **2** are consistent with the difference of 0.05 Å between the ionic radii of Th^{IV} and U^{IV} (av. Th—Cl and Th—N are 2.68(1) and 2.60(3) Å, compared with 2.63(1) and 2.55(2) Å for U—Cl and U—N distances).

[a] The average B—N, N—N, N—C and C—C distances and the average N—B—N angle of the ligand $HBPz_3$ are given.

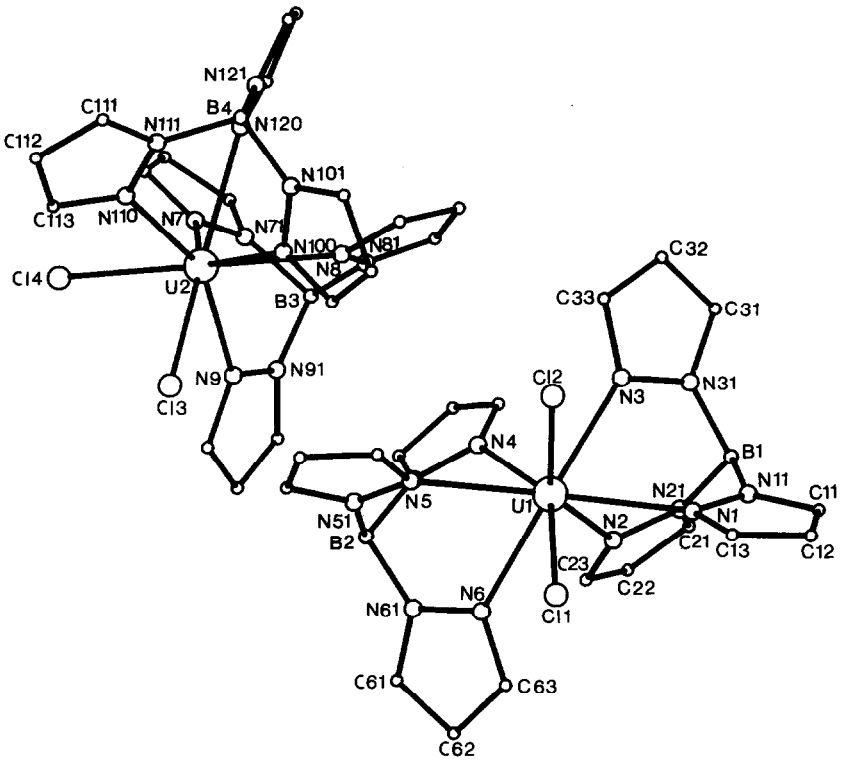

Fig. 3. PLUTO view of $UCl_2(HBPz_3)_2$, as they are in the asymmetric unit.

those of the related $UCl(OBu^t)(HBPz_3)_2$ and $UCl(OC_6H_5)(HBPz_3)_2$ complexes shows longer U—Cl bond distances in the latter compounds (2.697(2) and 2.682(6) Å, respectively) probably due to the larger size of the oxygen donor ligands. The U—N bond distances (av. 2.60(2) and 2.57(2) Å) fall within the range found for compound **2**.

The An—Cl bond distances in **1** and **2** can be compared with corresponding bond distances in the formally eight-coordinated compounds, $AnCl_2Cp''_2$ ($Cp'' = C_5H_3$-1,3-$(SiMe_3)_2$; An = Th^{IV}, 2.632(2) Å; An = U^{IV}, 2.579(2) Å).[21] The longer distances observed for the polypyrazolylborate complexes are certainly due to the larger size of the $(HBPz_3)^-$ ligand compared to the $(Cp'')^-$ ligand. Taking into account the recently introduced concept of the steric coordination number of a ligand,[22] the above formally eight-coordinate complexes have different steric coordination numbers of 7.80 for $AnCl_2(HBPz_3)_2$ and 7.20 for $AnCl_2Cp''_2$, which is in agreement with the longer An—Cl bond distances observed in the former complexes.

The referred analogy between the hydrotris(pyrazolyl)borate and the cyclopentadienyl ligands has sometimes led to a description of these types of compound in terms of a bent sandwich geometry. In MCp_2X_2 complexes the relevant angular parameters are the dihedral angle formed by the planes CpMCp (Cp = centre of gravity of cyclo-

pentadienyl) and XMX, which are found to be close to 90°, and the four Cp—M—X angles, which are identical. In the case of MCp_2XY complexes there are two sets of identical Cp—M—X and identical Cp—M—Y angles. For the hydrotris(pyrazolyl) borate complexes where structures are known, the corresponding parameters can be obtained by taking the boron atom as the centre of the tridentate ligand, and the values obtained are presented in Table 8.

It is apparent from the table that only for the BCTP complexes are the parameters considered in agreement with the bent sandwich geometry. For the majority of these complexes whose molecular structures are known, this type of description is inadequate, being, however, an easy way to distinguish SAP from BCTP complexes.

CONCLUSIONS

The structural analyses undertaken show that compounds **1** and **2** are not isomorphous. However, the coordination geometries are similar in the two compounds, SAP, distorted towards BCTP, with the thorium compound presenting a greater distorsion. This may be a consequence of the larger size of thorium which makes ligand–ligand repulsions in the coordination sphere of lesser importance (there are nine short intra-ligand contacts in **1** compared with 16 in **2**). Additionally, the thorium compound presents a few short intermolecular contacts,

(*Received* 23 *October* 1989; *accepted* 1 *March* 1990)

Abstract—Salts of oxoperoxofluorozirconates(IV), $[ZrO(O_2)F_2]^{2-}$ and $[ZrO(O_2)_2F]^{3-}$, have been prepared from the reaction of $ZrO_2 \cdot nH_2O$ with H_2O_2 and hydrofluoric acid at pH 6 and 12, respectively. No peroxozirconate could be obtained below pH 6. A μ-oxo species $[F_5Zr—O—ZrF_5]^{4-}$ has been isolated from a similar reaction at pH 5. The compounds have been characterized by chemical analyses, magnetic susceptibility and EPR measurements, IR and laser Raman spectroscopic studies. $(NH_4)_2[ZrO(O_2)F_2]$ in water reacts with SO_2(g) to produce a ternary complex $(NH_4)_2[ZrO(SO_4)F_2] \cdot 7H_2O$.

Investigation of various aspects of peroxo–metal systems[1–4] is of current interest. Synthesis and characterization, followed by studies of reactivity provide a systematic approach to this field. Some of our earlier papers dealt with this aspect of a few lighter transition metals[1,4,5] and as a sequel such studies have now been extended to zirconium. Information on peroxozirconates is scanty.[6] Complexes $[Zr(O_2)F_5]^{3-}$ and $[Zr_2(O_2)_2F_7]^{3-}$ are known and the structure of $(NH_4)_3[Zr(O_2)F_5]$ has been determined by X-ray crystallography.[8] There has been no report of solid diperoxozirconates(IV) except one in which diperoxo species were claimed[9] but not isolated. Our aim was to prepare newer peroxozirconates including diperoxozirconates(IV) from the reaction of ZrO_2 with H_2O_2 and F^-, and to rationalize the course of reactions through isolation of compounds at different stages of the reaction. It was also of interest to study the reaction of peroxozirconates with SO_2(g) in aqueous medium. This was important since the earlier reports[10] involved group VIII metal–peroxo species and the reactions were conducted in non-aqueous medium. This report presents an account of the preparation, characterization and reaction of salts of $[ZrO(O_2)F_2]^{2-}$ and $[ZrO(O_2)_2F]^{3-}$.

EXPERIMENTAL

The chemicals used were all reagent grade products. IR and laser Raman (LR) spectra were recorded on the instruments described earlier.[11–13] LR spectra were recorded only on solids. Magnetic susceptibilities were measured by the Gouy method; $Hg[Co(NCS)_4]$ was the calibrant. The pH values were measured with a Systronics type 335 digital pH meter and also with pH indicator (BDH) paper. The reactions and other manipulations were conducted in polyethylene apparatus. The water used for reactivity studies was deoxygenated by first boiling for 30 min under N_2 atmosphere and then cooling to room temperature, followed by bubbling of N_2(g) for 15 min. The water was stored in an airtight container. A suspension of $(NH_4)_2[ZrO(O_2)F_2]$ was prepared under N_2.

Synthesis of alkali metal or ammonium oxomonoperoxodifluorozirconates(IV), $A_2[ZrO(O_2)F_2]$ (A = Na, K *or* NH_4)

An aqueous solution (20 cm^3) of $ZrO(NO_3)_2 \cdot H_2O$ (1.0 g, 4 mmol) was treated with aqueous ammonia (sp.gr. 0.9) until $ZrO_2 \cdot nH_2O$ was completely precipitated. This was filtered off and washed thoroughly. To a water suspension of $ZrO_2 \cdot nH_2O$ was added 15 cm^3 (132.36 mmol) of

30% H_2O_2 with stirring followed by 1 cm^3 (24 mmol) of 48% HF, when a clear solution resulted. The pH of the solution was increased to 6 by adding AOH solution (20%) or aqueous ammonia (sp. gr. 0.9), whereupon a small amount of white product appeared. To ensure complete precipitation, 50 cm^3 of ethanol was added. The compound was filtered, washed 4–5 times with ethanol, and finally dried *in vacuo* over P_4O_{10}. Yields of $Na_2[ZrO(O_2)F_2]$, $K_2[ZrO(O_2)F_2]$ and $(NH_4)_2[ZrO(O_2)F_2]$ were 0.73 g(82%), 0.81 g (79%) and 0.75 g (87%), respectively.

Synthesis of sodium or ammonium oxodiperoxomonofluorozirconate(IV) *dihydrates*, $A_3[ZrO(O_2)_2F]\cdot 2H_2O$ (A = Na *or* NH_4)

The $A_3[ZrO(O_2)_2F]\cdot 2H_2O$ compounds were prepared in a manner analogous to that described above for the synthesis of $A_2[ZrO(O_2)F_2]$ except that the pH of the reaction solution was increased to 12. Yields of $Na_3[ZrO(O_2)_2F]\cdot 2H_2O$ and $(NH_4)_3[ZrO(O_2)_2F]\cdot 2H_2O$ were 0.87 g (71%) and 0.78 g (75%), respectively.

Isolation of alkali metal or ammonium μ-oxodecafluorodizirconates(IV), $A_4[F_5Zr—O—ZrF_5]$ (A = Na, K *or* NH_4)

The $A_4[F_5Zr—O—ZrF_5]$ complexes were isolated from reaction solutions obtained in a similar way to those described under the synthesis of $A_2[ZrO(O_2)F_2]$. However, the pH of the reaction solution was held at 5 instead of increasing it to 6. The compound was precipitated out by the addition of ethanol. Yields of $Na_4[Zr_2OF_{10}]$, $K_4[Zr_2OF_{10}]$ and $(NH_4)_4[Zr_2OF_{10}]$ were 1.37 g (72%), 1.73 g (80%) and 1.38 g (74%), respectively.

Reaction of $(NH_4)_2[ZrO(O_2)F_2]$ *with* SO_2(g). *Isolation of* $(NH_4)_2[ZrO(SO_4)F_2]\cdot 7H_2O$

Through an aqueous (25 cm^3) suspension of $(NH_4)_2[ZrO(O_2)F_2]$ (1 g, 4.69 mmol), SO_2(g) was slowly bubbled until the solution registered a pH value of 2–1. This was filtered and ethanol was added to initiate precipitation. It was allowed to stand for 2 h and then filtered to isolate the white crystalline product. The compound was washed with water and ethanol, and finally dried *in vacuo* over conc. H_2SO_4. The yield of $(NH_4)_2[ZrO(SO_4)F_2]\cdot 7H_2O$ was 0.97 g (47%).

Elemental analyses

Zirconium was estimated gravimetrically as ZrO_2.[14a] The peroxide content was determined by redox titration with standard solutions of $KMnO_4$[14b] or Ce^{4+}.[14c] Fluoride was precipitated as PbClF and chloride estimated by Volhard's method, from which the fluoride content was calculated.[14d] Nitrogen, potassium, sodium and sulphate were estimated by methods described previously.[11,15] The analytical results are given in Table 1.

RESULTS AND DISCUSSION

Synthesis

Peroxo–metal systems can be stabilized in the presence of an appropriate heteroligand at a suitable pH.[1,5,11–13] The present strategy was to react ZrO_2 with H_2O_2 and F^- in the presence of each other and also to evaluate the appropriate pH for the desired synthesis. The pH values conducive to the preparation of $[ZrO(O_2)F_2]^{2-}$ and $[ZrO(O_2)_2F]^{3-}$ were ascertained to be 6 and 12, respectively. While the salts of the monoperoxo complex were anhydrous, those of the diperoxo species were dihydrates. $A_3[ZrO(O_2)_2F]\cdot 2H_2O$ (A = Na or NH_4) were obtained, for the first time, in the solid state. In order to gain an insight into the course of the reaction, the product at pH 5 was isolated and characterized as a μ-oxo species, $[F_5Zr—O—ZrF_5]^{4-}$. It is possible that a peroxozirconate might have formed at this pH but decomposed leading to the μ-oxo complex as obtained. Such a problem is encountered in peroxo–metal chemistry.[16]

Characterization

The compounds are diamagnetic, EPR silent and sparingly soluble. They dissolve in an acidified (dil. H_2SO_4) solution in which the peroxozirconates(IV) quantitatively liberate active oxygen. The results of chemical analyses are consistent with the formulae, $A_2[ZrO(O_2)F_2]$, $A_3[ZrO(O_2)_2F]$ and $A_4[Zr_2OF_{10}]$. LR spectra of $A_4[Zr_2OF_{10}]$ could not be recorded owing to extensive fluoroescence, however, the IR spectra (Table 1) provide clear evidence for the ν(Zr—F) and Zr—F deformation modes.[7] Absence of any absorption at *ca* 950 cm^{-1} and the consistent appearance of a band at *ca* 740m,br cm^{-1} attest to the occurrence of Zr—O—Zr vibrations[17] in accord with a μ-oxo dimer. The diagnostic IR and LR signatures for $A_2[ZrO(O_2)F_2]$ and $A_3[ZrO(O)_2F]\cdot 2H_2O$ comprise ν(Zr=O), ν(O—O) (ν_1), ν(Zr—O_2) (ν_2,ν_3), and ν(Zr—F) modes (Table 1). The peroxide ligand binds the metal centre, in each case, in a triangular bidentate manner. Two additional IR bands at *ca* 1640s and *ca* 3455s cm^{-1} for the

Table 1. Analytical data and structurally significant IR and Raman bands of $A_2[ZrO(O_2)F_2]$ (A = Na, K or NH_4), $A_3[ZrO(O_2)_2F]\cdot 2H_2O$ (A = Na or NH_4) and $A_4[F_5Zr—O—ZrF_5]$ (A = Na, K or NH_4)

SO_4 modes

[a] Calculated values are given in parentheses. [b] Active oxygen. [c] Sulphate.

diperoxo complexes are in agreement with the presence of lattice water.[18,19]

Reaction of $SO_2(g)$ *with* $(NH_4)_2[ZrO(O_2)F_2]$

The oxoperoxodifluorozirconate(IV) readily reacted with $SO_2(g)$ in an aqueous medium as evident from a near quantitative solubility of the complex species during the bubbling of $SO_2(g)$ (*vide* Experimental). The reaction solution registered a pH value of 2–1 at that stage and the product isolated was characterized to be $(NH_4)_2[ZrO(SO_4)F_2]\cdot 7H_2O$.

The compound is diamagnetic in nature and sparingly soluble. The IR and LR spectra of the compound produced evidence for the complete absence of peroxide, which was also ascertained by chemical analysis. The spectra provide clear evidence for the ν(Zr=O) and ν(Zr—F) vibrations in similar regions to those of the other compounds reported herein and the expected bands for the presence of NH_4^+ and lattice water. For sulphate, the appearance of medium intensity ν_1 and ν_2 modes and the splitting of ν_3 and ν_4 vibrations into three bands each (Table 1), in contrast to the absence of ν_1 and ν_2 and occurrence of unsplit ν_3 and ν_4, suggest the lowering of the symmetry of SO_4^{2-} from T_d to C_{2v},[20] and its presence as a chelated ligand in the complex. The formation of the sulphato complex is explained in terms of an insertion of SO_2 into the O—O bond of the coordinated peroxide, without causing any reduction of the metal centre. This is an interesting reaction because it not only provides access to a new ternary complex of zirconium(IV), but also this route prevents the formation of a binary fluorozirconate(IV) which is normally a problem in the synthesis of mixed-ligand fluorozirconates(IV).

Concluding remarks

As in the case of titanium, monoperoxo and diperoxofluoro complexes of zirconium(IV) are capable of being synthesized under the appropriate experimental conditions. The pH of the reaction medium plays a very important role; a pH > 7 is required for the successful synthesis of diperoxo complexes of both titanium and zirconium. The peroxo compounds of zirconium are obtained as oxoperoxozirconate(IV) species containing a zirconyl (ZrO^{2+}) centre, unlike those of titanium[5] which contain titanium(IV) centres. Isolation of a μ-oxo-dizirconate(IV) species, $[F_5Zr—O—ZrF_5]^{4-}$, at pH $\geqslant 5 < 6$ suggests that such a complex might be the precursor for the oxomonoperoxozirconate(IV), however, the chances of peroxozirconate(IV) formation at a pH of *ca* 5 which may have decomposed to the μ-oxo complex either in the solution or in the process of its isolation, so often encountered in peroxo–metal chemistry,[16] should not be discounted. The complex $[ZrO(O_2)F_2]^{2-}$ ion reacts with $SO_2(g)$ in aqueous medium to afford the ternary $[ZrO(SO_4)F_2]^{2-}$ complex through insertion of SO_2 into the O—O bond.

Abstract—The preparation of cyclo-tetrakis[tri-*tert*-butoxysilanethiolatocopper(I)] from tri-*tert*-butoxysilanethiol and copper(II) acetate or CuCl or Cu_2O is described. The compound crystallizes as colourless monoclinic rods. The molecular structure is characterized by a nearly planar alternating Cu_4S_4-eight-membered ring with three-fold coordinated sulphur and two-fold coordinated copper atoms. According to the mass spectrum the tetrameric molecule is also preserved in the vapour phase. The compound was characterized spectroscopically by ^{29}Si, ^{13}C, ^1H NMR, IR and UV. Reactions with triphenylphosphine, 1,10-phenanthroline, and 2,2′-bipyridine afforded three adducts with formal stoichiometries $RSCu \cdot (PPh_3)_2$, $RSCu \cdot phen$ and $(RSCu)_2 \cdot bipy$, respectively.

Many of the recent developments in metal thiolate chemistry were stimulated by studies on metallothioneins, a unique class of metalloproteins which are polymetallic with exclusive coordination by the cysteine thiolate function.[2] As copper is one of the most abundant metallic elements in nature, copper–thiolate chemistry is of considerable current interest.

Complexes formed by copper(I) and alkyl or aryl thiolate ligands are numerous and their structures show a great variety. Insoluble compounds with RSCu stoichiometry are presumed to be non-molecular in structure.[3,4] On the other hand, the structures of monometallic linear $[Cu(SC_6HMe_4\text{-}2,3,5,6)_2]^-$[5] and trigonal planar $[Cu(SPh)_3]^{2-}$[6,7] anions, oligomeric copper(I) thiolate species such as tetrametallic $[Cu_4(SR)_6]^{2-}$ (R = Ph,[6,8] Me[8]), $\{Cu_4[(SCH_2)_2C_6H_4]_3\}^{2-}$[9] and pentametallic $[Cu_5(SPh)_7]^{2-}$,[10] $[Cu_5(SBu\text{-}t)_6]^-$[11,12] anions or octametallic neutral aggregates such as $[Cu(SC_6H_2Pr_3\text{-}i)]_8$[13] are known. Molecular structures were also determined for several copper thiolates bearing additional ligands such as triphenylphosphine in $Cu_2(SPh)_2(PPh_3)_4$,[14] $Cu_3(SPh)_3(PPh_3)_4$,[15] $Cu_4(SBu\text{-}t)_4(PPh_3)_2$,[3] $Cu_4(SPh)_4(PPh_3)_4$,[16] bis(diphenylphosphino)methane in $Cu_4[SC(CH_3)_2C_2H_5]_4[(PPh_2)_2CH_2]_2$,[17] thioxanthate in $Cu_8(SC_5H_{11})_4(S_2CSC_5H_{11})_4$,[18] pyridine nitrogen as in $Cu_6(SC_5H_3NSiMe_3)_6$[19] or tetrathiomolybdate group as in $[(PhS)CuS_2MoS_2]^{2-}$ and $[(PhS)CuS_2MoS_2Cu(SPh)]^{2-}$ anions.[20]

Some years ago we reported the preparation and molecular structure of the first silanethiolate, namely cyclotetrakis[tri-*tert*-butoxysilanethiolatosilver(I)], $[(t\text{-}C_4H_9O)_3SiSAg]_4$,[21] obtained by a reaction of tri-*tert*-butoxysilanethiol with silver nitrate in benzene–water. This was followed by syntheses and molecular structure determinations of

tri-*tert*-butoxysilanethiolates of thallium $[(t\text{-BuO})_3SiSTl]_2$,[22] mercury $[(t\text{-BuO})_3SiS]_2Hg$,[23] and lead $\{[(t\text{-BuO})_3SiS]_2Pb\}_2$.[24] All these silanethiolates were obtained with quantitative yields and in any case other products such as higher oligomers or polymers were found, suggesting that it is steric demand of the bulky $(t\text{-BuO})_3SiS$ ligand which probably reduces the tendency of thiolate sulphur to bridge metal centres and/or prevents close approach to thiolate units thus limiting the formation of oligomeric aggregates.

Copper complexes with silanethiolate ligands were never investigated. Herein, we report the preparation, molecular structure and some properties of cyclo-tetrakis[tri-*tert*-butoxysilanethiolatocopper(I)], $[(t\text{-}C_4H_9O)_3SiSCu]_4$ (**1**), the first structurally characterized copper silanethiolate complex.

EXPERIMENTAL

Syntheses

Tri-*tert*-butoxysilanethiol, $(t\text{-BuO})_3SiSH$, was prepared as described previously.[25] All other chemicals were commercial products. Solvents, if necessary, were dried according to common procedures.

Preparation of $[(t\text{-BuO})_3SiSCu]_4$ (1)

Three synthetic routes to the title complex were developed:

Method A. To a solution of $(t\text{-BuO})_3SiSH$ (7 g, 25 mmol) in 50 cm^3 of benzene, a solution of copper(II)acetate (5 g, 25 mmol) in 25 cm^3 of water was added and the resulting two-phase mixture shaken vigorously for *ca* 2 h until the silanethiol disappeared, as verified by TLC. The benzene layer was separated, washed twice with water, dried over magnesium sulphate and finally the benzene was removed *in vacuo*. The solid residue, containing in addition to **1** also bis(tri-*tert*-butoxysilyl)disulphide, was twice crystallized from isopropanol–benzene (3:1 v/v) yielding 2.12 g of pure colourless **1**; m.p. 222–223°C, yield 50%.

Method B. Copper(I) chloride (1.070 g, 10.7 mmol), $(t\text{-BuO})_3SiSH$ (2.772 g, 9.9 mmol), anhydrous Et_3N (1.05 g, 10.5 mmol) and 20 cm^3 of anhydrous benzene were mixed together under argon atmosphere and stirred for *ca* 30 min. Insoluble material was then removed by filtration and washed with a further 20 cm^3 portion of benzene. Both liquid phases were combined and evaporated to dryness *in vacuo*. The solid residue was recrystallized from *i*-PrOH–benzene, yielding 2.622 g of pure **1**; m.p. as above, yield 74%.

Method C. A solution of $(t\text{-BuO})_3SiSH$ (0.560 g, 2 mmol) in 2 cm^3 of anhydrous benzene was added to copper(I) oxide (0.144 g, 1 mmol) and the mixture refluxed with stirring under Ar for *ca* 7 h. Then 5 cm^3 of benzene was added and traces of the remaining Cu_2O were removed by filtration. Evaporation to dryness and subsequent recrystallization from *i*-PrOH–benzene afforded 0.585 g of pure **1**; m.p. as above, yield 84%. Found: C, 42.0; H, 7.9. Calc. for $Cu_4S_4Si_4O_{12}C_{48}H_{108}$: C, 42.0; H, 7.9%.

Reaction of **1** *with triphenylphosphine*

To a solution of **1** (1.370 g, 1 mmol) in 10 cm^3 of anhydrous benzene, Ph_3P (2.1 g, 8 mmol) was added, the mixture refluxed for 2.5 h under argon and then left overnight at room temperature. The deposited solid material was separated by filtration, washed with *n*-hexane and then recrystallized from hexane–ethanol (7:5 v/v) affording 3.366 g of colourless plates; m.p. 154–154.5°C. ^1H NMR spectrum: 7.20 ppm (m, 30H, C_6H_5), 1.35 and 1.15 ppm; (two broad poorly separated singlets, 27H, CH_3), and microanalytical data consistently indicated the composition $(t\text{-}C_4H_9O)_3SiSCu\cdot(PPh_3)_2$; yield 97%. When the **1** to Ph_3P molar ratio was only 1:4 the same product was obtained with a yield of *ca* 45%. Found: C, 66.6; H, 6.6. Calc. for $CuSSiO_3P_2C_{48}H_{57}$: C, 66.4; H, 6.6%.

Reaction of **1** *with* 1,10-*phenanthroline monohydrate* (phen·H_2O)

Phen·H_2O (0.396 g, 2 mmol) was added to 5 cm^3 of anhydrous benzene and refluxed until a clear solution was obtained. Then to the hot solution a solution of **1** (0.685 g, 0.5 mmol) in 3 cm^3 of anhydrous benzene was added. The mixture which rapidly turned deep red was left to stand for 1 day at room temperature. The dark red crystals which grew were collected, washed with hexane and dried *in vacuo*. 0.986 g of product was obtained; m.p. 164–166°C. Attempts to recrystallize the product from hot benzene resulted in partial decomposition. Microanalytical data suggested the composition $(t\text{-}C_4H_9O)_3SiSCu\cdot$phen; yield 94%. Found: C, 55.1; H, 6.7. Calc. for $CuSSiN_2O_3C_{24}H_{35}$: C, 55.1; H, 6.7%.

Reaction of **1** *with* 2,2′-*bipyridine* (bipy)

To a solution of **1** (0.785 g, 0.573 mmol) in 5 cm^3 of anhydrous hexane a solution of bipy (0.358 g, 2.292 mmol) in 10 cm^3 of anhydrous benzene was added. The mixture turned orange and after *ca* 1–2 min, fine pink–red crystals began to deposit. After 3 h, when the solution over the solid was colourless,

the crystals were collected, washed with hexane and dried *in vacuo*. 0.961 g of product was obtained, m.p. 186–188°C. From the hexane fraction, which analysed by TLC did not show the presence of starting **1**, the solvent was evaporated affording 0.175 g (~ 50%) of unreacted bipy, identified by a mixed melting point. According to the above result also microanalytical data pointed to the composition $[(t\text{-}C_4H_9O)_3SiSCu]_2 \cdot$ bipy. Yield quantitative. Found: C, 48.7; H, 7.5. Calc. for $Cu_2S_2Si_2N_2O_6C_{34}H_{62}$: C, 48.5; H, 7.4%.

ANALYTICAL PROCEDURES

Thin-layer chromatography

TLC was performed on Silufol 254 + 366 (Kavalier, CSSR) plates with hexane–benzene (4 : 1 v/v) as a mobile phase. The spots were visualized by UV (a pink–red spot of **1**, $R_F = 0.85$) and silver nitrate solution (in EtOH–H_2O 1 : 1) {black spot for **1** and brown spots for $(t\text{-BuO})_3SiSH$, $R_F = 0.66$ and $(t\text{-BuO})_3SiSH$, $R_F = 0.57$}.

Elemental analyses

Carbon and hydrogen contents were determined by the microcombustion method.[26] Melting points are uncorrected.

Spectral measurements

Spectral measurements were performed as follows: IR: 4000–400 cm^{-1}, Specord 75IR (C.Zeiss), solution in CCl_4; UV: 52,000–30,000 cm^{-1}, Specord UV–vis (C.Zeiss), 1.5×10^{-5} M solution in hexane, argon atmosphere; ^1H NMR: Varian 360A (60 MHz), solution in CCl_4 (TMS int.); ^{13}C NMR: Bruker AM 250 ($\nu_0 = 62.896$ MHz), solution in $CDCl_3$ (TMS int.); ^{29}Si NMR: Bruker AM 250 ($\nu_0 = 49.689$ MHz), solution in $CDCl_3$ (TMS int.), $Cr(acac)_3$ as a relaxation reagent at room temperature with inverse gated broad band proton noise decoupling; Mass spectrum: Varian Mat 8230 (E.I., 70 eV), direct inlet.

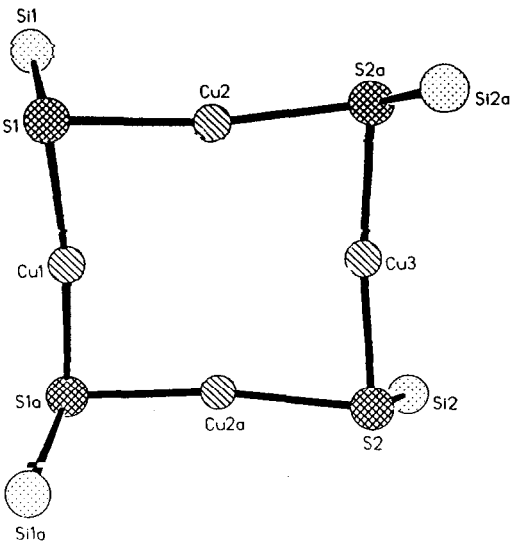

Fig. 1. Atom labelling for the central $Si_4S_4Cu_4$ part of the molecule of **1**.

Crystal and molecular structure determination of **1**

The crystal and molecular structure of **1** was determined by a single crystal diffraction study. Figure 1 shows a perspective drawing of the central $Si_4S_4Cu_4$ part of **1** with the atom labelling, and Fig. 2 a stereo pair of the whole molecule.

Atomic coordinates, displacement factor coefficients, full lists of bond lengths and angles and lists of F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Synthesis of **1**

The preparation of a new tetracopper(I) silanethiolate complex $[(t\text{-}C_4H_9O)_3SiSCu]_4$ (**1**) is readily achieved, commencing from either copper(II) or copper(I), however, the synthesis of **1** starting from

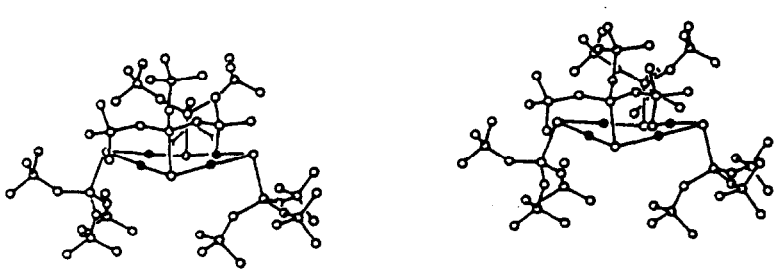

Fig. 2. Stereo pair of the molecule of **1**, hydrogen atoms are omitted for clarity.

copper(II) substrate as in eq. (1):

$$4\ Cu(OAc)_2 + 8\ (t\text{-}BuO)_3SiSH \longrightarrow [(t\text{-}BuO)_3SiSCu]_4 + 2\ [(t\text{-}BuO)_3Si]_2 + 8\ AcOH \quad (1)$$

seems to be of minor preparative importance since the half amount of introduced silanethiol is converted to the appropriate disulphide, which must be subsequently separated from the desired copper(I) silanethiolate **1**. On the other hand, the easy oxidation of silanethiol by copper(II) salts, analogous to those known for organic thiols, may also serve as a source of bis(tri-*tert*-butoxysilyl)disulphide, prepared by us previously using the more convenient oxidation of sodium silanethiolate by iodine, and characterized structurally.[27]

Much better results were obtained starting from copper(I) compounds. The route from copper(I) chloride and silanethiol, in the presence of tertiary amine as the HCl acceptor [eq. (2)], can be regarded

$$4\ CuCl + 4\ (t\text{-}BuO)_3SiSH + 4\ Et_3N \longrightarrow [(t\text{-}BuO)_3SiSCu]_4 + 4\ Et_3N \cdot HCl \quad (2)$$

as a classical one and gives a good yield of **1**. The best results, however, were obtained for the simplest case where silanethiol reacts with copper(I) oxide forming **1** and water only as a byproduct [eq. (3)]:

$$2\ CuO + 4\ (t\text{-}BuO)_3SiSH \longrightarrow [(t\text{-}BuO)_3SiSCu]_4 + 2H_2O. \quad (3)$$

This route has never been used before for the synthesis of copper thiolate complexes, maybe because

organic thiols are far less acidic than silanethiols.[28] As we have shown previously, mercury[23] and lead[24] molecular tri-*tert*-butoxysilanethiolates can also be obtained by the same method with quantitative yields.

Crystal and molecular structure of **1**

Cyclo - tetrakis[tri - *tert* - butoxysilanethiolato-copper(I)] (**1**) crystallizes monoclinically as colourless rods, melting at 222–223°C without decomposition. The crystal lattice parameters are given in Table 1, and the molecular structure of **1** is illustrated in Figs 1 and 2.

The molecule consists of four $(t\text{-BuO})_3SiSCu$ units, where every sulphur atom is triply coordinated and thus serves as a bridge for two adjacent, doubly coordinated copper atoms. The Cu_4S_4 core is almost planar since the mean shift of sulphur atoms from the Cu_4 plane was found to be only 32 pm. Such a structure type has never been observed previously for copper(I) thiolates although similar Cu_4X_4 cores have been found in other homoleptic copper(I) complexes, namely $(t\text{-BuOCu})_4$,[29] $(Me_3SiCH_2Cu)_4$[30] and $[CuCo(CO)_4]_4$[31] (here the Cu_4Co_4 cycle is distinctly non-planar). The molecule of **1** is of 2-C_2 symmetry (the two-fold axis passes through Cu(1) and Cu(3) atoms) and isomorphous with tetrameric silver tri-*tert*-butoxysilanethiolate, $[(t\text{-BuO})_3SiSAg]_4$, whose preparation and molecular structure were described by us previously.[21]

For both copper and silver silanethiolates the discrete eight-membered cyclic molecular units of alternating metal and sulphur atoms exhibit no secondary metal ···S interactions. This reflects the steric demand of the bulky tri-*tert*-butoxysilanethiolate ligand which prevents any close approach of the molecules and precludes any secondary bridging interaction to form oligomeric aggregates. In this sense the above silanethiolate ligand can be compared with the thiolate ligands which originate from $(PhMe_2Si)_3CSH$ and $(Me_3Si)_3CSH$ which, as it was shown recently by their investors Block and Zubieta,[32] behave similarly affording silver thiolates with small Ag_3S_3 and Ag_4S_4 cores, respectively.

Table 2 lists the selected interatomic distances and interatomic angles determined for the molecule of **1**.

As observed previously for the isomorphous silver silanethiolate,[21] for copper(I)silanethiolate (**1**) the displacement of copper atoms from linear coordination towards the centre of the Cu_4S_4 ring (S—Cu—S, average 172.8°) decreases the metal–metal distances. The *d*(Cu—Cu) value (285 pm), which is the same as determined for the closed $[Cu_{12}S_8]^{4-}$ cage,[33] is, however, substantially larger than the Cu—Cu single bond distance (234 pm). Significant deviations from co-linear S—Cu—S bonds were reported for the $[Cu_{12}S_8]^{4-}$ cage anion (S—Cu—S angle, 166.9–170.9°),[33] the neutral thiolate $[Cu(SC_6H_2Pr_3\text{-}i)]_8$, (S—Cu—S, average 177.5°),[13] and also for the anionic thiolate complexes containing not only triply but also doubly coordinated copper—$[Cu_5(SBu\text{-}t)_6]^-$ (S—Cu—S angles 169.2–173.4°)[12] and $[Cu_5(SPh)_7]^{2-}$ (S—Cu—S angle 175.2°).[10] These similarities are not restricted to the S—Cu—S angles since the Cu—S bonds forming these angles are also of comparable lengths. For **1** the Cu—S distances are 216.1 and 217.0 pm, and for the compounds mentioned above[10,12,13,33] the *d*(Cu—S) values are within the same limits.

It is remarkable that although in **1** sulphur is triply coordinated, the Si—S bond lengths, *d*(Si—S) 213.3 pm, are similar to those determined for two-fold bonded sulphur compounds (e.g. *d*(Si—S), 213.2 pm[27] in $[(t\text{-BuO})_3SiS]_2$).

Due to great similarities between the molecular structures of silver[21] and copper (this work) tri-*tert*-butoxysilanethiolates, a more detailed discussion about the latter is not necessary. The reader is asked to consult our previous paper[21] where all structural details are thoroughly discussed, since the general conclusions formulated there can be, in our opinion, applied also to the present case.

Properties of **1**

Cyclo - tetrakis[tri - *tert* - butoxysilanethiolato-copper(I)] (**1**) shows very good solubility in benzene, hexane and carbon tetrachloride. The solubility however falls with growing solvent polarity, so **1** is poorly soluble in acetonitrile and lower alcohols, and insoluble in water.

The IR spectrum of **1** (4000–400 cm^{-1}) contains only features typical for the $(t\text{-}C_4H_9O)_3SiS$ group (ν = 2970, 1470, 1385, 1360, 1235, 1200, 1185, 1060, 1015, 685, 635 and 530 cm^{-1}). This is consistent with previously reported[7,9] data for copper(I) thiolates pointing out that ν(Cu—S) stretching modes are at lower frequencies (350–300 cm^{-1}).

The UV absorption spectrum of **1** consists of a broad asymmetric band (λ_{max} 202 nm, $\varepsilon \sim 4600$) with a distinct shoulder (λ_{max} 225 nm, $\varepsilon \sim 2000$) and a second, well separated symmetric band (λ_{max} 285 nm, $\varepsilon \sim 1400$). The shortest wavelength maximum at *ca* 200 nm is attributed to the σ(Si—S) → σ^*(Si—S) transition, however, any detailed discussion on this interesting spectrum cannot be given without further investigations on the other silanethiolates. Such investigations are now in progress.

The ^1H, ^{13}C and ^{29}Si NMR spectra of **1** are very simple—only one singlet for CH_3 hydrogens at 1.35 ppm, two singlets for two different carbon atoms at 31.78 ppm (CH_3) and 74.46 ppm (CMe_3), and one singlet at −72.73 ppm for silicon atoms were detected, respectively. The above values are similar to those reported by us previously for Ag, Tl, Hg and Pb tri-*tert*-butoxysilanethiolates.[21–24]

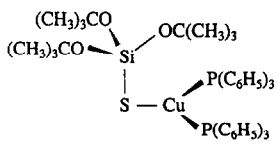
The mass spectrum of **1** shows a group of peaks at *m/z* 1368–1379 (max. abundance 20%) which can be attributed to the ions originating from the parent molecule with four copper atoms, on the basis of identity of both experimental and calculated isotope patterns. In the region above *m/z* 1000, two other groups of peaks were found—the group centred at *m/z* 1090 (5%) $[M-(t\text{-BuO})_3SiS]$ and the group at *ca m/z* 1030 (10%), most probably corresponding to the ions with $[(t\text{-BuO})_3SiSCu]_3$ composition. Some other peaks with abundances greater than 5% were found at *m/z* 586 (8%), 265 (23%), 209 (12%), 153 (33%), 135 (40%), 95 (25%) and 79 (27%), and the base peak at *m/z* 58 (100%). No peaks which could be attributed to ions with the $[(t\text{-BuO})_3SiSCu]_n$ (n = 1 or 2) composition were detected. The mass spectrum indicates that not only in the solid but also in the vapour phase the molecule of **1** is quite stable. The existence of $[(t\text{-BuO})_3SiSCu]_3$ molecules also seems possible. Although a homoleptic copper thiolate with a cyclic Cu_3S_3 core has not yet been prepared, the six-membered cycle of alternating silver and sulphur atoms was found in the $[(PhMe_2Si)_3CSAg]_3$ molecule.[32]

Compound **1** is stable to water and does not hydrolyse even in the presence of acetic acid, as has been seen from method (A) of its synthesis. An attempt however to prepare **1** from CuCl and $(t\text{-BuO})_3SiSH$ in benzene, in the absence of a hydrogen chloride acceptor, failed. Although the transient formation of small amounts of **1** was observed on TLC, it was quickly destroyed by evolving HCl finally giving a mixture of black copper sulphides.

In **1** copper is only doubly coordinated and it was thus interesting to investigate if it can further react with compounds which are known to be the good donor ligands. Reaction of **1** with trimethylphosphine was performed producing a high yield of colourless crystals of a new complex for which the formula $[(t\text{-BuO})_3SiSCu(PPh_3)_2]_n$ could be attributed on the basis of elemental analysis and

^{1}H NMR spectrum, however, the value of n remains unknown. From steric considerations it is of very low probability that the Cu_4S_4 core of **1** is preserved in the phosphine adduct. Although three complexes containing the Cu_4S_4 core and phosphine as an additional ligand are known—$(t\text{-BuSCu})_4(PPh_3)_2$,[3] $(C_5H_{11}SCu)_4(Ph_2PCH_2PPh_2)_2$[17] and $(PhSCu)_4(PPh_3)_4$[16]—in all of them a maximum of one phosphorus atom is coordinated to the copper atom. The same $SCuP_2$ stoichiometry as our phosphine ligated copper silanethiolate was found by Dance *et al.*[14] for $(Ph_3P)_2Cu(SPh)_2Cu(PPh_3)_2$, whose molecular structure is characterized by pseudo-tetrahedral coordination on copper (P_2CuS_2) and the unique planar stereochemistry at the sulphur atoms which is enforced by crowding of the 12 phenyl rings on the surface of the molecule. A similar structure could also be expected for $[(t\text{-BuO})_3SiSCu(PPh_3)_2]_n$ ($n = 2$) but, taking into account the steric hindrance caused by the very bulky $(t\text{-BuO}_3)SiS$ ligand, much greater than that of benzenethiolate, it seems doubtful.

The ^{1}H NMR spectrum of $[(t\text{-BuO})_3SiSCu(PPh)_2]_n$ in the methyl region consists of two broad singlets (ratio *ca* 2:1) separated by only 0.2 ppm, suggesting that the methyls are in different environments. This could be easily realized in the monometallic structure depicted below, where steric requirements are also minimized.



The structure has no precedents in the chemistry of neutral copper thiolate derivatives and requires further verification.

Compound **1** reacts also with 1,10-phenanthroline affording, almost quantitatively, dark red crystals of a new complex, poorly soluble in common organic solvents, with formal stoichiometry $(t\text{-BuO})_3SiSCu \cdot phen$, similar to that found for the phosphine complex if phosphorus atoms are substituted for the nitrogen atoms of phenanthroline.

Reaction of **1** with 2,2′-bipyridine gave, however, a different result, the formal stoichiometry of a pink–red complex, also formed quantitatively, was found to be $[(t\text{-BuO})_3SiSCu]_2 \cdot bipy$. Its solubility is even lower than that of the phenanthroline complex.

The most intriguing question arises from comparison of the stoichiometries of both amine complexes, which are completely different despite the great similarities exhibited by these ligands. Presently, the molecular structure of the phenanthroline and bipyridine derivatives of copper(I) silanethiolate are unknown, but the possibility that 2,2′-bipyridine does not act as a chelate ligand but forms a bridge between two metal centres cannot be excluded on consideration of recent results of Craven *et al.*[34] They reported a molecular structure of 4,4′-dimethyl-2,2′-bipyridylbis[pentacarbonylchromium(0)] where the orientation of the ligand pyridyl rings is mutually perpendicular and every nitrogen atom coordinates one chromium forming a bridged, binuclear structure. It is the first reported example of this type of coordination which, although possible for 2,2′-bipyridine, cannot be realized for 1,10-phenanthroline and, therefore, in particular cases can account for significant differences between complexes formed by both these ligands.

Abstract—The crystal structure of the carboxylic acid adduct of a tetracarboxylate-bridged dimeric species, $[Cu_2(RCO_2)_4(RCO_2H)_2]$, where RCO_2H = 2-phenoxybenzoic acid, has been determined by X-ray diffraction and refined to a residual $R = 0.037$ for 2827 observed reflections. The centrosymmetric dimer has a Cu—Cu separation of 2.602(1) Å, a mean Cu—O (plane) bond length of 1.960(3) Å and a Cu—O (axial) length of 2.182(3) Å, to the adducted acid molecule. The acid proton is hydrogen bonded to a cage carboxylate oxygen (O---O, 2.64(1) Å).

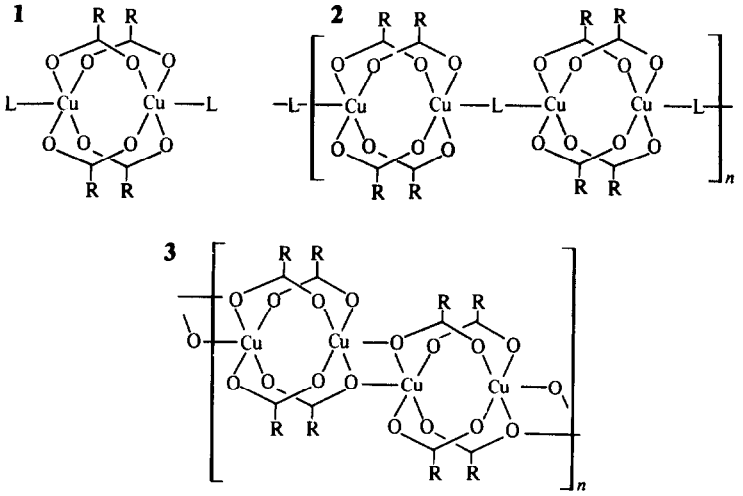
The number of copper(II) complexes of the type $[Cu_2(RCO_2)_4L_2]$ having tetra-(carboxylato-*O,O'*) bridges has increased since the first example (R = CH_3, L = H_2O) was reported by van Niekerk and Schoening,[1] so that the Cambridge Crystallographic Data Base now has more than 100 examples. These involve a diversity of carboxylic acid types and axially adducted (L) species, including nitrogen base as well as oxygen donor groups. Although the majority form discrete dimeric species (type 1), polymeric types may result from extension through the axial sites (types 2 and 3).

The type 2 (straight chain) polymer forms links through bifunctional L groups, e.g. L = pyrazine, R = CH_3;[2] L = hexamethylenetetramine, R = CH_3;[3] L = 1,4-dioxane, R = CH_3CH_2;[4] and L = 2-aminopyrimidine, R = (2-Cl·C_6H_4·OCH_2).[5]

The type 3 (step chain) motif involves a link between copper and the carboxylate oxygen of an adjacent dimer unit, as found in the anhydrous examples, R = CH_3CH_2;[6] R = $CH_3(CH_2)_2$;[7] R = (2-Cl·C_6H_4·OCH_2).[5]

The title compound, prepared from 2-phenoxybenzoic acid and having a stoichiometric formula $[Cu(RCO_2)_2(RCO_2H)]$, had the colour characteristics indicative of a dimeric copper species, which would suggest a rare acid adduct form of the type found for $[Cu_2(CH_3CO_2)_4](CH_3CO_2H)_2$.[8] However, a complex adduct of the type $[Cu(RCO_2)_2(H_2O)_2]\cdot 2[RCO_2H]\cdot 2H_2O$[9] (R =

* Author to whom correspondence should be addressed.



4-F·C_6H_4·OCH_2), also rare, could not be discounted.

EXPERIMENTAL

$[Cu_2(C_{12}H_{10}CO_2)_4(C_{12}H_{10}CO_2H)_2]$ was prepared by digesting an excess of $Cu(OH)_2 \cdot CuCO_3$ in hot (90°C) 50% aqueous ethanol. Dark green crystals grew from the filtered solution on standing for a period of several days at room temperature. An IR spectrum together with measured density and cell parameters indicated the presence of adducted acid molecules.

Crystal data

$C_{78}H_{56}Cu_2O_{18}$, $M_r = 1408.4$, monoclinic, space group $P2_1/c$, $a = 12.333(2)$, $b = 15.392(2)$, $c = 17.327(2)$ Å, $\beta = 98.55(1)°$, $V = 3252.6(7)$ Å^3, $F(000) = 1452$, $D_m = 1.47$ g cm^{-3}, D_c ($Z = 2$) = 1.437 g cm^{-3}, μ(Mo-K_α) = 7.6 cm^{-1}, max./min. transmission factors 0.847, 0.825, $T = 293$ K.

Data collection, structure solution and refinement

Intensity data were collected on a Nicolet R3m four-circle diffractometer (crystal monochromatized Mo-K_α radiation, $\lambda = 0.71073$ Å) from a crystal of dimensions $0.14 \times 0.16 \times 0.28$ mm. Of 4257 unique data collected up to $2\theta_{max} = 45°$, 2827 with $I > 2.5\sigma(I)$ were considered observed and used in structure refinement. Intensity variation of not greater than 1% in two standards monitored during the data collection period indicated negligible crystal decay. Data were corrected for absorption. The structure was solved by the automatic Patterson method of SHELXS-86[10] and refined by full-matrix least-squares (SHELX-76[11]) with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogens were located in a difference Fourier synthesis and their positional and isotropic thermal parameters were refined. The final R [$= \Sigma||F_o|-|F_c||/\Sigma|F_o|$] and R_w [$= \Sigma w(||F_o|-|F_c||^2/|\Sigma w|F_o|^2)^{1/2}$] values were 0.037 and 0.038, respectively, using $w = 0.95/(\sigma^2 F_o + 6.4 \times 10^{-4} F_o^2)$. Neutral atom scattering factors were used.[12]

Table 1. Bond distances (Å) and angles (°) about the coordination polyhedron

(a) Distances			
Cu—O(8)A	1.987(3)	Cu—O(9)B′	1.949(3)
Cu—O(9)A′	1.950(3)	Cu—O(9)C	2.182(3)
Cu—O(8)B	1.955(3)	Cu—Cu′	2.602(1)
(b) Angles			
O(8)A—Cu—O(8)B	90.2(1)	O(8)B—Cu—O(9)B′	169.0(1)

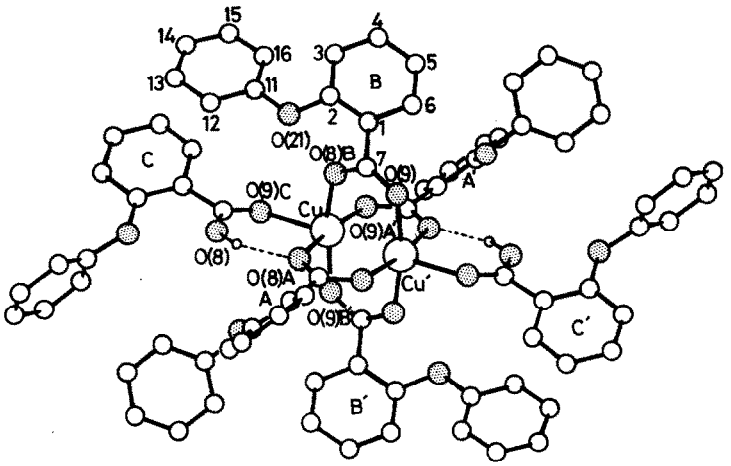

Fig. 1. Molecular configuration and atom naming scheme.

Atomic coordinates, thermal parameters, hydrogen atom coordinates, intraligand bond distances and angles, and observed and calculated structure factors have been deposited with the Editor as supplementary material, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre. Bond distances and angles about the coordination polyhedron are given in Table 1.

DISCUSSION

The complex forms discrete centrosymmetric tetracarboxylate bridged dimers of the copper(II) acetate hydrate type[1] (Fig. 1). The bond distances and angles about the dimer are considered normal for this system with Cu—O (equatorial) ranging from 1.949(3) to 1.987(3) Å [1.960(3) Å mean] and Cu—O (axial) 2.182(3) Å. The Cu—Cu separation is 2.602(1) Å. This value shows a much larger range throughout the series and is dependent upon a number of factors, including ligand and axial group types.[13] The most unusual feature of this structure is the presence of protonated acids, providing carboxyl oxygen atoms in the axial sites of the dimer. This represents only the second crystallographically described example of such a complex. The previous example was tetrakis-μ-[acetato-O,O']bis[acetic acid copper(II)],[8] prepared by treatment of dehydrated copper(II) acetate with acetic acid–acetic anhydride. The presence of water in this system results in the reversion to the conventional copper acetate hydrate structure, with water replacing acetic acid in the axial sites. The preparation of the

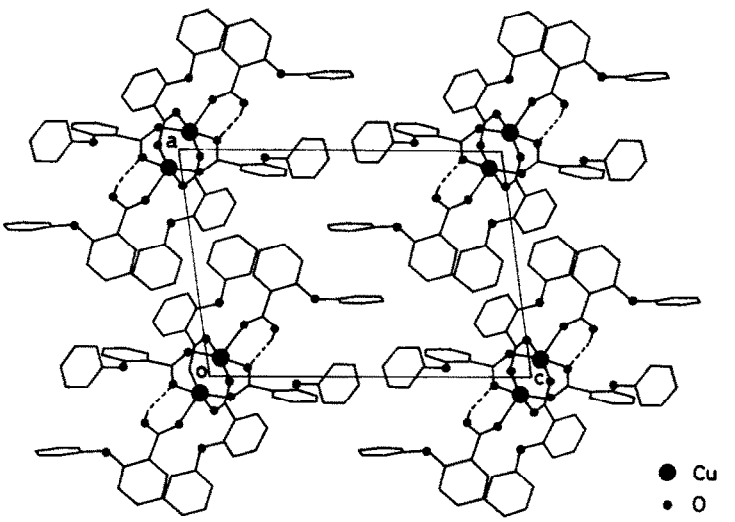

Fig. 2. Packing in the unit cell viewed down *b*.

title compound, however, involves a solution of the acid in aqueous ethanol so that the reason for incorporation of such sterically bulky groups in the axial sites is puzzling. A high concentration of unreacted acid in the crystallizing solution is normal with this method of preparation, but in no other examples has this type of incorporation of unprotonated acid been observed. Solvent molecules such as methanol,[8] ethanol,[14] 1,4-dioxane,[15] acetone,[16] dimethylformamide,[8,17] and dimethylsulphoxide[18] are common. Comparative bond lengths [Cu—O (axial) and Cu—Cu] for the acetic acid dimer are 2.197(2) and 2.581(1) Å, respectively.[8]

Packing of the dimers in the unit cell involves no significant inter-dimer associations (Fig. 2), a phenomenon not unusual with ligands having no typically associative peripheral groups. The stability of the axial group is enhanced by a strong O—H---O hydrogen bonding interaction [O---O, 2.64(1) Å], a feature in common with the acetic acid example where the comparative O---O distance is 2.62 Å.

ISOLATION AND X-RAY STRUCTURE DETERMINATION OF A SULPHUR-BRIDGED INCOMPLETE CUBANE-TYPE MOLYBDENUM(IV) AQUA CLUSTER, $[Mo_3S_4(H_2O)_9](CH_3 \cdot C_6H_4 \cdot SO_3)_4 \cdot 9H_2O$

HARUO AKASHI, TAKASHI SHIBAHARA* and HISAO KUROYA

Department of Chemistry, Okayama University of Science, 1-1 Ridai-cho, Okayama 700, Japan

(*Received* 9 *January* 1990; *accepted* 1 *March* 1990)

Abstract—The title compound was isolated in high yield (72%) from 4 M HPTS solution, and the X-ray crystal structure has been determined. The cluster cation has an approximate C_{3v} symmetry. The average Mo—Mo distance (2.735[8] Å) in the aqua complex is the shortest reported in complexes with Mo_3S_4 cores so far. Every SO_3^- moiety of the pts^- anion faces towards the complex cation.

The chemistry of the incomplete cubane-type sulphur-bridged molybdenum cluster with Mo_3S_4 cores has attracted much attention. Although the aqua ion, $Mo_3S_4(aq)^{4+}$, has been prepared and characterized in solution[1–3] and many X-ray structures of analogous complexes with Mo_3S_4 cores have been determined,[4,5] no X-ray structure of the aqua cluster itself has been reported as yet. Furthermore, cubane-type mixed-metal clusters with Mo_3MS_4 (M = Fe, Co, Ni, Cu, Sn, Hg) cores have been prepared from the aqua ion and corresponding metal and/or metal ions lately,[2,6] and the aqua ion, $Mo_3S_4(aq)^{4+}$, will be studied more actively.

We report here the preparation and X-ray structure analysis of an incomplete cubane-type molybdenum aqua cluster, $[Mo_3S_4(H_2O)_9](CH_3 \cdot C_6H_4 \cdot SO_3)_4 \cdot 9H_2O$ (**1**), which provides direct evidence for the existence of the incomplete cubane-type molybdenum(IV) aqua ion, $[Mo_3S_4(H_2O)_9]^{4+}$. As for the X-ray structure determination of metal cluster complex compounds with aqua ligands alone, only a few complex compounds are known and they all include *p*-toluenesulphonates as counteranions.[6,7] The role of the anion will also be discussed.

EXPERIMENTAL

Preparation of $[Mo_3S_4(H_2O)_9](CH_3 \cdot C_6H_4 \cdot SO_3)_4 \cdot 9H_2O$ (**1**)

The aqua ion, $Mo_3S_4(aq)^{4+}$ in 2 M HCl, which was obtained by the published procedure[1] was diluted to 10 times its original volume with water and was absorbed on Dowex 50W-X2 cation exchanger. Washing of the resin with 0.1 M HPTS (*p*-toluenesulphonic acid) to remove Cl^- ion, and elution with 4 M HPTS gave a green solution. Cooling of the eluted solution in a refrigerator for a few days gave green plate crystals; yield *ca* 72% based on $Mo_3S_4(aq)^{4+}$ in 2 M HCl. Found (Calc.): C, 23.9 (23.6); H, 4.0 (4.5)%.

X-ray data collection and structure determination

A crystal of **1** was mounted in a glass capillary. The crystallographic parameters are given in Table 1. The intensities of three standard reflections did not show any appreciable decay. The data were corrected for Lorentz and polarization effects. No absorption correction was applied. The structure was solved by a direct method[8] and refined by a block-diagonal least-squares technique. Application of an anisotropic thermal parameter to the sulphur atom [Sp(4)] in one of the four pts^- anions

Table 1. Summary of crystal data, intensity collections, and structure refinement parameters for $[Mo_3S_4(H_2O)_9](CH_3C_6H_4SO_3)_4 \cdot 9H_2O$

Formula	$Mo_3S_8O_{30}C_{28}H_{64}$
Mol. wt	1425.10
Crystal system	Triclinic
Space group	$P\bar{1}$
a (Å)	15.361(4)

c (Å)	12.084(5)
α (°)	95.32(3)
β (°)	108.85(3)
γ (°)	102.60(2)
V (Å^3)	2822.9(16)
Z	2
$d_{calc.}$ (g cm^{-3})	1.677
d_{obs} (g cm^{-3})	1.67
μ(Mo-K_α) (cm^{-1})	10.0
Crystal size (mm)	$0.32 \times 0.23 \times 0.25$
Radiation (λ) (Å)	Mo-K_α (0.71073)[a]
Data collection instrument	RIGAKU AFC-6A
Scan method	ω ($2 \leqslant 30°$), ω–2θ ($2\theta > 30°$)
Scan speed (° min^{-1})	2
Scan range (°)	$1.50+0.5 \tan\theta$
Background measurement (s)	5
Data collected	$\pm h, \pm k, +l$ ($2\theta \leqslant 50°$)
Total no. of reflections	10,680
Number of unique data[b]	4349
Number of variables	601
R (R_w) (%)[c]	6.01(7.77)

[a] Graphite-monochromatized.
[b] $|F_o| \geqslant 8\sigma(F_o)$.
[c] $R = \Sigma||F_o|-|F_c||/\Sigma|F_o|$;
$R_w = [\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2]^{1/2}$.
$w = 1/[\sigma^2(|F_o|)+g|F_o|^2]$; $g = 0.001$.

gave unreasonable O—S—O angles in the SO_3^- group, and we used isotropic thermal parameters for the sulphur atom and the three oxygen atoms [OP(41), OP(42) and OP(43)] attached to the sulphur atom. Isotropic thermal parameters were also used for the two disordered waters of crystallization [OW(8A), OW(8B), OW(9A) and OW(9B)]. Anisotropic thermal parameters were used for all other atoms. No attempt was made to locate hydrogen atoms. No chemically significant peaks were observed on the final difference Fourier map. Computations were performed on a FACOM M380 computer at Okayama University of Science. The programs in the UNICS[9] were employed. The figures were drawn by use of ORTEP.[10] The atomic scattering factors, with corrections for anomalous scattering of Mo and S, were taken from ref. 11.

RESULTS AND DISCUSSION

The structure of $[Mo_3S_4(H_2O)_9]^{4+}$ is shown in Fig. 1, and the interatomic distances and angles of the complex cation are collected in Table 2. The cation has an approximate symmetry of C_{3v}. The average Mo—Mo distance (2.735[8] Å) in the aqua complex is the shortest of the complexes with Mo_3S_4 cores so far reported. The complex with H_2O ligands as well as oxalato ones[5] has the second shortest Mo—Mo distance. No relevance can be found between Mo—Mo distances and charges of complexes with Mo_3S_4 cores.[4,5] The Mo—μ_2S and Mo—μ_3S distances are in the range of the values so far reported.

Every SO_3^- group, negatively charged moiety of the pts^- anion, faces towards the complex cluster cation as shown in Fig. 2. Some hydrogen bonds exist between coordinated water molecules and oxygens of SO_3^- groups: short contacts are collected in Table 3. Mean values of bond distances and angles in pts^- anions are listed in Table 4.

Isolation of the crystalline aqua compound from 4 M HPTS solution was achieved in a good yield by use of ion exchange techniques. Addition of solid HPTS to the aqua ion in 2 M HCl so as to make 4 M HPTS did not give any crystals. Hydrogen bonds between coordinated water molecules and pts^- anions (see below) stabilize crystalline products, but coordination of chloride ions to the Mo_3S_4 core prevents the aqua ion from being isolated in crystalline form: when the medium was changed from HPTS (1–4 M) to HCl (1–2 M), a shift (from 602 to 620 nm) of the absorption peak of the aqua ion was observed in the visible region of the electronic spectrum. To the best of our knowledge, all the aqua cluster compounds isolated as crystals include pts^- as counteranions and sulphur bridges between metal atoms within the cluster ions.[6,7] The X-ray

structures of the derivatives of the aqua ions with oxygen and sulphur bridge(s), $Mo_3O_{4-n}S_n(aq)^{4+}$ ($n = 0$–3), had been determined,[12] and we have tried to isolate the crystalline incomplete cubane-type aqua ions from 4 M HPTS solution, but in vain. Furthermore, in the corresponding tungsten aqua ions of $W_3O_{4-n}S_n(aq)^{4+}$ ($n = 0$–4), the sulphur-bridged one alone, $[W_3S_4(H_2O)_9]^{4+}$,[6] has been isolated as crystals.[13] These indicate that the presence of hydrogen bonds between the coordinated water molecules and pts^- anions is not the only determining factor in the formation of crystalline aqua compounds, but sulphur bridges may be also useful. However, there is no short contact between sulphur bridges and other atoms including atoms in pts^-, and we can not explain the role of the sulphur bridges in the crystallization at present.

Acknowledgement—This work was supported by a Grant-in-Aid for Scientific Research (No. 62470043) from the Ministry of Education, Science and Culture.

Supplementary materials available. The atomic coordinates and anisotropic thermal parameters, and bond distances and angles for pts^- groups, and tables of F_o and F_c values are deposited.

SYNTHESIS AND REACTIVITY OF 1,2- AND 1,4-DIHYDROXYARENE COMPLEXES OF CHROMIUM TRICARBONYL

HANS SCHUMANN,* ATTA M. ARIF and THOMAS G. RICHMOND†

Department of Chemistry, University of Utah, Salt Lake City, UT 84112, U.S.A.

(*Received* 29 *December* 1989; *accepted* 7 *March* 1990)

Abstract—Direct reaction of Me_3Si protected 1,2- or 1,4-dihydroxyarenes with $Cr(CO)_6$ affords fair to good yields of the corresponding $Cr(CO)_3$ complexes (**1a–4a**) which were characterized by ^1H and ^{13}C NMR and IR spectroscopic measurements. Removal of the Me_3Si protecting groups with $KF \cdot 2H_2O$ or $HBF_4 \cdot Et_2O$ afforded the 1,2- or 1,4-dihydroxyarene complexes **1b–4b** which were characterized in solution but their instability and air-sensitivity precluded their isolation. Proton transfer reactions were monitored by IR spectroscopy. The crystal structure of $2,3\text{-}(Me_3Si)_2C_{10}H_6Cr(CO)_3$ was determined in the space group $P2_1/c$ with $a = 11.019(4)$, $b = 17.613(9)$, $c = 11.843(4)$ Å, $\beta = 105.11(3)°$, $V = 2219.0$ Å^3, $Z = 4$. This synthetic route provides access to the π-coordination chemistry of 1,2-dihydroxyarenes which cannot be prepared by direct interaction of the arene with $Cr(CO)_6$.

Arene complexes of chromium tricarbonyl have played a central role in the development of organometallic chemistry and these complexes have found extensive application in organic synthesis.[1] Although a myriad of substituted arenes have been coordinated to the $Cr(CO)_3$ fragment, a successful synthesis of hydroquinone chromium tricarbonyl (**1b**) has only recently been reported by Wright who reacted 1,4-hydroquinone with $Cr(CO)_3(CH_3CN)_3$ in refluxing tetrahydrofuran.[2] Complex **1b** could not be isolated and was reported to be unstable in the higher boiling ether solvents typically employed in direct preparations from $Cr(CO)_6$. The hydroxyarene chemistry of $Cr(CO)_3$ has been investigated in some detail since Fischer's preparation[3] of $(HOPh)Cr(CO)_3$ by direct reaction of $Cr(CO)_6$ with phenol at 190°C. Aside from the above note, the π-coordination chemistry of 1,2- and 1,4-dihydroxyaromatics at $Cr(CO)_3$ is unexplored. Note that direct reaction of 1,2-quinones or catechols with $Cr(CO)_6$ results in O-bound chelates and oxidative decarbonylation of the metal centre.[4]

Our interest in these compounds is based on the potentially unusual redox chemistry of the π-coordinated dihydroxyaromatic that might be expected based on the known behaviour of the O-bound complexes of these ligands.[4] Ligand-based oxidation may involve changes in the coordination mode of the arene.[5] Attempts to generate coordinated dihydroxyarenes by protonation of coordinated quinones bound to later transition metals have been reported.[6] We thus sought a general route to these materials by a protecting group strategy. In this work we report that trimethylsilyl protected dihydroxyarenes react directly with $Cr(CO)_6$ to afford the corresponding $Cr(CO)_3$ complexes and removal of the trimethylsilyl groups provides a method of generating the desired materials. Although the dihydroxyaromatic chromium tricarbonyl complexes were sufficiently stable to be spectroscopically characterized in solution, attempts to isolate samples in the solid state resulted in decomposition to unidentified chromium(III) complexes. The crystal structure of the naphthalene derivative $2,3\text{-}(Me_3SiO)_2C_{10}H_6Cr(CO)_3$ is also reported.[7]

EXPERIMENTAL

All reactions were carried out under a nitrogen atmosphere using standard Schlenk techniques.[8]

† Author to whom correspondence should be addressed.

Solvents were purified by distillation from Na/benzophenone (ethers, alkanes) or P_2O_5 (CH_3CN, CH_2Cl_2). Other chemicals were reagent grade and used as received from commercial sources. Elemental microanalyses were performed by Desert Analytics, Tucson, AZ 85717, U.S.A. NMR spectra were recorded in 5 mm tubes on a Varian XL-300 spectrometer using solvent resonances for internal standards and reported in ppm from Me_4Si (δ). IR spectra were obtained in 1,2-$C_2Cl_2H_4$ using 0.1 mm pathlength CaF_2 cells on a Perkin–Elmer 298 spectrometer.

The ligands **1–4** were prepared according to the procedures outlined by Miller and co-workers[9] in approximately 80% yield after recrystallization from Et_2O–pentane. The following ligand NMR resonances were observed in addition to those contained in Table 1. **1**: ^1H, 0.22 ($SiMe_3$); ^{13}C, 0.14 ($SiMe_3$). **2**: ^1H, 0.32 ($SiMe_3$), 1.34 (CMe_3); ^{13}C, 0.14 ($SiMe_3$), 29.97, 34.67 (CMe_3). **3**: ^1H, 0.32, 0.38 ($SiMe_3$), 1.29, 1.38 (CMe_3); ^{13}C, 1.00, 2.29 ($SiMe_3$), 30.91, 31.81, 34.76, 35.61 (CMe_3). **4**: ^1H, 0.36 ($SiMe_3$); ^{13}C, 0.41 ($SiMe_3$).

The following general procedure[10] was used for the preparation of **1a–4a**. A suspension of 10 mmol of $Cr(CO)_6$ and 15 mmol of ligand **1–4** in 25 cm^3 5 : 1 (n-$Bu)_2O$–THF was heated in an oil bath at the reflux temperature for 1–3 days with periodic return of sublimed $Cr(CO)_6$ to the reaction mixture. The reaction was stopped when sublimation of $Cr(CO)_6$ ceased. Removal of solvent *in vacuo*, followed by recrystallization from CH_2Cl_2–pentane and drying *in vacuo*, afforded the desired products (see Scheme 1 for yields and IR data). Additional NMR data is collected below. **1a**: ^1H, 0.32 ($SiMe_3$); ^{13}C, 0.03 ($SiMe_3$). **2a**: ^1H, 0.41 ($SiMe_3$), 1.43 (CMe_3); ^{13}C, 0.42 ($SiMe_3$), 30.45, 34.93 (CMe_3). **3a**: ^1H, 0.40, 0.54 ($SiMe_3$), 1.29, 1.44 (CMe_3); ^{13}C, 0.97, 2.49 ($SiMe_3$), 30.80, 31.48, 34.34, 35.54 (CMe_3). **4a**: ^1H, 0.23 ($SiMe_3$); ^{13}C, 0.39 ($SiMe_3$). **2a**: Found; C, 54.7; H, 7.7. Calc. for $C_{23}H_{38}CrO_5Si_2$: C, 55.0; H, 7.6%. **3a**: Found: C, 54.5; H, 7.7. Calc. for $C_{23}H_{38}CrO_5Si_2$: C, 55.0; H, 7.6%. **4a**: Found: C,

51.8; H, 5.6. Calc. for $C_{19}H_{24}CrO_5Si_2$: C, 51.8; H, 5.4%.

Preparation of **4b**

To a solution of **4a** (1.76 g, 4.00 mmol) in 10 cm^3 of CH_3OH was added $HBF_4 \cdot Et_2O$ (3.7 g of a 52% solution in Et_2O, 10.0 mmol)[11] and the resulting solution stirred for 4 h, during which time the colour changed from red to orange. The solvent was removed under reduced pressure and the residue extracted with CH_2Cl_2. Addition of pentane and storage at −20°C afforded 0.47 g (40%) of orange powder which was isolated by filtration and dried *in vacuo*. Found: C, 49.7; H, 3.2. Calc. for $C_{13}H_8CrO_5 \cdot H_2O$: C, 49.7; H, 3.2%.

Crystallographic study of **4a**

A 0.47 × 0.35 × 0.35 mm red crystal was cleaved from a larger block obtained from CH_2Cl_2–pentane. The sample crystallizes in the space group $P2_1/c$ with $a = 11.019(4)$, $b = 17.613(9)$, $c = 11.843(4)$ Å, $\beta = 105.11(3)°$, $V = 2219.0$ Å^3, $Z = 4$. Of 3416 reflections measured (Syntex $P\bar{1}$, Mo-K_α) at ambient temperature, 2515 were unique and had $I > 3\sigma(I)$ and were used in the solution (Patterson) and refinement. Final refinement with all non-hydrogen atoms as anisotropic and hydrogen atoms as fixed isotropic contributions (244 variables) using an empirical absorption correction ($\mu = 6.319$ cm^{-1}) gave $R = 3.75$, $R_w = 3.95$, and GOF = 1.31. The highest peak in the final Fourier difference map was 0.260 e/Å^3 (Table 2).

RESULTS AND DISCUSSION

Trimethylsilyl protected hydroxyaromatics (**1–4**) were synthesized by a literature method.[9] Complexes **1a–4a** were prepared by extended reaction of $Cr(CO)_6$ and 1.5 equivalents of the ligand in 5 : 1 *n*-Bu_2O–THF at the reflux point in 15–85% isolated yields after recrystallization from CH_2Cl_2–pentane. Higher yields of the air-stable solids were obtained with the more highly substituted arenes. The complexes were characterized by elemental analysis (**2a–4a**) and exhibit the ν_{CO} bands expected for a C_{3v} $Cr(CO)_3$ group (see Scheme 1). Characteristic upfield shifts of the aromatic protons and carbons

upon coordination to $Cr(CO)_3$ are also observed (Table 1).

In the case of the deep red 2,3-$(Me_3SiO)_2C_{10}H_6Cr(CO)_3$ complex (**4a**), ^{1}H and ^{13}C NMR measurements are indicative of coordination to the unsubstituted ring and no isomeric products were detected. This is confirmed by a single crystal X-ray diffraction study of **4a** as shown in Fig. 1. Bond distances (Table 3) and angles (Table 4) appear normal in comparison with other naphthalene $Cr(CO)_3$ complexes,[12] with the Cr—C(9) and Cr—C(4) distances (av. = 2.31 Å) elongated compared to the other coordinated arene carbon–Cr distances (av. = 2.22 Å). The chromium atom is 1.744 Å from the mean plane of the six coordinated carbons.

Deprotection of **4a** was achieved by treatment with $HBF_4 \cdot Et_2O$ in CH_3OH to afford **4b** which was isolated as an orange microcrystalline powder in 40% yield. Microanalytical data suggest that **4b** exists as a hydrate. As given in Table 1, ^{1}H and ^{13}C NMR data indicate that the $Cr(CO)_3$ group remains coordinated to the unsubstituted arene ring.

Removal of the Me_3Si groups of **1a–3a** was accomplished by stirring with excess $KF \cdot 2H_2O$ in CH_2Cl_2 to afford **1b–3b** which are partially deprotonated by excess fluoride in solution. This is not unexpected given the great increase in acidity for $(C_6H_5OH)Cr(CO)_3$ relative to C_6H_5OH.[13] More rapid cleavage of the protecting groups was effected by wet $[(n\text{-}Bu)_4N]F$. However, in both instances the hygroscopic nature of these fluorides coupled with the sensitivity of the products **1b–3b** prevented reliable control of the degree of protonation. Thus a solution of **1b** prepared with $KF \cdot 2H_2O$ exhibits ν_{CO} bands approximately 20 cm^{-1} lower in frequency compared with the fully protonated material reported by Wright.[2] For example, deprotection of **2a** with $KF \cdot 2H_2O$ afforded **2b** with ν_{CO} = 1930 and 1831 cm^{-1}, but ν_{CO} = 1938 and 1838 cm^{-1} for the complex obtained from wet $[(n\text{-}Bu)_4N]F$. Addition of excess aqueous HBF_4 afforded the fully protonated material with ν_{CO} = 1951 and 1862 cm^{-1}. Thus the donor ability of the arene is only slightly influenced by the replacement of a proton for the Me_3Si group. Reaction of **2b** with 2.5 equivalents of KOH in CH_3CN afforded a complex with ν_{CO} = 1898 and 1784 cm^{-1} which is probably fully deprotonated. These proton transfer reactions appear to be reversible, although solutions slowly decomposed at room temperature. Regardless of the degree of protonation, ^{1}H and ^{13}C NMR spectra (Table 1) of **1b–3b**, prepared by $KF \cdot 2H_2O$ deprotection, definitely show that the arene remains coordinated to the $Cr(CO)_3$ unit. Fluorine NMR spectroscopic examination of a sample of **2a** prepared by deprotection with $[(n\text{-}Bu)_4N]_4F$ did not indicate the presence of HF which could conceivably hydrogen bond to the dihydroxyarene ligand.

Unfortunately, all attempts to isolate the protonated complexes **1a–3a** or their deprotonated forms (as K^+, $[(n\text{-}Bu)_4N]^+$, $[PPh_3Me]^+$ or $[PPN]^+$ salts) proved fruitless. Concentration of these solutions resulted in green, intractable solids. Perhaps O-bound coordination of the ligand is occurring along with oxidation to chromium(III).[4] Thus, these materials may have potential as ligands for other metal centres as recently reported for (phenoxide)$Cr(CO)_3$ complexes.[14] Although hydroquinone complexes of $Cr(CO)_3$ could not be isolated as solids, solution spectroscopic characterization of these materials shows that they can be generated from Me_3Si protected precurcors. In particular, this route provides access to the π-coor-

THE STRUCTURAL EFFECTS OF STERIC OVERCROWDING IN BIS(TRICYCLOHEXYLPHOSPHINE)PLATINUM(II) COMPLEXES: THE CRYSTAL AND MOLECULAR STRUCTURE OF *TRANS*-$PtBr_2(PCy_3)_2$

T. S. CAMERON, H. C. CLARK,* A. LINDEN and A. M. NICHOLAS

Department of Chemistry, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J3

(*Received* 31 *July* 1989; *accepted* 8 *March* 1990)

Abstract—The crystal and molecular structure of *trans*-$PtBr_2(PCy_3)_2$ has been determined. Crystals are triclinic, space group $P\bar{1}$, $a = 10.038(1)$, $b = 10.212(1)$, $c = 10.775(1)$ Å, $\alpha = 113.18(1)$, $\beta = 109.81(1)$, $\gamma = 91.51(1)°$, $V = 938.8$ Å^3, $Z = 1$ and $D_c = 1.620$ g cm^{-3}. Refinement, based on 4021 reflections with $I > 3\sigma(I)$ converged at $R = 0.032$. The structure consists of discrete *trans*-$PtBr_2(PCy_3)_2$ molecules in which steric overcrowding is indicated by a long Pt—P bond length of 2.345(1) Å and Br···C and Br···H non-bonded contact distances significantly smaller than the sum of the van der Waals' radii of the respective atoms. A comparison of structural parameters for *trans*-$PtXY(PR_3)_2$ (X, Y = H, Cl, Br or I; R = Me, Et or Cy) permits identification of the modes of the steric distortion in these complexes. For the symmetrical complexes (X = Y), Pt—P bond extension is found to be the principal type of distortion in response to unfavourably short intramolecular X···H and X···C non-bonded interactions that arise in these molecules on account of overcrowding.

Although many structure determinations have been made for phosphine complexes of platinum, only a few of the results permit a direct comparison to be made between the effects of tricyclohexylphosphine (PCy_3) and a less bulky triorganophosphine in a similar molecular environment.[1,2] Such comparisons are essential if one is to assess the effects of steric overcrowding on the geometry and reactivity of a platinum(II) phosphine complex. For example, the increase in the Pt—P bond distance by 0.055 Å when PMe_3 is replaced by PCy_3 in the complex *trans*-$PtI_2(PR_3)_2$, has been rationalized as a steric effect and significant non-bonded interactions have been identified in the PCy_3 complex.[3,4] However, it is difficult to determine the electronic component of this observed bond extension without further investigations of similar complexes.

In view of the importance of steric control in many reactions involving phosphine complexes it is desirable to have structural information which can be related to the bulk of the phosphine ligand. Accordingly, several PCy_3 complexes of platinum (II) containing additional bulky ligands have been prepared and structurally characterized.[1,5,6]

In this paper, the X-ray crystal structure analysis of *trans*-$PtBr_2(PCy_3)_2$ is reported and compared with the iodo[3] and chloro[7] analogues and with *trans*-$PtBr_2(PEt_3)_2$,[8] in an effort to determine the types of distortion which occur in response to non-bonded repulsive interactions in situations of varying steric demand by the ligands.[9]

EXPERIMENTAL

Yellow crystals of *trans*-$PtBr_2(PCy_3)_2$ [$^{31}P\{^1H\}$ NMR(CH_2Cl_2): δ 13.4 ($J_{P-Pt} = 2320$ Hz)][10] were obtained by slow crystallization from a dichloromethane solution of *cis*-$PtBr_2(PCy_3)_2$. The *cis* complex [$^{31}P\{^1H\}$ NMR(CH_2Cl_2): δ 16.9 ($J_{P-Pt} = 3585$ Hz)] was obtained either by the addition of stoichiometric amounts of 1 M $SnBr_4$ in CH_2Cl_2 to $PtO_2(PCy_3)_2$ in methanol[6] or tritylbromide to the dioxygen complex in dichloromethane.[11]

X-ray crystallographic structure determination

A crystal suitable for X-ray studies was mounted on a glass fibre. The data collection and refinement parameters are given in Table 1. The unit cell constants were obtained by least-square analysis of the diffractometer setting angles of 25 well-centred reflections with $2\theta = 28$–$32°$. The intensities were reduced to a standard scale using routine procedures.[12] Corrections for Lorentz and polarization factors were applied. An empirical absorption correction was applied using DIFABS.[13] Scattering factors for neutral atoms were those recorded in *International Tables for X-ray Crystallography*[14] and were corrected for the real part of anomalous dispersion.

The positions of the platinum, phosphorus and bromine atoms were obtained by the Patterson method and the remaining non-hydrogen atoms were located in a subsequent difference-Fourier synthesis. Refinement was carried out by using the SHELX-76[15] system. The hydrogen atom positions were determined from a difference-Fourier synthesis, and allowed to refine. C—H bond length constraints (1.08 Å) were applied to four hydrogen atoms only. The final refinements were with anisotropic temperature factors on the non-hydrogen atoms and individual isotropic temperature factors on the hydrogen atoms. A four-block matrix least-squares method was employed, minimizing $\Sigma w(|F_o| - |F_c|)^2$. The largest peaks in the final difference maps were 1.7 e Å^{-3} within 1.1 Å of the platinum atom and 0.60 e Å^{-3} elsewhere. No correction was applied for extinction.

Selected interatomic distances and interbond angles for *trans*-$PtBr_2(PCy_3)_2$ are given in Table 2. A diagram of the molecular structure with the numbering scheme for the atoms is given in Fig.

1(a) and a SPACEFILL[16] drawing is shown in Fig. 1(b).

RESULTS AND DISCUSSION

It has been suggested that a ligand X may affect Pt—P bond lengths *cis* to X via competition for the d_π electrons of platinum.[17] In order to study steric effects free from such interactions only *trans*-$PtXX'(PR_3)_2$ complexes, in which the π-interaction of X and X′ with platinum is negligible, have been considered. Furthermore, spherical monatomic

ligands (X) have been chosen so that their size can be described easily. Since the non-bonded interaction between X and the hydrogen and carbon atoms of the phosphine ligand that surrounds X is the feature of interest, the ligand size of X is described best by its van der Waals' radius.

The Pt—P and Pt—Y bond distances for a series of *trans*-$PtXY(PR_3)_2$ (R = Cy, Et or Me and X, Y = H, Cl, Br or I) are given in Table 3. The Pt—P bond lengths, for a chosen phosphine, increase progressively with increasing size of ligands X and Y. In addition, for any selection of X and Y, the Pt—P and Pt—Y bond distances in *trans*-$PtXY(PR_3)_2$ are significantly larger for R = Cy or *i*-Pr compared with R = Et or Me. These increases in Pt—P lengths are illustrated in Fig. 2 with a plot of r(Pt—P) vs r^*, the sum of the van der Waals' radii of X and Y [$r^* = r_{vw}(X) + r_{vw}(Y)$].

If steric effects control the variation in the Pt—P bond distance, the expected increase in Pt—P length with the progressive increase of the bulk of X and Y should be modulated in situations of less steric demand involving less bulky phosphines such as PMe_3 or PEt_3. Consequently, the observation that the magnitude of the increase of r(Pt—P) with r^* is larger for the bulkier phosphines is in agreement with steric modification of the Pt—P bond distance. Nevertheless, for the smaller phosphine ligands the increase in Pt—P distance could be due to a σ electronic effect as well because no significant non-bonded I···H or I···C interactions have been found, for example, in *trans*-$PtI_2(PMe_3)_2$. The non-linear larger variation in r(Pt—P) with r^* for L = PCy_3 warrants further investigation, presented below, of the structural parameters of the dihalo complexes, *trans*-$PtX_2(PCy_3)_2$, in an effort to understand how the bulk of X affects the bonding of these complexes.

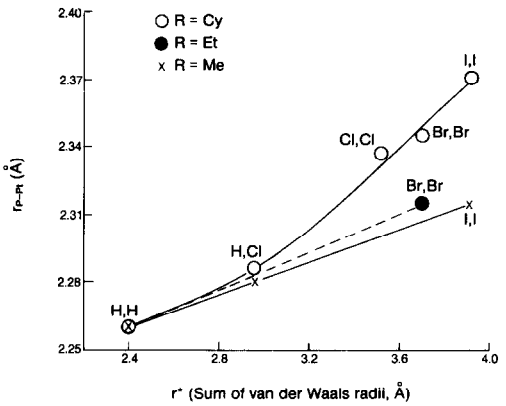

Fig. 2. A plot of the Pt—P bond distance, r(Pt—P) vs r^*, the sum of van der Waals' radii of X and Y, in *trans*-$PtXY(PR_3)_2$. The nature of X and Y is denoted by (X,Y) above the point corresponding to it. The van der Waals' radii of the atoms H, Cl, Br and I are 1.2, 1.75, 1.85 and 1.96 Å, respectively.

The unit cell volumes for the essentially isostructural complexes *trans*-$PtX_2(PCy_3)_2$, where X = Cl, Br and I, are V = 929.9, 938.8 and 988.8 $Å^3$, respectively, which demonstrates the effect of increase of the size of X.

In Table 4 the P—Pt—X angles listed in column 2 show a small deviation from the expected 90° value for an ideal square-planar geometry. This deviation decreases with an increase in the bulk of X. This is probably because ligand X has non-bonded interactions with both PCy_3 groups and for the very bulky X an opening of the P—Pt—X angle

to relieve strain due to one PCy_3 group is resisted by an increase in steric interactions of X with the other PCy_3 ligand. The absence of a significant increase in the mean Pt—P—C angles listed in column 3 of Table 4 with an increase in the size of X may be the result of steric repulsion between Cy groups of PCy_3 resisting further folding back of the phosphine ligand.

Recently, Powell[20] has shown that the Pt—P—C_T bending (where C_T is the centroid of the α-carbon atoms of the phosphine) is an important mode of distortion in phosphine complexes. For *trans* complexes Powell introduced a β value, where $\beta = 180° - \angle(PtPC_T)$, which has been correlated with electronic repulsion effects in the molecule. When X = Cl, only interactions between Cl and the most eclipsed Cy group are significant and the PCy_3 ligand can tilt away from that contact without necessitating much lengthening of the Pt—P bond and without causing severe interactions with other Cy groups. However, the decrease in β with an increase in ligand size may be a consequence of increased non-bonded interactions between all Cy groups and X.

Although there are several modes of distortion that are available in a square-planar complex for relief of steric strain, overcrowding is still present in molecules with very bulky ligands. To compare the extent of overcrowding in the halo complexes, significantly short non-bonded contact distances (r_{nb}) involving X···C and X···H are listed in Tables 5 and 6, respectively.

The r_{nb} values listed in Tables 5 and 6 indicate non-bonded interactions in all three complexes. There is a consistent decrease in Δ when Cl is replaced by Br, suggesting a significant increase in repulsive interactions in the bulkier bromo complex.

The repulsive force arising from a van der Waals' contact is very sensitive to a further decrease in the interatomic separation.[23] Consequently, if there is already a short, non-bonded contact between two atoms, even a small reduction in the contact distance will be precluded by a concomitant large increase in the repulsive force. Such a situation is present when Br is replaced by I. Here it would appear that the X···C(1) and X···C(13′) and the corresponding X···H interactions reach their limits and the large repulsive forces arising because of the additional bulk of I can no longer be accommodated. This results in significant lengthening of the Pt—P bond by 0.026(1) Å. On the other hand, when Cl is replaced by Br the overcrowding is not so severe as to require further lengthening of the Pt—P bond.

CONCLUSION

By considering structural parameters of *trans*-$PtXY(PR_3)_2$, the modes of steric distortion in these complexes have been identified. Pt—P bond length-

X···H(182′)	3.11	3.08(5)	−0.05	+0.03

[a] $\Delta = r_{nb} - [r_{vw}(X) + r_{vw}(H)]$. The relevant van der Waals' radii sums are I···H = 3.16 Å and Br···H = 3.05 Å.

[b] The hydrogen atoms are labelled so that the first two digits of the value in parentheses correspond to the label of the carbon atom (according to Fig. 1) to which it is attached.

ening is found to be the principal type of steric modification that occurs to overcome unfavourable X···H and X···C non-bonded intramolecular interactions that arise because of overcrowding. The extent of Pt—P bond lengthening increases with an increase in steric demand of all the ligands in the complex. An increase in the bulk of PR_3, X and Y is first accommodated mostly by a decrease in non-bonded contact distances, until further decreases cause severe steric strain that is then relaxed by Pt—P extension.

SQUARE, SULPHUR-BICAPPED TETRANIOBIUM CLUSTER COMPOUNDS

ELIZABETH BABAIAN-KIBALA, F. ALBERT COTTON* and PIOTR A. KIBALA

Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A&M University, College Station, TX 77843, U.S.A.

(*Received* 5 *February* 1990; *accepted* 8 *March* 1990)

Abstract—By addition of first PhSSPh and then PMe_2R (R = Ph, Me) to a solution of $NbCl_5$ that has been reduced with Na/Hg, the orange, crystalline compounds $Nb_4S_2(SPh)_8(PMe_2Ph)_4 \cdot C_7H_8$ (**1**) and $Nb_4S_2(SPh)_8(PMe_3)_4 \cdot C_7H_8 \cdot C_4H_8O$ (**2**) are obtained. They are closely related to the $[Nb_4S_2(SPh)_{12}]^{4-}$ anion previously reported by Christou and co-workers (L. Seela, J. C. Huffman and G. Christou, *J. Chem. Soc., Chem. Commun.* 1987, 1258). In each compound four niobium and two sulphur atoms form a tetragonal bipyramid with sulphur atoms at the apices. The mean Nb—Nb and Nb—S_{ap} distances are, respectively, 2.816(8) and 2.491(3) Å, for **1** and 2.812(6) and 2.494(3) Å for **2**. Each Nb—Nb bond (postulated to be single) is bridged by two SPh groups (mean Nb—S_{br} distances for **1** and **2** are 2.624(8) and 2.626(3) Å, respectively) and there is a phosphine ligand coordinated to each niobium atom (mean Nb—P distances for **1** and **2** are 2.706(1) and 2.677(4) Å, respectively). Compound **1** crystallizes in triclinic space group $P\bar{1}$ with unit cell dimensions: $a = 13.411(6)$, $b = 14.588(4)$, $c = 13.058(5)$ Å, $\alpha = 98.05(3)$, $\beta = 114.95(3)$, $\gamma = 66.35(3)°$, $V = 2210(2)$ Å^3 and $d_{calc} = 1.530$ for $Z = 1$. The structure was refined to $R = 0.0439$ and $R_w = 0.0590$ for 4740 reflections with $I > 3\sigma(I)$. Compound **2** crystallizes in monoclinic space group $C2/m$ with unit cell dimensions: $a = 19.333(10)$, $b = 19.965(8)$, $c = 12.048(5)$ Å, $\beta = 120.00(4)°$, $V = 4027(7)$ Å^3, and $d_{calc} = 1.466$ for $Z = 2$. The structure was refined to $R = 0.0547$ and $R_w = 0.0674$ for 1480 reflections having $I > 3\sigma(I)$.

As part of an extensive effort to develop the chemistry of niobium and tantalum in their lower valence states (II–IV) without the use of η^5-C_5H_5 or related ligands,[1] we have studied the reactions of solutions containing the lower-valent metals with various sulphur-containing ligands. In this paper we report the preparation of compounds containing a tetragonal bipyramid of composition Nb_4S_2, namely, $Nb_4S_2(SPh)_8(PMe_2R)_4$, where R = Ph, Me. We shall describe the preparation and structure of these molecules, compare their structural features with those in other compounds, especially Christou's $[Nb_4S_2(SPh)_{12}]^{4-}$ ion,[2] and discuss the bonding in the cluster.

EXPERIMENTAL

All solvents were dried over sodium–benzophenone ketyl and freshly distilled before use. $NbCl_5$ was purchased from Aesar Chemicals, PMe_2Ph and PMe_3 from Strem Chemicals.

Preparation of $Nb_4S_2(SPh)_8(PMe_2Ph)_4$ (1)

$NbCl_5$ (1.35 g, 4.97 mmol) was placed in a 100 cm^3 three-neck round-bottom flask. A side arm containing 1.91 g (8.76 mmol) of PhSSPh was connected to the flask. After addition of 50 cm^3 of toluene and 7.5 cm^3 of 4M Na/Hg, the mixture was stirred for 1.5 h. The PhSSPh was added to the flask and the mixture was stirred for 20 h. After a grey precipitate had formed the solution was heated to 60°C for 4 h then 10 cm^3 of THF was added. Upon

addition of 10 cm^3 of THF a brick-red solution formed, and was stirred for an additional 20 h. The solution was filtered and 0.70 cm^3 (5.24 mmol) of PMe_2Ph was added to the filtrate. This solution was gently heated at 40°C for 20 h and filtered again to separate a pale yellow precipitate from an orange solution. The filtered solution was transferred to a Schlenk tube and layered with 20 cm^3 of hexane. The crystalline product began depositing along the walls of the Schlenk tube after 10 days. Approximately 0.42 mg (21% yield based on $NbCl_5$) was obtained. Analysis, exp. (calc.) S: 16.91 (17.22).

Preparation of $Nb_4S_2(SPh)_8(PMe_3)_4$ **(2)**

$NbCl_5$ (0.5 g, 1.85 mmol) and 35 cm^3 of toluene were placed in a 100 cm^3 round-bottom flask equipped with a gas outlet. A side arm containing 0.70 g (3.21 mmol) of PhSSPh was connected to the flask. After addition of 3.7 cm^3 of 3M Na/Hg the mixture was stirred for 2 h. The PhSSPh and 5 cm^3 of THF were added to the flask. The resulting brick-orange solution was heated to 60°C and stirred for 2 h. The solution was then filtered and 0.20 cm^3 (1.96 mmol) of PMe_3 was added to the filtrate. This solution was gently heated at 50°C for 2 h and filtered again to separate a pale yellow precipitate from an orange solution. The filtered solution was transferred to a Schlenk tube and layered with 20 cm^3 of hexane. The red, rectangular crystals began to deposit along the walls of the Schlenk tube after 12 days.

X-ray crystallography

Both crystals were sealed with epoxy glue inside capillaries filled with degassed mineral oil to prevent decomposition in the air. Unit cell dimensions and Laue class were confirmed with oscillation photographs. For each crystal three control reflections monitored throughout the data collection showed no significant change in their intensities. Lorentz, polarization and empirical absorption correction were applied to the data. The general procedures, routine to this laboratory, are described elsewhere.[3] The data collection parameters are listed in Table 1.*

$Nb_4S_2(SPh)_8(PMe_2Ph)_4 \cdot C_7H_8$ **(1)**. The direct methods portion of the SHELXS-86 program revealed the positions of the heavy atoms. The tetramer was located around the inversion centre of the $P\bar{1}$ space group, making half of the tetramer the asymmetric unit. Consecutive least-squares cycles and difference Fourier maps completed the coordinated sphere about each metal atom. A toluene molecule was located around an inversion centre and successfully modelled and refined. In the final refinement all the atoms except the atoms of the solvent molecule were refined anisotropically. Hydrogen atoms were omitted.

$Nb_4S_2(SPh)_8(PMe_3)_4 \cdot C_7H_8 \cdot C_4H_8O$ **(2)**. Systematic absences indicated $C2/m$, Cm and $C2$ as possible space groups. The structure was initially solved in $C2/m$ space group and the failed attempts to refine the crystal in $C2$ and Cm space groups confirmed $C2/m$ as the correct choice. The direct methods portion of the SHELXS-86 program revealed the positions of the niobium, sulphur and phosphorus atoms. The tetramer was located around a $2/m$ symmetry site making a quarter of the molecule the asymmetric unit. The positions of the remaining atoms were derived through alternating use of least-squares refinements and Fourier maps. The phenyl rings of the SPh ligands were disordered in a way that could be described as resulting from rotation of the phenyl rings around the S—C bonds by 90°. This required refinement of the *ortho* and *meta* carbon atoms at half occupancy. The carbon atoms of the phosphine ligands were also disordered. The disorder of the two phosphine ligands in the asymmetric unit was modelled as resulting from rotation of the methyl groups around the Nb—P bonds by 180°. The two images of the first phosphine were refined at 50:50 occupancies while the two images of the second phosphine at 75:25 occupancies. A molecule of toluene and tetrahydrofuran were located around $2/m$ symmetry sites and were successfully modelled and refined. In the final refinement the niobium, sulphur and phosphorus atoms were refined anisotropically and the carbon atoms isotropically. Hydrogen atoms were not included in the refinement.

RESULTS

An ORTEP drawing of the $Nb_4S_2(SPh)_8(P)_4$ core is shown in Fig. 1, and the principal bond distances and angles are presented in Table 2.

The centre of each molecule is a tetragonal bipyramid formed by four niobium atoms in the equatorial plane and two sulphur atoms at the apical positions. Each Nb—Nb edge is bridged by two SPh groups, one above and one below the plane of the metal atoms. Each niobium atom is then

*Tables of atomic coordinates, structure factors, anisotropic thermal parameters and a complete list of bond distances and angles have been deposited with the Editor at Queen Mary and Westfield College and at the Cambridge Crystallographic Data Centre.

coordinated by a phosphine molecule with the phosphorus atom lying along an axis passing through the centre of the bipyramid and the niobium atom. The SPh groups are oriented so that all four S—C bonds on each side of the central Nb_4 plane are parallel. Thus, the entire central group of atoms, $Nb_4S_2(SC)_8P_4$, have essentially D_{4h} symmetry.

DISCUSSION

The oxidation state of the niobium atoms in the $Nb_4S_2(SPh)_8(PMe_2R)_4$ (R = Me, Ph) molecules is III. This, together with the mean Nb—Nb distance, leads very naturally to the idea that in the square array of niobium atoms there is a set of Nb—Nb single bonds. In addition to these, each niobium atom forms two bonds to capping sulphur atoms, four bonds to the nearest bridging sulphur atoms and a bond to the outer phosphorus atom. In total, therefore, each metal atom forms nine bonds. This is reminiscent of the situation in the trinuclear molybdenum and tungsten compounds[4] of the type $M_3X_2(O_2CR)_6L_3$ with X = O or CCH_3. The major difference is that a μ_3-X group can supply a sufficient number of electrons in orbitals of appropriate symmetry to form three ordinary M—X two-electron bonds.

In the case of a $(\mu_4\text{-S})M_4$ group, the four M atoms may provide a set of four σ orbitals properly directed for bonding to the S atom, but the S atom cannot provide the necessary set of four atomic orbitals. The symmetry-adapted linear combi-

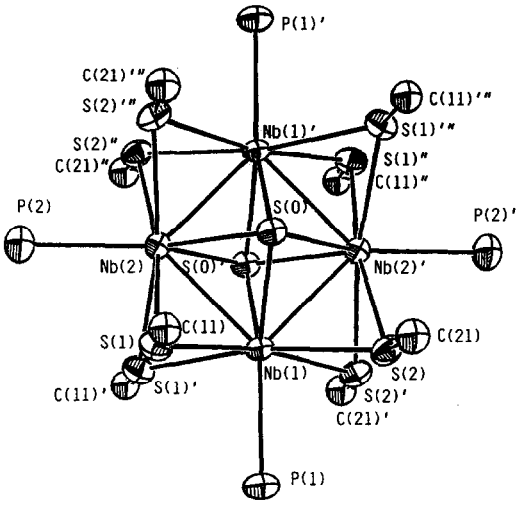

Fig. 1. An ORTEP drawing of the $Nb_4S_2(SPh)_8(PMe_2R)_4$ molecule. Some carbon atoms are omitted for clarity. Each atom is shown as its ellipsoid of thermal displacement contoured at the 50% probability level.

nations (SALCs) on the set of metal atoms will belong to *A*, *B* and *E* representations (for the set of eight in D_{4h} symmetry, A_{1g}, A_{2u}, B_{1g}, B_{2u} and E_g, E_u). The sulphur atom has only *s* (*A*), p_z (*A*) and p_x, p_y (*E*) orbitals available unless we assume that a d_{xy} (or $d_{x^2-y^2}$, depending on choice of *x* and *y* axis directions) also plays a role. If we restrict ourselves to only *s* and *p* orbitals, then the *B* SALCs must remain empty, non-bonding MOs, insofar as interaction with the capping sulphur atoms is concerned.

Nevertheless, the stability of the $Nb_4S_2(SPh)_8(PMe_2R)_4$ molecules can be attributed to the full utilization of all of the nine (five *d*, three *p*, and the *s*) orbitals of the metal atom valence shells and the occupation of all but two (B_{1g} and B_{2u}) of the molecular orbitals to which they contribute. One might, of course, wonder why niobium does not emulate molybdenum and tungsten in forming a trinuclear cluster with a central trigonal bipyramid in which all orbitals could be utilized. Probably the many bulky ligand side chains inhibit this sterically.

The occurrence of $(\mu_4\text{-S})M_4$ groups has a great many precedents. In recent years, for example, the work of Adams and co-workers[5] has produced a great many. In these compounds the M—S bond lengths are consistently in the range 2.4–2.5 Å, which may be compared with the mean value of 2.49 Å in the present case.

Christou and co-workers[2] have previously reported the compound $Li_4[Nb_4S_2(SPh)_{12}]\cdot 4THF$. The tetranuclear anion in this compound has practically the same structure as our $Nb_4S_2(SPh)_8(PMe_2R)_4$ molecules. The four PMe_2R molecules are replaced by terminal PhS^- ions and the arrangement of the bridging SPh groups is a little less regular. Two of the latter are oriented with their phenyl groups parallel to the Nb_4 plane instead of perpendicular. This difference may arise because of the packing requirements of the surrounding Li^+ ions and THF molecules, and it is certainly not of much importance. The principal dimensions of the cluster are practically the same as in the present case: Nb—Nb = 2.828(2) Å and Nb—S(cap) = 2.501(3) Å.

The synthetic chemistry in the two cases is, superficially at least, different. Christou used a dinuclear starting material, $Nb_2Cl_6(Me_2S)_3$, and his anion *may* have resulted from coupling of these without separation into mononuclear niobium intermediates. In our case, the starting material was $NbCl_5$ and we cannot say whether the overall reaction proceeds by initial formation of dinuclear intermediates or not. In both syntheses, there must be a step where the capping sulphur atoms are extracted from a species containing S—C bonds. In Christou's reaction this could be either Me_2S or PhS^-, while in our case it can only be PhS^-. This probably means that PhS^- was also the source in the other case as well.

In our synthesis we do not know whether the intermediate immediately preceding the final product is $[Nb_4S_2(SPh)_{12}]^{4-}$ (i.e. Christou's anion) or $[Nb_4S_2(SPh)_8Cl_4]^{4-}$, but these would seem to be the most likely. Some preference might be given to the former in view of its known existence. This can, of course, be tested by seeing if Christou's anion reacts directly with PMe_2Ph or other phosphines. We were able to prepare **1** and **2** using stoichiometries that were consistent with either of the two intermediates. We found that synthesis of **1** and **2** using stoichiometry that assumes $[Nb_4S_2(SPh)_8Cl_4]^{4-}$ as an intermediate takes less time and the products are obtained in better yields.

One final point concerns the possible existence of tantalum analogues in this type of M_4S_2 cluster compound. We have attempted to follow a similar procedure given in the experimental section substituting $TaCl_5$ for $NbCl_5$. However, the only product we have been able to isolate is $Ta_2S_2Cl_4(PMe_2Ph)_4$. We shall describe this compound and others related to it elsewhere.

Abstract—The 1:1 reaction between anhydrous ferric chloride and tris(2,4,6-trimethoxyphenyl)phosphine (TMPP) in benzene produces a reactive complex, **1**, with the empirical formula $FeCl_3$(TMPP). This compound undergoes a facile reaction with molecular oxygen at room temperature and 1 atm to give a dark green intermediate and a final orange product, $FeCl_3[O{=}P\{C_6H_2(OMe)_3\}_3]$ (**3**). Crystal data for **3**: $P\bar{1}$, $a = 12.23(1)$, $b = 14.06(1)$, $c = 13.13(1)$ Å, $\alpha = 110.78(7)$, $\beta = 109.89(8)$, $\gamma = 72.58(8)°$, $V = 1648(3)$ Å^3, $Z = 2$, $d_{calc} = 1.432$ g cm^{-3}, μ(Mo-K_α) = 7.976 cm^{-1}, $R = 0.068$, $R_w = 0.078$ for 374 parameters and 1606 data with $F_o^2 > 3\sigma(F_o)^2$. The structure consists of a tetrahedrally coordinated iron(III) centre ligated by three chlorides and one phosphine oxide ligand. This is the first example of a four-coordinate phosphine oxide complex of $FeCl_3$ and one of only several known examples of a neutral tetrahedral iron(III) complex. The synthesis and properties of **3** are presented and discussed.

We are currently investigating the chemistry of an unusual bulky phosphine ligand, tris(2,4,6-trimethoxyphenyl)phosphine (TMPP), a highly basic derivative of triphenylphosphine.[1] In the broad study of the coordination chemistry of this ligand, we have recently synthesized several TMPP compounds, each exhibiting an entirely different binding mode for TMPP: monodentate, as in $[Ag(TMPP)_2]^+$ and in $[Rh(TMPP)_2(CO)]^+$ (**a**),[2] bidentate as in $[Rh(TMPP)_2(CO)]^+$ (**b**),[2] chelating tridentate as in $[Rh(TMPP)_2]^{2+}$ or $Mo(CO)_3$(TMPP) (**c**),[3,4] and the combination bridging and

chelating tridentate mode as in our recently reported dimer $Rh_2(O_2CCH_3)_3[\{C_6H_2(OMe)_3\}_2\text{-}P\{C_6H_2(OMe)_2O\}](MeOH)$ (**d**).[5]

Our desire to elucidate the chemistry of TMPP with first-row transition metal halides prompted us to study its reactivity with iron(III) chloride. Our goal was to synthesize the neutral adduct $FeCl_3$(TMPP), stabilized by only one monodentate phosphine ligand, and to further study the interaction of this compound with small molecules. A perusal of the literature reveals that, to date, very few neutral $FeCl_3$ monophosphine adducts of a tetrahedral geometry have been fully characterized. Evidently the preferred formulation is the five-coordinate FeX_3L_2, where L is a phosphine or a phosphine oxide,[6] or FeX_3(L—L), where L—L is a bidentate diphosphine.[7] With regard to neutral four-coordinate iron(III) species, the syntheses of the complexes $FeCl_3(PPh_3)$,[8] $FeCl_3(PR_3)$ (R = Cy,[9] *t*-Bu[9b]), $FeCl_3(THF)$[10] and $FeCl_3(S_4N_4)$[11] have been reported. Crystal structures are known only for the last two examples.[10b,11] Recently the complex $FeI_3[SC(NMe_2)_2]$ was reported as the first example of a neutral FeI_3 derivative.[12]

In this paper we describe our efforts to understand an interesting series of reactions involving the 1:1 adduct of $FeCl_3$ and TMPP. The compound, which possesses the empirical formula $FeCl_3$(TMPP), reacts with molecular oxygen to form a moderately stable intermediate and a final stable phosphine oxide product. Herein we report the chemistry leading to the isolation and full characterization of $(R_3P{=}O)FeCl_3$, where R = 2,4,6-trimethoxyphenyl.

EXPERIMENTAL

Ferric chloride (anhydrous) was purchased from Strem Chemicals and was used without further purification. The phosphine ligand, TMPP, was prepared in our laboratories[13] according to a modification of a literature preparation[1a] and was recrystallized from EtOH. Solvents were dried and freshly distilled under nitrogen before use. Unless otherwise specified, all reactions were carried out under an argon atmosphere by using standard Schlenk-line techniques.

PHYSICAL MEASUREMENTS

IR spectra were recorded as Nujol mulls between CsI windows with a Nicolet 740 FT–IR spectrophotometer. Electronic absorption spectra were recorded on a Hitachi U-2000 or a Cary 17 spectrophotometer. SQUID susceptibility measurements were performed on a Quantum Design MPMS susceptometer housed in the Physics Department at Michigan State University.

Reaction of $FeCl_3$ *with* TMPP

Anhydrous $FeCl_3$ (150 mg, 0.90 mmol) was reacted with 1 equivalent of TMPP (500 mg, 0.90 mmol) in 10 cm^3 of carefully deoxygenated benzene. The reaction, which was stirred at room temperature for $\sim$ 5 h, produced a pale yellow solid over this period of time. The product was washed with copious amounts of fresh benzene and dried under a reduced pressure. After recrystallization from a mixture of CH_2Cl_2–benzene (10:1 v/v), the yield (relative to $FeCl_3$) was 70%. The product, **1**, is soluble in CH_2Cl_2, MeOH and EtOH, but is insoluble in other common solvents. Found: C, 46.0; H, 4.9; Cl, 15.3. Calc. for $C_{27}H_{33}Cl_3O_9PFe$: C, 46.6; H, 4.7; Cl, 15.3%. IR spectrum (CsI, Nujol mull), cm^{-1}: 1600 vs, 1580 vs, 1415 s, 1380 s, 1340 s, 1310 w, 1260 w, 1230 s, 1210 s, 1185 w, 1165 m, 1135 s, 1115 m, 1100 m, 1045 w, 1025 s, 950 m, 930 m, 920 m, 8910 w, 885 m, 820 s, 805 w, 790 w, 720 m, 690 w, 675 w, 665 w, 645 m, 520 w, 480 s, 430 m, 410 w, 400 w, 360 s, 300 m, 235 m. Electronic spectrum (Quartz, CH_2Cl_2), λ_{max}, nm (ε, M^{-1} cm^{-1}): 362 (8.59×10^3), 332 (1.23×10^4), 286 (sh), 260 (6.02×10^4).

Reaction of $FeCl_3$(TMPP) *with molecular oxygen*

An amount of $FeCl_3$(TMPP) (100 mg, 0.0864 mmol) was dissolved in CH_2Cl_2, with a constant stream of dry oxygen bubbling through the solution for 1 h. A colour change from yellow to dark green–black immediately ensued. A dark green residue was obtained by evaporation of the solvent. This intermediate, **2**, is tentatively formulated as $FeCl_3$(TMPP)O_2 (yield, relative to **1**: 90%). When the reaction solution was further exposed to oxygen (> 12 h), the solution slowly turned from green to orange. The solvent was removed *in vacuo* and a red–orange solid, $FeCl_3[O{=}P\{C_6H_2(OMe)_3\}_3]$ (**3**) was obtained (yield, relative to **1**: 89%). Suitable crystals of **3** were grown from a mixture of CH_2Cl_2–

MeOH (2 : 1 v/v). Found : C, 45.9; H, 4.7. Calc. for $C_{27}H_{33}Cl_3O_{10}PFe$: C, 45.6; H, 4.6%. IR spectrum (CsI, Nujol mull), cm^{-1}: 1600 vs, 1580 vs, 1410 s, 1380 s, 1340 s, 1300 w, 1230 s, 1210 s, 1185 w, 1165 m, 1125 s, 1105 s, 1070 m, 1025 w, 950 m, 920 m, 815 m, 740 w, 720 w, 700 w, 640 w, 525 w, 485 s, 450 m, 380 s, 340 w. Electronic spectrum (Quartz, CH_2Cl_2), λ_{max}, nm (ε, M^{-1} cm^{-1}): 375 (sh), 334 (8.08×10^3), 285 (sh), 258 (5.08×10^4).

X-ray crystallography

Data collection and reduction. Single crystals of $FeCl_3$(O=TMPP) suitable for X-ray crystallographic studies were grown from a CH_2Cl_2–MeOH solution of the compound at 0°C. An orange crystal with the approximate dimensions 0.28 mm × 0.20 mm × 0.13 mm was selected and mounted with epoxy cement on the tip of a glass fibre. Intensity and geometric measurements were performed on a Nicolet P3/F diffractometer at room temperature following general procedures described elsewhere.[14] A preliminary triclinic unit cell was determined by centring and indexing 14 reflections chosen from a rotational photograph. The cell was further refined by a least-squares determination of 12 reflections with $15 \leqslant 2\theta \leqslant 20$. Axial photographs and intensity data confirmed the choice of the triclinic cell.

Intensity data were collected at room temperature over the range 4–40° in 2θ, using a θ–2θ scan mode. In addition, three check reflections were measured at regular intervals during intensity data collection. A plot of the intensity of these reflections vs time showed that no decay in crystal quality had occurred. After averaging equivalent reflections, 2886 unique data remained of which 1606 were observed with $F_o^2 \geqslant 3\sigma(F_o)^2$.

Solution and refinement. All calculations were performed on a VAXSTATION 2000 computer by using the Structure Determination Package (SDP) programs from Enraf–Nonius. The position of the metal atom was obtained from a solution provided by the direct methods program in SHELXS-86. The positions of the remaining non-hydrogen atoms were located through a sequence of successive difference Fourier maps and least-squares cycles. All of the non-hydrogen atoms, except one carbon in the *meta*-position of a phenyl ring, were refined anisotropically. The final full-matrix refinement involved 374 parameters and 1606 data. The refinement converged with residuals, R and R_w of 0.068 and 0.078, respectively, and a quality-of-fit of 1.919. The final difference Fourier map showed a highest peak of 0.454 e/Å^3. A summary of crystallographic parameters is found in Table 1. A listing of selected bond angles and distances is given in Table 2. The complete listing of atomic and thermal parameters, bond angles and bond distances are available as supplementary material.

RESULTS AND DISCUSSION

From the reaction between equimolar amounts of $FeCl_3$ and $P[C_6H_2(OMe)_3]_3$, we isolated a yellow compound which is formulated as $FeCl_3$(TMPP) on the basis of spectroscopic and analytical data as well as similarities to the reported $FeCl_3(PPh_3)$[8] and $FeCl_3(PCy_3)$.[9] The broad and featureless ^1H NMR indicated that, as expected, the compound is paramagnetic. Magnetic susceptibility measurements revealed temperature-dependent paramagnetic behaviour which is either an indication of a chloride-bridged binuclear structure or a mixed spin-state six-coordinate iron(III) monomer.[15] Unfortunately, the fast atom bombardment mass spectrum shows only the presence of ($HTMPP^+$) (m/z = 533), so our attempts to assign a structure were not aided by this experiment. We do not favour an ionic formulation for **1** {i.e. $[FeCl_2(TMPP)_2][FeCl_4]$} due to the bulk of the TMPP ligands and because of the absence of characteristic ν(Fe—Cl) stretches for $[FeCl_4]^-$ (*vide infra*).

Upon exposure to dry oxygen, we initially obtain a green intermediate, **2**, which we have not as yet fully characterized. We are, of course, quite interested in this oxygen intermediate. It is under intense investigation by a variety of spectroscopic (IR, EPR, electronic) and magnetic methods. After further oxygen bubbling, the title compound, **3**, is formed in high yield. Production of phosphine oxide is known to occur with phosphines in the presence of $FeCl_3$ but the stabilization of intermediates in these reactions has not been noted to our knowledge.[6a,16] Evidently, the bis-phosphine oxide adducts, $FeCl_3(O{=}PR_3)_2$, are formed very quickly in this chemistry. No references to mono-phosphine oxide products, however, were ever made in this work. In the present case, the reaction to produce $O{=}PR_3$ occurs much more slowly. The formation of $FeCl_3[O{=}P\{C_6H_2(OMe)_3\}_3]$ by further reaction of the initial "$FeCl_3(TMPP)O_2$" complex, **2**, occurs slowly in pure dichloromethane but more rapidly in the presence of alcohols. It appears that protic solvents catalyse the transformation of **2** to **3**. We intend to fully investigate this chemistry and to elucidate the reaction mechanism. Interestingly, recent oxygen binding studies of nickel(II) complexes possessing the bulky tertiary phosphine P(*cyclo*-$C_6H_{11})_3$ have resulted in clean 1 : 1 nickel(II) : O_2 reactions that are sufficiently slow to allow for kinetic studies.[17]

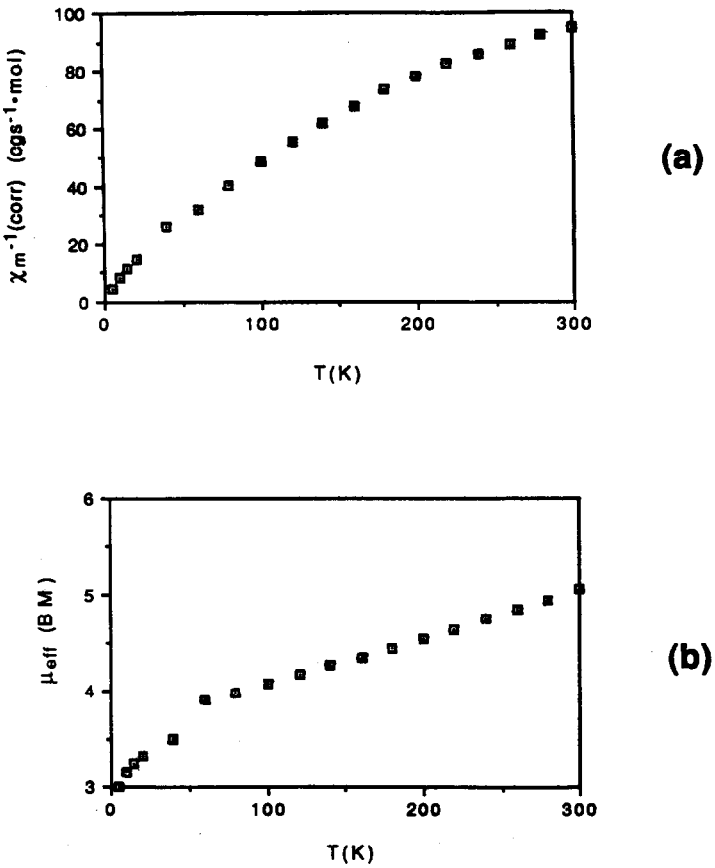

Fig. 1. Plots of (a) the reciprocal of the corrected molar magnetic susceptibility vs temperature and (b) the effective magnetic moment vs temperature for $FeCl_3$(TMPP).

Magnetic and EPR spectroscopic measurements

The room temperature magnetic moment (μ_{eff}) for $FeCl_3$(TMPP) is ~ 5.05 BM, which is much too low for a pure $S = 5/2$ Fe^{III} ground state. Spin equilibrium between $S = 1/2$ and $S = 5/2$ states for six-coordinate Fe^{III} is established in the literature[15] and may also account for the present observed magnetic behaviour. Plots of $1/\chi_m$(corr) vs T and μ_{eff} vs T for **1** are presented in Fig. 1(a) and (b). The compound $FeCl_3(OPR_3)$ exhibits magnetism that is indicative of isolated iron(III) ($S = 5/2$) metal centres. A plot of the corrected molar magnetic susceptibility vs $1/T$ follows the Curie–Weiss law: $\chi_m = C/T - \theta$ with a Weiss temperature $\theta = -1.6779$ K (Fig. 2).* The magnetic susceptibility at room temperature is 1.3050×10^{-2} emu/mol and $\mu_{eff} = 5.62$ BM ($\approx$ five unpaired electrons, tetrahedral Fe^{3+}, d^5). At low temperature

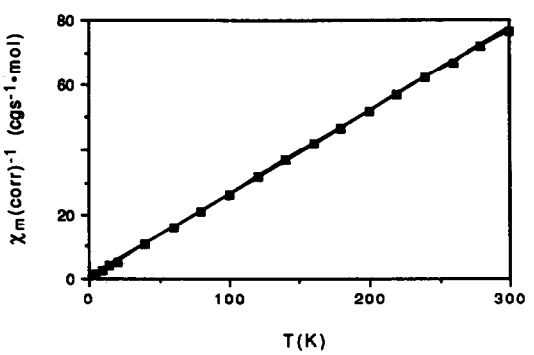

Fig. 2. Plot of the reciprocal of the corrected molar magnetic susceptibility vs temperature for $FeCl_3$(O=TMPP).

(−170°C), the EPR spectrum of $FeCl_3(O{=}PR_3)$ is characteristic of a pseudo-tetrahedral Fe^{3+} complex with a minor signal at $g = 7.44$ and a strong feature that appears at $g = 2.52$.

IR and electronic spectroscopy

IR spectra of **1** and **3** in the region 1700–400 cm^{-1} reveal the presence of the phosphine and phosphine

* A diamagnetic correction of -400.20×10^{-6} cgsu was applied based on -10×10^{-6} for Fe^{3+}, -70.2×10^{-6} for Cl^-, -320×10^{-6} for $OP[C_6H_2(OMe)_3]_3$.

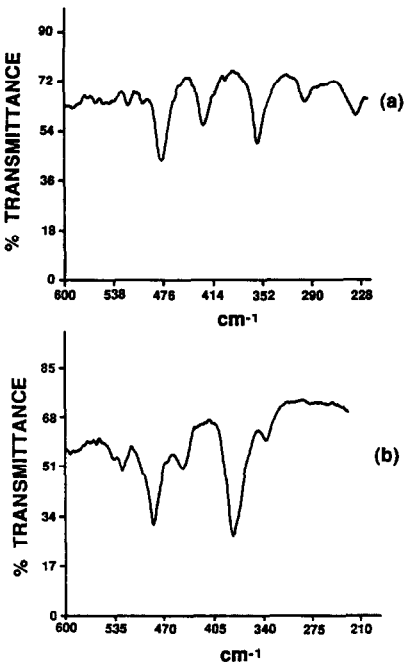

Fig. 3. Far-IR spectra of Nujol mull samples on CsI for (a) $FeCl_3$(TMPP) and (b) $FeCl_3$(O=TMPP).

oxide moiety, respectively. The far-IR spectra, presented in Fig. 3, are more useful in that they provide information about the local symmetry of the $FeCl_3$ group. Spectrum 3(b) for $FeCl_3(O{=}PR_3)$ is typical of that found for $FeCl_3$ adducts of C_{3v} symmetry. With two ν(Fe—Cl) stretches at 380 (s) and 340 (w), the far-IR spectrum of **3** is very similar to that reported for the tetrahedral anion $[FeCl_4]^-$ [378 (s), 330 (vw)][18] and the triphenylphosphine complex $FeCl_3(PPh_3)$ [370 (s), 320 (w)].[8] On the other hand, the phosphine derivative, **1**, exhibits three ν(Fe—Cl) modes at 360 (s), 300 (m) and 235 (m), indicative of a low molecular symmetry such as C_s. Consistent with this data is the interpretation of the structure as a six-coordinate monomer with an η^3-bonding mode for TMPP.

Electronic spectra are presented in Fig. 4. Compound **3** with λ_{max} values at 334 and 258 nm resembles that reported for NH_3FeCl_3 in the vapour phase (λ_{max}, 335 and 225).[19] The electronic absorption properties of $FeCl_3$(TMPP), displayed in Fig. 4(a), are similar to those of the aforementioned pyramidal $FeCl_3L$ species, although magnetic and IR data do not support such a structure for this molecule (*vide supra*).

X-ray crystal structure of $FeCl_3[OP\{C_6H_2(OMe)_3\}_3]$ (**3**)

An ORTEP drawing of $FeCl_3(O{=}TMPP)$ with the correct atom labelling scheme is shown in Fig. 5. Pertinent bond angles and distances are summarized in Table 2. The metal centre is surrounded by three chlorine atoms and the oxygen atom of a phosphine oxide ligand, resulting in an overall distorted tetrahedral coordination environment. The average Fe—Cl bond distance is 2.179[4] Å

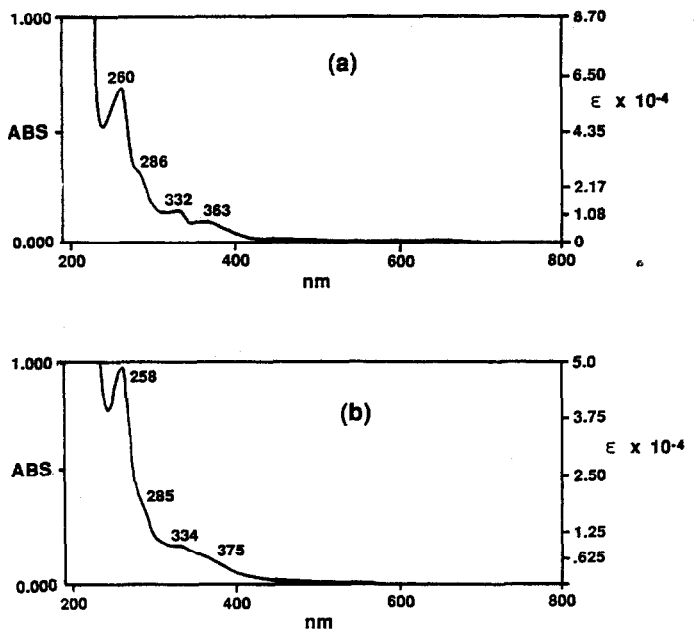

Fig. 4. UV–vis spectra performed in CH_2Cl_2 solution by using 1 cm quartz cells for (a) $FeCl_3$(TMPP) and (b) $FeCl_3$(O=TMPP).

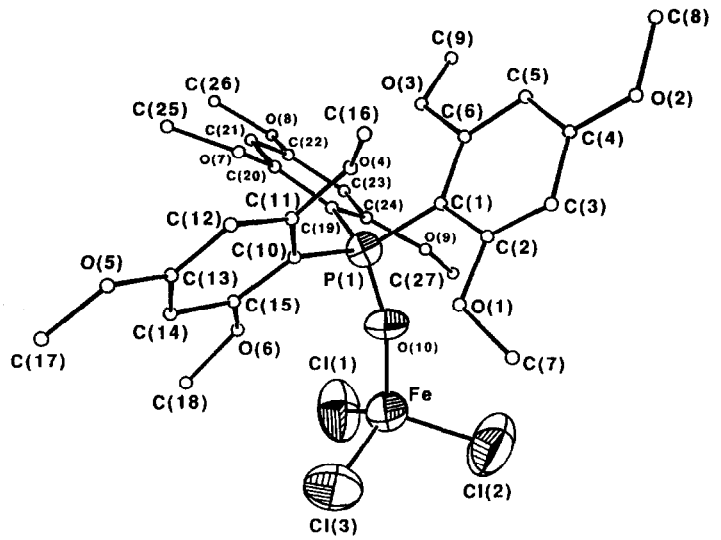

Fig. 5. ORTEP drawing of a single molecule of $FeCl_3[OP\{C_6H_2(OMe)_3\}_3]$ showing the atom labelling scheme. Phenyl group carbon and methoxy oxygen atoms are represented as small circles for clarity. All other atoms are represented by their 50% probability ellipsoids.

which is typical of the Fe—Cl distances found in salts of the anionic complex $\{FeCl_4\}^-$.[20] The angles ∠O—Fe—Cl vary from 108.6 to 110.8°, which is not a large difference, and may be due to a minor steric influence of the phosphine oxide which forms a bent interaction with the metal [∠Fe—O—P = 163.6(5)°]. As a result, the O—Fe—Cl bond angles are considerably distorted from an ideal tetrahedral geometry. The Fe—O bond distance of 1.791(6) Å in **3** is much shorter than the metal–oxygen distances found in similar tetrahedral phosphine oxide complexes such as $CoCl_2(O{=}PPh_3)_2$ for which the average Co—O distance is 1.999[9] Å.[21] Conversely, the P—O distance of 1.550(7) Å in the $FeCl_3(O{=}TMPP)$ case is much longer than the average corresponding distance in $CoCl_2(O{=}PPh_3)_2$ (P—$O_{(av)}$ = 1.499[9] Å).[21] These structural data are not to be interpreted strictly since a comparison of iron(III) and cobalt(II) chemistry must also take into consideration the oxidation state and size of the metal ion. It is, however, known that TMPP is much more donating than PPh_3,[7] thus phosphine oxide derivatives would be expected to follow the same trend in ligation properties. The average C—P—C bond angle for the $(O{=}PR_3$ group in **3** is 111.2(5)° which deviates considerably from the ideal tetrahedral geometry due to repulsions between the bulky trisubstituted phenyl rings. This results in a flattening out of the C—P—C angles.

In summary, few examples of neutral tetrahedral mono-adducts of $FeCl_3$ have been published. Singh and Rivest reported the existence of mono-tetrahedral adducts of $FeCl_3$ with triphenylarsine and triphenylphosphine in 1968.[8a] The formulation was confirmed by Mössbauer spectroscopy.[8b] In the early 1980's Von Thewalt reported the synthesis of two forms (α,β) of $FeCl_3(S_4N_4)$.[11] Recently Poli and Walker reported that mono-adducts of $FeCl_3$ can be prepared by using bulky tertiary phosphines such as tricyclohexylphosphine and tri-*t*-butylphosphine.[9b] Actually the synthesis of $FeCl_3(PCy_3)$ was reported as long ago as 1954 by Von Issleib and Brack.[9a] With the exception of $FeCl_3(THF)$[10b] and $FeCl_3(S_4N_4)$,[11] however, there are no crystallographically characterized examples of these complexes. As far as we are aware, the present study of $FeCl_3(O{=}TMPP)$ (**3**) represents the first example of a structurally characterized phosphine oxide adduct of $FeCl_3$.

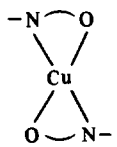
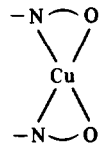
Abstract—A new class of binuclear copper(II) complexes, Cu_2L_2, yielded a series of tetranuclear copper(II) complexes, $Cu_2L_2(CuA_2)_2$, when mixed with CuA_2 in a 1 : 2 molar ratio (where LH_2 = 3,3′-dimethoxy-4,4′-bis(1-alkyl(R)triazene-1-oxide)biphenyl denoted as R-triaz-bp-OCH_3 and A = Cl, Br). No appreciable antiferromagnetic interaction was observed between any two sets of copper(II) centres as suggested by magnetochemical or ESR studies. The optical spectra suggest that the two sets of copper(II) centres have different geometries, the Cu_2L_2 based coppers are near square-planar while the CuA_2 based ones are near tetrahedral. The reason for the absence of magnetic interaction between any two copper(II) centres is discussed in the light of the structure of the complexes.

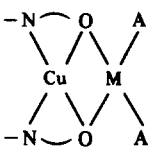
The unusual properties observed in the polynuclear metal complexes have maintained their interest over three decades. Recently, we reported the synthesis and studies of two novel series of binuclear copper(II) complexes, viz. bis-[3,3′-di(X)-substituted - 4,4′ - bis(3 - alkyl(R)triazene - 3 - oxide)-diphenyl]dicopper(II) denoted as $[Cu_2(R\text{-triaz-bp-}X)_2]$ (**1a**);[1,2] [3,3′-di(X)-substituted-4,4′-bis(salicylidinimino)diphenyl]dicopper(II) denoted as $[Cu_2(Sal\text{-bp-}X)_2]$ (**1b**).[3] Unlike the mononuclear analogues of these two series, which possess



type *trans* chelate groups,[4–6] the binuclear complexes, $[Cu_2(R\text{-triaz-bp-}X)_2]$ and $[Cu_2(Sal\text{-bp-}X)_2]$ contain *cis* chelation to give



type chromophores. This *cis* positioning of the oxygen ligating atoms may facilitate further coordination to another metal centre so as to give



type centres (**1c**), where A can be any end ligand atom or group such as halide or thiocyanate, respec-

tively. This type of continued bridging is not unusual.[7-11] Here we report the synthesis and characterization of the complexes, [Cu_2(R-triaz-bp-OCH_3)$_2$(CuA_2)$_2$] (**1c**) generated from **1a**.

EXPERIMENTAL

The details of the synthesis of the binuclear complexes which act as ligands for the present tetranuclear complexes were previously reported.[1-3] Mixing ethanolic solutions of the anhydrous cupric halides with the concentrated solutions of the binuclear complexes in chloroform immediately yields the tetranuclear complexes. The green, shiny precipitates obtained from triazene-1-oxide-based complexes were filtered and air-dried.

In a typical experiment, 422 mg ($\sim$ 0.5 mM) of the binuclear complex, Cu_2(CH_3-triaz-bp-OCH_3)$_2$, were dissolved in 25 cm^3 of chloroform to which were added 130 mg ($\sim$ 1.0 mM) of anhydrous cupric chloride dissolved in 10 cm^3 of absolute ethanol. A shiny, green and silky precipitate, obtained immedi-

ately, was filtered and dried under nitrogen. The filtrate was nearly colourless indicating a quantitative reaction between the dark brown solution of the binuclear complex and the green solution of the cupric halide (yield ~ 98%).

The microanalytical data were obtained on a Hewlett–Packard CHN analyser and the metal content from either the thiocyanate method[12] or atomic absorption spectrophotometry.

The room and variable temperature susceptibility measurements, using Pascal constants[13] for diamagnetic correction, were obtained on a Sartorius microbalance with a liquid helium cryostat using Faraday's method. Cupric sulphate pentahydrate ($CuSO_4 \cdot 5H_2O$) was used as the reference.

IR spectra from 4000 to 200 cm^{-1} were recorded on a Perkin–Elmer Model 283 spectrophotometer. The solution electronic spectra were obtained on a Cary 17D spectrophotometer and the solid-state spectra on a PARC Photoacoustic spectrometer. The X-band ESR spectra were recorded on a JEOL FE 3X spectrometer.

RESULTS AND DISCUSSION

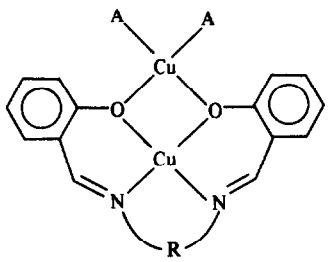
Infrared spectra

The C, H, N and metal analysis data are collected in Table 1 and are consistent with structure **1c**. The metal–halogen stretching frequencies and ν(M—Cl)/ν(M—Br) ratios are collected in Table 2. It is well known[14] that terminal metal–chloride stretches appear around 350 cm^{-1} and metal–bromide ones at 250 cm^{-1}, and also that the ratio ν(M—Cl)/ν(M—Br) (where M = Cu^{2+}, Zn^{2+}, Ni^{2+}, Co^{2+}) is in the order 1.30–1.35 for terminal metal–halogen bonds. The frequency ratios for the present complexes (~ 1.32) suggest that the halogen atoms are in terminal positions and not bridging.

Electronic spectra

The PAS spectra recorded for the tetranuclear copper(II) complexes exhibit well-resolved absorption bands at ~ 8000 and ~ 17,000 cm^{-1}. The solid-state electronic spectral data of the complexes are collected in Table 2, with that of the parent binuclear complexes given in parentheses. Representative spectra are given in Fig. 1.

In the case of the complexes shown in structure **2**, it is established that the square planarity of the



2

chelated inner coppers in the parent complex is enhanced upon further complexation with copper halides,[9,10,15] resulting in a hypsochromic (blue)

shift, with respect to the parent complex. The low energy transition is attributed to the lower symmetric (C_2) outer copper.

It is also observed that the heavier the halogens on the outer coppers are, the greater is the tetrahedral nature for the outer coppers.[16] Tetrahedral coppers generally possess their crystal-field absorption in the range 14,000–7000 cm^{-1}, whereas the square-planar ones possess theirs in the range 19,000–14,000 cm^{-1}. The appearance of two λ_{max}

values for the present complexes indicates the presence of two structurally distinct copper pairs, one outer pair in near tetrahedral geometry absorbing at $\sim 8000\ cm^{-1}$, and the other at near square planarity absorbing at $\sim 17{,}000\ cm^{-1}$. The parent binuclear complexes, from which the inner coppers of the present tetranuclear complexes originate, have been observed to absorb at $\sim 11{,}000\ cm^{-1}$ and a distorted square-planar geometry was assigned to them.[2] The shift of this band to higher energy upon extended complexation in obtaining the present complexes means that planarity is enhanced at the inner coppers. The higher energy band at $\sim 17{,}000\ cm^{-1}$ is assigned to the $d_{z^2} \leftarrow d_{x^2-y^2}$ transition of the inner copper, and the lower one at $\sim 8000\ cm^{-1}$ is assigned to the $B_1 \leftarrow A_1$ transition of the outer copper.

Magnetic and ESR spectral data

The magnetic system in the present complex can be represented as

$$Cu(1)\overset{J}{\cdots}Cu(2)\overset{J'}{\cdots}Cu(3)\overset{J}{\cdots}Cu(4),$$

with J' as the interaction energy between the two inner copper centres, and J being the interaction energy between one outer copper and one inner copper. The other possible interaction between Cu(1) and C(3) or Cu(2) and Cu(4) is negligible. The magnetic moment data of all the complexes, collected in Table 2, are normal. It was already reported that the magnetic interaction between the two coppers in the parent binuclear complexes is negligibly small.[2] The observation of normal magnetic moment data for the present tetranuclear complexes is interesting, since there are copper centres bridged only by oxygen atoms. Even cryomagnetic studies from 4.2 K did not give any indication of the presence of measurable antiferromagnetic interaction.

In a planar CuO_2Cu type magnetosphere, the extent of magnetic interaction depends on the Cu—O—Cu bridging angle, ϕ. For hydroxo-bridged systems the interaction energy, $2J$, is given by[6,17]

$$2J = -74.53\phi + 7270\ cm^{-1}.$$

It is implied that the angle ϕ where J is nearly zero is around 98°. For bulky substitution on oxygen atoms, this angle comes close to 90°. X-ray crystallographic studies could not be undertaken on the present complexes as it was difficult to grow single crystals of them. However, the Cu—O—Cu angle was tentatively calculated from the X-ray crystallographic data available on their parent representative binuclear complex, $Cu_2(CH_3\text{-triaz-bp-}OCH_3)_2$ and that on comparable complexes having a site, CuO_2CuA_2, as in the present complexes assuming planarity to the CuO_2Cu core.[18–20] The angle thus calculated was $\sim 87°$, close to 90°, resulting in a negligible magnetic interaction.

The absence of magnetic interaction is further proved from the *X*-band ESR spectral analysis. All the copper complexes exhibit well-resolved parallel and perpendicular ESR transitions. The peak profiles are invariant throughout the temperature range 77–340 K. No solution ESR studies could be carried out as the complexes are highly insoluble in most of the solvents. The resolution of the parallel and perpendicular absorptions may be due to the negligible presence of dipolar interactions. A representative room-temperature polycrystalline ESR spectrum is provided in Fig. 2, and the relevant data in Table 3. The $\Delta M_s = \pm 2$ half-field transition was not observed even with improved instrumental parameters. The relative intensity of the $\Delta M_s = \pm 2$ transition with respect to that of the normal $\Delta M_s = \pm 1$ transition is given by

$$\text{relative intensity} = \frac{C}{r^6}\left(\frac{9.1}{\nu}\right)^2$$

for interacting binuclear systems[21] and is independent of the value of J. Here C is a constant (approximately 22 for bivalent copper systems), ν is the operating ESR frequency in GHz and r the interacting Cu—Cu distance. In the present tetra-

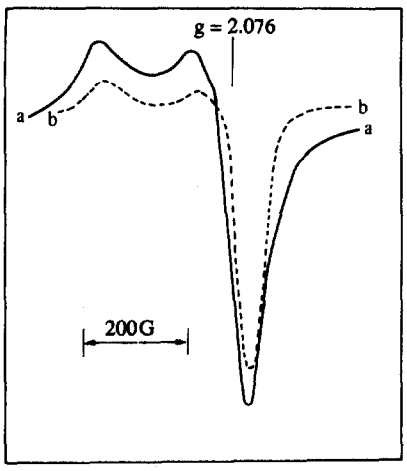

Fig. 2. *X*-band ESR spectra of (a) Cu_2(R-triaz-bp-OCH_3)$_2$ ($CuCl_2$)$_2$ and (b) Cu_2(R-triaz-bp-OCH_3)$_2$($CuBr_2$)$_2$ at room temperature.

nuclear complexes the distance between the closest copper atoms is *ca* 3 Å which gives $\sim 3.0 \times 10^{-2}$ as the relative intensity of the $\Delta M_s = \pm 2$ transition for an operating frequency of ~ 9.5 GHz. This very intense peak, could readily be observed by our instrument, but no $\Delta M_s = \pm 2$ transition was observed either at room temperature or 77 K implying the absence of antiferromagnetic interaction in the complexes.

Other indirect evidence for the absence of the magnetic interaction stems from the evident absence of zero-field splitting, D, given for the interacting binuclear complexes, by

$$D = \frac{1.39 \times 10^4 \times g}{r^3},$$

where g is the average g factor and r is the interacting Cu—Cu separation.[22,23] For $r = \sim 3$ Å and $g = \sim 2.15$, the value of D is calculated as ~ 1130 G implying the splitting of the normal $\Delta M_s = \pm 1$ transition separated by ~ 2260 G. No such split peaks were observed.

X-ray crystallographic molecular structure determinations would have provided interesting information but could not be undertaken due to the difficulty of generating a single crystal because of their insolubility in various solvents and thermal instability above 150°C.

THE CHEMISTRY OF CERAMIC GLAZES—II. THE INFLUENCE OF THE PRESENCE OF THE OXIDES Na_2O, CaO OR Al_2O_3 ON THE THERMOLYSIS OF LAPONITE. ^{29}Si, ^{23}Na AND ^{27}Al MASNMR STUDIES

ARVIND-PAL S. MANDAIR and WILLIAM R. McWHINNIE*

(*Received* 14 *December* 1989; *accepted* 21 *March* 1990)

Abstract—The influence of added oxides on the progress of the thermolysis of laponite at 1300°C was investigated. Calcium oxide promotes the depolymerization of the clay silicate lattice and, even at low CaO additions, mixed calcium/magnesium phases were identified; at higher additions akermanite was a dominant crystalline phase. Sodium oxide was even more effective as a depolymerizing agent; when the total molar proportion of Na_2O exceeded the total concentration of the other component oxides of laponite (Li_2O, MgO), a glass is formed and no crystalline phases were detected. By contrast, evidence was obtained that additions of Al_2O_3 could increase the degree of connectivity as evidenced by the formation of new alumino-silicate phases such as sillimanite; spinel, $MgAl_2O_4$, was a dominant crystalline phase at higher Al_2O_3 additions. The products of the reactions studied were examined using ^{29}Si, ^{23}Na and ^{27}Al MASNMR spectroscopy and this technique was shown to be particularly powerful for the study of systems in which glassy and crystalline phases co-exist.

Ceramic glazes are complex materials which are compounded from a variety of ingredients. These may include clay minerals, alkaline earth oxides (from carbonate precursors) together with feldspars, which function as a source of alkali metal oxides, alumina and extra silica; also silica itself is often an ingredient. Colouring oxides may also be present, e.g. transition metal oxides or perhaps materials such as SnO_2 or ZrO_2 which confer opacity to the glaze. We have made some attempts to follow chemical changes which occur when glazes are fired. Our approach has been to concentrate initially on one component and attempt to build up an understanding of the thermochemistry using a combination of resonance spectroscopies and XRD data. Thus we have investigated the thermolysis of the iron-containing minerals, montmorillonite and illite, using ^{57}Fe Mössbauer spectroscopy,[1] and have used the same technique to examine the chemical destination of iron in a simple feldspathic glaze maturing at 1280°C.[2] We have also investigated the thermochemistry (to 1300°C) of hectorite, a lithium–magnesium trioctahedral smectite clay, together with that of the synthetic counterpart laponite[3] using ^{29}Si MASNMR spectroscopy.

Laponite is attractive for NMR studies since it is virtually free of paramagnetic impurities which, if present in too great quantities,[3] may cause loss of resolution of the ^{29}Si MASNMR spectrum.[4] We therefore use laponite to pursue our studies and in this paper use a combination of ^{29}Si, ^{23}Na and, where appropriate ^{27}Al MASNMR spectroscopy, to investigate the influence of oxides such as CaO, Na_2O and Al_2O_3 on the thermolysis products of the clay at 1300°C.

EXPERIMENTAL

Materials

Laponite RD (laponite in this paper) in the sodium form was obtained from Laporte Industries Ltd [ideal formula: $Na_{0.67}(Mg_{5.33}Li_{0.67})Si_8O_{20}(OH)_4$]. Other materials were reagent grade.

* Author to whom correspondence should be addressed.

(a) *The effect of temperature on the reaction of a mixture of laponite and calcium oxide (constant composition).* Laponite (5 g) was mixed with calcium carbonate (to give a 1 : 1 CaO–SiO_2 molar ratio) until a homogeneous powder was obtained. The powder was transferred to a new porcelain crucible and fired in a Carbolyte furnace, under air, 400°C for 3 h. (Temperatures were monitored with a Pt/Rh thermocouple.) After firing, the crucible was removed from the furnace, covered with a lid, and allowed to cool completely in a desiccator overnight prior to grinding the product to a fine powder. (Material was selected from the centre of the mixture to eliminate problems arising from any surface reaction with the crucible.)

The procedure was repeated with identical mixtures of calcium carbonate and laponite at a range of temperatures to a mixture of 1300°C. This standard procedure was used for subsequent experiments.

(b) *The reaction of laponite at 1300°C with varying mole ratios (based on SiO_2) of calcium oxide.* Calcium carbonate was added to laponite (3 g) in increasing quantities (based on the mol % of CaO to the SiO_2 content) of laponite (see tables of data for details).

(c) *The influence of sodium oxide on the reaction of laponite–calcium oxide mixtures at 1300°C.* Laponite (3 g charges), calcium carbonate and sodium carbonate were mixed together in the molar proportions indicated in Table 3.

(d) *The influence of alumina (Al_2O_3) on the reaction of laponite–calcium oxide mixtures at 1300°C.* Mixtures of laponite (3 g charges) with calcium carbonate and alumina were prepared according to the proportions in Table 4.

Physical measurements

MASNMR spectra were obtained with a Bruker AC(E) 300 MHz spectrometer. The "magic angle" was set with KBr and Delrin rotor spinning rates were ~ 5 kHz. Frequencies were 59.580 MHz (^{29}Si), 79.392 MHz (^{23}Na) and 78.206 MHz (^{27}Al). IR spectra were recorded for KBr discs using a Perkin–Elmer 1710 FTIR instrument. XRD data were obtained with a Philips X-ray diffractometer using Co-K_α radiation with a typical scan speed of 1° 2θ min^{-1}. The d-spacings of the various phases present were calculated from 2θ values using standard Co-K_α charts.[5]

RESULTS

Table 1 gives the ^{29}Si chemical shifts (vs $(CH_3)_4Si$) for the laponite RD–CaO system (SiO_2–CaO = 1 : 1) fired to temperatures in the range 400–1300°C. Table 2 considers the influence on the ^{29}Si MASNMR data of varying quantities of CaO (all specimens fired to 1300°C). Table 3 gives ^{29}Si MASNMR data for the system laponite–Na_2O–CaO, together with the ^{23}Na MASNMR data. Tables 4 and 5 give the ^{29}Si and ^{27}Al MASNMR data, respectively, for the laponite–CaO–Al_2O_3 system. Figure 1 shows typical spectra. A complete tabulation of the IR data is available,[6] in this paper

selected data will be referred to in the text as required.

DISCUSSION

Initially the reaction of calcium oxide (supplied as carbonate) with laponite in a 1:1 mole ratio (based on the "SiO_2" content of laponite) will be considered as a function of kiln temperature. Subsequently, the influence of varying the quantity of CaO on the reaction of CaO and laponite at 1300°C is discussed. Finally, the effect of gradually replacing CaO with either Na_2O or Al_2O_3 ["SiO_2" (from laponite)–CaO–$M_nO_m = 1:x:1-x$] is considered.

The reaction of laponite and CaO (SiO_2–CaO = 1:1)

In the NMR discussion the now standard "Q" notation developed[7] by Engelhardt *et al.* is used, thus Q^2 will denote a SiO_4 tetrahedron forming two siloxane linkages to two other such tetrahedra via apical oxygen atoms.

Although the materials fired to temperatures up to 700°C gave several XRD reflections, these could not be assigned with confidence to any crystalline phases. Mixtures fired to 800 and 900°C gave definite evidence for the presence of the crystalline phase rankinite ($Ca_3Si_2O_7$). The mixture fired to 1000°C gave XRD data which were difficult to interpret. Some reflections which matched those expected for γ-Ca_2SiO_4 were seen, but this assignment was not supported by the NMR data. No positive evidence for enstatite ($MgSiO_3$) was obtained, yet NMR evidence for the presence of the pyroxene was definite (see below). The material was possibly a microcrystalline dispersion. Firing to 1300°C gave a material in which the major phase present was akermanite ($Ca_2MgSi_2O_7$) and the minor phases monticellite ($CaMgSiO_4$) and forsterite (Mg_2SiO_4) were noted.

The ^{29}Si MASNMR data in Table 1 give a more detailed picture of the reactions than do the XRD data. Mixtures fired to 400 and 500°C show one broad Q^3 resonance. Laponite heated alone gave sharper lines and showed some evidence of Q^2 sites also;[3] it is likely that in the present case the weak Q^2 resonances were not resolved. The mixture heated to 600°C gave a complex spectrum of several overlapping broad lines with a total spectral width of 750 Hz. The broad band at $\delta = -99.6$ ppm may arise from the presence of an amorphous phase; alternatively it may be derived from laponite since it has earlier been suggested that the lithium ions may migrate from their trioctahedral positions to crystal edges thereby increasing the shielding of the lattice silicon atoms.[3] Despite the absence of crystalline phases, the presence of $CaCO_3$ has induced a significantly greater breakdown of the laponite Q^3 silicate lattice than occurred when the clay was heated to 600°C alone.[3] IR data showed clearly that $CaCO_3$ was still present in substantial quantities at 600°C.

The batch fired to 700°C showed two broad, resolved resonances indicating the essentially amorphous nature of this sample. The Q^1 site ($\delta = -79.6$ ppm) which was just discernible at 600°C is much more prominent in the 700°C spectrum. It was beyond 800°C that further distinctive changes occurred. The IR data showed the onset of thermal decomposition of $CaCO_3$ at 800°C and the availability of CaO induces further change and the formation of more crystalline phases. The ^{29}Si MASNMR spectrum showed sharp resonances at −79.6 and −76.4 ppm. Oldfield and Janes have calculated[8] that both ^{29}Si chemical shifts for rankinite should occur at −79.4 ppm, whereas Lippmaa *et al.*[9] have observed two resonances at −79.6 and −76.6 ppm for synthetic rankinite. Given the XRD support above, it is clear that rankinite is the major crystalline phase present in the batches heated to 800 and 900°C.

By 1000°C no trace of rankinite remained. The peaks at −81.1 and −84.7 ppm are assigned to the pyroxene enstatite ($MgSiO_3$),[3] an expected product from the thermolysis of laponite. However, it is interesting to note that between 800 and 900°C depolymerization of the laponite Q^3 lattice to the Q^1 species has occurred, but the formation of the pyroxene at 1000°C requires a re-polymerization to Q^2. Thus, although enstatite is an expected product, the mechanism of formation is likely to be different to that when laponite alone is thermolysed. A second Q^2 phase was also present with $\delta = -84.7$ ppm, this is assigned to a second pyroxene mineral diopside [$CaMg(SiO_3)_2$]. The pyrosilicate akermanite ($Ca_2MgSiO_2O_7$) was identified by the resonance at $\delta = -73.8$ ppm.[9,10] The 1300°C reaction product contained akermanite as the major crystalline product, a fact confirmed by ^{29}Si MASNMR and XRD data. The two Q^0 resonances are assigned to forsterite (Mg_2SiO_4, −62.2 ppm) and monticellite ($CaMgSiO_4$, −66.2 ppm), the observed chemical shifts being in good agreement with those obtained independently by Lippmaa *et al.*[9] and Smith *et al.*[10]

The reaction of laponite with CaO *at* 1300°C (SiO_2–CaO = 1:x *where* $0.2 < x < 2.0$)

The influence of differing proportions of CaO on the product ratios at 1300°C was investigated. ^{29}Si

MASNMR data are given in Table 2. The conclusions from a combined NMR and XRD study are tabulated below where Ca(20) denotes a 20% addition of CaO, ticks and crosses denote the presence or absence of XRD evidence for the particular phase, and where the indicated references give literature support for the NMR assignments.

Phase	(^{29}Si)	Ca(20)	Ca(40)	Ca(60)	Ca(80)	Ca(100)	Ca(200)

The ternary system: laponite–calcium oxide–sodium oxide

A ceramic glaze will usually contain a quantity of an alkali metal oxide as a "fluxing" (glass forming) reagent. It is introduced to the raw glaze in a water insoluble form, e.g. as sodium or potassium feldspar. Laponite contains approximately 0.6% lithium and, given the choice of this clay as the silica source in these experiments, lithium which is a strong flux will contribute to glass formation;[3] also laponite was used as the sodium exchanged clay. Taking the silica content of laponite as unity, batches were made up with SiO_2–CaO–NaO = $1:x:1-x$, where $1-x$ is the *added* Na_2O. Table 3 details the ^{29}Si and ^{23}Na MASNMR shifts observed when these batches were fired to 1300°C; the table also details the actual Na–(Mg+Li+Ca) ratio taking account of the full constitution of the clay.

It is clear from Table 3 that at values of $(1-x)$ between 0.1 and 0.4 (where the total molar content of Li+Mg+Ca *exceeds* that of Na), sharp resonances assignable to the crystalline phases forsterite (−61.9 ppm), monticellite (−65.9 ppm) and akermanite (−72.2 ppm) are seen. In addition for $(1-x) = 0.2$ and above, a broad resonance to higher field is seen; beyond $(1-x) = 0.6$ (at which point the molar content of Na exceeds the combined molar content of Li+Mg+Ca) the spectrum is dominated by a broad resonance and no evidence of crystalline phases is seen.

For lower values of $(1-x)$, in addition to creating a glassy phase, the replacement of CaO by Na_2O alters the relative proportions of monticellite and akermanite. The broad resonance which ultimately dominates the spectrum beyond $(1-x) = 0.6$ is undoubtedly due to a glassy phase. Simple silicate glasses have been examined by Dupree *et al.*[11] and by Grimmer *et al.*,[12] and the ^{29}Si MASNMR data were shown to be consistent with a model based on a binary distribution. Laponite consists of Q^3 silicons, thus additions of Na_2O would initially promote the formation of Q^2 groups and, beyond a 33% addition, Q^1 groups will be formed. These simple arguments are complicated by the presence of MgO and CaO, however, in Fig. 2 the chemical shift of the broad resonance associated with the glassy phase is plotted against $(1-x)$. It is noted that a discontinuity occurs between $(1-x) = 0.4$ and 0.6; we believe this to represent the transition from an essentially Q^2 phase to a Q^1 phase. Also beyond $(1-x) = 0.6$ ions, Na^+, Li^+, Mg^{2+} and Ca^{2+} are incorporated in the glass structure. The observed chemical shifts of the Q^2 and Q^1 phases appear at higher field than would be expected for a simple Na_2O/SiO_2 glass,[11,12] however, the data are consistent with the incorporation of Mg^{2+} and Ca^{2+} which shift the resonances to more negative values.[13]

No attempt was made to deconvolute the broad resonance associated with the glass phase. The breath of the resonance may be attributed to a range of factors: variations in the Si—O—Si bond angles, variations in bond lengths, the co-existence of two Q^n types in some cases, and the combined presence of Na^+, Li^+, Mg^{2+} and Ca^{2+} as lattice modifiers.[14]

The ^{23}Na MASNMR spectra of these systems

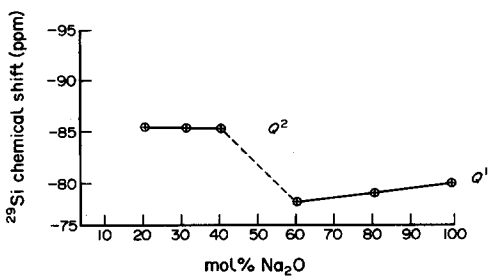

Fig. 2. ^{29}Si MASNMR chemical shift as a function of mol % Na_2O $(1-x)$ (SiO_2–CaO–Na_2O = $1:x:1-x$).

were featureless and showed signs of quadrupolar broadening, thus the "chemical shift" recorded in Table 3 cannot be assumed to represent the isotropic chemical shift. The resonance maximum is sensitive to the value of $(1-x)$ but not in an obviously consistent manner—at low values of $(1-x)$ when crystalline phases are present significant variation of the maximum was noted, however, once the glass phase dominated a more regular variation with $(1-x)$ was seen.

The ternary system: laponite–calcium oxide–aluminium oxide

The presence of alumina generated crystalline phases at all values of $(1-x)$ (Table 4). This is not surprising since it is known that the system $MgO[Al_2O_3]SiO_2$ may form the basis of a series of glass ceramics.[15] The phases identified by a combination of XRD and MASNMR are tabulated below.

For values of $(1-x)$ equal to and greater than 0.6, spinel ($MgAl_2O_4$) is clearly indicated in the XRD and the tetrahedral aluminium signals observed may be assigned to this phase. For $(1-x) = 0.8$ and 1.0, octahedral and tetrahedral signals are observed. Sillimanite contains aluminium in both octahedral and tetrahedral coordination, the ^{29}Si chemical shift and XRD evidence support the presence of this phase, but the combined presence of corundum and spinel (XRD) warn that at least part of the octahedral and tetrahedral signal intensity must arise from these sources. Thus it cannot be claimed that the ^{27}Al MASNMR data offer unambiguous support for the presence of sillimanite.

	Percentage replacement of CaO by Al_2O_3				
Phase	Al(20)	Al(40)	Al(60)	Al(80)	Al(100)
Akermanite ($Ca_2MgSi_2O_7$)	√	√	×	×	×
Forsterite (Mg_2SiO_4)	√	√	×	×	×
Monticellite ($CaMgSiO_4$)	√	√	×	×	×
Calcium aluminate $[Ca(AlO_2)_2]$	×	√	×	×	×
Spinel ($MgAl_2O_4$)	×	×	√	√	√
Corundum	×	×	×	√	√
Sillimanite (Al_2SiO_5)	×	×	×	√	√

Table 5 lists some data for the quadrupolar ($I = 5/2$) ^{27}Al nucleus. It is possible to differentiate "octahedral" and "tetrahedral" sites since the six-coordinate aluminium will resonate close to the standard $[Al(H_2O)_6]^{3+}$ (i.e. $\delta \sim 0$), whereas the tetrahedral environment gives resonances at lower field ($\delta \sim 50$–80 ppm). Since second-order quadrupole effects are not averaged to zero by "magic angle" spinning, it is dangerous to relate the observed peak maxima to isotropic chemical shifts.

Tetrahedral sites are observed for aluminium for all values of $(1-x)$ considered. At low values of $(1-x)$, e.g. 0.2, 0.4, this band may be attributed to calcium aluminate which was detected by XRD in the $(1-x) = 0.4$ case. A similar origin for the octahedral resonance for $(1-x) = 0.2$ is suggested.

(*Received* 20 *December* 1989; *accepted* 21 *March* 1990)

Abstract—Molybdenum(VI) has been mainly extracted with chelating reagents by non-polar solvents due to difficulties with polar solvents such as alcohols, ethers and esters. However, the coordinative donor solvents propylene carbonate, cyclohexanone and tri-*n*-butyl phosphate did extract molybdate albeit slowly. Each of the extracted species was identified to be hexamolybdate by the use of Raman spectroscopy. The extraction equilibrium involving cyclohexanone indicated that the main extracted species is the ion pair $H_3O^+(HMo_6O_{19})^-$ in the lower concentration of 1.0×10^{-3} M [Mo]; but both the species $H_3O^+(HMo_6O_{19})^-$ and $(H_3O^+)_2Mo_6O_{19}^{2-}$ are extracted in the higher concentration of molybdate (1.0×10^{-2}–1.0×10^{-1} M).

The formation of 12-molybdoheteropoly acid is the well-known procedure for the determination of trace amounts of P, As, Si and Ge.[1,2] 12-Molybdoheteropoly acid is generally extracted into the mixed solvents in order to avoid the influence of excess molybdate. Excess molybdate does not usually interfere with the extraction of 12-molybdoheteropoly acid. We found, however, that molybdate was gradually extracted from the weak acidic solution by propylene carbonate[3] and cyclohexanone,[4] among several other solvents. The coordinative solvating solvents such as propylene carbonate, cyclohexanone and tri-*n*-butyl phosphate appeared to be much more effective in the extraction of molybdenum(VI). The purpose of this study is to clarify both the mechanism of extraction of molybdenum(VI) and the extracted species with those solvents using Raman spectroscopy.

EXPERIMENTAL

A solution of molybdate was prepared from sodium molybdate, $Na_2MoO_4\cdot2H_2O$ (analytical grade), and standardized as the gravimetric oxinate.[5] Propylene carbonate was distilled under reduced pressure: b.p. 92°C at 4.5 mm.[6] Cyclohexanone and tri-*n*-butyl phosphate were of analytical reagent grade.

The time needed for equilibration is much longer than that required for the usual extracting procedure. A stoppered centrifuge tube, containing 10 cm^3 of molybdate solution and the organic solvent, was ordinally shaken for 1 h at 25 ± 0.1°C. The molybdate content of the aqueous solution before and after extraction was determined by atomic absorption spectrometry. Raman spectra were measured with a JASCO R800 instrument, using 514.5 nm (Ar^+, laser) as the excitation source.

RESULTS AND DISCUSSION

There are many species of polynuclear molybdate in the weak acidic solutions, as seen in some of the literature surveying molybdate species.[7–10] Our results from the Raman study also indicate that the main species of polynuclear molybdate are $Mo_7O_{24}^{6-}$, $Mo_8O_{26}^{4-}$ and $Mo_{12}O_{37}^{2-}$.[11] The hexamolybdate of $Mo_6O_{19}^{2-}$, in small quantities,

* Author to whom correspondence should be addressed.

appears only in the acidic solution of pH 1. Hexamolybdate seems to be unstable in aqueous solution.

Concerning the extraction of molybdenum(VI), there are some recent papers involving quaternary ammonium salts,[12–14] high-molecular weight amines[15–17] and a neutral organophosphorus extractant.[18] Cruywagen and Rypstra studied the extraction of molybdenum(VI) by tri-*n*-butyl phosphate.[18] They concluded that the polynuclear molybdate extracted is hexamolybdate, $Mo_6O_{19}^{2-}$, by the use of a UV absorption spectrometer. This result is also supported by our Raman studies. Figure 1(a)–(c) shows Raman spectra of the tri-*n*-butyl phosphate layer. Figure 1(a) shows the Raman spectrum of the extracted layer which contains the extracted molybdate species, tri-*n*-butyl phosphate solvent and the distributed water. Figure 1(b) is the Raman spectrum of the tri-*n*-butyl phosphate equilibrated with water of the same pH value. Figure 1(c) shows the Raman spectrum of the extracted species, which is obtained by subtracting Fig. 1(b) from Fig. 1(a). The Raman spectrum of Fig. 1(c) resembles closely that of tetrabutylammonium hexamolybdate, $[(C_4H_9)_4N]_2Mo_6O_{19}$, which was prepared by precipitation from acidified aqueous solution and then recrystallization with acetone.[19] Therefore, the extracted species is considered to be hexamolybdate, $Mo_6O_{19}^{2-}$, in tri-*n*-butyl phosphate.

Figure 2(a)–(c) shows Raman spectra of the propylene carbonate layer which contains the extracted

species, the distributed water and the solvent. Figure 2(b) shows the Raman spectrum of the propylene carbonate equilibrated with water of the same pH value. Figure 2(c) shows the Raman spectrum of the extracted species, which is obtained by subtracting Fig. 2(b) from Fig. 2(a). The Raman spectrum in Fig. 2(c) also resembles that of hexamolybdate. Hence the extracted species using propylene carbonate is hexamolybdate. We obtained the wrong conclusion concerning the extracted species in an earlier paper.[3] We must, therefore, correct our former conclusion that the main extracted species was the highly condensed polymer of c.a. 13.

Figure 3 shows the Raman spectra of both the cyclohexanone extract (solid line) and cyclohexanone (dotted line). Raman bands at 985, 958, 605, 287 and 206 cm^{-1} are closely related to those of hexamolybdate. Consequently, the extracted species is considered to be the hexamolybdate, $Mo_6O_{19}^{2-}$, in all the extractions using tri-*n*-butyl phosphate, propylene carbonate and cyclohexanone.

Next we investigated the extraction behaviour by cyclohexanone, since the extraction of molybdenum(VI) has been studied using tri-*n*-butyl phosphate[18] and propylene carbonate.[3] Figure 4 shows the extraction curves from the acidified molybdate solutions by cyclohexanone. As the concentration of molybdate increases, each curve shifts to the more acidic region, i.e. lower values of pH. But this does not imply that a different molybdate species is extracted from solutions of different concentrations. We obtain Fig. 5 when the data in Fig. 4 is replotted against the Z value, $Z = ([H^+]_{added} - [H^+]_{free})/[Mo]$, instead of pH, thus exhibiting approximately the polymerization degree of polynuclear molybdate.[10] Since three extraction curves

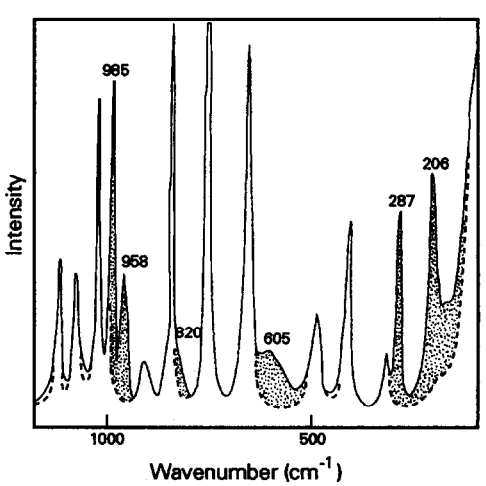

Fig. 3. Raman spectra of the extracted layer (solid line) and the blank solution of cyclohexanone (dotted line).

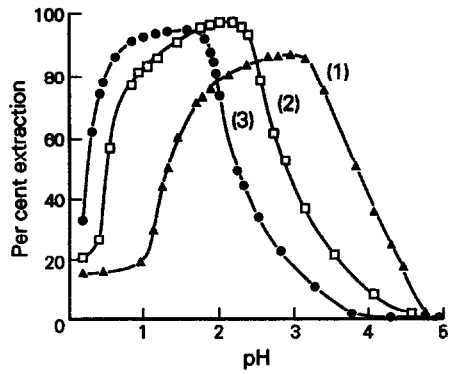

Fig. 4. Extraction curves of molybdenum(VI) by cyclohexanone: (1) 1.0×10^{-3} M, (2) 1.0×10^{-2} M and (3) 1.0×10^{-1} M.

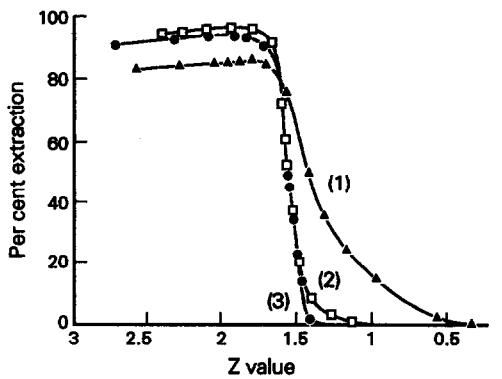

Fig. 5. Extraction curves plotted against the Z value of aqueous solutions: (1) 1.0×10^{-3} M, (2) 1.0×10^{-2} M and (3) 1.0×10^{-1} M.

almost coincide, it is expected that the same species are extracted in spite of the different molybdate concentrations. The extracted species should be hexamolybdate as both the Raman spectrum of the extract and the Z value of the molybdate solutions concur.

The distribution ratio of molybdic acid is plotted against the pH of the solutions in Fig. 6. The following equilibrium reaction is found for the extraction of hexamolybdate if the $(H_nMo_6O_{19})^{(2-n)-}$ species is considered to be mainly extracted as the ion pair with the oxonium ion, H_3O^+:

$$(H_nMo_6O_{19})^{(2-n)-} + (2-n)H_3O^+ \rightleftharpoons [(H_3O^+)_{2-n}(H_nMo_6O_{19})^{(2-n)-}]_{org.}$$

The extraction constant K_{ex} is given as follows:

$$K_{ex} = [(H_3O^+)_{2-n}(H_nMo_6O_{19})^{(2-n)-}]_{org}/([(H_nMo_6O_{19})^{(2-n)-}][H_3O^+]^{2-n}). \quad (1)$$

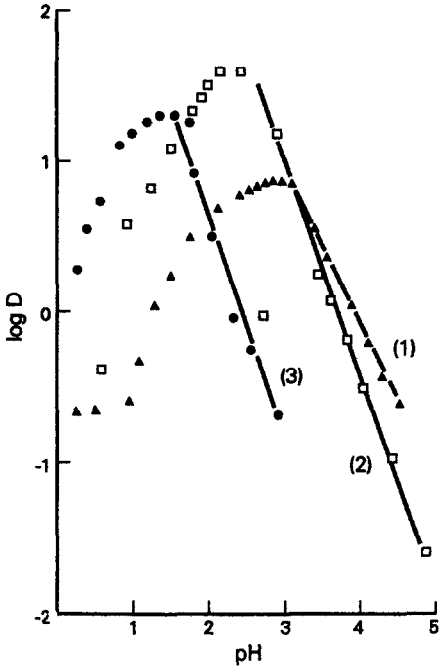

Fig. 6. Distribution equilibria of molybdenum(VI) by cyclohexanone: (1) 1.0×10^{-3} M, (2) 1.0×10^{-2} M and (3) 1.0×10^{-1} M.

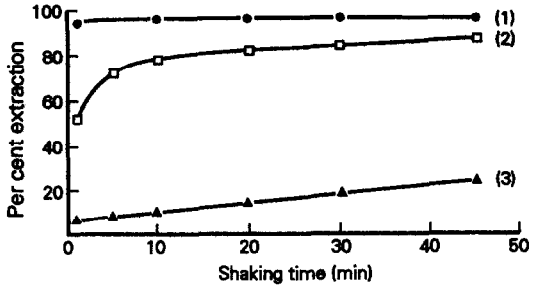

Fig. 7. The extraction rate of molybdenum(VI) by cyclohexanone: (1) 1.0×10^{-2} M, pH 2.0; (2) 1.0×10^{-2} M, pH 1.0; and (3) 1.0×10^{-3} M, pH 1.0.

The distribution ratio D is defined as

$$D = [(H_3O^+)_{2-n}(H_nMo_6O_{19})^{(2-n)-}]_{org}/[(H_nMo_6O_{19})^{(2-n)-}].$$

Equation (1) can be expressed as the logarithmic form:

$$\log D = (2-n)\log[H_3O^+] + \log K_{ex}. \quad (2)$$

When $\log D$ is plotted against the $\log[H_3O^+]$, the value of $2-n$ can be obtained from the slope of the straight line. Figure 6 shows that the values of $2-n$ are 1.0, 1.4 and 1.4 for the concentrations 1.0×10^{-3}, 1.0×10^{-2} and 1.0×10^{-1} M, respectively. This implies that the value of $n = 1$ is reasonable for the lower concentration of molybdate (1.0×10^{-3} M), but with the higher concentrations of molybdate (1.0×10^{-2} and 1.0×10^{-1} M) both species of $H_3O^+(HMo_6O_{19})^-$ for $n = 1$ and of $(H_3O^+)_2Mo_8O_{19}^{2-}$ for $n = 0$ should be extracted because the intermediate value of $2-n = 1.4$ can be obtained by mixing with the cases of $2-n = 1$ and $2-n = 2$.

Figure 7 shows the extraction rate for three different solutions of molybdate. The extraction rate is generally slow except in suitably acidic and concentrated molybdate solutions. This is attributable to the formation of hexamolybdate in quite small amounts in the weak acidic solutions.[11] The cyclohexanone molecule dissolved in aqueous molybdate solution can produce the extractable hexamolybdate during the mixing process of two phases in the extraction, as mentioned in an earlier paper.[11] This is the reason why the coordinative donor solvents such as cyclohexanone, propylene carbonate and tri-*n*-butyl phosphate are effective in the extraction of hexamolybdate. These solvents are able to produce the extractable species to some extent in aqueous solution due to their coordinative donor properties.

Acknowledgement—The authors thank Dr Ozeki for obtaining the Raman spectra.

(*Received* 2 *January* 1990; *accepted* 22 *March* 1990)

Abstract—A series of $Ru_2Cl(\mu\text{-}O_2CR)_4$ [R = C_2H_5 (**I**), cyclo-C_6H_{11} (**II**), C_6H_5 (**III**), *o*-ClC_6H_4 (**IV**), *o*-HOC_6H_4 (**V**)] complexes has been synthesized by reaction of $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ with the appropriate carboxylic acid. The reaction of these insoluble compounds with $AgBF_4$ in thf gives $[Ru_2(\mu\text{-}O_2CR)_4(thf)_2]BF_4$ (**VI**)–(**X**) which are soluble in polar organic solvents. The substitution in these complexes of the thf axial ligands in toluene by $OPPh_3$ or pyridine leads to new adducts of the type $[Ru_2(\mu\text{-}O_2CR)_4L_2]BF_4$ [L = $OPPh_3$ (**XI**)–(**XV**), L = py (**XVI**)–(**XIX**)] which are not easily accessible by other methods. The compounds have been characterized by elemental analysis, electrical conductance, magnetic susceptibility measurements and spectral data.

The influence of the axial and equatorial ligands on the chemistry of compounds with metal–metal bonds has been studied in some detail for several metals like rhodium[1–3] or molybdenum,[1,3–6] but is less known for ruthenium compounds. Thus, although several diruthenium(II, III) carboxylate compounds[1,7–11] have been described, and some of their physical properties have been reported,[12–18] the reactivity of these species has been little studied.

It has been proved in electrochemical studies[10,12,19–22] that the nature of the bridge ligand has an important influence on the electron density of the bimetallic centre. On the other hand, we have shown[23] that the triphenylphosphine oxide ligand reacts with the $[Ru_2(\mu\text{-}O_2CCH_3)_4]^+$ unit, giving $[Ru_2(\mu\text{-}O_2CCH_3)_4(OPPh_3)_2]^+$, whereas the triphenylphosphine ligand makes the $[Ru_2(\mu\text{-}O_2CCH_3)_4]^+$ core unstable. We are now studying the influence of the equatorial ligands on the reactivity of the $[Ru_2(\mu\text{-}O_2CR)_4]^+$ core towards axial ligands. In the present work we report the synthesis and characterization of the new species $Ru_2Cl(\mu\text{-}O_2CR)_4$ (R = cyclo-C_6H_{11}, *o*-ClC_6H_4, *o*-HOC_6H_4) and the adducts $[Ru_2(\mu\text{-}O_2CR)_4(thf)_2]BF_4$ (R = C_2H_5, cyclo-C_6H_{11}, C_6H_5, *o*-ClC_6H_4, *o*-HOC_6H_4). We have also studied the reactions of these thf adducts with triphenylphosphine oxide and pyridine.

RESULTS AND DISCUSSION

The reaction of $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ in a methanol–water (1 : 1) mixed solvent under reflux with alkyl or aryl carboxylic acids, for example CH_3CH_2COOH, cyclo-$C_6H_{11}COOH$, C_6H_5COOH, *o*-ClC_6H_4COOH or *o*-HOC_6H_4COOH, led to the substitution of the acetate groups giving the corresponding $Ru_2Cl(\mu\text{-}O_2CR)_4$ derivatives. The yields were high in the cases of R = C_6H_5, *o*-ClC_6H_4 and *o*-HOC_6H_4, which are insoluble in methanol–water. When R = C_2H_5 and cyclo-C_6H_{11}, the products are soluble in the reaction mixture and the yield is lower.

The reaction of these compounds with $AgBF_4$ in thf led to the formation of $[Ru_2(\mu\text{-}O_2CR)_4(thf)_2]BF_4$ in high yield. In all cases brown crystals have been isolated from brown–red solutions, except for the *o*-hydroxybenzoate and cyclo-hexylcarboxylate derivatives in which brown crystals of the adducts were isolated from a green solution of another uncharacterized compound.

The complexes $[Ru_2(\mu\text{-}O_2CR)_4(thf)_2]BF_4$ exchange the thf ligands readily in toluene by

*Author to whom correspondence should be addressed.

$OPPh_3$ giving the corresponding $[Ru_2(\mu\text{-}O_2CR)_4(OPPh_3)_2]BF_4$ compounds. The same reaction carried out in thf led to a mixture of the reaction product and the starting material indicating competition of the thf ligand with the $OPPh_3$ ligand to occupy the axial positions of the $[Ru_2(\mu\text{-}O_2CR)_4]^+$ unit.

Stephenson and Wilkinson[7] have observed that the reaction of pyridine with $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ in pure pyridine led to the rupture of the ruthenium–ruthenium bonds and the formation of $Ru(O_2CCH_3)_2(py)_2$ and $Ru(O_2CCH_3)_2(py)_4$ compounds; in contrast, the reaction of $[Ru_2(\mu\text{-}O_2CR)_4(thf)_2]BF_4$ with pyridine in toluene gave brown solids identified as $[Ru_2(\mu\text{-}O_2CR)_4(py)_2]BF_4$ which contain the Ru_2^{5+} unit. In addition to the brown solid, a green solution which presumably contains a $Ru(O_2CR)_2(py)_2$ compound was obtained when R = cyclo-C_6H_{11}. When R = *o*-HOC_6H_4, the solubilities of $[Ru_2(\mu\text{-}O_2C(o\text{-}HOC_6H_4))_4(py)_2]BF_4$ and the green product were very similar, so the pyridine adduct could not be obtained pure. A large excess of pyridine led to a decrease in the yield of the pyridine adducts and an increase in the green product.

A similar adduct, $[Ru_2(\mu\text{-}O_2CC_3H_7)_4(py)_2]Cl$, has been obtained by Drago *et al.*[24] by addition of an excess of pyridine to $Ru_2Cl(\mu\text{-}O_2CC_3H_7)_4$ in dichloromethane.

Table 1 contains yields, elemental analyses and some physical properties of the compounds obtained.

The IR spectra of the complexes in KBr discs contain strong absorption bands in the region 1500–1350 cm^{-1}, which are due to the antisymmetric and symmetric stretching vibrations of the RCOO bridged ligands. The absorption bands due to R and BF_4 groups are also observed.

In addition, the IR spectra of $[Ru_2(\mu\text{-}O_2CR)_4L_2]BF_4$ (L = py or $OPPh_3$) compounds show the characteristic absorptions of pyridine or triphenylphosphine oxide ligands.

The most characteristic absorption bands in the IR spectra are summarized in Table 2.

In the $[Ru_2(\mu\text{-}O_2CR)_4(thf)_2]BF_4$ derivatives no bands due to the thf ligand are observed. Similar behaviour showing the facile loss of the weakly coordinated axial thf ligand has been observed in the complexes $Ru_2(\mu\text{-}O_2CCH_3)_4(thf)_2$[25] and $[Ru_2(\mu\text{-}O_2CCH_3)_4(thf)_2]BF_4$.[23]

The presence of the thf ligand is shown in the ^1H NMR spectra in DMSO-d_6 solution; in these spectra two signals at 1.85 and 3.75 ppm due to free thf are observed in all cases. In these conditions the thf ligand is exchanged by molecules of DMSO solvent, and the free thf is observed.

Magnetic measurements were carried out from room temperature to 70 K and indicated that these compounds obey the Curie–Weiss law in this temperature range. The magnetic moments are in the range 4.6–3.7 BM per dimer (Table 2), which are in accordance with the values obtained by several authors for Ru^{II}–Ru^{III} compounds.[7,8] The values are consistent with species containing three unpaired electrons per dimer in accordance with the ground electronic configuration of $\sigma^2\pi^4\delta^2(\pi^*\delta^*)^3$.[16] Table 3 shows the variation of the magnetic susceptibilities with the temperature for the cyclohexylcarboxylate derivatives. The magnetic behaviour of the other compounds is very similar.

The electronic spectra (range 200–800 nm) of the complexes, in methanol solution, show two absorption bands. The band near 430 nm is assigned to $\pi(Ru\text{—}O, Ru_2) \rightarrow \pi^*(Ru_2)$, in agreement with Norman *et al.*[16] and Miskowski and Gray;[15] this transition is not sensitive to change of the carboxylate ligands, as has previously been observed in similar compounds.[15] The absorption near 280 nm is assigned to π(axial ligand) $\rightarrow \pi^*(Ru_2)$; usually this transition is sensitive to the axial ligands, but in these cases no change can be observed. This may be due to compounds such as $[Ru_2(\mu\text{-}O_2CR)_4(MeOH)_2]^+$ being formed in methanol and the electronic spectrum is the same in each case. Only, in the pyridine derivatives, are some shoulders observed, indicating that the substitution of the axial pyridine ligands by methanol is not complete. In the $[Ru_2(\mu\text{-}O_2C(o\text{-}HOC_6H_4))_4L_2]BF_4$ (L = thf, $OPPh_3$) compounds very intense bands are observed in the region 220–300 nm which probably include the π(axial ligand) $\rightarrow \pi^*(Ru_2)$ and intraligand transitions.

The conductivity measurements are in accordance in all cases with 1 : 1 electrolytes[26] (Table 1).

The elemental analyses and physical and spectroscopic properties of $[Ru_2(\mu\text{-}O_2CR)_4L_2]BF_4$ compounds are in accordance with a structure containing the $[Ru_2(\mu\text{-}O_2CR)_4]^+$ unit with L (L = thf, $OPPh_3$, py) occupying the axial positions, similar to that described for $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2]BF_4$[18] and $[Ru_2(\mu\text{-}O_2CCH_3)_4(OPPh_3)_2]BF_4$[27] whose crystal structures have been determined.

In conclusion, the variation in the nature of the equatorial carboxylate ligands does not cause a great change in the reactivity of these species. In fact, the reactivity is similar in all cases and only in the reaction with pyridine is the behaviour different; in this case when R = C_2H_5 the reaction is clean and only the adduct was obtained; in the other cases, particularly, when R = *o*-HOC_6H_4, the formation of the adduct was accompanied by the formation of a green uncharacterized compound, probably $Ru[O_2C(o\text{-}HOC_6H_4)]_2(py)_2$. Finally, in

the reaction with $AgBF_4$ a lower yield of the *o*-hydroxybenzoate derivative was observed.

EXPERIMENTAL

All reactions were carried out in an inert atmosphere, using standard Schlenk techniques. $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ was prepared by the literature procedure.[28] $RuCl_3 \cdot 3H_2O$ (Engelhard), C_2H_5COOH (Fluka), cyclo-$C_6H_{11}COOH$ (Merck), C_6H_5COOH (Probus), *o*-ClC_6H_4COOH (Fluka), *o*-HOC_6H_4COOH (Probus), $AgBF_4$ (Fluka), $OPPh_3$ (Probus) and pyridine (Probus) were obtained from commercial sources. Solvents were purified and distilled by standard methods except methanol which was used without previous purification.

Elemental microanalyses for C, N and H were

performed with a Perkin–Elmer 240 B microanalyser. IR spectra in the region 4000–200 cm^{-1} were recorded as KBr discs on a Perkin–Elmer 1330 IR spectrophotometer. Magnetic measurements were made with a magnetometer DSM 5 in the range 290–70 K. ^1H NMR spectra were obtained on a Varian XL-300 spectrometer. Electronic spectra in the region 200–800 nm were recorded on a Hewlett–Packard Vectra spectrophotometer. Molar conductivities were measured with a Philips PW 9526 digital conductivity meter using a Philips PW 9512/60 conductivity measuring cell.

Synthesis of $Ru_2Cl(\mu\text{-}O_2C_2H_5)_4$ **(I)**

To $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ (2 g, 4.2 mmol) in methanol–water (60 cm^3) (1 : 1) was added an excess of C_2H_5COOH (1.9 cm^3, 25.2 mmol). The reaction mixture was heated under reflux for 3 h giving a red–orange solution. This solution was filtered and

concentrated under reduced pressure. On standing at room temperature brown crystals of $Ru_2Cl(\mu\text{-}O_2CC_2H_5)_4$ were formed. The crystals were washed twice with methanol–diethyl ether (10 cm^3) (1 : 1) and dried *in vacuo*.

Synthesis of $Ru_2Cl(\mu\text{-}O_2CC_6H_{11})_4$ **(II)**

This compound was obtained by the method described above.

Synthesis of $Ru_2Cl(\mu\text{-}O_2CC_6H_5)_4$ **(III)**

This compound was prepared by the method described by Das and Chakravarty.[10]

To $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ (2 g, 4.2 mmol) in methanol–water (60 cm^3) (1 : 1) was added an excess of C_6H_5COOH (3.08 g, 25.2 mmol). The mixture was heated under reflux for 4 h, giving a brown solid and a red–brown solution. The mixture was cooled to room temperature. The solution was filtered out and the brown solid of $Ru_2Cl(\mu\text{-}O_2CC_6H_5)_4$ was washed twice with methanol–diethyl ether (10 cm^3) (1 : 1) and dried *in vacuo*.

Synthesis of $Ru_2Cl(\mu\text{-}O_2CR)_4$ [R = *o*-ClC_6H_4 **(IV)**, *o*-HOC_6H_4 **(V)**]

These compounds were obtained by the method described above.

Synthesis of $[Ru_2(\mu\text{-}O_2CC_2H_5)_4(thf)_2]BF_4$ **(VI)**

A suspension of $Ru_2Cl(\mu\text{-}O_2CC_2H_5)_4$ (1 g, 1.8 mmol) in 40 cm^3 of thf was treated with $AgBF_4$ (0.35 g, 1.8 mmol) and the mixture was stirred for 12 h. The precipitate of AgCl was removed by filtration over celite. The solution was concentrated under reduced pressure to one-third of its initial volume, and petroleum ether was added to give orange crystals of $[Ru_2(\mu\text{-}O_2CC_2H_5)_4(thf)_2]BF_4$.

The analogous $[Ru_2(\mu\text{-}O_2CR)_4(thf)_2]BF_4$ compounds [R = cyclo-C_6H_{11} **(VII)**, C_6H_5 **(VIII)**, *o*-ClC_6H_4 **(IX)**, *o*-HOC_6H_4 **(X)**] were obtained by the same method.

Synthesis of $[Ru_2(\mu\text{-}O_2CC_2H_5)_4(OPPh_3)_2]BF_4$ **(XI)**

To a suspension of $[Ru_2(\mu\text{-}O_2CC_2H_5)_4(thf)_2]BF_4$ (1 g, 1.3 mmol) in toluene (50 cm^3) was added $OPPh_3$ (0.72 g, 2.6 mmol). The reaction mixture was stirred at room temperature overnight. The solvent was removed by filtration and the yellow–brown solid was washed twice with diethyl ether (10 cm^3).

The solid was crystallized from CH_2Cl_2–petroleum ether giving brown crystals of $[Ru_2(\mu\text{-}O_2CC_2H_5)_4(OPPh_3)_2]BF_4 \cdot CH_2Cl_2$.

The analogous $[Ru_2(\mu\text{-}O_2CR)_4(OPPh_3)_2]BF_4$ compounds [R = cyclo-C_6H_{11} **(XII)**, C_6H_5 **(XIII)**, *o*-ClC_6H_4 **(XIV)**, *o*-HOC_6H_4 **(XV)**] were obtained by a similar method.

Synthesis of $[Ru_2(\mu\text{-}O_2CC_2H_5)_4(py)_2]BF_4$ **(XVI)**

Pyridine (0.2 cm^3, 2.6 mmol) was added to a suspension of $[Ru_2(\mu\text{-}O_2CC_2H_5)_4(thf)_2]BF_4$ (1 g, 1.3 mmol) in 40 cm^3 of toluene. The mixture was stirred for 12 h at room temperature, and the pre-

cipitate was collected by filtration, washed twice with diethyl ether and dried *in vacuo*.

The analogous $[Ru_2(\mu\text{-}O_2CR)_4(py)_2]BF_4$ compounds [R = cyclo-C_6H_{11} (**XVII**), C_6H_5 (**XVIII**), *o*-ClC_6H_4 (**XIX**)] were obtained by the same procedure.

(*Received* 8 *November* 1989; *accepted* 26 *March* 1990)

Abstract—The synthesis and electrochemical behaviour of [Ni(DL-CTH)L](ClO_4) and [Ni(Cy)L′](ClO_4), where DL-CTH is the racemic isomer of 5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane, Cy is 1,4,8,11-tetraazacyclotetradecane (Cyclam), L is dimethyldithiocarbamate (Me_2Dtc), diethyldithiocarbamate (Et_2Dtc), pyrrolidindithiocarbamate (PyrrDtc), ethylxanthogenate (Etxant), thioacetate (Tac) and acetate (Ac) and L′ are the same ligands except Tac and Ac, are described. The structure of [Ni(DL-CTH)(Et_2Dtc)](ClO_4) is also reported. This complex crystallizes in the monoclinic space group $P2_1/a$ with cell parameters $a = 19.551(4)$, $b = 13.446(3)$, $c = 11.428(3)$ Å, $\beta = 95.54(3)°$ and $Z = 4$. The isolated [Ni(DL-CTH)(Et_2Dtc)]$^+$ cation shows a distorted *cis*-octahedral coordination around the nickel(II) ion. The electrochemistry of these compounds indicates oxidation processes but with decomposition of the organic part, giving nickel(II) species with, probably, polymeric dithio derivatives.

The chemistry of derivatives derived from nickel(II) and 1,1-dithio ligands has been extensively studied.[1,2] All these compounds have two 1,1-dithio ligands, giving square-planar geometries with some rare octahedral exceptions.[3,4] They have interesting properties from industrial,[1,2] electrochemical[5] and magnetic[1,2,6] points of view. On the other hand, the properties of the macrocyclic cations [Ni(DL-CTH)]$^{2+}$, [Ni(Cy)]$^{2+}$ and their derivatives have been extensively studied.[7,8] These square-planar macrocyclic compounds have the possibility of folding, principally when they react with chelate ligands, to yield octahedral mixed-ligand compounds. Starting from this kind of reaction it would be interesting to synthesize new 1,1-dithio complexes in which the presence of the macrocyclic ligand allows the coordination of only one 1,1-dithio derivative. We report here two series of these new octahedral nickel(II) compounds with 1,1-dithio ligands and the above mentioned Cyclam and

* Author to whom correspondence should be addressed.

DL-CTH derivatives, being, consequently, the first rare octahedral complexes with only one 1,1-dithio ligand. Acetate and thioacetate derivatives with $[Ni(DL\text{-}CTH)]^+$ have been also prepared, with the aim of comparing the properties of sulphur derivatives with the oxygen ones. Electrochemistry of these new compounds has been studied to analyse the electrochemical behaviour of complexes with this unusual coordination with only one 1,1-dithio ligand and to compare with the most common square-planar bis(1,1-dithioligand)Ni^{II}. Starting from the electrochemical properties of these ligands, we studied the stabilization of the coupled nickel(II)–organic radical, related to $[Ni(DL\text{-}CTH)L]^+$, with L being an O-donor ligand, previously reported.[8]

EXPERIMENTAL

Synthesis

The complex $[Ni(DL\text{-}CTH)](ClO_4)_2$ was prepared by the method described by Tait and Busch.[9] The complex $[Ni(Cy)](ClO_4)_2$ was prepared by the method described by Bosnich *et al.*[7b] Acetate, thio and dithio ligands (alkaline salts, Fluka) were used without purification.

CTH *derivatives.* Equimolar amounts of $[Ni(DL\text{-}CTH)](ClO_4)_2$ and the corresponding acetate, thioacetate or 1,1-dithioalkaline salt, dissolved in the minimum amount of water, were mixed. The yellow colour of the solution immediately changed to blue–green, and the adduct compounds precipitated within a few minutes.

Cyclam *derivatives.* The same procedure was used, but some differences were observed. After mixing the reagents, no change in the colour of solution was observed and a violet precipitate was gradually formed in 5–6 h (Me_2Dtc and Et_2Dtc) or 2 days for PyrrDtc. For L = Etxant, after 1 day, an unidentified precipitate was removed by filtration. After a further day with constant stirring, a violet precipitate was formed. Recrystallization of this latter compound in acetonitrile gave the new complex as a microcrystalline powder. All the compounds are insoluble in water but very soluble in acetone, methanol and acetonitrile. Yield 20% for $[Ni(Cy)(Etxant)](ClO_4)$ and 80–90% for the remaining compounds. Attempts to prepare acetate and thioacetate derivatives under the same conditions were unsuccessful. Analytical data are summarized in Table 1.

Crystal structure determination

A prismatic crystal ($0.1 \times 0.1 \times 0.2$ mm) was selected and mounted on a Philips PW-1100 four-circle diffractometer. Unit cell parameters were determined from automatic centring of 25 reflections ($4 \leqslant \theta \leqslant 12°$) and refined by least-squares methods. Intensities were collected with graphite monochromatized Mo-K_α radiation, using the ω-scan technique, with scan width 0.8°, scan speed 0.03° s^{-1}. 2456 reflections were measured in the range $2 \leqslant \theta \leqslant 25°$; 1700 of which were assumed as observed when applying the condition $I \geqslant 2.5\sigma(I)$. Three reflections were measured every 2 h as orientation and intensity controls, and no significant intensity decay was observed. Lorentz–polarization but no absorption corrections were made.

The structure was solved by direct methods, using the MULTAN system of computer programs,[10] and refined by full-matrix least-squares, using the SHELX76 computer program.[11] The function minimized was $\Sigma w[[F_o]-[F_c]]^2$, where $w = (\sigma^2(F_o) + 0.0018[F_o]^2)^{-1}$; f, f' and f'' were taken from the *International Tables for X-ray Crystallography.*[12] Fifteen peaks were located around the chlorine atom, which could be assigned as oxygen positions

of the perchlorate ion, according to bond lengths; six of them were assigned an occupancy factor of 1/3 according to peak heights and the remaining nine were assigned an occupancy factor of 2/9. The position of all hydrogen atoms were computed and refined with an overall isotropic temperature factor, using a riding model, while the oxygen atoms were refined only isotropically, and the remaining non-hydrogen atoms anisotropically. The final R factor was 0.059 ($wR = 0.062$) for all observed reflections. Number of refined parameters = 356. Maximum shift/ESD = 0.2 in y of O(11); maximum and minimum peaks in final difference synthesis were 0.4 and -0.3 e Å^{-3}, respectively.

Crystal data for [Ni(DL-CTH)(Et_2Dtc)](ClO_4). $C_{21}H_{44}N_5S_2NiClO_4$, formula weight = 590.88, monoclinic, $a = 19.551(4)$, $b = 13.446(3)$, $c = 11.428(3)$ Å, $\beta = 95.54(3)°$, $V = 2990(2)$ Å^3, $P2_1/a$, $D_x = 1.308$ g cm^{-3}, $Z = 4$, $F(000) = 1256$, (Mo-K_α) = 0.71069 Å, μ(Mo-K_α) = 9.05 cm^{-1}, 298 K.

Physical measurements

IR spectra (4000–200 cm^{-1}) were recorded as KBr pellets with a Beckman IR-20A spectrophotometer. UV–vis spectra were recorded in acetonitrile solutions with a Perkin–Elmer 550-S spectrophotometer.

Voltammetric measurements were performed with the use of DACFAMOV 05-03 microcomputer controlled instrumentation with ohmic resistance compensation.[13] Rigorously deareated acetonitrile (Carlo Erba) was used as a solvent and (n-Bu_4N)PF_6 (0.1 M) as supporting electrolyte. Solutions were deaerated by means of a stream of nitrogen for 10 min and a nitrogen blanket was maintained above the solutions during the electrochemical measurements. Potentials were referred vs an Ag/AgCl (0.1 M KCl) electrode separated from the bulk of the solution by a medium porosity disc. The potential for the one-electron oxidation of ferrocene is 420 and 460 mV vs the Ag/AgCl (0.1 M KCl) electrode with or without ohmic resistance compensation, respectively. A platinum wire auxiliary electrode was used in conjunction with a platinum discs working electrode (TACUSSEL EDI rotating electrode, area 3.14 mm^2). Electrochemical oxidations were performed in acetonitrile with a platinum electrode using the same DACFAMOV 05-03 instrumentation but working at 0.2 V above the $E_{1/2}$.

EPR measurements were recorded with a Brucker ER-200 spectrometer working at X-band frequency.

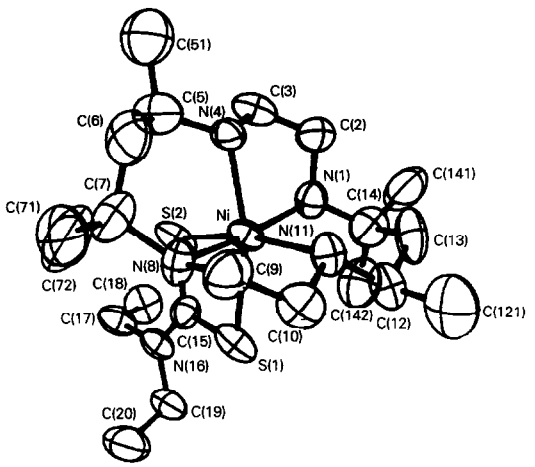

Fig. 1. Molecular structure of the [Ni(DL-CTH)(Et_2dtc)]$^+$ cation.

RESULTS AND DISCUSSION

Description of the structure

The crystal structure of [Ni(DL-CTH)(Et_2Dtc)](ClO_4) is formed from ClO_4^- and [Ni(DL-CTH)(Et_2Dtc)]$^+$ units, the latter showing a distorted *cis*-octahedral geometry around the nickel(II) ion. The structure of the cation is shown in Fig. 1, and the coordination environment of the nickel atom is shown in Fig. 2. Selected bond distances and angles are reported in Table 2.

The two sulphur atoms of the dithiocarbamate ligand occupy two *cis*-equatorial positions of the inner coordination sphere of the metal; the two Ni—S distances are 2.485(3) and 2.471(3) Å, which compare well with the values [2.449(3) and 2.448(2) Å] reported for the structure of the octahedral nickel–1,1-dithio compound bis(phenyldithioacetate)bis(pyridine)nickel(II).[3] These values are slightly longer than the same Ni—S distances

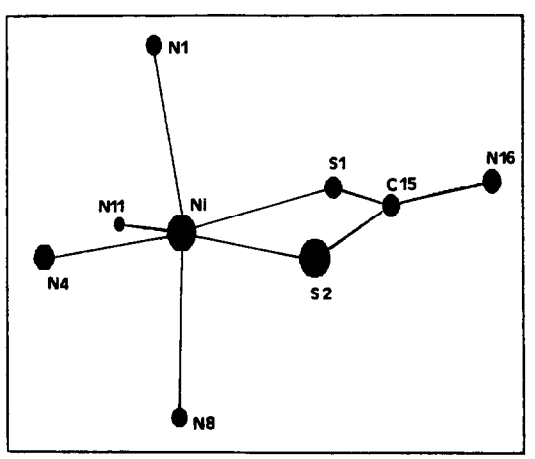

Fig. 2. Coordination environment of the nickel atom in the [Ni(DL-CTH)(Et_2dtc)]$^+$ cation.

in the square-planar nickel–1,1-dithio derivatives (2.1–2.2 Å),[1,2] as a result of the high-spin nature of the nickel(II) ion.

The four nitrogen atoms of the CTH ligand occupy the two remaining equatorial and the two axial positions. The two axial bond distances, Ni—N(1) and Ni—N(8) are slightly longer than the equatorial ones, suggesting that the coordination polyhedron can be described as an elongated octahedron. The metal–nitrogen distances are in agreement with those of analogous *cis*-octahedral complexes of nickel(II) with CTH.[14–18]

Mean values for C—S bond distances, C(15)—S(1) = 1.705(11) Å and C(15)—S(2) = 1.724(11) Å, are slightly longer than in the case of bis(phenyldithiacetate)bis(pyridine)nickel(II)

(1.68(1) and 1.69(1) Å, respectively).[13] The C(15)—N(16) bond distance is equal to 1.350(12) Å, a value in the range of the C—N bond values found in the literature for analogous dithiocarbamate compounds.[1,2]

Finally, it is important to underline that the Ni—S(2)—S(1)—N(4)—N(11) plane is very distorted. For example, the N(8)—Ni—S(2) angle is 101.8(3)°, while N(8)—Ni—S(1) is 86.5(3)°; N(8)—Ni—N(4), 88.7(4)° and N(8)—Ni—N(11), 83.4(4)°. Moreover, the S(1)—Ni—S(2) angle is 77.8(1)°, much lower than the reported values for a square-planar environment in different bis(dithiocarbamato)nickel(II) complexes (between 78 and 79.5°)[1,9] but similar to the same angle in the other known octahedral complex (72°).[3]

IR and electronic spectra

IR spectra of the new complexes show the ν(N—H) bands at 2870 (m, sh), 2930 (s), 2970 (s) and 3230 (s) cm^{-1} for Ni(DL-CTH) derivatives and at 2860 (s), 2920 (s), 2960 (m, sh) and 3250 (s) cm^{-1} for Ni(Cyclam) derivatives. Additional bands centred at 1100 (s, broad) and 620 (s) cm^{-1} confirm the presence of the ClO_4^- anion. The ν(C—N) stretching band is observed at 1500 and 1485 cm^{-1} for the dimethyl and diethyl derivatives of Ni(CTH) and at 1500 and 1490 cm^{-1} for the same Ni(Cyclam) derivatives, respectively. These values indicate a certain amount of double bond character [ν(C=N) = 1690–1640 cm^{-1}; ν(C—N) = 1350–1250 cm^{-1}].[20] For the two [Ni(macrocycle)Etxant](ClO_4) complexes, bands at 1210 and 1050 cm^{-1}, characteristic of the C—O—C group[21] are observed.

Vis–UV spectra are summarized in Table 3. Visible spectra are all very similar, showing well defined *d–d* and metal to ligand charge-transfer bands. Bands at 550–600 nm and 364–368 nm may be assigned to *d–d* transitions of the octahedral nickel(II): $^3A_{2g} \rightarrow {}^3T_{1g}(F)$ and $^3A_{2g} \rightarrow {}^3T_{1g}(P)$. The intense absorptions in the UV region, are typical of charge-transfer bands, similar to those observed in the analogous square-planar nickel(II) compounds.[1,2] The similarity of the visible spectra allows us to assume that the geometry of all the complexes must be very similar to [Ni(DL-CTH)(Et$_2$Dtc)](ClO_4), whose molecular structure is known, i.e. distorted octahedral coordination around the nickel(II) ion.

Electrochemistry

The cyclic voltammogram for complexes with Me$_2$Dtc, Et$_2$Dtc and PyrrDtc show two oxidation couples in the range studied (0 → +2 V), the first being reversible and the second being irreversible. This second irreversible couple occurs at high potentials (over +1.2 V). The remaining complexes with Ac, Tac and Etxant show only one irreversible oxidation couple. Consequently, by replacing the sulphur donor atoms by more electronegative oxygen atoms or the replacement of the inner nitrogen atom linked to the carbon atom (dithiocarbamate) by oxygen (xanthogenate), produces a radical difference in their electrochemical behaviour. The positions of the first couples, peak width and the intensity ratio are shown in Table 4. All these new complexes do not present any couple in the reduction region (until −2 V). Instead, square-planar starting complexes [Ni(DL-CTH)](ClO_4)$_2$, [Ni(Cy)](ClO_4)$_2$ and [Ni(dithiocarbamate)$_2$] undergo both reduction and oxidation processes in acetonitrile.[11,13] In Fig. 3 one typical cyclic voltammogram for these kinds of complexes is shown.

After controlled oxidation of these complexes, the frozen acetonitrile solutions do not produce any signal in the EPR spectra. This feature may indicate that this oxidation does not affect the nickel(II) cation but only the organic part, which undergo a

polymerization process, giving diamagnetic species. We can conclude, consequently, that if there is formation of organic radicals, these are unstable, even at low temperature.

CONCLUSIONS

New types of 1,1-dithio complex of nickel(II), with only one sulphur bidentate ligand and octahedral coordination, are synthesized and characterized by spectroscopic and X-ray measurements. These compounds show an unusual electrochemical behaviour: no reduction processes are present in the range 0 to −2 V, but one reversible couple appears between 0.375 and 0.686 V for the complexes with the R_2N–CS_2^- ligands. Attempts to obtain stable compounds by controlled oxidation were unsuccessful.

COMPLEXES OF THE PLATINUM METALS—XL.* HOMOLEPTIC TRIS(1,3-DIARYLTRIAZENIDO) COMPLEXES OF RUTHENIUM(III), OSMIUM(III), RHODIUM(III) AND IRIDIUM(III)

STEPHEN F. COLSON and STEPHEN D. ROBINSON†

Department of Chemistry, King's College London, Strand, London WC2R 2LS, U.K.

(*Received* 14 *March* 1990; *accepted* 2 *April* 1990)

Abstract—Homoleptic tris(triazenido) derivatives of ruthenium, osmium, rhodium and iridium, $M(ArNNNAr)_3$ (Ar = *p*-C_6H_4X; X = H, Me or Cl), have been prepared by treatment of the chlorides or chloro complexes—$RuCl_3$(aq.), $(NH_4)_2OsCl_6$(aq.), $RhCl_3$(aq.) and $(NH_4)_2IrCl_6$(aq.), respectively—with excess 1,3-diaryltriazene and triethylamine in boiling ethanol (M = Ru, Rh) or aqueous ethanol (M = Os, Ir). The sparingly soluble, air-stable, deep green (M = Ru, Os) or red–orange (M = Rh, Ir) complexes have been characterized by vibrational and NMR spectroscopy, and by magnetic measurements.

Since the discovery of 1,3-diaryltriazenes by Griess[2] in the mid-19th century the coordination chemistry of their conjugate bases, the 1,3-diaryltriazenide anions, has attracted sustained, albeit somewhat sporadic, interest.[3] Triazenide anions readily function as monodentate or bidentate—bridging or chelating—ligands in a wide range of complexes. However, work on simple homoleptic tris(triazenido) derivatives of the transition metals is remarkably sparse. Only four examples appear to be known, $Cr(PhNNNPh)_3$,[4,5] $Fe(PhNNNPh)_3$,[6] $Co(PhNNNPh)_3$,[7–9] and $Rh(p\text{-tolylNNNtolyl-}p)_3$,[10] and of these only the chromium(III) derivative has been fully characterized in the literature. The iron complex received only brief mention in a note on the general synthesis of transition metal triazenido complexes and, although the cobalt complex has been the subject of two independent X-ray diffraction studies,[8,9] details of its preparation and chemical or spectroscopic characterization do not appear to have been reported. The fourth member of the group $Rh(p\text{-tolylNNNtolyl-}p)_3$ received a passing mention some years ago in a paper from this laboratory, on the synthesis and characterization of some platinum group metal triazenido complexes containing phosphine and carbonyl ligands. Finally, while this paper was in preparation, tris(1,3-diphenyltriazenido) complexes of the p-block metals aluminium, gallium and indium analogous to the previously known indium(III) derivative[11] were reported.[12]

We now describe the synthesis and characterization of homoleptic 1,3-diaryltriazenido derivatives of ruthenium(III), osmium(III), rhodium(III) and iridium(III). Preliminary details of this work form part of the material disclosed in a recent note[13] on our current studies in the area of platinum metal triazene chemistry.

EXPERIMENTAL

General experimental techniques and conditions have been reported in an earlier paper.[14] Triazenes were prepared and purified by standard literature procedures.[15] Melting points and analytical data are given in Table 1 and spectroscopic data are collected in Table 2. Raman spectra were recorded using an argon ion laser source (5145 Å) for dark green samples and a krypton ion laser source (6471 Å) for red–orange samples.

Tris(1,3-*di*-p-*tolyltriazenido*)*ruthenium*(III)

A mixture of ruthenium trichloride trihydrate (0.2 g, 0.78 mmol), 1,3-di-*p*-tolyltriazene (1 g, 4.5 mmol) and triethylamine (1 g, 10 mmol) in ethanol (40 cm^3) was heated under reflux in a nitrogen atmo-

sphere for 3 h. After cooling, the solid product was filtered off, crystallized from benzene and washed successively with benzene, ethanol and diethyl ether, then dried *in vacuo* to afford dark green needle crystals (0.31 g, 51%).

The following were similarly prepared:

Tris(1,3-*diphenyltriazenido*)*ruthenium*(III) as dark green needle crystals (46.5%).
Tris(1,3-*di*-p-*chlorophenyltriazenido*)*ruthenium*(III) as dark green needle crystals (76.0%).

Tris(1,3-p-*tolyltriazenido*)*osmium*(III)

A mixture of ammonium hexachloro-osmate (0.2 g, 0.45 mmol), 1,3-di-*p*-tolyltriazene (0.6 g, 2.7 mmol) and triethylamine (4 g, 40 mmol) in ethanol (30 cm^3) and water (10 cm^3) was heated under reflux in a nitrogen atmosphere for 24 h. After cooling, the solid product was filtered off, crystallized from benzene and washed successively with benzene, ethanol and diethyl ether, then dried *in vacuo* to afford dark green needle crystals (0.15 g, 38%).

The following were similarly prepared:

Tris(1,3-*diphenyltriazenido*)*osmium*(III) as dark green needle crystals (37%).
Tris(1,3-*di*-p-*chlorophenyltriazenido*)*osmium*(III) as dark green needle crystals (31%).

Tris(1,3-*di*-p-*tolyltriazenido*)*rhodium*(III)

A mixture of rhodium trichloride trihydrate (0.2 g, 0.76 mmol), 1,3-di-*p*-tolyltriazene (0.75 g, 3.3 mmol) and triethylamine (2 g, 20 mmol) in ethanol (40 cm^3) was heated under reflux in a nitrogen atmosphere for 3 h. After cooling, the solid product was filtered off, crystallized from dichloromethane–ethanol and washed successively with ethanol and light petroleum, then dried *in vacuo* to afford orange microcrystals (0.27 g, 46%).

The following were similarly prepared:

Tris(1,3-*diphenyltriazenido*)*rhodium*(III) as maroon platelets (38%).
Tris(1,3-*di*-p-*chlorophenyltriazenido*)*rhodium*(III) as orange microcrystals (85%).
Tris(1,3-*di*-p-*methoxyphenyltriazenido*)*rhodium*(III) as red platelets (36.5%).

Tris(1,3-*di*-p-*tolyltriazenido*)*iridium*(III)

A mixture of ammonium hexachloro-iridate (0.2 g, 0.46 mmol), 1,3-di-*p*-tolyltriazene (0.6 g, 2.7 mmol) and triethylamine (4 g, 40 mmol) in ethanol (30 cm^3) and water (10 cm^3) was heated under reflux for 24 h in a nitrogen atmosphere. After cooling, the solid was filtered off, crystallized from dichloromethane–ethanol and washed successively with ethanol and light petroleum, then dried *in vacuo* to afford orange microcrystals (0.12 g, 31%).

The following were similarly prepared:

Tris(1,3-*diphenyltriazenido*)*iridium*(III) as orange microcrystals (33%).
Tris(1,3-*di*-p-*chlorophenyltriazenido*)*iridium*(III) as orange microcrystals (53%).

RESULTS AND DISCUSSION

The ruthenium and rhodium tris(1,3-diaryltriazenido) complexes, $M(ArNNNAr)_3$, were obtained by heating a mixture of the free triazene, triethylamine and the appropriate hydrated metal chloride, $MCl_3 \cdot 3H_2O$, under reflux in ethanol for 3 h. The corresponding osmium and iridium complexes were similarly prepared from the hexachloro complex salts, $(NH_4)_2MCl_6 \cdot nH_2O$, in aqueous ethanol using a much longer reaction time (*ca* 24 h). The ruthenium and osmium products crystallized as dark green, paramagnetic needles from benzene. The rhodium and iridium complexes were obtained from dichloromethane–ethanol as red–orange (M = Rh) or orange (M = Ir) diamagnetic microcrystalline solids. All are stable and are sparingly soluble in benzene or chlorinated solvents (CH_2Cl_2, $CHCl_3$) but insoluble in water, ethanol, diethyl ether and light petroleum.

Triethylamine is added to the reaction mixtures to assist in deprotonation of the triazenes. However, by raising the pH of the reaction mixture it may also serve to inhibit the acidolysis reactions to which triazenes are susceptible. The rather modest yields obtained, particularly in the osmium and iridium based reactions which involved long reaction times, suggest that even in the presence of triethylamine degradation of the free triazene may be a problem.

The vibrational spectra—IR and Raman—for the complexes $M(ArNNNAr)_3$ are virtually identical for a given aryl group, and are consistent with the presence of chelate triazenido ligands.[16] Selected vibrations are listed in Table 2. Proton NMR data for the diagmagnetic rhodium and iridium complexes are also given in Table 2. Magnetic data for the paramagnetic ruthenium and osmium complexes (1.75–1.80 and 1.82–1.86 BM, respectively) are consistent with their formulations as low-spin d^5 ruthenium(III) and osmium(III) species.

(*Received* 9 *January* 1990; *accepted* 3 *April* 1990)

Abstract—Cyclic voltammetry shows two reversible, one-electron reductions for the neutral complexes $[Fe_2(SR)_2(NO)_4]$ (R = alkyl), to provide successively $[Fe_2(SR)_2(NO)_4]^-$ and $[Fe_2(SR)_2(NO)_4]^{2-}$. The paramagnetic complexes $[Fe_2(SR)_2(NO)_4]^-$, which can also be prepared by chemical reduction of neutral $[Fe_2(SR)_2(NO)_4]$, have been characterized by ESR spectroscopy: the complexes $[Fe_2(SR)_2(NO)_4]^{2-}$, which are isoelectronic with the substitution-labile cobalt complexes $[Co_2(SR)_2(NO)_4]$, undergo ready reaction with phosphorus ligands. The di-anion $[Fe_2S_2(NO)_4]^{2-}$ also exhibits two reversible, one-electron reductions, but for $[Fe_2(S_2O_3)_2(NO)_4]^{2-}$ only the first reduction is reversible. The tetranuclear complex $[Fe_4S_3(NO)_7]^-$ undergoes three reversible, one-electron reductions to yield $[Fe_4S_3(NO)_7]^{x-}$ (x = 2, 3 and 4). For all these complexes, the oxidation reactions are complex and irreversible. The neutral paramagnetic complexes $[Fe(NO)(S_2CNR_2)_2]$ (R = alkyl) all show a reversible one-electron reduction: the diamagnetic intermediates, which can also be prepared by chemical reduction, readily lose NO.

In recent work, we have described the reactions of iron–sulphur–nitrosyl complexes, such as $[Fe_2(SR)_2(NO)_4]$ and $[Fe_4S_3(NO)_7]^-$ with both nucleophiles[1] and electrophiles.[2] With the exception of the chemical and electrochemical reduction[3,4] of the related complex $[Fe_4S_4(NO)_4]$ to yield $[Fe_4S_4(NO)_4]^-$ and $[Fe_4S_4(NO)_4]^{2-}$ and of $[Fe_4S_2(NO)_4(NCMe_3)_2]$ to its mono-anion, the known[5] redox chemistry of such complexes is very sparse. Here we report the electrochemical properties of the neutral complexes $[Fe_2(SR)_2(NO)_4]$ (R = alkyl, C_1–C_4 and $[Fe(NO)(S_2CNR_2)_2]$ (R = alkyl, C_1–C_3) and of the anionic complexes $[Fe_2S_2(NO)_4]^{2-}$, $[Fe_2(S_2O_3)_2(NO)_4]^{2-}$ and $[Fe_4S_3(NO)_7]^-$.

EXPERIMENTAL

Previously described methods were used for the preparation of $[Fe_2(SR)_2(NO)_4]$,[6,7] $Na_2[Fe_2(S_2O_3)_2(NO)_4]$,[7] $(Bu_4N)_2[Fe_2(S_2O_3)_2(NO)_4]$,[7] $Na[Fe_4S_3(NO)_7]$,[8] $Me_3S[Fe_4S_3(NO)_7]$,[2] $Me_3SO[Fe_4S_3(NO)_7]$[2] and $[Fe(NO)(S_2CNR_2)_2]$.[2] $Na_2[Fe_2S_2(NO)_4]$[8] was prepared from $Na[Fe_4S_3(NO)_7]$ and converted to $(Et_4N)_2[Fe_2S_2(NO)_4]$ by metathesis (Found: C, 34.1; H, 7.3; N, 14.9. $C_{16}H_{40}Fe_2N_6O_4S_2$ requires: C, 34.5; H, 7.3; N, 15.1%). $(Et_4N)[Fe_4S_3(NO)_7]$ was prepared from $Na[Fe_4S_3(NO)_7]$ by metathesis (Found; C, 14.6; H, 2.7; N, 16.8. $C_8H_{20}Fe_4N_8O_7S_3$ requires: C, 14.6; H, 3.0; N, 17.0%). $(Bu_4N)[Fe_4S_3(NO)_7]$ was similarly obtained. Bu_4NPF_6 was recrystallized by addition of ethanol to a hot saturated aqueous solution: the product was dried at 110°C. $(MeO)_3P$, $(BuO)_3P$ and PPh_3 were purchased from Aldrich and were used as received. Solvents were dried and purified using standard methods.[9]

Cyclic voltammetry measurements were made at 25°C using a three-electrode cell equipped with either a platinum or glassy-carbon working electrode, a platinum counter electrode, and a silver reference electrode: an Amel model 553 potentiostat was coupled to an Amel model 567 wave function generator. The background electrolyte was 0.2 mol dm^{-3} $(C_4H_9)_4NPF_6$ and experimental solutions were 3×10^{-3} or 6×10^{-3} mol dm^{-3}. All EMF values are referred to the ferrocene/ferricinium

couple;[10] in acetonitrile solution, the standard EMF of this couple, relative to the standard hydrogen electrode has been estimated[11] as +0.34 V. IR spectra were measured in THF solutions using a Perkin–Elmer model 1710 FTIR spectrometer. ESR spectra were measured in 1 mm quartz capillaries using a Bruker ER200D spectrometer, with di-*t*-butyl nitroxide as the standard for the measurement of line positions.

RESULTS AND DISCUSSION

Reduction of $[Fe_2(SR)_2(NO)_4]$

Solutions in tetrahydrofuran (THF) of the neutral complexes $[Fe_2(SR)_2(NO)_4]$ (R = Me, Et, *n*-Pr, *i*-Pr, *n*-Bu, *i*-Bu, *s*-Bu, *t*-Bu and CH_2COOCH_3) all undergo reversible reduction to mono- and di-anions. Cyclic voltammetry, using either glassy-carbon or oxidized platinum working electrodes at scan rates in the range 64–900 mV s^{-1}, showed two reversible, one-electron reductions, eq. (1):

$$[Fe_2(SR)_2(NO)_4] \rightleftharpoons [Fe_2(SR)_2(NO)_4]^- \rightleftharpoons [Fe_2(SR)_2(NO)_4]^{2-}. \quad (1)$$

Table 1 lists the corresponding $E^{\ominus}$ values, together with the mean diffusion coefficients. For the reduction to the mono-anion, the $E^{\ominus}$ values show a shift to more negative values as the electron donor properties of the R substituent increase: such behaviour was observed[12] with variation of the substitutent R in the tetranuclear clusters $[Fe_4S_4(SR)_4]^{2-}$. No such consistent trend was found for the rescond reduction, to the di-anions $[Fe_2(SR)_2(NO)_4]^{2-}$. A representative series of complexes, having R = Me, Et, *i*-Pr and *t*-Bu, were also studied in acetonitrile solution (Table 1): the variations in the $E^{\ominus}$ values closely follow the variations in THF solution, but the diffusion coefficients in THF are typically around one third the magnitude of those in acetonitrile. This attributed to the greater solvating capacity of THF.[13,14] From the $E^{\ominus}$ values, the equilibrium constants for the disproportionation equilibrium, eq. (2), were calculated (Table 1):

$$2[Fe_2(SR)_2(NO)_4]^- \overset{K_{disprop.}}{\rightleftharpoons} [Fe_2(SR)_2(NO)_4] + [Fe_2(SR)_2(NO)_4]^{2-}. \quad (2)$$

The values derived indicate that the mono-anions should be extremely stable to disproportionation, and indeed they were found to be long lived, in the absence of air. As expected from the very negative reduction potentials, the complexes $[Fe_2(SR)_2(NO)_4]^-$ are readily oxidized by air to the neutral species $[Fe_2(SR)_2(NO)_4]$.

Properties of $[Fe_2(SR)_2(NO)_4]^{x-}$

Reduction of THF solution of $[Fe_2(SMe)_2(NO)_4]$ with either sodium wire or $Li(BHEt_3)$ caused an immediate colour change from red–brown to deep green. Admission of air to the green solutions

allowed quantitative recovery of neutral $[Fe_2(SMe)_2(NO)_4]$. Bulk electrolysis in THF at −1.1 V relative to ferrocene/ferricinium, using Bu_4NPF_6 as background electrolyte, showed that the reduction was occurring with transfer of a single electron per $[Fe_2(SR)_2(NO)_4]$ unit and ESR examination of such an electrolysed solution, when R = Me, showed the presence of a single paramagnetic species having g at *ca* 1.99.

Reduction of a range of neutral complexes $[Fe_2(SR)_2(NO)_4]$ using excess $Li(BHEt_3)$ in THF gave in every case a green solution exhibiting a symmetric nine-line ESR spectrum (Table 2): for R = CMe_3, a second paramagnetic species was also present, having $g = 2.027$ and $A(^{14}N) = 2.7$ G, assigned as the known[1(a),5] complex $\{Fe(NO)_2(SCMe_3)_2\}^-$. The nine-line spectra showed no hyperfine coupling to α-hydrogen atoms in the R groups, and the relative intensities were consistent with hyperfine coupling to four equivalent $I = 1$ (^{14}N) nuclei: use of ^{15}N isotopic labelling caused the expected change to a five-line spectrum, with an increase of *ca* 40% in the $A(N)$ value. Consequently we assign the $g = 1.99$ species as $[Fe_2(SR)_2(NO)_4]^-$, in which the unpaired electron is delocalized such that the four nitrosyl ligands are equivalent. EHMO calculations on $\{Fe_2(SH)_2(NO)_4\}$ as a simple model for $[Fe_2(SR)_2(NO)_4]$ have shown[15] that the LUMO is concentrated primarily on the two irons, but also contains modest contributions from the nitrosyl ligands: the form of this orbital, which becomes the SOMO in $[Fe_2(SR)_2(NO)_4]^-$ can account[1(b),5] for the small $A(N)$ values observed in $\{Fe_2(SR)_2(NO)_4\}^-$.

The same reduced species, $[Fe_2(SR)_2(NO)_4]^-$, can be formed by reduction of neutral $[Fe_2(SR)_2(NO)_4]$ electrolytically, or with sodium or $Li(BHEt_3)$: the reduced species are long lived in the absence of air, and are quantitatively oxidized in air back to neutral $[Fe_2(SR)_2(NO)_4]$.

The behaviour of $[Fe_2(SR)_2(NO)_4]$ upon reduction may be contrasted with that of the closely analogous complex $[Fe_2(PPh_2)_2(NO)_4]$. This, upon reduction with sodium yields[16] $[Fe_2(PPh_2)_2(NO)_4]^{2-}$, the product of a two-electron transfer reaction; with $Li(BHEt_3)$, use of one equivalent provides the rearranged product $[(ON)_2Fe(\mu\text{-}PPh_2)(\mu\text{-}NO)Fe(NO)(PPh_2H)]^-$ in which hydride-transfer to phosphorus has occurred, while use of two equivalents converts this μ-NO complex to $[Fe_2(PPh_2)_2(NO)_4]^{2-}$. Thus under conditions in which chemical reduction of $[Fe_2(SR)_2(NO)_4]$ provides the mono-anion $[Fe_2(SR)_2(NO)_4]^-$, reduction of $[Fe_2(PPh_2)_2(NO)_4]$ provides the di-anion $[Fe_2(PPh_2)_2(NO)_4]^{2-}$.

The IR spectra of THF solutions of $[Fe_2(SR)_2(NO)_4]$ which had been reduced by excess $Li(BHEt_3)$ to form $\{Fe_2(SR)_2(NO)_4\}^-$ showed the characteristic pair of absorptions in the ν(NO) region to have been shifted by *ca* 100 cm^{-1} to lower energy, with the separation between the symmetric and asymmetric stretching frequencies of the $Fe(NO)_2$ fragments reduced from 25 to 20 cm^{-1} (Table 3). A similar shift was observed[16] upon reduction of $[Fe_2(PPh_2)_2(NO)_4]$ to $[Fe_2(PPh_2)_2(NO)_4]^{2-}$: in the neutral complex the ν(NO) absorptions occur at 1762 and 1748 cm^{-1} ($\Delta\nu = 14$ cm^{-1}), and for the di-anion there is a single, broad and presumably unresolved absorption at 1673 cm^{-1}. The ν-NO complex $[(ON)_2Fe(\mu\text{-}PPh_2)(\mu\text{-}NO)Fe(NO)(PPh_2H)]^-$ exhibits,[16] in addition to ν(NO) at 1420 cm^{-1} assigned to the bridging nitrosyl ligand, three absorptions assigned to terminal nitrosyl stretches at 1784, 1691 and 1651 cm^{-1}; it is probable, in view of the foregoing, that the 1670 and 1650 cm^{-1} absorptions arise from the terminal $Fe(NO)_2$ fragment.

When reduced solutions containing $[Fe_2(SR)_2(NO)_4]^-$ were aerated, in every case the low-frequency ν(NO) absorptions were cleanly and quantitatively replaced by the characteristic absorptions of the neutral complexes $[Fe_2(SR)_2(NO)_4]$.

The dinegative complexes $[Fe_2(SR)_2(NO)_4]^{2-}$ are 36-valence-electron species and are thus isoelectronic with the neutral cobalt complexes $[Co_2(SR)_2(NO)_4]$: these cobalt complexes have been shown[17] to be kinetically labile to ligand substitution. Thus $[Co_2(SPh)_2(NO)_4]$ undergoes rapid reaction at 25°C with two equivalents of PPh_3, to give the mononuclear complex $[Co(NO)_2(PPh_3)(SPh)]$ in almost quantitative yield. On the other hand, the neutral 34-valence-electron complex, $[Fe_2(SPh)_2(NO)_4]$, was found[17] to react only slowly with PPh_3, requiring forcing conditions, and providing $[Fe(NO)_2(PPh_3)_2]$ and Ph_2S_2 in a reduction involving both redox and substitution steps.

Lemoine[18] has recently introduced the concept of electron-induced nucleophilic substitution in reduced carbonyl clusters, and this suggested that substitution in $[Fe_2(SR)_2(NO)_4]$ by phosphorus nucleophiles could perhaps be accelerated by reduction of the iron complex to the 36-valence-electron di-anion: exploratory CV experiments appear to support this idea. For the couple $[Fe_2(SMe)_2(NO)_4]^-/[Fe_2(SMe)_2(NO)_4]^{2-}$ in THF, the ratio of i_A/i_c was reduced as aliquots of $P(OMe)_3$ were added: a linear relationship between i_a/i_c and added $P(OMe)_3$ was found throughout the region in which the ratio could be accurately measured ($1.0 \geqslant i_a/i_c > 0.4$). Extrapolation to $i_a/i_c = 0$ indicated a reaction stoichiometry $[Fe_2(SMe)_2(NO)_4]^{2-}$:$P(OMe)_3$ of 1:2. Similar stoichiometric ratios were found for the reactions between $[Fe_2(SEt)_2(NO)_4]^{2-}$ and $P(OMe)_3$ and between $[Fe_2(SCHMe_2)_2(NO)_4]^{2-}$ and $P(OBu)_3$. Further support for this concept may be derived from the preliminary report[19] that chemical reduction of $[Fe_2Cl_2(NO)_4]$ in the presence of either Ph_3P or $Ph_2PCH_2CH_2PPh_2$ yielded the neutral, d^{10} complexes, $Fe(NO)_2(phos)_2$ [phos = Ph_3P or $1/2(Ph_2PCH_2CH_2PPh_2)$].

Oxidation of $[Fe_2(SR)_2(NO)_4]$

For a range of complexes $[Fe_2(SR)_2(NO)_4]$ (R = Me, Et, *n*-Pr, *i*-Pr, *n*-Bu, *i*-Bu, *s*-Bu, *t*-Bu and CH_2COOCH_3), the oxidation is chemically irreversible, at both glassy-carbon and oxidized platinum electrodes, with E_p *ca*+1.1 V relative to ferrocene/ferricinium. In acetonitrile as solvent, a normal diffusion wave was observed with i_p proportional to $v^{1/2}$ for scan rates in the range 64–900 mV s^{-1}, but there was no reverse peak. A comparison of the i_p *vs* $v^{1/2}$ plots for the oxidation process with those for reduction of $[Fe_2(SR)_2(NO)_4]$ to $[Fe_2(SR)_2(NO)_4]^-$, for R = Me, Et, *i*-Pr and *t*-Bu, showed that in acetonitrile the number of electrons transferred, up to and including the rate limiting step of the irreversible process was 2.9. Further voltammetric scans showed no change from the initial scan, and no decomposition products were deposited on the electrode.

In dichloromethane as solvent, for all R studied, there was evidence for deposition of decomposition products on the electrode. If, after the oxidative step, the scan was repeated, the voltammogram collapsed: however, if the electrode was cleaned, or was taken to extreme negative potentials, and then scanned, the usual reduction waves were again observed. These observations indicate a deposit of decomposition product, removeable either mechanically or electrochemically. For the oxidation i_p was again proportional to $v^{1/2}$, showing that absorption occurs only after oxidation; the number of electrons transferred was determined as 2.8, similar to the value found in CH_3CN solutions.

The electron-transfer numbers above provide information only up to, and including, the rate limiting step, rather than providing a complete redox stoichiometry. The simplest oxidative decomposition which can be envisaged for $[Fe_2(SR)_2(NO)_4]$ would provide Fe^{2+}, RSSR and NO, corresponding to an overall four-electron oxidation.

Reduction of $[Fe_2(S_2O_3)(NO)_4]^{2-}$ *and* $[Fe_2(S_2O_3)_2(NO)_4]^{2-}$

Salts of Roussin's red anion, $[Fe_2S_2(NO)_4]^{2-}$, are cleanly and rapidly converted,[20,21] in CH_2Cl_2 solution, to salts of Roussin's black anion, $[Fe_4S_3(NO)_7]^-$: similar behaviour has now been observed in THF solutions. However, CH_3CN solutions are sufficiently stable to allow exploration of the redox properties of $[Fe_2S_2(NO)_4]^{2-}$. Two reversible, one-electron reductions were observed at a glassy-carbon electrode, eq. (3):

$$[Fe_2S_2(NO)_4]^{2-} \rightleftharpoons [Fe_2S_2(NO)_4]^{3-} \rightleftharpoons [Fe_2S_2(NO)_4]^{4-}. \quad (3)$$

The EMF values, relative to the ferrocene/ferricinium couple, are −1.08 and −1.68 V, respectively.

The μ-thiosulphato complex, $[Fe_2(S_2O_3)_2(NO)_4]^{2-}$, has recently been characterized,[7] in the solid state by X-ray crystallography, and in solution by ^{15}N NMR spectroscopy, using $[Fe_2(S_2O_3)_2(^{15}NO)_4]^{2-}$: the sodium salt is soluble in THF and the Bu_4N^+ salt in CH_2Cl_2. At a glassy-carbon elecrode, a THF solution of $Na_2[Fe_2(S_2O_3)_2(NO)_4]$ showed a reversible one-electron reduction at −1.310 V relative to ferrocene/ferricinium, corresponding to reduction to $[Fe_2(S_2O_3)_2(NO)_4]^{3-}$, but further reduction was only quasi-reversible for scan rates in the range 64–900 mV s^{-1}. In CH_2Cl_2 solution, at a platinum electrode, $(Bu_4N)_2[Fe_2(S_2O_3)_2(NO)_4]$ again showed a reversible one-electron reduction, at −1.276 V, but further reduction was wholly irreversible.

It is of interest that formation of a tetra-negative anion is reversible in the case of reduction of $[Fe_2S_2(NO)_4]^{2-}$ to $[Fe_2S_2(NO)_4]^{4-}$ [and of reduction of $[Fe_4S_3(NO)_7]^-$ to $[Fe_4S_3(NO)_7]^{4-}$ (see below)], but not for the reduction of $[Fe_2(S_2O_3)_2(NO)_4]^{2-}$, despite the apparently greater opportunity afforded for the delocalization of negative charge by the pendent S—SO_3 groups. Although the frontier orbitals calculated[7,15] for $[Fe_2S_2(NO)_4]^{2-}$ and for $[Fe_2(S_2O_3)_2(NO)_4]^{2-}$ are very similar, reduction of the thiosulphato complex to the tetra-negative anion could provide both an effective leaving group SO_3^{2-} and a stable residual cluster $[Fe_2S(S_2O_3)(NO)_4]^{2-}$.

Redox properties of $[Fe_4S_3(NO)_7]^-$

In THF solution, cyclic voltammetry of a range of salts $M^I[Fe_4S_3(NO)_7]$ ($M^I = Et_4N^+$, Bu_4N^+, Me_3S^+ or Me_3SO^+) at a glassy-carbon electrode showed reductive behaviour independent of the cation: for scan rates in the range 64–900 mV s^{-1}, three reversible, one-electron reductions were observed, with $E^\ominus$ values, relative to ferrocene/ferricinium of −1.31, −1.91 and −2.41 V, respectively, corresponding to eq. (4):

$$[Fe_4S_3(NO)_7]^- \rightleftharpoons [Fe_4S_3(NO)_7]^{2-} \rightleftharpoons [Fe_4S_3(NO)_7]^{3-} \rightleftharpoons [Fe_4S_3(NO)_7]^{4-}. \quad (4)$$

These EMF values show that, although very sensitive to aerial oxidation, the intermediate complexes, $[Fe_4S_3(NO)_7]^{2-}$ and $[Fe_4S_3(NO)_7]^{3-}$, are very stable to disproportionation: K values for the disproportionations described by eqs (5) and (6) are, respectively, 7.2×10^{-11} and 3.5×10^{-9}, implying considerable thermodynamic stability in the absence of oxygen.

$$2[Fe_4S_3(NO)_7]^{2-} \rightleftharpoons [Fe_4S_3(NO)_7]^- + [Fe_4S_3(NO)_7]^{3-} \quad (5)$$

$$2[Fe_4S_3(NO)_7]^{3-} \rightleftharpoons [Fe_4S_3(NO)_7]^{2-} + [Fe_4S_3(NO)_7]^{4-}. \quad (6)$$

For each of $Na[Fe_4S_3(NO)_7]$ in aqueous solution, $Et_4N[Fe_4S_3(NO)_7]$ in dichloromethane and $Me_3S[Fe_4S_3(NO)_7]$ in CH_3CN, the oxidation of the anion is a complex, multi-electron process which is chemically irreversible. From the peak current for the oxidation, when compared with the currents for the reductions described earlier, the number of electrons transferred was estimated as 8 ± 1: a value of 9 ± 1 was estimated for the analogous $Na[Fe_4Se_3(NO)_7]$ in acetonitrile. For the complete oxidative decomposition description by eq. (7), a total of nine electrons per anion are transferred:

$$[Fe_4X_3(NO)_7]^- \longrightarrow 7NO + 3X + 4Fe^{2+} + 9e^- \quad X = S, Se. \quad (7)$$

The overall waveform was indicative of the deposition of material on the electrode. Subsequent reduction of the absorbed material left the electrode clean, as judged by the subsequent repetition of the reduction to $[Fe_4S_3(NO)_7]^{x-}$ ($x = 2$, 3 and 4).

Redox properties of $[Fe(NO)(S_2CNR_2)_2]$

Solutions in THF of the neutral complexes $[Fe(NO)(S_2CNR_2)_2]$ (R = Me, Et, *n*-Pr) all exhibit a reversible, one-electron reduction, at platinum or glassy-carbon electrodes, eq. (8):

$$[Fe(NO)(S_2CNR_2)_2] \rightleftharpoons [Fe(NO)(S_2CNR_2)_2]^-. \quad (8)$$

The $E^\ominus$ values are −1.34, −1.39 and −1.38 V for R = Me, Et and *n*-Pr, respectively. Similar behaviour was observed in CH_2Cl_2, but in CH_3CN solutions, the ratio i_a/i_c was low at low scan rates, but approached unity as the scan rate increased. However, addition of free $[R_2NCS_2]^-$ to such solutions led to an increase in the i_a/i_c ratio, suggesting an equilibrium between the primary reduction product $[Fe(NO)(S_2CNR_2)_2]^-$ and its decomposition products, one of which is $[R_2NCS_2]^-$.

Chemical reduction of THF solutions of $[Fe(NO)(S_2CNR_2)_2]$ (R = Me or Et) using either sodium or $Li(BHEt_3)$ caused an immediate colour change from green to brown, accompanied by gas evolution. At the same time, the characteristic ESR spectrum disappeared: the diamagnetic nature of the reduction products was confirmed by the obser-

vation of clean ^{1}H NMR spectra. The IR spectra showed no trace of ν(NO).

These observations thus indicate that the neutral complexes $[Fe(NO)(S_2CNR_2)_2]$, in which the Fe—N—O group is linear,[1(b),22] undergo a one-electron reduction to give labile intermediates $[Fe(NO)(S_2CNR_2)_2]^-$ which are isoelectronic and thus presumably isostructural with neutral $[Co(NO)(S_2CNR_2)_2]$, where the Co—N—O group is non-linear[23] ($\angle$Co—N—O *ca* 135°). These intermediates readily lose NO to yield diamagnetic products.

Just as reduction of neutral $[Fe(NO)(S_2CNR_2)_2]$ yields a labile intermediate susceptible to NO loss, so too oxidation of neutral $[Co(NO)(S_2CNMe_2)_2]$,[24] by air, causes loss of NO, with formation of $[Co(S_2CNMe_2)_3]$. Despite the differing electron structures, $\{Co(NO)\}^8$ and $\{Fe(NO)\}$,[7] the complexes $[M(NO)(S_2CNMe_2)_2]$ (M = Co, Fe) show very similar electrochemical behaviour in THF, with a reversible, one-electron reduction, and an irreversible, one-electron oxidation.

Acknowledgements—We thank the Association for International Cancer Research for financial support, and Dr J. C. Walton for assistance in obtaining the ESR spectra.

A NEW CHROMOPHORIC AND REDOX-RESPONSIVE IONOPHORE CONTAINING A TRICYANOVINYL MOIETY

PAUL D. BEER* and HARRISON SIKANYIKA

Department of Chemistry, University of Birmingham, P.O. Box. 363, Birmingham B15 2TT, U.K.

(*Received* 28 *February* 1990; *accepted* 3 *April* 1990)

Abstract—The treatment of tetracyanoethylene (**1**) with N-phenylaza-15-crown-5 (**3**) gives a new chromophoric and redox-responsive ionophore, **5**, containing a tricyanovinyl redox-active moiety. The electronic absorption spectrum of **5** exhibits hypochromic shifts on binding alkali and alkaline earth metal cations. Cyclic voltammetric electrochemical investigations reveal **5** to electrochemically recognize Na^+ and K^+ guest cations resulting in shifts of the tricyanovinyl reduction wave to more anodic potentials.

With regard to the future design and development of new molecular sensory devices considerable interest is being shown in the syntheses of redox-active macrocyclic receptor molecules that contain a redox centre in close proximity to a host binding site.[1] We[1–3] and others[4–7] have demonstrated that such systems can electrochemically recognize cationic (metal, ammonium[8]) and anionic[9] (bromide) guest species. Recently we reported the first example of *selective* electrochemical recognition of the potassium guest cation in the presence of equimolar amounts of sodium and magnesium ions by a novel ferrocenyl bis-benzo-crown ether ionophore.[10] This paper describes the synthesis, coordination and electrochemistry of a new type of redox-responsive ionophore which incorporates the redox-active and chromophoric tricyanovinyl group into a benzo-aza-crown ether macrocycle.

RESULTS AND DISCUSSION

Syntheses

Tetracyanoethylene (**1**) is known to react with both tertiary and secondary aromatic amines, to give 4-tricyanovinylamines.[11] These compounds have been shown to be brilliant red and blue dyes with strong affinity for hydrophobic fibres. Adaption of this simple synthetic methodology led to the preparation of the new chromophoric and redox-responsive ionophore, **5**.

The addition of N,N-dimethylaniline (**2**) or N-phenylaza-15-crown-5 (**3**) to **1** dissolved in dry dimethylformamide (DMF), instantly gave an intense blue-coloured solution, whereupon after gentle warming and work-up (see Experimental), dark blue crystals of **4** and **5**, respectively, were isolated in excellent yields (see Scheme 1).

The structures of **4** and **5** were characterized by elemental analysis, mass spectrometry, IR and ^1H NMR spectroscopy. Both tricyanovinylarylamines exhibited in their respective IR spectra, a band in the range 2240–2200 cm^{-1} characteristic of the —C≡N stretch.

Electronic studies

The UV–vis light absorption properties of **4** and **5** were investigated in acetonitrile, scanning from 700 to 190 nm. These 4-tricyanovinylarylamines absorb visible light very strongly, a property consistent with the highly conjugated structure assigned to them. For example, **4** dissolves in acetonitrile to give a deep red solution ($\lambda_{max} = 517$ nm; $\varepsilon = 40{,}000$). A similar intense red solution is produced with **5** ($\lambda_{max} = 515$ nm; $\varepsilon = 39{,}000$) and the spectrum for **5** was also recorded after addition of stoichiometric molar equivalents of Na^+, K^+ and Mg^{2+} cationic guests, Fig. 1. Significant hypochromic shifts of the intramolecular charge-transfer absorption of **5** occur upon addition of each metal cation. The magnitude of this shift increases in the order $K^+ < Na^+ < Mg^{2+}$. That a hypochromic shift is observed suggests binding of a metal cationic guest at the aza-crown ether receptor site inductively reduces the electron density at the tricyanovinyl moiety hence quenching the electronic $n \rightarrow \pi^*$ excitation. As pointed out by Vogtle and coworkers,[12] both the binding strength and the electrostatic effect of the particular metal cation are important factors in determining the magnitude of the spectral shift a cation induces upon complexation to a chromophoric crown ether. Of the two monocations studied, the Na^+ cation apparently features the optimum compromise between these factors and, therefore, induces a larger shift than the K^+ cation. As expected from electrostatic considerations, the shift induced by the Mg^{2+} dication exceeds those of the monocations.

Electrochemical studies

The electrochemical properties of **4** and **5** were investigated in acetonitrile using cyclic voltammetry with $[n\text{-}Bu_4N]BF_4$ as the supporting elecrolyte. The cyclic voltammograms were also recorded after progressive addition of stoichiometric equivalents of Na^+, K^+ and Mg^{2+} and the results obtained are presented in Table 1.

Both **4** and **5** undergo a reversible one-electron reduction process and on adding Na^+ or K^+ cationic guests to **5** the respective reduction wave shifts to more anodic potentials. With the same metal cation insignificant shifts ($\Delta E < 10$ mV) are observed with **4**. These observations suggest the binding of the metal cation at the aza-crown ether receptor site of **5** inductively withdraws electronic charge via the conjugated bond linkages from the tricyanovinyl redox-active moiety, thus making this redox centre easier to reduce. It is noteworthy that Na^+, having a larger charge/radius ratio than K^+, induces a larger magnitude of anodic shift. Surprisingly the addition of one equivalent of Mg^{2+} to **5**, although resulting in an anodic shift of the cathodic peak potential, the redox process becomes irreversible and the anodic wave is no longer seen.

Conclusions

A new redox-active and chromophoric ionophore, **5**, containing the tricyanovinyl group appended to a phenyl aza-crown ether has been prepared whose electronic absorption spectrum exhibits hypochromic shifts on binding Na^+, K^+ and Mg^{2+} guest cations. The electrochemical recognition of Na^+ and K^+ by this ionophore results in anodic shifts of the tricyanovinyl reduction wave.

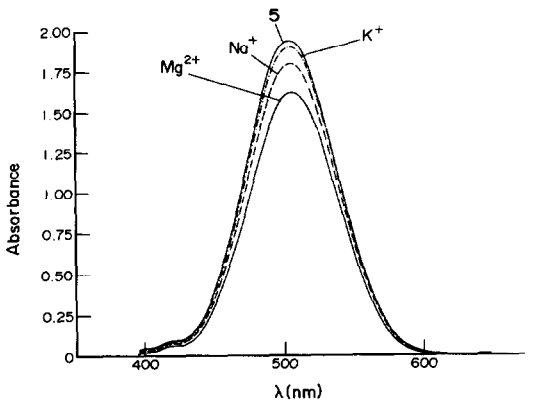

Fig. 1. The effect of Na^+, K^+ and Mg^{2+} (4 equiv.) on the visible absorption spectrum of **5** in acetonitrile at 21°C (concentration of **5** = 5.2×10^{-5} M).

Table 1. Electrochemical data

	4	**5**
$E_{1/2}$ (V)[a]	−0.64	−0.65
ΔE_p (mV)[b]	90	90
ΔE (Na^+) (mV)[c]	< 10	80
ΔE (K^+) (mV)[c]	< 10	20
ΔE (Mg^{2+}) (mV)	—	60[d]

[a] Obtained in acetonitrile solution containing 0.2 M $[n\text{-}Bu_4N]BF_4$ as supporting electrolyte. Potentials are quoted with reference to standard calomel electrode at 21 ± 1°C at 0.2 V s^{-1} scan rate.

[b] Separation between cathodic and anodic peak potentials of cyclic voltammograms; values for ferrocene under the same conditions ranged from 90 to 100 mV.

[c] Anodic shifts in reduction potential produced by presence of metal cation added as $MClO_4$ (4 equiv.).

[d] Anodic shift of the cathodic peak potential after addition of one equivalent of $Mg(ClO_4)_2$.

EXPERIMENTAL

Reactions were carried out under an atmosphere of dry nitrogen and solvents were distilled prior to use from an appropriate drying agent. ^{1}H NMR spectra were recorded at 400 and 270 MHz and ^{13}C NMR spectra at 100 and 67.8 MHz using tetramethylsilane (TMS) as internal standard. Microanalyses were performed by the Birmingham University Chemistry Department microanalytical service. Electrochemical measurements were performed using a PAR 174A polarographic analyser. Cyclic voltammetric measurements were carried out in acetonitrile solution containing 0.2 mol dm^{-3} [n-Bu_4N]BF_4 as supporting electrolyte using a platinum bead working electrode with ferrocene internal reference. Values are quoted relative to the saturated calomel reference electrode (SCE). Positive ion fast atom bombardment mass spectrometry was performed using a primary atom beam of argon (6 KeV) on a Kratos MS80 RF mass spectrometer coupled to a Kratos DS55 data system. UV and visible absorption spectra were recorded on a Schimadzu UV-240 spectrophotometer.

4-*Tricyanovinyl*-N,N′-*dimethylaniline* (**4**)

Tetracyanoethylene (TCNE) (**1**) (3.50 g, 0.027 mol) was added to a stirred solution of N,N-dimethylaniline (**2**) (12 cm^3, 0.095 mol) in dry DMF (15 cm^3) at 25–40°C. The mixture was stirred at 50–60°C for 20 min under N_2. The reaction mixture was poured on to ice-water (250 cm^3) and the precipitate was extracted with dichloromethane. After removal of the solvent, the residue was recrystallized twice from ethanol–pentane to yield **4** as deep blue crystals, 4.92 g (81%).

Melting point 172–174°C (lit.[11] 173–175°C), m/z 221. IR: 2220 cm^{-1} (—C≡N stretch). ^{1}H NMR ($CDCl_3$) δ: 3.23 (s, 6H, Me_2N), 6.75 (d, J = 9 Hz, 2H, ArH), 8.05 (d, J = 9 Hz, 2H, ArH). Found: C, 70.6; H, 4.2; N, 24.9. Calc. for $C_{14}H_{10}N_4$: C, 70.3; H, 4.5; N, 25.2%.

Compound **5** was prepared using the procedure described for **4** in 80% yield from TCNE (**1**) and N-phenylaza-15-crown-5 (**3**).

Melting point 130–132°C, m/z 369. IR: 2220 cm^{-1} (—C≡N stretch). ^{1}H NMR ($CDCl_3$) δ: 3.60–3.80 (m, 20H, crown-H), 6.70 (d, J = 9 Hz, 2H, ArH), 8.00 (d, J = 9 Hz, 2H, ArH). Found: C, 64.5; H, 6.4; N, 14.7. Calc. for $C_{21}H_{24}O_4N_4$: C, 63.6; H, 6.1; N, 14.1%.

HALODIOXORUTHENATE(VI) COMPLEXES AS CATALYSTS FOR THE OXIDATION OF ALCOHOLS

ANDREW C. DENGEL, WILLIAM P. GRIFFITH,* AHMED M. EL-HENDAWY† and JENNIFER M. JOLLIFFE

Inorganic Chemistry Laboratories, Imperial College of Science, Technology and Medicine, London SW7 2AY, U.K.

(*Received* 26 *March* 1990; *accepted* 3 *April* 1990)

Abstract—The new salts *trans*-(R-pyH)$_2$[RuO_2Cl_4] (R-py = pyridine and substituted pyridines), *trans*-R_2[RuO_2X_4] [X = Cl, Br; R = $Me_2NH(CH_2)_2NHMe_2$, $Me_2N(C_2H_4)_2NMe_2$]; (Ph_4P)[RuO_2Br_3], *trans*-(Ph_4P)$_2$[RuO_2Br_4] and *trans*-(Ph_4As)[$RuO_2Cl_3(OPPh_3)$] are reported. They function in dichloromethane or acetonitrile as two-electron catalysts for the oxidation of primary alcohols to aldehydes and of secondary alcohols to ketones, without competing olefinic bond cleavage, in the presence of N-methylmorpholine-N-oxide as co-oxidant. Vibrational spectra of the complexes are reported.

We have shown that oxo complexes of ruthenium(VI) are effective oxidants for alcohols, primary alcohols giving aldehydes[1–3] or carboxylic acids,[3,4] and secondary alcohols giving ketones,[1–4] often with good selectivity. In our earlier work on (Ph_4P)[RuO_2Cl_3] (prepared by the reaction of *trans*-[$RuO_3(OH)_2$]$^{2-}$ with excess HCl and Ph_4PCl) this was shown to be a mild and selective two-electron oxidant for alcohols;[3] the reagent was later used in a key step in the total synthesis of the natural product *iso*-drimeninol.[5] We were, however, unable to make the complex function catalytically at that time. We have shown recently that N-methylmorpholine-N-oxide (NMO) can be used as an efficient co-oxidant for [RuO_4]$^-$ [6] and for oxoruthenium(VI) complexes containing pyridine co-ligands,[1,2] and show here that [RuO_2Cl_3]$^-$, the new complexes [RuO_2Br_3]$^-$ and *trans*-[RuO_2Br_4]$^{2-}$, and also *trans*-[RuO_2Cl_4]$^{2-}$ (generated in solution[7] by adding excess Cl^- to [RuO_2Cl_3]$^-$) are efficient catalysts with NMO for the oxidation of alcohols with turnovers (turnover = mol product/mol catalyst) of up to 80 at room temperatures. New salts of *trans*-[RuO_2X_4]$^{2-}$ (X = Cl, Br), prepared by the passage of ruthenium tetraoxide vapour into a solution of a substituted pyridine or diamine in excess aqueous HX, can be used similarly as oxidation catalysts, as can the new triphenylphosphine oxide complex *trans*-(Ph_4As)[$RuO_2Cl_3(OPPh_3)$].

EXPERIMENTAL

Tetraphenylphosphonium dioxotrichlororuthenate (VI), (Ph_4P)[RuO_2Cl_3]

This was prepared by our earlier method[3] of adding excess Ph_4PCl and HCl to a basic solution of *trans*-[$RuO_3(OH)_2$]$^{2-}$ at 0°C.

Pyridinium and substituted pyridinium salts of trans-*dioxotetrachlororuthenate*(VI), trans-[RuO_2Cl_4]$^{2-}$

The preparation of *trans*-(4-^{t}BupyH)$_2$[RuO_2Cl_4] was typical. Ruthenium tetraoxide was generated as below from $RuO_2 \cdot nH_2O$ (0.75 g), $NaIO_4$ (2.75 g) and water (15 cm^3) and passed into an ice-cold solution of 4-^{t}butylpyridine (4-^{t}Bupy) (1.50 g, 11.1 mmol) in water (5 cm^3) and concentrated HCl (5 cm^3) until a dark red crystalline precipitate ceased to form. The solid was filtered off, washed with cold water (2 × 5 cm^3) and dried *in vacuo* immediately. The red salts *trans*-(R-pyH)$_2$[RuO_2Cl_4] [R-py = pyridine (py), 3-methylpyridine (3-Mepy), 3,4-dimethylpyridine (3,4-Me_2py), 8-hydroxyquinoline (8-

HQ) or 1,10-phenanthroline (phen)] were prepared similarly.

N,N,N′,N′-tetramethylpiperazonium dioxotetrahaloruthenate(VI), trans-$(Me_2N(C_2H_4)_2NMe_2)[RuO_2X_4]$ (X = Cl, Br)

The preparation of *trans*-$(Me_2N(C_2H_4)_2NMe_2)[RuO_2Cl_4]$ was typical. N,N,N′,N′-tetramethylpiperazonium dichloride was prepared from N,N,N′,N′-tetramethylethylenediamine and 1,2-dichloroethane by the method of Creighton and Taylor.[8] Ruthenium tetraoxide [generated as below from $RuO_2 \cdot nH_2O$ (0.50 g), $NaIO_4$ (1.80 g) and water (15 cm^3)] was passed into an ice-cold solution of $(Me_2N(C_2H_4)_2NMe_2)Cl_2$ (1.26 g, 3.0 mmol) in water (5 cm^3) and HCl (3 cm^3). The red crystalline product was filtered off, washed with cold water and dried *in vacuo*.

N,N,N′,N′-tetramethylethylenediammonium dioxotetrahaloruthenate(VI), trans-$(Me_2NH(CH_2)_2NHMe_2)[RuO_2X_4]$ (X = Cl, Br)

The preparation of *trans*-$(Me_2NH(CH_2)_2NHMe_2)[RuO_2Br_4]$ was typical. Ruthenium tetraoxide was generated as below [$RuO_2 \cdot nH_2O$ (0.50 g), $NaIO_4$ (1.8 g), water (15 cm^3)] and passed into an ice-cold solution of N,N,N′,N′-tetramethylethylenediamine (0.46 g, 4.0 mmol) in water (6 cm^3) and HBr (48%, 3.5 cm^3). The red crystalline product was filtered off, washed with cold water and dried *in vacuo*.

Tetraphenylphosphonium dioxotetrabromoruthenate(VI), trans-$(Ph_4P)_2[RuO_2Br_4]$

$(Ph_4P)[RuO_2Br_3]$ (0.20 g) was dissolved in dichloromethane (10 cm^3) and carbon tetrachloride (Analar grade; 1 cm^3). The green solution was reduced in volume until red in colour, and left at room temperature overnight. Red crystals of *trans*-$(Ph_4P)_2[RuO_2Br_4]$ appeared and were filtered off, washed with cold water and dried in a vacuum desiccator over silica gel.

Tetraphenylphosphonium dioxotribromoruthenate (VI), $(Ph_4P)[RuO_2Br_3]$

Ruthenium tetraoxide was generated by a method based on that of Nakata,[9] in which hydrated ruthenium dioxide ($RuO_2 \cdot nH_2O$; 1.5 g) was vigorously stirred with sodium periodate (5.5 g) in water (25 cm^3). It was passed into CCl_4 (Analar grade; 150 cm^3) using a stream of N_2 gas, and the resulting yellow solution was stirred overnight in a stoppered flask with 2.5 M NaOH solution. The red aqueous layer, containing the ruthenate ion, *trans*-$[RuO_3(OH)_2]^{2-}$, was separated and cooled to 0°C. To 10 cm^3 of this solution was added Ph_4PBr (1.05 g, 2.5 mmol) with stirring, followed by HBr (48%) dropwise until precipitation of an olive-green solid was complete. The solid was filtered off, washed with cold water (2 × 5 cm^3) and dried *in vacuo*.

Tetraphenylarsonium dioxotrichlorotriphenylphosphine oxide ruthenate(VI), trans-$(Ph_4As)[RuO_2Cl_3(OPPh_3)]$

Ruthenium tetraoxide was generated as above [$RuO_2 \cdot nH_2O$ (0.25 g), $NaIO_4$ (1.0 g) and water (15 cm^3)] and passed into a solution of triphenylphosphine (0.13 g, 0.05 mmol) and $Ph_4AsCl \cdot HCl \cdot H_2O$ (0.50 g, 0.10 mmol) in a minimum quantity of acetonitrile. After 3 h, the brown–green solution was reduced in volume, whereupon red–brown crystals appeared. These were filtered off, washed with diethyl ether and dried in a vacuum desiccator over silica gel.

Stoichiometric and catalytic oxidations

(i) *Stoichiometric.* The oxidation of *p*-methoxybenzyl alcohol by *trans*-$(4\text{-}^tBupyH)_2[RuO_2Cl_4]$ was typical. A stirred solution of *p*-methoxybenzyl alcohol (0.07 g, 0.51 mmol; a slight excess) in dichloromethane (5 cm^3) containing powdered 4 Å molecular sieves (0.25 g) was treated with *trans*-$(4\text{-}^tBupyH)_2[RuO_2Cl_4]$ (0.27 g, 0.50 mmol). After 2 h at room temperature the reaction solution was diluted with dichloromethane, filtered, washed with 1 M sodium thiosulphate solution (to remove the reduced ruthenium products), and dried over anhydrous $MgSO_4$. The solution was filtered, evaporated to dryness and the organic product either dissolved in minimum ethanol (for quantification as the 2,4-dinitrophenylhydrazone derivative), or in 10 : 1 petroleum ether (40–60°C) : ethyl acetate and purified by column chromatography (silica gel H) (for determination of yield by isolation and ^1H NMR study).

(ii) *Catalytic.* A similar procedure to that used in the stoichiometric oxidations was employed, except that a three-fold excess of NMO (with respect to the alcohol substrate) was added, and that a catalytic amount (10^{-2}–10^{-1} mmol) of the ruthenium oxidant was used. At the end of the 2 h reaction the dichloromethane solution was also washed with a saturated solution of copper(II) sulphate in order to remove NMO and its reduced products.

(iii) *Oxidations involving* $[RuO_2Cl_3]^-$ *and an excess of* Cl^-. The same procedure as in (ii) was used, with the addition of a 40-fold excess of tetra-

ethylammonium chloride, Et_4NCl. The green solution of $[RuO_2Cl_3]^-$ changed colour to red upon addition of the excess chloride, indicating formation in solution of the *trans*-$[RuO_2Cl_4]^{2-}$ species, as noted by Perrier and Kochi.[7] The alcohol was then added, along with excess NMO in the case of catalytic reactions.

General experimental

Carbon, hydrogen, nitrogen and halogen analyses were performed by Mr K. Jones of the Imperial College Microanalytical Department. Raman spectra were run as pressed discs with KBr supports on a Spex Ramalog V instrument with 5682 and 6471 Å krypton-ion excitation from a Coherent Radiation Innova 90 laser, and 5145 Å argon-ion excitation from a Coherent Radiation Innova 70 laser. IR spectra were recorded on a Perkin-Elmer 1720 (FT–IR) instrument as liquid paraffin mulls between KBr or CsI plates. ^1H NMR spectra were recorded on a Jeol 270 (FT) spectrometer, and UV–vis spectra on a Philips PU 8740 spectrometer using 10 mm quartz glass cells. In oxidation experiments the 2,4-dinitrophenylhydrazone derivatives were prepared using a saturated methanolic solution of 2,4-dinitrophenylhydrazine (acidified with sulphuric acid) and were compared with authentic samples.

RESULTS AND DISCUSSION

(a) *Oxidation studies*

In Table 1 we summarize our work on the oxidation of 11 alcohols, seven primary (of which four are unsaturated) and four secondary. Results are given for catalytic oxidations with $(Ph_4P)[RuO_2Cl_3]$; catalytic oxidations with $(Ph_4P)[RuO_2Cl_3]$ and an excess of chloride; stoichiometric and catalytic oxidations with *trans*-(4-^{t}BupyH)$_2$[RuO_2Cl_4] (the most organic soluble of the dioxotetrachlororuthenate(VI) salts); and catalytic oxidations with *trans*-$(Ph_4P)_2[RuO_2Br_4]$ and *trans*-$(Ph_4As)[RuO_2Cl_3(OPPh_3)]$. All oxidations were carried out at room temperature in dichloromethane solution, from which water was removed by using powdered molecular sieves; all catalytic oxidations were performed with NMO as the co-oxidant. In no case was there detectable oxidation of an alcohol in the presence of NMO but absence of ruthenium. There was no evidence of aerobic oxidation, as has been observed for several ruthenium oxidants, for example the oxoruthenium(VI) pyridine complexes $[Ru_2O_6(py)_4]$ and *trans*-$[RuO_2(py)_4]^{2+}$.[1]

Although it has been shown that $[RuO_2Cl_3]^-$ in acetonitrile as a stoichiometric oxidant attacks the olefinic double bond in *cyclo*hexene over a 2 h period giving a mixture of *cyclo*hexene oxide, 2-*cyclo*hexenone, 2-chloro*cyclo*hexenone and *cyclo*hexene chlorohydrin,[7] we find no competing double bond cleavage in the reaction of $[RuO_2Cl_3]^-$, *trans*-$[RuO_2X_4]^{2-}$ or *trans*-$[RuO_2Cl_3(OPPh_3)]^-$ over similar periods with unsaturated alcohols (cinnamyl alcohol, geraniol, chrysanthemyl alcohol, citronellol). In the catalytic reactions, turnovers are up to 70 for $(Ph_4P)[RuO_2Cl_3]$, 25 for *trans*-(4-^{t}BupyH)$_2$[RuO_2Cl_4] and 50 for *trans*-$(Ph_4P)_2[RuO_2Br_4]$ and *trans*-$(Ph_4As)[RuO_2Cl_3(OPPh_3)]$ over a 2 h period. By repeating the $[RuO_2Cl_3]^-$ stoichiometric and catalytic oxidations in the presence of a 40-fold excess of chloride (as Et_4NCl), the green trichloro species is converted to the red *trans*-$[RuO_2Cl_4]^{2-}$;[7] we find that the latter species is a more effective oxidant when prepared *in situ* than it is when used as its butylpyridinium salt. However, addition of excess chloride to oxidation reactions involving *trans*-(4-^{t}BupyH)$_2$[RuO_2Cl_4] decreases the yield and the catalytic turnover.

It is clear that *trans*-(4-^{t}BupyH)$_2$[RuO_2Cl_4] is a less effective oxidant than are $(Ph_4P)[RuO_2Cl_3]$ or *trans*-$(Ph_4P)_2[RuO_2Br_4]$. We believe that a possible reason for this is the potential coordinating ability of the butylpyridinium cation in its deprotonated form. We find that the electronic spectrum of *trans*-(4-^{t}BupyH)$_2$[RuO_2Cl_4] in dichloromethane solution is very similar to that of *trans*-(4-^{t}BupyH)[RuO_2Cl_3(4-^{t}Bu-py)] in the same solvent, suggesting that the following equilibrium is in operation (R = 4-^{t}Bupy):

$$(RH)_2[RuO_2Cl_4] \longleftrightarrow (RH)[RuO_2Cl_3(R)] + HCl.$$

Thus it seems likely that the *trans*-$[RuO_2Cl_3$(4-^{t}Bupy)$]^-$ species, isolated earlier in these laboratories,[1] is the predominant oxidizing species in solution in the latter system. Unlike $[RuO_2Cl_3]^-$, this species lacks a vacant coordination site, and this may be in some way responsible for its lower efficiency as an oxidant. It is interesting in this context to note that $[RuO_2Cl_3]^-$ and *trans*-$[RuO_2Cl_3(OPPh_3)]^-$ have comparable efficiencies as oxidants; this may arise from the lability of the weakly bound $OPPh_3$ ligand. It is also likely that salts of *trans*-$[RuO_2Br_4]^{2-}$ in solution dissociate to $[RuO_2Br_3]^-$.

It is clear that all of the species studied here are two-electron oxidants of alcohols to carbonyl compounds, and that they effect such reactions in a mild and selective manner. The best turnovers in catalytic systems are achieved using $(Ph_4P)[RuO_2Cl_3]$. Thus for example, 1.38 g (10 mmol) of *p*-methoxybenzyl alcohol is converted to 1.28 g (9.4

mmol, 94% conversion) of *p*-methoxybenzaldehyde by 81 mg (0.14 mmol) of $(Ph_4P)[RuO_2Cl_3]$ in the presence of excess NMO over a period of 2 h.

In the case of the unsaturated alcohols cinnamyl alcohol, citronellol, geraniol and chrysanthemyl alcohol, ^1H NMR of the products was used to check that no competing epoxidation or cleavage of the olefinic double bonds was occurring. In no case was any such reaction observed to have taken place: resonances due to the unsaturated aldehyde product and due to unreacted alcohol substrate were the only ones seen. The relatively low yields of unsaturated aldehydes obtained in the oxidation of these alcohols are thus likely to be due to lack of activation of the alcohol group and definitely not to attack of the olefinic bond.

(b) *Vibrational spectra and structure of the complexes*

Perrier and Kochi[7] have recently shown that $\{(Ph_3P)_2N\}[RuO_2Cl_3]$ contains a trigonal bipyramidal anion with *cis*-dioxo ligands in the equatorial plane, though only one IR band at 881 cm^{-1}, rather than the two expected, was observed assignable to a Ru=O stretch, ν(Ru=O). In $(Ph_4P)[RuO_2Cl_3]$, which from X-ray studies[7] is shown to have a 6:4 occupancy of trigonal bipyramidal and square-based pyramidal anions, they report two strong IR bands at 891 and 878 cm^{-1}.

Vibrational spectroscopic data for all the oxoruthenium(VI) complexes prepared are presented in Table 2. All of the salts $[RuO_2Cl_4]^{2-}$ show a very

[a] cm^{-1}; s = strong, m = medium, v = very; Raman bands in italics; solution data in parentheses, otherwise solid state.

[b] Calculated values in parentheses.

[c] X = Cl or Br.

[d] Phosphorus analysis.

[e] ν(ring), band arising from the two A_1 ring-stretching modes of the pyridinium or substituted pyridinium cation.

[f] ν(P=O) of the coordinated $OPPh_3$ ligand.

strong IR band in the region 850–820 cm^{-1} due to the asymmetric stretch of the *trans*-O=Ru=O ("ruthenyl") unit, $\nu_{as}(RuO_2)$, and a Raman band in the same region due to the symmetric stretch, $\nu_s(RuO_2)$, of the same unit. From the centrosymmetric nature of the ruthenyl unit in these species $\nu_{as}(RuO_2)$ should be IR active but Raman inactive, and the reverse for $\nu_s(RuO_2)$. It is therefore clear that the *trans*-$[RuO_2Cl_4]^{2-}$ salts are all octahedral, as shown by the X-ray crystal structure of *trans*-$\{(Ph_3P)_2N\}_2[RuO_2Cl_4]$.[7] Their IR spectra also have a strong band in the region 310–290 cm^{-1} which is likely to arise from the ν_{as}(Ru—Cl) stretch of the coordinated chloro ligands. Similarly, the salts $[RuO_2Br_4]^{2-}$ show strong bands in the 840–820 cm^{-1} region, indicating presence of the *trans*-RuO_2 unit in an octahedral structure, and strong IR bands in the 250–220 cm^{-1} region due to ν_{as}(Ru—Br). The tribromo complex $(Ph_4P)[RuO_2Br_3]$ displays two bands in the IR spectrum at 888 and 876 cm^{-1}, consistent with a trigonal bipyramidal structure containing a *cis*-O=Ru=O unit.

The $(Ph_4As)[RuO_2Cl_3(OPPh_3)]$ species shows a strong, sharp IR band at 825 cm^{-1} due to the asymmetric Ru=O stretch of a ruthenyl unit. Strong bands at 1186 and 1172 cm^{-1} are likely[10] to arise from ν(P=O) stretches of the triphenylphosphine oxide ligand, and the strong IR band at 290 cm^{-1} is likely to be due to ν_{as}(Ru—Cl).

2,6-BIS(DIPHENYLPHOSPHINO)PYRIDINE: A CONVENIENT SYNTHESIS AND COMPLEXATION BEHAVIOUR

H. CHRISTINA E. McFARLANE, WILLIAM McFARLANE* and ALAN S. MUIR

Department of Chemistry, City of London Polytechnic, Jewry Street, London EC3N 2EY, U.K.

(*Received* 21 *February* 1990; *accepted* 2 *April* 1990)

Abstract—The reaction between sodium diphenylphosphide and 2,6-difluoropyridine in liquid ammonia gives the title compound in 40% yield. The reactions of this potentially polydentate ligand with simple substrates like MeI, chalcogen and $M(CO)_6$ proceed via attack on phosphorus in preference to nitrogen, and the ^{31}P NMR and vibrational spectra of some of the products are reported.

Polydentate ligands containing both hard and soft donor atoms (e.g. N and P) are important for their potential to form bi- and polymetallic complexes containing two different types of metal atom. Examples of such ligands include 2-methyl-6-bis (diphenylphosphino)methylpyridine,[1] tris(2-pyridyl)phosphine,[2] tris(diphenylphosphinoethyl)-amine[3] and 2-(diphenylphosphinomethyl)pyridine.[4] Of special interest in this connection are 2-(diphenylphosphino)pyridine (**I**) and 2,6-bis(diphenylphosphino)pyridine (**II**) because of the rigidity of their skeletons which leads to fixed relative positions of the nitrogen and phosphorus atoms, and also because the nitrogen atom in a pyridine ring can display a degree of softness. However, the reported synthesis of **II** is not especially convenient[5,6] and it has not been used extensively as a ligand, the bulk of the published work being by Balch and co-workers.[7–11] We report here that the reaction in liquid ammonia between sodium diphenylphosphide and the readily available 2,6-difluoropyridine provides a convenient one-pot route to **II**. Previously, this approach has been used for the synthesis of a series of polykis(diphenylphosphino)benzenes.[12,13]

(II)

Transition metal complexes with four-membered chelate rings (e.g. for dppm) are well-known,[14–16] but calculations indicate that the degree of strain involved in monometallic bidentate coordination of **I** and **II** is considerable.[11] Only a few such complexes have been positively identified; e.g. $Ru(Ph_2Ppy)(CO)_2(Cl)_2$ with $\angle PRuN = 68.7°$, $\angle CPRu = 84.0°$[17] and $[Pt(Ph_2Ppy)_2Cl]^+$ with $\angle PPtN = 70.7°$, $\angle CPPt = 84.3°$.[18] Further reports of such chelation are not fully substantiated by spectroscopic or X-ray data,[19,20] although **I** may act as a tridentate ligand in reactions where orthometallation of one phenyl ring occurs.[21,22] The possibility of **II** acting in a monometallic tridentate mode can be discounted, although in the complex $[Rh_2\{(Ph_2P)_2py\}_2(CO)(I)]^+[BPh_4]^-$ it functions both as an NP chelator and as a phosphorus-bonded monodentate ligand.[11] Thus **I** and **II** have considerable potential for forming bi- and polymetallic systems with varying degrees of metal–metal interaction, and several studies of this have been undertaken.[7–11,17,18,23–26] In order to assess this type of behaviour it is desirable to have available data on the mono-coordinating abilities and we therefore present here reactions of **II** with methyl iodide, the chalcogens and the group VI metal hexacarbonyls, together with their NMR and some vibrational data. Some previous work is available on the analogous reacions of **I**.[6,27,28]

RESULTS AND DISCUSSION

The reaction between a liquid ammonia solution of sodium diphenylphosphide and 2,6-difluoro-

pyridine gives **II** in *ca* 40% yield as air-stable white crystals. Attempts to prepare **I** by this method resulted in mixtures containing much of the desired product. Compound **II** reacts with neat methyl iodide to yield an off-white solid whose elemental composition approximates to $(Ph_2P)_2py \cdot 3MeI$ but which loses MeI on standing at room temperature and which yields $(Ph_2P)_2py \cdot 2MeI$ (**XV**) on heating to 80°C for 3 h *in vacuo*. Compound **XV** has a single ^{31}P NMR resonance indicating that both methyl groups are bound to phosphorus; this was confirmed by appropriate ^{1}H and ^{13}C NMR spectra. Compound **XV** can also be made by reaction of **II** with excess MeI, with CH_2Cl_2 as a solvent, and as an intermediate in this reaction, the adduct $(Ph_2P)_2py \cdot MeI$ [$\delta(^{31}P) = -1.2$ and 14.9 ppm, $J(PP) = 2.4$ Hz] in which a single methyl group is bound to phosphorus was detected. The related complex $Ph_2Ppy \cdot MeI$ has been reported[28] and NMR data indicated methyl attachment to the phosphorus atom. Reactions of **II** with MeI in either THF or diethyl ether solution gave products whose ^{13}C and ^{1}H NMR spectra were indicative of solvent complexation, probably with the pyridine nitrogen atom. This competitive reaction made the isolation of pure compounds impossible in these solvents.

The slow aerial oxidation (over weeks) of **II** in THF/methanol gave the dioxide **III**, and the reaction of **II** with either sulphur or selenium proceeded stepwise and smoothly via the monosulphide **IV** and monoselenide **VI**, respectively, to yield the disulphide **V** and diselenide **VII**.

One mole of carbon monoxide was displaced from $M(CO)_6$ (M = Cr, Mo, W) by refluxing with **II** in diglyme to finally yield the bimetallic species, **VIII**, **X** and **XI**: the monometallic derivatives with one uncoordinated phosphorus can be detected by ^{31}P NMR as intermediates and data are included in Table 2 for the $W(CO)_6$ intermediate, **XII**. In reactions with *cis*-$Mo(CO)_4pip_2$[29] there was still no evidence of any attack by the pyridine nitrogen upon the metal centre, the two products being **XIII** and **XIV** which lose piperidine upon standing at ambient temperature, making accurate elemental analyses impossible.

Reaction of **II** with other substrates such as $HgCl_2$, $SnCl_2$ and Me_2SnCl_2 in CH_2Cl_2 led to ill-defined materials with substantially unaltered phosphorus chemical shifts, from which it can be concluded that initial coordination was via nitrogen. Addition of a considerable excess of the metal halide did result in some larger changes in $\delta(^{31}P)$ but the products were still intractable.

Elemental analyses of isolated compounds are given in Table 1 and NMR data in Table 2. The ^{31}P

chemical shifts of the chalcogen derivatives are in the expected regions and for the mono-derivatives **IV** and **VI** show that attack upon a remote site has little effect upon $\delta(^{31}P)$. The ^{31}P coordination chemical shifts[30] of **VIII**, **X** and **XI** are 62.5, 43.7 and 27.3 ppm, respectively, and as expected confirm the absence of chelate ring formation.

The chalcogen derivatives of **I** were observed in solution and are reported as **XVI**, **XVII** and **XVIII** in Table 2. Table 3 presents some IR and Raman data for **II**, **III** and **V** along with some general assignments. The IR spectra of **II** and **III** have been briefly reported[6] before but were not discussed, so reference was made to the documented spectra of Ph_3P[31,32] and 2,6-Me_2py.[33] The spectra are, as expected, dominated by the modes resulting from the phenyl moieties and various phosphorus/carbon vibrations; the modes solely from the pyridine function are obscured. In the case of **II**, the IR intense bands centred at 748 and 694 cm^{-1} are the C—H deformations and C—C ring modes typifying a mono-substituted aromatic compound, although

[b] Sample sealed in glass capillary.

they are very broad. Bands at 1094 cm^{-1} (R,IR), 698 and 703 cm^{-1} (R), and 506, 496, 486 and 465 cm^{-1} (R,IR) are probably related to the various phosphorus/carbon motions. These correspond with the X-sensitive P—C stretches and deformations reported for $(Ph)_3P$.[31,32]

Substitution on the two phosphorus atoms of **II** with either oxygen or sulphur leads to changes in the spectra. For the dioxide **III**, ν(P=O) was assigned to a band at 1160 cm^{-1} by Newkome and Hager;[6] in the current study a band was observed at 1160 cm^{-1} as well as a noticeably stronger doublet at 1199–1211 cm^{-1} in both the IR and Raman. The latter was assigned to ν(P=O) and compares with values of 1190 and 1193 cm^{-1} attributed to the respective mode in $(Ph)_3P{=}O$.[34] In the disulphide **V**, ν(P=S) was confidently assigned as 647 cm^{-1} (IR) and 645 cm^{-1} (R), both bands being intense. This compares with values of 634 cm^{-1} (IR) and 633 cm^{-1} (R) reported for $Ph_3P{=}S$.[34] The skeletal modes of **II** appear less perturbed in the Raman spectra of **III** and **V** than they are in the IR, any shifts or intensity changes being quite small except in some of the low frequency modes (data not reported < 380 cm^{-1}), although the mode at 1583 cm^{-1} is shifted to high frequency by 5–8 cm^{-1} in the complexes. In the IR spectra of both **III** and **V**, the band at 1435 cm^{-1} is greatly enhanced at the expense of the shoulder at 1422 cm^{-1}. Also, the band at 1094 cm^{-1} is enhanced and shifted to higher frequency (+23 cm^{-1} in **III**; +13 cm^{-1} in **VI**). The medium/strong band at 797 cm^{-1} in **II** is shifted to high frequency by *ca* 10 cm^{-1} and is split in both cases. The strong broad absorptions at 748 and 694 cm^{-1} split and sharpen considerably on complexation at phosphorus, although their centres shift by no more than 4 cm^{-1}; this suggests some band overlap in the parent diphosphine **II**. The 450–550 cm^{-1} region of the spectrum changes quite markedly in both **III** and **V**. The parent compound **II** has four weak bands in the 525–555 cm^{-1} region and three more intense bands centred at 495 cm^{-1}, with another strong band at 465 cm^{-1}. In **III** there is a strong complex of bands from 500 to 556 cm^{-1}, whereas in **V** a similar arrangement occurs from 471 to 522 cm^{-1}. These are probably perturbations to modes principally involving P/C motion. No detailed study of the vibrational spectra of the Group VI metal carbonyl complexes **VII**, **X** and **XI** was undertaken, but carbonyl stretching modes are noted in the range 1930–2080 cm^{-1}.

EXPERIMENTAL

^1H and ^{13}C NMR spectra were recorded at 89.6 and 22.5 MHz on a Jeol FX90 Q multinuclear Fourier transform spectrometer. ^{31}P measurements were made at 36.2 MHz on this instrument and at 24.2 MHz on a Jeol FX60 Fourier transform spectrometer. Solutions were usually made in dichloromethane, THF or diglyme, occasionally with C_6D_6 or $CDCl_3$ added to provide a field/frequency lock, and spectra were recorded at 22°C.

Raman spectra were recorded on a Coderg PHO instrument with excitation provided at 488 nm by a Coherent Radiation argon laser and with samples in sealed glass capillaries. IR spectra were recorded as KBr discs using a Perkin–Elmer 1710 FT–IR spectrometer.

2,6-Difluoropyridine was obtained from Fluorochem Ltd and was used as supplied. Manipulations were performed under atmospheres of dry ammonia or dry nitrogen. Degassed and dried solvents were utilized where necessary. Syntheses were of three main classes and general details are given.

(a) 2,6-*Bis(diphenylphosphino)pyridine* (II)

This was prepared using the method described previously for 1,2,4,5-tetrakis(diphenylphosphino)benzene,[13] with crystallization of the product achieved by trituration of the oily residue with methanol at least three times (yield, 40%).

(b) *Reactions of* II *with sulphur or selenium*

Compounds **V** and **VII** were prepared by reaction of stoichiometric quantities of the chalcogen with **II** in dichloromethane. ^{31}P NMR indicated almost immediate formation of the monosubstituted species **IV** and **VI**; the reaction with sulphur was complete within 12 h and that with selenium within 48 h. Products were isolated and recrystallized from carbon disulphide and industrial methylated spirits to remove any retained colloidal chalcogen.

(c) (i) *Reactions of* II *with Group* VI *metal carbonyls*

Reactions to prepare **XIII**, **X** and **XI** were performed by refluxing **II** with a slight stoichiometric excess of the appropriate hexacarbonyl in diglyme for up to 30 min or until the solution started to darken. Reactions were monitored by ^{31}P NMR. The diglyme solution was separated from any precipitated hexacarbonyl, concentrated *in vacuo* with sublimation of any hexacarbonyl residue, and precipitation of the product followed methanol addition. Crystals were washed with methanol and were sometimes recrystallized from diethyl ether and meth-

anol. Reactions with $Cr(CO)_6$ were carried out away from direct sunlight because of the possible photosensitive nature of the products.

(ii) *Reactions of* **II** *with* cis-$Mo(CO)_4(pip)_2$

1:1 and 1:2 molar ratios of reactants were refluxed in dichloromethane with the products **XIII** and **XIV** precipitating out of solution. These crystals lost piperidine on standing at ambient temperature.

Acknowledgements—We thank Dr P. N. Gates and Mr S. Richards (RHBNC) for assistance with vibrational spectroscopy, Mr B. Saunderson for microanalyses and the SERC and the National Advisory Board for support.

SYNTHESIS AND X-RAY CRYSTAL STRUCTURE OF A CHAIN POLYMER FORMED BY 1-METHYLHYDANTOIN WITH MERCURY(II)

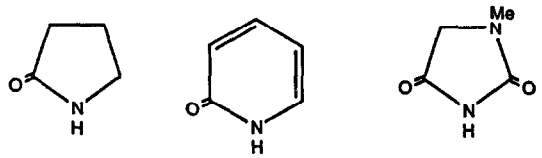
DAVID M. L. GOODGAME,* ARWA M. KHALED, CAROLINE A. O'MAHONEY and DAVID J. WILLIAMS

Chemistry Department, Imperial College of Science, Technology and Medicine, London SW7 2AY, U.K.

(*Received* 1 *March* 1990; *accepted* 2 *April* 1990)

Abstract—Reaction of 1-methylhydantoin ($C_4H_6N_2O_2$) with mercury(II) acetate in water or methanol yields the compound $Hg(C_4H_5N_2O_2)_2$ (**1**). Compound **1** is monoclinic $C2/c$ with $a = 13.536(5)$, $b = 12.462(2)$, $c = 26.580(9)$ Å, $\beta = 104.62(3)°$, $Z = 8$. The structure was refined on 2836 reflections to $R = 0.042$. The deprotonated 1-methylhydantoin ligands bind to mercury via nitrogen with essentially linear N—Hg—N bonding and with a nearly co-planar, "head–tail" disposition of the rings. Dimeric $(HgL_2)_2$ units are formed by two additional Hg—O bonds, and these dimers are further linked to produce polymeric chains via interdimer Hg—O linkages.

We have recently demonstrated that relatively simple ambidentate (N,O donor) ligands, such as 2-pyrrolidone (**I**)[1] or 2-pyridone (**II**),[2] can produce a



I II III

wide range of heterometallic, polynuclear complexes with unusual structures. An important, but not necessarily exclusive, component in such systems has been the use of mercury(II) to bind to a deprotonated ring nitrogen atom of the organic ligand, with consequent formation of an essentially linear N—Hg—N arrangement, leaving the exocyclic oxygen atoms free to bind to other metal ions.

In extending our work to include bridging ligands containing two carbonyl groups, each vicinal to the ring nitrogen, we have found it helpful to examine the geometry of the "parent" HgL_2 species. This information is available for some ligands of this type (1-methylthymine[3] and succinimide[4]) but for most potentially relevant bridging ligands of this class it is not. We report here the structure of HgL_2 (**1**), where L is the anion of 1-methylhydantoin (**III**).

EXPERIMENTAL

Preparations

Compound **1** precipitated as a white powder on mixing methanol solutions of **III** and mercury(II) acetate in a 2:1 mole ratio. Recrystallization from methanol gave colourless crystals. Found: C, 22.4; H, 2.2; N, 13.1. Calc. for **1**: C, 22.5; H, 2.4; N, 13.1%.

An analogous compound with 3-methyl-2-pyrrolidone (C_5H_8NO) was obtained by the same general procedure. $Hg(C_5H_7NO)_2 \cdot 0.5H_2O$: white solid, which separated over 2 days from MeOH–Et_2O solution, m.p. 190–192°C (dec.). Found: C, 29.6; H, 4.2; N, 6.8. Calc.: C, 29.6; H, 4.2; N, 6.9%.

X-ray studies

Crystal data for **1**: $C_{16}H_{20}Hg_2N_8O_8$, $M = 853.6$, monoclinic, $a = 13.536(5)$, $b = 12.462(2)$, $c = 26.580(9)$ Å, $\beta = 104.62(3)°$, $V = 4338$ Å^3, space group $C2/c$, $Z = 8$, $D_c = 2.61$ g cm^{-3}, Cu radiation, $\lambda = 1.54178$ Å, μ(Cu-K_α) = 275 cm^{-1},

* Author to whom correspondence should be addressed.

$F(000) = 3167$. Data were measured on a Nicolet R3m diffractometer with Cu-K_α radiation (graphite monochromator) using ω-scans. A crystal of dimensions $0.18 \times 0.18 \times 0.23$ mm was used. 2921 independent reflections ($2\theta \leqslant 116°$) were measured, of which 2836 had $|F_o| > 3\sigma(|F_o|)$ and were considered to be observed. The data were corrected for Lorentz and polarization factors; a numerical absorption correction (face-indexed crystal) was applied; maximum and minimum transmission factors were 0.112 and 0.007.

The structure was solved by direct methods. The non-hydrogen atoms were refined anisotropically. The positions of the hydrogen atoms were idealized, C—H = 0.96 Å, assigned isotropic thermal parameters, $U(H) = 1.2\ U_{eq}(C)$, and allowed to ride on their parent carbon atoms. The methyl groups were refined as rigid bodies. Refinement was by block-cascade full-matrix least-squares to $R = 0.042$, $R_w = 0.044$ $[w^{-1} = \sigma^2(F) + 0.00080F^2]$. The maximum and minimum residual electron densities in the final ΔF map were 1.63 and -1.98 eÅ^{-3}, respectively. The mean and maximum shift/error in the final refinement were 0.001 and 0.007, respectively. Computations were carried out on an Eclipse S140 computer using the SHELXTL system.[5]

Selected bond lengths and angles are listed in Table 1.

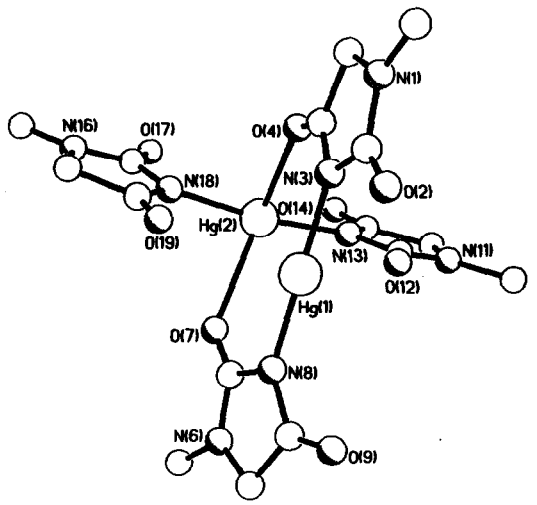


Fig. 1. Molecular structure of the $[HgL_2]_2$ dimer of compound **1**, with selected atom numbering.

RESULTS AND DISCUSSION

The X-ray analysis of **1** (Fig. 1) shows that the structure contains two crystallographically-independent HgL_2 units in which the deprotonated hydantoin anions bind to mercury via the nitrogen atom, so as to produce nearly linear N—Hg—N linkages [176.1(3)° at Hg(1) and 172.3(3)° at Hg(2)].

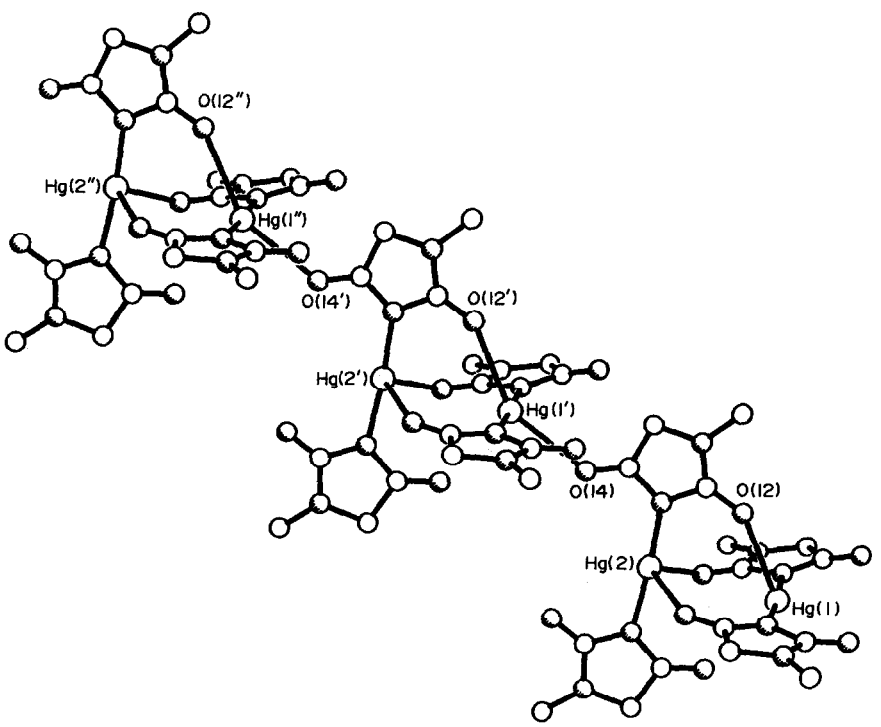

Fig. 2. Part of the Hg···O linked polymeric chain formed by **1** in the crystal.

Table 1. Selected bond lengths (Å) and angles (°) for **1**

Hg(1)—N(3)	2.007(7)	Hg(1)—N(8)	2.014(7)
Hg(2)—N(13)	2.018(8)	Hg(2)—N(18)	2.025(8)
Hg(2)—O(4)	2.730(7)	Hg(2)—O(7)	2.651(6)
N(3)—Hg(1)—N(8)	176.1(3)	N(13)—Hg(2)—N(18)	172.3(3)
O(4)—Hg(2)—O(7)	113.8(2)		

In both units the ligands adopt a near planar "head–tail" (*trans*-) geometry with respect to each other about N—Hg—N. The angles between the ligand mean planes about Hg(1) and Hg(2) are 13 and 10°, respectively. The Hg—N bonds are in the range 2.007(7)–2.025(8) Å and are similar to those we have observed[1] in the mercury complexes with 2-pyrrolidone.

Adjacent HgL_2 molecules lie with their planes nearly normal to each other and are weakly linked via two additional Hg–O bonds [2.651(6) and 2.730(7) Å, respectively] producing a dimeric $[HgL_2]_2$ unit. The O(4)Hg(2)O(7) angle is 113.8(2)°. The non-bonded Hg···Hg separation is 3.7 Å. There is an additional, weaker intradimer Hg···O linkage (2.83 Å) between Hg(1) and O(12). The complementary Hg(1)···O(19) distance is 3.0 Å.

In the crystal, the dimeric $[HgL_2]_2$ units are further linked via an additional Hg—O bond (2.75 Å) between Hg(1) and O(14′) to form a polymeric chain (Fig. 2). This arrangement is closely reminiscent of that observed[1] in the 2-pyrrolidone complex $[Hg_2(C_4H_6NO)_2Cl_2]_n$, but in **1** all the Hg···O interactions are weaker. There are no significant interchain contacts.

(*Received* 26 *January* 1990; *accepted* 5 *April* 1990)

Abstract—A new approach to the greater understanding of orientational and geometrical isomers in substituted carbonyl clusters is given with specific application to $Fe_3(CO)_{12-n}L_n$.

There is currently some considerable interest (see, for example, ref. 1) in the nature of $Fe_3(CO)_{12}$ and its substituted derivatives $Fe_3(CO)_{12-n}L_n$ in both solution and in the solid, but it is clear that a detailed appreciation of the complexities of the structures of these molecules is lacking. In this communication we wish to report a detailed analysis of the potential isomeric forms of these species. The method of analysis is general and the ideas presented herein may be applied to other cluster molecules and ions.

Little attention has been paid in the past to the ligand isomerism which can exist in cluster molecules and ions of the type M_mL_n, presumably because of the frequently complex relationship which exists between the central metal core and the peripheral ligating sphere.[2] Whereas isomerism in mononuclear molecules of type ML_n is, in general, relatively easily understood and described[3]—although even here the problem becomes increasingly difficult with increasing coordination number[4]—the higher coordination numbers and the lower symmetries quite often found for cluster molecules make for difficulty in any comprehensive and simple appreciation of the relationship between cluster isomers. In particular, problems have occurred due to failure to recognize the number of isomers that may exist for a given system, and also failure to understand the mechanisms by which interconversion between isomers may take place. For example, the apparently simple substituted molecule $Fe_3(CO)_{11}(PPh_3)$ can theoretically exist in (at least†) ten different isomeric forms, eight of which are energetically distinct as the ten isomers include two pairs of enantiomers. These are illustrated in Fig. 1. Failure to observe experimentally a given isomer in this and other cases is not unexpected and may be due either to differences in stability of the different isomers or to rapid interconversion in solution. Nevertheless, each isomer may be important for the chemistry of the molecule and consequently should not be ignored without justification.

It is convenient to describe cluster structures as consisting of two components: first the central metal core, and second, the surrounding ligand polyhedron.[2] These two parts of the molecule are frequently connected by essentially, non-directional bonds and the barrier to rotation of one polyhedron relative to the other is then small.[5] Thus, the iron triangle in $Fe_3(CO)_{12}$ may occupy three different orientations within the icosahedron of CO groups leading to three possible isomers (since the ligands are all the same), two with C_{2v} symmetry and one

* Author to whom correspondence should be addressed.

† This considers that the ligands adopt a *quasi*-icosahedral arrangement only, and that the Fe_3 triangle adopts either the C_{2v}-orientation shown in Fig. 2 or the D_3-form.[2] We have chosen to ignore the possibility of a C_{2v}-form with face-capping CO.[2] Clearly if account is taken of a possible cuboctahedral or anticuboctahedral arrangement then this number will be increased substantially. It is also assumed that L does not adopt a bridging position (but see text).

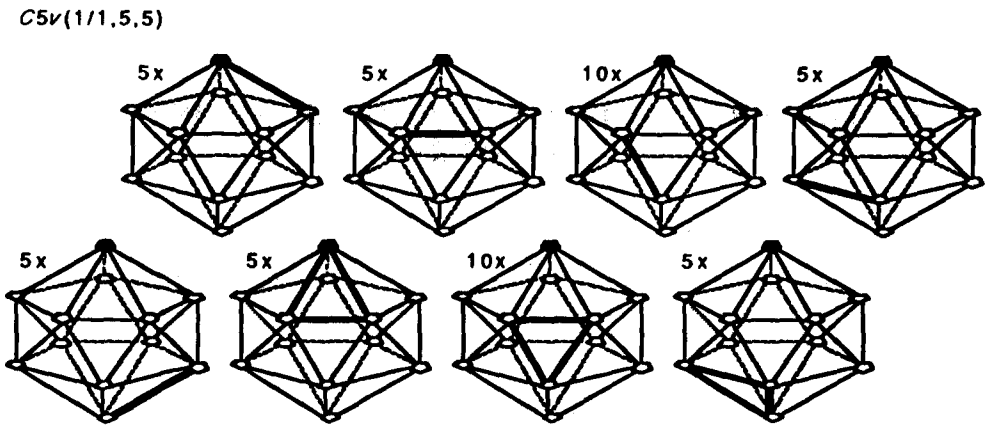

Fig. 1. Possible isomers of $Fe_3(CO)_{11}L$. The thick dark line indicates the position of M_3 within the ligand polyhedron. The single dark line is for a bridged structure. Thus each dark line defines a cluster geometry, and counting lines indicates numbers of isomers. Three thick dark lines indicate the geometry of the unbridged geometries. Thus each triangle defines a different unbridged geometry. 30 × etc., indicates the number of isomers which are indistinguishable from the one indicated (optical isomers are not separated).

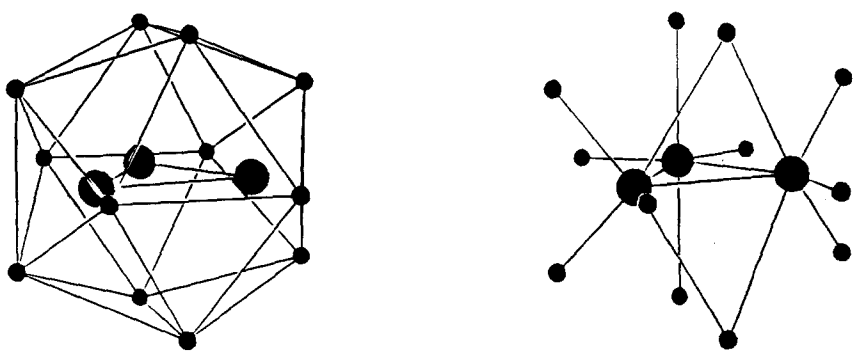

Fig. 2. Triangle in icosahedral (C_{2v}).

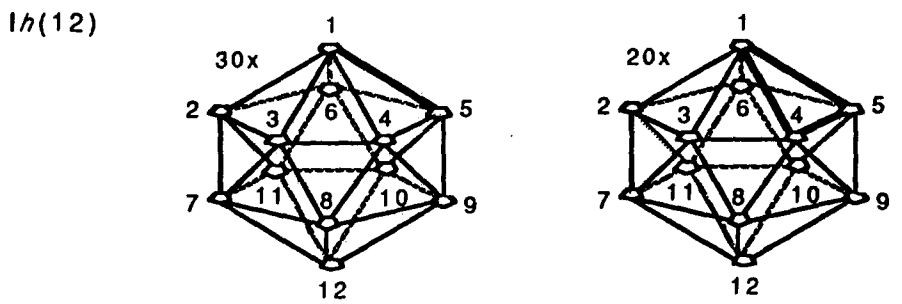

Fig. 3. The possible M_3 orientations within the $(CO)_{12}$ ligand polyhedron. Notation as in Figs 1 and 4.

* Strictly these arguments only apply to these molecules in solution. In the crystal, however, molecule packing may cause the molecules to adopt a lower symmetry, e.g. C_2 for $Fe_3(CO)_{12}$.

with D_3 symmetry (Fig. 2).* These form a class of isomers which we choose to call *orientational isomers*. The different isomers are schematically illustrated in Fig. 3, where the number of indis-

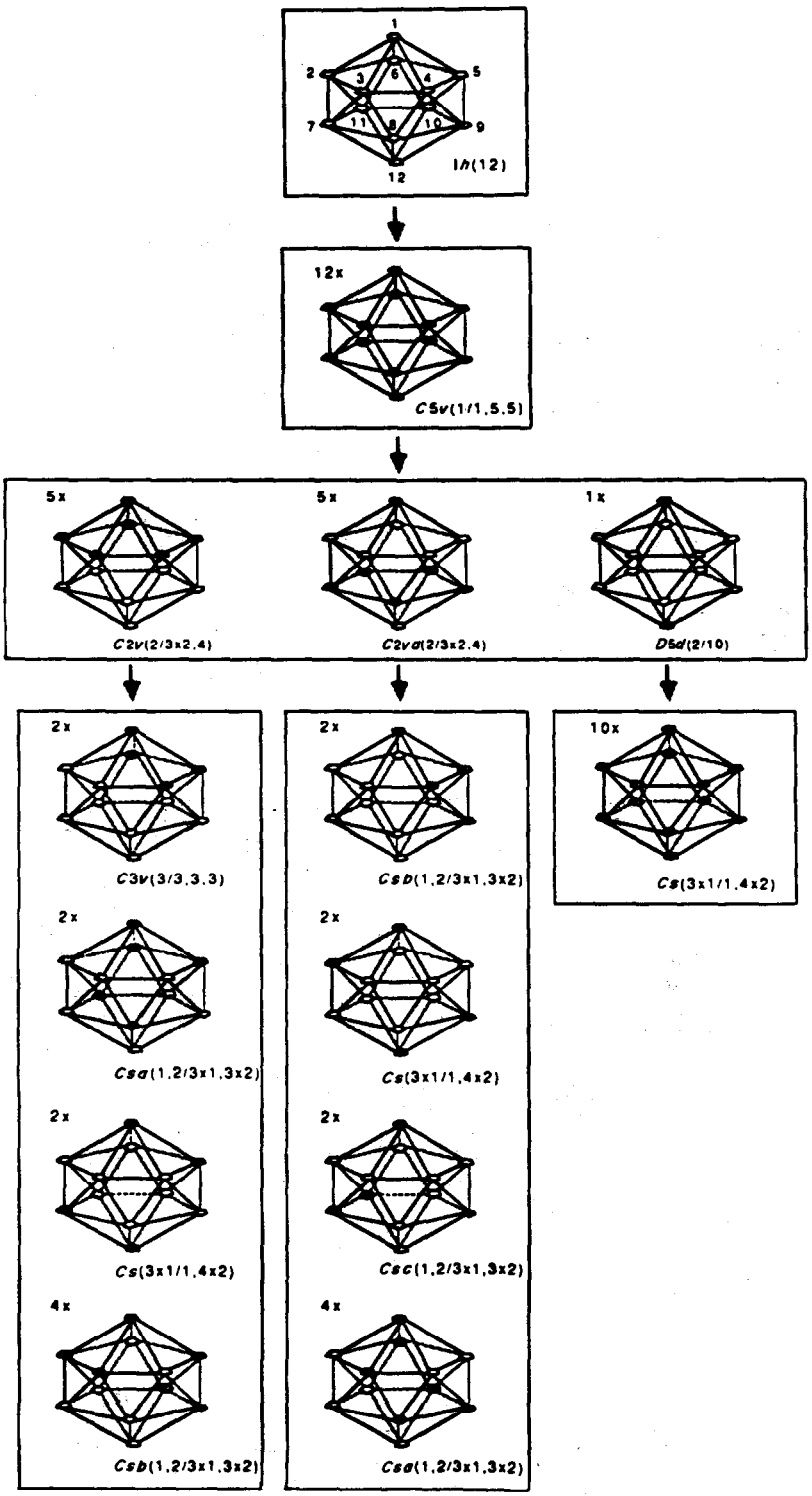

Fig. 4. The distinct ligand polyhedra for $(CO)_{12}$, $(CO)_{11}L$, $(CO)_{10}L_2$ and $(CO)_9L_3$. 12× etc., denotes the number of equivalent polyhedra in going from the previous step to the current one. C_{2v} (2/3 × 2,4) means the ligand polyhedron has C_{2v} symmetry, has two identical L, three pairs of identical COs, and one set of four identical COs. ● L; ○ CO; ● CO which is in an equivalent position to new L.

tinguishable (except in a labelled atom sense) isomers are also indicated. Orientational isomerism, the property of organizing one polygon or polyhedron (the metal cluster unit) within another (the ligand envelope), may be exhibited by a wide range of molecules in all states of aggregation. It is a particular property of carbonyl clusters but is also found in simpler systems such as $[Re_2Cl_8^{2-}]$.[7]

We now come to the second point concerning isomerism in clusters. An isolated ligand poly-

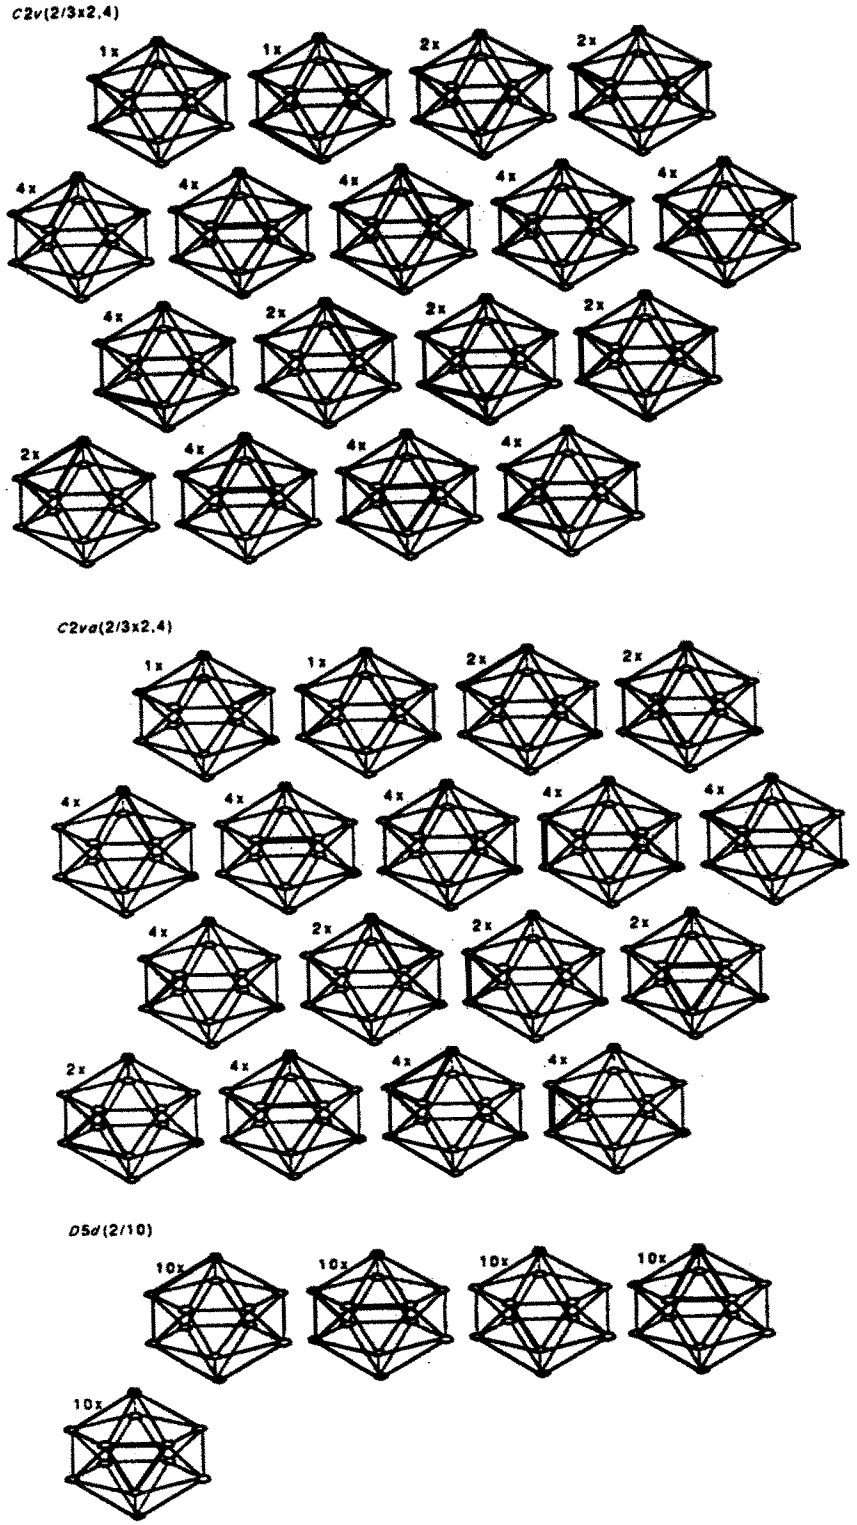

Fig. 5. Isomers for $Fe_3(CO)_{10}L_2$. Notation as in Figs 1 and 4.

hedron [for example the CO icosahedron in $Fe_3(CO)_{12}$] can undergo ligand substitution to produce new polyhedral forms such as $(CO)_{11}L$ or $(CO)_{10}L_2$. Because of the high symmetry of the parent polyhedron (all vertices are equivalent*), there is only one distinct monosubstituted ligand polyhedron (cf. Fig. 4). However, as mentioned above, when the metal polyhedron is inserted there are five distinguishable edge-bridged C_{2v} clusters (counting enantiomers as equivalent) and three distinguishable D_3 clusters. These are illustrated in Fig. 1, where the numbers of equivalent isomers of each kind are also indicated. If L can only be a terminal ligand then the second isomer illustrated in Fig. 1 will not occur.

The bis-substituted ligand polyhedron has three possible forms which we denote for simplicity the 1,2-form, the 1,7-form and the 1,12-form. Their relative weightings are 5:5:1. The more explicit labelling in the figures, e.g. $C2v(2/3 \times 2,4)$, indicates the symmetry of the ligand polyhedron in the absence of the metal triangle, the number of substituted ligands (in this case two), and the relationships between the remaining ligands (in this case there are three pairs of equivalent atoms and one set of four equivalent atoms). Now consider the consequence of inserting the Fe_3 triangle. As illustrated in Fig. 5 there are in total 23 distinct (once again counting enantiomers as indistinguishable)

* Incidentally, this is not general and only applies to the five platonic polyhedra.

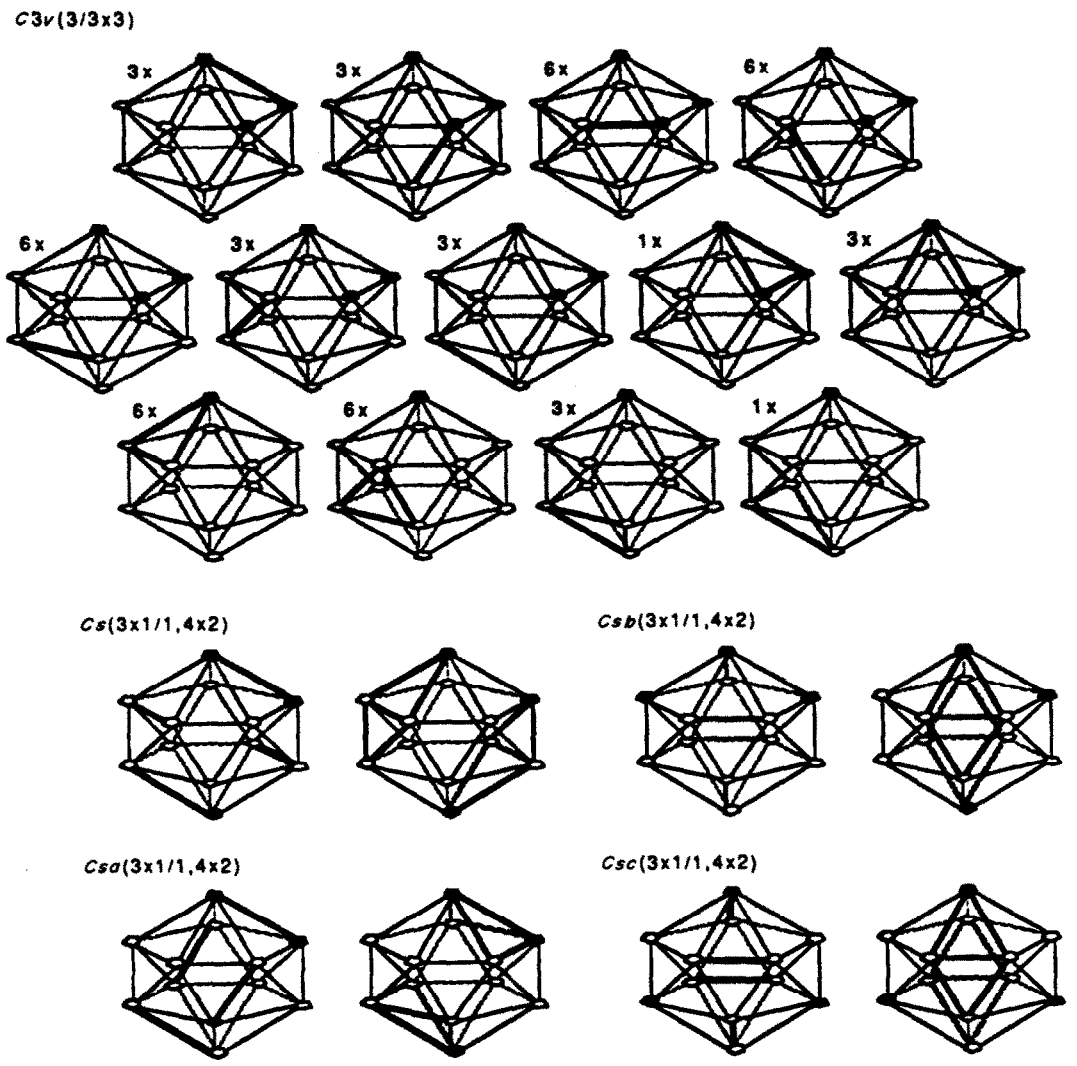

Fig. 6. Isomers of $M_3(CO)_9L_3$. Notation for C_{3v} geometry is as in Figs 1 and 4. Each C_s geometry has four unique edges and 13 sets of two equivalent edges and each edge correlates with a bridged cluster. The diagrams indicate the four unique edges. Each C_s geometry also has four unique faces and eight sets of two equivalent faces and each face correlates with an unbridged isomer. The diagrams indicate the unique faces.

edge-bridged isomers (seven of which involve bridge-site occupancy of the substituted ligand), and 16 distinct non-bridged isomers.

The number of isomers for $n > 2$ can be derived in the same manner. In general, the symmetry of these molecules is lower and the number of distinct isomers increases.

The mechanisms by which isomer interconversions may occur are moderately easy to visualize and understand within this model. They can be subdivided into two categories. (i) Those where interconversion between the various orientational isomers takes place by a simple librational motion (about the C_2-axis of the iron triangle) of the type recently described[6] for $Fe_3(CO)_{12}$ and other, related carbonyl clusters. Such a rearrangement leaves the ligand polyhedron essentially unchanged (though its metal–ligand bonding, and hence symmetry, may have changed). (ii) The second kind of rearrangement is when one ligand polyhedron is converted to another, e.g. when a 1,2-form changes to a 1,7-form in a bis-substituted cluster. This genuine ligand–polyhedron rearrangement is of a type described elsewhere, and more closely corresponds to the more traditional view of carbonyl fluxionality.

The factors which determine which isomers are observed are less easily defined. The relative statistical probabilities of the different isomers (cf. figures) influence the result, but the relative stabilities of the isomers and how much energy is required for rearrangement to occur are more significant. There is no doubt that a dominating contribution to the difference in energies between isomers is the steric constraints imposed by the ligand envelope. It is this which primarily governs the ligand polyhedron (i.e. icosahedral, or cuboctahedral or anti-cuboctahedral for 12 ligands) adopted in the ground state. The precise distribution of the ligands L within this polyhedron is, in our view, also governed mainly by steric arguments although undoubtedly electronic factors have a significant role to play. It is also important to note that although the idea of tertiary-phosphine bridges is somewhat alien to current views, this possibility should not be excluded from any mechanism of a high energy isomerization process. There is no intrinsic reason why this bonding mode should not exist, indeed we have recently observed it for the closely related ligand Ph_3Sb in the ground-state crystal structure of a cluster species. It simply represents a high(er) energy alternative.

In this communication we have attempted to reveal and unravel some of the complexities of cluster isomerism and to lay down some simple ground rules for a better appreciation of this widespread and frequently complicated phenomenon. We would again emphasize that the approach described here is not restricted to the trinuclear iron cluster carbonyls examined, but is general and may be applied to a wide range of cluster molecules and ions. The application of these ideas to a more comprehensive range of materials will be given in a subsequent, fuller report.

COMPETITIVE ALKYL AND HALIDE METATHESIS IN THE REACTIONS OF GRIGNARD REAGENTS WITH Tl{η^3-HB(3-Bu^{t}pz)$_3$}

RUNYU HAN, MAX BACHRACH and GERARD PARKIN*

Department of Chemistry, Columbia University, New York, NY 10027, U.S.A.

(*Received* 12 *March* 1990; *accepted* 17 *May* 1990)

Abstract—The reactions of Grignard reagents RMgX [RMgX = CH_3MgCl, CH_3MgBr, CH_3MgI, CH_3CH_2MgCl, $(CH_3)_2CHMgCl$ and $(CH_3)_3CMgCl$] with Tl{η^3-HB(3-Bu^{t}pz)$_3$} (3-Bu^{t}pz = 3-$C_3N_2Bu^tH_2$) show that metathesis of the Mg—R bond is favoured for X = Cl, Br, whereas metathesis of the Mg—X bond is favoured for X = I.

The η^3-tris(pyrazolyl)hydroborato ligand has been used extensively to provide well-defined coordination environments for both the transition metals[1] and, more recently, the *s*- and *p*-block elements.[2,3] Conventional methods for the introduction of tris(pyrazolyl)hydroborato ligands generally involve the metathesis of a metal–halide bond with either the potassium or thallium salts of the tris(pyrazolyl)hydroborato ligand. We have recently reported that tris(pyrazolyl)hydroborato ligands may also be introduced by the metathesis of the metal-*alkyl* bonds of R_2Mg,[3] R_3Al[4] and R_2Zn,[5] and were particularly interested in investigating whether such metal-alkyl bond metathesis is more or less favoured than that of the corresponding metal–halide bonds. Here we describe the reactions between Grignard reagents and the complex Tl{η^3-HB(3-Bu^{t}pz)$_3$} (3-Bu^{t}pz = 3-$C_3N_2Bu^tH_2$) which demonstrate that for this system alkyl substitution is competitive with halide substitution, but is highly dependent upon the Grignard reagent.

The reactions of the chloro and bromo Grignard reagents RMgX [RMgX = CH_3MgCl, CH_3MgBr, CH_3CH_2MgCl, $(CH_3)_2CHMgCl$ and $(CH_3)_3CMgCl$] with Tl{η^3-HB(3-Bu^{t}pz)$_3$} in a 1:1 molar ratio in Et_2O at room temperature, result in metathesis of the Mg—R bond, in preference to the Mg—X bond, to give {η^3-HB(3-Bu^{t}pz)$_3$}MgX [eq. (1)]:[6]

$$RMgX + Tl\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\} \xrightarrow{Et_2O} \{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}MgX + [TlR]. \quad (1)$$

The molecular structure of {η^3-HB(3-Bu^{t}pz)$_3$}MgCl has been determined by single crystal X-ray diffraction (Fig. 1) which confirms both the monomeric nature of the complex and the η^3-coordination mode of the tris(pyrazolyl)hydroborato ligand.†

* Author to whom correspondence should be addressed.

† Crystal data for {η^3-HB(3-Bu^{t}pz)$_3$}MgCl: $C_{21}H_{34}N_6BMgCl$, $M = 441.18$, orthorhombic, space group *Pnma* (No. 62), $a = 16.048(7)$, $b = 16.006(3)$, $c = 9.840(1)$ Å, $U = 2527(1)$ Å^3, $Z = 4$, $D_c = 1.16$ g cm^{-3}, $F(000) = 944$ electrons, μ(Mo-K_α) = 20 cm^{-1}, $T = 295$ K, crystal dimensions $0.36 \times 0.60 \times 0.66$ mm^3. Intensity data were collected on a Nicolet R3M diffractometer using monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å) and were corrected for Lorentz and polarization effects. A total of 3813 unique reflections were collected in the range $3 < 2\theta < 60°$, of which 1182 with $F_o > 6\sigma(F_o)$ were used in the structure determination. The structure was solved by direct methods and refined using standard difference map techniques. Most of the hydrogen atoms were located in the difference map after all the non-hydrogen atoms were located and refined anisotropically, but hydrogen atoms on carbon were allowed to refine in calculated positions [$d_{C-H} = 0.96$ Å; $U_{iso}(H) = 1.2U_{iso}(C)$]. Block-diagonal least-squares refinement converged to $R = 5.17$ ($R_w = 5.90$), with the maximum shift-to-σ ratio of 0.16 for the last cycle. The final difference map showed no significant features, with the highest final peak 0.2 e Å^{-3} near Mg. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.

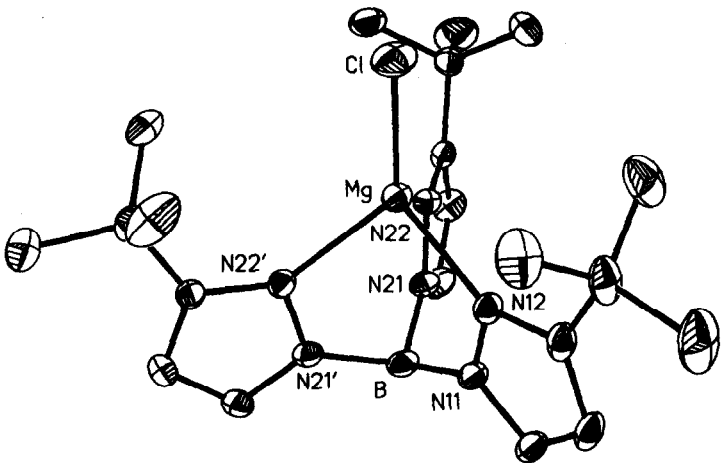

Fig. 1. ORTEP diagram of $\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}$MgCl. For clarity, thermal ellipsoids are shown at 20% probability. Selected bond distances (Å) and angles (°): Mg—Cl = 2.262(2), Mg—N(12) = 2.097(5), Mg—N(22) = 2.100(3), N(11)—N(12) = 1.379(6), N(21)—N(22) = 1.376(4), B—N(11) = 1.542(8), B—N(21) = 1.538(5); N(12)—Mg—N(22) = 93.7(1), N(22)—Mg—N(22)′ = 93.3(2), N(11)—B—N(21) = 110.0(3), N(21)—B—N(21)′ = 109.4(5), Cl—Mg—N(12) = 121.4(2), Cl—Mg—N(22) = 123.4(1).

In contrast to the sole formation of $\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}$MgX in the reaction of $Tl\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}$ with 1 equivalent of CH_3MgX (X = Cl, Br), the analogous reaction with CH_3MgI results in preferential metathesis of the Mg—I bond to give the methyl complex, $\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}MgCH_3$, as the major product [eq. (2)]:[6]

$$CH_3MgI + Tl\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\} \xrightarrow{(80\%)} \{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}MgCH_3 + TlI$$
$$\xrightarrow{(20\%)} \{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}MgI + [TlCH_3]. \quad (2)$$

These results demonstrate that the order of metathesis for this system is Mg—I > Mg—CH_3 > Mg—X (X = Cl, Br). The preferential metathesis of the Mg—I bond versus the Mg—CH_3 bond is another illustration of the observation that reactions of transition metal halide derivatives with Grignard reagents often result in halide exchange rather than alkylation.[7]

In order to assess whether the trend Mg—I > Mg—CH_3 > Mg—X (X = Cl, Br) represents a kinetic or thermodynamic preference for this system, it is necessary to examine the pathways that may lead to the formation of both $\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}$MgR and $\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}$MgX. Alkyl and halide ligands in solutions of Grignard reagents are kinetically labile, as evidenced by the Schlenk equilibrium [eq. (3)]

$$3RMgX \rightleftharpoons R_2Mg + MgX_2 \quad (3)$$

and the position and rate of re-establishment of this equilibrium, for which relatively little quantitative information is available, may have a critical effect on the observed product distribution.[8] As a result of this complexity there exists a manifold of reaction pathways that may independently lead to the products $\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}$MgX and $\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}$MgR, of which the competitive metathesis of the Mg—R and Mg—X bonds of RMgX is the most direct, and simplest, pathway. Although the system is undoubtedly complicated and consequently the analysis subject to uncertainty, there is evidence that supports the view that the observed products are a result of direct metathesis between $Tl\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}$ and RMgX. For example, the formation of $\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}$MgCl by the independent reaction of $Tl\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}$ with $MgCl_2$ is notably slower than the reaction with

RMgCl, which thus suggests that the reaction between Tl{η^3-HB(3-Bu^{t}pz)$_3$} and RMgCl does not proceed via reaction with $MgCl_2$ that is generated by the Schlenk equilibrium.* Considering the pathway involving direct metathesis of Tl{η^3-HB(3-Bu^{t}pz)$_3$} with RMgX, the formation of the product {η^3-HB(3-Bu^{t}pz)$_3$}MgX does not, *per se*, indicate that Mg—R bond metathesis is kinetically favoured over Mg—X bond metathesis. For example, if Mg—R bond metathesis was rapidly reversible [eq. (4)], i.e.

$$RMgX + Tl\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\} \rightleftharpoons \{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}MgR + TlX, \quad (4)$$

then the product {η^3-HB(3-Bu^{t}pz)$_3$}MgX could be formed as a result of the driving force of the irreversible decomposition of unstable [TlR] [eq. (5)]:[6]

$$RMgX + Tl\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\} \longrightarrow \{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}MgX + Tl + \text{dec.} \quad (5)$$

If the above hypothesis was correct, then it would be necessary for {η^3-HB(3-Bu^{t}pz)$_3$}MgR to react with TlCl to give {η^3-HB(3-Bu^{t}pz)$_3$}MgCl [eq. (6)]:

$$\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}MgR + TlCl \rightleftharpoons RMgCl + Tl\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\} \longrightarrow \{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}MgCl + Tl + \text{dec.} \quad (6)$$

However, TlCl does not react with {η^3-HB(3-Bu^{t}pz)$_3$}MgR to give {η^3-HB(3-Bu^{t}pz)$_3$}MgCl, and thus the formation of {η^3-HB(3-Bu^{t}pz)$_3$}MgX in the reactions of Tl{HB(3-Bu^{t}pz)$_3$} with RMgX are a result of kinetically favoured Mg—R bond metathesis. Other evidence mitigating against preferential Mg—X (X = Cl, Br) bond metathesis is that the product {η^3-HB(3-Bu^{t}pz)$_3$}MgCl is not formed by the reaction of {η^3-HB(3-Bu^{t}pz)$_3$}MgR with excess RMgCl [eq. (7)]:

$$\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}MgR + RMgCl \not\rightarrow \{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}MgCl + R_2Mg. \quad (7)$$

In contrast, {η^3-HB(3-Bu^{t}pz)$_3$}MgCl reacts with excess RMgX to give {η^3-HB(3-Bu^{t}pz)$_3$}MgR [eq. (8)]:

$$\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}MgX + RMgX \longrightarrow \{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}MgR + MgX_2. \quad (8)$$

Thus, for the chloro and bromo Grignard reagents, RMgX (X = Cl, Br), the observed results are most consistent with the formation of {η^3-HB(3-Bu^{t}pz)$_3$}MgX as a result of kinetically favoured Mg—R bond metathesis. Furthermore, the irreversible decomposition of [TlR] that accompanies the formation of {η^3-HB(3-Bu^{t}pz)$_3$}MgI in the reaction of Tl{η^3-HB(3-Bu^{t}pz)$_3$} with CH_3MgI [eq. (2)] implies that the formation of {η^3-HB(3-Bu^{t}pz)$_3$}$MgCH_3$ as the major product must be a result of more facile Mg—I bond over Mg—CH_3 bond metathesis. Although {η^3-HB(3-Bu^{t}pyz)$_3$}$MgCH_3$ would also be obtained from the reaction of Tl{η^3-HB(3-Bu^{t}pz)$_3$} with $(CH_3)_2Mg$[3a] generated by the Schlenk equilibrium, this sequence would result in the deposition of Tl metal, in contrast to the observed TlI. As such, it is unlikely that this pathway is responsible for the formation of {η^3-HB(3-Bu^{t}pyz)$_3$}$MgCH_3$ from CH_3MgI.

In conclusion, the reactions of Tl{η^3-HB(3-Bu^{t}pz)$_3$} with Grignard reagents may result in substitution of either the alkyl ligand to give {η^3-HB(3-Bu^{t}pz)$_3$}MgX, or the halide ligand to give {η^3-HB(3-Bu^{t}pz)$_3$}MgR. Chloro and bromo Grignard reagents give products arising from alkyl metathesis, whereas the iodo Grignard reagent CH_3MgI favours halide metathesis. The data suggest that these observations reflect a kinetic preference for Mg—X bond metathesis in the sequence Mg—I > Mg—CH_3 > Mg—X (X = Cl, Br) for the reactions of Grignard reagents with Tl{η^3-HB(3-Bu^{t}pz)$_3$}.

*$MgCl_2$ was stirred in Et_2O overnight in order to obtain a saturated solution before addition of Tl{η^3-HB(3-Bu^{t}pz)$_3$}. However, we can not exclude the possibility that the solvated form of $MgCl_2$ generated as a result of the Schlenk equilibrium may lead to higher concentrations of "$MgCl_2$" being present under the reaction conditions using RMgCl as the reagent.

6. The reactions were typically carried out by addition of the appropriate Grignard reagent to solution of $Tl\{\eta^3\text{-}HB(3\text{-}Bu^tpz)_3\}$ (50 mg) in Et_2O (15 cm^3) at room temperature, and the products analysed by ^1H NMR spectroscopy after work-up. The products $\{\eta^3\text{-}HB(3\text{-}Bu^tpz)_3\}MgR$ [R = CH_3, CH_2CH_3, $CH(CH_3)_2$] and $\{\eta^3\text{-}HB(3\text{-}Bu^tpz)_3\}MgX$ (X = Cl, Br, I) have been reported previously (ref. 3). The reactions were also accompanied by the deposition of Tl metal, consistent with the proposed decomposition pathway for $[TlCH_3]$ (H. Gilman and R. G. Jones, *J. Am. Chem. Soc.* 1946, **68**, 517), while the reaction with CH_3MgI was also accompanied by the deposition of TlI. Product distributions are not markedly affected by prolonged reaction times.

BOOK REVIEW

Gmelin Handbook of Inorganic Chemistry. Ge–Germanium. (Organogermanium Compounds. Part 2.) Published by the Gmelin Institute for Inorganic Chemistry of the Max Planck Society for the Advancement of Science, 8th Edn. Springer, Berlin, 1989, ISBN 3-540-93585-1, 398 pp.

This is the second volume on organogermanium compounds in the excellent series of Gmelin Handbooks. Part 1 dealt with the tetraorganyls and Me_3GeR compounds with R = substituted methyl, higher alkyls or cyclic alkyls; Part 2 continues in this theme with R = unsaturated or heterocyclic groups, although its majority is devoted to compounds of the type Et_3GeR. The literature has been covered up to 1985.

The Me_3GeR compounds covered include the following R: linear and branched-chain alkenyls in which the longest carbon chain is C_8, cyclic and polycyclic alkenyls; alkynyls; aryls; and heterocyclics. Systems are included in which all the above ligands are substituted with various combinations of *p*-block or transition metal moieties. The remainder of the volume then deals with Et_3GeR, for which R is similar to those mentioned above, but in addition includes the following: unsubstituted alkyls up to C_{12}; alkyls up to C_8 (mainly C_1 and C_2) substituted with aryls and/or a variety of functional groups involving *p*-block elements, as well as one transition metal; and cycloalkyls, both simple and substituted.

This series is renowned for its very high quality in both presentation and comprehensiveness, and this text is no exception. Most data are presented in tabular form supplemented by notes on the more important compounds; it includes details on preparation, physical properties, structure and spectroscopic data. The empirical formula and ligand formula indexes prove most useful for the location of specific compounds.

In conclusion, the book can be recommended unreservedly for those who require ready availability of detailed information on this subject.

FOREWORD

I am delighted to have the opportunity to serve as Guest Editor for a Polyhedron Symposium-in-Print on The Interplay of Theory and Experiment in Inorganic Chemistry. This special issue contains contributions on a variety of topics in inorganic chemistry, most of which highlight the synergy between theoretical and experimental studies in inorganic and organometallic chemistry. I wish to thank all the contributors to this issue for the high quality of the science reported, and for their patience during the process of putting the issue together. I also want to thank the capable professionals at Pergamon Press, especially Miss Sheryl Fellows, for seeing this project through to fruition.

Current research aside, there is another, more compelling reason for the publication of this Symposium-in-Print: To honour Professor Richard F. Fenske on his retirement from the University of Wisconsin-Madison after nearly 30 years of service to that institution. Dick Fenske has been one of the pioneers in the application of molecular orbital theory to large inorganic systems. He has been one of the strongest proponents, and one of the most careful practitioners, of the interplay between theory and experiment in inorganic chemistry. His research has always been characterized by careful, incisive analysis, from his seminal studies of the bonding in metal hexacarbonyls, to the development of the very popular Fenske–Hall molecular orbital method, to his most recent work on the theoretical understanding of NMR chemical shifts. Dick's lectures at scientific meetings were legendary exhibitions of the power of the spoken word; his proselytising "sermons" on inorganic theory did much to increase the interest in theoretical studies among experimental inorganic chemists.

Dick Fenske's contributions to our craft extend far past his published scientific contributions. He served as Chairman of his Department for six years and as Associate Dean for five years. He has been honoured for his teaching excellence by the University of Wisconsin. He has left a sizable legacy to universities throughout the United States as more than half of his PhD students have chosen academic careers.

The contributors to this Symposium-in-Print include Dick's friends, colleagues, and former students. I think I speak for all of us in thanking Dick for his contributions to science, his insight, his counsel, and his good humour and colleagiality. While we will miss his active involvement in inorganic chemistry, we wish him well in his retirement.

Abstract—The valence photoelectron ionizations of $[CpFe(\mu\text{-}NO)]_2$, $[Cp^*Fe(\mu\text{-}NO)]_2$, $[CpRu(\mu\text{-}NO)]_2$ and $[Cp^*Co(\mu\text{-}CO)]_2$ ($Cp = \eta^5\text{-}C_5H_5$ and $Cp^* = \eta^5\text{-}C_5(CH_3)_5$) are examined in comparison to several theoretical calculations of the electronic structure and bonding in these complexes. The photoelectron spectra of this group of complexes, when collected together, allow identification of the eight valence metal-based ionizations. There is considerable disparity among the various calculations on the predicted order of these ionizations. The combination of Fenske–Hall calculations with experimental observations of ionization *trends* between isoelectronic first row complexes [Fe(NO) vs Co(CO)], between first and second row complexes (Fe vs Ru), and between complexes with ring methylation (Cp vs Cp*) allows a consistent assignment of the valence ionizations. The interplay of theory and experiment gives unique insight into the nature of bridging ligand coordination and clarifies the relative strengths of metal–ligand and metal–metal interactions, in each complex. It is found that as many metal–metal antibonding orbitals are occupied as metal–metal bonding orbitals, so that the formal metal–metal bond order is zero. The interactions are important in defining the bonding and stability of the complexes. These interactions lead to large ligand character in two of the valence ionizations.

The understanding of electronic interactions between two metal centres and their coordinated ligands has been of fundamental experimental and theoretical interest.[1–8] One class of seemingly simple complexes which exhibit these interactions is represented by the following four complexes: $[CpFe(\mu\text{-}NO)]_2$, $[Cp^*Fe(\mu\text{-}NO)]_2$, $[CpRu(\mu\text{-}NO)]_2$ and $[Cp^*Co(\mu\text{-}CO)]_2$, where Cp is cyclopentadienyl and Cp* is pentamethylcyclopentadienyl. These complexes are isoelectronic and basically isostructural with one another. These metal dimers are bridged by either a carbonyl or nitrosyl and, with d^8 metal centres, formally possess a metal–metal double bond (see Fig. 1). Because of the relatively simple

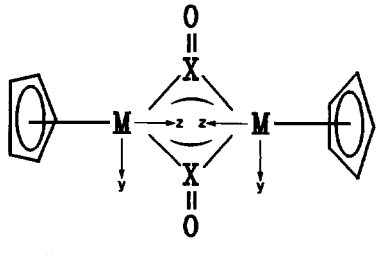

Fig. 1. Coordinate system for the planar D_{2h} $[CpM(\mu\text{-}XO)]_2$ dimers. The local coordinate system about each metal is right handed, so the x axis points above the plane for the left metal and below the plane for the right metal.

† Dedicated to Professor Richard F. Fenske, in appreciation of his pioneering contributions to theoretical and inorganic chemistry and, in particular for his sharing the excitement and joy of chemistry as my PhD mentor (D. L. L.).

ligands and high symmetry, these complexes offer a unique opportunity to study and understand supported metal–metal interactions. Study of the interplay between metal–metal bonding and antibonding combinations and the interaction of the cyclopentadienyl coordination to the metal valence levels, as well as the stabilization due to bridging ligand backbonding with both metal centres, is addressed through these complexes.

In this paper we examine the electronic structure and bonding of these systems through photoelectron spectroscopy. The evaluation of these spectra is difficult because of the large number and the extensive overlap of these valence ionizations. Photoelectron spectra have been reported previously for a few of these complexes.[3,4,8] However, the earlier assignments of the ionizations of these complexes are highly uncertain because of low resolution in the spectra and a lack of correlation with the ionizations of similar complexes. Fenske–Hall and *ab initio* calculations have been used to assist in the evaluation and understanding of these isolated photoelectron spectra, but a survey of these calculations shows a wide variety of possible interpretations even between similar calculational methods.

Comparison of HeI and HeII relative ionization intensities aids in the assignment of metal versus ligand based ionizations. We are also able to resolve vibrational fine structure in several ionization features. This provides direct information on the character and bonding nature associated with the ionization. The most extensive information on the bonding characteristics is obtained by observing the effects of chemical substitutions which perturb the electronic structure and ionization features. For example, the π donating ability of the cyclopentadienyl ligand is changed by substituting pentamethylcyclopentadienyl for standard cyclopentadienyl. This perturbation preferentially shifts the cyclopentadienyl and mixed cyclopentadienyl–metal ionizations to lower binding energy, allowing the identification of mixed cyclopentadienyl–metal ionizations from the other metal and metal-bridging ligand ionizations.[9] The comparison of $[Cp^*Fe(\mu\text{-}NO)]_2$ and $[Cp^*Co(\mu\text{-}CO)]_2$ represents a net proton shift from each of the bridging ligands to the metals. The ionization energy shifts (or lack of shifts) are used to identify bridging ligand interactions with the metal.[10] The metal-based ionizations of the ruthenium analogue are stabilized with respect to iron, and are used to identify strong metal–metal interactions. The spectra of these complexes are presented here and a discussion on the spectral assignment is given based on comparisons between this series of related complexes.

EXPERIMENTAL

Compounds

The $[(\eta^5\text{-}C_5H_5)Fe(\mu\text{-}NO)]_2$, $[(\eta^5\text{-}C_5H_5)Ru(\mu\text{-}NO)]_2$ and $[(\eta^5\text{-}C_5Me_5)Co(\mu\text{-}CO)]_2$ complexes were prepared and purified according to published procedures.[11–13] Useful quantities of the $[(\eta^5\text{-}C_5Me_5)Fe(\mu\text{-}NO)]_2$ complex could not be obtained by published procedures,[14] so an alternate (and more facile) synthetic route is reported here.[15] Specifically, it was found that $(\eta^5\text{-}C_5Me_5)Fe(NO)Br_2$ is easily reduced to $[(\eta^5\text{-}C_5Me_5)Fe(\mu\text{-}NO)]_2$ by zinc dust in THF. The novel $(\eta^5\text{-}C_5Me_5)Fe(NO)Br_2$ complex is prepared by treating $(\eta^5\text{-}C_5Me_5)Fe(CO)_2Br$ with NOBr in CH_2Cl_2.

Synthesis of $(\eta^5\text{-}C_5Me_5)Fe(NO)Br_2$

A Schlenk flask was charged with $(\eta^5\text{-}C_5Me_5)Fe(CO)_2Br$[16] (5.0 g, 15.3 mmol) and 100 cm^3 of CH_2Cl_2 and cooled to 0°C. A solution of NOBr[17] (prepared by dissolving 2 cm^3 of $NOBr_{(l)}$ in 50 cm^3 of CH_2Cl_2 at 0°C) was added dropwise over a period of 30 min until gas evolution had largely ceased and IR indicated the complete disappearance of $(\eta^5\text{-}C_5Me_5)Fe(CO)_2Br$. The reaction mixture was concentrated *in vacuo* to approximately 25 cm^3 and transferred to the top of a 3×20 cm column of SiO_2 prepared in CH_2Cl_2. Elution of the column with pure CH_2Cl_2 produced a brownish-green zone, which after solvent removal *in vacuo* yielded 4.3 g of brown, microcrystalline $(\eta^5\text{-}C_5Me_5)Fe(NO)Br_2$. Crystallization at room temperature by layering 50 cm^3 of ether over the crude product dissolved in 30 cm^3 of CH_2Cl_2 produced 4.0 g (10.5 mmol, 67%) of analytically pure material. ^1H NMR ($CDCl_3$): δ 1.82 (s) 15H ($\eta^5\text{-}C_5\mathit{Me}_5$); IR (KBr): ν(NO) 1816 cm^{-1}; Found: C, 31.61; H, 3.79; N, 3.49. Calc. for $C_{10}H_{15}NOBr_2Fe$: C, 31.53; H, 3.94; N, 3.67%.

Synthesis of $[(\eta^5\text{-}C_5Me_5)Fe(\mu\text{-}NO)]_2$

A Schlenk flask was charged with $(\eta^5\text{-}C_5Me_5)Fe(NO)Br_2$ (0.56 g, 1.47 mmol), zinc dust (5 g, 76 mmol), and a magnetic stir bar and was capped with a new septum. The flask was then subjected to several vacuum/purge cycles to ensure a rigorously pure nitrogen atmosphere. THF (80 cm^3) was carefully added via syringe. The mixture was vigorously stirred for 1 h, during which time the starting brownish-green reaction colour changed to a deep chocolate-brown and the solution IR of the mixture showed the complete disappearance of the starting material. The reaction mixture was transferred to

the top of a 2 × 10 cm column of Al_2O_3 (I) slurry-packed in THF; elution with pure THF produced a dark-brown zone. Dark-brown, microcrystalline $[(\eta^5\text{-}C_5Me_5)Fe(\mu\text{-}NO)]_2$ (0.30 g, 0.68 mmol, 93% yield) was isolated upon removal of solvent *in vacuo*. The spectral and analytical data for this material was completely consistent with that reported by Diel for $[(\eta^5\text{-}C_5Me_5)Fe(\mu\text{-}NO)]_2$.[14]

HeI photoelectron spectra

Photoelectron spectra were measured on a spectrometer with specially designed photon sources, ionization cells, 36 cm radius hemispherical analyser (McPherson), power supplies, counter interface, and collection methods that have been described elsewhere.[18–22] The argon ionization at 15.759 eV (±0.002 eV) was used as an internal calibration lock of the energy scale. The moderately air-sensitive samples were handled in the dry-box to minimize exposure to air and were loaded into the instrument by established procedures.[23] Instrument pressure during sublimation was between 10^{-6} and 10^{-5} torr and the complexes were sublimed at 120°C for $[CpFe(\mu\text{-}NO)]_2$, 93°C for $[Cp^*Fe(\mu\text{-}NO)]_2$, 136°C for $[CpRu(\mu\text{-}NO)]_2$ and 103°C for $[Cp^*Co(\mu\text{-}CO)]_2$, with an uncertainty of ±3°C. The only abnormality observed was in the spectrum of $[CpFe(\mu\text{-}NO)]_2$. The low intensity ionization at 8.5 eV in this spectrum is due to decomposition impurity and is found in the background before and after compound sublimation.

Because high signal-to-noise is required for the vibrational analysis, spectra were obtained over a series of days. Individual data scans were collected by scanning a region for anywhere from 0.1 to 1.0 s per data point. The individual data scans were then summed together resulting in total collect times of 10–80 s per data point for the metal and ligand regions. At no time did any of the ionization features in earlier scans differ from those in later scans. Shifts of the internal calibrant between scans were at all times less than half the energy separation between data points of the respective region during collection.

HeII photoelectron spectra

Samples were handled similarly in the HeII study. The HeII radiation source was a differentially pumped, charged particle oscillator type lamp based on designs previously described[24] except for HeII spectra of $[CpFe(\mu\text{-}NO)]_2$ and $[Cp^*Fe(\mu\text{-}NO)]_2$. For these samples a capillary discharge was used with the HeI lamp set-up. For comparison of HeI/HeII ionization band cross sections, spectra have been corrected for the experimentally-determined variation of electron transmission with kinetic energy of the spectrometer analyser.[25] The HeII (40.81 eV) spectra have also been corrected for ionizations from the HeIIβ (48.4 eV, 12%) source excitation.

Molecular orbital calculations

Molecular orbital calculations were performed using the Fenske–Hall method.[26] Fenske–Hall calculations were performed on $[CpFe(\mu\text{-}NO)]_2$ and $[CpCo(\mu\text{-}CO)]_2$. Basis functions 1*s* through 3*d* for iron and cobalt were taken from the tables of Richardson *et al.*[27] Exponents for the single ζ 4*s* and 4*p* orbitals were set at 2.0 and 1.6 for iron and cobalt. The carbon, nitrogen and oxygen atoms had double ζ 2*p* functions, while hydrogen possessed a single ζ function with an exponent of 1.2. The bond distances and angles used for the $[CpFe(\mu\text{-}NO)]_2$ system[28,29] and $[CpCo(\mu\text{-}CO)]_2$ system[30] were obtained from crystal structures and were idealized to C_{2h} symmetry. The C—H distances used in the calculations of each complex were taken as 1.1 Å.

ELECTRONIC STRUCTURE CALCULATIONS

Previous calculations

Ab initio and Fenske–Hall calculations have been performed previously on $[CpFe(\mu\text{-}NO)]_2$[3,5,7] and $[CpCo(\mu\text{-}CO)]_2$.[4–6] The ionization energies are estimated from the *ab initio* calculations by an analysis that partially accounts for the effects of electron relaxation and configuration interaction. The ionization energies are estimated from the Fenske–Hall calculations by Koopmans' approximation, as is customary with this method.[31] The complete description of each orbital is not always presented in the previous publications. Therefore we have also carried out a Fenske–Hall calculation on these complexes for more detailed analysis. Table 1 compares the results of various calculations. There is little agreement to be found between these calculations as to the predicted order of the ionizations.

The calculated molecular orbitals are discussed here in terms of local D_{2h} point group symmetry, where the overall five-fold symmetry of the cyclopentadienyl groups is simplified to cylindrical symmetry. The notation throughout uses σ, π and δ to refer to the symmetry interactions between metals, while the superscripted a or s refers to the antisymmetric and symmetric combination of orbitals with respect to the mirror plane between the two

Table 1. Relative order of molecular orbitals and ionization energies (in eV) from several calculations

metals. The subscripted $\parallel$ or $\perp$ indicates whether the orbital interactions are oriented within the plane of the metals and bridging ligands ($\parallel$) or whether the orbital interactions are oriented perpendicular to the plane of the metal and bridging ligands ($\perp$).

While most methods predict that the predominantly metal σ combination is the most stable metal-based orbital, the other seven metal–metal combinations shift relative positions depending upon the calculational method used. Note that even the two Fenske–Hall calculations do not produce the same order of the molecular orbitals, as a consequence of subtle differences in the metal 4*s* and 4*p* exponents and the exact bond distances used in the calculations.

Certain trends are observed between complexes and calculational methods. Fenske–Hall calculations suggest that the nitrosyl's backbonding capabilities are greater than the carbonyl's. The metal–metal π^* and π orbitals (involved with the bridging ligand backbonding) are found deeper down the stack for the nitrosyl versus carbonyl complexes.[5] However, this same expected trend is not reflected between the *ab initio* calculations of iron nitrosyl and cobalt carbonyl. The *ab initio* calculations tend to emphasize the importance of metal–ligand interaction over interactions between the two metals. This can be seen in the relatively narrow σ–σ^* separation versus the wider π–π^* separations in each *ab initio* calculation. The σ and σ^* interactions are predominantly metal-based interactions while the π and π^* interactions are supported through backbonding to the bridging ligands. The Fenske–Hall calculations tend to separate the σ and σ^* molecular levels more than the *ab initio* calculations.

As seen above, slight differences in geometries or basis functions can result in different molecular orbital order. This emphasizes the sensitivity of calculations on this molecular system to slight perturbations. Assignments of photoelectron spectra based solely on calculational results are, therefore, greatly suspect. However, a clearly delineated representation of the molecular orbital interactions for these complexes provides an understanding of the trends in ionization energy shifts with chemical substitutions. In the next section a qualitative description of the primary orbital interactions is given.

Molecular orbital analysis

The orbitals in these complexes are most clearly understood in terms of a fragment analysis. The metal, cyclopentadienyl and bridging ligand fragments may be combined in any order to obtain the same final result. For the purposes of understanding the ionizations of these complexes and the perturbations with ligand substitutions, we find it most useful to first combine a cyclopentadienyl and a metal, then form the CpM=MCp dimer, and finally add the bridging ligands. The qualitative interactions between these fragments are shown in Fig. 2.

Generally, the calculations on these d^8 metal dimers suggest an initial t_{2g} and e_g arrangement of metal orbitals. The e_g set of orbitals are metal orbitals situated for direct metal–cyclopentadienyl bonding (see Fig. 2, column A). These are composed of the d_{xz} and d_{yz} atomic orbitals of each metal, which mix with the filled e_1'' π orbitals of each cyclopentadienyl. The metal–metal interaction between these orbitals forms the metal–metal bonding and antibonding π combinations. The more stable t_{2g} set is composed of the $d_{x^2-y^2}$ and d_{xy} (δ interactions between metals) and the d_{z^2} (σ interactions between metals).

Once the bridging ligands are allowed to interact with the metal–metal dimer, four of the metal–metal molecular interactions (two of π type symmetry and two of δ type symmetry) are significantly stabilized through backbonding into the four π^* orbitals of the bridging ligands. Of these four metal-bridging ligand molecular orbitals (see Fig. 2, column C), the metal–metal π^* and π orbitals interact with the filled cyclopentadienyl e_1'' set, which is a destabilizing effect. A destabilization of 1.2 eV was found for a similar orbital of the monomer $Cp^*Co(CO)_2$[35] due to filled–filled interaction of the metal levels with the cyclopentadienyl ring levels. Therefore, the relative ordering between just these four metal–metal bridging ligand supported orbitals is clear. The most stable combinations are of δ symmetry. The π symmetry combinations of the metal, while stabilized by nitrosyl or carbonyl backbonding, are destabilized by filled–filled interactions with the cyclopentadienyl ligand.

The remaining four occupied orbitals are derived

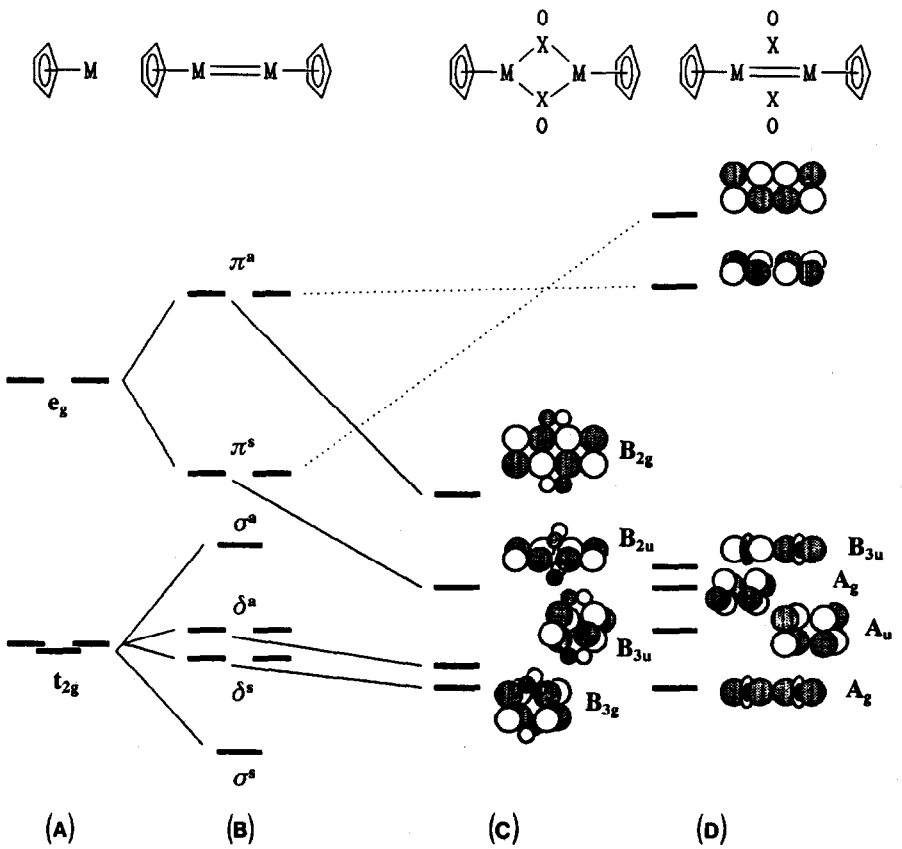

Fig. 2. Molecular orbital diagram of the metal–metal and metal–ligand interactions. (A) Metal–Cp interactions; (B) two metal–Cp interactions; (C) bridging ligand π^* backbonding interactions; (D) the remaining relative pure metal–metal interactions.

from the remaining metal–metal σ and δ interactions. These tend to be relatively unaffected by the bridging ligands. Of these four "pure" metal–metal interactions, only the $\delta^a{}_\perp$ antibonding orbital combination has a symmetry (A_u) which does not interact in any way with the bridging ligands. The other three "pure" metal–metal combinations may interact, by symmetry, with either the empty bridging ligand π^* orbitals (B_{3u} σ^a metal–metal combination) or the bridging ligands' σ donor orbitals (A_g σ^s and A_g $\delta^s{}_\parallel$ metal–metal combinations).

The remaining two empty orbitals have π and π^* symmetry and are unaffected by the bridging ligands' π^* backbonding capabilities. These are mainly required to accept electron density from the π donating cyclopentadienyl rings. The $\pi^s{}_\parallel$ combination is also set up to accept electron density from the bridging ligands' donor σ orbitals and is further destabilized.

The eight occupied combinations may be divided into three different subsets. One set contains two "e_g" metal–metal interactions which are destabilized by interaction with the cyclopentadienyl rings and stabilized by the bridging ligands. These will be labelled simply as $M^\ddagger$ in the figures and tables to designate that they are metal-based but contain substantial cyclopentadienyl and bridging ligand interactions. The second set contains two "t_{2g}" type metal–metal interactions which are stabilized by the bridging ligand's π^* backbonding interactions. These are labelled $M^\dagger$ in the figures and tables to designate metal-based interactions with substantial bridging ligand interactions. The third set contains four relatively "pure" σ and δ "t_{2g}" type metal–metal interactions and will be labelled M in the figures and tables.

The total ordering of the entire set of eight filled metal–metal interactions is highly uncertain at this point, depending on the electron-withdrawing power of the bridging ligands, the electron-donating ability of the cyclopentadienyl π system, the electron-donating ability of the bridging ligand σ interaction and the strength of interactions between metal orbitals.

PHOTOELECTRON RESULTS

Before discussing the complete assignments of the photoelectron ionizations, it is important to recognize several general features of the photoelectron spectra. Each spectral ionization profile will be discussed beginning at low ionization energy and proceeding to the higher energy ionizations. A total of eight metal ionizations should be present in each spectrum followed by four cyclopentadienyl ionizations separated to higher energy. The labelling of the photoelectron bands in the figures and tables reflect the predominant character of the ionization as either cyclopentadienyl or pentamethylcyclopentadienyl (labelled Cp) or metal (labelled M). As specified in the previous section, the label $M^\dagger$ is used to flag those ionizations which are found to contain metal and bridging ligand π^* backbonding character, while the label $M^\ddagger$ is used to flag those ionizations with metal, bridging ligand π^* backbonding and cyclopentadienyl ligand character.

The photoelectron data are modelled with analytical band shapes in order to obtain well-defined values for positions and band areas. Consistent values for the positions and areas, with known confidence limits, are important for comparisons of ionization band shifts between spectra. The data are represented analytically in terms of asymmetric Gaussian peaks. These are defined by parameters representing the position of the peak, the half-widths on the high (W_h) and low (W_l) binding energy sides of the peak and the amplitude of the peak as determined by program GFIT.[32,33] Vibrational fine structure is observed in several ionizations in these spectra. Vibrational progressions are modelled by symmetric Gaussians, where the high (W_h) and low (W_l) energy half-widths are constrained to be equal throughout an entire vibrational progression. The relative band areas are also evaluated in program GFIT to determine the relative ionization cross-section of the photoelectron band. The uncertainty in relative band area can be on the order of 15% for overlapping peaks or poorly defined baselines. For well-separated ionization bands that go to baseline between the peaks, the uncertainty is on the order of 5%.

Vibrational fine structure

A close-up of the low energy ionization region was collected for several of these complexes and vibrational fine structure was observed for [CpFe(μ-NO)]$_2$ and [Cp*Co(μ-CO)]$_2$. The frequencies are reported in Table 2 along with the vibrational frequencies found by IR for the neutral and anionic complexes.[11,14,29]

The vibrational progressions observed for [CpFe(μ-NO)]$_2$ are seen in Fig. 3. Two separate progressions are clearly observed in the ionization at 7.42 eV: a large separation, labelled ν(NO), with a frequency of 0.202(2) eV or 1632 ± 16 cm^{-1}, and a smaller progression with a frequency of 0.0516(5) eV (416 ± 4 cm^{-1}). The larger separation corresponds to the nitrosyl stretching frequency and is completely consistent with the known photoelectron behaviour of other nitrosyl or carbonyl[34,35]

Table 2. Vibrational frequencies of various dimers

	ν(XO) (cm^{-1}) Molecular charge			ν(M—X_2—M) (cm^{-1}) Ionization band

containing complexes. The ionization at lowest ionization energy (6.92 eV) also shows a vibrational progression with a 0.0533 eV energy separation or a 430 cm^{-1} frequency. These smaller frequencies are assigned to the M—X_2—M symmetric ring breathing mode. Vibrational structure observed in the photoelectron spectra generally corresponds to symmetric stretches.[36,37]

Ionizations which are weakly antibonding or non-bonding exhibit short vibrational progressions, in which the adiabatic and vertical ionization normally coincide. For these two ionizations, the leading narrow components at low intensity (indicated by the arrows) are attributed to hot bands. Results from Boltzmann's distribution supports the intensity pattern found for these leading components for spectra obtained at 120°C. This means that the adiabatic ionization is the most intense (vertical) for each of these ionizations and these two ionizations are relatively non-bonding. They will be assigned to reflect this observation.

In Fig. 4, the leading ionization of [Cp*Co(μ-CO)]$_2$, at 6.22 eV is observed to possess an ionization separated 0.216(20) eV to higher ionization energy or 1742 ± 160 cm^{-1}, a carbonyl vibrational stretching frequency. Although only barely resolved, the ionization intensity between the leading ionization and the next intense band at 6.61 eV clearly indicates the presence of the additional vibrational band. For neutral [Cp*Co(μ-CO)]$_2$, a single IR band at 1752 cm^{-1} is reported[38] and these values correspond well. The observation of the carbonyl stretching frequency in this leading ionization of the photoelectron spectrum supports the contention that the leading ionization in [Cp*Co(μ-CO)]$_2$ has carbonyl backbonding character, which is also indicated by previously published HeI/HeII comparisons.[4]

Modelling band shapes with vibrational progressions

The presence of the nitrosyl vibrational progression in [CpFe(μ-NO)]$_2$ leads to a pronounced asymmetric ionization profile with an additional intensity component at higher ionization energy. The ionization at 7.42 eV will be correlated in the next section to an orbital that is predominantly metal in character and which does not have any direct symmetry interaction with the π^* of the nitrosyls. This ionization is actually the least likely of the metal-based ionizations to possess vibrational

fine structure associated with the bridging nitrosyls. This metal-based ionization presumably activates the vibrational progression, because of its association with the M—X_2—M ring core, and it follows that the other metal-based ionizations will activate this progression as well. Therefore, the relative intensity and relative energy separation found for the nitrosyl vibrational structure on the ionization at 7.42 eV is used to define the model band profiles for other metal-based ionizations. This is illustrated in Fig. 3, where the NO vibrational components are indicated. The analytical model of this single ionization is expressed in the following equation:

$$C = A\,e^{-k(X-P/W_i)^2} + (0.26)A\,e^{-k(X-P-0.202/W_i)^2} \quad (1)$$

where C is the calculated counts, k is a constant $4\ln(2)$, A is the amplitude, P is the peak position and W_i is the half-width to low binding energy (W_l; $X < P$) or the half-width to high binding energy (W_h; $X > P$). Note that this function still only has four variable parameters. It does not use additional parameters, but merely alters the model band shape. With the use of this model, the photoelectron spectrum is represented accurately with the fewest number of variable parameters.

The example given in Fig. 5 illustrates the consequences of including and excluding the nitrosyl vibrational fine structure in the individual band contour model. In section A of Fig. 5, each ionization profile retains a vibrational component corresponding to nitrosyl vibrational fine structure. The overall spectral fit is good and the individual Gaussian bands have reasonable shapes and relative areas. Section B shows the overall spectral fit when the corresponding vibrationally excited nitrosyl bands are removed. When these eight Gaussian bands are allowed to converge to the data, as seen in section C, several of the individual Gaussian bands are found to shift into valleys previously occupied by the vibrationally excited nitrosyl band. The others increase in intensity and half-width to account for the area previously occupied by the shifting Gaussians. These Gaussian band positions and areas are clearly unreasonable representations of the eight ionizations in the spectrum.

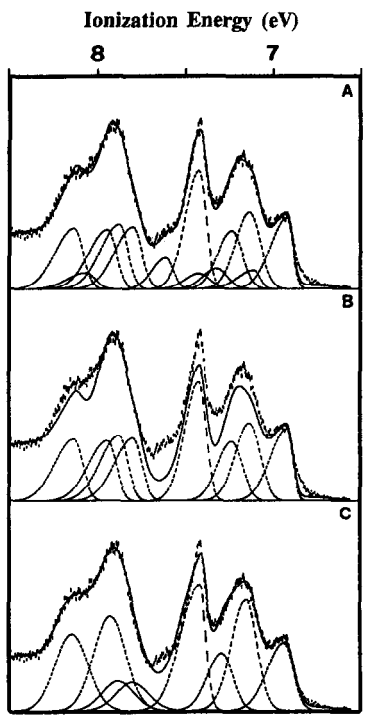

Fig. 5. Comparisons between photoelectron spectra (A) with nitrosyl vibrational fine structure included in the Gaussian band definition; (B) without fine structure (unconverged); (C) without fine structure (converged).

The spectra of both [CpFe(μ-NO)]$_2$ and [Cp*Fe(μ-NO)]$_2$ require the addition of the vibrationally excited band in order to reasonably account for the spectral features. However, these additional small bands are not plotted in the figures, as they visually complicate the illustration, while suggesting no additional insight. The ionizations in the HeII spectra are represented by the same peaks and positions as in the HeI spectra, allowing only the intensities to vary. The vertical ionization energies and relative areas of these complexes are reported in Table 3.

General photoelectron features

The HeI and HeII photoelectron spectra of [CpFe(μ-NO)]$_2$ are shown in Fig. 6. The leading ionization is observed at 6.92 eV and separated 0.22 eV from the next ionizations. The second band profile at 7.2 eV can not be fitted adequately with a single asymmetric Gaussian band, and the profile is well accounted for by two ionization bands. As further support of the presence of two ionizations under this band envelope, the band profile changes between HeI and HeII source energies, indicative of different HeI/HeII cross-section changes between the two ionizations under the one profile.

The distinct sharp ionization at 7.42 eV possesses a set of very narrow half-widths. Note that the overall half-width for this ionization is only 0.27 eV. All other ionization half-widths are of the order of $\sim$ 0.4 eV. This single ionization is expected to be relatively non-bonding because of the narrowness of the ionization. The vibrational fine structure analysis of this band in the previous section also showed that the adiabatic and vertical ionization energies coincide. This ionization is primarily metal in

character, as the HeI/HeII relative area increases relative to the ionization profile at 7.8 eV.

The ionization envelope starting at 7.8 eV obviously contains overlapping ionizations. The intense ionization at 7.88 eV in the HeI spectrum substantially decreases in the HeII spectrum, indicative of ligand contribution to this ionization. Also, the presence of other ionizations are needed to account for the area under the profile. The HeI/HeII behaviour of the shoulder at highest ionization energy (8.13 eV) suggests an ionization of predominantly metal character. This entire profile should account for a total of four overlapping ionization bands.

The ionization band at 9.6 eV correlates with the four characteristic cyclopentadienyl ionizations. This relative band intensity decreases substantially when viewed with HeII ionization source energy, as expected for predominantly cyclopentadienyl ligand character. This ionization is also very broad.

The general photoelectron features of $[Cp^*Fe(\mu\text{-}NO)]_2$ (see Fig. 7) are the same as those for $[CpFe(\mu\text{-}NO)]_2$. The major difference is a shift of all ionizations to lower ionization energy due to the presence of the electron donating pentamethylcyclopentadienyl rings. Some ionizations have shifted to a greater extent than others and those ionizations with the greater cyclopentadienyl character are expected to shift to a greater degree. Examina-

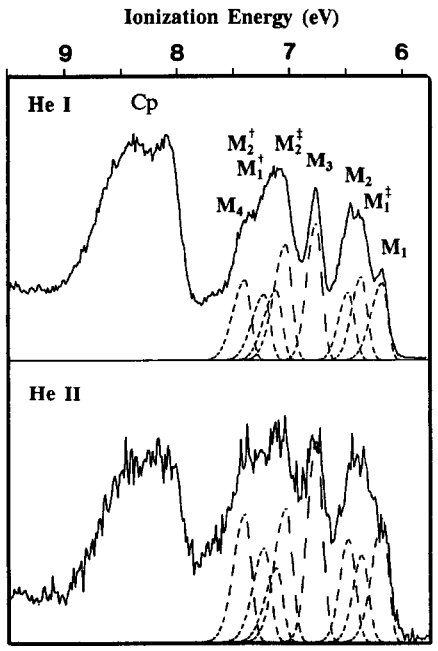

Fig. 7. HeI and HeII photoelectron spectra of $[Cp^*Fe(\mu\text{-}NO)]_2$. The dashed Gaussian bands indicate the position of the eight predominantly metal ionizations. See text for further discussion.

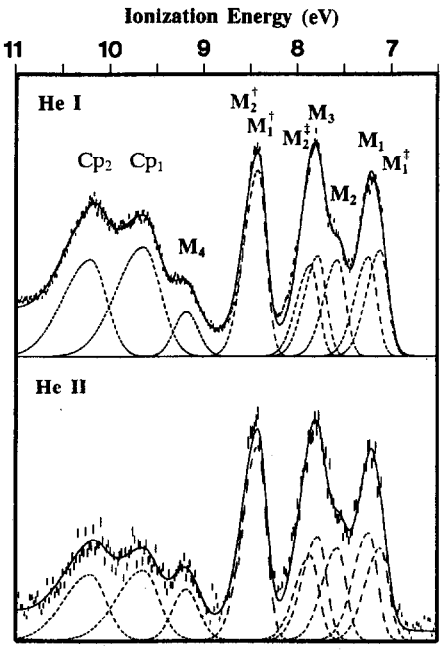

Fig. 8. HeI and HeII photoelectron spectra of [CpRu(μ-NO)]$_2$. The dashed Gaussian bands indicate the position of the eight predominantly metal ionizations and the two split cyclopentadienyl ionizations. The overall fit is given by the solid line through the photoelectron data.

tion of this effect and its usefulness in assigning these spectra will be discussed in greater detail in the next section.

The HeI/HeII photoelectron spectra of [CpRu(μ-NO)]$_2$, the second row counterpart to [CpFe(μ-NO)]$_2$, are given in Fig. 8. The leading intense ionization at 7.2 eV is nearly double the intensity of the ionization appearing as a shoulder at 7.58 eV. This suggests the presence of two narrow ionizations under the leading ionization profile. Two metal-based ionizations are assigned to the band profiles at 7.80 and at 8.42 eV. These bands are generally double the area and amplitude of the single ionization appearing as a shoulder at 7.58 eV. Both these intense ionizations will accommodate two ionizations, giving a total of seven ionizations between the energies of 7.10 and 8.50 eV. The eighth metal ionization is found at 9.20 eV. This broad ionization increases its relative intensity upon comparison between HeI and HeII data.

The broad ionizations at 9.6 and 10.2 eV significantly decrease in relative ionization intensity between HeI and HeII spectra, indicating ligand character. The ionization at 9.6 eV corresponds with the ionization energy found for the cyclopentadienyl ring ionizations of [CpFe(μ-NO)]$_2$. Since the second row ruthenium metal forms stronger interactions with the cyclopentadienyl rings as compared to the first row iron,[35,39] the ionizations at 10.2 eV (separated 0.6 eV to higher binding energy from the cyclopentadienyl ionizations at 9.6 eV) are also cyclopentadienyl ionizations. These are stabilized by interaction with the ruthenium metal e_g set. This metal–ring interaction is only hinted at in the broadness of the cyclopentadienyl ionization regions of [Cp*Fe(μ-NO)]$_2$ and [CpFe(μ-NO)]$_2$.

The overall spectrum of [Cp*Co(μ-CO)]$_2$ (see Fig. 9) is dissimilar in appearance to the ionization profile of [Cp*Fe(μ-NO)]$_2$. The spectrum of [Cp*Co(μ-CO)]$_2$ presents an ionization at 6.22 eV which is well-separated from the rest of the metal ionizations and has a profile typical in shape to that of a single ionization. The second ionization at 6.61 eV is the first of four overlapping ionizations found in the region from 6.61 to 7.04 eV. The precise locations and relative intensities of these overlapping ionizations are uncertain. The ionization found at 8.25 eV is due to the four cyclopentadienyl ionizations, at a similar energy to those found in [Cp*Fe(μ-NO)]$_2$. HeII ionization data as published by Green and others[4] indicate that the leading ionization at 6.22 eV decreases in relative ionization area, indicating a substantial percentage of ligand character in this ionization.

ASSIGNMENT OF PHOTOELECTRON SPECTRA

All the information available from the HeI/HeII comparisons, shifts between Co(CO) and Fe(NO) complexes, shifts between Cp and Cp* complexes, and between Fe and Ru metals is evaluated to determine the assignment of the photoelectron spectra

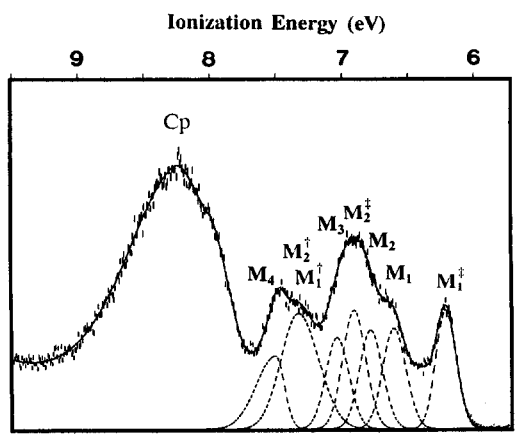

Fig. 9. HeI photoelectron spectrum of [Cp*Co(μ-CO)]$_2$. The dashed Gaussian bands indicate the position of the eight predominantly metal ionizations and the pentamethylcyclopentadienyl ionizations. The overall fit is given by the solid line through the photoelectron data.

of these compounds. Based on the confidence limits of the analysis of overlapping ionizations, any individual change in a band area or an ionization shift does not provide absolute proof of a band assignment. However, the collection of supporting changes leads to consistent band assignments. By using the trends associated with the chemical changes in these complexes, which are understood from previous studies of related cyclopentadienyl, carbonyl, and nitrosyl complexes, the eight predominantly metal ionizations may be confidently assigned without invoking calculations as the requisite of assignment. Listed below is a set of understood ionization trends applied to the spectra of these complexes.

(1) Pentamethylcyclopentadienyl (Cp*) ionizations are shifted $\approx$ 1.2 eV to lower ionization energy from cyclopentadienyl (Cp) ionizations.[9]
(2) Mixed Cp*–metal ionizations are shifted $\approx$ 0.8 eV to lower ionization energy from Cp–metal ionizations.[35]
(3) Metal-based ionizations are shifted $\approx$ 0.65–0.75 eV to lower ionization energy when Cp* is substituted for Cp.[35]
(4) The area of ligand-based ionizations relative to first row metal-based ionizations is less with HeII excitation than with HeI excitation.[40]
(5) Mixed ligand–metal ionizations will decrease proportionally in ionization area relative to more "pure" metal ionizations and increase proportionally in ionization area relative to more "pure" ligand ionizations.[41]
(6) The metal-based ionizations of $CpMn(CO)_3$ are $\approx$ 0.3 eV more stable than the metal-based ionization of $CpCr(CO)_2(NO)$ provided they were not involved in backbonding to the nitrosyl.[10] These complexes are related by the same proton shift from the metal to the ligand as the cobalt and iron complexes in this study.
(7) The metal ionizations stabilized by backbonding into the π^* of the bridging ligands are expected to be similar in energy between cobalt–carbonyl and iron–nitrosyl.[10] These ionizations experience a stabilization in the cobalt complex due to the metal's influence (trend 6) and a comparable destabilization due to the less effective backbonding to the carbonyl as compared to the nitrosyl. The net effect is little change in ionization energy.
(8) When comparing iron to ruthenium, all second row metal ionizations are stabilized with respect to the first row ionizations.[35]
(9) A sharp band profile with resolvable vibrational fine structure suggests relatively non-bonding molecular orbital character.

The shifts between the energies of corresponding ionizations of the four complexes {$[Cp^*Co(\mu\text{-}CO)]_2$, $[Cp^*Fe(\mu\text{-}NO)]_2$, $[CpFe(\mu\text{-}NO)]_2$ and $[CpRu(\mu\text{-}NO)]_2$} are given in Table 4, along with the assignments. The differences or shifts in ionization

Table 4. Shifts in photoelectron ionization bands between complexes[a]

Labels[b]			$[Cp^*Co(\mu\text{-}CO)]_2$ Shift (±0.04 eV)	$[Cp^*Fe(\mu\text{-}NO)]_2$ Shift (±0.04 eV)	$[CpFe(\mu\text{-}NO)]_2$ $[CpRu(\mu\text{-}NO)]_2$ Shift (±0.04 eV)
M_1	B_{3u}	σ^a	−0.42	+0.73	+0.32
M_2	A_g	$\delta^s_{\parallel}$	−0.23	+0.75	+0.34
M_3	A_u	$\delta^a_{\perp}$	−0.27	+0.65	+0.36
M_4	A_g	σ^s	−0.11	+0.73	+1.05
$M^{\dagger}_1$	B_{3u}	$\delta^a_{\parallel}$	−0.21	+0.68	+0.62
$M^{\dagger}_2$	B_{3g}	$\delta^s_{\perp}$	−0.10	+0.72	+0.48
$M^{\ddagger}_1$	B_{2g}	$\pi^a_{\parallel}$	+0.16	+0.76	−0.01
$M^{\ddagger}_2$	B_{2u}	$\pi^s_{\perp}$	+0.12	+0.84	−0.01
Cp			+0.09	+1.23	+0.04[c]

[a] The sign convention is defined so that the value, when added to the energy of an ionization of the molecule on the left, gives the energy of the corresponding ionization of the molecule on the right.

[b] The labels are grouped according to their mixed metal–ligand character. For the relative ionization order of each complex see Table 3 or Fig. 10.

[c] The shift in cyclopentadienyl ionizations between $[CpFe(\mu\text{-}NO)]_2$ and $[CpRu(\mu\text{-}NO)]_2$ is derived from the cyclopentadienyl ionization at lowest ionization energy in $[CpRu(\mu\text{-}NO)]_2$.

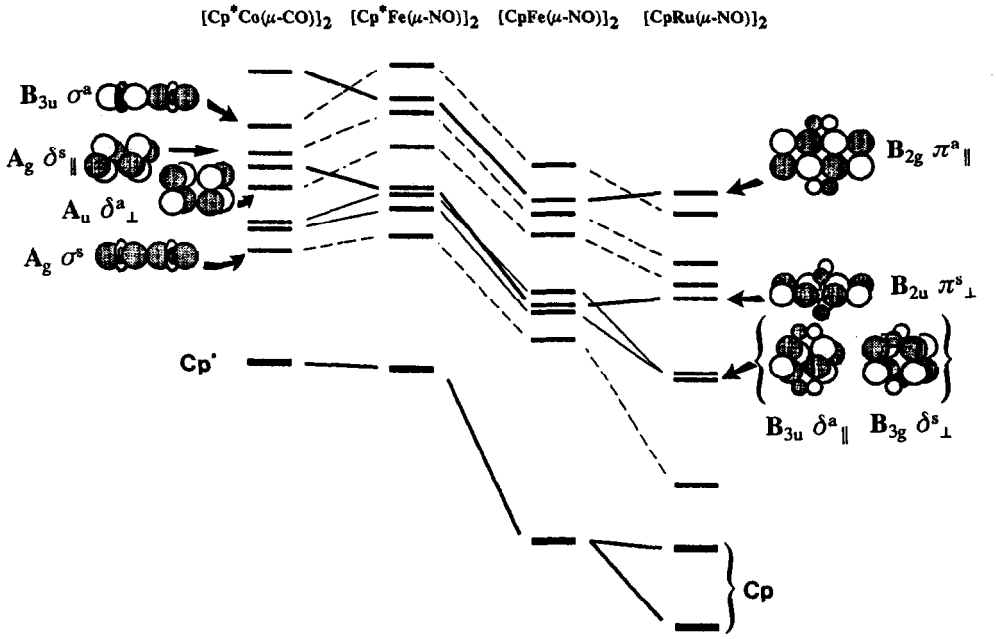

Fig. 10. Experimental energy correlation diagram. The four "pure" metal ionizations are depicted on the left of the figure and correlated between complexes with dashed lines. The two δ ionizations which are stabilized by backbonding to the bridging ligands are depicted on the right of the figure and correlated between complexes with solid lines. The two π ionizations which are stabilized by backbonding to the bridging ligands and destabilized by filled interactions with the cyclopentadienyl e_1'' orbitals are depicted on the right of the figure and correlated between complexes with dark solid lines.

energy between complexes are defined from the left to the right, in the table. Since the relative order of the closely spaced individual ionizations changes from complex to complex, the three general classes of ionizations with their assignments have been grouped together. The shifts of the "pure" metal ionizations (M_{1-4}) along with the metal and bridging ligand ionizations ($M^{\dagger}{}_{1,2}$) and the metal–ligand and cyclopentadienyl ionizations ($M^{\ddagger}{}_{1,2}$) are listed together in Table 4. The experimental ionization order is illustrated in the Fig. 10 and listed in Table 3. The assignment of the ionization bands with the symmetry designations in Table 3 can be easily correlated to the other figures and tables.

Analysis of these assignments will begin with the bands labelled $M^{\ddagger}{}_1$ and $M^{\ddagger}{}_2$ of the complexes [Cp*Fe(μ-NO)]$_2$ and [CpFe(μ-NO)]$_2$. $M^{\ddagger}{}_1$ and $M^{\ddagger}{}_2$ are assigned to the B_{2g} $\pi^a{}_{\|}$ and B_{2u} $\pi^s{}_{\perp}$ orbital symmetries, respectively. These two orbitals are unique in possessing cyclopentadienyl ligand character, nitrosyl backbonding character and metal–metal antisymmetric and symmetric π symmetry. In comparison to the more "pure" metal-based ionizations, $M^{\ddagger}{}_1$ and $M^{\ddagger}{}_2$ decrease in relative area from HeI to HeII excitation (trend 5). These same two ionizations shift position 0.76 and 0.84 eV to higher binding energy between the spectra of [Cp*Fe(μ-NO)]$_2$ and [CpFe(μ-NO)]$_2$, as expected for the partial cyclopentadienyl contribution to the character (trend 2). All the other metal-based ionizations shift an average of only 0.71 eV (trend 3).

Experimentally, the relative order of the B_{2g} $\pi^a{}_{\|}$ versus the B_{2u} $\pi^s{}_{\perp}$ is indeterminable. However, it is reasonable to expect the antisymmetric metal–metal combination, B_{2g} $\pi^a{}_{\|}$, to be the least stable of the pair. Since both combinations suffer to an equal degree from the filled cyclopentadienyl ring orbital donations into the filled metal π orbitals and assuming the stabilization gained from the bridging ligand backbonding with the metals is comparable between B_{2g} and B_{2u} combinations, then the only difference between the two combinations is the antibonding metal–metal destabilization of the B_{2g} versus the metal–metal bonding stabilization of the B_{2u} combination.[42]

When the spectrum of [CpRu(μ-NO)]$_2$ is compared to the spectrum of [CpFe(μ-NO)]$_2$, we expect the second row metal-based ionizations to be stabilized with respect to the first row metal ionizations (trend 9). All metal ionizations other than the $M^{\ddagger}{}_1$ and $M^{\ddagger}{}_2$ ionizations of [CpRu(μ-NO)]$_2$ are stabilized with respect to [CpFe(μ-NO)]$_2$ an average 0.53 eV. The greatest stabilization is found between

$[CpFe(\mu\text{-}NO)]_2$ and $[CpRu(\mu\text{-}NO)]_2$ for peak M_4 (1.05 eV). Because the ruthenium metal–metal bonding interactions should be progressively more important than first row iron metal–metal interactions, M_4 is assigned to the metal–metal $A_g\ \sigma^s$ interaction. The HeI/HeII comparison of $[CpRu(\mu\text{-}NO)]_2$ spectra suggests that ionizations $M^{\ddagger}_1$ and $M^{\ddagger}_2$ decrease in ionization area, indicative of cyclopentadienyl ligand character (trend 5). The ionization energies of bands $M^{\ddagger}_1$ and $M^{\ddagger}_2$ are destabilized 0.01 eV between $[CpFe(\mu\text{-}NO)]_2$ and $[CpRu(\mu\text{-}NO)]_2$.

HeI/HeII comparisons also identify the cyclopentadienyl ionization unquestionably in $[CpRu(\mu\text{-}NO)]_2$. The ionizations at 9.6 and 10.2 eV decrease markedly between the HeI and HeII spectra (trend 4). Also note that the splitting in the cyclopentadienyl ionizations indicates the importance of the second row metal ruthenium–cyclopentadienyl interactions.[35] The cyclopentadienyl–metal interactions are found at 10.2 eV, while the more "pure" cyclopentadienyl ionizations are found at 9.6 eV. This is reflected in a relative increase for HeII ionization area in the ionizations at 10.2 eV as compared to the more "pure" cyclopentadienyl ionizations at 9.6 eV. The cyclopentadienyl ionizations for the iron complex are also found at 9.6 eV, indicative of minimal first row cyclopentadienyl–metal interaction and of a nearly "pure" cyclopentadienyl ionization potential.

Two of the metal-based ionizations are labelled $M_1^{\dagger}$ and $M_2^{\dagger}$, because of evidence for significant interaction with the bridging ligands. These two bands are assigned to the $B_{3u}\ \delta^a_{\parallel}$ and $B_{3g}\ \delta^s_{\perp}$ ionizations. These are allowed by symmetry to strongly interact with the bridging ligands (see Fig. 2, column C). Since the $B_{3u}\ \delta^a_{\parallel}$ and $B_{3g}\ \delta^s_{\perp}$ are derived from the initially more stable metal "t_{2g}" set, these two are expected to be more stable than the corresponding $B_{2g}\ \pi^a_{\parallel}$ ($M^{\ddagger}_1$) and $B_{2u}\ \pi^s_{\perp}$ ($M^{\ddagger}_2$) nitrosyl backbonding interactions (derived from the less stable metal "e_g" set). Therefore, ionizations $M^{\dagger}_1$ and $M^{\dagger}_2$ of the $[CpRu(\mu\text{-}NO)]_2$ spectrum are assigned to be the two accidentally degenerate $B_{3u}\ \delta^a_{\parallel}$ and $B_{3g}\ \delta^s_{\perp}$ orbitals, sandwiched in energy between the most stable $A_g\ \sigma^s$ metal–metal ionization and the lowest lying metal–metal π symmetry ionization.

Of the remaining three unassigned "pure" metal–metal interactions, the ionization band M_3 of $[CpFe(\mu\text{-}NO)]_2$ and $[Cp^*Fe(\mu\text{-}NO)]_2$, clearly has a very sharp band profile and is expected to be relatively non-bonding in character. Figure 3 illustrates the vibrational progressions observed for $[CpFe(\mu\text{-}NO)]_2$ under the leading ionization at 6.92 eV and this sharp fourth ionization, at 7.42 eV. The very sharp and intense ionization at 7.42 eV, M_3, is assigned to the $A_u\ \delta^a_{\perp}$ molecular combinations. The $A_u\ \delta^a_{\perp}$ is the only molecular orbital of A_u symmetry. The Fenske–Hall calculation finds this orbital to be $\approx 100\%$ metal d_{xy} antibonding in character, with no possible stabilization factors due to the backbonding ligands and only weak interaction with the empty cyclopentadienyl e_2'' orbitals. The $\delta^a_{\perp}$ is best described as metal-based lone pairs with very little metal–metal interaction. The leading ionization of $[CpFe(\mu\text{-}NO)]_2$, M_1, is assigned to the $B_{3u}\ \sigma^a$, which is the only other orbital which is antibonding between the metals.

The last unassigned molecular orbital is the $A_g\ \delta^s_{\parallel}$ combination. This combination is assigned to the last remaining unassigned metal ionization, in $[CpFe(\mu\text{-}NO)]_2$ at 7.24 eV, M_2.

The assignment of the photoelectron spectrum of $[Cp^*Co(\mu\text{-}CO)]_2$ is obtained by applying a predicted ≈ 0.3 eV stabilization on all the metal "t_{2g}" ionizations of $[Cp^*Fe(\mu\text{-}NO)]_2$, (trend 6). If the four "pure" metal "t_{2g}" ionization shifts are evaluated between iron and cobalt (namely the $B_{3u}\ \sigma^a$, $A_g\ \delta^s_{\parallel}$, $A_u\ \delta^a_{\perp}$ and $A_g\ \sigma^s$), an average 0.27 eV stabilization is observed. This is in excellent agreement with the expected ≈ 0.3 eV stabilization. The $B_{3u}\ \delta^a_{\parallel}$ and $B_{3g}\ \delta^s_{\perp}$ ($M^{\dagger}_{1,2}$), which are metal combinations uninvolved with the cyclopentadienyl but involved with the backbonding bridging ligands, are stabilized only an average 0.16 eV. The metal π "e_g" ($M^{\ddagger}_{1,2}$) ionizations are then found to be destabilized an average 0.14 eV. These shifts between Fe(NO) and Co(CO) ionizations support the general assignment of "pure" metal ionizations (M_{1-4}), metal mixed bridging ligand ionizations ($M^{\dagger}_{1,2}$) and cyclopentadienyl–bridging ligand ionizations ($M^{\ddagger}_{1,2}$).

DISCUSSION

The trends in ionization features between the complexes allow assignment of the general characters of the ionizations without recourse to calculations. The analysis is based solely on the trends in the experimental data, but the assignments which emerge are also intuitively satisfying. The fourth ionization, $A_u\ \delta^a_{\perp}$, is relatively sharp and non-bonding. The three ionizations to lower ionization energy from the $A_u\ \delta^a_{\perp}$ contain substantial antibonding interactions, while the four ionizations to higher ionization energy contain substantial bonding interactions. For the iron complexes, the first ionization ($B_{3u}\ \sigma^a$) is σ antibonding between the metals and has little interaction with the ligands, the second ionization ($B_{2g}\ \pi^a_{\parallel}$) is π antibonding between the metals and antibonding with the cyclopentadienyl ring, but stabilized by backbonding to the nitrosyls. The stabilization by backbonding to the bridging

ligands is relatively less important for the ruthenium–nitrosyl and cobalt–carbonyl complexes, and this ionization becomes the first ionization. The third ionization ($A_g\ \delta^s_{\parallel}$) is weakly bonding between the metals but antibonding with the σ donor orbitals of the bridging ligands. On the other side of the non-bonding $A_u\ \delta^a$ ionization, the $B_{3u}\ \pi^s_{\perp}$, $B_{3u}\ \delta^a_{\parallel}$ and $B_{3g}\ \delta^s_{\perp}$ are stabilized by back-bonding to the bridging ligands, and the $A_g\ \sigma^s$ is stabilized by the metal–metal interaction.

All these complexes possess two d^8 metals and traditional electron counting leads to a metal–metal double bond. However, the occupied metal orbitals are:

$$(\sigma)^2(\delta_{\perp})^2(\delta_{\parallel}{}^*)^2(\pi_{\perp})^2(\delta_{\perp}{}^*)^2(\delta_{\parallel})^2(\pi_{\parallel}{}^*)^2(\sigma^*)^2.$$

In terms of symmetry interactions between the metals, as many antibonding orbitals as bonding orbitals are occupied, and a net zero formal metal–metal bond order is found. Although the formal metal–metal bond *order* is zero, the metal–metal bond *energy* is not zero. For instance, the $A_g\ \sigma^s$ ionization is broad, indicative of substantial bonding character in the metal–metal σ bonding symmetry orbital. The $B_{3u}\ \sigma^a$ ionization of $[Cp(Fe(\mu\text{-}NO)]_2$ is relatively narrow with resolved ligand vibrational structure. Thus the metal–metal σ antibonding symmetry orbital is more non-bonding between the two metals. The metal–metal bond energy in the σ bonding interaction is not completely cancelled by the σ antibonding interaction, and a net metal–metal σ bond results. The conclusion from these ionization characteristics of some net σ bonding between the metals is supported by the calculations of Hall.[8,43]

The bonding in the M—X_2—M ring looks more like a dimetallocyclobutadiene moiety. The molecular bonding may be perceived as two π bonding interactions which are formed through the bridging ligands' π^* backbonding orbitals. Further, the σ interactions between the bonding lone pairs of the bridging ligand into the empty metal acceptor levels accounts for bonding orbitals in the σ framework. The double bonds are not located directly between the two metals, but are coupled through the bridging ligand system. One, the $B_{2u}\ \pi^s_{\perp}$, is a π orbital delocalized around the ring with a node in the plane of the ring, somewhat like the totally symmetric $p\pi$ orbital in cyclobutadiene. The other is the $B_{2g}\ \pi^a_{\parallel}$, which is in the plane of the M—X_2—M ring. These dimetallocyclobutadiene orbitals stabilize the filled–filled interactions between the metals and cyclopentadienyl ligands.

This metal–metal π and π^* ionization pair is unique in that the separation between the π and π^* ionizations remains constant over all the complexes examined. The general separation between π and π^* is found to be 0.71 ± 0.03 eV for each complex. In contrast, the σ to σ^* separation for each complex varies from 1.94 eV separation for $[CpRu(\mu\text{-}NO)]_2$ to 1.21 eV separation for both iron complexes to 0.90 eV for $[Cp^*Co(\mu\text{-}CO)]_2$. The variable energy separation found between the metal–metal σ–σ^* ionizations is understood by simple periodic trends, where the second row metal ruthenium is expected to have the greatest orbital overlap and hence the largest metal–metal interaction. The iron centres (with formal 0 oxidation states) will have greater orbital overlap than the corresponding cobalt centres (with formal +1 oxidation states).

Earlier, when the assignment of the $[CpRu(\mu\text{-}NO)]_2$ complex was made, all metal-based ionizations were expected to stabilize from the corresponding iron complex. The π and π^* were found to be slightly destabilized (0.01 eV, see Table 4). This is one indication of the substantial ligand character in these ionizations. The leading ionizations of the $CpCo(CO)_2$ and $CpRh(CO)_2$ monomers[19] are similar in having a filled interaction with the cyclopentadienyl e_1'' orbitals and backbonding to the ligands. They were also found to be substantially ligand in character, without significant shifts of these ionizations between the first and second row analogues. The largest shifts in energy of the π and π^* pair between complexes is obtained with substitution of pentamethylcyclopentadienyl for cyclopentadienyl (0.80 eV). Otherwise, the substitution of second row metal for first row metal leaves the π/π^* system relatively unchanged in energy.

The substitution of cobalt carbonyl for iron nitrosyl also leaves the relative energy position of the π and π^* pair unaffected. For the cobalt system, the less effective backbonding capabilities of the bridging carbonyls are nearly countered by the more stable cobalt metal centres. However, the slight destabilization of the π/π^* pair (0.14 eV) illustrates the weaker carbonyl backbonding capabilities as compared to the nitrosyl.

CONCLUSIONS

The evaluation of these complicated photoelectron spectra strongly emphasizes the importance of comparing the ionizations of similar complexes. Through these comparisons, the complex spectra are assigned and the nature of individual ionizations of interest may be closely studied. The ionizations are sensitive to the interactions between the filled orbitals on the two metals, between the filled π orbitals on the metals and the filled cyclopentadienyl e_1'' orbitals, and between the filled π

and δ orbitals on the metals and the empty π^* orbitals on the bridging ligands. The relative dependence of the ionizations to these interactions vary from complex to complex. We observe that the direct metal–metal interactions are formally nonbonding according to the occupation of the bonding and antibonding levels. The bonding interactions are found through the bridging ligand–metal ring system, which compensates for individual antibonding orbital combinations between the metals and the cyclopentadienyls.

Photoelectron spectroscopic work on $[CpFe(CO)]_2$-$\mu(CO)_2$ and $[CpFe(CO)]_2$-$\mu(CH_2)$-$\mu(CO)$, which has shown that the substitution of a bridging methylene for a bridging carbonyl, significantly stabilized the leading ionization in $[CpFe(CO)]_2$-$\mu(CO)_2$. Since the better backbonding μ-CH_2 possesses only one π orbital (oriented parallel to the metal and bridging ligand plane) able to backbond with the complex, the leading ionization of $[CpFe(CO)]_2$-$\mu(CO)_2$ was confidently assigned to the parallel oriented metal–metal $\pi^a_{\parallel}$ interaction with substantial bridging ligand backbonding contribution.

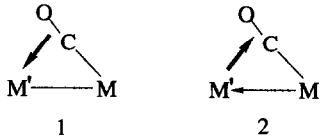
LINEAR SEMIBRIDGING CARBONYLS—III. CARBONYL AND THIOCARBONYL LIGANDS AS FOUR-ELECTRON DONORS†

ANDREW L. SARGENT and MICHAEL B. HALL‡

Department of Chemistry, Texas A&M University, College Station, TX 77843-3255, U.S.A.

Abstract—Parameter-free Fenske–Hall molecular orbital calculations predict the electronic structure and bonding of several heterobimetallic complexes containing linear semibridging carbonyl and thiocarbonyl ligands. The results suggest that the linear semibridging ligand acts as a four-electron donor only when the secondary metal centre is an electron-deficient early transition metal atom. When the secondary centre is a late transition metal atom, the linear semibridging ligand acts as a π-acceptor of electron density, even if the late metal has less than 18 electrons. Holes in the *d* shell of the early metal atoms are more prominent than those in the late metal atoms where the higher nuclear charge pulls the *d* electrons closer to the nucleus. The role of the semibridging ligand is to fill in the prominent holes in the *d* shell when they exist by donating electron density from an occupied π orbital. When there are no holes in the *d* shell, or when the holes are very small, the semibridging ligands accept electron density from the secondary metal centre into a π^* orbital.

Angelici and co-workers have recently reported the first semibridging thiocarbonyl complexes.[1,2] Experimental and theoretical evidence suggests that the thiocarbonyl (CS) ligand is not only a better π-donor than the carbonyl (CO) ligand, but is also a better π-acceptor.[3,4] This raises an interesting question: is the direction of electron density flow between a secondary metal centre and the semibridging CS ligand similar to that in analogous semibridging CO compounds? The direction of electron density flow between semibridging carbonyl ligands and secondary metal centres has been a point of controversy among chemists for several years. In the four-electron donor, or π-donor, model electron density flows from a π orbital of the semibridging carbonyl ligand to the secondary metal centre, M′, shown in **1**, whereas in the π-acceptor model, electron density flows from M′ to a π^* orbital of the semibridging ligand, as in **2**.



1 2

Crabtree has classified the different semibridging carbonyl complexes into three different types[5] that can be distinguished by the kind of metal atom in the secondary metal centre. Type I complexes typically contain early transition metal atoms, type II complexes contain atoms from the middle of the series, and type III contain late transition or main group atoms. Theoretical studies have been performed on examples of type II and type III complexes and have suggested that the π-acceptor model, **2**, most accurately represents the bonding in these two types of complexes.[6–9] The bonding in type I complexes, however, has not been analysed theoretically, but is thought to follow the π-donor model.[5]

We report the electronic structures of the following two semibridging thiocarbonyl complexes: $[HB(pz)_3](CO)_2W(\mu\text{-}CS)Mo(CO)_2(In)^2$ (**3**: In = η^5-$C_9H_7^-$, indenyl; $HB(pz)_3^- = HB(N_2C_3H_3)_3^-$,

hydrotris(1-pyrazolyl)borate), and $[HB(pz)_3](CO)_2(CS)WAu(PPh_3)$[1] (**4**). We also examine the electronic structures of a type I semibridging carbonyl complex, $CpCo(\mu\text{-}CO)_2ZrCp_2$[10] (**5**: Cp = η^5-C_5H_5), and a type III semibridging carbonyl complex, $Cp(CO)_3WAu(PPh_3)$[11] (**6**). The In group has been abbreviated to a Cp group in **3** and the PPh_3 ligands represented as PH_3 ligands in **4** and **6** for simplicity.

METHODS

Unparameterized Fenske–Hall[12] molecular orbital (MO) calculations were performed on the Department of Chemistry's VAX 11/780 computer. The atomic positions were taken directly from the crystal data. The molecular symmetry of each complex was C_1. To reduce the size of the calculations, the In ligand was replaced by a Cp ligand in **3**, and the phenyl groups of the PPh_3 ligands in **4** and **6** were replaced by hydrogen atoms at a P—H distance of 1.42 Å.

The basis functions for all non-hydrogen atoms were generated by the numerical Xα atomic orbital program of Herman and Skillman[13] used in conjunction with the Xα-to-Slater basis program of Bursten and Fenske.[14] Ground-state atomic configurations were used for all non-transition metal atoms. The transition metal atoms assumed $d^{n+1}s^0$ cationic configurations. The exponents for the valence s and p orbitals of the transition metal atoms were determined by minimizing the energy difference between the valence eigenvalues obtained from molecular calculations and the experimental ionization potentials of $M(CO)_6$ and $M'(PF_3)_4$ (M = Cr, Mo, W; M′ = Ni, Pd, Pt). The numerical Xα-atomic orbitals were fit to double-ζ analytical Slater type orbitals for the valence d orbitals of the transition metal atoms and for the valence p orbitals of non-transition metal atoms. All other orbitals were represented as single-ζ functions. The orbital exponent for hydrogen was 1.20. The population analysis of Mulliken[15] was used in the calculations to determine gross and overlap populations, in addition to individual atomic charges.

RESULTS AND DISCUSSION

Figure 1 shows the results of a Fenske–Hall MO calculation on our model of **3**, where the results in the atomic basis have been transformed into the results of the molecular orbitals of the fragments, $CpMo(CO)_2^+$ (**3a**), and $W(CS)(CO)_2HB(pz)_3^-$ (**3b**). The molybdenum fragment is represented as a d^4 cationic species with 25 fragment molecular orbitals (FMOs) doubly occupied. The tungsten fragment is represented as a d^6 anionic species and FMO 58 is the doubly-occupied HOMO.

The Mulliken gross populations indicate that there is substantial interaction between FMOs 26 and 58, the LUMO of **3a** and the HOMO of **3b**, respectively. Nearly 0.9 e^- is transferred to the "electron-poor" (14 e^-) fragment, **3a**, from the "electron-rich" (16 e^-) fragment, **3b**, to form a dative metal–metal single bond. The contour plot in Fig. 2(b) illustrates how the CS π^* component of FMO 58 contributes to the overlap of the two fragment molecular orbitals in forming the M—M bonding MO 79. This type of interaction is a pervasive feature in heterobimetallic semibridging carbonyl complexes and has been discussed previously.[8,9]

The unusual interaction in Fig. 1 is between the CS π (bonding) orbital (FMO 55) and an unoccupied Mo d orbital (FMO 27). A significant amount of electron density flows from the CS π orbital into the vacant Mo orbital, while an almost

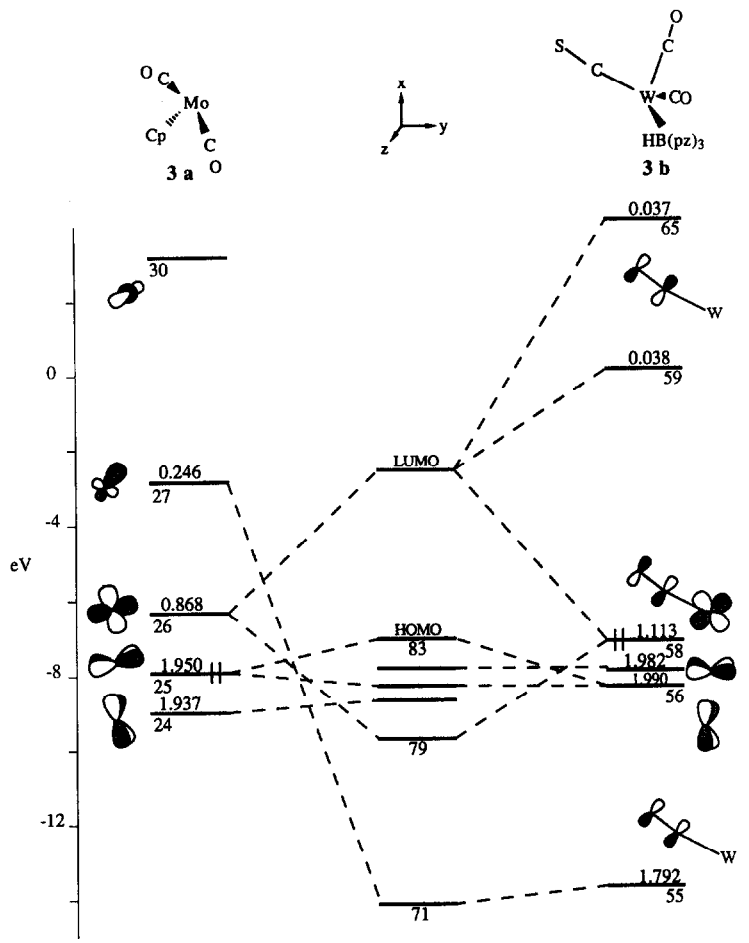

Fig. 1. Molecular orbital diagram of $[HB(pz)_3](CO)_2W(\mu\text{-}CS)Mo(CO)_2(Cp)$ constructed from $[HB(pz)_3](CO)_2W(\mu\text{-}CS)^-$ and $Mo(CO)_2(Cp)^+$ fragments. The principal components of the fragment molecular orbitals are drawn next to the corresponding energy levels. Significant Mulliken gross populations are listed with the fragment orbitals.

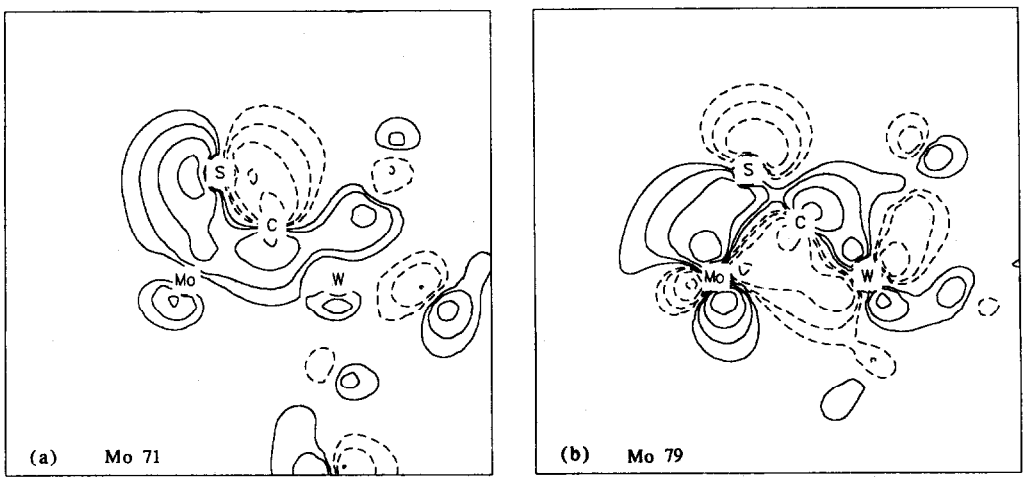

Fig. 2. Contour plots for selected valence orbitals of $[HB(pz)_3](CO)_2W(\mu\text{-}CS)Mo(CO)_2(Cp)$. Contours are geometric, differing by a factor of two, with the lowest contour of 0.01563 (e a.u.$^{-3}$)$^{1/2}$.

negligible amount flows from the occupied orbitals of **3a** back to the CS π^* orbital of **3b** (the π^* component is roughly equally distributed between FMOs 59 and 65). The CS ligand therefore acts as a π-donor. The contour plot, shown in Fig. 2(a), illustrates the importance of the S—Mo overlap in the interaction. To our knowledge, this is the first time that quantum chemical calculations have supported the four-electron donor model[17] for complexes with semibridging ligands.

To better understand the differences between CO and CS that give rise to the four-electron bonding mode in **3**, calculations were performed on the semibridging CO analogue of **3**. In these calculations, CO replaces the CS ligand and is positioned at sensible M—C and C—O distances (W—C distance = 1.954 Å; C—O distance = 1.167 Å). The results are shown in Fig. 3. The most obvious difference between the two calculations is that the CO π orbitals are more than 4 eV lower in energy than the corresponding CS π orbitals. Energetically, these CO orbitals are much less able to interact with the unoccupied Mo *d* orbital (FMO 27), and less density is transferred as a result.† Less density is also transferred back to the CO π orbital, reflecting the poorer π-accepting ability of CO compared to CS. The theory predicts that the CO analogue of **3** is less stable than **3** due to the reduced interaction between the semibridging ligand and the Mo fragment. This prediction is consistent with the experimental results: the CO analogue of **3** is stable in solution but decomposes in the solid state over a period of several hours.[2]

Since CS is a better π-acceptor as well as a better π-donor than CO,[3,4] some additional factor must influence whether the ligand donates electron density to, or accepts electron density from, the secondary metal centre. That the secondary metal centre is electron deficient is a tempting but incomplete answer. A previous report was devoted to describ-

† Notice that while the Mulliken gross population of the Mo FMO 27 is nearly 0.2 e^-, less than 0.1 e^- comes from the semibridging CO 1π orbital. The remainder of the density comes from the W FMO 58, which is allowed to mix due to the low symmetry of the complex.

ing how semibridging CO ligands readily accept electron density from electron-deficient metal centres.[9] The key difference is that the secondary metal centres described in that report are all late transition metal centres that are formally either d^8 or d^{10} species. The secondary metal atom in **3** is d^4 Mo, an early transition metal. The *d* functions of early transition metal atoms are more diffuse than those of later atoms of the series. Holes in the *d* shell are not only more prevalent for the early atoms in the transition series, but they are also more prominent in these atoms than they are in the late transition metal atoms where the higher nuclear charge pulls the *d* electrons closer to the nucleus. This contraction decreases the relative size of the holes. Early metals typically have larger holes in the *d* shell due to a combination of simply having fewer *d* electrons and holding these electrons in diffuse orbits. Therefore, they more readily accept density from semibridging ligands that are able to donate to help fill in the holes.

Substituting the electron-deficient, early transition metal fragment **3a** with an electron-deficient, late transition metal, $Au(PPh_3)$ (**4a**), yields $[HB(pz)_3](CO)_2(CS)WAu(PPh_3)$ (**4**).[1] One might expect that since there are no holes in the *d* shell on the Au fragment (represented as a d^{10} cationic species) the CS ligand would act as a π-acceptor and pick up density from one of the filled Au *d* orbitals. As the MO diagram in Fig. 4 shows, very little density flows into or out of the CS π orbitals. The principal interaction between the two fragments is between the HOMO of **4b** (FMO 58) and the LUMO of **4a** (FMO 9). Here we see the donation of a substantial amount of density from the former to the latter to form a dative M—M bond in MO 65. The only significant interaction that the CS ligand has with the Au fragment appears in MO 64, which is principally antibonding between a Au *d* orbital (FMO 9) and the CS carbon-centred σ lone pair orbital (FMO 55). Orbital 64 is stabilized by the Au sp_z hybrid (FMO 10) and a small amount of density flows from the CS ligand into the hybrid. The CS π^* orbital (FMO 59) gains only 0.077 e^- from the Au fragment, which is small compared to what has been found in some semibridging CO

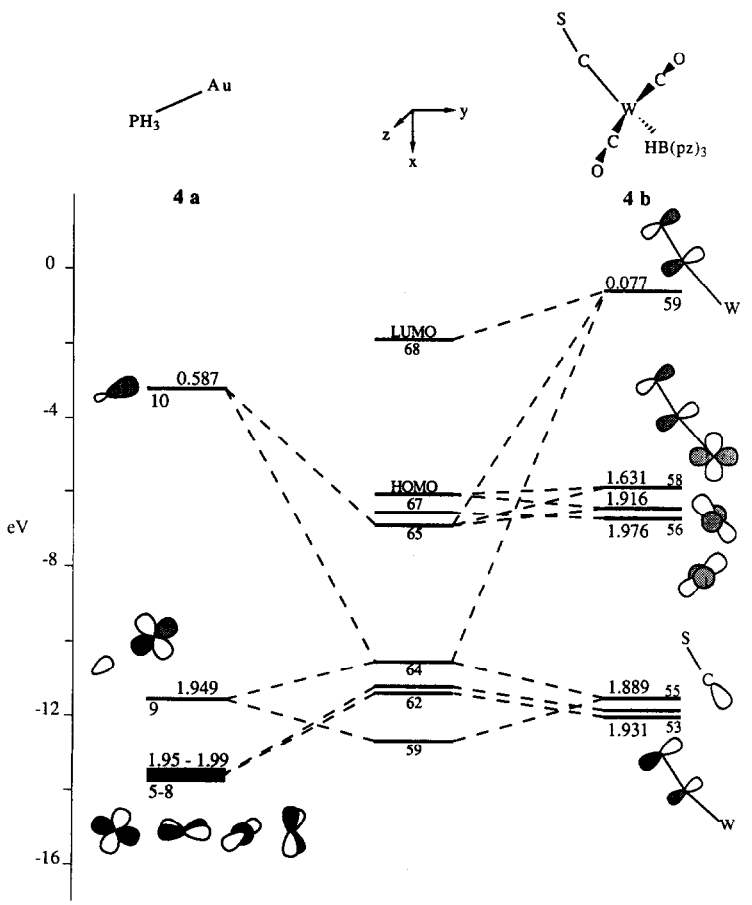

Fig. 4. Molecular orbital diagram of $[HB(pz)_3](CO)_2(CS)WAu(PH_3)$, constructed from $[HB(pz)_3](CO)_2(CS)W^-$ and $Au(PH_3)^+$ fragments.

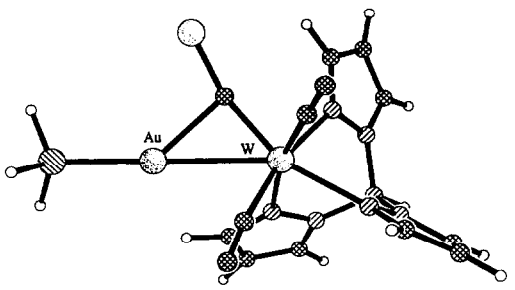
complexes,[9] especially considering that the CS ligand is a better π-acceptor than the CO ligand. One contributing factor might be that the long Au—W bond, at 2.825 Å, restricts the overlap between the Au d_{xy} and the CS π^* orbital, which is only 0.053.† Figure 5(a) indicates that the long bond may be due to steric interactions between the phenyl groups of PPh_3 and the $HB(pz)_3$ ligand. A smaller ligand in place of $HB(pz)_3$ might allow the M—M bond length to adjust to maximize the Au d_{xy}–CS π^* overlap and thereby allow more electron density to flow between them.

The semibridging CO analogue of **4** in which a Cp ligand replaces the $HB(pz)_3$ ligand coordinated to the W fragment, $Cp(CO)_3WAu(PPh_3)$[11] (**6**), is shown in Fig. 5(b). Comparing Figs 5(a) and (b) reveals that the steric interactions of the former are not present in the latter. While the Au—W bond length in **6** at 2.698 Å is shorter than that in **4**, the MO diagram in Fig. 6 suggests that no significant interaction exists between the Au fragment and the CO π orbitals. A contributing factor to this lack of interaction is the orientation of the phosphine ligand. That the Au—P axis in **6** is nearly linear to the Au—W axis hinders the interaction between the Au fragment and the CO π^* orbital for the following reason. The Au *d* orbital that is destabilized as a result of the ligand field splitting is the $d_{x^2-y^2}$, whereas the d_{xy} is the orbital that interacts with the semibridging CO ligand. Without this destabilization, the energy differerence between the d_{xy} and the CO π^* orbitals is too large to permit significant interaction.

This point is easily illustrated if we rotate the Au—P axis in **4** such that it is linear to the Au—W axis, shown in **7** and in Fig. 7. Comparison of the

† Typical values for metal *d*–semibridging CO overlap from previous calculations[8] are in the range of 0.1–0.2.



7

MO diagrams in Figs 4 and 7 show that the Au d_{xy} and $d_{x^2-y^2}$ orbitals switch positions as the ligand field changes. Note that the amount of electron density transferred in the dative M—M interaction increases as the phosphine group is rotated. The unoccupied Au sp_z hybrid (FMO 10) is directed along the M—M axis in **7** which increases the overlap with the W FMOs 58 and 57 (10–57 + 10–58 overlap = 0.379 in **4** and 0.431 in **7**) and allows for the greater transfer of charge. The bottom line concerning the bonding in **4** and **6** is that there is a minimal interaction between the secondary metal centre and the semibridging ligand. The lack of holes in the *d* shell precludes any π-donation from the semibridging ligand. A combination of factors prevents back donation to the semibridging ligand's π^* orbital to the extent that has been found for other, similar complexes.[9]

The final complex we wish to discuss is $CpCo(\mu\text{-}CO)_2ZrCp_2$[10] (**5**), a so-called type I semibridging carbonyl complex[5] in which the semibridging ligand is thought to act as a four-electron donor. The theoretical support for the four-electron donor model in the semibridging thiocarbonyl complex, **3**, raised our interest in whether theory would support this model in a known semibridging carbonyl complex involving an early metal centre. As in **3**, the secondary metal centre in **5** is an electron-deficient,

early transition metal atom. The results of the MO calculation are shown in Fig. 8. Both fragments are represented as closed-shell neutral species, where the d^2, 14 e^- Zr fragment as well as the d^8, 18 e^- Co fragment have 27 doubly-occupied orbitals prior to interaction. The most noteworthy interaction is that seen in MO 23 between Co FMO 13, the linear semibridging carbonyl π orbital, and Zr FMO 29, an unoccupied Zr d orbital. The Mulliken gross populations indicate that the CO π orbital donates roughly 0.1 e^- to a combination of unoccupied Zr d orbitals, FMOs 28 and 29. Despite the large energy gap between the interacting fragments, the diffuse d orbitals of the early transition metal Zr provide sufficient overlap with the CO π orbitals to yield significant interaction, as shown in the contour plot of Fig. 9(a). The semibridging CO ligand clearly acts as an electron donor to the secondary metal centre.

Note, however, that a significant, though not large, quantity of density is transferred back to the semibridging ligand's π^* orbital (FMO 32) from an occupied Zr orbital (FMO 27) in MO 53. Not only does the semibridging CO ligand donate electron density to the Zr fragment to help fill in holes in the d shell, but it also acts as an acceptor of density to a limited extent even with this very early metal.

Other features of the bonding in **5** that are worthy of note include the role of the symmetrically-bridging CO ligand. The 5σ orbital (FMO 21) donates a large amount of density (0.21 e^-) to one of the unoccupied Zr d orbitals. The contour plot of MO 43, shown in Fig. 9(b), shows how the CO σ (C lone pair) contributes to the Co—Zr σ overlap. The M—M bonding interaction in MO 50 is cancelled by the corresponding antibonding interaction in MO 53. The antibonding MO, however, gains significant stabilization from the symmetrically bridging ligand's π orbital (FMO 28) and as a result forms a three-centre, two-electron bond, shown in Fig. 9(c). This type of interaction has been discussed previously in detail.[8]

CONCLUSION

Theoretical support for the four-electron donor model of semibridging carbonyl and thiocarbonyl ligands has been presented. These linear semibridging ligands will act as four-electron donors only when the secondary metal centre is electron deficient and contains an early transition metal atom. The role of the semibridging ligand in this case is to help fill the large holes that are present in the *d* shell of the metal centre. Such holes are not only more prevalent in early transition metal centres, but are also more prominent than holes in the *d* shell of late transition metal centres where a higher nuclear charge contracts the orbits of the electrons and effectively reduces the size of the holes. Late transition metal centres are therefore more content to have fewer than 18 electrons in the valence shell and more readily form stable 14- and 16-electrons species. When secondary metal centres have fewer than 18 electrons and contain a late transition metal atom, the predominant role for the semibridging ligand is to function as a π-acceptor.

THE SYNTHESES, MOLECULAR AND ELECTRONIC STRUCTURES OF TWO μ^4-VINYLIDENE TETRAIRON CLUSTERS*

JOHN S. BRADLEY,† SUZANNE HARRIS,† ERNESTINE W. HILL and MICHELLE A. MODRICK

Exxon Research and Engineering Company, Route 22 East, Clinton Township, Annandale, NJ 08801, U.S.A.

Abstract—The syntheses, crystal structures and electronic structures of the new μ^4-vinylidene clusters, $Fe_4(CO)_{12}(C{=}C(OCH_3)_2)$ and $Fe_4(CO)_{12}(C{=}C(OCH_3)CH_3)$, are reported. $Fe_4(CO)_{12}(C{=}C(OCH_3)_2)$ was prepared by the methylation of $[Fe_4(CO)_{12}(CCO_2CH_3)]^-$ with trimethyloxonium fluoroborate in methylene chloride at 25°C. $Fe_4(CO)_{12}(C{=}C(OCH_3)CH_3)$ was prepared in an analogous manner from $[Fe_4(CO)_{12}(CC(O)CH_3)]^-$. $Fe_4(CO)_{12}(C{=}C(OCH_3)_2)$ crystallizes in the monoclinic space group $P2_1/c$ (C_{2h}^5 No. 14) with $a = 13.900(2)$, $b = 8.909(2)$, $c = 17.116(4)$ Å, $\beta = 94.59(2)°$; $\rho_{calc} = 2.03$ g cm^{-3} for mol. wt 645.6 and $Z = 4$. $Fe_4(CO)_{12}(C{=}C(OCH_3)CH_3)$ crystallizes in the monoclinic space group $P2_1/c$ (C_{2h}^5 No. 14) with $a = 28.441(6)$, $b = 9.204(2)$, $c = 17.466(4)$ Å, $\beta = 108.51(2)°$; $\rho_{calc} = 1.93$ g cm^{-3} for mol. wt = 629.6 and $Z = 8$. Both clusters have an open butterfly core of four iron atoms with the vinylidene ligand bound to all four metal atoms. Molecular orbital calculations using the Fenske–Hall method were carried out for the two clusters. The molecular and electronic structures of the molecules are compared with each other and with those of μ^4-methylidyne clusters. Although both of these clusters contain a formal C—C double bond in the vinylidene ligand, the presence of oxygen atoms in these ligands leads to a delocalized π system and only partial double bond character in this C—C bond. Changes in the structure of the cluster framework can be correlated with the oxygen content and thus double bond character in the vinylidene ligand.

The chemistry of transition metal clusters with an open butterfly geometry, bearing a μ^4-carbide ligand, and of their μ^4-methylidyne analogues, is of continuing interest. These compounds exhibit unique chemistry by virtue of the geometry of the binding site of the carbon ligand atom.[1] This family of molecules also has an additional attraction in that it may provide structural parallels to the chemisorbed state of organic molecules in four-fold sites on metal surfaces, parallels not provided by the higher symmetry molecular clusters most often found in organometallic cluster chemistry.

Some homometallic tetrairon clusters of this type which have been characterized by X-ray diffraction are shown in the Scheme 1. $Fe_4(CO)_{13}C$ (**1**),[2] $[Fe_4(CO)_{12}C]^{2-}$ (**2**)[3] and $[HFe_4(CO)_{12}C]^-$ (**3**)[4] all contain a μ^4-carbide ligand. $HFe_4(CO)_{12}CH$ (**4**)[5] is derived from **2** or **3** by protonation,[4,6] from **2** by oxidation under hydrogen,[6] or from **1** by treatment with hydrogen.[7] $[Fe_4(CO)_{12}(CCO_2CH_3)]^-$ (**5**) is derived from **1** by reaction with methanol,[2] and $[Fe_4(CO)_{12}(CC(O)CH_3)]^-$ (**6**) results from the reaction of methyl iodide with **2**.[3] The corresponding dianion of **6**, which has a similar structure, has also been reported.[8] $HFe_4(CO)_{12}(COCH_3)$ (**7**) is derived from the non-carbide cluster $[Fe_4(CO)_{12}]^{2-}$ by sequential methylation and protonation.[4] We have extended the range of μ^4-organic ligands in this cluster group by preparing two new μ^4-vinylidene clusters, $Fe_4(CO)_{12}(C{=}C(OCH_3)_2)$ (**8**) and $Fe_4(CO)_{12}(C{=}C(OCH_3)CH_3)$ (**9**) [eq. (1)].

Scheme 1.

In this paper we describe the synthesis and crystal structures of these clusters and compare the geometries and electronic structures of the molecules with each other and with those of μ^4-methylidyne clusters. A brief report of the preparation of **8** and **9** and the structure of **8** has appeared previously.[7]

EXPERIMENTAL

(1) *Syntheses*

All preparative procedures were performed in standard Schlenk glassware on a double manifold vacuum–nitrogen line. $Fe_4(CO)_{12}(C{=}C(OCH_3)_2)$ (**8**) was prepared by the methylation of $[Fe_4(CO)_{12}(CCO_2CH_3)]^-$ (**5**) with trimethyloxonium fluoroborate in methylene chloride at 25°C. $Fe_4(CO)_{12}(C{=}C(OCH_3)CH_3)$ (**9**) was prepared in an analogous manner from $[Fe_4(CO)_{12}(CC(O)CH_3)]^-$ (**6**). The starting materials for **8** and **9** were prepared by published procedures.[9]

$Fe_4(CO)_{12}(C{=}C(OCH_3)_2)$ (**8**). To a solution of $(C_2H_5)_4N[Fe_4(CO)_{12}(CCO_2CH_3)]$ (**5**) (1.50 g, 1.95 mmol) in methylene chloride (100 cm^3) was added trimethyloxonium tetrafluoroborate (0.291 g, 1.95 mmol) and the green–black mixture was stirred for 24 h. During this time the solution became a paler green, and the IR absorbances of the starting material were replaced by new bands at 2080, 2040, 2010, 1992 and 1950 cm^{-1}. The reaction mixture was evaporated to dryness under reduced pressure, and the residue extracted into boiling hexane (4 × 50 cm^3). The product, **8**, crystallizes on cooling the filtrate to room temperature. A second crop may be obtained by cooling the filtrate to −40°C. Combined yield of **8** = 0.800 g (1.24 mmol, 64%). Found: C, 29.19; H, 1.02; Fe, 33.79. Calc. for $C_{16}H_6O_{14}Fe_4$: C, 29.77; H, 0.94; Fe, 34.69%. IR (CH_2Cl_2): 2080, 2040, 2010, 1992, 1950 cm^{-1}. ^1H NMR (60 MHz, CD_2Cl_2, 25°C): 3.70 δ (OCH_3).

$Fe_4(CO)_{12}(C{=}C(OCH_3)CH_3)$ (**9**). To a solution of $(C_2H_5)_4N[Fe_4(CO)_{12}(CC(O)CH_3)]$ (5.0 g, 6.7 mmol) in methylene chloride (350 cm^3) was added trimethyloxonium tetrafluoroborate (1.0 g, 6.7 mmol) in an identical manner to the preparation of **8**. The colour of the solution changed from dark green to red–brown, and the progress of the reaction was monitored by the replacement of the IR absorbances of the starting material with those of the vinylidene product. After completion of the methylation reaction the solution was filtered and evaporated to dryness. Extraction into hexane followed by cooling to −50°C yielded black crystals of **9** (3.0 g, 4.8 mmol, 71%). Found: C, 30.40; H, 0.95; Fe, 35.12. Calc. for $C_{15}H_6O_{12}Fe_4$: C, 30.52; H, 0.96; Fe, 35.48%. ^1H NMR (60 MHz, CD_2Cl_2, 25°C): 2.21 δ ($=CCH_3$), 3.78 δ ($=COCH_3$).

(2) *X-ray crystallography*

The crystal structure of **8** was determined in the Analytical Sciences Laboratory, Exxon Research and Engineering Company. The crystal structure of **9** was determined at Crystalitics Inc., Lincoln, Nebraska.

The structure of $Fe_4(CO)_{12}(C{=}C(OCH_3)_2)$ (**8**). Crystals of **8** were grown from hexane at −40°C. Data were collected on an approximately cubic crystal, 0.44 mm on an edge, sealed under nitrogen in a glass capillary, on an Enraf–Nonius CAD-4 diffractometer using Mo-K_α radiation (λ = 0.7107 Å). The cluster crystallizes in the monoclinic space group $P2_1/c$ (C_{2h}^5 No. 14) with a = 13.900(2), b = 8.909(2), c = 17.116(4) Å, β = 94.59(2)°; ρ_{calc} = 2.03 g cm^{-3} for mol. wt 645.6 and Z = 4. Of 3696 reflections examined (scan range $0 < 2\theta < 50°$, ω–2θ scans, 2–7° min^{-1}), 1528 with $I > 2\sigma I$ were used in structure solution, using a combination of direct methods (MULTAN) and Fourier techniques, and refinement by full-matrix least-squares. No decay in intensity of three check reflections was observed during data collection. Data were corrected for absorption (μ = 27.6 cm^{-1}, psi scan, max/min 0.83–1.00) and for Lorentz and polarization factors. All non-hydrogen atoms were refined with anisotropic thermal parameters. Least-squares refinement converged to final residuals of R_1 = 0.054, R_2 = 0.044.[10] Interatomic distances and bond angles are given in Tables 1 and 2, respectively. The atom numbering scheme is shown in the ORTEP drawing of the molecule, Fig. 1, in which thermal ellipsoids are drawn to include 30% of the electron density.

The structure of $Fe_4(CO)_{12}(C{=}C(OCH_3)CH_3)$ (**9**). Crystals of **9** were grown from hexane at −40°C. Data were collected on a crystal measuring 0.42 × 0.42 × 0.70 mm, sealed under nitrogen in a glass capillary, on a four circle Nicolet Autodiffractometer. The molecule crystallizes in the monoclinic space group $P2_1/c$ (C_{2h}^5 No. 14) with a = 28.441(6), b = 9.204(2), c = 17.466(4) Å, β = 108.51(2)°; ρ_{calc} = 1.93 g cm^{-3} for mol. wt = 629.6 and Z = 8. The intensities of six check reflections were monitored over the period of data collection and no decay was observed. Of 5951 independent reflections collected ($0 < 2\theta < 45°$) 3364 with $I > 3\sigma(I)$ were used in the structure solution (SHELXTL direct methods) and refinement (cascade block-diagonal least-squares). Non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were not located. Least-

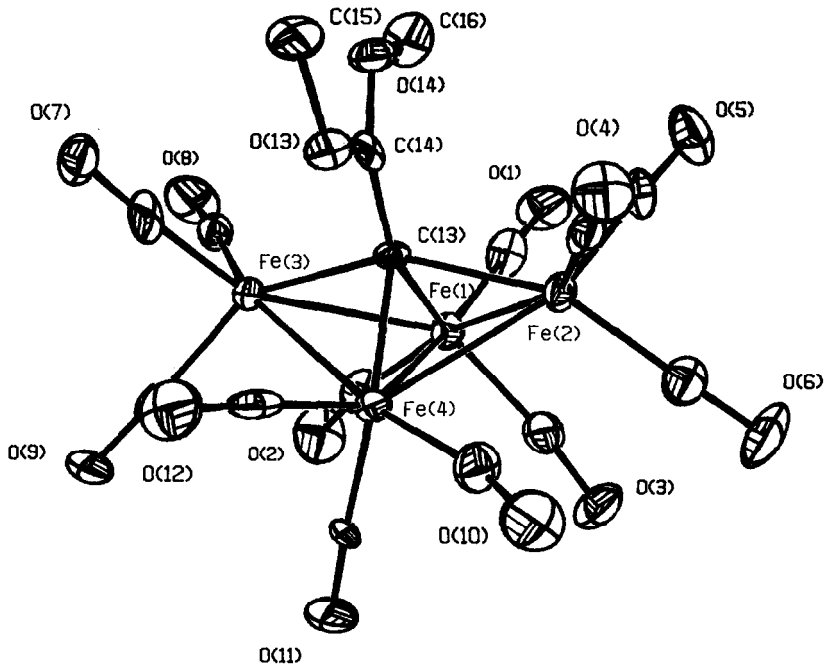

Fig. 1. ORTEP drawing of $Fe_4(CO)_{12}(C{=}C(OCH_3)_2)$ (**8**) showing 30% probability thermal ellipsoids. Only oxygen atoms for the carbonyls are numbered, and these define the carbon atom numbering scheme.

stallographically independent molecules of **9** present in the crystal are listed in Tables 1 and 2. The atom numbering scheme used is shown in the ORTEP drawing of one of the two molecules (Fig. 2), in which thermal vibration ellipsoids are drawn to include 30% of the electron density.

(3) *Molecular orbital calculations*

Molecular orbital calculations using the Fenske–Hall method[12] were carried out for **8** and **9**. Calculations for **2**, **5** and **6** have been reported previously,[13,14] and the results of those calculations

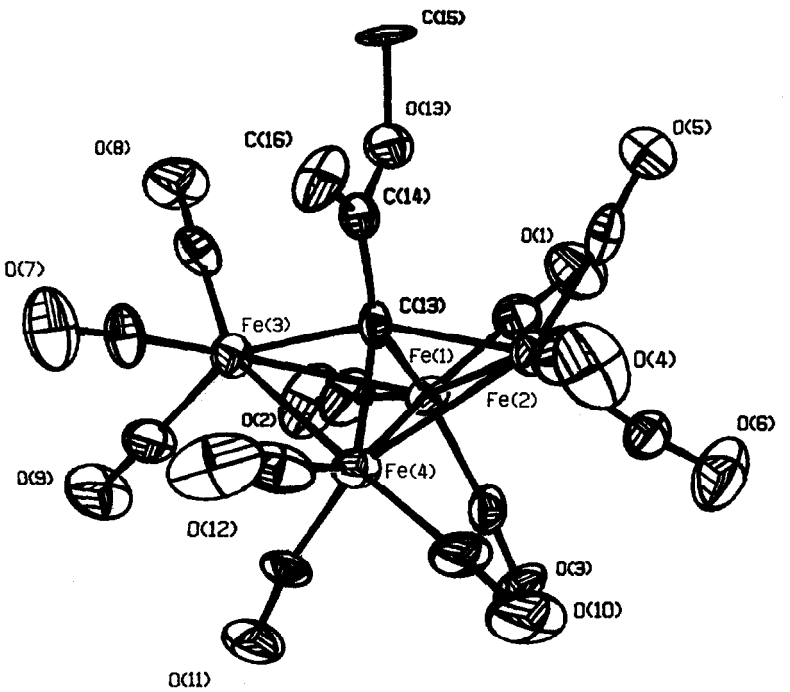

Fig. 2. ORTEP drawing of $Fe_4(CO)_{12}(C{=}C(OCH_3)CH_3)$ (**9**) showing 30% probability thermal ellipsoids.

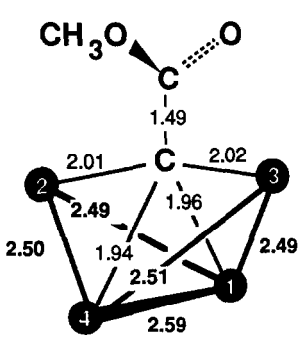
are used for comparison here. Atomic positions used in the calculations for **8** and **9** were taken from the crystal structures reported here. The 1*s* through 3*d* functions for iron were taken from Richardson *et al.*,[15] while the 4*s* and 4*p* functions were chosen to have exponents of 2.0. The carbon and oxygen functions were taken from the double-ζ functions of Clementi.[16] The valence 2*p* functions were retained as the double-ζ functions, while the 1*s* and 2*s* functions were reduced to the single-ζ form. An exponent of 1.2 was used for hydrogen. In all of the calculations the local coordinate system on the vinylidene carbon was oriented with the *x*-axis parallel to a line connecting the two hinge iron atoms, Fe_1 and Fe_4, the *y*-axis parallel to a line connecting the two wingtip iron atoms, Fe_2 and Fe_3, and the *z* axis pointing out of the cluster.

RESULTS AND DISCUSSION

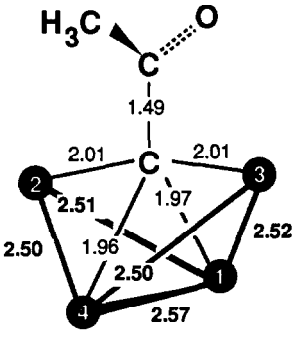
Structural parameters for **8** and **9** are listed in Tables 1 and 2. In making comparisons between the clusters we will use for **9** structural parameters which are the mean of those found for the two crystallographically independent molecules in the unit cell. The structures of the vinylidene clusters **8** and **9** are nominally similar in that the four iron atoms are arranged in an open butterfly configuration, each bearing three essentially linear terminal carbonyl ligands coordinated in the usual mutually orthogonal fashion to the iron atoms. The two clusters are also similar in that in each a vinylidene ligand $\rangle C{=}C(R_1)(R_2)$ is bonded in a μ^4-fashion through the vinylidene carbon to the four iron atoms which make up the core of the butterfly clusters.

Examination of the geometries of the Fe_4 units in the two clusters reveals subtle but significant differences between them. These differences can be most easily expressed by comparing the cluster structures of **8** and **9** with the structures of their anionic precursors **5** and **6**[14] (see Fig. 3). The dihedral angles between the wings of the butterfly in **8** (127°) and **9** (122°) are slightly smaller



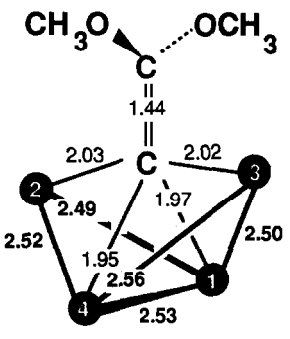
Dihedral = 130°

5



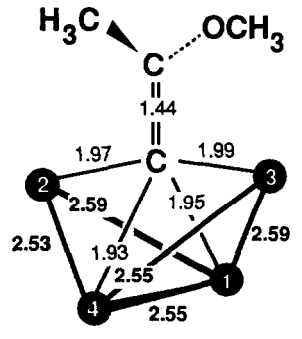
Dihedral = 128°

6



Dihedral = 127°

8



Dihedral = 122°

9

Fig. 3. Comparison of the structures of $Fe_4(CO)_{12}(C{=}C(OCH_3)_2)$ (**8**) and $Fe_4(CO)_{12}(C{=}C(OCH_3)CH_3)$ (**9**) with the structures of their precursors $[Fe_4(CO)_{12}(CCO_2CH_3)]^-$ (**5**) and $[Fe_4(CO)_{12}(CC(O)CH_3)]^-$ (**6**).

than those in **5** (130°) and **6** (128°). The two vinylidene clusters also differ slightly in their Fe—Fe bond lengths; for **8** the Fe(1)—Fe(2,3) and Fe(4)—Fe(2,3) distances are 2.50 and 2.55 Å (compared with 2.51 ± 0.01 Å for **5**), and for **9**, 2.59 and 2.54 Å (compared with 2.50 ± 0.01 Å for **6**). These differences are also reflected in the Fe—C(13) distances: for **8** the Fe(2,3)—C(13) distances are 2.02 ± 0.01 Å (2.01 Å in **5**) and the Fe(1,4)—C(13) distances are 1.96 Å (1.95 Å in **5**); for **9** the corresponding distances are 1.98 and 1.93 Å (2.01 and 1.96 Å for **6**). Finally, these differences can also be expressed in terms of the Fe(2)C(13)Fe(3) angles in the vinylidene clusters. In **8** and **9** the angles are 149.5° (147.9° in **5**) and 157.7° (148.6° in **6**). In short, while the geometry of **8** shows only small changes from the geometry of **5**, somewhat larger changes in geometry are observed in **9** in comparison with **6**. Most noticeable is the closing up of the Fe_4 butterfly framework which is observed in **9**. It should also be noted that the C(13)—C(14) distance in both **8** and **9** is 1.44 Å (compared to 1.49 Å in both **5** and **6**). The small change in this bond length between the methylidyne and vinylidene clusters is somewhat surprising, since the C(13)—C(14) bond in both **8** and **9** can be viewed formally as a double bond, while in both **5** and **6** this bond is viewed as a single bond. Examination of the structures of **8** and **9** also reveals substantial reorientations of the $Fe(CO)_3$ groups in both of these clusters. These reorientations, which can be viewed as rotations of the $(CO)_3$ groups, result in much less symmetric dispositions of the CO groups than are found in **5** and **6**.

In order to understand these changes in structure it is useful to compare the electronic, as well as the molecular structures, of these clusters with the same features of other members of the iron butterfly group of clusters. We have previously shown how the structures of carbido clusters such as **1**, **2** and **3**, which contain a μ^4-carbon atom, and those of methylidyne clusters such as **5** and **6**, which contain a μ^4-methylidyne ligand, reflect the electronic structures of both the $Fe_4(CO)_{12}$ core and the carbido carbon atom or methylidyne group.[13,14] In order to make an instructive comparison between all three classes of cluster, it is useful to review briefly the relationship between the electronic and geometric structures of the μ^4-carbon and μ^4-methylidyne clusters. In the μ^4-carbon clusters, **1**, **2** and **3**, the cluster geometry optimizes the interactions between the carbido carbon atom and the four iron atoms. The important Fe—C interactions are shown in Fig. 4. The near colinearity of the two wingtip iron atoms (Fe_w) and the μ^4-carbon atom leads to very strong C—Fe_w interactions. These include a σ overlap involving the C $2p_y$ orbital [Fig. 4(a)], and π overlaps involving the C $2p_x$ and $2p_z$ orbitals [Fig. 4(b,c)]. The C $2p_y$ orbital does not overlap with the hinge iron atoms (Fe_h), but both the p_x and p_z orbitals form σ bonds with the hinge iron atoms [Fig. 4(b,c)].

The geometries of the methylidyne clusters, **5** and **6**, reflect the formation of the C—C σ bond between

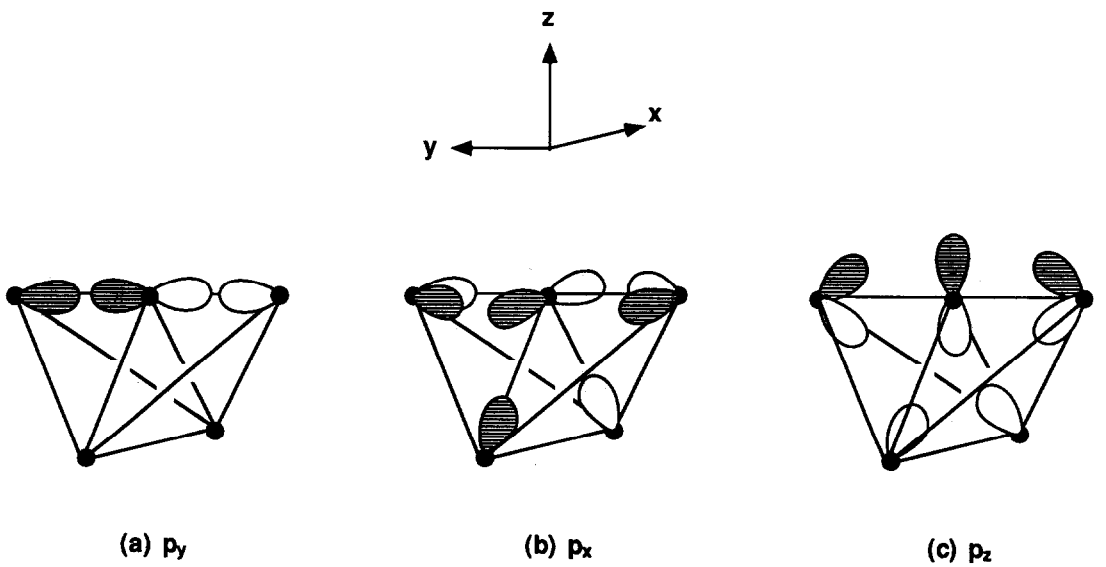


Fig. 4. Schematic representations of the bonding interactions between the carbido C p_y (a), p_x (b) and p_z (c) orbitals and the iron framework orbitals in $[Fe_4(CO)_{12}C]^{2-}$ (ref. 13). The local coordinate system on the carbon atom is defined as shown.

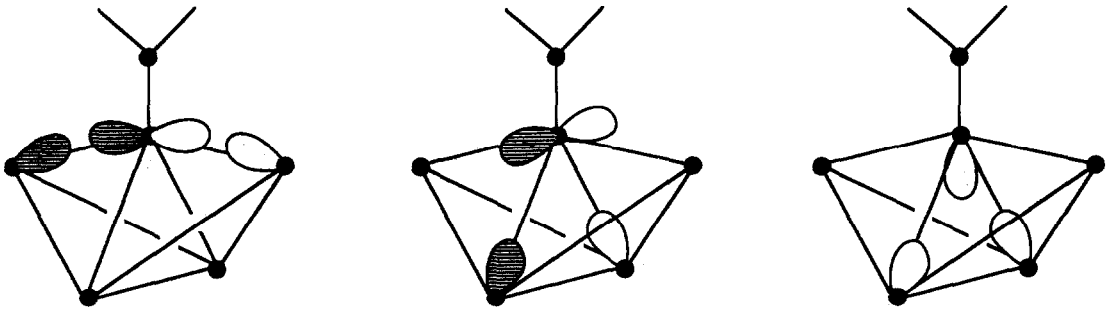
the μ^4-carbon atom and the carbomethoxy and acetyl groups.[14] The bond formation is accompanied by a folding back of the wings of the butterfly (the dihedral angle increases from 102 ± 2 to $129\pm1°$), a lengthening of the C—Fe_w distances (from 1.79 ± 0.01 to 2.02 ± 0.01 Å) and a shortening of the Fe_h—Fe_w distances (from 2.63 ± 0.01 to 2.51 ± 0.02 Å). In these derivatized clusters nearly all of the π bonding between the carbon atom and the wingtip iron atoms is lost and the σ bond between the carbon atom and the wingtip iron atoms is considerably weakened. This is illustrated in Fig. 5. The C $2p_z$ orbital, hybridized with the C $2s$ orbital, is used in bonding to the adjacent carbon atom. This leaves a C *sp* lone pair type orbital to bond with the hinge iron atoms [Fig. 5(c)], but no orbital for π bonding with the wingtip iron atoms. The C $2p_x$ orbital is unaffected by the formation of the C—C bond, but the much longer C—Fe_w distance results in the loss of most of the π bonding with the wingtip iron atoms. Finally, the σ bond between the C p_y orbital and the wingtip iron atoms is also weakened as a result of the longer C—Fe_w distance. The loss of bonding between the carbon atom and the Fe_w is compensated by the strengthening of the Fe_w—Fe_h bonds. At the same time, the C $2p_y$ orbital is somewhat stabilized by bonding to the adjacent carbon atom. Since the carbomethoxy and acetyl carbonyl groups in **5** and **6** lie in the xz plane, this allows the development of a small amount of double bond character between the methylidyne carbon and the adjacent sp^2 carbon.

In the methyilidyne clusters, **5** and **6**, the C—C bond can be viewed formally as a single bond. In the vinylidene clusters, **8** and **9**, on the other hand, the C—C bond can be viewed formally as a double bond, and we might expect both the interaction between the vinylidene group and the $Fe_4(CO)_{12}$ cluster core and the resulting cluster geometry itself to be somewhat different in **8** and **9** from that found in **5** and **6**. Instead, with only the small variations noted above, the cluster framework geometries of the vinylidene clusters **8** and **9** resemble those of their precursors **5** and **6**. The results of Fenske–Hall electronic structure calculations for the vinylidene clusters show that it is in fact not appropriate to view these ligands as having a localized double bond between the two carbons. At most, the C(13)—C(14) bond in these ligands is intermediate between single and double bond in character, and the small differences in geometry reflect the gradual appearance of partial double bond character in this C—C bond. The degree to which this occurs depends on the substituents on the vinyl carbon atom, C(14).

In the methylidyne clusters, **5** and **6**, the interaction between the methylidyne C $2p_y$ orbital and the cluster framework is illustrated as the interaction between a lone pair $2p_y$ orbital and the cluster framework [Fig. 5(a)]. That this is an appropriate picture can be seen by viewing the bonding in the methylidyne clusters in terms of the $Fe_4(CO)_{12}$ framework and the CC(O)R ($R = OCH_3$, CH_3) fragment. The CC(O)R fragment orbital which interacts with the wingtip metal framework orbitals is localized primarily on the methylidyne carbon and is C $2p_y$ in character. This is illustrated in Fig. 6(a) and (b), where schematic diagrams of this fragment molecular orbital (m.o.) in $[—CC(O)OCH_3]^-$ (6a) and $[—CC(O)CH_3]^-$ (6b) are shown. The coefficients of the atomic orbitals in each fragment molecular orbital are also indicated in Fig. 6. The methylidyne carbon $2p_y$ orbital makes a small contribution to two other lower lying



(a) (b) (c)

Fig. 5. Schematic representations of the bonding interactions between the μ^4-methylidyne carbon orbitals and the iron framework orbitals in the methylidyne clusters $[Fe_4(CO)_{12}(CCO_2CH_3)]^-$ (**5**) and $[Fe_4(CO)_{12}(CC(O)CH_3)]^-$ (**6**) (ref. 14). The coordinate system on the carbon atom is defined as in Fig. 4.

fragment π orbitals, but these lower lying orbitals are primarily localized on the oxygen end of the fragment and are bonding between oxygen and the sp^2-carbon. It is the π lone pair type orbital shown in Fig. 6(a) and (b) which participates in the bonding interaction shown in Fig. 5(a).

If the vinylidene fragments in clusters **8** and **9** actually incorporated a C—C double bond, we might expect the interaction between the vinylidene carbon and the wingtip iron atoms to be somewhat different from that shown in Fig. 5(a). A localized double bond between the two adjacent carbon atoms would preclude the presence of a C p_y non-bonding orbital. Instead, we would expect to observe an orbital with contributions from the p_y orbitals of both carbon atoms and a concentration of electron density in a region between the two carbons. This is not observed in the two vinylidene fragments, $—CC(OCH_3)_2$ and $—CC(OCH_3)CH_3$. Instead, the bonding within these two fragments more closely resembles the bonding in the methylidyne fragments in **5** and **6** described above. Both fragments have an orbital which is primarily C $2p_y$ in character [Fig. 6(c) and (d)], and once again it is this fragment orbital which participates in the cluster bonding interaction illustrated in Fig. 5(a). It is notable that this orbital is more localized on the vinylidene carbon in $—CC(OCH_3)_2$ than in $—CC(OCH_3)CH_3$, and we will discuss this difference below. In each fragment the vinylidene C $2p_y$ orbital also makes a smaller contribution to one or more lower energy π orbitals, but these lower energy orbitals are primarily bonding between the oxygen(s) and the sp^2 hybridized carbon.

When the electronic structure of the ligands is viewed in this light, we can understand the observed similarities and small differences in cluster geometry. As described above and illustrated in Fig. 5, the formation of a C—C bond in the methylidyne clusters **5** and **6** leads to the loss of nearly all C—Fe_w π bonding, so that the only remaining strong C—Fe_w interaction involves the non-bonding π type orbital localized on the methylidyne carbon atom [Fig. 5(a)]. In the vinylidene cluster **8**, bonding between the vinylidene group and the $Fe_4(CO)_{12}$ cluster is almost identical to that observed in clusters **5** and **6**. That is, the π lone pair orbital illustrated in Fig. 6(c) interacts with the metal framework in the manner illustrated in Fig. 5(a). This bonding mode and the consequent structure indicates that in **8** it is appropriate to view the C—C bond in the "vinylidene" ligand $—CC(OCH_3)_2$ as closer to a single bond than a double bond. In the vinylidene cluster **9** the interaction between the vinylidene group and the metal framework still resembles the interaction shown in Fig. 5(a), but, as shown in Fig. 6(d), the vinylidene π orbital involved in this interaction is not as strongly localized on the vinylidene carbon in **9** as it is in **8**. That is, we see a small shift in electron density away from the vinylidene carbon atom. The smaller dihedral angle in **9** can be correlated to the change in charac-

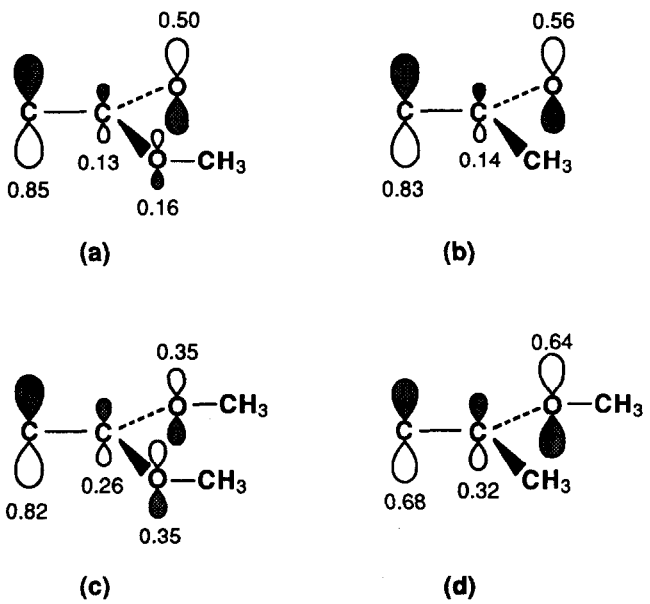


Fig. 6. Schematic representations of the orbitals on the methylidyne and vinylidene fragments, (a) $[CC(O)OCH_3]^-$, (b) $[CC(O)CH_3]^-$, (c) $CC(OCH_3)_2$ and (d) $CC(OCH_3)CH_3$, which interact with the wingtip iron atoms in each of the corresponding clusters. The coefficients of the atomic orbitals are indicated in each diagram.

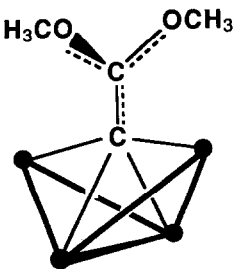
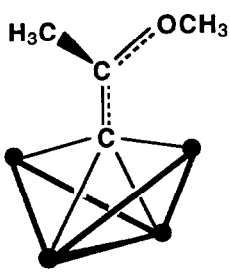
ter of this vinylidene orbital. Since the only interaction between the wingtip iron atoms and the vinylidene carbon atom requires the participation of the electrons which occupy this orbital, the metal framework of the cluster closes up around the vinylidene group in order to gain access to these electrons. Both the character of the vinylidene π orbital and the cluster geometry itself suggest that in **9** it is appropriate to view the C—C bond in the "vinylidene" ligand —$CC(OCH_3)(CH_3)$ as something intermediate between a single and a double bond.

It follows from these observations that in a vinylidene cluster containing a truly localized double bond an even smaller dihedral angle would be expected. Since the electrons needed for bonding between the vinylidene ligand and the wingtip iron atoms would now be localized between the two carbon atoms, it would be necessary for the metal framework of the cluster to close up even further than in **8** and **9** in order to gain access to these electrons. An example of a butterfly cluster containing a localized vinylidene ligand is found in $Fe_4(CO)_{12}(C{=}CHCH_3)$, which has also been synthesized in this laboratory. The structure of this cluster, which will be reported in a subsequent paper, demonstrates precisely this phenomenon.[17] The dihedral angle in this cluster is 104°. It is interesting to note that the analogous cluster $HFe_4(CO)_{12}(CBH_2)$, recently reported by Fehlner and co-workers[18] which should have a similar electronic structure, has a dihedral angle of 105°.

Appropriate depictions of clusters **8** and **9** are shown below. As discussed above the C—C double bond character in the vinylidene ligands is greater in **9** than in **8**. This increase in double bond character is accompanied by a shortening of the Fe—C bonds and a decrease in the dihedral angle between the two wings of the butterfly as shown in Fig. 3. This double bond character can be directly related to the number of oxygen atoms in the vinylidene group, since as the number of oxygen atoms decreases, the number of electrons available to participate in the π framework of the vinylidene group decreases, and



8



9

the C(13)—C(14) double bond character increases. The small amount of double bond character in the C(13)—C(14) bond is consistent with the relatively slight shortening of this bond which is observed in going from **5** or **6** to **8** or **9**. At the same time, we might have expected this bond to be shorter in **9** than in **8**. We must remember, however, that in the cluster, electrons which in the vinylidene fragment would occupy only the fragment orbital illustrated in Fig. 6(d) now occupy a delocalized cluster orbital which incorporates contributions from both that fragment orbital and the wingtip iron atoms. This delocalization of the electrons onto the metal cluster, which decreases any localized electron density between the two carbon atoms, is consistent with the absence of any shortening of the C—C bond.

Detailed comparisons between the CO coordination geometries in the pairs of molecules **5** and **8**, **6** and **9**, and **8** and **9** reveal marked distortions in the relative orientations of all four of the $Fe(CO)_3$ groups in **8** and **9**. For example, in going from **5** to **8** the two hinge $Fe(CO)_3$ groups rotate with respect to each other by $\sim 60°$, going from an almost perfectly eclipsed configuration to a staggered configuration. A similar relative rotation has been observed in the structure of the dianion of the acetylmethylidyne cluster **6**.[8] In **8** and **9**, rotations of the wingtip $(CO)_3$ groups are also observed. Just as for the dianion of **6**, the results of the molecular orbital calculations for **8** and **9** reveal no ready electronic explanation for these changes in CO orientation, and the reorientation of the $(CO)_3$ groups in **8** and **9** appears to be dictated by steric effects. Although we cannot give a full explanation of the relative magnitudes of these distortions, it is clear that in order to optimize the bonding interactions between the wingtip iron atoms and the vinylidene fragment, and at the same time accommodate the bulkiness of the substituents on the vinylidene ligand, the geometry of the $Fe(CO)_3$ units must severely distort.

Finally, it should be noted that the structures of the vinylidene clusters discussed here differ from the structures of other butterfly clusters such as $(\mu\text{-H})(\eta^5\text{-CpNi})Ru_3(CO)_9(\mu_4\text{-}\eta^2\text{-C}{=}CH\text{-}i\text{-Pr})$[19] and $(\eta^5\text{-CpFe})Co_3(CO)_7(\mu\text{-CO})_2(\mu_4\text{-}\eta^2\text{-C}{=}CH_2)$,[20] which also contain vinylidene ligands. In these latter clusters the vinylidene ligand does not lie in the plane of the two hinge atoms but instead leans over and binds in an η^2-manner to one of the wingtip metal atoms. At the same time, however, these latter clusters contain not only a localized vinylidene ligand, but also a heterometal and two extra cluster electrons. Comparisons between the electronic and

molecular structures of the simpler Fe_4 vinylidene clusters and the more complex heterometallic vinylidene clusters indicate that these are probably best viewed as two related but distinct groups of clusters. These comparisons will be described in a subsequent paper.[17]

SUMMARY

The syntheses, molecular and electronic structures of two μ^4-vinylidene tetrairon butterfly clusters, $Fe_4(CO)_{12}(C{=}C(OCH_3)_2)$ (**8**) and $Fe_4(CO)_{12}(C{=}C(OCH_3)CH_3)$ (**9**) have been described. The clusters have an open butterfly framework of four iron atoms with a vinylidene ligand bound to all four metal atoms, and in both clusters the vinylidene ligand is approximately co-planar with the two hinge iron atoms. The Fe_4C cores of the two clusters are similar in structure to the Fe_4C cores of their precursor methylidyne clusters, with the most noticeable differences being slightly smaller dihedral angles in the vinylidene clusters. The disposition of the CO ligands is much less symmetric in the vinylidene clusters than in their methylidyne precursors. This reorientation of the CO ligands appears to be dictated by steric crowding which results from the bulkiness of the substituents on the vinylidene ligand combined with the smaller dihedral angle between the two wings of the butterfly.

The small changes in core geometry can be attributed to the electronic structure of the vinylidene ligands. Although both clusters formally contain a C—C double bond in the vinylidene ligand, the presence of oxygen atoms in this ligand leads to a delocalized π system and only partial double bond character in the C—C bond. The double bond character increases as the number of oxygen atoms incorporated into the ligand decreases. The results of molecular orbital calculations show that changes in the structure of the cluster framework can be correlated with the double bond character in the vinylidene ligand, since an increase in double bond character leads to a shift in electron density away from the vinylidene carbon atom and a closing up of the butterfly framework around the vinylidene ligand.

MULTIPLY-BONDED DIMETAL FLUOROALKOXIDES—II. THE DISORDERED STRUCTURE OF $Mo_2(OC(CF_3)_3)_4(NMe_2)_2$ AND ITS IMPLICATIONS AS TO REARRANGEMENT BY AN INTERNAL FLIP*

RONALD G. ABBOTT, F. ALBERT COTTON† and LARRY R. FALVELLO

Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A&M University, College Station, TX 77843, U.S.A.

Abstract—The existence of the title compound, which was tentatively reported in 1977, has been confirmed and its structure studied crystallographically. It crystallizes in space group $P2_1/n$ with $a = 10.571(3)$, $b = 14.927(3)$, $c = 12.099(3)$ Å, $\beta = 103.21(3)°$, $V = 1859(2)$ Å^3, $Z = 2$. The centrosymmetric molecules have an anti, staggered rotational conformation, with the C_2N—Mo≡Mo—NC_2 group of atoms being essentially planar. There is a disorder such that 69% of the Mo_2 units lie in one direction and 31% in a nearly perpendicular direction. This is presumed to indicate that there are entire molecules that adopt these two different orientations. Although no more than one of each ligand atom could be discerned, all of them, especially those in the $(CF_3)_3C$ groups refined with unusually high thermal displacement parameters. The two Mo—Mo distances, 2.216(2) Å (69%) and 2.201(3) Å (31%), while different in a statistical sense (0.015(4) Å) are nearly equal and of the appropriate magnitude for a triple bond between the molybdenum atoms. The observed disorder leads to the concept that the Mo_2 unit might undergo internal flips from one orientation to the other within a ligand cage that need relax only slightly from one orientation to the other. This would provide a simple unimolecular mechanism for interchanging proximal and distal R groups on NR_2 ligands in this and related molecules.

As noted elsewhere,[1] an exploratory study of the reactions of fluorinated alcohols, specifically $(CF_3)_3COH$, C_6F_5OH and $(CF_3)_2CHOH$, with $Mo_2(NMe_2)_6$ and $W_2(NMe_2)_6$, as well as the characterization of the reaction products, is in progress in this laboratory. The only earlier mention of such chemistry in the literature was a brief report[2] of the reaction of $(CF_3)_3COH$ with $Mo_2(NMe_2)_6$. This afforded an orange solid which was considered to be possibly a mixture of compounds, although the mass spectrum had a multiplet corresponding to $Mo_2(OC(CF_3)_3)_4(NMe_2)_2^+$. We have now re-examined the reaction, shown that it does indeed afford $Mo_2(OC(CF_3)_3)_4(NMe_2)_2$, and carried out an X-ray crystallographic study of this compound. The crystal structure displays a discrete disorder of the Mo_2 unit (i.e. two such units can be recognized) within a ligand shell consisting of an unresolvable superposition of two nearly coincident sets of ligand atoms. The occurrence of this disorder can be rationalized and leads to a consideration, for the first time, of the possibility of internal flips of the M_2 unit within M_2X_6 molecules.

EXPERIMENTAL

$Mo_2(NMe_2)_6$ was prepared by a standard method,[3] and $(CF_3)_3COH$ was purchased from P.C.R. Incorporated, Jacksonville, Florida. X-ray crystallographic methods for data collection and processing were standard in this laboratory and have been described elsewhere.[4]‡

Preparation

$Mo_2(NMe_2)_6$ (100 mg, 0.22 mmol) was dissolved in 10 cm^3 of hexane and this solution was mixed with a solution of $(CF_3)_3COH$ (0.270 cm^3, 1.8 mmol) in 10 cm^3 of benzene. The resulting orange–red reaction mixture was stirred overnight. The

‡ Calculations were carried out on a Micro VAXII with the SDP package software.

reaction mixture was then taken to dryness under vacuum, which removed essentially all of the $[NH_2Me_2][(CF_3)_3CO]$ as well as the solvents. The solid residue was washed with benzene (10 cm^3) and then hexane (10 cm^3). The yield of bright orange microcrystals was *ca* 70%. It can be sublimed in a working vacuum (*ca* 10^{-3} mm) at 100°C without decomposition.

The ^1H NMR spectrum (CD_2Cl_2) shows two peaks, singlets of equal intensity, at δ 4.82 and 3.15, assignable to the distal and proximal methyl groups. IR peaks (cm^{-1}, KBr or mineral oil): 1310 (w), 1260 (m,br), 1170 (m,br), 980 (m), 950 (s), 800 (w), 790 (w), 735 (s), 550 (w).

Structure determination

The crystallographic characteristics of the compound and the usual information pertaining to the collection of data and refinement of the structure are summarized in Table 1. The crystal used to collect data was grown from benzene solution. The actual course of the solution and refinement procedure were not straightforward and will be explained in detail shortly.

RESULTS AND DISCUSSION

Preparation

The preparative reaction can be represented by the following chemical equation:

$$Mo_2(NMe_2)_6 + 8(CF_3)_3COH \longrightarrow Mo_2(OC(CF_3)_3)_4(NMe_2)_2 + 4[NH_2Me_2][(CF_3)_3CO].$$

It appears to proceed fairly cleanly and the product is obtained in relatively high (*ca* 70%) yield. The previous uncertainties[2] as to the course of the reac-

tion and the purity and identity of the orange product are thus removed. It may be noted that when a much larger mole ratio of $(CF_3)_3COH$ to $Mo_2(NMe_2)_6$ is used (as in ref. 2 where a 12:1 ratio was used) the homoleptic $Mo_2(OC(CF_3)_3)_6$ is still not obtained, but it becomes more difficult to purify the $Mo_2(O_2C(CF_3)_3)_4(NMe_2)_2$ because of the presence of excess alcohol and side products.

Structure

By using the direct methods routine embodied in the SHELXS-86 program a solution was obtained but it showed two high peaks about 1.0 Å apart. The higher of these was selected to be the unique molybdenum atom (the asymmetric unit should be half of the formula unit for $P2_1/n$ with $Z = 2$) and the usual procedure of searching for and refining the lighter atoms was carried out. It became clear rather quickly that this was not a viable approach, as the value of R remained around 0.35 and much of the rest of the molecule failed to appear.

Both high peaks found in the direct methods solution were then assigned as partially occupied molybdenum positions and their fractional occupancies were refined subject to the requirement that the fractions have a sum of unity. This led to a 0.69:0.31 ratio and R dropped to 0.20. All of the remaining non-hydrogen atoms were then found and no resolved disorder in any of the ligands was seen. It was necessary to apply bond length restraints to the $(CF_3)_3C$ groups to avoid false minima (SHELX-76), but at the end these were released and the refinement converged with the figures of merit stated in Table 1.

These figures of merit are not as good as those ordinarily expected and we attribute this to the fact that the ligand atoms (or some of them) are really two closely positioned partial atoms from the two differently oriented molecules. While they cannot be resolved and treated separately, treating them as single spherical atoms is only an approximation (albeit an unavoidable one) and denies us the precision to be expected when the atoms truly are single vibrating spheres. In addition, there may also be some small amount of the usual sort of disordering of CF_3 groups. The displacement parameters for all ligand atoms are unusually high (i.e. 6–8 $Å^2$ for O(1), O(2), N(3) and 16–26 $Å^2$ for the F atoms).

With due allowance for the disorder, the X-ray structure shows that the molecule has a centrosymmetric conformation arising from an *anti* rotational relationship of the two $Mo(OR)_2NMe_2$ halves. Tables 2 and 3 give bond lengths and bond angles, respectively, and Fig. 1 shows the major molecule. Additional crystallographic results are available.* The $C_2NMoMoNC_2$ set of atoms is practically planar and the two methyl groups of each NMe_2 ligand thus show a large chemical shift difference because of their proximal and distal relationship to the highly anisotropic Mo≡Mo bond. Figure 2 shows the two sets of metal atoms and how they are related to the single set of averaged ligand atom positions. Note that there is a centre of inversion.

The principal molecule (P, 69%) naturally contributes most to defining the average ligand positions and thus its internal dimensions are more reliable and realistic than those for the secondary molecule (S, 31%). This is shown in Fig. 3, where the important inner angles and distances for each are displayed. It must be emphasized that *in neither case* are the dimensions as reliable as the calculated ESDs would imply, because in neither case are the oxygen and nitrogen atoms exactly where they should be for that molecule.

* Atomic positional and displacement parameters, full lists of bond lengths and angles and F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

Table 3. Bond angles (in degrees)

O(1)—Mo(2)—O(2)	121.0(4)	C(12)—C(1)—C(13)	107(3)
O(1)—Mo(2)—N(3)	114.0(4)	O(2)—C(2)—C(21)	111(2)
O(2)—Mo(2)—N(3)	119.1(5)	O(2)—C(2)—C(22)	108(2)
Mo(1)—O(1)—C(1)	147.2(8)	O(2)—C(2)—C(23)	112(1)
Mo(2)—O(1)—C(1)	150.9(8)	C(21)—C(2)—C(22)	104(2)
Mo(1)—O(2)—C(2)	164.2(8)	C(21)—C(2)—C(23)	109(2)
Mo(2)—O(2)—C(2)	164.9(8)	C(22)—C(2)—C(23)	112(2)
Mo(1)—N(3)—C(31)	106(1)		

Numbers in parentheses are ESDs in the least significant digits.

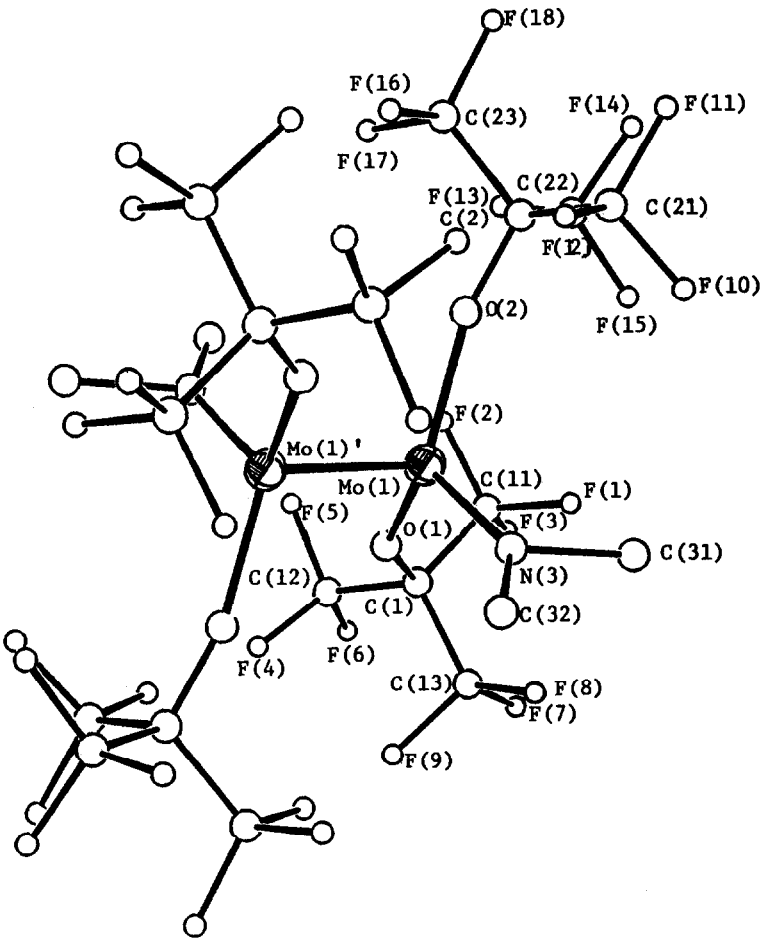

Fig. 1. An ORTEP drawing showing the ligand atoms and the two principal molybdenum atoms.

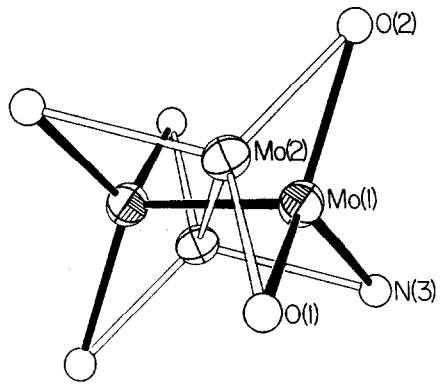

Fig. 2. A drawing of the average set of positions for the coordinated ligand atoms and the two orientations of the Mo_2 unit within it.

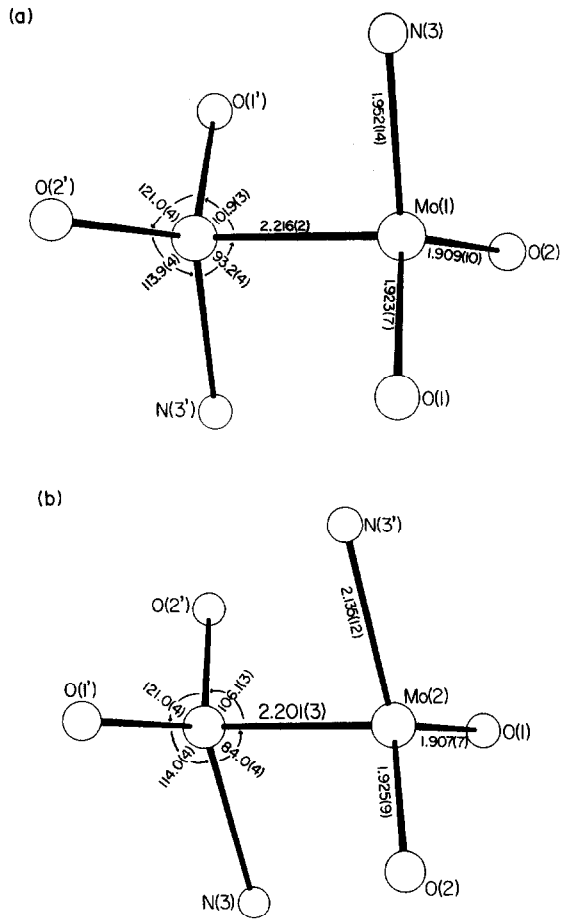

Fig. 3. Drawings showing key inner structural parameters for the principal and secondary molecules. Additional angles are:

O(2)—Mo(1)—Mo(1)′ = 106.7(2)°
O(1)—Mo(1)—N(3) = 114.7(4)°
O(1)—Mo(2)—Mo(2)′ = 103.1(3)°
O(2)—Mo(2)—N(3)′ = 119.1(5)°.

For the principal molecule, the Mo—O and Mo—N distances as well as the Mo—Mo—O and Mo—Mo—N angles are similar to those previously found in undisordered structures,[5] whereas those in the secondary molecule appear somewhat different, but, of course, are not to be taken seriously, as describing a true, single molecule.

Can internal flips occurs in M_2X_6 type molecules?

It has been recognized[6,7] that in M_2X_8 type species rearrangement (particularly isomerization) can occur by means of an internal flip of the M_2 unit from one axis to another within the nearly cubic array of eight X ligands. This is illustrated in Fig. 4(a). The idea that such a process might take place arose from the much earlier observations on the occurrence of disordering of the dimetal unit within the quasi-cubic cage of ligands in a number of cases, of which $[N(C_4H_9)_4]_2[Re_2I_8]$ provides the most spectacular example.[8]

Now that we have observed the first example of a similar type of disorder in an M_2X_6 molecule, the possibility of a comparable internal flip mechanism in M_2X_6 molecules comes into consideration. If the trigonal antiprism is idealized to an octahedron, just as in the M_2X_8 case the square parallelopiped can be idealized to a cube, there are four orientations for the M_2 unit, along the four lines between centres of opposite faces. Figure 4(b) shows two of these M_2 units.

The idealization of the set of six ligands to an octahedron in this case is well justified. By treating the centre of inversion at the midpoints of the Mo—Mo bonds as the centre, *C*, of the imagined octahedron, we have calculated the "bond" distances to the ligand atoms and the angles between the "bonds". These are listed in Table 4. It is clear that this octahedron is no more distorted than those found in many complexes that are normally described as octahedral. In addition, we have calculated the angles between the faces of the approximate octahedron, and these too are listed in Table 4. It is seen that all of them are close to the ideal angle of 109.5°.

While we are not asserting that in any real case the M_2 unit necessarily visits all orientations within the quasi-octahedron over a period of time, we do not rule that out. Nor do we argue that more than one orientation is necessarily accessible in reality, but it is worth pointing out the consequences in the present case of passing from one of the two observed orientations to the other. This can be appreciated by referring to Fig. 5, which shows the plane occupied by the principal pair of metal atoms, Mo(1)—Mo(1)′, the secondary pair,

Mo(2)—Mo(2)′, and the two NR_2 ligands, whose average positions and orientations are seen to be symmetrically related to both M_2 units.

When the dimetal unit is in the Mo(1)—Mo(1)′ orientation, C(31)/C(31)′ are the distal groups and C(32)/C(32)′ are the proximal ones. It has been known for a long time[9,10] that proximal and distal R groups exchange roles with a moderate activation energy (*ca* 12–14 kcal mol^{-1}) and it has been considered that the barrier arises mainly from a combination of steric interactions between ligands and some degree of M—N π-bonding (consistent with the planarity of the M—NR_2 unit). However, it may be seen in Fig. 5 that if the Mo_2 unit simply flips from the Mo(1)—Mo(1)′ to the Mo(2)—Mo(2)′ orientation, a concerted distal–proximal exchange for both NR_2 ligands is accomplished. Bonding of the metal atoms to the pairs of OR groups would also be maintained as Mo(1)→Mo(2) and Mo(1)′→Mo(2)′.

A similar kind of flip process could successively exchange all proximal and distal R groups in $M_2(NR_2)_6$ molecules. Experimental data presently available do not allow us to decide between this possibility and the more conventional and previously proposed processes of rotation (singly or, more probably, in some concerted fashion) about the M—N bonds. It is interesting to note that the

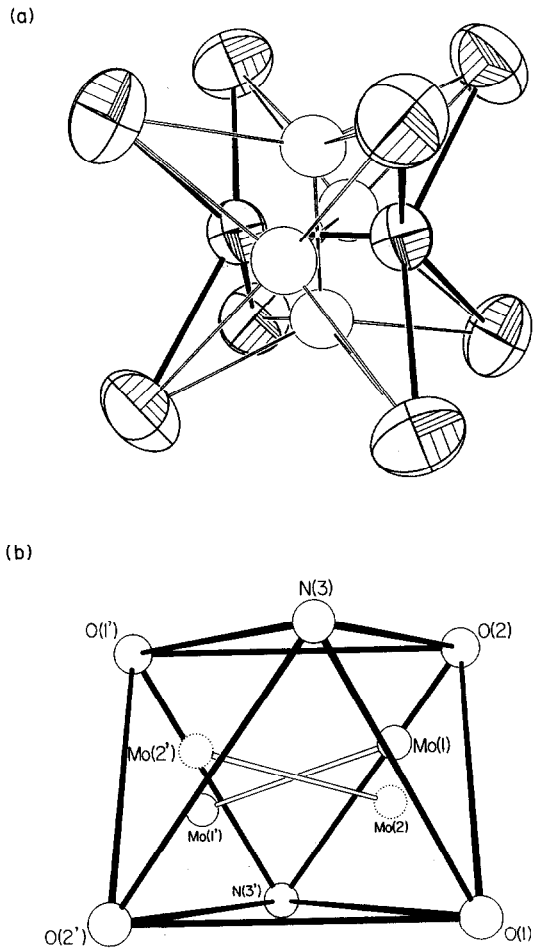

Fig. 4. (a) A quasi-cube of eight ligands with the M_2 unit in its three possible orientations; (b) a quasi-octahedron of six ligands with two of the four possible orientations of an M_2 unit within it.

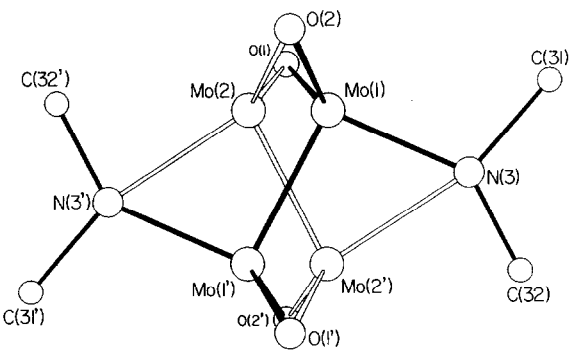

Fig. 5. A drawing showing how the distal and proximal character of the amido carbon atoms can be changed by flipping the Mo_2 unit within a fixed set of ligand atoms, while simultaneously preserving four properly oriented Mo—O bonds.

two processes should respond differently to increasing the size of the R groups, and that this may afford a means of choosing the correct one. As the R groups become bulkier, the rotational processes (even if concerted rotations about several bonds are invoked) would seem likely to show a significant increase in activation energy, since R groups on different NR_2 ligands would have to *pass* each other. On the other hand, the flip process can occur without any actual *passing* being required, although some bumping might occur. Therefore, the activation energy for the flip mechanism should be relatively insensitive to the bulk of the R groups. The only data available now that bear on this point are the $\Delta G^{\ddagger}$ values for $Mo_2(NMe_2)_6$ and $Mo_2(NEt_2)_6$, which are 11.5(2) and 13.6(5) kcal mol^{-1}, respectively. This rather small change is consistent with the operation of the flip process, but is not necessarily inconsistent with a concerted rotational process. Clearly, a more conclusive test can be devised, and we are pursuing that.

TWELVE-ELECTRON TETRANUCLEAR TUNGSTEN ALKOXIDE CLUSTERS ARE NOT TETRAHEDRAL. PREPARATION, STRUCTURE AND BONDING IN $W_4(O)(OPr^i)_{10}$ AND $W_4(O)(Cl)(OPr^i)_9$. COMPARISONS WITH THE BONDING IN CARBONYL CLUSTERS*

MALCOLM H. CHISHOLM,† CHARLES E. HAMMOND, JOHN C. HUFFMAN and JAMES D. MARTIN

Department of Chemistry and Molecular Structure Center, Indiana University, Bloomington, IN 47405, U.S.A.

Abstract—Addition of H_2O (0.5 equiv) to a hexane/Pr^iOH solution of $W_4(OPr^i)_{12}$ yields $W_4(O)(OPr^i)_{10}$ (**II**) which reacts further with NH_4Cl to give $W_4(O)(Cl)(OPr^i)_9$ (**I**). The NMR data for **I** and **II** are indicative of common structural features and the molecular structure of **I** has been determined in the solid state by a single crystal X-ray diffraction study. At −146°C: $a = 41.172(18)$, $b = 9.185(2)$, $c = 22.718(8)$ Å, $\beta = 97.15(2)°$, $Z = 4$ and $d_{calc} = 2.113$ g cm^{-3}. A $WCl(OPr^i)$ moiety caps a basal $W_3(\mu\text{-}O)(\mu\text{-}OPr^i)_2(OPr^i)_6$ moiety. The local WO_4 geometry for the tungsten atoms in the basal plane is square planar. Of particular note are the short W—W distances involving the capping $WCl(OPr^i)$ moiety (*ca* 2.45 Å) relative to those W—W distances in the basal plane (*ca* 2.90 Å). The bonding in compounds **I** and **II**, modelled as $W_4(O)(Cl)(OH)_9$ and $W_4(O)(OH)_{10}$, respectively, has been investigated by MO calculations employing the method of Fenske and Hall. The combination of the d^4-WCl(OH) fragment with the d^8-$W_3(O)(OH)_8$ fragment yields multiple M—M bond character between the capping tungsten atom and the three W—W atoms in the basal plane. Interesting analogies are seen between carbonyl and alkoxide clusters based on the isolobal principle d^3-$W(OR)_3 \leftrightarrow d^9$-$Co(CO)_3 \leftrightarrow d^9$-$Os(CO)_3^-$ and d^4-$WX_2 \leftrightarrow d^{10}$-$PtL_2$. Specific comments are made with respect to the bonding in $M_4(OR)_{12}$ (M = Mo, W), $M_4(CO)_{12}$ (M = Co, Rh, Ir) (**I**, **II**) and $Os_3Pt(H)_2(CO)(PR_3)$.

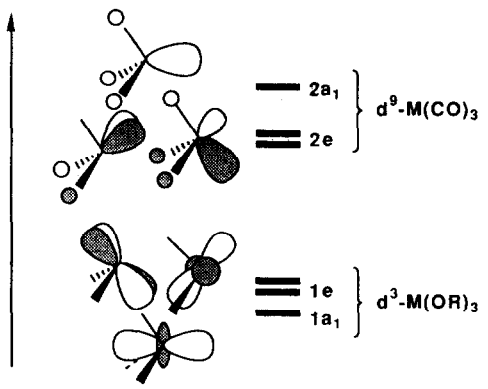
Of long standing interest to us has been the structure and bonding in 12-electron M_4 alkoxide supported clusters (M = Mo, W) formed by the coupling of two $(M{\equiv}M)^{6+}$ units. In the original report[1] on the preparation and characterization of $Mo_2(OR)_6$ compounds (R = Bu^t, Pr^i, CH_2Bu^t, CMe_2Ph) we speculated that reduction in steric bulk of the alkoxy ligands might lead to tetrahedral M_4 clusters, an electron-precise structure for a 12-electron M_4 unit having six M—M electron pairs.

Substitution of OR by halides led to a series of $Mo_4X_4(OPr^i)_8$ clusters[2,3] based on a square (X = Cl) or a butterfly (an opened tetrahedron) of metal atoms (X = Br and I), while the fluoride $Mo_4F_4(OBu^t)_8$[4,5] and the mixed alkoxide $Mo_4(OMe)_2(OPr^i)_{10}$[6] were found to contain bisphenoids and rectangles of metal atoms, respectively. The bridging ligands (F or OMe and OPr^i) united two localized $(M{\equiv}M)^{6+}$ units. For tungsten we found that $W_2(OPr^i)_6$ existed in solution equilibrium with $W_4(OPr^i)_{12}$ and that the latter contained a distorted rhombus of metal atoms, an inorganic analogue of cyclobutadiene.[7,8] With a further decrease in the bulk of the attendant alkoxide ligands (R = CH_2Pr^i, CH_2Hex^c, CH_2Pen^c and CH_2Bu^c) both molybdenum and tungsten gave $M_4(OR)_{12}$ compounds having a common structure based on a highly asymmetrical M_4 butterfly with three short M—M distances, *ca* 2.5 Å, two long M—M bonded distances, *ca* 2.8 Å, and one nonbonding M—M distance.[9]

These structures reveal the desire of the metal atoms to maximize M—M and M—L (L = ligand) bonding. However, it seems that M—M bonding

* Dedicated to Professor R. Fenske on the occasion of his retirement and in appreciation of his former students from whom we have learned much

† Author to whom correspondence should be addressed.



Scheme 1.

and M—L bonding are often in competition. For example, in the $M_2(OR)_6(M{\equiv}M)$ compounds the ethane-like structure indicates that M—M bonding wins at the expense of M—O bonding which would favour the Al_2X_6 fused tetrahedral structure.

We have previously noted the complementary nature of RO and CO ligands as π-buffers in early and late transition metal chemistry.[10] Furthermore, the frontier orbital relationship between d^3-$M(OR)_3$ (M = Mo, W) and d^9-$M(CO)_3$ fragments (M = Co, Rh, Ir), as shown in Scheme 1, provides the foundation for many similarities between di-, tri- and tetranuclear alkoxide and carbonyl clusters that coordinate common fragments, for example, as in $M_2(\mu\text{-X})$ compounds where X = alkyne or P_2, $M_3(\mu\text{-X})$ compounds where X = CR or P and $M_4(\mu_4\text{-C})$ compounds.[11,12] The tetranuclear carbonyl clusters $M_4(CO)_{12}$, where M = Co, Rh and Ir, have a tetrahedral M_4 core supported (M = Co, Rh)[13,14] or unsupported (M = Ir)[15] by carbonyl bridges. The tetrahedral alkoxide analogues $M_4(OR)_{12}$ (M = Mo, W) are conspicuous by their absence.

In this paper we describe the synthesis and characterization of tetranuclear 12-electron alkoxide clusters of tungsten, $W_4(O)(Cl)(OPr^i)_9$ and $W_4(O)(OPr^i)_{10}$, that adopt a novel structure based on a distorted tetrahedron of metal atoms having three short and three long bonds. This leads us to question whether or not any 12-electron M_4 cluster supported principally by alkoxide ligands would contain a tetrahedral M_4 unit. A preliminary aspect of this work has appeared.[16]

RESULTS AND DISCUSSION

Synthesis

The compound $W(O)(Cl)(OPr^i)_9$ (**I**) was discovered as a minor product formed in the preparation of $W_4(H)_2(OPr^i)_{14}$[17] from the reactants $W_2(O\text{-}Bu^t)_6$, $NaOPr^i/Pr^iOH$ (with adventitious H_2O) and $Me_2NH_2^+Cl^-$. Compound **I** is very soluble in hexane and is obtainable as orange crystals from Et_2O, forming above the solution on the walls of the flask. This allows for its isolation in analytically pure form, $[W_4Cl(O)(OPr^i)_9]\cdot 1/2Et_2O$, and easy separation from $W_4(H)_2(OPr^i)_{14}$ and $W_4(OPr^i)_{12}$ which are present in the reaction mixture.

In an attempt to elucidate how $W_4(O)(Cl)(OPr^i)_9$ was formed, $W_2(O\text{-}Bu^t)_6$ in hexanes was allowed to react with H_2O/Pr^iOH (1/2 equiv of H_2O in 10 equivalents of Pr^iOH). The ^1H NMR spectrum indicated a plethora of products. However, when addition of H_2O/Pr^iOH was preceded by addition of $HOPr^i$ forming $W_2(OPr^i)_6$, the reaction yielded $W_4(O)(OPr^i)_{10}$ (**II**) according to eq. (1) below. Crystals of $W_4(O)(OPr^i)_{10}$ were obtained from Et_2O, analytically pure for $[W_4(O)(OPr^i)_{10}]\cdot 1/2Et_2O$, but were unsuitable for X-ray analysis.

$$2''W_2(OPr^i)_6'' + H_2O \longrightarrow W_4(O)(OPr^i)_{10} + 2\,HOPr^i \quad (1)$$

Alternatively, $W_4(OPr^i)_{12}$ was dissolved in toluene-d_8 at room temperature [allowing for an equilibration with $W_2(OPr^i)_6$] and was allowed to react with $1/2H_2O$. ^1H NMR spectroscopy indicated the clean conversion to $W_4(O)(OPr^i)_{10}$. It is unclear whether the hydrolysis involves $W_2(OPr^i)_6$ or $W_4(OPr^i)_{12}$.

Spectroscopic characterization

The oxo ligand is confirmed as being derived from H_2O by carrying out the experiment using $H_2{}^{18}O$ and identifying the W—O—W stretching frequency in the IR spectrum. In **II**, $\nu = 667$ cm^{-1} and ^{18}**II**, $\nu = 635$ cm^{-1}, following closely to the harmonic oscillator model,[18] $\nu_{iso}/\nu_{ref} = (\mu_{ref}/\mu_{iso})^{1/2} \rightarrow \nu_{iso} = 0.9472 \times \nu_{ref}$. This knowledge permitted recognition of the W—O—W stretch $\nu = 678$ cm^{-1} in **I**. These W—O—W stretches are in the region expected for the symmetric stretch of bent M—O—M linkages.[19] In **I** there are two bands, $\nu = 515$ cm^{-1} and $\nu = 503$ cm^{-1} (Nujol mull). These diagnostic bands are at higher wave numbers than previously observed W—Cl bands by about 150 cm^{-1}. Their derivation is unclear at present but they may be due to the W—Cl coupling to other vibronic modes.

The ^1H NMR spectra of **I** and **II** indicate that the two compounds are structurally related, each having five different types of Pr^iO ligands as shown in Fig. 1. In both cases the unique non-dia-

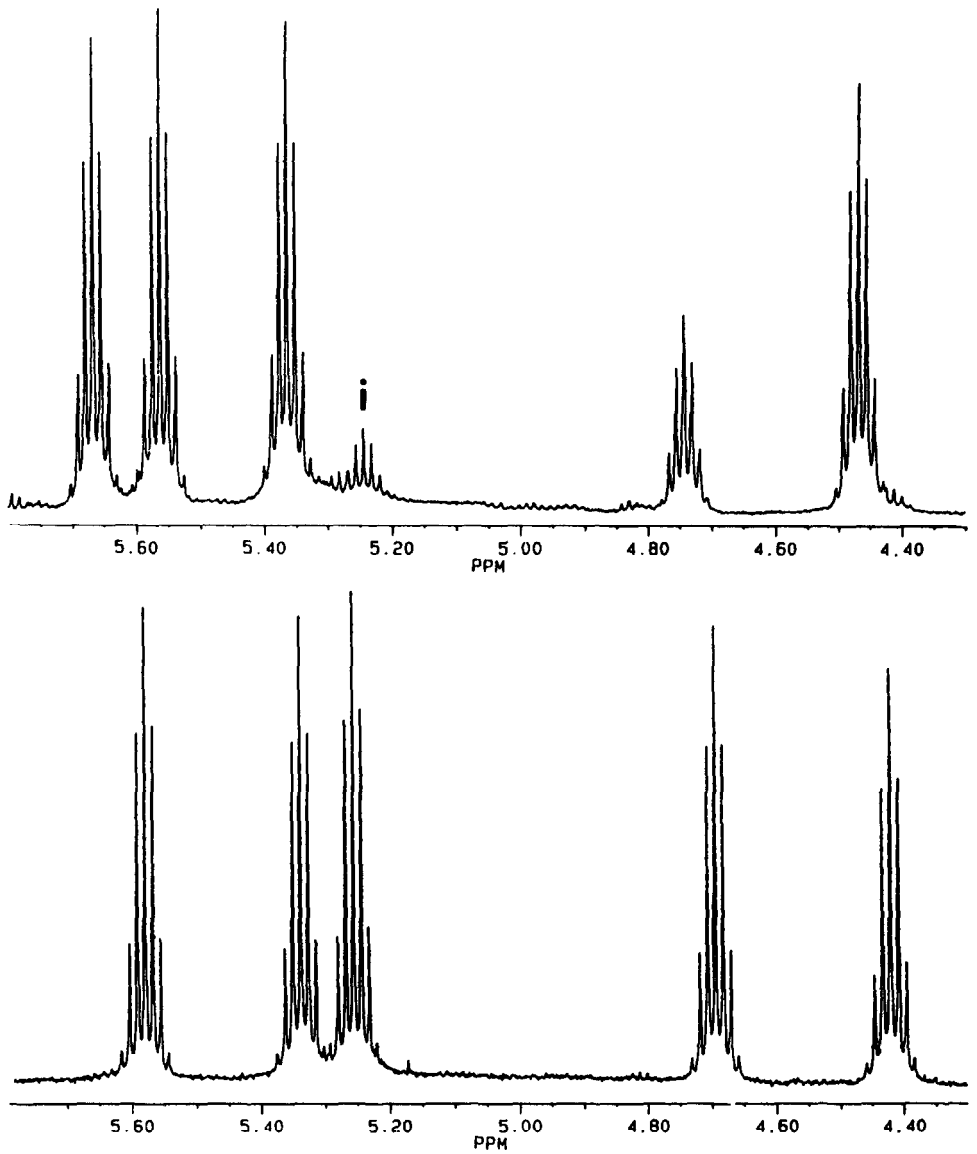


Fig. 1. ^1H NMR of the methine regions of $W_4(O)(Cl)(OPr^i)_9$ (top) and $W_4(O)(OPr^i)_{10}$ (bottom). The letter i denotes an impurity.

stereotopic methyl group is coupled to the methine at *ca* 4.7 ppm. Addition of excess $Me_2NH_2^+Cl^-$ to **II** causes the resonance at *ca* 4.7 ppm in the ^1H NMR spectrum to disappear, presumably, because $W_4Cl_2(O)(OPr^i)_8$ is formed. This suggests both ease and site selectivity for alkoxide ligand substitution by chloride ligands. The compound $W_4Cl_2(O)(OPr^i)_8$ has not, however, been isolated and fully characterized.

Solid-state and molecular structure

The molecular structure of **I** has been deduced from a single crystal X-ray study. Two ball-and-stick drawings that emphasize the W_4 pseudo-tetrahedron are shown in Fig. 2. A summary of crystallographic data is given in Table 1, and pertinent bond distances and angles are located in Tables 2 and 3, respectively.

The molecule consists of a $WCl(OPr^i)$ fragment, W(4), capping a triangle of tungsten atoms, W(1), W(2) and W(3), that is supported by two bridging Pr^iO ligands and one μ-oxo group together with two terminal OPr^i ligands per tungsten. The geometry of the WO_4 units in the basal W_3 unit is approximately square planar. Each terminal alkoxide is *trans* to a bridging oxygen atom of a μ-OPr^i or μ-oxo ligand. The oxo ligand, O(6), that is bonded to W(1) and

W(4)	Cl(5)	2.462(4)

W(2) is contained in a virtual mirror plane together with W(3), W(4), Cl(5) and O(39).

The most striking feature of the molecular structure is the presence of a two-coordinate tungsten atom capping a triangle of four-coordinate tungsten atoms such that the unbridged W—W distances are roughly 0.5 Å shorter than the bridged W—W distances.

Empirical bond strength–bond length relationships have been used to determine or assign oxidation states in oxides of molybdenum.[20] We have shown that this can be extended to alkoxide clusters of both molybdenum and tungsten if the assumption is made that W—O and Mo—O bond distances are equivalent.[9] This assumption is valid to within one or two hundredths of an Angstrom. The chloride ligand is considered a uninegative ligand and is solely bonded to W(4). This gives the oxidation states W(1) = W(2) = +3.5, W(3) = +3.3, and W(4) = +1.9 for a total charge of +12.2, in close agreement with the formal charge of +12 for the 12-electron W_4 cluster in which Cl and OR are counted as uninegative ligands.

The ^{1}H NMR spectrum of **I** is entirely consistent with the structure observed in the solid state. The structure of **II** can most reasonably be formulated as being related to that of **I** by the replacement of Cl by OPr^i. However, the spectroscopic equivalence of the two terminal alkoxide ligands of the $W(OPr^i)_2$ cap raises some question as to the orientation of this WX_2 fragment. If the alkoxide ligands of **II** lie within the mirror plane, as in the solid-state structure of **I**, then two methyne chemical shifts are expected unless they are accidentally degenerate or there is facile rotation of the WX_2 cap. Alternatively, the WX_2 fragment could lie perpendicular to the virtual mirror plane.

It is unlikely, given their orientation with respect to the rest of the molecule, that the alkoxide ligands of the $W(OPr^i)_2$ cap would be accidentally degenerate. Variable temperature ^{1}H NMR studies in d_8-toluene give no evidence of freezing out any rotation of the $W(OPr^i)_2$ cap even at −90°C. Assuming that in the frozen-out spectrum the methyne protons of these alkoxides would show a separation of chemical shifts similar to those from the various environments of the terminal alkoxide ligands in the trianglar base (0.1–0.4 ppm), no rotational barrier less than 10 kcal mol^{-1} would be frozen out, on the NMR time scale, even at −90°C. Molecular orbital calculations (see later) by both the Extended Huckel and Fenske–Hall methods support a low barrier to a rotation of this WX_2 (X = Cl or OR) cap above the triangular basal plane.

BONDING CONSIDERATIONS

The bonding in these clusters is best understood from a fragment molecular orbital FMO analysis.[21,22] We consider the clusters to be formed from the fragments W(Cl)(OR) or $W(OR)_2$ and $W_3(O)(OR)_8$ and have investigated the bonding by using the method of Fenske and Hall[23] for the model compounds $W_4(O)(Cl)(OH)_9$ and $W_4(O)(OH)_{10}$.

$W_4(O)(Cl)(OPr^i)_9$ (I)

The molecular orbitals of the $W_3(O)(OH)_8$ fragment are similar to those previously described[11,12] for the $W_3(OR)_9$ fragment of $W_3(OR)_9(\mu_3\text{-CMe})$, though the presence of the bridging oxo group results in a reduction of symmetry from C_{3v} to C_s and a loss of one electron from the M_3 cluster fragment. The orbitals of the WCl(OH) fragment are reminiscent of those expected for a WX_2 fragment except for the notable mixing of the $1a''$ and $2a''$ orbitals so as to minimize the π-antibonding between the tungsten d_π and oxygen p_π electrons. A simplified interaction diagram of these two fragments is given in Fig. 3.

On combining the fragments the filled $1a'$ and $1a''$ orbitals of WCl(OH) find their match with unoccupied $4a'$ and $2a''$ non-bonding orbitals of the tri-tungsten fragment. Similarly the $1a'$, $2a'$ and $1a''$

M—M bonding orbitals and the $3a'$ occupied non-bonding orbital of the W_3 fragment, made up of the in-phase combinations of tungsten z^2 orbitals, interact strongly with the respective $2a'$, $2a''$, $3a'$ and $4a'$ unoccupied orbitals of the WX_2 cap. The overlap populations corresponding to these interactions are given in Table 4. Placing electrons into M_3-non-bonding (or weakly antibonding) orbitals and withdrawing electrons from the M_3 bonding orbitals causes the Mulliken atomic charges of the tungsten atoms to be -0.631 for the capping atom and 1.407, 1.407 and 1.343 for those in the basal plane. This results in a severe weakening of the M—M bonding in the basal plane and M—M multiple bonding to the capping tungsten atom. The importance of the valence bond description

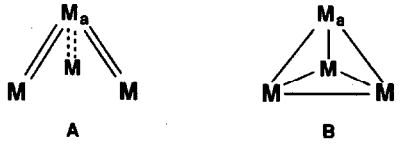
depicted by the resonance structure **A**, relative to that of **B**, is apparent, where M_a represents the apical metal atom, i.e. the $WCl(OPr^i)$ unit.



A slightly weaker interaction would be obtained were the W(Cl)(OH) fragment rotated by 180° such that the Cl bond was situated over the oxo bridge, **C**, rather than over the unique basal tungsten atom, **D**.

A discussion of the bonding in **I** would be incomplete without describing the orientational preference of the tungsten–alkoxide–chloride cap. The

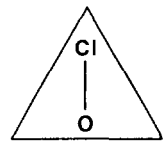
C



D

metal-based orbitals of the W(Cl)(OH) fragment are polarized away from the OH ligand slightly more than from the weaker donor Cl. Similarly the FMOs of the cluster fragment are polarized away from the oxo bridge toward the unique tungsten atom. This allows a maximum a' or σ-type overlap when oriented in configuration **D**, as found in the X-ray crystal structure, apparent from comparison of the overlap population tabulated in Tables 4 and 5. This same reasoning accounts for the slightly increased a'' or π-type overlap when the W(Cl)(OH) cap is rotated to orientation **C**. However, this better cap to cluster fragment a'' overlap in orientation **C** is at the expense of significantly increased M_a—Op_π antibonding (see Tables 6 and 7).

Table 6. Overlap populations corresponding to the interaction between W(4) and the Cl and OH ligands in orientation **C**[a]

	W(4)	
O *s*	0.288	$\sigma = 0.510$

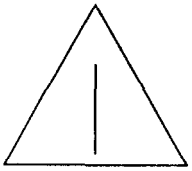
Cl *s*	0.180	$\sigma = 0.588$
pz	0.408	
px	0.154	$\pi = 0.120$
py	−0.034	

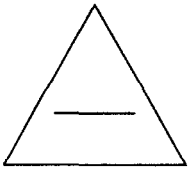
[a] σ Interactions come from the valence *s* and *pz* orbitals of Cl and O, whereas π-interactions are derived from overlap with the *px* and *py* orbitals.

$W_4(O)(OR)_{10}$ (II)

The bonding in **II** is very similar to that previously described for **I**. We have examined the bonding in **II** by examining the hypothetical molecule $W_4(O)(OH)_{10}$ with the $W(OH)_2$ fragment both parallel and perpendicular to the virtual mirror plane of the molecule, as in **E** and **F** below.



E



F

Minor differences arise in the bonding description of **I** and **II** because no significant stabilization of the $W(OH)_2$ fragment is achieved by mixing the $1a''$ and $2a''$ fragment orbitals. The substitution of an alkoxide for chloride makes the WX_2 cap a slightly poorer acceptor as seen by the reduced, compared with **I**, Mulliken atomic charges on each of the tungsten atoms. These are W(4) = −0.565, W(1) = W(2) = 1.375, and W(3) = 1.267 for **II** with the $W(OH)_2$ cap parallel to the molecular mirror plane. Nonetheless, to minimize antibonding with the stronger donor alkoxide ligands, the orbitals of the capping tungsten are polarized toward the rest of the cluster resulting in similar overlap populations to those seen in **I** (see Table 8). Rotation of the $W(OH)_2$ cap by 90° such that the fragment is perpendicular to the virtual mirror plane results in a slight decrease in the overlap population of the capping and basal fragments as seen in Table 9. The Walsh diagram, shown in Fig. 4, describes the destabilization of the metal-based molecular orbitals and reduction of the HOMO–

LUMO gap upon rotation. This is consistent with the proposal that **I** and **II** adopt a similar ground-state structure, but exhibit a low barrier to rotation of the WX_2 cap in solution.

Comparisons with carbonyl clusters

As we have pursued the structure and bonding in early transition metal alkoxide clusters we have found many to have a complement among the later-transition metal carbonyl supported clusters. We have previously discussed the relationships between the d^3-$W(OR)_3$ and d^9-$Co(CO)_3$ fragments and their respective clusters of formula M_4X_{12} and $M_3X_9(\mu_3\text{-}Y)$ where M = Co and X = CO, M = W and X = OR and Y = CR or P.[11,12] We here describe aspects of the bonding in $W_4(O)(Cl)(OPr^i)_9$ which are reminiscent of the hypothetical cluster $[Os_3(CO)_9(\mu_3\text{-}PtL_2)]^{2-}$ discussed by Hoffmann,[24] where the hydrides of $Os_3Pt(H)_2(CO)_{10}(PR_3)$[25] are treated as protons. The frontier molecular orbitals of the $Os_3(CO)_9^{2-}$ fragment are essentially equivalent to those of the $Co_3(CO)_9$ fragment, but formally have one less electron. Thus the $Os_3(CO)_9^{2-}$ fragment is related to the $Co_3(CO)_9$ fragment in a similar fashion to the $W_3(O)(OR)_8$ and $W_3(OR)_9$ fragments. Furthermore, an internal isolobal analogy of ML_2 fragments described in Scheme 2 relates the $1b_1$ and $2a_1$ orbitals of the d^4-WX_2 fragment to the b_2 and $3a_1$ orbitals of the d^{10}-PtL_2 fragment. Because of the respective orientation of their "π-type" orbitals, the b_1 or b_2, one might predict orthogonal orientation of the WX_2 and PtL_2 caps above the tri-tungsten or tri-osmium cluster fragments in the ground state. In both cases, however, low barriers to rotation are expected due to orthogonal sets of orbitals, and to the a_1 orbitals

Table 8. Overlap populations corresponding to the interaction of the $W(OH)_2$ fragment with the $W_3(O)(OH)_8$ fragment. The WX_2 cap is oriented parallel to the virtual mirror plane of the molecule, **E**

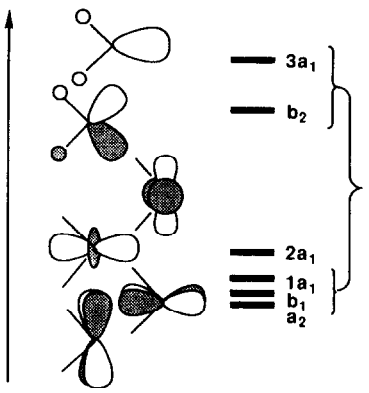

Scheme 2.

which are approximately invariant under rotation.

Though the WX_2 frontier orbitals are similar for d^4-WX_2 and d^{10}-PtL_2 they differ most notably in electron occupation, with the net result that the d^4-WX_2 fragment acts as an acceptor from M—M bonding orbitals of the basal $W_3(O)(OH)_8$ fragment. Such an interaction is not possible for a d^{10}-PtL_2 fragment. This then produces the obvious differences in the M—M distances within the alkoxide and carbonyl M_4 clusters under consideration.

Concluding remarks

The discovery of a new class of 12-electron W_4 alkoxide supported clusters $W_4(O)(OPr^i)_{10}$, $W_4(O)(Cl)(OPr^i)_9$ and $W_4(O)(Cl)_2(OPr^i)_8$ having the common structural feature of a d^4-WX_2 unit capping a $W_4(\mu\text{-}O)(\mu\text{-}OPr^i)_2(OPr^i)_6$ moiety, leads us once again to ponder whether or not the coupling of two $(W{\equiv}W)^{6+}$ units could yield a tetrahedral W_4^{12+} core. Given the several types of M_4^{12+} clusters supported by alkoxide ligands, the lack of the tetrahedral unit is quite striking. We now speculate why this is the case.

(1) Whenever coupling of two $(M{\equiv}M)^{6+}$ units occurs this is accompanied by ligand bridge formation—even when the $(M{\equiv}M)^{6+}$ units are retained as in $Mo_4F_4(OBu^t)_8$[2,3] and $Mo_4(OMe)_2(OPr^i)_{10}$.[6] Therefore, an unbridged $M_4(OR)_{12}$ molecule, an analogue of $Ir_4(CO)_{12}$, would seem unlikely based on considerations of optimizing metal–ligand bonding.

(2) We can think of building a pseudo-tetrahedral $M_4(OR)_{12}$ molecule by coupling a d^3-$M(OR)_3$ fragment with a nine-electron $M_3(\mu\text{-}OR)_3(OR)_6$ unit. This would be an analogue of the $M_3(\mu_3\text{-}X)(OR)_9$ compounds where X = CR′[26] or P.[27] From the present work, we see that this would not lead to a tetrahedral M_4 moiety because the MX_3 cap would act as an electron acceptor. However, the placing of the three alkoxides on the capping WX_3 unit would decrease the acceptor properties of the WX_3 unit relative to that seen for $W(Cl)(OPr^i)$.

(3) Finally, if we assume a tetrahedral M_4 moiety, we can ask the question—how may we dispose of 12 ligands so as to preserve this symmetry? The introduction of six edge-bridging ligands would leave six OR ligands for terminal and μ_3 sites—a situation that could not preserve tetrahedral symmetry. The only possible *pseudo*-tetrahedral geometry is based on a cubane-like structure having a central $M_4(\mu_3\text{-}OR)_4$ core. In a rigorous sense, a T_d-$M_4(OR)_{12}$ molecule could not be observed because the introduction of two terminal OR groups per metal atom would remove the C_3 element of symmetry. This not withstanding, there are known $M_4(\mu_3\text{-}L)_4L_8$ compounds and the bond-

Table 9. Overlap populations corresponding to the interaction of the $W(OH)_2$ fragment with the $W_3(O)(OH)_8$ fragment. The WX_2 cap is oriented perpendicular to the virtual mirror plane, F[a]

[a] This requires two orbitals of the MX_2 cap to change symmetry.

ing in these has been the subject of a recent theoretical analysis by Harris.[28] The local $X_2M(\mu_3\text{-}X)_3$ geometry may approximate either a trigonal bipyramid or a square-based pyramid. In both cases 12 electrons can be accommodated in M—M bonding molecular orbitals. Though we cannot discount the possibility that this type of structure may be eventually found it seems that this would be unlikely because the terminal OR groups would exert a *radial cluster influence*[29] thereby weakening the M—M bonding in the central M_4^{12+} core.

The alternative to a symmetrical disposition of ligands is one in which in one part of the molecule metal–ligand bonding is maximized and in another part metal–metal bonding is maximized. This is clearly seen in the structures of $M_4(OR)_{12}$ compounds (M = Mo, W; R = CH_2Pr^i, CH_2Hex^c, CH_2Pen^c, CH_2Bu^c) where one metal atom is coordinated to six OR groups and the other three metal atoms are coordinated to only four. Similarly in the present compounds a WX_2 group caps a W_4 $(\mu\text{-}O)(\mu\text{-}OPr^i)_2(OPr^i)_8$ unit. This disparity in coordination number leads to inequivalent oxidation states amongst the metal atoms within the cluster. It is interesting to note that the binary oxides M_2O_3 are not known for M = Mo and W. They are unstable with respect to MO_2 and the bulk metal, M. We propose that a symmetrical $M_4(OR)_{12}$ molecule (M = Mo, W) is similarly unstable with respect to a cluster of lower symmetry that favours local maximization of metal–ligand and metal–metal bonding.

EXPERIMENTAL

General

All reactions were carried out under an atmosphere of dry, oxygen-free nitrogen using standard Schlenk and glovebox techniques. Starting materials, $W_2(OBu^t)_6$[30] and $W_2(OPr^i)_6$,[8] were prepared by literature methods. All solvents were distilled from sodium benzophenone ketyl and stored over 4 Å molecular sieves. Isopropanol was dried over molecular sieves, but not distilled prior to use.

NMR spectra were recorded on Varian XL-300 and Bruker AM-500 spectrometers. IR spectra were recorded on a Perkin–Elmer 283 spectrometer. Elemental analyses were performed by Oneida Research Services Inc., Whitesboro, New York.

$W_4(O)(OPr^i)_{10}$

To a red solution of $W_2(OBu^t)_6$ (272 mg, 0.338 mmol) in hexane (10 cm^3), $HOPr^i$ (1 cm^3) was added while stirring to give a yellow solution. To this was added 1 equivalent of H_2O in $HOPr^i$ dropwise via a syringe and the solution darkened in colour with each drop. The solution was stirred for 4 h. The volatile components were removed and the sample was crystallized out of Et_2O (110 mg) to give $W_4(O)(OPr^i)_{10}(1/2Et_2O)$ in a moderate yield of 23.7%. The alkoxides are arbitrarily labelled a, b, c, etc. as a subscript in front of the three-bond coupling constant.

^1H NMR (500 MHz, 25°C, toluene-d_8): δ methines (2H, p) 5.58 ($^3_aJ_{HH}$ = 6.1 Hz), 5.37 ($^3_bJ_{HH}$ = 6.1 Hz), 5.25 ($^3_cJ_{HH}$ = 6.1 Hz), 4.69 ($^3_dJ_{HH}$ = 6.0 Hz), 4.42 ($^3_eJ_{HH}$ = 6.3 Hz); methyls (d); 1.57 (6H, $^3_bJ_{HH}$ = 6.1 Hz), 1.54 (6H, $^3_aJ_{HH}$ = 6.1 Hz), 1.54 (6H, $^3_bJ_{HH}$ = 6.1 Hz), 1.52 (6H, $^3_cJ_{HH}$ = 6.1 Hz), 1.49 (6H, $^3_cJ_{HH}$ = 6.1 Hz), 1.49 (6H, $^3_aJ_{HH}$ = 6.1 Hz), 1.39 (12H, $^3_dJ_{HH}$ = 6.0 Hz), 1.38 (6H, $^3_eJ_{HH}$ = 6.3 Hz), 1.26 (6H, $^3_eJ_{HH}$ = 6.2 Hz).

^{13}C NMR (125 MHz, 25°C, toluene-d_8): δ methines (1C, s), 83.0, 78.6, 77.8, 75.4, 71.5, methyls (s); 28.3 (1C), 28.2 (2C = 2), 27.8 (1C), 27.7 (1C), 27.4 (1C), 27.2 (1C), 26.8 (1C), 26.6 (1C), 26.5 (1C).

IR (Nujol mull, burnt orange, cm^{-1}): 1320 m, 1260 w, 1160 sh/m, 1118 s, 994 s, 943 sh/m, 841 m, 795 w, 667 w(ν_{W-O-W}), 595 m, 575 m, 456 w, 298 w.

Elemental analysis: Found: C, 26.43; H, 5.34. Calc. for $W_8C_{64}H_{50}O_{23}$ ($W_4(OPr^i)_{10}(O)\cdot 1/2Et_2O$): C, 27.86; H, 5.48%.

$W_4(^{18}O)(OPr^i)_{10}$

The same procedure was followed for synthesizing $W_4(^{18}O)(OPr^i)_{10}$ only $H_2{}^{18}O$ was used. The IR spectrum shows the W—^{18}O—W stretch at 635 cm^{-1}.

$W_4(O)(Cl)(OPr^i)_9$

Hexanes (15 cm^3) and isopropanol (12 cm^3) with presumably adventitious water were added at 23°C to 1.044 g (1.295 mmol) of $W_2(OBu^t)_6$ and 104 mg (1.267 mmol) of $Na(OPr^i)$. The solution was stirred for 12 h and the volatile components were removed *in vacuo*. To the solid residue was added 104 mg of $H_2NMe_2{}^+Cl^-$ as well as 25 cm^3 of hexanes and 5 cm^3 of isopropanol. The volatile components were removed *in vacuo*. The residue was dissolved in hexanes and filtered. From the hexane solution $H_2W_4(OPr^i)_{14}$ was isolated. The volatiles from the filtrate were removed *in vacuo* and Et_2O was added to try to crystallize more $H_2W_4(OPr^i)_{14}$. The previously unknown compound $W_4(O)(Cl)(OPr^i)_9\cdot 1/2Et_2O$ (mol. wt = 2722.41) crystallized, 20 mg isolated (0.58% yield).

Elemental analysis: Found: C, 25.55; H, 4.98. Calc. for $W_8C_{58}H_{136}Cl_2O_{21}$: C, 25.64; H, 5.06%.

$W_4(O)(Cl)_2(OPr^i)_8$

Toluene-d_8 (0.4 cm^3) at 25°C in a dry box was added to $W_4(O)(OPr^i)_{10}$ (34 mg, 0.0253 mmol) and $H_2NMe_2^+Cl^-$ (6 mg, 0.0735 mmol). The reaction solution was stirred for 18 h and then transferred to an NMR tube. The main product was identified by ^{1}H and ^{13}C NMR as $W_4(O)(Cl)_2(OPr^i)_8$.

^{1}H NMR (500 MHz, 25°C, toluene-d_8): δ methines (2H, p); 5.58, 5.53, 5.32, 4.45; methyls (d); 1.57 (6H), 1.52 (6H), 1.51 (12H), 1.48 (6H), 1.47 (6H), 1.33 (H), 1.27 (6H).

^{13}C NMR (125 MHz, 25°C, toluene-d_8): δ methines (s), 82.48, 80.29, 78.55, 76.20; methyls (s), 27.97, 27.48, 27.44, 27.23, 26.97, 26.78, 26.51, 26.48.

Computational procedures

The coordinates for the model compounds $W_4(O)(Cl)(OH)_9$ (I) and $W_4(O)(OH)_{10}$ (II) were taken from the X-ray crystal structure of $W_4(O)(Cl)(OPr^i)_9 \cdot 1/2Et_2O$ and idealized C_s symmetry. An O—H bond distance of 0.96 Å was used. All rotations of the WX_2 cap were about the axis perpendicular to the W(1)—W(2)—W(3) plane and passing through W(4). Rotations of 0–180° were examined for **I** and 0–90° for **II**.

Molecular orbital calculations were performed using the Extended Huckel method and the method of Fenske and Hall. Fragment molecular orbital calculations were performed using the Fenske–Hall method[23] on the fragments $W_3(O)(OH)_8$, W(Cl)(OH) and $W(OH)_2$. Atomic wave functions for the Fenske–Hall calculations were generated by a best fit to Herman–Skillman atomic calculations using the method of Bursten, Jensen and Fenske.[31] Contracted double-ζ representations were used for the tungsten 5*d* atomic orbitals, as well as the chlorine 3*p* and oxygen 2*p* atomic orbitals. Basis functions for the metal atoms were generated for a +1 oxidation state with valence tungsten 6*s* and tungsten 6*p* exponents fixed at 1.80. An exponent of 1.16 was used for the hydrogen 1*s* atomic orbital since it minimized the energy of methane.

Crystallographic studies

General operating procedures have been previously reported.[32]

$W_4(O)(Cl)(OPr^i)_9$. A small, almost equidimensional, piece was cleaved from a larger mass of crystals. The crystal was cooled to −146°C for characterization and data collection. An automated search of a limited hemisphere of reciprocal space yielded a set of reflections which exhibited monoclinic symmetry (2/*m*). The systematic extinction of *hkl* for $h-k = 2n+1$, and of *h0l* for $l = 2n+1$ lead to the possible space groups: *Cc* or *C*2/*c*. The choice of the centrosymmetric space group *C*2/*c* was confirmed by the successful solution and refinement of the structure. Data collection was undertaken as noted in Table 1. A total of 6513 reflections was collected within the given range. This number includes the standard reflections as well as the space group extinctions that were not due to the carbon-centring. Following the usual data reduction and averaging of redundant data, a unique set of 5594 reflections was obtained. 4851 reflections were considered observed by the criterion $F > 3.0\sigma(F)$. A plot of the standard reflections showed no systematic trends. No absorption correction was carried out as the crystal was lost before it could be measured.

The structure was solved after some difficulty using direct methods and Fourier techniques. Some of the difficulty was attributed to the larger than expected number of heavy atoms, as well as the large *a*-axis dimension. When the four tungsten atoms were located in an *E*-map, the remainder of the non-hyrogen atoms were located in a difference Fourier phased with the tungsten atoms. The asymmetric unit contains one W_4 complex and one half molecule of ether solvent located at a two-fold axis. All hydrogen atoms, except for those on the solvent, were introduced in fixed calculated positions. The full-matrix least-squares refinement was completed using anisotropic thermal parameters on the solvent atoms [O(43) through C(45)] and fixed hydrogen atoms. The final *R* was 0.051, *Rw*(*F*) was 0.050. The number of parameters varied was 390, including the scale factor and the isotropic extinction parameter.

The final difference map was essentially feature-

less; there were a few peaks of about 2 e/Å^3 in the close proximity of the tungsten atoms.

Abstract—The reaction of $[(Me_3Si)_2N]_2\overline{UN(SiMe_3)SiMe_2CH_2}$ with $\geqslant 4.5$ equivalents of t-butanol in toluene provides a green crystalline solid formulated as $U_2(OBu^t)_8(HOBu^t)$ on the basis of elemental analysis, ^1H NMR, IR and UV–vis spectroscopy. $U_2(OBu^t)_8(HOBu^t)$ reacts with $KOBu^t$ (or KH) to give the potassium salt $KU_2(OBu^t)_9$, with dry dioxygen to give $U_2(OBu^t)_9$, and with H_2O to give $U_3O(OBu^t)_{10}$. Temperature-dependent magnetic susceptibility measurements (2–250 K) on solid $U_3O(OBu^t)_{10}$ show Curie–Weiss behaviour from 90 to 250 K. Below 90 K the susceptibility becomes temperature independent with no evidence of magnetic ordering.

Early in the development of uranium(IV) chemistry, Gilman and co-workers reported the preparation of uranium(IV) alkoxides, $U(OR)_4$. These were obtained by alcoholysis of $[U(NEt_2)_4]_2$, or via the reaction of UCl_4 with LiOR in alcohol solution (R = Me, Et).[2] In the case of $U(OBu^t)_4$, a third procedure was advocated. Uranium tetrachloride and four equivalents of potassium amide were allowed to react in liquid ammonia, and the product, formulated as $U(NH_2)_4$ (not isolated), was treated with excess t-butanol [eq. (1)]:

$$UCl_4 + 4KNH_2 \xrightarrow{NH_3} \text{“}U(NH_2)_4\text{”} \xrightarrow{\text{excess } Bu^tOH} U(OBu^t)_4. \quad (1)$$

After removal of NH_3, a green solid was extracted into hexane and isolated by evaporation of the solvent. The identity of the final product as $U(OBu^t)_4$ was established solely on the basis of a uranium analysis. Six years later, Bradley *et al.* reported that they were unable to reproduce the synthesis of $U(OBu^t)_4$. Following Gilman's procedure, they isolated a grey–brown crystalline uranium(V) product, which was formulated as $UO(OBu^t)_3(Bu^tOH)$ on the basis of a uranium analysis and a valency determination.[3]

In 1979, Perego and co-workers claimed that they were able to prepare Gilman's $U(OBu^t)_4$ by a different route. They isolated a green solid by treatment of tetra(π-allyl)uranium(IV), $U(C_3H_5)_4$, with excess t-butanol in diethyl ether.[4] Characterization of the product as $U(OBu^t)_4$ was based on acceptable uranium analyses. Characteristic IR bands were also reported for $U(OBu^t)_4$, but no ^1H NMR data were presented. In view of subsequent work, however, it would appear that Perego's $U(OBu^t)_4$ is distinct from the compound reported by Gilman.

In 1984, Cotton and co-workers once again repeated Gilman's original procedure [eq. (1)] and, unlike Bradley *et al.*, they were able to isolate a green, hexane-soluble product. The latter was shown to be $KU_2(OBu^t)_9$ by X-ray crystallography.[5] The Cotton group indicated that rigorous exclusion of oxygen and water, and the maintenance of low temperatures ($\leqslant -10°C$) during work-up, were required to obtain this product pure and in reasonable yield. They also reported that, in

* For part IV, see ref. 1.

† This paper is dedicated to Professor Dick Fenske, friend and teacher, on the occasion of his retirement from the University of Wisconsin.

‡ Author to whom correspondence should be addressed.

solution, $KU_2(OBu^t)_9$ was slowly and spontaneously transformed into the mixed-valent diuranium(IV,V) compound $U_2(OBu^t)_9$. The same authors also found that another green uranium(IV) complex, viz. trinuclear $U_3O(OBu^t)_{10}$, could, in at least one instance, be isolated from the same reaction mixture.[6a] In a subsequent paper on $U_3O(OBu^t)_{10}$,[6b] the authors mentioned that their procedure for isolating the trimer differed from later preparations of $KU_2(OBu^t)_9$ in that the green hexane extract was kept at room temperature for an extended period of time.

Dormond *et al.*[7] have found that alcoholysis of the mononuclear uranium(IV) metallocycle complex, $[(Me_3Si)_2N]_2U\overline{N(SiMe_3)SiMe_2CH_2}$,[8] with either HO-2,6-$Me_2C_6H_3$ or Bu^tOH proceeds via initial rapid protonation of the U—C bond to form $[(Me_3Si)_2N]_3UOR$ complexes. It was also noted that, in the presence of an excess of either alcohol, substitution of amide ligands occurred. These multiply substituted products were not characterized further. We have recently shown that Dormond's procedure can be used to prepare $U(O\text{-}2,6\text{-}Bu^t_2C_6H_3)_4$, which is the first structurally characterized example of a monomeric $U(OAr)_4$ complex.[1] In this report, we describe the product obtained from the reaction of excess t-butanol with $[(Me_3Si)_2N]_2U\overline{N(SiMe_3)SiMe_2CH_2}$, some of its reaction chemistry, and its relationship to the compounds reported by Perego[4] and Cotton.[5,6]

RESULTS AND DISCUSSION

Synthesis and characterization

Reaction of $[(Me_3Si)_2N]_2U\overline{N(SiMe_3)SiMe_2CH_2}$ with $\geqslant 4.5$ equivalents of Bu^tOH in toluene [eq. (2)], results in complete substitution of amides for alkoxides, but the resulting complex does not have the empirical formula of $U(OBu^t)_4$. We formulate the green, hydrocarbon-soluble product as $U_2(OBu^t)_8(HOBu^t)$ on the basis of elemental analyses, ^1H NMR, IR and UV–vis spectroscopies, and chemical studies. The same compound can be prepared in an analogous fashion from $[U(NEt_2)_4]_2$ [eq. (3)]:[2,9]

$$[(Me_3Si)_2N]_2U\overline{N(SiMe_3)SiMe_2CH_2} + \geqslant 4.5Bu^tOH \xrightarrow[25°C]{\text{toluene}} 0.5\,U_2(OBu^t)_8(HOBu^t) + 3(Me_3Si)_2NH \quad (2)$$

$$[U(NEt_2)_4]_2 + \geqslant 9.0Bu^tOH \xrightarrow[25°C]{\text{toluene}} U_2(OBu^t)_8(HOBu^t) + 8Et_2NH. \quad (3)$$

The room temperature ^1H NMR spectrum of $U_2(OBu^t)_8(HOBu^t)$ in benzene-d_6 shows only one broad Bu^t signal (δ 1.5) and a broad signal at δ 13.0, which we assign as the OH proton. The intensity ratio of these two signals is *ca* 80 : 1. We were unable to "freeze out" a static structure in toluene-d_8 in the temperature range +25 to −90°C. A ν(O—H) stretch in the IR spectrum of $U_2(OBu^t)_8(HOBu^t)$ was not readily apparent. We tentatively assign it as the very weak band located at 3537 cm^{-1}. Other IR features are similar, but not identical, to those reported by Perego and co-workers[4] for their sample of $U(OBu^t)_4$.

$U_2(OBu^t)_8(HOBu^t)$ is stable in toluene at room temperature. It reacts readily with potassium t-butoxide or potassium hydride in toluene or hexane to generate $KU_2(OBu^t)_9$ [eqs (4)–(5)]:

$$U_2(OBu^t)_8(HOBu^t) + KOBu^t \xrightarrow{\text{toluene}} KU_2(OBu^t)_9 + HOBu^t \quad (4)$$

$$U_2(OBu^t)_8(HOBu^t) + KH \xrightarrow{\text{hexane}} KU_2(OBu^t)_9 + 0.5H_2. \quad (5)$$

Upon exposure to dry air, green solutions of $U_2(OBu^t)_8(HOBu^t)$ rapidly turn orange–red. The UV–vis spectrum of the latter is essentially identical to that reported by Cotton and co-workers for a sample of the crystallographically characterized mixed-valent compound $U_2(OBu^t)_9$ (Fig. 1).[5] These results, coupled with the fact that the UV–vis spectra of $U_2(OBu^t)_8(HOBu^t)$ and $KU_2(OBu^t)_9$ are very

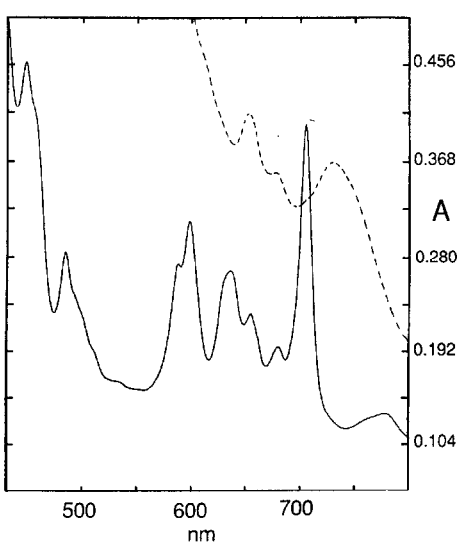

Fig. 1. Electronic absorption spectra of a 5.5×10^{-3} M hexane solution of $U_2(OBu^t)_8(HOBu^t)$ before (——) and after (– – –) exposure to dry air.

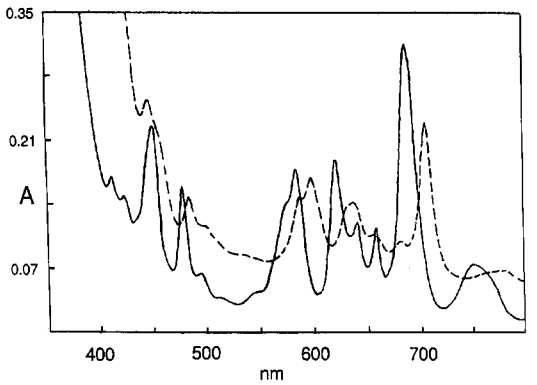

Fig. 2. Electronic absorption spectra of $U_2(OBu^t)_8(HOBu^t)$ (---) and $KU_2(OBu^t)_9$ (——), 3.1×10^{-3} M hexane solutions.

similar (Fig. 2), suggests that the compounds have similar structures. *Chem3D* representations of $KU_2(OBu^t)_9$ and the proposed structure of $U_2(OBu^t)_8(HOBu^t)$ are shown in Fig. 3.

We have also found that when toluene solutions of $U_2(OBu^t)_8(HOBu^t)$ are treated with oxygen-free H_2O, another green compound is reproducibly isolated in good yield [eq. (6)]:

$$3U_2(OBu^t)_8(HOBu^t)+2H_2O \xrightarrow{\text{toluene}} 2U_3O(OBu^t)_{10}+7HOBu^t. \quad (6)$$

The identity of the latter as $U_3O(OBu^t)_{10}$ was confirmed by comparison of the unit cell dimensions of a single crystal with those reported in the literature.[6] The ^1H NMR spectrum of $U_3O(OBu^t)_{10}$, which has not been reported previously is shown in Fig. 4. The 3:3:3:1 pattern is consistent with the solid state C_{3v} structure.[6] A *Chem3D* representation of $U_3O(OBu^t)_{10}$ is also shown in Fig. 3.

The $KU_2(OBu^t)_9$ used to record the spectrum shown in Fig. 2 was prepared in good yield directly from UCl_4 by the addition of 4.5 equiv. of $KOBu^t$ in THF [eq. (7)]. This method is more convenient than the original liquid ammonia synthesis. $KU_2(OBu^t)_9$ is thermally stable at room temperature under *rigorously* dry and anaerobic conditions.

$$UCl_4+4.5\text{eq. }KOBu^t \xrightarrow{\text{toluene}} 0.5\,KU_2(OBu^t)_9+4KCl. \quad (7)$$

When exposed to dry air, solutions of $KU_2(OBu^t)_9$ turn orange–red much more slowly (days) than do solutions of $U_2(OBu^t)_8(HOBu^t)$. This is consistent

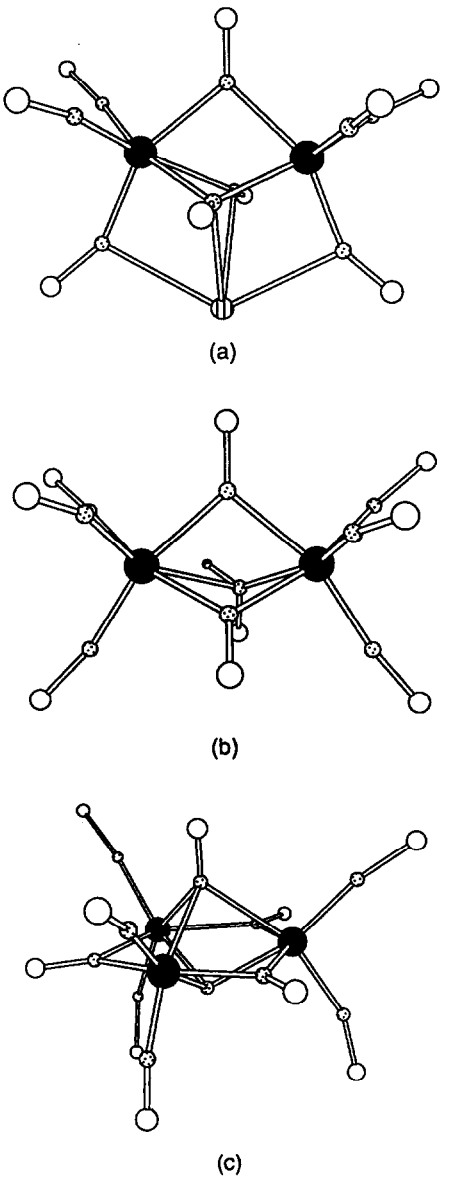

Fig. 3. *Chem3D*[18] representations of (a) $KU_2(OBu^t)_9$,[5] (b) $U_2(OBu^t)_8(HOBu^t)$ (proposed) and (c) $U_3O(OBu^t)_{10}$.[6] Uranium, oxygen, carbon and potassium atoms are indicated with black, speckled, open and hashed circles, respectively; the t-butyl methyl groups have been omitted from the drawings for clarity.

with Gilman's observations on the air-sensitivity of "$U(OBu^t)_4$".[2] $KU_2(OBu^t)_9$, like $U_2(OBu^t)_8(HOBu^t)$, also reacts with H_2O to produce $U_3O(OBu^t)_{10}$.* Thus, the reaction properties of both $KU_2(OBu^t)_9$ and $U_2(OBu^t)_8(HOBu^t)$ are complementary. A summary of all of this chemistry is given in Scheme 1.

Magnetic properties of $U_3O(OBu^t)_{10}$

As noted by Cotton,[6b] $U_3O(OBu^t)_{10}$ is structurally similar, in a qualitative sense, to the

* The presence or absence of small amounts of adventitious water in the synthesis of $KU_2(OBu^t)_9$ might account for the irreproducibility of the trimer synthesis.[6b]

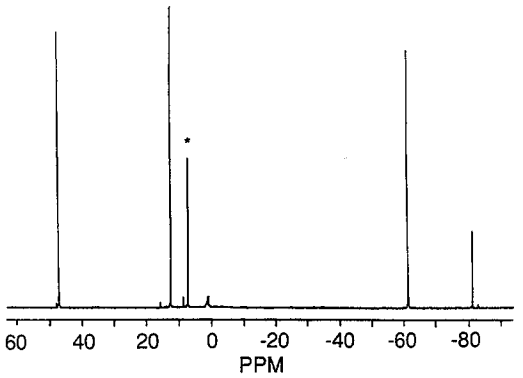

Fig. 4. ^{1}H NMR spectrum of $U_3O(OBu^t)_{10}$ in benzene-d_6 (*) at 22°C and 250 MHz.

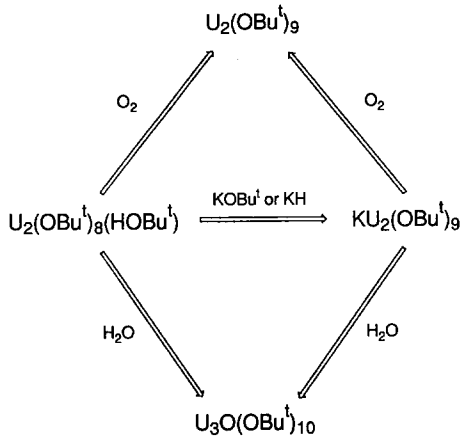

Scheme 1.

$M_3O(OR)_{10}$ cluster compounds (M = Mo or W; R = Pr^i) reported by Chisholm *et al.*[10] However, while the molybdenum(IV) and tungsten(IV) compounds contain M—M single bonds (d_{M-M} *ca* 2.5 Å), the U—U distance reported for the uranium trimer (3.573(1) Å) indicates that no U—U bonds are formed.[6] Uranium(IV), like molybdenum(IV) and tungsten(IV), has two electrons available for M—M bonding, but evidently the 5*f*–5*f* overlap is insufficient to stabilize U—U bonds.

The absence of metal–metal bonding in $U_3O(OBu^t)_{10}$ requires that the complex be paramagnetic. One indication of the latter is the isotropically shifted ^{1}H NMR spectrum shown in Fig.

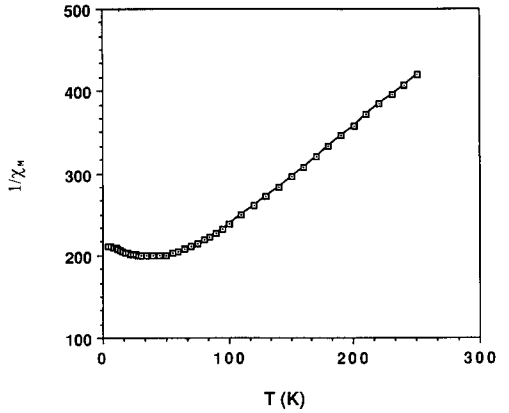

Fig. 5. Inverse susceptibility of $U_3O(OBu^t)_{10}$ vs temperature. The linear portion from 90 to 250 K was used to obtain the parameters given in the text.

4. The inverse of the molar magnetic susceptibility of $U_3O(OBu^t)_{10}$ in the temperature range 2–250 K is shown in Fig. 5. Above 90 K, the susceptibility follows the Curie–Weiss law

$$\chi_M = C/(T-\theta),$$

with $C = 0.78$, μ_{eff} (per uranium atom) $= 2.5\,\mu_B$ and $\theta = -88$ K.*

Below 90 K, the susceptibility deviates markedly from Curie–Weiss behaviour. One possibility to consider is magnetic ordering (i.e. antiferromagnetic coupling) in the trinuclear complex. Magnetic exchange phenomena have been claimed previously for two amide adducts of UCl_4, viz. $UCl_4 \cdot 3DMBA$ and $UCl_4 \cdot 3MAA$ (DMBA = N, N′-dimethylbenzamide; MAA = N-methylacetanalide).[12] The X-ray structures of these adducts are not known, but the authors assumed they were dimers and interpreted their susceptibility data, at least that portion from *ca* 70 to 280 K, in terms of a Heisenberg spin–spin interaction ($-2J\mathbf{s}_1 \cdot \mathbf{s}_2$) between the uranium centres. Assuming a Heisenberg coupling model, the Van Vleck equation for three interacting $S = 1$ ions arranged in an equilateral triangle is[13,14]

$$\chi_M = Ng^2\mu_B^2/kT \cdot [28e^{12J/kT} + 20e^{6J/kT} + 6e^{2J/kT}] \cdot [7e^{12J/kT} + 10e^{6J/kT} + 9e^{2J/kT} + 1]^{-1},$$

where J is the exchange energy and the other symbols have their usual meaning. Attempts to fit the molar susceptibility data to this equation, with J as the only variable, were unsatisfactory.†

The failure of the Heisenberg model prompts another explanation for the magnetic behaviour below 90 K. As noted above, uranium(IV) has a [Rn]$5f^2$ electron configuration. The ground *L*–*S* state of uranium(IV) is $^3H_4$. In an octahedral crystal-field, the $J = 4$ term splits into one singlet state,

* The values of C and μ_{eff} are comparable to those found for $[U(NEt_2)_4]_2$ and $[U(CH_3NCH_2CH_2NCH_3]_3$.[9,11]

† The susceptibility equation requires that χ_M decrease rapidly toward zero as $T \rightarrow 0$ K, which is clearly not the case with our data. We note that the expression for χ_M was derived assuming $g_x = g_y = g_z$, which need not be the case in the uranium(IV) cluster.

one doublet state and two triplet states.[15] In the trimer, the local symmetry about each uranium(IV) centre is only C_s. Lowering the symmetry to this level lifts all of the octahedral degeneracies. We propose that the empirical magnetic susceptibility is the sum of the susceptibilities of the three isolated uranium(IV) ions. The inverse susceptibility is nearly temperature independent in the region below 90 K and the measured results are consistent with a singlet ground state with a second singlet state (or states) located approximately 60 cm^{-1} above the former.*

SUMMARY

The history of "$U(OBu^t)_4$" dates back over 30 years. Early reports on the synthesis of this compound failed to provide conclusive proof for its existence.[2–4] In our opinion, Cotton and co-workers have established beyond reasonable doubt that the compound originally prepared in Gilman's laboratory was actually the potassium salt, $KU_2(OBu^t)_9$.[5] We have shown here that the alcohol adduct, $U_2(OBu^t)_8(HOBu^t)$, can be synthesized from well characterized starting materials, and have obtained spectroscopic data which support its formulation. We suggest that this is the same compound prepared by Perego and co-workers from $U(C_3H_5)_4$ and excess t-butanol.[4] We have also shown that Cotton's $KU_2(OBu^t)_9$ can be prepared from $U_2(OBu^t)_8(HOBu^t)$, or directly from UCl_4 and potassium t-butoxide. $KU_2(OBu^t)_9$ and $U_2(OBu^t)_8(HOBu^t)$ exhibit similar reactivity toward oxygen and water, and their UV–vis spectroscopic signatures indicate that they have similar structures.† Finally, we have developed a reproducible route to the previously reported trinuclear uranium(IV) complex, $U_3O(OBu^t)_{10}$, via hydrolysis of either $U_2(OBu^t)_8(HOBu^t)$ or $KU_2(OBu^t)_9$. $U_3O(OBu^t)_{10}$ is a promising starting material for further explorations of uranium(IV) cluster chemistry. Magnetic susceptibility data obtained on $U_3O(OBu^t)_{10}$ indicate that there is no magnetic ordering of its uranium(IV) centres down to 2 K.

It seems clear to us that $U(OBu^t)_4$ has not yet been reported in the literature. Since uranium(IV) compounds with sterically non-demanding ligands favour high coordination numbers (≥ 6), $U(OBu^t)_4$, assuming it can be isolated, will surely adopt an oligomeric structure, $[U(OBu^t)_4]_n$. Efforts to prepare this compound and related analogues are continuing in our laboratory.[17]

EXPERIMENTAL

General procedures

All reactions were carried out using standard techniques for the manipulation of air-sensitive materials. $[(Me_3Si)_2N]_2\overline{UN(SiMe_3)SiMe_2CH_2}$ was prepared and purified as described in the literature.[8] ^1H NMR spectra were recorded on an IBM AF250 spectrometer at 250 MHz. Chemical shifts are reported in ppm relative to the solvent ^1H impurity of benzene-d_6 (7.15 ppm).‡ IR spectra were recorded as Nujol mulls between KBr salt plates using a Digilab FTS-40 spectrophotometer. Electronic absorption spectra were recorded as hexane solutions using 1.0 and 0.10 cm matched quartz cells and a Perkin–Elmer Lambda 9 spectrophotometer. The X-ray powder pattern of $KU_2(OBu^t)_9$ was collected using a Siemens D-500 diffractometer with a θ–θ configuration. Low temperature (−90°C) single crystal X-ray data on $U_3O(OBu^t)_{10}$ were collected using a CAD-4 diffractometer. Elemental analyses were performed at Los Alamos using a Perkin–Elmer 2400 CHN Elemental Analyser and standard air-sensitive techniques. Samples were dried under high vacuum (10^{-4} torr) for 12 h. Hexane, toluene and THF were distilled under argon from sodium–potassium alloy and stored in a helium-filled dry-box operating at $\leq$ 1 ppm oxygen. Bu^tOH was dried by refluxing a benzene solution over magnesium, distilling the azeotrope and storing the solution in the dry-box. $KOBu^t$ was purchased from Aldrich and resublimed before use to remove non-volatile impurities.

Magnetic susceptibility data on $U_3O(OBu^t)_{10}$ were collected at the IBM T. J. Watson Research Center on a Quantum Design Superconducting Quantum Interference Device (SQUID) Magnetometer for temperatures ranging from 2 to 250 K at fields of 1 kOe and 10 kOe. Plots of magnetization vs field were linear at all temperatures. Data were background corrected for the sample tube (a 5 mm Pyrex NMR tube) and the ligands. The weight of the sample was 90 mg.

* The inverse molar susceptibilities of $[U(NEt_2)_4]_2$[9] and $U(SO_4)_2 \cdot 4H_2O$[16] also exhibit temperature independent behaviour at low temperature. Similar interpretations have been advanced to explain these observations.

† The latter point remains to be confirmed by X-ray crystallography. Structural characterization of $U_2(OBu^t)_8(HOBu^t)$ is in progress.

‡ The ^1H NMR spectra of the uranium complexes described in this paper are temperature *dependent*. The chemical shifts reported are for spectra collected at approximately 22°C.

$U_2(OBu^t)_8(HOBu^t)$

Excess Bu^tOH in benzene was slowly added to $[(Me_3Si)_2N]_2\overline{UN(SiMe_3)SiMe_2CH_2}$ (1.00 g, 1.39 mmol) in 20 cm^3 of toluene. The orange solution immediately turned green. The latter was stirred for 12 h at room temperature. The solution was evaporated to dryness *in vacuo* and the resulting green solid was recrystallized from hexane at −40°C and dried under high vacuum. Yield: 0.67 g, 85%. ^1H NMR (benzene-d_6, 22°C): δ 1.4 (br s, $C(CH_3)_3$); δ 13.0 (br s, O*H*). IR (cm^{-1}): 3537 (vw, OH); 1600 (w); 1352 (s), 1217 (ms), 1185 (s); 959 (vs); 903 (ms); 761 (m); 747 (mw); 726 (mw); 498 (ms); 474 (m). Found: C, 36.37, 36.26; H, 6.89, 6.84. Calc. for $C_{36}H_{82}O_9U_2$: C, 38.09; H, 7.29%.

$KU_2(OBu^t)_9$

UCl_4 (1.00 g, 2.63 mmol) was dissolved in 20 cm^3 of THF to give a green solution. 1.33 g (11.84 mmol) of $KOBu^t$ was added, in one portion, resulting in a colour change to purple–red and the formation of a white precipitate (KCl). Within a few minutes, the colour of the solution changed to green. After 12 h of stirring the solution was evaporated to dryness *in vacuo*. The green product was extracted into hexane and filtered through Celite. The volume was reduced and the solution cooled to −40°C, yielding 1.00 g of large green crystals, 65%. ^1H NMR (benzene-d_6, 22°C): δ 3.1 (s, 36H), 2.7 (s, 18H), −0.5 (s, 9H), −1.1 (s, 18H). IR (cm^{-1}): 1360 (s); 1350 (s); 1220 (s); 1197 (s); 1177 (vs); 1050 (mw); 1022 (w); 980 (s); 950 (vs); 921 (ms); 904 (s); 765 (ms); 755 (m); 665 (w); 523 (m); 494 (vs); 475 (s). Found: C, 36.61; H, 6.52. Calc. for $C_{36}H_{81}O_9KU_2$: C; 36.85; H, 6.97%. An X-ray powder pattern was in good agreement with the pattern calculated based on the single crystal data of Cotton *et al.*[5]

$U_3O(OBu^t)_{10}$

10 cm^3 of distilled H_2O were added to 500 cm^3 of toluene, and the resulting mixture was degassed by bubbling with HP argon for several hours. Addition of 50 cm^3 of this wet toluene to 1.0 g of either $KU_2(OBu^t)_9$ or $U_2(OBu^t)_8(HOBu^t)$ produced a slight colour change and the precipitation of a small amount of a solid. The solvent was immediately removed *in vacuo*. The green solid was extracted with hexane, the extracts were filtered and the green solution was stripped to dryness. At this point, a small amount of an unidentified impurity could be detected by ^1H NMR spectroscopy (δ 47.3, 46.0, 15.5, 8.8, −59.8, −60.8, −81.0; 1:2:1:2:1:2:1). The compound was recrystallized several times from hexane by slow cooling of a concentrated solution. The yields of $U_3O(OBu^t)_{10}$ from these reactions range from 50 to 80%. ^1H NMR (benzene-d_6, 22°C): δ 46.2 (s, 27H), 12.3 (s, 27H), −60.1 (s, 27H), −79.2 (s, 9H). Found: C, 32.63; H, 5.98. Calc. for $C_{40}H_{90}O_{11}U_3$: C, 32.87; H, 6.22%.

Abstract—Application of the INDO calculation of NMR chemical shift has been extended. Firstly, it is applied to the calculations of ^{13}C, ^{15}N and ^{17}O shieldings for a series of representative nitrogen- and oxygen-containing compounds. Then several ^{13}C shieldings of the three iron complexes $(C_5H_5)Fe(CO)_2CN$, $(C_5H_4)_2Fe(COH)_2$ and $(C_5H_4)Fe(CH_2OH)_2$ have been evaluated. The theoretical results are in good agreement with the experimental. In addition, it is found that the calculated diamagnetic contributions, $\sigma^d(M)$, of ^{13}C, ^{15}N and ^{17}O atoms exhibit a good linear relationship with the net charge, $\rho(M)$, on these atoms.

The rapid development of the NMR pulsed technique and its applications have aroused increasing interest in the analysis and explanation of ^{13}C, ^{15}N and ^{17}O shieldings. Therefore, it is hoped that there may be a theory and method of calculation which can not only be used to accurately elucidate experimental facts, but which are also rather simple. From this point of view, the semi-empirical scheme seems to be attractive.[1]

On the basis of the Sum-Over-States (SOS) perturbation theory, a semi-empirical molecular orbital theory of diamagnetism and shielding, and its simplified "average excitation energy" approximation have been proposed by Pople and coworkers. Thence many theoretical studies, based on EHMO,[2] INDO,[3] X_α-Scattered Wave,[4] MNDO,[5] approximations or *ab initio*[6,7] have been carried out, including authors' calculations of NMR chemical shifts of transition metal and lanthanum compounds.[8,9] These calculations can give experimentally observed trends in the chemical shifts and provide some useful qualitative results. However, there are some difficulties involved in this theory. First the working formulae with average ΔE^{-1} (the reciprocal of energy level difference) may cause considerable error. A more serious problem arises from the dependence of theoretical results upon the origin of coordinates.

In 1972, Ditchfield presented an *ab initio* SCF–MO perturbation theory of ^{13}C shielding employing gauge-invariant atomic orbitals (GIAO), which has marked an important breakthrough in NMR shielding theory.[10] Soon after this, Ellis *et al.* proposed an INDO perturbation theory of ^{13}C shieldings[11] which retains considerable *ab initio* computational accuracy, and at the same time, the CUP calculation time is greatly reduced. This approach marks the beginning of a new semi-empirical method of NMR shielding calculation. On the basis of INDO, a modified set of hydrogen, carbon and fluorine[12] INDO parameters lead to semi-quantitative agreement of the theoretical results with the experimental results.

* Dedicated to Professor R. F. Fenske, in appreciation of his inspiring guidance as my adviser during my stay as a visiting scholar (X. Z. You) at Wisconsin University in 1981.

† Author to whom correspondence should be addressed.

The present paper is concerned with extending the INDO/GIAO perturbation theory to include shielding calculations of transition metal complexes: so INDO parameters of the nitrogen and oxygen are modified by minimizing ^{13}C, ^{15}N and ^{17}O shielding differences between theoretical and experimental data for a series of representative nitrogen and oxygen-containing compounds; and some ^{13}C chemical shifts of several iron-containing complexes are evaluated by optimizing some iron INDO parameters.

Considering the level of approximation, the good agreement of the calculated values with the experimental data encouraged us to extend the theory to cover shielding calculations of other metal compounds.

METHOD OF CALCULATION

By assuming a homogeneous external perturbation field to be **B**, then gauge-invariant atomic orbitals can be represented as:

$$\chi_v = \{\exp[-(i/C)\mathbf{A}_v \cdot \mathbf{r}]\}\chi_v^0 = f_v\chi_v^0, \quad (1)$$

where $\mathbf{A}_v$ is a vector potential at nucleus v, $\mathbf{A}_v = \frac{1}{2}\mathbf{B}\times\mathbf{R}$, with $\mathbf{R}_v$ as the position vector of the atom upon which the unperturbed atomic orbital is centred.

Then the molecular orbitals are expanded as linear combinations of GIAO with complex coefficients C_{vi}:

$$\phi_i = \sum_v \chi_v C_{vi}. \quad (2)$$

Here, the density matrix is defined as

$$R_{\eta\sigma} = \sum_j^{\text{occ}} C_{\eta j}^* C_{\sigma j} = R_{\eta\sigma}^r + iR_{\eta\sigma}^i, \quad (3)$$

where superscripts r and i stand for the real and imaginary parts, respectively.

The Fock matrix F is represented as

$$F = H+G = (H^r+G^r)+i(H^i+G^i), \quad (4)$$

then the G matrix is generated to include shielding calculations of the transition metal complex in the case where p and q are centred on the same atom by the following:

$$\overset{r}{G}pp = \sum_{B\neq A} 2R_{BB}^r v_{AB} + \sum_\lambda^A 2R_{\lambda\lambda}^r[(pp\|\lambda\lambda) - 1/2(p\lambda|p\lambda)] \quad (5)$$

$$\overset{i}{G}pp = 0$$

$$\overset{r}{G}pq = \overset{r}{R}pq[3(pq|pq) - (pp|qq)]$$

$$\overset{i}{G}pq = -\overset{i}{R}pq[(pq|pq) - (pp|qq)]. \quad (6)$$

When p and q refer to different atoms A and B, the formulae for G and H are the same as in ref. 11. The one-centre Coulomb integrals $(pp|qq)$ and exchange integrals $(pq|pq)$ of s, p and d orbitals in eqs (5) and (6) can be evaluated by Condon–Shortley integration.[12,13]

By substituting the equation in refs 12 and 13 into eqs (5) and (6), we obtain the integral formulae adopted by Ellis *et al.*,[11] which show that eqs (5) and (6) are, indeed, extended formulae.

The shielding tensor, $\sigma_{\alpha\beta}(M)$, can be obtained from the definition using eqs (7)–(9):

$$\sigma_{\alpha\beta}(M) = \sigma_{\alpha\beta}^d(M,M) + \sigma_{\alpha\beta}^p(M,M) + \sum_{K\neq M}[\sigma_{\alpha\beta}^d(M,K) + \sigma_{\alpha\beta}^p(M,K)] \quad (7)$$

$$\sigma_{\alpha\beta}^d(M,K) = 2\sum_\mu^K\sum_\nu^K R_{\mu\nu}(0)\langle\chi_\mu^0|h''_{\alpha\beta}(M)|\chi_\nu^0\rangle \quad (8)$$

$$\sigma_{\alpha\beta}^p(M,K) = 2\sum_\mu^K\sum_\nu^K (\partial R_{\mu\nu}/\partial B_\alpha)_0\langle\chi_\mu^0|h_\beta^{10}(M)|\chi_\nu^0\rangle, \quad (9)$$

where $\sigma_{\alpha\beta}^d(M,K)$ and $\sigma_{\alpha\beta}^p(M,K)$ are the diamagnetic and paramagnetic contributions of nuclear screening, respectively, and $R_{\mu\nu}(0)$ are the unperturbated density matrix elements. The derivative of $R_{\mu\nu}$ with respect to a component B_α of **B** is numerically approximated using a different method

$$(\partial R_{\mu\nu}/\partial B_\alpha)_0 \approx iR_{\mu\nu}^i/B_\alpha. \quad (10)$$

In order to consider the different molecular environments of non-equivalent atoms, as in previous work, Slater's screening rules are used to modify the "old" exponents in the calculation of integrals of $\langle r^{-3}\rangle$ and $\langle r^{-1}\rangle$ types. The following modified expression can be used

$$\xi'_N = \xi_N + 0.175Q_N, \quad (11)$$

where ξ_N stands for the pre-modified "old" Slater's exponent[14] and ξ'_N the modified "new" exponent for atom N which may be carbon, nitrogen, oxygen or fluorine; Q_N is the net charge on atom N.

CHOICE OF PARAMETERS

Firstly, we used the INDO/GIAO calculation of ^{13}C, ^{15}N and ^{17}O chemical shifts for a representative set of nitrogen and oxygen compounds by modifying nitrogen and oxygen INDO $(I+A)/2$ and β parameters so as to minimize the average difference between theoretical and experimental data. Table 1 gives the "new" parameters of nitrogen and oxygen together with those of hydrogen and carbon from ref. 11.

Then we further modified some iron INDO parameters in order to reduce the error of shielding of

Table 1. Standard and "new" H, C, N and O INDO parameters

		Standard	"New"
Hydrogen	$(I+A)_s/2$	7.176	7.176
	β_0	−9.0	−12.0
Carbon	$(I+A)_s/2$	14.051	17.051
	$(I+A)_p/2$	5.572	8.572
	β_0	−21.0	−17.0
Nitrogen	$(I+A)_s/2$	19.316	23.5
	$(I+A)_p/2$	7.275	10.5
	β_0	−25.0	−22.5
Oxygen	$(I+A)_s/2$	25.390	29.5
	$(I+A)_p/2$	9.111	15.75
	β_0	−31.0	−27.8

carbon atoms C^1, C^2 and C^3 in the iron complex $(C_5'H_5)Fe(C^2O)_2C^3N$. The iron Slater exponents[15] are fixed during the modification process. In the course of reparameterization, we noticed that the $(I+A)_{4s}/2$ and $(I+A)_{4p}/2$ INDO parameters do not have much influence upon the calculated results, so hitherto we have kept them fixed and only altered $(I+A)_{3d}/2$, $\beta_{4s}(\beta_{4p}=\beta_{4s})$ and β_{3d} parameters. The final iron INDO parameters are listed in Table 2. The Slater–Condon parameters[16] used to evaluate one-centre Coulomb and exchange integrals of iron are listed in Table 3.

From Table 1, by comparing "new" parameters with "old" ones for all carbon, nitrogen and oxygen atoms, we find an obvious trend of increasing $(I+A)/2$'s, with decreasing β's. Moreover, the δ^p and σ^d data listed in Tables 4 and 9 show that the change of chemical shifts is mainly determined by paramagnetic terms, σ^p, that is to say, σ^p terms change considerably for different molecules, while σ^d terms do not.

Table 2. Iron INDO parameters

Exponents[15]	Electronegative	Bonded parameters
$\xi_{4s}=1.3585$	$(I+A)_{4s}/2=4.120$[16]	$\beta^0_{4s}=-12.0$
$\xi_{4p}=1.1601$	$(I+A)_{4p}/2=1.062$[16]	$\beta^0_{4p}=-12.0$
$\xi_{3d}=3.7266$	$(I+A)_{3d}/2=9.50$	$\beta^0_{3d}=-45.0$

RESULTS AND DISCUSSION

Fortran language has been used to code the computer program INDO/GIAO for the above-mentioned INDO/GIAO theory using a Burroughs-6933 computer. Using the INDO/GIAO program with the parameters presented in Tables 1 and 2, we have carried out the ^{13}C, ^{15}N and ^{17}O chemical shift calculations for four groups of compounds, including H, C, N, O and Fe atoms. Moreover, geometries are quoted from refs 17–19 and the one-centre integration including *d* orbitals in eqs (7)–(9) from ref. 9. The calculated results are given in Tables 4–7. The shift data are relative to reference molecules with low-field shifts being positive.

Tables 5 and 6 show that the ranges of ^{15}N and ^{17}O shieldings of the two selected groups of nitrogen- and oxygen-containing compounds are about 380 and 600 ppm, respectively. Moreover, the average differences between theoretical and experimental values are 16.79 and 30.34 ppm, respectively.

In order to check the availability of new nitrogen and oxygen INDO parameters for the ^{13}C chemical shift calculation, we have chosen some compounds containing hydrogen, carbon, nitrogen and oxygen atoms, and evaluated their ^{13}C shifts. The data listed in Table 4 give an average absolute error of about 28.71 ppm. The data in Tables 4–9 show a good semi-quantitative agreement between calculated and experimental values, not only for ^{15}N and ^{17}O, but also for the ^{13}C shifts.

A number of important effects are revealed. The observed low-field ^{13}C shift of C^aH_3CN relative to CH_3C^aN in Table 4 is ascribed to the multiple bonds. Marked effects of the nature of substituents on carbon and the type of bonding are also shown.

Nitrogen has some features that distinguish it from carbon because of the presence of unshared electron pairs. The data in Table 5 also show the overall agreement between the calculated and the observed shifts. The nitrogen shifts are greatly dominated by paramagnetic contributions.

Although the medium effects caused by the electron pair on the oxygen atom occurred, the ^{17}O data in Table 6 show an overall satisfactory agreement between the calculated and experimental results. Moreover, our results also show the trend of singly-bonded ^{17}O shift of about 200 ppm downfield from

water and the doubly-bonded shift at still lower field, which agree well with the *ab initio* level.

The chemical shift calculations of organometallic compounds are rather complicated. ^{13}C shifts of compound $(C_5H_5)Fe(CO)_2CN$ have already been calculated. It is seen from Table 7 that the present calculations seem to reflect the experimental trends more succinctly.

It must be emphasized that Figs 1–3 show a good linear relationship between the calculated diamagnetic terms, σ^d(M), of ^{13}C, ^{15}N and ^{17}O shifts,

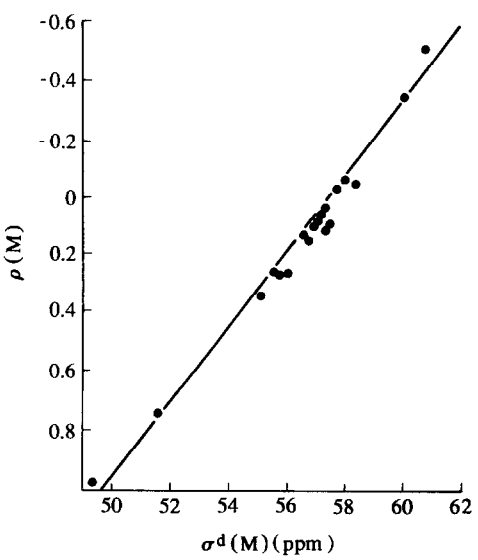

Fig. 1. ρ(M) of ^{13}C vs σ^d(M).

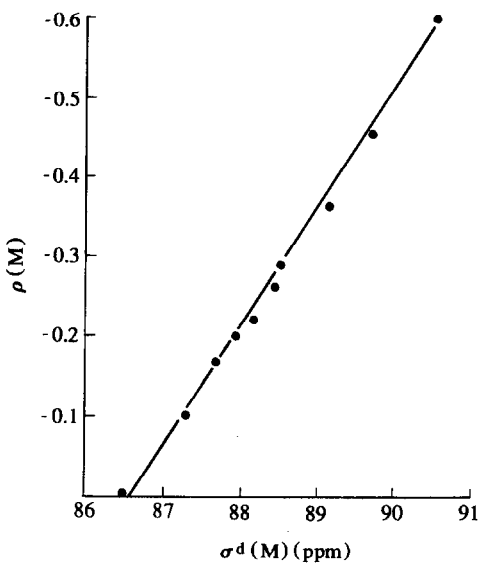

Fig. 2. ρ(M) of ^{15}N vs σ^d(M).

and the corresponding atomic net charge, β(M), on atom M.

The above-mentioned method has also been used to calculate the shieldings for more complicated organometallic compounds including *f* orbitals.[21]

SUMMARY AND CONCLUSIONS

The finite perturbation INDO method of ^{13}C shifts for hydrocarbons due to Ellis *et al.* has been extended to ^{13}C, ^{15}N and ^{17}O chemical shift cal-

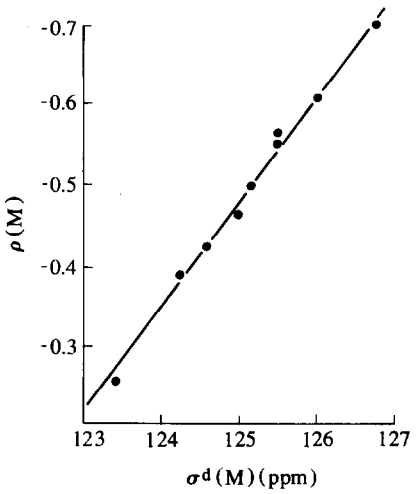

Fig. 3. ρ(M) of ^{17}O vs σ^d(M).

culations for a series of molecules including some organometallic compounds. The molecules treated cover a wide range of chemical environments and consequently a wide range of shieldings. A modified set of nitrogen, oxygen and carbon INDO parameters together with the careful selection of iron $(I+A)_{3d}/2$, β^0_{4s} and β^0_{3d} parameters lead to a reasonable agreement between calculated and experimental shifts. The computational scheme discussed in this paper is even better than the relevant X_α-Scattered Wave method for some shift calculations of organometallic compounds. Moreover, a close linear relationship between the diamagnetic terms σ^d(M) of ^{13}C, ^{15}N and ^{17}O shift, and the corresponding net atomic charge ρ(M) on atom M have been revealed.

Our calculation experiments showed high computational speed and good convergency even for rather complicated organometallic compounds including those having more than 100 molecular orbitals. It may therefore provide a suitable semiempirical method of chemical shift calculations for complicated metal complexes.

AN INVESTIGATION OF THE ELECTRONIC FACTORS THAT INFLUENCE STRUCTURAL DIFFERENCES BETWEEN *CIS*-$(CpMoCl)_2(\mu,\eta^4\text{-}Ar_4C_4)$ (Ar = *p*-TOLYL OR PHENYL) AND *TRANS*-$(CpNbCO)_2(Ph_2C_2)_2$†

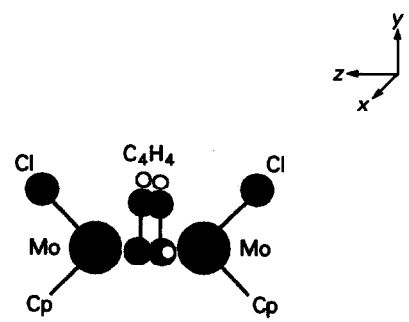
MARIA CLELIA MILLETTI‡ and M. DAVID CURTIS

Department of Chemistry, The University of Michigan, Ann Arbor, MI 48109-1055, U.S.A.

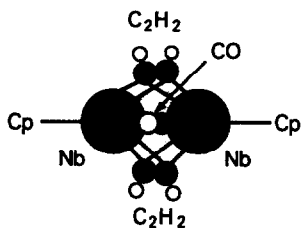
Abstract—The influence of geometric factors, such as *cis*/*trans* isomerism, and electronic factors, such as π donor vs π acceptor ligands and coupled and uncoupled acetylene ligands, on the stability of *cis*-$(CpMoCl)_2(\mu,\eta^4\text{-}Ar_4C_4)$ and *trans*-$(CpNbCO)_2(Ph_2C_2)_2$ is investigated through patterns in molecular orbital diagrams, size of HOMO/LUMO gap and total energies. The comparison between the two dimers involves rationalization of why the observed structures appear so different, when in fact both clusters have the same number of valence electrons. In the course of the investigation, other stable niobium chlorine complexes are discussed and the kinetic vs thermodynamic stability of *trans*-$(CpNbCO)_2(Ph_2C_2)_2$ is analysed.

An interesting series of new organometallic dimers has been synthesized as part of an ongoing investigation of metal–metal multiple bonds.[1] This paper will focus on two of these dimers: they are of the type $Cp_2M_2L_2R$, where M = Mo or Nb, L = CO or Cl, and R = μ,η^4-Ar_4C_4 or $(Ar_2C_2)_2$ (Ar = *p*-tolyl or phenyl).

More specifically, it is of interest to compare the structures of *cis*-$(CpMoCl)_2(\mu,\eta^4\text{-}Ar_4C_4)$ (**1**) and *trans*-$(CpNbCO)_2(Ph_2C_2)_2$ (**2**).[2] These two complexes have identical electron counts: niobium has one less valence electron than molybdenum, but the carbonyl ligand is considered a two-electron donor, while chlorine is a one-electron donor [both $(\mu,\eta^4\text{-}Ar_4C_4)^{2-}$ and $(Ph_2C_2)_2$ are eight-electron donors].[3] Despite sharing the same number of valence electrons these two dimers have very different structures:[4]§



1



2

The two molecules differ in their conformation (one is *cis* and the other *trans*) and in the molybdenum dimer the two alkyne ligands have coupled to form a $(\mu,\eta^4\text{-}Ar_4C_4)$ ligand, while in the niobium complex two separate acetylene groups are present.

† Dedicated to Professor Richard F. Fenske in recognition of his contribution to theoretical organometallic chemistry and in appreciation of his guidance as my PhD adviser (M.C.M).

§ The aryl and phenyl groups present in the dimers have been substituted by hydrogen atoms in order to simplify the molecular orbital calculations (see text).

The structural and electronic features that distinguish the molybdenum from the niobium dimer can be grouped into three categories: *cis* or *trans* arrangement, Cl or CO ligands, coupled C_4H_4 or uncoupled $(C_2H_2)_2$ alkyne ligands. This paper will attempt to explain why the molybdenum dimer prefers one set of features and the niobium dimer the other by using non-empirical molecular orbital calculations. The three aspects will first be studied separately, and then taken into consideration simultaneously in order to justify the observed structures. The results of the calculations will be analysed in terms of the nature and energy of the valence molecular orbitals, as well as the relative total energies of the complexes.

COMPUTATIONAL PROCEDURE

Calculations have been carried out by using the Fenske–Hall non-empirical method[5] on an IBM 3090-600 computer.[6] Atomic basis functions were employed; for oxygen, carbon and chlorine Clementi's double-ξ functions were used,[7] except for 1*s* and 2*s* functions, which were curve-fit to single-ξ by using the maximum overlap criterion.[8] The hydrogen exponent was set to 1.16. Molybdenum(I) and niobium(I) functions were obtained by performing an atomic X-α calculation on a set of optimized, orthonormal Slater-type orbitals.[9] In order to avoid working with metal outer functions that are too diffuse, the molybdenum 5*s* and 5*p* exponents were set to 1.85. The niobium 5*s* exponent was set to 1.602 and the 5*p* exponent to 1.259. The total energy for each molecule was calculated using the Hartree–Fock expression.[10,11]

The geometrical parameters used for the experimentally observed compounds [*cis*-$(CpMoCl)_2(\mu,\eta^4\text{-}Ar_4C_4)$,[3] *trans*-$(CpNbCO)_2(Ph_2C_2)_2$[2b] and *trans*-$(MeCp)_2Nb_2(Ar_2C_2)_2(\mu\text{-}Cl)_2$[12]] were taken from the actual X-ray structures, but, for simplicity of interpretation and greater ease in the calculations, the phenyl and *p*-tolyl substituents on the R ligands have been substituted by a hydrogen atom. Table 1 shows selected bond distances for the two basic dimer frames considered in this work: that of *cis*-$(CpMoCl)_2(C_4H_4)$ and that of *trans*-$(CpNbCO)_2(C_2H_2)_2$. These two geometries are also used for the structures of *cis*-$(CpNbCl)_2(C_4H_4)$ and *trans*-$(CpMoCO)_2(C_2H_2)_2$. For *cis*-$(CpMoCO)_2(C_4H_4)$, the Mo—C_{CO} bond distance was taken to be 1.99 Å, which is the value found in a series of $CpMo(CO)_3R$ complexes.[13] In *trans*-$(CpNbCl)_2(C_2H_2)_2$, the Nb—Cl bond distance was set to 2.25 Å.[14]

The geometry of *trans*-$(CpMoCl)_2(C_4H_4)$ cannot be made to match that of *trans*-$(CpNbCO)_2(C_2H_2)_2$ because the C_4H_4 ligand would be too close to the chlorine centres. Therefore, to obtain the geometry of the molybdenum dimer, half of the *cis*-$(CpMoCl)_2(C_4H_4)$ dimer was rotated by 180° along the Mo—Mo axis, leaving the C_4H_4 ligand in place. On the other hand, the arrangement in *cis*-$(CpNbCl)_2(C_2H_2)_2$ can be made to resemble that of the experimentally observed molybdenum dimer by rotating half of *trans*-$(CpNbCO)_2(C_2H_2)_2$ by 180° along the Nb—Nb axis and leaving the C_2H_2 ligands in place. Furthermore, the two cyclopentadienyl rings are moved closer together at a 45° angle to the M—M axis and the two carbonyl ligands are pointed away from, rather than at, each other. Bond lengths and angles for the other dimers were extrapolated from the known geometries.

RESULTS AND DISCUSSION

The two experimentally observed dimers

In order to study the influence of the three geometrical factors on the electronic structure of the title compounds, it is best to start from an analysis of the MO diagram for each of the two molecules. Figure 1 shows the MO diagram for *cis*-$(CpMoCl)_2(C_4H_4)$ (**1**). The HOMO/LUMO gap is fairly large (2.87 eV), pointing to the stability of the com-

plex.[15] The five valence molecular orbitals (two occupied and three unoccupied) are in an e+t pattern and are largely metal-based. A fairly large gap separates the SHOMO (Second Highest Occupied Molecular Orbital) from the next set of occupied orbitals, which is comprised of in-phase and out-of-phase combinations of Cl 3*p* orbitals. The lowest-energy molecular orbital shown (b_2) is part of the atomic Mo—C_4H_4 bonding interaction: only the end carbons of the C_4H_4 ligand are participating in the bond via a hybrid orbital that is pointing toward one of the metal centres† [see Fig. 5(c)]. The metal centres are bonding with a combination of their d_{xy} and d_{xz} orbitals.

Figure 2 shows the MO diagram for the other dimer, *trans*-$(CpNbCO)_2(C_2H_2)_2$ (**2**). The HOMO/LUMO gap is not as large as the one in the molybdenum complex, but it still indicates that **2** is a stable molecule. The valence molecular orbitals do not show the e+t pattern present in **1** and they receive larger contributions from the ligand orbitals. The first three unoccupied molecular orbitals are mainly CO π* in character, as usual for molecules with carbonyl ligands.[11] The HOMO and the SHOMO are metal–metal bonding, which is consistent with the experimental observation of a Nb—Nb bond length characteristic of a double bond between the centres.[2b,16] The two lowest levels shown in Fig. 2, b_g and a_u, contribute to the bonding between the metals and the acetylene ligands. This interaction can be compared to that between Mos and C_4H_4 in **1**, which was observed in the b_2 orbital of that molecule. In both molecular orbitals, the π* orbital on the acetylene ligand [see Fig. 6(c)] bonds with the d_{xy} orbital on niobium. In the b_g orbital, each of the acetylene ligands has an in-phase interaction with only one of the metals, while in the a_u level the ligands bond with both metal centres at the same time, forming a true bridge between them.

If the metal to R ligand interactions in the valence molecular orbitals of **1** and **2** are compared, a number of similarities become apparent. In both cases the bond occurs between one or more metal *d* orbitals of appropriate symmetry and the first empty level on the ligand. In the dimer, the resulting

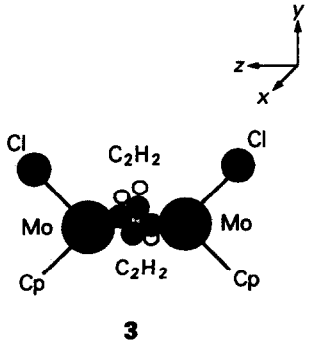
† The C_4H_4 ligand also contributes some small amount of electron density from the internal carbons, but the contribution is too small to be shown. The *p* orbitals on the internal carbons form out-of-phase combinations with the *p* orbitals on the end carbons shown in Fig. 1.

bonding level or levels are filled, so that the net result is metal-to-ligand electron density donation. Furthermore, the ligand orbital participating in the interaction is a linear combination of two *p* orbitals on each of the carbon centres involved. This mixing of atomic orbitals is necessary in order to redirect the ligand orbitals toward the metal centres, since in neither **1** or **2** are the carbon atoms along the metal–metal axis.

Since the ligand orbitals that are on the accepting side of this backbonding interaction have varying degrees of antibonding character between carbon centres,† the metal-to-ligand interaction effectively weakens the C—C bond in the R ligand. Further weakening of such bonds occurs when the low-lying, filled, *s* and *p* orbitals of the R ligand (see Figs 5 and 6) donate electron density to the metal centres through additional bonding molecular orbitals. These molecular levels are at lower energies, buried in the group of M—L and L—L bonding orbitals below the valence sets shown in Figs 1 and 2. This hypothesis of a net weakening of ligand C—C bonds is verified by experimental observations of C—C bond lengths in the coordinated ligands, which are longer than the C—C bond lengths in the isolated alkenes and alkynes.[2b]

C_4H_4 *vs* $(C_2H_2)_2$

The approach initially chosen to determine the role of the two different types of R ligand in the structure of the dimers was to consider a molybdenum complex with two acetylene ligands, *cis*-$(CpMoCl)_2(C_2H_2)_2$ (**3**) and a niobium complex with one C_4H_4 ligand, *trans*-$(CpNbCO)_2(C_4H_4)$ (**4**). Unfortunately, it is not possible to place a ligand such as C_4H_4, which wraps around the dimer in the plane perpendicular to the one containing the metals, on a *trans* frame such as that of the niobium complex. There is no orientation of the ligand that would prevent it from coming in too close proximity to the carbonyl ligands. This in part explains why the niobium dimer bonds to two distinct acetylene units, rather than one C_4H_4 ligand. To bond to the latter, the frame would have to adopt a *cis* configuration.



3

On the other hand, there are no difficulties in placing two acetylene units on the molybdenum *cis*-frame.

The molecular orbital diagram for **3** is shown in Fig. 3: the most striking feature of the diagram is the very small HOMO/LUMO gap (0.76 eV), combined with the comparatively large HOMO/SHOMO gap (1.32 eV). This suggests not only that **3** is an unstable complex, but also that oxidizing the molecule by two electrons might produce a more stable system. The fact that **3** is not stable is also confirmed by its total energy, which is higher than the total energy of **1** (see Table 2). Let us now investigate the electronic reasons why the *cis* molybdenum frame prefers one C_4H_4 to two C_2H_2 ligands.

Figures 1 and 3 show the same pattern of valence molecular orbitals consisting of five metal-based levels, two occupied and three unoccupied levels. The large gap that separates the metal-based orbitals from the Cl 3*p* orbitals in **1**, though, shrinks considerably in **3**. This is mostly due to the out-of-phase interaction of some of the chlorine *p* orbitals

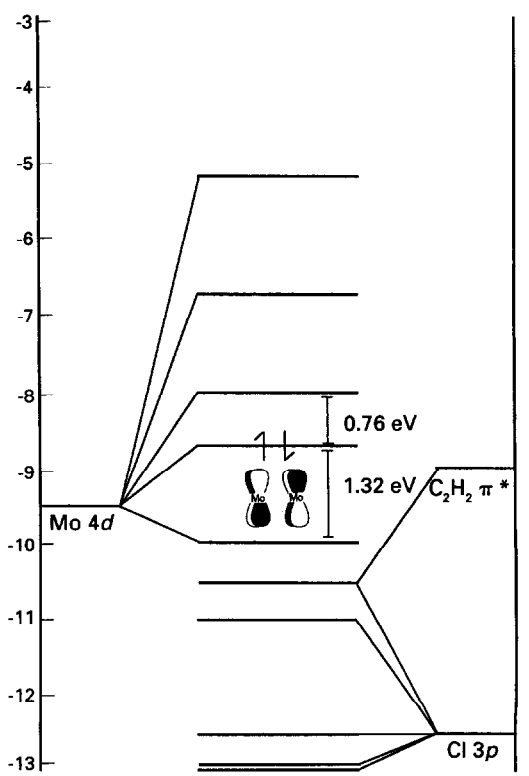


Fig. 3. Molecular orbital diagram for *cis*-$(CpMoCl)_2(C_2H_2)_2$ (**3**).

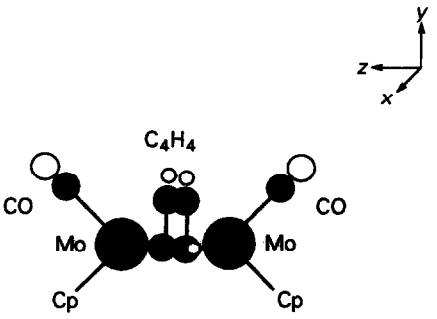
with the C_2H_2 π^* level, which causes them to rise in energy, closer to the five valence orbitals.

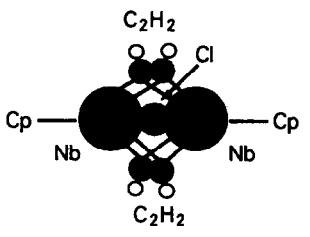
The difference in the size of the HOMO/LUMO gap between **1** and **3** is due to two factors working together: a lowering in energy of the LUMO and a destabilization of the HOMO. In **1**, the LUMO is mostly metal–metal antibonding, but its energy is raised further by an out-of-phase interaction between the metals and the σ_- orbital on C_4H_4. This interaction disappears in **3**, where there is no C_4H_4 ligand, and the LUMO is consequently lowered in energy. In both molecules, the HOMO contains an antibonding combination of metal-based orbitals. In **1**, it is a bent π interaction between $d_{x^2-y^2}$ and d_{yz} orbitals on both centres, and as such it does not involve a large amount of overlap between the two metals. In fact, only one of the lobes on each centre actually participates in the interaction, and the orbital is not greatly destabilized with respect to the metal *d* atomic orbitals. In **3**, the interaction has δ symmetry and it is between d_{xy} orbitals. Even though δ-type overlap is usually not large, it is still greater than the bent π-type overlap just mentioned. Therefore, the HOMO in **3** is more destabilized than the HOMO in **1**, which contributes to closing the HOMO/LUMO gap.

CO *vs* Cl

In order to determine the influence of the carbonyl and chlorine ligands on the structure of the dimers, two complexes are considered: *cis*-(CpMoCO)$_2$(C$_4$H$_4$) (**5**) and *trans*-(CpNbCl)$_2$(C$_2$H$_2$)$_2$ (**6**). The dimers are identical to the experimentally observed ones, except for having exchanged chlorine and carbonyl ligands.



5



6

Figure 4 shows the influence of the carbonyl ligands on the molecular orbitals of the molybdenum dimer. It is immediately apparent that the empty CO π^* orbitals participate in most of the valence molecular orbitals, both occupied and unoccupied. In particular, the low-lying empty orbitals in **1** are pushed to higher energies by an antibonding interaction between the metals and filled orbitals on the C_4H_4 ligand [σ_+ and σ_-; see

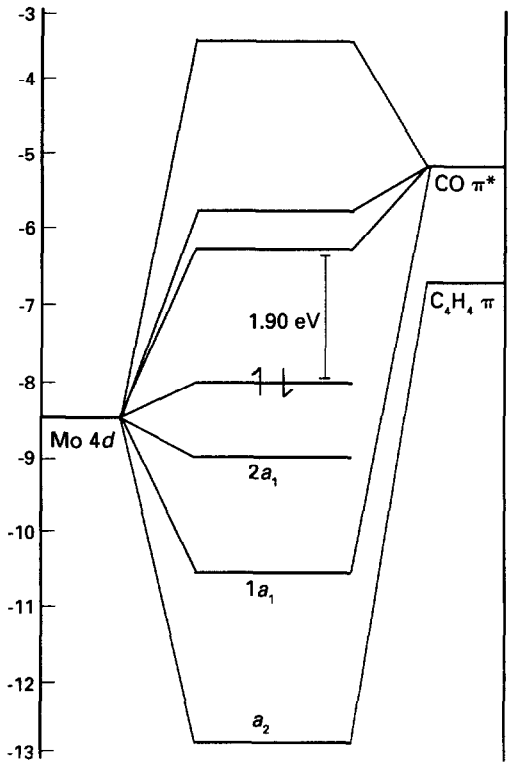


Fig. 4. Molecular orbital diagram for *cis*-$(CpMoCO)_2(C_4H_4)$ (**5**).

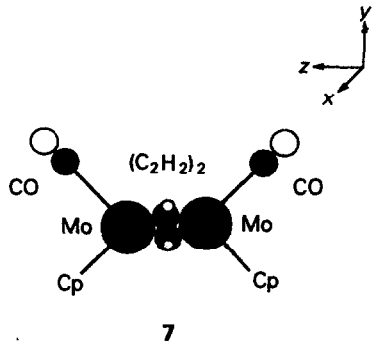
Fig. 5(a) and (b)]. In **5** these unoccupied orbitals are lowered in energy because of the participation of CO π^* levels, which substitute the C_4H_4 orbitals in the interaction with the metals. The C_4H_4 σ_+ and σ_- orbitals are instead greatly stabilized by ligand–ligand interaction with cyclopentadienyl π levels and they are found among the low-lying occupied orbitals of **5**. The lowering of unoccupied molecular orbitals in **5** becomes most important in the LUMO, where it contributes to the decrease in the HOMO/LUMO gap. The decreased size of the gap points to the fact that the molybdenum dimer is more stable with chlorine than with carbonyl ligands.

Despite these differences between these two molybdenum dimers, some of the features of their molecular orbital diagrams are similar. Two of the valence orbitals in **5** are analogous to two orbitals in the diagram for **1**: the M—C_4H_4, a_2 bonding orbital (b_2 in **1**), and the SHOMO of the molecule ($2a_1$ in **5** and a_1 in **1**), which is a Mo—Mo bonding interaction. The HOMO of **1**, which has contributions from Mo $d_{x^2-y^2}$ orbitals, is greatly stabilized in **5** (a_1 level) by a bonding interaction with CO π^* levels.

To investigate the effect of coupling and decoupling the R ligand on the *cis*-$(CpMoCO)_2$ frame, an additional calculation was performed on the molecule *cis*-$(CpMoCO)_2(C_2H_2)_2$ (**7**).



7

Table 2 shows that the dimer with the decoupled ligands (two C_2H_2 moieties) is less stable than its counterpart with the C_4H_4 ligand, both in terms of

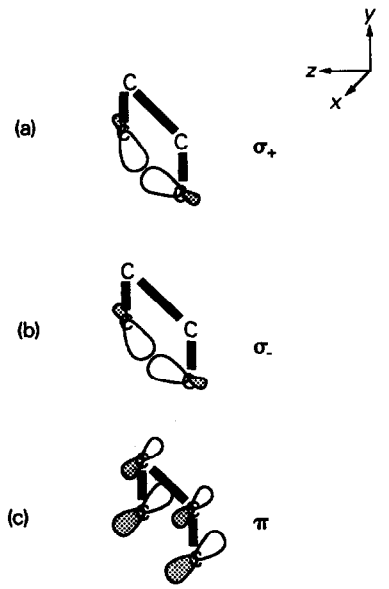


Fig. 5. Valence molecular orbitals of the $(C_4H_4)^{2-}$ ligand which participate in bonding with the metal centres. Orbitals *a* and *b* are filled, orbital *c* is unoccupied.

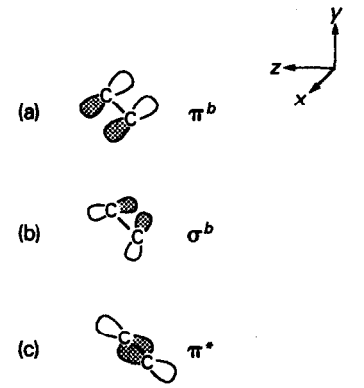

Fig. 6. Valence molecular orbitals of the C_2H_2 ligand which participate in bonding with the metal centres. Orbitals *a* and *b* are filled, orbital *c* is unoccupied.

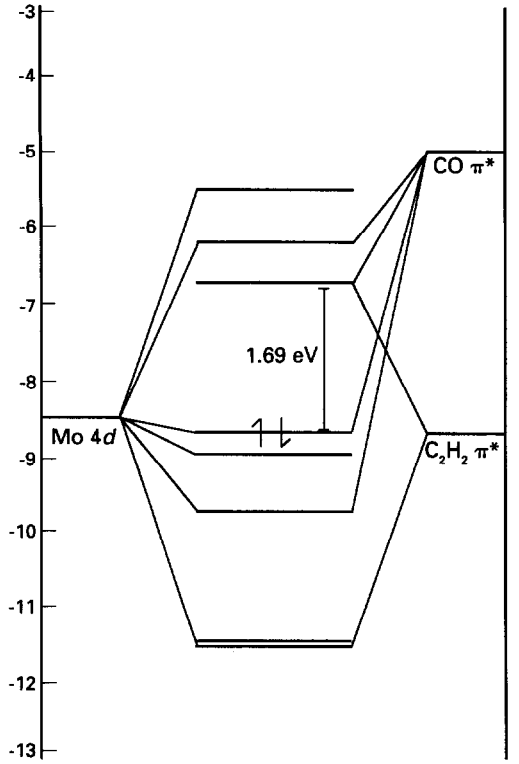

Fig. 7. Molecular orbital diagram for *cis*-(CpMoCO)$_2$ (C_2H_2)$_2$ (**7**).

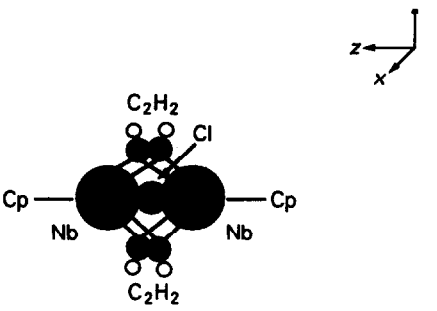

6

of CO π^* levels, which tend to push all low-lying unoccupied orbitals, including the LUMO, to lower energies. Also peculiarly absent in Fig. 8 is the participation of the empty C_2H_2 π^* level in bonding with the metals. In **2**, this bonding interaction is responsible for the stabilization of two valence molecular orbitals (a_u and b_g in Fig. 2); the lack of it causes the occupied valence orbitals of **6** ($1a_g$ and $2a_g$ in Fig. 8) to remain at higher energies. The C_2H_2 π^* levels in **6** contribute instead to a high energy virtual orbital, in which they combine in an antibonding fashion with Nb $d_{x^2-y^2}$ orbitals. In **2** this is not possible, since the $d_{x^2-y^2}$ orbitals form an out-of-phase combination with the CO π^* levels. There-

total energy and of HOMO/LUMO gap. Figure 7 is the molecular orbital diagram for **7**, which explains the stability trend just mentioned. Similarly to what is observed in Fig. 4, the diagram is dominated by the influence of the carbonyl π^* levels on most of the valence molecular orbitals. This pushes the virtual orbitals to lower energies, contributing to the relatively small HOMO/LUMO gap. Also common to both Figs 4 and 7 is the presence of one or more M—R ligand bonding orbitals (involving C_4H_4 π in Fig. 4 and C_2H_2 π^* in Fig. 7). In conclusion, then, the presence of a coupled or decoupled R ligand does not affect the electronic structure of dimers with frame *cis*-(CpMoCO)$_2$ as much as the presence of CO π^* levels does: complexes **5** and **7** show more similarities than differences in their molecular orbital diagrams.

The effect of substituting Cl for CO ligands was also studied for the *trans*-(CpNbCO)$_2$(C_2H_2)$_2$ dimer.

The molecular orbital diagram of **6** is shown in Fig. 8. As indicated on the diagram, the HOMO/LUMO gap for this molecule is quite large, actually larger than the one found in **2**. This is not an entirely surprising result, since some preliminary experiments indicate that **6** might also be an observed structure.[18] Again, the primary reason for the widening of the HOMO/LUMO gap is the absence

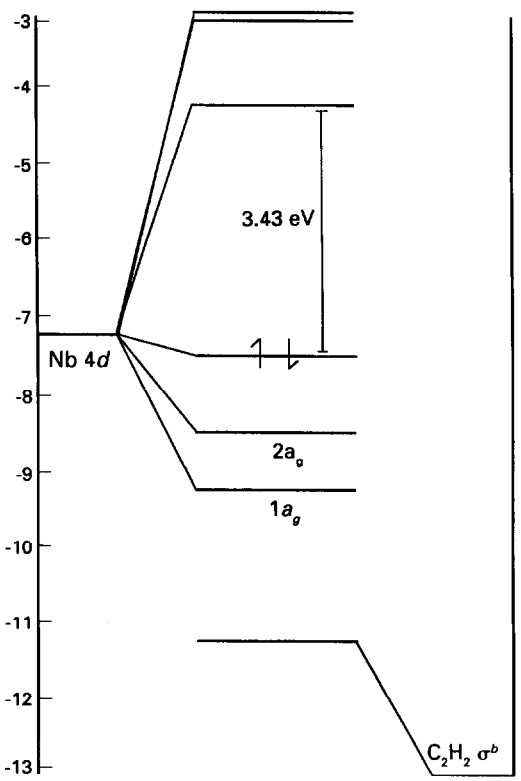

Fig. 8. Molecular orbital diagram for *trans*-(CpNbCl)$_2$(C_2H_2)$_2$ (**6**).

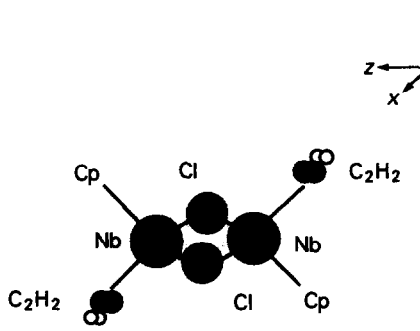
fore, the C_2H_2 π^* levels in **2** are free to combine with other metal orbitals in a bonding fashion, as they do in levels a_u and b_g.

There is one other niobium dimer related to **6** that has been observed experimentally:[12] *trans*-$Cp_2Nb_2(C_2H_2)_2(\mu\text{-}Cl)_2$ (**8**).



8

In this complex, which is otherwise identical to **6**, the acetylene ligands are terminal and it is the chlorine ligands that are bridging the metals. Figure 9 illustrates the fact that **8** is a stable compound with a large HOMO/LUMO gap (see Table 2 for the total energy value). Figures 8 and 9 show general agreement between the molecular orbitals of these two acetylene chlorine niobium dimers. In both cases there are six valence molecular orbitals, three occupied and three unoccupied. In **8**, all three occupied orbitals are more stabilized with respect to those in **6**. In particular, the two lowest levels are stabilized by a bonding interaction between the metals and the π^* orbitals on the C_2H_2 ligands, since the Nb d_{xy} orbitals have the appropriate symmetry to bond with the π^* levels of the acetylenes in terminal positions. But the principal factor that contributes to the widening of the HOMO/LUMO gap is the stabilization of the HOMO in **8** with respect to that in **6**. The lowering of this molecular orbital is also caused, even though indirectly, by the fact that the acetylenes in their new terminal positions are ideally suited to interact with the Nb d_{xy} orbitals. In **6**, the HOMO is a bonding combination of metal d_{z^2} and d_{xy} orbitals; while in **8**, because the d_{xy} orbitals participate in levels $1a_2$ and $2a_2$, the HOMO is just d_{z^2} in character. Therefore, the HOMO in the dimer with the bridging acetylenes has bent-π symmetry with a small overlap between centres and little stabilization; while the HOMO in the dimer with the bridging chlorines has σ symmetry, which leads to a larger stabilization of the molecular orbital.

† For details on the geometries of these two complexes, see the Computational Procedure section of this paper.

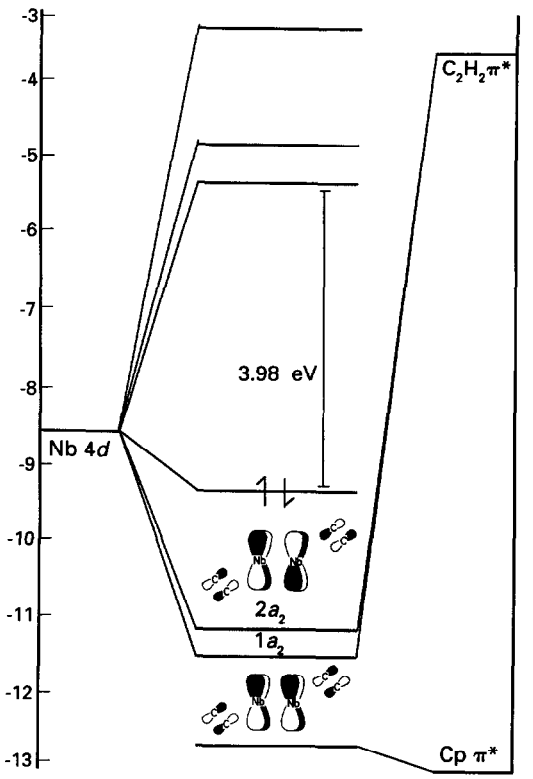


Fig. 9. Molecular orbital diagram for *trans*-$Cp_2Nb_2(C_2H_2)_2(\mu\text{-}Cl)_2$ (**8**).

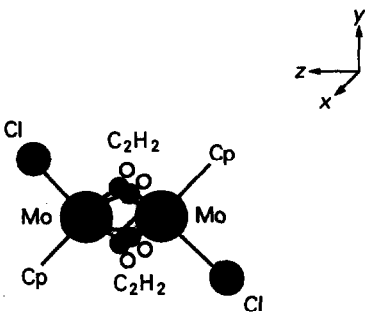
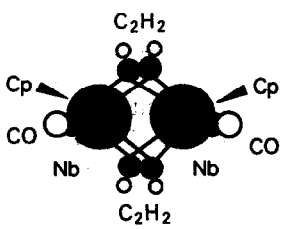
Cis *vs* trans

The last factor to be considered is the *cis* vs *trans* comformation of the dimers. To this purpose, calculations on two additional complexes were carried out: *trans*-$(CpMoCl)_2(C_4H_4)$ (**9**) and *cis*-$(CpNbCO)_2(C_2H_2)_2$ (**10**).†



9



10

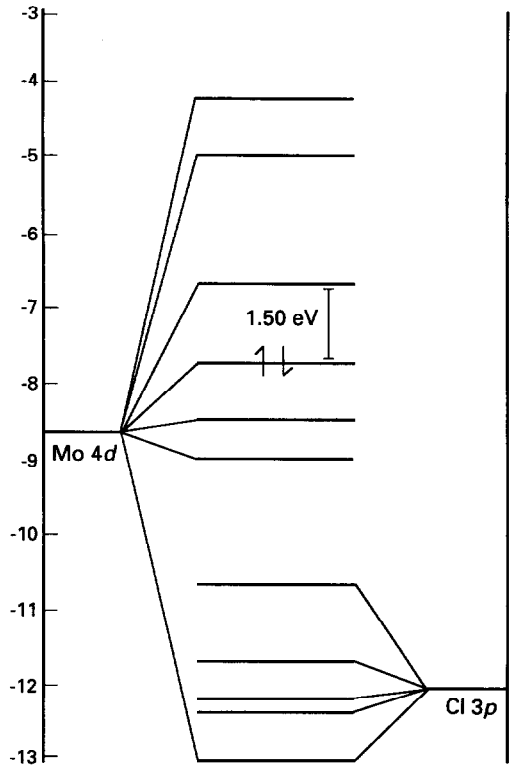


Fig. 10. Molecular orbital diagram for *trans*-(CpMoCl)$_2$ (C$_4$H$_4$) (**9**).

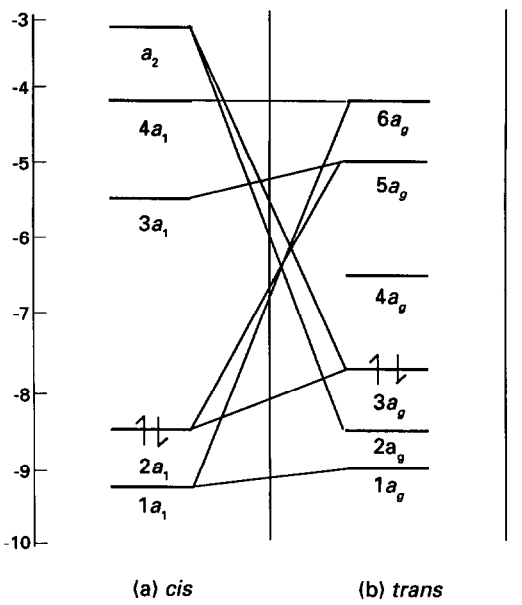

Fig. 11. Comparison of the valence molecular orbitals of **1** from Fig. 1(a) and those of **9** in Fig. 10(b). The lines between orbitals indicate how the orbitals in **a** mix give rise to the orbitals in **b**.

Figure 10 shows the molecular orbital diagram for **9**: when it is compared to the diagram in Fig. 1, it becomes apparent that the gross features in the two diagrams are roughly the same. There is a series of low-lying, ligand-based orbitals separated by a gap from metal-based, occupied and unoccupied valence orbitals. Because of the change in symmetry from *cis* to *trans*, though, much mixing of the molecular orbitals occurs and it becomes difficult to follow how each level changes in going from Fig. 1 to 10. Figure 11 gives some indication of the mixing that is occurring: the HOMO and SHOMO of the *cis* complex loosely translate into levels $1a_g$ and $3a_g$ of the *trans* complex. Similarly, the two lowest unoccupied orbitals of the *cis* dimer are related to $5a_g$ and $6a_g$ levels in the *trans* dimer; level $2a_g$ in part (b) of the figure, the SHOMO of the complex, most resembles the highest unoccupied level shown for the *cis* complex. The LUMO of the *trans* dimer is the only level that seems to have no counterpart in the *cis* dimer: it is a mixture of d_{yz} orbitals on both metal centres. Actually, this orbital plays a big role in making the *trans* molecule less stable than the *cis* one: its position between the HOMO and LUMO of part (a) of the figure is responsible for the markedly decreased size of the HOMO/LUMO gap (see Table 2). In summary, then, the *trans* conformation of the molybdenum dimer is less stable, according to both the total energy and the HOMO/LUMO gap, than the *cis* conformation. This arises from the presence of a new, metal-based level positioned between the HOMO and the LUMO. This orbital, which becomes the LUMO of the *trans* dimer, is mostly metal d_{yz} in character, but it is difficult to trace it back to the **1** dimer because of the extensive mixing occurring among the valence molecular orbitals.

Figure 12 shows the molecular orbital diagram for **10**, *cis*-(CpNbCO)$_2$(C$_2$H$_2$)$_2$. The overall pattern of orbitals in Figs 2 and 12 is similar: two, low-lying, metal-to-C$_2$H$_2$ π^* bonding orbitals (one for each metal centre); HOMO and SHOMO orbitals that are close in energy, are stabilized with respect to the niobium *d* atomic levels only to a small extent, and are Nb—CO π^* bonding in character; and three unoccupied orbitals that are mostly CO π^* in character. Despite these similarities, the HOMO/LUMO gap in **10** is significantly smaller than that in **2** (see Table 2), pointing to the fact that the *cis* dimer is not as stable as the *trans* conformation. This happens mostly because in **10** the first two virtual orbitals are significantly lower in energy. Unfortunately, an in depth examination of the atomic orbital contributions to these molecular levels gives no indication of why the lowering in energy occurs. Again, the transformation from *trans* to *cis* involves a change in symmetry for the

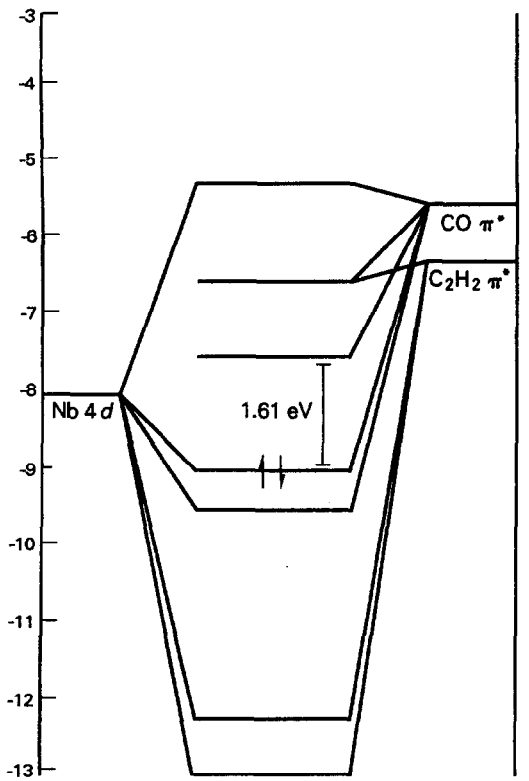

Fig. 12. Molecular orbital diagram for *cis*-$(CpNbCO)_2(C_2H_2)_2$ (**10**).

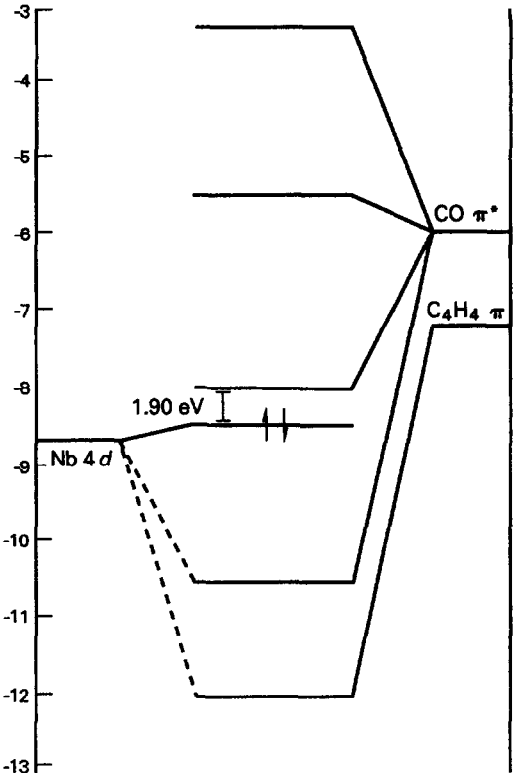

Fig. 13. Molecular orbital diagram for *cis*-$(CpNbCO)_2(C_4H_4)$ (**11**). (Dotted lines indicate minor contributions.)

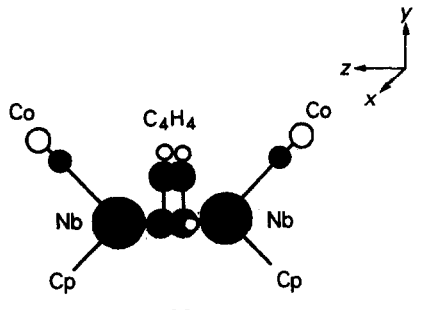
molecule and extensive mixing of the orbitals, which makes it difficult to trace changes in the composition of the levels. In addition, Table 2 shows that **10** has a lower total energy value than **2**, which is contrary to the trend in HOMO/LUMO gap mentioned above. This suggests that **2** might be a kinetically, but not thermodynamically, stable product.

One possible thermodynamic product would be *cis*-$(CpNbCO)_2(C_4H_4)$ (**11**), where the acetylene ligands in **2** have been coupled.



11

As previously mentioned, because of steric hindrance, which makes it impossible for the C_4H_4 ligand to exist in a *trans* dimer, **11** has also been made *cis*. Figure 13 shows the molecular orbital diagram of this complex. Both the HOMO/LUMO gap and total energy of the compound (see Table 2) indicate that **11** is in fact very unstable, with the smallest gap and highest energy of all the niobium dimers in the table. This is mostly due to the low-lying LUMO, which is mainly CO π^* in character. The carbonyl contribution pushes the molecular orbital particularly low in this complex because of the lack of metal *d* orbitals participation that usually destabilizes the virtual levels. It is a general trend, however, that the presence of carbonyl ligands in the dimers investigated in this work always causes the first few virtual orbitals to be low in energy because of contributions from CO π^* levels. This lies at the root of the instability of such complexes. If the thermodynamically stable complex related to **2** contains one or more carbonyl ligands, then it is possible that its structure be radically different from that of the dimer, in order for the complex to remain stable.

Overall influence of the three geometric factors

The last set of calculations involves substituting molybdenum atoms in the frame of **2** and niobium atoms in the frame of **1**. Analysing the results of calculations on *cis*-$(CpNbCl)_2(C_2H_4)$ (**12**) and *trans*-$(CpMoCO)_2(C_2H_2)_2$ (**13**) should help sum-

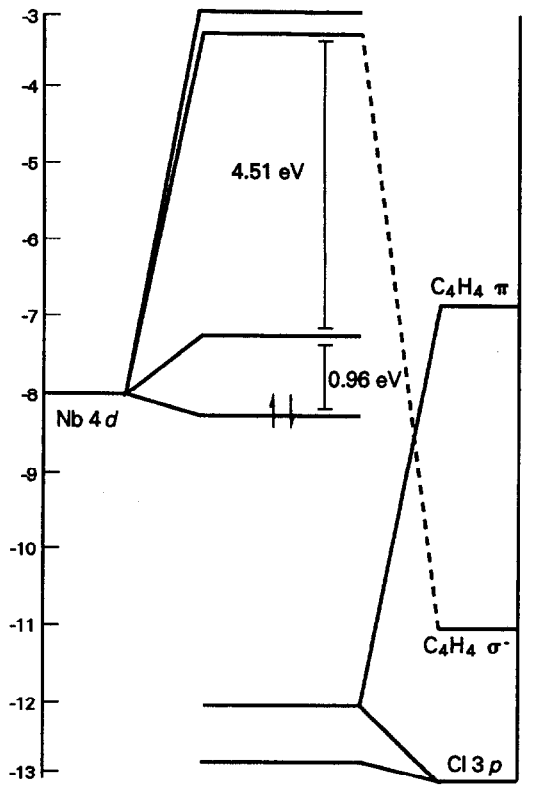


Fig. 14. Molecular orbital diagram for *cis*-(CpNbCl)$_2$(C$_4$H$_4$) (**12**).

marize the influence of all three geometric factors on the preferred geometry of the dimers and shed light on the reasons why molybdenum metals prefer a geometry like that in **1** and niobium metals prefer a **2**-type frame. The geometries of **12** and **13** are identical to those of **1** and **2**, except for the fact that the metals have been exchanged.†

Figure 14 is the molecular orbital diagram for **12**: the pattern of two, closely spaced orbitals that are almost degenerate with the metal *d* levels, plus two (or three) high-lying orbitals is the same in the diagrams of both **1** and **12** (compare Figs 1 and 14). In the case of **12**, though, the number of valence electrons is two less than that of **1**, since the metal centres are niobium and not molybdenum. Therefore, in **12** the HOMO and LUMO are closely-spaced levels around the metal *d* orbitals and consequently the gap between them is only 0.96 eV. This leads to the conclusion that **12** would be a very unstable complex. In fact, the gap between the first- and second-lowest virtual orbitals is so large (4.51 eV) as to suggest that a reduced form of the complex might be stable.

When molybdenum centres are substituted into the frame of dimer **2**, some changes occur in the character of the valence molecular orbitals. Figure 15 shows the diagram for **13**, which can be compared to that of **2**, in Fig. 2. They both show two, low-lying, metal-to-C$_2$H$_2$ π^* bonding orbitals and two, metal-based, moderately bonding orbitals. These last two levels are the HOMO and SHOMO of **2**, but in **13**, because of the extra valence electron in molybdenum with respect to niobium, there is an additional occupied level (a_g in Fig. 15). This orbital contributes to the bonding between the molybdenum centres and receives contributions from three molybdenum atomic orbitals. Since the a_g orbital comes between the HOMO and LUMO of Fig. 2, it substantially decreases the HOMO/LUMO gap of **13**, which in turn results in an unstable system.

CONCLUSIONS

From this series of calculations, a number of conclusions about the title compounds and related dimers can be drawn. Patterns of orbital symmetries and energies become apparent and it can be determined how they are influenced by the geometric structure and the type of ligands on the dimers. The principal question asked in this paper is why the two dimers assume different geometric configurations,

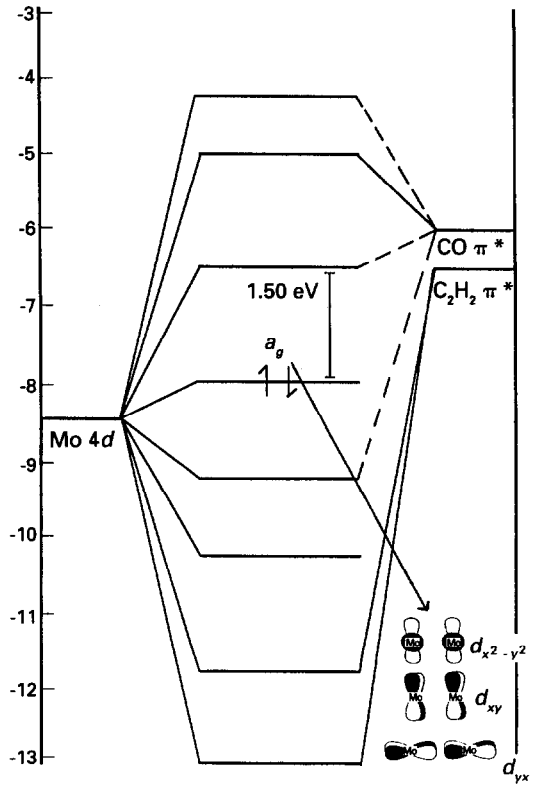

Fig. 15. Molecular orbital diagram for *trans*-(CpMoCO)$_2$(C$_2$H$_2$)$_2$ (**13**). (Dotted lines indicate minor contributions.)

† See footnote † on p. 1862.

when both clusters have the same number of valence electrons. The question is best answered by looking at Figs 14 and 15 and contrasting them with Figs 1 and 2. Such a comparison shows that each metal assumes the configuration that yields the largest HOMO/LUMO gap and therefore the most stable complex. If the metal is placed in the frame of the other complex, the difference in the number of metal valence electrons reduces the HOMO/LUMO gap drastically, which in turn diminishes the stability of the complex. Both the niobium and the molybdenum centres, therefore, assume the geometry that is appropriate to their number of valence electrons and type of ligands.

In examining the role of chlorine and carbonyl ligands in the dimers, it is also apparent that the π donor (Cl^-) has little influence on the valence molecular orbitals of the complex, since its p orbitals are found among the low-lying, filled levels of the molecule. On the other hand, the π acceptor ligand (CO) has a very strong influence on the molecular orbital composition of the complex, since its π^* virtual levels make up the majority of the low-energy, unoccupied orbitals of the molecule. The CO π^* influence usually leads to a lowering in the energy of such orbitals, and therefore it can potentially decrease the stability of the dimer.

When the coupled and decoupled forms of the R ligand (C_4H_4 and two C_2H_2) are compared, no dramatic differences are found. Both contribute to the bonding in the molecule with two, low-lying, filled levels that donate σ or π electron density to the metals and one virtual, π-type level that is used for metal-to-ligand backbonding (see Figs 5 and 6). The latter interaction gives rise to one (in the case of C_4H_4) or two (in the case of C_2H_2) markedly bonding molecular orbitals that have energies between those of the valence levels and those of the low-lying M—L and L—L levels.

The series of related compounds that has been investigated in this work could be augmented by additional, experimentally observed dimers which are variations on the basic geometries included in this paper.[19] In addition, more could be predicted based on the electronic factors influencing stability which are discussed above.[2b,12] Furthermore, there are other unanswered questions regarding these geometries, such as the relationship between substituent groups on the R ligands, their electron-withdrawing capabilities and bond angles and lengths in the complex.

Abstract—The X-ray structures of three metal alkyne complexes are presented: $Ir(PMe_2Ph)_3(MeC_2Me)^+$, $M(CO)_4(F_3CC_2CF_3)$ (M = Ru, Os). The iridium(I) complex adopts an unusual structure ("CS") which differs notably from that expected for four-coordinate d^8 ML_4 square-planar complexes. The structure resembles that of a square pyramid, with essentially C_s symmetry, with a short apical M—P bond (2.236 vs 2.31 Å for the basal M—P bonds), short M—C (2.01 Å) and long C—C bonds (1.306 Å), which indicate a strong metal–alkyne interaction. The ruthenium(0) and osmium(0) complexes adopt the expected pseudo-octahedral structure. The unusual CS structures, previously reported for cobalt(I) and iron(0) complexes, contrast with the square-planar structure of platinum(II) alkyne complexes. Fluxionality is present in the iridium complex, as well as in those of cobalt, and is attributed to a rapid intramolecular site exchange among inequivalent phosphorus ligands. The iridium complex reacts with additional ligands like alkynes and H_2. Extended Hückel calculations are presented to rationalize the structural and reactivity aspects of the whole family of d^8 ML_3(alkyne) species (M = Pt^{II}, Ir^{I}, Co^{I}, Fe^{0}). It is shown that the four-electron donation of an alkyne ligand is responsible for the unusual CS structure of certain of these ML_3(alkyne) species. The alkyne moieties induce a four-electron destabilization in the square-planar structure which is large for diffuse *d* orbitals such as those of iridium(I), cobalt(I), iron(0), but not of platinum(II). The fluxionality of the complexes is shown to be associated with an easy rotation of the alkyne about the metal–alkyne midpoint,

† This paper is dedicated to Richard Fenske for the advice and stimulus he provided to his student, K.G.C.

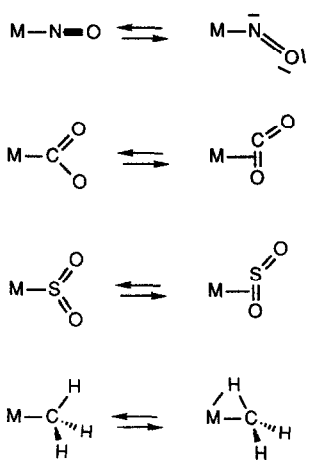
accompanied by a breathing motion of the M—L bonds of the ML_3 metal fragment. It is shown that unsymmetrical alkynes stabilize a conformation of the complex in which the ligand is turned by 90° with respect to the one presented here. The reactivity towards additional ligands is shown to be associated with the presence of a low-lying LUMO pointing away from the apical bond. Effects of substituents at the alkyne and of ligands at the metal are discussed. It is shown that it is the residual four-electron destabilization in $M(CO)_4$(alkyne) complexes which is responsible for the lability of CO ligands and thus for the ligand exchange process.

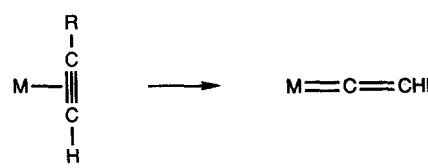
A number of ligands have the ability to exist in structurally isomeric forms (e.g. acyl, NO, CO_2, SO_2, alkyl, **1**). Such isomerism is associated with a change in the number of ligand electrons shared with the metal valence orbitals. Most often the isomeric bonding forms are identifiable by clearly defined structural changes, but there are a few cases where the structural changes are quite subtle and thus difficult to perceive even when accurate structural parameters are known. One such example is the alkyne ligand. Here, in the absence of clearly diagnostic structural changes with change in electron donor number, molecular stoichiometry is used to evaluate the donor number of the alkyne moieties. Thus, it is conventional to perform a valence electron count on the fragment ML_n to which the alkyne is attached. If it is a 16-electron fragment, alkyne→M donation from only one of the two orthogonal alkyne π orbitals is assumed ("two-electron donor alkyne"). If it is a 14-electron fragment, donation from both alkyne π orbitals *may* take place. The reason for the qualification on this latter conclusion is that, for certain early and late metals, a 16-valence electron count is found in many isolable compounds. For example, in the case to be considered here, iridium(I) and platinum(II) are frequently "content" with a 16-valence electron count, and thus the above method does not lead to a clear deduction about the alkyne–metal bonding in such ML_3(alkyne) complexes.



1

Scheme 1.

An interesting question that immediately arises concerns the consequences of having a ligand able to donate more electrons to the metal than this centre may accept. For instance, the well-known tendency of two-electron donor terminal alkynes to rearrange to vinylidene ligands [eq. (1)] may be rationalized by noting that such rearrangement diminishes the repulsion between the unused alkyne π-system and the filled metal *d* orbitals.[1] Internal alkynes in two-electron donor situations do not have this outlet, however.



(1)

The present work offers structural results on some relevant compounds, an analysis of the bonding in several of the problematic situations identified above, and a rationalization of the observed chemical reactivity for each.[2]

EXPERIMENTAL

General procedures

All manipulations were performed under purified N_2 or Ar using standard Schlenk techniques or a Vacuum Atmospheres glove box. Solvents were dried and deoxygenated by distillation over Na/K-benzophenone ketyl under N_2. Methylene chloride was distilled over P_2O_5 under N_2, then subjected to a minimum of three freeze–pump–thaw degassing cycles to remove residual O_2.

Proton and phosphorus NMR spectra were

obtained on a Nicolet NT-360 at 360 and 146 MHz, respectively. Carbon NMR spectra were recorded on either a Nicolet NT-360 (91 MHz) or Bruker AM-500 (125 MHz). Proton chemical shifts are reported in units of δ (ppm downfield from tetramethylsilane) and were measured relative to residual solvent protons. Carbon shifts are reported in units of δ (ppm downfield from tetramethylsilane) and were measured relative to solvent absorption. Phosphorus shifts are reported in units of δ (ppm downfield from external 85% H_3PO_4).

Preparation of $[Ir(PMe_2Ph)_3(MeO_2CC_2CO_2Me)_2]BF_4$

(1) *Reaction of* $[Ir(PMe_2Ph)_3(C_2Me_2)]BF_4$ *with* $MeO_2CC_2CO_2Me$. $[Ir(PMe_2Ph)_3(C_2Me_2)]BF_4$ (51 mg, 0.084 mmol) was placed in a Schlenk flask under N_2. THe solid was then dissolved in CH_2Cl_2 (10 cm^3), after which $MeO_2CC_2CO_2Me$ (0.042 cm^3, 0.34 mmol) was added by syringe. The solution was stirred for 10 h, resulting in no apparent colour change. Solvent and excess $MeO_2CC_2CO_2Me$ was removed *in vacuo*, quantitatively giving $[Ir(PMe_2Ph)_3(MeO_2CC_2CO_2Me)_2]BF_4$ as a red oil.

(2) *By reaction of* $[IrH_4(PMe_2Ph)_3]BF_4$ *with* $MeO_2CC_2CO_2Me$. To a CH_2Cl_2 solution containing $[IrH_4(PMe_2Ph)_3]BF_4$ (0.085 mmol) was added $MeO_2CC_2CO_2Me$ (0.05 cm^3, 0.41 mmol, 5 equiv) by syringe. After 30 min of stirring, the originally pale yellow solution had changed to dark orange. The solvent was removed *in vacuo*, and THF (4 cm^3) was added to precipitate a red solid. The solution was concentrated to half its original volume to promote further precipitation, and the product was filtered.

($6° \leqslant 2\theta \leqslant 45°$).[3] A systematic search of a limited hemisphere of reciprocal space revealed intensities with Laue symmetry and systematic absences consistent with space group $P2_1/n$. After correction for absorption, data processing gave a residual of 0.027 for 529 unique intensities which had been measured more than once. Four standards measured every 300 data showed no systematic trends.

The structure was solved using a combination of direct methods (MULTAN78) and Fourier techniques. After the non-hydrogen atoms had been located and refined, a difference Fourier map revealed most of the hydrogen atoms. All hydrogen atoms are placed in calculated positions prior to the final cycles of least-squares in which the non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were refined with isotropic thermal parameters.

The final difference map had a residual near iridium of 2 e/Å^3. All other residual peaks were well under 1 e/Å^3. The results† of the X-ray study are shown in Table 1 and Figs 1 and 2. Additional details are available as supplementary material. Refined C—H distances range from 0.84(7) to 1.18(8) Å.

X-ray diffraction study of $M(CO)_4(F_3CC_2CF_3)$ (M = Ru, Os)

A suitable crystal of the osmium compound was located and transferred to the goniostat using inert atmosphere handling techniques and cooled to −155°C for characterization and data collection.[3]

A systemetic search of a limited hemisphere of reciprocal space located a set of diffraction maxima with symmetry and systematic absences corresponding to the unique monoclinic cell $P2_1/n$. Subsequent solution and refinement of the structure confirmed this choice. Data were reduced to a unique set of intensities and associated sigmas in the usual manner. There was not significant decomposition at −155°C, based on the intensities of four standards monitored every 2 h.

The structure was solved by a combination of direct methods (MULTAN78) and Fourier techniques. Data were corrected for absorption before the final anisotropic refinement. A final difference Fourier indicated several other peaks of intensity 1.8–2.2 e/Å^3 in the vicinity of the osmium atom and no other features. The large "ripples" near the osmium are probably due to an inaccurate absorption correction. The results† of the structural study are shown in Table 2 and Fig. 3.

The ruthenium compound is isomorphous and the data collection proceeded as for M = Os. No absorption correction was necessary. A final different Fourier was featureless, the largest peak being 0.7 e/Å^3. The atom numbering is identical to that of the osmium analogue.

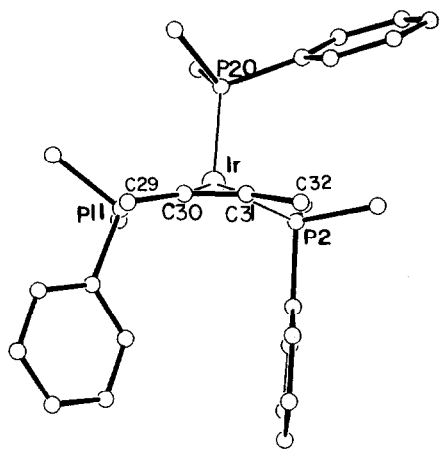

Fig. 1. ORTEP view of the cation $Ir(MeC_2Me)(PMe_2Ph)_3^+$, omitting hydrogens and showing selected atom labelling. This view emphasizes the approach to square-pyramidal geometry, with iridium lying above the approximate planar array of P11, P2, C30 and C31.

RESULTS

Structure of $Ir(MeC_2Me)(PMe_2Ph)_3BF_4$

$Ir(MeC_2Me)(PMe_2Ph)_3BF_4$ exists in the solid state as non-interacting $Ir(MeC_2Me)(PMe_2Ph)_3^+$ and BF_4^- ions. The closest approach of fluorine to iridium is 5.54 Å. The coordination geometry about iridium in the cation (Fig. 1) is clearly not planar or even distorted planar. Because of the large disparity in P—Ir—P angles (90.6, 94.0 and 106.1°) and Ir—P distances (2.309, 2.312 and 2.236 Å), it is equally inappropriate to characterize the coordination geometry as distorted tetrahedral. The one (idealized, non-crystallographic) symmetry element of the cation is a mirror plane containing P20, Ir and the C30—C31 midpoint. The phosphorus in this mirror plane has a dramatically shorter Ir—P distance than those involving the pair of "symmetry related" phosphines. To this "mirror symmetry" description can be added the observation that P2,

† Supplementary material available, anisotropic thermal parameters, parameters of the crystal and data collection, and all distances and angles have been deposited with the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

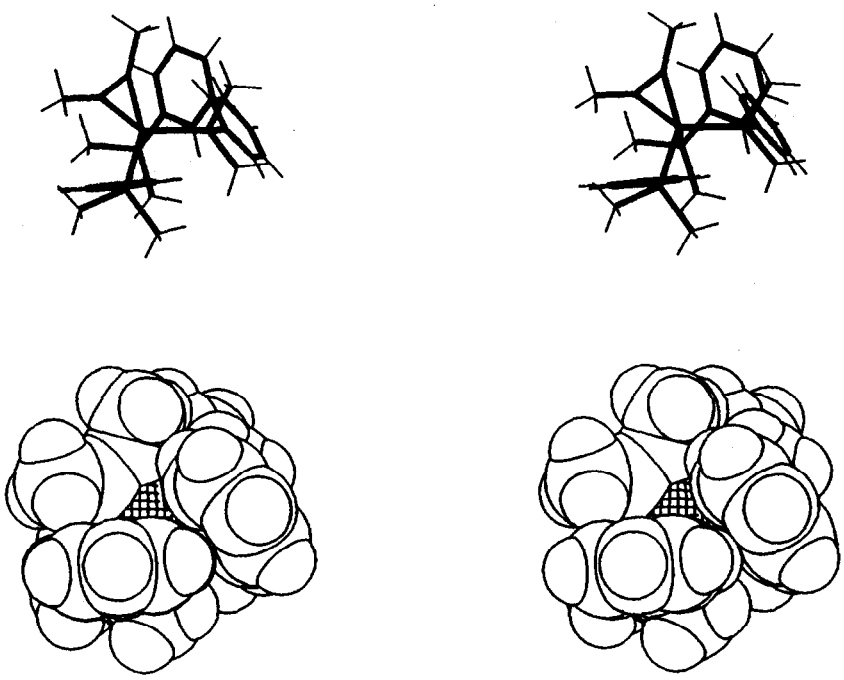

Fig. 2. Stereo stick figure and space-filling drawings of $Ir(MeC_2Me)(PMe_2Ph)_3^+$ from the direction opposite P20. The hatched atom is iridium. All C—H distances have been drawn at 1.08 Å.

P11 and alkyne carbons C30 and C31 are nearly planar (to ±0.04 Å), with iridium 0.49 Å above this plane (Fig. 1). Thus, because of the unique position of P20, the coordination geometry might be called quasi-trigonal planar (alkyne midpoint considered as one site) to which has been added a tightly bound P20 on the *pseudo*-three-fold axis. Alternatively (alkyne carbons considered as individual ligands), it might be described as square pyramidal. Consistent with both descriptions is the fact that the coordination sphere is fairly open (but shielded by *two* phenyl groups) *trans* to P20 (Fig. 2). There are no Ir···*ortho*-H distances short enough to suggest agostic donation; the shortest distance is 3.24 Å.

The Ir—P2 and Ir—P11 distances are indistinguishable from the Rh—P distances in $Rh(PMe_2Ph)_4^+$,[4] so it is the Ir—P20 distance which is unusually short. While the alkyne C30—C31 distance (1.306(8) Å) is lengthened from that in the free alkyne (1.213(1) Å),[5] such lengthening is not dramatically greater than in other coordinated alkynes.[6,7] Likewise, the $H_3C—C{\equiv}C$ angles here (138.9 and 145.7°) are quite unexceptional for coordinated alkynes. The Ir—C distances, however (2.01 Å), are remarkably shorter than the single bond Ir—C distances in *fac*-$IrMe_3(PMe_2Ph)_3$ (2.159 Å).[8] Both the unusual coordination geometry and the very short Ir—C and Ir—P20 distances require explanation.

$MeO_2CC_2CO_2Me$ *as a ligand on the* $Ir(PMe_2Ph)_3^+$ *fragment*

Reaction of $Ir(H_2)(H)_2(PMe_2Ph)_3^+$ with dimethyl acetylenediacarboxylate, under conditions used for the synthesis of $Ir(MeC_2Me)(PMe_2Ph)_3^+$, gives a bis-alkyne adduct $Ir(MeO_2CC_2CO_2Me)_2(PMe_2Ph)_3^+$ as the BF_4 salt. This molecule shows ^1H, ^{13}C and ^{31}P NMR spectra consistent with the following trigonal bipyramidal structure. The molecule is stereochemically rigid both with respect to phosphorus site exchanges and alkyne rotation. We have reported the analogous molecule $Ir(C_2H_4)_2(PMe_2Ph)_3^+$,[9] and have commented there on its rigidity. This analogy of $MeO_2CC_2CO_2Me$ to ethylene shows clearly that $MeO_2CC_2CO_2Me$ *can* serve as a formal two-electron donor. Finally, this same complex can be synthesized by displacement of MeC_2Me from $Ir(MeC_2Me)(PMe_2Ph)_3^+$, thus demonstrating that the butyne complex undergoes attack by nucleophiles.

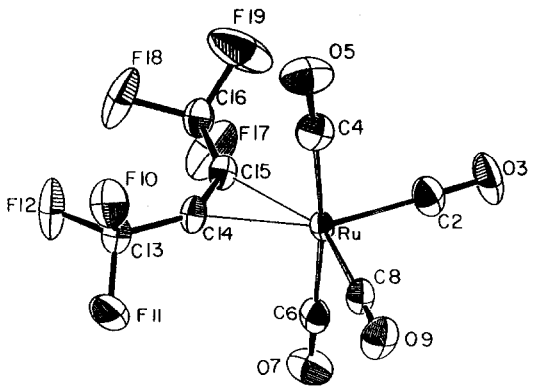

Fig. 3. ORTEP drawing of $Ru(CO)_4(F_3CC_2CF_3)$, showing atom labelling. The isomorphous osmium analogue is labelled identically.

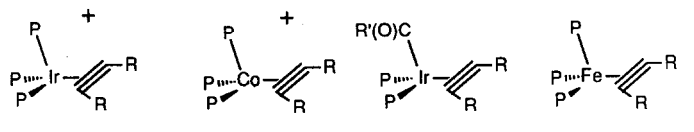
Structure of $M(CO)_4(F_3CC_2CF_3)$ (M = Ru, Os)

The ruthenium and osmium complexes, $M(CO)_4(F_3CC_2CF_3)$, form isomorphous crystals from pentane at −78°C. The structure (Fig. 3) of the ruthenium compound has the greater precision, due to the large influence of absorption for osmium, but the molecular dimensions of the two are indistinguishable within a 3σ criterion. The axial and equatorial M—C distances are equal, as are the M—C(alkyne) distances and the alkyne C≡C distances. The molecules have a faithful approach to C_{2v} symmetry. A distortion from the idealized angles of a trigonal bipyramid is the reduction of the equatorial/equatorial intercarbonyl angle (C2—M—C8) to 95.2(7)° (Os) and 98.68(18)° (Ru) and indicates that these molecules are perhaps better regarded as six-coordinate octahedral species with the $M(F_3CC_2CF_3)$ fragments approaching the metallacyclopropene bonding extreme. This view is reinforced by the solution "rigidity" of these compounds at ambient temperature and above as evidenced by their ^{13}C NMR spectra.[10] The corresponding angle in the analogous $Os(CO)_4(Me_3SiC_2SiMe_3)$ complex is larger (108.8(3)°) in accord with the weaker Os—$Me_3SiC_2SiMe_3$ interaction. This observation is further corroborated by the larger C—C—R angle of the coordinated alkyne in the latter (av. 156(2) vs 142(1)°) and longer M—C(alkyne) distances (av. 2.26(1) vs 2.13(2) Å). Also noteworthy is the bending of the axial carbonyls towards the alkyne: C4—M—C6 = 172.74(19)° for ruthenium and 172.6(6)° for osmium, as previously observed in $Os(CO)_4(Me_3SiC_2SiMe_3)$.[11]

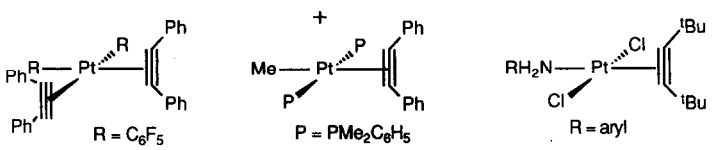
Two points bear mention in comparison to the bond lengths in $Ir(MeC_2Me)(PMe_2Ph)_3^+$. In the iridium complex, the C≡C distance is longer by 0.030 Å (five ESDs) and the M—C(alkyne) distances are shorter by 0.12 Å (20 ESDs). The alkyne is thus more tightly bound to the $Ir(PMe_2Ph)_3^+$ fragment that it is to $M(CO)_4$ (M = Os, Ru).

Analysis of the orbital interactions

For conventional ligands all $4d^8$ and $5d^8$ ML_4 complexes are square-planar. The introduction of an alkyne as a ligand induces a major change in the structure. More interestingly, the change of structure depends also on the nature of the metal. The known iridium(I) (**2**, **4**[12]), cobalt(I) (**3**)[13] and iron(0) (**5**)[14] alkyne complexes uniformly adopt a structure with approximate *Cs* symmetry ("CS"). They are distorted away from T_d symmetry and resemble a



2 **3** **4** **5**



6

square pyramid. The metal-to-apical ligand bond length is especially short. In all these complexes, the metal–alkyne distance is very short, and the C—C bond is notably stretched which indicates a strong metal–alkyne interaction. In contrast, the platinum(II)[15] (e.g. **6**) alkyne complexes are all square-planar ("SP") with the axis of the alkyne perpendicular to the PtL_3 plane. Why should *isoelectronic* compounds have different structures and different reactivity? These are the points we will address here.

Our analysis is based on extended Hückel calculations. Atomic and structural parameters are given in the Appendix. The results of the calculations of the SP and CS structures for model complexes MP_3(acetylene) ($M = Pt^{II}$, Ir^{I}, Co^{I}, Fe^{0}, $P = PH_3$) are given in Table 3. Only platinum prefers the square-planar structure; all other metals favour the CS geometry, in good agreement with the experimental result.

As a background for understanding the reason for the trends in Table 3, we must consider the energy difference between a SP and a CS structure with purely σ ligands. We start the analysis with a study of the simplest model of an ML_4 d^8 complex in which all ligands are H^-. In the CS structure the M—H bonds (1.7 Å) were aligned with the M—P and M—acetylene midpoint vectors of the title iridium structure.

Calculations on IrH_4^{3-} and PtH_4^{2-} show the square-planar structure to be strongly favoured by about 67 kcal mol^{-1} over the CS for both metals. This large preference is easily accounted for by the consideration of the d splitting, since the energy of the occupied d block faithfully reflects the total energies. In a square-planar structure, three non-bonding orbitals are below a weakly antibonding z^2 (z axis perpendicular to the molecular plane). Above this set is the highly destabilized x^2-y^2 which is pointing toward the four ligands. In a CS structure the d splitting is close to that of a T_d complex:[16] two non-bonding orbitals are below a set of three destabilized ones which are not degenerate, due to the absence of a C_3 axis. Assuming a closed shell electronic configuration, the square-planar structure has six electrons in non-bonding orbitals and two in a weakly antibonding one. In contrast, housing eight electrons in the CS structure results in a significant destabilization for four of them. *Thus four σ ligands prefer a square-planar arrangement for any metal.* The occurrence of another structure is then undoubtedly due to π-effects.

Table 3. Relative total energies (kcal mol^{-1}) of $M(PH_3)_3$(acetylene) for SP and CS structures. Bond lengths were taken from the stable isomer and were kept equal in the other isomer. For the CS structure the experimental angles were chosen. The angles at the metal for the CS structure for platinum(II) were chosen identical to that of iridium(I)

Metal	SP	CS
Pt^{II}	0.0	0.3
Ir^{I}	1.9	0.0
Co^{I}	11.3	0.0
Fe^{0}	19.6	0.0

Square-planar and CS alkyne complexes

To understand the factors that favour each structure we will compare the complexes of the two atoms of the third period, platinum(II) and iridium(I) in which variations of bond lengths are expected to be minimal. The interaction diagrams for the acetylene ligand in the square-planar (left-hand side) and CS (right-hand side) geometries are presented in Fig. 4. Since the diagrams for platinum and iridium look similar and differ by only small changes in energy, we have shown the interaction diagrams for iridium only. Comparison between the two metals relies on numerical evaluations and will be discussed in the text. Note that from now on the z axis is along the metal-to-acetylene midpoint direction.

We will start the discussion with the square-planar geometry. This structure has been considered numerous times.[17] However, in order to discuss the bonding in both SP and CS structures, it is necessary to describe the bonding in SP that is germane to our analysis. In a T shape ML_3,[17] three non-bonding (xz, yz, xy) orbitals are just below a weakly antibonding orbital which is essentially oriented perpendicular to the fragment plane (y^2 in our coordinated system). Higher above is an empty σ hybrid which is mostly extended toward the empty site. Bending the alkyne lifts the degeneracy of the π orbitals ($\pi_\perp$, $\pi_\parallel$, $\pi^*_\parallel$, $\pi^*_\perp$). Due to the high symmetry (C_{2v}) of the complex, the interaction diagram is very simple to build. The $\pi_\parallel$ orbital interacts very weakly with y^2 and strongly with the empty σ hybrid. This last interaction is responsible for the metal–acetylene σ bond. The empty acetylene $\pi^*_\parallel$ interacts with the occupied yz orbital. This interaction is responsible for the metal–ligand backbonding and is stabilizing. The actylene $\pi_\perp$ has only the symmetry of the occupied xz orbital (**7**). This interaction between two occupied orbitals induces a four-electron destabilizing interaction. No bond results from the interaction and it actually contributes to a decrease of

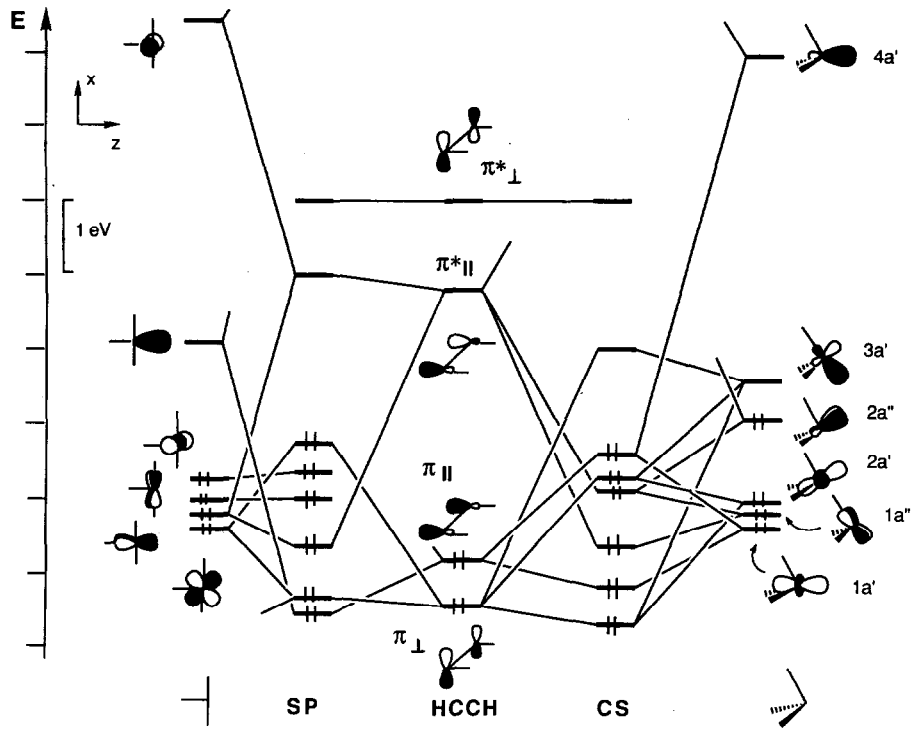


Fig. 4. Interaction diagram for a square-planar (SP) structure (left-hand side) and for the experimental (CS) structure for $IrP_3(HC_2H)^+$.

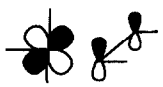
the total bonding between the two fragments. The higher empty orbital of acetylene, $\pi^*_\perp$, has the proper symmetry to stabilize the occupied metal xy orbital. However the interaction is very small since it is based on a δ type overlap. It will not be considered further.



7

The analysis for the CS structure begins with the orbitals of the CS MP_3 fragment which resembles that of a ML_3 piece of an octahedron with C_{3v} symmetry. The symmetry labels that will be used are those of the C_s symmetry point group. Three low-lying ($1a'$, $2a'$, $1a''$), essentially non-bonding orbitals close in energy, are below a set of three hybrids which are made of a well-known mixture of d, s and p metal orbitals.[18] These three orbitals separate into a set of two ($2a''$, $3a'$), which would have been degenerate in C_{3v} symmetry, and a high-lying $4a'$. In the present geometry of the CS MP_3 fragment, $2a''$ is below $3a'$ and can be considered as the HOMO of the fragment. As will be evident later, the relative order of these two orbitals will play a central role in the rotational orientation of the acetylene ligand. These three orbitals, which are M—P antibonding, are strongly hybridized away from these ligands and are thus perfectly suited for a strong interaction with the incoming acetylene ligand. In C_s symmetry, the four acetylene orbitals are $1a'$ ($\pi_\perp$), $2a'$ ($\pi_\parallel$), $1a''$ ($\pi^*_\parallel$) and $2a''$ ($\pi^*_\perp$). The low symmetry of the complex might have resulted in a complicated interaction diagram. However, the analysis remains relatively simple due to consideration of local symmetry.

The $\pi_\parallel$ ($2a'$) orbital overlaps essentially with the occupied metal $1a'$ and the empty $4a'$ orbitals while it encounters the nodal plane of the filled $2a'$ and empty $3a'$. The interaction between $\pi_\parallel$ and the metal $1a'$ orbital is destabilizing but it is fully compensated by the strong stabilization caused by $4a'$. This last interaction is responsible for the metal–acetylene σ bond. The empty $\pi^*_\parallel$ orbital ($1a''$) overlaps with the occupied metal $1a''$ and $2a''$ orbitals giving rise to the metal–acetylene backbonding (the later interaction is represented in **8**). Both of these interactions are stabilizing but $2a''$ plays a preferential role since it is closer in energy to $\pi^*_\parallel$. We will see later the consequences of this privileged role. The occupied $\pi_\perp$ ($1a'$) acetylene orbital is in fact well suited to overlap with the occupied metal $2a'$ and the empty metal $3a'$ orbitals, since all of these orbitals have a spatially close nodal plane. In

contrast, the metal $1a'$ and $4a'$ orbitals are essentially pointing toward the nodal lane of $\pi_\perp$ and therefore do not interact with it. The interaction between $\pi_\perp$ and metal $2a'$ is destabilizing, while that with the empty $3a'$ is stabilizing. This last interaction, represented in **9**, produces electron-transfer from $\pi_\perp$ into the empty metal orbital and forms a second type of π bond between the acetylene and the metal. Therefore in the CS geometry, the four-electron destabilization between $\pi_\perp$ and a metal d lone pair, is in part compensated by a two-electron stabilization. Finally, the last orbital to consider is $\pi^*_\perp$. In CS geometry, as in the square-planar structure, this orbital plays essentially no role since it is only involved in a δ type overlap with the occupied $2a''$ orbital.

8

9

The metal is thus bonded to the acetylene via three bonds, one σ and two π. This accounts for the short Ir—C distance (2.01 Å) when compared to other Ir—C bond lengths (e.g. 2.159 Å in *fac*-$IrMe_3(PMe_2Ph)_3$).[8] The acetylene tends to give electrons to the metal via both its $\pi_\parallel$ and $\pi_\perp$ orbitals. As nicely discussed in a recent review[19] this is usually described as a four-electron donation, although no such complete electron-transfer is ever at work. In the square-planar geometry, the acetylene cannot behave like a four-electron donor and is at most a two-electron donor via $\pi_\parallel$ since there is no empty metal orbital available to receive electrons from $\pi_\perp$. In the CS structure, the four-electron donating capability can be fully used since the metal has the proper number of empty orbitals to receive the electrons.

Now that we have built both interaction diagrams, we need to discuss why some metals prefer the square-planar structure and others the CS one. Recall that the σ effect strongly favours the square-planar geometry and that the preference for CS can only be due to π bonding. For this reason, the interaction of the acetylene $\pi_\parallel$ orbital with the metal fragment cannot make the difference between the two structures since it participates only in the formation of the metal σ bonds. Calculations do indeed indicate that the interaction energy involving $\pi_\parallel$ equally favours the square-planar geometry for both metals. In consequence, $\pi_\perp$ and $\pi^*_\parallel$ are the only orbitals of the acetylene that need to be considered.

Let us then first compare the interactions that give rise to π systems in both geometries. Since we are mostly interested in the unusual iridium structure, numerical values in the following section will be given for iridium(I).

The $\pi_\perp$ orbital is only participating in four-electron destabilization in SP while in CS it is able to find an empty orbital ($3a'$, **9**), into which to donate electrons (0.29 e^- are transferred), thus relieving a part of the four-electron destabilization. This effect favours CS.

Metal-to-acetylene backbonding occurs from a non-bonding d orbital in the SP geometry, whereas in the CS structure it utilizes a high-lying hybrid orbital (1.1. eV higher in energy than the non-bonding d) pointing toward the acetylene ligand (**8**). Therefore for both energy and overlap (0.20 in SP, 0.26 in CS) reasons, the backbonding is stronger in CS. Larger electron-transfer (0.53 e^- in SP, 0.76 in CS) into $\pi^*_\parallel$ in the CS structure confirms this analysis.

Both of these effects oppose the σ interactions, which favours SP. The outcome of these competitive effects can only be established by numerical calculations. In agreement with experiments, the calculations show that the iridium complex is more stable for a CS structure, while the platinum complex prefers a SP geometry (Table 3). Why is that so?

The main difference between the two metals relevant to our study is that the d orbitals of iridium(I) are at a higher energy and more diffuse than those of platinum(II). As a consequence, the backbonding from $2a''$ into $\pi^*_\parallel$ is larger for iridium than for platinum due to a smaller energy gap and a better overlap.† The situation is difficult for the case of $\pi_\perp$. The four-electron destabilization is exclusively controlled by overlap[20] and thus influences the diffuse iridium orbitals more than the contracted platinum orbitals. Consequently there is larger built in destabilization in the SP structure for iridium than for platinum. In the CS structure, the electron-transfer from $\pi_\perp$ into $3a'$ is similar for both metals because the larger energy gap between the two orbitals in the iridium case is compensated by the larger overlap (0.14 for Pt, 0.16 for Ir).

It appears then that, in order to overcome the large preference for the square-planar structure resulting from the σ interactions, both of the above factors must be present for the CS structure to be preferred. It requires first of all a large four-electron destabilization in the square-planar geometry and

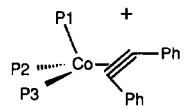
† Note that the interaction with $1a''$ follows the same trend but we will consider only $2a''$ since, being higher in energy and hybridized towards acetylene, it is responsible for the main interaction.

a large ability for back donation to stabilize CS. It is clear that the absence of a four-electron destabilization for *olefin* complexes leads to a square-planar geometry independent of the metal and the extent of back donation into the π^* orbital. Numerical calculations do indeed confirm this point. In summary, it is the *four-electron donation of an alkyne ligand which is responsible for the "unusual" CS structure of* ML_3*(alkyne) complexes* and any effect (e.g. increasing metal oxidation state or lowering the principal quantum number) which acts to quantitatively diminish the overlap between $\pi_\perp$ and the occupied metal *d* orbital will return the structure to the classical square-planar one.

The decrease in principal quantum number from iridium to cobalt might alter the ground-state structure, but the numerical calculations show that the CoP_3(acetylene)$^+$ (**3**) remains CS. This is because the shorter metal–carbon distances have maintained sufficient overlap with $\pi_\perp$. It follows that the isoelectronic iron(0) (**5**) complex is also CS.

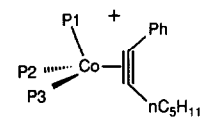
Alkyne rotation: Ground-state structure and fluxionality

The structure observed for cobalt necessitates consideration of another structural parameter: rotation of the alkyne about its midpoint. Both $Ir(MeC_2Me)(PMe_2Ph)_3^+$ and $Co(PhC_2Ph)(PMe_3)_3^+$ (**10**)[13] have the alkyne oriented perpendicular to the mirror plane of ML_3 ("horizontal"). Remarkably $Co[PhC_2(n\text{-pentyl})](PMe_3)_3^+$ (**11**)[21] has the alkyne eclipsing one Co—P bond ("vertical"). However, interconversion between the horizontal and vertical isomers is facile since these cobalt complexes were reported to be highly fluxional. Fluxionality is also present in the iridium complex described in this work. The ^{31}P, ^1H and ^{13}C NMR spectra of $Ir(MeC_2Me)(PMe_2Ph)_3^+$ at 25°C all indicate that there is rapid intramolecular site exchange among inequivalent phosphorus ligands. The data exclude dissociation of phosphine or butyne as the mechanism for such fluxionality. The barrier for this process is small, since the $^{31}P\{^1H\}$ NMR spectrum remains a singlet even at −95°C.



Co-P1 = 2.127Å
Co-P2(3) = 2.2081Å
P1-Co-P2 = 96°
P2-Co-P3 = 104°

10



Co-P1 = 2.168Å
Co-P2(3) = 2.131, 2.183Å
P1-Co-P2 = 103° av.
P2-Co-P3 = 95°

11

First let us point out that the P—M—P angles are significantly different in the horizontal and vertical structure. Comparing the cobalt complexes, the P1—Co—P2(3) angle is about 96° (90° for Ir) and the P2—M—P3 angle is 104° (106° for Ir) in the

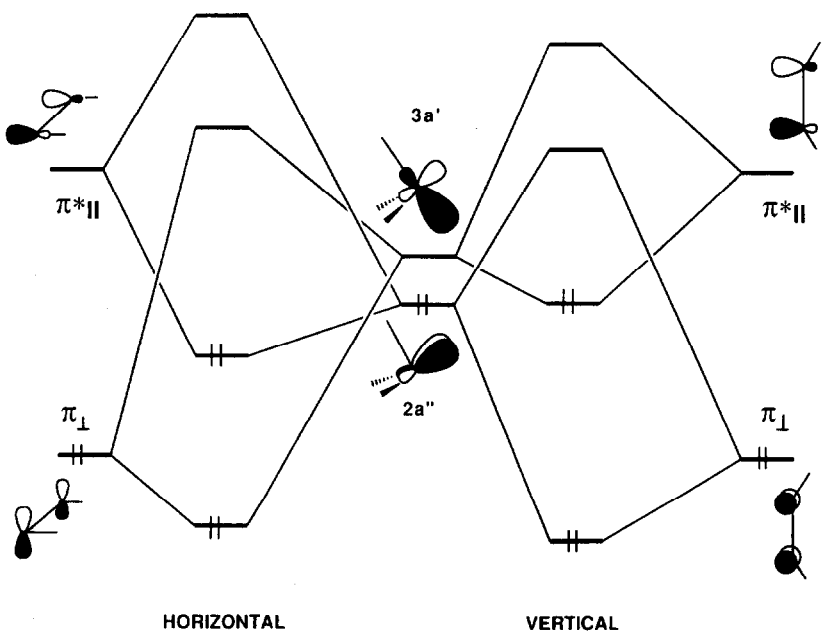


Fig. 5. Interaction diagram limited to the most relevant MOs for the horizontal (left-hand side) and the vertical (right-hand side) complex. In this diagram the structure of ML_3 corresponds to that observed in the horizontal isomer.

horizontal structure and, respectively, 103 and 95° in the vertical structure. As we will see there is, in fact, a pair of P—M—P angles best adapted to each conformer.

As a first step, we rotate the acetylene about its midpoint from the horizontal to the vertical orientation keeping the MP_3 angles at the values of the *horizontal structure*. Figure 5 shows that, during this rotation, $\pi_\perp$ and $\pi^*_\parallel$ have interchanged their partners on the metal. In the vertical conformation $3a'$ and $2a''$ interact with $\pi^*_\parallel$ and $\pi_\perp$, respectively. The rotation is energetically unfavourable since the stabilization of $2a''$ or $3a'$ by $\pi^*_\parallel$ is equivalent and thus $(3a^\circ + \varepsilon\pi^*_\parallel)$ is always higher in energy than $(2a'' + \varepsilon\pi^*_\parallel)$. The increased stabilization of $\pi_\perp$ in the vertical structure is too small to compensate the above effect. The vertical conformation would thus be more stable if $3a'$ were below $2a''$ in the ML_3 fragment. The angles between the phosphines determine the relative energies of these two orbitals. Since the $2a''$ and $3a'$ are composed to a large extent of *d* orbitals, the maximum of destabilization by the ligands occurs when the angle between the ligands is close to 90°. Thus a 90° angle between P2 and P3 destabilizes mostly $2a''$, while a 90° angle between P1 and P2(3) destabilizes mostly $3a'$ (we maintain a mirror plane through the Ir—P1 bond). In case the angles between the phosphines depart from this ideal 90° value, the higher destabilization is associated with the P—Ir—P angle that is closer to 90° as summarized in Fig. 6. Therefore the *angular relaxation of the* MP_3 *fragment is a determining factor for the stability of the vertical conformation.* It appears from the calculations that the vertical conformation becomes more stable when the geometry of MP_3 is relaxed to that observed in the experimental structure.

The rotation between horizontal and vertical conformers also alters M—P bond lengths. In the horizontal conformation, the M—P1 bond is significantly shorter than M—P2(3) while this is not so in the vertical conformer as shown in **10** and **11**. The unequal electron occupation of $2a''$ and $3a'$ in the acetylene complex in the two conformations is responsible for this fact. The $2a''$ orbital is equally antibonding with P2 and P3 while $3a'$ is much more antibonding with P1 than with P2(3) as represented in Fig. 6. In the horizontal conformation the electrons which are involved in the acetylene–Ir π bonds go into $(\pi_\perp + \varepsilon 3a')$ which is mostly centred on the acetylene part and in $(2a'' + \varepsilon\pi^*_\parallel)$ which is mostly centred onto $2a''$. Going to the vertical conformation, the electron occupation is reversed since the two MOs are now made up of $(\pi_\perp + \varepsilon 2a'')$, mostly on the acetylene and of $(3a' + \varepsilon\pi^*_\parallel)$, mostly on the metal $3a'$ orbital. Consequently turning the acetylene by 90° weakens mostly M—P1 and makes the three M—P bond lengths more equivalent. Although a better estimation of the structure of the MP_3 fragment accompanying the rotation of the acetylene is beyond the validity of the EHT method, the trend in the bond angle and bond length relaxation is well reproduced.

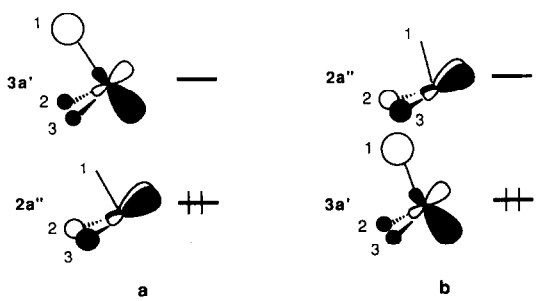

Fig. 6. Relative energy of the $(2a'', 3a')$ pair for (a) [P1—Ir—P2(3) = 90°, P2—Ir—P3 > 90°] and (b) [P1—Ir—P2(3) > 90°, P(2)—Ir—P3 = 90°].

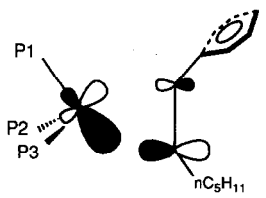
This conclusion provides an unusually detailed view of the occurrence and the energetic importance of ML_3 "breathing" during acetylene rotation. Note however that the difference in energy between $2a''$ and $3a'$ is small since the MP_3 geometry is not far from C_{3v} symmetry, where the two orbitals would be rigorously degenerate thus allowing free rotation of the acetylene. The consequence is a small activation energy for alkyne rotation in all situations, in full agreeement with observed rapid fluxionality of all molecules discussed here.

Since there is a strong correlation between the angles within the MP_3 substructure and the orientation of acetylene, what is the factor which will eventually determine the preferred structure? Since symmetrical alkynes prefer to be horizontal while the asymmetrical one prefers the vertical position, the influence of alkyne asymmetry was next investigated.

The phenyl substituent destroys the symmetry of the π orbitals of alkyne and increases the coefficient of the carbon which is far from the phenyl ring in the frontier orbitals.[22] Recall at this point that the most important interaction between MP_3 and acetylene is that of the back donation into $\pi^*_\parallel$. The interaction is thus optimal when the large lobe of $3a'$ (i.e. opposite the M—P1 bond) overlaps with the large lobe of $\pi^*_\parallel$ as shown in **12**. This is achieved in the vertical conformation when the phenyl ring is *syn* to P1.

Changes within the ML_3 fragment also influence the preferred structure. Consider the horizontal structure of the IrP2(acyl)(alkyne) complex (**4**) where the acyl ligand replaces P1. Since the acyl



12

group is a stronger σ donor than a phosphine, the $3a'$ orbital is always higher than $2a''$ (the $2a''$–$3a'$ energy gap in the fragment $Ir(acyl)P_2^+$ is considerably larger than in IrP_3^+). The lowering of $2a''$ with respect to $3a'$ is even increased by the angles between the ligands (105° between the two phosphines and 92 and 95° between the acyl and the two phosphines, i.e. a structure similar to the IrP_3^+ horizontal complex). The horizontal conformation with the acyl group occupying the site of P1 is thus observed. Although steric bulk might also influence these two angles (in particular in opening the angles between the phosphines and contracting those between the acyl and the phosphine), in this case also there is a nice correlation between the intimate structure of the metal fragment and the orientation of the acetylene.

Reactivity

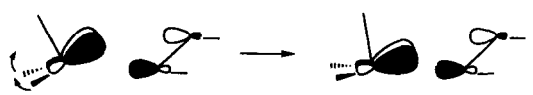
The $Ir(PMe_2Ph)_3(MeC_2Me)^+$ complex reacts easily with another alkyne or with H_2. The related cobalt complex **3** adds MeCN to give $Co(PMe_3)_3(MeCN)(PhC_2Ph)^+$.[13] All of these Lewis bases will seek out the LUMO of the metal complex, yet facile nucleophilic attack on an 18-electron complex might be viewed as unexpected. Therefore we now analyse the energy and spatial orientation of the LUMO of $IrP_3(acetylene)^+$ in the experimental (horizontal) conformation.

The LUMO, **13** of the complex is made of the

13

† It might be asked why this complex is not planar since $MeO_2CC_2CO_2Me$ is more adequately considered as a two-electron donor. However, the effect of $\pi_\perp$ is not offset totally and it is clear that it is not possible to determine in a reliable manner the limit between the SP and CS structures. The presence of iridium by itself substituted by strong σ donating ligand may have made the *d* block sufficiently diffuse to create a significant four-electron destabilization.

antibonding combination of $3a'$ and $\pi_\perp$ and is mostly centred on the $3a'$ orbital. This interaction is of moderate strength so that the LUMO remains at low energy and is also strongly developed *trans* to P1. Since the molecule approximates a square-pyramidal geometry the region *trans* to P1 is also the most sterically accessible. But why is the structure a square pyramid, that is why are P2 and P3 nearly in the Ir–acetylene plane? The dominant interaction between the metal fragment and the acetylene ligand is that between the high-lying occupied $2a''$ and $\pi^*_\parallel$, the one between the deeper $1a''$ and $\pi^*_\parallel$ being much smaller due to the larger energy gap. In order to maximize the dominant interaction, $2a''$ should point towards $\pi^*_\parallel$ as illustrated in **14**. This is achieved by putting P2 and P3 in the Ir–acetylene plane. Attendant diminution of the interaction between $2a''$ and $\pi^*_\parallel$ is of less importance. The LUMO in the square-pyramid type complex is at a particularly low energy since the overlap between $3a'$ and $\pi_\perp$ is smaller than in a more Td type structure.



14

Tuning the four-electron destabilization by an alkyne substituent and by ligand effects

The above discussion of d^8 $ML_3(alkyne)^q$ species calls into question the related family of compounds $M(CO)_4(alkyne)$ (M = Fe, Ru, Os), several of whose structures are reported here. Are these 20-valence electron species? In particular, what are the factors which control the thermodynamics of eq. (2)? There is a clearly defined preference for L =

$$ML_4(alkyne) \rightleftharpoons ML_3(alkyne) + L \qquad (2)$$

phosphine to favour the right-hand side of eq. (2), while L = CO favours the left-hand side. What electronic factors are at work? In addition, how is it possible to diminish the four-electron repulsion expected in compounds such as $Os(CO)_4(alkyne)$.

The introduction of acceptor ligands such as CO_2Me on the alkyne in the plane of the bent alkyne delocalizes the $\pi_\perp$ orbital. Its overlap with metal orbitals in both the SP and CS structures is thereby significantly diminished. Thus the four-electron destabilization is considerably decreased (it is mostly controlled by the overlap) and it could behave as a two-electron donor.† This explains the otherwise curious production of $Ir(MeO_2CC_2CO_2Me)_2(PMe_2Ph)_3^+$, a bis-alkyne complex, under

conditions which produce monoalkyne complexes for phenyl and alkyl substituted alkynes. We can now see that the undetected intermediate $Ir(MeO_2CC_2CO_2Me)(PMe_2Ph)_3^+$, of CS structure, has a very low-lying LUMO since $3a'$ is not significantly destabilized by $\pi_\perp$. It thus easily adds an additional alkyne ligand. Interestingly the neutral mono dicarbomethoxy complex of IrP2(acyl) complex whose structure has been discussed above, is stable.[12] Its lack of reactivity relative to the present cationic IrP_3 fragment may be due to the strong σ donating effect of the acyl that takes the place of P1. The corresponding $3a'$ and consequently the LUMO of the monoalkyne complex is higher, which diminishes its affinity for an additional ligand.

Alternatively one can diminish the four-electron destabilization by delocalizing the "offending" metal orbital. This can be achieved by introducing CO ligands on the metal. The *xz* lone pair is delocalized into the four π^*_{CO} orbitals and thus its overlap with the alkyne $\pi_\perp$ orbital is only weakly destablizing. However, the molecule shows reactivity characteristics which can be attributed to the residual four-electron destabilization. While the $M(CO)_4$(alkyne) species (M = Ru, Os; alkyne = HC_2H,[23] $Me_3SiC_2SiMe_3$,[11] $F_3CC_2CF_3$[10]) have been characterized by the full range of modern techniques, it is important to recall that, with the exception of the $F_3CC_2CF_3$ derivatives, the compounds are thermally unstable and indeed more so than the related $M(CO)_4L$ complexes (L being the classical two-electron donor CO or $H_2C{=}CH_2$[11,23]). They thus show evidence of the four-electron repulsion predicted by simple electron counting rules. The observation that $Ru(CO)_4(Me_3SiC_2SiMe_3)$ readily deposits $Ru_3(CO)_{12}$ and that the decomposition is slowed down by added free $Me_3SiC_2SiMe_3$[11] reveals that alkyne dissociation is one way in which the instability is manifested. In addition, however, the unit $M(CO)_3$(alkyne) represented an intermediate with special stability due to the availability of the four-electron donor alkyne unit. This can account for the rapid incorporation of ^{13}CO into $M(CO)_4$(alkyne) (alkyne = HC_2H, $F_3CC_2CF_3$)[10,23] and, at least in part for the unusual facile condensation reactions of these compounds with other 18-electron species.[10,23]

Equilibrium (2) can thus be easily displaced towards one or the other side by a fine tuning of the four-electron destabilization.

CONCLUSION

It is well accepted that isomeric forms of certain ligands can furnish different numbers of electrons to the metal. From this work it is now clear that the mirror-image situation can be observed on the metal: isomeric fragments can accept a different number of electrons. Thus a T shape ML_3 d^8 fragment is a two-electron acceptor while a pyramidal ML_3 d^8 fragment is a four-electron acceptor (this is why butadiene and other four-electron conjugated dienes coordinate to a pyramidal d^8 ML_3 fragment). An encounter between a ligand and a metal fragment may thus induce structural changes in both partners to optimize the bonding/accepting capability of each. A search for other examples of adaptation of ML_n fragment geometry to the active partner ligand should be fruitful.

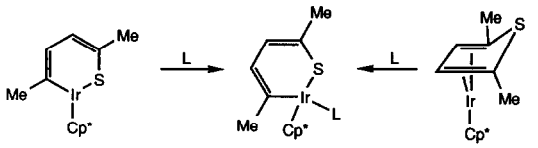
REACTIONS OF THE η^2- AND η^4-ISOMERS OF Cp*Ir(2,5-DIMETHYLTHIOPHENE) WITH PHOSPHINES, CO AND H_2†

JIABI CHEN, LEE M. DANIELS‡ and ROBERT J. ANGELICI§

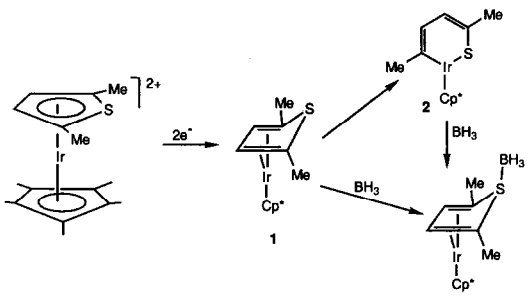
Department of Chemistry and Ames Laboratory, Iowa State University, Ames, IA 50011, U.S.A.

Abstract—The iridathiabenzene complex, Cp*Ir(η^2-2,5-Me_2T) (**2**), which may be formulated with a 16e$^-$ iridium centre, reacts with 2e$^-$ donor ligands (L = PMe_3, PMe_2Ph, $PMePh_2$, PPh_3, $P(OPh)_3$ and CO) to give adducts **3–8**; the structures of two of these



derivatives were determined by X-ray crystallography, and the bonding in their six-membered ring is contrasted with that in **2**. The η^4-thiophene complex Cp*Ir(η^4-2,5-Me_2T) (**1**) also reacts with L to give the same adducts, **3–8**; this reaction presumably involves **2** as an intermediate. Both **2** and **1** also undergo oxidative-addition with H_2 to give Cp*Ir(η^2-2,5-Me_2T)$(H)_2$ (**9**) which exists as the dihydride as determined by T_1 measurements.

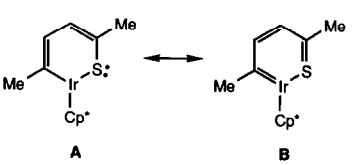
As part of our general interests in the mechanisms of the heterogeneously-catalysed hydrodesulphurization (HDS) of organosulphur compounds in petroleum feedstocks, we have explored various modes of thiophene coordination and reactivity in metal complexes as models for the reactions of thiophenes on HDS catalysts.[1] Based on preliminary studies,[2] we recently found[3] that a 2e$^-$ reduction of Cp*Ir(η^5-2,5-Me_2T)$^{2+}$ (where 2,5-Me_2T is 2,5-dimethylthiophene) produces Cp*Ir(η^4-2,5-Me_2T) (**1**) in which the thiophene is coordinated through only the four carbon atoms [eq. (1)]:



(1)

This isomer of Cp*Ir(2,5-Me_2T) is thermodynamically unstable with respect to the ring-opened isomer Cp*Ir(η^2-2,5-Me_2T) (**2**) to which it converts in the presence of basic alumina or amines as catalysts[4] [eq. (1)]. The sulphur of the thiophene in the η^4-complex (**1**) is an unusually good donor and readily forms a BH_3 adduct.[3,5] Surprisingly, the η^2-isomer (**2**) also reacts with BH_3 to undergo ring closure forming the same BH_3 adduct [eq. (1)].

The structure[4] of **2**, as determined by X-ray diffraction, contains an essentially planar six-membered ring which incorporates the four carbons, the iridium and the sulphur atoms. (The Cp* plane is perpendicular to the six-membered ring.) The structure and NMR studies of **2** strongly indicate that the π-system of the six-membered ring is delocalized and is best represented by two resonance forms, **A** and **B** [eq. (2)]:



(2)

In form **A**, the iridium is a 16e$^-$ centre and might be expected to add 2e$^-$-donating ligands. In form **B**, the iridium has 18e$^-$ but the carbene carbon is expected to be electrophilic and susceptible to attack by 2e$^-$-donating nucleophiles. In this study,

† Dedicated to Professor Richard F. Fenske, a theoretical chemist whose results actually had an impact on synthetic organometallic chemistry.

we examine the reactions of **2** with phosphines, CO and H_2, in order to determine whether the iridium or the carbene carbon is the centre of reactivity. Unexpectedly, the other isomer, **1**, an $18e^-$-complex, also reacts with the $2e^-$-donors to give the same products but at a slower rate.

EXPERIMENTAL

All reactions and product isolations were carried out under a N_2 atmosphere using Schlenk techniques. Reagent grade solvents were dried by refluxing over appropriate drying agents and stored over 4 Å molecular sieves under a N_2 atmosphere. Tetrahydrofuran (THF) and diethyl ether (Et_2O) were distilled over sodium benzophenone ketyl, while hexane and CH_2Cl_2 were distilled from CaH_2. The neutral Al_2O_3 (Brockmann, Activity I) used for chromatography was deoxygenated under high vacuum at room temperature for 16 h, deactivated with 5% (w/w) N_2-saturated water, and stored under N_2. PMe_3, PMe_2Ph, $PMePh_2$, PPh_3, $P(OPh)_3$ and $Ph_2PCH_2CH_2PPh_2$ (dppe) were purchased from Aldrich Chemical Co., and the gases CO and H_2 were used as purchased. Cp*Ir(η^4-2,5-Me_2T) (**1**) and Cp*Ir(η^2-2,5-Me_2T) (**2**) were prepared as previously reported.[4] Elemental analyses were performed by Galbraith Laboratory, Inc. The ^1H (Table 1) and ^{13}C NMR spectra were recorded on a Nicolet NT-300 spectrometer using deuteriated solvents as internal locks and references with respect to TMS. Electron ionization mass spectra (EIMS) were run on a Finnigan 4000 spectrometer. The melting points were determined in sealed N_2-filled capillaries and were not corrected.

Reaction of Cp*Ir(η^4-2,5-Me_2T) (**1**) *with* PMe_3 *to give* Cp*Ir(η^2-2,5-Me_2T)(PMe_3) (**3**)

Compound **1** (0.034 g, 0.077 mmol) was dissolved in 30 cm^3 of hexane at room temperature. To this solution was added PMe_3 (0.050 g, 0.657 mmol). The reaction solution was stirred at room temperature. The light yellow solution gradually turned a deeper yellow. After stirring for 48 h, the solvent was evaporated under vacuum, and the residue was chromatographed on Al_2O_3 (neutral) with hexane first and then hexane–Et_2O (20 : 1) as eluant. The yellow band was collected. After removal of solvent under vacuum, the crude product was recrystallized from hexane at −80°C to give 0.036 g (78%) of orange–yellow crystals of **3** (m.p. 141–142°C, decomp). MS: *m/e* 516 (M^+), 440 ($M^+ - PMe_3$), 404 ($M^+ - Me_2T$). Found: C, 44.53; H, 6.41. Calc. for $C_{19}H_{32}SPIr$: C, 44.25; H, 6.25%.

Reaction of Cp*Ir(η^2-2,5-Me_2T) (**2**) *with* PMe_3 *to give* **3**

To a solution of **2** (0.040 g, 0.091 mmol) in hexane (30 cm^3) was added PMe_3 (0.060 g, 0.789 mmol) at −60°C with stirring. The red solution rapidly turned yellow. After being stirred at −60 to −40°C for 1 h, the resulting solution was evaporated to dryness under vacuum. Further treatment of the yellow residue was similar to that described for reaction of **1** with PMe_3 to give orange–yellow crystals of **3**, yield 0.043 g (91%) (m.p. 142°C, decomp). MS: *m/e* 516 (M^+), 440 ($M^+ - PMe_3$), 404 ($M^+ - Me_2T$). Found: C, 44.21; H, 6.18. Calc. for $C_{19}H_{32}SPIr$: C; 44.25; H, 6.25%.

Reaction of **1** *with* PMe_2Ph *to give* Cp*Ir(η^2-2,5-Me_2T)(PMe_2Ph) (**4**)

Compound **1** (0.026 g, 0.059 mmol) was dissolved in 30 cm^3 of hexane at room temperature. To this solution was added PMe_2Ph (0.050 g, 0.362 mmol). The solution was stirred for 52 h at room temperature. The colour of the solution changed gradually from light yellow to orange–yellow. Further treatment of the resulting mixture as described above for **3** gave 0.020 g (59%) of orange crystals of **4** (m.p. 115–117°C, decomp). MS: *m/e* 578 (M^+), 466 ($M^+ - Me_2T$), 440 ($M^+ - PMe_2Ph$). Found: C, 49.95; H, 6.12. Calc. for $C_{24}H_{34}SPIr$: C, 49.89; H, 5.93%.

Reaction of **2** *with* PMe_2Ph *to give* **4**

To a solution of **2** (0.030 g, 0.068 mmol) in 30 cm^3 of hexane was added PMe_2Ph (0.090 g, 0.651 mmol) at −60°C. The red solution rapidly turned yellow. The reaction solution was stirred for 2 h at −60 to −40°C. Further treatment of the resulting mixture as described in the reaction with PMe_3 gave 0.036 g (92%) of **4** as orange crystals (m.p. 115–116°C, decomp). ^{13}C NMR ($CDCl_3$): δ 136.21, 135.54, 131.50, 129.63, 127.83, 124.42, 123.81, 121.17, 94.92, 38.65, 27.30, 15.50, 14.96, 8.52. MS: *m/e* 578 (M^+), 466 ($M^+ - Me_2T$), 440 ($M^+ - PMe_2Ph$).

Reaction of **1** *with* $PMePh_2$ *to give* Cp*Ir(η^2-2,5-Me_2T)($PMePh_2$) (**5**)

Compound **1** (0.030 g, 0.068 mmol) reacted, in a similar manner as described in the reaction with PMe_3, with $PMePh_2$ (0.140 g, 0.699 mmol) for 60 h at room temperature. Subsequent treatment as described for **3** gave 0.025 g (57%) of orange–red crystals of **5** (m.p. 146–147°C, decomp). MS: *m/e* 640 (M^+), 528 ($M^+ - Me_2T$), 440 ($M^+ - PMePh_2$). Found: C, 54.21; H, 5.81. Calc. for $C_{29}H_{36}SPIr$: C, 54.44; H, 5.67%.

Reaction of **2** *with* $PMePh_2$ *to give* **5**

Similar to the procedure described in the reaction of **2** with PMe_3, **2** (0.027 g, 0.061 mmol) reacted with $PMePh_2$ (0.120 g, 0.600 mmol) for 2 h at −60 to −40°C. Subsequent treatment of the reaction mixture in a manner similar to that described for **3** gave orange–red crystals of **5** (m.p. 146–148°C, decomp); yield 0.035 g (90%). MS: *m/e* 640 (M^+), 528 ($M^+ - Me_2T$), 440 ($M^+ - PMePh_2$). Found: C, 54.03; H, 5.76. Calc. for $C_{29}H_{36}SPIr$: C, 54.44; H, 5.67%.

Reaction of **1** *with* PPh_3 *to give* Cp*Ir(η^2-2,5-Me_2T)(PPh_3) (**6**)

The reaction of **1** (0.025 g, 0.057 mmol) with PPh_3 (0.045 g, 0.167 mmol) was performed in a manner similar to that described for the reaction of **1** with PMe_3 for 68 h at room temperature. Further treatment of the reaction mixture as described above for **3** gave 0.022 g (55%) of orange–red crystals of **6** (m.p. 197–198°C, decomp). MS: *m/e* 702 (M^+), 625 ($M^+ - Ph$), 590 ($M^+ - Me_2T$), 440 ($M^+ - PPh_3$). Found: C, 57.85; H, 5.82. Calc. for $C_{34}H_{38}SPIr$: C, 58.18; H, 5.46%.

Reaction of **2** *with* PPh_3 *to give* **6**

Similar to that described in the reaction of **2** with PMe_3, **2** (0.020 g, 0.045 mmol) was reacted with 0.040 g (0.153 mmol) of PPh_3 at −40 to −30°C for 2 h. Subsequent treatment of the resulting mixture in a similar manner as described for **3** yielded 0.028 g (88%) of orange–red crystals of **6** (m.p. 198–199°C, decomp). MS: *m/e* 702 (M^+), 625 ($M^+ - Ph$), 590 ($M^+ - Me_2T$), 440 ($M^+ - PPh_3$).

Reaction of **1** *with* $P(OPh)_3$ *to give* Cp*Ir(η^2-2,5-Me_2T)[$P(OPh)_3$] (**7**)

Compound **1** (0.020 g, 0.045 mmol) was dissolved in 30 cm^3 of hexane at room temperature. To this solution was added $P(OPh)_3$ (0.140 g, 0.450 mmol). The solution was stirred for 48 h, during which time the light yellow solution gradually turned orange. After evaporating the solution *in vacuo*, the residue was chromatographed on Al_2O_3 (neutral) with hexane first and then hexane–Et_2O (10 : 1) as the eluant. The solvent was removed from the yellow fraction under vacuum, and the crude product was recrystallized from hexane at −80°C to give 0.019 g

(56%) of orange crystals of **7** (m.p. 20–21°C, orange oil). MS: *m/e* 750 (M^+), 638 ($M^+ - Me_2T$), 440 ($M^+ - P(OPh)_3$). Found: C; 54.05; H, 4.91. Calc. for $C_{34}H_{38}O_3SPIr$: C, 54.45; H, 5.11%.

Reaction of **2** *with* $P(OPh)_3$ *to give* **7**

To a solution containing **2** (0.030 g, 0.068 mmol) in 30 cm^3 of hexane was added $P(OPh)_3$ (0.200 g, 0.645 mmol) at −60°C. The colour of the solution changed immediately from red to yellow. After being stirred for 1 h at −60 to −40°C, the resulting mixture was then treated in a similar manner as described above for **3** to give 0.044 g (86%) of orange crystals of **7** (m.p. 20–21°C, orange oil). MS: *m/e* 750 (M^+), 638 ($M^+ - Me_2T$), 440 ($M^+ - P(OPh)_3$).

Reaction of **1** *with* CO *to give* Cp*Ir(η^2-2,5-Me_2T)(CO) (**8**)

Compound **1** (0.035 g, 0.080 mmol) was dissolved in 50 cm^3 of hexane at room temperature; CO gas was bubbled through the solution over a period of 10 h during which time the light yellow solution gradually turned orange. After evaporating the solution, the residue was chromatographed on Al_2O_3 (neutral) with hexane as the eluant, and the yellow band was collected. After removal of the solvent *in vacuo*, the crude orange powdery product was recrystallized from hexane at −80°C to afford 0.027 g (73%) of orange–yellow needles of **8** (m.p. 121°C, decomp). IR (hexane) ν(CO): 2020 s cm^{-1}. MS: *m/e* 468 (M^+), 440 ($M^+ - CO$), 356 ($M^+ - Me_2T$). Found: C, 43.30; H, 5.00. Calc. for $C_{17}H_{23}OSIr$: C, 43.66; H, 4.96%.

Reaction of **2** *with* CO *to give* **8**

Compound **2** (0.053 g, 0.120 mmol) was dissolved in 50 cm^3 of hexane at −30°C; CO was bubbled through the solution over a period of 2 h during which time the colour of the solution changed from red to yellow. Further treatment of the resulting solution in a similar manner as described above for the reaction of **1** with CO afforded 0.050 g (89%) of orange–yellow needles of **8** (m.p. 121–122°C, decomp). IR (hexane) ν(CO): 2020 s cm^{-1}. MS: *m/e* 468 (M^+), 440 ($M^+ - CO$), 356 ($M^+ - Me_2T$). Found: C, 43.20; H, 5.09. Calc. for $C_{17}H_{23}OSIr$: C, 43.66; H, 4.96.

Reaction of **1** *with* H_2 *to give* Cp*Ir(η^2-2,5-Me_2T)$(H)_2$ (**9**)

Compound **1** (0.036 g, 0.082 mmol) was dissolved in 50 cm^3 of hexane at room temperature; H_2 was bubbled through the solution over a period of 24 h; during that time the light yellow solution gradually turned orange–red. After evaporating the solution *in vacuo*, the red residue was chromatographed on Al_2O_3 (neutral) with hexane as the eluant. The red band was collected. The solvent was removed under vacuum and the crude product was recrystallized from hexane at −80°C to yield 0.017 g (47%) of red crystals of **9** (m.p. 148–149°C, decomp). MS: *m/e* 442 (M^+), 441 ($M^+ - H$), 440 ($M^+ - 2H$). Found: C, 43.62; H, 5.48. Calc. for $C_{16}H_{25}SIr$: C, 43.51; H, 5.71%. The mother liquor from the recrystallization was again chromatographed in the same manner as described above to give a red fraction. The solvent was removed under vacuum and the dark-red residue was recrystallized from hexane at −80°C to afford 0.008 g (22%) of dark-red crystals of **2** (m.p. 147°C, decomp). ^1H NMR ($CDCl_3$): δ 7.47 (d, 1H), 7.34 (d, 1H), 3.10 (s, 3H), 2.79 (s, 3H), 1.93 (s, 15H).

Reaction of **2** *with* H_2 *to give* **9**

Compound **2** (0.050 g, 0.114 mmol) was dissolved in 50 cm^3 of hexane at room temperature; H_2 was bubbled through the solution over a period of 24 h during which time no obvious colour change was observed. Subsequent treatment of the resulting red solution in the same manner as described above for the reaction of **1** with H_2 gave 0.034 g (68%) of red crystals of **9** (m.p. 148–149°C, decomp). MS: *m/e* 442 (M^+), 441 ($M^+ - H$), 440 ($M^+ - 2H$).

X-ray crystal structure determinations of **4** *and* **5**

The crystals of complexes **4** and **5** suitable for X-ray diffraction were obtained by recrystallization from hexane–CH_2Cl_2 solution at −80°C. Single crystals of approximate dimensions $0.20 \times 0.50 \times 0.55$ mm for **4** and $0.13 \times 0.17 \times 0.11$ mm for **5** were mounted on the ends of glass fibres and coated with a thin layer of epoxy cement. The cell constants were determined from lists of reflections found by an automated search routine. Relevant crystallographic information for **4** and **5** appear in Table 2.

The structure of **4** was solved by the Patterson method. All of the non-hydrogen atoms appeared in a difference map produced after the successful placement of the iridium atom. Hydrogen atoms were not included in the model. Because of the large absorption correction applied based on the psi-scan data, a numerical absorption correction was applied to the unaveraged data set following isotropic least-squares refinement of all the non-hydrogen atoms.[6] After this correction, the new averaging agreement

Table 2. Crystallographic data for Cp*Ir(η^2-2,5-Me_2T)(PMe_2Ph) (**4**) and Cp*Ir(η^2-2,5-Me_2T)($PMePh_2$) (**5**)

^{a} $R = \Sigma ||F_o| - |F_c|| / \Sigma |F_o|$.
^{b} $R_w = [\Sigma w(|F_o| - |F_c|)^2 / \Sigma w|F_o|^2]^{1/2}$; $w = 1/\sigma^2(|F_o|)$.
^{c} Quality-of-fit = $[\Sigma w(|F_o| - |F_c|)^2 / (N_{obs} - N_{parameters})]^{1/2}$.

factor was 1.9% based on F_{obs}. In the final cycles of refinement, all of the atoms were given anisotropic temperature factors; the refinement included 244 variable parameters and converged with unweighted and weighted agreement factors[7] of $R = 0.0272$ and $R_w = 0.0468$.

For **5**, the structure was also solved by the Patterson method. Refinement was carried out with full-matrix least-squares calculations. In the final stages of refinement the iridium, phosphorus, sulphur and carbon atoms of the chelating ligand were given anisotropic thermal parameters. Hydrogen atoms were placed in calculated positions on the phenyl rings and on the trigonal carbon atoms of the chelating ligand, then used to calculate structure factors only. The final cycle of refinement included 174 variable parameters and converged with unweighted and weighted agreement factors[7] of $R = 0.0381$ and $R_w = 0.0479$. Bond distances and selected angles are presented in Tables 3 and 4 and ORTEP drawings of **4** and **5** are given in Figs 1 and 2, respectively.

RESULTS AND DISCUSSION

Reactions of Cp*Ir(η^2-2,5-Me_2T) (**2**) *and* Cp*Ir(η^4-2,5-Me_2T) (**1**) *with phosphorus ligands and* CO

Complex **2**, which can be formulated as having a 16 e$^-$-resonance form [A in eq. (2)], reacts readily, even at −60 to −40°C, with phosphorus-donor ligands to give the corresponding orange-coloured

Table 3. Selected bond distances (Å)[a,b] for Cp*Ir(η^2-2,5-Me_2T)(PMe_2Ph) (**4**) and Cp*Ir(η^2-2,5-Me_2T)($PMePh_2$) (**5**)

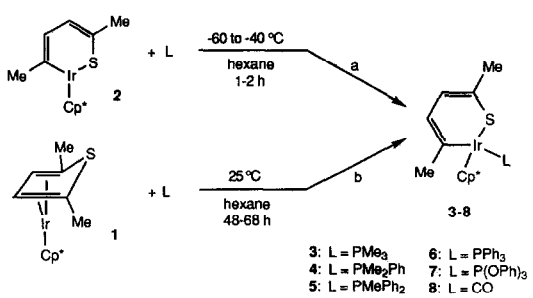
[a] Numbers in parentheses are ESDs in the least significant digits.

[b] Average C—C distances in the Cp* ring and average C—CH_3 distances are 1.435 and 1.51 Å, respectively, in **4** and 1.43 and 1.52 Å, respectively, in **5**.

18 e^--adducts Cp*Ir(η^2-2,5-Me_2T)(PR_3) [Eq. (3a)] in high isolated yields (> 86%). Complexes **3**–**7** are soluble in both polar and non-polar organic solvents and moderately air-sensitive in both the solid state and in solution. The complexes are characterized by their elemental analyses, mass spectra and ^{1}H NMR spectra (Table 1). The structures of **4** and **5** (see next section) were established by X-ray crystallography.



(3)

Although excesses of the phosphorus donor ligands were used in the reactions [eq. (3)], there was no evidence for further reaction of complexes **3**–**7** under these conditions. In an NMR tube reaction of **2** (or **1**) (10.0 mg, 0.023 mmol) with dppe (10.0 mg, 0.025 mmol) in 0.5 cm^3 of $CDCl_3$, the ^{1}H

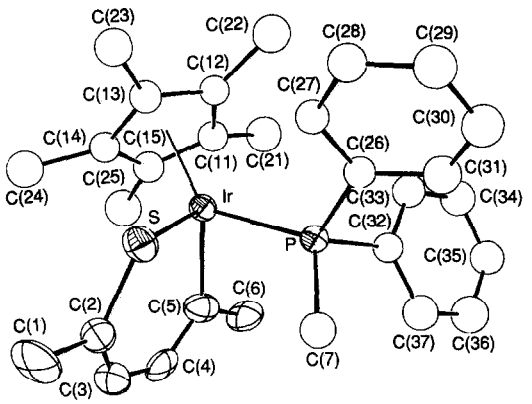

Fig. 2. ORTEP drawing of Cp*Ir(η^2-2,5-Me_2T)($PMePh_2$) (**5**).

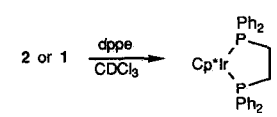
NMR spectrum indicated that **2** had completely reacted in 0.5 h (4 h for **1**) at room temperature. The product, Cp*Ir(dppe), of the reaction [eq. (4)] was identified by its Cp* (δ 1.91, 15H), methylene (δ 2.32–2.48 and 2.07–2.16, m, 4H), and Ph (δ 7.30–7.85, m, 10H) resonances and mass spectrum [*m/e* 726 (M^+) and 328 ($M^+ - dppe$)]; however, since it was quite unstable and dissociated to give free dppe during recrystallization from hexane or hexane–CH_2Cl_2, it could not be purified for elemental analysis. Neither 2,5-Me_2T nor other recognizable organic products were identified as products of the reaction [eq. (4)].



(4)

Although one might have expected the 18e^- complex Cp*Ir(η^4-2,5-Me_2T) (**1**) to react with phosphorus donors to give 2,5-Me_2T and Cp*IrL_2, this

[a] Numbers in parentheses are ESDs in the least significant digits.

reaction gives [eq. (3)] the same adducts **3**–**7** as were obtained from the reactions of **2**. However, **1** is much less reactive than **2**, requiring a higher reaction temperature (25°C) and longer reaction times (48–68 h), and the yields (55–78%) are somewhat lower. Qualitatively, the rates of reaction (3b) decrease as PMe_3 > PMe_2Ph > $PMePh_2$ > PPh_3 with PMe_3 requiring only 48 h and PPh_3 68 h. Somewhat surprisingly, $P(OPh_3)$ reacts faster than PMe_2Ph, $PMePh_2$ and PPh_3; which suggests that the small cone angle (128°) of $P(OPh)_3$ is important for its reactivity even though it is a weak base.[8]

The mechanism for the reaction of **1** with phosphorus-donors is likely to involve initial isomerization of **1** to **2**, catalysed by the phorphorus-donor ligand. Other bases, e.g. Et_3N, are known[4] to catalyse this isomerization. Since **2** would react rapidly [eq. (3a)] with phosphine, one would not expect to detect **2** as an intermediate in this reaction, and no intermediates were observed.

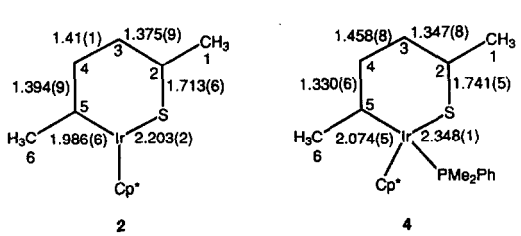
Like the phosphorus-donors, CO also reacts [eq. (3a)] with **2** under mild conditions (−30°C, 2 h) to give the orange–yellow adduct Cp*Ir(η^2-2,5-Me_2T)(CO) (**8**) in 89% yield [eq. (3a)]. Complex **1** also reacts [eq. (3b)] with CO to give **8** but more vigorous conditions (25°C, 10 h) are required. In this latter reaction, complex **2** was detected in the ^{1}H NMR ($CDCl_3$) spectrum of a sample taken during the reaction, which suggests that **2** is an intermediate in the reaction of **1** with CO. There is no evidence for products in which CO has inserted into the Ir—C bond.

Complex **8** is characterized by its elemental analysis, its IR spectrum showing a ν(CO) absorption at 2020 cm^{-1}, and its ^{1}H NMR spectrum (Table 1), which is very similar to those of the phosphorus-donor adducts, **3**–**7**. While **8** is soluble in both polar and non-polar organic solvents, these solutions are quite air-sensitive.

Structures of Cp*Ir(η^2-2,5-Me_2T)(PMe_2Ph) (**4**) *and* Cp*Ir(η^2-2,5-Me_2T)($PMePh_2$) (**5**)

The structures (Figs 1 and 2) of **4** and **5** are that of a piano stool with the P, S and C(5) "legs" at roughly right angles (86–93°) to each other. The cyclopentadienyl carbons, C(11)–C(15), of the Cp* rings lie in a plane (±0.008 Å in **4** and ±0.01 Å in **5**) and the five CH_3 carbons are an average of 0.13 Å (for **4**) and 0.17 Å (for **5**) out of this plane away from the iridium. The Ir—P bond distances, 2.252(1) and 2.255(3) Å, in **4** and **5**, respectively, are very similar to that (2.237(2) Å) in CpIr(CO)(PPh_3).[9]

The most interesting structural feature of these complexes is the η^2-2,5-Me_2T ligand. In complex **2**, the six-membered ring is planar and aromatic as determined from bond distances (Scheme 1) and NMR data.[4] The C—C bond distances in this ring are nearly equal suggesting a delocalized π-system, which may be described by resonance forms **A** and **B** [in eq. (2)] and we have termed an "iridathiabenzene". In the phosphine adducts, **4** and **5**, the six-membered ring is no longer planar and the bond distances have changed such that the ring is most appropriately represented by resonance form



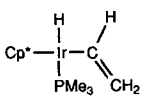
2 **4**

Scheme 1. Comparison of the six-membered rings in Cp*Ir(η^2-2,5-Me_2T) (**2**) and Cp*Ir(η^2-2,5-Me_2T)(PMe_2Ph) (**4**).

A which makes the η^2-2,5-Me_2T ligand a formal $2e^-$-donor and the two electrons from the phosphine ligand brings the iridium to an $18e^-$ count.

For a detailed structural comparison of **2** and the phosphine adducts, we have chosen adduct **4** because its structure refined better than **5**; however, the bond distances and angles in **5** are within experimental error the same as those in **4**. In contrast to the planar six-membered ring in **2**, only S, C(2), C(3), C(4) and C(5) are in a plane (± 0.06 Å) in **4**; the Ir is out of this plane by 0.69 Å; C(1) is 0.12 Å out of the plane toward the Ir and C(6) is 0.20 Å out of the plane away from Ir. Another measure of the non-planarity of the ring is the 148.8 (± 0.4)° dihedral angle between the S, Ir, C(5) and C(2), C(3), C(4) planes. The non-planarity of the rings in **4** and **5** suggests that the π-system is not delocalized in these complexes as it is in **2**.

Another indication is the change in bond distances in **4** as compared to **2**. In contrast to the nearly equal bond distances in the C(2)—C(3)—C(4)—C(5) part of the six-membered ring in **2**, in **4** the C(2)—C(3) (1.347(8) Å) and C(4)—C(5) (1.330(6) Å) bonds are considerably shorter than C(3)—C(4) (1.458(8) Å). The short distances are typical of $C(sp^2)$=$C(sp^2)$ double bonds (1.34 Å), while the longer distance (1.458(8) Å) is very close to that (1.48 Å) of a $C(sp^2)$—$C(sp^2)$ single bond. The C(2)—S distance (1.741(5) Å) is primarily a single bond since it is close to that (1.77 Å) of normal $C(sp^2)$—S single bonds[10,11] and substantially longer than $C(sp^2)$=S double bonds (1.61 Å).[12] Especially interesting is the Ir—C(5) distance (2.074(5) Å) which is 0.088 Å longer than in **2** and corresponds to an Ir—$C(sp^2)$ single bond as in compound **C**, where the Ir—C bond length[13] is



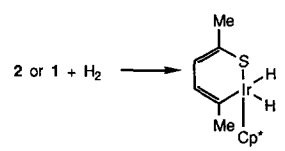
C

2.054(4) Å. Considering all of the bond distances, the bonding in **4** fits very well to the localized bonding represented by resonance form **A**.

Further support for this bonding comes from a comparison of the NMR spectra of **2** and **4**. In the ^{1}H NMR spectrum of **2**, the protons on C(3) and C(4) occur far downfield (δ 7.47 and 7.34, Table 1) consistent with a delocalized, aromatic ring. In **4** (and the other adducts), these protons are substantially upfield (δ 5.90 and 5.42) characteristic of olefinic protons. In the ^{13}C NMR spectrum of **2**, C(5) occurs at low field (δ 180.99)[4] indicating significant carbene character contributed by resonance form **B**. In contrast, there is no ^{13}C resonance in the δ 180 ppm region in the spectrum of **4**; thus, C(5) in **4** must be one of the eight signals in the range δ 121–136 (four for the Ph and four for the carbons in the six-membered ring). This upfield position means that C(5) does not have much carbene character but is in the region expected for a vinyl carbon as in compound **C**, in which the vinyl carbon signal occurs at δ 129.18.[13] Thus, the ^{1}H and ^{13}C NMR spectra of **4** are also consistent with its being best represented by resonance form **A**.

Reactions of Cp*Ir(η^2-2,5-Me_2T) (**2**) *and* Cp*Ir(η^4-2,5-Me_2T) (**1**) *with* H_2

As complex **2** is able to add $2e^-$-donor ligands [eq. (3a)], it can also undergo oxidative-addition with H_2 [eq. (5)] to give the red dihydride **9** in 68% yield. This product is characterized by elemental analyses, mass and ^{1}H NMR spectra. The singlet hydride resonance at δ −16.27 ppm integrates for 2H. A T_1 measurement on the hydride signal in **9**, in CD_2Cl_2 at −80°C, by the inversion–recovery method (180°-τ-90°, τ = variable) at 300 MHz on a Bruker WM 300 NMR instrument gave a value of 890 ms; this relatively long T_1 is consistent[14] with the formulation of **9** as a dihydride rather than as an η^2-H_2 complex.



(5)

9

Complex **9** is also prepared in 47% yield from the reaction of **1** with H_2. A by-product of this reaction is **2** which is isolated in 22% yield; the isolation of **2** suggests that it may be an intermediate in the reaction of **1** since **2** reacts with H_2 to give **9** under the same conditions. It appears that H_2 catalyses the isomerization of **1** to **2**, which does not occur under these conditions in the absence of H_2.

Refluxing a hexane solution of **9** under N_2 did not give any isolable products; neither complex **2** nor **1** was identified; only slow decomposition to uncharacterized products was observed.

CONCLUSION
